Compact disc (CD)-based technology offer enormous possibilities as BioMEMS (Bio-micro-electromechanical systems) for molecular screening in biosensing (*2*). In 2000, Kido et al. demonstrated the potential of this technology, developing disc-based immunoassay microarrays (*3*). Other authors (*4*−*6*) have been working on polycarbonate (PC) surface modification of discs to attach proteins and nucleic acids. Also, Yu (*7*) has developed strategies for the preparation of high-quality SAMs for electrochemical analysis on gold-metalized CDs. Regarding the use of CD reader technology, Barathur et al. modified the standard CD drive to use a laser-scanning microscope for analysis of a biocompact disc assay (*8*). Potyrailo et al. (*9*) used conventional optical disc drives for quantitative detection of Ca^{2+} and other ionic species by sensitive films deposited on conventional CD and DVD optical discs.

Preliminary evidence displayed by our research team (*10*) illustrated the potential of using compact disc surfaces as high throughput screening platforms. The immobilization of biomolecules on the PC face of CDs was a suitable strategy to perform genomic analysis, providing good results in sensitivity and hybridization. These studies were performed employing avidin−biotin methodology and using fluorescence microarray scanning for detection. The challenge now was the use of the PMMA-modified compact discs as support and the CD player as detector.

The chemical derivatization of PMMA, a material employed as a protective layer for the metallic film of the CDs,[1] would allow covalent and oriented immobilization of DNA or protein for microarraying. Lacquering the metallic layer of the compact disc with a chemically modified polymer is an interesting alternative for developing surfaces with specific chemical moieties and physical properties to covalently attach nucleic acid probes; advantages arise from the possibility to derivatize the polymer in solution after application on metal and the facility to apply it by spin-coating, sputtering, etc., achieving well finished surfaces. The problem is that most of the methods employed for the chemical modification of PMMA surfaces (*11*, *12*) require use in fluidic structures, affecting the optical and mechanical properties of the polymer. So, the described approaches are not applicable for our purposes.

PMMA microspheres have been successfully used for the immobilization of enzymes by aldehyde oxidation of the hydroxyl groups introduced in the PMMA using poly(vinyl alcohol) (*13*), design of microfluidic devices, metal deposition (*14*), and immobilization of proteins and DNA. Henry et al. (*15*) showed that aminated PMMA sheets can be used for the immobilization of enzymes in the restriction digestion of dsDNA. Waddell et al. (*16*) have developed a method using *N*-lithiodiaminepropane-modified PMMA slides as substrate to test the immobilization and hybridization of oligonucleotides in a microarray format. Christensen et al. (*17*) also proposed a chemical procedure to functionalize PMMA in an easier and faster manner than that previously described, by using hexamethylenediamine and glutaraldehyde or sulfo-EMCS ([*N*-ϵ-maleimidocaproyloxy]sulfosuccinimide ester). The density of immobilized and hybridized DNA was similar to those obtained on other PMMA-modified surfaces and silanized glass.

Although isocyanates potentially represent an ideal covalent DNA or protein immobilization chemistry (*18*), none of the previously published modifications of PMMA employ the isocyanate moiety for the covalent attachment of biomolecules. Isocyanates can react with many functional groups including amines, hydroxyls, and carboxyls, using soft conditions and aqueous media. Their reactivity renders them highly versatile, since these groups are present in nucleic acids, proteins, and other biomolecules. All these reasons make isocyanate highly attractive to develop derivatized supports for the covalent immobilization of probes.

In this work, a new DNA covalent immobilization approach based on the isocyanate modification of PMMA and its application by spin-coating on the metallic layer of the CDs is proposed. The goal of this research also involves a demonstra-

tion of the potential of our proposal by the development of microarray-based assays, reading the hybridization results with a CD player as detector.

EXPERIMENTAL PROCEDURES

Reagents. PMMA (ref 99530) sheets (1 mm thickness) were from Röhm (Darmstad, Germany). Ethanolamine and (3-isocyanatopropyl)triethoxysilane (ICPTS) were purchased from Acros (Barcelona, Spain) and Fluka (Madrid, Spain), respectively. Dowanol, Tween 20, streptavidin−horseradish peroxidase (strept-HRP) from *Streptomyces avidinii*, and 3,3′,5,5′-tetramethylbenzidine (TMB) substrate were purchased from Sigma-Aldrich (Madrid, Spain). Oligonucleotides (see Table 1) were from Sigma-Genosys (Suffolk, UK). All commercially available products were used without further purification. Oligonucleotide solutions were printed onto the desired surface by tip contact using a stamper, 6 × 4 pins, from V&P Scientific, Inc. (San Diego, CA).

Buffers employed were as follows: Saline sodium citrate (10 × SSC, 0.9 M sodium chloride, 0.09 M sodium citrate, pH 7); carbonate buffer (10 × CB, 0.5 M sodium carbonate, pH 11 and pH 9.6); phosphate buffer saline (10 × PBS, 0.08 M sodium phosphate dibasic, 0.02 M sodium phosphate monobasic, 1.37 M sodium chloride, 27 M potassium chloride pH 7.5); PBS-T (PBS containing 0.05% Tween 20); MES buffer (0.1 M 2-morpholinoethanesulfonic acid monohydrate, pH 3.5).

Apparatus. The Energy Dispersion Spectra (EDS) were obtained with a scattering electron microscope Jasco-SEM, resolution 59 eV (Easton, MD). Fluorescence scanner Genepix 4000B, from Axon Instruments (Union City, CA), was used to read fluorescent probes immobilized on chip.

Compact Discs. Golden CD-Rs, partially transparent (30% reflectivity), provided by U-Tech Media Corp. (Tau-Yuan Shien, China) were directly treated, keeping its original shape, or cut in chips of 55 × 25 mm size when necessary. These low reflectivity recordable compact discs (L-CD, 1.2 mm thick polycarbonate discs, with a gold reflective layer of 30 nm, 12 cm diameter) allow the laser (780 nm) to have two functions: (a) reflected light (30%) lets the laser follow the track, maintaining the rotation of the disc (autotracking), and (b) transmitted light (70%) reaches the microarray spots located on the upper side of the CD, detecting the hybridization intensities by the amount of precipitate produced by an enzymatic marker (HRP) and a substrate (TMB).

Disc Reader. A standard CD player from Plextor LLC (Fremont, CA) was used as detector. The drive uses the servo control system to center and focus the beam on the spiral data track across the whole disc surface. The CD reader uses the original design of the CD players, taking advantage of the CD driver optical system to accurately illuminate the polycarbonate face of the L-CD (partially reflecting the laser and transmitting the rest through the PMMA surface to the photodiode). The controlled parameters of the optical disc drive include positioning of the laser toward the disc, scanning the whole disc surface while controlling the spatial resolution, and the linear rotation velocity of the disc. A planar photodiode (SLSD-71N6, Silonex, Montreal, Canada), 25.4 mm long, with a spectral sensitivity of 0.55 A/W at 940 nm, and a spectral range between 400 and 1100 nm, transmitted laser light and converted it into an analog electrical signal.

A reflective photosensor (EE-SY125, Omron, Scahumburg) used to detect the analytical areas includes an infrared LED of 950 nm and a phototransistor with a sensing distance ranging from 0.5 mm to 2 mm. The operational principle of the photosensor is based on the detection of the different reflectivities between the sensing object and the disc. For that, the analytical areas are marked in the outer rim of the disc by low reflectivity trigger footprints of 3.5 cm size. Because the unmarked perimeter presents higher reflectivity, the photosensor detects the marked areas, providing a trigger signal to the data acquisition board in order to start capturing data exclusively from those zones.

A custom-built electronic board (DAB) incorporates the planar photodiode and the photosensor. The function of the board is 2-fold. First, the detection of analytical areas, and second the amplification of the analog signal. Both functions are carried out at the same time the CD drive performs its original function of reading and writing data. In this way, during the data acquisition process only the signals from the detection areas are digitized by the data acquisition board (DAQ), stored in the computer and deconvoluted into an image for further quantification. A scheme of the developed detection system is shown in Figure 1. The detector system is controlled by software running on a Windows-based computer connected to the PC through a universal serial bus interface (USB2.0) to become portable.

Custom software was written in Visual C++. The software provides the control for the CD/DVD driver to scan the surface of the disc, to modulate the disc linear rotation velocity to a specified spatial resolution, and to write data on the CD or DVD. Also, the software provides the control to the data acquisition board to configure the sampling frequency according to the disc rotation speed and desired angular resolution. To completely scan the surface of the L-CD, the software simulates the writing process of a 700 MB size file to a controlled disc rotation speed. The scan begins from the inner tracks of the disc, following the continuous spiral toward the outer tracks. The captured data of each detection area are represented within a sector that is formed by a set of arcs centered over a radial direction, starting from the inner toward the outer radial. The software collects the data of each area and stores them in independent files in uncompressed binary format and displays them into a graphical gray scale code image.

Because of the spatial difference between samples taken horizontally (each 13 μm) and vertically (each 1.6 μm), a graphical horizontal adjustment is done to display a proportional $x-y$ image. This software allows the image to be exported in a gray scale code to a compressed tif format or bitmap. Then, the images were processed with Photoshop 7.0 (Adobe Systems Inc., San Jose, CA), to map the lightest and darkest pixels into black and white before quantifying with GenePix software (Axon Inst., Union City, CA). Signal intensities of each spot were calculated by background subtraction.

Disc Surface Modification. *(a) PMMA Transamination.* PMMA (310 mg) was dissolved in THF (3 mL). Ethanolamine (1 mL) was added, and the mixture was refluxed for 5 h. After that, THF was removed under vacuum and the solid was dissolved in CH_2Cl_2. The organic phase was washed with MES buffer until the total removal of ethanolamine. The organic layer was dried with $MgSO_4$ and the solvent evaporated, providing the transaminated polymer as a colorless solid. The ^{1}H NMR spectrum showed 50% transaminated compound. ^{1}H NMR ($CDCl_3$): δ (ppm) 3.79 (t, CH_2OH), 3.57 (s+m, CH_3O and CH_2-NHCO), 1.87−1.78 (m, CH_2), 0.091 (s, CH_3), 0.806 (s, CH_3).

(b) Coating. The transaminated polymer was dissolved in Dowanol (5%). One milliliter of this solution was pipetted onto the metalized (gold) side of a standard L-CD for spin-coating at a centrifugal force of 47.33*g* (840 rpm). After that, the solvent was removed at 52 °C for 30 min.

(c) Isocyanate Treatment of Coated L-CD. Coated L-CDs were immersed into a solution of (3-isocyanatopropyl)triethoxysilane in 2-propanol (1%) for 10 min and cured at 62 °C for 15 min. Finally, they were washed with 2-propanol and dried at 62 °C.

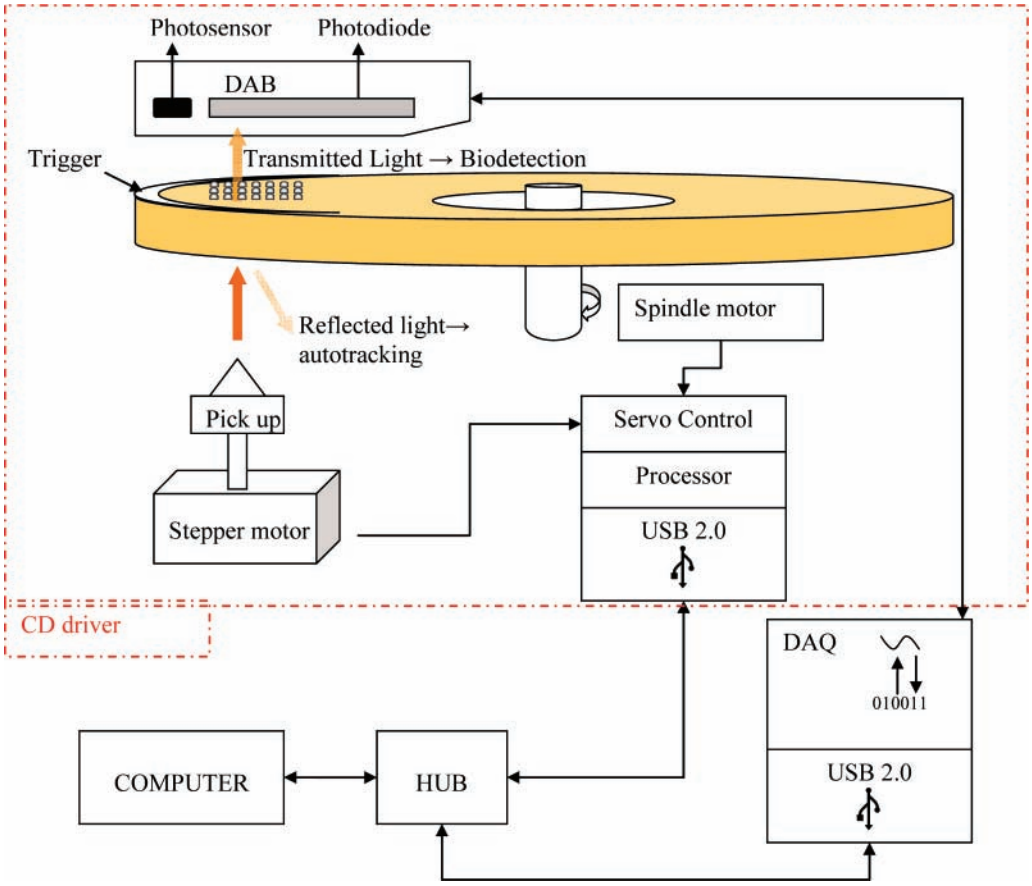

Figure 1. Schematic representation of the detection system. The set of servo systems (spindle and stepper motors) of the CD drive allows disc rotation and laser scanning. The transmitted light through the disc is transformed by the photodiode into an analog electrical signal (RF signal). At the same time, the photosensor detects the trigger footprints, starting the data collection on disc. The amplification/ detection board (DAB) is integrated into the CD drive unit and contains the planar photodiode and the photosensor. The data acquisition board (DAQ) digitizes the analog signals and transfers them to the computer for processing. On the disc, one detection area is represented.

Surface Behavior: DNA Immobilization and Hybridization Assays. Different 5′ Cy5-labeled and/or 3′ NH_2-ended oligonucleotides were employed for DNA immobilization and hybridization assays (Table 1). Amino-labeled DNA capture probes (SYM12 and SYM23) were serial diluted in carbonate buffer pH 11 ranging from 0.01 to 5 μM; 18 replicates (2 matrix of 3 × 3 spots) of each dilution were spotted on PMMA-modified chips. The fluorescence intensity of the spots was registered by the laser scanning detector to obtain a standard curve for the probes. Similar calibration curves for the Cy5-labeled target DNA were made. After immobilization and hybridization, the fluorescence signal of the spots was quantified and the amount of immobilized and hybridized DNA was calculated from the respective calibration curves.

Six 5′ Cy5-labeled, 3′ NH_2-ended oligonucleotide solutions (1 and 10 μM) were prepared employing different solvents: H_2O, 1 × PBS pH 7.5, and 1 × CB pH 11. Microarrays (3 × 3) of each solution were tip-contact-printed onto isocyanate-modified surfaces. L-CDs were then incubated for 2 h in a humid, dark chamber at room temperature. Then, the printed surfaces were washed with PBS-T and water and dried.

For the hybridization assays, the aminated probe SYM22 was covalently attached to the isocyanate surface as described above. Cy5-labeled target-DNA SYM8 was serial diluted between 0.1 and 1 μM in a mixture containing 6 × SSC, 0.6% SDS, 0.1% salmon sperm DNA, and 2% BSA. A 100 μL amount of the complementary oligonucleotide solution was dispensed on the microarrays and spread under a coverslip (22 × 22 mm). The temperature of hybridization was 37 °C, performing the incubation in a dark and humidified chamber for 1 h. After that, the slides were washed with 0.1 × SSC, 0.5% SDS for 15 min, and with 0.1 × SSC (5 min). Finally, the chips were rinsed with water and air-dried.

Table 1. Nucleotide Sequence of Probes and Targets Used

name	sequence (5′ to 3′)	5′ end	3′ end
SYM12	ACTGGTCGATCG	Cy5	C_6-NH_2
SYM23	TTACGATCGATTAGTTAGCCC-$(T)_{15}$	Cy5	C_7-NH_2
SYM8	AATGCTAGCTAATCAATCGGG	Cy5	none
SYM25	AATGCTAGCTAATCAATCGGG	biotin	none
SYM22	$(T)_{15}$-CCCGATTGATTAGCTAGCATT	none	C_7-NH_2

For hybridization assays on standard L-CDs, each disc was divided into eight printing zones and SYM22 was covalently attached as described above. Afterward, 35 μL of OVA in 1 × CB (pH 9.6) was dispensed on each printed area, spread under a coverslip, and incubated for 10 min at room temperature in a moist chamber. Then, L-CDs were washed 5 min with PBS-T and 5 min with water and air-dried. Biotin-ended target DNA (SYM25) was serial diluted between 0.001 and 0.2 μM in a mixture containing 6 × SSC, 0.6% SDS, 0.1% salmon sperm DNA, and 2% BSA. A 35 μL amount of the complementary oligonucleotide solution was dispensed on the microarrays and spread under a coverslip, performing the hybridization at 37 °C in a dark and humidified chamber, for 1 h. The discs were washed with PBS-T (15 min) and water (5 min) and air-dried. Following a similar procedure described by Cao et al. (*19*), 35 μL of 10 μg/mL streptavidin−HRP in 1 × PBS were deposited on each zone of the L-CD and incubated again for 20 min in a moist chamber at 37 °C. After rinsing with PBS-T (15 min) and water (5 min) and drying, 35 μL of TMB substrate solution was dispensed, causing a blue precipitate to appear on

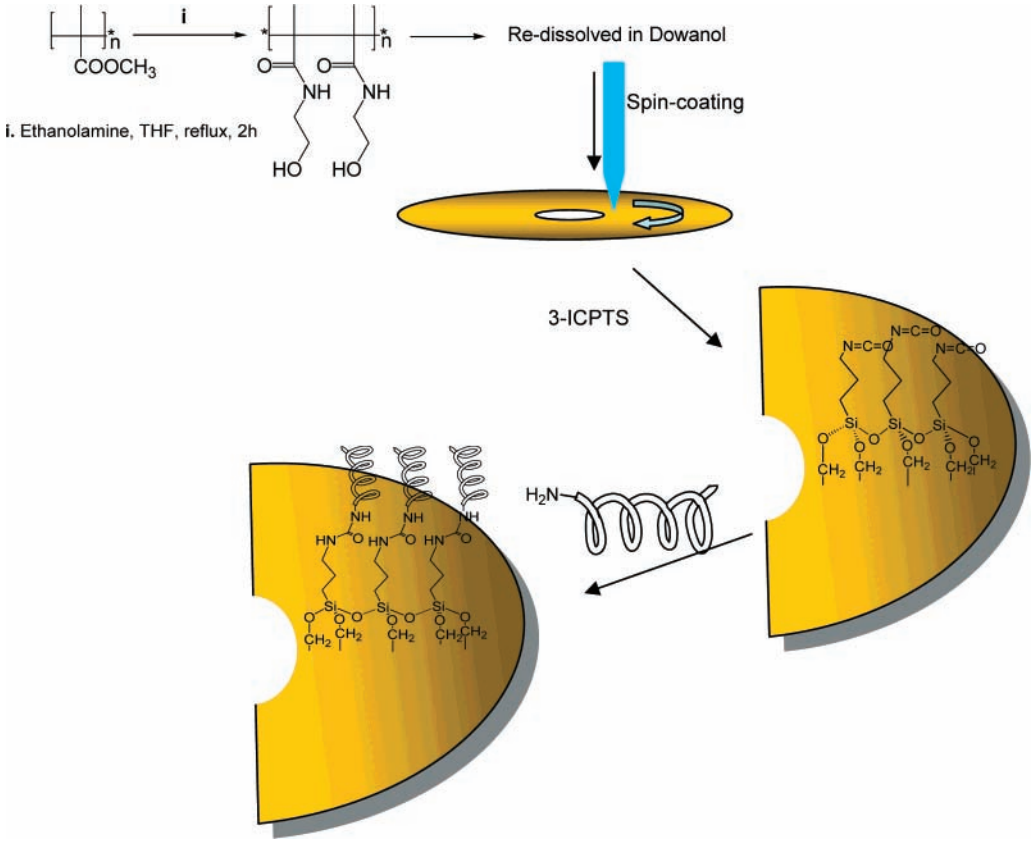

Figure 2. Scheme of the method for the covalent attachment of amino-ended oligonucleotides on L-CD surface.

the microarrays after 3 min. Results were read with the CD player as described above.

RESULTS AND DISCUSSION

L-CD Surface Modification. To achieve the covalent attachment of oligonucleotides onto the isocyanate-modified L-CD surface, the following three-step approach was investigated: (i) methyl ester transamination of PMMA employing ethanolamine in THF; (ii) spin-coating of the hydroxylated PMMA dissolved in Dowanol; (iii) introduction of the isocyanate moiety by the ether formation between the hydroxyl groups on PMMA and 3-isocyanatopropyltriethoxysilane (Figure 2).

The employment of organosilane allowed us to introduce a thin and homogeneous layer when working in a controlled manner. On the other hand, as isocyanate was chosen to attach the aminated oligomer, a urea bond was obtained. This bond is highly stable and easy to perform. The high reactivity of the isocyanate group results in a rapid coupling reaction and is particularly useful for covalent attachment of biomolecules such as nucleic acids, peptides, carbohydrates, lipooligosaccharides, etc.

The reaction of PMMA dissolved in THF with ethanolamine produced the aminolysis of the methyl ester, providing hydroxylated PMMA with a yield of around 50%, determined by NMR.

The modified polymer was dissolved in Dowanol for application of a thin layer onto the L-CD by spin coating and drying as described in the Experimental Section. The film thickness was 60 nm (measured by AFM and ellipsometry) with a high degree of homogeneity and reproducibility (tested by AFM and SEM).

For the organosilane treatment, selecting the proper solvent was a crucial point; thus, the mechanical and optical properties of the L-CDs must be unaltered in order to read the signals resulting from the hybridization assays. Most of the tested solvents (diethyl ether, tetrahydrofuran, dichloromethane, hexane) were promptly discarded; thus, they partially dissolved the base polymer (PC) and caused drastic alterations on the L-CD support. Finally, the selected solvent was 2-propanol. Also, different reaction concentrations, ranging from 0.1% to 5%, and times, between 10 min and 2 h, were studied.

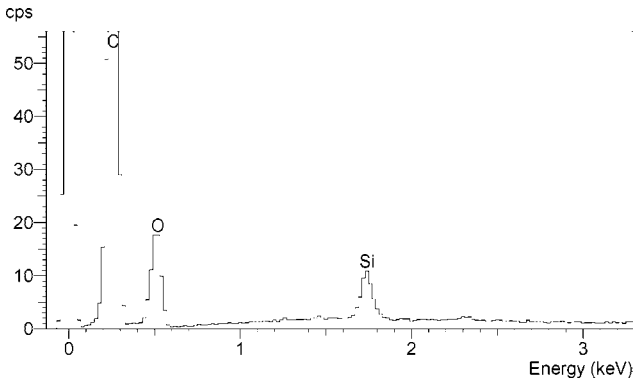

Figure 3. ED spectrum of the isocyanate-modified PMMA-L-CD surface.

To detect the effectiveness of ICPTS reaction onto hydroxylated PMMA-coated L-CDs, ED spectra were recorded; the presence of Si indicated that the organosilane reaction worked in a proper manner (Figure 3). Also, to examine the success of the reaction, the treated L-CDs were cut in chips (55 × 25 mm) and immersed into 4.5 mM fluoresceinamine dissolved in 2-propanol for 20 min. After washing, fluorescence was measured (λ_{exc} 485 nm; λ_{em} 580 nm), and the results were compared with different control chips to eliminate the solvent effect. This control is necessary, as the consecutive treatments produced an alteration of the surface and the fluorescein could swell the chip, resulting in high fluorescence signals. For that, treatment with fluoresceinamine was carried out for every step of the approach (raw L-CD, L-CD coated with hydroxylated PMMA, and isocyanate-treated L-CD) and compared.

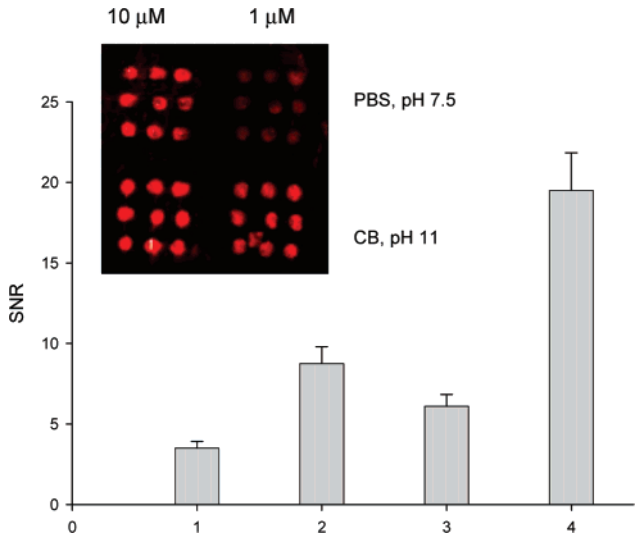

Figure 4. Results for oligomer immobilization on the isocyanate-modified L-CD surface using different buffers: (1) PBS, pH 7.5, 1 μM of probe; (2) PBS, pH 7.5, 10 μM of probe; (3) CB, pH 11, 1 μM of probe; (4) CB, pH 11, 10 μM of probe.

During the optimization process it was observed that the longer the treatment with organosilane the lower difference in fluorescence values with respect to the controls (similar conditions as for silanization but without the organosilane). This is explained considering that the solvent employed for the organosilane treatment did not alter the disc surface when short silanization times were applied, but prolonged exposure of PMMA to 2-propanol damaged the chip surface, lowering its transparency and producing a gummy texture.

Final conditions were chosen, limiting the time exposure to the organosilane solution (10 min, 1%) and curing the plastic after the treatment for 15 min at 62 °C. Oligomer immobilization was performed after the surface preparation.

DNA Immobilization. Under the chosen reaction conditions, L-CDs were prepared to assay the covalent attachment of oligonucleotides. For that, 1 μM and 10 μM 5′ Cy5-labeled, 3′ aminated oligonucleotide (SYM23) solutions were prepared in water, PBS buffer (pH 7.5), and carbonate buffer (pH 11). The oligonucleotide solutions were deposited onto the modified PMMA surfaces by tip-contact-printing. After immobilization, as explained in the Experimental Section, discs were cut in chips and the fluorescence of Cy5-labeled probes read using microarray laser scanning.

The best results were those employing CB, pH 11 (Figure 4), while results for water were far from that expected; the fluorescence at 1 μM and 10 μM was almost the same. This could be due to the unspecific adsorption and electrostatic forces. When working at pH values higher than 9, most of the amine groups in the oligomer exist as free amines and the nucleophilic attack of nitrogen to the isocyanate group is possible, providing a urea bond. However, at pH lower than 7, many of the amine groups exist as their ammonium salt and the covalent attachment is not possible, although it must be taken into account that this charged structure can adhere to the surface by electrostatic interactions as well as by hydrogen bonds.

In parallel, and in order to check the oligomer probe covalent attachment quality, several controls were performed employing raw L-CD, and hydroxyl-PMMA-coated L-CDs, raw and treated with 2-propanol. In all cases, the fluorescence signal was less than 10% of the fluorescence observed in isocyanate-modified L-CDs. Besides, to assess that all the attached oligomers were covalently bound to the disc surface, controls employing Cy5-labeled oligonucleotide without amine functionalization (SYM8) were printed on activated PMMA discs (blank assay), working in a way similar to that with amine-ended oligonucleotides. Again, the fluorescence signal was at the background level.

When the disc was inserted in the standard CD player and a recording simulation was done, the L-CD was read without presenting internal errors. It was concluded that the treatment proposed for oligomer immobilization on discs leave the L-CD available for further common use such as data recording, and the L-CD surface remained, to the naked eye, unaltered after the chemical treatment and oligomer attachment. This opens up an interesting application field of the developed methodology for performing chemical assays on the top of treated PMMA-L-CDs, using the bottom side (PC) to read it with the CD player laser, and for the registration of the analytical data and other management information. Another advantage of this methodology is the application of widely studied organosilane chemistry on CDs. By making use of these reagents, different ways of biomolecule covalent attachment are possible; for example, by employing a mercaptoorganosilane, thiol-ended biomolecules could be attached by formation of disulfide bridges.

To estimate the density of DNA single strands covalently attached to the surface, calibration assays were performed on treated L-CDs, employing SYM23 (analogous to SYM22, but Cy5-labeled). Considering the tip-contact dispensed volume (3 nL) and the averaged spot diameter, through the calibration curve, an immobilization density about 2 pmol/cm^2 for a 5 μM concentration of the spotted oligonucleotide was estimated. This value was in agreement with data found in the literature for glass (*20*) (2 pmol/cm^2), PMMA (*17*) (4 pmol/cm^2), and gold (*21*) (3 pmol/cm^2).

Hybridization on L-CD. One of the main concerns when preparing DNA microarrays is to achieve a good yield in hybridization assays. To check the performance of the developed approach, several experiments were conducted employing different concentrations of both DNA probe (1, 5, 10, and 20 μM) and Cy5-labeled complementary DNA strand (0.1, 0.2, 0.5, and 1 μM). The hybridization density (pmol/cm^2) was calculated from interpolation of the registered fluorescence value in the corresponding calibration curve.

Figure 5 shows the hybridization density reached at different sDNA probe concentrations, indicating that the best results correspond to 5 μM sDNA. Besides, it was observed that when probe concentration as high as 20 μM was assayed, the hybridization did not give good results; the spots were surrounded by a halo of fluorescence and presented a "black hole" at the center of the spot. This could be due to the high surface coverage with DNA probes that may cause a crowding effect, lowering the accessibility of the probes (*21*). Probably, repulsive electrostatic and steric interactions also increased with probe density. Likewise, by increasing the concentration of the complementary oligonucleotide solution, no significant improvement of hybridization efficiency was detected. Consequently, it was assumed that 0.1−0.2 μM hybridization solution and 5 μM DNA probe were the optimal for this assay. Related to immobilization density, the maximum hybridization efficiency was achieved between 2 and 4 pmol/cm^2. These results were in agreement with studies (*17*) performed on chemically modified PMMA, which provide oligonucleotide densities around 0.5 pmol/cm^2, employing similar hybridization conditions.

Finally, in order to demonstrate that the developed method is fully applicable to standard CD technology, discs were treated according to the described procedure, and different concentrations of SYM 22 probe (1, 5, 10, and 20 μM) were immobilized on the L-CD surface. After hybridization with serial dilutions of SYM 25 (0.2 to 0.001 μM), the L-CD was treated with HRP-conjugated streptavidin for 20 min, washed, and developed with

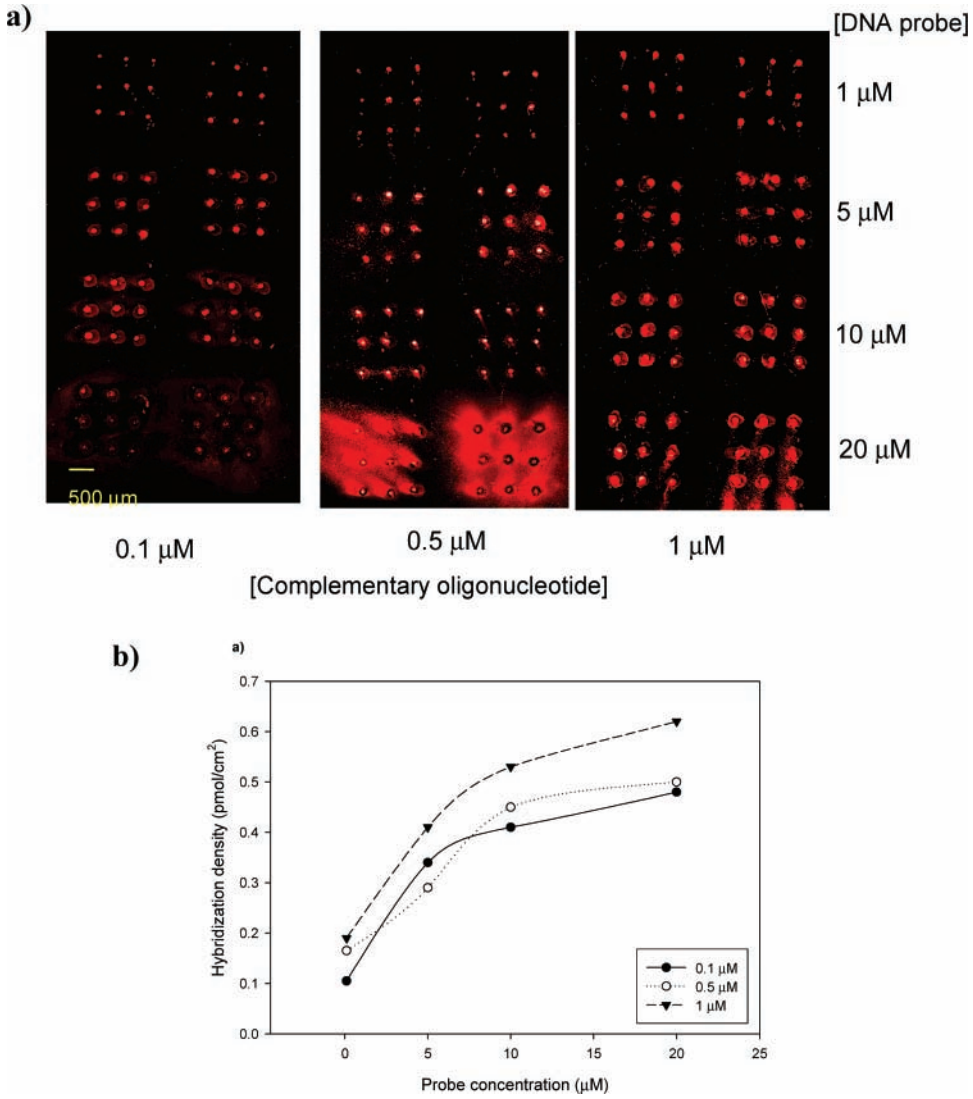

Figure 5. (a) Microarray picture of the hybridization assays performed on PMMA-modified L-CD employing Cy5-labeled complementary oligonucleotide and reading by microarray laser scanning. (b) Curves of hybridization density using different probe and target concentrations.

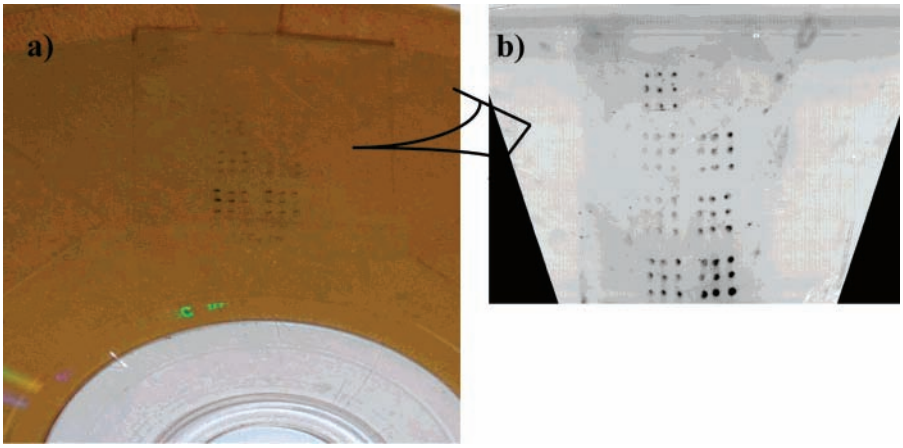

Figure 6. (a) Image of the microarray (blue spots) developed on modified L-CD after hybridization assay. (b) Magnification of the same image obtained with the CD player.

TMB for 3 min; the blue precipitate appeared in the matrixes where the hybridization happened (Figure 6) as read with the CD player.

Several controls were performed, avoiding the different working protocol steps: isocyanate treatment, covalent attachment of probe, OVA blocking of remaining isocyanate groups, hybridization solution and streptavidin−HRP incubation; none of them displayed blue points except when the OVA treatment was suppressed, as was expected.

Related to the detection system, similar trends where achieved employing conventional readers (Axon detector) or CD player. Thus, the best results were obtained for 5 μM of probe and 0.2 μM of hybridization solution although it was possible to detect concentrations of 0.005 μM hybridization solution (even by the

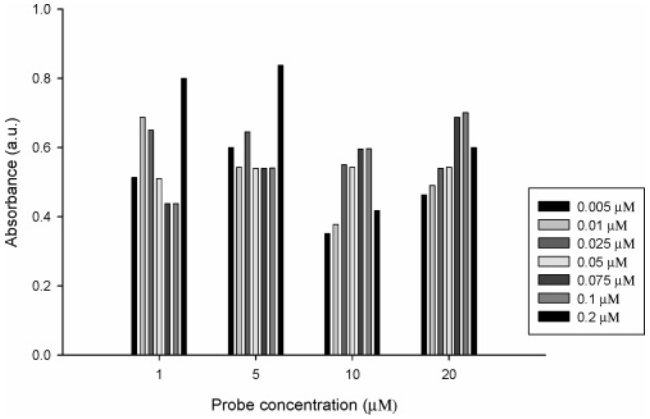

Figure 7. Signal intensity values read with the CD player for different probe and target concentrations.

naked eye). This is because of the higher sensitivity of the HRP labeling; thus, the developing procedure is based on an enzymatic reaction. The absorbance intensities of different concentrations of probe and target are shown in Figure 7. The most remarkable was that the highest signal is obtained for 5 μM probe and 0.2 μM target, as that which occurred in the assays with fluorescence detection. Also the high signal obtained for the lowest concentrations of hybridization solution provides an idea of the good sensitivity achieved from the disc isocyanate modification and CD player detection approach. These assays demonstrate that the proposed system works for qualitative detection; no quantification was intended, as the quantification protocol will depend on the application, but in general, intensity values can be converted into biologically relevant outputs by comparing the experimental and control elements present in a given microarray (*22*).

CONCLUSION

In this work a PMMA isocyanate modification is proposed for the covalent attachment of biomolecules, employing well established organosilane chemistry. The method retains the physical properties of the support, and its application is versatile and clean. The procedure is easily carried out and is compatible with aqueous media chemistry, which is crucial for its bioutility. Immobilization densities about 2 pmol/cm^2 were reached with oligonucleotides. The values were in agreement with other described methods for microarrays on modified PMMA, glass, and other surfaces.

The application on standard recordable compact discs opens an interesting field because of its potential advantages such as low fluorescent background, high quality materials at very low cost, high available surface (90 cm^2), and further use of laser technology found in the CD players as detectors, to be applied at point of need to health care or *in situ* environmental analysis.

ACKNOWLEDGMENT

We thank the MCYT (BIO 2000-0243-P4-03 and BQU 2003-02677) and Generalitat Valenciana (ACOMP06/12) for funding this project. D. Miguel García-Murillo, from Plexi S.A. (Valencia, Spain), is gratefully acknowledged for providing raw PMMA.

Received January 15, 2007; Revised Manuscript Received May 11, 2007

A cyclic RGD peptide-conjugated block copolymer, cyclo[RGDfK(CX-)]−poly(ethylene glycol)−polylysine (c(RGDfK)−PEG−PLys), was synthesized from acetal-PEG−PLys under mild acidic conditions and spontaneously associated with plasmid DNA (pDNA) to form a polyplex micelle in aqueous solution. The cyclic RGD peptide recognizes $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrin receptors, which play a pivotal role in angiogenesis, vascular intima thickening, and the proliferation of malignant tumors. The c(RGDfK)−PEG−PLys/pDNA polyplex micelle showed a remarkably increased transfection efficiency (TE) compared to the PEG−PLys/pDNA polyplex micelle for the cultured HeLa cells possessing $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins. On the other hand, in the transfection against the 293T cells possessing no $\alpha_v\beta_3$ and a few $\alpha_v\beta_5$ integrins, the TE of the c(RGDfK)−PEG−PLys/pDNA micelle showed no increase compared to the TE of the PEG−PLys/pDNA micelle. Flow cytometric analysis revealed a higher uptake of the c(RGDfK)−PEG−PLys/pDNA micelle than the PEG−PLys/pDNA micelle against HeLa cells, consistent with the transfection results. Furthermore, a confocal laser scanning microscopic observation revealed that the pDNA in the c(RGDfK)−PEG−PLys micelle preferentially accumulated in the perinuclear region of the HeLa cells within 3 h of incubation. No such fast and directed accumulation of pDNA to the perinuclear region was observed for the micelles without c(RGDfK) ligands. These results indicate that the increase in the TE induced by the introduction of the c(RGDfK) peptide ligand was due to an increase in cellular uptake as well as facilitated intracellular trafficking of micelles toward the perinuclear region via $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrin receptor-mediated endocytosis, suggesting that the cyclic RGD peptide-conjugated polyplex micelle has promising feasibility as a site-specifically targetable gene delivery system.

INTRODUCTION

With the increase in available information on various disease genes that has resulted from progress in the Human Genome Project, gene therapy is increasingly recognized as a promising therapy for many intractable diseases. Obviously, a major key to successful gene therapy is the development of gene vectors that are particularly effective for *in vivo* use. Nevertheless, there are many restrictions in the clinical application of viral vectors, which have played a pivotal role in gene therapy up to now, because of their safety issues, including antigenicity, as well as to the difficulty of formulating them with good quality control. These limitations of viral vectors have led to the recent trend in developing nonviral vectors with safety and high productivity as alternative systems to viral vectors.

One of the important challenges in the development of nonviral vectors is the system available for systemic injection, which must be stable enough to achieve longevity in the blood circulation but also be able to achieve high transfection efficiency (TE) in the target region with minimal toxicity. Lipoplex (*1*) and polyplex (*2*) systems based on cationic lipids and polymers, respectively, have been extensively studied as nonviral gene vectors for systemic administration. Nevertheless, there remain unresolved issues with these systems, because it is generally required that they contain excessive cationic lipids or polymers to increase solubility in an aqueous solution. Eventually, shifting their surface charge to a positive value induces nonspecific interaction with anionic components in the body such as plasma proteins and blood cells. This apparently hampers their applicability to systemic gene delivery. Polyplex micelles (*3*), characterized by the unique core−shell architecture of the hydrophilic shell layer surrounding their polyplex core, have the potential to acquire a so-called "stealth" property to minimize nonspecific interaction with biocomponents. Indeed, a polyplex micelle with poly(ethylene glycol) (PEG) as a hydrophilic shell layer achieved high stability in a medium containing serum compared to conventional lipoplexes and polyplexes and showed increased retention time in the bloodstream (*4*, *5*), suggesting that a polyplex micelle may be a promising candidate for a vector that can be used in systemic gene delivery. Nevertheless, in order to increase selective uptake into the target cells, appropriate ligands are preferably introduced into the surface of the polyplex micelles. In this way, surface-installed ligands are expected to enhance the uptake rate of the

polyplex micelles into the target cells by receptor-mediated endocytosis, which may lead to higher gene TE compared to the ligand-free polyplex micelles taken up by the cells through adsorptive or fluid-phase endocytosis (*6*−*8*).

In this study, acetal-poly(ethylene glycol)−polylysine (acetal-PEG−PLys) was synthesized as a precursor for constructing ligand-installed polyplex micelles. PLys, which is one of the first polymers used and well studied as a nonviral vector, was chosen as a cationic segment of the block copolymer. PLys-based polyplexes are known to show a relatively low TE against cultured cell lines compared to those having the endosomal escape function, such as polyethylenimine (PEI)-based polyplexes, but they have an advantage in stability even in a diluted condition, and they have shown an appreciable level of gene transfection in animal models (*5*, *9*). A cyclic RGD peptide (c(RGDfK)), which selectively recognizes $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrin receptors (*10*), was chosen as a ligand and introduced into the PEG terminus of aldehyde-PEG−PLys, derived from acetal-PEG−PLys, through a thiazolidine ring formation, and the c(RGDfK)−PEG−PLys block copolymer was obtained. It is generally known that the $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins are expressed on various cell types such as endothelial cells, osteoclasts, macrophages, platelets, and melanomas, and that they play a significant role in angiogenesis, vascular intima thickening, and the proliferation of malignant tumors (*11*). Therefore, gene delivery targeting the $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins is expected to be useful in the treatment of cancer and vascular diseases. Indeed, the c(RGDfK)−PEG−PLys/pDNA polyplex micelle thus prepared showed a remarkably increased TE compared to ligand-free polyplex micelles against the HeLa cells expressing $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins.

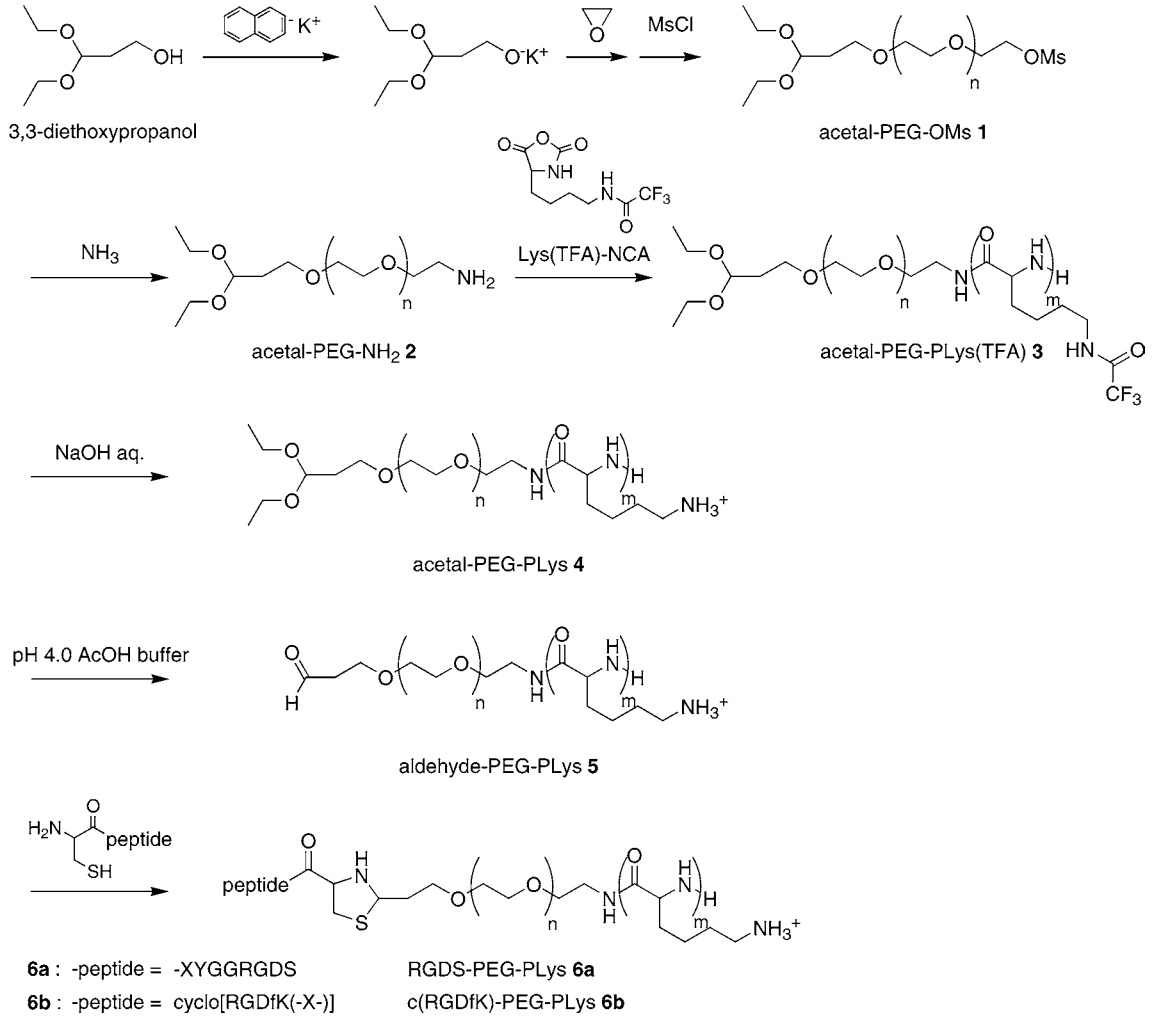
EXPERIMENTAL PROCEDURES

Materials. 3,3-Diethoxypropanol was purchased from Aldrich Chemical Co. Ltd. (Milwaukee, WI). Ammonia solution (25%), tetrahydrofuran (THF), *N*,*N*-dimethylformamide (DMF), *n*-hexane, methanesulfonyl chloride (MsCl), and triethylamine (TEA) were purchased from Wako Pure Chem. Co. Ltd. (Japan). Ethylene oxide (EO) was purchased from Sumitomo Seika Chemicals Co. Ltd. (Japan). THF was distilled according to the conventional procedure as previously reported (*12*). DMF was dehydrated using activated molecular sieves (4A) and distilled under reduced pressure. 3,3-Diethoxypropanol and *n*-hexane were distilled over sodium wire. MsCl, TEA, and EO were dried over calcium hydride followed by distillation. CXYGGRGDS (RGDS) and cyclo[RGDfK(CX-)] (c(RGDfK)) peptides (X = 6-aminocaproic acid; ϵ-Acp) were purchased from Peptide Institute, Inc. (Japan). The PEG−PLys block copolymer (PEG; 12 000 g/mol, polymerization degree of PLys segment; 73) was synthesized as previously reported (*13*). A micro BCA protein assay reagent kit was purchased from Pierce (Rockford, IL). The Luciferase assay kit was a product of Promega (Madison, WI). Plasmid pCAcc+Luc coding for firefly luciferase under the control of the CAG promoter was provided by the RIKEN Gene Bank (Japan), amplified in competent DH5α *Escherichia coli*, and then purified using a HiSpeed Plasmid MaxiKit purchased from QIAGEN Sciences Co., Inc. (Germany). FITC-labeled monoclonal antibodies against $\alpha_v\beta_3$ integrin, $\alpha_v\beta_5$ integrin, and mouse IgG were purchased from Cosmo Bio Co., Ltd. (Japan). QuantiLum recombinant luciferase was purchased from Promega (Madison, WI).

Measurements. Gel permeation chromatography (GPC) measurements were carried out using a TOSOH HLC-8220 equipped with TSKgel columns (G4000PWXL and G3000PWXL). The internal refractive index (RI) was used for detection of the polymer. DMF with 10 mM LiCl was used as an eluent at a flow rate of 0.8 mL min^{-1} at 40 °C. IR was measured with an IR Report-100 spectrometer (JASCO, Tokyo, Japan). ^{1}H NMR spectra were obtained with a JEOL EX300 spectrometer (JEOL, Tokyo, Japan). Chemical shifts are reported in ppm relative to the residual protonated solvent resonance.

Synthesis of RGDS−PEG−PLys 5a and c(RGDfK)−PEG−PLys 5b (Scheme 1). *Acetal-PEG-NH$_2$* ***2***. A THF solution of 3,3-diethoxypropanol (0.16 mL, 1 mmol) and potassium naphthalene (2.7 mL, 0.90 mmol) were mixed in THF (75 mL) to form potassium 3,3-diethoxypropanolate (PDP) as previously reported (*14*). After the mixture was stirred for 10 min, liquid EO (13.5 mL, 270 mmol) chilled below 0 °C was added to the solution with additional stirring at room temperature (r.t.) for 2 days. The reactant polymer was isolated by precipitation into diethyl ether and lyophilized from benzene to obtain acetal-PEG-OH (12.65 g, quant). Acetal-PEG-OH (6.01 g, 0.50 mmol) was then dissolved in THF (40 mL), followed by the addition of TEA (0.32 mL, 2.25 mmol). Subsequently, the solution was slowly added dropwise into MsCl (0.12 mL, 1.5 mmol) in THF (20 mL) and stirred at 0 °C for 2 h. The solution was poured into diethyl ether to precipitate acetal-PEG-OMs **1**. The recovered acetal-PEG-OMs **1** was dissolved in 25% ammonia solution (500 mL) and stirred at r.t. for 4 days. The volume of the solution was concentrated to 50 mL by evaporation and dialyzed sequentially against 0.125% ammonia solution and distilled water, followed by lyophilization to obtain acetal-PEG-NH$_2$ **2** (5.40 g, 90%).

Acetal-PEG−PLys(TFA) ***3***. N^{ϵ}-Trifluoroacetyl-L-lysine *N*-carboxyanhydride (Lys(TFA)-NCA) (3.59 g, 13.39 mmol, 80 equiv to **2**) prepared according to the protocol described in the literature (*15*) in DMF (40 mL) was added to acetal-PEG-NH$_2$ **2** (2.01 g, 167.5 μmol) in DMF (20 mL) and stirred at 40 °C for 2 days. The polymerization was monitored by IR. The reactant polymer was precipitated into AcOEt/hexane (4:6) and lyophilized in dioxane to obtain acetal-PEG−PLys(TFA) **3** (4.08 g, 73%).



Acetal-PEG−PLys ***4***. NaOH solution (1 N, 4 mL) was added to acetal-PEG−PLys(TFA) **3** (500 mg, 17.77 μmol) in MeOH (40 mL) and stirred at 40 °C for 24 h. The reacted polymer was purified by dialysis sequentially against 10 mM PBS solution (pH 7.0) and distilled water and lyophilized to obtain acetal-PEG−PLys **4** (498 mg, quant).

RGDS−PEG−PLys ***6a*** *and c(RGDfK)−PEG−PLys* ***6b***. Conjugation of the peptide into the PEG terminus of PEG−PLys was performed through thiazolidine ring formation using RGDS or c(RGDfK) peptide. RGDS−PEG−PLys **6a** was synthesized according to the typical procedure, as follows: Acetal-PEG−PLys **4** (39.1 mg, 1.64 μmol) was added to RGDS (15.2 mg, 16.4 μmol) in 0.2 M AcOH buffer (pH 4.0, 8 mL) and stirred at room temperature for 5 days. The reacted polymer was purified by dialysis sequentially against 10 mM PBS solution (pH 7.0) and distilled water and lyophilized to obtain RGDS−PEG−PLys **6a** (35.4 mg, 86%). Conjugation of the c(RGDfK) to acetal-PEG−PLys **4** was carried out in a similar way, e.g., c(RGDfK) (7.4 mg, 9.03 μmol) and acetal-PEG−PLys **4** (30.0 mg, 1.26 μmol) were used to obtain c(RGDfK)−PEG−PLys **6b** (26.6 mg, 87%).

Preparation of Polyplex Micelles. Each block copolymer and pDNA was dissolved separately in 10 mM Tris-HCl buffer (pH 7.4). The polymer solution in varying concentrations was added to a twice-excess volume of pDNA solution to form polyplex micelles with different compositions. The final pDNA concentration was adjusted to 33.3 or 50 μg/mL. The resulting solution was kept at r.t. overnight. The N/P ratio was defined as the residual molar ratio of the amino groups of PLys units to the phosphate groups of pDNA.

Ethidium Bromide Exclusion Assay. Polyplex micelle solutions (50 μg pDNA/mL) prepared at various N/P ratios were

Scheme 1. Syntheses of RGDS−PEG−PLys 6a and c(RGDfK)−PEG−PLys 6b

adjusted to contain 10 μg pDNA/mL with 2.5 μg ethidium bromide (EtBr)/mL and 150 mM NaCl by adding 10 mM Tris-HCl solution (pH 7.4) containing EtBr and NaCl. The solutions were kept at r.t. overnight. The fluorescence intensity of the sample solutions at 590 nm (excitation wavelength: 365 nm) was measured at 25 °C using a spectrofluorometer (ND-3300, NanoDrop, Wilmington, DE). The fluorescence intensity of naked pDNA was set at 100% and measured against a background of EtBr without pDNA.

Dynamic Light Scattering Measurement. The size of the polyplex micelles was evaluated by dynamic light scattering (DLS) using Nano ZS (ZEN3600, Malvern Instruments, Ltd., UK). A He−Ne ion laser (633 nm) was used as the incident beam. Polyplex micelle solutions (50 μg pDNA/mL) with an N/P = 2 were adjusted to a concentration of 10 μg pDNA/mL. The data obtained at a detection angle of 173 ° at 25 °C were analyzed by a cumulant method to obtain the hydrodynamic diameters and polydispersity indices (μ/Γ^2) of the micelles. The results reported are expressed as the mean values (±SEM) of three experiments.

ζ-Potential Measurement. The ζ-potential of polyplex micelles was evaluated by the laser-doppler electrophoresis method using Nano ZS with a He−Ne ion laser (633 nm). Sample solutions similar to those used for the DLS measurements were prepared. The ζ-potential measurements were carried out at 25 °C. A scattering angle of 17° was used in these measurements. The results are expressed as the mean values (±SEM) of three experiments.

Detection of $\alpha_v\beta_3$ and $\alpha_v\beta_5$ Integrin Receptors. 293T cells and HeLa cells were detached by pipetting and by harvesting with trypsin, respectively. Both types of cells were washed twice with PBS. The 1×10^6 cells and FITC-labeled antibody against $\alpha_v\beta_3$ or $\alpha_v\beta_5$ integrin (2 μg) were resuspended in 100 μL of Dulbecco's Modified Eagle Medium (DMEM) (containing 10% serum) and incubated on ice for 1 h in the dark. The cells were washed three times with cold medium and, after being resuspended in PBS, were analyzed using a flow cytometer (EPICS XL, Beckman Coulter, Inc.). The cytometric data were analyzed using EXPO32 software (Beckman Coulter, Inc., Fullerton, CA).

Transfection. HeLa and 293T cells were respectively seeded on 24-well culture plates (10 000 cells/well) and incubated overnight in 500 μL of DMEM containing 10% serum. After the medium was replaced with fresh medium, 20 μL of polyplex solution (50 μg pDNA/mL, N/P = 2) was applied to each well. The amount of pDNA was adjusted to 1 μg per well. After incubation for various lengths of time, the medium was replaced with 500 μL of fresh medium, followed by reincubation. The reincubation time was adjusted so the total incubation time would be 48 h. The luciferase gene expression was then evaluated based on the intensity of the photoluminescence using the Luciferase assay kit and a Luminometer (Lumat LB9507, BERTHOLD, Germany). The amount of protein in each well was concomitantly determined using a Micro BCA protein assay reagent kit. The relative light units were converted into the absolute amount of luciferase (ng) using a standard curve calibrated with recombinant luciferase (QuantiLum, Promega). One nanogram of luciferase corresponded to 9.1×10^7 RLU in our experiments; this was defined as the conversion factor.

Analysis of Cellular Uptake of Polyplex Micelles. pDNA was labeled with fluorescein as previously reported (*4*). Briefly,

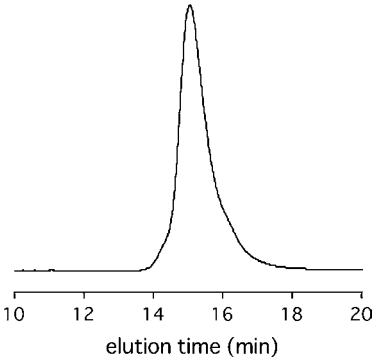


Figure 1. Gel permeation chromatogram of acetal-PEG−PLys(TFA) **3** (instrument TOSOH HLC-8220, detector RI, columns TSKgel G4000PWXL and G3000PWXL, eluent DMF with 10 mM LiCl, flow rate 0.8 mL min^{-1}, temperature 40 °C).

pDNA was labeled using a Label IT Nucleic Acid Labeling Kit (Mirus, Madison, WI). HeLa cells were seeded on six-well culture plates (100 000 cells/well) and incubated overnight in 1 mL of DMEM containing 10% serum. After the medium was replaced with fresh medium, 90 μL of polyplex solution (33.3 μg fluorescein-labeled pDNA/mL, N/P = 2) was applied to each well. The amount of fluorescein-labeled pDNA was adjusted to 3 μg per well. After various periods of incubation, the medium was removed and the cells were washed twice with PBS. After detachment by trypsin, the cells were resuspended in PBS and analyzed using the flow cytometer.

Confocal Laser Scanning Microscope (CLSM) Observation. pDNA was labeled with Cy5 in the same manner as fluorescein using the Label IT Nucleic Acid Labeling Kit. HeLa cells (30 000 cells) were seeded on a 35-mm glass base dish (Iwaki, Japan) and incubated overnight in 1 mL of DMEM containing 10% serum. After the medium was replaced with fresh medium, 90 μL of polyplex solution containing 3 μg Cy5-labeled pDNA (N/P = 2) was applied to a glass dish. After 3 h incubation, the medium was removed and the cells were washed twice with PBS. The intracellular distributions of the polyplex micelles were observed by CLSM following acidic late endosome and lysosome staining with LysoTracker Green (Molecular Probes, Eugene, OR) and nuclear staining with Hoechst 33342 (Dojindo Laboratories, Japan). The CLSM observation was performed using LSM 510 (Carl Zeiss, Germany) with a 63× objective (C-Apochromat, Carl Zeiss, Germany) at excitation wavelengths of 488 nm (Ar laser), 633 nm (He−Ne laser), and 710 nm (Mai Tai laser) for fluorescein, Cy5, and Hoechst 33342, respectively.

RESULTS

Synthesis of Peptide-Conjugated PEG−PLys (Scheme 1). The synthesis of acetal-PEG-OMs **1** has been previously reported (*14*). Briefly, PDP from 3,3-diethoxypropanol and potassium naphthalene initiated the anionic polymerization of EO to form acetal-PEG-OH (M_n 11 825, M_w 12 089, M_w/M_n 1.02), followed by the mesylation of alcohol using MsCl to obtain acetal-PEG-OMs **1**. Acetal-PEG-NH_2 **2** was then synthesized by amination of acetal-PEG-OMs **1** using ammonia solution and was confirmed to be unimodal with a narrow molecular weight distribution (M_w/M_n 1.03). Polymerization of Lys(TFA)-NCA using acetal-PEG-NH_2 **2** as an initiator led to the formation of acetal-PEG−PLys(TFA) **3**. A GPC of the obtained acetal-PEG−PLys(TFA) **3** showed a single peak with a narrow molecular weight distribution (M_w/M_n 1.12) (Figure 1). From the peak intensity ratio of the methylene protons of PEG (OCH_2CH_2, δ = 3.6 ppm) and the methylene protons of Lys(TFA) ($CH_2CH_2CH_2CH_2NH$, δ = 1.4, 1.5, 1.9, and 3.2 ppm) measured by ^{1}H NMR, the polymerization degree (DP) of Lys-(TFA) was calculated to be 70 (data not shown). Acetal-PEG−PLys **4** was then quantitatively obtained by the deprotection of acetal-PEG−PLys(TFA) **3** under basic conditions. From the ^{1}H NMR spectrum, the acetal group (CH_3CH_2O, δ = 1.2 ppm) was confirmed to be almost intact without converting to an aldehyde group (Figure 2). The DP of Lys was calculated to be 72 from the peak intensity ratio of the methylene protons of PEG (OCH_2CH_2, δ = 3.6 ppm) and the methylene protons of PLys ($CH_2CH_2CH_2CH_2NH_3$, δ = 1.4, 1.7, and 3.0 ppm) (Figure 2). The DP of acetal-PEG−PLys(TFA) **3** and acetal-PEG−PLys **4** were almost identical, indicating that main chain cleavage under the deprotection reaction was negligible.

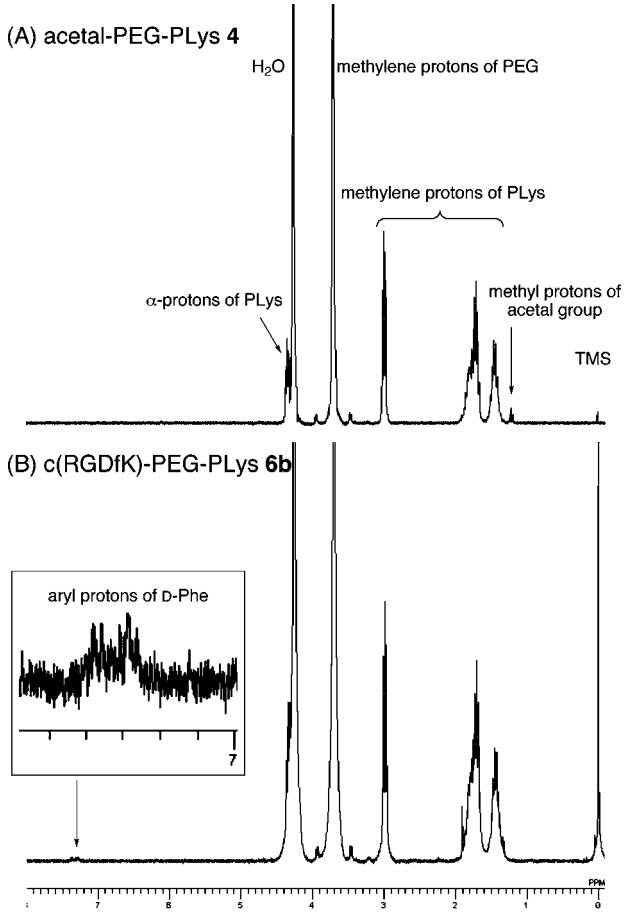

Figure 2. ^{1}H NMR spectra of acetal-PEG−PLys **4** (A) and c(RGDfK)−PEG−PLys **6b** (B) in D_2O at 80 °C.

Conjugation of peptide ligands into the PEG terminus of acetal-PEG−PLys **4** was achieved through the formation of a thiazolidine ring. The acetal group was deprotected under acidic conditions to an aldehyde group, giving aldehyde-PEG−PLys **5**. The aldehyde group is known to react with cysteine to form a stable thiazolidine ring (*16*). In this study, CXYGGRGDS (RGDS) and cyclo[RGDfK(CX-)] (c(RGDfK)), having an N-terminal cysteine residue (C: L-Cys), were reacted with acetal-PEG−PLys **4** under mild acidic conditions (pH 4.0) to prepare the peptide-conjugated PEG−PLys through thiazolidine formation. Note that Schiff base formation due to the reaction of the aldehyde and primary amino groups of the PLys segment was prohibited under the acidic conditions because of the complete protonation of the primary amino groups. The methyl protons of the acetal group (δ = 1.2 ppm) completely disappeared with the appearance of protons assigned to the aromatic rings of L-tyrosine (Y: L-Tyr:) (δ = 6.9 and 7.1 ppm) in the RGDS and D-phenylalanine (f: D-Phe) (δ = 7.3 and 7.4 ppm) in the c(RGDfK) (Figure 2). Based on the peak intensity ratios of the aromatic ring protons of peptide ligands and the methylene

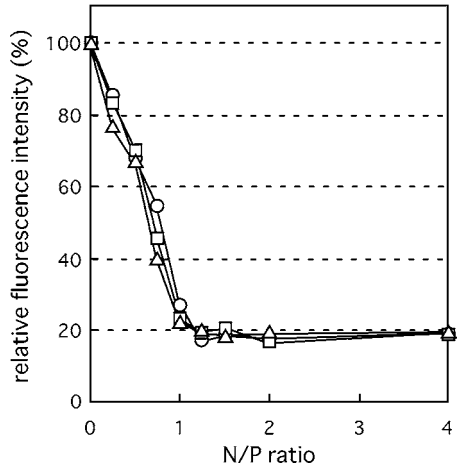

Figure 3. Ethidium bromide exclusion assays of PEG−PLys (open circle), RGDS−PEG−PLys (open square), and c(RGDfK)−PEG−PLys (open triangle). Fluorescence measurements were carried out as described in the Experimental Procedures.

Table 1. Size and ζ-Potentials of Polyplex Micelles

sample	cumulant diameter (nm)/ polydispersity index (μ/ Γ^2)	ζ-potential (mV)
PEG−PLys	124 ± 0.27/0.158 ± 0.014	−0.19 ± 0.195
RGDS−PEG−PLys	124 ± 0.88/0.177 ± 0.012	1.12 ± 0.349
c(RGDfK)−PEG−PLys	125 ± 1.00/0.166 ± 0.006	0.68 ± 0.238

protons of PEG (OCH_2CH_2, δ = 3.6 ppm), the introduction rates of peptide ligands were determined to be 100% in the RGDS−PEG−PLys **6a** and 66% in the c(RGDfK)−PEG−PLys **6b**.

Formation of Polyplex Micelles. Ethidium bromide (EtBr) is known to form an intercalating complex with double helical polynucleotides and subsequently show a striking enhancement of its fluorescence intensity (*17*). This enhancement is quenched by the formation of a complex between DNA and cationic components, because cationic components prevent EtBr from intercalating into the double-strand DNA. Thus, EtBr exclusion assay is frequently utilized to estimate the degree of pDNA condensation in the complex with a catiomer (*18*, *19*). As shown in Figure 3, as the N/P ratio increased, the fluorescence intensity in all the polyplex micelles decreased correspondingly and leveled off at around N/P = 1.25. This result indicates that the degree of pDNA condensation was not influenced by the introduction of peptide ligands. Table 1 summarizes the cumulant diameters and ζ-potentials of the polyplex micelles at N/P = 2. The cumulant diameters of all the micelles were approximately 125 nm with a moderate polydispersity index between 0.15 and 0.18. There was no change in the particle size because of the introduction of peptide ligands. Also, the ζ-potentials of all the polyplex micelles were approximately 0 mV. As previously reported (*5*, *18*), the PEG palisade surrounding the complex shields the charge of the micelles to maintain a very small absolute value in the ζ-potential even in the region of N/P > 1. All of the results of the EtBr assay, DLS analysis, and ζ-potential measurement suggest that the characteristics of the three types of polyplex micelles (PEG−PLys, RGDS−PEG−PLys, and c(RGDfK)−PEG−PLys) were quite similar regardless of the introduction of the peptide ligands.

Detection of $\alpha_v\beta_3$ and $\alpha_v\beta_5$ Integrin Receptors. To evaluate the expression of integrin receptors on the cell surface, flow cytometric analysis of 293T and HeLa cells was carried out using FITC-labeled antibodies (Figure 4). Flow cytometric analysis revealed that the 293T cells expressed almost no $\alpha_v\beta_3$ integrin and a slight amount of $\alpha_v\beta_5$ integrin, while the HeLa cells expressed a considerably higher amount of $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins than the 293T cells. These results implied that HeLa cells might show a higher uptake of the cyclic RGD peptide-conjugated polyplex micelles than 293T cells through integrin-mediated endocytosis.

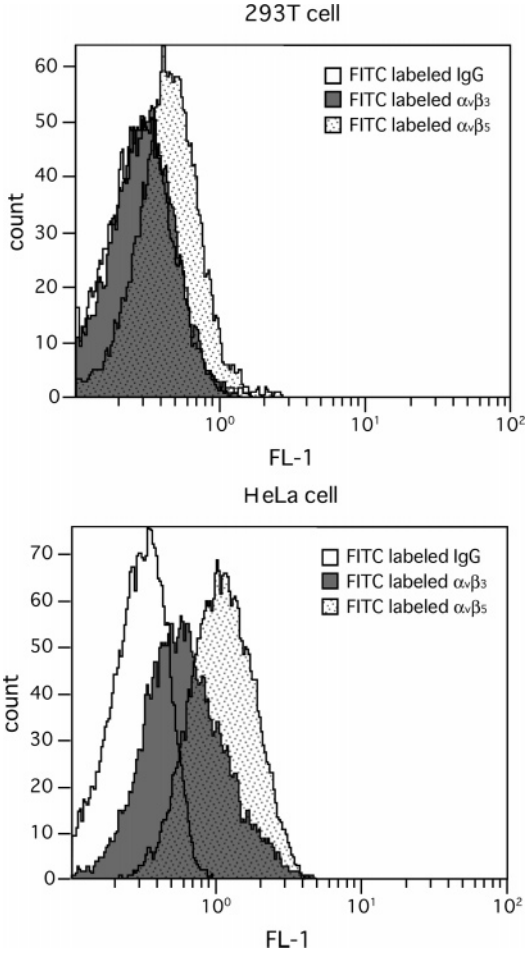

Figure 4. Flow cytometric analysis of integrin expression on 293T cells (left) and HeLa cells (right).

Transfection. *In vitro* TE of polyplex micelles was evaluated for 293T cells and HeLa cells at varying transfection times (Figure 5). PEG−PLys/pDNA micelles without the peptide ligand and RGDS−PEG−PLys/pDNA micelles with a linear RGD peptide ligand were used as controls. RGD peptide is the adhesion motif of extracellular matrix proteins for the various types of integrins (*20*, *21*). The linear RGD peptide showed a binding affinity for $\alpha_v\beta_3$ integrin approximately 1/1000 of that of the cyclic RGD peptide (*22*). In the transfection experiment using 293T cells, there were no differences in the TE of the three types of micelles at any of the transfection times. This finding is consistent with the observation that 293T cells showed low integrin expression (Figure 4). On the other hand, in the transfection experiment using HeLa cells, c(RGDfK)−PEG−PLys micelles achieved a significantly higher TE than PEG−PLys and RGDS−PEG−PLys micelles. It is reasonable to assume that HeLa cells might efficiently recognize c(RGDfK) ligands on the micelle through $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins expressed on their surface. Nevertheless, the TE of linear RGD peptide-conjugated micelles toward HeLa cells was comparable to that of the micelles without any ligand, suggesting that the binding affinity of the linear RGD peptide for the integrins might be insufficient to increase the TE.

Analysis of Cellular Uptake of Polyplex Micelles. The cellular uptake of the micelles into the HeLa cells was evaluated by a flow cytometer using fluorescein-labeled pDNA-incorporated micelles with varying incubation times (Figure 6). The amount of the uptake was always higher for c(RGDfK)−PEG−

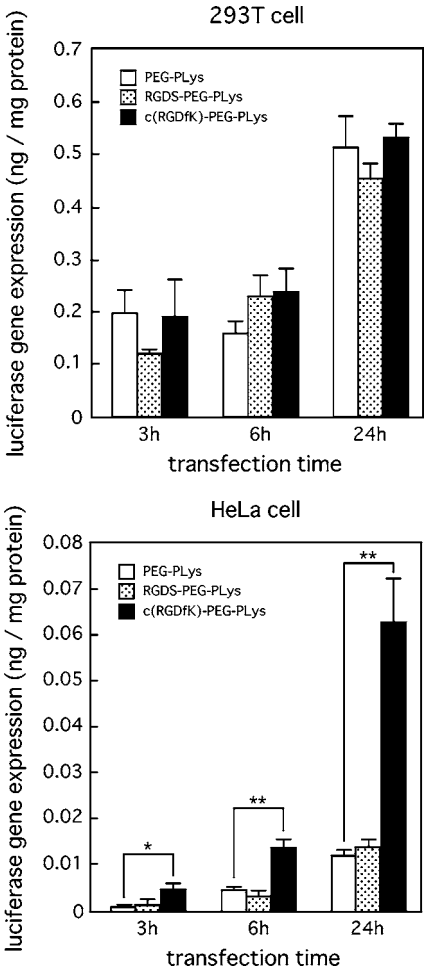

Figure 5. Effect of cell lines and transfection time on gene expression. 293T cells (left) and HeLa cells (right) were transfected with PEG−PLys, RGDS−PEG−PLys, and c(RGDfK)−PEG−PLys micelles prepared at N/P = 2 in a medium containing 10% serum. The data are the mean ± SEM, $n = 4$. $P^* < 0.05$ and $P^{**} < 0.01$.

PLys micelles than for PEG−PLys micelles at each incubation time, which suggests that the specific interaction of the cyclic RGD peptide with integrin receptors on the HeLa cells contributed to the uptake amount. In 24 h incubation, the amount of c(RGDfK)−PEG−PLys micelles that were taken up was 1.6 times the amount of PEG−PLys micelles taken up (Figure 6B). Nevertheless, c(RGDfK)−PEG−PLys micelles revealed an even higher TE of approximately 5 times that of the PEG−PLys micelles (Figure 5). This implied that other factors besides the enhanced uptake might also play a role in the enhanced TE observed for HeLa cells challenged with c(RGDfK)−PEG−PLys micelles.

Intracellular Distribution of Polyplex Micelles. The intracellular distribution of polyplex micelles was investigated by CLSM using Cy5-labeled pDNA-incorporated micelles with 3 h incubation, and typical images from this investigation are shown in Figure 7. A large fraction of the Cy5-labeled pDNA was still distributed near the cell membrane for the cells challenged with PEG−PLys polyplex micelles (Figure 7A). Alternatively, an appreciable accumulation of the Cy5-labeled pDNA in the perinuclear regions was observed for the cells challenged with c(RGDfK)−PEG−PLys polyplex micelles (Figure 7B). Further detailed observation using LysoTracker, which labels acidic late endosome and lysosome, revealed that the majority of c(RGDfK)−PEG−PLys polyplex micelles were localized in the acidic compartments as indicated by the yellow color in the merged fluorescence image of the Cy5-labeled pDNA (red) and LysoTracker (green), yet a fraction that did not co-localize with LysoTracker was also observed, suggesting that at least some of the polyplex micelles in the perinuclear regions may be located in a site other than the lysosomes.

DISCUSSION

There are many barriers to achieve effective transfection using nonviral gene vectors. Stability in the bloodstream and specific cellular uptake by the target tissues and organs are major obstacles, especially for *in vivo* gene delivery. Polyplex micelles with PEG as a hydrophilic shell layer have been shown to achieve an increased retention time in the bloodstream (*5*), and they are promising candidates for vectors that can be used for *in vivo* gene delivery. Also, the introduction of targetable ligands onto polyplex micelles has been reported, and some of the ligand-installed polyplex micelles have been demonstrated to be effective both in *in vivo* as well as *in vitro* transfection (*6*−*8*). The ligands on polyplex micelles may facilitate their internalization into the target cells, thus increasing the TE. A number of studies have aimed to find suitable ligands for this purpose (*23*), and cyclic RGD peptides have been highlighted as one of the promising candidates (*7*). Cyclic RGD peptides are well-known to selectively recognize $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins, which are overexpressed in angiogenic endothelial cells in tumors. Therefore, a targetable gene delivery system equipped with a cyclic RGD peptide as the ligand may be useful for antiangiogenic therapy for tumors (*24*, *25*).

In this study, to construct polyplex micelles showing integrin-mediated gene transfection, the novel synthetic route of a block copolymer with a c(RGDfK) peptide ligand was exploited as summarized in Scheme 1. The acetal group may be converted to an aldehyde group under acidic conditions. Thus, the TFA group was selected to protect the primary amino group of the lysine units, because it can be removed under basic conditions without any conversion of acetal groups to aldehyde groups. The introduction of peptide ligands was then carried out under mild acidic conditions with good yields in a one-pot reaction involving the conversion of acetal groups to aldehyde groups and the subsequent conjugation of the ligand through the formation of a thiazolidine ring as seen in Scheme 1. In this way, various peptide ligands having a cysteine end group (Cys-peptide) may be readily introduced into the block copolymer. Moreover, this type of conjugation reaction between aldehyde and Cys-peptide occurs selectively even in the presence of primary amines, because the formation of a Schiff base between a primary amine and an aldehyde is reversible and thus sensitive to pH, while the thiazolidine ring formation between the N-terminal cysteine and aldehyde is an irreversible reaction. This reaction is available for the introduction of various ligands into the block copolymer, not only peptides but also other ligand molecules possessing an N-terminal cysteine.

Indeed, as confirmed by the NMR spectra shown in Figure 2, the c(RGDfK) peptide, which can peculiarly recognize $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins, was successfully introduced into the PEG terminus of the PEG−PLys block copolymer as a targetable ligand molecule. The c(RGDfK)−PEG−PLys/pDNA micelle achieved a higher TE compared to nontargetable PEG−PLys and RGDS−PEG−PLys micelles against HeLa cells, which express an appreciable amount of $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins. In contrast, there was no difference in TE among these three types of polyplex micelles against 293T cells, which show a limited expression of $\alpha_v\beta_5$ integrin, but no expression of $\alpha_v\beta_3$ integrin. This result is consistent with a previous report which found that the $\alpha_v\beta_3$ integrin has an approximately 10-times higher binding affinity for the cyclic RGD peptide than the $\alpha_v\beta_5$ integrin (*26*), which suggests that the $\alpha_v\beta_3$ integrin may be involved in an increased TE against HeLa cells by means of the c(RGDfK)−PEG−PLys/pDNA micelle. Flow cytometric analysis (Figure

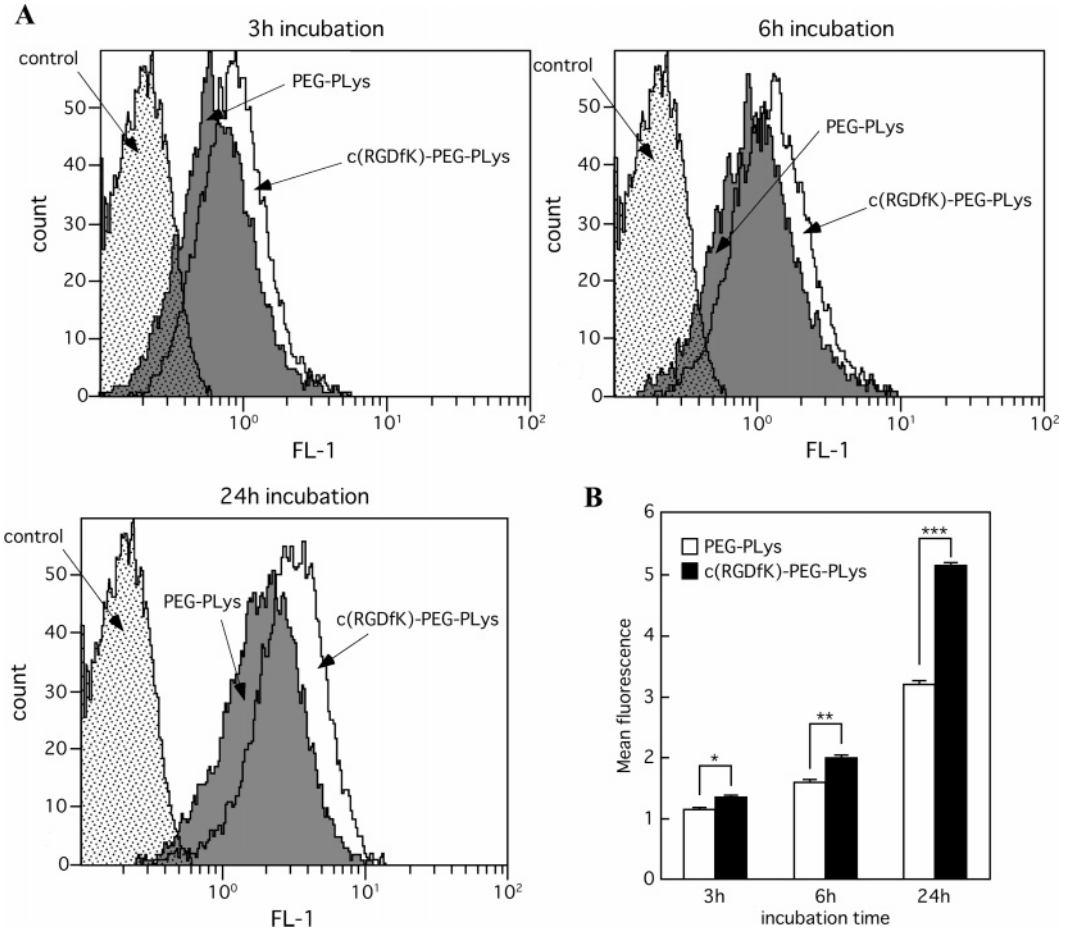

Figure 6. Cellular uptake of polyplex micelles. PEG−PLys and c(RGDfK)−PEG−PLys micelles loaded with fluorescein-labeled pDNA were applied to HeLa cells with varying incubation times. (A) Flow cytometric histogram profiles of time-dependent change in fluorescence intensity. (B) Mean fluorescence intensity at each incubation time. The data are the mean ± SEM, $n = 3$. $P^* < 0.05$, $P^{**} < 0.01$, and $P^{***} < 0.001$.

6) also suggests that the enhanced uptake of the c(RGDfK)−PEG−PLys/pDNA micelle might contribute to an increased TE against HeLa cells. Interestingly, the difference in the uptake ratio against the HeLa cells between the c(RGDfK) micelle and the ligand-free micelle became more significant with increased incubation time as seen in Figure 6. Integrin receptors are known to recycle to the plasma membrane through an endocytic cycle every 15−40 min (*27*). Consequently, this fast recycle of integrins might contribute to the facilitated uptake of the c(RGDfK) micelle into the HeLa cells in comparison with the ligand-free micelle. Nevertheless, as can be seen from Figures 5 and 6B, the uptake ratio is not simply correlated in a time-dependent manner with the TE. The ligand effect appeared to be more significant in the TE than in the uptake ratio, particularly after a prolonged time period such as 24 h. This result led us to assume that the c(RGDfK) ligand may also affect intracellular trafficking of the polyplex micelles. Indeed, a CLSM observation of HeLa cells challenged with polyplex micelles revealed a substantial difference in intracellular distribution between the PEG−PLys and c(RGDfK)−PEG−PLys micelles (Figure 7). In the cells challenged with the PEG−PLys polyplex micelle, a majority of pDNA was still distributed near the cell membrane, whereas in the same time frame of 3 h the cells with the c(RGDfK)−PEG−PLys polyplex micelle showed an appreciable accumulation of pDNA in the perinuclear region. It is noteworthy that a definite fraction of pDNA (colored red) in the perinuclear region did not co-localize with LysoTracker (colored green), suggesting that this fraction may be located in a compartment other than the acidic late endosome and lysosome. The $\alpha_v\beta_3$ integrin receptors have been reported to pass rapidly through the early endosomes, arriving at the perinuclear compartments approximately 30 min after internalization (*28*). Recent reports have shown an active transport pathway for a nonviral gene delivery system (*29*, *30*), in which microtubule-associated motor proteins have contributed to a rapid perinuclear accumulation of the polyplex within minutes after transfection. Also, recent studies have revealed that polyplexes in the perinuclear region but not in the acidic compartments significantly contribute to the effective transfection (*31*, *32*). These phenomena are consistent with our observation of a partial accumulation of the c(RGDfK)−PEG−PLys micelle in the perinuclear sites but outside of the acidic compartments, suggesting that the enhancement of the TE of the polyplex micelle by the introduction of cyclic RGD peptide ligands might be due not only to the enhanced uptake but also to the change in the intracellular trafficking route directed to the nucleus. It is likely that the micelle fraction distributed in nonacidic compartments near the nucleus may efficiently internalize into the nucleus when the cells are in the dividing phase, thus contributing to the increase in the transfection. Although the effective transport of the PLys-based polyplex micelles from the isolated compartment into the cytoplasm remains an issue because of inefficiency in the PLys function of facilitating the endosome-escaping step, the conjugation of c(RGDfK) ligands onto the polyplex micelle surface has great potential to improve the TE through modulated intracellular trafficking.

In conclusion, a successful synthetic route involving block copolymers conjugated with peptidyl ligands through thiazolidine ring formation was developed in this study. Cyclic RGD peptide-conjugated polyplex micelles showed an increased TE against HeLa cells possessing $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins because

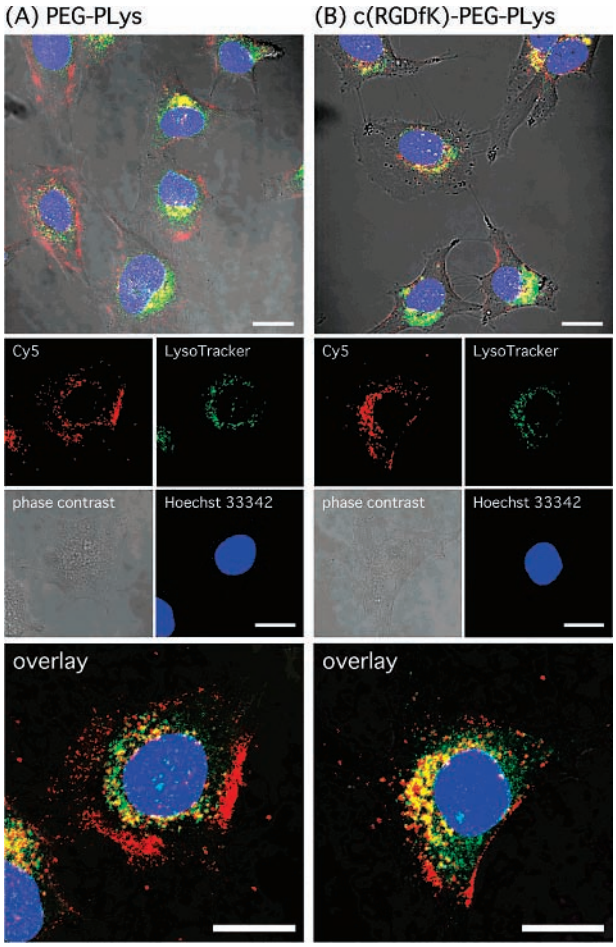

Figure 7. Intracellular distribution of pDNA challenged by the polyplex micelles. PEG−PLys and c(RGDfK)−PEG−PLys micelles loaded with Cy5-labeled pDNA (red) were incubated with HeLa cells for 3 h. The CLSM observation was performed using a 63× objective. The cell nuclei were stained with Hoechst 33342 (blue), and the acidic late endosome and lysosome were stained with LysoTracker Green (green). The scale bar represents 20 μm.

of enhanced uptake and a possible change in the route of intracellular trafficking. These results indicate that the introduction of various peptide ligands including c(RGDfK) peptide into the block copolymers is feasible and could eventually allow the construction of targetable polyplex micelles that are useful for site-specific gene therapy through a systemic route.

Surface Engineering of Quantum Dots for *In Vivo* Vascular Imaging

Ashwath Jayagopal, Patricia K. Russ, and Frederick R. Haselton*

Department of Biomedical Engineering, Vanderbilt University. Received January 21, 2007; Revised Manuscript Received July 22, 2007

Quantum dot−antibody bioconjugates (QD-mAb) were synthesized incorporating PEG cross-linkers and Fc-shielding mAb fragments to increase *in vivo* circulation times and targeting efficiency. Microscopy of endothelial cell cultures incubated with QD-mAb directed against cell adhesion molecules (CAMs), when shielded to reduce Fc-mediated interactions, were more specific for their molecular targets. *In vitro* flow cytometry indicated that surface engineered QD-mAb labeled leukocyte subsets with minimal Fc-mediated binding. Nontargeted QD-mAb nanoparticles with Fc-blockade featured 64% (endothelial cells) and 53% (leukocytes) lower nonspecific binding than non-Fc-blocked nanoparticles. Spectrally distinct QD-mAb targeted to the cell adhesion molecules (CAMs) PECAM-1, ICAM-1, and VCAM-1 on the retinal endothelium in a rat model of diabetes were imaged *in vivo* using fluorescence angiography. Endogenously labeled circulating and adherent leukocyte subsets were imaged in rat models of diabetes and uveitis using QD-mAb targeted to RP-1 and CD45. Diabetic rats exhibited increased fluorescence in the retinal vasculature from QD bioconjugates to ICAM-1 and VCAM-1 but not PECAM-1. Both animal models exhibited leukocyte rolling and leukostasis in capillaries. Examination of retinal whole mounts prepared after *in vivo* imaging confirmed the fluorescence patterns seen *in vivo*. Comparison of the timecourse of retinal fluorescence from Fc-shielded and non-Fc-shielded bioconjugates indicated nonspecific uptake and increased clearance of the non-Fc-shielded QD-mAb. This combination of QD surface design elements offers a promising new *in vivo* approach to specifically label vascular cells and biomolecules of interest.

INTRODUCTION

Inflammation is a complex process involving numerous cell types and surface proteins. It is characterized by leukocyte rolling and tethering along endothelial cells followed by transmigration into tissue, where their immunodefensive functions, such as phagocytosis, are elicited (*1*, *2*). Undesirable provocation of the inflammatory response is thought to be a detrimental feature of numerous diseases such as diabetes, atherosclerosis, and asthma (*3*−*6*). Treatment of inflammatory disease is challenging due to uncertainties associated with the roles of many of the cellular and biomolecular mediators. However, one developing strategy hinders inflammation by blockade of cell surface receptors either on the endothelium or on circulating leukocytes (*7*−*9*).

Detailed information about molecular mediators of inflammation might be acquired through *in vivo* imaging methods, since they can provide real-time data concerning the spatial and temporal dynamics of cellular activities and molecular expression throughout the time course of the disease. However, disadvantages of current imaging techniques include limited optical accessibility to tissue, invasiveness (*10*, *11*), low or unstable signal intensity due to the use of organic fluorophores (*12*−*14*), or low spatial and temporal resolution achieved by the use of radiolabeled antibodies (*15*). No available technique provides a framework for the simultaneous imaging of multiple molecular participants on moving leukocytes and stationary endothelium and leukocytes in real time.

Imaging inflammation is a difficult task, as the cell types of interest have one or more of the Fcγ receptor family (CD16, CD32, and CD64) which bind to Fc fragments of Immunoglobulin G (IgG) antibodies with variable affinity (*16*). Binding of bioconjugates to these receptors can yield false positive results when attempting to detect vascular cell surface targets. In addition, it is well-known that nanoparticulate probes are subject to rapid uptake by the tissues of the reticuloendothelial system, such as liver and spleen (*17*). These immunodefensive mechanisms serve to either rapidly clear the probe from the circulation or nonspecifically bind the probe. However, the many advantages afforded by nanoparticles as bioconjugates, particularly quantum dots (QD), which feature size-tunable visible-IR emission spectra, the need for only one excitation source, and high quantum efficiency, warrant new methods to facilitate their continued application (*18*, *19*). Recent work has indicated that the surface functionalization of PEG chains on the quantum dot surface can substantially reduce nonspecificity and clearance problems (*20*, *21*). In addition, many studies have established QD amenability to bioconjugation and ease of encapsulation in water-soluble coatings (*22*), and its incorporation within targeted *in vivo* imaging applications (*20*, *23*, *24*).

In this study, we selected spectrally distinct quantum dot (QD) nanocrystals to enable high-resolution, multispecies imaging using a previously developed, noninvasive *in vivo* retinal vascular imaging system (*25*). In this application, which pursues the detection of vascular targets, mitigation of nonspecific uptake and clearance mechanisms are essential. To address this, monoclonal antibodies (mAb) targeting leukocytes, neutrophils (*26*), or the cell adhesion molecules PECAM-1, ICAM-1, and VCAM-1 were site-specifically conjugated to PEG-maleimide-activated QD surfaces via 2-MEA to preserve mAb orientation and binding affinity (*27*). QD-mAb were then adsorbed with Fc-blocking $F(ab)_2$ fragments to reduce nonspecific immunorecognition. When incubated with endothelial cells or leukocytes *in vitro*, the shielded probes were found to be more specific for their targets relative to controls. *In vivo* retinal imaging of streptozotocin (STZ)-treated diabetic rats using QD-mAb revealed upregulation of ICAM-1 and VCAM-1 but not PECAM-1. Imaging of a rat model of endotoxin-induced uveitis (EIU)

RP−1, neutrophil (unknown)	Ms anti-rat RP−1 IgG2a (BD)	excitation filter E460SPUV v2 peak emission 405 nm	585 nm, detection filter 585WB40 or 620WB90
CD45, leukocytes (multiple essential functions)	Ms anti-rat CD45 IgG1 (BD)		655 nm, detection filter 655WB20
nonspecific	Ms IgG1 or IgG2a isotype control (BD)		565 nm, detection filter 565WB20

showed the expected increase in stagnant leukocytes in the microcirculation. The high photostability of QD permitted post-experimental histological observations which confirmed the *in vivo* results. Real-time imaging of QD-IgG_1 conjugates indicated rapid clearance of conjugates lacking Fc-blocking $F(ab)_2$ fragments from the circulation. The distinct spectral emission characteristics of the QD enabled the simultaneous imaging of up to four biomarkers or cell types within the same animal with high specificity.

EXPERIMENTAL PROCEDURES

Synthesis and Characterization of Shielded Quantum Dot-Antibody Conjugates. QD nanocrystals with approximately 80 NH_2 groups/nanoparticle (ITK−NH_2, Invitrogen Corp.) were surface-functionalized with a heterobifunctional PEG-based cross-linker (NHS-PEG-MAL, Nektar Therapeutics) to couple reduced antibodies to the surface, followed by Fc-shielding $F(ab)_2$ surface adsorption as shown in Scheme 1. (**1**) 1 uM of QD-ITK-NH_2 (1.2×10^{14} nanoparticles in 200 uL solution) were maleimide-activated by incubation with a 20-fold molar excess of NHS-PEG-MAL (MW: 5218) for 2 h in PBS with 10 mM EDTA, pH = 7.4 (PBS-EDTA) at room temperature. Excess NHS-PEG-MAL was removed using two exchanges of PBS-EDTA on a 100K MWCO Amicon Ultra-4 column. The solution was analyzed qualitatively for the presence of large aggregates (>200 nm) using fluorescence microscopy, and was filtered through a 100 nm syringe filter if aggregates were observed. (**2**) mAb (Table 1) were buffer-exchanged in 500 μg amounts into PBS-EDTA, with two exchanges on a 100K MWCO spin column device (Amicon Ultra-4, Millipore) according to manufacturer-supplied instructions. The retentate was resuspended to 10 mg/mL concentration in PBS-EDTA. The antibodies were then reduced specifically in the hinge region to create two monovalent IgG (r IgG) bearing 1−2 free sulfhydryl groups using 2-mercaptoethylamine (2-MEA, Pierce) (*28*) according to manufacturer's instructions. Briefly, 6 mg of 2-MEA was dissolved in 100 μL of PBS-EDTA, and 1 μL of this solution was added to each 10 μL of mAb solution. The mixture was reacted for 120 min at 37 °C on a slowly rocking platform. Excess 2-MEA was removed from mAb using a NAP-5

Scheme 1 [a]

desalting column (GE Healthcare) pre-equilibrated with degassed PBS-EDTA buffer according to manufacturer's instructions. The presence of free sulfhydryl groups generated from 2-MEA reduction was confirmed using Ellman's reagent (Pierce)

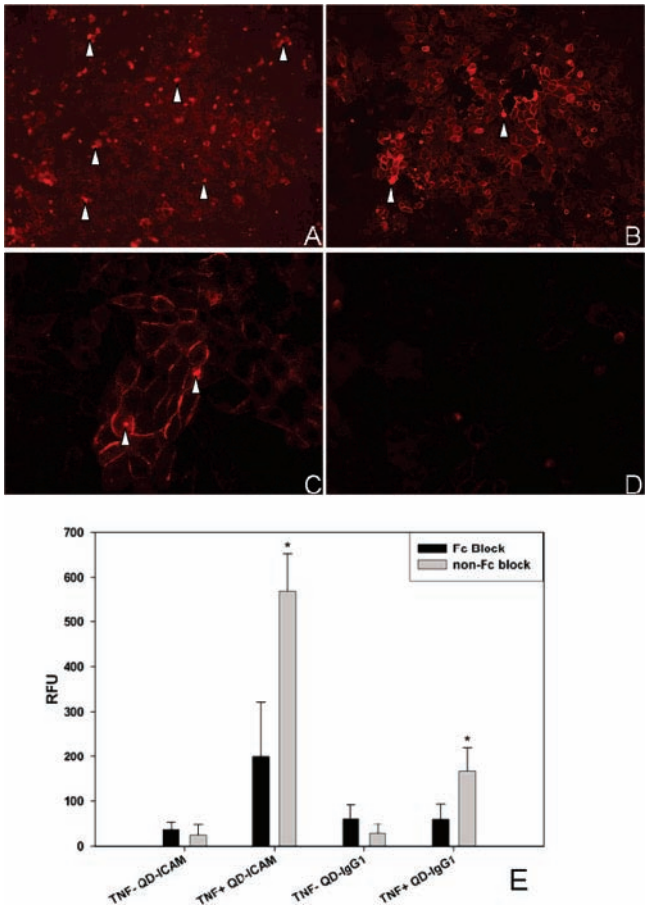

Figure 2. Comparison of Fc-blocked and non-Fc-blocked QD655-mAb conjugate specificity toward TNF-α-stimulated YPEN-1 (TNF+). (A−B) TNF+ YPEN-1 incubated with non-Fc-blocked (A) and Fc-blocked (B) QD655-anti-ICAM bioconjugates (magnification 100×). Arrowheads indicate possible Fc receptor capping, which was substantially reduced when using Fc-blocked conjugates. (C,D) TNF+ YPEN-1 incubated with non-Fc-blocked (C) and Fc-blocked (D) QD655-IgG_1 isotype control bioconjugates, with capping sites labeled with arrowheads (magnification 400×). (E) Mean image intensity analysis reveals lower nonspecific binding of bioconjugates featuring Fc blockade (reported as mean + S.D., $n = 3$ images per sample). Intensities for each matched Fc-blocked and non-Fc-blocked bioconjugate were compared by *t*-test for statistical significance ($P < 0.05$ indicated by asterisks).

on a Nanodrop ND-1000 spectrophotometer according to manufacturer's instructions. (**3**) The QD retentate from **1** was then added to the 2-MEA reduced and purified r IgG mixtures and incubated overnight at 4 °C. The following day, the reaction was terminated with 1 mg/mL L-cysteine (Sigma) to quench remaining maleimide groups. The QD-r IgG conjugates were purified by gel filtration chromatography according to manufacturer's instructions (Superdex 200, GE Healthcare). Fractions were eluted with PBS into 96-well microplates and evaluated by a UV−vis and fluorescence spectrophotometry (Nanodrop ND-1000 and ND-3300) or a fluorescence microplate spectrophotometer (Biotek Synergy HT) in order to identify appropriate QD-mAb fractions and to evaluate conjugation efficiency. In six separate conjugations of r IgG_{2a} to QD655, the average conjugation efficiency measured by UV−vis absorbance spectrophotometry on pooled QD-bound and unbound r IgG fractions was 59.33 ± 11.34%. This corresponds to 18 r IgG/QD. (**4**) The bioconjugate fraction was incubated with goat anti-mouse IgG (Fc-specific) blocking $F(ab)_2$ (Sigma) at molar concentrations equal to primary antibody concentrations for 1 h at room temperature, and the resulting mixture was filtered through a 0.22 μm syringe filter and stored at 4 °C until use. On the day of animal imaging, bioconjugates were briefly spun in an Eppendorf 5415R microcentrifuge for 10 min at 10 000 *g* to remove QD-mAb aggregates, reserving the supernatant for use. The supernatant was examined by fluorescence microscopy to ensure the absence of QD aggregates (>200 nm).

Flow Cytometry. Whole blood was collected in 2 × 3 mL aliquots from male Long-Evans rats into BD Vacutainer tubes spray-lined with K_3EDTA. Erythrocytes were lysed by incubation with BD PharMLyse at a 20:1 ratio of lysis buffer to whole blood for 15 min in the dark at room temperature to obtain a diffuse red suspension of white blood cells. The solution was then centrifuged at 400 *g* in an Allegra X-22R unit with swinging bucket rotor (Beckman) at room temperature. The leukocyte pellet was rinsed in 500 μL PBS (pH = 7.2) containing 0.5% BSA, and 0.1% sodium azide (staining buffer) to reduce shedding of membrane antigens. Each pellet was rinsed twice with staining buffer. The cells were resuspended to a 1×10^6 leukocytes/mL concentration, and were incubated for 45 min with one of the following in staining buffer: 50 nM each of QD585-anti-RP-1 conjugate, QD585-anti-CD45 conjugate, Fc-blocked QD585-isotype control IgG_1, maleimide-activated and L-cysteine quenched QD585, Fc-blocked QD585-isotype control IgG_{2a}, non-Fc-blocked QD585-IgG_{2a} isotype control, or 1 ug phycoerythrin (PE)-anti-RP-1 conjugate (BD Pharmingen). A separate unlabeled fraction was also retained for analysis. All samples were immediately analyzed (n =

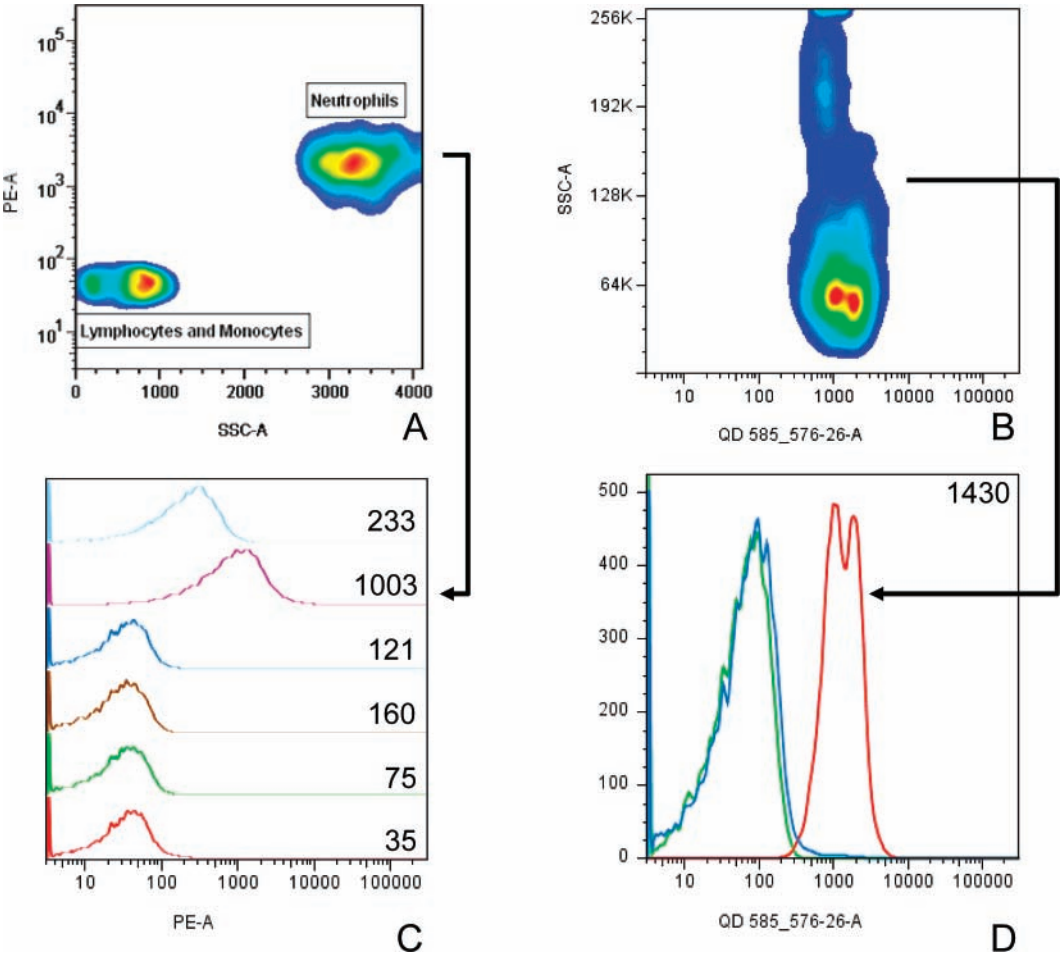

Figure 3. FACS analysis of leukocytes labeled with QD-mAb bioconjugates *in vitro*. (A) QD585-anti-RP-1 (Fc-blocked) specific labeling of neutrophils in peripheral blood. (B) QD585-anti-CD45 (Fc-blocked) labeling of all leukocyte subsets, with arrow from B to D indicating fluorescence histogram of gated leukocytes (D). (C) Gated neutrophil populations from rat peripheral blood (arrow from A to C shows a gated neutrophil population used for analysis of 1 sample), (488 nm Ar laser excitation, phycoerythrin (PE) emission filter (585/42 nm)), with mean fluorescence intensity of each sample indicated in bold. Light blue: PE-anti-RP-1 dye-labeled positive control mAb. Purple: QD585-anti-RP-1 (Fc-blocked). Blue: QD585 quenched with L-cysteine. Brown: QD-Ms-IgG2a isotype non-Fc blocked. Green: QD-Ms-IgG2a isotype Fc blocked. Red: Unlabeled rat peripheral blood. (D) Rat leukocytes labeled with QD585-anti-CD45 (red, gated leukocytes from (B)), QD585-Ms IgG1 Fc blocked isotype control (blue) or unlabeled (green).

20,000 gated events) using a BD LSR II multicolor flow cytometer equipped with a 488 nm Ar laser. Rat leukocyte subtypes could be readily resolved by forward and side scatter profiles as previously described (*29*). Band-pass emission filters were set at 585/42 nm to analyze QD or PE-labeled cells. Analysis was conducted using *Flowjo 7.0* (Treestar Software).

Cell Culture and Immunofluorescence Microscopy. YPEN-1 (CRL-2222, ATCC) rat prostate endothelial cells were cultured to confluency on Lab-Tek II 8-well chambered coverslips with media containing minimum essential medium (Eagle) with 2 mM L-glutamine and Earle's BSS adjusted to contain 1.5 g/L sodium bicarbonate, 0.1 mM nonessential amino acids, and 1.0 mM sodium pyruvate, supplemented with 0.03 mg/mL heparin; fetal bovine serum, 5%. YPEN-1 were stimulated with 30 ng/mL TNF-α in media overnight as previously described (*30*) to upregulate cell adhesion molecules, or incubated with media alone as a control. The next day, YPEN-1 were rinsed with one wash of media and incubated with 10 nM amounts of QD bioconjugates for 1 h at 37 °C as follows: QD655-anti-PECAM, QD655-anti-ICAM, QD655-anti-VCAM, QD655 (reactive maleimide group quenched with 1 mg/mL L-cysteine), and QD-isotype control IgG_1 in Fc-blocked forms as described above or as synthesized without the Fc-blocking step. Cells were then rinsed six times in Dulbecco's PBS containing Ca and Mg, pH = 7.4, and incubated with 4% paraformaldehyde in PBS for 15 min at 25 °C, followed by rinsing three times, 5 min each, with PBS with 50 mM glycine. Fixed cells were imaged using a Nikon TE2000U inverted fluorescence microscope with filter settings as shown in Table 1. These experiments were performed in triplicate. Images were acquired using a Hammamatsu C7780 12-bit color CCD in conjunction with *Image Pro Plus 5.1* (Media Cybernetics).

Preparation of Animal Subjects. All experimental procedures were approved by the Vanderbilt University Institutional Animal Care and Use Committee. Diabetes was induced in Long-Evans rats by intraperitoneal injection of 65 mg/kg streptozotocin (STZ, Sigma) in 0.1 mM sodium citrate, pH = 4.5, with the same number of rats remaining untreated as experimental controls ($n = 6$ per group). Elevated blood sugar (>250 mg/dL) was confirmed in STZ treated animals. Endotoxin-induced uveitis (EIU) was initiated in Long-Evans rats by intraperitoneal injection of 200 μg lipopolysaccharide. Controls were age-matched untreated rats ($n = 6$ per group). Animals were anesthetized with intraperitoneally administered 15/85% ketazine/xylazine prior to imaging. Tail vein catheterization was performed for injection of QD-mAb. Both eyes were dilated with 1 drop each of 2.5% phenylephrine hydrochloride and 1% tropicamide ophthalmic solutions (Alcon). The right eye was placed on the plano-concave lens previously filled with 2% methyl cellulose (Aqua Poly-Mount, Polysciences).

***In Vivo* Retinal Imaging.** Our imaging design is based on a previously published technique (*25*), in which an inverted

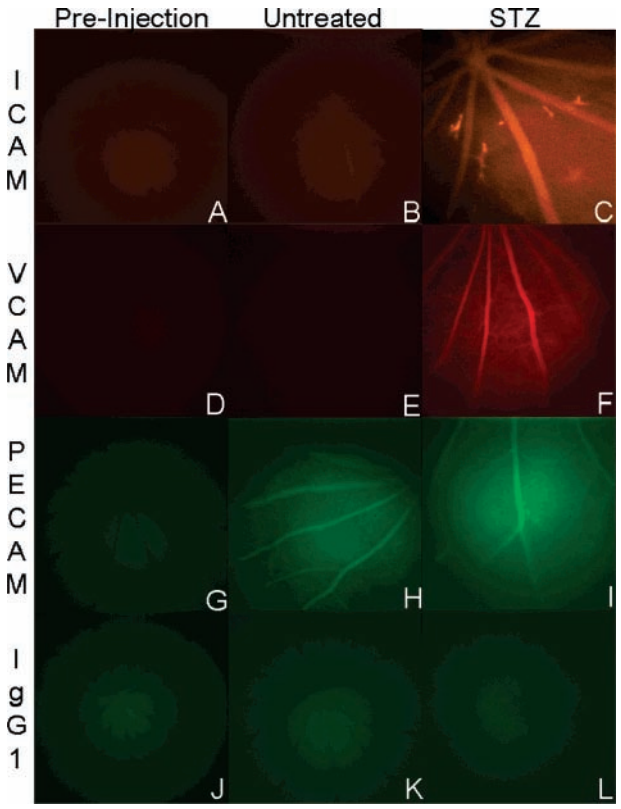

Figure 4. Frames from *in vivo* digital videos of STZ treated and untreated rat retinas. Pre-injection digital videos using the appropriate fluorescence filters for the spectrally distinct biomarkers of interest (left column; A, D, G, J) were acquired prior to bioconjugate injection. QD585-anti-ICAM, QD655-anti-VCAM, QD525-anti-PECAM, and QD565-Ms IgG_1 were systemically injected in STZ-treated rats. Untreated control rat fundi (middle column; B, E, H, K) and STZ-treated rat fundi (right column; C, F, I, L) were imaged either 30 min (ICAM) or 90 min (VCAM, PECAM, IgG_1) postinjection under identical acquisition settings used for background autofluorescence measurements for each biomarker channel. Fluorescence enhancement due to target binding in untreated controls (B, E, H, K) was primarily observed for PECAM (H). The retinal vasculature of STZ-treated rats (C, F, I, L) showed a marked increase in fluorescence due to binding of QD-mAb conjugates to ICAM (C) and VCAM (F), with at least 5-fold increases in fluorescence intensity over background measured for labeled vasculature. Injection of conjugates to PECAM (I) produced similar levels of fluorescence under both conditions (H, I). Fluorescence signal from nonspecific IgG_1 mAb bioconjugates (J−L) was not detected in either control or STZ retinas. Images shown were acquired at imaging intervals resulting in optimal signal-to-noise ratio.

fluorescence microscope (TE2000U Eclipse, Nikon) with 4× and 10× objectives and a plano-concave −6 D lens (Edmund Scientific) on the microscope stage were utilized to image the rat retinal circulation. In this study, this technique was modified to include a high sensitivity Andor Bioimaging iXon 885 EMCCD camera (Andor Bioimaging), Hamamatsu C7780 color camera, Exfo X-cite 120 metal halide lamp (Exfo Life Sciences), and a pulsed xenon arc flashlamp excitation source (FX 4400, Perkin-Elmer) triggered by a function generator configured for square wave output at 20 Hz (Tektronix). The metal halide lamp and flashlamp were utilized for the imaging of stationary endothelial targets and circulating leukocytes, respectively. Following measurements of pre-injection tissue autofluorescence levels in each QD-specific emission channel, QD-mAb were injected via the tail vein catheter. Injectate consisted of 200 μL of a 500 nM solution in PBS-EDTA. Initial digital sequences were acquired using exposures ranging from 20 to 200 ms (depending on the QD and the filter set, Table 1) at 110 ms intervals. Subsequent sequences were acquired at approximately 30 min intervals for 2.5 h. In four animals, a QD-IgG_1 isotype control was used as a negative control. Animals were sacrificed with 150 mg/kg sodium pentobarbital administered via tail vein catheter.

Immunofluorescence Microscopy of Retinal Tissue. Following euthanization of animals, both eyes were enucleated. Retinal flat mounts were prepared of the right eye, which was the eye imaged by our *in vivo* retinal imaging system. Eyes were fixed in 4% paraformaldehyde in PBS overnight and flat-mounted on a microscope slide mounted with fluorescence mounting media. The left eye was fixed in 4% paraformaldehyde and paraffin embedded for sectioning. Sections and flat mounts were analyzed by fluorescence microscopy (Nikon TE 2000U) using the same filters as those used in *in vivo* imaging (Table 1).

Image Analysis. For analysis of QD-mAb binding to YPEN-1, fluorescence micrographs acquired under identical settings and conditions (matched cell densities in field of view) were measured in the Red CCD channel (the chip with which QD655 emission is captured) for fluorescence intensity using *Image Pro Plus 5.1*. From these data, the mean Red channel fluorescence intensity was obtained and standard deviation determined. Background correction was performed on image intensities by subtracting the mean Red CCD channel intensity obtained from the same density of unlabeled YPEN-1. Intensities were analyzed for statistical significance using an unpaired two-tailed *t*-test (*SigmaStat 3.0*, SYSTAT). Background-corrected data was then plotted using *SigmaPlot 9.0* (SYSTAT). Statistical significance was interpreted by $P < 0.05$.

For *in vivo* image quantification of leukostasis, the area of image analysis of rat fundi was a circle of two optic disk diameters from the center, allowing for counts of stagnant leukocytes and observations of leukocyte trafficking and cell adhesion molecule expression within major arteries and veins as well as the microcirculation. A leukocyte was assumed to be stagnant if no displacement larger than one cell diameter was observed within 60 s of continuous imaging. The number of stagnant QD-labeled cells was quantified for STZ, EIU, and wild-type retinas postacquisition from digital video using *Andor iQ 1.6*, and compared using an unpaired two-tailed *t*-test in *SigmaStat 3.0*.

Quantitative analysis of Fc-blocked and non-Fc-blocked QD-IgG_1 bioconjugates was performed by analyzing 60 consecutive digital frames of wild-type rat retina before and after systemic injection of 500 nM (200 uL) of each probe. An observation area of 2 optic disc diameters from center was utilized for the analysis. Using *Andor iQ 1.6* image analysis software, the mean fluorescence intensity of 60 consecutive frames was plotted as a function of time. Data were plotted using *SigmaPlot 9.0*.

RESULTS

***In Vitro* Studies.** In cell culture studies, the QD655-mAb Fc-shielded conjugates specifically labeled CAMs on TNF-α-stimulated YPEN-1 rat endothelium (TNF+) (Figure 1A−D; Figure 2B,E). In order to simulate the *in vivo* environment, no traditional immunofluorescence blocking steps (e.g., serum, Fc receptor blocking mAbs) were utilized. Under TNF+ conditions, a statistically significant increase in Fc-blocked QD655-anti-VCAM binding to YPEN-1 (Figure 1B,D) was observed, whereas TNF+ conditions did not significantly affect QD655-anti-PECAM binding (Figure 1A). These observations were consistent with previous reports (*31, 32*). QD655-anti-ICAM bioconjugates bound TNF+ YPEN-1 by over 10-fold as compared to untreated cells (Figure 2E). A strong reduction in nonspecific binding was observed when comparing binding of Fc-blocked and non-Fc-blocked QD655-anti-ICAM bioconjugates (Figure 2A,B,E). A reduction in nonspecific binding was also observed when comparing measured intensities of YPEN-1 labeled with Fc-blocked or non-Fc-blocked QD655-isotype control IgG_1 nanoparticles (Figure 2C−E), suggesting that the

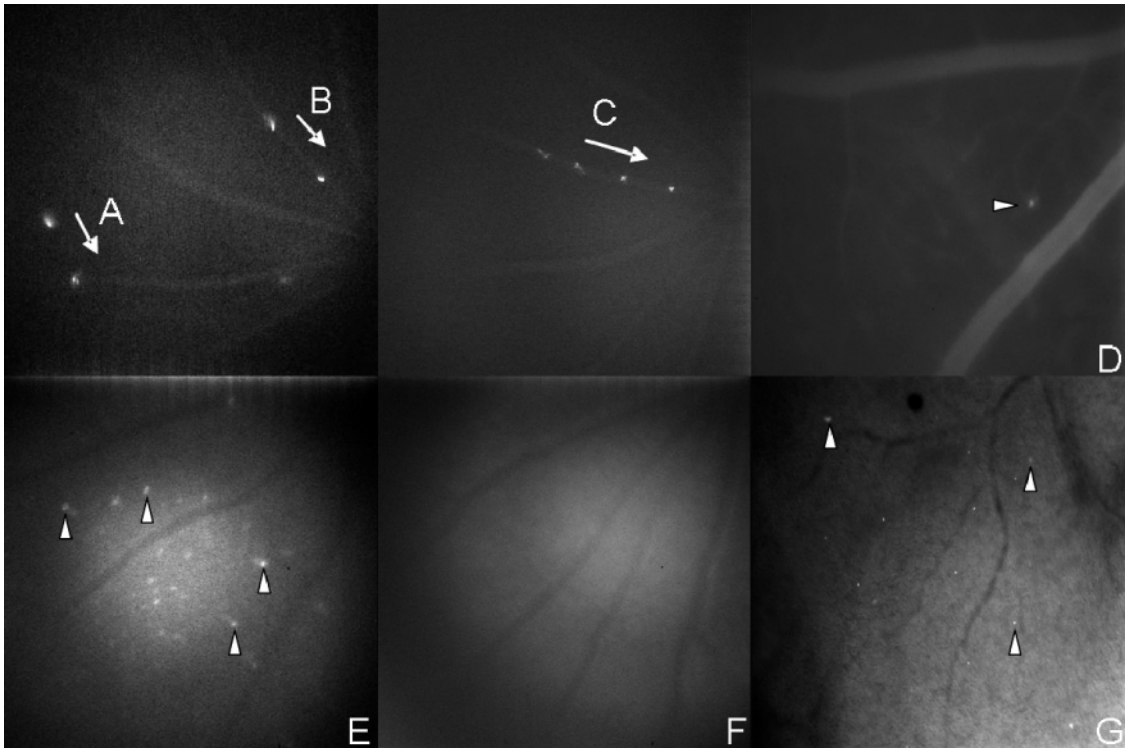

Figure 5. *In vivo* imaging of endogenously QD-mAb-labeled leukocyte trafficking in two rat models of inflammation. The CCD acquired images with exposure times ranging from 50 to 200 ms with 110 ms between exposures. Flowing of QD585-RP-1 labeled cells in vessels (A,B) or leukocyte rolling (C) in STZ model as detected by four pulses of a xenon flashlamp at 50 ms intervals within 30 min of probe injection. Leukostasis was frequently observed in the STZ-treated rat model (D in right panel). Stagnant neutrophil appears as a hyperfluorescent dot in the microcirculation. Stagnant neutrophils were continuously visible in the retinal vasculature for over 1 h of *in vivo* imaging. Stagnant leukocytes labeled *in vivo* with QD655-anti-CD45 were present at high densities in EIU rat models (E) relative to untreated controls (F). Stagnant neutrophils labeled in STZ-streated diabetic animals were visible in postmortem retinal flat mounts (G).

Fc fragment is responsible for a substantial percentage of QD-mAb nonspecific binding. Immunofluorescence analysis of YPEN-1 indicated that non-Fc-blocked QD655-mAb constructs were aggregated in focal locations along cell membranes, shown by arrowheads (Figure 2A−C). This observation may be due to two features: the upregulation of Fcγ receptors on endothelial cells following TNF-α stimulation, and the patching and capping effect observed previously for Fc receptor−ligand combinations (*33*). Specifically, patching and capping refers to the accumulation of surface-bound IgG-Fc receptor pairs at distinct, punctate locations at the membrane to form clumps of Fc receptor-IgG pairs. This incidence of cap formation was less evident in TNF+ YPEN-1 cells incubated with Fc-blocked bioconjugates (Figure 2B). Maleimide-quenched QD which were not conjugated to Mab (Figure 1C) did not bind appreciably to cell surfaces. These data collectively suggest that nonspecific binding of unshielded probe was likely due to the binding of mAb Fc fragment to endothelial Fc receptors.

Fc-blocked QD585-anti-RP-1 (neutrophils) and QD585-anti-CD45 (leukocyte common antigen) were shown to retain bioactivity and specificity *in vitro* (Figure 3). QD585-anti-RP-1 conjugates were shown to specifically bind to neutrophils and not other leukocyte subsets (Figure 3A), and QD585-anti-CD45 were shown to label the three main subclasses of leukocytes as shown by flow cytometric analysis of erythrocyte-lysed whole blood (Figure 3B,D). QD-anti-RP-1 was observed to have over 4-fold enhancement in fluorescence over PE-RP-1 (1003 vs 233), a positive control antibody coupled to phycoerythrin (Figure 3C). QD585-IgG2a (matching the isotype of QD585-anti-RP-1), when Fc-blocked with an anti-Fc $F(ab)_2$ fragment, featured 53% lower mean fluorescence levels than that due to the non-Fc-blocked conjugate (Figure 3C), indicative of reduced nonspecific binding of Fc-blocked bioconjugates. Fc-blocked QD585-anti-CD45 conjugates used to label leukocytes yielded a mean fluorescence of 1430, over 17-fold greater than cells labeled with Fc-blocked QD-IgG_1 isotype control (82) and 22-fold greater than unlabeled cells (65) (Figure 3D).

***In Vivo* Imaging.** Intravenous injection of QD bioconjugates targeted to ICAM-1 or VCAM-1 resulted in a maximum increase in vascular fluorescence in streptozotocin (STZ)-treated diabetic rats within 30 and 90 min, respectively (Figure 4). This increase in fluorescence was observed in major vessels as well as the microcirculation. Control rat retinas did not exhibit the same fluorescence intensity with either the ICAM (Figure 4A−C) or VCAM (Figure 4D−F) conjugates. Injection of QD anti-PECAM produced increases in fluorescence which were similar in both STZ-treated and untreated animals (Figure 4G−I). Injection of QD-IgG1, a nonspecific control, did not result in fluorescence signal accumulation in the retinal vasculature to any appreciable degree throughout the duration of imaging up to 2.5 h (Figure 4J−L).

Intravenous injection of QD585-anti-RP-1 conjugates enabled the fluorescence detection and long-term tracking of neutrophils in STZ-treated diabetic animals as shown in Figure 5A−D. Using a pulsed xenon flashlamp, we visualized individual free-flowing leukocytes (Figure 5A,B), leukocyte rolling along endothelial walls (Figure 5C), and leukostasis (Figure 5D) in major vessels as well as capillaries. Individual neutrophils were resolved in all vessels including arteries, and an increase in QD-anti-RP-1 positive stagnant neutrophils in the microcirculation was observed in the STZ-treated group (5.83 ± 2.86, $n = 6$) vs untreated animals (0.50 ± 0.55, $n = 6$) ($P < 0.01$). Fluorescence micrographs of stagnant neutrophils in flat-mounted STZ-treated rat retinas confirmed *in vivo* observations (Figure 5G).

Injection of the QD655-anti-CD45 bioconjugate in LPS-treated EIU rat models revealed a significant number of stagnant leukocytes in the microcirculation relative to untreated animals (Figure 5E,F). The number of QD-anti-CD45 positive stagnant

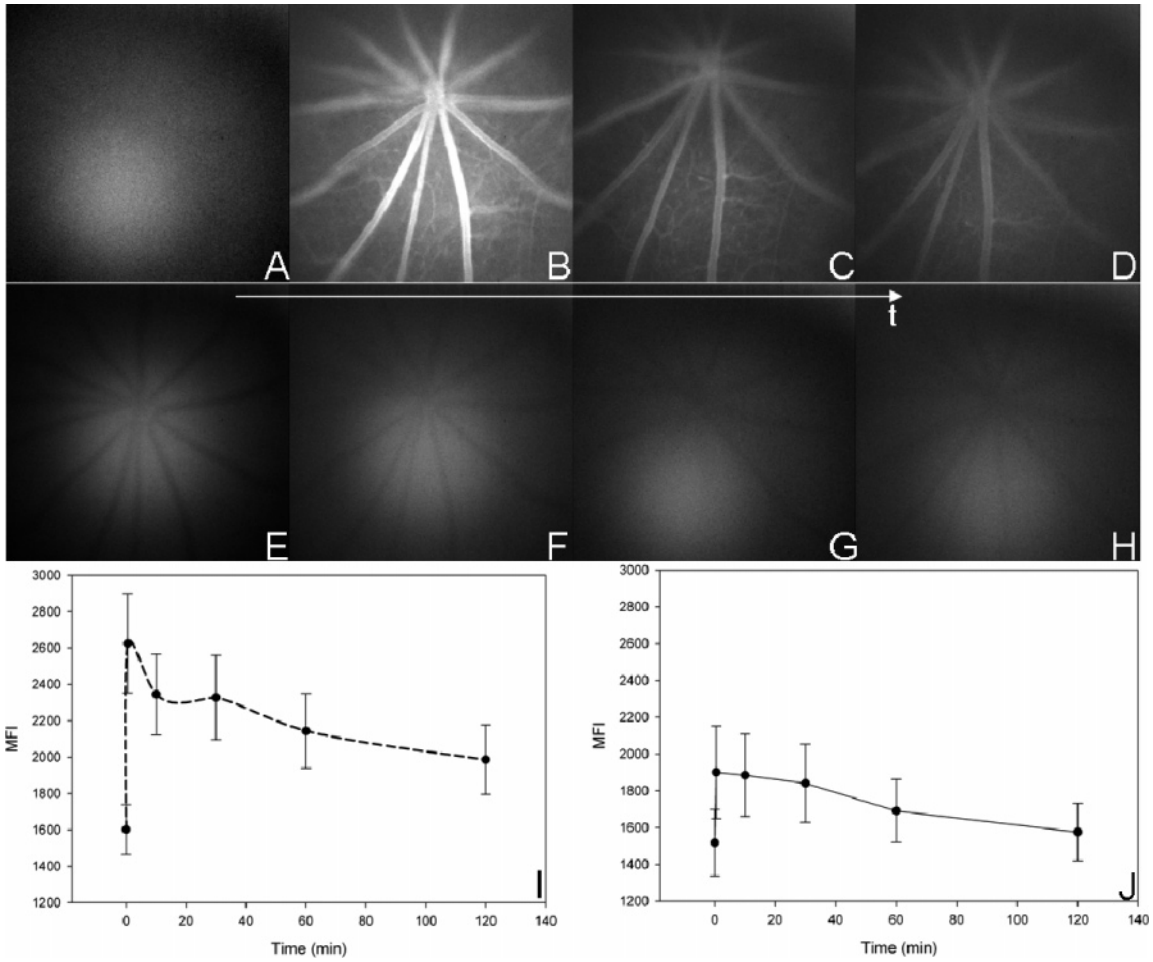

Figure 6. Comparison of Fc-blocked (A−D, I) and non-Fc-blocked (E−H, J) QD-IgG$_1$ mAb bioconjugates *in vivo*. (A) Pre-injection autofluorescence in QD655 emission channel. (B−D) Fc-blocked QD655-IgG$_1$ in retina observed 12 s postinjection (B) where the first pass of bolus through retinal circulation is observed, 1 h postinjection (C), and 2 h postinjection (D), by which time Fc-blocked QD655-induced fluorescence is still above background levels (I, dashed line). (E) Autofluorescence levels in QD565 channel. (F−H) non-Fc-blocked QD565-IgG$_1$ bolus was not qualitatively visible at 12 s postinjection (F), and subsequent image acquisitions at 1 h (G) and 2 h (H) revealed eventual return of image intensity to pre-injection levels (J, solid line), suggesting a relatively rapid clearance and/or uptake of non-Fc-blocked QD-mAb.

leukocytes in LPS-treated rat retinas (20.33 ± 8.73, $n = 6$) was elevated over control retinas (2.17 ± 1.17, $n = 6$) *in vivo* ($P < 0.01$).

Ten seconds after tail vein injection, comparison of the retinal fluorescence from Fc-shielded and non-Fc-shielded bioconjugates showed significantly less fluorescence from the non-shielded bioconjugate (Figure 6). Tracers injected intravenously into a tail vein travel through the hepatic circulation, heart, and lungs before the remainder reaches the eye. Our data indicate that non-Fc-blocked nonspecific QD-IgG$_1$ is cleared rapidly within 2 h of circulation, returning retinal fluorescence levels to pre-injection values (Figure 6E−H,J). For Fc-blocked non-specific QD-IgG$_1$, an apparent bolus is observed within 12 s of injection (Figure 6B), and fluorescence levels by 2 h have not returned to background values (Figure 6A−D,I). These results suggest that Fc blockade substantially enhances the circulation lifetime of the QD-mAb due to reduced uptake and clearance.

***Ex Vivo* Imaging of Retinal Tissue.** Immunofluorescence analysis of flat-mounted retinas showed correlation of *in vivo* features, such as enhanced CAM expression areas within the microcirculation, with *ex vivo* microscopy (Figure 7A,B). Analysis of postmortem retinal tissue also indicated low nonspecific binding of Fc-shielded bioconjugates (Figure 7C,D) within blood vessels. The microcirculation in a flat mount from an EIU rat featured leukocyte adhesions and extravasations similar to those observed *in vivo* (not shown), and similar to the result shown for the STZ-treated rat (Figure 5G).

DISCUSSION

Fc-blocked QD-mAb were found to be specific for CAM and leukocyte targets, as shown by immunofluorescence (Figures 1,2), flow cytometry (Figure 3), and *in vivo* and *ex vivo* retinal imaging (Figures 4−7). QD-IgG that were nonspecific in reactivity did not bind to retinal vasculature (Figure 6), which suggests that Fc-blocked QD-antibody bioconjugates feature reduced nonspecific binding tendencies while retaining the native binding affinity conferred by the mAb. Our technique, employing PEGylation, 2-MEA reduction, and Fc-blockade by Fc-specific F(ab)$_2$, is a rapid, cost-effective method for the site-specific bioconjugation and immune-shielding of mAb on nanoparticle surfaces. The 2-MEA reduction process was found to work equally well on mouse IgG$_1$ and IgG$_{2a}$ subclasses using the same protocol. As an alternative to removal of the Fc fragment from the antibody, we choose instead to adsorb it with an antibody fragment which itself has no Fc region. Nontargeted QD-IgG conjugates adsorbed with an Fc-blocking F(ab)$_2$ were less susceptible to nonspecific binding to leukocyte and endothelial cell surfaces compared to the same conjugates without Fc-blockade (Figures 1−3). This may be the result of steric inhibition conferred upon the bioconjugate by the F(ab)$_2$, which reduces Fc receptor access to its Fc fragment binding site on the IgG. Fc-blockade of CAM-targeted QD did not affect their binding affinities toward endothelial cell proteins *in vitro* or *in vivo* (Figures 1,2,4). Fc-blockade by itself also may potentially

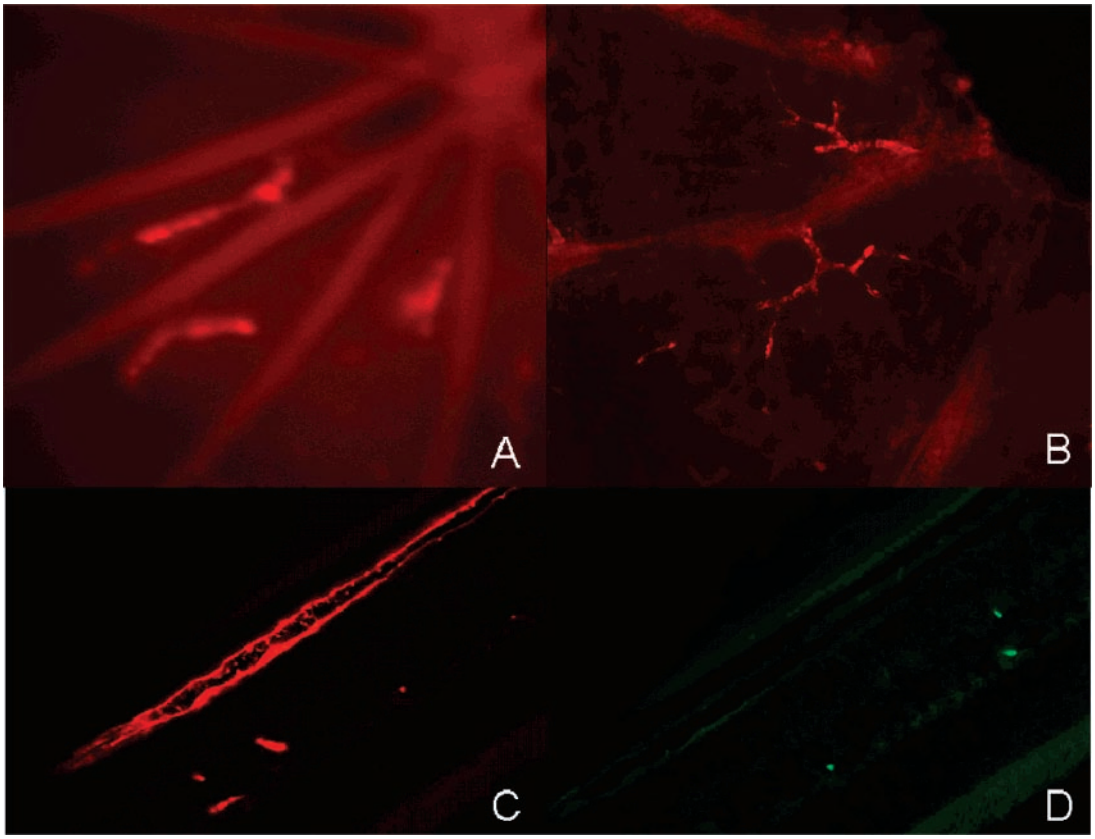

Figure 7. *In vivo* microcirculatory VCAM-1 expression (A) can be confirmed using immunofluorescence analysis postmortem (B), as shown for QD655-anti-VCAM-1 labeled vasculature. While QD655-VCAM-1 (Fc-blocked) conjugates were shown to specifically stain vasculature in retinal histological sections (C), no background staining due to QD-IgG_1 (Fc-blocked) was observed above background autofluorescence levels (D).

enhance the circulation half-life of QD-mAb when employed in conjunction with PEG. Fc-blocked, nontargeted QD-IgG were present in the retinal circulation in much higher fluorescence levels relative to the same dose of non-Fc-blocked constructs (Figure 6), suggesting that Fc-blockade of IgG may substantially reduce first-pass nonspecific clearance of probes due to liver and spleen immunorecognition. Therefore, our probe design features target selectivity with a reduced tendency for nonspecific binding.

Analogues of our strategy exist for reduction of nonspecific binding of bioconjugates for *in vitro* applications, and we have applied these *in vitro* techniques for the first time to *in vivo* imaging. For example, the commercial reagent FcBlock (anti-CD16, anti-CD32, BD Biosciences) has long been utilized to block Fc receptors on hematopoietic and endothelial cells prior to immunofluorescence (*34*) or flow cytometric (*35*) analysis for the reduction of background staining using cell surface protein antibodies. Direct blockade of the Fc *fragment* of antibodies rather than Fc receptors occurs often in biology. Blockade of the antibody Fc domain with streptococcal proteins has been found to reduce Fc-mediated nonspecific binding (*36*). Herpes Simplex Virus type 1 (HSV-1), when bound by an IgG, uses its Fcγ receptors to occupy the Fc fragment of the same IgG, thus preventing Fc-mediated immunodefensive mechanisms (*37*). By adsorption of the QD-IgG conjugate with an Fc-targeted $F(ab)_2$, it is likely that the adsorbed fragment makes the Fc binding site of the targeting antibody sufficiently inaccessible to immune surveillance, thus enhancing specificity and circulation time.

Other strategies to reduce Fc-mediated immune recognition of antibodies or antibody-based bioconjugates are reported in the literature. Specifically, antibody fragmentation techniques using papain, pepsin, or ficin require several reaction steps and much reagent quantity and time optimization for each antibody species and subclass, and generally do not yield a biomolecule with a site-specific cross-linking site suitable for nanoparticle conjugation. Instead, primary amines which reside in the antigen-binding site of the antibody could be cross-linked to the nanoparticle, obliterating its antigen binding affinity following bioconjugation. Protein engineering techniques now provide for a means of producing antibody fragments with engineered hinge region cysteines (Fab′) which allow for site-specific nanoparticle conjugation while preserving the antigen-binding region (*38*, *39*). However, this process is time-consuming and costly, and may not be suitable in applications where multiple IgGs are to be conjugated to nanoparticles for multiplexed imaging on a small scale, or where IgG targets are quickly examined and replaced for purposes of drug discovery or biology. Our process provides for the site-specific conjugation of antibodies to nanoparticles, without IgG subclass-specific optimization, with similar benefits of immune system evasion afforded by antibody fragmentation techniques.

Our *in vivo* imaging results are consistent with studies of ICAM and VCAM expression in diabetic and nondiabetic tissue, in which their upregulation is implicated in an inflammatory cascade that causes various complications of the disease (*6*, *40*, *41*). QD fluorescence due to ICAM and VCAM expression is apparent on major vessels as well as the microcirculation in disease models, which appears as an out of focus fluorescent background behind the major vessels (Figure 4A−F). QD targeted against PECAM, a panendothelial marker, produced increases in fluorescence which were similar in both STZ-treated and untreated animals (Figure 4G−I), thus suggesting its utility as an internal control or vascular counterstain in this imaging application. Our technique was found to be suitable for the long-term imaging of stagnant leukocytes commonly observed in both the STZ-treated rat model of diabetes (*6*, *9*) and the LPS-treated rat model of EIU (*42*).

Photobleaching is a problem with current techniques which probe leukocyte dynamics *in vivo*, such as acridine orange fluorography (*43*, *44*). Thus, long-term imaging of leukocytes is hindered. Using QD-based fluorography, we were able to continuously observe entrapped leukocytes in the circulation over an hour of continuous illumination without bleaching (Figure 5). Therefore, our QD-based imaging technique constitutes a potential alternative to current methods of imaging leukocytes due to the ability to simultaneously image multiple leukocyte subsets and stationary biomarkers with one excitation source with high specificity.

Our imaging technique provides noninvasive optical access to the *in vivo* retinal vasculature and continuous monitoring of vascular events. Spatial resolution on the order of a cell is achieved with this technique. QD have superior optical properties, such as high quantum efficiency and photostability, as well as distinct size-tunable emission wavelengths with the need for only one excitation source. By harnesseing these QD properties while immune-shielding the nanoparticle surface, it was readily possible to image three CAMs and one leukocyte subset within the same animal, without spectral overlap, using one blue excitation source to sufficiently illuminate QD-tagged species within the circulation. This feature enables detailed multiplexed studies of disease and biological processes. We used this approach to simultaneously observe the molecular expression of three different biomarkers, while also observing leukocyte-endothelial interactions. Other applications of this imaging strategy could readily be applied to studies in which multiple cellular and biomolecular vascular functions remain to be elucidated such as cancer, ocular angiogenesis, and atherosclerosis. While qualitative information was primarily presented in this initial application of our technique, we foresee the calculation of additional parameters including rolling velocities for various subtypes, relative fluorescence intensities of specific biomolecules along vascular walls, density of entrapped leukocytes, and important features of the inflammatory process *in vivo*.

ACKNOWLEDGMENT

We thank J.M. Higginbotham for assistance with flow cytometry, E.J. Dworska for assistance with tissue culture, and D.W. Piston for flash trigger equipment. This work was supported, in part, by grants from the National Institutes of Health (F.R. Haselton, PI, EY13451, EY017522), Vanderbilt University Discovery Grant Program, and Vanderbilt Vision Research Training Grant (J.D. Schall, PI, T32-EY07135-13).

Coupling into the Base Pair Stack Is Necessary for DNA-Mediated Electrochemistry

Alon A. Gorodetsky, Omar Green, Eylon Yavin, and Jacqueline K. Barton*

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received February 12, 2007; Revised Manuscript Received April 24, 2007

The electrochemistry of DNA films modified with different redox probes linked to DNA through saturated and conjugated tethers was investigated. Experiments feature two redox probes bound to DNA on two surfaces: anthraquinone (AQ)-modified uridines incorporated into thiolated DNA on gold (Au) and 2,2,6,6-tetramethylpiperidine 1-oxyl (TEMPO)-modified uridines in pyrene-labeled DNA on highly oriented pyrolytic graphite (HOPG). The electrochemistry of these labels when incorporated into DNA has been examined in DNA films containing both well matched and mismatched DNA. DNA-mediated electrochemistry is found to be effective for the TEMPO probe linked with an acetylene linker but not for a saturated TEMPO connected through an ethylenediamine linker. For the AQ probe, DNA-mediated electrochemistry is found with an acetylene linker to uridine but not with an alkyl chain to the 5′ terminus of the oligonucleotide. Large electrochemical signals and effective discrimination of intervening base mismatches are achieved for the probes connected through the acetylene linkages, while probes connected through saturated linkages exhibit small electrochemical signals associated only with direct surface to probe charge transfer and poor mismatch discrimination. Thus DNA electrochemistry with these probes is dramatically influenced by the chemical nature of their linkage to DNA. These results highlight the importance of effective coupling into the π-stack for long-range DNA-mediated electrochemistry.

INTRODUCTION

Numerous studies in solution have shown that the DNA duplex can serve as an effective medium to transport charge (*1*−*5*). DNA-mediated charge transport (CT) in solution exhibits exquisite sensitivity to perturbations in the intervening base stack such as single base mismatches (*6*), bulges (*7*, *8*), and protein binding (*9*−*11*). Previous work has shown that self-assembled DNA monolayers on both gold and graphite can also mediate charge transport over significant distances (*12*−*14*). In particular, electrochemistry at DNA-modified electrodes has been demonstrated in both a chip-based format for mismatch detection (*15*, *16*, *17*) and as a tool for monitoring protein/DNA interactions (*18*−*23*).

Assays based on DNA CT have frequently made use of solution-borne substrates that interact with duplex DNA at the electrode surface (*12*−*15*). To further develop electrochemical detection strategies based on DNA CT, it is necessary to explore electroactive probes that are covalently tethered to duplex DNA. Electrochemistry of DNA monolayers modified with daunomycin, ferrocene, methylene blue, and anthraquinone has shown that these redox-active reporters covalently linked to DNA can function as DNA-bound electrochemical probes (*24*−*34*). However, important questions remain regarding the nature of charge transfer to these probes, which may proceed either via the base pair stack of DNA or by direct contact of the probe with the surface.

Daunomycin has displayed particularly large electrochemical signals when used as a covalently attached probe (*24*−*26*). The size of the signals associated with this probe likely reflect its intimate intercalation within the base pair stack (*35*, *36*), as can be seen in crystal structures of daunomycin bound to DNA. Furthermore, breaks in the sugar phosphate backbone were shown to have no significant effect on the electrochemistry of covalently attached daunomycin (*26*); base mismatches, on the other hand, cause a dramatic attenuation of the signal (*24*). These observations are consistent with DNA CT occurring through the base pair stack rather than through the sugar−phosphate backbone.

Ferrocene/DNA conjugates have been employed in DNA electrochemistry experiments and, in particular, to examine the importance of the linkage between DNA and the redox active probe (*27*). Interrupting conjugation of the ferrocene label with the base pair stack results in an almost complete loss of the electrochemical signal. Furthermore, the location of the ferrocene label within a DNA monolayer was found to affect dramatically the magnitude of the electrochemical signals (*29*, *31*). A well coupled ferrocene−uridine derivative exhibited a larger electrochemical signal at the top of the DNA monolayer than in close proximity to the surface (*29*). However, the opposite effect was observed for a poorly coupled ferrocene; an alkyl chain-derivatized ferrocene connected to the top of a DNA monolayer exhibited a smaller signal than the same ferrocene moiety incorporated in close proximity to the surface (*31*).

There remains some controversy about the effects of DNA conformation on electrochemical behavior of ferrocene, however. Recently, Anne and Demaille explored the electrochemistry of a ferrocene label attached to the 5′ terminus of duplex DNA (*37*). These ferrocene labels were not conjugated into the base pair stack but still afforded strong electrochemical signals. Elastic bending of 5′ ferrocene-labeled DNA was suggested as the cause of the electrochemical signals observed. It was concluded that bending of the DNA could account for the electrochemistry of all DNA bound probes. This conclusion was in direct contrast to those based upon the ferrocene data already described (*29*, *31*). Further, these investigations did not account for the role of the linkage between DNA and ferrocene, nor the effect of sequence context on electrochemical signals.

Experiments with covalently tethered methylene blue have underscored the importance of intercalative stacking for DNA-mediated electrochemistry (*28*). In low salt buffers, intercalation is detected electrochemically in DNA films containing methylene blue tethered distally at the top of the film. Simply changing to a high ionic strength buffer leads to the complete loss of electrochemical signal in the DNA film; methylene blue, though still covalently attached, cannot bind by intercalation under these conditions. Thus intercalative stacking appears necessary for efficient reduction of the attached probe by DNA-mediated CT. Notably, recent studies have also demonstrated the effectiveness of methylene blue in assays based on surface to probe charge transfer without DNA mediation (*38, 39*).

In this work we focus on two established probes of DNA CT to explore in more detail how the linkage to DNA affects the efficiency of DNA-mediated electrochemistry. We have utilized two different redox active markers that can be covalently attached to DNA. Anthraquinone (AQ) has been extensively studied in electrochemical assays based on DNA-mediated CT. For example, AQ has been applied to the electrochemical monitoring of primer extension reactions at Au surfaces (*29*). Additionally, AQ-modified uridines have been used for detection of single nucleotide polymorphisms (*32, 33*) and of duplex to triplex conversions at DNA-modified Au surfaces (*34*). Recent studies in our group have also examined uridine modified with 2,2,6,6-tetramethyl-3,4-dehydro-piperidine-N-oxyl (3,4-dehydro-TEMPO) as a probe of DNA CT from a redox-active protein to DNA (*40*). Notably, the acetylene linkage connecting the probe to the uridine was shown to be crucial for determining its effectiveness as an electron trap for DNA CT using electron paramagnetic resonance (EPR) spectroscopy.

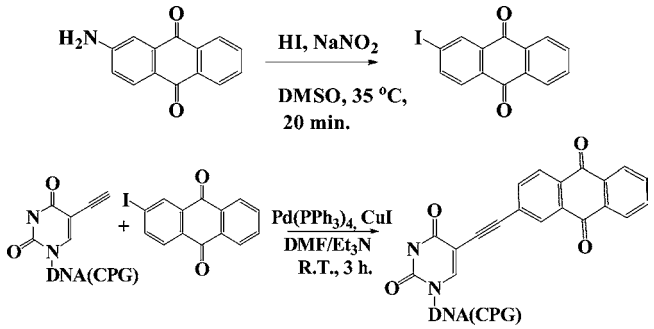
Here we present the electrochemistry of DNA duplexes featuring AQ-modified uridines on Au and TEMPO-modified uridines on highly oriented pyrolytic graphite (HOPG). The observations reported for the AQ and TEMPO probes make them particularly well suited for establishing a correlation between the linkage connecting the probe to the DNA and the effectiveness of the probe in assays based on DNA-mediated electrochemistry. On DNA-modified HOPG, we examine the difference between a modified 3,4-dehydro-TEMPO moiety connected to the base pair stack via an acetylene linker and a saturated TEMPO connected via an ethylenediamine linker. On DNA-modified Au, we examine the difference between an AQ moiety connected to the base pair stack via an acetylene linker and an AQ linked via an alkyl chain to the 5′ terminus of the DNA. Electrochemistry with these probes is dramatically influenced by the chemical nature of their linkage to DNA.

EXPERIMENTAL SECTION

Materials. All phosphoramidites and reagents for DNA synthesis were purchased from Glen Research with the exception of the 5-ethynyluracil phosphoramidite, which was purchased from Berry and Associates. All organic reagents (acetonitrile, dichloromethane, *N*,*N*-dimethylformamide, pyridine, tetrahydrofuran, triethylamine, and 40% aqueous methylamine solution) were purchased from Aldrich in the highest available purity and used as received. All buffers were freshly prepared and filtered using a 0.45 μm filter prior to use. Tetrakis(triphenylphosphine)-Pd(0) was purchased from Strem Chemicals. Technical grade 2-aminoanthraquinone was obtained from Aldrich, and anthraquinone-2-carbonyl chloride was purchased from TCI America. The synthesis of 2-iodoanthraquinone has been previously described (*41*). TEMPO was purchased from Aldrich. The preparation of 4-diamoethylene-2,2,6,6-tetramethyl-3,4-dehydropiperidine-*N*-oxyl (ethylenediamine TEMPO) (*42*) and 4-ethynyl-2,2,6,6-tetramethyl-3,4-dehydropiperidine-*N*-oxyl (acetylene-3,4-dehydro-TEMPO) (*40, 43*) followed established literature procedures.

Oligonucleotide Synthesis. Oligonucleotides were prepared using standard phosphoramidite chemistry on an ABI 392 DNA Synthesizer. DNA was purified by HPLC on a reverse phase C18 column with acetonitrile and ammonium acetate as the eluents. Unless otherwise noted, all oligonucleotides were cleaved from the resin with concentrated ammonium hydroxide (NH_4OH) prior to purification. The desired products were characterized by UV−visible spectroscopy and MALDI-TOF mass spectrometry.

Synthesis of Pyrene-Modified Oligonucleotides. DNA was modified with pyrene at the 5′ terminus by following a previously reported procedure (*13*). In brief, oligonucleotides were prepared by solid-phase synthesis with an unprotected hydroxyl group at the 5′ terminus. The 5′-OH was treated with a 120 mg/mL solution of carbonyldiimidazole in dioxane for 2 h followed by an 80 mg/mL solution of 1,6-diaminohexane for 30 min. Subsequently, the free amine was treated with 1-pyrenebutyric acid, *N*-hydroxysuccinimide ester, resulting in the desired pyrene moiety linked to the 5′ terminus. The oligonucleotides were deprotected with concentrated NH_4OH at 60 °C for 6 h.



Synthesis of Thiol-Modified Oligonucleotides. The synthesis of DNA featuring a thiol at the 5′ terminus followed previously established procedures (*44*). In brief, oligonucleotides were prepared by solid-phase synthesis with the commercially available C6 S−S linker phosphoramidite incorporated at the 5′ terminus. The oligonucleotides were deprotected in NH_4OH at 60 °C for 12 h. Dithiothreitol (100 mM) was subsequently added to reduce the disulfide, leaving a free thiol at the 5′ terminus.

Synthesis of TEMPO-Modified Oligonucleotides. The synthesis of acetylene 3,4-dehydro-TEMPO-modified DNA has been previously described (*40*). The 5′ DMT-protected 5-iodouridine was Pd coupled to the acetylene-modified 3,4-dehydro-TEMPO in THF. The 3′-OH of the product of this reaction was subsequently converted to its phosphoramidite form. The phosphoramidite was dissolved in acetonitrile and used immediately for DNA synthesis.

The synthesis of the ethylenediamine TEMPO-modified DNA was carried out according to a protocol adapted from the literature (*42*). DNA featuring a 5-bromouridine at the position targeted for modification was synthesized on a solid support. A ∼0.5 M aqueous solution of the ethylenediamine TEMPO was added to the 5-bromouridine-modified DNA on solid support with the resulting slurry incubated at 60 °C overnight. This incubation resulted in the ethylenediamine TEMPO replacing the bromine, and in cleaving the DNA from the bead and deprotecting the bases. Prior to HPLC purification, the aqueous phase was washed with dichloromethane to remove excess ethylenediamine TEMPO.

Synthesis of Anthraquinone-Modified Oligonucleotides. The modification of DNA with anthraquinone was carried out as shown in Scheme 1. 2-Iodoanthraquinone was synthesized according to literature precedent (*41*) DNA containing a 5-ethynyluracil at the position targeted for modification was synthesized on a solid support. The beads were placed in an oven-dried flask which had been charged with 2.5 mL of DMF/Et_3N (3.5:1.5). 2-Iodoanthraquinone (60 mmol) and CuI (60 mmol) were added to the flask, and the solution was flushed with argon. $Pd(PPh_3)_4$ (30 mmol) was then added to the flask, and the solution was again flushed with argon. The mixture was allowed to stir at ambient temperature for 3 h under argon. Subsequently, the beads were washed with a 5% (w/v) EDTA solution, DMF, CH_3CN, and CH_2Cl_2 in succession to remove excess reagents. The DNA was cleaved from the resin and deprotected at 60 °C for 20 min with a 1:1 mixture of 40%

Scheme 1. Conditions for Synthesis of 2-Iodoanthraquinone and Its Coupling to Ethynyluracil-Modified DNA[a]

[a] The synthesis of 2-iodoanthraquinone was performed according to literature procedure (*41*). The coupling of the 2-iodoanthraquinone to the ethynyluracil-modified DNA was performed while the DNA was still attached to controlled pore glass (CPG) solid support.

aqueous methylamine and a saturated ammonium hydroxide solution. *m/z* calculated 5417, found 5416. λ_{max}nm (M^{-1} cm^{-1}) 260 ($\in$ 158 400), 320 ($\in$ 58 000), 394 ($\in$ 43 800).

Attachment of AQ at the 5′ terminus of DNA was carried out using procedures modified from the literature and Glen Research protocols (*44*−*47*). DNA with a six-methyl carbon chain terminated with a monomethoxytrityl (MMT)-protected amine was incorporated at the 5′ terminus on the solid support. The MMT-protecting group was removed from the 5′ amine with 3% trichloroacetic acid in CH_2Cl_2. A 0.5 M solution of anthraquinone-2-carbonyl chloride in CH_2Cl_2/Et_3N (10:1) was added to the amine-modified DNA on a solid support. The resulting slurry was incubated overnight. The beads were subsequently washed with copious amounts of CH_2Cl_2 to remove excess reagents. The DNA was cleaved from the resin at 60 °C for 20 min with a 1:1 mixture of 40% aqueous methylamine and a saturated ammonium hydroxide solution. *m/z* calculated 5615, found 5614.

Formation of DNA Monolayers. DNA films were formed on SPI-1 grade HOPG electrodes (SPI, Inc.) with a surface area of 0.08 cm^2, or on commercially available Au electrodes (BAS, Inc.) with a surface area of 0.02 cm^2, as previously described (*12, 13*). Duplex DNA (in 5 mM sodium phosphate, 50 mM NaCl, pH 7.1) was formed by combining equimolar amounts of the pyrene or thiol-modified strand with TEMPO or AQ-labeled complements, respectively. Duplex DNA (25−50 μM) was deposited onto HOPG or Au over a period of 24−48 h. Mg^{2+} was included to minimize electrostatic repulsion between the duplexes and ensure well packed monolayers on both HOPG and Au (*12, 13*). Longer incubation times (48 h) and lower incubation temperatures (4 °C) generally improved film formation. Electrodes being compared were prepared under equivalent conditions. Also, electrodes were brought to ambient temperature prior to electrochemical analysis.

Electrochemical Measurements. Electrochemical data were collected using a CH Instruments 760B potentiostat. Electrochemical experiments were performed at ambient temperature in 5 mM sodium phosphate, 50 mM NaCl, pH 7.1, under anaerobic conditions. All measurements reported for working electrodes were taken versus a platinum (Pt) auxiliary. Either a saturated calomel electrode or a silver/silver chloride electrode (Ag/AgCl) was used as the reference electrode. Square wave voltammetry was performed at 15 Hz, and cyclic voltammetry was performed at 50 mV/s.

Surface Characterization. All atomic force microscopy (AFM) measurements were performed using an MFP-3D atomic force microscope from Asylum Research, Inc. (Santa Barbara, CA). The HOPG block was mounted in a custom designed glass chamber before being modified with DNA as described. AFM

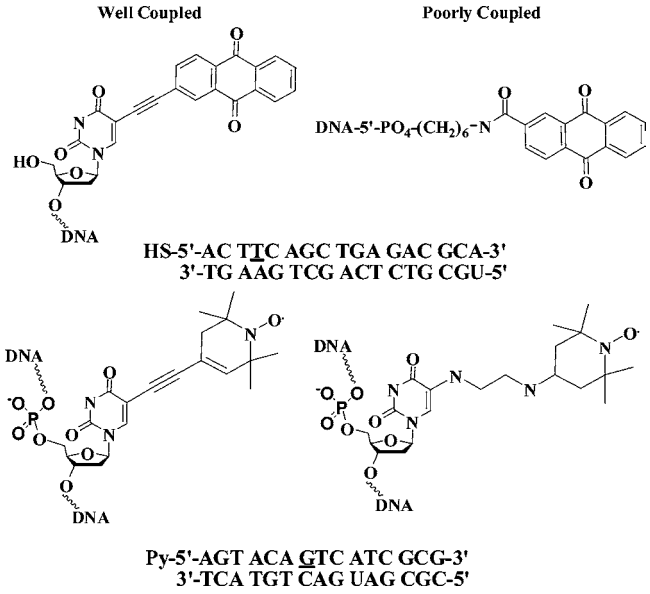


Figure 1. Sequences and probes used during the course of these studies. The DNA sequence used for each electrochemical marker is shown below the structures of the markers. Top: structures of well and poorly coupled AQ; -SH indicates the position of thiol modification on DNA. Bottom: structures of well and poorly coupled TEMPO and its derivative; Py- indicates the position of pyrene modification on DNA. The location of the mismatch is underlined, and the location of the electrochemical probe is indicated by uracil (U).

measurements were performed in buffer containing 5 mM sodium phosphate, 50 mM NaCl, pH 7.1, either in contact (constant force) or tapping mode. Commercially available silicon tips were utilized for all experiments.

RESULTS

Electrochemical Probes and DNA Sequences. The electrochemical probes and sequences examined are illustrated in Figure 1. Two redox active probes were tested, AQ and TEMPO-based moieties, and the probes were each linked to the base pair stack in two ways. The AQ was attached to a modified uridine via an acetylene linker and to the 5′ phosphate terminus via a six-carbon alkane linker. The synthesis of the acetylene-linked AQ moiety involved coupling of 2-iodoanthraquinone to ethylnyl-modified DNA (Scheme 1). Although DNA has previously been modified via Sonogashira conditions (*48, 49*), these syntheses involved halogenated bases incorporated into DNA coupled to ethynyl-containing molecules. 3,4-Dehydro-TEMPO was attached to a modified uridine by an acetylene linker, and TEMPO was connected via an ethylenediamine linker. The acetylene linkage and the 3,4-dehydro-TEMPO probe were designed to allow for efficient coupling of the probe into the base pair stack, whereas the alkane linkage was intended to insulate the probe electronically from the base pair stack. TEMPO experiments were performed with a 15-mer sequence modified with a pyrene on the complementary strand. The 15-mer sequence selected to compare the acetylene and saturated TEMPO probes is that utilized extensively by our laboratory (*12, 15*) and others (*27*) in characterizing different redox probes for DNA-mediated redox chemistry. Many experiments have been used to demonstrate, however, for a variety of probes that DNA-mediated electrochemistry is independent of DNA sequence and length (<30 bp) (*12, 13, 15, 18, 24*−*26*). It should be noted that electrochemistry experiments were also carried out on the 10-mer TEMPO probes that had been utilized in solution experiments with similar results (data not shown) (*40*). Anthraquinone experiments are described using a 17-mer oligonucleotide sequence containing a 5′-thiolate on the

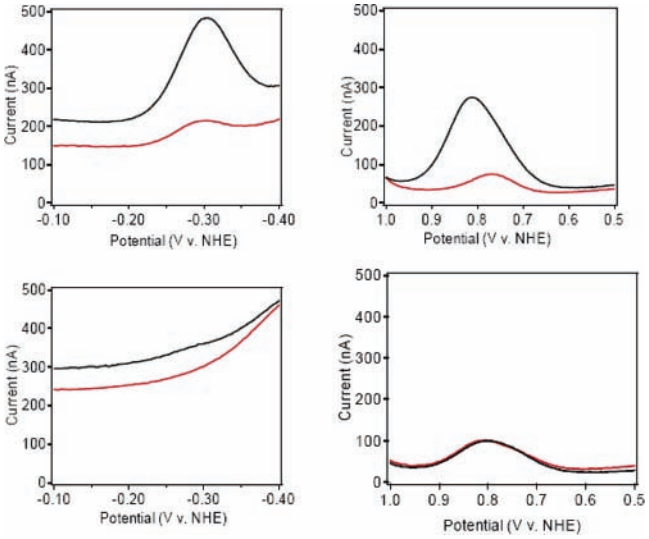

Figure 2. Square wave voltammetry of AQ and TEMPO-modified DNA. Voltammograms for DNA modified with the acetylene-linked AQ (top left), the acetylene-linked 3,4-dehydro-TEMPO (top right), the alkane-linked AQ (bottom left), and the alkane-linked TEMPO (bottom right) are shown. Voltammograms of well matched DNA are shown in black, and voltammograms of DNA featuring a CA mismatch are shown in red. All experiments were performed in 5 mM sodium phosphate, 50 mM NaCl, pH 7.1.

strand complementary to that modified with AQ. Several different AQ-modified DNA sequences 14−17 base pairs in length were prepared with comparable results obtained (data not shown). Since neither of these redox probes intercalate directly into the DNA base stack, they depend upon their links to the stacked uridine within the helix for π-coupling. Hence parallel experiments with these assemblies should give insight into the effect of DNA−probe linkages on DNA-mediated electrochemistry.

Two different surfaces, Au and graphite, are utilized for these electrochemical experiments. Studies involving AQ-modified DNA were performed on standard Au electrodes since the aromatic AQ moiety may directly adsorb to the graphite surface, impeding proper formation of DNA monolayers. Experiments utilizing TEMPO-modified DNA take advantage of the extended potential range afforded by HOPG. Since thiols are known to undergo oxidation at the large positive biases necessary for oxidation of TEMPO, HOPG is more suitable for exploring the electrochemistry of this marker.

Electrochemical measurements were used to assess the CT yields from the surface to the redox active probe. The efficiency of DNA CT was determined by direct comparison of peak currents and integrated charge obtained using square wave and cyclic voltammetry. Peak potentials reported were obtained using SWV and are reported versus NHE.

Electrochemistry of the Acetylene-Linked Probes. Large electrochemical signals are observed for probes linked to the DNA via an acetylene unit. Figure 2 shows the SWV of the acetylene-linked AQ and TEMPO moieties. A reversible electrochemical signal is found at −301 (±7) mV versus NHE for AQ-modified DNA on Au, and the signal is stable for a minimum of two hundred scans under anaerobic conditions. The magnitudes and potentials of the AQ signals are similar to those previously reported (*29*−*34*). As expected for a surface-bound species, a plot of peak current as a function of scan rate is linear for the DNA-bound AQ (*50*), and the electron-transfer rate was estimated to be approximately 30 s^{-1} (Supporting Information). This electron-transfer rate is consistent with previous electrochemical studies of DNA-modified surfaces using similar alkylthiol linkages to bind the DNA to the Au surface (*24*, *26*). A reversible electrochemical signal is also observed at 810 (±20) mV versus NHE for the 3,4-dehydro-TEMPO-modified DNA on graphite. The potential of the signal observed for the 3,4-dehydro-TEMPO-modified DNA is similar to that previously reported for the free label in solution (*40*). It is important to note that the TEMPO signal is electrochemically unstable and rapidly decays upon repeated scanning when attached to an electrode or to graphite felt (*51*, *52*). Therefore, a plot of peak current as a function of scan rate could not be easily obtained for this marker. As expected, controls run with well matched, unmodified DNA reveal no electrochemical signals at the potentials reported for the 3,4-dehydro-TEMPO and AQ-modified DNA (data not shown).

The introduction of a mismatch below the two labels causes a significant attenuation of the electrochemical signal (Figure 2 and Table 1). For AQ-modified DNA, the peak current is reduced from 160 (±50) nA for well matched DNA to 40 (±20) nA for DNA featuring a CA mismatch. For the 3,4-dehydro-TEMPO-modified DNA, the peak current is reduced from 250 (±100) nA for well matched DNA to 30 (±15) nA for DNA featuring a CA mismatch below the probe. It is noteworthy that the introduction of a CA mismatch above the 3,4-dehydro-TEMPO probe has little effect on the magnitude of the peak current (Supporting Information).

Electrochemistry of the Poorly Coupled Probes. Small electrochemical signals are observed for probes connected to the DNA via an alkane linkage. Figure 2 also shows SWVs for the alkane-linked AQ and TEMPO moieties. A small signal centered at −330 (±60) mV vs NHE, whose reversibility cannot be judged, is observed for the AQ-modified DNA on Au. The size of this signal makes it difficult to obtain a plot of peak current as a function of scan rate. The signal is reduced by almost 2 orders of magnitude in comparison to the acetylene-linked AQ probe (Table 1) with a drop in peak current from 160 (±50) nA to 9 (±4) nA. For the ethylenediamine-linked TEMPO label, a reversible signal is found at 800 (±10) mV vs NHE. Unlike the AQ, the magnitude of the TEMPO signal is reduced by only 4-fold upon altering the linkage from an acetylene to an alkane; the peak current drops from 250 (±100) nA for the acetylene-linked 3,4-dehydro-TEMPO to 60 (±20) nA for the ethylenediamine-linked TEMPO. As with the AQ case, the smaller size and instability of the TEMPO signal make it difficult to plot peak current as a function of scan rate.

In contrast to that seen for the acetylene-linked probes, the introduction of a mismatch below the alkane-linked AQ and TEMPO labels does not lead to substantial reductions in the electrochemical signals (Figure 2). Incorporation of a CA mismatch below the alkane AQ has virtually no effect on the electrochemical signal. The electrochemical signals are small for both well matched and mismatched DNA making quantitative evaluation difficult. Similarly, incorporation of a CA mismatch below the ethylenediamine-linked TEMPO does not lead to a diminution in the electrochemical signal. Well-defined electrochemical signals are observed with and without the mismatches for these ethylenediamine-linked, TEMPO-modified DNAs. Peak currents of 60 (±20) nA are found for well matched TEMPO-modified DNA, and peak currents of 70 (±10) nA are found for DNA featuring a CA mismatch below the TEMPO.

Surface Characterization. To aid in the proper interpretation of electrochemical data, surface characterization is necessary. DNA monolayers on both HOPG and Au have previously been examined using scanning probe microscopy, radioactive labeling, and electrochemical techniques (*13*, *53*, *54*, *55*). Previous AFM measurements found smooth films with depths corresponding to duplexes oriented at a ∼45° angle with respect to the surface. As a complement to our electrochemical studies, we also examined DNA monolayers with or without appended

Table 1. Electrochemical Characteristics of DNA Modified with Electroactive Moieties

	AQ[a]		TEMPO[a]	
DNA sequence[a]	peak current[b] (nA)	potential[c] (mV)	peak current[b] (nA)	potential[c] (mV)
well coupled	160 (±50)	−301 (±7)	250 (±100)[d]	810 (±20)[d]
CA mismatch	40 (±20)	−302 (±8)	34 (±15)[d]	800 (±50)[d]
poorly coupled	9 (±4)	−330 (±60)	64 (±17)	800 (±11)

[a] See Figure 1 for structures and sequences. Well coupled and CA mismatch DNA sequences contain sequences with marker moieties attached to the DNA through an ethynyl linkage. Well coupled DNA strands are fully complementary, and CA mismatch strands contain a CA mismatch at the position indicated in Figure 1. Poorly coupled DNA sequences have the electroactive molecule coupled through a saturated linkage, as shown in Figure 1. [b] Peak currents are reported from square wave voltammetry (SWV). SWV was performed at 15 Hz in 5 mM sodium phosphate, 50 mM NaCl, pH 7.1, under anaerobic conditions. Electrochemical data were compiled over a minimum of five trials. Experiments were performed with a SCE reference electrode and a Pt wire auxiliary electrode. [c] All electrochemical potentials are reported vs NHE. [d] DNA modified with 3,4-dehydro-TEMPO.

electrochemical markers on HOPG (Supporting Information). These monolayers were found to be indistinguishable from those previously examined.

DISCUSSION

Electrochemical Reduction of the Acetylene-Linked Probes Is Mediated by DNA Duplex. For efficient DNA-mediated CT, it is necessary for the electrochemical probe to be directly coupled into the base pair stack. Our data provide strong evidence that the acetylene-linked probes are reduced in a DNA-mediated fashion. The largest signals are found for 3,4-dehydro-TEMPO and AQ moieties connected to the DNA by an acetylene linker. The inclusion of a CA mismatch below either of these probes significantly attenuates the electrochemical signal, a hallmark of DNA-mediated CT.

Interestingly, previous reports of DNA modified with AQ-labeled uridines allow for a strong correlation to be drawn between the nature of the DNA−probe linkage and the size of the electrochemical signal. The signals obtained here for an unsaturated tether integrate to current densities of 7900 nA/cm^2. Gooding and co-workers have previously reported the electrochemistry of a partially saturated tether whose current densities integrate to a value of ∼1500 nA/cm^2 (*29, 30*). Further, Okamoto and co-workers have found current densities on the order of ∼300 nA/cm^2 for a fully saturated linkage (*32, 33*). A clear trend emerges from these values: a linkage which allows for conjugation of the probe into the base pair stack leads to larger redox signals and more effective electrochemistry.

DNA-mediated electrochemistry is observed for the acetylene-linked probes at both positive and negative potentials. DNA is expected to be repelled from the surface at negative potentials and attracted to the surface at positive potentials (*53, 56*). Assays based on DNA-mediated electrochemistry rely on DNA maintaining an upright orientation; CT can then take place through the base pair stack. However, at positive potentials direct contact of the probe with the surface is possible if sufficient space surrounding each duplex is available. It has been shown that in a close packed monolayer, the DNA is not able to make direct contact with the surface (*56*). Therefore, assays based on DNA CT may be possible even for probes which are reduced at positive potentials.

Electrochemical Reduction of Alkane-Linked Probes Do Not Depend on DNA Mediated Electrochemistry. Electrochemical experiments with alkane-tethered TEMPO and AQ labels support the notion of direct surface to probe charge transfer for these assemblies. Changing from an acetylene linkage to an alkane linkage minimizes electronic coupling, and the signals observed for such linkages are associated with pathways of charge-transfer that are not DNA-mediated. The lack of mismatch discrimination observed for either of these probes strongly supports the notion of direct surface to probe CT for these cases. Since there is no effect upon inclusion of a mismatch in the DNA sequence, this electrochemistry cannot be mediated by the base pair stack.

The current densities obtained for the alkane-linked TEMPO and AQ labels are much smaller than those of the acetylene-linked probes. The peak current densities obtained from SWV are 400 nA/cm^2 and 200 nA/cm^2 for the TEMPO and AQ, respectively. Anthraquinone is a poor intercalator which should not interact strongly with the base pair stack, and TEMPO does not intercalate. Therefore the smaller signals for these probes are reasonable since the CT pathway to each of these probes involves poor electronic coupling. Furthermore, it is not unexpected that the TEMPO label exhibits larger current densities compared to the AQ label. The AQ is reduced at negative potentials, where DNA is repelled from the surface, making reduction of the probe by direct CT from the surface less likely (*53, 56*). On the other hand, the TEMPO is oxidized at positive potentials where the DNA can electrostatically contact the surface, making direct surface to probe charge-transfer more likely (*53, 56*).

Electronic Coupling into the Base Pair Stack Governs the Size of the Electrochemical Signal. Electrochemical signals that are far smaller than expected based on surface coverage are observed for the acetylene-linked probes versus that expected when compared to the electrochemical signal of intercalated daunomycin (*24*). Previous reports for daunomycin have revealed surface coverages of 35−45 pmol/cm^2 based upon charge integration (*24, 25*). These values are similar to the theoretical maximum coverage of the surface by a DNA monolayer. However, far lower apparent surface coverages are obtained for the two acetylene-linked probes presented here; cathodic waves give peak currents (Table 1) which roughly translate to surface coverages of 6 and 8 pmol/cm^2 for the AQ and TEMPO-modified DNA, respectively.

How can the dramatic difference in signal intensities be reconciled? Covalently attached daunomycin has a particularly intimate association with the base pair stack and raises the melting temperature of the duplex by 20 °C upon crosslinking (*35, 36*). On the other hand, the bulky AQ moiety only raises the melting temperature of the DNA duplex by 4 °C compared to unmodified DNA (Supporting Information). Therefore, it is reasonable to assume that the AQ is not as well coupled into the DNA base stack. This lack of electronic coupling would account for the smaller electrochemical signals observed relative to daunomycin.

In order to investigate if the apparent discrepancy in surface coverage is due to the AQ and TEMPO moieties interfering with surface formation, the monolayers were examined by scanning probe microscopy. Previous work has shown that even subtle structural variations in the DNA monolayer can be easily detected with a high-resolution AFM tip (*54*). However, we observed no obvious differences between the morphology of monolayers formed with acetylene-TEMPO-modified DNA and unmodified, well matched DNA (Supporting Information).

DNA Charge Transfer with Acetylene and Alkane-Linked Probes. The two linkages may provide different electron-transfer pathways from the electrode to the marker, as illustrated

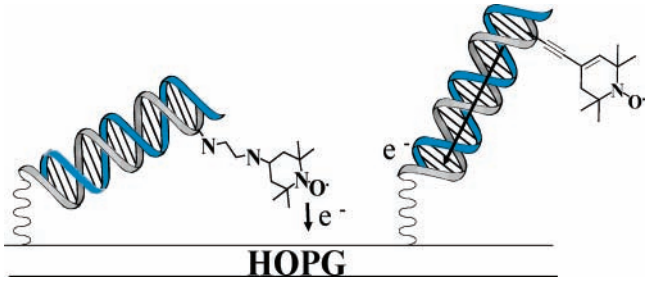

Figure 3. Schematic representation of two possible modes of charge transfer from an electroactive label incorporated into DNA. Direct interaction of the diaminoethane-linked TEMPO probe with the surface is shown on the left, and DNA-mediated electrochemistry to the well coupled probe is shown on the right.

schematically in Figure 3. When the probes are effectively coupled into the base pair stack through an acetylene linkage, the yield of DNA-mediated electrochemistry is high and charge transfer through the DNA base pair stack takes place. Large electrochemical signals result, and perturbations within the base pair stack can be easily detected. When the probes are insulated from the base pair stack through a σ-bonded alkane linkage, the yield of DNA-mediated electrochemistry is low and alternative charge-transfer pathways are dominant. Small electrochemical signals are observed and perturbations within the base pair stack are not easily detected.

These results can now be used to reexamine some of the data obtained from experiments involving long-range oxidative damage to DNA. Adequate sensitivity to mismatches or lesions can only be achieved with probes that are well coupled into the DNA base pair stack. Consequently, solution studies with covalently attached anthraquinone provide a particularly interesting example of the necessity of coupling into the DNA base pair stack. For example, in direct agreement with the electrochemical data presented here, anthraquinone linked to the 5′ terminus of DNA by an alkane chain has exhibited poor mismatch sensitivity in some contexts (*46*). Additionally, a direct comparison of the ability of various photooxidants to promote DNA-mediated CT showed that even changing the length of the linker connecting the anthraquinone had a significant effect on the yields of oxidative damage. In the same study, significant differences were found between poorly coupled probes that bind by an end-capping mode and well coupled probes that bind by an intercalative mode. Therefore, it is important to note that DNA CT reveals the characteristics not only of the DNA sequence employed but also of the redox probe.

Consideration of the inherent sensitivity of DNA CT to the linkage of the redox probe to the DNA base pair stack can also be extended to solution studies of protein/DNA interactions. A uridine modified with the TEMPO moiety was utilized as an electron trap for DNA bound repair enzymes (*40*). Notably, the linkage connecting the TEMPO to the uridine was shown to be crucial for determining its effectiveness as an electron trap in EPR experiments. When the TEMPO moiety is connected to a uridine by an unsaturated acetylene linkage, large EPR signals result, consistent with the larger electrochemical signals observed for this probe. On the other hand, when the TEMPO probe is connected by a saturated linkage, small EPR signals result, consistent with the smaller electrochemical signals observed.

Implications. Subtle structural changes can have a significant effect on the sensitivity of redox active reporters in DNA-mediated electrochemistry. Clearly, the utility of labels that are covalently attached to DNA depends upon their interaction with the base pair stack of DNA. Assays based on DNA-mediated CT necessitate well coupled probes that are highly sensitive to even subtle perturbations in the base pair stack.

This need is clearly illustrated by the electrochemical characteristics of AQ and TEMPO when coupled to DNA via a saturated linker versus being conjugated into the base stack. The electrochemistry of the acetylene-linked 3,4-dehydro-TEMPO and AQ is shown to be DNA-mediated. In contrast, charge transfer to the alkane TEMPO on HOPG and the alkane AQ on Au must proceed through an alternate direct surface-to-marker pathway. The data presented makes it clear that linkers conjugated into the base pair stack afford larger electrochemical signals, revealing a direct connection between the electronic structures of DNA-bound probes and their electrochemical properties.

DNA-modified electrodes are a powerful tool for directly comparing the electrochemistry of various redox active probes that are bound to DNA. DNA-mediated electrochemistry clearly allows the base pair stack to be probed directly. However, surface to probe charge transfer, while useful in other contexts, does not allow for the DNA base pair stack to be interrogated. In fact, the impressive sensitivity of DNA CT chemistry allows for the transduction of small structural changes into large electrochemical differences. As observed in the current study, the linkage directly governs the electrochemical characteristics of the probe. For electrochemical assays to be successful, it is crucial to tailor the probe to the desired application.

Biofunctionalized Surfactant Mesophases as Polyvalent Inhibitors of Cholera Toxin

Anastasios Polyzos,*,† Malcolm R. Alderton,‡ Raymond M. Dawson,‡ and Patrick G. Hartley†

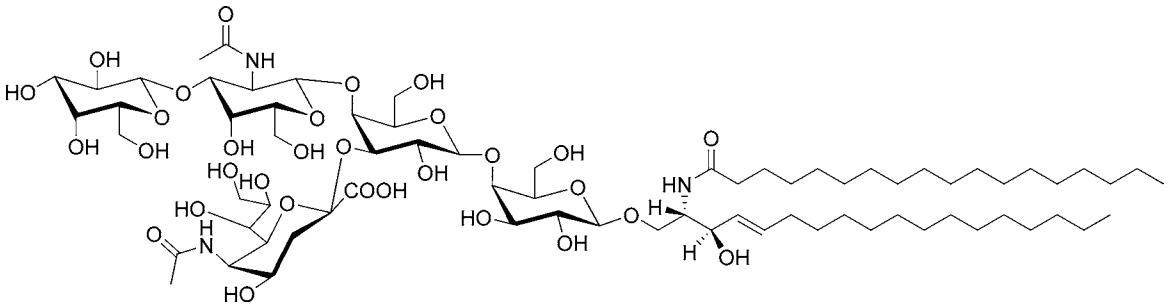
CSIRO Molecular and Health Technologies, Bayview Avenue, Clayton South, Victoria 3169, Australia, and DSTO Melbourne, Defence Science and Technology Organisation, P.O. Box 4331, Melbourne, Victoria 3001, Australia. Received February 25, 2007; Revised Manuscript Received July 9, 2007

The cubic lyotropic mesophase composed of the ganglioside G_{M1} and the synthetic surfactant phytantriol has been employed as a scaffold to prepare a polyvalent inhibitor of cholera toxin (CT). Surfactant mixtures containing up to 20% (w/w) G_{M1}/phytantriol afforded a hydrated insoluble gel-like material, which retained an inverse cubic phase (Q) structure in excess water and at 22 °C, as confirmed using small-angle X-ray scattering. The G_{M1}-functionalized mesophases bind up to 98.8% of CT from solution containing 100 ng/mL of CT with a dissociation constant (K_d) of 67−73 nM. The estimated IC_{50} values for the mesophase systems were 0.1−0.27 μM. The inhibitory effect of the mesophases may be enhanced through the high internal surface area of the inverse cubic phase in addition to the optimal self-orientation of G_{M1} ligand to match the distribution of binding sites on the toxin surface. As a result, polyvalent inhibitor materials manufactured using these mesophase structures do not require precise control of ligand distribution, which offers advantages with respect to complexity of synthesis and formulation when compared to more rigid and conformationally restricted materials. This approach provides a route to a unique class of polyvalent inhibitors, which should be broadly applicable to a range of bacterial and plant toxins.

INTRODUCTION

Cholera toxin (CT) is a heterohexameric protein which is secreted by the Gram-negative bacteria *Vibrio cholerae* (*1*) and is the agent responsible for the diarrheal disease cholera. The toxin architecture consists of a catalytic A subunit that is surrounded by an axisymmetric arrangement of five identical B subunits (*2*), and it therefore belongs to the AB_5 class of toxins. Within the lumen of the gastrointestinal tract, toxin endocytosis is mediated by the polyvalent recognition of the cell surface receptor lipid, ganglioside G_{M1} (Figure 1) (*2*), by the B pentamer (*3*). The enzymatic A subunit then separates from the B-pentamer and translocates into the cytosol, where it effects the stimulation of cyclic adenosine monophosphate (cAMP) production. This results in an active efflux of salts and water from the lumen, an accumulation of intestinal fluids in the gut, and diarrhea. An attractive approach to developing cholera prophylactics or therapeutics involves the development of receptor-binding antagonists that interfere with B-subunit recognition of the cell surface receptor. Crystallographic elucidation of the structure of CT has led to the extensive characterization of the recognition of G_{M1} by the binding epitopes in the pentameric B-subunits (*4*, *5*). These studies reveal that the terminal galactose of the G_{M1} oligosaccharide binds to a shallow binding epitope on each B subunit (*6*). Hence, the development of molecular mimics of the terminal galactose and sialic acid groups on the G_{M1} oligosaccharide are of interest (*7*).

CT receptor-binding antagonists, or inhibitors, fall into two classes. The first class comprises low molecular weight galactose derivatives, such as *m*-nitrophenyl galactose (MNPG) (*8*), that reversibly bind to one or more binding sites on the B-pentamer of CT. This class of inhibitor, also known as a monovalent inhibitor, has proven only moderately successful due to their relatively low affinity (*9*), which can be attributed to the weak binding interaction with the receptor site. The second class of inhibitors are known as polyvalent inhibitors. Polyvalent inhibitors, which are generally macromolecules, employ multiple binding moieties (typically galactose functionalities) to take advantage of the pentameric nature of the B subunit-cell surface receptor interaction. Structure-based inhibitors that incorporate five or ten single-site inhibitors covalently coupled to a central core have been reported (*10*, *11*), resulting in remarkable gains in CT inhibitor activity compared to the monovalent analogues (*7*, *12*−*15*). A variety of polyvalent scaffolds using generic backbones have been developed including random-coil and cyclic polypeptide-based glycopolymers (*16*). Further, oligosaccharide-derivatized dendrimers (glycodendrimers), which are hyperbranched polymers with a narrow size distribution, have been used as polyvalent scaffolds (*17*, *18*). The polyvalent display of mono- and oligosaccharides at the glycodendrimer surface has resulted in binding enhancements of up to 3 orders of magnitude compared with the monovalent analogue (*19*). The limitation associated with the rational design of polyvalent CT inhibitors is that their design is heavily reliant on crystallographic information, where the geometry and the dimensions of the polyvalent macromolecules must match the spatial distributions of binding epitopes on the B pentamer. As such, in pentameric and decameric inhibitors, the spacer length between the central core and pendant galactose groups must be optimized, using numerous structural derivatives to achieve optimal binding. Further, the display of galactose derivatives on polymeric scaffolds may not contain the requisite complimentary geometry to match the CT epitope surface, and these restrictions may often lead to modest binding affinities.



We have recently introduced a new class of polyvalent scaffold based on lyotropic (solvent containing) mesophases (*20*). In the presence of water, these systems develop from the

Figure 1. The structures of G_{M1} (1) and phytantriol (2).

aggregation of lipid molecules into a liquid crystalline phase, forming a three-dimensional bilayer structure with a high degree of internal order and structural uniformity. These self-assembled structures include the lamellar phase (L_α), which is comprised of sheets of stacked bilayer sheets and the inverse hexagonal phase (H_{II}) which can be conceptualised as infinitely packed cylindrical rods with an aqueous interior. Of particular interest is the bicontinuous inverse cubic phase in which a surfactant bilayer is folded onto an infinitely periodic minimal surface (IPMS) (*21*) consisting of infinite interwoven arrays of saddle surfaces with zero mean curvature and constant negative Gaussian curvature (*22*, *23*). The middle of the bilayer, defined by the terminal methyl groups of the intersecting hydrophobic moieties, forms the IPMS and the hydrophilic parts interface with the bulk water. This molecular architecture affords distinct aqueous regions that form two continuous water networks (or channels) throughout the cubic phase. Long-range crystallographic periodicity is found in such structures, with crystallographic space groups including the *Im*3*m*, *Pn*3*m*, and *Ia*3*d* having been reported (*24*, *25*).

The inverse cubic mesophase is thermodynamically stable and coexists in equilibrium with excess water over a broad temperature range. The resulting self-assembled material, in contrast to other aggregate systems such as micelles, is stable to dilution in water. These properties, and in particular the internal three-dimensional cubic nanostructure, have been exploited in biological applications such as protein entrapment and crystallization (*26*, *27*) as well as drug delivery (*28*−*33*). We reasoned that the cubic mesophase provides the appropriate hydrophilic and hydrophobic microenvironments reminiscent of the cell membrane, which should be favorable for biological ligand-receptor recognition (*31*). We further reasoned that owing to the high surface area of the internal mesophase structure (up to 400 m^2/g) (*34*), the inverse cubic phase provides an excellent scaffold for the immobilization of a high concentration of mobile monomeric antagonists which might facilitate self-arrangement of the ligands resulting in a polyvalent interaction. Such self-arrangement mitigates the requirement of a rigid molecular architecture currently employed in the design of polyvalent inhibitors. We have recently demonstrated the utility of this approach by incorporating synthetic galactose-functionalized surfactants within cubic phases for the sequestration of the plant toxin ricin (*20*). Here, we demonstrate for the first time a cubic phase toxin inhibitor based on the naturally derived lipid receptor for cholera toxin, ganglioside G_{M1} (Figure 1). The interaction between G_{M1} and CT is well characterized and involves a very strong binding interaction (K_d, 0.7−7 nM) (*35*).

The matrix we have employed for supporting the bioactive G_{M1} is the bicontinuous cubic phase of the inverse type formed by the surfactant 3,7,11,15-tetramethyl-1,2,3-hexadecanetriol or 'phytantriol' (Figure 1). The inverse cubic phase of phytantriol exists over a broad temperature range (*36*) and importantly, is not susceptible to hydrolysis that other surfactants such as glycerol monoolein (GMO) may undergo. We have studied both the physical chemistry and binding efficacy of G_{M1} functionalized cubic phases. We believe that this approach demonstrates the potential for inverse cubic phases in either bulk or dispersed forms to act as generic scaffolds for the design of polyvalent inhibitors which target a large class of biotoxins (*37*).

EXPERIMENTAL PROCEDURES

Preparation of G_{M1}/Phytantriol Mixtures. Monosialoganglioside (G_{M1}) (95%) obtained from bovine brain was purchased from Sigma Aldrich. 3,7,11,15-tetramethyl-1,2,3-hexadecanetriol (phytantriol) (96%) was purchased from Aldrich and was used without further purification. Dichloromethane was HPLC grade and used without further purification. The required quantity of G_{M1} was suspended in phytantriol and dissolved in a solution of 10 mL of 20% methanol/dichloromethane. The mixture was thoroughly dissolved until an optically transparent solution resulted. The solvent was then removed using rotary evaporation at a temperature of 40 °C for 25 min @ −68 kPa to afford a clear viscous oil.

Phase Behavior Observations by Polarizing Microscopy. Each sample mixture was placed between a microscope slide and coverslip and placed into the slide holder of a Mettler FP82HT hot stage controlled by a FP90 central processor. Water was dispersed at the edge of the coverslip, and capillary action drew the water between the two glass surfaces to surround the surfactant mixture. The sample was heated from room temperature (20 to 22 °C) at 2 °C/min or less. The interaction of water with the G_{M1}/phytantriol mixtures was viewed using an Olympus IX-70 microscope equipped with crossed polarizing lenses. Images were captured using a Canon EOS 300D digital camera. These 'water penetration scans' were usually performed in the temperature range 22−100 °C ± 0.5 °C.

Small-Angle X-ray Scattering (SAXS). The lipid phases in the presence of excess water were used for SAXS. Samples were analyzed at 22 °C. The hydrated mesophase systems did not exhibit any signs of instability under the conditions described. All small-angle X-ray scattering analyses were performed using a Bruker Nanostar SAXS camera equipped with a position sensitive 2-D "Hi-Star" detector using point collimated copper K_α radiation. Experiments were performed under a low-pressure

helium atmosphere to minimize background scattering. The gels were prepared with excess water and placed between two mica windows taped to a 1 mm stainless steel spacer. This was clamped to the analysis geometry by a stainless steel plate. Data acquisition was performed at a sample-to-detector distance of 23 cm which facilitated analysis of intensity behavior over the wavevector range: $0.0498\ \text{Å}^{-1} \leq q \leq 0.950\ \text{Å}^{-1}$. The scattering profiles of the empty sample geometries were subtracted from the final scattering profile of the sample (per-pixel subtraction) after first correcting for the intensity of the X-ray beam.

Assay for Cholera Binding by Lyotropic Mesophases. Nunc-Immuno 96-microwell flat-bottom plates with a Maxisorp surface were obtained through Medos Company, Melbourne, Australia. Phosphate-buffered saline (PBS) was prepared by dissolving a tablet from Sigma-Aldrich in 200 mL of deionized distilled water. The resultant solution comprised 0.01 M phosphate, 0.137 M NaCl, and 0.0027 M KCl, pH 7.4 at 25 °C. PBS-Tween was prepared by dissolving the contents of a sachet from Sigma-Aldrich in 1 L of deionized distilled water. This gave a solution of 0.01 M phosphate, 0.138 M NaCl, 0.0027 M KCl, 0.05% Tween 20, pH 7.4, at 25 °C. Cholera toxin from *Vibrio cholerae* Inaba 569B (azide free) was obtained from List Biological Laboratories, Campbell, CA. The toxin was received as a powder, dissolved in 1.0 mL of deionized distilled water, and then stored at 2 °C. The reconstituted cholera toxin contained 1 mg of protein in 1.0 mL of 0.05 M Tris, 0.2 M NaCl, and 0.001 M Na_2EDTA at pH 7.5. The solution was diluted with PBS-Tween immediately prior to assays. Purified polyclonal goat anti-cholera toxin was a product of Biogenesis, Poole, UK. All other materials were obtained from Sigma-Aldrich, Sydney, Australia. Monosialoganglioside G_{M1} from bovine brain was obtained as 1 mg of powder. It was dissolved in 1 mL of methanol, stored at −20 °C, and diluted just before use. The substrate solution for alkaline phosphatase was prepared by dissolving two *p*-nitrophenyl phosphate tablets and two TRIS buffer tablets from Sigma-Aldrich in 11 mL of deionized distilled water.

Stock solutions (50 mg/mL or 23 mg/mL) of the surfactant mixtures were prepared in methylene chloride. Serial dilutions of the mixtures in dichloromethane were prepared to give the appropriate concentration. Ten-microliter aliquots of the serial dilutions were placed in glass test tubes, and the solvent was allowed to evaporate for 1−2 h in a fume cupboard at room temperature (20 °C). The movement of air in the fume cupboard facilitated the rapid evaporation of the solvent. Cholera toxin solution, of a concentration between 1.0 and 100 ng/mL in blocking buffer (PBS-Tween with 0.25% bovine serum albumin; 130 μL), was added to the tubes, and they were placed on a rocker platform and gently oscillated for 24 h at room temperature. Aliquots (100 μL) of the supernatants from these tubes were then added to immobilized G_{M1} in Nunc microtiter plates, and the cholera toxin assay was performed as described below. Additional runs were performed both without the mesophase solution and in the presence of pure phytantriol (without G_{M1}) as controls.

In the standard cholera toxin assay, all incubations were at room temperature (20−22 °C), with a volume per well of 0.1 mL except for the incubation with blocking buffer (0.36 mL). After each incubation, the microtiter plate was emptied and washed three times with PBS-Tween. An additional wash with distilled water was performed before addition of the alkaline phosphatase substrate. The wells of a microtiter plate received 100 ng/mL of G_{M1} in PBS and were left overnight (ca. 16 h) before rinsing with PBS-Tween and sequential treatment with blocking buffer, cholera toxin from the assay supernatant (100 μL in blocking buffer), goat anti-cholera toxin antibody (1:8000 dilution in blocking buffer), rabbit anti-goat alkaline phosphatase conjugate (1:2000 dilution in blocking buffer), and substrate (*p*-nitrophenyl phosphate solution). Incubation times were 1 h for the blocking buffer, antibody, and conjugate and 1.5−3 h for the cholera toxin. The microtiter plate was shaken on a plate shaker (Ratek Instruments, Melbourne, Australia) during incubations with cholera toxin and the two antibody solutions. After addition of substrate, the absorbance was read at 405 nm at 2.5-min intervals for 17.5 min in an ICN Titertek-Plus MS212 plate reader, and the steady-state rate of increase of absorbance was calculated. Each experiment was performed at least twice.

A calibration curve for solution cholera toxin (CT) concentration (1.0−100 ng/mL) *versus* rate of change of absorbance per minute (abs/min) for each ELISA assay was constructed. The data was conveniently fit using a logarithmic relationship (*20*).

$$\text{abs/min} = A + B.\ln[\text{CT}] \quad (1)$$

The *A* and *B* factors in the above relationship were obtained from the linear plot of ln[CT] *versus* abs/min. These factors were then used to derive a residual CT concentration (final [CT]) and % binding in solutions which were exposed to mesophase test samples. The data are plotted in Figures S1 and S2 (Supporting Information) for the G_{M1}/phytantriol mesophase formulations. For each mesophase mixture, six concentrations of G_{M1}/phytantriol were submitted to binding assay ($0.13-1.3 \times 10^4$ ng/mL and $0.065-6.5 \times 10^3$ ng/mL for 10% G_{M1}/phytantriol and 20% G_{M1}/phytantriol, respectively), as described above. The percentage binding of CT by the mesophase mixtures for the highest concentration of CT studied (100 ng/mL) is reported in Figure 5.

Equilibrium dissociation constants (K_d) for the binding of CT by mesophase components were calculated using the relationship (eq 2), where the reciprocal of the equilibrium association constant (K_a) gives K_d. The K_a value was calculated from the estimated equilibrium concentration of the G_{M1}−CT complex (MT), the equilibrium concentration of unbound G_{M1} (M) and cholera toxin (T), (eq 3).

$$K_d = 1/K_a \quad (2)$$

$$K_a = [\text{MT}]/[\text{M}].[\text{T}] \quad (3)$$

The model assumes a 1:1 stoichiometry for (MT), since unambiguous determination of polyvalent binding equilibria introduces significant complexity into equilibrium binding analysis.

Table 1. G_{M1}/Phytantriol Liquid Crystalline Phases Assigned in the Presence of Excess Water

	temperature regime of phases (°C)			
mixture	L_α	Q	H_{II}	L_{II}
100% phytantriol	-	<23−54	54−67	68−100
10% G_{M1}/phytantriol	-	<23−60	60−85	85−100
20% G_{M1}/phytantriol	-	<23−46	<46−70	70−100
30% G_{M1}/phytantriol	<22−28	<28−29	-	30−60
40% G_{M1}/phytantriol	<26−30	<30−33	-	35−52

RESULTS AND DISCUSSION

We focused our initial studies on obtaining mesophase mixtures in which a high concentration of G_{M1} could be incorporated into phytantriol, while retaining the inverse cubic phase structure. Four mixtures were prepared each with a loading of G_{M1} between 10 and 40% w/w. The structure and presence of phases for the G_{M1}/phytantriol mixtures was qualitatively identified by light polarizing microscopic observation as excess water diffused into the surfactant mixture ('water penetration scans'). Table 1 compares the temperature for the first appearance of phases at the surfactant-water interface and the tem-

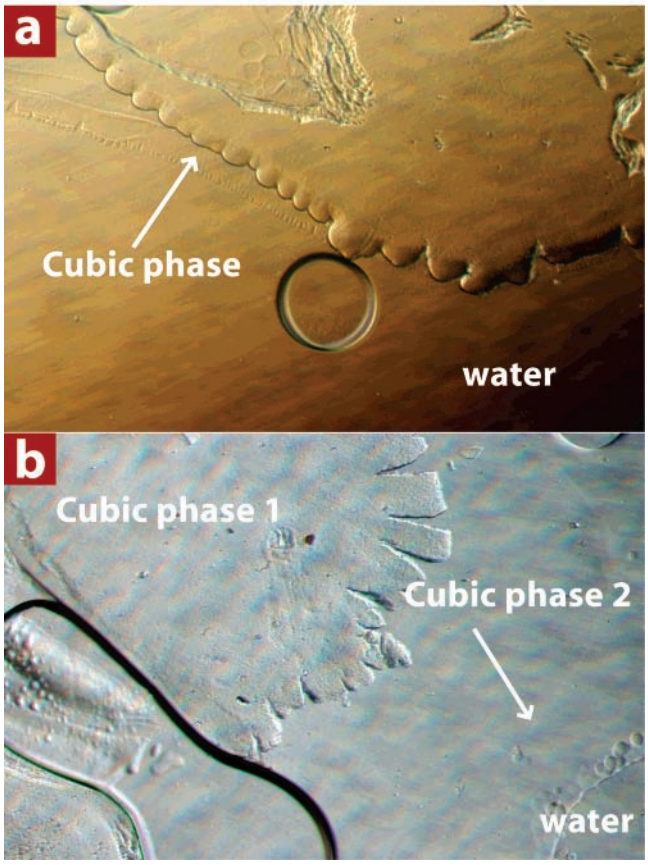

Figure 2. Polarized optical microscopy images of representative mesophase mixtures. (A) 10% G_{M1}/phytantriol ($T = 37.0$ °C) and **(B)** 20% G_{M1}/phytantriol ($T = 40.0$ °C) in excess water.

perature range over which they are present for the G_{M1}/phytantriol mixtures. The microscopy data shows that a cubic phase (Q) was exhibited by all mesophase mixtures at ambient temperature. Figure 2 shows representative light polarizing microscope images for the 10% G_{M1}/phytantriol and 20% G_{M1}/phytantriol, respectively. The inverse cubic phase behavior of each phase was characterized by non-birefringence and irregular morphologies (indicating high viscosity) at the aqueous interface. For the 10% and 20% G_{M1}/phytantriol mixtures, the phase behavior in excess water follows the sequence of cubic (Q) to inverse hexagonal (H_{II}), followed by a mobile isotropic phase ($H_{II} \rightarrow L$) with increasing temperature. The mobile isotropic phase was characterized by a non-birefringent optical property and low viscosity, detailed by the flow of air bubbles in the isotropic phase close to the bulk aqueous region. This phase was assigned as reversed micellar (L_{II}), which are the expected phase transitions with decreasing water content (*38*). This is similar to the phase sequence recently reported by Barauskas and Landh (*36*) for phytantriol in excess water ($Q \rightarrow H_{II} \rightarrow L_{II}$). It is important to note however, that the $Q \rightarrow H_{II}$ phase transition temperature of the phytantriol used in the present study occurred at 54 °C, while Barauskas and Landh report a lower temperature of 44 °C. Other groups have also observed a higher temperature for this phase transition (*39*).

When the ganglioside G_{M1} concentration was increased to 30−40% in phytantriol, the resemblance to the pure phytantriol phase behavior was lost. At these higher loadings of ganglioside, the phase transitions followed the order of lamellar (L_α) to cubic phase (Q) followed by a transition to a reversed micellar (L_{II}), ($L_\alpha \rightarrow Q \rightarrow L$). Thus, unlike the 10% and 20% G_{M1}/phytantriol mixtures, the higher loading of ganglioside appeared to destabilize the Q phase, which also appeared over a very narrow temperature range (25−33 °C). A plausible reason for the observed instability of the Q phase, in addition to the appearance of the L_α at higher G_{M1} concentrations, is the modification of mesophase curvature derived from the difference in molecular packing geometry of the ganglioside and phytantriol. We assume that that G_{M1} is homogeneously distributed within the phytantriol matrix and the mode of insertion involves the occupation of the pentasaccharide at the aqueous interface, with the ceramide hydrophobe embedded into the interior of the surfactant bilayer, packing with the terpenoid chains of phytantriol. The packing of each lipid is described by the critical packing parameter, S, which is described by the relationship $S = \nu(\alpha_0 l_C)^{-1}$, where ν is the molecular volume of the chains, l_C is the molecular length of the chains, and α_0 is the optimal headgroup area for each amphiphile monomer. When the packing parameter is less than unity ($S < 1$), the resulting aggregate is curved toward the hydrophobic region as in normal micellar aggregates (L_I), while for molecules where $S \approx 1$, a cylindrical molecular geometry is suggested, resulting in the formation of a flat bilayer (lamellar phase). On the other hand, if the amphiphile contains a hydrophobic moiety that occupies a large volume and correspondingly small headgroup, then $S > 1$ and the aggregate is curved toward the polar region, as observed with cubic or inverse hexagonal phases. Qualitatively, phytantriol displays an inverted cone-shaped molecular geometry derived from the small triol-containing headgroup and terpenoid tail that occupies a large molecular volume (*40*), thus $S > 1$. An inspection of the structure of G_{M1} reveals a wedge-shaped molecular geometry based on relative cross-sectional area of 40 Å^2 (*41*) for the ceramide and 95 Å^2 (*42*) for the hydrated G_{M1} pentasaccharide headgroup, affording a critical packing parameter of less than unity ($S < 1$). In general, negative interfacial curvature increases, with respect to water, in proceeding from a lamellar to cubic to an inverse hexagonal phase transition ($L_\alpha \rightarrow Q \rightarrow H_{II}$) (*38*). Thus, the incorporation of an increased mole fraction of G_{M1} into the bilayer of phytantriol forces a reduction in the net negative curvature relative to water, owing to the geometric incompatibility of the two lipids. Moreover, the formation of a lamellar phase (L_α) observed at room-temperature suggests that a 30−40% w/w G_{M1} loading completely disrupts (flattens) the interfacial curvature. Accordingly, the highest concentration of ganglioside that could be incorporated into phytantriol, while retaining mesophase structure, was 20% w/w, and the compositions reported here represent the upper limit of G_{M1} loading within the phytantriol mesophase matrix. Accordingly, the 10% G_{M1}/phytantriol and 20% G_{M1}/phytantriol mesophase mixtures were examined in greater detail as potential cholera toxin (CT) inhibitors.

A detailed structural analysis for the 10% G_{M1}/phytantriol and 20% G_{M1}/phytantriol mesophase mixtures was performed using SAXS. The SAXS diffraction patterns for each of these mixtures, as shown in Figure 3, verified cubic phase structures in excess water at room temperature (22 °C). This study evidence a periodic (cubic) structure for both samples, supporting the cross-polarizer microscopic observations. The Bragg reflections for each sample gave reciprocal spacings in the ratio $1{:}\sqrt{2},\sqrt{4},\sqrt{6}$, etc., which was consistent with the cubic phase with a $Im3m$ (Q^{229}) spacer group (*22*). The allowed Bragg reflections for an $Im3m$ space group correspond to $h\ k\ l = 110$, 200, 211, 220, 310, 222, 321, etc. The intense 110, 200, and 211 reflections were conclusively assigned as the first three reflections for the $Im3m$ (Q^{229}) space group observed for each mesophase mixture. The higher order reflections (220, 310, 222, 321, etc.) exhibited a weak intensity and could not be unambiguously assigned. Figure 4 shows the plot of q ($= 2\pi/d$) for the observed reflections as a function of $(h^2 + k^2 + l^2)^{1/2}$. The plot generated a straight line, passing through the origin, which is the expected trend behavior for the cubic phase (*43*). The

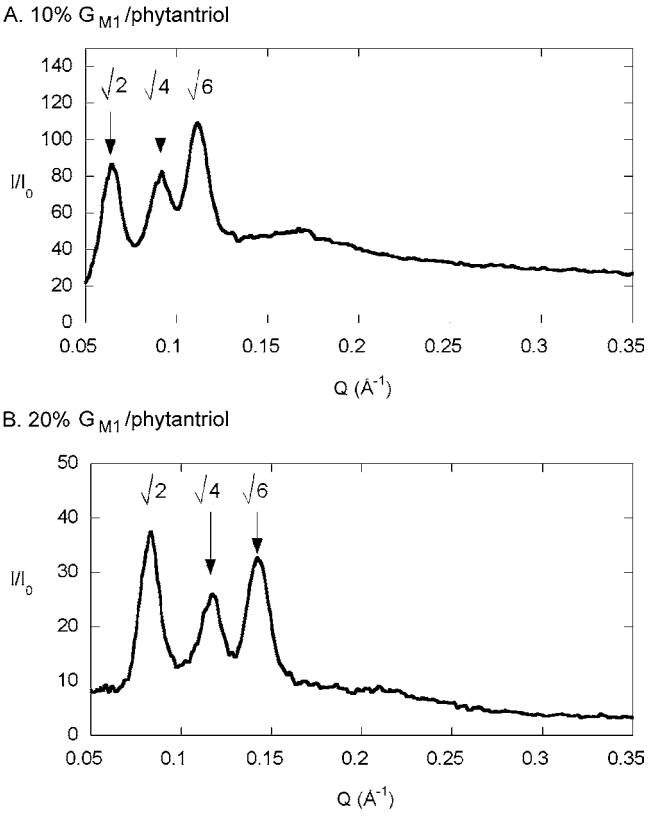

Figure 3. SAXS diffraction patterns obtained from the cubic phases of the **(**A**)** 10% G_{M1}/phytantriol and **(**B**)** 20% G_{M1}/phytantriol in excess water at 22 °C. The Bragg reflections gave higher order reciprocal spacings in the ratio 1:√2,√4,√6.

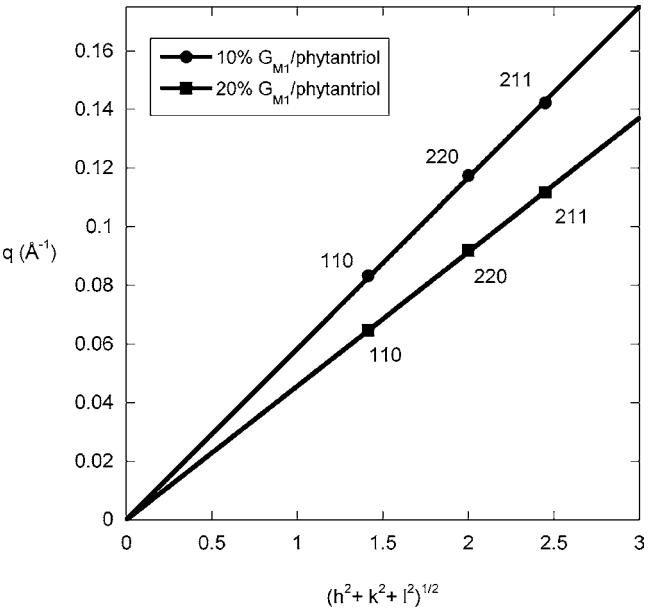

Figure 4. Plots of the reciprocal *d*-spacings (*q*) as a function of the Miller indices, $(h^2 + k^2 + l^2)^{1/2}$ from the observed reflections in the SAXS diffraction patterns for the 10% and 20% G_{M1}/phytantriol mixtures in excess water. The linearity of the plots and the intercept through the origin is consistent with the cubic phase with a *Im*3*m* (Q^{229}) spacer group. From the slope of the plots, the calculated lattice parameters (α) were 107.1 Å and 137.3 Å for 10% G_{M1}/phytantriol and 20% G_{M1}/phytantriol, respectively.

graph shows a good fit to data for the indexing of the observed diffraction peaks, confirming *Im*3*m* symmetry for both phases. Interestingly, pure phytantriol adopts a cubic phase with a *Pn*3*m* (Q^{224}) space group in the presence of excess water (*36*). Thus, in excess water and at room temperature, the addition of 10−20% G_{M1} to pure phytantriol induces a phase transition from *Pn*3*m* symmetry to the *Im*3*m* space group. For different cubic phases (Q), interfacial curvature of the polar region decreases in moving from *Ia*3*d* → *Pn*3*m* → *Im*3*m* (*44*), again indicating that introduction of the G_{M1} lipid induces a reduction in negative interfacial curvature of the phytantriol mesophase. This behavior is consistent with the light polarizing microscopic observations of increased lamellar tendency on addition of G_{M1} described earlier. A similar *Pn*3*m* → *Im*3*m* phase transition was demonstrated by Engblom et al. (*45*, *46*) for the related inverse system, monoolein, with the addition of the lipid, distearoylphosphatidylglycerol (DSPG). We reason that the addition of the G_{M1} lipid increases the effective headgroup area (α_0) within the mesophase, thereby decreasing the critical packing parameter value (*S*), leading to an overall reduction in negative interfacial curvature, as described earlier.

Further structural analysis of the G_{M1}/phytantriol mixtures revealed that the phytantriol liquid crystalline phase swells with the addition of ganglioside. From the slope of the plot of q (= $2\pi/d$) *versus* $(h^2 + k^2 + l^2)^{1/2}$ (Figure 4), the lattice parameters (α) for each cubic unit cell were estimated. Thus, the calculated lattice parameters (α) were 107.1 Å and 137.3 Å for 10% G_{M1}/phytantriol and 20% G_{M1}/phytantriol, respectively. The dimension of the cubic unit cell for pure phytantriol, as described by the lattice parameter (α), has been reported to be 64−66 Å (*36*). This represents an increase in α of approximately 54%, under the given conditions. The swelling of the related liquid crystalline (cubic) phase of monoolein (*45*−*48*) with the addition of sodium cholate or cationic surfactants has also been observed (*49*). The uptake of solvent by the ternary monoolein systems is due to the long-range electrostatic repulsion of the charged bilayers as the concentration of the cationic component is increased. The swelling of the liquid crystalline phase in the G_{M1}/phytantriol systems is most likely a result of the reduced negative curvature of the cubic phase due to addition of ganglioside G_{M1} to phytantriol, as discussed earlier. The reduction of the negative curvature of the lipid/water interface of G_{M1}/phytantriol systems is accompanied with an affiliated increase of the surface area of the aqueous interface which promotes the diffusion of additional water into the mesophase structure. An important implication of this effect is that the expansion or 'tuning' of aqueous pore channels of the phytantriol (*Im*3*m*) cubic phase can be controlled by increasing the fraction of G_{M1}.

Cholera toxin uptake by mesophase formulations using an enzyme linked immunosorbent assay (ELISA) were performed. The ELISA assay results for the residual CT in solution, following exposure to 100 ng/mL of cholera toxin to G_{M1}/phytantriol mesophases samples, are shown in Figure 5. The data shows that the toxin has a very high affinity for each of the mesophase preparations and demonstrates that approximately 13 ng/mL of the 10%, and 6.5 ng/mL of the 20% G_{M1}/phytantriol mixtures, respectively, is capable of removal of 95−99% CT. To facilitate comparison with other polyvalent inhibitors of CT, we calculated the IC_{50} values for each of the mesophase mixtures (IC_{50} is the molar concentration of an antagonist that produces 50% maximal inhibitory response). An IC_{50} of 0.27 μM and 0.10 μM was determined for the 10% and 20% G_{M1}/phytantriol mixtures, respectively (Table 2). The estimated IC_{50} compared favorably with the IC_{50} for pentavalent and decavalent inhibitors, which have generally micromolar activity (*10*, *11*, *18*). The authors do acknowledge that the literature IC_{50} values were obtained with water soluble inhibitors, and therefore direct comparison with IC_{50} values from water insoluble mesophase inhibitors reported herein may not reflect the differences in inhibitory activity. Accordingly, the comparison between IC_{50}s are indicative of inhibitor activity, and

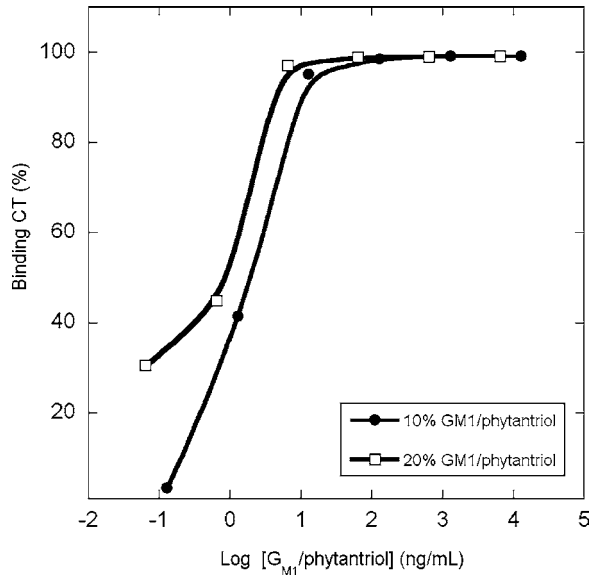

Figure 5. Percent binding of cholera toxin (CT) (100 ng/mL) as a function of mesophase concentration (ng/mL) by the 10% and 20% G_{M1}/phytantriol mesophase systems.

Table 2. Estimated Binding Parameters and IC_{50} Values

mesophase	IC_{50} (μM)	K_d (nM)
10% G_{M1}/phytantriol	0.27	73
20% G_{M1}/phytantriol	0.10	67
phytantriol	-	5.64×10^7

the preparation of a water soluble dispersion of the mesophase will generate IC_{50} values *via* a classical competitive inhibition binding assay.

The equilibrium dissociation constant, K_d, which is a measure of the affinity of the interaction, was calculated to be 73 nM for the 10% G_{M1}/phytantriol mesophases and 67 nM for the 20% G_{M1}/phytantriol mixture. The reported K_d is the average value obtained from a range of K_d values estimated for the different samples. The estimated K_d is reported on the basis of a 1:1 G_{M1}/CT binding interaction. Although the binding of G_{M1}/CT involves a 1:5 stoichiometry, the estimation of K_d *via* a 1:1 interaction simplifies the binding affinity calculation and facilitates direct comparison with literature values, which also assume an equimolar reaction (*35*, *50*). The similar K_d values suggest a comparable affinity of CT for each mesophase. However, the difference in absolute value may be attributed to incomplete equilibrium between toxin and mesophase. This may also account for the considerably higher dissociation constants than those recently estimated for G_{M1} immobilized in liposomes ($K_d = 0.26$ nM) using surface plasmon resonance (SPR) (*50*). An important consideration with the comparison of K_d values with those obtained from G_{M1}-functionalized liposomes, is that the mesophases are bulk gel-like materials and not dispersed particles. It is reasonable to assume that the liposomal systems have a large surface area for the presentation of G_{M1} for binding with the toxin. This facilitates rapid diffusion and binding of the CT to surface G_{M1}, leading to the establishment of equilibrium between toxin and receptor. The diffusion kinetics of CT within the bulk mesophase gel studied here may be limited compared to these dispersed liposome systems. Work is continuing to prepare cubic mesophase nanoparticles to optimize surface area and binding kinetics (*51*).

The pure phytantriol control shows that nonspecific binding to the mesophases is minimal at the concentrations studied, as demonstrated by the performance of the gels relative to the phytantriol. Referring to Table 2, the low affinity of pure phytantriol is evidenced by a large dissociation constant (K_d, 5.64×10^7 nM), which is approximately 8×10^5-fold greater than the G_{M1}-functionalized mesophases. This data suggests that the mechanism of CT immobilization by the mesophase mixtures involves the specific interaction of G_{M1} and CT. In addition to the absence of a specific binding interaction for the pure phytantriol systems, the geometric constraints of the *Pn*3*m* space group for pure phytantriol may reduce CT diffusion within the aqueous channels compared with the G_{M1}/phytantriol mixtures (which have a more 'open' *Im*3*m* space group). The *Im*3*m* has a higher water content than the *Pn*3*m* cubic phase and the higher levels of hydration (*38*) favor protein diffusion within the (G_{M1}/phytantriol) phase structure.

We further reason that the polyvalent recognition of CT by the immobilized G_{M1} is aided by the lateral diffusion of the ganglioside within the phytantriol bilayer to promote alignment of the B-subunit binding epitope with the G_{M1} pentasaccharide group. The reorganization of G_{M1} provides an additional favorable entropic contribution that promotes B-subunit-G_{M1} interaction. Supporting this hypothesis is the observed mobility of G_{M1} in monolayer or vesicle bilayers (*52*, *53*) and the lateral diffusion of lipids within inverse cubic mesophases (*22*, *54*). By virtue of the possible lateral mobility of G_{M1} within the mesophase bilayer, the requirement for ligands to be incorporated into rigid molecular architectures with precise spatial arrangement, such as dendrimers, is mitigated. It must be noted that the accurate location of bound toxin within the aqueous regions of the mesophase structure is unknown. We speculate that the protein adhesion to the mesophase must involve a combination of diffusion at the periphery, penetration of the aqueous channels of the surfactant assembly (*31*), and binding at the exterior surface. Further experimental evidence is required to confirm this postulate.

CONCLUSION

The demonstration of cholera toxin binding by a ganglioside-functionalized cubic mesophase is a significant advance in the development of cubic mesophase polyvalent inhibitors of AB_x-type toxins. To our knowledge this is the first example of the functionalization of an inverse cubic mesophase with lipid receptors to selectively bind cholera toxin. We have shown that phytantriol provides an excellent inert surfactant scaffold for inhibitor immobilization due to the retention of cubic phase behavior at high loadings of glycolipid and at physiological temperature, as shown by SAXS and water penetration studies. Furthermore, control measurements demonstrated that the phytantriol matrix shows minimal nonspecific binding of cholera toxin, demonstrating the tuneable specificity of these systems. A key feature of the mesophases is that the requirement for the incorporation of toxin structural data into inhibitor design is mitigated because of the possible lateral mobility of the toxin antagonists with the mesophase bilayer. The reorganization of ligands within the bilayer with toxin recognition is a unique mechanism that is unavailable to conformationally restricted polyvalent inhibitors. These results support our novel approach for the use of lyotropic mesophase systems as a new class of polyvalent affinity ligands in the development of new antitoxin prophylactics and therapeutics. Work is presently continuing to prepare cubic phase nanoparticles that will enable evaluation of mesophase particles as antitoxins by classical inhibition assay.

Received March 8, 2007; Revised Manuscript Received May 31, 2007

The therapeutic application of siRNA shows promise as an alternative approach to small-molecule inhibitors for the treatment of human disease. However, the major obstacle to its use has been the difficulty in delivering these large anionic molecules *in vivo*. In this study, we have investigated whether siRNA-mediated knockdown of p38 MAP kinase mRNA in mouse lung is influenced by conjugation to the nonviral delivery vector cholesterol and the cell penetrating peptides (CPP) TAT(48−60) and penetratin. Initial studies in the mouse fibroblast L929 cell line showed that siRNA conjugated to cholesterol, TAT(48−60), and penetratin, but not siRNA alone, achieved a limited reduction of p38 MAP kinase mRNA expression. Intratracheal administration of siRNA resulted in localization within macrophages and scattered epithelial cells and produced a 30−45% knockdown of p38 MAP kinase mRNA at 6 h. As with increasing doses of siRNA, conjugation to cholesterol improved upon the duration but not the magnitude of mRNA knockdown, while penetratin and TAT(48−60) had no effect. Importantly, administration of the penetratin or TAT(48−60) peptides alone caused significant reduction in p38 MAP kinase mRNA expression, while the penetratin−siRNA conjugate activated the innate immune response. Overall, these studies suggest that conjugation to cholesterol may extend but not increase siRNA-mediated p38 MAP kinase mRNA knockdown in the lung. Furthermore, the use of CPP may be limited due to as yet uncharacterized effects upon gene expression and a potential for immune activation.

INTRODUCTION

The discovery of RNA interference (RNAi) and the application of short interference RNA (siRNA) for the knockdown of protein expression through mRNA degradation has revolutionized the area of functional genomics (*1*, *2*). Thus, siRNA macromolecules composed of double-stranded RNA 21−23 nucleotides in length are now commonly used in cell-based studies to investigate gene function. Furthermore, a number of academic groups and biotechnology companies are investigating the utility of siRNA as a therapeutic approach in the treatment of diseases such as macular degeneration, hepatitis C infection, and cancer (*3*−*6*).

Compared with small molecule inhibitors, the relatively large size and anionic charge of siRNA means that one of the key barriers to their *in vivo* use is the availability of effective approaches for delivery both to specific tissues and across the plasma membrane. Since intravenous siRNA administration is subject to first-pass metabolism, unless a liver condition is being targeted (i.e., hepatitis C infection), therapeutic application is limited to tissues where siRNA localization for extended periods is possible, e.g., following intra-ocular injection for the treatment of macular degeneration. In the case of the lung, the structure of the tissue permits direct access to large numbers of cells within the branching airways and alveoli, an estimated surface area of 400 m^2 in man. Importantly, the facility of topical delivery via intranasal, intratracheal, or aerosol administration suggests the lung as an ideal target organ for siRNA-based therapeutics. Indeed, studies have shown that siRNA-mediated attenuation of cytokine (*7*) and heme oxygenase-1 expression (*8*) during acute lung injury. Similarly, intranasal and intratracheal siRNA administration have been shown to prevent parainfluenza and respiratory syncytial virus (PIV and RSV, respectively) infection in mice (*9*−*12*) and severe acute respiratory syndrome (SARS) infection in rhesus monkeys (*13*).

In the majority of these studies, cationic lipids (e.g., lipofectin) and polymers (e.g., PEI and dendrimers) have been employed to package and deliver the siRNA to the lung. However, generic application of these strategies is limited by drawbacks such as toxicity and siRNA-mediated induction of immune responses through Toll-like receptors (TLR) (*14*−*16*). In an attempt to circumvent these problems, we examined the utility of chemical conjugation of siRNA to the nonviral delivery vector cholesterol and the cell-penetrating peptides (CPP) penetratin and TAT-(48−60) to improve siRNA-mediated mRNA knockdown in the mouse lung. Specifically, we attempted to target the constitutively expressed p38 mitogen-activated protein (MAP) kinase (also known as MAPK14). Activation of this protein is known

to be important in the release of multiple pro-inflammatory mediators including tumor necrosis factor (TNF)-α and interleukin (IL)-1. Indeed, many pharmaceutical companies are developing small-molecule inhibitors that target p38 MAP kinase to be used in the treatment of a host of inflammatory diseases including rheumatoid arthritis, Crohn's disease, chronic obstructive pulmonary disease, and psoriasis (*17*, *18*).

Chemical conjugation of siRNA to cholesterol has been shown to facilitate intracellular siRNA uptake *in vitro* (*19*) and *in vivo* (*20*). In the latter case, intravenous administration of cholesterol-conjugated siRNA was shown to silence endogenous apolipoprotein B (ApoB) gene expression in the liver and jejunum, resulting in decreased plasma levels of apoB protein and total cholesterol (*20*). Interestingly, a recent study has shown that the delivery of siRNA targeted to ApoB can be further increased ~20-fold compared to cholesterol conjugation by formulation in stabilized nucleic acid lipid particles (SNALP) (*21*). Additional evidence of the utility of cholesterol for oligonucleotide delivery is provided in a recent report showing cholesterol-mediated delivery of 2′-O-methyl- and phosphorothioate-modified single-stranded RNA for the knockdown of microRNA expression in the liver, lung, kidney, heart, intestine, fat, skin, bone marrow, muscle, ovaries, and adrenal glands following intravenous injection (*22*).

The CPP TAT(48−60) and penetratin are short cationic peptides derived from the HIV-1 TAT *trans*-activator protein (*23*, *24*) and the insect *Antennaedia* homeoprotein (*25*) that have been extensively used for the *in vitro* and *in vivo* delivery of biologically active peptides and proteins (*26*, *27*). Significantly, CPP have been shown to mediate uptake of a range of biological and nonbiological cargos, which has led to the suggestion that they may represent a universal, nontoxic approach for the delivery of oligonucleotides (*28*−*31*). Interestingly, although no studies have examined the utility of CPP for the *in vivo* delivery of siRNA, this possibility is supported by reports showing penetratin-mediated delivery of siRNA and antisense into isolated neurons (*32*−*34*) and TAT(48−60)−siRNA conjugate-mediated knockdown of eGFP and CDK9 expression in HeLa cells (*35*).

In this report, we demonstrate that intratracheal administration of siRNA achieved a limited attenuation of mRNA expression in the lung for an endogenous, constitutively expressed target, p38 MAP kinase. However, although conjugation to cholesterol, TAT(48−60), or penetratin facilitated knockdown of p38 MAP kinase mRNA in a mouse cell line, only cholesterol−siRNA conjugates were found to influence target gene mRNA levels *in vivo*. Importantly, since both CPP inhibited p38 MAP kinase mRNA expression *in vivo*, but not *in vitro*, we document the existence of as yet uncharacterized CPP bioactivity. Moreover, the detection of innate immune response induction by penetratin−siRNA but not TAT(48−60)−siRNA conjugates suggests differential cellular uptake mechanisms between the two CPP.

EXPERIMENTAL METHODS

siRNA Conjugation and Annealing. Initial screening studies were performed with pre-annealed and PAGE-purified siRNA obtained from Dharmacon, Inc. (Lafayette, USA), using the following sequences: A—sense, 5′-GCACACUGAUGAUGAGAUGUU-3′; antisense, 5′-CAUCUCAUCAUCAGUGUGCUU-3′; B—sense, 5′-ACAUUCGGCUGACAUAAUUUU-3′; antisense, 5′-AAUUAUGUCAGCCGAAUGUUU-3′; C—sense, 5′-GGGAGGUGCCCGAACGAUAUU-3′; antisense, 5′-UAUCGUUCGGGCACCUCCCUU-3′; mismatch 1 (MM1)—sense, 5′-CCGAGGUGGCGGAACGAUAUU; antisense, 5′-UAUCGUUCCGCCACCUCGGUU-3′; mismatch 2 (MM2)—sense, 5′-GCGAGCUGCGCGAAGGAUAUU-3′; antisense, 5′-UAUCCUUCGCGCAGCUCGCUU-3′.

The synthesis of disulfide-linked constructs was performed by Dr. Brian Sproat at Integrated DNA Technologies (Leuven, Belgium). Npys-activated C-terminal Cys containing TAT(48−60 − grkkrrqrrrpppqc) and penetratin (rqikiwfqnrrmkwkkc) peptides with N-terminal acetyl and C-terminal amide functions were obtained from American Peptide Company Inc. (Sunnyvale, USA) and conjugated to the 5′-end of the sense strand of sequence C (HS-$(CH_2)_6$-OP(O_2^-)-GGGAGGUGCCCGAACGAUAUidT) via disulfide exchange under denaturing conditions in the presence of urea. The two peptide−RNA conjugates were purified by preparative anion-exchange HPLC under denaturing conditions, desalted, and supplied as lyophilized sodium salts. The purity of the final products was determined by analytical anion-exchange HPLC and electrospray mass spectroscopy with deconvolution. For analytical HPLC, constructs were eluted through MonoQ 5/5 columns (Amersham Biosciences, Piscataway, NJ) with a linear gradient from 10% to 50% buffer B in buffer A + B during 30 min at a flow rate of 1 mL/min, with the effluent monitored by UV spectroscopy at 260 and 280 nm. For HS-$(CH_2)_6$-OP(O_2^-)-GGGAGGUGCCCGAACGAUAUidT, analytical HPLC buffer A consisted of 10 mM $LiClO_4$, 20 mM Tris−HCl, 50 μM EDTA, and 8 M urea, pH 7.4; and buffer B was as buffer A with a [$LiClO_4$] of 600 mM. For the penetratin and TAT(48−60) peptide−RNA conjugates, $LiClO_4$ was substituted with NaCl at 10 mM and 1 M for buffers A and B, respectively. For Chol-$(CH_2)_6$-S-S-$(CH_2)_6$-O-P(O_2^-)-O-GGGAGGUGCCCGAACGAUAUidT, a linear gradient of 10% to 100% buffer B in A + B over 40 min elution at 1 mL/min was used, with buffers prepared in 20% v/v acetonatrile, pH 7.4, in the absence of urea, and 10 mM or 1 M NaCl (buffers A and B, respectively). The cholesterol-conjugated sense strand RNA was synthesized directly in solid phase using the commercially available cholesterol phosphoramidite coupled to a $(CH_2)_6$-S-S-$(CH_2)_6$ linker at the 5′-end of the RNA. Mismatch studies in animals were performed with MM2-5′- H_2N-CO-CH_2-S-$(CH_2)_6$-OP(O_2)-GCGAGCUGCGCGAAGGAUAUidT-3′; antisense, 5′-UAUCCUUCGCGCAGCUCGCUidT-3′.

For annealing, 240 nmol of lyophilized siRNA−sense strand or sense strand conjugates were resuspended at 240 μM concentrations in sterile Dulbecco's phosphate buffered saline (PBS; Sigma, Poole, UK) and then mixed by pipetting with an equal volume of antisense strand (5′-UAUCGUUCGGGCACCUCCCUidT-3′) resuspended in PBS at equimolar concentrations, to give a final siRNA concentration of 1 nmol/μl. Annealing was performed by heating to 95 °C for 5 min on a Peltier element thermal cycler block followed by slow cooling over a period of 1 h.

siRNA Construct Analysis and Quality Control. Annealing products were examined upon a precast 20% polyacrylamide Tris borate ethylenedinitrilotetraacetic acid (EDTA) gel (Invitrogen, Carlsbad, CA), RNA visualized by SybrGold staining as recommended by the manufacturer (Invitrogen), and documented using a computer-controlled UVP GelDoc-It Imagining System (Fisher) fitted with an ethidium bromide filter. Image analysis was performed using the *UVP Labworks Image Acquisition and Analysis* software version 4.6.00.0 (Media Cybernetics, Inc., Atlanta, GA). LPS content in dosing preparations was determined using the PyroGene Recombinant Factor C Endotoxin Detection System according to the manufacturer's instructions (Cambrex Bio Science Wokingham Ltd, Wokingham, UK).

To assess siRNA and siRNA conjugate susceptibility to RNases in a simulated lung microenvironment, stability studies were carried out in murine bronchoalveolar lavage (BAL) fluid. This was collected from three terminally anaesthetized male BALB/c mice (20−25 g) following exposure of the lungs by

three repeat lavages of 0.3 mL of RPMI media (Invitrogen). All collected media was pooled and stored at −20 °C. To assess siRNA stability in BAL fluid, annealed siRNA and siRNA constructs were incubated in excess volumes of 95% v/v murine BAL fluid at 37 °C. 20 μL volumes were removed at set time points, gel loading buffer II (Invitrogen) was quickly added to a final 1× concentration, and the mixture was snap-frozen in liquid nitrogen. Samples were thawed on ice, and 10 pmol quantities were analyzed by polyacrylamide gel electrophoresis (PAGE).

***In Vitro* Cell Culture Studies.** L929 cells were grown to 70% confluence in DMEM (Sigma) supplemented with 10% fetal calf serum, 1% penicillin/strepavidin/glutamine, and 5 mM nonessential amino acids (Invitrogen). On the day of transfection, cells were trypsinised and resuspended at 2×10^5 in media. siRNA, siRNA−Lipofectamine 2000 (Invitrogen) complexes prepared to the manufacturer's instructions, or siRNA conjugates were diluted to 2× the final indicated concentration in OptiMEM (Invitrogen) and mixed with an equal volume of cell suspension to give a final serum concentration of 5% FCS. The cells were then plated into a 96-well plate in triplicate in a volume of 100 μL (1×10^4 cells/well) and incubated for 24 h at 37 °C before either RNA extraction or measurement of cell viability using the MTT assay (Sigma) was carried out.

***In Vivo* Procedures.** All *in vivo* procedures were carried out under local ethics approval and in strict accordance to the 1986 Animals (Scientific Procedures) Act. Groups of 6−18 male BALB/c mice (20−25 g) were sedated with 4% Halothane in O_2 and given the indicated dose of siRNA, mismatch, siRNA conjugates, TAT(48−60), penetratin, polyinosinic/polycytidylic acid (poly(I:C); Sigma), or LPS from *Escherichia coli* 0111: B4 (Sigma) in 20 μL volumes by intratracheal administration. Animals were sacrificed at the indicated time points using an overdose of pentobarbitone (200 mg/kg intraperitoneally).

RNA Extraction and Determination of p38 MAP Kinase mRNA Expression. Cell culture samples were extracted using the Qiagen RNeasy mini kits according to the manufacturer's instructions (Qiagen, Crawley, UK). Animal tissues were gently removed immediately after confirmation of death and stored in RNA*later* according to the manufacturers' instructions (Sigma). Total RNA was extracted by rotor/stator homogenization in Tri Reagent (Sigma) using an Ultraturrax T18 homogenizer (Fisher Scientific), followed by isopropanol precipitation of the aqueous phase and reconstitution in RNase-free water (Promega, Southampton, UK). Yield and purity were determined by spectrophotometric measurement of the absorbance at 260 nm and 280 nm.

For the determination of p38 MAP kinase mRNA expression, mouse-specific Taqman primers and probes were obtained from the "Assay on Demand" service provided by Applied Biosystems (assay no. Mm00442497_m1, Applied Biosystems, Applera Corp., Warrington, UK). Real-time PCR was performed using the one-step Quanti-Tect RT-PCR Kit (Qiagen) in a MicroAmp 96-well reaction plate (Applied Biosystems). Each well contained 25 ng total RNA, 300 nM of forward and reverse transcription primers, and 125 nM Taqman probe in a reaction volume of 25 μL. All sample and nontemplate control reactions were performed in the ABI Prism 7700 Sequence Detection System (Applied Biosystems) in triplicate. Comparative slopes of the relationship between log[RNA] and C_t (gradient = −3.3) for both the gene of interest and the endogenous control 18S (Applied Biosystems) indicated that the comparative C_t method ($\Delta\Delta C_t$) could be used for the relative quantification of gene expression. Data were analyzed on the *Prism* version 4.03 statistic analysis package (GraphPad Software, Inc., San Diego, CA) using nonparametric analysis of variance followed by Tukey post-tests where appropriate.

Measurement of Cytokine Protein Expression. Lungs were gently removed immediately after confirmation of death and snap-frozen in liquid nitrogen, then stored at −80 °C. Frozen lung was homogenized in ice-cold RIPA buffer (25 μg/mL aprotinin, 10 μg/mL leupeptin, 10 μg/mL pepstatin A, 5 mM dithithreitol, 0.5 mM phenylmethylsulphonyl fluoride, 2 mM sodium orthovanadate, 1.25 mM sodium fluoride, 1 mM sodium pyrophosphate; Sigma) at a ratio of 1 mL per 100 mg tissue, using an Ultraturrax T18 homogenizer. The homogenates were then spun in a refrigerated (4 °C) tabletop microcentrifuge at 21 000 *g* for 20 min. The supernatants were removed and stored at −20 °C. Total protein content was determined by Bradford Assay (Bio-Rad, Hertfordshire, UK) according to the manufacturer's instructions. Tissue tumor necrosis factor (TNF)-α, interleukin (IL)-12 p40 (DuoSet ELISA kits; R&D Systems Europe, Abingdon, UK), and interferon (IFN)-α (PBL laboratories, Piscataway, NJ) were measured by sandwich ELISA and normalized for total protein content.

Histology. The 5′-end Cy3-labeled antisense strand (Dharmacon) was annealed to the appropriate sense strand, and 10 nmol of the resulting Cy3-labeled siRNA, penetratin−siRNA, TAT−siRNA, or cholesterol−siRNA or equimolar amounts of Cy3 alone were given by intratracheal administration. Whole lungs were collected 3 h later and fixed in 4% formaldehyde−supplemented phosphate buffered saline (Sigma). After fixation, the samples were rinsed in 70% EtOH, dehydrated, and embedded in paraffin. Paraffin sections (3 μm, Leica microtome, Leica Microsystems, Milton Keynes, UK) were rehydrated, rinsed in Tris−buffered saline pH 7.6 (Sigma), and stained with the DNA-binding fluorochrome Hoechst 33342 (Sigma). After mounting in Aqua Perm mountant (484975 Life Sci. International), Cy3 (red channel) and Hoechst 33342 (green channel) were visualized on an epifluoresence microscope (Olympus BX10, Olympus Sveridge AB, Solna, Sweden) equipped with a high-resolution Olympus DP-50 digital camera (Olympus Sveridge AB) linked to a computerized image analysis system (Viewfinder Lite, v1, Pixera Co, and Image-Pro Plus v 4.5, Media Cybernetics). Cy3−siRNA positive cell phenotypes in the lung parenchyma alveolar macrophages were distinguished from structural alveolar cells by immunohistochemical visualization of the macrophage marker F4/80 (*36*). Briefly, after rehydration the slides were subjected to antigen retrieval through mild proteinase K digestion (Sigma). After blocking the nonspecific binding sites, sections were incubated with a monoclonal rat anti-murine F40/80 (dilution 1:50, clone CI: A3−1, Serotec Ltd, Oxford, UK) for 1 h. After repeated rinsing, the immunoreactivity was detected by an Alexa 448 conjugated goat anti-rat antibody (green channel).

RESULTS

TAT(48−60), Penetratin, and Cholesterol-Mediated siRNA Knockdown of p38 MAP Kinase mRNA in a Mouse Cell Line. Initial studies were focused upon the identification of an optimum siRNA sequence for p38 MAP kinase mRNA knockdown. To this end, the concentration-dependent knockdown achieved by three siRNAs was determined in the L929 mouse fibroblast cell line at 24 h (Supporting Information Figure S1) following reverse transfection with Lipofectamine 2000. Thus, an efficacious sequence (C) was selected that gave a maximal knockdown of 87% and an EC_{50} of 139 pM when transfected into the cells with lipofectamine (Figure 1). As a negative control, we identified a four mismatch siRNA sequence that gave no significant knockdown except at the highest concentration of 100 nM, where we observed a p38 MAP kinase mRNA reduction of ∼20% (Figure 1). To facilitate the conjugation of TAT(48−60), penetratin, or cholesterol upon siRNA, the 5′-end of the siRNA sense strand was modified with a C6-thiol

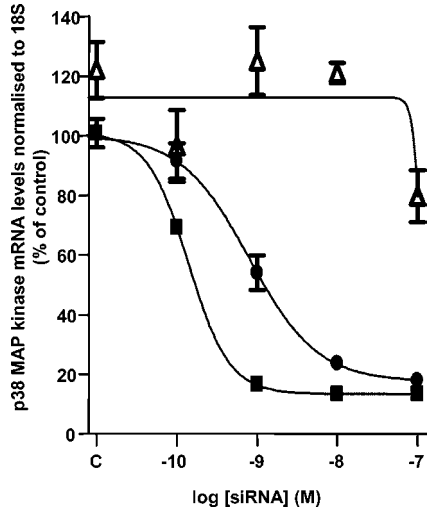

Figure 1. Addition of the C6 linker to a p38 MAP kinase siRNA causes a shift in EC_{50} without affecting maximal knockdown. L929 cells were reverse-transfected with the indicated concentrations of siRNA (square), C6 linker modified siRNA (circle), or mismatch control (open triangle) using Lipofectamine 2000; the RNA was extracted at 24 h; p38 MAP kinase mRNA levels were determined by TaqMan RT-PCR, normalized against 18S, and plotted as the percentile expression of lipofectamine-treated controls (means ± SEM of three independent experiments).

linker, providing a thiol group for disulfide conjugation with a cysteine residue on the CPP (Analytical HPLC and electrospray mass spectrograms available in Supporting Information Figure S2). C6-thiol linker-modified sense strands and CPP−sense strand conjugates were then annealed to the antisense strand to yield siRNA duplexes. To evaluate the impact of the conjugation of the C6-thiol linker group on the biological action of the siRNA, C6-thiol modified siRNA duplexes were transfected using lipofectamine 2000 in cultured L929 fibroblasts. Addition of the C6-thiol linker to the siRNA had no significant effect upon the magnitude of knockdown but caused a shift in the EC_{50} to 798 pM (Figure 1). Visual examination of CPP−siRNA constructs showed no precipitation, while separation on 20% polyacrylamide gels demonstrated the formation of discrete annealed products (Figure S2). In contrast, annealing of the cholesterol−siRNA gave a higher molecular weight product, suggesting the formation of higher-order structures.

The biological action of siRNAs conjugated to TAT(48−60), penetratin, or cholesterol was then examined *in vitro* following a 24 h incubation in the absence of any transfection reagent (i.e., Lipofectamine 2000). Figure 2 shows that equimolar concentrations of siRNA incubated in the absence of Lipofectamine 2000, TAT(48−60) peptide, or penetratin peptide had no effect upon p38 MAP kinase mRNA levels. In contrast, the TAT(48−60)−, penetratin−, and cholesterol−siRNA conjugates produced a small but significant knockdown of 36% ± 6%, 20% ± 3%, and 28% ± 7%, respectively, at 10 μM (Figure 2). Examination of all the constructs showed no significant cellular toxicity at 24 h (Supporting Information Figure S4).

siRNA-Mediated mRNA Knockdown of p38 MAP Kinase in Mouse Lung. Examination of the relative levels of p38 MAP kinase expression in mouse tissues indicated constitutive expression in the lung (Supporting Information Figure S5). To ascertain the capacity of siRNA to down-regulate p38 MAP kinase mRNA levels, increasing doses of the C6-thiol linker-modified siRNA were administered intratracheally, and the effect upon p38 MAP kinase mRNA expression was determined over a 24 h period. From Figure 3, it can be seen that all doses of the linker-modified siRNA (50 nmol, 10 nmol, or 1 nmol siRNA) produced a significant (∼30−45%) mRNA knockdown at 6 h. However, this effect appeared transient, and only animals dosed with 50 nmol showed significantly attenuated gene expression at 12 h (30 ± 5%) and 24 h (20 ± 6%). Administration of 10 nmol mismatch control produced no significant down-regulation of p38 MAP kinase expression over the 24 h period (Figure 4).

Effect of Conjugation to TAT(48−60), Penetratin and Cholesterol upon siRNA-Mediated mRNA Knockdown of p38 MAP Kinase in the Mouse Lung. We next investigated whether the duration and magnitude of p38 MAP kinase mRNA knockdown could be influenced by conjugation of the siRNA to TAT(48−60), penetratin, or cholesterol (Figure 4). TAT(48−60)−siRNA showed 20−30% knockdown at all time points, although this was only significant at 12 h. However, though this knockdown was comparable to that achieved by equimolar doses of unconjugated siRNA, administration of the TAT(48−60) peptide alone produced a comparable and statistically significant knockdown at all time points examined, suggesting the CPP as a modulator of p38 MAP kinase expression. Similarly, although the penetratin−siRNA conjugate appeared to show increased knockdown (47 ± 9%) at 6 h, the peptide alone also caused significant reduction (30 ± 7%) of p38 MAP kinase mRNA levels. In contrast, cholesterol-conjugated siRNA increased the duration but not the magnitude of the response: significant reduction of p38 MAP kinase mRNA expression was seen both at 6 h (28 ± 9%) and at 12

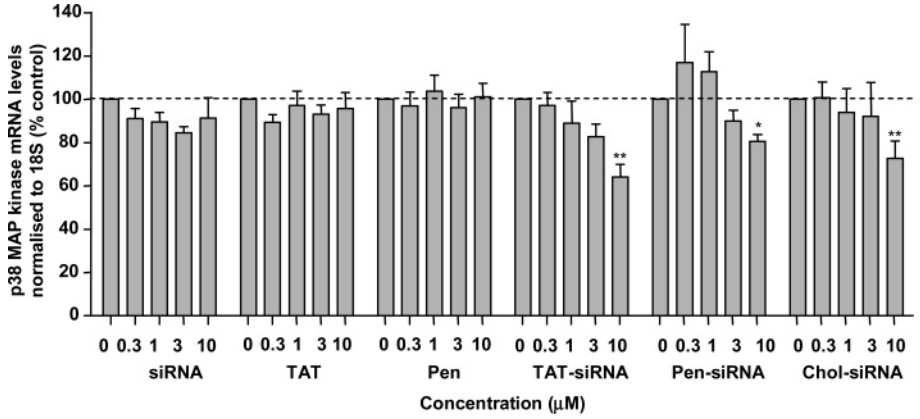

Figure 2. Conjugation of cell penetrating peptides or cholesterol facilitates siRNA-mediated p38 MAP kinase knockdown *in vitro* in the absence of transfection reagents. L929 cells were incubated for 24 h with the indicated concentrations of siRNA without Lipofectamine 2000, TAT(48−60) peptide (TAT), penetratin peptide (Pen), or siRNA conjugated to TAT(48−60), (TAT-siRNA), penetratin (Pen-siRNA) or cholesterol (Chol-siRNA) in the absence of transfection reagents; RNA was extracted; p38 MAP kinase mRNA levels were determined by Taqman RT-PCR, normalized to 18S, and plotted as the percentile expression of lipofectamine treated controls (means ± SEM of three independent experiments; *p* vs nontreated controls: * <0.05; ** <0.01).

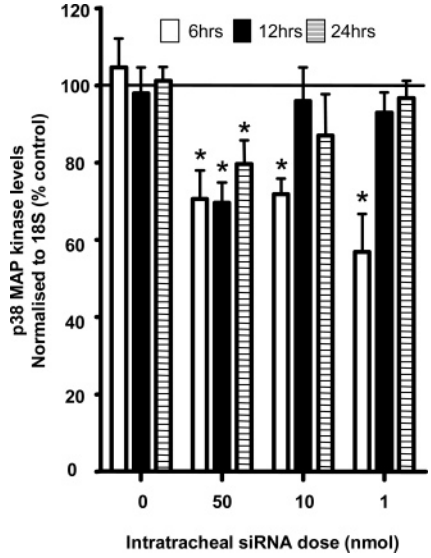

Figure 3. Intratracheal administration of a p38 MAP kinase siRNA in mice results in acute (6 h) but limited (<45%) mRNA knockdown in the whole lung, with the duration of knockdown dependent on the siRNA dose. Mice were dosed intratracheally under halothane anaesthesia with increasing amounts of siRNA in 20 μL PBS volumes; the lungs were removed at the indicated timepoints; RNA was extracted; p38 MAP kinase mRNA levels were determined by TaqMan RT-PCR normalized against 18S and plotted as the percentile expression of vehicle-treated (PBS) controls (values are means ± SEM of 6−18 animals; *p* vs time-matched PBS-treated controls: * <0.05).

h (42 ± 13%), at levels comparable to those achieved by the 50 nmol dose of unconjugated siRNA. Because of the highly lipophilic nature of cholesterol and the resultant low solubility in water, we were unable to determine if this was a direct result of the administration of cholesterol to the lung.

Histological Studies of siRNA and siRNA Conjugate Distribution. To determine the distribution of the siRNA and siRNA conjugates in the lung, the 5′-end of the antisense strand was labeled with the fluorochrome Cy3. At 3 h post-administration, histological analysis showed intense staining of macrophages within the parenchyma and sub-epithelial tissue of bronchi and bronchioles, which suggested that these might represent the principal target cell population (Figure 5). In addition, we observed intense and scattered staining of epithelial cells within the bronchi and bronchioles, which appeared to be an all-or-nothing response. Only rarely were positively stained alveolar epithelial cells detected. siRNA conjugation to penetratin or cholesterol did not influence the cellular labeling pattern (results not shown); however, conjugation to TAT(48−60) appeared to cause a small increase in the staining intensity and number of Cy3-positive cells, with some increase in nuclear staining (Figure 5). In contrast, dosing with equimolar amounts of Cy3 dissolved in PBS produced diffuse staining around the large bronchi and blood vessels (data not shown).

Examination of siRNA and siRNA Conjugate Stability *in Vivo.* To determine whether our observations might have been influenced by siRNA and siRNA conjugate stability, we examined the degradation profile following exposure to mouse BAL fluid. Although BAL fluid incubation resulted in the appearance of a single double-stranded cleavage product, full-length siRNA could still be detected at >7 h (Figure 6). Identical stability and cleavage patterns were seen with the TAT(48−60)−siRNA, penetratin−siRNA, and cholesterol−siRNA, implying that conjugation of such delivery moieties has no significant effect upon siRNA stability, nor were the higher-order structures observed in annealed chol-siRNA gels capable of improving siRNA stability (Supporting Information Figure S3). Importantly, as the shift in gel mobility appears to be entirely due to siRNA cleavage, both the TAT(48−60) and penetratin peptides and the conjugation chemistry are stable in BAL fluid over this time range. Examination of the breakdown product using MALDI-TOF mass spectral analysis showed that the AUidT was cleaved from the 3′-end of the sense strand while the U residue was cleaved from the 5′-end of the antisense strand, most probably by the action of an RNase A-like activity, to produce a blunt-ended siRNA (*37*).

Examination of the Effect of siRNA, CPP, and siRNA Conjugates upon the Innate Immune Response *in Vivo.* Previous reports have suggested that siRNAs are capable of stimulating the innate immune response through binding to Toll-like receptors (TLR)-3, -7, and -8 within the endosomes (*38*).

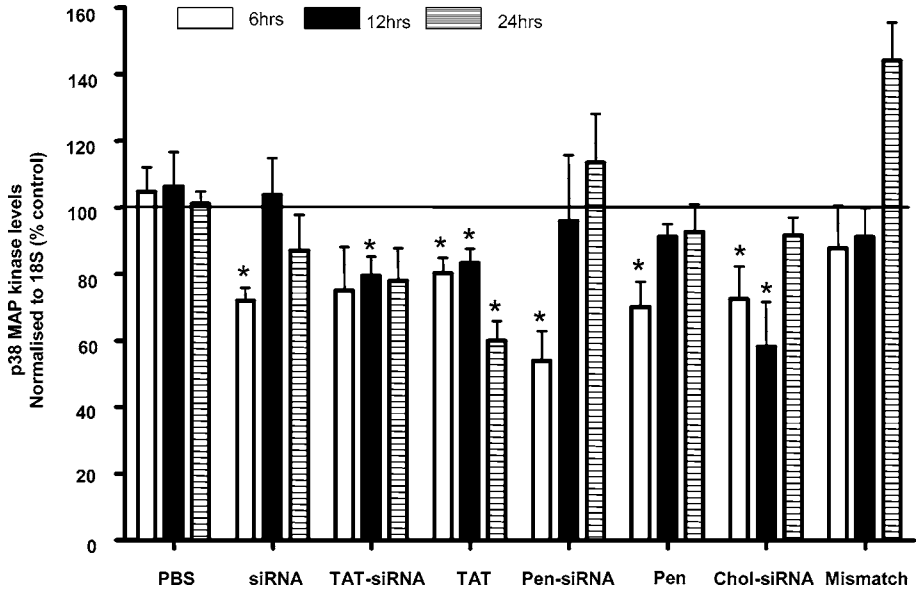

Figure 4. Intratracheal administration of a single 10 nmol dose of the cell penetrating peptides TAT(48−60) (TAT) or penetratin (Pen) causes p38 MAP kinase mRNA downregulation in the whole lung, without improving p38 MAP kinase siRNA (siRNA) knockdown efficiency when conjugated to the siRNA (TAT−siRNA and Pen−siRNA, respectively), whereas cholesterol conjugation extends the duration but not magnitude of knockdown achieved by the siRNA. Mice were dosed under halothane anaesthesia in 20 μL PBS volumes; the lungs were removed at the indicated timepoints; RNA was extracted; p38 MAP kinase mRNA levels were determined by TaqMan RT-PCR normalized against 18S and plotted as the percentile expression of vehicle-treated (PBS) controls (values are means ± SEM of 6−18 animals; *p* vs time-matched vehicle-treated controls: * <0.05).

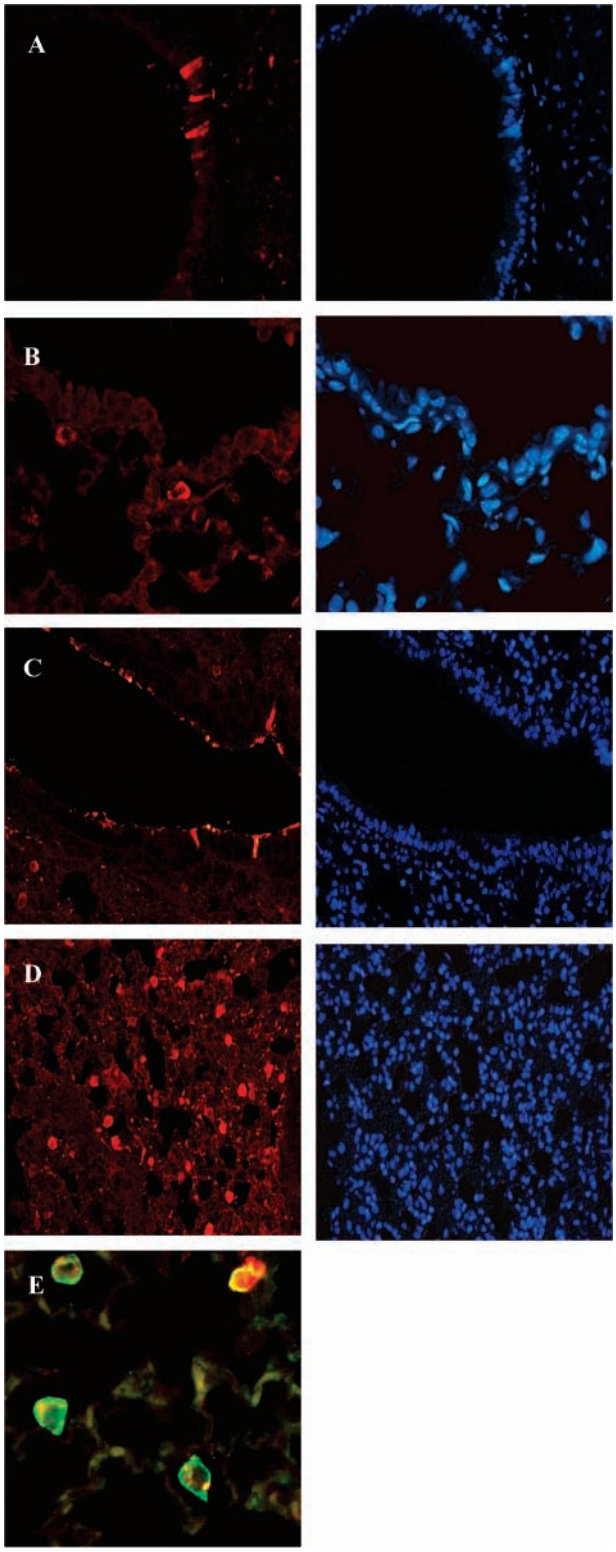

Figure 5. Histological analysis of the lung distribution of intratracheally dosed Cy3 (red) labeled siRNA (panels A, B, and E) and Cy3 labeled siRNA conjugated to the cell penetrating peptide TAT(48−6) (panels C and D) indicates scattered uptake in bronchial epithelial cells (panels A and C), as well as peribronchial (panel B) and parenchymal (panel D) macrophages, as confirmed by use of a macrophage specific marker, F4/80 (panel E), with TAT conjugation conferring limited increases in staining density and nuclear uptake. Mice were dosed with 10 nmol doses under halothane anaesthesia in 20 μL PBS volumes; the lungs were removed after 3 h, fixed, paraffin embedded, sectioned, and counterstained for DNA with Hoechst 33342 (blue) or the macrophage specific marker F4/80 by immunofluorescence (Alexa 448 − green; magnification: panels A, C, D, 5×; panel B, 20×; panel E, 40×).

To eliminate the possibility that the observed reductions in p38 MAP kinase mRNA expression might have resulted from the activation of this response, we measured the levels of the immune markers IFN-α, TNF-α, and IL-12 p40 in whole lung. As expected, the positive controls lipopolysaccharide (LPS) and poly(I:C), known activators of the immune response through of TLR4 and TLR3, respectively, induced a robust increase in IFNα production at 6 h while LPS increased TNFα at 1 h (Figure 7). Interestingly, with the exception of penetratin−siRNA, none of the experimental agents induced an immune response following intratracheal administration; in the case of penetratin−siRNA, we observed a significant increase in the expression of TNF-α and IL-12p40, as well as elevated release of IFN-α (Figure 7). As a control for contaminating LPS in the dosing preparations, potentially influencing p38 MAP kinase expression, or inducing immune activation, measurement of LPS content was included in our siRNA quality control process. Crucially, LPS levels were <0.01 EU among all preparations, significantly below the concentration believed to activate TLR-4-mediated responses (*14*).

DISCUSSION

In this paper, we have investigated the utility of the cell-penetrating peptides TAT(48−60) and penetratin and the lipidic carrier cholesterol in improving siRNA-mediated knockdown of endogenous mRNA expression in the mouse lung. The chosen target was p38 MAP kinase, a key component of inflammatory signal transduction pathways whose inhibition can ameliorate inflammatory responses (*17*, *18*), constitutively expressed in a variety of lung-associated cell types including epithelial, endothelial, macrophage, eosinophil, fibroblast, and smooth muscle cell types. The quantities of siRNA employed in our investigation, which were approximately 37.5 mg/kg (50 nmol), 7.5 mg/kg (10 nmol), and 0.75 mg/kg (1 nmol), are comparable to those reported as efficacious in lung. Thus, a 2 mg/kg siRNA dose was employed to attenuate heme oxygenase 1 (HO-1) expression (*8*) and a 5 mg/kg dose was found to reduce RSV and PIV titer in the lung (*12*). Following intratracheal administration, sequence-specific siRNA-mediated p38 MAP kinase mRNA knockdown was observed as early as 6 h, implying rapid uptake and action of naked siRNA upon the target gene mRNA levels. However, the short duration of knockdown observed with 1 nmol and 10 nmol doses, quickly reversed within 12 h, suggested that naked siRNA might be rapidly degraded and that its action might be extended through chemical stabilization. Indeed, BAL fluid stability studies showed that, even though full-length siRNA could still be recovered at 7 h, cleavage did indeed occur, detectable as early as 15 min.

An alternative hypothesis might be the existence of feedback mechanisms that maintain the mRNA level of the constitutively expressed p38 MAP kinase through increased transcription. Failure to detect this *in vitro* could be ascribable to the cell line used; however, our *in vitro* studies allowed the identification of a potent and selective siRNA sequence. Insofar as the utility of siRNA in the regulation of gene expression in the lung has been pursued, to our knowledge we are the first to report an attempt to manipulate an endogenous, constitutively expressed gene. Indeed, little is known about the biochemistry of p38 MAP kinase mRNA level homeostasis, as research has focused on phosphorylation of the protein, a key part of the inflammatory signal transduction process (*17*, *18*). In this respect, we have observed no significant change in p38 MAP kinase mRNA expression in the mouse lung 4 h after a 30 min challenge with 0.1 mg/mL aerosolized LPS (0.88 ± 0.29-fold p38 MAP kinase relative mRNA levels to saline-challenged controls (Moschos, unpublished data). Therefore, MAPK14 mRNA levels are either not affected by cellular stress signals such as LPS-induced

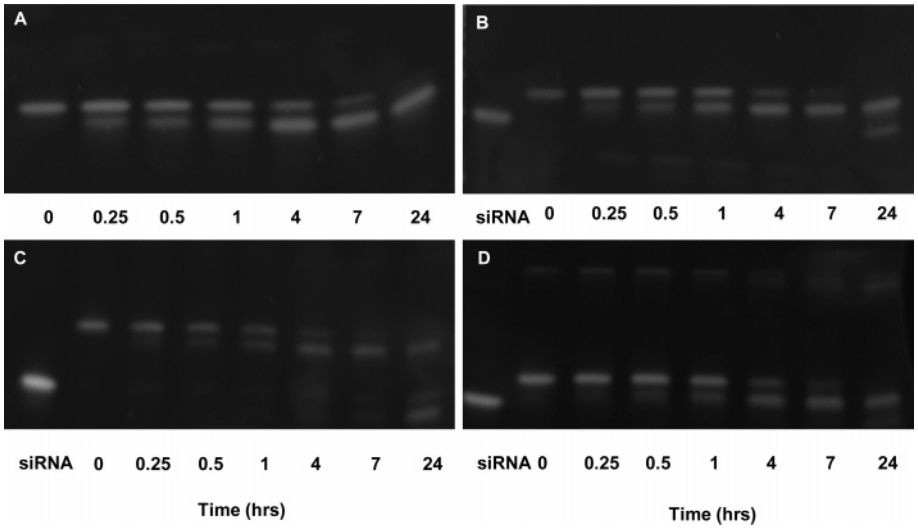

Figure 6. Stability of p38 MAP kinase siRNA (A) and siRNA conjugated to the cell penetrating peptides TAT(48−60) (B) and penetratin (C), as well as cholesterol (D) in mouse lung bronchoalveolar lavage fluid. siRNA and constructs were incubated in 95% v/v mouse lung BAL fluid at 37 °C for the indicated times, and 10 pmol quantities were analyzed by 20% TBE PAGE using the SybrGold stain.

inflammation or are closely monitored and strictly maintained at specific levels. Our findings of an apparent limit on the maximal mRNA knockdown achievable *in vivo* lends further weight to this hypothesis; we were unable to overcome this threshold, since increasing the siRNA dose to 50 nmol improved the duration but not the magnitude of the response. Notwithstanding homeostasis, additional contributors to the limited knockdown could be uneven lung distribution, localization in the immediate epithelial cell layer, or poor cellular uptake. We therefore examined the distribution of Cy3-labeled siRNA by histology and showed uptake into macrophages and scattered airway epithelial cells. However, the total tissue mRNA down-regulation by about 30−45% was comparable to that seen in the liver following intravenous administration of cholesterol-linked *and* stabilized siRNA (*20*).

To improve upon the duration and magnitude of p38 MAP kinase mRNA knockdown, we examined the effect of chemical conjugation of siRNA to a number of nonviral molecular delivery vectors, including cholesterol and the cell-penetrating peptides TAT(48−60) and penetratin. Since a free hydroxyl group at the 5′-end of the antisense strand is thought to be crucial to the mechanism of RNA interference (*39, 40*), these delivery moieties were conjugated to the 5′-end of the sense strand via a C6-thiol linker. To dissociate the sense strand from the delivery vector in the cytosol, we included a disulfide bond within our conjugation chemistry, believed to be cleaved intracellularly. Examination of the biological action of this modified siRNA *in vitro* showed that conjugation of the C6-thiol linker increased the EC_{50} but did not affect the maximal level of mRNA knockdown (∼85%). This magnitude of efficacy in cell culture is similar to that reported for other siRNAs that have been successfully used *in vivo* (*41*), thus ratifying our choice of conjugation chemistry.

Unlike the mouse studies, examination of the p38 MAP kinase knockdown in cells showed no effect of naked siRNA at concentrations up to 10 μM. In contrast, the cholesterol, penetratin, and TAT(48−60) constructs produced a small (20−40%) but significant mRNA knockdown without inducing toxicity. Importantly, this was determined to be siRNA-specific, as no effect was observed by equimolar quantities of the two unconjugated CPP. However, the uptake mechanism appears highly inefficient, since these concentrations were >100 000× higher than those effective with Lipofectamine 2000. Surprisingly, previous cell-based studies using siRNA conjugated to cholesterol, penetratin, or TAT(48−60) (*35*) gave values reportedly in the sub-micromolar range. The reason for these differences is presently unknown, although they could be related to the gene target, cell type, and/or the type of synthetic construct. The majority of investigators have, like ourselves, attached the delivery vector to the 5′-end of the sense strand *via* a disulfide bond (*19, 32−34*), although Chiu et al. (*35*) attached TAT(48−60) to the 3′-end of the antisense strand, and in the report by Soutschek et al. (*20*), the cholesterol moiety was conjugated to the 3′-end of the sense strand via a pyrrolidone linker. Crucially, unlike ourselves, many investigators do not report post-conjugation HPLC purification in the presence of denaturing agents to remove excess, unconjugated cationic CPP from CPP−siRNA conjugates. As with electrostatically based delivery systems such as cationic lipids and polymers, omission of this purification step is likely to result in the formation of complexes between excess CPP and CPP−siRNA conjugates that might increase the efficacy of uptake (*42*).

Despite the low potency of our conjugates in culture, we proceeded to *in vivo* investigations, since we were administrating solutions of 500 μM (20 μL of 10 nmol), concentrations 50× greater than those effective *in vitro*. Significantly, these studies failed to show an effect of conjugation to the cell-penetrating peptides TAT(48−60) or penetratin upon lung distribution, magnitude, or duration of p38 MAP kinase mRNA knockdown. Strikingly, penetratin peptide alone induced a significant down-regulation in p38 MAP kinase mRNA expression at 6 h and, in the case of TAT(48−60), this was also observed at 12 and 24 h. These data therefore document a biological action of these peptides upon gene expression, or associated regulatory processes. The mechanism underlying this response is not currently known, nor is the extent or consequence of the gene modulation enacted by CPP *in vivo*. The lack of adverse reactions or behavior at 24 h following peptide administration implies that this does not involve lung toxicity in the form of necrosis or apoptosis. Indeed, in associated studies in our laboratory using the lung epithelial cell line A549 exposed to TAT(48−60) and penetratin, we have been unable to detect toxicity at concentrations up to 30 μM (*43*). Alternatively, down-regulation of p38 MAP kinase mRNA expression might occur following the interaction of CPP with extracellular or intracellular targets. Indeed, extracellular CPP−protein interactions are likely as Fotin-Mleczek *et al.* (*44*) have shown that both TAT(48−60) and penetratin induce clathrin-dependent uptake of the TNF-α and EGF receptors without their activation, though the exact

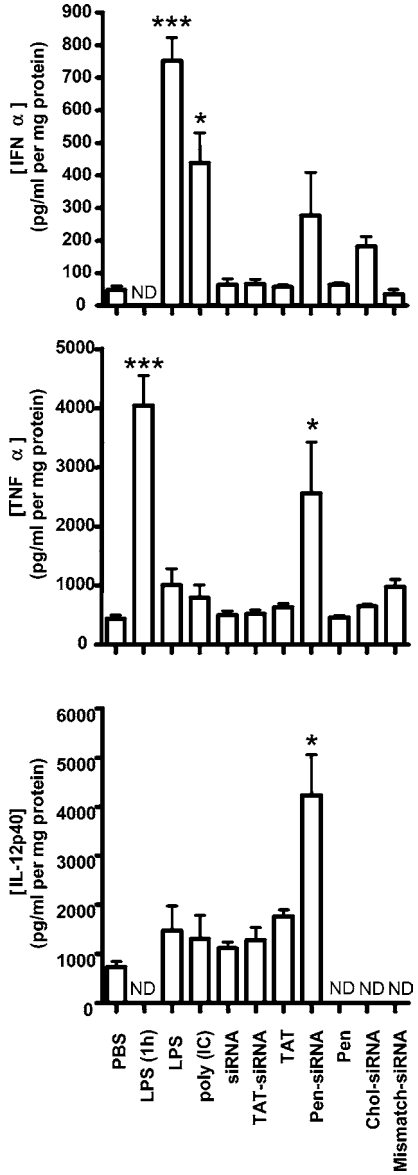

Figure 7. Intratracheal administration of a single 10 nmol dose of the cell penetrating peptides TAT(48−60) (TAT) or penetratin (Pen), a p38 MAP kinase siRNA (siRNA), or conjugates of this siRNA to TAT-(48−60) (TAT-siRNA) or cholesterol (Chol-siRNA) but not a penetratin−siRNA conjugate (pen-siRNA), do not elicit inflammatory cytokine release in murine lung tissue. Mice were dosed under halothane anaesthesia in 20 μL PBS volumes; the lungs were removed at 6 h, protein extracted; interferon α (IFN-α), tumor necrosis factor α (TNF-α), and interleukin 12 p40 (IL-12 p40) content was determined by sandwich ELISA and expressed as pg/mL per mg total protein (p vs PBS-treated controls: * <0.05; *** <0.001; ND = not determined due to lack of sample).

mechanism is unknown. Also, given the fact that CPP are derived from the DNA binding domains of transcription factors and are highly positively charged, it might be envisaged that, once taken up into cells at high concentrations, these peptides directly interfere with gene transcription. Interestingly, the high-affinity binding of CPP to both plasma membranes and genomic DNA has previously been shown to result in erroneous conclusions about the mechanism of CPP uptake (*45*, *46*). Interpretation of our findings as an indication of global gene expression perturbation by CPP is restricted by the lack of effect of CPP on the expression of MAPK14 *in vitro* even at concentrations as high as 10 μM. In terms of a direct effect of CPPs in the regulation of MAPK14 gene expression, lack of specific effects on the MAPK14 locus by means of CPP−DNA interactions can be postulated only under the assumption that no significant sequence differences exist between the genome of the BALB/c mice used in our *in vivo* experiments and that of the L929 cell line (derived from C3H/An mice). Instead, a more likely scenario would favor CPP targeting the signal transduction pathways or transcriptional regulators of MAPK14 gene expression. Alternatively, the viral origin of some CPP coupled to the internalization of cytokine receptors might be expected to activate the antiviral innate response, resulting in inhibition of transcription. However, such a mechanism would appear unlikely, as associated pro-inflammatory marker release *in vivo* was not detected.

Investigation of the immunological response *in vivo* showed that penetratin−siRNA but not TAT(48−60) or cholesterol conjugate administration induced an innate immune response, possibly through activation of TLR-3, -7, and/or -8 (*38*). Liposomal delivery of siRNA containing immunostimulatory sequences has been shown to be necessary for activation of these Toll-like receptors, underscoring the importance of the uptake mechanism in TLR-mediated immune activation by siRNA. Significantly, none of the currently known immunostimulatory siRNA motifs are found in the siRNA sequence we administered *in vivo*, nor did siRNA, TAT, or penetratin alone induce an innate immune response. Thus, our data suggest that either penetratin-mediated siRNA delivery is accomplished in a different manner from that of the TAT and cholesterol conjugates or the individual conjugates are subject to different biochemical fates once in the cytosol.

In contrast to the CPP, although cholesterol conjugation failed to increase the magnitude of p38 MAP kinase knockdown, it extended the duration of mRNA knockdown. However, although gel electrophoresis indicated the formation of higher molecular weight complexes in cholesterol siRNA conjugates, this did not improve upon siRNA stability in BAL fluid, nor was it found to improve upon lung distribution according to our histological investigations.

Overall, these studies have demonstrated siRNA-mediated knockdown of the endogenous, constitutively expressed gene, p38 MAP kinase, in the mouse lung. Although cholesterol increased the duration of the knockdown, the fact that the magnitude of the responses was unaffected following conjugation to cholesterol, TAT(48−60), or penetratin suggests that either these CPP are unable to increase cellular delivery and distribution or , under these circumstances, maximal responses can be achieved with naked siRNA alone. However, since both TAT and penetratin alone induced changes in gene expression, we believe that, despite the widespread success of CPP for the delivery of biologically active peptides and proteins *in vivo* (*26*, *27*), these results highlight a need to continue to elucidate the mechanisms of CPP bioactivity in order to determine their application in the delivery of biopharmaceuticals. This contention is further supported by our findings that penetratin−siRNA but not TAT(48−60)−siRNA conjugates caused activation of the innate immune response, which implies that these have different intracellular fates.

Comparative *in Vitro* and *in Vivo* Studies on Long-Wavelength Photosensitizers Derived from Bacteriopurpurinimide and Bacteriochlorin p_6: Fused Imide Ring Enhances the *in Vivo* PDT Efficacy

Yihui Chen,[†] William R. Potter,[†] Joseph R. Missert,[†] Janet Morgan,[‡] and Ravindra K. Pandey*,[†]

Medicinal Chemistry Division, PDT Center, and Department of Dermatology, Roswell Park Cancer Institute, Buffalo, New York 14263. Received March 15, 2007; Revised Manuscript Received June 22, 2007

In situ conversion of bacteriochlorophyll-a, present in *Rhodobacter sphaeroides* (*Rb. sphaeroides*) gave bacteriopurpurin-18 in modest yield, which in a sequence of reactions was converted into two series of bacteriochlorins: bacteriopurpurinimide and bacteriopurpurin p_6 with and without a fused imide ring system, respectively. To determine the effect of overall lipophilicity in photosensitizing efficacy, these bacteriochlorins were independently reacted with HBr gas and subsequently treated with various alkyl alcohols to afford the corresponding alkyl ether derivatives as diastereomeric mixtures (the R- and S-isomers were obtained in almost equal ratios). Between the two series of bacteriochlorins, the bacteriopurpurinimides containing a fused imide ring system were found to be more effective *in vivo* (C_3H mice bearing RIF tumors). To investigate the effect of the presence of the chiral center at position 3 of the most effective purpurinimide **9** [3(1′-heptyloxy)ethyl-3-deacetyl-bacteriopurpurin-18-*N*-hexylimide propyl ester], the acetyl group was replaced with a hydroxymethyl substituent and converted into 3(1′-decyloxy)methyl-3-deacetyl-purpurin-18-*N*-hexylimide methyl ester **26** with a similar lipophilicity. Interestingly, compared to **26**, the bacteriopurpurinimide **9** was found to be more effective, suggesting that the chiral center at position 3 certainly plays an important role in photosensitizing activity. Among a series of alkyl ether analogues, between the PDT efficacy and the lipophilicity (log *P* and log *D*) calculated by computational methods (*PALLAS* program), a parabolic relationship was observed to some extent. However, it was limited to a particular series, e.g., compounds with similar log *P* values between bacteriopurpurinimides and bacteriochlorin e_6 did not produce similar *in vivo* efficacy. As expected, within a series, a linear relationship was observed between the log *P* values and the HPLC retention times of the photosensitizers. Some of the mitochondrial localized photosensitizers showed a significant peripheral benzodiazepine binding (PBR) affinity. However, limited correlation between PBR binding affinity and *in vivo* PDT efficacy was observed. Compared to the naturally occurring bacteriochlorophyll-a, the bacteriopurpurinimides with fused imide ring system showed higher *in vitro/in vivo* stability. In contrast to methyl pyropheophorbide-a, the ester functionalities in bacteriopurpurinimide did not convert into the corresponding carboxylic acid by the enzyme esterases.

INTRODUCTION

Photodynamic therapy (PDT) is a relatively new modality for the treatment of various forms of cancer (*1*−*16*). PDT requires three elements: a photosensitizer, light, and oxygen. Following the absorption of light (*17*), the photosensitizer is transformed from its ground singlet state (S_0) into an electronically excited triplet state (T_1, $\sim 10^{-2}$ s) via a short-lived excited singlet state (S_1, $\sim 10^{-6}$ s). The photosensitizer at the excited triplet state can undergo a photochemical process (a type II reaction), which results in the conversion of stable triplet oxygen ($^3O_2$) to the short-lived but highly reactive singlet oxygen ($^1O_2$), the putative cytotoxic agent. In water, the lifetime of $^1O_2$ is approximately 1−3 μs, whereas in most organic solvents, the lifetime is 4−50 times longer. However, the lifetime of $^1O_2$ is considerably shorter in cellular systems, ranging from 100 ns in the lipid regions of membranes to 250 ns in the cytoplasm. Therefore, the diffusion range of $^1O_2$ is predicted to be limited to approximately 45 nm in cellular media. Because the diameter of human cells ranges from approximately 10 to 100 μm, they cannot diffuse more than a single cell length. Thus, the site of the primary generation of $^1O_2$ determines which subcellular structures may be accessed and attacked (*1*). Therefore, the tissue-penetration distance of light is a very important consideration for PDT when targeting tissues far from the light source. It is well-established that both the absorption and scattering of light by tissue increases as the wavelength decreases (*1*). Heme protein in tissue accounts for most of the absorption of light in the visible region. Light penetration drops off rapidly below 550 nm. However, it doubles from 550 to 630 nm and doubles again up to 700 nm, and then tissue penetration increases a further 10% as the wavelength moves toward 800 nm. Light wavelengths of 700−800 nm light therefore provide the optimum tissue penetration depth together with sufficient energy for singlet oxygen formation. To take advantage of this to treat more deeply seated tumors, it becomes necessary to develop photosensitizers exhibiting long-wavelength absorptions in this range.

The porphyrins and related tetrapyrrolic systems are among the most widely studied of all macrocyclic compounds (*17*). Porphyrins are 22π-electron aromatic macrocycles that exhibit characteristic optical spectra with a strong $\pi-\pi^*$ transition around 400 nm (Soret band) and usually four Q bands in the visible region. In the porphyrin system, two of the peripheral double bonds in opposite pyrrolic rings are cross-conjugated and are not required to maintain aromaticity. Thus, reduction

of one or both of these cross-conjugated double bonds (to give chlorins and bacteriochlorins, respectively) maintains much of the aromaticity, but the change in symmetry results in bathochromically shifted Q bands with higher extinction coefficients. Most bacteriochlorins exhibit long-wavelength absorptions between 740 and 800 nm, so they could be potentially useful for deeply seated tumors.

During the past decade, several naturally occurring bacteriochlorins have been evaluated for *in vitro* and *in vivo* efficacy. Some of them have shown significant *in vivo* photosensitizing efficacy. Unfortunately, these compounds were found to be quite unstable under PDT protocols and decomposed into the corresponding chlorins or porphyrin systems.

Therefore, the synthesis of stable bacteriochlorins with appropriate photochemical properties has been an important goal to obtain long-wavelength photosensitizers for PDT. In our previous studies with several chlorins, we observed that the five-member isocyclic ring (λ_{max} 660 nm) in methyl pheophorbide-a could be converted into the related chlorins bearing either a fused six-member anhydride or imide ring systems and named purpurin-18 and purpurinimide, respectively. The presence of such fused ring systems extended their long-wavelength absorptions from 660 to 700 nm (*18*). In spite of their high stability *in vitro*, results obtained from *in vivo* reflectance spectroscopy indicated that compounds containing the six-member imide ring system were more stable *in vivo* than the photosensitizers with anhydride and isoimide ring systems (*19*). Among these alkyl ether analogues, the purpurinimides were found to be quite effective for photodynamic therapy. Due to a close structural relationship between the purpurinimide and bacteriopurpurinimide moieties, our objective was to translate those parameters which were most efficacious in the purpurinimides to the bacteriopurpurinimide systems and compare their photosensitizing efficacy. To investigate the impact of the fused imide ring system, a series of open-chain bacteriochlorins (bacteriochlorin p_6) with variable lipophilicity were also prepared. The bacteriochlorins evaluated in our present study were derived from bacteriopurpurin-18, which in turn was isolated from *Rb. sphaeroides* by following the methodology developed in our laboratory.

EXPERIMENTAL PROCEDURES

Chemistry. ^{1}H NMR spectra were recorded in $CDCl_3$ solutions at 400 MHz on a Bruker instrument. Chemical shifts are reported in ppm with $CDCl_3$ as internal standard (for ^{1}H, 7.26 ppm). Mass spectral analysis was performed in the Biopolymer Facility, Roswell Park Cancer Institute, Buffalo, and Michigan State University, East Lansing, Michigan. UV−vis spectra were recorded on a Varian (Cary-50 Bio) spectrophotometer. Column chromatographic separations were performed over silica gel 60 (70−230 mesh) or neutral alumina (Brockmann grade III, ∼150 mesh). Preparative TLC was performed on silica 20 × 20 cm^2 TLC plates (Analtech). *Rb. sphaeroides* was purchased from Porphyrin Products (Frontier Scientific Inc., Logan, Utah).

3-Acetylbacteriopurpurin-18 Propyl Ester (1). 350 mL (∼440 g) *Rb. sphaeroides* (purchased from Frontier Scientific Inc., Logan, UT) was dissolved in 800 mL 1-propanol. It was filtered, and 20 g KOH was added to the filtrate. The reaction mixture was stirred at room temperature for 1 h under a stream of air bubbled through the solution. It was then extracted with CH_2Cl_2/THF after adjusting the pH to 2−3. The organic layer was dried over sodium sulfate. Evaporation of the solvent gave a purple residue, which was dissolved in THF, and the solvent was evaporated. This process was repeated several times until there was no absorption at 756 nm and a strong peak appeared at 813 nm. The residue was chromatographed on a silica column eluting first with *n*-hexane, then with 1% v/v acetone/CH_2Cl_2, and finally with 2% v/v acetone/CH_2Cl_2. The appropriate eluates were combined and the solvent was evaporated and precipitated as purple−red crystals from CH_2Cl_2/*n*-hexane. Yield: 200 mg. Mp: 245 °C. UV−vis λ_{max} (nm, CH_2Cl_2): 364 (ϵ 8.91 × 10^4), 412 (ϵ 5.36 × 10^4), 545 (ϵ 3.4 × 10^4), 815 (ϵ 5.53 × 10^4). ^{1}H NMR (400 MHz, $CDCl_3$, δ ppm): 9.21 (s, 1H, 5-H), 8.78 (s, 1H, 10-H), 8.62 (s, 1H, 20-H), 5.18−5.12 (m, 1H, 17-H), 4.39−4.26 (m, 2H, 1H for 7-H, 1H for 18-H), 4.14−4.06 (m, 1H, 8-H), 3.99−3.91 (m, 2H, COOC*H*$_2$CH$_2$CH$_3$), 3.63 (s, 3H, 12-CH$_3$), 3.54 (s, 3H, 2-CH$_3$), 3.15 (s, 3H, CH$_3$C), 2.76−2.67 (m, 1H, -C*H*HCH$_2$COOC$_3$H$_7$), 2.50−2.40 (m, 2H, 8-C*H*$_2$CH$_3$), 2.40−2.31 (m, 1H, -CH*H*CH$_2$COOC$_3$H$_7$), 2.13−1.95 (m, 2H, -CH$_2$C*H*$_2$COOC$_3$H$_7$), 1.80 (d, J = 7.17 Hz, 3H, 7-CH$_3$), 1.70 (d, J = 6.82 Hz, 3H, 18-CH$_3$),1.65−1.50 (m, 2H, COOCH$_2$C*H*$_2$-CH$_3$), 1.1 (t, J = 6.46 Hz, 3H, 8-CH$_2$C*H*$_3$), 0.85(t, J = 7.30H$_z$, 3H, -COOCH$_2$CH$_2$C*H*$_3$), −0.30 (s, 1H, NH), −0.65 (s, 1H, NH). Anal. Calcd for $C_{36}H_{40}N_4O_6$: C, 69.21; H, 6.45; N, 8.97. Found: C, 69.54; H, 6.74; N, 8.67. Mass Calcd for $C_{36}H_{40}O_6N_4$: 624.3. Found: 625.6 (M + 1). HRMS, Calcd: 624.2948. Found: 624.2916.

Note: The purple residue obtained after adjusting the pH to 2−3 mainly contained the 3-acetylbacteriopurpurin-18 carboxylic acid and the corresponding propyl ester, which on refluxing with THF for 1 h hydrolyzed the ester functionality and the 3-acetylbacteriopurpurin-18 carboxylic acid was obtained as a major product.

3-Acetylbacteriopurpurin-18-*N*-hexylimide Propyl Ester (4). 3-Acetylbacteriopurpurin-18 propyl ester **1** (180 mg) dissolved in CH_2Cl_2 (20 mL) was treated with a large excess of hexylamine (0.5 mL) at room temperature for 24 h. The disappearance of the 813 nm band and the appearance of a new 753 nm absorption indicated the formation of the intermediate amide system. The solvent and the excess amine were then evaporated under high vacuum (<25 °C) to give a residue, which was dissolved in CH_2Cl_2 and treated with diazomethane to convert the carboxylic acid to the corresponding methyl ester (about 45 min); a catalytic amount of methanolic KOH was added and the mixture was stirred for 1−2 min. The disappearance of the absorption band at 753 nm and appearance of a new peak 822 nm indicated the completion of the reaction. Following the standard workup, the residue was chromatographed over a silica column eluting with acetone/CH_2Cl_2 (2% v/v). The appropriate fractions were combined. The residue obtained after removing the solvents was crystallized from CH_2Cl_2/*n*-hexane as purple−red crystals in 58.5% yield (120 mg). Mp: 200 °C. UV−vis λ_{max} (nm, CH_2Cl_2): 364 nm (ϵ 6.06 × 10^4), 413 (ϵ 3.64 × 10^4), 545 (ϵ 2.57 × 10^4), 822 (ϵ 4.85 × 10^4). ^{1}H NMR (400 MHz, $CDCl_3$, δ ppm): 9.23 (s, 1H, 5-H), 8.80 (s, 1H, 10-H), 8.62 (s, 1H, 20-H), 5.35−5.29 (m, 1H, 17-H), 4.43 (t, J = 6.03 Hz, 2H, -NC*H*$_2$(CH$_2$)$_4$CH$_3$), 4.33−4.27 (m, 2H, 1H for 7-H, 1H for 18-H), 4.13−4.07 (m, 1H, 8-H), 3.93−3.87 (m, 2H, COOC*H*$_2$CH$_2$CH$_3$), 3.71 (s, 3H,12-CH$_3$), 3.54 (s, 3H, 2-CH$_3$), 3.16 (s, 3H, CH$_3$C), 2.68−2.62 (m, 1H, -C*H*HCH$_2$COOC$_3$H$_7$), 2.39−2.33 (m, 3H, 1H for -CH*H*CH$_2$-COOC$_3$H$_7$, 2H for 8-C*H*$_2$CH$_3$), 2.00−1.94 (m, 2H, -NCH$_2$C*H*$_2$-(CH$_2$)$_3$CH$_3$), 1.82 (d, J = 6.90 Hz, 3H, 7-CH$_3$), 1.74 (d, J = 6.91 Hz, 3H, 18-CH$_3$), 1.63−1.57 (m, 2H, -CH$_2$C*H*$_2$COOC$_3$H$_7$), 1.53−1.47 (m, 2H, -COOCH$_2$C*H*$_2$CH$_3$), 1.45−1.37 (m, 4H, -NCH$_2$CH$_2$C*H*$_2$ C*H*$_2$CH$_2$CH$_3$), 1.33−1.26 (m, 2H, -(CH$_2$)$_4$C*H*$_2$-CH$_3$), 1.10 (t, J = 6.89 Hz, 3H, 8-CH$_2$C*H*$_3$), 0.95 (t, J = 7.60 Hz, 3H, N(CH$_2$)$_5$C*H*$_3$), 0.85 (t, J = 7.30H$_z$, 3H, -COOCH$_2$-CH$_2$C*H*$_3$), −0.5 (s, 1H, NH), −0.72 (s, 1H, NH). Mass Calcd for $C_{42}H_{53}O_5N_5$: 707.4. Found 707.9 (M + 1). HRMS, Calcd: 707.4046. Found: 707.4051.

3-(1-Hydroxy)ethyl-3-deacetylbacteriopurpurin-18-N-hexylimide Propyl Ester (5). Bacteriochlorin **4** 200 mg (0.283

mmol) was dissolved in 5 mL CH_2Cl_2. Sodium borohydride (500 mg) and 1 mL methanol were added to the reaction mixture. The reaction was monitored by TLC and UV−vis spectrophotometry. The disappearance of the 822 nm band and the appearance of a new band at 787 nm indicated the completion of the reaction (reaction time: 20 min). Following the standard workup, the residue was chromatographed on a silica column eluting with acetone/CH_2Cl_2 (2% v/v), and the title compound was obtained after crystallizing from CH_2Cl_2/*n*-hexane as purple−red crystals in almost quantitative yield. Mp: >300 °C. UV−vis λ_{max} (nm, CH_2Cl_2): 367 (ϵ 1.11 × 10^5), 417 (ϵ 5.82 × 10^4), 536 (ϵ 4.02 × 10^4), 787 (ϵ 4.73 × 10^4). ^{1}H NMR (400 MHz, $CDCl_3$, δ (ppm): 8.81 and 8.79 (two singlets, 5-H), 8.62 (s, 1H, 10-H), 8.33 (s, 1H, 20-H), 6.23−6.17 (m, 1H, 3-CH_3C*H*(OH)-), 5.28−5.23 (m, 1H, 17-H), 4.43−4.37 (m, 2H, -NC*H*$_2$(CH_2)$_4$$CH_3$), 4.23−4.15 (m, 2H, 1H for 7-H, 1H for 18-H), 4.05−3.99 (1H, m, 8-H), 3.96−3.90 (m, 2H, -COOC*H*$_2$-CH_2CH_3), 3.65−3.59 (s, 3H, 12-CH_3), 3.28−3.21 (s, 3H, 2-CH_3), 2.63−2.57 (m, 1H, -C*H*HC$H_2$$COOC_3H_7$), 2.51−2.45 (m, 1H, -CH*H*C$H_2$$COOC_3H_7$), 2.33−2.27 (m, 2H, 8-C*H*$_2$$CH_3$), 2.06−2.00 (d, J = 6.63 Hz, 3H, 3-C*H*$_3$CH(OH)-), 1.96−1.90 (m, 2H, NCH_2C*H*$_2$ (CH_2)$_3$$CH_3$), 1.78 (2d overlapped, each d for one isomer, J = 7.06 Hz, 3H, 7-CH_3), 1.68 (2d overlapped, each d for one isomer, J = 7.21 Hz, 3H, 18-CH_3), 1.58−1.52 (m, 4H, 2H for -CH_2C*H*$_2$$COOC_3H_7$, 2H for -$COOCH_2$C*H*$_2$$CH_3$), 1.43−1.38 (m, 6H, -NC$H_2$$CH_2$(C*H*$_2$)$_3$$CH_3$), 1.09 (t, 3H, J = 7.53 Hz, 8-CH_2C*H*$_3$), 0.913 (t, 3H, J = 7.08HZ, -N(CH_2)$_5$C*H*$_3$), 0.82 (t, J = 7.30H$_z$, 3H, -$COOCH_2CH_2$C*H*$_3$), −0.05 (s, 1H, NH), −0.39 (s, 1H, NH). Mass Calcd for $C_{42}H_{55}O_5N_5$: 709.4. Found: 09.9 (M + 1). HRMS, Calcd: 709.4203. Found: 709.4222.

3-Vinyl-3-deacetylbacteriopurpurin-18-*N*-hexylimide Propyl Ester (6). The bacteriochlorin **5** (40 mg) was dissolved in 5 mL dry dichloromethane. HBr gas was bubbled through the solution for 2 min, and the reaction mixture was stirred at room temperature under an argon atmosphere for 5 min. The solvent and the excess hydrogen bromide were then evaporated under high vacuum (at or below 30 °C) to give a residue. Another 40 mg **5** in dichloromethane solution and then 200 mg potassium carbonate were added. The reaction mixture was stirred for an additional 30 min. Following the standard workup, the residue was chromatographed on a silica column with acetone/CH_2Cl_2 (2% v/v), and the title compound was obtained in 85% yield (33 mg). UV−vis λ_{max} (nm, CH_2Cl_2): 366 (ϵ 1.02 × 10^5), 417 (ϵ 4.53 × 10^4), 538 (ϵ 3.91 × 10^4), 796 (ϵ 5.55 × 10^4). ^{1}H NMR (400 MHz, $CDCl_3$, δ ppm): 8.622 (s 1H, 5-H), 8.50 (s, 1H, 10-H), 8.395 (s, 1H, 20-H), 7.77 (dd, J_1 = 11.92 Hz, J_2 = 18.3 Hz, 1H, 3-C*H*═CH_2), 6.185 (d, J = 18.3 Hz, 1H, 3-CH═C*H*H), 6.075 (d, J = 11.92 Hz, 1H, 3-CH═CH*H*), 5.33−5.27 (m, 1H, 17-H), 4.48−4.42 (m, 2H, -NCH_2(CH_2)$_4$$CH_3$), 4.23−4.17 (m, 2H, 1H for 7-H, 1H for 18-H), 4.06−3.99 (m, 1H, 8-H), 3.96−3.91 (m, 2H, -COOC$H_2$$CH_2CH_3$), 3.68−3.61 (s, 3H, 12-$CH_3$), 3.27 (s, 3H, 2-$CH_3$), 2.68−2.63 (m, 1H, -C*H*HCH_2-$COOC_3H_7$), 2.36−2.29 (m, 3H, 1H for-CH*H*C$H_2$$COOC_3H_7$, 2H for 8-C*H*$_2$$CH_3$), 2.03−1.96 (m, 2H, -NC$H_2$C*H*$_2$($CH_2$)$_3$$CH_3$), 1.80 (d, J = 7.09 Hz, 3H, 7-CH_3), 1.73 (d, J = 7.70 Hz, 3H, 18-CH_3), 1.60 (t, J = 7.4 Hz, 2H, CH_2C*H*$_2$$COOC_3H_7$), 1.51−1.46 (m, 4H, 2H for -N(CH_2)$_2$C*H*$_2$(CH_2)$_2$$CH_3$, 2H for -$COOCH_2$C*H*$_2$-$CH_3$), 1.46−1.39 (m, 4H, -N($CH_2$)$_3$C*H*$_2$C*H*$_2$$CH_3$), 1.11 (t, J = 7.21 Hz, 3H, 8-CH_2C*H*$_3$), 0.96 (t, J = 6.91 Hz, 3H, -N(CH_2)$_5$C*H*$_3$), 0.85 (t, J = 7.30 Hz, 3H, -$COOCH_2CH_2$C*H*$_3$), −0.01 (s, 1H, NH), −0.354 (s, 1H, NH). Mass Calcd for $C_{42}H_{53}O_4N_5$: 691.4. Found: 691.8 (M + 1). HRMS, Calcd: 691.4097. Found: 691.4090.

3-(1-Methoxy)ethyl-3-deacetylbacteriopurpurin-18-*N*-hexylimide Propyl Ester (7) Bacteriochlorin **5** (40 mg) was dissolved in dry dichloromethane (5.0 mL). HBr gas was bubbled through the solution for 2 min, and stirred at room temperature under an argon atmosphere for 5 min. The solvent and the excess hydrogen bromide were then evaporated under anhydrous high vacuum (at or below 30 °C) to give a residue, which was not characterized, but immediately redissolved in dry dichloromethane (5.0 mL) and reacted with methanol (1.0 mL) in the presence of anhydrous potassium carbonate (200 mg). The reaction mixture was stirred for 30 min. After the standard workup, the residue was chromatographed on a silica column, eluting with acetone/CH_2Cl_2 (2% v/v), and the title compound was obtained in 86.5% yield (41 mg) as a viscous oil. UV−vis λ_{max} (nm, CH_2Cl_2): 367 (ϵ 1.12 × 10^5), 417 (ϵ 5.81 × 10^4), 536 (ϵ 4.04 × 10^4), 787 (ϵ 4.75 × 10^4). ^{1}H NMR (400 MHz, $CDCl_3$, δ ppm): 8.78 and 8.73 (two singlets, 5-H), 8.61 (s, 1H, 10-H), 8.33 (s, 1H, 20-H), 5.63−5.57 (m, 1H, 3-CH_3C*H*(OCH_3)), 5.29−5.24 (m, 1H, 17-H), 4.45−4.40 (m, 2H, -NCH_2(CH_2)$_4$$CH_3$), 4.23−4.16 (m, 2H, 1H for 4-H, 1H for 18-H), 4.05−3.99 (m, 1H, 8-H), 3.94−3.87 (m, 2H, -COOCH_2-CH_2CH_3), 3.63 (s, 3H, 12-CH_3), 3.50 (s, 3H, -OCH_3), 3.25 (s, 3H, 2-CH_3), 2.63−2.58 (m, 1H, -C*H*HC$H_2$$COOC_3H_7$), 2.36−2.29 (m, 3H, 1H for-CH_2CH*H*$COOC_3H_7$, 2H for 8-C*H*$_2$$CH_3$), 1.99 (d, J = 6.58 Hz, overlapped like a quaterlet, 3H, 3-C*H*$_3$-CH(OCH_3)), 2.04−1.97 (m, 2H, -NCH_2C*H*$_2$(CH_2)$_3$$CH_3$), 1.78 (t, J = 7.4 Hz, 2H, -$COOCH_2$C*H*$_2$$CH_3$), 1.70 (2d, J = 7.15, 3H, 7-CH_3), 1.53−1.47 (m, 11H, 2H for -CH_2C*H*$_2$$COOC_3H_7$, 3H for 18-$CH_3$, 6H for NCH_2CH_2C*H*$_2$C*H*$_2$C*H*$_2$$CH_3$,), 1.13 (t, J = 7.21 Hz, 3H, 8-CH_2C*H*$_3$), 0.94 (t, J = 6.91 Hz, 3H, -N(CH_2)$_5$C*H*$_3$), 0.82 (t, J = 7.30 Hz, 3H, -$COOCH_2CH_2$C*H*$_3$), 0.05 (s, 1H, NH), −0.33 (s, 1H, NH). Mass Calcd for $C_{43}H_{57}O_5N_5$: 723.4. Found: 724.1 (M + 1). HRMS, Calcd: 723.4359. Found: 723.4395.

3-(1-Propyloxy)ethyl-3-deacetylbacteriopurpurin-18-*N*-hexylimide Propyl Ester (8). Bacteriochlorin **5** (45 mg) was reacted with 1-propanol following the procedure of preparing bacteriochlorin **7**, The title compound was obtained in 86.5% yield (41 mg) as a viscous oil. 3-Acetylbacteriopurpurin-18-methyl Ester (11). When preparing bacteriochlorin **1** starting from *Rb. sphaeroids*, 350 mL (about 440 g) as described as above, 3-acetyl-purpurin-18 carboxylic acid (**2**) was also obtained in the crude product. After treating crude **2** with diazomethane, the corresponding methyl ester (**11**) was obtained. To purify **11**, it was chromatographed on a silica column eluting with acetone/CH$_2$Cl$_2$ (2% v/v), and the title compound was obtained as purple−red crystals after crystallizing from CH$_2$Cl$_2$/*n*-hexane. Yield: 650 mg. Mp: 272 °C. UV−vis λ_{max} (nm, in CH$_2$Cl$_2$): 364 (ϵ 8.91 × 10^4), 418 (ϵ 5.36 × 10^4), 545 (ϵ 3.4 × 10^4), 815 (ϵ 5.53 × 10^4). ^{1}H NMR (400 MHz, CDCl$_3$, δ ppm): 9.21 (s, 1H, 5-H), 8.78 (s, 1H, 10-H), 8.62 (s, 1H, 20-H), 5.16−5.10 (m,1H, 17-H), 4.33−4.27 (m, 2H, 1H for 7-H, 1H for 18-H), 4.11−4.05 (m, 1H, 8-H), 3.63 (s, 3H, 12-CH$_3$), 3.57 (s, 3H, -COOCH$_3$), 3.52 (s, 3H, 2-CH$_3$), 3.15 (s, 3H, CH$_3$C), 2.73−2.67 (m, 1H, -C*H*HCH$_2$-COOCH$_3$), 2.45−2.39 (m, 2H, 8-C*H*$_2$CH$_3$), 2.38−2.32 (m, 1H, -CH*H*CH$_2$ COOCH$_3$), 2.03−1.97 (m, 2H, -CH$_2$C*H*$_2$COOCH$_3$), 1.80 (d, *J* = 7.17 Hz, 3H, 7-CH$_3$), 1.70 (d, *J* = 6.82 Hz, 3H, 18-CH$_3$), 1.1 (t, *J* = 6.46 Hz, 3H, 8-CH$_2$C*H*$_3$), −0.30 (s, 1H, NH), −0.65 (s, 1H, NH). Mass Calcd for C$_{34}$H$_{36}$N$_4$O$_6$·H$_2$O: C, 66.42; H, 6.24; N, 9.12. Found: C, 66.30; H, 5.90; N, 8.99. Mass Calcd for C$_{34}$H$_{36}$N$_4$O$_6$: 596.3. Found: *m*/*e* 596.8 (M + 1). 3-Formylbacteriopurpurin-18-*N*-hexylimide (24). The bacteriochlorin **23** (100 mg) was dissolved in THF (20 mL). Osmium tetroxide (300 mg) dissolved in CCl_4 (3 mL) and sodium periodate (2000 mg) in water (10 mL) were added. The reaction mixture was stirred for 20 h and monitored by UV−vis spectrophotometry. The disappearance of the long-wavelength absorption band at 796 nm and appearance of a new peak at 830 nm indicated the completion of the reaction. The reaction mixture was then extracted with dichloromethane, washed with 2% acetic acid/water solution and then with water (3 × 200 mL). After the standard workup, the residue was purified by preparative chromatography, and the title compound was obtained in 50% yield (50 mg). Mp: 265 °C. HPLC Analysis. The photosensitizers' purity was determined using an HPLC system consisting of a Waters 600 controller, Waters 996 diode array detector, and a Waters Delta 600 fluid delivery system, equipped with a Waters Symmetry C18 column (5 μm, 100 Å, of dimensions 4.6 × 150 mm, Waters part #WAT 045905). The solvent was 100% methanol at a flow rate of 1.0 mL/min. Peak detection was set to the wavelengths corresponding to the absorption peaks of each compound. The retention times (RT) of all the compounds are listed in Table 1.

Method for Determine Singlet-Oxygen Generating Efficacy. A SPEX 270M Spectrometer (Jobin Yvon) equipped with an InGaAs photodetector (Electro-Optical Systems Inc., U.S.A.) was utilized for acquisition of $^1O_2$ emission spectra. A diode pumped solid-state laser (Verdi, Coherent) at 532 nm was used to excite the photosensitizers and reference samples (Rose Bengal purchased from Fisher Scientific, Hampton, NH) at room temperature. The $^1O_2$ yield for Rose Bengal in methanol solution is $Q_\Delta = 0.80$. All samples were dissolved in methanol solution purchased from J. T. Baker (Phillipsburg, NJ), which was used without purification. Once dissolved in methanol, the sample was transferred into a quartz cuvette where it was placed directly in front of the entrance slit of the spectrometer, and the exciting laser beam was directed at 90° relative to the collection of emission. Long-pass filters, 538AELP and 950 LP (Omega Optical, U.S.A.), were used to attenuate the excitation laser light and fluorescence from dyes as a means of studying singlet oxygen phosphorescence, which peaked at around 1270 nm.

Formulation of Photosensitizers. Similar to most of the porphyrin-based compounds, the photosensitizers discussed in this study were insoluble in water and were formulated in 1% Tween 80/water solution. In a typical experiment, 3 mg of a photosensitizer was taken in a mortar and 100 μL Tween 80 was added. It was mixed with a pestle until it turned into a viscous paste and was left overnight in the dark for 12 h. The next day, 10 mL 5% D5W (5% dextrose solution in water) was added to it slowly with continuous mixing and filtered *via* a 0.2 μm cellulose acetate sterile syringe filter. 100 μL of the solution was taken in a cuvette and diluted 30-fold with methanol to disaggregate the compound, and the OD was measured, which in addition to the extinction coefficient values was used for determining the concentrations of the photocensitizers by following the Beer−Lambert law.

Biological Studies. *Tumor vs Skin Uptake by in Vivo Reflectance Spectroscopy.* The *in vivo* reflection data were collected by delivering monochromatic light through a quartz fiber in contact with the tissue in question. At a measured distance (typically ∼5 mm) from the delivery fiber, a pickup fiber was placed in contact with the surface. Both fibers were perpendicular to the tissue surface. Very low optical power levels (about 1 μW) are necessary in these experiments to avoid PDT effects during measurement. Light that entered the pickup fiber was conducted to a silicon photodiode detector. The detector circuit measured the photocurrent that was linear in power over 7−8 orders of magnitude. Because of the optical properties of tissue, the spectral range of greatest utility is the region between 600 and 1000 nm. In this spectral range, the probability of diffuse scattering of photons by tissue is greater than the probability of absorption. The wavelength of light was varied by scanning the monochromator, and a spectrum of diffusely scattered photons was recorded. To calculate the concentration, we used the longest absorption wavelength. The drug concentration C is calculated by eq 1.

$$C = \frac{1}{2\cdot\epsilon}\left\{-\sqrt{\mu_s{}^2 + \frac{4}{3}\alpha_0{}^2} + \sqrt{\mu_s{}^2 + \frac{4}{3}\left(\frac{\mathrm{OD}}{r} + \alpha_0\right)^2}\right\} \quad (1)$$

In this equation, ϵ is the molar extinction coefficient, α_0 is the intrinsic tissue attenuation, OD is the diffuse optical density, μ_s is the reduced scattering coefficient, and r is the distance from the detector to the tissue in question (5 mm). For a specific compound, we measured its molar extinction coefficient (ϵ) by the Beer−Lambert Law, eq 2.

$$A = \epsilon l c \quad (2)$$

In this equation, A is the absorbance, ϵ is the molar extinction coefficient, l is the distance that the light travels through the material, and c is the concentration. We measured α_0 and μ_s by another method: C^{14} drug labeling and chemical dissolution of the tissue. It was found that, for RIF tumor in C3H mice, the value of α_0 was 3.3 cm^{-1} and the value of μ_s was 4.9 cm^{-1}.

Intracellular Localization of Photosensitizers. To determine subcellular localization, photosensitizers were coincubated with organelle-specific fluorescent probes. RIF cells were seeded at 2×10^5 on poly(L-lysine)-coated coverslips in 6-well plates and cultured for 24 h to allow attachment and spreading. Photosensitizers at appropriate concentrations (typically 0.5−2 μM) were

added to cells in culture medium, and the cells incubated for 24 h at 37 °C, 5% CO_2, in the dark. To determine subcellular localization, cells were coincubated with fluorescent probes (Molecular Probes, Invitrogen Carlsbad, CA) known to target mitochondria (Rhodamine 123, 1 μM) or lysosomes (yellow−green Fluospheres 0.1 μm diameter, 1:10 000 dilution). Photosensitizers and Fluospheres were added 24 h prior to microscopy, the latter with gently rocking, and the R-123 was added during the final 30 min of incubation. The cells were then rinsed briefly with phosphate-buffered saline (PBS) and examined immediately by fluorescence microscopy (Zeiss Axiovert 35, Carl Zeiss, Inc., Germany) with a 200 W mercury arc lamp light source.

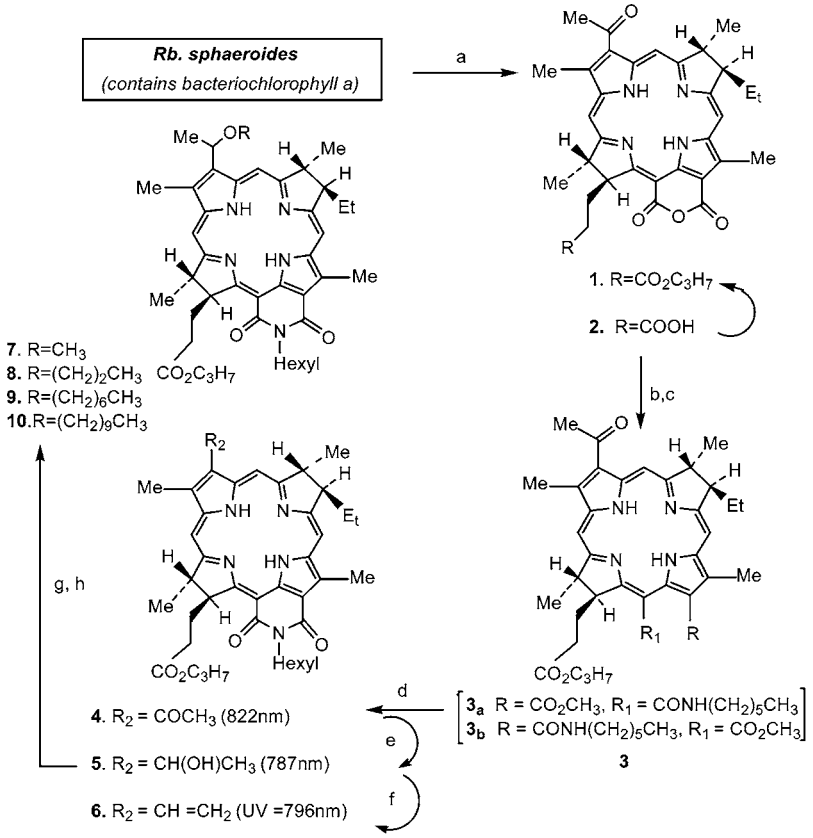
Fluorescence was imaged with a CCD camera and intensifier and processed with Metamorphose 4.5 (Universal Imaging Corp., Downington, PA). Images of photosensitizers and colocalizing dyes in the same field were taken in rapid succession. Photosensitizers were detected using a combination of 530−580 nm excitation and 600 nm dichroic/615 nm long-pass emission filters. R-123 and Fluospheres were detected using 445−490 nm excitation and 510 dichroic/520−560 nm long-pass/emission filters. The results obtained by using Fluospheres as a counterstain did not show any lysosomal colocalization, so they are not shown in the Results section.

Method for Determining in Vitro Efficacy (MTT Assay). RIF cells were grown in α-DMEM with 10% fetal calf serum, and penicillin and streptomycin (*20*). Cells were maintained in 5% CO_2 and 95% air at 100% humidity. For phototoxicity studies, RIF cells were plated in 96-well plates at a density of 1×10^4 cells well, in complete medium. 24 h later, compounds were added to a final concentration of 1.5 μM. After 24 h incubation in the dark at 37 °C, the cells were irradiated with laser light from an argon pumped dye laser using fluences of 0−12 J/cm^2 at a dose rate of 5.6 mW/cm^2. After PDT, the cells were washed once, placed in complete medium, and incubated for 48 h. Cells were incubated with 10 μL/well of 4 mg/mL MTT for the final 4 h. The MTT-containing medium was removed, and 100 μL DMSO was added to solubilize the formazan crystals. The absorbance of the wells was read on a microtiter plate reader at a wavelength of 560 nm. The results were plotted as percent growth vs days after treatment.

Evaluation of in Vivo Photosensitizing Efficacy. C3H mice (10 mice/group) were injected subcutaneously on the shoulder with 3×10^5 RIF-1 cells in 40 μL of complete α-MEM. Tumors were permitted to grow to treatment size (4−5 mm) The day before light treatment, the mice were injected intravenously (*via* lateral tail vein) with photosensitizers in 1% Tween-80/D5W at the selected dose in approximately 0.2 mL. At 24 h postinjection, mice were restrained without anesthesia in Plexiglas holders, designed to expose to light only the tumor and a 2−4 mm margin of skin. The mice were treated with laser light (135 J/cm^2 at 75 mW/cm^2). The animal experiments were conducted under the animal protocol approved by the Institute IACUC committee.

Following treatment, the tumor dimensions (orthogonal diameters) were measured by caliper every other day for tumor growth/regrowth assays. The tumor volume, *V*, was calculated with the formula $V = (lw^2/2)$, were *l* is the longest axis of the tumor and *w* is the axis perpendicular to *l*. Mice were euthanized when tumors reached the endpoint volume of 400 mm^3. Mice were considered cured if there was no palpable tumor by day 90.

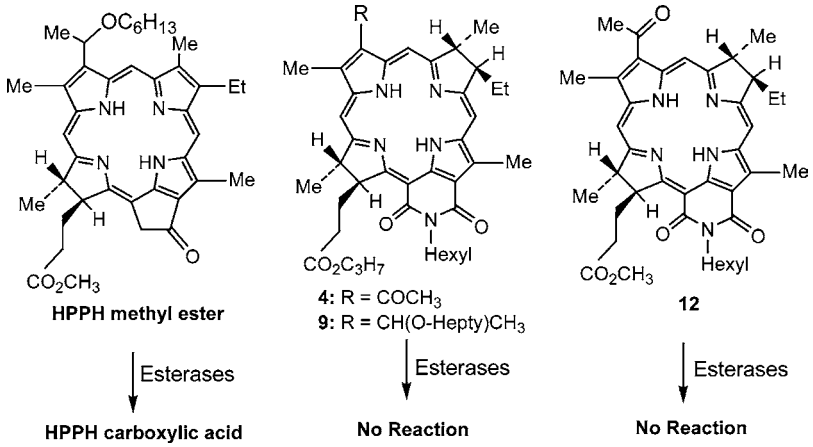
Procedure for Competitive Binding to the Peripheral-Type Benzodiazopine Receptor. To labeled 5 mL disposable glass borosilicate tubes were added 1×10^6 cells in 50 μL Tris buffer (25 mM, pH 7.4), 50 μL ^{3}H-PK11195 (45 nM final concentration), and 50 μL competitor (cold PK11195 or photosensitizers). Final concentrations (molar) of the competitors were 1×10^9, 1×10^{-8}, 1×10^{-7}, 5×10^{-7}, 1×10^{-6}, 5×10^{-6}, 1×10^{-5}, 5×10^{-5}, and 1×10^{-4} diluted in Tris buffer. The background control contained no cells, 50 μL ^{3}H-PK11195, and 100 μL Tris buffer, and the maximum binding control contained 50 μL Tris buffer instead of competitor. Samples were incubated for 1 h at 4 °C, and then the incubation was inhibited by dilution with 3 mL of Tris buffer. The cells were filtered by vacuum on GF/C Whatman filters presoaked in Tris buffer containing 0.5% polyethyleneimine to prevent nonspecific binding to the filter. The filters were washed 3 times each with 4 mL of Tris buffer. The filters were transferred to scintillation vials and 4 mL of scintillation fluid (Universol, ICN) was added. The vials were shaken to dissolve ^{3}H-PK11195 and left in the dark to equilibrate, and the radioactivity of the samples was counted in a beta counter. The concentration of competitor at which 50% of ^{3}H-PK11195 binding was inhibited (IC50) was calculated to determine the binding of competitors compared to PK11195.



RESULTS AND DISCUSSION

Chemistry. *Alkyl Ether Analogues of N-Substituted Bacteriopurpurinimides. Rb. sphaeroides* enriched with bacteriochlorophyll-a (*21, 22*) was converted into bacteriopurpurin propyl ester **1** by following the methodology developed in our laboratory (Scheme 1). Reaction of **1** (λ_{max} 813 nm) with hexylamine produced an isomeric mixture of amides $\mathbf{3_a}$ and $\mathbf{3_b}$, which under base-catalyzed intramolecular cyclization afforded the corresponding *N*-hexylimide **4** with a strong long-wavelength absorption at 822 nm (in CH_2Cl_2). In our previous studies with a series of alkyl ether analogues of purpurinimides, we observed a linear correlation between the overall lipophilicity and PDT efficacy. To investigate the effect of such substitutions in the bacteriopurpurinimide system, two different approaches were used.

In our first approach, purpurinimide **4** was initially reacted with sodium borohydride and the corresponding (1-hydroxyethyl)purpurinimide **5** (λ_{max} 787 nm) was isolated in almost quantitative yield. Dehydration of **5** with *o*-dichlorobenzene at 140 °C for 2−3 min produced the corresponding 3-vinyl analogue **6** in ∼60% yield (λ_{max} 796 nm). Further reaction of **6** with 30% HBr/AcOH and then with dry methanol generated a mixture of the desired 3-(1-methoxy)ethyl-*N*-hexylpurpurinimide **7**, the related 3-(1′-hydroxy)ethyl analogue **5**, and the corresponding dehydration product **6**. In our second approach, HBr gas was bubbled through a solution of 3-(1-hydroxy)ethylpurpurin-*N*-hexylimide **5** in dry dichloromethane for 2 min. The solvent was evaporated under high vacuum, and the residue so obtained was redissolved in dry dichloromethane and reacted with dry methanol for 40 min in the presence of anhydrous potassium carbonate. After the standard workup, the desired methyl ether derivative **7** was obtained in about 90% yield. Compared to the HBr/AcOH method, the HBr gas method was found to be more efficient for the synthesis of **7** and other related purpurinimides **8**−**10** with fewer decomposition products. The resulting bacteriopurpurinimides exhibited long-wavelength absorptions at 787 nm (ϵ = 47 300 in dichloromethane). Thus, when compared to Photofrin, hematoporphyrin derivative (630 nm, ϵ = 5000), HPPH [3-(1-hexyloxyethyl) pyropheophorbide-a, 660 nm, ϵ = 47 500), and the alkyl ether analogues of purpurin-18-*N*-alkylimide (700 nm, ϵ = 45 000), significant red shifts of 157, 127, and 87 nm respectively were observed.



Although all the imide analogues shown in Scheme 1 were obtained in good yield, the starting bacteriopurpurin-18 was always isolated as a mixture of the propyl ester **1** and the corresponding carboxylic acid **2**. The overall yield was consistent; however, the individual components were isolated in variable yields from the different batches of *Rb. sphaeroides*. Several methods were followed to convert the carboxylic

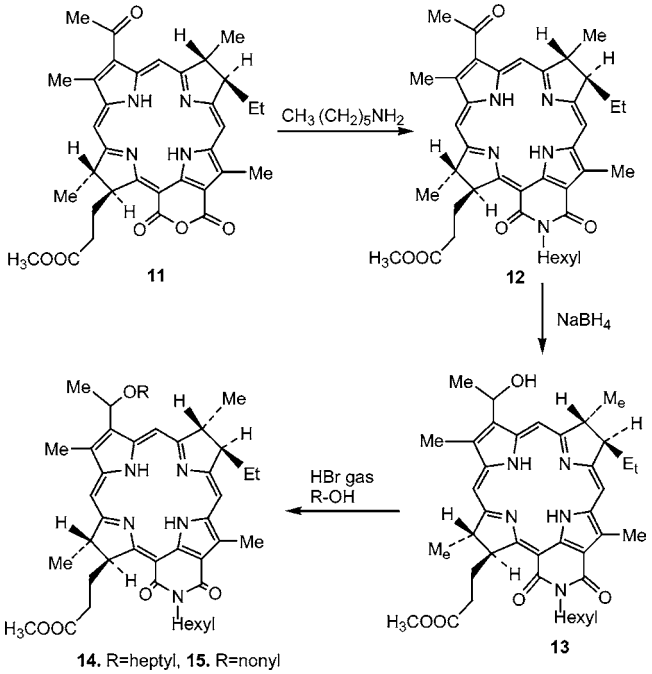
Reagents: a. KOH/1-propanol, H_2SO_4; b. $NH_2N(CH_2)_5CH_3$; c. CH_2N_2; d. KOH/M_eOH; e. N_aBH_4; f. o-dichlorobenzene(140°C, 2min); g. HBr/AcOH or HBr gas; h. ROH.

Scheme 2. Specificity of *in Vitro* and *in Vivo* Esterase Hydrolysis



analogue **2** to the corresponding propyl ester **1**, but in general, the yield at the esterification step was low. Therefore, the bacteriopurpurin-18 was left refluxing in THF for a longer period of time until all the bacteriopurpurin-18 propyl ester was converted into the corresponding carboxylic acid, which upon diazomethane treatment afforded the corresponding methyl ester **11**.

Our next step was to prepare a series of the alkyl ether analogues of bacteriopurpurinimide methyl ester **15** with lipophilicity similar to that of the corresponding propyl ester **9** and to compare their photosensitizing efficacy under similar treatment conditions. Before synthesizing a series of alkyl ether analogues, we thought it necessary to look at the *in vivo* stability of the bacteriopurpurinimides containing the methyl or propyl ester substituents.

Previously, in a related study we observed that the methyl ester analogue of 3-devinyl-3(1′-hexyloxyethyl)-pyropheophorbide-a (HPPH), which is currently in phase I/II human clinical trials, was quite stable *in vivo*, except the methyl ester group was converted into the corresponding carboxylic acid (Scheme 2).

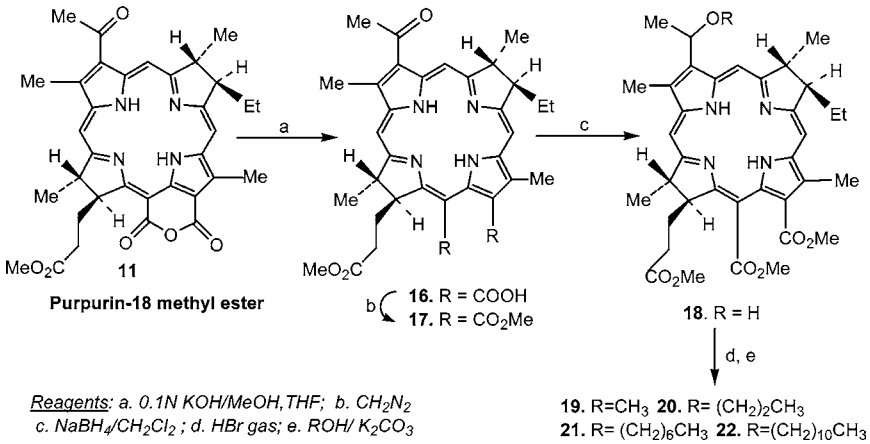
The *in vivo* conversion of the methyl ester to the corresponding carboxylic acid was possibly due to the presence of certain esterases specific for ester hydrolysis. To our surprise in an *in vitro* experiment, in contrast to the results obtained from the methyl ester of HPPH, no ester hydrolysis was observed in the bacteriopurpurinimides containing either the methyl or propyl ester functionality, which suggests that the presence of the fused imide ring system might inhibit the activity of the enzyme. The extraction of the photosensitizer **9** from RIF tumors in mice at

Scheme 3. Synthesis of a Series of Bacteriopurpurin-18-*N*-hexylimide Methyl Ester

24 h postinjection also showed no ester hydrolysis, which demonstrated the *in vivo* stability of the methyl and propyl ester functionalities in the bacteriopurpurinimide system. The log *P* values (a measure of the lipophilicity of the molecules) of the various alkyl ether analogues of bacteriopurpurinimide methyl ester were determined with the computer program module of the *PALLAS* system. The objective was to compare the *in vivo* biological efficacy of bacteriopurpurinimides (methyl ester vs propyl ester) with similar lipophilicity. Among the bacteriopurpurinimides containing propyl or methyl ester functionalities, compounds **7**−**10**, **14**, and **15** with *P* values ranging from 8.18 to 12.72 were synthesized (Scheme 3).

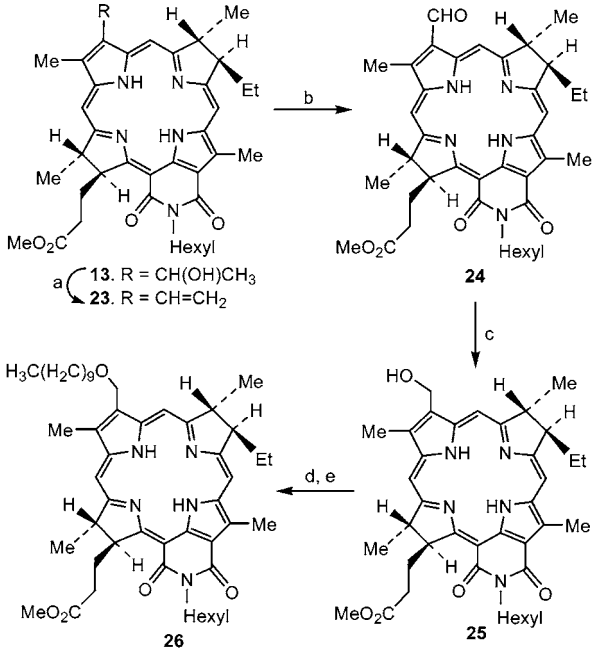
Alkyl Ether Derivatives of Bacteriopurpurin p_6. Among the chlorin-based photosensitizers derived from chlorophyll-a, certain chlorin p_6 analogues are reported to be effective PDT agents (*23*). However, in our own *in vivo* study with a series of chlorin analogues, the open-chain compounds were found to be less effective than those containing the fused isocyclic and imide ring systems. To investigate the structural requirements of the effective photosensitizers in the bacteriochlorin system, we synthesized a series of alkyl ether derivatives of bacteriochlorin p_6 and compared their efficacy with the alkyl ether analogues of *N*-hexylbacteriopurpurinimide.

To investigate a possible correlation between lipophilicity and PDT efficacy, the alkyl ether derivatives of bacteriochlorin p_6 **19**−**22** with log *P* values ranging from 6.18 to 11.19 were prepared by following the methodology depicted in Scheme 4. In brief, the six-member anhydride ring of bacteriopurpurin-18 methyl ester under basic conditions was cleaved into the corresponding bacteriochlorin p_6 dicarboxylic acid **16**, which upon treatment with diazomethane yielded bacteriochlorin p_6 trimethyl ester **17** in 80% overall yield. The hydroxy analogue **18** obtained from **17** by sodium borohydride reduction was converted into the corresponding alkyl ether analogues **19**−**22** by following the standard methodology.



Synthesis of Bacteriopurpurinimide without Introducing any Chirality at Position-3[1]. Among all the alkyl ether analogues of purpurinimide and bacteriochlorin p_6, the 3-(1-heptyloxy)-ethyl-3-deacetylbacteriopurpurin-18-*N*-hexylimide propyl ester **9** tested as a mixture of R- and S-isomers was found to be the most effective (see the biological results). For investigating the importance of the chirality (position 3) in photosensitizing efficacy, bacteriochlorin **26** without any chirality at this partcular position was prepared. For compound **26** to have a similar lipophilicity as that of **9** (log $P = 11.19$), a decyl ether group was introduced at position 3 by following the reaction sequences illustrated in Scheme 5. In brief, the 3-vinyl bacteriochlorin **23** (the dehydration product of **13**) was first converted into the corresponding formyl derivative **24** in good yield by reacting **23** with a mixture of OsO_4 and sodium periodate ($NaIO_4$). Reduction of **24** by sodium borohydride and subsequent treatment with HBr gas/*n*-decyl alcohol produced the corresponding alkyl ether derivative **26** in 94% yield.

Photophysical Properties. All bacteriochlorins showed high singlet-oxygen producing efficiency (>40%) (see Table 1) and exhibited a strong long-wavelength absorption >750 nm. However, compared to bacteriopurpurinimides, the bacteriochlorin p_6 analogues exhibited a slight blue shift in their electronic absorption spectra (see Figure 1).



Biological Studies. *Determination of Tumor vs Skin Uptake by in Vivo Reflectance Spectroscopy.* The tumor and skin uptake of each compound was determined by *in vivo* reflectance spectroscopy (*24*, *25*), which measures transmittance of light through tissue in anesthetized C3H mice bearing RIF tumors. The optical transmittance as a function of wavelength was recorded before and after the i.v. injection of the photosensitizer at a dose of 5.0 μmol/kg.

The *in vivo* drug absorption spectrum is best displayed by taking the ratio of the postinjection spectrum to the preinjection spectrum. The tumor vs skin ratio of the bacteriopurpurinimides and their log *P* values calculated by *PALLAS* are summarized in Table 1. All photosensitizers showed a greater uptake in tumor vs skin at 24 h postinjection, indicating some degree of tumor

Reagents: a. o-dichlorobenzene (140°C, 2min); b.OsO_4/$NaIO_4$; c. $NaBH_4$; d. HBr gas; e: $C_{10}H_{21}OH$

selectivity; varying from less than 2 (compound **26**) to almost 10 (compound **14**). Similar to the bacteriopurpurinimides, the bacteriochlorin p_6 analogues were also found to be quite stable both *in vitro* and *in vivo*. This might be due to its two ester groups being directly linked to the bacteriochlorin ring. Tumor and skin concentrations at different time points postinjection for the representative bacteriopurpurinimides **9** and **26** and bacteriochlorin p_6 **22** are plotted in Figure 2.

In Vitro Photosensitizing Efficacy. The *in vitro* photoactivity of the synthetic bacteriochlorins was determined in RIF cells by MTT assay (*26*) (see Experimental Procedures). To determine the optimum drug concentration, One of the bacteriochlorins, **9**, was initially tested at three different concentrations (1.5, 2.0, and 2.5 μM) producing good phototoxicity with no dark toxicity at 1.5 μM, with a light dose of 12 J/cm^2, The other photosensitizers (bacteriopurpurinimides **7**, **8**, **10**, **14**, **15**, and **26** and bacteriopurpurins p_6 **19**−**22**) were evaluated under similar experimental conditions and demonstrated similar phototoxity (Figure 3). The IC_{50} values of these compounds are summarized in Table 2.

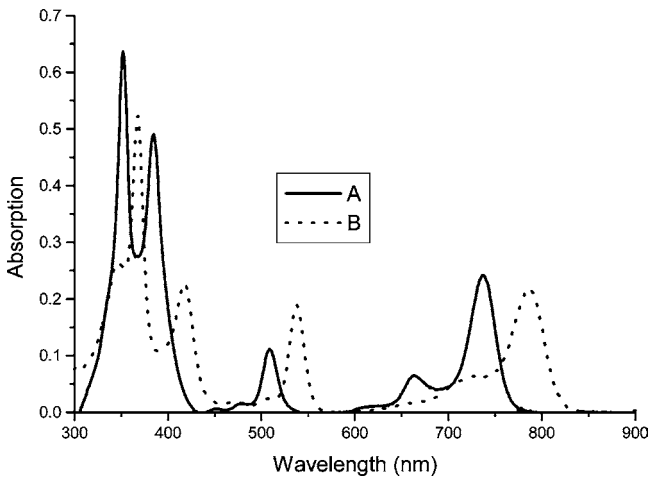

Figure 1. The electronic absorption spectra of compound **22** (A) and **9** (B) in dichloromethane at equimolar concentration (4.6 μM).

In Vivo Photosensitizing Efficacy of Bacteriopurpurinimides. To relate the molecular structure of the photosensitizers to their *in vivo* therapeutic response, the photosensitizing efficacies of four propyl ester analogues **7**−**10** were determined in C3H mice bearing RIF tumors (10 mice/group). Groups of mice with tumors of 4−5 mm diameter were treated at 0.4 μmol/kg and 135 J/cm^2 at 790 nm (*in vivo* absorption) at 24 h postinjection, and the tumor response (reappearance of tumor) was recorded. Among the alkyl ether analogues, the 3-(1-methoxy)ethyl **7** (log $P = 8.18$) and 3-(1-propyloxy)ethyl **8** (log $P = 9.16$) produced limited activity. Bacteriochlorin **9** containing a heptyl ether group with log $P = 11.19$ showed excellent PDT efficacy with 5/10 mice tumor-free at day 90. The corresponding bacteriochlorin **10** with a decyl ether group (log $P = 12.72$) showed similar activity: 4/10 mice tumor-free on day 90 (Figure 4). The photosensitizers **7** and **8**, which were found to be quite effective *in vitro*, showed limited *in vivo* photosensitizing ability suggesting that, in addition to tumor uptake, other factors such as intracellular localization of the drug may also be playing an important role in the final outcome of the therapy.

For preliminary screening, each compound was evaluated in mice (10 mice/group) bearing RIF tumors at variable drug doses and a fixed light dose. However, further studies with a larger group of mice, necessary for selecting the best photosensitizer, showed similar efficacy, and these studies are currently in progress. At lower doses (e.g., 0.1 μmol/kg; see Figure 5), none of these compounds showed any significant long-term efficacy.

The photosensitizing ability of bacteriopurpurinimide **26** was compared with compounds **9** and **15** possessing similar overall lipophilicity. As can be seen from the data summarized in Figures 4 and 5, compared to compound **26** (2/10 mice tumor-free on day 90), both purpurinimides **9** and **15** showed increased activity. These results suggest that the chiral center in position 3^1 is not indispensable, but plays an important role to achieve enhanced efficacy. Interestingly, photosensitizers **9** and **14** with propyl and methyl ester functionality, respectively, bearing the heptyl and nonyl ether groups at position 3 showed similar efficacy. However, it should be realized that, while the *in vivo* results discussed in this paper are important to relate the structure−activity relationships, they are very preliminary. Extensive *in vivo* study with larger group of mice is required for selecting the best compound from the most promising candidates.

In Vivo Photosensitizing Efficacy of Bacteriochlorin p_6. Bacteriochlorins p_6 **19**−**22** were evaluated for *in vivo* PDT efficacy at two different doses. At a dose of 1.0 μmol/kg, both **21** and **22** showed some photosensitizing efficacy with cure rates of 20% and 10%, respectively. However, at a reduced dose (0.4 μmol/kg, an effective dose for certain bacteriopurpurinimides including compound **9**), these analogues produced limited photosensitivity (Figures 6). Even though the calculated log P values for bacteriochlorin **22** and bacteriopurpurinimide **9** were quite close (log $P = 11.19$), a significant difference in long-term cure between these photosensitizers was observed.

Intracellular Localization. Many porphyrin-based compounds can be observed intracellularly with a fluorescence microscope (*27*). Most photosensitizers localize to cytosolic targets such as the Golgi, endoplasmic reticulum, mitochondria, lysosomes, and membranes. It has been reported that intracellular localization of the photosensitizers could be an important determinant for photosensitizing activity. In general, most of the photosensitizers that localize in mitochondria (primary or secondary targets) were found to be quite effective. Therefore, the effective bacteriopurpurinimides **9** and **26** and the bacteriopurpurin p_6 **22** with limited efficacy were evaluated for intracellular localization by routine methods. As can be seen in Figure 7, both

compound	7	8	9	10	14	15	19	20	21	22	26
IC_{50}(J/cm^2)	2.8	2.56	3.81	2.25	2.68	2.05	4.12	3.95	5.0	3.28	2.86

bacteriochlorins derived either from bacteriopurpurinimide or bacteriochlorin p_6 localized primarily in mitochondria.

Comparative Peripheral Benzodiazepine Receptor (PBR) Binding Affinity. Peripheral benzodiazepine receptor (PBR) is an 18 kDa protein of the outer mitochondrial membrane, and one intriguing aspect of this protein is its possible role as a target for PDT (*27*). Therefore, using the labeled high-affinity PBR ligand PK11195 as a tool, we measured the ability of

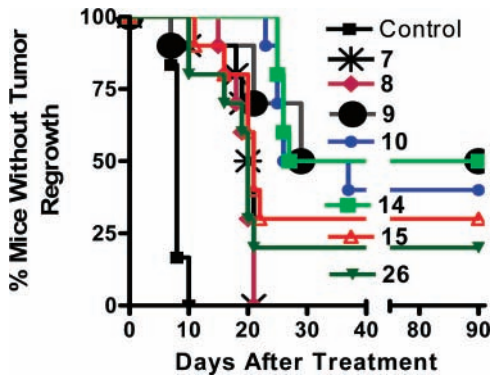

Figure 4. *In vivo* photosensitizing efficacy of photosensitizers **7**−**10**, **14**, **15**, and **26** in C3H mice (10 mice/group) bearing RIF tumors at a dose of 0.4 μmol/kg. The mice were treated with laser light (790 nm, 135 J/cm^2) at 24 h postinjection of the drug.

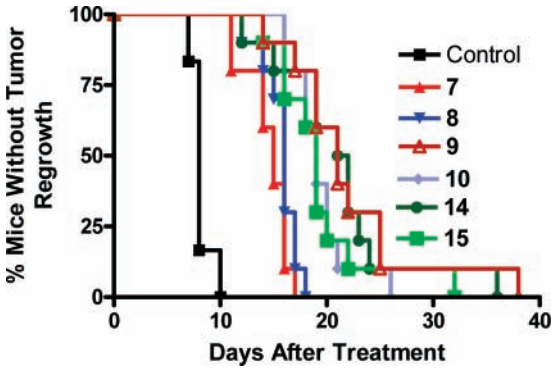

Figure 5. *In vivo* photosensitizing efficacy of photosensitizers **7**−**10**, **14**, and **15** in C3H mice (10 mice/group) bearing RIF tumors at a dose of 0.1 μmol/kg. The mice were treated with laser light (790 nm, 135 J/cm^2) at 24 h postinjection of the drug.

compounds **19**−**22** to displace ^{3}H-PK11195 from its specific cellular binding site, the isoquinoline (IQ) site on PBR, using known methodology (*27, 28*). Significant displacement of ^{3}H-PK11195 by compounds **19**−**22** was observed (Figure 8). For example, compounds **19**, **20**, and **21** displaced more than 70% ^{3}H-PK11195 at 10^{-4} M, while bacteriochlorin p_6 **22** displaced about 51% ^{3}H-PK11195. However, under similar experimental conditions, the most effective bacteriopurpurinimide **9** did not show any significant binding affinity (*28*) (see Table 3). The IC_{50} displacement values of these compounds are listed in Table 3. These results suggest that there is no direct correlation between the photosensitizing efficacy and the PBR binding affinity of the photosensitizers discussed in our present study.

CONCLUSION

Unstable bacteriochlorophyll-a was converted into a series of highly stable bacteriochlorins (related bacteriopurpurinimide and bacteriochlorin p_6) with strong long-wavelength absorptions at 787 and 737 nm, respectively. Among photosensitizers with high log *P* values and higher molecular weights (>500), the regular octanol/water method to determine the overall lipophilicity was not a practical approach. Therefore, for drug design the computational methods in determining log *P* and log *D* values, which are quite common in drug development, was used. Log *D*, a pH-dependent version of log *P*, is a descriptor of the octanol−water distribution coefficient for partitioning of ionizable species in biphasic media and accounts for mixtures of species that may exist at any given pH. In order to compare the *in vivo* efficacy of photosensitizers derived from bacteriopurpurinimide and bacteriochlorin p_6 with overall lipophilicity, both log *P* and log *D* values were calculated (the octanol/water

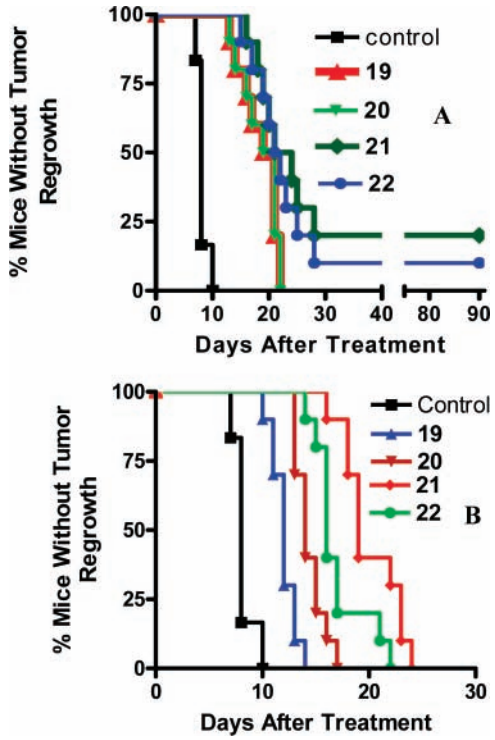

Figure 6. *In vivo* photosensitizing efficacy of bacteriochlorin p_6 **19**−**22** in C3H mice (10 mice/group) bearing RIF tumors at doses of (A) 1.0 μmol/kg and (B) 0.4 μmol/kg. The mice were treated with laser light (790 nm, 135 J/cm^2) at 24 h postinjection of the drug.

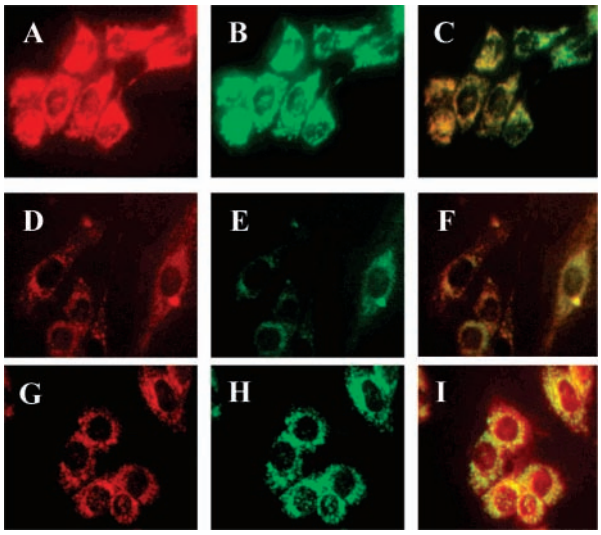

Figure 7. Comparative intracellular localization of **9**, **22**, and **26** with Rhodamine 123: (A) **9**; (B) Rhodamine 123; (C) overlap of **9** and Rhodamine 123; (D) **22**; (E) Rhodamine 123; (F) overlap of **22** and Rhodamine 123; (G) **26**; (H) Rhodamine 123; and (I) overlap of **26** and Rhodamine123.

method is not suitable for compounds with molecular weight of >500). At physiological pH, the calculated values of log *P* and log *D* for both series of photosensitizers were quite close. In a homologous series of the alkyl ether derivatives of both purpurinimide and bacteriopurpurinimide, a parabolic relationship between the overall lipophilicity and PDT was observed to some extent. However, compounds with the same log *P* value in two independent series did not show similar efficacy. These observations were similar to those reported previously by us in SAR and QSAR studies of a series of pyropheophorbide-a analogues (*29*, *30*). As expected, a linear correlation between the calculated log *P*/*D* values and HPLC retention times of a particular series of compounds was observed. Interestingly, compared to more effective bacteriopurpurinimide analogues, bacteriochlorin p_6 derivatives with limited PDT efficacy showed significant PBR binding affinity. These results further confirm that the PBR binding affinity of a photosensitizer has no direct correlation with photosensitizing efficacy as reported previously by us (*28*) and others (*31*) in other studies.

Received March 26, 2007; Revised Manuscript Received June 1, 2007

A novel approach for the preparation of a biotinylated dendrimer-based MRI agent **5** is described, in which a unique disulfide bond in the core of the Gd(III)-1B4M-DTPA chelated G2 PAMAM dendrimer was reduced and then attached to a maleimide-functionalized biotin. The new MRI agent **5** features a well-defined dendron structure and a unique biotin functionality. Immobilization of up to four copies of biotinylated dendrimer **5** to fluorescently labeled avidin yields a supramolecular avidin−biotin−dendrimer-Gd(III) complex. Validation of the complex in mice bearing ovarian cancer tumors demonstrates that the avidin−biotin−dendrimer targeting system efficiently targets and delivers sufficient amounts of chelated Gd(III) and fluorophores (e.g., Rhodamine green) to ovarian tumors to produce visible changes in the tumors by both MRI and optical imaging, respectively. Thus, the avidin−biotin−dendrimer complex may be used as a tumor-targeted probe for dual-modality magnetic resonance and fluorescence imaging.

INTRODUCTION

Diffuse peritoneal metastasis, or "seeding", is a common and often fatal complication of ovarian cancer (*1*). While detection of metastatic disease is essential for proper surgical cytoreduction and improved survival of the patient (*2*−*4*), the current imaging modalities for peritoneal disease using intravenously administered iodinated contrast media for computed tomography (CT) or gadolinium (Gd(III)) chelates for magnetic resonance imaging (MRI) are nonspecific, insensitive, and unable to provide the surgeon with intraoperative guidance. The surgical removal of peritoneal disease is complicated by poor visual contrast between the tumor and normal tissue under white light, making the identification of small peritoneal implants difficult. Therefore, it is of interest to improve the detection of small foci of peritoneal metastasis. A desirable agent would be targeted to cancer but also allow dual labeling such that the probe could be used as an MRI contrast agent in the preoperative setting for surgical planning purposes and as an optical contrast agent in the operative setting to guide the surgeon to small lesions.

MRI is widely used in both diagnostic and clinical medicine as well as biomedical research, because it offers high spatial resolution without ionizing radiation. The addition of targeted intraperitoneal MR contrast media potentially could increase the conspicuity of lesions within the peritoneum compared with intravenously injected contrast media (*5*, *6*). Dendrimers, highly branched synthetic polymers (*7*), can serve as an excellent scaffold for the basis of multimodal contrast media. Dendrimer-based contrast agents have a higher molar relaxivity than simple Gd(III) complexes such as Gd(III)-diethylenetriaminepentaacetic acid (Gd(III)-DTPA, Magnevist) and Gd(III)-*N*,*N*′,*N*″,*N*‴-tetracaroxymethyl-1,4,7,10-tetraazacyclododecane (Gd(III)-DOTA, Dotarem) because they bind multiple Gd(III) chelates (*8*−*10*) (which increases local Gd(III) concentrations), and slow the molecular tumbling time (*11*), thus increasing the magnetic relaxivity of individual Gd(III) ions (*5*). Newer families of dendrimers (*12*) possess a disulfide function (cystamine) core (Figure 1) which, when treated with traditional redox chemistry, provides a site for the introduction of the highly specific and efficient maleimide and sulfhydryl coupling reaction. This in turn permits the half-dendrimer to form a conjugate with peptides, monoclonal antibodies, biotin, or other targeting moieties.

Targeted agents are preferred over nontargeted methods, since they not only increase the target-to-background ratio but provide much more tissue specificity than nontargeted agents. An example of a targeting moiety is the 68 kDa tetrameric glycoprotein, avidin, which binds with high capacity to lectins differentially expressed on the surface of many cancer cells such as ovarian cancer (*13*−*16*). These lectins are surface proteins that specifically binds to carbohydrate moieties on glycolipids and glycoproteins such as avidin and other galactosylated proteins (*13*−*16*). Avidin is an excellent targeting moiety, because once bound, the protein and its conjugates are internalized into the cell while unbound avidin reenters the circulation, is absorbed to the liver, and is eventually eliminated via the hepatobiliary system, effectively reducing the background signal (*13*−*16*). Biotinylated dendrimers provide an exceptional structure to which the molecular targeting agent, avidin, could be attached; the biotin−avidin interaction is among the strongest known ($K_{ass} = 1.7 \times 10^{15}\ M^{-1}$) (*17*). Previous work has shown that the biotin−avidin targeting system efficiently targets and increases the delivery of avidin-conjugated-biotinylated dendrimer-Gd(III) complexes to the ovarian cancer cell line, SHIN3 (*18*−*20*). Moreover, the biotin−avidin targeting system coupled

to MRI contrast agents has been successfully exploited to investigate blood volume and vascular permeability (*21*). Avidin also possesses the added benefit of having sites to which an optical fluorophore agent can be attached, thus providing the opportunity for dual-modality imaging.

Herein, we describe the synthesis and testing of an intraperitoneally delivered dendrimer-based, avidin−biotin targeted, dual-reporter probe to detect peritoneal tumors in mice using the SHIN3 ovarian cancer model.

MATERIALS AND METHODS

2-Methyl-6-(*p*-aminobenzyl-*N*-[5-oxopentanoic acid])diethylene-*N*,*N*,*N*′,*N*″,*N*″-penta-*tert*-butylacetate hydroxysuccinimidyl ester (NHS-1B4M-DTPA) was prepared as previously described (*22*). *N*-hydroxysuccinimide (NHS), 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDCI), peptide sequence grade trifluoroacetic acid, and $Gd(OAc)_3 \cdot xH_2O$ were purchased from Sigma-Aldrich Co. (St. Louis, MO) and were used as received. Generation 2 cystamine core PAMAM dendrimer was obtained from Dendritic Nanotech, Inc. (Midland, MI) as a 15.35% w/w solution in MeOH. *N*-(2-Aminoethyl)-aminomethyl polystyrene was purchased from Novabiochem (Laüfelfingen, Switzerland). Maleimide-PEO_2-biotin and immobilized TCEP disulfide reducing gel were purchased from Pierce Biotechnology, Inc. (Rockford, IL).

Avidin was purchased from Pierce Biochemical, Inc. (Milwaukee, WI). Rhodamine green-succinimidyl ester (RhodG) was purchased from Invitrogen/Molecular Probes, Inc. (Eugene, OR).

All experiments with moisture- and/or air-sensitive compounds were carried out under a dried N_2 or Ar atmosphere. Column chromatography was conducted using Merck 60 Silica Gel (70−230 mesh). Thin-layer chromatography (TLC) was performed on silica gel 60 F-254 plates from EM Reagents (Gibbstown, NJ). Water was purified using a Hydro Ultrapure Water Purification system (Rockville, MD) prior to all experiments.

Proton and ^{13}C NMR data were obtained using a Varian Gemini 300 MHz instrument and chemical shifts are reported in ppm on the δ scale relative to TMS, TSP, or residual solvent. Proton chemical shifts are annotated as follows: ppm (multiplicity, coupling constant (Hz), integration). Low- and high-resolution mass spectra (HRMS) were obtained on a Waters' LCT Premier time-of-flight mass spectrometer using electrospray ionization (ESI/TOF/MS) in positive ion mode operated at a resolution of 10 000. The electrospray capillary voltage was 3 kV, and the sample cone voltage was 60 V. Desolvation temperature was 225 °C, and the desolvation gas was nitrogen at 300 L/h. Accurate masses were obtained using the lock spray mode with Leu-Enkephalin as the external reference compound. Elemental analyses were performed in duplicate by Desert Analytics (Tucson, AZ) using the combustion analysis method for C, H, N and S, and the inductively coupled plasma-atomic emission spectroscopy (ICP-AES) method for determining the percentage of Gd. MALDI-TOF mass spectral data were obtained by the Scripps Center for Mass Spectrometry (La Jolla, CA).

Dendrimer conjugation and purity was assessed by size exclusion HPLC (SE-HPLC) using a Beckman System Gold (Fullerton, CA) equipped with a Model 126 solvent delivery module and a Model 168 UV detector (λ 254 and 280 nm) controlled by *32 Karat* software. Size exclusion chromatography was performed on a Tosohaas G2000SW, 10 μm, 7.8 mm × 30 cm column (Montgomeryville, PA) using phosphate buffered saline (PBS) solution as the eluent (0.5 mL/min).

Cystamine Core Dendrimer 1B4M-DTPA Conjuate (2). Typical procedure: Cystamine core PAMAM G2-dendrimer **1** (0.31 g, 0.093 mmol) was added to a solution of NHS-1B4M-DTPA (3.00 g, 2.98 mmol) in DMSO (15 mL). The mixture was stirred at room temperature for 24 h and then treated with *N*-(2-aminoethyl)aminomethyl polystyrene (0.60 g, loading ≥2.00 mmol/g). After stirring an additional 24 h, the reaction mixture was filtered, diluted with CH_2Cl_2 (50 mL), and washed with H_2O (50 mL). The organic layer was concentrated under reduced pressure to afford crude **2**. The crude product was then treated with pure trifluoroacetic acid (10 mL) and stirred for 18 h. The solution was then evaporated and the residue was washed with hexane (2 × 30 mL) and dissolved in H_2O (30 mL). The dendrimer solution was adjusted to pH = 5 with 1 N aqueous NaOH, exchanged to H_2O using a Centriprep 3 (MW cutoff 3000 Da), and lyophilized to give **2** as a white solid (0.76 g, 62% yield).

MALDI-TOF: *m*/*z* 9304, calcd for $[G2(1B4M)_{10}(CF_3COOH)_2Na_{23}(H_2O)_{412})^{2+}]$ 9431; found 9429. SE-HPLC: R_t = 14.8 min. Elemental Analysis calcd for $[G2(1B4M)_{12}(CF_3COO)_5Na_{23}(H_2O)_{52}]$: C, 45.10; H, 6.37; N, 11.72;, S, 0.51; found: C, 44.93, 44.78; H, 5.87, 5.46; N, 11.65, 11.76; S, 0.85, 0.75.

Cystamine Core Dendrimer 1B4M-DTPA Gd(III) (3). To a solution of **2** (100 mg, ∼11 μmol) in 0.3 M citrate buffer (10 mL, pH = 4.5) was added $Gd(OAc)_3 \cdot xH_2O$ (56.8 mg, 0.17 mmol). The solution was stirred at room temperature for 12 h and then transferred to a Centriprep 3 centrifugal filter device with a 3000 Da cutoff membrane and subjected to exhaustive ultrafiltration with deionized water while monitoring with SE-HPLC. The retentate was lyophilized and product **3** was obtained as a yellow solid (89 mg, ∼72%).

MALDI-TOF: *m*/*z* 11249, calcd for $[G2(Gd\text{-}1B4M)_{11}(1B4M)(C_6H_7O_3)_4Na_{32}(H_2O)_{446}]$ 10961; found 10957. SE-HPLC: R_t = 15.3 min. Elemental Analysis calcd for $[G2(Gd\text{-}1B4M)_{11}(1B4M)(C_6H_7O_3)_4Na_{32}(H_2O)_{43}]$: C, 40.22; H, 5.39; N, 10.16; S, 0.44; Gd, 11.83. Found: C, 40.05, 40.18; H, 4.45, 4.45; N, 10.52, 10.51; S, 0.61, 0.49; Gd, 11.47, 11.48.

Cleavage of Cystamine Core Dendrimer 1B4M-DTPA Conjugate and Preparation of Biotin Conjugate (4). An aqueous solution of **2** (0.1 g, ∼11.1 μmol) in 10 mL was added to the immobilized TCEP reducing gel solution (2 mL) and the

reaction mixture was gently stirred for 2 h. The reducing gel was filtered through a glass wool plugged glass pipet. Maleimide-PEO_2-biotin was added (17.5 mg, 33.3 μmol) and the mixture was stirred under N_2 atmosphere for 18 h. The reaction solution was then transferred to a Centriprep 3 (MWCO 3000 Da) and subjected to exhaustive filtration with deionized water, monitored by SE-HPLC. Finally, the retentate was lyophilized and the product **4** was obtained as a white solid (68 mg, ~51%).

^{1}H NMR (D_2O, 300 Hz) δ 7.42 (d, J = 7.2 Hz, aromatic protons of 1B4M chelates), 7.27 (d, J = 6.6 Hz, aromatic protons of 1B4M chelates), 4.58 (m, SCHC*H* of biotin), 4.32 (m, SCH_2CH of biotin), 3.95−3.60 (m), 3.40 (br), 3.22 (s), 2.69 (m), 2.47 (m), 2.37 (br), 2.19 (m), 1.88 (br), 1.56 (m), 1.27 (m), 1.25−1.00 (br). MALDI-TOF: *m*/*z* 4837, 5482, 5952, 6597, 7139, calcd for [G1Biotin(1B4M)$_4$, $C_{203}H_{326}N_{50}O_{69}S_2$; G1Biotin(1B4M)$_5$, $C_{230}H_{362}N_{54}O_{81}S_2$; G1Biotin(1B4M)$_6$, $C_{257}H_{398}N_{58}O_{93}S_2$; G1Biotin(1B4M)$_7$, $C_{284}H_{434}N_{62}O_{105}S_2$; G1Biotin(1B4M)$_8$, $C_{311}H_{470}N_{66}O_{117}S_2$]: 4632, 5241, 5849, 6457, 7065. SE-HPLC: R_t = 15.8 min. Elemental Analysis calcd for [G1(1B4M)$_6$($C_{23}H_{35}N_5O_7S$)Na_5(H_2O)$_{25}$]: C, 47.81; H, 7.17; N, 12.64; S, 1.00. Found: C, 47.88, 47.65; H, 7.17, 7.05; N, 12.56, 12.42; S, 0.91, 0.92.

Cleavage of Cystamine Core Dendrimer 1B4M-DTPA Gd(III) Conjugate (5). *Method A.* An aqueous solution of **3** (80 mg, ~7.2 μmol) in 5 mL was added to the immobilized TCEP reducing gel solution (1 mL) and the reaction mixture was gently stirred for 2 h. The reducing gel was filtered through a glass wool plugged glass pipet. Maleimide-PEO_2-biotin was added (7.9 mg, 15 μmol) and the mixture was stirred under N_2 atmosphere for 18 h. The reaction solution was then transferred to a Centriprep 3 (MWCO 3000 Da), exchanged to deionized water, and the completion of the filtration was monitored by SE-HPLC. The retentate was lyophilized and the product **5** was obtained as a white solid (46 mg, ~49%).

Method B. To a solution of **4** (20 mg, ~3.3 μmol) in 0. 3M citrate buffer (10 mL, pH = 4.5) was added $Gd(OAc)_3{\cdot}xH_2O$ (10.0 mg, 30.0 μmol). The solution was stirred at room temperature for 12 h and then transferred to a Centriprep 3 (MWCO 3000 Da) and subjected to exhaustive filtration with deionized water while monitoring with UV spectrometer at 650 nm using arsenazo III as an indicator (*23*). The retentate was lyophilized and the product **5** was obtained as a yellow solid (10 mg, ~47%).

MALDI-TOF: *m*/*z* 5475, 6243, 6902, 7666, 8328, calcd for [G1Biotin(Gd-1B4M)$_4$(CH_3COO^-)$_3{\cdot}$(H_2O)$_3$, $C_{209}H_{322}Gd_4N_{50}O_{78}S_2$; G1Biotin(Gd-1B4M)$_5$($CH_3COO^-$)$_3{\cdot}$($H_2O$)$_2$ Na, $C_{236}H_{350}Gd_5N_{54}O_{89}S_2Na$; G1Biotin(Gd-1B4M)$_6$($CH_3COO^-$)$_2H_2O$, $C_{261}H_{377}Gd_6N_{58}O_{98}S_2$; G1Biotin(Gd-1B4M)$_7$($CH_3COO^-$)$_2H_2O$, $C_{288}H_{407}Gd_7N_{62}O_{110}S_2$; G1Biotin(Gd-1B4M)$_8$$NaH_2O$, $C_{311}H_{432}Gd_8N_{66}O_{118}S_2Na$]: 5476, 6241, 6903, 7664, 8328. SE-HPLC: R_t = 16.4 min. Elemental Analysis calcd for [G1(1B4M)$_6$$Gd_{5.4}$($C_{23}H_{35}N_5O_7S$)($C_6H_7O_3$)$_2$$Na_{18}$($H_2O$)$_{32}$]: C, 39.81; H, 5.85; N, 10.06; S, 0.79; Gd, 10.51. Found: C, 39.57; H, 5.25; N, 10.50; S, 0.74; Gd, 10.55.

Cleavage of Cystamine Core Dendrimer Conjugate (6). An aqueous solution of **1** (60.6 mg, 18.1 μmol) in 5 mL was added to the immobilized TCEP reducing gel solution (2 mL) and the reaction mixture was gently stirred for 1 h. The reducing gel was filtered through a 50 mL tube top filter (Corning). Maleimide-PEO_2-biotin was added (19.0 mg, 36.2 μmol) and the mixture was stirred under N_2 atmosphere for 2.5 h. The reaction solution was lyophilized and the product **6** was obtained as an oil (66.0 mg, ~83%). ^{1}H NMR (D_2O, 300 Hz) δ 4.58 (m, 1H), 4.40 (m, 1H), 3.66 (s, 4H), 3.60 (m, 6H), 3.48 (t, J = 6.3 Hz, 16H), 3.38 (m, 8H), 3.30 (t, J = 6.9 Hz, 12H), 3.12 (t, J = 6.3 Hz, 16H), 2.98 (dd, J = 12.6, 6.0 Hz, 1H), 2.84 (t, J = 6.9 Hz, 28H), 2.76 (d, J = 12.6 Hz, 1H), 2.62 (t, J = 6.9 Hz, 12H), 2.50 (t, J = 6.9 Hz, 2H), 2.42 (t, J = 6.9 Hz, 28H), 2.23 (t, J = 6.9 Hz, 2H), 1.60 (m, 4H), 1.41 (m, 2H). ESI: *m*/*z* 2199.8, calcd for $C_{95}H_{183}N_{34}O_{21}S_2$ $[M + H]^+$, 2200.4.

Synthesis of Avidin Rhodamine Green Conjugate. Avidin (2 mg, 29 nmol) in Na_2HPO_4 (pH = 8.5, 495 μL, 0.1 M) was reacted with Rhodamine green-succinimidyl ester in DMSO (50 nmol, 5 μL, 10 mM) and was incubated at room temperature for 15 min. The mixture was then purified and the buffer changed to PBS (pH = 7.4) with Sephadex G50 (PD-10; GE Healthcare, Milwaukee, WI). The avidin-conjugated Rhodamine green (Av-RhodG) stock solution was stored at 4 °C.

The protein concentration of the Av-RhodG stock solution was determined with the Coomassie Plus Protein Assay Kit (Pierce Chemical Co., Rockford, IL) by comparing the absorption of the stock solution at 595 nm with a UV−vis system (8453 Value UV-Bis System, Agilent Technologies, Palo Alto, CA) against the absorption of solutions with known concentrations of avidin (100, 200, and 400 μg/mL). The final concentration of avidin in the Av-RhodG stock solution was determined to be ~0.022 mM. The stock solution concentration of RhodG was determined by the absorption at 504 nm measured after avidin was attached to the biotinylated dendrimer with a UV−vis system (8453 Value UV-Bis System, Agilent Technologies, Palo Alto, CA) to confirm the average number of RhodG molecules conjugated to each avidin molecule. The stock solution concentration of Rhodamine green dye was 0.033 mM. Thus, the ratio of RhodG to Avidin was determined to be ~1.5.

Reaction of Biotinylated Dendrimer 5 with the Avidin−Rhodamine Green. Avidin (800 μL, 0.15 mM in PBS) was mixed with Av-RhodG stock solution (200 μL, 0.022 mM in 1X PBS) at room temperature. Biotinylated dendrimer **5 (**2.98 mg) was added to this 1 mL solution at room temperature. Following the addition of unconjugated avidin, the final Av-RhodG concentration of the solution was 0.0044 mM, and through elemental analysis, the final Gd(III) concentration of the solution was found to be ~2 mM. This reaction was characterized by the HABA binding assay (*24*). In summary, HABA-avidin reagent was prepared according to the manufacturer's instructions by adding 300 μL of 10 mM HABA solution and 5 mg of avidin to 9.7 mL of PBS. HABA-avidin-biotinylated dendrimer sample was prepared by mixing 100 μL of biotinylated dendrimer solution (1 mg/mL PBS) with the 900 μL of HABA-avidin reagent. Afterward, the UV absorbance at 500 nm was recorded as 0.992 and 0.508 for 900 μL of HABA-avidin reagent and 1000 μL of HABA-avidin-biotinylated dendrimer solution, respectively. Using the calculation method described by the vendor ((Pierce Chemicals), approximately 0.75 biotin was conjugated to each dendrimer molecule.

Molar Relaxivity Measurements. Stock solutions of the biotinylated dendrimer **5** (5.0 Mm in Gd), biotinylated dendrimer-avidin-RhodG conjugate (1.25 mM in Gd), and native G2 dendrimer **1** (5.0 mM in Gd) were diluted to concentrations of 0.25 mM, 0.5 mM, 0.75 mM, and 1 mM in PBS. Solutions of Gd(III)-DTPA (Magnevist) at 1.97 mM, 0.99 mM, and 0.18 mM were prepared in PBS and used as a reference standard. Relaxivity measurements were obtained at ~22 °C using a 3-Tesla clinical scanner (Signa Excite, GE Medical System, Waukesha, WI) equipped with a rectangular single loop receiver coil (84 × 126 × 6 mm^3). A series of single-slice 2D multiple spin echo images of all the solutions were acquired at the same time with a TE around 9 ms and using different repetition times (TR = 167, 312, 625, 1250, 2500, and 5000 ms). The R_1 map was calculated from the averaged image of the 8 echo images at each TR and the R_2 map was calculated from the TR = 5000 ms image in *ImageJ* ((http://rsb.info.nih.gov/ij) using the MRI analysis plug-in (http://rsb.info.nih.gov/ij/plugins/mri-analysis.html). The T_1 and T_2 relaxivities, r_1 and r_2, were determined

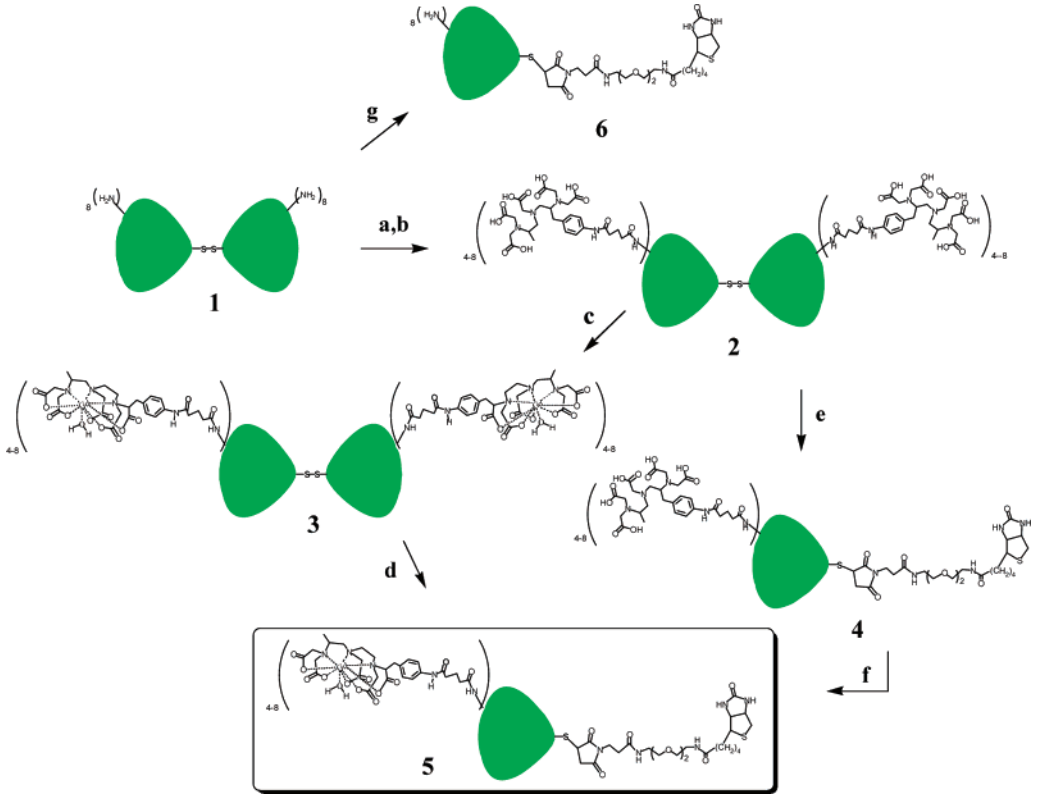

Figure 2. Synthesis of the monobiotinylated dendron for use as an MRI contrast agent. from the slope of R_1 or R_2 vs [Gd(III)] determined from region of interest measurements.

Cell Line and Cell Culture. SHIN3, an established ovarian cancer cell line (provided by Dr. Imai, Nara, Japan) (*20*), was used for generating intraperitoneal disseminated tumors. SHIN3 cell lines were grown in RPMI 1640 medium (Gibco, Gaithersburg, MD) containing 10% fetal bovine serum (Gibco), 0.03% L-glutamine at 37 °C, 100 U/mL penicillin, and 100 μg/mL streptomycin in 5% CO_2.

Tumor Model. All procedures were carried out in compliance with the Guide for the Care and Use of Laboratory Animal Resources (1996), the National Research Council, and were approved by the National Cancer Institute Animal Care and Use Committee. Xenografts of intraperitoneal (i.p.) tumor were introduced by an i.p. injection of 2×10^6 SHIN3 cells suspended in 200 μL of PBS in 6−8 week old female athymic nude mice (National Cancer Institute Animal Production Facility, Frederick, MD). Mice were used at 21 days post-implantation of the tumor cells.

Magnetic Resonance Imaging (MRI). All images for this study were obtained using a 3T clinical scanner (Signa Excite, GE Medical System, Waukesha, WI) equipped with a modified Alderman-Grant receive-only mouse coil (38 mm in diameter × 70 mm in length).

Mice were anesthetized using gas mixtures of 1.5−2.5% isofluorane in O_2 to maintain a respiration rate of ∼30 bpm during the acquisition of all images. Each mouse was given an i.p. injection of 300 μL of a 2 mM [Gd(III)] (600 nmol of Gd(III)) solution. A T_1-weighted 3D-fast spoiled gradient echo image (matrix size of 256 × 512 pixels, slice thickness of 0.6 mm, repetition time of 11.2 ms, echo time of 3.9 ms, and 4 averages; total scan time of 3 min 41 s.) and a T_2-weighted multislice fast spin echo short time inversion recovery (FSE-STIR) fat suppressed image (matrix size of 192 × 384 pixels, slice thickness of 1.0 mm, repetition time of 5000 ms, echo time of 46.3 ms, 2 averages, and inversion time of 175 ms; total scan time of 5 min 30 s) were obtained prior to injection of the imaging agent ($t = 0$ h), at 2 h postinjection ($t = 2$ h), at 4 h postinjection ($t = 4$ h), and 6.5 h postinjection ($t = 6.5$ h). The mice were allowed to recover from anesthesia in between imaging time points.

Fluorescence Imaging. After the final MR image was acquired for each mouse, the mouse was sacrificed by CO_2 inhalation. The abdominal wall was then incised and the abdominal cavity was exposed for spectral fluorescence imaging using the Maestro *In Vivo* Imaging System (CRi, Inc., Woburn, MA). Whole abdominal images were obtained using a 445−490 nm band-pass excitation filter and a 515 nm long-pass emission filter. The tunable filter was automatically stepped in 10 nm increments from 500 to 800 nm, while the camera captured images at each wavelength interval with constant exposure. Spectral unmixing was performed using the Maestro software (CRi, Inc., Woburn, MA) to create unmixed and composite images of RhodG and autofluorescence spectra.

Histological Studies of Tumor Tissue. SHIN3 tumor xenografts were confirmed by histological methods as previously reported (*16*). In summary, every fluorescent nodule produced through avidin−fluorophore binding contained cancer cells as visualized by standard hematoxylin and eosin stain; no false positives were found.

RESULTS AND DISCUSSION

Biotin is a small, naturally occurring vitamin that binds with high specificity and affinity ($K_{ass} = 1.7 \times 10^{15}$ M^{-1}) to avidin (*17*). The "avidin chase-biotin" system has been coupled to MRI contrast agents to rapidly clear blood pool agents to the liver in order to investigate blood volume and vascular permeability (*21*). In the present experiment, our goal was to use the binding

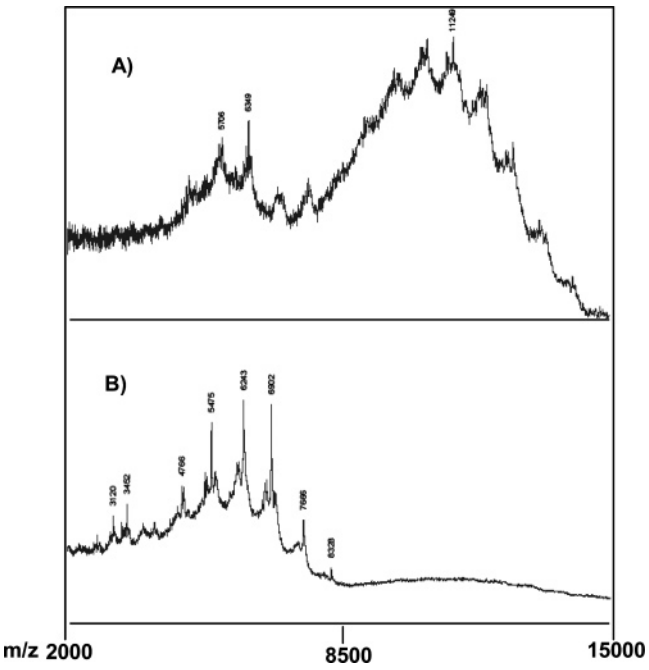

Figure 3. MALDI-TOF mass spectra of (A) cystamine core dendrimer chelated Gd(III) conjugate **3** and (B) biotinylated dendrimer **5**.

affinity of avidin for cell surface lectins found on ovarian cancer cells to provide targeted imaging using dendrimers to amplify the MR signal. To synthesize a single biotinylated dendrimer **5**, dendrimer **1** was reacted with 2 equiv of NHS-1B4M-DTPA (*22*) per each primary amine available on the surface of the dendrimer at pH = 7 in DMSO (Figure 2). After the reaction mixture was stirred under N_2 atmosphere for 24 h, *N*-(2-aminoethyl)aminomethyl polystyrene resin was added as a reactive scavenger to remove excess NHS-1B4M-DTPA. After stirring for 18 h, the resin was removed by filtration; the resulting mixture was diluted with CH_2Cl_2 and then washed with H_2O. The organic layer was concentrated and treated with pure trifluoroacetic acid (TFA) to cleave the *tert*-butyl protecting group esters on the 1B4M-DTPA for future complexation of Gd(III) ions. To purify dendrimer **2**, the TFA was first evaporated and the residue was then dissolved in deionized water. The aqueous solution was transferred to a Centriprep 3 with a 3000 Da cutoff membrane and subjected to exhaustive filtration with deionized water while monitoring with SE-HPLC. The retentate was lyophilized, and the product was obtained as a white solid with an overall 62% yield.

Last, the 1B4M-DTPA moieties on the functionalized dendrimer **2** were used to complex Gd(III) by addition of a solution of $Gd(OAc)_3$ in 0.3 M citrate buffer at pH = 4.5. Excess Gd(III) was removed by exhaustive filtration. Product **3** was isolated as a white powder after lyophilization in 72% yield. A single peak with a retention time of 14 min by SE-HPLC indicated the excellent purity of agent **3**.

Dendrimer **2** was also analyzed by MALDI-TOF mass spectrometry. The mass spectra give rather broad signals; however, the mass peak pattern was consistent with previous dendrimer MALDI-TOF mass analysis (*22*). In the case of 1B4M-DTPA modified dendrimer **2**, a mixture of functionalized dendrimers was actually observed, corresponding to 8−16 chelators being covalently attached to the dendrimer. Among them, the dendrimer with 12 conjugated 1B4M-DTPA chelators gave the highest-intensity mass signals. For Gd(III)-complexed dendrimer **3**, the mass peak pattern was very similar to that of **2**. However, each mass signal was shifted ~157 × *n* (*n* = number of chelators) higher mass units, indicating each 1B4M-DTPA moiety on the dendrimer **2** fully complexed Gd(III).

Reducing the disulfide bond within the dendrimer core was critical for attaching biotin or other promising targeting moieties. Several disulfide reducing agents such as dithiotreitol (DTT), tris(2-carboxyethyl)phosphine (TCEP), and immobilized TCEP were evaluated for this step. All were able to reduce the disulfide bond and produce a free sulfhydryl dendron product as determined by both an Ellman's test and SE-HPLC. However, immobilized TCEP was finally chosen because its use eliminated the need for exhaustive dialysis to separate the reduced dendrimer from the reducing agent and thus minimize potential reoxidation of the sulfhydryl dendron back to the disulfide dendrimer. Thus, immobilized TCEP reducing gel was added to an aqueous solution of dendrimer **3** and gently stirred for 2 h. Thereafter, the reducing gel was filtered off by using a glass pipet with a glass wool plug. The filtrate was used for the

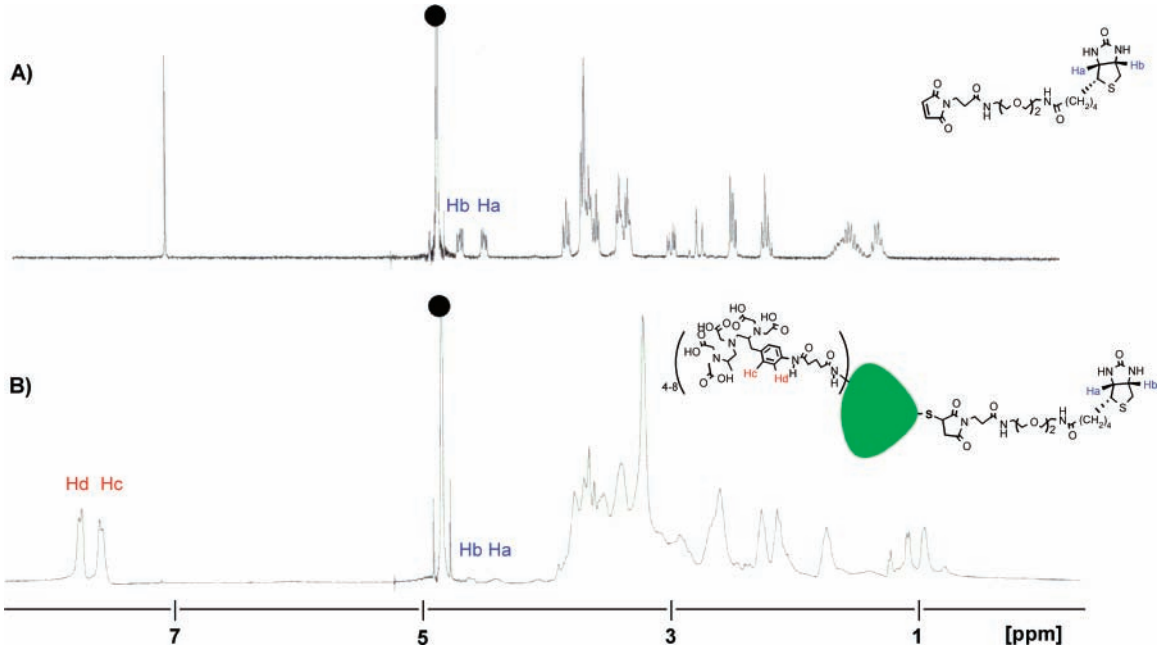

Figure 4. ^1H NMR spectra (300 MHz, 295 ± 1 K, D_2O) of (A) maleimide-PEO_2-biotin and (B) biotinylated cystamine core dendrimer chelated conjugate **4**. The residual solvent signals are marked as ●.

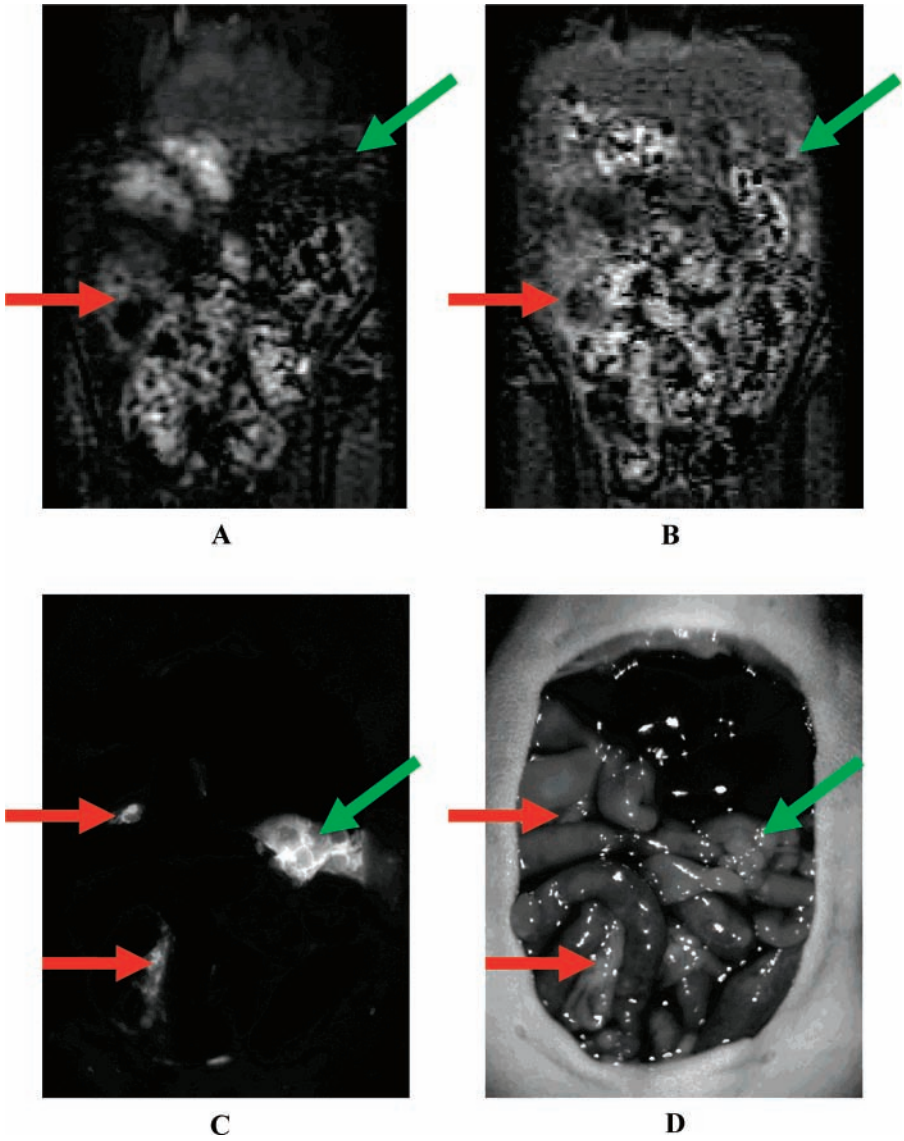

Figure 5. (a) T_1-weighted MR image obtained prior to contrast agent injection ($t = 0$) reveals an area of tumor growth (low signal intensity) below the liver, stomach, and spleen in the left abdomen (blue arrow) and adjacent to the gastrointestinal tract in the lower right abdomen (orange arrow). (b) T_1-weighted MR image obtained at 6.5 h after i.p. injection of the dual contrast agent reveals signal enhancement on the surface of the tumors (blue and orange arrows). (c) Spectrally unmixed optical image demonstrates fluorescence corresponding to sites of tumor (arrows). (d) White-light photo of the exposed abdomen confirms the presence of tumor in the locations predicted by MR and optical imaging although they are considerably more difficult to see.

coupling reaction with maleimide-PEG-biotin. The average number of the sulfhydryls was determined using Ellman's reagent, and thus, the concentration of the free thiol-bearing dendrimer was calculated to be twice as much as dendrimer **3**, indicating that the disulfide bonds inside the dendrimer were reduced quantitatively.

A 1.1 equiv quantity of maleimide-PEG-biotin was used for the conjugation to sulfhydryl dendrons, and the reaction mixture was then stirred under N_2 atmosphere overnight. The resulting mono-biotin-functionalized dendrimer **5** was separated from low molecular weight impurities by dialysis as described above and lyophilized. SE-HPLC, CHN elemental analysis, and MALDI-TOF mass spectra were employed to characterize agent **5**. Typically, SE-HPLC spectra showed a new peak with a retention time of ~16 min, ~1 min later compared to its precursor. As expected, MALDI-TOF mass spectra showed a mixture of single biotinylated dendrimers bearing ~5 Gd(III)-1B4M-DTPA moieties, respectively, while mass signals of dendrimers with 5 and 6 chelators have much higher intensity than others (Figure 3). Notably, the most distinct mass signal for each biotinylated dendrimer is not $M^+ + H$ but molecular ion plus several counter-ions (e.g., acetate ions) and H_2O molecules. One possible explanation is that each Gd(III)-DTPA moiety on the dendrimer **5** has one open coordination site for H_2O molecule and also 3 positive charges that electronically attract counter-ions (i.e., acetate ions). In terms of the number of chelators, this analytical result of 4−8 chelators on the biotinylated dendrimer **5** was consistent with that of its precursor dendrimer **3** attaining 8−16 1B4M-DTPA moieties.

The extent of biotinylation and ratio of biotin to dendrimer were determined by the HABA-avidin assay (*24*). Upon addition of biotinylated dendrimer **5** (100 μL, ~1.54×10^{-4} mM) to a solution of avidin (900 μL, ~7.35×10^{-3} mM in PBS buffer) containing 10 equiv of HABA per binding site, HABA was displaced by biotinylated dendrimer, resulting in a decrease in the UV absorption at 500 nm from 1.01 to 0.53. By using an extinction coefficient of 34 000 M^{-1} cm^{-1} for HABA/avidin samples at 500 nm, 0.73 biotin structures per dendrimer were calculated. This binding assay confirmed that avidin could be successfully employed as a supramolecular scaffold to carry multiple copies (up to four) of Gd(III)-DTPA biotin-functionalized dendrons.

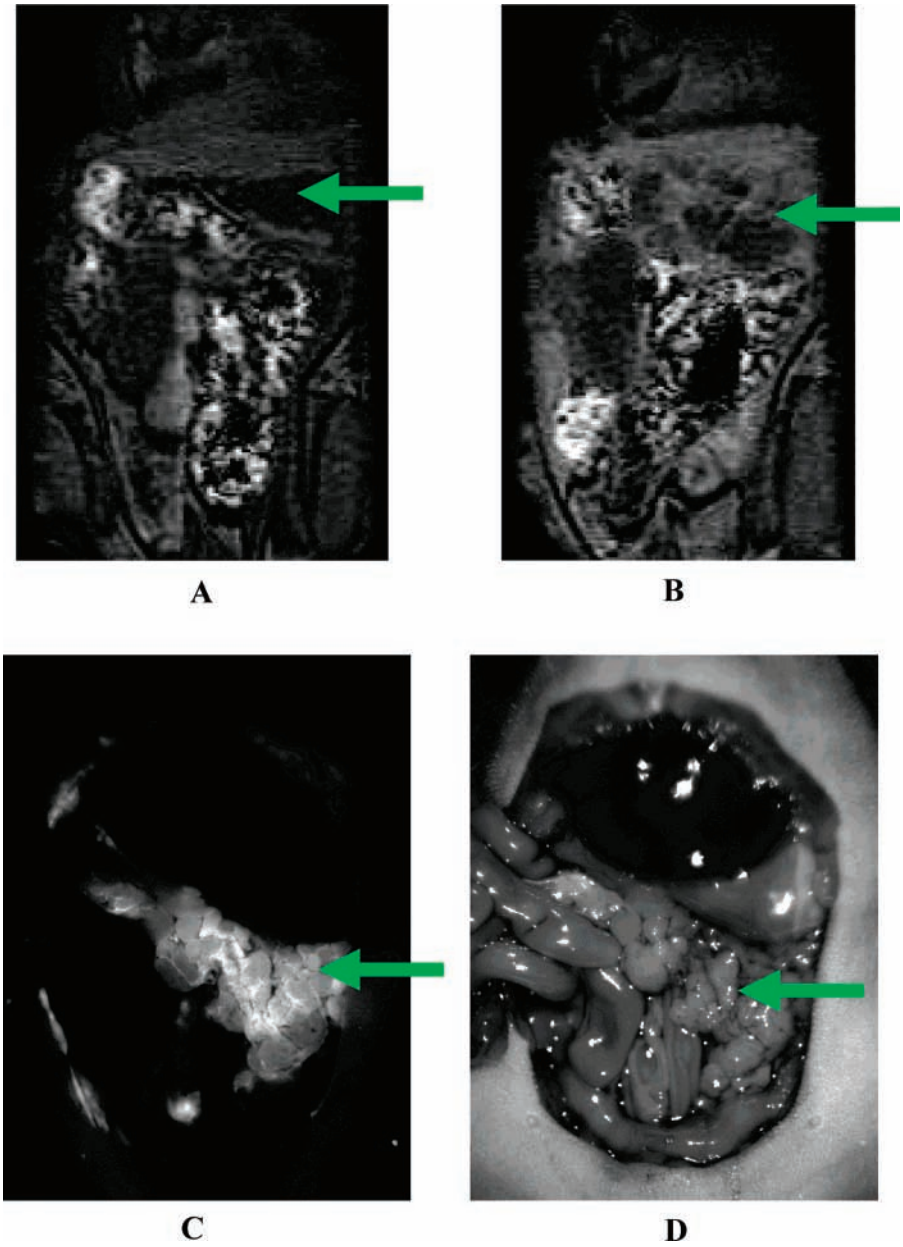

Figure 6. (a) T_1-weighted MR image obtained prior to contrast agent injection ($t = 0$) reveals a tumor (low signal intensity) below the liver and stomach in the left abdomen (blue arrow). (b) T_1-weighted MR image obtained at 6.5 h reveals signal enhancement from the edge of the tumor (blue arrow). (c) Spectrally unmixed optical image demonstrates fluorescence within the tumor. (d) White-light photo of the exposed abdomen confirms the presence of tumor in the locations predicted by MR and optical imaging.

Using the above conditions, dendrimers **1** and **2** could also be reduced to produce a unique sulfhydryl group and then coupled with maleimide-PEO_2-biotin to generate **6** and **4**, respectively, which were characterized by ^{1}H NMR, ESI-MS, and SE-HPLC. Typically, in ^{1}H NMR spectra of **4** and **6** (Figure 4), two diagnostic signals at ~4.38 and 4.56 ppm from the SCHC*H* and SCH_2CH protons of the biotin moiety were evident, while disappearance of the signal for the maleimide protons at ~6.90 ppm indicated complete removal of unbound biotin compounds after purification by exhaustive filtration. For compound **4**, a ~1:5 ratio of biotin/chelate was obtained by comparing the integrals of the signals from the biotin SCHC*H* and SCH_2CH protons (4.20−4.60 ppm) and the characteristic aromatic protons (7.15−7.60 ppm) from the 1B4M-DTPA. SE-HPLC spectra showed that reduced dendrimer **4** had a retention time ~0.8 min longer than **2**, supportive of the decreased size of **4**. For **6**, the $[M + H]^+$ peak (theoretical, 2200.4; found, 2199.8) on ESI-MS spectra confirmed this compound's identity.

Saturation of amino-terminated dendrimer 6 with NHS-1B4M-DTPA, following by deprotection of *tert*-butyl ester and incorporation of Gd(III), provides an alternative approach to generate biotinylated agent **5**. Additionally, other imaging labels can be also envisioned, for example, fluorescence dyes, being combined with 1B4M-DTPA (e.g., MRI agents) by attachment with 8 amino groups in the periphery of **6** for targeted multimodality imaging purposes.

Attempts were made to react biotinylated dendrimer **6** directly with NHS-1B4M-DTPA and then remove the *tert*-butyl esters with TFA for preparation of **4**. However, in our hands, isolation of the desired product **4** from excess 1B4M-DTPA chelators using the 3000 cutoff membrane Centriprep was not successful due to the ~6000 molecular weight dendrimer agent **4** significantly passing through the membrane during the extensive

dialysis process. Alternate isolation methods are currently being pursued to provide for the flexibility of alternate agent preparations that this route might permit.

Biotinylated-Dendrimer Conjugated to Avidin-Rhodamine Green. The avidin−biotin targeting system can be a carrier biomolecule to deliver imaging and/or therapeutic agents into cancer cells that express β-D-galactose receptors, namely, ovarian and colorectal adenocarcinoma cells (*13*−*16*). Previous studies have demonstrated the efficacy of the avidin−biotin targeting system. For example, while a G4 dendrimer conjugated with radioactive antisense oligo-DNA was able to independently increase delivery of the antisense oligo-DNA to SHIN3 cells, this delivery was further enhanced through avidin−biotin targeting (*18*). Additionally, avidin−biotin targeting of optical fluorophores to SHIN3 cells improved the ability to detect tiny foci of peritoneal implants (*16*). The avidin−biotin targeting system has also been employed as an internalizing tumor-targeting reagent in ovarian cancer to potentially deliver large quantities of Gd(III) (in the form of biotinylated Gd(III)-1B4M functionalized G6 dendrimers) for Gd-neutron capture therapy (*19*). However, inability to accurately control the 1:1 biotin−dendrimer ratio compromised the reproducibility of the avidin−biotin−dendrimer complex. In the current study, the design strategy takes advantage of a new family of dendrimers that possess a cystamine core (*12*). A single biotin moiety was attached to a reduced dendron using well-established sulfhydryl and maleimide chemistry. Through this approach, it is likely that the control of the incorporation of dendrimer moieties into the avidin complex will be more accurate.

Furthermore, avidin has the added benefit of being able to be conjugated to an optical fluorophore, thus allowing for dual-modality imaging. A dual-reporter probe has a distinct clinical advantage over a single-reporter probe in that a dual-reporter probe can be used in both preoperative planning and during the surgical debulking procedure for peritoneal metastases. However, the different sensitivities of the two types of imaging reporters require different amounts of each type of reporter to be employed to assemble the complex. In this case, to account for the much higher sensitivity of optical fluorescence compared to MR, the number of optical fluorophores required to produce an acceptable fluorescence image is much smaller when compared to the number of Gd(III) complexes required for an MR image. Using 100% Rhodamine green-conjugated avidin as the targeting vector will result in an overwhelming amount of Rhodamine green being delivered to the ovarian cancer cells and would potentially increase self-quenching of that signal. For this reason, preparation of the biotin−dendrimer agent included the addition of unlabeled avidin (nonfluorescent) to effectively dilute the concentration of Rhodamine green-conjugated avidin molecules to 0.0044 mM as compared to the ~2 mM concentration of Gd(III) ions on the surface of the dendrons. This method of preparation corrected for the sensitivity differences between the two modalities generating a solution that would deliver sufficient amount of Gd(III) complexes for an acceptable MR image while maintaining an adequate concentration of Rhodamine green to provide an acceptable optical image with the added benefit of limiting possible fluorescence self-quenching.

Relaxivity. The T_1 relaxivity measurements for the native G2 dendrimer (**1**), the biotinylated dendron (**5**), biotinylated dendrimer-avidin-RhodG conjugate, and Gd(III)-DTPA (Magnevist) were 14.7 mM^{-1} s^{-1} ($R^2 = 1$), 11.0 mM^{-1} s^{-1} ($R^2 = 0.99$), 12.4 mM^{-1} s^{-1} ($R^2 = 1$), and 5.3 mM^{-1} s^{-1} ($R^2 = 1$), respectively. These results confirm previous reports (*5*, *8*−*11*) that dendrimers have higher relaxivity compared to low-molecular-weight contrast agents such as Gd(III)-DTPA (Magnevist) and demonstrate that the biotinylation of the dendron and the conjugation of avidin to the biotinylated dendron do not adversely affect this enhancement.

Magnetic Resonance Images and Optical Fluorescent Images. The T_1-weighted MR images obtained prior to injection of the biotinylated dendrimer-avidin-RhodG conjugate (Figures 5a and 6a) failed to detect tumors (which are low in signal intensity) in the abdomen. The images acquired at 2 and 4 h (not shown) demonstrated that free contrast agent remained within the peritoneal cavity, making it impossible to identify specific tumor binding. However, images acquired at 6.5 h were clear of excess unbound conjugate. The T_1-weighted MR images (Figures 5b and 6b) showed areas of enhancement on the surface of the tumors as confirmed by spectral fluorescence imaging (Figures 5c and 6c), white-light photos (Figures 5d and 6d), and histology (*16*). In all cases, the areas of signal enhancement in the T_1-weighted images corresponded to hyperintense areas in T_2-weighted STIR images. The spectral fluorescence imaging (Figures 5c and 6c) demonstrated intense RhodG fluorescence while minimizing background fluorescence which, in combination with all images obtained, suggests that biotinylated dendrimer-avidin-RhodG conjugate was in fact targeting and enhancing visualization of SHIN3 tumor cells.

In conclusion, a novel synthetic approach for the preparation of a single biotinylated dendrimer-based MRI agent conjugated to fluorescently labeled avidin has been presented. Higher-generation dendrimers (e.g., G3−G8) with cystamine cores are currently being explored for this application. Additionally, in principle, any interesting biological targeting groups bearing a maleimide moiety can be now attached to a Gd(III)-DTPA functionalized dendrimer in a site-specific operation. Thus, this synthetic route provides a versatile strategy for designing and synthesizing targeted dendrimer-based MRI agents. Ongoing research is focused on constructing dendrimer−monoclonal antibody and dendrimer−peptide conjugates for use in targeted radiation therapy and imaging.

Antisense Oligodeoxynucleotide-Conjugated Hyaluronic Acid/Protamine Nanocomplexes for Intracellular Gene Inhibition

Hyejung Mok, Ji Won Park, and Tae Gwan Park*

Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Daejeon 305-701, South Korea.
Received April 3, 2007; Revised Manuscript Received May 17, 2007

Green fluorescent protein (GFP) antisense oligodeoxynucleotide (ODN) was covalently conjugated to hyaluronic acid (HA) via a reducible disulfide linkage, and the HA−ODN conjugate was complexed with protamine to increase the extent of cellular uptake and enhance the gene inhibition efficiency of GFP expression. The HA−ODN conjugate formed more stable polyelectrolyte complexes with protamine as compared to naked ODN, probably because of its increased charge density. The higher cellular uptake of protamine/HA−ODN complexes than that of protamine/naked ODN complexes was attributed to the formation of more compact nanosized complexes (∼200 nm in diameter) in aqueous solution. Protamine/HA−ODN complexes also showed a comparable level of GFP gene inhibition to that of cytotoxic polyethylenimine (PEI)/ODN complexes. Since both HA and protamine are naturally occurring biocompatible materials, the current formulation based on a cleavable conjugation strategy of ODN to HA could be potentially applied as safe and effective nonviral carriers for ODN and siRNA nucleic acid therapeutics.

INTRODUCTION

Recently, efficient and specific down-regulation of therapeutically important genes has received special attention to treat various genetic and infectious diseases, including cancer (*1*−*3*). Nucleic acid-based drugs, such as antisense oligodeoxynucleotide (ODN), ribozyme, and small interfering RNA (siRNA), have been shown to inhibit expression of target proteins at post-transcriptional level. While they show highly sequence-specific gene silencing behaviors, critical delivery problems such as poor intracellular uptake and severe enzymatic degradation still remain to be solved for successful in vivo therapeutic applications (*4*−*6*). To improve their intracellular uptake and nuclease-resistant stability, a variety of cationic agents including polymers, polypeptides, and lipids were complexed with anionic nucleic acid drugs to produce nanosized polyplexes and lipoplexes. The nanoscale complexes can readily be transported into cells via an endocytic pathway while protecting the genetic drugs from degradation by nucleases. Among the cationic synthetic polymers, poly(ethylenimine) (PEI) and poly L-lysine (PLL) have been widely used to form nanosized polyelectrolyte complexes to deliver plasmid DNA, ODN, and siRNA (*7*−*12*). It is generally known that high molecular weight (MW) PEI and PLL produce more stable polyplexes with plasmid DNA than low MW polyplexes, generally resulting in increased gene transfection efficiency (*13*). This is because the charge density (the number of charges per polymer chain) of cationic polymers plays an utmost important role in maintaining the colloidal structural stability of polyelectrolyte nanocomplexes, especially in the transfection medium containing high salt concentration. The charge density effect on complex stability is closely related to inter- and intramolecular chain entanglement and mixing degree of two oppositely charged polyelectrolytes upon complexation. However, using high MW PEI and PLL as nonviral gene carriers has often elicited harmful cytotoxic effects, adversely influencing gene transfection efficiency. For producing stable and compact polyplexes, two oppositely charged polyelectrolytes (cationic polymer and DNA) must have sufficient charge densities for complexation. To form stable and non-cytotoxic polyplexes with ODN, reducible or self-degradable cationic polymers have been used to increase charge density for improved complex stability without compromising the cytotoxicity problem (*14*−*17*). The immediate degradation of reducible or self-degradable cationic polymers after cellular uptake produced less cytotoxic low MW fragments tolerable to the cells.

Antisense ODN is a single strand DNA composed of about 20 nucleotides with MW of around 5000, which has very low charge density compared to plasmid DNA with MW of a few million. Accordingly, when ODN was complexed with cationic polymers, the resultant ODN polyplexes often exhibited much reduced colloidal stability than that of the plasmid DNA polyplexes, mainly because of insufficient charge density of ODN.

Protamine is a nontoxic, cationic, and naturally occurring polypeptide which is known to provide unique membrane-translocating and nuclear-localizing activities because of its arginine-rich sequence (*18*−*22*). Although protamine has been used as a condensing agent for ODN, the transfection efficiency of protamine/ODN polyelectrolyte complexes was far less than that of high MW PEI or PLL (*23*, *24*). This was probably because both protamine and ODN did not have sufficient MW and charge density to form stable colloidal complexes, in addition to the presence of weak basic guanidine groups in protamine.

In this study, antisense GFP ODN was conjugated to anionic and biocompatible HA via a cleavable disulfide linkage to increase the charge density of ODN. HA, composed of *N*-acetyl-D-glucosamine and D-glucuronic acid, was expected to provide enough charge density to the conjugated ODN. The HA−ODN conjugate was complexed with clinically acceptable low MW protamine to improve the stability of HA−ODN/protamine polyelectrolyte complexes and increase gene inhibition efficiency. Anti-sense GFP ODN was used for conjugation to HA. HA−ODN/protamine complexes were physically characterized,

and their inhibition extent of GFP expression was evaluated using HEK293 cells.

MATERIALS AND METHODS

Materials. Hyaluronic acid (sodium salt form, MW 17 000) was obtained from Lifecore Biomedical (Chaska, MN). Dialysis membrane (MW cutoff, 50 000) was a product from Spectrum (Houston, TX). GFP Antisense ODN (GAGCTGCACGCTGCCGTC, 5′ amine modification, MW 5656) was purchased from Bioneer (Daejeon, Korea). Plasmid DNA (pEGFP-C1) was extracted from transformed *Escherichia coli* by a standard alkaline lysis technique and purified by a DNA-purification column which was obtained from QIAGEN (Valencia, CA) according to the manufacturer's instruction. The purity and concentration of plasmid DNA was determined by measuring the absorbance ratio at 260/280 nm using a spectrophotometer (UV-1601, Shimadzu, Japan). *N*-Succinimidyl 3-(2-pyridyldithio)-propionate (SPDP) was purchased from Pierce (Rockford, IL). Dulbecco's phosphate-buffered saline (PBS), fetal bovine serum (FBS), and DMEM were purchased from Gibco BRL (Grand Island, NY). A pEGFP-C1 vector was obtained from BD Bioscience Clontech (Palo Alto, CA). Protamine, [1-ethyl-3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC), PEI (branched, MW 25 K), cystamine, and dithiothreitol (DTT) were purchased from Sigma (St. Louis, MO). Cell counting kit-8 (CCK-8) was obtained from Dojindo Laboratories (Kumamoto, Japan). All other chemicals and reagents were of analytical grade.

Methods. *Synthesis and Characterization of ODN-Conjugated Hyaluronic Acid.* For preparation of thiol-modified hyaluronic acid (HA, MW 17 000), HA (200 mg) dissolved in PBS solution (pH 7.0) was added into 4 mL of dimethyl sulfoxide (DMSO)/deionized water mixture (50/50 (v/v)) containing EDC (194 mg) and HOBt (138 mg). To the solution was added cystamine (229 mg) for conjugation overnight. After treating with DTT (DTT:cystamine molar ratio = 4:1), the whole solution was dialyzed against deionized water using a membrane (MW cutoff: 3500) for 2 days and lyophilized. ^{1}H NMR spectra were taken with a Brucker DRX 300 NMR operating at 300.13 MHz by using D_2O to determine the degree of cystamine modification. The degree of thiol substitution in HA was calculated based on the molar ratio of thiol groups in thiolated HA to the total carboxylic acid groups in unmodified HA. The amount of thiol groups per HA chain was also quantified by the Ellman's assay.

To prepare the HA−SS−ODN conjugate (HA−ODN), 2-pyridyl disulfide-activated ODN was first synthesized by adding SPDP (275 μg) in DMSO to the PBS solution (pH 7.4) containing 5′-amine-modified antisense ODN (500 μg). After reaction for 5 h at room temperature, the unreacted SPDP was removed by using a desalting column (D-Salt dextran desalting column, Pierce, Rockford, IL). The activated ODN (340 μg) was reacted with 2.4 mg of thiol-modified HA in PBS solution at room temperature for 2 days. The unreacted antisense ODN was removed by dialysis against deionized water (MWCO 10 000). The resulting product, HA−ODN conjugate, was analyzed by polyacrylamide gel (20%) electrophoresis. The electrophoresis was carried out at a voltage of 120 V for 1 h in TAE buffer solution (40 mM Tris-HCl, 1% (v/v) acetic acid, 1 mM EDTA). Antisense ODN was visualized by ethidium bromide (EtBr) staining. HA−ODN conjugate was also analyzed by gel permeation chromatography (GPC) using a Waters 510 HPLC pump system (Waters 486, Waters, Milford, MA) equipped with a refractive index detector (Shodex RI-71, Kawasaki, Japan). GPC analysis was performed on a column (Ultrahydrogel 250, 7.8 × 300 mm, Waters) using distilled water as an eluant with a flow rate of 1 mL/min. To evaluate cleavability of the disulfide linkage for HA−ODN conjugate, the sample was incubated in 50 mM of glutathione solution for 1 h or 2 h and injected to the GPC system to separate the fraction of cleaved ODN from the HA−ODN conjugate.

Preparation and Characterization of Protamine/HA−ODN Complexes. Naked ODN or HA−ODN conjugate (4 μg) dissolved in 100 μL of PBS (pH 7.4) solution was mixed with various amounts of desalted protamine (0.4, 2, 4, and 64 μg) dissolved in 100 μL of PBS solution. After incubation for 15 min at room temperature, 2.8 mL of PBS solution was added to the mixture. To determine the hydrodynamic diameter of nanocomplexes formed from ODN or HA−ODN with protamine, the resulting complex solutions were analyzed by a dynamic light scattering instrument (Zeta-Plus, Brookhaven, NY). To evaluate stability of the protamine/HA−ODN complexes, a polyanion competition assay was done as previously reported (*25*). After preparation of nanocomplexes from ODN or HA−ODN (nucleotide 1 μg) with protamine (16 μg) by incubation in 20 μL of PBS solution for 15 min, different amounts of heparin (0, 4, 10, 50, and 100 μg) were added to the solution and incubated for 15 min. The mixture solution was subjected to 1% agarose gel electrophoresis running at 100 V for 20 min. The fraction of decomplexed ODN by heparin was visualized in the gel by staining with EtBr.

Intracellular Uptake Assay. HEK293 cells were maintained in DMEM medium supplemented with 10% FBS, 100 units/mL penicillin, and 100 μg/mL streptomycin at 37 °C in a humidified atmosphere of 5% CO_2. Cells were regularly passaged at subconfluence and plated on a four-well chamber slide at 24 h before transfection. On the next day, the cells were transfected with protamine/ODN or protamine/HA−ODN complexes formulated at a protamine/ODN weight ratio of 7.5. To visualize antisense ODN, a FITC-labeled sense ODN having a complementary sequence to antisense GFP ODN (FITC-sense ODN) was hybridized with either naked ODN or HA−ODN conjugate. After 5 h incubation, cells were washed three times with cold PBS solution and fixed with 1% (w/v) paraformaldehyde solution for 30 min at 4 °C. The nucleus was stained with DAPI (4′,6-diamidino-2-phenylindole) dye, a double strand DNA specific marker. Uptake of antisense ODN within the HEK293 cells was visualized by confocal microscopy (Carl Zeiss, Germany).

Cell Culture and Transfection. For GFP gene silencing experiments, GFP plasmid DNA was cotransfected with protamine/ODN or protamine/HA−ODN complexes to HeLa cells (human cervical cancer cell line), according the previously published method with minor modifications (*26*). Briefly, the cells were cotransfected in serum free medium with pEGFP-C1 plasmid (1 μg) using Lipofectamine 2000 reagent (2 mg/mL, Invitrogen, Carlsbad, CA) and protamine/ODN or protamine/HA−ODN complexes formulated at a protamine/ODN weight ratio of 1.5 and 6 (ODN amount: 1 μg). Polyelectrolyte complexes formed from PEI and naked ODN (1 μg) formulated at an N/P ratio of 8 were used as a positive control. After 5 h incubation, medium was replaced with new DMEM medium containing 10% FBS. After 48 h, transfected cells were harvested by treating with a cell lysis solution (1% Triton X-100 in PBS solution) and centrifuged to remove cell debris. The supernatant was analyzed to determine the amount of GFP protein expression using a spectrofluorophotometer (SLM-AMINCO 8100, SLM Instruments Inc., Rochester, NY) with an excitation and emission wavelength at 488 and 507 nm, respectively. All values were normalized by the cellular protein amount which was determined by the Micro-BCA protein assay (Pierce, Rockford, IL). Relative GFP expression level was then calculated as relative percentage using that of pEGFP-C1 transfected HeLa cells as 100% (*26*).

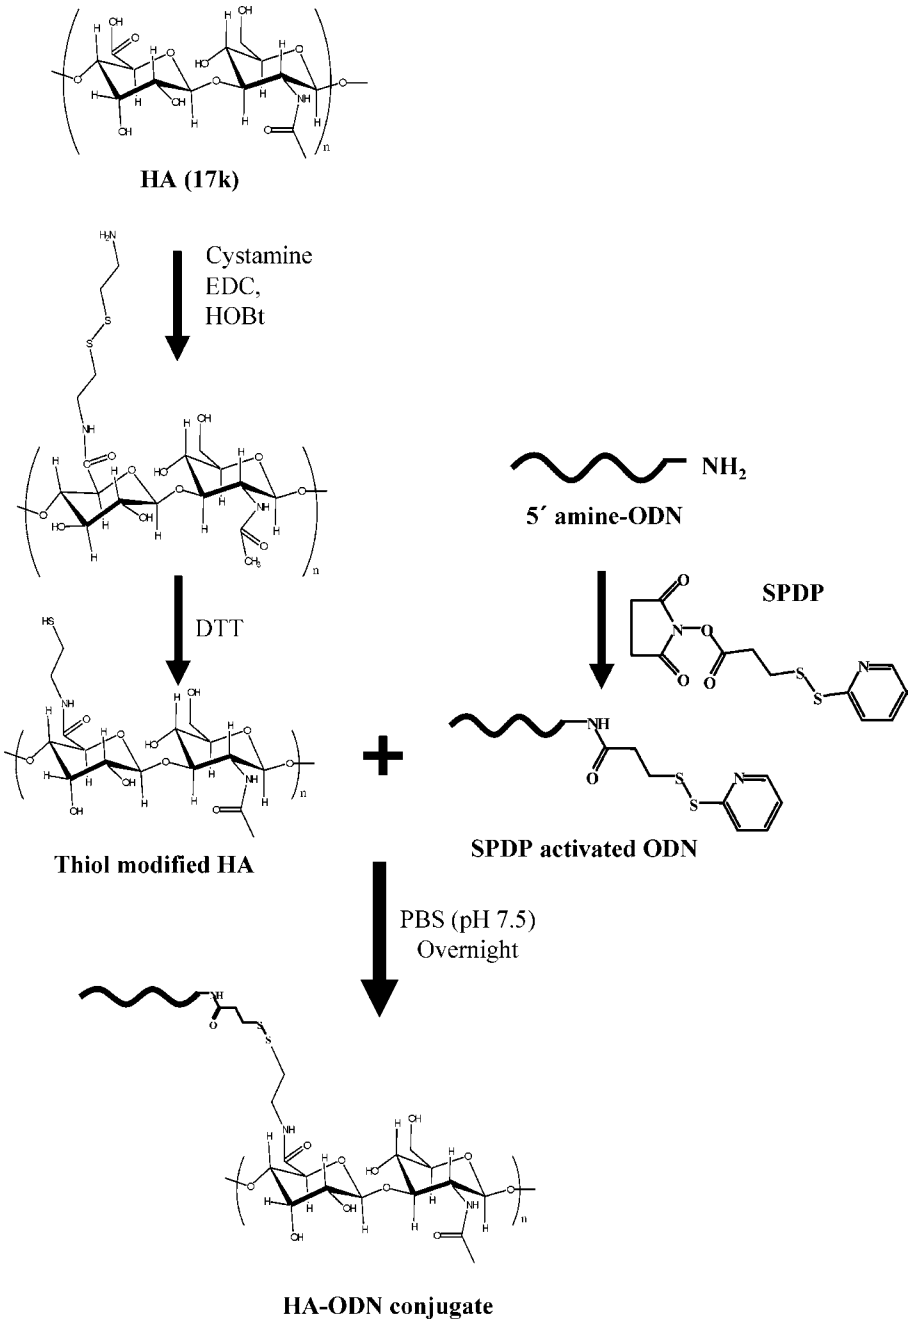

Figure 1. Synthetic scheme of thiolated HA and HA−ODN conjugate.

The cytotoxicity of the two cationic polymers, protamine and PEI, was evaluated by the CCK-8 cell viability assay which depends on the mitochondrial dehydrogenase activity of the cells. HEK 293 cells were seeded in a 96-well plate at a density of 1×10^4 cells per well and grown in DMEM medium supplemented with 10% (v/v) fetal bovine serum for 24 h at 37 °C. On the next day, protamine or PEI was added to the culture medium to give a final concentration of 0 to 160 μg/mL. After further incubation for 24 h, the number of viable cells was determined by the CCK-8 cell viability assay according to the manufacturer's protocol.

RESULTS AND DISCUSSION

Synthetic schemes of thiol-modified hyaluronic acid (HA) and HA−ODN conjugate are shown in Figure 1. The degree of cystamine substitution in the total carboxylic acid group in HA was 27.4 ± 3.4% as quantified by ^{1}H NMR (data not shown). The conjugation extent of cystamine was determined by relating the relative peak area of $NHCH_2CH_2SH$ (2.55 ppm) protons of cystamine to that of $COCH_3$ (1.86 ppm) protons of HA. The degree thiol substitution in HA was 20.8 ± 9.2%, and the number of thiol group in HA after DTT treatment was 8.8 ± 3.9 per HA chain, as quantified by Ellman's assay.

The primary amine group at the 5′-end of antisense ODN was first reacted with an active NHS group of a hetero-bifunctional cross-linker, SPDP (*N*-succinimidyl 3-(2-pyridyldithio)propionate), to produce 2-pyridyl disulfide-activated ODN. Thiol-modified HA was then added to the 2-pyridyl disulfide-activated ODN to obtain the HA−SS−ODN conjugate (HA−ODN) via a sulfhydryl exchange reaction. The HA−ODN conjugate was purified by using a gel elution method and analyzed by gel electrophoresis. Figure 2a shows the 20% polyacrylamide gel electrophoresis result, indicating that HA−ODN conjugate was successfully synthesized.

To calculate the number of ODN molecules conjugated onto the HA backbone, naked ODN and HA−ODN conjugate were

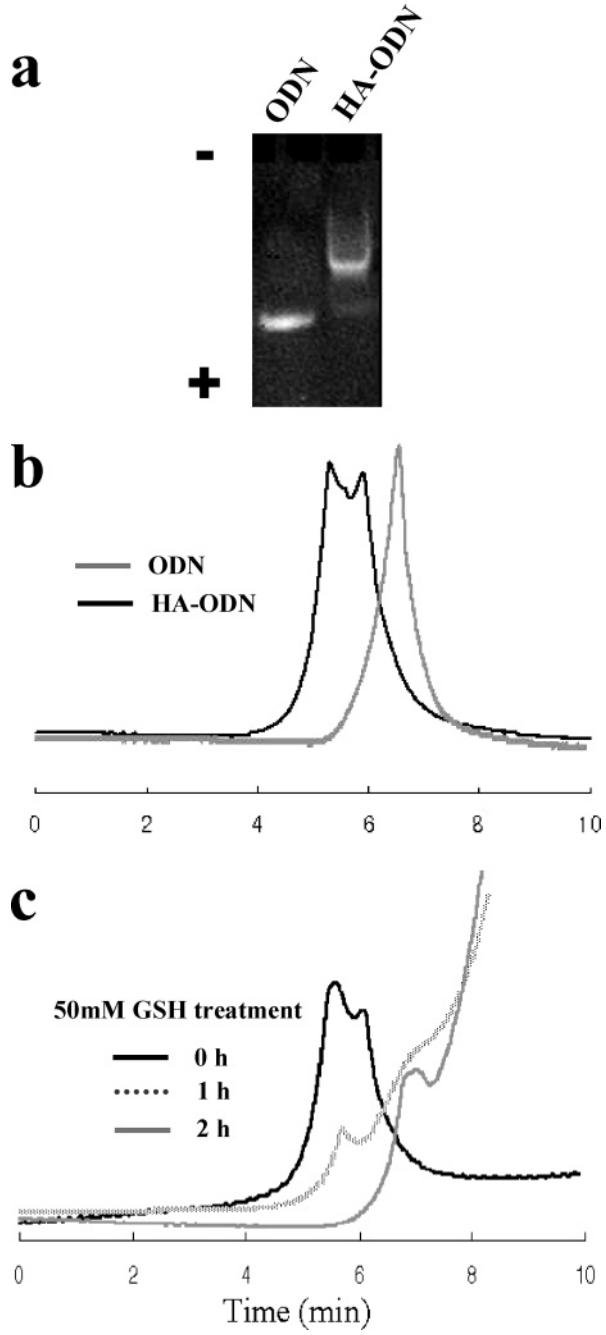

Figure 2. (a) Migration profiles of unconjugated ODN and HA−ODN conjugate in 20% polyacrylamide gel. (b) GPC result of unmodified ODN and HA−ODN conjugate. (c) Time-dependent cleavage of disulfide linkage in the HA−ODN conjugate when incubated in the medium containing 50 mM glutathione.

analyzed by GPC, using a series of dextran molecules with different molecular weights as standards (Figure 2b). The HA−ODN conjugate eluted earlier at a retention time corresponding to MW 22 700, while the naked ODN was eluted later at a peak position of MW 5656. From the GPC results, the number of ODN per HA chain was 0.83 ± 0.15, which was simply calculated based on the difference in elution times between HA−ODN conjugate and naked ODN. The calculation for the number of ODN molecules on the HA chain based on the MW difference, however, was somewhat misleading, because highly charged HA−ODN conjugate and ODN had different hydrodynamic volumes from neutral dextran molecules that were used as standards in the GPC analysis. It should be noted that the HA−ODN conjugate was eluted as doublet peaks in the chromatogram, implying that roughly one or two ODN chains

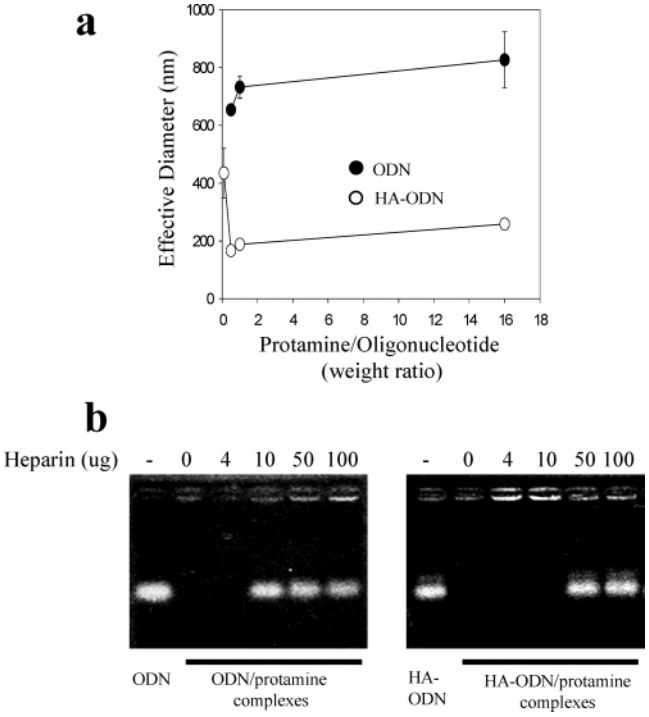

Figure 3. (a) Effective diameter of protamine/ODN and protamine/HA−ODN polyelectrolyte complexes as determined by dynamic light scattering. (b) Stability of polyelectrolyte complexes in the presence of competing polyanion, heparin. Protamine/ODN and protamine/HA−ODN complexes were incubated with various amount of heparin prior to loading on 1% agarose gel.

were conjugated onto the HA backbone. To verify that the disulfide linkage of HA−ODN conjugate could be cleaved in reducing condition, the HA−ODN conjugate was incubated in a solution containing 50 mM glutathione (GSH). Figure 2c shows that free ODN is liberated from the conjugate as a result of cleavage of the disulfide linkage between HA and ODN. The doublet peak for the HA−ODN conjugate disappeared progressively, and a new peak for the released free ODN fraction appeared gradually with increasing incubating time. The sharply increasing signal observed in the late elution time was due to the nonspecific effect of GSH present in the sample. After 2 h incubation in reductive condition, a free form of ODN was completely regenerated from the conjugated form. The main reason for the introduction of a cleavable disulfide linkage in the HA−ODN conjugate was to release an intact form of antisense ODN into the cytosol. It is known that the cytoplasmic space maintains a reductive microenvironment mainly by the presence of high GSH concentrations of up to 10 mM (*27*). It was postulated that the free form of ODN might have a better gene silencing activity than the conjugated form of HA−ODN because the steric hindrance effect of adjacent HA on binding to a target mRNA sequence was likely to be minimized (*28*).

Dynamic light scattering (DLS) analysis revealed that the HA−ODN conjugate could form much smaller complexes than the unconjugated ODN (Figure 3a). The hydrodynamic sizes of protamine complexes with ODN and HA−ODN conjugate were 653.5 ± 5.1 nm and 166.0 ± 13.9 nm at a protamine/ODN weight ratio of 0.5, respectively. This suggests that HA−ODN conjugate could produce more stable and compact complexes with protamine primarily because of the increased charge density. The conjugated HA provided additional anionic charges for the formation of complexes between protamine and ODN. When increasing the protamine/ODN weight ratio, the diameters of protamine/HA−ODN conjugate complexes were still around 200 nm, while those of protamine/ODN complexes were about 800 nm. Gel retardation assay was also performed

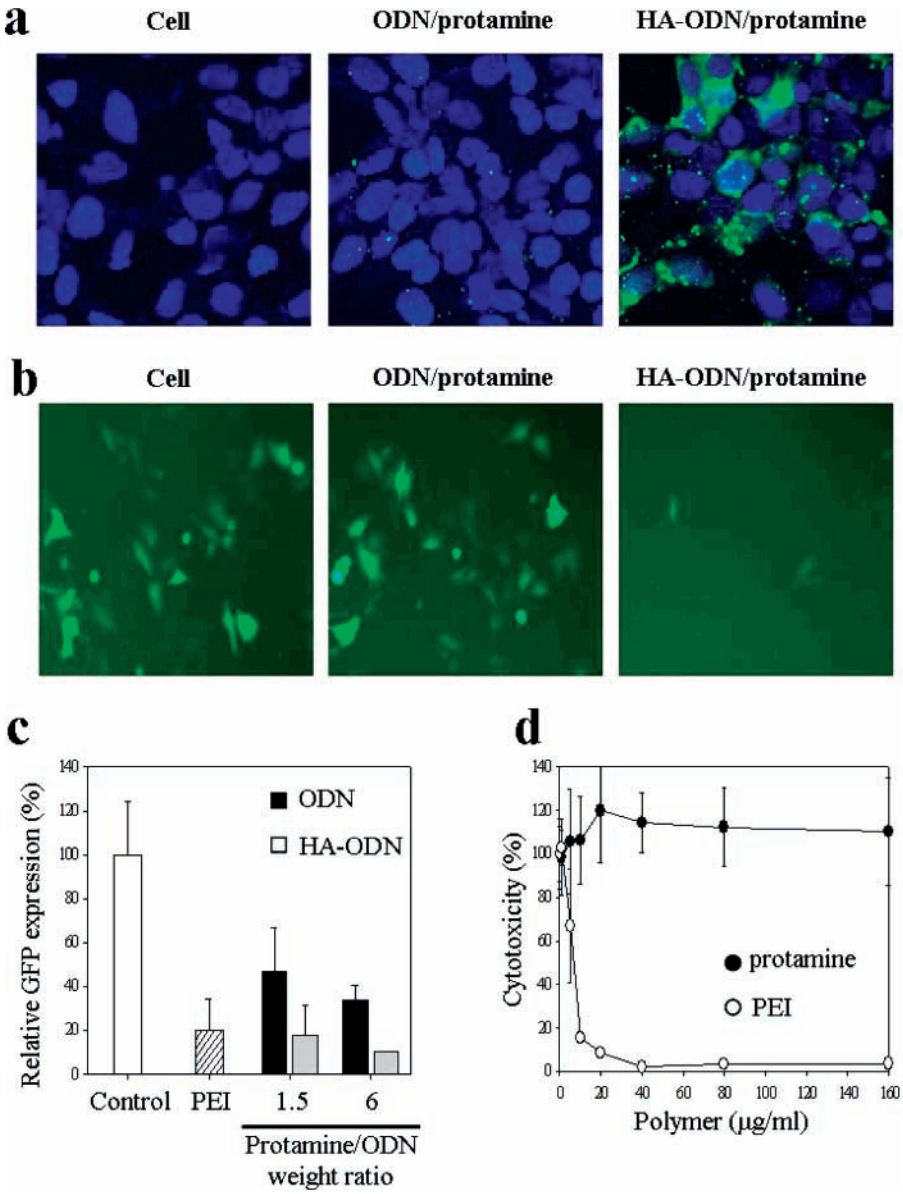

Figure 4. (a) Intracellular uptake protamine/ODN (middle panel) and protamine/HA−ODN/(right panel) complexes in HEK293 cells. FITC-labeled sense ODN was annealed to antisense ODN to visualize the cellular uptake. PBS treated cells were used as a control (left panel). (b) Inhibition degree of GFP gene expression in HeLa cells treated with protamine/ODN and protamine/HA−ODN complexes as observed by fluorescence microscopy. (c) The extent of GFP expression was quantitatively analyzed by determining intracellular fluorescence intensity after cell lysis. to confirm that ODN and HA−ODN conjugate could form nanoscale complexes with protamine by electrostatic interactions. Complete gel retardation of ODN and HA−ODN conjugate complexes was observed at a protamine/ODN weight ratio of 1 (data not shown).

To evaluate the relative structural stability of protamine/ODN and protamine/HA−ODN complexes, a competing polyanion, heparin, at various concentrations was added to induce decomplexation. After incubation with heparin, the fraction of decomplexed ODN was visualized in the gel (Figure 3b). Protamine/ODN and protamine/HA−ODN complexes were completely decomplexed at heparin concentrations of 10 μg and 50 μg, respectively. A 5-fold higher heparin concentration was required to destabilize the protamine/HA−ODN complexes than for the protamine/ODN complexes. It should be noted in Figure 3b that both ODN and HA−ODN conjugate bands appeared at the same migration position in the gel. This was because of the fact that 1% agarose gel electrophoresis did not provide sufficient resolution to separate the two species having a MW difference of around 20 000−30 000. From the above results, it is reasonable to say that HA−ODN conjugate formed more stable polyelectrolyte complexes than naked ODN. The stability and size of DNA polyplexes play an important role in promoting cellular uptake and enhancing gene transfection efficiency. It was reported that the size of polyplexes should be less than or around 200 nm for facile intracellular transport by an endocytic pathway (*29*). The DLS and heparin-induced decomplexation assay clearly indicate that more stable and compact polyplexes can be produced by conjugating ODN molecules to a highly charged HA chain backbone by increasing the charge density of HA−ODN conjugate for electrostatic interactions with protamine.

Figure 4a represents confocal images of HEK 293 cells incubated with protamine/ODN and protamine/HA−ODN complexes, respectively. The nuclei of cells were stained with the DAPI dye, which appeared blue. To visualize intracellular uptake of ODN and HA−ODN, an FITC-labeled sense ODN strand was used to hybridize an antisense ODN strand. The annealed FITC-labeled double strand ODN was used for complex formulation. Protamine/HA−ODN complexes appeared

scattered as green fluorescent dots within the cytosolic space of cells (Figure 4a right panel). They were likely to be preferentially located within the endosomal and lysosomal vesicles after cellular uptake. On the other hand, cells treated with PBS (left panel), protamine/ODN complexes (middle panel), and sense-FITC ODN only (data not shown) showed no measurable green fluorescent intensities. The confocal images evidently suggest that the conjugation of ODN to HA could greatly enhance the extent of intracellular uptake by producing more stable nanosized polyelectrolyte complexes suitable for intracellular endocytosis.

Protamine/HA−ODN and protamine/ODN complexes (formulated with a single strand GFP antisense ODN) were cotranfectected with GFP plasmid formulated with Lipofectamine to HeLa cells. Their GFP gene inhibition degrees were comparatively evaluated by fluorescence microscopy as shown in Figure 4b. In the fluorescent images, it can be seen that protamine/HA−ODN complexes formulated at a protamine/ODN weight ratio of 1.5 inhibit expression of GFP to a greater extent (right panel), compared to protamine/ODN complexes (middle panel). The extent of GFP inhibition was quantitatively analyzed by measuring intracellular GFP fluorescence intensity after cell lysis. Protamine/HA−ODN conjugate complexes prepared at a protamine/ODN weight ratio of 1.5 and 6 showed more significant inhibition of GFP gene expression than the protamine/ODN complexes (Figure 4c). It is also noticeable that increasing the weight ratio of protamine/ODN enhances the extent of GFP expression. High molecular weight PEI (25 k) was used as a control in this study. PEI/ODN complexes exhibited 19.7 ± 14.5% of GFP gene expression at an N/P ratio of 8, which is known to be an optimal condition for gene transfection (*30*). Protamine/ODN and protamine/HA−ODN complexes prepared at a protamine/ODN weight ratio of 1.5 showed 46.9 ± 19.5% and 17.5 ± 13.7% of GFP expression levels, respectively. The results imply that the greater extent of gene silencing effect observed for protamine/HA−ODN complexes was mostly because of enhanced complex stability and compact complex size without causing any cytotoxic effects. Furthermore, the reductive cleavage of the disulfide linkage between HA and ODN released out unconjugated and intact ODN species into the cytoplasm, which additionally contribute to the effective inhibition of GFP expression. Although protamine/HA−ODN and PEI complexes showed similar gene silencing levels, PEI was very cytotoxic in contrast to protamine at the same weight ratio, as measured by the CCK8 assay (Figure 4d). Thus, the more biocompatible protamine compared to any other cationic synthetic polymers such as PEI and PLL could be used as an effective condensing agent for the HA−ODN conjugate.

Last, it is worthwhile to note that low MW HA fraction is known to be internalized into cancer cells overexpressing HA receptors such as CD44 via receptor-mediated endocytosis. It was recently reported that HA conjugated chemical drugs including paclitaxel showed higher intracellular uptake and better therapeutic efficiency compared to unconjugated ones (*31*−*33*). Various water insoluble drugs could be conjugated in a cleavable or noncleavable manner to HA. HA−conjugated drugs could be solubilized in aqueous solution as self-assembling micelles, enabling intravenous administration. Moreover, HA-based prodrugs were expected to show target-specific cellular uptake against HA receptor-positive cells. In this study, we introduced the HA−ODN conjugation approach to increase the stability of nanosized complexes with protamine. It cannot be ruled out that protamine/HA−ODN conjugate polyplexes could possibly be internalized within cells via HA−receptor mediated endocytosis to some extent, in addition to the nonspecific endocytic mechanism. Quite recently, we reported that siRNA-encapsulated HA nanogels could be delivered into cells by HA receptor-mediated endosytosis (*34*). Thus, more detailed studies will be necessary to elucidate the cellular uptake mechanism.

In conclusion, antisense ODN was conjugated to HA, a negatively charged natural polysaccharide, to increase the charge density of the resultant conjugate for facile complexation with another naturally occurring polypeptide, protamine. Stable and non-cytotoxic protamine/HA−ODN complexes were formed, which exhibited a comparable gene silencing level to a cytotoxic PEI-based ODN formulation. The current novel ODN formulations prepared only from naturally occurring and clinically safe materials would have potential applications for siRNA delivery in the future.

Resonant electron oscillations on the surface of noble metal nanoparticles (Au, Ag, Cu) create the surface plasmon resonance (SPR) that greatly enhances the absorption and Rayleigh (Mie) scattering of light by these particles. By adjusting the size and shape of the particles from spheres to rods, the SPR absorption and scattering can be tuned from the visible to the near-infrared region (NIR) where biologic tissues are relatively transparent. Further, gold nanorods greatly enhance surface Raman scattering of adsorbed molecules. These unique properties make gold nanorods especially attractive as optical sensors for biological and medical applications. In the present work, gold nanorods are covalently conjugated with a nuclear localization signal peptide through a thioalkyl-triazole linker and incubated with an immortalized benign epithelial cell line and an oral cancer cell line. Dark field light SPR scattering images demonstrate that nanorods are located in both the cytoplasm and nucleus of both cell lines. Single cell micro-Raman spectra reveal enhanced Raman bands of the peptide as well as molecules in the cytoplasm and the nucleus. Further, the Raman spectra reveal a difference between benign and cancer cell lines. This work represents an important step toward both imaging and Raman-based intracellular biosensing with covalently linked ligand−nanorod probes.

INTRODUCTION

Nanobiotechnology and nanomedicine are emerging fields engendered by the convergence of multiple scientific fields for biologic applications and the recently discovered novel properties of materials at the nanoscale. Nanoparticles, because of their small sizes and unique properties, have been widely used in drug delivery (*1*−*4*), cellular imaging (*5*−*9*), and biomedical diagnostics and therapeutics (*10*−*13*). Plasmonic nanoparticles are especially useful for these applications because of their enhanced resonant absorption and scattering properties as well as strong Raman scattering, which are essential properties for their applications in photothermal therapy (*14*−*25*), optical imaging (*26*−*31*), and Raman probe design (*32*−*38*).

Nuclear targeting of nanoparticles in live cells is generating widespread interest because of the prospect of developing novel diagnostic and therapeutic strategies such as gene therapy. However, nuclear delivery of the nanoparticles requires bypassing the formidable barriers of the cellular membrane and the nuclear membrane. The cellular membrane endocytoses nonspecific particles on the cell surface, enveloping them with a phopholipid membrane and restricting interaction with the general cell cytoplasm. The nuclear membrane is a double-layer membrane marked with nuclear pores that allow diffusion of molecules and selective uptake into the nucleus. One common approach to targeted nuclear delivery is the conjugation of drug molecules and nanoparticles to nuclear membrane-penetrating peptides.

Gold nanoparticles are examples of extremely attractive candidates for attachment to such carrier peptides due to their small sizes, ease of preparation and bioconjugation (*39*, *40*), strong absorbing and scattering properties (*41*−*44*), as well as their well-known biocompatibility (*45*). Tkachenko et al. (*46*, *47*), using video-enhanced color differential interference contrast microscopy, have demonstrated nuclear entry of 20 nm gold nanospheres indirectly conjugated to various nuclear localization signal (NLS) peptides through a shell of bovine serum albumin (BSA) protein. However, these gold nanospheres only absorb in the visible region, thus limiting their use in *in vivo* applications such as in photothermal therapy, which requires near-infrared region where the light penetration is optimal.

Unlike gold nanospheres, gold nanorods possess unique optical properties ideal for *in vivo* applications. They have two surface plasmon absorption bands, a strong long-wavelength band due to longitudinal oscillation of their electrons and a weak short wavelength band around 520 nm due to the transverse electronic oscillation (*42*, *43*, *48*−*51*). The longitudinal absorption band is very sensitive to the size of the nanorods. By increasing the aspect ratio (length divided by width), the longitudinal absorption maximum red-shifts with an increase in the absorption intensity. This provides the opportunity for their applications as near-infrared photoabsorbers and scatterers (*23*).

Gold nanorods also provide a scaffold for observing surface-enhanced Raman scattering (SERS) (*52*−*59*). The well-developed synthesis of nanorods with different aspect ratios provides the opportunity to tune the surface plasmon band to the excitation laser to obtain the largest enhancement. It has been shown that the enhancement factors on the order of 10^4−10^5 could be observed for the adsorbed molecules on gold nanorods, while no such enhancement was observed on nanospheres (*52*). Biological species are known to have small Raman scattering cross section and sensitivity toward photochemical damage and interference from fluorescence when UV or visible laser excitation is used. In order to overcome these difficulties, the size of gold nanorods can be adjusted to have its enhancement in the near-infrared region away from the biomolecular

Scheme 1. Synthesis of Thiolalkyl-Triazole Linked NLS Peptide[a]

[a] Conditions: (a) NaN_3, DMF, 110 °C; (b) MsCl, Et_3N, CH_2Cl_2, rt; (c) potassium thioacetate, THF, reflux; (d) conc. HCl, methanol, reflux; (e) alkyne-modified NLS (PC-37044-PI), TBTA, CuI, DMF, rt. Abbreviations: MsCl, methanesulfonyl chloride; TBTA, Tris-(benzyltriazolylmethyl)amine.

excitation transitions that could lead to fluorescence or photochemical decomposition. Moreover, the surface chemistry of gold nanorods allows for multiple functionalization so that the capping molecules, such as cetyltrimethylammonium bromide (CTAB), could be replaced or conjugated with many functional groups (*60*−*63*).

In the present work, we describe the preparation of gold nanorods directly conjugated to a simian virus (SV40) NLS peptide through a thioalkyl-triazole linker. Using a simple conventional microscope in the dark field, we are able to image the intracellular localization of these nanorods. Furthermore, cellular components are observed by surface-enhanced Raman scattering of these gold nanorod−peptide conjugates. Our results demonstrate that these nanorods are useful for cellular delivery applications, especially nuclear targeting and cellular components sensing.

EXPERIMENTAL PROCEDURES

Materials. 11-Bromoundecan-11-ol and all chemicals used for the synthesis of gold nanorods are purchased from Sigma Aldrich. Anhydrous solvents and other reagents are purchased and used without purification. Analtech silical gel plate (60 F_{254}) is used for analytical TLC, and UV light is used to examine the spots. Tris-(benzyltriazolylmethyl)amine (TBTA) is prepared by using the procedure described by Chan et al. (*64*). Alkyne-modified NLS (PCS-37044-PI) is synthesized by the solid-phase method at Peptide International, Louisville, Kentucky. NMR spectra are recorded on a Varian-Gemini 400 magnetic resonance spectrometer. ^{1}H NMR spectra are recorded in parts per million (ppm) relative to the peak of $CDCl_3$, (7.24 ppm). Mass spectra are recorded at the Georgia Institute of Technology mass spectrometry facility in Atlanta.

Synthesis of Thiolalkyl-Triazole Linked NLS Peptide (Scheme 1). *1. Synthesis of 1-Azidoundecan-11-ol (**1**).* This compound is synthesized by adapting the method of Shon et al. (*65*). Briefly, sodium azide (1.2 g, 18.5 mmol) is added to a solution of 1-bromoundecan-11-ol (2.0 g, 7.96 mmol) anhydrous DMF (20 mL). The reaction mixture is heated to 110 °C in a pressure tube and stirred continuously for 24 h. The reaction mixture is then cooled to room temperature and quenched with distilled water (30 mL). The cooled reaction mixture is extracted with anhydrous diethyl ether (3 × 20 mL), and the combined organic layers are washed with distilled water (3 × 20 mL) and dried over Na_2SO_4. The solvent is removed and concentrated *in vacuo* to give 1.275 g (75%) of **1** as pale yellowish oil. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 1.25−1.38 (14H, m), δ 1.50−1.60 (4H, m), δ 3.22 (2H, t, J = 7.2 Hz), δ 3.61 (2H, t, J = 7.2 Hz).

*2. Synthesis of 1-Azidoundecan-11-methylsulfonate (**2**).* Triethylamine (4.35 mL, 31.2 mmol) is added to a solution of 1-azidoundecan-11-ol **1** (2.42 g, 11.3 mmol) in anhydrous CH_2Cl_2 (100 mL). The reaction mixture is stirred for 15 min at 0 °C, and then methanesulfonyl chloride (2.41 mL, 31.2 mmol) is added. The reaction mixture is allowed to warm up to room temperature and stirring continued for 2 h. The reaction mixture is quenched with ice-cold distilled water (35 mL) and extracted

with anhydrous diethyl ether (2 × 35 mL). The combined organic layer is washed in succession with 1 N HCl, distilled water, saturated $NaHCO_3$, and again with distilled water. The organic layer is dried over Na_2SO_4 and concentrated *in vacuo* to give 2.934 g (89%) of **2** as pale yellowish oil. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 1.25−1.40 (14H, m), δ 1.53−1.60 (2H, m), δ 1.68−1.75 (2H, m), δ 2.97 (3H, s), δ 3.22 (2H, t, J = 6.8 Hz), δ 4.19 (2H, t, J = 6.8 Hz).

*3. Synthesis of 1-Azidoundecan-11-thioacetate (**3**).* Potassium thioacetate (2.02 g, 6.79 mmol) is added to a solution of 1-azidoundecan-11-sulfonate **2** (1.00 g, 3.43 mmol) in anhydrous THF (10 mL). The reaction mixture is degassed, refilled with argon, and heated under reflux for 3 h. The reaction mixture is quenched with ice-cold distilled water (30 mL) and extracted with anhydrous diethyl ether (3 × 30 mL). The combined organic layer is dried over Na_2SO_4 and concentrated *in vacuo* to give 856 mg (87%) of **3** as yellowish oil. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 1.23−1.38 (14H, m), δ 1.50−1.60 (4H, m), δ 2.29 (3H, s), δ 2.83 (2H, t, J = 7.6 Hz), δ 3.22 (3H, t, J = 7.6 Hz).

*4. Synthesis of 1-Azidoundecane-11-thiol (**4**).* A solution of 1-azidoundecane-11-thiolacetate **3** (0.1 g. 0.369 mmol) in anhydrous methanol (7.0 mL) is first degassed and refilled with argon. Concentrated HCl (0.4 mL) is added to the solution, and the resulting mixture is refluxed for 3 h. The reaction mixture is quenched with distilled water (10 mL) and extracted with anhydrous diethyl ether (2 × 10 mL). The organic layer is dried over Na_2SO_4 and concentrated *in vacuo* to give 85 mg (100%) of **4** as yellowish oil. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 1.25−1.38 (14H, m), δ 1.53−1.62 (4H, m), δ 2.50 (2H, q, J = 15.2 Hz, 7.2 Hz), δ 3.23 (2H, t, J = 5.6 Hz).

*5. Synthesis of Thiolalkyl-Triazole Linked NLS Peptitde (**5**).* Anhydrous CuI (0.003 g, 0.011 mmol) and tris-(benzyltriazolylmethyl)amine (0.007 g, 0.011 mmol) is added to a solution of 1-azidoundecane-11-thiol **4** (0.02 g, 0.079 mmol) and alkyne-modified NLS peptides PC-37044-PI (0.05 g, 0.039 mmol) in anhydrous DMF (2 mL). The solution is stirred at room temperature under argon for 48 h. Excess DMF is removed *in vacuo*, and the residue is quenched with distilled water (5 mL). The resulting mixture is extracted with dichloromethane (2 × 10 mL) to remove unreacted 1-azidoundecane-11-thiol **4**. The remaining aqueous layer is frozen in an acetone−dry ice bath and concentrated *in vacuo* to give 50 mg (43%) of **5** as a brown solid. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 0.83 (2H, t, J = 6.0 Hz), δ 1.23−1.36 (6H, m), δ 1.42−1.54 (3H, m), δ 1.56−1.68 (1H, m), δ 2.13−2.24 (2H, m), δ 2.40−2.50 (5H, m), δ 2.66−2.80 (2H, m), δ 2.87 (1H, s), δ 3.29 (1H, t, J = 8.0 Hz), δ 3.34−3.54 (1H, m), δ 3.62−3.78 (1H, m), δ 4.10−4.30 (1H, m), δ 7.26−7.36 (1H, m), δ 7.64−7.88 (3H, m), δ 7.94 (1H, s), δ 8.10−8.32 (2H, m). MS (MALDI, CHCA) calcs for $[C_{67}H_{123}N_{23}O_{13}S + H]^+$ 1490.9, found 1491.0.

Synthesis of Gold Nanorods and Peptide Conjugation. The gold nanorods are synthesized according to the seed-mediated growth method (*66*). Briefly, 600 uL 0.01 M ice-cold sodium borohydride is quickly added into a 10 mL 0.5 mM stirring auric acid, which is dissolved in 0.2 M CTAB solution. 2−5 nm gold nanoparticles are formed after 2 min as a seed solution. In a separate flask, 1 mL of 4 mM silver citrate is added to 50 mL growth solution, which contains 0.2 M CTAB, 0.15 M benzyldimethylammonioum chloride hydrate (BDAC), and 1 mM auric acid. 0.07 mL of 0.0788 M ascorbic acid is added to the growth solution to reduce the auric acid to form $HAuCl_2$ solution. 0.08 mL seed solution is injected into the growth solution to initiate the rod formation and growth. In this procedure, gold nanorods with absorption maximum at 650 nm (aspect ratio of 2.4) are obtained overnight. For the conjugation of peptide **5** to gold nanorods, 100 μL 1 mM peptide **5** is added to 10 mL gold nanorod solution (OD_{650} = 1.0), and the mixture is left to react for 72 h. The unbound peptide is separated by centrifugation at 5000 rpm for 10 min.

Cell Culture and Cellular Delivery of Peptide-Conjugated Gold Nanorod. One nonmalignant epithelial cell line, HaCaT (human keratinocytes), and one malignant epithelial cell lines, HSC 3 (human oral squamous cell carcinoma), are cultured on coverslips in DMEM (Dulbecco's Modification of Eagle's Medium, Cellgro) plus 10% FBS (fetal bovine serum, Gem Cell) at 37 °C under 5% CO_2 for 24 h. The DMEM medium is then taken out and rinsed with PBS buffer. Fresh DMEM medium containing 1 nM thioalkyl-triazole peptide/Au nanorod conjugates is added, and the cells are put back in the incubator for 2 h. After the incubation of the nanorods, the cells are rinsed with PBS buffer, fixed with paraformaldehyde, coated with glycerol, and sealed with another coverslip.

Dark Field Imaging. The dark field images are taken under an inverted Olympus IX70 microscope. A dark field condenser (U−DCW) with a numerical aperture between 0.9 and 1.2 is used to deliver a very narrow beam of white light from a tungsten lamp to the sample. A 100×/1.35 oil Iris objective (UPLANAPO) is used to collect only the scattered light from samples. In this mode, the samples with highly scattering properties are shown as a bright object in a dark background.

Raman Measurements. The Raman spectra are obtained with a Holoprobe series 5000 Micro-spectrometer (Kaiser Optical Systems, Inc., Ann Arbor, MI) in a 180° reflective configuration with a 50× objective. The excitation wavelength is 785 nm from a diode laser. The spectral resolution is 5 cm^{-1}, and the laser power is 25 mW. Each spectrum is obtained in 10 s collection time with six accumulations.

RESULTS AND DISCUSSION

Peptide Conjugation to Gold Nanorods. The use of NLS for targeting of proteins, peptides, nucleic acids, and small organic molecules to the cell nucleus has been extensively investigated (*46, 47, 67−72*). One of the most studied is the NLS of SV40 large T antigen, which has been shown to act as a "Trojan horse", efficiently distributing appended payloads into the cell nucleus (*68*). However, the chemical syntheses of NLS-conjugated payloads are very difficult, often requiring technically challenging compound purification and characterization protocols. In the case of nanoparticle−peptide conjugates, an alternative synthetic approach has been to indirectly couple these nanoparticles to carrier peptides through a secondary protein, such as bovine serum albumin (BSA) protein (*46, 47*). The resulting conjugates are large and possess highly branched polypeptides that are very difficult to characterize.

We observe in this study that thiol-terminated NLS peptides incorporating appropriate spacer groups could be easily accessed by Cu(I)-catalyzed cycloaddition reaction (click chemistry) (*71*) between an alkyne-terminated NLS, such as PC-37044-PI, and an appropriate azidothiols (Scheme 1). Subsequent reaction of the resulting thioalkyl-triazole linked NLS **5** with gold nanorods which are stabilized with CTAB molecules yields peptide-conjugated gold nanorods by forming Au−S bonds between the peptide and the gold surface. There are some other previous reports of bioconjugation to gold nanoparticles through Au−S bonds. For example, HS-mPEG has been reported to rapidly assemble onto gold nanoshells through Au−S bonds within 1 h (*14*). In this case, there are no capping molecules on the surface of the gold layer. In comparison to a bare gold surface, it takes a longer time to assemble thiolated molecules to the surface of gold nanorods. The adsorption of HS-mPEG onto gold nanorods requires stirring for 24 h (*61*), while thiolated DNA is bound to gold nanorods after 72 h of incubation (*73*). Gold nanorods are capped with CTAB surfactants, which form a bilayer structure around the gold surface (*74*). The inner layer

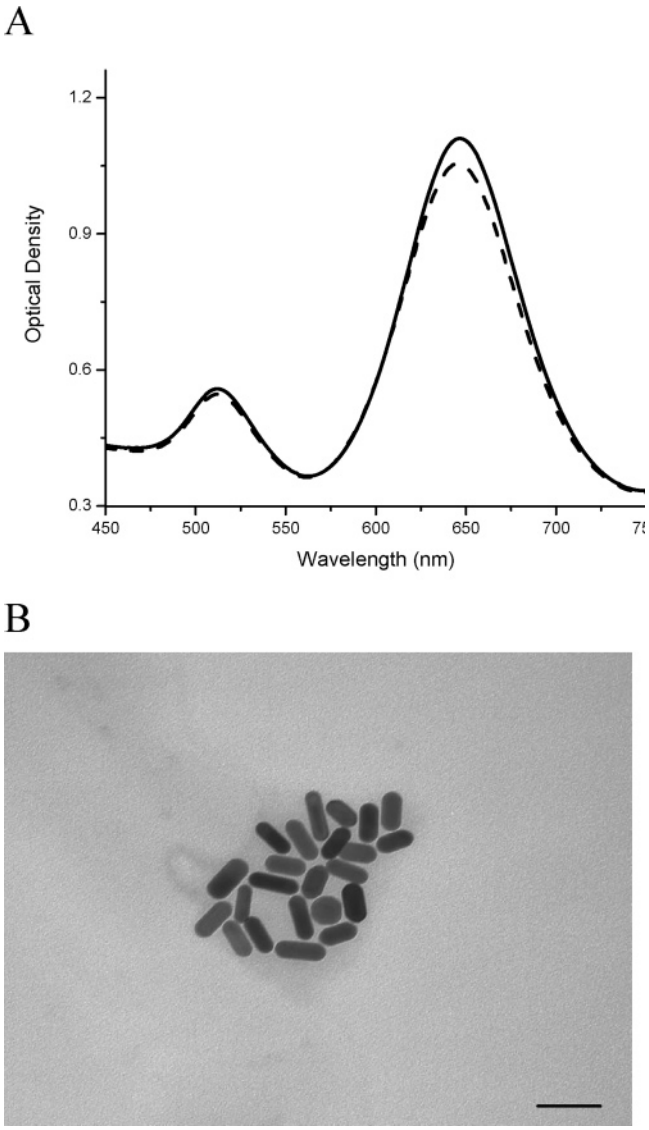

Figure 1. A. Absorption spectra of gold nanorods (solid line) and peptide conjugated gold nanorods (dashed line). B. TEM image of gold nanorods. Scale bar: 50 nm.

of the surfactants is bound to the gold surface via the surfactant headgroups. In our work, the thiolated peptide and gold nanorod solution are left for up to 72 h. The absorption spectra in Figure 1 show that there is no change in the peak position after CTAB replacement, but the peak intensity decreases slightly. This intensity damping is due to the increase of the positive charge on the capping molecules when positive CTAB is replaced by more positively charged peptide molecules.

SERS of the Peptide-Conjugated Gold Nanorods. Figure 2 shows a comparison of the Raman spectrum of the peptide-conjugated gold nanorods with that of the pure peptide and CTAB-capped gold nanorods. It can be seen that the Raman spectrum of the peptide-conjugated gold nanorods show some signals from CTAB molecules, which indicates that a small proportion of the CTAB molecules remained on the rod surface. It is very interesting to note that the amide I C═O stretching vibration of the peptide at 1665 cm^{-1} is not enhanced when it is bound to the nanorod surface. The CH bending at 1432 cm^{-1} for the peptide is shifted to 1440 cm^{-1} on the rod surface. The amide III C−N stretching at 1240 cm^{-1} is the same for peptide and peptide bound to gold nanorods. The amide II N−H vibrations (1500−1570 cm^{-1} region) are not observed in both the peptide powder and the peptide bound onto gold nanorods. The thioalkyl-triazole linker shows a strong CH_2 rocking

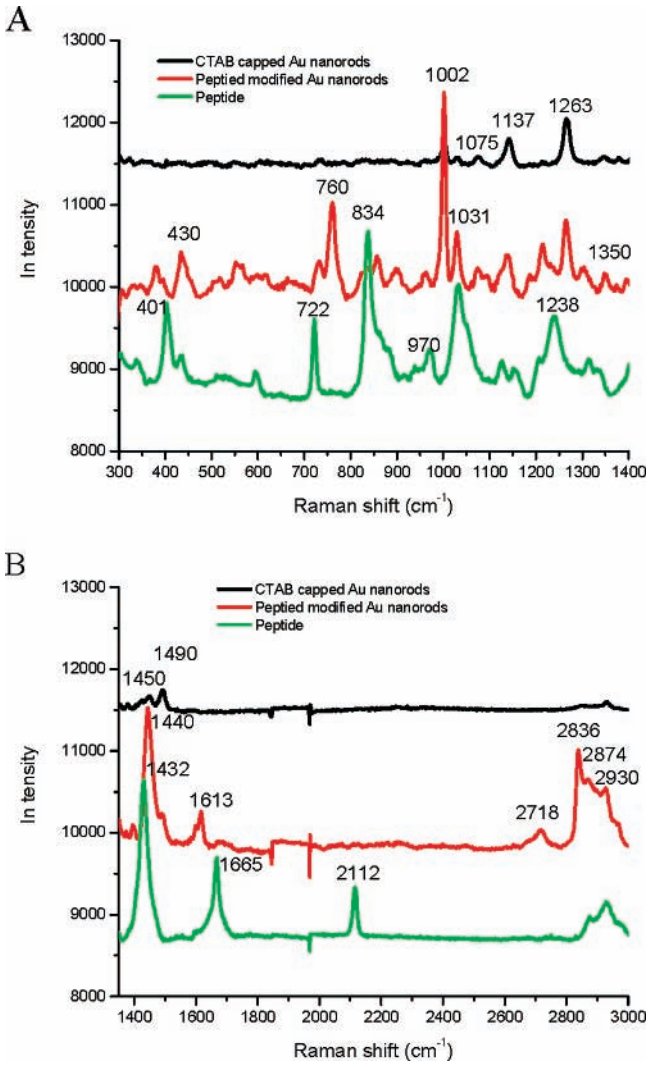

Figure 2. SERS of CTAB capping molecules on gold nanorods, thioalkyl−triazole−peptide on gold nanorods and Raman spectrum of peptide. A. 300−1400 cm^{-1} region. B. 1400−3000 cm^{-1} region.

vibration at 760 cm^{-1} (*75*) and C−C stretch at 1092 cm^{-1} (*75*, *76*). The CH bending is found to overlap with the CH bending in the peptide at 1440 cm^{-1} (*52*). The C−N stretch in CTAB molecules overlaps with C−N stretch in the thioalkyl-triazole to give a strong peak at 1002 cm^{-1} (*52*). The C−H stretching vibrations of the peptide, the thioalkyl-triazole, and the CTAB are at 2836 cm^{-1} and 2930 cm^{-1} (*52*, *76*). The peptide residues show their strong COO^- deformation at 722 cm^{-1} (*77*). The signal at 831 cm^{-1} is assigned to the proline and valine C−C stretch, and the 1031 cm^{-1} signal is assigned to C−N stretch vibrations from glycine and proline (*77*).

The CTAB capping molecules show strong Raman bands at 1137 cm^{-1} for the C−C stretch vibrations, 1267 cm^{-1} for δ (CH) of the $CH_2-N+(CH_3)_3$ groups and 1450 cm^{-1} and 1490 cm^{-1} for CH_2 bending vibrations (*52*). From Figure 2, it can be seen that these bands are still observed in the Raman spectrum of the peptide-conjugated gold nanorods due to the incomplete replacement of the CTAB molecules. In comparison to the Raman spectrum of the antibody-conjugated gold nanorods in which CTAB molecules are not replaced (*78*), the intensity of these bands in the peptide-conjugated gold nanorods are much weaker due to the replacement of the capping molecules with the thiolated peptide.

Light Scattering Images of Peptide-Conjugated Gold Nanorods Inside Cells. Figure 3 shows the dark field light scattering images of cells after incubation with 1nM CTAB

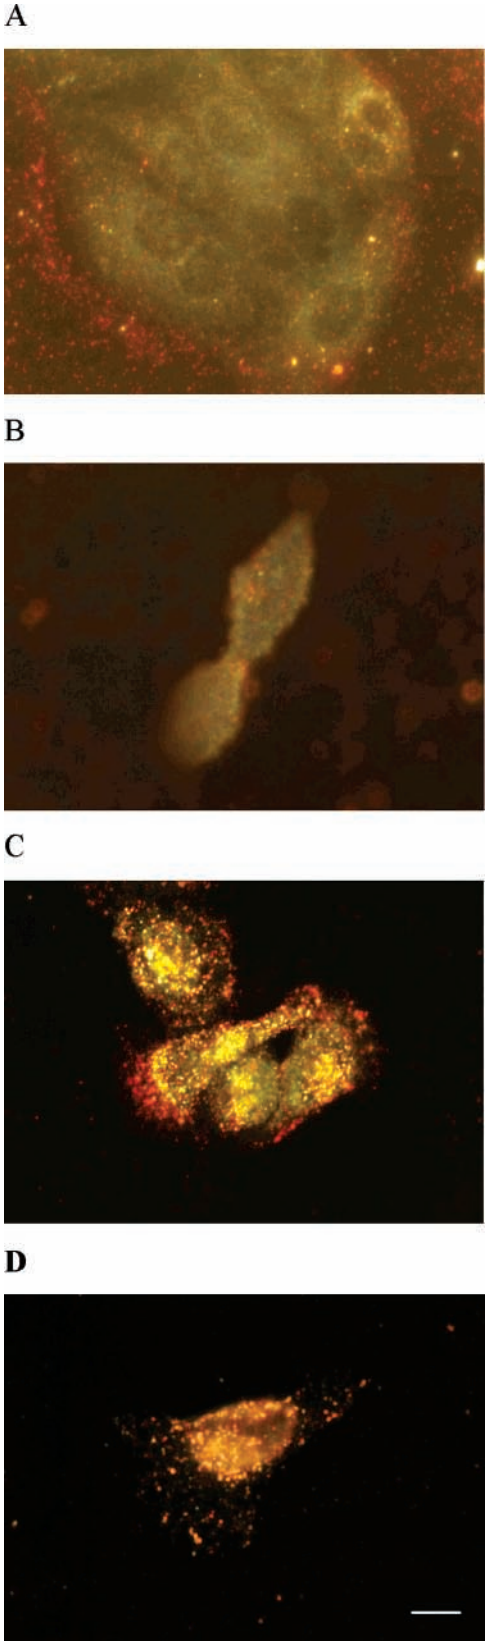

Figure 3. Dark field light scattering images of cells after incubation with gold nanorods and peptide-conjugated gold nanorods for 2 h. A. HaCat normal cells incubated with gold nanorods. B. HSC cancer cells incubated with gold nanorods. C. HaCat normal cells incubated with peptide-conjugated gold nanorods. D. HSC cancer cells incubated with peptide-conjugated gold nanorods. Peptide conjugation promotes the cellular uptake of gold nanorods. Scale bar: 10 μm.

capped nanorods and 1nM thioalkyl−triazole−peptide conjugated gold nanorods for 2 h. It can be seen clearly that, while the CTAB-capped gold nanorods are not efficiently absorbed by the cells, the thioalkyl−triazole−peptide conjugated gold nanorods enter into both cell lines with much higher efficiency. This result indicates that peptide conjugation enhances the cellular uptake of the gold nanorods. Importantly, it is worth noting that the observed enhancement of gold nanorod uptake took place in medium containing a very low concentration of peptide-conjugated nanorods (~1 nM) within a very short incubation time (2 h). This enhanced gold nanorod uptake may be due to the receptor-mediated endocytosis. Moreover, we observed that the thioalkyl−triazole−peptide conjugated nanorods are distributed into both nucleus and cytoplasm in either normal or cancer cells. However, the nanorods are more concentrated in the nucleus of the cancer cells. Reasons for increased nuclear distribution particles in the malignant cells could reflect increased specific and active uptake of the NLS peptide or decreased regulation of passive uptake of cytoplasmic components due to the disruption of the normal cellular process. It is quite possible that the nuclear pores of the nuclear membrane which routinely restrict entrance into the nucleus may be faulty and thereby facilitate the penetration of the peptide-conjugated nanorods into the nucleus. Identification of alterations in cellular pathways, such as nuclear pore function, by this multimodal method suggests further avenues of investigation that may yield novel methods of exploiting cellular defects of carcinogenesis for therapeutic applications.

SERS of Peptide-Conjugated Gold Nanorods Inside Cells. The Raman spectra of cells incubated with the peptide-conjugated gold nanorods are also measured (Figure 4). The Raman laser spot covers the major part of a single cell. Statistically, over twenty cells for each cell line are measured. They gave similar spectra with slight differences in some peak intensities. Shown in Figure 4A,B are five typical spectra for both normal and cancer cells. Figure 4C compares a typical spectrum of a normal and cancer cell as well as the spectrum when the peptide-conjugated nanorods are outside the cells. Spectra of the peptide-conjugated gold nanorods reveal a difference pre- and post-cellular uptake. New bands at 620, 655, and 1158 cm^{-1} are observed after cellular translocation of the conjugates. The 620 cm^{-1} band is due to protein COO^- wag vibrations and tyrosine δ (ring) vibrations (*79*). The 655 cm^{-1} band is due to an overlapping of a strong tyrosine vibration and the guanine bands (*36*, *80*). The DNA backbone vibrations are reflected most likely at bands in the region between 1030 and 1137 cm^{-1}, such as 1058 cm^{-1} for the DNA C−O stretch (*76*) and 1094 cm^{-1} for O−P−O vibrations (*81*). The 1155 cm^{-1} band could be assigned to chromatin and histone octamer Raman signals (*80*). The intensities around 820 and 850 cm^{-1} bands are greatly increased inside the cells. This indicates that such residues as phenylalanine (830 cm^{-1}, CH_2 rock) and tyrosine (850 cm^{-1}, ring breath) in cell proteins (*77*) are probably enhanced. The lysine Raman signal at 900 cm^{-1} (*77*) in the peptide is shifted to 914 cm^{-1} when it is present inside the cells, suggesting interaction of this residue with the cell components. The Raman intensity of the thioalkyl-triazole C−N stretch band at 760 cm^{-1} inside the cell is greatly decreased in comparison to that outside the cells. This suggests a change in linker conformation upon nanorod translocation into the cells.

The normal and cancer cells show some differences in their Raman signals as well. The 731 cm^{-1} line which is assigned to adenine (*82*) is stronger in the cancer cells than that in the normal cells. In addition, a peak at 398 cm^{-1} is observed only in cancer cells. All these spectral differences might be useful for cancer diagnostics.

Feld, Kneipp, and some other groups have demonstrated that individual and aggregated gold nanospheres could be useful for single cell micro-Raman spectroscopy (*32*−*38*). However, the

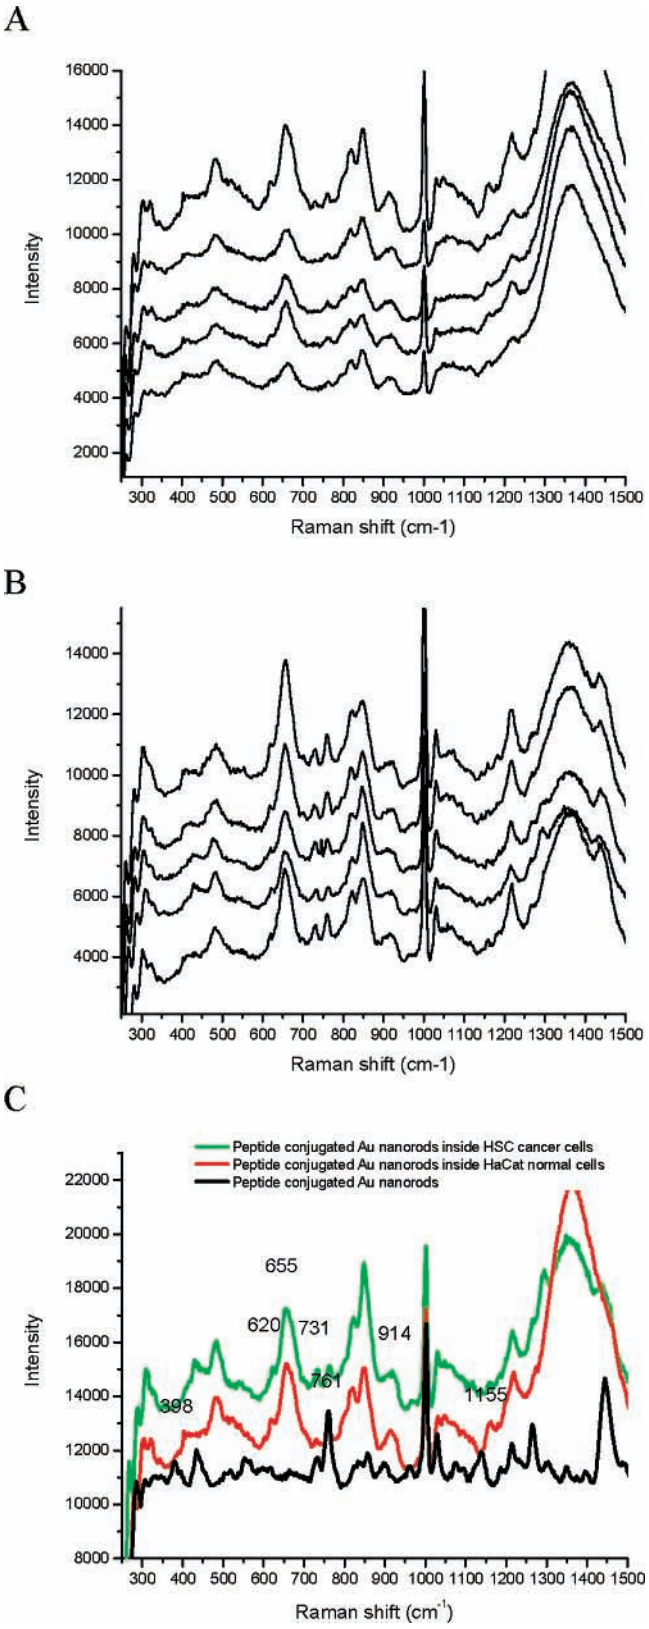

Figure 4. Raman spectra of peptide-conjugated gold nanorods inside HaCat normal cells (A) and HSC cancer cells (B). The Raman spectrum of the peptide-conjugated gold nanorods outside cells is shown in (C) as the bottom curve for comparison. Raman spectra from five cells for each cell line are shown.

inability of controlled delivery of the particles within the cell has limited their applications. The data in this project suggest that the intracellular distribution of the particles inside the cell can be controlled and simultaneously provides information regarding the local biochemical environment. Identification of spectral differences, such as an increased adenine signal within the cancer cell nucleus, provides detailed biochemical information at the molecular level with concurrent imaging of the particles in subcellular compartments. This multiomodal and ultrasensitive probe has a significant potential for a range of investigative and medical diagnostic applications.

CONCLUSIONS

We have demonstrated in this work that gold nanorods, directly conjugated to a SV40 virus NLS peptide through a thioalkyl-triazole linker, could be efficiently delivered into cells within a very short time. Multimodal optical sensing is available with Raman spectroscopy and dark field light scattering imaging. The peptide-conjugated gold nanorods are translocated into both the cytoplasm and the nucleus portion. Raman spectra reveal an enhanced signal of the NLS peptide as well as molecules from both the cytoplasm and the nucleus. In addition, in this pilot study, the Raman signal distinguishes the malignant from nonmalignant cells. This study demonstrates that gold nanorods can be used for nuclear targeting as a novel type of imaging-based contrast agents and an ultrasensitive Raman probe for intracellular molecular sensing as well.

ACKNOWLEDGMENT

M.A.E. thanks the Miller Foundation at the University of California at Berkeley for their hospitality during his tenure as a Miller visiting professor. We thank Professor Paul Edmonds for the use of his cell culture facilities. We also like to thank the support of NCI Center of Cancer Nanotechnology Excellence (CCNE) Award (U54CA119338).

A Macrophage−Nanozyme Delivery System for Parkinson's Disease

Elena V. Batrakova,*[,†,‡] Shu Li,[†,‡] Ashley D. Reynolds,[§] R. Lee Mosley,[§] Tatiana K. Bronich,[†,‡] Alexander V. Kabanov,[†,‡,⊥] and Howard E. Gendelman[†,§,∥]

Center for Drug Delivery and Nanomedicine, Department of Pharmaceutical Sciences, Center for Neurovirology and Neurodegenerative Disorders, and Department of Pharmacology and Experimental Neuroscience, University of Nebraska Medical Center, Omaha, Nebraska, and Department of Chemistry, M.V. Lomonosov Moscow State University, Moscow, Russia. Received May 23, 2007; Revised Manuscript Received July 16, 2007

Selective delivery of antioxidants to the substantia nigra pars compacta (SNpc) during Parkinson's disease (PD) can potentially attenuate oxidative stress and as such increase survival of dopaminergic neurons. To this end, we developed a bone-marrow-derived macrophage (BMM) system to deliver catalase to PD-affected brain regions in an animal model of human disease. To preclude BMM-mediated enzyme degradation, catalase was packaged into a block ionomer complex with a cationic block copolymer, polyethyleneimine-poly(ethylene glycol) (PEI-PEG). The self-assembled catalase/PEI-PEG complexes, "nanozymes", were ca. 60 to 100 nm in size, stable in pH and ionic strength, and retained antioxidant activities. Cytotoxicity was negligible over a range of physiologic nanozyme concentrations. Nanozyme particles were rapidly, 40−60 min, taken up by BMM, retained catalytic activity, and released in active form for greater than 24 h. In contrast, "naked" catalase was rapidly degraded. The released enzyme decomposed microglial hydrogen peroxide following nitrated alpha-synuclein or tumor necrosis factor alpha activation. Following adoptive transfer of nanozyme-loaded BMM to 1-methyl 4-phenyl 1,2,3,6-tetrahydropyridine-intoxicated mice, ca. 0.6% of the injected dose were found in brain. We conclude that cell-mediated delivery of nanozymes can reduce oxidative stress in laboratory and animal models of PD.

INTRODUCTION

The need for delivery of therapeutic polypeptides to affected brain tissues in Alzheimer's and Parkinson's diseases, AD and PD) (*1*−*3*), infectious (meningitis, encephalitis, prion disease, and HIV-related dementia) (*4*, *5*), stroke (*6*, *7*), lysosomal storage (*8*, *9*), obesity (*10*, *11*), and other metabolic and inflammatory diseases of the central nervous system (CNS) is of immediate need and cannot be overstated.

An important component of metabolic and degenerative diseases of the nervous system involves inflammation (*12*). Such inflammatory activities are profound, as they lead to excessive production of pro-inflammatory products and reactive oxygen species (ROS) that lead in part, to cell death and neurodegeneration. We posit that by affecting neuroinflammatory activities during disease, such as through the use of targeted antioxidants or drugs that inhibit the production or formation of pro-inflammatory cytokines and eicosanoids, the levels of ROS as well as other neurotoxins could be reduced, resulting in improved disease outcomes (*13*). However, such approaches have been limited, as drugs must not only penetrate the BBB but also find themselves in sufficient concentrations to affect ongoing disease mechanisms. Moreover, as inflammatory mechanisms are a likely early event for disease, therapeutic modalities must be used early and frequently. The limitation of drug delivery is one major obstacle confronting the development of new treatment paradigms for nervous system disorders.

One such disease is PD, the second most prevalent neurodegenerative disorder in people over 65. This disease is characterized by lack of the neurotransmitter dopamine due to a loss of dopaminergic neurons within the SNpc and their innervations to the striatum. PD neuropathology involves brain inflammation, microglia activation, and subsequent secretory neurotoxic activities, including ROS production, that play crucial roles in cell damage and death (*14*−*17*). PD brains show reduced levels of antioxidant enzymes and antioxidants (*18*−*20*) resulting in a reduced capacity to manage oxidative stress and associated neurodegeneration. Mounting evidence supports the notion that antioxidants can inhibit inflammatory responses and protect dopaminergic neurons in laboratory and animal models of PD (*21*−*27*). Catalase catalyzes the conversion of hydrogen peroxide, a known ROS, to water and molecular oxygen with one of the highest turnover rates for all known enzymes. In an *in vitro* model of PD, catalase was shown to rescue primary cultured cerebellar granule cells from ROS toxic effects (*13*, *28*). Furthermore, a low molecular mass catalase activator, rasagiline, induced neuroprotection in a mouse model of PD (*29*). Few clinical trials have been performed using low molecular mass antioxidants, of which the most extensive used is α-tocopherol and deprenyl to inhibit the rate of PD progression (*30*). However, and as described above, most of the trials failed to show significant improvements because of restricted transport of α-tocopherol across the blood−brain barrier (BBB) and the time following the disease the drugs were used (*31*).

Recent works from our laboratories demonstrate that bone-marrow derived monocytes (BMM) can be used as carriers of nanoformulated drugs, both in the periphery and across the BBB (*32*, *33*). Entry into the brain occurs as a consequence of the establishment of a chemokine gradient induced through neuroinflammatory responses (*34*, *35*). Thus, we have sought to develop replicate PD-like model systems for testing the utility

of cell-based delivery. First, divergent inflammatory cues were used to stimulate ROS production from microglia and included nitrated alpha synuclein (N-α-syn), thought to be released extracellularly in PD and elicit immune activation (*36*−*38*). Second, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced inflammation served as a gradient for BMM ingress into the brain. It is well-documented that following inflammatory cues, leukocytes are recruited to the brain through diapedesis and chemotaxis (*39*−*43*). Monocyte-macrophages can migrate across the brain paracellular spaces crossing junctional complexes of brain endothelial cells (*44*, *45*). Their combat arsenal consists of engulfing foreign particles and liberating engulfed substances by exocytosis. All together, these features make it possible to exploit macrophages as carriers to affect neuroinflammatory processes (*46*−*49*).

Here we used BMM as a vehicle for carriage of therapeutic concentrations of catalase to the brain. We found that a major obstacle for success in this approach is that macrophages efficiently disintegrate engulfed particles (*49*). Therefore, it is crucial to protect the activity of the enzyme inside of the cell-carrier. Incorporation into polymeric nanocarries (nanospheres, liposomes, micelles, nanoparticles) can provide such protection (*50*−*60*). Early work by V.A. Kabanov et al. demonstrated that use of interpolyelectrolyte complexes can immobilize enzymes (*61*−*63*). The enzyme polyelectrolyte complexes can be prepared at the nanoscale by self-assembly of enzymes with oppositely charged block polyelectrolytes containing ionic and nonionic water soluble blocks (*64*, *65*). The resulting nanoparticles contain a core of protein−polyelectrolyte complex surrounded by a shell of water soluble nonionic polymer such as polyethylene glycol (PEG). In the current work, we immobilized catalase by reacting it with a cationic block copolymer, polyethyleneimine-poly(ethylene glycol) (PEI-PEG), previously used for delivery of polynucleotides (*66*). The resulting block ionomer complexes of catalase ("nanozymes") are taken up by BMM. We present evidence that such modification protects catalase against degradation in BMM, that BMM release nanozymes in the external medium for at least 4−5 days, and that BMM can carry nanozymes to the brain in the MPTP model of PD.

EXPERIMENTAL PROCEDURES

Materials. Catalase from bovine liver, polyethylenimine (PEI) (2K, branched, 50% aq solution), sulforhodamine-B (SRB), sodium dodecylsulfate (SDS), Sephadex G-25, and Triton X-100 were purchased from Sigma-Aldrich (St-Louis, MO). Methoxypoly(ethylene glycol) epoxy (Me-PEG-epoxy) was purchased from Shearwater Polymer Inc., Huntsville, AL (custom synthesis).

BMM. Bone marrow cells extracted from murine femurs (C57BL/6, female mice) as described (*32*) were cultured for 10 days in the media supplemented with 1000 U/mL macrophage colony-stimulating factor (MCSF) (a generous gift from Wyeth Pharmaceutical, Cambridge, MA). The purity of monocyte culture was determined by flow cytometry using FACSCalibur (BD Biosciences, San Jose, CA).

Microglia. Brains from C57BL/6 neonates (1−3 days old) were removed, washed with ice-cold HBSS, and mashed into small pieces. Supernatant was replaced for 2.5% trypsin and DNAse solution (1 mg/mL) and incubated for 30 min at 37 °C, and then 1 mL of ice cold FBS with 10 mL HBSS was added. The mixture was centrifuged (5 min, 1500 rpm, 4 °C), and complete media with MCSF was added to the pellet. The cells were cultured until maturation (typically 10 days).

MPTP. For MPTP-intoxication recipient C57BL/6, mice were treated as described (*67*). After 12 h, MPTP-treated mice were injected i.v. with the 50 μCi/mouse of ^{125}I-labeled nanozyme alone or nanozyme loaded into BMM (10×10^6 cells/mouse, 4 mice/group). After 24 h mice were sacrificed and the amount of radioactivity in major organs (brain, spleen, liver, lungs, and kidney) was detected by 1480 gamma-counter Wizard 3 (Perkin-Elmer Life Sciences, Shelton, CT). The amount of the delivered enzyme was expressed as a percent of the injected dose for the whole organ.

PEI-PEG Conjugates. The copolymer was synthesized using a modified procedure (*68*) by conjugation of PEI and Me-PEG-epoxy. Briefly, Me-PEG-epoxy water solution was added to 5% PEI in water and incubated overnight at RT. To purify from the excess of PEI (as well as from low molecular weight residuals), the obtained conjugates were dialyzed in SpectraPore membrane tubes with cutoff 6000−8000 Da against water (twice replaced) for 48 h and then concentrated *in vacuo*. For final purification, the conjugate was dissolved in 20 mL of 100% methanol and then added dropwise to 400 mL of ether. The precipitate was centrifuged (400*g*, 5 min), washed twice with ether, and dried in an exicator. Detailed characterization of the product was performed by spectrophotometry and mass spectrometry as reported (*68*).

Block Ionomer Complexes. Given amounts of the catalase (1 mg/mL) and the block copolymer (2 mg/mL) were separately dissolved in phosphate-buffered saline (PBS) at RT. A solution of the enzyme was added dropwise to the block copolymer solution at constant stirring. The +/− charge ratio (Z) was calculated by dividing the amount of amino groups of PEI-PEG protonated at pH 7.4 (*66*) by the total amount of Gln and Asp in catalase. A combination of physicochemical methods (electrophoretic retention, dynamic light scattering (DLS), and transmission electron microscopy (TEM)) was used to characterize composition, size, dispersion stability, morphology, shape, and structure of the obtained nanoparticles, as described previously (*69*−*72*).

Electrophoretic Retention. The formation of polyion complexes was examined by acrylamide gel shift assay. Enzyme complexes at various Z were loaded in a 7.5% acrylamide gel with 5 mM Tris, 50 mM glycine, pH 8.3, under nondenaturizing conditions (in the absence of SDS) to preserve the complex. The protein bands were visualized with rabbit polyclonal anti-catalase (Ab 1877, Abcam Inc, Cambridge, MA; 1:6000) and secondary horseradish peroxidase anti-rabbit Ig Ab (Amersham Life Sciences, Cleveland, OH; 1:1500). The specific protein bands were visualized using a chemiluminescence kit (Pierce, Rockford, IL).

Light Scattering Measurements. Effective hydrodynamic diameter and zeta-potential of nanozymes was measured by photon correlation spectroscopy using 'ZetaPlus' Zeta Potential Analyzer (Brookhaven Instruments, Santa Barbara, CA) as described previously (*73*, *74*).

TEM. A drop of catalase/PEI-PEG dispersion ($Z = 1$) in PBS was placed on Formvar-coated copper grid (150 mesh, Ted Pella Inc., Redding, CA). The dried grid containing nanozymes was stained with vanadyl sulfate and visualized using a Philips 201 transmission electron microscope (Philips/FEI Inc., Briarcliff Manor, NY).

Catalase and Catalase Activity. The activity of the enzyme in polymer nanoparticles (*75*) was studied using the reaction rate of hydrogen peroxide decomposition by catalase or nanozymes at various charge ratios and was determined by monitoring the change in absorbance at 240 nm (the extinction coefficient of H_2O_2 is 44×10^6 M^{-1} cm^1).

Labeling Catalase with Alexa Fluor 594 and Rhodamine Isothiocyanate (RITC). For loading and release studies, the enzyme was labeled with Alexa Fluor 594 Protein Labeling Kit (A10239, Molecular probes, Inc., Eugene, OR) according to the manufacturers protocol. For confocal microscopy studies, cata-

lase was labeled with RITC. Briefly, catalase was dissolved in 0.1 M sodium carbonate buffer, pH 8.5 (1 mg/mL), and treated with RITC (10 mg/mL) in DMSO for 2 h at RT. Labeled catalase was purified from low molecular weight residuals by gel filtration on a Sephadex G-25 column (1 × 20 cm) in PBS at elution rate 0.5 mL min^{-1} and lyophilized.

Accumulation and Release of Nanozymes in BMM. BMM grown on 24-well plates (2.5 × 10^6cells/plate) (*76*, *77*) were preincubated with assay buffer (122 mM NaCl, 25 mM $NaHCO_3$, 10 mM glucose, 3 mM KCl, 1.2 mM $MgSO_4$, 0.4 mM K_2HPO_4, 1.4 mM $CaCl_2$, and 10 mM HEPES) for 20 min. Following preincubation, the cells were treated with the Alexa-Fluor 594 labeled enzyme (0.7 mg/mL) in assay buffer alone or nanozyme for various time points. After incubation, the cells were washed three times with ice-cold PBS and solubilized in Triton X 100 (1%). For measures of nanozyme released from BMM, loaded BMM were incubated with fresh media at various time points. Fluorescence in each sample was measured by a Shimadzu RF5000 fluorescent spectrophotometer (λ_{ex} = 580 nm, λ_{em} = 617 nm). The amount of nanozyme was normalized for protein content and expressed in μg of enzyme per mg of the protein for loading experiments and μg enzyme per mL media as mean ± SEM (n = 4).

Intracellular Localization of Nanozymes. Monocytes grown in the chamber slides (*77*) were exposed to RITC-labeled nanozyme (Z = 1) for 24 h at 37 °C. Following incubation, the cells were fixed in 4% paraformaldehyde and stained with F-actin-specific Oregon Green 488 phalloidin and a nuclear stain, ToPro-3 (Molecular Probes, Inc., Eugene, OR). Labeled cells were examined by a confocal fluorescence microscopic system ACAS-570 (Meridian Instruments, Okimos, MI) with argon ion laser (excitation wavelength, 488 nm) and corresponding filter set. Digital images were obtained using the CCD camera (Photometrics) and Adobe Photoshop software.

Antioxidant Activity Measures. Mature mouse BMM were loaded with the enzyme alone or nanozymes (Z = 1) for 1 h and washed with PBS, and fresh media was added to the cells. Following various time intervals, the media was collected and antioxidant activity of the enzyme released from BMM was assayed by the rate of hydrogen peroxide decomposition.

Ampex Red Dye Fluorescence Assay. Murine microglial cells seeded in 96-well plates (0.1 × 10^6 cells/well) were either stimulated with tumor necrosis factor alpha (TNF-α) (200 ng/mL) for 48 h or with nitrated alpha-synuclein (N-α-syn) (0.5 μM) to induce ROS production. In parallel, BMM grown in 24-well plates were loaded with "naked" catalase (1 mg/mL) or nanozyme for 1 h and then incubated with Krebs-Ringer buffer (145 mM NaCl, 4.86 mM KCl, 5.5 mM glucose, 5.7 mM NaH_2PO_4, 0.54 mM $CaCl_2$, 1.22 mM $MgCl_2$, pH 7.4) for 2 h to collect catalase released from the cells into the supernatant (Figure 5A). Following incubation, the supernatants collected from BMM loaded with "naked" catalase or nanozyme were supplemented with Ampex Red Dye stock solution (10 U/mL HRP, 10 mM Ampex Red). For N-α-syn stimulation of microglia, supernatants were also supplemented with 0.5 μM aggregated N-α-syn. Obtained solutions were added to the activated microglial cells, and the decomposition of ROS by "naked" catalase or nanozyme was measured by fluorescence at λ_{ex} = 563 nm, λ_{em} = 587 nm. The effect of the supernatants collected from nonloaded BMM or loaded with PEI-PEG alone on ROS decomposition was evaluated in comparison to the control experiments.

^{125}I-Labeling of Catalase Nanozyme. To obtain ^{125}I-labeled catalase nanozyme, the protein solution in PBS (1 mg/mL) was incubated for 15 min with Na^{125}I (1 mCi) in the presence of IODO-BEADS Iodination Reagent (Pierce, Rockford, IL) and then purified from nonconjugated label using D-salt Desalting Columns (Pierce, Rockford, IL). ^{125}I-labeled catalase (400 μCi/mL, 0.7 mg/mL) was supplemented with PEI-PEG block copolymer (Z = 1) and loaded into mature monocytes (80 × 10^6 BMM in 1 mL of medium) for 2 h at 37 °C. After incubation, the loaded monocytes were washed three times with ice-cold PBS.

Statistical Analysis. For the all experiments, data are presented as the mean ± SEM. Tests for significant differences between the groups were done using one-way ANOVA with multiple comparisons (Fisher's pairwise comparisons) using GraphPad Prism 4.0 (GraphPad software, San Diego, CA). A minimum p value of 0.05 was estimated as the significance level for all tests.

RESULTS

Manufacture and Testing of Nanozymes. Block ionomer complexes spontaneously form by mixing block ionomers with either oppositely charged surfactants or polyelectrolytes (*64*, *78*−*80*). Neutralization of the polyion charges leads to formation of hydrophobic domains, which segregate in aqueous media into a core of polyion complex micelles. Water-soluble nonionic segments of block ionomers (for example, PEG) prevent aggregation and macroscopic phase separation. As a result, these complexes self-assemble into particles of nanoscale size and form stable aqueous dispersions (Figure 1A). Catalase has a net negative charge under physiological conditions. Therefore, the polyion complexes were obtained in phosphate buffer (pH 7.4) by mixing the enzyme (1 mg/mL) and PEI-PEG (2 mg/mL), which is positively charged.

Catalase and PEI-PEG complexes were obtained at various +/− charge ratios (Z = from 0 to 4). They were subjected to electrophoresis under nondenaturizing conditions and then transferred to nitrocellulose membranes. The protein bands were visualized with antibodies to catalase (Figure 1B). The band intensity decreased as the copolymer increased. This suggested that complexes formed that were unable to enter the gel and was confirmed by DLS. Addition of PEI-PEG to catalase solution (1 mg/mL) resulted in particles of nanoscale size with relatively low polydispersity index (about 0.1−0.2), while no particles were detected for catalase alone.

Particle size depended on the charge ratio, ionic strength, and pH (Figure 1, parts C, D, and E). In PBS, the effective diameter increased as the charge ratio increased and then stabilized at ca. 90 to 100 nm at the charge ratio (Z) of 1 and above (Figure 1C). The zeta-potential was increased upon increasing the amount of the block copolymer (Figure 1C). At a constant charge ratio (Z = 1) large aggregates over 600 nm were formed in the absence of salt (Figure 1D). Addition of salt decreased the particle size which stabilized at ca. 90 nm as the NaCl concentration reached 0.15 M. It is likely that large nonequilibrium polyelectrolyte complex aggregates form upon mixing the catalase and PEI-PEG solutions. In the absence of salt these aggregates could not equilibrate and remained "frozen" due to a low rate of polyion interchange (*81*, *82*). As salt was added the polyion interchange was accelerated, resulting in formation of small (equilibrium) particles. These particles were stable in an approximate range of pH 7.4 to 11.5 but irreversibly aggregated when pH was decreased below or increased above this range (Figure 1E). Within this range the catalase and PEI-PEG were oppositely charged. The aggregation of the complexes was linked to protonation and charge inversion of catalase (pI = 6.5) at low or deprotonation of PEI at high pH. Overall, nanozyme particles were stable under physiological pH and ionic strength. Under these conditions the particles were close to spherical (Figure 1D). No changes in the enzymatic activity of catalase were observed at charge ratios used for subsequent cell loading, delivery, and release experiments (Supporting Information, Figure S-1).

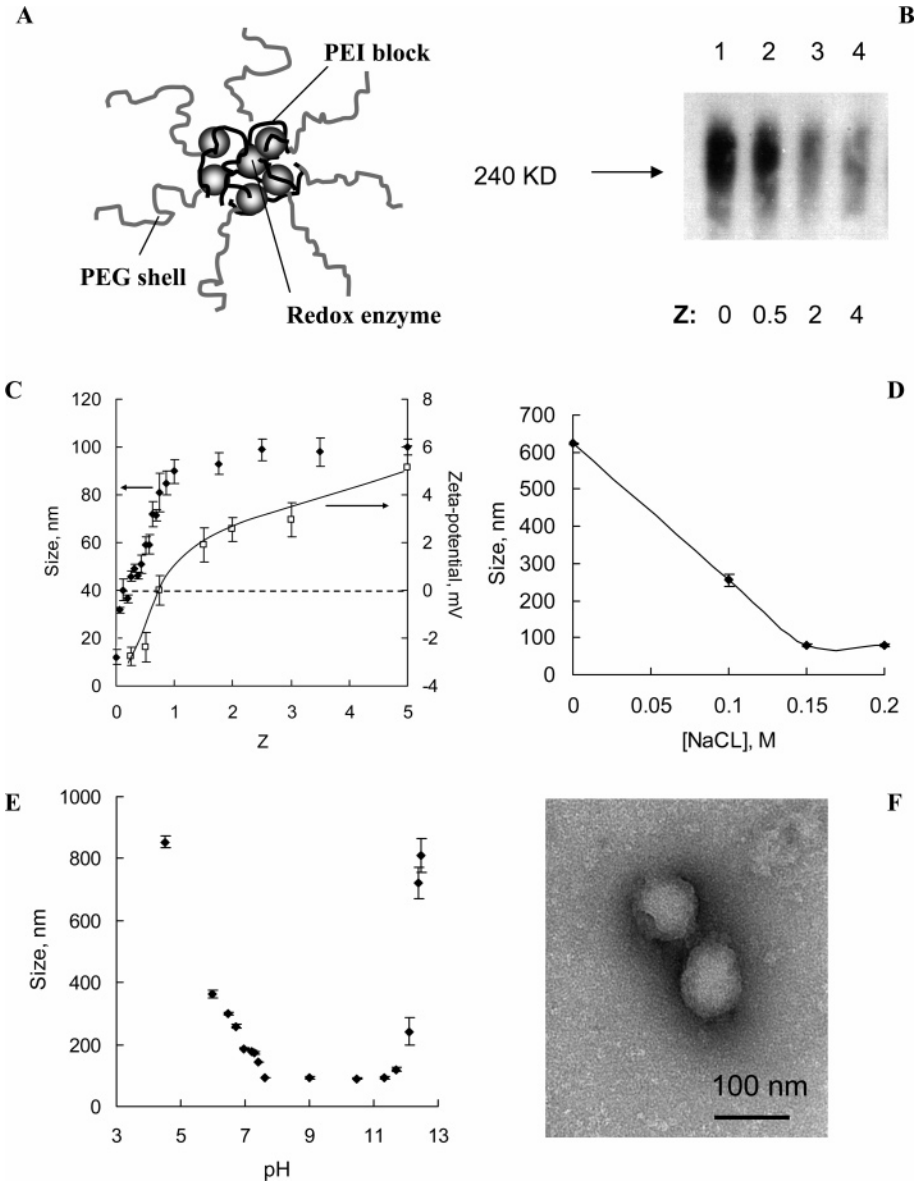

Figure 1. Characterization of catalase nanozyme. A: Schematic presentation of the enzyme-polyion complex structure. B: Gel retardation assay of the enzyme/polyion complexes at various Z. Samples were subjected to gel electrophoresis in polyacrylamide gel (7.5%) under nondenaturing conditions (without SDS). Line 1: enzyme alone; lines 2−4: enzyme/PEI-PEG complexes with progressive increasing of *Z* (0.5, 2, 4). C−E: Characterization of catalase/polyion complex by DLS. Changes in cumulant diameter (C−E) and zeta-potential (C) of catalase nanozyme with various: C: *Z* in PBS solutions; D: ionic strength ($Z = 1$, pH 7.4); E: pH ($Z = 1$, [NaCl] = 0.15M). F: TEM images of catalase nanozyme ($Z = 1$). Bar represents 100 nm.

Loading of Catalase Nanozymes in BMM. Initially, using the sulforhodamine-B (SRB) cell viability assay, we demonstrated that nanozymes (as well as catalase or copolymer alone) did not induce BMM cytotoxicity over a wide range of concentrations (0.03 to 1000 μg catalase per mL) (Supporting Information, Figure S-2). The accumulation kinetics suggested a rapid uptake of both free catalase and nanozyme in BMM (Figure 2A). Notably the free enzyme was taken up in BMM almost twice as fast as the nanozyme. At 60 min time point the loading of BMM with nanozyme was ca. 30 μg catalase/10^6 cells. The uptake of the nanozyme at the 60 min time point decreased as the charge ratio increased (Figure 2B), which may be due to the effect of the PEG corona. The confocal microscopy data suggested vesicular and/or cytoplasmic localization of RITC-labeled catalase administered to BBM in nanozyme (Figure 2C).

Nanozyme Release from BMM. Mature BMM were preloaded with Alexa Fluor 594-labeled catalase nanozyme (60 min) and then cultured in the fresh media for different time intervals. The loaded BMM released catalase in the external media for at least 4−5 days (Figure 3). During the same period, the amount of the enzyme associated with the cells was proportionally decreased. Exposure of nanozyme-loaded BMM to 10 μM phorbol myristate acetate (PMA), a potent activator of the protein kinase C pathway and ROS generation (*83*), enhanced enzyme release in the media by ca. 50% (Supporting Information, Figure S-3). This suggested that release of nanozyme from BMM may be dependent on cell activation.

BMM Released Nanozyme Activity. BBM loaded with "naked" catalase or nanozyme were placed in a fresh media, and the activity of the enzyme released in the media was determined at different incubation time intervals. Contrary to BMM loaded with free catalase that was practically inactive after the release, the nanozyme-loaded cells released active enzyme for at least 24 h (Figure 4A). The maximal activity of the released enzyme was observed for BMM loaded with nanozyme prepared at the stoichiometric ratio, $Z = 1$ (Figure 4B). All together, this suggests that incorporation of catalase

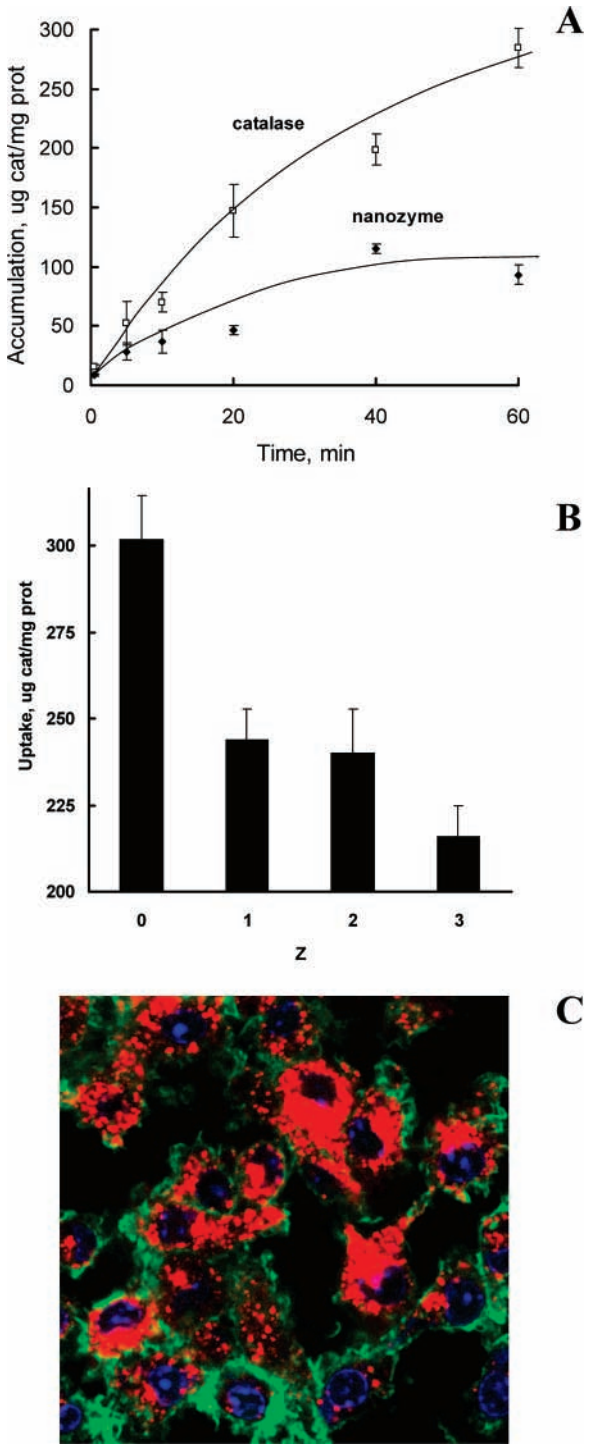

Figure 2. A: Kinetics of "naked" catalase and nanozyme ($Z = 1$) accumulation in monocytes. Cells were treated with the Alexa Fluor 594 labeled enzyme or nanozyme at various time points. Following incubation, the cellular content was collected, and the amount of fluorescence was measured by fluorescent spectrophotometer ($\lambda_{ex} =$ 580 nm, $\lambda_{em} = 617$ nm). Data represent means ± SEM ($n = 4$); B: Accumulation of catalase nanozymes in BMM at various Z. C: Intracellular localization of RITC-labeled catalase nanozyme in BMM. Cells grown on cover slips were loaded with catalase/PEI-PEG complex ($Z = 1$) (red staining) for 24 h. Following the incubation, the cells were fixed and stained with F-actin−specific Oregon Green 488 phalloidin (green) and a nuclear stain, ToPro-3 (blue). Images were obtained by confocal fluorescence microscopic system ACAS-570.

in a block ionomer complex with PEI-PEG results in protection and sustained release of active catalase from BMM.

Modulation of ROS Released by Activated Microglia. To assess the antioxidant capacity of the catalase nanoformulations

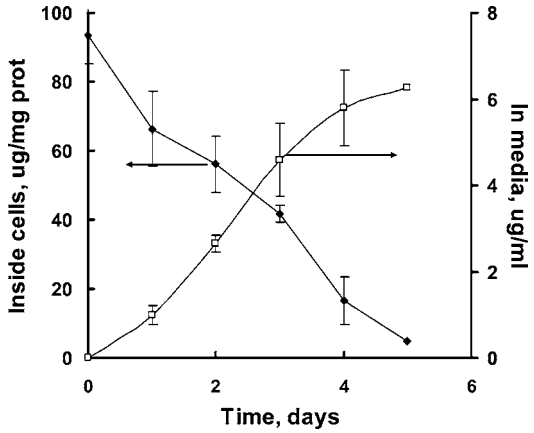

Figure 3. Release profile of catalase nanozyme from BMM. Cells were loaded with catalase/PEI-PEG complex ($Z = 1$) for 1 h, washed with PBS, and incubated with catalase-free media for various time intervals. Amount of catalase released into the media and retained in the cells was accounted by fluorescent spectrophotometry. Data represent means ± SEM ($n = 4$).

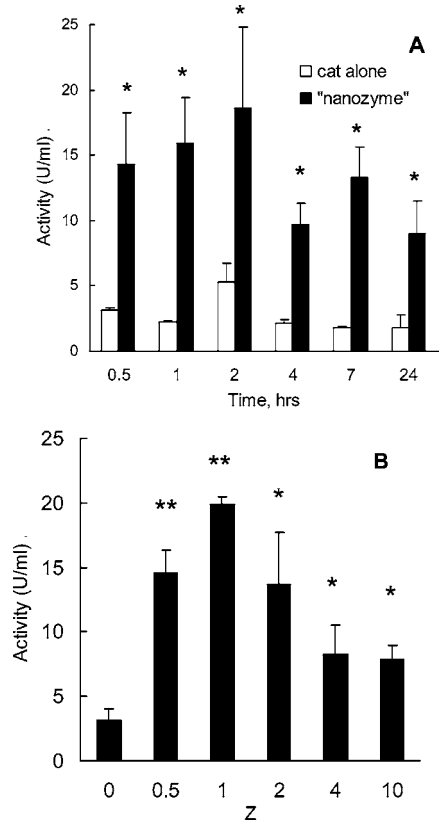

Figure 4. Preservation of enzymatic activity of catalase against degradation in BMM. A: "Naked" catalase or nanozyme ($Z = 1$) were loaded into BMM, and cells were washed and incubated with catalase-free media for various time intervals. The activity of catalase released from BMM was determined by spectrophotometry. B: Catalase polyion complexes with various compositions (Z) were loaded into the cells and incubated in catalase-free media for 2 h. Then, the media was collected and assessed for catalase activity by spectrophotometry. Data represent means ± SEM ($n = 4$). Statistical significance of nanozyme activity compared to catalase alone is shown by asterisks: (*) $p < 0.05$, (**) $p < 0.005$.

on microglial ROS production, BMM loaded with "naked' catalase or nanozyme were incubated for 2 h in Krebs-Ringer buffer, and the reluctant supernatant was then collected and added to TNF-α (200 ng/mL)-stimulated microglial cells. The catalase in the supernatants collected from the catalase- or nanozyme-loaded BMM decomposed hydrogen peroxide by

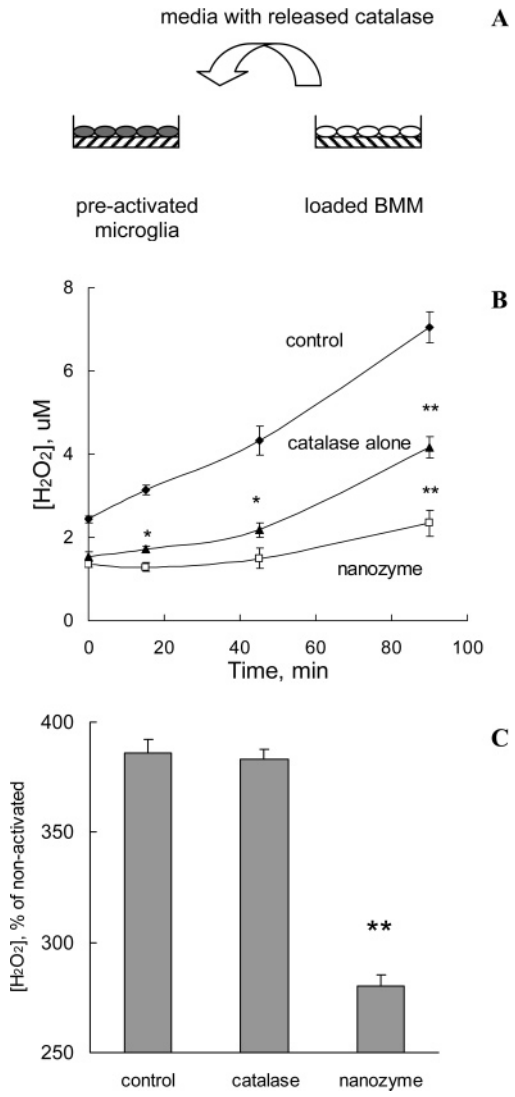

Figure 5. Modulation of microglial-derived ROS by catalase nanozyme released from BMM (A: overall scheme). "Naked" catalase or catalase nanozyme ($Z = 1$) were loaded into BMM. Then, cells were washed and incubated in Kreb's Ringer buffer for 2 h. In parallel, murine microglial cells were either stimulated with (B) 200 ng/mL TNF-α (48 h), or (C) 0.5 μM N-α-syn. Then, supernatants collected from BMM with the released enzyme were supplemented with Amplex Red and HRP solutions and added to the activated microglial cells. Control activated microglia was incubated with fresh media (B) or 0.5 μM aggregated N-α-syn (C). The amount of H_2O_2 produced by microglial cells and decomposed by catalase released from BMM was detected by fluorescence. Data represent mean ± SEM ($n = 6$). Statistical significance of the amount of H_2O_2 decomposed by released from BMM nanozyme or catalase, compared to activated microglia (control) is shown by asterisks: (*) $p < 0.05$, (**) $p < 0.005$.

microglia (Figure 5A). A greater effect was observed by nanozyme, which was consistent with its ability to preserve enzyme activity in carrier cells. Furthermore the supernatants collected from unloaded BMM (Figure 5B) or from BMM loaded with PEI-PEG alone (Supporting Information, Figure S-4) had little, if any, effect on the hydrogen peroxide level. To determine whether these findings could be reproduced in microglia activated by stimuli typically found in PD, cells were stimualted with 0.5 μM N-α-syn. Aggregated N-α-syn present as cytoplasmic bodies in PD are released following the death of dopaminergic neurons and are a major component of Lewy bodies (*84*) . These aggregated proteins are hypothesized to serve as a stimulus for microglial activation (*36*, *85*). Once again, the level of hydrogen peroxide was significantly reduced with

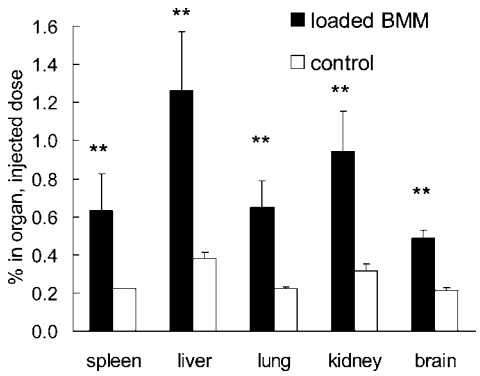

Figure 6. Biodistribution of ^{125}I-labeled nanozyme in MPTP-treated mice. Mice were injected with BMM (10×10^6 cells/mouse) loaded with catalase nanozyme ($Z = 1$, 50 μCi/mouse) or with nanozyme alone (control group). Twenty-four hours later mice were sacrificed and the amount of radioactivity was measured in various organs. Data represent mean ± SEM ($n = 4$). Statistical significance of the BMM-loaded nanozyme transport compared to the nanozyme alone group is shown by asterisks: (**) $p < 0.005$.

the addition of supernatants from nanozyme loaded BMM (Figure 5C). All together this study suggests that nanozyme released from BMM can attenuate oxidative stress resulting from activation of microglia.

Biodistribution of ^{125}I-labeled Catalase in MPTP-treated Mice. To determine if BMM carrying nanozyme could reach brain subregions with active neuroinflammatory disease reflective of human PD, we used the MPTP model. Two groups of MPTP-intoxicated C57Bl/6 mice were either injected intravenously with free nanozyme containing ^{125}I-labeled catalase or received adoptively transferred nanozyme-loaded BMM. Twenty four hours after injection there were significant increases in the radioactivity levels in spleen, liver, lung, kindney, and brain in the groups receiving adoptive transfer compared to groups treated with nanozyme alone (Figure 6). Noteworthy, after the adoptive transfer about 0.6% of the injected dose was found in the brain which was twice what was found in animals injected with free nanozyme. All together these data provide initial evidence that adoptive transfer of nanozyme loaded BMM can increase the delivery of the enzyme to the brain as well as other peripheral tissues known to be sites of macrophage tissue migration.

DISCUSSION

Efficient transport of therapeutic polypeptides to the brain is required for successful therapies for neurodegenerative and neuroinflammatory diseases. To this end, we examined whether BMM could be used as vehicles for delivery of a potent antioxidant, catalase. Indeed, it has long been known that macrophages and microglia as well as other mononuclear phagocytes can endocytose colloidal nanomaterials, for example, liposomes or nanosuspensions, and subsequently carry and release the drug to site of tissue injury, infection, or disease (*32*, *33*, *35*, *46*, *86*).

Moreover, the abilities of BMM to cross BBB was also investigated (*87*−*94*). In particular, it was demonstrated that monocytes infiltrate the brain in the MPTP mouse model of PD (*91*−*93*). Indeed, MPTP toxicity stimulated transient and global increases in the rate of monocyte infiltration into the midbrain, stratum, septum, and hippocampus. In these prior studies, the maximal accumulation of the monocyte-macrophages in the brain was observed 1 day after the MPTP treatment. On the basis of these data, we hypothesize that catalase-loaded monocytes adoptively transferred in MPTP-treated mice can deliver enzyme to regions of the brain most affected in PD and including the substantia nigra and striatum.

To protect against catalase degradation inside the BMM, the protein was immobilized in the block ionomer complex with a cationic block copolymer, PEI-PEG. The resulting nanoparticles, nanozymes, were ca. 60 to 100 nm in size and stable in physiological conditions (pH, ionic strength). We optimized the composition and structure of nanozymes to achieve high loading in BMM and preserve catalase activity. Internalization of foreign particles, as well as the exocytotic secretion, is one of the most basic functions in macrophages (*95*). This study demonstrated that BMM can accumulate a significant amount of nanozyme (ca. 30 μg catalase/10^6 cells) in a relatively short time period (about 40−60 min), followed by its sustained release during 4−5 days into the external media. This also suggested that nanozyme-loaded cells after adoptive transfer may have sufficient time to reach the brain and release catalase. Moreover, it was reported (*96*−*98*) that exocytosis can be stimulated by activation of monocytes and macrophages. Our experiment shows that release of nanozyme by BMM can be enhanced by stimulation with PMA.

We also demonstrate that block ionomer complex protects activity of catalase inside the host cells. Notably, the nanozyme-loaded BMM released active enzyme in the media for at least 24 h. Furthermore, the culture supernatants collected from nanozyme-loaded BMM had potent antioxidant effects in our assay for ROS produced by microglia activated with either N-α-syn or TNF-α. Thus, these cell culture models suggest that nanozyme-loaded BMM can mitigate oxidative stress that may be associated with the neurodegenerative process. Finally, we provide initial *in vivo* evidence that adoptive transfer of nanozyme-loaded BMM can increase delivery of labeled enzyme into the tissues including 2-fold increase in the amount of the enzyme in the brain in MPTP-treated mice. Interestingly, considerable amount of the labeled enzyme was also found in the brain after injection of the nanozyme alone. We cannot exclude that in this case the nanozyme may be taken up by circulating monocytes, which then carry the enzyme to the brain. Our further experiments will examine the possibilities for increasing nanozyme transport specifically to the areas of neurodegeneration and evaluate neuroprotective effects in PD models.

Overall, we demonstrate that BMM loaded with catalase incorporated into a protective polymer container and has therapeutic potential. We are cautiously optimistic that these studies will lead to development of new technologies based on cell-mediated delivery of therapeutic polypeptides that can attenuate oxidative stress and elicit anti-inflammatory responses that may be widely useful in the treatment of neurodegenerative disorders.

ACKNOWLEDGMENT

This study was supported by Tobacco Settlement Funds awarded to University of Nebraska, NSF DMR-0071682 to A.V.K. and 2 R37 NS36126, 1 P01 NS043985-01, 5 P01 MH64570-03, and P20 RR15635 to H.E.G. We would like to thank Dr. Sergey Vinogradov for assistance in synthesis of PEI-PEG and Drs. Jonathan Kipnis and Mark Thomas for valuable discussions.

New Noninvasive Methodology for Real-Time Monitoring of Lipid Flip

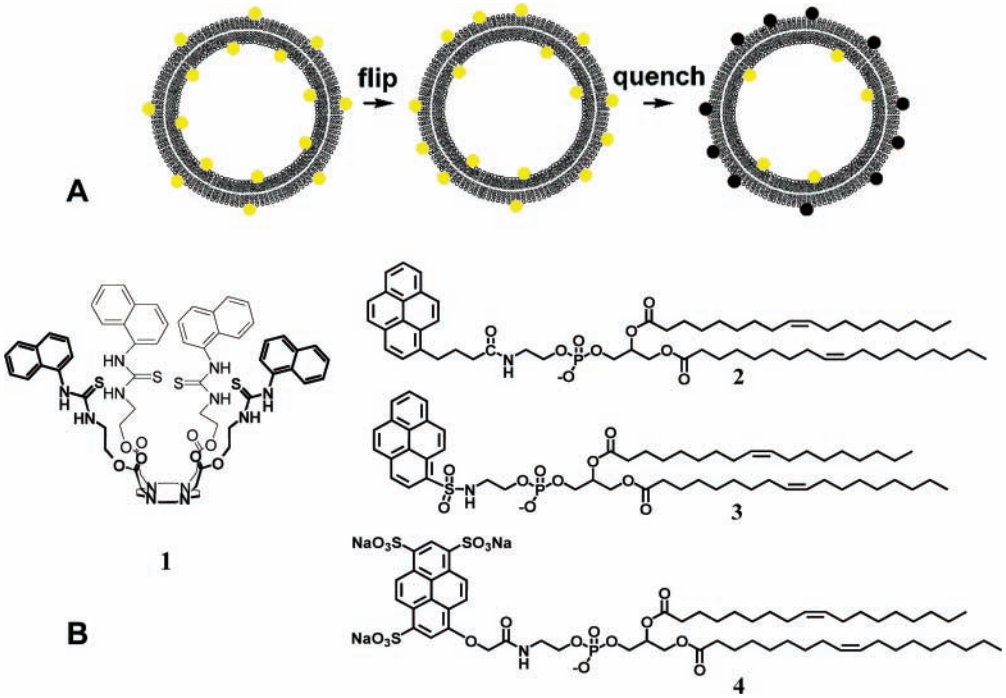
Christine A. Winschel,[†] Vivek Kaushik,[†] Galya Abdrakhmanova,[‡] Sheena M. Aris,[†] and Vladimir Sidorov[†,*]

Department of Chemistry, Virginia Commonwealth University, Richmond, Virginia 23284-2006, and Department of Pharmacology and Toxicology, Virginia Commonwealth University, Richmond, Virginia 23298. Received May 25, 2007; Revised Manuscript Received July 4, 2007

A new methodology for the detection of lipid flip was developed. This methodology relies on the quenching of the fluorescence of the cascade-blue-labeled lipid through complex formation with a membrane-impermeable cyclen-tetranaphthalenethiourea synthetic receptor for this dye. The high affinity of the receptor to cascade-blue label allows the use of micromolar concentrations of this receptor during the experiment. At these low concentrations, the receptor does not interfere with the membrane integrity and, therefore, renders this new methodology less invasive to the model and cell membranes than commonly utilized 7-nitro-1,2,3-benzoxadiazol-4-yl (NBD)-dithionite methodology. Unlike with the NBD-dithionite assay, where the fluorescence quenching of the NBD group is achieved through its chemical modification, this new assay relies on the noncovalent interactions between cascade-blue label and the receptor. Therefore, the quenching can be reverted by either competitive displacement of the lipid-attached label with a water-soluble substrate or by enzymatic degradation of the receptor leading to the label release and fluorescence dequenching. We demonstrate that this new methodology is suitable for the study of lipid flip in both model spherical bilayer membranes and in-vitro experiments.

INTRODUCTION

Lipid flip detection assays allow monitoring of the activity of enzymes known as flippases, floppases, and scramblases (*1*) and their fully synthetic (*2*−*5*) or peptide analogues (*6*, *7*). These enzymes control the transmembrane distribution of lipids in cells and are responsible for membrane asymmetry. Lipid translocation mediated by these enzymes is associated with apoptosis (*8*−*12*) and blood clotting (*13*, *14*). The synthetic molecules capable of lipid flipping can be considered as developmental therapeutics for several disorders (*15*, *16*), such as Scott syndrome and vascular complications in Alzheimer's disease (*17*, *18*). Furthermore, flip of cationic lipids may greatly improve the efficiency of nonviral gene delivery systems (*19*). To date, three major assays are utilized for the monitoring of lipid flip in model spherical bilayers (liposomes). The first method relies on the flip of transferable fluorescent 7-nitro-1,2,3-benzoxadiazol-4-yl (NBD)-labeled lipid from the donor liposomes to the acceptor liposomes containing nontransferable rhodamine-labeled lipid that serves as a fluorescence quencher (*20*). The second methodology is based on removal of the fluorescent lipid (*21*) from the bilayer outer leaflet by incubation with serum albumin (*22*). The most conventional way for detection of flippase activity is based on the irreversible quenching of the fluorescence of NBD-labeled lipids in cells (*23*) or liposomes (*24*, *25*) with 10−60 mM sodium dithionite ($Na_2S_2O_4$, Scheme 1A). The extent of lipid flip is assessed from the residual fluorescence of liposomes after the application of the quencher. Because of its anionic character, dithionite exhibits low permeability to the hydrophobic bilayer membrane and therefore does not rapidly quench the fluorescence of the lipid located on the inner bilayer leaflet but quickly quenches the fluorescence of lipid residing on the outer leaflet. The assay has numerous intrinsic deficiencies arising from the high concentration of the quencher required for the assay, the reductive nature of this reagent, and some permeability of the quencher to the bilayer membrane. Thus, it has been shown recently that sodium dithionite diffusion through the bilayer is similar or faster than that of unfacilitated lipid flip (*26*). Potentially, dithionite can reduce the disulfide cross-links found in some flippases. For example, wild type human P-glycoprotein (Pgp), which is a known flippase (*27*), facilitates the lipid flip to a lesser extent than Pgp treated with the reducing agent because of inhibitory disulfide cross-links between nucleotide binding sites (*28*). In contrast, the activity of human scramblase protein is suppressed by reducing reagents because of the reduction of disulfide cross-links (*29*). These examples demonstrate that dithionite may affect the flipping activity of enzymes in a dual way and, therefore, cannot be used in the real time monitoring experiments.



EXPERIMENTAL PROCEDURES

General. The ^{1}H NMR spectra were recorded on a Varian AS400 instrument operating at 400.130 MHz or Varian Mercury instrument operating at 299.865 MHz. Chemical shifts are reported in ppm relative to the residual protonated solvent peak. The mass spectra were recorded on a Micromass Q-TOF 2 instrument (Manchester, UK) using the electrospray technique (positive and negative modes were used). The samples were introduced into the mass spectrometer using a flow rate of 10 μL/min, the needle voltage was set at 3500 V with ion source at 110 °C, and the cone voltage was set at 35 V. All spectrophotometric experiments were carried out on a Fluoromax 3 (Jobin-Yvon/Horriba) spectrophotometer. The pH of solutions was monitored with a Corning 350 pH/ion analyzer, using a Ag/AgCl pH-sensitive electrode (Accumet). Chromatography was performed using 60−200 mesh silica purchased from Baker and 40−120 μm Sephadex G-75 purchased from Aldrich. Thin layer chromatography was performed on Kieselgel 60 F254 and Uniplate Silica Gel GF silica-coated glass plates and visualized by UV and I_2. High-pressure extrusion was performed on the Avanti miniextruder with a 0.1 μm polycarbonate membrane. All chemicals, solvents, and dyes were purchased from Aldrich, Sigma, Fluka, and Invitrogen. Egg yolk phosphatidylcholine, L-α-dioleoylphosphatidylethanolamine

Scheme 1. Schematic Representation of Lipid-Flip Detection Assay and Structures of the Compounds Used in the Present Study[a]

[a] A. Liposomes containing fluorescently labeled lipids are treated with membrane-impermeable quencher. Alterations in the residual fluorescence of the lipids from inner bilayer leaflet serve as the measure of lipid flip. B. Structures of the receptor **1** and fluorescently labeled lipids used in the present study.

(DOPE), *N*-(7-nitro-2−1,3-benzoxadiazol-4-yl)-(1,2-dioleoyl-sn-glycero-3)-phosphoethanolamine (NBD-PE), and *N*-(1-pyrenesulfonyl)-(1,2-dioleoyl-sn-glycero)-3-phosphoethanolamine (lipid **3**) were purchased from Avanti Polar Lipids.

Synthesis. Cyclen **1** was synthesized as reported (*30*).

Lipid **2** was synthesized in a one-step procedure as follows: 1,2-Dioleoyl-sn-glycero-3-phosphoetyanolamine (DOPE) (33 mg, 0.044 mmol) and 1-pyrenebutyric acid (68 mg, 0.177 mmol, 4-fold excess) were dissolved in 2 mL of DMF. A 1 mL solution of N,N′-dicyclohexylcarbodiimide (DCC) (37 mg, 0.177 mmol, 4-fold excess) and 4-dimethylaminopyridine (22 mg, 0.177 mmol, 4-fold excess) was added dropwise at 0 °C. The reaction was allowed to come to room temperature and was stirred for 12 h. The solution was removed under reduced pressure and purified by column chromatography (silica gel, gradient of $CHCl_3$ and MeOH) yielding 9 mg of pure product (0.009 mmol, 20%). ^{1}H NMR ($CDCl_3$, δ): 8.18 (br s, 1H), 7.82−8.10 (m, 7H), 7.72 (br s, 1H), 5.28 (br s, 4H), 4.34 (br s, 1H), 4.12 (br s, 2H), 4.02 (br s, 2H), 3.94 (br s, 2H), 3.50 (s, 8H), 3.28 (br s, 3H) 2.50−0.80 (br m, 59H). MS (ESI, high-resolution) $[M]^-$: 1012.5525 calculated for $C_{61}H_{91}NO_9P^-$ 1012.644.

Lipid **4** was synthesized in a two-step procedure:

(i) 1,2-Dioleoyl-sn-glycero-3-phosphoethanolamine (50 mg, 0.067 mmol) was dissolved in 5 mL of CH_2Cl_2, and diisopropylethylamine(20 μL, 0.115 mmol, 1.7-fold excess) was added. A solution of bromoacetyl bromide (20 μL in 1 mL of CH_2Cl_2, 0.23 mmol, 3.4-fold excess) was added to the reaction mixture dropwise. The reaction mixture was stirred for 12 hrs at room temperature, and the solvent and excess reagents were removed under reduced pressure to afford crude *N*-(2-bromoacetyl)-1,2-dioleoyl-sn-glycero-3-phosphoethanolamine. The crude product was purified by column chromatography (silica gel, methanol: CH_2Cl_2 6:94) to give 53 mg of the pure product (0.061 mmol, 91%). ^{1}H NMR ($CDCl_3$, δ): 10.36 (br s, 2H), 5.33 (app p, 2H, J = 2.4 Hz), 4.39 (br s, 1H), 4.13 (br s, 1H), 3.93 (br s, 2H), 3.79−3.65 (m, 4 H), 3.18−3.05 (m, 4H), 2.38−2.30 (m, 2H), 2.00 (app q, 4 H, J = 5.7 Hz), 1.73 (m, 2H), 1.65−1.15 (m, 48 H), 0.87 (app t, 6 H, J = 5.7 Hz). MS (ESI, high-resolution) $[M]^-$: 862.5907, calcd for $C_{43}H_{78}BrNO_9P^-$ 862.4598.

(ii) *N*-(2-Bromoacetyl)-1,2-dioleoyl-sn-glycero-3-phosphoethanolamine (10 mg, 0.011 mmol) was dissolved in 2 mL of acetone, potassium carbonate (10 mg, 0.072 mmol, 6.5-fold excess) was added, and the reaction mixture was stirred for 40 min at room temperature. Then, 8-hydroxypyrene-1,3,6-trisulfonic acid sodium salt (10 mg, 0.019 mmol, 1.7-fold excess) was added, and the reaction mixture was stirred for 48 h under reflux. The solvent was evaporated under reduced pressure, and the residual solid was partitioned in chloroform−water. The organic layer was separated, and the solvent was removed under reduced pressure. The crude product was purified by the size exclusion chromatography (Sephadex G-75 as solid phase, Millipore water as mobile phase) to afford 4 mg of pure lipid **4** (potassium salt, 0.0029 mmol, 26%). ^{1}H NMR ($CDCl_3$, δ): 7.70 (m, 1H), 7.51 (m, 1H), 7.10 (br s, 1H), 6.96 (br s, 1H); 6.82−6.73 (m, 2H), 5.37 (app s, 2H), 4.69 (app s, 1H), 4.38−4.33 (m, 4 H), 4.15 (br s, 2H), 3.89 (s, 1H), 3.62 (br s, 2H), 2.36−2.25 (m, 2H), 2.0 (m, 4H), 1.66−1.10 (m, 48H), 0.72 (app t, 6H, J = 5.7 Hz). (ESI) $[M]^{2-}$: 658.4895, calcd for $C_{59}H_{85}K_2NO_{19}PS_3^{2-}$ 658.1948.

Preparation of Symmetric Liposomes for Lipid-Flip Monitoring Assays. Egg yolk L-α-phosphatidylcholine (EYPC ethanol solution, 60 μL, 79 μmol) and chloroform solution of labeled lipid (NBD-PE, lipid **2**, **3**, or **4**, 20−50 μL, 79 nmol) were dissolved in a $CHCl_3$/MeOH mixture to give a 1:1000 mixture of labeled lipid:EYPC, the solution was evaporated under reduced pressure, and the resulting thin film was dried under high vacuum for 2 h. The lipid film was hydrated for 40 min in 1.2 mL of sodium phosphate buffer (10 mM sodium phosphate, pH = 6.4, 100 mM NaCl). During hydration, the suspension was submitted to three freeze−thaw cycles (dry ice/acetone, water at room temperature). The resulting suspension of large multilamellar vesicles (1 mL) was submitted to high-pressure extrusion at room temperature. The LUV suspension was purified by size exclusion chromatography (SEC) (stationary

phase: Sephadex G-75, mobile phase: sodium phosphate buffer of the same composition) and diluted with the same sodium phosphate buffer to give a stock suspension with the total lipid concentration of 33 mM (assuming 100% of lipid was incorporated into liposomes).

Preparation of Asymmetric Liposomes with Excess of Lipid 4 in the Outer Bilayer Leaflet. The stock suspension of liposomes (30 μL), symmetrically labeled with lipid **4** (see above), was diluted with 2 mL of phosphate buffer (10 mM sodium phosphate, pH = 6.4, 100 mM NaCl), and a solution of lipid **4** in DMSO (10 μL, 0−100 μM) was added. This suspension was preincubated for 10 min prior the experiments. The immediate fluorescence monitoring resulted in lower initial fluorescence levels, probably due to the slow incorporation of lipid **4** into the liposomal exterior from the individual lipid **4**-formed liposomes and self-quenching of the lipid **4** fluorescence in these liposomes due to high local concentration of the cascade-blue label (*31*).

Kinetic Fluorescence Quenching Experiments with Symmetrically Labeled LUVs. In a typical experiment, 50 μL of LUVs labeled with lipid **2**, **3**, **4**, or NBD-PE (stock solution) was suspended in 1.95 mL of the phosphate saline buffer (10 mM sodium phosphate, pH = 6.4, 100 mM NaCl) and placed into a thermostated spectrophotometric cell. The suspension of liposomes was gently stirred throughout the entire course of experiment. The emission of labeled lipid (397 nm for lipids **2** and **3**, 434 nm for lipid **4**, and 534 nm for NBD-PE) was monitored with the excitations at 317, 354, 402, and 460 nm, respectively. The emission and excitation slits of the spectrophotometer were set at 5 nm, time increments were set at 1 s, and the integration time was set at 1 s. The temperature of the spectrophotometric cell was set at 25 °C. During the experiment, 20 μL of a 0−5 mM DMSO solution of cyclen **1** or 1 M aqueous solution of sodium dithionite was added through the injection port. At the end, the experiments were terminated by the injection of 40 μL of 20% aqueous solution of Triton X-100. In the case of experiments with variable amounts of Triton-X-100, 40 μL injections of the corresponding Triton X-100 aqueous solutions were performed. Binding constant and the maximum emission loss with the confidence interval values were computed using the homemade nonlinear regression curve-fitting program. The 1:1 binding model was used.

Kinetic fluorescence quenching experiments with asymmetrically labeled LUVs were carried out analogously, except that the suspension of asymmetric LUVs described above were used without further dilution.

Cell Culture. HEK 293 cells were obtained from ATCC (Manassas, VA) and maintained at 37 °C with 5% CO_2 in an incubator. The culture medium used was minimum essential medium (MEM) supplemented with 10% fetal bovine serum (FBS), 100 U/mL penicillin, and 100 μg/mL streptomycin (all from Invitrogen Corp, Carlsbad, CA). A2780 human ovarian carcinoma cells were a generous gift from Dr. Stephen Williams, Ovarian Cancer Program, Fox Chase Cancer Center, Philadelphia, PA. A2780 cells were cultured in Roswell Park Memorial Institute (RPMI) (Gibco: Invitrogen, Carlsbad, CA) in 5% FBS, 5% BCS (bovine calf serum), 0.25% penicillin/streptomycin. Cells were routinely passaged at 80−90% confluency.

Confocal Imaging. The activity of the compounds tested was evaluated using confocal microscopy. HEK 293 cells were plated on 12-mm round glass cover slips pretreated with poly-D-lysine (BD Biosciences, Bedford, MA). Prior to experiment, the cover slips with the cells were washed with PBS, transferred to a small experimental chamber (Warner Instruments, Hamden, CT) mounted on the stage of an Olympus confocal microscope (Olympus FV 300, Tokyo, Japan) equipped with a ×40/0.95 water immersion objective and cooled, charge-coupled device camera. Bath solution (in mM): 140 NaCl, 3 KCl, 2 $MgCl_2$, 25 D-glucose, 10 HEPES, and 2 $CaCl_2$, with pH adjusted to 7.4 with NaOH (all from Sigma Aldrich (Atlanta, GA)). Cells were visualized and selected for an experiment using the brightfield system. The excitation light to the preparation was supplied from a 405 nM diode laser, LD-405 (Olympus). The ultraviolet excitation wavelength was controlled by a mirror unit that filtered the excitation at 360−370 nm and the emission at 420−460 nm levels. Digital images (640 × 480 pixels) were obtained and processed using Fluoview v.5.0 software (Olympus), and preset settings for DAPI (4,6-diamidino-2-phenylindole) were acquired. Experiments were performed at room temperature (22−25 °C). During the experiment, 10 μL of 300 μM DMSO solution of lipid **4** or **2** was added to the bath solution (1 mL), followed by the addition of 10 μL of 2.5 mM DMSO solution of cyclen **1**.

Cell Growth Inhibition Assays. For the MTT (3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide) assay, A2780 human ovarian carcinoma cells were plated at a density of 6500 cells per well in a 96-well plate and incubated overnight at 37 °C in a 5% CO_2 atmosphere. Stock solutions of sodium dithionite, 100 mM in media, and cyclen **1** compound, 5 mM in DMSO, were made fresh prior to each use. Cells were treated at 10 mM and 25 μM concentrations of sodium dithionite and cyclen **1**, respectively, for 72 h. After medium removal, cells were washed twice with cold PBS and incubated with MTT (2 mg/mL in PBS) for 3 h. The excess MTT (Sigma, St. Louis, MO) was then removed, the dye dissolved in 100 μL of DMSO (Sigma, St. Louis, MO), and absorbance read on a Molecular Devices Vmax kinetic microplate reader at 540 nm. Transmission images of the cells were obtained on an Olympus IX70 microscope, using 20× magnification.

RESULTS AND DISCUSSION

Identification of Appropriate Components for the Lipid-Flip Detection Assay. We have recently developed a synthetic receptor, cyclen thiourea **1**, which is capable of selective binding of anionic pyrene-based dyes with submicromolar affinity under near physiological conditions (*30*). This receptor is impermeable to the bilayer membrane and quenches 90−99% of the fluorescence of pyrene-based dyes. We hypothesized that this type of receptor should be able to quench the fluorescence of the accessible portion of pyrene-labeled phospholipids residing on the outer leaflet of the bilayer membrane of liposomes upon its exogenous application. Such quenching of the fluorescence of the outer portion of the labeled lipid should provide the basis for a new lipid-flip detection assay. The high affinity of cyclen **1** to the anionic pyrene-based dyes should warrant the low micromolar concentration range required for the fluorescence quenching and therefore provide less invasive conditions for the lipid-flip detection than in the otherwise analogous NBD-dithionite assay.

In order to verify the validity of such an approach we synthesized two pyrene-labeled phospholipids: dioleoylphosphatidylethanolamine-pyrenebutyric acid **2** and dioleoylphosphatidylethanolamine-hydroxypyrene trisulfonate **4**, and also tested the commercially available dioleoylphosphatidylethanolamine-pyrene-sulfonamide **3**. Previously, we identified the hydrophobic effect rather than electrostatic or hydrogen-bonding interactions as the major driving force for the complex formation between pyrene-based dyes and cyclen **1**. Therefore, it was reasonable to expect that neutral pyrene labels of phospholipids **2** and **3** will also bind to cyclen **1**.

Phospholipids **2** and **3** feature a neutral pyrene label tethered by linkers of variable length. Phospholipid **2** was the most hydrophobic lipid among three probes because of nonpolar nature of pyrene group and substantially higher hydrophobicity

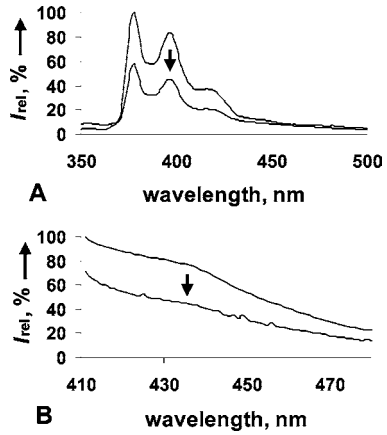

Figure 1. Fluorimetric characterization of interactions of cyclen **1** with fluorescently labeled LUVs. A. Emission spectra (ex = 317 nm) of LUVs labeled with lipid **2** in the absence (top spectrum) and in the presence (bottom spectrum) of 20 μM cyclen **1**. B. Emission spectra (ex = 402 nm) of LUVs labeled with lipid **4** in the absence (top spectrum) and in the presence (bottom spectrum) of 20 μM cyclen **1**. LUVs in all experiments were suspended in 1% DMSO in the phosphate saline buffer.

of amide linker than that of sulfonamide linker of lipid **3** (*32*). Therefore, lipid **2** was expected to diffuse across bilayer membranes with the highest rate, whereas the trianionic character of the cascade-blue label (*33*) in the phospholipid **4** was expected to prevent any unmediated diffusion of this lipid across the membrane.

First, we prepared three sets of large unilamellar liposomes (LUVs) from egg yolk phosphatidylcholine (EYPC) containing 0.1 mol % of the pyrene-labeled lipids **2**−**4** evenly distributed between the inner and outer leaflets of the bilayer. The emission spectra for the suspensions of these three sets of liposomes were recorded in the presence (20 μM) and in the absence of cyclen **1.** No apparent changes in the fluorescent spectrum were observed upon addition of cyclen **1** to the LUVs labeled with lipid **3**. This is probably because the short length of the linker connecting the pyrene label to the phospholipids caused the immersion of the pyrene moiety into the hydrophobic region of the bilayer, thus making this label inaccessible to cyclen **1**.

The identical experiments with LUVs containing phospholipids **2** and **4** revealed 46% and 41% fluorescence intensity loss, respectively, upon addition of 20 μM cyclen **1** (Figure 1). However, the kinetic experiments, where the maximum fluorescence intensity was monitored as a function of time, revealed that the fast loss of 46% of fluorescence by LUVs containing lipid **2** was followed by a somewhat slower phase of quenching, resulting in the overall 80% loss of the fluorescence in only 20 min (not shown). These results can be explained by the high rate of unmediated diffusion of lipid **2** across the bilayer membrane and subsequent quenching of the fluorescence of the exposed lipid by extravesicular cyclen **1**. However, the secondary phase of the fluorescence quenching in LUVs labeled with polar phospholipid **4** was negligibly slow, consistent with the expected slow unmediated flipping rate for this lipid. The kinetic quenching experiments were terminated by application of 0.5% of the detergent Triton X-100, which resulted in a complete lysis of LUVs and exposure of the inaccessible portion of the fluorescent lipids to cyclen **1**.

Application of cyclen **1** to LUVs labeled with lipid **4** and lysis of these LUVs with the detergent Triton X-100 gave 87% of the fluorescence quenching. However, the fluorescence of the LUVs labeled with lipid **2** increased upon application of Triton X-100 and even exceeded the original fluorescence of the cyclen **1**-free suspension of LUVs. This is most likely because of repartitioning of nonpolar pyrene headgroup of lipid **2** into the hydrophobic core of the Triton X-100 micelles, accompanied by the decomposition of the complex formed from lipid **2** and cyclen **1**. This observation made lipid **2** a less attractive probe for lipid-flip monitoring, and most of the further work was carried out with the polar lipid **4**.

Kinetic Experiments under Lipid-Flip Mimicking Conditions. In order to find the optimal concentration of cyclen **1** required for the quenching of the fluorescence of lipid **4**, we carried out a series of kinetic titration experiments, where the emission intensity of LUVs treated with variable amounts of cyclen **1** was monitored as a function of time (Figure 2A). Application of variable amounts of cyclen **1** resulted in various degrees of fluorescence quenching; however, the apparent saturation was observed at cyclen **1** concentrations above 10 μM.

The extent of fluorescence quenching by cyclen **1** can be interpreted in terms of complex formation between lipid **4** and cyclen **1**; therefore, the fluorescence data were fitted into the binding isotherm (Figure 2B, 1:1 stoichiometry was assumed). The kinetics of fluorescence quenching clearly consisted of two phases, where the primary fast phase was likely due to the interactions of the outer leaflet portion of lipid **4**, and the slower phase was due to the lipid flipping from the inner leaflet into the outer leaflet, followed by complex formation. The secondary phase was almost linear for all traces; therefore, linear fit of the data points in the secondary phase time interval (300−800 s for all traces) and extrapolation to the time of the cyclen **1** injection (60 s in all traces) allowed us to assess the extent of lipid quenching in the primary phase accurately. These data were fitted into the binding isotherm, and the maximum fluorescence quenching and apparent binding constant K_a were assessed. The found values for these two parameters were 46 ± 2% and 4.8-($\pm$1.5) × 10^5 M^{-1}, respectively. A similar data fit was performed for the fluorescence intensity values after lysis of LUVs by Triton X-100. The corresponding values for the maximum fluorescence quenching and binding constant K_a were assessed as 92 ± 4% and 2.1($\pm$1.5) × 10^5 M^{-1}, respectively. The maximum fluorescence quenching by cyclen **1** before and after the lysis of liposomes is consistent with the hypothesis that the membrane-impermeable receptor quenches 50% of the fluorescence in the symmetrically labeled LUVs, whereas the similar values of K_a before and after the lysis suggest that the detergent produced little effect on the complex formation. The assessed binding constant for the lipid **4**−cyclen **1** complex was approximately 10 times lower than that assessed for the complex of a water-soluble dye 8-hydroxypyrene-1,3,6-trisulfonic acid (HPTS) reported previously (*30*); however, the affinity of cyclen **1** to the dye attached to the lipid remained high enough to allow the detection of lipid flip with micromolar concentrations of cyclen **1**.

Next, we performed experiments with LUVs exhibiting asymmetry in the distribution of the labeled lipid between the inner and outer bilayer leaflets. The residual fluorescence at the end of experiments increased as the total concentration of cyclen **1**−lipid **4** complex increased. However, the ratio between fluorescence quenching upon application of 20 μM cyclen **1** and fluorescence quenching upon application of Triton X-100 changed proportionally to the excess of labeled lipid in the outer leaflet of the bilayer (Figure 2C). Subtraction of the residual fluorescence and normalization of the fluorescence intensity to 100% of symmetrical LUVs gave a set of traces with the extent of cyclen **1**-induced fluorescence quenching proportional to the amount of labeled lipid in the outer leaflet (Figure 2D). At the same time, the extent of fluorescence quenching upon application of the detergent remained constant, consistent with the unchanged amount of labeled lipid residing on the inner leaflet of the bilayer. These observations suggest that the proposed

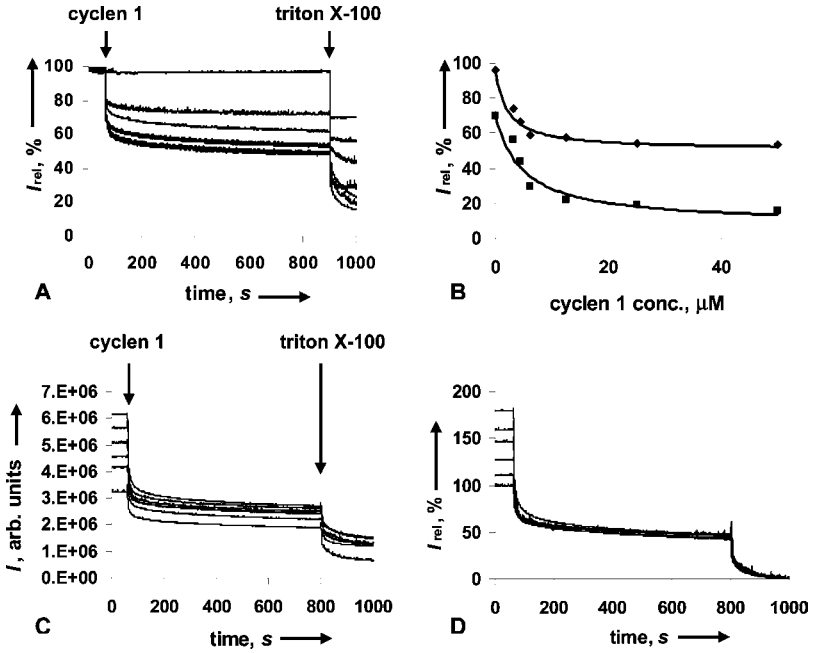

Figure 2. Kinetic monitoring of the fluorescence (ex = 402 nm, em = 434 nm) of LUVs labeled with lipid **4** in the presence of cyclen **1.** A. Fluorescence of symmetrically labeled LUVs in the presence of variable amounts of cyclen **1.** From top to bottom the traces at 500 s denote fluorescence of LUVs in the presence of 0, 3.1, 4.5, 6.3, 12.5, 25, and 50 (μM) cyclen **1**. Time events: 60 s: 20 μL of 0−5 mM DMSO solution of cyclen **1** was injected into 2 mL of LUVs suspension; 900 s: 40 μL of aqueous 25% solution of Triton X-100 was injected. B. Points in the upper trace correspond to the fluorescence intensity values from (A) extrapolated to the maxima of the fast quenching (see main text for explanation). Points in the bottom trace correspond to the fluorescence intensity values after the lysis of LUVs with Triton X-100. Continuous lines in both traces represent best fits to a 1:1 binding model. **C**. Kinetic monitoring of the fluorescence of LUVs asymmetrically labeled with lipid **4**. From bottom to top at 30 s traces denote LUVs containing 0.25, 0.31, 0.38, 0.5, 0.68, and 0.75 μM (bulk concentration) lipid **4** in the outer leaflet and 0.25 μM lipid **4** in the inner leaflet. Time events: 60 s*:* 20 μL of 2 mM DMSO solution of cyclen **1** was injected into 2 mL of LUVs suspension; 900s: 40 μL of aqueous 25% solution of Triton X-100 was injected. D. Data from (C) after subtraction of the residual fluorescence and normalization to 100% of the fluorescence of symmetrical LUVs.

methodology is indeed suitable for the assessment of the lipid distribution between the inner and outer leaflets of liposomal membranes.

In the envisioned mode of interaction between lipid **4** and cyclen **1,** cyclen **1** binds to the cascade-blue label of lipid **4** at the surface of the bilayer membrane. Therefore, it was possible that the receptor bound to the membrane was perturbing the integrity of this membrane, thus affecting the rate of the lipid flip. In order to find whether this was the case, we performed an additional experiment with symmetrically labeled LUVs containing 0.5 mol % of lipid **4**. This five times higher concentration of lipid **4** would introduce five times more of cyclen **1** upon binding. If cyclen **1** interferes with the integrity of the bilayer membrane, a different rate of lipid **4** quenching in the secondary slow phase would be observed. However, the kinetic trace obtained in the experiment with these new LUVs was identical (except the absolute fluorescence intensity) to that obtained for the LUVs labeled with 0.1 mol % of lipid **4**, including the extent of fluorescence quenching in the fast phase and the slope of the fluorescence quenching in the secondary slow phase. Therefore, we concluded that cyclen **1** does not perturb the integrity of the bilayer membrane in the range of concentrations of cascade-blue label used in these experiments, and it does not affect the rate of the lipid flip.

Reversibility of Binding. The NBD-dithonite lipid flip assay relies on the irreversible covalent modification of the NBD label by reduction of the nitro group to an amino group, which leads to the loss of fluorescence. In contrast, the pyrene-cyclen **1**-based assay relies on the noncovalent and, therefore, potentially reversible interactions of the fluorescent label with the receptor. Two independent methods can be considered for such binding reversal: first, a competitive displacement

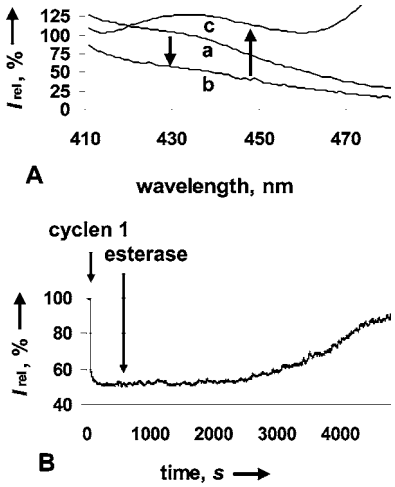

Figure 3. Reversibility of cyclen **1**−lipid **4** complexation. A. Emission spectra of the LUVs labeled with lipid **4** (ex = 402 nm): (a) spectrum of LUVs in the presence of 1% DMSO (blank experiment); (b) spectrum of LUVs in the presence of 5 μM cyclen **1** and 1% DMSO; (c) spectrum of LUVs in the presence of 5 μM cyclen **1**, 1% DMSO, and 5 μM HPTS. The intensities were normalized to 100% of the emission intensity of cyclen **1**-free set of LUVs (trace a) at 434 nm. B. Kinetic monitoring of the fluorescence intensity of LUVs labeled with lipid **4** upon application of 10 μM cyclen **1**, followed by the application of porcine liver esterase (150 U).

of the fluorescent label, attached to the lipid with the water-soluble substrate for the same receptor and, second, degradation of the receptor leading to the release of the phospholipid label.

The first method has a disadvantage where all the identified substrates for the receptor cyclen **1** are fluorescent dyes with spectral characteristics similar to that of cascade-blue label of

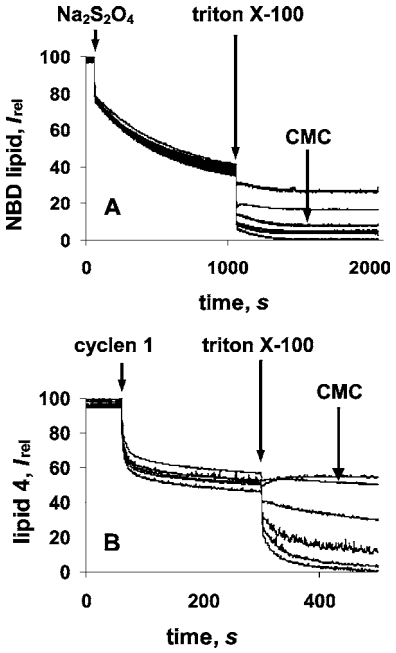

Figure 4. Comparison of NBD-dithionite and cyclen **1**−lipid **4**−lipid flip monitoring assay in the presence of variable amounts of Triton X-100**.** A. Kinetic monitoring of the fluorescence of NBD-labeled LUVs treated with 60 mM $Na_2S_2O_4$ and varying amounts of Triton X-100. From top to bottom the traces at 1500 s denote application of 0.12, 0.17, 0.22, 0.36, 0.72, 1.45, and 2.9 (mM) Triton X-100. Please note a significant fluorescence quenching at 0.17 mM (below CMC) concentration of Triton X-100 (second trace from top). B. Kinetic monitoring of the fluorescence of lipid **4**-labeled LUVs treated with 20 μM cyclen **1** and varying amounts of Triton X-100. From top to bottom the traces at 400 s denote 0.12, 0.22, 0.36, 0.72, 1.45, 2.9 (mM) Triton X-100. Please note that the application of submicellar and micellar concentrations of Triton X-100 (two upper traces) resulted in a little loss of the fluorescence quenching. In both figures, the traces were normalized by the subtraction of the residual fluorescence observed in the sample with highest amount of Triton X-100, and adjustment to 100% of the initial fluorescence values.

lipid **4**. The largest spectral window, however, was found for the cascade-blue label of lipid **4** (ex = 402 nm, em = 434 nm) and its synthetic precursor, HPTS (ex = 405 nm, em = 510 nm). The displacement experiments, where a suspension of LUVs labeled with lipid **4** was originally treated with 5 μM cyclen **1** and then with 0−10 μM HPTS, demonstrated an increase of the fluorescence intensity at 434 nm (ex = 402 nm) upon addition of HPTS (Figure 3A). Yet, a substantial contribution of the HPTS emission to the total intensity of the fluorescence at this wavelength made this approach nonpractical. We are currently screening other potential candidate molecules that might form strong complexes with cyclen **1** and displace cascade-blue label of lipid **4**.

To demonstrate the possibility for the second approach, we decided to enzymatically degrade cyclen **1**. The thiourea units of cyclen **1** are tethered to the cyclen scaffold via ester-type linkers, making cyclen **1** a suitable substrate for a variety of esterases. In the course of the kinetic experiment, the fluorescence of LUVs labeled with lipid **4** was monitored as a function of time. The application of 10 μM cyclen **1** resulted in the loss of 43% fluorescence. Application of 150 U of porcine liver esterase resulted in a gradual increase of the fluorescence, which reached 90% of the original intensity in approximately 1.5 h (Figure 3B). This example demonstrates that the bound portion of lipid **4** can be released if required during the lipid-flip monitoring experiment.

Comparative Invasiveness of Cyclen 1 and Sodium Dithionite. Another potential disadvantage of the NBD-dithionite assay can arise from the fact that dithionite is the anion of inorganic

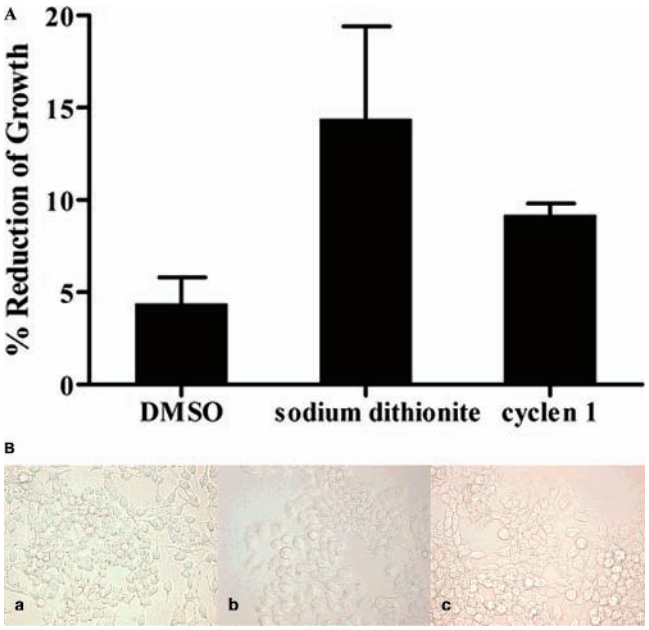

Figure 5. Relative nontoxicity of cyclen **1**. A. Results of growth inhibition assay (A2780 cell line) relative to untreated cells. B. Images of A2780 cells from the growth inhibition assays: (a) untreated cells, (b) cells in the presence of 0.5% DMSO; (c) cells in the presence of 25 μM cyclen **1** and 0.5% DMSO.

salt and can therefore be taken up by cellular transporters, for example sulfate-anion exchangers (*34*). Such internalization of dithionite would result in the reduction of the NBD-label residing on the inner leaflet of the bilayer and may lead to the false-positives in the in vitro experiments. A large molecule of cyclen **1** will unlikely be a substrate for cellular transporters; therefore, no such false positive identification of lipid-flip activity should be expected. We demonstrated this potential advantage of cyclen **1**-based assay in an experiment with LUVs under ion-transport mimicking conditions. It has been shown that detergents at sublytic (below CMC) concentrations form transient pores in the bilayer membranes that may allow passage of small molecules (*35*−*37*). Specifically, sublytic concentrations of Triton X-100 were shown to increase permeability of erythrocyte membranes to small ions (Na^+, Cl^-) but not to the relatively large molecules (glucose) (*38*). We performed a parallel series of kinetic experiments with LUVs containing NBD-labeled phospholipid and LUVs labeled with lipid **4** (Figure 4). The slope of the secondary quenching phase was substantially higher for the LUVs labeled with NBD-PE than with lipid **4**. This is probably because of a higher rate of unmediated transmembrane diffusion of sodium dithionite than that of cyclen **1** at their operating concentrations. As can be seen, the fluorescence decay upon injection of Triton X-100 to LUVs labeled with lipid **4** and treated with 20 μM cyclen **1** was observed only at Triton X-100 concentration exceeding CMC (0.22 mM) (*39*). However, in similar experiments with NBD-labeled LUVs, treated with 60 mM $Na_2S_2O_4$, a substantial decrease in the fluorescence was observed after application of submicellar concentrations of the detergent.

Physiological Compatibility of Cyclen 1. To demonstrate the relative nontoxicity of cyclen **1**, we performed a series of cell growth inhibition assays in the presence of cyclen **1** and sodium dithionite at concentrations relevant to the lipid-flip monitoring assays.

These assays revealed 10% inhibition of cell growth in the presence of 25 μM cyclen **1**, compared to untreated cells, and approximately 5% cell growth inhibition compared to the cells treated with relevant amounts of DMSO (0.5%), consistent with physiological compatibility of this receptor (Figure 5A). Treat-

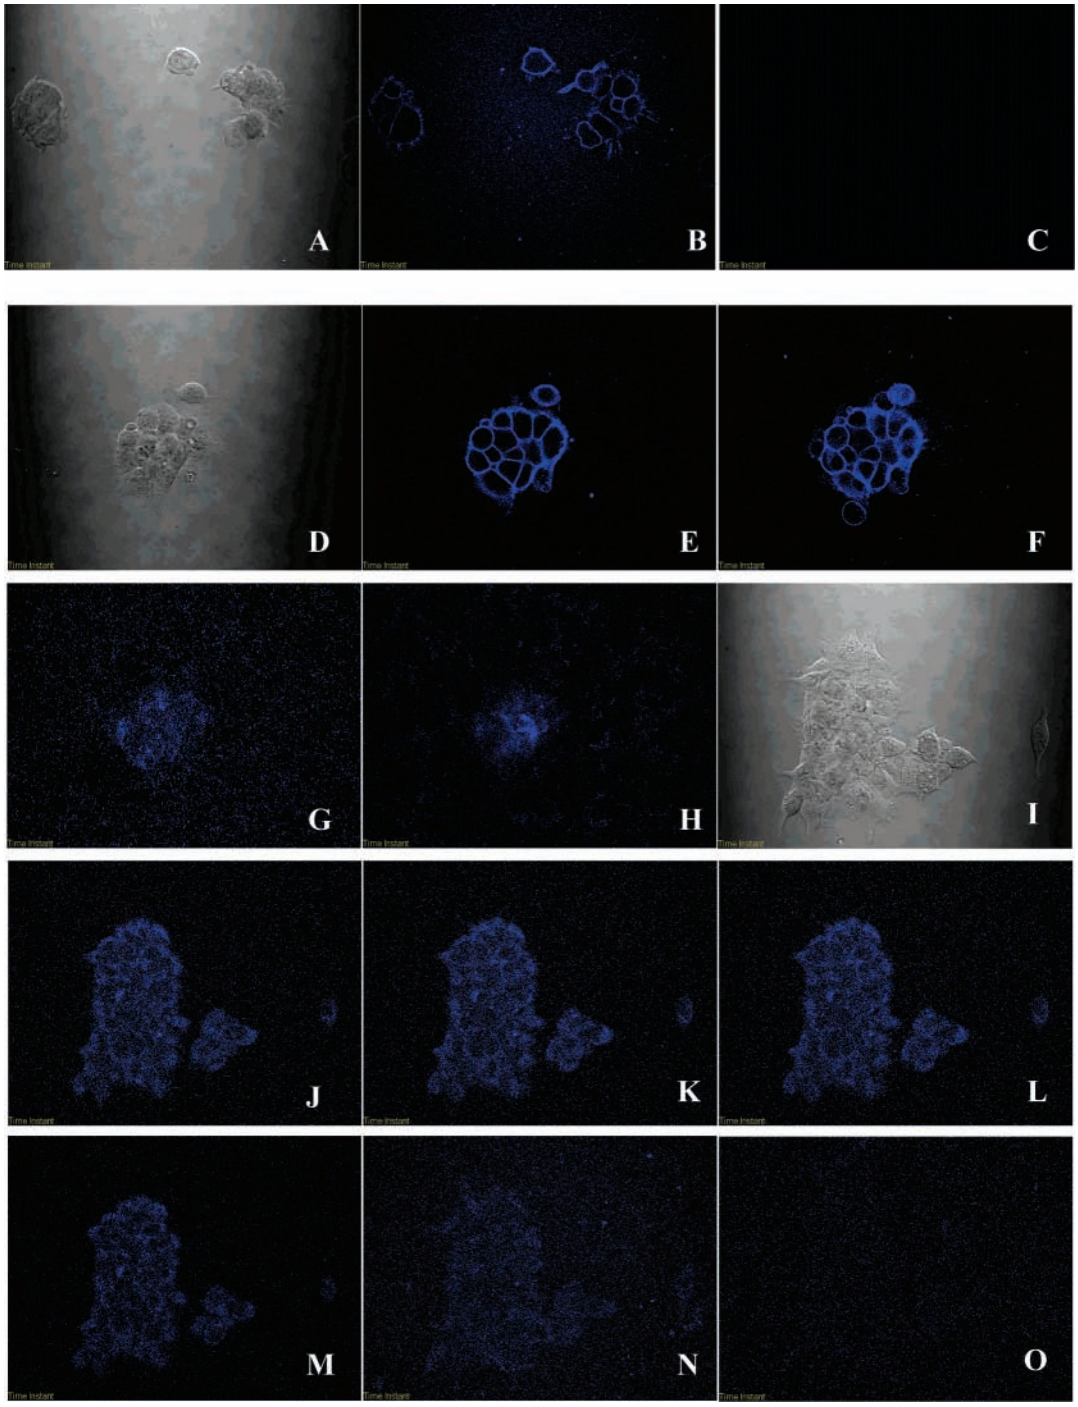

Figure 6. Confocal microscopy images of HEK-293 cell clusters. Images A−C, D−H, and I−O correspond to three distinct sets of cell clusters. A. Brightfield image of the first set of cell clusters. Consequent fluorescence images of the first set of clusters immediately after addition of lipid **4** (B) and upon addition of the quencher cyclen **1** (C, the time interval between additions of lipid **4** and cyclen **1** was less than 5 min). D**.** Brightfield image of the second set of cell clusters. Consequent fluorescence images of the second set of clusters immediately after addition of the lipid **4** (E), after 1 h of incubation with the lipid **4** (F), immediately (G) and 20 min (H) after the addition of the quencher cyclen **1**. I. Brightfield image of the third set of cell clusters. Consequent fluorescence images of the third set of clusters immediately after the addition of lipid **2** (J), after 30 min (K) and 1 h (L) incubation with the lipid **2**; immediately (M**),** 10 min (N), and 20 min (O) after the addition of the quencher cyclen **1**.

ment of the cells with the smallest concentration of sodium dithionite used in the lipid-flip monitoring assays (10 mM) resulted in 15% growth inhibition. No morphological signs of cell damage or death was observed upon treatment with cyclen **1** (Figure 5B).

Applicability of New Methodology to the in Vitro Studies. Finally, we demonstrated that the cyclen **1**-based lipid flip monitoring assay can be utilized for in vitro studies. A series of confocal microscopy imaging experiments on HEK-293 cells showed that the application of lipid **4** resulted in its rapid partitioning into the outer membranes of the cells (Figure 6A−C). Immediate application of cyclen **1** (20 μM) resulted in a complete fluorescence quenching consistent with the fact that all lipid **4** was accessible to the receptor. However, the incubation of the cells with lipid **4** for 1 h resulted in partial diffusion of lipid **4** into the internal membranes of cellular organelles. Application of 20 μM cyclen **1** in this case resulted in the fluorescence quenching of the outer cell membranes, but some residual fluorescence of the cell interior was still observed (Figure 6D−H). Finally, we performed staining of the cells with

lipid **2**, which has high permeability to the membrane barriers (Figure 6I−O). Unlike with lipid **4**, no preferential staining of the outer membranes was observed but rather even distribution of the fluorescent lipid within the cellular interior. A subsequent application of lipid **1** resulted in the fluorescence quenching, which was complete after 15 min of incubation.

These experiments demonstrate that a lipid **4**−cyclen **1** pair provide a suitable pair for the lipid flip monitoring in in-vitro experiments. The focus of our future studies will be a real-time monitoring of the flippase activity of Pgp, using a lipid **4**−cyclen **1** lipid flip monitoring assay.

As with any other fluorimetric methodology, the interpretation of the results obtained through the lipid **4**−cyclen **1** lipid-flip detection assay requires some care because of the possible effects of the non-natural cascade-blue label attached to the lipid molecule. However, the highly anionic character of the cascade-blue label makes a flip of such conjugated lipids more difficult than that of the less polar natural lipids, and therefore no false-positive flippase activity should be detectable by this new methodology. As an alternative, the hydrophobic lipid **2** in place of lipid **4** can be utilized, although with some limitations, to test the flip of less polar substrates.

CONCLUSION

In conclusion, we developed a new methodology for monitoring of lipid flip in both model and cell membranes. This methodology relies on the micromolar concentrations of the fluorescence quencher cyclen **1** and therefore has better compatibility with the physiological conditions than the commonly utilized NBD-dithionite methodology which relies on high millimolar concentrations of sodium dithionite. Unlike with NBD-dithionite assay, where the dithionite causes the irreversible quenching of the fluorescence of NBD-labeled lipid, cyclen **1** forms a noncovalent complex with cascade-blue labeled lipid. The noncovalent nature of such interactions provides a possibility for the reversal of binding through the displacement of the cascade-blue labeled lipid by a water-soluble substrate for cyclen **1**. Alternatively, the complex between cyclen **1** and lipid **4** can be decomposed through the enzymatic degradation of cyclen **1**. The focus of our future studies will be a real-time monitoring of the flippase activity of Pgp, using a lipid **4**−cyclen **1** lipid flip monitoring assay.

ACKNOWLEDGMENT

This work was supported by VCU, NSF (grant ECS-0508381) and the Jeffress Memorial Trust (grant J-764). We thank Prof. Nicholas Farrell for consultations regarding cell proliferation assays, Prof. Sarah Rutan for critical reading and John B. Mangrum for high-resolution MS analysis. The authors thank Prof. Leslie Satin and Dr. Min Zhang from the Department of Pharmacology and Toxicology at VCU for their expertise in confocal imaging.

Radiolabeling of Bombesin-Like Peptide with ^{99m}Tc: ^{99m}Tc-Litorin and Biodistribution in Rats†

Kubra Durkan, Fatma Yurt Lambrecht,* and Perihan Unak

Department of Nuclear Applications, Institute of Nuclear Sciences, Ege University, Bornova 35100, Izmir, Turkey. Received December 26, 2006; Revised Manuscript Received July 19, 2007

Bombesin-like peptides are related to several human cancer receptors, including small cell lung, prostate, breast, colon, and pancreatic cancers. Litorin, an amphibian bombesin peptide derivative, is found to stimulate the contraction of smooth muscle, to stimulate gastrin, gastric acid, and pancreatic secretion, and to suppress the nutriment in in vivo experiments. In the present study, litorin was labeled with ^{99m}Tc by the stannous chloride procedure. Labeling yield is 95 ± 1.4%, as determined by radio thin layer chromatography (RTLC) and radio high performance chromatography (RHPLC). Results of in vitro studies demonstrated a high stability in serum and cysteine solutions. In vivo biodistribution was investigated with normal male Albino Wistar rats. Biodistribution data showed fast clearance, low intestinal accumulation, and significant uptake in bombesin/gastrin releasing peptide (BN/GRP) receptor rich tissues such as the pancreas (23.56 ± 0.01 %ID/g 30 min pi). It can be blocked partially by previous administration of 'cold' litorin. The results showed specificity of the uptake. As ^{99m}Tc-litorin displays good radiolabeling and biodistribution, it is a potentially useful radiopharmaceutical for detection of bombesin receptor-expressing cancers.

INTRODUCTION

Radiolabeled peptides have exhibited great potential for imaging and therapy of tumors in recent years. Peptides have some favorable characteristics: they are readily synthesized, are inexpensive, and can withstand rigid chemical conditions for modifications and radiolabeling. Furthermore, because of their low molecular weight, small peptides are expected to efficiently penetrate into tumor tissue, exhibit a faster clearance, and thus lead to better tumor-to-background ratios than high molecular weight compounds such as monoclonal antibodies and their constructs (*1*−*7*).

The amphibian 14-amino acid peptide bombesin (BN) is part of the super family of bombesin-like peptides that also includes the mammalian homologue gastrin relasing peptide (GRP) and the related neuromedin B (NMB) (*1*). The gastrin releasing peptide has been found to produce a wide range of biological responses in peripheral tissues as well as in the central nervous system, for instance stimulation of gastrointestinal hormone release, exocrine secretion, and maintenance of circadian rhythms (*1*, *2*, *8*−*11*).

Bombesin-like peptides exert their effects on target cells by binding to surface G protein-coupled receptors characterized by the typical configuration of seven transmembrane domains (*12*). They have a wide range of physiological activities, including stimulation of the release of numerous gastrointestinal hormones, stimulation of pancreatic enzyme secretion effects on the central nervous system, such as thermoregulation, and inhibition of thyroid-stimulating hormone (*13*). In addition to these physiological effects, it also plays an important role in cancer. Initiation of its interaction with the GRP receptor promotes tumor growth in a number of normal and human cancer cells both in culture and in nude mice xenografts (*12*, *14*). On the other hand, it has been established that BN/GRP receptors are expressed in resected human biopsy specimens of mainly small lung cancers, prostate carcinomas, gastric, pancreatic, colon cancer, and breast carcinomas often at much higher densities than in normal surrounding tissue; this provides at molecular basis for GRP-R-targeted diagnostic imaging and/or internal radiotherapy of malignant lesions with radiolabeled bombesin analogues. In addition, the high frequency of these tumors has had a synergic effect in stimulating research on novel bombesin-like radiotracers for effective in vivo targeting of GRP-R-positive neoplastic disease (*12*−*15*). Furthermore, the use of BN/GRP antagonists as carrier molecules for targeting cytotoxic drugs to tumor cells has recently been proposed (*12*).

Some peptides structurally related to bombesin were discovered from amphibian skin and divided into three groups: (1) bombesin family that includes bombesin and alytesin; (2) ranatensin family that includes ranatensin, litorin; (3) their derivatives and the phyllolitorin family (*16*). Litorin (pGlu-Gln-Trp-Ala-Val-Gly-His-Phe-Met-NH_2) has an amino acid sequence similar to that of bombesin.

Rapid pharmacokinetics is ideal for labeling peptides with a radioisotope that has a short half-life, such as technetium-99m. Among all radioisotopes used in nuclear medicine, Tc-99m is still the most widely applied for diagnostic purposes, mainly because of ready availability, low cost, excellent imaging properties, favorable dosimetry, and high specific activity.

The development of ^{99m}Tc-labeled BN/GRP analogues for cancer imaging would be even more promising. For this reason, various ^{99m}Tc- or ^{111}In-labeled bombesin analogues could probably allow early noninvasive diagnosis of GRP receptor-positive tumors by SPECT in nuclear medicine (*1*, *2*, *8*, *10*−*15*, *17*−*23*). The aim of the present work is to develop a ^{99m}Tc-labeled bombesin-like peptide for tumor imaging. Litorin was labeled with Tc-99m, and its radiopharmaceutical potential was investigated with biodistribution studies in normal male Albino Wistar rats.

EXPERIMENTAL PROCEDURES

Materials. $Na^{99m}TcO_4$ was supplied by the Department of Nuclear Medicine of Ege University, as $^{99}Mo/^{99m}Tc$ generator eluent (Monrol, Istanbul-Turkey). Litorin was obtained from Phoenix Pharmaceuticals Inc., Germany. All other chemicals were from Merck Chemical Co.

Radiolabeling with ^{99m}Tc. Radiolabeling of litorin with Tc-99m was performed via the stannous (II) chloride method. Litorin was dissolved in distilled water at 1 mg/50 mL concentration. The solution of peptide was distributed in 10 μg/500 μL aliquots in eppendorf vials that were stored at −20 °C. $SnCl_2{\cdot}2H_2O$ (1 mg) was freshly prepared by dissolving in 1 mL distilled water and 25 μL of stannous chloride solution was added to the eppendorf vial containing 5 μg/250 μL litorin solutions. pH was adjusted to 3 by using HCI (0.1N) or NH_3 (0.1N). After the $SnCl_2{\cdot}H_2O$ solution was added to the vial, about 55.5 MBq $Na^{99m}TcO_4$ was added. It was left to incubate for 25 min at room temperature.

Radiochemical Analysis. Effects of pH, amount of stannous chloride on labeling percentage, and serum stability time were investigated.

Radio-TLC Analysis. RTLC was done with a Sigma ITLC chamber using 10 × 1.5 cm^2 RTLC-SG strips. After development, they were dried, covered by sellotape, and cut into 0.5 cm strips. These were counted with a Cd(Te) detector equipped with a RAD 501 single channel analyzer (Isin Electronic Co., Izmir, Turkey). Two different solution systems were used as a developing solution: ACD [citrate-dextrose buffer solution (Eczacibasi-Baxter)] and acetone.

Radio-HPLC Analysis. HPLC analysis was performed on a low-pressure gradient HPLC system with LC-10 ATvp quaternary pump, UV detector (Shimadzu SPD-10ATvp, Macherey-Nagel, EC 250/4.6 Nucleodur 100-5 C18 column) and 20 μL loop and equipped with a Cd(Te) detector equipped with a RAD-501 single channel analyzer. HPLC was run using a gradient of 0.1% TFA in H_2O (solvent A) and 0.1% TFA in CH_3CN (solvent B) at a flow rate of 1 mL/min. The HPLC gradient system was begun with a solvent composition of 95% A and 5% B and reached to 60% A and 40% B in 20 min. The UV detector was settled at 240 and 280 nm.

Serum Stability of ^{99m}Tc-Litorin. ^{99m}Tc-Litorin (300 μL) was incubated with fresh human serum (600 μL) in duplicate at 37 °C through 24 h. During incubation, the sample was analyzed at 15 min, 1, 2, 3, 4, and 24 h. The amount of free pertechnetate in the samples was determined by RTLC using ACD and acetone as medium.

Partition Coefficient. A 100 μL aliquot of radiolabeled peptide was added to a test tube containing 3 mL of each of n-octanol and water. The tube was vortexed, for 1 h at room temperature, and then centrifuged at 3000 rpm for 5 min. Aliquots (0.5 mL) of each phase were taken for counting. The partition coefficient was determined by the function: Partition coefficient = $\log_{10}$(counts in n-octanol layer/ counts in aqueous layer) (*15*).

Cysteine Challenge. ^{99m}Tc-Litorin was tested for instability toward cysteine. A fresh cysteine solution was prepared (0.5 mg mL^{-1} in 0.1 M PBS, pH 7.0) and diluted to different concentrations. A known amount of the radiolabeled peptides was incubated with an excess amount of cysteine (100 fold molar excess compared to the peptide) at 37 °C for 1 h. Radiochemical purity was determined by RTLC.

Biodistribution in Normal Rats. The institutional Animal Review Committee of Ege University approved the animal experiments. Male, 24 weeks rat Albino Wistar rats (average weight 150−200 g) were used for the biodistribution in the groups of three per time point. The pH of ^{99m}Tc-litorin (0.1 μg litorin, specific activity 401 GBq/μmol) was adjusted to 7, using 0.1 N NH_3. The solution was then passed through a 0.22 μm Millipore filter. ^{99m}Tc-Litorin was injected into the tail vein. Animals were sacrificed under intense ether atmosphere at 30, 90, 180, and 300 min postinjection and main organs and blood were removed, weighed, and counted. Biodistribution data were calculated as the percent injected dose per gram tissue (%ID/g).

In Vivo Blocked Experiments. Receptor blocking studies were also carried out where cold litorin was administered to the animals for *in vivo* saturation of GRP receptors prior to an injection of ^{99m}Tc-litorin. In this study, each animal received 1 μg of cold litorin i.v., 30 min prior to the injection of ^{99m}Tc-litorin (specific activity 401 GBq/μmol). They were sacrificed at 30 min postinjection, the main tissues were removed, the radioactivity was counted, and %ID/g tissue was calculated.

Statistical Analysis. Differences in the mean values of measured activities were evaluated statistically by SPSS 10 program (Univariate Variance Analyses and Pearson Correlation). Probability values <0.05 were considered to be significant.

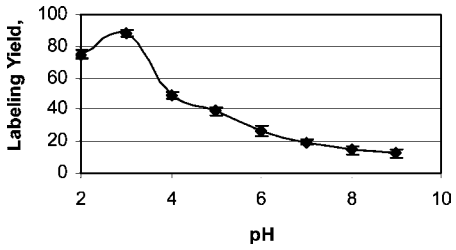

Figure 2. Effect of pH on radiolabeling yield of ^{99m}Tc-litorin.

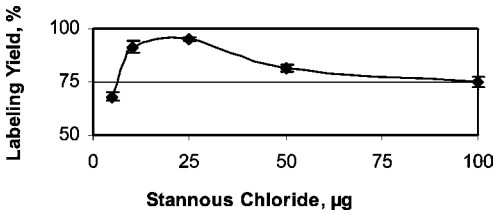

Figure 3. Effect of stannous chloride concentration on radiolabeling yield of ^{99m}Tc-litorin.

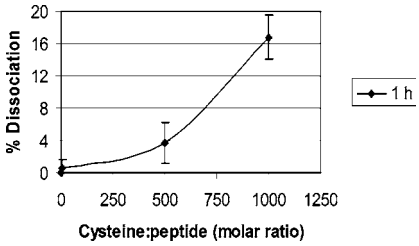

Figure 4. Dissociation of ^{99m}Tc from ^{99m}Tc-litorin following incubation with cysteine at different molar ratios (mean ± SD, $n = 3$).

A Pearson Correlation between the organs of blocked and unblocked animals, testing for ^{99m}Tc-litorin, was obtained.

RESULTS AND DISCUSSION

Radiolabeling. By RTLC, reduced-Tc-99m ($R_f = 0.08$) and ^{99m}Tc-litorin ($R_f = 0.07$) are separated from free $^{99m}TcO_4^-$ ($R_f = 1.00$) using acetone as medium. With ACD solution, reduced Tc-99m ($R_f = 1.00$) and $^{99m}TcO_4^-$ ($R_f = 0.72$) moved to the front, whereas ^{99m}Tc-litorin ($R_f = 0.07$) is almost immobile. In radio-HPLC analysis (Figure 1) retention time values of ^{99m}Tc-litorin, reduced Tc-99m, and pertechnetate are 3.24, 3.78, and 5.31 min, respectively.

Influence of pH on radiolabeling yields was examined in the pH range 2−9 (Figure 2), the optimum being pH 3. Experiments with 5−100 μg of $SnCl_2$ indicated a maximum at 25 μg (Figure 3). On the other hand, the labeling yield decreased with high levels of $SnCl_2$.

Serum stability results showed that *in vitro* stability of the radiolabeled peptide was quite high. Labeling percentage was found 87.4 ± 1.1 and 67.5 ± 5.0 at 4 and 24 h, respectively.

Partition coefficient results show that the partition coefficient of litorin was calculated as theoretical partition coefficient = −2.33 ± 0.96, and the experimental partition coefficient of ^{99m}Tc-litorin was found as −1.12 ± 0.8. Radiolabeled peptide also exhibits low lipophilicity.

Cysteine challenge study shows that the incubation of ^{99m}Tc-litorin with excess cysteine did not produce any significant transchelation to cysteine. A maximum of 16.8 ± 2.7% radioactivity was displaced to cysteine, which indicates that the bond strength of the radiolabeled peptide is high (Figure 4).

Biodistribution in Normal Animals. The biodistribution evaluation of ^{99m}Tc-litorin in normal male Albino Wistar rats at 30, 90, 180, and 300 min is shown in Figure 5.

Maximum uptake of radioactivity was observed in the pancreas ($p = 0.01$), spleen ($p = 0.02$), prostate ($p = 0.08$), and kidneys ($p = 0.01$) as 23.56 ± 0.01, 4.73 ± 0.83, 0.41 ± 0.01, and 11.93 ± 0.8 %ID/g, 30 min postinjection, respectively. On the other hand, that in liver and small intestine was 0.36 ± 0.08 and 0.38 ± 0.02 %ID/g at 30 min. While the uptake of ^{99m}Tc-litorin increased in kidneys, liver, and small intestine to 46.01 ± 2.0, 1.28 ± 0.5,and 0.80 ± 0.06 %ID/g, the uptake in pancreas was almost same (24.41 ± 0.5 %ID/g) at 90 min. That in kidneys, small intestine, and liver still increased to 90 min. Excretion of the radioactivity from the body is high by the renal pathway (46.01 ± 2.0 %ID/g in kidney, 90 min) and low by the hepatobiliary pathway (1.28 ± 0.5 %ID/g in liver and 0.80 ± 0.06 %ID/g in small intestine, 90 min). Karra et al. found similar results when $^{99m}Tc-P_2S_2-BBN(7-14)$ analogue (*23*) was used. They showed that the labeled compound was eliminated mainly through the kidneys to the urinary tract, without any significant retention in the kidneys (*14*). The radiolabeled peptide has a tendency to accumulate in kidneys as a result of its low lipophilicity (*2*, *11*, *15*, *21*). ^{99m}Tc-Litorin has low hepatobiliary clearance and predominantly renal excretion. Accumulation of radioactivity in the liver is also low: 0.36 ± 0.08 %ID/g at 30 min postinjection.

Only small amounts of radioactivity remain in kidneys, liver, and spleen at 180 min: 0.17 ± 0.02, 0.008 ± 0.001, and 0.08 ± 0.01 %ID/g, respectively. Therefore, the labeled peptide exhibits rapid clearance from nontarget tissues.

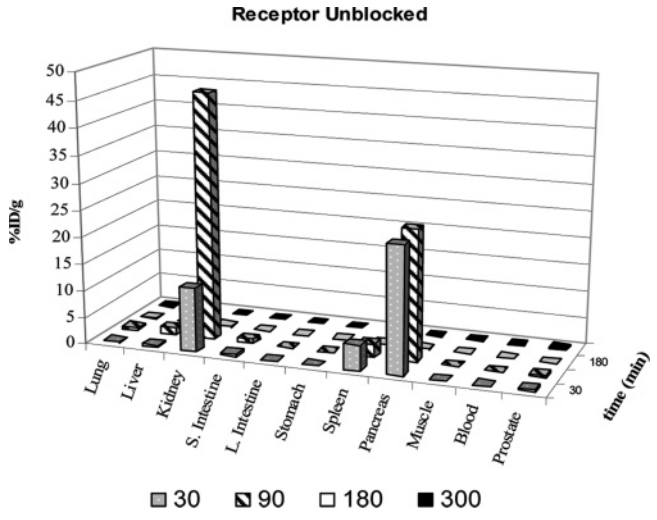

Figure 5. Organs biodistribution data at 30, 90, 180, and 300 min after injection of ^{99m}Tc-litorin in normal male Albino wistar rats.

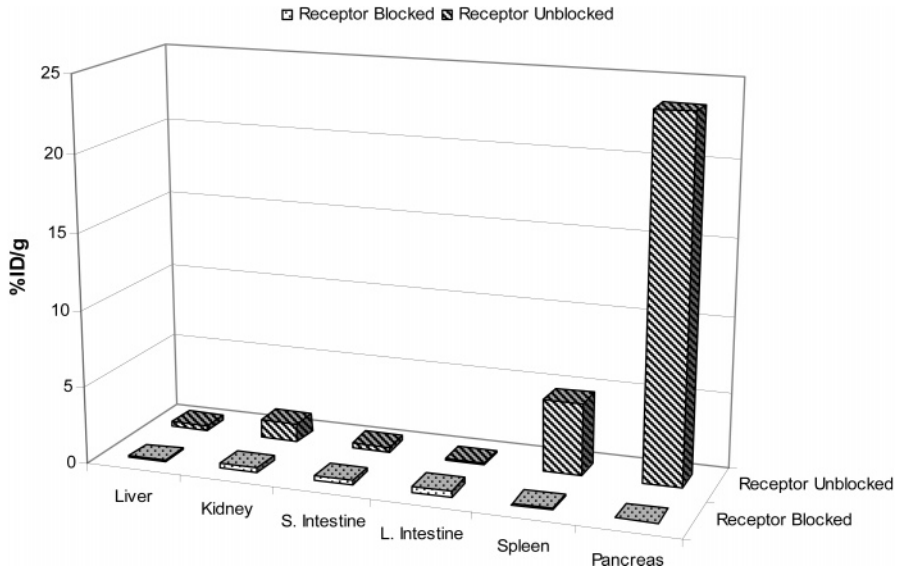

Figure 6. Blocked biodistribution data at 30 min after injection of ^{99m}Tc-litorin in normal male Albino wistar rats (SD: ±0.01−0.03).

In this study, a significant uptake (23.56 ± 0.01 %ID/g, 30 min postinjection) of the radioactivity was found for the pancreas. This demonstrates the ability of ^{99m}Tc-litorin to target BN/GRP receptor-expressing cells in vivo. The pancreas, which expresses BN receptors, has been used as a target by other investigators for the biological evaluation of newly developed radiolabeled BN analogues (*21*, *23*, *13*). The highest pancreas/blood and pancreas/muscle ratios were 472 and 2356, respectively, at 30 min postinjection. The ratios are higher than in another study in which the ratios (23 and 74, 2 h postinjection) were obtained by Lin et al. using [DTPA^1, Lys^3 (^{99m}Tc-Hx-DADT),Tyr^4]BN (*13*). On the other hand, in the study performed by Karra et al., the pancreas/muscle and pancreas/blood ratios were found to be 80 and 22, respectively, at 4 h postinjection (*23*).

Results of receptor-blocked experiments with litorin confirmed the specificity of ^{99m}Tc-litorin toward the BN/GRP receptor (Figure 6). The difference in the uptake of labeled peptide with and without subcutaneous injection of 1 μg of litorin are significant in the pancreas (0.01 ± 0.01, 23.56 ± 0.01) at 30 min. Little additional uptake was observed in the small intestine (0.38 ± 0.02 %ID/g at 30 min). In animals pretreated with cold litorin, this uptake was significantly reduced (0.28 ± 0.02 %ID/g at 30 min), implying an at least partially specific GRP-R process. 'Cold' peptide is able to reduce uptake in rich tissues, such as the pancreas by 98% and small intestine, by 27%. Acini cells of the pancreas, submucosal layer of the small intestine, circular muscle, and submucosal layer of the colon, as well as the circular muscle of gastric fundus and antrum, all have been shown to express BN/GRP receptors (*12*, *13*) and corresponding accumulation of Tc-99m peptide.

Receptor-blocked results showed that the uptake also decreased in prostate (the uptake in unblocked and blocked 0.41 ± 0.01, 0.19 ± 0.03 %ID/g at 30 min, respectively). Bombesin is a specific growth factor for prostate cancer (*22*), but ^{99m}Tc-litorin uptake is definitely less than with the pancreas. Equally, it is hampered by administration of 'cold' litorin.

The uptake in the stomach was small: 0.01 ± 0.008 %ID/g, 30 min, 0.04 ± 0.01 %ID/g, 90 min. This implies the absence of considerable in vivo decomposition and re-formation of pertechnetate (*2*, *15*).

CONCLUSION

Although, the molecular structure of our labeled complex is unknown, ^{99m}Tc-litorin is assumed to be a complex with litorin attached to reduced Tc-99m. Radiolabeling yield of ^{99m}Tc-litorin is over 95% by using of 5 μg of litorin and 25 μg of $SnCl_2$ at pH 3 in 25 min reaction time at room temperature.

In conclusion, the biodistribution of ^{99m}Tc-litorin in normal animals features high and specific pancreas uptake. The results of the present study are sufficiently encouraging to justify further evaluation of the radiolabeled peptide as a possible GRP-based tumor imaging agent.

Surface Modification of Poly(L-lactic acid) Membrane via Layer-by-Layer Assembly of Silver Nanoparticle-Embedded Polyelectrolyte Multilayer

Da-Guang Yu,*[,†] Wen-Ching Lin,*[,‡] and Ming-Chien Yang[‡]

Department of Textile Science, Nanya Institute of Technology, Chung-Li, Tao-Yuan, Taiwan, and Department of Polymer Engineering, National Taiwan University of Science and Technology, Taipei, Taiwan. Received April 20, 2006; Revised Manuscript Received October 13, 2006

The improvement of hydrophilicity, antibacterial activity, hemocompatibility, and cytocompatibility of poly(L-lactic acid) (PLLA) membrane was developed via polyelectrolyte multilayer (PEM) immobilization. Colloidal silver nanoparticles were prepared by using dextran sulfate (DS) as a stabilizer to precede chemical reduction by dextrose. The polysaccharide PEMs, including chitosan (CH) and dextran sulfate (DS)-stabilized silver nanosized colloid (DSS), were successfully deposited on the aminolyzed PLLA membrane in a layer-by-layer (LBL) self-assembly manner. The obtained results showed that the contact angle of PLLA membranes decreased with PEMs grafting layers and reached a steady value after four bilayers of coating, hence suggesting that full coverage was achieved. The PLLA−PEM membranes with DSS as the outermost layer could resist platelet adhesion and human plasma fibrinogen (HPF) adsorption, while prolonging the blood coagulation time. The PLLA−PEM membranes could possess antibacterial activity against Methicilin-resistant *Staphylococus aureus* (MRSA). In addition, the proliferation and viability of human endothelial cells (ECs) on PLLA−PEM membranes could be significantly improved. Overall results demonstrated that such a fast, easy processing and shape-independent method for an antithrombogenic coating can be used for applications in hemodialysis devices.

1. INTRODUCTION

Nowadays, great efforts are being devoted to the development of biodegradable materials in potential applications such as waste management, agriculture, tissue engineering, and clinical treatment (*1*−*3*). Biodegradable polyesters have the excellent water-resistance properties of synthetic polymers as well as the biocompatibility and biodegradability of agricultural-based raw materials. Recently, Poly(L-lactic acid) (PLLA) displayed better processability, improved breaking elongation, lower cost, and improved fabrication ability into compositescompared to other biodegradable synthetic polymers (*4*−*6*) and are complementary to other renewable resource-based materials. However, surface-induced thrombosis and protein fouling of biodegradable polymers should be the most serious problems in applications as blood-contacting materials (*7*, *8*). It is well-known that endothelialization (*9*, *10*) is one approach to solve this problem. Incomplete coverage of endothelial cells (ECs) on the vascular graft surfaces and the subsequent myointimal hyperplasia are the main reasons for the long-term failure of the small-diameter vascular graft (*11*, *12*). Due to the lack of bioactive functionality, PLLA commonly used in tissue engineering is not always suitable for cell adhesion. In consequence, attempts have been engaged to chemically modify the PLLA surface to favor polymer−cell interaction.

The layer-by-layer (LBL) self-assembly of polycations and polyanions into multilayers has emerged as an efficient, versatile, yet easy technique to develop biologically active surfaces. The method depends on the sequential charge inversion of a polymeric surface upon successive immersions of this surface in solutions of oppositely charged polyelectrolytes. Recently, application of the electrostatic LBL self-assembly technique in biomedical engineering was widely developed in artificial tissues (*13*−*18*). Herein, we describe the preparation and properties of a new bioactive immobilization on a PLLA membrane for hemodialysis or endovascular devices based on the LBL self-assembly of polysaccharides, chitosan (CH), and dextran sulfate (DS).

During the past few decades, silver nanoparticles have attracted considerable interest because of their potential applications, such as electromagnetic interference shielding, antibiocidal medical device, and surface-enhanced Raman scattering (*19*, *20*). However, widely used reducing agents in chemical reduction, such as sodium borohydride, hydrazine, and formamide, should be toxic with high risk. In the present study, $AgNO_3$ was the chosen as precursor for the chemical reduction process. Some forms of inorganic silver have been demonstrated to be effective against burns, severe chronic osteomyelitis, urinary tract infections, and central venous catheter infections (*21*). It has been reported that silver contents show an antibacterial property, even at low concentrations in the parts per billion range (*22*). Silver nanoparticles have been reported recently as antibacterial agents against *E. coli*, *S. epidermidis*, and methicillin-resistant *S. aureus* (MRSA) (*23*). In general, colloidal silvers selectively bind to thiol groups, which are widely distributed in bacterial cell wall proteins, and may also bind to bacterial DNA. The pathogens suffocate and die, and are cleared out of the body by the immune, lymphatic, and elimination systems (*24*). Colloidal silver can be taken indefinitely, because it is unlikely to provoke much bacterial resistance as there are a variety of mechanisms of toxicity. Unlike pharmaceutical antibiotics, which destroy beneficial enzymes, colloidal silver leaves these beneficial enzymes intact. Thus, colloidal silver is absolutely safe for humans, plants, and all multicelled living matter (*25*).

We report here novel coatings for PLLA substrates created by the formation of insoluble interpolymeric complexes generated by depositing oppositely charged polyelectrolytes in an LBL

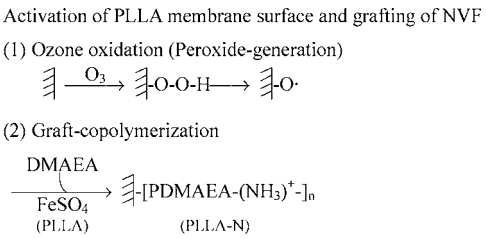

Figure 1. The chemical scheme of PDMAEA immobilization on PLLA membrane via ozone treatment and graft copolymerization.

assembly manner. The polysaccharide PEMs included chitosan (CH) and dextran sulfate (DS)-stabilized silver nanosized colloid (DSS). The non-cytotoxic dextran sulfate (DS) and dextrose served as stabilizer and reducing agent, respectivel,y to form well-distributed silver nanosized colloid (DSS). To characterize the as-fabricated PLLA membranes, measurements of X-ray photoelectron spectroscopy (XPS), field-emission scanning electron microscopy (FE-SEM) and atomic force microscopy (AFM) were performed. The hemocomptibility was evaluated by the plasma protein adsorption, platelet adhesion, and surface-induced thrombogenicity. The in vitro antibacterial activity and cytocompatibility of the resultant PLLA membrane was also accessed. We hope the method of surface modification can contribute to the progress in development of PLLA-related medical devices.

2. EXPERIMENTAL SECTION

2.1. Materials. PLLA chips were purchased from Eastman Corp, Taiwan. Chitosan (M_w = 390 kD, about 85% deacetylation) was obtained from the Taiwan Textile Research Institute, Taiwan. Human plasma fibrinogen (HPF) was purchased from Calbiochem Co., U.S.A. Dextran sulfate (M_w = 500 kD, sulfation degree 16−19%) was supplied by MDBio, Inc., Taiwan. Anticoagulant citrate dextrose (ACD) human blood was provided from the Blood Center in Taiwan. 2-(Dimethylamino)-ethyl methacrylate (DMAEA) was purchased from Aldrich. These chemicals were reagent grade and used without further purification.

2.2. Preparation of DS-Stabilized Silver Nanoparticles. $AgNO_3$ (purity ≥ 99%, Aldrich) was used as a precursor in the preparation of the silver nanoparticles. Dextran sulfate (DS) was used as the stabilizer under chemical reduction by dextrose. The reaction scheme was similar to the silver mirror reaction. Briefly, 0.01 M $AgNO_3$, 0.01 M NaOH, and 0.02 M NH_4OH were mixed thoroughly together for 1 h. Then, 1 mL of the silver alkali solution was added into a 2 wt % DS solution for 30 min, and subsequently added to 10 wt % of dextrose (Sigma). The reaction temperature was maintained at 60 °C by a water bath in the dark. The morphology of nanosized silver colloids was observed using a transmission electron microscope (Philips CM 200) after 20× dilution with ethanol and ultrasonic treatment.

2.3. Surface Modification. Chloroform solutions containing 10 wt % PLLA polymer were stirred for 6−8 h at 25 °C and cast on a glass plate. The solution was allowed to evaporate slowly at 25 °C for 6 h. The resulting membranes with about 0.1 mm thickness were then dried at 50 °C for 24 h. The aminolyzed PLLA membrane was prepared in accordance with the chemical scheme, as shown in Figure 1. The extruded PLLA membranes were ultrasonically cleaned in isopropyl alcohol (IPA) for 15 min prior to surface grafting. Subsequently, as-cleaned membranes were cut into pieces of 2 × 2 cm^2 and treated with 10 g/m^3 of ozone density. The ozone was generated using an ozone generator (Kang I Ozone Enterprise Co., Ltd., Taiwan), and the ozone concentration was controlled by an Ozone UV Photometric Analyzer (SOZ-6000, SKEI Electronics Co., Ltd., Japan). After ozone oxidation for a determined time, the membranes were degassed under vacuum for 5 min to remove ozone adsorbed on the membranes. Afterward, the membranes were immersed in 20 mL of 20 wt % NVF in a glass tube purged with nitrogen, adding 0.1 mL of 0.015 M $FeSO_4$/0.005 M H_2SO_4 to carry out graft polymerization at 60 °C for 120 min. The aminolyzed PLLA (PLLA−N) was rinsed with phosphate buffer solution (PBS, pH 7.4) and double-distilled water to remove the unreacted monomer and homopolymers.

Solutions of DSS, 1 mg/mL in 0.14 M aqueous NaCl, and CH, 1 mg/mL in 0.1 M acetic acid (pH 3.8) containing 0.14 M NaCl, were prepared separately. Ultrapure water was used in all experiments (Milli-Q system, Millipore). The multilayer buildup was accomplished by sequential dipping of the substrate in the polysaccharide solution (alternating between DSS and CH), followed by a 15 min adsorption and a wash with a flow of 0.14 M NaCl. Finally, the samples were extensively cleaned with ultrapure water and freeze-dried at −52 °C using a freeze-dryer (model ZDG, vacuum Freeze Drier, China) for 24 h. The PLLA membranes modified with CH/DSS polyelectrolyte multilayers (PEMs) were defined as PLLA−DSS(CH−DSS)$_n$, where n represented the number of PEMs.

2.4. Determination of Surface Grafting Density. According to our previous work (*26*−*30*), the peroxide groups were tested by a 1,1-diphenyl-2-picrylhydrazyl (DPPH) method. Briefly, ozone-treated TPU membranes were placed in 20 mL of benzene containing 2.5 × 10^{-5} M 1,1-diphenyl-2-picrylhydrazyl (DPPH, Sigma) and kept at 70 °C for 24 h to decompose the peroxides. The DPPH molecules binding to the free radicals formed were quantified from the difference in absorbance at 520 nm between the original and the residual DPPH solutions. The surface density of sulfate groups of DS and amino groups was determined by dyeing with toluidine blue O (Sigma, U.S.A.) and C.I. Acid Orange 7 (Tokyo Kaseo Kogyo Co., Japan), respectively. The dye concentration was determined using an ultraviolet (UV) spectrometer (Ultrospec 1100 pro, Biochrom, Ltd., Cambridge, U.K.).

2.5. Surface Characterization Analysis. Elemental analysis of PEMs on modified PLLA membranes was performed using XPS (ESCALAB 250, Thermo VG Scientific, West Sussex, U.K.) equipped with Mg Kα at 1253.6 eV and 150 W power at the anode. The contact angles of the membranes were evaluated using a contact angle goniometer (DSA 100, Krüss GmbH, Hamburg, Germany) at 25 °C (*28*). The streaming potential (ΔE_{str}) and ζ potential were determined with a tester (EKA088, Austria) using 0.01 M KCl, 8 × 10^{-4}M Na_2HPO_4, and 2 × 10^{-4}M NaH_2PO_4 as the testing solution (pH 7.4). The relationship between ζ potential and streaming potential could be denoted as follows

$$\zeta = 4\pi\eta k_b \Delta E_{str}/\epsilon \Delta P$$

where ζ is ζ potential, ΔE_{str} is streaming potential, ΔP is driving pressure, η is solution viscosity, ϵ is the dielectric constant, and k_b is bulk conductivity.

The surface morphology was further examined using FE-SEM (JSM-6500F, JEOL, Japan) and AFM (MMAFM-2, Santa Barbara, CA).

2.6. Protein Adsorption. The 2 × 2 cm^2 pieces of as-fabricated samples were immersed in 1 mg/mL of HPF (M_w = 341 000, clottable proteins > 95%; Calbiochem, U.S.A.) PBS 7.4 solution with shaking at 100 rpm and 37 °C for 24 h. The membrane was gently taken out and rinsed 5 times with PBS. The sample was placed in a glass bottle with 1 wt % aqueous solution of sodium dodecyl sulfate (SDS) and shaken for 60 min at room temperature to remove the protein adsorbed on the surface. The protein contents of the individual samples were measured colorimetrically using the BCA reagents (Pierce

Chemical Company, U.S.A.) (*31*). The absorption at 570 nm was measured using an ultraviolet spectrometer. The calibration curve was preset by measuring varying protein concentrations in SDS solution.

2.7. Blood Coagulation. To obtain platelet-rich plasma (PRP), the ACD blood was centrifuged at 100 *g* for 20 min at 4 °C to separate the blood corpuscles. Subsequently, a portion of the PRP was further centrifuged at 2000 *g* for 20 min at 4 °C to obtain the platelet-poor plasma (PPP). The in vitro determination of platelet adhesion and coagulation times was in accordance with our previous study (*28*), including activated partial thrombin time (APTT); prothrombin times (PT) were determined using an automated blood coagulation analyzer (CA-50, Sysmex Corp., Kobe, Japan).

2.8 Cytocompatibility evaluation (*32*). The human endothelial cells (ECs) were isolated from human umbilical cord veins of a new bornbaby with 1.0 mg/mL collagenase (type I, Sigma)/phosphate buffer solution (PBS, pH 7.4) for 20−25 min at room temperature. The as-prepared PLLA membranes were fixed with vacuum grease to the bottom of six 15 mm polystyrene Petri dishes without biomaterial deposit to prevent them from floating in the growth media. The human EC cell suspension (100 μL) with a cell density of 2.5×10^5 cell/disk of isolated ECs were routinely seeded on the beds prelaid with native or modified PLLA membranes as well as on tissue culture polystyrene (TCPS) (Nunc, Denmark) as a control. The ECs were incubated in a culture medium consisting of 10% (v/v) fetal calf serum (FCS, Sijiqing Biotech Co., China) in humidified air containing 5% CO_2 at 37 °C. After incubation for 24 h, the culture medium was changed, and then changed again every 2 days. The cell attachment and proliferation ratio were averaged from five parallel measurements at 12 h and 4 days, respectively, by trypsinization of the human ECs using a Neubauer hemacytometer on an inverted light microscope to count the number of cells. The cell proliferation ratio was defined as $(N_2 - N_1)/N_1$, where N_1 and N_2 represent the cell number per well at 12 h and 4 days, respectively. The MTT (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrasodium bromide; Sigma) assay was used to measure the viability of the fibroblasts (*33*). In addition, after 3 days culture in the 6 well plate, in which 100 μL of the MTT assay (5 mg/mL) was added to each well and incubated at 37 °C for 4 h, the blue formazan reaction product was dissolved by adding 0.5 mL DMSO and diluting to 2 mL with PBS. The absorbance was measured at 490 nm using a microplate autoreader. The relative viability ratio was defined as $(A_{sample} - A_{blank})/A_{control} - A_{blank}$, where A_{sample}, $A_{control}$, and A_{blank} represent the absorption at 490 nm per well of specimen and TCPS at incubation time (68−72 h), and blank disk, respectively.

2.9. Antibacterial Activity Evaluation. Bactericidal activity was evaluated on the basis of the killing rate by the viable cell counting technique against Methicilin-resistant *Staphylococus aureus* (MRSA). One loopful of the bacteria was inoculated in 10 mL of nutrient agar and incubated at 37 °C for 18−24 h; then, 20 mL PBS (composed of 0.2 M Na_2HPO_4, 0.2 M NaH_2PO_4, 0.5 g NaCl, and 2 g/L Tween 80 to 1000 mL) was added. After mixing, 1 mL of the solution was transferred into 9 mL of nutrient broth, and mixed with a vortex mixer. The bacteria solution was diluted with PBS to 1.5×10^5 cells/mL and placed in flasks (6 samples of 0.4 g/sample for each group). After incubating at 37 °C for 0−24 h, 20 mL of PBS was added and stirred for 30 s. Consecutive dilutions were made by taking 1 mL of the previous solution and mixing with 9 mL of PBS. From the diluted solution, the surviving bacteria were determined by the spread plate method. After inoculation, the plates were kept at 37 °C, and the colonies were counted after 18−24 h (*30*).

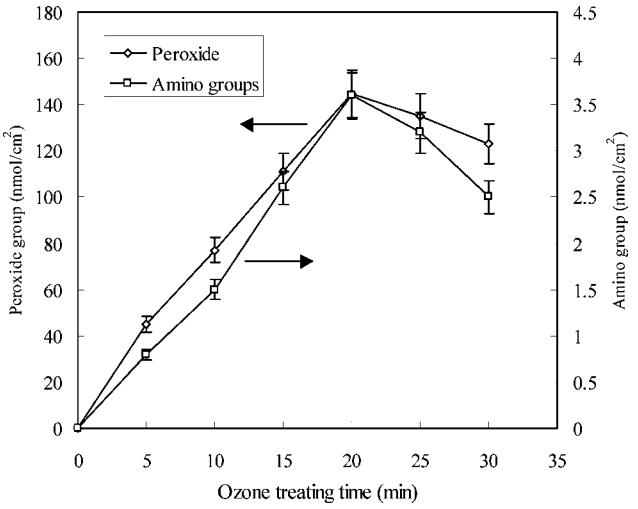

Figure 2. Peroxide and amino group graft density vs ozone treating time determined by DPPH method and dye assay.

3. RESULTS AND DISCUSSION

3.1. The Ozone Treatment of PLLA Membranes. Surface modification of the polymer membrane becomes important when polymeric material is in contact with a physiological component such as blood and living tissue. Zhu et al. (*6*) have developed a novel technique to introduce free amino groups onto polyester scaffolds via aminolyzing the ester groups with diamine. Positively charged chitosan was then deposited onto the aminolyzed poly(L-lactic acid) (PLLA) membrane surface in an LBL assembly manner using poly(styrene sulfonate) sodium salt (PSS) as a negatively charged polyelectrolyte. In the present study, the surface modification was based on the chemical schemes described in Figure 1. By inducing oxidization to modify the PLLA surface with ozone, peroxide groups were easily generated on the surface. The maximum amount (144.8 nmol/cm^2) of peroxide groups appeared at 20 min of ozone exposure and leveled off to a constant value, as shown in Figure 2. The amount of peroxide groups decreased with prolonged treatment time. This was probably attributed to the increase in cross-linking between those peroxide groups or free radicals on the surface of the membrane after prolonged ozone attack. In other words, those peroxides were partially converted into inactive species and thus reduced the free radicals.

Those peroxides were broken by redox-polymerization and provided active species to initiate poly(DMAEA) on the surface of the PLLA membrane. Hence, the aminolyzed PLLA membrane was fabricated. It could be found that the grafting density of the amino group (3.21 nmol/cm^2) was inducted at 20 min of ozone exposure. The multilayer coating procedure was initiated by the immobilization of an aminolyzed PLLA substrate (PLLA−N), yielding a positively charged surface, subsequently placed in contact alternating with a solution of the polyanion DSS and a solution of the polycation CH.

3.2. Formation of DS-Stabilized Silver Nanosized Colloid. To prepare nanosized silver colloid via the chemical reduction method, it is very important to choose an appropriate stabilizer and reducing agent. Generally speaking, a stabilizer agent absorbs on the solid−liquid interface and forms a layer of molecular membrane to hinder contact between the particles. At the same time, it will reduce surface tension, thereby reducing the absorption capability of the capillary. In this work, the water-soluble polymer stabilizer, namely, dextran sulfate (DS), was employed as a stabilizer agent. Colloidal silver nanoparticles were prepared by using dextran sulfate (DS) as a stabilizer to precede chemical reduction by non-cytotoxic dextrose. Because of having moderate reduction power, dextrose was chosen as the reducing agent in this work.

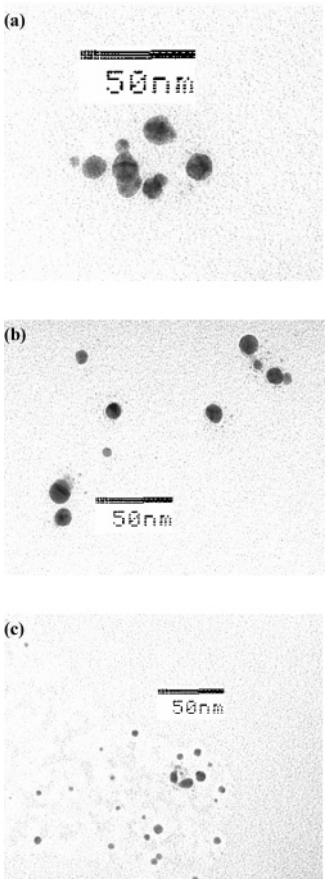

Figure 3. TEM image and corresponding particle analysis of DS-stabilized nanosized silver colloid: (a) 0.5 wt % DS, (b) 1 wt % DS, (c) 2 wt % DS-stabilized silver colloid.

When NaOH was used to promote the reduction reaction, the precursor solution $AgNO_3$ would quickly turn the dark color of pure Ag_2O precipitate. When the NH_4OH was added, the solution became clear, due to the formation of $[Ag(NH_3)_2]^+$. It is possible that at the very beginning of this synthesis process some Ag_2O was formed by the following reaction:

$$2Ag^+ + 2OH^- \rightarrow Ag_2O + H_2O$$

$$Ag_2O + 4NH_3 + H_2O \rightarrow 2[Ag(NH_3)_2]^+ + 2OH^-$$

Subsequently, when adding into DS solution and dextrose, the complex solution gradually changed into a yellowish green color as the reaction was completed. Presumably, it suggested that silver ion was reduced into extremely fine silver particles, which then gradually agglomerated into a stable size distribution. A longer DS molecule chain might provide a physical barrier to slow down the agglomeration process, thus enabling the stabilization process to those silver colloids. No aggregation or decomposition of the silver nanoparticles occurred even after six months storage.

During this process, DS is expected to inhibit the further aggregation of silver nanoparticles and to stabilize the dispersed silver nanoparticles in solution. Figure 3 showed the TEM image of silver nanosized colloid with DS as a stabilizer at the different concentration. The average size of 2 wt % DS-capped silver nanoparticles (7−10 nm) is less than that of 0.5 wt % DS-capped particles (15−20 nm). Using DS as a stabilizer in the chemical reduction process resulted in smaller and more uniform silver nanosized colloids. However, the colloidal silver solution turned turbid after 30 min stirring in the absence of DS. Shin et al. (*33*) proposed that silver nanoparticles were prepared by using poly(vinylpyrrolidone) (PVP) as a stabilizer and γ-irradiation with a size range of 10 to 30 nm. Zhao et al. (*34*) reported that spherical silver nanoparticles capped by mercaptosulfonic acid with a diameter of about 8 nm were prepared by chemical reaction.

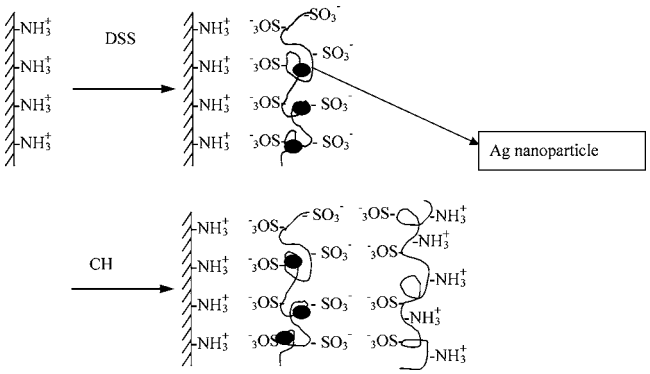

Figure 4. The schematic representation of LBL self-assembly process with oppositely charged PEMs on an aminolyzed PLLA membrane surface. Colloidal silver nanoparticles were prepared by using DS as a stabilizer to precede chemical reduction by dextrose.

3.3. Monitoring the LBL Deposition Process onto PLLA Surface. In principle, the adsorption of DSS carrying more than one equal charge allows for charge reversal on the surface, which has two important consequences: (1) repulsion of equally charged molecules and thus self-regulation of the adsorption and restriction to a single layer (2). The ability of oppositely charged molecules to be adsorbed is a second step on top of the first one. The alternative LBL deposition was fabricated by CH and DSS electrostatic adsorption, as described in Figure 4. Chitosan, a polycationic repeating monosaccharide may be combined with the polyanionic DSS such that ionic cross-linking results in hydrogel formation. They appeared to be polyelectrolyte complexes obtained by the formation of polyanion−polycation interactions held between ammonium functions of chitosan and sulfate groups of DSS. The multilayer buildup procedure was monitored next by measuring the dye-staining assay. As listed in Table 1, the amount of CH and DSS in the coating increased with the number of PEMs, showing that the two polyelectrolytes follow a typical multilayer construction mechanism.

3.4. Surface Characterization. Figure 5 and Table 2 showed the XPS survey wide-range spectra of PLLA and PLLA−DSS-(CH−DSS)$_5$ from binding energies 100−600 eV. As illustrated, from the PLLA−PEM membrane was found the additional Ag_{3d} (395 eV), N_{1s} (400 eV), and S_{2p} peaks (167 eV) in comparison with that of native PLLA. These spectra showed the success of Ag-nanoparticle-embedded PEM immobilization on the surface of the PLLA membrane.

The evolution of surface topography throughout the PEM construction process was assessed using FE-SEM, as shown in

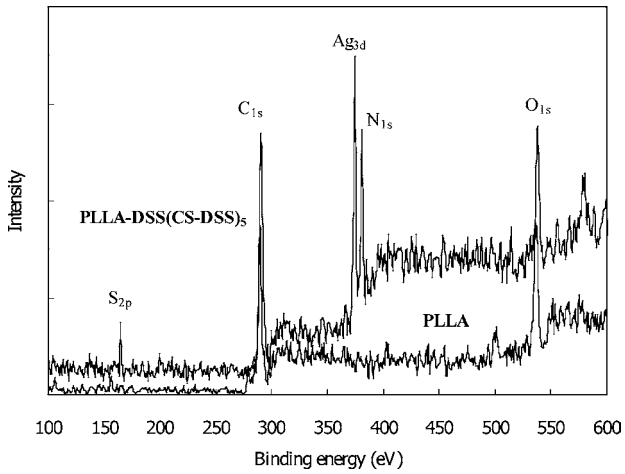

Figure 5. The XPS survey scan spectra of as-fabricated PLLA membranes, which represented relative intensity vs binding energy (100−600 eV).

Table 2. Elemental Compositions of the Modified PLLA Membrane Surfaces with CH−DSS PEM Immobilization

	atomic %				
membrane type	C%	O%	N%	S%	Ag%
PLLA	79.1	20.9	0	0	0
PLLA−DM	77.34	20.86	1.8	0	0
PLLA−DSS−CH	75.4	22.5	1.9	0.13	0.07
PLLA−DSS(CH−DSS)$_3$	74.2	23.2	2.3	0.17	0.13
PLLA−DSS(CH−DSS)$_5$	72.7	24.1	2.7	0.27	0.21

Figure 6. It was worth noting that the more PEM layers deposited the rougher the PLLA membrane was. These surface features were gradually masked in the coated surfaces and replaced by PEM clusters. These structures increase in size with the number of layers, reaching a layer height on the scale of hundred of nanometers to micrometers. It is understood in the assembly that membranes grow homogeneously when the roughness and size of the pores is far greater than the molecular size of CH or DS. It was found that the three-dimensional and porous structure layer onto PEM-deposited PLLA membrane. After four bilayers are deposited, the surface became smoother (Figure 6d).

Table 3 illustrated the contact angle of PEMs immobilized on PLLA membranes. Deposition of PEMs on the PLLA membrane resulted in a sharp decrease of the contact angle (31.2 ± 3.2° for PLLA−DSS(CH−DSS)$_4$ vs 69.4 ± 4.1° for PLLA). This result suggested that the CH/DSS PEM deposition apparently improves the hydrophilicity of PLLA membrane. Note that the contact angle further decreased with an increasing number of layers, reaching an angle of about 31° upon deposition of four bilayers and remaining constant upon further polyelectrolyte layer deposition. There were no further changes in the contact angle, thus indicating that at least four bilayers were necessary to mask the substrate with respect to the properties of the multilayer/water interface. The contact angles displayed a distinct oscillation as the outermost layer changed from DS to chitosan, demonstrating the greater hydrophilicity of samples containing DS as the outermost layer than those with chitosan as the outermost layer. However, the same outermost layer did not present the same contact angle. This may be due to the layer interpenetration between neighboring DSS and CH molecules where the segments of the underlying layer are able to influence the surface hydrophilicity. This is likely the main reason for the slow growth of the layer thickness after assembling some layers due to the weakening of surface charge. These results were similar to those of Thierry et al. (*18*) and Zhu et al. (*6*). Figure 7 illustrated the ζ potential of PEM-immobilized PLLA membranes. Deposition of a layer of

Table 3. Contact Angle Data as a Function of the Layer Number of DS and CS, where 1−5 Number Membranes Have DS as the Outermost Layer[a]

sample	contact angle (°)
PLLA	69.4 ± 4.6
PLLA−N	58.2 ± 2.6
PLLA−DSS	54.3 ± 3.2
PLLA−DSS−CH	63.2 ± 2.1

PLLA−DSS(CH−DSS)$_4$CH	44.2 ± 2.1
PLLA−DSS(CH−DSS)$_5$	33.5 ± 1.5

[a] (n = 6, mean ± std).

PLLA-N resulted in a sharp increase of the contact angle (+24 mV for PLLAT-N vs 0 for PLLA). The ζ potential of PLLA−DSS and PLLA−DSS−CH was −34 mV and +18 mV, respectively. It may be due to the layer interpenetration between neighboring DS and CH membranes where the segments of the underlying layer are able to influence the surface charge. However, we found that the ζ potentials were −37 mV and −36 mV for PLLA−DSS(CH−DSS)$_4$ and PLLA−DSS(CH−DSS)$_5$, respectively, in other words, deposition of four bilayers and remaining constant upon further polyelectrolyte layer deposition, thus indicating that at least four bilayers were necessary to mask the substrate. The results were consistent with contact angle values.

3.5. Protein Adsorption and Platelet Adhesion of Surface-Modified PLLA. Figure 8 showed the relationship of HPF adsorption and platelet adhesion onto the surface-modified PLLA membranes. It was clear that the adsorbed amount decreased on PLLA−PEMs with DSS as the outermost layer, but increased with CH as the outermost layer. The reason is probably the electrostatic effect. The isoelectric point of HPF in the blood is 4−6; thus, these proteins normally carry a negative charge in the blood (pH 7.4). Considering chitosan alone, it is possible to evaluate the percentage of amino groups at pH 7.2−7.4. Because the pK_a of chitosan is 6.5 (*35*), it still carried a positive charge at pH between 7.2 and 7.4 (12% < $[NH_3^+]/[NH_2]$ < 20%). Owing to the electrical attraction, the adsorption of proteins was promoted. On the other hand, when PLLA−chitosan was linked with DS, it showed that HPF had no binding affinity to DS, due to the electrostatic repulsive interaction between SO_3^- groups of DS and HPF. Similarly, the platelets carry a negative charge; therefore, the adhesion behavior corresponded to HPF adsorption. As mentioned above, the ζ potential was influenced by the PEM structure; the HPF adsorption and platelet adhesion of PLLA−DSS(CH−DSS)$_4$ would reach the steady state (33μg/cm^2 and 14%). Nevertheless, the adsorbed amounts were significantly curtailed in comparison with that of native PLLA (110μg/cm^2 and 32%). Baumann et al. (*8*) studied the reduced adsorption of plasma proteins, such as fibrinogen and albumin onto heparin-immobilized surfaces. They demonstrated that immobilization of the CH/DSS PEMs might exert a heparin-like efficiency.

3.6. Blood Anticoagulation of Surface-Modified PLLA. It is well-known that protein adsorption and platelet adhesion should be a critical index for evaluating compatibility of blood with artificial surfaces. The blood coagulation cascade includes the intrinsic pathway, the extrinsic pathway, and the common pathway. The activated partial thromboplastin time (APTT) and plasma recalcification time (PT) are used to examine mainly the extrinsic and intrinsic pathways, respectively. Figure 9 shows that the clotting times of the native and PLLA-N membranes

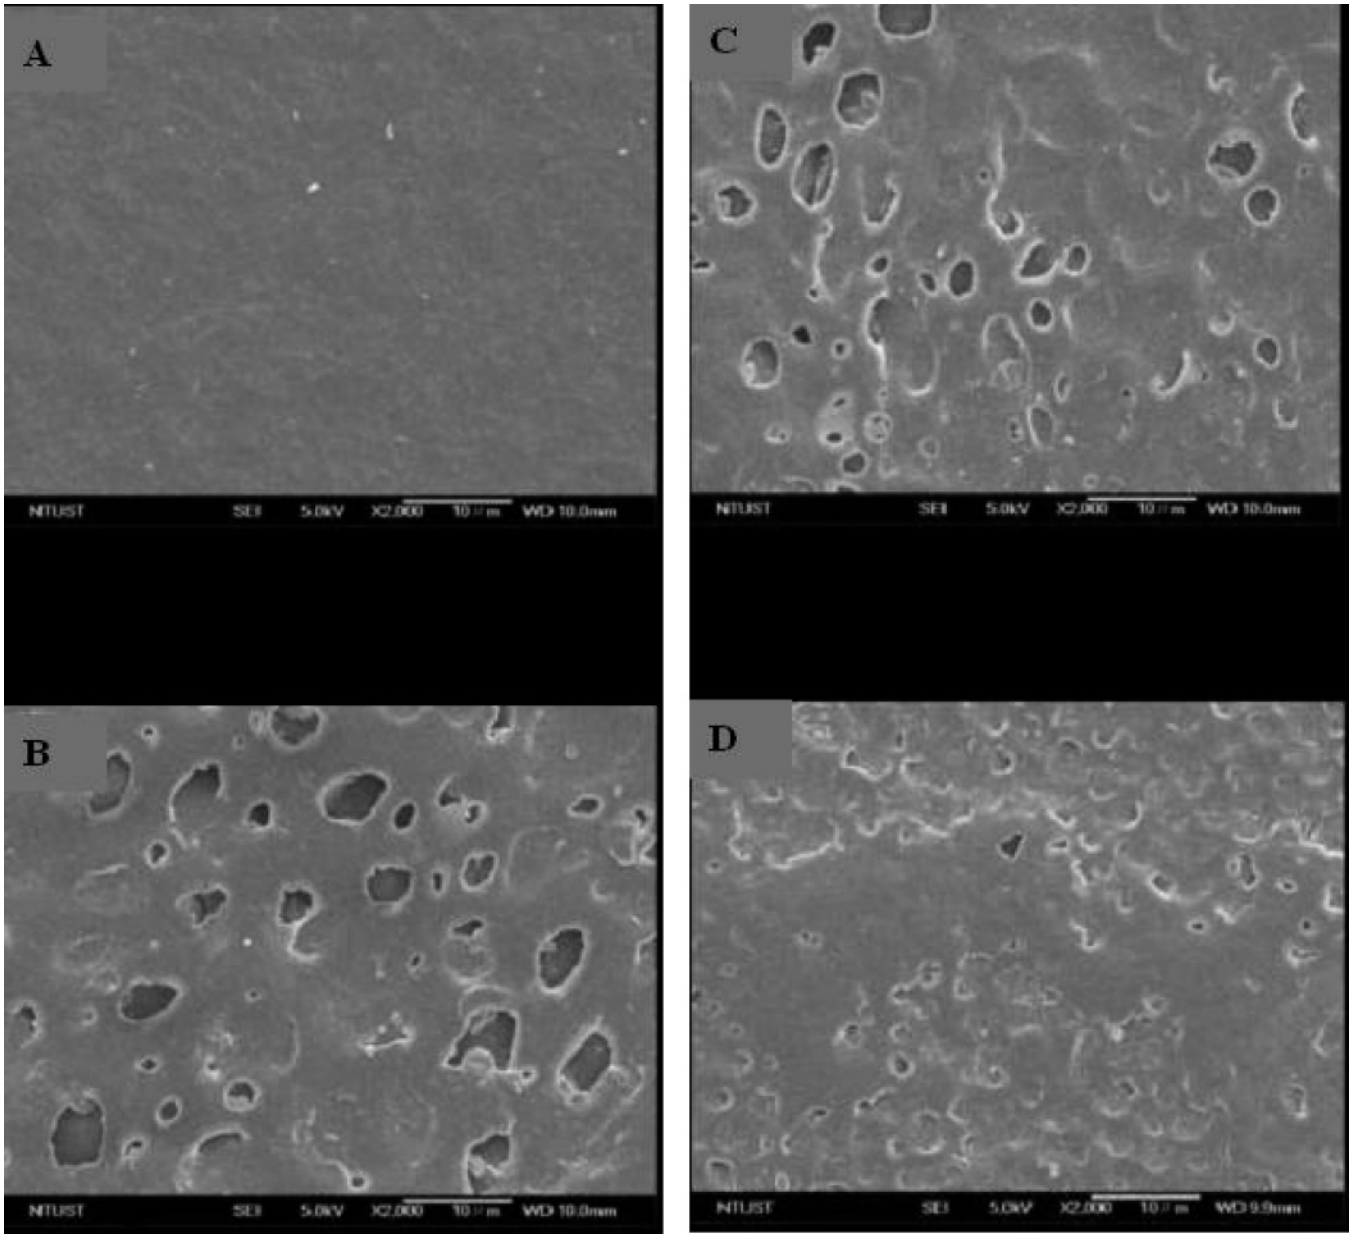

Figure 6. FE-SEM images of the PLLA membrane surface: (A) native PLLA control, (B) three bilayer (PLLA−DSS(CH−DSS)$_3$), (C) four bilayers (PLLA−DSS(CH−DSS)$_4$), and (D) five bilayers PLLA−DSS(CH−DSS)$_5$).

were nearly the same as that of human plasma (the negative control), whereas the clotting times of PEM-immobilized PLLA membranes were longer. This suggested that dextran sulfate should be an effective agent in prolonging the blood clotting time (*36*). Besides, it was also confirmed that positively charged surfaces (CH-grafted) are generally thromobogenic, while uniformly negatively charged surfaces tend to be antithrombogenic (DS-grafted). This result demonstrated that the PEMs with dextran sulfate as the outmost layer provided the PLLA membrane with heparin-like activity in terms of antithrombogenic properties. Serizawa et al. (*37*) have studied the alternating anti- vs procoagulant activity of ultrathin polymer films prepared by the LBL assembly technique against human blood. Dextran sulfate and chitosan were selected as polymers with anti- and procoagulant activities, respectively. They also concluded that the outermost surface was the key factor in the anticoagulant activity observed, rather than the total film thickness.

3.7. Cytocompatibility. Figure 10 displays the cell attachment of native and surface-modified PLLA membranes on the growth of human ECs.

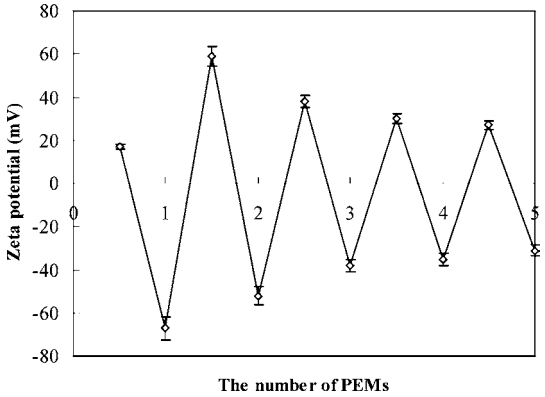

Figure 7. ζ-Potential data as a function of the layer number of DS and CH. 0.5 values represent membranes with CH as the outermost layer, whereas 1−5 number membranes have DS as the outermost layer (PLLA−N, +24 mV; PLLA−DSS, −44 mV) (n = 6).

The order of the amount of cell attachment was PLLA−DSS-(CH−DSS)$_3$ > PLLA−DSS(CH−DSS)$_4$ > PLLA−DSS(CH−

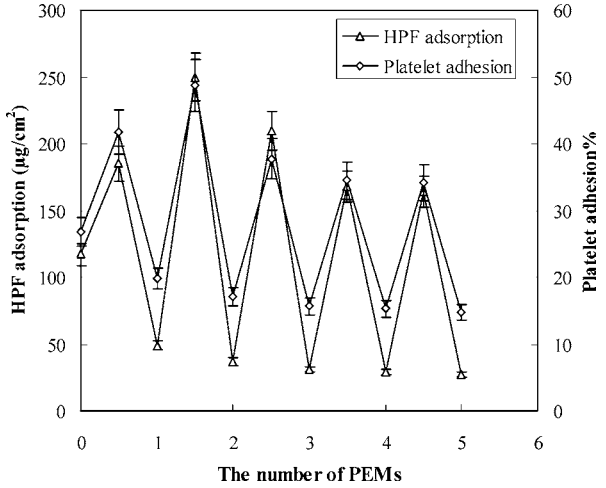

Figure 8. The comparison of HPF and platelet adhesion as a function of the number of layers of PEM (PLLA: HPF adsorption (μg/cm^2)/ platelet adhesion % = 110/32).

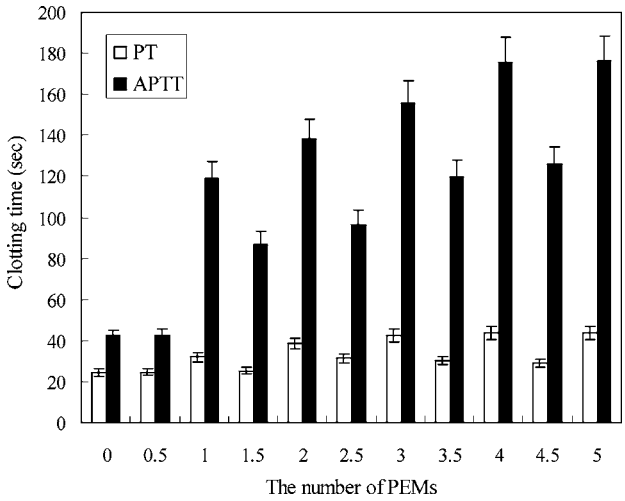

Figure 9. APTT and PT as a function of the number of layers of CH/ DSS PEMs (plasma control: APTT/PT = 47/32 s).

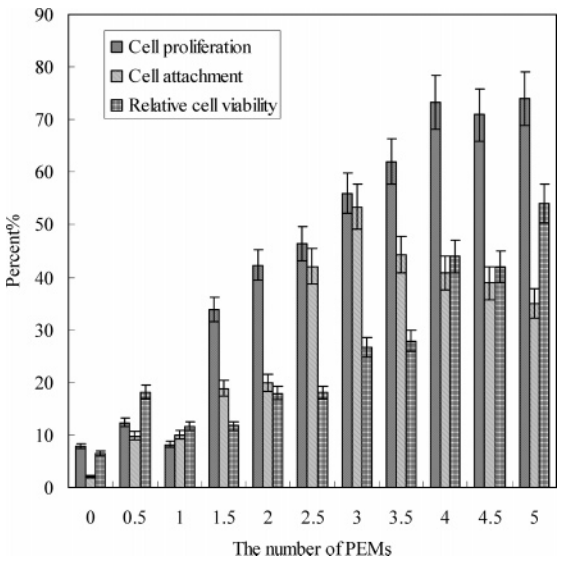

Figure 10. The comparison of cell attachment, proliferation, and relative viability of human ECs on as-prepared PLLA membranes (n = 6). The TCPS acted as the100% control.

DSS)$_5$ > PLLA−DSS(CH−DSS)$_2$ > PLLA−DSS(CH−DSS)$_1$ > PLLA. It suggested that the cell attachment depended apparently on the morphology of the PEM layers on the PLLA membranes. According to the results of FE-SEM (Figure 6), it was found that PLLA−DSS(CH−DSS)$_3$ had the roughest and most porous structure; therefore, cells were easy to immerse or embed into the PEM layer. The cell activity on PLLA assembled with three bilayers of PEMs was apparently better than that on native PLLA. However, it was found that the ECs represented higher viability (52.2%) and proliferation (73.2%) on PLLA−DSS(CH−DSS)$_5$ than on PLLA−DSS(CH−DSS)$_3$ (26.4% and 54.5%). It suggested that higher cell attachment could not lead to higher cell viability and proliferation. Besides, deposition of only one DSS layer on PLLA-N resulted in lower cell activity and proliferation compared with one bilayer of DSS/chitosan. Relative cell viability of 8.2% and proliferation ratio of 11.6% were measured for the PLLA−DSS(CH−DSS)$_1$, while 12.4% and 18.2% were obtained for the one PLLA−DSS−CH. However, cell viability and proliferation showed no obvious difference between PLLA−DSS(CH−DSS)$_4$ (43.2%/72.2%) and PLLA−DSS(CH−DSS)$_1$CH (42.2%/71.6%). These results demonstrate that the negatively charged DSS is not as effective as CH in enhancement of cytocompatibility due to either the charge repulsion or disadvantageous surface chemistry at lower bilayer immobilization number. As pointed out above, defects may exist on the one bilayer-modified PLLA surface in the manner of LBL deposition, whereas those were fully covered by more than four bilayers of modified PLLA. Richert et al. (*38*) have studied the short-term interactions of chondrosarcoma cells with polyelectrolyte multilayer films built up by the alternate adsorption of poly(L-lysine) (PLL) and poly(L-glutamic acid) (PGA). They proposed that PGA-ending films were found to prevent the adsorption of serum proteins, whereas important protein adsorption was always observed on PLL-ending films. These results show that cell interactions with polyelectrolyte films can be tuned by the type of outermost layer and the number of layers in the film.

Furthermore, appropriate electronic equilibrium of PEMs should be considered. It is well-known that the higher surface density of the amino group has led to more cell attachment (*39*, *40*). These cationic charges of chitosan could certainly improve the cell attachment through the interaction with the negatively charged cell surface. However, they suggested that chitosan seems to be cytostatic toward fibroblasts: it is not cytotoxic, but inhibits cell proliferation. It suggests that an extremely high level of adhesion of fibroblasts on chitosan-based materials would alter their growth, thereby reducing fibroblast migration and resulting in inhibition of cell proliferation. Thus, it is the inhibition of human EC cell migration that inhibits cell proliferation. In the present study, the positive charges of the amino groups of chitosan were being shielded by the negatively charged sulfate of DSS. Therefore, chitosan alone cannot be considered a suitable biomaterial for in vitro human ECs cell cultivation. In a word, the cell attachment, proliferation, and viability depended on the polyelectrolyte equilibrium of immobilized CH/DSS PEMs on the PLLA surface via LBL assembly technique.

3.8. Antibacterial Activity Assessment. Figure 11 showed the effect of silver nanoparticles on the log plots of viable growth curves against methicillin-resistant *S. aureus* (MRSA). After soaking for 24 h, the silver content in the bulk was too little to determine using an inductively coupled plasma atomic emission spectrometer (ICP) (S-35, Kontron, Germany) at a wavelength of 328.068 nm (data no show). When in contact with native PLLA, the bacteria grew from 1×10^5 to 2.5×10^7 CFU/mL. However, when in contact with PLLA−PEMs, the concentration of bacteria reduced rapidly and died out after incubating at 37 °C for 12 h. In particular, it was observed that the significant reduction in the number of MRSA began to occur at 3 h for

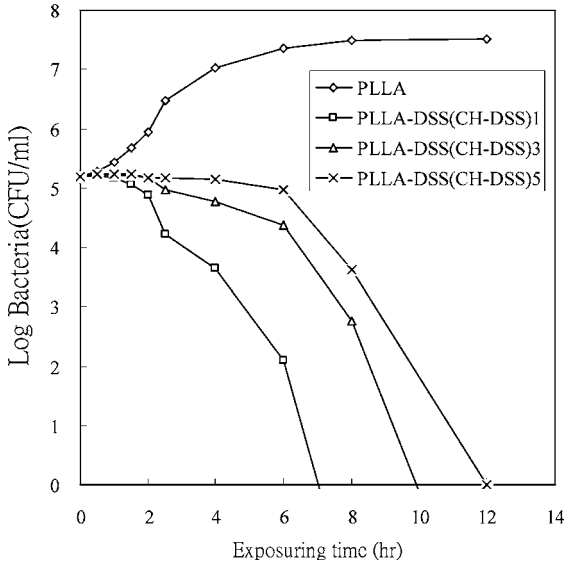

Figure 11. Antibacterial activity was expressed as a measure of MRSA in PEM-modified PLLA membranes.

silver-embedded PLLA−DSS(CH−DSS)$_5$. This suggested that the antibacterial activity was enhanced with the increase of PEM layer.

Lee et al. (*41*) reported that, when Ag nanoparticles existed within the multilayers, the Ag ions that were produced at the surfaces of the nanoparticles are the source of antibacterial activity. Furthermore, the oxidation of zerovalent Ag to Ag ions would occur to a greater extent in the nanocomposite thin films. The diffusion of Ag ions out of the multilayers is rapid compared to the ionization process. Therefore, in the present study, the formation of Ag nanoparticles would reduce the amount of Ag ion released from the nanocomposite films. In view of the results, the Ag nanoparticle-embedded PEM-immobilized PLLA membranes possessed effective and long-tern antibacterial activity.

4. CONCLUSIONS

In conclusion, herein it was ascertained that the versatile CH/DSS PEMs have been successfully immobilized onto the aminolyzed PLLA membrane surface in a LBL assembly manner. The PLLA membranes deposited with four bilayers with DSS as the outermost layer can suppress the protein adsorption and platelet adhesion and greatly prolong blood coagulation time. The human endothelial cell (EC) attachment, proliferation, and viability depended on the polyelectrolyte equilibrium and morphology of immobilized CH/DSS PEM layers on the PLLA surface. Besides, the as-prepared PLLA membranes exhibited antibacterial activity against MRSA. Overall, results demonstrated that the current research explores the construction of CH/DSS multilayers on biomedical PLLA membrane via LBL method, developing a fast, simple-to-process, and shape-independent method for antithrombogenic coating in the application of hemodialysis devices.

Preactivated Carboxyl Linker for the Rapid Conjugation of Alkylamines to Oligonucleotides on Solid Support

Alexandre V. Lebedev,* David Combs, and Richard I. Hogrefe

Trilink Biotechnologies, Inc., San Diego, California 92121. Received December 18, 2006; Revised Manuscript Received July 9, 2007

A C_{10} linker phosphoramidite reagent terminated with a succinimidyl-activated carboxyl group was prepared and used to couple to the 5′-end of an oligonucleotide synthesized on a solid support. The succinimidyl-activated carboxyl functionality can be used for rapid conjugation of amines to oligonucleotides on solid support or it can be hydrolyzed to form a carboxylic acid functionality. The activated linker was successfully used for conjugation of several primary and secondary aliphatic amine derivatives (including biotin and fluorescein cadaverine) onto a solid support-bound 12-mer DNA oligonucleotide at scales ranging from 0.15 to 1.0 μmol. The overall yields of the conjugation products after AMA deprotection and cleavage from the solid support ranged from 43 to 75% of the total oligonucleotide product. This value is significant, as it includes oligonucleotide synthesis, coupling of the linker, and conjugation of the amine. In addition, the entire process of oligonucleotide synthesis, linker coupling, amine conjugation, deprotection, and cleavage of the oligonucleotide from solid support can be accomplished in 1 day.

INTRODUCTION

The preparation of 5′- or 3′-modified oligonucleotides containing conjugated functionalities, such as biotin, fluorescent dyes, or hydrophobic groups, is often accomplished through the use of an oligonucleotide end modified with a primary amino group (*1*, *2*). In most cases, the 5′-alkylamino group of a deprotected (and typically purified) oligonucleotide is coupled with compounds containing an activated carboxyl or isothiocyanate functionality to form amide or thiourea bonds. We considered the plausibility of reversing the coupling partners by placing an activated carboxyl group directly on the 5′-end of the oligonucleotide for reaction with an alkylamine derivative.

An ideal modifying reagent for oligonucleotides would be a phosphoramidite linker terminated with an activated carboxyl group. Furthermore, the activated carboxyl group of the linker would need to be compatible with the conditions of oligonucleotide synthesis including linker coupling and oxidation (or sulfurization). The ability of such functionality to survive these conditions has not been reported. Because the activated carboxyl group cannot survive treatment with strong base, the conjugation reaction with alkylamine derivative must be performed on support-bound, linker-modified oligonucleotide prior to oligonucleotide deprotection and cleavage. However, we saw a number of advantages to solid-phase conjugation, such as high throughput preparation and a combinatorial chemistry approach to oligonucleotide conjugation chemistry.

Herein we describe the synthesis of a novel heterobifunctional C_{10}-linker containing an activated carboxyl group (succinimidyl ester) on one end and a 2-cyanoethylphosphoramidite on the other end. The linker is coupled to the 5′-end of the oligonucleotide on solid support via efficient P(III) phosphoramidite chemistry and oxidized using standard protocols. The resulting succinimidyl-modified oligonucleotide is very stable on solid support and can be stored at low temperature until needed. Direct conjugation of the alkylamine derivative to the succinimidyl activated carboxyl function can be done under mild conditions. The synthesized oligonucleotide 5′-conjugate can then be cleaved from solid support and deprotected using the versatile AMA (ammonium hydroxide/methylamine) treatment procedure. While providing a convenient way for 5′-conjugation of amines to oligonucleotides on solid support, the approach is compatible with preparation of the oligonucleotide conjugates containing alkylamino linkers in other locations, such as the 3′-terminus, offering a more convenient way to prepare unusual double conjugates.

EXPERIMENTAL PROCEDURES

All oligonucleotide synthesis reagents were obtained from Glen Research Corporation (Sterling, VA). Oligonucleotide synthesis was done on a ABI Expedite 8909 DNA synthesizer using standard manufacturer-suggested procedures. The alkylamine derivatives and other chemicals used in this study were commercial products (Fisher Scientific, Sigma-Aldrich, Pierce, Molecular Probes). DMF should be free of amine contaminants. HPLC was accomplished on a Beckman, Inc. (Fullerton, CA) System Gold Nouveau Model 126 with Model 168 photodiode array detector. NMR spectra were recorded on a Bruker Model AX 500 spectrometer (NuMega, San Diego, CA). Electrospray and FAB mass spectrometry analyses were done by HT Laboratories (San Diego, CA).

Succinimidyl 10-Hydroxydecanoate (**2**). To a solution of 10-hydroxydecanoic acid (20 g, 106 mmol) in dioxane (200 mL) at room temperature was added *N*-hydroxysuccinimide (12.2 g, 106 mmol) followed by *N*,*N*′-dicyclohexylcarbodiimide (22.8 g, 106 mmol). After 45 min, the precipitate was removed by filtration, and the solvent was evaporated. The resulting solid was dissolved in ethyl acetate (500 mL), and the organic solution was washed with 5% $NaHCO_3$ (2 × 100 mL) and brine (100 mL), dried over anhydrous $MgSO_4$, filtered, and concentrated in vacuo. Crude compound **2** was purified by silica gel chromatography (hexane−ethyl acetate) to afford the desired succinimidyl ester (20.8 g; 69% yield). ^{1}H NMR ($CDCl_3$): 3.46 (t, 2H, J = 7 Hz), 2.75 (s, 4H), 2.59 (t, 2H, J = 7 Hz), 1.62−1.72 (m, 2H), 1.29−1.47 (s+m, 12H). Mass spectrum (FAB^+): m/z 286 $(M + H)^+$, (Electrospray$^-$): m/z 284 $(M - H)^-$; calculated mass: 285.

Succinimidyl 10-(2-Cyanoethyl-*N*,*N*′-diisopropylphosphoramidyl)-decanoate (3). Succinimydyl 10-hydroxydecanoic acid **2** (3.7 g; 13.0 mmol) was dissolved in 100 mL of anhydrous dichloromethane, cooled to 0 °C, and 3.40 mL (1.5equiv, 19.5 mmol) of diisopropylethylamine added, followed by 3.48 mL (1.2 equiv, 15.6 mmol) of 2-cyanoethyl *N*,*N*′-diisopropylchlorophosphoramidite. After 1 h of stirring at room temperature, the solvent was evaporated. Purification was done by silica gel chromatography with heptane−ethyl acetate 1:1 with 1% triethylamine, yielding 44% of pure product (2.76 g). ^{1}H NMR ($CDCl_3$): 3.8 (m, 2H), 3.6 (m, 4H), 2.8 (s, 4H), 2.6 (m, 4H), 1.7 (m, 2H), 1.5 (m, 2H), 1.2 (s, 10H), 1.1 (m, 12H). ^{31}P NMR ($CDCl_3$): 147.0 ppm. Mass spectrum (electrospray): *m*/*z* 486 (MH^+), calculated mass: 485.

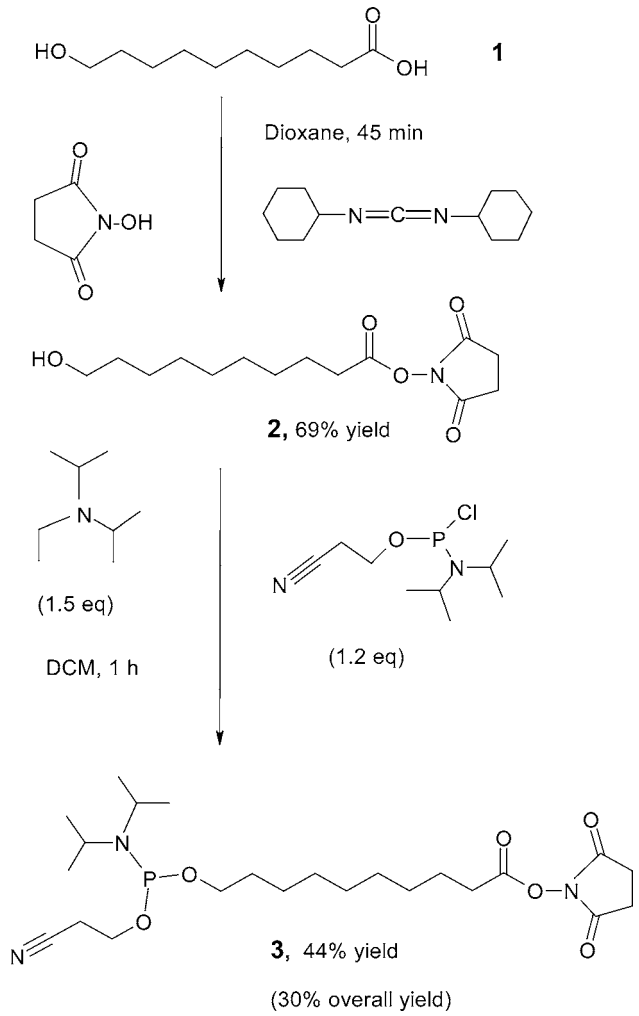
Coupling of Linkers to Oligonucleotides. The phosphoramidite linker **3** was dissolved in anhydrous acetonitrile (<30 ppm of water) to a concentration of 0.1 M and stored over molecular seives (3 Å) overnight prior to use. One micromol scale coupling and oxidation was performed on an Expedite 8900 using standard parameters for solid-phase oligonucleotide synthesis.

For manual 1.0 μmol scale couplings of the linker **3** on column, the detritylated oligonucleotide synthesized on solid support was washed with 30 mL of anhydrous acetonitrile using a syringe and dried using a stream of argon gas. The linker **3** (20 equiv; 200 μL) was drawn into a 1 mL syringe. The activator (0.45 M tetrazole in acetonitrile, 200 μL) was drawn into another 1 mL syringe. The syringes were placed on opposite ends of the column and the reagent passed back and forth for exactly 1 min, at which time the reagent was completely drawn into a syringe. The phosphite triester intermediate **5** was then oxidized immediately for 1 min using (1*S*)-(+)-(10-camphorsulfonyl)-oxaziridine (0.1 M in acetonitrile; 2 mL) using the two-syringe method as described in this paragraph. The column was washed with 2 × 10 mL of acetonitrile and dried with a stream of argon gas.

Conjugation of Alkylamines to an Oligonucleotide with Activated Carboxyl Group. The alkylamine derivative was dissolved at 0.15 M concentration in dry *N*,*N*-dimethylformamide containing 0.4 M triethylamine (best if used within 1 day).

For 0.15 μmol scale syntheses, 4.0 mg of the support with bound 12-mer oligonucleotide intermediate **6** was transferred from the column into a 1.5 mL screw cap plastic tube, and 100 μL of alkylamine solution (15 μmol, 100 equiv) was added. The tube was placed on a shaker for 30 min at room temperature, then centrifuged and the alkylamine solution removed by pipet. The support was then sequentially washed with 1000 μL of DMF containing 0.4 M triethylamine, 1000 μL of DMF, and 1000 μL of acetonitrile, with vortex mixing to ensure completed rinsing of the support.

For 1.0 μmol scale syntheses, the support (ca. 25 mg) with bound 12-mer oligonucleotide intermediate **6** was transferred from the column into a 1.5 mL screw cap plastic tube, and 500 μL of alkylamine solution (75 μmol, 75 equiv) was added. The remainder of the procedure is identical to the 0.15 μmol scale conjugation described above. Alternatively, the 1.0 μmol scale conjugation was performed in the column using the manual two-syringe technique similar to that described above for the coupling of the activated linker. Reagent concentration/equivalent and incubation time are similar to the 1.0 μmol scale conjugation described in the preceding paragraph for 0.15 μmol scale conjugation. After the reaction, the alkylamine solution is drawn into one syringe and the support in the column is washed sequentially with 10 mL of DMF containing 0.4M TEA, 10 mL of DMF, and 10 mL of acetonitrile, followed by drying of the column with a stream of argon gas.



Deprotection and Cleavage of Oligonucleotide Conjugate (7). For 1.0 μmol scale reaction, 1 mL of AMA (1:1 mixture of 28% concentrated ammonium hydroxide and 40% methylamine in water) was added to a 4 mL glass vial containing the solid support obtained from conjugation step (see above). The vial was capped and incubated for 10 min at 65 °C. The solution was removed with a pipet, and the solid support was washed sequentially with 1 mL of AMA and 1 mL of water. The deprotection solution and washes were combined, concentrated in a SpeedVac concentrator, and analyzed by either anion-exchange or reverse-phase HPLC. For the 0.15 μmol scale the AMA solution (200 μL) was added to 1.5 mL screw cap plastic tube containing support with oligonucleotide conjugate and treated as above.

HPLC Analysis of Oligonucleotide Conjugate (8). The crude material was analyzed using a Waters μBondapak analytical column (15 μm, C18 3.9 × 30 mm) with linear gradient of acetonitrile in 100 mM TEAA, pH 7.2 (0−50% over 40 min, 1 mL/min). Anion exchange HPLC analyses were performed using a Dionex DNAPac PA-100 column (4 × 250 mm) with a gradient of 1M LiCl in 25 mM Tris base, pH 10.0 (0−50% over 40 min, 1 mL/min).

Example of Preparation of 5-[(5-Aminopentyl)thioureidyl]-fluorescein Oligonucleotide Conjugate (8) at 1 μmol Scale. Fluorescein cadaverine was dissolved in *N*,*N*-dimethylformamide containing 0.4M triethylamine to a concentration of 23.5 mM. A 300 μL (7.0 μmol of fluorescein cadaverine) amount of this solution was drawn into a 1 mL syringe and attached to the column containing support-bound oligonucleotide **6** with an activated carboxyl group. Conjugation was performed using the two-syringe method (see above) for 30 min at room temperature, at which time the reagent was completely expelled into a glass vial. The solid support in column was washed sequentially with DMF (10 mL), acetonitrile (2 × 10 mL), and a 1:1 mixture of acetonitrile/water (8 × 10 mL) until no color was noted in the washes. The final wash was with methanol (10 mL), followed by DCM (10 mL), and the support was dried on the column under a flow of argon. The deprotection and cleavage of the conjugate from the support was performed with AMA procedure as described above. The product was isolated by anion exchange HPLC, and the yield of isolated compound was estimated to be greater than 0.70 μmol of the 12-mer DNA conjugate as calculated by the UV measurements at 260 nm. The molecular mass of the conjugate was confirmed by mass spectrometry (electrospray): mass found 4368 ($M - H^+$); mass calculated 4368 ($M - H^+$).

Preparation of Carboxylic Acid Derivative of Oligonucleotide (9). Method 1. For a 1.0 μmol scale synthesis ca. 25 mg of support-bound oligonucleotide intermediate **6** was transferred into a 1.5 mL screw cap plastic tube, and 800 μL of aqueous 0.5 M sodium hydroxide was added. The mixture was incubated at room temperature for 24 h, neutralized by 1 M monobasic sodium phosphate (400 μL), and transferred to a 4 mL cap screw glass vial containing 2.4 mL of concentrated ammonium hydroxide. After incubation for 4 h at 55 °C, the mixture was centrifuged, and the supernatant was collected, evaporated, and redissolved in 100 mM TEAA (20 mL, pH 7.2). The resulting mixture was centrifuged, and the supernatant was loaded onto a Waters μBondapak C18 column (19 × 300 mm, 15 μm) equilibrated with 100 mM TEAA pH 7.2. Elution was performed with a gradient of acetonitrile from 0 to 50% over 50 min (10 mL/min). The major peak was collected and dried in a SpeedVac concentrator and the resulting product **9** desalted on a SepPak cartridge (Waters) using water−acetonitrile (1:1) as an eluent. The molecular mass of the conjugate was confirmed by mass spectrum (electrospray): mass found 3896 ($M - H^+$); mass

Scheme 1. Preparation of the C_{10}-Linker 3

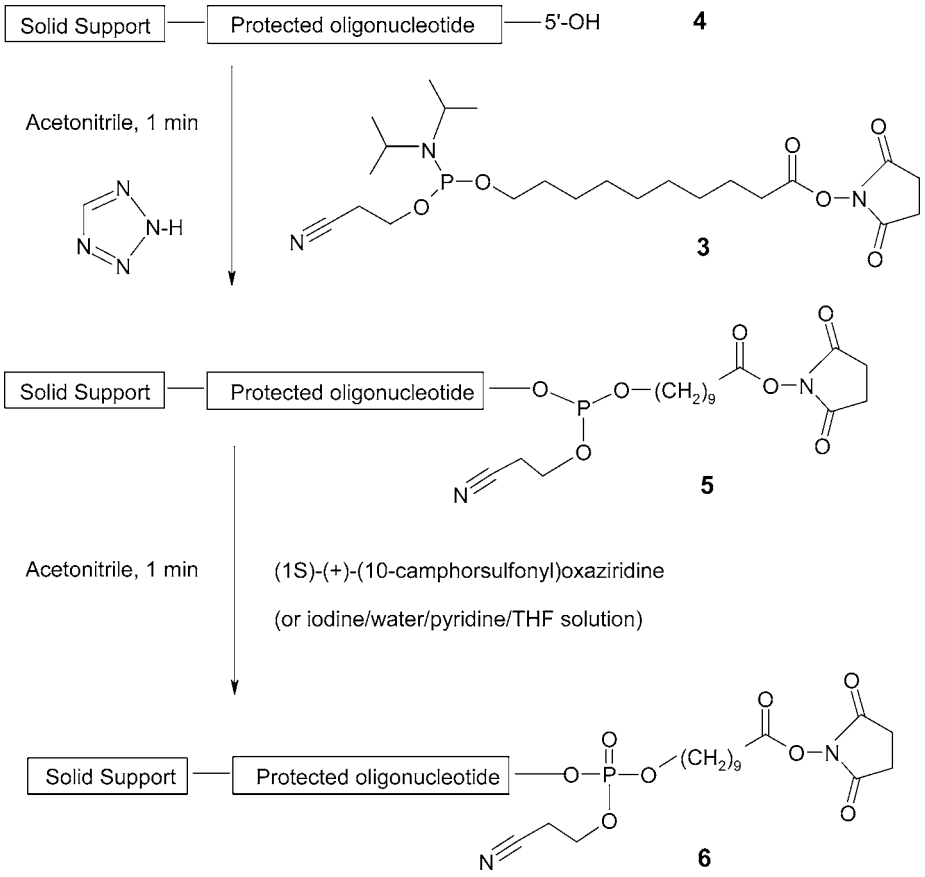
(calcd) = 3896 ($M - H^+$). The isolated yield: 47% (54 OD units at 260 nm).

Method 2. For a 1.0 μmol scale synthesis ca. 25 mg of support-bound oligonucleotide intermediate **6** was transferred into a 1.5 mL screw cap plastic tube, and 800 μL of 0.4M sodium hydroxide solution (methanol−water = 4:1) was added. The mixture was incubated at elevated temperature (48 h at 30 °C) to complete the reaction and neutralized by 1 M monobasic sodium phosphate (350 μL). The mixture was diluted with 15 mL of 100 mM TEAA (pH 7.2), and the carboxylic acid oligonucleotide derivative **9** was isolated and purified as described above.

RESULTS

Preparation of Linker 3. The heterobifunctional C_{10}-linker was prepared in two steps (Scheme 1). First, *N*-hydroxysuccinimide was coupled to 10-hydroxydecanoic acid **1** in the presence of *N*,*N*′-dicyclohexylcarbodiimide. Next, 2-cyanoethyl phosphoramidite was attached to the hydroxyl function of the intermediate **2** using chloro-*N*,*N*-diisopropylamino-2-cyanoethoxyphosphine and *N*,*N*-diisopropylethylamine mixture in dichloromethane resulting in a 30% overall isolated yield of the heterobifunctional linker **3** after silica gel chromatography.

Coupling of the Linker 3 to the Oligonucleotide on Solid Support. Solid-phase coupling of linker **3** to solid-bound oligonucleotide **4** is illustrated in Scheme 2. First, the 12-mer oligonucleotide d(GAT CTG CGA ACT) was synthesized on an Expedite 8909 DNA synthesizer using standard phosphoramidite chemistry on a solid support. The 5′-DMT-group was removed, and coupling of the linker **3** to the support-bound oligonucleotide was accomplished either on an Expedite 8909 Synthesizer or using a two-syringe manual procedure as described in Experimental Procedures. The manual procedure is appropriate when linker **3** is to be coupled to one or a few oligonucleotides in order to save reagents, while the Expedite 8909 Synthesizer is normally utilized when linker **3** is to be coupled to a larger set of oligonucleotides. The coupling efficiency of both automated and manual procedures was identical.



The oxidation of the phosphite triester intermediate **5** during fully automated synthesis was performed immediately after coupling the linker with standard oxidizing reagent (I_2/water/pyridine/THF). Alternatively, manual oxidation could be performed with either the standard iodine oxidizing reagent or with (1*S*)-(+)-(10-camphorsulfonyl)oxaziridine (Scheme 2). The latter is preferred because it does not require the presence of base or water (as does the iodine-based oxidation reagent) and yields a cleaner product compared to iodine oxidation (determined by HPLC analyses, data not shown). Although the oxaziridine reagent performs better, it is currently too expensive to replace I_2/water/pyridine/THF mixture in standard automated syntheses.

Conjugation of Alkylamines to an Oligonucleotide with an Activated Carboxyl Group. The solid support carrying 12-mer oligonucleotide intermediate **6** with an attached activated linker after oxidation can be used immediately for conjugation of alkylamines or can be stored for future use. Our experiments showed that the oligonucleotide intermediate **6** is stable for at least one week at room temperature or up to 6 months at −20 °C without significant loss of activated carboxyl function. A typical conjugation procedure involved reaction of support bound 12-mer oligonucleotide intermediate **6** with the corresponding alkylamine derivative in dry *N*,*N*-dimethylformamide containing 0.4M triethylamine at room temperature (Scheme 3). The reactions were performed at 1.0 μmol scale directly in the column, using the manual two-syringe technique, or at a 0.15 to 1.0 μmol scale after transferring the support to either a glass vial or plastic tube. Both approaches gave similar results.

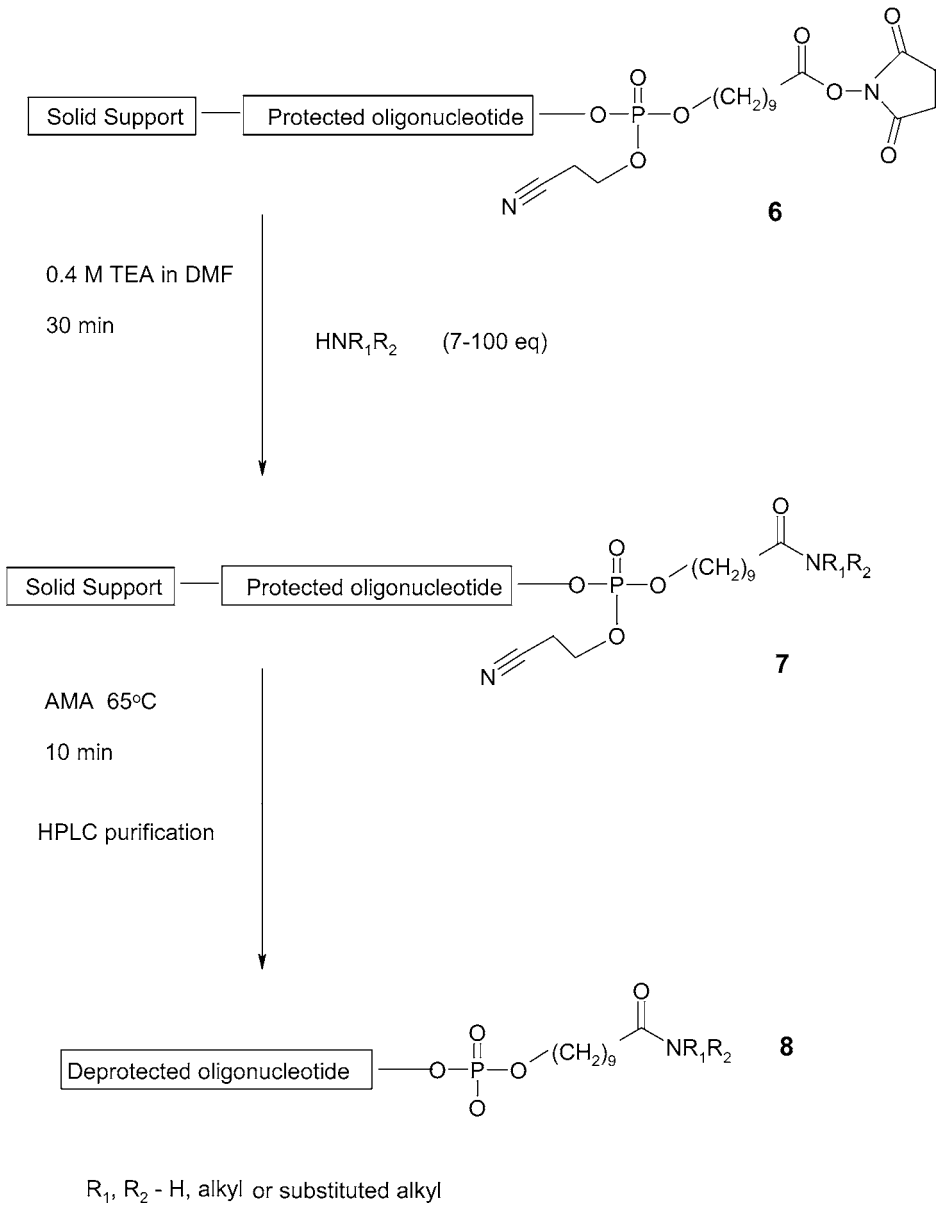
Since the alkylamine derivatives are normally stable in DMF (in contrast to traditional compounds with activated carboxyl acids, which degrade rapidly), any recovered excess reagent can be re-used "as is" in subsequent reactions without any change to the conjugation protocol. (For multiple reuses of the alkylamine solutions, the reaction time may be elongated to compensate for the decrease in the concentration of the consumed alkylamine derivative.) This was tested experimentally, and two subsequent conjugations resulted in similar yields of the conjugate **8**. By comparison, the activated carboxyl acid derivatives, which are used to couple with amine-derivatized oligonucleotides, are normally used in aqueous buffers. A total loss of the activated carboxyl function occurs by unavoidable hydrolysis, preventing reuse of solutions of activated carboxylic acid derivatives.

Deprotection of Nucleoside Bases and Removal of the Oligonucleotide Conjugate 7 from Solid Support. For deprotection of the conjugate **7** we used the AMA procedure introduced by Reddy and co-workers to deprotect DNA and RNA oligonucleotides (*3*, *4*). Our findings suggest that AMA is a very versatile and clean way to deprotect many oligonucleotide conjugates, including methylphosphonate and phosphorothioate oligonucleotide derivatives (data not shown). At room temperature, AMA deprotection is complete in less than 90 min, and at 65 °C it takes only 10 min to complete deprotection and to cleave the oligonucleotide product (**8**) from solid support (1 h AMA treatment at 65 °C does not reduce the yield). Combined solution, supernatant, and solid support washes were concentrated on a SpeedVac concentrator and can be directly purified

Scheme 2. Attachment of C_{10}-Linker to a Solid-Support-Bound Oligonucleotide

by HPLC. As an important note, we found that AMA treatment of an activated carboxylic acid oligonucleotide intermediate **6** leads to formation of methylamide conjugate **8**, while treatment with concentrated ammonium hydroxide gives an amide derivative **8**. Therefore, amine conjugations need to be performed prior to deprotection of the oligonucleotide; otherwise the activated carboxyl functionality will be lost.

Analysis and Purification of the Conjugate 8. The crude material was analyzed and purified using either anion exchange or reverse phase HPLC. Typically, the product was retained on reverse phase (and anion exchange) columns, eluting several minutes after the starting oligonucleotide with the linker only and other failure products. Integration of the HPLC profile of the crude mixture after deprotection allows estimation of the overall yield of the 12-mer oligonucleotide conjugate **8**.



Model Study of Conjugation of Alkylamine Derivatives. A number of different alkylamine derivatives were conjugated to the support-bound oligonucleotide intermediate **6**. Those derivatives included primary and secondary amines with linear or branched alkyl chains containing different substituents such as a hydroxyl group, a carboxyl group, an aliphatic amine, an aromatic amine, biotin, and fluorescein.

The complete results of the RP HPLC analyses of the crude mixtures of all synthesized amide oligonucleotide derivatives are presented in Table 1. The estimated yields of the final product were 43−75%, as determined by the integrated area of the HPLC profiles at 260 nm. When the yield of final conjugate **8** was normalized to the area of methylamine-conjugated oligonucleotide (after AMA treatment of the intermediate **6**), the overall efficiency of the conjugation step in most cases is estimated to be in the range 78−98%. In these studies, there were few exceptions. The yield of conjugate **8** was lower for 1,4-diaminobutane and 1,6-diaminohexane reactions because of formation of byproducts. In both cases the major byproduct observed was a compound with a longer RP HPLC retention time compared to that for a respective conjugate **8** (1−3 min longer). Although the structure of the major byproduct was not investigated, we speculate that it could be a molecule consisting of two oligonucleotides attached to one diamine. For 4-aminobutyric acid reaction less efficient conversion of the intermediate **6** to conjugate **7** was observed in parallel with a formation of several unidentified byproducts with shorter and longer HPLC retention times. When intermediate **6** was reacted with 2-carboxymethyl-1-aminobenzene, no conjugation product was detectable after 1.5 h of incubation at room temperature.

The synthesis of the fluorescein cadaverine conjugate was performed with a lower molar excess of the dye−alkylamine (7.0 vs 100 equiv used above, Table 1) over oligonucleotide intermediate **6**. Nevertheless, the HPLC analysis of the crude mixture (Figure 1, Table 1) shows that there was no loss in the efficiency of the conjugation of fluorescein cadaverine in comparison to other conjugations. By HPLC analysis, the estimated yield of the dye-conjugated oligonucleotide (Figure 1b) was >70%, while the yield of the precursor oligonucleotide (before coupling of the linker and conjugation of fluorescein cadaverine (Figure 1a) was >75%. Therefore, the coupling of the activated carboxyl linker and subsequent conjugation of the fluorescein cadaverine was accomplished with better than 90% conversion. Moreover, the recovered fluorescein cadaverine solution from that synthesis was used for conjugation to another portion of the oligonucleotide intermediate **6** giving nearly the same yield of fluorescein cadaverine conjugate as in the previous conjugation.

Preparation of Carboxylic Acid Derivatives of Oligonucleotides. The succinimidyl ester group of the linker attached to the oligonucleotide intermediate **6** can be converted directly to a carboxylic acid function (Scheme 4). A typical procedure

Scheme 3. Conjugation of Alkylamine to Succinimidyl-Activated Oligonucleotide 6 on Solid Support

involves a treatment of solid-bound oligonucleotide intermediate **6** with 0.4 M sodium hydroxide in methanol−water (4:1) solution. The reaction is incubated at elevated temperature (~ 40 °C) overnight or at 30 °C for 2 days (monitoring the reaction progress by HPLC) and neutralized by monobasic sodium phosphate buffer. The nucleoside base protecting groups are removed during this procedure. The product **9** is isolated by reverse phase HPLC. Notably, LiOH may be substituted for NaOH in this procedure (0.1M LiOH in methanol−water = 1:2).

Alternatively, the intermediate **6** can be converted to carboxylic acid derivative **9** by a treatment with 0.5 M sodium hydroxide in water. However, the additional treatment of that mixture with concentrated ammonium hydroxide (or AMA) is required to complete deprotection of the nucleoside bases.

DISCUSSION

This novel heterobifunctional C_{10}-linker has several outstanding properties. The reagent is made in two steps, is relatively inexpensive, and can be utilized for automated solid-support coupling. The precursor phosphoramidite reagent has been stable for more than 2 years when stored in the freezer at −70 °C. Furthermore, 0.1 M acetonitrile solution of the reagent **3** stored over molecular sieves in the refrigerator is stable for at least 10 days.

The main advantage of the activated carboxyl function is an opportunity to use alkylamine-derivatized compounds for conjugation reaction rather than the corresponding active ester or isothiocyanate compounds. The alkylamine derivatives are easier synthetic targets for a variety of reasons, and many potential candidates for conjugation to oligonucleotides are already available commercially as amines.

The alkylamine derivative is typically stable during the conjugation reaction, and the recovered alkylamine solution can be used in subsequent conjugation reactions without further manipulation. The oligonucleotide intermediate **6** with attached activated carboxyl linker on dry CPG-support is stable for at least a week at room temperature and for several months at −20 °C, thus allowing preparation of a stock supply of precursor oligonucleotide **6**. Because of these advantages, it is possible to rapidly screen combinations of alkylamine derivatives and oligonucleotide sequences using this technology. In addition, the activated carboxylic function of the oligonucleotide intermediate **6** can be hydrolyzed with sodium hydroxide or lithium

hydroxide to an oligonucleotide derivative **9** containing a terminal carboxylic acid group.

The conjugation technology on solid support has several inherent advantages. It is very efficient and gives good yield with minimal effort. The entire process of oligonucleotide synthesis, linker coupling, conjugation, and deprotection requires minimal postsynthetic chemistry and can be accomplished on an automated synthesizer within 1 day. The approach is adaptable up to a 15 μmol scale synthesis and is expected to readily scale-up for production of therapeutically relevant oligonucleotide conjugates.

However, one major consideration is whether the oligonucleotide conjugate moiety is stable to standard conditions of nucleoside base deprotection. If the conjugate is not expected to be stable to the concentrated ammonium hydroxide conditions required to deprotect oligonucleotides under normal circum-

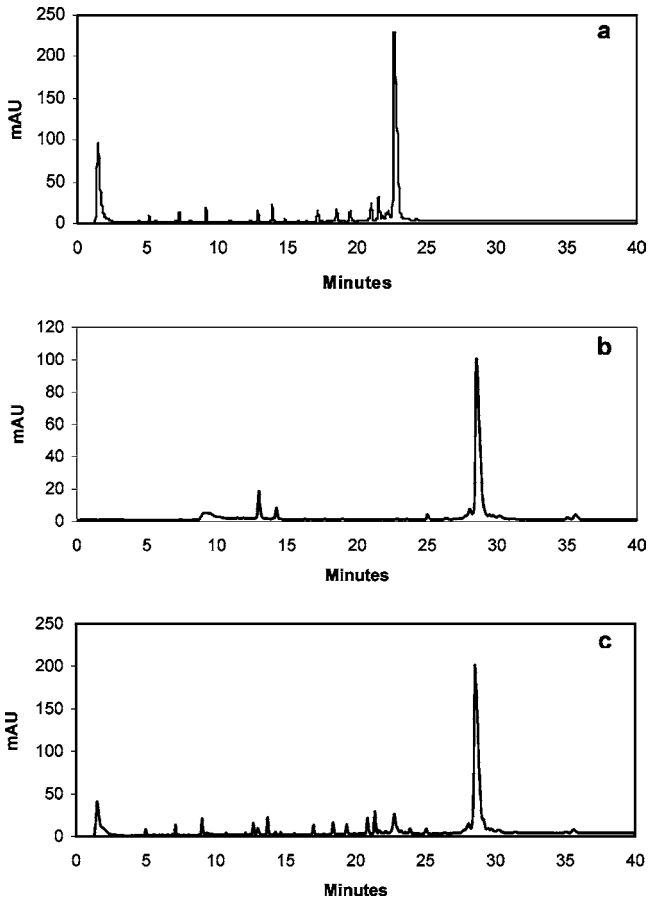

Figure 1. Anion exchange HPLC analyses on the crude mixture after AMA deprotection and cleavage from solid support: (a) d(GAT CTG CGA ACT) precursor **4**; (b and c) fluorescein cadaverine conjugate **8** of d(GAT CTG CGA ACT). Detection: at 260 nm (a, c) or at 500 nm (b).

stances, we suggest utilizing AMA for deprotection. Using AMA deprotection is completed within 90 min at room temperature or in 10 min at 65 °C. In very sensitive cases, we recommend using fast deprotecting phenoxyacetyl phosphoramidite monomers for oligonucleotide synthesis in combination with mild deprotection/cleavage conditions such as 50 mM potassium carbonate in methanol at room temperature (*5*).

The synthesis of DNA−oligonucleotide conjugates on solid support described above has been tested for a series of different alkylamine derivatives (Table 1) as well as for oligonucleotides with different sequences and backbones (data not shown). In all cases the results are very similar to those reported in this manuscript.

ACKNOWLEDGMENT

The technical assistance provided by Katelyn Hanesana, Paul Imperial, Kristin Aquino in oligonucleotide synthesis, and Sean Ahearn in organic synthesis, is highly appreciated. Authors are thankful to Dr. Natasha Paul for helpful discussions and proofreading the manuscript.

Synthesis and Gene Transfer Activities of Novel Serum Compatible Cholesterol-Based Gemini Lipids Possessing Oxyethylene-Type Spacers

Avinash Bajaj,[†] Paturu Kondaiah,[‡] and Santanu Bhattacharya*[,†,§]

Department of Organic Chemistry and Department of Molecular Reproduction, Development and Genetics, Indian Institute of Science, Bangalore 560 012, and Chemical Biology Unit of JNCASR, Bangalore 560 064, India. Received January 11, 2007; Revised Manuscript Received March 26, 2007

Four novel cholesterol-based gemini cationic lipids differing in the length of oxyethylene-type spacers [$-CH_2-(CH_2-O-CH_2)_n-CH_2-$] between each ammonium headgroup have been synthesized. These formed stable suspensions in aqueous media. Cationic liposomes were prepared from each of these lipids individually and as mixtures of cationic lipid and DOPE. These were used as nonviral gene delivery agents. All the cholesterol-based gemini lipids induced better transfection activity than their monomeric counterpart. Inclusion of DOPE in co-liposomal formulation of the cationic gemini lipid potentiates their gene transfer activity significantly. A major characteristic feature of these oxyethylene spacer based cholesterol gemini lipids was that serum does not inhibit the transfection activity of these gemini lipids, whereas the transfection activity of their monomeric counterpart decreased drastically in the presence of serum. One of the cholesterol-based gemini lipids **2a** possessing a $-CH_2-CH_2-O-CH_2-CH_2-$ spacer showed the highest transfection activity.

INTRODUCTION

Viral vectors, although capable of ensuring high levels of transgene expression, suffer from many disadvantages like generation of toxic inflammatory responses, possibility of random integration into host chromosome, limited insert size of virally packaged therapeutic gene, possibility of generating replication-competent virus through recombination with host genome, and so forth (*1*−*4*). Therefore, the development of effective and safe genetic carriers is the key to achieving clinical success for gene therapy.

Major nonviral gene delivery reagents mainly comprises two types: polymers and cationic lipids (*5*). Cationic polymers like polyethyleneimines (PEI) (*6*), polylysines (*7*, *8*), have already been studied in detail for gene transfection. Cationic liposomes are promising tools for delivery of genes, because of their lower toxicity, very low immunogenicity, convenient preparation, and so forth, as compared to their viral counterparts. Among cationic lipids, various structure−activity investigations have been reported using different types of cationic lipids with variation of hydrophobic parts, linker region, headgroups, and others (*9*−*17*).

We have been investigating the role of various molecular modifications in different synthetic lipids on their membrane level properties and their further influence on gene delivery (*18*−*20*). The functional group that links the polar head group and the hydrocarbon chains of such lipid molecules plays a crucial role in their utilization in gene transfer events. Thus, *N*-[1-(2,3-dioleyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride (DOTMA[1]), which contains an ether linkage between the headgroup and the long alkyl chains shows greater *in vivo* transfection efficiency than the corresponding ester analogue *N*-[1-(2,3-dioleyl)]-*N*,*N*,*N*-trimethylammonium chloride (DOTAP) (*21*, *22*). We have shown the effect of this linkage functionality on the gene transfection efficiencies of cholesterol-based amphiphiles. It was observed that cholesterol-based cationic lipids bearing ether linkages between cholesterol backbone and headgroup possessed greater transfection capability as compared to other linkages (*23*, *24*).

Gemini (dimeric) surfactants have also been found to possess transfecting abilities. The effect of the nature of the spacer, hydrocarbon chains, and headgroups on the aggregation and transfection properties has been studied in detail in the case of gemini surfactants (*16*, *25*−*30*). The gemini analogue of the lipid is also known to exist in natural cell membranes. For instance, cardiolipin, a glycerol-bridged phosphatidic acid, is a dimeric lipid that occurs in the heart and skeletal muscles (*31*). Taking inspiration from the cardiolipins, we reported for the first time the synthesis and membrane-forming properties of pseudoglyceryl gemini lipids with polymethylene spacers (*32*). The aggregation properties of these gemini lipids were found to depend on the length of the spacer (*33*). Later on, Ahmad et al. showed the transfection activities of cardiolipin-based gemini lipids (*34*, *35*). Recently, we reported that the properties of cationic gemini lipids were quite different when oxyethylene-based spacers were employed in place of polymethylene chains (*36*). We also described the gene transfection properties of gemini lipids where the monomeric cholesterol based units are connected by polymethylene spacer (*37*). Herein, we present the synthesis and transfection properties of cholesterol-based biscationic (**2a**−**2d**) gemini lipids, where each lipid monomer is connected at the level of headgroup via oxyethylene-based spacer chains of variable length (Figure 1).

In this paper, we describe the detailed, optimized synthetic procedures and transfection activities of these new biologically active compounds. To put our results into appropriate perspective, we compared the transfection activities of these new gemini cationic lipids with that of monomeric lipid **1**. We have observed

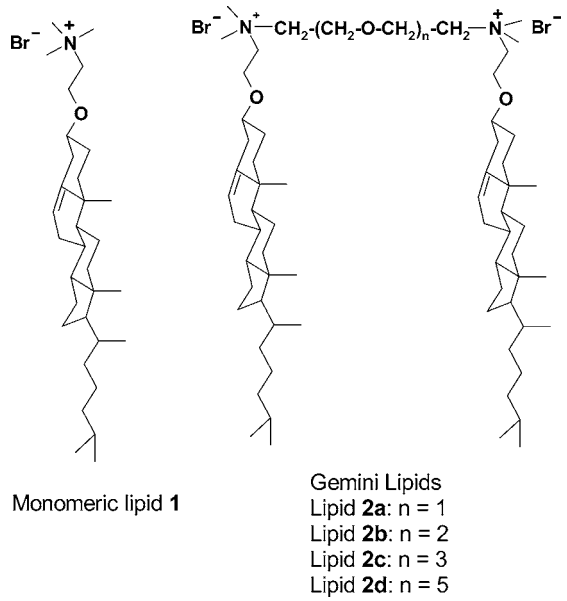

Figure 1. Molecular structures of cholesterol-based cationic monomeric lipid **1** and gemini lipids (**2a**−**2d**) synthesized and used for transfection studies.

significantly enhanced gene transfection activities of these gemini lipids as compared to the monomeric counterpart. Serum is known to inhibit the transfection efficiency of cationic liposomes, whereas the major distinguishing feature of these gemini lipids is that they are able to transfect the mammalian cell lines even in the presence of serum.

EXPERIMENTAL PROCEDURES

Materials and Methods. All reagents, solvents, and chemicals used in this study were of the highest purity available. The solvents were dried prior to use. Column chromatography was performed using 60−120 mesh silica gel. NMR spectra were recorded using Jeol JNM λ-300 (300 MHz for ^{1}H and 75 Hz for ^{13}C) spectrometer. The chemical shifts (δ) are reported in ppm downfield from the internal standard: TMS, for ^{1}H NMR and ^{13}C NMR. Mass spectra were recorded on a Kratos PCKompact SEQ V1.2.2 MALDI-TOF spectrometer or on a MicroMass ESI-TOF spectrometer or Shimadzu table-top GC-MS or ESI-MS (HP1100LC-MSD). Infrared (IR) spectra were recorded on a Jasco FT-IR 410 spectrometer either using KBr pellets or neat. Gemini lipids were synthesized as described below and were characterized fully by their ^{1}H NMR, ^{13}C NMR, mass spectra, and elemental analysis.

General Method for Synthesis of Gemini Lipids (2a−2e). A mixture of cholest-5-en-3β-oxyethan-*N*,*N*-dimethyl amine (*24*) (0.2 mmol) and an appropriate α,ω-dibromoalkoxyalkanes (0.07 mmol) in dry MeOH−EtOAc (4 mL, v/v 1/1) was refluxed over a period of 48−72 h in a screw-top pressure tube, after which TLC indicated complete disappearance of the starting dibromide. After that, the reaction mixture was cooled and solvent was evaporated to furnish a crude solid. It was repeatedly washed with ethyl acetate to remove any cholest-5-en-3β-oxyethan-*N*,*N*-dimethyl amine, and the residue was finally subjected to repeated crystallization from a mixture of MeOH and EtOAc. The product yields ranged from 50% to 60%. The purities of the individual lipids were ascertained from TLC; the R_f ranged from 0.2 to 0.3 in 10:1 $CHCl_3$/MeOH. All the new gemini lipids were fully characterized by ^{1}H NMR, ^{13}C NMR, mass spectrometry, and C, H, N analysis. Pertinent spectroscopic and analytical data are given below.

*Lipid **2a***. ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.67 (s, 6H), 0.85−2.29 (m, 82H), 3.19 (m, 2H), 3.49 (s, 12H), 3.93 (br m, 8H), 4.01 (br s, 4H), 4.29 (br s, 4H), 5.35 (d, J = 4.5 Hz, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 11.65, 18.50, 19.13, 20.87, 22.34, 22.58, 23.65, 24.08, 27.73, 27.80, 27.93, 28.01,31.65, 31.70, 35.60, 35.99, 36.57, 36.75, 38.54, 39.31, 39.53, 42.11, 49.89, 52.59, 55.98, 56.50, 61.57, 64.60, 65.25, 79.80, 121.17, 139.64. *Lipid **2d***. ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.67 (s, 6H), 0.85−2.35 (m, 82H), 3.19 (m, 2H), 3.49 (s, 12H), 3.63 (br s, 12H), 3.73 (br s, 4H), 3.95 (br s, 12 H), 4.06 (br s, 4H), 5.35 (d, J = 4.5 Hz, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 11.83, 18.69, 19.34, 21.04, 22.53, 22.78, 23.82, 24.26, 27.98, 28.14, 28.19, 31.83, 31.88, 35.76, 36.16, 36.75, 36.90, 38.75, 39.48, 39.69, 42.29, 49.86, 52.69, 55.99, 56.50, 61.88, 64.74, 65.06, 70.14, 70.35, 70.45, 70.54, 79.88, 122.35, 139.87. ESI-MS: 1206.1 [M^{+2} + Br^-]. Anal. ($C_{64}H_{134}O_7N_2Br_2 \cdot 3H_2O$) C, H, N.

Liposome Preparation. Each lipid or its mixture with DOPE in the desired mole ratio was dissolved in dry chloroform in autoclaved Wheaton glass vials. Thin films were made by evaporation of the organic solvent under a steady stream of dry nitrogen. Last traces of organic solvent were removed by keeping these films under high vacuum overnight. Freshly autoclaved Milli-Q water was added to individual film such that the final concentration of the cationic lipid was maintained at 0.5 mM. The mixtures were kept for hydration at 4 °C for 10−12 h and were subjected to repeated freeze−thaw cycles (ice-cold water to 60 °C) with intermittent vortexing to ensure hydration. Sonication of these suspensions for 15 min in a bath sonicator at 60 °C afforded closed cationic liposomes, as evidenced from transmission electron microscopy. Liposomes were prepared and kept under sterile conditions. Formulations were stable, and no precipitation was observed within 3 months if stored at 4 °C.

Transmission Electron Microscopy. Freshly prepared aqueous suspensions of lipid−DNA complexes were examined under transmission electron microscopy by negative staining using 1% uranyl acetate. A 10 μL sample of the suspension was loaded onto Formvar-coated, 400 mesh copper grids and allowed to remain for 1 min. Excess fluid was wicked off the grids by touching their edges to filter paper, and 10 μL of 1% uranyl acetate was applied on the same grid, after which the excess stain was similarly wicked off. The grid was air-dried for 30 min, and the specimens were observed under TEM (JEOL 200-CX) operating at an acceleration voltage of 120 keV. Micrographs were recorded at a magnification of 5000−20 000×.

Plasmid DNA. pEGFP-c3 (Clontech, USA), which encodes for an enhanced green fluorescence protein (GFP) under a CMV promoter, was amplified in *Escherichia coli* (DH5α) and purified using Qiagen Midi Prep Plasmid Purification protocol

(Qiagen, Germany). Purity of the plasmid was checked by electrophoresis on 1.0% agarose gel. Concentration of the DNA was estimated spectroscopically by measuring the absorption at 260 nm and confirmed by gel electrophoresis. The plasmid preparations showing a value of $OD_{260}/OD_{280} > 1.8$ were used.

Cell culture. Cells (HeLa) were cultured in Dulbecco's Modified Eagle's Medium (DMEM; Sigma) supplemented with 10% fetal bovine serum (FBS) in T25 culture flasks (Nunc, Denmark) and were incubated at 37 °C in a humidified atmosphere containing 5% CO_2. Cells were regularly passaged by trypsinization with 0.1% trypsin (EDTA 0.02%, dextrose 0.05%, and trypsin 0.1%) in PBS (pH 7.2).

Cytotoxicity. Toxicity of each cationic lipid formulation toward HeLa cells was determined using 3-(4,5-dimethyl thiazole-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction assay following literature procedures (*38*, *39*). MTT gets converted to an insoluble blue dye, formazan, in actively respiring cells. The assay estimates the concentration of the formazan formed, which in turn gives a measure of the population of cells that are metabolically active.

A range of liposomal concentrations 5−30 μM were investigated for toxicity studies. Cytotoxicity of the lipid formulations optimal for transfection experiments was determined under conditions exactly the same as transfection conditions. Nearly 12 000 cells/well were plated in 96 well plates. After 24 h, optimized lipid/DOPE formulations were complexed with 0.2 μg of the DNA at various N/P ratios for 30 min. DNA−lipid complexes were added to the cells in the absence of serum. After 6 h of incubation, lipoplexes were removed, and 200 μL of media with 10% FBS was added. After 42 h, 20 μL of MTT solution was added, and the cells were incubated further for 4 h. Blue formazan crystals were seen when checked under the microscope. Media was removed, and 200 μL of DMSO was added per well. The absorbance was measured using a microtiter plate reader. The % viability was then calculated as [{A590-(treated cells) − background]/[A590(untreated cells) − background}] × 100.

Transfection Procedure. All transfection experiments were carried out in HeLa cells in antibiotic-free media unless specified otherwise. In a typical experiment, 24 well plates were seeded with 45 000 cells/well in antibiotic-free media 24 h before transfection such that they were at least ∼70% confluent at the time of transfection. For transfection, lipid formulation and DNA were serially diluted separately in DMEM containing no serum to have the required working stocks. DNA was used at a concentration of 0.8 μg/well unless specified otherwise. The lipid and DNA were complexed in a volume of 200 μL by incubating the desired amount of lipid formulation and DNA together at room temperature for about 30 min. The lipid concentrations were varied so as to obtain the required lipid/DNA (N/P) charge ratios. Charge ratios here represent the ratio of charge on cationic lipid (in mol) to nucleotide base molarity and were calculated by considering the average nucleotide mass of 330. After 30 min of complexation, 200 μL of media were added to the complexes (final DNA concentration = 12.12 μM). Old medium was removed from the wells, cells were washed with DMEM, and lipid−DNA complexes in 200 μL media were added to the cells. The plates were then incubated for 6 h at 37 °C in a humidified atmosphere containing 5% CO_2. At the end of the incubation period, medium was removed, and cells were washed with DMEM; 500 μL of DMEM containing 10% FBS was added per well. Plates were further incubated for a period of 42 h before checking for the reporter gene expression. Green fluorescent protein (GFP) expression was examined by fluorescence microscopy and was quantified by flow cytometry analysis. All the experiments were done in duplicate, and results presented are the average of at least two such independent experiments done on two different days. For comparison, transfections using lipid **1** were performed using optimized lipid/DOPE ratio (*24*) of 1:1 at N/P ratio of 1.0, using 0.8 μg of plasmid DNA.

For transfections in the presence of serum, lipid and DNA were separately diluted in serum-free media as already mentioned, and the complexation was done in serum-free media (200 μL) for 30 min. The complex was then diluted to 400 μL with DMEM containing 20% FBS so as to achieve a final serum concentration of 10%. The cells were then incubated with this complex for 6 h. At the end of the incubation period, medium was removed, and cells were washed with DMEM; 500 μL of DMEM containing 10% FBS was added per well. For transfections at 30% and 50% of serum concentrations, complexes were diluted to 400 μL with DMEM containing 60% FBS or with neat FBS, respectively.

Gel Electrophoresis. To examine the complexation of DNA with cationic lipid suspensions at different lipid−DNA ratios, we prepared lipid−DNA complexes at different lipid−DNA charge ratios in an identical manner as was done with transfection experiments using 0.2 μg of the plasmid DNA. After 30 min of incubation, these complexes were electrophoretically run on a 1.0% agarose gel. The uncomplexed DNA moved out of the well, but the DNA that was complexed with lipid remained inside the well (*40*).

Flow Cytometry. The reporter gene expression was examined by fluorescence microscopy at regular intervals and was quantified 48 h post-transfection by flow cytometry. The percentages of transfected cells were obtained by determining the statistics of cells fluorescing above the control level wherein nontransfected cells were used as the control. Approximately 10 000 cells were analyzed to obtain the statistical data, which have been presented as the average of at least two independent measurements. For flow cytometry analysis, ∼48 h post-transfection, old medium was removed from the wells; cells were washed with PBS and trypsinized by adding 100 μL of 0.1% trypsin. To each well, 200 μL of PBS containing 20% FBS was added. Duplicate cultures were pooled and analyzed by flow cytometry immediately using a Becton and Dickinson flow cytometer equipped with a fixed laser source at 488 nm.

FACS Analysis. FACS data were analyzed by public domain *WinMDI* software to eliminate data from cell debris (particles smaller than cells), dead cells, and clumps of two or more cells. Subcellular debris and clumps can be distinguished from single cells by size (estimated by the intensity of low-angle forward-scatter). Dead cells have lower forward-scatter and higher side-scatter than living cells. The FACS scans had been configured to display the fluorescence signals only from those particles with a specified set of scatter properties, namely, living single cells. This is called a scatter-gated fluorescence analysis. Therefore, the data from dead cells had been eliminated by gating out brightly fluorescent cells.

RESULTS AND DISCUSSION

Chemistry. Four cholesterol-based gemini lipids possessing oxyethylene-based spacer chains have been synthesized. Each lipid differed from the others based on the spacer lengths [$-CH_2-(CH_2-O-CH_2)_n-CH_2-$]. These gemini lipids have been synthesized from the precursor cholest-5-en-3β-oxyethan-*N*,*N*-dimethyl amine by Menshutkin reaction with the corresponding α,ω-dibromoalkoxyalkanes. The synthesis of precursor cholest-5-en-3β-oxyethan-*N*,*N*-dimethyl amine and monomeric lipid **1** has already been reported (*24*). All the gemini lipids have been purified by repeated precipitation with MeOH, EtOAc, and acetone. All the gemini lipids were fully characterized by ^{1}H NMR, ^{13}C NMR, ESI-MS, and C, H, N analysis.

Aggregate Formation from Cationic Gemini Cholesterol Lipids. Upon hydration, each of the gemini cholesterol lipids

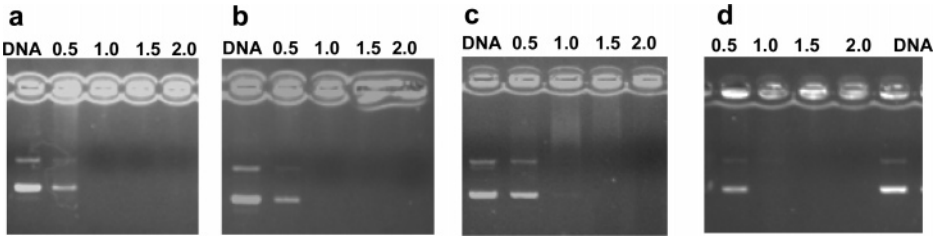

Figure 2. Electrophoretic gel patterns for lipoplex-associated DNA in gel retardation for gemini cholesterol lipids: (a) **2a**; (b) **2b**; (c) **2c**; (d) **2d**. The N/P ratios are indicated at the top of each lane. 0.2 μg of the DNA was complexed with liposomes at various N/P ratios for 30 min, and lipoplexes were run electrophoretically on 1% agarose gel.

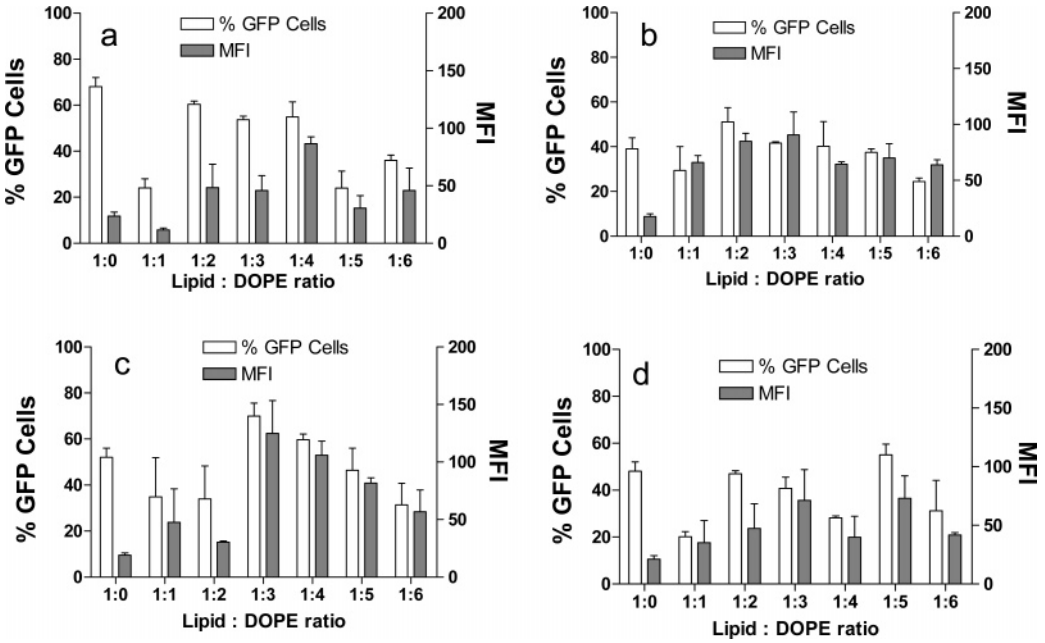

Figure 3. Transfection efficiencies of cholesterol-based gemini lipids with various mole ratios of DOPE: (a) **2a**; (b) **2b**; (c) **2c**; (d) **2d**. Concentration of the DNA = 0.8 μg/well, and lipids were used at N/P ratio of 0.5. Lipoplexes were incubated with cells for 6 h. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis after 48 h of transfection.

was found to disperse easily in water. All the lipid molecules mentioned here formed stable suspensions in water. The suspensions formed from lipids were found to be translucent. Generally, TEM examination of air-dried, aqueous suspensions revealed the existence of closed vesicle-like aggregate structures for all the gemini lipids (not shown). The aggregates formed from all the gemini lipids ranged from 30 to 80 nm in size. When compared, all gemini lipid aggregates were generally found to be smaller in size as compared to the aggregates of monomeric lipid **1**, which ranged ~100 ± 30 nm in size (not shown).

Mixed Liposome Formation with 1,2-Dioleoyl-L-α-glycero-3-phosphatidyl Ethanolamine (DOPE). Liposomes could be conveniently prepared from a mixture of gemini lipid with helper lipid 1,2-dioleoyl-L-α-glycero-3-phosphatidyl ethanolamine (DOPE) by first subjecting the films of lipid mixtures to hydration, repeated freeze−thaw cycles, and followed by sonication at 60 °C for 15 min. All the gemini lipid/DOPE formulations formed optically transparent suspensions. Liposomes were prepared under sterile conditions and were resonicated for 5 min at room temperature before transfection experiments. The vesicular suspensions were sufficiently stable, and no precipitation was observed within 3 months if stored at 4 °C.

Gel Electrophoresis. To characterize the electrostatic binding interactions between the plasmid DNA and the mixed cationic liposomes as a function of different N/P charge ratios (or lipid/DNA mole ratios), we performed conventional electrophoretic gel retardation assays (Figure 2). All gemini lipid suspensions were able to retard the plasmid DNA from the well at N/P ratio of 1.0. It should be noted that every gemini molecule possesses two hard charges, which indicates that the whole plasmid DNA gets retarded at a lipid/DNA mol ratio of 0.5. Significant retardation of DNA was also observed at an N/P ratio of 0.5 (or lipid/DNA mole ratio of 0.25) as well.

Transfection Biology. To find out the optimized transfection efficiency, both the number of transfected cells and the mean fluorescence intensity (MFI) have been considered. The MFI defined for GFP-positive cells reveal that the level of GFP expression with a higher MFI value correlates positively with high GFP expression (*41*). These data were obtained from flow cytometric analysis. Figure 3 clearly indicates that individual lipid formulations were able to transfect the high number of cells, but the MFI observed was very low. When cells transfected with individual lipids were observed under the fluorescence microscope (not shown), very few green fluorescent cells were visible. This is confirmed by FACS analysis, which showed very low MFI.

Optimization of Lipid/DOPE Ratio. Naturally occurring lipid such as DOPE has been known to increase the efficiency of transfection in lipid-mediated gene transfer applications. In order to see the most effective formulations, transfections with identical lipid/DNA mole ratios (or N/P ratio), varying the mole ratio of gemini lipids (**2a**−**2d**) in DOPE, were performed (Figure 3). FACS analysis (Supporting Information) indicates that incorporation of DOPE enhances the transfection efficacy of gemini lipids dramatically, especially in terms of MFI. When cells transfected with lipid−DOPE co-liposomes were observed

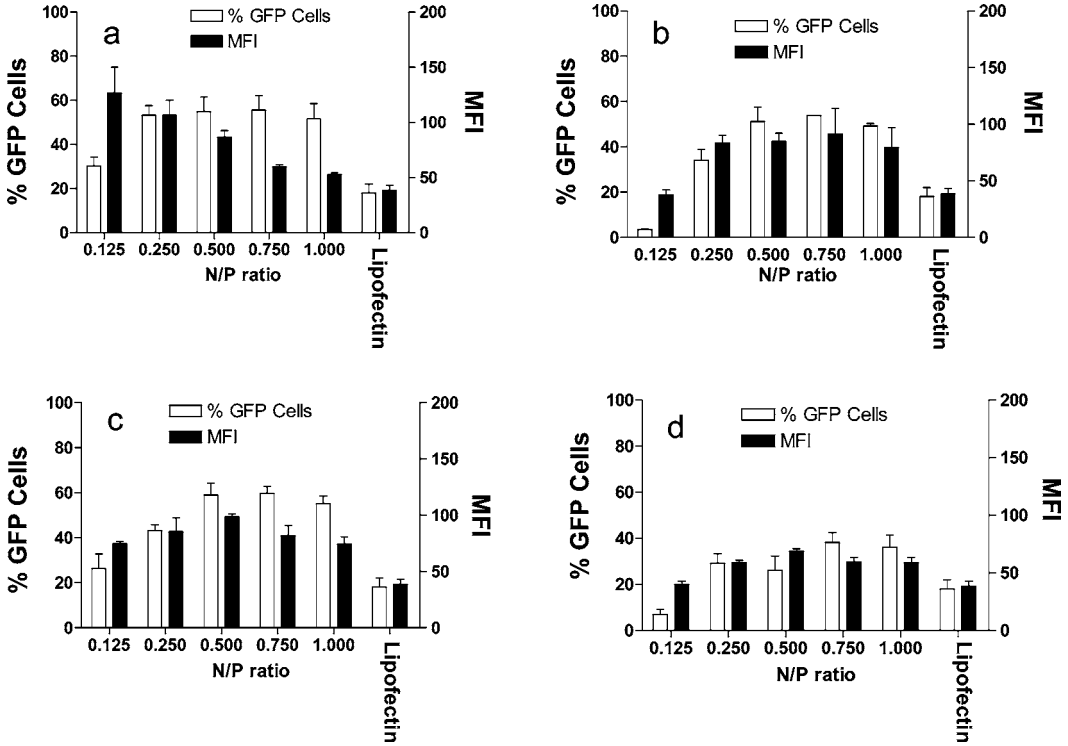

Figure 4. Transfection efficiencies of gemini lipids using optimized lipid/DOPE formulations at various N/P ratios in the absence of serum (−FBS−FBS). (a) **2a**; (b) **2b**; (c) **2c**; (d) **2d**. Concentration of the DNA = 0.8 μg/well. Lipoplexes were incubated with cells for 6 h. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis after 48 h of transfection.

under the fluorescence microscope, we observed highly fluorescent cells which were confirmed by the increase in MFI observed from FACS analysis. In our studies, we had considered both the number of transfected cells and the MFI for optimizing the transfection efficacies of gemini lipids, both as the number of transfected cells and the amount of gene expression matter for successful gene therapy.

The optimized lipid/DOPE ratio was found to vary with the length of the oxyethylene spacer of gemini lipids. Lipid **2a** showed maximum gene transfection activity at a lipid/DOPE ratio of 1:4, whereas **2b** showed maximum activity at a lipid/DOPE ratio of 1:2, and with further increase in DOPE mole ratio, transfection activity started to decrease. Gemini lipid **2c** showed maximum activity at a lipid/DOPE mol ratio of 1:3. Lipid **2a** at a lipid/DOPE ratio of 1:4 was able to transfect nearly 50% of the cells with MFI of 100, whereas **2b** was able to show the same activity at a lipid/DOPE mole ratio of 1:2. Lipid **2c** at a lipid/DOPE mole ratio of 1:3 was found to be most effective, transfecting nearly 60% of cells with MFI greater than 100, and with further increase in the DOPE mole ratio, transfection efficiency decreased. Lipid **2d** was not found to be highly effective at any of the lipid/DOPE ratios, although maximum transfection activity was observed at a lipid/DOPE mol ratio of 1:5. While comparing all the gemini lipids, lipid **2c** was found to be the most effective gemini lipid and even required a lower mole percentage of DOPE as compared to other gemini lipids. Each gemini lipid required different amounts of DOPE for optimized transfection efficiency; this may be because of the change in the balance between hydrophilicity and hydrophobicity of the gemini lipids.

Optimization of N/P Ratio. After optimization of the lipid/DOPE mole ratio for each gemini lipid, all the gemini lipids were tested by taking the identical amount of DNA (0.8 μg) and varying the amount of lipid using the respective optimized lipid/DOPE ratio. Lipid **2a** was able to transfect a maximum of 50% of the cells with an MFI of 100 at N/P ratio of 0.25, whereas lipid **2b** formulations could transfect approximately the same number of cells but with low MFI at N/P ratio of 0.5 (Figure 4). Transfection efficiency of the lipid **2a** formulation decreased at higher N/P ratios, especially in terms of MFI. Gemini lipid **2c** was able to transfect more than 60% of the cells at N/P ratio of 0.5 with MFI of ∼100. While comparing the transfection efficiencies, the lipid **2b** formulation induced a lower transfection efficiency than lipid **2a**, whereas the transfection efficiency of the lipid **2c** formulation was greater than that of lipid **2b** and was comparable to that of **2a**. The lipid **2d** formulation was found to be the least effective gene delivery agent in this series of gemini cholesterol lipids. All the gemini lipids followed a bell-shaped graph when transfection efficiencies were plotted against N/P ratio. When all the gemini lipids were compared at N/P ratio of 0.5, lipid **2a** and **2c** formulations were found to be the best transfecting agents.

Effect of Serum. One of the serious shortcomings of the cationic lipid-mediated gene delivery, especially involving *in vivo* trials, is that the transfection is inefficient particularly in the presence of serum proteins. Serum proteins that are negatively charged are known to interact with cationic lipids, thereby competing with DNA for cationic lipids, leading to inhibition of transfection. To have better potential especially in gene therapy, it is important to have reagents that are capable of delivering and expressing an external gene inside a cell in the presence of serum. There are very few reports of cationic lipids, including our own, which induce transfection activity even in the presence of serum (*19*, *42*, *43*). Therefore, we planned to study the efficiencies of these cholesterol-based gemini lipids in the presence of serum as well and compared the transfection activities of these lipid formulations against a commercially available reagent, Lipofectin. To our pleasant surprise, serum did not inhibit the transfection efficiency of any of the gemini lipids; an enhancement in transfection efficiency was even observed in the presence of 10% serum conditions (Figure 5). Gemini lipid **2a** showed better transfection efficiency in the presence of serum. Nearly 60−70% of the cells were found to be transfected with MFI of 100−135 using the lipid

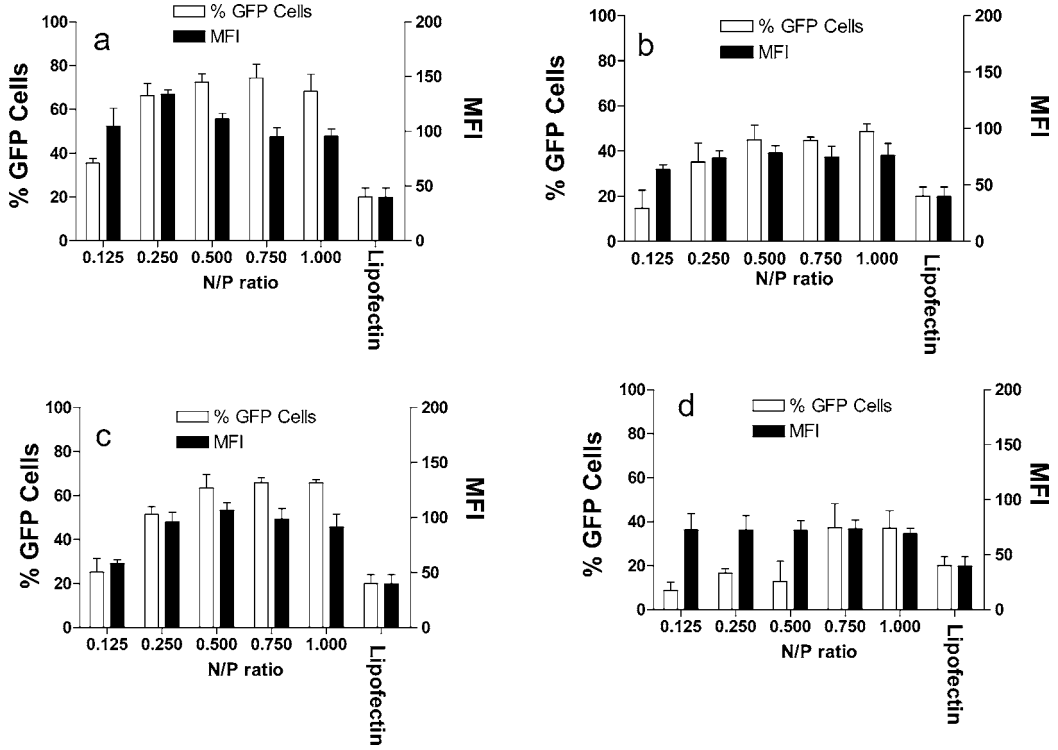

Figure 5. Transfection efficiencies of gemini lipids using optimized lipid/DOPE formulations at various N/P ratios in the presence of 10% FBS (−FBS+FBS). (a) **2a**; (b) **2b**; (c) **2c**; (d) **2d**. Concentration of the DNA = 0.8 μg/well. Lipoplexes were incubated with cells for 6 h. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis after 48 h of transfection.

2a formulation at N/P ratio of 0.25 in the presence of 10% serum conditions. Serum also did not affect the transfection efficiency of gemini lipid **2b**, although efficiency was lower than that of the lipid **2a** formulation. The transfection efficiency of lipid **2c** was nearly 60−70% of cells with MFI of 100−110 at N/P ratio of 0.5. Gemini lipid **2d** was much less efficient in the presence of 10% serum as compared to other gemini lipids. Therefore, all the gemini lipids (except **2d**) were found to show high transfection activity in the presence of serum.

Gemini Lipids vs Monomeric Lipid. To put our results into proper perspective, we compared the transfection activities of the cholesterol gemini lipid formulations with those of their corresponding monomer. Figure 6 shows the transfection efficiencies of the gemini lipids (**2a**−**2d**) in comparison with that of monomeric lipid **1** formulation.

Although the monomeric lipid **1** showed transfection efficiency of ∼60%, but the mean fluorescence intensity in the case of monomeric lipid **1** was much lower as compared to any of the gemini lipids tested (Figure 6). MFI indirectly tells the amount of the protein expressed in the cells, which gives the number of copies of the plasmids delivered inside the cell. It is clear that each gemini lipid shows enhanced mean fluorescence intensity as compared to the monomeric lipid counterpart **1.** Figure 6b shows that there is a dramatic decrease in the transfection efficiency of the monomeric lipid **1** in the presence of 10% serum conditions, whereas in the case of gemini lipids, there is hardly any effect on the transfection activity in the presence of serum. The lipid **2a** formulation was found to transfect nearly 70% of the cells with MFI of ∼100, whereas formulations based on monomeric lipid **1** transfected only nearly 20% of cells with very low MFI of ∼40.

Therefore, in conclusion, all gemini lipids were much better transfecting agents as compared to the monomeric lipid **1**. Among gemini lipids, the lipid **2a** formulation was found to be the best transfecting agent in the presence of serum, whereas the lipid **2d** formulation was least effective.

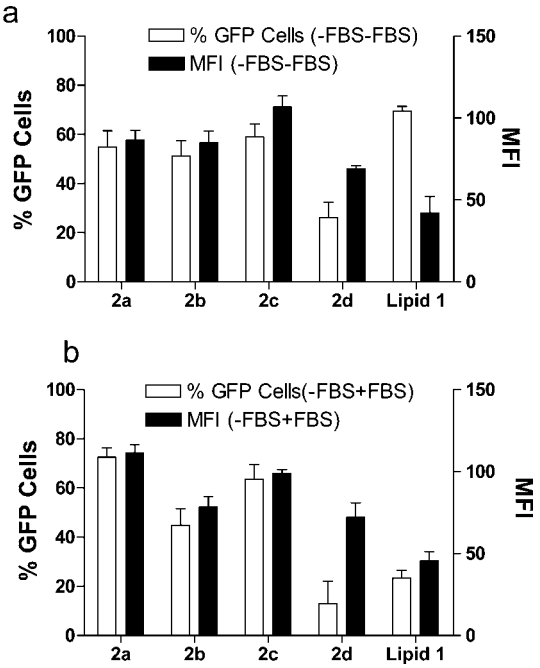

Figure 6. Comparative transfection efficiencies of gemini lipids (**2a**−**2d**) and monomeric lipid **1** in the absence (−FBS−FBS) and presence of 10% serum (−FBS+FBS). Concentration of the DNA = 0.8 μg/well. Lipoplexes were incubated with cells for 6 h. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis after 48 h of transfection.

GFP Assay at High Serum Concentrations. To see the effect of high concentrations of serum on the gene transfection efficiencies, we performed the gene transfection efficiencies using optimized lipid/DOPE formulations at 30% and 50% serum concentrations (Figures 7 and 8). The lipid **2a**/DOPE formulation was able to transfect ∼50% of cells at 30% and

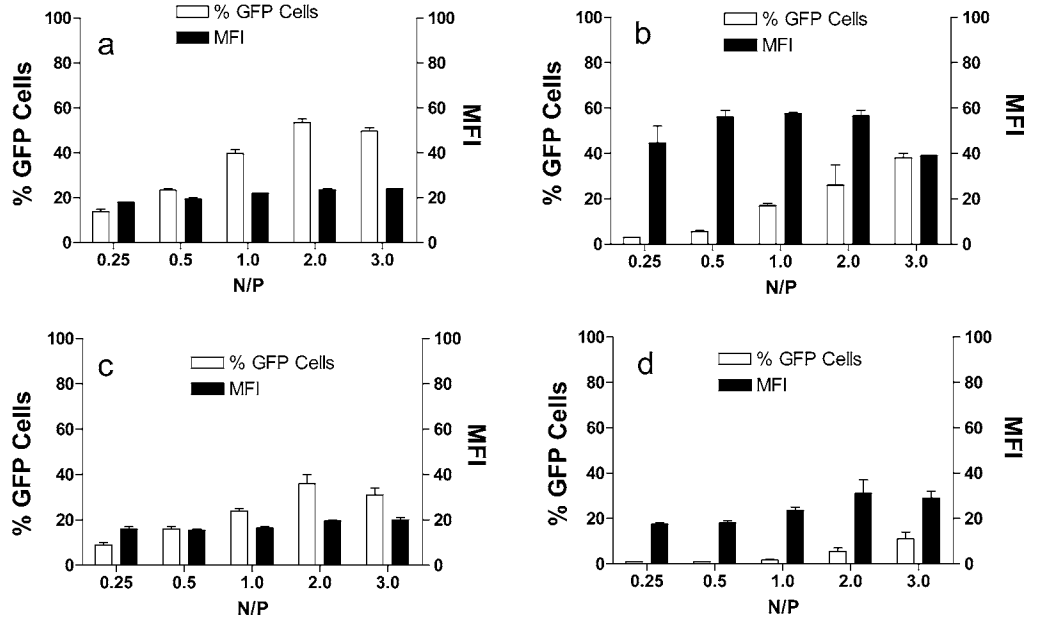

Figure 7. Transfection efficiencies of gemini lipids using optimized lipid/DOPE formulations at various N/P ratios in the presence of 30% FBS. (a) **2a**; (b) **2b**; (c) **2c**; (d) **2d**. Concentration of the DNA = 0.8 μg/well. Lipoplexes were incubated with cells for 6 h. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis after 48 h of transfection.

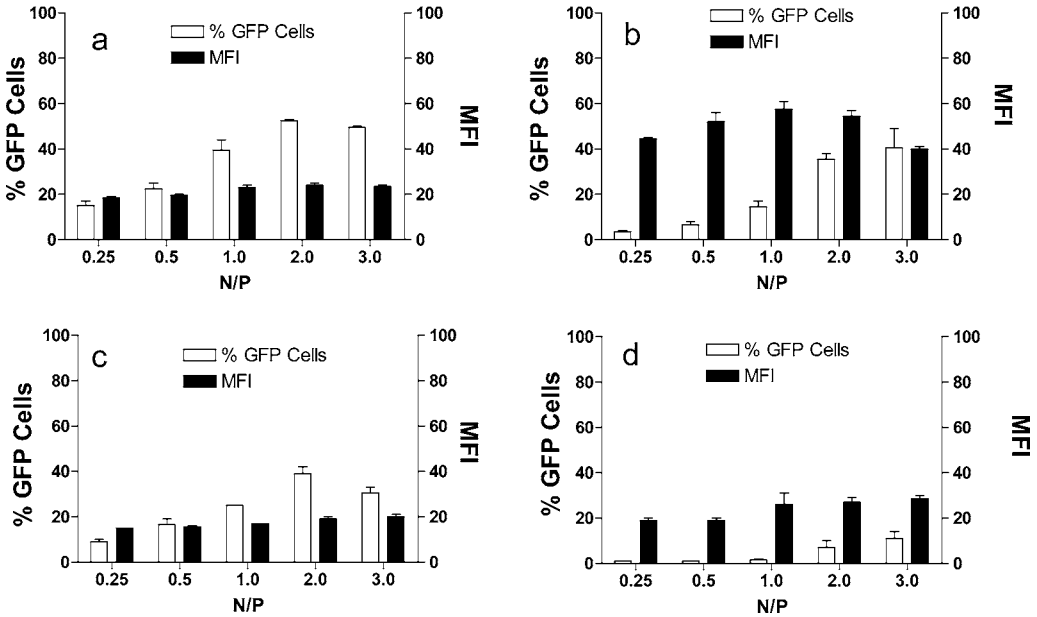

Figure 8. Transfection efficiencies of gemini lipids using optimized lipid/DOPE formulations at various N/P ratios in the presence of 50% FBS. (a) **2a**; (b) **2b**; (c) **2c**; (d) **2d**. Concentration of the DNA = 0.8 μg/well. Lipoplexes were incubated with cells for 6 h. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis after 48 h of transfection.

50% serum concentrations, although there was a decrease in the MFI at higher serum conditions and maximum transfections were observed at N/P ratio of 2.0. This is expected, because at such higher serum conditions, negatively charged serum proteins start to compete with DNA for complexation with cationic lipids. One major characteristic feature of the lipid **2a** formulation is that there is no effect on the number of cells getting transfected even in the presence of high concentrations of serum. Therefore, it indicates that serum does not inhibit the number of transfected cells but reduces the amount of the DNA delivered inside the cells as indicated by FACS analysis. Lipid **2b** is able to transfect nearly 40% of the cells at N/P ratio of 3.0 at 30% and 50% serum conditions. The MFI observed in the case of lipid **2b** formulations was nearly twice that of the lipid **2a** formulation, which indicates that lipid **2b** was able to deliver double the amount of DNA into the cells as compared to the lipid **2a** formulation, whereas the transfection efficacy of commercially available Lipofectin diminished completely at higher serum concentrations. Lipid **2c** was able transfect 30% of cells with low MFI at N/P ratios 2.0−3.0. Lipid **2d** was not able to transfect at high serum concentrations.

Effect of Variation of the Amount of DNA. To see whether the varying the amount of DNA affects the transfection efficiency of gemini lipids, we have performed transfection experiments with all gemini lipids at N/P ratios of 0.25 and 0.5, varying the amount of DNA from 0.4 to 2.0 μg. We did not observe any increase in gene transfection activity by varying the amount of DNA in all cases of gemini lipids, except gemini lipid **2a**, which showed an enhancement in gene delivery when 0.4 μg of DNA was used (Figure 9). This indicates that lipid **2a** is more efficient at low DNA concentrations. Lipid **2a** was able to transfect nearly 70% of cells with MFI of ∼170 at an

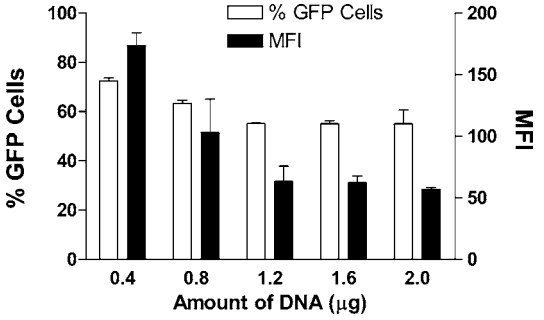

Figure 9. Effect of the variation of the amount of the DNA on gene transfection efficiency of gemini lipid **2a**/DOPE (1:4 mol ratio) formulation at N/P ratio of 0.5. Lipoplexes were incubated with cells for 6 h. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis after 48 h of transfection.

N/P ratio of 0.5. Therefore, among all gemini lipids, the lipid **2a** formulation was found to be the best, transfecting nearly 70% of cells using 0.4 μg of DNA at an N/P ratio of 0.5.

Cytotoxicity. The cytotoxic effects of the cationic lipids toward HeLa cells had been examined in detail, as shown in Figure 10. First, all the liposome formulations of lipids had been tested at different concentrations of 5, 10, 15, 20, and 30 μM, as the maximum amount of lipid used in all transfection is 18.8 μM. All the lipid formulations were found to be nontoxic at all lipid concentrations, except lipid **2d** formulation, where 80% cell viability was found at 20 μM concentration and 70% cell viability at 30 μM concentration (Figure 10a). To see the effect of the DOPE on cell viability, we also investigated the cell viability assays on HeLa cells using optimized lipid/DOPE formulations at different concentrations of 5, 10, 15, 20, and 30 μM (Figure 10b). Lipid/DOPE formulations were also found be nontoxic at all concentrations, except lipid **2d** where nearly 80% cell viability was found. The lipid **2d** formulation was also found to be the least efficient transfecting agent among the series of lipids studied herein. Lipid−DNA lipoplexes using optimized lipid/DOPE formulations were studied for cell viability assays. More than 80% cell viability was observed with all formulations at all N/P ratios (Figure 10c).

Characterization of Lipid−DNA Complexes. Morphology of lipid/plasmid complexes was visualized under a transmission electron microscope after negative staining using uranyl acetate. The complexes formed with the best gemini lipids (**2a** and **2c**) at their optimized transfection ratios with plasmid DNA revealed some distinct morphological changes depending on the length of the spacer in between the cationic ammonium headgroups of the gemini cholesterol lipid molecules (Figure 11). The lipoplexes formed from gemini lipid **2a**/DNA showed a tendency to form "elongated" structures (Figure 11a). It appears the lipid vesicles are organized on the templates of plasmid DNA surface. In contrast, the lipid **2c**/DNA complexes showed aggregation during such complexation, leading to the formation of irregular morphologies.

CONCLUSIONS

We have presented here the syntheses of four cholesterol-based gemini cationic lipids, which bear oxyethylene-based spacers in between the headgroups. These gemini lipids are dimers of the monomeric lipid **1**, which also possess a nonhydrolyzable ether-type linkage between the cationic headgroup and cholesterol backbone. The gemini lipids differ from each other in the number of oxyethylene groups present between the headgroups. The gemini lipids have been synthesized in a single step from cholest-5-en-3β-oxyethan-*N*,*N*-dimethylamine, by reacting with appropriate α,ω-dibromoalkoxyalkanes.

Electron micrographs showed the presence of vesicle-like aggregates formed from the aqueous suspensions of these gemini

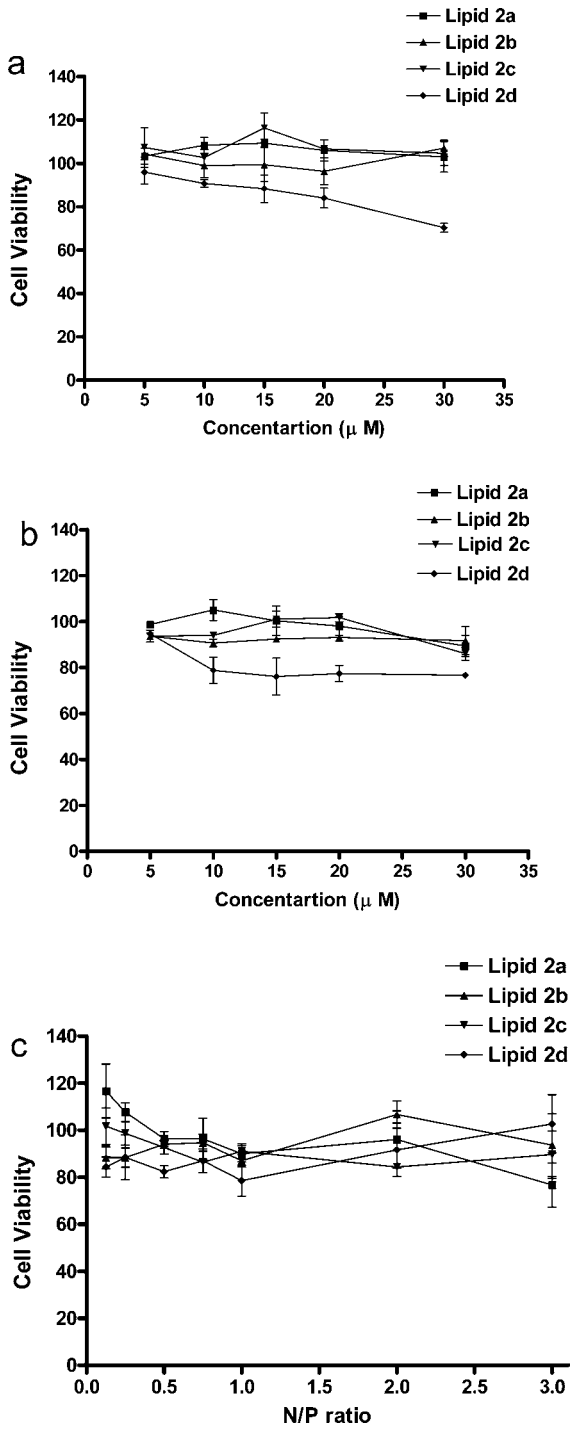

Figure 10. (a) Cytotoxicity exhibited toward HeLa cells by liposomes. (b) Cytotoxicity exhibited toward HeLa cells by optimized lipid/DOPE co-liposomes. (c) Cytotoxicity toward HeLa cells by lipoplexes at different N/P ratios using optimized lipid/DOPE formulations. All the experiments were performed in triplicate in 96-well plates. The % viability was then calculated as [{A590(treated cells) − background]/[A590(untreated cells) − background}] × 100.

lipids. All gemini cholesterol lipids were able to transfect the mammalian cells. Incorporation of an oxyethylene spacer between the cationic ammonium headgroups dramatically increased the transfection activities of the gemini cholesterol lipids as compared to their monomeric counterparts.

Serum is known to be a major impediment for *in vivo* applications of cationic liposomes. All the gemini lipid formulations were, however, able to transfect the mammalian cells even in the presence of serum, in contrast to their monomeric lipid counterparts, where a dramatic decrease in transfection efficacy

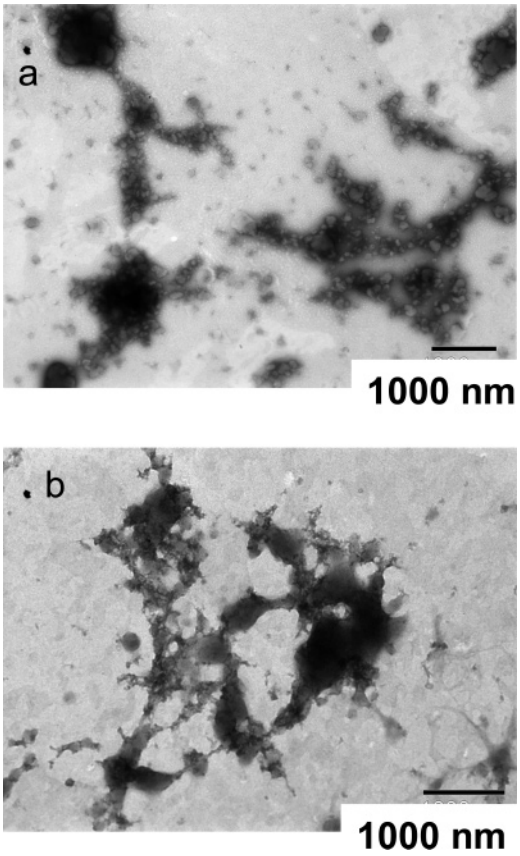

Figure 11. Transmission electron micrographs for the lipoplexes prepared from most effective gemini lipid/DOPE liposome/DNA complexes at the optimized N/P ratio. (a) **2a**; (b) **2c**.

was observed. The transfection efficiency of gemini lipid **2a** was in fact enhanced in the presence of 10% serum conditions. The lipid **2a** formulation was able to transfect nearly 70% of the cells with high MFI. A characteristic feature of the lipid **2a** formulation is that highest transfection efficiency was achieved using only 0.4 μg of the DNA at an N/P ratio of 0.5. The lipid **2c** formulation was found to be effective at a lipid/DOPE ratio of 1:2 and also compatible in the presence of serum. The lipid **2d** formulation was found to be the least effective.

Maximum transfection efficacies of gemini lipids were observed at N/P ratios of 0.5−0.75 in the absence of serum, whereas we observed the complete complexation of DNA at N/P ratios higher than 1.0. Similar observations have also been reported by others. Complete retardation of the plasmid DNA is not essential for maximum gene transfection efficacy. There are many interactions including hydrophobic interactions between liposomes and DNA and between lipoplexes and cell membranes, other than electrostatic interactions, that may be responsible for enhanced gene transfection activities at low N/P ratios.

Although the precise molecular mechanism for their compatibility in the presence of serum is beyond the scope of this presentation, these results indicate that gemini cholesterol lipids with proper design may afford new carriers which may be useful in the field of gene therapy. Cytotoxicity assay shows nearly 80% of the cell viability at the optimum lipid/DNA concentrations. Since the resulting gemini lipids and their liposomes with DOPE are stable both chemically and as colloidal suspensions, these could be used for more practical applications.

Received January 23, 2007; Revised Manuscript Received May 14, 2007

The use of dendritic cells (DC) for the development of therapeutic cancer vaccines is attractive because of their unique ability to present tumor epitopes *via* the MHC class I pathway to induce cytotoxic $CD8^+$ T lymphocyte responses. C-Type membrane lectins, DC-SIGN and the mannose receptor (MR), present on the DC surface, recognize oligosaccharides containing mannose and/or fucose and mediate sugar-specific endocytosis of synthetic oligolysine-based glycoclusters. We therefore asked whether a glycotargeting approach could be used to induce uptake and presentation of tumor antigens by DC. To this end, we designed and synthesized glycocluster conjugates containing a $CD8^+$ epitope of the Melan-A/Mart-1 melanoma antigen. These glycocluster−Melan-A conjugates were obtained by coupling glycosynthons: oligosaccharyl-pyroglutamyl-β-alanine derivatives containing either disaccharides, a dimannoside (Manα-6Man) or lactoside, or a Lewis oligosaccharide, to Melan-A 16−40 peptide comprising the 26−35 HLA-A2 restricted T cell epitope, extended with an oligolysine stretch at the C-terminal end. We showed by confocal microscopy and flow cytometry that fluorescent-labeled Melan-A glycoclusters containing either dimannoside or Lewis oligosaccharide were taken up by DC and concentrated in acidic vesicles; conversely lactoside glycopeptides were not at all taken up. Furthermore, using surface plasmon resonance, we showed that dimannoside and Lewis−Melan-A conjugates bind MR and DC-SIGN with high affinity. DC loaded with these conjugates, but not with the lactose−Melan-A conjugate, led to an efficient presentation of the Melan-A epitope eliciting a $CD8^+$ T-lymphocyte response. These data suggest that synthetically designed glycocluster−tumor antigen conjugates may induce antigen cross-presentation by DC and represent a promising tool for the development of tumor vaccines.

INTRODUCTION

Dendritic cells (DC) are antigen-presenting cells critical for the induction of adaptive immune responses (*1*, *2*). After capturing and internalizing antigen in peripheral organs, they efficiently associate antigenic peptides derived by limited proteolysis to nascent MHC class I protein and expose these MHC class I peptide complexes on their surface, a process termed cross-presentation. Cross-presentation of tumor epitopes to cytotoxic T cell (CTL) precursors in peripheral lymphoid organs (*1*) contributes to the induction of cytotoxic responses to microbes and tumors (*3*). Several C-type lectins and lectin-like receptors, abundantly expressed on the surface of DC, bind sugars in a calcium-dependent manner using highly conserved carbohydrate-recognition domains (CRDs) (*4*). Among these, the mannose specific receptor (MR, CD206) binds and internalizes glycoproteins containing terminal mannose, *N*-acetylglucosamine, or fucose (*5*, *6*), and the dendritic-cell-specific ICAM-3 grabbing nonintegrin (DC-SIGN, CD209) (*7*) binds mannose oligosaccharides (*8*) and fucose-containing glycans (*9*−*11*). The sugar specificity was determined by using oligolysine-based Lewis type oligosaccharide clusters (*9*) and synthetic glycoconjugates (*10*) and by screening an extensive glycan array (*11*). While DC-SIGN and MR act similarly in mediating endocytosis and receptor recycling, they may differ in routing their ligands to distinct intracellular compartments. It was reported that DC-SIGN ligand complexes are targeted to late endosomes/lysosomes (*12*), while MR is preferentially targeted to early endosomes (*13*).

DC membrane lectins which mediate efficient sugar-specific endocytosis could be potentially exploited for glycotargeting tumor antigens to enhance cross-presentation. It is known that sugar−lectin interactions depend on the density of the partners (see for reviews, refs *14*, *15*), so that there is a stringent requirement of clustered patches of carbohydrate ligands for high binding to the protein receptors (*16*, *17*). High affinity binding ligands for membrane lectins have therefore been produced such as neoglycoproteins, prepared by covalent attachment of sugars to a protein, (see for reviews, refs *15*, *18*, *19*); multivalent glycosylated peptides were obtained by coupling monosaccharides derivatives to polylysine (*20*, *21*), as well as to oligolysine (*22*, *23*). Glycoclusters were recently synthesized in our laboratory by coupling glycosynthons to small oligolysine-based peptides (*24*). Glycosynthons (*25*, *26*) were prepared by an original two-step one-pot procedure involving the oligosaccharide reducing sugar and a peptide with a glutamyl residue in the N-terminal position. We previously showed that oligolysine substituted with dimannosides or Lewis oligosaccharides were taken up by dendritic cells (*9*, *27*).

In this study, we asked whether glycoclusters, specific for either DC-SIGN or MR and able to be internalized by DC, might

represent efficient vectors to induce the cross-presentation by DC of a tumor epitope. We designed glycoclusters containing a 25 amino acid long peptide of the Melan-A/Mart-1 protein (a melanoma tumor antigen): Melan-A 16−40 peptide, containing the A27L analogue of the HLA-A*0201 restricted Melan-A epitope (26−35) (*28*−*30*). This epitope is a good model for developing vaccine targets for melanoma patients, as it is highly expressed by about half of melanoma tumors (*31*).

We report here the synthesis and characterization of glycocluster−Melan-A peptide conjugates containing the Melan-A (26−35) A27L epitope and either Manα-6Man (DiMan) or a mixture of Lewis^a and Lewis^x oligosaccharides (Lewis) chosen on the basis of their affinity for MR and DC-SIGN, or Galβ-4Glc (lactose or Lac) selected as a negative control, based on the fact that the lactose glycocluster is not recognized by DC (*9*). The capacity of DC to internalize fluorescent-labeled Melan-A glycopeptides was checked by confocal microscopy and flow cytometry. The kinetic constants for the binding of the glycocluster−Melan-A conjugates to MR and DC-SIGN were measured by surface plasmon resonance. Interestingly, DC loaded with DiMan− and Lewis−Melan-A glycopeptides allowed activation of a specific $CD8^+$ T cell clone. On the basis of present results, these glycopeptides are discussed as a putative new cellular vaccination approach.

EXPERIMENTAL PROCEDURES

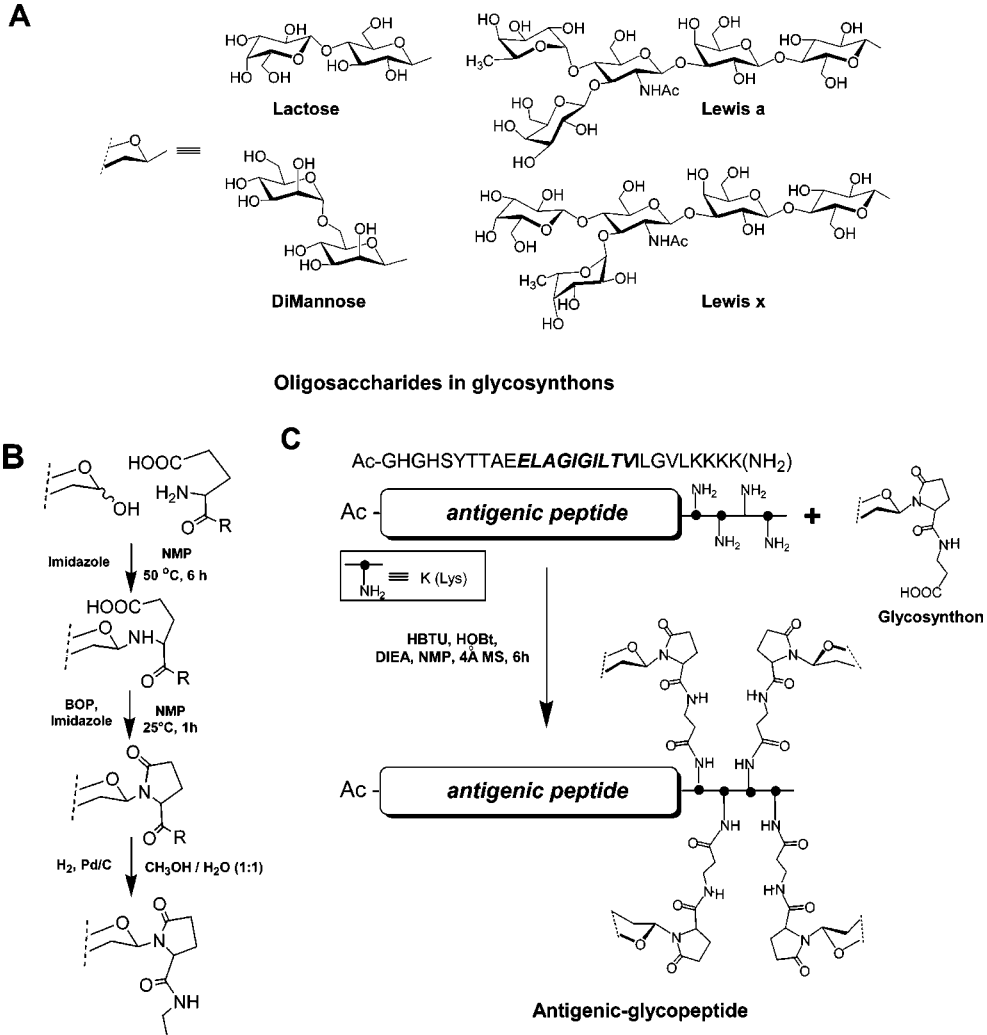
Materials. Chemicals were purchased from Sigma-Aldrich (Saint-Quentin Fallavier, France) unless otherwise mentioned. Benzotriazol-1-yloxy-tris(dimethylamino)phosphonium hexafluorophosphate (BOP) and 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) were from Richelieu Biotechnologies (Saint-Hyacinthe, QC, Canada). *N*-Methylpyrrolidone (NMP) was from Applied Biosytems (Foster City, CA). Triethylammonium phosphate (TEAP), 1-hydroxybenzotriazole (HOBt), *N*,*N*-diisopropylethylamine (DIEA), and *tert*-butyl methyl ether (TBME) were from Senn Chemical AG (Dieslldorf, Switzerland). Lactose and *N*,*N*-diisopropylethlamine (DIEA) were from Janssen Chimica (Beerse, Belgium). Manα-6Man disaccharide was from Dextra laboratories (Reading, UK). A mixture of Lewis^a and Lewis^x oligosaccharides isolated from human milk were a kind gift from Dr. Gérard Strecker (Lille, France). L-Glu-βAla-OBn was purchased from CNH Technologies (Woburn, MA). Melan-A (16−40)−oligo K containing the promiscuous $CD8^+$ (26−35) A27L analogue epitope, Ac-GHGHSYTTAE*ELAGIGILTV*ILGV-LKKKK, was synthesized by NeoMPS systems (Strasbourg, France). Spectra/Por regenerated cellulose membrane (cutoff M_r 1000) was used for the dialysis. Mannosylated serum albumin and fucosylated serum albumin (Man−BSA and Fuc−BSA, respectively) were prepared as previously described (*18*) and contained 25 ± 3 sugar residues per molecule.

Chromatography. Conjugates were purified by gel filtration on a Biogel P-4 (Bio-Rad, Oxfordshire, England) column (2 × 45 cm) stabilized and eluted with 50 mM acetic acid. The flow rate was 0.5 mL/min. Analytical reverse-phase high performance liquid chromatography (RP-HPLC) separations were performed with a Waters 2690 (Milford, MA) system linked to a Waters 996 photodiode array detector, using an Alltech C18 column (5 μm, 4.6 mm × 250 mm) at a flow rate of 1 mL/min, with detection at 254 nm (or 280 nm) at 25 °C (solvent A: 0.1% TEAP in H_2O; solvent B: 0.1% TEAP in acetonitrile; gradient from 70% A/30% B to 2% A/98% B in 20 min).

Mass Spectrometry. MALDI-TOF mass spectra were recorded on a Biflex III instrument (Bruker, Wissembourg, France), in positive mode using α-cyano-4-hydroxycinnamic acid as a matrix.

Synthesis of Glycocluster−Antigenic Peptide Conjugates. *General Procedure for Coupling Glycosynthons and Melan-A−Oligo K (Scheme 1).* The glycosynthons (glycosyl-pyroglutamyl-β-alanine derivatives) were obtained according to (*25*). Briefly, an oligosaccharide was allowed to react with α-glutamyl-β-alanyl benzyl ester in the presence of imidazole, and the glycosylamine derivative obtained was stabilized by an *in situ* intramolecular acylation using BOP. Then, the hydrogenolysis of the benzyl ester afforded the expected glycosynthons in high yields.

The coupling of glycosynthons to the peptide-oligo K was carried out using amide coupling reagents. A mixture of glycosynthon (0.01 mmol), 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU, 0.01 mmol), 1-hydroxybenzotriazole (HOBt, 0.01mmol), and 4 Å molecular sieve beads (25 mg) in *N*-methylpyrrolidone (NMP, 1 mL) was stirred for 20 min under N_2 atmosphere. A solution of Melan-A (16−40)-oligo K peptide (0.0015 mmol) in *N*-methylpyrrolidone (200 μL) and 2 M *N*,*N*-diisopropylethylamine in *N*-methylpyrrolidone (20 μL) were added, and the mixture was stirred for another 6 h. The molecular sieve beads were removed, and 10 volumes of *tert*-butyl methyl ether (TBME) was added: the precipitated crude product was collected upon centrifugation. The pellet was dissolved in water (1 mL) and passed through a Biogel P-4 column with 50 mM acetic acid as an eluent, and the fast eluting sugar-containing fractions identified by a microscale resorcinol−H_2SO_4 assay (*32*) were pooled, dialyzed (cutoff M_r 1000), and lyophilized to obtain the glycocluster−Melan-A conjugate as a white fluffy powder (yield ≈ 55%).



The glycocluster−peptide conjugates were analyzed by HPLC: Lac−Melan-A, DiMan−Melan-A, and Lewis−Melan-A have a retention times of 7.50, 7.51, and 6.48 min, respectively, as compared to 6.98 min for Melan-A. These glycocluster−peptide conjugates were analyzed by MALDI-TOF mass spectrometry; the glycocluster−peptide derivatives appeared to be predominantly the trivalent derivatives. DiMan−Melan-A, Lac−Melan-A, and Lewis−Melan-A conjugates gave molecular ion peaks at $m/z = 4640.94$, 4639.08, and 6165.24, respectively, corresponding to their $[M + K]^+$ ions. In addition, $[M + K]^+$ adducts at $m/z = 5147.48$ and 5145.49 for DiMan−Melan-A and Lac−Melan-A, respectively, were also observed, corresponding to the tetravalent derivatives.

General Procedure To Add Fluorescent Probe on Glycocluster−Melan-A Conjugates. A solution of iodoacetamido-fluorescein (2 μmol in 15 μL of NMP) was added to the glycocluster−Melan-A conjugate (1 μmol) in 500 μL of carbonate buffer (pH 8.5) and stirred at room temperature for 2 h in darkness. The reaction mixture was purified by gel chromatography, Ultrogel GF05 (1.5 cm × 20 cm) column; the fluorescent glycopeptide was eluted with 10 mM acetic acid and was lyophilized. The concentration was determined by absorbance measurement at 495 and 280 nm, assuming that fluorescein $\epsilon_M^{1\,cm}$ at 488 nm is 80 000 and at 475 nm is 26 000 and tyrosine $\epsilon_M^{1\,cm}$ at 488 nm is 1400.

Cells. DC-IL-13 were provided by IDM (Immuno Designed Molecules, Paris) in frozen vials; they were obtained from monocytes isolated by elutriation from peripheral blood mononuclear cells differentiated in the presence of GM-CSF and IL-13 (*33*). These DC were used immediately upon thawing or plated and cultured in Aim-V medium supplemented with 500 units/mL GM-CSF and 50 ng/mL IL-13 before use.

For cross-presentation experiments, DC-IL-4 were used. Briefly, healthy HLA-A*0201 donor PBMC was obtained by Ficoll separation. Monocytes and lymphocytes were isolated by elutriation (Aventi J-20, Beckman Coulter) and frozen. DC (DC-IL-4) were generated by culturing the monocyte-enriched fraction in six-well plates using 3×10^6 cells/well in 3 mL of RPMI containing 1% nonautologous plasma, 100 IU/mL GM-CSF (Abys), and 300 U/mL IL-4 (AbCys). The cytokines were

added to the cultures at day 0 and 2. On day 5, DC were harvested and used in antigen cross-presentation experiments. M77−84 is a HLA-A2 restricted Melan-A (26−35) specific $CD8^+$ T cell clone obtained from tumor-infiltrating lymphocytes (TIL) of a melanoma patient (*34*).

Cell Reagents. A soluble fragment of the human MR consisting of the eight C-type CRDs (MMR1−8) and the extracellular domain of DC-SIGN were kindly provided respectively by Maureen Taylor and Kurt Drickamer (London, UK).

Flow Cytometry Analysis of Endocytosis. Freshly thawed DC-IL-13 (10^6 cells in 100 μL of Aim-V medium) were incubated for 2 h at 37 °C in the presence of 10 μM fluorescein-labeled glycopeptides. After being washed in PBS, DC were further incubated for 30 min at 4 °C in the absence or in the presence of 50 μM monensin. Monensin is a proton/sodium ionophore which transports monovalent cations (Na^+ and H^+) across membranes and, thereby, equilibrates the external and internal pH of organelles in intact cells. Therefore, monensin neutralizes intracellular acidic compartments, allowing the recovery of fluorescein fluorescence quenched in acidic environment; a higher fluorescence intensity of the monensin-treated cells compared to that of untreated cells demonstrate that the conjugate had reached acidic compartments upon endocytosis (*35*). Cell-associated fluorescence was assessed using a BD-LSR flow cytometer, and the data were analyzed with the Cell Quest software (BD Biosciences).

Confocal Microscopy Analysis. DC-IL-13 plated on cover slip after thawing and overnight incubation in complete medium were incubated for 2 h at 37 °C with 1 μM fluorescein-labeled glycopeptides, washed, and either fixed immediately 20 min in PBS containing 4% formaldehyde at room temperature or further incubated 2 h in medium before fixation. Coverslips were mounted on slides in a PBS/glycerol mixture (1:1 v/v) containing 1% 1,4-diazabicyclo[2.2.2]octane (DABCO) as an antifading agent and fixed 20 min in PBS containing 4% formaldehyde at room temperature. Cell fluorescence was analyzed with a confocal imaging system MRC-1024 (Bio-Rad) equipped with

a Nikon Optiphot epifluorescence microcope and a ×60 planapo objective (numerical aperture 1.4). The krypton/argon laser was tuned to produce a 488 nm beam. Images were recorded with a Kalman filter average of 5−10 images.

Surface Plasmon Resonance. Surface plasmon analyses (see for a review, ref *36*) were performed on a BIAcore 2000 biosensor system (BIAcore Inc., Uppsala, Sweden). The carboxymethyl dextran CM-5 research grade sensor chip and ethanolamine-HCl solution (pH 8.5) were obtained from BIAcore Inc.; the immobilization reagents (*N*-ethyl-*N*′-(dimethylaminopropyl)carbodiimide, (EDC) and *N*-hydroxysuccinimide, (NHS) were purchased from Sigma. All solutions were filtered using a 0.22 μm of polytetrafluoroethylene membrane syringe filter and degassed prior use. Extracellular soluble fragments (MMR1−8) of the human MR (*37*−*39*) and of the human DC-SIGN (*8*) were immobilized on a CM5 sensor chip. The fragment of MR (MMR1−8) contains all the domains necessary for Ca^{2+}-dependent binding of mannose, *N*-acetylglucosamine, and fucose-terminated glycoconjugates and binds such ligands as the whole receptor does. These soluble extracellular fragments containing the CRDs of human MMR1−8 (45 μg/mL) and DC-SIGN (20 μg/mL) in 10 mM sodium acetate at pH 4.5 were covalently immobilized using a standard amine coupling procedure according to the immobilization wizard. In a typical procedure, the carboxymethyl dextran surface was activated using freshly mixed 100 mM NHS and 400 mM EDC solutions, followed by lectin coupling (immobilization time of 8 min and a constant flow rate of 20 μL/min). The remaining activated groups were blocked with 1 M ethanolamine at pH 8.5, and efficient fixation was indicated by a large increase in the refractive index, in both cases, about 5000 RU (relative units, RU). The control flow cell was also activated by EDC-NHS and then blocked by using 1 M ethanolamine. The biosensor experiments were carried out in the running buffer (pH 7.4, 10 mM HEPES, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 150 mM, NaCl, 17 mM NaN_3, 0.005% P20 BIAcore surfactant). For binding studies, the temperature was kept at 25 °C and the flow rate was 20 μL/min for both the association and dissociation steps during 5 and 10 min, respectively. The binding capacity of the immobilized lectin fragments was ascertained by using Man−BSA and Fuc−BSA neoglycoproteins; then, binding experiments with glycocluster−antigenic peptide conjugates at concentrations from 0.1 μM to 5 μM were carried out. The glycocluster−peptide conjugate solutions were prepared in the running buffer containing 1 mg/mL BSA (99% purity). Regeneration was carried out using two consecutive pulses of 30 μL of the running buffer containing 1 M NaCl and 0.3 M methyl α-mannopyranoside and 1 mg/mL BSA.

Dendritic Cell Cross-Presentation to MelanA/MART-1 Specific T Cells. Immature DC (DC-IL-4) were incubated at 37 °C with various concentrations of Melan-A-glycopeptide. Maturation stimuli, 100 μg/mL poly I/C (Sigma) and 10 ng/mL TNF-α (Abcys) were added 3 h later. After an 18 h incubation at 37 °C, DC were washed and 10^5 loaded DC were co-incubated with 10^5 M77−84 cells in the presence of 10 μg/mL Brefeldin A (Sigma). After 6 h at 37 °C, cells were fixed and intracellular IFN-γ was stained as described (*40*). Briefly, cells were fixed in 4% paraformaldehyde for 10 min at room temperature and then stained with phycoerythrin (PE)-conjugated monoclonal antibody (mAb) specific for IFN-γ (Pharmingen BD). Antibody dilutions and washes were performed with PBS containing 1 mg/mL BSA and 1 mg/mL saponin at room temperature. After staining, cells were suspended in PBS and analyzed on a FACScan (BD Biosciences) with a gate set on T cells (on the FSC−SSC dot plot).

RESULTS

Design and Synthesis of Glycocluster−Melan-A Conjugates. The Melan-A peptide stands for Melan-A (16−40) A27L with the sequence: Ac-G[16]HGHSYTTAE*E*[26]*LAGIGILTV*[35]-ILGVL[40]KKKK, (Ac, for acetyl) containing a variant of the HLA-A2-restricted $CD8^+$ epitope (26−35) *ELAGIGILTV* instead of EAAGIGILTV, ended by a tetralysine tail. The *ELAGIGILTV*, A27L analogue binds to HLA-A2 better than the natural peptide because of an altered anchor residue (*29*, *30*).

The synthesis of the glycocluster−antigenic peptide conjugates involved the synthesis of glycosynthons containing Galβ-4Glc (lactose, Lac), Manα-6Man (DiMan), or Lewis oligosaccharides (a mixture of Lewis[a] and Lewis[x] oligosaccharides). The coupling of glycosynthons: Galβ-4Glc-βGlp-Ala-OH, Manα-6Man-βGlp-Ala-OH, and Lewis-βGlp-Ala-OH to Melan-A was carried out using amide coupling reagents HBTU/HOBT, to afford Lac−Melan-A, DiMan−Melan-A, and Lewis−Melan-A, respectively (Scheme 1). After purification on a Biogel column, the glycopeptides were analyzed by MALDI-TOF mass spectroscopy, showing a high proportion of trivalent conjugates and a small proportion of tetravalent derivatives.

Uptake of Fluorescent-Labeled Melan-A Glycopeptides by Dendritic Cells (DC-IL-13). Dendritic cells were incubated 2 h at 37 °C with fluorescent glycopeptides and analyzed by confocal microscopy. As expected, DiMan−Melan-A and Lewis−Melan-A were efficiently internalized and were found in numerous vesicles (Figure 1A) after 2 h pulse chase (lower panel) as well as immediately upon incubation (upper panel); conversely, Lac−Melan-A was not internalized by DC (data not shown) in agreement with our previous data (*9*), showing that DC are devoid of galactose or lactose-binding proteins. The cell-associated fluorescence was analyzed by flow cytometry. Monensin treatment was used to increase the fluorescence intensity of the endocytosed material (Figure 1B). The enhancement of cell fluorescence intensity, 1.5-fold upon addition of monensin, is proof that upon endocytosis, the fluorescein-labeled glycopeptide was contained in acidic compartments.

Surface Plasmon Resonance Analysis. The extracellular moieties of DC-SIGN and MR (MMR1−8) were immobilized on chips, leading to ΔRU values of 5200 and 5700 for DC-SIGN and MR, respectively. In preliminary experiments, we confirmed the binding activity of the immobilized lectins by evaluating their capacity to bind Man−BSA and Fuc−BSA neoglycoproteins. The binding profiles and the kinetic constants were in good agreement with our earlier results (*9*), indicating that the immobilized lectins did retain their binding activity (data not shown).

Solutions of DiMan−Melan-A, Lewis−Melan-A, and Lac−Melan-A were injected over a period of 5 min, followed by a dissociation time of 10 min with a glycopeptide-free buffer. It is noteworthy to mention that upon the injection of glycocluster−Melan-A conjugates on the SPR chips, the regeneration of the lectin-immobilized surface with methyl-α-mannoside solutions was inefficient. To circumvent this problem, the glycocluster−Melan-A conjugates were injected in the presence of 1 mg/mL BSA; the regeneration solution contained 1 mg/mL BSA and 1 M NaCl in addition to methyl-α-mannoside. The presence of BSA efficiently prevents nonspecific hydrophobic interactions derived from the presence of a large number of aliphatic amino acid residues in the antigenic Melan-A peptide.

Both DiMan−Melan-A and Lewis−Melan-A conjugates, injected onto the flow cell containing immobilized DC-SIGN, elicited a clear concentration-dependent response indicative of their binding; this is illustrated in Figure 2 for DiMan−Melan-A. During the binding of Lewis−Melan-A to MMR1−8, the slope (k_{bind})of the association curve was quite small and the

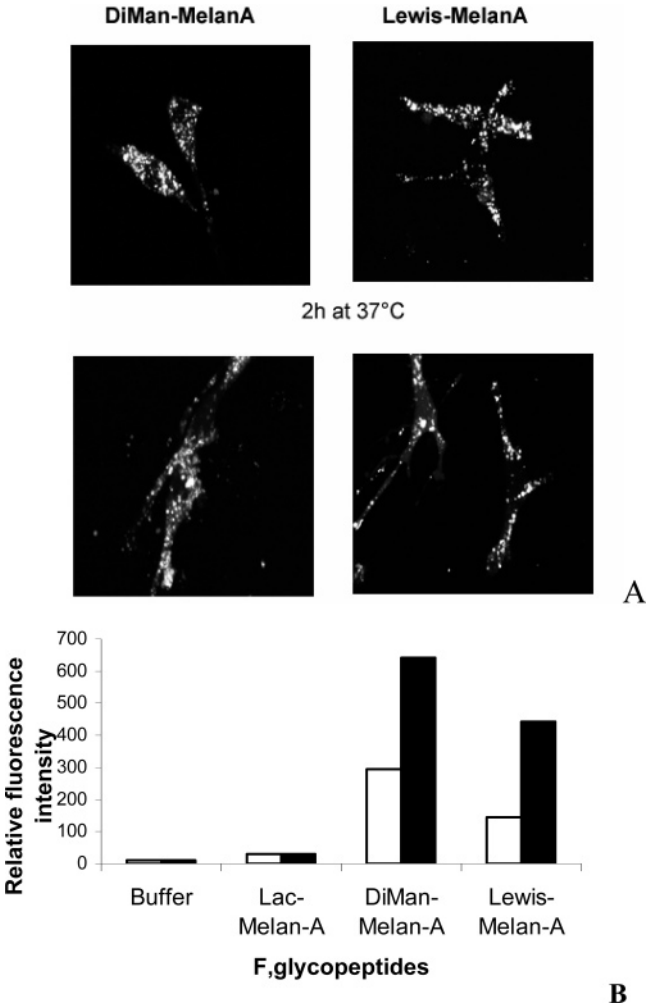

Figure 1. A. Confocal microscopy analysis of glycopeptide uptake by dendritic cells. DC plated on glass coverslips were incubated 2 h at 37 °C with F-DiMan-Melan-A or F-Lewis−Melan-A and fixed before mounting (*upper panels);* alternatively, DC were incubated 2 h at 37 °C with the glycosylated antigens and further chased 2 h without them before fixation (*lower panels).* B. Flow cytometry analysis of the uptake of F-glycopeptides by dendritic cells. DC were incubated for 2 h at 37 °C in the presence of either F-DiMan−Melan-A or F-Lewis−Melan-A, or F-Lac−Melan-A. Fluorescence intensity was measured by flow cytometry following postincubation in the absence (open bars) or in the presence (closed bars) of monensin.

RU signal linearly increased along with the duration of the Lewis−Melan-A injection (data not shown).

In a SPR binding study, the slope of the curve corresponding to the association phase depends on (k_{bind}), the experimental kinetic constant with a value of:

$$k_{bind} = k_{ass}\, g_0 + k_{diss}$$

where $k_{bind} = k_{ass}g_0 + k_{diss}k_{ass}$ stands forthe kinetic association constant, k_{diss} for the kinetic dissociation constant, and g_0 for the free ligand (i.e., the free glycopeptide) concentration. The dissociation profiles from immobilized DC-SIGN were characteristic for each of the two conjugates: that of Lewis−Melan-A was more than 10 times slower ($k_{diss} = 6.8 \times 10^{-5}$ s^{-1}) compared to that of DiMan−Melan-A ($k_{diss} = 8.8 \times 10^{-4}$ s^{-1}). In the binding to immobilized DC-SIGN, the calculated equilibrium association constants K_a ($K_a = k_{ass}/k_{diss}$) were 6.2×10^6 and 5.3×10^7 L mol^{-1} for DiMan−Melan-A and Lewis−Melan-A, respectively (Table 1).

It was previously shown from inhibition experiments that the mannose-based glycoclusters have a high affinity for MR (*9*).

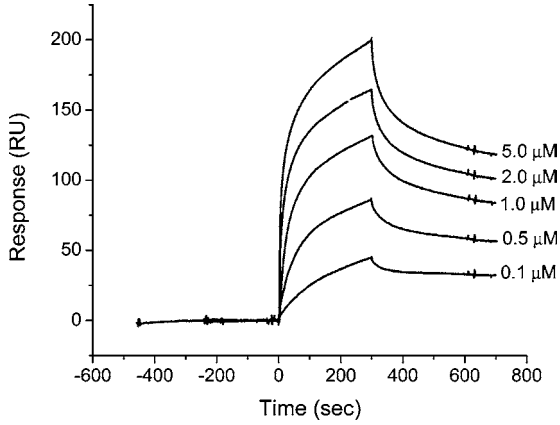

Figure 2. Surface plasmon resonance analysis of the concentration-dependent binding of DiMan−Melan-A conjugate with the immobilized extracellular domain of DC-SIGN. Solutions of DiMan−Melan-A (0.1 μM to 5 μM concentration range) were prepared in the running buffer containing 1 mg/mL BSA (pH 7.4) and were injected over a period of 5 min, with a dissociation interval of 5 min.

Table 1. SPR Derived Kinetic Constants for the Binding of Glycocluster−Peptide Conjugates to Immobilized DC-SIGN and MR Lectins

	K_a (L mol^{-1})	k_{diss} (s^{-1})
	DC-SIGN Extracellular	
DiMan−Melan-A	6.2×10^6	8.8×10^{-4}
Lewis−Melan-A	5.3×10^7	6.8×10^{-5}
Lac−Melan-A	NB[a]	NB[a]
	MMR1−8	
DiMan−Melan-A	2.5×10^7	6.7×10^{-4}
Lewis−Melan-A	*b*	*b*
Lac−Melan-A	NB[a]	NB[a]

[a] NB: No binding observed. [b] The kinetic constants could not be calculated.

This was confirmed with the binding of DiMan−Melan-A ($K_a = 2.5 \times 10^7$ L mol^{-1}) to immobilized MR. Lewis−Melan-A showed a poor association with MR and a very slow dissociation precluding the determination of the kinetic constants. Lac−Melan-A did not give any detectable response, in agreement with the failure of lactoside-based glycoconjugates to bind DC lectins (Table 1).

Glycocluster−Melan-A Conjugate Uptake by DC Induces Melan-A Epitope Presentation. In order to evaluate the capacity of glycocluster−Melan-A conjugates to serve as agents for antigen vectorization into DC, DC were incubated with the various glycocluster Melan-A conjugates and the presentation of the Melan-A (27−35) A27L peptide on DC was analyzed by measuring the activation of a specific T cell clone by intracellular IFN-γ labeling. As shown in Figure 3, DC incubated with DiMan−Melan-A and Lewis−Melan-A, but not with Lac−Melan-A conjugates, induced a clone response. The level of this response, shown by the fraction of IFN-γ labeled lymphocytes, was correlated with the glycocluster dose. When DC were incubated at 4 °C with DiMan−Melan-A and Lewis−Melan-A peptide, the clone activation was negligible (data not shown).

DISCUSSION

DC-SIGN or MR-specific antibody−antigen conjugates (*43*−*46*) have been used for the induction of tumor antigen cross-presentation by DC. Glycosylated antigen targeting to macrophages or DC lectin receptors was already used, but only to induce antigen presentation by MHC class II molecules. Indeed, glycoside-clustered tetanus toxoid (among other antigens) conjugates were shown to induce MR dependent antigen

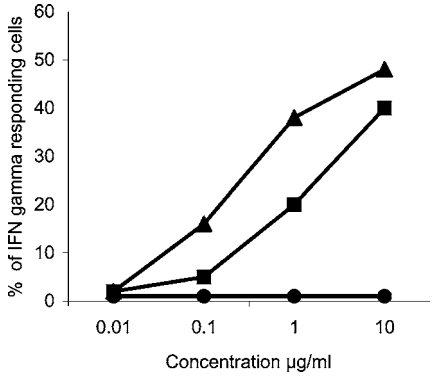

Figure 3. Response of Melan-A (26−35) specific $CD8^+$ T cell clone upon glycocluster−Melan-A conjugate uptake by DC. HLA-A*0201+ DC were incubated 18 h with various doses of DiMan−Melan-A (▲), Lewis−Melan-A (■) or Lac−Melan-A (●). Poly I/C and TNF-α were added 3 h after the beginning of the incubation. DC were then washed and cultured with HLA-A*0201 restricted Melan-A (26−35) specific $CD8^+$ T cell clone, in the presence of brefeldin-A to inhibit secretion. After 6 h, cells were fixed and intracytoplasmic staining of IFN-γ was performed and analyzed by flow cytometry.

presentation by macrophages on MHC class II molecules (*47*); mannosylated tetanus toxoid or proinsulin was shown to induce the uptake and targeting of these antigens to the MHC class II pathway (*48*). So far, there has been no report of glycotargeting of human DC lectins for the induction of tumor antigen presentation *via* the MHC class I pathway, a process called cross-presentation.

The aim of this study was to investigate whether glycotargeting of MR and DC-SIGN is a promising strategy to induce tumor antigen uptake by DC and to favor the MHC class I cross-presentation pathway. Our aim was to design a general route to synthesize glycocluster−tumor antigen conjugates with the flexibility of varying either the sugar moieties or the peptide epitope. In order to synthesize glycocluster−tumor antigenic peptide conjugates, two strategies were considered: (i) coupling of glycosynthons to an oligolysine template added to one of two ends of the antigenic peptide and (ii) synthesis of an oligolysine-based glycocluster (*24*) followed by an attachment to an antigenic peptide. The former strategy was selected, and four lysine residues were appended at the C-terminal end of the antigenic peptide Melan-A chosen for the study in order to allow attachment of up to four glycosynthons per molecule. Along this line, glycocluster−Melan-A peptide conjugates were prepared in a one-pot reaction involving the coupling of pyroglutamyl-based glycosynthons to ϵ-amino groups of lysine residues present at the C-terminal end of the peptide. This approach allowed an efficient attachment of DiMan-, Lewis-, and Lac-glycosynthons to the Melan-A 16−40 sequence and an efficient recovery of the glycocluster−Melan-A conjugates. In previous papers (*9*, *27*), we showed that DiMan-glycoclusters and Lewis-glycoclusters were taken up by DC. In order to monitor the cell uptake of the glycocluster−Melan-A conjugates, they were substituted with a fluorescent probe. The glycocluster−Melan-A, being devoid of any cysteine residue, has two histidine resisues (H^{17},H^{19}) that were fluoresceinylated by allowing iodoacetamido fluorescein to react at neutral pH; this procedure is based on the fact that iodoacetamide leads to carboxymethylation of the imidazole moiety of histidine as previously described (*41*, *42*). Here, we report that glycosylated antigenic peptides bearing DiMan- and Lewis-oligosaccharides were efficiently taken up in slightly acidic compartments, while the lactose-based glycopeptides were not.

A series of SPR experiments were carried out to evaluate the apparent binding of glycocluster−Melan-A conjugates to the DC membrane lectins, MR and DC-SIGN. Owing to the relatively high molecular weight of the glycocluster−Melan-A conjugates, in the present work, we were able to determine the association constants of the glycocluster−Melan-A conjugates by direct surface plasmon resonance measurements of their binding to the immobilized lectins, while in our earlier report (*9*), by using low molecular weight glycoclusters, the binding constants were deduced from their ability to inhibit the binding of neoglycoproteins (Man−BSA or Fuc−BSA). Here, we showed that DiMan−Melan-A and Lewis−Melan-A exhibited a high apparent affinity for DC-SIGN and MR (MMR1−8) lectins. However, their binding behavior differed. The binding constant K_a of DiMan−Melan-A to MMR1−8 was 4 fold higher than that to DC-SIGN; this difference is related to the association rate, not to the dissociation rate. In contrast, the binding constant K_a of Lewis−Melan-A to DC-SIGN was 10 times higher than that of DiMan−Melan-A; this difference is related to the dissociation rate of Lewis−Melan-A from this lectin, which is 10 times slower than that of DiMan−Melan-A. The binding of DiMan−Melan-A to DC-SIGN and MMR1−8, and that of Lewis−Melan-A to DC-SIGN, being within the 10^{-7} L mol^{-1} range clearly shows that these glycopeptides benefit from an avidity effect similar to that shown with the glycoclusters themselves (*9*). In the case of the interaction between Lewis−Melan-A and MMR1−8, no kinetic constant could be obtained, precluding any determination of the binding parameters. This result sheds light onto our previous negative results, when, by using a competitive approach, we were not able to show any interaction (*9*) between Lewis glycoclusters and immobilized MR. As expected, Lac−Melan-A did not exhibit any significant binding to either DC-SIGN or MMR1−8 lectins, in agreement with the fact that the lactose-based glycocluster is not a ligand for either DC-SIGN or MR. Therefore, in the present study, by direct SPR measurements with glycocluster peptide conjugates, we were able to demonstrate a binding of DiMan−Melan-A to DC-SIGN and to determine the binding parameters, while with small glycoclusters used as inhibitors of a neoglycoprotein binding, we were not able to detect interaction between DiMan glycoclusters and DC-SIGN (*9*).

In addition, glycocluster−Melan-A conjugates were clearly shown to serve as agents for antigen vectorization into DC. The fact that DC incubated with DiMan−Melan-A and Lewis−Melan-A allowed activation of specific CTL clones, and that DC incubated with Lac−Melan-A did not induce such a peptide presentation, strongly suggest that glycocluster−Melan-A conjugates induce Melan-A epitope cross-presentation through a sugar-specific mediated uptake, a subsequent intracellular routing, and an epitope processing through the MHC class I presentation pathway. As stated above, the efficacy of this antigen cross-presentation, as well as its time-course and dose−ligand dependency, is being investigated to ascertain the putative interest of glycotargeting tumor antigens to DC lectins for the stimulation of tumor specific T cell responses in cancer patients.

Having assessed the binding affinities of DiMan−Melan-A and Lewis−Melan-A to DC membrane lectins, their uptake by DC, their capacity to induce the presentation by DC of the epitope ELAGIGILTV of Melan-A (26−35) A27L on HLA-A2, inducing CTL specific clones activation, we find that such glycoconjugates are promising for DC-mediated *ex vivo* and/or *in vivo* cellular vaccination.

ACKNOWLEDGMENT

This work was supported by grants from la Ligue Nationale Contre le Cancer (AC.R, Commité du Loiret and F. J Labellisation 05), Fondation pour la Recherche Médicale (FRM), Cancéropôle Grand Ouest, and Institut National du Cancer (INCA, projet libre 2005, F. Jotereau). We are grateful to Maureen Taylor and Kurt Drickamer (Imperial College, London)

for kindly providing us with fibroblasts expressing MR and DC-SIGN and with MMR1−8 and DC-SIGN lectins, and for critical reading of the manuscript. We thank Prof. Gérard Stecker (University of Lille, France) for providing Lewis oligosaccharides, and Dr. Natacha Frison for the synthesis of fluorescent glycoclusters. We thank Margarita Salcedo (IDM, Paris) for kindly providing us with the DC-IL-13 and for critical reading of the manuscript, and C. Buré for her skillful help with MALDI, CBM-CNRS, Orléans). O.S. thanks La Ligue Nationale Contre le Cancer for the postdoctoral fellowship. ED is Assistant Professor (Université d'Orléans), ACR is Research Director (Inserm), MM is Emeritus Professor (Université d'Orléans).

NOTE ADDED IN PROOF

A recently published paper (Burgdorf et al. (2007) Distinct pathways of antigen uptake and intracellular routing in CD4 and CD8 T cell activation. *Science 216*, 612−616) clearly demonstrates that mannose receptor-mediated endocytosis of ovalbumin (OVA), used as a soluble model antigen, targets early endosomes and enables its cross-presentation to $CD8^+$ T cells. In the conclusion they suggest that "targeting antigen to the MR may represent an avenue for improving vaccines aimed at inducing $CD8^+$ T cells mediated immunity against viruses or tumors".

Self-Assembled Nano-Bioreactor from Block Ionomers with Elevated and Stabilized Enzymatic Function

Akifumi Kawamura,[†] Atsushi Harada,*[,†] Kenji Kono,[†] and Kazunori Kataoka*[,‡,§]

Department of Applied Chemistry, Graduate School of Engineering, Osaka Prefecture University, 1-1 Gakuen-cho, Naka-ku, Sakai, Osaka 599-8531, Japan, Department of Materials Engineering, Graduate School of Engineering, and Center for NanoBio Integration, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan. Received January 24, 2007; Revised Manuscript Received July 7, 2007

Core-cross-linked polyion complex (PIC) micelles entrapping trypsin in the core were prepared by mixing trypsin and poly(ethylene glycol)-*block*-poly(α,*β*-aspartic acid) in aqueous medium, followed by the introduction of glutaraldehyde cross-linkages. Trypsin incorporated into the core-cross-linked micelles showed high storage stabilities, and the initial enzymatic activity of trypsin was maintained even after standing for one week at ambient temperature. Further, stable compartmentalization of trypsin into the core-cross-linked micelles led to a unique modulation in the enzymatic functions including an improved thermal tolerability with an increased maximum reaction rate compared to native trypsin.

INTRODUCTION

Immobilized enzymes have been utilized in numerous applications including bioreactors, biosensors, and therapeutics (*1*−*5*). The major advantage of immobilized enzymes is an improvement in the storage and operational stabilities, which is especially crucial for proteolytic enzymes showing autolysis reaction. Conventionally, solid and porous matrices, including agarose, cellulose, and silica, have been used to immobilize enzymes through physical adsorption or covalent attachment. Also, water-soluble conjugates of enzymes with various polymers have been prepared (*6*−*9*). A novel approach to the immobilization of enzymes at the nanometric scale is the supramolecular assembly of nanoreactors. Noteworthy in this regard is the core−shell-type polyion complex (PIC) micelles formed from block ionomers. Charged enzymes can be incorporated into PIC micelles driven by electrostatic interaction in aqueous medium (*10*−*13*). Indeed, egg white lysozyme with cationic character was successfully incorporated into the core of PIC micelles through complexation with poly(ethylene glycol)-*block*-poly(α,*β*-aspartic acid) (PEG-PAA). Lysozyme-incorporated PIC micelles showed unique features including the on−off switching of an elevated enzymatic reaction synchronized with an external electric field. However, in the case of entrapping proteolytic enzymes (e.g., trypsin) in the micelles, autolysis was facilitated due to an increase in the local concentration of the enzyme. This problem has been recently overcome by the introduction of cross-linking into the core of PIC micelles (*14*). The tolerability of trypsin in PIC micelles, which is a typical proteolytic enzyme that selectively cleaves the bond adjacent to Lys and Arg, was dramatically improved by introducing cross-linking in the core of the micelles. Glutaraldehyde was used as a cross-linking reagent of the PIC micelles prepared by mixing trypsin and PEG-PAA. The core-cross-linked PIC micelles had a hydrogel core of nanoscopic size, formed by the cross-linking of trypsin and PAA, and an outer PEG shell layer. The core-cross-linked micelles might provide unique features in the field of nanoscopic enzymatic reactions.

Here, we studied in detail the enzymatic function of the core-cross-linked PIC micelles entrapping trypsin. Note that the Schiff base linkages in the cross-linked PIC micelles may undergo reductive amination to form alkylamine linkages. The amidase activity of entrapped trypsin in the micelle was evaluated by colorimetric assays using L-lysine *p*-nitroanilide as a substrate, both before and after the reductive amination. A remarkable improvement in the storing stability of trypsin was observed as a result of the compartmentalization of the enzyme into the cross-linked core of the PIC micelles. Further, an appreciable increase in the optimal temperature as well as a significantly improved tolerance to urea in the enzymatic reaction were achieved in the cross-linked micelles.

EXPERIMENTAL PROCEDURES

Materials. Poly(ethylene glycol)-poly(α,*β*-aspartic acid) block copolymer [PEG-PAA; 12 000 g/mol of PEG Mw; 68 of polymerization degree in PAA segment] was synthesized as described previously (*10*). Bovine pancreas trypsin, L-lysine *p*-nitroanilide and 3-methyl-2-benzothiazolinone hydrazone were purchased from Sigma (St. Louis, MO) and used without further purification. Sodium cyanotrihydroborate ($NaBH_3CN$), $Na_2HPO_4 \cdot 12H_2O$, $NaH_2PO_4 \cdot 2H_2O$, and 70% glutaraldehyde were reagent grade and were purchased from Wako Pure Chemical Industries (Osaka, Japan).

Preparation of Core-Cross-Linked PIC Micelles Entrapping Trypsin in the Core. Given amounts of trypsin and PEG-PAA were separately dissolved in sodium phosphate buffer (10 mM; pH 7.4) at 4 °C. The solutions were mixed at the optimum mixing ratio for PIC micelle formation, i.e., the ratio of the number of Asp residues in PEG-PAA against the total number of Lys and Arg residues in trypsin to be 0.75. The mixed

solution was stored at 4 °C for 30 min, and then 70% glutaraldehyde solution was added to prepare cross-linked micelles with varying cross-linking ratios (GR). The cross-linking ratio (GR) was defined as the residual molar ratio of aldehyde group to lysine in the solution. The cross-linked PIC micelle solution was then kept at 4 °C for 30 min. In order to remove excess glutaraldehyde, the cross-linked PIC micelle solution was dialyzed against buffer. The removal of free glutaraldehyde was confirmed from the absence of aldehyde species in the dialysate, as determined by colorimetric assay using 3-methyl-2-benzothiazolinone hydrazone. Then, $NaBH_3$-CN was added to the solution to convert the Schiff base linkages to alkylamine linkages by reductive amination. The reductive amination step was also confirmed by colorimetric assay using 3-methyl-2-benzothiazolinone hydrazone.

Dynamic Light Scattering Measurements. Dynamic light scattering (DLS) measurements were carried out using a DLS-700 spectrometer (Otsuka Electronics Co., Ltd., Japan) equipped with an Ar ion laser (λ = 488 nm) at 25 °C. The detection angle was fixed at 90°. The average diameter and polydispersity index were obtained by the cumulant method, and the size distribution was obtained by histogram analysis.

Evaluation of Amidase Activity of Trypsin. The amidase activity of trypsin was evaluated using L-lysine *p*-nitroanilide as a substrate. The reaction rates of the native trypsin and trypsin incorporated into the core-cross-linked micelles were determined by monitoring the change in the absorbance at 410 nm, where the wavelength for the extinction coefficient of *p*-nitroaniline after mixing of the trypsin solution and substrate solution is 8800 cm^{-1} M^{-1}. The initial reaction rate was determined from the slope of the change in the absorbance at 410 nm during the period between 150 and 250 s after mixing.

RESULTS AND DISCUSSION

The cross-linkages in the core of PIC micelles, which were prepared from trypsin and PEG-PAA, were introduced using glutaraldehyde as cross-linking reagent for the stabilization of the micellar structure. There is known to be two types of cross-linkages in the cross-linking reaction of amine compounds by glutaraldehyde: One is the Schiff base linkage formed between the primary amino group of the Lys residue in trypsin and the aldehyde group of glutaraldehyde, and the other cross-linkage involves the formation of a quaternary pyridinium structure (see Supporting Information). We have recently confirmed the formation of the quaternary pyridinium structure for lysozyme-entrapped PIC micelles cross-linked using glutaraldehyde by spectroscopic analysis (*15*). Further, the quaternary pyridinium structure might also be formed in trypsin-entrapped PIC micelles cross-linked by glutaraldehyde. Reduction of the Schiff base and pyridinium structure using $NaBH_3CN$ as a reductant results in the formation of saturated alkylamines, further stabilizing the micelle structure due to the formation of the stable covalent bonds. The nonreacted aldehyde groups in the core-cross-linked PIC micelles were also reduced to hydroxyl groups by $NaBH_3$-CN treatment, which was confirmed by using 3-methyl-2-benzothiazolinone hydrazone as an aldehyde-detecting reagent. Figure 1 shows the size distribution of PIC micelles before and after the reductive amination. Unimodal size distribution was maintained even after this treatment. Also, the reduction process induced no change in the average diameter and polydispersity index (μ_2/Γ^2), which were determined by the cumulant analysis of dynamic light scattering measurements (69.6 nm, μ_2/Γ^2 = 0.04 for the original sample; and 68.9 nm, μ_2/Γ^2 = 0.06 for the sample after the treatment).

As an evaluation of the stabilized enzymatic function, the storage stability of the amidase activity of trypsin was studied by using L-lysine *p*-nitroanilide as a substrate. Figure 2 shows

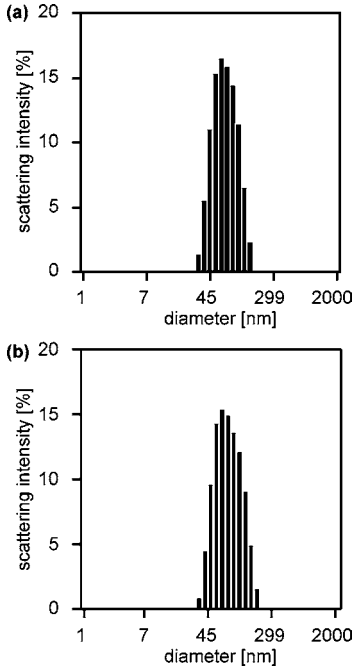

Figure 1. Size distributions of core-stabilized micelles before (a) and after (b) reductive amination, as measured by dynamic light scattering (GR = 100; detection angle 90°; temperature 25 °C).

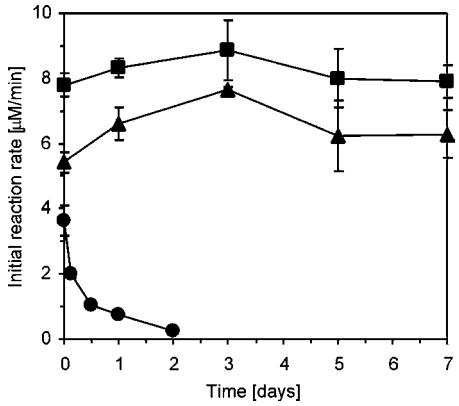

Figure 2. Time course of the enzymatic reaction rate of native trypsin (●) and trypsin incorporated into nonreduced (▲) and reduced (■) micelles at 25 °C. (Trypsin concentration 16.8 μM; substrate concentration 5 mM. The plots are presented as the average of three experiments ± SD.)

the time-dependent change in the initial reaction rate for both native trypsin and trypsin incorporated into the nonreduced and reduced micelles. The initial reaction rate of native trypsin immediately decreased due to autolysis, and there was no detectable activity after 2 days incubation. On the other hand, the trypsin incorporated into the nonreduced and reduced core-cross-linked micelles maintained a constant reaction rate even after 1 week incubation at 25 °C, indicating that the autolysis of trypsin was effectively prevented due to being incorporated into the core-cross-linked micelles. In the cross-linked core, the migration of trypsin molecules was highly restricted, thereby inhibiting their mutual contact. As a result, the autolysis of trypsin was effectively inhibited. There was no difference in the storage stability of trypsin activity between the nonreduced and reduced micelles. This effect will be discussed later on the basis of the enzymatic reaction constants. Further, it should be noted that the reaction rate of the trypsin incorporated into the core-cross-linked micelles was appreciably higher than that of native trypsin, suggesting that the amidase activity of trypsin might increase through the entrapment into the core of the

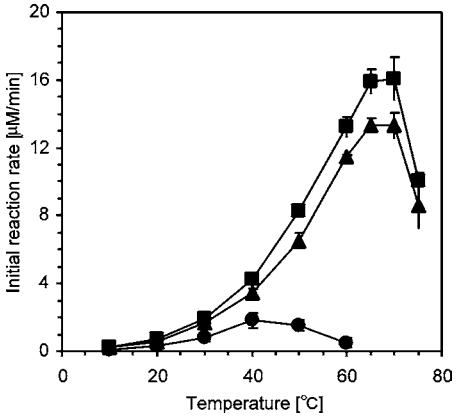

Figure 3. Temperature dependence of the enzymatic reaction of native trypsin (●) and trypsin incorporated into nonreduced (▲) and reduced (■) micelles. (Trypsin concentration 4.2 μM; substrate concentration 1.25 mM. The plots are presented as the average of three experiments ± SD.)

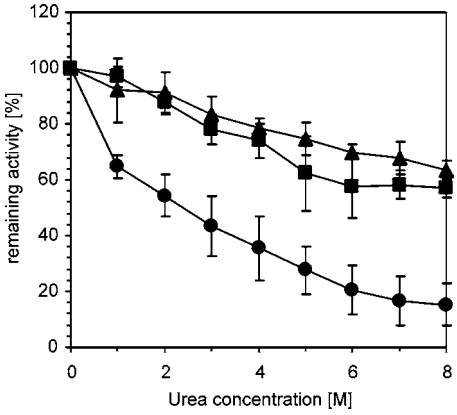

Figure 4. Change in relative remaining activity with urea concentration for native trypsin (●) and trypsin incorporated into nonreduced (▲) and reduced (■) micelles. (Trypsin concentration 16.8 μM; substrate concentration 5.0 mM; The initial reaction rates of native trypsin and trypsin incorporated into nonreduced and reduced micelles were 4.3 ± 0.1, 7.3 ± 0.7, and 8.9 ± 0.9 μM/min, respectively. The plots are presented as the average of three experiments ± SD.)

micelle. For the stabilized enzymes physically or chemically immobilized in polymer networks, the decreased enzymatic activity through the immobilization was often observed, which was induced by the restriction of the mobility of enzyme as well as by the limited solute transfer (*16*, *17*). No decrease in enzymatic activity of trypsin in the micelles might be due to the unique characteristics of core-cross-linked micelles including small size and core−shell structure with enzyme molecules stably entrapping into the core surrounded by a biocompatible and hydrophilic shell layer, providing a uniform distribution of stabilized enzymatic nanoreactor and maintenance of substrate diffusion.

The entrapment of trypsin into the micellar cross-linked core induced a substantial shift in the optimal temperature of the enzymatic reaction, as compared to native trypsin. Figure 3 shows the temperature dependence of the enzymatic reaction rate of both the native trypsin and the trypsin incorporated into the nonreduced and reduced micelles. In the case of native trypsin, a maximum reaction rate was observed at 40 °C, and this reaction rate gradually decreased in the higher-temperature region due to thermal denaturation. Obviously, the optimal temperature of the trypsin activity increased from 40 to 65 and 70 °C, respectively, for the nonreduced and reduced micelles. Various types of trypsin stabilized by polymers have been evaluated on their thermal stability, and the highest optimal temperature of stabilized trypsin in such a way was 65 °C reported by Fernandez et al. (*18*, *19*). In their study, trypsin conjugated with the derivatives of cyclodextrin showed an increased optimal temperature of trypsin, but the autolysis reaction was not completely prevented. The significant increase in the optimal temperature up to 70 °C obtained in the present study of the PIC micelle system might be due to the effective stabilization of the trypsin molecule by the introduction of the cross-linked structure in the matrix of the micellar core. In the core of the cross-linked micelles, cross-linkages were formed not only between the trypsin−trypsin molecules, but also between the primary amino groups at the ω-end of the PAA segments and the aldehyde groups in glutaraldehyde, i.e., trypsin−trypsin and trypsin−polymer cross-linkages, forming a hybrid nanogel structure. Consequently, the thermal-denaturing temperature of trypsin shifted to a higher temperature through the immobilization into the nanogel network, thus avoiding the thermal unfolding of the protein structure. It is worth noting that, in the immobilized trypsin in the micellar core, the spatial arrangement of the Asp-His-Ser catalytic triad in the trypsin molecule should be maintained even at 70 °C.

The stabilized spatial arrangement of the catalytic triad in the core-cross-linked micelles was also supported by the results of the tolerated trypsin activity against urea addition. Figure 4 shows the change in the relative remaining activity, defined as the ratio of the initial enzymatic reaction rate in the presence and absence of urea. Urea is well-known as a strong breaker of hydrogen bonding, as well as a disruptor of hydrophobic interaction, including enzyme denaturation in a concentration dependent manner. Indeed, the relative remaining activity of native trypsin gradually decreased with increasing urea concentration, and became lower than 50% at 3.0 M urea. On the other hand, even at 8.0 M urea, the trypsin incorporated into the core-cross-linked micelles maintained more than 60% of its relative remaining activity, indicating that the spatial arrangement of the catalytic triad in the cross-linked micelles was preserved even at high urea concentration. These results shown in Figures 3 and 4 suggest that the original tertiary structure of the trypsin molecule in the micelles might be effectively stabilized through chemical cross-linking.

As seen in Figures 2 and 3, the trypsin incorporated into the core-cross-linked micelles always showed higher initial reaction rates compared with native trypsin, suggesting that the enzyme incorporated into core-cross-linked micelles exhibits apparently enhanced activity. In order to evaluate the difference in the amidase activity of native trypsin and trypsin in the nonreduced and the reduced micelles, enzymatic reaction constants were determined by preparing Lineweaver−Burk plots (Figure 5). The good linear relations observed between the reciprocals of the initial reaction rate and the substrate concentration in the Lineweaver−Burk plots was confirmed not only for native

Table 1. Enzymatic Reaction Constants of Native Trypsin and Trypsin Incorporated into the Core-Cross-Linked Micelles

	k_{cat} [min^{-1}]	K_m [mM]	k_{cat}/K_m [M^{-1} min^{-1}]
native trypsin	0.236 (1.0)[a]	1.11 (1.0)[a]	213 (1.0)[a]
trypsin in nonreduced micelle	0.482 (2.0)[a]	1.14 (1.0)[a]	423 (2.0)[a]
trypsin in reduced micelle	0.689 (2.9)[a]	1.23 (1.1)[a]	560 (2.6)[a]

[a] These values were relative values against the values of native trypsin.

trypsin, but also for the trypsin incorporated into the reduced and nonreduced micelles. This linear relation indicates that the enzymatic function of trypsin incorporated into the core-cross-linked micelles can be kinetically analyzed on the basis of the Michaelis−Menten equation. The obtained enzymatic reaction constants, the catalytic rate constant (k_{cat}), the Michaelis constant (K_m), and k_{cat}/K_m, were summarized in Table 1. It was observed that the K_m values remained almost unchanged following the incorporation of trypsin into the core-cross-linked micelles, indicating that the affinity between trypsin and the substrate did not change. On the other hand, the k_{cat} values of the core-cross-linked micelles were approximately two to three times higher than that of native trypsin. The higher reaction rates of trypsin in the core-cross-linked micelles, as compared to those of native trypsin, were ascribed to an increase in the k_{cat} values. It is well-known that trypsin has a catalytic site constituted of the Asp-His-Ser triad (*20*−*22*). In this catalytic site, the nucleophilicity of the hydroxyl group of Ser increases through a proton-transfer process in the Asp-His dyad, in which the carboxylate group of Asp stabilizes the imidazolium ion of the His residue. We recently found that a part of the carboxylate group of the Asp residue in PEG-PAA stabilized an imidazolium ion of the His residue in the catalytic triad, thus accelerating the catalytic reaction of trypsin (*23*). This effect might also be induced in the core-cross-linked micelles as a means to increase the catalytic constant, as compared to native trypsin.

CONCLUSION

Core-cross-linked PIC micelles, prepared from trypsin and PEG-PAA, were effectively formed in both a reduced and a nonreduced state, both entrapping trypsin in the core. Both a remarkable improvement in the storing stability and a significant increase in the optimal temperature of the trypsin activity, as well as the marked resistance to denaturation by urea, were all confirmed as effects of the incorporation of trypsin into the core-cross-linked micelles. Note that there were few reports on the immobilization method of enzymes which attained increases in both the enzymatic activity and the optimal temperature. Most of the conventional enzyme-immobilized systems showed an apparent decrease in enzymatic activity due to the mass-transfer effect attributed to the restricted mobility of the enzyme as well as to the limited diffusion of the solute molecules (*16*, *17*). In the case of the core-cross-linked micelles, the enzymes were fixed to each other by the cross-linking reagent to form a nanoscopic hydrogel domain consisting of several tens of enzyme molecules. Since the size of the domain was sufficiently small, the diffusion of the substrate might not be the rate-determining step of the enzyme reaction. As a result, the mass-transfer effect was not significant for the core-cross-linked micelles. This is also an advantage of the cross-linked PIC micelle systems when compared to the conventional immobilization of enzymes in gel matrices with significantly larger dimensions. These core-cross-linked micelles incorporating enzymes represent a new entity of supramolecular nanobioconjugates, which are expected to find significant application in both the medical and bioengineering fields.

Mexico, Gerencia de Aplicaciones Nucleares en la Salud, Instituto Nacional de Investigaciones Nucleares, Ocoyoacac, Edo. Mex., Mexico, and Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Mexico City, Mexico. Received February 12, 2007; Revised Manuscript Received April 11, 2007

Two synthetic procedures for HYNIC oxytocin labeling were developed: one based on an orthogonal protection approach and the other with prelabeled (Boc)HYNIC-(Fmoc) amino acids. Both procedures were compared and applied to the preparation of several HYNIC−oxytocin derivatives where ligand position and amino acid (lysine and phenylalanine) were varied. Additionally, an oxytocin derivative labeled with HYNIC in the α-amino group of the Cys^1 residue was also prepared. ^{99m}Tc-ethylendiaminediacetic acid (EDDA) labeling efficiencies were examined for all the derivatives, resulting in two candidates which showed affinity for the oxytocin receptor. Further biochemical experiments demonstrated that ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-$CONH_2$ could be used as a potential radiopharmaceutical for breast cancer diagnosis.

INTRODUCTION

Recently, the development of target-specific diagnostic pharmaceuticals (TSP) has heightened the interest in studying the different chemical aspects involved in the production of these agents. In general, diagnostic TSP consist of a specific vector, a linker, a ligand, and a metal ion. The vector is the moiety acting as a carrier to the specific target. The usage of vectors such as organic compounds, antibodies, proteins, and peptides has been widely reported in the literature (*1*). However, peptides are of particular interest, given that sequence target specificity can be easily monitored by techniques such as phage display (*2*), and peptide synthesis and modification can be chemically accomplished by solid-phase peptide synthesis (SPPS). The linker is the intermediate group connecting the ligand with the vector and selection depends on either the metabolic characteristics desired for the TSP or the maintenance of the ligand as far as possible from the vector to minimize activity modification of the vector due to the proximity of the ligand. The ligand is the molecule in charge of forming a thermodynamically and kinetically stable complex with the metal ion of interest. The selection of the metal ion depends on its nuclear, physical, and magnetic properties, given a particular application. For instance, ^{99m}Tc is used in radiodiagnostics, and Gd^{3+} is used in contrast agents for magnetic resonance imaging (MRI). In particular, ^{99m}Tc is used in nearly 80% of all single-photon emission computed tomography (SPECT) diagnostic radiopharmaceuticals currently used in nuclear medicine (*3*), given its optimal half-life time (6 h), wide availability, and low-energy particle emission (*4*). Therefore, peptides labeled with ligands that form stable metal complexes with ^{99m}Tc are thoroughly studied as diagnostic tools (*5*). Among the chelators, HYNIC (2-hydrazinnicotinic acid) (*6*) (Figure 1a) is of particular interest, because

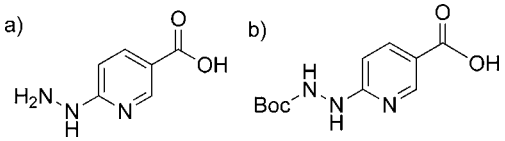

Figure 1. (a) HYNIC and (b) Boc-HYNIC.

it shows a high labeling efficiency (rapid and high yield radiolabeling) and its usage with various co-ligands (e.g., ethylendiaminediacetic acid, tricine, and glucoheptonate) allows for easy modification of the hydrophilicity and pharmacokinetics of the ^{99m}Tc -labeled small peptides (*7*). Given the implications of chelate-labeled peptides, the study of the influence of ligand position within a peptide sequence on targeting specificity and properties of the peptide is of great interest. The most common way to attach a ligand to a peptide has been through the N-terminus or the ϵ-amino group of lysine by means of protected derivatives of the ligand for SPPS (Figure 1b). However, this limits the possibilities of creating peptide libraries for screening purposes. Additionally, several lysine-protected derivatives have been prepared (*8*, *9*) and are commercially available (e.g., Bachem Bioscience Inc. USA, Advanced ChemTech Inc. USA, Merck KGaA, Germany) to specifically attach ligands to peptides through lysine residues by orthogonal protection procedures (*10*). Recently, a chemical procedure for introducing DOTA-lysine (DOTA-Lys) or DOTA-phenylalanine (DOTA-Phe) within a peptide sequence using standard SPPS was reported, and thus, a small peptide library was created and monitored for peptide activity (*11*). Similarly, a HYNIC-Lys derivative (Scheme 1, compound **6**) was reported for site-specific labeling of a calcitonin salmon peptide (*12*). In that work, the synthesis was accomplished by reacting Boc-HYNIC succinimide with Nα-Fmoc lysine. However, the desired product was obtained in moderate yields after purification by HPLC, given the formation of a Boc-HYNIC-(Nα-Fmoc $Lys)_2$ subproduct. Thus, although the procedure is simple and partially works with amino acids and its derivatives containing a free aliphatic amino group (lysine), it has not been proven to work for amino aromatic amino acid derivatives, given its low nucleophilicity. Additionally, the moderate yields of the HYNIC-Lys and

subproduct formation are fully attributed to the free carboxylic acid of the Nα-Fmoc amino acid. In spite of the existence of different chemical procedures for generating ligand−peptide libraries based on solid-phase peptide synthesis, there have been few reports related to the generation of these libraries for screening purposes of diagnostic or therapeutic agents. Therefore, in this work, we present a generalized procedure for the synthesis of HYNIC Lys (**6**) and Phe (**12**) (Schemes 1 and 2, respectively) derivatives based on functional group protection. To demonstrate the utility of these derivatives, a small library of the bioactive peptide oxytocin (OT) labeled with HYNIC was prepared. Additionally, the procedure was compared with an orthogonal protection approach for the controlled positioning of HYNIC in OT. Oxytocin is an important hypothalamic cyclic neurononapeptide (NH_2-$Cys^1Tyr^2Ile^3Gln^4Asn^5Cys^6Pro^7Leu^8Gly^9$-$CONH_2$) that plays an important role in many reproductive and behavioral functions. OT structure−activity relationships have been widely studied, and the following characteristics may be noted: (a) The cyclic part of the peptide (Cys^1-Cys^6) is more important in conferring binding selectivity for the OT receptor (OTR) compared to the linear tripeptidic part ($Pro^7Leu^8Gly^9$) (*13*); (b) the replacement of the $CONH_2$ terminal group for COOH leads to less active OT derivatives; (c) the tripeptide tail of OT is important for binding, and Pro^7Leu^8 can be replaced by a variety of residues (moreover, OT derivatives with reduced potency are obtained when Pro^7 is substituted by a residue that induces conformational constraints) (*14*); and (d) the deaminoCys^1−oxytocine derivative is more active than OT (*15*) and has higher stability to oxytocinase degradation (*16*). However, structure−activity relationships for OT−ligand conjugates are unknown.

Recently, novel sites for OT receptor expression have been detected, including breast cancer cells, bone cells, myoblasts, cardiomyocytes, endothelial cells, and in ovarian carcinoma (*17*, *18*). Although the mechanism is not completely understood, in tumors, OT acts as a growth regulator, and it has been demonstrated that in some cases it has an growth-inhibiting effect (mammarian carcinomas, neoplastic epithelial, nervous or bone cells, and ovarian carcinoma cells), while in others, it promotes cell proliferation (trophoblast and endothelium neoplastic cells) (*19*). Additionally, it has been recently recognized that the placental leucine aminopeptidase (P-LAP) acts as an OT-degrading aminopeptidase (oxytocinase) in endometrial adenocarcinoma tissues and ovarian cancer, and it has been suggested that the system OT-OTR-P-LAP might be involved in cellular growth for this type of cancers (*18*). Thus, we hypothesized that the presence of P-LAP might counterattack the growth-inhibiting effect of the OT degrading it. If such a mechanism exists, then it is important to consider that OT-radiolabeled derivatives stable to P-LAP might serve as diagnostic or therapeutic agents for different cancer cells.

As for OT−ligand conjugates, there are scarce reports (*20*, *21*), and no OT libraries with different ligand position and nature have been reported specifically for HYNIC derivatives.

EXPERIMENTAL PROCEDURES

General Procedures. ^1H and ^{13}C nuclear magnetic resonance spectra were taken using a JEOL Eclipse 200 MHz spectrometer and referenced to a tetramethylsilane standard. Chemical shifts are reported as parts per million (δ), with splitting patterns designated as singlet (s), doublet (d), triplet (t), multiplet (m), or double of doublets (dd). Coupling constants are reported in hertz. Melting points were taken in a Fisher Johns melting point apparatus. HPLC peptide analysis and purification were performed on a HP1050 instrument equipped with a 1050 series diode array UV−vis detector, while quantitative analysis was carried out on a C18 Jupiter column 5 μm, 250 × 4.6 mm 300

Å, and purification was done on a C18 Jupiter column 10 μm, 250 × 10 mm 300 Å, both from Phenomenex. Products were eluted at a flow rate of 1 mL/min (4.8 mL/min for semipreparative HPLC) using a linear gradient [(100:0) to (0:100) in 35 min] of H_2O/TFA (0.1%) and acetonitrile/H_2O/TFA (90/10/0.1). MS-ESI analysis was performed in an Agilent 1100 series instrument LC-MSD trap. Peptides were lyophilized in a FreeZone 2.5 Labconco lyophilizer.

Microwave-assisted solid-phase peptide synthesis was carried out following Fmoc standard protocols. Microwave-assisted reactions were carried out in a Microwave Accelerated Reaction System, Mars X, version 047928, CEM corporation. Reaction conditions were as follows: swelling, 1 pulse of 120 s at 15 W; coupling, 4 pulses of 15 s at 100 W; capping, 3 pulses of 30 s at 75 W; deprotection, 3 pulses of 30 s at 75 W. To avoid racemization, cooling was applied after each pulse to keep reaction temperature below 60 °C. Peptides were synthesized on a 0.1 mmol scale using single-step couplings of 2 equiv Fmoc-amino acids, 2 equiv coupling agent and HOBt, and 6 equiv DIPEA in DMF and capping of free, unreacted amino groups with a 4.75 % v/v acetic anhydride solution in NMP. Coupling and capping completion was monitored with the ninhydrin test. Following linear peptide assembly, cleavage from the resin and final deprotection were carried out with TFA/thioanisole/1,2-ethanedithiol/anisole (9:0.5:0.3:0.2) at 25 °C for 2 h. The resin was filtered off and the filtrate dried with a gentle nitrogen flow, and peptides were precipitated with cold diethyl ether (−20 °C). Precipitate was filtered, washed with cold ether, and dried. Into the resulting residue, a 10 mM solution of 2,2′-bispyridyl disulfide in methanol was added. The resultant solution was stirred at room temperature, and peptide oxidation completion was monitored by HPLC. The solvent was removed, and the residue was redisolved in 10% acetic acid. Peptides were purified by reverse-phase HPLC, lyophilized, and characterized by MS-ESI.

2-(1*H*-Benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), *N*-Hydroxybenzotriazole (HOBT), Fmoc-L-amino acids, and resins (Wang resin for −COOH peptides and Rink amide for $-CONH_2$ peptides) were obtained from Novabiochem (San Diego, CA). All other chemicals and solvents were purchased from commercial sources and were used without further purification.

Synthesis. Compounds **2**, **3**, **4**, **7**, **8**, **9**, and **10** were prepared following procedures reported in the literature, and the characterization data (^{1}H and ^{13}C NMR, MS-ESI, elemental analysis) were in agreement with the proposed structure and what is reported (*11*).

Nα-(Carbobenzyloxy)-Nϵ[6-*(tert-butoxycarbonylhydrazinpyridyn)-3-carboxyl]*-L-*Lysine Benzyl Ester (**5**).* 6-Boc-hydrazinpyridyn-3-carboxylic acid (248 mg, 0.98mmol), HBTU (371 mg, 0.98 mmol), and DIPEA (0.88 g, 6.8 mmol) were dissolved, followed by the addition of compound **4** (362 mg, 0.98 mmol). The resultant solution was stirred at room temperature for 1 day, and reaction completion was monitored by HPLC (Gemini polymeric column, 5 μm, 250 × 4.6 mm, Phenomenex, linear gradient from 85% DI−H_2O/15% MeCN to 10% DI−H_2O/90% MeCN in 20 min, at a flow of 1.0 mL/min and spectrophotometric detection at 254 and 275 nm). After reaction completion, the solvent was removed by rotary evaporation, and the product was purified by chromatography column in silica gel 60 (70−230 mesh), using ether as eluent. The fractions containing the product were collected, and the solvent was removed, yielding 0.53 g (90%) of colorless oil. R_f = 0.36 (SiO_2, ethyl acetate). ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS) δ 8.4(s, 1H), 7.8 (d, J = 8.8 Hz, 1H), 7.3 (s, 10H), 7.1 (s, 1H), 6.8 (s, 1H), 6.5 (d, J = 8.8 Hz, 1H), 5.8 (s, 1H), 5.0 (m, 4H), 4.3 (m, 1H), 3.2 (m, 2H), 1.9−1.4 (m, 6H), 1.5 (s, 9H). ^{13}C NMR (50 MHz, $CDCl_3$, 25 °C, TMS) δ 171, 165, 160, 155, 154, 146, 136, 134, 127, 121, 104, 81, 66, 65, 52, 38, 30, 28, 27, 21. MS-ESI: *m*/*z* 605 (calcd. 605) $[M]^+$; Anal. ($C_{32}H_{39}N_5O_7$) C, H, N.

*Nϵ[6-(tert-butoxycarbonylhydrazinpyridyn)-3-carboxyl]-Nα-(fluorenilmethoxycarbonyl)-*L-*lysine (**6**).* Compound **5** (300 mg, 0.49 mmol) was dissolved in ethanol (15 mL), and 10% Pd/C catalyst (40 mg) was added. The reaction mixture was set in a Parr hydrogenation apparatus and was purged with H_2 (10×), and pressure was set to 40 psi for 2 days. At the end of the reaction, the solution was filtered to remove the catalyst, and the solvent was removed by rotary evaporation. The residue was vacuum-dried, yielding 180 mg (97%) of a white solid. R_f = 0.9 (SiO_2, MeOH) corresponding to the nonprotected amino acid derivative. mp = 220 °C. ^{1}H NMR (200 MHz, 25 °C, DMSO-d_6) δ 8.9 (s, 1H), 8.6 (s, 1H), 8.5 (d, J = 2.4 Hz, 1H), 7.9 (dd, J = 2.4 Hz, 8.8 Hz, 1H), 7.3 (s, 1H), 6.5 (d, J = 8.8 Hz, 1H), 3.5 (s, 2H), 3.2 (m, 2H), 1.8−1.2 (m, 6H), 1.4 (s, 9H). ^{13}C NMR (50 MHz, 25 °C, DMSO-d_6) δ 171, 166, 156, 148, 136, 121, 104, 80, 46, 44, 30, 28, 27, 23. MS-ESI: *m*/*z* 381 (calcd. 381) $[M]^+$, 404 (calcd. 404) $[M + Na]^+$; Anal. ($C_{17}H_{27}N_5O_5$) C, H, N.

The obtained intermediate (50 mg, 0.13 mmol) was dissolved in DMSO (2 mL) and was set under inert atmosphere and 0 °C in an ice bath. Fmoc-succinimide (40 mg, 0.13 mmol) in DMSO (2 mL) was slowly added under inert atmosphere. The reaction mixture was allowed to stand at RT overnight, and the reaction completion was monitored by HPLC and MS-ESI. Reaction conversion was quantitative, and therefore the reaction mixture can be used without purification for SPPS. The solvent was removed by rotary evaporation, and the product was purified by column chromatography in silica gel 60 (70−230 mesh) using as eluents $CHCl_3$, $CHCl_3$/MeOH (50/50), and $CHCl_3$/MeOH (15/85) successively. The fractions containing the product were collected, and the solvent was removed, yielding 77 mg (98%) of off-white solid. R_f = 0.74 (SiO_2, $CHCl_3$/MeOH 15/85). ^{1}H NMR (200 MHz, 25 °C, DMSO-d_6) δ 8.8 (s, 1H, -CH^6-, arom. pyridine), 8.6 (s, 1H, Boc-NH-N*H*-), 8.5 (d, J = 2.4 Hz, 1H, Boc-N*H*-NH-), 8.3 (s, 1H, -CH_2−N*H*CO-pyridine), 7.9 (d, J = 8.8 Hz, 1H, -CH^4-, arom. pyridine), 7.8 (m, 2H, arom. Fmoc), 7.7 (d, J = 7.2 Hz, 2H, arom. Fmoc), 7.5 (m, 2H, arom. Fmoc), 7.3 (m, 2H, arom. Fmoc), 6.5 (d, J = 8.8 Hz, 1H, -CH^3-, arom. pyridine), 4.3−4.2 (m, 3H, -C*H*-CH_2-OCO-, Fmoc), 3.9 (m, 1H, -C*H*-COOH), 3.2 (m, 2H, -CH_2-NHCO-pyridine), 1.8−1.5 (m, 4H, -$(CH_2)_2$-), 1.4 (s, 11H, -$C(CH_3)_3$, -CH_2-). ^{13}C NMR (50 MHz, 25 °C, DMSO-d_6) δ 173 (-COOH), 165 (-NHCO-pyridine), 156 (-NHCOO-Fmoc and Boc), 148 (-C^{6}H-, arom. pyridine), 143 (arom. Fmoc), 141 (arom. Fmoc), 139 (-C^{4}H-, arom. pyridine), 129 (arom. Fmoc), 128 (arom. Fmoc), 127 (arom. Fmoc), 124 (-C^{5}H-, arom. pyridine), 110 (-C^{3}H-, arom. pyridine), 79 (-*C*$(CH_3)_3$), 66 (-CH_2-, Fmoc), 54 (-*C*H-COOH), 47 (-CH-, Fmoc), 31 (-CH_2-), 28 (-CH_2-), 25 (-C(*C*$H_3)_3$), 22 (-CH_2-). MS-ESI: *m*/*z* 627 (calcd. 627) $[M + Na]^+$; Anal. ($C_{32}H_{37}N_5O_7$) C, H, N.

*Nα-(carbobenzyloxy)-Nϵ[6-(tert-butoxycarbonylhydrazinpyridyn)-3-carboxyl]-*L-*Phenylalanine Benzyl Ester (**11**).* 6-Boc-hydrazinpyridyn-3-carboxylic acid (0.177 g, 0.7 mmol), HBTU (0.7 mmol, 0.266 g), and DIPEA (0.636 g, 4.9 mmol) were dissolved in acetonitrile (3 mL), followed by compound **10** (0.28 g, 0.7 mmol). The resultant mixture was irradiated by MW 100 W for 20 min. Solvent was removed by rotary evaporation, and the product was purified by chromatography in silica using ethyl ether as eluent. Fractions containing the product were collected, the solvent was removed by rotary evaporation, and the residue was dried under reduced pressure, yielding 0.35 g (80%) of a yellow oil. R_f = 0.66 (SiO_2, Et_2O). ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS) δ 8.6 (s, 1H), 7.9 (d, J = 8.8 Hz, 1H), 7.5 (d, J = 7.8 Hz, 2H), 7.2 (s, 10H), 6.9 (d, J = 7.8 Hz, 2H), 6.6 (d, J

= 8.8 Hz, 1H), 5.2 (m, 4H), 4.6 (m, 1H), 3.0 (s, 2H), 1.5 (s, 9H). ^{13}C NMR (50 MHz, $CDCl_3$, 25 °C, TMS) δ 170, 164, 160, 155, 154, 146, 135, 133, 130, 128, 127, 121, 120, 104, 81, 66, 65, 54, 36, 28. MS-ESI: *m/z* 639 (calcd.) 639 $[M]^+$; Anal. ($C_{35}H_{37}N_5O_7$) C, H, N.

Nα-(fluorenylmethoxycarbonyl)-Nϵ[6-*(tert-butoxycarbonylhydrazinpyridyn)-3-carboxyl]*-L-*Phenylalanine* (**12**). Compound **11** (0.2 g, 0.31 mmol) was dissolved in ethanol (15 mL), and 10% Pd/C catalyst was added (20 mg). The reaction mixture was set in a Parr hydrogenation apparatus and purged with H_2 (10×), and the pressure was set to 40 psi for 2 days. At the end of the reaction, the solution was filtered to remove the catalyst, and the solvent was removed by rotary evaporation. The residue was vacuum-dried, yielding 125 mg (98%) of a yellow solid. R_f = 0.9 (SiO_2, MeOH), corresponding to the nonprotected amino acid derivative. mp = 250 °C. ^{1}H NMR (200 MHz, 25 °C, DMSO-d_6) δ 11.0 (s, 1H), 8.9 (s, 1H), 8.8 (s, 1H), 8.7 (d, J = 2.4 Hz, 1H), 8.2 (dd, J = 2.4 Hz, 8.8 Hz, 1H), 7.7 (d, J = 8.6 Hz, 2H), 7.6 (s, 1H), 7.2 (d, J = 8.6 Hz, 2H), 6.5 (d, J = 8.8 Hz, 1H), 3.9 (m, 1H), 3.1 (m, 2H), 2.1 (s, 2H), 1.4 (s, 9H). ^{13}C NMR (50 MHz, 25 °C, DMSO-d_6) δ 170, 164, 161, 156, 148, 139, 138, 130, 129, 128, 120, 105, 79, 54, 28. MS-ESI: *m/z* 415 (calcd. 415) $[M]^+$; Anal. ($C_{20}H_{25}N_5O_5$) C, H, N.

The obtained intermediate (50 mg, 0.13 mmol) was dissolved in DMSO (2 mL) and was set under inert atmosphere and 0 °C in an ice bath. Fmoc-succinimide (40 mg, 0.13 mmol) in DMSO (2 mL) was slowly added under inert atmosphere. The reaction mixture was allowed to stand at RT overnight, and reaction completion was monitored by HPLC and MS-ESI. Reaction conversion was quantitative, and therefore the reaction mixture can be used without purification for SPPS. The solvent was removed by rotary evaporation, and the product was purified by column chromatography in silica gel 60 (70−230 mesh) using as eluents $CHCl_3$, $CHCl_3$/MeOH (50/50), and $CHCl_3$/MeOH (15/85) successively. The fractions containing the product were collected, and the solvent was removed, yielding 74 mg (97%) of light yellow solid. R_f = 0.58 (SiO_2, $CHCl_3$/MeOH 15/85). ^{1}H NMR (200 MHz, 25 °C, DMSO-d_6) δ 9.0 (s, 1H, -CH^6-, arom. pyridine), 8.8 (s, 1H, Boc-NH-N*H*-), 8.7 (d, J = 2.4 Hz, 1H, Boc-N*H*-NH-), 8.0 (d, J = 8.6 Hz, 1H, -CH^4-, arom. pyridine), 7.8 (m, 2H, arom. Peptide Conjugates Technetium-99m Labeling. Radiolabeling was carried out in a glass vial by adding 10 μL (10 μg) of each HYNIC−OT derivative, 0.5 mL of tricine/ethylendiaminediacetic acid (EDDA) solution (40 mg of tricine plus 20 mg of EDDA in 1 mL of 0.2 M phosphate buffer), 25 μL of $SnCl_2$ solution (1 mg/mL of stannous chloride in 10 mM HCl), and 740−1110 MBq (0.5 mL) of ^{99m}Tc-pertechnetate (^{99}Mo/^{99m}Tc generator system, GETEC-Mexico), followed by incubation at 90 °C for 30 min in a dry block heater.

Evaluation of Radiochemical Purity. Radiochemical purity analyses were performed by instant thin-layer chromatography on silica gel (ITLC-SG, Gelman Sciences), solid-phase extraction (Sep-Pak C-18 cartridges), and reverse-phase high-performance liquid chromatography (HPLC).

ITLC-SG analysis was accomplished using three different mobile phases: 2-butanone to determine the amount of free $^{99m}TcO_4^-$ (R_f = 1), 0.1 M sodium citrate pH 5 to determine ^{99m}Tc-coligand and $^{99m}TcO_4^-$ (R_f = 1), and methanol/1 M ammonium acetate (1:1 v/v) for ^{99m}Tc-colloid (R_f = 0). R_f values of the radiolabeled peptide in each system were 0.0, 0.0, and 0.7−1.0, respectively.

The Sep-Pak cartridges were preconditioned with 5 mL of ethanol, followed by 5 mL of 1 mM HCl and 5 mL of air. An aliquot of 0.1 mL of the labeled peptide was loaded on the preconditioned Sep-Pak cartridge, followed by 5 mL of 1 mM HCl to elute free $^{99m}TcO_4^-$. The radiolabeled peptide was eluted with 3 mL of ethanol/saline (1:1), and the hydrolyzed−reduced ^{99m}Tc or ^{99m}Tc-colloid remained in the cartridge.

HPLC analyses were carried out with a Waters instrument running Millenium software with both radioactivity and UV-photodiode array in-line detectors, and YMC ODS-AQ S5 column (5 μm, 4.6 × 250 mm) at a flow rate of 1 mL/min using the gradient system described above. In this system, retention times for free $^{99m}TcO_4^-$, ^{99m}Tc-coligand, and ^{99m}Tc-EDDA/HYNIC-OT were 3 min, 3.5−4.5 min, and 12 min, respectively.

Plasma Stability. A volume of 10 μL of the labeled peptide solution (0.8 μg/10 μL) was incubated at 37 °C with 1 mL of fresh normal female human plasma, and also with 1 mL of phosphate buffer as a control. Radiochemical stability was determined by taking samples of 50 μL at different times from 30 min to 24 h for analysis. The plasma protein in 50 μL of the sample was precipitated with acetonitrile and centrifuged at 1000 *g* for 5 min; the supernatant was removed, diluted 1:7 with saline solution, and analyzed by reverse-phase HPLC.

Competition Assay. In order to evaluate the biological integrity of the labeled peptides, a radioimmunoassay (RIA) was carried out comparing the competition of the labeled peptides and the unlabeled peptide binding to a limited quantity of specific antibody (Oxytocin radioimmunoassay kit, Peninsula Laboratories Inc., Bachem). ^{125}I-OT was used as the "gold" standard (IC_{50} = 0.05 nM), and the unlabeled peptide (oxytocin) was used in the range 1−128 pg/100 μL (0.01−1.28 nM). ^{99m}Tc-EDDA/HYNIC-Lys^8-OT-$CONH_2$ and ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-$CONH_2$ (both obtained with radiochemical purities higher than 96%) were purified by reverse-phase HPLC in order to eliminate the cold peptide and to obtain a radioligand concentration less than 1 pg/100 μL useful for the competition assay.

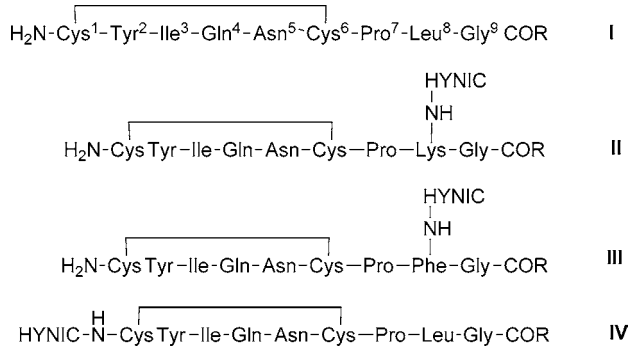
A plot of % B (binding)/Bo (total binding less nonspecific binding) versus the log of the unlabeled OT concentrations was generated for each labeled peptide: ^{125}I-OT, ^{99m}Tc-EDDA/HYNIC-Lys^8-OT-$CONH_2$, and ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-

$CONH_2$. The IC_{50} was calculated as the concentration of competitor (unlabeled OT) inhibiting 50% of the radioligand binding.

Cell Lines. Human breast carcinoma cell MCF7 line was originally obtained from ATCC (USA). The cells were routinely grown at 37 °C, with 5% CO_2 atmosphere and 100% humidity in RPMI medium supplemented with 10% newborn calf serum and antibiotics (100 μg/mL streptomycin).

Internalization Assay and Nonspecific Binding. MCF7 cells (1×10^6) supplied with fresh medium were incubated in 6-well plates with about 200 000 cpm of ^{99m}Tc-EDDA/HYNIC-Lys^8-OT-$CONH_2$ or ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-$CONH_2$ (0.2 nmol total peptide) for 2 h at 4 °C. Afterward, the preincubation cells were washed three times with ice-cold culture medium. Warmed culture medium was added to the plates, which were incubated in triplicate at 37 °C for 2, 4, 6, and 24 h in order to allow internalization. Cell-surface bound radioligand was removed in two steps of 5 min acid wash (50 mM glycine−HCl/100 mM NaCl, pH 2.8) at room temperature. Cells were solubilized by incubation with 1 N NaOH at 37 °C to determine internalized radioligand. Results were expressed as the percentage of total activity internalized. The nonspecific binding was determined in parallel but in the presence of 10 μM cold OT (Bachem-USA) to block OT receptor cells. Differences in the obtained cell binding data were evaluated with the Student *t* test.

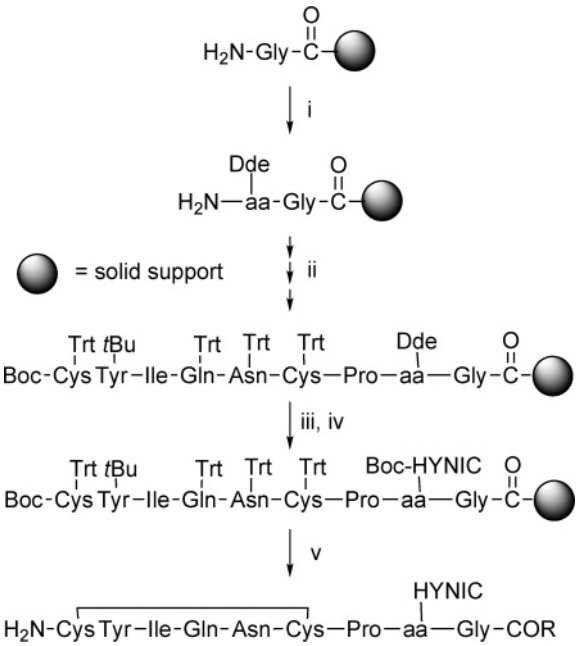
Imaging. Tumor uptake studies in mice were carried out according to the rules and regulations of the Official Mexican Norm 062-ZOO-1999.



Athymic male mice (20−22 g) were kept in sterile cages with sterile wood-shavings bed; constant temperature, humidity, and noise; and 12:12 light periods. Water and feed (standard PMI 5001 feed) were given ad libitum. Tumors were induced by subcutaneous injection of MCF7 cells (1×10^6) resuspended in 0.2 mL of phosphate-buffered saline, into the backside of 6−7 week old nude mice. The sites of injection were observed at regular intervals for the appearance of tumor formation and progression.

Athymic mice with induced tumors were used for imaging studies. ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-$CONH_2$ or ^{99m}Tc-EDDA/HYNIC-Lys^8-OT-$CONH_2$ (~1.11 MBq) in 0.04 mL was injected in the tail vein. The nude mice ($n = 4$) with the implanted tumors were scanned with a gamma camera with a pinhole collimator 2 h after the radiopharmaceutical was injected in the tail vein.

RESULTS



An orthogonal protection strategy was followed to prepare HYNIC-Lys and HYNIC-Phe as shown in Schemes 1 and 2. Thus, intermediates **4** and **10** were obtained in excellent yields. The later derivatives have the α-amino and carboxylic acid groups protected with Cbz and Bn, respectively. Intermediates **4** and **10** were reacted with Boc-HYNIC (Figure 1b) using HBTU as activating agent, to generate intermediates **5** and **11**. While this stage was smooth for the lysine derivative, ligand conjugation with **10** was not completed even after several days of reaction. In a first attempt to drive to completion the ligand coupling step with **10**, a succinimide active ester of Boc-HYNIC was used, giving similar results to those obtained with HBTU. Further attempts varying reaction conditions were also unsuccessful. As an alternative, microwave-assisted coupling was carried out, and thus, product **11** was obtained in high yield after 20 min irradiation at 100 W. The next steps for both amino acids proceeded without further complications, obtaining compounds **6** and **12** in good overall yields (76% and 61%, respectively) and enantiopurity.

Scheme 3 [a]

[a] (**I**) Oxytocin, (**II**) HYNIC-Lys^8-oxytocin, (**III**) HYNIC-Phe^8-oxytocin, and (**IV**) HYNIC-Cys^1-oxytocin. R = −OH or $-NH_2$.

Scheme 4. Synthesis of Oxytocin-HYNIC Peptides by SPPS Following an Orthogonal Protection Approach[a]

[a] (i) Dde-Lys or Dde-Phe (aa) coupling followed by Fmoc removal; (ii) succesive amino acid coupling; (iii) Dde removal with 2% hydrazine; (iv) Boc-HYNIC coupling; (v) protecting groups and peptide removal from solid support, cysteine oxidation, purification, and characterization.

The nanopeptide neurohypophysial hormone oxytocin (Scheme 3, **I**, R = $-NH_2$) was chosen as a model to demonstrate the utility of usage of derivatives **6** and **12** for the controlled HYNIC positioning of peptides during SPPS and henceforth for generating HYNIC−peptide libraries to screen specific activity.

The linear part of OT was chosen as one of the targets to place HYNIC within the peptide based on previous knowledge. For this work, the Leu^8 residue was selected as the point to be substituted by the HYNIC-Lys (Phe) residues (Scheme 3, **II** and **III**). Additionally, for comparison, the synthesis of **II** and **III** was also carried out following an orthogonal protection approach (Scheme 4) using a *N*-2-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethylamine (Dde)-protected lysine derivative (Figure 2a) commercially available or a *p*-aminophenylalanine derivative protected with Dde in the *p*-amino group recently prepared by our group (unpublished results) (Figure 2b). A HYNIC-α-amide-Cys^1 derivative was also synthesized despite the fact that the ligand stays inside the cyclic part of the peptide (Scheme 3, **IV**). In all cases, peptides were prepared with both carboxylic and amide groups by using different solid supports. Synthesis of these derivatives and the OT native peptide was

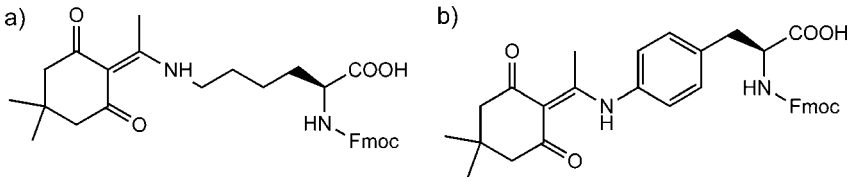


Figure 2. (a) Nϵ-Dde-Nα-Fmoc-lysine and (b) pN-Dde-Nα-Fmoc-phenylalanine.

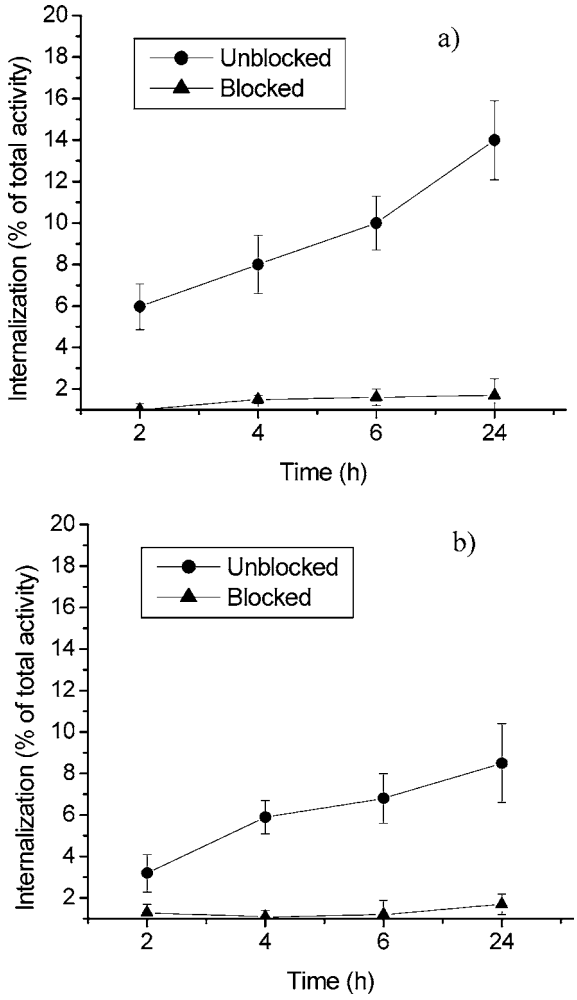

Figure 3. Time-dependent internalization of (a) ^{99m}Tc-EDDA/HYNIC-Lys^8-OT-CONH$_2$ and (b) ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-CONH$_2$ in unblocked and blocked MCF7 cells expressed as % of total activity (mean ± sd, $n = 3$). Blocked cells were incubated with an additional receptor blocking dose of unlabeled OT in order to determine the nonspecific binding of radioactivity.

carried out using commercially available reagents following standard Fmoc SPPS protocols, and step reactions were assisted by microwave radiation in order to minimize reaction times and to demonstrate the suitability of using this procedure for the quick generation of peptide-ligand libraries. The microwave-assisted synthesis of the full peptides was accomplished very rapidly (ca. 40 min per peptide, not considering purification), which compared to classical SPPS protocols (ca. 30 h, not considering purification) is very attractive for generating peptide conjugate libraries. Following cleavage from the resin and total deprotection, cysteine oxidation for the crude peptides was obtained quantitatively in 5 min using 2,2′-bispyridyl disulfide. Crude cyclic peptides were purified by semipreparative HPLC yielding peptides **I**−**IV**. The global yield for peptides **II** and **III** prepared via the HYNIC prelabeled amino acids **6** and **12** was approximately 20% in both cases and 40% when the same peptides were prepared by an orthogonal protection approach, all carried out under the same nonoptimized reaction conditions

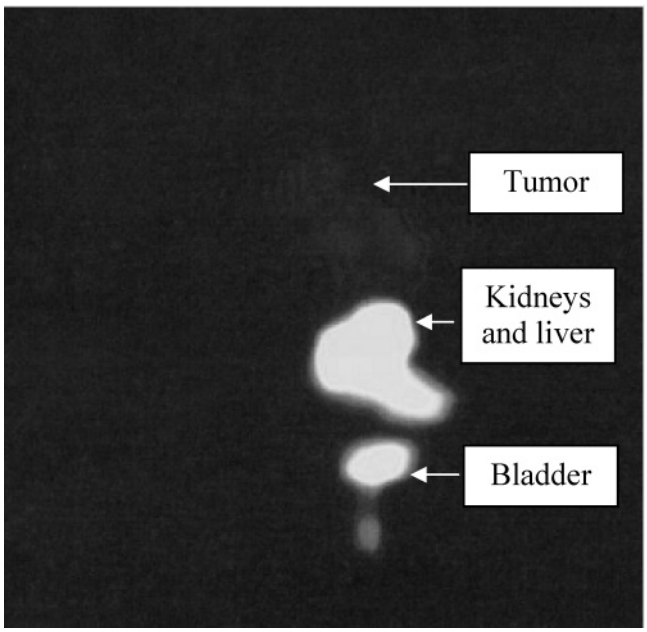

Figure 4. Uptake of ^{99m}Tc-EDDA/HYNIC-Lys^8-OT-CONH$_2$ in tumor MCF7 cells in athymic mouse (whole mouse).

(reaction time, reactant equivalents, temperature, etc.). On the other hand, yields were not dependent on the type of resin used for the synthesis. Furthermore, higher global yields can be obtained when reaction conditions are independently optimized for each peptide for a given procedure.

Peptide labeling efficiencies of these peptides with ^{99m}Tc and EDDA were tested, and the results showed low labeling yields for **I** and **III** (10% and 40%, respectively), while for **II** and **IV**, yields above 96% were obtained. In addition, a 40% ^{99m}Tc-EDDA labeling efficiency for a Boc,Fmoc-deprotected HYNIC-Phe derivative of **12** was observed. Biological integrity of the labeled OT peptides ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-CONH$_2$ and ^{99m}Tc-EDDA/HYNIC-Lys^8-OT-CONH$_2$ was determined by a radioimmunocompetition binding assay. Thus, it was found that a ^{125}I-OT peptide has an IC_{50} value of 0.05 nM, while peptides ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-CONH$_2$ and ^{99m}Tc-EDDA/HYNIC-Lys^8-OT-CONH$_2$ have IC_{50} values of 0.2 and 1 nM, respectively. Therefore, IC_{50} values less than 10 nM indicate that both peptides maintain an important biological recognition. After 24 h in human plasma, the radiochemical purity of ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-CONH$_2$ remained higher than 90%, while the radiochemical purity of ^{99m}Tc-EDDA/HYNIC-Lys^8-OT-CONH$_2$ decreased to 15%.

Results of the in vitro assays showed a rapid internalization and a specific receptor binding of ^{99m}Tc-EDDA/HYNIC-Lys^8-OT-CONH$_2$ and ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-CONH$_2$ to MCF7 cells, since there were significant differences in the percentage of uptake between blocked receptor and unblocked receptor cells at different times ($p < 0.05$) (Figure 3). In vivo images of ^{99m}Tc-EDDA/HYNIC-Lys^8-OT-CONH$_2$ and ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-CONH$_2$ showed that the highest non-specific uptake was found in the kidneys and in lower amounts in the liver (Figures 4 and 5). However a clear tumor uptake

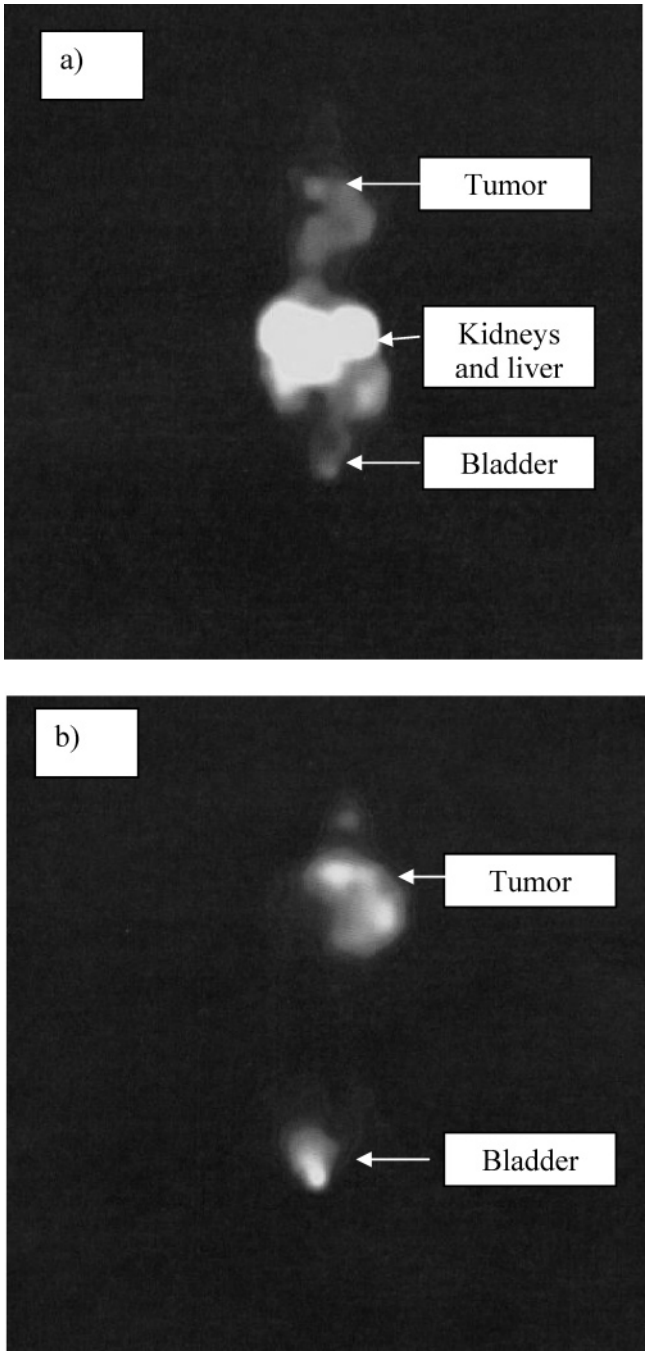

Figure 5. Uptake of ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-CONH$_2$ in tumor MCF7 cells in athymic mouse: (a) whole mouse; (b) mouse with dissection of internal viscera to highlight tumor uptake.

was only observed for ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-CONH$_2$ (Figure 5).

DISCUSSION

In this work, unlike the report indicated above for the synthesis of the lysine derivative **6** (*12*), blocking the carboxylic acid group was done to minimize side reactions such as mixed ligand−amino acid anhydride formation, and thus, **6** was prepared in a good overall yield. Moreover, as for the phenylalanine derivative, the observed lack of reactivity of **10** can be explained by the weaker nucleophilicity of the *p*-amino group in Phe when compared to the ϵ-amino aliphatic group of the lysine derivative. Furthermore, the MW-assisted ligand coupling with **10** gives an alternative for the future efficient synthesis of Phe−ligand peptide libraries when either an orthogonal protection or a prelabeled amino acid approach is followed.

The lower peptide yields obtained for the prelabeled amino acid approach when compared to the orthogonal protection procedure can be attributed to an increase in peptide aggregation in the resin, given the higher probability of hydrogen bonding formation due to the HYNIC unit being readily attached to the solid support.

The HYNIC−OT radiolabeling results show that ^{99m}Tc is complexed to the peptide through HYNIC and also that labeling efficiency depends on the nature of the amino acid where HYNIC is attached. The poor ^{99m}Tc labeling efficiency for **III** can be attributed to a lower electron-donation ability of the hydrazine group of HYNIC toward the metal, provoked by the conjugation of the ligand to the *p*-amino aromatic amino acid and not by the conjugate−peptide structure.

As previously mentioned, it has been shown that OT receptors have weak selectivity to peptides sharing the same cyclic part (from Cys^1 to Cys^6). This indicates that the cyclic part of OT is more important in conferring binding affinity for the OT receptor compared with the linear tripeptidic part of the hormone (from Pro^7 to Gly^9) (*13*). However, our results showed that peptide−ligand conjugation in the tripeptide part diminishes binding affinity to a higher extent than when the peptide is labeled in the Cys^1 residue. This is opposite to what has been hypothesized previously on the basis of what is known of the nonconjugated peptide (*18*, *19*).

^{99m}Tc-EDDA/HYNIC-Lys^8-OT-CONH$_2$ degradation in plasma and its poor in vivo tumor uptake might be caused by the effect of the oxytocinase enzyme, which acts on the N-terminal Cys^1 residue (*16*). Furthermore, the plasma stability and in vivo tumor uptake of ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-CONH$_2$ could support the hypothesis that the introduction of HYNIC-Cys^1 produces a protective steric effect on the amide bond susceptible to hydrolysis by P-LAP, which acts on the N-terminal Cys^1 residue.

These results justify further in vitro and in vivo evaluations of ^{99m}Tc-EDDA/HYNIC-Cys^1-OT-CONH$_2$ as a potential radiopharmaceutical for diagnosis of OT receptor overexpressing tumors and might be useful for further understanding of the OT cancer regulation mechanisms, particularly where OT has shown to have an inhibitory growth effect.

Finally, we can conclude that, when designing peptide-based ligand conjugates for diagnostic or therapeutic applications and determining the best ligand position, the use of conventional wisdom (such as known structure−activity relationships for the nonconjugated peptide) as prescribed by numerous studies may be a time-saving, and on occasion convenient, approach. However, as this work has demonstrated, challenging conventional wisdom—while time-consuming and seemingly foolhardy—can also lead to exciting possibilities. This research has provided and demonstrated the utility of different chemical tools to generate ligand−peptide libraries when searching for that metal−peptide conjugate that can have the desired characteristics.

Self-Organized Nanogels Responding to Tumor Extracellular pH: pH-Dependent Drug Release and *in Vitro* Cytotoxicity against MCF-7 Cells

Kun Na,[†] Eun Seong Lee,[‡] and You Han Bae*[,‡]

Division of Biotechnology, The Catholic University of Korea, 43-1 Yeokgok 2-dong, Wonmi-gu, Bucheon-si, Gyeonggi-do 420-743, Korea, and Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, 421 Wakara Way, Suite 315, Utah 84108. Received February 14, 2007; Revised Manuscript Received June 8, 2007

The principal objective of this study was to fabricate doxorubicin-loaded self-organized nanogels composed of hydrophobized pullulan (PUL)-N_α-Boc-L-histidine (bHis) conjugates. Their responses to tumor extracellular pH (pH_e) were determined, and they were also evaluated with regard to their anticancer efficacy against breast cancer cell lines (MCF-7). bHis was grafted to a PUL-deoxycholic acid (DO) conjugate (PUL−DO) via an ester linkage. PUL−DO/bHis conjugates with two different degrees of bHis substitutions (PUL−DO/bHis36 and PUL−DO/bHis78) were synthesized. PUL−DO/bHis nanogels formed via dialysis at a pH of 8.5 evidenced larger particle sizes (<140 nm) and lower critical aggregation concentrations (CACs) than did the PUL−DO nanogels (90 nm). The pH-dependent CAC of PUL−DO/bHis78 changed dramatically, from 1.2 μg/mL at pH 8.5, to 10 at 7.0, and to 660 at 6.2. A similar tendency in pH-dependent size was also noted. The ionization of the imidazole ring in bHis is principally responsible for pH dependency. The bHis moieties function as a switching tool responding to external pH. Doxorubicin (DOX)-loaded nanogels were assessed for pH-dependent releasing kinetics. The release rate of DOX from the PUL−DO/bHis78 nanogels increased significantly with reductions in pH. This resulted in increased cytotoxicity (30% cell viability at a dose of 10 μg/mL DOX equivalent) against sensitive MCF-7 cells at a pH of 6.8 and low cytotoxicity at pH 7.4 (65% cell viability at an identical dose). The results show that PUL−DO/bHis nanogels may potentially be employed as anti-tumor drug carriers.

INTRODUCTION

The switching of release kinetics in nanocarriers of anticancer drugs, from a slow rate during circulation to a fast rate at tumor sites, has been hypothesized to benefit chemotherapy, as the dose−response relationship (log[dose] vs cell viability) of most anticancer drugs evidence a typical sigmoidal curve, where the viability sharply decreases as drug concentration increases above a certain threshold value (*1*−*4*). It is believed that slow release prior to the reaching of the target tumor site reduces drug-induced side effects, while fast release kinetics tend to improve tumor treatment (*5*−*7*).

To realize such switching properties of release kinetics, a variety of approaches have been attempted, including the construction of thermoresponsive polymeric micelle systems that respond to hyperthermic conditions (42 °C) (*2*), and pH-sensitive systems that respond to endosomal pH via the cleavage of pH-labile chemical bonds (*8*). This research group has reported novel pH-responsive nanosystems predicated on acidic sulfonamide (*1*, *4*, *9*−*11*) and basic histidine chemistries (*3*, *12*−*14*) which effect the switching of a variety of physicochemical properties of nanocarriers, including surface hydrophobicity, drug release rates, and stability, by lowering the pH from 7.4 to 6.8. Among these systems, it was shown that mixed micelles constructed from poly(L-histidine) (polyHis)-*b*-PEG and polylactide-*b*-PEG evidenced a destabilization pH that was tunable to the tumor extracellular pH (around pH 6.8) and early endosomal pH, via alterations in the micelle composition (*12*, *13*). The imidazole ring of histidine harbors lone electron pairs on the unsaturated nitrogen that confers pH-dependent amphoteric properties (*15*−*17*). In addition, the dissociated block copolymer of polyHis and PEG evidence a profound endosomolytic property, which might facilitate drug escape from endosomal sequestration. This micelle system was shown to be effective in the treatment of sensitive and drug-resistant tumors in both *in vitro* and animal experiments (*14*). One of the disadvantages of this micelle system is its time- and labor-intensiveness, coupled with the high cost of polymer preparation, including synthesis, purification, and the relatively limited yields possible.

To devise a more practical method for the preparation of nanosystems with equivalent or similar pH sensitivity to polyHis-based micelles, the nanogel approach was adopted in this study, in place of the polymeric micelles. Hydrophobized polysaccharides self-assemble via the appropriate methods into nanogels consisting of multicores and a hydrophilic shell, allowing for the achievement of low Gibb's energy in water. The nanogels enclose water-insoluble drugs within their cores, thus minimizing interactions with biological components (*18*, *19*). The nanogels can be further functionalized as the result of the abundance of hydroxyl groups along the polymer chain.

Pullulan (PUL; Scheme 1a) is a linear polysaccharide which harbors an α-(1-6)-linked maltotriosyl repeating unit, and is known to be biocompatible. Its derivatives have been evaluated with regard to their potential use in the pharmaceutical industry and the biomedical field (*19*, *20*). Deoxycholic acid (DO; Scheme 1b), a bile acid, can function as a noncovalent cross-linking moiety, forming polycores in the nanogel. *N*-Boc-histidine (bHis; Scheme 1d) was introduced as a pH-sensitive moiety into a PUL/DO conjugate. All conjugation occurred via the formation of an ester linkage between the hydroxyl group of PUL and the carboxyl group on DO and bHis. Doxorubicin-loaded PUL−DO/bHis nanogels were evaluated via the monitoring of pH-dependent drug release behavior and cytotoxicity against sensitive breast tumor cells (MCF-7).

Scheme 1. Chemical Structures of Pullulan (PUL) (a), Deoxycholic Acid (DOCA) (b), N_α-Boc-L-histidine (bHis) (d), and Synthesis Schemes of PUL−DO (c) and PUL−DO/bHis Conjugates (e)

EXPERIMENTAL PROCEDURES

Materials. Pullulan (PUL) (MW: 200 000 kDa) was acquired from Hayashibara (Okayama, Japan). Deoxycholic acid (DO), N_α-Boc-L-histidine (bHis), folate (Fol), dicyclohexyl carbodiimide (DCC), 4-dimethylaminopyridine (DMAP), doxorubicin (DOX), and pyrene were obtained from the Sigma Chemical Company (St. Louis, Mo, USA). All other chemicals utilized in this study were of reagent grade.

Synthesis of PUL−DO and PUL−DO/bHis Conjugates. All conjugations between the PUL hydroxyl group and the DO and His carboxyl groups were conducted via the conventional carbodiimide reaction. First, PUL−DO was synthesized via DCC- and DMAP-mediated ester formation. 12 mM of DO was added to dried DMSO containing 0.1 mM of PUL, 15 mM of DCC, and 12 mM of DMAP, and maintained at room temperature for 24 h. The reactant mixture was then filtered and dialyzed for 2 days against distilled water using a dialysis tube (molecular cutoff: 12 000 kDa). The distilled water was changed every 3 to 6 h. The PUL−DO conjugate (Scheme 1c) was recovered via filtration and thoroughly washed with diethyl ether and distilled water, after which it was lyophilized. In order to completely remove the nonreactants, the lyophilized sample was again dissolved in DMSO and dialyzed against distilled water. This process was repeated 3 times. The conjugation of His into PUL−DO was conducted via a similar method for PUL−DO. 50 and 100 mM quantities of His were added to dried DMSO containing 700 mg of PUL−DO, DCC (55 and 110 mM), and DMAP (40 and 80 mM), respectively, and maintained for 24 h at room temperature (Scheme 1e). The other steps were similar to the PUL−DO conjugation method.

The degree of substitution (DS), which is defined as the number of DO and His groups per 100 anhydroglucose units of PUL, was determined via nuclear magnetic resonance (^{1}H NMR, 300 MHz). The NMR measurements were obtained with all samples dissolved in DMSO-d_6 (Aldrich, Milwakee, WI). The ^{1}H NMR spectra of PUL−DO (Supporting Information Figure S-1): δ 0.6 to δ 2.3 (−CO−C***H***$_2$− on DO) for DO and broad multiple peaks in the range 3−5.5 ppm for PUL. The degree of substitution (DS) was calculated at a ratio of δ 5.0 (proton peak of −O−C***H***$_2$−O− on the glucose of PUL) to δ 2.3 (−CO−C***H***$_2$− on DO). The number of DO units per 100 PUL glucose units DS was 8.36. The ^{1}H NMR spectra of PUL−DO/His was as follows: δ 0.8−1.0 (−C***H***$_3$− on Boc group) and δ 6.8 and δ 7.6 (−C***H***− on imidazole ring) for His. The degree of substitution (DS) was calculated at the ratio of δ 5.0 (proton peak of −O−C***H***$_2$−O− on the glucose of PUL) to δ 4.7 (−C***H***− on His). DS of PUL−DO/bHis36 and PUL−DO/bHis78 were 36 and 78, respectively.

Preparation of Self-Organizing Nanogels from the Conjugates. Self-organizing nanogels were prepared via the dialysis method (molecular cutoff: 2000 kDa). Each 50 mg portion of conjugate was dissolved in 20 mL of DMSO. The solutions were then stirred at room temperature and dialyzed for 3 days against distilled water. The solution was filtered with a 0.45 μm filter in order to remove the precipitated material.

Measurement of the pK_a Values of PUL−DO/bHis Conjugates. The pK_a values of PUL−DO/bHis conjugates were determined via classical acid−base titration. The conjugates were dissolved in deionized water, and then the solution was adjusted to a pH of 2 with 1 M HCl. The diluted solution was then titrated with 1 M NaOH solution in a stepwise manner in order to obtain the titration profiles. NaCl solution (identical concentration) was employed as a control and compared with the buffering effects of the conjugates.

Light Transmittance of Nanogel Solution. The optical transmittance of the nanogel solution (1 g/L) at various pHs

was measured at 500 nm using a Varian Cary 1E UV/vis spectrometer. The pH was lowered gradually via the addition of 0.01 M HCl solution, and the relative transmittances (%) at differing pH values were expressed relative to the transmittance at pH 9.0 (100%).

Particle Size Analysis. The particle size was determined via dynamic light scattering (DLS; Zetasizer 3000, Malvern Instruments LTD, UK), using an argon ion laser at a wavelength of 488 nm and a scattering angle of 90°. Each of the samples was filtered through a 0.45 μm filter directly into a precleaned cylindrical cell (diameter: 10 mm). The sample concentration was maintained at 1.0 mg/mL.

Measurement of Critical Aggregation Concentration (CAC). A stock solution of pyrene (6.0×10^{-2} M) in acetone was prepared and stored at 5 °C until use. In order to measure the steady-state fluorescence spectra, this solution was added to distilled water, yielding a pyrene concentration of 12.0×10^{-7} M. The solution was then distilled under vacuum at 60 °C for 1 h in order to remove the acetone from the solution. The acetone-free pyrene solution was mixed together with solutions containing self-organized nanogels at a range of concentrations from 1×10^{-4} mg/mL to 1.0 mg/mL. The final pyrene concentration in each sample solution was 6.0×10^{-7} M, which is nearly equal to its solubility in water at 25 °C (*21*).

Morphological Observations of the PUL−DO/bHis Nanogels. In order to observe the nanoparticles in a dried state, a drop of the self-organized nanogels was dissolved in water and positioned on a carbon-coated copper grid, then dried under vacuum at 30 °C. The samples were observed without staining via transmission electron microscopy (TEM; Philips CM 30, Philips Electron Optics, Eindhoven, The Netherlands) at 80 kV.

DOX Loading and Release. DOX·HCl (0.1 mM) and 1.3 molar equiv triethylamine were allowed to react in dimethylsulfoxide (DMSO) (3 mL) to form the DOX basic adduct. Each of the conjugates (50 mg) was added to the DOX solution, and the mixture was stirred overnight at 4 °C in darkness. The conjugate/DOX solution was then transferred to dialysis tubing (Spectra/Por; molecular weight cutoff: 1000 kDa) and dialyzed against a 0.01 M phosphate buffered saline (PBS) solution (pH = 8.5) for 3 days at 25 °C. The buffer was exchanged with fresh solution every 3 h for the first 24 h, and then daily. The solution was then filtered through a 0.45 μm filter in order to remove any polymer or drug that had precipitated out of solution, and was freeze-dried in order to obtain the DOX-loaded nanogels. To evaluate the drug-loading capacity of these nanogels, a freeze-dried sample was added to DMF, stirred vigorously for 2 h, then sonicated for 3 min. The resultant solution was centrifuged for 30 min at 20 000 × *g*, and the supernatant was analyzed with an ultraviolet (UV) spectrophotometer at 490 nm. Using a linear standard curve out of free DOX in *N*,*N*-dimethylacetamide (DMAc), the loading amounts could be calculated and were determined to be 13 ± 4.4%, 19 ± 6.1%, and 24 ± 6.9% (w/w) for PUL−DO, PUL−DO/bHis36, and PUL−DO/bHis78, respectively.

The release rate was measured at various pHs (7.8, 7.4, 6.8, and 6.2) as follows: 2 mL of the drug-loaded nanogel solution (1 g/L) was transferred in 10 mL of PBS to a dialysis tube. The release medium was stirred at 100 rpm at 37 °C. PBS buffer was used at the same ionic strength. At the predetermined sampling time, all of the media were removed and replaced with fresh solution in order to maintain a sink condition. The amount of DOX in the solution was determined via UV spectroscopy at 490 nm.

Cytotoxicity of DOX-Loaded Nanogels at Different pH. MCF-7 cells (5×10^4 cells/mL) harvested as a monolayer from growing cells were seeded in a 96-well plate in 200 μL of RPMI 1640 medium 24 h prior to the cytotoxicity test. Free DOX or DOX-loaded nanogels in RPMI 1640 medium (in PBS pH 7.4 or 6.8 and adjusted with 0.1 N NaOH or 0.1 N HCl) were prepared immediately prior to use, as in the previously described report (*12*), added to the medium-removed 96-well plates with different DOX concentrations, and incubated for 48 h. Chemosensitivity was assessed via the tetrazolium salt MTT assay. 100 μL of PBS at a pH of 7.4 containing 20 μL of MTT (1.2 mM) solution was added to each well. The plate was incubated for an additional 4 h, and then 100 μL of DMSO was added to each well. The absorbance of each well was read on a microplate reader using a test wavelength of 570 nm and a reference wavelength of 630 nm.

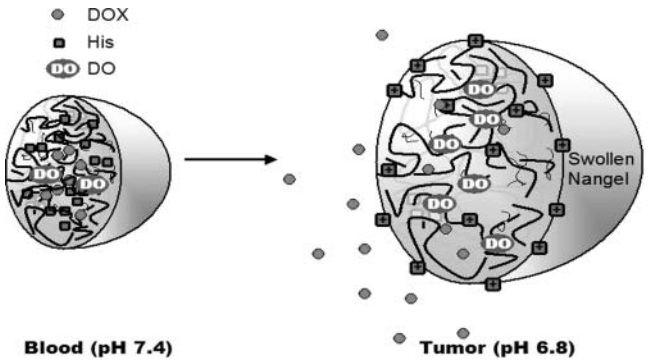

Figure 1. Schematic representation of pH-dependent anti-cancer drug release from proposed pH-sensitive PUL−DO/bHis nanogels. At normal pH (7.4), the nanogels are stable, and so the drug release rate is slower. However, at tumor acidic pH (6.8), the nanogels evidence swelling or disruption behavior as the result of changes in internal structure, resulting in accelerated drug release.

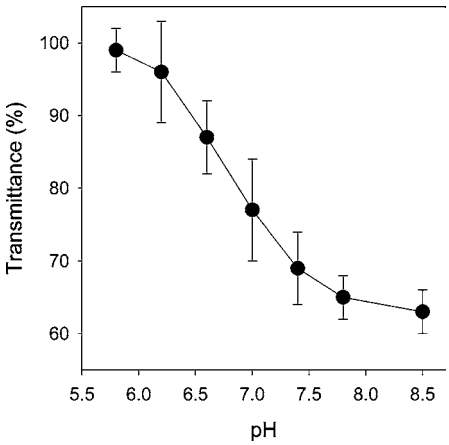

Figure 2. Change in transmittance of PUL-His66 nanogels (1 g/L) on decreasing pH. Data represent a mean ± SD; $n = 3$.

Statistical Analysis. Statistical analyses were conducted using the *SPSS* software package (version 11.0, SPSS Inc., Chicago). The descriptive data are presented as the means ± standard deviations. The cytotoxicities of the three groups (PUL−DO, PUL−DO/bHis78, and free DOX) against the MCF-7/DOX cells were compared via ANOVA tests. The differences were considered significant if the p value was less than 0.05.

RESULTS AND DISCUSSION

In order to develop an easy process for the acquisition of self-organized nanogels responding to tumor pH_e, we synthesized PUL−bHis conjugates with ester linkages between OH in PUL and COOH in His (degree of substitution of N_α-Boc-L-histidine (His) per 100 anhydroglucose unit of pullulan: 66). The conjugates evidenced a pH-sensitive dissociation in the pH range 7.8−6.2 (Figure 2). After dialysis for the preparation of the nanogel from PUL−His conjugate at pH 8.5, a considerable

Table 1. Physicochemical Characterization of Self-Assembled Nanogels on the pK_a, Critical Aggregation Concentrations (CAC), and Particle Sizes at pH 8.5

sample name	DS[a−1] of DO	DS[a−2] of bHis	pK_a[b]	CAC[c] (μg/mL)	d[d] ± SD (nm)
PUL−DO	8.36			5.6	85 ± 68
PUL−DO/bHis36	8.36	35.88	6.7	3.6	109 ± 84
PUL−DO/bHis78	8.36	78.39	6.4	1.2	130 ± 94

[a] DS indicates the degree of substitution in conjugates based on the ^{1}H NMR results. [a−1]Degree of substitution of deoxycholic acid (DO) per 100 anhydroglucose units of pullulan. [a−2]Degree of substitution of N_α-Boc-L-histidine (bHis) per 100 anhydroglucose units of pullulan. [b] pK_a values of bHis in the conjugates were determined via classical acid−base titration. The conjugates were dissolved in deionized water, and the solution was adjusted to pH 10 with 1 M NaOH. The diluted solution was then titrated via a stepwise decrease of 0.1 N HCl solution in order to determine the titration profiles. NaCl solution (identical concentration) was used as a control for comparison of the buffering effects with those of the conjugates. [c] Critical aggregation concentration (CAC) in aqueous solution (pH 8.5) as determined by fluorescence spectroscopy. [d] Mean diameter in aqueous solution (pH 8.5) measured by DLS.

reduction in the transmittance of the solution was observed, which is indicative of the formation of nanogels in aqueous media (pH 8.5). As the pH decreased, the transmittance increased continuously until a pH of 6.2 was reached. In particular, at pH values below 7.4, the change was more dramatic. Unfortunately, the nanogels evidenced neither sufficient loading efficiency for an anti-tumor drug (DOX, below 6 wt %) nor good drug loading capacity at a pH of 7.4 (Supporting Information Figure S-2). This result is quite similar to our previous result (*21*). Thus, we elected to employ a hydrophobically modified polysaccharide in order to improve drug loading and holding. DO was selected as a hydrophobic moiety, as its potential has already been established in a variety of reports (*22*, *23*).

Physicochemical Characterization of PUL−DO/bHis Nanogels. The pK_a of imidazole in PUL−DO/bHis36 and PUL−DO/bHis78 was estimated via classical acid−base titration, in order to define their ionization patterns. The value of PUL−DO/bHis78 was found to be lower than that of PUL−DO/bHis36 (Table 1). In general, as monomers with cationic groups are coupled to polymers with hydrophobic segments, the pK_a of the groups normally shifts toward a lower range of pH. As the hydrophobic and chargeable groups are in close proximity (*24*), the hydration of the chargeable groups is reduced as the result of influence from the hydrophobic segment. Thus, it appears that this tendency resulted in different pK_a values between PUL−DO/bHis36 and PUL−DO/bHis78.

The size of self-organized nanogels and size distributions at pH 8.5 were assessed by DLS. Both PUL−DO/bHis nanogels prepared via the dialysis method at pH 8.5 evidenced particle sizes below 140 nm (Table 1). In order to trace the self-organizing behavior of PUL−DO/bHis conjugates in PBS buffer (pH 8.5), the CACs of PUL−DO/bHis36 and PUL−DO/bHis78 were measured using pyrene as a fluorescence probe. The CACs of PUL−DO/bHis nanogels, determined from the change of the intensity ratio (I_{338}/I_{335}) of pyrene according to the concentration of the conjugates, were lower than that of PUL−DO. These results indicate that the His groups in the conjugate contributed to the increase in hydrophobicity. Their lower CAC values may result in the maintenance of the stability of nanogels in the bloodstream.

In order to elucidate the effects of pH on the organization of the nanogels, various dialysis pH values (pH_{dia}) in the range 8.5−5.8 were employed for the preparation. Changes in the CAC values of PUL−DO/bHis36 and PUL−DO/bHis78 nanogels prepared at various pH_{dia} values are shown in Figure 3a. Although the change in CAC was negligible with decreasing pH_{dia} from 8.5 to 7.4, at pH_{dia} 6.8 the CACs increased drastically.

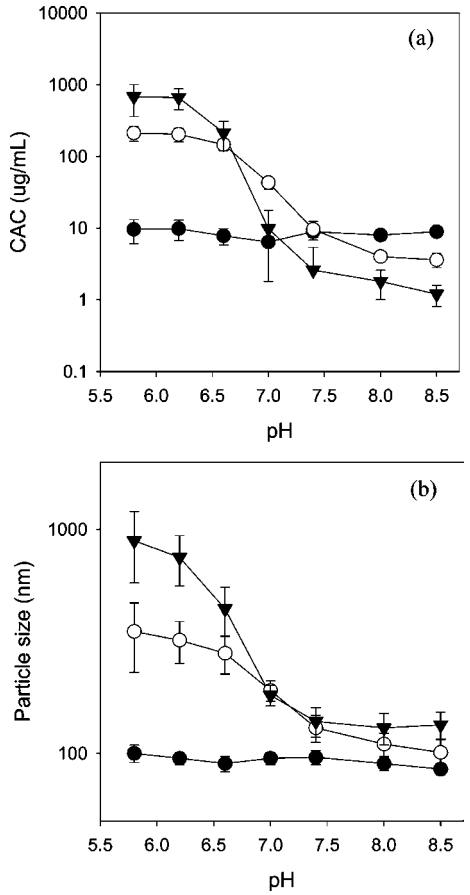

Figure 3. Changes in critical aggregation concentration (CAC) (a) and particle size (b) of self-organized nanogels on decreasing pH: PUL−DO (●), PUL−DO/bHis36 (○), and PUL−DO/bHis78 (▼) nanogels. Data are expressed as the means ± SD; $n = 3$.

PUL−DO/bHis78 evidenced a sharper transition with pH; up to a pH_{dia} of 7.0, the CACs were in the range 1−10 μg/mL, but at a pH_{dia} of 6.2, the CAC increased by approximately 600 times. This result was attributable to the fact that the imidazole in the His group was altered from hydrophobicity to hydrophilicity as the result of ionization. At pH_{dia} values below 7.0, the imidazoles of the His groups are well-ionized and contribute to inter- or intramolecular electrostatic repulsions for the dissociation of the nanogels, while at pH_{dia} values above 7.0, deionized imidazole enhanced the hydrophobic interactions. Of course, the CAC of the PUL−DO nanogel evidenced no dramatic difference. The pH-sensitive behavior of the PUL−DO/bHis nanogel was also verified via particle size analysis at various pHs (Figure 3b). The sizes of the nanogels in the pH range 8.5−7.8 remained similar. However, the sizes of PUL−DO/bHis78, in particular, increased to 750 nm at pH 6.2, from 140 nm measured at pH 7.4. Many investigations into the size of tumor vascular pores have reported gap openings significantly larger than those observed along vessels in normal tissues (*25*, *26*). The average size of tumor vascular pores is generally 400−600 nm (*25*). This fact and the particle size results suggest the possibility of prolonged retention of PUL−DO/bHis nanogels in tumors. Gels of smaller size may pass into normal blood vessels (pH 7.4), and accumulate at tumor sites (lower pH) by virtue of their enhanced permeability and retention (EPR) effects (*26*). The retention time of entrapped nanogels at tumor sites may be prolonged by these larger tumor vascular pores.

The changes in particle size were induced via particle disruption or swelling of the gel as the result of the imidazole ionization in the His group. In order to define the mechanism, the morphology of PUL−DO/bHis78 was observed at a pH of

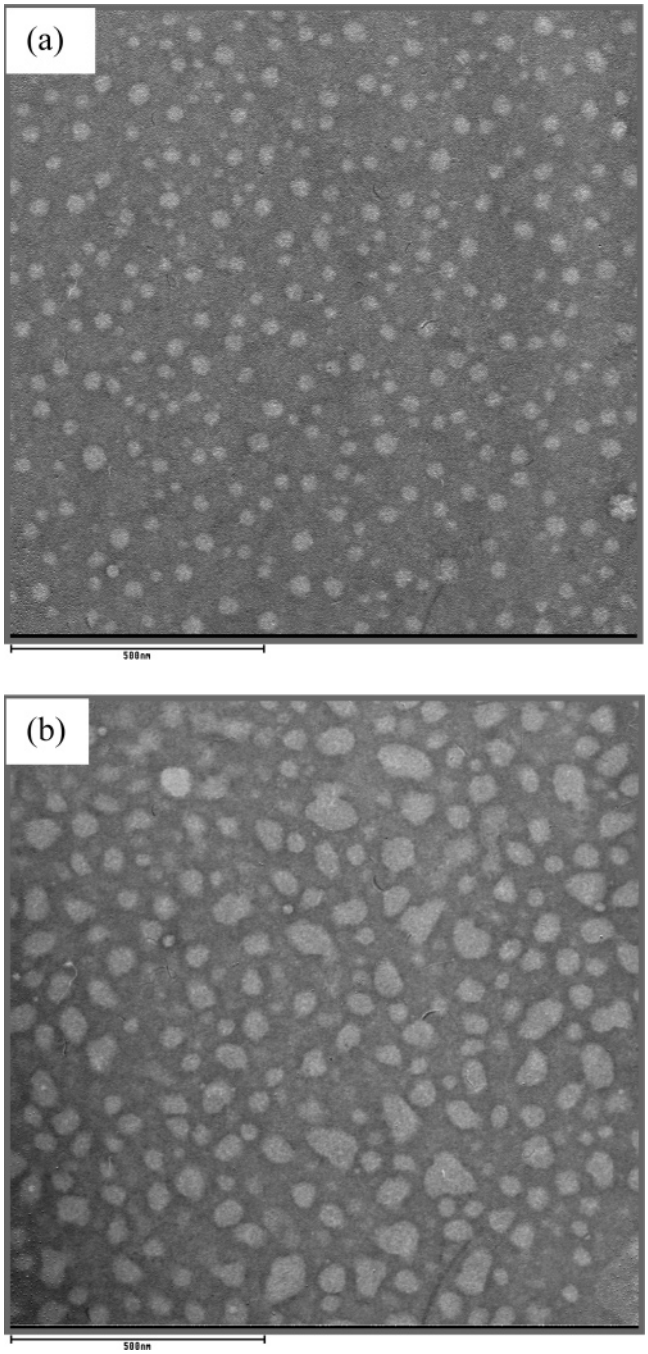

Figure 4. Transmittance electron microscopic (TEM) images of PUL−DO/bHis78 nanogels (scale bar = 500 nm) at pH 8.5 (a) and 6.2 (b). Bar means 500 nm.

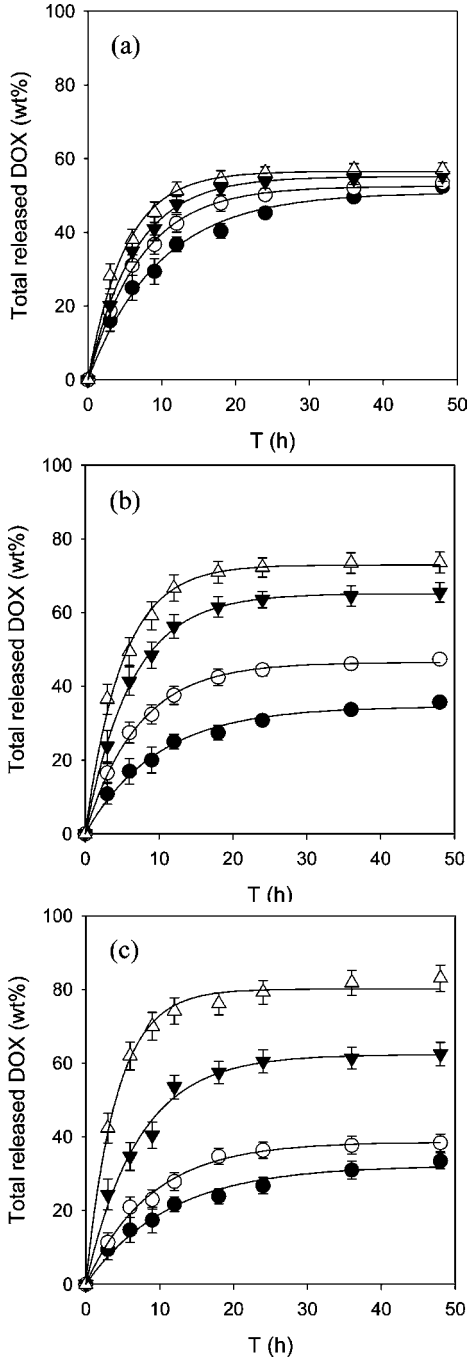

Figure 5. DOX release kinetics from PUL−DO (a), PUL−DO/bHis36 (b), and PUL−DO/bHis78 (c) self-organized nanogels loaded around physiological pH values: pH 8.0 (●), 7.4 (○), 6.8 (▼), and 6.2 (△). Data are expressed as the means ± SD; $n = 3$.

8.5 and 6.2 by TEM (Figure 4). The nanogel at pH 8.5 evidenced well-dispersed "irregular polygons" of 30−50 nm (Figure 4a), which is not consistent with the DLS results. We already reported that the differences in size between the dried and swollen nanogels resulted from the huge hydrodynamic volume of the nanogels (*21*). At a pH of 6.2, PUL−DO/bHis nanogel size increased to 100−300 nm and its morphology was not maintained (Figure 4b). This result shows that the nanogel at slightly acidic pH values was disrupted as a result of the alternation of internal structures by imidazole ionization in the His group.

pH-Sensitive DOX Release Behavior of PUL−DO/bHis Nanogel. The *in vitro* release profiles of DOX from PUL−DO/bHis36 and PUL−DO/bHis78 at various pHs (8.0, 7.4, 6.8, and 6.2) were examined, and the results are shown in Figure 5. The release of DOX from PUL−DO evidenced some slight pH-dependent behavior; i.e., the amount of DOX released increased with decreasing medium pH as the result of the pH-dependent solubility of DOX (a weak base, $pK_b = 8.22$) (Figure 5a). In cases of PUL−DO/bHis36 and PUL−DO/bHis78, DOX release also evidenced pH dependency (Figure 5b,c). The pH dependency of PUL−DO/bHis78 was more profound than that of PUL−DO/bHis36. Graphs from the release test were analyzed by the exponential rise model equation, $y = a(1 - e^{-bx})$. Here, the equation elucidates the pH-sensitive DOX release. Slope "a" in the equation indicates pH sensitivity in drug release. The

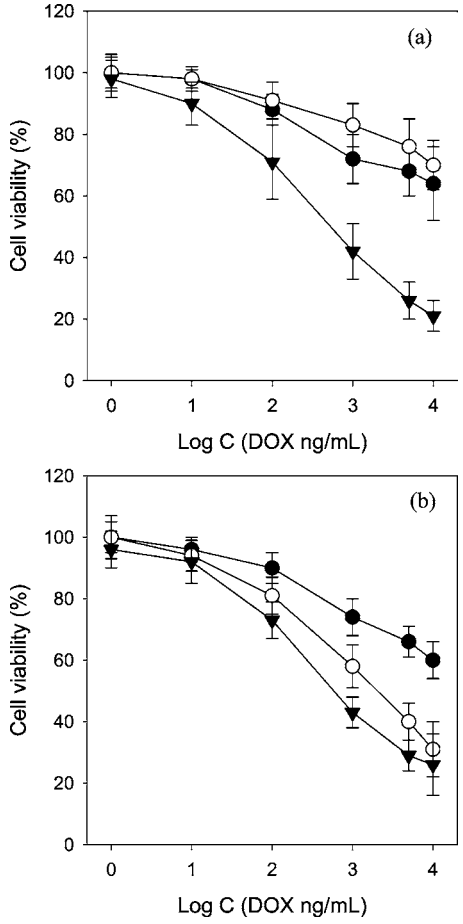

Figure 6. Cytotoxicity of DOX-loaded PUL−DO and PUL−DO/bHis78 nanogels against MCF-7 cells, as a function of drug concentration at (a) pH 7.4 and (b) 6.8: PUL−DO (●), PUL−DO/bHis78 (○), and free DOX (▼). Data are expressed as the means ± SD; $n = 7$.

model was predominantly predicated on diffusivity, whereas the drug solubility also affects the model. We developed this equation to determine the "pH-sensitivity DOX release behavior". The regression equations for PUL-DO/bHis78 at various pHs were as follows: $y = 32.2137(1 - e^{-0.0891x})$, $y = 38.5969(1 - e^{-0.1142x})$, $y = 62.3356(1 - e^{-0.1400x})$, and $y = 80.0910(1 - e^{-0.2410x})$ for pH 8.0, 7.4, 6.8, and 6.2. The equation evidenced a good correlation factor, in that the R^2 values were 0.9983, 0.9994, 0.9991, and 0.9997, respectively. It is known that the release rate of a drug incorporated in a hydrophobic domain depends on the solubility and diffusivity of the drug (*21*). However, studies of polymeric nanogels prepared from stimuli-sensitive amphiphilic polymers have demonstrated that the drug release rate can be altered rapidly via the deformation of the inner core induced by changes in environmental conditions (Figure 1). Therefore, pH-accelerated DOX release from PUL−DO/bHis nanogels may be consistent with pH-induced structural changes. The ionized imidazole in the gel at lower pH values may create charge−charge repulsions between His-grafted chains or the swelling of the core by the hydrophilization of His, resulting in interior structural changes of the PUL−DO/bHis nanogels. This phenomenon may accelerate DOX release rates at pH values below 6.8.

Cytotoxicity of PUL−DO/bHis Nanogels to MCF-7 Cells. The majority of solid tumors have been shown to evidence lower extracellular pH (around 6.8) than the surrounding tissues and blood (pH 7.4) (*27*−*29*). The vasculature of tumors is frequently inadequate to provide sufficient oxygen and nutrients for the expanding tumor cell population. The production of lactic acid under hypoxic conditions and the hydrolysis of ATP in an energy-deficient environment contribute to an acidic microenvironment, which has been detected in many tumor types. Therefore, the *in vitro* cytotoxicity of PUL−DO/bHis78 nanogels to MCF-7 cells at two different pH values (7.4 and 6.8) were compared in Figure 6. A method for the maintenance of a given pH in the medium during experiment was previously reported (*12*). In addition, for the maintenance of the pH of RPMI 1640 medium during cell culture, we utilized RPMI 1640 medium containing PBS (1 M) solution and checked for changes in the pH of the culture medium prior to the tests. Although a negligible change in pH in the culture medium was detected after 2 days of incubation, this did not affect the cell cytotoxicity results.

At a pH of 7.4, we noted no significant differences in the cytotoxicity of PUL−DO and PUL−DO/bHis78 nanogels at the DOX concentration range of 1.0 ng/mL to 10 μg/mL (Figure 6a). However, at a pH of 6.8, the DOX-loaded PUL−DO/bHis78 evidenced significantly enhanced cytotoxicity, whereas the DOX-loaded PUL−DO nanogels (as a control) evidenced no pH effects on cytotoxicity (Figure 6b). The pronounced cytotoxicity of PUL−DO/bHis78 at pH 6.8 may be attributed to the enhanced release rate of DOX in Figure 5. After our group reported a potential way to effectively deliver anti-cancer drugs using polyHis-based micelles (*13*, *14*), His-based nanocarriers have received a great deal of attention as an anti-tumor drug carrier (*30*, *31*). Yang et al. reported the direct conjugation of histidine to poly(2-hydroxyethyl aspartamide) (PHEA) and octadecylamine-grafted PHEA via an ester linkage (*30*). However, this system may be quite difficult to construct as compared to the polyHis system, as the polymer was predicated on poly(2-hydroxyethyl aspartamide) (PHEA-His) and C18-grafted PHEA (PHEA-g-C18-His). In particular, the nanocarrier did not evidence significant differences in drug release with pH, unlike the polyHis-based polymeric micelles due to the lack of flexibility, which is instrumental in the swelling and compressing properties of the nanocarrier. Park et al. also demonstrated the use of *N*-acetyl histidine-conjugated glycol chitosan self-assembled nanoparticles for intracytoplasmic drug delivery (*31*). The nanoparticles were synthesized in PBS buffer via the EDC reaction, resulting in a lower rate of the conjugation of *N*-acetyl histidine to glycol chitosan. Thus, their nanoparticles did not evidence pH-sensitive behavior such as pH-dependent dissociation and drug release as compared to polyHis-based micelles. Therefore, the cytotoxicity of PUL−DO/bHis 78 nanogel indicates that the nanogel is a very superior carrier for anti-cancer drug delivery.

CONCLUSIONS

In order to develop a self-organized nanogel responsive to tumor extracellular pH on the basis of histidine chemistry via a conjugation approach, a self-organized nanogel from PUL−DO/bHis conjugates was investigated with regard to its efficacy as an anti-tumor carrier. Nanogels prepared at pH 8.5 were smaller than 140 nm. The CAC of the PUL−DO/bHis78 nanogel dropped sharply with increasing pH_{dia}. Its size also significantly increased to 750 nm at pH 6.2 from 130 nm at pH 8.5 as a result of the particle destabilization induced by the ionization of imidazole in bHis moieties at lower pH values. Moreover, lower pH enhanced the rate of release of the loaded DOX from PUL−DO/bHis nanogels. At tumor pH_e (pH 6.8), the PUL−DO/bHis78 nanogels evidenced drastically augmented cytotoxicity as compared to that observed at normal pH, resulting from the enhanced release rate. The continuous study of polymeric nanogels harboring bHis may prove the efficacy of tumor targeting on the basis of tumor pH_e.

Received March 2, 2007; Revised Manuscript Received May 30, 2007

The DNA compacting properties of polyamines (especially spermine) are well-known, hence the use of spermine as the cationic part in several synthetic DNA carriers. Here, we describe the synthesis of modified spermines, with a "lipophosphoramidate" as the lipidic part, and their use for efficient *in vitro* transfection. Physicochemical measurements (particle size, zeta potentials, pK_a determination) and gel retardation assays were also performed. Theoretical membrane-disrupting ability was established by FRET. Taken together, our results indicate that lipophosphoramidates constitute an interesting alternative to "classical" lipidic parts of cationic lipids used as DNA carriers.

INTRODUCTION

Together with polymers, cationic lipids hold the most important place among synthetic carriers for gene delivery. In these vectors, the lipidic part generally consists of a cholesteryl group or two $C_{12}-C_{20}$ saturated or unsaturated hydrocarbon chains. To the first category belong, for instance, the commercial DC-Chol (*1*), BGTC (a bis-guanidinium cholesterol derivative) (*2*), and Lipid 67 (a spermine cholesterol derivative) (*3*) (Scheme 1).

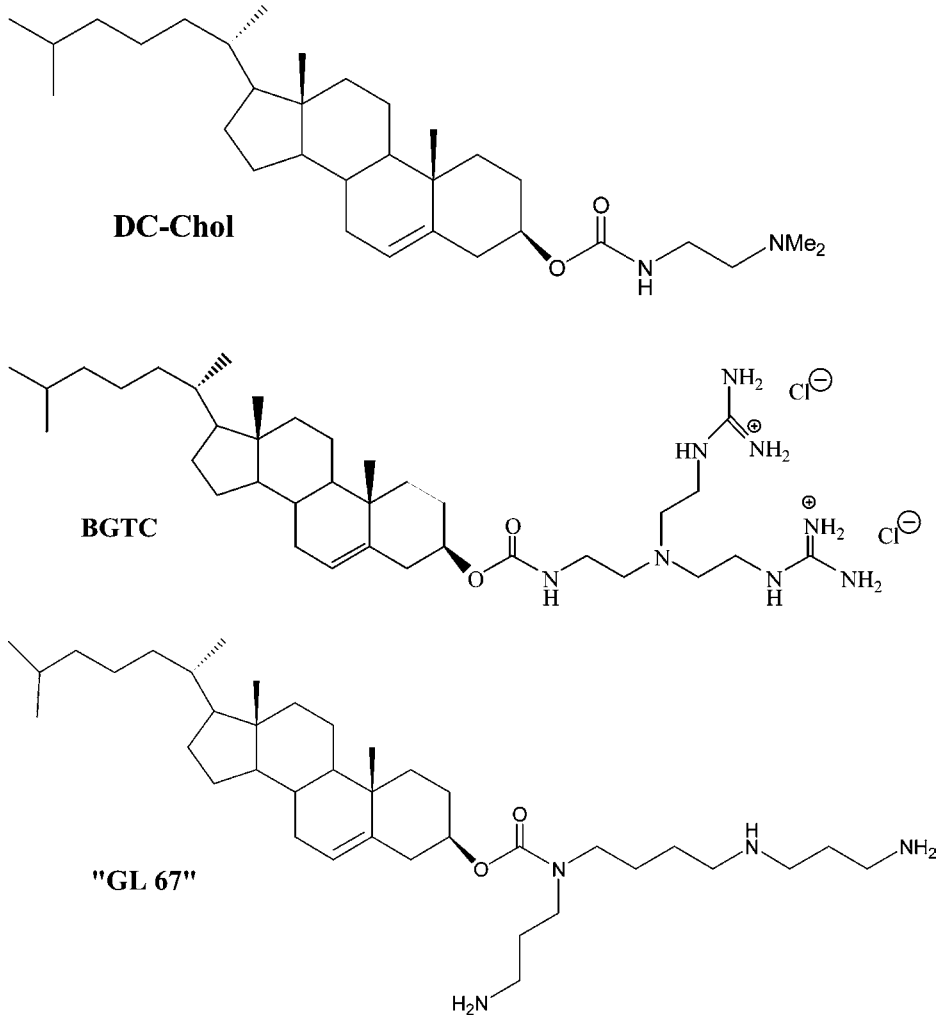
Chronologically, DOTMA (*4*) is the first representative of the second category, and since 1987, several dozen cationic lipids bearing two hydrocarbon chains, with various spacers and polar heads, have been published (*5*, *6*). Some representative examples are given in Scheme 2.

Because of its compacting properties, the naturally occurring spermine was used as the polar head in several carriers, and among them, apart from Lipid 67 already quoted, appear DOGS (*7*) and DOSPA, the cationic part of Lipofectamine (*8*). Since lipophosphoramidates proved to be efficient for *in vivo* gene delivery when associated with ammonium, phosphonium, or arsonium cations (*9*), we wondered about their efficiency when associated to spermine as the cationic part.

EXPERIMENTAL PROCEDURES

Syntheses of Lipidic Spermines. Solvents were freshly distilled on appropriate driers and reactions run under nitrogen atmosphere. All compounds were fully characterized by ^{1}H (400 MHz), ^{13}C (100 MHz), and ^{31}P (121.49 MHz) NMR spectroscopy (Bruker AC 300 and Advance DRX 400 spectrometers). Coupling constants *J* are given in hertz. The following abbreviations were used: s for singlet, d doublet, t triplet, q quadruplet, qt quintuplet, and m for multiplet. When needed, ^{13}C heteronuclear HMQC and HMBC were used to unambiguously establish structures.

N^4-(3-Phtalimidopropyl)-N^1,N^8,N^{12}-tris-tert-butyloxycarbonyl−Spermine ***6***. SpermineBoc$_3$ (1 g, 2 mmol, 1 equiv) and *N*-(3-bromopropyl)phthalimide (666 mg, 2.48 mmol, 1.25 equiv) were dissolved in dry acetonitrile (30 mL) with an excess of K_2CO_3 (1.37 g, 9.95 mmol, 5 equiv). The mixture was stirred for 18 h under reflux. Then, acetonitrile was evaporated under vacuum, and the crude product was dissolved in methylene chloride (50 mL). The organic layer was washed with $NaHCO_3$ (2 × 50 mL) and water (50 mL), dried with $MgSO_4$, and evaporated to give after purification by column chromatography ($CHCl_3$/EtOH 100:0 to 80:20) 910 mg of compound **6** (66%). R_f = 0.50 ($CHCl_3$/EtOH 90:10). ^{1}H NMR (DMSO-d_6): 7.84 (m, 2H), 7.82 (m, 2H), 6.70 (m, 2H), 3.57 (t, *J* = 7.2, 2H), 3.07 (m, 4H), 2.89 (m, 2H), 2.87 (m, 2H), 2.37 (t, *J* = 6.6, 2H), 2.30 (t, *J* = 6.8, 2H), 2.29 (t, *J* = 6.8, 2H), 1.68 (qt, *J* = 7.2, *J* = 14.1, 2H), 1.53 (m, 2H), 1.44 (qt, *J* = 6.7, *J* = 13.2, 2H), 1.37 (m, 2H), 1.34 (m, 27H), 1.27 (qt, *J* = 6.7, *J* = 13.9, 2H). ^{13}C NMR (DMSO-d_6): 167.9, 155.5, 154.6, 134.3, 131.6, 122.9, 78.2, 77.4, 77.2, 52.9, 51.1, 50.9, 44.3, 38.3, 37.6, 36.0, 28.4, 28.2, 28.1, 28.0, 26.8, 25.7, 23,7.



N^4-(3-Aminopropyl)-N^1,N^8,N^{12}-tris-tert-butyloxycarbonyl−Spermine ***7***. Compound **6** (880 mg, 1.28 mmol, 1 equiv) and an excess of hydrazine monohydrate (1.98 mL, 64 mmol, 50 equiv) were dissolved in THF/EtOH (80:20; 20 mL). The mixture was stirred 5 h at 80 °C and then 18 h at 50 °C. After evaporation under reduced pressure, the residue was dissolved in $CHCl_3$ (50 mL) and washed with 5% sodium hydroxide solution (2 × 50 mL). The organic phase was separated, dried over anhydrous magnesium sulfate, filtered, concentrated, and subjected to flash chromatography using 3% NH_4OH/MeOH to give the desired amine **7** (573 mg, 80%). R_f = 0.42 (MeOH + 5% NH_4OH). ^{1}H NMR (DMSO-d_6): 6.70 (m, 2H), 3.08 (m, 4H), 2.90 (m, 2H), 2.87 (m, 2H), 2.53 (m, 2H), 2.35 (m, 2H), 2.30 (m, 2H), 2.29 (m, 2H), 1.58 (m, 2H), 1.51 (m, 2H), 1.44 (m, 2H), 1.37 (m, 2H), 1.35 (m, 27H), 1.29 (m, 2H). ^{13}C NMR (DMSO-d_6): 155.5, 154.6, 78.2, 77.4, 77.2, 53.1, 51.5, 51.1, 48.6, 48.6, 39.8, 38.4, 37.6, 28.9, 28.7, 28.2, 28.0, 27.0, 26.2, 23.8.

General Procedure for the Synthesis of Phosphoramidate−Spermines ***3*** *and* ***9***. Fatty phosphites (1 equiv) and 1 equiv of triprotected spermine **1** or 3-aminopropylspermine **7** were dissolved in anhydrous CH_2Cl_2. Then, 10 equiv of CCl_4 and 1.5 equiv of DIPEA were added. The reaction was carried out under a nitrogen atmosphere and stirred for 1 h at 0 °C and

then for 18 h at room temperature. After evaporation under reduced pressure, the residue was dissolved in $CHCl_3$ (50 mL) and washed with water (2 × 50 mL). The organic phase was separated, dried over anhydrous magnesium sulfate, filtered, and evaporated to give after purification by column chromatography ($CHCl_3$/EtOH 100:0 to 50:50) the desired compounds **2** (**2a**, R = $C_{14}H_{29}$; **2b**, R = $C_{18}H_{35}$) and **8** (**8a**, R = $C_{14}H_{29}$; **8b**, R = $C_{18}H_{35}$).

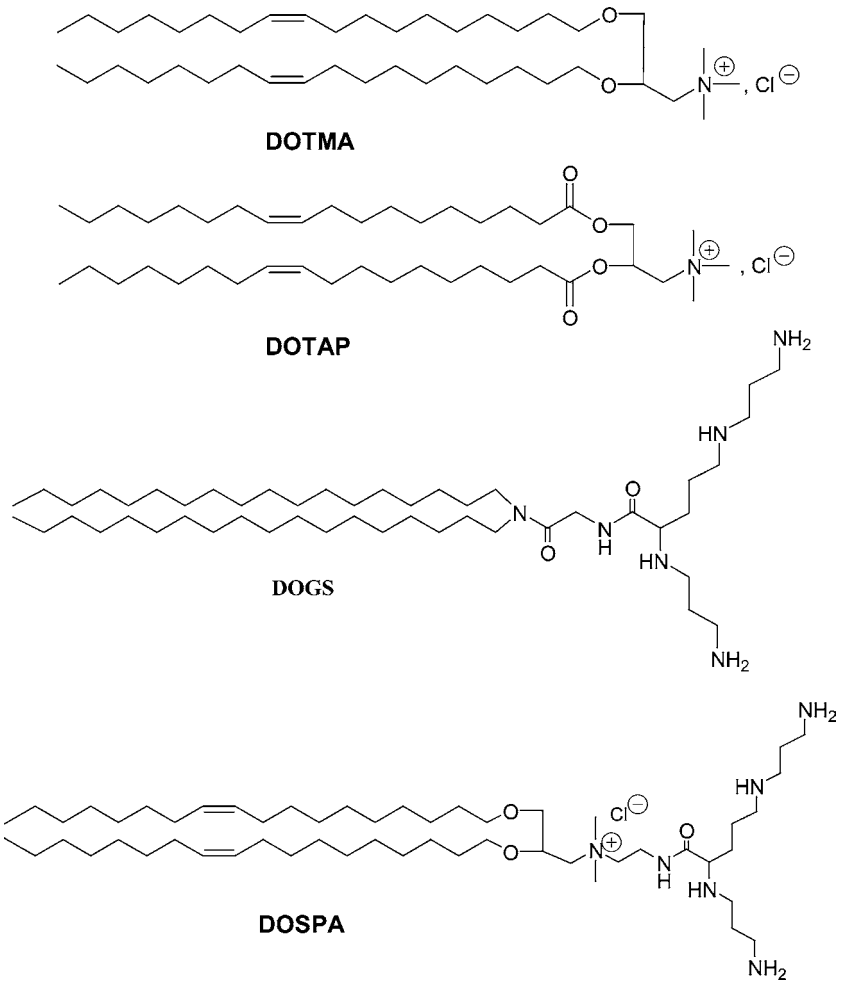
NMR data for **2a**: ^{1}H ($CDCl_3$) 5.28 (s, 2H), 3.95 (m, 4H), 3.22−2.94 (m, 12H), 1.80−1.25 (m, 12H), 1.44 (m, 27H), 1.30−1.25 (m, 44H), 0.80 (t, J = 6.7, 6H). ^{31}P ($CDCl_3$) 11.25.

NMR data for **2b**: ^{1}H ($CDCl_3$) 5.32 (s, 4H), 4.05 (m, 4H), 3.25−2.93(m, 12H), 1.99 (m, 8H), 1.57−1.64 (m, 12H), 1.44 (m, 27H), 1.29−1.20 (m, 44H), 0.88 (t, J = 6.7, 6H). ^{31}P ($CDCl_3$) 11.85.

NMR data for **8a**: ^{1}H ($CDCl_3$) 5.28 (s, 2H), 3.95 (m, 4H) 3.42−2.94 (m, 10H), 2.42 (m, 6H), 1.80−1.64 (m, 14H) 1.44 (m, 27H), 1.30−1.25 (m, 44H) 0.80 (t, J = 6.7, 6H). ^{31}P ($CDCl_3$) 9.71.

NMR data for **8b**: ^{1}H ($CDCl_3$) 5.34 (s, 4H), 3.98 (m, 4H), 3.15−2.95 (m, 10H), 2.43 (m, 6H), 1.99 (m, 8H), 1.80−1.64 (m, 14H), 1.43 (m, 27H), 1.29−1.20 (m, 44H), 0.89 (t, J = 6.7, 6H). ^{31}P ($CDCl_3$) 9.70.

Protected phosphoramidates (**2a**,**b** or **8a**,**b**) were then deprotected into a CH_2Cl_2−CF_3CO_2H (1/1 v/v) mixture during 2 h at room temperature (RT). After washing with water, then drying ($MgSO_4$), solvent was split off. Phosphoramidates−spermines **3** (**3a**, R = $C_{14}H_{29}$; **3b**, R = $C_{18}H_{35}$) and **9** (**9a**, R = $C_{14}H_{29}$; **9b**, R = $C_{18}H_{35}$) were obtained quantitatively as their trifluoroacetic salts.



NMR data for **3a**: ^{1}H (DMSO-d_6) 3.83 (m, 4H), 2.99 (m, 2H), 2.96 (m, 2H), 2.89 (m, 2H), 2.87 (m, 2H), 2.86 (m, 2H), 2.76 (t, J = 7.5, 2H), 1.98 (q, J = 7.3, 2H), 1.75 (q, J = 6.9, 2H), 1.59 (m, 2H), 1.55 (m, 4H), 1.53 (m, 2H), 1.22 (m, 44H), 0.80 (t, J = 6,7, 6H). ^{13}C (DMSO-d_6) 65.9, 47.1, 45.5, 44.3, 43.7, 37.1, 36.7, 26.9, 24, 23.3, 30.5, 30−20, 13.9. ^{31}P (DMSO-d6) 11.21.

NMR data for **3b**: ^{1}H (DMSO-d_6) 5.3 (m, 4H), 3.81 (m, 4H), 2.98 (m, 2H), 2.85 (m, 2H), 2.83 (m, 2H), 2.75 (m, 2H), 2.63 (m, 2H), 2.60 (m, 2H), 1.96 (m, 8H), 1.72 (m, 2H), 1.70 (m, 2H), 1.55 (m, 4H), 1.46 (m, 2H), 1.38 (m, 2H), 1.22 (m, 44H), 0.84 (t, J = 6.9, 6H). ^{13}C (DMSO-d_6) 129.6, 65.5, 48.2, 46.2, 45.1, 42.2, 39.7, 36.7, 29.7, 27.5, 27.1, 26.5, 25.1, 24.7, 30−20, 13.8. ^{31}P (DMSO-d_6) 10.87.

NMR data for **9a**: ^{1}H (DMSO-d_6) 5.74 (m, 1H), 3.81 (m, 4H), 2.85 (t, J = 7.2, 2H), 2.77 (t, J = 7.4, 2H), 2.74 (m, 2H), 2.72 (m, 2H), 2.63 (m, 2H), 2.38 (t, J = 6.5, 2H), 2.36 (t, J = 6.5, 2H), 2.33 (t, J = 6.8, 2H), 1.70 (m, 2H), 1.61 (m, 2H), 1.53 (m, 2H), 1.48 (m, 2H), 1.40 (m, 2H), 1.37 (m, 2H), 1.22 (m, 44H), 0.84 (t, J = 6.6, 6H). ^{13}C (DMSO-d_6) 65.8, 52.7, 50.5, 50.2, 48.5, 45.7, 39.5, 37.5, 37.2, 29.7, 28.9, 28.8, 28.7, 26.1, 24.7, 30−20, 14. ^{31}P (DMSO-d_6) 10.20.

NMR data for **9b**: ^{1}H (DMSO-d_6) 5.3 (m, 4H), 4.81 (m, 1H), 3.80 (m, 4H), 2.85 (m, 2H), 2.82 (m, 2H), 2.76 (m, 2H), 2.74 (m, 2H), 2.72 (m, 2H), 2.40 (m, 2H), 2.38 (m, 2H), 2.33 (m, 2H), 1.96 (m, 8H), 1.78 (m, 2H), 1.62 (m, 2H), 1.55 (m, 2H), 1.49 (m, 2H), 1.48 (m, 2H), 1.39 (m, 2H), 1.22 (m, 44H), 0.84 (t, J = 6.6, 6H). ^{13}C (DMSO-d_6) 129.6, 65, 52.6, 50.7, 47.5, 44.9, 39, 37.3, 37, 29.9, 28.9, 28.8, 28.7, 26.5, 25, 24.4, 30−20, 13.8. ^{31}P (DMSO-d_6) 10.72.

Scheme 2. Some Cationic Lipids with a Double-Tailed Hydrocarbon Chain

*N^4-Chlolesteryl−Spermine **5***. To a mixture of 0.688 g of triBocSpermine **1** (1.37 mmol) and 0.360 mL (2.06 mmol) of diisopropylethylamine (DIPEA) into CH_2Cl_2 (10 mL) at 0 °C is added a solution of 0.614 g of cholesterylchloroformate (1.37 mmol) into CH_2Cl_2 (10 mL). The mixture is kept 1 h at 0 °C, then 18 h at RT under nitrogen atmosphere. After washing (H_2O) and drying ($MgSO_4$), the solvent is split off. Purification was accomplished by column chromatography (silica gel), eluting with a gradient of 5−20% EtOH in CH_2Cl_2, and led to 0.8 g (64%) of the triprotected compound **4** as white crystals. ^{1}H NMR ($CDCl_3$) 5.37 (s, 1H), 5.29 (s, 2H), 4.50 (m, 1H), 3.40−3.05 (m, 12H), 2.38−2.20 (m, 2H), 2.10−1.05 (m, 61H), 1.01 (s, 3H), 0.91 (m, 3H), 0.86 (d, J = 6.5, 6H), 0.68 (s, 3H).

Compound **4** was then deprotected as described above, and the cholesterylspermine **5** was thus obtained quantitatively. ^{1}H NMR ($CDCl_3$) 5.37 (s, 1H), 4.50 (m, 1H), 3.40−3.05 (m, 12H), 2.32−2.15 (m, 2H), 2.10−0.94 (m, 34H) 0.99 (s, 3H), 0.91 (m, 3H) 0.86 (d, J = 7, 6H), 0.67 (s, 3H).

*N^4-Chlolesteryl-(4-amidopropyl)−Spermine **11***. From 0.874 g of cholesterylchloroformate (1.95 mmol), 1.09 g of triprotected 4-aminopropylspermine **7** (1.95 mmol), and 0.5 mL of DIPEA (2.92 mmol) into 30 mL of CH_2Cl_2, with the same conditions as for the synthesis of **5**, 1.23 g (1.26 mmol, 65%) of the triprotected derivative **10** is obtained as white crystals after purification by column chromatography (silica gel, eluting with a gradient of 5−50% EtOH in CH_2Cl_2). ^{1}H NMR ($CDCl_3$) 5.37 (s, 1H), 5.29 (s, 2H), 4.48 (m, 1H), 3.22−2.95 (m, 10H), 2.43−2.20 (m, 8H), 2.05−1.01 (m, 63H), 1.01 (s, 3H), 0.91 (m, 3H), 0.86 (d, J = 6.5, 6H), 0.68 (s, 3H).

Deprotection in a CF_3CO_2H/CH_2Cl_2 mixture as described above led quantitatively to cholesteryl derivative **11**. ^{1}H NMR ($CDCl_3$) 5.37 (s, 1H), 4.48 (m, 1H), 3.22−2.90 (m, 10H), 2.43−2.15 (m, 8H), 2.05−1.01 (m, 36H), 1.01 (s, 3H), 0.91 (m, 3H), 0.86 (d, J = 6.5, 6H), 0.68 (s, 3H).

***In Vitro* Experiments.** *Cell Culture.* Two different cell lines (A549 and HeLa) were used. The alveolar type II epithelial cell line A549 (*19*) and the human adenocarcinoma epithelial cell line HeLa were obtained from the American Type Culture Collection (respectively, cat. no. CCL-185 and ccl-2, ATCC, Rockville, MD). These cells were grown in D-MEM (Gibco-BRL, UK) and supplemented with 10% fetal calf serum (FCS) (Gibco-BRL, UK) and 100 U/mL of penicillin/streptomycin. All the cells were maintained in a humidified incubator with 5% CO_2 at 37 °C.

Complex Formulation. Each cationic lipid was prepared alone or in combination with the neutral colipid DOPE (w/w = 1:1). Lipids were kept and formulated in chloroform solutions; then, chloroform was removed by rotary evaporation to produce dried lipid films. A total of 1 mL of sterile pyrogen-free DI water per milligram of lipid was added, and the vials were sealed and stored at 4 °C overnight. Vesicles were then prepared by sonicating the aqueous suspension for 10 min in a bath sonicator.

Cationic lipid/DNA complexes were formed as follows: plasmid DNA (1 μg) was diluted with sterile pyrogen-free deionized water and added to the lipid solution in a polystyrene tube. Lipoplexes were kept at room temperature for 30 min before being used for transfection.

Determination of the Lipoplex Charge Ratio. The charge ratio was calculated theoretically as the molar ratio of the cationic lipids to DNA. In order to study the impact of the formulation on gene expression, various charge ratios (±) were prepared with a constant amount of pDNA (1 μg). As a control, 2 μL of

Lipofectamine (Invitrogen) was used, accordingly to manufacturer's instructions, and in these conditions, for 1 μg of delivered DNA, the N/P ratio is equal to 2.

Transfection Protocol. Cells were seeded 24 h before transfection onto a 24-well plate at a density of 100 000 cells per well and incubated overnight in a humidified 5% CO_2 atmosphere at 37 °C. Transfection was performed as described by Felgner et al. (*4*) with the following modifications. Appropriate amounts of the cationic lipids and the plasmid vector in OptiMem were complexed, and about 200 μL was added to each well. After 2 h 30 min incubation at 37 °C, the medium was removed, and fresh medium was added. Following a further 48 h at 37 °C, the cells were assayed for luciferase expression using a chemiluminescent assay (Promega). Assays were carried out as described by the manufacturer. The total protein concentration of the cell culture was determined using the BC assay kit (Uptima). Luciferase activity of each condition was expressed as total relative light units (Total RLU) per mg of total protein. Results are reported as means ± SEM.

DNA Binding Ability. To 1 μg of plasmid DNA in Optimem (Gibco) were added cationic lipids at concentrations corresponding to an N/P charge ratio ranging from 0.5 to 8. The mixture was incubated for 30 min at room temperature. The complexes were subjected to electrophoresis in 1% agarose gel at 100 V, 90 mA. The gel was stained with ethidium bromide (10 mg/mL) and visualized on an UV illuminator (Fischer Bioblock).

FRET Experiments. The FRET method described by Pagano et al. (*10*) was used for assaying membrane fusion. In this method, membranes labeled with a combination of fluorescence energy transfer donor and acceptor lipid probes, respectively, NBD-PE and Rhod-PE (both from Molecular Probes), are mixed with unlabeled cationic lipids.

As the labeled membrane, we used liposomes made with L-α-phosphatidylcholine (PC) and fluorescent probes, or liposomes made with PC, L-α-phosphatidylethanolamine (PE), L-α-phosphatidyl-L-serine (PS), cholesterol (Chol), and fluorescent probes, (PC/PE/PS/Chol/NBD-PE/Rhod-PE approximately 44/25/10/20/0.8/0.2 m/m), a lipid composition close to that of the plasma membrane. All lipids were from Sigma. Stock solutions of each lipid were prepared in chloroform and stored in the dark, at 4 °C. Aliquots of these solutions were mixed and dried under reduced pressure. The dried lipid film formed was hydrated with a 5 mM Hepes buffer (pH 7 or pH 5.5) containing NaCl (150 mM). Suspensions were vigorously vortexed for 5 min and sonicated at 40 °C for 10 min.

Stock solutions of each cationic lipid were prepared in chloroform (5 $g.L^{-1}$). An aliquot was dried under reduced pressure, and liposome suspensions (1 $g.L^{-1}$) were prepared as described before.

Labeled and unlabeled liposomes were added in a buffer solution and vortexed. The final Rhod-PE and NBD-PE concentrations were 6.10^{-8} $mol.L^{-1}$ and 3.10^{-7} $mol.L^{-1}$. The labeled membrane final concentration was 15 $mg.L^{-1}$, corresponding approximately to 2.10^{-5} M for PC.

The Rhod-PE/lipid ratio was chosen after determination of the FRET efficiency versus Rhod-PE/PC molar ratio. A ratio close to 0.003 was chosen so that lipid fusion undergoes a significant decrease of FRET efficiency. NBD-PE concentrations did not affect the FRET efficiency as described before (*10*).

Fluorescence measurements were performed 1 h later, at room temperature, by exciting the sample at 450 nm. A Varian Cary Eclipse Fluorescence spectrophotometer was used. Following each measurement, liposomes were disrupted with Triton X-100 (1% final concentration) in order to eliminate energy transfer and to allow the determination of the concentration of NBD-PE from its emission intensity.

Table 1. Potentiometric Determination of the pK_a of Phosphoramidate−Spermines

	3b	**9b**	spermine [18]
pK_1	10.60	11.10	10.8
pK_2	9.80	10.78	10.0
pK_3	7.00	8.62	8.8
pK_4	< 2	6.78	7.90

The efficiency of energy transfer was calculated from the fluorescence emission intensity of NBD-PE at 530 nm by using eq 1

$$E = 1 - F/F_0 \quad (1)$$

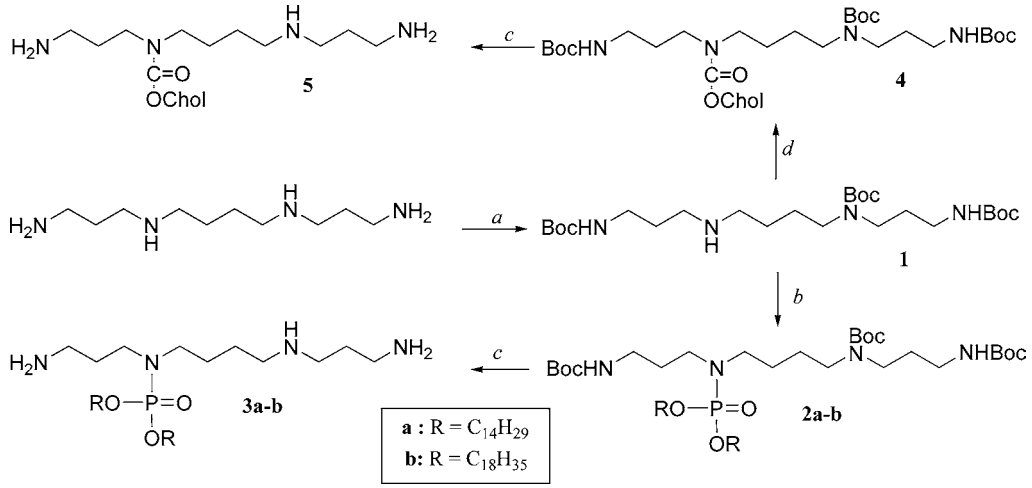
Fluorescence intensities were recorded in the presence (F_0) and absence (F) of Triton X-100. Values obtained in the presence of Triton X-100 were corrected for sample dilution and for the effect of Triton-X on the quantum yield of NBD-PE.

The relative fluorescence intensity, E_R (in %), is calculated using relation 2

$$E_R = (E_{mix}/E_{lab}) \times 100 \quad (2)$$

where E_{mix} and E_{lab} are the FRET efficiency calculated in the presence (E_{mix}) or absence (E_{lab}) of unlabeled liposomes for a same labeled liposome concentration.

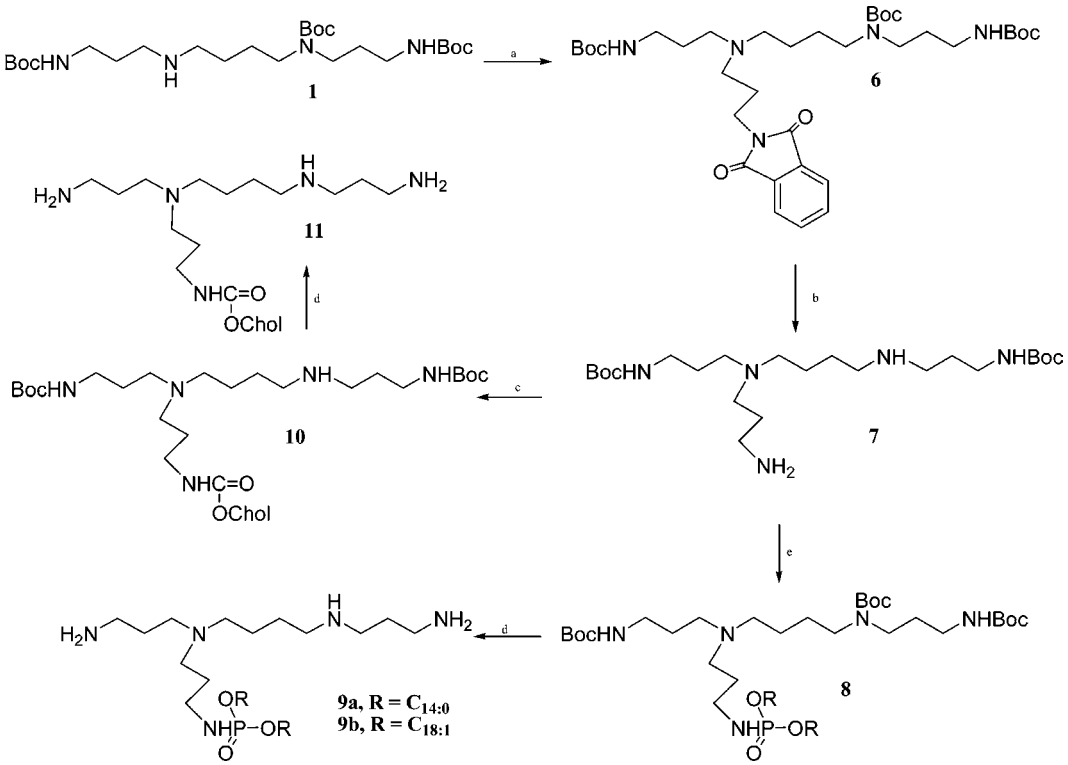
pK_a Determinations. Potentiometric measurements were performed in a jacketed cell thermostated at 25.0 °C, kept under inert atmosphere of purified argon, using an automatic titrator (Metrohm, DMS Titrino 716) connected to a microcomputer. The free hydrogen concentrations were measured with a glass−Ag/AgCl combined electrode (Metrohm) filled with 0.1 M NaCl. The electrode was calibrated in order to read $-\log[H^+]$, designated as p[H], by titration of a small quantity of diluted HCl by standardized NaOH at 0.02 M ionic strength and 25 °C (and determining the equivalent point by the Gran's method) followed by adjustment of the meter by using the program GLEE so as to minimize the calculated p[H] vs observed values. log K_w for the system, defined in terms of $\log([H^+][OH^-])$, was found to be −13.78 at the ionic strength employed and was maintained fixed during refinements (*11*, *12*). NaCl was employed as the supporting electrolyte to maintain the ionic strength at 0.10 M.



Potentiometric measurements obtained from NaOH titration of protonated polyamines were made at about 1 mM in concentration and ionic strength μ = 0.10 M (NaCl). Each titration makes use of at least 10 points per neutralization of a hydrogen ion equivalent, and titrations were repeated until a satisfactory agreement was reached. A minimum of three sets of data was used in each case to calculate the overall stability constants and their standard deviations. The standard deviations obtained for the different recognition constants were ±0.02 of the last significant digit reported in Table 1. The range of accurate p[H] measurements was considered to be 2−12. Equilibrium constants and species distribution diagrams were calculated by using the program *HYPERQUAD 2003* (*13*).

The stability constants K_{lh} were noted with respect to ternary species L_lH_h where l and h are, respectively, the stoichiometric number of L (ligand) and H (proton).

RESULTS AND DISCUSSION



Syntheses of Lipidic Spermines. One of the most popular routes to phosphoramidates is the reaction of a hydrogen phosphite with an amine, in the presence of carbon tetrachloride (*14*). We adapted this procedure for reacting lipidic phosphites with spermine, first triprotected with Boc-ON (*15*), thus leading to lipophosphorylated spermines **3a** (R = $C_{14:0}$) or **3b** (R = $C_{18:1}$), after TFA deprotection (lipidic phosphites were obtained

by reaction of fatty alcohols with diphenyl phosphite). For the purpose of comparison with other lipidic parts, the cholesteryl derivative of spermine **5** was synthesized and obtained unambiguously by reaction of cholesteryl chloroformate with Boc-triprotected spermine **1** and TFA deprotection (Scheme 3).

During our previous work on phosphonolipids as DNA carriers, we noticed that, when an ammonium cation was replaced by a phosphonium or arsonium (i.e., a more bulky polar head), a good transfection efficiency required a longer spacer between the cationic part and the phosphoryl group (*16*, *17*). So, we also designed and synthesized analogues of lipids **3** and **5** including a longer spacer between spermine and the lipidic part. For that purpose, the Boc-triprotected spermine with a pendant aminopropyl arm was first synthesized from Boc-triprotected spermine **1** and 3-bromopropylphtalimide, then hydrazinolysis of the phtalimide protecting group. Subsequent reaction with fatty phosphites or cholesteryl chloroformate led to phosphoramidates **9a** and **9b** or cholesteryl derivative **11,** after deprotection (Scheme 4).

***In Vitro* Biological Tests.** *In Vitro Transfection Efficiency.* Two different cell lines (A549 and HeLa) were used to compare the efficiency of the different lipidic parts, without (**3b**, **5**) or with a spacer (**9b**, **11**), and with (+D) or without DOPE added. The efficacy of each lipid (expressed as luciferase activity) was established for an increasing N/P charge ratio from 0.5 to 8, according to routinely used and previously described procedures (*4*, *9*, *16*). As an example, Chart 1 shows the values of total RLU/mg of protein for HeLa cells, according to increasing N/P

Chart 1. Comparison of Charge Ratio and DOPE Influence on the Transfection Efficiency for HeLa Cell Line

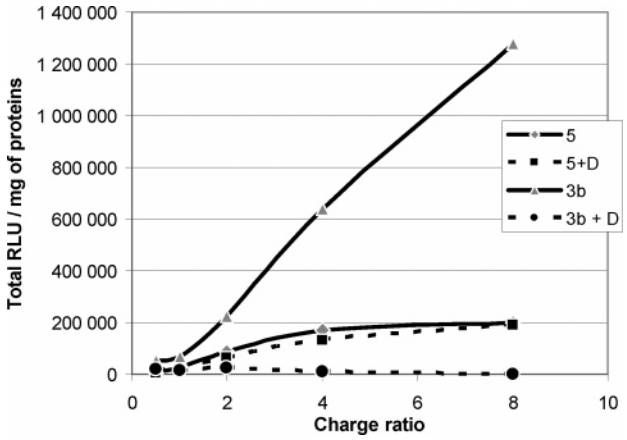

Chart 2. Luciferase Activity for HeLa Cells[a]

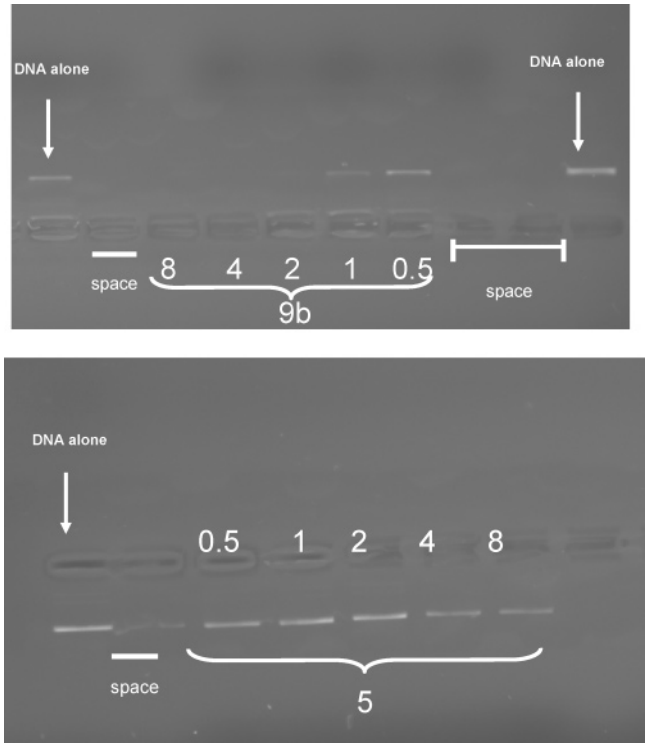
ratios. Charts 2 and 3 indicate the average efficiencies of each lipid at its better N/P ratio (marked on top of each bar). Using the above-mentioned protocols and formulations, the efficacy of the phosphoramidates has the same magnitude as lipofectamine or slightly higher, whereas the cholesteryl derivatives were about ten times lower. But, insofar as the lipid/DOPE ratio used was the same (1:1) in all our experiments, these results have not a comparative but only an indicative value, since formulations were not optimized for each lipid. Compound **5**, for instance, was reported as most efficient at a 1:2 lipid/DOPE ratio (*3*).

DNA Binding Ability. Electrophoretic mobility of plasmid DNA was examined with increasing N/P ratios (0.5−8) using 1% agarose gel (DNA was visualized by ethidium bromide staining). Complete binding of DNA was observed at an N/P ratio lower than 2 for phosphoramidate **9b**, for instance, whereas binding was not complete at a N/P ratio of 8 for cholesteryl spermine **5** (Figure 1).



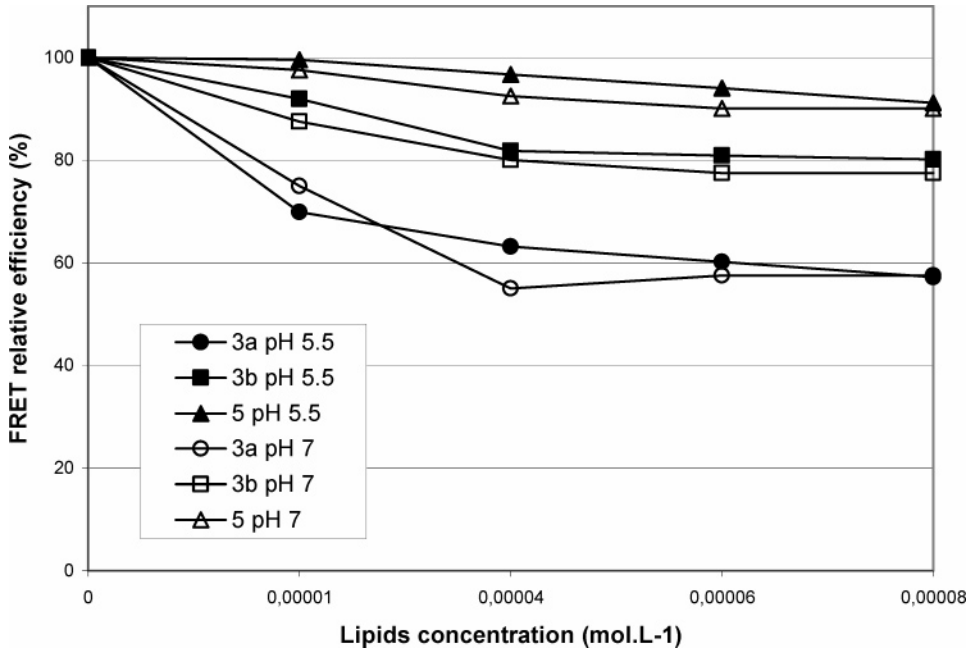


Figure 1. DNA binding ability of phosphoramidate **9b** and cholesteryl **5**.

FRET Experiments. In an attempt to explain these results, we undertook a comparative study toward the ability of these lipidic spermines to disrupt an artificial membrane with a lipid composition close to that of the plasma membrane. We exploited the widely used fluorescence resonance energy transfer (FRET) technique (*10*). Briefly, this technique depends upon the interactions that occur between two fluorophores when the emission band of one (the energy donor) overlaps with the excitation band of the second (the energy acceptor) when the probes are in close proximity. If a couple of two lipidic fluorophores, one energy donor (NBD-PE, for instance) and one energy acceptor (Rho-PE, for instance) is introduced into a liposome, any fusion event of such a doubly labeled liposome with a second liposome (devoid of any fluorophore) will decrease the efficiency of resonance energy transfer. Thus, any decrease in FRET efficiency provides evidence for membrane fusion.

The model membrane was made with PC, L-α-phosphatidylethanolamine (PE), L-α-phosphatidyl-L-serine (PS), cholesterol (Chol), and fluorescent probes (PC/PE/PS/Chol/NBD-PE/Rhod-PE approximately 44/25/10/20/0.8/0.2 m/m). To that membrane were added the different lipidic spermines at increasing concentrations from 10^{-6} to 10^{-4} mol/L, with DOPE added (1:1 m/m) or not, in each case. Chart 4 (no DOPE added) is a representative example of the observed differences between cholesteryl spermine **5** (90% average efficacy) and phosphoramidates **3a** and **3b** (60% and 80% average efficacy, respectively).

From this example, a correlation between FRET and *in vitro* efficacies seems to appear, since phosphoramidates **3a** and **3b** exhibited lower FRET values than cholesteryl derivative **5**, thus indicating a theoretical greater membrane-disrupting ability, at a pH of 7 (extracellular) or 5.5 (endosomal). However, as the curves were practically merged for the two pH values, there is

Chart 4. Comparative FRET Efficiency of Phosphoramidates 3 and Cholesteryl 5 at pH 5.5 and 7

no obvious endosomal acidity-induced advantage for lipophosphoramidates. The same experiments conducted with compounds **9a**, **9b**, and **11** gave rather similar results, but the lack of reproducibility to get homogeneous vesicles, notably with cholesteryl derivative **11**, made those results (and therefore a comparison) inconclusive (data not shown).

Sizes and pK_a. Another difference lies in the behavior of these lipids in water: after 5 min in an ultrasonic bath, the average sizes of the particles of each suspended lipid (1 mg/mL) were 2800 and 640 nm for cholesteryl derivatives **5** and **11**, compared to 290 and 770 nm for phosphoramidates **3b** and **9**.

The pK_a values of the two phosphoramidates **3b** and **9b** were determined by potentiometric titration (see Experimental Procedures for details) and quoted in Table 1. When compared to the pK_a of spermine, the presence of the lipidic phosphoramidate obviously leads to a decrease of the basicity of the third amine in the case of **3b** (7.0 vs 8.8 for spermine) and of the fourth for **9b** (6.78 vs 7.9 for spermine).

CONCLUSION

As previously observed in the case of monocationic lipids (*9*), the use of a lipophosphoramidate group, as linker between the lipidic part and the cationic head, is a very attractive approach to design synthetic vectors for DNA delivery. In this study, the lipophosphoramidate lipidic group has been attached either directly or *via* a short spacer on a spermine unit. In a will of comparison, the spermine has been also functionalized with a cholesterol unit, acting as the lipidic part, *via* a carbamate group. We observed that the influence of the lipid part on the transfection efficiency is important. Notably, the spermine−lipid vectors having two oleoyl chains attached on a phosphoramidate group are the most efficient. Also, the addition of DOPE as a neutral helper lipid in the formulation has no effect in the case of compound **9b** or a dramatically negative effect in the case of compound **3b**. When the spermine−phospholipid is formulated alone, the presence or absence of a spacer between the spermine unit and the phosphoramidate group has only a low influence on the transfection results. As in the case of DOGS (*7*), the introduction of a lipidic group close to the third amine of spermine lowers the value of its pK_a, thus widening the field of basicity, hence, probably, an increased "buffer effect". This explanation could be one of the reasons for the efficiency of compounds **3b** and **9b**.

However, the standard formulations used were not optimized, with regard to the optimal cationic lipid/DOPE ratios (which, of course, are not necessarily the same for each compound) or concerning the sizes of lipidic vesicles in water. Since liposomes have sizes from 290 nm for lipid **3b** to 2800 nm for cholesteryl **5** (and no attempt was made to reduce these sizes), comparisons must be taken cautiously and have only an indicative value.

Since the last pK_a values of **3b** and **9b** are 7.0 and 6.78, respectively, these tri- and tetraamines can be considered polycationic species at the physiological pH despite the fact that a local variation of pH could modify the cationic state of these vectors. In another work (*20*), we examined the transfection efficacies of lipophosphoramidates bearing a couple of cations (N^+/P^+ or N^+/As^+), permanent regardless of the pH. Transfection assays with these dicationic compounds, performed on the same cell lines (HeLa and A549), with the same experimental conditions, systematically resulted in luciferase levels twice as high.

Nevertheless, the lipophosphoramidate group constitutes an interesting alternative to the "classical" cholesteryl or double aliphatic chains generally used as the lipidic part in cationic lipids. As lipophosphoramidates were found especially efficient for *in vivo* experiments when associated to an ammonium, a phosphonium, or an arsonium cation, the *in vivo* activity of lipids **3** and **9** will be evaluated in the near future.

ACKNOWLEDGMENT

Di(azacrown) Conjugates of 2′-*O*-Methyl Oligoribonucleotides as Sequence-Selective Artificial Ribonucleases

Teija Niittymäki, Pasi Virta, Kaisa Ketomäki, and Harri Lönnberg*

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received March 2, 2007; Revised Manuscript Received July 5, 2007

Functionalized 2′-*O*-methyl oligoribonucleotides bearing two 3-(3-hydroxypropyl)-1,5,9-triazacyclododecane ligands attached via a phosphodiester linkage to a single non-nucleosidic building block have been prepared on a solid-support by conventional phosphoramidite chemistry. The branching units employed for the purpose include 2,2-bis(3-hydroxypropylaminocarbonyl)propane-1,3-diol, 2-hydroxyethyl 3′-*O*-(2-hydroxyethyl)-*β*-D-ribofuranoside, and 2-hydroxyethyl 2′-*O*-(2-hydroxyethyl)-*β*-D-ribofuranoside. Each of these has been introduced as a phosphoramidite reagent either into the penultimate 3′-terminal site or in the middle of the oligonucleotide chain. The dinuclear Zn^{2+} complexes of these conjugates have been shown to exhibit enhanced catalytic activity over their monofunctionalized counterpart, the 3′-terminal conjugate derived from 2-hydroxyethyl 3′-*O*-(2-hydroxyethyl)-*β*-D-ribofuranoside being the most efficient cleaving agent. This conjugate cleaves an oligoribonucleotide target at a single phosphodiester bond and shows turnover and 1000-fold cleaving activity compared to the free monomeric Zn^{2+} chelate of 1,5,9-triazacyclododecane.

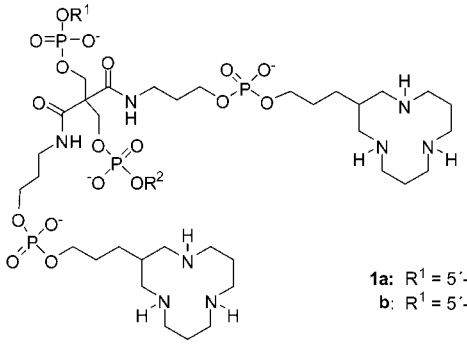
INTRODUCTION

Development of artificial ribonucleases, i.e., agents able to cleave RNA phosphodiester bonds sequence-selectively, has been the subject of numerous studies during the past decade (*1*−*6*). Such man-made catalysts are believed to find applications as artificial restriction enzymes with which large RNA molecules could be tailored in a predesign manner *in vitro* (*7*−*11*) and hopefully also as chemotherapeutic agents capable of silencing an overexpressed gene by recognizing and destroying the respective mRNA (*12*−*16*). Although recent advances in gene silencing by short double-stranded RNAs (siRNA) (*17*−*21*) has diminished the interest in conventional antisense approaches, the recognition of multiple roles of RNA in gene regulation has simultaneously made RNA an object of extensive studies. Accordingly, development of tools useful in chemical manipulation of RNA, such as artificial ribonucleases, still appears worthwhile.

Most of the artificial ribonucleases described so far consist of a metal ion chelate tethered to an oligonucleotide or PNA-oligomer that serves as a sequence-recognizing moiety (*1*−*6*), although some purely organic conjugates have recently been introduced (*22*−*24*). Among the metal-ion-dependent conjugates, those derived from lanthanide ion chelates exhibit the highest cleaving activity (*25*−*31*), followed by nucleases based on intracellularly occurring Cu^{2+} (*32*−*36*) and Zn^{2+} ions (*37*−*41*). The most efficient lanthanide ion conjugates, *viz.* the 5′-tethered Dy^{3+}-texaphyrin oligonucleotide conjugates (*28*), exhibit a half-life of 2 h at pH 7.5 and 37 °C, when used in a stoichiometric amount compared to the oligoribonucleotide target. The best Cu^{2+}- and Zn^{2+}-based cleaving agents, *viz.* the Cu^{2+} (*34*) and Zn^{2+} complexes (*39*) of intrachain 2,9-dimethyl-5-aminophenanthroline−oligonucloeotide conjugates, in turn, show under the same conditions half-lives of 8 and 9 h, respectively. A comparable cleaving activity, but at a lower Zn^{2+} concentration, has been obtained with a dinuclear Zn^{2+} complex of a conjugate bearing a 5′-terminal 3,5-bis[di(pyridin-2-ylmethyl)aminomethyl]phenoxy group (*38*). By simultaneous use of 3′- and 5′-tethered Cu^{2+}-terpyridine conjugates that hybridize to the target leaving no gap between them, the half-life is reduced to 5 h (*36*) and by covalent 3′,5′-bridging of the two oligonucleotide conjugates to 2.5 h (*35*). With the most efficient metal-ion-independent oligonucleotide conjugates, the 5′-tris(2-aminobenzimidazole) conjugates, a half-life of 12 h at pH 8 and 37 °C has been achieved (*22*).

We have previously reported on synthesis of 1,5,7-triazacyclododecane conjugates of 2′-*O*-methyloligoribonucleotides (*42*) and on studies of the cleaving activity of their 3d transition metal chelates (*40*). The advantage of such conjugates is that they bind 3d transition metal ions more tightly than 2,9-dimethylphenanthroline conjugates, but unfortunately they cleave the target RNA 1 order of magnitude more slowly than the phenanthroline conjugates. We now report on synthesis of difunctionalized oligonucleotides bearing two 3-(3-hydroxypropyl)-1,5,9-triazacyclododecane ligands attached via a phosphodiester linkage to a single non-nucleosidic building block, either to 2,2-bis(3-hydroxypropylaminocarbonyl)propane-1,3-diol (**1a**,**b**), 2-hydroxyethyl 3′-*O*-(2-hydroxyethyl)-*β*-D-ribofuranoside (**2a**,**b**), or 2-hydroxyethyl 2′-*O*-(2-hydroxyethyl)-*β*-D-ribofuranoside (**3a**,**b**). Interestingly, the Zn^{2+} complex of conjugate **3a**, bearing the azacrown ligands close to the 3′-terminus, exhibits a 15-fold enhanced catalytic activity over its monofunctionalized counterpart. The catalytic activity of this conjugate is equal to that of the most efficient Zn^{2+}- or Cu^{2+}-based artificial ribonucleases described so far.

EXPERIMENTAL PROCEDURES



General Methods and Materials. The NMR spectra were recorded at 500 MHz. The chemical shifts are given in ppm from internal TMS and the coupling constants in hertz. The mass spectra of small molecular compounds were recorded by EI ionization and those of oligonucleotides and their conjugates by ESI ionization. For details, see the Supporting Information.

The chimeric 2′-*O*-methylribo/ribo oligonucleotides (**4**−**6**) used as targets for the artificial ribonucleases and as reference material for identification of the cleavage site (**7**−**9**) were

[a] Reagents and conditions: (i) levulinic anhydride, DMAP, pyridine, (ii) aq 80% AcOH, (iii) DMTrCl, pyridine, (iv) 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite, tetrazole, acetonitrile.

assembled from commercially available 2′-*O*-methyl- and 2′-*O*-triisopropylsilyloxymethyl-protected 2-cyanoethyl-*N*,*N*-diisopropylphosphoramidite building blocks (Glen Research) by conventional phosphoramidite strategy using a 1.0 μmol scale and following the standard RNA-coupling protocol of Applied Biosystems 3400 DNA synthesizer. The artificial ribonucleases **1**−**3** were prepared as described below. The buffer reagents and salts employed were of reagent grade. All buffer solutions were prepared in sterilized water, and sterilized equipment was used for their handling.

***N*,*N*′-Bis[3-(levulinoyloxy)propyl]-2-methoxy-1,3-dioxane-5,5-dicarboxamide (11).** *N*,*N*′-Bis(3-hydroxypropyl)-2-methoxy-1,3-dioxane-5,5-dicarboxamide (**10**, Scheme 1) was synthesized as described earlier (*43*). A mixture of **10** (4.0 g, 12 mmol), levulinic anhydride (62 mmol) and a catalytic amount of 4-dimethylaminopyridine in pyridine (30 mL) was stirred overnight at room temperature and evaporated to dryness. The residue was dissolved in dichloromethane and washed with 5% aqueous $NaHCO_3$. The organic phase was dried with Na_2SO_4 and evaporated to dryness. Purification of the crude product by silica gel chromatography (first 50% EtOAc in dichloromethane and then 5% MeOH in dichloromethane) yielded 5.7 g (86%) of **11** as brownish oil. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.69 (br s, 2H), 5.31 (s, 1H), 4.51 (d, 2H, J = 12.0 Hz), 4.16−4.12 (m, 6H), 3.41 (s, 3H), 3.41−3.33 (m, 4H), 2.77 (m, 4H), 2.63 (t, 4H, J = 6.8 Hz), 2.20 (s, 6H), 1.87 (m, 4H); ^{13}C NMR ($CDCl_3$, 125 MHz): δ 206.8, 175.9, 169.5, 169.0, 109.6, 65.1, 62.1, 53.1, 50.8, 38.0, 36.9, 35.1, 29.8, 28.4, 28.0; MS (EI): M^+ requires 516.2, found 515.

2,2-Bis(hydroxymethyl)-*N*,*N*′-bis[3-(levulinoyloxy)propyl]-malondiamide (12). A mixture of **11** (2.7 g, 5.3 mmol) in 80% aqueous AcOH (50 mL) was stirred for 2 h at room temperature

Scheme 2 [a]

[a] Reagents and conditions: (i) allyl alcohol, $BF_3{\cdot}Et_2O$, dichloromethane, (ii) allyl methyl carbonate, $Pd(OAc)_2$, PPh_3, THF, reflux for 15 min, (iii) (1) NaOMe/MeOH, (2) NaH, 4-methoxybenzyl chloride, DMF, (iv) (1) OsO_4, $NaIO_4$, H_2O, dioxane, (2) $NaBH_4$, EtOH, dichloromethane, (v) levulinic anhydride, DMAP, pyridine, (vi) H_2, Pd/C, EtOH, (vii) DMTrCl, pyridine, (viii) 2-cyanoethyl *N*,*N*-diisopropylphosphonamidic chloride, NEt_3, dichloromethane.

and evaporated to dryness. The residue was coevaporated several times with water and then subjected to a silica gel column. Chromatographic purification (0 to 10% MeOH in dichloromethane) afforded 1.8 g (70%) of **12** as a colorless oil. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.74 (t, 2H, J = 5.6 Hz), 4.11 (t, 4H, J = 6.1 Hz), 3.90 (s, 4H), 3.36 (m, 4H), 2.76 (dd, 4H, J = 6.7 Hz, 6.3 Hz), 2.58 (dd, 4H, J = 6.7 Hz, 6.3 Hz), 2.19 (s, 6H), 1.85 (m, 4H); ^{13}C NMR ($CDCl_3$, 125 MHz): δ 207.0, 173.0, 171.5, 64.1, 61.8, 58.1, 37.9, 36.4, 35.1, 29.8, 28.3, 27.9; MS (EI): M^+ requires 474.2, found 474.

2-(4,4′-Dimethoxytrityloxymethyl)-2-hydroxymethyl-*N*,*N*′-bis[3-(levulinoyloxy)propyl]malondiamide (13). 4,4′-Dimethoxytrityl chloride (1.3 g, 3.7 mmol) was slowly added to a mixture of **12** (1.8 g, 3.7 mmol) in dry pyridine (10 mL), and the mixture was then stirred overnight at room temperature. After evaporation, the residue was dissolved in dichloromethane and washed with 5% aq $NaHCO_3$. The organic phase was dried with Na_2SO_4 and evaporated to dryness. The residue was coevaporated with toluene and purified by silica gel chromatography (0 to 10% MeOH in dichloromethane) to give 1.71 g (59%) of **13** as a colorless oil. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.51 (t, 2H, J = 5.8 Hz), 7.40−7.16 (m, 9H), 6.84 (m, 4H), 4.14 (t, 1H, J = 6.0 Hz), 4.09 (t, 4H, J = 6.1 Hz), 3.90 (m, 2H), 3.81 (s, 6H), 3.47 (s, 2H), 3.39 (m, 4H), 2.76 (m, 4H), 2.58 (m, 4H,), 2.20 (s, 6H), 1.84 (m, 4H); ^{13}C NMR ($CDCl_3$, 125 MHz): δ 206.7, 173.0, 172.8, 170.6, 158.6, 144.3, 135.2, 130.1, 129.1, 127.7, 126.9, 112.9, 86.4, 65.3, 64.2, 63.9, 62.0, 61.8, 58.5, 57.6, 55.3, 55.2, 37.9, 36.6, 36.3, 29.9, 28.4, 28.3, 27.9; MS (ESI): $[M+Na]^+$ requires 799.3, found 799.7.

2-Cyanoethyl 3-(4,4′-Dimethoxytrityloxy)-2,2-bis[*N*-(3-levulinoyloxypropyl)carbamoyl]propyl *N*,*N*-Diisopropylphosphoramidite (14). Compound **13** (1.6 g, 2.0 mmol) was dried by repeated coevaporations with dry acetonitrile and dissolved in dry acetonitrile (2.0 mL). 2-Cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite (0.83 mL, 2.6 mmol) and tetrazole (4.5 mL of 0.45 M solution in acetonitrile, 2.01 mmol) were added to the mixture, and the reaction was then allowed to stir at room temperature for 2 h. Acetonitrile was removed in vacuo, saturated aq $NaHCO_3$ was added to the residue, and the product was then extracted with dichloromethane. The organic phase was separated, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (1% triethylamine in EtOAc) to yield 1.6 g (80%) of the product (**14**) as a colorless oil. ^{1}H NMR ($CDCl_3$, 500 MHz): δ 7.51 (t, 1H, J = 5.8 Hz), 7.44 (m, 2H), 7.34−7.29 (m, 7H), 7.23 (m, 1H), 4.14−4.02 (m, 4H), 3.81 (s, 6H), 3.75−3.71 (m, 2H), 3.66 (s, 2H), 3.56−3.50 (m, 2H), 3.37−3.24 (m, 4H), 2.77−2.74 (m, 4H), 2.59−2.54 (m, 4H), 2.19 (s, 6H), 1.83−1.77 (m, 4H), 1.18, 1.16, 1.10 and 1.10 (each s, each 3H); ^{13}C NMR ($CDCl_3$, 125 MHz): δ 206.6, 172.7, 169.9, 169.7, 158.6, 144.2, 135.2, 130.0, 128.0, 127.9, 127.0, 113.2, 86.6, 64.9, 64.8, 63.5, 62.0, 61.9, 58.6, 58.5, 55.2, 53.5, 45.4, 45.3, 43.3, 37.9, 36.5, 29.9, 28.4, 27.9, 24.5, 23.5, 23.0, 20.3, 19.3; ^{31}P NMR ($CDCl_3$, 200 MHz): δ 149.2; HRMS (ESI) $[M + Na]^+$ requires 999.4491, found 999.4461.

Allyl 2,5-Di-*O*-acetyl-3-*O*-allyl-β-D-ribofuranoside (18a) and Allyl 3,5-Di-*O*-acetyl-2-*O*-allyl-β-D-ribofuranoside (18b). An equimolar mixture of isomeric allyl di-*O*-acetyl-β-D-ribofuranosides (**16a**,**b**, each 19%) and allyl tri-*O*-acetyl-β-D-ribofuranoside (**17**; 39%) was obtained by boron trifluoride-promoted glycosidation of 1,2,3,5-tetra-*O*-acetyl-β-ribofuranose (**15**) with allyl alcohol in dichloromethane (*44*) (Scheme 2). The di-*O*-acetylated products (**16a**,**b**; 5.0 g, 18 mmol), allyl methyl carbonate (4.1 mL, 36 mmol), $Pd(OAc)_2$ (80 mg, 0.36 mmol, 0.02 equiv), and Ph_3P (0.48 g, 0.18 mmol, 0.1 equiv) were dissolved in THF (50 mL), and the mixture was refluxed for 15 min and then evaporated to dryness (*45*). The residue was purified by silica gel chromatography (20% EtOAc in petroleum ether) to yield 3.0 g (52%) of allyl 2,5-di-*O*-acetyl-3-*O*-allyl-β-D-ribofuranoside (**18a**) and 2.0 g (34%) of allyl 3,5-bis-*O*-acetyl-2-*O*-allyl-β-D-ribofuranoside (**18b**). The isomers were obtained as colorless oils. **18a**: ^{1}H NMR ($CDCl_3$, 500 MHz) δ

5.90−5.81 (m, 2H), 5.28 (m, 2H, 5.25 (d, 1H, J = 4.4 Hz), 5.01 (s, 1H), 4.86 (dd, 1H, J = 11.4, 2.9 Hz), 4.24−4.04 (m, 5H), 3.99−3.94 (m, 2H), 2.14 (s, 3H), 2.10 (s, 3H); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 170.8, 169.9, 133.9, 133.6, 118.0, 117.7, 104.3, 78.9, 77.6, 73.8, 72.1, 68.3, 64.8, 20.9, 20.8; HRMS (ESI) $[M + Na]^+$ requires 337.1258, found 337.1257. **18b**: ^{1}H NMR ($CDCl_3$, 500 MHz) δ 5.91−5.83 (m, 2H), 5,31−5.27 (m, 2H), 5.22−5.20 (m, 2H), 5.13 (dd, 1H, J = 6.1 Hz, 5.3 Hz), 5.06 (d, 1H, J = 0.6 Hz), 4.37−4.32 (m, 2H), 4.23 (m, 1H), 4.13−4.03 (m, 4H), 3.98 (m, 1H), 2.13 (s, 3H), 2.09 (s, 3H); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 170.7, 170.3, 134.0, 133.8, 117.6, 117.3, 104.9, 80.5, 78.8, 73.1, 72.0, 68.5, 64.5, 20.9, 20.8; HRMS (ESI) $[M + Na]^+$ requires 337.1258, found 337.1255.

Allyl 2,5-Di-*O*-(4-methoxybenzyl)-3-*O*-allyl-*β*-D-ribofuranoside (19a). Compound **18a** (2.3 g, 7.2 mmol) was dissolved in 0.1 mol L^{-1} methanolic sodium methoxide (25 mL). The mixture was stirred at ambient temperature for 1 h, neutralized by addition of strongly acidic cation-exchange resin, and filtered. The filtrate was evaporated to dryness, and the residue was dissolved in dry DMF (7.0 mL) and cooled to 0 °C. NaH (60% dispersion in mineral oil, 0.63 g, 16 mmol) and 4-methoxybenzyl chloride (2.4 mL, 18 mmol) were added, and the mixture was then stirred overnight at ambient temperature. Water (20 mL) was added, and the product was extracted by diethyl ether (2 × 20 mL). The organic phases were combined, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (20% EtOAc in petroleum ether) to yield 2.9 g (86%) of the product (**19a**) as a colorless oil. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.33−7.27 (m, 4H), 6.91−6.87 (m, 4H), 5.94−5.82 (m, 2H), 5.28−5.22 (m, 2H), 5.19−5.16 (m, 2H), 5.04 (s, 1H), 4.66 (d, 1H, J = 11.8 Hz), 4.61 (d, 1H, J = 11.8 Hz), 4.56 (d, 1H, J = 11.8 Hz), 4.52 (d, 1H, J = 11.8 Hz), 4.30 (ddd, 1H, J = 7.0 Hz, 6.3 Hz, 3.7 Hz), 4.19 (m, 1H), 4.03−3.90 (m, 4H), 3.83 (s, 3H), 3.82 (s, 3H), 3.64 (dd, 1H, J = 10.6 Hz, 3.6 Hz), 3.54 (dd, 1H, J = 10.6 Hz, 6.1 Hz); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 159.4, 159.1, 134.5, 134.2, 130.5, 129.9, 129.7, 129.3, 117.4, 117.3, 113.8, 113.7, 104.5, 80.5, 79.2, 78.5, 72.8, 71.9, 71.5, 71.2, 68.2, 55.3, 55.3; HRMS (ESI) $[M + Na]^+$ requires 493.2197, found 493.2200.

Allyl 3,5-Di-*O*-(4-methoxybenzyl)-2-*O*-allyl-*β*-D-ribofuranoside (19b). 19b was obtained from **18b** (1.0 g, 3.3 mmol) as described for **19a**. The product (**19b**) was a colorless oil in a 75% yield (1.2 g). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.29−7.26 (m, 4H), 6.90−6.86 (m, 4H), 5.97−5.83 (m, 2H), 5.35−5.16 (m, 4H), 5.07 (s, 1H), 4.56 (d, 1H, J = 11.6 Hz), 4.53 (d, 1H, J = 11.7 Hz), 4.49 (d, 1H, J = 11.7 Hz), 4.48 (d, 1H, J = 11.6 Hz), 4.30 (ddd, 1H, J = 6.3 Hz, 6.3 Hz, 3.9 Hz), 4.20 (m, 1H), 4.17−4.08 (m, 2H), 4.04 (dd, 1H, J = 7.0 Hz, 4.7 Hz), 3.96 (m, 1H), 3.84 (d, 1H, J = 4.8 Hz), 3.83 (s, 3H), 3.82 (s, 3H), 3.59 (dd, 1H, J = 10.7 Hz, 3.8 Hz), 3.49 (dd, 1H, J = 10.6 Hz, 6.0 Hz); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 159.3, 159.1, 134.5, 134.2, 130.5, 130.0, 129.6, 129.3, 117.6, 117.3, 113.8, 113.7, 104.5, 80.5, 79.9, 78.2, 72.8, 72.1, 71.5, 71.1, 68.3, 55.3, 55.3; HRMS (ESI) $[M + Na]^+$ requires 493.2197, found 493.2182.

(2-Hydroxyethyl) 3-*O*-(2-hydroxyethyl)-2,5-di-*O*-(4-methoxybenzyl)-*β*-D-ribofuranoside (20a). Osmium tetroxide (2.5 wt. % solution in 2-methyl-2-propanol, 1.0 mL, 80 μmol) was added to a mixture of **19a** (2.9 g, 6.1 mmol) in water−dioxane (1:4 *v*/*v*, 20 mL) (*46*). After 1 h stirring, the mixture was cooled to 0 °C, the solvent volume was increased to 80 mL, and $NaIO_4$ (6.6 g, 31 mmol) was slowly added. The reaction was then stirred at ambient temperature for 5 h. The resulted aldehyde intermediate was extracted with ethyl acetate (3 × 20 mL). The organic phases were combined, dried with Na_2SO_4, and evaporated to dryness. The residue was dissolved in a mixture of dichloromethane−ethanol (1:2, *v*/*v*, 30 mL), and then $NaBH_4$ (1.2 g, 31 mmol) was added. After 5 h stirring, the excess $NaBH_4$ was destroyed by addition of saturated ammonium chloride (20 mL) and the product was extracted with dichloromethane (3 × 15 mL). The organic phases were combined, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (10% MeOH in dichloromethane) to yield 1.8 g (60%) of **20a** as a colorless oil. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.32−7.27 (m, 4H), 6.92−6.88 (m, 4H), 5.02 (s, 1H), 4.66 (d, 1H, J = 11.5 Hz), 4.59 (d, 1H, J = 11.9 Hz), 4.59 (d, 1H, J = 11.5 Hz), 4.48 (d, 1H, J = 11.9 Hz), 4.21 (m, 1H), 4.13 (dd, 1H, J = 7.6 Hz, 4.6 Hz), 3.94 (d, 1H, J = 4.6 Hz), 3.82 (s, 6H), 3.77−3.63 (m, 7H), 3.58 (m, 1H), 3.54−3.50 (m, 2H), 3.19 (dd, 1H, J = 6.7 Hz, 5.7 Hz), 2.47 (t, 1H, J = 6.2 Hz); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 159.5, 159.4, 129.8, 129.6, 129.4, 113.9, 113.8, 105.5, 80.1, 79.6, 78.4, 72.9, 72.1, 71.9, 71.3, 68.9, 61.9, 61.7, 55.3, 55.3; HRMS (ESI) $[M + Na]^+$ requires 501.2095, found 501.2087.

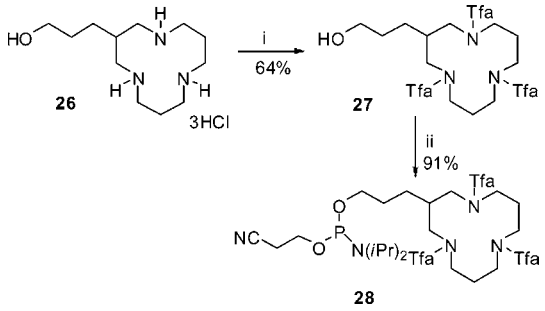
(2-Hydroxyethyl) 2-*O*-(2-Hydroxyethyl)-3,5-di-*O*-(4-methoxybenzyl)-*β*-D-ribofuranoside (20b). 20b was synthesized from **19b** (1.1 g, 2.4 mmol) as described for **20a**. The product (**20b**) was obtained as a colorless oil in a 46% yield (0.52 g). ^{1}H NMR ($CDCl_3$, 500 MHz) β 7.29−7.22 (m, 4H), 6.91−6.87 (m, 4H), 5.00 (s, 1H), 4.53 (d, 1H, J = 11.8 Hz), 4.51 (d, 1H, J = 11.2 Hz), 4.44 (d, 1H, J = 11.2 Hz), 4.41 (d, 1H, J = 11.8 Hz), 4.23 (dd, 1H, J = 7.6 Hz, 4.3 Hz), 4.19 (m, 1H), 3.82 (s, 3H), 3.81 (s, 3H), 3.82−3.60 (m, 10H), 3.45 (dd, 1H, J = 10.7 Hz, 3.6 Hz), 3.32 (t, 1H, J = 6.5 Hz), 2.62 (t, 1H, J = 6.2 Hz); ^{13}C NMR ($CDCl_3$, 125 MHz) β 159.5, 159.3, 129.7, 129.7, 129.6, 129.5, 113.9, 113.8, 105.9, 81.4, 80.0, 77.1, 72.9, 72.5, 72.4, 71.5, 68.5, 61.9, 61.8, 55.3, 55.3; HRMS (ESI) $[M + Na]^+$ requires 501.2095, found 501.2072.

(2-Levulinoyloxyethyl) 3-*O*-(2-Levulinoyloxyethyl)-2,5-di-*O*-(4-methoxybenzyl)-*β*-D-ribofuranoside (21a). Levulinic anhydride (0.90 g, 4.2 mmol) was added to a mixture of **20a** (0.56 g, 1.2 mmol) in pyridine (10 mL). After 3 h stirring, saturated $NaHCO_3$ (20 mL) was added to the mixture and then the product was extracted with ethyl acetate (3 × 20 mL). The organic phases were combined, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography to yield 0.73 g (92%) of the product (**21a**) as a colorless oil. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.33−7.26 (m, 4H), 6.91−6.87 (m, 4H), 5.02 (d, 1H, J = 0.8 Hz), 4.66 (d, 1H, J = 11.7 Hz), 4.62 (d, 1H, J = 11.7 Hz), 4.55 (d, 1H, J = 11.7 Hz), 4.51 (d, 1H, J = 11.7 Hz), 4.27 (ddd, 1H, J = 6.9 Hz, 5.9 Hz, 3.8 Hz), 4.23−4.19 (m, 3H), 4.10 (ddd, 1H, J = 12.0 Hz, 7.0 Hz, 3.4 Hz), 3.98 (dd, 1H, J = 7.0 Hz, 4.7 Hz), 3.92 (dd, 1H, J = 4.7 Hz, 0.8 Hz), 3.84 (ddd, 1H, J = 11.4 Hz, 5.7 Hz, 3.4 Hz), 3.82 (s, 3H), 3.82 (s, 3H), 3.70−3.57 (m, 4H), 3.53 (dd, 1H, J = 10.7 Hz, 5.8 Hz), 2.76−2.70 (m, 4H), 2.60−2.53 (m, 4H), 2.20 (s, 3H), 2.18 (s, 3H); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 206.5, 206.5, 172.7, 172.6, 159.4, 159.2, 130.3, 129.9, 129.5, 129.3, 113.8, 113.7, 105.2, 80.5, 79.6, 79.3, 72.8, 72.0, 71.0, 68.4, 65.2, 63.7, 63.5, 55.3, 55.3, 37.8, 37.8, 29.9, 29.8, 27.8, 27.8; HRMS (ESI) $[M + Na]^+$ requires 697.2831, found 697.2860.

(2-Levulinoyloxyethyl) 2-*O*-(2-Levulinoyloxyethyl)-di-*O*-(4-methoxybenzyl)-*β*-D-ribofuranoside (21b). 21b was synthesized from **20b** (0.50 g, 1.0 mmol) as described for **21a**. The product (**21b**) was obtained as a colorless oil in an 81% yield (0.57 g). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.29−7.24 (m, 4H), 6.90−6.86 (m, 4H), 5.03 (s, 1H), 4.56 (d, 1H, J = 11.5 Hz), 4.51 (d, 1H, J = 11.7 Hz), 4.48 (d, 1H, J = 11.5 Hz), 4.47 (d, 1H, J = 11.7 Hz), 4.29−4.20 (m, 4H), 4.10 (ddd, 1H, J = 11.9 Hz, 7.1 Hz, 3.4 Hz), 4.04 (dd, 1H, J = 7.1 Hz, 4.7 Hz), 3.86−3.79 (m, 4H), 3.82 (s, 3H), 3.82 (s, 3H), 3.61 (ddd, 1H, J = 11.3 Hz, 7.0 Hz, 3.4 Hz), 3.59 (dd, 1H, J = 10.6 Hz, 3.7 Hz), 3.48 (dd, 1H, J = 10.6 Hz, 5.9 Hz), 2.76−2.73 (m, 4H), 2.60−2.54 (m, 4H), 2.20 (s, 3H), 2.19 (s, 3H); ^{13}C NMR

($CDCl_3$, 125 MHz) δ 206.5, 206.5, 172.7, 172.6, 159.3, 159.2, 130.3, 130.0, 129.5, 129.3, 113.8, 113.7, 105.2, 81.1, 80.6, 78.2, 72.8, 72.2, 70.9, 68.5, 65.2, 63.8, 63.5, 55.3, 55.3, 37.9, 37.8, 29.9, 29.8, 27.9, 27.9; HRMS (ESI) $[M + Na]^+$ requires 697.2831, found 697.2851.

(2-Levulinoyloxyethyl) 5-*O*-(4,4′-Dimethoxytrityl)-3-*O*-(2-levulinoyloxyethyl)-β-D-ribofuranoside (23a). Compound **21a** (0.65 g, 0.96 mmol) was dissolved in ethanol (10 mL). Pd/C (10% Pd/C, 50% wet with water, 0.13 g) was added, and then hydrogen was bubbled through the mixture for 2 h at ambient temperature. The mixture was filtered, the filtrate was evaporated to dryness, and the residue was purified by silica gel chromatography to yield 0.37 g (88%) of the (2-levulinoyloxyethyl) 3-*O*-(2-levulinoyloxyethyl)-β-D-ribofuranoside (**22**) as a colorless oil. HRMS (ESI) $[M + Na]^+$ requires 457.1680, found 457.1699. Compound **22** was dissolved in pyridine (5 mL), and then DMTrCl[1] (0.29 g, 0.86 mmol) was slowly added. The reaction was stirred overnight at ambient temperature. Saturated $NaHCO_3$ (20 mL) was added to the mixture, and the product was extracted with dichloromethane (3×20 mL). The organic phases were combined, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (80% EtOAc in petroleum ether) to yield 0.54 g (93%, 82% from **21a**) of the product (**23a**) as a colorless oil. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.50−7.47 (m, 2H), 7.38−7.35 (m, 4H), 7.32−7.29 (m, 3H), 7.23 (m, 1H), 6.86−6.83 (m, 4H), 5.03 (s, 1H), 4.27 (ddd, 1H, J = 12.1 Hz, 5.1 Hz, 2.9 Hz), 4.20−4.15 (m, 4H), 4.13−4.08 (m, 2H), 3.83 (ddd, 1H, J = 11.4 Hz, 5.2 Hz, 3.4 Hz), 3.81 (s, 6H), 3.72 (ddd, 1H, J = 11.2 Hz, 5.2 Hz, 3.0 Hz), 3.68−3.60 (m, 2H), 3.32 (dd, 1H, J = 10.0 Hz, 4.5 Hz), 3.19 (dd, 1H, J = 10.0 Hz, 5.0 Hz), 3.00 (d, 1H, J = 3.1 Hz), 2.77−2.74 (m, 2H), 2.71−2.69 (m, 2H), 2.57−2.54 (m, 2H), 2.52−2.49 (m, 2H), 2.20 (s, 3H), 2.18 (s, 3H); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 206.7, 206.5, 172.6, 172.6, 158.5, 144.9, 136.1, 136.0, 130.0, 130.0, 128.2, 127.8, 126.8, 113.1, 107.4, 85.9, 80.6, 80.2, 73.4, 68.7, 65.5, 64.2, 63.5, 63.4, 55.2, 37.9, 37.9, 29.8, 29.8; HRMS (ESI) $[M + Na]^+$ requires 759.2987, found 759.3007.

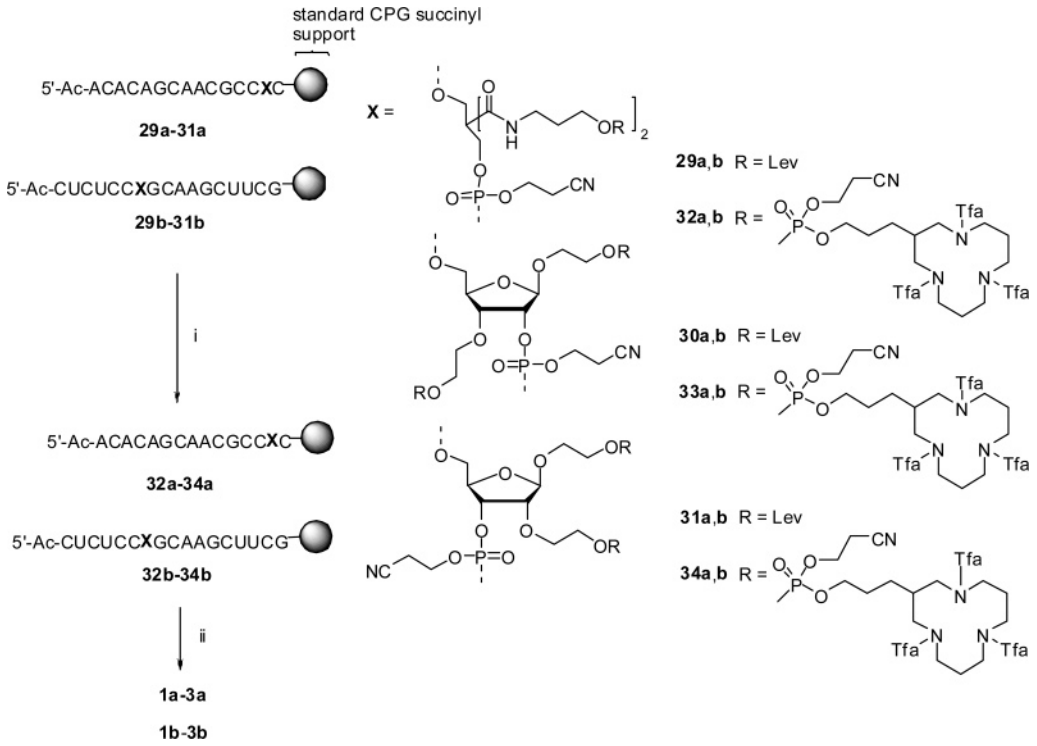


(2-Levulinoyloxyethyl) 5-*O*-(4,4′-Dimethoxytrityl)-2-*O*-(2-levulinoyloxyethyl)-β-D-ribofuranoside (23b). 23b was synthesized from **21b** (0.55 g, 0.82 mmol) as described for **23a**, except that the 2-levulinoyloxyethyl 2-*O*-(2-levulinoyloxyethyl)-β-D-ribofuranoside intermediate was used without chromatographic purification. The product (**23b**) was obtained as a colorless oil in a 70% overall yield (0.42 g). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.51−7.49 (m, 2H), 7.40−7.36 (m, 4H), 7.31−7.27 (m, 2H), 7.22 (m, 1H), 6.85−6.82 (m, 4H), 5.08 (d, 1H, J = 1.4 Hz), 4.34−4.21 (m, 4H), 4.14−4.08 (m, 2H), 3.94 (ddd, 1H, J = 11.4 Hz, 5.3 Hz, 3.4 Hz), 3.88 (ddd, 1H, J = 11.3 Hz, 5.6 Hz, 3.3 Hz), 3.86 (dd, 1H, J = 4.8 Hz, 1.4 Hz), 3.81 (s, 6H), 3.80 (ddd, 1H, J = 11.3 Hz, 6.6 Hz, 3.4 Hz), 3.66 (ddd, 1H, J = 11.4 Hz, 7.1 Hz, 3.3 Hz), 3.34 (dd, 1H, J = 10.0 Hz, 3.6 Hz), 3.15 (dd, 1H, J = 10.0 Hz, 5.5 Hz), 2.80−2.77 (m, 2H), 2.72 (d, 1H), J = 8.4 Hz), 2.70−2.67 (m, 2H), 2.63−2.60 (m, 2H), 2.50−2.46 (m, 2H), 2.21 (s, 3H), 2.16 (s, 3H); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 206.7, 206.5, 172.7, 172.6, 158.4, 145.0, 136.1, 136.1, 130.1, 130.1, 128.2, 127.8, 126.7, 113.1, 104.8, 85.9, 83.6, 83.1, 71.6, 68.9, 65.6, 64.7, 63.4, 55.2, 37.9, 37.8, 29.8, 29.8, 27.9, 27.8; HRMS (ESI) $[M + Na]^+$ requires 759.2987, found 759.3015.

2-Cyanoethyl [(2-Levulinoyloxyethyl) 5-*O*-(4,4′-dimethoxytrityl)-3-*O*-(2-levulinoyloxyethyl)-β-D-ribofuranoside-2-yl] *N,N*-Diisopropylphosphoramidite (24). 2-Cyanoethyl *N,N*-diisopropylphosphonamidic chloride (91 μL, 0.41 mmol) was added to a mixture of **23a** (0.25 g, 0.34 mmol) and triethylamine (0.24 mL, 1.7 mmol) in dichloromethane (3.0 mL) under nitrogen. The mixture was stirred for 1 h at ambient temperature and then subjected directly to a silica gel column. Elution with 1% triethylamine in EtOAc yielded 0.30 g (95%) of the product (**24**) as a colorless oil. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.51−7.49 (m, 2H), 7.40−7.36 (m, 4H), 7.31−7.28 (m, 2H), 7.24−7.20 (m, 1H), 6.86−6.82 (m, 4H), 5.15 and 5.01 (s 0.48H and s 0.52H), 4.30−4.10 (m, 7H), 3.96−3.87 (m, 2H), 3.81 and 3.80 (s and s, 6H), 3.82−3.53 (m, 8H), 3.41−3.37 (m, 1H), 3.15−3.12 (m, 1H), 2.73−2.64 (m, 6H), 2.55−2.43 (m, 4H), 2.18 (s, 6H), 2.17 (s, 3H), 2.17 (s, 3H), 1.23−1.19 (m, 12H); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 206.5, 206.5, 172.6, 172.6, 158.4, 145.0, 145.0, 136.2, 136.1, 130.1, 130.1, 128.2, 128.2, 127.8, 126.7, 117.9, 117.7, 113.1, 106.5, 106.4, 85.7, 85.7, 80.3, 80.3, 79.2, 78.8, 75.0, 74.8, 73.5, 73.4, 68.5, 68.0, 65.5, 65.4, 63.9, 63.7, 63.6, 63.5, 63.4, 59.0, 58.9, 58.0, 57.8, 55.2, 43.4, 43.3, 43.2, 43.0, 37.8, 37.8, 29.8, 27.8, 27.8, 24.7, 24.6, 24.6, 24.5, 20.4, 20.4; ^{31}P NMR ($CDCl_3$, 200 MHz) δ 150.6, 149.8; HRMS (ESI) $[M + H]^+$ requires 937.4246, found 937.4290.

2-Cyanoethyl [(2-Levulinoyloxyethyl) 5-*O*-(4,4′-dimethoxytrityl)-2-*O*-(2-levulinoyloxyethyl)-β-D-ribofuranoside-3-yl] *N,N*-Diisopropylphosphoramidite (25). 25 was synthesized from **23b** (0.19 g, 0.26 mmol) as described for **24**. The product (**25**) was obtained as a colorless oil in an 89% yield (0.24 g). ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.54−7.50 (m, 2H), 7.41−7.30 (m, 6H), 7.27−7.22 (m, 1H), 6.91−6.88 (m, 4H), 5.05 (m, 1H), 4.43−4.10 (m, 7H), 3.95−3.52 (m, 10H), 3.79 and 3.79 (s and s, 6H), 3.39 (dd, 0.63H, J = 10.4 Hz, 2.5 Hz), 3.29 (dd, 0.37H, J = 10.2 Hz, 2.7 Hz), 3.09−3.05 (m, 1H), 2.77−2.74 (m, 2H), 2.69−2.66 (m, 3H), 2.55−2.52 (m, 2H), 2.49−2.46 (m, 1H), 2.44−2.35 (m, 2H), 2.15, 2.14 and 2.11 (each s, 6H), 1.17, 1.16, 1.15, 1.15, 1.14, 1.13, 1.00, 0.99 (each s, 12H); ^{13}C NMR (CD_3CN, 125 MHz) δ 206.8, 206.8, 206.7, 172.6, 172.6, 172.5, 172.5, 158.6, 145.3, 136.2, 136.1, 130.1, 130.1, 130.1, 128.1, 128.0, 127.8, 127.8, 126.8, 118.6, 118.3, 113.1, 113.0, 105.6, 105.2, 85.8, 85.7, 82.3, 82.3, 82.2, 82.2, 81.5, 81.5, 81.4, 73.0, 72.9, 72.3, 72.2, 68.7, 68.5, 65.4, 65.4, 64.3, 63.9, 63.7, 63.6, 63.1, 58.6, 58.4, 54.9, 54.9, 43.0, 43.0, 42.9, 42.9, 37.5, 37.4, 29.0, 28.9, 27.7, 27.7, 27.6, 24.1, 24.1, 24.0, 23.9, 23.9, 23.8, 20.0, 20.0, 19.9, 19.9; ^{31}P NMR ($CDCl_3$, 200 MHz) δ 149.6, 149.1; HRMS (ESI) $[M + H]^+$ requires 937.4246, found 937.4283.

1,5,9-Tris(2,2,2-trifluoroacetyl)-3-(3-hydroxypropyl)-1,5,9-triazacyclododecane (27). The 3-(3-hydroxypropyl)-1,5,9-triazacyclododecane trihydrochloride (**26**, Scheme 3) was synthesized as earlier described (*42*). Freshly distilled methyl trifluoroacetate (7.1 mL, 71 mmol) was added in two portions to a mixture of **26** (1.0 g, 3.0 mmol) and NaOMe (0.96 g, 18 mmol) in MeOH (10 mL). The reaction was stirred at ambient temperature for 48 h, and then ethyl acetate (200 mL) and 1 mol L^{-1} aqueous hydrogen chloride (20 mL) were added to the



Scheme 3 [a]

[a] Reagents and conditions: (i) methyl trifluoroacetate, NaOMe, MeOH, (ii) 2-cyanoethyl *N,N*-diisopropylphosphonamidic chloride, NEt_3, dichloromethane.

[1] Abbreviations: All, allyl; CPG, controlled pore glass; DMAP, 4-dimethylaminopyridine; DMTr, 4,4′-dimethoxytrityl; HEPES, 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid; Lev, levulinoyl (4-oxopentanoyl); PMB, 4-methoxybenzyl; Tfa, trifluoroacetyl.

Scheme 4 [a]

[a] Reagents and conditions: (i) (1) hydrazine hydrate, pyridine, AcOH (0.124/4/1, v/v/v, 1h at 25 °C) (2) two consecutive standard phosphoramidite couplings with **28** (600 s coupling time, 0.1 mol L^{-1} solution of **28** in acetonitrile), (ii) aq NH_3, 15 h at 55 °C.

mixture. The organic phase was separated, washed with saturated $NaHCO_3$ and NaCl solutions, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (70% EtOAc in petroleum ether) to yield 0.98 g (64%) of the product (**19**) as white foam. ^{1}H NMR (MeOD, 500 MHz) δ 4.10−3.15 (m, 14H), 2.64−1.92 (m, 5H), 1.72−1.28 (m, 4H); HRMS (ESI) $[M + H]^+$ requires 518.1696, found 518.1717.

2-Cyanoethyl 3-[1,5,9-Tris(2,2,2-trifluoroacetyl)-1,5,9-triazacyclododecan-3-yl]propyl *N*,*N*-Diisopropylphosphoramidite (28). Cyanoethyl *N*,*N*-diisopropylphosphonamidic chloride (0.49 mL, 2.2 mmol) was added to a mixture of **27** (0.94 g, 1.8 mmol) and triethylamine (1.27 mL, 9.0 mmol) in dichloromethane (10 mL) under nitrogen. The mixture was stirred for 1 h at room temperature and then directly applied onto a silica gel column (0.4% triethylamine and 80% EtOAc in petroleum ether as an eluent). The chromatographic purification yielded 1.2 g (91%) of the product (**28**) as white foam. ^{1}H NMR (CD_3-CN, 500 MHz) δ 4.05−3.00 (m, 18H), 2.65 (t, 2H, J = 6.0 Hz), 2.50−1.90 (m, 5H), 1.75−1.25 (m, 4H), 1.19−1.15 (m, 12H); ^{31}P NMR ($CDCl_3$, 200 MHz) δ 148.0, 147.7, 147.6, 147.5, 147.4; HRMS (ESI) $[M + Na]^+$ requires 740.2594, found 740.2594.

Synthesis of the 2′-*O*-Methyl Oligoribonucleotide Conjugates (1a−3a, 1b−3b). The 2′-*O*-methyl oligoribonucleotide conjugates (**1a**−**3a**, **1b**−**3b**, Chart 1) were assembled on an Applied Biosystems 3400 DNA synthesizer in 1.0 μmol scale using conventional phosphoramidite chemistry and following the standard RNA coupling protocol (Scheme 4). Coupling efficiency of branching units **24** and **25** was equal to that of the commercially available 2′-*O*-methylnucleoside phosphoramidites (0.1 mol L^{-1} solutions of **24** and **25** in acetonitrile, 600 s coupling time). Building block **1** was somewhat less reactive, requiring two consecutive coupling cycles (0.1 mol L^{-1} solutions of **1** in acetonitrile, 600 s coupling time, twice) and prolonged detritylation time [three consecutive standard detritylation treatments (3% DCA in dichloromethane)]. Once the 2′-*O*-methyl oligoribonucleotide chains were assembled to obtain **29a**−**31a** and **29b**−**31b**, the levulinoyl protections were manually removed by 0.5 mol L^{-1} hydrazine acetate solution (0.124/4/1 $NH_2NH_2 \cdot H_2O$/pyridine/AcOH *v*/*v*/*v*, 1 h at 25 °C). The deprotected resin-bound oligonucleotides were washed with pyridine, MeOH, and acetonitrile, dried, and reset to the DNA synthesizer. The azacrown phosphoramidite reagent (**28**) was then coupled using two consecutive standard couplings (0.1 mol L^{-1} solution of **4** in dry acetonitrile, 600 s coupling time, twice). Fully protected resin-bound 2′-*O*-methyl oligoribonucleotide conjugates (**32a**−**34a**, **32b**−**34b**) were released from the support and deprotected by concentrated ammonia (15 h at 55 °C). The crude product mixtures were filtered, and the filtrates were evaporated to dryness, dissolved in water, and then subjected to RP HPLC purification. Purity of the crude conjugates (**1a**−**3a**, **1b**−**3b**) ranged from 20 to 30% (according to RP HPLC chromatograms). Isolated yields of the conjugates were 10 to 15% [according to UV absorbances of dissolved **1a**−**3a**, **1b**−**3b**]. The authenticity of the conjugates was verified by MS(ESI) and MS(MALDI) spectroscopy. Three main multiply charged peaks in the MS(ESI) spectra are listed below. **1a**: MS(ESI) $[(M - nH)/n]^{-n}$, n = 6, 7, and 8 requires 690.4, 789.1, and 920.8, found 690.2, 789.0, and 920.6, **2a**: MS(ESI) $\{[M + Na - (n + 1)H]/n\}^{-n}$, n = 6, 7, and 8 requires 918.2, 786.8 and 688.4, found 920.0, 788.6 and 690.0, **3a**: MS(ESI) $[(M - nH)/n]^{-n}$, n = 7, 8, and 9 requires 783.4, 685.4, and 609.1, found 784.9, 686.4, and 610.3. **1b**: MS(ESI) $\{[M + Na - (n + 1)H]/n\}^{-n}$, n = 7, 8, and 9 requires 879.7, 769.6, and 684.0, found 881.3, 771.2, and 685.5, **2b**: MS(ESI) $[(M - nH)/n]^{-n}$, n = 7, 8, and 9 requires 870.6, 761.6, and 676.9, found 870.4, 761.6, and 676.9, **3b**: MS(MALDI) $(M + H)^+$ requires 6102, found 6103.

Kinetic Measurements. The reactions were carried out in Eppendorf tubes immersed in a water bath, and the temperature of which was maintained at 35.0 ± 0.1 °C. pH was adjusted to 7.3 with a HEPES buffer (0.1 mol L^{-1}) prepared in sterilized water. The Zn^{2+} ion was added as a nitrate salt to give the overall metal ion concentration of 90 or 180 μmol L^{-1}. The

ionic strength was adjusted to 0.1 mol L^{-1} with sodium nitrate. The concentration of the artificial nuclease (**1a**−**3a**, **1b**−**3b**) was 9 or 18 μmol L^{-1} and that of the target (**4**−**6**) 18 or 36 μmol L^{-1}. 4-Nitrobenzenesulfonate ion was used as an internal standard. The total volume of the reaction mixture was 200 μL in each kinetic run. Aliquots of 20 μL were withdrawn at suitable intervals and cooled immediately to 0 °C, and the reaction was quenched by adding aqueous hydrogen chloride (1.0 μL of 1.0 mol L^{-1} solution). This results in release of the Zn^{2+} ion from the azacrown ligand and markedly decelerates the reaction, since the metal ion-catalyzed cleavage of RNA is known to be first-order in hydroxide ion concentration at pH < 7 (*47*). After this, the composition of the samples was quantified by capillary zone elctrophoresis (Beckman Coulter P/ACE MDQ CE System) using a fused silica capillary (inner diameter 50 μm, effective length 50 cm). Inverted polarity, citrate buffer (0.2 mol L^{-1}, pH 3.1) and −30 kV voltage were used. The temperature of the capillary was kept at 25 °C. Hydrodynamic injection at 2 psi for 8 s was applied. Between each analytical run, the capillary was flushed for 3 min with water, 10 mmol L^{-1} aqueous hydrogen chloride, and the background electrolyte buffer. The quantification of the target and product oligonucleotides was based on comparison of their UV absorption at 254 nm to that of the internal standard. The peak area was first normalized by dividing it by the migration time and then by the similarly normalized peak area of the internal standard. First-order rate constants for the cleavage of the target oligonucleotides (**4**−**6**) by the artificial nucleases (**1a**−**3a**, **1b**−**3b**) were obtained by applying the integrated first-order rate law to the disappearance of the target oligonucleotide.

The site of cleavage within target **4** was determined by spiking with reference oligonucleotides **7**−**9**. Each of these was added one after another to a sample containing the cleaved target and the sample was then subjected to capillary electrophoresis. Oligonucleotide **8** comigrated with the product obtained by cleaving **4** with either **1a** or **2a**, while addition of **7** or **9** resulted in appearance of a new peak in the electropherogram.

RESULTS AND DISCUSSION

Synthesis of the Phosphoramidite Reagents (14, 24, 25, 28). Preparation of the artificial nucleases (**1a**−**3a**, **1b**−**3b**) bearing two azacrown ligands attached to a single non-nucleosidic building block was based on standard solid-supported phosphoramidite chemistry. For this purpose, three different non-nucleosidic branching units were prepared and converted to 4,4′-dimethoxytritylated 2-cyanoethyl *N*,*N*-diisopropylphosphoramidite building blocks (**14**, **24**, **25**) as outlined in Schemes 1 and 2. In each building block, the two hydroxy functions aimed at allowing subsequent attachment of the azacrown ligands were protected as levulinic acid esters. As shown previously (*43*, *48*, *49*), this group may be conveniently removed on a solid-support by brief treatment with hydrazinium acetate in pyridine.

The precursor of the bis(hydroxymethyl)malondiamide-derived building-block, *N*,*N*′-bis(3-hydroxypropyl)-2-methoxy-1,3-dioxane-5,5-dicarboxamide (**10** in Scheme 1), was synthesized as described earlier (*43*). The hydroxypropyl arms of this precursor were esterified with levulinic anhydride (**11**) and the orthoester protection was removed (**12**). One of the exposed hydroxy groups was then protected as a DMTr ether (**13**), and the other one was phosphitylated to obtain **14**.

The ribose-based branching units (**24**, **25**) were prepared from commercially available 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (**15** in Scheme 2). A mixture of allyl 2,5- and 3,5-di-*O*-acetyl-β-D-ribofuranosides (**16a** and **16b**), together with allyl 2,3,5-tri-*O*-acetyl-β-D-ribofuranoside, was obtained in one step by BF_3 promoted glycosidation with allylic alcohol (*44*). The exposed hydroxyl group was then allylated under neutral condition with allyl methyl carbonate in the presence of $Pd(OAc)_2$ and triphenylphosphine (*45*). After this step, the isomers, *viz.* allyl 2,5-di-*O*-acetyl-3-*O*-allyl-β-D-ribofuranoside (**18a**) and allyl 3,5-di-*O*-acetyl-2-*O*-allyl-β-D-ribofuranoside (**18b**), were separated, and the base-labile acetyl protections were removed and replaced with 4-methoxybenzyl (PMB) groups (**19a**,**b**). OsO_4 hydroxylation and concomitant $NaIO_4$ oxidation converted the allyl groups to 2-oxoethyl groups, which were subsequently reduced to 2-hydroxyethyl groups with $NaBH_4$ (**20a**,**b**) (*50*). The hydroxyl groups were esterified with levulinic anhydride (**21a**,**b**), the PMB protections were removed by Pd/C-catalyzed hydrogenolysis, and the 5-hydroxy group was protected with a DMTr-group (**23a**,**b**). Phosphitylation of the remaining secondary hydroxy function gave **24** and **25**.

Previously prepared (*42*) 3-(3-hydroxypropyl)-1,5,9-triazacyclododecane (**26**) was converted to trifluoroacetyl-protected phosphoramidite reagent (**28**) as outlined in Scheme 3, i.e., by acylation of the nitrogen atoms with methyl trifluoroacetate in the presence sodium methoxide (**27**) and subsequent phosphitylation of the hydroxypropyl tether (**28**).

Synthesis of the Artificial Ribonucleases (1a−3a, 1b−3b). To verify the applicability of the branching building blocks (**14**, **24**, **25**) to the standard automated oligoribonucleotide synthesis, the coupling of these blocks was first followed by DMTr-cation assay and RP HPLC analysis of the released oligonucleotide aliquots. The coupling efficiency of the ribose-based building blocks (**24**, **25**) turned out to be equal to that of the commercially available 2′-*O*-methylribonucleoside building blocks: the coupling was quantitative in 600 s (standard RNA-coupling protocol, 0.1 mol L^{-1} phosphoramidite solution used). By contrast, two consecutive coupling cycles (2 × 600 s, 0.1 mol L^{-1} solution of **14** in acetonitrile) had to be used with the malondiamide-derived block (**14**) to achieve a satisfactory 95% coupling. For this building block, a prolonged detritylation time (three consecutive standard detritylation cycles) was also needed, consistent with previous observations (*43*, *51*, *52*). These exceptions apart, the 2′-*O*-methyloligoribonucleotides incorporating one of the branching units (**14**, **24**, or **25**) close to the 3′-terminus (**29a**−**31a**) or in the middle of the chain (**29b**−**31b**) were assembled in 1 μmol scale, using conventional phosphoramidite chemistry and following the standard RNA coupling protocol (Scheme 4). After chain assembly, the levulinoyl protections were removed by 1 h treatment with 0.5 mol L^{-1} hydrazinium acetate in pyridine and then the trifluoroacetyl-protected azacrown phosphoramidite (**28**) was coupled. Two consecutive coupling cycles (2 × 600 s, 0.1 mol L^{-1} solution of **28** in acetonitrile) were used for this simultaneous phosphorylation of the two hydroxyalkyl branches to obtain the support-anchored conjugates **32a**−**34a** and **32b**−**34b**. These fully protected conjugates were released into solution and deprotected by a slightly prolonged ammonolytic treatment (concd aq NH_3, 15 h at 55 °C) and purified by RP HPLC (Figure 1). Purity of the crude conjugates (**1a**−**3a**, **1b**−**3b**) ranged from 20 to 30%. The isolated yields varied from 10 to 15%. Authenticity of the conjugates was verified by MS(ESI) and MS(MALDI) spectroscopy.

Cleavage by the 3′-Tethered Conjugates (1a−3a). The cleaving activity of conjugates **1a**−**3a**, bearing the two azacrown moieties close to the 3′-terminus of a 15-mer 2′-*O*-methyl oligoribonucleotide, was determined by using a 20-mer chimeric ribo/2′-*O*-methylribo oligonucleotide (**4**) as a target. Within this target, the 3′-terminus consisted of 9 2′-*O*-methylribonucleotides, ensuring efficient hybridization with the fully complementary artificial nuclease, and the 11 non-methylated nucleotides at the 5′-terminus constituted the actual target sequence incorporating scissile ribonucleoside 3′-phosphodiester bonds. The artificial

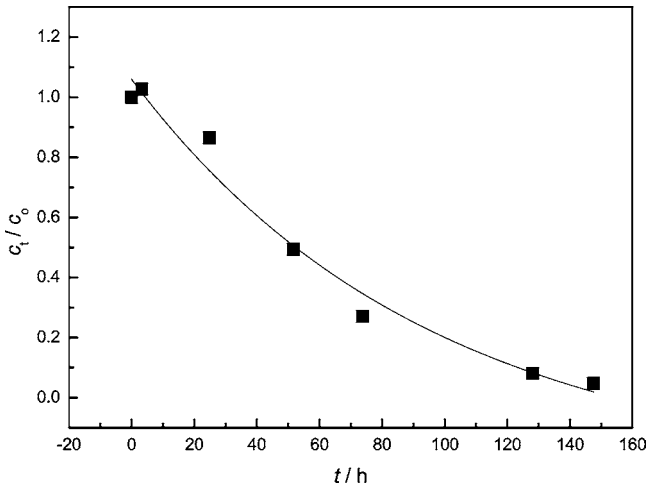


Figure 1. Cleavage of chimeric ribo/2′-*O*-methylribo oligonucleotide **4** by the Zn^{2+} complex of artificial nuclease **1a** in HEPES buffer (0.1 mol L^{-1}, I = 0.1 mol L^{-1} with $NaNO_3$) at pH 7.3 and 35 °C. The concentration of **4** and the initial concentration of **1a** (c_o) was 18 μmol L^{-1} and that of Zn^{2+} 90 μmol L^{-1}.

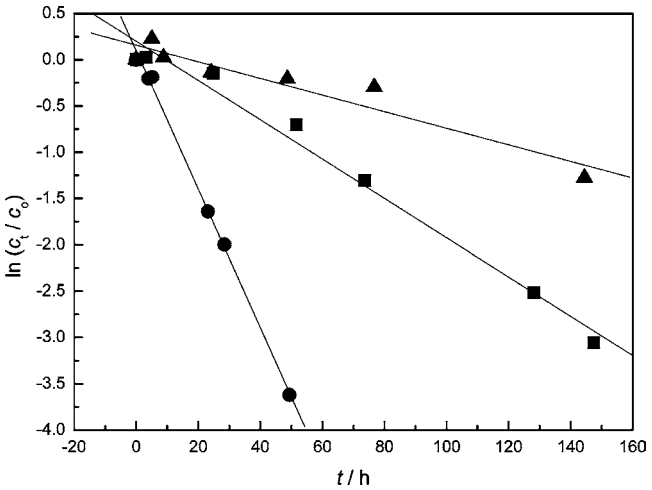

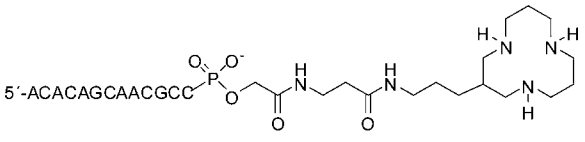

Figure 2. Cleavage of chimeric ribo/2′-*O*-methylribo oligonucleotide **4** by the Zn^{2+} complex of artificial nucleases **1a**−**3a**, using the target and cleaving agent at equimolar concentration. The logarithmic concentration of **4** plotted against time. For the conditions, see the legend of Figure 1. Notation: **1a** (■), **2a** (●), **3a** (▲).

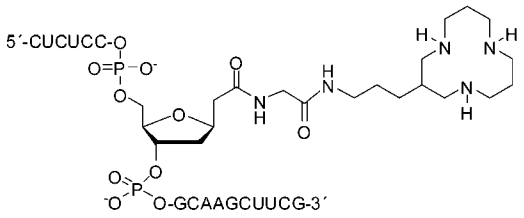

nuclease and target were incubated at equimolar concentration (18 μmol L^{-1}) and 35 °C in a HEPES buffer (0.1 mol L^{-1}, pH 7.3, I = 0.1 mol L^{-1} with $NaNO_3$) containing 90 μmol L^{-1} $Zn(NO_3)_2$. Aliquots were withdrawn at appropriate intervals, and their composition was determined by zone capillary electrophoresis. The progress of the cleavage of **4** by nuclease **1a** is shown in Figure 1 as an illustrative example. As seen from Figure 2, the breakdown of target **4** obeyed first-order kinetics with all the cleaving agents studied (**1a**−**3a**). Spiking of the product mixture with oligonucleotides **7**−**9** revealed that **1a**−**3a** all cleaved the target at the 5′-C(6)pA(7)-3′ bond, i.e., at 5′-side of the nucleoside (A7) opposite to the non-nucleosidic unit bearing the azacrown ligands.

Interestingly, the catalytic activity of **1a**−**3a** differs considerably in spite of structural similarity of the cleaving agents. We have shown previously (*40*) that monofunctionalized oligonucleotide conjugate **35** (Chart 2), having the same base sequence as **1a**−**3a**, cleaves target **4** at the 5′-A(7)pG(8)-3′ bond, the first-order rate constant being $(1.4 \pm 0.1) \times 10^{-6}$ s^{-1} under the experimental conditions of the present study. The rate constants obtained now with **1a**, **2a**, and **3a** are $(5.9 \pm 0.3) \times 10^{-6}$ s^{-1}, $(2.08 \pm 0.05) \times 10^{-5}$ s^{-1}, and $(2.5 \pm 0.3) \times 10^{-6}$ s^{-1}, respectively (Table 1). In other words, all the di(azacrown) conjugates are better catalysts than their mono(azacrown) counterpart, the increase in the catalytic activity being most remarkable with **2a**, 15-fold compared to **35**. The cleaving ability of **2a** is equal to that reported (*39*) for 2,9-dimethyl-5-aminophenanthroline−oligonucloeotide conjugates. Compared to the Zn^{2+} chelate of monomeric 1,5,9-triazacyclododecane at the same concentration (18 μmol L^{-1}), the rate acceleration is 1000-fold (*53*).

Table 1. First-order Rate Constants for the Cleavage of Target 4 by the Zn^{2+} Complexes of Oligonucleotide Di(azacrown) Conjugates 1a−3a and Targets 5 and 6 with Conjugates 1b−3b in 0.10 mol L^{-1} HEPES Buffer at pH 7.3 and 35 °C (I = 0.1 mol L^{-1} with $NaNO_3$)

cleaving agent	target	c(cleaving agent), μmol L^{-1}	c(target), μmol L^{-1}	$c(Zn^{2+})$, μmol L^{-1}	k, 10^{-6} s^{-1}
1a	**4**	18	18	90	5.9 ± 0.3
2a	**4**	18	18	90	20.8 ± 0.5
3a	**4**	18	18	90	2.5 ± 0.3
1a	**4**	18	18	180	6.3 ± 0.3
2a	**4**	18	18	180	20.7 ± 0.9
1a	**4**	9	36	90	0.27 ± 0.01
2a	**4**	9	36	90	0.76 ± 0.08
1b	**5**	18	18	90	0.9 ± 0.3
2b	**5**	18	18	90	1.7 ± 0.1
3b	**5**	18	18	90	1.1 ± 0.2
1b	**6**	18	18	90	1.2 ± 0.1
2b	**6**	18	18	90	1.7 ± 0.1
3b	**6**	18	18	90	1.0 ± 0.1

The effect of metal ion concentration on the cleavage rate was studied with conjugates **1a** and **2a**. The concentration of Zn^{2+} was increased to 180 μmol L^{-1} keeping the other conditions unchanged. The rate constants obtained were within the limits of experimental errors equal to those obtained at $[Zn^{2+}]$ = 90 μmol L^{-1} (Table 1), suggesting that the binding of Zn^{2+} to **1a** and **2a** is virtually quantitative. The reaction shows turnover in spite of the fact that the cleavage site is outside the complementary region between the cleaving agent and the target. As seen from Figure 3, the breakdown of target **4** at least roughly obeys first-order kinetics when present in 4-fold excess compared to the cleaving agent.

Artificial ribonucleases **1b** and **2b**, incorporating two azacrown ligands in the middle of the chain, cleaved targets **5** and **6**, forming upon hybridization a 3- and 5-nucleotide bulge, respectively, opposite to the azacrown moieties (Table 1). The cleavage was, however, less efficient than with **1a**−**3a**. Again the cleaving agent derived from the 1-*O*,3-*O*-funtionalized ribofuranosyl building block (**2b**) was most efficient, but the catalytic activity was more than 1 order of magnitude lower than with its 3′-terminal counterpart, **2a**. In fact, the catalytic

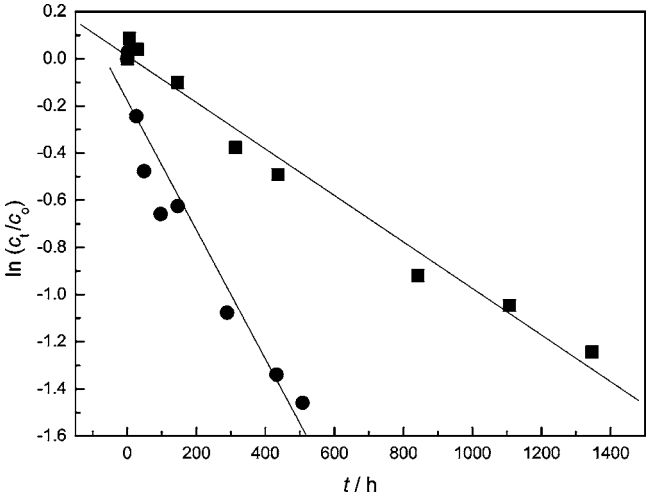

Figure 3. Cleavage of chimeric ribo/2′-*O*-methylribo oligonucleotide **4** by the Zn^{2+} complex of artificial nucleases **1a** and **2a** on using the target in 4-fold excess compared to the cleaving agent. The logarithmic concentration of **4** plotted against time. For the conditions, see Table 1. Notation: **1a** (■), **2a** (●).

activity was only double compared to that of the monofunctionalized azacrown conjugate **36** (*40*). The other two intrachain conjugates, **1b** and **3b**, cleaved **5** and **6** approximately as readily as the monofunctionalized **36**.

The origin of the high catalytic activity of the 1-*O*,3-*O*-tethered di(azacrown) conjugate (**2a**) compared to its 1-*O*,2-*O*-tethered isomer (**3a**) or mono(azacrown) counterpart (**35**) remains obscure. Either the two azacrown moieties of **2a** act in a cooperative manner, or the orientation of the 3-*O*-tethered group is optimal for the cleavage. Of these two alternative explanations, the latter appears more attractive. Cleavage of dinucleoside-3′,5′-monophosphates by a number of dinuclear Zn^{2+} bis(azacrown) chelates has been previously studied (*54*). Enhanced catalytic activity over the mononuclear Zn^{2+} chelate is observed only when one of the chelate moieties anchors the cleaving agent to a neighboring uracil base and, hence, brings the other chelate moiety in the proximity of the phosphodiester bond. This kind of rate-acceleration by additional anchoring to a base moiety in the vicinity of the scissile bond cannot be strictly excluded in the present case, but for the following reasons it appears less probable. First, there is no uracil base in the 5′-terminal ribo sequence of target **4** that would allow efficient anchoring (*55*). Second, the di(azacrown) unit in **2a** is so flexible that binding of one of the chelate moieties to any base or phosphate moiety near the cleavage site hardly increases the local concentration of the catalytic chelate moiety much more than already reached by hybridization.

In summary, the present study shows that tethering of two azacrown ligands to the 3′-terminus of a 2′-*O*-methyl oligoribonucleotide increases the catalytic efficiency by more than 1 order of magnitude compared to the corresponding monoazacrown-derivatized oligonucleotide. Half-lives shorter than 10 h are achieved at equimolar concentration of the target and cleaving agent under physiological conditions. The cleavage shows turnover. The efficiency of the cleaving agent, however, depends on the site of attachment of the azacrown moieties, in spite of marked overall flexibility of such constructs. Di(azacrown)-functionalized intrachain conjugates also cleave their bulged complementary sequences, but the catalytic activity is not much higher than that of their mono(azacrown) counterparts.

Biotinylated Anisomycin: A Comparison of Classical and "Click" Chemistry Approaches

Iain A. Inverarity,[†] Romain F. H. Viguier,[†] Philip Cohen,[‡] and Alison N. Hulme*[,†]

The School of Chemistry, University of Edinburgh, Kings Buildings, West Mains Road, Edinburgh, EH9 3JJ, United Kingdom, and MRC Protein Phosphorylation Unit, School of Life Sciences, University of Dundee, Dow Street, Dundee, DD1 5EH, United Kingdom. Received March 13, 2007; Revised Manuscript Received June 14, 2007

Two approaches to the synthesis of biotinylated derivatives of the stress-activated protein kinase (SAPK) pathway activator anisomycin have been investigated. Attachment of the biotin moiety to the central core was achieved either through the use of a classical displacement reaction on α-halo carbonyl derivatives of biotin or through a copper(I)-catalyzed 1,3-dipolar Huisgen cycloaddition ("click") coupling of biotinylated azides to propargyl-marked analogues of anisomycin. In each case, the resultant *N*-linked molecular probes were found to be active in SAPK pathway immunoblot assays, while their *O*-linked counterparts were inactive. However, in sharp contrast to the classical coupling approach which results in low coupling yields, the aqueous "click" coupling process was found to deliver high yields of biotinylated probes, making it the conjugation method of choice. A survey of the available methods for the addition of a propargyl marker onto a range of chemical functionalities strongly suggests that this copper(I)-catalyzed 1,3-dipolar Huisgen cycloaddition approach to biotinylation may be generally applied.

INTRODUCTION

Despite rapid advances in the generation and testing of small molecule libraries in recent years (*1*−*3*), current strategies for the identification of the biological targets of library members in forward chemical genetics screens still require the synthesis of an appropriate molecular probe. The structure of this molecular probe is typically based on an active library member, which has been modified by introduction of a tag (biotin, photoactive, or fluorescent label) (*4*−*7*). Selective biotinylation has been widely used over the last 30 years as a method for purification and identification of a range of targets (*8*). The popularity of this strategy stems from the peculiarly tight binding of biotin to (strept)avidin (K_d of 10^{-15} M) (*9*), which means that affinity chromatography methods based around this partnership are particularly useful for the identification of the binding partners of high-affinity small molecules where there is an abundant protein receptor. A notable recent example of this strategy includes the identification of the biological target of L-685,485 (a potent γ-secretase inhibitor) as the PS1 protein (*10*), while further examples of this approach encompass the biotinylation of a range of biologically active molecules including carbohydrates (*11*), steroids (*12*), and a number of drugs such as ezetimibe (a cholesterol inhibitor) (*13*), and paclitaxel (an anti-cancer compound) (*14*).

The pyrrolidine antibiotic anisomycin **1a** was first isolated from *Streptomyces roseochromogenes* and *S. griseolus* in 1954 (*15*). Over subsequent years, a series of studies have confirmed the structure and absolute stereochemistry as 2*R*,3*S*,4*S* for the three stereocentres around the pyrrolidine ring (*16*−*19*). Since its discovery, anisomycin has been found to generate many interesting biological responses including anti-fungal activity (*20*), protein synthesis inhibition (*21*), and anti-tumor activity in the nanomolar region (*22*). In addition, over the past fifteen years anisomycin has been used as a chemical stimulant of the stress-activated protein kinase (SAPK) pathways at subinhibitory levels (Figure 1) (*23*−*28*). The SAPK pathway is a distinct signaling branch within the mitogen activated protein kinase (MAPK) superfamily. The core unit of the MAPK pathways is a three-membered protein kinase cascade whose components are highly conserved in structure and organization. In this cascade, the MAPKs are phosphorylated and activated by a MAPK kinase (MAPKK/MKK). The MAPKK are "dual-specific" kinases that catalyze the phosphorylation of MAPKs at Thr and Tyr sites, specifically targeting a Thr-X-Tyr motif on MAPK (where X is proline and glycine for the JNK/SAPK1 and p38/SAPK2 modules, respectively) (*29*, *30*). Regulation of these pathways results in controlled activation of downstream kinases and transcription factors including c-Jun, ATF-2, and MAPKAP-K2. Regulation of the SAPK pathways is of interest across a broad range of fields, as it is thought to play a role in a range of conditions such as ischemic brain injury resulting from stroke episodes (*31*), cancer (*32*), and Alzheimer's disease (*33*). Although the precise target of anisomycin is unknown, the downstream effects on the SAPK pathways have been well-documented (*29*−*30*). The treatment of mammalian, yeast, and insect cells with anisomycin is known to strongly activate both the JNK/SAPK1 and p38/SAPK2 pathways, resulting in phosphorylation of their substrates, such as JNK and MAPKAP-K2, respectively.

Previous structure−activity relationship (SAR) studies for activation of the JNK/p38 pathways by anisomycin gave us an insight into the core functionality required to stimulate this phenotypic response, and hence allowed us to hypothesize potential sites for biotinylation. Principally, these studies showed that the presence of an ester functionality at the C(3) position on the pyrrolidine ring was essential for activity, with both the C(3) acetate (anisomycin, **1a**) and C(3) propionate ester **1b** shown to be active compounds (Figure 2) (*34*). In addition, both the C(4)-H **2a** and C(4)-Me **2b** analogues were found to activate the SAPK pathways, with the C(4)-H analogue exhibiting similar levels of activation to that of anisomycin (*34*). More recent work has shown that, while the N(1)-Bn analogue **1c** generates a strong activation of the SAPK pathways (*35*), simultaneous

dibenzylation of N(1) and C(4)-OH, analogue **1d**, is not tolerated. These results suggest that the C(3) and C(4) sites are unsuitable for conjugation as biotinylated probes. However, the N(1) position is tolerant of relatively bulky functionalization, particularly as an amino- rather than an amido/carbamate-type linkage (*36*). Furthermore, a survey of the literature relating to the bioactivity of anisomycin in other cellular assays led us to postulate that conjugation of the phenolic oxygen might also be possible (*22*). We therefore set out to synthesize a series of biotinylated molecular probes coupling to the anisomycin scaffold through either the pyrrolidine nitrogen or the phenolic oxygen.

EXPERIMENTAL SECTION

General Methods. All reactions involving air- or water-sensitive reagents were carried out under an atmosphere of nitrogen using flame- or oven-dried glassware. Unless otherwise noted, starting materials and reagents were obtained from commercial suppliers and were used without further purification. CH_2Cl_2 and Et_3N were distilled from calcium hydride. Anhydrous methanol, DMF, and acetonitrile were used as supplied. Unless otherwise indicated, organic extracts were dried over anhydrous sodium sulfate and concentrated under reduced pressure using a rotary evaporator. Purification by flash column chromatography was carried out using Merck Kieselgel 60 silica gel as the stationary phase. IR spectra were measured on a Perkin-Elmer Paragon 1000 FT-IR spectrometer as thin films unless otherwise stated. ^{1}H and ^{13}C NMR spectra were measured on Bruker DPX360 and Bruker AVA600 instruments; *J*-values are in hertz. Fast atom bombardment (FAB) mass spectra were obtained using a Kratos MS50TC mass spectrometer at The University of Edinburgh.

Complete Protease Inhibitor tablet was obtained from Roche (Lewes, Sussex, UK), cell culture media from Gibco (Paisley, UK), precast Bis-Tris gradient SDS-polyacrylamide gels, running buffer, and transfer buffer from Invitrogen (Paisley, UK), and enhanced chemiluminescence (ECL) reagents from Amersham (Bucks, UK). Phospho-specific antibodies that recognize JNK1/2 phosphorylated at Thr183 or unphosphorylated JNK1/2 were purchased from Biosource (Nivelles, Belgium), while horseradish peroxidase-conjugated secondary antibodies were from Pierce (Cheshire, UK).

Coupling to C_2 Biotinylated Iodoacetamide 4. *2′-N-Biotinylamino-eth-1-yl 4′-(2″-acetoxyeth-1″-yl)phenyloxyacetamide 5*. To biotinylated iodoacetamide **4** (20.0 mg, 40.0 μmol) in DMF (1.5 mL) was added phenol **3** (10.0 mg, 40.0 μmol), followed by K_2CO_3 (6.00 mg, 40.0 μmol). The solution was stirred for 48 h at 80 °C. The solution was concentrated *in vacuo*, and the residue was purified by flash chromatography [10% MeOH/CH_2Cl_2] to give phenol ether **5** as a colorless solid (17.0 mg, 34.4 μmol, 86%). R_f [10% MeOH/CH_2Cl_2] = 0.30. ^{1}H NMR δ (360 MHz, DMSO) 8.12 (1H, t, *J* 5.2, $N_{17}H$), 7.87 (1H, t, *J* 5.2, $N_{14}H$), 7.17 (2H, d, *J* 8.7, Ar*H*), 6.89 (2H, d, *J* 8.7, Ar*H*), 6.42 (1H, br s, N_6H), 6.36 (1H, br s, N_4H), 4.42 (2H, s, $C_{19}H_2$), 4.30−4.27 (1H, m, C_3H), 4.15 (2H, t, *J* 7.0, $C_{26}H_2$), 4.12−4.08 (1H, m, C_7H), 3.15 (4H, dt, *J* 9.9, 5.6, $C_{15}H_2$, $C_{16}H_2$), 3.10−3.04 (1H, m, C_8H), 2.81 (2H, t, *J* 7.0, $C_{25}H_2$), 2.80 (1H, dd, *J* 12.3, 5.2, $C_2H_AH_B$), 2.56 (1H, d, *J* 12.3, $C_2H_AH_B$), 2.04 (2H, t, *J* 7.3, $C_{12}H_2$), 1.97 (3H, s, OA*c*), 1.64−1.23 (6H, m, C_9H_2, $C_{10}H_2$, $C_{11}H_2$). ^{13}C NMR δ (90.7 MHz, DMSO) 172.3 (1C, C_{13}, Q), 170.2 (1C, OA*c*, Q), 167.8 (1C, C_{18}, Q), 162.6 (1C, C_5, Q), 156.6 (1C, Ar, Q), 130.4 (1C, Ar, Q), 129.5 (2C, *Ar*H, CH), 114.4 (2C, *Ar*H, CH), 66.7 (1C, C_{19}, CH_2), 64.2 (1C, C_{26}, CH_2), 60.7 (1C, C_7, CH), 59.0 (1C, C_3, CH), 55.1 (1C, C_8, CH), 39.6 (1C, C_2, CH_2), 38.3 (1C, C_{16}, CH_2), 37.8 (1C, C_{15}, CH_2), 34.9 (1C, C_{12}, CH_2), 33.2 (1C, C_{25}, CH_2), 28.0 (1C, C_{10}, CH_2), 27.8 (1C, C_9, CH_2), 24.9 (1C, C_{11}, CH_2), 20.5 (1C, OA*c*, CH_3). *m/z* (FAB, THIOG) 507 ([M + H]$^+$, 29%), 91 (75). Coupling to C_6 Biotinylated Iodoacetamide 9. *6′-N-Biotinylamino-hex-1-yl 4′-(2″-acetoxyeth-1″-yl)phenyloxyacetamide **10**.* To biotinylated iodoacetamide **9** (20.0 mg, 47.0 μmol) in DMF (5.0 mL) was added **3** (8.60 mg, 47.0 μmol), followed by K_2CO_3 (6.60 mg, 47.0 μmol). The solution was stirred for 48 h at 80 °C. The solution was concentrated *in vacuo*, and the residue was purified by flash chromatography [5% to 15% MeOH/CH_2Cl_2] to give phenol ether **10** as a colorless solid (20.0 mg, 33.8 μmol, 72%). R_f [10% MeOH/CH_2Cl_2] = 0.16. ^{1}H NMR δ (600 MHz, DMSO) 8.03 (1H, t, *J* 5.7, $N_{21}H$), 7.72 (1H, t, *J* 5.7, $N_{14}H$), 7.17 (2H, d, *J* 8.5, Ar*H*), 6.88 (2H, d, *J* 8.5, Ar*H*), 6.41 (1H, br s, N_6H), 6.35 (1H, br s, N_4H), 4.42 (2H, s, $C_{23}H_2$), 4.31−4.29 (1H, m, C_3H), 4.15 (2H, t, *J* 6.9, $C_{30}H_2$), 4.13−4.11 (1H, m, C_7H), 3.10 (2H, br q, *J* 6.8, $C_{20}H_2$), 3.09−3.07 (1H, m, C_8H), 3.00 (2H, br q, *J* 6.7, $C_{15}H_2$), 2.60 (1H, dd, *J* 12.5, 5.0, $C_2H_AH_B$), 2.81 (2H, t, *J* 6.7, $C_{29}H_2$), 2.57 (1H, d, *J* 12.5, $C_2H_AH_B$), 2.04 (2H, t, *J* 7.4, $C_{12}H_2$), 1.97 (3H, s, O*Ac*), 1.64−1.21 (14H, m, C_9H_2, $C_{10}H_2$, $C_{11}H_2$, $C_{16}H_2$, $C_{17}H_2$, $C_{18}H_2$, $C_{19}H_2$). ^{13}C NMR δ (151.5 MHz, DMSO) 171.6 (1C, C_{13}, Q), 170.1 (1C, O*Ac*, Q), 167.3 (1C, C_{22}, Q), 162.5 (1C, C_5, Q), 156.2 (1C, Ar, Q), 130.4 (1C, Ar, Q), 129.7 (2C, *Ar*H, CH), 114.5 (2C, *Ar*H, CH), 66.9 (1C, C_{23}, CH_2), 64.4 (1C, C_{30}, CH_2), 60.9 (1C, C_7, CH), 59.0 (1C, C_3, CH), 55.2 (1C, C_8, CH), 39.7 (1C, C_2, CH_2), 38.1 (1C, C_{15}, CH_2), 38.0 (1C, C_{20}, CH_2), 35.1 (1C, C_{12}, CH_2), 33.3 (1C, C_{29}, CH_2), 29.0, 28.9, 28.8, 28.1, 27.9, 25.9, 25.2 (7C, C_9, C_{10}, C_{11}, C_{16}, C_{17}, C_{18}, C_{19}, CH_2), 20.6 (1C, O*Ac*, CH_3). *m/z* (FAB, THIOG) 563 ($[M + H]^+$, 49%), 91 (70). HRMS (FAB, NOBA) (found: $[M + H]^+$, 563.2907. $C_{28}H_{43}N_4O_6S$ requires *m/z*, 563.2903).

*C_6-Classical N-Linked Anisomycin Biotin Molecular Probe **11**.* To biotinylated iodoacetamide **9** (20.0 mg, 47.0 μmol) in DMF (5.0 mL) was added anisomycin **1a** (12.6 mg, 47.0 μmol), followed by K_2CO_3 (6.60 mg, 47.0 μmol). The solution was stirred for 48 h at 80 °C. The solution was concentrated *in vacuo*, and the residue was purified by flash chromatography [5% to 15% MeOH/CH_2Cl_2] to give *N*-linked probe **11** as a colorless solid (11.0 mg, 16.5 μmol, 35%). R_f [10% MeOH/CH_2Cl_2] = 0.19. ^{1}H NMR δ (360 MHz, DMSO) 7.74 (1H, t, *J* 5.6, $N_{14}H$), 7.68 (1H, t, *J* 5.6, $N_{21}H$), 7.06 (2H, d, *J* 8.6, Ar*H*), 6.80 (2H, d, *J* 8.6, Ar*H*), 6.43 (1H, br s, N_6H), 6.36 (1H, br s, N_4H), 5.29 (1H, d, *J* 4.8, O*H*), 4.59 (1H, dd, *J* 4.9, 2.2, $C_{27}H$), 4.32−4.28 (1H, m, C_3H), 4.14−4.10 (1H, m, C_7H), 3.89−3.85 (1H, m, $C_{26}H$), 3.70 (3H, s, O*Me*), 3.42−3.38 (1H, m, $C_{25}H_MH_N$), 3.26 (1H, d, *J* 15.9, $C_{23}H_XH_Y$), 3.19−3.13 (1H, m, $C_{28}H$), 3.11−2.98 (5H, m, C_8H, $C_{15}H_2$, $C_{20}H_2$), 2.97 (1H, d, *J* 15.9, $C_{23}H_XH_Y$), 2.81 (1H, dd, *J* 12.3, 5.1, $C_2H_AH_B$), 2.75−2.72 (1H, m, $C_{29}H_SH_T$), 2.59−2.57 (1H, m, $C_{29}H_SH_T$), 2.57 (1H, d, *J* 12.3, $C_2H_AH_B$), 2.31 (1H, dd, *J* 10.4, 3.5, $C_{25}H_MH_N$), 2.06 (3H, s, O*Ac*), 2.04 (2H, t, *J* 7.4, $C_{12}H_2$), 1.49−1.25 (14H, m, C_9H_2, $C_{10}H_2$, $C_{11}H_2$, $C_{16}H_2$, $C_{17}H_2$, $C_{18}H_2$, $C_{19}H_2$). ^{13}C NMR δ (90.7 MHz, DMSO) 171.7 (1C, C_{13}, Q), 169.9 (1C, C_{22}, Q), 169.6 (1C, O*Ac*, Q), 162.5 (1C, C_5, Q), 157.4 (1C, *Ar*, Q), 130.7 (1C, *Ar*, Q), 129.7 (2C, *Ar*H, CH), 113.6 (2C, *Ar*H, CH), 78.9 (1C, C_{27}, CH), 72.9 (1C, C_{26}, CH), 65.6 (1C, C_{28}, CH), 60.8 (1C, C_7, CH), 60.1 (1C, C_{25}, CH_2), 59.0 (1C, C_3, CH), 57.1 (1C, C_{23}, CH_2), 55.2 (1C, C_8, CH), 54.7 (1C, O*Me*, CH_3), 39.7 (1C, C_2, CH_2), 38.2 (1C, C_{20}, CH_2), 37.9 (1C, C_{15}, CH_2), 35.0 (1C, C_{12}, CH_2), 32.8 (1C, C_{29}, CH_2), 29.2, 28.9, 28.0, 27.8, 25.9, 25.5, 25.2 (7C, C_9, C_{10}, C_{11}, C_{16}, C_{17}, C_{18}, C_{19}, CH_2), 20.9 (1C, O*Ac*, CH_3). *m/z* (FAB, NOBA) 648 ($[M + H]^+$, 5%), 307 (50), 77 (70). HRMS (FAB, THIOG) (found: $[M + H]^+$, 648.3435. $C_{32}H_{50}N_5O_7S$ requires *m/z*, 648.3431).

*Synthesis of Biotinylated Azides **15** and **16**.* Safety in the handling of sodium azide and other azides: (*37*) Sodium azide is toxic (LD_{50} oral (rats) = 27 mg kg^{-1}) and can be absorbed through the skin. It decomposes explosively upon heating to above 275 °C; hence, its use in airbags in the automotive industry. Sodium azide reacts vigorously with CS_2, bromine, nitric acid, dimethyl sulfate, and a series of heavy metals, including copper and lead. In reaction with water or Brønsted acids, the highly toxic and explosive hydrogen azide is released. It has been reported that sodium azide and polymer-bound azide reagents form explosive di- and triazidomethane with CH_2Cl_2 and $CHCl_3$, respectively.

Heavy-metal azides that are highly explosive under pressure or shock are formed when solutions of NaN_3 or HN_3 vapors come into contact with heavy metals or their salts. Heavy-metal azides can accumulate under certain circumstances, for example, in metal pipelines and on the metal components of diverse equipment (rotary evaporators, freeze drying equipment, cooling traps, water baths, waste pipes), and thus lead to violent explosions. Some organic and other covalent azides are classified as toxic and highly explosive, and appropriate safety measures must be taken at all times.

*2-Azido-1-ethylamine **17***. To a solution of 2-chloro-1-ethylamine (500 mg, 4.31 mmol) in water (5 mL) was added sodium azide (840 mg, 12.9 mmol), and the reaction mixture was heated at 80 °C for 15 h. The solution was basified with KOH (solid) and extracted with ether. The organics were dried and concentrated to give amino azide **17** as a volatile colorless oil (371 mg, 4.31 mmol, 100%). ν_{max}(neat)/cm^{-1} 3375, 2104. ^{1}H NMR δ (360 MHz, $CDCl_3$) 3.30 (2H, t, *J* 5.7, C*H*$_2$), 2.79−2.74 (2H, m, C*H*$_2$), 1.43 (2H, s, N*H*$_2$). ^{13}C NMR δ (90.7 MHz, $CDCl_3$) 54.2 (1C, CH_2), 40.9 (1C, CH_2). *m*/*z* (ESI+) 194 ([2M + H]$^+$). All spectroscopic data were in good agreement with that of the literature (*38*).

*6-Azido-1-hexylamine **18***. A solution of 6-amino-hexan-1-ol (1.17 g, 10.0 mmol) and $SOCl_2$ (3.28 mL, 45.0 mmol) in toluene (10 mL) was heated at reflux for 1 h. The solvent was removed *in vacuo*, and the intermediate 6-chloro-1-hexylamine was obtained as a hygroscopic solid. *m*/*z* (ESI+, MeOH) 136 ([M + H]$^+$, 100), 138 ([M + H]$^+$, 33). To a solution of sodium azide (1.95 g, 30.0 mmol) in water (10 mL) was added 6-chloro-1-hexylamine and the reaction was stirred at 90 °C for 2 h. The solution was basified (pH 12−14) with KOH (solid), extracted with CH_2Cl_2, dried ($MgSO_4$), and concentrated *in vacuo*. The amino azide **18** was obtained as a colorless solid (1.28 g, 9.01 mmol, 90% over two steps). ^{1}H NMR δ (360 MHz, DMSO) 3.40−3.20 (4H, m, C*H*$_2$NH$_2$, C*H*$_2$N$_3$), 1.75−1.45 (4H, m, 2CH$_2$), 1.41−1.22 (4H, m, 2CH$_2$). ^{13}C NMR δ (90.6 MHz, DMSO) 51.0 (1C, CH_2), 39.4 (1C, CH_2), 29.6 (1C, CH_2), 29.5 (1C, CH_2), 27.2 (1C, CH_2), 26.8 (1C, CH_2). *m*/*z* (ESI+, MeOH) 143.0 ([M + H]$^+$, 100%). HRMS (FAB, NOBA) (found: [M + H]$^+$, 143.1297. $C_6H_{15}N_4$ requires *m*/*z*, 143.1297).

*N-Biotinyl-2-azido-1-ethylamine **15***. To a solution of biotin succinimidyl ester **19** (60.0 mg, 170 μmol) in methanol (2 mL) was added triethylamine (73.0 μL, 530 μmol) and 1-azidoethylamine **17** (90.0 mg, 1.06 mmol). The reaction mixture was stirred at RT for 6 h. The solution was concentrated *in vacuo*, and the residue was purified by flash chromatography [8% to 12% MeOH/CH_2Cl_2] to give biotinylated azide **15** as a colorless solid (48.0 mg, 160 μmol, 94%). R_f [8% MeOH/CH_2Cl_2] = 0.19. ν_{max}(neat)/cm^{-1} 3286, 2103, 1694, 1651. ^{1}H NMR δ (360 MHz, DMSO) 8.06 (1H, t, *J* 5.8, N$_{14}$*H*), 6.44 (1H, br s, N$_6$*H*), 6.38 (1H, br s, N$_4$*H*), 4.31−4.28 (1H, m, C$_3$*H*), 4.16−4.12 (1H, m, C$_7$*H*), 3.32 (2H, t, *J* 5.8, C$_{16}$*H*$_2$), 3.23 (2H, t, *J* 5.8, C$_{15}$*H*$_2$), 3.09−3.07 (1H, m, C$_8$*H*), 2.87 (1H, dd, *J* 12.5, 5.1, C$_2$*H*$_A$H$_B$), 2.56 (1H, d, *J* 12.5, C$_2$H$_A$*H*$_B$), 2.07 (2H, t, *J* 7.4, C$_{12}$*H*$_2$), 1.52−1.28 (6H, m, C$_9$*H*$_2$, C$_{10}$*H*$_2$, C$_{11}$*H*$_2$). ^{13}C NMR δ (90.7 MHz, DMSO) 172.7 (1C, *C*$_{13}$, Q), 163.0 (1C, *C*$_5$, Q), 61.2 (1C, *C*$_7$, CH), 59.4 (1C, *C*$_3$, CH), 55.7 (1C, *C*$_8$, CH), 50.2 (1C, *C*$_{16}$, CH$_2$), 40.1 (1C, *C*$_2$, CH$_2$), 38.4 (1C, *C*$_{15}$, CH$_2$), 35.4 (1C, *C*$_{12}$, CH$_2$), 28.4 (1C, *C*$_{10}$, CH$_2$), 28.3 (1C, *C*$_9$, CH$_2$), 25.4 (1C, *C*$_{11}$, CH$_2$). *m*/z (FAB, THIOG) 313 ([M + H]$^+$, 48%), 45 (100). HRMS (FAB, THIOG) (found: [M + H]$^+$, 313.1445. $C_{12}H_{21}N_6O_2S$ requires *m*/*z*, 313.1447).

*N-Biotinyl-6-azido-1-hexylamine **16***. To a solution of 6-azido-1-hexylamine **18** (316 mg, 1.46 mmol) and triethylamine (202 μL, 1.46 mmol) in methanol (20 mL) was slowly added a solution of biotin succinimidyl ester **19** (500 mg, 1.46 mmol) in methanol (10 mL). The reaction was stirred overnight at RT. The solution was concentrated *in vacuo*, and the residue was purified by flash chromatography [5% MeOH/CH_2Cl_2] to give biotinylated azide **16** as a pale yellow solid (479 mg, 1.30 mmol, 89%). R_f [10% MeOH/CH_2Cl_2] = 0.11. ν_{max}(neat)/cm^{-1} 3301, 2099, 1704, 1638. ^{1}H NMR δ (360 MHz, DMSO) 7.76 (1H, t, *J* 5.5, N$_{14}$*H*), 6.44 (1H, br s, N$_6$*H*), 6.38 (1H, br s, N$_4$*H*), 4.32−4.29 (1H, m, C$_3$*H*), 4.15−4.11 (1H, m, C$_7$*H*), 3.31 (2H, t, *J* 6.9, C$_{20}$*H*$_2$), 3.12−3.06 (1H, m, C$_8$*H*), 3.01 (2H, dt, *J* 12.5, 6.7, C$_{15}$*H*$_2$), 2.82 (1H, dd, *J* 12.5, 5.1, C$_2$*H*$_A$H$_B$), 2.58 (1H, d, *J* 12.5, C$_2$H$_A$*H*$_B$), 2.04 (2H, t, *J* 7.4, C$_{12}$*H*$_2$), 1.54−1.25 (14H, m, C$_9$*H*$_2$, C$_{10}$*H*$_2$, C$_{11}$*H*$_2$, C$_{16}$*H*$_2$, C$_{17}$*H*$_2$, C$_{18}$*H*$_2$, C$_{19}$*H*$_2$,). ^{13}C NMR δ (90.7 MHz, DMSO) 172.1 (1C, *C*$_{13}$, Q), 163.0 (1C, *C*$_5$, Q), 61.3 (1C, *C*$_7$, CH), 59.4 (1C, *C*$_3$, CH), 55.7 (1C, *C*$_8$, CH), 50.8 (1C, *C*$_{20}$, CH$_2$), 39.9 (1C, *C*$_2$, CH$_2$), 38.5 (1C, *C*$_{15}$, CH$_2$), 35.5 (1C, *C*$_{12}$, CH$_2$), 29.3, 28.5, 28.3, 26.2, 26.1, 25.6, 25.5 (7C, *C*$_9$, *C*$_{10}$, *C*$_{11}$, *C*$_{16}$, *C*$_{17}$, *C*$_{18}$, *C*$_{19}$, CH$_2$). *m*/z (FAB, THIOG) 369 ([M + H]$^+$, 58%), 258 (46). The solution was stirred for 15 h at RT. The solution was concentrated *in vacuo*, and the residue was purified by flash chromatography [8% to 15% MeOH/CH_2Cl_2] to give *N*-linked probe **25** as a colorless solid (64.0 mg, 95.0 μmol, 73%). R_f [20% MeOH/CH_2Cl_2] = 0.35. ^{1}H NMR δ (360 MHz, 323 K, DMSO) 8.13 (1H, br s, $C_{22}H$), 7.58 (1H, t, *J* 5.6, $N_{14}H$), 7.09 (2H, d, *J* 8.6, Ar*H*), 6.83 (2H, d, *J* 8.6, Ar*H*), 6.26 (1H, br s, N_6H), 6.23 (1H, br s, N_4H), 5.06 (1H, br s, O*H*), 4.58 (1H, dd, *J* 4.9, 2.1, $C_{28}H$), 4.33 (2H, t, *J* 7.0, $C_{20}H_2$), 4.32−4.28 (1H, m, C_3H), 4.15−4.12 (1H, m, C_7H), 3.98 (1H, br d, *J* 13.9, $C_{24}H_XH_Y$), 3.90−3.86 (1H, m, $C_{27}H$), 3.75 (1H, br d, *J* 13.9, $C_{24}H_XH_Y$), 3.72 (3H, s, O*Me*), 3.25−3.10 (2H, m, $C_{26}H_MH_N$, $C_{29}H$), 3.08 (1H, ddd, *J* 8.1, 6.6, 4.8, C_8H), 2.98 (2H, br q, *J* 6.6, $C_{15}H$), 2.91 (1H, dd, *J 13.3, 4.6*, $C_{30}H_SH_T$), 2.83 (1H, dd, *J* 12.4, 5.1, $C_2H_AH_B$), 2.60 (1H, d, *J 13.3*, $C_{30}H_SH_T$), 2.81 (1H, d, *J* 12.4, $C_2H_AH_B$), 2.41−2.32 (1H, m, $C_{26}H_MH_N$), 2.05 (2H, t, *J* 7.3, $C_{12}H_2$), 2.04 (3H, s, O*Ac*), 1.82 (2H, qn, *J* 7.0, $C_{19}H_2$), 1.70−1.20 (12H, m, C_9H_2, $C_{10}H_2$, $C_{11}H_2$, $C_{16}H_2$, $C_{17}H_2$, $C_{18}H_2$). ^{13}C NMR δ (90.7 MHz, DMSO) 171.8 (1C, *C_{13}*, Q), 169.5 (1C, O*Ac*, Q), 162.6 (1C, *C_5*, Q), 157.6 (1C, Ar, Q), 142.3 (1C, *C_{23}*, Q), 130.4 (1C, Ar, Q), 129.6 (2C, *Ar*H, CH), 123.4 (1C, *C_{22}*, CH), 113.5 (2C, *Ar*H, CH), 78.9 (1C, *C_{28}*, CH), 72.3 (1C, *C_{27}*, CH), 64.7 (1C, *C_{29}*, CH), 60.9 (1C, *C_7*, CH), 59.0 (1C, *C_3*, CH), 58.8 (1C, *C_{26}*, CH_2), 55.0 (1C, *C_8*, CH), 54.7 (1C, O*Me*, CH_3), 49.0 (1C, *C_{20}*, CH_2), 47.3 (1C, *C_{24}*, CH_2), 39.5 (1C, *C_2*, CH_2), 38.0 (1C, *C_{15}*, CH_2), 34.9 (1C, *C_{12}*, CH_2), 31.9 (1C, *C_{30}*, CH_2), 29.4 (1C, *C_{19}*, CH_2), 28.6, 27.9, 27.8, 25.5, 25.2, 25.0 (6H, *C_9*, *C_{10}*, *C_{11}*, *C_{16}*, *C_{17}*, *C_{18}*, CH_2), 20.4 (1C, O*Ac*, CH_3). *m/z* (FAB, THIOG) 672 ($[M + H]^+$, 38%), 91 (88). HRMS (FAB, THIOG) (found: $[M + H]^+$, 672.3540. $C_{33}H_{50}N_7O_6S$ requires *m/z*, 672.3543).

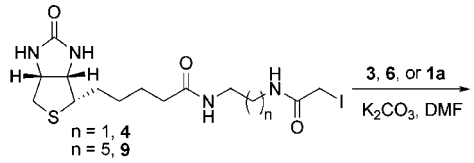
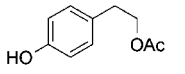
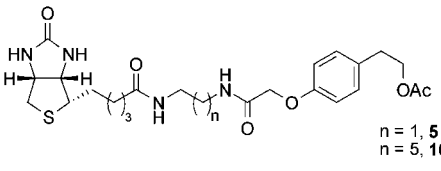
Immunoblot Assays. (*34*, *35*, *39*) *Cell Culture and Stimulation.* Human embryonic kidney (HEK) 293 cells were cultured at 37 °C, 95% air/5% CO_2, in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% foetal bovine serum, 100 U/mL penicillin, 100 μg/mL streptomycin, and 2 mM L-glutamine. Anisomycin **1a** was dissolved at 10 mg/mL (38 mmol L^{-1}) in DMSO, while the other compounds (**5**, **7b**, **8**, **10**, **11**, **20**, **21b**, **22**, **23**, **24b**, **25**) were dissolved in DMSO at 38 mmol L^{-1}. Cells (9 mL of cell culture) were incubated with the library members by addition of 9 μL of anisomycin solution, anisomycin analogue in DMSO, or DMSO as a control.

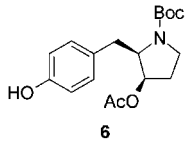
Cell Lysis. After stimulation for 30 min, the media was aspirated and the cells lysed in 50 mM Tris/HCl, pH 7.5, containing 1 mM EDTA, 1 mM EGTA, 1 mM sodium orthovanadate, 10 mM sodium β-glycerophosphate, 5 mM sodium pyrophosphate, 50 mM sodium fluoride, 0.27 M sucrose, 1% (v/v) Triton X-100, 0.1% (v/v) 2-mercaptoethanol, and Complete Protease Inhibitor cocktail (one tablet per 50 mL). Lysates were centrifuged at 13 000 *g* for 10 min at 4 °C and the supernatants (termed "cell extract") were removed. Protein concentrations were determined according to the method of Bradford (*40*).

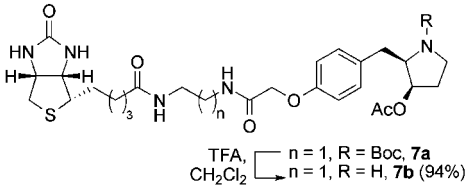


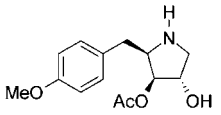
Immunoblotting. Samples were denatured in SDS, run on polyacylamide gels, and transferred to nitrocellulose membranes. The membranes were incubated for 1 h at room temperature in 50 mM Tris−HCl pH 7.5, 150 mM NaCl, 0.2% (v/v) Tween, and 5% (w/v) skimmed milk powder. Primary antibodies were added to 10 mL of the previous buffer and incubated at 4 °C overnight. The membranes were then washed four times with buffer (5 min per wash) to remove the excess primary antibody. The membranes were then incubated with the secondary antibody at room temperature for 1 h. After washing six times with buffer to remove the excess secondary antibody (5 min per wash), immunoreactive proteins were visualized *via* enhanced chemiluminescence reagent according to the manufacturer's instructions.

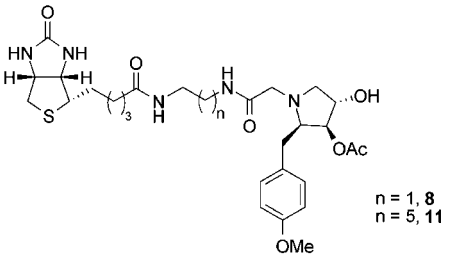










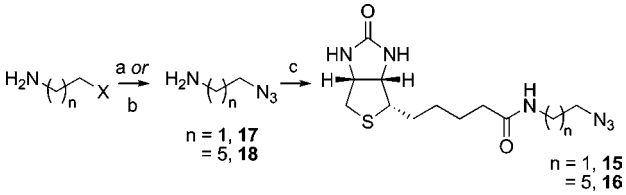


RESULTS AND DISCUSSION

Traditional approaches to the design of functional biotin molecular probes are often based on the formation of peptide and ester bonds (*8*). However, for biotinylation of anisomycin at either the pyrrolidine nitrogen (*N*-linked) or phenolic oxygen (*O*-linked), this approach was ruled out first due to the SAR data, which suggests that only amine derivatives are able to activate the SAPK pathways, and second due to the known poor stability of phenolic esters. We therefore turned our attention to the classical nucleophilic displacement reaction of α-halo carbonyl derivatives of biotin by each of these functionalities. In designing appropriate biotin derivatives for coupling, two linker lengths were identified for the carbon chain between the active small molecule (anisomycin) and the functional tag (biotin): a short commercially available C_2 linker, and a longer C_6 linker. To allow us to establish whether any false positives were caused in the immunoblot assays from activation by these linkers, the synthesis of a series of structurally related, but SAPK-inactive, control probes was also envisaged.

The monoacetate of 2-(4-hydroxyphenyl)ethanol **3** was chosen as a simple model of the anisomycin core (*41*), allowing initial

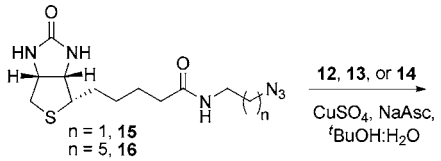
Table 1. Classical Nucleophilic Displacement Reactions of Anisomycin and Analogues to Give *O*-Linked and *N*-Linked Biotinylated Molecular Probes



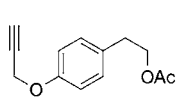
Substrate	Coupled Product	Yield
 **3**	 n = 1, **5** n = 5, **10**	**5** 86% **10** 72%
 **6**	 TFA, CH_2Cl_2 n = 1, R = Boc, **7a** n = 1, R = H, **7b** (94%)	**7a** 31%
 **1a**	 n = 1, **8** n = 5, **11**	**8** 34% **11** 35%

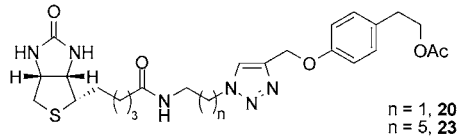
investigations into the conditions required for the nucleophilic displacement coupling to give *O*-linked biotinylated probes. Promising initial results were obtained in the reaction of **3** with commercially available iodoacetyl biotin **4**, which occurred readily upon heating at 80 °C in DMF in the presence of potassium carbonate, to give the desired product **5** in 86% yield (Table 1). However, rather disappointingly, heating the analogous Boc-protected C(4)-H analogue of anisomycin **6** (*35*) gave only a low yield of coupled material **7a** (31%), while *N*-alkylation of anisomycin **1a** under the same conditions was found to be only marginally more successful, giving 34% of the C_2-biotinylated probe **8** (Table 1). The longer C_6-linked iodoacetyl biotin derivative **9** was shown to exhibit a similar pattern of reactivity when coupled to the simple model **3** (72%) and anisomycin **1a** (35%) under identical conditions (Table 1) to give biotin-conjugated analogues **10** and **11**, respectively. With these more-complex substrates, the highly polar nature of the starting materials and resultant biotinylated products, combined with low conversions, gave rise to difficult separation procedures. Thus, while the coupling of simple substrates can be achieved in good yield using this classical nucleophilic displacement methodology, on more complex substrates it was found to be highly unsatisfactory.

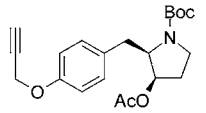
In a contrasting approach, the synthesis of a number of biotinylated probes was envisaged using an extension of our recent marked library strategy (*35*). In this strategy, a biocompatible marker is attached onto the small molecule's scaffold; this marker plays no role in the screening process itself, but facilitates the formation of a range of molecular probes from active marked library members. Having previously utilized the highly popular copper(I) catalyzed Huisgen 1,3-dipolar cycloaddition reaction as a means of formation of fluorescent molecular probes from marked library members (*35*), we sought to extend this strategy to the synthesis of biotinylated probes (*42*). To this end, propargylation of the monoacetate of 2-(4-hydroxyphenyl)ethanol **3**, the Boc-protected C(4)-H analogue of anisomycin **6**, and anisomycin **1a** was carried out in DMF to give the *O*-linked (**12**, **13**) and *N*-linked (**14**) "click" precursors in excellent yield (77%, 99% (*35*), and 99% (*35*), respectively). The C_2 **15** and C_6 **16** biotinylated azides required by this approach are readily prepared by coupling alkylamino azides **17** or **18** to biotin *N*-hydroxy succinimidyl ester **19** in high yield (94% and 89%, respectively; Scheme 1).

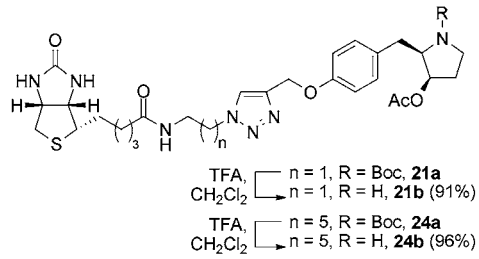


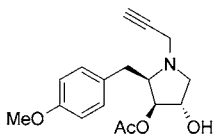
Scheme 1. Preparation of C_2 and C_6 Biotinylated Azides[a]

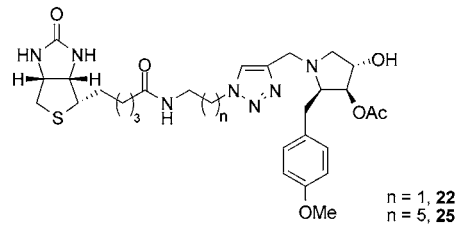












[a] Reagents and Conditions: (a) NaN_3, H_2O, 80 °C, 15 h (n = 1, X = Cl; 100%); (b) (i) $SOCl_2$, $PhCH_3$, 110 °C, 1 h; (ii) NaN_3, H_2O, 90 °C, 2 h (n = 5, X = OH; 90% over two steps); (c) biotin NHS (**19**), MeOH, Et_3N, rt, 6−15 h (n = 1, 94%; n = 5, 89%).

Using standard coupling conditions [10 mol % $CuSO_4$, 20 mol % NaAsc, ^{t}BuOH/H_2O (1:1)] for the copper(I)-catalyzed Huisgen 1,3-dipolar cycloaddition reaction (*43*−*44*), the propargyl derivative of the model of the anisomycin core **12** was coupled to the C_2 biotinylated azide **15** to give **20** in high yield (Table 2). Applying the same reaction conditions to the *O*-linked (**13**) and *N*-linked (**14**) precursors resulted in gratifyingly high yields of products (**21a** and **22**, Table 2). When the linker chain length was extended through coupling to the related C_6 azide

Table 2. Copper(I) Catalyzed Huisgen 1,3-Dipolar Cycloaddition Coupling Reactions of *O*-Linked and *N*-Linked Propargyl Anisomycin Derivatives to Give Biotinylated Molecular Probes

Substrate	Coupled Product	Yield
 **12**	 n = 1, **20** n = 5, **23**	**20** 86% **23** 75%
 **13**	 TFA, CH_2Cl_2 → n = 1, R = Boc, **21a** → n = 1, R = H, **21b** (91%); TFA, CH_2Cl_2 → n = 5, R = Boc, **24a** → n = 5, R = H, **24b** (96%)	**21a** 70% **24a** 76%
 **14**	 n = 1, **22** n = 5, **25**	**22** 71% **25** 73%

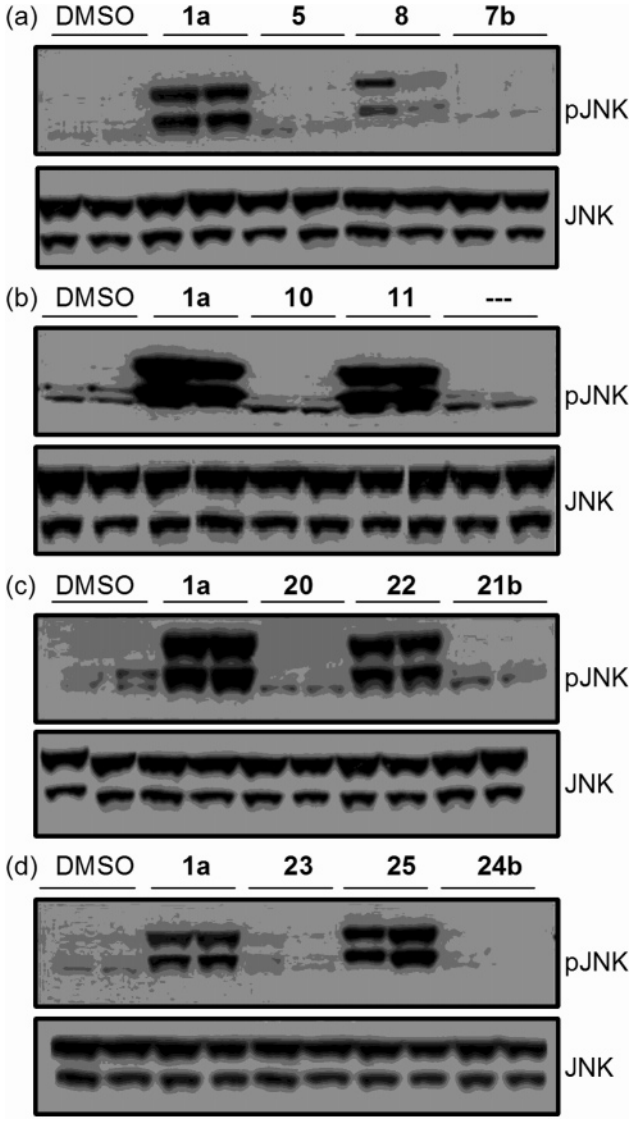
16, comparable reactivity was observed, and the control **23**, *O*-linked **24a**, and *N*-linked **25** probes were also isolated in excellent yields (Table 2). In all cases, the products were isolated as discreet chemical entities which could be fully characterized using a range of spectroscopic techniques (1D and 2D NMR experiments, including COSY, HSQC, and HMBC), and which were shown to be single regioisomers around the triazole core. The high purity and high yields of conjugation that are possible using this "click" methodology, combined with the relative ease of production of a range of linker lengths and functionalities for the biotinylated azide, make this an extremely attractive synthetic approach to biotinylation.

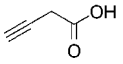
The relative levels of activation of the SAPK1 pathway by the classical and "click" biotinylated probes generated in this study were screened using an immunoblot assay for phosphorylation of JNK1/2 in HEK-293 cells (Figure 3). For this study, Boc-protected pyrrolidines **7a**, **21a**, and **24a** were deprotected (TFA, CH_2Cl_2) in high yield (91−96%) to give the corresponding pyrrolidines **7b**, **21b**, and **24b** (Tables 1 and 2) which were used in the SAPK pathway activation assays. The observed activation levels were scaled against anisomycin and DMSO (strong activator and control respectively). These assays showed that, independent of the coupling strategy used, the *O*-linked biotinylated probes (C_2: **5**, **7b**, **20**, **21b**; C_6: **10**, **23**, **24b**) were inactive, whereas their *N*-linked counterparts (C_2: **8**, **22**; C_6: **11**, **25**) were found to be comparable in the levels of activation they induced to anisomycin **1a**. Levels of SAPK1 activation also appear to be relatively unaffected by the length of linker (C_2 or C_6) in both classical and "click" series; although we anticipate that the nature (all-carbon, PEG, etc.) and length (C_2, C_6, etc.) of linker is likely to be of far greater significance in future affinity chromatography studies using these biotinylated molecular probes. Overall, these results were in good accord with our previous studies into the synthesis of fluorescent molecular probes (*35*).

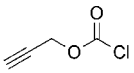
A survey of the methods available for the selective derivatization of a range of chemical functionalities (Table 3), suggests that this "click"-based approach to biotinylation might be applicable to a wide range of substrates. Chemical coupling of a propargyl marker to small molecules may be readily achieved using commercially available (or easily prepared) reagents, and can be tailored to fit diverse synthetic strategies. By matching the chemical reactivity of the propargyl reagent to the known SAR profile of a small molecule, both in terms of site of attachment (*e.g.*, *O*-linked or *N*-linked probes in this study) and resultant functionality (*e.g.*, amine, amide, or carbamate formation; see Table 3), a series of propargyl derivatives may be readily synthesized. Subsequent coupling of these propargyl derivatives with a biotinylated azide under standard "click" coupling conditions allows the rapid and high-yielding synthesis of biotinylated probes.

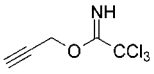
CONCLUSIONS

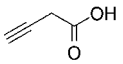
The attachment of a propargyl group (or "marker") to a small molecule core may be achieved using a wide range of reagents to common chemical functionalities. Through examining the known SAR of the SAPK pathway activator anisomycin, two potential sites for the rapid development of molecular probes were identified. In these, phenolic methyl and pyrrolidine *N*-benzyl groups were replaced by the propargyl marker to give small molecules which retain comparable activity to their parent

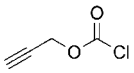












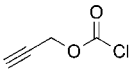


Figure 3. Effect of anisomycin and biotinylated conjugates on the phosphorylation of JNK1/2 isoforms in HEK-293 cells. The cells were exposed to DMSO (lanes 1 and 2), anisomycin **1a** (lanes 3 and 4), and the analogues indicated (lanes 5−10), each dissolved in DMSO: (a) classical C_2 probes; (b) classical C_6 probes; (c) click C_2 probes; (d) click C_6 probes. The cells were lysed and an aliquot (20 μg of lysate protein) was denatured in SDS, subjected to electrophoresis on a 10% polyacrylamide gel, transferred to a nitrocellulose membrane, and immunoblotted with an antibody that recognized JNK1/2 phosphorylated at Thr183 or with an antibody that recognized phosphorylated and unphosphorylated JNK1/2 equally well.

structures. Of these two lead compounds, the *N*-linked precursor was found to allow the development of active biotinylated probes, while derivatization of the *O*-linked precursor led to a loss of phenotypic response. Although these assay results were mirrored by molecular probes formed using classical nucleophilic displacement coupling strategies, low reaction yields were shown to be inherent to this alternate methodology. Thus, the versatility of precursor synthesis, mild coupling conditions, high yields, and excellent regioselectivity found using the "click"-based strategy renders it the method of choice in conjugative routes to biotinylated molecular probes.

ACKNOWLEDGMENT

We thank the BBSRC (Studentship to IAI), and MRC for financial support of this work; and the Scottish Executive/Royal Society of Edinburgh (Research Fellowship to ANH). We thank Dr. Ian Sadler and Juraj Bella for assistance with NMR studies and Dr. Simon Morton for technical assistance with the immunoassays.

Dicationic Lipophosphoramidates as DNA Carriers

Mathieu Mével,[†] Tristan Montier,[‡] François Lamarche,[†] Pascal Delépine,[‡] Tony Le Gall,[‡] Jean-Jacques Yaouanc,[†] Paul-Alain Jaffrès,[†] Dominique Cartier,[†] Pierre Lehn,[‡] and Jean-Claude Clément*[,†]

UMR CNRS 6521, Université de Bretagne Occidentale, UFR Sciences, 6, Avenue Le Gorgeu, C.S. 93837, F-29238 Brest cedex 3, France, and INSERM U 613, Université de Bretagne Occidentale, C.S. 2653, F-29275 Brest cedex, France. March 14, 2007; Revised Manuscript Received May 30, 2007

Lipophosphoramidates with two different permanent cations as polar heads were synthesized and evaluated for their gene transfer activity. Physicochemical measurements (particle size, zeta potentials) and gel retardation assays were also performed. *In vitro* biological evaluation was conducted with A542 and HeLa cell lines, and cytotoxicity determined by a chemiluminescent assay. The set of results indicates that, on the whole, dicationic lipophosphoramidates constitute an interesting alternative to their monocationic analogues.

INTRODUCTION

The use of cationic lipids for mediating DNA transfection has become widespread. Since the pioneering work of Felgner et al. (*1*), this trend has grown rapidly, so that now a variety of such compounds have been described and asserted as DNA carriers for future applications to gene therapy (*2*, *3*). Mixing an anionic plasmid DNA with variable amounts of cationic lipids (in terms of ± charge ratio) results in a "lipoplex", whose transfection efficiency will generally vary according to that ratio. In our previous *in vitro* experiments with phosphonolipids (*4*, *5*) or lipophosphoramidates (*6*), optimal ± ratios were in the range 2−4. Lower ratios exhibited lower efficiency and higher, generally, an increased cytotoxicity.

A possible way to lower the proportion of cationic lipid to DNA is to increase twofold (or more) the number of cations of the lipid. Moreover, additional cations could increase the strength of the interaction with DNA. Indeed, many examples of polycationic lipids are reported, notably lipidic polyamines. Their different amino groups are protonated at variable pH, leading to multicationic species, especially once internalized into cells (*2*). Permanently polycationic compounds are less numerous. Apart from polymers or bis-guanidinium derivatives (*7*), most of them are recorded as "gemini" (*8*). Some examples of gemini compounds used as DNA carriers are described, and in all quoted compounds, the cations are quaternary ammoniums (*9*−*15*).

We have previously shown that monocationic "phosphonolipids" (*4*, *5*) and "lipophosphoramidates" (*6*) had good transfection efficacy, together with moderate cytotoxicity. Moreover, the replacement of the ammonium by a phosphonium or arsonium head group was generally beneficial in terms of efficiency and cytotoxicity. So, we wondered about the behavior of such phosphorylated derivatives including two cations, identical or different, e.g., an ammonium plus a phosphonium, or an ammonium plus an arsonium, for instance. Furthermore, one can suppose that the arrangement of the two cations and the lipidic part (e.g., in single file or T-shaped) would lead to different interactions with DNA, hence a different efficacy. That is the case for cholesteryl polyamines, for instance, where the T-shaped arrangement was found to be more efficient than the linear one (*16*).

EXPERIMENTAL PROCEDURES

1. Materials and Reagents. Diisopropylethylamine (DIPEA) was dried and distilled over KOH. Fatty phosphites were synthesized by heating diphenyl phosphite (1 equiv) with tetradecanol or oleoyl alcohol (2 equiv) for 3 h at 120 °C and elimination of the produced phenol by distillation under vacuum. Bromopropyltrimethylammonium bromide **2** was purchased from Aldrich. Solvents were freshly distilled on appropriate driers and reactions run under nitrogen atmosphere. All compounds were fully characterized by ^{1}H (400 MHz), ^{13}C (100 MHz) and ^{31}P (121.49 MHz) NMR spectroscopy (Bruker AC 300 and Advance DRX 400 spectrometers). Coupling constants *J* are given in hertz. The following abbreviations were used: s for singulet, d doublet, t triplet, q quadruplet, qt quintuplet, and m for multiplet. High-resolution mass spectroscopy (HRMS) (ESI) was performed at the "Centre Régional des Mesures Physiques de l'Ouest", Rennes, France.

O,*O*-Ditetradecyl-*N*-(dimethylaminopropyl)phosphoramidate **1a** and *O*,*O*-dioleoyl-*N*-(dimethylaminopropyl)phosphoramidate **1b** Ditetradecyl phosphite (2.37 g, 5 mmol) or dioleoyl phosphite (2.91 g, 5 mmol), dimethylaminopropylamine (0.63 mL, 5 mmol), CH_2Cl_2 (15 mL), and $CBrCl_3$ (0.55 mL, 5.5 mmol) were mixed and cooled at 5 °C. DIPEA (0.96 mL, 5.5 mmol) was then added and the temperature kept 1 h at 5 °C, then 1 h at room temperature (RT). Solvent was discarded under reduced pressure, then DIPEA halides were precipitated in diethyl ether and filtered off. Purification of crude products was accomplished by column chromatography (silica gel), eluting with a chloroform/methanol (9/1) mixture. Compound **1a** ($C_{14:0}$) is a white solid (80% yield), and **1b** ($C_{18:1}$) a pale yellow oil (80% yield).

NMR data for **1a**: ^{1}H ($CDCl_3$) 0.86 (t, $^{3}J_{H-H}$ = 6.6, 6H), 1.26 (m, 44H), 1.65 (m, 4H), 1.66 (q, $^{3}J_{H-H}$ = 6.7, 2H), 2.22 (s, 6H), 2.35 (t, $^{3}J_{H-H}$ = 6.9, 2H), 2.98 (m, 2H), 3.47 (m, 1H), 3.98 (m, $^{3}J_{H-H}$ = $^{3}J_{P-H}$ = 6.4, 4H). ^{13}C ($CDCl_3$) 14.1, 22.6−32.0, 25.5, 30.3 (d, $^{3}J_{P-C}$ = 6.2), 40.3, 45.2, 57.2, 66.1 (d, $^{2}J_{P-C}$ = 6.6). ^{31}P ($CDCl_3$) 9.76.

NMR data for **1b**: ^{1}H ($CDCl_3$) 0.86 (t, $^{3}J_{H-H}$ = 6.6, 6H), 1.26 (m, 44H), 1.65 (m, 4H), 1.68 (m, 2H), 1.99 (m, 8H), 2.21 (s, 6H), 2.34 (m, 2H), 3.01 (m, 2H), 3.52 (m, 1H), 3.98 (m, $^{3}J_{H-H}$ = $^{3}J_{P-H}$ = 6.4, 4H), 5.32 (m, 4H). ^{13}C ($CDCl_3$) 14.1,

22.6−32.0, 25.4, 30.3 (d, $^3J_{P-C}$ = 6.2), 40.1, 45.4, 57.1, 66.1 (d, $^2J_{P-C}$ = 6.6), 129.6, 129.7. ^{31}P ($CDCl_3$) 9.77.

*3-Iodopropyltrimethylphosphonium Iodide **3***. Into 50 mL of degassed toluene were added under nitrogen atmosphere diiodopropane (1.32 mL, 12 mmol) and 10 mL of a 1 M solution of trimethylphosphine in THF (Aldrich). The mixture was then heated for 3 days at 40 °C. After cooling at RT, the white precipitate was washed twice with 10 mL of pentane and dried under vacuum (82% yield).

NMR data: ^{1}H (DMSO-d_6) 1.85 (d, 9H), 2.03 (q, 2H), 2.24 (m, 2H), 3.33 (t, 2H). ^{13}C (DMSO-d_6) 7.3, 7.4, 23.8, 24.9. ^{31}P (DMSO-d_6) 28.4.

HRMS (ESI): *m*/*z* calcd (*z* = 1) 244.9956; found 244.9953 (an ionization cluster [2C$^+$, I$^-$] was also observed at *m*/*z* 617).

*3-Iodopropyltrimethylarsonium Iodide **4***. Into 50 mL of degassed toluene were added under nitrogen atmosphere diiodopropane (2.27 mL, 20.7 mmol) and trimethylarsine (1.95 mL, 18.4 mmol). After heating for 6 days at 70 °C and cooling at RT, the white precipitate was washed twice with 10 mL of pentane and dried under vacuum (86% yield).

NMR data: ^{1}H (CD_3CN) 1.86 (s, 9H), 2.08 (q, $^3J_{H-H}$ = 6.9, 2H), 2.42 (m, 2H), 3.28 (t, $^3J_{H-H}$ = 6.8, 2H). ^{13}C (CD_3CN) 5.7, 7.7, 26.0, 27.1.

HRMS (ESI): *m*/*z* calcd (*z* = 1) 288.9434; found 288.9441 (an ionization cluster [2C$^+$, I$^-$]$^+$ was also observed at *m*/*z* = 705.

*Dicationic Lipophosphoramidates **5**, **6**, And **7***. Into 2 mL of CH_3CN were added **1a** (632 mg, 1.1 mmol) or **1b** (751 mg, 1.1 mmol) and 1 mmol of the "oniums" **2** (261 mg), **3** (372 mg), or **4** (416 mg). The mixture was heated at 70 °C for 3 days, then the solvent discarded under reduced pressure. The residues were precipitated and washed in ethyl acetate, then dried under vacuum. Ditetradecyl dicationic compounds **5a**, **6a**, and **7a** are off-white powders. Dioleoyl **5b**, **6b**, and **7b** are yellow to orange waxes. All yields were in the range 90−92%.

NMR data for **5a**: ^{1}H (DMSO-d_6) 0.85 (t, $^3J_{H-H}$ = 6.6, 6H), 1.24 (m, 44H), 1.57 (m, 4H), 1.80 (m, 2H), 2.19 (m, 2H), 2.82 (m, 2H), 3.07 (s, 6H), 3.12 (s, 9H), 3.27 (m, 2H), 3.34 (m, 4H), 3.95 (m, $^3J_{H-H}$ = $^3J_{P-H}$ = 6.4, 4H), 5.01 (m). ^{13}C (DMSO-d_6) 13.9, 16.5, 20.1−31.3, 24.1, 29.0 (d, $^3J_{P-C}$ = 6.2), 37.7, 50.0, 52.4, 59.6, 61.5, 61.9, 66.1 (d, $^2J_{P-C}$ = 6.6). ^{31}P (DMSO-d_6) 9.34.

NMR data for **5b**: ^{1}H (DMSO-d_6) 0.85 (t, $^3J_{H-H}$ = 6.6, 6H), 1.24 (m, 44H), 1.57 (m, 4H), 1.80 (m, 2H), 1.97 (m, 8H), 2.19 (m, 2H), 2.84 (m, 2H), 3.06 (s, 9H), 3.11 (s, 9H), 3.27 (m, 2H), 3.34 (m, 4H), 3.95 (m, $^3J_{H-H}$ = $^3J_{P-H}$ = 6.4, 4H), 5.01 (m, 1H), 5.31 (m, 4H). ^{13}C (DMSO-d_6) 13.9, 16.8, 20.1−31.3, 25.1, 29.0 (d, $^3J_{P-C}$ = 6.2), 36.3, 51.0, 53.4, 59.6, 61.8, 62.1, 66.1 (d, $^2J_{P-C}$ = 6.6). ^{31}P (DMSO-d_6) 9.40.

NMR data for **6a**: ^{1}H (DMSO-d_6) 0.87 (t, $^3J_{H-H}$ = 6.6, 6H), 1.27 (m, 44H), 1.57 (m, 4H), 2.10 (m, 2H), 2.27 (d, 9H), 2.48 (m, 2H), 2.80 (m, 2H), 3.08 (m, 2H), 3.39 (s, 6H), 3.70 (m, 2H), 3.77 (m, 2H), 3.84 (m, $^3J_{H-H}$ = $^3J_{P-H}$ = 6.4, 4H), 4.17 (m, 1H). ^{13}C (DMSO-d_6) 10.0 (d), 14.1, 17.7, 20.5, 22.7−32.1, 25.7, 30.5 (d, $^3J_{P-C}$ = 6.2), 37.9, 52.3, 62.8, 63.2, 67.1 (d, $^2J_{P-C}$ = 6.6). ^{31}P (DMSO-d_6) 9.01, 27.9.

NMR data for **6b**: ^{1}H (DMSO-d_6) 0.87 (t, $^3J_{H-H}$ = 6.6, 6H), 1.27 (m, 44H), 1.57 (m, 4H), 1.99 (m, 2H), 2.11 (m, 2H), 2.27 (d, 9H), 2.46 (m, 2H), 2.80 (m, 2H), 3.07 (m, 2H), 3.38 (s, 6H), 3.70 (m, 2H), 3.78 (m, 2H), 3.95 (m, $^3J_{H-H}$ = $^3J_{P-H}$ = 6.4, 4H), 4.18 (m, 1H), 5.45 (m, 4H). ^{13}C (DMSO-d_6) 10.0 (d), 14.1, 17.0, 20.5, 22.7−32.1, 25.7, 30.5 (d, $^3J_{P-C}$ = 6.2), 38.0, 52.4, 62.9, 63.3, 67.0 (d, $^2J_{P-C}$ = 6.6), 129.7, 130.0. ^{31}P (DMSO-d_6) 9.1, 28.1.

HRMS (ESI): *m*/*z* calcd (with *z* = 2) 400.3526; found 400.3533 (an ionization cluster [2C$^+$, I$^-$]$^+$ was also observed at *m*/*z* 927).

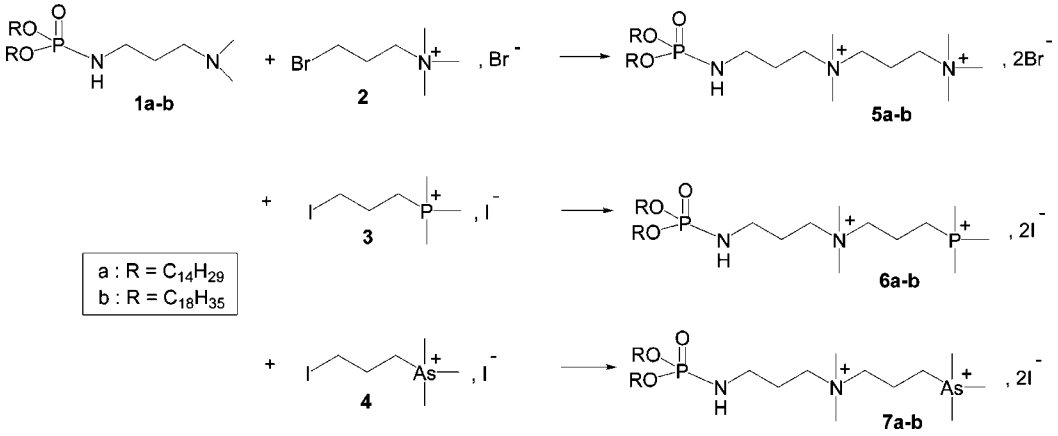
NMR data for **7a**: ^{1}H (DMSO-d_6) 0.87 (t, $^3J_{H-H}$ = 6.6, 6H), 1.27 (m, 44H), 1.57 (m, 4H), 2.11 (m, 2H), 2.30 (s, 9H), 2.60 (m, 2H), 2.90 (m, 2H), 3.08 (m, 2H), 3.35 (s, 6H), 3.66 (m, 2H), 3.72 (m, 2H), 3.84 (m, $^3J_{H-H}$ = $^3J_{P-H}$ = 6.4, 4H), 4.24 (m, 1H). ^{13}C (DMSO-d_6) 9.0, 13.6, 14.1, 22.7−32.1, 29.5, 25.4, 30.5 (d, $^3J_{P-C}$ = 6.2), 37.8, 51.1, 63.0, 67.1 (d, $^2J_{P-C}$ = 6.6). ^{31}P (DMSO-d_6) 9.11.

NMR data for **7b**: ^{1}H (DMSO-d_6) 0.87 (t, $^3J_{H-H}$ = 6.6, 6H), 1.27 (m, 44H), 1.57 (m, 4H), 1.99 (m, 2H), 2.06 (m, 2H), 2.32 (s, 9H), 2.55 (m, 2H), 2.86 (m, 2H), 3.08 (m, 2H), 3.37 (s, 6H), 3.68 (m, 2H), 3.74 (m, 2H), 3.95 (m, $^3J_{H-H}$ = $^3J_{P-H}$ = 6.4, 4H), 4.11 (m, 1H), 5.45 (m, 4H). ^{13}C (DMSO-d_6) 9.7, 14.1, 14.8, 19.3, 22.7−32.1, 25.8, 30.5 (d, $^3J_{P-C}$ = 6.2), 38.1, 52.3, 63.8, 67.0 (d, $^2J_{P-C}$ = 6.6), 129.7, 130.0. ^{31}P (DMSO-d_6) 9.05.

*O,O-Dioleoyl-N-(3-(N-imidazolyl)propyl)phosphoramidate **10***. Into 15 mL of CH_2Cl_2 were added $CBrCl_3$ (0.55 mL, 5.5 mmol), 3-aminopropylimidazole (0.59 mL, 5 mmol), and dioleoyl phosphite (2.91 g, 5 mmol). After cooling at 5 °C, DIPEA (0.96 mL, 5.5 mmol) was added and the mixture kept at this temperature for 1 h, then 1 h at RT. Solvent was evaporated and DIPEA halides filtered off, after precipitation from diethylether. Purification of crude product was accomplished by column chromatography (silica gel), eluting with a chloroform/methanol (9/1) mixture. Dioleoyl phosphoramidate **10** was isolated as a yellow wax (80% yield).

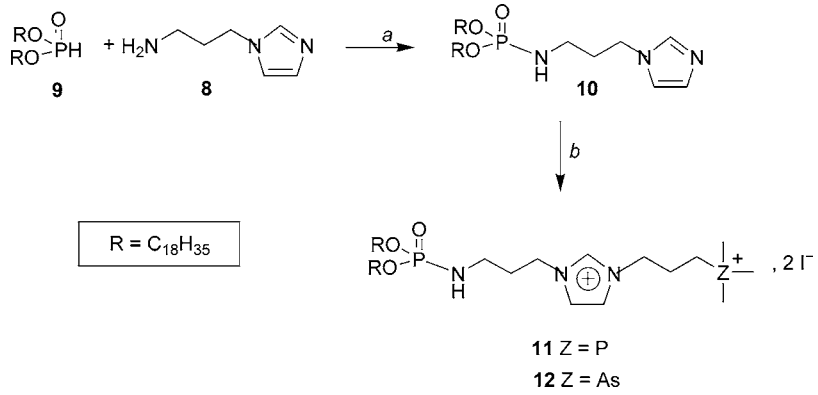
NMR data for **10**: ^{1}H ($CDCl_3$) 0.86 (t, $^3J_{H-H}$ = 6.6, 6H), 1.26 (m, 44H), 1.65 (m, 4H), 1.94 (q, $^3J_{H-H}$ = 6.7, 2H), 1.99 (m, 8H), 2.89 (m, 2H), 3.61 (m, 1H), 3.98 (m, $^3J_{H-H}$ = $^3J_{P-H}$ = 6.4, 4H), 4.03 (t, $^3J_{H-H}$ = 6.9, 2H), 5.32 (m, 4H), 6.92 (s, 1H), 7.04 (s, 1H), 7.49 (s, 1H). ^{13}C ($CDCl_3$) 13.2, 21.8−31.0, 24.7, 29.7 (d, $^3J_{P-C}$ = 6.2), 37.1, 43.0, 65.4 (d, $^2J_{P-C}$ = 6.6), 117.9, 128.4, 128.8, 129.1, 136.4. ^{31}P ($CDCl_3$) 9.57.

*Dicationic Lipophosphoramidates **11** And **12***. To 2 mL of CH_3CN were added 0.781 mg (1.1 mmol) of phosphoramidate **10** and 372 mg (1 mmol) of onium **3** or 416 mg (1 mmol) of onium **4**. The mixture was heated at 70 °C for 3 days, then the solvent evaporated. After precipitation from ethyl acetate, dicationic phosphoramidates **11** (P^+) and **12** (As^+) were isolated as yellow to orange waxes (90−95% yield).



NMR data for **11**: ^{1}H ($CDCl_3$) 0.87 (t, $^3J_{H-H}$ = 6.6, 6H), 1.27 (m, 44H), 1.57 (m, 4H), 1.99 (m, 8H), 2.15 (d, 9H), 2.18 (m, 2H), 2.62 (m, 2H), 2.99 (m, 2H), 3.05 (m, 2H), 3.93 (m, 1H), 3.95 (m, $^3J_{H-H}$ = $^3J_{P-H}$ = 6.4, 4H), 4.41 (m, 2H), 4.66 (m, 2H), 5.45 (m, 4H), 7.37 (s, 1H), 7.97 (s, 1H), 9.89 (s, 1H). ^{13}C ($CDCl_3$) 10.0 (d), 14.1, 20.5, 22.7−32.1, 24.0, 30.5 (d, $^3J_{P-C}$ = 6.2), 30.7, 38.0, 47.8, 49.0, 67.0 (d, $^2J_{P-C}$ = 6.6), 129.7, 130.0, 122.0, 123.4, 136.7. ^{31}P ($CDCl_3$) 9.52, 27.89. ^{15}N ($CDCl_3$) 201.7, 203.4, 341.5.

NMR data for **12**: ^{1}H ($CDCl_3$) 0.87 (t, $^3J_{H-H}$ = 6.6, 6H), 1.27 (m, 44H), 1.57 (m, 4H), 1.99 (m, 8H), 2.19 (m, 2H), 2.25 (d, 9H), 2.66 (m, 2H), 2.99 (m, 2H), 3.03 (m, 2H), 3.86 (m, 1H), 3.95 (m, $^3J_{H-H}$ = $^3J_{P-H}$ = 6.4, 4H), 4.42 (m, 2H), 4.60 (m, 2H), 5.45 (m, 4H), 7.53 (s, 1H), 7.94 (s, 1H), 9.85 (s, 1H). ^{13}C ($CDCl_3$) 9.2, 14.1, 21.8, 22.7−32.1, 24.1, 30.5 (d, $^3J_{P-C}$ = 6.2), 31.2, 37.7, 47.5, 49.4, 67.0 (d, $^2J_{P-C}$ = 6.6), 129.7, 130.0, 121.7, 123.1, 137.0. ^{31}P ($CDCl_3$) 9.52. ^{15}N ($CDCl_3$) 201.7, 203.4, 341.5.



*O,O-Dioleoyl-N-(N,N-bis-(3-(dimethylamino)propyl)))phosphoramidate **14***. Dioleoylphosphite (2.91 g, 5 mmol), 3,3′iminobis-(*N*,*N*-dimethylpropylamine) **13**, CH_2Cl_2 (15 mL), and CCl_4 (2 mL, 10 mmol) were mixed at 5 °C. DIPEA (0.96 mL, 5.5 mmol) was then added and the mixture kept for 1 h at 5 °C, then 1 h at RT. Solvents were discarded and DIPEA halides precipitated and filtered from diethyl ether. Dioleoyl phosphoramidate **14** was isolated as a yellowish oil (88% yield).

NMR data for **14**: ^{1}H ($CDCl_3$) 0.87 (t, $^3J_{H-H}$ = 6.6, 6H), 1.25 (m, 44H), 1.63 (m, 4H), 1.70 (m, 4H), 1.99 (m, 8H), 2.25

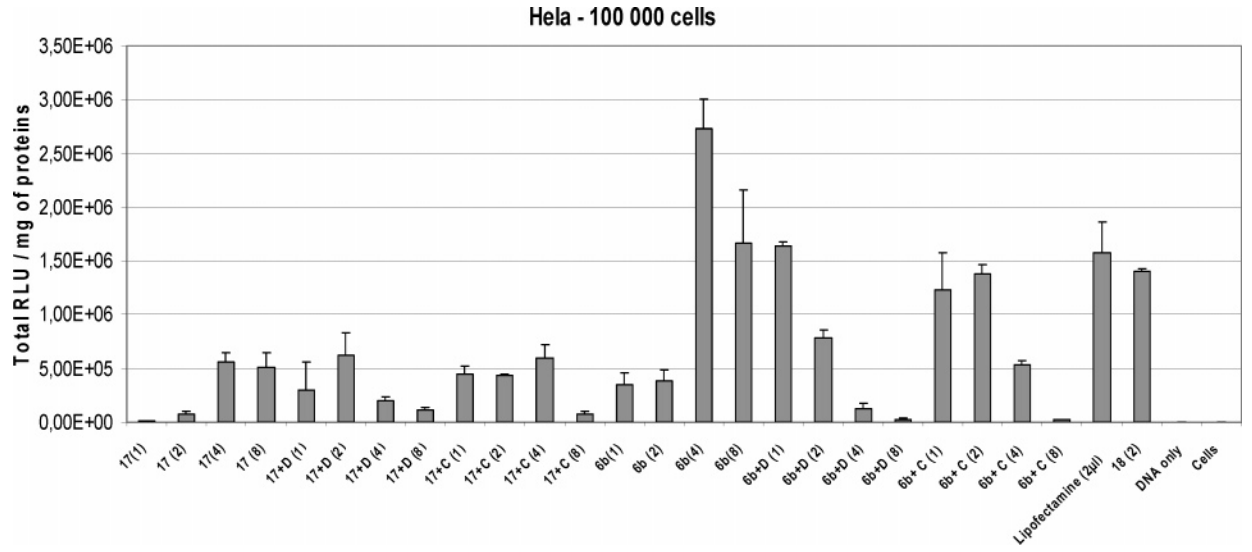
***2. In Vitro* Experiments.** *Cell Culture.* Two different cell lines (A549 and HeLa) were used. The alveolar type II epithelial cell line A549 and the human adenocarcinoma epithelial cell line HeLa were obtained from the American Type Culture Collection (respectively, cat. nos .CCL-185 and ccl-2, ATCC, Rockville, MD). These cells were grown in D-MEM (Gibco-BRL, UK) and supplemented with 10% fetal calf serum (FCS) (Gibco-BRL, UK) and 100 U/mL of penicillin/streptomycin. All the cells were maintained in a humidified incubator with 5% CO_2 at 37 °C.



Complex Formulation. Each cationic lipid was prepared alone or in combination with the neutral co-lipid DOPE (w/w = 1:1). Lipids were kept and formulated in chloroform solutions; then, chloroform was removed by rotary evaporation to produce dried lipid films. A total of 1 mL of sterile pyrogen-free DI

water per milligram of lipid was added, and the vials were sealed and stored at 4 °C overnight. Vesicles were then prepared by sonicating the aqueous suspension for 10 min in a bath sonicator.

Cationic lipid/DNA complexes were formed as follows: plasmid DNA (1 μg) was diluted with sterile pyrogen-free deionized water and added to the lipid solution in a polystyrene tube. Lipoplexes were kept at room temperature for 30 min before being used for transfection.

Determination of the Lipoplex Charge Ratio. The charge ratio was calculated theoretically as the molar ratio of the cationic lipids to DNA. In order to study the impact of the formulation on gene expression, various charge ratios (±) were prepared with a constant amount of pDNA (1 μg). As a control, 2 μL of Lipofectamine (Invitrogen) was used, accordingly to manufacturer's instructions, and in these conditions, for 1 μg of delivered DNA, the N/P ratio is equal to 2.

Transfection Protocol. Cells were seeded 24 h before transfection onto a 24-well plate at a density of 100 000 cells per well and incubated overnight in a humidified 5% CO_2 atmosphere at 37 °C. Transfection was performed as described by Felgner et al. (*1*), with the following modifications. Appropriate amounts of the cationic lipids and the plasmid vector in OptiMem were complexed, and about 200 μL was added to each well. After 2 h 30 min incubation at 37 °C, the medium was removed, and fresh medium was added. Following a further 48 h at 37 °C, the cells were assayed for luciferase expression using a chemiluminescent assay (Promega). Assays were carried out as described by the manufacturer. The total protein concentration of the cell culture was determined using the BC assay kit (Uptima). Luciferase activity of each condition was expressed to total relative light units (Total RLU) per milligram of total protein. Results are reported as means ± SEM.

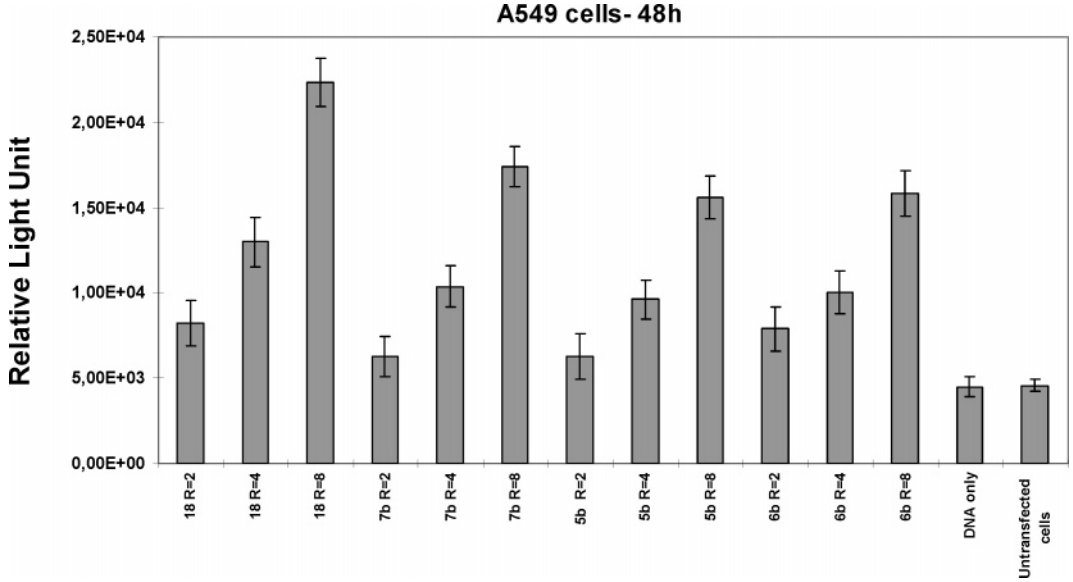
[a] Without (−) or with (+) DOPE (1:1) added. [b] The better ± ratio in the range 1−8 is quoted. [c] Because of values about a decade lower, no comparison was made with monocationic lipids.

Determination of Cell Toxicity. The toxicity of the different lipid/DNA complexes was determined by using a chemiluminescent assay (TOXILIGHT − Cambrex, Liège, Belgium). Twenty-four hours before the assay, the cells were plated in a 24-well plate (100 000 cells per well). Transfections were performed as described above, and the cells were incubated for 48 h at 37 °C. The toxicity assay was then carried out as specified by the manufacturer. This kit quantitatively measures the release of adenylate kinase (AK) from damaged cells into the surrounding medium. The reaction involves two steps. The first one involves the addition of ADP as a substrate for AK. In the presence of AK, the ADP is converted to ATP for assay by bioluminescence. Then, the bioluminescence method utilizes an enzyme Luciferase, which catalyzes the emission of photons from ATP and luciferin. By combining both reactions, the emitted light intensity is directly related to the AK concentration. The relative light units (RLU) were conversely proportional to the number of living cells. Untransfected cells were used as a reference.



3. DNA Binding Ability. To 1 μg of plasmid DNA in Optimem (Gibco) were added cationic lipids at concentrations corresponding to an N/P charge ratio ranging from 0.5 to 8. The mixture was incubated for 30 min at room temperature. The complexes were subjected to electrophoresis in 1% agarose gel at 100 V, 90 mA. The gel was stained with ethidium bromide (10 mg/mL) and visualized on an UV illuminator (Fischer Bioblock).

4. Sizes and ζ Potential Determination. Particle size and ζ potentials were determined using a Malvern Zetasizer 3000 HAS. For lipids alone, 2.7 mM (about 3 mg/mL) solutions in 10 mM Hepes buffer were prepared. Then, 0.2 mL of the solution was put into the cuvette and diluted up to 4 mL with Hepes. For lipoplexes, plasmidic DNA (2.5 μg) in Optimem (20 μL) was added to 5.5 μL (± ratio = 4) or 11 μL (± ratio = 8) of the above lipid 2.7 mmol solution diluted in 0.2 mL of Optimem, and left at RT for 30 min. The solution was then diluted to 4 mL with 10 mM Hepes buffer into the cuvette for measurement.

RESULTS AND DISCUSSION

1. Synthesis of Dicationic Lipophosphoramidates. We thus sought a synthetic route to "dicationic lipophosphoramidates". For the "in single file" ones, since the phosphoramidate **1** is easily accessible by a Todd-Atherton reaction (*17*), a subsequent quaternarization by haloalkyl "onium" salts **2**, **3**, or **4** would lead directly to dicationic phosphoramidates **5**, **6**, or **7**, respectively. Bromopropyltrimetylammonium **2** is commercially available, whereas iodopropyltrimethylphosphonium **3** and arsonium **4** were synthesized by adapting a procedure described for bromopropyltrimethylphosphonium (*18*). Indeed, heating

Chart 3. Cell Toxicity of Monocationic 18 and Dicationic 5b, 6b, and 7b

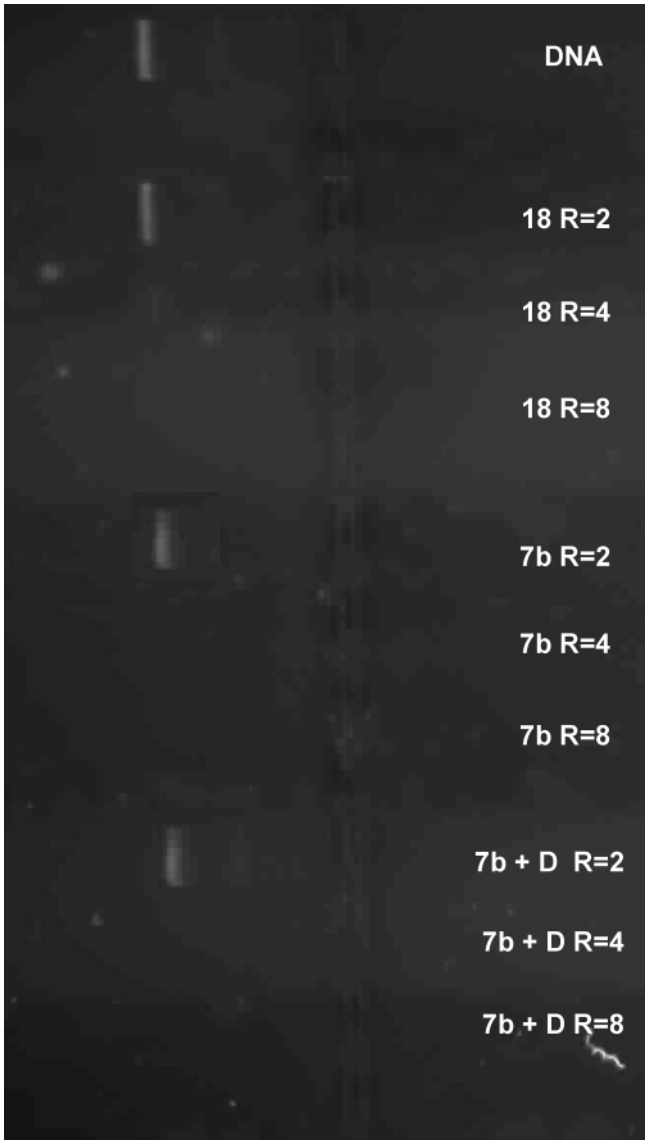


Figure 1. DNA binding ability of monocationic lipid **18** and dicationic **7b**.

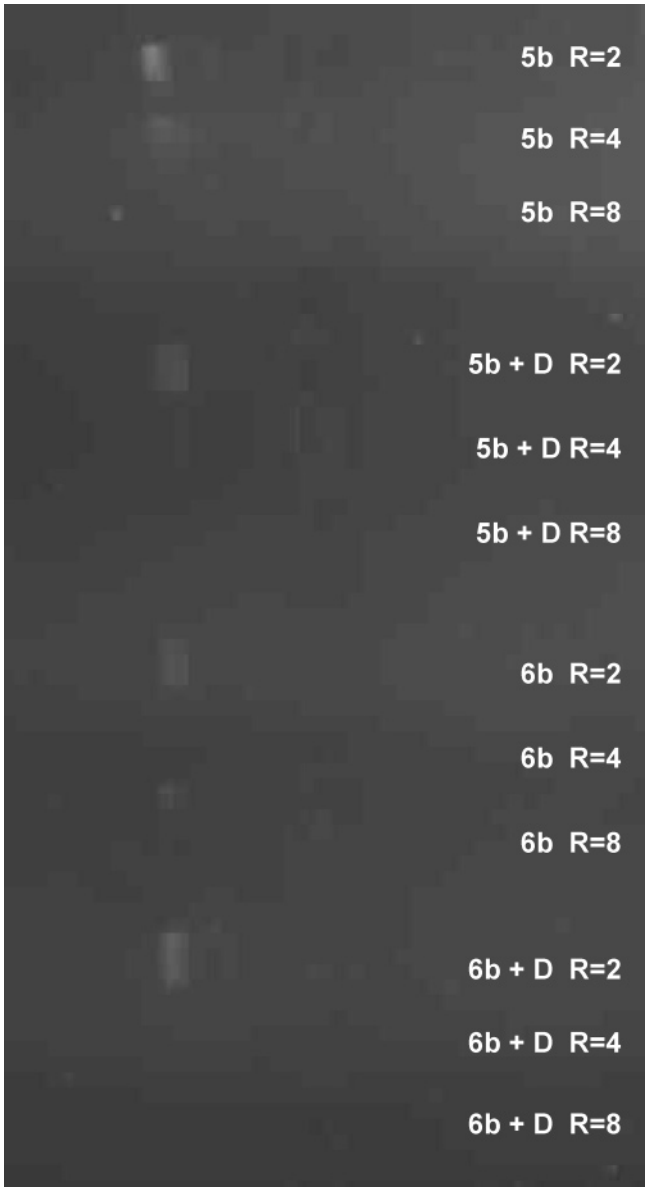

Figure 2. DNA binding ability of dicationic lipids **5b** and **6b**.

salts **2**, **3**, and **4** with an equivalent quantity of dimethylamino phosphoramidate **1** in acetonitrile at 70 °C for 3 days led to the wanted dicationic compounds **5**, **6**, and **7** in a 90−92% yield range (Scheme 1).

Then, we considered synthesizing imidazolium cations too, since some DNA carriers with such polar heads have been described (*19*). Propylimidazole phosphoramidate **10** was easily accessible from aminopropylimidazole **8** and fatty phosphite **9**. Quaternarization by the same onium salts **3** or **4** led to dicationic compounds **11** and **12** with excellent yields (90−95%) (Scheme 2).

A T-shaped dicationic phosphoramidate **15** was also synthesized from triamine **13** and fatty phosphite **9**, followed by a quaternarization of the resulting diamino compound **14** with methyl iodide (Scheme 3). However, its *in vitro* efficiency was lower than the corresponding "in single file" diammonium **5** (see below), and that way was not continued further.

In comparison with the already described (*6*) very efficient monocationic lipophosphoramidates **16**−**19** (Scheme 4), these dicationic compounds were then evaluated for their transfection efficiency, their cytotoxicity, and their DNA binding ability. Some physicochemical parameters (lipoplexes size, zeta potentials) were also established.

2. Transfection Efficiency and Cytotoxicity. Transfection efficiency (expressed as luciferase activity) of dicationic compouds was performed on two different cell lines (A549 and HeLa), in comparison with monocationic phosphoramidates **16**−**19**, according to routinely used and previously described procedures (*5*, *20*). Each lipid was tested at increasing ± charge ratios (*1*−*8*). Charts 1 and 2 show an example of the superiority of dicationic **6b** (ammonium/phosphonium) vs monocationic **17** (phosphonium) or **18** (arsonium).

Table 1 recapitulates the observed efficiencies for each dicationic lipid described above. As a general rule, dicationic lipids **5**, **6**, and **7** exhibit slightly greater values than the corresponding monocationic ones, at the same ± charge ratio, and are more efficient without DOPE added. On the other hand, dicationic lipids **11b** and **12b** with a central imidazolium core exhibit rather disappointing lower values. T-shaped diammonium **15** shows less efficiency than the corresponding "in single file" **5b**.

Insofar as at the same ± charge ratio dicationic lipids require half the material as the monocationic ones, a lower cytotoxicity was expected. To that effect, the toxicity of the different lipoplexes was determined by using a chemiluminescent assay (see the Experimental Procedures for details).

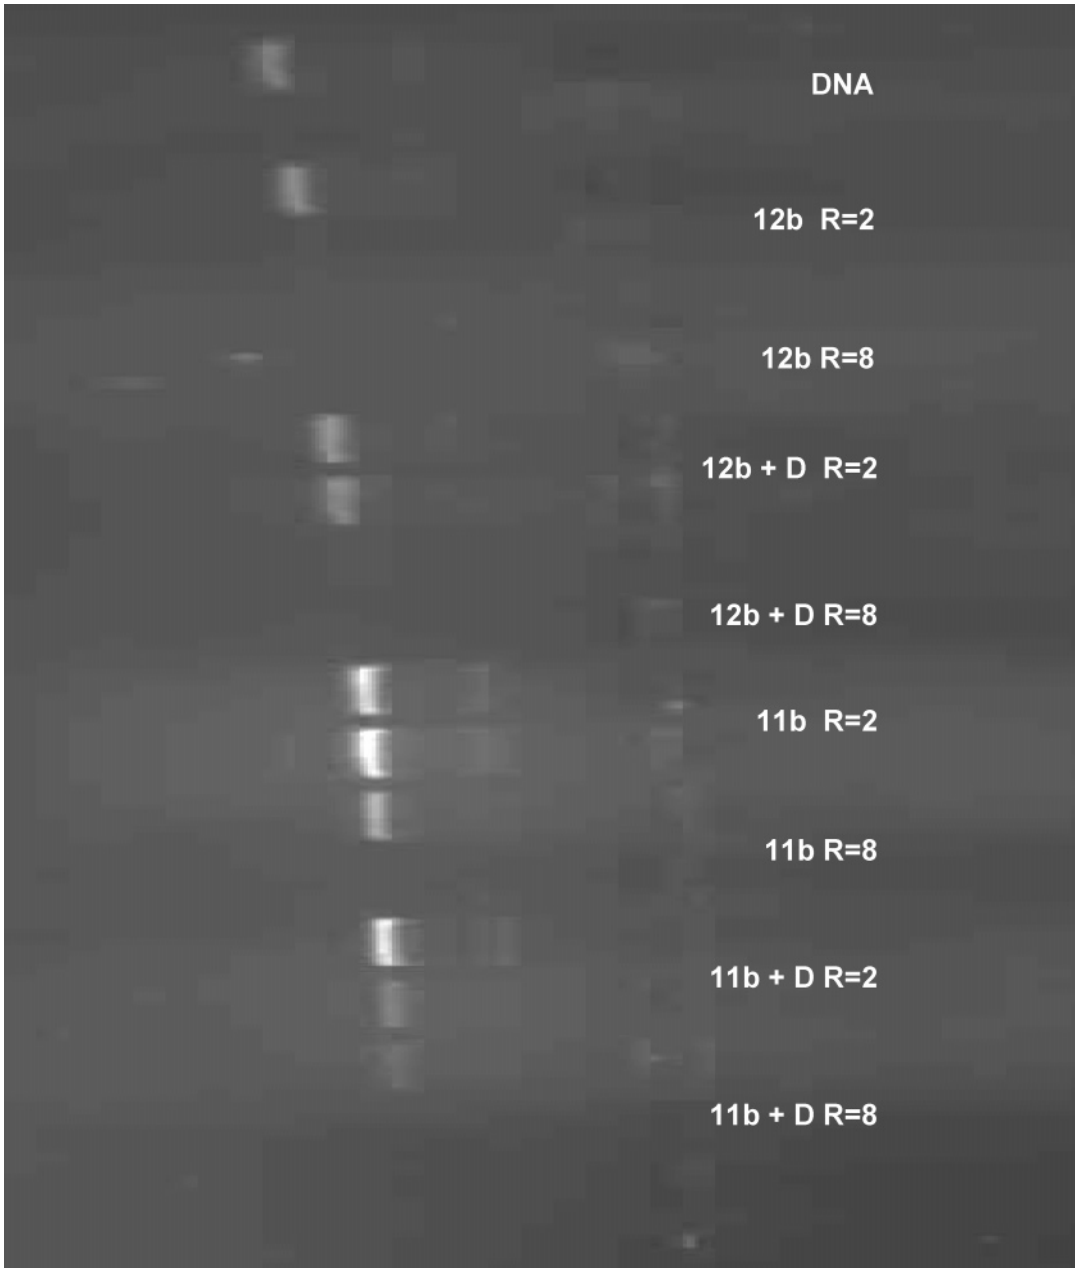

Figure 3. DNA binding ability of dicationic lipids **11b** and **12b**.

Chart 3 presents a comparison among dicationic lipids **5b**, **6b**, and **7b** and monocationic **18** (more RLUs are detected, more the cytoxicity increases correlated to the toxicity of the tested cationic lipid formulations). For each ± charge ratio (2, 4, or 8), the cytotoxicity of dicationic compounds is about one-third lower than that of **18**.

3. DNA Binding Ability. Electrophoretic mobility of plasmid DNA was examined with increasing N/P ratios (*2*−*8*) using 1% agarose gel (DNA was visualized by ethidium bromide staining). Complete binding of DNA was observed at an N/P ratio lower than 4 for phosphoramidates **5b**, **6b**, **7b**, and **18**, whereas binding was not complete at an N/P ratio of 4 for imidazolium compound **12b** or 8 for **11b** (Figures 1−3). This difference may explain the lower values quoted above.

4. Lipoplex Sizes and ζ Potentials. On the basis of purely electrostatic interactions, dicationic lipids were anticipated to be better DNA-condensing amphiphiles than their monocationic analogues. In other words, the hydrodynamic diameters for lipoplexes prepared from lipids **5**−**7** and **11**−**12** were expected to be smaller than those prepared from monocationic lipids.

Table 2. Sizes and ζ Potentials of Lipids and Their Lipoplexes (formulation without neutral co-lipid)

	size (μm)			ζ potential (mV)		
		lipoplex			lipoplex	
lipid no	lipid alone	$r = 4$	$r = 8$	lipid alone	$r = 4$	$r = 8$
5b	175	240	235	69	26	33
6b	176	268	249	80	19	46
7b	146	187	175	79	30	43
11b	100	328	344	90	20	24
12b	140	332	328	85	20	26
15	259	-	-	89	26	39
18	210	247	229	62	44	60

Table 2 recapitulates sizes and ζ potentials for lipids alone and their lipoplexes (at a ± charge ratio of 4 and 8) (see Experimental Procedures for details).

Indeed, average diameters of dicationic lipids are in the 100−175 range, compared to 210 for monocationic **18**, for lipids alone, but the lipoplex of **18** appears in the same range as dicationics. Changing lipid for lipoplex is accompanied by a 35−50 mV downshift of the ζ potentials for dicationic lipids,

whereas the same change keeps the values basically unchanged for **18**, at the same ± charge ratio. From these data, a correlation between size, ζ potentials, and transfection efficacies of lipoplexes is not obvious. The same conclusions were made by Chaudhuri et al., from a series of cationic amphiphiles containing mono-, di-, and trilysine headgroups (*21*).

CONCLUSION

The synthesis of permanently charged dicationic phosphoramidates was reported. The new vectors were readily obtained in good yield by using as a key reaction a Todd-Atherton coupling followed by a quaternarization step involving a halogeno-alkane ω-functionalized by either an ammonium, a phosphorinum, or an arsonium. The central cationic charge is either an ammonium or an imidazolium. Moreover, the synthesis of a T-shaped diammonium phosphoramidate was reported in high yield. These dicationic lipophosphoramidates are slightly more efficient than their monocationic analogues for *in vitro* gene delivery. The best vector for the transfection of the two cell lines studied (A549 and Hela) is compound **6b**, which is characterized, on the polar head, by the presence of a central ammonium and a terminal phosphonium. Furthermore, its cytotoxicity is about one-third lower than that of the monocationic vector **18**. In another work (*22*), we have examined the transfection efficacies of lipophosphoramidates bearing a spermine as the polar head. Biological evaluation was performed on the same cell lines as above and in the same experimental conditions. Spermine derivatives expressed luciferase levels one-half the values of permanently dicationic compounds described here. Since monocationic phosphoramidates exhibit interesting *in vivo* activity (*6*), their dicationic analogues are currently under investigation to this end.

3-Amino-4-(2-((4-[^{18}F]fluorobenzyl)methylamino)methylphenylsulfanyl)benzonitrile, an F-18 Fluorobenzyl Analogue of DASB: Synthesis, *in Vitro* Binding, and *in Vivo* Biodistribution Studies

3-Amino-4-(2[^{11}C]methylaminomethylphenylsulfanyl)benzonitrile (C-11 DASB) exhibits excellent *in vitro* and *in vivo* properties toward the serotonin transporter. If labeled with a longer physical half-life radioisotope, this ligand could be more attractive to research groups lacking an on-site cyclotron or lacking C-11 synthesis capabilities. We produce *p*-[^{18}F]fluorobenzyl iodide on a routine basis to synthesize several neuroimaging agents. Therefore, it was straightforward for us to substitute the DASB precursor with this prosthetic group and assess its biological properties. We designed a different synthesis strategy to obtain the DASB precursor (desmethyl DASB). Herein we report an efficient and facile synthetic route that provides higher chemical yields of 3-amino-4-(2-aminomethylphenylsulfanyl)benzonitrile and related analogues. In addition, we report our results from incorporating *p*-[^{18}F]fluorobenzyl iodide in DASB precursor and its affect on the *in vitro* and *in vivo* biological properties of the DASB.

INTRODUCTION

The neurotransmitter serotonin (5-hydroxytryptamine, 5HT) plays an important role in the regulation of a variety of brain functions such as mood, appetite, sleep, behavioral traits, anxiety, depression, sexual disorders, and pain (*1*, *2*). The serotonin transporter (SERT) is located presynaptically on the cell bodies and terminals of the 5-HT neurons. The SERT are distributed throughout the brain in varying densities with the highest density in the raphe and thalamus. The main function of SERT is to regulate serotonin in the synaptic cleft via the reuptake mechanism. SERT transfers 5HT from the synapse into the nerve terminals, thus terminating the 5-HT signal. Diminished synaptic 5HT in turn leads to depression and related disorders. Chemicals that block SERT action have found utility in the treatment of depression, panic disorder, post-traumatic stress disorder, and obsessive compulsive disorder (*3*−*5*). Therefore, accurate quantification of SERT density is critical in understanding the role of SERT on serotonin neurotransmission.

Noninvasive *in vivo* imaging of the SERT with positron emission tomography (PET) would provide accurate quantitative information. PET imaging has been quite effective in assessing drug occupancy on SERT and dopamine transporter (DAT) to evaluate efficacy of novel drugs in humans using specific ligands (*6*, *7*). (+)-[^{11}C]McN5652 was the first PET probe to interrogate SERT in humans (*8*). A variety of psychiatric disorders including mood disorder, alcoholism, and patients with drug abuse problems were studied using this probe (*9*, *10*). Unfortunately, slow kinetics of this tracer in the brain (*11*) limited its utility. Therefore, developing another generation of more effective SERT probes became the goal of various laboratories. To achieve that goal, several PET ligands were developed over the past decade (*12*, *13*). An F-18 analogue of McN5652 (FMe-McN5652) was also developed showing higher target to nontarget tissue ratio and faster tracer kinetics than the parent (+)-[^{11}C]McN5652 (*14*, *15*). Unfortunately, quantification capabilities using FMe-McN5652 and other biological factors limited the utility of this ligand (*14*). To obtain a probe with higher affinity and potency, several investigators explored another series of compounds incorporating a diaryl sulfide motif (*12*, *16*, *17*). One of the lead compounds from this series, 3-amino-4-(2-[^{11}C]methylaminomethylphenylsulfanyl)benzonitrile (C-11 DASB) showed a higher signal-to-noise ratio and faster brain uptake kinetics than (+)-[^{11}C]McN5652. C-11 DASB was further assessed for its imaging characteristics and found to be a preferred ligand to study SERT (*18*, *19*).

Despite excellent specificity and sensitivity of C-11 DASB to SERT, the short half-life of C-11 (20 min) remains an obstacle for many PET groups to utilize this ligand who lack an on-site cyclotron facility. Introducing an F-18 isotope with a longer half-life ($t_{1/2}$ 110 min) while maintaining the DASB template would facilitate its use for longer scanning sessions and more importantly at remote centers without an on-site cyclotron facility. Although previous attempts to incorporate F-18 in a DASB motif were somewhat successful (*13*), the results were less than convincing to replace C-11 DASB with the newly developed ligands. This kept the search for an effective F-18-labeled DASB analogue open. In our laboratories, we routinely synthesize [^{18}F]fluorobenzyl iodide to synthesize various ligands for neuroimaging applications (*20*−*22*). It was important for us to assess the feasibility of incorporating the [^{18}F]fluorobenzyl iodide in DASB precursor and study its affect on *in vitro* and *in vivo* characteristics. Toward that goal, we designed an F-18-labeled analogue by replacing one of the *N*-methyl groups with a *p*-fluorobenzyl group. During the synthesis of the DASB precursor, 3-amino-4-(2-aminomethylphenylsulfanyl)benzonitrile, we also developed a more efficient and facile synthesis to prepare the intermediate 3-amino-4-(2-aminomethylphenylsulfanyl)benzonitrile and related compounds in higher yields. In addition, we report the synthesis of 3-amino-4-(2-[(4-fluoroben-

zyl)methylamino]methylphenylsulfanyl)benzonitrile (FBASB), its *in vitro* binding, and *in vivo* biodistribution studies in normal rats and mice.

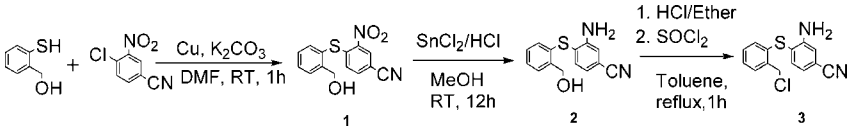
EXPERIMENTAL PROCEDURES

All reactions were carried out under an inert atmosphere with dry solvents, under anhydrous conditions, unless otherwise stated. Reagents and solvents were purchased from commercial suppliers and were used without further purification. Melting points were determined on an Electrothermal "MEL-TEMP" melting point apparatus and are uncorrected. Flash column chromatography was carried out over silica gel (60 Å, Mallinckrodt, Baker). ^{1}H NMR data was acquired on a Bruker Advance 300 DPX spectrometer. All chemical shift values are reported in ppm (δ). Elemental analyses (C, H, N) were determined by Atlantic Microlab, Inc., and the analytical results were within $\pm$0.4% of the theoretical values for the formula given.

Radioactivity levels in tissues were assessed with a Packard Cobra γ-counter. High-pressure liquid chromatography (HPLC) was performed in isocratic mode with a Varian 9010 LC pump, a variable wavelength 9050UV VIS detector (*23*) (Varian Corp, Palo Alto, CA) set at 254 λ, and a radioisotope detector (Bioscan Inc, Washington, D.C.) attached to Varian's chromatography software package (Varian Corp, Palo Alto, CA). The HPLC system used for purification of ^{18}F-labeled FBASB was a C-18 reverse-phase ODS, 10 $\times$ 250 mm 5μ column (Phenomenex, Torrence, CA) eluted with MeOH: 0.1 M ammonium formate (80:20) at 5 mL/min. The desired peak was eluted at 16 min using this system. Quality control of purified product was performed using a Varian HPLC system and a microsorb reverse phase C-18 column 250 $\times$ 4.6 mm eluted with MeOH:0.1 M ammonium formate (80:20) at 1 mL/min and was eluted at 14 min.

Preparation of 4-(2-Hydroxymethylphenylsulfanyl)-3-nitrobenzonitrile (1). A mixture of 2-mercaptobenzyl alcohol (2.00 g, 14.28 mmol), 4-chloro-3-nitrobenzonitrile (3.12 g, 17.13 mmol), K_2CO_3 (3.13 g, 22.64 mmol), and copper powder (0.272 g, 4.28 mmol) was added to DMF (20 mL), and the reaction mixture was stirred under argon for 1 h. Afterward, the reaction mixture was diluted with water (50 mL), and the desired compound was extracted in ethyl acetate (3 $\times$ 50 mL). The combined extracts were washed with water (2 $\times$ 50 mL) and dried (Na_2SO_4), and the solvent was removed using a rotary evaporator. A yellow foamy residue thus obtained was purified by flash chromatography using a silica gel column and eluting it with dichloromethane. The yellow solid powder was recrystallized from CH_2Cl_2/hexane to furnish the desired compound **1** as a yellow solid (3.52 g, 86%): mp 126−130 °C, lit. (*23*). 120−126 °C, ^{1}H NMR (300 MHz, $CDCl_3$) δ 8.54 (d, J = 1.8 Hz, 1H, Ar-*H*), 7.74 (dd, J = 0.9, 7.8 Hz, 1H, Ar-*H*), 7.64 (dt, J = 1.5, 7.5 Hz, 1H, Ar-*H*), 7.57 (dd, J = 1.2, 7.8 Hz, 1H, Ar-*H*), 7.51 (dd, J = 1.8, 8.4 Hz, 1H, Ar-*H*), 7.47 (dt, J = 1.5 and 7.5, Hz, 1H, Ar-*H*), 6.81 (d, J = 8.4 Hz, 1H, Ar-*H*), 4.76 (d, J = 5.7 Hz, 2H, C*H*$_2$OH), 1.95 (t, J = 5.7 Hz, 1H, CH$_2$O*H*).

Preparation of 3-Amino-4-(2-hydroxymethylphenylsulfanyl)benzonitrile (2). Compound **1** (4.10 g, 14.33 mmol) was dissolved in methanol (40 mL), and 12 N HCl (30 mL) was added. The suspension was cooled to 0 °C, and $SnCl_2$ (10.351 g, 45.87 mmol) was added. The reaction mixture was stirred overnight at room temperature. The mixture was diluted with H_2O (50 mL), and the compound was extracted in ethyl acetate (3 $\times$ 50 mL). The combined organic layers were washed with a saturated aqueous solution of $NaHCO_3$ (2 $\times$ 10 mL), followed by water (2 $\times$ 20 mL), dried, and concentrated. The yellow solid was purified using flash column chromatography and eluting with ethyl acetate/hexanes (1:2). Further recrystallization of this product in CH_2Cl_2/hexane yielded the desired compound **2** as a yellow solid (3.11 g, 85%): mp 122−125 °C, lit. (*23*) mp 121−124 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.47 (dd, J = 1.5, 7.2 Hz, 1H, Ar-*H*), 7.18−7.31 (m, 3H, Ar-*H*), 7.03 (dd, J = 1.2, 7.5 Hz, 1H, Ar-*H*), 6.92−6.96 (m, 2H, Ar-*H*), 4.82 (d, J = 6.0 Hz, 2H, C*H*$_2$OH), 4.44 (bs, 2H, Ar-N*H*$_2$), 2.06 (t, J = 6.0 Hz, 1H, CH$_2$O*H*).



Preparation of 3-Amino-4-(2-chloromethylphenylsulfanyl)benzonitrile (3). To a solution of **2** (2.00 g, 7.81 mmol) in diethyl ether (5 mL + few drops of MeOH) was added a solution of HCl in diethyl ether (5 mL, 2.0 N). After 10 min, the ether was evaporated, and toluene (20 mL) was added followed by a slow addition of thionyl chloride (1.71 mL). After refluxing for 1 h (clear solution) under argon atmosphere, the reaction mixture was cooled to room temperature. The compound was extracted in ethyl acetate (20 mL), the organic layer was washed with a saturated solution of $NaHCO_3$ (5 mL) and dried over Na_2SO_4. The solvent was removed under vacuum to give solid material **3** in 93% yields. This crude product was used for the next reaction without further purification.

Preparation of 3-Amino-4-(2-isoindole-1,3-dionemethylphenylsulfanyl)benzonitrile (4). A mixture of **3** (0.50 g. 1.82 mmol) and potassium phtalimide (0.675 g, 3.64 mmol) in DMF (20 mL) was heated at 100 °C for 1 h. The reaction mixture was cooled to room temperature, and water (20 mL) was added. The product was extracted in ethyl acetate (3 $\times$ 25 mL), and the combined organic layer was dried over Na_2SO_4. After removing the solvent, the yellow solid residue was recrystallized from ethyl acetate/hexanes to yield **4** in 76% yield as a yellowish crystalline solid. Mp 180−183 °C, ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.85−7.89 (m, 2H, Phth-*H*), 7.73−7.78 (m, 2H, Phth-*H*), 7.32 (m, 1H, Ar-*H*), 7.26 (m, 1H, Ar-*H*), 7.15−7.24 (m, 3H, Ar-*H*), 7.08 (dd, J = 1.8, 7.8 Hz, 1H, Ar-*H*), 6.9 (m, 1H, Ar-*H*), 5.06 (s, 2H, C*H*$_2$N), 4.55 (bs, 2H, Ar-N*H*$_2$). Anal. ($C_{22}H_{15}N_3O_2S$) C, H, N.

Preparation of 3-Amino-4-(2-aminomethylphenylsulfanyl)benzonitrile (5). A solution of **4** (0.350 g, 0.909 mmol) and hydrazine (0.062 mL, 1.99 mmol) in anhydrous ethanol (15.00 mL) was refluxed for 2 h under argon atmosphere. The reaction mixture was cooled to room temperature, and volatiles were removed using a rotary evaporator. The white residue thus obtained was dissolved in 40% aq KOH (50 mL) and extracted in ether (3 $\times$ 25 mL), and the combined organic layer was dried over Na_2SO_4. After removal of the solvents, the oily residue was purified with flash column chromatography using acetone/ethyl acetate (1:9) as the solvent to give a thick yellow syrup in 98% yields. Treatment with HCl in ether yielded the desired compound **5** as a white crystalline material. mp 133−137 °C, ^{1}H NMR (300 MHz, DMSO) δ 13.40 (bs, 1H, N*H*), 8.60 (bs, 1H, N*H*), 7.50−7.60 (m, 1H, Ar-*H*), 7.30−7.38 (m, 2H, Ar-*H*), 7.20−7.25 (m, 1H, Ar-*H*), 7.13 (d, J = 1.5 Hz, 1H, Ar-*H*), 6.93−7.02 (m, 2H, Ar-*H*), 4.98 (s, 2H, C*H*$_2$NH$_2$). Anal. ($C_{14}H_{13}N_3S\cdot HCl\cdot 0.5H_2O$) C, H, N.

Preparation of 3-Amino-4-(2-(4-fluorobenzyl)aminomethylphenylsulfanyl)benzonitrile (6). To a solution of **3** (0.800 g, 2.91 mmol) in acetonitrile (10 mL) were added 4-fluorobenzylamine (0.667 mL, 5.83 mmol) and triethylamine (1.22 mL, 8.75 mmol). After refluxing for 1 h, the reaction mixture was cooled to room temperature and the solvent was removed under vacuum. The oily residue was further purified using flash column chromatography on silica gel and eluting with ethyl acetate/hexane (1:4). The compound thus obtained was further recrystallized from CH_2Cl_2/hexanes to yield **6** as a white fluffy solid in 90% yield. mp 98−99 °C, ^{1}H NMR (300 MHz, $CDCl_3$). δ 7.12−7.36 (m, 6H, Ar-*H*), 6.98−7.04 (m, 3H, Ar-*H*), 6.92−6.95 (m, 2H, Ar-*H*), 4.59 (bs, 2H, Ar-N*H*$_2$), 3.92 (s, 2H, benzylic *CH*$_2$), 3.81 (s, 2H, benzylic *CH*$_2$), 1.60 (bs, 1H, N*H*). Anal. ($C_{21}H_{18}FN_3S$) C, H, N.

Scheme 1. Synthesis of Substituted Benzyl Chloride 3, a Key Intermediate in the Preparation of Various Substituted Benzyl Amines

Preparation of 3-Amino-4-(2-methylaminomethylphenylsulfanyl)benzonitrile (8). To a solution of **3** (0.400 g, 1.45 mmol) in acetonitrile (5 mL) was added 40% aqueous methylamine (1.132 mL, 14.59 mmol), followed by triethylamine (0.610 mL, 4.37 mmol). After the reaction mixture was refluxed for 1 h, it was cooled to room temperature and the solvent was removed. The residue was dissolved in ethyl acetate (20 mL), and the organic layer was washed with water (3 × 5 mL) and dried over Na_2SO_4. The solvent was removed *in vacuo*, and the oily residue was further purified using flash column chromatography and eluting with acetone as a thick viscous oil. Recrystallation of this oily residue using CH_2Cl_2/hexanes yielded **8** as a white crystalline compound in 72% yields. mp 93−96 °C, ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.32−7.37 (m, 2H, Ar-*H*), 7.21−7.27 (m, 1H, Ar-*H*), 7.12−7.19 (m, 1H, Ar-*H*), 7.00 (dd, J = 1.5, 7.8 Hz, 1H, Ar-*H*), 6.91−6.94 (m, 2H, Ar-*H*), 4.73 (bs, 2H, Ar-N*H*$_2$), 3.89 (s, 2H, C*H*$_2$NHMe), 2.47 (s, 3H, CH$_2$-NH*Me*), 1.53 (bs, 1H, CH$_2$N*H*Me). Anal. ($C_{15}H_{15}N_3S$) C, H, N.

Preparation of 3-Amino-4-(2-(4-fluorobenzyl)methylaminomethylphenylsulfanyl)benzonitrile FBASB (9). To a solution of **8** (0.025 g, 0.092 mmol) and DBU (0.042 mL, 0.278 mmol) in dry acetonitrile (2 mL) was added 4-fluorobenzyl bromide (0.014 mL, 0.111 mmol). The reaction mixture was stirred at room temperature for 12 h under argon. The solvent was removed, and the oily residue was purified using column chromatography and eluting with ethyl acetate/hexane (1:6) to yield colorless oil in 72% yields. Compound **9** was obtained as an HCl salt by treating the oily residue with HCl in ether. Mp 166−170 °C, ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.44 (d, J = 7.8 Hz, 1H, Ar-*H*), 7.30−7.35 (m, 3H, Ar-*H*), 7.12−7.18 (m, 2H, Ar-*H*), 6.92−7.02 (m, 5H, Ar-*H*), 4.61 (bs, 2H, Ar-N*H*$_2$), 3.67 (s, 2H, benzylic *CH*$_2$), 3.56 (s, 2H, benzylic *CH*$_2$), 2.10 (s, 3H, NC*H*$_3$). Anal. for HCl salt. ($C_{22}H_{20}FN_3S\cdot HCl\cdot H_2O$) C, H, N.

Radiochemical Synthesis of [^{18}F]FBASB. The F-18 FBASB was obtained via N-alkylation of 3-amino-4-(2-methylaminomethylphenylsulfanyl)benzonitrile (**8**) using [^{18}F]fluorobenzyl iodide ([^{18}F]FBI) as the intermediate. The alkylating group [^{18}F]-FBI was prepared as previously described (*24*). Briefly, [^{18}F]-FBI was reacted with 3-amino-4-(2-methylaminomethylphenylsulfanyl)benzonitrile in DMF and triethylamine at 106 °C for 10 min followed by HPLC purification using a C-18 column eluted with MeOH: 0.1 M ammonium formate (80:20) to yield the desired product in 36 ± 8% radiochemical yields (EOS) and >99% radiochemical purity. The specific activity of FBASB was 4900 ± 1100 Ci/mmol (n = 7).

***In Vitro* Binding.** Affinity of FBASB to 5-HT transporter sites was determined using cortical membranes from rat brains as described (*25*). The binding affinity was determined from binding of 0.4 nM [^{3}H]paroxetine with 50 mg of the rat cortical membrane. The nonspecific binding was determined from binding of 10 μM fluoxetine to the membrane. Potencies were calculated from displacement curves using 7−10 concentrations of unlabeled compound. The K_i values were calculated using the Cheng−Prusoff (*26*).

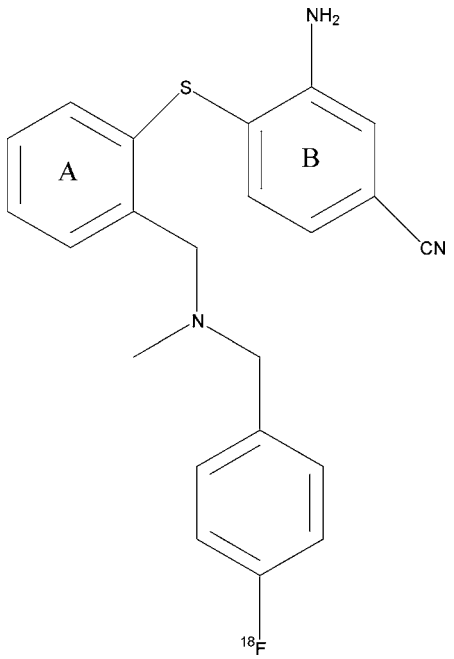
Biodistribution Studies. *In vivo* biodistribution of [^{18}F]-FBASB was performed in normal rats and mice. A group of animals was injected with 20 μCi of [^{18}F]FBASB each via a tail vein injection. At 30, 60, and 120 min postinjection, groups of five animals were killed and the tissue of interest excised, weighed, and counted for radioactivity on a gamma counter. Radioactivity uptake in various tissues was calculated as a percent-injected dose per gram of tissue (%ID/g tissue) by counting the dose standard of appropriate count rate along with the tissues.

RESULTS AND DISCUSSION

In order to synthesize the desired compound **9**, we prepared several intermediate compounds. Another compound of interest for us was compound **3** since this would provide a convenient route to place a variety of radiolabeled prosthetic groups. Compound **4** would provide a convenient single step route to synthesize a wide array of substituted amines. In addition, compound **8** (3-amino-4-(2-methylaminomethylphenylsulfanyl)-benzonitrile) was also of special interest since this compound is widely used as a precursor to serotonin transporter ligand DASB and is commonly known as MASB.

Our first goal was to obtain compound **3**. This would be a common intermediate to obtain several compounds of our interest. The synthetic strategy is shown in Scheme 1. To accomplish this, we started our synthesis with commercially available 2-thiobenzyl alcohol. Copper-catalyzed coupling of thiobenzyl alcohol with 4-chloro-3-nitrobenzonitrile using K_2CO_3 as a base and DMF as a reaction solvent provided product **1** in 86% yields (Scheme 1).

The next step was to reduce the nitro group on the benzonitrile ring (Figure 1, ring B) to the corresponding amine. Wilson et al. reported such reduction by heating a corresponding nitro compound with hydrazine hydrate and ferric chloride in ethanol for 3 days to obtain the desired compound in 49% yield (*23*). In an effort to improve chemical yields and to reduce the overall reaction time, we explored various other reduction methods. We found that a reduction of nitro compound **1** by using tin(II) chloride in HCl and stirring the reaction mixture at room temperature overnight was a simple, fast, and high yielding



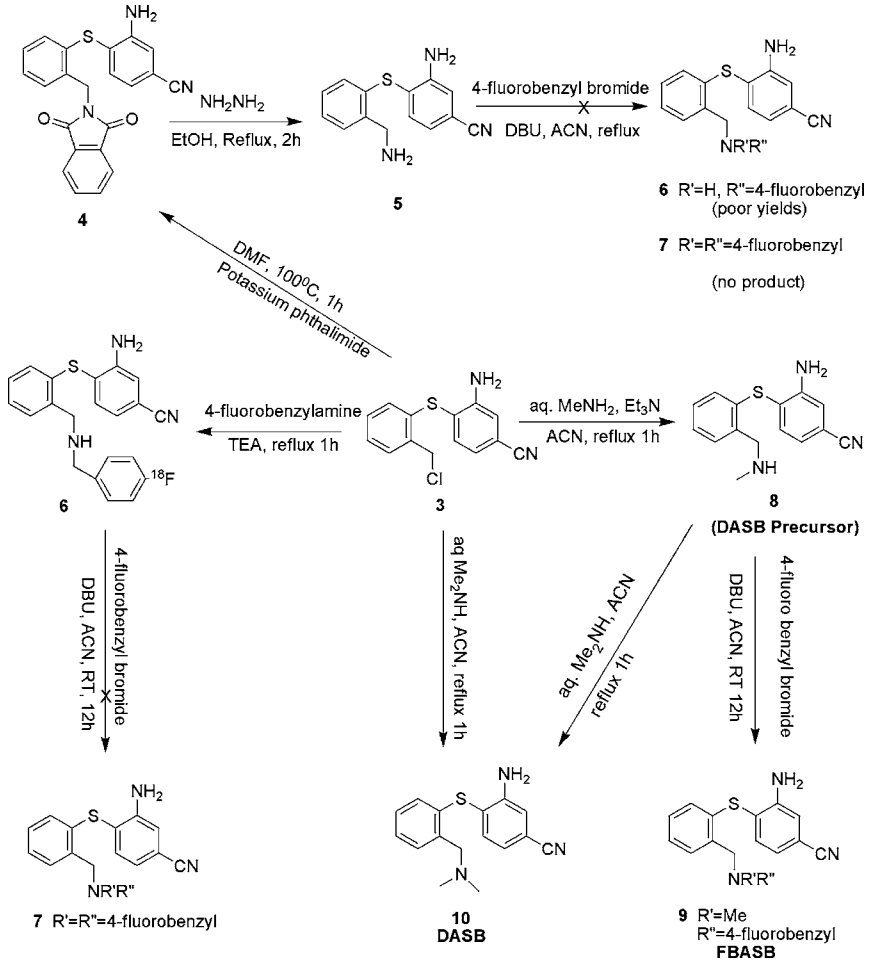


Figure 1. Structure of FBASB. The designation of rings A and B represent the assignments referred to in the discussion section.

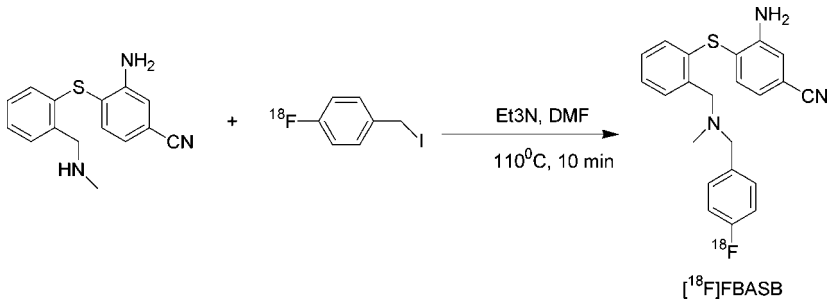
Scheme 2. Synthesis of FBASB, DASB, and Precursor of DASB[a]

[a] This scheme depicts an improved synthesis of precursor to DASB, and FBASB. this scheme highlights the significance of compound **3** as a key intermediate in the synthesis of various dialkylamines. It also shows the utility of compounds **6** and **8** as important intermediates to synthesize a variety of substituted amines.

procedure. Using this procedure, followed by a routine workup of the reaction mixture, we obtained the desired compound **2** in 85% yields. Others have also successfully used tin chloride for facile reduction of the nitro groups while use of hydrazine hydrate resulted in incomplete reduction of nitro compound (*27*). Benzyl alcohol **2** was refluxed with thionyl chloride in toluene to provide corresponding benzyl chloride **3** in 93% yields. Our next goal was to synthesize compound **5** with a methylamine group at 2-position on the phenyl ring A.



A previously reported method (*28*) used coupling of thiosalicylic acid with chlorobenzenes followed by reaction with thionyl chloride to produce acid chloride. Subsequent reaction with ammonia yielded the corresponding amide. Reduction of this amide with BH_3/THF complex delivered the desired benzylamine (*28*). To simplify and improve the reaction conditions and overall scheme, we adopted a different synthetic route. We explored conversion of benzyl chloride to a thalimide intermediate. As shown in Scheme 2, heating benzyl chloride **3** with potassium thalimide at 100 °C in DMF for 1 h gave 76% of thalimide **4** which on refluxing with hydrazine in ethanol for 2 h produced the target compound **5** in 98% yield. For our synthetic scheme, we found the use of thalimide as a free amine synthon to be a rapid, efficient, and high yielding intermediate. Reacting **3** with substituted amines yielded a wide selection of analogues of **5** viz. compounds **6, 8, 9, 10**.

Reaction of compound **5** in acetonitrile with excess *p*-fluorobenzyl bromide and DBU as a base did not yield the expected *N*,*N*-bis(4-fluorobenzyl)amino compound **7**. Instead, a small amount of compound **6** (a monobenzylated derivative) was detected with the majority of the recovered compound as the starting material. Thereafter, we decided to synthesize compound **6** and **7** in a step by step manner using an alternate strategy as depicted in Scheme 2.

Reaction of the benzyl chloride **3** with *p*-fluorobenzyl amine in refluxing acetonitrile using Et_3N as the base provided compound **6** in 90% yields (Scheme 2). Our subsequent efforts to react compound **6** with *p*-fluorobenzyl bromide and DBU or Et_3N as a base in acetonitrile failed to yield compound **7** (Scheme 2). One possible explanation for this failed reaction could be the presence of bulky functionality (i.e. *p*-fluorobenzyl group on benzylic nitrogen) causing steric hindrance that in turn hampered the second *p*-fluorobenzyl group substitution. The other factor responsible for these failed attempts could be due to a highly electronegative fluorine atom (Pauling scale of electronegativity: $F = 4.0$, $H = 2.1$) rendering benzylic nitrogen less basic through negative inductive effect, this in turn preventing benzylation. These factors may have been also responsible for our previous failed attempts in synthesizing compound **7** from compound **5** (Scheme 2), where only a small quantity of compound **6** was obtained instead.

Refluxing compound **3** with 40% aqueous methylamine in acetonitrile for 1 h produced compound **8** in 74% yields. Compound **8** is an important compound since this is used as a precursor to synthesize C-11-labeled DASB. Wilson et al. (*23*) reported synthesizing compound **8** by directly reacting the corresponding benzyl alcohol (compound **2**, Scheme 2) first with thionyl chloride to generate **3** in situ and then reacting it with 40% aqueous methylamine for 24 h at room temperature. The

Scheme 3. Radiochemical Synthesis of [^{18}F]FBASB Using [^{18}F]FBI as a Synthon

yields for the desired product remained modest (37%). We preferred isolating compound **3** and purifying this product before its subsequent reaction with methyl amine. Using this approach, we obtained **8** in higher purity and yields. Despite isolating and purifying benzyl chloride **3** followed by reaction with methylamine, our method remains a convenient and high yielding procedure to synthesize compound **8** (precursor for DASB). Following this procedure, it is simple to perform a large-scale synthesis of DASB precursor.

Compound **9** was obtained in 72% yield by reacting compound **8** with *p*-fluorobenzyl bromide using DBU as a base. Reacting **3** or **8** with aqueous dimethylamine and refluxing in acetonitrile provided compound **10**. Using this strategy, we were able to synthesize compounds **6**, **8**, **9**, and **10** in high overall yields. In addition, we synthesized compound **4** that serves as a useful intermediate to synthesize various substituted amines.

In vitro binding of FBASB, i.e., **9**, to SERT as assessed by rat membrane homogenate was 0.51 ± 0.11 μM. Although the *in vitro* binding of FBASB was significantly lower than that for the DASB (*19*), the *in vitro* binding for the desmethyl analogue of FBASB, i.e., compound **6** was 4.04 ± 0.95 nM, a value several fold higher than the N-methylated analogue **9**. Similarly, binding for the unsubstituted benzylamine **5** was 0.070 ± 0.015 μM, a 7-fold higher binding affinity toward SERT than the substituted analogue **9**. These *in vitro* results further echo earlier findings on compounds with a tropane template that the N-substitution reduces 5HT potency and a reduced 5HT affinity for methylated analogues of compounds with similar motif as ours (*25*). Although demethylation of compound **9** lead to reduced affinity toward SERT, we did not screen this compound against other receptors and transporters.

Radiochemical synthesis of [^{18}F]FBASB was accomplished as shown in Scheme 3. Reaction of [^{18}F]FBI with compound **8** provided [^{18}F]FBASB in 36 ± 8% radiochemical yield (EOS). These radiochemical yields are comparable to other radiotracers routinely synthesized in our laboratory using the [^{18}F]FBI synthon. After HPLC purification, the radiochemical purity of this product was >99%. The total synthesis time to produce [^{18}F]FBASB was ~140 ± 20 min including the reformulation and quality control assays on the final product. The entire synthesis was a remote operated process and required minimal intervention from the production staff.

In our earlier attempts to modify chemical structure of a routinely used dopamine transporter ligand FCT by replacing the chloro group on the phenyl ring with alkyl, despite a high *in vitro* binding affinity of the newer analogue, we observed a complete blockade of brain penetration (*29*). Therefore, for the current study, our interest was to first ascertain if this compound penetrates into the rat brain. The results from the biodistribution studies show 0.34 ± 0.02% of the injected dose in rat brain at 30 min. In comparison, [^{11}C]DASB uptake was 0.89 ± 0.39% and 0.33 ± 0.07% injected dose per gram of brain at 30 and 60 min, respectively (*30*). These results swayed us to investigate if there is any preferential distribution of this ligand between target and nontarget sites within the brain. In addition, we wanted to investigate if this compound exhibits resistance to *in vivo* dehalogenation. Therefore, we performed biodistribution studies in mice to ascertain F-18 distribution in the whole body as well as differential distribution in various brain tissues. The results from these *in vivo* biodistribution studies are shown in Figure 2.

Although the radioactivity accumulation in all organs remained low, the major sites of retention of F-18 at 60 and 120 min were the kidneys, liver, and muscles. Each of these organs showed less than 0.9% of the injected dose per gram of tissue. The F-18 uptake in the next highest uptake organ was the lung with 0.37 ± 0.09% and 0.23 ± 0.08% injected dose per gram of tissue at 60 and 120 min, respectively. F-18 uptake in the muscles was 0.32 ± 0.09% ID/g at 120 min, and muscle remained the tissue with the third highest uptake of radioactivity, perhaps from increased lipophilicity of FBASB due to the fluorobenzyl group in the molecule. Similar to that seen from our rat studies, [^{18}F]FBASB showed resistance to *in vivo* dehalogenation in mice. At 120 min, the F-18 uptake in the bones was 0.14 ± 0.07 %ID/g.

Further studies were performed to assess a differential distribution pattern of F-18 within brain tissues. In these studies, cerebellum was chosen as tissue with nonspecific binding (*30*). As seen from F-18 uptake data, the radioactivity distribution remained quite homogeneous throughout the brain with slightly higher uptake in the thalamus when compared to that for the cerebellum. For example, at 60 min the F-18 uptake in the rat cerebellum was 0.16 ± 0.03 %ID/g as compared to 0.21 ± 0.08, %ID/g in the hypothalamus.

Specific to nonspecific ratio in the mouse brain at 60 min time points is shown in Figure 3. Although, at 60 min, the specific to nonspecific uptake ratio remained higher than 1 for most SERT rich tissue, the amplitude of this ratio was significantly lower than DASB and other related SERT specific compounds. While all tissues show specific to nonspecific ratios better than 1 at 60 min, cerebellum to tissue ratio for the cortex, thalamus, and hypothalamus improved slightly with time.

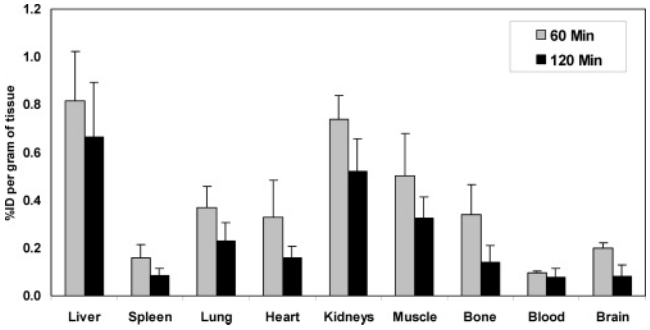


Figure 2. Tissue distribution of F-18 in mice at 60 and 120 min after injecting F-18 FBASB via the tail vein injection. An overall low radioactivity in all normal tissue and further reduction in accumulation at a 2 h time point supports rapid clearance of radiotracer from the body. Low bone uptake at 1 and 2 h further supports its resistance to dehalogenation.

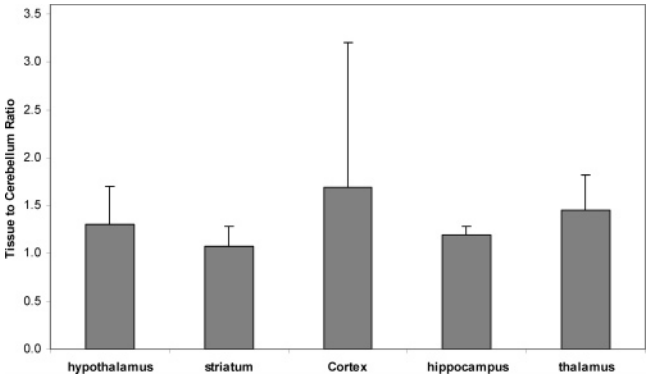

Figure 3. Tissue to cerebellum ratio for the F-18 FBASB at 60 min as derived from F-18 uptake in the mouse brain.

Despite slightly better ratios in SERT specific tissues, the properties of this ligand remained marginal for the imaging application. Nonetheless, *in vivo* results are in agreement with *in vitro* binding affinity results toward the SERT. Owing to its higher *in vitro* affinity, the desmethyl analogue **8** may exhibit better biodistribution properties and selectivity toward SERT than that seen with the [^{18}F]FBASB. It is also likely that the substitution of less bulky prosthetic groups, such as fluoromethyl or fluoroethyl would yield a more promising SERT ligand.

In summary, we synthesized an F-18 analogue of DASB using a simple and facile radiochemical synthesis procedure. Low binding affinity of this compound resulted in low brain uptake along with low selectivity toward SERT rich tissues, resulting in a poor specific to nonspecific uptake ratio.

In conclusion, we herein describe a rapid and high yielding synthesis to prepare a key intermediate precursor necessary to synthesize [^{11}C]DASB. In addition, this paper describes a facile and high yielding synthesis of another key intermediate that could aid in the synthesis of a wide array of compounds with application in PET and SPECT.

ACKNOWLEDGMENT

We thank Jessica Stukes for her assistance with tissue biodistribution studies and the cyclotron staff for providing help with obtaining F-18 radioisotope. We are thankful to Drs. Steve Childers and Li Wu for their help with performing the *in vitro* binding assay. This research was supported in part through a grant from National Institutes of Health (CA105382 to P.K.G.).

Design of a Thermocontrollable Protein Complex

Yoshihiko Fujita, Hisakage Funabashi, Masayasu Mie, and Eiry Kobatake*

Department of Biological Information Graduate School of Bioscience and Biotechnology, Tokyo Institute of Technology, 4259 Nagatsuta-cho, Midori-ku, Yokohama, Kanagawa 226-8501, Japan. Received April 11, 2007; Revised Manuscript Received June 27, 2007

It is widely recognized that stimuli-responsive nanostructures play a promising role in nanodevices for medical treatments and experimental tools. We have designed and constructed a basic structure which controls the distance between two termini domains through temperature reversibility. Our structure, shaped like a bouquet, is composed of two proteins, α-helix and elastin-like protein (ELP). α-Helices align and bundle the ELP while ELP twists and forms a fiber-like structure at warm temperatures. This ELP conformational change alters the distance between the structure termini at the site opposite the α-helix. We connected enhanced yellow fluorescent protein (EYFP) and enhanced cyan fluorescent protein (ECFP) at the structure's two termini to evaluate the distance using fluorescence resonance energy transfer (FRET) efficiency. These proteins spontaneously formed a complex which decreased the distance between the two fluorescent proteins located at its termini, at physiologically relevant temperatures. This change was repeated with complete reversibility ($n = 5$).

INTRODUCTION

External modification of nanomachine function and conformation is essential. In the past, chemically based, simple molecular machines were constructed (*1*−*3*). These machines could change structural conformation in response to an external chemical or physical stimulation with complete reversibility. Natural biomotor molecules also have been discovered (*4*−*6*). However, few artificial biomaterial-based molecular machines have been constructed due to the unpredictable nature of biomaterials.

To create these biomaterial-based machines, one approach was to position a new stimuli-responsive tag on existing biomaterials (*7*, *8*). The characteristics of these biomaterials are constantly controlled by external chemical or physical stimulation. Modification of the existing natural biomolecule, by exploiting its original conformation and function, can create highly functional machines. However, the degree of design freedom is limited, as this approach highly depends on the original biomolecule conformation. An alternate approach is to design biomaterial building blocks that form biomachines using a bottom-up strategy. Many structures composed of nucleic acids (*9*) or peptides (*10*, *11*) have been constructed using this technique; however, few can be controlled by external stimulation.

A temperature-responsive protein complex we designed in this article contains artificial α-helices and ELP. Three artificial α-helices, A, B, and C (*12*, *13*) (we call them helixA, helixB, and helixC, respectively, in this paper), served as self-assembly domains along with ELP, since they are small and assemble into a highly stable heterotrimer coiled coil up to approximately 80 °C. The amino acids sequence $(GVGVP)_n$, which is one of the ELPs derived from the hydrophobic region of elastin (*14*, *15*), shrinks under warm conditions to form fibril structures (*16*) and aggregations called coacervation. Since its conformational change is well-characterized and completely reversible with temperature change, we adopted $(GVGVP)_n$ as the temperature-responsive domain. A model of the structure at high temperature is proposed as a β-spiral structure composed of three twisted $(GVGVP)_n$ (*17*). On the basis of this model, we expected that, when the opposite sites were bundled, the two domains fused to $(GVGVP)_n$ individually could be approximated at high temperature. Then, we constructed helixA−$(GVGVP)_n$, helixB−$(GVGVP)_n$, and helixC−$(GVGVP)_n$ recombinant proteins, which contain the α-helix in order to align the termini of the $(GVGVP)_n$. These proteins were expected to spontaneously form a trimer, aligning the termini by α-helices, bringing the opposite termini together at high temperatures and subsequently releasing them at low temperatures. In this study, we fused ECFP and EYFP to the helixA−$(GVGVP)_n$ and helixB−$(GVGVP)_n$, respectively, and were able to control the distance between the ECFP and EYFP (Figure 1). This study demonstrates future possibilities of this structure becoming a thermoresponsive part for complete biomaterial-based machines which can be expressed and assembled in cells.

EXPERIMENTAL PROCEDURES

Plasmid Construction. The ELP, helixA, helixB, and helixC genes were obtained by elongating partially hybridized two DNA oligonucleotides. About 20 bases at the 3′ end of one oligonucleotide were hybridized with a region at the 5′ end of another oligonucleotide, followed by a polymerase reaction. Enhanced cyan fluorescent protein (ECFP) and enhanced yellow fluorescent protein (EYFP) genes were amplified by PCR, from pECFP-N1 (BD Biosciences, Clontech) and pEYFP-actin (BD Biosciences, Clontech), respectively. All the genes were cloned on pBluescriptII SK (+) (Stratagene) and then sequenced (Beckman; CEQ2000XL). ELP tandem repeats (×18, 36, and 72) were constructed by recursive directional ligation (*18*) between *Bam*HI and *Bgl*II sites. The expression plasmids for the helices (helixA, helixB, and helixC) and fluorescent proteins (ECFP and EYFP) were constructed by ligating the cloned coding DNA fragments with a modified pET28b (Novagen) vector and digested with *Nco*I and *Xho*I or *Bam*HI and *Bgl*II, respectively. The expression plasmids for helixA−$(GVGVP)_n$−ECFP, helixB−$(GVGVP)_n$−EYFP, helixC−$(GVGVP)_n$, $(GVGVP)_n$−ECFP, and $(GVGVP)_n$−EYFP fusion proteins were constructed by inserting each cloned gene fragment into the modified pET28b in the order described.

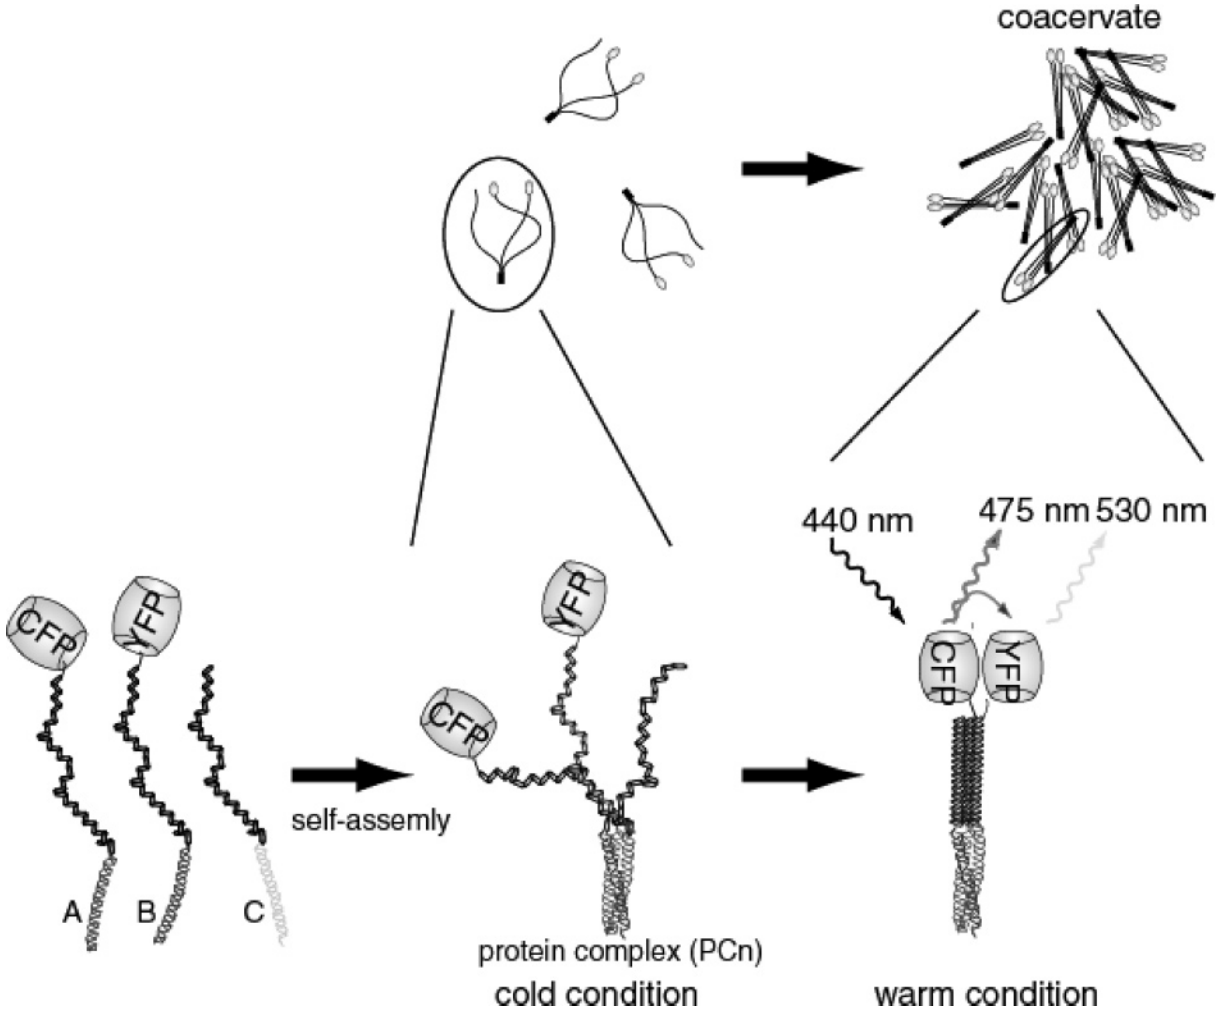

Figure 1. Schematic diagram of PC_n. Upper illustration indicates a macroscopic view; lower is a microscopic view. The helix parts assemble independently and form a protein complex (PC_n). Under cold conditions, the fluorescent proteins at the termini of $(GVGVP)_n$ reside away from each other due to the relaxed nature of the $(GVGVP)_n$ components. As the temperature increases and the $(GVGVP)_n$ components stabilize, the two fluorescent proteins come close together. The distance between them then decreases due to its inverse temperature transition.

Protein Expression and Purification. The expression vectors were transformed into the *E. coli* strain BL21(DE3). LB medium, supplemented with 20 μg/mL kanamycin, was inoculated with transformed cells from confluent precultures and incubated with shaking at 37 °C. When the OD660 reached between 0.5 and 0.6, expression was induced by adding IPTG, reaching a final concentration of 1 mM. The cells containing pET28b-helixA, pET28b-helixB, pET28b-helixC, pET28b-ECFP, pET28b-EYFP, pET28b-helixA-$(GVGVP)_n$-ECFP, pET28b-helixB-$(GVGVP)_n$-EYFP, or pET28b-helixC-$(GVGVP)_n$ were harvested after induction for 16 h at 16 °C, and centrifuged at 2000 *g* for 3 min at 4 °C. The cells with pET28b-$(GVGVP)_n$-ECFP, and pET28b-$(GVGVP)_n$-EYFP were harvested after induction for 6 h at 30 °C. Next, the pellets were lysed by 1×BugBuster (Novagen) including benzonase nuclease (Novagen), and the cell lysates were centrifuged at 16 000 *g*, for 15 min at 4 °C, to remove insoluble cellular debris. The proteins with $(GVGVP)_n$ ($n \geq 36$) were purified using the modified method of inverse transition cycling (*19*) and then dissolved in PBS. Other proteins were purified according to the standard metal affinity chromatography protocol of His-Select Nickel Affinity Gel (Sigma) and dialyzed with PBS using a Slide-A-Lyzer Dialysis Cassette (Pierce). The purified protein concentrations were determined using the BCA Protein Assay Kit (Pierce) and then stored at −80 °C. The purified proteins are listed in Figure 2.

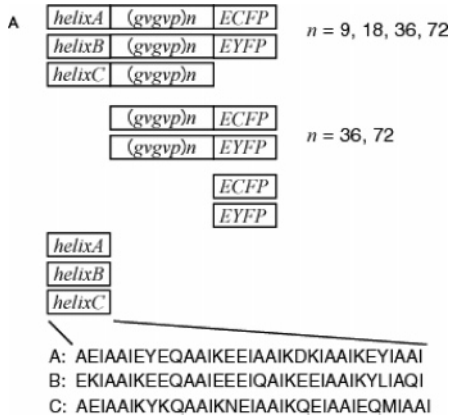

Figure 2. Constructed proteins. helixA, helixB, and helixC are the artificial helices. The repetitive number of the GVGVP (*n*) was indicated at the right. Proteins are fused with polyhistidine tag. The amino acids sequences are indicated at the bottom.

Protein Complex Preparation. A protein complex with various lengths of $(GVGVP)_n$ was prepared by incubating a mixture containing equal amounts of helixA−$(GVGVP)_n$−ECFP, helixB−$(GVGVP)_n$−EYFP, and helixC−$(GVGVP)_n$ in PBS for 30 min at 4 °C. Mixtures of fluorescent proteins (ECFP and EYFP) only, without helixA and helixB ($(GVGVP)_n$−ECFP, $(GVGVP)_n$−EYFP, and helixC−$(GVGVP)_n$), were also prepared as above and served as negative controls. The protein

complex consisting of helixA−$(GVGVP)_n$−ECFP, helixB−$(GVGVP)_n$−EYFP, and helixC−$(GVGVP)_n$ is named PC_n (*n* indicates the number of the repeated GVGVP peptapeptide) in this article.

Estimation of FRET Efficiency. The PC_{72} was prepared in 700 μL of PBS and incubated at 4 °C for 20 min. The fluorescent spectra excitation under cold conditions was measured at 425 nm excitation immediately after transfer to the spectrofluorometer (Jasco, FP-777). The sample was heated with a dryer and immediately measured in the same manner to obtain the fluorescent spectra under warm conditions. The spectra measurements were then normalized by dividing intensity from 450 to 600 nm by that at 475 nm.

To estimate fluorescence resonance energy transfer (FRET) efficiency, the fluorescence of the purified protein was determined using the CYTOFLUOR Multi-Well Plate Reader series 4000 (PerSeptive Biosystems). The PC_n solutions were prepared directly on a 96-well ELISA plate (Sumilon) in 200 μL of PBS and gently vortexed. After a 20 min incubation at each preset temperature, the fluorescent signal was obtained using 440/40 nm, 485/20 nm, and 530/10 nm filters for excitation, ECFP emission, and EYFP emission, respectively. At each temperature, FRET efficiency was defined as the fluorescent intensity ratio $I(530 \pm 10\ nm)/I(485 \pm 20\ nm)$. Sequential measurements of the same sample were taken at low through to high temperatures.

To test temperature reversibility, protein complexes were prepared as described above. The fluorescent signals were obtained first at 37 °C, followed by at 4 °C sequentially. This measurement was repeated five times on the same sample.

Protein Complex Coacervation. The inverse phase transition temperature was determined by monitoring absorbance to quantify the turbidity of the solution as a function of temperature at 350 nm, using a UV−visible spectrophotometer DU-7500 (Beckman) equipped with a multicell thermal controller. The protein solutions were heated 1 °C every minute, from 25 °C to 55 °C. Turbidity was calculated by subtracting the absorbance at 25 °C from each absorbance reading. The inverse phase transition temperature was defined as the temperature where the liquid absorbance is midway between the two parallel lines, tangent to the slope of the data at the beginning and end of the analysis.

Complex Disruption Test. Protein self-assembly was inhibited by blocking the helix region in the components (helixA−$(GVGVP)_n$−ECFP, helixB−$(GVGVP)_n$−EYFP, and helixC−$(GVGVP)_n$) of the PC_n using the respective counterpart helices, i.e., helixA and helixB for helixC−$(GVGVP)_n$, helixB and helixC for helixA−$(GVGVP)_n$−ECFP, and helixC and helixA for helixB−$(GVGVP)_n$−EYFP. Aliquots of components (0.4 μM) with counterparts, whose concentrations were 0.1, 0.2, 0.4, 0.8, or 1.6 μM, were prepared and incubated for 1 h at room temperature in order to block the helix regions. Next, the blocked components were mixed in 200 μL of PBS to obtain the solutions containing 0.1 μM of each blocked component. The final concentrations of the α-helix counterparts in prepared samples were 0.075, 0.15, 0.3, 0.6, and 1.2 μM.

RESULTS AND DISCUSSION

Temperature Control of the Distance between Proteins. First, we investigated the change in distance between ECFP and EYFP at various temperatures by measuring the fluorescent spectra of assembled PC_{72} (Figure 3A), which consists of helixA−$(GVGVP)_{72}$−ECFP, helixB−$(GVGVP)_{72}$−EYFP, and helixC−$(GVGVP)_{72}$ as described in the Experimental Section. At low temperatures (approximately 4 °C), the fluorescent light derived from EYFP was undetected. In contrast, at high temperatures, a remarkable peak occurred around 530 nm, suggesting that FRET from ECFP to EYFP had occurred. These

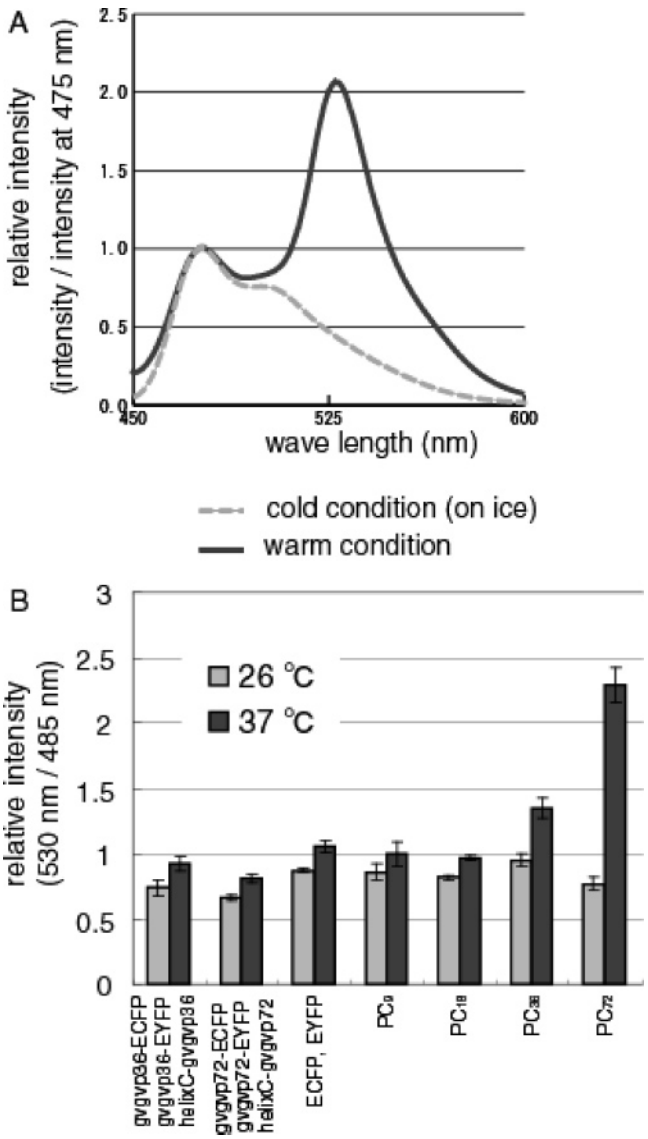

Figure 3. (A) The normalized fluorescent spectra of PCs (helixA-$(GVGVP)_{72}$-ECFP, helixB-$GVGVP)_{72}$-EYFP, and helixC-$(GVGVP)_{72}$) under cold conditions (broken line) and warm conditions (solid line). (B) Complex FRET efficiencies at various lengths of (GVGVP), at 26 °C (open bar) and 37 °C (filled bar). The fluorescence data are the mean ± SD from four separate samples.

results indicate that the two fluorescent proteins came close at the warm temperature, as illustrated in Figure 1. The shapes of the relative fluorescent intensity did not change significantly except for the intensity at 530 nm which was emission maxima of EYFP, at low or high temperatures. That is, the FRET signal can be detected even if the light scattering of coacervation might affect the emission light from the fluorescent proteins.

To optimize fluorescent protein approximation by temperature, the FRET efficiencies of PC_n having various lengths of $(GVGVP)_n$ with or without the helix were tested (Figure 3B). The PC_n's ($n = 9, 18$), which have a short $(GVGVP)n$, caused only a slight increase in FRET efficiency at 37 °C, and reached control levels. This slight increasing in FRET efficiency is due to the inactivation of the ECFP by temperature. The apparent FRET efficiency increased because both ECFP and EYFP indicated the thermal inactivation with heating, but the intensity of ECFP more rapidly decreased over that of EYFP. In contrast, an obvious FRET signal was detected in the PC_n ($n = 36, 72$) samples. This is not a false FRET signal due to the decrease of ECFP fluorescence light depending on the inactivation of the ECFP by temperature, because the control, which is a mixture

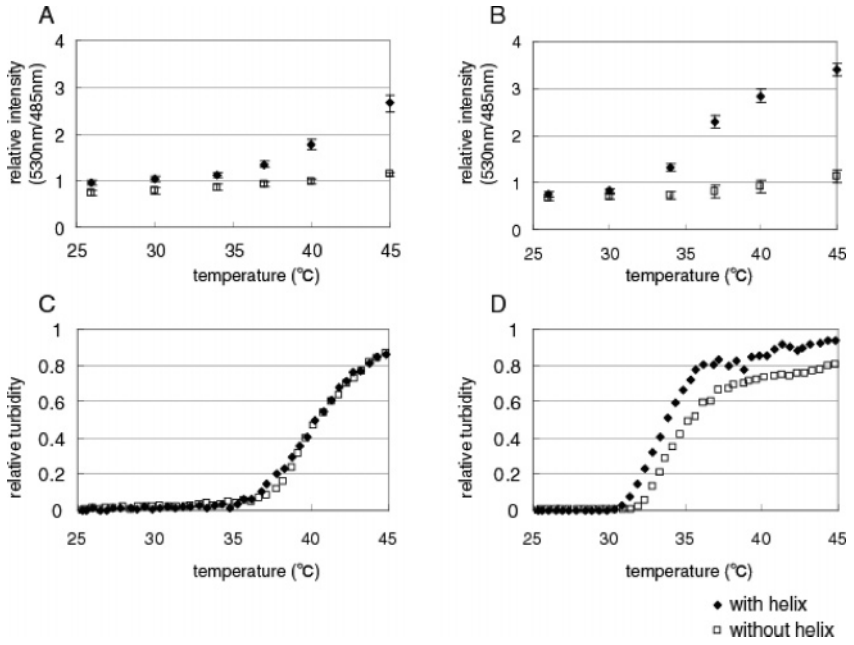

Figure 4. The FRET and turbidity profiles of the PC_{36} or PC_{72} with (filled diamond) or without (open square) helixA and helixB regions. (A) FRET profiles under the same conditions as (C). (B) FRET profiles under the same conditions as (D). The fluorescence data are the mean ± SD from four separate samples. (C) Turbidimetric profiles of the PBS solutions containing 0.1 μM PC_{36} with or without helixA and helixB regions. (D) Similar data as (C) but in a PC_{72} solution.

of ECFP and EYFP, did not cause an obvious increase of the signal. The effect of thermal inactivation of fluorescent proteins on the FRET signal may exist, but only slightly. In addition, FRET efficiency of the PC_{72} was higher than PC_{36}. This result suggests that long $(GVGVP)_n$s twist and form more stable fiber structures at 37 °C than shorter sequences. This coincides with research on the relationship between coacervation transition temperature and length of $(GVGVP)_n$ (*20*).

Comparison of FRET with Turbidity Profiles. When coacervation occurs, FRET increases derived from intercomplex proximity must be taken into account. To determine whether the increase of FRET is due to the intercomplex proximity by coacervation or intracomplex proximity due to a protein complex conformational change, we compared FRET and the turbidity of solutions containing 0.1 μM of helixA−$(GVGVP)_n$−ECFP, helixB−$(GVGVP)_n$−EYFP, and helixC−$(GVGVP)_n$ (PC_n, n = 36 or 72) with solutions containing 0.1 μM of $(GVGVP)_n$−ECFP, $(GVGVP)_n$−EYFP, and helixC−$(GVGVP)_n$ (nonhelix-PC_n, n = 36 or 72). The former protein group contains the α-helix region that self-assembles, while the $(GVGVP)_n$−ECFP and $(GVGVP)_n$−EYFP in the latter group do not contain these helices.

Improvements in FRET efficiency have been detected in PC_n solutions, while no changes have been detected in non-helix-PC_n (Figure 4A,B). Although differences in FRET efficiency have been observed in solutions with or without helixA and helixB, only small differences in the turbidimetric profiles have been detected (Figure 4C,D). The FRET derived from intercomplex proximity by the coacervation was expected to be dependent on the turbidity regardless of the helices. Thus, these results suggest that increases in FRET efficiency were derived from intracomplex proximity, since increased FRET efficiency was not detected in the samples without an α-helix that formed coacervates. The fact that FRET efficiency of PC_{72} with helixA and helixB increased throughout the higher temperature (>35 °C), despite the turbidity, increased a little supports the hypothesis. Presumably, the FRET efficiency is mainly dependent on the stability of the microscopic structure formed by $(GVGVP)_n$. It is notable that the temperature at which the FRET signal rises shifts to lower when the longer $(GVGVP)_n$ is used. This indicates that the distance between ECFP and EYFP can be controlled at various temperatures by changing the length of (GVGVP).

The small difference between the turbidity profiles of PC_{72} with or without helixA and helixB was speculated as follows. ELP molecules including GVGVP need three steps before coacervation (*21*). First, ELP changes from random structure into a β-turn-like structure. Second, ELPs associate with each other and form a microscopic structure which includes just a few ELP molecules. Third, the microscopic structures assemble into macroscopic aggregation. They suggest that the process from step 1 to step 2 is stoichiometric; that is, this process is dependent on the concentration of ELP. In the case of a protein complex with helixA and helixB, the microscopic concentration of $(GVGVP)_n$ was high because a helix put one $(GVGVP)_n$ close to other $(GVGVP)_n$'s conjugated with counterpart helices. This proximity effect promoted the process from step 1 to step 2 of $(GVGVP)_{72}$. Consequently, the temperature of the coacervation decreased, and intensity increased more rapidly. On the other hand, the microscopic structure of $(GVGVP)_{36}$ is less stable than that of $(GVGVP)_{72}$ because the free energy difference between the monomeric state and the associated state is dependent on the length of ELP (longer ELP indicates larger free energy difference). Thus, even if the microscopic concentration increases by proximity effect, $(GVGVP)_{36}$ could form fewer microscopic structures than $(GVGVP)_{72}$, and we could not detect the small change as turbidity.

Complex Disruption by Counterparts. To confirm whether the FRET signal disappeared when the complex was inhibited, the α-helix region in the PC_{72} was blocked by monomer α-helice binding. FRET efficiencies of the mixed solutions containing the components of PC_{72} and α-helices decreased with increasing concentrations of α-helices at 37 °C (Figure 5).

FRET efficiency attenuation at low counterpart concentrations (0−0.1 μM) was greater than high concentrations (>0.2 μM). This nonlinear inhibition can be explained through interactions between the counterpart helices. Counterpart helices' binding to the helix regions of the PC_n components was nearly complete

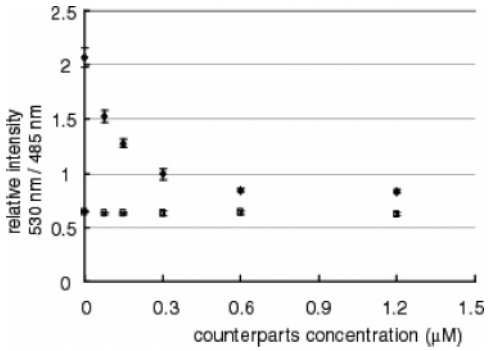

Figure 5. FRET efficiencies of the PC_{72} containing various concentrations of the counterpart α-helices. FRET efficiencies at 37 °C (filled diamond) and 4 °C (open square) as indicated, where each component of the PC_{72} was 0.1 μM.

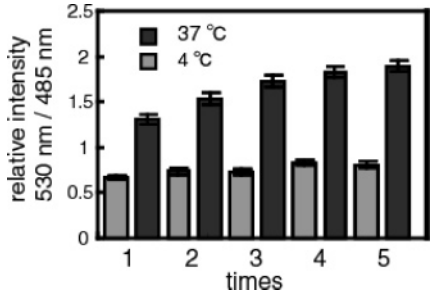

Figure 6. Reversibility of 0.1 μM of PC_{72}. FRET efficiencies of PC_{72} were sequentially measured at 4 °C (open bar) and 37 °C (filled bar) five times.

at low concentrations. In contrast, when there were many counterpart helices, they bound with other monomeric helices and formed stable complexes which were not capable of blocking the components. Thus the exceeded helices could not block the components efficiently. This inhibition indicates that domain proximity at the PC_n termini requires helices that permit individual protein bundling.

Reversibility Test. To control PC_n termini domain function, conformational reversibility is necessary. Therefore, we repeatedly measured FRET efficiencies, alternating between 4 °C and 37 °C as illustrated in Figure 6. FRET efficiency increased at 37 °C and decreased at 4 °C in all cycles. Even after four cooling and warming cycles, FRET efficiency consistently decreased at 4 °C. This result suggests that changing temperature could control the distance between the domains positioned at the PC_{72} termini in a reversible manner. An upward trend in the FRET efficiency is explained by two possibilities. The first is the difference between thermal inactivation rates of ECFP and EYFP described above. The second is the incorrect homocomplex of helices. Some protein complexes might contain only ECFP or EYFP, such as a complex containing helixA−$(GVGVP)_n$−ECFP, helixA−$(GVGVP)_n$−ECFP, and helixC−$(GVGVP)_n$, at the start condition, because the same helix can form a homodimer or trimer coiled coil (*12*, *13*). During thermal cycling, these incorrect complexes were substituted to assemble correct heterotrimer complexes. Thus, the upward trend of the FRET efficiency should have been observed.

CONCLUSION

Our designed recombinant proteins, helix-$(GVGVP)_n$, spontaneously formed a trimeric complex. The FRET signal from EYFP indicated that its temperature-induced conformational change promoted ECFP and EYFP proximity. Moreover, this conformational change was reversible. This complex, although composed of amino acids, behaved much like a machine. Thus, this complex has the potential to function as basic components in the construction of future biomaterial-based machines. In this study, fluorescent proteins modeled the functional domain. Alternate proteins could be used in their place, which are activated by multimerizaton or complementation. Thus, we have the ability to control multimeric proteins as typified by DNA binding proteins or split enzymes by altering the external temperature.

A problem of the undesirable coacervation between complexes must be solved to use it in liquid because the steric hindrance is expected. This problem may be overcome by modifying the $(GVGVP)_n$ or fixing complexes on a solid structure, such as a cell membrane. Although a simple heterotrimer coiled coil was used in this paper in order to distinguish between ECFP and EYFP, and indicate whether proximity occurs or not, we can replace them with not only multimeric helices but also transmembrane helices (*22*). We also have to consider undesirable effects on cells when this thermal control is applied to cells. It is impossible to completely remove the effects on cells in principle as long as the thermal control is used; the effects, however, will reduce when the activity-controllable temperature is set around 37 °C by an appropriate length of $(GVGVP)_n$. Therefore, this approach has an advantage in the situation where the effects on cells are well-known or simplicity, speed, or reversibility is required.

Our adjustable protein complexes can be expressed and formed in cells, since they are composed of amino acids. Once the plasmids coding this protein complex were introduced into cells, the additional harmful injection is unnecessary every time we would like to activate the interest function. Therefore, this proposed method may control cellular function without causing additional damage.

A Robust and Convergent Synthesis of Dipeptide−DOTAM Conjugates as Chelators for Lanthanide Ions: New PARACEST MRI Agents

Filip Wojciechowski,[†] Mojmir Suchy,[†,‡] Alex X. Li,[‡] Hassan A. Azab,[§] Robert Bartha,[‡] and Robert H. E. Hudson*[,†]

Department of Chemistry, The University of Western Ontario, London, Ontario, Canada N6A 5B7. Received April 16, 2007; Revised Manuscript Received July 11, 2007

A generally applicable synthetic approach to dipeptide−DOTAM conjugates has been developed which is based on the peralkylation of 1,4,7,10-tetraazacyclododecane (cyclen) with protected *N*-iodoacetyl dipeptides. Standardized procedures were used for the alkylation, metalation, and purification of the resultant lanthanide complexes. Using this approach, we have been able to rapidly and reliably prepare and screen five different ligands each with up to six lanthanide ions. This preliminary investigation has identified several paramagnetic compounds with strong chemical exchange saturation transfer (PARACEST) properties in water at physiological temperature and pH. Extension of the synthetic approach to a wide variety of amino acids is possible.

INTRODUCTION

Over the course of the past decade, there have been dramatic developments in the use of chelated lanthanide metals as contrast agents in magnetic resonance imaging (MRI). The recognition that chemical exchange saturation transfer (CEST) via proton exchange (*1*) could be exploited for generating MR contrast has led to new ligand designs. Subsequently, it has been shown that paramagnetic lanthanide ions induced a large hyperfine shift of the bound water protons and exchangeable protons in the ligand framework, and that MR signal modulation could be generated if the exchange rate of the spins with bulk water was slow (*2*). Selective saturation of these exchangeable spins led to a new method of generating MRI contrast now referred to as PARACEST: paramagnetic chemical exchange saturation transfer (*2*). The PARACEST effect has been exploited to image or otherwise detect biologically important metabolites, such as glucose (*3*) and lactate (*4*), and to measure physiologic parameters such as temperature (*5*) and pH by a ratiometric method (*6*, *7*). A further advantage of employing the PARACEST effect is that one ligand may be endowed with different magnetic properties by the use of different lanthanide(III) ions (*7*, *8*).

The syntheses of tetra-substituted 1,4,7,10-tetraazacyclododecanes (cyclens) has been well-documented in the literature. The reaction of the cyclic polyamine with electrophiles is the most common route for the synthesis of tetra-substituted cyclen. Even so, there exists little by way of standard procedures for enabling systematic variation of the periphery of a derivatized cyclen. It has been established previously that the tetraamide derivatives of cyclen are an important structural feature for the slow exchange of bound water with bulk water in the sample and also provide a pool of exchangeable protons in the ligand (*6*, *7*, *9*−*11*). Therefore, a straightforward and reliable synthetic route to a variety of peptide-decorated cyclens may produce interesting ligands with potential to be used as PARACEST MRI agents. The compounds described herein are structurally related to the lanthanide chelators 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) and 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetamide (DOTAM) (*12*), as shown in Figure 1.

To access peptide-decorated cyclens, there are two obvious routes to consider: the coupling of appropriately protected amino acids to DOTA, which has been reported to give a low yield (*13*), or the alkylation of cyclen with N-terminal haloacetyl amino acids, which can proceed in very good yields (*14*−*18*). The latter approach is shown herein to provide a robust and flexible route to a diverse selection of dipeptide-conjugated DOTAM derivatives (Scheme 1).

In this synthetic scheme, the DOTAM−ligand framework is preserved while the nature of the periphery is readily varied. This approach has proven to be very efficient and convenient, permitting the synthesis of ligands possessing neutral (N-Gly-Phe-C), basic (N-Gly-Lys-C), and acidic (N-Asp-Glu-C) amino acids with minimal protecting group manipulations. We also describe a convenient and reproducible size-exclusion purification method for the isolation of metalated compounds. The MR behavior of the metalated ligands has been determined. It is shown that Eu^{3+}-DOTAM-(Gly-Phe)$_4$ possesses a large CEST effect at physiological temperature and pH while Nd^{3+}-DOTAM-(Gly-Lys)$_4$ and Yb^{3+}-DOTAM-(Gly-Lys-OMe)$_4$ possess CEST effect associated with amide protons.

EXPERIMENTAL SECTION

General Experimental Procedures. All amino acids (naturally occurring L-isomers) and reagents were commercially available, unless otherwise stated. All solvents were HPLC grade and used as such, except for CH_2Cl_2 and THF (dried over Al_2O_3, in a solvent purification system) and water (18.2 MΩ/cm). Organic extracts were dried with Na_2SO_4, and solvents were removed under reduced pressure by rotary evaporation. Flash column chromatography (FCC) was carried out using silica gel, mesh size 230−400 Å. Size exclusion chromatography (SEC) was carried out on Bio-Gel P2, 45−90 μm mesh resin (20 g, column size 15 × 2 cm per 0.1 mmol of compound). Ten fractions (10 mL each) were collected. Fractions were identified by 5% solution of ninhydrin in AcOH/EtOH (tetraacetyl-Gly-Lys-OH and Gly-Lys-OMe cyclen derivatives); by I_2 vapors (tetraacetyl-Asp-Glu-OH derivatives); or by UV/I_2 vapors (tetraacetyl-Gly-Phe-OH and Asp-Phe-OH derivatives). Scheme 1. Retrosynthetic Analysis of Lanthanide(III) Complexes of Cyclen−Oligopeptide Conjugates

lation of the ligands was confirmed by inspection of the ^1H NMR spectra (Supporting Information), MS (ESI-TOF) spectrograph, or by HPLC analysis of the reaction mixture and fractionated products. Effective separation of the metalated ligand from free metal by SEC was confirmed by MS (ESI-TOF) analysis of the fractions. Thin layer chromatography (TLC) was carried out on Al-backed silica gel plates; compounds were visualized by UV light or I_2 vapors. Melting points were obtained on a Fisher−Johns apparatus and are uncorrected. Specific rotations $[\alpha]_D$ were determined at ambient temperature using a 5 mL, 10 cm path length cell; the units are 10^{-1} deg cm^2 g^{-1} and the concentrations are reported in g/100 mL. NMR spectra of the synthetic intermediates were recorded on 400 MHz spectrometer for ^1H; δ values were referenced as follows: $CDCl_3$ (7.23 ppm); DMSO-d_6 (2.49 ppm); D_2O (4.75 ppm) for ^{13}C (125 MHz) $CDCl_3$ (77.0 ppm); DMSO-d_6 (39.5 ppm). Chemical exchange saturation transfer (CEST) spectra were acquired on a 400 MHz (9.4 T) Varian INOVA AS400 spectrometer. The CEST effect was measured by recording the bulk water signal intensity as function of presaturation frequency. The basic pulse sequence consisted of a 10 s presaturation pulse (B_1 = 14 μT) followed by a hard (13.8 μs) 90° pulse and a 3 s data acquisition (receiver bandwidth = 6400 Hz, repetition time = 13 s). All CEST spectra were recorded at a ligand concentration of 10 mM in a NaH_2PO_4 (10 mM), pH 7.0, buffer at near-physiologic temperature (37 or 38 °C). Mass spectra (MS) were obtained using electron impact (EI) and electrospray (ES) for ionization. Peptide sequences are denoted in the conventional way from left-to-right, N-to-C terminus.

Synthesis. *N-Chloroacetylglycine (**1a**).* Glycine (30 g, 0.4 mol) was dissolved in 2.5 N NaOH (400 mL, 1.0 mol), and diethyl ether (200 mL) was added. The mixture was cooled (0 °C), and the solution of chloroacetyl chloride (32 mL, 0.4 mol) in 150 mL of ether was added dropwise over 30 min. The mixture was stirred for 45 min at 0 °C, then allowed to gradually warm up to rt while stirring for further 2 h. The organic layer was separated, and the aqueous layer was extracted with Et_2O (100 mL). The aqueous layer was acidified (pH 2) and extracted with EtOAc (4 × 250 mL). The combined ethyl acetate extracts were washed with 100 mL of brine, dried, and concentrated to afford a colorless oil. Hexanes (200 mL) were added to the obtained oil, and the solvent was removed to give a white solid. The crude product was recrystallized from EtOAc to give the title compound in 43% yield. mp 105−106 °C. ^1H NMR (DMSO-d_6) δ 12.68 (br s, 1H); 8.51 (t, J = 5.0 Hz, 1H); 4.13 (s, 2H); 3.79 (d, J = 5.9 Hz, 2H).

*O-Chloroacetyl-N-hydroxysuccinimide (**5**).* DCC (15.5 g, 75.0 mmol) was dissolved in a minimum amount of THF and added dropwise to a solution (cooled to 0 °C) of NHS (8.7 g, 75.0 mmol) and chloroacetic acid (7.1 g, 75.0 mmol) in THF (200 mL). The reaction was stirred for 5 h at 0 °C, the precipitate (*N*,*N*′-dicyclohexylurea) was filtered off, and the filtrand was washed with 50 mL of THF. Hexanes (50 mL) were added and the filtrate was set aside for 12 h at 5 °C. Additional amounts of *N*,*N*′-dicyclohexylurea were filtered off, and the filtrate was concentrated in vacuo. The product was triturated with 100 mL of hexanes, set aside at 5 °C for 2 h, and the product collected by filtration. White solid, 11.9 g (83%); mp 109−110 °C (lit. 120 °C (*19*)). ^1H NMR ($CDCl_3$) δ 4.36 (s, 2H); 2.86 (s, 4H).

*Aspartic Acid β-Methyl Ester Hydrochloride (**4**).* Methanol (MeOH, 100 mL) was placed in a round-bottom flask (**I**) and cooled to 0 °C. Acetyl chloride (AcCl, 33.4 g, 0.42 mol) was added dropwise over a period of 30 min (caution: the reaction is exothermic and dropwise addition is necessary), and the mixture was stirred for a further 30 min at 0 °C. A solution of aspartic acid (40.0 g, 0.3 mol) in MeOH (100 mL) in a separate round-bottom flask (II) was cooled to 0 °C, and the cold (0 °C) methanolic HCl generated in the flask I was added to the flask II. After 3 h at 0 °C, the ice bath was removed and stirring continued for a further 8 h at rt. The reaction mixture was concentrated to approximately $^1/_3$ of its original volume (bath temperature not exceeding 25 °C). Diethyl ether (Et_2O, 500 mL)

was added and the solution was set aside for 12 h at 0 °C. The white precipitate was filtered off to give 47.7 g (87%) of methyl ester **4**, mp 190−193 °C (lit. 191−193 °C (*20*)). ^{1}H NMR (D_2O) δ 4.30 (t, J = 5.5 Hz, 1H); 3.67 (s, 3H); 3.05 (m, 2H).

*N-Chloroacetyl-Asp(OMe)-OH (**1b**).* Aspartic acid β-methyl ester (**4**) (10.9 g, 50 mmol) was dissolved in dioxane/H_2O (1:1, 250 mL), and the solution was cooled to 0 °C. Na_2CO_3 (5.3 g, 50 mmol) was added to the solution, followed by stirring (at 0 °C) for 30 min. Another portion of Na_2CO_3 (5.3 g, 50 mmol) was added, followed by portionwise addition of *O*-chloroacetyl-*N*-hydroxysuccinimide (**5**) (9.58 g, 50 mmol). The mixture was stirred for 2 h at 0 °C, and for 12 h at rt. Organic impurities were removed by extraction with EtOAc (200 mL); the aqueous phase was acidified (pH 2) with HCl (36%) and was extracted with EtOAc (4 × 100 mL). The combined organic extracts (obtained after adjusting the pH to 2) were dried and concentrated to afford a colorless oil (9.10 g, 81%); the product was partially contaminated with NHS (approximately 15 mol %). ^{1}H NMR ($CDCl_3$) δ 10.48 (br s, 1H); 7.68 (br d, J = 7.5 Hz, 1H); 4.87 (m, 1H); 4.10 (m, 1H); 3.71 (s, 3H); 3.10 (dd, J = 17.5 Hz, 3.5 Hz, 1H); 2.89 (dd, J = 17.5 Hz, 3.5 Hz, 1H); 2.74 (s, 1H). ^{13}C NMR 173.0, 172.8, 171.4, 167.1, 52.2, 48.7, 42.1, 35.4, 25.3. HRMS (EI) *m/z*: found 224.0321, calcd 224.0278 for $C_7H_{11}ClNO_5$ $[M + H]^+$. LRMS (EI) *m/z* (rel abundance): 224 $[M + H^+]$ (100), 192 (9), 178 (10), 116 (48).

*Coupling of N-Chloroacetylglycine (**1a**) with H-Phe-OEt·HCl and H-Lys(Boc)-OMe·HCl to Give **2a** and **2b**.* General procedure: To a stirred suspension of *N*-chloroacetylglycine (**1a**, 455 mg, 3 mmol) in dry CH_2Cl_2 (25 mL), NHS (345 mg, 3 mmol) and DCC (805 mg, 3.9 mmol) were added (at 0 °C). Separate suspensions of H-Phe-OEt·HCl (687 mg, 3 mmol) and H-Lys-(Boc)-OMe·HCl (890 mg, 3 mmol) in dry CH_2Cl_2 (5 mL) were treated with Et_3N (840 μL, 6 mmol) and were stirred for 10 min at rt before addition to the mixture containing NHS, DCC, and *N*-chloroacetylglycine. The mixtures were stirred for 18 h at rt; the precipitate (*N*,*N*′-dicyclohexylurea and Et_3N·HCl) was filtered off; the filtrates were consecutively washed with 1 M HCl and brine (30 mL each) and were dried to afford white solids, purified by trituration in Et_2O (*N*-chloroacetyl-Gly-Phe-OEt, 882 mg, 90%) or by crystallization using CH_2Cl_2/hexane solution (*N*-chloroacetyl-Gly-Lys(Boc)-OMe, 1.08 g, 91%).

N-Chloroacetyl-Gly-Phe-OEt (**2a**), amorphous white solid; $[\alpha]^{25}_D$ +20 (c 0.50, CH_2Cl_2). ^{1}H NMR (DMSO-d_6) δ 8.44 (br d, D_2O exch., J = 7.5 Hz, 1H); 8.37 (br t, D_2O exch., J = 5.5 Hz, 1H); 7.27 (m, 2H); 7.20 (m, 3H); 4.43 (ddd, J = 6 Hz, 6 Hz, 1 Hz, 1H); 4.10 (s, 2H); 4.02 (q, J = 7 Hz, 2H); 3.73 (m, 2H); 2.99 (dd, J = 6 Hz, 6 Hz, 1H); 2.90 (dd, J = 8.5 Hz, 8.5 Hz, 1H); 1.08 (t, J = 7 Hz). ^{13}C NMR (DMSO-d_6) δ 171.3, 168.4, 166.1, 137.0, 129.1, 128.3, 126.6, 60.6, 53.7, 42.5, 41.8, 36.8, 13.9. HRMS (EI) *m/z*: found 326.1035 (326.1033 calcd for $C_{15}H_{19}ClN_2O_4$). LRMS (EI) *m/z* (rel abundance): 326 $[M]^+$ (5), 224 (16), 176 (100), 120 (55), 91 (37).

N-Chloroacetyl-Gly-Lys(Boc)-OMe (**2b**), white crystals, mp 83−84 °C; $[\alpha]^{25}_D$ −11 (c 0.47, CH_2Cl_2). ^{1}H NMR ($CDCl_3$) δ 7.42 (br s, D_2O exch., 1H); 6.94 (br d, D_2O exch., J = 7 Hz, 1H); 4.71 (br t, D_2O exch., J = 5.5 Hz, 1H); 4.56 (ddd, J = 7.5 Hz, 7.5 Hz, 1 Hz, 1H); 4.08 (s, 2H); 4.04 (d, J = 5.5 Hz, 2H); 3.73 (s, 3H); 3.08 (ddd, 6 Hz, 6 Hz, 1 Hz, 2H); 1.85 (m, 1H); 1.72 (m, 1H); 1.47 (m, 2H); 1.42 (s, 9H); 1.31 (m, 2H). ^{13}C NMR ($CDCl_3$) δ 172.5, 167.9 , 166.6, 156.2, 79.2, 52.5, 52.2, 43.0, 42.3, 39.9, 31.5, 29.5, 28.4, 22.3. HRMS (EI) *m/z*: found 394.1745 (394.1745 calcd for $C_{16}H_{29}ClN_3O_6$). LRMS (EI) *m/z* (rel abundance): 394 $[M + H]^+$ (53), 360 (27), 338 (60), 294 (100), 225 (51), 100 (30).

*Coupling of N-Chloroacetyl-Asp(OMe)-OH (**1b**) with H-Glu-(OMe)-OMe·HCl or H-Phe-OEt·HCl to give **2c** and **2d**.* General procedure: To a stirred suspension of *N*-chloroacetyl-Asp-(OMe)-OH (**1b**, 4.47 g, 20.0 mmol) in dry THF (50 mL), NHS (2.30 g, 20.0 mmol) and DCC (4.54 g, 22.0 mmol) were added (at 0 °C) and the suspension was stirred for 1 h at 0 °C. Separate suspensions of H-Glu(OMe)-OMe·HCl (4.66 g, 22.0 mmol) or H-Phe-OEt·HCl (4.30 g, 22.0 mmol) in dry THF (50 mL) were treated with Et_3N (3.2 mL, 22.0 mmol) and were stirred for 1 h at 0 °C, followed by the addition to the mixture containing NHS, DCC, and *N*-chloroacetyl-Asp(OMe)-OH. The ice baths were removed and separate mixtures were stirred for 12 h at rt, and the precipitate (*N*,*N*′-dicyclohexylurea and Et_3N·HCl) was filtered off. The filtrates were concentrated and were extracted with EtOAc (150 mL). The organic extracts were consecutively washed with 1 M NaH_2PO_4 (pH 2.0, adjusted with H_3PO_4) (2 × 50 mL), a saturated aqueous solution of $NaHCO_3$ (2 × 50 mL), and brine (50 mL); were dried over Na_2SO_4 and concentrated to give oils. The obtained oils were dissolved in EtOAc (75 mL), the solutions were set aside for 5 h at 5 °C, and more of the precipitated *N*,*N*′-dicyclohexylurea was filtered off. The filtrates were concentrated. Compound **2c** was purified by trituration with Et_2O/hexanes (1:1, 100 mL) to afford an off-white solid which was further triturated with MeOH/Et_2O/hexanes (1:1:4, 150 mL) to give *N*-chloroacetyl-Asp(OMe)-Glu(OMe)-OMe (**2c,** 5.8 g, 76%). Compound **2d** was triturated with Et_2O/hexanes (1:1, 100 mL) to obtain an off-white solid, recrystallized form acetone/hexanes (1:3, 65 mL) to give *N*-chloroacetyl-Asp(OMe)-Phe-OEt (**2d**, 6.19 g, 81%).

N-Chloroacetyl-Asp(OMe)-Glu(OMe)-OMe (**2c**), white solid; $[\alpha]^{25}_D$ −37 (c 0.54, MeOH). ^{1}H NMR ($CDCl_3$) δ 7.79 (d, J = 8 Hz, 1H); 7.29 (d, J = 8 Hz, 1H); 4.82 (m, 1H); 4.51 (m, 1H); 4.08 (m, 2H) 3.69 (s, 3H); 3.69 (s, 3H); 3.64 (s, 3H); 2.99 (dd, J = 17 Hz, 4.5 Hz, 1H); 2.66 (dd, J = 17 Hz, 6.5 Hz, 1H); 2.36 (m, 2H); 2.17 (m, 1H); 1.97 (m, 1H). ^{13}C NMR ($CDCl_3$) δ 173.2, 172.2, 171.5, 169.7, 166.3, 52.4, 52.2, 52.0, 51.8, 49.3. 42.4, 35.5, 29.8, 26.6. HRMS (EI) *m/z*: found 381.1056 $[M + H^+]$ (calcd 381.1065 for $C_{14}H_{22}ClN_2O_8$). LRMS: *m/z* (rel. abundance): 381 $[M + H]^+$ (100), 225 (25).

N-Chloroacetyl-Asp(OMe)-Phe-OEt (**2d**), white solid, mp 115−116 °C; $[\alpha]^{25}_D$ −18 (c 0.56, MeOH). ^{1}H NMR ($CDCl_3$) δ 7.88; (d, J = 7.8 Hz, 1H); 7.29 (m, 3H); 7.13; (d, J = 7.0 Hz, 2H); 6.92; (d, J = 7.8 Hz, 1H); 4.78 (m, 2H); 4.17 (q, J = 7.2 Hz, 2H); 3.98 (m, 2H); 3.72 (s, 3H); 3.17 (dd, J = 13.9 Hz, 5.7 Hz, 1H); 3.17 (dd, J = 13.9 Hz, 6.6 Hz, 1H); 3.0 (dd, J = 17.3 Hz, 3.6 Hz, 1H); 2.63 (dd, J = 17.3 Hz, 6.9 Hz, 1H); 1.25 (t, J = 7.2 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ 172.0, 170.7, 169.2, 166.1, 135.5, 129.1, 128.3, 126.9, 61.4, 53.3, 52.0, 49.1, 42.1, 37.3, 35.0, 13.9. HRMS (EI) *m/z*: found 398.1252 $[M^+]$ (calcd 398.1243 for $C_{18}H_{23}ClN_2O_6$). LRMS (EI) *m/z* (rel. abundance): 398 $[M^+]$ (10), 176 (100), 120 (35), 102 (33).

*Conversion of N-Chloroacetyldipeptides **2a** and **2b** to N-Iodoacetyldipeptides **3a** and **3b.*** Sodium iodide (2.25 g, 15 mol) was added to separate solutions of *N*-chloroacetyl-Gly-Phe-OEt (**2a**, 817 mg, 2.5 mmol) or *N*-chloroacetyl-Gly-Lys(Boc)-OMe (**2b**, 985 mg, 2.5 mmol) in acetone (15 mL). The mixtures were stirred for 18 h at rt, concentrated to ca. $^1/_4$ of their original volumes, diluted with EtOAc (25 mL), and finally washed with 10% solution of Na_2SO_3 (25 mL). The aqueous layers were extracted with EtOAc (20 mL), and the combined organic extracts were dried and concentrated to afford white solids, purified by trituration in Et_2O (*N*-iodoacetyl-Gly-Phe-OEt, 816 mg, 78%) or by crystallization using 1:1 acetone/hexane solution (*N*-iodoacetyl-Gly-Lys(Boc)-OMe, 1.01 g, 83%).

N-Iodoacetyl-Gly-Phe-OEt (**3a**), amorphous white solid; $[\alpha]^{25}_D$ +30 (c 0.50, CH_2Cl_2). ^{1}H NMR (DMSO-d_6) δ 8.42 (br m, D_2O exch., 2H); 7.27 (m, 2H); 7.20 (m, 3H); 4.43 (ddd, J = 8 Hz, 8 Hz, 1 Hz, 1H); 4.02 (q, J = 7 Hz); 3.70 (m, 2H); 3.68 (s, 2H); 2.98 (dd, J = 6 Hz, 6 Hz, 1H); 2.90 (dd, J = 8.5 Hz, 8.5 Hz, 1H); 1.08 (t, J = 7 Hz). ^{13}C NMR (DMSO-d_6) δ 171.3,

168.5, 167.8, 136.9, 129.1, 128.2, 126.6, 60.5, 53.7, 42.0, 36.9, 33.3, 13.9. HRMS (EI) *m/z*: found 418.0347 [M^+] calcd (418.0390 for $C_{15}H_{19}IN_2O_4$). LRMS (EI) *m/z* (rel abundance): 418 [$M]^+$ (5), 225 (20), 176 (100), 120 (41), 91 (19).

N-Iodoacetyl-Gly-Lys(Boc)-OMe (**3b**), white crystals, mp 101−102 °C; $[\alpha]^{25}_D$ −11 (c 0.45, CH_2Cl_2). ^{1}H NMR ($CDCl_3$) δ 7.12 (br s, D_2O exch., 1H); 6.87 (br d, D_2O exch., J = 7.5 Hz, 1H); 4.72 (br t, D_2O exch., J = 6 Hz, 1H); 4.56 (ddd, J = 7 Hz, 7 Hz, 1 Hz, 1H); 4.01 (m, 2H); 3.75 (s, 2H); 3.74 (s, 3H); 3.10 (ddd, 6 Hz, 6 Hz, 1 Hz, 2H); 1.87 (m, 1H); 1.74 (m, 1H); 1.50 (m, 2H); 1.44 (s, 9H); 1.36 (m, 2H). ^{13}C NMR ($CDCl_3$) δ 172.5, 168.5, 168.2, 156.2, 79.3, 52.5, 52.3, 43.6, 40.0, 39.9, 31.4, 29.5, 28.4, 22.4. HRMS (EI) *m/z*: found 486.1086 (486.1056 calcd for $C_{16}H_{28}IN_3O_6$). LRMS (EI) *m/z* (rel abundance): 394 [$M]^+$ (5), 385 (36), 187 (21), 142 (100), 128 (14), 84 (36).

*Conversion of N-Chloroacetyldipeptides **2c** and **2d** to N-Iodoacetyldipeptides **3c** and **3d***. Sodium iodide (9.0 g, 60 mmol) was added to separate solutions of *N*-chloroacetyl-Asp(OMe)-Glu(OMe)-OMe (**2c**, 3.81 g, 10.0 mmol) or *N*-chloroacetyl-Asp-(OMe)-Phe-OEt (**2d**, 3.84 g, 10.0 mmol) in acetone (50 mL). The mixtures were stirred for 1 h at rt and for 2 h at 45 °C, cooled to rt, concentrated to ca. $^1/_4$ of their original volumes, diluted with EtOAc (100 mL), and finally washed with 10% solution of Na_2SO_3 (4 × 25 mL). The aqueous layers were extracted with EtOAc (25 mL), and the combined organic extracts were dried and concentrated to afford white solids which were purified by trituration in acetone/hexanes (1:10 v/v, 100 mL) to give *N*-chloroacetyl-Asp(OMe)-Glu(OMe)-OMe (**3c**, 3.89 g, 82%) or *N*-chloroacetyl-Asp(OMe)-Phe-OEt (**3d**, 4.31 g, 90%).

N-Iodoacetyl-Asp(OMe)-Glu(OMe)-OMe (**3c**), white solid; $[\alpha]^{25}_D$ −27 (c 0.56, MeOH). ^{1}H NMR ($CDCl_3$) δ 7.57 (d, J = 7.8 Hz, 1H); 7.32 (d, J = 7.6 Hz, 1H); 4.81 (m, 1H); 4.48 (m, 1H); 3.70 (m, 2H) 3.64 (s, 6H); 3.59 (s, 3H); 2.85 (dd, J = 17.0 Hz, 4.7 Hz, 1H); 2.69 (dd, J = 16.8 Hz, 6.4 Hz, 1H); 2.34 (m, 2H); 2.12 (m, 1H), 1.94 (m, 1H). ^{13}C NMR ($CDCl_3$) δ 173.0, 171.7, 171.4, 170.0, 167.9, 52.3, 52.0, 51.8, 51.7, 49.6, 35.5, 29.8, 26.7. HRMS (EI) found 472.0339 [M^+] (calcd 472.0343 for $C_{14}H_{21}IN_2O_8$) LRMS *m/z* (%): 472 [M^+] (5), 440 (5), 345 (5), 270 (20), 144 (100).

N-Iodoacetyl-Asp(OMe)-Phe-OEt (**3d**), white solid; $[\alpha]^{25}_D$ −19 (c 0.54, MeOH). ^{1}H NMR ($CDCl_3$) δ 7.29 (m, 3H); 7.14; (d, J = 7.2 Hz, 2H); 6.94; (d, J = 8.0 Hz, 1H); 4.75 (m, 2H); 4.15 (q, J = 7.2 Hz, 2H); 3.70 (s, 3H); 3.63 (m, 2H); 3.14 (dd, J = 13.9 Hz, 6.0 Hz, 1H); 3.07 (dd, J = 13.9 Hz, 6.6 Hz, 1H); 2.96 (dd, J = 17.2 Hz, 3.9 Hz, 1H); 2.61 (dd, J = 17.3 Hz, 6.9 Hz, 1H); 1.25 (t, J = 7.2 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ 171.4, 170.6, 169.6, 167.7, 135.6, 129.0, 128.2, 126.8, 61.2, 53.5, 51.9, 49.5, 37.4, 35.4, 13.8. HRMS (EI) *m/z*: found 490.0597 [M^+] (calcd 490.0598 for $C_{18}H_{23}IN_2O_6$). LRMS (EI) *m/z* (rel. abundance): 490 [M^+] (10), 270 (20), 176 (100), 102 (50).

*Alkylation of Cyclen with Iodoacetyl Dipeptides **3a**, **3b**, **3c**, and **3d***. *N*-Iodoacetyl-Gly-Phe-OEt (**3a**, 836 mg, 2 mmol), *N*-iodoacetyl-Gly-Lys(Boc)-OMe (**3b**, 971 mg, 2 mmol), *N*-iodoacetyl-Asp(OMe)-Glu(OMe)-OMe (**3c**, 950 mg, 2 mmol), and *N*-iodoacetyl-Asp(OMe)-Phe-OEt (**3d**, 985 mg, 2 mmol) were added (at rt) to a stirred solution of cyclen (86 mg, 0.5 mmol) and diisopropylethylamine (350 μL, 2 mmol) in acetonitrile (7 mL). The mixtures were stirred for 18 h at 50 °C (**3a** and **3b**) or 70 °C (**3c** and **3d**), cooled to rt, diluted with EtOAc (25 mL), and washed with 10% solution of Na_2SO_3 (25 mL). The aqueous layers were extracted with EtOAc (20 mL), and the combined organic extracts were dried and concentrated to afford white solids, purified by repeated (twice) trituration with hexanes.

Tetraacetyl-Gly-Phe-OEt cyclen (**6a**, 653 mg, 98%), white solid; $[\alpha]^{25}_D$ −10 (c 0.50, CH_2Cl_2). ^{1}H NMR ($CDCl_3$) δ 7.40−7.08 (m, D_2O exch., 7H); 4.74−4.62 (m, 1H); 4.14−3.79 (br m, 4H); 3.30−3.01 (br m, 4H); 2.82−2.26 (br m, 4H); 1.24−1.11 (m, 3H). ^{13}C NMR ($CDCl_3$) δ 171.9, 171.4, 171.3, 169.4, 167.8, 136.2, 129.3, 128.5, 126.9, 61.6, 61.4, 56.5, 54.6, 54.0, 53.7, 42.8, 42.4, 37.7, 37.6, 14.0. HRMS (ESI) *m/z*: found 1355.6617 [M + Na]$^+$ (calcd 1355.6652 for $C_{68}H_{92}N_{12}O_{16}Na$).

Tetraacetyl-Gly-Lys(Boc)-OMe cyclen (**6b**, 777 mg, 97%), white solid, $[\alpha]^{25}_D$ −30 (c 0.50, CH_2Cl_2). ^{1}H NMR ($CDCl_3$) δ 7.79 (br s, D_2O exch., 1H); 7.45 (br s, D_2O exch., 1H); 4.98 (br s, D_2O exch., 1H); 4.46−4.43 (br m, 1H); 4.05−3.95 (br m, 2H); 3.71 (s, 3H); 3.52−2.62 (br m, 4H); 3.07 (ddd, J = 6.5 Hz, 6.5 Hz, 1 Hz); 2.05−1.98 (br m, 2H); 1.85−1.76 (br m, 2H); 1.51−1.34 (br m, 2H); 1.41 (s, 9H). ^{13}C NMR ($CDCl_3$) δ 173.1, 172.7, 172.0, 156.9, 79.0, 52.5, 52.4, 50.6, 49.0, 41.1, 40.1, 33.8, 29.4, 28.4, 25.6, 24.9. HRMS (ESI) *m/z*: found 1623.9191 [M + Na]$^+$ (calcd 1623.9185 for $C_{72}H_{128}N_{16}O_{24}$-Na).

Tetraacetyl-Asp(OMe)-Glu(OMe)-OMe cyclen (**6c**, 670 mg, 87%), white solid; $[\alpha]^{25}_D$ −7 (c 0.69, CH_2Cl_2). ^{1}H NMR ($CDCl_3$) δ 7.88 (m, 2H); 7.34 (m, 2H); 7.17 (m, 2H); 4.51 (m, 4H); 4.19 (m, 4H); 3.79 (m, 3H); 3.36 (m, 36H); 2.77 (m, 10H); 2.60 (m, 12H); 2.10 (m, 8H); 1.86 (m, 4H); 1.71 (m, 4H). ^{13}C NMR ($CDCl_3$) δ 173.0, 172.8, 171.8, 171.7, 171.6, 171.4, 171.2, 170.3, 170.1, 52.2, 52.1, 51.7, 51.6, 51.4, 49.5, 49.1, 35.4, 29.6, 26.3. HRMS (ESI) found 1571.6516 [M + Na]$^+$ (calcd 1571.6446 for $C_{64}H_{100}N_{12}O_{32}Na$).

Tetraacetyl-Asp(OMe)-Phe-OEt cyclen (**6d**, 800 g, 98%), white solid; $[\alpha]^{25}_D$ −8 (c 0.61, CH_2Cl_2). ^{1}H NMR ($CDCl_3$) δ 7.37−7.07 (m, D_2O exch., 7H); 4.78−4.66 (m, 1H); 4.20−4.08 (m, 3H); 3.62 (s, 3H); 3.49−2.38 (m, 8H); 1.35−1.18 (m, 3H). ^{13}C NMR ($CDCl_3$) δ 171.9, 171.8, 171.2, 170.1, 135.8, 129.2, 128.2, 128.1, 126.6, 61.3, 61.2, 55.7, 53.3, 53.2, 51.8, 51.6, 49.0, 37.0, 34.7, 13.8. HRMS (ESI) *m/z*: found 1643.7426 [M+Na]$^+$ (calcd 1643.7497 for $C_{80}H_{108}N_{12}O_{24}Na$).

*Hydrolysis of Tetraacetyl-Gly-Phe-OEt Cyclen (**6a**)*. A solution of NaOH (384 mg, 9.6 mmol) in water (2.5 mL) was added to a stirred solution of tetraacetyl-Gly-Phe-OEt cyclen (**6a**, 800 mg, 0.6 mmol) in THF (2.5 mL). The mixture was stirred for 2 h at rt, then cooled to 0 °C, and the pH was adjusted to 4 (2.5 M HCl), after which an oil spontaneously separated. The water was decanted and the oil which deposited on the flask walls was triturated with Et_2O (twice) to afford tetraacetyl-Gly-Phe-OH cyclen (**7**) as a white solid (550 mg, 75%); $[\alpha]^{25}_D$ −10 (c 0.50, EtOH). ^{1}H NMR (DMSO-d_6) δ 12.80 (br s, D_2O exch., 1H); 8.46−8.30 (br m, D_2O exch., 2H); 7.26−7.16 (m, 5H); 4.45−4.40 (br m, 1H); 3.80−3.64 (br m, 2H); 3.24−2.65 (br m, 4H); 3.05−3.00 (m, 2H); 2.90−2.84 (m, 2H). ^{13}C NMR (DMSO-d_6) δ 172.8, 170.8, 170.7, 137.5, 129.2, 128.3, 126.5, 56.07, 53.7, 41.7, 41.5, 36.8, 33.4. HRMS (ESI) *m/z*: found 1222.6270 [M + H]$^+$ (calcd 1222.3242 for $C_{60}H_{77}N_{12}O_{16}$).

*Deprotection of Tetraacetyl-Gly-Lys(Boc)-OMe Cyclen (**6b**)*. Tetraacetyl-Gly-Lys(Boc)-OMe cyclen (**6b**, 150 mg, 0.094 mmol) was dissolved in TFA (1.5 mL), and the mixture was stirred for 15 min at rt. It was concentrated to afford tetraacetyl Gly-Lys-OMe cyclen tetratrifluoroacetate (**8**, 155 mg, 100%) as a slightly yellow oil which was used directly for further reactions.

*Hydrolysis of Tetraacetyl-Gly-Lys-OMe Cyclen Tetratrifluoroacetate (**8**)*. A solution of NaOH (2.5 M, 940 μL) was added to a solution of tetraacetyl-Gly-Lys-OMe cyclen tetratrifluoroacetate **8** (155 mg, 0.094 mmol) in MeOH (900 μL). The mixture was stirred for 2 h at 60 °C, MeOH was evaporated, and the mixture was neutralized (using 2 M HCl). It was subjected to size exclusion chromatography; fractions containing the product were combined and were freeze-dried to afford

tetraacetyl-Gly-Lys-OH cyclen (**9**) as a colorless oil (97 mg, 90%), $[\alpha]^{25}_D$ −167 (c 0.27, H_2O). ^{1}H NMR (D_2O) δ 3.83 (br s, 1H); 3.69 (s, 2H); 3.62−3.58 (m, 2H); 3.13−2.62 (br m, 4H); 2.89−2.83 (m, 2H); 1.90−1.72 (m, 2H); 1.67−1.52 (m, 2H); 1.41−1.20 (m, 2H). ^{13}C NMR (D_2O) δ 178.9, 170.5, 55.2, 50.9, 49.3, 42.2, 39.4, 31.3, 26.5, 22.1. HRMS (ESI) *m/z*: found 1145.6628 $[M + H]^+$ (calcd 1145.6642 for $C_{48}H_{89}N_{16}O_{16}$).

*Hydrolysis of Tetraacetyl-Asp(OMe)-Glu(OMe)-OMe Cyclen (**6c**).* A solution of NaOH (2.5 M, 2 mL) was added to a solution of tetraacetyl-Asp(OMe)-Glu(OMe)-OMe cyclen (**6c**, 155 mg, 0.1 mmol) in MeOH (2 mL). The mixture was stirred for 2 h at 60 °C, MeOH was evaporated, and the mixture was neutralized (using 4 M HCl). It was subjected to size exclusion chromatography; fractions containing the product were combined and were freeze-dried to afford tetraacetyl-Asp-Glu-OH cyclen (**10**) as a colorless solid (103 mg, 75%); $[\alpha]^{25}_D$ +7 (c 0.62, H_2O). ^{1}H NMR (D_2O) δ 4.39−4.36 (m, 1H); 3.98−3.93 (m, 1H); 3.71−3.57 (m, 2H); 3.24−3.02 (m, 4H); 2.07−2.03 (m, 2H); 1.89−1.83 (m, 1H); 1.74−1.64 (m, 1H). ^{13}C NMR (D_2O) δ 181.9, 181.8, 179.0, 55.4, 52.3, 34.0, 28.8, 28.5. HRMS (ESI) *m/z*: found 1381.4708 $[M + H]^+$ (calcd 1381.4767 for $C_{52}H_{77}N_{12}O_{32}$).

*Hydrolysis of Tetraacetyl-Asp(OMe)-Phe-OEt Cyclen (**6d**).* A solution of NaOH (2.5 M, 7.5 mL) was added to a solution of tetraacetyl-Asp(OMe)-Phe-OEt cyclen (**6d**, 610 mg, 0.38 mmol) in MeOH (7.5 mL). The mixture was stirred for 20 min at 60 °C, MeOH was evaporated, and the mixture was cooled to 0 °C and was acidified (pH 2, using 4 M HCl). The oily product deposited on the flask wall and the water was decanted. The residue was triturated with Et_2O (twice) to afford tetraacetyl-Asp-Phe-OH cyclen (**11**) as a colorless solid (530 mg, 95%); $[\alpha]^{25}_D$ +7 (c 0.73, DMSO). ^{1}H NMR (DMSO-d_6) δ 12.74 (br s, D_2O exch., 2H); 8.85 (br s, D_2O exch., 1H); 8.42 (br s, D_2O exch., 1H); 7.32−7.17 (m, 5H); 4.63−4.37 (m, 2H); 3.78−3.73 (m, 1H); 3.45−2.55 (m, 9H); ^{13}C NMR (DMSO-d_6) δ 172.8, 172.6, 172.1, 169.1, 137.6, 129.2, 128.3, 126.5, 65.0, 56.1, 53.8, 48.9, 36.8, 36.5, 36.4, 18.6, 15.2. HRMS (ESI) *m/z*: found 1453.5862 $[M + H]^+$ (calcd 1453.5800 for $C_{68}H_{85}N_{12}O_{24}$).

*Treatment of Tetraacetyl-Gly-Phe-OH Cyclen (**7**), Tetraacetyl-Gly-Lys-OH Cyclen (**9**), Tetraacetyl-Asp-Glu-OH Cyclen (**10**), and Tetraacetyl-Asp-Phe Cyclen (**11**) with Lanthanide(III) Chlorides.* Separate solutions of tetraacetyl-Gly-Phe-OH cyclen (**7**, 114 mg, 0.094 mmol), tetraacetyl-Gly-Lys-OH cyclen (**9**, 107 mg, 0.094 mmol), tetraacetyl-Asp-Glu-OH cyclen (**10**, 130 mg, 0.094 mmol), and tetraacetyl-Asp-Phe-OH cyclen (**11**, 137 mg, 0.094 mmol) in water (3 mL) were treated with lanthanide(III) chlorides (0.094 mmol) as follows: tetraacetyl-Gly-Phe-OH cyclen ($EuCl_3 \cdot 6H_2O$, $NdCl_3 \cdot H_2O$, $TmCl_3 \cdot 6H_2O$, and $YbCl_3 \cdot 6H_2O$); tetraacetyl-Gly-Lys-OH cyclen ($DyCl_3 \cdot 6H_2O$, $EuCl_3 \cdot 6H_2O$, $NdCl_3 \cdot H_2O$, $TbCl_3 \cdot 6H_2O$, $TmCl_3 \cdot 6H_2O$, and $YbCl_3 \cdot 6H_2O$); tetraacetyl-Asp-Glu-OH cyclen ($EuCl_3 \cdot 6H_2O$, $NdCl_3 \cdot H_2O$, $TmCl_3 \cdot 6H_2O$, and $YbCl_3 \cdot 6H_2O$); tetraacetyl-Asp-Phe-OH cyclen ($EuCl_3 \cdot 6H_2O$). Reaction mixtures were treated with NaOH (2.5 M solution) to adjust the pH to 9 and were stirred for 18 h at rt followed by size exclusion chromatography. The fractions containing the lanthanide(III) complexes were combined and were isolated as dry solids by lyophilization.

Eu^{3+} tetraacetyl-Gly-Phe-OH cyclen (**12**), white solid; ^{1}H NMR (D_2O) δ 24.44 (s); 21.93 (s); 8.50 (s); 7.83 (s); 7.47 (s); 7.36 (s); 7.10−6.80 (m); 6.59−6.58 (m); 6.38 (s); 6.22 (s); 6.04 (s); 3.57−2.05 (m); 1.50 (s); −3.08 (s); −3.78 (s); −4.49 (s); −5.04 (s); −8.03 (s); −8.91 (s); −9.20 (s); −9.91 (s); −11.66 (s); −12.05 (s); −13.06 (s). *Treatment of Tetraacetyl-Gly-Lys-OMe Cyclen Tetratrifluoroacetate (**8**) with Lanthanide(III) Chlorides.* Solutions of tetraacetyl-Gly-Lys-OMe cyclen tetratrifluoroacetate (**8**, 155 mg, 0.094 mmol) in water (3 mL) were treated with lanthanide(III) chlorides ($DyCl_3 \cdot 6H_2O$, $EuCl_3 \cdot 6H_2O$, $NdCl_3 \cdot H_2O$, $TbCl_3 \cdot H_2O$, $TmCl_3 \cdot 6H_2O$, and $YbCl_3 \cdot 6H_2O$, 0.094 mmol). Reaction mixtures were treated with NaOH (2.5 M solution) to adjust the pH to 9 and were stirred for 18 h at rt. The reaction mixtures were subjected to size exclusion chromatography. The fractions containing the lanthanide(III) complexes were combined and were freeze-dried to afford colorless oils.

Dy^{3+} tetraacetyl-Gly-Lys-OMe cyclen (**16**), colorless oil; ^1H NMR (D_2O) δ 35.31 (s); 26.08 (s); 13.01 (s); 10.42 (s); 9.19 (s); 8.78 (s); 8.61 (s); 6.82 (s); 6.45 (s); 6.29 (s); 4.08−4.00 (m); 3.80 (s); 3.49−3.42 (m); 3.28 (s); 3.14 (s); 3.05−2.66 (m); 2.04−1.69 (m); 1.47−1.32 (m). *Selective Deprotection of di-Cbz-His-OMe (**33**).* A suspension of di-Cbz-His-OMe (*21*) (**33,** 1.65 g, 3.77 mmol) in 30% HBr in AcOH (25 mL) was stirred until a clear solution was obtained (ca. 90 min) at rt. The mixture obtained was cooled to 0 °C, Et_2O (50 mL) was added, and the mixture was set aside for 30 min at 0 °C. Separated precipitate was filtered off, was washed with Et_2O, and was dried to afford H-His(Cbz)-OMe·2HBr (1.42 g, 81%) of sufficient purity for the next reaction.

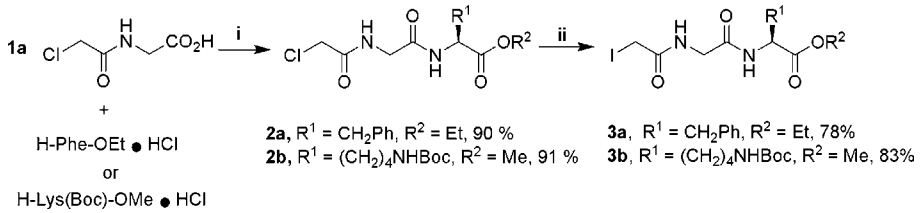
H-His(Cbz)-OMe·2HBr (**34**), white solid, mp 166−68 °C (167−167.5 °C lit. (*22*)); $[\alpha]^{25}_D$ +13 (c 0.39, H_2O). ^1H NMR (DMSO-d_6) δ 8.37 (s, 1H); 8.30 (br s, D_2O exch., 2H); 7.48 (m, 3H); 7.40 (m, 3H); 5.43 (s, 2H); 4.33 (m, 1H); 3.71 (s, 3H); 3.04 (m, 2H). ^{13}C NMR (DMSO-d_6) δ 168.5, 164.7, 137.4, 134.5, 129.2, 128.6, 128.4, 126.5, 118.2, 53.2, 52.8, 51.1, 34.5. HRMS (EI) *m/z*: found 303.1223 (free amine) (calcd 303.1219 for $C_{15}H_{17}N_3O_4$). LRMS (EI) *m/z* (rel abundance): 303 $[M]^+$ (10), 152 (23), 110 (24).

*Chloroacetyl-Gly-His(Cbz)-OMe (**35**).* To a stirred solution of *N*-chloroacetylglycine (277 mg, 1.5 mmol) in dry THF (15 mL) were added NHS (173 mg, 1.5 mmol) and EDC·HCl (863 mg, 4.5 mmol). The mixture was stirred for 18 h at rt and then was concentrated. The residue was dissolved in water (30 mL) and was extracted with EtOAc (30 mL + 3 × 20 mL). The combined organic extracts were dried and concentrated to afford 257 mg (70%) of *O*-hydroxysuccinimidyl *N*-chloroacetylglycinate. This was dissolved in dry THF (10 mL), H-His(Cbz)-OMe·2HBr (481 mg, 1.03 mmol) and Et_3N (580 μL, 4.13 mmol) were added, and the mixture was stirred for 2 h at rt. The solvent was evaporated; the residue was dissolved in EtOAc (30 mL) and was washed with water (30 mL). The aqueous phase was extracted with EtOAc (20 mL), combined organic extract was dried and was concentrated, and the residue was subjected to flash column chromatography (FCC) on 20 g SiO_2 (hexane/acetone, 1:1) to afford 203 mg (45%, based on *O*-hydroxysuccinimidyl *N*-chloroacetylglycinate, 31%, based on *N*-chloroacetylglycine) of chloroacetyl-Gly-His(Cbz)-OMe (**35**).



Chloroacetyl-Gly-His(Cbz)-OMe, colorless oil; $[\alpha]^{25}_D$ −35 (c 0.29, DMSO). ^1H NMR ($CDCl_3$) δ 8.03 (s, 1H); 7.58 (br d, D_2O exch., J = 7.5 Hz, 1H); 7.41 (m, 5H); 7.34 (br m, D_2O exch., 1H); 7.20 (s, 1H); 5.38 (s, 2H); 4.84 (m, 1H); 4.07 (d, J = 1.5 Hz, 2H); 4.03 (m, 2H); 3.68 (s, 3H); 3.08 (dd, J = 9.5 Hz, 5.5 Hz, 1H); 3.00 (dd, J = 11 Hz, 4.5 Hz, 1H). ^{13}C NMR ($CDCl_3$) δ 171.2, 167.8, 166.3, 148.2, 138.8, 137.0, 133.8, 129.2, 128.8, 128.7, 114.7, 70.0, 52.5, 51.9, 42.9, 42.4, 29.2. HRMS (ESI) *m/z*: found 459.1057 $[M + Na]^+$ (calcd 459.1047 for $C_{19}H_{21}ClN_4O_6Na$).

*Iodoacetyl-Gly-His(Cbz)-OMe (**36**).* Sodium iodide (415 mg, 2.79 mmol) was added to a solution of chloroacetyl-Gly-His-(Cbz)-OMe (**35**, 203 mg, 0.46 mmol) in acetone (6 mL). The mixture was stirred for 18 h at rt, the solvent was then evaporated, and the residue was dissolved in EtOAc (30 mL). The organic phase was washed with 10% $NaHSO_3$ solution (30 mL) and the aqueous wash was back-extracted with EtOAc (20 mL). The combined organic extracts were dried and concentrated. The residue was subjected to FCC on 25 g SiO_2 (hexane/acetone, 1:1) to afford 204 mg (83%) of unstable iodoacetyl-Gly-His(Cbz)-OMe (**36**).

Iodoacetyl-Gly-His(Cbz)-OMe, colorless solid; ^1H NMR ($CDCl_3$) δ 8.05 (s, 1H); 7.42 (br m, D_2O exch., 6H); 7.21 (s, 1H); 6.90 (br m, D_2O exch., 1H); 5.40 (s, 2H); 4.85 (m, 1H); 4.01 (d, J = 5 Hz, 2H); 3.72 (s, 2H); 3.69 (s, 3H); 3.11 (dd, J = 10 Hz, 5.5 Hz, 1H); 3.02 (dd, J = 10.5 Hz, 4.5 Hz, 1H). HRMS (ESI) *m/z*: found 551.0419 $[M + Na]^+$ (calcd 551.0404 for $C_{19}H_{21}IN_4O_6Na$).

*Iodoacetyl-Gly-Arg(NO_2)-OMe (**39**).* To a solution of *N*-chloroacetylglycine (**1a**, 303 mg, 2 mmol) in dry THF (20 mL) was added NHS (230 mg, 2 mmol). The mixture was cooled to 0 °C, DCC (536 mg, 2.6 mmol) was added, and the mixture was stirred for 1 h at 0 °C, followed by the addition of H-Arg(NO_2)-OMe·HCl (**37**, 539 mg, 2 mmol) and Et_3N (560 μL, 4 mmol). The cooling bath was removed and the mixture was stirred for 18 h at rt. The solvent was evaporated and the residue was subjected to FCC on 75 g SiO_2 (CH_2Cl_2/MeOH/NH_4OH, 80:20:1). Evaporation of the eluate afforded 615 mg of chloroacetyl-Gly-Arg(NO_2)-OMe (**38**), containing ca. 20% of *N*,*N*′-dicyclohexylurea, as determined by analysis of the ^1H NMR spectrum. The impure *N*-chloroacetyl-dipeptide **38** was

Scheme 2. Synthesis of *N*-Iodoacetyl-Gly-Phe-OEt (3a) and *N*-Iodoacetyl-Gly-Lys(Boc)-OMe (3b)[a]

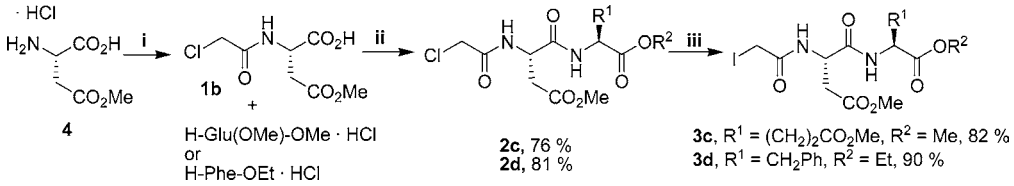
[a] Reagents and conditions: (i) NHS/DCC, Et_3N, CH_2Cl_2, 18 h, rt; (ii) NaI (6.0 equiv), acetone, 18 h, rt.

dissolved in acetone (15 mL), and NaI (736 mg, 4.91 mmol) was added. The mixture was stirred for 18 h at rt, a small amount of SiO_2 was added, the solvent was evaporated, and the residue was subjected to FCC on 50 g SiO_2 (CH_2Cl_2/MeOH/NH_4OH, 80:20:1). Evaporation of the eluate afforded 583 mg (64%, based on *N*-chloroacetylglycine) of iodoacetyl-Gly-Arg(NO_2)-OMe (**39**).

Iodoacetyl-Gly-Arg(NO_2)-OMe, colorless solid; $[\alpha]^{25}_D$ −12 (c 0.41, MeOH). ^{1}H NMR (DMSO-d_6) δ 8.46 (br m, D_2O exch., 2H); 8.32 (br d, D_2O exch., J = 7.5 Hz, 1H); 7.81 (br d, D_2O exch., J = 7.5 Hz, 2H); 4.25 (m, 1H); 3.73 (m, 2H); 3.68 (s, 2H); 3.61 (s, 3H); 3.13 (m, 2H); 1.60 (m, 4H). ^{13}C NMR (DMSO-d_6) δ 172.2, 172.1, 168.6, 168.0, 56.7, 52.0, 51.6, 42.1, 28.1. HRMS (ESI) *m/z*: found 481.0285 $[M + Na]^+$ (481.0309 calcd for $C_{11}H_{19}IN_6O_6Na$).

*Alkylation of Cyclen with Iodoacetyl-Gly-Arg(NO_2)-OMe (**39**).* To a solution of cyclen (15 mg, 0.086 mmol) in acetonitrile (6 mL), ethyldiisopropylamine (60 μL, 0.34 mmol) was added. The mixture was stirred for 30 min at rt followed by the addition of iodoacetyl-Gly-Arg(NO_2)-OMe (**39**, 158 mg, 0.34 mmol). The stirring continued for 18 h at rt, at which time the product had separated from solution. Conveniently, the solvent was decanted and the residue was washed with acetonitrile (2 × 5 mL) and was dried to afford 46 mg (46%) of triacetyl-Gly-Arg(NO_2)-OMe cyclen (**40**).

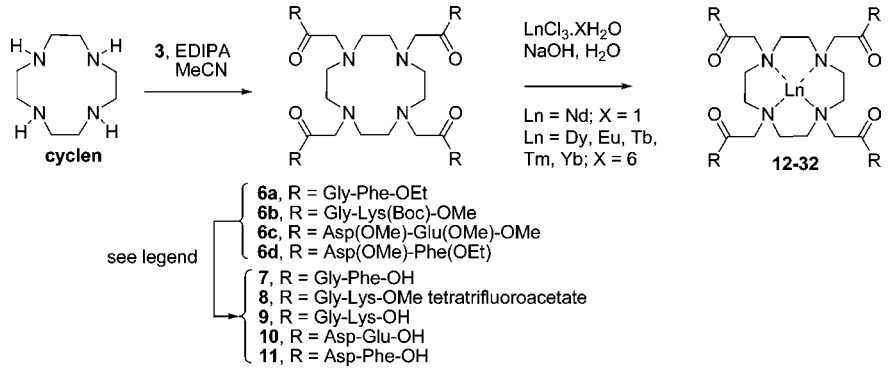
Triacetyl-Gly-Arg(NO_2)-OMe cyclen (**40**), colorless solid; $[\alpha]^{25}_D$ −53 (c 0.38, MeOH). ^{1}H NMR (D_2O) δ 4.40 (m, 3H); 3.92 (m, 6H); 3.68 (3, 9H); 3.29−3.06 (m, 12H); 2.98−2.67 (m, 16H); 1.87 (m, 3H); 1.72−1.56 (m, 9H). ^{13}C NMR (DMSO-d_6) δ 172.3, 172.2, 171.7, 171.2, 170.8, 169.6, 169.3, 168.9, 159.3, 52.0, 51.7, 49.2, 41.5, 41.4, 40.3, 38.8, 38.5, 33.4, 28.2, 25.3, 24.9, 24.8, 24.7, 24.6, 24.5. HRMS (ESI) *m/z*: found 1163.5588 $[M + H]^+$ (calcd 1163.5630 for $C_{41}H_{75}N_{22}O_{18}$).



RESULTS AND DISCUSSION

Our synthetic scheme required the alkylation of cyclen with the appropriate reactive dipeptide derivatives. Our initial approach to *N*-haloacetyl-dipeptides involved the synthesis of fully protected, side chain and C-terminus, α-*N*-Boc-dipeptides. After *t*-butyloxycarbonyl (Boc) removal, the N-terminus of an otherwise fully protected dipeptide was further reacted with bromoacetyl bromide to give the required *N*-bromoacetyl-dipeptide. This approach proved to be difficult to execute as the success of the reaction was highly dependent on the dipeptide sequence. Additionally, we also attempted, without much success, to couple partially protected (free N-terminus) dipeptides to DOTA. Although these approaches may be successful in certain cases, we did not consider either of them to be a generally applicable route to cyclen−tetra(oligopeptide) conjugates. We decided to pursue an alternative convergent strategy in order to circumvent the above-mentioned problems and also avoid the tedious synthesis of individual α-*N*-Boc-dipeptides and eliminate a step that involved a protecting group manipulation. Our strategy involved first preparing *N*-chloroacetylglycine as a convenient precursor to a variety of *N*-chloroacetylglycyl−(amino acid) compounds. Schotten-Baumann acylation of glycine with chloroacetyl chloride gave *N*-chloroacetylglycine (**1a**) in 43% yield after recrystallization from ethyl acetate, similar to the reported procedure (*23*). Unlike more reactive α-haloacetamides that may not tolerate the presence of nucleophiles, the *N*-chloroacetylglycine was stable to handling, storage, and amide bond forming reactions. Therefore, next, a straightforward *N*-hydroxysuccinimide (NHS)/dicyclohexylcarbodiimide (DCC) promoted coupling (*24*) of *N*-chloroacetylglycine (**1a**) with H-Phe-OEt·HCl or H-Lys(Boc)-OMe·HCl afforded *N*-chloroacetyl-Gly-Phe-OEt (**2a**) and *N*-chloroacetyl-Gly-Lys(Boc)-OMe (**2b**) in excellent yield (Scheme 2).

In our experience, the alkylation of cyclen proceeded quite slowly with the *N*-chloroacetylamino acids. The alkylation reaction generally required halide exchange to a more active derivative to be high-yielding. Although cyclen may be reacted in a one-pot procedure with *N*-chloroacetyl-dipeptides **2a** and **2b** in the presence of excess NaI and K_2CO_3, we have found that the success of peralkylation was variable. Therefore, we decided to perform the Finkelstein reaction and isolate the *N*-iodoacetyl-dipeptides prior to their use. This permitted us to conveniently monitor the consumption of the *N*-iodoacetyl-dipeptides during its use by TLC analysis of the reaction mixture. Thus, treatment of **2a** and **2b** with NaI in acetone proceeded smoothly, and *N*-iodoacetyl-dipeptides **3a** and **3b** were obtained in approximately 80% yield (Scheme 2). An upfield shift of the methylene peak in the ^{1}H NMR is observed upon conversion of *N*-chloroacetyl-dipeptides **2** to *N*-iodoacetyl-dipeptides **3**. The *N*-iodoacetyl-dipeptides are stable and easily isolable solids that may be stored for prolonged periods without deterioration.



The above strategy was also extended to the synthesis of cyclen containing aspartic acid as the second amino acid; the key compound toward the synthesis of such molecules is *N*-chloroacetyl-Asp(OMe)-OH (**1b**). This compound was prepared by first monoesterification of aspartic acid to its β-methyl ester (**4**) with methanolic HCl (*20*). Initial attempts at acylating **4** involved neutralization of the hydrochloride salt with 1 equiv of sodium hydroxide followed by the addition of 1 equiv of sodium carbonate and dropwise addition of chloroacetyl chloride. Although this procedure gave **1b** in 56% yield as an oil, it was contaminated with the side product chloroacetic acid, which proved difficult to remove. In order to improve the acylation yield and to avoid hydrolysis of the β-methyl ester, we decided to react **4** with *O*-chloroacetyl-*N*-hydroxysuccinimide (**5**). Using sodium carbonate and a 1:1 mixture of dioxane/H_2O, this reaction gave **1b** in a crude yield of 81%, slightly contaminated with NHS as judged by ^{1}H NMR. Without purification, **1b** was condensed with H-Glu(OMe)-OMe·HCl or H-Phe-OEt·HCl to give *N*-chloroacetyl-Asp(OMe)-Glu(OMe)-OMe (**2c**) and *N*-chloroacetyl-Asp(OMe)-Phe-OEt (**2d**), using NHS/DCC. At this point, NHS was easily eliminated by extraction against aqueous sodium bicarbonate. Treatment of **2c** and **2d** with NaI in acetone gave *N*-iodoacetyl-Asp(OMe)-Glu(OMe)-OMe (**3c**), and *N*-iodoacetyl-Asp(OMe)-Phe-OEt (**3d**) in very good yields (Scheme 3).

Scheme 3. Synthesis of *N*-Iodoacetyl-Asp(OMe)-Glu(OMe)-OMe (3c) and *N*-Iodoacetyl-Asp(OMe)-Phe-OEt (3d)[a]

Scheme 4. Synthesis of Cyclen−Oligopeptide Conjugates 7−11 and Their Treatment with Lanthanide(III) Chlorides[a]

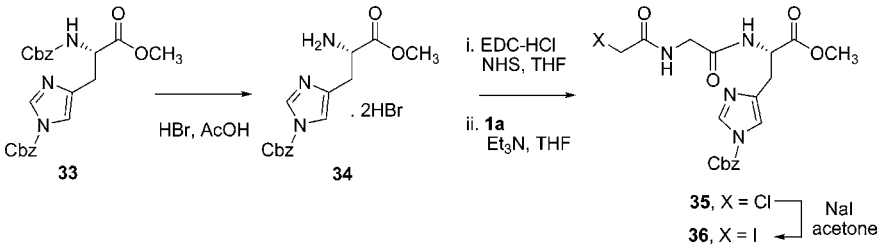
[a] Reagents and Conditions. **6a** → **7**: NaOH, THF/H_2O. **6b** → **8**: TFA. **6b** → **9**: (i) TFA, (ii) NaOH, MeOH/H_2O. **6c** → **10**: NaOH, MeOH/H_2O. **6d** → **11**: NaOH, MeOH/H_2O.

With *N*-iodoacetyl-dipeptides **3a**−**3d** in hand, we investigated the alkylation of cyclen (Scheme 4). The use of potassium carbonate did not give satisfactory conversion as judged by TLC, and we turned to ethyldiisopropylamine (EDIPA, Hünig's base), which gave acceptable results. The alkylation reactions were carried out at 50 °C in MeCN, using 4 equiv of *N*-iodoacetyl-dipeptides **3a** or **3b** and EDIPA. Slightly higher temperatures (70 °C) were used for the alkylation of cyclen with the more bulky compounds **3c** and **3d**. Tetraalkylated cyclen−oligopeptide conjugates **6** were obtained in excellent yields (>90%). To obtain the desired ligands for the complexation with lanthanides, protecting groups were removed as described in Scheme 4. Saponification of **6a**, **6c**, and **6d** afforded compounds **7** (Gly-Phe-OH), **10** (Asp-Glu-OH), and **11** (Asp-Phe-OH), respectively. Treatment of compound **6b** with TFA gave **8** (Gly-Lys-OMe tetratrifluoroacetate), which without further purification under the conditions of basic hydrolysis gave **9** (Gly-Lys-OH). Cyclen−oligopeptide conjugates **7** and **11** were purified by trituration with Et_2O, while conjugates **9** and **10** were purified by size exclusion chromatography on desalting gel with an exclusion limit of 1800 Da.

Currently, there are numerous literature reports describing the synthesis of lanthanide(III) complexes derived from cyclen. Various reaction conditions (elevated temperatures (*25*, *26*), slightly acidic pH (*27*−*29*), and slightly basic pH (*6*)) have been employed in order to prepare lanthanide(III) cyclen complexes. As described in the literature, the workup usually involves filtration of insoluble particles followed by the concentration of the filtrate without any further purification (*30*, *31*). Alternatively, the reaction mixtures are sometimes centrifuged, and the supernatant is concentrated as described above (*32*). Less water-soluble complexes are purified by precipitation of their methanolic solutions with Et_2O (*25*) or by trituration with Et_2O (*33*). Oftentimes, the crude material obtained after concentration is used directly, without any form of purification (*7*, *16*). To the best of our knowledge, a general procedure for the purification of cyclen derived lanthanide(III) complexes has not been described. Taking into account this lack of consistent purification of lanthanide(III) complexes, and the fact that compounds **12**−**32** are very water-soluble and resist precipitation, we have decided to establish a widely applicable method for the purification of lanthanide(III) complexes of cyclen−oligopeptide conjugates and test its scope. Ligands **7**−**11** have been treated with 1 equiv of various lanthanide(III) chlorides in water under slightly basic conditions (pH 9) (Scheme 4). The conditions for introducing the metal are gentle enough to retain the C-terminal ester, e.g., **16**−**21**. This was also true in the case of DOTAM-(Gly-Phe-OEt)$_4$ (**6a**), which was metalated; however, the complexes were not sufficiently soluble in water and they were abandoned.

Once the ligands were metalated, the resulting complexes were isolated and purified by size exclusion chromatography (SEC) in deionized water (*34*). The SEC gel that was used had an exclusion limit of 1800 Da and was found to be widely applicable for the purification of water-soluble lanthanide(III) complexes with a molecular weight of approximately 1000−1800 Da—i.e., most conceivable dipeptide DOTAM conjugates. Compounds with a molecular weight well in excess of 1800 Da would be better purified using a desalting gel with a higher exclusion limit. The fractions containing the compounds were identified by UV/I_2 vapors (Gly-Phe-OH and Asp-Phe-OH complexes), ninhydrin test (Gly-Lys-OH and Gly-Lys-OMe complexes), or I_2 vapors (Asp-Glu-OH complex). Chemical yields for the purified complexes varied from 44% to 98%, as listed in Table 1. All the prepared complexes were characterized by HR MS (ESI- TOF) and ^{1}H NMR spectroscopy.

The synthetic approach reported herein is convenient and robust because it reliably works for a number of diverse dipeptides without modification and utilizes known or commercially available amino acid derivatives. Two notable exceptions were found in the attempted preparation of tetraacetyl-Gly-His-OMe and tetraacetyl-Gly-Arg-OMe. These compounds are potentially interesting targets due to the presence of additional exchangeable protons in the ligand periphery and the nature of the side chain functional groups.



We approached the tetraacetyl-Gly-His-OMetarget by first preparing the bis(Cbz)-protected-histidine methyl ester (**33**) as described in the literature (*21*). Treatment of **33** with 30% HBr in AcOH (*22*) resulted in selective removal of Cbz group from the amino group, while the protecting group on the imidazole

[a] Eu(III) Asp-Phe-OH (**32**) was achieved in 71 mg, 47%.

Scheme 5. Synthesis of Haloacetyl-Gly-His(Cbz)-OMe 35 and 36

Scheme 6. Synthesis of Triacetyl-Gly-Arg(NO$_2$)-OMe Cyclen (40)

ring remained intact (Scheme 5). The possibility of coupling of dihydrobromide **34** with *N*-chloroacetylglycine was then investigated. The reaction was troublesome and low-yielding. The best conditions proved to be EDC·HCl and NHS in the presence of Et_3N (Scheme 5), which afforded chloroacetyl-Gly-His(Cbz)-OMe (**35**) in 40% yield. Application of the Finkelstein reaction gave the rather unstable iodoacetyl-Gly-His(Cbz)-OMe (**36**) (Scheme 5). This compound underwent massive decomposition in solution in less than 1 h, as observed by ^{1}H NMR in $CDCl_3$ or DMSO-d_6. Nonetheless, the alkylation of cyclen was attempted; however, no product of alkylation was detected which was likely due to instability of *N*-iodoacetyl-dipeptide **36**. Attempts to prepare *N*-iodoacetyl-dipeptide **36** *in situ* were unsuccessful. The reactivity of chloroacetyl-Gly-His(Cbz)-OMe (**35**) toward the alkylation of cyclen appeared to be insufficient even at elevated temperatures.

The synthesis of the required dipeptide electrophile to approach tetraacetyl-Gly-Arg-OMe was achieved much more readily. The NHS/DCC mediated coupling of *N*-chloroacetylglycine with H-Arg(NO$_2$)-OMe (**37**) afforded chloroacetyl-Gly-Arg(NO$_2$)-OMe (**38**) (Scheme 6), containing a small amount of *N*,*N*′-dicyclohexylurea. The Finkelstein reaction of **38** proceeded smoothly, and iodoacetyl-Gly-Arg(NO$_2$)-OMe (**39**) was isolated in 64% overall yield (Scheme 6). Alkylation of cyclen was carried out in acetonitrile using EDIPA as a base. Surprisingly, the trialkylated cyclen **40** formed exclusively and was found to deposit on the flask walls at room temperature. Metalation of **40** (using $EuCl_3 \cdot 6H_2O$ and $NdCl_3 \cdot H_2O$) could not be achieved even at elevated temperatures and slightly basic pH. The origin of the lack of chelation by this ligand is not understood at this time. Since ligand **40** could not be metalated, no studies were carried out toward the tetraalkylation of cyclen with iodoacetyl-Gly-Arg(NO$_2$)-OMe (**39**) nor on removal of guanidine protecting group.

With the intention of the discovery of new MRI PARACEST agents that generate signal variation by the CEST effect, we have acquired CEST spectra (*2*) of the metalated ligands under conditions of near-physiological temperature and pH. The results of this survey are presented in Figure 2. The observed CEST effects are the result of the intrinsic properties of the compound as well as the experimental conditions. Since all CEST spectra were measured under identical experimental conditions, the differences in the observed CEST effects were likely due to alterations in the exchangeable proton lifetimes. For example, a CEST effect was observed from bound water protons when the exchange rate of bound water with bulk water was slow (M = Eu^{3+}, Nd^{3+}). Conversely, no bound water CEST effect was observed for metal complexes when the exchange between bound and bulk water was relatively fast (M = Dy^{3+}, Tb^{3+}, Tm^{3+}, Yb^{3+}). However, for the latter metals, it is possible in some instances to observe the CEST effect from the protons bound to the amide nitrogen. This phenomenon may be exploited to measure the pH of the environment if the signal intensity is observably sensitive to pH and reasonably resolved from the

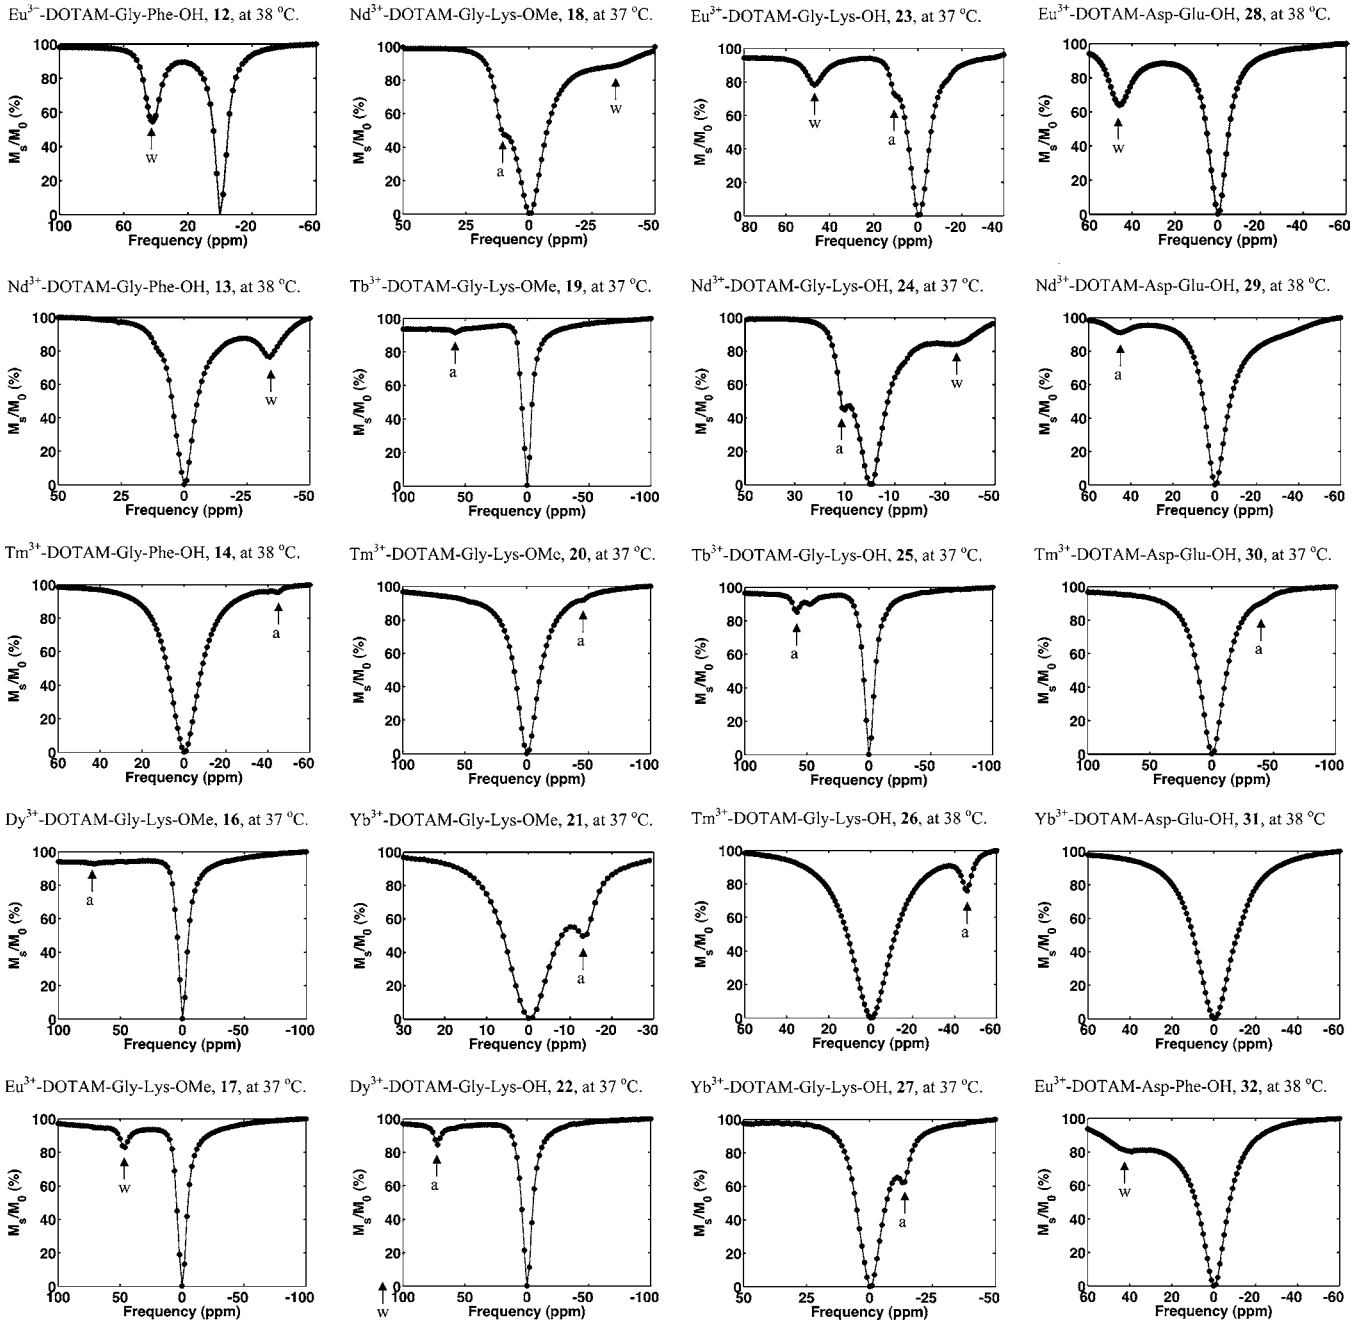

Figure 2. CEST spectra for compounds **12**−**32** determined at 10 mM concentration, pH 7.0. All spectra were collected using a 9.4 T NMR spectrometer with saturation power of 14 μT (saturation time = 10 s) at the temperature indicated. CEST signals due to bound water and amide protons are marked by an arrowhead and denoted (w) or (a), respectively.

bulk water signal, e.g., **24**. In limited circumstances, it is possible to simultaneously observe the signal due to bound water and amide protons under conditions close to physiological pH and temperature (M = Nd^{3+}). One compound did not produce an observable CEST effect (**31**), while another compound could not be measured under the conditions employed due to limited solubility (**15**).

Our methodology can be used to readily prepare a number of ligated metals to examine their potential utility as MRI PARACEST agents. The most strongly bound water signals are found for ligands containing Eu^{3+}. For example, the Eu^{3+}-DOTAM-Gly-Phe-OH complex **12** clearly exhibits bound water saturation at approximately 43 ppm from bulk water. This compound has a large CEST effect (∼45%) at physiological temperature and pH (Figure 2). The chemical shift of the bound water is also sensitive to temperature (0.3 ppm/°C, data not shown), and will be investigated for its ability to measure temperature *in vivo*. The CEST spectrum of Eu^{3+}-DOTAM-Asp-Glu-OH **28** is qualitatively similar to that of Eu^{3+}-DOTAM-Gly-Phe-OH **12**, but with a slightly smaller CEST effect. The bound water signals for the Eu^{3+}-containing complexes **17** and **23** are evident at approximately the same chemical shift (43 ppm) but with weaker intensity, as compared to the aforementioned compounds. Since both Eu^{3+}-DOTAM-Gly-Phe-OH **12** and the Eu^{3+}-DOTAM-Asp-Glu-OH **28** exhibited a large CEST effect from the bound water, we were interested in the effect of combining the nature of the dipeptide; thus, Eu^{3+}-DOTAM-Asp-Phe-OH **32** was prepared and studied. Rather than increasing the CEST effect, this complex only showed a small CEST effect due to the bound water at 43 ppm.

Many of the complexes, especially those containing Tm^{3+}, Tb^{3+}, or Dy^{3+}, exhibit very small CEST effects due to the amide protons (e.g., **14**, **16**, **19**, **20**, **22**, **25**, **30**), yet this is not always the case—a clear CEST signal is observed for **26** (*cf.* **20** and

26). The two complexes, Tm^{3+}-DOTAM-Gly-Lys-OMe **20** and Tm^{3+}-DOTAM-Gly-Lys-OH **26**, highlight the impact of subtle structural changes on the MR properties of the complex. Ligands **8** and **9** differ by the nature of the peripheral groups, the former being a neutral methyl ester and the latter an anionic carboxylate (under the conditions of measurement), but curiously the CEST effect contributed by the amide protons is greater for complexes of **9** for M = Tm^{3+}, Tb^{3+}, and Dy^{3+}. The ytterbium (Yb^{3+}) complex of both **8** and **9**, i.e., Yb^{3+}-DOTAM-Gly-Lys-OMe **21** and Yb^{3+}-DOTAM-Gly-Lys-OH **27**, possesses amide protons that produce a CEST effect at −15 ppm and −18 ppm, respectively. For these complexes, the amide proton saturation is better resolved from the bulk water saturation compared to Nd^{3+}-DOTAM-Gly-Lys-OME **18** and Nd^{3+}-DOTAM-Gly-Lys-OH **24**, making the observation of changes with pH easier. However, saturation of the bound water pool was not detected in the Yb^{3+}-containing complexes. Simultaneous observation of the CEST effect produced by the amide and bound water protons may be an advantage for pH measurement using ratiometric methods (*6*, *7*). A CEST effect was observed simultaneously for bound water and amide protons in several compounds. The Nd^{3+}-DOTAM-Gly-Lys-OMe complex **18** showed a broad CEST signal due to bound water at approximately −35 ppm and an amide CEST effect a 11 ppm, not fully resolved from the bulk water signal. Upon hydrolysis of the terminal ester groups of the ligand and subsequent metalation, the Nd^{3+}-DOTAM-Gly-Lys-OH complex **24** exhibited more clearly resolved CEST effects from bound water (−34 ppm) and amide protons (11 ppm). Both signals are clearly observed under the same experimental conditions. The CEST effect from amide protons is very sensitive to pH (data not shown), which potentially may be used to measure the pH of the environment of the complex (*5*, *6*).

In summary, we have demonstrated a reliable and convergent synthesis of several new dipeptide−DOTAM conjugates. This approach relies largely on available commercial reagents and a minimum of protecting group manipulations. It is easy to imagine extending this approach of diversification of the ligand periphery by incorporating other natural or unnatural amino acids. Each ligand was used to chelate a variety of lanthanide(III) ions, and the resulting complexes were examined for MR-CEST effects. A number of the compounds produced interesting CEST spectra, validating this approach for the discovery of new lead compounds. Currently, we are extending this synthetic approach to the screening of a variety of amino acids for useful PARACEST properties.

ACKNOWLEDGMENT

The authors thank the Natural Sciences and Research Council of Canada (RHEH), the Ontario Research and Development Challenge Fund, and the Canadian Institutes of Health Research Strategic Training Program in Cancer Research and Technology Transfer for supporting this work. Ms. Paula Pittock of the Biological Mass Spectrometry Laboratory at the University of Western Ontario and Mr. Doug Hairsine of the Department of Chemistry Mass Spectral Facility are thanked for expert assistance with collection and analysis of mass spectral data.

Received April 17, 2007; Revised Manuscript Received May 29, 2007

The synthesis of propargylated pentaerythrityl phosphodiester oligomers (PePOs) was achieved using a DNA synthesizer with a bis-propargylated pentaerythritol-based phosphoramidite. An azido fucose derivative was reacted under "click" chemistry conditions activated by microwaves to construct a series of glycosylated PePOs bearing 4, 6, 8, and 10 L-fucose residues. Binding to the fucose-specific bacterial lectin (PA-IIL) was determined for the fucosylated PePOs through an enzyme-linked lectin amplification competition assay. The IC_{50} values measured are 10−20 times better than for monovalent L-fucose and denotate for a "macromolecular" effect rather than a "cluster" effect.

INTRODUCTION

Carbohydrates are involved in numerous biological events such as cell-to-cell communication, signal transduction, and viruses or bacterial infection (*1*−*4*). Lectins are carbohydrate receptors with typically weak affinities for monovalent interactions with K_d values in the millimolar range (*5*−*12*). Multivalency (*13*−*17*) is often required in order to overcome the low affinity observed between carbohydrates and lectins, according to the so-called "cluster effect" (*18*−*26*).

Synthetic organic chemists and biochemists have designed a series of strategies to mimic the "cluster effect" by preparing and studying the binding of glycoclusters (*27*−*59*) to lectins based on various scaffolds such as peptides (*37*, *38*, *57*), glycosides (*34*, *60*), cyclodextrins (*29*, *39*, *43*), pentaerythritol (*28*, *53*), cyclic peptides (*41*, *48*, *51*), or calix[4]arenes (*31*, *35*). Other multivalent carbohydrate macromolecules such as glycopolymers (*61*−*68*) and glycodendrimers (*19*, *69*−*72*) have also been studied for their improved binding to lectins in comparison to monovalent species.

In each family, glycoclusters display a specific geometry and a controlled number of carbohydrate moieties at their surface and appear as promising multivalent carbohydrate structures for studying lectin−carbohydrate interactions. The synthesis of glycoclusters remains rather complicated particularly due to the difficulty of their purification. Nevertheless, there are no examples of glycocluster based on an oligonucleotidic or pseudo-oligonucleotidic scaffold, even though a few examples of glycoconjugates with oligonucleotides (*27*, *44*, *45*, *50*, *73*) have been reported, but these compounds display only a limited number of carbohydrates and do not display a phosphodiester backbone.

We present herein a flexible synthetic approach to afford rapidly and easily fucosylated pentaerythrityl phosphodiester oligomers (PePOs) based on a bis-2,2-saccharidyl-1,3-propanediol phosphodiester scaffold (Figure 1). Their synthesis was based on a combination of oligonucleotide phosphoramidite chemistry on solid support and microwave-assisted click chemistry. The PePOs exhibited only one nucleotide at the pseudo-3′-end as a tag for the determination of glycosylated PePOs concentration by UV analysis. The propargylated PePOs were conveniently prepared using a phosphoramidite dialkyne building block, which was coupled several times using a DNA-like synthesis on solid support. Carbohydrate moieties were then introduced from their azide derivatives by 1,3-dipolar cycloaddition (*74*−*82*) according to our previously reported procedure (*83*−*85*) leading to the desired PePOs glycoclusters. The solid-supported oligonucleotidic automated synthesis allows for a rapid and efficient preparation of propargylated PePOs with control of the number of propargyl residues. An excess of reagents can be used to reach quantitative yields for each cycle with washings to remove them. Click chemistry on a solid support is an efficient method for the rapid and efficient multiple labeling with azido carbohydrate derivatives. Finally, the cleavage from the solid support was achieved with concomitant deprotection of the glycosylated PePOs which were used without further purification. The thymidine residue introduced at the pseudo-3′-end allows for the determination of the quantity of material present in the final solution.

Fucosylated PePOs bearing 4, 6, 8, and 10 carbohydrate residues were synthesized as potential ligands for *Pseudomonas aeruginosa* lectin (PA-IIL). Recently, a series of bacterial lectins

have been identified that display micromolar affinities for their ligands (*86*). Among them, PA-IIL has been identified in *Pseudomonas aeruginosa*, an opportunistic bacterium that is life-threatening for immunosuppressed and cystic fibrosis patients and that displays increasing resistance to antibiotics. PA-IIL is a fucose-binding lectin that has been well-characterized for its high affinity for fucose (*87*, *88*) and its interaction with other monosaccharides (*89*) and oligosaccharides (*90*). The lectin is a tetramer, and the high avidity provided by multivalent ligands could make these compounds of interest for anti-adhesive therapy against bacterial infection.

EXPERIMENTAL PROCEDURES

Material and Methods. Thin-layer chromatography (TLC) was carried out on aluminum sheets coated with silica gel 60 F_{254} (Merck). TLC plates were inspected by UV light ($\lambda = 254$ nm) and developed by treatment with a mixture of 10% H_2SO_4 in EtOH/H_2O (1/1 v/v) followed by heating. Silica gel column chromatography was performed with Geduran silica gel Si 60 (40−63 μm) purchased from Merck (Darmstadt, Germany). ^{1}H and ^{13}C NMR spectra were recorded at 23 °C using Bruker Advance DRX300 or DRX500 spectrometers with the residual solvent as the internal standard. The following abbreviations are used to explain the observed multiplicities: s, singlet; d, doublet; dd, doublet of doublet; ddd, doublet of doublet of doublet; t, triplet; td, triplet of doublet; q, quadruplet; m, multiplet; br, broad; p, pseudo. Structure elucidation was deduced from 1D and 2D NMR spectroscopy which allowed, in most cases, complete signal assignments based on COSY, HSQC, and HMBC correlations. NMR solvents were purchased from Euriso-Top (Saint Aubin, France). HRMS (LSIMS) mass spectra were recorded in the positive mode using a Thermo Finnigan Mat 95 XL spectrometer. MS (ESI) mass spectra were recorded in the positive mode using a Thermo Finnigan LCQ spectrometer. Optical rotations were measured using a Perkin-Elmer polarimeter. MALDI-ToF spectra were recorded on a PerSeptive Biosystem Voyager DE apparatus using 2′,4′,6′-trihydroxyacetophenone as a matrix.

***O*-(4,4′-Dimethoxytrityl)-Pentaerythritol 1**. Pentaerythritol (2.7 g, 20 mmol) was dried by coevaporation in dry pyridine (3 × 10 mL) and then dissolved in dry pyridine (120 mL). Dimethoxytrityl chloride (5.42 g, 16 mmol) was added to the solution, and the reaction was stirred at room temperature for 16 h. The reaction was quenched with methanol (2 mL), stirred for 10 min, and then poured into aqueous saturated $NaHCO_3$ (300 mL). The aqueous layer was extracted with CH_2Cl_2 (3 × 150 mL). The organic layers were combined, dried (Na_2SO_4), filtered, and evaporated. The residue was purified by chromatography on silica gel (CH_2Cl_2/MeOH 99:1 to 94:6, v/v) affording the monotritylated pentaerythritol **1** (2.2 g, 30%) as a pale yellow foam. $R_f = 0.50$ (CH_2Cl_2/MeOH, 9:1, v/v). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 2.36 (br s, 3H), 3.10 (s, 2H), 3.65 (br s, 6H), 3.71 (s, 6H), 6.74−7.31 (m, 13H). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 45.3, 53.5, 55.2, 63.9, 64.6, 86.5, 113.3, 127.0, 128.0, 130.0, 135.6, 144.6, 158.6.

1-*O*-(4,4′-Dimethoxytrityl)-2,2-bis-propargyloxymethyl-1,3-propanediol 2. Sodium hydride (1.16 g, 29.1 mmol, 60% in oil) was added at 0 °C to a solution of monotritylated pentaerythritol **1** (2.2 g, 4.8 mmol) in dry THF (30 mL). The reaction was stirred for 10 min before adding propargyl bromide (3.3 mL, 29.1 mmol, 80% in toluene) at room temperature (rt). The resulting milky solution was stirred for an additional 3 h at rt. The solution was diluted with CH_2Cl_2 (80 mL), and the organic layer was washed with cold water (50 mL), brine (50 mL), and then dried (Na_2SO_4), filtered, and evaporated. The residue was purified by chromatography on silica gel (CH_2Cl_2/MeOH 99.5:0.5 to 97:3, v/v) affording the bis-propargylated pentaerythritol **2** (2.2 g, 89%) as pale yellow foam. $R_f = 0.45$ (cyclohexane/CH_2Cl_2/Et_3N, 7:2:1, v/v/v). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 2.35 (m, 3H), 3.05 (s, 2H), 3.48−3.60 (m, 6H), 3.70 (s, 6H), 4.02 (s, 4H), 6.73−7.26 (m, 13H). ^{13}C NMR ($CDCl_3$, 100 MHz): δ 11.7, 45.1, 46.3, 53.5, 55.2, 58.7, 62.3, 65.3, 70.3, 74.5, 86.0, 113.0, 113.1, 126.7, 127.8, 128.2, 129.2, 130.1, 136.0, 145.0, 158.4. HRFABMS (positive mode, nitrobenzylic alcohol) *m/z*: calcd for $C_{32}H_{34}O_6$ $[M + H]^+$ 514.2355, found 514.2365.

3-(4,4′-Dimethoxytrityloxy)-2,2-bis(propargyloxymethyl)-propyl (2-cyanoethyl *N*,*N*-diisopropyl)-phosphoramidite 3. Alcohol **2** (680 mg, 1.32 mmol) and diisopropylammonium tetrazolide (113 mg, 0.66 mmol) were dried three times by coevaporation with anhydrous acetonitrile, then dissolved in anhydrous CH_2Cl_2 (8 mL) before addition of 2-cyanoethyl tetraisopropylphosphorodiamidite (503 μL, 1.58 mmol) at rt. The resulting mixture was stirred at room temperature for 3 h, then diluted with EtOAc (50 mL). The organic layer was washed with brine (2 × 100 mL), dried (Na_2SO_4), filtered, and evaporated. The residue was purified by chromatography on silica gel (cyclohexane/CH_2Cl_2 100/0 to 80/20 with 4% Et_3N) affording the phosphoramidite **3** (800 mg, 85%) as an oil. $R_f =$ 0.60 (cyclohexane/CH_2Cl_2/Et_3N, 7:2:1, v/v/v). ^{1}H NMR ($CDCl_3$, 200 MHz): δ 1.15−1.24 (m, 12H), 2.40 (m, 2H), 2.54 (t, 2H, $J = 6.5$ Hz), 3.15 (br s, 2H), 3.45−3.74 (m, 10H), 3.81 (s, 6H), 4.09−4.12 (m, 4H), 6.76−7.49 (m, 13H). ^{13}C NMR ($CDCl_3$,-100 MHz): δ 20.3, 20.4, 24.6, 24.6, 26.92, 26.93, 29.7, 30.2,

30.3, 43.0, 43.1, 43.5, 45.5, 45.6, 46.3, 53.4, 55.2, 58.2, 58.4, 58.6, 58.7, 61.2, 62.2, 62.4, 69.4, 74.1, 74.2, 80.0, 85.6, 112.9, 117.7, 126.6, 127.6, 128.3, 130.3, 136.3, 145.3, 158.3. ^{31}P NMR ($CDCN_3$, 80 MHz): δ 148.6. HRFABMS (positive mode, nitrobenzylic alcohol) *m/z*: calcd for $C_{41}H_{52}O_7N_2P_1$ $[M + H]^+$ 715.3512, found 715.3522.

8-Azido-3,6-dioxapent-1-yl 2,3,4-tri-*O*-acetyl-α-L-fucopyranoside 5. A solution of L-fucose (1 g, 6.1 mmol) and 2-[2-(2-chloroethoxy)ethoxy]ethanol (3 mL, 20.6 mmol) was stirred at rt for 5 min, followed by the dropwise addition of BF_3·Et_2O (1.54 mL, 12.2 mmol). The reaction mixture was stirred at 100 °C for 5 h, and the solution turned yellow then dark brown. The crude mixture was then poured into pyridine (35 mL), and acetic anhydride (7 mL) was then added at 0 °C. The solution was stirred at rt for 48 h, then poured into iced water (100 mL), and the aqueous layer was extracted with EtOAc (150 mL). The organic layer was washed with water (100 mL), then saturated aqueous $NaHCO_3$ (100 mL), and then dried (Na_2SO_4), filtered, evaporated to dryness, and coevaporated with toluene (4 × 30 mL). The oily residue was purified by flash silica gel column chromatography (CH_2Cl_2 then CH_2Cl_2/EtOAc 4:1) to afford the intermediate 1-chloro-3,6-dioxapent-8-yl 2,3,4-tri-*O*-acetyl-L-fucopyranoside **4** (718 mg) as a colorless oil and as an α/β (3:1) mixture of anomers. A solution of **4** (718 mg, 1.63 mmol), sodium azide (1.06 g, 16.3 mmol), and *n*-tetrabutylammonium iodide (300 mg, 0.81 mmol) in DMF (20 mL) was stirred at 90 °C for 16 h. The solution was diluted with water (100 mL) and the aqueous layer extracted with CH_2Cl_2 (2 × 150 mL). The organic layers were combined, dried (Na_2SO_4), filtered, and evaporated to dryness. The oily residue was purified by flash silica gel column chromatography (hexane/$CHCl_3$ then hexane/$CHCl_3$/acetone 2:1:1) to afford **5** (441 mg, 16%) as a pale yellow oil. A first crop of the α anomer (113 mg) was obtained, followed by two additional crops of 226 mg and 102 mg of α/β mixture of anomers in 4:1 and 1:1 ratios, respectively. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 1.13 (d, 3H, $J_{6,5}$ = 6.6 Hz, H-6), 1.98, 2.07, 2.16 (3s, 3 × 3H, 3 × C*H*$_3$CO), 3.40 (t, 2H, J = 5.2 Hz, C*H*$_2$N$_3$), 3.60−3.85 (m, 11H, OC*H*$_2$, H-5), 4.23 (q, 1H, $J_{5,6}$ = 6.6 Hz, H-5), 5.10−5.17 (m, 2H), 5.30 (dd, 1H, $J_{2,1}$ = 1.1 Hz, $J_{2,3}$ = 3.4 Hz, H-2), 5.34−5.40 (m, 1H).

General Procedure for the Automated Synthesis of Propargylated PePOs 6a−d. The syntheses of propargylated PePOs **6a−d** were performed on a DNA synthesizer (381A, ABI) on 1 μ molar scale using standard phosphoramidite chemistry with commercial LCAA-CPG solid-supported 5′-*O*-dimethoxytrityl-thymidine (500 Å) and phosphoramidite **3**. The pseudo-oligonucleotidic chain elongation cycle was as follows: Dedimethoxytritylation was performed with trichloroacetic acid (3% in CH_2Cl_2) for 60 s; coupling was performed with **3** (0.09 M in acetonitrile, 18 molar eq) activated with benzylthiotetrazole (0.3 M in acetonitrile) for 60 s; oxidation was performed with I_2 (0.1 M in THF/pyridine/water 90:5:5, v/v/v) for 20 s; and capping was performed with a 1:1 solution of Cap A (Ac_2O in pyridine/THF 1:1:8, v/v/v) and Cap B (10% *N*-methylimidazole in THF) for 16 s. An average yield of phosphoramidite coupling of >98.5% was obtained.

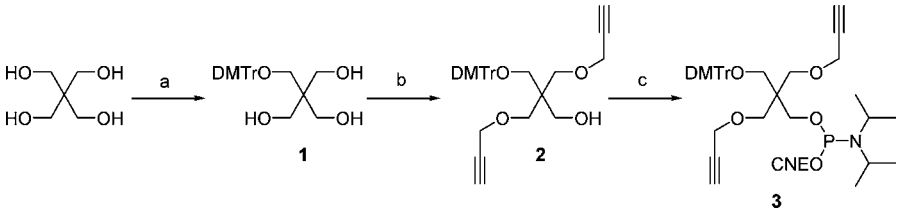

Table 1. Quantities and MALDI-ToF Data Obtained for PePOs 8a−d

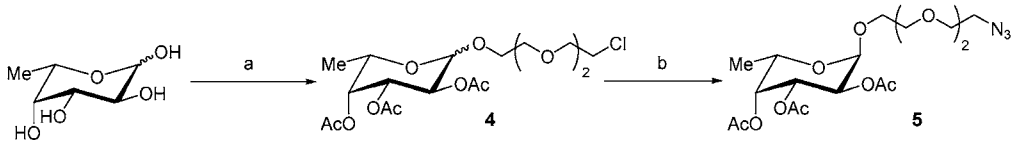
glycosylated PePOs	quantity obtained (mg)	number of moles (μmol)	$[M - H]^-$ calcd	$[M - H]^-$ found
8a	0.88	0.43	2074.99	2075.29
8b	1.89	0.63	2991.87	2992.12
8c	2.43	0.62	3908.75	3908.22
8d	2.77	0.57	4825.63	4825.43

General Procedure for the Synthesis of Fucosylated PePOs 8a−d. Solid-supported propargylated PePOs **6a−d** were transferred into a microwave vial; and azido fucose derivative **5** (0.6 M in MeOH, 5 molar equiv per alkyne), $CuSO_4$ (0.1 M in water, 0.2 molar equiv per alkyne), and sodium ascorbate (0.25 M in water, 1 molar equiv per alkyne) were added, and the solution was completed with water and MeOH to obtain a final volume of 200 μL water/MeOH (1/1). The vial was sealed, then irradiated with microwaves for 30 min at 60 °C to afford **7a−d**. Treatment of the beads with concentrated aqueous ammonia for 2 h at rt afforded the fucosylated PePOs **8a−d**. The concentration of the glycosylated PePOs was determined by UV measurement at 260 nm based on the extinction coefficient of thymidine (ϵ^{260nm} = 8700 L.mol^{-1}.cm^{-1}) and characterized by MALDI-ToF mass spectrometry (Table 1).



ELLA (Enzyme-Linked Lectin Assay) Experiments. ELLA experiments were conducted using 96-well microtiter plates (Nunc Maxisorb) coated with polymeric α-L-fucose (5 μg/mL; Lectinity Holding, Inc., Moscow) diluted in carbonate buffer, pH 9.6 (100 μL), for 1 h at 37 °C. After blocking at 37 °C for 1 h with 100 μL per well of 3% (w/v) BSA in PBS (pH 7.4), plates were incubated at 37 °C for 1 h with 100 μL of biotinylated PA-IIL at 0.1 μg/mL in the presence of an increasing amount of competitors **8a−d**. After washing with T−PBS (PBS containing 0.05% Tween), 100 μL of streptavidin−peroxidase conjugate (dilution 1:10 000; Boehringer-Mannheim) was added and left for 1 h at 37 °C. The color was

developed using 100 μL per well of 0.05 M phosphate/citrate buffer containing *O*-phenylenediamine dihydrochloride (0.4 mg/mL) and urea hydrogen peroxide (0.4 mg/mL) (Sigma-Aldrich). The reaction was stopped by the addition of 50 μL of 30% H_2SO_4. Absorbance was read at 490 nm using a microtiter plate reader (Bio-Rad; model 680).

RESULTS AND DISCUSSION

The PePOs display a pentaerythritol residue between each phosphodiester linkage providing two functional groups with a high geometrical flexibility for an optimal arrangement of the ligands through space in order to reach high affinities. A triethylene glycol linker between the saccharide and the triazole was selected for its hydrophilic properties for a better display of the carbohydrate moieties on the periphery of the glycocluster.

Preparation of the Building Blocks. Automated synthesis requires orthogonally protected multifunctional scaffolds where each functional group can be activated selectively for reacting with the next entity. Pentaerythritol was selected as a tetrafunctional molecule which can be easily desymmetrized through simple reaction schemes. Monoprotection of pentaerythritol with dimethoxytrityl chloride provided the triol **1** (Scheme 1) (*91*). Alkylation of **1** using a large excess of propargyl bromide yielded the bis-propargylated alcohol **2** in good yield. Reaction of alcohol **2** with 2-cyanoethyl tetraisopropylphosphorodiamidite activated with diisopropylammonium tetrazolide provided the expected phosphoramidite **3**. This molecule is presenting a masked alcohol and a phosphoramidite moiety for the DNA-like chain elongation, as well as two propargyl residues for a further conjugation with carbohydrate azide derivatives using a [3+2]-cycloaddition reaction (*83*, *85*).

The synthesis of azido-carbohydrates is required for their conjugation by click chemistry on the propargyl residues. The control of the anomeric configuration of sugars is often crucial for optimal and selective binding to lectins. The *O*-acyl or Fischer stereoselective glycosylation methods were selected for the preparation of the α-L-fucoside derivative (Scheme 2). Glycosylation of L-fucose with chlorotriethylene glycol under Fischer conditions afforded a mixture of anomers (α/β 3/1), which was directly peracetylated to obtain L-fucoside **4**. The separation of each anomer was unsuccessful at that point. Subsequent azidation of **4** afforded the corresponding azide derivative **5** (*92*) with the same α/β distribution. Each anomer was isolated pure after a flash silica gel column chromatography.

Solid-Supported Synthesis of PePOs. The dialkyne phosphoramidite building block **3** was coupled starting from a commercial solid-supported thymidine applying a phosphoramidite elongation cycle on a DNA synthesizer. The thymidine present at the pseudo-3′-end of the polyglycosyl nucleic acid was used as a UV tag for HPLC analyses, as well as for the determination of concentrations in material in solution. The thymidine functionalized beads were subjected to a standard sequence of detritylation, phosphoramidite coupling under benzylthiotetrazole activation, oxidation, and capping used for the synthesis of oligonucleotides (Scheme 3). This cycle was repeated 2, 3, 4, and 5 times to obtain the oligoalkyne nucleic acids **6a**−**d**, respectively. After elongation, 1,3-dipolar cycloaddition was achieved on solid support (*83*, *85*) using the α-L-

Table 2. Competition of Binding of PA-IIL to Polymeric α-L-Fucose with the Fucosylated PePOs 8a−d

fucosylated PePOs	valency	IC_{50} (μM)	relative potency[a]	potency per fucose residue[b]
L-fucose[c]	1	5.60	1	1.0
8a	4	0.70	8	2.0
8b	6	0.40	14	2.3
8c	8	0.35	16	2.0
8d	10	0.25	22.4	2.2

[a] Calculated as the ratio of L-fucose to glycosylated PePOs IC_{50} values. [b] Calculated as the ratio of relative potency to the number of fucose residues. [c] L-Fucose was selected as the monovalent reference for the comparison of IC_{50} values.

fucoside azide derivative **5** to obtain the fully protected glycosylated PePOs **7a−d**. Aminolysis of the protecting groups (i.e., acetates and cyanoethyls) and concomitant cleavage from the solid support using concentrated aqueous ammonia afforded the fully deprotected glycosylated PePOs **8a−d** in solution with high purity and good yield. Each glycocluster was analyzed by HPLC and characterized by MALDI-ToF mass spectrometry (see Supporting Information). The quantities of available materials in solution were determined by UV measurements at 260 nm based on the extinction coefficient of thymidine.

Binding Studies. The affinity of the glycosylated PePOs for PA-IIL was studied using an enzyme-linked lectin assay (ELLA). The fucosylated PePOs **8a−d** were evaluated for binding to PA-IIL. A clear inhibition of the fixation of the lectin on the polymeric α-L-fucose was observed. The results obtained show that multivalency is responsible for an improved binding to the lectin (Table 2). The negative charges present on the phosphodiester linkages of the fucosylated PePOs **8a−d** did not prevent binding to the lectin. PA-IIL is a tetramer in solution, with each monomer requiring two calcium ions for binding fucose (*93*). These multivalent structures are good ligands of PA-IIL, since the IC_{50} values measured for the fucosylated PePOs are in the submicromolar range (0.25−0.70 μM) in comparison with the value observed for L-fucose of 5.6 μM. The higher affinity observed for these multivalent scaffolds in comparison to monovalent species (L-fucose) may also be explained by a relatively high flexibility and a good distribution of the L-fucose moieties on the PePOs due to a good solubility of the phosphodiester and ethylene glycol linkages in aqueous media, providing large freedom of movement to the ligands in solution. The number of carbohydrate residues displayed on the nucleic acid-like backbone is slightly influencing the binding to the lectin, and 6 to 8 fucose residues appear to be sufficient for a high interaction with PA-IIL, since a plateau was almost reached.

The enhancement observed cannot be attributed to a "cluster" effect, since the potency per carbohydrate is only of 2 for every multivalent ligand **8a−d**, regardless of the number of fucose residues. The increased binding of these multivalent carbohydrate ligands is more likely to be attributed to the recently described "macromolecular" effect (*36*).

Avidin−Biotin−PEG−CPA Complexes as Potential EPR-Directed Therapeutic Protein Carriers: Preparation and Characterization

Shan Ke,[†,‡] John C. Wright,[†] and Glen S. Kwon*[,‡]

Department of Chemistry, University of Wisconsin−Madison, 1101 University Avenue, Madison, Wisconsin 53706-1322, and Division of Pharmaceutical Sciences, School of Pharmacy, University of Wisconsin−Madison, 777 Highland Avenue, Madison, Wisconsin 53705-2222. Received May 21, 2007; Revised Manuscript Received July 10, 2007

Bovine carboxypeptidase A (CPA) conjugated with biotinylated poly(ethylene glycol) (PEG) has been synthesized and characterized in terms of stoichiometry and half-life of the avidin−biotin−PEG(s)−CPA complex. The half-lives for dissociation are 3.34 days for the avidin−biotin−PEG(3400)−CPA 1:1 complex, 3.65 days for the avidin−biotin−PEG(5000)−CPA 1:1 complex, 3.91 days for the avidin−biotin−PEG(3400)−CPA−PEG(2000) 1:1 complex, and 2.74 days for the avidin−biotin−PEG(5000)−CPA−PEG(2000) 1:1 complex. The slow dissociation demonstrates the stability of complexes using a PEGylated biotin terminus as a linker with avidin. The stoichiometry of the biotin−PEGylated CPA with avidin was determined by the 2,6-ANS method, and the results are consistent with measurements of the stoichiometry using size exclusion chromatography. The stoichiometries are 1:2 for the avidin−biotin−PEG(3400)−CPA complex and the avidin−biotin−PEG(3400)−CPA−PEG(2000) complex, 1:1 for the avidin−biotin−PEG(5000)−CPA complex, and 1:4 for the avidin−biotin−PEG(5000)−CPA−PEG(2000) complex. These findings stress both the importance of the length of a PEG chain as an appropriate spacer between the biotin terminus and a functional group, and the great potential of the avidin−biotin−PEGylated-protein complex as a therapeutic protein delivery system for solid tumor prodrug targeting.

INTRODUCTION

Successful applications of chemotherapy for clinical cancer treatments are limited by deficient drug cytotoxic concentration and systemic toxicity arising from low selectivity for tumors over the normal cells (*1*). Antibody-directed enzyme prodrug therapy (ADEPT) has been explored as an answer to the challenge of delivering sufficient cytotoxic reagents to tumor tissues in the monoclonal antibody therapies for solid tumors (*2*−*4*). The benefit from the ADEPT is based on a catalytic conversion of a large number of prodrug molecules into cytotoxins by each targeted enzyme. However, even though monoclonal antibodies recognize certain proteins that are found on the surface of some cancer cells, so far the most striking understanding in monoclonal antibody therapy is that only 1 to 10 parts per 100 000 of the administered monoclonal antibodies can reach the target in vivo (*1*, *5*).

The enhanced permeability and retention (EPR) effect is another important method in antitumor drug delivery. This method exploits the ineffective tumor lymphatic drainage, and the defective vessels within and between the endothelium and basement membranes of various tumors, where the macromolecules can extravasate more easily and localize in the tissue intrastitial space. Through the EPR effect, the prolonged plasma circulation of macromolecules such as the polymer-conjugated drugs leads to significant passive tumor targeting (*6*−*8*).

We propose a new EPR-directed enzyme prodrug therapy (EDEPT) based on the EPR effect of macromolecules. Bovine carboxypeptidase A (CPA) was chosen as the prototype of our series of targeted enzymes. The capacity of CPA to hydrolyze the first peptide or amide bond at the carboxyl or C-terminal end of proteins and peptides offers an important way to generate the active methotrexate (MTX) from the inactive prodrug of MTX, such as Phe-MTX (*9*, *10*). Ideally, the release of the cytotoxic MTX only occurs in the vicinity of tumor cells, thereby sparing normal cells from concomitant destruction. This type of drug release might be accomplished by pretargeting CPA to the tumors through the EPR effect.

In the field of polymer-conjugated drugs, poly(ethylene glycol) (PEG) is a highly investigated polymer. PEG's importance in pharmaceutical and biotechnical applications originates from its modification of biological macromolecules, such as peptides and proteins. The potential benefits include shielding these macromolecules from being uptaken by the reticuloendothelial system (RES), decreasing the protein immunogenicity, and preventing recognition and degradation by proteolytic enzymes (*11*−*13*). Moreover, PEG modification also increases the apparent size of an enzyme and thus reduces the renal filtration of the enzyme (*14*).

Previous research on PEGylated CPA has demonstrated that CPA conjugated with two PEG chains has a much higher accumulation in a tumor than CPA conjugated with one PEG chain because the former's plasma circulation time is longer (*15*). Also, positive tumor accumulation of a non-biodegradable poly(vinylpyrrolidone) polymer occurs when it is administered using a molecular weight greater than the glomerular filtration threshold of ∼87 000 Da (*16*, *17*). Therefore, we attempted to increase the molecular weight of CPA above the glomerular filtration threshold by PEGylation to prolong the plasma circulation time. However, to achieve a high tumor-to-blood ratio, the concentration of a PEGylated CPA in the circulation system must be kept as low as possible. Since the removal of PEG or PEGylated proteins depends primarily on the renal filtration, it is necessary to keep the molecular weight of PEGylated CPA smaller than the glomerular filtration threshold. To solve this dilemma, we propose using an avidin−biotin−PEG−CPA complex system as a potential drug delivery system (DDS) for EDEPT. We hypothesize that the ideal avidin−

biotin−PEG−CPA complex with a molecular weight higher than the glomerular filtration threshold might dissociate avidin and biotin−PEG−CPA in the circulation system and be cleared by the renal system, but also that the half-life of the avidin−biotin−PEG−CPA complex might be sufficiently long for significant tumor accumulation.

The avidin−biotin system has an extremely high binding affinity and has been explored as a molecular linker apparatus in biosensors, purifications, and syntheses of important molecules for biotechnology (*18*, *19*). Yet such strong avidin−biotin binding interaction also limits the applications of the system in some fields requiring facile capture and release (*20*). Research on the effects of biotinylated derivatives on the binding constant has been reported (*21*). For example, PEGylated biotin has a lower affinity with avidin than biotin (*22*). Our previous research on intermolecular interactions of avidin and PEGylated biotin demonstrates that a PEG chain can alter not only the affinity but also the stoichiometry of the avidin−biotin complex system. Following these findings, in this work we focused our research on (i) increasing the molecular weight of CPA by biotin−PEGylation and successive formation of the avidin−biotin−PEG−CPA complexes, and (ii) adjusting the stoichiometry and the half-life of the avidin−biotin−PEG−CPA complex systems by the PEG chains. The aim is for novel, reversible, and nonimmunogenic complexes as a DDS for EDEPT.

EXPERIMENTAL PROCEDURES

Materials. Commercially available analytical grade or higher materials were used, except for the aqueous crystalline suspension of bovine carboxypeptidase A (CPA) and the PEGylated biotins. Bovine CPA, D-biotin, and hippuryl-L-phenylananine (hipp-L-phe) were obtained from Sigma (St. Louis, MO). Avidin was purchased from Pierce (Rockford, IL). PEG(2000)-SPA, biotin−PEG(3400)-NHS, and biotin−PEG(5000)-NHS were obtained from Nektar (Huntsville, AL). 2,6-Anilinonaphthalenesulfonate (2,6-ANS) was obtained from Molecular Probes (Carlsbad, CA).

PEGylation of CPA. CPA was obtained as an aqueous crystalline suspension and purified as described elsewhere (*23*). Briefly, the crystals were washed with Millipore pure water and centrifuged three times. The protein pellet was collected. Bicarbonate buffer with a high salt concentration (0.5 M $NaHCO_3$/0.5M NaCl, pH 8.0) was added until the entire protein pellet dissolved. This CPA bicarbonate buffer solution was then sterile-filtered with a 0.4 μm filtration disc from Millipore to remove the insoluble impurities. The concentration of the CPA solution was determined by the absorption at 278 nm using the molar absorptivity of 6.41×10^4 M^{-1} cm^{-1}. The CPA solution was stored at 4 °C until use.

Biotin−PEG(3400)−CPA was prepared by conjugating CPA with the *N*-hydroxysuccinamide ester of biotinylated PEG 3.4 kDa (biotin−PEG(3400)-NHS). Biotin−PEG(3400)-NHS solution was prepared in the same bicarbonate buffer and immediately added dropwise into a 0.20 mM stirred CPA solution, which was cooled by incubation in an ice bath. A sufficient yield of biotin−PEG(3400)−CPA was achieved using a 1.25:1 reaction molar ratio of biotin−PEG(3400)-NHS to CPA with a 120 min PEGylation time. PEGylation of CPA with biotin−PEG(5000)-NHS was performed using the same reaction conditions.

Biotin−PEG(3400)−CPA−PEG(2000) and biotin−PEG(5000)−CPA−PEG(2000) were prepared in two steps. First, CPA was PEGylated using a succinimidyl propionate derivative of PEG, PEG(2000)-SPA, by the same PEGylation conditions described above. After CPA−PEG(2000) was separated and collected through SEC (the concentration of CPA−PEG(2000) decreased to $\sim 10^{-6}$ M), we PEGylated CPA−PEG(2000) immediately with biotin−PEG(3400)-NHS or biotin−PEG(5000)-NHS at a 2:1 reaction molar ratio of PEG-NHS/CPA−PEG.

Purification of Biotin−PEGylated CPA. The purification of biotin−PEGylated CPA was achieved by size-exclusion chromatography (SEC) on an ÄKTA fast protein liquid chromatograph (FPLC) system (Pharmacia, Piscataway, NJ). The PEGylation mixtures were loaded directly into a Superose 12/30 HR column preequilibrated by PBS buffer. The elution buffer was also PBS buffer (pH 7.4) with a flow rate 0.50 mL/min, and the UV detector measured the absorbance at 280 nm. The fractions of the targeted biotin−PEGylated CPAs were collected and stored at 4 °C until use.

Because the ultraviolet−visible spectra of biotin−PEG(3400)−CPA, biotin−PEG(5000)−CPA, biotin−PEG(3400)−CPA−PEG(2000), and biotin−PEG(5000)−CPA−PEG(2000) are the same as that of native CPA, the concentrations of these four biotin−PEGylated CPAs were first roughly determined by the absorption at 278 nm using the molar absorptivity of native CPA. After determining the stoichiometry of the binding of their avidin complexes, their concentrations were measured using a displacement titration where a standard D-biotin or a biotin−PEGylated CAP titrant displaced weakly bound 2,6-ANS from the fluorescent 2,6-ANS-avidin complex.

The molecular weight and the degree of the PEGylation of the purified biotin−PEGylated CPA were determined by MALDI−TOF mass spectroscopy using a Bruker REFLEX II (Billirica, MA), equipped with a reflectron, a 337 nm nitrogen laser, and delayed extraction. Native CPA was used as the external calibrant, and the matrix chosen for this study was a freshly prepared, saturated sinapic acid solution in acetonitrile/water (50% V/V). Briefly, the sample solutions were prepared before measurement with a typical concentration of 1 mg/mL. A 1 μL amount of the matrix and sample were mixed in a spot plate, and then a 0.5 μL sample of the mixture was deposited on the target. Analysis was performed using the reflectron mode, and the results were averaged over at least 50 shots with the laser power just above the threshold of ion formation/desorption. In particular, the samples of biotin−PEGylated CPAs for MALDI−TOF mass spectroscopy were specially purified by SEC using the volatile ammonium acetate buffer as the elution solution (*24*).

Quantitative Assay for Stoichiometry of Biotin−PEGylated CPA with Avidin. Two biotin-binding assays were exploited to determine the stoichiometry of the binding of biotin−PEG(s)−CPA with avidin. The first was based on the use of the dye 2,6-anilinonaphthalene sulfonate (ANS), which binds to avidin and can be removed by the addition of biotin or biotinylated derivatives (*25*). D-Biotin solution was prepared as the primary standard to titrate the avidin solution. The standardized avidin solution was then used as the secondary standard to titrate the unknown biotin−PEG(s)−CPA solutions. Generally, we added the primary standard D-biotin solution or the unknown biotin−PEGylated CPA solution in increments to 20 mL of a PBS buffer containing about 0.50 nmol of avidin and 10 nmol of 2,6-ANS. After each addition, the fluorescence was excited at 328 nm (bandwidth of 10 nm) and measured at 408 nm (bandwidth of 10 nm), using a Shimadzu RF-1501 spectrofluorophotometer (Shimadzu, Tokyo 101-8448, Japan). A typical titration required ~1.5 h.

The second assay was based on the SEC chromatography of the avidin−biotin−PEG−CPA complexes. Briefly, 0.50 mL 1×10^{-6} M avidin PBS solutions were added with various amounts of biotin−PEG(s)−CPAs that the ratios of the two mixture components ranged from 0.5 to 6. After 24 h incubation at room temperature to ensure the equilibrium, these mixture solutions were loaded into a Superose 12/30 HR column in the

ÄKTA FPLC system to perform the SEC chromatography. A quantitative evaluation of the biotin/avidin stoichiometry was achieved from the presence of the peaks of 1:1, 1:2, 1:3, or 1:4 avidin−biotin−PEG(s)−CPA complexes in the SEC chromatography against the molar ratio of avidin/biotin−PEG−CPA. PBS buffer (pH 7.4) was employed as the elution buffer with a flow rate 0.50 mL/min and the absorbance was measured at 280 nm.

Quantitative Assay for Half-Life of Avidin−Biotin−PEG(s)−CPA Complex. Of the four avidin−biotin−PEG(s)−CPA complexes, the 1:1 avidin−biotin−PEG(s)−CPA complex has the longest half-life and was chosen for our dissociation rate constant investigation. The 1:1 avidin−biotin−PEG(s)−CPA complex was purified and collected by SEC separation after biotin−PEG(s)−CPA and avidin were mixed with a 1:1 molar ratio in PBS buffer for ∼2 h at room temperature. Once a 1:1 complex was collected, the kinetic dissociation rate constant k_{off} was immediately analyzed from the active ligand displacement by adding D-biotin (∼500 mol/mol of avidin) to 30 mL ∼5 × 10^{-7} M 1:1 avidin−biotin−PEG(s)−CPA complex solution. Since a large excess of D-biotin prevented reassociation of biotin−PEG(s)−CPA with avidin, the dissociation became first order with respect to the concentration of the 1:1 avidin−biotin−PEG(s)−CPA complex. Aliquots of 300 μL mixture were loaded to a Superose 12/30 HR column in the FPLC ÄKTA system to monitor the relative concentrations of 1:1 avidin−biotin−PEG(s)−CPA complexes after the indicated incubation times (recorded from the introduction of excess D-biotin) at room temperature. The hydrolysis product of PEG(3400)-NHS or NHS was utilized as the internal standard to remove any effects of drift in the FPLC system during the long measurement period. The natural logarithm of the relative peak height of the avidin−biotin−PEG(s)−CPA complex compared with the internal standard was plotted against the incubation times. From the slope of the plot, k_{off} and the half-life were determined. Since the peaks of 1:1 avidin−biotin−PEG(s)−CPA complexes overlap with the peaks of avidin and biotin−PEG(s)−CPAs in SEC chromatography, OriginPro 7.0 Gaussian peak fitting software was applied to deconvolute these overlapped peaks.

Surface Plasmon Resonance (SPR) for Half-Life of Streptavidin-Biotin−PEG(s)−CPA Complex. SPR analysis was performed using a Biacore 2000 with a streptavidin (SA) sensor chip. The SA sensor chips were docked into the instrument and were preconditioned by applying three consecutive 1-min injections of 1.0 M NaCl in 50 mM NaOH solution with running PBS buffer at 20 μL/min. After that, the flow rate was adjusted to 10 μL/min, and 10 μL of biotin−PEGylated CPA solution with the concentration on the order ∼10^{-6} M in PBS buffer was injected. SPR measurements were made using standard procedures.

Previous research shows that the binding between avidin and PEGylated biotin is temperature dependent (*26*), and all data in the present study were specifically collected at 24 °C.

RESULTS

PEGylation of CPA. Because none of both the fifteen lysine groups and C-terminal carboxylic acid on CPA is involved in its enzymatic hydrolysis of the peptide bond, PEGylation was performed using biotin−PEG-NHS to conjugate lysine ϵ-NH_2 groups or C-terminal carboxylic acid on CPA (*27*). PEGylated CPAs with one biotin terminus were chosen for study to delete the unwanted cross-linked products when we formulated the avidin−biotin−PEG(s)−CPA complexes. After various reactions were tested, the PEGylation conditions to yield biotin−PEG−CPA with one biotin terminus were optimized as 1.25:1.0 molar ratio of biotin−PEG-NHS per CPA in 0.50 M $NaHCO_3$/0.50 M NaCl buffer (pH 8.0) with 2 h reaction time in the ice bath. The PEGylation reaction stoichiometry might increase to 2:1 of PEG-NHS/CPA because of self-hydrolysis of PEG-NHS with water during storage. Although it was not necessary to site-specifically PEGylate the lysine groups on CPA, PEGylation generated a highly heterogeneous distribution of m-biotin−PEG−CPA products where m indicates the number of PEG chains coupled on CPA such as di-biotin−PEG−CPA and tri-biotin−PEG−CPA (Figure 1). Purification of biotin−PEG−CPA was necessary and was achieved through SEC chromatography. Hydrophobic interaction chromatography was also tried but worked poorly for this application because PEGs also bind to chromatography media that have hydrophobic interactions (*28*).

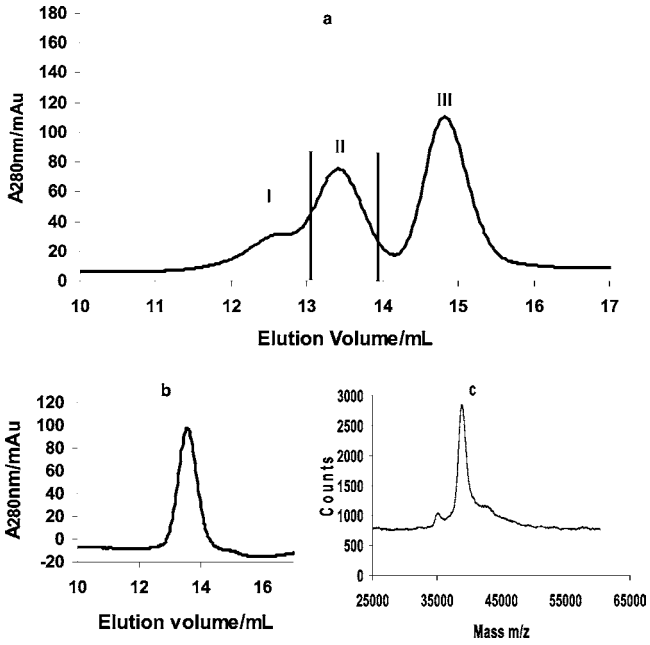

Figure 1. (a) Fractionation of biotin−PEG(3400)−CPA conjugates after PEGylation, using a Superose 12/30 HR column on an ÄKTA FPLC system. Peak I is from the tri- and di-biotin−PEG(3400)−CPA mixture, Peak II is from mono-biotin−PEG(3400)−CPA and Peak III is from unmodified native CPA. The elution buffer was PBS buffer (pH 7.4), with a flow rate of 0.50 mL/min. (b) SEC chromatogram of Fraction II. (c) MALDI-TOF mass spectroscopy of Fraction II.

Previous research shows that di- or tri−PEG−CPA has a longer circulatory half−life than mono−PEG−CPA (*15*). We prepared biotin−PEG−CPA−PEG′, in which there are two conjugated PEG chains to protect CPA during circulation and only one of them has a biotin terminus that acts as a linker and a spacer with avidin. Such PEGylation was achieved by two steps as shown in Figure 2. The PEGylation conditions and purification procedure were the same as those for the biotin−PEG−CPA preparation, except that PEG-SPA(2000) was used for the first PEGylation and that the reaction stoichiometry increased to 2:1 of PEG-NHS/PEG−CPA in the secondary PEGylation.

Stoichiometry of Avidin−Biotin−PEG−CPA Complex. Although avidin has four binding sites for biotin/biotinylated derivatives, PEG can alter the stoichiometry. For example, a 1:1 stoichiometry was found for the avidin−biotin−PEG(5000) complex in our previous work. The 2,6-ANS fluorometric analysis was performed to measure the stoichiometry of biotin−PEGylated CPA with avidin and the results are shown in Figure 3. Biotin−PEG(3400)−CPA and biotin−PEG(3400)−CPA−PEG(2000) accessed two sites on avidin while biotin−PEG(5000)−CPA accessed only one. In contrast, it was surprising to find that biotin−PEG(5000)−CPA−PEG(2000) accessed all

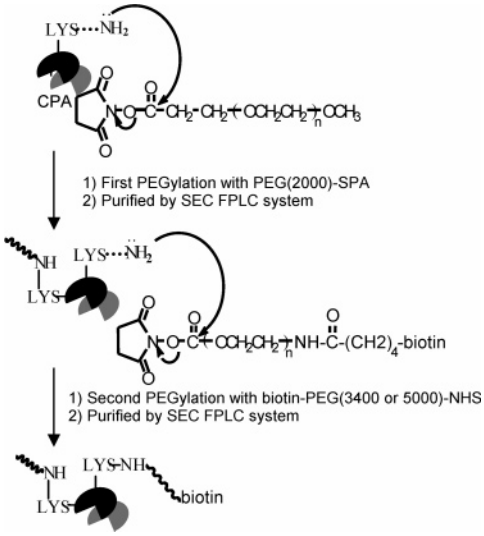

Figure 2. Scheme for the synthesis of biotin−PEG−CPA−PEG′.

four sites on avidin. It appears that biotin−PEG(5000)−CPA bound on avidin sterically hinders the binding to both the adjacent and the oppositely located biotin binding sites on avidin, while biotin−PEG(5000)−CPA−PEG(2000) does not have such steric hindrance.

To obtain independent evidence of the binding stoichiometry, we also investigated the avidin−biotin−PEG−CPA complex system using size exclusion chromatography (SEC). The peak positions in SEC indicate the size of the complex and therefore the stoichiometry. As shown in Figure 4a, three identifiable peaks corresponding to avidin (Peak A), biotin−PEG(5000)−CPA (Peak B), and the avidin−biotin−PEG(5000)−CPA complex (Peak C) were present in the chromatogram. No free biotin−PEG(5000)−CPA was seen when it was mixed with avidin at molar ratio 0.5:1, while excess avidin appeared as Peak A and the avidin−biotin−PEG(5000)−CPA complex appeared as Peak C. When the molar ratio was increased to 1:1, Peak A almost vanished whereas the area of Peak C doubled. After mixing avidin with a 2-fold and 4-fold molar excess of biotin−PEG(5000)−CPA, the elution position and the area of Peak C did not change significantly, except that Peak B from excess biotin−PEG(5000)−CPA began to appear. On the basis of this information, we conclude the avidin−biotin−PEG(5000)−CPA complex stoichiometry is 1:1. In contrast, except for the excess avidin and biotin−PEG(5000)−CPA−PEG(2000) that appeared as peaks A and B in Figure 4b, there were four other peaks labeled C, D, E, and F. If the biotin−PEG−CPA/avidin ratio increased from 1:1.5 to 2:1, the areas of Peak E and F increased while the areas of Peak A, C, and D decreased. When the ratio was larger than 4:1, the A, C, D, and E peaks disappeared while Peak B appeared. Peak F in the 6:1 mixture did not change significantly compared with that from the 4:1 mixture. Accordingly, the stoichiometry for the avidin−biotin−PEG(5000)−CPA−PEG(2000) complex must be 1:4, and peaks C, D, E, and F must correspond to the 1:1, 1:2, 1:3, and 1:4 avidin−biotin−PEG−CPA complexes, respectively. The same strategy was applied for the avidin−biotin−PEG(3400)−CPA complex and the avidin−biotin−PEG(3400)−CPA−PEG(2000) complex, and the stoichiometries for both systems were determined to be 1:2.

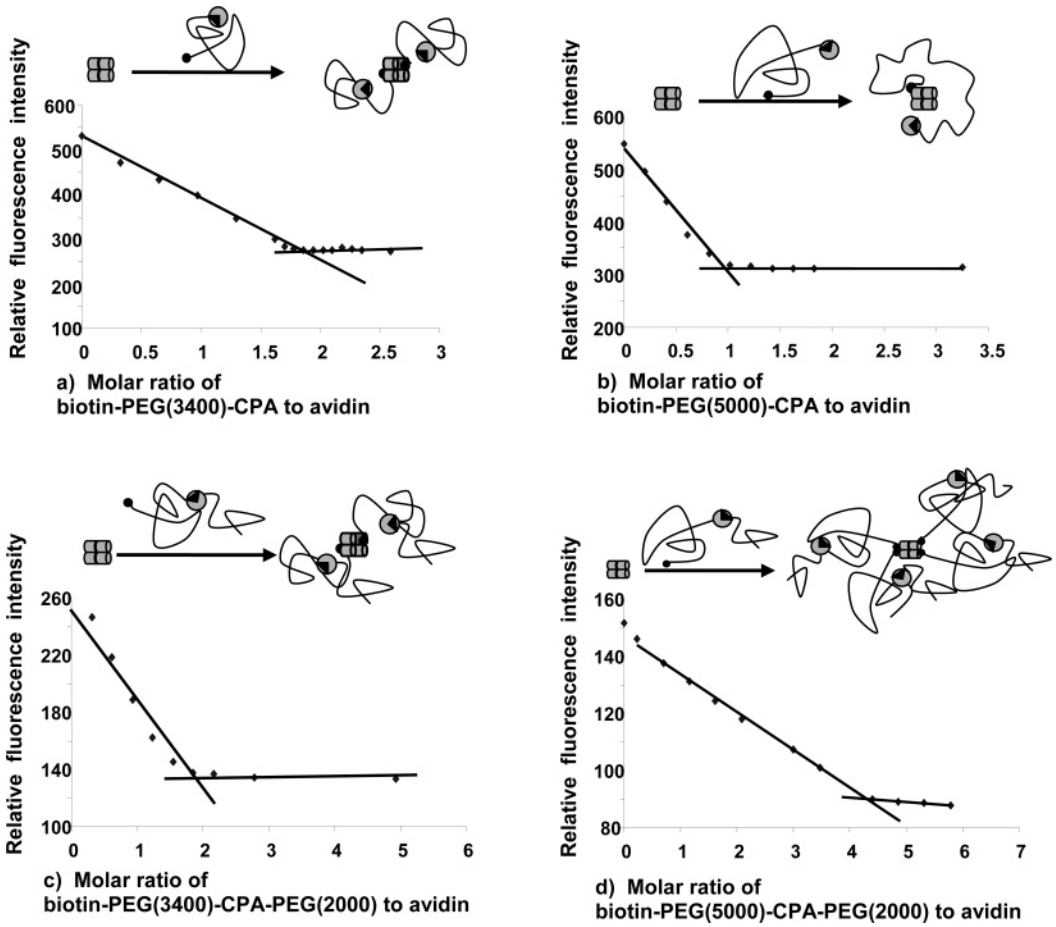

Figure 3. Titration curves of 2,6-ANS fluorometric assay for stoichiometry of the avidin−biotin−PEG−CPA complex are (a) biotin−PEG-(3400)−CPA, (b) biotin−PEG(5000)−CPA, (c) biotin−PEG(3400)−CPA−PEG(2000), and (d) biotin−PEG(5000)−CPA−PEG(2000) with avidin/2,6-ANS in PBS buffer (pH: 7.4).

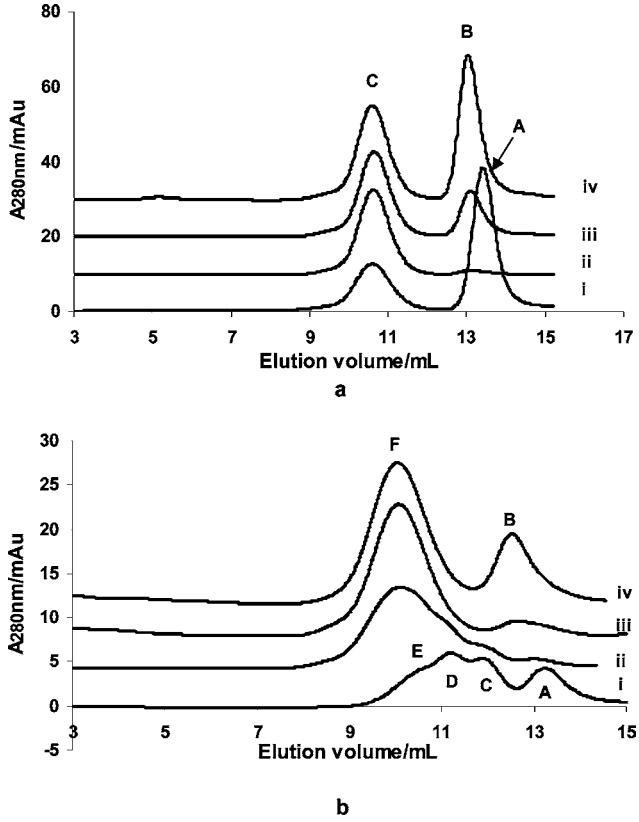

Figure 4. SEC elution profiles of (a) the avidin−biotin−PEG(5000)−CPA complex vs molar ratio of avidin to biotin−PEG(5000)−CPA, i, 1:0.5; ii, 1:1; iii, 1:2; iv, 1:4; and (b) the avidin−biotin−PEG(5000)−CPA−PEG(2000) complex vs molar ratio of avidin to biotin−PEG(5000)−CPA−PEG(2000), i, 1.5:1; ii, 1:2; iii, 1:4; iv, 1:6. Chromatograms were obtained using a Superose 12/30 HR column on an ÄKTA FPLC system. Eluting buffer was PBS buffer (pH 7.4) with a flow rate of 0.50 mL/min.

Table 1. Stoichiometry and Half-Life of Avidin−Biotin−PEG−CPA Complexes at 24 °C

	stoichiometry with avidin	MW (kDa)	$t_{1/2}$ (day)[b] from SEC	$t_{1/2}$ (day)[c] from SPR
biotin−PEG(3400)−CPA	1:2	142.3	3.34	2.09
biotin−PEG(5000)−CPA	1:1	105.7	3.65	2.60
biotin−PEG(3400)−CPA−PEG(2000)	1:2	146.3	3.91	4.14
biotin−PEG(5000)−CPA−PEG(2000)	1:4	233.0	2.74	1.26

[a] MW, molecular weight of the avidin−biotin−PEG−CPA complex with the maximum stoichiometry. [b] $t_{1/2,}$ half-life of the 1:1 avidin−biotin−PEG−CPA complex from SEC chromatography analysis. [c] $t_{1/2,}$ half-life of the 1:1 avidin−biotin−PEG−CPA complex from SPR analysis.

Half-Life of Avidin−Biotin−PEG(s)−CPA Complex. Because the tailing factors of avidin, biotin−PEG−CPA and their complexes are almost equal to one in SEC, their overlapped peaks were deconvoluted with the OriginPro 7.0 Gaussian peak fitting illustrated in Figure 5. The natural logarithm of the relative peak height of the 1:1 avidin−biotin−PEG(5000)−CPA complex decreased linearly with time so the dissociation of the biotin−PEG(5000)−CPA from avidin followed pseudo-first-order kinetics (*29*). The pseudo-first-order dissociation rate constants (k_{off}) are the slopes of the temporal decay and have the following values: 1.32×10^{-4} min^{-1} for the 1:1 avidin−biotin−PEG(5000)−CPA complex, 1.44×10^{-4} min^{-1} for the 1:1 avidin−biotin−PEG(3400)−CPA complex, 1.76×10^{-4} min^{-1} for the 1:1 avidin−biotin−PEG(5000)−CPA−PEG(2000) complex, and 1.23×10^{-4} min^{-1} for the 1:1 avidin−biotin−PEG(3400)−CPA−PEG(2000) complex. The corresponding half-lives are 3.6 days, 3.3 days, 2.7 days, and 3.9 days.

The dissociation rate constant (k_{off}) of biotin−PEGylated CPA on the SA sensor chip was determined to be on the order of 10^{-6} s^{-1} from SPR analysis. The data, together with the stoichiometries, are summarized in Table 1

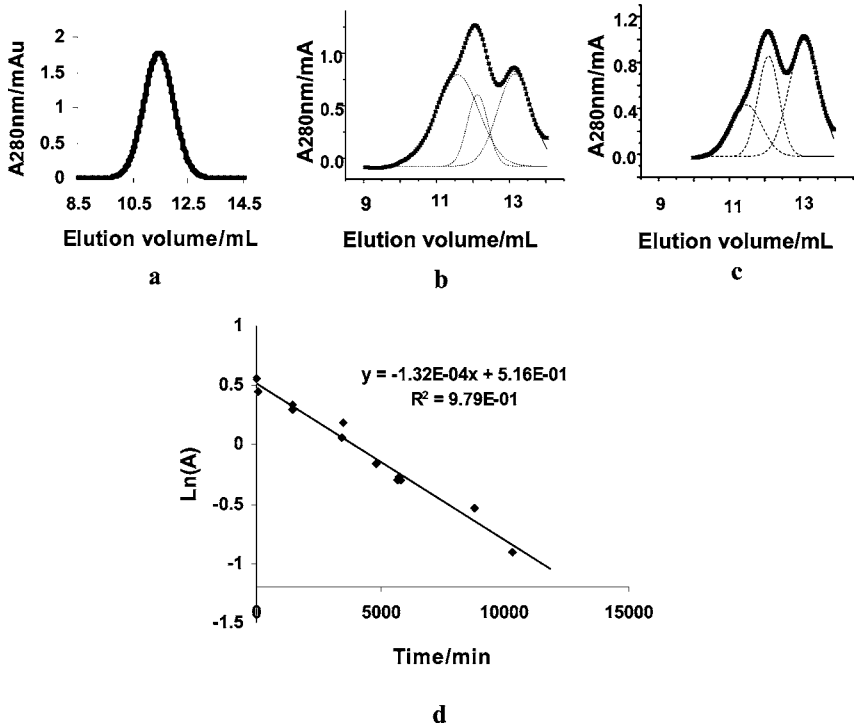

Figure 5. Elution profile of dissociation of the 1:1 avidin−biotin−PEG(5000)−CPA complex using a Superose 12/30 HR column on an ÄKTA FPLC system. (a) incubation time = 0; (b) incubation time = 7059 min; (c) incubation time = 10276 min; (d) 1:1 avidin−biotin−PEG(5000)−CPA complex dissociation rate at 24 °C. The peak at elution position ~11.45 mL is from the 1:1 avidin−biotin−PEG(5000)−CPA complex and A in Ln(A)is the relative peak height of the complex in SEC chromatography. The elution buffer was PBS buffer (pH 7.4) with a flow rate of 0.50 mL/min. The dash lines (-----) stand for the deconvoluted peaks using OriginPro 7.0 Gaussian peak fitting.

DISCUSSION

Stoichiometry. The stoichiometries of avidin binding with biotin−PEG(3400)−CPA (1:2), biotin−PEG(5000)−CPA (1:1), and biotin−PEG(3400)−CPA−PEG(2000) (1:2) support our previous conclusion that, as a spacer, PEG can block the further binding of biotin derivatives with avidin. But it was also surprising to find that biotin−PEG(5000)−CPA−PEG(2000) accesses all four binding sites on avidin.

While the avidin−biotin−PEG(3400) complex has a 1:4 stoichiometry, biotin−PEG(3400)−CPA only accesses two oppositely located biotin binding sites on avidin. This 1:2 stoichiometry is attributed to the increased steric hindrance from PEG and CPA, as well as to the electrostatic repulsion among CPAs (*9*). The hindrance and repulsion also result in a 1:2 stoichiometry for the avidin−biotin−PEG(3400)−CPA−PEG-(2000) complex.

The 1:1 stoichiometry with avidin shows that the biotin−PEG(5000)−CPA hinders the binding to not only adjacent but also oppositely located biotin binding sites on avidin, as observed in biotin−PEG(5000) (to be published). We speculate that the attractive interaction between PEG and avidin should be stronger than that between PEG and CPA; thus, the PEG-(5000) chain surrounds avidin instead of CPA, even though CPA is first conjugated with PEG(5000). It is also possible that PEG-(5000) is large enough to surround avidin while it is not for CPA. PEG(5000) has a Flory radius of 60 Å (*30*), avidin has dimensions of approximately 56 Å × 50 Å × 40 Å (*31*), and CPA has dimensions of approximately 51 Å × 60 Å × 47 Å (*32*).

In contrast, avidin is not surrounded by the PEG chain in the avidin−biotin−PEG(5000)−CPA−PEG(2000) complex since biotin−PEG(5000)−CPA−PEG(2000) is able to access all four binding sites of avidin. This inability to surround avidin may occur because the PEG−PEG repulsion between PEG(2000) and PEG(5000) prevents PEG(5000) from surrounding avidin. Moreover, the release of biotin−PEG(5000)−CPA from avidin by introduction of biotin also indicates the flexibility of such a surrounding. The observed 1:2 stoichiometry of the avidin−biotin−PEG(3400)−CPA−PEG(2000) complex and the 1:4 stoichiometry of the avidin−biotin−PEG(5000)−CPA−PEG-(2000) complex may mean that the longer PEG can relieve more electrostatic repulsion among CPAs and that the electrostatic repulsion among CPAs may be stronger than PEG−PEG steric repulsion.

Half-Life. The duration of efficacy of a protein ligand complex cannot be determined by the in vitro measured equilibrium dissociation constant but rather depends on the complex dissociation rate constants (k_{off}) or half-life (*33*). As we proposed, the ideal avidin−biotin−PEG(s)−CPA complexes would dissociate but still have a prolonged plasma circulation for the sufficient accumulation in tumor tissues through the EPR effect. Optimization of the half-life of the complex is therefore crucial for such a drug delivery. The results show that the dissociation half-life and the stoichiometry of the complex can be adjusted by the lengths of the PEG chains, and the half-lives of these 1:1 complexes are about 3−4 days, which is very promising (Table 1). In addition, since the 1:4 complex dissociates to 1:3 and 1:2 and finally 1:1, the 1:4 complex can be explored for a drug release with a relatively constant concentration over a long period.

We also obtained the dissociation rate constant (k_{off}) of these biotin−PEGylated CPAs with streptavidin using the surface plasmon resonance (SPR) analysis. A streptavidin sensor chip was used because an avidin chip was not available through Biacore. The dissociation rate constants determined from the SPR analysis are different than those determined by the solution-based method (see Table 1). This result reflects the difference between avidin and streptavidin, as well as a variety of potential artifacts in surface-based measurements (*34*, *35*). It signals the advantage of the solution-based method, which is closer to the physical environment involved in drug delivery applications. Although it is simpler to obtain the data by SPR, we use the data from the solution-based method in all of our work.

It was reported that PEG could create attractive interactions among proteins and cause protein crystallization or aggregation (*36*). To investigate the stability of our system, we kept biotin−PEG(3400)−CPA, biotin−PEG(3400)−CPA−PEG(2000), biotin−PEG(5000)−CPA, biotin−PEG(5000)−CPA−PEG(2000), avidin−biotin−PEG(3400)−CPA complex, avidin−biotin−PEG(5000)−CPA complex, avidin−biotin−PEG(3400)−CPA−PEG(2000) complex, and avidin−biotin−PEG(5000)−CPA−PEG(2000) complex in a refrigerator at 4 °C. We did not find any precipitation or any obvious SEC peak from the aggregated proteins over three weeks. This observation means that these complexes can be kept at least for three weeks without precipitation and aggregation.

The study on PEGylated CPA shows that the attachment of up to three PEG to CPA improves CPA catalytic properties (*15*). Following the same strategy using hipp-L-phe, we simply evaluated the enzymatic hydrolysis capacity of CPA in a 1:4 complex of avidin−biotin−PEG(5000)−CPA−PEG(2000) and in a 1:2 complex of avidin−biotin−PEG(3400)−CPA−PEG-(2000) by comparison with native CPA. It appears that CPA in both complexes has similar catalytic properties to those of native CPA. Even though these preliminary findings show that CPA does not lose its enzymatic capacity during the PEGylation and formation of the avidin−biotin−PEG(s)−CPA complexes, the systemic investigation of the enzymatic ability, bioactivity, and pharmacokinetic properties of these complexes will definitely be our next approach in this field.

CONCLUSIONS

The aim of the present study is to investigate the practical potential of the avidin−biotin−PEG−CPA complex as a novel DDS for MTX prodrug EPR-directed pretargeting. Basic steps include synthesis of biotin−PEG(s)−CPA, formation of the avidin−biotin−PEG(s)−CPA complexes, and analytical procedures to measure the stoichiometries and half-lives of the complexes. The results show (i) the molecular weights of the avidin−biotin−PEG−CPA complexes are in the same order as that of an antibody, (ii) the stoichiometries of avidin−biotin−PEG−CPA complexes are 1:4 for avidin−biotin−PEG(5000)−CPA−PEG(2000), 1:2 for avidin−biotin−PEG(3400)−CPA and avidin−biotin−PEG(3400)−CPA−PEG(2000), and 1:1 for avidin−biotin−PEG(5000)−CPA, and (iii) the half-lives of these 1:1 complexes are around 3−4 days at 24 °C so the dissociation kinetics are slow enough for typical tumor accumulations through EPR. On the basis of the half-life and stoichiometry, the avidin−biotin−PEG−CPA complexes or their analogues have potential as a new protein drug delivery system, in which the avidin−biotin−PEG−CPA complex acts as both the transporting device and the targeting device, while CPA is the drug moiety for the prodrug pretargeting strategy.

In addition, the data in the present study provides information on four interactions that can alter the binding of avidin with biotin in avidin-biotin-PEG(s)-CPA complexes: (i) the steric repulsion between PEG−PEG; (ii) the interaction among the attached functional groups on the second terminus of PEG, such as the electrostatic repulsion among the conjugated CPAs; (iii) the interaction between the attached functional group and PEG, such as that PEG chains relieve the interaction among CPAs; (iv) the surrounding of PEG around avidin. Both the length of a PEG chain and the interactions of the attached functional

groups on PEG should be considered when a PEG chain is chosen as an appropriate spacer.

ACKNOWLEDGMENT

We thank Dr. McClain for his assistance in fluorometric assay for the stoichiometry quantitative evaluation and helpful discussion of the paper.

Truman Memorial Veterans' Hospital, Columbia, Missouri 65201. Received May 31, 2007

Bombesin (BBN) peptide exhibits high selectivity and affinity for the gastrin-releasing peptide receptor (GRPr). The GRPr is overexpressed on many human cancer cell types, thus making BBN a potent delivery vehicle for radionuclide targeting. In this study, the biologically active minimal sequence BBN(7−14) was labeled using the novel Tc '4 + 1' mixed-ligand system, [Tc(NS_3)(CN−R)], in which Tc(III) is coordinated by a monodentate isocyanide linker bearing the peptide and the tetradentate, tripodal chelator, 2,2′,2″-nitrilotriethanethiol (NS_3). BBN(7−14) was N-terminally modified with Gly-Gly-Gly, βAla, and Ser-Ser-Ser spacer groups (X) and functionalized with 4-(isocyanomethyl)benzoic acid (L1) or 4-isocyanobutanoic acid (L2), resulting in a series of [M(NS_3)(L−X−BBN(7−14))] conjugates (M = ^{99m}Tc, Re). The isocyanide ligand frameworks were introduced using novel bifunctional coupling agents. The spacer groups (X), the monodentate isocyanide units, and a tetradentate NS_3 chelator bearing a pendant carboxylic acid (NS_3COOH) were proposed as pharmacological modifiers. ^{99m}Tc-labeling was performed in a two-step procedure by first preparing ^{99m}Tc-EDTA/mannitol followed by reactions with the isocyanides and NS_3 or NS_3COOH ligand frameworks. The ^{99m}Tc complexes were obtained with a radiochemical yield of 30−80% depending on the amount of the isocyanide (20−100 nmol) used. These new conjugates were purified by reversed-phased high-performance liquid chromatography (RP-HPLC) to give a radiochemical purity of ≥95%. The ^{99m}Tc conjugates exhibited high *in vitro* stability (>90%, 24 h). Analogous nonradioactive Re conjugates were synthesized and characterized by electrospray ionization mass spectrometry (ESI-MS). RP-HPLC analyses of the Re conjugates indicated that they exhibited identical retention times to the corresponding ^{99m}Tc conjugates under identical HPLC conditions, demonstrating structural similarity between the two metalated species. The [Re(NS_3)(L−X−BBN(7−14))] conjugates exhibited GRPr affinity in the nanomolar range as demonstrated by *in vitro* competitive binding assays using PC-3 human prostate cancer cells. *In vitro* internalization/externalization assays indicated that ∼65% of [^{99m}Tc(NS_3)(L2−βAla−BBN(7−14))] conjugate was either surface-bound or internalized in PC-3 cells. Cell-associated activity for all other ^{99m}Tc conjugates was below 20%. Biodistribution studies of [^{99m}Tc(NS_3)(L−βAla−BBN(7−14))], L = L1 or L2, in normal, CF-1 mice showed minimal accumulation in normal pancreas (a tissue expressing the GRPr in high density in rodent models) and rapid hepatobiliary elimination. Introduction of a carboxyl group onto the NS_3 ligand framework had only minimal effects to increase renal excretion. Activity distribution and accumulation was highly dominated by the relatively lipophilic '4 + 1' complex unit.

INTRODUCTION

The development of radiotracers based upon peptides as targeting moieties for tumors has been a focus of research over the past decade. Design and development of specific radiotracers of this type vary broadly by type of peptide and the radiolabeling approach used (*1*−*5*). The pharmacological properties of radiometal-labeled peptides are highly dependent on the conjugated metal complex. Therefore, it would be useful to have as wide a spectrum of alternative labeling systems as possible. As part of our ongoing research to establish a new labeling system for peptides, we have developed '4 + 1' mixed-ligand complexes of Tc and Re, [M(NS_3)(CN−R)], where Tc/Re(III) is coordinated by a monodentate isocyanide or phosphine ligand framework and a tetradentate tripodal chelator. The '4 + 1' mixed-ligand approach features high stability, mild labeling conditions, well-defined complexes, and the possibility of varying the chelator and monodentate ligand. '4 + 1' complexes have been studied under various structural−chemical aspects and assessed on the labeling of some biomolecules. For example, there are studies on '4 + 1' conjugates of serotonin receptor ligands and fatty acids, but only exemplary studies on neurotensin (*8*−*13*) as a peptide have been reported (*6*−*11*). Herein, bombesin was selected as biomolecule to further study '4 + 1' complexes for the ^{99m}Tc-labeling of peptides.

Among the peptides for tumor targeting, bombesin (BBN), a tetradecapeptide binding with high affinity to the gastrin-releasing peptide receptor (GRPr), has recently gained increasing

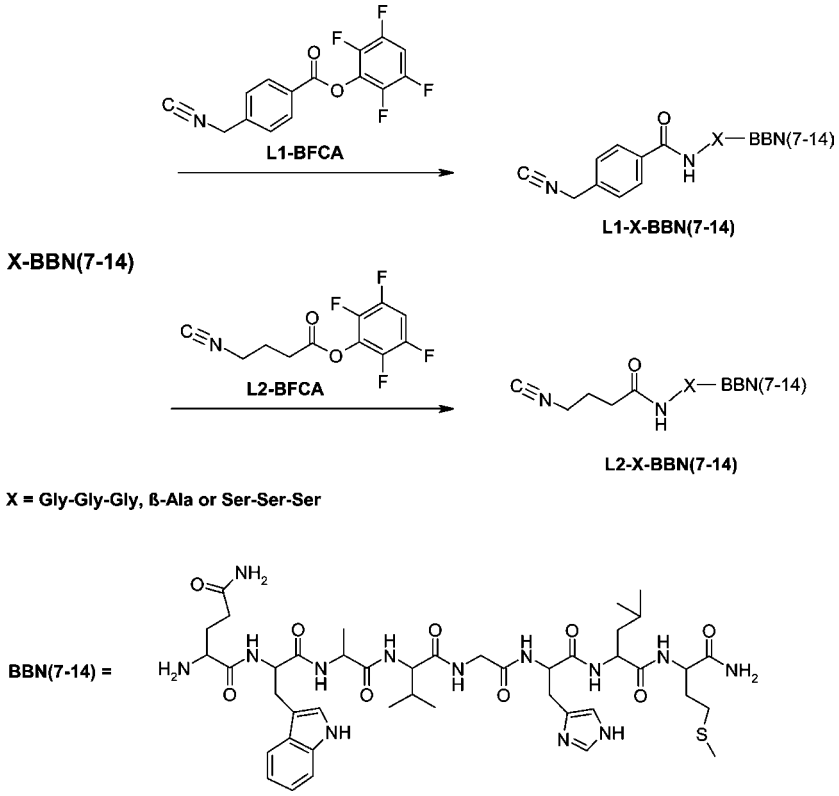
attention. The GRPr is overexpressed on a variety of tumors including commonly diagnosed breast and prostate cancers and rarer pancreatic and small-cell lung cancers (*1*, *12*, *13*). Many radiolabeled bombesin derivatives have been designed showing varying pharmacokinetic behavior depending on the radiolabeling approach, the pharmacokinetic modifier or spacer between the radiometal-chelate and the N-terminus, and specific modifications in the peptide sequence. Research investigations have examined BBN derivatives radiolabeled with ^{64}Cu (*14*−*17*), ^{18}F (*18*−*20*), ^{68}Ga (*19*, *20*), ^{125}I (*21*−*23*), ^{111}In (*24*−*26*), ^{177}Lu (*25*, *27*−*29*), ^{188}Re (*30*−*32*), and ^{90}Y (*25*).

Many studies have focused on radiolabeling of BBN peptide with ^{99m}Tc as well, exploiting favorable physical characteristics/nuclear properties, ready availability, and simple handling of this radioisotope. For example, ^{99m}Tc has a $t_{1/2}$ of 6 h, emits an imageable γ photon of 140 keV (89% abundance), is readily available from a ^{99}Mo/^{99m}Tc generator, and is used in more than 85% of all diagnostic patient applications in nuclear medicine (*33*). Radiolabeld BBN conjugates containing the Tc(V) monooxo $[Tc{=}O]^{3+}$ core coordinated by N_3S (*34*−*37*), N_2S_2 (*37*−*40*), or Tc(V) dioxo $[O{=}Tc{=}O]^{+}$ core chelated by N_4 (*41*, *42*) and P_2S_2 ligands (*43*), as well as organometallic Tc(I) conjugates containing the $[^{99m}Tc(CO)_3]^{+}$ metal fragment (*44*−*48*), have been extensively investigated. Various limitations are associated with some labeling concepts, such as low radiochemical yield, extended reaction time, high temperature, high pH values, and high lipophilicity of the radiometal chelate. In the series of the applied labeling systems so far, the novel '4 + 1' concept might be an alternative.

The ^{99m}Tc complexes were generally coupled directly to the N-terminus of BBN(7−14) (*36*, *42*, *47*) or *via* spacer groups to BBN-derived peptides. For example, Gly-Gly-Gly (*48*), Ser-Ser-Ser (*46*), βAla, and 5-aminovaleric, 8-aminooctanoic, and 11-aminoundecanoic acid (*36*, *43*) have been studied as spacers or pharmacokinetic modifying linker groups. ^{99m}Tc-tricarbonyl complexes conjugated to [DPhe^6, βAla^{12}, Nle^{14}]BBN(6−14) or [Cha^{13}]BBN(7−14) have been exclusively studied by Bläuenstein and co-workers (*47*). ^{99m}Tc(V)−N_4 complexes have been conjugated to [Pro^1, Tyr^4]BBN or [Pro^1, Tyr^4, Nle^{14}]BBN as well as *via* the *p*-[(carboxymethoxy)acetyl]aminobenzyl group to BBN(7−14), [Nle^{14}]BBN(7−14) or [DPhe^6, Leu-NHEt^{13}, *des*-Met^{14}]BBN(6−14) (*26*, *41*, *42*). Gourni et al. have studied ^{99m}Tc conjugates of BBN(2−14) using Xaa-Gly-Gly (Xaa = Gly, methylglycine, dimethylglycine, mercaptoacetic acid) as the chelating ligand frameworks and 6-aminohexanoic acid as the pharmacokinetic modifier (*49*). Baidoo et al. have extensively investigated ^{99m}Tc(V)−N_2S_2 complexes conjugated *via* Lys^3 to [Lys^3]BBN or [DTPA^1, Lys^3, Tyr^4]BBN (*38*−*40*). All of the aforementioned ^{99m}Tc conjugates exhibited affinity for the GRPr and a biodistribution behavior that is influenced specifically by the choice of metal center, chelator, linking substituent, or peptide targeting vector. The best biodistribution results have been achieved by conjugates consisting of BBN(7−14) or an analog of them and a hydrophilic ^{99m}Tc complex placed at a certain distance from the BBN(7−14) sequence.

To study the potential of '4 + 1' complexes for bombesin labeling, we herein report on the synthesis and characterization of novel Tc/Re(III) BBN(7−14) conjugates where the metal (M = ^{99m}Tc, Re) is coordinated by a monodentate isocyanide-functionalized BBN derivative and a tetradentate, tripodal chelator, 2,2′,2″-nitrilotriethanethiol (NS_3), resulting in a series of [M(NS_3)(L−X−BBN(7−14))] conjugates. BBN(7−14) was N-terminally modified with Gly-Gly-Gly, βAla, and Ser-Ser-Ser spacer groups (X) and functionalized with 4-(isocyanomethyl)benzoic acid (L1) or 4-isocyanobutanoic acid (L2). The peptides X−BBN(7−14) were selected from our previous studies where their ^{99m}Tc conjugates containing a N_3S or tricarbonyl framework showed promising *in vitro* and *in vivo* characteristics (*36*, *46*, *48*). Radiolabeling studies, *in vitro* cell binding affinity studies, internalization/externalization assays, and biodistributions in normal CF-1 mice are reported.



EXPERIMENTAL PROCEDURES

Materials. The tetradentate ligand 2,2′,2″-nitrilotriethanethiol (NS_3) was synthesized as previously described (*6*). 2,2′,2″-Nitrilotriethanethiol was precipitated as the oxalate and applied as such. *N*,*N*-bis(2-mercaptoethyl)cysteine (NS_3COOH) and 2,3,5,6-tetrafluorophenyl 4-(isocyanomethyl)benzoate (L1-BFCA) were synthesized according to previously published procedures (*9*). [Re(NS_3)(PMe_2Ph)] was prepared according to the methods of Pietzsch et al. (*7*). Na$^{99m}TcO_4$ was eluted from a commercial ^{99}Mo/^{99m}Tc generator (Mallinckrodt). RP-HPLC analyses and purification were performed on a Waters 600E system equipped with a Varian 2550 variable absorption detector and a solid sodium iodide crystal radiometric detector. Solvents were of HPLC grade and purchased from Fisher Scientific (Chicago, IL). The gradient and HPLC conditions were as follows: eluent A, 0.1% (v/v) trifluoroacetic acid (TFA) in acetonitrile; eluent B, 0.1% (v/v) TFA in water; eluent C, 0.1 M NH_3 in acetonitrile, eluent D, 0.1 M NH_3 in water. System 1: Jupiter 5 μ C18 300 Å (Phenomenex), 250 × 10 mm, gradient elution using eluents A and B: 5−70% A in 25 min, 3 mL/min. System 2: Jupiter 5 μ C18 300 Å (Phenomenex), 250 × 4.6 mm, gradient elution using eluents A and B: 5−70% A in 25 min, 1.5 mL/min. System 3: Gemini 5 μ C18 (Phenomenex), gradient elution using eluents C and D: 20−80% C in 20 min, 3 mL/min. System 4: Jupiter 4 μ Proteo 90 Å (Phenomenex), 250 × 10 mm, gradient elution using eluents A and B: 20−80% A in 20 min, 3 mL/min. System 5: Jupiter 4 μ Proteo 90 Å (Phenomenex), 250 × 4.6 mm, gradient elution using eluents A and B: 20−80% A in 20 min. Elemental analyses were performed on a LECO elemental analyzer CHNS-932. Electrospray ionization mass spectrometry (ESI-MS) was performed using a Micromass Tandem Quadropole Mass Spectrometer (Quattro LC) or by Synpep Corporation (Dublin, CA). Nuclear magnetic resonance spectra were recorded on a 400 MHz Varian Inova 400 spectrometer. IR spectra were measured on the FTIR spectrometer IR 2000 (Perkin-Elmer) using KBr pellets. TLC strips were scanned using a Raytest Rita radioanalyzer. ^{125}I-[Tyr^4]BBN was obtained from NEN Life Sciences Products, Inc. (Boston, MA). All other compounds and solvents were purchased from Sigma-Aldrich (St. Louis, MO) and used without further purification.

Methods. *1. Solid-Phase Peptide Synthesis (SPPS).* GGG−BBS(7−14), βAla−BBS(7−14), and SSS−BBS(7−14) were synthesized on an automated solid-phase peptide synthesizer (Perkin-Elmer Applied Biosystem model 432) using traditional Fmoc chemistry and Rink amide resin (25 μmol). Each coupling step was performed using HBTU and appropriate Fmoc-protected amino acids (75 μmol) including the following side-chain protecting groups: Gln(Trt), Trp(Boc), His(Trt), and Ser(tBu). The final products were cleaved by a standard procedure using a cocktail containing thioanisol, water, ethanedithiol, and trifluoroacetic acid. Typical yields of the crude peptides were 75−85%. The crude materials were purified by RP-HPLC (system 1) and the solvent removed on a SpeedVac concentrator. ESI-MS was used to determine the molecular mass of the prepared peptides. HPLC (system 2): t_R = 12.2 min for GGG−BBN(7−14), t_R = 12.2 min for βAla−BBN(7−14), t_R = 12.3 min for SSS−BBN(7−14). ESI-MS (*m*/*z*) found (calcd): 1111.4 (1111.5) for $[GGG{-}BBN(7{-}14)]^{+}$, 1011.5 (1011.5) for $[\beta Ala{-}BBN(7{-}14)]^{+}$, 1201.5 (1201.6) for $[SSS{-}BBN(7{-}14)]^{+}$.

2. Synthesis of 2,3,5,6-Tetrafluorphenyl 4-Isocyanobutanoate (L2-BFCA). The bifunctional coupling agent L2-BFCA was

Scheme 1. Introduction of Isocyanides onto Bombesin Derivatives (BFCA = Bifunctional Coupling Agent)

prepared from 4-aminobutanoic acid *via* 4-(formylamino)-butanoic acid and 2,3,5,6-tetrafluorphenyl 4-(formylamino)-butanoate.

2.1. Synthesis of 4-(Formylamino)butanoic Acid. 194 mmol of 4-aminobutanoic acid were dissolved in 1 mL of acetic anhydride and 150 mL formic acid and refluxed at 100 °C. After a period of time, the temperature was increased to 115 °C and maintained for 8 h. The solvent was removed and the precipitate stirred in a solvent mixture of diethyl ether, acetonitrile, and ethyl acetate (30/5/5, v/v/v). After decanting and repeating the procedure, a white granular product was collected, washed with diethyl ether, and dried *in vacuo*. Yield: 35% white powder. Anal. ($C_5H_9NO_4$) found (calcd): C 44.9 (45.7), H 6.9 (6.9), N 10.5 (10.7).

2.2. Synthesis of 2,3,5,6-Tetrafluorphenyl 4-(Formylamino)-butanoate. 15.2 mmol of 4-(formylamino)butanoic acid and 15.2 mmol of *N*-hydroxysuccinimide were dissolved in 10 mL of anhydrous dimethylformamide. A solution of 15.2 mmol dicyclohexylcarbodiimide in 10 mL dimethylformamide was added and the reaction mixture stirred for 12 h at room temperature. After filtering, the solution was concentrated, filtered once again, and the solvent removed *in vacuo*. The residue was dissolved in acetonitrile/trichloromethane (1/1, v/v), precipitated by addition of diethyl ether, and dried *in vacuo*. Yield: 45% white powder. Anal. ($C_{11}H_9F_4NO_4$), found (calcd): C 44.1 (44.8), H 3.3 (3.1), N 4.9 (4.7).

2.3. Synthesis of L2-BFCA. 2.2 mmol of 2,3,5,6-tetrafluorphenyl 4-(formylamino)butanoate and 2.6 mmol of triphenylphosphine were mixed in a solution of 2.2 mmol of tetrachloromethane, 5 mL of trichloromethane, and 2.2 mmol of triethylamine. The reaction mixture was stirred at 50 °C for 3 h and the solvent removed *in vacuo*. The residue was washed with diethyl ether. The product was purified by column chromatography on silica gel 60 using a mixture of acetonitrile/trichloromethane/*n*-hexane (15/10/5, v/v/v) as the eluents. The product was collected and evaporated *in vacuo*. Yield: 35% pale yellow oil. Anal. ($C_{11}H_7F_4NO_2$), found (calcd): C 50.3 (50.6), H 2.7 (2.7), N 5.2 (5.4). ESI-MS (*m*/*z*) found (calcd) $[M + H]^+$: 262.1 (262.0). IR (KBr, cm^{-1}): 1790 (st, C=O), 2152 (m, C≡N). ^1H NMR (CD_3CN): 2.07 (m, 2H, CH_2CH_2-CH_2), 2.87 (t, J = 7.4 Hz, 2H, $CH_2C(O)$), 3.56 (tt, $^2J_{NH}$ = 2.0 Hz, $^3J_{HH}$ = 6.6 Hz, 2H, CH_2NC), 7.31 (m, 1H, H_{arom}). ^{13}C NMR (CD_3CN): 24.11 (s, $CH_2CH_2CH_2$), 29.83 (s, $CH_2C(O)$), 40.54 (t, J = 6.1 Hz, $CNCH_2$), 103.98 (m, $C_{arom}H$), 130−150 (very small signals not evaluated, $C_{arom}F$), 157.19 (s, CN), 169.04 (s, C(O)).

3. Synthesis of [L−X−BBN(7−14)], L = L1, L2, X = GGG, βAla, SSS. The isocyanides were introduced onto BBN(7−14) by conjugation with active esters L1-BFCA and L2-BFCA as depicted in Scheme 1. Briefly, 5 μmol of GGG−BBN(7−14), βAla−BBN(7−14), or SSS−BBN(7−14) were dissolved in 1 mL of dimethylformamide containing 15 μmol triethylamine. 5 μmol of either L1-BFCA or L2-BFCA were added. After being stirred for 6 h at room temperature, the solvent was removed *in vacuo*. The residues were dissolved in a mixture of acetonitrile and water (∼1/1) and then purified by RP-HPLC (system 3). The collected fractions were lyophilized to yield final conjugates as white powders. Yield: 20−30%. ESI-MS (*m*/*z*) found (calcd): 1255.0 (1254.6) for [L1−GGG−BBN(7−14)]$^+$, 1154.8 (1154.6) for [L1−βAla−BBN(7−14)]$^+$, 1344.6 (1344.6) for [L1−SSS−BBN(7−14)]$^+$, 1206.9 (1206.6) for [L2−GGG−BBN(7−14)]$^+$, 1107.9 (1106.6) for [L2−βAla−BBN(7−14)]$^+$, 1296.7 (1296.6) for [L2−SSS−BBN(7−14)]$^+$.

4. Preparation of ^{99m}Tc '4 + 1' Radiolabeled Bombesin Derivatives. ^{99m}Tc-labeled bombesin derivatives and the corresponding Re analogues are depicted in Figure 1. ^{99m}Tc labeling was performed in a two-step procedure similar to that described in ref *9*. Eluate of a ^{99}Mo/^{99m}Tc generator (0.2−1.5 GBq) was added to a kit formulation containing 1 mg Na_2EDTA, 5 mg mannitol, and 0.1 mg $SnCl_2$ in freeze-dried form under nitrogen. The solution was allowed to stand at room temperature for 20 min. The radiochemical purity was checked using TLC silica gel 60 W strips (Merck). ^{99m}Tc-EDTA/mannitol migrates to the solvent front in water and remains at the origin in acetone. The

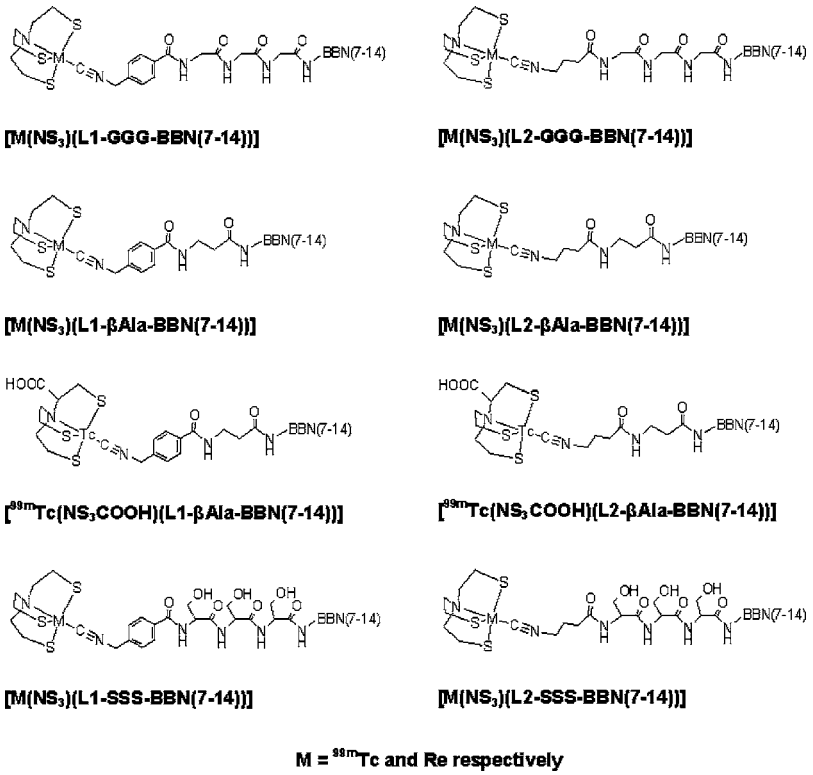


Figure 1. ^{99m}Tc and Re '4 + 1' complex-bearing bombesin derivatives.

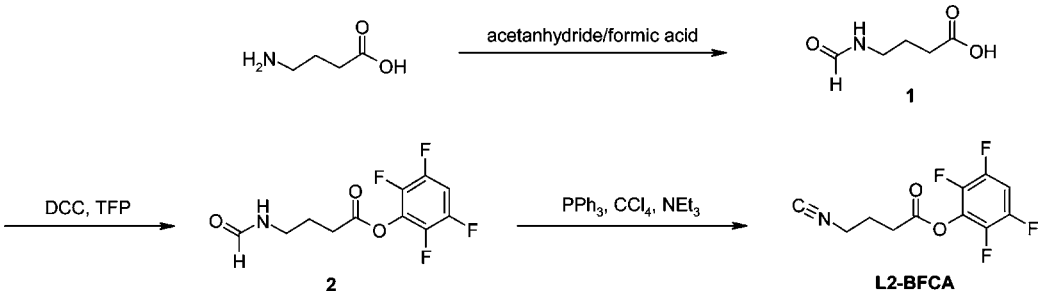
radiochemical yield is usually >90%. 0.3 mg of NS_3 or NS_3-COOH were added to ^{99m}Tc-EDTA/mannitol, and the solution was transferred to a vial containing 0.05−0.2 mg isocyanide-modified BBN(7−14). Methanol was added so that it constituted $^1/_3$ of the volume of the labeling mixture. After flushing the space above the solution with argon, the vial was heated at 50 °C for 2 h. The radiolabeled conjugates were purified by RP-HPLC (system 4). For *in vitro* and *in vivo* studies, product fractions were collected and HPLC solvents evaporated under a nitrogen stream. The conjugates were dissolved in a solution of 1 mg bovine serum albumin in 1 mL water. Bovine serum albumin was used to minimize adhesion on vial surfaces for conjugates of this general type. HPLC (system 5): coelution with the analogous Re conjugates; for t_R of the Re conjugates, see below.



5. Synthesis of [Re(NS3)(L2−BFCA)]. L2−BFCA (0.22 mmol), dissolved in 3 mL trichloromethane, was added to 0.2 mmol [Re(NS_3)(PMe_2Ph)] dissolved in 3 mL trichloromethane. The mixture was stirred at room temperature for 1 h, evaporated, and the residues washed with diethyl ether. The product was precipitated from trichloromethane after adding methanol and diethyl ether. Yield: 90% olive-brown powder. Anal. ($C_{17}H_{19}F_4NO_2ReS_3$), found (calcd): C 32.0 (31.8), H 3.1 (3.0), N 4.3 (4.4). ESI-MS (*m*/*z*) found (calcd) $[M + Na]^+$: 665.1 (665.0). IR (KBr, cm^{-1}): 1783 (st, C═O), 1982 (st, C≡N). ^{1}H NMR (CD_3CN): 2.15 (m, 2H, $CH_2CH_2CH_2$), 2.6−3.2 (bs, 12H, CH_2CH_2SH), 3.04 (t, J = 3.9 Hz, 2H, $CH_2C(O)$), 4.77 (t, J = 6.2 Hz, 2H, CH_2NC), 7.30 (m, 1H, H_{arom}). ^{13}C NMR (CD_3CN): 28.70 (s, $CH_2CH_2CH_2$), 30.52 (s, $CH_2C(O)$), 43.79 (s, CN_2S), 44.69 (s, $CNCH_2$), 58.72 (s, NCH_2CH_2S), 103.98 (m, $C_{arom}H$), 169.04 (s, C(O)).

6. Synthesis of [Re(NS3)(L−X−BBN(7−14))], L = L1, L2, X = GGG, βAla, SSS. The Re '4 + 1' complexes were introduced onto BBN(7−14) by conjugation with the active esters [Re(NS_3)(L1−BFCA)] and [Re(NS_3)(L2−BFCA)]. The formulas of the products are depicted in Figure 1. 5 μmol of GGG−BBN(7−14), βAla−BBN(7−14), or SSS−BBN(7−14) was dissolved in 1 mL of dimethylformamide containing 15 μmol triethylamine. 5 μmol [Re(NS_3)(L1−BFCA)] or [Re(NS_3)-(L2−BFCA)] was added. After being stirred for 6 h at room temperature, the solvent was removed *in vacuo*. The residues were dissolved in a mixture of acetonitrile and water (1/1) and purified by semipreparative HPLC (system 4). Fractions were collected and lyophilized. Yield: 20−30% green powder. ESI-MS (*m*/*z*) found (calcd) $[M + H]^+$: 1636.1 (1635.5) for [Re(NS_3)(L1−GGG-BBN(7−14))], 1536.5 (1535.5) for [Re(NS_3)-(L1−βAla−BBN(7−14))], 1727.6 (1725.6) for [Re(NS_3)(L1−SSS−BBN(7−14))], 1588.1 (1587.5) for [Re(NS_3)(L2−GGG−BBN(7−14))], 1488.8 (1487.5) for [Re(NS_3)(L2−βAla−BBN(7−14))], and 1678.6 (1677.6) for [Re(NS_3)(L2−SSS−BBN(7−14))]. HPLC (system 5): t_R = 13.3 min for [Re(NS_3)(L1−GGG−BBN(7−14))], t_R = 14.0 min for [Re(NS_3)(L1−βAla−BBN(7−14))], t_R = 12.2 min for Re(NS_3)(L1−SSS−BBN(7−14)), t_R = 12.3 min for [Re(NS_3)(L2−GGG−BBN(7−14))], t_R = 12.9 min for [Re(NS_3)(L2−βAla−BBN(7−14))], and t_R = 11.8 min for [Re(NS_3)(L2−SSS−BBN(7−14))].

7. Receptor Binding Assays for [Re(NS3)(L−X−BBN(7−14))], L = L1, L2, X = GGG, βAla, SSS. The IC_{50} (inhibitory concentration 50%) values of [Re(NS_3)(L−X−BBN(7−14))] conjugates were determined by a competitive displacement cell binding assay using ^{125}I-Tyr^4-bombesin as the radiolabeling displacement ligand. Approximately 3×10^4 cells (suspended in D-MEM/F-12K media containing 0.01 M MEM and 2% BSA, pH = 5.5) were incubated at 37 °C for 1 h in the presence of 20 000 cpm ^{125}I-Tyr^4-bombesin (8.2×10^{-15} mol, 2200 Ci/mmol) and increasing concentrations of [Re(NS_3)(L−X−BBN-(7−14))] conjugate. Upon completion of the incubation, the reaction medium was aspirated, and the cells were washed four times with media. Cell-associated radioactivity was determined by counting in a Packard Riastar γ counting system. IC_{50} values were calculated using *Sigma Plot* graphing software.

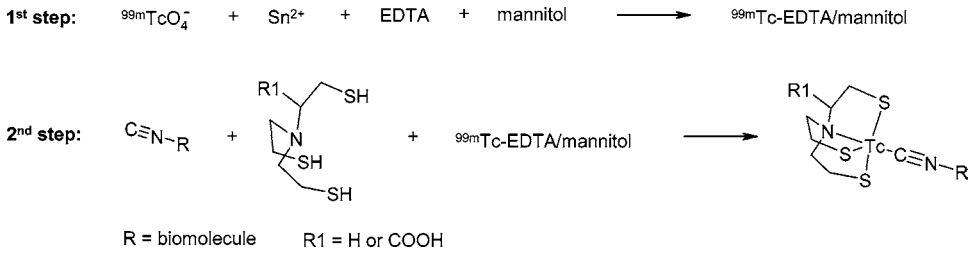
8. In Vitro Evaluation of the Internalization and Externalization Properties of 99mTc Conjugates in Human, PC-3, Prostate Cancer Cells: *In vitro* internalization analyses of [^{99m}Tc(NS_3)(L−X−BBN(7−14))] conjugates were carried out by incubation of ~3×10^4 cells (in D-MEM/F-12K media

Scheme 2. Reaction Route to L2-BFCA

containing 0.01 M MEM and 2% BSA, pH = 5.5) in the presence of ~20 000 cpm [^{99m}TcNS$_3$)(L−X−BBN(7−14))] at 37 °C for selected time points of 15, 30, 45, 60, 90, and 120 min. Upon completion of the incubation, the reaction medium was aspirated, and the cells were washed four times with media. Surface-bound radioactivity was removed by washing the cells with 0.2 N acetic acid/0.5 M NaCl (pH = 2.5). The percent of internalized, cell-associated radioactivity as a function of time was determined by counting in a Packard Riastar γ counting system. Externalization studies were performed after a 45 min internalization period. The cellular medium was washed (3×) with buffer (room temperature) and resuspended for further incubation. Selected sampling at 0, 15, 30, 45, 60, and 90 min post-internalization was performed by an initial cold buffer wash of the cells, followed by washing with acetic acid/saline (pH = 2.5 at 4 °C). The percent of externalized radioactivity as a function of time was determined by counting in a Packard Riastar γ counting system. Internalization and externalization curves (least-squares best-fit line) were generated by *D-plot* graphing software.

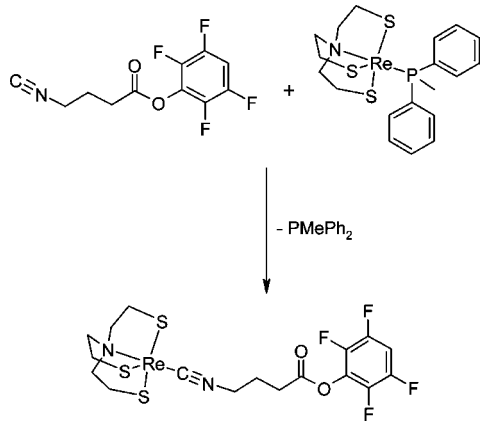
9. Biodistribution of [^{99m}Tc(NS$_3$)(L1−βAla−BBN(7−14))], [^{99m}Tc(NS$_3$)(L2−βAla−BBN(7−14))], [^{99m}Tc(NS$_3$COOH)(L1−βAla−BBN(7−14))], and [^{99m}Tc(NS$_3$COOH)(L2−βAla−BBN-(7−14))] in Normal, CF-1 Mice. Mice were housed five animals per cage in sterile micro-isolator cages in a temperature- and humidity-controlled room with a 12 h light/12 h dark schedule. The animals were fed autoclaved rodent chow (Ralston Purina Company, St. Louis, MO) and water *ad libitum*. All animal studies were conducted in accordance with the highest standards of care as outlined in the NIH guide for Care and Use of Laboratory Animals and the Policy and Procedures for Animal Research at the Harry S. Truman Memorial Veterans' Hospital. The biodistribution studies of the [^{99m}Tc(NS$_3$)(L−X−BBN(7−14))] conjugates were determined in normal CF-1 mice. The mice were injected with 0.2 MBq (~0.5 × 10^{-10} g) of the ^{99m}Tc conjugate in 100 μL of isotonic saline *via* the tail vein. The mice were euthanized, and tissues and organs were excised from the animals at 1 h postinjection (p.i.). Subsequently, the tissues and organs were weighed and counted in a NaI well counter, and the percent injected dose (% ID) and % ID/g of each organ or tissue was calculated. The % ID in whole blood was estimated assuming a whole-blood volume of 6.5% of the total body weight. The animals were sacrificed at 1 h p.i. The tissues were removed, weighed, and counted as previously described.

RESULTS AND DISCUSSION



To couple the '4 + 1' complexes, BBN(7−14) bearing N-terminal βAla, Ser-Ser-Ser, and Gly-Gly-Gly as spacer groups X to serve as pharmacokinetic modifiers for the radiolabeled '4 + 1' conjugate were selected on the basis of previously published results: ^{99m}Tc-labeling using the N_3S chelator linked via βAla as spacer group to BBN(7−14) did not affect receptor affinity and showed a remarkable pancreatic uptake as well as the highest degree of renal excretion compared to analogous compounds containing a 5-, 8-, or 11-carbon spacer (*36*). ^{99m}Tc-tricarbonyl-labeled BBN(7−14) conjugates containing Ser-Ser-Ser as the spacer were similar regarding receptor affinity and pancreatic uptake while exhibiting a more extensive urinary excretion (*46*). BBN(7−14) conjugated to a ^{99m}Tc-tricarbonyl complex via a Gly-Gly-Gly spacer showed predominant urinary excretion but only low uptake into the pancreas (*48*).

The X−BBN(7−14) derivatives were conveniently synthesized by standard solid-phase peptide synthesis and characterized by ESI-MS. The isocyanides 4-(isocyanomethyl)benzoic acid (L1) and the smaller and more flexible 4-isocyanobutanoic acid (L2) may also serve as a modifier of the pharmacokinetic properties of the radiolabeled peptides. For the preparation of isocyanide-modified peptides, the isocyanide-containing active esters L1-BFCA (*9*) and L2-BFCA were designed to serve as bifunctional coupling agents (BFCA). L2-BFCA was prepared as described in Scheme 2. Briefly, formylation of 4-aminobutanoic acid produced product **1**. Esterification of **1** with 2,3,5,6-tetrafluorophenol to produce **2**, followed by reduction using PPh_3 in CCl_4 and triethylamine, afforded the final product L2-BFCA. Conversion of the formylamino derivative **2** to the isocyanide was performed according to a previously published procedure (*50*). The novel L2-BFCA was characterized by elemental analysis, ESI-MS, IR, and ^{1}H and ^{13}C NMR.



L1-BFCA and L2-BFCA allow for convenient coupling of the isocyanide group to peptides. However, it is not possible to use L1-BFCA and L2-BFCA in standard solid-phase peptide synthesis due to conversion of the isocyanide group to an N-formyl amino derivative in acidic media. Furthermore, acidic HPLC eluents comprising acetonitrile, water, and TFA, as normally used for purification of peptides on silica-based, reverse-phase columns, are not recommended. Conversion of isocyanide-modified BBN(7−14) to the N-formyl amino derivative was not immediately observed in the chromatographic profiles when analyzing conjugates by RP-HPLC using a TFA-containing mobile phase. However, purification in this way with subsequent neutralization after collection of the product resulted in a considerable amount of the N-formyl amino derivative. Therefore, purification of the isocyanide BBN(7−14) conjugates was performed using a mobile phase containing 0.1 M ammonia and a polymer-based RP column. The obtained ESI-MS data were consistent with the molecular weights calculated for each compound.

Preparation of ^{99m}Tc-labeled conjugates was performed in a similar manner to a previously published labeling procedure (*9*). The protocol is a two-step procedure and is outlined in Scheme 3. The radiochemical yields were around 30−80% (RP-HPLC) and were dependent upon the amount of isocynaide (20−100 nmol) in the reaction mixture. Methanol was added to the labeling mixture so that it constituted approximately $^1/_3$ of the volume. This was done to prevent precipitation development during the labeling reaction, which would inherently decrease the radiochemical yield. The lipophilic precipitation product was formed by the NS_3 ligand, tin, and ^{99m}Tc species. The labeled compounds were purified by HPLC to give a radiochemical purity of higher than 95%. The ^{99m}Tc conjugates eluted with

Scheme 3. ^{99m}Tc-Labeling Reaction

Scheme 4. Synthesis of [Re(NS$_3$)(L2-BFCA)]

retention times approximately 3 min longer than the nonmetalated isocyanide derivatives, allowing for collection of compounds of very high specific activity. The HPLC elution profiles of the labeling mixture and of the purified compound [^{99m}Tc(NS$_3$)(L1−βAla−BBN(7−14))] are shown in Figure 2. The peak at t_R = 8.4 min is a complex containing ^{99m}Tc and the NS$_3$ ligand but no isocyanide. The identity of the formed [^{99m}Tc(NS$_3$)(L−X−BBN(7−14))] conjugates were revealed by comparing their HPLC profiles with chromatograms of the analogous Re compounds which eluted at the same retention times (Figure 2). The stability of the [^{99m}Tc(NS$_3$)(L−X−BBN-(7−14))] conjugates in the HPLC eluate and in PBS were higher than 90% after 24 h.

Instabilities of a peptide labeled *via* a radiometal chelate can be caused by decomposition of the metal complex and/or the peptide. Previous studies have examined the stability of ^{99m}Tc '4 + 1' complexes showing that there was no decomposition of the ^{99m}Tc chelate in plasma, rat blood, and *in vivo*, as well as no transchelation by glutathione (*7*, *9*). A limitation of the ^{99m}Tc-labeled BBN conjugates presented here could be seen in the proteolytic instability of the peptide sequence. However, there are several examples in the literature of nonstabilized bombesin derivatives exhibiting *in vivo* results as outlined in the Introduction which indicate that BBN(7−14) might be sufficiently stable for *in vivo* imaging applications.

For a convenient synthesis of Re '4 + 1' complex-conjugated peptides, active esters containing Re '4 + 1' complexes analogous to the complex structure of the ^{99m}Tc conjugates were prepared. They were obtained from [Re(NS$_3$)(PMe$_2$Ph)] by exchanging the monodentate phosphine with L1-BFCA or L2-BFCA (Scheme 4). In contrast to the free isocyanide-bearing peptides, standard RP-HPLC using TFA containing mobile phases is possible. The organometallic Re/Tc−C bond exhibits a high stability in strongly acidic media (*6*). The purity (≥95%) of the [Re(NS$_3$)(L−X−BBN(7−14))] conjugates was confirmed by HPLC. ESI-MS data obtained were consistent with the calculated molecular weights.

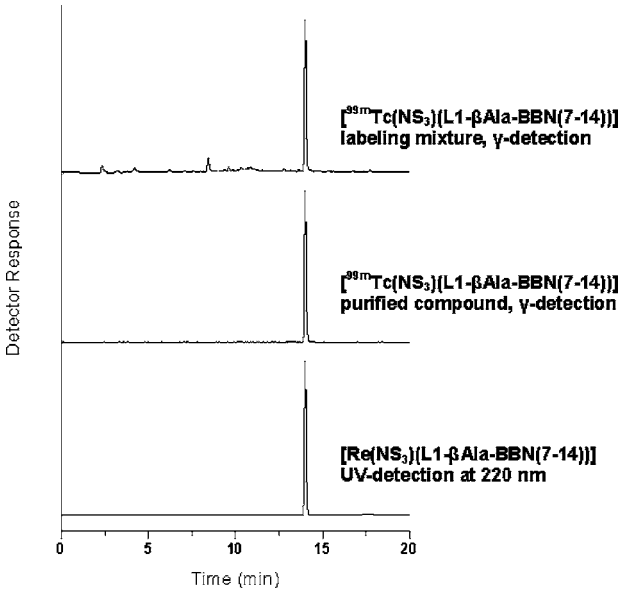


Figure 2. RP-HPLC (system 5) elution profiles of [^{99m}Tc(NS$_3$)(L1−βAla−BBN(7−14))] and [Re(NS$_3$)(L1−βAla−BBN(7−14))].

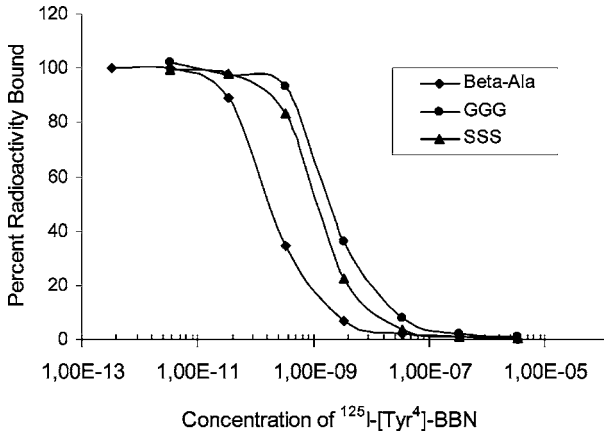

Figure 3. Displacement of ^{125}I-[Tyr^4]BBN by [Re(NS$_3$)(L1−X−BBN-(7−14))], X = βAla, GGG, SSS, from PC3 cells, n = 3.

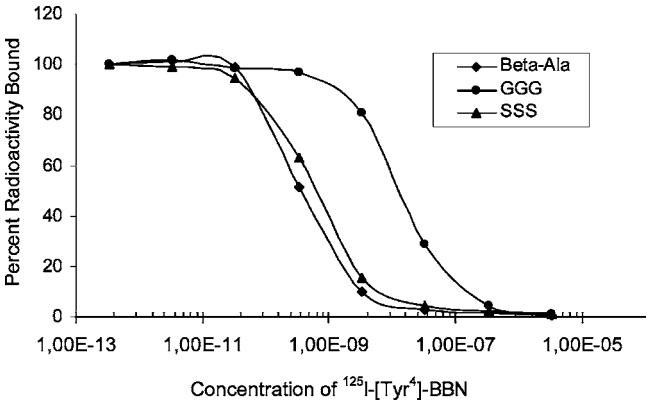

Figure 4. Displacement of ^{125}I-[Tyr^4]BBN by [Re(NS$_3$)(L2−X−BBN-(7−14))], X = βAla, GGG, SSS, from PC3 cells, n = 3.

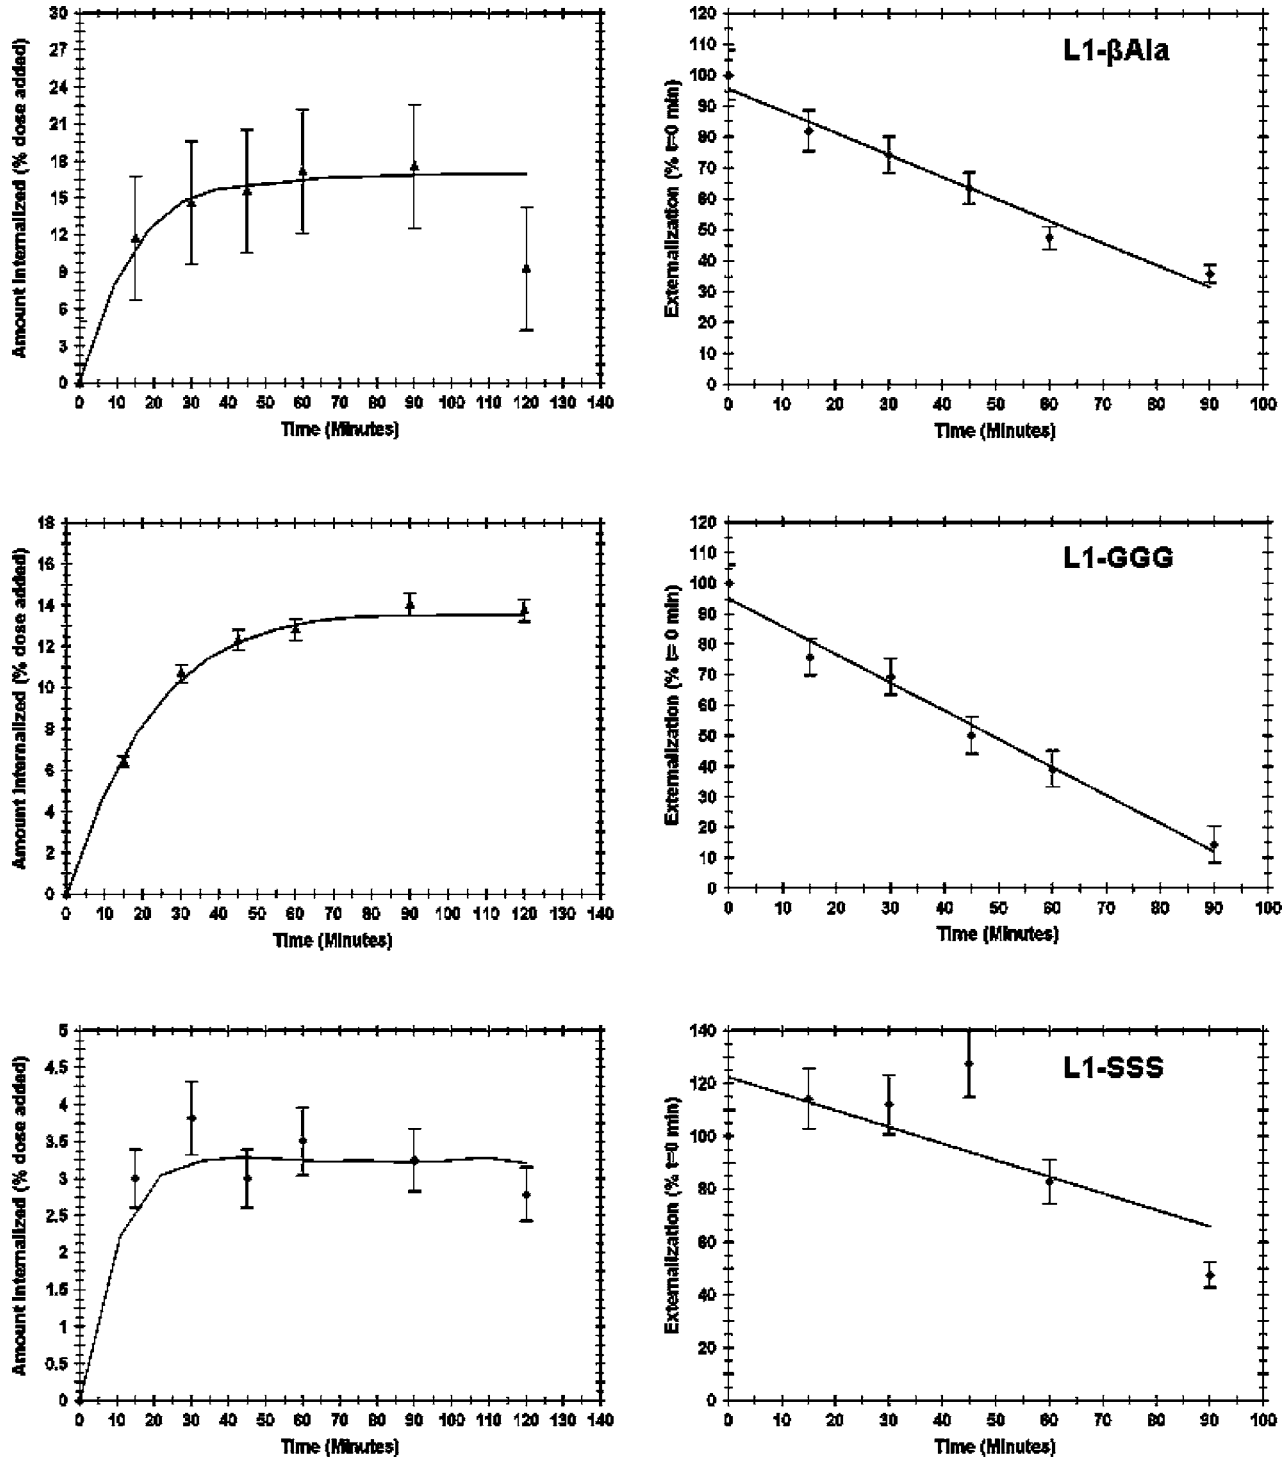

Figure 5. Internalization and externalization studies of [^{99m}Tc(NS$_3$)(L1−X−BBN(7−14))], X = βAla, GGG, SSS, using PC-3 cells.

Table 1. IC_{50} Values of [Re(NS$_3$)(L−X−BBN(7−14))] Obtained by Displacement of ^{125}I-[Tyr^4]BBN from PC-3 Cells, $n = 3$

Re '4 + 1' Conjugates	IC_{50} (nM)
[Re(NS$_3$)(L1-GGG-BBN(7−14))]	1.9 ± 0.4
[Re(NS$_3$)(L1-βAla-BBN(7−14))]	0.20 ± 0.04
[Re(NS$_3$)(L1-SSS−BBN(7−14))]	1.2 ± 0.1
[Re(NS$_3$)(L2-GGG-BBN(7−14))]	1.4 ± 0.1
[Re(NS$_3$)(L2-βAla-BBN(7−14))]	0.35 ± 0.03
[Re(NS$_3$)(L2-SSS−BBN(7−14))]	0.65 ± 0.32

Affinity of the [Re(NS$_3$)(L−X−BBN(7−14))] conjugates to GRP receptors overexpressed on PC-3 cells was determined by a competitive binding displacement assay (Figures 3 and 4). IC_{50} values, ranging from 0.20 ± 0.04 to 1.9 ± 0.4 nM, show low variation and indicate a high affinity for the GRPr for all of the new conjugates (Table 1). The spacer group βAla, in comparison with Gly-Gly-Gly or Ser-Ser-Ser, resulted in the highest receptor affinity. The aromatic or aliphatic isocyanides L1 or L2 did not cause a significant difference in receptor binding. The determined IC_{50} values are highly comparable to those previously reported for X−BBN(7−14), X = Gly-Gly-Gly, βAla, Ser-Ser-Ser, N-terminally bearing $[Re(CO)_3]^+$ moieties, or Re−N$_3$S complexes (*36*, *46*, *48*).

Figures 5 and 6 summarize the results of studies to assess the degree of uptake (internalization) and efflux (externalization) of the [^{99m}Tc(NS$_3$)(L−X−BBN(7−14))] conjugates in PC-3 cells. The significance of the internalization experiments was to demonstrate the agonist activity of the ^{99m}Tc conjugates.

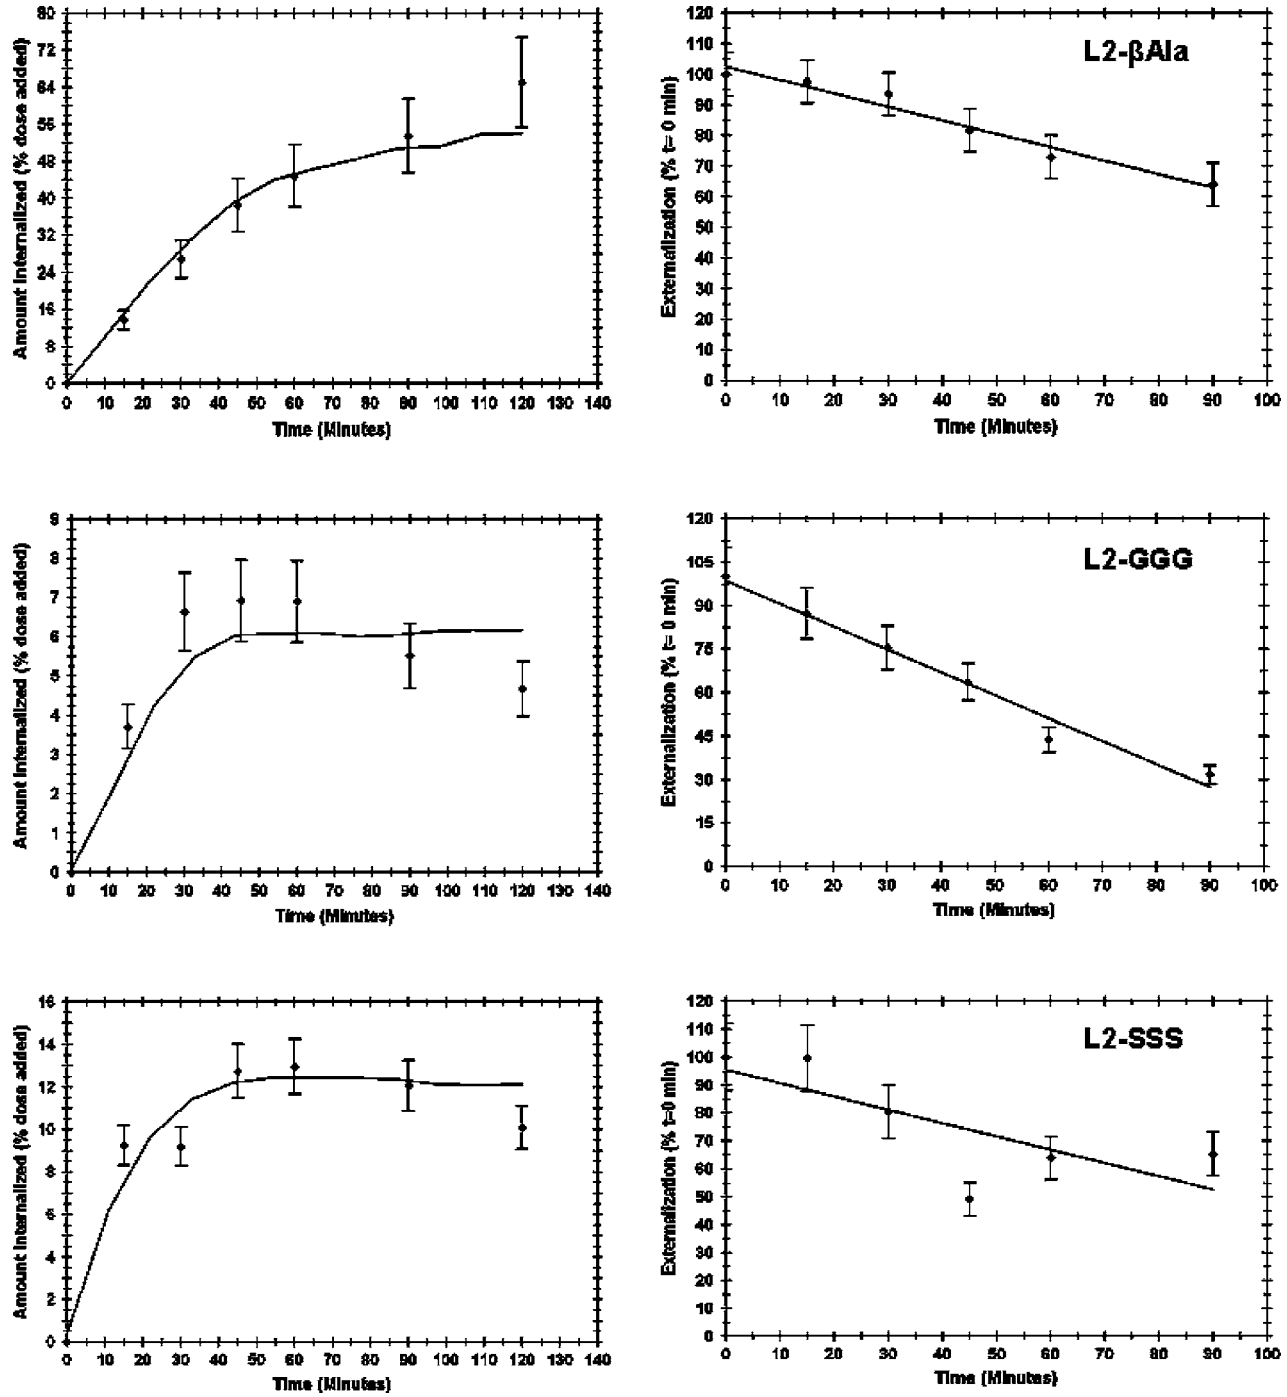

Figure 6. Internalization and externalization studies of [^{99m}Tc(NS$_3$)(L2−X−BBN(7−14))], X = βAla, GGG, SSS, using PC-3 cells.

Radioligands acting as agonists are inherently internalized into the cell, often resulting in prolonged activity within the cell. Of all the conjugates evaluated in this series, [^{99m}Tc(NS$_3$)(L2−βAla−BBN(7−14))] exhibited the highest degree of cellular uptake. Up to ∼65% of the total activity administered was internalized at 120 min. For all of the other conjugates, the maximum of internalized activity ranged from approximately 10% to 20% of the total activity administered between 60 and 80 min post incubation. The amount of internalized activity for these conjugates is comparable to (or slightly lower than) other metalated X−BBN(7−14) conjugates previously reported (*36*, *46*, *48*). To assess the externalization of ^{99m}Tc activity from PC-3 cells, at time point 45 min incubation, cells were washed with the pH 2.5 buffer to remove any surface-bound activity and then incubated in pH 7.4 media. Measurements up to 90 min incubation showed that ∼70% of the ^{99m}Tc activity for [^{99m}Tc(NS$_3$)(L2−βAla−BBN(7−14))] and ∼60% for [^{99m}Tc(NS$_3$)(L2−SSS−BBN(7−14))] remained trapped in the cells, whereas about 20−40% of the internalized ^{99m}Tc activity remained in the cells for the other [^{99m}Tc(NS$_3$)(L−X−BBN-(7−14))] conjugates. The externalization data for [^{99m}Tc(NS$_3$)-(L2−βAla−BBN(7−14))] and [^{99m}Tc(NS$_3$)(L2−SSS−BBN(7−14))] is comparable with previous studies of similar BBN(7−14) conjugates (*36*, *46*, *48*), whereas a lesser amount of ^{99m}Tc activity remained trapped in PC-3 cells for all of the other [^{99m}Tc(NS$_3$)(L−X−BBN(7−14))] conjugates as compared to previously published reports (*36*, *46*, *48*).

[^{99m}Tc(NS$_3$)(L−βAla−BBN(7−14))], L = L1 or L2, showed favorable *in vitro* receptor binding and cellular uptake/internalization in PC-3 cells and were selected as candidates from a [^{99m}Tc(NS$_3$)(L−X−BBN(7−14))] series for biodistribution studies in normal CF-1 mice. Analogous conjugates were

Table 2. Biodistribution of [^{99m}Tc(NS$_3$)(L1−βAla−BBN(7−14))], A; [^{99m}Tc(NS$_3$)(L2−βAla−BBN(7−14))], B; [^{99m}Tc(NS$_3$COOH)(L1−βAla−BBN(7−14))], C; [^{99m}Tc(NS$_3$COOH)(L2−βAla−BBN(7−14))], D; in Normal Mice (% ID/g ± SD, 1 h p.i., n = 4 or 5)

also evaluated where the NS_3 coligand was replaced by NS_3-COOH. The selection of the tetradentate coligand NS_3COOH bearing a pendant carboxyl group in comparison to NS_3 based on our previously published results showed that the introduction of the carboxyl group decreases the lipophilicity and the liver uptake of small '4 + 1' model complexes (*9*). Decreasing the lipophilicity of a ^{99m}Tc-labeled BBN derivative by introducing carboxyl groups via coupling of DTPA as a pharmacokinetic modifier was demonstrated by Lin et al. (*40*).

Results of the biodistribution studies in normal CF-1 mice are summarized in Table 2. There is minimal ^{99m}Tc activity uptake in the stomach, indicating that there is little or no *in vivo* dissociation of ^{99m}Tc from the ligands to produce $^{99m}TcO_4^-$. After 1 h i.v. administration, the compounds rapidly accumulated in the liver and were excreted *via* the intestines. Accumulation in the pancreas, an accessible tissue expressing the GRPr in high density, was very low. This can probably be attributed to rapid accumulation in liver and hepatobiliary excretion that decreases the concentration of the ^{99m}Tc conjugates in the blood pool, lessening the concentration of radiolabeled conjugate available for receptor uptake. Rapid hepatobilary excretion and the fact that there are only minimal differences between the biodistribution profiles for all of the compounds indicates that the biodistribution profiles are highly dominated by the '4 + 1' complex unit. These findings compared with the pharmacokinetic behavior of other ^{99m}Tc conjugates of the general type X−BBN(7−14), X = Gly-Gly-Gly, βAla, Ser-Ser-Ser (*36*, *46*, *48*), where renal/urinary excretion is the primary mode of elimination of conjugate from the body, suggests that the radiometal complex unit is significant for the biodistribution of these radiolabeled ^{99m}Tc conjugates. ^{99m}Tc conjugates of X−BBN(7−14), where X = βAla and 5-aminovaleric, 8-aminooctanoic, and 11-aminoundecanoic acid (*36*), have demonstrated a rise in lipophilic character associated with the increasing length of the linker. This results in an increased hepatobiliary elimination, whereas pancreatic uptake decreases. High lipophilic ^{99m}Tc conjugates of this series containing the 8- and 11-carbon atom spacer have a similar degree of hepatobiliary excretion compared to the ^{99m}Tc '4 + 1' conjugates described herein.

CONCLUSION

The work presented herein describes the preparation and characterization of novel BBN(7−14) conjugates bearing ^{99m}Tc/Re '4 + 1' complexes, so far only exemplarily assessed on peptides (*9*). The concept of isocyanide modification by bifunctional coupling agents as well as conjugation using Re '4 + 1' complex-bearing active esters proved to be very convenient for peptide modification. The '4 + 1' complex units conjugated *via* spacers to the BBN(7−14) N-terminus were well-tolerated by the GRP receptor. Using βAla as spacer compared to Gly-Gly-Gly and Ser-Ser-Ser resulted in slightly higher receptor binding affinity. In contrast to receptor binding assays, the '4 + 1' complex BBN(7−14) conjugates described herein showed greater variation with regard to PC-3 cell uptake and externalization. Here, only [^{99m}Tc(NS$_3$)(L2−βAla−BBN(7−14))] exhibited characteristics roughly comparable to previously reported BBN(7−14) conjugates (*36*, *46*, *48*). Biodistribution studies showed rapid hepatobiliary excretion of the conjugates, a likely cause of the low uptake in target-specific pancreatic tissue. The biodistribution profile is dominated by the '4 + 1' complex unit. In order to decrease the lipophilicity of the ^{99m}Tc complex unit, a carboxyl group was introduced onto the NS_3 chelate. This only slightly changed the biodistribution behavior of the conjugates, further indicating that more wide-ranging modifications of the '4 + 1' complex unit are necessary to produce site-directed conjugates of this general type. This should be facilitated by the bulk tolerance shown when attaching metal units *via* the N-terminus of BBN(7−14).

ACKNOWLEDGMENT

The authors would like to thank the University of Missouri−Columbia School of Medicine, Department of Radiology, for funding a working stay of J.-U. Kunstler at the University of Missouri−Columbia and the Harry S. Truman Memorial Veterans' Hospital. We would also like to acknowledge the University of Missouri−Columbia School of Medicine and the Harry S. Truman Memorial Veterans' Hospital for providing laboratory space and resources for completion of this work.

Design of Aminated Poly(1-vinylimidazole) for a New pH-Sensitive Polycation To Enhance Cell-Specific Gene Delivery

Shoichiro Asayama,* Takashi Sekine, Hiroyoshi Kawakami, and Shoji Nagaoka

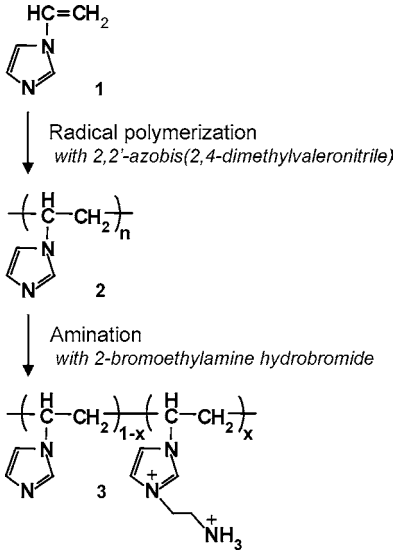
Department of Applied Chemistry, Tokyo Metropolitan University, 1-1 Minami-Osawa, Hachioji, Tokyo 192-0397, Japan
Received June 7, 2007; Revised Manuscript Received July 24, 2007

Poly(1-vinylimidazole) (PVIm) with aminoethyl groups has been synthesized as a new pH-sensitive polycation to enhance cell-specific gene delivery. The resulting aminated PVIm (PVIm-NH_2) was water-soluble despite deprotonation of the imidazole groups at physiological pH, as determined by acid−base titration and solution turbidity measurement. Hemolysis assay showed that PVIm-NH_2 enhanced membrane disruptive ability at endosomal pH, owing to the protonation of the imidazole groups with a pK_a value around 6.0. Agarose gel retardation assay proved that the introduced aminoethyl groups worked as anchor groups to retain DNA. Furthermore, the ternary complex of DNA, PVIm-NH_2, and a poly(L-lysine) conjugated with lactose molecules, PLL-Lac, at pH 7.4 dissociated the PLL-Lac polycation by protonation of the imidazole groups of PVIm-NH_2 at pH 6.0. The resulting PVIm-NH_2/DNA binary complexes easily released DNA, as compared with the PLL-Lac/PVIm-NH_2/DNA ternary complex, which was examined by competitive exchange with dextran sulfate. By using PVIm-NH_2 as a pH-sensitive DNA carrier, as well as PLL-Lac as a cell-targeting DNA carrier, the resulting ternary complex specifically mediated the gene expression, which depended on the protonation of the imidazole groups, on human hepatoma HepG2 cells with asialoglycoprotein receptors. These results suggest that the cell-specific gene delivery mediated by PLL-Lac was enhanced by PVIm-NH_2 as a new pH-sensitive polycation.

INTRODUCTION

In gene delivery systems, the formation of DNA−carrier polyion complexes is a key factor for new designs of efficient delivery (*1*−*3*). The carrier design typically focuses on the ability of a ligand to bind tightly to its target. The ligand−receptor complexes on the cell plasma membrane are internalized into acidic endosomal vesicles, where they are subjected to a significant pH change from pH 7 to 5 (*4*). Subsequently, the targeting ligands are routed to the degradation in the acidic compartment following endosomal vesicles or are recycled to the cell surface (*5*). Such fate of ligands leads us to create the DNA−polyion complexes dissociating ligand molecules in response to pH. In general, targeting ligands are unnecessary to make DNA complexes escape from endosomal vesicles. The endosomal escape is one of the critical factors for efficient gene delivery. If the carrier stably retains DNA during the delivery to the target site and easily releases DNA after the escape from endosomal vesicles, gene delivery is expected to be more efficient. Therefore, we have designed a DNA ternary complex, with a pH-sensitive and ligand polycation, that stably retains DNA at physiological pH and dissociates the ligand polycation in response to endosomal pH. The resulting DNA binary complex is expected to promote the endosomal escape by the physicochemical/biochemical properties of the pH-sensitive polycation and the DNA release by the easier competitive exchange with anionic biomacromolecules than shown by the ternary complex.

Recently, pH-sensitive polymers such as poly(ethylenimine) (PEI[1]), which is able to capture protons entering an endosome, have been used to achieve efficient release of the delivered material from endosomes (*6*−*8*). PEI induces swelling of the endosomes that leads to membrane disruption, that is, the proton sponge effect. On the other hand, we have already reported the biphasic polycation (*9*) consisting of a poly(1-vinylimidazole) (PVIm) backbone and lactosylated poly(L-lysine) (PLL-Lac) side chains as a DNA carrier with a proton-buffering effect at endosomal pH (*10*). Furthermore, we have already synthesized poly(L-histidine) with several aminoethyl groups, that is, aminated poly(L-histidine) (PLH-NH_2), to make complexes with DNA (*11*, *12*). The protonation of imidazole groups of the resulting PLH-NH_2 at pH 6.0 has triggered the dissociation of PLL-Lac from the PLL-Lac/PLH-NH_2/DNA ternary complex (*13*). Although pH-sensitive ternary complexes such as imidazole-containing polyhistidine/polylysine-transferrin/DNA complexes (*14*) are reported (*15*), our concept that DNA ternary complexes dissociate ligand polycations in response to endosomal pH, resulting in DNA binary complexes, has no precedent, to the best of our knowledge. However, neither biphasic polycation nor PLH-NH_2 exhibited significant transfection activity.



In this study, to realize efficient gene expression, we have designed PVIm with several aminoethyl groups, that is, "aminated PVIm" (PVIm-NH_2), by extracting the advantages of both the biphasic polycation and PLH-NH_2. PVIm is a water-soluble homopolymer possessing many imidazole groups with a pK_a around 6.0. Despite a large capacity for H^+ buffering at endosomal pH, PVIm has difficulty in forming complexes with DNA at physiological pH because its imidazole groups are negligibly charged at pH 7.4. The introduced aminoethyl groups with a pK_a around 10 are expected to work as anchor groups to retain DNA. The DNA ternary complex with the resulting

PVIm-NH_2 and PLL-Lac, the β-galactose residues of which are ligands for an asialoglycoprotein receptor (ASGP-R) expressed on hepatocytes or hepatoma cells (*16*), is therefore expected to dissociate the PLL-Lac ligand polycation at endosomal pH. Consequently, PVIm-NH_2 as a pH-sensitive polycation promises to enhance the cell-specific gene delivery mediated by the PLL-Lac as a ligand polycation.

EXPERIMENTAL PROCEDURES

Materials. 1-Vinylimidazole (VIm) was purchased from Aldrich Chemical Co. (Milwaukee, WI) and was distilled under reduced pressure. 2,2′-Azobis(2,4-dimethylvaleronitrile) (V-65) was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan) and was recrystallized from ethanol. 2-Bromoethylamine hydrobromide was purchased from Kanto Chemical Co., Inc. (Tokyo, Japan). PEI solution, salmon testis deoxyribonucleic acid (DNA) sodium salt, and fluorescein isothiocyanate (FITC) isomer I were from Sigma Chemical Co. (St. Louis, MO). All other chemicals of a special grade were used without further purification.

Synthesis of PVIm-NH_2. The synthetic route to PVIm-NH_2 is shown in Scheme 1. VIm (**1**) (300 μL) and V-65 (15.8 mg) as an initiator were dissolved in 2.7 mL of *N*,*N*-dimethylformamide. Radical polymerization reaction was carried out for 2 h at 45 °C. After the reaction, the content was poured into a large excess of acetone, and the precipitate was dried in vacuo. The resulting polymer (**2**) (25 mg) and 2-bromoethylamine hydrobromide (3.75 g) were dissolved in 12.5 mL of dimethyl sulfoxide. The reaction mixture was incubated at 40 °C for 5 days, followed by dialysis against distilled water using a Spectra/Por 7 membrane (molecular weight cutoff = 10^3) to remove unreacted 2-bromoethylamine. The resulting polymer (**3**) was obtained by freeze-drying.

Gel Filtration Chromatography (GFC). GFC was carried out using a JASCO PU-980 pumping system (Tokyo, Japan) at the flow rate of 1.0 mL/min with a Shodex OHpak SB-804 HQ column (Showa Denko K.K., Tokyo, Japan). The aqueous solution containing 0.5 M CH_3COOH and 0.2 M $NaNO_3$ was used as a mobile phase. One hundred microliters of a 1 mg/mL sample was injected into the column. Eluate was detected by a refractive index detector (RI-1530, JASCO). Calibration was made with polyethylene glycol standards.

^{1}H NMR Spectroscopy. Each polymer (3 mg) was dissolved in 700 μL of D_2O (99.8 atom % deuterium; Acros). The ^{1}H NMR spectra (400 MHz) were obtained by a JEOL JNM-AL400 spectrometer (Tokyo, Japan).

Acid−Base Titration and Turbidity Measurement of PVIm-NH_2. To 1.5 mL of an aqueous solution of the polymer (3.3 mg/mL) was added a 1 M NaOH solution, and the basic polymer solution (pH 10) was titrated with a 1 M HCl solution. The pH value was checked with a pH-meter (model F-52T, Horiba, Kyoto, Japan). The titration was carried out by the stepwise addition of 1 M HCl and stopped at pH 3.5. The turbidity of the solution during the titration was measured by monitoring the absorbance at 500 nm with a spectrophotometer (model Ubest-55, JASCO, Tokyo, Japan).

Assay for the Interaction between PVIm-NH_2 and Serum Protein. The mixture of PVIm-NH_2 (0.5 mg/mL) and 50% heat-inactivated fetal bovine serum (FBS) was incubated at 37 °C. As a control, PEI (0.5 mg/mL) was used. The turbidity of the solution during the incubation was measured by monitoring the absorbance at 700 nm.

Hemolysis Assay. The stock solution (10 mg/mL) of PVIm-NH_2 was diluted to 670 μg/mL with 10 mM sodium phosphate buffer (pH 7.4, 6.0, or 5.0) containing 130 mM NaCl. Then, 150 μL of the polymer solution was incubated with 20 μL of sheep preserved blood (Cosmo Bio Co., Ltd., Tokyo, Japan) for 90 mim at 37 °C. After centrifugation (13000 rpm, 1 min, 4 °C), the released hemoglobin was determined by measuring the absorbance at 577 nm of the 10-fold diluted supernatant.

Agarose Gel Retardation Assay. Salmon testis DNA was dissolved in PBS (−) at 0.9 mg/mL. The resulting DNA stock solution was added to the polymer solutions in 50 mM sodium phosphate buffer (pH 7.5 or 6.0) at various polymer/DNA ratios. The final diluted concentration of DNA was adjusted to 60 μg/mL. After 30 min of incubation at room temperature, each sample (corresponding to 0.6 μg of DNA) was mixed with a loading buffer and loaded onto a 1% agarose gel containing 1 μg/mL of ethidium bromide (EtBr). Gel electrophoresis was run at room temperature in 50 mM sodium phosphate buffer (pH 7.5 or 6.0) at 50 V for 15 min. The DNA bands were visualized under UV irradiation.

Synthesis of PLL-Lac. Poly(L-lysine) (PLL) hydrobromide (50 mg; number-average degree of polymerization = 266) and lactose monohydrate (288 mg) were preincubated at 37 °C for 3 days in 7.5 mL of sodium borate buffer (0.1 M, pH 8.5) (*17*). Then, a reducing agent, $NaBH_3CN$, was added to the mixture of PLL and lactose in 10 mL of the sodium borate buffer at a final concentration of 0.3 M. The reaction mixture was incubated at 37 °C for 3 days. The degree of amino group modification (approximately 100 mol %) was examined by the primary amino group determination with fluorescamine (*18*). The reaction mixture was dialyzed against distilled water using a Spectra/Por 7 membrane (molecular weight cutoff = 10^3) to remove unreacted lactose, followed by freeze-drying. For fluorescent labeling, the resulting PLL-Lac (10 mg) and FITC isomer I (1 mg) were dissolved in 1.1 mL of 10 mM K_2CO_3. The reaction mixture was incubated at room temperature for 2 h, followed by dialysis against distilled water using a Spectra/Por 7 membrane (molecular weight cutoff = 10^3) to remove unreacted FITC. The resulting polypeptide was obtained by freeze-drying.

Cell Viability Assay. HepG2 cells (a gift from the Japan Health Sciences Foundation), human hepatoma cell line, were cultured in tissue culture flasks containing Dulbecco's modified Eagle's medium supplemented with 10% heat-inactivated FBS. The cells were seeded at 1×10^4 cells/well in a 96-well plate and incubated overnight at 37 °C in a 5% CO_2 incubator. The cells were treated with each polymer (0−400 μg/mL) and incubated for 24 h at 37 °C. By further incubation for 4 h, the cell viability was measured using the Alamar Blue assay (*19*) in triplicate.

Transfection Procedure. In a typical 96-well plate experiment, 1×10^4 cells/well HepG2 cells were transfected in

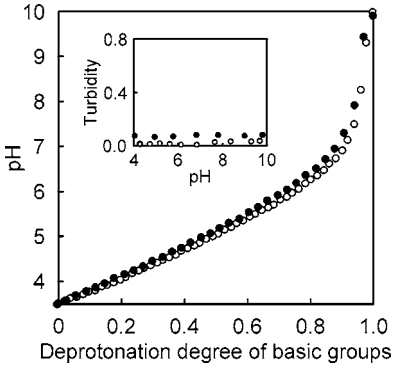

Figure 1. Acid−base titration curves of polymers: (●) PVIm-NH_2; (○) PVIm. Basic polymer solutions were titrated with the stepwise addition of 1 M HCl. The horizontal axis is normalized as the deprotonation degree based on the total basic groups of each polymer. The deprotonation degree indicates the ratio of the amount of deprotonated basic groups to that of total basic groups at the indicated pH. (Inset) Effect of pH on the solubility of the polymers in water (3.3 mg/mL): (●) PVIm-NH_2; (○) PVIm. The turbidity was measured by monitoring the absorbance at 500 nm of the polymer aqueous solution during the acid−base titration.

Dulbecco's modified Eagle's medium supplemented with 10% heat-inactivated FBS by the addition of 15 μL of PBS (−) containing 200 ng of plasmid DNA encoding the modified firefly luciferase (pGL3-Control Vector; from Promega Co.) and complexed with polycations. After 1 day of incubation in the presence or absence of chloroquine at a 100 μM final concentration, the medium was removed and the cells were further incubated for 3 days in the Dulbecco's modified Eagle's medium supplemented with 10% FBS. Then, the cells were subjected to the luciferase assay (Promega kit) according to the manufacturer's instruction. Luciferase activities were normalized by protein concentrations and are presented as relative light units (RLU). Protein concentrations were determined by BCA protein assay kit (Pierce) according to the manufacturer's instruction.

RESULTS AND DISCUSSION

Synthesis of PVIm-NH_2. As shown in Scheme 1, PVIm (**2**) was reacted with 2-bromoethylamine hydrobromide for one-step introduction of amino groups. The GFC profile (results not shown) of the resulting polymer (**3**) indicated that unreacted 2-bromoethylamine reagents were removed by the purification process, including dialysis. The number-average molecular weight of the isolated polymer determined by GFC was about 8.1×10^3. The ^{1}H NMR spectrum of the resulting polymer showed the characteristic signals of both PVIm (*20*) [δ 1.8−2.2 (methylene), 2.3−3.7 (methine), 6.4−7.2 (imidazole)] and aminoethyl (δ 3.2−4.0) moieties. To examine whether the properties of imidazole and amino groups were preserved, we carried out the acid−base titration of the polymer solution, as shown in Figure 1. The imidazole protons of PVIm were gently dissociated around pH 6, whereas the resulting polymer exhibited slight dissociation around pH 10 as well as gentle dissociation around pH 6. The proton dissociation around pH 6 and 10 was attributed to that of imidazole and amino groups, respectively, of the resulting polymer. The slight dissociation of amino protons was almost consistent with the content (approximately 2.5 mol %) of introduced aminoethyl groups determined by the primary amino group determination with fluorescamine (*18*). Thus, we have synthesized PVIm with aminoethyl groups, that is, "PVIm-NH_2."

Physicochemical and Biochemical Properties of PVIm-NH_2. It should be noted that the aqueous solution of PVIm-NH_2 as well as that of PVIm exhibited no significant turbidity above pH 6 (Figure 1, inset). On the other hand, in our previous study, PLH-NH_2 exhibited precipitation above pH 6.0 owing to the deprotonation of the imidazole groups (*11*, *12*). In this study, PVIm-NH_2 was water-soluble despite the deprotonation of the imidazole groups. Therefore, we examined how the water solubility of PVIm-NH_2 influenced the solution stability in serum protein (FBS). No significant turbidity is observed during the incubation of PVIm-NH_2 with serum protein (results not shown). The aqueous solution of PEI as a control of pH-sensitive polymer (*6*−*8*), on the other hand, exhibits turbidity during the incubation with the serum. Because the water solubility of PVIm-NH_2 was probably sufficient, the polymers dispersed in the medium as colloidal particles without undergoing particle aggregation despite the possession of the cationic amino groups. However, the cationic PEI interacting with anionic serum protein presumably reduced the electrostatic repulsion among the colloidal particles, inducing particle aggregation to exhibit turbidity (*21*). These results suggest that no significant effect on a rapid aggregate formation of serum proteins is induced by PVIm-NH_2.

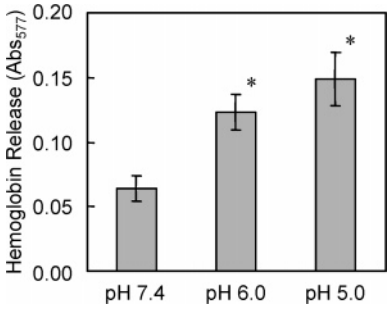

Figure 2. Effect of pH on the hemolytic activity of PVIm-NH_2. Erythrocytes were incubated with PVIm-NH_2 for 90 min at 37 °C in 10 mM sodium phosphate buffer (pH 7.4, 6.0, or 5.0) containing 130 mM NaCl. The released hemoglobin was determined by measuring the absorbance at 577 nm (Abs_{577}). The Abs_{577} at 100% hemolysis achieved with hypotonic treatment is 0.453 ± 0.065. Symbols and error bars represent the mean and standard deviation of the measurements made in paired samples ($n = 3$). ∗ indicates statistical significance ($p < 0.002$) when compared to the pH 7.4 value.

To examine the interaction of PVIm-NH_2 with real cell membranes, the effects on the hemolytic activity were investigated. As shown in Figure 2, PVIm-NH_2 caused negligible hemolysis at pH 7.5, whereas the hemolytic activity significantly increased at pH 6.0 as well as pH 5.0. These results suggest that the membrane disruptive ability of PVIm-NH_2 increased at endosomal pH. It is therefore expected that PVIm-NH_2 enhances the ability to escape from acidic endosomal vesicles.

Then, we examined whether PVIm-NH_2 formed the polyion complex with DNA by agarose gel electrophoresis. As shown in Figure 3, DNA was stained by EtBr, which was intercalated between base pairs of duplex DNA. The intercalation of EtBr increases the fluorescence, so that EtBr is effective for the detection of DNA (*22*). Each lane contains the same amount of DNA, and lanes 2−6 and lanes 2′−6′ contain increasing amounts of the unmodified PVIm (**2**) and the PVIm-NH_2 (**3**), respectively. Even in the presence of an excess amount of the unmodified PVIm at pH 7.4, most of the DNA migrated into the plus pole of the gel, which suggested that the DNA and PVIm exhibited no complex formation owing to the almost complete deprotonation of the imidazole groups (see Figure 1). In the case of PVIm-NH_2, on the other hand, the bands were retained at the origin when the DNA was mixed with an excess of PVIm-NH_2 (lanes 4′−6′). In particular, almost no free DNA was observed at the imidazole/phosphate ratio of 40 (lane 6′), which almost corresponded to the amino/phosphate ratio of 1. These results suggest that the PVIm-NH_2 formed the DNA complex at the stoichiometric charge ratio of DNA to introduced aminoethyl groups; that is, the introduced aminoethyl groups

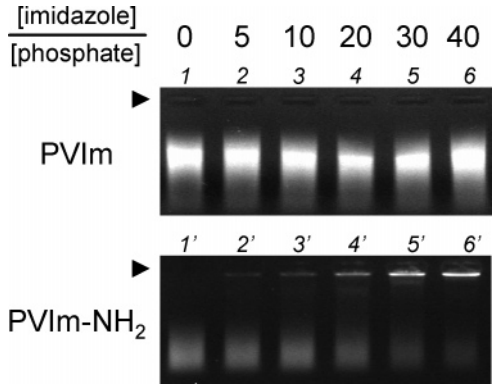

Figure 3. Analysis of the formation of the complex between DNA and the polymers by agarose gel electrophoresis; interaction of PVIm (lanes 1−6) or PVIm-NH_2 (lanes 1′−6′) with DNA: lanes 1 and 1′, DNA alone; lanes 2−6 and 2′−6′, DNA/polymer mixtures at different unit ratios relative to imidazole groups of polymer per phosphate group of DNA ([imidazole]/[phosphate]); lanes 2 and 2′, 5×; lanes 3 and 3′, 10×; lanes 4 and 4′, 20×; lanes 5 and 5′, 30×; lanes 6 and 6′, 40×. Solid arrowhead indicates the well where each sample was loaded.

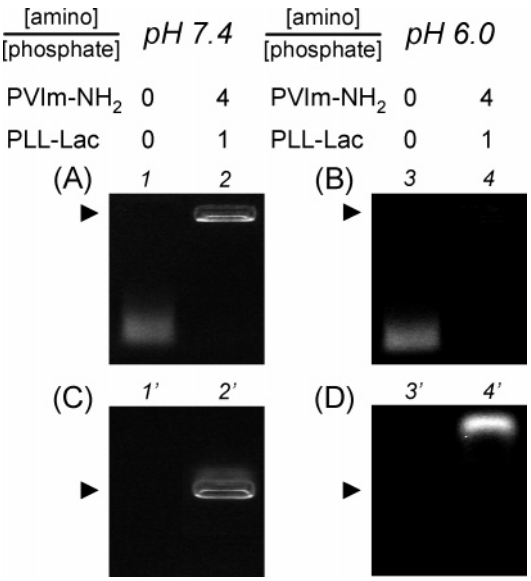

Figure 4. Analysis of the pH-dependent formation of PLL-Lac/PVIm-NH_2/DNA ternary complexes in the presence (A, B) or absence (C, D; where PLL-Lac was labeled with FITC) of EtBr: lanes 1, 1′, 3, and 3′, DNA alone; lanes 2, 2′, 4, and 4′, PLL-Lac/PVIm-NH_2/DNA mixtures, where the unit ratios relative to amino groups of PVIm-NH_2 and PLL-Lac per phosphate group of DNA ([amino]/[phosphate]) are 4 and 1, respectively. PLL-Lac/PVIm-NH_2/DNA mixtures were loaded at pH 7.4 (A, C) or pH 6.0 (B, D). Solid arrowhead indicates the well where each sample was loaded.

worked as anchor groups to retain DNA. Furthermore, the resulting complexes showed a significant fluorescence owing to EtBr staining. These results suggest that the DNA in the complex was not completely compacted (*23*). A similar observation was previously reported in the case of the soluble complexes between DNA and the polycation grafted with water-soluble polymer chains such as dextran (*24*). In this study, the nonionic PVIm backbone seems to solubilize the DNA complexes and to reduce DNA compaction at physiological pH.

pH-Dependent Dissociation of Carbohydrate Ligand Polycations from DNA Ternary Complexes. We have already reported the concept that DNA ternary complexes dissociate ligand polycations in response to endosomal pH (*13*). In this study, as shown in Figure 4, we examined the pH-dependent dissociation of PLL-Lac from the DNA ternary complexes with PLL-Lac and PVIm-NH_2 by agarose gel electrophoresis. At pH 7.4, the band was retained at the origin when DNA was mixed with PLL-Lac and PVIm-NH_2 ($[\text{amino group}]_{\text{PLL-Lac}}/[\text{phosphate group}]_{\text{DNA}} = 1$; $[\text{amino group}]_{\text{PVIm-NH2}}/[\text{phosphate group}]_{\text{DNA}} = 4$) (Figure 4A). It should be noted that the band retained at the origin at pH 7.4 disappeared at pH 6.0 (Figure 4B). These results suggest that the protonation of imidazole groups of PVIm-NH_2 at pH 6.0 induced the coil−globule transition of DNA and inhibited the EtBr intercalation (*22*, *25*).

In the above experiments, however, the formation of the polyion complex with PLL-Lac was unclear. Therefore, we labeled PLL-Lac with FITC and examined whether PLL-Lac formed the polyion complex with DNA by agarose gel electrophoresis in the absence of EtBr. At pH 7.4, the band was also retained at the origin (Figure 4C). It is therefore confirmed that PLL-Lac formed the polyion complex with DNA at pH 7.4; that is, DNA, PVIm-NH_2, and PLL-Lac formed ternary complexes at pH 7.4. At pH 6.0, on the other hand, it is worth noting that PLL-Lac migrated into the minus pole of the gel (Figure 4D). The migration into the minus pole suggests that the PLL-Lac polycation was dissociated from the DNA complex. Taking these results into account, PLL-Lac/PVIm-NH_2/DNA ternary complexes at pH 7.4 have dissociated the PLL-Lac polycations by the protonation of the imidazole groups of PVIm-NH_2 at pH 6.0, resulting in PVIm-NH_2/DNA binary complexes.

Stability of PVIm-NH_2/DNA Binary or PLL-Lac/PVIm-NH_2/DNA Ternary Complexes. The interaction between oppositely charged polyelectrolytes (polyions) is very strong, and the dissociation of the polyion complexes is unlikely under physiological ionic strength conditions. However, the DNA ternary complexes successfully dissociate ligand polycations in response to endosomal pH, resulting in DNA binary complexes. Therefore, the stability of the PVIm-NH_2/DNA binary or PLL-Lac/PVIm-NH_2/DNA ternary complexes was examined. To examine the complex stability, we attempted to release DNA from the polyion complex by competitive exchange with other polyanions (*26*). For effective transfection, the release of DNA should not happen outside the target cell, whereas that must occur somewhere inside to allow binding of the transcription machinery. In biological fluids, the proteins borne by various anionic polysaccharides circulate. As an extreme case, dextran sulfate was used as a polyanion; that is, agarose gel electrophoresis was carried out after the binary or ternary complex was incubated with dextran sulfates. The results are shown in Figure 5. As the concentration of the dextran sulfate increased, the DNA increasingly migrated (lanes 3−6) in the case of the PVIm-NH_2/DNA binary complex. On the other hand, in the case of the PLL-Lac/PVIm-NH_2/DNA ternary complex, almost no DNA migrated even in the presence of the higher concentration of the dextran sulfate (lane 6′). These results suggest that the PVIm-NH_2/DNA binary complex released the DNA by exposure to polyanions and that the PLL-Lac/PVIm-NH_2/DNA ternary complex stably retained the DNA. We have therefore expected the PLL-Lac/PVIm-NH_2/DNA ternary complex, which results in the PVIm-NH_2/DNA binary complex by the pH-dependent dissociation of the PLL-Lac, to lead effective gene expression.

Cell-Specific Gene Delivery by the PLL-Lac/PVIm-NH_2/DNA Ternary Complex. To confirm the required property as gene carrier, we first carried out a cytotoxicity assay (additional results not shown). The cell viability of HepG2 hepatoma cells did not significantly decrease when the PVIm-NH_2 was added up to the concentration of 400 μg/mL, which was higher than the transfection conditions. The PLL-Lac exhibited the same tendency as the PVIm-NH_2. On the other hand, little viability was observed when the control PEI was added up to 200 μg/mL. Furthermore, the PLL-Lac/PVIm-NH_2/DNA ternary complex also had no apparent cytotoxicity (results not shown). These results suggest that the PVIm-NH_2, as well as PLL-Lac, with no apparent cytotoxicity promises to be an effective gene carrier.

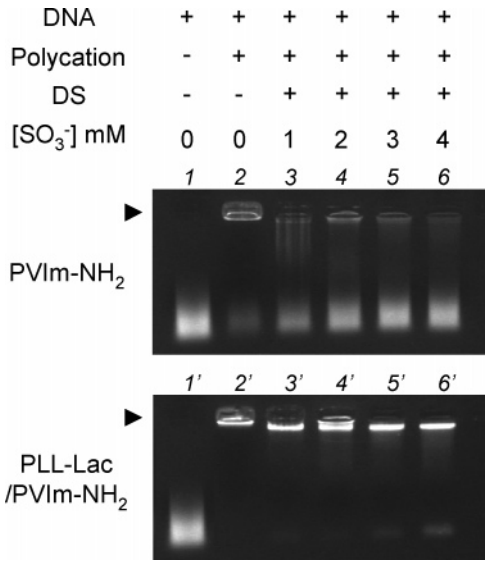

Figure 5. Release of DNA from PVIm-NH_2/DNA binary or PLL-Lac/PVIm-NH_2/DNA ternary complexes by dextran sulfates (DS) as assessed by agarose gel electrophoresis: lanes 1 and 1′, DNA alone; lanes 2 and 2′, 0 mM; lanes 3 and 3′, 1 mM; lanes 4 and 4′, 2 mM; lanes 5 and 5′, 3 mM; lanes 6 and 6′, 4 mM. The PVIm-NH_2/DNA ($[amino]_{PVIm-NH2}/[phosphate]_{DNA} = 4$; lanes 2−6) or PLL-Lac/PVIm-NH_2/DNA ($[amino]_{PVIm-NH2}/[phosphate]_{DNA} = 4$, $[amino]_{PLL-Lac}/[phosphate]_{DNA} = 1$; lanes 2′-6′) mixtures were incubated for 10 min at room temperature in the presence (lanes 3−6 and 3′−6′) or absence (lanes 2 and 2′) of DS (0−4 mM as sulfate group), followed by loading into the gel. Solid arrowhead indicates the well where each sample was loaded.

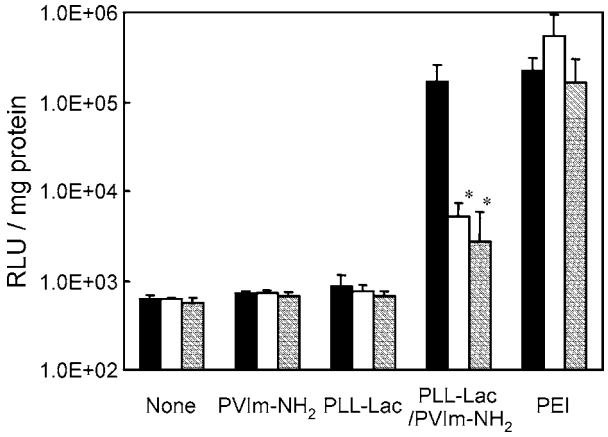

Figure 6. Transfection of luciferase gene to HepG2 (black bars), FR (white bars), or MC3T3-E1 (slashed bars) cells by the PLL-Lac/PVIm-NH_2/DNA ternary complex ($[amino]_{PVIm-NH2}/[phosphate]_{DNA} = 4$, $[amino]_{PLL-Lac}/[phosphate]_{DNA} = 1$). PLL-Lac/DNA and PVIm-$NH_2$/DNA binary complexes were prepared at an [amino]/[phosphate] ratio of 5, and the PEI/DNA complex was prepared at the N/P ratio of 15. The cells (1×10^4 cells/well) were transfected by adding 200 ng of plasmid DNA complexed with the polycations for 1 day in the presence of 10% FBS. Gene expression was determined 3 days later as RLU normalized by protein concentrations. Symbols and error bars represent the mean and standard deviation of the measurements made in paired samples ($n = 3$). $*$ indicates statistical significance ($p < 0.02$) when compared to the HepG2 value.

As a result of no apparent cytotoxicity, we finally examined the gene expression mediated by the PLL-Lac/PVIm-NH_2/DNA ternary complex. HepG2 cells are a human hepatoma cell line, so that ASGP-Rs are expressed on the cell surface (*16*). As shown in Figure 6, the PLL-Lac/PVIm-NH_2/DNA ternary complex mediated remarkable gene expression, which was almost the same level as that mediated by the control PEI, on HepG2 cells. On both skin fibroblast (FR) and immature osteoblast-like (MC3T3-E1) cell line with no ASGP-R on the cell surface, on the other hand, the ternary complex mediated little gene expression, which was significantly lower than the expression on the HepG2 cells. The control PEI preserved remarkable gene expression even on both FR and MC3T3-E1 cells. Furthermore, the gene expression mediated by the PLL-Lac/PVIm-NH_2/DNA ternary complex on HepG2 cells decreased in the presence of not free maltose but free lactose as a competitor (*27*) (additional results not shown). Although it is unclear if only a small percentage of cells took up the complexes and then had high expression or if a large percentage of these cells were transfected, as is implied, which is the topic of our future investigation, these results suggest that the PLL-Lac/PVIm-NH_2/DNA ternary complex with β-galactose residues recognized the HepG2 cells via ASGP-Rs on the cell surface.

It is worth noting that the PLL-Lac/PVIm-NH_2/DNA ternary complex showed gene expression values 200 and 230 times higher than that of the PLL-Lac/DNA and PVIm-NH_2/DNA, respectively, binary complex. Furthermore, gene expression mediated by the PLL-Lac/PVIm-NH_2/DNA ternary complex was significantly decreased by the treatment of HepG2 cells with chloroquine (additional results not shown), which is a weak base known to inhibit lysosomal hydrolases by reducing the acidification of the endosomal/lysosomal compartments (*28*, *29*). The chloroquine is a diprotic weak base that accumulates in acidic organelles as a function of the pH gradient present between the organelle and the external medium (*30*). Because the incubation of target cells with chloroquine blocks the acidification of the endosomes and lysosomes, the PVIm-NH_2 should encounter a less acidic pH during endocytosis, resulting in less protonation of the imidazole group. In the presence of chloroquine, therefore, gene expression mediated by the ternary complex with the imidazole groups of PVIm-NH_2 was decreased. However, because there was less degradation at a less acidic pH during endocytosis, gene expression increased in the case of the PLL used as a control polycation with no pH sensitivity. These results suggest that the gene delivery mediated by PVIm-NH_2 is dependent on the protonation of the imidazole groups of the PVIm backbone leading to the membrane disruptive ability at endosomal pH (see Figure 2 as well as Figure 1) as well as the proton sponge effect (*6*, *8*) and to the pH-dependent dissociation of PLL-Lac (see Figures 4 and 5). Taking these results into account, although an intercellular colocalization study of labeled PLL-Lac, PVIm-NH_2, and DNA is now in progress for more detail investigation, the synergistic effect of the PLL-Lac and PVIm-NH_2 is considered to succeed in cell-specific efficient gene delivery and to depend on the protonation of the imidazole groups of PVIm-NH_2.

CONCLUSION

We have synthesized the new pH-sensitive polycation PVIm-NH_2 and evaluated the physicochemical and biochemical properties of the pH-sensitive gene carrier. The resulting PVIm-NH_2 was water-soluble despite deprotonation of the imidazole groups at physiological pH and exhibited membrane disruptive ability at endosomal pH. By using PVIm-NH_2 as a pH-sensitive DNA carrier, as well as PLL-Lac as a cell-targeting DNA carrier, the resulting DNA ternary complex at pH 7.4 dissociated PLL-Lac by the protonation of the imidazole groups of PVIm-NH_2 at pH 6.0. The resulting PVIm-NH_2/DNA binary complexes easily released DNA, as compared with the PLL-Lac/PVIm-NH_2/DNA ternary complex. The ternary complex mediated the cell-specific gene delivery attributed to the PLL-Lac, and the gene expression depended on the protonation of the imidazole groups of PVIm-NH_2. Consequently, PVIm-NH_2 as a new pH-sensitive polycation enhanced cell-specific gene delivery by PLL-Lac. The synergistic effect of the cell-targeting PLL-Lac

and the pH-sensitive PVIm-NH_2 in this study is expected to offer unique design for gene delivery systems.

TECHNICAL NOTES

Multiple Labeling of Antibodies with Dye/DNA Conjugate for Sensitivity Improvement in Fluorescence Immunoassay

Qin Zhang and Liang-Hong Guo*

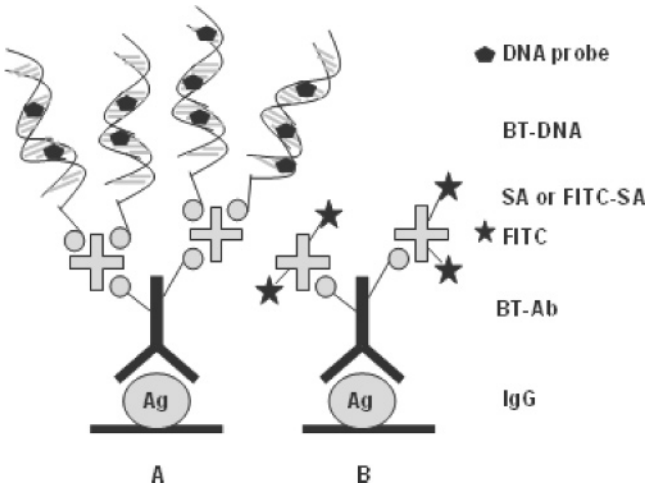
State Key Laboratory of Environmental Chemistry and Ecotoxicology, Research Center for Eco-environmental Sciences, Chinese Academy of Sciences, P.O. Box 2871, 18 Shuangqing Road, Beijing 100085, China. Received September 17, 2006; Revised Manuscript Received June 27, 2007

Fluorescence immunoassays are widely used in life science research, medical diagnostics, and environmental monitoring due to the intrinsically high specificity, simplicity, and versatility of immunoassays, as well as the availability of a large variety of fluorescent labeling molecules. However, the sensitivity needs to be improved to meet the ever-increasing demand in the new proteomics era. Here, we report a simple method of attaching multiple fluorescent labels on an antibody with a dye/DNA conjugate to increase the immunoassay sensitivity. In the work, mouse IgG adsorbed on the surface of a 96-well plate was detected by its immunoreaction with biotinylated goat anti-mouse antibody. A 30 base pair double-stranded oligonucleotide terminated with biotin was attached to the antibody through the biotin/streptavidin/biotin interaction. Multiple labeling of the antibody was achieved after a fluorescent DNA probe was added into the solution and bound to the oligonucleotide at high ratios. By comparison with fluorescein-labeled streptavidin, the assay with the dye/DNA label produced up to 10-fold increase in fluorescence intensity, and consequently about 10-fold lower detection limit. The multiple labeling method uses readily available reagents, and is simple to implement. Further sensitivity improvement can be obtained by using longer DNAs for antibody labeling, which can incorporate more fluorescent dyes on each DNA.

INTRODUCTION

Immunoassays are widely used in life science research, drug discovery, clinical diagnostics, and environmental monitoring due to their high specificity, simplicity, and versatility. In general, in order to detect and quantify the formed antibody−antigen complex in the immunoassay, a label is attached to the antibody to generate a detectable signal. Since Berson and Yalow (*1*) first introduced radioisotope-labeled immunoassays in 1959, a variety of labels have been developed (*2*), including fluorescent dyes and metal complexes (*3*), enzymes for colorimetric (*4*), chemiluminescent (*5*), and amperometric detection (*6*), and metal chelates for electrochemiluminescent assays (*7*). Among them, fluorescence immunoassay perhaps offers one of the best combinations in terms of label stability, assay robustness, detection sensitivity, and multiplexity. As such, it has become the standard detection platform for protein microarrays (*8*).

However, the sensitivity of the current fluorescence immunoassay technology needs to be improved substantially to meet the demand in the proteomics study. Unlike gene detection in which the nucleic acid target can be amplified by PCR by orders of magnitude, currently there is no amplification technique for proteins. Therefore, sensitivity improvement for protein detection relies on signal amplification. In 1992, Sano et al. established the immuno-PCR method by using nucleic acids as immunoassay labels and amplifying them by PCR after the immunoreaction (*9*). As a result of nucleic acid amplification, the detection limit is improved by 100- to 10 000-fold (*10*). The limitation of immuno-PCR is that it employs gel electrophoresis, PCR-ELISA, or real-time PCR for assay readout, which adds a substantial amount of time and reagent cost. In addition, it is difficult to implement the method in the protein microarray technology.



An alternative approach for signal amplification in fluorescence immunoassay is to increase the number of labels conjugated to each antibody. This can be done by either attaching multiple labels at multiple sites of the antibody with only one label at each site or attaching multiple labels at one site with a macromolecular carrier. Due to the finite size and hydrophobic nature of most fluorescent dyes, the multiple-site approach suffers from reduced immunoreactivity and increased nonspecific binding of the labeled antibody. In the single-site approach, an organic dendrimer (*11*, *12*) or protein loaded with a large number of fluorescent dyes (*13*) is linked covalently or noncovalently (e.g., through biotin−streptavidin interaction) to the antibody at a single site. The single-site linkage minimizes structural alteration of the antibody, thus maintaining its native immunoreactivity. The challenge of this approach is the synthesis and purification of dye-conjugated macromolecules.

More recently, fluorescent micro- and nanometer-sized particles have drawn much attention as a new type of nonisotopic immunoassay labels. Because each particle contains hundreds or even thousands of fluorescent entities, its emission is substantially brighter than the most efficient organic dyes. In 1998, Alivisatos (*14*) and Nie's group (*15*) described separately the application of semiconductor nanocrystals (quantum dots) in biological detections. The new label exhibited such advantageous features as single excitation wavelength, tunable emission wavelength, and improved photostability. Immunoassay sensitivity can also be improved by using fluorophore-doped silica (*16*) and latex beads (*17*). As with the quantum dots, the

Scheme 1. Illustration of the Two Immunoassay Labeling Formats for the Detection of Goat Anti-Mouse Antibody Using the Conjugate Label (A) and Dye Label (B)[a]

[a] Mouse IgG of various concentrations is coated on a 96-well plate. Biotinylated goat anti-mouse antibody is reacted with mouse IgG. (A) The dye/DNA conjugate with multiple DNA probes is attached to the antibody through the biotin-streptavidin-biotin linkage. (B) The molecular label fluorescein is attached to the antibody by the biotin−streptavidin interaction.

difficulties include the uniformity of the particle, conjugation of biomolecules, dispersion in aqueous solution, and reaction kinetic.

In the work described below, we employed a 30 base pair biotinylated double-stranded oligonucleotide as a carrier for the conjugation of multiple fluorescent dyes. It was attached to a biotin-modified goat anti-mouse antibody through the high-specificity, high-affinity biotin−streptavidin interaction. A highly fluorescent DNA probe, SYBR Green I, binds in situ to the oligonucleotide at high ratios by the specific binding interaction with DNA. Because the free (unbound) probe does not emit fluorescence, measurement can be performed without a wash step. A direct comparison was made with fluorescein-labeled streptavidin in the immunological detection of goat anti-mouse antibody on a mouse IgG-coated 96-well plate (Scheme 1). The dye/DNA conjugate labeled immunocomplex produced up to 10-fold increase in the fluorescence intensity.

EXPERIMENTAL PROCEDURES

Fluorescein isothiocyanate (FITC) was purchased from Amresco (Solon, OH), and SYBR Green I from Invitrogen (Carlsbad, CA). Biotinyl-*N*-hydroxysuccinimide (BT-NHS) was from Sigma (St. Louis, MO). Streptavidin was obtained from Promega (Madison, WI). Bovine serum albumin fraction V (BSA), mouse IgG, and goat anti-mouse IgG were from Xinjingke Corp. (Beijing, China). All buffers were prepared in high-purity water from a Millipore Milli-Q (Biocel) purification system. Unless specified, all antibodies were dissolved in phosphate buffered saline (PBS, 137 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 1.5 mM KH_2PO_4, pH 7.4) containing 0.1% BSA and 0.1% NaN_3.

Biotinylated goat anti-mouse antibody (BT-Ab) was obtained by mixing the antibody with BT-NHS at a molar ratio of 5.6 BT-NHS: 1 antibody in 0.1 M sodium bicarbonate, pH 9.15, for 4 h at room temperature with stirring. After the reaction, the remaining free BT-NHS was separated from the antibody by gel filtration on a D-Salt polyacrylamide desalting column from Pierce (Rockford, IL). The antibody concentration was determined by its absorbance at 280 nm on a UNICO UV-2800 visible spectrophotometer (Shanghai, China). The biotin content was determined with the HABA/avidin reagent from Sigma (St. Louis, MO), and was found to be 1.9 biotins per antibody. Mouse IgG, goat anti-mouse IgG, and streptavidin were labeled with FITC by following the same procedure. The protein and FITC concentration of the labeled biomolecules were determined by absorbance at 280 nm and 495 nm, respectively, and the label ratios were 2.0, 4.0, and 3.5 per protein, respectively. They were stored at 4 °C in the dark until use.

A 30 base pair biotinylated double-stranded oligonucleotide (BT-DNA) was obtained by hybridizing two complementary single-stranded oligonucleotides purchased from Invitrogen (Shanghai, China): strand A, biotin-5′-TTT TTT TTT GCG GGT AAC GTC AAT ATT AAC TTT ACT CCC-3′; strand B, 5′-GGG AGT AAA GTT AAT ATT GAC GTT ACC CGC-3′. The nine thymine nucleotides on strand A are designed to minimize possible spatial hindrance to binding with streptavidin. The two oligonucleotides were mixed in 2 × SSC buffer (0.3 M NaCl, 30 mM sodium citrate, pH 7.0), denatured at 95 °C for 5 min on a Biometra T-Gradient thermocycler (Goettingen, Germany), and then naturally cooled down to room temperature. The concentration of the oligonucleotide was determined by absorbance at 260 nm.

The following is an optimized immunoassay protocol for the detection of mouse IgG using the dye/DNA conjugate labels. First, a white 96-well plate was coated with 100 μL mouse IgG of various concentrations (in 50 mM $NaHCO_3$, pH 9.6, with 0.01% rabbit IgG) by incubating overnight at 4 °C. The plate was washed three times with 300 μL of washing buffer (50 mM Tris, 50 mM NaCl, 0.1% Tween 20, pH 8.0). The plate was then blocked overnight at 4 °C with 300 μL of 1% BSA in PBS, pH 7.4. The plate was washed as above. In the second step, 100 μL of 784 μg/mL BT-Ab in dilution buffer (0.1% BSA, 50 mM Tris, 50 mM NaCl, pH 8.0) was added into the coated well and incubated at 37 °C for 2 h with shaking. The plate was again washed. In the third step, 100 μL of 7.4 μg/mL streptavidin was added into the well and reacted at 37 °C for 2 h with shaking, then washed. In the fourth step, BT-DNA was added and reacted at 37 °C for 1 h with shaking, and washed again. Finally, SYBR Green I was added into the plate and incubated for 10 min at room temperature with shaking. The fluorescence intensity was measured on a Thermo Electron Varioskan Flash luminescence spectrometer (Waltham, MA) with 495 nm excitation, 520 nm emission, 5 nm slit width, and 515 nm cutoff filter. In the dye-labeled immunoassay, fluorescence of fluorescein was measured with 495 nm excitation, 525 nm emission, 5 nm slit width, and 515 nm cutoff filter.

RESULTS AND DISCUSSION

As described above, our strategy is to use a strand of DNA as a carrier to attach multiple fluorescent dyes to an antibody at a single site. The dye/DNA conjugate is not presynthesized, but rather formed in situ as part of the immunoassay. For this strategy to work, there are a few requirements for the fluorescent label. First of all, it must bind to DNA only, not to proteins or immunoglobulins. And the binding stoichiometry is preferably high to ensure a high labeling ratio. Second, the quantum yield of the DNA-bound probe should be comparable to that of the commonly used fluorescent dyes such as fluorescein, Cy-3, Cy-5, and rhodamine, which is in the range 0.1−0.9 (*18*). Third, fluorescence of the unbound probe should be minimal so that the immunoassay can be quantified without wash.

Among the commercially available fluorescent DNA probes, PicoGreen, SYBR Green I, SYBR Gold, and YOYO-1 fulfill the above requirements (*19*). SYBR Green I was selected in our work because its fluorescence excitation and emission maximum wavelengths are close to that of fluorescein, to which the SYBR Green/DNA conjugate is going to be compared. To characterize the binding interaction between SYBR Green and

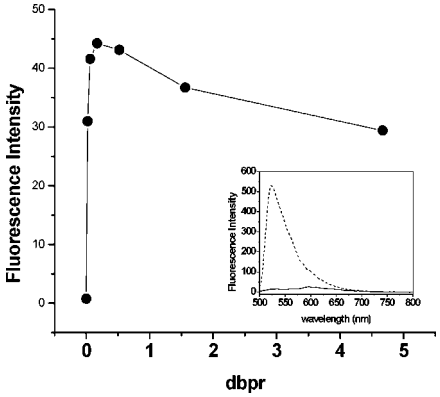

Figure 1. Fluorescence intensity of SYBR Green as a function of the dye to base pair ratio (dbpr). The DNA probe is titrated from 0 to 2.1 μM into a 0.15 μM (base pair) solution of the biotinylated oligonucleotide in 50 mM Tris/50 mM NaCl, pH 8.0. Inset shows the fluorescence emission spectra of the free (solid line) and oligonucleotide-bound dye at 0.02 dbpr (dotted line).

BT-DNA, the probe was titrated into the BT-DNA solution at increasing dye to base pair ratios (dbpr). As illustrated in Figure 1, the fluorescence intensity increased rapidly from 0 to 0.17 dbpr, reached a plateau between 0.17 and 0.52 dbpr, and started to drop at higher ratios. Vitzthum and co-workers have investigated the fluorescent response of SYBR Green I after binding with double-stranded (ds-) and single-stranded (ss-) plasmid DNA (heat-denatured) (*20*). In ds-DNA, the fluorescence increased gradually with the dye concentration until 2 dbpr, after which it became constant. In ss-DNA, however, the response increased more rapidly with the dye concentration, reached the maximum at 0.2 dbpr, and then dropped with further increase of dbpr. The reduction in fluorescence at high dbpr was attributed to self-quenching. The dependence of fluorescence on dbpr with BT-DNA in our work resembles more closely that of ss-DNA in Vitzhum's investigation. This can be explained by the fact there are nine unpaired thymine bases in BT-DNA that bear the characteristics of ss-DNA. Due to the quenching effect, binding constant and stoichiometry between the probe and BT-DNA cannot be determined from the fluorescence titration curve. Cosa et al. revealed (*19*) that the quantum yield of SYBR Green I was 0.69 when bound to double-stranded calf thymus DNA, an increase of more than 1500-fold over the free dye. The drastic enhancement was also observed for the dye/BT-DNA conjugate, as shown in the inset of Figure 1. Furthermore, at the same dye concentration of 20 nM, the emission intensity of SYBR Green/BT-DNA conjugate with 0.22 dbpr is 88% of that of fluorescein-labeled streptavidin (FITC-SA), indicating that the quantum yields of the two fluorescent dyes are similar. All the experimental data obtained above support our notion that the SYBR Green/BT-DNA conjugate can be used effectively to attach multiple fluorescent labels in immunoassays.

After the fluorescence property of the SYBR Green/BT-DNA conjugate was investigated, a 96-well plate based immunoassay for the detection of mouse IgG was carried out. The assay protocol described in the Experimental Section was established after a series of optimization experiments were performed to determine the optimal concentration, reaction time, and temperature for IgG/BT-Ab immunoreaction and biotin/streptavidin binding. The results of the optimization experiments are described in the Supporting Information.

The optimal condition for the binding of BT-DNA/SYBR Green conjugate to the surface-attached IgG/BT-Ab/SA immunocomplex was investigated as follows. The concentrations of the reagents for the formation of the immunocomplex were 30

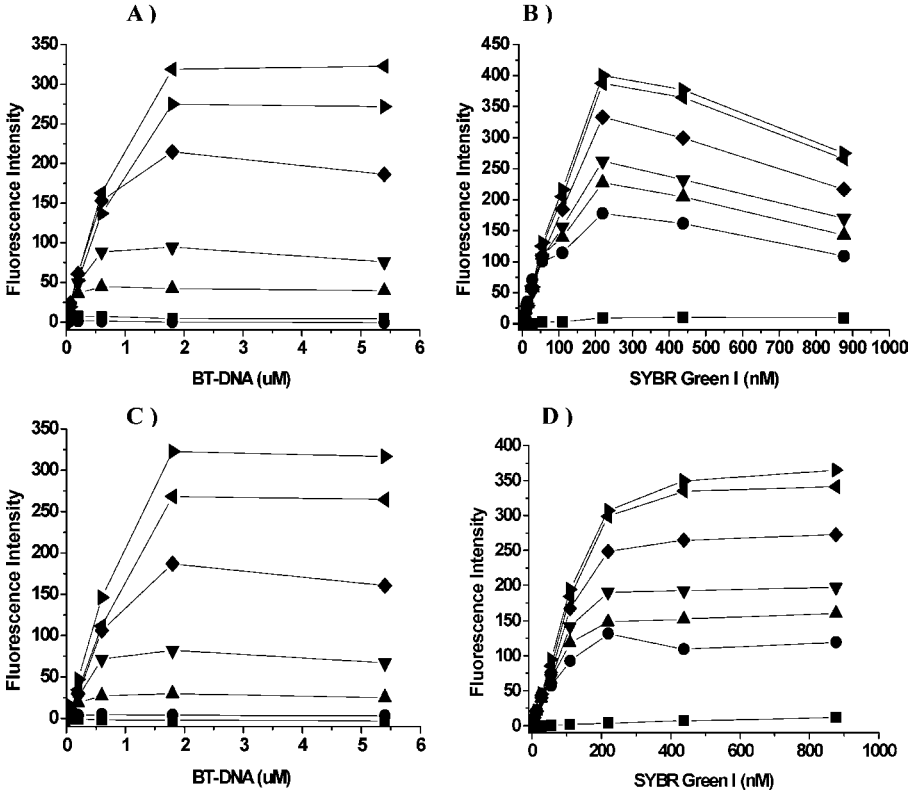

Figure 2. Fluorescence intensity of the SYBR Green/BT-DNA conjugate attached to the IgG/BT-Ab/SA complex formed on a 96-well plate as a function of BT-DNA (A,C) and SYBR Green (B,D) concentration. Different curves in (A) and (C) correspond to 0 nM (●), 14 nM (■), 27 nM (▲), 55 nM (▼), 110 nM (◆), 219 nM (right-facing solid triangle), and 438 nM (left-facing solid triangle) SYBR Green. Different curves in (B) and (D) correspond to 0 μM (■), 0.04 μM (●), 0.12 μM (▲), 0.37 μM (▼), 1.11 μM (◆), 3.33 μM (left-facing solid triangle), and 10 μM (right-facing solid triangle) BT-DNA. Fluorescence was measured before (A,B) and after (C,D) plate wash to remove unbound dyes.

μg/mL IgG for plate coating, 784 μg/mL BT-Ab for immunoreaction, and 7.4 μg/mL (114 nM) SA for BT-Ab binding. BT-DNA of various concentrations was then added to the plate. After binding of BT-DNA to SA on the surface, SYBR Green I was added into the plate from 0 to 876 μM at approximately 2-fold increments for each BT-DNA concentration. Fluorescence intensity was measured, first without wash (in the presence of excessive SYBR Green), then after wash to remove unbound dye molecules. From Figure 2A,C, it is apparent that the binding site for BT-DNA on the plate surface is saturated when the DNA concentration exceeds 1.8 μM. An increase in the dye concentration only enhanced the detection signal, and had no effect on the saturation concentration of BT-DNA. In the unwashed measurement, the light intensity reached its maximum with 219 nM SYBR Green in solution, and decreased at higher concentrations (Figure 2B). This is similar to the trend observed in the solution study of the dye/BT-DNA binding reaction illustrated in Figure 1. The fact that the signal starts to decrease at the same dye concentration but is independent of BT-DNA concentration suggests the reduction is due to quenching by the free dye molecules in solution. This notion is further supported by the results displayed in Figure 2D for the washed measurement. Once excessive SYBR Green molecules were removed from the plate, there was no loss of fluorescence at high dye concentrations. Therefore, a combination of 1.8 μM BT-DNA and 219 nM dye produced the most intense signal in the unwashed measurement, whereas the intensity was slightly lower for the washed assay.

After all the reaction parameters were optimized, a direct comparison was made between the dye label and the dye/DNA conjugate label format in the immunoassay for mouse IgG. The experiment is illustrated in Scheme 1. IgG coating and BT-Ab reaction were performed in the same way for the two labeling formats, with the IgG concentration varied from 0 to 30 μg/mL. In the conjugate-labeled assay, 120 nM unlabeled SA was reacted with BT-Ab on the plate. BT-DNA (1.8 μM) and SYBR Green (219 nM for the nonwashed assay and 438 nM for the washed assay) were then added sequentially to the plate and reacted. The fluorescence was measured first without wash, then with wash. In the dye-labeled assay, 120 nM FITC-SA was reacted with the biotin group on the antibody and its fluorescence measured after wash. A more preferred way for carrying out the single-label assay would be to use a biotin−dye conjugate to bind to the unlabeled SA. Unfortunately, most of the conjugates lose their fluorescence upon binding to streptavidin (*17*), and cannot be used. The results obtained in the comparison experiment are shown in Figure 3. The signal is subtracted by the background, which was found to be caused by the scattered light, not by nonspecific binding of the DNA probe. In both assays, the fluorescence signal is progressively higher with increasing IgG concentration, suggesting that both methods can be used for quantitative detection of immunoassays. However, in the whole range of the IgG concentration examined, the intensity of the SYBR Green/DNA labeled assay is persistently higher than the dye-labeled assay by about 8-fold. The calculated limit of lower detection (3 times the standard deviation above the blank) is 1.7 μg/mL for the dye-labeled assay and 0.14 μg/mL for the dye/DNA conjugate-labeled assay, respectively. Obviously, the dye/DNA multiple labeling strategy improved the detection sensitivity for IgG by 10-fold.

To evaluate the specificity of the assay for mouse IgG, an experiment was carried out in which the surface-adsorbed protein was replaced with either rabbit IgG or BSA, while keeping the protein concentration the same as mouse IgG. The subsequent assay procedure was also the same as for mouse IgG. As illustrated in Figure 4, at a protein concentration of 30 μg/mL, the fluorescence intensity of either rabbit IgG or BSA

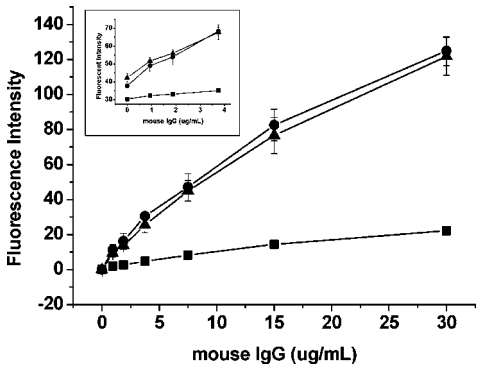

Figure 3. Fluorescence immunoassay for the detection of mouse-IgG on a 96-well plate using the SYBR Green/BT-DNA conjugate label and fluorescein molecular label. Mouse-IgG was dissolved in 50 mM $NaHCO_3$, pH 9.6, with 0.01% rabbit IgG. The concentrations of the reagents used in the assay were 4.9 μM BT-Ab for the immunoreaction, 120 nM FITC-SA (filled square) in the dye-labeled assay, or 120 nM unlabeled SA/1.8 μM BT-DNA/438 nM SYBR Green (filled triangle) in the washed conjugate labeled assay, or 120 nM unlabeled SA/1.8 μM BT-DNA/219 nM SYBR Green (filled circle) in the unwashed conjugate-labeled assay. Inset is an expanded view.

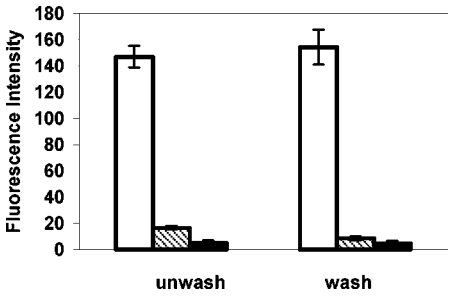

Figure 4. Comparison of fluorescence immunoassay for mouse-IgG (open column), rabbit IgG (hatched column), and BSA (filled column) on a 96-well plate using the SYBR Green/BT-DNA conjugate label. The concentrations of the reagents used in the assay are the same as in Figure 3 for the unwashed (left) and washed (right) assay.

sample is very low by comparison with that of mouse IgG. The result indicates that the immunoassay is highly specific for mouse IgG.

As discussed in the Introduction, although there are a few approaches reported in the literature of employing the multiple-label strategy for signal amplification in immunoassays, none of them can be readily adopted for the sensitive detection of protein microarrays, which is highly sought after due to the low concentration in biological samples and lack of target amplification method. While chemiluminescence has been proven to be a very sensitive detection method, it is very difficult to implement the method on microarrays, since the light-emitting species are not confined to the surface (*22*). Immuno-PCR has been reported to improve the immunoassay sensitivity by 100- to 10 000-fold (*11*), but requires a separate set of assay for DNA quantitation. The covalent labeling approach using organic polymers or proteins as the label carrier faces a severe challenge in chemical synthesis and post-labeling purification. By comparison, the dye/DNA conjugate approach reported in this paper uses all the common reagents such as biotin, streptavidin, oligonucleotides, and fluorescent DNA probes. Multiple labeling of antibodies is achieved in situ by reacting with the oligonucleotide and DNA probe on a 96-well plate. There is even no need to remove the unbound dyes before measurement. If one is concerned about the assay time, the BT-Ab/SA/BT-DNA can be premixed at a controlled ratio to save time. Furthermore, the signal amplification efficiency can potentially be enhanced substantially by using longer DNAs to carry more fluorescent

dyes. DNA markers of 150 to 300 base pairs are commonly used in immuno-PCR (*23*). By simple extrapolation, such a long DNA sequence would increase the fluorescent signal by 50−100 fold over the dye-labeled assays, and probably with similar improvement in detection sensitivity. The improved sensitivity would be very attractive for protein microarray detection.

Received March 14, 2007; Revised Manuscript Received July 7, 2007

Poly(ethylene glycol) (PEG)-conjugated human serum albumin (HSA) incorporating the tetrakis(α,α,α,α-*o*-amidophenyl)porphinatoiron(II) derivative (FeP) [PEG(HSA−FeP)] is a unique plasma protein-based O_2 carrier as a red blood cell substitute. The aqueous solution of PEG(HSA−FeP) [mw of PEG: 2-kDa (PEG_2) or 5-kDa (PEG_5)] was evaporated on a glass surface to produce a red-colored solid membrane. Scanning electron microscopy observations revealed that the PEG_2(HSA−FeP) membrane consisted of two parts: (i) a surface layer made of a fibrous component (10 μm thickness), and (ii) a bottom layer of an amorphous phase (5 μm thickness). The condensed solution provided a thick membrane (70 μm), which also has the amorphous bottom layer. On the other hand, the PEG_5(HSA−FeP) produced homogeneous membrane made of the fibrous component. The FeP active sites in the solid membrane formed very stable O_2-adduct complexes at 37 °C with a half-lifetime of 40 h. The O_2-binding affinity of the PEG_2(HSA−FeP) membrane ($P_{1/2}$ = 40 Torr, 25 °C) was 4-fold lower than that in aqueous solution, which is kinetically due to the low association rate constant. The membrane was soluble again in water and organic solvents (ethanol and chloroform) without deformation of the secondary structure of the protein. The addition of hyaluronic acid gave a free-standing flexible thin film, and it can also bind and release O_2 as well. These O_2-carrying albumin membranes with a micrometer-thickness would be of significant medical importance for a variety of clinical treatments.

INTRODUCTION

Covalently surface-modified proteins with poly(ethylene glycol) (PEG) show a number of unique properties that make them of interest in a range of practical applications (*1*−*6*). The most beneficial effect of the PEG conjugation from a biological aspect is to confer a nonimmunogenicity to the proteins, rendering them invisible in the body (*7*−*10*). Several classes of protein drugs, such as enzymes and cytokines, have already been approved by the FDA (*4*, *5*), and one of the expected compounds is a PEG-conjugated hemoglobin (PEG-Hb) for use as artificial blood (*11*, *12*). The optimized product has completed a phase I trial and is currently undergoing a phase II safety study (*13*). Second, the PEG modification allows the proteins to be soluble in nonaqueous solvents (benzene, ethanol, and chloroform, etc.) (*14*−*16*). In organic solutions, the proteins exhibited new characteristics, for example, a high thermal stability and a different substrate selectivity. Third, the aqueous PEGylated proteins can be dried on a flat surface to produce solid membranes without any loss of their original activities. However, only limited characterization has been performed on the PEG-conjugated proteins in the solid state.

Recombinant human serum albumin (HSA) incorporating the tetrakis{α,α,α,α-*o*-(1-methylcyclohexanamido)phenyl}-porphinatoiron(II) derivative (FeP, Figure 1) (HSA−FeP) is a unique plasma protein-based O_2 carrier (*17*, *18*). This entirely synthetic hemoprotein can reversibly bind and release O_2 under physiological conditions (pH 7.4, 37 °C) in a fashion similar to Hb. It has also been demonstrated that the surface decoration of HSA−FeP by PEG improved its circulation persistence in the bloodstream (*19*). The PEG(HSA−FeP) is now the most promising material for an entirely synthetic red blood cell substitute.

We have recently found that the aqueous PEG(HSA−FeP) solution cast on the glass surface produces a very smooth solid membrane. The spectroscopic measurements revealed that a reversible O_2 binding to FeP took place in the red-colored membrane. We now report our new findings on the layered film structures of the PEG-conjugated artificial hemoprotein and their O_2-binding behavior.

EXPERIMENTAL PROCEDURES

Materials and Apparatus. All reagents were purchased from commercial sources as special grades and used without further purification. 2-{8-(2-Methylimidazolyl-1-yl)octanoyloxymethyl}-5,10,15,20-tetrakis{α,α,α,α-o-(1-methylcyclohexanamido)-phenyl}porphinatoiron(II) (FeP) was synthesized according to our previously reported procedures (*17*, *20*). Recombinant HSA was provided by the NIPRO Corp. (Osaka, Japan). 2-Iminothiolane hydrochloride (IMT) was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). α-[3-(3-Maleimido-1-oxopropyl)amino]propyl-ω-methoxy PEG [averaged mw: 2333, Sunbright ME-020MA, PEG_2, and averaged mw: 5207, Sunbright MEMAL-50H, PEG_5) was purchased from the NOF Corp. (Tokyo, Japan). Hyaluronic acid sodium salt (HA, mw: 1.9−2.7 × 10^3 kDa) was a gift from Shiseido Co., Ltd. (Tokyo, Japan). The water was deionized using Millipore Elix and Simpli Lab-UV. The UV−vis absorption spectra were recorded using an Agilent 8453 UV−visible spectrophotometer fitted with an Agilent 89090A temperature control unit. The circular dichroism (CD) spectra were obtained using a JASCO J-820 spectropolarimeter over the range of 200−250 nm.

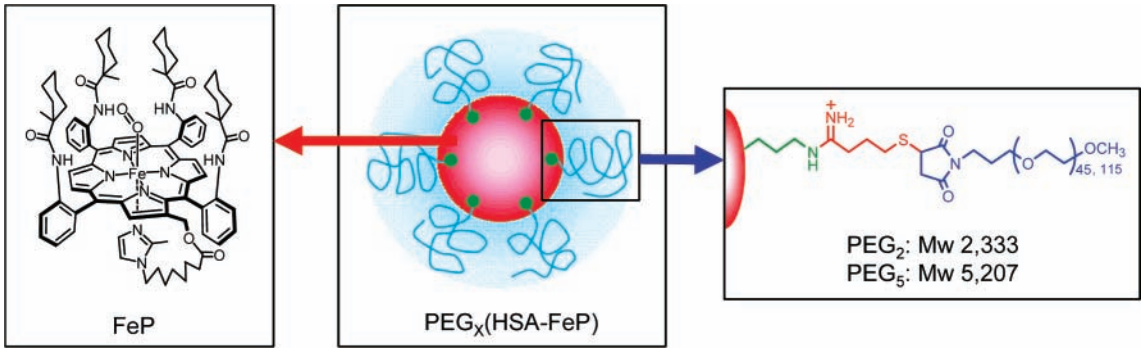

Figure 1. Structure of the PEG$_X$(HSA−FeP) molecule.

Preparation of PEG$_X$(HSA−FeP) Solid Membranes. The phosphate-buffered saline (PBS) solutions of PEG$_X$(HSA−FeP) (X = 2 or 5) were prepared with IMT and PEG$_X$ (pH 7.4, [HSA] = 5 wt %, FeP/HSA = 4/1 (mol/mol)) according to our previously reported methods (*19*). The binding number of the PEG$_X$ chain on the HSA−FeP surface was determined by the MALDI-TOF MS spectra (*19*). The PBS solution was dialyzed using a Spectra/Por 1 regenerated cellulose dialysis membrane (MWCO: 6−8 kDa, Spectrum Labratories, Inc.) against the pure water to remove any included electrolytes. The obtained aqueous solution of PEG$_X$(HSA−FeP) (CO adduct complex, 0.5 mL) was spread on a glass plate [30 × 40 mm, thickness: 0.12−0.17 mm, Matsunami Glass Ind., Ltd. (Osaka, Japan)] and evaporated at an ambient temperature in the dark for 12 h, which produced a red-colored transparent solid membrane.

For the scanning electron microscopy measurements, the samples on the glass plate were sputtered with Pd−Pt using a Hitachi E-1030 ion sputter. The SEM observations were performed using a Hitachi S-4500S field emitted scanning electron microscope.

Furthermore, 0.5 mL of an aqueous solution of hyaluronic acid (HA, 0.2, 0.4, 0.6, 0.8, 1.0 wt %) was added to the PEG$_2$-(HSA−FeP) solution (CO adduct complex, 0.5 mL, [HSA] = 5 wt %). The mixture was poured into a poly(styrene) balance dish (44 × 44 × 15 mm) and dried at room temperature in the dark. After 12 h, the formed membrane was gently peeled off and characterized.

The water content of the solid membrane was measured by thermogravimetric-differential thermal analysis using a Rigaku TG8120 instrument at a hearing rate of 10 °C/min.

O_2-Binding Parameters. The O_2 binding to PEG$_X$(HSA−FeP) is expressed by eq 1,

$$\text{PEG}_X(\text{HSA}-\text{FeP}) + \text{O}_2 \underset{k_{\text{off}}}{\overset{k_{\text{on}}}{\rightleftharpoons}} \text{PEG}_X(\text{HSA}-\text{FeP}(\text{O}_2)) \quad (1)$$

where the O_2 binding equilibrium constant $K = k_{on}/k_{off}$.

The PEG$_X$(HSA−FeP) membrane or PEG$_2$(HSA−FeP)/HA hybrid membrane on the glass plate was placed in a 1-cm quartz cuvette for the spectral measurements, which was sealed tightly with a rubber septa. The O_2-binding affinity (gaseous partial pressure at which 50% of FeP was dioxygenated, $P_{1/2} = 1/K$) was determined by the spectral changes at various O_2/N_2 pressures (*17*, *19*, *20*). The UV−vis absorption spectra were recorded within the range of 350−700 nm. The half-lifetime of the autoooxidation of the FeP(O_2) complex was determined by the time-course of the absorption change at 426 nm. The association and dissociation rate constants for O_2 (k_{on}, k_{off}) to the PEG$_X$(HSA−FeP) membrane or PEG$_2$(HSA−FeP)/HA hybrid membrane were measured by a competitive rebinding technique using a Unisoku TSP-1000WK laser flash photolysis instrument (*17*, *19*, *20*).

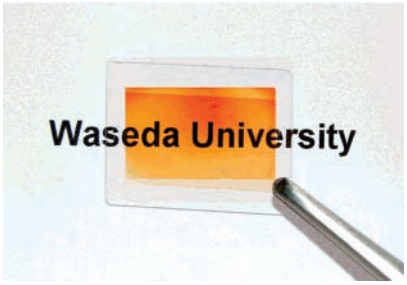

Figure 2. Photograph of the PEG$_2$(HSA−FeP) solid membrane on the glass plate.

RESULTS AND DISCUSSION

Structure of PEG$_X$(HSA−FeP) Membrane. The PEGylation of HSA−FeP (FeP/HSA = 4/1 (mol/mol)) was readily accomplished under mild conditions using the commercially available IMT and maleimide-terminated PEG (*19*). The average number of the PEG chain on the HSA−FeP surface was modulated to 6.0; the viscosity and colloid osmotic pressure of the PBS solution of this molecule ([HSA] = 5 wt %) satisfied the clinical requirements of a red blood cell substitute (*19*). The solution was subsequently desalted by dialysis against pure water and spread on the glass plate. After drying overnight at room temperature, a red-colored transparent solid membrane was formed (Figure 2). The HSA−FeP without the PEG modification did not produce such a homogeneous thin film, only affording a brittle membrane with many cracks.

Scanning electron microscopy observations of the PEG$_2$-(HSA−FeP) membrane showed a uniform thickness of 15 μm and a very smooth surface [Figure 3a,b)]. From a careful inspection of the side-view, we found that the membrane consists of two parts: (i) the surface layer with a thickness of 10 μm made of a highly oriented fibrous component, and (ii) the bottom layer with a thickness of 5 μm made of an amorphous phase (Figure 3b). Cutting the glass plate with a lateral force, the PEG$_2$-(HSA−FeP) membrane was extended and produced long fibers with a width of 350 nm (Figure 3c). The condensed solution ([HSA] = 15 wt %) provided a thick membrane with a thickness of 70 μm, which also has the amorphous bottom layer of 5 μm (Figure 3d). Interestingly, the membrane prepared on the poly-(styrene) dish was mainly composed of the amorphous layer; the surface fibrous phase was less than 20% (Figure 3e). On the other hand, water evaporation of the PEG$_5$(HSA−FeP) solution ([HSA] = 5 wt %) on the glass surface provided a homogeneous membrane, which is made of the fibrous component. The precise mechanism of the fiber formation during the water evaporation process is still not clear, but our results show that the structure of the PEG$_X$(HSA−FeP) membrane is very dependent on the surface feature of the substrate and the chain length of the PEG.

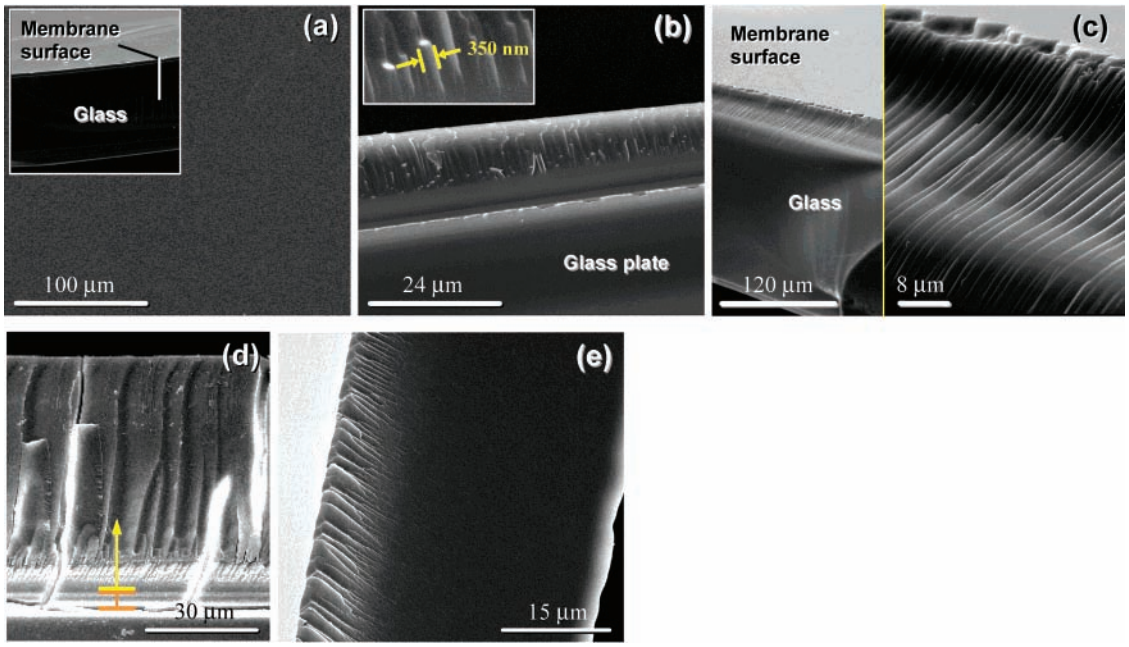

Figure 3. SEM images of the PEG_2(HSA−FeP) membrane on the glass plate. (a) Top-view of the very smooth surface without any crack. (b) Side-view of the membrane section, showing a surface layer made of fibrous component and a bottom layer made of an amorphous phase. (c) Extended nanofiber structure of the surface layer. (d) Thick membrane with a 5 μm amorphous bottom layer (indicated by orange bars) on the glass surface. (e) Membrane prepared on the poly(styrene) surface.

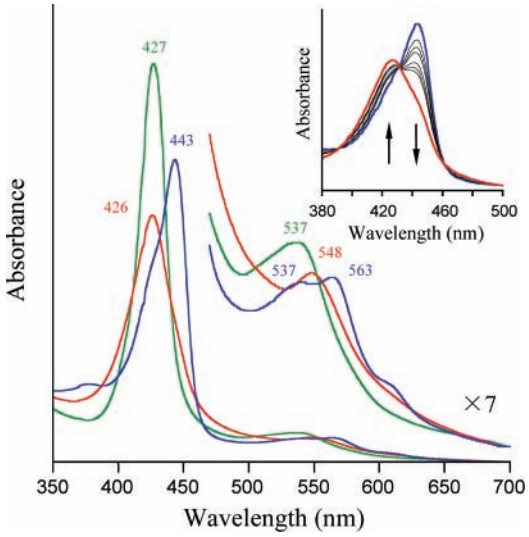

Figure 4. UV−vis absorption spectral changes of the PEG_2(HSA−FeP) membrane on the glass plate at 25 °C (blue line: under N_2, red line: under O_2, green line: under CO). The inset shows the spectral changes at various O_2-partial pressures (P_{O_2}: 0, 10, 19, 30, 76, 114, 152, 760 Torr from blue to red line).

O_2-Binding Properties. The UV−vis absorption spectrum of the PEG_X(HSA−FeP) membrane showed an absorption maxima (λ_{max}) at 427 and 537 nm, indicating the formation of the CO-coordinate low-spin state of FeP (Figure 4) (*17*, *19*−21). This suggested that the ferrous carbonyl complex was retained during the water evaporation for 12 h at an ambient temperature. Light irradiation to the membrane using a 500-W halogen lamp under a 100% O_2 for 20 min led to the CO dissociation and O_2-adduct complex formation of FeP (λ_{max}: 426, 548 nm). By flowing N_2 to the membrane in the quartz cuvette, the UV−vis absorption spectrum shifted to that of a high-spin ferrous complex with an intramolecularly coordinated 2-methylimidazolyl group (λ_{max}: 443, 537, 563 nm). These spectral changes were repeatedly observed and found dependent on the O_2-partial pressure (0 Torr ↔ 760 Torr), which demonstrated that the reversible dioxygenation of FeP took place in the membrane. The half-lifetime of the autoxidation ($\tau_{1/2}$) of the FeP(O_2) to Fe^{3+}P was 40 h at 37 °C, which is 3-fold longer than the value in the PBS solution.

The O_2-binding affinity of the PEG_2(HSA−FeP) membrane ($P_{1/2}$ = 40 Torr, 25 °C) determined from the UV−vis absorption spectral changes at various O_2/N_2 pressures (Figure 4 inset) was 4-fold lower (high $P_{1/2}$) than that of the monomeric PEG_2(HSA−FeP) in water (Table 1). Since the O_2 coordination to the Fe porphyrin is an exothermic reaction, the O_2-binding affinity of the membrane decreased at 37 °C ($P_{1/2}$ = 61 Torr). In contrast, PEG_5(HSA−FeP) membrane showed the identical O_2-bidnig affinity to that in aqueous PBS solution ($P_{1/2}$ = 11 Torr, 25 °C).

In order to elucidate the O_2-binding kinetics of the PEG_X-(HSA−FeP) membrane, flash photolysis experiments were carried out. The time course of the absorption change after the laser pulse irradiation to the PEG_2(HSA−FeP) membrane in the quartz cuvette exhibited two first-order kinetics. We previously reported that the binding processes of O_2 to HSA−FeP and PEG_X(HSA−FeP) in aqueous media were fitted to a double-exponential expression, giving two different association rate constants for the fast and slow reactions (k_{on} and k'_{on}) (*19*, *22*). It has been interpreted that the O_2 recombination to FeP in the protein could be affected by the each nanoscopic environment around the accommodation site, for example, a steric hindrance of the amino acid residue and difference in polarity. The k'_{on} was used to be approximately one-third of the k_{on} (*17*, *19*, *22*). Nevertheless, the ratio of k'_{on}/k_{on} observed in the PEG_2-(HSA−FeP) membrane was less than one-tenth (Table 1). We then theorized that this can be attributed to the O_2 diffusion in the two parts of the membrane. In the major surface layer of the fibrous component, the diffusion of the O_2 could be slower than in water, and it could be much slower in the amorphous bottom phase. The following results support our assumption. (i) The thickness ratio of the two layers (10 μm/5 μm = 2.0) corresponds well to the molar ratio of the k_{on} and k'_{on} (= 2.1). (ii) The absorption decay accompanied with the O_2 rebinding

to the PEG_5(HSA−FeP) membrane, which consists of the homogeneous fibrous layer, was fitted by single exponential, giving only one association rate constant k_{on}.

The low O_2-binding affinity of the solid membrane of PEG_2-(HSA−FeP) compared to that in the PBS solution is kinetically due to the low association rate constants (Table 1). Even though this result was in significant contrast to the fact that the similar solid membrane of human Hb with maltose (Hb/maltose = 6/4, wt/wt) could not bind O_2 under the same conditions, its O_2-binding affinity was extremely low ($P_{1/2}$ = 760 Torr) (*23*). Since the quaternary structure of Hb was restrained in the solid form, its tense-state conformation cannot change to a relaxed-state with a high O_2-binidng affinity (*24*). In the PEG_X(HSA−FeP) membrane, the protein scaffold was solidified by a bulk water evaporation; however, it would not dramatically influence the dioxygenation of FeP, because the O_2-binding equilibrium is not synchronized with the quaternary structure of the HSA matrix.

PEG_X(HSA−FeP) in Organic Solutions. We have found that the PEG modification enables HSA−FeP to dissolve in organic solvents. The red-colored PEG_X(HSA−FeP) membrane was homogeneously soluble not only in water but also in ethanol and chloroform. The CD spectrum of the membrane showed a different pattern compared to that in aqueous media (Figure 5). The intensity ratio of the double minimum peaks at 208 and 222 nm (I_{208}/I_{222}) of rHSA or PEG_X(HSA−FeP) is normally 1.1 (*25*, *26*), while the membrane showed 0.9. Interestingly, the redissolved aqueous and ethanol solutions both showed the same spectra as the original aqueous HSA. This result implies that the change of the secondary structure in the protein in the solid and liquid states is reversible. The ethanolic PEG_X(HSA−FeP) also exhibited the same absorption changes upon exposure to O_2 and N_2. These organic solutions can also be cast on a glass surface to form identical PEG_X(HSA−FeP) membranes.

PEG_2(HSA−FeP) Membrane with Hyaluronic Acid. An attempt to isolate the PEG_X(HSA−FeP) membrane from the glass surface unfortunately failed, because it was rather fragile, when peeled off. We then added a supporting polymer to the protein solution and prepared the solid membrane on a glass plate or a poly(styrene) dish. Hyaluronic acid (HA), which is known as a glycosaminoglycan component of connective tissues, hyaline body and extracellular matrix, was selected as the biocompatible polymer support (*27*). We also expected that the high water retention capability of HA may have a positive effect on retarding the proton-driven oxidation of the FeP(O_2) complex. Water evaporation of the PEG_2(HSA−FeP)/HA mixture [0.5 mL/0.5 mL, total [HSA] = 2.5 wt %, total [HA] = 0.2 wt %] on the glass plate or poly(styrene) dish produced the red-colored uniform solid membranes. It could not be isolated from the glass plate but was easily peeled off from the poly(styrene) surface, providing a free-standing thin film of the PEG_2(HSA−FeP)/HA hybrid [Figure 6a]. The formation of the flexible film was quite dependent on the HA content. When the total concentration of HA is 0.2−0.5 wt %, we could readily obtain the membrane from the plastic surface. The SEM observations of the film showed that it was made of a homogeneous layer with a relatively coarse structure (Figure 6b). In contrast, the film cast on the glass plate consists of the two-layered form: a major course phase and bottom dense phase (Figure 6c). This implies

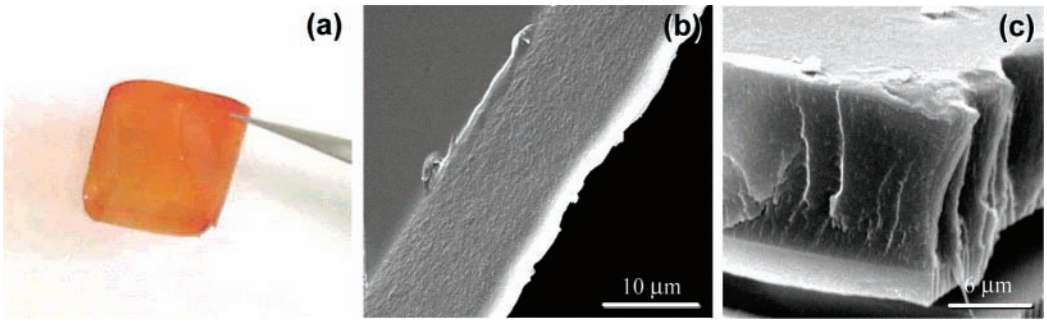

Figure 6. PEG_2(HSA−FeP)/HA membrane. (a) Photograph of the free-standing flexible film, which is prepared on the poly(styrene) surface. (b) SEM of the isolated film. (c) SEM of the membrane prepared on the glass surface.

that the membrane structure of the PEG_2(HSA−FeP)/HA is also influenced by the surface properties of the substrate.

The UV−vis absorption spectral pattern reversibly changed from that of the five-N-coordinate high-spin ferrous complex under an N_2 atmosphere (λ_{max}: 445, 540, 566 nm) to that of the O_2-adduct complex under an O_2 atmosphere (λ_{max}: 426, 545 nm). The O_2-binding parameters of the PEG_2(HSA−FeP)/HA membrane showed a tendency similar to the PEG_2(HSA−FeP) film; the low O_2-binding affinity ($P_{1/2}$ = 32 Torr, 25 °C) is mainly due to the slow association rate constant (Table 1). The half-life of the O_2-adduct complex was 40 h at 37 °C; we could not see any water retention effect of HA that could prolong the stability of FeP(O_2). The water content of the PEG_2(HSA−FeP) membrane and PEG_2(HSA−FeP)/HA membrane were determined by the differential thermal analyses to be 6.5 wt % and 6.6 wt %, respectively.

CONCLUSIONS

The stable solid membranes of a PEGylated artificial hemoprotein have been prepared, and their O_2-binding properties were physicochemically characterized in relation to the layer morphology. The red-colored thin film is soluble again in water and organic solvents (ethanol, chloroform) without any deformation of the secondary structure of the protein. The addition of hyaluronic acid as the polymer support gave the free-standing flexible film. These O_2-binding albumin membranes are a red blood cell substitute with a micrometer-thickness that can be preserved anywhere (e.g., on a shelf and in an ambulance) and reproduced as a saline solution at anytime (e.g., at the scene of a disaster). Furthermore, it would be of great medical importance for a variety of clinical treatments, such as O_2-enriched coating agents for medical devices or artificial organs and an O_2-transporting adhesive plaster for wound healing.

Reaction of the Indole Group with Malondialdehyde: Application for the Derivatization of Tryptophan Residues in Peptides

Alexandra Foettinger,† Michael Melmer, Alexander Leitner, and Wolfgang Lindner*

Received January 2, 2007; Revised Manuscript Received June 14, 2007

A method for the selective modification of tryptophan residues based on the reaction of malondialdehyde with the indole nitrogen of the tryptophan side chain at acidic conditions is presented. The condensation reaction is quantitative and leads to a substituted acrolein moiety with a remaining reactive aldehyde group. As is shown, this group can be further converted to a hydrazone using hydrazide compounds, but if hydrazine or phenylhydrazine are used, release of the free indole group is observed upon cleavage of the substitution. Alternatively, secondary amines such as pyrrolidine may also act as cleavage reagents. This general reaction scheme has been adapted and optimized for the derivatization of tryptophan-containing peptides and small N-heterocyclic compounds. It serves as the basis of a reversible tagging scheme for Trp-peptides or molecules of interest carrying indole structures as it allows the specific attachment and removal of a reactive group that may be used for a variety of purposes such as affinity tagging.

INTRODUCTION

Chemical labeling strategies in the field of peptide and protein analysis play an increasingly important role not only for structure elucidation, but also for quantitative purposes. In this context, derivatization reactions are used to introduce stable isotopes that enable relative quantification or to enrich certain classes of peptides and proteins via affinity tags (*1*, *2*). Furthermore, labeling and cross-linking reactions can be used for protein conformation studies, especially in combination with mass spectrometry (*3*−*5*). Moreover, for the determination of residues contributing to active sites of, e.g., receptor proteins or enzymes, dedicated derivatization reactions can be applied (*6*, *7*).

Tryptophan is an interesting target for the development of chemical tagging strategies. It is a low abundance amino acid with 1.1% frequency (*8*), but approximately 90% of proteins contain at least one tryptophan residue in their sequence (*9*). There are several well-known methods for the derivatization of tryptophan residues in peptides and proteins, most of them targeting the C-2 or C-3 position of the indole ring (see Figure 1). 2-Hydroxy-5-nitrobenzylbromide, for example, finds broad application for the investigation of the role of Trp in active sites of enzymes (*6*, *7*) for the estimation of the tryptophan content in proteins (*10*, *11*) and has recently been used for the determination of the surface accessibility of Trp residues in proteins (*12*). Another frequently used group of reagents are sulfenyl halides. Compounds like 2-nitro- and 2,4-dinitrophenylsulfenylchloride reacting at the 2-position of the indole group can be used for studying active sites of enzymes (*13*). Applications in the field of proteomics, including relative quantification studies employing stable isotope-labeled analogues, were reported (*14*−*16*); *N*-bromosuccinimide is a derivatizing reagent used for similar applications (*17*). Another method, selectively targeting the indole nitrogen, uses rhodium carbenoids for the derivatization of tryptophan residues in proteins as recently reported by Antos et al. (*18*).

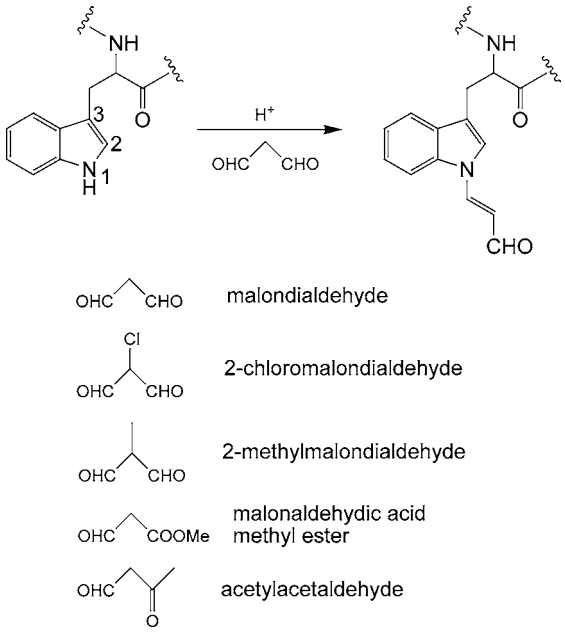

Figure 1. Reaction of the indole group of tryptophan in a peptide with malondialdehyde (MDA) and alternative reagents used in the study.

The principal reaction of the indole ring of the tryptophan side-chain with dicarbonyl compounds like acetylacetaldehyde or malondialdehyde (MDA) has already been briefly described in the 1960s by Teuber et al. (*19*, *20*) but was not followed up since then. The authors investigated the reaction on a synthetic scale for carbazole- and indole-type compounds in concentrated hydrochloric acid. Under these conditions, malondialdehyde also reacts with the guanidine group of arginine forming a pyrimidine (*21*) as reported by King and recently followed by work in our group (*22*).

We have investigated this reaction for the purpose of labeling arginine residues in peptides and observed a side reaction with tryptophan residues during optimization not observed by King.

Further studies have now revealed that the modification corresponds to a condensation product with the indole nitrogen as shown in Figure 1, in accordance with Teuber's previous work. Here, we report how this reaction scheme can be adapted for the selective derivatization of tryptophan residues in peptides and can be applied for the introduction of functional tags.

EXPERIMENTAL PROCEDURES

Materials. The derivatization reagents, 1,1,3,3-tetramethoxypropane (TMP) and 1,1,3,3-tetraethoxypropane (TEP), were from Aldrich (Steinheim, Germany). 1,1,3,3-tetraisopropoxypropane (*22*), 2-methylmalondialdehyde (*23*), and the sodium salt of MDA (*24*) were synthesized in-house.

All other chemicals and reagents were from Fluka (Buchs, Switzerland), Sigma (Deisenhofen, Germany), Aldrich, or Acros Organics (Geel, Belgium). All model peptides were acquired from Bachem and used as received (Weil am Rhein, Germany).

Instrumentation. Liquid chromatography−mass spectrometry was performed on an Agilent 1100 HPLC system coupled to an Agilent MSD Trap SL quadrupole ion trap mass spectrometer (Agilent Technologies, Waldbronn, Germany) equipped with a standard electrospray source. Chromatographic separations were performed on a BetaBasic-18 column (150 × 4.6 mm, 3 μm, Thermo Electron Corporation, Runcorn, UK) equipped with a guard column containing the same material. The mobile phases for gradient elution were (A) 0.1% (v/v) formic acid in water and (B) 0.1% (v/v) formic acid in acetonitrile. The gradient was as follows: 0−5 min 5% B, 5−25 min 5−50% B, 25−30 min 50% B, 30−35 min 50−5% B, and 35−40 min 5% B. The flow rate was set to 0.7 mL min^{-1} and the column temperature to 25 °C. UV absorption was monitored at 230 nm using an Agilent 1100 variable wavelength detector.

For direct infusion experiments, samples were introduced with a syringe pump (kd scientific, Holliston, MA) at a flow rate of 5 μL min^{-1}.

Preparation and Characterization of the MDA Derivative of *N*-Acetyltryptophan (N-Ac-Trp) as Model/Reference Compound. Approximately 100 mg of N-Ac-Trp (400 μmol) was dissolved in 10 mL of 80% aqueous TFA and 800 μL of TMP (~10-fold molar excess) was added dropwise. The solution was stirred at room temperature for 1 h. Then, the solvent was evaporated in vacuo, and the product was taken up in ethyl acetate and purified by flash chromatography on silica with the mobile phase consisting of ethyl acetate, methanol, and acetic acid (40/1/1, v/v/v). Following removal of the solvents in vacuo, an intensively yellowish colored product was obtained in 72% yield.

^{1}H NMR (d_6-DMSO, 400 MHz): 9.49 (d, 1H), 8.55 (d, 1H), 8.09 (d, 1H), 7.90 (d, 1H), 7.77 (s, 1H), 7.62 (d, 1H), 7.35 (t, 1H), 7.26 (t, 1H), 6.4 (m, 1H), 4.56 (m, 1H), 3.18 (q, 1H), 3.08 (q, 1H), 1.83 (s, 3H) ppm.

^{13}C NMR (d_6-DMSO, 100 MHz): 191.95 (aldehyde C═O), 173.46 (carboxyl C═O), 169.58 (N-acetyl C═O), 145.84 (Ar CH), 136.45 (Ar), 130.26 (Ar), 124.31 (Ar CH), 123 (Ar CH), 122.92 (Ar CH), 119.84 (Ar CH), 119.68 (Ar), 112.58 (Ar CH), 111.09 (Ar CH), 52.76 (N-acetyl CH_3), 27.31 (CH_2), 22.81 (CH) ppm.

MS (ESI-quadrupole): $[M + H]^+ = 301.4$.

UV spectrum (methanol): 209, 272, 332 nm (ϵ 2.81 × 10^{-5}, 1.63 × 10^{-5}, 2.36 × 10^{-5} L mol^{-1} cm^{-1}).

Fluorescence spectrum (methanol): $\lambda_{exc.,max} = 230$ nm, $\lambda_{em.,max} = 380$ nm.

Analytical-Scale Derivatization Procedure for Trp-Containing Peptides. Typically, 50 μg of peptide was dissolved in 50 μL of aqueous acidic solution (hydrochloric acid, TFA, or acetic acid), and a 100-fold molar excess of TMP (0.9 μL) or TEP (1.2 μL) was added. After a reaction time of 1 h (at room temperature), the reaction mixture was diluted with water (1:10 for TFA and 1:100 for HCl conditions, respectively) and purified by solid-phase extraction on reversed-phase C_{18} material (100 mg sorbent, Phenomenex, Torrence, CA) to remove the acid and excess reagents. The elution solution was either used directly for infusion experiments or evaporated to dryness with nitrogen and redissolved in mobile phase for LC-MS analysis.

Formation of the Hydrazones. Typically, 50 μg of MDA-labeled peptide was dissolved in 200 μL ammonium acetate buffer (pH adjusted to 5 with acetic acid) containing 10 to 20 mM of hydrazide reagent (50−100 fold molar excess). Usually, the reaction proceeded for 1−2 h.

Cleavage Reaction Using Hydrazine Dihydrochloride. 50 μg of labeled peptide was incubated in 200 μL of a 20 mM aqueous hydrazine dihydrochloride solution with the pH adjusted to approximately 3 with acetic acid. The reaction mixture was incubated for 1 h at 50 °C to achieve complete cleavage.

Cleavage Reaction Using Pyrrolidine. 50 μg of labeled peptide was incubated in 200 μL of a water/acetonitrile mixture (50:50, v/v) containing 500 mM pyrrolidine. The reaction mixture was left for 1 h at room temperature to achieve complete cleavage.

Hazardous Substances Statement. Hydrazine dihydrochloride is a toxic and potentially carcinogenic reagent and should be handled with special care. Appropriate safety precautions should be taken when handling concentrated acids and bases.

RESULTS AND DISCUSSION

Reaction of the Indole Group of Tryptophan Residues with MDA−Reaction Conditions and Specificity. As mentioned in the Introduction, a side reaction with tryptophan residues was observed during MDA-labeling of arginine residues in peptides (*22*). To investigate this phenomenon further, dedicated studies were carried out using *N*-acetyltryptophan as a model compound. Using conditions comparable to the analytical-scale reaction for arginine labeling (12 M hydrochloric acid, room temperature), the N-Ac-Trp MDA-derivative was isolated in preparative scale (see Experimental Procedures for details). Characterization by ^{1}H and ^{13}C NMR as well as mass spectrometry allowed us to assign a structure like that shown in Figure 1, corresponding to a condensation product of MDA with the indole nitrogen in the form of an acrolein-type derivative.

To explore the possibility of applying this reaction for the modification of Trp-containing peptides, we studied whether lower concentrations of HCl or other organic acids can also be used for this reaction in order to avoid side reactions with arginine residues in peptides. Throughout this optimization procedure, N-Ac-Trp and the standard peptides PTHIK**W**GD, HPKRP**W**IL, L**W**MR, KG**W**K, and A**W** were used as model analytes. The reactivity was evaluated by means of mass spectrometry using an ion trap mass spectrometer with electrospray ionization either by direct infusion of the sample solution or by LC-MS.

First, we elucidated whether analyte-friendly conditions for a complete derivatization reaction can be achieved in reasonable time, avoiding degradation of the analytes and the occurrence of side reactions. Therefore, kinetic studies were performed with N-Ac-Trp at different concentrations of aqueous HCl (0.1, 1, 3, 6, and 12 M in water), TFA (20%, 50%, and 80% in water and 100%, v/v), and acetic acid (50% and 80% in water and 100%, v/v), and the reaction was followed by LC-MS and LC-UV. As a reagent, malondialdehyde may be applied in its commercially available acetal form (as tetramethoxy- or tetraethoxypropane) from which MDA is formed in situ during the reaction. Selected results illustrating the reaction kinetics in HCl

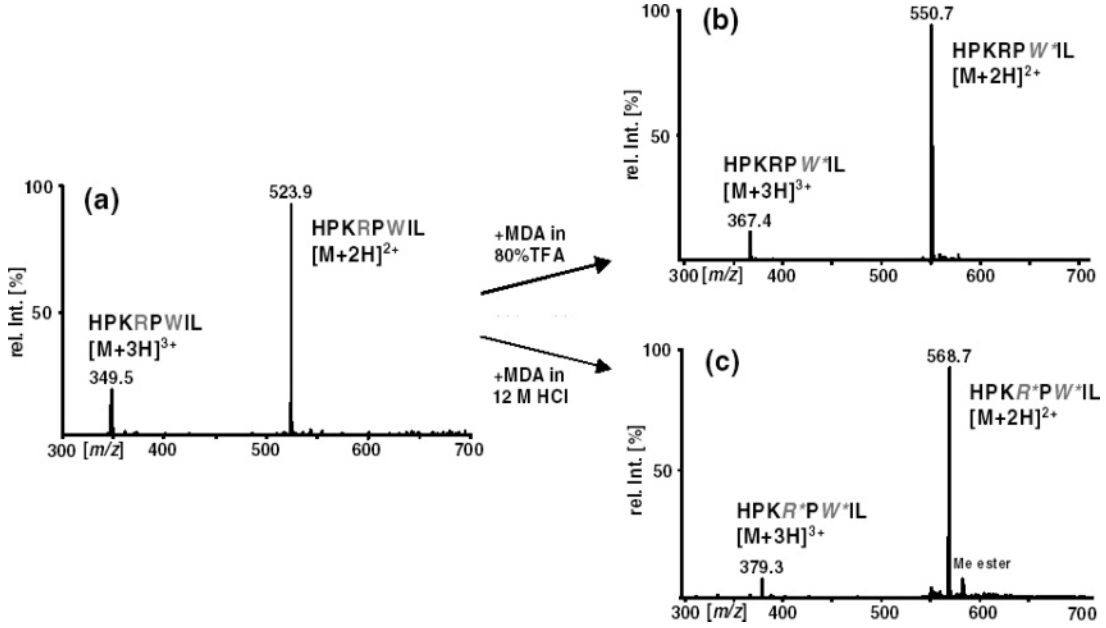

Figure 2. Mass spectra of the peptide HPKRPWIL (a) in the free form ($[M + 2H]^{2+} = 523.9$, $[M + 3H]^{3+} = 349.5$), (b) after MDA derivatization of Trp-residues in 80% TFA ($[M + 2H]^{2+} = 550.7$, $[M + 3H]^{3+} = 367.4$), and (c) after MDA derivatization of Trp and Arg residues in 12 M HCl ($[M + 2H]^{2+} = 568.7$, $[M + 3H]^{3+} = 379.3$). Modified residues are marked with asterisks.

and TFA solutions are shown as Supporting Information (Figures S1−S3).

Generally, the reaction proceeds in the presence of all three acids, but in acetic acid, even at a very high concentration, the reaction is not quantitative after 1 h (data not shown). When using smaller amounts of acid such as 1 M HCl or 20% TFA or less in aqueous solution, the formation of Schiff bases with amino groups that are usually present in amino acids and peptides (N-terminus, lysine) is observed and the yield of the desired reaction product is reduced. Consequently, we found that at least 3 M HCl or 50% of TFA in water are necessary to achieve complete indole group reaction within 1 h at room temperature and to avoid Schiff base formation. Using aqueous TFA (usually 80%), no side reactions such as Schiff base formation or conversion of the guanidine group of arginine (*22*) are observed. In contrast, when using HCl the reaction with arginine residues has to be considered, which always proceeds to some extent in the presence of HCl but completely only at 12 M HCl (*22*). An example of the derivatization reaction at different conditions is given in Figure 2 for the model peptide HPKRPWIL.

Additionally, ester formation with the alcohol released from the MDA−acetal is observed under hydrochloric acid conditions which could be minimized by using the isopropyl−acetal of MDA or the sodium salt of MDA (*24*) which are, however, not commercially available. Reaction yields (>98% for 80% TFA and ∼40% for 12 M HCl) were determined by using the synthetically prepared N-Ac-Trp MDA adduct as external standard for quantification by HPLC-UV, again favoring TFA conditions. Therefore, for all further experiments, 80% TFA was used unless otherwise stated.

Expansion of the Reaction Concept toward Other Analytes and Reagents. In order to elucidate the broader applicability of the MDA-based reaction, we tested various compounds at the optimized reaction conditions. These were, on one hand, various indole and tryptophan derivatives, but also other N-heterocyclic compounds. As already found by Teuber (*19*, *20*), carbazoles react in the same way as the indole group under the conditions we applied. Additionally, 3-chloroindazole and 3-indazolinone also reacted, whereas indazole itself did not react. Pyrrole was found to give the corresponding product at least partially. For pyrazole, benzotriazole, and benzimidazole derivatives, no reaction product was observed.

To explore the full potential of the reaction type outlined in Figure 1, reagents structurally related to malondialdehyde were also tested, and the reaction products were again evaluated by LC-MS. The 2-substituted derivatives of MDA, 2-chloromalondialdehyde and 2-methylmalondialdehyde, were found to react, but much more slowly than MDA itself. In TFA, almost no product was detected, and with hydrochloric acid as the medium even after a reaction time of 2 h, conversion was not complete for Trp−peptides, as could be judged from the underivatized analytes still present. Malonaldehydic acid methyl ester (applied as 3,3-dimethoxypropionic acid methyl ester), carrying one aldehyde and one ester group, does also react with the indole nitrogen in TFA as well as HCl. LC-MS experiments revealed that the reaction proceeds quantitatively with tryptophan and Trp-containing peptides, as no unmodified analytes were observed, but it turned out that the product is chromatographically not homogeneous (whereas the MDA derivative is). Another disadvantage of this reagent is that side products formed by the reagent itself were observed which interfere with the analysis of the derivatized peptides (e.g., as coeluting peaks during LC-MS analysis). Acetylacetaldehyde (used as the dimethylacetal) also reacts according to the general reaction scheme shown in Figure 1 as observed previously by Teuber et al. (*19*, *20*) but establishes the same problem concerning disturbing side products.

Reagents having only keto groups, but no aldehyde functionalities such as acetylacetone and acetoacetateic acid methyl ester, did not show any reactivity toward the indole group. Using dichloroacetaldehyde (applied as the diethylacetal) as the reagent, no condensation product was observed, and monoaldehydes like propionaldehyde and butyraldehyde did not react in a defined way as well. Although formation of a double bond is possible in principle, this has not been observed, and a mixture of different products was observed by MS analysis. These were not characterized in detail, although evidence for cross-linking processes (i.e., aminal formation) was obtained from LC-MS/MS experiments.

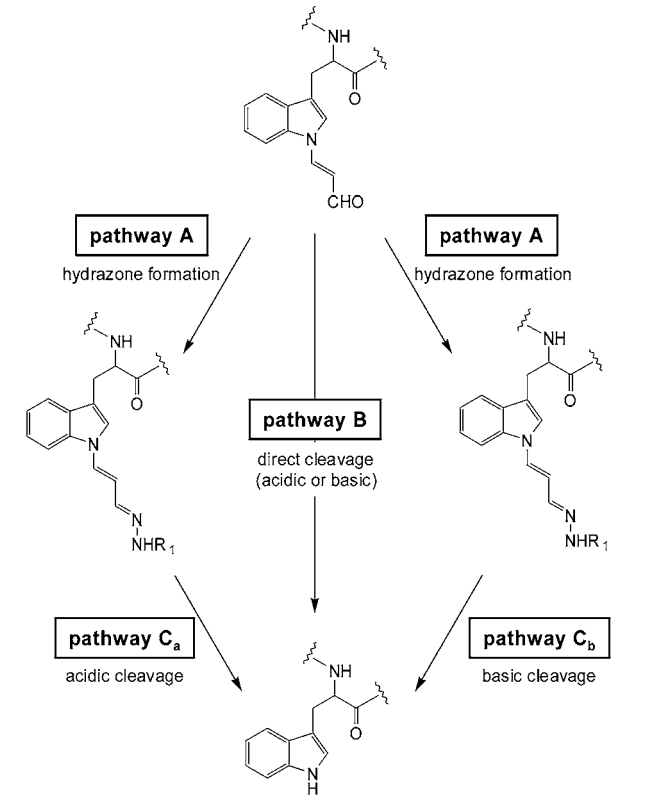

Figure 3. Reaction pathways of the tryptophan−MDA condensates (N-acroleinyl derivatives) that were evaluated in this study. For details, see text.

Further Reactions of the α,β-Unsaturated Aldehyde Derivatives. The α,β-unsaturated aldehyde group resulting from the reaction of the tryptophan side chain with malondialdehyde, which de facto corresponds to a 3-substituted acrolein moiety, opens up the possibility for further reactions. Such carbonyl groups typically react with amino groups or hydrazines or carbazides to Schiff base-type products (see Figure 3). Dinitrophenylhydrazine, for instance, is a classical reagent used for the analysis of small aldehydes often applied in environmental chemistry (*25*), and also for studying protein oxidation (*26*).

Hydrazone formation (pathway A in Figure 3) was successfully tested with 2,4-dinitrophenylhydrazine and semicarbazide using the peptide PTHIKWGD as model analyte (see Figure 4). Using phenylhydrazine, however, we noticed the removal of the initially present acroleinyl label, resulting in the unlabeled indole moiety of the peptide being observed (reaction pathway B in Figure 3). Instability of the condensation product upon addition of excess phenylhydrazine was already noticed by Teuber in the 1960s (*19*). To investigate this in more detail, different hydrazines (phenylhydrazine, benzylhydrazine, hydrazine) and hydrazides (benzylhydrazide, acethydrazide, semicarbazide) were tested for their reactivity, and we observed that hydrazides, with a carbonyl group next to the hydrazine group, form stable adducts with the aldehyde (pathway A), while hydrazines lead to cleavage of the whole MDA adduct resulting in the free indole group (pathway B). 2,4-Dinitrophenylhydrazine seems to be an exception, but the explanation might be that the electron withdrawing nitro groups significantly influence

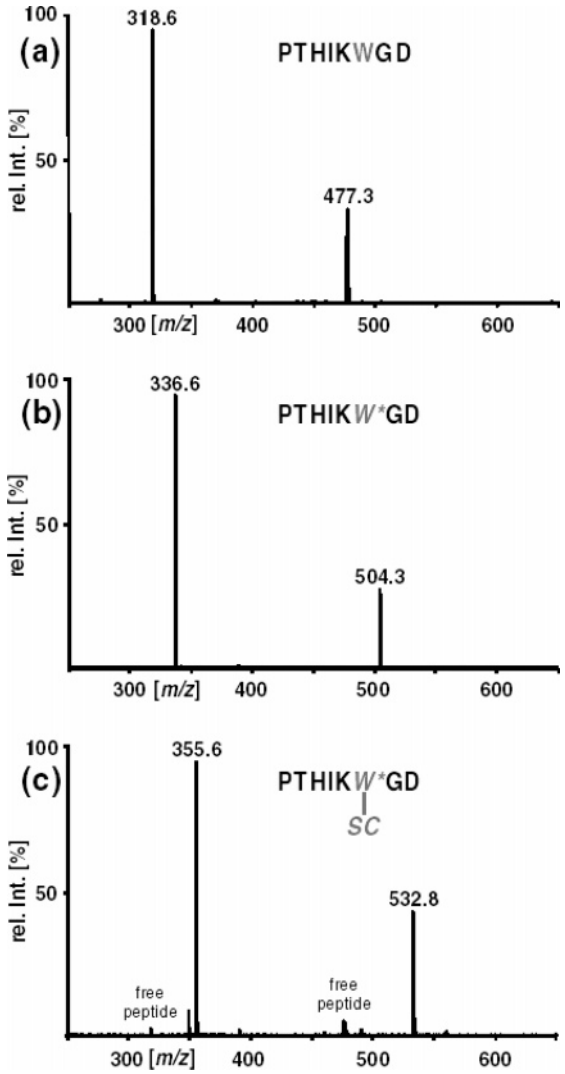

Figure 4. Mass spectra of the peptide PTHIKWGD (a) in the free form ($[M + 2H]^{2+} = 477.3$, $[M + 3H]^{3+} = 318.6$), (b) after reaction with MDA ($[M + 2H]^{2+} = 504.3$, $[M + 3H]^{3+} = 336.6$), and (c) after further reaction of the acroleinyl moiety (free aldehyde) to the semicarbazone ($[M + 2H]^{2+} = 532.8$, $[M + 3H]^{3+} = 355.6$).

the properties of the molecule. As a third option, we incubated a hydrazone-labeled peptide with hydrazine under acidic conditions, also resulting in the parent compound (see pathway C in Figure 3).

The conditions for both reactions, the hydrazone formation and the cleavage of the MDA derivative with hydrazine, were optimized concerning pH, buffer, temperature, and reagent excess followed by LC-MS analysis. Acetate and phosphate buffers were tested at different pH values. For hydrazone formation (pathway A), approximately 50-fold molar reagent excess at a pH of 5−7 was found to be the optimum. A slight increase in reaction speed can be achieved by increasing the temperature from room temperature to 50 °C. At acidic pH conditions, the hydrazones are unstable when the reagent excess is removed. In contrast, the hydrazone bond remains stable in alkaline milieu (pH > 9). The optimal results for the cleavage reaction (pathways B and C_a) were found using hydrazine (applied as the dihydrochloride salt) in ammonium acetate solution at a pH of approximately 3. Increasing the temperature during the cleavage step to 50 °C makes the reaction significantly faster. Using N-Ac-Trp as a model analyte, the individual yields of the three reaction steps (MDA adduct formation, conversion to a hydrazide using acethydrazide, cleavage using hydrazine) were evaluated under optimized conditions. Accord-

ing to LC-MS data, all reactions proceeded with yields in excess of 90%. Furthermore, these reaction conditions were found to be fully compatible with the integrity of a number of model peptides covering all proteinogenic amino acids, as no degradation products were observed in noticeable amounts.

The release of the free indole moiety upon addition of hydrazine is only observed at acidic or neutral pH. Incubation under alkaline conditions, for example, with hydrazine or phenylhydrazine in methanol, leads to formation of a stable hydrazone that can be detected by HPLC-MS, but upon acidification, the whole label is released, leading to the free indole moiety. This very specific cleavage reaction is only possible for the malondialdehyde adduct but not for products resulting from the reaction with the other reagents such as malonaldehydic acid methyl ester (see Figure 1). This led us to the assumption that cleavage of the N-linked acroleinyl substituent only occurs after intermediate formation of the hydrazone, which seems to activate the cleavage reaction. When this process cannot be promoted, the cleavage reaction according to Figure 3 (pathways B and C_a) does not occur.

As an alternative route for the removal of the MDA adduct, we investigated an amine-mediated nucleophilic cleavage. A similar strategy was employed by Villarasa and co-workers (*27*) for the cleavage of N-substituted nucleosides resulting from the reaction with methyl propynoate (other bases may be used as well (*28*, *29*)). Several primary and secondary amines were studied, including ammonium hydroxide, diethylamine, pyrrolidine, and piperidine. Removal of the acroleinyl group from the indole nitrogen was possible with all reagents to some extent, but pyrrolidine consistently gave the best results in terms of reaction speed and clean reaction. Even at room temperature, quantitative cleavage was observed in 1 h upon incubation with 500 mM pyrrolidine in aqueous or hydroorganic medium (water/acetonitrile, 50:50, v/v). Pyrrolidine-mediated cleavage is possible both directly from the MDA adduct (pathways B) and via the hydrazone (pathway C_b).

Conclusions and Outlook; Potential Applications of the Reversible MDA Tag on Tryptophan Residues. In this contribution, we have described the adaptation and optimization of the condensation reaction of malondialdehyde (MDA) with the indole nitrogen of tryptophan residues in peptides under strongly acidic conditions. The resulting acroleinyl label at the indole nitrogen can be used for further reactions, e.g., Schiff base formation, as we have shown for the formation of hydrazides. Cleavage of these MDA labels to the free indole group was found to be possible with reagents such as hydrazine (at acidic conditions) and pyrrolidine (at alkaline conditions).

This highly chemoselective cascade of reactions, including the cleavage of the MDA "tag" resulting in the release of the free intact indole group, opens up the possibility for various highly interesting applications. For instance, we have now developed a solid-phase capture strategy for tryptophan-containing peptides involving a solid support carrying hydrazide groups (*30*). This protocol can be used for the selective enrichment of other analytes of interest that carry indole moieties from complex samples such as biofluids. Furthermore, labels for specific fluorescence detection or isotope labels and so forth could be introduced via the acroleinyl group, always with the possibility of complete cleavage of the label at a later stage, resulting in the unlabeled, intact starting analytes. This could be important for further MS analysis, because high molecular mass labels or tags may be problematic when LC-MS and MS/MS analysis is performed if they show decreased sensitivity or unfavorable fragmentation properties (*31*). This has also been observed for some MDA-labeled Trp−peptides that show dominant cleavage of water during MS/MS, but can be overcome by release of the free indole group before MS analysis.

ACKNOWLEDGMENT

The authors would like to thank the FWF (Austrian Science Fund, project #P15482) for financial support.

The functionalization of nanoparticles is *conditio sine qua non* in studies of specific interaction with a biological target. Often, their biological functionality is achieved by covalent binding of bioactive molecules on a preexisting single surface coating. The yield and quality of the resulting coated and functionalized superparamagnetic iron oxide nanoparticles (SPIONs) can be significantly improved and reaction times reduced by using solid-phase synthesis strategies. In this study, a fixed bed reactor with a quadrupole repulsive arrangement of permanent magnets was assayed for SPION surface derivatization. The magnet array around the fixed bed reactor creates very high magnetic field gradients that enables the immobilization of SPIONs with a diameter as low as 9 nm. The functionalization on the surface of immobilized 25 nm 3-(aminopropyl)trimethoxysilane-coated SPIONs (APS-SPIONs) was performed using fluorescein-isothiocyanate directly, and by the SV40 large T-antigen nuclear localization signal peptide (PKKKRKVGC) conjugated to acryloylpoly(ethylene glycol)-*N*-hydroxysuccinimide, where the PEG reagent is conjugated first to create a functionalized nanoparticle and the peptide is added to the acryloyl group. We show that the yield of reactant grafted on the surface of the APS-coated SPIONs was higher in solid-phase within the fixed bed reactor compared to conventional liquid-phase chemistry. In summary, the functionalization of SPIONs using a magnetically fixed bed reactor was superior to the liquid-phase reaction in terms of the yield, reaction times required for derivatization, size distribution, and scalability.

INTRODUCTION

In recent years, functionalized superparamagnetic iron oxide nanoparticles (SPIONs) have found applications in magnetic resonance imaging (*1*), hyperthermia (*2*), the study of molecular interactions (*3*), and in drug (*4*) and gene delivery (*5*). In order to improve the biological targeting capability and therefore the pharmacodynamics, chemical or biological reagents having a strong affinity for target cells and high efficiency for nanoparticle internalization must be conjugated to the SPION surface (*6*).

The bottom up approach of building nanoparticles from the superparamagnetic core to an outer functional layer of bioactive molecules offers flexibility when designing drug or gene delivery carriers. Recent research on the attachment of these bioactive molecules and handling of these particles has been focused on synthesis, purification, and biofunctionalization of the SPIONs with synthesis routes in liquid-phase (*7*). Multistep liquid-phase synthesis is time-consuming and laborious because each addition reaction on the SPION surface is followed by a purification step such as magnetic sedimentation (*8*), size exclusion chromatography (*7*), or dialysis. In addition, repeated magnetic sedimentation of the SPIONs may cause irreversible agglomeration of the nanoparticles (*9*). Although ultrasonication is often applied to dissociate the bead agglomerations, it may cause damage to the bound active molecules, resulting in an overall decrease of their biological activity. The use of size exclusion chromatography in repeated multistep modification results in dilution of the particles upon each purification step and in a loss of particles after each purification step on the column.

In order to bypass the need for repeated purification and to ensure a continuous working process, we immobilized SPIONs as a stationary solid phase in a column using a high gradient permanent magnetic field. For functionalization of the immobilized particles during solid-phase synthesis, the chemical reagent is conducted over the SPIONs as a solid support. Although solid-phase synthesis on a polymer support is widely described (*10*), to our knowledge the solid-phase multistep biofunctionalization of SPIONs in a magnetic fixed bed reactor has not been shown.

In this magnetic fixed bed reactor the immobilization of the magnetic particles is based on the attractive force exerted on the magnetized particles by a magnetic field gradient. This force, F_{mag}, on the SPION with inducible magnetization, M, on an external flux density, B, perpendicular to a magnet (z-direction) with the magnetic volume V_{mag} can be described by the following relation:

$$F_{mag} = \frac{1}{2} \cdot V_{mag} M \frac{\partial B}{\partial z} \quad (1)$$

This equation shows that the force on a particle is depending on the magnetic field gradient. As well, the magnetic volume of the particles and the magnetization of the particles play an important role on the force. According to this equation a higher force is exerted onto larger particles compared to particles with a smaller magnetic volume. Therefore, especially for magnetic trapping of small particles, the creation of high magnetic field gradients is important.

In this study, we used a fixed bed reactor with a quadrupole arrangement of magnets for the (bio)-modification of SPIONs.

The immobilization of SPIONs onto the fixed bed reactor and the subsequent functionalization of SPIONs are shown by different examples. We demonstrated that surface derivatization of SPIONs can be produced directly with this instrument configuration. Our data indicates that the efficiencies, product qualities, and recovery rates of the functionalized nanoparticles produced by solid-phase synthesis were superior to those obtained using conventional liquid-phase methods.

MATERIALS AND METHODS

Fixed Bed Reactor. A model fixed bed reactor was build from Inox as the solid support for the 20 FeNdB magnets (Maurer Magnets, M662056, 40/10/5 mm (l/w/h)) assembled to four stacks containing five magnets each, a Teflon tube (Semadeni 4.8 mm outer diameter, 3 mm inner diameter), and a soft magnetic iron-nickel alloy (Goodfellow; 52% Fe, 48% Ni; diameter 0.5 mm; $H_C = 20$ A/m, $M_S = 1.6$ T, permeability 25 000). The Fe−Ni-alloy wire is used to increase the magnetized surface area for efficient magnetic immobilization. In general, iron-nickel alloys exhibit a wide range of magnetic properties in relation to their nickel content. The high nickel alloys have high initial permeability but low saturation, whereas the low nickel alloys are lower in initial permeability but higher in saturation induction. All tubing was connected to two pumps (Knauer K 1001) which were also made of Teflon. UV and conductivity measurements of the efflux were performed online by the detectors of an Äkta prime FPLC chromatography system connected directly to the outlet of the fixed bed reactor.

Particle Synthesis. All chemicals were of analytical reagent grade and used without further purification. Ultrapure deionized water (Seralpur delta UV/UF setting, 0.055 μS/cm) was used in all synthesis steps. Dialysis tubing with a molecular weight cut off at 12 000 Da was used for purification (D-9527 Sigma, cellulose membrane). Superparamagnetic nanoparticles were prepared by alkaline coprecipitation of ferric and ferrous chlorides in aqueous solution (*11*−*13*). A 185 mL amount of a 0.086 M $FeCl_3 \cdot 6H_2O$ solution and 185 mL of a 0.043 M $FeCl_2 \cdot 4H_2O$ solution were mixed and precipitated with concentrated ammonia (volume fraction 30%) while stirring vigorously. The black precipitate, which immediately formed, was washed several times with ultrapure water until the pH decreased from 10 to 7. The solid fraction was collected and refluxed in a mixture of 2 M nitric acid (40 mL) and 0.27 M aqueous $Fe(NO_3)_3 \cdot 9H_2O$ (60 mL) for 1 h. During this step the initial black slurry turned brown and the formation of nitric oxide could be observed. The system was allowed to cool to room temperature, the magnetic nanoparticles were sedimented on a permanent magnet, the supernatant was discarded, and 100 mL of ultrapure water was added to the slurry, which immediately dispersed. The brown suspension was dialyzed for 2 days against 0.01 M nitric acid and stored at 4 °C.

3-(Aminopropyl)triethoxysilane Coating of SPIONs. Superparamagnetic iron oxide nanoparticles were coated with 3-(aminopropyl)triethoxysilane (APS) via a sonochemical route. A 400 μL amount of ferrofluid (from concentrations ranging from 12 mg to 0.6 mg iron/mL) were added to 9.6 mL of ethanol in a 50 mL polystyrene vessel. Subsequently 1.5 mL of aqueous ammonia (volume fraction 25%) and 1 mL of APS were added, and the mixture was continuously sonicated for 1 h in an ultrasound horn (Ultrasons Annemasse, Sonimasse S20). The reaction was carried out at a molar ratio of 1:35:15 APS/ethanol/H_20. After sonication the sample was centrifuged at 30 000 g for 25 min (Jouan, GR2022). The supernatant was discarded, and the pellet was resuspended in ultrapure water. This process was repeated three times. The magnetic particles were sedimented overnight on a permanent magnet (Maurer Magnets, Switzerland, $B_r = 300$ mT), and the clear supernatant was removed and the particles were re-dispersed in water (*14*). The particles having a mean diameter of 25 ± 2 nm consisted of 94% of γ-Fe_2O_3 (w/w) and 6% aminopropyl silica (w/w) as determined by atomic emission spectroscopy and had a saturation magnetization of 58 emu/g, which reflects the composition of the beads as the uncoated SPIONs showed a saturation magnetization of 61 emu/g (*14*).

Iron Determination (Prussian Blue colorimetric assay). A 50 μL amount of various concentrations (0.25 to 50 μg) of APS-coated particles before and after modification were dissolved for 1 h in 6 N HCl (100 μL/well of a 96-well plate), 100 μL of a 5% solution of $K_4[Fe(CN)_6]$ (Merck) in H_2O was added, and the absorbance at was read after 10 min at 690 nm in a multiwell plate reader (Infinite M200, Tecan). Each experiment was repeated in triplicate at least three times.

Determination of Immobilization Efficiency onto the Fixed Bed Reactor. APS-SPIONs (8 mg of iron) dispersed in 16 mL of 20 mM borate buffer at pH 7.5 were injected at a flow rate 0.2 mL/min and the amount of immobilized iron was determined by Prussian Blue colorimetric assay after continuous washing of the reactor with 10 mL of buffer at the same flow rate. A Teflon tube (Semadeni 4.8 mm outer diameter, 3 mm inner diameter) without and with one and two Fe−Ni-alloy wires (Goodfellow; 52% Fe, 48% Ni; diameter 0.5 mm; $H_C = 20$ A/m, $M_S = 1.6$ T, permeability 25 000) with a length of 70 mm were inserted.

Labeling of APS-Coated SPIONs with FITC. The coupling of fluorescein-isothiocyanate (FITC, Fluka) in a polystyrene vessel (50 mL) was carried out by adding 6 mL at 0.1 mg/mL of FITC in 20 mM borate buffer at pH 7.5 to 500 μg of APS-coated SPIONs. The mixture was allowed to react for 1 h at room temperature (with and without mixing). After the reaction, the dispersion was washed six times with 6 mL of 20 mM borate buffer at pH 7.5 by using a magnet to sediment the particles followed by aspiration of the supernatant using a pipet.

Parallel to the reaction in the liquid phase, 500 μg of APS-coated SPIONs was loaded onto the fixed bed reactor. The flow was stopped for 20 min so all the SPIONs were attached to the fixed bed column. After the reactor was loaded with APS-SPIONs, 6 mL of 0.1 mg/mL of FITC in 20 mM borate buffer at pH 7.5 was circulated over the immobilized particles for 1 h at a flow rate of 3.5 mL/min, which corresponds to a flow speed of 50 cm/min. After the reaction, the particles were washed with 150 mL of 20 mM borate buffer pH 7.5.

The amount of FITC immobilized onto the surface of the particles was determined in a Tecan Infinite M200 microplate reader using a 96-well plate (Falcon Microtest 96). Each well contained 250 μL of sample. Three fluorescence standard curves were generated using either pure FITC (from 1 ng/mL to 500 ng/mL) or FITC (from 1 ng/mL to 500 ng/mL) with APS-SPIONs added at concentrations of 5 μg/mL and 50 μg/mL, respectively. Fluorescence was measured at an excitation wavelength of 490 ± 9 nm and an emission wavelength of 520 ± 20 nm. The amount of immobilized FITC onto the surface of the nanoparticles was finally estimated using a concentration of 5 μg/mL APS-coated SPIONs for both reaction types (solid- and liquid-phase). Because of the high absorption coefficient of APS-SPIONs, the fluorescence was determined at SPION concentrations of 5 μg/mL of iron. Using higher APS-SPION concentrations, e.g., 50 μg/mL iron the amount of FITC is underestimated. However, because of possible quenching effects, these measurements should be considered as a comparison of the fluorescence between the two synthetic methods rather than absolute FITC loading (*15*, *16*).

Synthesis of Nuclear Targeting Peptide. For the fabrication of the nuclear targeting peptide with the sequence PKKKRKVGC, the following protected amino acids were used: Fmoc-Pro-OH,

Fmoc-Lys(Boc)-OH, Fmoc-Arg(Pbf)-OH, Fmoc-Val-OH, Fmoc-Gly-OH and Fmoc-Cys(Trt)-OH, (Novabiochem). The NovaSyn TGR resin (loading: 0.23 mmol/g) was used as the solid-phase support. All solvents were dried over molecular sieves 3A (Fluka). Peptide syntheses were performed using a PSW1100 peptide synthesizer (Chemspeed AG) according to the manufacturer's instructions. After completion, the resin was recovered and the cleavage was carried out with trifluoroacetic acid (TFA)/triisopropylsilane (TIS)/H_2O (94:5:1) for 4 h at room temperature with shaking. The peptide was precipitated directly from the cleavage cocktail into cold diethyl ether (800 mL), collected using a filter, dried under vacuum, and stored at −20 °C. The peptide was dissolved in 0.1% TFA in water just prior to purification. The peptide was purified via preparative scale reverse-phase HPLC using a Waters Ultrapurification system with a preparative Atlantis dC18 column (19 × 150 mm) and mobile phases of acetonitrile and 0.1% (v/v) TFA in water. The peptide was sequenced using ESI+ MS/MS in a Thermo Scientific LTQ Linear Ion Trap mass spectrometer equipped with an Advion Biosciences electrospray source.

The resulting PKKKRKVGC peptide was labeled with Alexa Fluor 568 carboxylic acid, succinimidyl ester (Invitrogen) according to the manufacturers instructions and is referred to as Alexa Fluor 568-PKKKRKVGC in this work. The labeled peptide was purified using a Waters 2695 Alliance system with fluorescence detector and a Waters Atlantis dC18 column (4.6 × 150 mm). The final product displayed a molecular weight of 2005.96 Da as measured using a Waters ZQ single quadropole mass spectrometer in ESI+ mode, which corresponds precisely to a 1 dye one peptide conjugate plus charge (M + H).

Nuclear Targeting Peptide and PEG Functionalization of APS Coated SPIONS. APS-coated SPIONs were functionalized in a first step with acryloylpoly(ethylene glycol)-*N*-hydroxysuccinimide (acryl-PEG-NHS, 3400 Da; Nektar Therapeutics, Huntsville, AL). To 1 mg of APS-coated SPIONs, 3 mg of acryl-PEG-NHS (6 mg/mL) was added and mixed for 20 min (control experiment in beaker) or recirculated for 20 min at a flow rate 3.5 mL/min (50 cm/min) over the immobilized particles in the fixed bed reactor. After the reaction of the N-hydroxysuccinimide site of the acryl-PEG-NHS to the amino groups of the APS-SPIONs, the particles were washed by sedimenting the modified particles three times for 1 h on a FeNdB (Maurer Magnets, M695.8) magnet and subsequently adding 1 mL of 20 mM borate buffer at pH 7.5 each time. The particles derivatized in the fixed bed reactor were washed by continuously flushing the immobilized particles with 150 mL of 20 mM borate buffer at pH 7.5.

After completion of the washing, 1.85 mg of Alexa Fluor 568-PKKKRKVGC in 6 mL of 20 mM borate buffer at pH 7.5 was added to both the fixed bed reactor and the beaker and were either recirculated or shaken for 1 h. Next, an additional washing step was performed as described previously. Following the wash, active acrylate groups were quenched by adding 1 mL of 4 mg/mL cysteine (Acros Organics) to both reactions and allowed to react for 2 h again with either recirculation (fixed bed) or shaking of the mixture (beaker). After quenching, the mixture was again washed as described previously.

For the quantification of the fluorescence in the supernatant and on the SPION surfaces of both reaction types, fluorescence standard curves with the Alexa Fluor 568 were measured at an excitation wavelength of 578 ± 9 nm and an emission wavelength of 605 ± 20 nm.

Centrifugal Filters and Size-Exclusion Chromatography for Particle Purification. A 2.5 mL amount of APS-coated SPIONs (500 μg/mL) dispersed in 20 mM borate buffer (pH 7.5) was loaded into a size exclusion column (GE Healthcare, disposable PD-10 desalting columns) pre-equilibrated with 30 mL of 20 mM borate buffer (pH 7.5). The eluent was collected according to the supplier's instructions, and the amount of iron was measured with the Prussian Blue colorimetric assay. As well, 2.5 mL of APS-coated SPIONs (500 μg/mL) dispersed in 20 mM borate buffer (pH 7.5) was loaded into a centrifugal filter (Millipore, Amicon Ultra - 4, Ultracel − 30k). The filter was centrifuged (Jouan, GR2022) at 4000*g* for 20 min. The amount of iron in the recovered sample from the filter was determined by Prussian Blue colorimetric assay.

Phase Transfer of SPIONs in Solid-Phase. A 2 mL amount of APS-coated SPIONs (500 μg/mL) dispersed in 20 mM borate buffer (pH 7.5) was loaded in the reactor. The phase transfer from aqueous phase to organic phase was achieved by applying a solvent gradient. Therefore, ethanol in water (volume fraction 50%) was introduced in the reactor for 10 min (1 mL/min), followed by ethanol (volume fraction 99.8%) for another 10 min with the same flow rate using a HPLC-pump (Waters 515). Then, dry *N*,*N*-dimethylformamide (DMF, VWR Prolabor) was introduced in the reactor for 20 min (1 mL/min). The exchange of DMF solution was controlled via Masslynx software and was run by means of preparative HPLC-MS system (Waters 2695 Alliance).

Size and Zeta Potential Determination. Light-scattering measurements were carried out at 90° on a photon correlation spectrometer (PCS) from Brookhaven equipped with a BI-9000AT digital autocorrelator. The CONTIN method was used for data processing. The concentration of iron oxide nanoparticles was set to 0.025 mg iron/mL for all measurements. The theoretical refractive index of magnetite (2.42) was used to calculate the number-weighted distribution from the raw-intensity weighted data (*17*). Zeta-potential measurements were performed using the same setting, equipped with a platinum electrode. The electrode was cleaned for 10 min in an ultrasonic bath prior to each measurement and pre-equilibrated for 2 min in an aliquot of the sample. For size and zeta-potential the nanoparticles were diluted in a 20 mM borate buffer solution, pH 7.5. Viscosity, refractive index, and dielectric constant of pure water were used to characterize the solvent.

Atomic Emission Spectroscopy. Atomic emission spectroscopy with inductive coupled plasma (PerkinElmer, ICP-Plasma 2000) was used for the analysis of the iron and silica content of the APS-SPION beads.

Transmission Electron Microscopy. Transmission electron microscopy (TEM) was performed using a Phillips CM-20 microscope operating at 200 kV. For sample preparation, dilute drops of suspensions were allowed to dry slowly on carbon-coated copper grids.

Magnetic Measurements. Magnetic field strengths were measured with an M-Test MK IV Maurer Magnetic AG.

REACTOR SET-UP AND RESULTS

Description of the Fixed Bed Reactor. A protocol for the immobilization and enhanced surface modification of SPIONs in a magnetic fixed bed reactor was developed. In order to create a high magnetic field gradient, four magnet assemblies, each consisting of a stack of 5 FeNdB magnets with a resulting surface remanence magnetization of 0.66 T, were placed repulsive to each other. An INOX bloc was used as the support for the magnet arrangement (Figure 1A). The distance between the magnets was controlled by screws leaving space for the insertion of a tube in the core of the reactor. High gradients of several hundred T m^{-1} were generated with this magnetic arrangement (Figure 1B). Within 10 mm of distance from a single stack of five single magnets a gradient of 55 T/m was measured. For 2 stacks of magnets the magnetic field at half distance between them was always zero. The magnetic field gradient increased to 250 T/m for 2 stacks of magnets at a

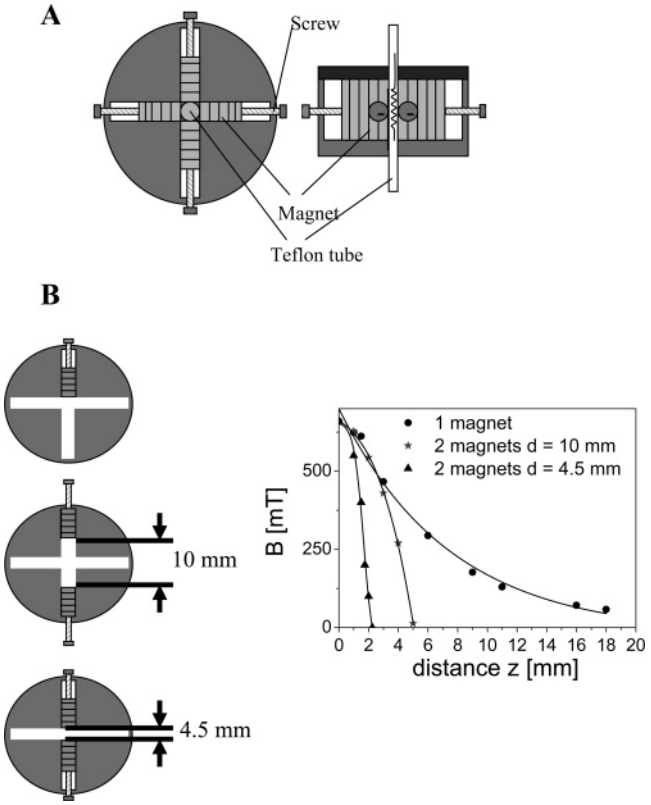

Figure 1. (A) Schematic view of the fixed bed reactor with a quadropole arrangement of magnets. Four stacks of five FeNdB magnets are inserted repulsive to each other into a support and are screwed to small distances. (B) Magnetic field, *B* [mT], as a function of the distance from the magnet using different magnetic assemblies. For simplification, only half of the distance between the magnets (when using two magnets) is shown in Figure B.

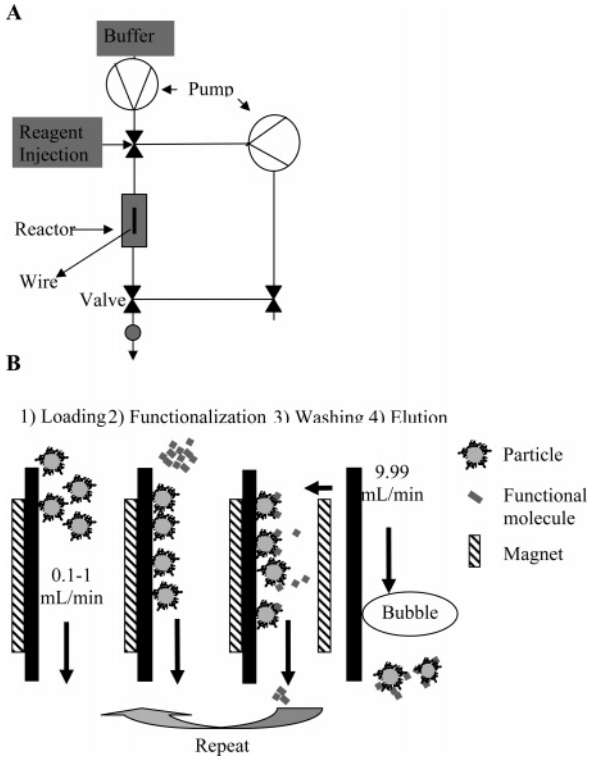

Figure 2. (A) Schematic representation of the fixed bed reactor for nanoparticle modification connected to two pumps. (B) Functionalization scheme for SPIONs in the fixed bed reactor. Particles are loaded at low flow rates onto the surface (1) and are subsequently functionalized by passing the reactive species over the immobilized nanoparticles in the bypass loop at high flow rates (2). Particles can be washed by running the washing buffer through the column (3). After functionalization of the particles, they can be eluted by removing the magnetic field and introducing bubbles at high flow rates (4).

distance of 10 mm (Figure 1B). The gradient was only determined for two stacks of magnets and could not be measured for shorter distances between the magnets and more stacks (three and four stacks of magnets) because of the geometry of the measuring device.

A Teflon tube with 4.5 mm outer and 3 mm inner diameter was inserted into the hole in the middle of the magnet arrangement. The magnets were placed in the vicinity of each other so that the outer diameter of the Teflon tube wall determined the distance between the magnets and hence the magnetic field gradient.

Immobilization experiments with 3-(aminopropyl)triethoxysilane-coated SPIONs (APS-SPIONs) with a mean diameter of 25 ± 2 nm were performed onto the magnetic reactor. The amounts of immobilized APS-SPIONs into the reactor with and without Fe−Ni-alloy magnetic wires were measured by Prussian Blue colorimetric assay. Within the Teflon tube without wire 677 ± 118 μg, with one wire 1285 ± 95 μg, and with two wires 1582 ± 77 μg of Fe was immobilized. When using only one magnet in the fixed bed reactor, 70 ± 11 mg of Fe was immobilized onto the tube without the wire. Therefore, the immobilization efficiency is dependent on the available area and the magnetic field gradient. One way to locally increase the gradient of the magnetic field is to place a ferromagnetic wire in the region of the magnetic field; in fact, the higher the curvature of this wire (i.e., the smaller the diameter), the larger the gradient of the magnetic field and hence the greater the force acting on the SPIONs (*18*), which explains the loading efficiency data with and without the Fe−Ni-alloy coils inserted into the tube.

The fixed bed reactor was connected to two pumps, one of which was solely used for circulating the reagents in a closed circuit over the immobilized sample (Figure 2A). The other pump was used for washing and injecting the sample and reagents.

The flow scheme for a general functionalization of APS-SPIONs is shown (Figure 2B). The SPIONs were either loaded onto the support at flow rates of 0.1−1 mL/min (1.4−14.1 cm/min) or preincubated for several minutes with zero flow for higher immobilization efficiency of the particles. Further functionalization was performed by injecting a functional molecule onto the fixed bed reactor in a closed circuit at a flow rate of 3.5 mL/min (50 cm/min) that allowed for passing the molecule several times over the immobilized particles. In addition, this minimized the diffusion limiting reaction by convection especially for large molecules and highly viscous solution (e.g., proteins, polymers). After reaction with the particles, the unbound molecules were washed away with a washing buffer. For elution of the particles from the fixed bed reactor, the magnet is removed and bubbles are injected at flow rates of 9.99 mL/min (maximal flow rate of pump). Using this procedure the particles can be completely recovered from the magnetic reactor.

Different pumps were used for washing and recirculation of the buffer and reagents. The pump type employed was important with respect to the resistance of the immobilized nanoparticles in the flow. Low pulse HPLC pumps, Knauer K 1001, and an annular gear pump, mzr-S05 from HNP Microsysteme GmbH, showed better performance than an Äkta prime system (Amersham), or different peristaltic pumps which eluted the particles at flow rates of only 0.1 mL/min.

Biofunctionalization of Coated Superparamagnetic Iron Oxide Nanoparticles. The derivatization of the particle surface

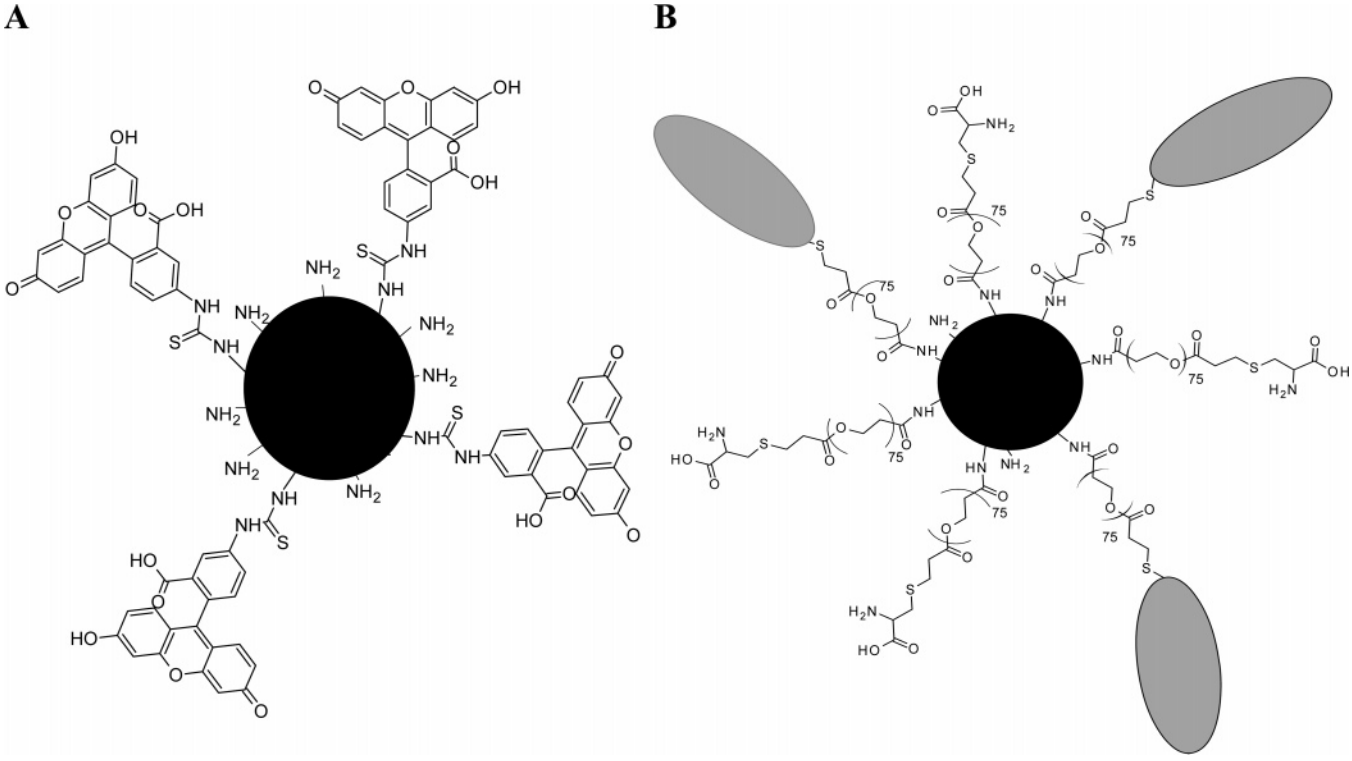

Figure 3. Biofunctionalized particles created by the modification of APS-coated nanoparticles. (A) Modification of APS-SPIONs with fluorescein-isothiocyanate (FITC) and (B) immobilization of an acryl-PEG-NHS polymer followed by the polymer modification with an Alexa Fluor 568 dye labeled nuclear targeting peptide (simplified as gray ovals) were performed. Unreacted acrylate was quenched with cysteine.

Table 1. Summary of Data Obtained for the Functionalization of APS-SPIONs in the Liquid- and Solid-Phase Synthesis

		solid-phase synthesis	liquid-phase synthesis
APS-SPIONs	mean size [nm]	25 ± 2	
	zeta-potential [mV]	33 ± 0.9	
FITC-APS-SPIONs	mean size [nm]	96 ± 15	1047 ± 180
	zeta-potential [mV]	−21.9 ± 0.9	−10.8 ± 0.5
	Fe recovery [%]	98	96
	fluorescence (ratio)	2.5	1
PEG-APS-SPIONs	mean size [nm]	75 ± 13	107 ± 29
	zeta-potential [mV]	−20.7 ± 0.7	−11.07
	Fe recovery [%]	91	61
Alexa Fluor 568-peptide-PEG-APS-SPIONs	mean size [nm]	78.7 ± 0.7	210 ± 109
	zeta-potential [mV]	−11.2 ± 0.48	−15.4 ± 0.28
	Fe recovery [%]	91	62
	fluorescence (ratio)	2.9	1

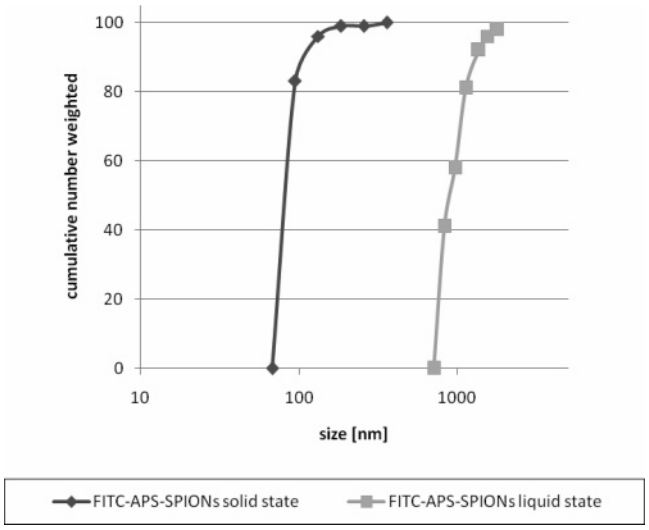

Figure 4. Cumulative number weighted size distribution determined by photon correlation spectroscopy of FITC-functionalized SPIONs as synthesized in solid phase and liquid phase.

was achieved using different compounds and was characterized by means of fluorescence, zeta-potential, and size measurements. These derivatizations included the immobilizations of a small chemically activated molecule, fluorescein-isothiocyanate (FITC), and a heterobifunctional poly(ethylene glycol) followed by peptide conjugation (Figure 3). All experiments were performed in the aforementioned fixed bed reactor in parallel to typical optimized surface chemistry protocols in the liquid phase for a comparison between solid- and liquid-phase synthesis. A summary of the obtained data can be found in Table 1.

FITC was coupled directly to the amino groups of APS-SPIONs. The amount of FITC immobilized during the solid-phase synthesis in the fixed bed reactor was determined to be 466 ng/mg iron, whereas in the liquid-phase synthesis 184 ng/mg of FITC was determined to be on the surface of the APS-SPIONs. Therefore, 2.5 times more dye was immobilized onto the same amount of particles in the fixed bed reactor. The zeta-potential and size of the FITC-APS-SPION surface from the particles produced in both synthesis routes was also determined. The zeta-potential decreased from 33.3 ± 0.9 mV for APS-SPIONs to −21.9 ± 0.9 mV in the solid-phase synthesis and to −10.8 ± 0.5 mV in the liquid-phase. These data corroborate that more FITC can be immobilized onto the APS-SPION surface in the fixed bed reactor. Also, the size of the APS-coated particles and the functionalized APS-SPIONs as obtained after synthesis was determined by photon correlation spectroscopy (PCS). The size of the FITC-APS-SPIONs obtained by the solid-phase synthesis was smaller with a mean diameter of 96 ± 15 nm compared to the agglomerates of 1047 ± 180 nm obtained for particles from the liquid-phase synthesis in 20 mM borate buffer at pH 7.5 (Figure 4).

The synthesis of the PEG-APS-SPIONs (Figure 3B) included the conjugation of the heterobifunctional PEG (*19*) via the N-hydroxysuccinimidyl ester (NHS) with the amino groups on

the surface of the APS-SPIONs. The coating of the APS-SPIONs by PEG can be qualitatively shown by monitoring the zeta-potential of the PEG-APS-SPION composites. Upon pegylation of the surface in the fixed bed reactor the zeta-potential decreased from 33.3 ± 0.9 mV for the APS-SPIONs to −20.7 ± 0.7 mV when recirculating the acryl-PEG-NHS over the immobilized nanoparticles at a flow rate of 3.5 mL/min as the amount of positively charged amino groups decreased on the surface of the APS-SPIONs. Upon coating of the APS-SPIONs with PEG using the liquid-phase method, the positive zeta-potential decreased from 33.3 ± 0.9 mV to −11.2 ± 0.7 mV (Table 1) at pH 7.5. The pegylated surfaces in both cases were therefore negatively charged and the particles were well electrostatically and sterically stabilized for use in biological buffers and cell media (data not shown).

Recirculation of the acryl-PEG-NHS over the immobilized APS-SPIONs resulted in a significantly lower zeta-potential compared to vigorously shaking (1000 min^{-1}) in the liquid-phase reaction. This lower zeta-potential reveals that the surface coupling chemistry was more efficient in the fixed bed reactor compared to the liquid-phase synthesis. Without recirculation, the zeta-potential did not decrease significantly and remained positive at 30.1 ± 0.5 mV, indicating that only small quantities of PEG were bound to the surface of the SPIONs. The acryl-PEG-NHS solution was very viscous, and the data shows that the diffusion of the acryl-PEG-NHS to the surface of the particles is the rate-limiting step for the reaction, as the diffusion time for this relatively large molecule is relatively long.

In addition, upon coating of the APS-SPIONs with PEG, the mean diameter of the nanoparticles increased from 25 ± 2 nm for the APS-coated SPIONs to either 75 ± 13 nm ($n = 6$) in the solid-phase synthesis or to 107 ± 29 nm ($n = 4$) for the PEG-APS-SPIONs as measured after modification in the beaker, respectively.

Given the data from the previous experiments, a sophisticated multistep functionalization of the APS-SPION bead surface was undertaken. This included the peptide modification of the APS-coated SPIONs for the nuclear targeting of cells. The nuclear targeting peptide PKKKRKVGC was coupled onto the surface of the modified SPIONs via the cysteine terminal site. The peptide was labeled with an Alexa Fluor 568 fluorescent probe as previously described for the determination of the immobilization efficiency. This peptide sequence contains the 7-mer functional site PKKKRKV (*20*) derived from the SV40 large T antigen nuclear localization signal that is responsible for nuclear targeting.

The coupling of the Alexa Fluor 568 nuclear targeting peptide was done by the reaction of the cysteine thiol group on the peptide with the acrylate group of the heterobifunctional PEG (acryloylpoly(ethylene glycol)-*N*-hydroxysuccinimide, acryl-PEG-NHS) via Michael addition. The fluorescence of the particles and the supernatant was measured for the quantification of the bound peptide. The functionalization of the PEG-APS-SPIONs with this peptide had no influence on the size of the composite particles as produced in the reactor (78.7 nm), whereas the mean size of the particles produced in the liquid phase increased significantly from 107 to 210 nm. These significantly larger compounds consisted of agglomerates of individual nanoparticles, which could not be redispersed. This is a major result of our study which proves the superior properties of solid-phase compared to liquid-phase derivatized particles. Because of quenching effects of the surface-bound peptide, the fluorescence in the washing solution from the reactor and the supernatant of the liquid-phase synthesis were analyzed. This showed that 99% of the peptide was bound onto the surface of the PEG-APS-SPIONs in the reactor.

The iron recovery rate determined by Prussian Blue assay of the particles was higher when using the fixed bed reactor compared to liquid-phase synthesis. When modifying APS-SPIONs batches equivalent to 500 μg of Fe to peptide-PEG-APS-SPIONs, 91% of the iron could be recovered from the solid-phase synthesis whereas only 62% were recovered from the liquid-phase particle modification route. This high loss of particles is mainly due to incomplete sedimentation of the particles when washing after each modification step. For complete sedimentation of the particles in the liquid-phase reaction, 8 h per washing step in the given PEG solution was required.

This incomplete washing of the particles may also be a reason for obtaining higher sizes for the liquid-phase modified particles, as larger particles with a higher magnetic content tend to sediment faster than smaller particles which are therefore easier lost during the washing steps. Again this result showed that there was less agglomeration of the particles and a better stabilization of the SPIONs upon coating with the heterobifunctional polymer in the fixed bed reactor.

All these results for the functionalization of APS-coated SPIONs showed that immobilization efficiencies of the different molecules to the particle surface were better in the solid-phase synthesis compared to the liquid-phase synthesis. This showed that the mass transport of the small molecules, peptide, and polymer through the immobilized layer of particles is given. Less agglomerated particles after immobilization of the protein were obtained in the magnetic reactor.

Other methods for particle purification such as size exclusion chromatography and centrifugal filtration were tested, too. However, APS-SPIONs could not be recovered from the size exclusion resin (Sephadex G-25) of the PD-10 column. The use of centrifugal filters for purification and concentration of the particles led to very low yields, because 89% of the SPIONs stuck to the filter wall. Therefore, these commonly used methods were not useful as purification and/or concentration methods for these particles after surface derivatization.

In other experiments, this reactor setup proved as well suitable for phase transfer of uncoated SPION particles dissolved in water to organic solvents. Immiscibility problems were overcome by running a gradient of the respective solvents over the column. Particle agglomeration of the eluted SPIONs was not observed. This allows for easy solvent exchange compared to liquid-phase synthesis, where the most rapid option for solvent exchange is the sequential washing the SPIONs by centrifugation of the particles at speeds over 30 000 g for at least 1 h. This new fixed bed technology opens a large processing window for further chemistry on the SPIONs.

DISCUSSION

The fixed bed reactor system for solid-phase surface modification of superparamagnetic nanoparticles displayed various advantages compared to the modification of particles performed using conventional liquid-phase chemistry. Comparing the amount of molecules on the surface of the particles, the main advantage of this reactor is that the surface derivatization of APS-coated SPIONs in the fixed bed reactor was more efficient than the surface modification done in liquid phase. The recovery rate of the injected SPIONs was very high (91−98%) compared to liquid-phase synthesis where a lot of particles are lost because of incomplete settling of the particles during washing.

The modification of particles within the magnetic reactor was less time-consuming because of faster and more efficient purification steps which can be performed by a continuous washing of the product at high flow rates. This was especially observed when modifying the particles with high viscosity polymers such as PEG. This is advantageous for multistep

reactions when high product purity and fast sequential reactions are required.

It was also observed that the polydispersity of the functionalized particles in the reactor was lower compared to surface modifications carried out in the liquid phase. This indicates that particle−particle interactions during the coating process in the solid phase are minimized.

SPIONs and the APS-coated SPIONs used in these experiments have a low colloidal stability in most of the buffers used during a typical chemical modification procedure. Therefore, very low concentrations of particles need to be used to minimize flocculation. In addition, high concentrations of buffer cannot be used (data not shown). Much higher amounts of SPIONs can be functionalized in the magnetic reactor therefore minimizing high costs or difficulties to manufacture reagents (e.g., proteins). With the fixed bed reactor the scale-up of the reaction is easier than in liquid phase. Scale-up can be relatively simple by augmenting the amount of magnetic support or increasing the size of the inserted magnets.

The surface derivatization process of the SPIONs in the fixed bed reactors can be automated, which will allow for functionalization of SPIONs in an efficient way. This also allows for more reproducibility of the functionalization and better quality control of the end product: the production of cell-specific magnetic resonance imaging (*21*) and targeted drug delivery agents (*22*) at a low-cost using an automated production process. These functional SPION materials can then be readily scaled-up using a system that can be operated by nonexpert users.

CONCLUSION AND OUTLOOK

This proof-of-principle fixed bed reactor presented in this paper was satisfactory for carrying out single and multiple step chemistry on immobilized superparamagnetic iron oxide nanoparticles. In addition to the well-known advantages of solid-phase synthesis such as ease of purification, all functionalizations done in this reactor were superior to the liquid-phase synthesis in terms of recovery rate of particles, size distribution, and yield. Next generation reactors will be built totally automated and equipped with online measurement devices for more advanced multistep modifications on the particle surface.

The peptide modifications of the APS-SPIONs showed potential in further experiments for the biological localization of functionalized SPIONs and isolation of cell compartments (personal communication). Yielding sizes of particles smaller 150 nm was therefore important, as these particle systems were efficiently taken up by cells via endocytotic pathways (*23*).

Received May 25, 2007; Revised Manuscript Received July 12, 2007

Pentafluorophenyl esters of 5- and 6-carboxyfluorescein-3′,6′-*O*-dipivalate can be easily separated in multigram quantities by column chromatography. The individual isomers were converted into stable phosphoramidites suitable for oligonucleotide synthesis. The use of the cyclohexylcarbonyl (Chc) protecting group instead of pivaloyl (Piv) facilitates the separation of isomers. The fluorescence spectra of 5- and 6-carboxyfluoresceins on oligonucleotides were compared.

INTRODUCTION

Carboxy derivatives of fluorescein (*1*) are widely used for labeling of biomolecules (*2*), e.g., in DNA biotechnology applications (*3*−*7*). The mixture of 5- and 6-isomers of carboxyfluorescein **1** can be easily obtained by condensation of 1,2,4-benzenetricarboxylic anhydride and resorcinol (*1*, *8*). However, the individual isomers are highly preferred as labels because of physicochemical and spectral homogeneity of labeled species. The separation of 5- and 6-isomers of fluorescein derivatives was reported by fractional crystallization (*9*−*15*) or extensive chromatography (*16*−*18*). The fluorescence of fluorescein is determined by the xanthene moiety, but can be finely modulated by various substituents in the benzene ring (*19*). Thus, it was of interest to compare the spectral properties of individual regioisomers of carboxyfluorescein when attached to an oligonucleotide. Surprisingly, we were unable to find any literature precedent for this.

The pivaloyl group is a convenient protection for fluorescein hydroxyls in phosphoramidite reagents for the synthesis of labeled oligonucleotides (*17*, *20*−*23*). Oligonucleotides containing carboxyfluorescein as an amide derivative (FAM) in the 5′-terminal position are the most useful conjugates applicable as DNA probes or PCR primers (the nonmodified 3′ terminus is suitable for elongation by DNA polymerases). There is no need to introduce multiple FAMs into an oligonucleotide because fluorescein is prone to self-quenching (*8*). Although both 5- and 6-FAM phosphoramidites for 5′-terminal labeling are commercially available (*24*, *25*), they are (a) rather expensive and (b) derived from primary alcohols, thus reducing their stability during storage as acetonitrile solutions in a DNA synthesizer (*26*).

EXPERIMENTAL PROCEDURES

General. Reagents and solvents obtained from commercial suppliers were used without further purification. CH_2Cl_2 was used freshly distilled from CaH_2. HPLC-grade DMF was distilled under reduced pressure and stored over 4 Å molecular sieves under argon. Other solvents were used as received. *N*,*N*-Diisopropylamino-2-cyanoethoxychlorophosphine was prepared as described (*27*, *28*).

500 MHz ^{1}H, 125.7 MHz ^{13}C, and 202.4 MHz ^{31}P NMR spectra were recorded on a Bruker DRX-500 spectrometer and referenced to $CDCl_3$ (7.26 ppm for ^{1}H and 77.1 ppm for ^{13}C), DMSO-d_6 (2.50 ppm for ^{1}H and 39.5 ppm for ^{13}C) (*29*), and 85% aq H_3PO_4 (0.00 ppm for ^{31}P). 564.4 MHz ^{19}F NMR spectra were recorded on a Varian Unity NMR spectrometer and referenced to $PhCF_3$ as the internal standard (−63.72 ppm for ^{19}F). ^{1}H−^{13}C gradient-selected HMQC and HMBC spectra were obtained by using 2048 (t_2) × 256 (t_1) complex point data sets, zero-filled to 2048 (F_2) × 1024 (F_1) points. The spectral widths were 13 and 200 ppm for ^{1}H and ^{13}C dimensions, respectively. HMBC spectra were measured with a 50 ms delay for the evolution of long-range couplings. ^{1}H NMR coupling constants are reported in hertz (Hz) and refer to apparent multiplicities. High-resolution mass spectra (HRMS) were recorded in positive-ion mode using an IonSpec FT ISR mass spectrometer (MALDI) or PE SCIEX QSTAR pulsar mass spectrometer (ESI). Melting points were determined using a Boetius heating table and are uncorrected. Analytical thin-layer chromatography was performed on Kieselgel 60 F_{254} precoated aluminum plates (Merck); spots were visualized under UV light (254 nm). Silica gel column chromatography was performed using Merck Kieselgel 60 0.040−0.063 mm. The oligonucleotide synthesis was carried out on a BiosSet ASM-700 instrument on a 200 nmol scale using standard manufacturer's protocols. Oligonucleotides were isolated using electrophoresis in 20% denaturing (7 M urea) PAGE in Tris−borate buffer, pH 8.3, and desalted by gel filtration on a Sephadex G-25 column in saltless buffer. MALDI-TOF mass spectra of oligonucleotide conjugates were recorded in positive-ion mode on a Bruker Ultraflex spectrometer. UV absorption spectra were recorded using a Varian Cary-500 spectrophotometer in a 0.1 M carbonate buffer pH 8.3−9.5. Fluorescence studies in the same buffer were performed using a large-aperture apparatus described earlier (*30*). The fluorescence quantum yields Φ_f were measured by the relative method using a standard of fluorescein in 0.1 M NaOH ($\Phi_f = 0.95 \pm 0.03$) (*31*). The measurements were performed at an angle of 90° to the exciting light beam. The optical density of the solutions in the 1 cm quartz cell at the excitation wavelength

did not exceed 0.1. The values of Φ_f were corrected with the refractive index of the solvent; the measured refractive indexes of 0.1 M NaOH and carbonate buffer were 1.3335 and 1.3340 at 20 °C, respectively. Fluorescence lifetimes were determined by the method of time-correlated single-photon counting using a PRA 3000 nanosecond lifetime fluorometer. The parameters of the fluorescence decays were analyzed using T900 software (Edinburgh Instruments). The samples used in quantum yield and fluorescence lifetime measurements were not degassed.

Cyclohexanecarboxylic anhydride (*32*) was prepared as follows. A mixture of cyclohexanecarboxylic acid (1 equiv) and $SOCl_2$ (1.5 equiv) was heated for 4 h at 60 °C, then evaporated and distilled under reduced pressure to give cyclohexanecarbonyl chloride (91%, bp 71−73 °C/10 Torr). The chloride (50.7 g, 0.346 mol) was dissolved in benzene (350 mL); pyridine (56 mL, 0.69 mol) and cyclohexanecarboxylic acid (44.9 g, 0.35 mmol) were added subsequently; and the mixture was stirred for 2.5 h at 60 °C, then cooled, filtered, and evaporated. The residue was distilled *in vacuo* to afford Chc_2O as a colorless liquid (68.8 g, 91%, bp 125−135 °C/1 Torr). ^{1}H NMR ($CDCl_3$) δ = 2.38 (tt, 2H, $J_{a,a}$ = 11.2 Hz, $J_{a,e}$ = 3.7 Hz, H-1*a*), 1.94 (m, 4H, H-2*e*,6*e*), 1.76 (m, 4H, H-3*e*,5*e*), 1.63 (m, 2H, H-4*e*), 1.46 (m, 4H, H-2*a*,6*a*), 1.25 (m, 6H, H-3*a*,4*a*,5*a*). ^{13}C NMR ($CDCl_3$) δ = 171.9 (2C, *C*O), 44.0 (2C, C1), 28.4 (4C, C2,6), 25.6 (2C, C4), 25.2 (4C, C3,5).

5(6)-Carboxy-3′,6′-*O*-diacylfluoresceins, Pentafluorophenyl Esters (4a−d); General Procedure. To the magnetically stirred, ice-cooled solution of 5(6)-carboxyfluorescein **1** (20.00 g, 53.2 mmol) in DMF (100 mL) was added dropwise diisopropylethylamine (36.3 mL, 213 mmol) followed by trimethylacetic or cyclohexylcarbonic anhydride (117 mmol). The reaction solution was stirred at room temperature for 72 h, protected from light. The solvent was rotary-evaporated, and residue was dissolved in CH_2Cl_2 (170 mL) and EtOAc (350 mL), washed with 1 M phosphate buffer (3 × 300 mL, pH 7.0), and dried over $MgSO_4$. After evaporation of solvents, the remaining residue was dried in high vacuum overnight. Then, it was dissolved in EtOAc (400 mL), ice-cooled, and pentafluorophenol (11.75 g, 63.9 mmol) in EtOAc (50 mL), followed by dropwise addition of the solution of DCC (13.15 g, 63.8 mmol) in EtOAc (150 mL) within 1 h. After 2 h, the cooling was removed, and the mixture was stirred overnight at room temperature. The precipitate of dicyclohexylurea was filtered off, and the solution was concentrated to dryness. The residue was purified by column chromatography on silica gel eluting with $CHCl_3$; desired fractions were combined and evaporated to dryness. The resultant foam was dissolved in toluene (55 mL), and hexane (400 mL) was added. After crystallization at −20 °C overnight, the precipitate formed was filtered off and dried *in vacuo* to give the mixture of isomers as a white crystalline solid (25.28 g, 67% of **4a** + **4c** or 28.73 g, 71% of **4b** + **4d**). The solids were separated by chromatography on a silica gel column (850 g) with a step gradient of EtOAc in toluene (toluene → 0.1% EtOAc → 1% EtOAc in toluene) as the mobile phase to afford pure individual isomers **4a** (15.57 g, 62%) and **4c** (9.55 g, 38%) or **4b** (17.09 g, 59%) and **4d** (11.40 g, 40%) as white foams.

Amides 5a−d; General Procedure. To a solution of activated ester **4a−d** (5.0 mmol) in CH_2Cl_2 (60 mL), *trans*-4-aminocyclohexanol hydrochloride (0.76 g, 5.0 mmol) and DIEA (1.74 mL, 10.0 mmol) were added. The suspension was diluted with DMF (60 mL) and stirred overnight at room temperature to give a homogeneous solution. The latter was diluted with $CHCl_3$ (200 mL), washed with water (4 × 200 mL), dried over Na_2SO_4, and evaporated to dryness. The residue was purified by chromatography on a silica gel column (100 g) with a step gradient of MeOH (0 → 5%) in toluene as the mobile phase to give amides **5a−d** as white amorphous foams.

Phosphoramidites 6a−d; General Procedure. Amide **5a−d** (4.0 mmol) was evaporated with dry CH_2Cl_2 (2 × 50 mL), dissolved in dry CH_2Cl_2 (50 mL) and DIEA (4.4 mmol, 0.765 mL), followed by addition of *N*,*N*-diisopropylamino-2-cyanoethoxychlorophosphine (1.04 g, 4.4 mmol), and the mixture was stirred under argon for 1 h. After conversion of the starting compound was complete (monitoring by TLC, Me_2CO−toluene 3:7 + 1% pyridine v/v/v), the mixture was washed with 5% $NaHCO_3$ (50 mL) and sat NaCl (60 mL). The organic layer was dried over Na_2SO_4 during 1 h, evaporated to dryness, and the residue was purified by chromatography on a silica gel column (100 g) with 5% acetone in toluene + 1% pyridine (v/v/v) as the mobile phase. Fractions containing product were combined and evaporated. The resulting phosphoramidite was dissolved in dry toluene (25 mL) and precipitated into hexane (350 mL). The obtained compound was filtered, dissolved in CH_2Cl_2, and evaporated to dryness to afford compounds **6a−d** as white amorphous solids.

RESULTS AND DISCUSSION

Our aim was to prepare stable and inexpensive 5- and 6-FAM phosphoramidites and to study the fluorescence of the regioisomers on an oligonucleotide. The synthesis of phosphoramidite reagents is given in Scheme 1. First, we found that 5(6)-carboxyfluorescein-3′,6′-*O*-dipivalate **2** (*17*) can be converted into pentafluorophenyl (Pfp) ester (similar as described for isobutyryl derivatives (*8*)) and the resulting mixture (**4a** + **4c**) is easily resolved by column chromatography on silica gel in

[a] $\lambda^{abs}_{max}$and λ^{fl}_{max} − absorbance and fluorescence wavelength maxima; $\Delta\nu^{fl}_{1/2h}$− half-width of the emission spectrum. [b] Φ_f − fluorescence quantum yield; τ_f − average fluorescence lifetime; $k_f = \Phi_f/\tau_f$ − emission rate constant. [c] Error limits are ±40 cm^{-1} (**7a**) and ±30 cm^{-1} (**7b**).

toluene in multigram quantities. Then, we examined the cyclohexylcarbonyl (Chc) as a protecting group for fluorescein. It was found that 3′,6′-*O*-diacylation of 5(6)-carboxyfluorescein with Chc_2O proceeds smoothly and gives similar yields (71% for two-step one-pot procedure **1** → **3** → (**4b** + **4d**) compared to 67% for **1** → **2** → (**4a** + **4c**)). However, the more pronounced difference in chromatographic mobility between **4b** and **4d** (ΔR_f 0.09) in toluene makes their separation easier than Piv derivatives **4a** and **4c** (ΔR_f 0.07). The small difference in mobility ($\Delta\Delta R_f$ 0.02) can be felt strongly while separating decigram quantities of these isomer derivatives.

The structures of compounds **4a**−**d** were assigned using 2D $^1H-^{13}C$ HMQC and HMBC NMR spectra.

trans-4-Aminocyclohexanol was reported as an achiral precursor for phosphoramidites which are more stable in acetonitrile solution than phosphoramidites derived from primary alcohols (*26*). The individual regioisomers of pentafluorophenyl esters **4a**−**d** were reacted with *trans*-4-aminocyclohexanol to give amides **5a**−**d** in high yields. The following phosphitylation with *N*,*N*-diisopropylamino-2-cyanoethoxychlorophosphine furnishes the desired phosphoramidites **6a**−**d** (Scheme 1).

Reagents **6a**−**d** were used in the last coupling step of machine-assisted solid-phase DNA synthesis for the preparation of 5′-labeled 23-mer 5′-**X**CACTTTGTATATTGGTTGAAACT-3′. The conjugates prepared were cleaved from their supports, deprotected by conc aq ammonia treatment at 55 °C overnight, analyzed by reversed-phase HPLC and MALDI-TOF MS, and purified by PAGE for fluorescence studies. Reagents **6a** and **6b** gave conjugate 5′-(5-FAM)-CACTTTGTATATTGGTTGAAACT-3′ (**7a**) (Chart 1); the products from two syntheses were identical by HPLC and MALDI-TOF MS and showed the same electrophoretic mobilities. There was no substantial difference in the amounts of isolated products. In a similar manner, the use of reagents **6c** or **6d** gave one labeled oligonucleotide−5′-(6-FAM)-CACTTTGTATATTGGTTGAAACT-3′ (**7b**). Conjugates **7a** and **7b** were characterized by UV−vis and fluorescence spectra (Figure 1, Table 1).

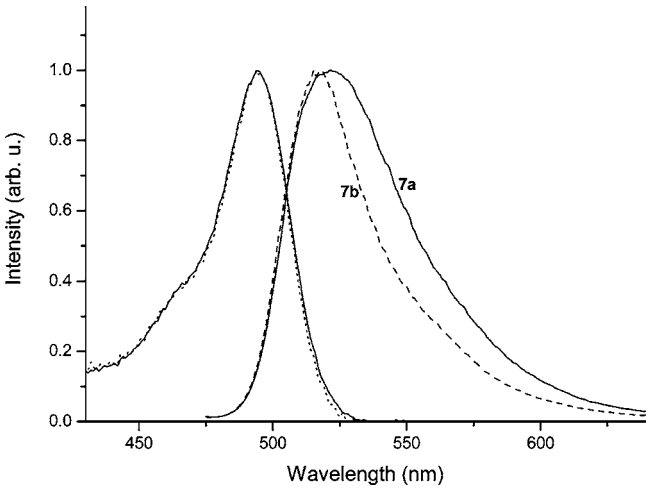

Figure 1. Normalized absorption (left) and fluorescence (right) spectra of labeled oligonucleotides **7a** (straight lines) and **7b** (doted and dashed lines) in sodium carbonate buffer, pH 8.35, excitation at λ = 470 nm.

There is no difference between UV−vis absorbances of 5- and 6-FAM attached to an oligonucleotide (Figure 1). The study of fluorescent properties of 5- and 6-FAM isomers in the usual pH range for fluorescein (8.35−9.5) showed that the differences in their photophysical characteristics depending on the pH are within error limits. In contrast, spectroscopic characteristics of 5- and 6-FAM are not essentially similar: 5-isomer displays a 3−5 nm red shift of the fluorescence maximum against 6-isomer (Figure 1, Table 1). The emission band in the spectrum of 5-FAM is substantially broader.

The obvious consequences from the presented data for 5- and 6-FAM are that these dyes in aqueous solutions within the pH range 8.35−9.5 have similar absorbance and fluorescence quantum yields, and, therefore, similar fluorescence brightness.

However, in the case of multiplex detection of several fluorochromes, the sharper emission band of 6-FAM could be an advantage.

To conclude, we have shown that 5- and 6-carboxyfluoresceins can be easily separated as Pfp esters of 3′,6′-*O*-diacyl derivatives, and Chc is the acyl protecting group of choice for this procedure; inexpensive phosphoramidite reagents can be easily prepared from the above esters in two steps; spectroscopic and photophysical data for 5- and 6-FAM on oligonucleotide were collected and compared.

ACKNOWLEDGMENT

We thank Marina Zhilinskaya and Youri Habrus for the oligonucleotides synthesis, BFBR (project B06R-004) and RFBR (projects 06-04-81019 and 06-03-32426) for the financial support; Z. Shenkarev, K. Nadezhdin, A. Paramonov, and Shemyakin-Ovchinnikov Institute NMR Spectrometry Facility (registry no. 98-03-08) for NMR spectra. We are also grateful to A.P. Stupak and V.N. Knyukshto for help in fluorescence measurements.

The majority of clinically used contrast agents (CAs) for magnetic resonance imaging have low relaxivities and thus require high concentrations for signal enhancement. Research has turned to multivalent, macromolecular CAs to increase CA efficiency. However, previously developed macromolecular CAs do not provide high relaxivities, have limited biocompatibility, and/or do not have a structure that is readily modifiable to tailor to particular applications. We report a new family of multivalent, biomacromolecular, genetically engineered protein polymer-based CAs; the protein backbone contains evenly spaced lysines that are derivatized with gadolinium (Gd(III)) chelators. The protein's length and repeating amino acid sequence are genetically specified. We reproducibly obtained conjugates with an average of 8–9 Gd(III) chelators per protein. These multivalent CAs reproducibly provide a high relaxivity of 7.3 mM^{-1} s^{-1} per Gd(III) and 62.6 mM^{-1} s^{-1} per molecule. Furthermore, they can be incorporated into biomaterial hydrogels via chemical cross-linking of the remaining free lysines, and provide a dramatic contrast enhancement. Thus, these protein polymer CAs could be a useful tool for following the evolution of tissue engineering scaffolds.

One significant barrier to the development of new generations of biocompatible materials, particularly tissue engineering hydrogels, is the inability to noninvasively evaluate the properties and performance of the biomaterial over time (*1–6*). Magnetic resonance imaging (MRI) is capable of whole animal or human imaging at high spatial and temporal resolution and is an ideal modality for evaluating tissue engineering scaffolds *in vivo* (*7–11*). Exogenous contrast agents (CAs) increase the relaxation rate ($1/T_1$) of water protons and therefore improve image contrast. However, current clinically used CAs have low relaxivities (3–7 mM^{-1} s^{-1}) (*12*) and thus must be used at high concentrations for useful MRI signal enhancement (*12*).

T_1 CAs provide positive contrast by employing a paramagnetic ion (typically gadolinium, Gd(III)). The efficacy of a contrast agent is dominated by three parameters: q, the number of coordinated water molecules; τ_m, the residence lifetime; and τ_R, the rotational correlation time (*13*). Current clinically used small-molecule CAs are limited by their fast τ_R. More recently, these small-molecule CAs have been attached via covalent or noncovalent interactions to a number of macromolecules, including albumin (*14*), carbohydrates (*15*), linear polymers such

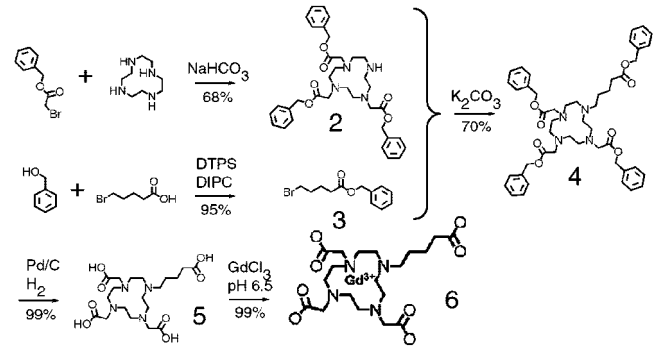
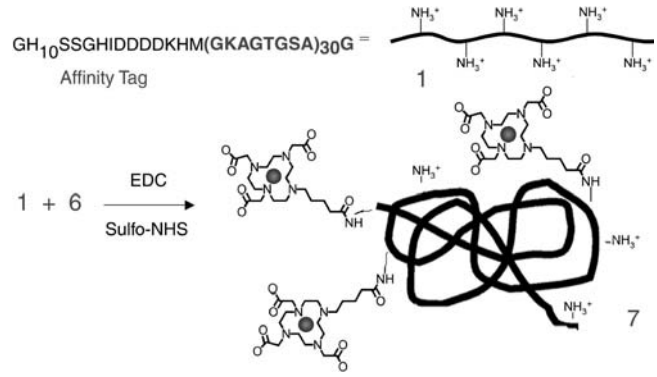
as polylysine (*16*), dendrimers (*17*), viral capsids (*18*), and liposomes (*19*). These multivalent CA designs are advantageous because they increase τ_R, Gd(III) concentration, and CA retention *in vivo*. Previously, researchers have tracked tissue engineering scaffolds *in vivo* by MRI without using any exogenous CAs (*20, 21*) or using soluble small-molecule CAs with a single Gd(III) chelator (*22, 23*). Recently, Bull et al. synthesized a self-assembled peptide amphiphile (PA)-based biomaterial scaffold, in which an MRI CA was incorporated, creating the first biomaterial designed for subsequent MRI-based *in vivo* fate mapping (*11*).



Here, we report the design, synthesis, and characterization of a novel family of multivalent, macromolecular CAs based on genetically engineered proteins with repetitive sequences that form the backbone for subsequent chemical modification with Gd(III) chelators. These "protein polymer" CAs have high relaxivities in aqueous solution. Moreover, they provide a dramatic contrast enhancement when covalently cross-linked into protein-based hydrogels. The artificial protein polymers were generated by controlled cloning and recombinant protein expression in *E. coli* and were designed to satisfy the specific criteria of water solubility, controlled reactivity, and ability to be cross-linked into hydrogels that could be useful for tissue engineering applications. In contrast to other biocompatible polymers such as dextran and other chemically synthesized and/or modified polymers, we can control the precise monomer composition, sequence, and chain length of these protein scaffolds. Affinity chromatography affords pure, monodisperse biopolymers with evenly spaced, primary amine reactive sites, which serve as an ideal scaffold for CA modification.

The protein polymer backbone we used comprises 30 repeats of the amino acid sequence G**K**AGTGSA, providing 30 reactive primary amines (ϵ-amino groups of lysines) that are available for derivatization (*24*). The 21 825 Da protein polymer (molar mass confirmed by MALDI; see Supporting Information (SI)) is water-soluble and can be produced in high yield. Circular dichroism spectroscopy shows that the protein adopts a random-coil (unfolded) configuration in aqueous solution (see SI) (*25*), thereby avoiding particular secondary structures that could potentially lead to decreased τ_R (such as a cylindrical α-helix). The macrocyclic chelate that coordinates the Gd(III) ion is a chemically synthesized derivative of 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) (*26*). The three acetate arms chelate the Gd(III), while the carboxylate group on the 5-carbon arm is used for covalent attachment to the primary amine of the lysine residues via amide bond formation.

A multistep controlled cloning method was used to create the 720 base pair gene that encodes the protein polymer (*25*), and standard transformation and expression protocols were used to produce the 264 amino acid–protein polymer, **1** (see SI) (*27*). The pET19b expression vector into which the gene was ligated contains an N-terminal histidine fusion tag, GH_{10}SSGHIDDDDKHM, enabling protein purification via Ni-NTA affinity chromatography under denaturing conditions (*27*). In a typical expression, up to ~60 mg/L of culture medium are obtained after purification. Further details are given in the SI.



The Gd(III) chelator was synthesized using a hydrogenation-labile protection scheme with benzyl 2-bromoacetate and benzyl 5-bromopentanoate as the chelating arms of the macrocycle (Scheme 1). The addition of three benzyl 2-bromoacetate arms to cyclen was followed by the addition of benzyl 5-bromopentanoate. Global deprotection by hydrogenation of the chelator and subsequent metalation with $GdCl_3$ afforded **6,** which subsequently was conjugated to the protein polymer. The synthesis and characterization of the chelator is described in the SI.

Scheme 1. Synthesis of Gd(III) Chelator Using a Hydrogenation-Labile Global Deprotection Scheme [a]

[a] Gd(III) was chelated before conjugation to the protein to ensure that all chelators contained Gd(III).

Scheme 2. Conjugation of Gd(III) Chelator to Protein Polymer Backbone through Amide Bond Formation Using EDC and Sulfo-NHS, where ~8–9 Chelators Per Protein Molecule Are Available for Conjugation

The coupling reaction between the lysine residues of **1** and **6** was carried out in aqueous 0.1 M 4-morpholineethanesulfonic acid (MES), 0.5 M NaCl buffer with 1-ethyl-3-carbodiimide hydrochloride (EDC), and *N*-hydroxysulfosuccinimide (sulfo-NHS), which are water-soluble peptide bond-forming agents (Scheme 2) (*28*). We chose to conjugate premetallated chelators to the protein polymer in order to simplify the synthetic process, avoid solubility issues, and guarantee that each chelator contains a Gd(III) ion. MALDI-MS analysis of the conjugate confirmed that an average of ~8–9 out of a possible 31 lysines per molecule are typically derivatized using this procedure ($n = 4$), but we have achieved up to 15 Gd(III)-conjugated sites per protein molecule in some cases. The conjugation efficiency of this reaction is limited by a competing hydrolysis reaction involving water molecules. The derivatization with Gd(III) chelators introduces a small degree of polydispersity, since the positions of the chelators along the backbone are different in each individual CA, but these CAs can still be well-characterized by MALDI due to the monodispersity of the protein polymer backbone. As determined through relaxivity and inductively coupled plasma (ICP)-MS measurements, the CAs display relaxivities of 7.3 ± 0.4 mM^{-1} s^{-1} per Gd(III) ion ($n = 4$) and 62.6 ± 3.5 mM^{-1} s^{-1} per protein molecule complex, which is the product of the number of Gd(III) chelators per protein backbone times the relaxivity per Gd(III). Synthetic polymers such as dendrimers and metallofullerenes display molecular relaxivities of ~35 mM^{-1} s^{-1} (*29*) and ~60 mM^{-1} s^{-1} (*30*), respectively. There are a few examples of natural protein-based CAs that display greater molecular relaxivities (cowpea chlorotic mottle virus, ~200–400 mM^{-1} s^{-1} per viral conjugate (*31*), apoferritin, ~800 mM^{-1} s^{-1} per protein complex (*32*), MS2

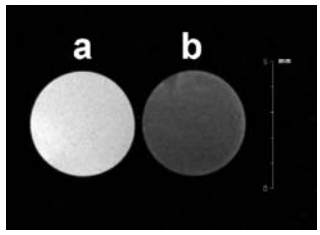


Figure 1. MR images acquired at 14.1 T with TR 250.0 ms, TE 10.2 ms. (a) Glutaraldehyde-cross-linked hydrogel doped with **7** with an added Gd(III) concentration of 0.8 mmol. (b) Control hydrogel without contrast agent.

viral capsid, ~7200 mM^{-1} s^{-1} (*18*)). Even though some of these CAs have shown higher relaxivities per molecule, our new protein polymer CAs avoid some disadvantages associated with these other CAs. As compared with synthetic polymers, protein polymers consist of amino acids, so they are biodegradable and should not have any toxic byproducts (chelated Gd(III) is nontoxic). The above-mentioned natural protein CAs are less easily tunable and modifiable, so the relaxivity, size of the CAs, toxicity, *in vivo* circulation time, and mode of excretion cannot be as easily modulated. On the other hand, protein polymers can be precisely designed for the particular application and point of use; they can be customized to vary protein lengths and the spacing and number of lysines for conjugation to Gd(III) chelators. Additionally, these protein polymer CAs can be derivatized with other biological moieties for additional functionality, such as targeting and intracellular translocation.

To demonstrate one useful application of these new protein polymer-based CAs, tracking the evolution of tissue engineering hydrogels over time, we prepared 5.8% (w/v) protein-based hydrogels in aqueous solution in 5 mm NMR tubes for MR imaging experiments. The protein–CA conjugate, **7**, was doped into a solution of unconjugated protein polymer, **1**, and the free amines were cross-linked with 45 μL of 25% glutaraldehyde to form a gel (see SI). One advantage of these protein polymer-based CAs is that at least 50% of the primary amines on the backbone remain underivatized and are available for covalent cross-linking to form the hydrogel, as well as assisting in water solubility. Thus, once cross-linked to other proteins within a hydrogel, the multivalent CAs can only be removed from the hydrogel as a result of hydrolysis of the scaffold and not as a result of diffusion. The MR images show that the hydrogel incorporating **7** is homogenous and exhibits dramatically higher MRI contrast than the hydrogel formed from a protein polymer control (Figure 1).

In conclusion, a combination of biosynthetic and chemical methods has been used to create high-contrast, multivalent, protein polymer-based MRI CAs. We have demonstrated a reliable synthetic protocol that allows conjugates to be characterized by MALDI and provides reproducible relaxivity results, both per molecule and per Gd(III). As shown in MR images, this protein polymer-based CA can be incorporated into a hydrogel and yields dramatic contrast enhancement, which could be a useful tool for following the evolution of tissue engineering scaffolds *in vivo*. We plan to employ other cross-linking mechanisms and hydrogel media to create a family of biocompatible tissue engineering scaffolds that can be fate-mapped *in vivo* by MRI, enabling tracking of both the cellular ingrowth and the scaffold degradation over time.

Protease-Sensitive Fluorescent Nanofibers

Benedict Law,[†] Ralph Weissleder, and Ching-Hsuan Tung*

Center for Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, Charlestown, Massachusetts 02129. Received February 16, 2007; Revised Manuscript Received September 17, 2007

We report the design and synthesis of enzyme-responsive nanofibers. The fibers are composed of self-assembled hydrophobic β-sheet peptides incorporating protease-sensitive domains, fluorescent reporters, and hydrophilic poly(ethylene glycol) (PEG) units. Using urokinase plasminogen activator (uPA) as a model system, nanofibers were developed to release fluorescent fragments upon uPA incubation. These protease-sensitive nanofibers may have considerable biomedical applications as diagnostic sensors or for protease-assisted drug deliveries.

INTRODUCTION

A variety of nanomaterials have shown promise in biomedical applications (*1*–*3*). Over the past few years, several synthetic materials have emerged from biological systems and have been developed as sensors or for drug delivery. Self-assembly peptides can provide a high degree of flexibility and smartness when constructed into bioresponsive materials (*4*). For instance, self-complementary nanofibers have been proposed as scaffolds for tissue engineering, drug delivery, and imaging agent development (*5*, *6*). These fibers are typically assembled from simple building blocks driven by noncovalent interactions. Peptide nanofibers have been designed, by using the biotin-sandwich approach, to provide specific and prolonged local myocardial delivery of survival factor, ICF-1 in cell-based therapies (*7*). Another study designed heparin-tagged nanofibers as sustained release system for grow factors such as FGF-2 or VEGF to promote angiogenesis (*8*). Importantly, these assemblies are often quite stable and homogenous in biological conditions.

One of the approaches to fine-tune bioresponsiveness is to incorporate environmentally sensitive chemical moieties into nanomaterials. For example, we have previously demonstrated that protease-responsive matrices composed of multiple peptide substrates (kldlkl-SGRSANA-dlkldlkl-NH_2, lowercase letters indicated D-amino acid, and upper-case letters indicated L-amino acid) could be synthesized (*9*). Here, the self-assembly nature of β-sheets was adapted to develop highly stable nanofibers. The core sequences were designed to incorporate the following (Figure 1): (1) a hydrophobic β-sheet segment, $[kldl]_3$ (*10*), which consisted of D-amino acids to avoid nonspecific proteolytic digestion at the C-terminus, (2) an α-methyl-substituted poly(ethylene glycol) (mPEG) hydrophilic polymer attached at the N-terminus to prevent potential aggregation, (3) a specific peptide substrate (SGRSANA) positioned in the middle of the hydrophobic and hydrophilic segments that has been employed previously for in vivo protease imaging (*11, 12*). The substrate is highly degradable by uPA (*13*), an enzyme known to have distinct roles in tumor growth, invasion, migration, and angiogenesis by facilitating the breakdown of extracellular matrix (ECM)[1] through proteolytic cascades (*14*–*16*), and finally (4) a conjugated fluorescein derivative, 5(6)-fluorescein isothiocyanate (FITC), as an optical reporter.

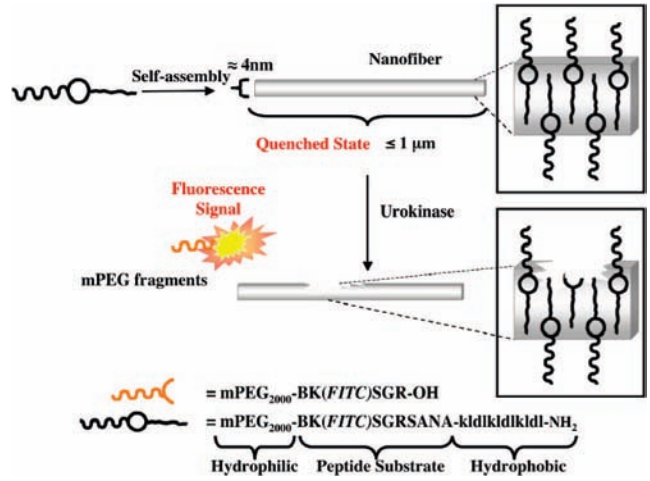

Figure 1. Design of uPA sensitive nanofibers. The fibers are composed of multiple PEG2000–peptide conjugates ($mPEG_{2000}$-BK(*FITC*)SGR-SANA-$[kldl]_3$-NH_2, where B = β-alanine). Each conjugate consists of a uPA peptide substrate (SGRSANA, L-amino acid) inserted in between the hydrophilic ($mPEG_{2000}$) and hydrophobic ($[kldl]_3$, D-amino acid) fractions. In addition, a fluorescein isothiocyanate (FITC) is introduced onto individual peptides as the optical reporter. In 10 mM of PBS buffer (pH 7.4), the mPEG2000–peptide conjugates self-assemble spontaneously to form filaments with organized structures, so that the fluorophores are arranged in close proximity and result in fluorescence quenching. Upon addition of uPA, the substrate site is cleaved, leading to release of the fluorescent hydrophilic fragments ($mPEG_{2000}$-BK(*FITC*)SGR) and resulting in fluorescence recovery.

EXPERIMENTAL PROCEDURES

Chemicals. All solvents were purchased from Fisher Scientific (Fair Lawn, NJ). All D- and L-amino acids were supplied by Novabiochem (San Diego, CA). α-Methyl-substituted poly-

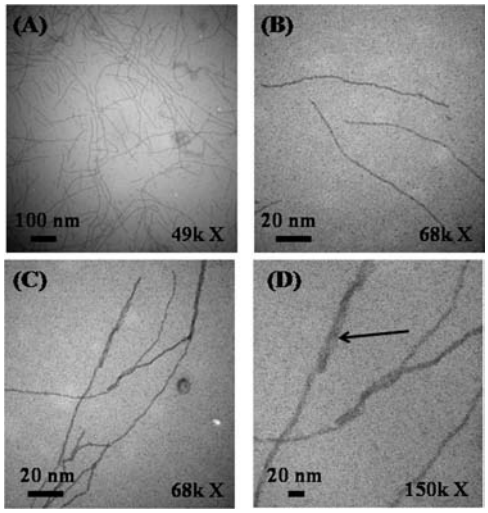

Figure 2. TEM images of protease-sensitive nanofibers. Images of fibers are shown at different magnifications (A,B). All samples were negatively stained with uranyl formate to provide contrast. Some fibers self-assemble to form supercoil networks (black arrow, C,D).

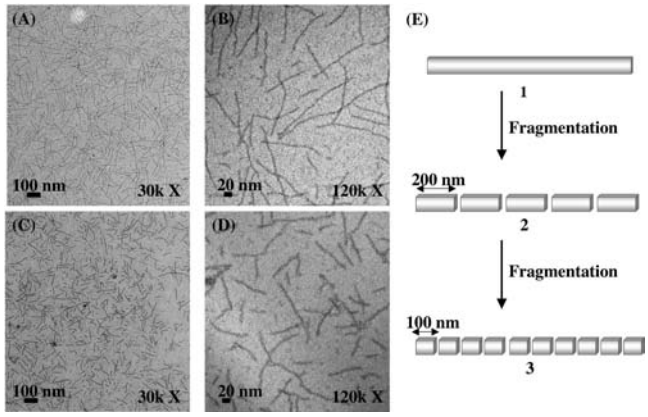

Figure 3. Size control of nanfibers. TEM images of 200 nm nanofiber **2** (A,B) and 100 nm nanofiber **3** (C,D). All samples were negatively stained with uranyl formate to provide contrast. (E) Schematic presentation indicates the synthesis of nanofiber **3**.

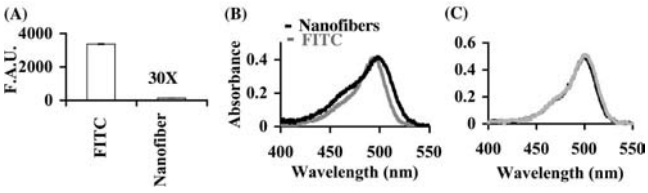

Figure 4. Optical properties of 100 nm nanofiber **3**. (A) Relative fluorescence intensities of FITC and fibers in PBS buffer (10 μM). The nanofiber was 30× less fluorescent than free FITC. The absorption spectra of FITC and nanofiber **3** in (B) PBS buffer and (C) methanol. The spectra were normalized at 494 nm.

(ethylene glycol) *N*-hydroxysuccinimide ester ($mPEG_{2000}$-NHS ester) was purchased from Nektar Therapeutics (San Carlos, CA). Amiloride, anisole, ethandithiol, 5(6)-fluorescein isothiocyanate (FITC), thioanisole, urokinase (EC: 3.4.21.73), and all other chemicals were obtained from Sigma-Aldrich (St. Louis, MO).

Peptide Synthesis. Peptide synthesis was performed on an automated solid-phase peptide synthesizer (ABI-433A, Applied Biosystems, Foster City, CA) employing the traditional Nα-Fmoc methodology on Rink amide resin (280 mg, 0.1 mmol). Side-chain protections were Arg(Pbf), Asn(Trt), Lys(Boc), and Ser(tBu). Lys(ivDde) was used for selective deprotection on solid phase prior to FITC conjugation. All amino acids (10 equiv) were attached to the resin by stepwise elongation using 2(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU)/*N*-hydroxybenzotriazole (HOBt)/*N*,*N*-diisopropylethylamine (DIEPA) as the coupling reagent in *N*-methylpyrrolidone (NMP). mPEG-NHS (avg MW = 2470, 500 mg, 0.2 mmol) in DMSO (4 mL) was coupled to the peptide resin (140 mg, 0.05 mmol), initiated with the addition of DIEPA (1 mL), and subjected to further gentle shaking for 3 h at room temperature. The resulting resin was washed three times with 2% (v/v) hydrazine monohydrate in DMF (10 mL) for 5 min to selectively remove ivDde (4,4-dimethyl-2,6-dioxocyclohexylidene)-3-methylbutyl) side-chain amino protecting group. FITC (151 mg, 0.4 mmol) and DIEPA (1 mL) were dissolved in DMSO (4 mL). The solution was then added to the resin and further shaken for 3 h at room temperature. After drying with methanol, the peptide was cleaved from the resin with addition of a cleavage cocktail containing TFA/thioanisole/ethandithiol/anisole 90/5/3/2 (5 mL) for 3 h at room temperature. The filtrate was collected and precipitated into methyl-*tert*-butyl ether at 4 °C. Crude mPEG–peptide conjugates were purified by high-performance liquid chromatography (HPLC) (Ranin, Worburn, MA). MALDI-TOF mass spectrometry (Tufts Medical School, Core Facility, Boston, MA) confirmed the average mass ions for all synthetic conjugates. The concentrations of all peptides were determined by UV absorbance for their attached FITC moieties ($\varepsilon = 65 \times 10^{-3}$ M^{-1} cm^{-1} at 490 nm) in methanol.

Synthesis of Nanofibers 1, 2, and 3. The peptide ($mPEG_{2000}$−BK(*FITC*)SGRSANA-[kldl]$_3$, 20 mg) or the control sequence ($mPEG_{2000}$−BK(*FITC*)SGASNRA-[kldl]$_3$, 20 mg) was dissolved in 50% (v/v) acetonitrile in water (5 mL). The solution mixtures were stirred vigorously overnight inside a fume hood to evaporate the solvent. The resulting fibers **1** were then purified by size-exclusion chromatography (P-10 Biogel, Bio-Rad, Hercules, CA). Concentrations were determined by UV absorbance for their attached FITC moieties in methanol. To control the lengths of the preparations, the nanofiber solutions were passed through a mini-extruder (Avanti Polar Lipids Ltd., Alabaster, AL) using polycarbonate membranes (Whatman, Florham Park, NJ) with 0.4 μm and 0.2 μm pore sizes for the synthesis of 200 nm **2** and 100 nm **3** fibers, respectively. After 10 passages, the solutions were collected and further purified by size-exclusion chromatography to remove the smaller fragments. The amounts were determined by UV absorbance for their attached FITC concentrations in methanol.

Transmission Electron Microscopy. All images were recorded by transmission electron microscopy (Tecnai G^2 Spirit BioTWIN, Hillsboro, OR) equipped with an AMT 2k CCD camera at Harvard Medical School (Department of Cell Biology, Boston, MA). All samples were negatively stained with uranyl formate (*17*). Briefly, the samples were diluted with water and absorbed onto the formvar/carbon coated grids. Excess samples were blotted off on a filter paper. The grids were then floated on small drops (5 μL) of uranyl formate solutions 2% (v/v) for a few minutes and then blotted off. The samples were dried and examined in the TEM.

Enzyme Digestion Study by Fluorescence Imaging. Fluorescence imaging was performed by a reflectance fluorescence imaging system that has been described previously. Band-pass filters (Omega Optical, Brattleboro, VT) were employed to adjust the corresponding excitation wave bands for FITC. Stock nanofibers **3** (400 μM) in PBS buffer (10 mM, pH 7.4, 50 μL) or control fibers (400 μM) containing a scrambled uPA substrate sequence (SGASNRA) in PBS buffer (10 mM, pH 7.4, 50 μL) were loaded onto individual wells of a clear-bottom 96-well

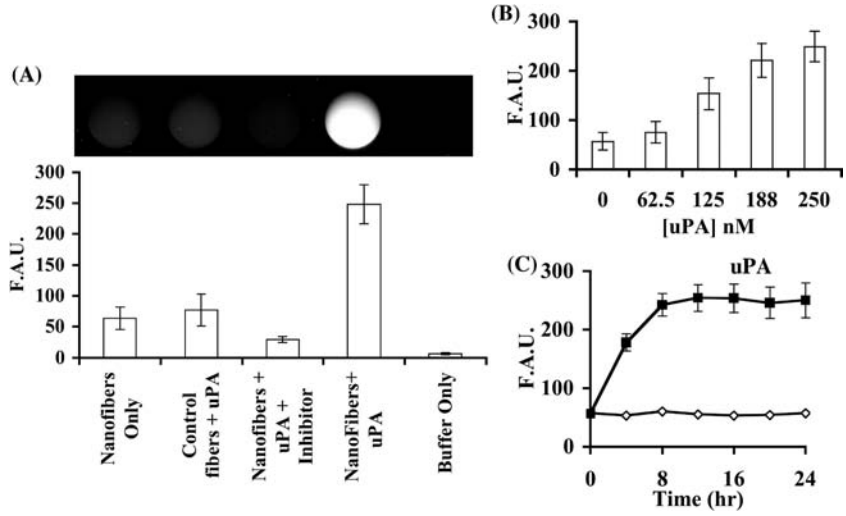

Figure 5. Enzyme responsiveness. (A) Activation of 100 nm nanofiber **3** (100 μM) in different conditions at 24 h after incubation with uPA (250 nM) in 10 mM of PBS buffer (pH 7.4) at room temperature. No enzyme was added in the negative control. Nanofibers containing a scrambled uPA substrate sequence (SGASNRA) were synthesized as control fibers. Amiloride (1 mM) was used as the inhibitor to coincubate with enzyme. The concentrations of nanofibers or the controls were 100 μM. All samples were imaged in a 96-well plate by a reflectance imaging system. Individual wells were chosen as the region of interest (R.O.I.). (B) Fluorescence intensities of nanofibers (100 μM) at 24 h after incubation with various uPA concentrations (0–250 nM). (C) Fluorescence intensities plotted against time (hr) following activation of nanofiber **3** (100 μM) with (■) or without uPA (250 nM) (◇).

plate (Corning, Corning, NY). PBS (10 mM, pH 7.4, 50 μL) or amiloride (4 mM) dissolved in PBS (10 mM, pH 7.4, 50 μL) was added to the corresponding wells. After 24 h incubation at room temperature, the plates were imaged with the exposure time of 10 min per image for four images. The entire wells were chosen as the region of interest (R.O.I.), and the relative fluorescence intensities were further analyzed by using computer software (Kodak Digital Science 1D software, Rochester, NY). To investigate whether the fluorescence activation of **3** was uPA-dependent, stock nanofibers **3** (400 μM) in PBS buffer (10 mM, pH 7.4, 50 μL) were loaded onto the wells of a clear-bottom 96-well plate. Different concentrations of urokinase (from 0 to 250 nM, 0–9.45 units, 150 μL) were then added to the corresponding wells. After 24 h incubation at room temperature, the plates were imaged as described above. For kinetic experiments, the enzyme-treated and -untreated samples were imaged every 4 h over a period of 24 h.

RESULTS AND DISCUSSION

The complete peptide–polymer conjugate ($mPEG_{2000}$−BK-(*FITC*)SGRSANA-$[kldl]_3$) was synthesized in solid phase employing the standard Fmoc chemistry on Rink amide resins. Following peptide synthesis, mPEG-NHS with average molecular weight of 2470 Da was attached at the N-terminus. To introduce the fluorescein reporter group, Lys(ivDde) was employed as the amino acid building block. The protecting group, ivDde, was selectively removed by hydrazine prior to fluorophore conjugation. The cleaved peptides were purified by HPLC, and the average molecular mass ($[M + H]^+ = 4755$) was confirmed by MALDI-TOF.

The morphology of any designed assemblies can be influenced by modifying hydrophobic/hydrophilic ratios (*18*). The employed hydrophobic β-sheet segment ($[kldl]_3$) (*10*) and several similar ionic self-complementary peptides are known to form amyloid-type fibers (*19, 20*). Nanofibers were assembled by dissolving pegylated peptides in a mixture of acetonitrile and water, followed by solvent evaporation. Nanofibers assembled spontaneously into unique structures of homogenous width and length (Figure 2A and B). The widths of fiber **1** observed by TEM were extremely narrow (approx. 4 nm). In contradiction to previous reports (*19, 21*), we did not observe cylindrical tubes (approx. 50 nm in diameter). Intermediate helical ribbons with the longer fibers (>1 μm), indicating an early sign of lamination, were found infrequently (Figure 2C and D). The nanofibers did not fuse into nanotubes (*20*), presumably because the conjugated mPEG2000 in **1** sterically prevents aggregation.

To prepare homogenous nanofibers, the assembled samples were physically disrupted into shorter fragments by passing them through a mini-extruder. This procedure is similar to routinely used methods for producing homogenous liposomes. Depending on the pore sizes of the employed polycarbonate membranes, nanofibers with approximate lengths of 200 nm for **2** and 100 nm for **3** were obtained (Figure 3). The fragmented fibers (2 μM) had similar physical properties as the original fibers **1**, and there was no aggregation or cross-linking between fibers. Further experiments are underway to study the long-term stability of these fibers.

The conjugated FITC fluorophores of **3** positioned in close proximity resulted in nearly complete quenching (96%) of fluorescence in intact nanofibers (Figure 4A). When compared to the same concentrations of free FITC, the normalized (at 494 nm) absorption spectrum in PBS buffer was broadened and had an increased peak maximum (at 460 nm) (Figure 4B). In contrast, when **3** was completely dissociated in methanol, the absorption overlapped with the free FITC (Figure 4C), thus providing evidence that fluorescence quenching of **3** is caused by structural orientations of the nanofiber assemblies.

The core nanofiber peptide was designed to contain a uPA cleavage site (SGRSANA) for proteolytic digestion. We hypothesized that the assembled nanofibers could thus respond to uPA by releasing FITC-conjugated fragments ($mPEG_{2000}$-BK(*FITC*)SGR) when cleaved (Figure 1). To study enzymatic activation, the nanofibers **3** (100 μM) were incubated with uPA (250 nM) for 24 h. We observed an up to 4-fold increase in fluorescence intensity (Figure 5A), which was uPA-concentration dependent (Figure 5B). In the presence of amiloride (1 mM), an inhibitor of uPA, fluorescence remained at the baseline level. Enzyme selectivity was further confirmed by using control nanofibers. Here, the substrate cleavage site was substituted with a scrambled peptide sequence (SGASRNA). As expected, in the presence of uPA, there was no activation of the control

nanofibers. To study digestion kinetics, nanofibers **3** were analyzed serially over time. In the absence of uPA, the fluorescence baseline remained constant with time, suggesting that the formulations were stable. The fluorescence increases reached a plateau after 8 h using 250 nM of uPA. Further experiments are underway to analyze the morphological changes of the nanofibers after enzymatic digestion.

In summary, using hydrophobic β-sheet peptides as core materials, we have developed a new type of protease-sensitive nanofiber. The materials are easy to synthesize and self-assemble into fibers with homogeneous nanometer diameters. The lengths of these fibers can be controlled by membrane filtration. Proof-of-principle experiments demonstrated that these nanofibers could be made protease-sensitive and biodegradable. These novel materials could have important applications in in vivo protease imaging or as enzyme-responsive biopolymers for systemic drug delivery.

Energy Transfer between CdSe/ZnS Core/Shell Quantum Dots and Fluorescent Proteins

Vitor R. Hering,*[,†] Gary Gibson,[‡] Robert I. Schumacher,[†] Adelaide Faljoni-Alario,[†] and Mário J. Politi[†]

Departamento de Bioquímica, Instituto de Química, Universidade de São Paulo, São Paulo, SP 05513-970, Brazil, and Hewlett-Packard Laboratories, Palo Alto, California 94304. Received April 25, 2007; Revised Manuscript Received September 11, 2007

Fluorescent proteins from the green fluorescent protein (GFP) family interact strongly with CdSe/ZnS quantum dots. Photoluminescence of GFP5 is suppressed by red-emitting CdSe/ZnS quantum dots with high efficiency in a pH-dependent manner. The elevated degree of quenching, around 90%, makes it difficult to analyze the remaining signal, and it is not clear yet whether FRET is the reason behind the quenching. When the donor is a green-emitting CdSe/ZnS quantum dot and the acceptor is the HcRed1 protein, it is possible to detect quenching of the donor and sensitized emission from the acceptor. It was verified that the sensitized emission has the low anisotropy characteristic of FRET. The present characterization identifies donor–acceptor pairs formed by fluorescent proteins and CdSe/ZnS quantum dots that are suitable for the exploration of cellular events. These donor–acceptor pairs take advantage of the exceptional photochemical properties of quantum dots allied with the unique ability of fluorescent proteins to act as gene-based fluorescent probes.

INTRODUCTION

CdSe/ZnS core/shell quantum dots and fluorescent proteins belonging to the green fluorescent protein (GFP) family provide components among which Förster resonance energy transfer (FRET) is possible. The emission and absorption profiles of these elements can be matched to optimize FRET, and the distances can be kept below 10 nm. The occurrence of FRET in such system suggests a great diversity of possible donor–acceptor pairs and, because both components play important roles as biological labels, potential usefulness in cell biology experiments that make use of donor–acceptor labels.

CdSe/ZnS core/shell quantum dots have large absorption cross sections, high photoluminescence (PL) quantum yields (QY), size-tunable PL spectra covering the region from blue to red, exceptional photochemical stability (*1*, *2*), and good dispersibility in biological fluids (*3–6*). The GFP family is composed of a group of homologous, colored, compact proteins that spontaneously generate their own fluorophore (*7–9*). These proteins also cover the visible spectrum and have been extensively used as gene-based probes in molecular and cell biology (*10*).

Förster resonance energy transfer (*11*) between two fluorophores is typically observed over distances of less than 10 nm. Because FRET efficiency is strongly dependent on the distance separating the FRET pair and the relative orientation of the fluorophores, FRET can be used to analyze molecular interaction with high precision (*11–14*).

In this letter, we describe some aspects of the interaction between quantum dots and fluorescent proteins, with particular emphasis on the evidence for FRET between these components.

Our interest in the interaction between fluorescent proteins and semiconducting nanocrystals was piqued by the observation that GFP5 binds to 2-mercaptoethanol-covered ZnS nanocrystals, synthesized in accordance to Kosravi et al. (*15*). This was accomplished by cloning the gene coding for GFP5 into the HIS-tagging vector pET28a (Qiagen) and expressing it in *E. coli*. GFP5 contains three mutations from wild-type GFP aimed at improving bacterial expression (*16*). After purification, GFP5 was poured into a suspension of ZnS nanocrystals, and it was observed that it coprecipitates with them. GFP5 bound to these nanocrystals retains its photoluminescence. Following this first evidence, a further step was given by substituting the ZnS nanocrystals by red-emitting CdSe/ZnS core/shell quantum dots coated with mercaptoundecanoic acid (MUA), henceforth denoted QD-R. The quantum dots were purchased from NN-Laboratories and had a photoluminescence peak at 638 nm. Once the carboxylic end groups of MUA are exposed over the surfaces of the QDs, and given the usual pK_a of carboxylic acids (~4.5) of isolated molecules or even attached as surface groups (pK_{app} ~4.5 – 6.0), negatively charged particles will predominate at pH's ≥ 6.0. (*17*). The photoluminescence of GFP5 overlaps with the absorption spectrum of the QDs, as can be seen in Figure 1.

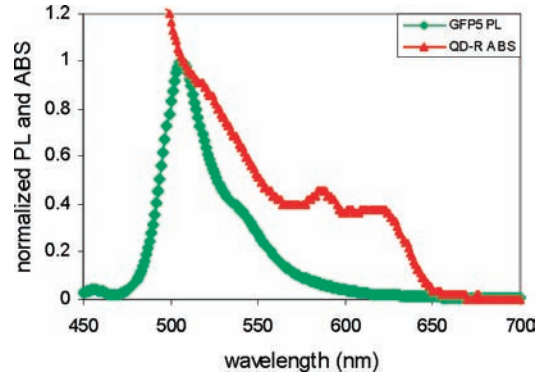

Figure 1. Normalized photoluminescence (PL) spectrum of GFP5 and absorption (ABS) spectrum of red-emitting CdSe/ZnS core/shell QD solutions.

Using the measured spectral overlap and a value of 79% for the quantum yield of GFP5 (*10*), we calculated a Förster radius (*12*) of 4.2 nm for the pair GFP5-QD-R. Because the diameter of the GFP5 barrel is 2.4 nm and its height is 4.2 nm (*8*) and the MUA coating thickness of the QDs is around 1 nm (data

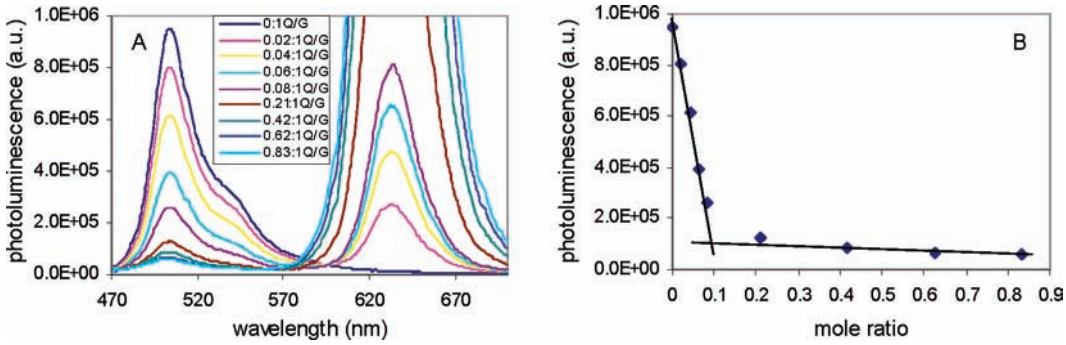

Figure 2. (A) Evolution of the photoluminescence spectra of GFP5 in GFP5-QD-R assemblies vs increasing QD-R (Q) to GFP5 (G) molar ratio. (B) Photoluminescence of GFP5 at 505 nm as a function of GFP5:QD-R mole ratio.

provided by NN-Laboratories), the central fluorophore of GFP5 may be sufficiently close to the quantum dot to allow FRET. In fact, the titration of red-emitting CdSe/ZnS quantum dots in a solution containing GFP5 results in quenching of the photoluminescence of GFP5 (see Figure 2A). The concentration of GFP5 was kept fixed at 24 nM, and the concentration of QD-R was increased from 0 to 20 nM. The GFP5-QD-R assemblies were prepared in dilute aqueous solutions where the effects of absorption of the incident light, reabsorption of PL, and aggregation of nanoparticles were negligible. The solutions also contained 5 mM NaCl and 5 mM NaH_2PO_4, and the pH was adjusted to 6 with NaOH. The excitation was performed at 395 nm, which coincides with the first absorption peak of GFP5 (*16*). There is no wavelength where GFP5 could be selectively excited, because the broad absorption of the QD-Rs covers the entire GFP5 absorption spectrum. The overlap of absorption spectra made it difficult to verify that the quenching of the PL of GFP5 resulted in any sensitized emission of the quantum dots. The stoichiometry for the GFP5-QD-R complex formation at pH 6 and room temperature were determined by the mole ratio method (*18*) using the quenching of the photoluminescence of GFP5 as the property to map the complexation. From the plot of photoluminescence quenching versus mole ratio (see Figure 2B), a stoichiometry of 10:1 for the GFP5-QD-R complex was established. It is important to note that the hydrodynamic radius of QD-R (nanocrystal plus MUA) is 10 nm (data provided by NN-Laboratories), which provides a surface area large enough to accommodate 10 GFP5 molecules.

The formation of the GFP5-QD-R complexes is driven by electrostatic interactions, as shown by the pH dependence of the GFP5 PL quenching. At a pH of 6, 90% of the GFP5 emission is quenched at a 0.5:1 molar ratio of QD-R to GFP5. At pH 8, 75% of the GFP5 emission is quenched, while at pH 10, there is only a 10% quenching of the PL of GFP5. There are no major variations in PL intensities of GFP5 and QD-R as the pH is raised from 6 to 10, as can be seen in the control experiments demonstrating the pH dependence of PL intensities for the quantum dots and fluorescent proteins (see Supporting Information). In the Supporting Information is also presented the reversibility of the GFP5 PL quenching as the pH is raised from 6 to 10.

Circular dichroism (CD) measurements verified that the suppression of the PL of GFP5 did not result from denaturing of its secondary structure (see Figure 3). At pH 6 and with a QD-R/GFP5 molar ratio of 0.4, where the PL quenching is near maximum, the secondary structure of GFP5 appears substantially unchanged when exposed to QD-Rs.

To verify that FRET is occurring between the GFP5 and QD-R elements, anisotropy and nanosecond time-resolved fluorimetry measurements were undertaken. FRET would be expected to increase GFP5 anisotropy and reduce its fluorescence lifetime (*12–14*). Unfortunately, these measurements were

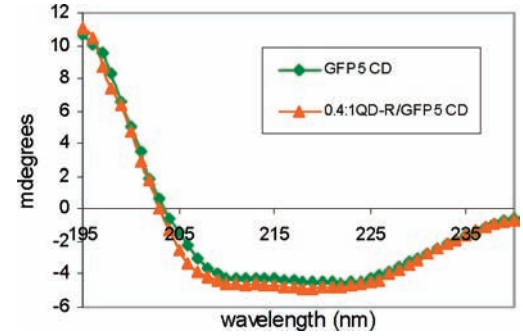

Figure 3. Circular dichroism spectra of GFP5 and GFP5 assembled to quantum dots are nearly identical, suggesting that the quantum dots do not denature the secondary structure of GFP5.

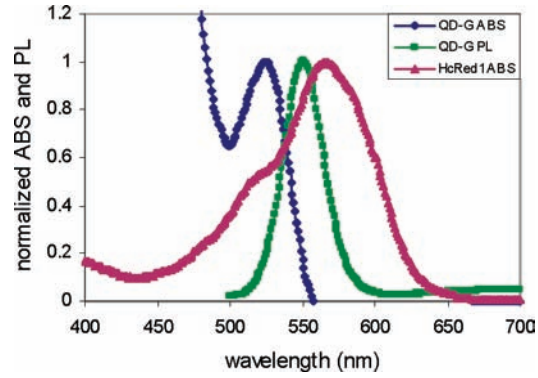

Figure 4. Normalized absorption and photoluminescence spectra of green-emitting CdSe/ZnS core/shell QDs and absorption spectrum of HcRed1 protein solutions.

inconclusive, because the strong GFP5 PL quenching, coupled with the need to keep the QD-R concentration low to avoid aggregation, resulted in poor signal-to-noise ratios. One explanation for these results is the possibility that the fraction of GFP5 complexed to the QD-Rs was completely quenched so that the remaining emission due to the uncomplexed fraction dominated the signal (*19*). Also, it is possible that charge transfer to the QD-R (in addition to energy transfer) contributes to the GFP5 PL quenching (*20*), despite the fact that GFP5 fluorophore is buried inside a proteic barrel that surrounds and protects it (*7, 21*).

Alternative ways to determine whether the observed PL quenching is due to FRET are under investigation. One possibility would be to selectively excite the GFP5 through a chemiluminescent reaction and then observe the eventual sensitized emission from the QD-Rs. GFP has a chemiluminescent resonance energy transfer pair *in vivo*, the protein aequorin (*10, 22*), that could be used for such finality.

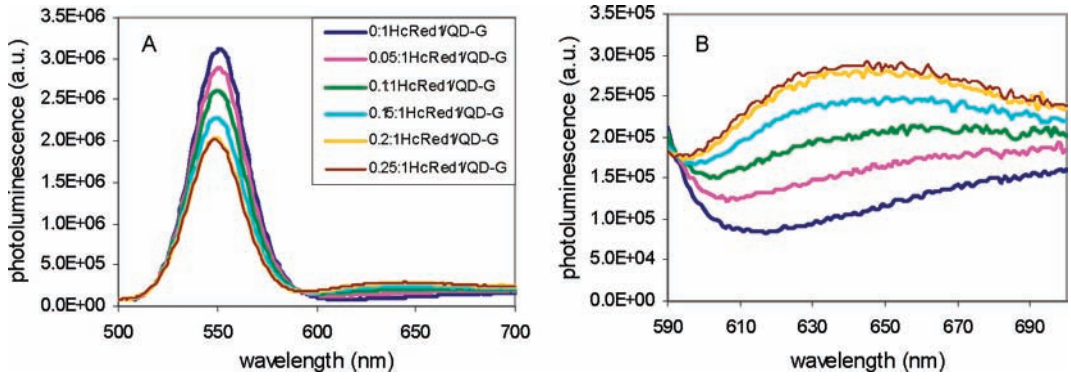

Figure 5. (A) Evolution of the photoluminescence spectra of HcRed1 protein in QD-G-HcRed1 assemblies vs increasing HcRed1 to QD-G molar ratio. (B) Amplified view of the 590–700 nm region of part A enables us to better observe HcRed1-sensitized emission.

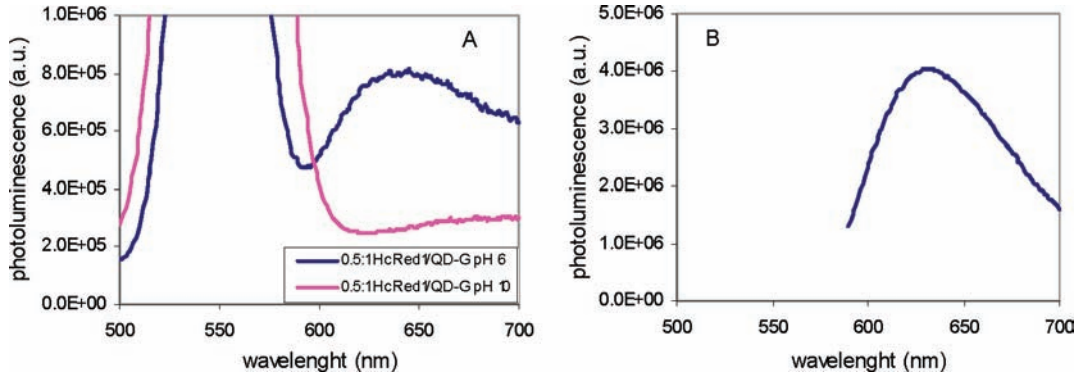

Figure 6. (A) pH dependency of the sensitized emission from HcRed1 complexed with green-emitting quantum dots. (B) PL of HcRed1 directly excited at 545 nm.

Alternatively, the larger two-photon cross section of GFP in comparison to the that of the QDs (*23, 24*) could be used to selectively excite this protein with 800 nm radiation and then try to observe the sensitized emission from the QD-Rs. The possibility of increasing the distance between GFP5 and the QD-Rs by the incorporation of an additional capping layer over the QD-Rs (*25*) is also being considered, aiming to reduce the efficiency of the quenching and make the remaining PL intensity of GFP5 appropriate for anisotropy and time resolved analysis.

In the meantime, an inverted approach was investigated where a GFP homologous red-emitting protein, HcRed1, has been used together with a green-emitting CdSe/ZnS mercaptoundecanoic acid coated quantum dot (henceforth denoted QD-G), forming a pair where the QD-G is the donor and HcRed1 is the acceptor. The overlap between QD-Gs emission and HcRed1 absorption can be seen in Figure 4. The broad absorption spectrum of the quantum dots enabled us to find a wavelength interval, around 425 nm, where the quantum dots are selectively excited.

Excited at 425 nm, the PL intensity of the quantum dots is partially suppressed by the titration of HcRed1 (see Figure 5A). The suppression is not intense as in the case of GFP5 and QD-R, but the selective excitation enabled us to observe a subtle sensitized emission from HcRed1 (see Figure 5B). The concentration of QD-Gs was kept fixed at 33 nM, and the concentration of HcRed1 was augmented from 0 to 8 nM. The assemblies were prepared in dilute aqueous solutions where the effects of absorption of the incident light, reabsorption of PL, and aggregation of nanoparticles were negligible. The solutions also contained 5 mM NaCl and 5 mM NaH_2PO_4, and the pH was adjusted to 6 with NaOH.

The formation of the HcRed1–QD-G complexes is also driven by electrostatic interactions, as shown by the pH dependence of the sensitized emission. At a pH of 6, it is possible to observe the sensitized emission at a 0.5:1 molar ratio of HcRed1 to QD-G excited at 425 nm. At pH 10, no sensitized emission is observed (see Figure 6A) in spite of an increase in the PL intensity of HcRed1 when excited with 545 nm and no major variation in the PL intensity of the QD-G (see Supporting Information). The PL spectrum of HcRed1 excited at 545 nm has the same profile of the sensitized emission (see Figure 6B).

Detection of sensitized emission anisotropy is a technique that enables the characterization of FRET with high contrast (*13, 26*). Sensitized emission is highly depolarized, because the orientation of emitted light is not wholly constrained by the excitation polarization (*27*). Due to the relatively large size and slow rotational diffusion, PL emission from fluorescent proteins is highly anisotropic (*26, 27*). In the case of HcRed1, the anisotropy of the PL obtained by direct excitation is nearly 0.4. The anisotropy of the sensitized emission of HcRed1, measured in the excitation interval from 400 to 470 nm, is below 0.1. The low anisotropy of the sensitized emission contrasting with the elevated anisotropy of the direct PL emission provides strong evidence that FRET occurs between QD-Gs and HcRed1.

Other pairs of QD and fluorescent proteins are under present consideration. The protein HcRed1 may be substituted by other red-emitting fluorescent proteins with higher quantum yields to be the acceptors with green- or yellow-emitting quantum dot donors. Actually, HcRed1 has a quantum yield of only 0.05 (*28*), which may account for the low intensity of its sensitized emission. The proteins mCherry, tdTomato, and mStrawberry (*29*) would be attractive acceptor candidates, due to their elevated quantum yield and brightness. tdTomato (*29*), in particular, has a quantum yield of 0.69 and brightness superior to that of fluorescein. An optimized donor–acceptor pair would be convenient for in-depth characterization and quantification of FRET parameters and for high-contrast *in vivo* investigations.

ACKNOWLEDGMENT

The authors thank Dr. Jim Haseloff for providing the gene coding for GFP5. V.R.H. was supported by a grant from Numina Nanotecnologia Ltda. The authors wish to express their gratitude to the Brazilian funding agencies CNPQ, FAPESP, and CAPES, being also thankful for the support from the Biochemistry Department of the Chemistry Institute of the University of São Paulo, Brazil.

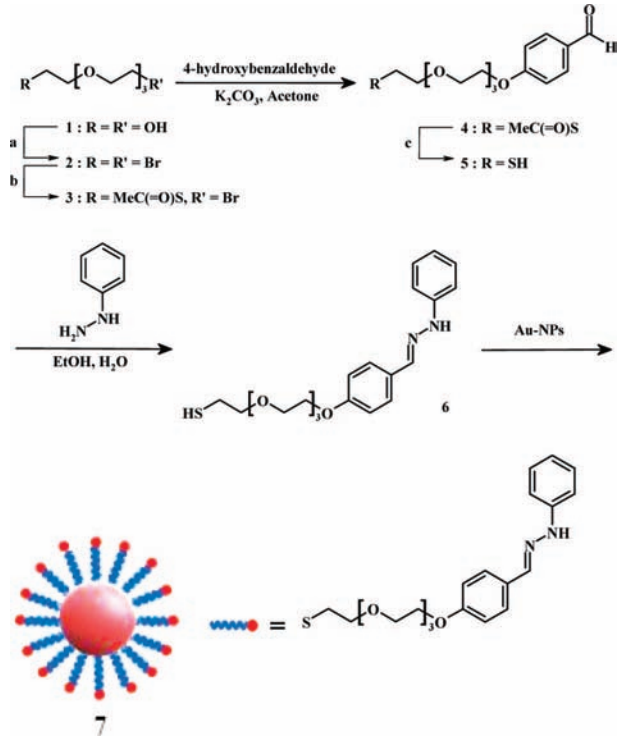
Received June 20, 2007; Revised Manuscript Received September 20, 2007



Arylhydrazones were linked onto gold nanoparticles through the poly(ethylene glycol) spacer to produce a new type of photoinduced DNA-cleaving nanomaterials with great potency.

INTRODUCTION

Nanobioscience and technology possess enormous potential, as their development could lead to new materials beneficial to human life. Prominent progress has been observed in various fields, including drug delivery, DNA sequencing, biosensor, biomolecular separation, magnetic resonance imaging, and so forth (*1–6*). Among various nanoparticles (NPs), gold nanoparticles (Au-NPs) are most stable and, thus, suitable for biological systems. Their inert surface prevents undesired reactions from taking place with different functional groups of biomolecules (*7*); yet, Au-NPs can still be capped with water-soluble organic compounds (*8, 9*) or biomolecules through thiols (*10*). For example, Mirkin (*11–13*), Yeh (*14*), and co-workers functionalized Au-NPs with 3′- and/or 5′-thiol oligonucleotides. Russell et al. (*15*) used a thiolated ethylene glycol anchor chain with various lengths to link lactose derivatives to preformed Au-NPs.

We planned to develop nanoparticles that bear multi-DNA cleaving "warheads". It is necessary for the warheads to be controlled by a trigger, which can be used to initiate the DNA-nicking process. These new functional nanoparticles may possess the following features and advantages: 1. The DNA-cleaving potency could be enhanced dramatically because of the high local density of warheads, many of which are attached to one nanoparticle nucleus. 2. The warheads as "soft" moieties are attached onto the "hard" core of nanoparticles, which could serve as bullets of a gene gun (*16–18*). Consequently, the DNA-cleaving warheads can be delivered to a specific location by mechanical force. 3. The solubility of the hybrids can be adjusted by spacers, which link the warheads to nanoparticles. Our research group has been developing new artificial agents for cleaving nucleic acids under control conditions (*19–22*). Among these agents, arylhydrazones were found stable and can nick DNA by use of UV light as the trigger (*22*). Herein, we report our success in the attachment of arylhydrazones onto gold nanoparticles to form a new class of DNA-cleaving materials. Being water-soluble, these hybrid nanomaterials were manipulated without difficulty in aqueous solutions for nicking DNA upon UV irradiation.

Scheme 1. Synthesis of Arylhydrazone-Conjugated Au-NPs[a]

[a] Reagents and conditions: (a) PBr_3, 60 °C, 4.0 h; (b) thioacetic acid, NaOH, THF, 25 °C, 6.0 h; (c) NaOH, MeOH, 25 °C, 5.0 h.

RESULTS

Our synthetic strategy for incorporation of an arylhydrazone onto Au-NPs is shown in Scheme 1. The starting material Au-NPs with diameters of 13 ± 1.8 nm were prepared by reduction of $HAuCl_4$ with sodium tricitrate according to the established procedure (*23, 24*); meanwhile, poly(ethylene glycol) (PEG) was used as the spacer. Thus, we treated tetraethylene glycol (**1**) with PBr_3 in ether to give the corresponding dibromide **2**. Protection of one terminal in **2** with a stoichiometric amount of thioacectic acid in the presence of NaOH in THF led to thioacetate **3**. Coupling of **3** with *p*-hydroxybenzaldehyde in the presence of K_2CO_3 in acetone provided PEG-containing

benzaldehyde **4**, in which the acetyl group was deprotected with methanolic NaOH under carefully controlled conditions (*25*). The desired free thiol **5** was isolated in 77% yield by flash chromatography packed with silica gel. Its characteristic SCH_2 protons appeared at 2.72 ppm with $J = 7.2$ Hz and the benzaldehydic singlet proton at 9.85 ppm in the ^1H NMR spectrum. A downfield resonance for the benzylic carbon exhibited at 190.63 ppm in its ^{13}C NMR spectrum. Furthermore, a strong absorption at 1692 cm^{-1} associated with the conjugated C═O stretch also appeared in its IR spectrum. Condensation of this benzaldehyde **5** with phenylhydrazine gave the corresponding phenylhydrazone **6** with $m/z = 404.1765$. In its ^{13}C NMR spectrum, eight peaks showed up between 112.85 and 159.39 ppm for the aromatic carbons; meanwhile, the newly generated benzylic N═C carbon shifted to 159.39 ppm. The N═CH proton resonated at 7.62 ppm in its ^1H NMR spectrum.

To obtain conjugated target materials, we treated the ~13 nm Au-NPs with a large excess (500–1000 equiv) of phenylhydrazone **6** (2.0 mL, 10 mM) in water at 25 °C for 4.0 h. The desired hybrid **7** was produced and isolated by centrifuge; a red solution of its colloids in water was attributed to their surface plasmon resonance (*26*, *27*). The centrifuge process assured the following DNA-cleaving results coming from hybrid nanoparticles **7** instead of the organic molecule **6**. Because the Au-NPs were attached by the HS-PEG-arylhydrazone ligand through the sulfide terminal, we observed a hyperchromic and bathochromic shift by 5 nm in the UV spectra in situ. These results are consistent with reports on spectral surface plasmon resonance shifts for the thiols on Au-NPs (*28*). By using the displacement method with mercaptoethanol reported by Nie et al. (*29*), we determined the number of ligands **6** per particle as 55–60 on average. In this experiment, the concentration of displaced hydrazone-containing thiol **6** from hybrid **7** was compared with that from freshly synthesized **6** at λ 345 nm of UV spectrometry.

Furthermore, the transmission electron microscopy (TEM) was used for determination of the nanoscale structures. We dropped a casting solution of nanoparticles onto carbon-coated copper grids. The distribution of gold cores of hybrid **7** is shown in Figure 1a, which indicates that the nanoparticles were well-dispersed. The amplified TEM in Figure 1b reveals that spherically shaped particles were obtained; of which the diameter of 13 ± 1.9 nm as the average was estimated on the basis of 120 sampled arylhydrazone–PEG-capped nanoparticles (*30*, *31*).

To investigate the DNA-cleaving ability, we dissolved the water-soluble Au-PEG–arylhydrazone colloids **7** (2.0 nM) in a sodium phosphate buffer (pH 7.4) and 10% ethanol containing the supercoiled circular φX174 RFI DNA (form I; 50 μM/base pair). These solutions were irradiated with UV light (312 nm, 1.43 mW/cm^2) under aerobic conditions at room temperature for 2.0 h. By analyzing the results from gel electrophoresis on 1.0% agarose gel with ethidium bromide staining, we found

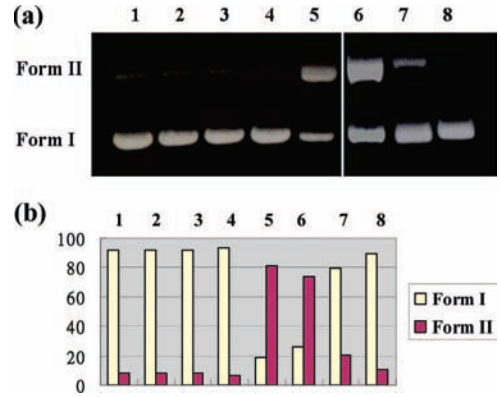

Figure 2. (a) Single-strand cleavages of supercoiled circular φX 174 RFI DNA: lane 1, DNA alone; lane 2, 13 nm gold nanoparticles in the dark; lane 3, 13 nm gold nanoparticles under UV light; lane 4, Au-NPs hybrid **7** in the dark; lanes 5–8, 2.0 nM, 500 pM, 100 pM, and 20 pM of Au-NPs hybrid **7** under UV light. (b) Percentages of form II/form I for lanes 1–8.

that the hybrid **7** caused single-strand cleavages of DNA efficiently to give the relaxed circular DNA (i.e., form II; see lane 6 of Figure 2). Our results shown in lane 7 indicate that hybrid **7** was able to cleave DNA at a concentration as low as 1.00×10^2 pM.

To seek for the essential factors of the DNA nicking, we performed two control experiments. The first was to carry out the experiment under the same conditions except in the dark (see lane 4). The second involved UV irradiation; however, we replaced Au-PEG–arylhydrazone hybrid (**7**) by Au-NPs (see lane 3). These results indicate that the DNA were not damaged; thus, both the UV light and the integrated Au-PEG–arylhydrazone were essential for DNA nicking. Moreover, the positive results shown in lanes 5 and 6 clearly indicate that the Au-NP cores did not significantly inhibit UV light to activate arylhydrazones on the shell, although they showed UV absorption at 520 nm.

DISCUSSION

There are three reasons to tether arylhydrazones onto the shell of Au-NPs by use of the PEG strands. First, an alkoxy substitutent can enhance the DNA-cleaving ability of arylhydrazones, which generate aminyl (R_2N) and iminyl (R_2C═N) radicals upon UV irradiation (*22*). A terminal oxygen atom of triethylene glycol for its connection to the arylhydrazone serves this purpose. Moreover, the great enhancement of DNA-cleaving potency may also indicate that the oxygen-containing PEG spacers prevented the nitrogen-containing radicals absorbed by gold surface, as reported by Meisel et al. (*32*). Second, the citrate anions were coordinated to the Au^I shell, although the core of our Au-NPs was Au^0 (*13*). When we treated the Au-NPs with salts, aggregations often took place among particles, and color changed from red to dark blue. This problem was circumvented after we attached the PEG spacers onto Au-NPs. The stability came from the steric repulsion effect of the tethered PEG spacers, which improved the dispersion of the Au-NPs–PEG–arylhydrazone particles in aqueous media. Third, the PEG strands on the surface of the functionalized Au-NPs improved their hydrophilicity. This effect enabled the hybrid nanoparticles of **7** to approach and, thus, to cleave the DNA target with ease.

Our previous findings indicate that the hydrophobic organic compound, *p*-methoxylbenzaldehyde *p*-methoxylphenylhydrazone (PMBH), can cleave DNA at a concentration as low as 50 μM (*22*). The current findings indicate that arylhydrazone-containing Au-NPs **7** cleaved DNA at a much lower concentration (i.e., 2.0 nM). In comparison with PMBH, the efficacy of the hybrid **7** was improved by a factor of $>10^4$ despite each

nanoparticle containing 55–60 warheads. Although the total warhead number on each nanoparticle could be increased, we tried not to keep it overcrowded. This design is on the basis of our speculation that, otherwise, coupling reactions might take place among the radical warheads after their generation upon UV irradiation.

Our results shown in lanes 5–7 of Figure 2 indicate that only form II DNA (open-circular product) was generated through single-strand breaks; meanwhile, the formation of form III DNA (i.e., linear product) resulting from double-strand breaks was not observed. The generation of form III DNA has to come from two separate single-stand cleavage events in close proximity. Therefore, we consider that the high efficiency of DNA single-strand breaks may be derived from the nanoparticles bearing multiradical warheads toward all directions on their spherical surface. When these hydrophilic "maces" with a high local density of radicals bumped into DNA, the chance for nicking a single strand would be much higher than individual organic radicals, such as the aminyl (R_2N) and the iminyl ($R_2C{=}N$) radicals. The efficiency resulting from the mace, however, may not be necessarily extendable to the double-strand break event. Further works will be in due course in order to have good insight into this intriguing issue.

Recently, Mirkin et al. (*33*) reported a novel strategy for intracellular gene regulation with oligonucleotide-modified Au-NPs. They demonstrate that nanoparticle-bound antisense oligodexoyonucleotides can be degraded by DNase. On the other hand, Liu and Lu (*34*) developed colorimetric biosensors on the basis of DNAzyme-assembled Au-NPs. In the presence of Pb^{2+}, the DNAzyme catalyzes specific hydrolytic cleavage of the substrate strand, which disrupts the formation of the nanoparticle assembly. Up to the present date, these two approaches are likely to be the only published examples that involve cleavage of nanoparticles conjugated with DNA or oligonucleotides. In both examples, the cleaving "warheads" are not attached to the nanoparticles. In contrast, the currently developed conjugate materials **7** possessed warheads on their shells and can be regarded as a new type of DNase.

In conclusion, gold nanoparticles conjugated with arylhydrazones through thiol-based PEG ligands (i.e., **7**) were successfully synthesized. The diameters of these new nanoparticles with spherical shape were 13 ± 1.9 nm as observed by TEM. Upon triggering by 312-nm UV light, hybrid **7** cleaved supercoiled DNA to give a relaxed circular shape at a concentration as low as 2.0 nM. To the best of our knowledge, this is the first example of nanoparticles with the DNA-cleaving property.

Surface Re-engineering of Pancreatic Islets with Recombinant azido-Thrombomodulin

Cherie L. Stabler,[†] Xue-Long Sun,[‡] Wanxing Cui, John T. Wilson, Carolyn A. Haller, and Elliot L. Chaikof*

Departments of Surgery and Biomedical Engineering, Emory University, Atlanta, Georgia 30322, and School of Chemical and Biomolecular Engineering, Georgia Institute of Technology, Atlanta, Georgia 30332. Received July 25, 2007; Revised Manuscript Received October 2, 2007

Chemoselective conjugation of an azido-functionalized thrombomodulin to pancreatic islets was achieved by Staudinger ligation to a surface-bound bifunctional poly(ethylene glycol) linker. The presence of the tethered thrombomodulin resulted in a significant increase in the production of activated protein C with a reduction in islet-mediated thrombogenicity. This report highlights the potential of tissue-targeted chemistry to reduce donor cell mediated procoagulant and proinflammatory responses.

Type 1 diabetes results from the autoimmune destruction of insulin-producing pancreatic beta cells and inevitably leads to dependence upon exogenous insulin for control of blood glucose. The transplantation of donor human islets into the liver of diabetic recipients is a promising treatment strategy, but remains limited by a high rate of early islet destruction due to the instant blood-mediated inflammatory reaction (IBMIR) triggered by the interaction of infused islets with blood (*1–3*). IBMIR is initiated by the activation of the coagulation and complement systems, which promotes rapid leukocyte infiltration of the donor islet graft (*4*). Heparin, low-molecular-weight dextran sulfate, melagatran, and activated protein C have been used to minimize IBMIR (*5–8*). Systemic delivery of these anticoagulants at therapeutic doses, however, substantially increases the risk of bleeding. We have postulated that biochemically re-engineering the islet surface with constituents that serve to inhibit the activation of the coagulation cascade would provide a novel strategy to reduce IBMIR (Figure 1A). Specifically, we have developed a scheme to conjugate human recombinant thrombomodulin (*r*TM) to the islet surface through bifunctional poly(ethylene glycol) (PEG) linkers in a chemo-and bioorthogonal fashion (Figure 1B). Thrombomodulin (TM), an endothelial cell transmembrane protein, binds thrombin and inactivates its known procoagulant–proinflammatory properties (*9*). In addition, the TM–thrombin complex rapidly activates circulating protein C (APC), which inactivates clotting factors **Va** and **VIIIa**, thereby serving as a negative feedback system by reducing new thrombin generation (*10, 11*). In this regard, re-engineering islet surfaces with TM and localizing the activation of protein C may provide a novel strategy to reduce IBMIR.

Recent innovations in protein engineering and bioorganic synthesis facilitate incorporation of special tags into recombinant proteins for site-specific modification and immobilization through selective chemical reactions that are orthogonal to the diverse functionality of biological systems (*12*). For example, using a biosynthetic approach, we have recently created a short TM construct containing the thrombin and protein C binding

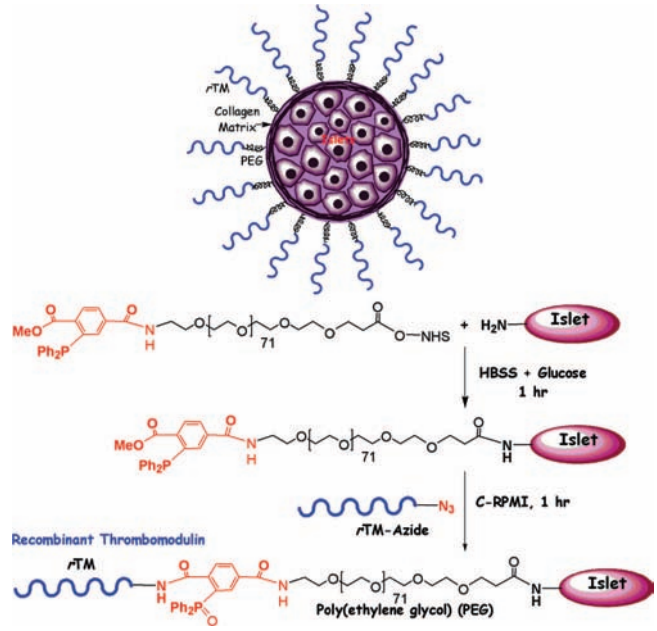

Figure 1. PEGylation and subsequent Staudinger ligation between recombinant azido-thrombomodulin and the PEG–phosphine linker.

regions and terminated with an artificial "non-natural" amino acid, azido (N_3)-alanine, at the C-terminus of the protein (*13*). The azide has secured a prominent role as a unique chemical handle for bioconjugation. We have made extensive use of the azide as a chemical handle for site-specific PEGylation in solution via Staudinger ligation and immobilization of proteins on artificial surfaces via azide-alkyne [3 + 2] cycloaddition (*13, 14*). The Staudinger ligation is particularly advantageous, as it can be performed in living systems without physiological harm, in high yield, and within short time periods offering the potential to re-engineer a variety of cell and tissue surfaces (*15*).

PEG has been widely used to functionalize solid surfaces for inert and biocompatible surface engineering, as well as to limit immunogenicity and prolong the circulating half-life of proteins and peptides for drug delivery. Recently, it has been suggested that PEG grafted onto the collagen matrix of isolated islets could inhibit pathways leading islet xenograft rejection (*16*). Specifically, PEGylation leads to a reduction in antibody/complement-mediated cytotoxicity (*16*). Under this premise, we utilized a

bifunctional PEG linker to chemoselectively target recombinant azido-TM to the surface of living islets in a two-step process with the goal of creating a localized anti-inflammatory environment and reducing islet thrombogenicity.

The bifunctional PEG linker, with a triphenylphosphine (phosphine-PEG-NHS) at one end and a succinimidyl active ester at the other, was synthesized from commercially available amino-PEG-carboxylic acid, as described in Supporting Information. Pancreatic islets were isolated and purified from B10.BR mice using standard techniques by intraductal injection of rodent collagenase (Sigma, MO) (*17*). After culturing islets for 48 h, islets were transferred to a 12 μm plate insert (Millipore, MA) within a 24 well plate. RPMI media was flushed from the islets using PBS (Mediatech, VA). Following washes, the mouse islets were incubated for 1 h with 4 mM phosphine-PEG-NHS in PBS supplemented with 11 mM glucose solution. After a PBS wash, the islets were incubated for 1 h with recombinant azido-TM in fully supplemented RPMI. To elucidate the specificity of the reaction, confocal imaging, slot blot analysis, and ELISA were performed on several test groups, including (i) islets receiving no treatment; (ii) islets undergoing PEGylation alone; (iii) islets incubated solely with azido-TM; and (iv) islets treated sequentially with PEGylation and azido-TM. Since the recombinant azido-TM was expressed as fusion protein bearing a unique N-terminal S-Tag, a FITC-labeled anti-S-Tag antibody was used to detect islet bound TM (Figure 2).

The sequential two-step reaction with both linker and TM led to significant islet labeling, which was not observed on islets exposed solely to azido-TM or PEG linker alone (Figure 2A–D). Slot blot analysis of cell lysates confirmed the presence of human recombinant TM only on mouse islets treated with both linker and azido-TM (Figure 2E). Moreover, an ELISA assay performed with a horseradish peroxidase (HRP) conjugated antihuman TM antibody demonstrated a 10-fold increase in antibody binding to remodeled islet surfaces when compared to untreated islets or to those treated with linker alone ($p < 0.05$; Figure 2F).

Confocal fluorescence imaging using a live/dead staining protocol confirmed preservation of islet viability after surface treatment with linker and Staudinger ligation of azido-TM (Figure 3A). Likewise, glucose-stimulated insulin secretion, as a measure of islet function, was unchanged after surface treatment (Figure 3B). Significantly, a 7-fold increase in protein C activation was observed for islets conjugated with the recombinant azido-TM compared to untreated or pegylated islets (Figure 3C). Moreover, TM conjugation substantially delayed clot formation upon incubation of untreated islets in human plasma. The calculated half-maximal clotting times were 8.15 ± 0.67 min for untreated islets, 9.88 ± 0.49 min for pegylated islets, and 14.08 ± 2.07 min for TM-treated islets ($p < 0.05$).

To date, traditional coating techniques have focused on passive barrier methods that either immunoisolate or immuno-

camouflage transplanted cells from the host. The generation of a bioactive coating through tissue-targeted chemistry serves not only to mask cell surface proteins, but also to provide a means to alter the local microenvironment of the islet graft. In the process, islet-mediated procoagulant and proinflammatory responses are reduced, which may lead to a substantial improvement in clinical outcomes. In principle, the chemical scheme illustrated in this report highlights the potential to immobilize a wide array of functionally complex constituents onto the islet surface in order to actively manipulate the donor–host tissue interface.

Received January 18, 2007; Revised Manuscript Received June 7, 2007

A smart contrast agent for magnetic resonance imaging (MRI) can be used to exploit an enzymatic activity specific to the tissue or disease state signified by converting an MRI-inactivated agent to an activated MRI agent. In this study, a β-galactopyranose-containing gadolinium(III) complex [Gd(DOTA-FPG)(H_2O)] was designed, synthesized, and characterized as being potentially suitable for a bioactivated MRI contrast agent. The ^{17}O NMR experiments were conducted to estimate the water exchange rate k_{ex}^{298} and rotational correlation time τ_R^{298}. The k_{ex}^{298} value of [Gd(DOTA-FPG)(H_2O)] is similar to that of [Gd(DO3A-bz-NO_2)(H_2O)]. The rotational correlation time value of [Gd(DOTA-FPG)(H_2O)] is dramatically longer than that of [Gd(DOTA)(H_2O)]$^-$ Relaxometric studies show that the percentage change in the T_1 value of [Gd(DOTA-FPG)(H_2O)] decreases dramatically in the presence of β-galactosidase and human serum albumin. The T_1 change percentage of [Gd(DOTA-FPG)(H_2O)] (60%) is significantly higher than those of Egad and gadolinium(III)-1-(4-(2-(1-(4,7,10-triscarboxymethyl-(1,4,7,10-tetraazacyclododecyl)))-ethylcarbamoyloxymethyl)-2-nitrophenyl)-β-D-glucopyronuronate. The signal intensity of the MR image for [Gd(DOTA-FPG)(H_2O)] in the presence of human serum albumin and β-galactosidase (2670 $\pm$ 210) is significantly higher than that of [Gd(DOTA-FPG)(H_2O)] in the sodium phosphate buffer solution (1490 $\pm$ 160). In addition, the MR images show a higher-intensity enhancement in CT26/β-gal tumor with β-galactosidase gene expression but not for the CT26 tumor without β-galactosidase gene expression. We conclude that [Gd(DOTA-FPG)(H_2O)] is a suitable candidate for a bioactivated MRI contrast agent in tracing gene expression.

INTRODUCTION

Molecular imaging is providing a sensitive and specific method for the detection and localization of the biochemical appearance *in vivo*. Magnetic resonance imaging (MRI) offers several advantages over other clinical diagnostic techniques for molecular imaging, including high spatial resolution, noninvasiveness, high anatomical contrast, and lack of harmful radiation. However, sensitivity of MRI to depicting a small molecule is constrained by the ubiquitous protons in the body, resulting in a high background and low signal to noise ratio (SNR). Hence, the alternative amplification strategies using smart contrast agents are required to yield a higher sensitivity (*1*).

Nonspecific contrast agents such as [Gd(DTPA)(H_2O)]$^{2-}$ (H_5DTPA = 3,6,9-tri(carboxymethyl)-3,6,9-triazaundecanedioic acid) (Magnevist, gadopentetate), [Gd(DTPA-BMA)(H_2O)] (H_3DTPA-BMA = 1,7-bis[(*N*-methylcarbamoyl)methyl]-1,4,7-tris(carboxymethyl)-1,4,7-triazaheptane) (Omniscan, gadodiamide), and [Gd(DOTA)(H_2O)]$^-$ (H_4DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) (Dotarem, gadoterate) are widely available for clinical use. They provide a nonspecific distribution pattern that allows measurement of tissue profusion, vascular permeability, or vascular volume. These parameters can be fitted by fast pharmacologic modeling and imaging techniques or steady-state imaging techniques (*2*, *3*). However, the true molecular targets cannot be ideally displayed with these approaches. Different signal characteristics upon interacting with the specific target by smart contrast agents could provide new ways for detecting the stages of biological molecules. Theoretically, smart contrast agents exhibit a strong signal alteration upon target interaction whether there is a bioactivated effect or not. This makes them ideal candidates for molecular imaging because they have the highest SNR for molecular target identification.

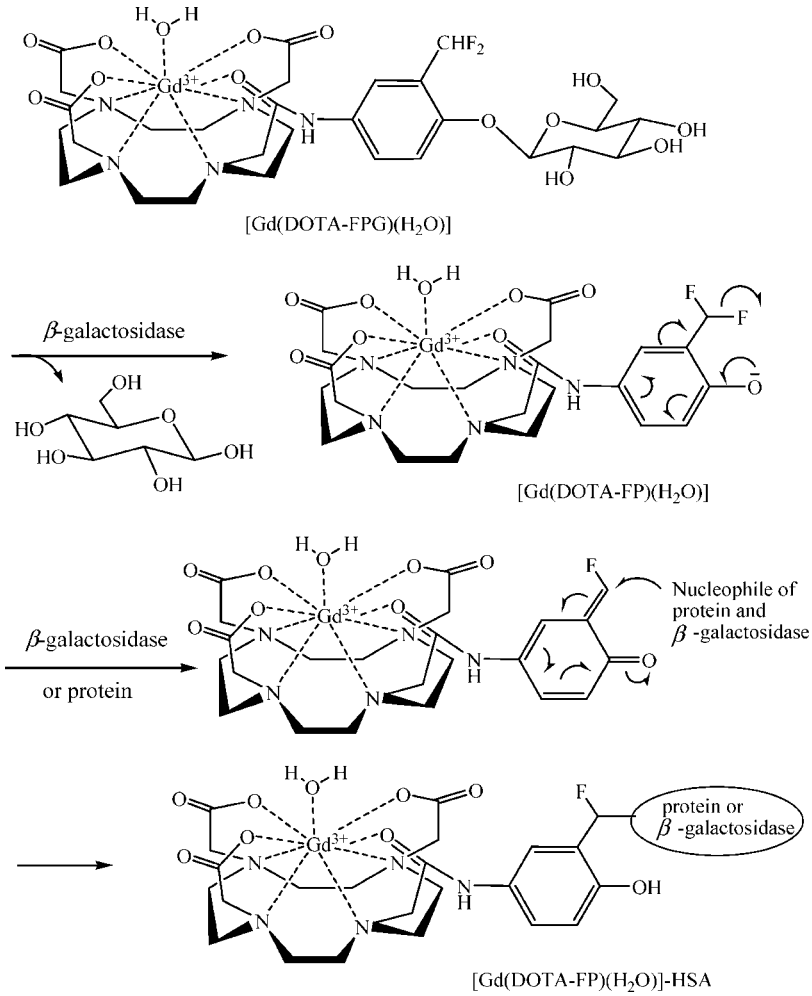
Scheme 1. Synthetic Scheme of DOTA-FPG[a]

[a] Reagents and conditions: (i) NaOH, TBAB, H_2O, CH_2Cl_2, 73%; (ii) DAST, CH_2Cl_2, 94%; (iii) H_2, Pd/C, ethyl acetate, 85% (*35*); bromoacetyl bromide, dimethylamine, CH_2Cl_2, 32%; (v) DO3A-tris-^{t}butyl ester (**7**), triethylamine, CH_2Cl_2 (*36*); $NaOCH_3$, CH_3OH; (vii) TFA, 45% for three steps.



The smart MR contrast agents carry out structural changes upon target interaction, which significantly change their signal properties (e.g., increasing the number of inner-sphere water molecules, *q*) (*4*). Enzyme-activated contrast agents for MRI have been developed and characterized (*1, 5*). These gadolinium(III) chelates developed an MR signal amplification strategy based on oxidoreductase-mediated polymerization of paramagnetic monomer into oligomers of higher relaxivity. Other enzyme motifs such as β-galactosidase, often used as a reporter gene in molecular biology, have been explored for a smart contrast agent for MRI (*4, 6, 7*). In this system, the route of water exchange to the gadolinium chelate is blocked by an enzymatically cleavable galactopyranoside substrate. β-Galactosidase activity results in an increase in T_1 relaxivity, and thus, the signal intensity increased in the T_1-weighted image. The feasibility of detecting β-galactosidase expression in *Xenopus laevis* embryos has been evaluated (*6, 8*).

The synthesis and characterization of Gd(III) complexes with poly(amino carboxylate) had been investigated in our previous studies (*9–12*). In this study, we design, synthesize (Scheme 1), and characterize the enzymatic contrast agent [Gd(DOTA-FPG)(H_2O)] (H_3DOTA-FPG = 1-(2-difluoromethyl-4-(1-(4,7,10-triscarboxymethyl-(1,4,7,10-tetraazacyclodecyl))acetamido)phenyl)-β-D-galactopyranose), which can be activated by β-galactosidase. In an attempt to achieve improvements in enzyme-mediated relaxivity enhancement, we decided to link a bioactivated residue onto gadolinium(III) chelate in order to achieve conjugation and, therefore, a higher molecular weight of the final product obtained. This chelate consists of a gadolinium(III) complex and an enzymatic moiety, 2-difluoromethylphenyl-β-galactopyranoside, which can be cleaved when there is the existence of β-galactosidase. The nucleophile of human serum albumin (HSA) and β-galactosidase will attack [Gd(DOTA-FP)(H_2O)] (H_3DOTA-FP = 1-(6-fluoromethylene-4-(1-(4,7,10-triscarboxymethyl(1,4,7,10-tetraazacyclodecyl)) acetamido)cyclohexa-2,4-dienone) complex to form biomacromolecules (*13*) [Gd(DOTA-FP)(H_2O)]-HSA and [Gd(DOTA-FP)(H_2O)]-β-galactosidase. The higher relaxivity (r_1) of the [Gd(DOTA-FP)(H_2O)]-HSA is achieved as a result of the larger rotational correlation time value of the macromolecule [Gd-(DOTA-FP)(H_2O)]-HSA as shown in Scheme 2. ^{17}O NMR relaxation rates and angular frequencies of the free Gd(III) complex in the presence and absence of HSA and β-galactosidase at variable temperatures will be reported. Furthermore, the effect of β-galactosidase on the longitudinal relaxation time (T_1) of Gd(III) complex will be investigated. Finally, the MR images of Gd(III) chelate in the presence and absence of β-galactosidase and HSA, animal model with and without β-galactosidase expression will be performed.

EXPERIMENTAL PROCEDURES

Materials. 1-(2-Difluoromethyl-4-aminophenyl)-2,3,4,6-tetraacetyl-β-D-galactopyranose (*13*) and 4,7,10-(tris-^{t}butylcarboxymethyl)-(1,4,7,10-tetraazacyclodecane) (DO3A-tris-^{t}butyl ester) (*14, 15*) were prepared by the previously published method. D(+)-Galactose was purchased from Acros. 2-Hydroxy-5-nitrobenzaldehyde, tetra-*N*-butylammonium bromide (TBAB), and diethylaminosulfur trifluoride (DAST) were purchased from Lancaster. All other reagents used for the synthesis of the ligand were purchased from commercial sources, unless otherwise noted. ^{17}O-enriched water (20.3%) was purchased from Isotec Inc. Human serum albumin (HSA, product no. A-1653, fraction V powder 96–99%) and β-galactosidase (product no. G5635–5KU, grade VIII from *Escherichia coli*) were purchased from Sigma

Scheme 2. Proposed Mechanism of HSA to Bind to [Gd(DOTA-FPG)(H_2O)]

and used without any further purification. The molecular weights were assumed to be 66.5 kDa (HSA) and 465 kDa (β-galactosidase). β-Gal Staining Kit was purchased from Invitrogen. The 100 mM sodium phosphate buffer solution was used to maintain the pH of all solutions (pH = 7.4) containing HSA. ^{1}H (400 MHz) and ^{13}C (100 MHz) NMR spectra were recorded on a Varian Gemini-400 spectrometer with 5 mm sample tubes. The ^{13}C NMR spectra were referenced internally relative to 3-(trimethylsilyl)-1-propanesulfonic acid for D_2O. The concentration of Gd(III) complex was determined by ICP-MS with a Perkin-Elmer OPTIMA 2000.

Synthesis. *1-(2-Formyl-4-nitrophenyl)-2,3,4,6-tetraacetyl-β-D-galactopyranose (**3**).* A solution of 2-hydroxy-5-nitrobenzaldehyde (8.29 g, 49.61 mmol) in CH_2Cl_2 (100 mL) was stirred at room temperature with an aqueous solution of 1 N NaOH (50 mL) and tetra-*N*-butylammonium bromide (TBAB) (10.99 g, 33.1 mmol). A solution of 2,3,4,6-aceto-α-D-bromogalactopyranose (13.60 g, 33.07 mmol) was added to this stirred mixture at room temperature. The synthesis of 2,3,4,6-aceto-α-D-bromogalactopyranose was prepared by the previously published method. The mixture solution was stirred for 3 days. The mixture solution was evaporated and yielded a bright yellow oil. Then, the oil was dissolved in CH_2Cl_2 and washed with 2 N NaOH solution (4 × 250 mL) and water several times. After collecting the organic phase, the goal compound was obtained by evaporating the solvent. Purification by chromatography (silica, CH_2Cl_2) gave a yellow viscous solid. The yellow solid was crystallized in diethyl ether, and this led to the production of a white solid. Collected solid and evaporated to dryness, yield 11.98 g (72.82%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 10.31 (s, 1H, -CHO), 8.66 (dd, 1H, ArH), 8.38 (dd, 1H, ArH), 7.27 (d, 1H, ArH), 5.60 (dd, 1H, sugar, -CH-), 5.50 (d, 1H, sugar, -CH-), 5.30 (d, 1H, sugar, -CH-), 5.18 (dd, 1H, sugar, -CH-), 4.20 (m, 3H, sugar, -C*H*- and -CH_2OAc), 2.06 (m, 12H, -OAc). ^{13}C NMR (100 MHz, $CDCl_3$): δ 20.47, 20.56, 20.61, 61.26, 66.56, 68.06, 70.23, 71.76, 98.77, 115.76, 124.34, 125.75, 130.10, 143.28, 162.04, 169.29, 169.94, 170.03, 170.23, 187.02. ESI-MS: calcd *m*/*z* 497.4, found 498.8 $[M + H]^+$. Anal. Calcd for $C_{21}H_{23}NO_{13}$: C 50.71, H 4.66, N 2.82. Found: C 50.33, H 4.78, N 2.90.

*1-(2-Difluoromethyl-4-nitrophenyl)-2,3,4,6-tetraacetyl-β-D-galactopyranose (**4**).* Diethylaminosulfur trifluoride (DAST) (3.81 mL) was added to a solution of 1-(2-formyl-4-nitrophenyl)-2,3,4,6-tetraacetyl-β-D-galactopyranose (11.98 g, 24.08 mmol) in dry CH_2Cl_2 (300 mL). The reaction was stirred at ambient temperature under N_2 for 6.5 h. The reaction mixture was quenched by the addition of ice and extracted twice with CH_2Cl_2 (100 mL). The combined organic layers were washed successively with water and brine and dried over $MgSO_4$. The above solution was filtered and concentrated by rotary evaporation, which yielded a yellow crude compound. Purification by chromatography (silica, CH_2Cl_2) collected the first point and gave a yellow solid (11.82 g, 94.49%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.47 (dd, 1H, ArH), 8.32 (dd, 1H, ArH), 7.23 (d, 1H, ArH), 6.70–6.98 (t, 1H, -CF_2H), 5.56 (dd, 1H, sugar, -CH-), 5.50 (d, 1H, sugar, -CH-), 5.15(m, 2H, sugar, -CH-), 4.20 (m, 3H, sugar, -C*H*- and -CH_2OAc), 2.06 (m, 12H, -OAc). ^{13}C NMR (100 MHz, $CDCl_3$): δ 20.49, 20.56, 20.61, 30.88, 61.31, 66.58, 67.74, 70.18, 71.72, 99.25, 107.54, 109.91, 112.28, 114.91, 122.73, 122.77, 122.81, 122.86, 127.68, 143.07, 158.65, 158.72, 169.50, 169.95, 170.03, 170.23. ESI-MS: calcd *m*/*z* 519.4, found

520.0 $[M + H]^+$. Anal. Calcd for $C_{21}H_{23}F_2NO_{12}$: C 48.56, H 4.46, N 2.70. Found: C 48.36, H 4.55, N 2.71.

*1-(2-Difluoromethyl-4-aminophenyl)-2,3,4,6-tetraacetyl-β-D-galactopyranose (***5***).* Pd/C (10% Pd, 0.22 g) was added to a stirring solution of 1-(2-difluoromethyl-4-nitro-phenyl)-2,3,4,6-tetraacetyl-β-D-galactopyranose (11.23 g, 21.62 mmol) in ethyl acetate under 1.5 atm H_2. This step was repeated until the pressure stopped decreasing. Purification by chromatography (silica, CH_2Cl_2) can produce a yellow solid (8.98 g, 84.86%) and concentrated the pure compound in a vacuum. ^{1}H NMR (400 MHz, $CDCl_3$): δ 6.66–6.97 (m, 4H, ArH and -CF_2H), 5.45 (m, 2H, sugar, -CH_2-), 5.09 (dd, 1H, sugar, -CH-), 4.87 (d, 1H, sugar, -CH-), 4.24 (dd, 1H, sugar, -CH-), 4.16 (dd, 1H, sugar, -CH-), 4.02 (t, 1H, sugar, -CH-), 2.06 (m, 12H, -OAc). ^{13}C NMR (100 MHz, $CDCl_3$): δ 20.54, 20.61, 20.63, 61.31, 66.82, 68.34, 70.69, 71.01, 101.04, 108.75, 111.10, 112.51, 112.54, 112.58, 112.62, 113.45, 117.81, 118.35, 141.99, 169.60, 170.09, 170.21, 170.34. ESI-MS: calcd *m/z* 489.4, found 490.8 $[M + H]^+$. Anal. Calcd for $C_{21}H_{25}F_2NO_{10}$: C 51.54, H 5.15, N 2.86. Found: C 51.34, H 5.28, N 2.75.

*1-(2-Difluoromethyl-4-(1-bromoacetamido)phenyl)-2,3,4,6-tetraacetyl-β-D-galactopyranose (***6***).* 1-(2-Difluoromethyl-4-aminophenyl)-2,3,4,6-tetraacetyl-β-D-galactopyranose (8.94 g, 18.27 mmol) was dissolved in CH_2Cl_2 (60 mL) and treated with 40% dimethylamine (2.31 mL, 18.30 mmol). Bromoacetyl bromide (1.59 mL, 18.30 mmol) was dissolved in CH_2Cl_2 (40 mL) and dropped into the above solution in an ice bath overnight. Then, the reaction was treated with dilute HCl, dilute $NaHCO_3$ solution, and water. The organic solution was evaporated and washed with diethyl ether to give a pure white solid (3.61 g, 32.38%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.19 (s, 1H, ArH), 7.79 (d, 1H, ArH), 7.58 (s, 1H, -NH-), 7.13 (d, 1H, ArH), 6.98–6.70 (t, 1H, -CF_2H), 5.50 (m, 2H, sugar, -CH_2-), 5.12 (dd, 1H, sugar, -CH-), 5.01 (d, 1H, sugar, -CH-), 4.24 (dd, 1H, sugar, -CH-), 4.16 (dd, 1H, sugar, -CH-), 4.02 (t, 1H, sugar, -CH-), 4.03 (s, 2H, -CH_2Br), 2.06 (m, 12H, -OAc). ^{13}C NMR (100 MHz, $CDCl_3$): δ 20.55, 20.64, 20.67, 29.24, 61.37, 66.73, 68.04, 70.48, 71.27, 100.13, 108.31, 110.67, 113.02, 116.17, 118.26, 118.30, 118.34, 124.00, 132.55, 132.54, 163.51, 169.61, 170.06, 170.17, 170.34. ESI- MS: calcd *m/z* 610.4, found 611.7 $[M + H]^+$. Anal. Calcd for $C_{23}H_{26}BrF_2NO_{11}$: C 45.26, H 4.29, N 2.29. Found: C 45.02, H 4.44, N 2.36.

1-(2-Difluoromethyl-4-(1-(4,7,10-triscarboxymethyl-(1,4,7,10-tetraazacyclodecyl))-acetamido)phenyl)-β-D-galactopyranose (DOTA-FPG, **8***).* DO3A-tris-^{t}butyl ester (1.05 g, 2.04 mmol), KI (0.0354 g, 0.21 mmol), and triethylamine (0.545 mL, 3.93 mmol) were dissolved in CH_3CN (50 mL); 1-(2-difluoromethyl-4-(1-bromoacetamido)phenyl)-2,3,4,6-tetraacetyl-β-D-galactopyranose (1.18 g, 1.93 mmol) was added to the solution, and the mixture was stirred for 2 h. The synthesis of DO3A-tris-^{t}butyl ester was prepared by the previously published method. After 2 h, the mixture was warmed to 50 °C and stirred for 24 h. The solvent was removed by rotary evaporation. The acetyl group was removed by reaction with $NaOCH_3$ and dry CH_3OH (50 mL) for 2 h. Deprotection of *tert*-butyl ester group was achieved by stirring at room temperature in trifluoroacetic acid (TFA) (20 mL) for 12 h. After 12 h, the solution was quenched with water and adjusted to pH 11 with ammonium hydroxide. Next, this compound was purified by AG 1 × 8 anion exchange resin column (200–400 mesh, HCO_2^- form, eluted first with H_2O (2 L) and then with a gradient of formic acid) and then collected and concentrated 0.02–0.03 N formic acid solution to give major product. The trace of formic acid was removed by coevaporation with water (200 mL) five times, yielding 0.65 g (45.02%) of DOTA-FPG as a yellow viscous oil. ^{1}H NMR (400 MHz, D_2O): δ 7.61 (s, 1H, ArH), 7.48 (d, 1H, ArH), 7.18 (d, 1H, ArH), 7.03 (t, 1H, -CF_2H), 4.98 (d, 1H, sugar, -O-CH-O), 3.92 (d, 1H, sugar, -CH-), 3.61 (m, 9H, sugar and DOTA, -CH- and -CH_2-), 3.35 (s, 8H, DOTA, -N-CH_2-CO-), 3.02 (m, 12H, DOTA, -CH_2-). ^{13}C NMR (100 MHz, D_2O): δ 7.40, 22.43, 18.01, 48.16, 50.90, 51.32, 53.30, 55.25, 55.56, 56.40, 60.67, 61.31, 68.39, 70.37, 72.53, 75.46, 101.11, 109.43, 111.76, 114.10, 116.33, 117.48, 19.04, 120.53, 123.49, 123.71, 125.38, 125.81, 129.78, 130.94, 132.14, 151.37, 156.84, 169.85, 170.17, 174.33, 197.37. HRMS (FAB^+): *m/z* 708.0 $[M + H]^+$. Anal. Calcd for $C_{29}H_{43}F_2N_5O_{13}$: C 49.22, H 6.12, N 9.90. Found: C 49.42, H 6.08, N 9.95.

Preparation of Lanthanide Complexes. The Gd(III) and Eu(III) complexes were prepared by dissolving the DOTA-FPG (0.58 mmol) in H_2O (10 mL) and adjusting the pH of the solution to 6.5 with dilute NaOH. $LnCl_3$ (0.57 mmol, dissolved in 5 mL H_2O and brought to pH = 6.5 with NaOH) was added dropwise, maintaining pH at 5.5–6.0 with dilute NaOH periodically. The mixture solution was stirred at room temperature. After 2–3 days, the pH showed no change and the formation of Ln(III) chelate was considered complete. The pH was brought to 8.0, and the solution was centrifuged to remove excess lanthanide ions as $Ln(OH)_3$ and verified by the xylenol orange test. The trace $Ln(OH)_3$ was removed by filtration through a 200 nm nylon filter, and the solution was then evaporated under reduced pressure. The purity of [Gd(DOTA-FPG)(H_2O)] and [Eu(DOTA-FPG)(H_2O)] was determined by HPLC and identified by mass. The HPLC chromatograms of these complexes were deposited as Supporting Information (Figures 1S–2S).

Reversed-Phase High-Performance Liquid Chromatography (HPLC) Method. The HPLC experiments were performed on an Amersham ÄKTAbasic 10 instrument equipped with an Amersham UV-900 detector and Amersham Frac-920 fraction collector. Supelco RP-C18 column (5 μm, 4.6 × 250 mm; and 5 μm, 10 × 250 mm) were used.

^{17}O NMR Measurements. For the variable-temperature ^{17}O NMR measurements of [Gd(DOTA-FPG)(H_2O)], [Gd(DOTA-FP)(H_2O)], and [Gd(DOTA-FP)(H_2O)]-HSA, the components and pH values of the utilized solutions were as follows: 20 mM [Gd(DOTA-FPG)(H_2O)] in 100 mM sodium phosphate buffer solution, 5.5% ^{17}O isotope, pH = 7.4; 20 mM [Gd(DOTA-FPG)(H_2O)] in 100 mM sodium phosphate buffer solution, 2 μM β-galactosidase, 5.5% ^{17}O isotope, pH = 7.4; 20 mM [Gd(DOTA-FPG)(H_2O)] in 100 mM sodium phosphate buffer solution, 2 μM β-galactosidase, 4.5% (w/v) human serum albumin (HSA), 5.5% ^{17}O isotope, pH = 7.4. The measurement of the ^{17}O longitudinal, transverse relaxation rates and chemical shift were carried out with a Varian Gemini-400 (9.4 T, 54.2 MHz) spectrometer equipped with a 10 mm probe using an external D_2O lock. The Varian 600 temperature control unit was used to stabilize the temperature in the range 278–323 K. The samples were sealed in glass spheres adapted into 10 mm NMR tubes to eliminate susceptibility corrections to the chemical shift.

Data Analysis. The simultaneous least-squares fitting of ^{17}O NMR data was determined by fitting the experimental data using the program *SCIENTIST* for WINDOWS by Micromath, version 2.0.

MR Experiments. Relaxation Time Measurement. The longitudinal relaxation times (T_1) in different buffer solutions of Gd(III) complex were measured to determine relaxivity (r_1). The measurements were made using a NMR relaxometer operating at 20 MHz and 37.0 ± 0.1 °C (NMR-120 Minispec, Bruker). Before each measurement, the relaxometer was tuned and calibrated. The values of r_1 were determined from five data points generated by an inversion–recovery pulse sequence. To study the effect of β-galactosidase enzyme on the r_1 value of [Gd(DOTA-FPG)(H_2O)] solutions, β-galactosidase isolated from *Escherichia coli* was used. The *Escherichia coli* enzyme was reconstituted with 0.1 M sodium phosphate buffer, pH = 7.4 at

25.0 ± 0.1 °C, and proved its activity with *p*-nitrophenyl-β-D-galactopyranoside (PNPG). For the longitudinal relaxation time (T_1) measurements of [Gd(DOTA-FPG)(H_2O)] in the presence and absence of β-galactosidase and HSA, the components of the utilized solutions were as follows: (a) 0.5 mM [Gd(DOTA-FPG)(H_2O)] in 100 mM sodium phosphate buffer solution; (b) 0.5 mM [Gd(DOTA-FPG)(H_2O)] and 2 μM β-galactosidase in 100 mM sodium phosphate buffer solution; (c) 0.5 mM [Gd(DOTA-FPG)(H_2O)] and 0.5 mM HSA in 100 mM sodium phosphate buffer solution; (d) 0.5 mM [Gd(DOTA-FPG)(H_2O)], 0.5 mM HSA and 2 μM β-galactosidase in 100 mM sodium phosphate buffer solution. The percentage change of T_1 value in these solutions was plotted against the incubation time. These measurements were made in triplicate to reduce systematic error in the relaxation time (T_1) measurements.

Cells and Animal Model. CT26 colon carcinoma cells were obtained from American type Culture Collection (Manassas, VA). Recombinant β-galactosidase retrovirus was packaged by cotransfection of pVSVG with pLNCX-LacZ into GP2-293 cells (Clontech, BD Biosciences, USA). After 48 h, the culture medium was filtered, mixed with 8 μg/mL polybrene, and added to CT26 colon carcinoma cells. The cells were selected in G418 and reclone to generate CT26/β-gal cells. Cells were grown in Dulbecco's Minimal Essential Medium (Sigma, St Louis, MO, USA) supplemented with 10% heat-inactivated bovine calf serum, 100 units/mL penicillin and 100 μg/mL streptomycin at 37 °C in an atmosphere of 5% CO_2. 6–8 week old female Balb/c mice were purchased from National Laboratory Animal Center, Taipei, Taiwan. Animal experiments were performed in accordance with institutional guidelines.

The CT26 and CT26/β-gal tumors were conducted with three Balb/c mice via subcutaneous injection of 100 μl (10^6 cells) phosphate buffer solution suspension into the right or left shoulder regions of mouse. The CT26 and CT26/β-gal tumors took one to three weeks to reach a predetermined size. The experiment was performed three weeks after implantation, at which time the tumors measured at least 0.5 cm in diameter.

Functional β-galactosidase in Vitro. Functional expression of β-galactosidase in cells was measured by staining CT26 or CT26/β-gal cells with β-galactosidase activity by the β-Gal Staining Kit according to the manufacturer's instructions. Cells were grown in 6 well plates and fixed with 3 mL fixation solution at room temperature for 10 min. The plate was washed twice with phosphate buffer solution, and 2 mL staining solution (1 mg/mL X-gal) was added at room temperature until the cell stained blue. Cells were examined on an upright microscope (Olympus BX41, Japan).

Cytotoxicity of Gd(III) Chelate. CT-26 cells were seeded overnight in 96-well plates. Graded concentrations of [Gd-(DOTA-FPG)(H_2O)] were added into CT-26 cells in the presence and absence β-galactosidase (2 μg/well) in triplicate for 24 h at 37 °C. The cells were subsequently incubated for 48 h in fresh medium. Cell viability was determined by the ^{3}H-thymidine incorporation assay. Cells were harvested with a filtermate apparatus and incorporated radioactivity was determined on a Top-Count scintillation counter. Results are expressed as percent inhibition of ^{3}H-thymidine incorporation as compared to untreated cells by the following formula:

$$\% \text{ inhibition} = (\text{cpm}_{\text{sample}} - \text{cpm}_{\text{background}})/(\text{cpm}_{\text{control}} - \text{cpm}_{\text{background}}) \times 100$$

Histological Analysis of Functional β-galactosidase in Vivo. CT26 and CT26/β-gal tumors were excised and embedded in Tissue-Tek OCT in liquid nitrogen and sectioned into 10 μm slices. The tumor sections were stained for β-galactosidase activity by the β-Gal Staining Kit as described above and counterstained with nuclear fast red. All sections were examined under phase contrast microscope.

In Vitro MR Studies of [Gd(DOTA-FPG)(H_2O)]. For the MR images of [Gd(DOTA-FPG)(H_2O)] and its enzymatic cleavage, the components and pH values of the utilized solutions were as follows: (a) 0.8 mM [Gd(DOTA-FPG)(H_2O)], 2 μM β-galactosidase, and 0.8 mM HSA in 100 mM sodium phosphate buffer solution pH = 7.4; (b) 0.8 mM [Gd(DOTA-FPG)(H_2O)] and 0.8 mM HSA in 100 mM sodium phosphate buffer solution pH = 7.4; (c) 0.8 mM [Gd(DOTA-FPG)(H_2O)] in 100 mM sodium phosphate buffer solution pH = 7.4; (d) 0.8 mM [Gd(DOTA-FPG)(H_2O)] and 2 μM β-galactosidase in 100 mM sodium phosphate buffer solution pH = 7.4; (e) sodium phosphate buffer solution. The solutions were transferred to 1.5 mL test tubes for MR imaging. MR imaging was performed with a clinical 1.5T superconductive MR scanner (Gyroscan ACS-NT; Philips Medical Systems, Best, The Netherlands) and a knee coil. MR pulse sequence included T1-weighted (TR/TE 100/10 ms) two-dimensional spin–echo sequence. Mean signal intensities for the test tubes were measured in the central section of the imaging volume with use of operator-defined regions of interest with a minimum of 10 pixels per region. To compare differences in SI data among various test tubes, analysis of variance for repeated measurements was used. Mean data were compared with the Scheffe test. A P value of less than 0.05 was considered to indicate a statistically significant difference.

In Vivo MR Studies of [Gd(DOTA-FPG)(H_2O)] for Animal Model. The Balb/c mice ($n = 3$) established CT26 and CT26/β-gal tumors in the left and right shoulder regions, respectively, were anesthetized with 40–50 mg/kg intraperitoneal sodium pentobarbital. The mouse was then placed in an animal coil. MR imaging was performed using a clinical 3.0 T superconductive MR scanner (Signa; GE Medical Systems, Milwaukee, WI). T1-weighted (TR/TE 100/13 ms) transaxial images were obtained before and after intravenous injection of 0.3 mmol/kg [Gd(DOTA-FPG)(H_2O)]. The following parameters were used: two excitation, slice thickness = 3 mm, matrix = 256 × 224, field of view = 8 cm, one signal acquisition, and imaging time = 1.6 min. Postcontrast scans were obtained every 5 min for half an hour.

RESULTS

Synthesis of the Ligand. The starting material 2,3,4,6-aceto-α-D-bromogalactopyranose was synthesized by methods in the literature (*4*). The ligand DOTA-FPG was prepared as follows. First, 2-hydroxy-5-nitrobenzaldehyde was successfully alkylated on the hydroxyl group with 2,3,4,6-aceto-α-D-bromogalactopyranose. Second, the aldehyde group was fluorinated, and the nitro group was hydrogenated to the amino group. Then, the bromoacetyl group was used as a linker to bind DO3A-tris-^{t}butyl ester and 2-difluoromethylphenyl-β-galactopyranose. Finally, the ligand DOTA-FPG underwent hydrolysis with $NaOCH_3$ and TFA. The ligand DOTA-FPG was analyzed by HPLC and showed one peak, which was identified by ESI-MS to confirm its purity. The HPLC chromatogram of this ligand is deposited as Supporting Information (Figure 3S).

Luminescence Method for Establishing Solution Hydration States. Luminescence lifetime data have been obtained for the complex [Eu(DOTA-FPG)(H_2O)] to determine the number of inner-sphere water molecules in the aqueous solution (*16–18*). The luminescence lifetime (τ) has been determined in both H_2O and D_2O ($\tau_{H_2O} = 0.590$ ms and $\tau_{D_2O} = 1.90$ ms). The [Eu(DOTA-FPG)(H_2O)] complexes containing 1.23 and 1.10 inner-sphere water (Table 1) were calculated by eqs 1 and 2 as follows

$$q = 1.05[\tau_{H_2O}^{-1} - \tau_{D_2O}^{-1}] \quad (1)$$

$$q = 1.2\,[(\tau_{H_2O}^{-1} - \tau_{D_2O}^{-1}) - 0.25] \quad (2)$$

Table 1. Relaxivity r_1 of [Gd(DOTA-FPG)(H_2O)], [Gd(DOTA-FPG)(H_2O)]/β-gal, [Gd(DOTA-FPG)(H_2O)]/HSA, [Gd(DOTA-FPG)(H_2O)]/β-gal + HSA, [Gd(HP-DO3A)(H_2O)], [Gd(DOTA)(H_2O)]$^-$, and [Gd(DTPA)(H_2O)]$^{2-}$ in 100 mM sodium phosphate buffer solution at 37.0 ± 0.1 °C and 20 MHz

complex	pH	relaxivity r_1/mM^{-1} s^{-1}
[Gd(DOTA-FPG)(H_2O)]	7.4 ± 0.1	3.96 ± 0.04
[Gd(DOTA-FPG)(H_2O)]/β-gal [a]	7.4 ± 0.1	3.77 ± 0.09
[Gd(DOTA-FPG)(H_2O)]/HSA [b]	7.4 ± 0.1	7.58 ± 0.06
[Gd(DOTA-FPG)(H_2O)]/β-gal + HSA [c]	7.4 ± 0.1	15.5 ± 0.2
[Gd(HP-DO3A)(H_2O)][d]	7.5 ± 0.1	3.65

[Gd(DTPA)(H_2O)]$^{2-}$[f]	7.6 ± 0.1	3.89 ± 0.03

[a] [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase (2 μM). [b] [Gd(DOTA-FPG)(H_2O)] in the presence of human serum albumin (HSA) (0.5 mM). [c] [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase (2 μM) and human serum albumin (HSA) (0.5 mM). [d] Data obtained from ref (*23*). [e] ref (*22*). [f] ref (*24*).

where q is the number of water molecules bound to metal ions, τ_{H_2O} is the luminescence half-life in H_2O solution and τ_{D_2O} is the luminescence half-life in D_2O solution. The q value is obtained from the luminescence study.

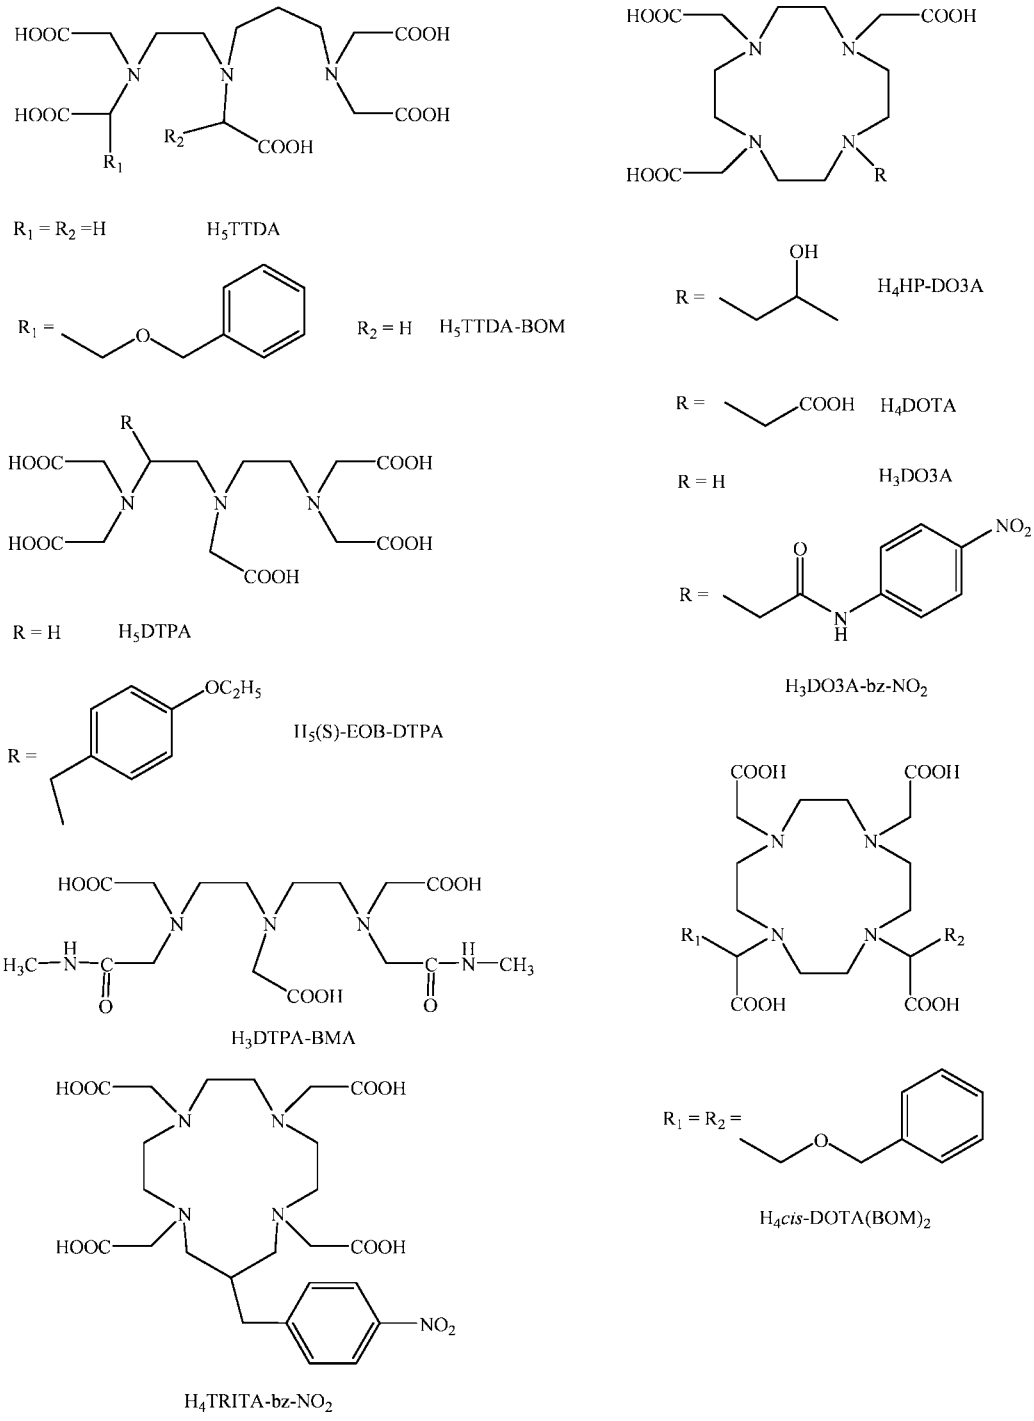
Relaxometric Studies of the Gd(III) Complex. The longitudinal water proton relaxivity (r_{1p}) results from the contribution arising from water molecules in the inner and outer coordination spheres as in eq 3

$$r_{1p} = R_{1p}^{is} + R_{1p}^{os} \quad (3)$$

The outer sphere term, R_{1p}^{os} , describes the contribution arising from the water molecules diffusing near the paramagnetic chelate (*19*). For compounds of similar size, it can be assumed that the outer-sphere mechanism makes a similar contribution at high magnetic flux densities (>0.1 T). Therefore, the small differences in relaxivity can be ascribed to differences in R_{1p}^{is} . The contribution arising from the exchange of the water molecules directly coordinated to the paramagnetic metal ion is obtained by eq 4 as follows (*20, 21*)

$$R_{1p}^{is} = [C]q/[55.6(T_{1M} + \tau_M)] \quad (4)$$

where [*C*] represents the molar concentration of the gadolinium(III) complex, τ_{1M} is the longitudinal relaxation time of the inner-sphere water protons and τ_M is the residence lifetime of the bound water. The longitudinal relaxivity (r_1) value of [Gd(DOTA-FPG)(H_2O)] in the presence and absence of β-galactosidase and HSA compared with [Gd(DOTA)(H_2O)]$^-$ (*22*), [Gd(HP-DO3A)(H_2O)] (*23*) (H_3HP-DO3A = 1,4,7,10-tetraazacyclododecane-1-(2-hydroxylpropyl)-4,7,10-triacetic acid), and [Gd(DTPA)(H_2O)]$^{2-}$ (*24*) (the structural formula shown in Chart 1) are shown in Table 1. The relaxivity (r_1) of [Gd(DOTA-FPG)(H_2O)] is slightly higher than those of [Gd(DOTA)(H_2O)]$^-$, [Gd(HP-DO3A)(H_2O)], and [Gd(DTPA)(H_2O)]$^{2-}$. It is quite clear that introducing 2-difluoromethylphenyl-β-galactopyranoside into DOTA increases the relaxivity value. The relaxivity of [Gd(DOTA-FPG)(H_2O)]/β-gal is slightly lower than that of [Gd(DOTA-FPG)(H_2O)] because of the β-galactopyranoside residue removed from [Gd(DOTA-FPG)(H_2O)] by β-galactosidase. The relaxivity of [Gd(DOTA-FP)(H_2O)]/β-gal + HSA (15.5 ± 0.2 mM^{-1} s^{-1}) is about 4-fold higher than that of [Gd(DOTA-FPG)(H_2O)]. This is due to cleavage of [Gd(DOTA-FPG)(H_2O)] by β-galactosidase and subsequent conjugation to proteins to form the macromolecules [Gd(DOTA-FP)(H_2O)]-β-gal and [Gd(DOTA-FP)(H_2O)]-HSA.



The presence of proteins, small molecules, or ions in Gd(III) chelate solution can affect the relaxivity of the Gd(III) complex. Relaxivity (r_1) measurements obtained in solutions of varying species not only describe how the Gd(III) complex responds to that composition but also provide coordinate information occurring at the Gd(III) center. The native lysosomal environment of β-galactosidase is acidic, with maximum activity observed between pH 4 and 5. The relaxivity values of [Gd(DOTA-FPG)(H_2O)] in two different buffer solutions were thus measured at pH = 5.0. The [Gd(DOTA-FPG)(H_2O)] chelate under 10 mM pyridine and 100 mM sodium chloride buffer solution at pH = 5.0 has a relaxivity (r_1) of 3.88 ± 0.02 mM^{-1} s^{-1}. However, for this chelate in 100 mM acetate buffer solution at pH = 5.0, the r_1 value is 3.63 ± 0.01. The slight difference between these buffer solutions may be attributed to the coordinating ability of the buffer constituents. The coordinating ability of pyridine is weaker than that of acetate buffer (*7*). The r_1 values at pH = 5.0 in different buffer solutions are only slightly lower than that of sodium phosphate buffer solution at pH = 7.4, which indicates that [Gd(DOTA-FPG)(H_2O)] is still stable in a native lysosomal environment.

In this study, the [Gd(DOTA-FPG)(H_2O)] under the sodium phosphate buffer solution in the absence or presence of β-galactosidase and HSA, the longitudinal relaxation time (T_1) change percentage was investigated under different incubation times as shown in Figure 1. The relaxation time (T_1) of [Gd(DOTA-FPG)(H_2O)] under the sodium phosphate buffer solution maintains constant T_1 values over 45 min. This result implicates that the [Gd(DOTA-FPG)(H_2O)] chelate is cleaved by β-galactosidase to form macromolecules [Gd(DOTA-FP)(H_2O)]-β-gal and [Gd(DOTA-FP)(H_2O)]-HSA in the presence of β-galactosidase and HSA. The bound relaxivity (r_1^b) (25.0 mM^{-1} s^{-1}) for the noncovalent [Gd(DOTA-FPG)(H_2O)]/HSA adduct was also obtained by the proton relaxation enhancement method (*25, 26*) and ultrafiltration studies. (*27–29*) The studies of [Gd(DOTA-FPG)(H_2O)] noncovalently bound to HSA were deposited as Supporting Information (Figures S2–S4).

Proof of the Proposed Mechanism by LC/MS. In order to mimic HSA or enzyme proteins to bind to the Gd(III) chelate, L-lysine was used to prove this proposed mechanism. The HPLC chromatograms of (a) 1.0 mM [Gd(DOTA-FPG)(H_2O)] alone, (b) 1.0 mM [Gd(DOTA-FPG)(H_2O)] in the presence of 2 μM β-galactosidase, and (c) 1.0 mM [Gd(DOTA-FPG)(H_2O)] in the presence of 2 μM β-galactosidase and excess L-lysine in pH 7.4 Tris buffer were shown in Figure 2a–c, respectively. From Figure 2a, [Gd(DOTA-FPG)(H_2O)] was detected at 19.9 min and confirmed by LC-MS (ESI$^+$): calcd *m*/*z* 861.9, found *m*/*z* 862.6 [M + H]$^+$. A peak of [Gd(DOTA-FP)(H_2O)] at 24.6 min as shown in Figure 2b was obtained when [Gd(DOTA-FPG)(H_2O)] was incubated with β-galactosidase and was proven by LC-MS (ESI$^+$): calcd *m*/*z* 679.75, found *m*/*z* 680.22 [M + H]$^+$. From Figure 2c, a peak of [Gd(DOTA-FP)(H_2O)]-L-lysine was detected at 30.2 min and confirmed by LC-MS (ESI$^+$): calcd *m*/*z* 825.94, found *m*/*z* 827.28 [M + H]$^+$. These results indicate that [Gd(DOTA-FPG)(H_2O)] can bind generally to protein in the presence of β-galactosidase and HSA.

Water-Exchange Rate and Rotational Correlation Time Studies of Gd(III) Complexes. The experimental ^{17}O NMR data for [Gd(DOTA-FPG)(H_2O)] complex in the presence and absence of β-galactosidase and HSA is deposited as Supporting Information (Tables 1S–3S); that is, the ^{17}O NMR chemical shifts ($\Delta\omega$, longitudinal ($1/T_{1r}$) and transverse ($1/T_{2r}$) relaxation rates were analyzed simultaneously (eqs 1S–9S used in Supporting Information S1). The results are plotted in Figure 3 with the corresponding curve representing the results of the best fitting of the data according to the equations. As illustrated by Table 2, there are a large number of parameters influencing the data obtained by the different techniques. The ^{17}O NMR technique has the advantage that the outer-sphere contributions

Chart 1

to the relaxation rates are negligibly small, which is a consequence of the oxygen nucleus being closer to the paramagnetic center when bound to the inner-sphere.

Cytotoxicity of Gd(III) Chelate. The cytotoxicity of [Gd(DOTA-FPG)(H_2O)] was also investigated by incubating various concentrations of [Gd(DOTA-FPG)(H_2O)] with CT-26 cells. After 72 h, cell viability was examined by the ^{3}H-thymidine incorporation into cellular DNA. Figure 4 shown that the IC_{50} value of [Gd(DOTA-FPG)(H_2O)] to CT26 cells was larger than 100 μM, demonstrating that [Gd(DOTA-FPG)(H_2O)] displayed low-cytotoxicity to CT26 cells after β-galactosidase activation.

MR Imaging Studies of Enzymatic Activation of Gd(III) Chelate. The percentage change in r_1 generated by enzymatic conversion of [Gd(DOTA-FPG)(H_2O)] can be visualized by MR images. The MR images of [Gd(DOTA-FPG)(H_2O)] solution placed in 1.5 mL (11 mm $\times$ 39 mm) microtubes in the presence and absence of β-galactosidase and HSA were shown in Figure 5 ($p < 0.05$). The signal intensity values of the MR images for these Gd(III) complex solutions were also given in Figure 5, indicating that a high signal intensity of [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase and HSA was obtained.

Characterization of Functional β-Galactosidase in Vitro and in Vivo. To verify the enzymatic activity of the β-galactosidase in cells, CT26 and CT26/β-gal cells were stained with X-gal and the cells examined under a microscope as shown in Figure 6. The results indicated that CT26/β-gal cells, but not the parental CT26 cells, converted X-gal to a blue color, demonstrating that β-galactosidase on the CT26/

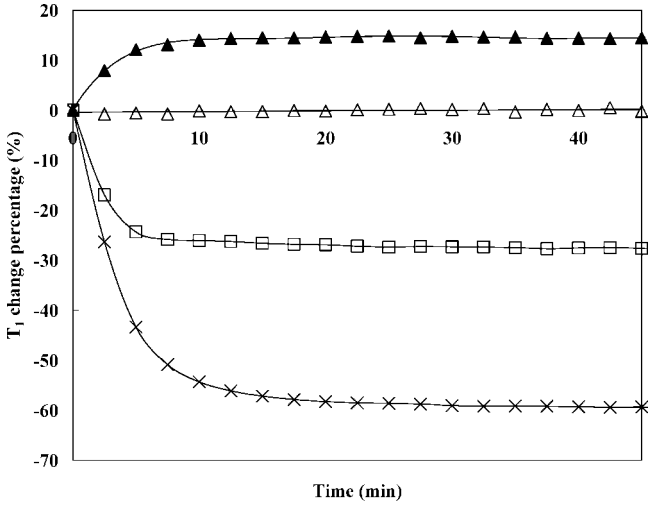


Figure 1. Change in T_1 (%) of enzyme-catalyzed hydrolysis of [Gd(DOTA-FPG)(H_2O)] measured at 20 MHz 37.0 ± 0.1 °C. (□) 0.5 mM [Gd(DOTA-FPG)(H_2O)] in 100 mM sodium phosphate buffer solution; (▲) 0.5 mM [Gd(DOTA-FPG)(H_2O)] and 2 μM β-galactosidase in 100 mM sodium phosphate buffer solution; (□) 0.5 mM [Gd(DOTA-FPG)(H_2O)] and 0.5 mM HSA in 100 mM sodium phosphate buffer solution; (□) 0.5 mM [Gd(DOTA-FPG)(H_2O)], 2 μM β-galactosidase, and 0.5 mM HSA in 100 mM sodium phosphate buffer solution.

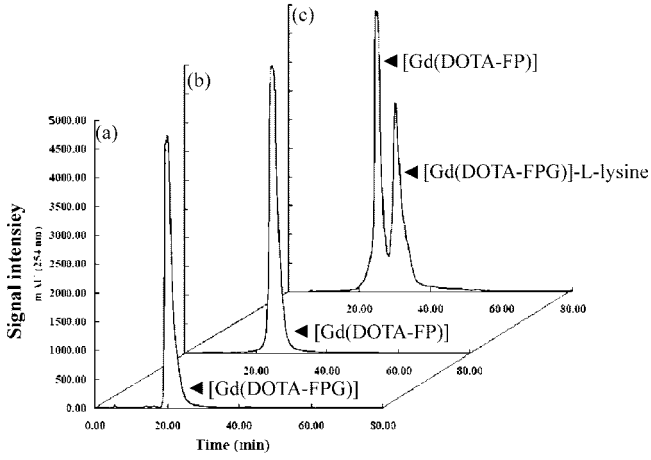

Figure 2. The HPLC chromatograms of [Gd(DOTA-FPG)] incubated with 2 μM β-galactosidase and bound to L-lysine. (a) 1.0 mM [Gd(DOTA-FPG)(H_2O)] alone, (b) 1.0 mM [Gd(DOTA-FPG)(H_2O)] in the presence of 2 μM β-galactosidase, and (c) 1.0 mM [Gd(DOTA-FPG)(H_2O)] in the presence of 2 μM β-galactosidase and excess L-lysine in pH 7.4 Tris buffer and 298 K. HPLC conditions: gradient of 100% to 0% water in CH_3OH as organic phase; flow rate 0.5 mL/min; wavelength set at 254 nm; reverse-phase C18 column used.

β-gal cells was functionally active. To investigate whether the β-galactosidase activity was still functionally active in vivo, the tumor sections were also stained with X-gal and the sections examined under a microscope as shown in Figure 7. Histological staining for β-galactosidase activity revealed a strong blue color in CT26/β-gal tumors but not in parental CT26 tumors. This result shows that β-galactosidase on the CT26/β-gal tumors was functionally active in vivo.

MR Images Studies in Vivo. To investigate whether sites of β-galactosidase expression could be noninvasively imaged, Balb/c mice bearing established CT26 and CT26/β-gal tumors in their left and right shoulder regions, respectively, were intravenously injected with 0.3 mmol/kg [Gd(DOTA-FPG)(H_2O)]. The MR images of the animal and time-signal intensity change of the tumor were shown in Figure 8, indicating that [Gd(DOTA-FPG)(H_2O)] can act as a MRI contrast agent for noninvasive imaging of gene expression in vivo.

DISCUSSION

As shown in Figure 1, the [Gd(DOTA-FPG)(H_2O)] complex is cleaved to form a smaller molecular weight [Gd(DOTA-FP)(H_2O)] under the sodium phosphate buffer solution at pH = 7.4 in the presence of β-galactosidase, and then conjugated to the β-galactosidase to form the macromolecule [Gd(DOTA-FP)(H_2O)]-β-galactosidase. However, there is only a small amount of cleaved [Gd(DOTA-FPG)(H_2O)] conjugated to β-galactosidase due to the concentration of β-galactosidase (2 μM) being significantly lower than that of [Gd(DOTA-FPG)(H_2O)] (0.5 mM). Thus, the percentage change in longitudinal relaxation time (T_1) increases about 15%. Furthermore, for the [Gd(DOTA-FPG)(H_2O)] in human serum albumin under sodium phosphate buffer solution at pH = 7.4 in the presence of β-galactosidase, the percentage change in longitudinal relaxation time (T_1) significantly decreased by about 60%. The reason is that [Gd(DOTA-FPG)(H_2O)] is cleaved to form a small molecule [Gd(DOTA-FP)(H_2O)], and then conjugated to β-galactosidase and human serum albumin to form the macromolecules [Gd(DOTA-FP)(H_2O)]-HSA and [Gd(DOTA-FP)(H_2O)]-β-galactosidase. Therefore, the relaxation time (T_1) is dramatically lower than those of the above two conditions. In comparison with the bioactivated contrast agent 4,7,10-tri(acetic acid)-1-(2-β-galactopyranosylethoxy)-1,4,7,10-tetraazacyclododecane gadolinium (Egad) (*4*) and gadolinium(III)-1-(4-(2-(1-(4,7,10-triscarboxymethyl-(1,4,7,10-tetraazacyclododecyl)))ethylcarbamoyloxymethyl)-2-nitrophenyl)-β-D-glucopyronuronate (*7*), the T_1 change percentages were 20% and 15%, respectively. Therefore, the T_1 change percentage of [Gd(DOTA-FPG)(H_2O)] is significantly higher than those of the above two bioactivated contrast agents. In addition, for the [Gd(DOTA-FPG)(H_2O)] and human serum albumin in sodium phosphate buffer solution at pH = 7.4 in the absence of β-galactosidase as a control experiment, longitudinal relaxation time is slightly decreased by about 25%, which is a result of the liphophilic [Gd(DOTA-FPG)(H_2O)] noncovalently bound to human serum albumin. The lower binding constant (K_A) (9.0 ± 0.1 × 10^2 M^{-1} and bound fraction (33.8%) of [Gd(DOTA-FPG)(H_2O)] to HSA were obtained by E and M titrations (*25, 26*) and used to explain the result of the percentage change in relaxation time (T_1) of [Gd(DOTA-FPG)(H_2O)] chelate in HSA without β-galactosidase decreasing by only 25%.

As shown in Table 2, the scalar coupling constant values of [Gd(DOTA-FPG)(H_2O)] only and [Gd(DOTA-FPG)(H_2O)] in the presence and absence of β-galactosidase and HSA, $A/\hbar$, are very similar to those obtained for other Gd(III) complexes (−3.4 × 10^6 and −3.8 × 10^6 rad s^{-1} for [Gd(DOTA)(H_2O)]$^-$ (*30*) and [Gd(DO3A-bz-NO_2)(H_2O)] (H_3DO3A-bz-NO_2 = 1-(4-nitrobenzyl)methylcarbamoyl-4,7,10-tri(acetic acid)tetraazacyclododecane) (*31*), respectively) with one inner-sphere water molecule. Over the whole temperature range, the transverse ^{17}O relaxation rates ($1/T_{2r}$) increase with increasing temperature, indicating that this system is in the slow exchange regime. However, there is degradation of the protein at temperatures higher than 50 °C for the [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase and [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase and HSA in ^{17}O NMR experiments. Therefore, the temperatures of these ^{17}O NMR experiments are in the range 278–323 K. $1/T_{2r}$ is determined by the relaxation rate of the coordinated water molecule ($1/T_{2m}$), which is influenced by the water residence lifetime ($\tau_M = 1/k_{ex}$), the longitudinal electronic relaxation rate ($1/T_{1e}$), and the scalar coupling constant ($A/\hbar$). The k_{ex}^{298} (2.54 × 10^6 s^{-1}) value of

[d] 20 mM [Gd(DOTA-FPG)(H_2O)] under 100 mM sodium phosphate buffer solution, 2 μM β-galactosidase, 4.5% (w/v) HSA, 5.5% ^{17}O isotope. [e] Data obtained from ref (*30*). [f] ref (*33*). [g] ref (*31*). [h] ref. (*32*).

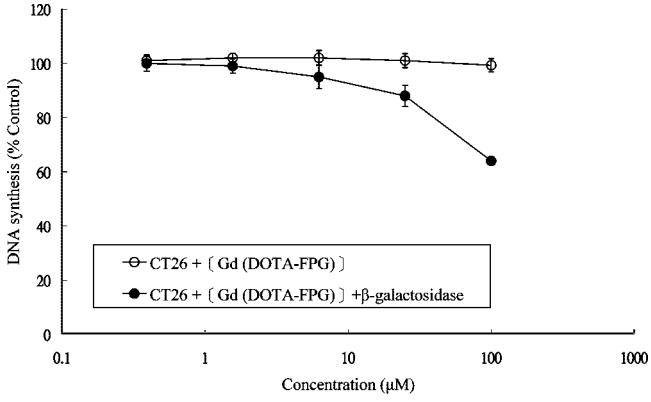

Figure 4. Cytotoxicity of [Gd(DOTA-FPG)(H_2O)] to CT26 cells. CT-26 (○) or CT-26 in the presence of β-galactosidase (•) was incubated with graded concentrations of [Gd(DOTA-FPG)(H_2O)]. Cellular DNA synthesis was measured 72 h later. Results represent the mean of results from three separate wells. Error bars show the standard error of the mean.

[Gd(DOTA-FPG)(H_2O)] is similar to those of [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase ([Gd(DOTA-FP)(H_2O)]) (1.32×10^6 s^{-1}) and [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase and HSA ([Gd(DOTA-FP)(H_2O)]-HSA) (1.64×10^6 s^{-1}) These k_{ex}^{298} values are also similar to those of the Gd(III) complexes with DO3A- and DTPA-monoamide derivatives ([Gd(DO3A-bz-NO_2)(H_2O)] (1.6×10^6 s^{-1}) (*31*) and [Gd(DTPA-*N*′-MA)(H_2O)]$^-$ (H_4DTPA-*N*′-MA = *N*-(methylcarbamoylmethyl)diethylenetriamine-*N*,*N*′,*N*-tetraacetic acid) (1.9×10^6 s^{-1}) (*32*).

As has been observed above, the water exchange rate decreases from [Gd(TRITA-bz-NO_2)(H_2O)]$^-$ (H_4TRITA-bz-NO_2 = 12-(*p*-nitrobenzyl)-1,4,7,10-tetraazacyclo-tridecane-1,4,7,10-tetraacetic acid) (120×10^6 s^{-1}) (*33*) to the [Gd(DOTA-FPG)(H_2O)] (2.54×10^6 s^{-1}) with one inner-sphere water molecule. This rate of decrease is accompanied by an increase in $\Delta H\ddagger$. Since the result for the Gd(III) complex with DOTA-FPG obeyed this trend, we conclude that water exchange on the [Gd(DOTA-FPG)(H_2O)] complex takes place most probably via a limiting dissociative D mechanism (*34*).

At 298 K, the τ_R^{298} value of [Gd(DOTA-FPG)(H_2O)] (228 ps) shown in Table 2 is significantly higher than that of [Gd(DOTA)(H_2O)]$^-$ (90 ps) (*30*) but is similar to [Gd(DO3A-bz-NO_2)(H_2O)] (210 ps) (*31*). It indicates that the introduction of the 2-difluoromethylphenyl-β-galactopyranoside in DOTA increases the τ_R^{298} value and causes the relatively high relaxivity of the [Gd(DOTA-FPG)(H_2O)] complex, compared to the previous results for [Gd(DOTA)(H_2O)]$^-$ and [Gd(HP-DO3A)(H_2O)]. A similar relationship between the τ_R^{298} value and the relaxivity (r_1) was observed in Gd(III) complexes with TTDA

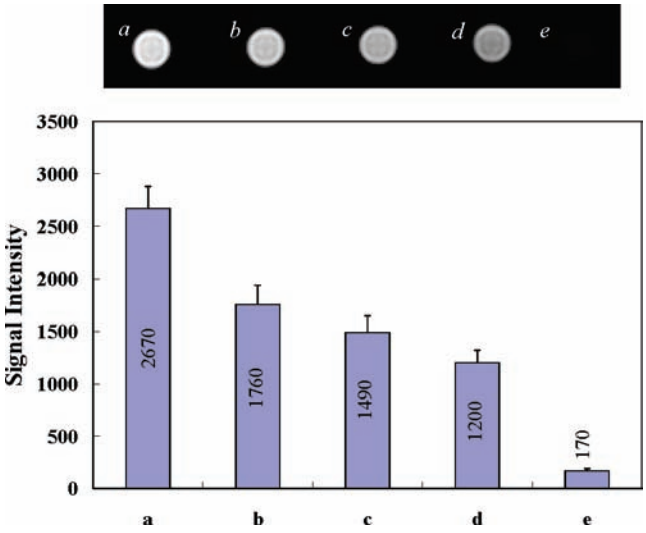

Figure 5. Representative T_1-weighted (TR/TE 100/10 ms) MR images of solutions and the signal intensity in test tubes at 1.5 T MR scanner: (a) sodium phosphate buffer solution with [Gd(DOTA-FPG)(H_2O)], β-galactosidase and HSA; (b) sodium phosphate buffer solution with [Gd(DOTA-FPG)(H_2O)] and HSA; (c) sodium phosphate buffer solution with [Gd(DOTA-FPG)(H_2O)]; (d) sodium phosphate buffer solution with [Gd(DOTA-FPG)(H_2O)] and β-galactosidase; (e) sodium phosphate buffer solution.

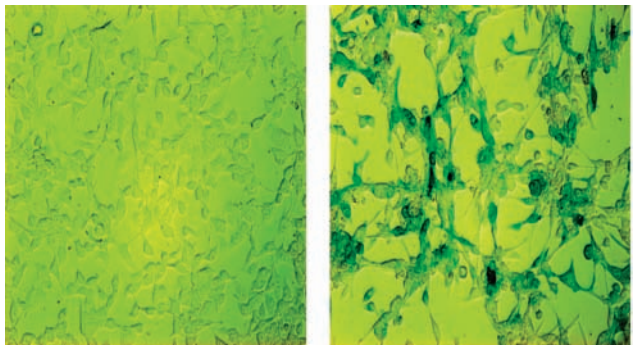

Figure 6. Cell display of functional β-galactosidase. CT26 cells (left) and CT26/β-gal cells (right) were stained with β-galactosidase activity by the β-Gal Staining Kit (1 mg/mL X-gal) before examination under an upright microscope.

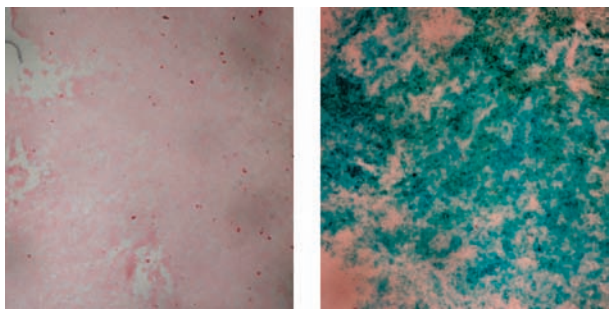

Figure 7. Histological analysis of functional β-galactosidase in vivo. Sections of CT26 (left) and CT26/β-gal (right) tumor were stained with β-galactosidase activity by the β-Gal Staining Kit and viewed under phase contrast microscope.

(H_5TTDA = 3,6,10-tri(carboxymethyl)-3,6,10-triazadodecanedioic acid) (*11*) and TTDA-BOM (H_5TTDA-BOM = 6-carboxymethyl-benzyloxymethyl-3,10-di(carboxymethyl)-3,6,10-triazadodecanedioic acid) (*12*). The attainment of high relaxivities can be expected when the molecular reorientational correlation time of the complexes is lengthened to the nanosecond range

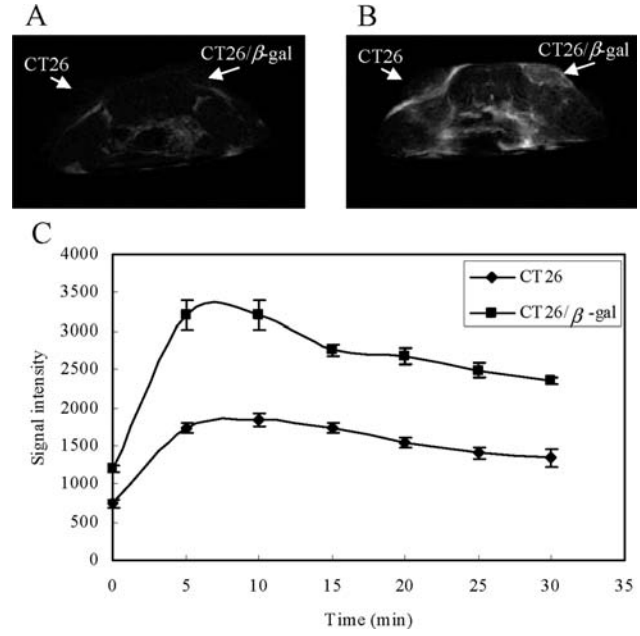

Figure 8. Representative T_1-weighted (TR/TE 100/13 ms) MR images of animal model at 3.0 T MR scanner: (A) precontrast images; (B) at 10 min after intravenous injection of 0.3 mmol/kg [Gd(DOTA-FPG)(H_2O)] intensity enhancement of CT26/β-gal tumor; (C) time-signal intensity change of the CT26 and CT26/β-gal tumors after injection of 0.3 mmol/kg [Gd(DOTA-FPG)(H_2O)].

(*25*). At 298 K, the τ_R^{298} value of [Gd(DOTA-FPG)(H_2O)] is higher than that of [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase, but is significantly lower than that of [Gd-(DOTA-FPG)(H_2O)] in the presence of β-galactosidase and HSA. These results can be employed to explain the percentage change in T_1 values of Gd(III) chelate increasing by 15% in the presence of β-galactosidase and decreasing by 60% in the presence of β-galactosidase and HSA.

The signal intensity of [Gd(DOTA-FPG)(H_2O)] only in 100 mM sodium phosphate buffer solution (1490 $\pm$ 160) is higher than that of [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase enzyme (1200 $\pm$ 120) (Figure 5) attributed to the molecular reorientational correlation time (τ_R^{298}) decreasing after the galactopyranoside residue was removed as shown in Table 2. The nucleophile of β-galactosidase attacks the Gd(III) chelate after the galactopyranoside residue is removed; however, the concentration of β-galactosidase is significantly lower than that of the Gd(III) complex. In addition, the signal intensity of [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase and HSA (2670 $\pm$ 210) is significantly higher than that of [Gd-(DOTA-FPG)(H_2O)] in the sodium phosphate buffer solution. The nucleophile of the higher molecular weight HSA (66.5 kDa) mainly attacks the Gd(III) chelate and the high relaxivity of the Gd(III) chelate conjugate is obtained. The T_1-mediated enhancement of [Gd(DOTA-FPG)(H_2O)] was altered by the action of β-galactosidase yielding the expected high signal intensity for MR imaging. These results are in agreement with the previous percentage change in relaxation time (T_1) decreasing by 60%. The [Gd(DOTA-FPG)(H_2O)] complex under the sodium phosphate buffer solution in the presence of HSA was conducted as a control experiment. The signal intensity of its MR imaging is slightly higher than that of [Gd(DOTA-FPG)(H_2O)] in sodium phosphate buffer solution but is significantly lower than that of [Gd(DOTA-FPG)(H_2O)] in the presence of HSA and β-galactosidase. Therefore, the expected high signal intensity of [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase and HSA obtained is attributed to HSA and β-galactosidase conjugated to Gd(III) chelate.

The signal intensity of the CT26/β-gal tumor (3210 ± 190) is significantly higher than CT26 tumor (1830 ± 80) ($p < 0.05$) at 10 min (Figure 8). This intense enhancement clearly indicates that [Gd(DOTA-FPG)(H_2O)] can be activated by CT26/β-gal tumors. These results are consistent with the previous percentage change in T_1 significantly decreasing in the presence of β-galactosidase and HSA. The main reason is attributed to its higher rotational correlation time (τ_R^{298}) of [Gd(DOTA-FP)(H_2O)]-HSA after the galactopyranoside residue is removed and conjugated to protein. Therefore, [Gd(DOTA-FPG)(H_2O)] may be a potential MRI contrast agent for imaging gene expression.

In conclusion, a novel bioactivated magnetic resonance imaging contrast agent containing galactopyranoside residue, [Gd(DOTA-FPG)(H_2O)], was designed and synthesized. The percentage change in longitudinal relaxation time (T_1) decreased to 60% of enzymatic cleavage of [Gd(DOTA-FPG)(H_2O)] in the presence of β-galactosidase and HSA. This indicates that the HSA and β-galactosidase conjugate to the Gd(III) chelate after the galactopyranoside residue is removed. A significant signal intensity enhanced by MR images was also observed for [Gd(DOTA-FPG)(H_2O)] solution in the presence of β-galactosidase and HSA. Moreover, the signal intensities of tumors with β-galactosidase gene expression are significantly higher than those of tumors without β-galactosidase gene expression in vivo. Therefore, [Gd(DOTA-FPG)(H_2O)] possesses enzymatic cleavage and a longer rotational correlation time, as well as higher percentage change in relaxation time (T_1) and higher signal intensity of the MR image in the presence of β-galactosidase and protein. This might result in a new type of contrast agent to trace gene expression by MRI.

ACKNOWLEDGMENT

We are grateful to the National Science Council of the Republic of China for financial support under Contract Nos. NSC 95-2627-M-037-001 and NSC 95-2623-7-037-001-NU. This research was also supported in part by grants from National Health Research Institutes under Contract No. NHRI-EX-95-9424EI.

Supporting Information Available: Additional experimental data and spectra as outlined in the text. This material is available free of charge via the Internet at http://pubs.acs.org.

Solid-Phase PEGylation of Recombinant Interferon α-2a for Site-Specific Modification: Process Performance, Characterization, and *in Vitro* Bioactivity

Byung Kook Lee,[†] Jin Sook Kwon,[†] Hyung Jin Kim,[†] Shuichi Yamamoto,[‡] and E. K. Lee*,[†]

Bioprocessing Research Laboratory, Department of Chemical Engineering, Hanyang University, Ansan, Korea 426-791, and Department of Chemical Engineering, Yamaguchi University, Tokiwadai, Ube 755-8611, Japan. Received August 7, 2006; Revised Manuscript Received August 1, 2007

'Solid-phase' PEGylation, in which a conjugation reaction attaches proteins to a solid matrix, has distinct advantages over the conventional, solution-phase process. We report a case study in which recombinant interferon (rhIFN) α-2a was adsorbed to a cation-exchange resin and PEGylated at the N-terminus by 5, 10, and 20 kDa mPEG aldehydes through reductive alkylation. After PEGylation, a salt gradient elution efficiently purified the mono-PEGylate of unwanted species such as unmodified IFN and unreacted PEG. Mono-PEGylation and purification were integrated into a single, chromatographic step. Depending on the molecular weight of the mPEG aldehyde, the mono-PEGylation yield ranged from 50 to 65%. Major problems associated with the solution-phase process such as random or uncontrollable multi-PEGylation and post-PEGylation purification difficulties were overcome. N-terminus sequencing and MALDI-TOF mass spectrophometry confirmed that the PEG molecule was conjugated only to the N-terminus. A cell proliferation study indicated reduced antiviral activity of the mono-PEGylate compared to that of the unmodified IFN. As higher molecular weight PEG was conjugated, *in vitro* bioactivity and antibody binding activity, as measured by a surface plasmon resonance biosensor, decreased. Nevertheless, trypsin resistance and thermal stability were considerably improved .

INTRODUCITON

Recombinant interferon (rh-INF) α-2a was developed as an antiviral immunostimulator and is clinically used for the treatment of chronic hepatitis B and C as well as cancers, such as Kaposi's sarcoma and hairy-cell leukemia (*1*). Several disadvantages of parenteral administration include frequent injections, that is, 3 times a week, because of a short lifetime in blood circulation (*2–4*), high immunogenicity causing fever, vomiting, and so forth (*5, 6*), and poor solution stability causing a significant drop in *in vitro* bioactivity (*7–9*). To overcome these drawbacks, the cytokine surface is chemically modified by conjugation with a water-soluble synthetic polymer, poly-(ethylene glycol) (PEG). The improvements in half-life by PEGylation are well documented (*10, 11*) and PEGylated interferon-α is currently on the market (e.g., PEGASYS, PEG-Intron[c]).

PEGylation is a reaction between a functional group of an activated PEG molecule and specific amino acid residues, such as lysine, on a protein surface. Frequently, PEGylation results in nonsite-specificity and multiple attachments, which might mask or interfere with the receptor binding sites, causing a dramatic decrease in *in vitro* bioactivity (*12–14*). To solve this problem, site-specific PEGylation has been employed. Specifically, reductive alkylation of the N-terminus amine was achieved by conjugating a methoxy PEG (mPEG) molecule under acidic conditions (*15–17*) and was reported to maintain bioactivity (*18*). However, the current practice of reductive alkylation occurs in the solution phase, and three to four purification steps are required to remove undesired species, such as the reducing agent, unreacted PEG, and multi-PEGylates (*19*).

In this study, we propose solid-phase PEGylation for the modification of interferon α-2a. Monkarsh et al. used CM-52 cellulose resin for the solid-phase PEGylation of interferon α-2a to generate various positional isomers of interferon α-2a mono-PEGylates (*20*). PEGylation with pyridyl PEG was performed at a high pH, and site-specificity was not achieved. In our study, the protein is first adsorbed to the surface of an ion exchange matrix through electrostatic interactions. mPEG aldehyde with different molecular weights (MW 5, 10, and 20 kDa) were introduced at an acidic pH to a reducing agent. The mPEG reacts primarily with the α-amine at the N-terminus for reductive alkylation. The process is called solid-phase PEGylation because the protein is PEGylated while attached to a solid phase, and only the desired PEGylate can be eluted from the matrix with the proper technique. This process reproducibly yielded N-terminus mono-PEGylate (*21, 22*). Various characterization methods, such as Edman degradation, trypsin-digested peptide mapping, and MALDI-TOF, were used to confirm mono-PEGylation. Two-dimensional (2-D) electrophoresis was performed to investigate the changes in molecular weight and the isoelectric point of the mono-PEGylate. Cationic exchange chromatography was used to reveal the separation behavior of the unmodified and mono-PEGylated proteins. Gel permeation chromatography (GPC) was used to recover the mono-PEGylate in a purified form. Antiviral activities were evaluated by cell proliferation, and immunoreactivity was assessed by antibody binding activity using a surface plasmon resonance biosensor. In addition, antitrypsin and thermal stability were evaluated.

MATERIALS AND METHODS

Materials. Purified rhIFN-α-2a was a gift from Korean GreenCross Corp. (YongIn, Korea). mPEG aldehydes of 5, 10, and 20 kDa (nominal MW) were purchased from Sun Bio, Inc. (Anyang, Korea). Sodium cyanoborohydride ($NaBH_3CN$) and other buffers of reagent grade were purchased from Sigma (St.

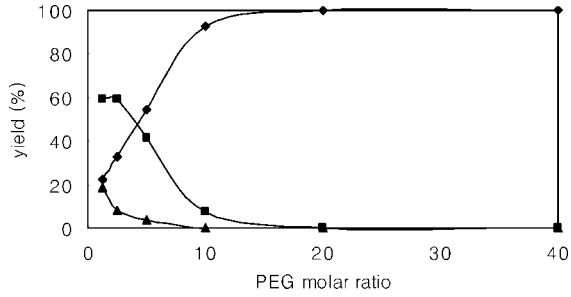

Figure 1. Solution phase PEGylation yield of multi-PEGylated (♦), mono-PEGylated (■), and unPEGylated IFN (▲) in 20 mM $NaBH_3CN$.

Louis, MO, U.S.A.) The chromatographic resins, CM-Sepharose and SP-Sepharose, for the solid-phase PEGylation, were purchased from Amersham Biosciences (Uppsala, Sweden). Bradford dyes and SDS–PAGE chemicals were from Bio-Rad, Inc. (Hercules, CA, U.S.A.) Superose 12HR 10/30 (Amersham Biosciences, Uppsala, Sweden) was used for GPC. Ettan IPGphor IEF system (Amersham Biosciences, Uppsala, Sweden) was used for 2-D electrophoresis.

Solution-Phase PEGylation of rhIFN-α-2a with mPEG Aldehydes. Solution-phase PEGylation of rhIFN-α-2a with 5 kDa mPEG-aldehyde was performed for 2 h at room temperature with 0.1 M sodium phosphate buffer (SPB, pH 4.0) in the presence of 20 mM $NaBH_3CN$. The PEG-to-protein molar ratio was 1.25, 2.5, 5, 10, and 20.

Solid-Phase PEGylation of rhIFN-α-2a with mPEG Aldehydes. The basic process was as follows: One milliliter of a 2 mg/mL solution of rhIFN-α-2a in 50 mM acetate buffer (pH 4.0) was fed at 1 mL/min through a CM-Sepharose Hi-Trap column (1 mL bed volume). The column was pre-equilibrated with 0.1 M SPB at pH 4.0. Unadsorbed IFN was removed with 6 mL of SPB at 1 mL/min. Fifteen milliliters of the mPEG aldehyde solution containing 20 times the IFN molar ratio and 25 mM $NaBH_3CN$ was circulated at 0.01 mL/min for 120 min. Ten milliliters of equilibrium buffer (0.1 M SPB, pH 4.0) was circulated to wash the unreacted mPEG. The PEGylate was eluted by applying a linear salt gradient from 0.1 M to 0.6 M of 1 M NaCl SPB from 5 to 40 min at a rate of 0.5 mL/min.

To calculate the PEGylation yield, the mono-PEGylate was collected from the appropriate fractions of the cation exchange and GPC. The protein content of the mono-PEGylate was analyzed by a Bradford assay.

The eluate mixture was further purified using a GPC column (approximately 23.6 mL bed volume). After 1 mL sample loading, the column was eluted with 0.1 M SPB (pH 4.0) at 0.4 mL/min.

2-D Electrophoresis. To measure the pI values of the PEGylate, 2-D electrophoresis was performed using an Ettan IPGphor (Amersham Biosciences, Uppsala, Sweden). Each sample was prepared to a protein concentration of 15–20 μg/mL, dialyzed to reduce the salt concentration below 10 mM, and freeze-dried. The protein was rehydrated in a buffer (8 M urea, 2% (w/w) CHAPS, 0.002% (w/v) bromophenol blue, and 50 mM dithiothreitol) at 20 °C for 12 h before feeding it to a 2-D electrophoresis strip (pH 3–10). For primary electrophoresis, a total of 32,000 V/h was applied. The 2-D electrophoresis strip was added to an equilibration buffer (50 mM tris-HCl, 6 M urea, 30% (v/v) glycerol, 2% (w/v) SDS, and 0.002% (w/v) bromophenol blue at pH 8.8) and equilibrated for 30 min before secondary electrophoresis. The gel was silver stained.

Analysis of N-Terminal Mono-PEGylation. The degree and site of PEGylation of the recovered fraction of mono-PEGylate from cation exchange and GPC were analyzed. First, the mass increase due to PEGylation was checked by mass analysis using a MALDI-TOF mass spectrometer. The samples were desalted with Poros R2 resins (Applied Biosystems, CA, U.S.A.) using a narrow GELoader tip (Eppendorf, Germany). One microliter of the PEGylate solution was mixed with 1 μL of the matrix solution (sinapinic acid saturated in 0.1% TFA/acetonitrile, 7:3). One microliter of the mixture was deposited on a MALDI target plate. Mass spectra of positively charged ions were recorded on a Bruker Ultraflex instrument (Bruker Daltonik, Germany) operated in linear mode, with a 337 nm nitrogen laser, 39 ns pulse duration, and 25 kV acceleration voltage (*18*).

The native and mono-PEGylate were exposed to tryptic digestion, and the peptide fragment containing the N-terminus (1313.6 Da) was identified from the database and the mass spectra of the native IFN digestion. Edman degradation was performed on the PEGylate to confirm that the modified N-terminus did not have a terminal amino acid, as the covalently modified amine was known to resist peptide cleavage by 1-fluoro-2,4-dinitrobenzene (FDNB).

Purity Analysis by RP-HPLC. A C4 RP-HPLC column (Phenomenox, Torrance, CA, U.S.A.) was used to separate the PEGylate from the unmodified protein and assess the purity. The equilibrium buffer was 0.1% trifluoracetic acid (TFA) in deionized water, and the elution buffer was 0.1% TFA in 80% acetonitrile. Twenty microliters of the sample was injected into the column, after which the equilibration buffer was circulated for 10 min at 1 mL/min. For elution, a mixture of the equilibrium buffer and the elution buffer was fed by applying a gradient from 0% to 100% of the elution buffer.

Far-UV Circular Dichloism Analysis. A spectropolarimeter (Model J-715, Jasco, Japan) was used to determine if the secondary protein structures were disrupted by the PEGylation reaction. The spectrum and excitation wavelength were 190–250 nm and 200–230 nm, respectively, and the path length was 0.5 mm.

Bioassays for Antiviral Activity and Immunoreactivity. Antiviral activity of the PEGylated IFN was compared to unmodified IFN by quantifying the surviving Madin–Darby bovine kidney (MDBK) cells after being infected with the vesicular stomatitis virus (VSV) (*23*, *24*). The molecules were compared by quantifying the binding activity of a monoclonal antibody (product # 21100-2, R&D Systems, Minneapolis, MN, U.S.A.) using a surface resonance plasmon (SPR) system (Biacore 3000, Biacore AB, Uppsala, Sweden) equipped with a CM5 chip. The antibody was immobilized on the chip as a ligand, and the binding with PEGylated IFN was compared to that of the control, unmodified IFN. The *in vitro* immunoassay based on the SPR technique was reported to provide reliable information on immunoreactivity (*25–27*).

Proteolytic and Thermal Stability Analysis. The in-serum stability of the IFN PEGylate was indirectly evaluated by comparing antitrypsin stability with unmodified IFN. Purified IFN PEGylate from the GPC eluate was freeze-dried. Trypsin from Promega, Inc. (Madison, WI, U.S.A.) was dissolved at 100 mg/mL in 50 mM ammonium bicarbonate buffer (pH 7.8). Freeze-dried IFN or IFN PEGylate was added to the trypsin solution at a mass ratio of 30:1 protein to trypsin. The mixture was incubated at 37 °C for 12 h. Samples were taken every 30 min, and 50 μL of 20% TFA was added to stop the trypsin reaction. The change in IFN peak height was measured. Assuming the reaction rate was a first-order reaction, the constant could be calculated and compared. Thermal stability was evaluated by monitoring the turbidity increase at 340 nm caused by thermal aggregation when the protein solution was exposed to 50 °C (*28*).

RESULTS AND DISCUSSION

Solution-Phase PEGylation. To compare with solid-phase PEGylation, solution-phase PEGylation experiments were per-

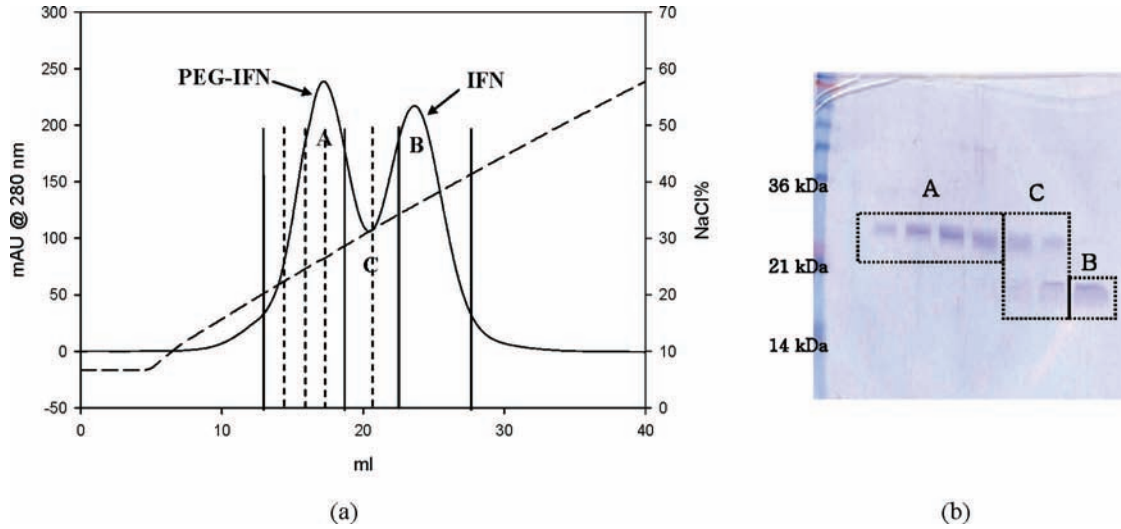

Figure 2. Elution chromatogram from CM-Sepharose. The column was eluted by feeding SPB containing 1 M NaCl at 0.5 mL/min with a salt gradient from 0.1 M to 0.6 M NaCl for 35 min.

formed at a pH of 4.0 for 2 h using 20 mM $NaBH_3BN$ as a reducing agent. The PEG-to-protein molar ratio was varied (1.25, 2.5, 5, 10, 20, and 40) to investigate its effect on the degree of PEGylation. The mono-PEGylate yield was determined by scanning PAGE with a densitometer, as shown in Figure 1. The multi-PEGylation yield increased at molar ratios higher than 10, such that nearly all of the PEGylates were multi-PEGylates. At a lower molar ratio (1.25 and 2.5), the mono-PEGylation yield was ca. 60%, and the multi-PEGylation was 20–30%. The mono-PEGylation decreased to nearly zero at a molar ratio of 20. The higher yield of multi-PEGylation and lower yield of mono-PEGylation would require more post-PEGylation purification steps. Monkarsh et al. performed solution-phase PEGylation at pH 10 at a molar ratio of 1 to obtain 11 isomers and used SP-HPLC to purify the isomers (*20*).

Solid-Phase PEGylation. The effects of resin and reaction pH on the mono-PEGylate yield were investigated with CM- and SP-Sepharose at pH 3.0, 3.5, 4.0, and 4.5. CM-Sepharose at pH 4.0 produced the highest PEGylation yield. In this condition, the effects of the PEG-to-protein molar ratio and the $NaBH_3CN$ concentration were studied by varying the molar ratio from 10, 20, 30, to 40, and the reductant concentration from 10, 20 to 40 mM. The best result was obtained at a 20:1 PEG-to-protein ratio at 20 mM $NaBH_3CN$ concentration (data not shown). As the reaction time increased, the PEGylate yield increased, and after 100 min, the reaction reached a plateau. To this end, the reaction time was set at 120 min for subsequent experiments.

Solid-Phase Mono-PEGylate and Separation Behavior. Figure 2 shows the elution profile from the CM-Sepharose column after PEGylation. Mono-PEGylated IFN predominantly eluted in the first peak (A) at 0.15–0.28 M NaCl and the unreacted, native IFN in the second peak (B) at 0.34–0.39 M NaCl. PEGylated IFN eluted earlier because of masking or shielding of the N-terminus amine group by PEGylation, resulting in the weakened interaction of the protein with the resin. Corroborating the results of Figure 2, Seely suggested the PEG-to-protein molar ratio of the PEGylates determined the elution order from an ion exchange column, regardless of cationic or anionic exchange type (*30*). Fee and Mason observed a significant change in pI after PEGylation (*32*). However, when the isoelectric points and molecular weights of the 5, 10, and 20 kDa mono-PEGylates were measured by 2-D electrophoresis, the PEGylation did not alter the pI value, only increased the molecular weights, as shown in Figure 3. The identical pI values

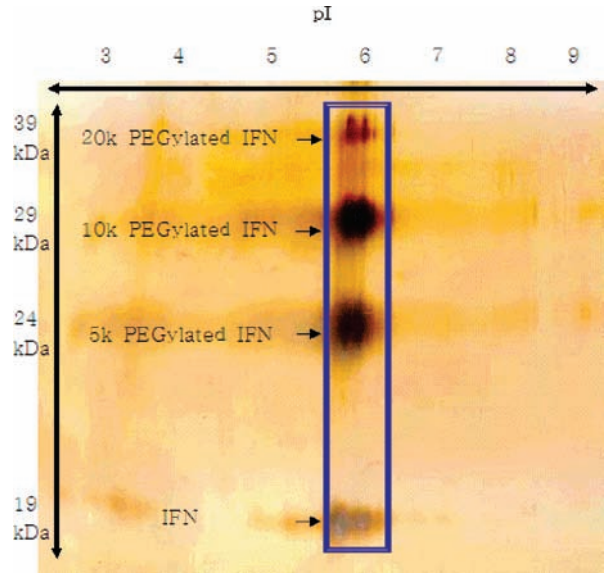

Figure 3. 2-D electrophoresis of the mono-PEGylated IFNs with 5, 10, and 20 kD mPEG aldehydes.

indicate identical electrostatic interactions with the cation exchange resin, resulting in the same column retention time. To this end, the retention time difference, shown in Figure 2, was likely due to the shielding effect by conjugated 5 kDa PEGs.

The separation between the two peaks was not definitive, requiring analysis of the overlapped fraction by GPC (Superose 12 HR). Figure 4 shows that the mono-PEGylate (with 5 kDa mPEG aldehyde) and unmodified IFN were nearly completely separated approximately 5 min apart in retention time. Furthermore, Figure 5 shows that the 10 and 20 kDa PEG PEGylates could also be well separated, suggesting that GPC could serve as a powerful separation step to recover the desired PEGylate (*33*). Figure 6 shows that the native and mono-PEGylate (with 5 kDa PEG) separated by RP-HPLC with C4 resin. The mono-PEGylate eluted after the native protein, indicating that the surface hydrophobicity increased by PEGylation. Additionally, circular dichloism analysis revealed that the secondary structure changed little by mono-PEGylation (data not shown).

Multi-PEGylation, often seen in solution-phase PEGylation, was avoided by solid-phase PEGylation for several different reasons. First, the reactivity of the lysine residues was sup-

pressed by the reductive alkylation condition (e.g., a low pH) (*12*). Second, certain lysine residues might be buried by the electrostatic interactions between the protein and the resin (*13*). Third, the frequency of protein contact with the PEG molecules was reduced because the protein was attached to a solid surface.

The reduced reactivity may be responsible for the relatively lower yield of solid-phase PEGylation. The mono-PEGylate yield in the recovered eluate was 62, 58, and 51% with 5, 10, and 20 kDa PEG, respectively (approximately 32% of the IFNs were not modified). However, Kinstler et al. achieved a 92% yield of N-terminus, mono-PEGylated rh-GCSF (granulocyte colony stimulating factor) by the solution-phase method using aldehyde PEG at an acidic pH for reductive alkylation (*17*). However, the yield with the rh-IFN (consensus) was about 66%, which was comparable to our data. Solid-phase PEGylation generated a small amount of multi-PEGylate (24%), and about 32% of the IFNs were not PEGylated.

The mono-PEGylate and the unmodified IFN could be easily separated, as shown in Figure 2, and the unmodified IFN could be recycled for an additional PEGylation to improve the yield. The geometrical interference of the CM-Sepharose resin micropores with the PEG molecules and the associated diffusional problems could be responsible for the lower yield, as witnessed by the increasing PEG molecular weight.

These results suggest that several potential advantages of solid-phase PEGylation could be realized. First, site-specific, mono-PEGylation was achieved. Second, impurity removal and isolation of the desired PEGylate was integrated into one unit operation. Third, the burden of post-PEGylation purification could be much reduced, as at least 3 to 4 purification steps were required to purify the desired PEGylate from solution-phase PEGylation (*34*).

Site Specificity of N-Terminus Mono-PEGylate. To verify the conjugation of single molecule of PEG to the N-terminus, we performed both mass spectrometry of the digests before and after PEGylation and Edman degradation of the N-terminus amino acid of the PEGylate. From the mass spectra of the PEGylate digests, we confirmed that the peptide fragment containing the N-terminus of the native digest disappeared and that a new peak emerged, reflecting the mass increase due to PEG conjugation (*29*). Figure 7 shows that the mass of the peptide fragment (1313 Da) increased by conjugated PEG molecular weight, that is, 6314 for 5 kDa of PEG, indicating that the PEG was indeed conjugated to the N-terminus. However, the MW of the PEGylated N-terminus peptide fragments showed broader peaks due to a wider PEG MW distribution than that of the nominal MW. In addition, the N-terminus sequencing by Edman degradation revealed that the N-terminus could not be degraded after four cycles (data not shown), as the covalently modified α-amine resisted peptide cleavage by FDNB because the N-terminus was conjugated by

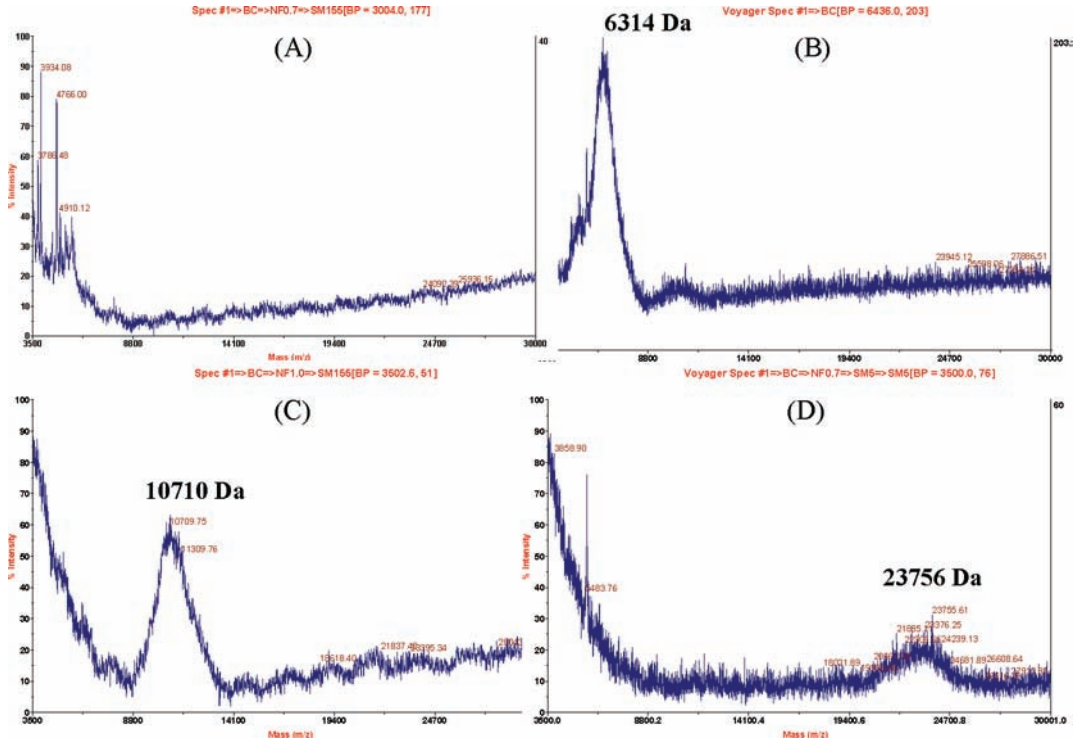

Figure 7. Mass spectra of (A) native IFN, (B) 5 kD mono-PEGylated IFN, (C) 10 kD mono-PEGylated IFN, and (D) 20 kD mono-PEGylated IFN peptide fragments containing N-termini.

Table 1. Biological Activity of IFN and PEGylated IFN

	mean biological activity (MIU/mg)	relative activity (%)	SD ($n = 5$)	CV (%)
IFN	201	100.0	19	9.5
5 kDa PEG-IFN	141	70.6	37	26
10 kDa PEG-IFN	110	55.3	38	26
20 kDa PEG-IFN	43	21.3	37	26

Table 2. Immunoreactivity of IFN and PEGylated IFN

	relative immunogenicity (%)	SD ($n = 4$)	CV (%)
IFN	100.0	1.51	0.01
5 kDa PEG-IFN	48.0	0.25	
10 kDa PEG-IFN	23.0	0.35	
20 kDa PEG-IFN	15.0	0.43	

PEG (*35*). The MS data combined with the Edman degradation results strongly indicated the attachment of a PEG molecule to the N-terminus.

When Monkarsh et al. performed solid-phase PEGylation on IFN α-2a (*20*), however, the PEGylation pH was 10, which would cause an amine coupling reaction for nonsite-specificity. As a result, Monkarsh et al. obtained 11 positional, isomeric mono-PEGylates. To obtain a single species of mono-PEGylate, multiple separation steps would be required. By using reductive alkylation at a lower pH, we were able to obtain a single species of mono-PEGylate and circumvent the multistep separation.

***In Vitro* Bioactivity Analysis of the Mono-PEGylated IFN.** It is well documented that the *in vitro* bioactivity of a protein decreases after PEGylation and decreases further as the PEG MW increases. We observed the same phenomenon with the IFN. As shown in Table 1, the antiviral activity of the mono-PEGylated IFN with 5, 10, and 20 kDa PEG was approximately 71%, 55%, and 21% of the native IFN, respectively. The significant loss of *in vitro* bioactivity could be outweighed by such pharmacokinetic benefits as improved stability (*30*).

Immunoreactivity of the PEGylates was indirectly evaluated by antibody binding activity. Table 2 shows that the immunoreactivity of the mono-PEGylated IFN with 5, 10, and 20 kDa PEG was approximately 48%, 23%, and 15% of the native IFN, respectively. Antibody binding activity corroborates the intrinsic *in vitro* bioactivity of the protein, which decreased in proportion to the MW of the conjugated PEG. It was previously reported that the monoclonal antibody epitope consists of three sites located between Leu 30 and Ile 53 (*16*, *17*). The antibody binding activity of the PEGylate could be significantly affected by the conjugation because of the location of the epitope near the N-terminus.

Stability Analysis of the Mono-PEGylated IFN. Most of the injected biopharmaceutical proteins are degraded in the blood stream from various serum proteases (*14*, *17*), and the protein stability could be significantly improved by PEGylation. In this study, we evaluated the enhanced stability of the mono-PEGylates by measuring and comparing trypsin resistance *in vitro*. Theoretically, there should be a difference in the amount of degradation between the native and mono-PEGylated IFNs because of PEG interference of the trypsin cleavage process (*17*). Assuming that the degradation follows first-order kinetics, the reaction rate constant was calculated to quantitatively assess the stability enhancement effect. Figure 8 shows the rate constant (k) decreasing from 0.82×10^{-2} min^{-1} to 0.50×10^{-2} min^{-1} upon mono-PEGylation with 5 kDa PEG. The stability could be further improved by conjugating a higher MW PEG with potentially improved stability in the blood stream (*36*).

Improvement of the mono-PEGylate thermal stability was evaluated by monitoring the aggregation decrease at 50 °C. As shown in Figure 9, the native IFN aggregated rapidly in 100 min, whereas the mono-PEGylates showed no aggregation for 240 min. The aggregation at an elevated temperature may be explained by reduced thermodynamic stability of the altered protein structures and an increased hydrophobic interaction from exposed hydrophobic patches. The conjugated PEG might swim around the hydrophobic patches to suppress hydrophobic interactions. This hydrophobic mechanism might be similar to

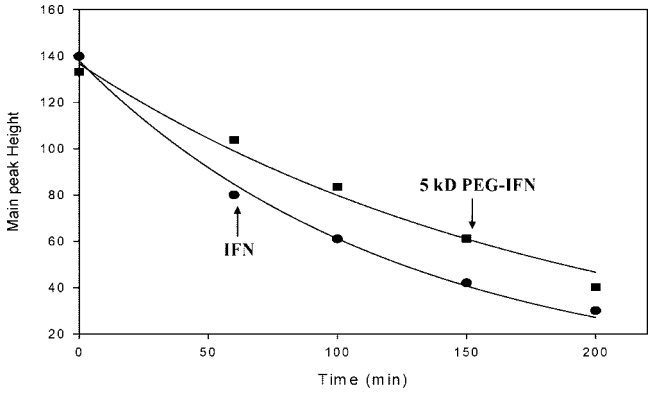

Figure 8. Time course profiles of trypsin digestion of native (●) and mono-PEGlated (■) IFNs.

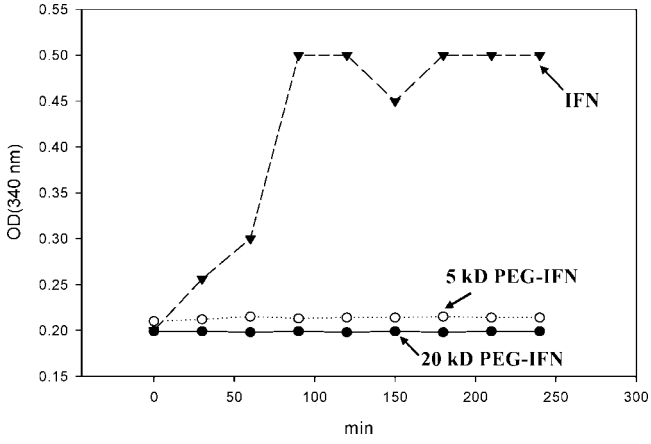

Figure 9. Thermal stability of the native (▼) and modified IFNs conjugated by 5 kD PEG (○) and 20 kD PEG (●).

hydrophobic interactions suppressing the aggregation of *in vitro* refolding enhancements (*31*). The effect of the conjugated PEG on the maintenance of protein structure is still not fully understood, though both antitrypsin and thermal stabilities were significantly improved by N-terminus mono-PEGylation.

CONCLUSIONS

To improve blood circulation stability and reduce immunoreactivity, rhIFN α-2a was modified with solid-phase conjugation of mPEG aldehyde and N-terminus amine. A cation-exchange resin, CM-Sepharose, was used as the solid matrix, and the mono-PEGylate was separated from the unmodified protein. It is suggested that the advantages of solid-phase PEGylation, such as site-specific PEGylation and primary isolation of the mono-PEGylate, can be achieved in a single unit operation. The site-specificity was confirmed by mass spectrometry of the peptide digests and also by N-terminus sequencing using Edman degradation. The mono-PEGylate exhibited reduced antiviral activity and immunoreactivity, and the degree of reduction was proportional to the MW of the conjugated mPEG. The trypsin resistance and thermal stability were significantly improved by mono-PEGylation. Compared to the conventional solution-phase process, solid-phase PEGylation has the potential to avoid multi-PEGylation and minimize post-PEGylation purification.

Synthesis and *in vitro* Behavior of Multivalent Cationic Lipopeptide for DNA Delivery and Release in HeLa Cells

Kewei Wang,[†] Xuehai Yan,[†] Yue Cui,[†] Qiang He,[†,‡] and Junbai Li*[,†]

Beijing National Laboratory for Molecular Sciences (BNLMS), International Joint Lab, CAS Key Lab of Colloid and Interface Science, Institute of Chemistry, Chinese Academy of Sciences, Beijing 100080, People's Republic of China, and Max Planck Institute of Colloids and Interfaces, Golm/Potsdam D-14476, Germany. Received October 8, 2006; Revised Manuscript Received August 7, 2007

We report here that a synthesized multivalent cationic lipopeptide can be used for the delivery and release of gene assembled into lipopeptide vesicles. It is found experimentally that the synthesized lipopeptide is safe for gene therapy because of its biocompatibility and the innocuity of the hydrolysis products, such as lipids and amino acids. The experimental results also show that the assembled DNA/lipopeptide complex has high transfection efficiency in HeLa cells compared to that of the selected commercial reagent, which represents a novel vector for the delivery of therapeutic DNA.

INTRODUCTION

Somatic gene therapy is becoming attractive in medical diagnosis and treatment of various inherited diseases and cancers (*1, 2*). The viral and synthetic vectors for gene delivery are the most common methods (*3–10*), with viral vectors being remarkably efficient in transfecting mammalian cells. These methods have the disadvantage of a lack of biosafety (*11–13*), with recent clinical trials showing that the viral vectors cause a severe inflammatory response and insertional mutagenesis (*14, 15*). Synthetic cationic lipids are attracting considerable attention as gene vectors because of their biosafety and other inherent advantages over viral vectors. Pioneering research indicates that synthetic vectors have the advantage of ease and variability of preparation, lack of immunogenicity, and a capacity to deliver large pieces of DNA, thus allowing for the delivery of artificial chromosomes (*16–18*).

The design of safe and effective gene transfection reagents is still a challenge in gene therapy. Gene transfection with cationic lipids needs to overcome a mass of cellular barriers, including the formation of synthetic vector/DNA complexes and their initial binding to the cell surface, endocytosis, endosomal escape, nuclear entry, and final expression. Herein, we report on the design and synthesis of a novel multivalent cationic lipopeptide (MCL) (Scheme 1). The MCL displays a distinct advantage in gene therapy in view of its biocompatibility, functional expansibility, relative ease of synthesis, and controllable charge density. When hydrolyzed by trypsin, the MCL becomes negative, and the vesicles undergo a charge-reversal process. The bound DNA by MCL vesicles is then excluded from the anionic productions, thus enhancing gene transfection efficiency. This process is obviously different from the previous vectors (*19–24*). The present findings are expected to broaden the application of cationic amphiphiles with peptide headgroups in nonviral gene therapy.

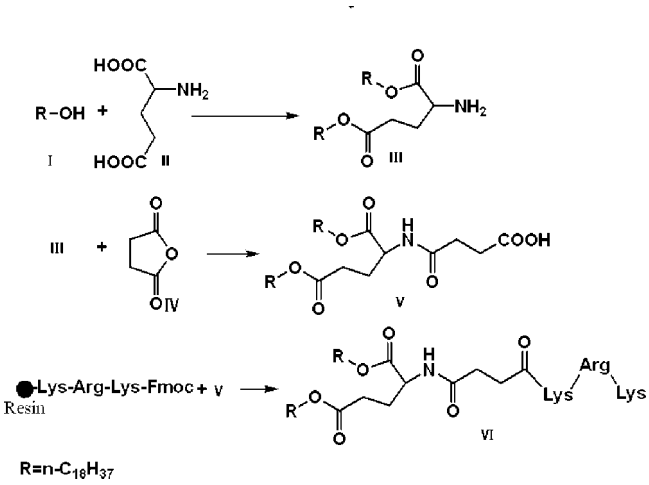
EXPERIMENTAL PROCEDURES



Materials. Ethidiium bromide (EtBr), Trypan blue, trypsin and *N,N*-diisopropylethylamine were purchased from Sigma. The reference transfection reagent (frequently used for control experiments) containing 1,2-dioleoyl-3-trimethylammoniopropane (DOTAP) and dioleoylphosphotidyl-ethanolamine (DOPE) (1:1 w/w) were obtained from Avanti (*25, 26*). Monster green fluorescent protein phGFP vector (phGFP) was from Promega. All chemicals were used as received without further purification. The water used through out all of the experiments was purified with a Milli-Q system from Millipore Co.

Synthesis. The lipopeptide was synthesized on the basis of a previously reported protocol (Scheme 1) (*27*). Briefly, *n*-octadecanol (I) was esterified with equivalent L-glutamic acid (II) to obtain dialkyl L-glutamate (III), under the action of a catalytic amount of *p*-toluene-sulfonic acid in toluene, and refluxed for 2 h. Then the amino group of compound III was coupled with succinic anhydride (IV) by ring opening. Equivalent molar amounts of succinic anhydride and III were added into anhydrous THF (refluxed over Na) and refluxed for 3 h under catalysis by *N,N*-diisopropylethylamine. Solvent THF was removed under vacuum. The residue was recrystallized from acetone to get V with a yield of 85.6%. The tripeptide was synthesized using standard solid-phase 9-fluorenylmethoxycarbonyl (Fmoc) chemistry by Shanghai Sangon Co. (China). The peptide was assembled on Wang resin, incorporating a linker to generate the C-terminal amide upon cleavage of the peptide from the resin. The resin-bound peptide was N-terminally acetylated by reaction with amphiphile V to get the lipopeptide (VI). The target compound was purified to 95% with HPLC on a reversed-phase C18 column, with gradients of acetonitrile in water containing 0.1% TFA to obtain a white powder. The structure of the target molecule was confirmed by ^{1}H NMR spectra (300 M), elemental analysis, and mass spectroscopy (MS). ^{1}H NMR ($CDCl_3$, 300M) δ ppm 0.88 (t, 6H), 1.25 (s, 66H), 1.55–1.66 (m, 10H), 1.95–2.05 (m, 3H), 2.10–2.21 (m, 3H), 2.30–2.45 (m, 7H), 2.48–2.63 (m, 6H), 2.64–2.83 (m, 6H), 4.06 (t, 4H), 4.14 (t, 4H), 4.56–4.67 (m, 2H), 6.51–6.64 (m, 2H), 11.05 (s, 1H). MALDI-MS: Calcd for $[C_{63}H_{121}N_9O_{10}+H]^+$1164.9; found, 1165.2. Elemental analysis: C, 64.68%; H, 10.10%; N, 11.03% (theory: C, 64.97%; H, 10.47%; N,10.82%).

Liposome Preparation. A chloroform solution of the MCL (1 mg/mL) was dried by rotary evaporation to form a thin film. The film was kept under vacuum for 4 h to ensure the complete

Scheme 1. Synthesis Scheme of Multivalent Cationic Lipopeptide

removal of the residual solvent. The dried lipid was hydrated at 37 °C under a N_2 stream with the appropriate amount of deionized water. The final concentration was 1 mM, and the solution was stored at 4 °C. The morphology of the liposome negatively stained by uranyl acetate was observed by transmission electron microcopy (TEM).

Characterization of MCL/DNA Complexes. MCL/DNA complexes were formed by adding DNA solution to MCL liposome dispersion at a charge ratio of 1:2. The obtained samples are also used for the transfection experiments. The morphology of the complex was observed by laser scanning confocal microscopy (LSCM, Olympus FV500). For the measurements of fluorescence microscopy, liposome stock solutions were stained with 0.2 mol % DOPC-NBD, and DNA was labeled using the 5′TAMRA probe. The zeta-potential of the complexes were measured by the ZetaPALS (phase analysis light scattering) technique at pH 7.4 at room temperature (25 °C).

DNA Binding Affinities. DNA binding studies were achieved using competitive displacement fluorometric assay using EtBr as previously reported (*28*). MCL liposome dispersion was mixed with DNA (prestained with EtBr) at different charge ratios of MCL/DNA (0.1:1 to 2:1). A serial of MCL/DNA complexes were obtained for the purpose of DNA binding tests. It is noted that each sample contains 24 μg of calf thymus DNA, 2.8 μg of EtBr, and the appropriate amount of cationic lipid. Water was added to each well in the array, achieving a final volume of 2 mL per well. Fluorescence intensity was measured on a fluorescence spectrophotometer (Hatchi F4500) after incubation at room temperature for 20–25 min.

DNA Release. The above obtained EtBr-DNA/MCL complex was hydrolyzed by trypsin at room temperature for 5 h. The fluorescence intensity was recorded with a fluorescence spectrophotometer (Hatchi F4500) in real time. The variation of the fluorescence intensity reflects the amount of free DNA in the system.

Cell Culture and Transfection Experiments. HeLa cells were cultured in Dulbecco's modified Eagle's medium (DMEM, Gibco BRL) supplemented with 1% penicillin and streptomycin at 37 °C in a humid 5% CO_2 environment, reseeding the cells every 2–4 days to maintain subconfluency. When the HeLa cells reached about 90% confluency, they were split into 24-well plates with a 1:4 ratio using a standard trypsin-based technique. MCL liposome with GFP plasmid DNA was diluted in DMEM at the charge ratio 2:1. The mixture was incubated for 15 min at room temperature before being added to the cells. Transfections were performed over 16 h referencing previously reported methods (*29, 30*). The amount of DNA was the same as that used in the naked DNA control and positive control experiments (commercially available transfection reagents). After incubation

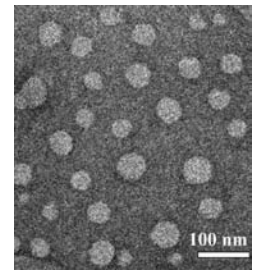

Figure 1. TEM Image of the MCL liposomes.

at 37 °C and 5% CO_2 for 2 h, the medium in the wells was gently removed, and fresh growth medium was added. Naked DNA controls were carried out with 0.1 mL of serum-free DMEM medium with 0.5 μg of plasmid DNA. Positive controls were carried out with the reference transfection reagent at the same charge ratio. The transfected cells were observed by fluorescence microscopy (Olympus IX 70). Transfection efficiencies were assessed by a flow cytometer (FCM) at 48 h post-transfection. The parallel samples of MCL, negative control, naked DNA, and positive control were dyed with Trypan blue in order to detect the viability of cells.

RESULTS AND DISCUSSION

The synthesized MCL comprises a hydrophobic moiety with a cationic peptide headgroup, as shown in Scheme 1 (*27*). The headgroup bears two positive charges at pH 7.4 resulting in a high membrane charge density, which enables a high binding affinity with DNA. In addition, the peptide group can be easily degraded by enzymes, allowing DNA to escape from the complex. This design allows lipids to exhibit different charges, spacers, chain lengths, and functional groups.

The TEM image in Figure 1 shows that the MCL can form well dispersed vesicles in the solution. The diameter of the vesicles is about 60 ± 20 nm. The laser scanning confocal microscopy (LSCM) measurement (Figure 2) shows that the addition of DNA into MCL solution results in the coexistence of MCL liposomes with DNA. Figure 2A displays the NBD-labeled vesicles that are shown in green. Figure 2B displays

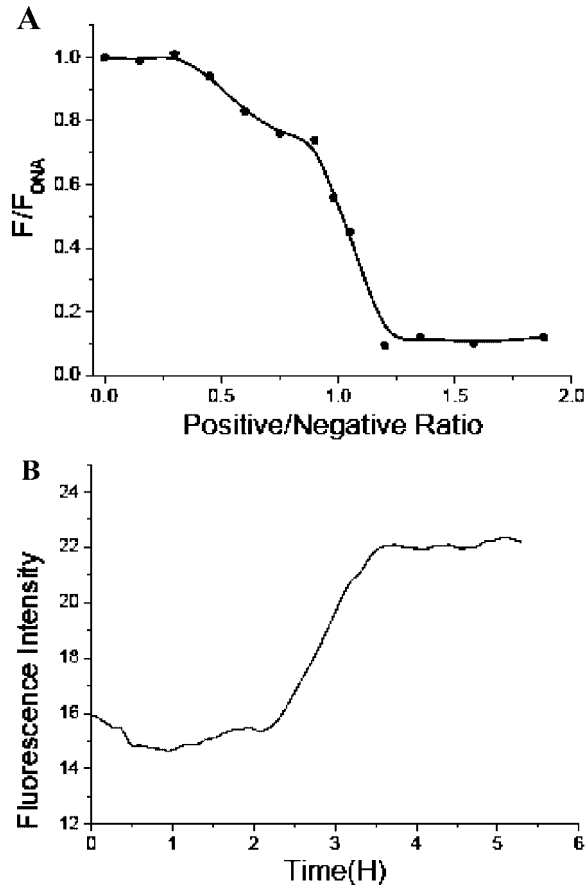

Figure 3. (A) EtBr displacement assay showing the fluorescence intensity as a function of MCL/DNA charge ratio. (B) EtBr displacement assay showing the fluorescence intensity as a function of time after adding the trypsin into the MCL/DNA complexes.

the TAMRA-labeled DNA as red dots by detecting the same sample using another filter. As can be seen, the two images are consistent in both the shape and area of the aggregates. Figure 2C gives the double contributions of NBD-labeled liposomes and TAMRA-labeled DNA. The image in Figure 2D shows the morphology of the complex in transmission mode.

The transfection efficiency of lipoplexes was known to depend strongly on the surface charge of the lipoplex (*31, 32*). We measured the surface potential of MCL liposomes and MCL/DNA complexes (2:1 in charge ratio). The data for the zeta-potential is +31.5 (±0.8 mV) for MCL and +22.3 (±1.6 mV) for MCL/DNA complexes, respectively. It shows that the zeta-potential values for both surfaces are positive, which will increase the ability of the MCL/DNA complexes to adhere to the membrane surface of the cells.

To further verify the binding of DNA with MCL liposomes, we performed the experiments with a standard EtBr-DNA fluorescence quenching exclusion assay. Fluorescence intensity was collected at various charge ratios of MCL to DNA. The results are shown in Figure 3A. EtBr will fluoresce as it intercalates in the middle of the base pairs of DNA and self-quench in solution. When DNA binds with MCL liposomes, EtBr will be displaced. Consequently, the intensity of fluorescence will decrease until all DNA is incorporated into the MCL/DNA complexes at the isoelectronic point. Figure 3A shows that the fluorescence intensity indeed decreases at the isoelectronic region. It means that the MCL liposome and DNA have formed vectors of MCL/DNA complexes.

The change of fluorescence intensity was recorded in real time, while the EtBr-DNA/MCL solution was incubated with trypsin at pH 7.2 at room temperature. Figure 3B shows the

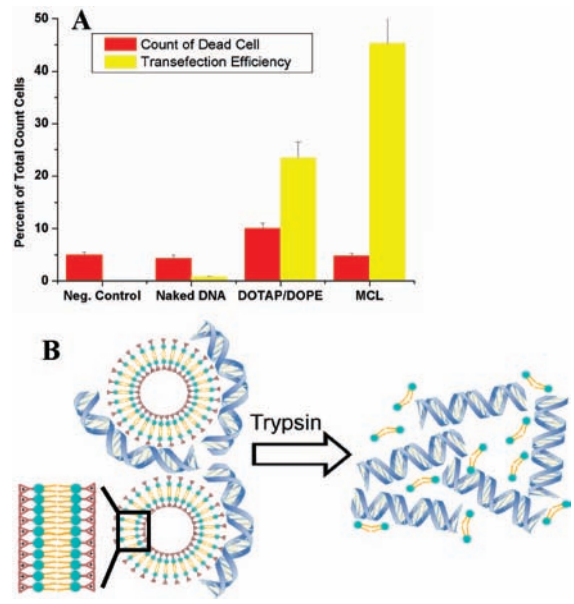

Figure 4. (A) Experimental results of gene transfection efficiency and cytotoxicity in HeLa cells. (B) Proposed mechanism of the DNA release from the MCL/DNA complex after trypsin hydrolysis.

change of the fluorescence intensity of the EtBr-DNA/MCL solution after adding trypsin to the complex. An increase of fluorescence intensity over time is observed. It indicates that EtBr is re-intercalated in base pairs of DNA since the hydrolysis of peptide results in the charge reversal of the lipid headgroups. The fluorescence data also shows that DNA is released from the complexes accompanied by enzymatic hydrolysis.

HeLa cells were split into 24 wells and incubated for 16 h. MCL and the commercial transfection reagent were separately mixed with a plasmid DNA, which contained a reporter gene of phMGFP. Then the plasmid DNA and its mixture with MCL and commercial transfection reagent were added into the HeLa cell wells for the transfection measurements. The fluorescence microscopy images displayed that a great deal of GFP was generated in the transfected cells (see Supporting Information). In order to quantify the ability of MCL to enter cells, flow cytometry was employed to precisely determine the transfection efficiency. As shown in Figure 4A, the transfection efficiency of MCL is about two times that of the commercial transfection reagent, which serves as a reference system. For the naked plasmid DNA, the transfection efficiency is essentially negligible. However, in the presence of MCL, the transfection efficiency is about 45 ± 5%.

To investigate the toxicity of MCL, the ratio of dead cells was detected by cell counters. The total number of dead cells in the negative control (red bar in Figure 4A) is similar to that containing plasmid DNA and MCL, which means that the MCL has no influence upon cell growth. However, the number of dead cells increases after the addition of the commercial transfection reagent. The above results suggest that the MCL has innocuity for cell transfection.

Through the above experiments, we propose that the transfection of DNA/MCL complexes in cells will undergo the following process, as shown in Figure 4B. First, the plasmid DNA binds to the headgroups of the cationic peptide of MCL vesicles. Then, the MCL/DNA vesicles will enter the HeLa cells (e.g., via endocytosis), and trypsin in the cell will hydrolyze the peptide of the plasmid DNA/MCL complexes. The charge reversal of the vesicles will repel DNA and assist DNA to escape from the endosome for the subsequent transcription (*33, 34*). This process is readily performed and thus enhances DNA transfection efficiency.

CONCLUSIONS

In conclusion, we demonstrate that the synthesized multivalent cationic lipopeptide (MCL) can be safely used for the delivery and release of genes. The assembled MCL vesicles have high affinity to bind with DNA through electrostatic interaction. This peptide is biocompatible, and the hydrolytic products, such as lipids and amino acids, are also innoxious. The transfection experiments show that the lipopeptide as vesicles can enhance gene transfection efficiency compared to that of the commercial reagent. Therefore, such a synthesized multivalent cationic lipopeptide represents a new type of vector for the delivery of therapeutic DNA.

Metastatic melanoma remains an incurable disease, and there is a great need for novel therapeutic modalities. We have recently identified melanin as a target for radionuclide therapy of melanoma and demonstrated the feasibility of this approach using a 188-rhenium (^{188}Re)-radiolabeled melanin-binding decapeptide to fungal melanin known as 4B4. Although the results indicated that radiolabeled melanin-binding decapeptide had activity against melanoma, that peptide also manifested high kidney uptake and this might become a concern during clinical trials. We hypothesized that by identifying peptides with different amino acid composition against tumor melanin we might be able to decrease their kidney uptake. Using the Heptapeptide Ph.D.-7 Phage Display Library, we identified three heptapeptides that bind to human tumor melanin. These peptides were radiolabeled with ^{188}Re via HYNIC ligand, and their comprehensive biodistribution in A2058 human metastatic melanoma tumor-bearing nude mice was compared to that of ^{188}Re-4B4 decapeptide. While tumor uptake of heptapeptides was quite similar to that of ^{188}Re-4B4 decapeptide, there was dramatically less uptake in the kidneys at both 3 h (6% ID/g vs 38%) and 24 h (2% ID/g vs 15%) postinjection. Administration of one of the generated heptapeptides, ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg, to A2058 human metastatic melanoma-bearing nude mice resulted in significant retardation of the tumor growth. Immunofluorescence showed that in spite of their relatively small size heptapeptides were not able to penetrate through the membranes of viable melanoma cells and bound only to extracellular melanin, which provides assurance that they will be safe to healthy melanin-containing tissues during radionuclide therapy. Thus, these heptapeptides appear to have potentially significant advantages for targeted therapy of melanoma relative to existing melanin-binding peptides.

INTRODUCTION

The incidence of melanoma is rising (*1*), and it is an important cause of cancer among young patients (30–50 years). This disease currently affects ~40 000 new patients each year in the US, and there are an estimated 100 000 cases worldwide (*2, 3*). Metastatic melanoma is almost always fatal (*4*) with the median survival time of 8.5 months and an estimated 5 year survival of 6% (*4*). Therapeutic options for metastatic melanoma are limited, and there has been little change in the prognosis for this disease in the past 25 years (*5*).

Most melanomas are pigmented by the presence of melanin. Some melanomas are called "amelanotic" because they are not black or darkly pigmented. However, even amelanotic melanomas contain some melanin (*6, 7*), which makes this pigment a convenient target for the development of radionuclide therapy of metastatic melanoma. The multiplicity of compounds which could potentially serve as "delivery vehicles" of radionuclides to melanoma tumors can be divided into three groups: molecules that bind to melanin, molecules that are melanin precursors, and molecules that bind to melanogenesis-related proteins (reviewed in ref (*8*)).

We have recently demonstrated the feasibility of targeting melanin, an intracellular melanocyte pigment, to deliver cytotoxic radiation to human melanoma cells *in vivo* using a fungal melanin-binding monoclonal antibody (mAb 6D2) with promising therapeutic results (*9*). Later, we expanded this approach to peptides by performing experimental melanoma therapy with 188-rhenium (^{188}Re)-labeled fungal melanin-binding decapeptide 4B4 (*10*) and carried out a comprehensive safety evaluation of this treatment (*11*). The results indicated that radiolabeled melanin-binding peptides have activity against melanoma and that these reagents could be potentially useful against this tumor. Peptides are attractive antitumor agents because they are easily synthesized, are nonimmunogenic, provide rapid clearance from the circulation, and penetrate tissues more thoroughly than larger molecules such as antibodies (*12*). On the other hand, peptides are rapidly degraded by the enzymes in the bloodstream and lack the effector functions conferred by an antibody constant region. The problem of rapid clearance can be ameliorated somewhat by synthesis using D-amino acids, but there is always a concern that peptides can bind to kidney cells and produce nephrotoxicity. This is a particular concern for melanin-binding peptides, because these are usually cationic (*10*), and thus can bind to the negatively charged kidney basement membrane. Clinical trials of radiolabeled peptides suggest that the risk of nephrotoxicity is a function of such characteristics of a peptide molecule as its mass, charge, and clearance pathways as well

as the chemical and physical characteristics of the radionuclide (*13*). When radiolabeled fungal melanin-binding peptides were used for experimental melanoma therapy, they showed high kidney uptake (*11*). Although there was no long-term nephrotoxicity, this issue could become a concern during clinical trials. Thus, there is a clear need to improve melanin-binding peptides by decreasing their kidney uptake. Here, we describe the isolation and characterization of melanin-binding peptides from peptide libraries with dramatically reduced kidney-binding capacity.

EXPERIMENTAL PROCEDURES

Reagents and Cells. The Ph.D.-7 Phage Display library Kit including the Heptapeptide Phage Display Library, −28 gIII sequencing primer, −96 gIII sequencing primer, and *E. coli* ER2738 host strain were purchased from New England Biolabs. The library has complexity in excess of two billion independent clones, which is sufficient to contain most if not all of the $20^7 = 1.28 \times 10^9$ possible heptapeptide sequences. The Detection Module Recombinant Phage Antibody System used to quantify bound phage was purchased from Amersham Biosciences. QIAPrep Spin M13 Prep columns were purchased from Qiagen. HRP-labeled anti-M13 monoclonal conjugate was purchased from GE Healthcare. HRP-labeled Streptavidin for quantification of the biotinylated peptides and subsequent binding strength determination was purchased from Fisher Scientific. Highly pigmented human melanoma cells MNT1 (*14*) were a gift from Dr. V. Hearing (NIH, Bethesda, MD). Human metastatic pigmented melanoma cells A2058 cells (ATCC, Mannassas, VA) were grown in Dulbecco's Modified Eagle's Medium with 4 mM L-glutamine, 4.5 g/L glucose, and 1.5 g/L sodium bicarbonate. This medium was supplemented with a 10% fetal bovine serum and 5% penicillin–streptomycin solution. Cells were grown at 37 °C in 75 cm^2 cell culture flasks. Subculturing was done at 80–95% confluence at subcultivation ratios of 1:6 and 1:12. Cell layers were dispersed with 0.25% (w/v) Trypsin–EDTA (1×). The cell line Hep 3B2.1–7 (*Homo sapiens* hepatatocellular carcinoma) was purchased from ATCC (cat no HB-8064). Cells were grown routinely in Eagle's Minimum Essential Medium (EMEM) (ATCC) containing 10% FBS (Sigma) at 37 °C in 5% CO_2 incubator.

Preparation of Plates for Melanin-Specific ELISA. Melanin from MNT-1 human melanoma cells was purified as in ref (*11*), and suspended at 2 mg/mL concentration in deionized H_2O. Approximately 150 μL was added to each well of 96 well plates and the solution gently agitated overnight. The melanin-coated wells were then baked at 80 °C for ½ h and blocked with 2% dry milk for 1 h followed by 5 mg/mL BSA in deionized H_2O.

Panning Procedure. Ten microliters of the original phage library (New England Biolabs) was diluted to 100 μL with TBST (TBS + 0.1% [v/v] Tween-80) and the resulting 110 μL pipeted onto one melanin-coated well. The plate was incubated at room temperature for 1 h with gentle agitation. The phages were then discarded and the well washed, to remove nonbinders, 10 times with TBST and excess liquid blotted after each wash. The bound phage was eluted with 0.2 M glycine–HCl (pH 2.2) in 1 mg/mL BSA by rocking the plate gently at room temperature for 10 min. The eluate was pipeted into a microcentrifuge tube, neutralized with 15 μL of 1 M Tris–HCl (pH 9.1) and titered onto LB/IPTG/Xgal plates to determine the concentration of the phage eluate. It was amplified by incubating at 37 °C with vigorous shaking with an early log phase ER2738 culture for 4.5 h. Purification was performed by first centrifuging the culture at 9000 rpm at 4 °C to pellet the ER2738 cells. The supernantant was removed and treated with 1/6 equivalent volume of PEG/NaCl. After cooling overnight at 4 °C, the resulting suspension was again centrifuged at 9000 rpm. The resulting pellet was collected and resuspended in 1 mL TBS. Further centrifugation pelleted residual cells, and 80% of the suspension was collected. One-sixth of equivalent volume of PEG/NaCl was added and the solution incubated on ice for 1 h. The suspension was microcentrifuged at 4 °C for 20 min and the supernatant removed and discarded. The pellet was resuspended in 200 μL TBS. The concentration of the phage was determined by titering onto LB/IPTG/Xgal plates. The process was repeated twice using the obtained eluate (volume-corrected to yield 2×10^{11} phages) for panning with reduced panning time and increasing Tween concentration).

Isolating Clones. The final eluate was plated onto a LB/IPTG/Xgal plate to yield approximately 50 individual clones. Twenty-four clones from the plate were chosen at random and amplified by incubation with 1 mL of early log phase ER2738 culture. The resulting amplified eluates were purified as described above and each plated titered and plated again to yield a plate with approximately 20 individual plaques. Four plaques from each plate were amplified in 1 mL of early log phase ER2378 and the 4 resulting cultures pooled. The cultures were centrifuged at 9000 rpm for 10 min and 80% of the supernatant was removed. The removed supernatant was centrifuged again and 80% of the supernatant removed for extraction of phage DNA. The phage DNA was extracted by elution on QIAPrep Spin M13 Prep. The resulting DNA was amplified by standard molecular biology techniques. Twenty-four phages were selected for DNA sequencing, which was performed at the AECOM DNA Sequencing Core Facility.

Selection of Phages with the Best Melanin-Binding Properties. The phages with the best melanin-binding properties were selected by analyzing the concentration of the phages in the wells coated with melanin as compared to the concentrations in the noncoated wells. To obtain the concentrations of phage, the wells were first treated with an HRP/anti-M13 monoclonal antibody conjugate over a period of 1 h until binding had occurred. Subsequently, the excess conjugate was removed and the wells were washed. Quantitative amounts of HRP substrate (ABTS) and peroxide were added, and after a period of 10 to 30 min, changes in the color of the solution were analyzed for absorbance at 492 nm. The changes in absorbance at 492 nm are directly related to the amount of HRP enzyme present and as such to the amount of bound phage.

Synthesis of Biotinylated and HYNIC-Conjugated Heptapeptides. The best phage binders were selected as above, and the displayed heptapeptides were synthesized from L-amino acids with biotin at the N terminus by Peptides International (KY) for immunofluorescence experiments. To minimize enzymatic degradation *in vivo*, for radiolabeling purposes the same heptapeptides were synthesized by Anaspec from D-amino acids with a hydrazinonicotinamide (HYNIC) chelate appended to the N terminus. An additional heptapeptide, AspGlyAlaTrpMetGlyAla, whose sequence was derived from the sequence of previously described irrelevant decapeptide P601G AspGlyAlaSerTyrSer-TrpMetTyrGlyAla (*10*), was also synthesized in a biotinylated form and with HYNIC ligand as a random control. Biotinylated and HYNIC-conjugated heptapeptides were analyzed by HPLC on a VYDAC 250 mm analytical column equipped with a supporting guard column using the following gradient (A, 0.05% TFA in H_2O; B, 0.05% TFA in acetonitrile; 10–60% A over 50 min at 1 mL/min). The resulting HPLC confirmed the HPLC data obtained from the manufacturers.

Immunofluorescence of A2058 Melanoma Cells. The binding of the biotinylated heptapeptides to A2058 melanoma cells *in vitro* was analyzed by immunofluorescence as in ref (*10*). Approximately 10^6 melanoma cells were blocked for nonspecific binding by incubation in SuperBlock (Pierce, Rockford, IL) for 1 h at 37 °C. Biotinylated heptapeptides were then incubated with the cells for 1 h followed by addition of streptavidin

conjugated to fluorescein isothiocyanate (FITC). The slides were viewed with an Olympus AX70 microscope (Melville, NY) equipped with a FITC filter. Irrelevant biotinylated heptapeptide AspGlyAlaTrpMetGlyAla was used as a negative control.

Radiolabeling of Heptapeptides. The ^{188}Re-perrhenate eluted in saline from ^{188}W/^{188}Re generator was reduced by adding $SnCl_2$ (20 μL of 20 mg/mL 0.1 M HCl) to a suspension of 20 mg sodium glucoheptonate and 400 μL ^{188}Re-perrhenate. The resulting suspension was thoroughly mixed and incubated for 1 h at 37 °C. The reduction was assessed by SG-ITLC in dry acetone. One hundred microliters of a freshly prepared solution of 2 mg HYNIC–heptapeptide dissolved in 1 mL NH_4OAc (0.15 M, pH 4) was placed in a 1.5 mL microcentrifuge tube. To this solution was added approximately 600 μCi of reduced ^{188}Re (up to 400 μL). The resulting solution was incubated in the dark at room temperature for 1 h. The extent of radiolabeling was checked by SG-ITLC developed in 0.15 M NH_4OAc, pH 4. If necessary, the ^{188}Re-HYNIC–heptapeptides were purified from unreacted ^{188}Re on the reverse-phase C18 column. The column was primed with methanol followed by equilibration with NH_4OAc. The sample was then loaded onto the column and the column washed with 5 × 250 μL 0.125 M NH_4OAc followed by 2 × 250 μL 0.5 M NH_4OAc. The radiolabeled HYNIC–heptapeptides were eluted with 2 × 3 mL MeOH. The methanol was removed by evaporation under a nitrogen stream. SG- ITLC (0.15 M NH_4OAc, pH 4) was used to confirm the radiochemical purity of ^{188}Re-HYNIC–heptapeptides.

Binding of ^{188}Re-HYNIC–Heptapeptides to MNT1 and A2058 Melanoma Cells. To investigate the binding of radiolabeled heptapeptides to MNT1 human pigmented melanoma cells, the whole cells in increasing amounts from 1.3 to 15 million per sample were placed into the microcentrifuge tubes preblocked with 1% BSA to prevent nonspecific protein binding in 0.5 mL PBS, and radiolabeled heptapeptides in 0.19 nM concentration were added. In blocking experiments, the cells were preblocked with 10 μg per sample of the respective "cold" heptapeptide. The samples were incubated at 37 °C for 1 h. The suspensions were centrifuged at 1500 rpm for 20 min to pellet the cells, the supernatant was transferred into a different tube, and the radioactivity of the cells and of the supernatant was then counted in a gamma counter. For measuring the binding of heptapeptides to the lysed cells, the experiments were conducted as above, but MNT1 or A2058 cells were osmotically lysed immediately before the binding experiment. For estimation of association equilibrium constants K_a, the radiolabeled heptapeptides were added in increasing amounts (from 0.053 nM to 0.53 nM) to the lysed MNT1 or A2058 lysed cells (5×10^6 cells per centrifuge tube). After 1 h incubation at 37 °C, the activity in the tubes was counted in a gamma counter, the cells were collected by centrifugation, and the pellets were counted. Scatchard analysis was used to compute the heptapeptide association equilibrium constants K_a as in ref (*15*).

Biodistribution of ^{188}Re-HYNIC–Heptapeptides. All animal studies were carried out in accordance with the guidelines of the Institute for Animal Studies at the Albert Einstein College of Medicine. For biodistribution in tumor-bearing mice, melanoma tumors were induced by injecting approximately 8×10^6 A2058 human melanoma cells in 100 μL of the cell-growing medium into the right flank of female nude mice. Ten days after implantation, the tumors reached 0.3–0.7 cm in diameter. To study the biodistribution of four different ^{188}Re-HYNIC–heptapeptides and ^{188}Re-HYNIC–4B4 decapeptide (*11*) as a control, 30 tumor-bearing mice were divided into 5 groups of 6 mice each. Each group was further subdivided into 2 groups of 3 mice each. Each radiolabeled peptide was administered to 2 groups of mice at a dosage of 40 μCi (50 μg) in 100 μL via the tail vein. After 3 h and 24 h, respectively, the first and second groups of each set of mice were sacrificed and internal organs and the tumor taken, blotted from blood, weighed, counted in a gamma counter, and percent Injected dose per gram calculated.

To prove the specificity of peptide uptake in melanoma tumors, the biodistribution of ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg was studied in nude mice bearing two different xenografts—human hepatocellular carcinoma and A2058 metastatic melanoma. For this purpose, 8×10^6 A2058 human melanoma cells and 10^7 Hep 3B human hepatocellular carcinoma cells in 100 μL of the cell-growth medium were injected into the right and left flanks, respectively, of female nude mice. The biodistribution experiment was performed essentially as above except that only tumors, blood, and muscle were taken.

To investigate the influence of D-lysine coinjection on the uptake of ^{188}Re-HYNIC–heptapeptides in kidneys and other major organs, one group of six female CD-1 mice were injected with 40 μCi (50 μg) of ^{188}Re-HYNIC-ThrThrHisGlnPheProPhe in 100 μL via the tail vein, while another group received the same heptapeptide coinjected with D-lysine (400 mg/kg body weight). Three mice from each group were sacrificed at 3 and 24 h, and the biodistribution was performed as above.

Therapy of A2058 Tumor-Bearing Mice with ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg Heptapeptide. The A2058 tumors were initiated in nude mice as described above. When the tumors reached 0.7–0.8 cm in diameter, the mice were randomized into four groups of six mice. Groups 1–3 received IP injections of 1.0 mCi ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg heptapeptide, a matching amount of "cold" HYNIC-AsnProAsnTrpGlyProArg heptapeptide (0.2 μg), or 1.0 mCi ^{188}Re-HYNIC-4B4 decapeptide, respectively. Control group # 4 was left untreated. On day 7, the treatment of animals in groups 1–3 was repeated with the same doses. The size of the tumors was measured in three dimensions with calipers immediately before administration of peptides and on days 3, 6, 14, 17, 21, 25, 32, and 35. The tumor volume was calculated by multiplying the product of the three perpendicular diameters by 0.5.

Correlative Histology/Immunofluorescence of A2058 Melanoma Tumors. To establish the colocalization of heptapeptides with melanin in melanoma tumors, consecutive slides of A2058 melanoma tumors were stained with hematoxylin and eosin (H&E) or were incubated with the biotinylated AsnProAsnTrpGlyProArg heptapeptide for 1 h followed by addition of streptavidin conjugated to fluorescein isothiocyanate (FITC). The slides were viewed with an Olympus AX70 microscope (Melville, NY) equipped with a FITC filter. Irrelevant biotinylated heptapeptide AspGlyAlaTrpMetGlyAla was used as a negative control.

Scintigraphic Imaging. Two mice out of each group treated with radiolabeled peptides in therapy experiments were anesthetized with Isoflurane and scintigraphically imaged for 2 min on a Siemens gamma camera equipped with *ICON* image processing software.

Statistical Analysis. The nonparametric Wilcoxon rank sum test was used to compare organs uptake in biodistribution studies and tumor sizes in therapy studies. The Student's *t* test for unpaired data was employed to analyze differences in binding between heptapeptides. The differences were considered statistically significant when P values were <0.05.

RESULTS

Selection of Tumor Melanin-Binding Phages and Synthesis of Heptapeptides. Twenty-four unique peptides from 24 individually isolated clones were identified (Table 1). Although no consensus sequence was identified throughout these peptides, the sequence "aromatic"−*−* "aromatic" occurred in approximately 25% of the peptides (where * represents an

[a] The peptides with the best binding are highlighted in green, "a" represents an aromatic amino acid, +/− the charge of the amino acid, and * an irrelevant amino acid.

irrelevant amino acid and "aromatic" an aromatically based amino acid). More specifically, the aromatic amino acids were represented by histidine, a positively charged amino acid, in 50% of these cases. Histidine was also found extensively throughout the majority of the other peptide sequences. The best tumor melanin-binding phages were identified by comparing the binding of the phages to the melanin-coated well versus the non-melanin-coated wells (first round of selection, Figure 1a). From this group of clones, 8 of the best binders were chosen for further study (selected phages are highlighted in green in Table 1). These phages were then subjected to the second round of selection by performing ELISA for fourfold serial dilutions of the phage starting from 1.2×10^{12} pfu/mL. Of 8 phages, the 3 best binding phages were identified on the basis of comparison of the binding curves obtained from the melanin-coated wells and the uncoated wells (Figure 1b). As a result, 3 heptapeptides—HisThrThrHisHisArgAsn, AsnProAsnTrp GlyProArg, and ThrThrHisGlnPheProPhe—identified as 4D, 3D, and 1C in Table 1, respectively, were synthesized in biotinylated form and HYNIC-conjugated form for further in vitro and in vivo evaluation.

Heptapeptides Binding To Melanoma Cells *in Vitro.* The binding of heptapeptides to A2058 melanoma cells in culture was studied by immunofluorescence. Figure 2a shows that the biotinylated HisThrThrHisHisArgAsn heptapeptide bound only to nonviable melanoma cells. Nonviable cells apparently released their melanin or had permeable cell membranes that allowed access of the peptide to melanin (Figure 2a, right panel). No binding was observed to viable cells with intact cell membranes (Figure 2a, left panel). Control biotinylated hep-

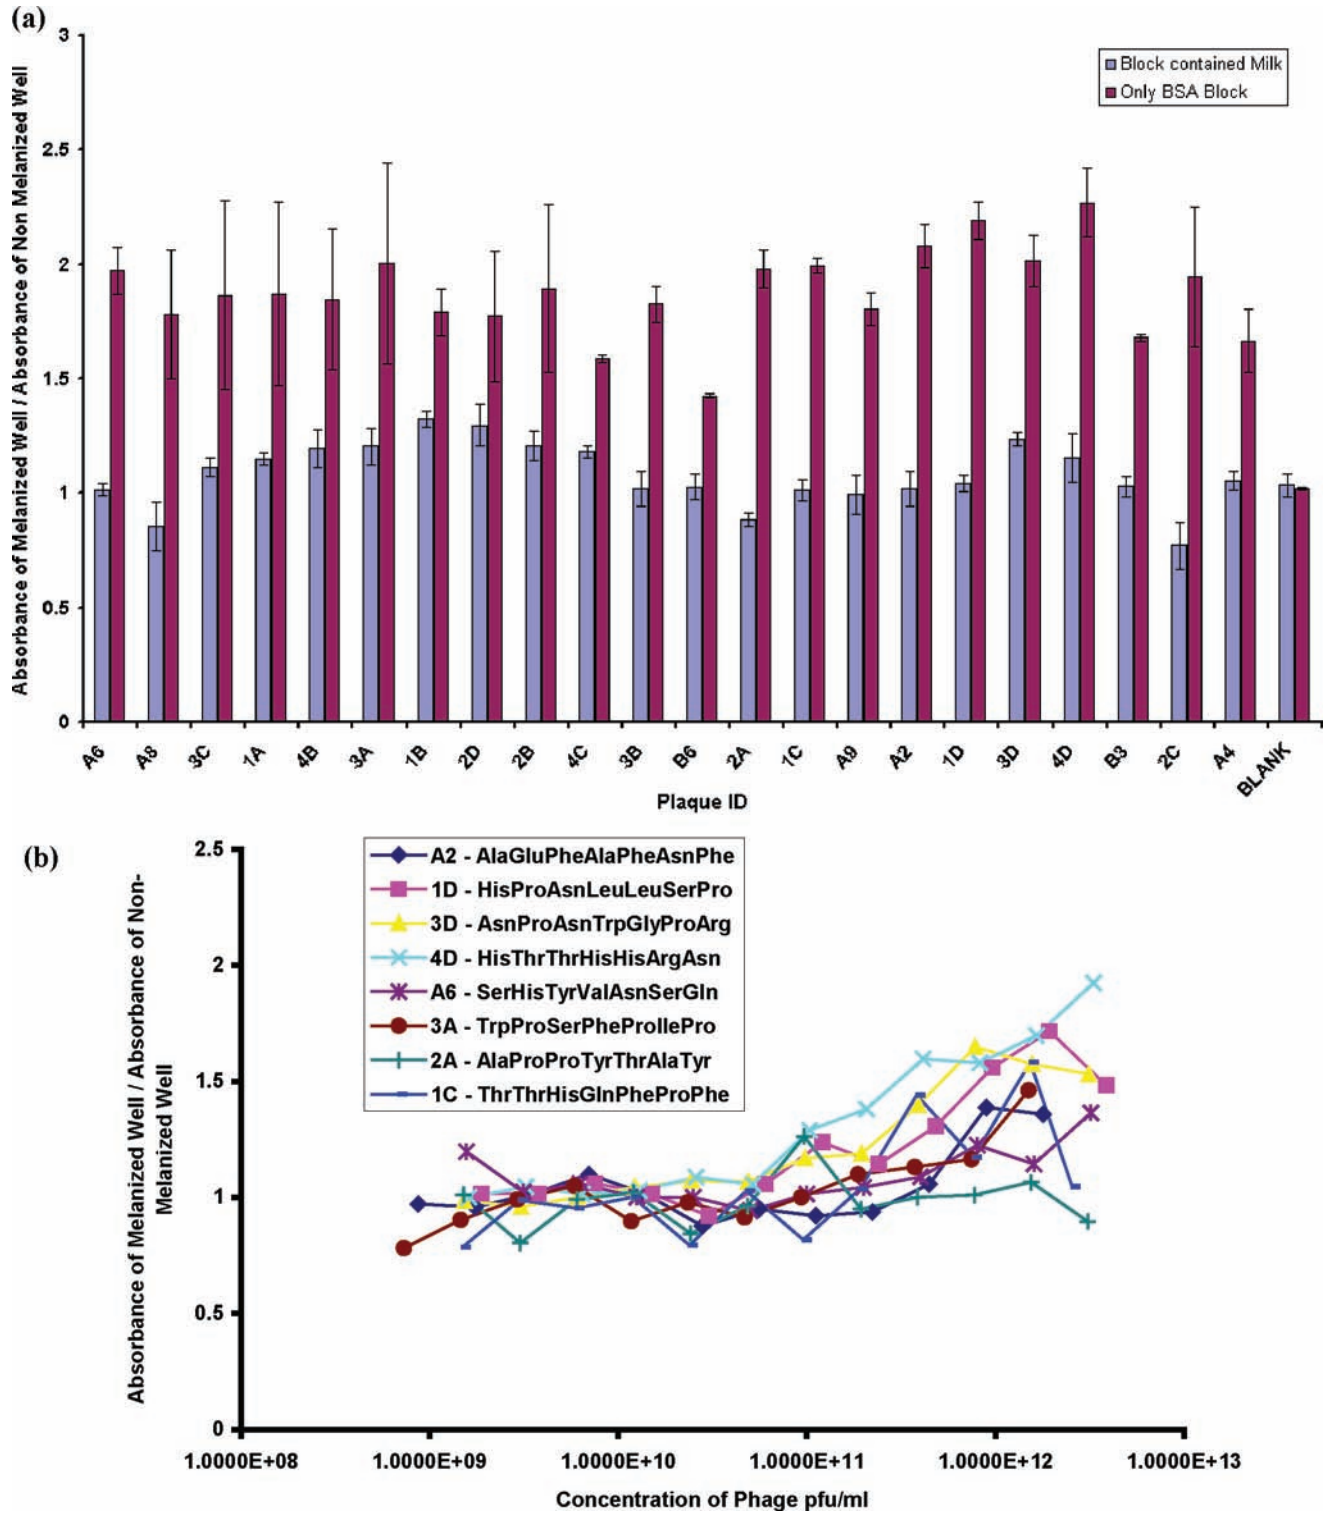

Figure 1. Selection of human tumor melanin binding phages from PhD-7 library. (a) First round of selection: plot of the absorbance ratios for the phages in melanized to nonmelanized wells. The wells were coated with melanin derived from MNT1 melanoma cells. Different blocking conditions were employed to ensure maximal blocking of nonspecific binding. (b) Second round of selection: binding curves resulting from ELISA of the best binding phages showing the ratio of the absorbance of the melanized to nonmelanized wells. Dilutions were fourfold starting at 1×10^{12} pfu/mL.

tapeptide AspGlyAlaTrpMetGlyAla did not bind to either viable or dead A2058 cells (results not shown).

Radiolabeling of HYNIC-Conjugated Heptapeptides. Labeling of HYNIC-conjugated heptapeptides with ^{188}Re resulted in an average of 92% yields for HisThrThrHisHisArgAsn, ThrThrHisGlnPheProPhe, AsnProAsnTrpGlyProArg, and Asp GlyAlaTrpMetGlyAla heptapeptides allowing for their use in cell binding and biodistribution experiments without further purification.

Binding of Radiolabeled Heptapeptides To Mnt1 and A2058 Melanoma Cells. First, we investigated whether ^{188}Re-labeled AsnProAsnTrpGlyProArg, ThrThrHisGlnPheProPhe,

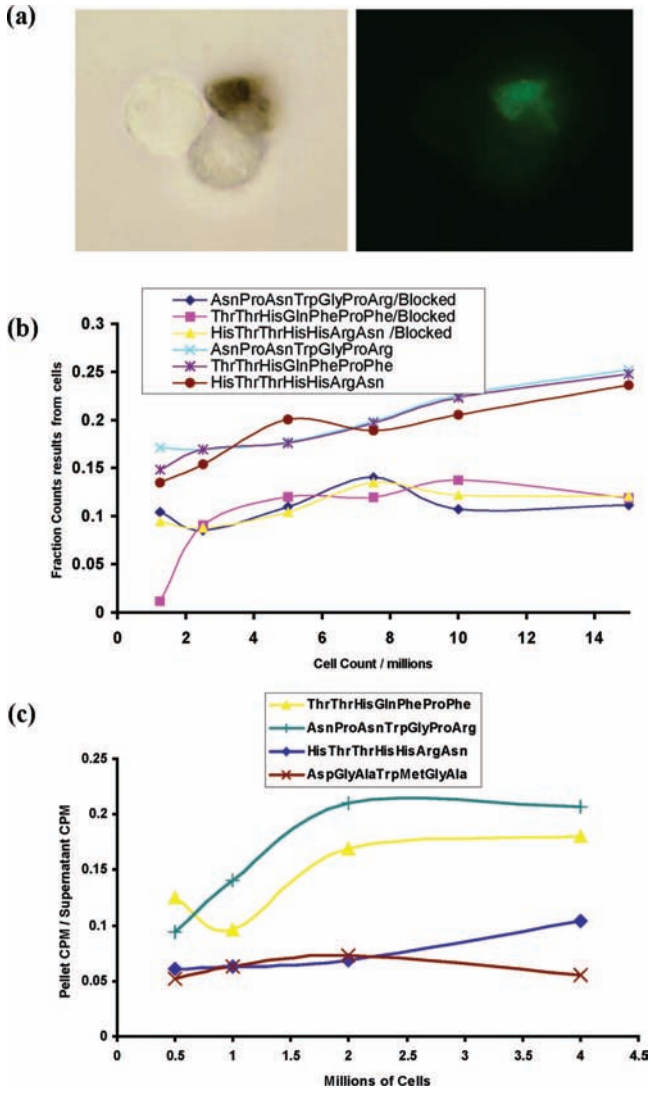

Figure 2. Binding of the heptapeptides to MNT1 and A2058 human melanoma cells. (a) Immunofluorescence image of biotinylated HisThrThrHisHisArgAsn heptapeptide binding to A2058 melanoma cells in culture. (b) Binding of heptapeptides to the whole MNT1 highly melanized melanoma cells. In blocking experiments, the MNT1 cells were preblocked with 10 μg per sample of the respective "cold" heptapeptide. (c) Binding of ^{188}Re-labeled HYNIC–heptapeptides to lysed A2058 cells.

and HisThrThrHisHisArgAsn heptapeptides would bind to whole highly melanized with eumelanin MNT1 melanoma cells (*11*), as melanin from those cells was used for selection of phages. The preparations of whole MNT1 cells contain approximately 10% nonviable cells (as per Trypan blue dye assay) in which melanin is accessible to the peptides. The binding to the MNT1 cells was proportional to the overall number of cells per sample and was decreased 2-fold by preblocking the cells with an excess of "cold" heptapeptides, proving that the binding of ^{188}Re-labeled peptides was specific (Figure 2b). Interestingly, the binding of all three of the above heptapeptides to MNT1 cells was very similar. The osmotic lysis of MNT1 released melanin from all cells in preparations, which increased the percentage binding to almost 100% (results not shown). Scatchard analysis of the binding to the lysed cells allowed estimation of the K_a for AsnProAsnTrpGlyProArg, ThrThrHisGlnPheProPhe, and HisThrThrHisHisArgAsn as $(7.1 \pm 0.5) \times 10^7$ M^{-1}. As A2058 metastatic melanoma cells are only slightly pigmented with pheomelanin, the binding of peptides to the lysed A2058 cells was significantly lower than binding to the

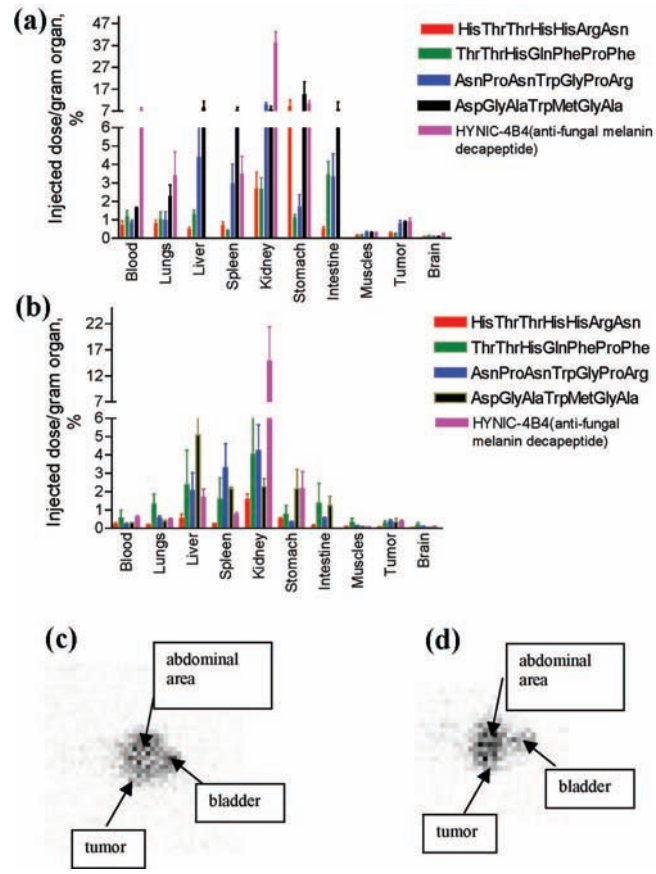

Figure 3. Biodistribution and scintigraphic imaging of ^{188}Re-labeled HYNIC–heptapeptides and ^{188}Re-labeled HYNIC–4B4 decapeptide in nude mice bearing A2058 human melanoma tumors (a) 3 h biodistribution post IV injection; (b) 24 h biodistribution post IV injection; (c) 1 h scintigraphic image of a mouse injected IP with ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg; (d) 3 h scintigraphic image of a mouse injected IP with ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg. The mice were imaged laying on their backs.

lysed MNT1 cells with the highest value of 20% observed for AsnProAsnTrpGlyProArg (Figure 2c). The unrelated control peptide AspGlyAlaTrpMetGlyAla practically did not bind to A2058 cells, while HisThrThrHisHisArgAsn binding reached only 10% at the high cell number (Figure 2c). The two best binders to the A2058 cell line, AsnProAsnTrpGlyProArg and ThrThrHisGlnPheProPhe, had K_a values of 1.5 and 1.1×10^7 M^{-1}, respectively.

Biodistribution and Scintigraphic Imaging of ^{188}Re-HYNIC–Heptapeptides in A2058 Melanoma Tumor-Bearing Mice. The biodistribution of AsnProAsnTrpGlyProArg, ThrThrHisGlnPheProPhe, and HisThrThrHisHisArgAsn heptapeptides and irrelevant AspGlyAlaTrpMetGlyAla was compared to that of fungal melanin-binding decapeptide 4B4 (Figure 3a,b). A dramatic difference in kidney uptake was observed between heptapeptides and 4B4 decapeptide at both 3 h (2.5–12% ID/g vs 38%) and 24 h (1.8–2.4% ID/g vs 15%) postinjection ($P = 0.001$). Melanin-specific heptapeptides showed greater stability *in vivo* than irrelevant heptapeptide AspGlyAlaTrpMetGlyAla or 4B4 decapeptide as judged by the lower stomach uptake of tumor melanin-specific heptapeptides ($P = 0.02$). Though the tumor to blood ratios were less than 1 for the heptapeptides used in biodistribution, for AsnProAsnTrpGlyProArg peptide tumor to blood ratio was almost 1 (0.92), which was a significant improvement in comparison to 4B4 decapeptide (tumor to blood ratio 0.12). Tumor uptake of both heptapeptides and decapeptide was modest at 0.5–1% ID/g at 3 h and decreased approximately 5-fold to 0.1–0.2% ID/g at

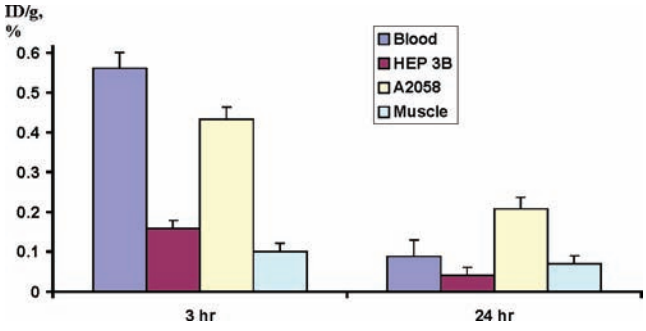

Figure 4. Comparative biodistribution at 3 and 24 h of ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg heptapeptide in nude mice bearing two different xenografts: hepatocellular carcinoma and A2058 melanoma.

24 h. Importantly for therapy, however, the tumor to muscle uptake for these subcutaneous tumors was around 3. Overall, the best biodistribution pattern in terms of low kidney uptake, high stability, and relatively stable tumor uptake was observed for AsnProAsnTrpGlyProArg and ThrThrHisGlnPheProPhe heptapeptides, which was consistent with their higher binding to A2058 melanoma cells *in vitro*. In order to visualize tumor uptake, we imaged mice injected with the ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg peptide on a gamma camera (Figure 3c,d). At both 1 and 3 h postinjection, most of the activity was localized to the abdominal cavity with practically no activity in the blood pool, thus confirming very fast clearance of the peptide from the blood. The tumor was visible at both 1 h (Figure 3c) and 3 h images (Figure 3d).

Biodistribution of ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg in Nude Mice with Hepatocellular Carcinoma and A2058 Melanoma Xenografts. To confirm the specificity of heptapeptide uptake in melanoma tumors, the biodistribution of ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg heptapeptide was also performed in mice bearing two different tumor xenografts on their flanks. The uptake of heptapeptide in A2058 melanoma tumors was 3 times higher than in hepatocellular carcinoma at 3 h postinjection and 5 times higher at 24 h (Figure 4).

Effect of D-Lysine Coinjection on Biodistribution of Heptapeptides. Co-injection of ThrThrHisGlnPheProPhe with D-lysine (400 mg/kg) did not reduce kidney uptake of the peptide. In fact, lysine coinjection was found to increase kidney uptake: At 3 h postinjection, there was 4 times more peptide in the kidneys of mice coinjected with D-lysine compared to control mice ($P = 0.003$) (Figure 5). Even after 24 h, the profound effect was still evident in the mice to whom D-lysine was administered compared to controls (3-fold difference).

Correlative Histology/Immunofluorescence of A2058 Melanoma Tumors. In order to establish the colocalization of heptapeptides with melanin in melanoma tumors, consecutive slides of A2058 melanoma tumors were stained with H&E or were incubated with the biotinylated AsnProAsnTrpGlyProArg heptapeptide. Biotin-AsnProAsnTrpGlyProArg localized in the melanin-rich areas of A2058 tumors (Figure 6a), while irrelevant control heptapeptide did not (results not shown).

Therapy of A2058 Tumor-Bearing Mice with ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg Heptapeptide. To examine the effects of radiolabeled melanin-binding heptapeptides on A2058 tumors, we selected ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg, as this peptide showed the best biodistribution pattern in terms of relatively high tumor uptake, low kidney uptake, and good stability *in vivo*. Three groups of six A2058 tumor-bearing nude mice with tumors of 0.7–0.8 cm in diameter were treated IP with (1) 2 × 1.0 mCi ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg; (2) 2 × "cold" HYNIC-AsnProAsnTrpGlyProArg (0.2 μg each injection); or (3) 2 × 1.0 mCi ^{188}Re-HYNIC–4B4 decapeptide 7 days apart. Mice in the control group were left untreated. Two treatments with peptides were given because this regimen proved effective in the earlier study with ^{188}Re-HYNIC–4B4 decapeptide in MNT1 melanoma tumor-bearing mice (*11*). ^{188}Re-HYNIC–4B4 decapeptide was used as a control because of its success in treatment of MNT1 tumors (*11*) and comparability to ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg uptake in A2058 tumors in this study. The A2058 tumors grew aggressively in the untreated group, and the last surviving mouse had to be sacrificed on day 35 because of the size of its tumor. Significantly slower ($P << 0.01$) tumor growth was observed in all treatment groups with ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg slowing the tumor growth more efficiently ($P = 0.02$) than "cold" HYNIC-AsnProAsnTrp GlyProArg or ^{188}Re-HYNIC–4B4 decapeptide from day 25 posttreatment. Interestingly, "cold" HYNIC-AsnProAsnTrp GlyProArg was almost as efficient in slowing down tumor growth as ^{188}Re-HYNIC–4B4 decapeptide.

DISCUSSION

During the past decade, radiolabeled peptides that bind to different receptors on a variety of tumors have been investigated as potential therapeutic agents in both the preclinical and clinical settings (*16*). Preclinical studies of the radiolabeled peptides in melanoma treatment have concentrated on melanocyte-stimulating hormone (MSH) receptor with efforts directed primarily at the synthesis of metal-cyclized α-MSH peptide analogues such as Re-(Arg(11))CCMSH (*17*). The first therapy with ^{188}Re-(Arg(11))CCMSH in B16/F1 murine melanoma and TXM13 human melanoma-bearing mouse models was reported to result in the reduction of the tumor growth rate and prolonged survival in the treatment groups (*18*). We have recently demonstrated that ^{188}Re-labeled fungal melanin-binding decapeptide 4B4 was effective against experimental MNT1 human melanoma and was safe for normal melanized tissues (*11*). As no human melanin-binding peptides have been reported, for the proof-of-principle experiments targeting melanin in the tumors with radiolabeled melanin-binding peptides (*11*), we utilized the peptides that were originally generated to fungal melanin for purposes unrelated to cancer research (*10*). Although no nephrotoxicity was noted in those studies, the high kidney uptake of the 4B4 fungal melanin-binding peptide prompted the search for the peptides with lower kidney uptake. In this study, we generated the peptides to human melanin in an attempt to provide the structural solution to the problem of high kidney uptake.

During the past decade, phage display has been extensively used in cancer research (reviewed in ref (*19*)). Phage display can be utilized for the fast identification of biologically active ligands for molecules already determined to be important in cancer development, for creating a profile of peptide ligands for a particular cancer cell type, and for the identification of organ and tumor homing peptides. The limitations of the phage display approach are conformational differences between the peptides fused to phage coat proteins and chemically synthesized peptides, which can result in inferior binding of chemically synthesized peptides to their target when compared to the original phages (*20*).

The availability of the commercially available PhD-7 phage display library allowed us to generate heptapeptides that were subsequently selected for their tumor melanin-binding properties by ELISA. These heptapeptides were less aromatic and less positively charged than melanin-binding decapeptides recovered by screening on fungal melanin (*10*). Surprisingly, in spite of their small size, the heptapeptides were not able to penetrate through the membranes of viable A2058 human melanoma cells and bound only to the melanin in nonviable cells or released from the dead cells as demonstrated by immunofluorescence.

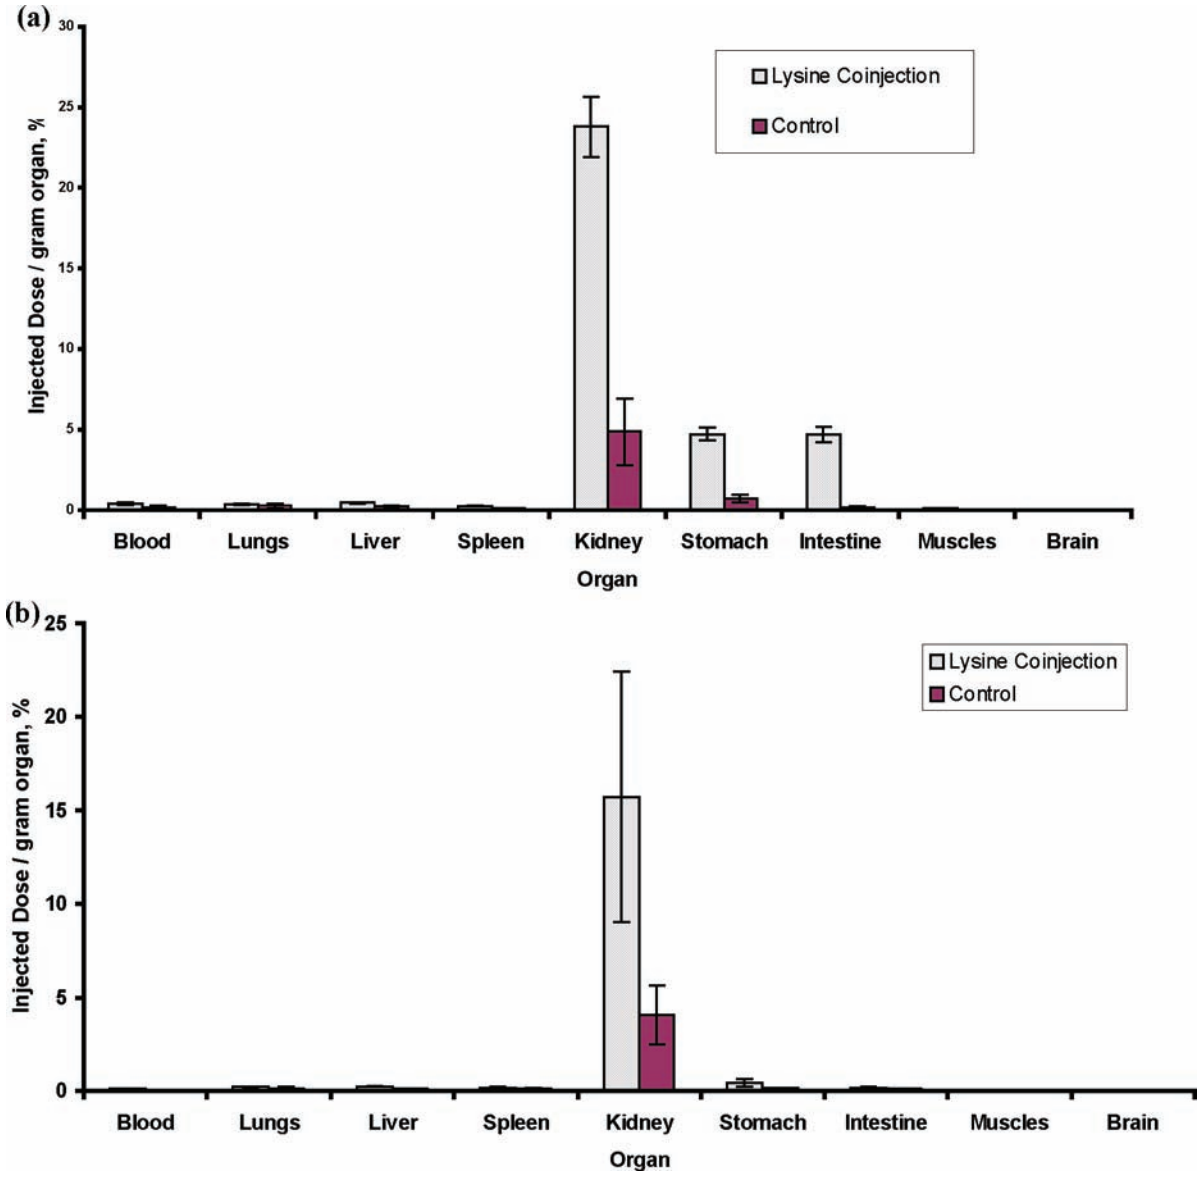

Figure 5. Comparative biodistribution of ^{188}Re-labeled HYNIC-ThrThrHisGlnPheProPhe heptapeptide in non-tumor-bearing CD-1 mice injected IV with peptide alone or coinjected with D-lysine (400 mg/kg body weight): (a) 3 h postinjection; (b) 24 h postinjection.

This result is encouraging, as the inability of heptapeptides to penetrate through cell membranes will minimize toxicity to healthy melanized cells during therapy.

When administered to tumor-bearing mice, both ^{188}Re-labeled heptapeptides and ^{188}Re-labeled decapeptide 4B4 exhibited tumor uptake in A2058 human metastatic melanoma tumors. This is encouraging, as the panel of heptapeptides was developed against black eumelanin from MNT1 melanoma tumors (*8*) and decapeptide 4B4 against black fungal melanin (*10*). In contrast, A2058 tumor cells are pigmented with pheomelanin, a yellow or reddish-brown melanin-type pigment. Both pheomelanin and eumelanin are negatively charged and share some structural similarity, with both types found in melanomas where eumelanin is the predominant pigment in primary tumors, while pheomelanin is associated with metastatic melanomas and progression of the disease (*21*). The predominance of pheomelanin in A2058 cells resulted in relatively low binding of heptapeptides to the tumors. Since melanoma is a very heterogeneous disease, melanin in the patients' tumors will be most likely represented by both eumelanin and pheomelanin, and even so called "amelanotic" melanomas do contain some melanin to ensure targeting with heptapeptides (*22, 23*). In addition, it is worthwhile to note that in a very recent study Newton et al. used phage display methodology to generate α-MSH peptide analogues for the purpose of imaging melanoma tumors (*24*) and observed relatively low uptake of peptides and phages in the tumors. The unrelated control peptide AspGlyAlaTrpMetGlyAla also showed some tumoral accumulation in our biodistribution study. However, it was unstable *in vivo*, which was manifested by high stomach, liver, and intestine uptake. Its high stomach uptake was most likely due to ^{188}Re-perrhenate presence resulting from *in vivo* decomposition of peptide. As pigmented cells can express sodium iodide symporter (NIS) (*25*), the uptake in the tumor seen for AspGlyAlaTrpMetGlyAla may actually be the binding of ^{188}Re-perrhenate to NIS. The specificity of heptapeptides for tumor melanin was proven by preferential uptake of ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg in A2058 melanoma xenografts in mice bearing hepatocellular carcinoma and melanoma xenografts simultaneously and by colocalization of biotin-AsnProAsnTrpGlyProArg with melanin on tumor slides.

In our earlier studies, we estimated the number of nonviable cells in experimental melanoma tumors by subjecting the cells from melanoma tumors grown in nude mice to Trypan blue

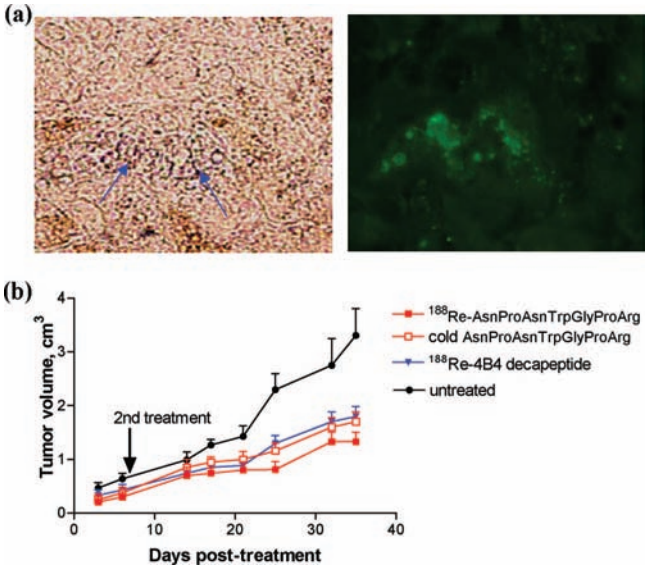

Figure 6. Colocalization of ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg heptapeptide with melanin in melanoma tumors and therapy of A2058 tumor-bearing mice with the same heptapeptide. (a) Left: H&E stained A2058 melanoma tumor slide. Melanin deposits are shown with blue arrows. Right: immunofluorescence with biotinylated AsnProAsnTrp GlyProArg. (b) A2058 tumor-bearing nude mice with tumors of 0.7–0.8 cm in diameter were treated IP with (1) 2 × 1.0 mCi ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg; (2) 2 × "cold" HYNIC-AsnProAsnTrpGlyProArg (0.2 μg each injection); or (3) 2 × 1.0 mCi ^{188}Re-HYNIC–4B4 decapeptide 7 days apart. Mice in the control group were left untreated. Points represent means of tumor size of 6 mice. The bars represent standard deviation.

assay. Approximately 7% of all cells (melanoma and connective tissue) turned to be nonviable in non-necrotic tumors, and up to 40% of cells were nonviable in necrotic tumors (Dadachova et al., unpublished observations). Apparently, this number of cells was sufficient to provide the target for the radiolabeled peptides. In spite of modest tumor uptake, significantly slower ($P << 0.01$) tumor growth was observed in all treatment groups with ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg slowing the tumor growth more efficiently ($P = 0.02$) than "cold" HYNIC-AsnProAsnTrpGlyProArg or ^{188}Re-HYNIC–4B4 decapeptide from day 25 posttreatment. "Cold" HYNIC-AsnProAsnTrp GlyProArg was almost as efficient in slowing down tumor growth as ^{188}Re-HYNIC–4B4 decapeptide, suggesting that the peptide has a therapeutic effect independent of the attached radionuclide. The mechanism for this phenomenon is unknown, but in prior studies, we also observed that "cold" melanin-binding mAb 6D2 had some therapeutic effect on melanoma tumors (*9*). We speculate that melanin-binding peptides and mAbs might be absorbed into the surface of melanin where they become immunogenic and elicit an immune response that triggers localized inflammation that produces an antitumor effect. The explanation for higher efficacy of the radiolabeled heptapeptide may be the combination of the biological effect of the peptide with the deep penetration of the small peptide into the tumor and "cross-fire" irradiation of distant cells by the energetic β-emissions of ^{188}Re providing relatively homogenous irradiation of the tumor. Also, in the future, it might be possible to increase tumor uptake of these heptapeptides using site-directed mutagenesis or peptide arrays.

Since the purpose of the study was to generate melanin-binding peptides with low kidney uptake, we paid particular attention to uptake of radiolabeled heptapeptides in this organ. The kidney uptake of heptapeptides described in this study was on average 7 times less than that for ^{188}Re-labeled decapeptide 4B4. This is a dramatic improvement in the biodistribution pattern of melanin-binding peptides, given that kidneys are a major concern for toxicity during therapy with radiolabeled peptides (*13*). Interestingly, an attempt to further decrease kidney uptake of the ^{188}Re-labeled heptapeptide pharmacologically by coadministration of positively charged amino acid D-lysine, which was supposed to block the negative charge on cell membranes in the proximal tubules and thus prevent heptapeptide retention after glomerular filtration, paradoxically increased its uptake by several fold. Interestingly, the same phenomenon was observed when ^{188}Re-labeled decapeptide 4B4 was coadministered to mice with D-lysine (E. Dadachova, unpublished observations). The explanation of this phenomenon is yet to be found, as molecular mechanisms of renal reabsorption of peptides used in radionuclide therapy have not been clarified. For example, radiolabeled somatostatin peptide analogues have been used in clinical practice since the late 1980s, but only very recently has evidence been presented to suggest that the molecular mechanism of [^{111}In-DTPA]octreotide uptake in renal proximal tubules involves multiligand scavenger receptor megalin (*26*).

In conclusion, by utilizing phage display technique, we generated a panel of tumor melanin-binding heptapeptides which when radiolabeled with ^{188}Re demonstrated 7-fold lower kidney uptake in mice than previously reported ^{188}Re-labeled fungal melanin-binding decapeptide. Administration of one of the generated heptapeptides, ^{188}Re-HYNIC-AsnProAsnTrpGlyProArg, to A2058 human metastatic melanoma-bearing nude mice resulted in significant retardation of the tumor growth. In spite of their relatively small size, heptapeptides were not able to penetrate through the membranes of viable melanoma cells and bound only to extracellular melanin, which provides assurance that they will be safe to healthy melanin-containing tissues during radionuclide therapy of melanoma. Thus, these heptapeptides can be potentially developed into efficient and safe delivery vehicles for targeted radionuclide therapy of melanoma.

ACKNOWLEDGMENT

The authors would like to thank NIH-designated Albert Einstein College of Medicine Cancer Center for providing funding for this work; Dr. M. Torres for help with the phage display library; Dr. L. Mintz for advice on the peptides synthesis; and Dr. X-G. Wang for supplying hepatocellular carcinoma cells.

A simple and convenient strategy has been put forward to fabricate smart fluorescent magnetic wheat germ agglutinin-modified trifunctional nanospheres (WGA-TFNS) for recognition of human prostate carcinoma DU-145 cells which are surface-expressed with sialic acid and *N*-acetylglucosamine. These TFNS can be easily manipulated, tracked, and conveniently used to capture and separate target cells. The presence of wheat germ agglutinin on the surface of WGA-TFNS was confirmed by FTIR, biorecognition of carboxymethyl chitin-modified quantum dots (CM-CT-QDs), and bacterium *Staphylococcus aureus*. The success in recognizing DU-145 cells by the WGA-TFNS indicates that WGA-TFNS could be applicable.

INTRODUCTION

Lectins, which can be found in most organisms, ranging from viruses and bacteria to plants and animals (*1*), form a family of natural nonenzymatic proteins/glycoproteins that bind monosaccharides and oligosaccharides with high specificity, although they are not products of an immune response. Each lectin molecule contains typically two or more carbohydrate binding sites. When they interact with cells, they will not only specifically recognize and bind to the carbohydrate residues on the cell surface, but also cause cross-linking of the cells and their subsequent agglutination (*1*). Lectins also have cytoadhesive and cytoinvasive properties, and can initiate vesicular transport processes based on their recognizing and binding to carbohydrate residues on a cell surface (*2*). Therefore, lectins have been widely used in drug delivery systems (*3*).

Wheat germ agglutinin (WGA), derived from cereals and one of the most widely characterized and least immunogenic lectins, is a dimer consisting of two identical 18 kDa subunits and four carbohydrate binding sites. Since WGA receptors, such as *N*-acetylglucosamine (GlcNAc) and sialic acid, are commonly expressed on surface plasma membranes of most types of neurons in the brain, among a number of lectins with different carbohydrate-binding specificities (*4*), WGA can be used as an effective tracer in a variety of neural systems. As WGA can also recognize some types of cancer cells, it has already been used in some drug delivery applications (*5*).

Nanomaterials, especially nanomaterial-based functional nanodevices, are increasing in their popularity with researchers and manufacturers. Among them, magnetic nanoparticles are extensively studied and widely used for drug delivery, magnetic treatment, and magnetic separation due to their small size, single magnetic domain structures, and superparamagnetism (*6–14*). Fluorescent semiconductor quantum dots (QDs) are another important type of nanoparticles, which have broad excitation and size-dependent photoluminescence with narrow emission bandwidth covering a wide spectral range. By using a single wavelength, many particles with different sizes and different compositions can be simultaneously excited. Furthermore, the QDs exhibit unusual photochemical stability and relatively high photoluminescent quantum yields (*15–19*). By embedding QDs with different emission colors into polymer spheres, a large number of encoded and distinguishable microbeads can be obtained. QD-embedded polymer microspheres are expected to be used in gene expression, high-throughput screening, and medical diagnostics (*20*). On the other hand, magnetic nanoparticle filled beads have been used in the biomedical field, such as immunomagnetic separation and nucleic acid hybridization (*11, 21*). However, in many biomedical and clinical diagnostic fields, there has always been some need for materials with the functions of both magnetic separation and fluorescence tracking. The common strategy is to anchor magnetic nanoparticles and organic fluorophores, respectively, to two kinds of molecules that can interact with each other. The method is complicated, time-consuming, and inefficient (*11, 12, 14*). Several new methods have been developed recently based on the use of QDs and magnetic nanoparticles (*22–30*). Among them, the method developed by us is to construct fluorescent–magnetic bifunctional nanospheres by co-embedding the fluorescent quantum dots and γ-Fe_2O_3 magnetic nanoparticles into single swelling-poly(styrene/acrylamide) copolymer nanospheres (*22, 26–28*). The nanospheres are fluorescence-trackable and magneto-manipulatable, and demonstrate their capability of specific cell targeting after surface-modification with some specific reagents such as folic acid (*22, 26, 27*). Subsequently, they were successfully used in apoptotic Hela cell recognition (*28*). Here, we present WGA-modified trifunctional nanospheres for recognition of human prostate carcinoma DU-145 cells based on a new strategy of convenient modification of fluorescent–mag-

netic bifunctional nanospheres, which will be universally applicable for GlcNAc and sialic acid recognition.

EXPERIMENTAL PROCEDURES

Fabrication of Fluorescent–Magnetic Bifunctional Nanospheres. In order to fabricate fluorescent–magnetic bifunctional nanospheres (BFNS) (*22, 26, 27*), some related building materials should be first synthesized. CdSe/ZnS QDs, with the diameter between 3 and 6 nm, were synthesized by the method described in a previous report (*31*). The synthesis of nano-γ-Fe_2O_3 (ca. 8 nm in diameter) was as reported (*27, 32*). Poly(styrene/acrylamide) copolymer nanospheres (St-AAm, 100–250 nm in diameter) were produced from styrene (St) and acrylamide (AAm) by means of emulsifier-free polymerization by the previously reported method (*33*). St-AAm was subsequently modified with hydrazine through the surface amide functional groups, producing a reactive nanosphere surface for future modification and attachment (*27*). The hydrazinized St-AAm was denoted as H_2N-St-AAm.

On the basis of the above building materials, the bifunctional nanospheres were fabricated as described below (Scheme 1) (*22, 26, 27*). Both the QDs and the nano-γ-Fe_2O_3 dispersed in hexane were washed several times to remove any impurities, and the nanoparticles and copolymer nanospheres were dried before use. Hydrazinized bifunctional nanospheres (H_2N-BFNS) were produced by swelling the H_2N-St-AAm in a solvent mixture containing 5% (vol) chloroform and 95% (vol) butanol, and adding a controlled amount of CdSe/ZnS QDs and nano-γ-Fe_2O_3 to the mixture. For example, a typical ratio used in the present work was 3:1 QDs/Fe_2O_3. The mixture was then ultrasonicated until it became a well-dispersed suspension. The mixture was ultrasonicated for a further 30 min, centrifuged, and washed with butanol three times. The resultant H_2N-BFNS with both fluorescence and magnetism were dispersed in ultrapure water for use.

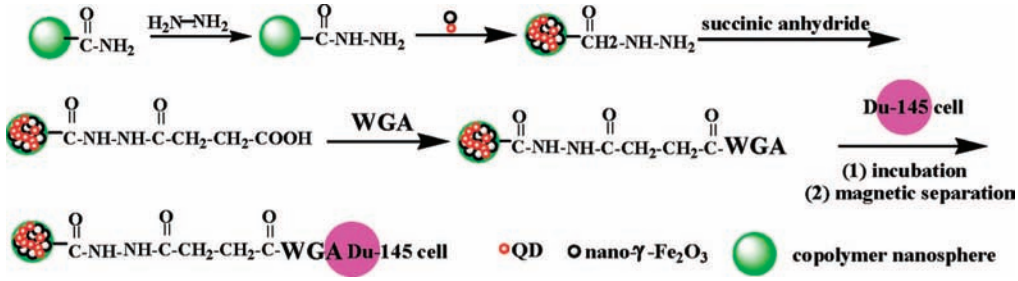
Construction of Wheat Germ Agglutinin-Modified Trifunctional Nanospheres. 0.1 g of succinic anhydride was added to 5 mL of 10 mg/mL H_2N-BFNS aqueous solution. The pH of the reaction system was adjusted to 4 with 1 M NaOH. The reaction lasted for 2–3 h. Then, the product was centrifuged at 12 000 rpm for 10 min several times to remove the excess succinic anhydride. The final product HOOC-BFNS was kept in 0.1 M phosphate buffer solution (PBS) (pH 6.5).

The tube with the solution containing the HOOC-BFNS was put onto a magnetic scaffold for ca. 5 min, and then the HOOC-BFNS were attracted by magnetic force, allowing the solvent to be removed easily. The attachment method was similar to that previously reported (*2, 34*). The HOOC-BFNS were thoroughly washed with 0.1 M PBS (pH 6.5). After that, ca. 5 mg of HOOC-BFNS were activated with 100 mM 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDAC) and 100 mM *N*-hydroxysuccinimide (NHS) in l mL of 0.1 M PBS (pH 6.5) for 30 min at room temperature with continuous shaking. The activated HOOC-BFNS were then washed with l mL of 0.1 M PBS (pH 7.4). To covalently immobilize WGA onto the BFNS surface, 90 μL of activated HOOC-BFNS were reacted with 10 μL of WGA (3.6 mg/mL, dissolved in 0.1 M PBS at pH 7.4) for 4 h at room temperature with continuous shaking to form fluorescent magnetic wheat germ agglutinin modified trifunctional nanospheres (WGA-TFNS). The tube containing WGA-TFNS was put onto the magnetic scaffold to remove any unreacted WGA and then washed with 0.1 M Tris–HCl (pH 7.5, containing 1 mM $CaCl_2$ and 1 mM $MgCl_2$). The resultant WGA-TFNS were dispersed in 400 μL of the same Tris–HCl solution.

Because nano-γ-Fe_2O_3 and QDs in WGA-TFNS would influence the characterization of WGA on the surface of WGA-TFNS, WGA-St-AAm was constructed to facilitate the characterization. WGA-St-AAm was prepared according to the procedure similar to that of WGA-TFNS. The washed HOOC-St-AAm was dispersed in 1 mL of 0.1 M PBS (pH 6.5), then activated with 100 mM EDAC and 100 mM NHS in l mL of 0.1 M PBS (pH 6.5) for 30 min at room temperature with continuous shaking, followed by centrifuging at 12 000 rpm for 40 min to remove excess activation reagents and further washing with l mL of 0.1 M PBS (pH 7.4) by centrifuging at 12 000 rpm for 40 min. Subsequently, 950 μL of activated HOOC-St-AAm was reacted with 50 μL of WGA (3.6 mg/mL, dissolved in 0.1 M PBS at pH 7.4) for 4 h at room temperature with continuous shaking to form WGA-St-AAm. WGA-St-AAm was purified by centrifugation at 12 000 rpm for 40 min to remove excess WGA, and finally dispersed in l mL of 0.1 M PBS (pH 7.4).

Characterization. An Acc. V Spot Maqn scanning electron microscope (SEM) operated at 20 kV was used to characterize the surface morphology of the H_2N-St-AAm nanospheres. The size and dispersity of the nano-γ-Fe_2O_3 and H_2N-St-AAm were characterized by transmission electron microscopy (TEM) on a JEOL-JEM 2010 microscope operated at 200 kV using a Gatan Dual Vision 300 W CCD camera. High-resolution TEM (HRTEM) images of BFNS were obtained on a JEOL-JEM 2011 microscope operated at 200 kV. Chemical composition of the products was examined by energy-dispersive X-ray microanalysis (EDX) using an Oxford Link ISIS system attached to the JEM-2011 microscope. A small electron beam (5–10 nm) was normally chosen for the EDX studies. The X-ray diffraction pattern of the nano-γ-Fe_2O_3 was determined on a D/max-RC diffractometer with Cu (40 kV, 50 mA) as the target.

Fluorescence images were recorded with a Zeiss HRC Axiocam (3900 $\times$ 3900 pixels) camera attached to a Zeiss inverted optical microscope (Axiovert 200M) or an Olympus IX70 inverted fluorescence microscope with a 100 W mercury arc lamp, U-MWU (330–385/400/420nm) and U-MWB filters (450–480/500/515 nm) and an oil-immersion objective (100$\times$).



WGA on the surface of WGA-TFNS was characterized by FTIR spectroscopy. H_2N-St-AAm, HOOC-St-AAm, and WGA-St-AAm were lyophilized for FTIR analysis. The infrared spectra of the samples were obtained on a Thermo Nicolet 360 FT-IR spectrophotometer. Pressed pellets were prepared by grinding the powder specimens with KBr in an agate mortar.

Cell Culture and Recognition of Cells by WGA-TFNS. *Staphylococcus aureus* (*S. aureus*) was precultured overnight in 5 mL of Luria-Bertain (LB) culture medium at 37 °C. Then, 100 μL of precultured *S. aureus* suspension was added to 5 mL of LB culture medium, incubated at 37 °C for 6 h with shaking, and kept at 4 °C for further experiments.

S. aureus agglutination was used to confirm the presence of WGA on the WGA-TFNS surface. 0.5 mL of *S. aureus* suspension was harvested by centrifugation at 8000 rpm for 5 min, washed twice with 0.1 M Tris–HCl (pH 7.5, containing 1 mM $CaCl_2$ and 1 mM $MgCl_2$), and resuspended in 400 μL of the same Tris–HCl solution. The mixture of 150 μL of WGA-TFNS and harvested *S. aureus* suspension was incubated at 37 °C for 25 min, magnetically separated on a magnetic scaffold, washed with the 0.1 M Tris–HCl solution, and resuspended in 200 μL of the 0.1 M Tris–HCl solution for imaging.

DU-145 cells (a human prostate carcinoma cell line) were used for the recognition by WGA-TFNS. Cells were routinely cultured at 37 °C in a flask containing RPMI 1640, supplemented with 10% fetal bovine serum (FBS), 100 μg/mL penicillin G, 100 μg/mL streptomycin sulfate, 1.8 mg/mL $NaHCO_3$ and 25 mM HEPES in a humidified atmosphere with 5% CO_2 (in air).

Scheme 1. Construction of a Fluorescent Magnetic Wheat Germ Agglutinin Trifunctional Nanosphere and Its Capturing a Human Prostate Carcinoma Du-145 Cell

Experiments of DU-145 cell capture and separation by WGA-TFNS were carried out as described below. About 1×10^6 DU-145 cells were first cultured in a flask and then detached using trypsin–EDTA solution, and collected by centrifugation at approximately 1000 rpm for 5 min at room temperature. Subsequently, the cells were washed with cold 1 × PBS, resuspended in 900 μL of 1 × PBS and incubated with 100 μL of 5 mg/mL WGA-TFNS for 30 min at room temperature. Besides WGA, Dolichos biflorus agglutinin (DBA), another kind of lectin that can bind with *N*-acetyl-D-galactosamine (GalNAc), was used as a control for WGA. DBA-TFNS were fabricated according to the same procedure as for WGA-TFNS mentioned above.

Examination of the Capacity of WGA-TFNS to Capture DU-145 Cells. DU-145 cells were first cultured in a flask and then detached using trypsin–EDTA solution, and collected by centrifugation at approximately 1000 rpm for 5 min at room temperature. Subsequently, the cells were washed with cold 1 × PBS, resuspended in 1 × PBS, and the cell concentration was determined by hemocytometry. Then, WGA-TFNS were added to DU-145 cell suspension and incubated for 30 min at room temperature and isolated with a magnetic scaffold, and then the uncaptured DU-145 cells in solution were counted.

Cytotoxicity of WGA-TFNS Examined by Trypan Blue Dye Exclusion Assay. DU-145 cells were plated in a 6-well tissue culture plate. After the cells became confluent, the cells were washed twice with 1 × PBS and added with WGA-TFNS, then incubated for 30 min at room temperature. After incubation, DU-145 cells were washed twice with 1 × PBS after redundant WGA-TFNS were removed, then trypsinized and resuspended in RPMI 1640 culture media. DU-145 cells were centrifuged at 1000 rpm for 5 min and dispersed in 1 × PBS, then DU-145 cell solution was mixed with Trypan blue dye (0.8% w/v) in equal volume, staining for 2 min. More than 200 stained and unstained cells (viable cells could not be stained by Trypan blue) were counted by hemocytometry. The cell viability was calculated below.

Cell viability [%] = (number of viable cells/total cell number) × 100

DU-145 cells cultured without WGA-TFNS under the same experimental conditions were used as the control.

RESULTS AND DISCUSSION

Fluorescent Magnetic Bifunctional Nanospheres. Trifunctional nanospheres or smart nanobiodevices simultaneously with fluorescence, magnetism, and biotargeting properties will be a powerful tool for biotracking, bioimaging, bioseparation, clinical diagnosis, and biomedical fundamental research. In view of the structural features (Scheme 1), the formation of the fluorescent magnetic bifunctional nanospheres is an important basis for construction of a variety of smart nanobiodevices.

By our simple and convenient approach (*22*, *26*, *27*), perfect bifunctional nanospheres (Figure 1) can be readily fabricated by embedding both the CdSe/ZnS QDs and the nano-γ-Fe_2O_3 into the swelling H_2N-St-AAm nanospheres simultaneously. The hydrophilic amide (-$CONH_2$) groups of the copolymer tend to be located towards the outer surface of the nanospheres, while the hydrophobic moieties are found in the interior, leading to the formation of hydrophobic hollow cavities, since the copolymer nanospheres are synthesized in an aqueous solution. Both hydrophobic QDs and γ-Fe_2O_3 can be embedded in weakly polar organic solvent (*22*). Therefore, it is believed that the embedment is completed via hydrophobic interactions. As shown in Figure 1, the nanoparticles are widely distributed in the nanospheres. The strong ultrasonication is usually used to prevent the nanoparticles from adsorbing on the surface, and consequently, the surface of the nanospheres is relatively clean as observed from the TEM images. It is reasonable to believe that the particles are actually embedded in the copolymer nanospheres rather than deposited on the surface. When the nanospheres, embedded with QDs and γ-Fe_2O_3, are dispersed in a polar aqueous solution, the embedded hydrophobic nanoparticles are unable to leak from the hydrophobic cavities. No detectable leakage was observed in the resultant H_2N-BFNS, even after 1 week of consecutive ultrasonication. Therefore, the H_2N-BFNS are stable if no chemical that can decompose and denature the nanospheres is present in solution, and any operation, which can denature the nanospheres, is avoided.

H_2N-BFNS were found to have good dispersivity as can be seen from Figure 2. If the numbers of embedded QDs and γ-Fe_2O_3 nanoparticles increase, the fluorescence of the nanospheres will become stronger, and the magneto-manipulation time will be shorter. Strong fluorescence of QDs enables us to observe the light spot from a single QD with the naked eye. Therefore, there are no rigorous requirements for the number of embedded nanoparticles and the reproducibility of the exact embedding amounts.

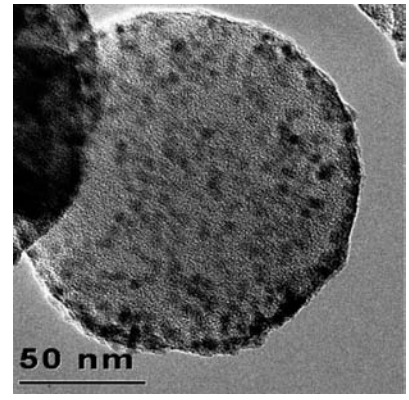


Figure 1. TEM image of a fluorescent magnetic bifunctional nanosphere embedded with both QDs and nano-γ-Fe_2O_3.

Strategy for the Modification and Biofunctionalization of the BFNS. As mentioned above, the reactive group of St-AAm for the coupling purpose is the amide on its surface. Since the scheme for the synthesis of the copolymer nanospheres is emulsifier-free, the surface is relatively clean and convenient for conjugating with other molecules. In most cases, it is difficult to anchor any other molecules, especially biomacromolecules, onto the surface of St-AAm, either due to the steric hindrance or due to insufficient reactivity of the amide group on the surface. Therefore, keeping the reactive group away from the surface of St-AAm or converting the amide into another more reactive group is crucial for further biofunctionalization.

As shown in Scheme 1, modification of St-AAm with hydrazine through the surface amide functional groups will produce a relatively reactive nanosphere surface with hydrazide groups. Subsequent co-embedment of CdSe/ZnS QDs and nano-γ-Fe_2O_3 into the H_2N-St-AAm will create H_2N-BFNS to facilitate both future application and construction of trifunctional nanospheres. End carboxyl groups can be readily generated on the surface via another amide linkage to form HOOC-BFNS by reaction of the surface hydrazide of H_2N-BFNS with succinic anhydride. It is due to the magnetism of HOOC-BFNS that the resulting product can be easily separated. The end carboxyl functionalization enables the nanospheres to decrease in steric hindrance and supply a flexible choice of functional groups for attachment to many molecules. The coupling via carboxyl groups can retain the bioactivity of proteins, and the resultant products containing BFNS can be easily separated and purified.

WGA with four carbohydrate binding sites can be conveniently attached to the nanosphere surface through an amide bond between its amino group and the carboxyl on the surface of HOOC-BFNS to produce WGA-TFNS targeting GlcNAc- or sialic acid-containing species.

Characterization of WGA-TFNS. The characterization of nanomaterials, especially nanosized bioconjugates or bioprobes, is extremely important for nanobiotechnology but is also very difficult. Consequently, any attempt to carry this out is highly significant. In the present work, we tried to employ FTIR spectroscopy and also biorecognition assay to characterize the WGA-TFNS.

FTIR Confirmation. FTIR is a powerful characterization tool with the capability of discriminating among various types of covalent bonds. In the present work, FTIR was used to confirm the conjugation of WGA onto the St-AAm surface. As mentioned in the Experimental Procedures, due to the influence of nano-γ-Fe_2O_3 and QDs in WGA-TFNS on the characterization of WGA on the surface of WGA-TFNS, WGA-St-AAm was used as the substitute for WGA-TFNS in the characterization experiments.

Figure 3 gives the FTIR spectra of H_2N-St-AAm, HOOC-St-AAm, and WGA-St-AAm. For H_2N-St-AAm, FTIR spectra showed a broad band near 3442 cm^{-1}, which corresponds to the amine stretching vibration. After pretreating with succinic anhydride (spectrum b), there were two enhanced peaks at 1159 and 1072 cm^{-1} associated with the stretching vibration of the C–N bond of the amide group, showing that succinic anhydride had reacted with H_2N-St-AAm to simultaneously produce HOOC-St-AAm with more amide linkages and carboxyl groups on the surface of the nanospheres for further binding to WGA.

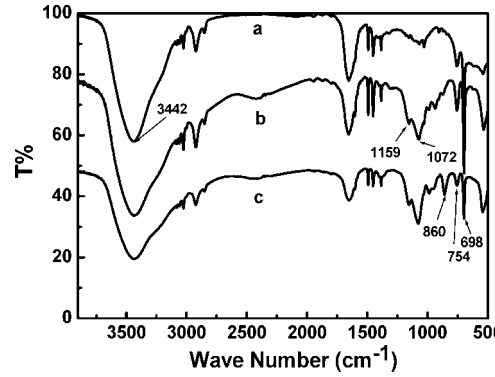

Figure 3. FTIR spectra of H_2N-St-AAm (a), HOOC-St-AAm (b), and WGA-St-AAm (c).

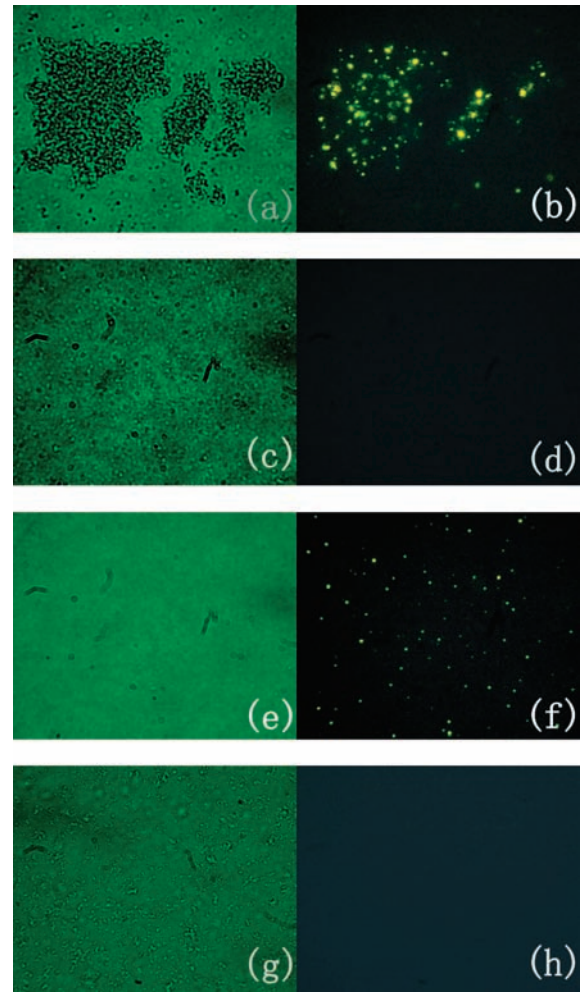

Figure 4. Microscopic images of CM-CT-QDs in the presence of WGA-St-AAm (a,b) or HOOC-St-AAm (c,d), CM-CT-QDs only (e,f) (as the control), and MAA-QDs in the presence of WGA-St-AAm (g,h): bright field (a,c,e,g); fluorescence (b,d,f,h).

For all the three kinds of nanosphere samples, two peaks of phenyl out-of-plane bending vibration at 754 and 698 cm^{-1} could be seen. However, for WGA-St-AAm (spectrum c), the peak at 860 cm^{-1} was obviously enhanced, which may be ascribed to the phenylalanine and tyrosine in the WGA (*35*).

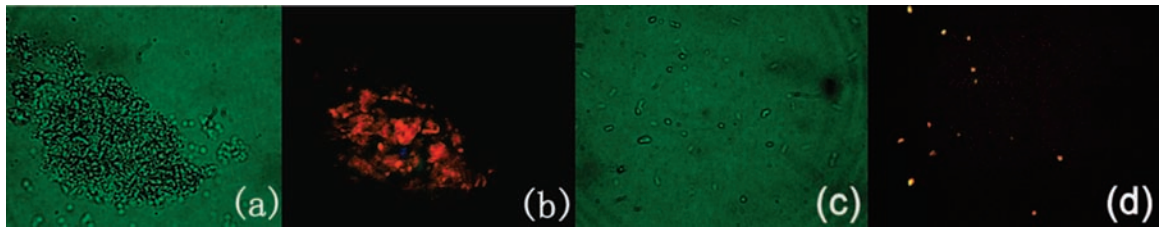

Figure 5. Microscopic images of WGA-TFNS having been incubated with *Staphylococcus aureus* (a,b) at 37 °C for 25 min. Magnetically separated on a magnetic scaffold, washed with 0.1 M Tris–HCl (pH 7.5, containing 1 mM $CaCl_2$ and 1 mM $MgCl_2$), and resuspended in 0.1 M Tris–HCl. Control experiment: WGA-TFNS and *E. coli* were incubated at 37 °C for 30 min. Bright field (a,c); fluorescence (b,d).

Biorecognition Assays. Since WGA can recognize chitin (*36*), which has four carbohydrate binding sites to chitin (*1*), carboxymethyl chitin-modified QDs (*37*) (CM-CT-QDs) can be an ideal probe for the presence of WGA on the surface of WGA-St-AAm. In order to further validate the conjugation of WGA onto the St-AAm surface, CM-CT-QDs were added to WGA-St-AAm and HOOC-St-AAm, respectively (all of them were dispersed in 0.1 M PBS at pH 7.4), and then allowed to react for 30 min. The mixture was centrifuged to remove excess CM-CT-QDs and washed with 0.1 M PBS (pH 7.4). The final product was dissolved in 0.1 M PBS and imaged with a microscope. Because the isoelectric point of WGA is about pH 9, it will be positively charged at pH 7.4, while CM-CT-QDs are negatively charged. In order to confirm that the binding of carboxymethyl chitin to WGA results from specific recognition rather than simply electrostatic interaction, negatively charged mercaptoacetic acid modified QDs (MAA-QDs) was used to examine the electrostatic interaction with WGA-St-AAm.

As shown in Figure 4, when WGA-St-AAm reacted with CM-CT-QDs, the apparent aggregation of WGA-St-AAm was observed in the same field of vision whether in bright or fluorescent field (Figure 4a,b). The pattern (Figure 4b) of fluorescence from CM-CT-QDs evidently indicates that the chitin of CM-CT-QDs had bound to WGA on the WGA-St-AAm surface, further resulting in aggregation due to synchronous exertion of multiple binding sites of WGA. But under the same conditions, no aggregation of HOOC-St-AAm was found (Figure 4c), and also no fluorescence from CM-CT-QDs was observed (Figure 4d), suggesting that CM-CT-QDs could not interact with HOOC-St-AAm without WGA. On the other hand, MAA-QDs could only make WGA-St-AAm slightly aggregate, not so remarkably as with CM-CT-QDs, and no fluorescence from MAA-QDs was observed (Figure 4g,h). This is because MAA-QDs could not strongly bind to WGA-St-AAm and had been washed off. The particle size of CM-CT-QDs was much smaller than WGA-St-AAm. Therefore, CM-CT-QDs could not be observed in bright field. However, the fluorescence of CM-CT-QDs could be seen clearly (Figure 4e,f), implying that CM-CT-QDs were of good dispersivity without aggregation. These experiments confirmed that WGA was indeed present on the surface of WGA-St-AAm, namely, on the surface of WGA-TFNS.
