

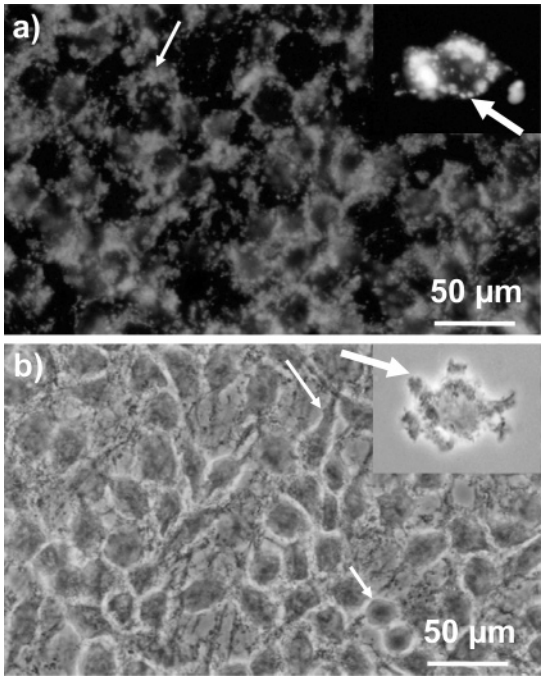

Figure 6. (a) Fluorescence microscopy (λ_{ex} = 546 nm and λ_{en} = 590 nm) imaging of monolayer cultures of microglial cells after incubation with TRITC fluorescent nanoparticles. (b) Phase contrast image of the field shown in part a. Thin arrows point both elongated and ovoid microglia. In the inserts, bold arrow shows (a) vesicles of internalized nanoparticles; (b) a typical membrane bud of activated microglia.

cells changed their shape and became ovoid with buds at the external border of the cytoplasm membrane (Figure 6b, insert). These outgrowths were characteristic of the macrophagic behavior induced by the activation with C6 extracts.

The fluorescent particles appeared both inside the cells with a perinuclear location and adsorbed at their surface (Figure 6a, thin arrow). The large dots at the periphery of the cell bodies were strongly fluorescent with a size suggesting that the beads concentrated as aggregates whatever the internalization processes (Figure 6a, insert). Independently of the chemical nature of the particles, they appear highly taken up by the activated microglial cells.

Flow cytometry is a system for sensing cells or particles as they move in a liquid stream through a laser or light beam past a sensing area. The flow cytometric analyses were performed on three sets of samples: (i) fluorescent nanoparticles alone and (ii) on microglial cells before and (iii) after fluorescent nanoparticles uptake (Figure 7). A procedure makes it possible to trace areas delimiting the interesting statistical events (cell population or free nanoparticles), called gates G1 and G2, on the "dots plots", from which the one-dimensional histograms are generated. This technique was used to estimate the contribution of the fluorescent signal of each sample and to check the contribution of the free nanoparticles, which remain in the cellular samples despite all the washing procedures.

Microglia cells (Figure 7A, gate 2) can be easily distinguished from free nanoparticles (Figure 7C, gate 1) because of their higher size. Indeed, gate 1 area gathered most of the free nanoparticles, whereas the cells spread in the area defined by gate 2. The cells, whatever the situation (after particle uptake (Figure 7F) or not (Figure 7A)), displayed similar distributions, and the overlapping distribution of free nanoparticles is very low. The analysis of fluorescence in the different gates in all the cases (control cells, free nanoparticles, cells with internalized nanoparticles) allowed us to estimate the contribution of free nanoparticles to the microglia signal. Indeed, from the histograms, it is possible to obtain, for either the whole statistical

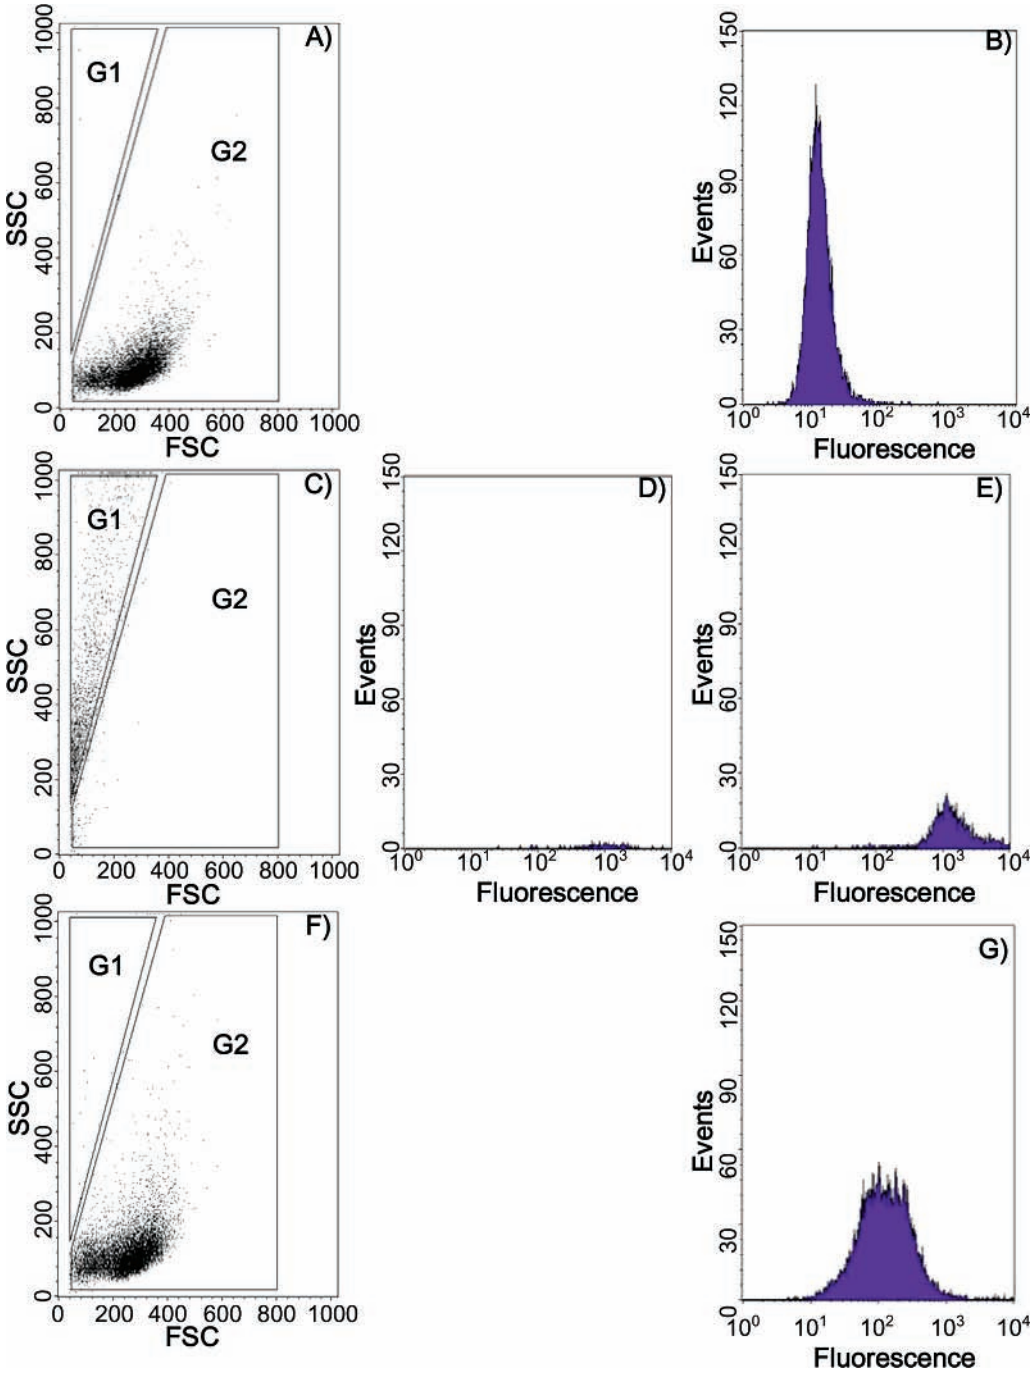

Figure 7. Flow cytometric data. The flow cytometric analyses were performed with control microglial cell cultures (A and B), free fluorescent nanoparticles (C, D, and E), and microglial cells after incubation with these particles (F and G). A, C, and F represent dot-plot of the scatters FSC (Forward SCatter, representative of the cell size, transmitted light) and SSC (Side SCatter, representative of the cell granularity, which depends on the density and the volume of intracellular organelles, diffracted light). B, D, E, and G are histograms of fluorescence: B, D, and G represent fluorescence observed in gate 2, and E, fluorescence observed in gate 1. Each dot represents one event. The scales in A, C, F (0−1000) are arbitrary scales representing increasing intensity of signal.

event or those inside each gate area, their contribution to the signal (% of events), their fluorescence average value, and the percentage of the total response (*P*) (Table 3).

The *P* assessment for the microglial cells before the uptake defines the level of contribution of the autogenerated fluorescence due to the cells themselves which also contributes to the total signal after the uptake (Figure 7B, 14 arbitrary units (a.u.); see Table 3). The contribution to the final signal *P* of the free particles, which are still present despite the various rinses at the end of the particle incubation with the cells, has been estimated in both G1 and G2 gated areas. In the G1 area, it is around 1.5 au (Table 3). The 5% contamination rate of free particles (Figure 7C, Table 3) in gate 2 has been used to estimate the contribution of the free remaining nanoparticles in the cellular sample (Figure 7F, Table 3). This contribution was less than 0.1% ($1.5 \times 5\% = 0.075$, to be compared to 166). Therefore, the relative contributions to the final fluorescence signal *P* (166 a.u.) of microglia cells after particle uptake are 91.5% from internalized particles, 8.4% from cellular autofluorescence ($14 \times 99.3\% = 13.9$ to be compared to 166), and 0.1% from free nanoparticles.

MR images were achieved on activated microglia (trapped in agarose gel) before and after incubation with of the two sets of metal oxide nanoparticles: Al_2O_3−APS−DTPA Gd (Figure

Table 3. Fluorescence Characterization of the Microglial Cells and the Fluorescent Nanoparticles

	% of events[a]		avg fluoresc, f_{av}[b]		$P = \% \times f_{av}$ (a.u.)[c]	
	G1	G2	G1	G2	G1	G2
unlabeled cells	0.7	99.3	14	14	0.1	14
free particles	94	5	1500	1100	1410	55
microglia cells after particle uptake	0.2	99.3	774	167	1.5	166

[a] The percentage of events (% of events) characterizes the statistical repartition of the populations (cells or particles) as defined in gates 1 (G1) and 2 (G2) (Figure 7). [b] The mean fluorescence is representative of the statistical average value after analysis of the fluorescence as described in these areas (Figure 7). [c] $P = \% \times f_{av}$ is the product of (% of events) by the average fluorescence and evaluates the relative contribution of the particles inside the microglial gate (G2) in the global signal of fluorescence. The reported values are the average of three independent experiments with a relative error that did not exceed 6%.

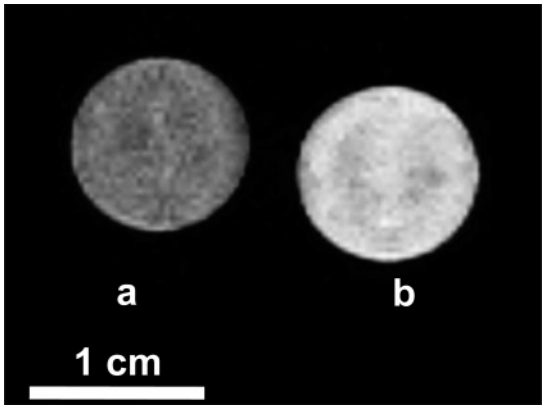

Figure 8. T_1-weighted images of microglia before and after incubation with 170 nM Al_2O_3−APS−DTPA-Gd. Images were performed with a typical T_1-weighted FLASH sequence as described in Experimental Procedures: (a) image of the control microglia before exposition to nanoparticles, (b) image of the microglia after incubations with the MRI contrast agents.

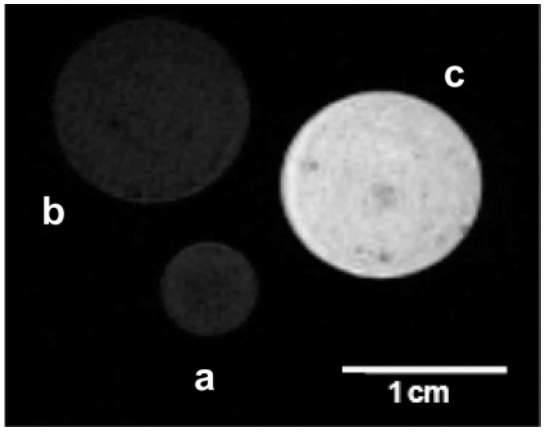

Figure 9. T_1-weighted image of microglial cells before and after incubation with 170 nM SiO_2−APS−DTPA-Gd. (a) 170 nM nanoparticles in solution, (b) microglial cells control, and (c) microglial cells after nanoparticle incubation. The signal-to-noise ratio of samples was homogeneous on all the slices.

8) and SiO_2−APS−DTPA Gd (Figure 9). Figure 8 shows a 2D slice of these cells obtained at 4.7 T with a T_1-weighted image (TE/TR = 1.7/100 ms, flip angle: 90°). The microglia cells exhibited T_1-relaxation times of 2357 and 1470 ms, respectively, before and after the internalization of Al_2O_3−APS−DTPA Gd.

The signal-to-noise ratios for cells before (Figure 8a) and after (Figure 8b) the uptake of Al_2O_3−APS−DTPA-Gd nanoparticles were 14.8 ± 1 and 20.7 ± 1, respectively. This 1.4 factor observed between the two images has been evaluated on the entire samples. This phenomenon was due to a decrease in water T_1-relaxation time once microglia cells were exposed to nanoparticles.

In the case of SiO_2−APS−DTPA-Gd nanoparticles, (Figure 9), the signal-to-noise ratio values on T_1-weighted images increased from 12 to 45, before and after nanoparticle incubation, respectively (3.75 ratio). This higher contrast of the SiO_2-based particles is directly correlated to a higher concentration of Gd^{3+} ions on the particles and therefore to the higher specific surface area (220 m^2/g) as compared to Al_2O_3 particles which only exhibit a 100 m^2/g specific surface area.

The determination of the relaxivity of the different samples (nanoparticles at 170 nM, microglia before and after nanoparticle internalization) shows that T_1 decreases from 2482 ± 10 ms (microglia control) to 753 ± 10 ms once nanoparticles were internalized; T_1 for the 170 nM nanoparticles solution was 1700 ± 10 ms.

These data allowed the estimation of the nanoparticle amount accumulated in microglia cells. Indeed, a 4.6 μM concentration of the cell-internalized nanoparticles can be deduced from the relaxivity curve of the SiO_2−APS−DTPA Gd nanoparticles (Figure 5). This value is 27-fold higher than that of incubated solution (170 nM). However, this high concentration value may nevertheless be strongly minimized because of two phenomena. On one hand, the relaxation time measured by MRI has two components: one obtained from the cellular content and the other from the agarose gel in which the microglia cells were diluted (as described in Experimental Procedures). Indeed, the cellular volume (20×10^6 microglia cells used in this experiment) was about 100 μL, representing one tenth of the volume of the entire sample. Thus, the nanoparticle concentration in the cells could be, in fact, ten-times higher than 4.6 μM. Moreover, assuming that the particles present in the cells are in vesicles, the contrast agent concentration may even be higher. On the other hand, Terreno et al. have already demonstrated that a T_1-saturation effect occurred when the nanoparticles are concentrated in the cell vesicles (*55*, *56*). Indeed, high concentrations of macromolecules, stored in these compartments, significantly reduce the mobility of water and of the gadolinium chelates, resulting in a "quench" of the relaxation enhancement. Thus, it again induces an underestimation of the amount of internalized gadolinium-grafted nanoparticles in the microglia cells.

With regards to these *in vitro* results, we may assume that this reconcentration of nanoparticles in microglial cells will allow *in vivo* experiments to be performed. Indeed, when chemoattracted to brain tumors these microglial cells increase the concentration of MRI agents in the desired area. Additionally, even if the nanoparticle amount in the cells decreases with time because of, for example, the release of the contrast agents or mitosis, their vesicle concentration will still be high enough to generate a positive contrast on MR images, since the "quench-effect" is lower.

Moreover, the imaging sequences used to detect the lanthanide contrast agents display a low sensitivity to susceptibility effects and minimize the imaging artifacts at high fields. These sequences are currently used for clinical MRI detection of

tumors as well as angiography. In fact, T_1-weighted MRI showed a strong *in vitro* contrast between control microglial cells and those after Gd nanoparticle uptake (a 3.75 ratio). Indeed, Vuu et al. have already demonstrated that Gd−Rh−NP which exhibited a 146% increase when internalized *in vitro*, were also visualized *in vivo* (*57*). The comparison with these results suggests that more reliable information than with iron oxide particles are expected in the next future for *in vivo* studies (*12*). In addition, the development of other specific sequences and the ease in their application such as magnetization transfer or inversion recovery will also lead to the achievement of higher contrasts and the adaptation of the contrast level to the studied tissue versus its environment.

CONCLUSION

The grafting of high-spin paramagnetic gadolinium chelates on nanoparticle surfaces such as alumina and silica nanoparticles offers a new strategy for the synthesis of contrast agents for MRI detection of cell populations capable of phagocytosis. In this situation, the advantage of gadolinium as a contrast agent is to generate a hypersignal for the observed populations, and the role of the nanoparticles is to facilitate the internalization through the membrane as well as to induce high local concentration of Gd^{3+} ion around the particle. This internalization property is a characteristic function of activated macrophages known to be chemoattracted and strongly accumulate particularly in brain pathological situations, including tumors. This type of detection will be straightforward for *in vivo* analysis in association with a high spatial resolution and open the route for more efficient contrast agents for MR cell tracking than the superparamagnetic contrast agents.

Protein microarrays are playing an increasingly important role in the discovery and characterization of protein−ligand interactions. The uniform orientation conferred by site-specific immobilization is a demonstrable advantage in using such microarrays. Here, we report on a general strategy for fabricating gold surfaces displaying a protein in a uniform orientation. An azido group was installed at the C-terminus of a model protein, bovine pancreatic ribonuclease, by using the method of expressed protein ligation and a synthetic bifunctional reagent. This azido protein was immobilized by Staudinger ligation to a phosphinothioester-displaying self-assembled monolayer on a gold surface. Immobilization proceeded rapidly and selectively via the azido group. The immobilized enzyme retained its catalytic activity and was able to bind to its natural ligand, the ribonuclease inhibitor protein. This strategy provides a general means to fabricate microarrays displaying proteins in a uniform orientation.

INTRODUCTION

Protein−protein, protein−DNA, and protein−small-molecule interactions underlie biological chemistry. High-throughput approaches for the discovery and characterization of these various protein−ligand interactions can elucidate complicated biological pathways. In addition, the screening of small-molecule libraries for agonists and antagonists can provide leads for drug development. Recyclable devices that detect biomarkers in body fluids can be used to diagnose human diseases. All of these challenges could be met with the use of protein microarrays (*1*−*7*).

Microarrays that present proteins in a uniform orientation exhibit both a markedly greater capacity to bind ligands (*8*−*11*) and more reproducible biological function (*12*) than do protein arrays generated by random immobilization. Microarrays of uniformly oriented DNA have long been produced on a large scale and used with notable success in studies of gene function (*13*−*16*). The production of DNA microarrays is made facile by the ease with which oligonucleotides can be prepared by chemical synthesis (*17*) and incorporated into large fragments by DNA polymerase (*18*). By comparison, the fabrication of protein microarrays is much more arduous. Notable advances are being made in the chemical synthesis of proteins (*19*), but this technology is still nascent. The immobilization of natural proteins is complicated by their chemical complexity, as each of the 20 proteinogenic amino acids bears a side chain with distinct physicochemical properties, and the reactivity of the same amino acid can vary according to its position in the three-dimensional structure. Post-translational modifications confer additional diversity (*20*). Other difficulties result from the intrinsic fragility of proteins, which have modest conformational stability and can be damaged upon chemical modification. Accordingly, new strategies are needed to immobilize proteins while maintaining their integrity.

Proteins have been immobilized on surfaces, both noncovalently and covalently (*21*). Noncovalent immobilization has been achieved by physical adsorption (*22*, *23*) and affinity tag-mediated complex formation (*24*, *25*). Covalent immobilization, however, results in more robust arrays. A common strategy, immobilization by attack of the nucleophilic side chain of lysine or cysteine residues, typically proceeds at multiple sites and thus yields an array in which the proteins have a random orientation (*26*, *27*). In contrast, site-specific covalent immobilization, via a unique natural (*8*, *11*, *28*) or nonnatural residue, affords a uniformly oriented protein array.

The azido group is chemically inert to the functional groups found in nature. Accordingly, the azido group is being exploited widely by chemical biologists (*29*), including in the site-specific immobilization of proteins and peptides by the Huisgen 1,3-dipolar azide−alkyne cycloaddition (*30*−*32*) and Staudinger ligation (*32*−*34*). A limitation, however, has been the difficulty of installing an azido group in a particular position in a protein. Recently, we developed a general method for appending the C-terminus of proteins with an azido group (*35*). Specifically, we used a bifunctional reagent bearing an α-hydrazino acetamido and azido group to cleave the transient thioester generated on the C-terminus of the target protein fused to an intein, thereby labeling the protein with an azido group on the C-terminus (Scheme 1). This azido group was available for site-specific installation of a fluorophore by the Huisgen 1,3-dipolar azide−alkyne cycloaddition.

Here, we report a general method for the site-specific immobilization of a protein. As a model protein, we choose one of the most thoroughly studied enzymes, bovine pancreatic ribonuclease (RNase A (*36*); EC 3.1.27.5). The immobilized protein was detected with a standard immunoassay, which does not report on the integrity of the protein. The choice of RNase A provides two rigorous means to assess its structure and function. First, RNase A is an efficient catalyst of RNA cleavage, and its catalytic activity provides a measure of its conformational integrity. Second, the affinity of the ribonuclease inhibitor protein (RI) for RNase A is extremely high (*37*), and this interaction provides an independent report on the structure

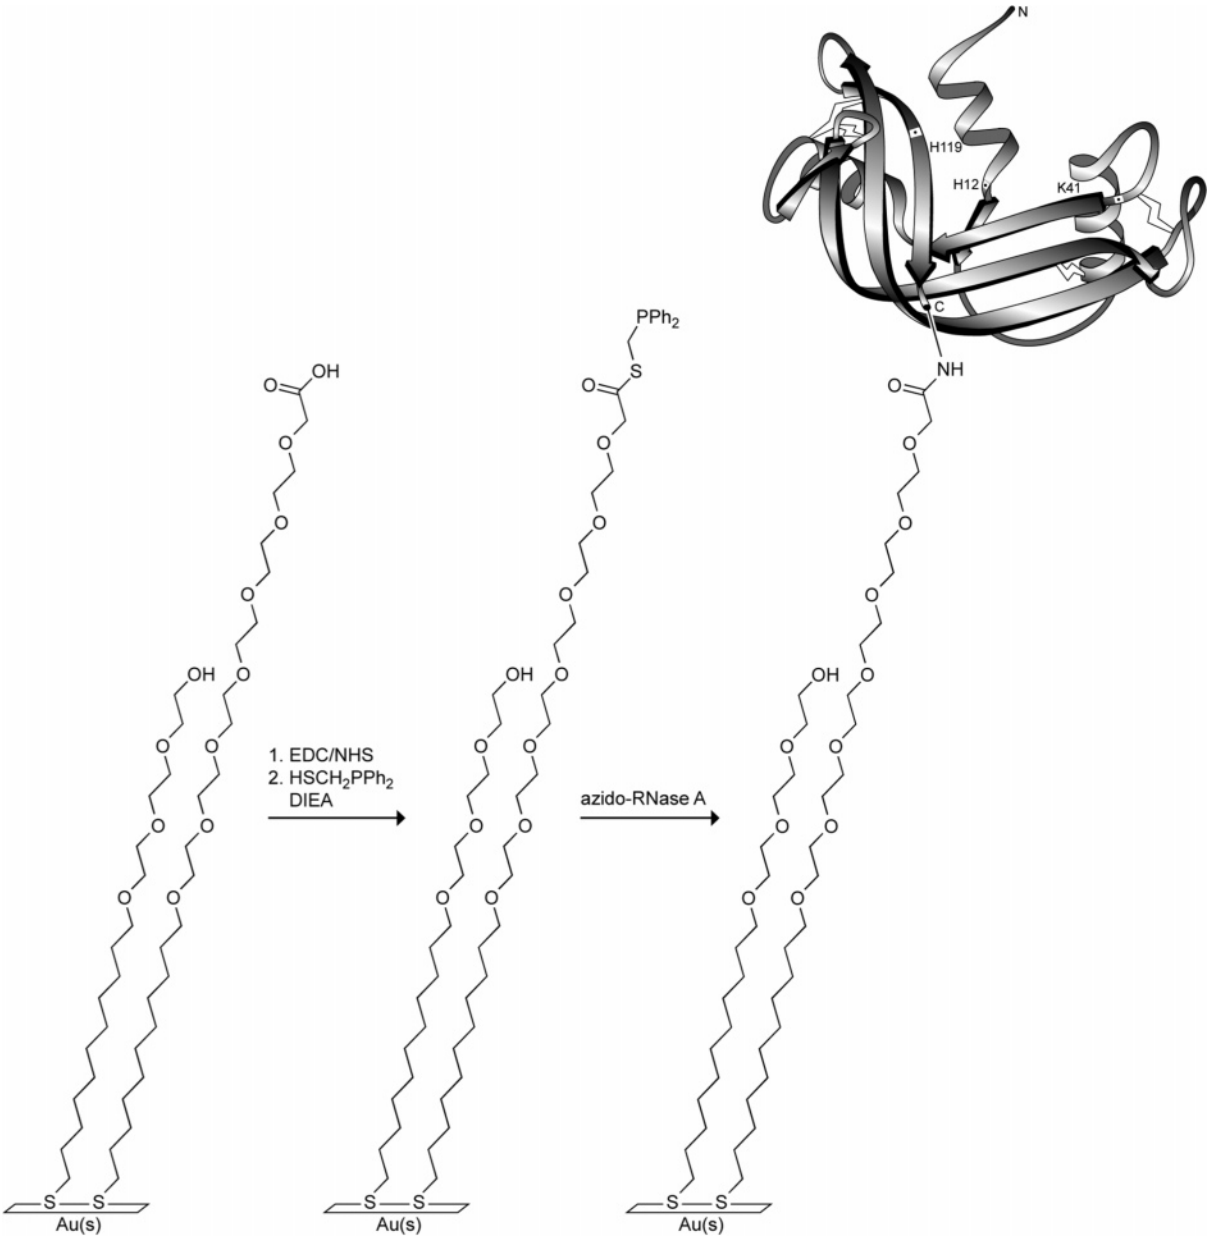
and function of the immobilized protein. Our strategy was to react an azido-RNase A (Scheme 1) (*35*) with a phosphinothioester group displayed on self-assembled monolayers (SAMs) of alkane thiols on a gold surface (Scheme 2). The resulting Staudinger ligation (*19, 38*−*40*) immobilized the protein in a form that retained its biological function.

MATERIALS AND METHODS

Materials. Silicon chips coated with gold prepared by physical vapor deposition as described previously (*41*) and were a generous gift from C.-H. Jang. Alkane thiols $HS(CH_2)_{11}(OCH_2CH_2)_6OCH_2CO_2H$ and $HS(CH_2)_{11}(OCH_2CH_2)_3OH$ were from Prochimia (Gdansk, Poland). A fluorogenic ribonuclease substrate, 6-carboxyfluorescein−dArU$(dA)_2$−6-carboxytetramethylrhodamine (6-FAM−dArU$(dA)_2$−6-TAMRA), was from Integrated DNA Technologies (Coralville, IA). Two-hand AtmosBags were from Sigma−Aldrich (St. Louis, MO).

Azido-RNase A was produced as described previously (Scheme 1) (*35*). Wild-type RNase A was from Sigma−Aldrich. Human RI was prepared as described previously and was a generous gift from R. J. Johnson and G. A. Ellis. Anti-RNase A rabbit primary antibody was from Biodesign International (Kennebunk, ME). AlexaFluor 488-conjugated anti-rabbit secondary antibody was from Molecular Probes (Eugene, OR). Anti-RI chicken primary antibody was from Genetel (Madison, WI). Fluorescein-conjugated anti-chicken secondary antibody was from Abcam (Cambridge, MA).

Instrumentation. Fluorescence measurements for assaying ribonucleolytic activity were made with a QuantaMaster 1 photon-counting spectrofluorimeter equipped with sample stirring (Photon Technology International, South Brunswick, NJ). Immunoassays of immobilized RNase A and RI bound to the immobilized RNase A were visualized with a GeneTac UC4 × 4 fluorescence scanner (Genomic Solutions, Ann Arbor, MI). The optical thickness of SAMs and proteins on the gold chips was determined with a AutoEL ellipsometer (Rudolf Research, Flanders, NJ).



Preparation of Phosphinothioester-Displaying SAMs of Alkane Thiols on Gold Chips. Alkane thiol solutions were prepared by dissolving $HS(CH_2)_{11}(OCH_2CH_2)_6OCH_2CO_2H$ and $HS(CH_2)_{11}(OCH_2CH_2)_3OH$ in ethanol to a final concentration of 0.25 mM each. The oligo(ethylene oxide) $HS(CH_2)_{11}(OCH_2CH_2)_3OH$ is included to discourage the nonspecific adsorption of protein (*42*), which can be problematic (*43*). Gold chips were cleaned under a stream of Ar(g) and immersed in the alkane thiol solution for at least 18 h. After rinsing thoroughly with ethanol and drying under a stream of Ar(g), the chips were overlaid with an aqueous solution containing *N*-hydroxysuccinimide (NHS, 50 mM) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC, 200 mM) for 7 min to generate succinimidyl esters in situ. Diphenylphosphinomethanethiol (PPh_2CH_2SH) was synthesized as described earlier previously (*44*), and was dissolved in anhydrous DMF to a concentration of 0.10 M. *N,N*-Diisopropylethylamine (DIEA) was added to a concentration of 0.12 M. The resulting solution (in a 25 mL flask), succinimidyl ester displaying chips (in a Petri dish containing a water-soaked absorbent paper to serve as a humid chamber), and azido-RNase A (10 μM in 5% v/v DMF(aq)) were placed in a two-hand AtmosBag along with vials containing anhydrous DMF (20 mL/vial), water (20 mL/vial), and 25 mM sodium phosphate buffer at pH 7.5 (20 mL/vial). The AtmosBag was sealed and connected to the house vacuum on one end and an Ar(g) supply on the other end. The air inside the bag was removed by using the house vacuum and flushing twice with Ar(g) before finally filling up the bag with Ar(g). The diphenylphosphinomethanethiol−DIEA solution was transferred into a small empty vial, and succinimidyl ester displaying chips were incubated in that vial for 2 h. The phosphinothioester-displaying chips thus produced were rinsed with DMF (2 × 20 mL) and then with water (2 × 20 mL).

Immobilization of Azido-RNase A by Staudinger Ligation. Azido-RNase A (1 μL, 10 μM in 5% v/v DMF(aq)) was incubated on phosphinothioester-displaying chips for 1, 5, 10, and 15 min inside the AtmosBag (Figure 1). The chips were subsequently rinsed with 25 mM sodium phosphate buffer at pH 7.5 (20 mL) and removed from the AtmosBag. They were then incubated in 25 mM sodium phosphate buffer at pH 7.5 (1.0 mL) for 30 min to remove protein bound nonspecifically.

Detection of Immobilized RNase A. A chip displaying immobilized RNase A was overlaid with anti-RNase A rabbit primary antibody (100 μg/mL in 25 mM sodium phosphate buffer at pH 7.5) for 30 min. The chip was then rinsed with 25 mM sodium phosphate buffer at pH 7.5 (2 × 20 mL), and incubated in the same buffer for 15 min. The chip was subsequently overlaid with AlexaFluor 488-conjugated anti-rabbit secondary antibody (2.0 μg/mL in 25 mM sodium phosphate buffer at pH 7.5) for 30 min. Finally, the chip was rinsed with 25 mM sodium phosphate buffer at pH 7.5 (2 × 20 mL), incubated in the same buffer for 15 min, and scanned with a Genomic Solutions GeneTac UC4 × 4 Fluorescence Scanner using a gain of 50.

Ribonucleolytic Activity Assay on Immobilized RNase A. A phosphinothioester-displaying chip was overlaid with azido-RNase A (10 μM in 5% v/v DMF(aq)) in an Ar(g) atmosphere to immobilize RNase A. The chip was rinsed with 25 mM sodium phosphate buffer at pH 7.5 (2 × 20 mL) and then introduced into a vial containing a solution (22 mL) of 0.10 M 2-(*N*-morpholino)ethanesulfonic acid (MES)−NaOH buffer at pH 6.0 containing 0.10 M NaCl. A fluorogenic substrate of RNase A, 6-FAM−dArU$(dA)_2$−6-TAMRA (10 μL of a 40 μM

Scheme 2. Site-Specific Protein Immobilization on a SAM by Staudinger Ligation[a]

[a] The three active-site residues and N- and C-termini are indicated explicitly.

solution) was introduced into the vial, and the vial was placed on a shaker. Aliquots (2.0 mL) were withdrawn at known time intervals, and their fluorescence was measured ($\lambda_{ex} = 493$ nm, $\lambda_{em} = 515$ nm). After 1 h, excess wild-type RNase A (20 μL of a 2.8 mg/mL solution) was added to obtain a value of fluorescence after complete cleavage of the substrate. A phosphinothioester-displaying chip was overlaid with wild-type RNase A (10 μM in 5% v/v DMF(aq)), and the assay was performed again. As a negative control, a similar assay was performed on a phosphinothioester-displaying chip which was not overlaid with RNase A. The percentage of the fluorescent substrate cleaved at various time intervals in the negative control was subtracted from the corresponding values for azido- and wild-type RNase A, and plotted against time to generate the graph in Figure 2.

Detection of RI Bound to Immobilized RNase A. Azido-RNase A (1 μL, 10 μM in 5% v/v DMF(aq)) was spotted on phosphinothioester-displaying SAMs on a gold chip for 15 min in an AtmosBag filled with Ar(g). The chip was removed from the bag, rinsed with 25 mM sodium phosphate buffer at pH 7.5 (2 × 20 mL), and incubated in the same buffer for 30 min to remove nonspecifically bound RNase A. RI (10 μM in 25 mM sodium phosphate buffer at pH 7.5 containing 10 mM DTT) was overlaid on the chip for 10 min at 4 °C. The chip was then rinsed with 25 mM sodium phosphate buffer at pH 7.5 containing 10 mM DTT (2 × 20 mL) and incubated in the same buffer for 15 min.

Immunoassay. After RI binding, the chip was overlaid with bovine serum albumin (2.0 mg/mL in 25 mM sodium phosphate buffer at pH 7.5) for 15 min. The chip was rinsed with 25 mM sodium phosphate buffer at pH 7.5 (2 × 20 mL), and subsequently incubated with anti-RI chicken primary antibody (12.5 μg/mL in 25 mM sodium phosphate buffer at pH 7.5) for 15 min. The chip was rinsed with 25 mM sodium phosphate buffer at pH 7.5 (2 × 20 mL), incubated in the same buffer for 15 min, and subsequently overlaid with fluorescein-conjugated anti-chicken secondary antibody (1.5 μg/mL in 25 mM sodium phosphate buffer at pH 7.5) for 15 min. The chip was rinsed with 25 mM sodium phosphate buffer at pH 7.5 (2 × 20 mL), incubated in the same buffer for 15 min, and then scanned with

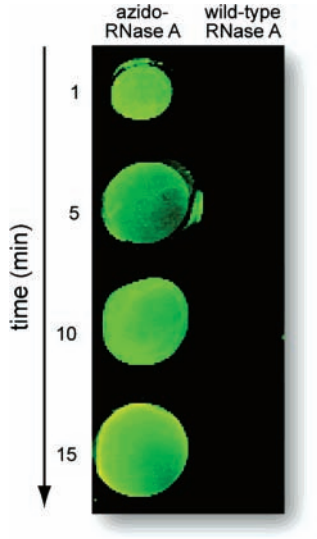


Figure 1. Time course and specificity of immobilization of azido-RNase A. Azido-RNase A and wild-type RNase A (each 10 μM) were spotted on a phosphinothioester-displaying chip for various times. The chip was overlaid with an anti-RNase A primary antibody (10 μg/mL) and a secondary antibody conjugated to AlexaFluor 488 (2 μg/mL).

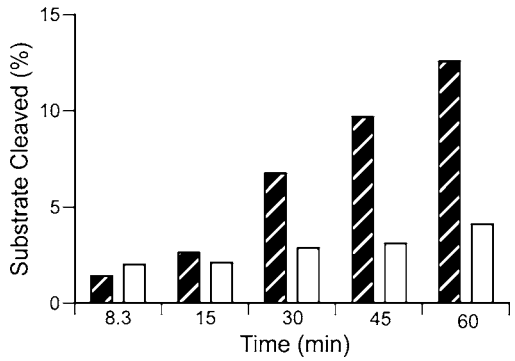

Figure 2. Catalytic activity of immobilized RNase A. Phosphinothioester-displaying chips were incubated with azido-RNase A (hatched bars) or wild-type RNase A (open bars), and assayed for ribonucleolytic activity by using a fluorogenic substrate.

a Genomic Solutions GeneTac UC4 × 4 fluorescence scanner using a gain of 50.

Ellipsometry. Ellipsometric measurements were performed to determine the optical thicknesses of the SAMs, RNase A, and RI on the gold surface. The measurements were performed with a wavelength of 632 nm and an angle of incidence of 70°. The optical thickness reported is the average from seven different surface locations. A slab model was used to interpret these constants in which the slab (SAM and protein) was assumed to have an index of refraction of 1.46.

RESULTS AND DISCUSSION

Generation of Phosphinothioester-Displaying SAMs on Gold. SAMs of alkane thiols on gold were prepared by incubating gold-coated silicon chips in an ethanolic solution containing equimolar quantities of $HS(CH_2)_{11}(OCH_2CH_2)_6OCH_2CO_2H$ and $HS(CH_2)_{11}(OCH_2CH_2)_3OH$. Subsequently, the chips were overlaid with an aqueous solution of EDC/NHS to produce succinimidyl ester-displaying chips. Diphenylphosphinomethanethiol was synthesized in multigram quantities by a procedure described previously (*44*), and was reacted with succinimidyl ester-displaying chips to generate phosphinothioester-displaying chips. The resultant phosphinothioester-displaying SAMs of alkane thiols on gold surfaces provide a highly homogeneous surface for performing the Staudinger ligation. These surfaces are significantly better defined than that of a glass slide, which had been used previously for Staudinger ligation (*33*, *34*, *45*), thereby enabling the use of high-precision techniques such as ellipsometry, surface plasmon resonance (*46*), and liquid crystal methods (*11*, *47*) for the detection of ligand binding.

Azido-RNase A Immobilization by Staudinger Ligation. Azido-RNase A (in 5% v/v DMF(aq)) was incubated on phosphinothioester-displaying chips for immobilization by Staudinger ligation (Scheme 2). A time course of immobilization of azido-RNase A is depicted in Figure 1. The immobilized RNase A was detected by an immunoassay utilizing a primary anti-RNase A antibody and a fluorescent secondary antibody. Protein immobilization proceeded rapidly, with a significant fluorescence signal being clearly observable after only 1 min. The rapidity of this reaction is reminiscent of that for the immobilization of azido-peptides to glass slides with a phosphinothioester-mediated Staudinger ligation (*33*).

Exposure of a protein to a phosphinothioester-displaying chip could lead to undesirable protein immobilization via a side chain of the protein. For example, RNase A has 10 lysine residues, any one of which could attack the phosphinothioester via its nucleophilic ϵ-amino group, thereby resulting in random immobilization. Additionally, the protein could be immobilized noncovalently onto the surface by hydrophobic interactions with the phenyl groups of the phosphinothioester. To probe for these possible immobilization routes, wild-type RNase A was incubated adjacent to azido-RNase A on phosphinothioester-displaying SAMs on gold. No significant immobilization of wild-type RNase A was observed during the time scale required for substantial azido-RNase A immobilization (Figure 1), thereby establishing that the immobilization of azido-RNase A proceeded exclusively via the azido group. Longer incubation times (>1 h) did result in detectable immobilization of wild-type RNase A (data not shown), highlighting the benefit of the rapidity of the Staudinger ligation.

Attempts to immobilize azido-RNase A in purely aqueous solutions of various pH were unsuccessful (data not shown). The presence of a small quantity of polar organic solvent (here, 5% v/v DMF) is required, perhaps for adequate solubilization of the immobilized phosphinothioester. A version of the Staudinger ligation has been used to immobilize proteins in purely aqueous solutions (*34*), though this method requires a long incubation period (4 h) and installs a racemic nonnatural moiety—a phosphine oxide—into the immobilized protein.

Activity of Immobilized RNase A. Enzymatic activity assays were performed with phosphinothioester-displaying chips incubated with azido-RNase A for 10 min. These chips were incubated in solutions containing 6-FAM−$dArU(dA)_2$−6-TAMRA, which is a fluorogenic substrate for RNase A (*48*). After 1 h, the fluorescence intensity from a chip incubated with azido-RNase A had increased substantially relative to one incubated with wild-type RNase A (Figure 2). Thus, the azido-RNase A was immobilized preferentially, and immobilization did not destroy its enzymatic activity.

Binding to Immobilized RNase A. A phosphinothioester-displaying chip was overlaid with azido-RNase A, and subsequently overlaid with RI. Another phosphinothioester-displaying chip was incubated with wild-type RNase A, and then overlaid with RI. Both chips were assayed for the presence of RI by an immunoassay that involved a primary antibody to RI and a fluorescent secondary antibody. The chip that was overlaid with azido-RNase A had a high fluorescence signal, whereas the chip incubated with wild-type RNase A produced negligible fluorescence (Figure 3A). This result demonstrated that the RI detected on the surface was bound to

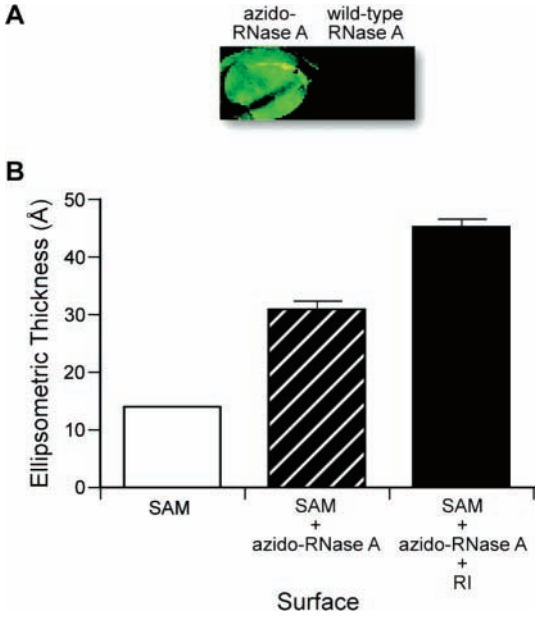

Figure 3. Binding of RI to immobilized RNase A. (A) Immunoassay with a primary anti-RI antibody and a secondary antibody conjugated to fluorescein. (B) Ellipsometric thickness before and after incubation with azido-RNase A, and after the addition of RI.

the immobilized RNase A, and was not binding to the surface nonspecifically.

Ellipsometric measurements corroborated these findings (Figure 3B). Upon incubation of azido-RNase A on phosphinothioester chips for 10 min, the ellipsometric thickness of the surface increased by 16.9 Å. Exposure to RI resulted in a further increase of 14.3 Å. That the increase in thickness upon RI binding was less than the increase in thickness upon azido-RNase A immobilization is surprising, as RI (molecular mass ~51 kDa) is a larger protein than RNase A (molecular mass ~14 kDa). One explanation is that the immobilization of RNase A via its C-terminus forces RI to bind obliquely to the surface, causing a smaller increase in the thickness than expected from lineal binding. Another explanation is that the binding of RI molecules to a few immobilized RNase A molecules creates steric hindrance to other incoming RI molecules. Consequently, not all of the immobilized RNase A molecules would form a complex with RI, producing a smaller than expected increase in ellipsometric thickness. To obtain additional information, we measured the ribonucleolytic activity of the immobilized RNase A after incubation with excess RI. Only half of the activity was lost, consistent with steric hindrence preventing half of the RNase A molecules from forming a complex with RI.

SUMMARY

We have developed a general strategy for the site-specific immobilization of a protein on SAMs on a gold surface. Immunoassays, assays of enzymatic activity, and ellipsometric measurements revealed that the immobilized protein retained its structure and function. We envisage numerous applications of our strategy, which could be applicable to any protein. For example, we expect that our strategy could be useful for the high-throughput screening of ligands, in diagnostic applications that detect disease markers in clinical samples, and in industrial processes that utilize immobilized enzymes as recyclable catalysts (*49*).

Tailoring Protease-Sensitive Photodynamic Agents to Specific Disease-Associated Enzymes

Doris Gabriel,† Marino A. Campo,† Robert Gurny, and Norbert Lange*

Laboratory of Pharmaceutics and Biopharmaceutics, Section of Pharmaceutical Sciences, University Lausanne, University Genève, 30 Quai Ernest-Ansermet, CH-1211, Geneva, Switzerland. Received October 13, 2006; Revised Manuscript Received March 27, 2007

We have developed novel polymeric photosensitizer prodrugs (PPPs) for improved photodynamic therapy. In PPPs, multiple photosensitizer units are covalently coupled to a polymeric backbone via protease-cleavable peptide linkers. These initially non-photoactive compounds become fluorescent and phototoxic after specific enzymatic cleavage of the peptide linkers and subsequent release of the photosensitizer moieties. Tethering the photosensitizer via a short and easily modified amino acid sequence to the polymeric backbone allows for the targeting of a wide variety of proteases. Model compounds, sensitive to trypsin-mediated cleavage, with different pheophorbide a-peptide loading ratios and backbone net charges were evaluated with respect to their solubility, "self-quenching" capacity of fluorescence emission, and reactive oxygen species (ROS) generation. In addition, linker sequence impaired selectivity toward enzymatic cleavage was demonstrated either by incubating PPPs with different enzymes having trypsin-like activity or by introducing a single D-arginine mutant in the peptide sequence. In vitro cell culture tests confirmed dose-dependent higher phototoxicity of enzymatically activated PPPs compared to the nonactivated conjugate after irradiation with white light. These data suggest that similar compounds adapted to disease-associated proteases can be used for selective photodynamic therapy.

INTRODUCTION

Photodynamic therapy (PDT[1]) has emerged as a promising therapeutic option for the treatment of cancer and other nonmalignant diseases. It combines the simultaneous use of a photosensitizer (PS), oxygen, and light to locally generate cytotoxic reactive oxygen species (ROS) causing the destruction of unwanted tissues (*1*, *2*). This treatment has several advantages over surgery and radiotherapy: it is comparatively noninvasive, it can be targeted accurately, repeated doses can be given without the total-dose limitations associated with radiotherapy, and the healing progress results in little or no scarring. PDT can usually be done on an outpatient or day-case basis; it is convenient for the patient and has few or no side effects. However, one of the main drawbacks of PDT is unfavorable biodistribution and lack of selective accumulation of conventional PSs in the target tissue. Although passive and active targeting strategies have been shown to enhance the specific delivery of PS to the site of disease, none of the exploited active targeting strategies has led to the development of a clinically relevant compound until today (*3*).

Photodynamically induced collateral damage to vital tissue structures within the irradiated area demand that PSs or PS precursors become photoactive specifically at the target site, in response to the disease environment. Exploiting enhanced proteolytic activities, a hallmark in several pathologic conditions involving tissue remodeling and invasion (*4*−*8*), is a novel concept for enzyme-mediated activation of polymeric photosensitizer prodrugs (PPPs). In so-called first-generation conjugates, multiple PSs are directly coupled to a poly(L-lysine) backbone (PLL). In this configuration, the PPP is non-phototoxic due to energy transfer between PS moieties. Proteolytic cleavage of the polymeric backbone by enzymes leads to PS activation and to an increase in phototoxicity. We and others have already demonstrated the advantages of such strategy in vitro (*9*) and in vivo (*10*). Nonetheless, these photodynamic agents are limited to targeting selected proteases capable of degrading the polymeric backbone. In order to broaden the spectrum of this targeting strategy to a wide variety of disease-related proteases, we propose the use of a peptidic linker between the PS and a stable polymeric backbone, whose sequence will determine the proteolytic enzyme being targeted. This approach will allow for a more specific targeting of proteases and prevent nonspecific activation by backbone degradation.

In the present study, we describe the synthesis and evaluation of novel PPPs that follow this strategy. Activation of the PPP occurs by abrogation of the intramolecular interaction between photosensitzers, induced by enzymatic cleavage of the polymer−photosensitizer linker and release of truncated photosensitizer−peptide fragments. In contrast to first-generation conjugates, where enzymatic cleavage occurs on the polymeric backbone, the loading ratio and restoration of phototoxicity are limited by neither available cleavage sites on the polymeric backbone nor the release of potentially quenched fragments.

These newly designed second-generation pheophorbide a-peptide−poly(L-lysine) conjugates are designed to have molecular weights (≥50kDa) above the renal excretion limit and are, thus, expected to have prolonged plasma half-lives and EPR targeting capability (*11*). Small water-solubilizing backbone protecting units will maintain the resulting conjugate at an estimated size of 70 kDa, therefore helping the PPP to elude the immune system and prevent a reaction from the organism after repeated treatments.

In our studies, pheophorbide a was chosen as the photosensitizer because of its photochemical properties, including high absorption in the range 660−680 nm, allowing for deeper tissue penetration (*12*, *13*). Furthermore, pheophorbide a is a natural compound with a known toxicological profile. However, the developed synthetic strategy can be easily adapted to other photosensitizer moieties.

EXPERIMENTAL PROCEDURES

Chemicals. All commercial reagents were used as obtained. Anhydrous forms of acetonitrile, *N*,*N*-dimethylformamide (DMF), dimethylsulfoxide (DMSO), dichloromethane (DCM), diethyl ether, methanol, and ethyl acetate, as well as *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC), *N*-hydroxysuccinimide (NHS), *N*,*N*-diisopropylethylamine (DIPEA), trypsin (bovine pancreas), poly(L-lysine) HBr (25 KDa), HGly-2-chlorotrityl resin (1.1 mmol/g), FmocAlaOH, Fmoc-D-Arg(Pbf)OH, Fmoc-L-Arg(Pbf)OH, FmocGlyOH, FmocPheOH, FmocSer(*t*-Bu)OH, FmocThr(*t*-Bu)OH, O-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*,*N*-tetramethyluronium hexafluorophosphte (HATU), and 1 M picrylsulfonic acid aqueous solution were purchased from Fluka (Buchs, Switzerland). Pheophorbide a was purchased from Frontier Scientific (Logan, UT). D-MEM+GlutaMAX I medium, as well as HBSS and D-PBS solutions were purchased from GIBCO (Invitrogen, Basel, Switzerland). 4-Aminobenzamidine dihydrochloride, thrombin (bovine plasma), and elastase (type l, porcine pancreas) were obtained from Sigma-Aldrich (Buchs, Switzerland).

General Procedures. Mass spectra were recorded using a Finnigan MAT SSQ 7000 (Thermo Electron Co. Waltham, MA). Fluorescence measurements were done with a SPEX Fluoromax (Perkin-Elmer, Wellesley, MA excitation at 400 nm and emission at 670 nm). UV/vis data were obtained using a Cintra 40 UV/vis spectrometer (GBC, Dandenong, Australia).

Preparation of Pheophorbide a-NHS Ester and *N*-Succinimidyl (1-methyl-3-pyridinio)formate Iodide. Synthesis of Pheophorbide a-NHS ester using EDC/NHS chemistry, as well as preparation of *N*-succinimidyl (1-methyl-3-pyridinio)formate iodide, was done as described previously (*9*, *14*).

Peptide Synthesis. The synthesis of the trypsin-cleavable peptide Gly-Thr-Phe-(L)Arg-Ser-Ala-Gly and the control Gly-Thr-Phe-(D)Arg-Ser-Ala-Gly were performed manually on HGly-2-chlorotrityl resin 200−400 mesh (1.1 mmol/g, 0.355 g, 0.39 mmol) using the standard FMOC strategy (*15*). Peptides were purified by RP-HPLC and obtained in >95% purity. ES-MS: 695.6 ($[M + H]^+ = 695.4$ calculated for $C_{29}H_{47}N_{10}O_{10}^+$) and 348.3 ($[M + 2H]^{2+} = 348.2$ calculated for $C_{29}H_{48}N_{10}O_{10}^{2+}$).

Pheophorbide−Peptide Conjugates. To a solution of the corresponding peptide (15 mg, 1.62×10^{-5} mol) in DMSO (1.0 mL) was added pheophorbide a-NHS ester (0.5 equiv, 5.6 mg) in DMSO (1.5 mL). The reaction was allowed to proceed for 4 h after the dropwise addition of DIPEA (2.0 equiv). The reaction was quenched by adding water (2.5 mL) and TFA to pH 3. Pheophorbide−peptide conjugates were purified by preparative RP-HPLC (Waters Delta 600 HPLC) on a C8, Nucleosil 300−10 column (Macherey-Nagel) using a 0.1% TFA water/acetonitrile gradient (flow rate = 20 mL/min). Eluting products were monitored by dual UV/vis absorbance at 230 nm and 400 nm and were obtained as green solids after lyophilization. ESI-MS: 1269.9 ($[M + H]^+ = 1269.6$ calculated for $C_{64}H_{81}N_{14}O_{14}^+$) obtained for both L and D configured pheophorbide−peptide conjugates.

Final Assembly of PPP. To a solution of the corresponding pheophorbide−peptide (1.8 mg, 1.3×10^{-6} mol), PLL (25 kDa) (1.07 mg, 4.34×10^{-8} mol, 5.1×10^{-6} mol of ϵ-NH_2 functions), and HATU (1.3 equiv based on pheophorbide−peptide to be activated) in DMSO (0.5 mL) was added DIPEA (3 equiv based on the number of ϵ-NH_2 functions of PLL) and the mixture was stirred under argon overnight (14 h). Loading of 30 PS units per PLL was confirmed by analytical RP-HPLC monitoring of the reference pheophorbide−peptide peak ($\lambda_{abs} = 400$ nm), which completely disappeared during the reaction, giving rise to a single, new, and broader peak corresponding to the polymeric conjugate.

In order to cap the remaining free ϵ-NH_2 functions of PLL, *N*-succinimidyl (1-methyl-3-pyridinio)formate iodide (1.5 mg, 1.1 equiv based on the number of free ϵ-NH_2 functions remaining on PLL) in DMSO (0.1 mL) was added to the reaction mixture and the reaction allowed to proceed for 1 h. The reaction mixture was then quenched by adding a water/acetonitrile (70/30) mixture (3.0 mL) and TFA to pH 3. The resulting solution was filtered and purified by SEC using a Sephacryl S-100 (Amersham Biosciences, Otelfingen, Switzerland) column and 30:70:0.00025 acetonitrile/water/TFA as eluent. The fraction containing the product was lyophilized to yield the desired product as a green solid. UV/vis (H_2O): 287.6 (29 707 M^{-1} cm^{-1}), 390.0 (122 128 M^{-1} cm^{-1}), 504.4 (13 803 M^{-1} cm^{-1}), 623.6 (8402 M^{-1} cm^{-1}), 667.6 (43 510 M^{-1} cm^{-1}).

Note: Conjugates carrying 6 and 18 PS moieties per PLL chain were prepared by a similar procedure as the one described above but used the corresponding amounts of pheophorbide−peptide (0.3 mg and 1.08 mg, respectively) and *N*-succinimidyl (1-methyl-3-pyridinio)formate iodide (1.9 mg and 1.7 mg, respectively).

Enzymatic Cleavage of Pheophorbide−L-Peptide and Control Pheophorbide−D-Peptide. Enzymatic cleavage of the pheophorbide−peptide by trypsin (0.5 mg/mL) was confirmed by monitoring the released fragment pheophorbide a-Gly-Thr-Phe-Arg by analytical HPLC. Either pheophorbide−L-peptide or control pheophorbide−D-peptide at equimolar concentration with respect to pheophorbide a in PBS was incubated with the enzyme at 37 °C. After 30 min, aliquots of the digestion mixture were quenched with TFA and subjected to analytical HPLC analysis, using a Nucleodur C18 gravity 3 μ CC 125/4 column from Macherey-Nagel and a linear acetonitrile/0.1% TFA−water gradient. Fluorescence was detected on a Merck Hitachi FL detector L7480 at an emission wavelength of 670 nm and excitation wavelength at 405 nm. The same conditions were used to monitor the release of cleaved fragments from the PPP.

Fluorescence Measurements of Undigested PPP. The optical density for each of the aqueous solutions containing the PPP carrying either 6, 18, or 30 PS units per PLL chain was adjusted to 0.125 at 667 nm, setting the PS concentration to 3.5 μM. The fluorescence intensity of each of these equimolar solutions was measured at 37 °C using a SPEX Fluoromax (Perkin-Elmer, Wellesley, MA) setting the excitation at 400 nm and emission at 670 nm.

ROS Measurements in Aqueous Media Using Iodide. ROS were measured by a modified procedure previously described by Mosinger (*16*), in which the I_3^- (286 nm absorbance band) generated by ROS oxidation of I^- in aqueous media was monitored (*9*). Briefly, to 0.6 mL of D-PBS buffered solutions containing PPPs at equimolar concentrations with respect to pheophorbide a, NaI was added in aqueous solution to obtain a final concentration of 0.625 M, and the

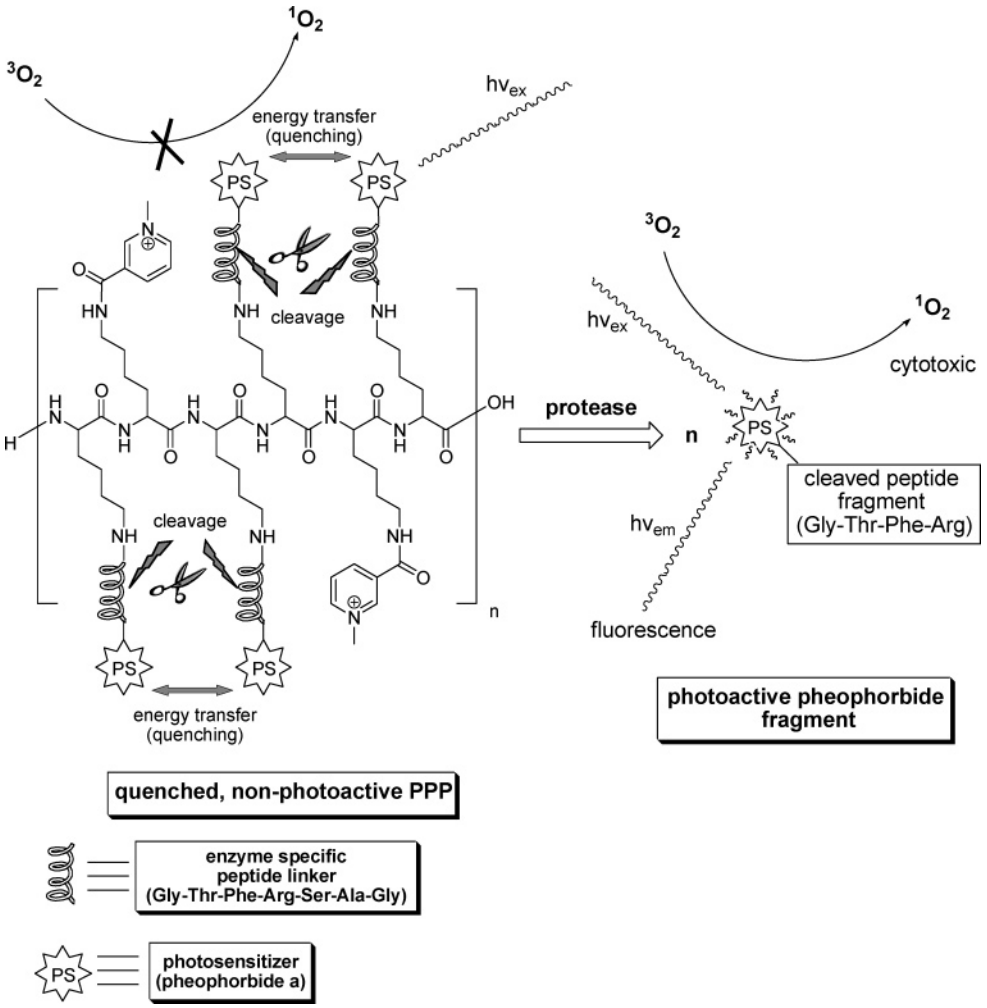

Figure 1. Principle of probe activation and schematic structure. Intramolecular energy transfer between closely positioned photosensitizers is assumed to efficiently depopulate irradiation-excited first and triplet states, resulting in reduced fluorescence and energy transfer to molecular triplet oxygen. Enzymatic cleavage leads to the release of photosensitizer−peptidyl fragments, which in turn are free to diffuse and fully photoactive again.

UV−vis spectra were recorded as background. Then, the mixtures were irradiated with white light (3.72 J/cm^2), and the UV−vis spectra were again recorded to yield the actual increase in optical density.

In Vitro Enzymatic Activation of PPPs. For in vitro protease-mediated activation, PBS buffered solutions of the PPP (corresponding to 10 μM pheophorbide a) containing 2.5% DMSO were treated with trypsin, thrombin, and elastase (180 μL, 7 nmol/mL). Samples were incubated at 37 °C in the dark, and aliquots were sampled in DMSO (75%) to measure the fluorescence spectra in a quartz microcuvette at 37 °C using $\lambda_{ex} = 400$ nm and $\lambda_{em} = 675$ nm. Activation experiments with the control PPP were performed under identical conditions. The relative increase in fluorescence was calculated as follows: $(FL_{max} - FL_E)/(FL_0)$, where FL_{max} is the fluorescence of the activated probe after 15 min, FL_E the fluorescence of the enzyme in buffer, and FL_0 corresponds to the fluorescence of the nondigested PPP.

Cell Culture. GFP transfected human urothelial bladder cancer cell line T24 was grown as monolayers and was a kind gift from S. Cloutier (CHUV Hospital, Lausanne, Switzerland). The cells were routinely maintained by serial passage in D-MEM+GlutaMAX I medium supplemented with 10% FCS, 100 μL/mL streptomycin, and 100 IE/mL penicillin in 5% CO_2/95% air at 37 °C.

Cell Culture Toxicity Studies. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide assay (MTT assay) was used to assess dark and phototoxicity of activated and nonactivated PPP. For this, 100 μL of a cell suspension (seeding density: 85 000 cells/mL) were plated into 96-well plates and allowed to grow overnight.

Cells were exposed for 30 min to increasing concentrations of either intact or predigested PPP in complete medium containing 10% FCS, 2.5% DMSO, and the trypsin inhibitor *p*-aminobenzamidine (2 mg/mL) for the enzyme (0.3 mg/mL) predigested PPP. After incubation, cells were washed three times with HBSS, complete medium was added, and cells were irradiated with white light (13.5 J/cm^2). Dark toxicity was determined in an identical manner but without irradiation. Cell survival was assessed 18 h later by adding 50 μL MTT (1 mg/mL) in complete medium. Following incubation for 3 h at 37 °C, formazan crystals were dissolved with 200 μL DMSO per well. Absorbance at 525 nm was read after overnight incubation with a Bio Rad (model 550) plate reader. The signal was normalized to 100% viable cells (incubated with 2.5% DMSO for PPP or 2.5% DMSO, trypsin [0.3 mg/mL] and *p*-aminobenzamidine (2 mg/mL) in complete medium for preactivated PPP) and 0% viable cells (incubated with 0.25% Triton X in D-PBS). Thus, percentage survival was calculated as follows:

$$(A_{(\text{conc.X})} - A_{(0\%\text{survival})})/(A_{(100\%\text{survival})} - A_{(0\%\text{survival})}) \times 100$$

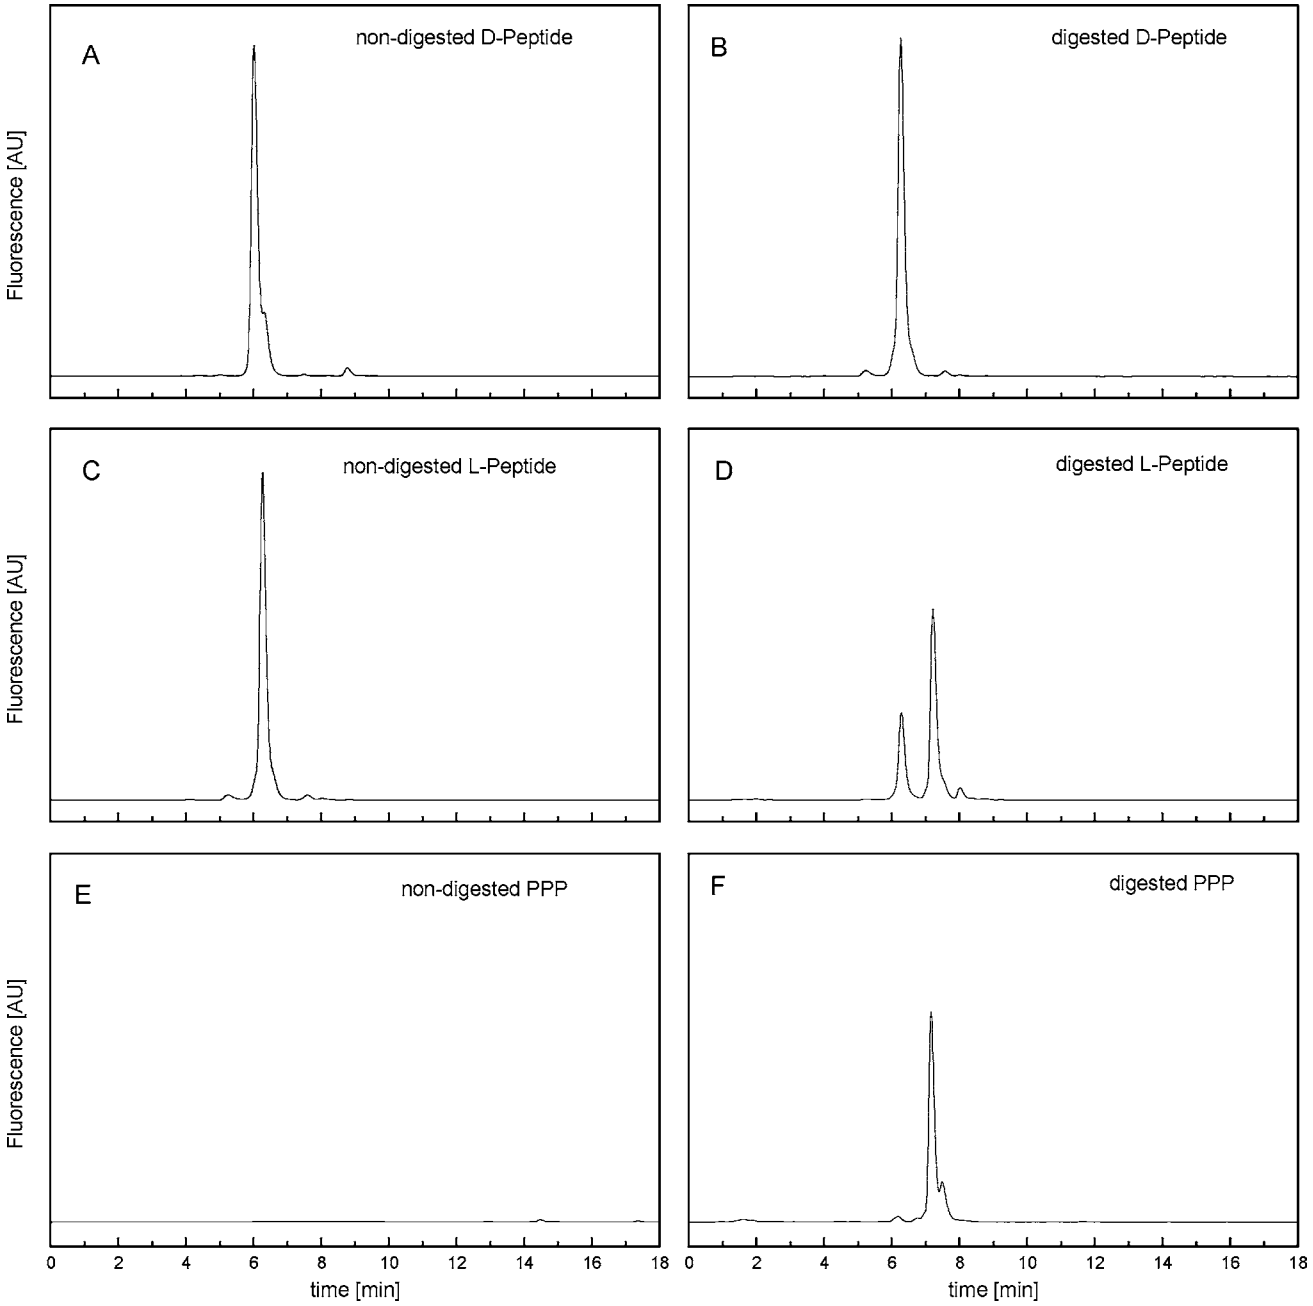

Figure 2. Analytical HPLC trace of the undigested (A,C,E) and digested (B,D,F) pheophorbide−peptide and PPP, respectively. (A) The negative control peptide pheophorbide-Gly-Thr-Phe-(D)Arg-Ser-Ala-Gly before enzymatic degradation. (B) The control peptide pheophorbide-Gly-Thr-Phe-(D)Arg-Ser-Ala-Gly following incubation with trypsin; the D-arginine-containing control peptide was not cleaved. (C) The pheophorbide-Gly-Thr-Phe-(L)Arg-Ser-Ala-Gly and (D) after incubation with trypsin gives rise to a new peak corresponding to the more lipophilic pheophorbide-Gly-Thr-Phe-(L)Arg fragment. (E) The corresponding HPLC trace of the nondigested PPP. (F) After incubation of the PPP, a peak corresponding to the cleaved fragment observed in (D) appears.

where $A_{(\text{conc.X})}$ corresponds to the absorbance of wells incubated with various concentrations of PPP or activated PPP; $A_{(100\%\text{survival})}$ represents the positive and $A_{(0\%\text{survival})}$ the negative control values.

All results were obtained from six replicate measurements per condition.

Confocal Fluorescence Microscopy. T24+ cells were seeded into falcon cell culture inserts (Becton Dickinson Labware, Franklin Lakes, NJ) and allowed to attach overnight. Cells were then incubated for 30 min with either the activated or nonactivated PPP at a final concentration of 5 μM pheophorbide a equivalents, in a mixture of D-PBS, medium, and FCS (6:3:1). To avoid cell detachment, *p*-aminobenzamidine (2 mg/mL) was added to the medium containing the trypsin (0.3 mg/mL) activated conjugate prior to incubation. Cells were washed three times with 2 mL HBSS before visualization of fluorescence and cellular localization pattern of the photosensitizer by confocal fluorescence microscopy using a Zeiss Axiovert 510 microscope (Carl Zeiss, Jena, Germany). Fluorescence emission was monitored at $\lambda > 650$ nm for the photosensitizer and from 520 to 550 nm for GFP, using a diode laser excitation at 405 nm.

Statistical Analysis. Statistical significance between the different values was assessed with a Student's *t*-test, and results were expressed as means ± S.D. p values ≤ 0.05 were considered significant.

RESULTS

Synthetic Strategy. PPPs were prepared using a convergent strategy in the following fashion. First, a peptide substrate with

Table 1. Direct Comparison between Second- and First-Generation PPP (data given in brackets from ref 1)[a]

PS units/PLL chain	Water solubility (in terms of PS concentration (mM))	Quenching efficiency[b] (1-FL/FL_o)	Quenching factor[b] (FL_o/FL)	Relative photodynamic response[c] (optical density at 286 nm)

[a] FL_o = fluorescence intensity of the nonquenched conjugate carrying one PS unit per chain, and FL = fluorescence intensity of conjugate carrying a given number of PS units per chain. [b] Measurements were carried out under identical concentrations of the PS by adjusting the optical density at 667 nm. [c] Relative photodynamic response of PPP was noted after irradiating with white light (3.7 J/cm^2) the solutions containing the PPP + NaI under equimolar concentration of the PS. Photodynamic response was measured by monitoring the increase in optical density at 286 nm (I_3^-). The following formula was used to calculate the normalized *x*-fold increase in optical density at 286 nm [value = (increase in optical density for PPP*x* − increase in optical density for reference PPP (loaded with 30 PS units per chain)) increase in optical density for reference PPP)].

an amino acid sequence that is recognized and cleaved by trypsin was assembled manually on the solid phase using the Fmoc strategy. Chemoselective conjugation of pheophorbide a to the N-terminus of the peptide via a stable amide bond produced pheophorbide a−peptide conjugates, which were then covalently coupled via the C-terminus to the ϵNH_2 functions of PLL (25 kDa) at different loading ratios. Finally, in order to increase water solubility and to protect the polymer backbone from nonspecific enzymatic degradation, the free remaining lysine chains of PLL were capped with 1-methylnicotinic acid units. A schematic representation of PPPs and activation mechanism is given in Figure 1.

Synthesis of the Pheophorbide−Peptide Conjugates and Evaluation of the Trypsin Substrate Specifity. The peptide sequence Gly-Ala-Leu-Ala-Thr-Phe-Arg-Ser-Ala−Ala-Val-Ser-Thr has been reported as a good substrate for trypsin and chymotrypsin (*17*). The core parent sequence Thr-Phe-Arg-Ser-Ala was slightly modified by introducing a glycine spacer at the N and C-termini, respectively, for covalent attachment to either the photosensitizer pheophorbide a or to the ϵ-NH_2 of the PLL backbone. Substituting the L-arginine by a D-arginine residue gave a noncleavable control sequence. The identity of the two peptides was confirmed by ES-MS analysis (695.6 ([M + H]$^+$ = 695.4 calculated for $C_{29}H_{47}N_{10}O_{10}^+$ and 348.3 ([M + 2H]$^{2+}$ = 348.2 calculated for $C_{29}H_{48}N_{10}O_{10}^{2+}$) after purification of the resulting crudes by preparative RP-HPLC. The subsequent chemoselective coupling of *N*-hydroxysuccinimide pheophorbide a activated ester to the N-terminus of either of the two peptides yielded pheophorbide a-Gly-Thr-Phe-(L)Arg-Ser-Ala-Gly (pheophorbide−L-peptide) and pheophorbide a-Gly-Thr-Phe-(D)Arg-Ser-Ala-Gly (pheophorbide−D-peptide). ESI-MS analysis after preparative RP-HPLC purification confirmed the identity of the obtained products (1269.9 ([M + H]$^+$ = 1269.6 calculated for $C_{64}H_{81}N_{14}O_{14}^+$).

Analytical RP-HPLC analysis was used to monitor the cleavage of the two pheophorbide−peptides by trypsin, revealing that only the substrate pheophorbide−L-peptide was recognized and cleaved by the enzyme, whereas the control was stable to enzymatic cleavage (Figure 2). Furthermore, the site of cleavage for the L-arginine-containing sequence was confirmed to be at the C-terminus of the arginine residue in accordance with reported preferential trypsin cleavage sites (*18*). This was determined by ESI-MS analysis of the isolated pheophorbide a-Gly-Thr-Phe-(L)ArgOH fragment obtained after enzymatic digestion [M + H]$^+$ = 1054.51 calculated for $C_{56}H_{68}N_{11}O_{10}^+$.

Synthesis and Physicochemical Properties of Trypsin-Selective PPPs. Finally, trypsin-sensitive PPPs were assembled by chemoselective conjugation of the C-terminal carboxylic function of the pheophorbide−peptide conjugates to the PLL backbone. The remaining free side chains of the PLL backbone were capped by reaction with *N*-succinimidyl(1-methyl-3-pyridinio)formate iodide salt to yield the final conjugates. This

moiety was used to enhance PPP water solubility and to protect the polymeric backbone from nonspecific enzymatic degradation.

Covalent coupling of different amounts of pheophorbide−peptide moieties to ϵ-NH_2 functions of the polymer resulted in PPPs carrying 6, 18, and 30 PS units per polymer chain. RP-HPLC monitoring of coupling reactions confirmed them to be quantitative for all investigated loading ratios.

A direct correlation between fluorescence quenching and ROS generation of the PS pheophorbide a is well-documented in the literature using dendrimer constructs (*19*). Data for the quench-

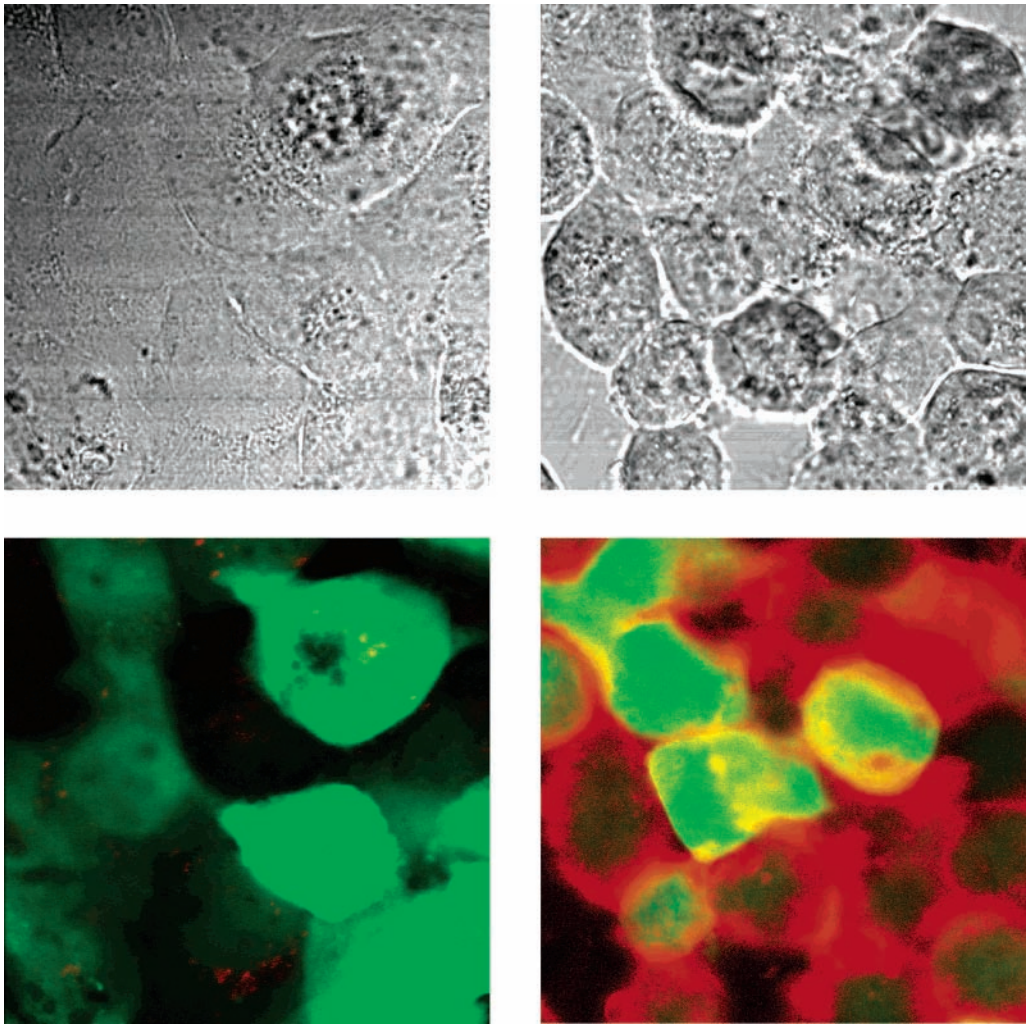

Figure 5. Confocal fluorescence micrographs (bottom panel) and corresponding trans-illumination images (top panel) (magnification 120×) of T24+ cells incubated with nondigested PPP (left panel) and with digested PPP (right panel).

ing of fluorescence emission and ROS generation of fully assembled second generation PPP with different photosensitizer loadings are summarized in Table 1. Photodynamic response and fluorescence emission decrease with increasing loading to a similar extent as for first-generation conjugates. Water solubility of both generations PPPs decreased with photosensitizer loading, although the second-generation PPPs were more soluble, probably due to the use of the alleged solubilizing moieties.

Enzymatic Activation of PPP in Vitro. Peptide linker imparted selectivity of photosensitizer activation was demonstrated by assaying PPP cleavage with different trypsin-like proteases. Figure 3 shows the relative increase in fluorescence emission after in vitro digestion with trypsin, elastase, and thrombin, respectively. Incubation with the control PPP gave essentially no change in fluorescence. Furthermore, protease-mediated fluorescence activation was prevented by inhibiting trypsin activity with *p*-aminobenzamidine (data not shown). These results indicate that N-terminal introduction of the relative bulky, hydrophobic photosensitizer pheophorbide a and C-terminal coupling to the polymeric backbone did not interfere with enzymatic cleavage of the peptide substrate. Furthermore, there are similarities in the sequence of our peptide linker and a previously reported substrate for plasmin and human kallikrein 2, two cancer-related enzymes (*20*).

Phototoxicity Evaluation in Vitro. Dark and phototoxicity of the PPP carrying 30 PS units per chain were evaluated on a human T-24 bladder epithelium cancer cell line. In vitro predigestion of our model compounds was a necessary step for PPP activation, as levels of secreted proteases within the cell culture medium are generally low. In addition, the trypsin-like enzymes meant to be targeted with the chosen peptide linker are rapidly neutralized in the presence of serum, and the locally enhanced proteolytic activity within cancerous or inflamed tissue is difficult to mimic in cell cultures. Normalized percentages of cell survival of irradiated and nonirradiated cells after incubation with increasing concentrations of the corresponding activated or nonactivated PPP are shown in Figure 4. Within the studied concentration range, neither the activated PPP nor the nonactivated PPP showed significant dark toxicity. However, upon white light irradiation (13.5 J/cm^2), the activated PPP showed a significantly higher phototoxicity than the nonactivated one ($p < 0.05$), in the 3.5−6.5 μM concentration range.

Intracellular Localization. The subcellular localization of the PPP in its active and inactive forms within T24+ cells was visualized by confocal fluorescence microscopy. Pictures were taken after 30 min of incubation and thorough washing under identical microscope settings. Figure 5 shows a granular distribution pattern for the nonactivated PPP versus a more homogeneous distribution for the activated PPP within the GFP expressing cells. Cells treated with the activated PPP appeared brightly fluorescent when compared to those treated with the nonactivated PPP. Although GFP is not equally expressed at the same level in all T24+ cells, phase contrast images (top panel) show that porphyrin-mediated fluorescence is associated with the presence of cells. In the case of the

nonactivated PPP in the left panel of Figure 5, small fluorescent spots presumably due to nonspecific lysosomal degradation can be seen.

DISCUSSION

Protease-mediated release of prodrugs and toxins for cancer chemotherapy has been proposed already some years ago (*21*−*25*). Recent research aims to further enhance prodrug delivery using long-circulating polymeric conjugates (*26*−*28*) or additional targeting moieties (*29*).

By using first-generation PPPs, it has been shown recently that this approach can successfully be implemented into PDT in vitro and in vivo. Although these conjugates have a substantially higher molecular weight than our novel second-generation PPPs, tumor eradication was demonstrated in a mouse xenograph model (*10*). The latter emphasizes that despite this high molecular weight sufficient tumor penetration can be achieved with these compounds. However, as mentioned above, the application of first-generation PPPs is limited to the targeting of proteases able to digest the polymeric backbone such as the lysosomal cystein−protease Cathepsin B. Therefore, nonspecific activation in normal cells might occur with such compounds. Our "low" molecular weight second-generation PPPs might circumvent this drawback and allow for the targeting of other disease-specific proteolytic activities. Furthermore, nonspecific degradation of the polymeric backbone could be totally prevented by our protecting moieties, avoiding nonspecific activation by lysosomal proteases to a large extent.

We suggest that our newly developed polymeric protease-mediated photodynamic agents are of particular value for cancer phototherapy for the following reasons: First, the use of polymeric conjugates allows for passive targeting by the EPR effect. Second, specific proteolytic activation of the PPP at the tumor site will minimize collateral damage to healthy tissue structures within the irradiated area. The use of a peptide linker makes this strategy amenable to targeting a wide variety of disease-related extracellular proteases. Third, tumor penetration and uptake of photosensitizer−peptidyl fragments into cells might be facilitated by passive diffusion. Furthermore, released photosensitizer−peptide fragments are lipophilic and only poorly water-soluble, which is expected to result in slower systemic clearance. Finally, light is applied specifically at the tumor site, and thus cytotoxic ROS are efficiently produced only within the irradiated area in the presence of activated photosensitizer and oxygen.

In the current research, we have prepared second-generation PPPs for the targeting of enzymes with trypsin-like activity. These PPPs are water-soluble and have a polymeric backbone that is stable to nonspecific enzymatic degradation. The developed synthetic strategies can be easily adapted to other peptide linkers whose sequences will determine the enzyme being targeted. Protease-mediated activation of these PPP gave rise to a pronounced increase in fluorescence and phototoxicity in vitro.

Together, the gathered in vitro data suggest that the developed PPPs are promising for the systemic delivery of photodynamic agents, and further in vivo studies are currently underway.

The employment of carriers to enhance drug selectivity is one of the strategies to increase the efficacy and reduce the side effects of antitumor therapy. The concept of a modular carrier system (MCS) was developed to construct a complex drug having a high efficacy and selectivity. An MCS employs diverse units or modules: beside the therapeutic unit, an addressing unit (e.g., an antibody) serves to direct the drug to its target, and a multiplying unit has the role of increasing the number of biological active moieties the system can carry. In this paper, we report on the synthesis of a modular carrier system in which the role of multiplying unit is given to a [5:1]-fullerene hexakis adduct. This fullerene hexaadduct has five malonate spacers which can bind two therapeutic units (the photosensitizer pyropheophorbide-*a*) each, for a total of ten, and a longer malonate spacer which serves for the conjugation to the addressing unit, the monoclonal antibody rituximab. Confocal microscopy studies using Epstein−Barr virus-transformed B-lymphocytes and Jurkat cells showed that the antibody conjugate conserves the affinity for its receptor (CD20) and its selectivity toward CD20 positive B-lymphocytes. On the contrary, the antibody-free complex did not show any bounding or intracellular uptake.

INTRODUCTION

The enhancement of drug selectivity is the most important task of modern investigations directed to improve the efficacy and reduce the side effects of anticancer therapy. The idea of binding a drug to an addressing unit with specificity for tumor tissue was formulated a long time ago (*1*). Several carrier systems have been used for this purpose, like liposomes (*2*), lipoproteins (*3*), dendrimers (*4*), or polymers (*5*), but antibodies or antibody fragments were the most selective molecules (*6*, *7*). One inconvenience of using tumor-specific antibodies is the loss of their biological activity when many drug units are covalently bound to their peptide backbone (*8*). The concept of the modular carrier system (MCS) was developed as a solution to this problem (*9*). In an MCS, diverse units or modules are combined to construct a complex drug with diverse specific functions. Besides the therapeutic unit, an addressing unit (e.g., an antibody) serves to direct the drug to the target, and a multiplying unit has the role of increasing the number of drug moieties the system can carry. In this way, a number of drug units can be loaded on a tumor-specific antibody. Dendrimers and polymers were proposed as multiplying units (*10*, *11*). In particular, dendrimers became of rising interest in different fields of biophysical research due to their highly branched and well-defined architecture having a high number of functional end groups (*12*). C_{60}-fullerene adducts are good candidates to be used as the core of multiplying units. Fullerene hexakis adducts have an octahedral addition pattern, which allows the six substituents occupying spread positions with minimal steric interactions (*13*). So-called [5:1]hexaadducts are well-known in fullerene chemistry. In such adducts, one position can be occupied by the addressing unit, while the other five positions are suitable for spacers bearing drug moieties. The fullerene's ability to scavenge free radicals (*14*) and its spherical shape, which could adapt to active sites of enzymes (*15*), make the use of C_{60} in medical research particularly interesting. Recently, a communication appeared reporting the conjugation of fullerene derivatives with the antibody ZME-18 (*16*). The authors used water-soluble fullerenes and reached C_{60}/antibody molar ratios of 42:1 and 15:1 without the loss of antigen binding ability. Although one of the two water-soluble derivatives had no activated group for covalent binding to the monoclonal antibody (mAb), it still showed similar results to the derivative with a binding site. The authors therefore concluded that in such immunoconjugates the fullerene moieties are not necessarily connected to the antibody through a covalent bond.

In this paper, we report the synthesis of a modular carrier system in which the role of multiplying unit is given to a [5:1]-fullerene hexakis adduct. This fullerene hexaadduct has five malonate addends, which can bind two pyropheophorbide-*a* **2** units each, and a longer malonate spacer with an activated ester moiety, which serves for the conjugation to one addressing unit, the mAb rituximab. Rituximab is a genetically engineered chimeric murine/human mAb directed against the CD20 antigen found on the surface of normal and malignant B lymphocytes (*17*). The antibody is an IgG_1 κ immunoglobulin containing murine light- and heavy-chain variable region sequences and human constant region sequences. Rituximab is composed of two heavy chains of 451 amino acids and two light chains of 213 amino acids (based on cDNA analysis) and has an

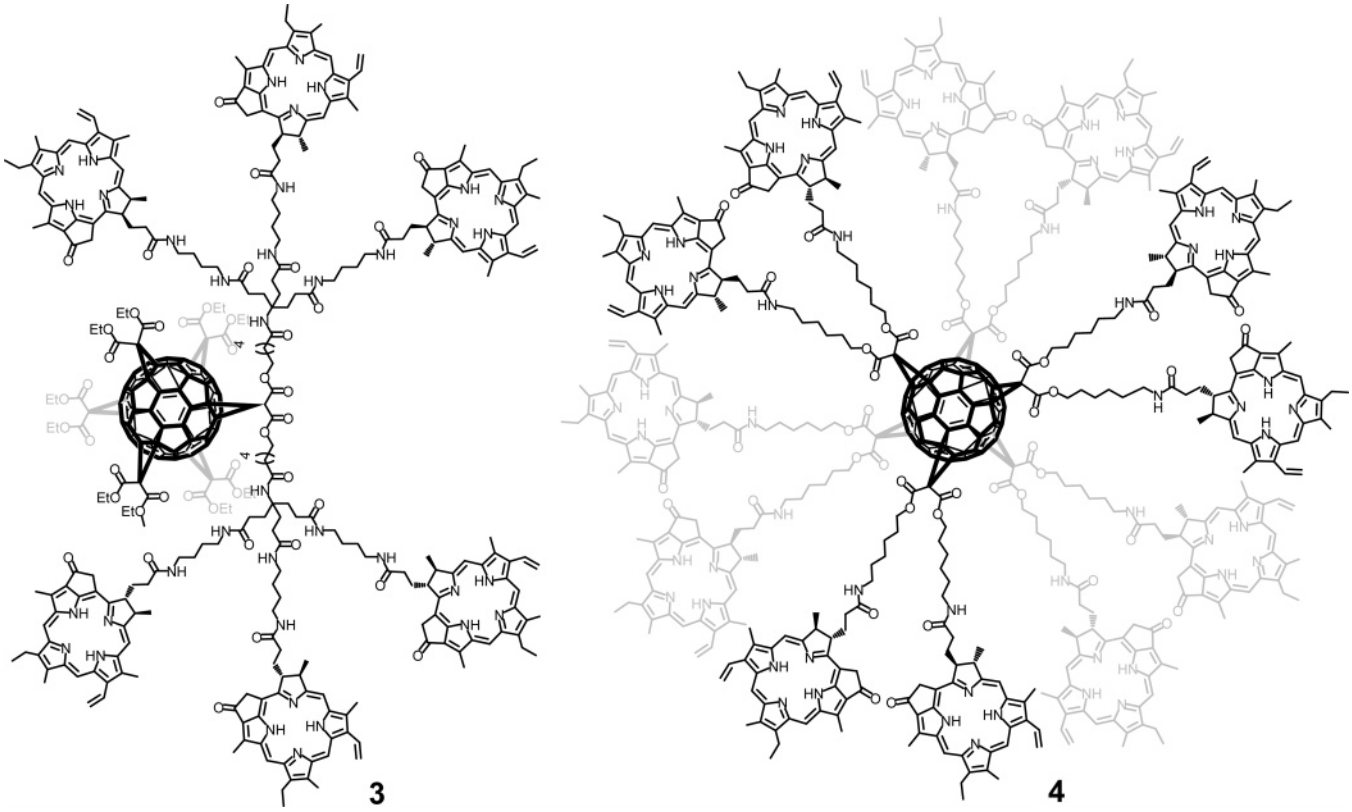

Figure 1. [5:1]Fullerene hexaadduct **3** and fullerene hexaadduct **4** carrying 6 and 12 pyropheophorbide-*a* moieties, respectively.

approximate molecular weight of 145 kDa. Rituximab has a binding affinity for the CD20 antigen of approximately 8.0 nM (*17*). This monoclonal antibody is an already approved drug and is indicated for the treatment of patients with relapsed or refractory, low-grade or follicular, CD20-positive, B-cell non-Hodgkin's lymphoma (NHL).

The therapeutic unit, pyropheophorbide-*a* (**2**) (*18*) is a photosensitizer (PS) which might be used in photodynamic therapy (PDT). This is a treatment of cancerous and noncancerous diseases (*19*), which involves the administration of a PS and light. By irradiation of the region to be treated, the PS is activated and can induce the generation of singlet molecular oxygen followed by a sequence of reactions generating other reactive oxygen species (*20*). **2** has optimal photophysical properties for its use as PS: it has an absorption maximum at 668 nm with high extinction coefficient ($\epsilon_{668\ nm} = 4 \times 10^4\ M^{-1}\ cm^{-1}$) and an emission maximum at 672, and the singlet oxygen quantum yield in ethanol using pheophorbide-*a* as reference was estimated to be 0.52 (*21*). Moreover, it has a free carboxylic group which can be used for attaching it to the multiplying unit.

In previous works, in which we employed antibodies as carriers for photosensitizers, we found that the dye's ability to produce singlet oxygen and the antibody's ability to recognize its antigen strongly decrease when a high number of dye molecules are covalently bound to the antibody (*8*). We concluded that the use of a multiplying unit may be necessary to increase the local concentration of drugs without a decrease of the antibody's biological activity. The choice of a [5:1]-fullerene hexakis adduct as the multiplying unit came after several studies with different fullerene adducts carrying a different number of photosensitizers. First, we prepared fullerene mono- and hexaadducts carrying two pyropheophorbide-*a* (**2**) moieties. The investigation of the photophysical properties of these derivatives showed that in the fullerene monoadduct an efficient photoinduced electron transfer occurs between the exited pyropheophorbide-*a* (**2**) moieties and the fullerene core. This event results in a dramatic reduction of PSs singlet oxygen quantum yield. On the contrary, in the fullerene hexaadduct, the π-system is broken up and C_{60} cannot act as a strong electron-acceptor anymore (*22*−*24*). As a direct consequence, the in vitro phototoxicity of the fullerene monoadduct was significantly inferior to that of the fullerene hexaadduct carrying the same number of PSs (*25*). Successively, we synthesized fullerene hexaadducts carrying six (**3**) (*26*, *27*) and twelve (**4**) (*27*, *28*) pyropheophorbide-*a* moieties (Figure 1). It was found that dye molecules covalently linked to one fullerene moiety could interact with each other, forming energy traps. A very fast and efficient delivery of the excitation energy to a trap can therefore occur. As a result, the fluorescence as well as the singlet oxygen quantum yields of the different complexes were reduced with increasing number of dye molecules per complex (*26*−*28*). This was confirmed by in vitro cell experiments (*36*): While the fullerene adduct loaded with six PS moieties (**3**) still has a significant phototoxic activity against lymphoid T-cells, the [6:0] adduct loaded with twelve PSs (**4**) is not phototoxic.

A [5:1]fullerene adduct analogous to **4** and carrying ten pyropheophorbide-*a* moieties (**5**) has been prepared for the coupling with the mAb. **5** has an activated carboxylic ester group at the end of a long alkyl chain, which serves for the covalent binding to an amino group of the antibody. The reason we chose **5** for the coupling with rituximab is that the analogous compound **4** turned out to be photostable even under high-energy irradiation while other carriers (diaminobutane dendrimers) were completely fragmented under the same conditions (*28*). In this way, we avoid a possible overlap of the conjugate biological activity and light-caused effects like disconnection of the antibody from the fullerene adduct.

EXPERIMENTAL PROCEDURES

Chemicals and Characterization of the Samples. C_{60} was obtained from Hoechst AG/Aventis and separated from higher

fullerenes by a plug filtration process (*29*, *30*). The monoclonal antibody rituximab was bought as pharmaceutical preparation Mabthera, (Roche, Germany). The antibody concentration in the preparation is 10 mg/mL. Chemicals and solvents were used as received unless otherwise noted. Solvents were dried using standard procedures (*31*). Pyropheophorbide-*a*-NHS ester and malonate **6** and malonate **7** were prepared according to literature procedures (*26*). Column chromatography was performed on silica gel 32-63, 60 Å, MP Biomedicals. ^{1}H and ^{13}C NMR spectra were recorded on JEOL JMM EX 400 and JEOL GX 400 instruments; an asterisk indicates a resonance of a pyropheophorbide-*a* proton or carbon atom; the atom indices are given according to the literature (*32*). FAB mass spectrometry was performed with Micromass Zabspec and Varian MAT 311A instruments; MALDI-TOF mass spectrometry was done on an AUTOFLEX instrument from Bruker Daltonics GmbH. Standard UV/vis spectra were recorded on a Shimadzu UV-3102 PC UV/vis NIR scanning spectrophotometer. IR spectra were either taken with a Bruker Vector 22 spectrometer or an ASI React IR-1000 spectrometer. HPLC was performed with a Shimadzu Liquid Chromatograph LC-10AT equipped with an SCL-10AVP system controller, LC-8A preparative liquid chromatographs, a diode array detector, and a UV/vis detector, on a Nucleosil 100−5 column. All compounds decomposed prior to melting. All reactions were performed in nitrogen atmosphere.

Synthesis. *20-Hydroxyeicosyl Methylmalonate **9***. A solution of 1,20-dihydroxyeicosane **8** (4.13 g, 13 mmol) and pyridine (4 mL, 52 mmol) in dry THF (500 mL) was cooled in an ice bath under nitrogen. Malonyl dichloride (1.4 mL, 13 mmol) was diluted in dry THF (20 mL) and added dropwise over a period of 1 h via a dropping funnel. The reaction mixture was stirred for 6 h at room temperature. CH_2Cl_2 (200 mL) was added, and the mixture was washed with water (150 mL, three times). After drying over $MgSO_4$, the solvent was removed in vacuo. Flash chromatography on silica (1. $CHCl_3$ 2. $CHCl_3$/ethyl acetate 95:5) yielded **9** as a white solid (yield: 1.96 g, 37%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): δ = 4.11 (t, ^3J = 6.7 Hz, 2H, $COOCH_2$), 3.72 (s, 3H, CH_3), 3.61 (t, ^3J = 6.6 Hz, 2H, CH_2O), 3.36 (s, 2H, $OOCCH_2COO$), 2.61 (tt, ^3J = 6.8 Hz, ^3J = 6.8 Hz, 2H, CH_2CH_2O), 1.63 (tt, ^3J = 6.8 Hz, ^3J = 6.7 Hz, 2H, $COOCH_2CH_2$), 1.39 (bs, 32H, CH_2). ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C, TMS): δ = 176.1 (CO), 166.6 (CO), 65.7, 63.1, 52.5, 41.4, 32.8, 29.7, 29.6, 29.5, 29.4, 29.2, 28.4, 26.2, 25.7, 25.7, 23.5. IR (ATR): ν = 3331 cm^{-1}, 2918, 2849, 1737 (CO), 1463, 1339, 1200, 1154, 1061, 1031, 729. MS (FAB, NBA): *m*/*z* = 416 [M$^+$]. Anal. calcd (%) for $C_{24}H_{46}O_5$ (414.34): C 69.52, H 11.18. Found: C 69.74, H 10.98.

*[1-(Methoxycarbonyl)-1-(20-hydroxyeicosyl)oxycarbonyl]-1,2-methano [60]-fullerene **10***. C_{60} (2.5 g, 3.47 mmol) was dissolved in dry toluene (1200 mL), resulting in a dark purple solution. The solution was stirred until the C_{60} was completely dissolved. Afterward, CBr_4 (1.7 g, 5.1 mmol) and the malonate **9** (1.4 g, 3.37 mmol) were added. DBU (800 μL, 5.2 mmol) was diluted in toluene (50 mL) and added dropwise over a period of 1 h to the stirred solution at room temperature. After the solution was stirred for another 12 h, the reaction mixture was controlled by thin layer chromatography to reveal unreacted C_{60}, the monoadduct **10**, as well as traces of bis- and trisadducts. The toluene was almost completely removed in vacuo and the remaining solution transferred to a flash chromatography column. Flash chromatography on silica gel with toluene yielded unreacted C_{60} as first fraction (0.98 g, 39%). **10** was obtained as a brown powder which was dried in vacuo (yield: 1.65 g, 42%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): δ = 4.48 (t, ^3J = 6.5 Hz, 2H, $COOCH_2$), 4.07 (s, 3H, CH_3), 3.61 (t, ^3J = 6.7 Hz, 2H, CH_2O), 1.81 (tt, ^3J = 6.6 Hz, ^3J = 6.7 Hz, 2H, $COOCH_2CH_2$), 1.54 (m, 2H, CH_2CH_2O), 1.44 (m, 2H, $CH_2CH_2CH_2O$), 1.22 (bs, 30H, CH_2). ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C, TMS): δ = 164.5 (CO), 163.9 (CO), 145.4, 145.4, 145.4, 145.1, 144.9, 144.9, 144.1, 143.3, 143.3, 142.4, 142.2, 142.1, 141.2, 139.4, 139.1 (58C, C_{60} sp^2), 71.5 (2C, C_{60} sp^3), 67.5, 63.2, 53.9, 52.4, 32.6, 29.5, 29.4, 29.3, 29.0, 28.4, 25.8, 25.58. IR (KBr): ν = 2921 cm^{-1}, 2851, 1741 (CO), 1462, 1430, 1267, 1233, 1187, 1060, 749. MS (FAB, NBA): *m*/*z* = 1132 [M$^+$]$^+$, 720 [C_{60}^+]. UV/vis (CH_2Cl_2): λ_{max} (ϵ) = 257 nm (113 000 mol^{-1} dm^3 cm^{-1}), 325 (35 000), 425 (2100). Anal. calcd (%) for $C_{84}H_{44}O_5 \times 0.5CHCl_3$ (1191.3): C 85.08, H 3.76. Found: C 85.58, H 3.63.

*[5:1]Hexakis Adduct **11***. Monoadduct **10** (1.37 mg, 1.2 mmol) was dissolved in degassed, dry toluene (250 mL). 9,10-Dimethylanthracene (2.50 mg, 12 mmol) was added and the mixture stirred for 12 h at room temperature under protection from light. Malonate **7** (6.10 g, 12.1 mmol) and CBr_4 (4.03 g, 12.1 mmol) were added subsequently to the reaction flask. DBU (3.18 mL, 21.0 mmol) was diluted in dry toluene (20 mL) and added dropwise over a period of 1 h. Precleaning on silica gel (CH_2Cl_2/ethyl acetate 60:40) and subsequent purification by preparative HPLC (Nucleosil 5 μm, CH_2Cl_2/ethyl acetate 74:26) gave **11** as a yellow solid (yield: 1.07 g, 24.1%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): δ = 4.76 (bs, 10H, NH), 4.22 (t, ^3J = 6.3 Hz, 20H, $COOCH_2$), 4.22 (t, ^3J = 6.3 Hz, 2H, $COOCH_2$), 3.83 (s, 3H, OCH_3), 3.60 (t, ^3J = 6.6 Hz, 2H, CH_2O), 3.06 (m, 20H, NCH_2), 1.66 (m, 22H, $COOCH_2CH_2$), 1.54 (m, 2H, CH_2CH_2O), 1.40 (s, 90H, CH_3), 1.50−1.20 (m, 94H, CH_2). ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C, TMS): δ = 164.3 (CO), 163.8 (CO), 156.0 (NHCO), 145.7 (C_{60} sp^2), 141.1 (C_{60} sp^2), 78.9 (10C, $OC(CH_3)_3$), 69.1 (C_{60} sp^3), 66.9, 63.0, 53.6, 45.5, 40.5, 32.8, 29.9, 29.7, 29.6, 29.4, 28.4, 28.3, 26.4, 25.7, 25.6. IR (ATR): ν = 2975 cm^{-1}, 2930, 2856, 1743, 1689, 1516, 1365, 1244, 1212, 1165, 714. MS (FAB, NBA): *m*/*z* = 3635 [M$^+$], 3579 [M − *t*Bu$^+$], 3536 [M$^+$ − Boc], 3479 [M$^+$ − Boc-*t*Bu], 3435 [M$^+$ − 2×Boc], 3336 [M$^+$ − 3×Boc], 3235 [M$^+$ − 4×Boc], 3135 [M$^+$ − 5×Boc]. UV/vis (CH_2Cl_2): λ_{max} (ϵ) = 244 nm (93 600 mol^{-1} dm^3 cm^{-1}), 280 (73 100), 496 (500). Anal. calcd for $C_{209}H_{264}N_{10}O_{45} \times 2CH_2Cl_2$ (3801.8): C 66.58, H 7.10, N 3.68. Found: C 66.65, H 7.08, N 3.67.

*[5:1]Hexaadduct Tosylate **12***. The hexaadduct **11** (460 mg, 0.126 mmol), trimethylamine hydrochloride (102 mg, 1.07 mmol), and triethyamine (2 mL, 14 mmol) were dissolved in dry CH_2Cl_2 (150 mL). The reaction mixture was cooled to 0 °C. Tosyl chloride (182 mg, 1 mmol) was dissolved in CH_2Cl_2 (30 mL) and added dropwise over a period of 1 h, keeping the temperature below 5 °C. After the mixture was stirred for 12 h at room temperature, the solvent was evaporated. Flash chromatography on silica (1. CH_2Cl_2, 2. CH_2Cl_2/ethyl acetate 70:30) yielded **12** as an orange solid (yield: 380 mg, 79%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): δ = 7.75 (d, ^3J = 8.2 Hz, 2H, aryl-H), 7.31(d, ^3J = 8.3 Hz, 2H, aryl-H), 4.75 (bs, 10H, NH), 4.22 (t, ^3J = 6.3 Hz, 20H, $COOCH_2$), 3.98 (t, ^3J = 6.5 Hz, 2H, CH_2OSO_2), 3.82 (s, 3H, OCH_3), 3.06 (m, 20H, NCH_2), 2.42 (s, 3H, aryl-CH_3), 1.65 (m, 22H, $COOCH_2CH_2$), 1.61 (m, 2H, $CH_2CH_2OSO_2$), 1.40 (s, 90H, CH_3), 1.50−1.20 (m, 94H, CH_2). ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C, TMS): δ = 164.3 (CO), 163.8 (CO), 156.0 (NHCO), 145.7 (C_{60} sp^2), 144.6, 141.1 (C_{60} sp^2), 133.2, 129.7, 127.8, 78.9 ($OC(CH_3)_3$), 70.7, 69.1, 69.0 (C_{60} sp^3), 67.1, 66.8, 53.5, 45.5, 40.5, 29.9, 29.7, 29.6, 29.5, 29.4, 29.2, 28.9, 28.8, 28.4, 28.3, 28.1, 27.9, 26.4, 25.7, 25.6, 25.3, 21.6 (1C, 27). IR (ATR): ν = 2976 cm^{-1}, 2930, 2857, 1742, 1692, 1515, 1365, 1242, 1214, 1167, 1043, 753, 714. MS (FAB, NBA): *m*/*z* = 3789 [M$^+$], 3733 [M$^+$ − *t*Bu], 3690 [M$^+$ − Boc], 3633 [M$^+$ − Boc-*t*Bu], 3490 [M$^+$ − 3×Boc], 3390 [M$^+$ − 4×Boc], 3289 [M$^+$ − 5×Boc], 3188 [M$^+$ − 6×Boc]. UV/vis (CH_2Cl_2): λ_{max} (ϵ) = 244 nm (90 100 mol^{-1} dm^3 cm^{-1}), 280 (69 000), 496 (420). Anal. calcd

for $C_{216}H_{270}N_{10}O_{47}S \times 2CH_2Cl_2$ (3955.8): C 66.11, H 6.97, N 3.54, S 0.81. Found: C 65.83, H 7.14, N 3.56, S 0.47.

*[5:1]Hexaadduct Azide **13***. The hexaadduct **12** (202 mg, 0.053 mmol) and sodium azide (60 mg, 0.9 mmol) were dissolved in 4 mL of dry DMF and stirred for 16 h at room temperature. The solvent was removed in vacuo. Flash chromatography on silica (CH_2Cl_2/ethyl acetate 70:30) yielded **13** as an orange solid (yield: 160 mg, 82%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 4.76$ (bs, 10H, NH), 4.22 (t, $^3J = 6.5$ Hz, 20H, $COOCH_2$), 4.14 (t, 2H, $COOCH_2$), 3.83 (s, 3H, OCH_3), 3.22 (t, $^3J = 6.9$ Hz, 2H, CH_2N_3), 3.06 (m, 20H, $NHCH_2$), 1.66 (m, 20H + 2H, $COOCH_2CH_2$), 1.56 (tt, 2H, CH_2-CH_2N_3), 1.40 (s, 90H, CH_3), 1.45−1.20 (m, 94H, CH_2). ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 164.3$ (CO), 163.8 (CO), 156.0 (NHCO), 145.7 (C_{60} sp^2), 141.1 (C_{60} sp^2), 78.9 ($OC(CH_3)_3$), 69.1 (C_{60} sp^3), 66.9, 53.6, 51.5, 45.4, 40.5, 29.9, 29.7, 29.7, 29.6, 29.6, 29.5, 29.4, 29.2, 28.8, 28.3, 28.3, 26.7, 26.4, 25.7, 25.6. Found: C 67.36, H 7.30, N 5.00.

*Decakis Pyropheophorbide-a[5:1]fullerene Hexaadduct Azide **14***. The hexakis adduct **13** (160 mg, 0.04 mmol) was dissolved in methanol (30 mL) and hydrochloric acid (5 mL, 4 N in 1,4-dioxane) was added. After stirring for 3 h at room temperature, the solvent was removed in vacuo. The orange decakis ammonium salt was used without any further purification for the next transformation. The deprotected hexakis adduct (55 mg, 0.018 mmol) was dissolved in brine (50 mL). $CHCl_3$ (50 mL) and triethylamine (200 μL) were added, and the organic layer was washed twice with brine. After this solution was dried over Na_2SO_4, pyropheophorbide-*a*-NHS ester **6** (170 mg, 0.27 mmol) was added and the solution stirred for 72 h at room temperature. Evaporation of the solvent and subsequent size exclusion chromatography (1. Bio-Beads SX3 2. Bio-Beads SX1, $CHCl_3$) yielded a black−green solid. Additional flash chromatography with silica ($CHCl_3$/methanol, 93.5:7.5) yielded **14** as a dark green solid (yield: 85 mg, 74%). ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 8.83$* (m, 10H, β), 8.54* (m, 10H, α), 8.20* (m, 10H, δ), 7.48* (m, 10H, 2a), 6.21* (bs, 2H + 1H, CONH, $NHCO-C_4H_8$), 6.11* (bs, 8H, CONH), 5.86* (m, 20H, 2b), 4.91* (m, 10H, 10), 4.64* (m, 10H, 10), 4.22* (m, 10H, 7), 3.96* (m, 10H, 8), 3.96 (m, 20H + 2H, $COOCH_2$), 3.64 (s, 3H, OCH_3), 3.25−2.60* (m, 30H + 30H + 20H + 30H + 20H + 2H, 1a, 3a, 4a, 5a, $NHCH_2$, CH_2N_3), 2.40* (m, 10H, 7a/b), 2.10* (m, 20H, 7a/b), 1.88* (m, 10H, 7a/b), 1.54* (m, 30H, 8a), 1.35* (m, 30H + 20H + 2H, 4b, $COOCH_2CH_2$), 1.24−1.03 (m, 94H, CH_2), −0.15* (bs, 10H, NH), −2.16* (s, 10H, NH). ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 195.9$, 172.4, 171.5, 164.1, 163.6, 160.3, 154.7, 150.2, 148.4, 146.0, 144.5, 141.0, 140.8, 137.1, 135.7, 135.5, 131.1, 129.5, 129.5, 128.7, 127.2, 121.9, 107.9, 105.5, 105.5, 103.2, 96.5, 92.6, 69.0, 67.6, 66.7, 51.6, 51.4, 49.6, 49.4, 47.8, 45.4, 39.1, 32.8, 31.9, 30.2, 29.6, 29.5, 29.4, 29.1, 28.7, 28.1, 26.6, 26.2, 25.3, 23.9, 22.7, 18.9, 17.2, 11.8, 11.2, 11.1, 10.9. IR (ATR): $\nu = 2961$ cm^{-1}, 2923, 2855, 2095, 1743, 1688, 1617, 1498, 1367, 1260, 1218, 1057, 978, 793. MS (Maldi-TOF, 2,5-dihydroxybenzoic acid): $m/z = 7833$ [M$^+$] (calcd 7826.55). MS (FAB, NBA): $m/z = 7821$ [M$^+$]. UV/vis (CH_2Cl_2): λ_{max} (ϵ) = 281 nm (184 600 mol^{-1} dm^3 cm^{-1}), 324 (220 900), 400 (623 200), 413 (621 300), 509 (708 000), 540 (60 600), 613 (55 900), 669 (287 600). Anal. MS (Maldi-TOF, 2,5-dihydroxybenzoic acid): $m/z = 8028.57$ [M$^+$] (calcd 8025.76), 7803, 7394. UV/vis (CH_2Cl_2): λ_{max} (ϵ) = 279 (175 900 mol^{-1} dm^3 cm^{-1}), 322 (211 900), 399 (592 980), 413 (588 100), 510 (67 200), 540 (57 500), 613 (53 100), 669 (273 300).

Rit*−*5. The conjugation of **5** with the antibody Rituximab **Rit** was performed by dissolving **5** (5.5 mg, ∼0.7 μmol) in a little DMF (∼3 mL), which was then added to a stirred solution of **Rit** (10 mg/mL in 100 mg solution, ∼0.7 μmol) at pH 9. The concentration of DMF in the final reaction mixture did not exceed 35%. After 12 h at 4 °C, the crude mixture was purified by size exclusion chromatography (Bio-Gel P-60 eluent: PBS/DMF 80:20) to give a light green fraction of **Rit**−**5**. Unreacted **5** was recovered in the second fraction. The yield of the antibody conjugate **Rit**−**5** was calculated to be about 90% by adjusting the antibody's protein absorption to that before the reaction. Thus, the sample contained approximately 10% of nonreacted antibody.

Cell Culture. Epstein−Barr virus (EBV) transformed human B-lymphocytes, B-lymphoma cells (Ramos), and human T-lymphocytes (Jurkat cells: clone E 6−1) were used. Jurkat and Ramos cells were purchased from ACACC. EBV transformed B-lymphocytes were kindly provided by Dr. S. Lobitz (Otto-Heubner-Centrum für Kinder- and Jugendmedizin, Charité, Berlin). Cell lines were cultivated in 50 mL flasks in 5 mL RPMI 1640 medium containing Glutamax-I, supplemented with 10% fetal calf serum (FCS), 100 μg/mL streptomycin, and 100 IE/mL penicillin. Cells were cultivated at 37 °C in 100% humidity and 5% CO_2 and were seeded in new medium every 2−3 days.

Laser Scan Microscopy. The ability of the conjugate to bind the antigen CD20 was proven using a confocal laser scanning microscope (CLSM 510, Zeiss) equipped with a Helium-Neon

Scheme 1. Synthesis of the [5:1]Fullerene Hexaadduct Azide 13

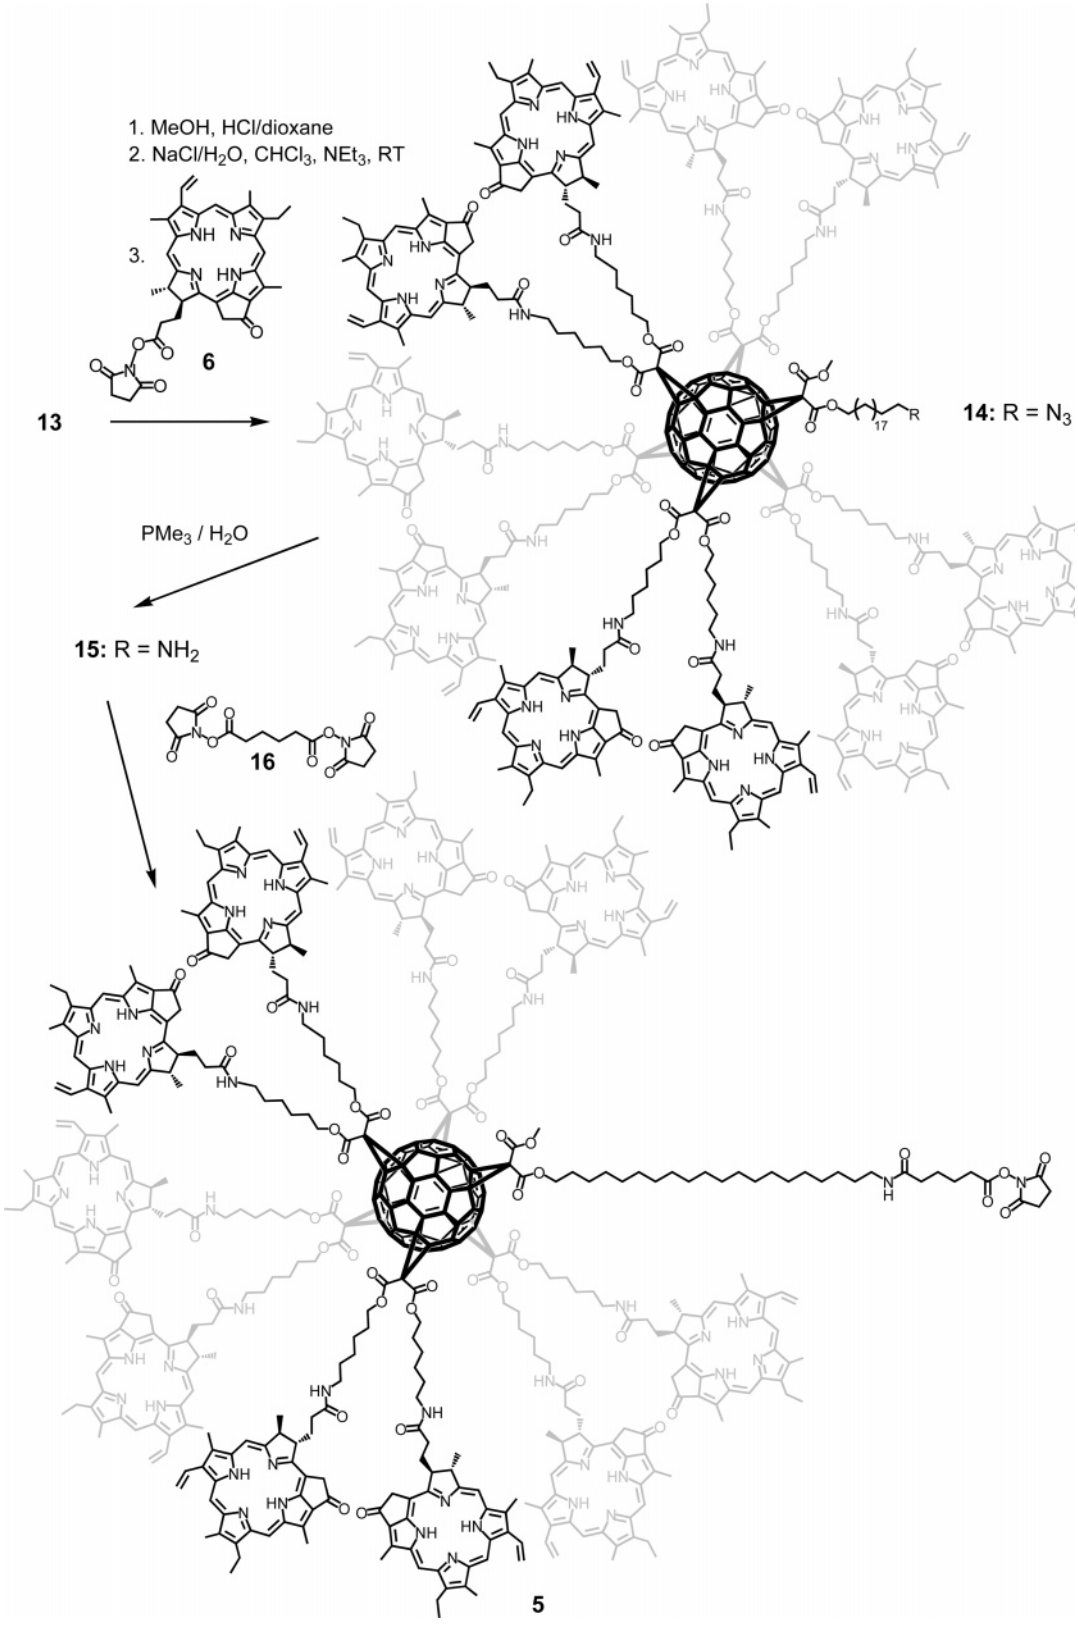
laser. Pictures of the fluorescence of pyropheophorbide-*a* (**2**) were taken by exciting the PS at $\lambda_{exc} = 633$ nm and capturing the fluorescence at an emission wavelength $\lambda_{em} > 650$ nm using a long-pass filter (LP 650). Cells were incubated 24 h with the conjugate **Rit**−**5** (0.5 μmol as determined from the intensity of the last Q-band of the absorption spectrum of **Rit**−**5**), with the fullerene adduct **5** (0.5 μmol) and with compound **3** (0.8 μmol), which served as the positive control (*30*). The final concentration of the pyropheophorbide-*a* moieties was approximately 5 μmol (equivalent concentration). Cells incubated with the solvent were used as the negative control. After incubation, the cells were washed twice with phosphate buffered solution (PBS) and observed at the CLSM. Pictures were taken of transmitted light as well as fluorescence light. Transmitted and fluorescent light were then merged using the *Paint Shop Pro 7* software.

Cell Vitality and Proliferation. Cell vitality and proliferation were measured by the XTT test (Roche). The assay is based on the conversion of the yellow tetrazolium salt XTT into an orange formazane dye by the activity of mitochondria dehydrogenase in metabolically active cells. The amount of formazane product was analyzed spectrophotometrically at the absorbance of 492 nm. The reference wavelength was at 650 nm. The blank optical density (OD) was subtracted from the samples OD, and the percentage of cell vitality and proliferation was determined as follows: $(OD_{sample}/OD_{reference}) \times 100$. Bars represent the standard deviations for three experiments.

RESULTS AND DISCUSSION

Synthesis. After establishing a protocol for the synthesis of multi-pyropheophorbide-*a* conjugates (*26*, *27*), we applied it to the preparation of the synthetically much more demanding system **5** (Scheme 2). **5**, which is a fullerene [5:1]hexakis adduct, has a lower symmetry than the previously synthesized C_{60} hexakis adduct **4** (*26*); even more challenging is the attachment of an activated ester for coupling of the whole carrier system to an antibody. Due to the various reaction conditions during the synthesis of **5** and the inherent sensitivity of the pyropheophorbide-*a* moieties, very mild methods had to be used for generating the active ester unit. It also should be introduced at a very late point in the synthesis.

We decided to make an azide derivative which can be reduced easily to an amine and then coupled to a diester derivative, preferably the bis-active ester of an aliphatic dicarboxylic acid. The size of monoclonal antibodies, typically around 130−150 kDa, as well as the dimensions of the fullerene−pyropheophorbide-*a* conjugate **5**, requires the introduction of a long spacer unit between fullerene and active ester to allow for an efficient coupling reaction.



Starting from 1,20-dihydroxyeicosane **8**, the coupling with methyl malonylchloride yielded the corresponding malonate **9** in 37%; given the fact that **8** is poorly soluble, this yield is quite acceptable. The malonate **9** was attached to C_{60} by the well-established Bingel reaction (*33*) giving the monoadduct **10** in good yields. Subsequent coupling of five BOC-protected malonates **7** (*26*) to the monoadduct **10** by using the template activation method with 9,10-dimethyl anthracene (*34*) yielded the [5:1]hexakis adduct **11**. Here, purification with preparative HPLC was necessary to remove the pentakis adduct impurities. The overall yield after the purification steps was 24%.

The spectroscopic properties of **11** clearly show its constitution. Of particular importance are the resonances of the sp^3-carbon atoms of the fullerene core at 69.1 ppm. The typical C_{60} hexakis adduct bands at 271 and 281 nm in the UV/vis spectrum adds further support to the [5:1] structure. Tosylation of the free alcohol functionality of **11** gave the fullerene tosylate **12** which, after substitution of the tosyl group with sodium azide in DMF, gave the azido compound **13** in high yields (Scheme 1). The azide stretching vibration at 2095 cm^{-1} together with the NMR data unambiguously prove the formation of **13**. It should be pointed out that **13** not only is a very useful precursor for the project presented here, but may also be employed as a carrier/docking unit for other drugs.

After removal of the BOC protecting groups with HCl in dioxane, which liberates a decaamino compound (not isolated), and subsequent coupling with the NHS-active ester of pyropheophorbide-*a* **6** (*26*), the decapyropheophorbide-*a* [5:1]-fullerene hexaadduct **14** with an intact azide group was obtained. The reduction of the azido group of **14** to an amino group was performed by a modified Staudinger reaction (*35*) using trimethylphosphine in THF/water (Scheme 2). The resulting amine **15** could not be isolated or characterized. Nevertheless, the MALDI-TOF mass spectrum of the crude mixture shows clearly the molecular ion peak of the amino compound **15** at 7807.20 (calculated 7800.56) as the main signal. The molecular ion peak of the adduct **14** appears as a small signal at 7836.22 (calculated 7826.55) (see Supporting Information). Compounds **6**−**14** were fully characterized by standard spectroscopic and analytical methods.

The reaction of **15** with a large excess of adipinic acid−bis-NHS ester **16** gave compound **5** with one remaining activated carboxylic acid group. This active ester group is the aforementioned coupling unit which provides the covalent bond between the fullerene−pyropheophorbide-*a* residue and the monoclonal antibody Rituximab—or, in the future, other proteins. The ^1H NMR spectrum of **5** (see Supporting Information) shows quite well resolved signals, which is in contrast to the spectrum of the symmetrical dodecakis pyropheophorbide-*a* fullerene conjugate **4** (*26*) where all signals were rather broad. The signals of the chlorin moiety can be clearly assigned as well as those of the malonate spacer groups. Unfortunately, the resonances

Scheme 2. Synthesis of the Decakis Pyropheophorbide-*a* [5:1]Fullerene Hexaadduct 5 with Active Ester Docking Unit

of the active ester unit cannot be resolved, because they are hidden under the much more intense signals of the other groups. Fortunately, the successful generation of the active ester **5** can be proven with the MALDI-TOF mass spectrum (see Supporting Information). The main signal at 8028.82 can be assigned to the molecular ion peak (calculated 8025.76), whereas the smaller signal at 7802.34 can be assigned to either the unreacted amino compound **15** (calculated 7800.56) or a fragmentation product. This proves clearly the formation of compound **5** as the main component.

Synthesis of the Antibody Conjugate. We used the monoclonal antibody Rituximab (**Rit**) which was obtained from Hoffmann La Roche and is distributed under the commercial name MabThera. MabThera is a sterile, clear, colorless,

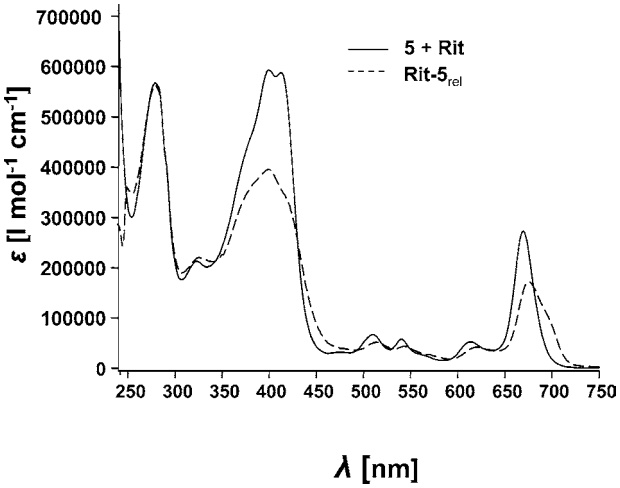


Figure 2. UV−vis spectrum of a mixture of compound **5** with the pure antibody and of the antibody conjugate (**Rit**-**5**).

preservative-free liquid concentrate for intravenous administration, supplied at a concentration of 10 mg/mL in 100 mg (10 mL) single-use vials. The product is formulated for intravenous administration in 9.0 mg/mL sodium chloride, 7.35 mg/mL sodium citrate dihydrate, 0.7 mg/mL polysorbate 80, and sterile water for injection. The pH is adjusted to 6.5.

The conjugation of **5** with the antibody **Rit** was performed by dissolving **5** in as little DMF as possible to allow solubility but to prevent denaturation of **Rit**. This solution was then added to the aforementioned solution of the antibody adjusted to pH 9, keeping the total amount of DMF below 35%. The separation from unreacted **5** and other small-molecule impurities was achieved by size exclusion chromatography (Bio-Gel P-60 eluent: PBS/DMF 80/20) to give a light green fraction of **Rit**−**5**. Figure 2 reports the UV−vis absorption spectra of the immunoconjugate **Rit**−**5** and a solution of **5** and Rituximab (1:1). In order to estimate the antibody/C_{60} ratio, we adjusted the conjugate's protein absorption band at 270 nm to that of the unreacted antibody. By integration over the last Q-band of **5** which stems from the pyropheophorbide *a* units, and comparison of this value with that one of **Rit**−**5**, we determined that the antibody/C_{60} ratio is approximately 1:0.9. It has to be noted that the Q-band of the antibody−fullerene complex is much broader compared to that of **5**. This means that the antibody strongly affects the pyropheophorbide-*a* moiety even in the ground state.

We are convinced that we have achieved a covalent attachment—and not an electrostatic interaction—of the fullerene derivative **5** to the antibody **Rit**, because (i) we observed clear bands on the chromatography column in contrast to broad or tailing bands in case of a breakup of electrostatically coupled components, and (ii) **5** does not contain charged groups or highly polarizable substituents, which could form coulomb complexes. In our opinion, it is more convenient that the drug complex is covalently bonded to the addressing unit. If a drug is merely absorbed on the mAb, once the carrier system is administered, it could be released or sequestered from other plasma proteins (i.e., albumin) before it has reached the target tissue.

Antigen Binding Ability. The monoclonal antibody rituximab **Rit** binds to the membrane receptor (CD20), which is exclusively expressed by normal B-lymphocytes or cancer B-cells, i.e., non-Hodgkin's lymphoma. The binding of the antibody conjugate **Rit**−**5** to the complement protein CD20 was tested on transformed B-lymphocytes by detecting the fluorescence of pyropheophorbide-*a* moieties with a confocal fluorescence microscope. The selectivity of the immunoconjugate **Rit**−**5** for the targeted B-cells was tested by comparison with its binding efficiency to cells which do not express the CD20 receptor (Jurkat cells). The uptake of C_{60} derivatives **5** and **3** was also tested on both cell lines. The comparison of the uptake of **5** with that of the conjugate **Rit**−**5** should give an idea of the efficiency of the antibody as addressing unit. **3**, a [5:1]-fullerene hexaadduct loaded with six pyropheophorbide-*a* moieties, which was shown to be taken up by Jurkat cells, served as positive control for cellular internalization. All dyes were applied in concentrations as such that the equivalent concentration of pyropheophorbide-*a* in each sample was approximately 5 μmol. Finally, cells incubated without any photosensitizer or antibody conjugate were used as reference to distinguish the autofluorescence of the cells. Fluorescence pictures were taken 24 h after incubation. Four different fields were observed with a confocal laser scan microscope. Pictures of both transmitted and fluorescence light were taken for each sample. Superimposed images were then created to clearly show the localization of the fluorescence on cell membranes or in the cell. Figure 3 reports a summary of the analyzed cells.

The T-lymphocytes used as reference did not show any autofluorescence, while a weak autofluorescence was detected in B-lymphocytes. The fluorescence of bound or taken-up photosensitizer (i.e., cells incubated with **3**, Figure 3C) had higher intensity than the autofluorescence of the cells and was clearly discernible from it. The hexakis pyropheophorbide-*a* [5:1]fullerene hexaadduct **3** was taken up by both cell types, and its fluorescence was detected mainly in the cytoplasm and in the perinuclear region. Compound **5** was not taken up by Jurkat and B-cells, which has obviously nothing to do with the size of the fullerene adduct; otherwise, **3** would not have been taken up either. The long lipophilic chain of **5** may have a detrimental influence on its intracellular uptake. The fact that **5** is not taken up makes the enhancement of delivery efficiency that can be reached by the use of an addressing unit even more remarkable. In fact, B-cells incubated with the antibody conjugate **Rit**−**5** had a bright fluorescence on a restricted region of the plasma membrane. The pictures clearly show that the immunoconjugate binds to surface receptors and that it is not internalized by the cells. These results demonstrate that the conjugation with the fullerene adduct **5** does not negatively influence the affinity of the antibody for its antigen. No fluorescence was detected when the same immunoconjugate was incubated with Jurkat cells. This means that **Rit**−**5** selectively recognizes B-lymphocytes without binding to T-cells which do not express the CD20 membrane receptor. In cytotoxicity experiments, the **Rit**−**5** preparation exhibited dark toxicity toward Ramos cells (CD20+ B-lymphoma cells) but not toward Jurkat cells (Figure 4). The immunoconjugate preparation gave the same cytotoxicity as the pure antibody. This means that the immunocojugate **Rit**−**5** has the same affinity for the CD20 receptor as the pure antibody and, furthermore, the same biological activity. However, it has to be considered that the immunoconjugate preparation may contain unreacted rituximab together with **Rit**−**5**, which may be the cause for the dark cytotoxicity. Further experiments considering dark and phototoxicity dependent on the incubation concentration of the **Rit**−**5** preparation will better demonstrate the biological activity of the immunoconjugate.

Our results show that fullerene hexakis adducts are useful multiplying units for modular carrier systems to be used in photodynamic therapy and can be potentially useful in any therapy in which a higher selectivity for the target is required. The special structure and chemistry of C_{60} and the use of long spacers allow the coupling of many drug moieties to a monoclonal antibody avoiding the inactivation of the antibody antigen-specific site. Confocal microscopy studies showed that the antibody conjugate **Rit**−**5** conserves its affinity for the CD20

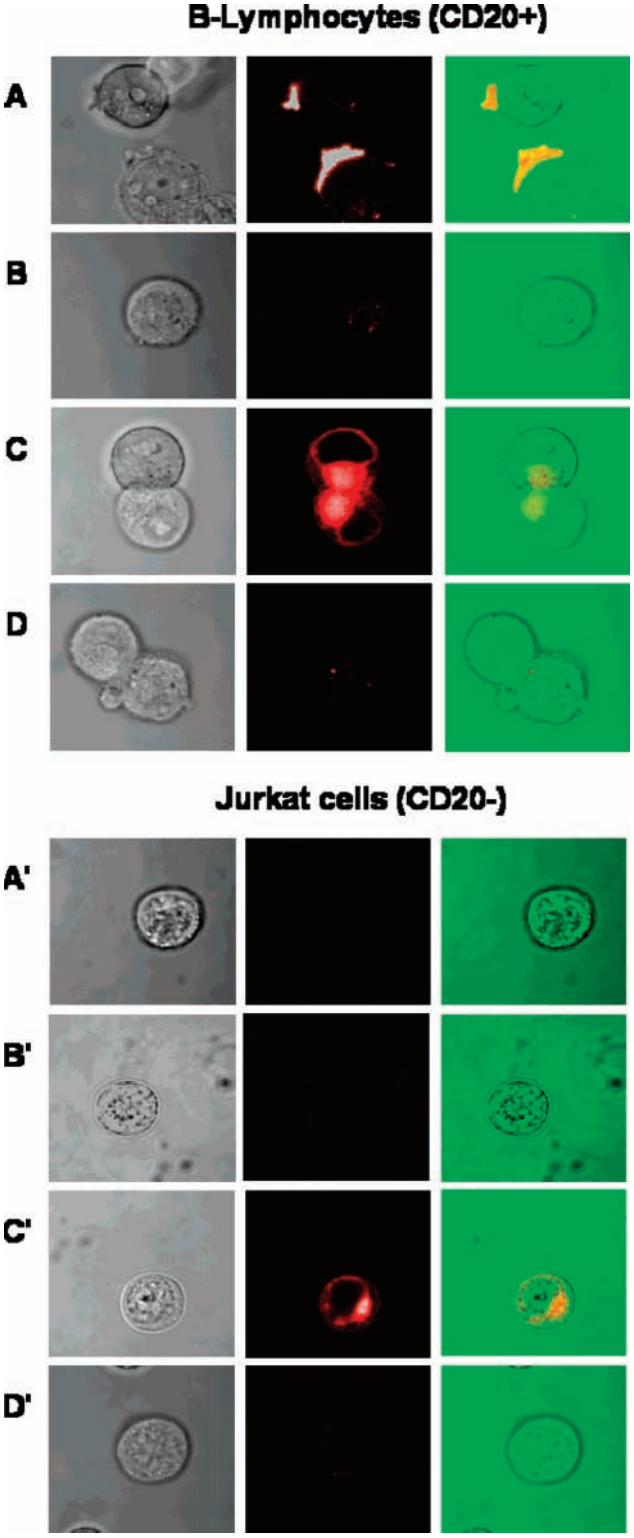

Figure 3. Binding of the conjugated antibody **Rit-5** to CD20 positive (CD20+) B-lymphocytes, and CD20 negative (CD20−) Jurkat cells. Both cells lines were incubated with the conjugated antibody (A, A′) and with the fullerene complexes **5** (B, B′) and **3** (C, C′) at a final pyropheophorbide-*a* equivalent concentration of ∼5 μmol. Cells incubated without any PS were used as reference (D, D′). After incubation, cells were washed twice and observed at the confocal laser scanning microscope (CLSM 510, Zeiss) using λ_{exc} = 633 nm and λ_{em} > 650 nm.

receptor and its selectivity toward CD20 positive B-lymphocytes. On the contrary, the antibody-free complex **5** did not show any bounding or intracellular uptake.

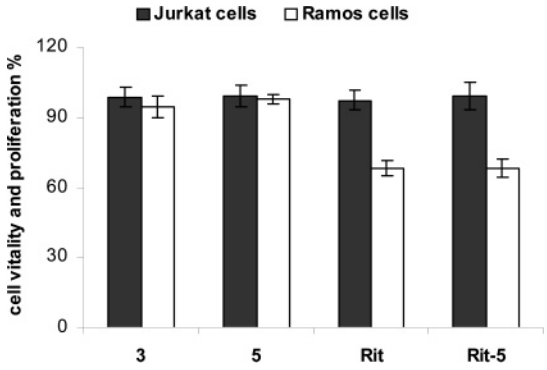

Figure 4. Cytotoxicity of immunoconjugate **Rit-5** toward Ramos cells (CD20+) and Jurkat cells (CD20−). Cells were incubated 24 h with 0.1 μmol **Rit-5**, fullerene adducts **5** and **3**, and the pure antibody rituximab (**Rit**). Cells incubated without any compound were used as reference. Cell vitality and proliferation were detected with the XTT test 24 h after incubation. Percentages were calculated with respect to reference cells.

In our future work, the introduction of a photounstable bond at the PS side will be pursued. In this way, once the modular carrier system has reached the target cells, the drug moieties can be released through irradiation and successively reach those intracellular compartments where the phototoxic effect is mostly efficient.

ACKNOWLEDGMENT

The authors thank the Deutsche Forschungsgemeinschaft (DFG) for financial support (F.R., F.B.: grant no. BO 1353/2-1,2; E.A.E., B.R.: grant no. RO 1042/9-3,4; E.A.E., B.R.: grant no. Coupling of Biotin−(poly(ethylene glycol))amine to Poly(D,L-lactide-*co*-glycolide) Nanoparticles for Versatile Surface Modification

Barbara Weiss,[‡] Marc Schneider,[‡] Leon Muys,[‡] Sebastian Taetz,[‡] Dirk Neumann,[§] Ulrich F. Schaefer,[‡] and Claus-Michael Lehr*[,‡]

Biopharmaceutics and Pharmaceutical Technology, and Junior Research Group Drug Transport, Center for Bioinformatics, Saarland University, Saarbruecken, Germany. Received November 2, 2006; Revised Manuscript Received April 1, 2007

Generally, polymeric nanoparticles (NP) for drug targeting are designed to entrap the drug moiety in the core and to present the targeting moiety on the surface. However, in most cases, common preparation techniques of polymeric NP need to be specifically arranged for each compound to be entrapped or attached. In the present work, we introduce a method for versatile conjugation of targeting moieties to the surface of preformed, polymeric NP. Moreover, due to taking advantage of biotin−avidin interactions, our regime opens the additional possibility of a rapid fluorescence labeling of NP. Poly(D,L-lactide-*co*-glycolide) (PLGA) NP in the size of 210 nm were prepared by the classic oil-in-water method. Such NP were functionalized with biotin−(poly(ethylene glycol))amine (BPEG) by means of cyanuric chloride chemistry. The amount of surface-associated biotin was 850 pmol per milligram of polymer, corresponding to roughly 2650 molecules of biotin per NP. When drawn to scale, such surface coating appeared to be well-suited for subsequent binding of avidin or avidin-linked ligands. By resonant mirror measurements, we could prove specific binding of biotinylated NP to a NeutrAvidin (NAv)-coated surface. Furthermore, after coupling of NAv-linked fluorescence dyes to BPEG-functionalized NP, differences in binding and uptake could be demonstrated using two epithelial cell lines (Caco-2, A549).

1. INTRODUCTION

Polymeric nanoparticles (NP) have turned out to be a promising carrier system for a number of active pharmacological ingredients (API), because they allow controlled release, drug targeting, and overcoming certain biological barriers such as the blood−brain barrier (*1*−*4*), the skin (*5*−*9*), or the intestinal mucosa (*10*−*13*).

In this context, biocompatible and biodegradable polymers are highly preferred, as they are eliminated from the body as small, nontoxic fragments after having served their intended purpose (*14*). Well-known examples of such polymers are the aliphatic poly(esters) poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and their copolymers poly(lactic acid-*co*-glycolic acid) (PLGA); they have been extensively used since the 1970s for biomedical applications like sutures, fibers, fracture repairs, implants, and vascular grafts (*15*). Later, mainly PLA and PLGA have also been applied for the preparation of NP (*4*, *6*, *16*−*21*), which resulted in a variety of well-established methods for preparation and drug entrapment (*14*, *15*). Nowadays, a major interest of research is the synthesis of novel biodegradable polymers for the preparation of NP with different drug-loading properties, controlled release, and predictable degradation (*22*−*28*). Most of them are block copolymers (*22*, *23*, *26*) or polymer blends (*27*), often also containing PLGA or PLA subunits (*26*−*28*).

Generally, nanoparticulate drug targeting systems may bear different functionalities. The inner functionality is reflected by the NP core encapsulating the active moiety, small drug molecules (*6*, *8*, *29*−*32*), or therapeutic proteins (*16*, *33*−*35*). The active compound is stabilized toward the physiological environment, and its release can be controlled by the composition and structure of the polymer matrix. Complementarily, the outer functionality of a NP is represented by the NP surface which may establish specific and nonspecific interactions with the target, e.g., some particular cells, tissues, or organs. With regard to drug targeting, specific interactions between NP and the target cells or tissues are favored, requiring a sufficient number of targeting ligands on the NP surface to be available for such interaction (*36*−*38*).

In literature, diverse approaches describe the preparation of biodegradable biotinylated homopolymers (*39*) and block copolymers (*40*−*42*), which may be subjected to nanoparticle preparation. The aim of this study was to develop a procedure for surface functionalization of preformed NP for a subsequent versatile conjugation of targeting ligands and/or fluorescence dyes under mild conditions. Such a method may be applicable to various formulations of PLGA NP, which may eventually already contain an API, without any alteration of the NP preparation procedure. For this purpose, we chose the avidin−biotin system, as avidin (Av) and its homologues streptavidin (SAv) and NeutrAvidin (NAv) exhibit very high affinities ($K_d = 10^{-13}-10^{-16}$ M) and rapid and stable binding to biotin (*43*, *44*). Taking into consideration the presence of free carboxylic acid groups on the surface of NP made of poly(esters) like PLA, PLGA, PGA, and diverse lactide and/or glycolide containing blends and block copolymers (*23*, *26*, *27*), we have opted for an approach where surface-biotinylated NP bind to conjugates of avidin (or homologues). Consequently, both targeting moieties (antibodies, Fab fragments, etc.) as well as fluorescence labels can be easily linked to the surface of thus-functionalized NP as long as they are available as conjugates of avidin (or homologues) (Figure 1A).

In the present study, an effective surface biotinylation of preformed PLGA NP cores could be demonstrated. PLGA NP were characterized for their size, ζ potential, and surface

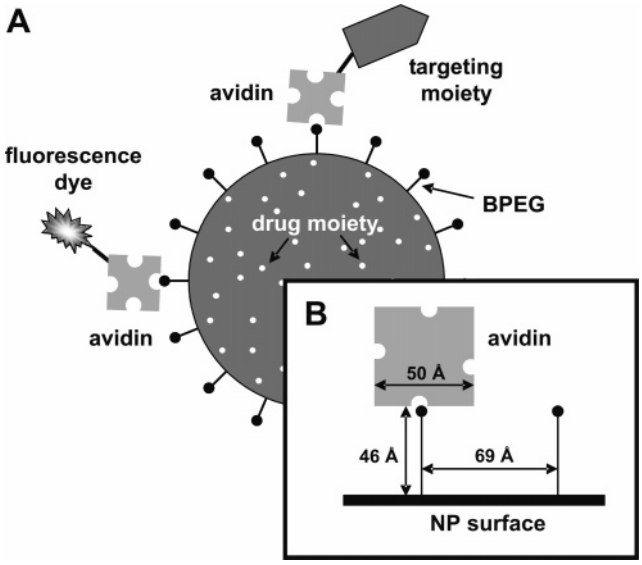

Figure 1. Schematic illustration of a surface-modified PLGA NP by means of BPEG. Part A gives an overview of the aims of the study. Versatile binding of targeting moieties is realized by employing avidin (and homologues) conjugates. Binding of fluorescence dye conjugated avidin (and homologues) introduces the possibility of additional fluorescence labeling of the NP. Part B represents a virtual zoom into the NP surface. Assuming homogeneous distribution of the BPEG molecules on the NP surface, the mean distance is calculated to 69 Å. The length of the BPEG molecule is determined to be roughly 46 Å. The size of avidin is reported to 50 Å × 50 Å × 40 Å with the biotin binding sites at a distance of 29.5 and 20 Å.

characteristics before and after biotin functionalization. The particle-associated biotin amount was determined to scale. Resonant mirror measurements gave evidence for specific binding of biotinylated NP to a NAv surface. For the first evaluation of the ease of application in a biological system, differences in binding and uptake of NP were studied in two epithelial cell lines after labeling the NP with different Av-linked fluorescence dyes.

2. METHODS AND MATERIALS

2.1. Materials. Poly(D,L-lactide-*co*-glycolide) (PLGA) (Resomer RG 50:50 H; inherent viscosity 0.31 dL/g) was kindly provided by Boehringer Ingelheim (Boehringer Ingelheim GmbH & Co. KG, Ingelheim, GE). Biotin−(poly(ethylene glycol))amine (BPEG) was obtained from Sigma (Sigma Chemical Co., St. Louis, MO). Poly(vinyl alcohol) (PVA) (Mowiol 4−88) was bought from Kuraray (Kuraray Specialities GmbH, Frankfurt am Main, GE). NeutrAvidin biotin-binding protein (NAv), avidin−FITC conjugate (FITC-Av), streptavidin−FITC conjugate (FITC-SAv), and NeutrAvidin−FITC conjugate (FITC-NAv) were purchased from Pierce (Perbio Science Deutschland GmbH, Bonn, GE). NeutrAvidin−Rhodamin Red−X conjugate (Rho-NAv) was obtained from Invitrogen (Molecular Probes, Inc., Eugene, OR). Rhodamine ricinus communis agglutinin I (Rho-RCA) and fluorescein wheat germ agglutinin (FITC-WGA) were obtained from Vector (Vector Laboratories, Inc., Burlingame, CA). Dulbecco's modified Eagle's medium (DMEM), RPMI-1640, nonessential amino acids (NeAA), and fetal bovine serum (FBS) were bought from GIBCO (Invitrogen Corp., Carlsbad, CA). All other chemicals were of analytical grade. Phosphate buffered solution pH 7.4 (PBS) was composed of KCl 0.20 g/L, NaCl 8.00 g/L, KH_2PO_4 0.20 g/L, and $Na_2HPO_4 \cdot 2H_2O$ 1.44 g/L.

2.2. Preparation of Biotin−(Poly(ethylene glycol)amine-Coated PLGA Nanoparticles. PLGA NP were prepared by a single emulsion method (*45*). Briefly, 100 mg of PLGA was dissolved in 5 mL of ethyl acetate and emulsified into a 1% PVA solution. The system was stirred at room temperature for 2 h at 800 rpm on a magnetic stirrer and then homogenized for 10 min using an Ultra-Turrax T 25 Mixer (Janke and Kunkel GmbH & Co., Staufen, GE) at 13 500 rpm. The volume was filled up to 50 mL with demineralized water, and the organic solvent was evaporated using a rotary evaporator.

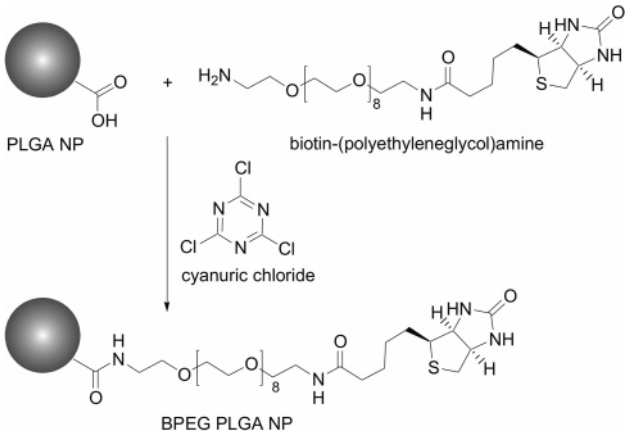

Figure 2. Reaction of chemical surface modification of PLGA NP resulting in BPEG PLGA NP.

BPEG-coated PLGA NP (BPEG PLGA NP) were generated from PLGA NP via a triazine-promoted amidation of the carboxylic acid groups present on the PLGA NP surface. The technique has been frequently described in the literature (*46*−*48*); here, it was adapted to surface modification of PLGA NP. The carboxylic acid groups formed activated intermediates with cyanuric chloride and, subsequently, the desired carboxyl amides in a single one-step reaction (Figure 2). The amino groups for the amidation reaction were derived from BPEG. 1 mL of PLGA NP suspension was supplemented with 1 mL of saturated cyanuric chloride solution and 50 μL of 10 mg/mL BPEG solution and incubated at room temperature for 24 h under gentle shaking on a horizontal shaker. BPEG PLGA NP were rinsed from excessive reagents by dialysis against 2 L of demineralized water for 24 h using a dialysis membrane with a cutoff of 100 000 Da (Spectra Por CE, Carl Roth GmbH, Karlsruhe, GE). The dialysis water was renewed after 8 h of dialysis time. In case blank PLGA NP were used for comparison, they were also dialyzed as described above. The NP concentration was determined via the residue of a defined volume of NP suspension after lyophilization. NP were prepared with a total of $n = 3$ to 5 batches.

2.3. Physicochemical Characterization of the Nanoparticles. *2.3.1. Particle Size and Surface Charge (ζ potential).* For determination of particle size and ζ potential, the NP suspensions were 100-fold diluted in demineralized water and analyzed using a Zetasizer Nano ZS (Malvern Instruments, Malvern, UK). The measurement of the NP size was based upon photon correlation spectroscopy (PCS). This technique yields the particle mean diameter and the polydispersity index (PI), which is a dimensionless measure for the broadness of the particle size distribution. The ζ potential was analyzed by laser Doppler anemometry using the same instrument in appropriate settings. Results are expressed as mean ± SD.

2.3.2. Morphology Study. NP shape and surface properties were imaged by means of scanning probe microscopy (SPM). NP samples were prepared as dense layers by mounting a drop of a freshly prepared NP suspension on a silicon wafer and air-drying. Imaging was performed using a Bioscope SPM and a Nanoscope IV controller (Veeco Instruments, Santa Barbara, CA) in a vibration-free environment. For all measurements, tapping mode was employed using a commercially available

pyramidal tip (silicon, Ultrasharp, MikroMasch, Tallinn, EST) on a cantilever with a length of 230 μm. The resonance frequency was approximately 170 kHz, the nominal force constant 40 N/m, and the scan frequency between 0.1 and 1 Hz.

2.4. Particle-Associated Biotin Amount. The amount of biotin on BPEG PLGA NP was determined by means of FluoReporter Biotin Quantitation Assay (Molecular Probes, Invitrogen GmbH, Karlsruhe, GE). This assay uses Biotective Green reagent which consists of Av labeled with a fluorescence dye and with quencher dye ligands occupying the biotin binding sites. The ligand quenches the fluorescence through fluorescence resonance energy transfer. By addition of any biotin, the ligand is displaced from Biotective Green reagent, yielding fluorescence proportional to the amount of added biotin. The assay was performed according to the protocol of the manufacturer. NP suspensions were used in concentrations between 0.49 and 0.88 mg/mL, and experiments were performed with three batches and with a total of $n = 2$ to 3 samples each. The background was subtracted. Results are expressed as mean $\pm$ SD.

2.5. Modeling of Biotin−(Poly(ethylene glycol))amine. To determine the dimensions of BPEG, we built a single stretched molecule using the program *HyperChem Professional 7.1* (Hypercube, Inc., Gainesville, FL). The geometry optimization was performed on a personal computer employing the MM+ force field. For the energy minimization, we used a conjugate gradient method with a termination value of the root-mean-square gradient of 0.1 kcal/mol/Å according to the HyperChem manual.

2.6. Binding of FITC Conjugated Proteins (FITC-Av, FITC-SAv, FITC-NAv) to Nanoparticles. 100 μL samples of BPEG PLGA NP and PLGA NP suspensions ($\sim$1 mg/mL) were incubated with 25 μL of FITC-Av (1 mg/mL), FITC-SAv (1 mg/mL), and FITC-NAv (1 mg/mL), respectively, for 10 min under gentle shaking and protection from light. The suspensions were centrifuged for 5 min at 23 147 $\pm$ 66 g, and the supernatant was removed. NP were washed by resuspension in 1 mL of PBS, centrifuged again, and finally resuspended in 50 μL of PBS. In all resuspension steps, NP pellets were treated with ultrasound for 2 min ($n = 3-5$). In pre-experiments, a separation of NP on the size order of 210 nm by centrifugation at 23 147 $\pm$ 66 g (no NP detectable in the supernatant by PCS) and a complete removal of free proteins in solution by the described washing procedure were confirmed.

The binding of FITC conjugated proteins to BPEG PLGA NP and PLGA NP was investigated and visualized by confocal laser scanning microscopy (CLSM) which was performed using a Bio-Rad MRC-1024 CLSM (Bio-Rad Laboratories, Hercules, CA) equipped with an argon/krypton laser. The objective used was an oil immersion objective 40$\times$ (NA = 1.3). The excitation wavelength was $\lambda = 488$ nm, and the fluorescence signal was collected with a band-pass filter (Zeiss 520/35) in the green wavelength range. For each set of samples, the same detector settings were chosen.

2.7. Resonant Mirror System (RMS) Adhesion Studies. The interaction of BPEG PLGA NP and PLGA NP with two differently modified surfaces was examined by means of a RMS (IAsys, Cambridge, UK). First, the interaction of the NP with a NAv-coated surface was investigated.

In a second run, the binding sites of NAv were blocked using a 0.02 mg/mL BPEG solution (incubation time $\sim$4.5 min) to study possible nonspecific binding of NP with this surface.

Briefly, NP suspensions were added to the coated sensor chip and allowed to bind to the surface. The adhesion process was monitored, and the measurements were stopped after 5 to 10 min. The vertical displacement of the vibrostirrer was set to 0.425 mm, and the temperature of the instrument was set to 25 °C.

Table 1. Size, Polydispersity Index (PI), and ζ Potential of PLGA NP and BPEG PLGA NP

	size [nm]	PI	ζ potential [mV]
PLGA NP	207 $\pm$ 4	0.042 $\pm$ 0.017	−32.0 $\pm$ 3.6
BPEG PLGA NP	207 $\pm$ 2	0.051 $\pm$ 0.004	−23.0 $\pm$ 4.1

The concentrations of BPEG PLGA NP and PLGA NP were 0.5 and 1.2 mg/mL, respectively. The NAv-functionalized surface was generated by incubating a biotin-coated cuvette (Thermo Electron LED GmbH, Langenselbold, GE) with NAv as described in the IAsys standard immobilization protocol. All reactions were performed in PBS.

2.8. Cell Culture. *2.8.1. Caco-2 Cells.* Caco-2 cells, clone C2BBe1, were purchased at passage 60 from American Tissue Culture Collection (ATCC; Manassas, VA) and used at passages 70 to 91. Cells were grown to a confluency of approximately 90% in 75 cm^2 T-flasks with DMEM supplemented with 10% FBS and 1% NeAA. Thereby, the culture medium was changed every second day, and the temperature was 37 °C in an atmosphere of around 85% relative humidity and 5% CO_2.

2.8.2. A549 Cells. A549 cells (ATCC no. CCL-185) were purchased at passage 82 from ATCC (American Type Culture Collection, Manassas, VA) and used at passages 88 to 110. Cells were grown to a confluency of approximately 90% in 75 cm^2 T-flasks with RPMI-1640 supplemented with 10% FBS. Thereby, the culture medium was changed every second day, and the temperature was 37 °C in an atmosphere of around 85% relative humidity and 5% CO_2.

2.8.3. Uptake Studies. After trypsinization, Caco-2 and A549 cells were seeded on LAB-TEK chamber slides (Nalge Nunc International, Rochester, NY) at densities of roughly 20 000 and 12 500 cells/mL, respectively, and grown for 3 days. Uptake of test substances was evaluated after 6 and 24 h of incubation with a test substance at 37 °C under protection from light. In the case of the 24 h incubation time, the supernatant was replaced by cell culture medium after 6 h. For localization of fluorescent NP, cell membranes were stained using Rho-RCA and FITC-WGA, respectively, by incubation with a 5 μg/mL solution in PBS for 10 min at 37 °C under protection from light. Cells were washed twice with PBS and fixed by 10 min of incubation with 4% formaldehyde solution at room temperature under protection from light. Again, cells were washed twice and then subjected to CLSM, which was performed as described in section 2.6. In the red wavelength range, the excitation wavelength was $\lambda = 568$ nm, and the fluorescence signal was collected with a long-pass filter (Zeiss LP585). Test substances were 0.5 mg/mL BPEG PLGA NP, which were preincubated with FITC-NAv or Rho-NAv in excess for 30 min, dialyzed in order to remove unbound proteins, and 1:1 diluted with the respective growth medium. References were as follows: (i) blank growth medium, (ii) a 25 μg/mL FITC-NAv or Rho-NAv solution in the respective growth medium, and (iii) a 25 μg/mL FITC-NAv or Rho-NAv solution in the respective growth medium additionally containing 0.5 mg/mL of blank PLGA NP. The concentrations of the FITC-NAv and Rho-NAv solutions were well above the maximum of NP-associated fluorescent proteins in a 0.25 mg/mL BPEG PLGA NP solution when all biotin molecules bound to one FITC-NAv or Rho-NAv molecule.

3. RESULTS

3.1. Physicochemical Properties of Biotinylated Nanoparticles. PCS measurements showed that size and PI of BPEG PLGA NP and PLGA NP were practically the same, i.e., there was no measurable increase in size of the original PLGA NP after functionalization with BPEG. Particle size distributions were monodisperse. However, the ζ potential changed from −32 mV to −23 mV (Table 1).

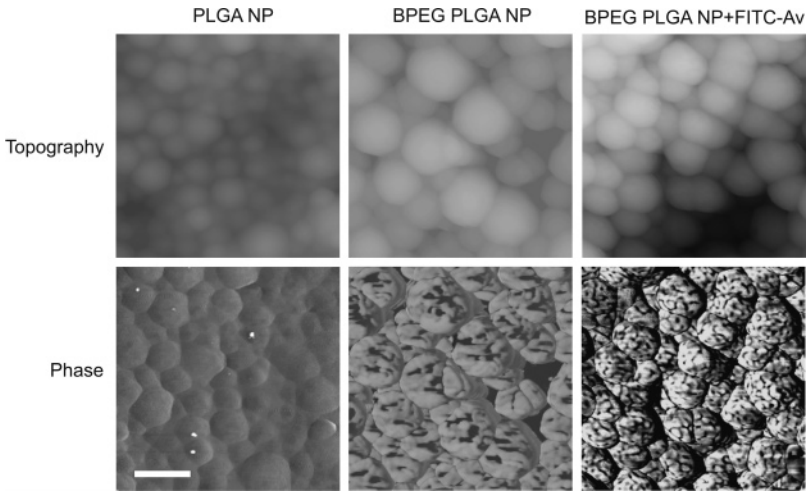

Figure 3. SPM topography and phase images of PLGA NP, BPEG PLGA NP, and BPEG PLGA NP with associated FITC-Av (bar = 250 nm).

Figure 3 presents SPM images of PLGA NP, BPEG PLGA NP, and BPEG PLGA NP with associated FITC-Av. Before subjection to SPM measurements, successful binding of FITC-Av to BPEG PLGA NP was confirmed via CLSM. The SPM topography images show the particle shape and surface structure. Blank PLGA NP exhibited a spherical particle shape and a smooth surface. Obviously, these properties were not affected by surface modification, as can be seen from the height images of BPEG PLGA NP and BPEG PLGA NP with associated FITC-Av. However, the phase images of those samples showed clear structural differences, in contrast to the original PLGA NP. These alterations reflect changes of the local elastic and/or adhesive properties as a consequence of surface biotinylation of PLGA NP and also due to the binding of FITC-Av to thus-modified surface.

FluoReporter Biotin Quantitation Assay was used to quantitatively analyze the extent of surface modification of PLGA NP resulting in BPEG PLGA NP. By that method, an amount of 845 ± 145 pmol of biotin attached to the surface of 1 mg of BPEG PLGA NP was determined. Assuming a particle density of 1.25 g/mL (which corresponds to the real density of PLGA according to the information of the manufacturer), an approximate number of 2600 biotin molecules on the surface of one single average-sized (210 nm) BPEG PLGA NP could be calculated. Assuming that BPEG chains are evenly distributed on the NP surface, the mean distance of two chains would be 69 Å. The length of the BPEG chains was calculated to maximally 46 Å. In solution, we would expect the BPEG molecule to adopt a more or less coiled conformation; here, however, to roughly estimate surface conditions we deliberately assumed the molecule to exist in a stretched conformation. The size of Av is reported to be 50 Å × 50 Å × 40 Å with the biotin binding sites being distances of 29.5 and 20 Å from each other (*49*). The dimensions of such a BPEG-functionalized NP surface are drawn to scale in Figure 1B, indicating that each single BPEG graft on the NP surface should be well accessible to Av.

3.2. Selection of Suitable Avidin Homologues for Further Functionalization. Each of the three proteins FITC-Av, FITC-SAv, and FITC-NAv bound to BPEG PLGA NP, whereas only FITC-Av and FITC-SAv exhibited binding to blank PLGA NP, obviously due to nonspecific interactions. In these cases, we could visualize green fluorescent single NP or particle aggregates by means of CLSM. Figure 4A shows an image of BPEG PLGA NP with surface-bound FITC-NAv. In contrast, we did not find binding of FITC-NAv to blank PLGA NP (Figure 4B). Consequently, due to apparently weak nonspecific particle binding, we chose NAv for further RMS measurements and ligand coupling.

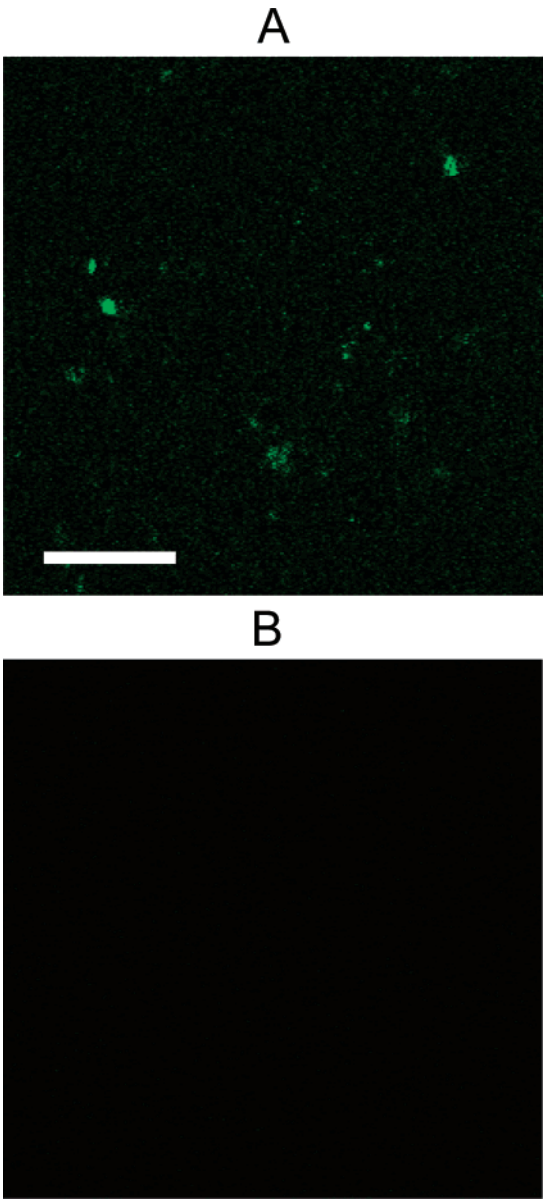

Figure 4. CLSM visualization of FITC-NAv-treated BPEG PLGA NP (A) and PLGA NP (B) (bar = 20 μm).

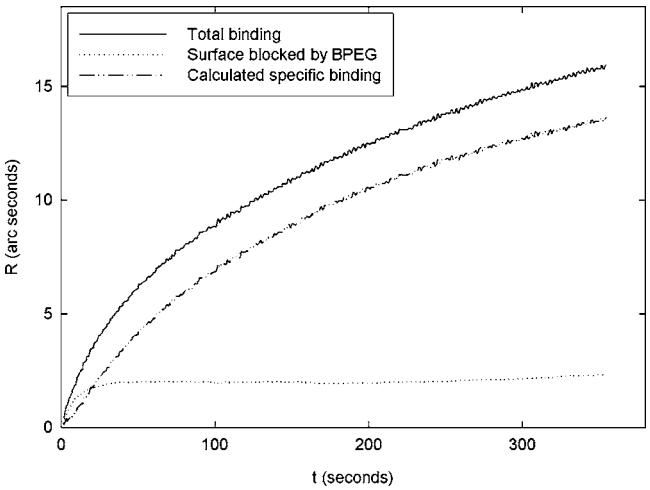

Figure 5. Results of resonant mirror system (RMS) adhesion studies: interactions of BPEG PLGA NP with a NeutrAvidin (NAv) surface and a NAv surface with BPEG-blocked biotin binding sites. An additional curve calculated as the difference of both binding curves represents the extent of specific binding.

BPEG PLGA NP and PLGA NP without protein treatment and BPEG PLGA NP and PLGA NP which were incubated with FITC-NAv with blocked biotin binding sites were imaged as a control. Those samples did not exhibit any fluorescence under the same conditions, indicating that there was no binding of FITC-NAv to the NP under such conditions.

3.3. RMS Measurements. Using RMS, we first studied the binding of BPEG PLGA NP with a NAv-functionalized surface (total binding) (Figure 5). We obtained a clear response; however, the binding curve did not reach equilibrium during the measurement, possibly due to particle rearrangement on the NAv-coated surface. There was no observable NP dissociation, and particles could not be washed easily from the surface, indicating a strong binding. In a second experiment, nonspecific binding was studied by blocking the biotin binding sites of a NAv-coated functionalized cuvette using free BPEG. Here, we received only a small response. The extent of specific binding of BPEG PLGA NP to the NAv surface is described by a calculated curve, which was obtained by subtracting the curve representing the nonspecific binding from the curve representing the total binding. Again, the curve did not reach equilibrium for reasons described above.

For comparison, we also investigated the binding behavior of nonfunctionalized PLGA NP to a NAv surface. Here, the equilibrium response was very small and readily established after approximately 100 s.

3.4. Uptake Studies. Figure 6 shows *xz* cross sections from a stack of confocal laser scans of Rho-RCA-stained A549 cells, Rho-RCA-stained Caco-2 cells, and FITC-WGA-stained Caco-2 cells after 6 and 24 h incubation with fluorescent NP formulations. In order to investigate and visualize binding and uptake, we applied FITC-NAv-labeled NP if the cell membranes were stained with Rho-RCA and Rho-NAv-labeled NP if the membranes were stained with FITC-WGA.

In the case of A549 cells, NP appeared in close association with the cell membranes after 6 h of incubation, whereas we found a clear NP uptake after 24 h. In the case of Caco-2 cells, there was no particle uptake even after 24 h of incubation. However, particles were attached to the cell membranes.

These results in Caco-2 cells were found with both FITC-NAv and Rho-NAv labeled BPEG PLGA NP, thus evidencing the suitability of this approach for rapid versatile fluorescence labeling.

In the case of all references, no fluorescence within the cells or at the cell membranes was found that had derived from the protein solutions (images not shown).

4. DISCUSSION

The overall goal of this study was the evaluation of a procedure for surface functionalization of preformed NP made from biodegradable polymers such as PLGA. Surface-modified NP are intended to be used for subsequent versatile conjugation of targeting moieties and for rapid fluorescence labeling under mild conditions.

Preformed PLGA NP were modified by easy covalent binding of a biotin derivative via a short PEG spacer (Figure 2). The biotinylated particle surface forms a platform for further specific binding of Av (and homologues) conjugated compounds, which may be either targeting moieties or fluorescence dyes, by brief incubation in aqueous medium (Figure 1A). By this NP modification method, harsh preparation conditions like shearing or heating or the presence of organic solvents are avoided. Another benefit of this technique concerns the detachment of compounds from the NP surface for potential targeting purposes. If NP are made from functionalized polymers (*39*, *42*, *50*), ongoing polymer erosion may uncover further active groups, thus leading to a subsequent rebinding of detached proteins. Using this preparation, it cannot be entirely excluded that BPEG and the activating agent cyanuric chloride might also interpenetrate the NP cores during biotinylation reaction. However, due to selected process parameters (i.e., aqueous dispersion, hydrophobic polymer), the reaction is supposed to preferably take place at the NP−water interface. Therefore, in contrast to NP from modified polymers, the core of the BPEG PLGA NP is not expected to provide further biotin groups as soon as they are cleaved from the surface, i.e., specific rebinding is most unlikely.

Regarding the biocompatibility of BPEG PLGA NP, biotin is a natural vitamin, and both substances, PEG and PLGA, may be considered nontoxic (as they are part of FDA-approved drug products for parenteral administration).

Surface functionalization of PLGA NP to yield BPEG PLGA NP did not involve an increase in size as determined by PCS, i.e., any change in the hydrodynamic diameter was beneath the detection limit (Table 1). As evidenced in SPM studies, surface modification of PLGA NP and binding of Av to BPEG PLGA

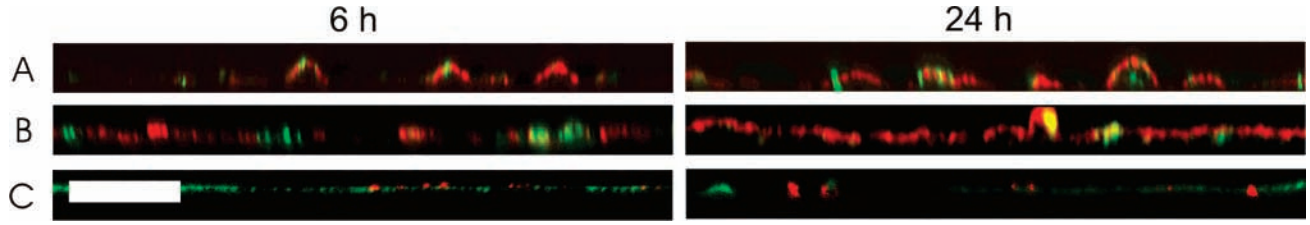

Figure 6. *xz* cross sections from a stack of confocal laser scans (apical up) of Rho-RCA-stained A549 cells (A), Rho-RCA-stained Caco-2 cells (B), and FITC-WGA-stained Caco-2 cells (C). Cells were imaged after 6 and 24 h incubation with FITC-NAv-labeled BPEG PLGA NP (in the case of Rho-RCA-stained A549 and Caco-2 cells) and Rho-NAv-labeled BPEG PLGA NP (in the case of FITC-WGA-stained Caco-2 cells) (rows A and B: bar = 50 μm × 5 μm. row C: bar = 20 μm × 9 μm).

NP did not lead to changes in particle shape and surface structure (Figure 3). Obviously, however, as indicated in the phase images, those modifications resulted in changes of elasticity or adhesion of the cantilever tip.

We found a decrease in the ζ potential for the BPEG PLGA NP in comparison to nonmodified PLGA NP (Table 1). The negative surface charge of both particle species is attributed to the presence of carboxyl end groups derived from PLGA chain ends. However, in the case of the BPEG PLGA NP, the particle surface was partially shielded, owing to covalent modification of the carboxyl groups by means of BPEG molecules. The PEG chain linking the biotin compound with the NP core consisted of ten ethylene oxide subunits and was conceived to facilitate the surface-modification reaction by provision of amino groups and, at the same time, to increase biotin flexibility while protein binding.

Studying the binding specificity of Av and its homologues to BPEG PLGA NP and PLGA NP, we found specific binding to BPEG PLGA NP only in the case of NAv. This finding has to be attributed to the character of the proteins: Av and its bacterially produced counterpart SAv represent positively charged glycoproteins with a well-known tendency of nonspecific interactions with negatively charged compounds, e.g., PLGA NP. NAv is manufactured from Av by deglycosylation, consequently, reducing charge and nonspecific binding (*51*).

The binding specificity was confirmed in RMS measurements where BPEG PLGA NP showed specific binding to a NAv-coated surface (Figure 5). Attachment of BPEG PLGA NP to the NAv surface did not reach equilibrium during the measurement, which probably is to be attributed to particle rearrangement; in contrast, minor nonspecific binding of PLGA NP was completed rapidly.

For drug delivery applications, investigation and imaging of NP in biological systems, their penetration pathways, and their final localization at cellular or tissue level is of major interest (*9*, *18*, *52*). Common strategies represent the entrapment of fluorescence markers or visualizable drugs and the imaging of NP by fluorescence, confocal, or multiphoton microscopy (*6*, *9*, *52*, *53*). The present work illustrates the application of fluorescence-labeled BPEG PLGA NP to demonstrate differences in binding and uptake behavior between flat squameous epithelial cells from the alveolar epithelium (A549) in comparison to the relatively thick columnar epithelial cells from the intestinal mucosa (Caco-2) (Figure 6). Moreover, dependent on the staining of the cell membranes, we applied NP decorated with different fluorescent NAv conjugates, thus demonstrating the ease of versatile fluorescence labeling of BPEG PLGA NP.

From calculations to scale of the surface of BPEG PLGA NP, we hypothesized that particles are optimally covered by BPEG molecules. Presumably, those molecules are able to reach each site on the particle surface due to the flexibility of their PEG spacer in order to mediate specific binding of Av (and homologues). Considering Av and homologues that are tetrameric, with four biotin binding sites, it is evident that this fact may lead to binding of biotin molecules derived from several NP, and subsequently to cross-linking. Nowadays, in order to overcome this cross-linking problem, one can find different approaches in the literature. Active monomeric Av and SAv mutants have been produced by means of biotechnological methods (*54*, *55*). Since monomerization of those proteins generally involves loss of biotin binding affinity, a NAv-coated tetramer with only one functional biotin binding subunit was recently developed (*56*).

Those protein mutants would help to avoid particle cross-linking, whereas the choice of NAv as biotin binding protein can further minimize nonspecific binding. Such a refinement of our approach by using monovalent NAv appears very possible; however, this is still a subject of ongoing research.

5. CONCLUSION

Successful surface biotinylation of preformed PLGA NP, representing a model for NP from any other polymer exhibiting free carboxylic acid groups, can be demonstrated. Without interfering with or being dependent on the methods of NP preparation and drug loading, our approach allows versatile surface decoration with targeting moieties and fluorescence labels under mild conditions, provided they are available as conjugates of NAv. Binding studies and calculations to scale of the surface conditions of biotinylated NP revealed optimal conditions for subsequent specific binding of Av conjugated ligands. In a first biological evaluation with A549 and Caco-2 cells, BPEG PLGA NP enabled us to demonstrate differences in binding and uptake.

ACKNOWLEDGMENT

Boehringer Ingelheim is kindly acknowledged for providing the polymer. We would like to thank Jens Schaefer (Department of Pharmaceutics and Biopharmacy, Philipps-University Marburg) for his help with the Zetasizer measurements. D. Neumann is financially supported by the Deutsche Forschungsgemeinschaft (DFG grant BIZ 4/1).

Received November 21, 2006; Revised Manuscript Received March 29, 2007

Most current nanotoxicology research is focused on examining the influence of nanomaterials at the tissue and cellular levels. To explore these interactions on the molecular level, new carboxyfullerenes interact with transport proteins at the molecular level. The carboxyfullerenes exhibited an unusual mode of binding outside the calyx of β-lactoglobulin (a typical representative of lipocalin family of barrier liquid proteins). The complexes were studied by various techniques, including mass spectrometry, UV/vis and circular dichroism spectroscopy, chromatographic methods, gel electrophoresis, and dynamic light scattering. The fullerene ligands were transferred from β-lactoglobulin to human serum albumin (a representative of a blood transport protein), thus providing a model of how fullerene-based nanomaterials interact with biomolecules and are transported in biological systems.

INTRODUCTION

During the past decade, research related to carbonaceous nanomaterials has increased, because these materials have potential in applications ranging from biosensor components (*1*, *2*) to therapeutics (*3*) to diagnostic agents (*4*). In this context, fullerenes and their derivatives have great potential because of their unique structural (*5*, *6*), physical (*7*, *8*), and chemical properties (*9*−*12*). Bioactivity of fullerenes has been demonstrated in antibacterial (*13*), neuroprotection (*14*), DNA cleavage (*15*, *16*), and apoptosis (*17*) assays.

Taking into account that fullerene industrial production approaches the scale of tens of tons per year (and may reach hundreds of tons in the future), human and environmental exposure to carbonaceous nanomaterials will undoubtedly increase. In a light of this prospect, studies have begun to appear in the literature addressing the toxicity of nanomaterials. Specifically, acute toxicity studies of nanocolloidal suspensions of C_{60} fullerene clusters (nanoC_{60}) in water have been performed on several environmentally relevant species, such as freshwater crustaceans and fish (*14*). Hughes and co-workers found that growth of prokaryotic cells is inhibited upon exposure to low concentrations of nanoC_{60} (*18*). Cytotoxicity of fullerene has been shown for both normal (*19*−*22*) and carcinogenic cells (*20*−*22*). West and co-workers reported that nanoC_{60} suspensions disrupt normal cellular function through lipid peroxidation (*21*). All these studies indicate the potential risk of uncontrolled exposure to our environment to fullerene-based nanomaterials.

Current knowledge of the toxicology of carbonaceous nanomaterials suggests that these materials may have adverse effects at their portals of entry into living organisms, particularly the respiratory and digestive systems and the skin (*23*). Most nanotoxicology research is focused on examining the influence of nanomaterials at the tissue and cellular levels, while interactions of carbon nanomaterials with native proteins, especially transport proteins, remain mostly unexplored. Only a few complexes of fullerene derivatives with proteins have been reported. This includes enzyme inhibition by fullerene-based compounds (*24*, *25*) and interactions with some other proteins such as a fullerene-specific antibody (*26*, *27*), lysozyme (*28*), cytochrome C (*29*), bovine and human serum albumins (*30*−*32*), and apomyoglobin (*33*, *34*). However, in most cases, the reported information provides only partial data on the structure and properties of these fullerene−protein complexes.

Our recent studies have been aimed at preparing novel complexes of fullerenes with transport proteins in an attempt to elucidate the structure and properties of these materials. These studies should lead to better understanding of the biodelivery of carbon nanomaterials. In the present study, we focused on lipocalins, a family of transport proteins present in serum, lymph, and barrier liquids, such as saliva and mucus. The lipocalins are a family of small secreted proteins, characterized by similarity in their tertiary structures and molecular recognition properties. These proteins bind to hydrophobic molecules (such as retinol) and to specific cell-surface receptors (to promote endocytosis) (*35*, *36*).

Bovine β-lactoglobulin (β-LG) is a typical representative of the lipocalin family of proteins and was selected as a model compound for the preparation of lipocalin−fullerene complexes. Here, we report preparation of complexes formed by interaction of β-LG with carboxyfullerene (CF) and structural characterization of these compounds. We then showed how a fullerene ligand could be transported to the human serum albumin (HSA) to model carbonaceous nanomaterial delivery from an epithelial liquid barrier protein to a major blood transport protein.

EXPERIMENTAL SECTION

Preparation and Separation of β-LG/CF Complexes. Carboxyfullerene was synthesized according to previously reported methods (*37*−*39*). Bovine β-lactoglobulin, fine chemicals, and solvents were purchased from Sigma-Aldrich. A solution of 4.0 mg of β-LG (1 equiv) in 2 mL of sodium phosphate buffer (20 mM, pH 7.2) and 4, 10, 20, or 40 μL of 100 mM CF in DMSO (2, 5, or 10 equiv, respectively) was incubated for 2 h at 37 °C and then overnight at 10 °C. Additional incubations were prepared in phosphate buffer (20 mM) at pH 6.2 and pH 8.2 at the same concentrations. The complexes were separated from noncomplexed CF on a Sephadex G-25 gel permeation column (Pharmacia Biotech) with sodium phosphate buffer (20 mM, pH 7.2). No differences in the extent of complexation were found among incubations with β-LG A, β-LG B, or a mixture of these proteins; therefore, the latter was used in our further studies.

The buffer concentration was reduced by reloading the complex-containing fraction on a second Sephadex G-25 column

and eluting the complex with sodium phosphate buffer (1 mM, pH 7.2). The resulting solution was lyophilized for storage and further experiments. After reconstitution in water, the concentration of complex in solution was determined by UV−vis spectroscopy and a BioRad protein assay (BioRad).

Liquid Chromatography. All HPLC analyses were performed on an Agilent 1100 chromatograph equipped with diode-array detector (Agilent). Size-exclusion liquid chromatography of β-LG, CF, and β-LG/CF complexes was performed on a 4.6 mm × 3.0 cm TSK-gel Super SW2000 column (Tosoh Bioscience) using a sodium phosphate/sodium chloride buffer (100 mM sodium phosphate, pH 7.2, and 100 mM sodium chloride) as the isocratic eluent at a flow rate of 0.2 mL/min.

Ion exchange chromatography analyses of starting materials and incubated mixtures were performed on an SP Sepharose column (HiTrap SP FF, Amersham Biosciences) using sodium phosphate/citric acid (20 mM, pH 4.2) as the starting buffer and sodium phosphate/citric acid/sodium chloride (100 mM sodium phosphate, pH 7.2, and 400 mM sodium chloride) as the elution buffer. A total of 72 fractions (200 μL each) were collected on a Costar UV 96-well plate (Corning), and absorption of each fraction was analyzed by a microplate reader (SpectraMax M2, Molecular Devices) at 280 and 485 nm.

Mass Spectrometry. Mass spectrometric analyses were performed on a Finnigan LCQ Classic ion-trap mass spectrometer (Finnigan) equipped with a standard ESI source. The ESI source was operated at 3.5 kV, and the capillary was set to 150 °C and 50 V. Raw data were processed using *ZNova ProMass* version 1.4 software (Novatia).

Dynamic Light Scattering. Particle sizing was performed at 25 °C using a high-performance particle size analyzer ALV-NIBS/HPPS (ALV-Laser Vertriebsgesellschaft). Freshly prepared solutions of β-LG, CF, and β-LG/CF complex in sodium phosphate buffer (20 mM, pH 7.2) were filtered through a 0.2 μm filter. In all experiments, a final concentration of 100 μM protein was used. The particle size was calculated by the autocorrelation function of the ALV sizer software.

Circular Dichroism. Circular dichroism measurements were performed on a spectrophotometer equipped with a temperature-controlled cell holder (202 Model, Aviv Biomedical). Spectra of protein samples (2 μM) dissolved in a sodium phosphate buffer (20 mM, pH 7.2) were recorded at room temperature in the 190−400 nm spectral range (in 1 nm steps); each spectrum (averaged over 10 scans) was corrected according to the appropriate blank.

Docking Studies. The three-dimensional structure of the β-LG protein was obtained from Protein Data Bank (1BEB). A three-dimensional structure of CF was obtained from Hartee-Fock energy-minimization calculations (*Gaussian 03*, Gaussian.com). Molecular docking calculations were performed using the PatchDock algorithm (*40*, *41*). In order to estimate the CF binding site on β-LG, the PatchDock algorithm was applied without any a priori data to indicate putative CF binding sites.

RESULTS AND DISCUSSION

***β*-LG/CF Complexes Preparation.** A series of incubations of native β-LG A, β-LGB, or a mixture of these proteins was performed with different amounts of CF ligand (under various pH conditions and salt concentrations). Using the analytical methods described below, all these experiments produced very similar results and showed the formation of stable β-LG/CF complexes.

Size Exclusion Chromatography. Analyses of the β-LG/CF complexes were performed by high-performance, size exclusion liquid chromatography (SEC-HPLC) coupled to a diode array UV−vis detector. Figure 1 presents chromatograms of the CF ligand, the β-LG protein, and the β-LG/CF complex.

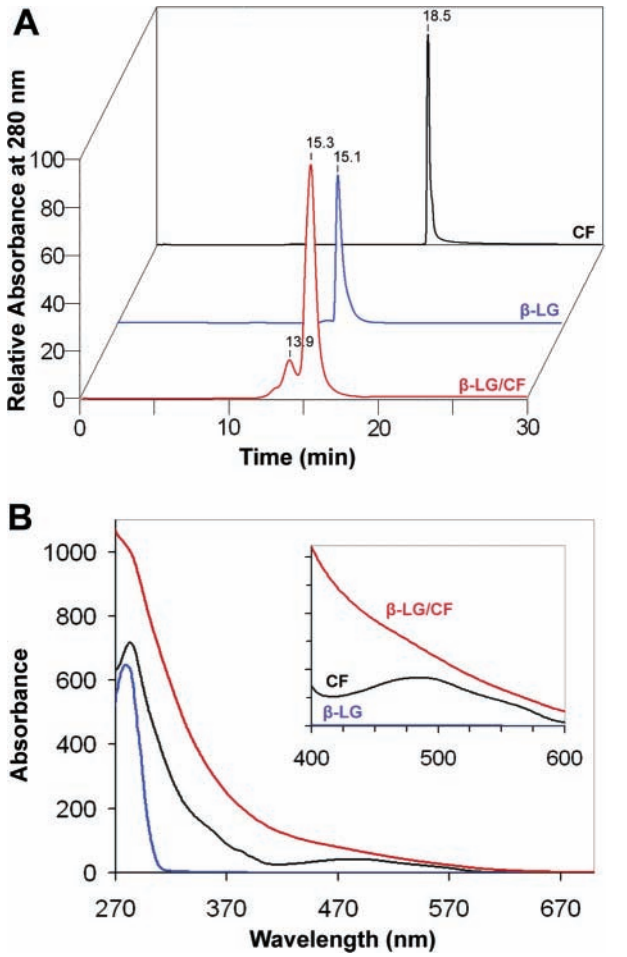

Figure 1. (A) Size exclusion chromatograms (monitored at 280 nm): blue, β-LG protein; red, β-LG/CF complex; black, unbound CF ligand. (B) Corresponding UV−vis spectra obtained using a diode array detector: blue, β-LG protein; red, β-LG/CF complex; black, unbound CF ligand.

Table 1. CF Content (equivalents) in β-LG/CF Complexes

incubation ratio [β-LG]:[CF]	ratio of [CF]:[β-LG] in β-LG/CF complex		
	pH 7.2	pH 6.2	pH 8.2
1:2	1:1.0	1:1.7	1:1.0
1:5	1:1.9	1:2.9	1:2.0
1:10	1:2.6	1:3.2	1:2.8

These size exclusion chromatograms clearly show that under our elution conditions the retention time of the proposed β-LG/CF complex (RT = 15.3 min) closely matched that of the free β-LG host (RT = 15.1 min), unambiguously showing very similar sizes of both molecules.

Determination of CF Ligand Binding Stoichiometry. Different host-to-ligand ratios were present in the β-LG/CF complexes. Protein-to-ligand ratios were obtained from analyses of purified complexes prepared under various experimental conditions by comparing the amount of the CF ligand in a certain complex (determined at $\lambda_{max} = 485$ nm, $\epsilon = 4800$ M^{-1} cm^{-1}) to the amount of β-LG protein in the same complex (determined by the BioRad protein assay). Our quantitative analyses of complexes showed that these complexes contained up to three bound CF ligands per a single β-LG host, depending on the amount of the CF ligand used in complexes preparation (Table 1). These unusually high binding ratios between the β-LG host and the CF ligand are in contrast to the typical binding mode of this protein, in which a calix hydrophobic cavity functions

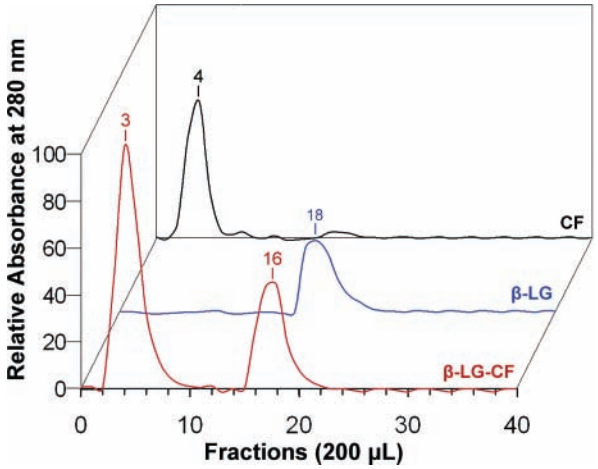

Figure 2. Ion-exchange chromatograms (monitored at 280 nm): blue, β-LG protein; red, β-LG/CF complex; black, unbound CF ligand.

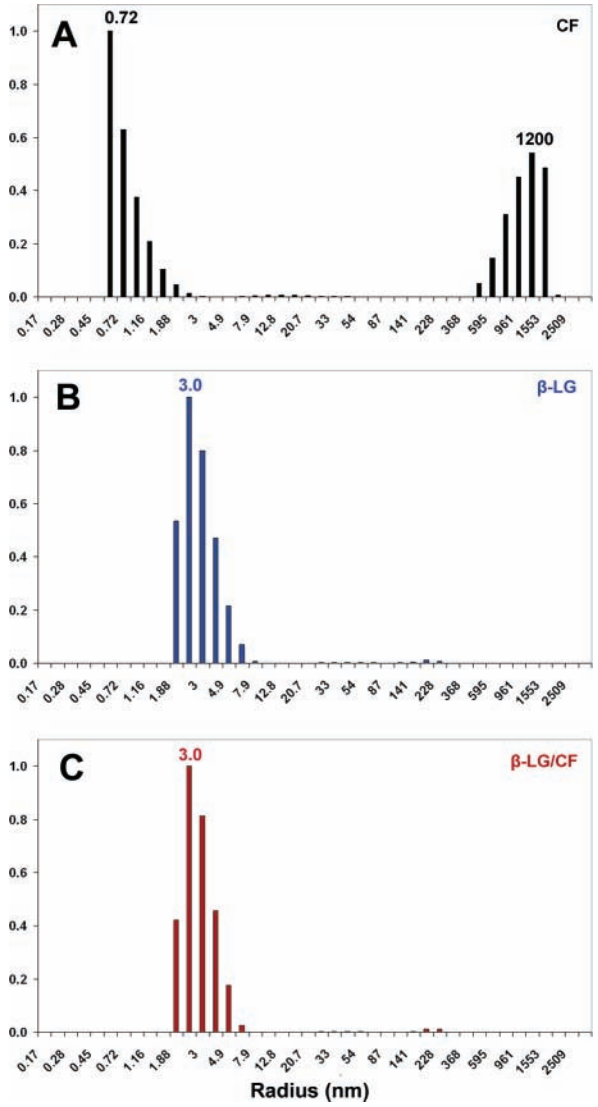

Figure 3. DLS analyses. (A) Unbound CF ligand. (B) Dimer of β-LG protein. (C) β-LG/CF complex.

as a single binding site for ligand (*35*). This observation suggests that there are alternative sites for ligand binding or aggregates formation.

Ion Exchange Chromatography. We first explored the possibility that binding between CF and β-LG is stabilized through ionic interactions by analyzing the complexes by ion exchange chromatography (IEC); IEC should disrupt most ionic interactions. On IEC, the free β-LG protein and β-LG/CF complex were observed, unambiguously showing that the interactions between the CF ligand and the β-LG host are mostly hydrophobic. There was only a small difference in retention time between complex and free protein. This could be explained by small differences in the overall charge of the free host versus the complex, as the latter contains more carboxylic groups (Figure 2).

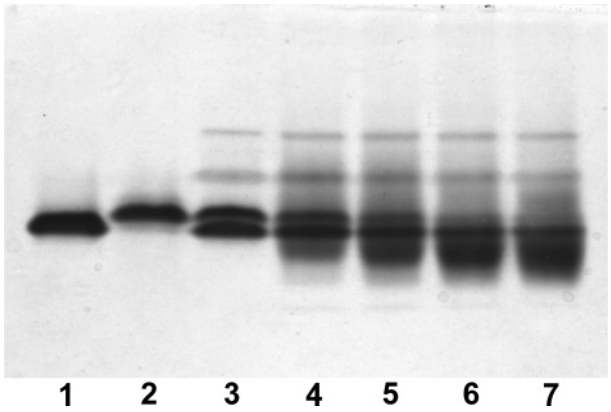

Figure 4. Native polyacrylamide gel electrophoresis of β-LG/CF complexes. Lanes contain (1) β-LG A; (2) β-LG B; (3) β-LG A/β-LG B mixture; β-LG/CF at ratios of (4) 1:2, (5) 1:5, (6) 1:10, and (7) 1:20.

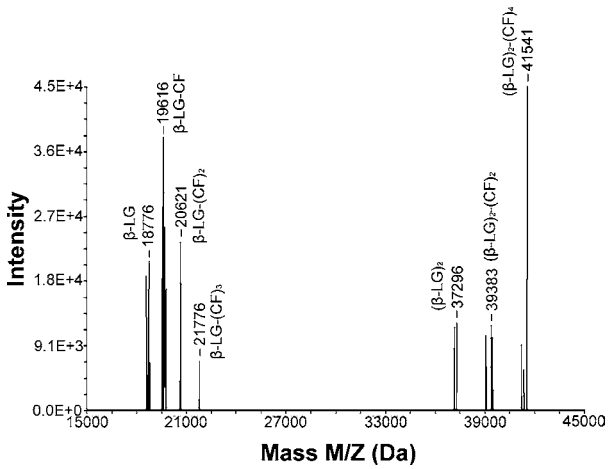

Figure 5. Deconvoluted ESI-mass spectra of β-LG/CF complex.

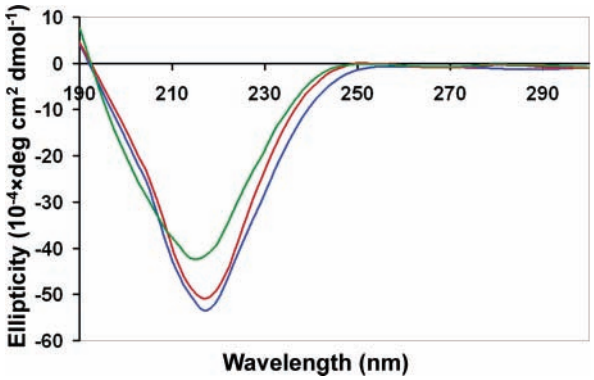

Figure 6. Circular dichroism spectra of β-LG protein (blue) and β-LG/CF mixtures in ratios of 1:5 (red) and 1:20 (green).

Dynamic Light Scattering. Our next step was to exclude the possibility of nonspecific binding of β-LG protein to clusters formed by CF molecules (*42*). We performed dynamic light scattering (DLS) experiments, examining aqueous solutions of the CF ligand, the free β-LG protein, and the purified β-LG/CF complex. In aqueous solution, we observed two populations

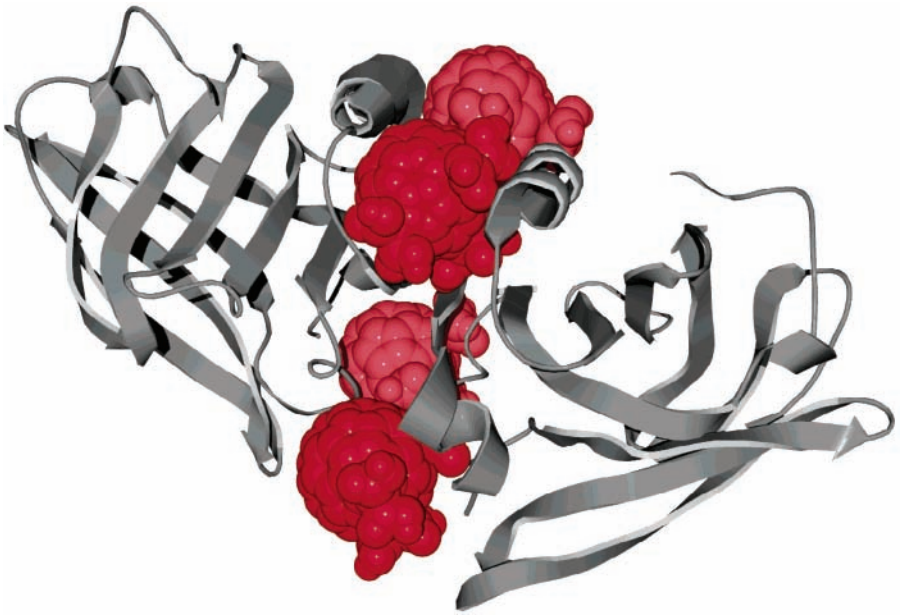

Figure 7. Representative, high-score docking model of the β-LG/CF complex; the β-LG dimer is shown as a ribbon model (gray) and the four CF ligands as space-filling models (red).

of CF particles with average sizes of 1 and 1200 nm (broadly distributed), corresponding to single CF molecules and large CF clusters, respectively (Figure 3A). In solutions of the free β-LG protein and the purified β-LG/CF complex, only one type of CF species was observed with an average size of 3 nm (Figure 3B,C). The latter results are in excellent agreement with the approximately 3.5 nm size structure reported for β-LG dimer (PDB: 1BEB) (*43*). The DLS experiment results suggest that a process of β-LG−CF complex formation proceeds through CF clusters dissolution by β-LG protein and may represent a mechanism by which fullerene nanoclusters undergo an uptake into biological systems.

Gel Electrophoresis. Native polyacrylamide gel electrophoresis (PAGE) was used as an additional technique to examine the size, the overall charge, and the stability of the β-LG/CF complexes. The PAGE results showed progressive disappearance of bands of the free protein and appearance of diffuse bands with that migrated more rapidly through the gel than free protein, corresponding to complexes, as the concentration of CF increased (Figure 4). The faster mobility of β-LG/CF complexes probably results from a larger number of the incorporated CF ligands, producing compounds with higher overall negative charge, but similar size to native proteins, as shown in the DLS experiments.

Mass Spectrometry. Electrospray mass spectrometry (ESI-MS) analysis of a representative purified β-LG/CF complex was performed. The deconvoluted ESI-MS spectrum of this material (Figure 5) revealed the presence of a β-LG dimer bound to up to four CF ligands and additional peaks corresponding to β-LG/CF complexes with 1:3 binding stoichiometry. These β-LG/CF complexes had remarkable stability, as most noncovalent protein complexes do not remain intact under these mass spectrometry conditions. Notably, these results are in agreement with the data obtained by UV−vis spectroscopy and the stoichiometry determination previously described (Table 1), which showed 1:2.8 protein-to-ligand ratio for the same complex.

Circular Dichroism. To assess the structural features of these complexes, we explored whether the β-LG protein remains folded close to its native conformation in the β-LG/CF complex. For these purposes, circular dichroism (CD) spectroscopy studies of β-LG/CF complexes were performed. All the measured CD spectra of these complexes exhibited a typical negative peak with a minimum around 215 nm, as previously reported for β-LG (*44*). A series of complexes in which the ratio between β-LG and CF was progressively increased were evaluated. The ellipticity of the complex noticeably decreased upon addition of 20 excess equivalents of the CF ligand (Figure 6). These results strongly suggest that the native structure of the β-LG protein is only slightly affected (mostly in α-helix regions) by binding of CF, even when multiple CF ligands are bound.

Docking Studies. To explore possible CF-binding sites on the β-LG dimer interface, docking calculations were performed using the dimer (PDB: 1BEB) structure of β-LG (*40*, *41*). In our models, the first CF unit was located in the interface formed between β-LG monomers, near the α-helix (Figure 7). The resulting structure was used as a basis for further docking experiments as more CF units were added in each round of calculations, producing a model in which four ligands bound near the dimerization site (Figure 7). These docking results are strongly supported by experimental observations; we found that CF binding by β-LG was unaffected by changes in pH conditions and therefore nonrelated to the Tanford transition (*45*), as the Tanford transition involves pH-dependent movement of EF loop, controlling the entry to β-LG's calyx binding site. Moreover, in good correlation with CD results, docking studies showed interactions between CF units and the main α-helices of β-LG dimer, located near the dimerization site.

Delivery of CF from the β-LG/CF Complex to HSA. Nanomaterials can enter the human body through different ports, including lungs and intestines, and then undergo rapid translocation through the bloodstream to other vital organs (*23*). The pharmacokinetic behavior of different types of nanoparticles requires detailed investigation, starting at the molecular biochemical level. For the first time, we were able to monitor the transport of nanomaterial between two biochemical systems: CF dissociated from the β-LG/CF complex, where β-LG represented a barrier liquid protein, and bound to a blood plasma protein (represented by HSA). Specifically, 25 μM β-LG/CF complex (at a 1:3 ratio) was incubated with 25 μM HSA protein in phosphate buffer (20 mM, pH 7.2). Transport of CF ligand from the β-LG/CF complex to HSA was monitored by SEC-HPLC (Figure 8), using the previously described HSA-CF complex as a reference standard (*31*). At 485 nm, the noncomplexed proteins exhibited almost no absorbance (dark blue

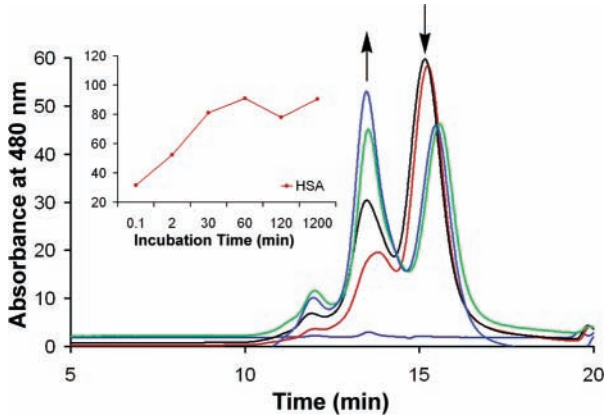

Figure 8. Delivery of CF ligand from β-LG/CF complex to HSA, monitored by size exclusion chromatography (at 485 nm). Dark blue, HSA and β-LG proteins without CF; red, after incubation of 0.1 min; black, 2 min; green, 120 min; light blue, 1200 min. Inset: time-dependent changes in relative fullerene content in HSA-CF complexes during CF delivery process.

chromatogram; Figure 8), thus allowing us to detect only CF-containing compounds. As expected, the larger-size HSA-CF complex eluted with a shorter retention time than β-LG/CF (13.6 and 15.3 min, respectively). CF uptake by HSA was clearly observed even at the beginning of the process (after only 0.1 min incubation, red chromatogram; Figure 8). Over the time course, the intensity of the peak at 13.6 min gradually increased, while the peak at 15.3 min decreased (insert, Figure 8). The HSA-CF complex in these experiments was spectroscopically and chromatographically identical to the previously reported HSA-CF (1:1 protein-to-ligand) complex (*31*). The observed process of CF transfer from β-LG/CF to HSA is very rapid, which could be explained by significant differences in CF affinity toward these proteins. The HSA-CF complex has a relatively high binding constant of 1.2×10^7 M^{-1} as determined by fluorescence titration (*31*). A binding constant for CF to β-LG could not be precisely determined due to the presence of multiple competing binding sites (see Supporting Information). After 60 min of incubation, CF uptake by HSA reached a maximum. However, it is expected that, in the real world, the amount of serum albumin protein will be far greater than the amount of lipocalin, thus leading to more complete ligand depletion in β-LG/CF complex.

CONCLUSIONS

The characterization of the complex formed by CF and β-LG reported here provides insight into how fullerene-based nanomaterials interact with native liquid barrier proteins. Capable of multiple carbonaceous ligand binding, a representative lipocalin protein, β-lactoglobulin, bound efficiently to carboxyfullerene. Moreover, we provide the first example of transfer of CF from one protein, β-lactoglobulin, to another, albumin, in a model of the delivery process of nanomaterials in biological systems.

Department of Chemistry, University of Arizona, Tucson, Arizona 85721, and Departments of Radiology, Biochemistry, and Molecular Biophysics, Arizona Cancer Center, Tucson, Arizona 85724. Received November 22, 2006; Revised Manuscript Received April 19, 2007

We demonstrate the potential utility of multivalent ligands as targeting agents for cancer imaging or therapy by determining the binding of homobivalent ligands to their corresponding receptors. This manuscript details the synthesis and evaluation of a series of bivalent ligands containing two copies of the truncated heptapeptide version of [Nle^4-D-Phe^7]-α-melanocyte stimulating hormone (NDP-α-MSH), referred to as MSH(7). These were connected with various semirigid linkers containing Pro-Gly repeats, with or without flexible poly(ethylene glycol) (PEGO) moieties at their termini. Modeling data suggest a distance of 20−50 Å between the ligand binding sites of two adjacent G-protein coupled receptors, GPCRs. These bivalent ligands were observed to bind with higher affinity compared to their monovalent counterparts. Data suggest these ligands may be capable of cross-linking adjacent receptors. An optimal linker length of 25 ± 10 Å, inferred from these ligands, correlated well with the inter-receptor distance estimated through modeling. Although there was no difference in maximal binding affinities between the ligands constructed with the Pro-Gly repeats versus those constructed with the PEGO inserts, the PEGO-containing ligands bound with high affinities over a greater range of linker lengths.

INTRODUCTION

Current cancer treatments suffer from a lack of specificity for cancer cells. Using peptide ligands for specific delivery of a drug or a contrast agent to the site of action has been demonstrated for a number of cancers using many different ligand−receptor pairs (*1*). However, a limitation of this approach is that targeting an individual receptor requires that it be overexpressed or mutated in the cancer and nowhere else in the body. While such target receptors may be available for some cancers, they are not widely prevalent. Hence, alternative targeting strategies are required. We hypothesize that specific targeting of cancer cells could be achieved through the development of multivalent ligands directed toward unique combinations of cell surface proteins that are expressed on the target cancer cells compared to normal cells. By targeting combinations, these ligands can be more specific for the cells of interest while circumventing nonspecific interaction with healthy tissues. As a proof of the concept that such cell surface proteins can indeed be targeted specifically, we chose to mimic the cancer cells through overexpression of MC4 receptors because of our considerable experience with MC4 receptors (*2, 3*). Thus, in order to demonstrate that multivalent peptide ligands bind to their target receptors with increased affinity and cooperativity, we have constructed ligands containing two copies of MSH(7),[1] a truncated version of [Nle^4-D-Phe^7]-α-melanocyte stimulating hormone (NDP-α-MSH) (*2*), a peptide hormone analogue that binds specifically to the melanocortin receptors. These two MSH(7) ligands are separated by a linker, which is constructed with different amino acids and/or organic derivatives in order to provide differences in flexibility and length.

Previously, we described the synthesis and evaluation of a series of short homobivalent MSH(4) His-D-Phe-Arg-Trp-NH_2 and MSH(6) Nle-Glu-His-D-Phe-Arg-Trp-NH_2 ligands which bind to cells expressing the human melanocortin 4 receptor (hMC4R) with increased affinity and apparent cooperativity compared to their monovalent counterparts (*3*). However, the linkers used in these studies were likely too short to allow for cross-linking of multiple receptors. Thus, the increased binding affinity and positive cooperativity observed in these studies were most likely due to "statistical" binding, wherein affinity is apparently increased through increased local concentrations, and not receptor "clustering", wherein multiple receptors are bound by the same multivalent ligand (*4*) (Figure 1). In order to improve the likelihood that multivalent ligands simultaneously cross-link receptors, we have constructed homobivalent MSH(7) ligands with linkers that are longer and more flexible than those previously investigated.

It has been documented that the hMC4 receptors can form homodimers (*5*) and that other melanocortin receptors can form

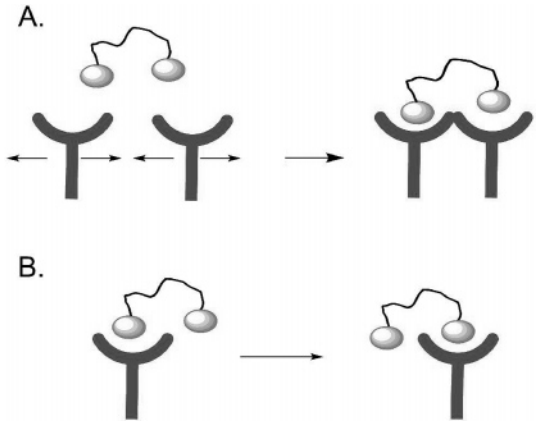

Figure 1. Two of the four potential modes of multivalent ligand binding. A. The *cluster effect* results in recruitment of receptors on the cell surface to allow for multiple receptor−ligand interactions. B. The *statistical effect* allows ligands to bind to single binding sites on a receptor based on increased local effective concentration of the ligand.

homo- or heterodimers (*6*). The lack of high-resolution data for G-protein coupled receptors (GPCRs) has made it difficult to elucidate the 3D structure of these receptors, thus further complicating the task of rationally designing multivalent ligands that could span the distance between adjacent GPCRs. Early estimates suggest that this distance is at least 40 Å (*7*−*9*). The crystal structure of rhodopsin (*10*) has made it possible to model the structures of additional members of the GPCR family of proteins based on computer-aided modeling by homology. For example, the human melanocortin 4 receptor (hMC4R) has been modeled on the basis of sequence homology and the known rhodopsin structure (*11*). This model was used to assist in the determination of the linker lengths needed to span the distance between adjacent GPCR binding sites.

In addition to difficulties in estimating the size and location of the receptor binding pockets, it is also relatively difficult to estimate the actual length of the linkers in question. This difficulty arises due to the fact that the peptide type linkages used to construct these linkers will be flexible, thus permitting folding and secondary structure. We used the estimation that one amino acid residue is roughly equivalent to 1.2 Å, an estimation based on the average linear distance between atoms in a peptide bond and the assumption that at least one conformer of these linkers can exist in a stretched conformation with little or no secondary structure (*12*). Upon binding, the linker may lose its folding to be stretched in extended conformations.

This manuscript details the construction and evaluation of a family of homobivalent MSH(7) ligands with linkers ranging in length from 18 to 148 atoms that could span distances over 100 Å (Table 1). A series of control ligands also were constructed in which MSH(7) was attached to only one end of the various linkers (ligands **1**−**5**, Table 1) to allow for a direct determination of the influence of the linker on the binding affinity of the ligand to the receptor. Pro-Gly repeats were chosen as the building blocks for the linker unit, as this semirigid construct provided the best results in our initial studies (*3*). The Pro residues add rigidity to the overall linker structure, while the Gly residues provide for some flexibility. Five bivalent ligands were synthesized with these Pro-Gly repeat regions (ligands **6**−**10**, Table 1) directly corresponding to the monovalent ligands. As an added feature, PEGO units were either themselves used as linkers or were incorporated into the termini of Pro-Gly repeats (ligands **11**−**16**, Table 1). As it has been proposed that the first binding event serves to tether the multivalent ligand to the cell surface (*13*), we hypothesized that the addition of these flexible PEGO moieties to the ends of the linkers would provide a greater opportunity for the ligand to explore more volume and thus have greater opportunity to find and bind multiple receptors at once.

EXPERIMENTAL PROCEDURES

Chemical Materials. *N*-α-Fmoc-protected amino acids were purchased from SynPep (Dublin, CA) or from Novabiochem (San Diego, CA). Rink amide Tentagel S resin was acquired from Rapp Polymere (Tubingen, Germany). HCTU, HOBt, and HOCt were purchased from IRIS Biotech (Marktredwitz,

[a] Ligands **1**−**5** represent the control monovalent ligands which are similar in structure to the bivalent ligands **6**−**10**. Ligands **11**−**16** have the PEGO units incorporated into the linker structure for added flexibility. *n* indicates the total number of data points used to generate the binding curve and the resulting EC_{50} value.

Germany). For the *N*-α-Fmoc-protected amino acids, the following side chain protecting groups were used: Arg(N^g-Pbf); Glu(*O*-*t*Bu); His(N^{im}-Trt); Ser(*O*-*t*Bu); Trp(N^i-Boc). Peptide synthesis solvents, reagents, and acetonitrile for HPLC were reagent grade, were acquired from VWR (West Chester, PA) or Aldrich-Sigma (Milwaukee, WI), and were used without further purification unless otherwise noted. The solid-phase synthesis was performed in fritted syringes using Domino manual synthesizer obtained from Torviq (Niles, MI).

The purity of the final products was checked by analytical RP-HPLC using a Waters Alliance 2695 separation model with a Waters 2487 dual wavelength detector (220 and 280 nm) on a reverse-phase column (Waters Symmetry 4.6 × 75 mm, 3.5 μm). Peptides were eluted with a linear gradient of aqueous CH_3CN/0.1% CF_3CO_2H at a flow rate of 1.0 mL/min. Purification of ligands was achieved on a Waters 600 HPLC using a reverse-phase column (Vydac C-18, 15−20 μm, 22 × 250 mm). Peptides were eluted with a linear gradient of CH_3CN/0.1% CF_3CO_2H at a flow rate of 5.0 mL/min. Separation was monitored at 230 and 280 nm.

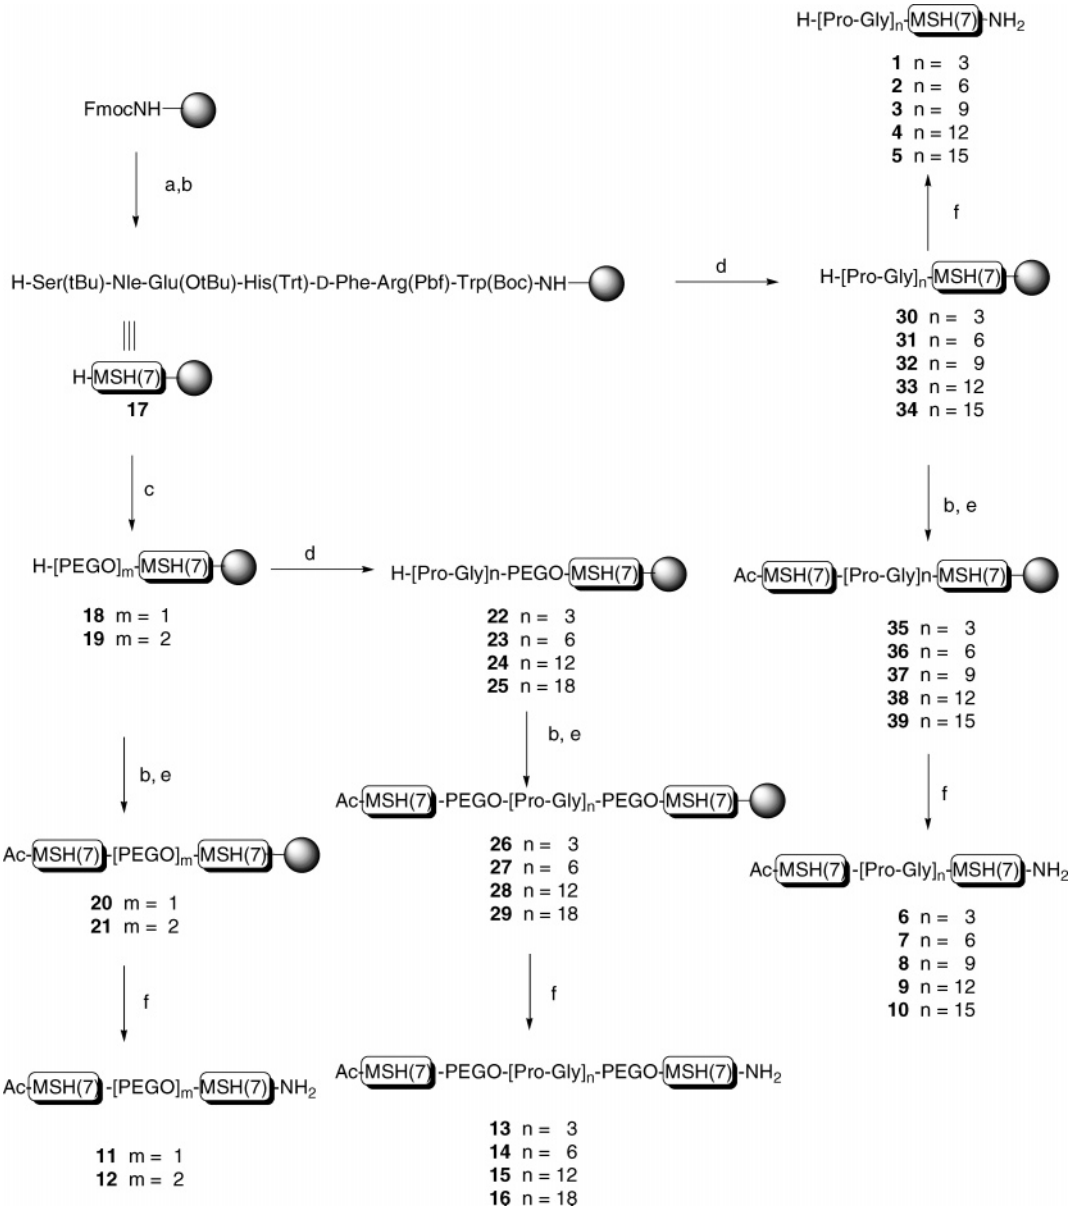
Size exclusion chromatography was performed on a borosilicate glass column (2.6 × 250 mm, Sigma, St. Louis, MO) filled with medium-sized Sephadex G-25 or G-10. The compounds were eluted with an isocratic flow of 1.0 M aqueous AcOH. Structures were characterized by ESI (Finnigan, Thermoquest LCQ ion trap instrument) or MALDI-TOF (Bruker Reflex-III, α-cyanocinnamic acid as a matrix). For internal calibration, an appropriate mixture of standard peptides was used with an average resolution of 8000−9000. High-resolution mass measurements were carried out on a FT-ICR IonSpec 4.7T instrument.

Solid-Phase Synthesis. The Rink resin was washed with DMF, and the N^α-Fmoc protecting group was removed with 1:1 or 1:4 piperidine in DMF, as the case may be (1 × 2 min and 1 × 20 min). The resin was washed successively with DMF, DCM, DMF, and then a solution of 1.0 M HOBt in DMF, and DMF, and the next N^α-Fmoc amino acid was coupled using preactivated 0.3 M HOCt or HOBt esters in THF (3 equiv of N^α-Fmoc amino acid, 3 equiv of HOCt/HOBt, and 3 equiv of DIC). The resin slurry was stirred for 2 h or until the bromophenol test became negative. If the test failed, the resin was washed with DMF, and the amino acid was coupled again by the HCTU/2,4,6-lutidine procedure (0.3 M solution of 3 equiv of N^α-Fmoc amino acid, 3 equiv of HCTU, and 6 equiv of 2,4,6-lutidine in DMF) for 3 h or by a preformed symmetric anhydride (3 equiv of N^α-Fmoc amino acid and 1.5 equiv of DIC in a 1:1 DMF−DCM mixture) until the Kaiser test was negative. If the second coupling did not result in a negative Kaiser test, the resin was washed with DMF, and the free amino groups were capped with 50% Ac_2O in pyridine for 10 min.

After coupling Trp(N^i-Boc), Arg(N^g-Pbf), D-Phe, His(N^{im}-Trt), Glu(*O*-*t*Bu), Nle, and Ser(*O*-*t*Bu) sequentially to the Rink amide resin, Gly and Pro were attached alternatively as many times as needed to synthesize the control ligands **1**−**5** (Scheme 1). Assembly of the second ligand, MSH(7), was carried out by the procedure described above to give ligands **6**−**10**. Similarly for the synthesis of ligands **11**−**16**, after the assembly of MSH(7) sequence on the resin, the flexible linker PEGO was attached, by first adding diglycolic anhydride and then activating the free carboxylate as an imidazolide for the attachment of 4,7,10-trioxa-1,13-tridecanediamine (*3*). This was followed by stepwise assembly of repetitive Pro-Gly linker units. Another PEGO attachment followed by the second MSH(7) sequence and N-terminal acetylation yielded resin bound protected precursors of compounds **11**−**16** (Scheme 1). A cleavage cocktail (10 mL per 1 g of the resin) consisting of CF_3CO_2H (91%), H_2O (3%), $HSCH_2CH_2SH$ (3%), and PhSMe (3%) was injected into the resin, and the mixture was agitated at room temperature for 3 h. The solution was filtered off, the resin was washed with CF_3CO_2H (2 × 3 min), the liquid phases were concentrated under a stream of nitrogen, and the product was precipitated using cold Et_2O. The products **1**−**16** were washed three times with cold Et_2O, lyophilized, purified, and characterized as described above. Mass spectral and HPLC characterization data are given in Table 2.

Molecular Modeling. Conformational searches and molecular dynamics were performed with *MacroModel* v 9.1 implemented under the Maestro 7.5 interface on a Linux workstation. The *MacroModel* implementations of Merck Molecular Force Field (MMFF), AMBER*, and OPLS all-atom force fields were used (*14*). AMBER* is a reparametrized AMBER force field containing a new set of torsional parameters that more closely reproduces *ab initio* calculations on the conformational preferences of simple peptides (*15*). For solution-phase calculations, the GB/SA continuum model for water was used. Amide bonds were required to be trans except in the case of proline whose imide bonds were intentionally sampled and accepted with either cis or trans geometry in the conformational searches.

Conformation Search. Conformational searches were performed with the systematic Monte Carlo method of Goodman and Still (*16*). For each search, 5000 starting structures were generated and minimized until the gradient was less than (0.05 kJ/mol)/Å, using the truncated Newton−Raphson method implemented in *MacroModel*. Duplicate conformations and those with energy greater than 50 kJ/mol above the global minimum were discarded.



Monte Carlo/Stochastic Dynamics. All simulations were performed at 310 K with Monte Carlo/stochastic dynamics (MC/SD) hybrid simulation algorithm (*17*) with either the AMBER* all-atom force field or the new OPLS-2005 force field in *MacroModel 9.1*. A time step of 1.5 fs was used for the stochastic dynamics (SD) part of the algorithm. The MC part of the algorithm used random torsional rotations between ±60° and ±180° that were applied to all rotatable bonds except the proline amide C−N bond where the random rotations between ±0° and ±180° were applied. No torsion rotations were applied to bonds in the pyrrolidine ring of proline, as the barriers are low enough to permit adequate sampling from the SD part of the simulation. The total simulation time was 1000 ps, and samples were taken at 1 ps interval, yielding 1000 conformations for analysis.

G-Protein Coupled Receptor Size Estimations. The PDB file of a recently described bovine rhodopsin protein in a trigonal crystal form (1GZM) (*18*) was loaded into the *DeepView* program (Swiss-Pdb Viewer Program, http://www.expasy.org/spdbv/). This program allows distances between different residues on the GPCR structure to be measured. Several residues on the outer edges of the transmembrane domain were chosen, and distances across the GPCR were measured. The "width" of the GPCR was taken as the average of eight of these measured distances.

Cell Culture. HEK293 cells overexpressing the human melanocortin 4 receptor (hMC4R) were used to assess the binding at the hMC4R. The hMC4R vector was originally received from Dr. Ira Gantz, University of Michigan (*19*). The coding region of the hMC4R gene was expressed in pcDNA3.1 (Invitrogen, V790−20). Hek293/hMC4R cells were grown in Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% FBS.

Lanthanide-Based Binding Assays. Lanthanide-based competitive binding assays were conducted according to the method which has been previously described (*20*). In brief, HEK293/hMC4R cells were plated in black and white 96-well isoplates

Scheme 1. Solid-Phase Synthesis of MSH(7) Peptides 1−16[a]

(Wallac, 1450−584) at a density of 12 000 cells/well and were allowed to grow for 3 days. On the day of the experiment, media was aspirated from all wells. 50 μL of nonlabeled ligand and 50 μL of Eu-labeled ligand (final concentration of 10 nM for Eu-NDP-α-MSH) were added to each well. Ligands were diluted in binding media (DMEM, 1 mM 1,10-phenanthroline, 200 mg/L bacitracin, 0.5 mg/L leupeptin, 0.3% BSA), and samples were tested in quadruplicate, unless otherwise noted. Cells were incubated in the presence of ligand for 1 h at 37 °C. Following the incubation, cells were washed 3× with 250 μL wash buffer (50 mM Tris−HCl, 0.2% BSA, 30 mM NaCl). Enhancement solution (Perkin-Elmer; 1244−105) was added (100 μL/well), and the plate was incubated for at least 30 min at 37 °C prior to reading. The plates were read on a Wallac VICTOR^3 instrument using the standard Eu TRF measurement (340 nm excitation, 400 μs delay, and emission collection for 400 μs at 615 nm).

Data Analysis. Data from at least five independent binding experiments were compiled into a single competition curve and were analyzed with *GraphPad Prism* software using the sigmoidal dose−response (variable slope) classical equation for nonlinear regression analysis. The total number of data points used to generate each binding curve is indicated by *n* in Table 1.

RESULTS

Synthesis. The synthesis of ligand dimers **6**−**16** consisting of two MSH(7) ligands connected in a head-to-tail fashion by PEGO and/or Pro-Gly linkers and monovalent controls **1**−**5** is depicted in Scheme 1. The heptapeptide MSH(7) was constructed on Rink amide Tentagel S resin (initial loading 0.2 mmol/g). Resin **17** retained all side chain protecting groups, except for the *N*-terminal Fmoc protecting group. PEGO linkers were attached to the *N*-terminal of **17**, giving $[PEGO]_m$ resins **18** and **19.** The resin **18** was proportionally split for synthesis of compounds **11** and **12** or for synthesis of longer ligands **13**−**16**. For the ligands **11** and **12**, the free amine groups of resins **18** and **19** were coupled with Fmoc-Trp(N^i-Boc)-OH, and solid-phase peptide synthesis continued to complete the second MSH-

(7) sequence, then acetylated, giving resins **20** and **21**. To the second portion of resin **18** already split into four reactors, Pro-Gly linkers were alternatively coupled to the *N*-terminus of **18**, giving resins **22**−**25**. PEGO linker was attached, and the second ligand was built up similar to **20** and **21**, giving acetylated resins **26**−**29**. Analogously, resin **17** was split into five portions for the attachment of Pro-Gly linkers, giving resins **30**−**34**. For the synthesis of monomers **1**−**5** and dimers **6**−**10**, each of the above resins **30**−**34** was split. The synthesis of second ligand was carried out, giving resins **35**−**39**. All resin precursors **20** and **21** and **26**−**39** were simultaneously deprotected and cleaved from the Rink resin using a mixture of trifluoroacetic acid, 1,2-ethanedithiol, thioanisole, and water (91/3/3/3) that produced the desired compounds **1**−**16**. Peptides **1**−**16** were purified by size exclusion chromatography and reverse-phase C_{18} preparative HPLC and were characterized by ESI-MS and/or MALDI-TOF mass spectrometry, and/or FT-ICR (Table 2).

Linker Length Estimate. The 3D structure of the hMC4R has been modeled on the basis of the sequence homology and crystal structure of rhodopsin (*11*). We used the crystal structure of a recently published bovine rhodopsin protein, with two protein molecules per asymmetric unit (*18*) to determine the width of the hMC4R and to estimate the distance between two adjacent ligand binding sites. Using the *DeepView/Swiss-Pdb Viewer* program to visualize the 3D structure of rhodopsin, we measured the "width" of the GPCR dimer and found that the average distance from edge to edge was ∼70 Å at the widest point (Figure 2A).

For the hMC4R, four transmembrane domains (TM), viz., TM3, TM4, TM5 and TM6, are integral in forming the ligand-binding pocket of this GPCR. On the basis of this arrangement of the TM domains, the center of the binding pocket is estimated to be located ∼12 Å from the nearest edge of the receptor (Figure 2A). If two adjacent receptors have their binding pockets facing each other in a head-to-head arrangement (Figure 2B), the distance between the centers of these binding pockets would be ∼25 Å. If the binding pockets are arranged in a head-to-tail fashion or a tail-to-tail fashion, the distance between the binding sites would be expected to increase (Figure 2C,D, respectively). Additionally, it must be noted that annular lipids may be associated with receptors and thus would be expected to add an additional 8 Å to the distance based on an estimated cross-sectional area of ∼45 $Å^2$ (*21*−*23*). Furthermore, these estimations assumed that, upon dimerization, each receptor maintained its overall dimensions and that the two receptors did not participate in domain swapping. With these assumptions, the length needed to span the distance between these binding sites was estimated to be between 20 and 50 Å. This estimation implies that linkers shorter than 20 Å (e.g., (*3*)) cannot cross-link multiple GPCRs.

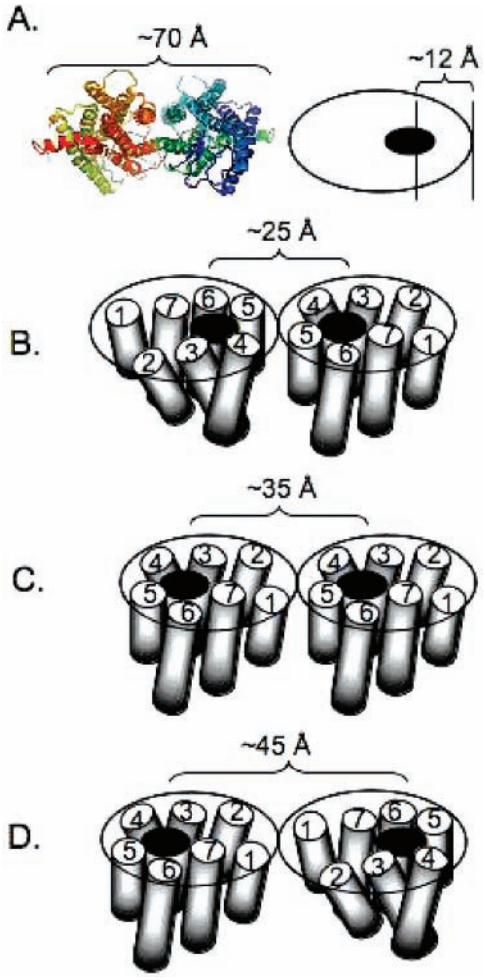

Figure 2. The distance estimations between the binding sites of two adjacent GPCRs (modeled from pdb 1GZM). A. The binding site is estimated to be ∼12 Å from the nearest edge of the receptor. When the receptors are arranged in a head-to-head (B), tail-to-head (C), or tail-to-tail fashion (D), the estimated distances between the binding pockets are 25, 35, and 45 Å, respectively. These distances do not account for the presence of additional lipids or domain swapping as was discussed in the text.

Modeling of Linkers and Homobivalent Ligands. The compounds **7**, **8**, and **14** (Table 1) displayed the highest affinity in our lanthanide-based binding assays. As is evident, the linker

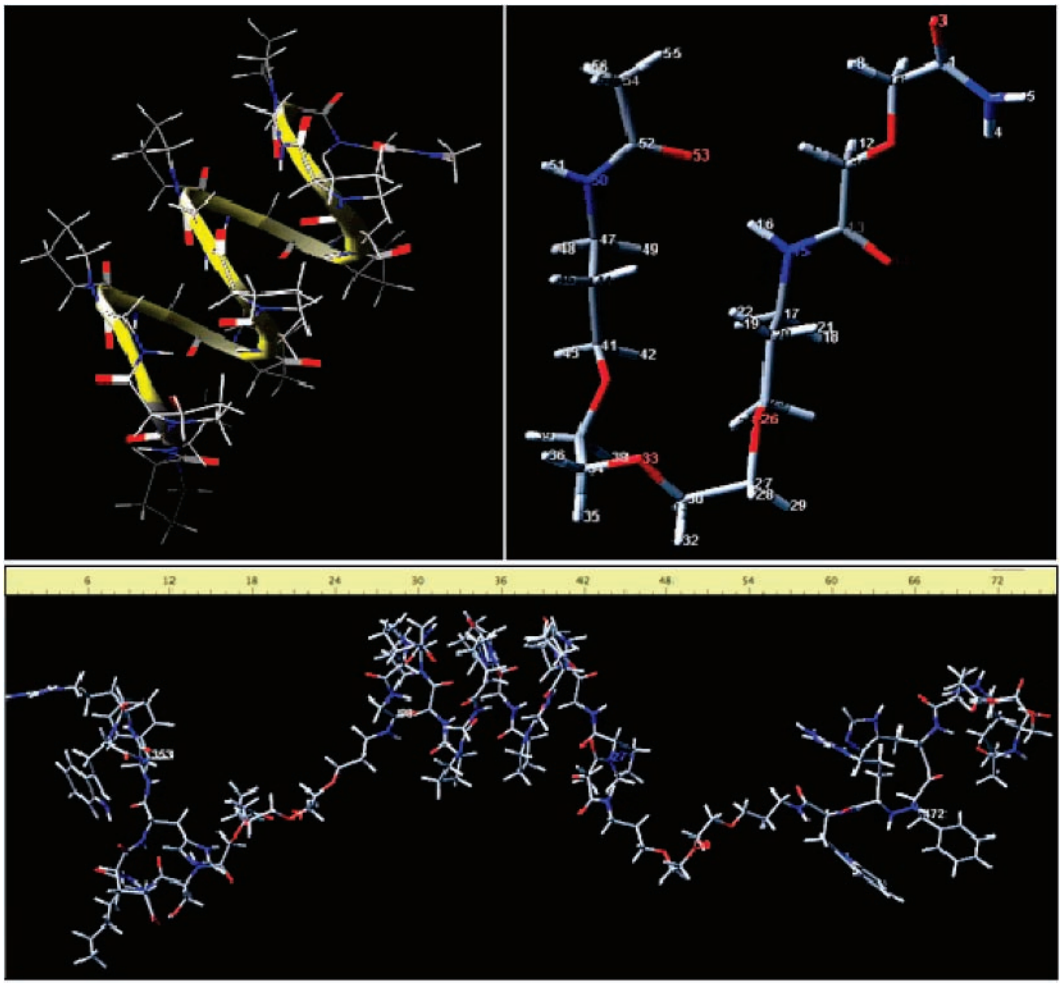

Figure 3. Computational study of -[Pro-Gly]- and -[PEGO]- linkers and a model homobivalent ligand to investigate the conformation, distance span of the linkers, and overall linker moiety. Part A (top left) shows a $[PG]_9$ repeat taking a 6_{17}-helical conformation. MD simulation of this conformation at 310 K shows a significant helical pattern in the entire sample set of 1000 conformations with length ranging from 15 to 29 Å. Part B (top right) shows the PEGO linker in a bent conformation at global minimum. As expected, the linker shows a high degree of flexibility in MD simulations, with distance span between two ends ranging from 4 to 18 Å. Part C (bottom) shows a hypothetical homobivalent ligand, with ruler above, to indicate the approximate distance span of different subunits. The distances calculated from the GPCR dimer study and the modeling of linkers correlate quite well with the binding data.

lengths in terms of atoms do not bear any correlation with activity, as a whole range of compounds having linker lengths from 36 to 76 atoms displayed similar affinities, irrespective of the nature of the linkers. This indicates either a secondary structure formation or a large degree of inherent flexibility of the linkers such that the bivalent mode of binding of MSH epitopes is preserved but the overall conformation of the linker region is reasonably different among compounds. Modeling of the Pro-Gly repeats and PEGO linkers bears out both of these possibilities. These maximum entropy methods indicated that a semirigid helical structure for Pro-Gly-based linkers and a very flexible conformation for PEGO spacers were allowable conformations.

Initially, Monte Carlo conformational searches were performed separately on model rigid linker peptides $[PG]_n$ ($n = 3$, 6, 9) and the flexible linker PEGO. As can be seen from Figure 3a, an 18-mer Pro-Gly (PG) sequence folded into a helical structure in the lowest-energy conformer with a triangular shape (viewed perpendicular to axis) similar to a polyproline helix type II (*24*). However, the Pro-Gly helix was broader with a pitch of 5 Å per seven residues. This lowest-energy conformer was further investigated using Monte Carlo/stochastic dynamics simulations at 310 K for 1000 ps of simulation time. This revealed that this 18-mer could span a distance of 5−10 Å per seven-residue turn with an average of 7 Å from the population sample set, while still retaining a significant helical shape. Therefore, the PG repeat is predicted to be stabilized in a semirigid conformation as was anticipated in the initial design of our rigid linkers. Additionally, the per-residue span of 0.8−1.6 Å indicated here roughly correlates with the span of 1.2 Å unit from linear sequence estimations that were used initially. However, it must be noted here that the distance ranges from dynamic simulations are not linear distances measured along the C_α backbone but instead are spatial distances based upon the pitch of modeled helix. Further experimental verification of these results is presently being investigated in our group.

A similar study set of conformational searches and MD simulations on the flexible PEGO linker revealed that it could assume a bent conformation at the global minimum, as one would expect (Figure 3b) and that the population contained many low-energy conformers with linear (open) shapes. This indicates that a 20-atom PEGO spacer can take any number of conformations with a distance range 4−18 Å long. The fact is evident, as the solvent medium can easily replace most of the hydrogen bonds in the open conformation that it forms with itself in the bent conformation.

We also investigated a model ligand, Ac-MSH(7)-PEGO-$[PG]_9$-PEGO-MSH(7)-NH_2 to investigate the conformation and dynamics of this compound with respect to linker mobility and space interrogation by the attached ligands. Figure 3c shows

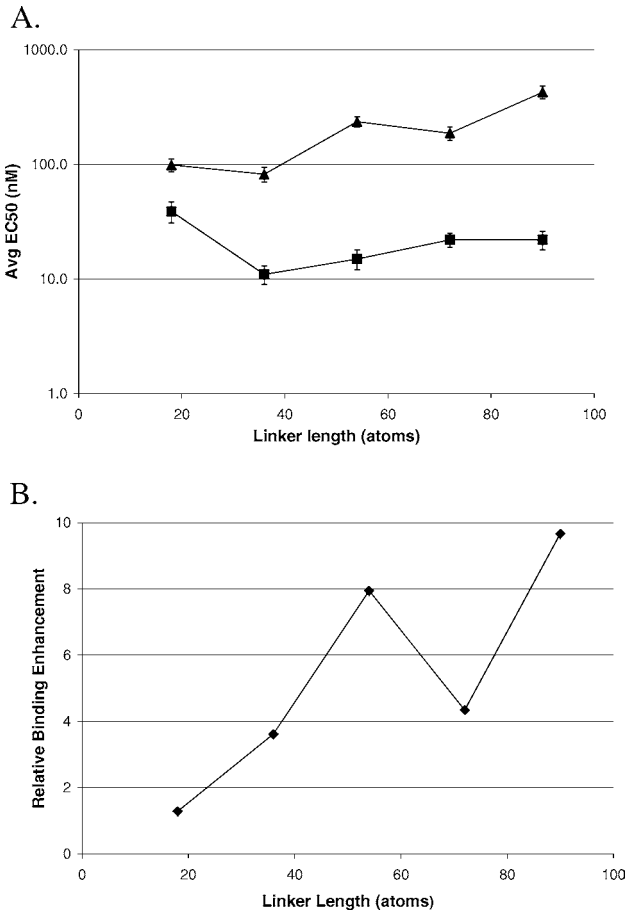

Figure 4. Binding results of monovalent ligands versus bivalent ligands. Binding of the ligands was tested via competition with Eu-NDP-α-MSH. A. Bivalent ligands (■) bind with a higher affinity than their corresponding monovalent ligands (▲). B. The affinity enhancement was calculated by the equation: EC_{50}monovalent/2(EC_{50}bivalent). Results represent the average of at least five independent experiments, each done in quadruplicate, and error bars indicate the standard deviation.

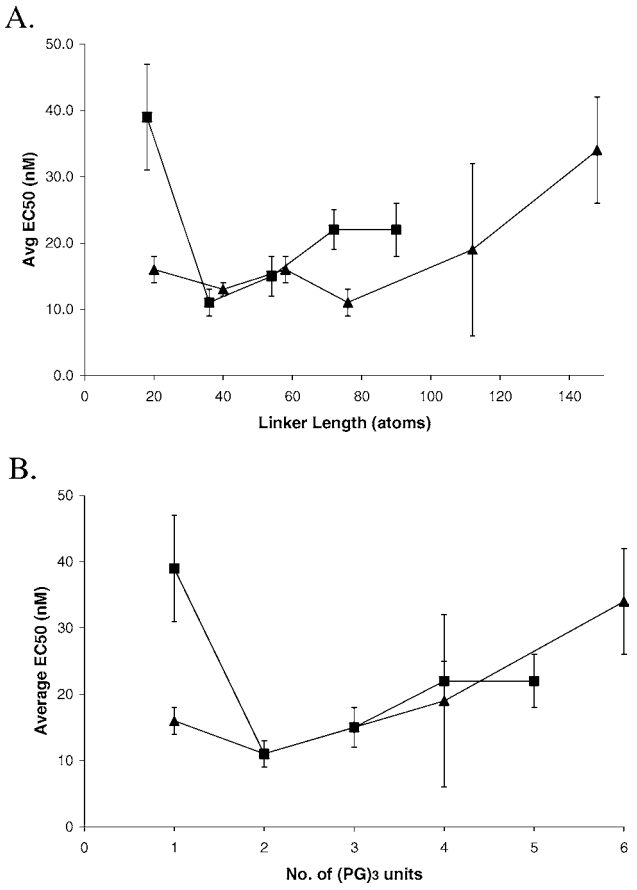

Figure 5. A. Binding results of the two classes of bivalent MSH(7) ligands. Binding of the ligands was tested via competition with Eu-NDP-α-MSH. The bivalent ligands constructed with the PEGO inserts (▲) do not bind with higher affinity compared to the bivalent ligands constructed primarily from Pro-Gly repeats (■). Results represent the average of at least five independent experiments, each done in quadruplicate, and error bars indicate the standard deviation. B. Comparison of compounds with the same number of PG repeats. Only one set of compounds showed increased binding affinity upon incorporation of PEGO inserts.

the ligand along with a ruler in angstrom units. The MD simulation results included populations of both open and closed conformations (MSH epitopes either further apart or closer together). Although the difference in energy between these two conformations was quite large, we believe the binding of MSH epitopes to the receptors could relieve this energy difference. Therefore, the open conformation may more closely resemble the binding mode. Upon the basis of these models, the lengths spanned by the linkers in the ligand library were estimated, as shown in Table 1. It is worth noting that these linker lengths correlated quite well with the inter-receptor distances of 25 ± 10 Å estimated from the modeled GPCR dimers reported above and in the literature (*25*).

Homobivalent Ligands with Longer Linkers Bind with an Increased Affinity. Ligand binding was evaluated via the lanthanide-based binding assay that has been described previously (*20*). In all cases, the bivalent constructs of MSH(7) bound with more than 10-fold higher affinities compared to the ligands composed of monovalent MSH(7) plus the linker (Figure 4A). In order to assess the enhancement in binding affinity of the bivalent ligand relative to the monovalent ligand, the EC_{50} of the monovalent ligand was divided by twice the EC_{50} for the bivalent ligand, accounting for the presence of two binding subunits in the bivalent ligand compared to only one in the monovalent ligand. Even following this correction, Figure 4B indicates that a significant enhancement is still detected when observing bivalent versus monovalent ligand binding. The trend relating linker length to average EC_{50} followed a similar pattern for the control monomers and the dimers.

Ligands **7** and **8**, with linker lengths of 36 and 54 atoms (10−20 Å and 15−30 Å, respectively), showed the highest binding affinity of all compounds in the Pro-Gly series. The estimated linker lengths for these compounds (25 ± 10 Å), were identical to the estimated inter-receptor distance obtained through modeling.

Addition of Flexible Ends to Overall Rigid Linkers Provides no Further Increase in Affinity. Although compounds **11**−**14** have similar and appreciable activity, the flexibility of the PEGO linkers precluded using these compounds for distance estimation (*vide infra*; see also Figure 3B). Nonetheless, it was notable that, while the maximum affinities of the PEGO series were not higher than those of the Pro-Gly series, they retained high-affinity binding over a wider range of ligand sizes (Table 1, Figure 5A). Notably, 20-atom compound **11** and 76-atom compound **14** bound with significantly higher affinity ($p < 0.001$) compared to the similarly sized, 18-atom compound **6** and 72-atom compound **9**, respectively. To directly compare compounds with and without PEGO units, binding data were plotted as a function of Pro-Gly units. In this analysis (Figure 5B), only the shortest PEGO compound showed significant improvement in binding over PG alone. It is also noteworthy that, for both series, the affinity decreases

with increasing linker length, after the minimum, optimal length criterion of 2 PG repeats is met.

DISCUSSION

We have synthesized 16 MSH(7)-containing ligands and confirmed their binding to the hMC4R in whole cell assays. All 11 of the homobivalent ligands bound with at least a 10-fold greater affinity than the corresponding monovalent controls. The conjugation of linkers to monovalent MSH(7) did not significantly decrease the binding affinity of the ligand when linkers were shorter than 40 atoms. As the linker lengths increased beyond 40 atoms, significant decreases in the binding affinities were observed. This can be attributed to the increased translational and rotational entropies associated with longer linkers (*26*). Thus, the linker is interfering with the ligand receptor interactions leading to a decreased affinity.

Bivalent ligands bound with an enhanced affinity compared to monovalent ligands. On the basis of our modeling studies, linkers longer than ~25 Å allowed both ligands to reach and simultaneously bind adjacent receptors. Although we hypothesize that the enhanced affinity observed with the bivalent ligands is a result of the receptor clustering mechanism, we cannot conclusively demonstrate this in this experimental system. Such a demonstration will require a heterobivalent system, which is currently under investigation.

We originally hypothesized that the addition of flexible PEGO moieties to the ends of the otherwise relatively rigid linker would enhance ligand binding by allowing the dimer to investigate more space, thus increasing the likelihood of finding and binding to a second receptor. While this may be the case, the results are not dramatic. The 76-atom PEGO-decorated dimer **14** bound with an EC_{50} of 11 ± 2 nM, while the corresponding 72-atom [PG] dimer **9** bound with a significantly higher 22 ± 3 nM. However, the 112-atom compound **15** (19 nM) and the 90-atom compound **10** (22 nM) were not significantly different. This would suggest that either the structures or the distance spans of these linkers are similar enough that they do not demonstrate any effects on ligand binding. The effect of PEGO was most evident in the short linkers. The 20-atom PEGO-linked dimer **11** bound with significantly higher affinity (EC_{50} = 16 ± 2 nM) compared to the corresponding 18-atom PG-linked dimer **6** (39 ± 8 nM). Both Pro-Gly and PEGO-$[PG]_n$-PEGO-based linkers were expected to possess a certain degree of inherent flexibility, especially the PEGO-based linker. Computational modeling revealed that linkers could assume multiple conformations with a range of distance due to this inherent flexibility. Whereas Pro-Gly may maintain a more or less rigid structure (as evident from the helical structure in MD simulations, the PEGO-$[PG]_n$-PEGO was more free to take a linear or bent shape overall and could assume a wider range of distances. For example, compound **14** had a predicted linker length of 18−56 Å, which was a larger range compared to compound **7,** which had a range of only 10−20 Å. Thus, it is predicted that these two linker types can assume different overall geometries. Because of lower flexibility, the Pro-Gly series provided a clearer picture of the distance between two receptors. Notably, the PEGO series maintained high-affinity binding, even out to lengths of 100 atoms, beyond which there appeared to be a decrease in binding affinity.

In summary, the optimal linker length to span two GPCRs in our model was 25 ± 10 Å, and this generally fits with the binding data for the Pro-Gly series. However, the significant bioactivity of compound **6** suggests that a distance may be less than 25 Å. This may indicate either a statistical effect of two epitopes or domain swapping among receptors. The present study cannot make a conclusive statement with respect to this mode, and additional work will need to be completed to further assess the actual optimal linker length and differentiation in binding modes. Moreover, this distance will most likely vary depending on the exact receptor evaluated and may change when evaluating heterovalent binding which involves different types of receptors. Finally, the only way to demonstrate actual cross-linking of multiple receptors using our experimental system requires the evaluation of heterovalent ligands. Such work is currently underway, and the results from the experiments reported here will be used to design linkers for our future work involving heterovalent ligands for direct targeting of cancer cells.

ACKNOWLEDGMENT

In Vitro and in Vivo Evaluation of ^{64}Cu-Labeled DOTA−Linker−Bombesin(7−14) Analogues Containing Different Amino Acid Linker Moieties

Jesse J. Parry,[†] Thomas S. Kelly,[†] Rebecca Andrews,[†] and Buck E. Rogers[†,‡,*]

Department of Radiation Oncology and the Alvin J. Siteman Cancer Center, Washington University School of Medicine, St. Louis, Missouri 63110. Received December 7, 2006; Revised Manuscript Received March 13, 2007

The gastrin-releasing peptide receptor (GRPR) is overexpressed on a variety of tumor types and has been targeted with radiolabeled peptides for detection and therapy of these cancers. Analogues of the 14 amino acid bombesin (BN) peptide have been radiolabeled with both gamma- and positron-emitting radionuclides for detection of GRPR-expressing tumors. We have previously evaluated BN analogues radiolabeled with the positron-emitter, copper-64 (^{64}Cu), that contained various aliphatic linkers placed between the BN peptide and the 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) chelator. These studies showed that the analogues could be used for positron-emission tomographic (PET) imaging of GRPR-positive tumors in mice but clinical translation would be hindered by significant uptake in background tissues. Therefore, the purpose of this study was to determine if the use of amino acid linkers placed between the DOTA chelate and the BN peptide would reduce nontarget tissue uptake, while maintaining good prostate tumor uptake. The linkers studied utilized three amino acid combinations of glycine (G), serine (S), or glutamic acid (E). *In vitro* assays in PC-3 cells showed that the glutamic acid-containing linkers had poor binding and internalization, while the other analogues had IC_{50} values <100 nM and good internalization. *In vivo*, these same analogues demonstrated tumor-specific uptake and good imaging characteristics that were comparable to, or better than the previously reported ^{64}Cu-labeled DOTA−BN analogues. Overall, this study shows that BN analogues containing amino acid linkers can be used for the PET imaging of GRPR-expressing prostate cancer and that these linkers lead to lower background tissue uptake.

INTRODUCTION

Bombesin (BN) is a 14 amino acid peptide that was originally purified from amphibian skin (*1*). This peptide is also active in mammals exerting various physiological effects such as regulating smooth muscle contraction, stimulating action of gastric contraction, and increasing insulin secretion (*2*). BN and BN-like peptides exert their effect through binding to members of the BN receptor family that consists of four receptor subtypes including the neuromedin B receptor (BB1), the gastrin-releasing peptide receptor (GRPR, BB2), the orphan receptor subtype (BB3), and the amphibian receptor (BB4) (*3*−*6*). The bombesin receptor subtype 2 (GRPR) has been shown to be overexpressed on various human tumors and tumor cell lines and thus has been a successful target for the detection and treatment of these cancers. Therapeutic targeting of GRPR has been accomplished through a number of approaches including the development of BN antagonists, conjugation of cytotoxic agents to BN analogues, and attachment of therapeutic radionuclides to BN analogues (*7*−*12*). Similarly, diagnostic radionuclides have been attached to BN analogues for the noninvasive detection of GRPR-expressing neoplasms via imaging.

Noninvasive imaging of GRPR-expressing tumors has been proposed using BN analogues radiolabeled with ^{99m}Tc or ^{111}In for gamma ray scintigraphy or with positron-emitting radionuclides for imaging by positron-emission tomography (PET) (*13*−*20*). In general, BN agonists consisting of either the full length BN peptide (*15*, *20*) or just the C-terminal amino acids of BN have been evaluated (*17*, *18*), although there are some examples of BN antagonists being used (*21*). Our previous studies have used the C-terminal amino acids of BN (BN(7−14)) conjugated to the macrocyclic chelate 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) for radiolabeling with ^{64}Cu for PET imaging of GRPR-expressing tumors (*17*, *22*). These studies used aliphatic linkers between the DOTA and BN(7−14) which likely led to their excretion via the hepatobiliary pathway and is one possible reason for the high retention of radioactivity in the liver. The goal of this study was to evaluate ^{64}Cu-labeled DOTA−BN(7−14) analogues that contain amino acid linkers between DOTA and BN(7−14) in order to reduce the accumulation of radioactivity in the liver that is observed with the aliphatic linkers. Another source of accumulation of radioactivity in the liver that will not be addressed in these studies is from the known dissociation of ^{64}Cu from the DOTA complex.

The amino acid linkers in this study contain glycine (G), serine (S), and glutamic acid (E), and we specifically evaluated GGG, GSG, GSS, GEG, and GEE as linkers. The DOTA−linker−BN(7−14) conjugates evaluated in this manuscript are shown in Figure 1. We hypothesized that the insertion of the serines into the linker would reduce the lipophilicity of the conjugate and thus reduce liver accumulation of radioactivity, while the insertion of glutamic acids would decrease the lipophilicity, but also increase the overall negative charge of the conjugate and therefore reduce kidney accumulation. The conjugates were evaluated for binding to PC-3 human prostate cancer cells, and the ^{64}Cu-labeled conjugates were evaluated for internalization into these cells. The tumor localization and normal tissue accumulation of the ^{64}Cu-labeled analogues were then analyzed in acute *in vivo* biodistribution studies and in

noninvasive small animal PET imaging studies using mice bearing PC-3 xenografts.

EXPERIMENTAL PROCEDURES

Cell Line and Bombesin Analogues. The human prostate adenocarcinoma cell line PC-3 was obtained from the American Type Tissue Culture Center (Manassas, VA), and the cells were maintained in 45% RPMI 1640, 45% Ham's F-12, and 10% heat inactivated fetal bovine serum (FBS). The media components were obtained from Invitrogen (Carlsbad, CA), with FBS from Sigma Chemical Company (St. Louis, MO). Five DOTA−linker−BN(7−14) analogues (DOTA−GGG−BN(7−14), DOTA−GSG−BN(7−14), DOTA−GSS−BN(7−14), DOTA−GEG−BN(7−14), and DOTA−GEE−BN(7−14)) were synthesized by CS Bio Co. (Menlo Park, CA) using standard Fmoc chemistry. The DOTA as the tris(*tert*-butyl)-protected, mono-(*N*-hydroxysuccinimide ester) was purchased from Macrocyclics Inc. (Dallas, TX) for use in solid-phase synthesis. The crude synthetic yield of all peptide analogues was >90% of theoretical yield. The crude peptides were then purified by semipreparative HPLC to give a 10% yield of pure peptide. Final purity was determined by reversed-phase HPLC with a gradient of 80% Solvent A (0.1% CF_3COOH/H_2O) to 50% Solvent B (CF_3COOH/CH_3CN) over 20 min. The purities were: DOTA−GGG−BN(7−14) 97.88%; DOTA−GSG−BN(7−14) 95.67%; DOTA−GSS−BN(7−14) 98.34%; DOTA−GEG−BN(7−14) 94.34%; DOTA−GEE−BN(7−14) 96.85%. Peptide identities were confirmed by ES-MS: DOTA−GGG−BN(7−14) ($C_{65}H_{101}N_{20}O_{19}S_1$), calcd $(M + H)^+$ *m/z* 1497.25, found 1497.60; DOTA−GSG−BN(7−14) ($C_{66}H_{103}N_{20}O_{20}S_1$), calcd $(M + H)^+$ *m/z* 1527.28, found 1527.40; DOTA−GSS−BN(7−14) ($C_{67}H_{105}N_{20}O_{21}S_1$), calcd $(M + H)^+$ *m/z* 1557.30, found 1557.40; DOTA−GEG−BN(7−14) ($C_{68}H_{105}N_{20}O_{21}S_1$), calcd $(M + H)^+$ *m/z* 1569.30, found 1569.40; DOTA−GEE−BN(7−14) ($C_{71}H_{109}N_{20}O_{23}S_1$), calcd $(M + H)^+$ *m/z* 1641.32, found 1641.67.

Competitive Binding Assay. The IC_{50} values of the five individual DOTA−linker−BN(7−14) analogues were determined using a competitive binding assay with ^{125}I-Tyr^4−BN (Amersham Biosciences, Piscataway, NJ) as previously described (*23*). Briefly, PC-3 cells were grown to confluence and collected in cold 4 mM EDTA + 0.05% potassium chloride. Increasing amounts of the DOTA−linker−BN(7−14) analogues ranging from 0.1 ng to 10 μg in 10 μL PBS + 0.1% BSA were added to 1×10^6 cells (100 μL) in triplicate. To this was added 100 μL of ^{125}I-Tyr^4−BN (0.05 nM) to each tube such that the final concentration of the analogues ranged from 1 nM to 100 μM. The tubes were then incubated at 4 °C with shaking for 1 h. After incubation, 3 mL of cold PBS + 0.1% BSA were added to each tube, and all of the tubes were centrifuged at 1500 rpm for 10 min at 4 °C. The supernatants were then aspirated, and the amount of cell-associated radioactivity was determined by gamma counting on a Packard II gamma counter (Perkin-Elmer, Boston, MA). The data were then plotted in GraphPad Prism 3 Software (San Diego, CA) using the sigmoidal dose response equation, with % radioactivity bound versus log of the DOTA−linker−BN(7−14) concentration for the determination of the IC_{50} values.

Radiolabeling of Bombesin Analogues. Positron-emitting copper-64 (^{64}Cu, $t_{1/2} = 12.7$ h, β^+, 0.656 MeV, 17.4%; β^-, 0.573 MeV, 39%) was produced on a CS-15 cyclotron at Washington University School of Medicine (St. Louis, MO) as described (*24*). All five bombesin analogues were radiolabeled with ^{64}Cu as previously described (*17*). Briefly, $^{64}CuCl_2$ (~300 μCi) was diluted with at least a 10-fold excess of 0.1 M NH_4OAc (pH = 5.5) and added to 3 μg of the BN analogues such that the final volume was ~100 μL. The mixture was incubated at room temperature for 30 min in the presence of 2,5-dihydroxybenzoic acid (100 μg) to prevent radiolysis. The radiochemical purity of the radiolabeled peptides was determined using radioTLC on Whatman $MKC_{18}F$ reversed-phase TLC plates (Whatman Inc., Florham Park, NJ) with 10% ammonium acetate:methanol (30:70) as the mobile phase. The TLC plates were scanned on a BioScan Imaging Scanner (Washington, D.C.), and the radiolabeled peptides were used immediately without purification for in vitro and in vivo assays.

Internalization of Radiolabeled Bombesin Analogues. Confluent PC-3 cells were collected and plated in six-well plates at a concentration of 5×10^5 cells per well. On the following day, the cells were washed with Hank's Balanced Salts Solution (HBSS) and 1 mL of internalization media (DMEM plus 30 mM HEPES, 2 mM L-glutamine, 1 mM sodium pyruvate, and 1% BSA) was added. To three of the six wells per plate was added 10 μg of Tyr^4−BN (Sigma Chemical Company, St. Louis, MO) to act as a block. Following the addition of block, ^{64}Cu-labeled BN peptides were added to each well (0.5 μCi), such that the final concentration of the radiolabeled peptide was approximately 1 nM. The plates were then incubated at 37 °C for 15, 30, 60, 120, 240, or 1200 min, upon which the media was aspirated, and the cells were washed twice with cold HBSS. The cells were then washed twice with HBSS plus 20 mM sodium acetate, pH 4.0, and these washes were collected for the determination of surface-bound radioactivity. Then to each well was added 1 mL of 10 mM sodium borate + 1% SDS to facilitate cell lysis. The lysates were then collected to determine

Table 1. IC_{50} Values of DOTA−linker−BN(7−14) Peptides versus ^{125}I-Tyr^4−BN[a]

compound	IC_{50} (nM)
DOTA−GGG−BN(7-14)	50.0 ± 16.2
DOTA−GSG−BN(7-14)	81.8 ± 34.3
DOTA−GSS−BN(7-14)	31.7 ± 6.0
DOTA−GEG−BN(7-14)	2160 ± 718
DOTA−GEE−BN(7-14)	19300 ± 4050

[a] The data are shown as nM ± SEM for 4−6 experiments, each performed in triplicate.

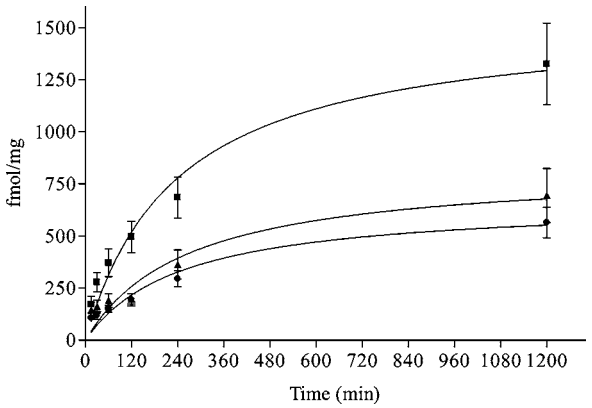

Figure 2. Internalization of ^{64}Cu-DOTA−GGG−BN(7−14) (circles), ^{64}Cu-DOTA−GSG−BN(7−14) (triangles), and ^{64}Cu-DOTA−GSS−BN(7−14) (squares) into PC-3 cells. Cells were incubated with the ^{64}Cu-labeled analogues for various times with or without Tyr^4−BN as an inhibitor. After acid washing of the cells to remove cell surface radioactivity, the cells were lysed and collected, and the amount of internalized radioactivity was counted. The data are shown as the mean of 3−4 experiments ± SEM, with each experiment being performed in triplicate.

the internalized fraction of the radiolabeled BN analogues. Both surface-bound radioactivity and internalized radioactivity were determined by counting the samples in a Packard II gamma counter. The data were normalized to protein amounts in which the protein content of the wells was determined using the Pierce BCA Protein Assay Kit (Rockford, IL) in a separate set of plates in which no radioactivity was added. The data are represented as fmol/mg internalized radioactivity versus time.

Biodistribution Studies. All animal studies were performed under the Guidelines for the Care and Use of Research Animals through the Washington University Animal Studies Committee. Female 3−4 week-old SCID mice (Taconic, Hudson, NY) were implanted subcutaneously (s.c.) on the rear flank with 1×10^7 PC-3 cells, which had been mixed 1:1 with Matrigel Basement Membrane Matrix (Becton Dickinson, Palo Alto, CA), to a volume of 200 μL. The tumors were allowed to grow for 21 days (tumor weight ∼230 mg) upon which the mice ($n = 3-5$ per group) were intravenously (i.v.) injected with ∼7 μCi (∼60 ng) of ^{64}Cu-DOTA−linker−BN(7−14). The animals were then sacrificed either 1, 4, or 24 h postinjection, and blood, liver, kidney, muscle, pancreas, and tumor were extracted, weighed, and processed for gamma counting. For each biodistribution, one additional group of mice were coinjected i.v. with 100 μg of Tyr^4−BN to act as a block and the mice were sacrificed at 1 h postinjection. The percent injected dose per gram of tissue (% ID/g) was determined by decay correction of the ^{64}Cu-DOTA−linker−BN(7−14) for each sample normalized to a standard of known weight, which was representative of the injected dose.

Imaging of PC-3 Xenografts. PC-3 cells were implanted as described above, but on the axillary thorax instead of the hind limb. The mice ($n = 3-4$ per group) were injected i.v. with ∼100 μCi (∼300 ng) of ^{64}Cu-DOTA−linker−BN(7−14) with or without 100 μg of Tyr^4−BN, anesthetized with 1−2% isoflurane, positioned supine, and imaged on a microPET FOCUS 220 (Concorde Microsystems, Knoxville, TN) (*25*) at 1, 4, and 24 h after injection of the radiolabeled analogues. CT images were obtained using a MicroCAT II System (ImTek Inc., Knoxville, TN) at 1 and 24 h after administration and coregistered with the microPET images at those time points. The microPET acquisition times were 10 min for the 1 and 4 h images and 20 min for the 24 h images. The images were reconstructed with an Ordered-Subset Estimation Maximization (OSEM) algorithm and employing the corrections for scatter and attenuation. The scanner was cross-calibrated using an ^{18}F-filled mouse-size cylindrical uniform phantom with a known activity. The relative beta decay branching ratios of ^{64}Cu to ^{18}F were taken into account for absolute quantitation measurements. Regions of interest were drawn to encompass the entire tumor to determine an average activity concentration (nCi/cc) in the tumor. To calculate the % ID/g of tumor, the nCi/cc was divided by the nCi injected (decay corrected to the scan start time) and multiplied by 100.

Statistical Analysis. All data are presented as the mean ± SEM. The Student's *t*-test was used to determine statistical significance at the 95% confidence level, with $p < 0.05$ being considered significantly different.

RESULTS

Competitive Binding Assay. The relative affinity of the five BN analogues was determined in a competitive binding assay, where various concentrations of the analogues were used to inhibit the binding of ^{125}I-Tyr^4−BN to PC-3 cells. The IC_{50} values for the analogues are shown in Table 1. The IC_{50} values for the analogues containing the GGG, GSG, and GSS linkers were not significantly different from each other but were significantly less than the GEG and GEE linkers. The IC_{50} of DOTA−GEG−BN(7−14) was significantly less than for DO-

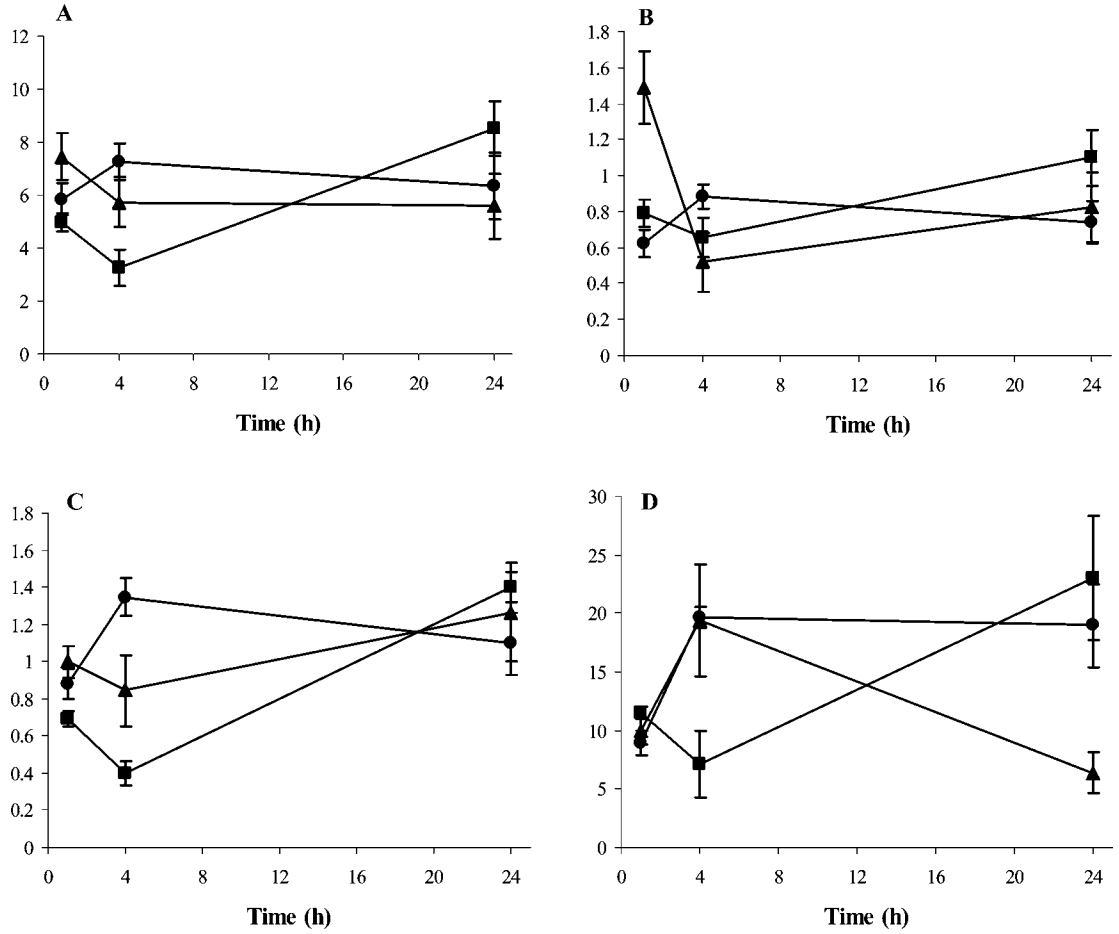

Figure 3. Tumor/blood (A), tumor/liver (B), tumor/kidney (C), and tumor/muscle (D) ratios for ^{64}Cu-DOTA−GGG−BN(7−14) (circles), ^{64}Cu-DOTA−GSG−BN(7−14) (triangles), and ^{64}Cu-DOTA−GSS−BN(7−14) (squares) in mice bearing PC-3 xenografts. The data are expressed as the mean ± SEM of the tumor-to-tissue ratio for each mouse for 3−5 mice per time point.

TA−GEE−BN(7−14) (2.2 ± 0.7 μM vs 19.3 ± 4.0 μM respectively, $p < 0.001$).

Radiolabeling and Internalization. The five BN analogues were all radiolabeled with ^{64}Cu in >95% radiochemical purity and at a specific activity of ∼100 μCi/μg (∼157 Ci/mmol) for the internalization and biodistribution studies. A specific activity of ∼300 μCi/μg (∼470 Ci/mmol) was used for the small animal PET imaging studies. Figure 2 shows that the internalization of ^{64}Cu-DOTA−GGG−BN(7−14) was similar to the internalization of ^{64}Cu-DOTA−GSG−BN(7−14), with no significant differences in the amount internalized at any of the time points. The amount of ^{64}Cu-DOTA−GSS−BN(7−14) internalized was significantly greater than the amount of ^{64}Cu-DOTA−GGG−BN(7−14) and ^{64}Cu-DOTA−GSG−BN(7−14) internalized at all time points except for 15 min. Curve fitting showed that the maximum internalizations were 670, 830, and 1550 fmol/mg for ^{64}Cu-DOTA−GGG−BN(7−14), ^{64}Cu-DOTA−GSG−BN-(7−14), and ^{64}Cu-DOTA−GSS−BN(7−14), respectively. The initial velocities of internalization were 0.83, 0.93, and 2.12 fmol/mg/min for ^{64}Cu-DOTA−GGG−BN(7−14), ^{64}Cu-DOTA−GSG−BN(7−14), and ^{64}Cu-DOTA−GSS−BN(7−14), respectively, as determined by linear regression of the data from 0 to 240 min. There was a small amount of internalization of ^{64}Cu-DOTA−GEG−BN(7−14) over the first 4 h (<30 fmol/mg) that increased to ∼160 fmol/mg at 20 h. No significant internalization was observed for ^{64}Cu-DOTA−GEE−BN(7−14) over the time course of the study. The amount of surface-bound radioactivity for all of the BN analogues was never greater than 140 fmol/mg at any of the time points measured. Since the internalization of ^{64}Cu-DOTA−GEG−BN(7−14) and ^{64}Cu-DOTA−GEE−BN(7−14) was negligible and their affinity for GRPR was low, we did not evaluate these compounds further in the *in vivo* biodistribution and imaging studies.

Biodistribution Studies. Both ^{64}Cu-DOTA−GGG−BN(7−14) and ^{64}Cu-DOTA−GSS−BN(7−14) demonstrated good blood clearance from 1 to 24 h, while ^{64}Cu-DOTA−GSG−BN-(7−14) showed relatively constant blood values (Table 2). However, the blood levels of ^{64}Cu-DOTA−GSG−BN(7−14) were significantly lower than ^{64}Cu-DOTA−GGG−BN(7−14) at 1 h ($p < 0.005$) and ^{64}Cu-DOTA−GSS−BN(7−14) at 1 h ($p < 0.005$) and 4 h ($p < 0.05$). Similar to the blood, the liver activity of ^{64}Cu-DOTA−GSG−BN(7−14) did not significantly decrease over time and was significantly lower than ^{64}Cu-DOTA−GGG−BN(7−14) and ^{64}Cu-DOTA−GSS−BN(7−14) at 1 h ($p < 0.003$ for both). The liver activity of ^{64}Cu-DOTA−GSS−BN(7−14) was also significantly lower than for ^{64}Cu-DOTA−GGG−BN(7−14) at 1 h ($p = 0.03$) and 24 h ($p = 0.04$). The amount of radioactivity in the kidneys was significantly lower for ^{64}Cu-DOTA−GSG−BN(7−14) at 1 h ($p = 0.005$) and 24 h ($p = 0.05$) compared to ^{64}Cu-DOTA−GGG−BN(7−14) and at 1 h ($p < 0.001$) and 4 h ($p < 0.02$) compared to ^{64}Cu-DOTA−GSS−BN(7−14). Thus, at early time points, ^{64}Cu-DOTA−GSG−BN(7−14) generally had lower normal tissue accumulation compared to the other analogues.

The ^{64}Cu-DOTA−GSG−BN(7−14) had significantly less tumor uptake than ^{64}Cu-DOTA−GGG−BN(7−14) at all time points ($p < 0.02$) and ^{64}Cu-DOTA−GSS−BN(7−14) at 1 h ($p < 0.01$). The tumor uptake of all compounds was significantly inhibited by administration of an excess of Tyr^4−BN ($p < 0.001$; Figure 5A) at 1 h. The GRPR-positive pancreas also

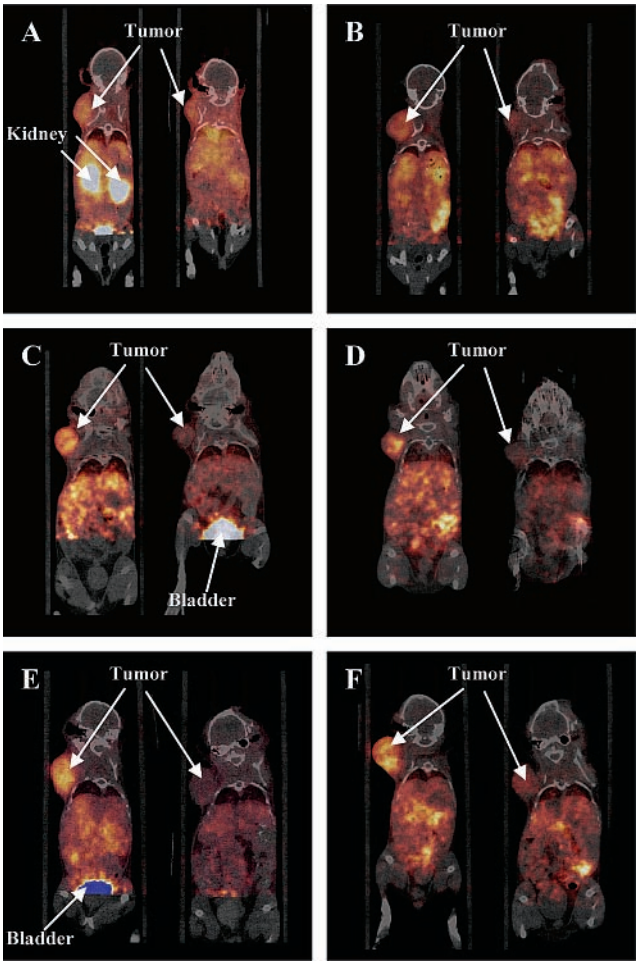

Figure 4. Coronal microPET images with coregistered CT of mice bearing PC-3 xenografts in the axillary thorax at 1 h (A, C, E) and 24 h (B, D, F). The mice were injected i.v. with ^{64}Cu-DOTA−GGG−BN(7−14) (A, B), ^{64}Cu-DOTA−GSG−BN(7−14) (C, D), or ^{64}Cu-DOTA−GSS−BN(7−14) (E, F). The mice on the left of each frame were not injected with blocking agent, while the mice on the right received 100 μg of Tyr^4−BN as an inhibitor.

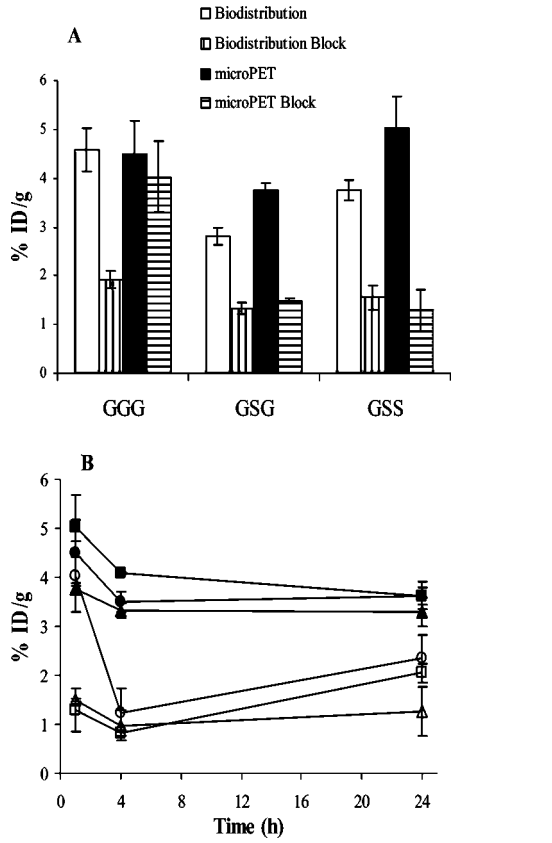

Figure 5. Comparison of tumor uptake at 1 h between biodistribution data (white bars) and microPET imaging data (black bars) for the ^{64}Cu-labeled analogues containing the GGG, GSG, and GSS linkers (A). GRPR-mediated uptake is demonstrated by the hatched bars for both the biodistribution (vertical) and imaging (horizontal) studies. The tumor uptake of ^{64}Cu-DOTA−GGG−BN(7−14) (circles), ^{64}Cu-DOTA−GSG−BN(7−14) (triangles), and ^{64}Cu-DOTA−GSS−BN(7−14) (squares) over time as determined by microPET imaging is shown in part B. The open symbols represent the ^{64}Cu-labeled analogue that was coinjected with blocking agent. The biodistribution data represent the mean ± SEM of 3−5 mice per group, while the imaging data represent the mean ± SEM of 2−3 mice per group.

showed good uptake of all of the ^{64}Cu-labeled analogues (>10% ID/g at 1 h) and all were significantly inhibited ($p < 0.0002$) by administration of the blocking agent. Approximately 70−80% of the radioactivity cleared from the pancreas from 1 to 24 h for ^{64}Cu-DOTA−GSG−BN(7−14) and ^{64}Cu-DOTA−GSS−BN(7−14), while only ∼50% cleared for ^{64}Cu-DOTA−GGG−BN(7−14). This is in contrast to the tumors, where ∼40% of the radioactivity cleared for all of the analogues.

The tumor/blood, tumor/liver, tumor/kidney, and tumor/muscle ratios for the analogues over time are shown in Figure 3. Although ^{64}Cu-DOTA−GSG−BN(7−14) generally had lower normal tissue uptake than the other analogues, the tumor uptake was also lower and thus greater tumor/normal tissue ratios were not achieved. An exception to this is the tumor/liver ratios at 1 h (Figure 3B). ^{64}Cu-DOTA−GSG−BN(7−14) had a significantly higher ($p < 0.02$) tumor/liver ratio (1.49 ± 0.20) at 1 h than either ^{64}Cu-DOTA−GGG−BN(7−14) (0.62 ± 0.08) or ^{64}Cu-DOTA−GSS−BN(7−14) (0.79 ± 0.08). In fact, there were no other significant differences in tumor/liver ratios between the analogues at any of the other time points. ^{64}Cu-DOTA−GSG−BN(7−14) had significantly higher tumor/blood and tumor/kidney ratios than ^{64}Cu-DOTA−GSS−BN-(7−14) at 1 and 4 h ($p < 0.05$ for all). There were no differences observed between the analogues at 24 h except for the tumor/muscle, where ^{64}Cu-DOTA−GSG−BN(7−14) was significantly less than the other analogues ($p < 0.02$). In general, the tumor/tissue ratios are similar for the various analogues except that the ^{64}Cu-DOTA−GSS−BN(7−14) is inferior to the other analogues in terms of the blood and kidney ratios at early time points.

Imaging of PC-3 Xenografts. Small animal PET/CT images of ^{64}Cu-DOTA−GGG−BN(7−14), ^{64}Cu-DOTA−GSG−BN-(7−14), ^{64}Cu-DOTA−GSS−BN(7−14) at 1 and 24 h are shown in Figure 4. This figure shows a representative single slice of the coronal PET/CT images for mice bearing PC-3 xenografts. The mice on the left did not receive blocking agent, while the mice on the right received 100 μg of Tyr^4−BN. These images show good tumor uptake of the three analogues at both 1 and 24 h that was inhibited when an excess of Tyr^4−BN was administered. The 1 and 24 h blocking of ^{64}Cu-DOTA−GGG−BN(7−14) was not as efficient as with the other two analogues and this was confirmed in the quantitative data (Figure 5A). Background activity is observed due to the hepatobiliary clearance of the analogues. Figure 5A shows a comparison of the PC-3 tumor uptake of the analogues as determined from the biodistribution studies and the microPET imaging studies. This shows that the tumor uptake of the analogues were similar between the biodistribution studies and the imaging studies, although the tumor uptake was significantly higher as determined by microPET for ^{64}Cu-DOTA−GSG−BN(7−14) ($p <$ 0.02). The tumor uptake of all of the analogues was significantly inhibited by administration of the blocking agent in the

biodistribution studies, while significance was not reached for ^{64}Cu-DOTA−GGG−BN(7−14) in the imaging studies. Figure 5B shows that all of the analogues had similar tumor uptake over time with the GSS linker having significantly better uptake than the other two at 4 h ($p < 0.05$).

DISCUSSION

Numerous BN analogues have been radiolabeled with a variety of radioactive metals for detection and therapy of GRPR-expressing neoplasms and discussed in a recent review (*19*). In general, most of these studies have utilized γ-emitting radiometals for their potential as single photon emission computed tomographic (SPECT) imaging agents. Recently, there has been an interest in developing radioactively labeled BN analogues for PET imaging utilizing ^{64}Cu, ^{68}Ga, and ^{18}F (*14*, *17*, *18*, *20*, *22*, *26*). Our laboratory has focused on BN analogues labeled with ^{64}Cu for PET imaging of both breast and prostate cancer (*17*, *22*). These analogues have utilized aliphatic linkers between the DOTA chelator and the BN peptide and have shown good tumor localization and imaging. However, they have also resulted in high accumulation of radioactivity in the liver and kidneys. In this study, we report the evaluation of analogues that contain amino acid linkers between DOTA and BN(7−14) that alter the overall lipophilicity and charge with the intention of lowering background activity. The analogues were evaluated for their binding to GRPR, internalization into PC-3 human prostate cancer cells, and *in vivo* tumor localization by biodistribution and imaging studies.

The purpose of this study was to evaluate three amino acid linkers between the chelator and BN(7−14). We hypothesized that the introduction of amino acids that were hydrophilic or contained a negative charge would help reduce radioactive accumulation in the liver and kidneys. Thus, serines (S) were used to add hydrophilicity to the linker because of the presence of the hydroxyl group side chain, and glutamic acids (E) were used to add negative charges to the linker. The pK_a of the acid side chain of glutamic acid is 4.07 and thus should be highly deprotonated at physiologic pH, leading to the negative charge. Since positively charged compounds are known to accumulate in the kidneys, these negative charges should reduce the kidney accumulation. A recent study by Alves et al. compared a GGG linker between BN(7−14) and a ^{99m}Tc-chelate complex to a SSS linker (*27*). This study showed that the analogue with the GGG linker had liver and kidney uptakes of 5.8% and 7.9% ID/g, respectively, at 1 h postinjection that dropped to 2.1% and 2.7% when the SSS linker was used. Thus, it has been demonstrated that changes in the amino acid linker sequence can have a profound effect on normal tissue uptake.

As seen in Table 1, the peptides that had linkers containing glutamic acids (E) had significantly higher IC_{50} values than the other peptides. The IC_{50} values (∼30 nM to 80 nM) of the other analogues were similar to that previously reported by our group for an analogue with an aliphatic linker (DOTA−Aoc−BN(7−14) = 90 nM). Johnson et al. shows the three-dimensional structure of ^{177}Lu-DOTA−Aoc−BN(7−14) as determined from two-dimensional NMR (*9*). This shows the helical structure of BN(7−14) that is responsible for binding to GRPR, with the linker and metal-chelator extending away from the peptide. The low affinity binding of the glutamic acid-containing linkers in this study may be due to a disruption of this helical structure by the negative charges of the linker.

The internalization of the analogues containing the GGG, GSG, and GSS linkers are shown in Figure 2 and demonstrate agonist-like behavior that is consistent with similar constructs (*27*). The internalization curves are similar for ^{64}Cu-DOTA−GGG−BN(7−14) and ^{64}Cu-DOTA−GSG−BN(7−14), while ^{64}Cu-DOTA−GSS−BN(7−14) shows a more rapid internalization as well as a higher degree of internalization. Other reports have shown a more rapid internalization of radiolabeled BN analogues in PC-3 cells where saturation was reached in 1 to 2 h (*14*, *16*, *27*, *28*), while this study shows that analogues only reached ∼44% saturation by 4 h. It is not clear why ^{64}Cu-DOTA−GSS−BN(7−14) internalizes more rapidly than the other analogues or why internalization appears to be slower than reported by others in this cell line. It has generally been thought that internalization of these analogues is important for their use as diagnostic imaging agents, although a recent publication suggests that noninternalizing somatostatin antagonists are preferred for imaging rather than internalizing agonists (*29*).

The biodistribution study (Table 2) shows that ^{64}Cu-DOTA−GSG−BN(7−14) has lower liver uptake at 1 h compared to the other analogues, while ^{64}Cu-DOTA−GSS−BN(7−14) has lower uptake at 4 and 24 h. This would agree with the hypothesis that the addition of serines to the linker will lead to lower liver accumulation of radioactivity, although, one might predict that the liver radioactivity of ^{64}Cu-DOTA−GSS−BN(7−14) should also be lower than ^{64}Cu-DOTA−GSG−BN(7−14) at 1 h. The liver uptake of ^{64}Cu-DOTA−GSS−BN(7−14) at 1, 4, and 24 h was lower than we had previously reported for similar analogues containing 6-, 8-, or 12-carbon linkers between DOTA and BN(7−14) where the values ranged from ∼7.0 to 8.8% ID/g at 1 h and ∼4.1 to 9.6% ID/g at 24 h. Yang et al. has shown a similarly high liver uptake of ^{64}Cu of ∼9 to 12% ID/g from 1.5 to 12 h using an ϵ-aminocaproic acid linker between DOTA and BN(7−14) (*20*). They also demonstrated that the liver uptake was reduced to ∼4% ID/g from 1 to 4 h when the full length BN peptide was used and DOTA was conjugated to a lysine substituted in the third position (*20*). It has also been shown that ^{64}Cu dissociates from DOTA *in vivo* and transchelates to other proteins that can lead to high blood and liver accumulation of radioactivity (*30*). Thus, the use of other chelators that have improved *in vivo* stability for their copper complexes may reduce the liver uptake even further. Two recent examples of chelators with improved stability for their copper complexes include the cross-bridged cyclam chelator, CBTE2A, and the hexa-aza cage chelator, SarAr (*31*−*33*).

As previously mentioned, the analogues containing the glutamic acid linkers were not evaluated *in vivo* due to their low binding and internalization into PC-3 cells. Therefore, we did not determine if these analogues had lower uptake of radioactivity in the kidney compared to the other analogues. ^{64}Cu-DOTA−GSG−BN(7−14) generally had lower kidney uptake than the other analogues, and all three analogues demonstrated GRPR-specific tumor uptake as determined by the blocking studies. The amount of tumor uptake ranged from ∼2.8 to 4.6% ID/g for the three analogues. This tumor uptake was similar to that reported for other ^{64}Cu-labeled analogues in the same animal model that ranged from ∼3.0 to 5.5% ID/g at 1 h or 2 h postinjection (*14*, *17*, *20*). We previously reported that ^{64}Cu-DOTA−Aoc−BN(7−14) had tumor/blood and tumor/liver ratios of ∼4 and ∼0.4, respectively, in this tumor model (*17*). Here we show (Figure 3) that the tumor/blood and tumor/liver ratios generally range from ∼4 to 8 and ∼0.6 to 1.2, respectively. These ratios are also improved compared to a recent study where aliphatic linkers were evaluated in a breast tumor model (*22*). Thus, these studies show that the ^{64}Cu-labeled analogues with the amino acid linkers had comparable tumor uptake to other ^{64}Cu-labeled analogues previously reported, but with improved tumor/tissue ratios due to lower radioactive accumulation in normal tissues.

The PET/CT images (Figure 4) show good tumor uptake of ^{64}Cu-DOTA−GGG−BN(7−14), ^{64}Cu-DOTA−GSG−BN(7−14), and ^{64}Cu-DOTA−GSS−BN(7−14) (mice on the left) which confirms the uptake observed in the biodistribution studies. The

tumor uptake was specific, as the signal decreased upon administration of the blocking agent (mice on the right), although the 1 h image for ^{64}Cu-DOTA−GGG−BN(7−14) did not show efficient receptor blockade. The images also show the background hepatobiliary clearance of the peptides, and the 1 h PET/CT slice for ^{64}Cu-DOTA−GGG−BN(7−14) (Figure 4A) shows the kidney and bladder radioactivity. Analysis of the imaging data shows that there is good agreement with the biodistribution data (Figure 5A) and that the tumor uptake of the analogues was inhibited at all time points except for ^{64}Cu-DOTA−GGG−BN(7−14) at 1 h (Figure 5B). These images show that the tumor can be clearly delineated with these analogues but that the background activity in the intestinal tract and rapid clearance of the activity through the bladder may preclude imaging of lesions in these areas.

In conclusion, we evaluated five ^{64}Cu-DOTA−linker−BN(7−14) analogues that consisted of different amino acid linkers and found that the use of negatively charged glutamic acid residues significantly reduced the affinity of these analogues for GRPR as well as internalization into GRPR-expressing cells. The other analogues showed specific tumor uptake and good imaging characteristics that were comparable to or better than previously reported ^{64}Cu-labeled DOTA−BN analogues. However, these results may be further improved by additional modification of the linkers and/or use of chelators that are more kinetically inert when forming complexes with copper than the DOTA chelator evaluated here.

ACKNOWLEDGMENT

The authors gratefully acknowledge Nicole Fettig, Margaret Morris, Amanda Roth, Lori Strong, and Dawn Werner for performing the biodistribution and imaging studies. Jerrel Rutlin and Dr. Richard LaForest are thanked for analysis and helpful discussions of the imaging data. Dr. Jason Lewis and Ronald Chen are thanked for critical reading of the manuscript. This work was supported, in part, by a grant from the American Cancer Society (RSG-00-067-04-CCE). The production of ^{64}Cu at Washington University School of Medicine is supported by NCI Grant R24 CA86307, and small animal imaging is supported by an NIH/NCI SAIRP Grant R24 CA83060.

A Novel Conjugable Translocator Protein Ligand Labeled with a Fluorescence Dye for in Vitro Imaging

Mingfeng Bai,[†] Shelby K. Wyatt,[†] Zeqiu Han,[‡] Vassilios Papadopoulos,[‡] and Darryl J. Bornhop*[,†]

Department of Chemistry, Vanderbilt University, VU Station B 351822 Nashville, Tennessee 37235-1822, and Department of Biochemistry & Molecular and Cellular Biology, Georgetown University Medical Center, BSB Room 315, 3900 Reservoir Road NW, Washington, DC 20057. Received December 11, 2006; Revised Manuscript Received April 2, 2007

A conjugable analogue of the benzodiazepine 4′′-chlorodiazepam (Ro5-4864), C_6Ro5-4864 was synthesized to probe the binding sites of translocator protein (18 kDa; TSPO), previously known as the peripheral benzodiazepine receptor for molecular imaging. The amino group in this analogue allows universal conjugation to signaling molecules. Lissamine−C_6Ro5-4864, synthesized from C_6Ro5-4864 and a lissamine fluorescence dye, was investigated in this study. This imaging agent exhibited micromolar binding affinity ($K_i = 2.6\ \mu$M) to TSPO and was successfully imaged in TSPO rich glioma and breast cancer cell lines. These findings suggest that C_6Ro5-4864 may provide opportunities in imaging disease states where TSPO levels are affected, such as cancer and neurologic diseases.

INTRODUCTION

Molecular imaging (MI) has emerged as an important multidisciplinary area which involves radiology, chemistry, biology, biochemistry, physics, engineering, and medicine. MI combines molecular agents with imaging tools to follow specific molecular pathways in the body and can be widely applied in locating, diagnosing, and treating disease. Synthetic chemistry is essential to MI by providing potent imaging agents.

The translocator protein (18 kDa), TSPO, previously known as the peripheral-type benzodiazepine receptor has become an interesting target in MI (*1*). TSPO is a mitochondrial protein which is associated with a variety of biological activities such as cell proliferation, apoptosis, immunomudulation, steroidogenesis, and transport of porphyrin and heme (*1*−*3*). TSPO is ubiquitously expressed in human body, with high level of expression in non-neoplastic diseases such as ischemia, brain damage induced by toxins, viral encephalitis, hepatic encephalopathy, epilepsy, nerve degeneration, and trauma (*4*). TSPO overexpression has also been observed in various cancers including breast, glioma, prostate, colorectal, esophageal, ovarian, and small cell lung cancer (*4*).

Several selective and potent TSPO ligands have been developed, such as benzodiazepines (Ro5-4864), isoquinoline carboxamides (PK11195), indolacetamide derivatives (FGIN-1−27), pyrisanoindole derivatives (SSR180575), and phenoxylphenyl acetamide derivatives (DAA1106 or DAA1097). The study of TSPO, an important mitochondrial membrane protein is currently limited because only two ligands that exist are conjugable to signaling moieties for tracking and quantitation. An FGIN analogue was labeled with a fluorophore (NBD) which is not ideal for in vitro imaging due to the low molar extinction coefficient ($\sim$ 8000 L mol^{-1} cm^{-1}) (*5*, *6*). Our lab developed a PK11195 analogue which has a six-carbon linker and a terminal primary amino group (*7*). Development of conjugable forms of the numerous PBR ligands would facilitate the study of TSPO and possibly allow for it to be used as a target for in vivo imaging.

A conjugable form of PK11195 has been reported, and the molecule has been coupled to a lanthanide chelate (*7*) and a fluorescence dye (*8*). These TSPO-targeted agents showed good TSPO binding activity, allowing in vitro molecular imaging studies. Ro5-4864 and PK11195 are reversible competitive inhibitors of each other, and they show distinct biological properties in inflammation (*9*), depression (*10*), nociception (*11*), and apoptosis enhancement (*4*). Given these facts, to further study TSPO function in relation to its expression levels, a conjugable form of Ro5-4864 was deemed as a necessity.

We report herein the synthesis of a conjugable form of Ro5-4864 having a six-carbon spacer (C_6Ro5-4864). Through the primary amino group, this molecule can be conjugated to a variety of signaling moieties, thus allowing the use of different imaging modalities. Lissamine−rhodamine B sulfonyl chloride, a fluorescence dye with a high molar extinction coefficient (88 000 L/mol cm in methanol), was selected for conjugation to C_6Ro5-4864. The resulting TSPO-targeted fluorophore, lissamine−C_6Ro5-4864, labels TSPO-expressing cells selectively and shows promise for MI studies in imaging disease states where TSPO levels are affected, either as the cause or the outcome of the disease.

EXPERIMENTAL PROCEDURES

7-Chloro-5-(4-chlorophenyl)-1-methyl-1*H*-benzo[1,2,4]-triazepin-2-one (2). (5-Chloro-2-(methylamino)phenyl)(4-chlorophenyl)methanone **1** (2 g, 7 mmol) and ethyl carbazate (1.5 g, 17 mmol) were stirred at 210 °C for 3.5 h. After the reaction was cooled to room temperature, the product was purified by column chromatography on silica gel by eluting with 1:3 ethyl acetate/hexanes to yield **2** as a yellow solid (774 mg, 34%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.38−7.53 (6H, m), 7.15 (1H, d, J = 8.7 Hz), 7.05 (1H, d, J = 2.7 Hz), 3.29 (3H, s); MS (MALDI)$^+$ m/z 320.3 ([M + H]$^+$, 100%).

(6-Bromohexyloxy)(*tert*-butyl)dimethylsilane (4). To a solution of 6-bromo-1-hexanol (906 mg, 5 mmol) in dichloromethane (25 mL) at 0 °C was added imidazole (1.02 g, 15 mmol). After 5 min, 4-(dimethylamino)pyridine (DMAP) (60 mg, 0.5 mmol) was added, followed by *tert*-butyldimethylsilyl chloride (1.5 g, 10 mmol). The resulting solution was stirred at 0 °C for 2 h, quenched with 30 mL water, and extracted with

dichloromethane (3 × 30 mL). The organic layers were combined, dried over sodium sulfate, and concentrated by vacuum rotary evaporation. The product was purified by silica gel chromatography using 1:20 ethyl acetate/hexanes as the eluent. Compound **4** was isolated as a colorless liquid (1.3 g, 88%). ^{1}H NMR 300 MHz ($CDCl_3$) δ 3.60 (t, J = 6.3 Hz, 2H), 3.40 (t, J = 6.9 Hz, 2H), 1.86 (q, J = 5.1 Hz, 2H), 1.54−1.35 (m, 6H), 0.89 (s, 9H), 0.04 (s, 6H). MS (GC): 295, 293 [M•].

(*Z*)-3-(6-(*tert*-Butyldimethylsilyloxy)hexyl)-7-chloro-5-(4-chlorophenyl)-1-methyl-1*H*-benzo[*e*][1,2,4]triazepin-2(3*H*)-one (5). Sodium hydride (60% in mineral oil) (20 mg, 0.5 mmol) was added to a stirring solution of compound **2** (256 mg, 0.8 mmol) in dry DMF (4 mL). The mixture was stirred under argon for 30 min. Compound **4** was then added to the mixture, and the resulting mixture was stirred for another 30 min. The reaction solution was poured into 50 mL of a stirring 1 M ammonium chloride solution at 0 °C. The mixture was transferred to a separation funnel and extracted with ethyl ether (3 × 40 mL). The organic layers were combined, dried over sodium sulfate, and concentrated by vacuum rotary evaporation. The crude product was purified by silica gel chromatography using gradient 1:20 to 1:4 ethyl acetate/hexanes as the eluent to give a yellow oil (349 mg, 89%). ^{1}H NMR 400 MHz ($CDCl_3$) δ 7.55−7.53 (m, 2H), 7.46 (dd, J = 8.8, 2.4 Hz, 1H), 7.41−7.39 (m, 2H), 7.12 (d, J = 8.8 Hz, 1H), 7.06 (d, J = 2.4 Hz, 1H), 3.73 (bs, 1H), 3.55 (t, J = 2.4 Hz, 2H), 3.23 (s, 3H), 1.65 (bs, 2H), 1.49−1.43 (m, 2H), 1.33−1.24 (m, 5H), 0.88 (s, 9H), 0.02 (s, 6H). MS (ESI)$^+$: 556.2 Da [M + Na]$^+$.

(*Z*)-7-Chloro-5-(4-chlorophenyl)-3-(6-hydroxyhexyl)-1-methyl-1*H*-benzo[*e*][1,2,4]triazepin-2(3*H*)-one (6). Tetrabutylammonium fluoride (TBAF) (3.5 mL 1 M solution in THF) was added to a stirring solution of compound **5** (377 mg, 0.7 mmol) in THF (2.5 mL) at 0 °C. The reaction solution was stirred at 0 °C for 3 h, quenched with 30 mL of water, and extracted with ethyl ether three times. The organic layers were combined, dried over sodium sulfate, and concentrated by vacuum rotary evaporation. The crude product was purified by column chromatography (silica gel) using 1:2 ethyl acetate/hexanes as eluent. Compound **6** was collected as a pale yellow oil (281 mg, 95%). ^{1}H NMR 300 MHz ($CDCl_3$) δ 7.55−7.53 (m, 2H), 7.46 (dd, J = 9.0, 2.4 Hz, 1H), 7.41−7.38 (m, 2H), 7.12 (d, J = 8.7 Hz, 1H), 7.06 (d, J = 2.4 Hz, 1H), 3.72 (bs, 1H), 3.61−3.56 (m, 3H), 3.23 (s, 3H), 1.69−1.62 (m, 2H), 1.57−1.48 (m, 2H), 1.37−1.24 (m, 5H). ^{13}C NMR 75 MHz ($CDCl_3$) δ 163.6, 161.1, 145.5, 136.5, 134.5, 131.7, 130.3, 129.2, 129.0, 128.8, 128.5, 120.9, 62.8, 51.5, 35.5, 32.6, 27.7, 26.6, 25.4. MS (ESI)$^+$: 442.2 Da [M + Na]$^+$.

(*Z*)-6-(7-Chloro-5-(4-chlorophenyl)-1-methyl-2-oxo-1*H*-benzo[*e*][1,2,4]triazepin-3(2*H*)-yl)hexyl 4-Methylbenzenesulfonate (7). A solution of compound **6** (182 mg, 0.43 mmol) and triethylamine (188 μL, 1.3 mmol) in dry dichloromethane (6 mL) was stirred at 0 °C for 5 min. *p*-Toluenesulfonyl chloride (298 mg, 1.56 mmol) was added slowly to the above solution. The resulting mixture was warmed to room temperature and stirred overnight. The reaction was then quenched with 20 mL of water and extracted with dichloromethane (3 × 20 mL). The combined organic layers were dried over sodium sulfate and concentrated by vacuum rotary evaporation. The crude product was purified by silica gel chromatography using a 1:19 to 2:3 ethyl acetate/hexanes gradient as eluent. Compound **7** was isolated as a yellow oil (238 mg, 96%). ^{1}H NMR 300 MHz ($CDCl_3$) δ 7.77 (dm, J = 8.1 Hz, 2H), 7.54−7.51 (m, 2H), 7.46 (dd, J = 8.7, 2.4 Hz, 1H), 7.52−7.39 (m, 2H), 7.33 (d, J = 7.8 Hz, 2H), 7.12 (d, J = 8.7 Hz, 1H), 7.06 (d, J = 2.4 Hz, 1H), 3.97 (t, J = 6.3 Hz, 2H), 3.70−3.40 (m, 2H), 3.23 (s, 3H), 2.44 (s, 3H), 1.62−1.55 (m, 4H), 1.31−1.21 (m, 4H). MS (ESI)$^+$: 596.3 Da [M + Na]$^+$.

C_6Ro5-4864 (8). A sealed tube with a solution of compound **7** (25 mg, 44 μmol) in methanol (1 mL) was cooled to −78 °C and flushed with ammonia gas. After about 2.5 mL liquid ammonia was condensed, the tube was sealed and warmed to room temperature. The reaction was stirred under room temperature overnight. The mixture was concentrated by nitrogen flow, redissolved by dichloromethane, and treated with a saturated sodium bicarbonate solution. The mixture was extracted with dichloromethane three times. The organic layers were combined, dried over sodium sulfate, and concentrated by vacuum rotary evaporation. The crude product was purified by column chromatography (silica gel) using a gradient with dichloromethane and dichloromethane/methanol/ammonia (6:1:0.1) as the eluent. C_6Ro5-4864 was collected as a pale yellow oil (14 mg, 77%). ^{1}H NMR 300 MHz ($CDCl_3$) δ 7.55−7.51 (m, 2H), 7.45 (dd, J = 8.7, 2.4 Hz, 1H), 7.41−7.37 (m, 2H), 7.12 (d, J = 8.7 Hz, 1H), 7.06 (d, J = 2.4 Hz, 1H), 3.80−3.45 (m, 2H), 3.23 (s, 3H), 2.62 (bs, 2H), 1.65 (bs, 2H), 1.49−1.38−1.24 (m, 8H). ^{13}C NMR 75 MHz ($CDCl_3$) δ 163.6, 161.1, 145.5, 136.4, 134.5, 131.7, 130.2, 129.2, 129.0, 128.8, 128.5, 120.9, 51.5, 42.1, 35.5, 33.7, 27.7, 26.6, 26.5. MS (ESI)$^+$: 419.3 Da [M + H]$^+$.

Lissamine−C_6Ro5-4864. A mixture of lissamine rhodamine B sulfonyl chloride (mixed isomers) (10 mg, 17 μmol), C_6-Ro5-4864 (8 mg, 19 μmol), and triethylamine (15 μL) in dry dichloromethane (1.6 mL) was stirred at room temperature under argon flow for 2 h. The product was purified through column chromatography (silica gel) using a mixture of 24:1 dichloromethane:methanol as the eluent. Lissamine−C_6Ro5-4864 was isolated as a pink solid (Isomer I, 3.2 mg, 19%; Isomer II, 2.2 mg, 13%). ^{1}H NMR 500 MHz ($CDCl_3$) **Isomer I**: δ 8.81 (d, J = 2.0 Hz, 1H), 7.96 (dd, J = 8.0, 1.5 Hz, 1H), 7.55−7.53 (m, 2H), 7.47 (dd, J = 8.5, 2.5 Hz, 1H), 7.41−7.39 (m, 2H), 7.29 (d, J = 9.5 Hz, 2H), 7.20 (d, J = 8.0 Hz, 1H), 7.15 (d, J = 9.0 Hz, 1H), 7.07 (d, J = 2.0 Hz, 1H), 6.81 (dd, J = 9.5, 2.5 Hz, 2H), 6.66 (d, J = 2.5 Hz, 2H), 4.99 (t, J = 6.5 Hz, 1H), 3.50−3.59 (m, 8H), 3.23 (s, 3H), 3.01 (q, J = 7.0 Hz, 2H), 1.69−1.58 (m, 6H), 1.55−1.50 (m, 2H), 1.29 (t, J = 7.5 Hz, 14H). **Isomer II**: δ 8.66 (s, 1H), 8.38 (dd, J = 8.0, 1.0 Hz, 1H), 7.52−7.50 (m, 2H), 7.46 (dd, J = 8.5, 2.5 Hz, 1H), 7.38−7.36 (m, 2H), 7.23 (d, J = 7.5 Hz, 1H), 7.17 (d, J = 9.5 Hz, 1H), 7.14 (d, J = 9.0 Hz, 1H), 7.04 (d, J = 2.5 Hz, 1H), 6.85 (dd,

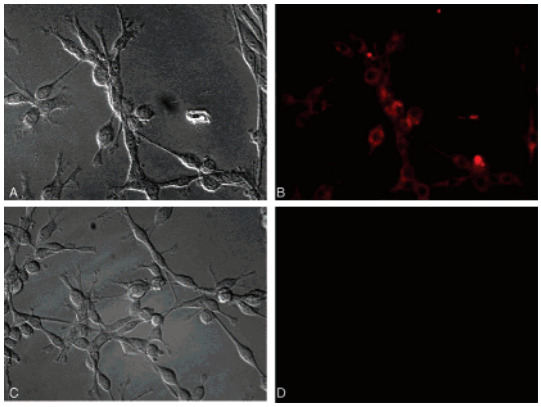

Figure 2. Fluorescence imaging of C6 rat glioma cells: (A) phase contrast microscopy of cells dosed with lissamine−C_6Ro5-4864; (B) fluorescence imaging of cells dosed with 100 nM lissamine−C_6Ro5-4864; (C) phase contrast microscopy of cells dosed with lissamine dye; (D) fluorescence imaging of cells dosed with 100 nM lissamine dye (control).

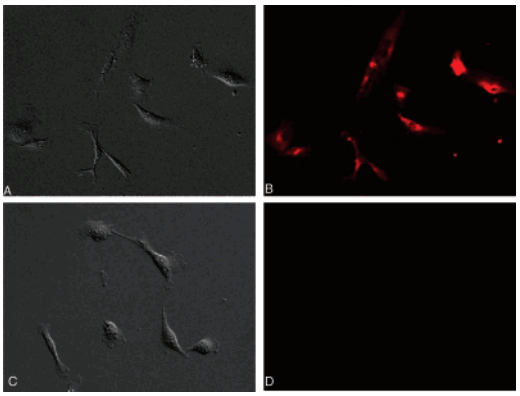

Figure 3. Fluorescence imaging of MDA-MB-231 human breast cancer cells: (A) Phase contrast microscopy of cells dosed with lissamine−C_6Ro5-4864; (B) fluorescence imaging of cells dosed with 100 nM lissamine−C_6Ro5-4864; (C) Phase contrast microscopy of cells dosed with lissamine dye; (D) fluorescence imaging of cells dosed with 100 nM lissamine dye (control).

J = 9.5, 1.5 Hz, 2H), 6.70 (d, J = 2.5 Hz, 2H), 5.24 (bs, 1H), 3.63−3.55 (m, 8H), 3.21 (s, 3H), 2.89 (q, J = 6.5 Hz, 2H), 1.72−1.61 (m, 9H), 1.33 (t, J = 7.5 Hz, 14H). MS $(ESI)^+$: 981.4 Da $[M + Na]^+$. Rf 0.23 (Isomer I), 0.14 (Isomer II) (4% methanol in dichloromethane).

Spectroscopic Characterization. The lissamine−C_6Ro5-4864 absorption and emission spectra (Figure 1) were obtained using a Shimadzu 1700 UV−vis spectrophotometer and ISS PCI spectrofluorometer at room temperature on a 5 μM sample.

Binding Studies. C6 glioma cells were cultured in Dulbecco's modified Eagle medium (DMEM)-F12 medium (Gibco/Invitrogen) supplemented with 0.5% FBS and 2.5% horse serum (HS) at 3.7% CO_2. Cells were scraped from 150 mm culture dishes into 5 mL of phosphate-buffered saline (PBS), dispersed by trituration, and centrifuged at 500*g* for 15 min. Cell pellets were resuspended in PBS and assayed for protein concentration. [^{3}H]PK11195 binding studies on 30 μg of protein from cell suspensions were performed as previously described (*12*). Displacement studies using increasing concentrations of lissamine−C_6Ro5-4864 were performed in the presence of 15 nM [^{3}H]PK11195. Data were analyzed using PRISM software (vs 4.0, GraphPad, Inc., San Diego, CA).

Cell Imaging. C6 rat glioma and MDA-MB-231 human breast carcinoma cells were plated in MaTek dishes. The growth media was removed and replaced with media containing the contrast agent. C6 and MDA-MB-231 cells were dosed with 100 nM lissamine−C_6Ro5-4864 for 30 min at 37 °C under 5% CO_2. Cells dosed with 100 nM free lissamine dye were imaged as control. At the end of the incubation time, cells were rinsed with PBS three times and imaged under a Nikon Eclipse TE2000-U microscope (Lewisville, TX).

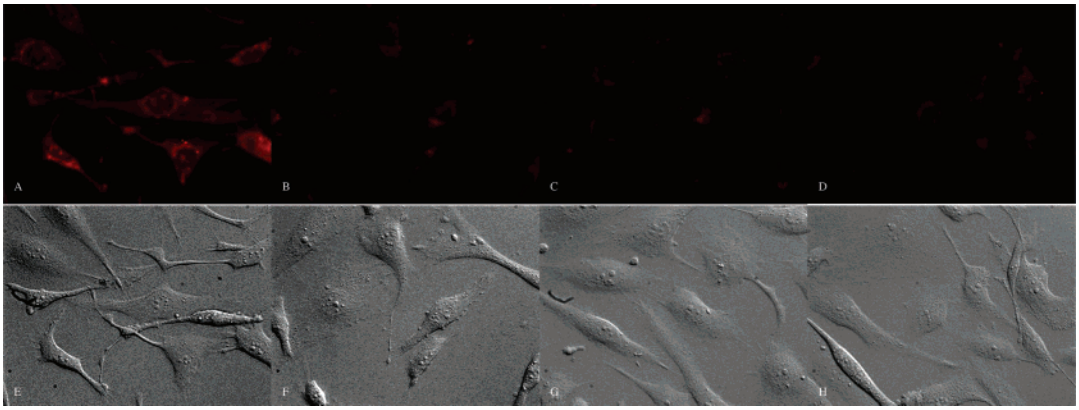
In Vitro Competition. MDA-MB-231 human breast carcinoma cells were plated in MaTek dishes. The growth media was removed and replaced with media containing the contrast agent. Unchallenged MDA-MB-231 cells were dosed with 5 μM lissamine−C_6Ro5-4864. Unchallenged cells were dosed with 5 μM lissamine−C_6Ro5-4864 and PK1195 (500 nM, 5 μM or 50 μM). All cells were incubated for 30 min at 37 °C under 5% CO_2. At the end of the incubation time, cells were rinsed with PBS three times and imaged under a Nikon Eclipse TE2000-U microscope (Lewisville, TX).

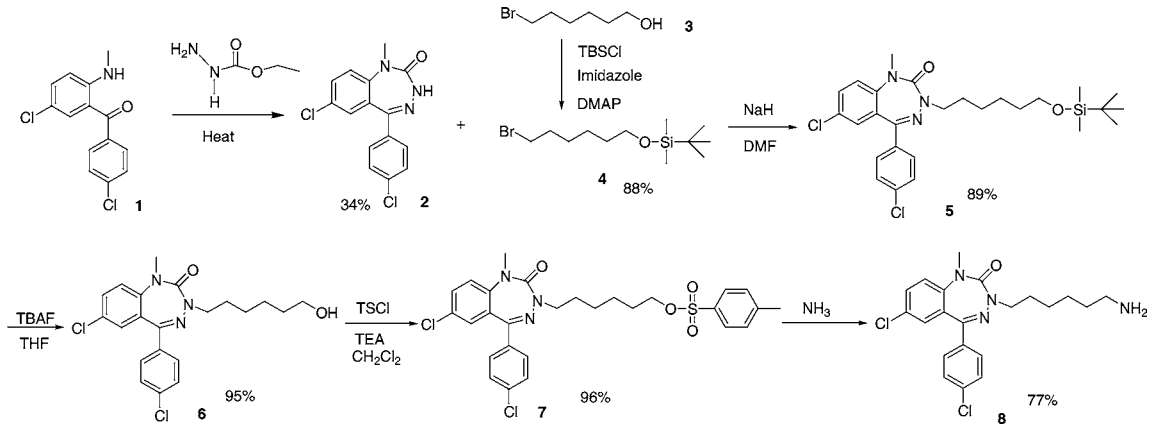
RESULTS AND DISCUSSION

Synthesis. The overall goal of this synthetic effort was to construct a conjugable TSPO ligand with a biologically active portion of Ro5-4864. (5-Chloro-2-(methylamino)phenyl)(4-chlorophenyl)methanone **1** was synthesized from commercially available 4-chloro-phenylacetonitrile and 4-chloronitrobenzene as reported (*13*). After several unsuccessful attempts using semicarbazide and high-boiling solvents to induce a ring-closure reaction with **1**, we synthesized the triazepinone **2** by heating a mixture of ethyl semicarbazide and **1** at 210 °C without any solvent (Scheme 1). The *tert*-butyldimethylsilyl (TBS)-protected six-carbon linker **4** was added to **2** by an N-alkylation reaction. It is noteworthy that two other linkers, 1,3-dihydro-1,3-dioxo-2*H*-isoindole-2-hexanoic acid and 6-nitrohexanoic acid were also employed, but we were unsuccessful in achieving the final product. After the TBS group in **5** was removed via TBAF, the hydroxyl group in **6** was converted to a tosyl group and subsequently reacted with ammonia to yield the final product **8**.

Since the commercially available lissamine−rhodamine B sulfonyl chloride is a mixture of two isomers (Scheme 2), the N-sulfonylation reaction between C_6Ro5-4864 and the fluorescence dye produced two isomer products. It was possible to isolate these two products through silica gel column chromatograph (R_f is 0.23 for isomer I and 0.14 for isomer II in 4% methanol in dichloromethane). Isomers I and II have a similar maximum absorption (isomer I: 561 nm; isomer II: 563 nM) and emission (isomer I: 583 nm; isomer II: 585 nm) wavelength to that of the free lissamine dye (Abs = 568 nm and Fluo = 583 nm) and Liss-ConPK11195 (Abs = 571 nm and Fluo = 585 nm) (Figure 1) (*8*). However, the molar extinction coefficients of the produced isomers are significantly different (isomer I: 175 000 L/mol cm; isomer II: 91 000 L/mol cm). Isomer I has much higher ϵ than lissamine−rhodamine B sulfonyl chloride (ϵ = 88 000 L/mol cm), which indicates that C_6Ro5-4864 produces a positive effect on lissamine's absorptive property. The molar extinction coefficient of Liss-ConPK11195 was reported as 350 000 L/mol cm, which is lower than isomer I but higher than isomer II. Isomer I was selected for imaging due to the relative high absorption and fluorescence (Figure 1).

Cell Imaging and Binding Study. The cellular uptake of lissamine−C_6Ro5-4864 was examined in C6 rat glioma and MDA-MB-231 human mammary adenocarcinoma cells by fluorescence microscopy. Both cell types were previously shown to contain relatively high levels of TSPO (*14*, *15*). The resulting images were compared with those obtained using the same concentrations of the free lissamine dye as control. Cell uptake of lissamine−C_6Ro5-4864 was observed in fluorescence images of both cell lines (Figures 2and 3, panel B) while the control exhibited no significant fluorescence. Images using Liss-ConPK11195 showed similar quality (*8*).





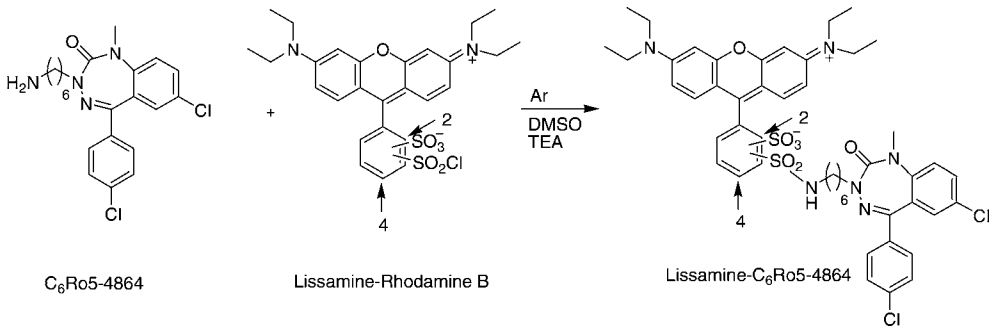


Figure 4. Fluorescence imaging of MDA-MB-231 human breast cancer cells: (A) fluorescence imaging of cells dosed with 5 μM lissamine−C_6Ro5-4864; (B) fluorescence imaging of cells dosed with 5 μM lissamine−C_6Ro5-4864 and 500 nM PK11195; (C) fluorescence imaging of cells dosed with 5 μM lissamine−C_6Ro5-4864 and 5 μM PK11195; (D) fluorescence imaging of cells dosed with 5 μM lissamine−C_6Ro5-4864 and 50 μM PK11195; (E−H) corresponding phase contrast microscopy.

Scheme 1 . Synthesis of C_6-Ro5-4864

Scheme 2 . Synthesis of Lissamine−C_6Ro5-4864

Radioligand binding studies further demonstrated specific binding of lissamine−C_6Ro5-4864 to the TSPO protein. In these studies, [^{3}H]PK11195, the well characterized diagnostic TSPO drug ligand, was used as the competitive radioligand. The concentration of lissamine−C_6Ro5-4864 tested varied from 10^{-11} M to 10^{-4} M in the competitive binding assays performed. The K_i value derived from IC_{50} was calculated to be 2.6 ± 1.4 μM, which is similar to Liss-ConPK11195 (1 μM) (*8*). Even though the binding affinity is significantly lower than that of [^{3}H]Ro5-4864 (K_i = 5 nM) (*16*), the selective binding of lissamine−C_6Ro5-4864 to TSPO is clearly shown and visualized. The specificity of lissamine−C_6Ro5-4864 to TSPO is further verified by in vitro competition study. In this experiment, MDA-MB-231 cells were treated with 5 μM lissamine−C_6Ro5-4864 and PK11195 with different concentrations as competitor. Challenged cells showed reduced fluorescence signal compared to unchallenged cells (Figure 4). Taken together these data suggest that lissamine−C_6Ro5-4864 is a promising TSPO targeted MI agent.

CONCLUSIONS

We synthesized and characterized a conjugable form of the benzodiazepine Ro5-4864, C_6Ro5-4864, which can be conjugated to a variety of signaling moieties for TSPO-targeted imaging. This TSPO ligand has been coupled to a fluorescent dye, and the resulting imaging agent, lissamine−C_6Ro5-4864, displays attractive optical properties for fluorescence microscopy imaging. The specific binding of this agent to TSPO was demonstrated by radioligand binding studies and live cell imaging on MDA-MB-231 breast cancer and C6 glioma cells.

Synthesis and Testing of a Binary Catalytic System for Imaging of Signal Amplification *in Vivo*

Alexei Bogdanov, Jr.,* Hye-Won Kang, Manuel Querol, P. Hendrik Pretorius, and Anna Yudina†

Department of Radiology, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, Massachusetts 01655. Received December 18, 2006; Revised Manuscript Received February 21, 2007

We report a binary targeted enzymatic system that is composed of two covalent monoclonal antibody conjugates for specific labeling of cellular targets *in vivo*. The system utilizes low-molecular weight peroxidase-reducing substrates synthesized by linking 5-hydroxytryptamine (serotonin) with DTPA (5HT−DTPA) for magnetic resonance and radionuclide imaging or with Cy5.5 for near-infrared optical imaging. Initially, the conjugation reaction conditions were optimized to achieve a low level of antiepidermal growth factor receptor (EGFR) antibody (EMD 72000) modification with the *N*-hydroxysuccinimide ester of 4-hydrazinonicotinate acetone hydrazone (SANH), yielding mAb−HNH conjugate. The resultant modified antibodies were incubated with the periodate-oxidized peroxidase (HRP) or 4-formylbenzoyl-conjugated glucose oxidase (GO), followed by the purification of the resultant mAb−enzyme conjugates by size-exclusion HPLC. The conjugates were further characterized by electrophoresis and were tested by cross-titration on A431 EGFR+ squamous carcinoma or SW620 adenocarcinoma cells (negative control). The conjugates at the optimized concentration ratios were further tested using near-infrared fluorescence microscopy in the presence of Cy5.5 monocarboxy-5-hydroxytryptamide. Further *in vitro* experiments demonstrated that (1) antibody binding was specific and could be inhibited by free antibody; (2) both antibody conjugates exhibited high enzymatic activity after the binding to the cells; (3) ^{111}In-labeled 5-HT−DTPA was avidly binding to EGFR-positive cells only if both HRP- and GO-conjugates were bound to the cells. The conjugates were tested *in vivo* using a SPECT imaging experiment, which demonstrated the accumulation of ^{111}In-labeled 5-HT−DTPA substrate at the site containing both conjugates.

INTRODUCTION

In vivo targeting of disease-specific molecules has been a subject of investigation as a diagnostic tool for decades, primarily with a goal of detecting and treating cancer (*1*). Recent advances in the use of therapeutic monoclonal antibodies suggested that the old paradigm has been finally transformed into a highly important clinical tool (*2*). The two major reasons for this success are (1) identification of relevant target molecules and signaling cascades; (2) elimination of immunogenicity through new technologies, i.e., antibody engineering (including humanization of monoclonal antibodies) (*3*). In addition, a variety of semisynthetic and engineered alternatives to mouse hybridoma-secreted monoclonal antibodies have emerged since the 1990s, including single chain antibodies (*4*) and minibodies (*5*), phage display library-derived peptides (*6*, *7*), and aptamers (*8*, *9*). In general, the use of protein engineering and combinatorial techniques are expected to significantly shorten the development of new targeted agents and to utilize mainly *in vitro*-based selection procedures. The engineered molecules with a single target-binding domain or sequence can be further di- or multimerized to increase the avidity and target tissue accumulation (*10*). In diagnostic imaging this is frequently achieved by using the imaging component (i.e., nanoparticle) as a multimeric reactive center (*11, 12*). Regardless of whether single-, bi-, or multimeric targeted molecules are used for delivery of diagnostic compounds, the results of *in vivo* imaging depend largely on the distribution of the image signal-generating component of the targeted imaging drug or a construct (reviewed in (*13*)). This component can be linked to targeting molecules either directly (i.e., radionuclide (*14*) or a fluorochrome (*15*)) or indirectly (e.g., linked via polymeric carrier (*16*, *17*) and incorporated into liposomes or micelles (*18*)).

Alternatively, a pretargeting approach can be used for *in vivo* imaging and therapy (*19*−*21*). This concept includes *in vivo* administrations of targeting and imaging compounds that are separated in time. This approach is based on high affinity/complementarity of imaging compounds or conjugates to targeting molecules, which are administered first. By carefully choosing pharmacokinetics of the first (targeted) molecule and the second (imaging ligand) molecule, it is feasible to improve sensitivity of imaging because of the higher target-to-background ratios. Since most of the high-affinity receptor-specific molecules (e.g., antibodies, their fragments, and dimerized scFv (*14*, *22*)) have relatively long blood half-lives, the availability of a "waiting time window" allows clearance of free targeting molecules. This eliminates the unnecessary and lengthy exposure to imaging ligand that could lead to increased immunogenicity and/or undesirable dosimetry profiles. Consequently, the pretargeting approach was adapted to labeled biotin (*23*), small molecular weight imaging ligands (*24*, *25*), oligonucleotides (*26*), oligonucleotide analogues (*27*), polymers (*28*), and conjugates of avidin with imaging ligands (*29*).

We hypothesized that pretargeting strategy could be combined with enzyme-mediated signal amplification for *in vivo* imaging (*30*) and applied this concept for imaging cell-surface receptors in human carcinomas using MRI (*31*). We report here a binary EGF[1]-receptor (EGFR) targeted catalytic system based on enzymatically coupled conversion of fluorochrome- and radionuclide-labeled imaging substrates into the tissue-bound species

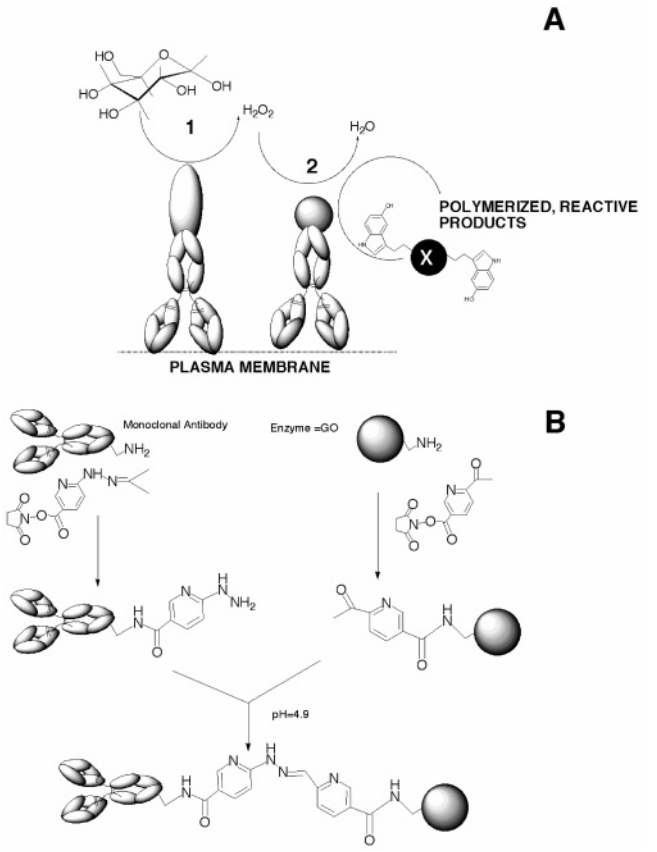

Figure 1. A. A scheme of the proposed two-enzyme (binary) targeted signal amplification system. The first conjugate (mAb−GO) provides the source of peroxide by oxidizing glucose, which is present in the extracellular milieu. The second conjugate (mAb−HRP) reduces peroxide and oxidizes imaging substrates bearing hydroxyindole or hydroxybenzene groups. X = paramagnetic element, radionuclide, fluorochrome. B. Antibody−enzyme conjugation via the formation of a stable hydrazone.

(schematically shown in Figure 1A). We anticipate that such binary systems could be useful for single- or multimodality imaging of EGFR and other cancer-specific cell-surface targets.

MATERIALS AND METHODS

Peroxidase-Reducing Substrate Synthesis and Characterization. Synthesis of di-5-hydroxytryptamide−DTPA (5HT−DTPA) was performed as described by us previously (*32*, *33*). Briefly, to a suspension of DTPA-bis(anhydride) (0.357 g, 1 mmol) in 30 mL of dry DMF was added a solution of 2.2 mmol of dry triethylamine and 2.2 mmol of 5-hydroxytryptamide (serotonin) in 10 mL under argon, and the mixture was stirred at room temperature for 48 h. The completion of the reaction was determined by using C18 RP-TLC. The solvent was removed under vacuum, and the crude mixture was solubilized in 50 mL of 0.5 M triethylammonium acetate in water (50 mL, pH 7.0). The solution was washed twice with 25 mL of methylene chloride and evaporated again to give a white powder. The powder was solubilized in MeOH and precipitated by slow acetone diffusion. This procedure was repeated three times to afford di-5-hydroxytryptamide−DTPA with a yield of 58%. ^{1}H NMR (DMSO-d_6), δ (ppm): 2.70 (4H, t, J = 7.6 Hz), 2.89 (4H, t, J = 7.6 Hz), 3.10 (4H, m), 3.21 (4H, s), 3.24 (4H, s), 3.29−3.31 (4H, m), 3.46 (2H, s), 6.56 (2H, dd, J_1 = 6.4 Hz, J_2 = 2.2 Hz), 6.93 (2H, d, J = 2.1 Hz), 7.02 (2H, d, J = 2.1 Hz), 7.09 (2H, d, J = 8.6 Hz), 8.42−8.45 (2H, m), 10.05 (2H, s). FAB-MS: 710, $^+$. The obtained chelate was purified by using preparative HPLC (HAISIL 100 C-8, Higgins Analytical, 10−90% acetonitrile/water gradient (yield, 40%).

Fluorescent substrate (Cy5.5 monocarboxy-5-hydroxytryptamide, Figure 1S) was synthesized by reacting 1.1 molar excess of 5-hydroxytryptamine with Cy5.5-NHS (GE Healthcare Bio-Sciences Corp., Piscataway NJ) in DMF in the presence of triethylamine. The reaction product was precipitated using 10 volumes of acetone:diethyl ether (1:2 by vol), dried under argon, and purified by using C18 HPLC (Discovery C18 column, Supelco, St. Louis, MO) and a gradient of acetonitrile in 0.1 M triethylammonium acetate, pH 7.0 (see Supporting Information).

The peroxidase-reducing properties of synthesized substrates were tested by spectrofluorometry (5HT−Cy5.5) using a Cary Eclipse instrument (Varian Inc., Palo Alto, CA) as well as test labeling with ^{111}In and analytical separation on a C18 HPLC column (Discovery, Supelco, Sigma-Aldrich, St. Louis, MO). Approximately 1 μg of peroxidase and glucose oxidase conjugates was combined with various concentrations of substrates in the presence of 5 mM glucose in PBS, pH 7.5, and incubated for 10 min. Additionally, human serum albumin was added at 40 mg/mL (final concentration) in some experiments. Fluorescence was assayed by measuring changes of fluorescence spectra in the range of 690−800 nm using excitation at 675 nm (Cary Eclipse, Varian) in the presence or absence of serum albumin (see Figure 2S).

Synthesis of Antibody Conjugates. Monocolonal antibodies (humanized EMD72000 mAb (*34*) and mouse mAb 425 (*35*, *36*) were provided by Merck KGaA, Darmstadt, Germany. Antibodies were dialyzed against 10 mM PBS, pH 7.5, before use. The concentration of NHS esters in commercially available preparations of *N*-hydroxysuccinimidyl 4-hydrazinonicotinate acetone hydrazone (SANH) and *N*-hydroxysuccinimidyl-C6−4-formylbenzoate (C6-SFB, both were obtained from Pierce Chemical Co., Rockford, IL) was determined by measuring *N*-hydroxysuccinimide release upon hydrolysis at pH 8.5 using spectrophotometry at 260 nm (ϵ_{260} = 8500 M^{-1} cm). Twelve nanomoles of mAb in 0.2 mL of 0.1 M sodium bicarbonate, pH 8, was covalently modified using 1.5 μL of SANH in DMF (60 nmol of active ester, i.e., 5-fold molar excess over the protein) and incubated for 30 min at room temperature. The modified antibodies were purified on Tween-20 blocked BioSpin P-30 minicolumns (Bio-Rad, Hercules, CA) equilibrated with 0.1 M sodium acetate, pH 4.9.

Stock solution of recombinant glucose oxidase (GO) from *Aspergillus niger* (EMD Merck-Calbiochem) was dialyzed with 0.1 M sodium acetate, pH 4.9. To 0.2 mL of 120 μM glucose oxidase (24 nmol) in 0.1 M sodium bicarbonate, pH 8, was added 2 μL of 44 mM C6-SFB (88 nmol) in DMF on a Vortex mixer. After 30 min incubation, GO-formyl benzoate was purified on BioSpin P-30 minicolumns as described above. Horseradish peroxidase (100 nmol, Type IX, Sigma) in 0.25 mL of 0.1 M sodium acetate, pH 7, was oxidized using a 5-fold molar excess of sodium periodate for 30 min in the dark, and the reaction was stopped by adding 0.1 M glycerol (final concentration) and purified as above. The amount of covalently conjugated 4-hydraziniumnicotinate was determined by using 4-nitrobenzaldehyde and measuring absorbance at 380 nm (ϵ = 22000 M^{-1} cm); conjugated 4-formylbenzoyl groups were determined by spectrophotometry at 350 nm (ϵ = 18000 M^{-1} cm). Protein concentrations were determined by using Micro BCA assay (Pierce).

4-Hydraziniumnicotinate-modified antibodies (final concentration, 2 mg/mL) were combined with the enzymes bearing aldehyde groups at molar ratios ranging from 1:3 to 1:1.5

[1] Abbreviations: DPBS, Dulbecco's phosphate-buffered saline; EGF, epidermal growth factor; GO, glucose oxidase; HRP, horseradish peroxidase; mAb, monoclonal antibody; DTPA, diethylenetriamine pentaacetic acid; SPECT, single photon emission computed tomography.

(antibody:enzyme) at pH 4.9. The incubation was completed in 12 h, and 2-hydrazinopyridine was added (final concentration 0.1 mM) to block the remaining aldehyde groups. The reaction mixture was loaded onto a Superdex 200 column (GE-Healthcare) and eluted with 0.1 M ammonium acetate, pH 7.0, at 0.5 mL/min. The peaks that were eluted earlier than 150 kD IgG marker protein and containing peroxidase or glucose oxidase activity were pooled separately, concentrated, and washed with PBS using Amicon Ultra-4 centrifugal filter units with an Ultracel-50 membrane (Millipore, Billerica MA) at 2800*g*. Concentrated conjugates were analyzed using 4−15% gradient SDS-PAGE minigels run at 60 V, followed by gel fixation and staining with Flamingo fluorescent reagent (Bio-Rad).

Radioiodination and Fluorescent- and ^{111}In-Labeling. A 100 μL amount of monoclonal antibodies (A425 mAb and EMD72000 mAb at 1 mg/mL) was radioiodinated by using Na^{125}I (Perkin-Elmer, Boston, MA) using Iodogen-coated tubes (Pierce) as described by the manufacturer and purified by using PD10 columns (GE-Healthcare). Radiochemical purity by ITLC-G was higher than 98% and exceeded 90% by SDS electrophoresis. Fluorescent labeling of A425 mAb was achieved by using a 5-fold molar excess of Alexa Fluor 488 NHS ester (Invitrogen) in 0.1 M sodium carbonate, pH 8.5, followed by purification on Bio-Spin P30 minicolumns (Bio-Rad).

Labeling of 5-HT−DTPA was performed by adding 800 μCi of ^{111}In chloride to a solution of 50 μg 5-HT−DTPA (65 nmol) in 0.1 mL of 10 mM sodium citrate, pH 5.0. After 15 min incubation, HPLC runs on a Discovery C18 analytical column eluted with a 10−75% acetonitrile gradient in water routinely showed a 95% binding of ^{111}In radioactivity to 5-HT−DTPA.

Cell Culture Experiments. A431 human squamous carcinoma, SW620 human adenocarcinoma, and MDCK epithelial cells were obtained and grown as recommended by ATCC. Cells were seeded on the surface of coverslip-bottomed chambers (Lab-Tek Chambered glass coverslips, Electron Microscopy Sciences, Hatfield, PA) for fluorescence microscopy or in 96-well plates for antibody-binding experiments. Alternatively, cells were detached using nonenzymatic methods, fixed with 4% formaldehyde, and used at $2-4 \times 10^5$/well for binding experiments. Binding experiments were performed in triplicate, curve fitting, and statistical analysis performed by using Prism 4 (Graph Pad Software Inc.).

EGFR expression on A431 cells was monitored by using Alexa Fluor 488-labeled A425 mouse monoclonal antibodies followed by flow cytometry (FACSCalibur, Beckton-Dickinson). In all binding experiments 0.2 μm-filtered 5% horse serum in DPBS, pH 7.2, was used for serial dilutions of the antibodies and conjugates. Peroxidase activity was determined by using ABTS substrate (Sigma-Aldrich). Glucose oxidase activity was determined by using a 1 μg/mL solution of horseradish peroxidase in 2 mM ABTS, 5 mM glucose, 10 mM sodium citrate, pH 6.0. In both cases, endpoint changes of optical density were measured at 405 nm after a 30 min incubation at room temperature (M5 plate reader, Molecular Devices Inc.).

Fluorescence microscopy was performed using inverted Nikon TE2000 Eclipse microscope equipped with Cy5.5 excitation/emission epifluorescence filters and CoolSNAP-HQ CCD (MVI Inc., Avon, MA). Cells were incubated with mAb−enzyme conjugates (1 μg/mL each conjugate in 0.2% BSA/DPBS) followed by washing in DPBS and incubating with 2 μM 5HT−Cy5.5, 5 mM glucose in DPBS. Control experiments were performed in the presence of Cy5.5-labeled A425 anti-EGFR antibody or 2 μM 5HT−Cy5.5, 5 mM glucose in DPBS in the absence of conjugates.

Experiments with 5-HT−[^{111}In]DTPA were performed in A431 cells or SW620 cells seeded in 96-well plates. Cells were incubated with various amounts of mAb−GO/mAb−HRP conjugate mixtures (concentration range 0−10 μg/mL of each mAb conjugate) or mAb conjugates incubated with the cells individually at the same concentrations. Cells were washed with 0.2% horse serum in DPBS followed by adding 1 nmol of 5-HT−[^{111}In]DTPA/well in 0.2 mL of 5 mM glucose in DPBS. In 30 min at room temperature, the cells were lysed and radioactivity was determined by gamma-counting (Packard Cobra 5003 gamma counter).

***In Vivo* Single Photon Computed Tomography Imaging (SPECT).** *In vivo* experiments were approved by UMass Medical School Institutional Animal Care and Use Committee. Initially, 0.25 mL of Matrigel (BD Biosciences, San Jose, CA) was mixed on ice with 5 μL aliquots of 0.2 mg/mL mAb−HRP and mAb−GO conjugate, respectively. Athymic (*nu/nu*) female mice (NCI) were injected with the above solution in a femoral muscle. The contralateral femoral muscle was injected with 0.25 mL of Matrigel alone. After Matrigel solidification, 0.2 mL of saline containing 500 μCi of 5HT−DTPA[^{111}In] was injected into a tail vein. HiSPECT imaging was performed at 4 h postadministration of the labeled substrate using Prism 3000 3-head SPECT (Picker, Cleveland, OH) using pyramid collimators equipped with six-pinhole whole body aperture plates allowing 40 × 90 mm field-of-view (Bioscan, Washington, D.C./Scivis Gmbh). The images were collected under anesthesia for a total of 20 min and reconstructed using Bioscan software. Biodistributions were performed after the experiment, and radioactivity was determined as above.

RESULTS

Characterization of Model Cell Lines. Using fluorescent anti-EGFR antibody and SW620 cells as negative control, we initially verified that A431 cells were more than 95% positive for EGFR expression by flow cytometry. In experiments with radiolabeled anti-EGFR monoclonal antibodies (mouse A425 anti-EGFR and EMD72000 mAbs), we determined that nonfixed A431 cells had approximately 1.06×10^6 total binding/uptake sites per cell. As shown by using fixed cells, at least 60% of these sites represented the true receptor binding sites. On the average, 425−450 ng of antibody saturated all binding sites on the surface of one million live A431 cells. EGFR-negative cells showed negligible amounts of cell surface association: the experiments with both MDCK and SW620 cells showed no concentration-dependent binding in both cell-based ELISAs and radioimmunoassays.

Conjugate Synthesis. Initially, we tested hydrazone bond formation between the SANH-modified antibody and SFB-modified glucose oxidase (Figure 1B) using hydraziniumnicotinate:mAb ratios in the range of 15:1 to 10:1 and various SFB:GO ratios. As a result, coincubation of the modified proteins resulted in a very rapid formation of conjugates. Within 2 h, light scattering at 600 nm increased two times. The conjugates formed at 80% antibody consumption yield showed little precipitation after centrifuging at 13000*g* for 10 min and eluted in the void volume of Superdex 200 columns (1.3×10^6 D exclusion limit). However, cell ELISA and cross-titration on A431 cells with HRP and GO mAb conjugates (Figure 2A) showed that GO conjugates were outcompeted by peroxidase conjugates in cell-based ELISA assays, indicating a substantial loss of antibody affinity in large conjugates formed with GO. According to the results of the 4-nitrobenzaldehyde reaction, after lowering SANH:mAb molar ratio to 5:1, four hydraziniumnicotinate groups were covalently linked per protein molecule, on the average. At this mAb modification ratio, the formation of large conjugates was avoided if both GO and HRP were reacted with mAbs at the ratio of 1.5 mol of enzyme per 1 mol of antibody. Higher enzyme:mAb ratios usually resulted in undesirable large macromolecular conjugates. Conjugates

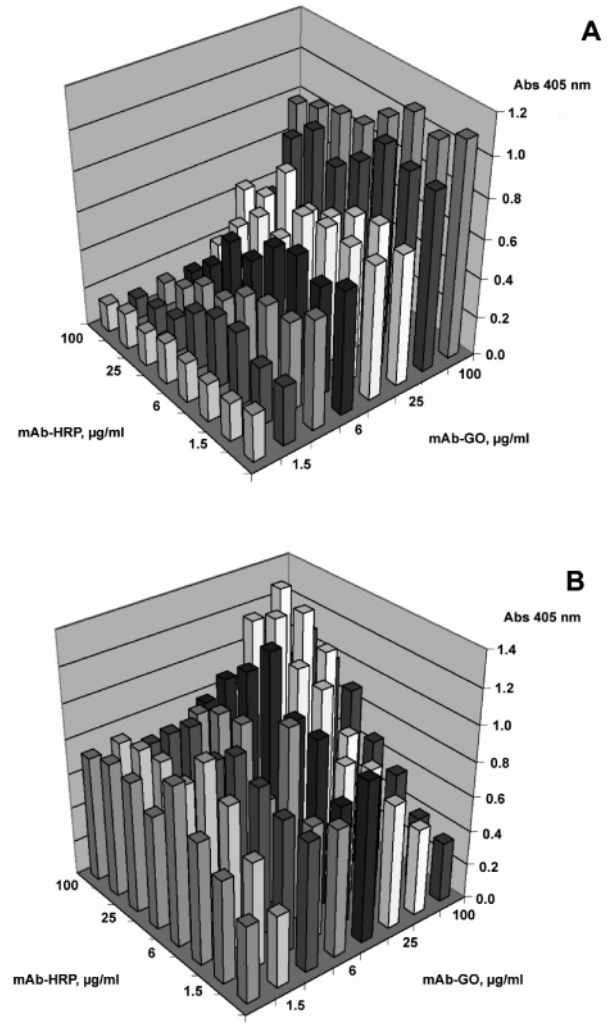

Figure 2. Cross-titration of A431 cells in 96-well plates using EMD72000 antibody conjugates. A. An example of titration results showing mAb−GO conjugates outcompeted by mAb−HRP. B. an example of titration using optimized mAb−GO conjugates that preserve binding affinity.

obtained by using lower active ester/mAb ratios showed more favorable cross-titration profiles (Figure 2B) with less competition between the conjugates for cell binding sites. The preparative size-exclusion chromatography results (Figure 3A) suggest that two major peaks corresponding to 670 and 410 kD products in the case of GO and one peak having an average mass of 400 kD in the case of HRP were formed as a result of covalent conjugation. The corresponding SDS gel electrophoresis (Figure 3B) revealed heterogeneity of conjugation products showing the 400 kD HRP-linked product alongside higher order conjugates. The analysis of glucose oxidase−mAb conjugation products showed some dissociation into a free GO subunit and remaining conjugated product (320 kD, free 90 kD subunit and 410 kD conjugate). The first peak of eluted GO conjugates showed the presence of conjugates with a higher molecular mass. After blocking free aldehyde groups, the conjugates preserved their immunoreactivity and stability for 10−14 days with no detectable changes in enzymatic activity.

Cell Culture Experiments. Testing of conjugates using cross-titration showed that there is an optimal range of 5−1.2 μg conjugate/96 wells of GO and HRP (i.e., per 5×10^4 cells, on the average) which resulted in similar optical density values (greater than 1 AU under conditions used) and showed only a minor apparent concentration-dependent competition for cell binding sites. In these experiments the rate-limiting hydrogen peroxide was supplied by glucose oxidase-mediated oxidation

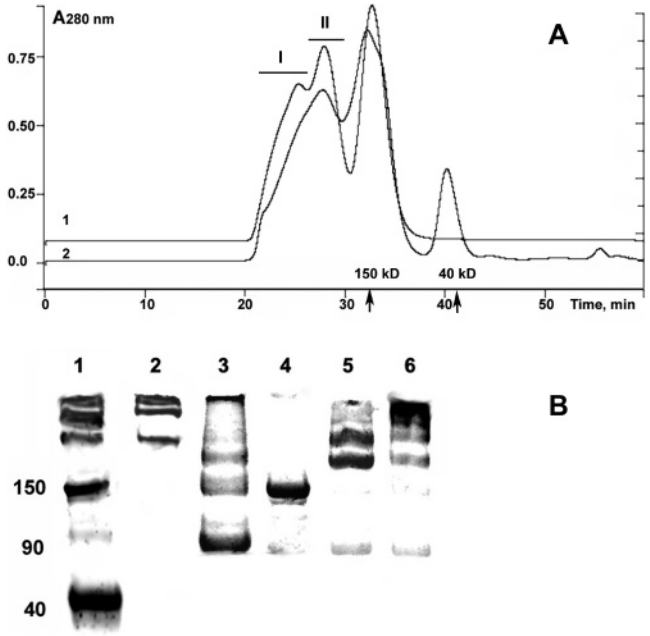

Figure 3. A. Size-exclusion HPLC separation of mAb conjugates with GO from the free antibody/GO peak (indicated by an arrow below "150 kD") (profile 1) and mAb−HRP conjugate separation from free HRP ("40 kD" arrow, profile 2). B. Gradient is 5−15% acrylamide/SDS gel electrophoresis: lane 1, mAb−HRP reaction mixture; lane 2, mAb−HRP conjugates; lane 3, mAb−GO reaction mixture; lane 4, mAb standard; lane 5, lower molecular weight conjugate peak of purified mAb−GO conjugates (peak II, Figure 3A); lane 6, higher molecular weight mAb−GO conjugates (peak I, Figure 3A).

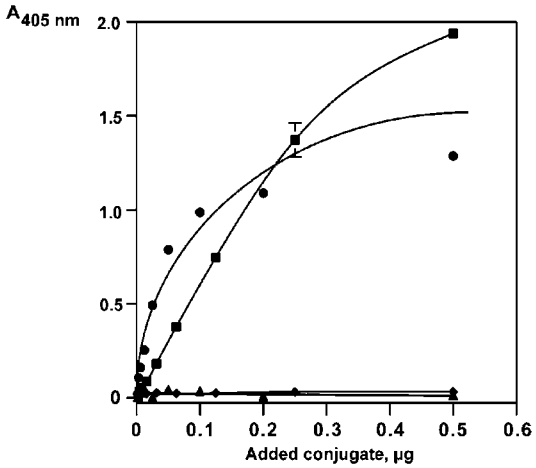

Figure 4. Cell ELISA: the dependence of peroxidase ABTS reaction signal from the conjugate concentration. HRP activity was determined directly (circles); GO activity was determined indirectly by using a 1 μg/mL solution of horseradish peroxidase in 2 mM ABTS, 5 mM glucose, 10 mM sodium citrate, pH 6.0 (squares). Nonspecific cell-associated activities of peroxidase (triangles) and glucose oxidase (diamonds) were measured in the presence of the excess of nonconjugated mAb (10 μg/mL). Data presented as mean ± SD ($n = 3$).

of D-glucose, which was present at 5 mM non-rate-limiting concentration. The enzymatic activity in the wells was then monitored after the conjugates were separately incubated with the cells (Figure 4). The ABTS reaction was performed either directly, i.e., in the presence of noninhibiting concentrations of hydrogen peroxide for determining mAb−HRP concentration-dependent binding, or indirectly, in the presence of an excess amount of HRP (0.1 μg of peroxidase/well) and 5 mM glucose to track the concentration dependence of mAb−GO binding. These experiments revealed the concentration-dependent binding of HRP conjugate and GO concentration-dependent hydrogen

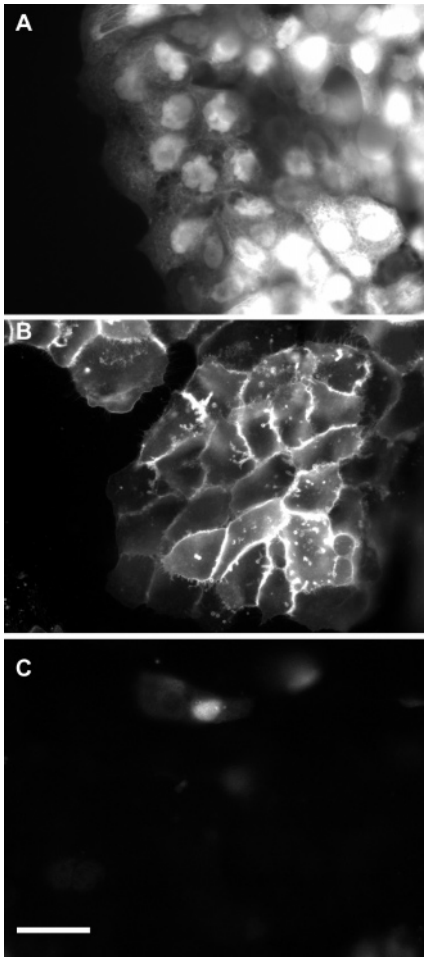

Figure 5. A. Fluorescence microscopy of A431 cells incubated with a mAb−HRP and mAb−GO conjugates (1 μg/mL) followed by 2 μM 5HT−Cy5.5 substrate, 5 mM glucose in DPBS. B. Fluorescence microscopy of A431 cells stained with Cy5.5-labeled A425 anti-EGFR monoclonal antibody (10 μg/mL). C. A431 cells incubated with a free 2 μM 5HT−Cy5.5 substrate in the absence of antibody conjugates.

peroxide release that was detected by enzymatically coupled HRP/ABTS reaction. In the presence of 10 μg of free mAb, enzymatic activity was completely absent due to binding inhibition (Figure 4).

Cells were then incubated in the presence of a mixture of 1 μg of mAb−HRP and mAb−GO each, washed, and treated with a near-infrared fluorescent substrate 5HT−Cy5.5 (see Figure 1S). This substrate was efficiently oxidized in the presence of glucose, GO, and HRP with a resultant loss of fluorescence (Figure 2S). However, if albumin was present in the solution, about 50% of the fluorescence was rescued (Figure 2S). After adding the substrate to cells, we observed a bright labeling of cell membranes, cytoskeleton, and nucleus (Figure 5A). The observed distribution of oxidized 5HT−Cy5.5 in the cells was markedly different from the distribution of Cy5.5−mAb (either 425 or EMD72000) on the surface of the cells (Figure 5B). If cells were incubated with the free dye in the absence of conjugates, only very few cells were permeated by the substrate (Figure 5C).

The formation of cell-bound products of 5-hydroxytryptamide oxidation was proven by using radioactively labeled di-5HT−[^{111}In]DTPA (90% radiochemical purity, see Figure 3S). In the presence of both HRP− and GO−mAb conjugates we observed binding of radioactivity to cells (Figure 5). The obtained cell protein-normalized binding curves suggested that the simultaneous presence of both conjugates in the well was essential for ^{111}In radioactivity association with cells since none of the

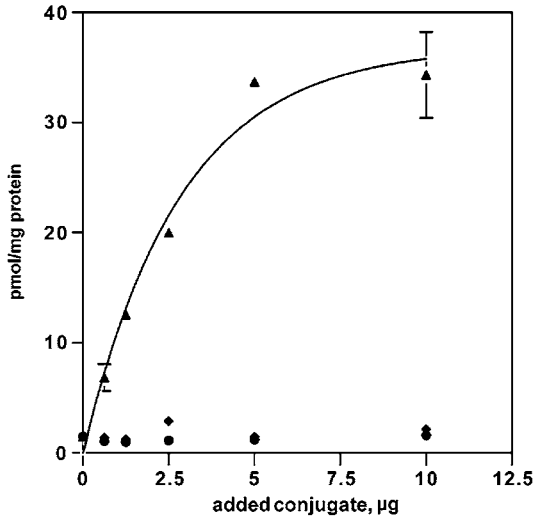

Figure 6. A431 cells incubated with a mixture of mAb−GO and mAb−HRP antibody conjugates at the concentrations indicated (triangles) or each conjugate separately (mAb−GO, diamonds; mAb−HRP, circles) in the presence of 5-HT−[^{111}In]DTPA (1 nmol/well in 5 mM glucose/DPBS). Data presented as mean ± SD (n = 3).

conjugates that individually bound to A431 cells showed the ability to oxidize the substrate with the formation of the cell-binding species.

***In Vivo* Experiments.** Finally, to establish whether the presence of conjugates can be detected *in vivo*, we performed a feasibility experiment by using a model *in vivo* system. We used a Matrigel semipermeable matrix pellet that served as a colocalization site of both conjugates used at the optimized concentrations. On the basis of *in vitro* data, the estimated 1 μg of each of the conjugates in 0.25 mL of Matrigel was the lowest saturating concentration required for the HRP−GO-coupled system to oxidize and convert the substrate with high efficacy. We mixed the conjugates with Matrigel at 4 °C and injected the solution into femoral muscles of mice. Contralateral enzyme-free Matrigel muscle injection served as a control. After the injection of a dose of [^{111}In]-labeled di-5HT−DTPA and 4 h of waiting to ensure the clearance of free molecule, we assessed binding of the substrate to Matrigel using SPECT imaging with subsequent biodistribution. The imaging allowed reconstruction of the remaining radioactivity (11% of injected dose, 60 μCi/mouse) distribution in the animals. We observed the overall higher signal in the conjugate-containing Matrigel implant if compared to the control. SPECT imaging allowed us to establish that the reacted substrate was retained primarily in the outer layer of Matrigel (Figure 6A). The model colocalization implant had bound [111In] radioactivity (5.2% injected dose/g) that was 7 times higher than the control (0.7% injected dose/g). The biodistribution showed that other major sites of activity accumulation were colon (1.1% injected dose/g) and bladder, suggesting some hepatobiliary excretion in addition to kidney filtration.

DISCUSSION

We previously reported that gadolinium (Gd) relaxivity increases as a result of oligomerization of phenolic chelates of Gd (*32*, *37*). The applications of this water relaxation effect ("MR signal amplification") were reported for imaging myeloperoxidase activity in model systems (*33*, *38*). The extension of this imaging approach beyond MRI suggested that similar substrates labeled with radionuclides could also be useful for imaging endogenous peroxidase activity (*39*). The accumulated data suggests that targeted delivery of enzymes capable of converting "imaging prodrugs" into reactive species could be

potentially used for imaging of a variety of target molecules *in vivo*. Recent reports describing metabolic cell surface biotinylation for cell targeting (*40*), as well the use Gd-amplification step for MRI of human carcinoma-targeted delivery (*31*), demonstrated the feasibility of the developed approach for *in vivo* imaging. Importantly, the use of "in situ catalysis" allows signal amplification in one step, without the need for additional adaptor proteins or multivalent particles. The approach is based on the delivery of targeted enzymes *in vivo* through biodistribution and clearance, followed by a chase with the imaging substrate ("prodrug"), biodistribution phase, and rapid clearance of free substrate. The latter scenario was modeled *in vivo* in this study. In addition, we summarized the results of the experiments aimed at synthesis, characterization, and testing of a binary catalytic targeted system that could be used for amplification-pretargeting of cell receptors *in vivo*.

We chose humanized anti-EGF receptor antibody (matuzumab) as a model because of the emerging use of these antibodies in treating advanced pancreatic cancer (*41*) and non-small cell lung cancer (*42*) as well as squamous cell carcinomas of head and neck (*43*). Our preliminary experiments demonstrated that hydrazone bond formation offers a simple and reliable approach allowing conjugation of these antibodies with glucose oxidase and peroxidase, respectively. However, the preservation of affinity of the resultant conjugates was critically dependent on the degree of antibody modification and molar ratios of reacting macromolecules. Only by selecting low modification ratios could we obtain conjugates with average masses lower than 700 kD that retained high affinity to cell EGF receptors. The optimized ratios of obtained purified conjugates were used to test two potential imaging substrates.

First, a covalent conjugate of 5-hydroxytryptamide and Cy5.5 dye was tested as a potential candidate for optical imaging of amplification-pretargeting. Near-infrared fluorochrome conjugation was chosen because of the known favorable tissue scattering and absorption characteristics of near-infrared fluorescence *in vivo* (*44*). Fluorescence microscopy of A431 cells incubated with GO− and HRP−mAb conjugates followed with a near-infrared substrate showed that unlike Cy5.5-labeled antibodies or nonoxidized substrate, the oxidized substrate was interacting with intracellular components (cytoskeleton and nuclei) which suggests chemical reactivity of the oxidized 5HT−Cy5.5. Apparently, the behavior of oxidized substrate was similar to that of myeloperoxidase-treated 5HT−DTPA(Gd) (*33*). The latter was binding tightly to albumin only after the enzyme-mediated oxidation. Overall, HRP-mediated oxidation of the near-infrared substrate resulted in a loss of fluorescence which was dramatically lowered by the presence of proteins or cells in the incubation medium.

Fluorescence microscopy results were supported by a demonstration of a highly specific cell binding of the second substrate tested in this study (5HT−[^{111}In]DTPA). The binding of radioactivity to cells was detected only if both GO and HRP conjugates were bound to the cells. The high specificity of radioactive substrate conversion into cell-binding species suggested that a colocalization of both conjugates at the same site or organ could potentially lead to very high target/background ratios provided the nonbound substrate does not have secondary nonspecific sites of accumulation *in vivo*. To test the potential use of the targeted catalytic system for imaging in live animals, we chose a model system previously used by us for myeloperoxidase activity imaging *in vivo* (*38*, *39*). This model system allows creation of a semipermeable reservoir that provides an artificial binding site for the enzyme-specific substrate.

On the basis of SPECT image reconstruction results (Figure 7), we concluded that imaging allows differentiation between artificial extracellular matrix implants which contained both conjugates and control implants lacking HRP and GO activity. This study suggested the need for further optimization of the time window between the administration of the radioactive substrate and imaging. It also suggested potential feasibility of targeted imaging in realistic models of human cancers. The advantage of such systems is in the potential high specificity of the imaging signal, which depends on efficiency of colocalization of both conjugates at the target site. However, there are still unsolved problems associated with the use of multicomponent targeting systems: (1) the need to account for potential differences in biodistribution between two conjugate components; (2) to need to attenuate the potential immune response to enzymes; (3) the need to control the size of conjugates to avoid nonspecific trapping of aggregated glucose oxidase-conjugated antibodies in the lung capillaries (*45*). It has been shown in the past that conjugated and unconjugated glucose oxidase has low systemic toxicity (*46*). The problem of conjugate aggregation was, in general terms, solved by developing an optimized conjugation protocol. However, the toxicity to tumor cells as a result of targeted delivery (*47*, *48*) should be treated as a factor that could potentially influence the imaging results.

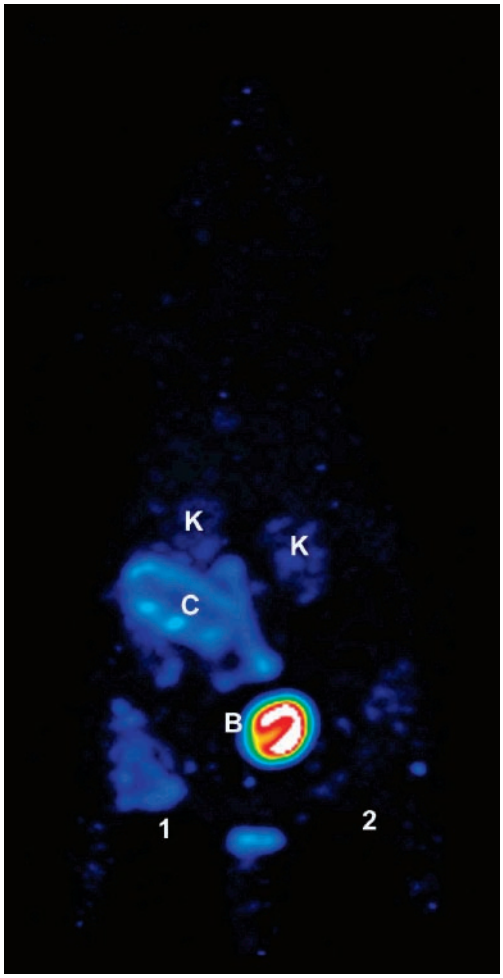

Figure 7. Single photon imaging of a mouse injected with a 0.25 mL Matrigel implant containing 1 μg each of mAb−HRP and mAb−GO (indicated as 1) and control implant 2. The animal was injected with 500 μCi of 5-HT−[^{111}In]DTPA followed by a 4 h waiting time window. SPECT imaging (20 min acquisition) was performed using Bioscan pinhole collimators using a three-head SPECT instrument.

In conclusion, we demonstrated that (1) the optimization of conjugation conditions results in stable covalent conjugates of antibodies with high yields of minimally cross-linked products; (2) the use of binary catalytic system could be potentially applied to several molecular imaging techniques (MRI, optical, and

radionuclide imaging); (3) binary targeted catalytic system enables imaging based on site-specificity, reducing substrate conversion into the cell-reactive species.

ACKNOWLEDGMENT

The authors acknowledge the input by Dr. Iris Verel (Philips Research) made during the initial phase of this work; Oncology Research, Global Preclinical R&D Merck KGaA for providing EMD72000 (Matuzumab). We are grateful to Dr. Mary Rucskowski (UMMS) for her help with radiochemical facility support. This work was supported in part by NIH RO1 EB000858.

In Vivo Antitumor Activity of the Folate-Conjugated pH-Sensitive Polymeric Micelle Selectively Releasing Adriamycin in the Intracellular Acidic Compartments

Younsoo Bae,[†,‡] Nobuhiro Nishiyama,[†,‡] and Kazunori Kataoka*[,†,‡,§]

Center for Disease Biology and Integrative Medicine, Graduate School of Medicine, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-0033, Japan, and Center for NanoBio Integration and Department of Materials Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan. Received December 26, 2006; Revised Manuscript Received March 2, 2007

Cancer treatment efficacy and safety of the environmentally sensitive polymeric micelle drug carriers were significantly increased by optimizing the number of ligands on their surface. These micelles were designed to target the cancerous tumors through the interaction between folate and its receptors that overexpress on the cancer cell membrane while achieving pH-controlled drug release in the intracellular acidic compartments such as endosomes and lysosomes. In order to elucidate the effects of folate on cytotoxicity, biodistribution, anticancer activity, and pharmacological properties, folate concentration on the surface of the micelles was controlled by precise synthesis of two different amphiphilic block copolymers that self-assemble into spherical micelles, folate−poly(ethylene glycol)−poly(aspartate-hydrazone-adriamycin) with γ-carboxylic acid activated folate and methoxy-poly(ethylene glycol)−poly(aspartate-hydrazone-adriamycin) without folate. It is of significance that, although folate conjugation induced an extremely small change in tumor accumulation of the micelles, folate-conjugated micelles showed lower in vivo toxicity and higher antitumor activity over a broad range of the dosage from 7.50 to 26.21 mg/kg, which was 5-fold broader than free drugs.

INTRODUCTION

Precise control of the amount and uniform distribution of ligands on nanoparticles is one of the most challenging assignments in the design of polymeric drug carriers for successful active drug targeting (*1*−*3*). Indeed, a large number of studies have shown that active drug targeting is promising for effective cancer treatment (*4*−*7*). However, the questions about how many ligands are necessary for achieving efficient active drug targeting of the polymeric drug carriers are still controversial and remain to be elucidated further. In particular, when such drug carriers are tailored to deliver anticancer drugs to cancer cells systemically, it is of significant importance to confirm whether the ligand conjugation maintains their pharmacokinetic properties without decreasing antitumor activity. It is because anticancer drugs are normally highly toxic, inducing serious side effects, and although ligands can increase the interaction between the drug carriers and targeted cells in the body, they might also induce an increase in the cellular interaction with nontargeted cells, that we are not willing to deliver drugs. In order to answer these questions, we have to prepare first a drug carrier with optimal amounts of ligands, whose chemical and biological properties are fairly well established and then ascertain whether ligand installation induces any change in its biological properties.

The rationales for tumor-specific drug delivery with polymers have been reported during the past decades and are based on the characteristics of tumor tissues such as disordered and leaky vasculatures, a thick extracellular matrix, and other microenvironmental peculiarities including the hypoxic environment, expression of cancer-specific receptors, and excessive secretion of cytokines (*8*−*9*). One of the widely accepted methodologies for polymeric drug delivery is to target leaky tumor vessels and the poorly developed lymphatic drainage in the tumor tissues so that polymers and their drug conjugates can pass the tumor blood vessel wall and then accumulate in tumor tissue for a prolonged time. This methodology is explained as the enhanced permeability and retention (EPR) effect, providing the most probable theory for passive drug targeting (*10*). Nevertheless, recent studies have revealed that tumor-targeting drug delivery cannot be completely achieved only by the EPR effect because polymeric drug carriers often encounter difficulties in accessing cancer cells in the deeper place of the tumor tissues or in interacting with the targeted cells after accumulation (*11, 12*). Polymeric drug carriers are normally required to have biocompatibility and high molecular weight to prevent protein adsorption that induces recognition by the body defense system and to increase the tumor accumulation via the EPR effect, respectively. However, these efforts frequently result in low cellular uptake of polymeric drug carriers after extravasation, reducing the actual drug concentration within the tumor due to the stagnation around the tumor tissue. As a result, we should inject polymeric drug carriers with a higher amount compared to free drugs to deliver a sufficient amount of drugs to the tumor. This is also the reason the current polymeric drug delivery systems urgently need to improve their targeting efficiency. From these aspects, active targeting has been believed to clear the problems by facilitating polymeric drug delivery systems (*13*). Active targeting can be achieved by installing ligands to the polymers or polymer assemblies so that they can interact with receptors that express on the targeted sites such as cancer cell membranes. Nevertheless, it is obvious that active targeting

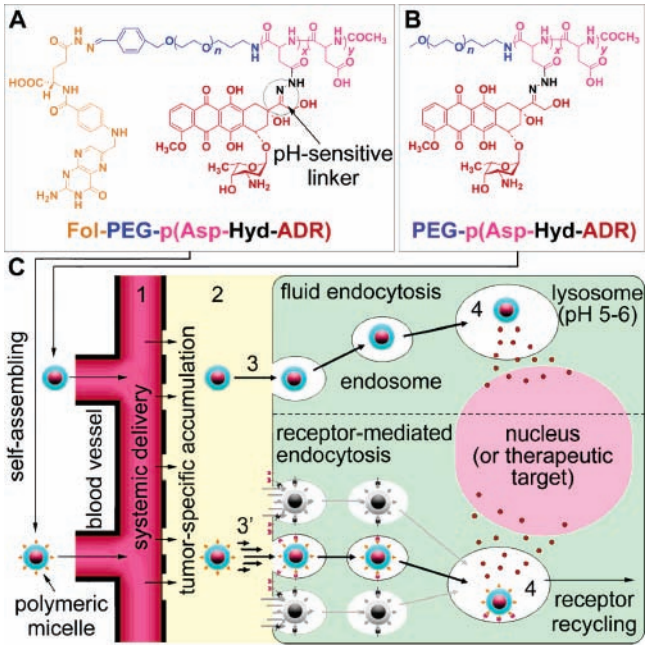

Figure 1. Design of polymeric micelles and the rationale for active drug delivery. Chemical structures of folate−poly(ethylene glycol)−poly(aspartate-hydrazone-adriamycin) and methoxy-poly(ethylene glycol)−poly(aspartate-hydrazone-adriamycin) block copolymers (A and B). As shown in panel C, these polymers can self-assemble into the polymeric micelles that can effectively achieve systemic drug delivery and tumor-specific accumulation (1 and 2). The micelles are then uptaken by the cancer cells via fluid endocytosis (3) or receptor-mediated endocytosis (3′) depending on surface design for accelerating endocytosis (e.g., folate conjugation). Anticancer drugs, adriamycin (ADR), that are conjugated through a pH-sensitive hydrazone bond can be released from the micelles in the acidic intracellular compartments such as endosomes or lysosomes where pH ranges from 5 to 6 (4).

cannot be achieved until passive targeting of drug carriers is successfully accomplished.

Amphiphilic block copolymers are useful tools for the preparation of supramolecular assemblies. By precisely controlling their molecular weight and the hydrophilic/hydrophobic balance, we can prepare spherical supramolecular nanoassemblies, also known as "the polymeric micelles", with a hydrophilic shell that envelopes a hydrophobic core (*14*). The polymeric micelle is considered to be one of the most successful polymeric drug carrier formulations, because it is characterized by high drug loading contents, prolonged blood circulation, and selective tumor accumulation (*15*). Most notably, their chemical, biological, and pharmacological properties have been widely studied, and thus we can easily investigate the effect of active targeting (*16, 17*). In this study, poly(ethylene glycol)−poly(β-benzyl-L-aspartate) block copolymers (PEG−PBLA) were synthesized for the basic platform for the preparation of the polymeric micelles, and these micelles were further functionalized to conjugate anticancer drugs and ligands. Figure 1 shows the chemical structures of the block copolymers used in this study. Anticancer drugs, adriamycin (ADR), were conjugated to the side chains of the core-forming poly(aspartic acid) block through a hydrazone linkage, which can be selectively cleaved under the acidic conditions with pH ranging from 5 to 6, corresponding to the intracellular vesicles such as the endosomes and lysosomes (*18*). In our previous studies, we have reported that this intracellular pH-sensitive polymeric micelle showed remarkably low toxicity and high in vivo efficacy (*19*). It was also confirmed that the pH-sensitive micelles can release drugs selectively by responding to a decrease in intracellular pH of the cell, and therefore, drug leakage from the micelles decreases during the blood circulation and tumor-specific drug delivery efficiency increases. In the meantime, folate was conjugated at the end of the shell-forming poly(ethylene glycol) (PEG) block for active targeting. Folate, an anionic form of folic acid, is a vitamin B9 that helps the production and maintenance of new cells. Originally, folate was necessary for the restoration of the DNA damage that may induce cancer. However, interestingly, cancer cells overexpress folate-binding proteins (FBPs) on their cell membranes (*20, 21*). This is probably due to the DNA replication that is supported by folate, which is also a prerequisite for the cancer growth. More interestingly, cancer cells are believed to reduce chemotherapeutical response by regulating intracellular folate concentration (*22*). Therefore, we can actively guide polymeric drug carriers to cancer cells in the body by folate conjugation (*23*). It must be noticed that FBP binding activity of folate drastically changes depending on its activated state, which is distinguished by an inactive α- and active γ-carboxyl activated form (*24*). Herein, we conjugated folate to PEG at its γ-carboxyl position to maintain its activity by precision synthesis as reported elsewhere (*25*−*27*).

The objectives of this research are to ascertain whether folate conjugation can enhance antitumor efficacy of the pH-sensitive micelles without deteriorating the characteristics of the micelles as a long-circulating drug carrier with high tumor accumulation, and to determine how much folate concentration is optimum for achieving effective passive and active drug targeting simultaneously. Such information would be beneficial to the future design and preparation of ligand-installed multifunctional polymeric drug carriers for cancer treatment.

EXPERIMENTAL PROCEDURES

Materials and Devices. Acetic anhydride (AA), chloroform ($CHCl_3$), *N*,*N*-dimethyl formamide (DMF), dimethyl sulfoxide (DMSO), hexane, methanol (MeOH), methanesulfonyl chloride (CH_3SO_2Cl), triethylamine (TEA), trifluoroacetic acid (TFA), trifluoroacetic anhydride (TFAA), and tetrahydrofuran (THF) were purchased from Wako Pure Chemical Industries, Japan. DMF, hexane, and THF were distilled twice following standard procedures. Carbazic acid *tert*-butyl ester (CAt-BE) and potassium carbonate (K_2CO_3) were purchased from Tokyo Kasei Organic Chemicals, Japan. These chemicals were used without further purification. Daunorubicin (DAU), folic acid (Fol), 4-(diethoxymethyl)benzaldehyde, and sodium borohydride ($NaBH_4$) were purchased from Sigma Chemical, U.S.A. Ethylene oxide (EO) was from Sumitomo Seika Chemicals, Japan, and dried over calcium hydride followed by distillation. β-Benzyl-L-aspartate (BLA) was from Sigma, and α-methoxy-ω-amino-poly(ethylene glycol) (MeO-PEG-NH_2) was from Nippon Oil and Fats, Japan. PEG was purified using an ion-exchange gel column (CM-Sephadex C-50, Amersham Pharmacia Biotech, U.S.A.) prior to the synthesis of the block copolymers. Adriamycin hydrochloride (ADR) was kindly provided by Nippon Kayaku, Japan, and its purity was checked by reversed-phase liquid chromatograpy (RPLC). Sephadex LH-20 gel was from Amersham Pharmacia Biotech, Sweden. Gel permeation chromatography (GPC) analysis was carried out using a TOSOH HLC-8220 equipped with TSK-GEL columns (G4000PWXL and G3000PWXL). Internal refractive index (RI) and ultraviolet−visible absorption (UV) detectors were used. DMF containing 10 mM of LiCl was used as an eluant at a flow rate of 0.8 mL/min at 40 °C. ^1H NMR spectra were measured with a JEOL EX300 spectrometer (JEOL, Japan). Flow cytometric analysis was performed with EPICS XL Flow Cytometry Systems (Beckman Coulter, U.S.A.). The multimode reader Mithras LB 940 (Berthold Technologies, U.S.A.) was used for in vitro cytotoxicity evaluation using a CellTiter-Glo luminescent cell viability assay kit (Promega, U.S.A.).

Cell Lines and Animals. A human pharyngeal cancer cell line KB was purchased from Health Science Research Resources Bank, Japan. Cells were cultured in Dulbecco's Modified Eagle cell culture Medium (DMEM, Sigma, U.S.A.) containing 10% FBS under a humidified atmosphere with 5% CO_2 at 37 °C. CD-1 nude mice (female, 6-week-old) were purchased from Charles River, Japan. The animals were cared for and all experiments were performed in compliance with the Guide for the Care and Use of Laboratory Animals as adopted and promulgated by the National Institutes of Health. The number of independent experiments is stated as *n*, and the experimental data are expressed as mean and mean ± SEM for relative and absolute values, respectively.

Synthesis of Self-Assembling Amphiphilic Block Copolymers. In this study, we synthesized two different types of self-assembling amphiphilic block copolymers for the preparation of the micelles, folate−poly(ethylene glycol)−poly(aspartate-hydrazone-adriamycin) [Fol−PEG−p(Asp-Hyd-ADR)] and methoxy-poly(ethylene glycol)−poly(aspartate-hydrazone-adriamycin) [PEG−p(Asp-Hyd-ADR)]. Synthesis methods for these block copolymers were previously reported elsewhere (*25*). Briefly, Fol−PEG−p(Asp-Hyd-ADR) was synthesized via seven steps as follows.

a. Synthesis of Heterobifunctional α*-4-(Diethoxymethyl)-benzylacetal-*ω*-amine-poly(ethylene glycol) (aceBz-PEG-NH_2).* 4-(Diethoxymethyl)benzaldehyde (5 g) was reduced with $NaBH_4$ (1 g) in dry ethanol (100 mL). Obtained 4-(diethoxymethyl)-benzylalcohol (0.19 g) was then mixed with potassium naphthalene (115 mg) in dry THF (30 mL) to prepare potassium 4-(diethoxymethyl)benzylalkoxide, followed by the addition of distilled EO (11.9 g) for anionic polymerization to obtain aceBz-PEG-OH. After 2 days of reaction at 25 °C, CH_3SO_2Cl (0.62 g) and TEA (0.82 g) were added to aceBz-PEG-OH in 25 mL of THF to prepare an intermediate product aceBz-PEG-OSO_2CH_3, which was then mixed with ammonia solution (25%) to produce aceBz-PEG-NH_2.

b. Selective Functionalization of Folic Acid at its γ*-Position of the Glutamate Residue with Hydrazide (Fol-hyd).* An excess amount of TFAA (3 mL) was added dropwisely to folic acid (2 g) in THF (20 mL) to prepare N_{10}-(trifluoroacetyl)pyrofolic acid. This pyrofolic acid (500 mg) was reacted with CAt-BE (1.6 g) in 20 mL of dry DMF at 40 °C overnight. Prepared folate-hydrazide-BOC was treated with TFA to obtain Fol−Hyd.

c. Preparation of β*-benzyl-*L*-aspartate N-Carboxy Anhydride (BLA−NCA).* 5.77 g of triphosgene was added to 10 g of β-benzyl-L-aspartate in 150 mL of dry THF at 40 °C, and the reaction was allowed to proceed until the solution became clear. Prepared β-benzyl-L-aspartate *N*-carboxy anhydride (BLA−NCA) was purified by recrystallization from hexane.

*d. Ring-Opening Polymerization of BLA−NCA by Using aceBz-PEG-NH_2 as a Macroinitiator to Obtain 4-(Diethoxymethyl)benzyl Acetal−poly(ethylene glycol)−poly(*β*-benzyl-*L*-aspartate) (aceBz−PEG−PBLA).* 6 g of aceBz−PEG−NH_2 with molecular weight of 12 000 and 5 g of BLA−NCA were dissolved in 30 mL and 10 mL of DMSO, respectively. NCA solution was added to PEG solution at 40 °C, and the reaction was allowed to proceed for 2 days.

e. ω*-Amino Group Protection for aceBz−PEG−PBLA Block Copolymers, Followed by* α*-Acetal Group Deprotection and Subsequent Conjugation of Fol−hyd at the End of the PEG Chain (Fol−PEG−PBLA).* The ω-amino group of aceBz−PEG−PBLA was protected by AA to prevent dimerization between aldehyde−benzyl−poly(ethylene glycol)−poly(β-benzyl-L-aspartate) (CHO−Bz−PEG−PBLA) block copolymers, which can be prepared by deprotecting acetal groups of aceBz−PEG−PBLA with 0.1 N HCl aqueous solution. End-group protected CHO−Bz−PEG−PBLA (250 mg) was then mixed with Fol−Hyd (50 mg) in dry DMF to prepare Fol−PEG−PBLA.

Table 1. Polymer Compositions

compound	composition[a]	polydispersity index[d] (Mw/Mn)	drug loading content (wt %)
PEG-PBLA	12−42[b]	1.12	
Fol-PEG-PBLA	12−40[b]	1.14	
PEG-p(Asp-Hyd-ADR)	12−42−33−15[c]		33.84
Fol-PEG-p(Asp-Hyd-ADR)	12−40−34−14[c]		34.32

[a] The compositions of the block copolymers are abbreviated *X*−*Y* and *X*−*Y*−*Z*−*A*. The letter *X* stands for molecular weight × 10^{-3} of poly(ethylene glycol), while *Y*, *Z*, and *A* denote the numbers of aspartic acid, hydrazide, and adriamycin (ADR), respectively. [b] The values were calculated from the peak area ratio determined by ^{1}H NMR between poly(ethylene glycol) and benzyl groups of the PBLA block. [c] The numbers of hydrazide groups and ADR were determined by ^{1}H NMR and reversed-phase liquid chromatography (RPLC), respectively. [d] Polydispersity was measured for PEG−PBLA and Fol−PEG−PBLA to ensure the purity of starting materials.

f. Substitution Benzyl Esters at the Side Chain of Fol−PEG−PBLA with Drug-Binding Hydrazide Groups to Prepare Fol−PEG−p(Asp-Hyd). 500 mg of Fol−PEG−PBLA was dissolved in 10 mL of dry DMF, and anhydrous hydrazine (0.62 mg) was added to the solution. The reaction was allowed to proceed at 40 °C for 2 h, followed by deprotection of remained benzyl groups with 0.1 N NaOH aqueous solution at 25 °C. Polymers were dialyzed against 0.25% ammonia solution and collected by freeze-drying.

g. Conjugation of ADR at Its 13-C Carbonyl with the Hydrazide Groups of Fol−PEG−p(Asp-Hyd) through a pH-Sensitive Schiff Base Linkage. Fol−PEG−p(Asp-Hyd) (100 mg) in 50 mL of DMSO was mixed with an excess amount of ADR-HCl (100 mg) with respect to drug-binding hydrazide residues. The mixed solution was stirred at room temperature for 3 days. After precipitation from ether, Fol−PEG−p(Asp-Hyd-ADR) was redissolved in 10 mL of DMF and purified by gel filtration using a Sephadex LH-20 column. In the case of PEG−p(Asp-Hyd-ADR), MeO-PEG-NH_2 was used as a macroinitiator for BLA−NCA polymerization at step (d) instead of aceBz−PEG-NH_2, following the procedures from steps (e) to (g).

Preparation of the Folate-Conjugated pH-Sensitive Polymeric Micelles. The folate-conjugated pH-sensitive polymeric micelles were prepared from Fol−PEG−p(Asp-Hyd-ADR) alone or in combination with PEG−p(Asp-Hyd-ADR) block copolymers in various molar ratios to change folate contents (0%, 1%, 2%, 5%, 10%, 25%, 50%, and 100%). We distinguish the micelles from Fol−PEG-p(Asp-Hyd-ADR) and PEG−p(Asp-Hyd-ADR) by the notations of FMA and MA, which denote folate-conjugated micellar adriamycin and micellar adriamycin, respectively. For the preparation of FMA and MA, 250 mg of each Fol−PEG−p(Asp-Hyd-ADR) and PEG−p(Asp-Hyd-ADR) were dissolved in 5 mL of DMSO. Polymer solutions were then added dropwise into 95 mL of Tris−HCl buffer solution (10 mM, pH 7.4), sonicated at 25 °C for 10 min, and diluted further with 900 mL of Tris−HCl buffer. The polymer solutions were concentrated by Amicon Ultra-15 Centrifugal Filter Units (Millipore, U.S.A.) with molecular weight cutoff (MWCO) 30 000 kDa. 12 mL of the solutions in each swinging bucket rotor were spun at 1500 *g* at 25 °C for 15 min. During repetitive centrifugation, additional Tris−HCl buffer was added to the solutions until DMSO was completely removed. Concentrated micelle solutions were filter-sterilized and stored in aliquots at 4 °C for future use. Drug concentration was determined by UV at 490 nm, based on the calibration curve of free ADR.

Table 2. Particle Size and ζ Potential of the Micelles with Varying Folate Contents

	folate conjugation[a] (%)							
	0 (MA)	1 (FMA1)	2 (FMA2)	5 (FMA5)	10 (FMA10)	25 (FMA25)	50 (FMA50)	100 (FMA100)
particle size[b] (nm)	64.21	65.34	63.79	68.35	69.22	72.51	77.47	91.29
polydispersity index (μ/Γ^2)	0.1018	0.0951	0.1096	0.1232	0.1318	0.1437	0.1661	0.1973
ζ potential (mV)	−0.39	0.11	−0.67	−1.07	−1.98	−2.33	−6.95	−9.25

[a] It was determined by the mixing ratio of folate-conjugated block copolymers to the block copolymers without folate conjugation. [b] The micelles were filter-sterilized using 0.45 μm filter units (Millex-HV, Millipore, Co., Ltd., U.S.A.) prior to the measurements.

In Vitro Cytotoxicity Assay. In order to determine in vitro cytotoxicity of the micelles, a human pharyngeal cancer cell line KB was incubated with FMA, MA, and free ADR in various concentrations, changing exposure time. Exponentially growing KB cells were seeded on a 96-well culture plate (2000 cells/well) and preincubated for 24 h, followed by coincubation with the samples. After 3 and 24 h, cell culture media were replaced with fresh media, and the cells were incubated further for additional 24 h. The number of viable cells was determined by CellTiter-Glo luminescent cell viability assay ($n = 8$) that provides a convenient, rapid, and sensitive procedure based on quantitation of ATP, which signals the presence of metabolically active cells (*28*).

Flow Cytometric (FCM) Analysis. Cellular uptake of the micelles was analyzed by an EPICS XL Flow Cytometry Systems (Beckman Coulter, U.S.A.) monitoring autofluorescence of ADR accumulated in the cell. KB cells were seeded on a 12-well culture plate (30 000 cells/well) and preincubated for 24 h, followed by coincubation with FMA, MA, and ADR (10 mg/mL) for 3 and 24 h. The cells were then washed three times with PBS, detached by trypsinization, spun down by centrifugation, and dispersed again in PBS for FCM analysis. Data were acquired and processed with the accompanying software (*EXPO 32*).

Surface Plasmon Resonance (SPR) Analysis. Interaction between FBP and the micelles was analyzed by surface plasmon resonance (SPR) measurements using BIAcore 3000 (Biacore, Sweden). FBP was immobilized on the surface of a sensor chip (3 ng/mm^2 of FBP per channel), following the procedures provided by the manufacturer. FBP binding effects of both FMA and MA were evaluated at a flow rate of 10 μL/min with a concentration of 200 μg/mL. The micelles were allowed to flow for 30 min, and all samples were tested by replacing sensor chips on which FBPs were newly immobilized.

Pharmacological Study. Tumor-bearing mice were prepared by transplanting KB cells on the abdominal region of CD-1 nude mice (female, 6-week-old, $n = 6$, Charles River, Japan). When the tumor volume reached 100 mm^3, the micelles and free ADR as control were intravenously injected in a volume of 0.1 mL/10 g body weight. The drug dose was 10 mg/kg for both free ADR and the micelles (ADR equivalent). After drug injection, the blood, tumor, and major organs (heart, kidney, liver, and spleen) were collected at 0.5, 1, 3, 6, 9, and 24 h, followed by HPLC analysis as previously reported (*19*). Briefly, plasma was separated from the blood, and the tissues were homogenized prior to the measurements. Daunorubicin (DAU) was added to the specimens as an internal standard in 2 μg/mL, depending on sample amount. 200 μL of 10 mM HCl solution was then added to the specimens to cleave drug conjugation, and 1 mL of 100 mM ammonia buffer (pH 9.0) was applied after 24 h incubation. 5 mL of $CHCl_3$/MeOH (2:1) mixed solution was also added to the solution, and ADR and DAU were extracted by vigorous vortexing at 25 °C for 15 min. The organic layer was collected using Pasteur pipets and evaporated at 40 °C after centrifugation (1900 *g*, 15 min, 4 °C). Dry drugs were redissolved in 100 μL of DMF and injected to RPLC equipped with a μ Bondasphere 5μ C4 300 column and a fluorescence detector (Ex 485 nm, Em 560 nm). The area under the curve of concentration (AUC) vs time was calculated by the trapezoidal rule with the time points of 0.5, 1, 3, 6, 9, and 24 h. The unit for AUC is defined as % dose/mL plasma × h or % dose/g organ × h for the blood or other tissues (tumor, kidney, liver, spleen, and heart), respectively.

Table 3. Time-Dependent Increase in Cytotoxicity and Cellular Uptake of the Micelles ($n = 8$)[a]

sample	exposure time (h)	IC_{50}[b] (μg/mL ± SD)	relative index[c]	cellular uptake[d] (%)
ADR	3	0.069 ± 0.014	1.97	100.00
	24	0.035 ± 0.011	1	100.00
FMA100	3	0.172 ± 0.017	4.91	92.51
	24	0.041 ± 0.012	1.17	94.95
MA	3	N.D.[e]	N.D.[e]	40.20
	24	0.263 ± 0.013	7.51	82.05

[a] Data were obtained from the eight independent experiments using a human pharyngeal cancer cell KB. [b] IC_{50} means the inhibitory concentration of the drugs required for reducing 50% of cell proliferation. The drug concentration of the micelles was calculated with respect to free ADR equivalents. [c] Relative index means the ratio between the IC_{50} of free ADR after 24 h incubation and the samples. [d] Cellular uptake of the micelles was analyzed by flow cytometric analysis monitoring autofluorescence of ADR accumulated in the cell. [e] N.D. means not determined.

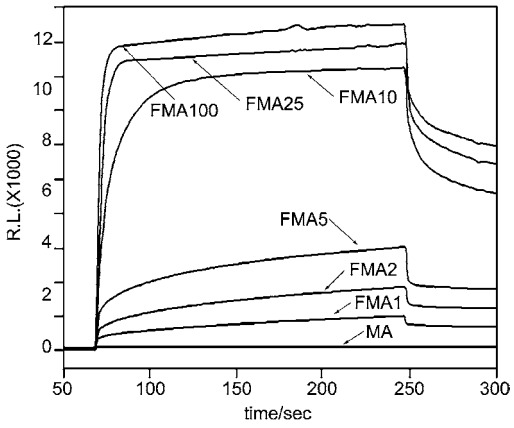

Figure 2. Surface plasmon resonance (SPR) analysis. FBP-binding selectivity of folate-conjugated micelles was evaluated by SPR measurements (eluent, 100 mM phosphate buffer; pH 7.4; flow rate, 10 mL/min; density of folate-binding protein, 3 ng/mm per channel; sample concentration, 200 μg/mL). Folate concentration on the surface of the micelles was varied to determine the optimum substitution rate.

In Vivo Antitumor Activity Evaluation. Tumor-bearing mice were prepared as described above. The micelles were injected from the tail vein three times with a four day interval in various doses (5, 10, 20, and 40 mg/kg). This administration schedule was based on the optimum regimen for free ADR as a control. However, free ADR was applied to the mice in limited doses (5, 10, and 15 mg/kg) due to the serious toxicity. Tumor growth and body weight of mice were checked at every second day. Tumor volume was calculated as volume $V = {}^1/_2 \times LW^2$, where the letters L and W denote the long and short diameters of the tumor tissue. Cancer treatment efficacy was analyzed by a treatment to control (T/C) ratio $= (V_c - V_t) \times 100/V_c$, where

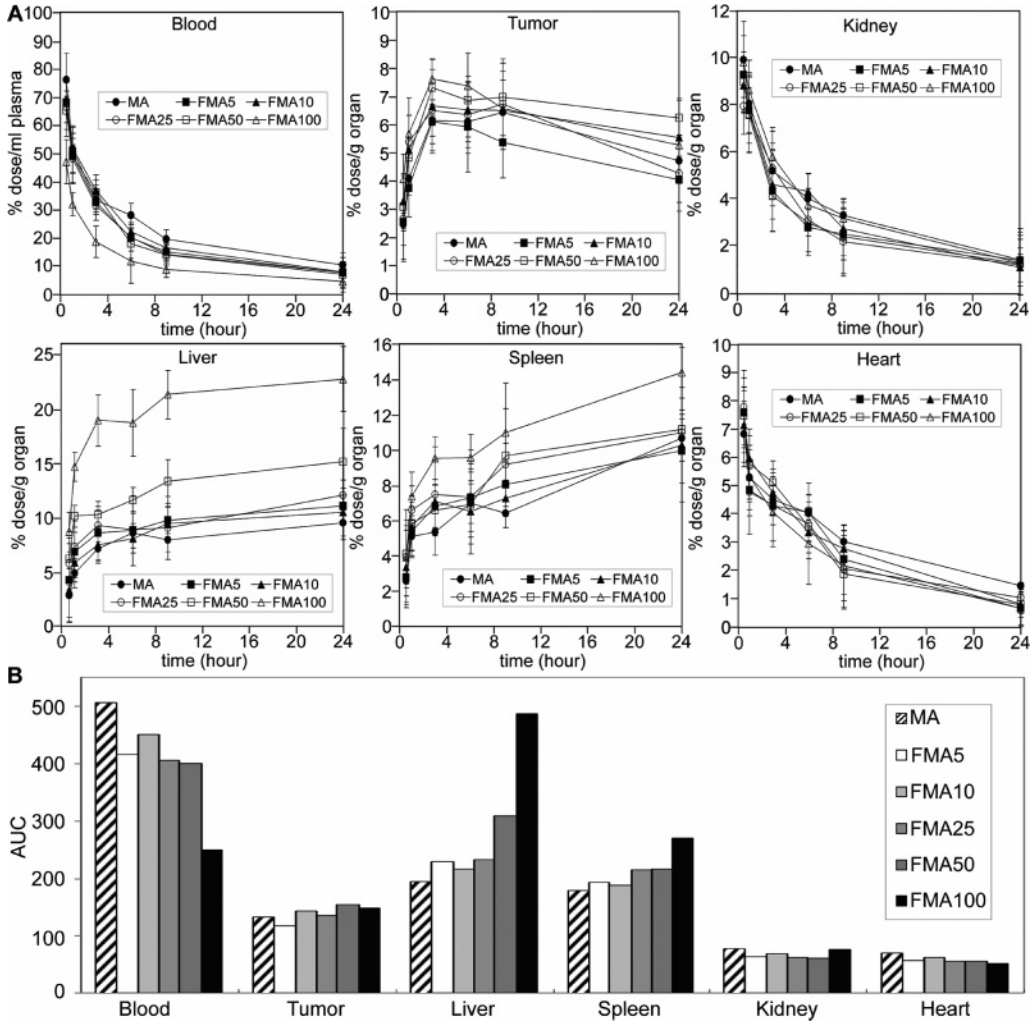

Figure 3. Pharmacokinetic profiles. Distribution of the micelles with varying folate amounts was measured in the blood compartment, tumor tissue, and major organs such as the liver, spleen, kidney, and heart (A). Experiments were carried out using tumor-bearing CD-1 nude mice (female, 6-week-old, $n = 6$) when the tumor volume reached 100 mm^3. Data are expressed as mean and mean ± SEM for relative and absolute values, respectively. Accumulation amounts for each micelle are compared in terms of the areas under the curve of concentration (AUC) vs time up to 24 h time period (B).

V_c and V_t are the mean tumor volumes of the control and the treated mice, respectively. The effective dose (ED) of each micelle was determined as the T/C ratio = 50, which means the average tumor volume of the mice decreased 50% of control values by drug treatments. The toxic dose (TD) was defined as the dose that causes 20% decrease in body weight of the mice after drug injection.

RESULTS AND DISCUSSION

Preparation of the Folate-Conjugated pH-Sensiive Polymeric Micelles (FMA). The molecular weight and composition distributions of self-assembling amphiphilic block copolymers, folate−poly(ethylene glycol)−poly(aspartate-hydrazone-adriamycin) [Fol−PEG−p(Asp-Hyd-ADR)] and α-methoxy-poly(ethylene glycol)−poly(aspartate-hydrazone-adriamycin) [PEG−p(Asp-Hyd-ADR)], were determined by GPC and ^{1}H NMR. Table 1 shows that these block copolymers were successfully prepared with a controlled number of hydrazide groups and ADR. It is noticeable that Fol−PEG−p(Asp-Hyd-ADR) block copolymers did not form any dimers or aggregates after folate conjugation. In addition, most notably, folate was functionalized only at γ-carboxylate position of its glutamate residue in this study by precision synthesis, as we previously reported elsewhere (*25*). This enables every folate molecule that is conjugated to the block copolymers to remain active, distinguishing our system from other folate conjugates. In many studies, folate molecules have been conjugated by using carbodiimide coupling reagents. The folate conjugated in this way is prone to making a mixture of α- and γ-carboxylate-functionalized forms. Because the α-carboxylate-functionalized form of folate loses its activity, the carbodiimide coupling method is substantially accompanied by the problems of undesirable introduction of inactive folate, which induces insufficient conjugation or incorrect quantification of active folate (*23*, *24*). To the contrary, herein we can exclude the possibility that folate becomes inactive after conjugation, and therefore, it is able to clearly investigate the effects of folate conjugation on the biological properties of the micelles.

The particle size and ζ potential of the micelles were analyzed by Zetasizer Nano (Malvern, U.K.), and data are summarized in Table 2. Each micelle from Fol−PEG−p(Asp-Hyd-ADR) and PEG−p(Asp-Hyd-ADR) was abbreviated as FMA and MA, which denote folate micellar adriamycin and micellar adriamycin (without folate), respectively. The successive number after the abbreviated term of FMA in some descriptions indicates the mol % of Fol−PEG−p(Asp-Hyd-ADR) block copolymers in the micelles. For instance, FMA10 means that the micelles were prepared from 10% of Fol−PEG−p(Asp-Hyd-ADR) and 90% of PEG−p(Asp-Hyd-ADR) block copolymers. In all cases, the micelles exhibited particle sizes between 60 and 90 nm, while the distribution was narrow and monodisperse. Surface charge

of the micelles became negative, which is probably due to the carboxylic group remaining at the α-position of glutamate of the folate molecule. Although the micelle size slightly increased as folate concentration increased, these data demonstrate that the size and surface charge of the prepared micelles were still suitable for tumor-specific accumulation via the EPR effect after folate conjugation. When the micelle solutions were concentrated, however, aggregation between particles was observed in the case of FMA100. Such aggregation was able to be suppressed by decreasing the folate substitution ratio. Considering that MA (or FMA0) showed no aggregation during concentration, it is most probable that folate substitution increases the local concentration of folate molecules on the micelle surface, and thus, FMA aggregated due to the intermicellar hydrophobic interaction (*29*). Nevertheless, it must be noted that the micelles stably dispersed with 60−90 nm diameter up to 5 mg/mL concentration irrespective of folate substitution ratio. Because a high drug loading content (∼30 wt %) is one of the characteristic advantages of the micelles, injecting the micelles above this concentration would not be realistic in terms of determining the injection dosage of ADR whose lethal dose ranges from 12.7 to 13.2 mg/kg. Therefore, it is concluded that the micelles with varying folate contents were stable at a size suitable for systemic drug delivery with sufficient drug concentration.

Folate Conjugation Significantly Increased in Vitro Cytotoxicity and Cellular Uptake of the Micelles. Table 3 shows a change in proliferation of KB cells treated by FMA100, MA, and free ADR and cellular uptake. It is of interest that the 50% inhibitory concentrations (IC_{50}) of cell growth decreased significantly in the case of the micelles by folate conjugation. Notably, cytotoxicity of FMA100 was as high as that of free ADR after 24 h incubation despite their different internalization mechanisms. In our previous studies, it is confirmed that this pH-sensitive micelle, which was designed to selectively release drugs in the intracellular region, requires relatively long exposure time sufficient for inhibiting cell growth (>10 h). It is because the micelles are required to enter the cell first and to release drug by sensing pH so that the released drugs accumulate in cell nuclei to intercalate with DNA, inducing cell death. In comparison with MA, FMA100 showed efficient cytotoxicity with a short exposure time of 3 h. These results suggest that folate conjugation promotes the interaction between the micelles and the cell. It is generally known that KB cells overexpress folate-binding proteins (FBPs) on the cell membrane, and therefore the FBPs can take up FMA100 to the cell interior efficiently via receptor-mediated endocytosis. Such enhanced cellular uptake probably induced higher cytotoxicity of FMA100 even with short exposure time. This hypothesis was also confirmed by flow cytometric analysis. As also summarized in Table 3, cellular uptake of FMA100 increased by folate conjugation, and such an increment corresponds well with enhanced cytotoxicity. Consequently, it is confirmed that folate conjugation enhanced cytotoxicity of the micelles by increasing cellular uptake and intracellular drug concentration.

FMA Recognized Folate-Binding Proteins (FBPs) Selectively and Strongly. Although in vitro cytotoxicity assay and flow cytometric analysis have proven that high efficacy of FMA was due to the increased intracellular drug concentration, the scientific evidence that elucidates the role of folate in accelerating cellular uptake was still required. In order to confirm the interaction between FMA and folate binding proteins (FBPs), we carried out surface plasmon resonance (SPR) analysis by using a sensor chip on which FBP molecules were immobilized. It is also of great importance to verify how folate concentrations affect FBP binding properties of the micelles, so we prepared FMA with varying folate substitution rates from 100% to 0%.

Table 4. Tumor-Specific Accumulation of the Micelles

sample	blood	tumor	liver	spleen	kidney	heart
AUC[a]						
MA	506.42	132.67	194.45	179.37	76.96	69.48
FMA5	415.53	117.13	229.35	193.65	63.15	57.01
FMA10	450.38	143.60	215.97	187.98	68.45	61.79
FMA25	405.17	135.48	233.33	215.24	61.58	55.59

[a] AUC denotes the area under a concentration curve that is obtained from the pharmacokinetic study with time points at 0.5, 1, 3, 6, 9, and 24 h. Values were calculated on the basis of the trapezoidal rule up to 24 h after intravenous injection. The unit for AUC is defined as % dose/mL plasma × h or % dose/g organ × h for the blood or other tissues (tumor, kidney, liver, spleen, and heart), respectively. [b] K_b value is defined as [$K_b = C_{tissue}/C_{blood}$] where C_{tissue} and C_{blood} are the drug concentrations in the tissue and the blood, respectively. Each K_b value indicates distribution of the drugs in the vascular space ($K_b < 0.1$), extracellular space ($0.1 < K_b < 0.5$), and intracellular space ($0.5 < K_b$). [c] Tumor selectivity of the micelles was determined by calculating the relative accumulated concentrations between the tumor tissues and each organ (AUC_{tumor}/AUC_{organ}).

Figure 2 shows SPR signal intensity versus time for individual micelle samples. The micelles were flowed into the sensor channel for 3 min and rinsed with fresh buffer solution. The signal change indicates that FMA binds promptly and strongly to FBP in various folate contents while MA showed no interaction with FBP. Interestingly, FMA was able to recognize FBP even with 10% folate substitution ratio. However a significant decrease was found in the FBP binding effect between FMA10 and FMA5. In the meantime, the folate substitution rates can be converted from a percent to mol wt % on the basis of the molecular weight of block copolymers and the mixing ratio. It shows that 100% folate substitution ratio corresponds to 16.9 mmol wt % for a single micelle, and FMA10 and FMA5 were calculated to contain 1.7 and 0.8 mmol % of folate molecules, respectively. Therefore, these data revealed that the micelles require only a small quantity of folate to recognize FBPs. Folate is known to have a high affinity for FBP ($K_d < 1$ nM), and such high affinity seems to provide a strong binding property of FMA (*23, 24*).

Optimum Amounts of Folate-Facilitated Tumor Targeting Properties of the Micelles with Long Blood Circulation. The information regarding the relation between the amount of folate and biodistribution of the micelles is of primary importance to determining the compositions of FMA. Such compositions should be considered to maintain the balance between passive and active tumor targeting to realize an ultimate goal of drug delivery systems. For these reasons, we have investigated the biodistribution of FMA by changing folate contents. Figure 3 shows the distribution of the micelles in the blood compartment, tumor tissues, and major organs such as the liver, spleen, kidney, and heart after the intravenous injection. The area under a concentration curve (AUC) shows that the micelles circulated

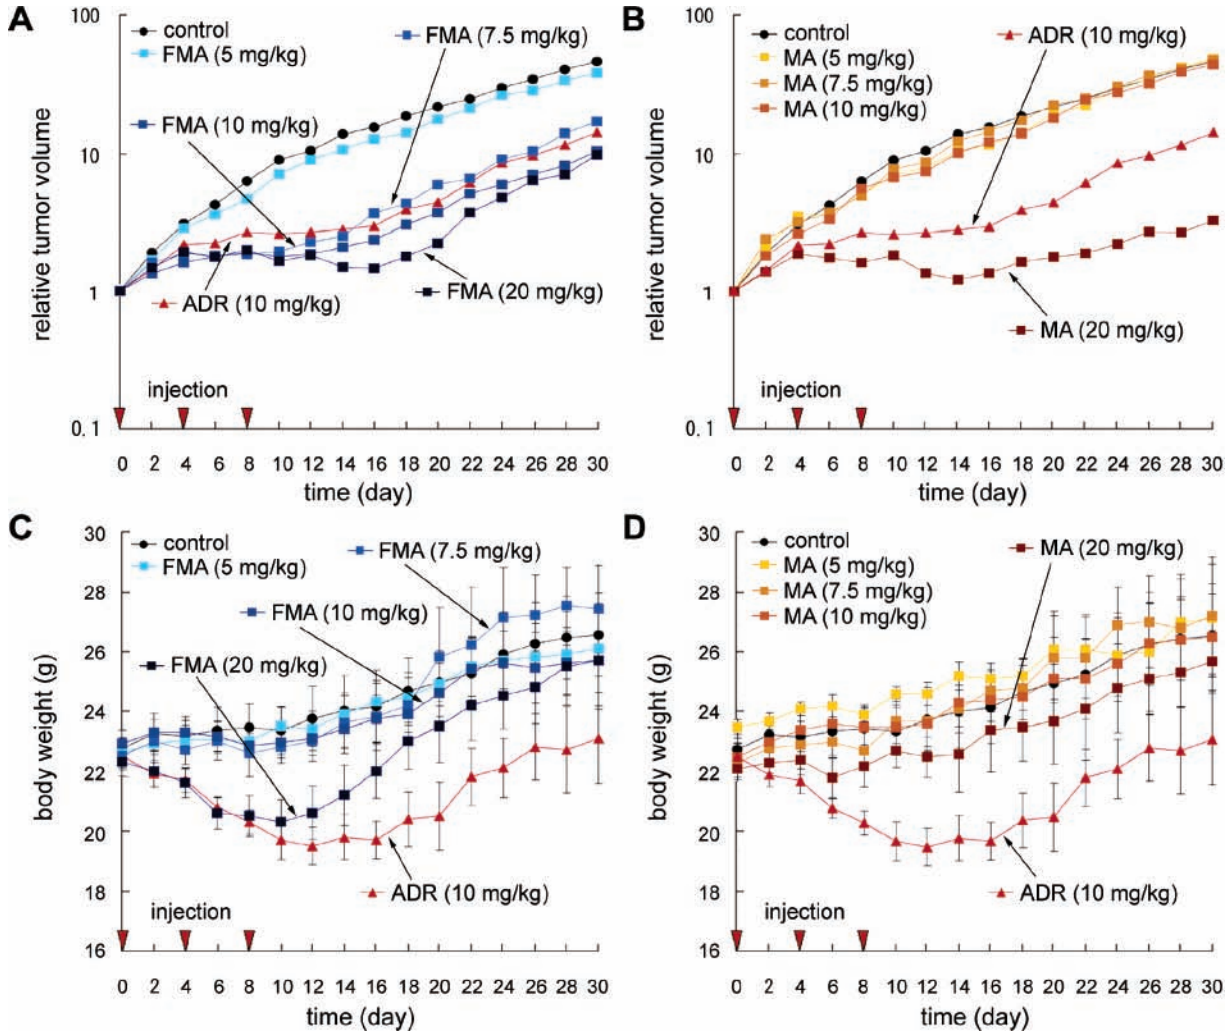

Figure 4. Tumor size and body weight change. The figure shows effective tumor-suppressing activity and low change in body weights over a broad range of injection doses of the folate-conjugated micelles (A and C). It clearly shows that the dose for effective tumor treatments decreased by folate conjugation compared to the micelles without folate, while toxicity remained lower than free drugs (B and D). Administrations were carried out 3 times with a 4 day interval into tumor-bearing CD-1 nude mice (female, 6-week-old, $n = 6$). The micelle doses are shown as ADR equivalents. Data are expressed as mean and mean ± SEM for relative and absolute values, respectively.

in the blood for a long time and their accumulation in tumor tissue increased significantly during the period of 24 h compared to normal organ. In the case of MA, the results correspond well with our previous data that revealed that the intracellular pH-sensitive micelles are characterized by prolonged circulation time in blood and tumor-specific accumulation (*19*). Such characteristic pharmacokinetic properties are considered to result from controlled drug release that can enhance the drug delivery efficiency of the micelles to the solid tumors. Regarding FMA, it is of interest that folate conjugation does not significantly affect the long-term circulation property of the micelles. FMA circulated in the blood for a prolonged time irrespective of folate content. However, the micelle accumulation in the liver as well as in the tumor changes obviously depending on the folate amount. As summarized in Table 4, a clear difference in tumor-specific accumulation was found between FMA and MA. The AUC values for each organ exhibit that FMA with a higher folate content showed a lower tumor-targeting property compared to MA. These results might be due to an increase in accumulation in the liver. Micelle accumulation in the liver was most probably due to the high FBP affinity of the micelles with increased folate concentration. In the meantime, the K_b values, which indicate the drug distribution within inter- and intracellular compartments, show that cellular uptake of FMA increased in tumor cells while remaining low in normal tissues. Nevertheless, the pharmacokinetic data also indicate that the possibility cannot be completely excluded that the micelles underwent nonspecific accumulation in normal organs after folate conjugation. It is not only because the K_b values increased, but also because the tumor to organ ratio (TOR) decreased as folate amounts increased. Accumulation in the liver increased, predominantly decreasing tumor-specific delivery efficiency. One of the previous studies showed that folate conjugation can induce higher hepatic clearance of the conjugates (*30*). Although expression of FBP in the liver would be suggested as a likely reason for the hepatic clearance, we considered that excessive conjugation of folate could increase accumulation of the micelles in normal organs. Therefore, it is concluded that the amount of folate should be carefully determined to facilitate tumor-targeting properties while maintaining long-term blood circulation. This would help us to minimize nonspecific distribution of the micelles in the body. Most noticeably, accumulation of the micelles in the tumor tissues did not significantly differ before and after folate conjugation in terms of pharmacokinetic profile. These findings indicate that the EPR effect seems to still be a major factor in determining the tumor accumulation of drug carriers for active targeting within a 24 h time range. In other words, folate conjugation would mainly affect the distribution of the micelles after extravasation rather than regulate migration of the micelles from the blood compartments to the tumor tissue.

FMA Showed Lower Toxicity and Higher Efficacy than Free Drug. The SPR analysis and biodistribution studies revealed that the optimum amount of folate conjugation is of significant importance to achieve passive and active drug targeting simultaneously. From the obtained data above, we selected FMA10 as the optimum micelle composition for further studies, which was believed to be the most suitable for the best performance in terms of tumor-specific drug delivery. In order to elucidate how folate affects in vivo antitumor activity of the micelles in detail, we have injected FMA, MA, and free ADR into the CD-1 nude mice implanted with human pharyngeal cancer KB cells by changing the dosage. Figure 4 show the changes in tumor size and body weight after drug administration. Free ADR was injected as a control, and it suppressed tumor growth at a dose of 10 mg/kg. The mice were also treated with different doses of free ADR, but there was no effect at 5 mg/kg. At a dose of 15 mg/kg, free ADR showed severe toxicity. These results indicated that free ADR was safe to exhibit the efficacy only within an extremely narrow dose range from 10 to 15 mg/kg. Indeed, body weight reduction was observed even at a dose of 10 mg/kg in the case of free ADR. In contrast to free ADR, MA was able to suppress tumor growth over a broad range of doses ranging from 20 to 40 mg/kg, while its toxicity was significantly low. Such effective and safe antitumor activity of the micelles was consistent with our previous results, which demonstrated the usefulness of intracellular pH-sensitive drug delivery (*18, 19*). Nevertheless, the effective dose (ED) of MA was relatively high compared to free ADR. In case of FMA, however, tumor growth was effectively suppressed with the same dose range of MA, but surprisingly, its ED decreased from 20 to 7.5 mg/kg while toxicity remained low. This value is even lower than the ED of free ADR (10 mg/kg), indicating that the micelles became more effective than free drug by folate conjugation. Therefore, these experimental data clearly elucidate that the drug carrier can show higher efficacy than free drug by optimally balancing passive and active tumor targeting properties as well as controlling drug release profile. It should be emphasized that, although the pharmacokinetic study showed that folate conjugation did not significantly improve the tumor-specific accumulation of the micelles, in vivo antitumor activity experiments clearly show that FMA is more effective to the cancer treatment than free ADR in terms of efficacy and safety. These results also support our hypothesis described above that active targeting seems to mainly affect the distribution profile of the drug carriers within the tumor tissues after extravasation rather than in the blood compartment. It is certain that more studies on this topic should be investigated further in the future. Nevertheless, it is of great importance that the ED of FMA decreased compared to free ADR as well as MA. A lowered dose is obviously beneficial for preventing possible long-term toxicity to the patients. From these aspects, it is concluded that our in vivo studies clearly demonstrate the effects of folate conjugation on active targeting drug delivery.

Folate Conjugation Decreased Effective Dose while Maintaining the Broad Therapeutic Window of the Micelles. The range of drug concentrations that provide the efficacy safely is known as the therapeutic window. If the injection dose is lower than this range, the drug cannot show its efficacy. To the contrary, if the injection dose is higher than the therapeutic window, the drug will induce either acute or chronic toxicity. In this study, animal studies have shown that FMA is more effective and safer than free drugs. In order to provide more objective criteria for evaluating efficacy of FMA, we analyzed antitumor activity of the micelles by calculating a treatment to control (T/C) ratio. Figure 5 exhibits the relation between the T/C ratio and a dosage. Each curve provides information about the tumor-suppressing efficacy of FMA, MA, and free ADR with respect to the control. Effective dose (ED) and toxic dose (TD) were defined as the doses that induce 50% of tumor growth (ED_{50}) and reduce 20% of body weight during the treatment, respectively. As drug concentrations increased, tumor growth suppression efficiency increased by all drug formulations. However, when we compare the effective doses, ED_{50} of free ADR is obviously close to its TD while ED_{50} of the micelles remained low compared to their TD. Namely, the safe dose of free ADR was only 3.96 mg/kg, but in contrast, FMA and MA were safely injectable between 20.03 and 23.75 mg/kg, respectively. These values correspond to 5.05- and 5.99-fold broader dose ranges than free drug. In particular, ED_{50} of FMA became lower than that of free ADR, and these results exemplify how active drug targeting is promising for cancer treatment. Most notably, such low toxicity and high efficacy were achieved by determining the optimum amount of folate on the micelle surface.

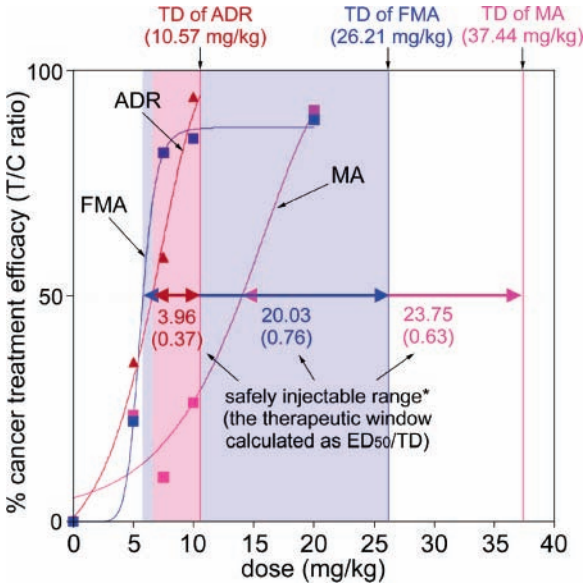

Figure 5. Treatment-to-control (T/C) ratio. Cancer treatment efficacy of the micelles was evaluated by comparing the therapeutic windows of FMA10, MA, and ADR, which were calculated from the ratio of ED_{50} to TD. ED_{50} and TD were defined as the effective dose that induces 50% decrease in tumor volume and the toxic dose that reduces 20% of body weight of mice, respectively. The data show the dose range in which each sample can be safely injected while achieving effective cancer treatments.

CONCLUSIONS

Integration of multiple functions into a single nanoparticle can broaden the possibilities of the macromolecular drug delivery systems for their future applications in the clinic. In this study, we have prepared a multifunctional polymeric micelle that is implemented with intracellular pH-dependent drug-releasing functionality and folate-mediated cancer cell targeting property simultaneously. By precision synthesis and preparation of the pH-sensitive micelles with varying folate contents, we were able to elucidate that the ligand-installed micelles for active drug targeting can be more effective than free drug in terms of antitumor activity, safety, pharmacokinetics, and bioavailability. It is of great interest that folate conjugation did not significantly improve the tumor accumulation of the micelles in the body because it induced a prominent increase in accumulation in the liver. However, when folate concentration was adjusted to achieve minimum ligand−receptor interaction, folate-conjugated micelles showed an effective cancer treatment efficiency that was even higher than free drugs as well as the micelles without folate conjugation. These findings clearly demonstrated that the

balance between passive and active drug targeting should be carefully considered to maximize the drug delivery efficiency as well as cytotoxic activity of the polymeric drug carriers.

Dual-Surface-Modified Bacteriophage MS2 as an Ideal Scaffold for a Viral Capsid-Based Drug Delivery System

Ernest W. Kovacs, Jacob M. Hooker, Dante W. Romanini, Patrick G. Holder, Katherine E. Berry, and Matthew B. Francis*

Department of Chemistry, University of California, Berkeley, California 94720-1460, and Materials Sciences Division, Lawrence Berkeley National Labs, Berkeley, California 94720. Received January 8, 2007; Revised Manuscript Received February 16, 2007

With the development of covalent modification strategies for viral capsids comes the ability to convert them into modular carrier systems for drug molecules and imaging agents. With this overall goal in mind, we have used two orthogonal modification strategies to decorate the exterior surface of genome-free MS2 capsids with PEG chains, while installing 50−70 copies of a fluorescent dye inside as a drug cargo mimic. Despite the very high levels of modification, the capsids remained in the assembled state, as determined by TEM, size-exclusion chromatography, and dynamic light scattering analysis. The ability of the polymer coating to block the access of polyclonal antibodies to the capsid surface was probed using a sandwich ELISA, which indicated a 90% reduction in binding. Further experiments indicated that biotin groups placed at the distal ends of the polymer chains were still capable of binding to streptavidin, despite their proximity to the PEG layer. Finally, a modular strategy was developed for the attachment of small-molecule targeting groups to the polymer chains through an efficient oxime formation reaction. As a result of these studies, a robust and versatile new platform has emerged for the potential delivery of therapeutic cargo.

INTRODUCTION

The robust, monodisperse architectures of viral capsids have emerged as attractive scaffolds for the construction of new materials (*1*). With the goal of adding new function to these structures, numerous studies have demonstrated that their exterior surfaces can be functionalized with peptides (*2*), fluorescent dyes (*3, 4*), polymers (*5*−*8*), carbohydrates (*9*, *10*), oligonucleotides (*11*), and other organic molecules (*2*, *3*, *8*) through the use of carefully planned bioconjugation reactions. In terms of inorganic materials, the capsids have also served as templates for the positioning of gold nanoparticles (*12*), the deposition of metal oxides (*13*), and the coordination of gadolinium ions (*3*, *14*) for magnetic resonance imaging (MRI). Similarly, the interior surfaces of some viral capsids have been exploited as "cages" that can template the growth of inorganic nanocrystals (*1*, *15*−*17*) and display organic functionality (*8*, *18*). Beyond these synthetic methods, much attention has also been devoted to the genetic manipulation of capsid proteins to present peptide sequences with desired function. Specifically, capsid protein fusions have been expressed to display antigenic peptides on their surfaces (*19*−*22*), and the evolution of peptide sequences via phage display (*23*−*25*) has achieved promising and widely applicable success for a number of applications.

In terms of biomedical applications, the construction of spherical nanomaterials with differentiated surfaces could offer particularly attractive systems for the delivery of therapeutic agents. As suggested in Figure 1, an ideal construct for these purposes would consist of an externally modified surface presenting multiple copies of a ligand that targets specific cell receptors, while also providing resistance to antibody binding that would neutralize the carriers before reaching their destinations. Interior modification strategies could then be used to install a high payload of imaging agents, drug cargo, or other molecules of biomedical interest in a modular fashion, with the advantage that internal functionality would be expected to exert minimal effects on biodistribution. Even in the absence of specific targeting ligands, passive accumulation of these materials could occur in solid tumors through the enhanced permeability and retention (EPR) effect (*26*−*28*). Though we have previously demonstrated the dual surface covalent modification of the tobacco mosaic virus (TMV) with small molecules and polymers (*8*), there remain no examples of spherical capsids that have been simultaneously modified on both their exterior and interior surfaces to access these materials. This is largely due to structural instabilities that are introduced upon high levels of modification and the relatively limited number of bioconjugation strategies that are available to differentiate the two surfaces.

As part of our efforts to build such materials, we have constructed the first genome-free icosahedral capsids selectively modified on both their exterior and interior surfaces. Utilizing orthogonal coupling strategies, we have successfully appended over 180 PEG chains, average molecular weight 2000 or 5000 (PEG-2000 or PEG-5000), to the exterior surface of bacteriophage MS2, while decorating its interior surface with 50−70 fluorescein molecules as our initial drug cargo mimic. This dual-surface modification has been achieved in only two protein modification steps with high overall recovery. In vitro ELISA assays, furthermore, have shown that the extensive PEGylation achieved in our system effectively masks the epitopes of the native capsid surface. We have also developed a modular strategy to attach targeting groups to the distal ends of the polymer chains through chemoselective oxime formation reactions. These constructs represent the complete synthetic exploitation of the three-dimensional space afforded by the capsids and provide a promising platform for future biomedical applications.

EXPERIMENTAL PROCEDURES

General Procedures and Materials. Unless otherwise noted, all chemicals were analytical grade, obtained from commercial sources, and used without further purification. All nonaqueous

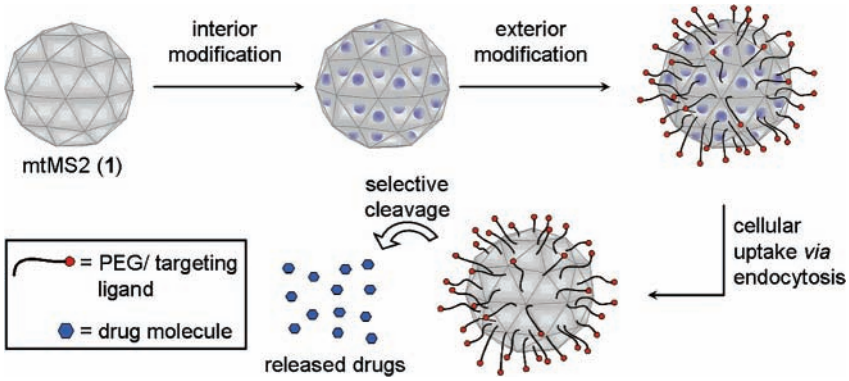

Figure 1. General strategy for the construction of multifunctional drug delivery vessels derived from genome-free (mtMS2) viral capsids.

reactions were carried out under a nitrogen atmosphere using distilled solvents. Water (ddH_2O) used in biological procedures or as a reaction solvent was deionized using a NANOpure purification system (Barnstead, USA). All organic solvents were removed under reduced pressure using a rotary evaporator. PEG polymers were purchased from Nektar Therapeutics. Fluorescein derivative FAM-SE was purchased from Molecular Probes.

Instrumentation. UV−vis spectroscopic measurements were conducted on a Tidas-II benchtop spectrophotometer (J&M, Germany). General desalting and removal of other small molecules of protein samples were achieved using BioSpin G-25 centrifuge columns (Amersham Biosciences, USA) or NAP-5 gel filtration columns (Amersham Biosciences, USA). Protein samples were concentrated by way of centrifugal ultrafiltration using Amicon Ultra-4 or Ultra-15 100 kDa molecular weight cutoff spin columns (Millipore, USA).

^{1}H NMR and ^{13}C NMR spectra were measured with a Bruker AVQ-400 (400 MHz) spectrometer. Chemical shifts are reported as δ in units of parts per million (ppm) relative to dimethyl sulfoxide-d_6 (δ 2.50, pentet) or chloroform-d_3 (δ 7.26, singlet). Multiplicities are reported as follows: s (singlet), d (doublet), t (triplet), q (quartet), dd (doublet of doublets), m (multiplet), br (broadened), or app (apparent). Coupling constants are reported as a J value in hertz (Hz). The number of protons (n) for a given resonance is indicated nH and is based on spectral integration values. ^{13}C NMR spectra are reported as δ in units of parts per million (ppm) relative to dimethyl sulfoxide-d_6 (δ 39.50, septet) or chloroform-d_3 (δ 77.2, singlet).

Transmission electron microscopy (TEM) images were obtained at the UC-Berkeley Electron Microscope Lab using a FEI Tecnai 12 transmission electron microscope with 100 kV accelerating voltage. Protein samples were prepared for TEM analysis by applying 5 μL of an analyte solution at approximately 0.1 mg/mL to carbon-coated copper grids for 3 min followed by rinsing with ddH_2O. The grids were then exposed to 5 μL of a 1% solution of uranyl acetate (UA) for 1.5 min as a negative stain. After excess stain was removed by blotting, the grid was allowed to dry until analysis.

Matrix assisted laser desorption−ionization time-of-flight (MALDI-TOF) mass spectra were obtained on a Voyager-DE system (Appled Biosystems, USA). Application of 0.5 μL of a matrix solution containing 2,4,6-trihydroxyacetophenone (THAP) (38 mg/mL in 2:1 MeCN/ddH_2O with 7 mg/mL ammonium chloride) was followed immediately by simultaneous application of 1 μL of analyte solution in ddH_2O and 0.5 μL of glacial acetic acid. A repeat addition of another 0.5 μL aliquot of the THAP matrix solution was followed by air-drying for 0.5 h or until analysis.

For protein analysis, sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) was accomplished on a Mini-Protean apparatus from Bio-Rad (Hercules, CA). Samples were combined 1:1 (v/v) with gel loading buffer containing SDS, DTT, and bromophenol blue and heated at 95 °C for approximately 15 min. After removal of the completed gels from their cassettes, the bottom portions containing unbound dye were excised promptly, after which the gels were submerged in the appropriate solution for rinsing or imaging. Commercially available markers (Bio-Rad) were applied to at least one lane of each gel for calculation of apparent molecular masses. Fluorescence visualization of gels was obtained by UV transillumination at 302 nm. Visualization of protein bands was accomplished by staining with Coomassie Brilliant Blue R-250. Gel imaging was performed on an EpiChem3 Darkroom system (UVP, USA). Protein recovery and/or degree of modification was estimated from standard optical density measurements of the observed gel bands with *LabWorks* software (version 4.0.0.8, UVP).

All size, ζ potential, and protein melting curve data were obtained using a Zetasizer Nano Series (Malvern Instruments Limited, UK). For size and melting curve measurements, analyte solution at approximately 0.5 mg/mL in aqueous buffer was sterile-filtered into glass cuvettes equipped with a Teflon cap. For ζ potential measurements, analyte solution at approximately 0.5 mg/mL in 10 mM Na_2HPO_4, pH 7.3, was sterile-filtered directly into disposable ζ cells equipped with electrodes and a folded capillary (Malvern Instruments Limited, UK).

MS2 (natMS2 and mtMS2). Routine propagation, purification, and characterization of the native bacteriophage MS2 (natMS2) followed by subsequent production of genome-free "empty" MS2 capsids (mtMS2) was accomplished using previously reported methods (*18*, *44*, *45*). A typical 1 L culture of natMS2 yields approximately 30 mg of phage. Genome removal is accomplished with over 90% protein recovery.

5-Amino-*N*-(2-amino-ethyl)-2-nitrobenzamide (4). A 200 mL flame-dried round-bottom flask equipped with a magnetic stir bar was charged with a solution of 5-amino-2-nitrobenzoic acid (750 mg, 4.12 mmol, 1 equiv) in distilled pyridine (25 mL) under an argon atmosphere. To the stirred solution was added 1,1′-carbonyldiimidizole (CDI, 1.00 g, 6.18 mmol, 1.5 equiv) at rt. After 45 min, all of the 5-amino-2-nitrobenzoic acid had been converted to the active imidizole amide, at which point the reaction solution was cooled to 0 °C and treated with a solution of ethylene diamine (1.48 g, 24.7 mmol, 6 equiv) in pyridine (25 mL). Reaction progress was monitored by TLC (1:1 MeOH/CH_2Cl_2). The reaction solution was heated to 80 °C. After 12 h, the solution was cooled to rt and concentrated under reduced pressure. Purification was accomplished by flash chromatography (1:9 $CHCl_3$/MeOH) affording **4** as a pure yellow solid (767 mg, 83% yield): ^{1}H NMR (400 MHz, DMSO-d_6): δ, 2.60 (t, 2H, J = 6.0 Hz), 3.14 (app q, 2H, J = 6.0 Hz), 6.43 (d, 1H, J = 2.4 Hz), 6.56 (dd, 1H, J = 2.4, 9.2 Hz), 6.72 (br s, 2H), 7.89 (d, 1H, J = 9.2 Hz), 8.27 (t, 1H, 5.6 Hz). ^{13}C NMR (100 MHz, DMSO-d_6): δ, 41.6, 43.3, 112.3, 112.7, 127.9,

133.3, 137.7, 155.1, 167.5. HRMS (EI+) calculated for $C_9H_{12}N_4O_3$ ($[M + H]^+$) 225.0982, found 225.0984.

5-Amino-*N*-(2-[FAM-amido]-ethyl)-2-nitrobenzamide (5). To a microcentrifuge tube was added **4** (10 mg, 45 μmol), FAM-SE (23 mg, 49 μmol), anhydrous triethylamine (12.4 μL, 89 μmol), and anhydrous DMF (77 μL). After thorough vortexing, the resulting dark orange mixture was protected from light and heated at 65 °C for 1.5 h. (Reaction progress was monitored by way of C8 reversed-phase HPLC followed by MALDI-TOF MS.) After cooling to room temperature, the resulting product mixture was used without further purification. Unused portions were protected from light and stored in aliquots at 4 °C.

FAM-Azo-labeled mtMS2 Conjugate (2). *(a) Formation of Diazonium Salt **6**.* To a 50 μL solution of **5** in DMF (100 mM) chilled to 4 °C was added 25 μL of a 4 °C aqueous solution of *p*-toluene sulfonic acid monohydrate (800 mM), followed immediately by 25 μL of a 4 °C aqueous solution of sodium nitrite (200 mM). The resulting bright yellow mixture was thoroughly vortexed and allowed to incubate at 4 °C for 15 min.

(b) Diazonium Coupling Reaction. To a 12.2 mL aqueous buffered solution of mtMS2 (1.0 mg/mL, 0.89 μmol of Y85, pH 8.5, 100 mM NaHPO4) at 4 °C was added 89 μL of a solution of **6** (4.45 μmol). After briefly vortexing, the resulting orange solution was held at 4 °C for 15 min. The reaction mixture was then diluted to 14 mL, after which 1.4 g of poly(ethylene glycol), average molecular weight 6000 (PEG-6000), and 409 mg of NaCl were added. The resulting heterogeneous mixture was then centrifuged at 13 000 rcf for 0.5 h to precipitate assembled MS2 capsids selectively. Further purification via FPLC removed residual polymer and free dye, while final centrifugal ultrafiltration yielded intact, pure, stable FAM-MS2 conjugate **2** with an overall protein recovery of approximately 90% with conversion levels of 50−80 FAM/capsid.

General Procedure for PEGylation of MS2 Capsids. To 100 μL of an MS2 sample (1 mg/mL, 70 μM in 150 mM $NaHCO_3$ buffer, pH 8.4) was added 1.82 mmol of PEG-NHS (MW = 2000 or 5000). The reaction mixture was vortexed gently for 18 h at room temperature and then subjected to FPLC purification and final centrifugal ultrafiltration as described above.

Production of Polyclonal Anti-MS2 Antibodies. The production of polyclonal anti-MS2 antibody (Ab) sera was performed as a 90 d accelerated protocol by Covance Research Products (Denver, PA).

Sandwich ELISA Assay. Affinity-purified polyclonal anti-MS2 Abs were diluted 1000-fold into 50 mM $NaHCO_3$ buffer, pH 8.2, added (50 μL/well) to Reacti-Bind 96-Well EIA Plates (Pierce Endogen, USA), and incubated overnight at 4 °C. The plates were then washed once with phosphate buffered saline containing 0.1% Tween-20 and 0.05% NaN_3 (PBSTween/azide), followed by a single wash with PBS/azide, before being blocked with 2% bovine serum albumin (BSA) in PBS/Tween/azide. After 2 h of incubation at rt, the plates were washed three times with PBS/Tween/azide, once with PBS/azide, and dried briefly. To each well was next added 50 μL of the appropriate MS2 or control protein sample at a concentration of 10−100 000 ng/mL, diluted in 2% BSA in PBS/Tween/azide. After 2 h of incubation at rt, the plates were washed as before. A previously prepared polyclonal anti-MS2 Ab-horseradish peroxidase (Ab-HRP) conjugate was diluted 100-fold in PBS/Tween (no azide) and added (50 μL/well) to the plates, which were then incubated at room temperature for 2 h. The plates were washed three times with PBS/Tween and once with PBS before addition (100 μL/well) of 1-Step ABTS substrate solution (Pierce Endogen). Following a 15−30 min incubation at room temperature, each well was quenched with 100 μL of a 1% aqueous solution of SDS. Absorbance readings were measured at 405 and 410 nm on a 96-well plate reader.

Biotin-Conjugated MS2 Pull-Down Assay. A 50 μL slurry of Immunopure Immobilized Avidin (Pierce) was washed several times with 50 mM NaH_2PO_4 buffer (pH 7.4) before a final centrifugation (1 min, 5000 rcf). After removal of the resulting supernatant, 50 μL of biotin-conjugated MS2 (0.5 mg/mL in NaH_2PO_4 buffer, pH 7.4) or an appropriate control was added. The resulting heterogeneous mixture was vortexed moderately for 15 h at rt, with one aliquot (20 μL) being removed after 1 h following centrifugation of the mixture. Removed aliquots were subjected to SDS-PAGE gel analysis as described above.

Bis-*N*-alkoxyphthalimido−poly(ethylene glycol), M_n 2291. A flame-dried, nitrogen-purged 250 mL round-bottom flask equipped with a magnetic stir bar was charged with *N*-hydroxyphthalimide (3.58 g, 22 mmol), triphenylphosphine (5.5 g, 21 mmol), and poly(ethylene glycol) (M_n 2000, 20 g, 10 mmol). The flask was evacuated and purged with nitrogen. Freshly distilled methylene chloride (100 mL) was added, and the mixture was stirred at rt to dissolve the solids. After 15 min, some heterogeneity persisted. While stirring, the mixture was treated in small portions with diisopropyl azodicarboxylate (DIAD, 4.3 mL, 22 mmol). The rate of addition was determined by the persistence of an orange color. The color was allowed to fade between each addition of DIAD (~0.25 mL). Once the DIAD addition was complete, the solution became homogeneous. After 12 h of stirring, the solution was diluted into 3 L of diethyl ether and stirred vigorously at 4 °C for 30 min. The white precipitate was collected via suction filtration and dried in vacuo for 3 h. ^{1}H NMR of the dried precipitate indicated unreacted poly(ethylene glycol) in addition to the desired product. The collected material was subjected to identical reaction conditions and purification above, ultimately yielding bis-*N*-alkoxyphthalimido−poly(ethylene glycol) as a pure white solid (15.4 g, 6.72 mmol, 67%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 3.4−3.8 (poly(ethylene glycol) signals), 3.85, (t, 4H), 4.36, (t, 4H), 7.75 (m, 4H), 7.82 (m, 4H).

Bis(aminooxy)poly(ethylene glycol), M_n 2030 (12). A 100 mL round-bottom flask was charged with a solution of bis-*N*-alkoxyphthalimido−poly(ethylene glycol) (7.5 g, 3.3 mmol) in methylene chloride (35 mL). The solution was treated in one portion with hydrazine hydrate (0.9 mL, 7.2 mmol, ~22% in H_2O) and stirred vigorously at rt for 1 h. The resulting, pasty off-white solid was removed by filtration. The clear eluent was diluted into 2.5 L of diethyl ether and stirred vigorously for 1 h at 4 °C, yielding a fine white precipitate. The solid was isolated by filtration and dried in vacuo for 3 h, affording **12** as a white powder (6.1 g, 3.0 mmols, 91%), which was used without further purification. ^{1}H NMR (400 MHz, $CDCl_3$): δ 3.4−3.8 (poly(ethylene glycol) signals), 5.5 (s, amine signals).

Coumarin−PEG Conjugate (14). To a stirred solution of coumarin-334 (**13**, 8.5 mg, 0.03 mmol) in methylene chloride (5 mL) was added **12** as a solid (38 mg, 0.02 mmol). Once the solid had dissolved completely, trifluoroacetic (20 μL) acid was added. After 2 h at rt, the reaction solution was poured slowly into 250 mL of diethyl ether. Precipitation occurred slowly over the course of 1 h, at which time the mother liquor was carefully decanted. The yellow solid was dissolved in ~2 mL of CH_2Cl_2 and again precipitated from diethyl ether. The yellow solid was used without further purification. Reversed-phase HPLC analysis of the solid indicated a ratio of 1:2 single/double coupled coumarin−PEG with no free coumarin-334 remaining. Stoichiometry for protein reactions was estimated on the basis of this ratio.

4-Formylbenzoic Acid 2,5-Dioxopyrrolidin-1-yl Ester (15). A stirred solution of *p*-formylbenzoic acid (200 mg, 1.33 mmol), *N*-hydroxysuccinimide (230 mg, 2.0 mmol), and *N*,*N*-diisopropylethylamine (520 μL, 3.0 mmol) in dry THF (25 mL) was cooled to 0 °C and treated in one portion with *N*,*N*-dicyclohexylcarbodiimide (310 mg, 1.5 mmol). The solution was stirred at 0 °C for 30 min and then allowed to warm to rt. Reaction progress was monitored by TLC (EtOAc). After 2 h at rt, the solution was concentrated under reduced pressure and then diluted with methylene chloride (25 mL). Insoluble material was removed by filtration, and the solution was again concentrated under reduced pressure. The remaining mixture was again filtered, and the eluent was applied to a silica-gel column. Flash chromatography (EtOAc/hexanes) afforded **15** as a pure white solid (310 mg, 94% yield). ^{1}H NMR (500 MHz, $CDCl_3$): δ 2.92 (s, 4H), 8.01 (d, 2H, $J = 8.0$ Hz), 8.28 (d, 2H, $J = 8.0$ Hz), 10.12 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$): δ 25.7, 129.7, 130.0, 131.2, 140.3, 161.1, 168.9, 191.2.

Aldehyde-Functionalized mtMS2 Capsids (16). A 1.0 mL buffered solution of mtMS2 (100 μM in "monomer", 100 mM NaH_2PO_4, pH 9.0) was treated with 50 μL of a solution of **15** (20 mM in DMF). The resulting solution was incubated at rt on a rotating shaker for 2 h. The mtMS2 conjugate was purified from unreacted small-molecule impurities using size-exclusion chromatography (NAP-10). Labeling efficiency was determined by ESI-MS to be ~1:3:2 (unlabeled/single conjugate/double conjugate) distribution of adducts with a small amount of triple modification noted.

RESULTS AND DISCUSSION

Our target scaffold, bacteriophage MS2, possesses many desirable features with regard to both processing and synthesis. It is a $T = 3$ icosahedral virus, with a 27 nm protein capsid composed of 180 identical copies of a 13.7 kDa subunit (*29*, *30*). Native MS2 (natMS2) is safe, easily handled, readily propagated in multi-milligram quantities in broth cultures, and remains indefinitely stable upon storage in aqueous buffer at 4 °C (*31*, *32*). In addition, we have previously shown that natMS2 possesses impressive stability to a broad range of temperature, pH, ionic strength, and organic cosolvent conditions, and is capable of forming genome-free "empty" capsid shells (mtMS2, **1**) that exhibit nearly identical resistance to disassembly and denaturation under extreme conditions to that of natMS2 (*18*). Crucial to our internal modifications is the fact that MS2 possess 32 pores per capsid, each approximately 1.8 nm in diameter. These structural features provide ready access to its interior space for moderately sized particles and reagents, including functionalized drug molecules, for covalent attachment.

The abundance of reactive amines (the coat protein N-terminus, Lys 106, and Lys 113) presented on the nat- or mtMS2 exterior allows for facile and high-yielding modification via *N*-hydroxysuccinimide esters (Figure 2b). However, the key to selectivity for our dual surface modification strategy is the targeting of an interior amino acid side chain with orthogonal reactivity to lysine and cysteine residues. We have previously shown that this can be accomplished by functionalizing Tyr 85, which is displayed on the interior face of each monomer after capsid assembly. Following the removal of the RNA genome, this residue can undergo a rapid and efficient coupling to the diazonium salt of p-nitroaniline to install an azo linkage *ortho* to the phenolic moiety of the tyrosine (Figure 2a) (*18*).

As an elaboration of this strategy, the current study began with the synthesis of aniline **4**, which bears the nitro group that is required to achieve high coupling efficiency and an aliphatic amino group that can be functionalized selectively with virtually any commercially available NHS-ester. This is demonstrated for fluorescein derivative FAM-SE in Figure 3. The resulting aniline derivative (**5**) was then converted to diazonium salt **6** before being exposed to mtMS2 in a 5-fold excess (relative to capsid monomers) for 15 min. After gel filtration to remove small molecules and any dissociated monomers, the resulting conjugate (**2**) was recovered at 90% with each intact particle encapsidating 50−70 fluorescein dyes (as determined by MALDI-TOF MS and UV−vis analysis). We were particularly interested in these fluorescent anilines, as they can serve as useful visualization probes for subsequent cell-based assays. In addition, the large size of the aniline−dye conjugate (MW $\approx$ 600) demonstrates that access to the capsid interior is permitted for relatively large molecules, potentially including many drugs.

With the internally labeled capsids in hand, the exterior surface was passivated through the attachment of poly(ethylene glycol) (PEG) chains (*33*, *34*). As previously demonstrated for a vast array of biomacromolecules and small molecules (*35*, *36*), PEG conjugation reduces the humoral immune response in vivo, improves serum half-life, enhances bioavailability, and minimizes proteolytic cleavage. In the case of viral capsids, PEG conjugation has been shown to reduce the immunogenicity of adenovirus-based gene delivery vectors (*37*), as well as improve its prospects for oral delivery (*38*). In addition, PEG conjugation to cowpea mosaic virus (CPMV) has been observed to alter the levels of serum antibodies following inoculation (*7*). Through the clever use of blue fluorescent antibodies, PEG chains have also been shown to prevent the binding of small molecule antigens displayed on the surface of CPMV.

In the context of MS2, the attachment of PEG chains was first accomplished through the reaction of **2** with commercially available PEG-NHS esters (MW = 2000 or 5000), affording conjugates **3a** and **3b** with essentially complete conversion (Figure 2c). Gel filtration using S-300 resin followed by centrifugal concentration removed the excess PEG after bioconjugation was complete. For both polymers, single, doubly, and triply modified capsid monomers were observed by SDS-PAGE. In comparison to other viral capsid-based scaffolds, this level of PEG coverage is unprecedented, adding over 1800 kD of polymer (in the case of the PEG-5000) to the surface of each capsid. This coverage was obtained without any observable protein precipitation or denaturation, in contrast to what has been observed previously for other viral particles. Fluorescence imaging of the gel for conjugates **3a** and **3b** confirmed that the PEG-modified capsid monomers retained the dye molecules attached to the inner surface. The selectively differentiated conjugates were obtained with an overall protein recovery (two steps) of over 80%.

The assembly state of the doubly modified capsids was determined using several analytical techniques. Analytical size exclusion chromatography and TEM analysis (Figure 2d,e) indicated the presence of intact capsids with no indication of protein monomers. In addition, the spherical nature of the capsid conjugates made them particularly amenable to characterization by dynamic light scattering (DLS) (Table 1). Virtually identical particle diameters were observed for natMS2, mtMS2, and **2**, each measuring 27−29 nm. Upon conjugation of the PEG-2000 chains (**3a**), an effective diameter of 34 nm was observed, with a further increase to 41 nm upon conjugation of the PEG-5000 chains (**3b**). Further determination of each particle's ζ potential indicated that the inherent excess negative surface charge of MS2 (−19.40 mV) is reduced significantly upon PEGylation, a property that is highly desirable to avoid bioaccumulation in drug delivery formulations (*39*, *40*). Interestingly, thermal denaturation studies (also monitored using DLS) indicated that the dual surface-functionalized particles remained fully assembled up to 58 °C, with no apparent effects from the polymer coating. This value is identical to that measured for natMS2 itself.

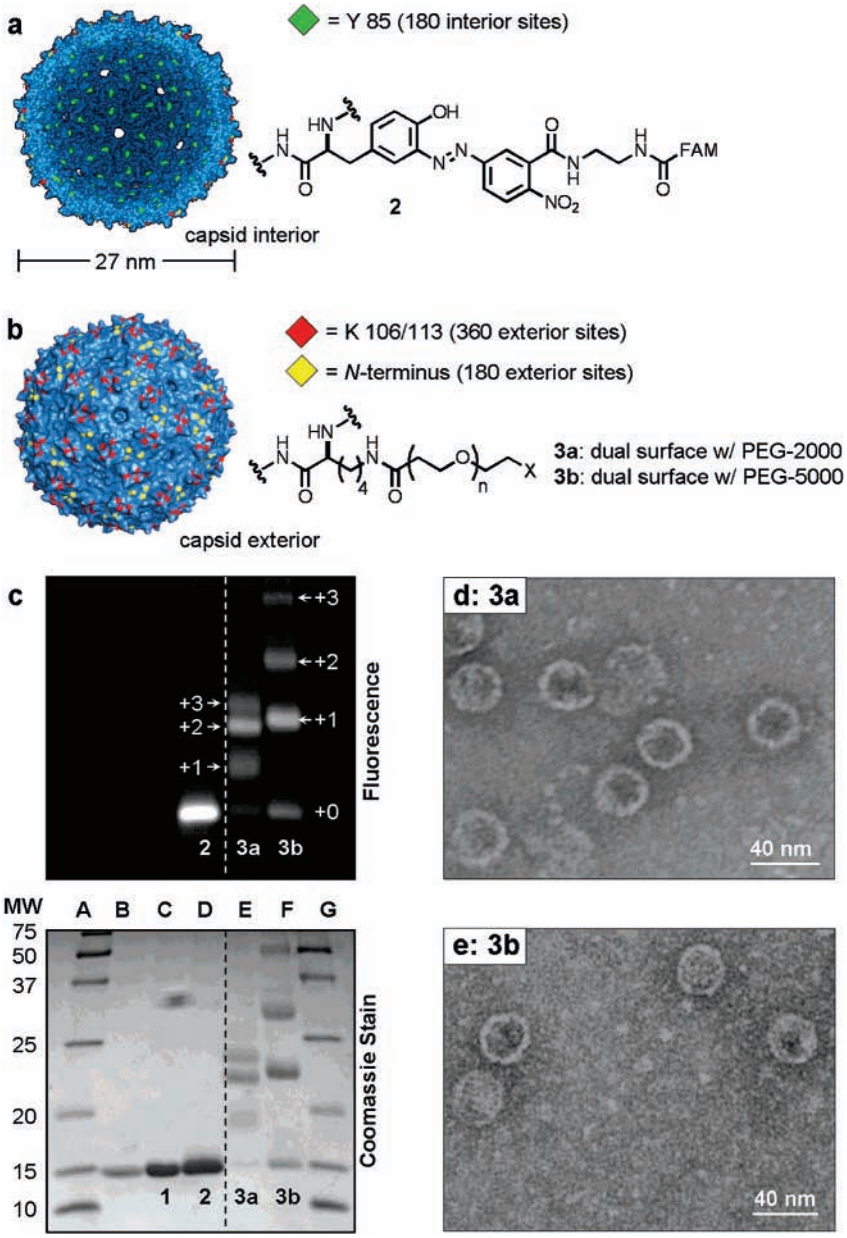

Figure 2. Dual surface modification of MS2 capsids. (a) Tyrosine 85 of the interior capsid surface undergoes rapid diazonium coupling with *p*-nitroaniline derivatives, including large dye conjugates. (b) Up to 360 accessible amino groups (lysines 106, 113, and the *N*-terminus) on the capsid exterior are readily modified with PEG-NHS esters. (c) SDS-PAGE analysis confirming both PEGylation (via MW shift) and dye attachment (fluorescent bands) for capsid monomers after disassembly. The arrows indicate coat proteins modified with 1, 2, or 3 PEG chains. Lanes A and G: MW markers, listed in kDa. Lane B: natMS2. Lane C: mtMS2 (**1**) + aniline **5**. Lane D: **2**. Lane E: **3a**. Lane F: **3b**. (d,e) In addition to other methods, the assembly state of the modified capsids was confirmed by TEM analysis after staining with $UO_2(OAc)_2$.

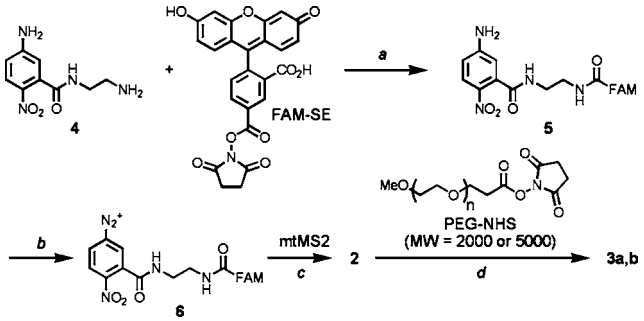

Figure 3. Dual surface modification sequence. Reagents and conditions: (a) DMF, Et_3N, 65 °C, 1.5 h, >95%; (b) $NaNO_2$, *p*-TsOH, 0 °C, 0.75 h; (c) **6** (5 equiv), pH 8.5, 0 °C, 5 min, 90% protein recovery; (d) pH 8.4, rt, 15 h, 90% protein recovery.

To determine the ability of the PEG chains to mask the capsid surface from antibody recognition, we subjected our samples to a sandwich ELISA assay. Using rabbit-derived anti-native MS2 polyclonal antibodies for detection and capture, identical maximum antibody binding was achieved with natMS2, mtMS2, or conjugate **2** under the full range of protein concentrations tested. This indicates that the native epitopes of the MS2 capsid remain intact after genome removal and subsequent internal modification with **6** (Figure 4). In contrast, PEG-2000 conjugate

Table 1. Properties of MS2 Conjugates Obtained from DLS Measurements[a]

sample	avg particle size[a]	ζ potential[b]	disassembly temp[c]
mtMS2	28.9 ± 1.1 nm	−19.4 ± 2.3 mV	58−61 °C
2	27.5 ± 0.9 nm	−21.5 ± 1.4 mV	58−61 °C
3a	34.5 ± 0.7 nm	−11.4 ± 0.6 mV	58−61 °C
3b	40.9 ± 1.0 nm	−5.0 ± 2.1 mV	58−61 °C

[a] Average of ten separate measurements. [b] Average of three separate measurements. [c] Reported as the point at which additional peaks (±50% of established particle size) emerge as >4% of the volume distribution for a single particle size measurement.

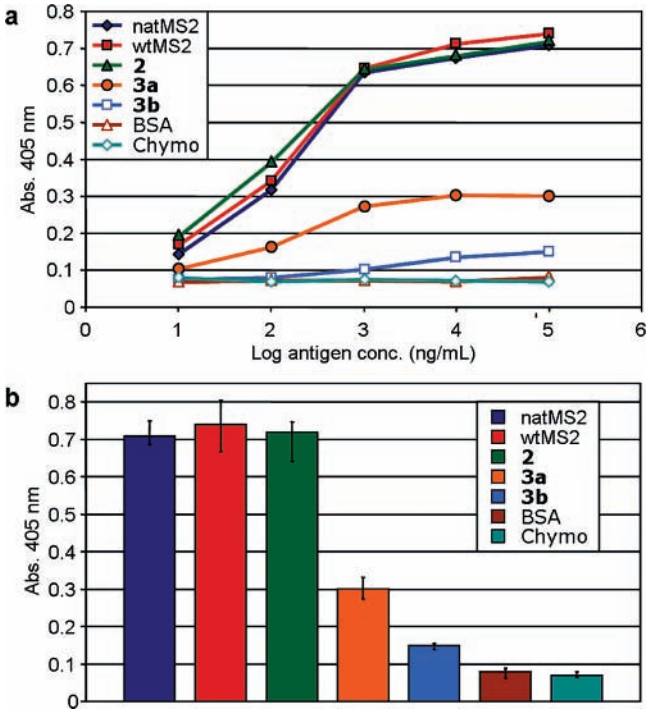

Figure 4. Polyclonal anti-natMS2 antibody response to MS2 capsids, as determined by ELISA. (a) ELISA response for the sample antigen concentration from 10 ng/mL to 0.1 mg/mL. (b) Comparative antibody binding for antigen concentration at 0.1 mg/mL. BSA = bovine serum albumin and chymo = α-chymotrypsinogen (negative controls).

3a exhibited greater than 65% reduction in antibody binding, while PEG-5000 conjugate **3b** showed nearly 90% reduction at the highest concentration of antigen sample tested (Figure 4b).

A number of functional groups have been shown to direct attached cargo to specific tissue types in vivo. In terms of small molecules, folate (*41*), transferrin (*42*), and vitamin B_{12} (*43*, *44*), have been particularly successful for the targeting of solid tumors, and a growing collection of peptides that target organs of interest have been identified through the use of phage display techniques (*45*). In addition to shielding the capsid surface from antibody recognition, it was envisioned that the polymer chains could be used to display these molecules to gain similar control of cellular uptake for MS2-derived drug carriers. However, a key consideration of this technique is the ability of the small molecules to reach their targets in the presence of the PEG layer. To test this, samples of mtMS2 capsids were biotinylated using commercially available NHS esters bearing (in the case of **8a** and **8b**) or lacking (in the case of **7**) PEG chains, Figure 5a. For biotin-3k-PEG conjugate **8a**, SDS-PAGE analysis indicated that 30% of the monomers had been functionalized, while for biotin-PEG-5000 conjugate **8a**, the level of modification was 70%. These differences in reactivity were attributed to degradation of the NHS esters during storage prior to use. Nonetheless, this method produced samples displaying 50−100 biotin groups at the end of the polymer chains.

The resulting samples were exposed to avidin beads for 1 and 15 h, after which the samples were centrifuged to remove the captured MS2 from solution. SDS-PAGE analysis of the remaining supernatants revealed 82% recovery for mtMS2 capsids as a negative control, Figure 5b,c. Surprisingly, similar levels (87%) of mtMS2 capsids functionalized with biotin (**7**) were also recovered, suggesting that the capsid surface hinders the ability of the avidin groups to reach the displayed ligands. In contrast, both of the PEG−biotin conjugates were removed from solution using this method, indicating that the small-molecule ligands had access to the solution surrounding the PEG layer. After 15 h of exposure to the resin, 90% of the capsids

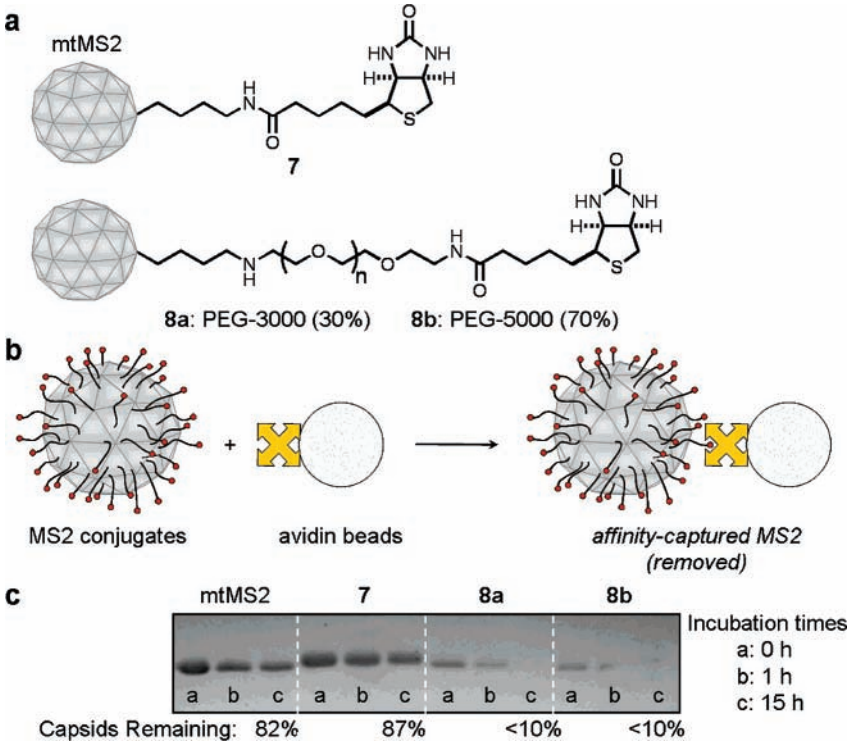

Figure 5. Accessibility of small molecules displayed on the distal ends of MS2-PEG conjugates. (a) Biotinylated samples of MS2 were prepared through reaction of the corresponding NHS esters with genome-free capsids. Densitometry measurements after SDS-PAGE analysis and Coomassie staining indicated that ∼30% of the monomers were labeled in the case of **8a** and 70% of the monomers were labeled in the case of **8b**. (b) Conjugates **7**, **8a**, and **8b** were incubated with avidin beads for 0, 1, and 15 h. (c) Following centrifugation, the MS2 remaining in the supernatant was analyzed by SDS-PAGE. The percentages reported were determined by densitometry analysis after Coomassie staining. For the polymer-conjugated samples, only the band corresponding to unlabeled monomers is shown.

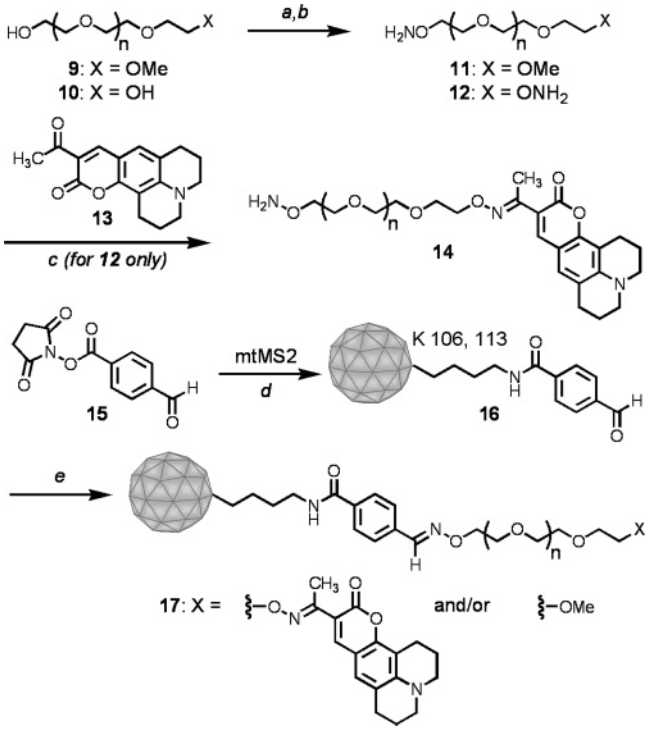

Figure 6. Chemical strategy for the installation of PEG chains bearing small-molecule targeting groups. Reagents and conditions: (a) DIAD, *N*-hydroxyphthalimide, CH_2Cl_2, rt, 12 h (see Experimental Procedures); (b) $NH_2NH_2 \cdot xH_2O$ (2.2 equiv), CH_2Cl_2, rt, 1 h; (c) CH_2Cl_2, 0.1% TFA; (d) 100 mM NaH_2PO_4 aqueous buffer, pH 9.0, rt, 2 h; (e) 25 mM NaH_2PO_4 aqueous buffer, pH 6.5, 1.5 h, rt.

were removed from solution for both **8a** and **8b**. It should be noted that these effects will vary dramatically for each ligand−receptor combination; however, this experiment serves to validate the placement of targeting groups at the ends of the polymer chains.

Following the success of this experiment, the final synthetic component of these studies was the development of a modular strategy for the coupling of a wide variety of small molecules to the ends of the PEG chains. Oxime formation was chosen for this purpose, as it proceeds rapidly and chemoselectively under mild reaction conditions in aqueous media (*46*). In a previous report, we have explored the use of singly functionalized PEG−alkoxyamines, such as methoxy-terminated **11**, for the modification of ketones introduced on the surface of the tobacco mosaic virus (*8*). For this study, precursors to doubly functionalized PEG-bis-alkoxyamines were prepared through the displacement of the alcohol groups of PEG-diol **10** using hydroxyphthalamides under Mitsunobu conditions (Figure 6). Hydrazinolysis subsequently afforded bis-alkoxyamine **12**, which could be condensed with ketones and aldehydes in CH_2Cl_2 using catalytic TFA. Fluorescent coumarin−ketone **13** was used in these model studies, as it can be visualized readily after SDS-PAGE analysis of the bioconjugates.

To bind to the remaining alkoxyamine group of **14**, aldehydes were installed on the surface of mtMS2 capsids using NHS ester **15**. Following removal of the small molecules using gel filtration, MALDI-MS analysis indicated ~90% conversion of the capsid monomers to single, double, and triple conjugates. These groups were attached to the alkoxyamine groups in aqueous phosphate buffer, pH 6.5, in 1.5 h at rt. The unreacted PEG chains were removed using gel filtration, and the samples were analyzed using SDS-PAGE with fluorescence visualization of the attached coumarin, followed by Coomassie staining. Using this method, high levels of conversion could be obtained to the singly, doubly, and triply conjugated species (Figure 7). Using

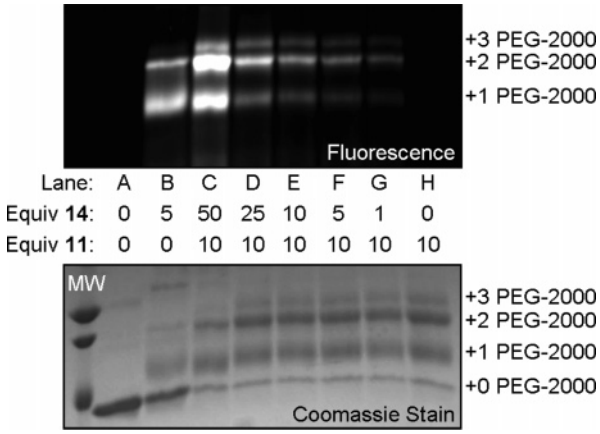

Figure 7. Attachment of functionalized PEG chains to the aldehyde groups of MS2 conjugate **16** through oxime formation. All reactions were carried out in 25 mM phosphate buffer, pH 6.5, for 1.5 h, using the indicated ratios of **14** and **11**. The remaining polymer was removed via gel filtration before SDS-PAGE analysis. From bottom to top, the MW markers correspond to 15, 20, and 25 kD.

this method, the number of ligands that are displayed can be modulated by varying the ratio of labeled PEG (**17**) to methoxy-PEG (**11**), as observed by changes in fluorescence intensity for samples with the same overall PEG coverage.

Through these studies, we have demonstrated the ability of MS2 viral capsids to undergo a facile, site-selective dual surface modification to afford unique hybrid drug delivery vehicles. These conjugations were achieved in high overall yield, were accomplished without the need for site-directed mutagenesis, and produced particles that are as resistant to disassembly and denaturation as the native capsid. Our exterior PEGylation levels match or exceed previous reports for other viral particles, resulting in a nearly 90% reduction in antibody binding of the capsid surface. The interior modification strategy demonstrates that access to the interior is readily permitted for large "druglike" dye molecules, while further expanding the utility of tyrosine-selective reactions to achieve bioconjugations that are orthogonal to lysine and cysteine modification strategies. Further studies are underway to monitor the biodistribution and serum half-life of these particles in vivo using animal models. In addition, we are investigating the optimal degradable linkage for the interior surface attachment of drug cargo. The ability of targeting ligands to enhance capsid uptake in specific cell lines is also being explored.

ACKNOWLEDGMENT

These studies were generously supported by the Chemical Biology Graduate Program in the Department of Chemistry at UC Berkeley (NRSA Training Grant 1 T32 GMO66698), the Biomolecular Materials Program at Lawrence Berkeley National Labs (DE-AC02-05CH11231), and the NIH (GM072700-01). Synthesis and Characterization of PAMAM Dendrimer-Based Multifunctional Nanodevices for Targeting $\alpha_v\beta_3$ Integrins

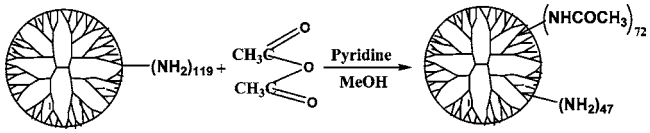
Wojciech G. Lesniak,[†,§] Muhammed S. T. Kariapper,[†,§] Bindu M. Nair,[†] Wei Tan,[‡] Alan Hutson,[‡] Lajos P. Balogh,*[,†] and Mohamed K. Khan[†]



NanoBiotechnology Center at RPCI, Department of Radiation Medicine, and Department of Biostatistics, Roswell Park Cancer Institute, Elm and Carlton Streets, Buffalo, New York 14263. Received January 10, 2007; Revised Manuscript Received April 2, 2007

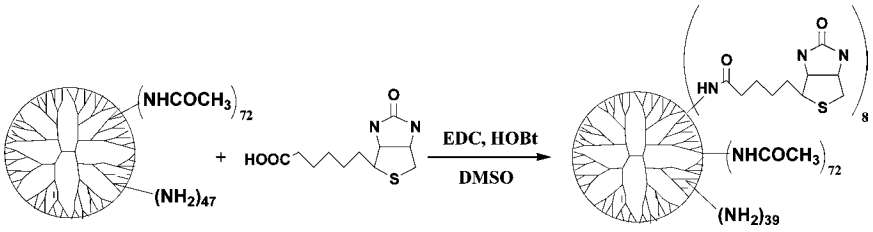
We have synthesized a stable and clinically relevant nanodevice (cRGD-BT-ND; ND for short) that exhibits superior binding to the biologic target $\alpha_v\beta_3$ integrins, when either compared to the same free cRGD peptide or to the biotinylated nanodevice without covalently attached peptides (BT-ND). Selective targeting of $\alpha_v\beta_3$ integrins was achieved by coupling cyclic cRGD peptides to the nanodevice (ND) surface, while biotin groups (BT) were used for amplified detection of bound cRGD-BT-ND by anti-biotin antibody or avidin linked to horseradish peroxidase after binding. The synthesis involved the following steps: the amino-terminated ethylenediamine core generation 5 poly(amidoamine) (PAMAM_E5.NH_2) dendrimer was first partially acetylated and then biotinylated, and residual primary amine termini were converted to succinamic acid groups (SAH), some of which finally were conjugated with cRGD peptide residues through the amino group of the lysine side chain. The starting material and all derivatives were extensively characterized by polyacrylamide gel electrophoresis (PAGE), size exclusion chromatography (SEC), potentiometric acid−base titration, MALDI-TOF, and NMR. Cytotoxicity of all dendrimer derivatives was examined in B16F10 melanoma cell cultures using the XTT colorimetric assay for cellular viability. Binding of nanodevices to the biological target was determined using plates coated with human $\alpha_v\beta_3$ integrin and $\alpha_v\beta_3$ receptor expressing human dermal microvascular endothelial cells (HDMECs). The PAMAM_E5.$(NHAc)_{72}(NHBT)_8(NHSAH)_{35}(NHSA\text{-}cR\ GD)_4$ nanodevice is nontoxic within physiologic concentration ranges and specifically binds to the $\alpha_v\beta_3$ integrins, apparently much stronger than the cyclic cRGD peptide itself.

INTRODUCTION

We are developing a novel Systemic Targeted Radiation Therapy (START) approach utilizing a dendrimer-based platform to detect and treat primary and metastatic cancers. As a first step using poly(amidoamine) (PAMAM) dendrimer we have synthesized the multifunctional nanodevice that selectively binds to $\alpha_v\beta_3$ integrins. PAMAM dendrimers are water soluble, well-defined polymers, built from symmetric dendrons, containing β-alanine subunits, emanating from a core (*1*, *2*). These polymers are nearly ideal delivery vehicles, as they are not broken down by enzymes and are generally removed from the bloodstream by the filter organs (*3*−*6*). PAMAMs can be prepared to be nonimmunogenic, nonmutagenic, and nontoxic (see, e.g., *7*). Modifiable terminal functionalities of dendrimers offer a multipurpose mode to covalently attach drugs, diagnostic/imaging modules, and targeting moieties (*8*). PAMAMs have been already used as delivery vehicles for oligonucleotides, antisense oligonucleotides, oligonucleotide arrays, and chemotherapeutic cancer drugs (*9*−*11*). They have also been utilized as templates for composite nanoparticles, which allows them to host inorganic nanoclusters (*12*), thus providing a way to integrate desirable properties of inorganic materials and biofriendly polymers, and yielding several new imaging and therapy applications (*13*−*15*).

Scheme 1

During the design of this ND[1], we considered the following. The $\alpha_v\beta_3$ integrins are highly overexpressed on the angiogenic endothelial cells present in tumors, and are not available for binding in normal blood vessels (*16*). This feature can be exploited to target nanodevices (NDs) to endothelial cells of tumor microvasculature by covalently attaching $\alpha_v\beta_3$ targeting peptides to the surface of each nanodevice. For this purpose four copies of a specific cyclic RGD peptide (Phe(f)-Lys-Arg-Gly-Asp, abbreviated to cRGD) were conjugated with dendrimer. We used a peptide that strongly binds to the $\alpha_v\beta_3$ integrins and is already in clinical trials (*17*), making the nanodevice potentially more clinically useful than other permutations of RGD peptides (*10*). Additionally, it is a more stable cyclic RGD peptide compared to cyclization achieved via disulfide bond.



During the design, we have considered that toxicity of nanodevices, including dendrimers, often results from the presence of excessive positive charges (*7*, *11*, *15*). For this reason, we converted the unused primary amine surface groups that would have been positively charged (thus potentially toxic) at biologic pH values (pH = 5.5−7.5), to carboxylate groups by reacting them with succinamic anhydride.

Exact measurement of biodistribution is a prerequisite for the construction of efficient medical nanodevices that carry therapeutic or imaging agents to cancer cells. In the present literature, dendrimer-based nanodevices are often tracked by covalently attaching fluorescent dye molecules to the macromolecules. The apparent disadvantage of that method is that attaching large aromatic molecules to a dendrimer surface has to change the biodistribution of the dendrimer nanodevices. In our ND we used biotin as a label on the ND that can selectively be detected by labeled antibodies. We have conjugated eight biotin moieties per dendrimer to detect the presence of dendrimers sensitively and selectively after localization, as it is described in Experimental Procedures below. Using nanodevices labeled with multiple biotin units results in considerable signal amplification, while it does not disturb the biodistribution of the nanodevice.

EXPERIMENTAL PROCEDURES

General. Ethylenediamino-core poly(amidoamine) PAMAM dendrimer of generation 5 (PAMAM_E5.NH_2) was purchased from Dendritech Midland, MI, in methanol solution (14.17 wt %). Succinic anhydride, pyridine, acetic anhydride, biotin, bovine serum albumin, absolute methanol, dimethyl sulfoxide (DMSO), 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide, and 1-hydroxybenzotriazole were obtained from Aldrich and used as received. Cyclic RGD peptide (Phe(f)-Lys-Arg-Gly-Asp) was acquired from Peptides International (Louisville, KY) and characterized by HPLC, electrospray ionization-TOF MS, and amino acid analysis before use. $\alpha_v\beta_3$ Integrin was purchased from Chemicon International (Temecula, CA). Immuno-Pure Avidin HRP and *o*-phenylenediamine were obtained from Pierce (Rockford, IL). Regenerated cellulose dialysis membranes

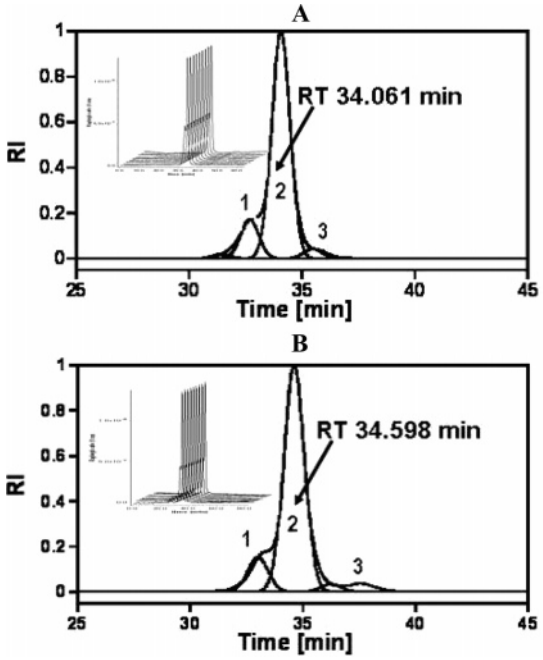

Figure 1. (A) Molecular mass distributions of the starting material E5.NH_2 dendrimer, and (B) the E5.$(NHAc)_{72}(NHB)_8(NHSAH)_{35}$-$(NHSAcRGD)_4$ nanodevice shown by their RI signals (insert, MALLS data). Fit of RI signals was performed using Gaussian deconvolution of SEC chromatograms using PeakFit software. The starting material contains (A1) $(E5.NH_2)_2$ dimers (16.42%), (A2) E5.NH_2 generation five dendrimers (80.42%), and (A3) a small amount of trailing generation E4.NH_2 (3.15%). Average molecular mass of M_n = 27 280, M_w = 30 280 with a polydispersity of M_w/M_n = 1.110 were obtained for this material. The final product (B) contains modified dimers (B1 = 16.32%); modified E5 derivatives (B2 = 80.22%) and a small amount of modified trailing generation (B3 = 3.46%). (Respective molecular masses calculated from PeakFit are M_n = 34080, M_w = 38 067, and M_w/M_n = 1.117).

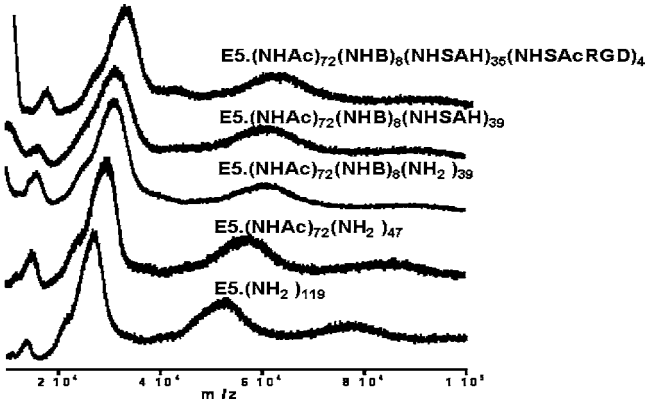

Figure 2. MALDI-TOF spectra of starting dendrimer, of the intermediates, and of the final nanodevice using 2,5-dihydroxybenzoic acid (DHB) as a matrix.

(MWCO = 2000 and 10 000) were acquired from Fisher. Water used in the experiments was purified by a Milli-Q Plus 185 water purification system (Millipore, Bedford, MA) with resistivity higher than 18 MΩ cm^{-1}. Starting material and all derivatives were characterized by polyacrylamide gel electrophoresis (PAGE), and size exclusion chromatography equipped with three detectors: multiangle laser light scattering, UV−vis diode-array, and refractive index (SEC-MALLS-DAD-RI), potentiometric acid−base titration, matrix assisted laser desorption ionization-time-of-flight (MALDI-TOF) mass spectrometry, and nuclear magnetic resonance (NMR).

Synthesis of PAMAM_E5.$(NHAc)_{72}(NHBT)_8(NHSAH)_{35}$-$(NHSAcRGD)_4$. *(1) Synthesis of PAMAM_E5.$(NAc)_{72}(NH_2)_{47}$ Dendrimer (Scheme 1).* A 100 mL amount of methanol solution containing 3.08 g ($n = 1.13 \times 10^{-4}$ mol) of PAMAM_E5.NH_2 dendrimer was placed in a 250-mL round-bottom flask. Then 100 mL of methanol solution with 1.53 g ($n = 1213 \times 10^{-2}$ mol) of pyridine and 0.98 g ($n = 9.60 \times 10^{-3}$ mol) of acetic anhydride was added. After 24 h, methanol was evaporated on a rotary evaporator. The residue was dissolved in water and dialyzed (using cellulose membrane with 2000 MWCO) against water for 3 days to remove byproducts and excess reactants. The obtained solution was filtered and lyophilized.

(2) Synthesis of PAMAM_E5.$(NHAc)_{72}(NHBT)_8(NH_2)_{39}$. Nanodevice (Scheme 2). A 0.08 g biotin ($n = 3.28 \times 10^{-4}$ mol) was dissolved in 50 mL of dimethyl sulfoxide (DMSO) in a 250-mL round-bottom flask then 0.13 g ($n = 6.78 \times 10^{-4}$ mol) of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDC) and 0.09 g ($n = 6.66 \times 10^{-4}$ mol) 1-hydroxybenzotriazole (HOBt) was added and mixed for 0.5 h at room temperature to obtain active ester. Then 50 mL of DMSO solution containing 1.04 g ($n = 3.55 \times 10^{-5}$ mol) of PAMAM_E5.$(NAc)_{72}(NH_2)_{47}$ dendrimer (product obtained in the first step of the synthesis) was added to the mixture and stirred for an additional 24 h under nitrogen atmosphere. The reaction mixture was diluted with water and dialyzed for 3 days using cellulose membrane with 10 000 MWCO, filtered, and lyophilized.

(3) Synthesis of PAMAM_E5.$(NHAc)_{72}(NHBT)_8(NHSAH)_{39}$ Nanodevice (Scheme 3). A 0.83341 g ($n = 2.73 \times 10^{-5}$ mol) of PAMAM_E5.$(NAc)_{72}(NH-BT)_8(NH_2)_{39}$ (product obtained in the second step of the synthesis) was dissolved in 50 mL of DMSO solution and placed in a 250-mL round-bottom flask. Then 0.68 g ($n = 6.73 \times 10^{-3}$ mol; 4 mol equivalents compared to the remaining terminal NH_2 groups; number of amino termini was calculated based potentiometric titrations) of succinic anhydride was added with vigorous stirring. The reaction was stopped after 24 h by diluting the reaction mixture with water. Byproducts and excess reactants were removed by dialysis using cellulose membrane with 10 000 Da MWCO. The retentate was filtered, and the resulting solution was lyophilized.

(4) Synthesis of PAMAM_E5.$(NHAc)_{72}(NHBT)_8(NHSAH)_{35}$ $(NHSAcRGD)_4$ Nanodevice (Scheme 4). A 50 mL amount of DMSO stock solution containing 0.19 g ($n = 6.00 \times 10^{-6}$ mol) of PAMAM_E5.$(NHAc)_{72}(NHBT)_8(NHSAH)_{39}$ (product obtained in the previous step of synthesis) was placed in a 250-mL round-bottom flask. Then 0.19 g of EDC and 0.08 g HOBt (4 mol equiv compared to terminal COOH groups) were added and stirred for 0.5 h to form active ester. Then 50 mL of DMSO solution containing 0.03 g ($n = 4.97 \times 10^{-5}$ mol) of c-RGD peptide was added. Reaction was stopped after 24 h by diluting the reaction mixture with water. Byproducts and excess reactants were removed by dialysis using cellulose membrane with 10 000 Da MWCO. The retentate was filtered, and the resulting solution was lyophilized.

Analytical Methods. *Size Exclusion Chromatography (SEC).* Analysis was performed using an Alliance Waters 2690 separation module equipped with a Waters UV−vis detector, a Wyatt Dawn laser photometer, Optilab interferometric refractometer, and Waters Ultrahydrogel columns. Phosphate buffer (0.05 M, pH 2.5) with 0.025% sodium azide was used as mobile phase. The flow rate was maintained at 0.6 mL/min. Sample concentration was kept at 2 mg/mL, and 100 μL was injected. Data was elaborated using Astra and PeakFit software.

Potentiometry. Dendrimers were dissolved in NaCl (0.1 M) solution at a concentration of 0.5 mg/mL, and the pH was set to around 3. In the case of each sample, the same number of moles (adjusted by the volume) was titrated. Titrations were performed at room temperature, under nitrogen atmosphere,

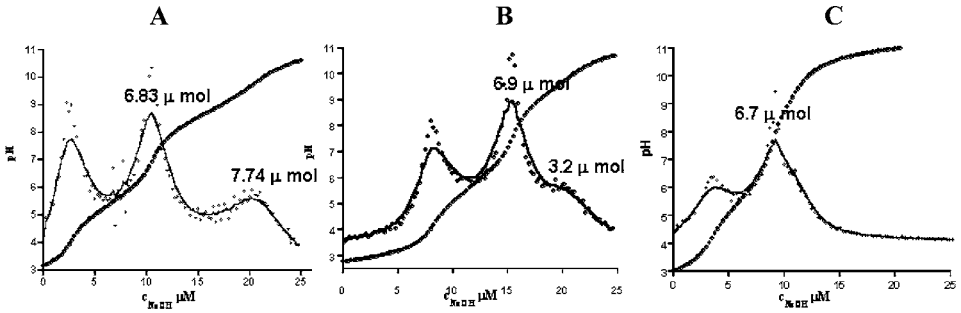

Figure 3. Potentiometric titration curves of (A) the PAMAM_E5.NH_2 amino-terminated dendrimer (starting material), (B) its acetylated derivative obtained after the first step of synthetic path, clearly showing shift of the end point of titration of primary aminogroups upon acetylation, and (C) E5.$(NHAc)_{72}(NHBT)_8(NHSAH)_{39}$ showing disappearance of NH_2 groups.

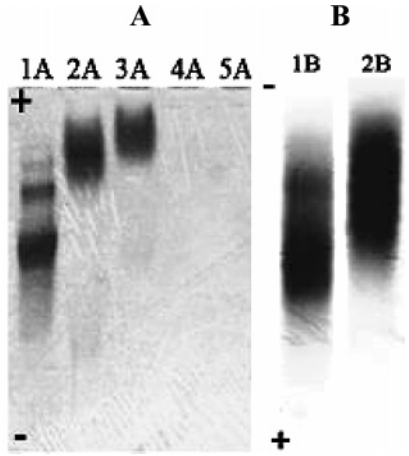

Figure 4. PAGE of starting dendrimer, nanodevice intermediates, and the final product: (1A) E5.$(NH_2)_{119}$, (2A) E5.$(NHAc)_{72}(NH_2)_{47}$, (3A) E5.$(NHAc)_{72}(NHBT)_8(NH_2)_{39}$, (4A) E5.$(NHAc)_{72}(NHBT)_8(NHSAH)_{39}$, (5A) E5.$(NHAc)_{72}(NHBT)_8(NHSAH)_{35}$-$(NHSAcRGD)_4$, (1B) E5.-$(NHAc)_{72}(NHBT)_8(NHSAH)_{39}$, (2B) E5.$(NHAc)_{72}(NHBT)_8(NHSAH)_{35}$-$(NHSAcRGD)_4$.

using Molspin automated titration system, a Mettler-Toledo combination InLab electrode, and NaOH (0.1 M) as a titrant.

Polyacrylamide Gel Electrophoresis. PAGE of PAMAM dendrimers was performed using a vertical electrophoresis system (Model FB-VE10-1 FisherBiotech) with a commercial power supply (Model EC135−90; Thermo Electron Corporation), precast 4−20% gradient express gels for PAGE (BioExpress), and Tris-glycine (TG) native (pH = 8.3). Separations typically required 1.5 h min at 200 V. Into each sample well, 2 μL of a sample solution composed of 2 or 3 μL of 1 mg/mL PAMAM dendrimer and 2 or 3 μL of sucrose dye solutions (50% sucrose, 1% methylene blue) was injected. Developed gel was stained with 0.025% Comassie Blue R-250 in 40% methanol and 7% acetic acid aqueous solution overnight. The gels were destained with 7% (v/v) acetic acid and 5% (v/v) methanol in water.

Matrix-Assisted Laser Desorption Ionization-Time-of-Flight Mass Spectrometry. Spectra of dendrimer nanodevices were recorded on a Bruker Biflex IV spectrophotometer, using 2,5-dihydroxybenzoic acid (DHB) as a matrix. First 0.5 μL of matrix was placed on the target, plated, and evaporated. Then 0.5 μL of the dendrimer (~1.5 mg/mL) was spotted over the matrix. Matrix and dendrimer were dissolved in 75% ACN and 0.1% TFA aqueous solution. For each spectrum, 100 shots and 50% of laser power was applied. For each spectrum, 100 shots and 50% of laser power was applied.

Nuclear Magnetic Resonance. Spectra were recorded using Bruker AMX 400 MHz, D_2O as solvent, and at sample concentrations 20 mg/mL.

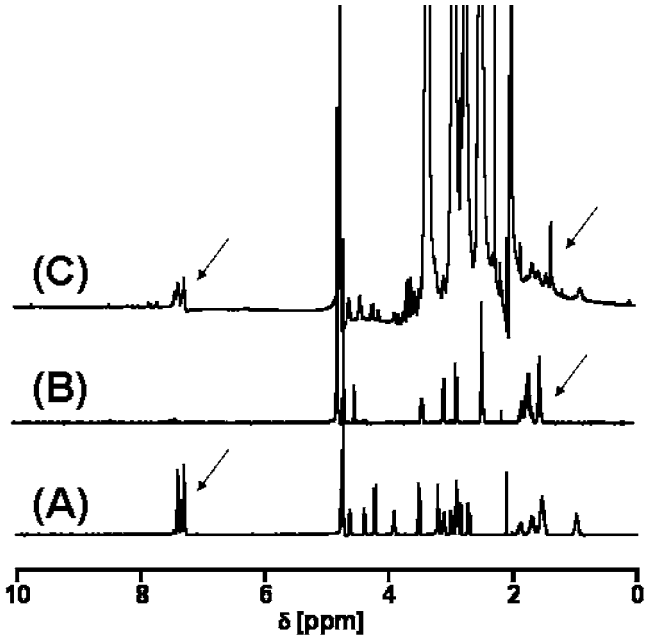

Figure 5. ^{1}HNMR spectra of (A) c-RGD, (B) biotin, and (C) cRGD-BT-ND revealing the presence of c-RGD peptide and biotin in the sample of cRGB-BT-ND well seen in the aromatic range of the spectrum pointed by arrows.

Biological Studies. *Toxicology Studies of the cRGD-BT-ND and the Four Intermediate Materials Leading Up to Its Synthesis.* Toxicity studies were conducted *in vitro*, using MatLyLu prostate cancer cells and B16F10 melanoma cells in tissue culture and 10, 100, 250, 500, 1000, and 2000 nM of ND. All samples were replicated in quintuplets. Tissue culture-treated 96-well microtiter plates were coated with cells and incubated at 37 °C, 5% CO_2, for 24 h. The following day, nanodevices in defined amounts were added to the plates, which were further incubated for 24 h and 48 h. To measure cell viability at different time points, plates were then treated with XTT (sodium 3′-[1-(phenylaminocarbonyl)-3,4-tetrazolium]-bis-(4-methoxy-6-nitro)benzenesulfonic acid hydrate) according to manufacturer's instructions (Roche Diagnostics Corporation, Indianapolis, IN). Briefly, at 0, 24, and 48 h time points, cell culture medium was removed, and an aliquot of 100 μL of fresh medium was added to each well. Then an aliquot of 50 μL of XTT working solution prepared according to manufacturer instructions was added to each well using multichannel pipet. After 3 h incubation in the dark at 37 °C, the absorbance at 490 nm was recorded using a plate reader.

Statistical Analysis of the Toxicity Experiment. To assess differences among six dose levels at each time reading and differences among three time readings at each dose level, the

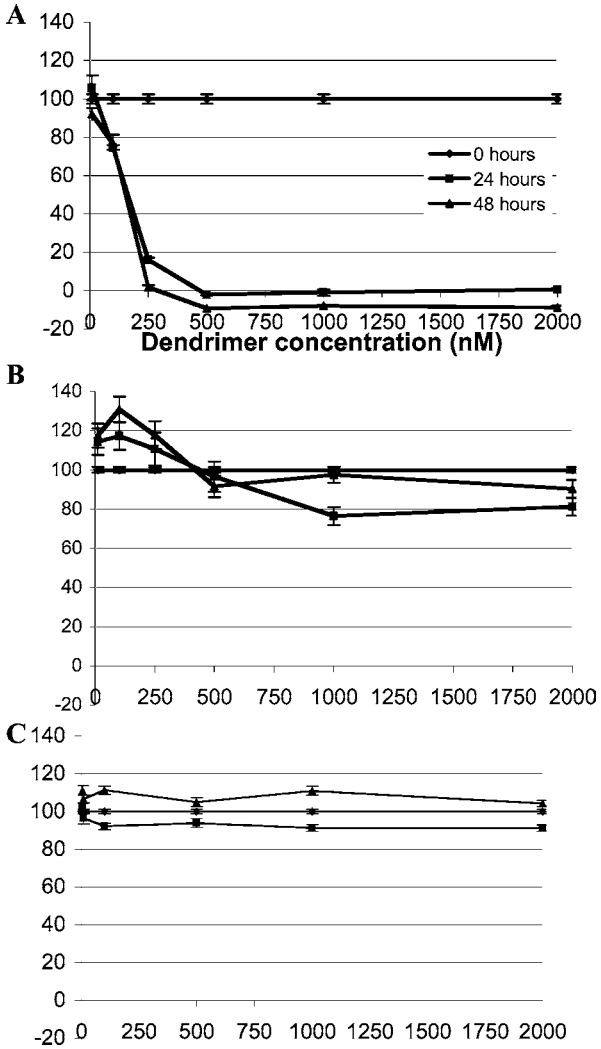

Figure 6. B16 cell viability in the presence of (A) PAMAM_E5.NH_2 and (B) cRGD-BT-ND and (C) HDMEC viability in the presence of cRGD-BT-ND at 0, 10, 100, 250, 500, 1000, and 2000 nM concentrations and 0, 1, and 2 days.

Wilcoxon test was used. Tests for overall group differences were done at a 0.05 level of significance. If there was a significant difference for overall comparison, the Bonferroni adjusted test was used to perform pairwise comparisons. All statistical analyses were carried out using SAS (version 9.1) statistical software (Cary, NC).

Nanodevice Binding to $\alpha_v\beta_3$ Integrin in Vitro. An aliquot of 100 μL (0.5 μg/mL) of purified $\alpha_v\beta_3$ integrin receptor (Chemicon Int., Temecula, CA) in coating buffer (50 mM Tris, pH 7.4; 100 mM NaCl and 1 mM each of $CaCl_2$, $MnCl_2$, and $MgCl_2$,) was immobilized in a 96-well microtiter plate overnight at 4 °C. The wells were washed once with binding buffer (50 mM Tris HCl, pH 7.4, 100 mM NaCl, 1 mM $CaCl_2$, 1 mM $MnCl_2$, 1 mM $MgCl_2$, and 35 mg/mL bovine serum albumin) and incubated with the same for 2 h at room temperature. The plate was then washed three times with binding buffer and an aliquot of 100 μL of BT-ND or cRGD-BT-ND (13.8 μM) added and incubated for 3 h at 4 °C. Competition assay was conducted adding 4-, 40-, and 400-fold excess of cRGD-peptide (Peptide International, Louisville, KY) simultaneously with the nanodevice. At the end of this incubation period, the plate was washed five times with binding buffer. The bound biotinylated NDs were detected by Immuno-Pure Avidin conjugated with horseradish peroxidase (product no. 21123; Pierce, Rockford, IL), which was subsequently developed using *o*-phenylenediamine and the absorbance at 450 nm recorded according to the manufacturer's directions (*18*).

Nanodevice Binding to Human Dermal Microvasculature Cells (HDMECs). HDMECs were seeded (50 000 cells per well) and grown on chamber slides (Lab Tek) in conditioned endothelial culture medium EBM Bullet kit 2 (Cambrex, Walkersville, MD). After 2 days at 50% confluence, cells were treated with 1 μM nanodevices for 5 h at 37 °C and washed five times with PBS buffer, fixed with cold acetone, and dried. Cells were then freeze-thawed (−80 °C) and blocked for 1 h with 4 mg/mL BSA in PBS followed by 1 h incubation with FITC labeled anti-biotin antibody (Vector Labs, Burlingame, CA) according to the manufacturer's instruction at room temperature. Cells were washed four times with PBS buffer, and DAPI counterstain was added.

RESULTS AND DISCUSSION

We have synthesized the targeted dendrimer nanodevice (cRGD-BT-ND) as follows. The starting material, PAMAM_E5.NH_2 amino-terminated dendrimer (abbreviated as E5.NH_2), was partially acetylated (1, NHAc) and then biotinylated (2, NHBT), followed by converting the rest of primary amine termini to succinamic acid groups (3, NHSAH), and finally conjugated with four cRGD peptides (4, NHSAcRGD) as described by the following reaction sequence (in which subscripts correspond to number of measured functional groups):

$$\text{E5.}(NH_2)_{119} \Rightarrow \text{E5.}(NHAc)_{72}(NH_2)_{47} \quad (1)$$

$$\text{E5.}(NHAc)_{72}(NH_2)_{47} \Rightarrow \text{E5.}(NHAc)_{72}(NHBT)_8(NH_2)_{39} \quad (2)$$

$$\text{E5.}(NHAc)_{72}(NHBT)_8(NH_2)_{39} \Rightarrow \text{E5.}(NHAc)_{72}(NHBT)_8(NHSAH)_{39} \quad (3)$$

$$\text{E5.}(NHAc)_{72}(NHBT)_8(NHSAH)_{39} \Rightarrow \text{E5.}(NHAc)_{72}(NHBT)_8(NHSAH)_{35}(NHSAcRGD)_4 \quad (4)$$

The acetylation was performed first to obtained a more uniform distribution of the functional groups within nanodevice (ND) molecules and decrease their toxicity since positively charged (amino-terminated) PAMAM dendrimers are know to be toxic (*7*). Biotin (BT) was selected as the reporter moiety for ND detection using labeled antibodies. In addition it is much smaller compared to commonly used fluorescent dyes that can potentially affect biological activity of NDs. Last, carboxyl groups of succinamic acid were used for cRGD peptides conjugation via amide bound with lysine side chain amino group, which is not involved in the binding of the peptide to $\alpha_v\beta_3$ integrins. Derivatives in each synthetic step were purified and characterized by polyacrylamide gel electrophoresis (PAGE) and size exclusion chromatography equipped with three detectors: multiangle laser light scattering, UV−vis diode-array and refractive index (SEC-MALLS-DAD-RI), potentiometric acid−base titration, matrix assisted laser desorption ionization - time-of-flight (MALDI-TOF) mass spectrometry, and nuclear magnetic resonance (NMR), providing complementary results for thorough analysis.

SEC was used to determine the composition, average molecular mass, and polydispersity of the nanodevices. Figure 1 compares the SEC data of the (A) starting material and of the (B) final product (cRGD-BT-ND). The value of polydispersity index (M_w/M_n) changed only by 0.007, indicating that all components of the starting material were equally modified. Light scattering data confirmed the corresponding increase of the molecular mass throughout the synthesis, even though the hydrodynamic volume slightly decreased as indicated by longer

Table 1. Characterization of Dendrimer Nanodevices

retention times (as pointed out in the graph). Unmodified and fully protonated PAMAM_E5.NH_2 dendrimer is in an extended conformation at acidic pH (pH = 2.5 for SEC-MALLS). This extended structure reduces in size after its terminal amino groups are substituted, accompanied by the decrease of charge of the nanodevice. Figure 2 presents successive mass spectra of all analyzed compounds. The shift in the spectra toward higher molecular masses after each synthesis step indicates successful modifications of intermediates with the selected terminal functional groups during the construction of the required ND structure. Figure 3 shows examples of titration curves and their derivatives for the (A) PAMAM_E5.$(NH_2)_{119}$ dendrimer, (B) its partially acetylated derivative (PAMAM_E5.$(NHAc)_{72}$-$(NH_2)_{47}$), and (C) the E5.$(NHAc)_{72}(NHBT)_8(NHSAH)_{39}$ intermediate. Degree of acetylation can be precisely measured by acid–base titration, because the acetamide termini cannot be protonated within the investigated pH range. The inflection point related to deprotonation of primary amino groups shifts from 7.74 (Figure 3A) to 3.2 mol equiv (Figure 3B) of the titrant, indicating that 60% of initial amino groups were acetylated. However, position of end points of titration of tertiary amines does not change (Figure 3A 6.83 μmol and Figure 3B 6.9 μmol; the observed 0.07 μmol difference is within the experimental error). Similarly, the number of conjugated BT molecules and succinamic acid termini can be determined since amide groups formed upon modification of terminal NH_2 groups with these functionalities cannot be protonated, eventually leading to the disappearance of the deprotonation peak as shown in the titration curve of the intermediate obtained after succinamination (Figure 4C). In polyacrylamide gel electrophoresis (PAGE) (Figure 4) all synthetic products exhibited different electrophoretic mobilities as expected, indicating the decrease of positive charge due to increasing substitution of free terminal amine groups of NDs. After conversion of the primary amines to succinamic acid termini, the resulting intermediates become negatively charged and migrate toward the positive electrode (image B in Figure 4). Change of polarity indicates that substitution of remaining amino groups of E5.$(NHAc)_{72}(NHB)_8(NH_2)_{39}$ biotinylated dendrimer with succinamic acid was successful. ^{1}H NMR confirmed the presence of all functional groups in the cRGD-BT-ND (Figure 5). Average numbers of functional groups in the consecutive products were determined by analyzing all characterization data collected in Table 1. It must be pointed out that increase of the molecular mass of the nanodevice after succinamination, as measured by MALDI and MALLS, indicates conversion of only 10–11 primary amino groups, which is most likely due to structural changes occurring upon modification (decrease of hydrodynamic radius changing dn/dc values). However, potentiometric titration indicated the conversion of all terminal NH_2 groups into succinamic acid (Figure 3C), which was further confirmed by PAGE analysis (Figure 4B). In this scenario, the number of succinamic acid moieties must equal to 39, the number of available amine groups.

We next carried out biologic characterization of the NDs, namely *in vitro* toxicity and binding to integrins. Cytotoxicity of all dendrimer derivatives, concentrations varying from 10 to 2000 nM, was examined in B16F10 melanoma cell cultures using the XTT colorimetric assay for cellular viability. Only the positively charged surfaced starting material PAMAM_E5.NH_2 was toxic to B16F10 cells at or above 250 nM (Figure 6A), killing the cells after 24 h incubation. cRGD-BT-ND did not show any significant reduction in cell viability up to a device concentration of 500 nM. At very high concentrations, at or above 1000 nM, we observed ~20% decrease in the cell viability after 24 h posttreatment compare to untreated cells (statistical analysis by Wilcoxon test indicated $p = 0.0003$ compare to untreated). The cell viability was recovered to the levels of the untreated cell after 2 days posttreatment at 2000 nM concentration ($p = 0.2991$). The cRGD-BT-ND was also nontoxic to MatLyLu prostate cancer cells at all concentrations tested, with proliferation rates close to that of control cells (data not shown). We also tested the effect of cRGD-BT-ND on

human dermal microvasculature cells (HDMEC). The cRGD-BT-ND did not show any significant toxicity toward HDMECs (Figure 6C). At 24 h the statistical test gave a significant ($p = 0.0283$) but biologically irrelevant (<10%) difference, and by 48 h posttreatments, there was no significant different in the overall value for all six dose levels tested ($p = 0.0977$).

The cRGD-BT-NDs were then shown to specifically bind *in vitro* to plates coated with human $\alpha_v\beta_3$ integrin. The cRGD targeted ND displayed superior specific binding compared to the control (biotinylated ND without cRGD, i.e., E5.$(NHAc)_{72}$-$(NHBT)_8(NHSAH)_{39}$). Even a 400-fold excess of free cyclic cRGD peptide was unable to displace over 25% bound RGD-BT-ND (Figure 7) in a competitive binding experiment. The binding of NDs to cultured cells was performed using $\alpha_v\beta_3$ receptor-expressing human dermal microvascular endothelial cells (HDMECs). Our results show that only the cRGD-coupled biotinylated NDs notably bind to HDMECs (Figure 8C). This is the first *in vitro* data showing specific ligand (cRGD)$-\alpha_v\beta_3$ receptor binding by these NDs.

In summary, we have synthesized biotinylated and cRGD peptide-conjugated carboxylate-terminated dendrimer NDs from commercially available amino-terminated PAMAM_E5.NH_2 dendrimer. Importantly, we attached a form of cRGD that is already in clinical trial as an anti-angiogenic agent and therefore may have more applicability in humans than other forms. Analytical data indicate successful modifications of dendrimers according to designed terminal functionalities. We have determined the composition of the ND (cRGD-BT-ND) by comparing results of different analytical methods to provide insight into the complex structure of these dendrimer-based NDs. Detailed characterization is a crucial factor in understanding their biological response. The final ND is nontoxic within physiologic concentration ranges and shows superior binding to the biologic target $\alpha_v\beta_3$. Strong binding is a prerequisite for constructing targeted NDs that can carry therapeutic or imaging agents to cancer cells (*19*).

Received January 11, 2007; Revised Manuscript Received April 26, 2007

We have developed multifunctional fluorescent surface enhanced Raman spectroscopic tagging material (F-SERS dots) composed of silver nanoparticle-embedded silica spheres with fluorescent organic dye and specific Raman labels for multiplex targeting, tracking, and imaging of cellular/molecular events in the living organism. In this study, F-SERS dots fabricated with specific target antibodies (BAX and BAD) were employed for the detection of apoptosis. The F-SERS dots did not show any particular toxicity in several cell lines. The F-SERS dots could monitor the apoptosis effectively and simultaneously through fluorescent images as well as Raman signals in both cells and tissues with high selectivity. Our results clearly demonstrate that F-SERS dots can be easily applicable to multiplex analysis of diverse cellular/molecular events important for maintaining cellular homeostasis.

INTRODUCTION

The current development of nanotechnology has led to a strong motivation for the connection between nanoscience and biology. In fact, scientific interests between nanotechnology and biology are based on the perceptions that nanotechnology offers biology new tools and that biology offers nanotechnology access to new types of functional nanosystems (*1*). In this regard, recent efforts in such nanobio fusion technology have been partly focused on the development of nonradioactive tagging technology for the investigation of complex interplay of biomolecules, because it may provide safe, specific, and stable alternatives. Up to now, several types of tagging materials have been developed for the application into biology. For example, fluorescence-based materials and semiconductor quantum dots have been used widely. However, some intrinsic problems such as broad emission profiles leading to peak overlapping in fluorescence/emission tagging, difficulties in surface modification, and potential safety issues in quantum dots have impeded the practical application into biology (*2*).

Apoptosis, a form of programmed cell death, plays a critical role in the maintenance of cells by providing a controlled cell deletion to a balanced cell proliferation. Apoptosis is characterized by specific morphological changes such as nuclear fragmentation, membrane blebbing, and cell shrinkage. At the molecular level, apoptosis represents a collection of intricate pathways with many proteins actively participating in activities from cell signals. Failure of tumor cells to undergo apoptosis translates into malignant potential (*3*). Therefore, multiplex detection of several key targets important for apoptosis should provide critical clues for cells/tissues to cope with diverse abnormal cellular stimulation.

Up to the present, diverse bioapplications have emerged from several nanoparticles. The addition of fluorescence properties to nanoparticles may offer new potential for *in vitro* and *in vivo* imaging (*4*). There have been several reports on tagging strategy using Raman spectroscopy featuring the narrow band structure for multiplex biological targeting (*5*−*10*). However, such previous reports have still not reached a stage for multiplex detection at once. Recently, our multidisciplinary research group reported a simple and highly reproducible procedure to generate a new type of Raman tag called surface-enhanced Raman spectroscopic dots (SERS dots) in which Raman scatterings of the molecules adsorbed thereon are dramatically enhanced (*2*). Current study, therefore, has been motivated by the exploratory use of unique advantages of fluorescence-based tracking and imaging of the site of interest as a first step and then subsequent characterization by SERS-based multiplex reading of signals important for cellular/molecular changes. For this purpose, we have developed specific fluorescent SERS dots (F-SERS dots) composed of silver nanoparticle-embedded silica spheres with fluorescent dye and specific Raman labels. Here, we report that F-SERS dots can be employed for multiplex targeting, tracking, and imaging of apoptosis at once in cells/tissues. This concept of multifunctional F-SERS dots may serve as a platform technology for the diagnostic as well as therapeutic application in the future.

EXPERIMENTAL PROCEDURES

Preparation of F-SERS Dot. Silica nanoparticles of *ca.* 120 nm size were prepared by the Stöber method (*11*). A 1 mL portion of ammonium hydroxide (27%) was added into 78 mL

ethanol (95%) and 10 mL H_2O, and then 5 mL (22.4 mmol) of tetraethylorthosilicate (TEOS) was added into the solution. The solution was stirred with a magnetic bar vigorously for 12 h at 25 °C. The resulting silica colloids were centrifuged and washed with ethanol several times. To obtain mercapto-functionalized silica nanoparticles (MSNP), 300 mg portion of silica nanoparticles was dispersed in ethanol, and then 150 μL of 3-mercaptopropyltrimethoxysilane (MPTS) and 300 μL of ammonium hydroxide were added to the colloidal solution. The mixture was stirred with a magnetic bar vigorously for 12 h at 25 °C again. The resulting MSNPs were centrifuged and washed with ethanol several times to remove excess reagents. Silver nanoparticles were embedded on the surfaces of silica nanoparticles by the Sn^{2+}-reduction method (*12*). At first, 160 mg of silica nanoparticles were dispersed in water/ethanol solution (15 mL/15 mL), and then 100 μL of trifluoroacetic acid (TFA) and 100 mg of $SnCl_2$ were added. The mixture was stirred vigorously for 1 h at 25 °C. The resulting silica nanoparticles were centrifuged and washed with ethanol (20 mL × 3). The Sn^{2+}-coated silica nanoparticles were redispersed in 250 mL of water, and 50 mL of 6 mM $AgNO_3$ was added dropwise under vigorous magnetic stirring at 25 °C. The dispersion was centrifuged and washed with water (30 mL × 2 times) and ethanol (30 mL × 2 times) to remove excess reagents.

In order to introduce the dual signals of Raman spectroscopy and fluorescence to the silica nanoparticles, 4-aminothiophenol (ATP) and 4-mercaptotoluene (MT) were used as Raman spectroscopic coding chemicals, and fluoresceinisothiocyanate (FITC) and Alexafluoro 647 (AF647) as fluorescent tagging chemicals. First of all, Raman chemicals were introduced together with MPTS allowing a self-assembled monolayer on the silver surface of silica nanoparticles. Raman chemicals (10 mL of 5 mM in ethanol) and MPTS (10 mL of 50 mM in ethanol) were mixed and added into a 50 mg portion of silver-embedded silica nanoparticles. The dispersion was stirred vigorously for 1 h at 25 °C. The colloids were centrifuged and washed with ethanol (20 mL × 3 times) and water (20 mL). These silica nanoparticles were dispersed in 20 mL of water, and 30 μL of aqueous sodium silicate (27%) was added into the dispersion and stirred vigorously for 12 h at 25 °C (*13*). The resulting colloids were centrifuged and washed with water (20 mL × 3) and ethanol (20 mL) to remove excess reagents. In the next step, a fluorescent layer was introduced onto silica nanoparticles labeled with Raman signals. For this process, the conjugates of 3-aminopropyltriethoxysilane (APS) and fluorescence dyes were synthesized. In the case of FITC, FITC (10 μL of 8 mM in DMSO) was added into the APS (100 μL of 19.2 mM in ethanol), and the resulting solution was stirred for 6 h at 25 °C. Then, the FITC−APS conjugate, 20 μL of TEOS, and 40 μL of aqueous ammonium hydroxide (25%) were added into the 20 mg portion of silica nanoparticles with Raman labels. The mixture was stirred vigorously for 12 h at 25 °C. The resulting nanoparticles (F-SERS dots) were centrifuged and washed with ethanol thoroughly. Thereafter, the surface of F-SERS dots was modified with a hydrophilic spacer, *N*-fluorenylmethylcarbonyl-NH-triethylene glycol-NH-$COCH_2$-CH_2COOH (Fmoc-TEG-COOH). This spacer was synthesized from 4,7,10-trioxa-1,13-tridecanediamine by the literature procedure (*14*). F-SERS dots (20 mg) were dispersed in *N*,*N*-dimethylformamide (DMF) and aliquots (0.1 mmol) of Fmoc-TEG-COOH, *N*,*N*-diisopropylcarbodiimide (DIC), *N*-hydroxybenzotriazole (HOBT), and diisopropylethylamine (DIEA) were added into the dispersion, consecutively. The mixture was shaken vigorously for 6 h at 30 °C. After the coupling reaction, Fmoc protecting groups were removed from the spacer on F-SERS dots by 20 vol % piperidine/DMF solution for 30 min at 25 °C. The resulting triethylene glycol (TEG) grafted F-SERS dots (F-SERS dots/TEG-NH_2) were centrifuged and washed with ethanol thoroughly.

Antibody Conjugation onto F-SERS Dots. F-SERS dots/TEG-NH_2 were treated with 0.1 mmol of 3-maleimidopropionic acid *N*-hydroxysuccinimide ester in DMF for 2 h at 25 °C. The resulting nanoparticles were centrifuged and washed with DMF, water, and PBS (100 mM, pH 7.4). Before antibody conjugation, full-bodied antibody was reduced and fragmented into two parts (*15*). This procedure was applied to bcl2-associated death promoter (BAD) and bcl2-associated X protein (BAX) antibodies. Antibody (20 μL, 100 μg/mL) was pretreated with 5 μL of ethylenediaminetetraaceticacid (EDTA, 0.5 M, pH 8.0), and then followed by adding 2 μL of 2-mercaptoethylamine (MEA, 0.312 mmol) and 5 μL of 0.5 M EDTA in 200 μL of PBS (pH 7.4). The mixture was incubated at 37 °C for 90 min. The resulting half-fragmented antibody was purified by gel filtration using Sephadex G-25 and then used for conjugation without additional handling. The 200 μL of reduced antibody solution was added into 10 mg portion of maleimide-modified F-SERS dots dispersed in PBS (100 mM, pH 7.4). The dispersion was incubated at 25 °C for 2 h. The F-SERS dots/TEG−antibody conjugates were centrifuged and washed with PBS containing 0.1 wt % Tween 20 (1 mL × 3 times), and PBS (1 mL × 2 times), consecutively.

Annexin V Conjugation onto the F-SERS Dots. The amine termini of F-SERS dots/TEG-NH_2 were modified to carboxyl termini for immobilizing Annexin V. F-SERS dots/TEG-NH_2 (10 mg) was dispersed in 10 mM succinic anhydride and 10 mM DIEA in DMF, and shaken for 2 h at 30 °C. They were centrifuged and washed with DMF (1 mL × 3 times), H_2O (1 mL × 3 times). They were redispersed in 2-(*N*-morpholino)-ethanesulfonic acid buffer (MES, 25 mM, pH 6.0), followed by adding 50 μL of 5 mg/mL 1-ethyl-3-[3-(dimethylamino)-propyl]carbodiimide hydrochloride (EDC) and 50 μL of 5 mg/mL *N*-hydroxysuccinimide (NHS) in MES buffer. The dispersion was incubated for 1 h at 25 °C. The activated nanoparticles were washed with MES (1 mL × 3 times) and redispered in MES buffer. Immediately, 20 μL of 100 μg/mL Annexin V was added into the activated nanoparticles mixture and incubated for 2 h at 25 °C. The resulting F-SERS dots−Annexin V conjugates were treated with 10 mM ethanolamine in PBS for 30 min for quenching the unreacted activating sites, and washed with PBS containing 0.1 wt % Tween 20 (1 mL × 3 times), and PBS (1 mL × 2 times), consecutively.

Cell Culture and Viability Assay. Normal lung epithelial cells (WI-38), and breast mammary gland epithelial cancer cell (SK-BR3) were obtained from Korea Cell Line Bank (Seoul, Korea), and lung squamous carcinoma cells (H226) were obtained from ATCC (American Type Culture Collection). H226 and SK-BR3 cells were cultured in RPMI-1640 with 10% fetal bovine serum (FBS, Hyclone, Logan, UT), and WI-38 cells were cultured in MEM with 10% FBS. Cultures were maintained at 37 °C in 5% CO_2 atmosphere. Effects of F-SERS dots on viability of several cell lines were determined using a CCK-8 assay kit according to manufacturer's protocol (Dojindo, Kumamoto, Japan). Briefly, cells were seeded at 5×10^4 cells on each well and treated with F-SERS dots for 24 h. Samples were analyzed in triplicate. Results were expressed as a percentage of viable cells of untreated control.

Detection of Apoptosis in Cells. Cells were treated with 0.1 μM staurosporine (STS, Sigma-Aldrich, St. Louis, MO) for 24 h in order to induce apoptosis. Our preliminary works indicate that STS at this concentration is sufficient to induce significant apoptosis in diverse cell lines used in this study. Annexin V is a calcium-dependent phospholipid-binding protein with high affinity for phosphatidylserine (*16*). Therefore, Annexin V-

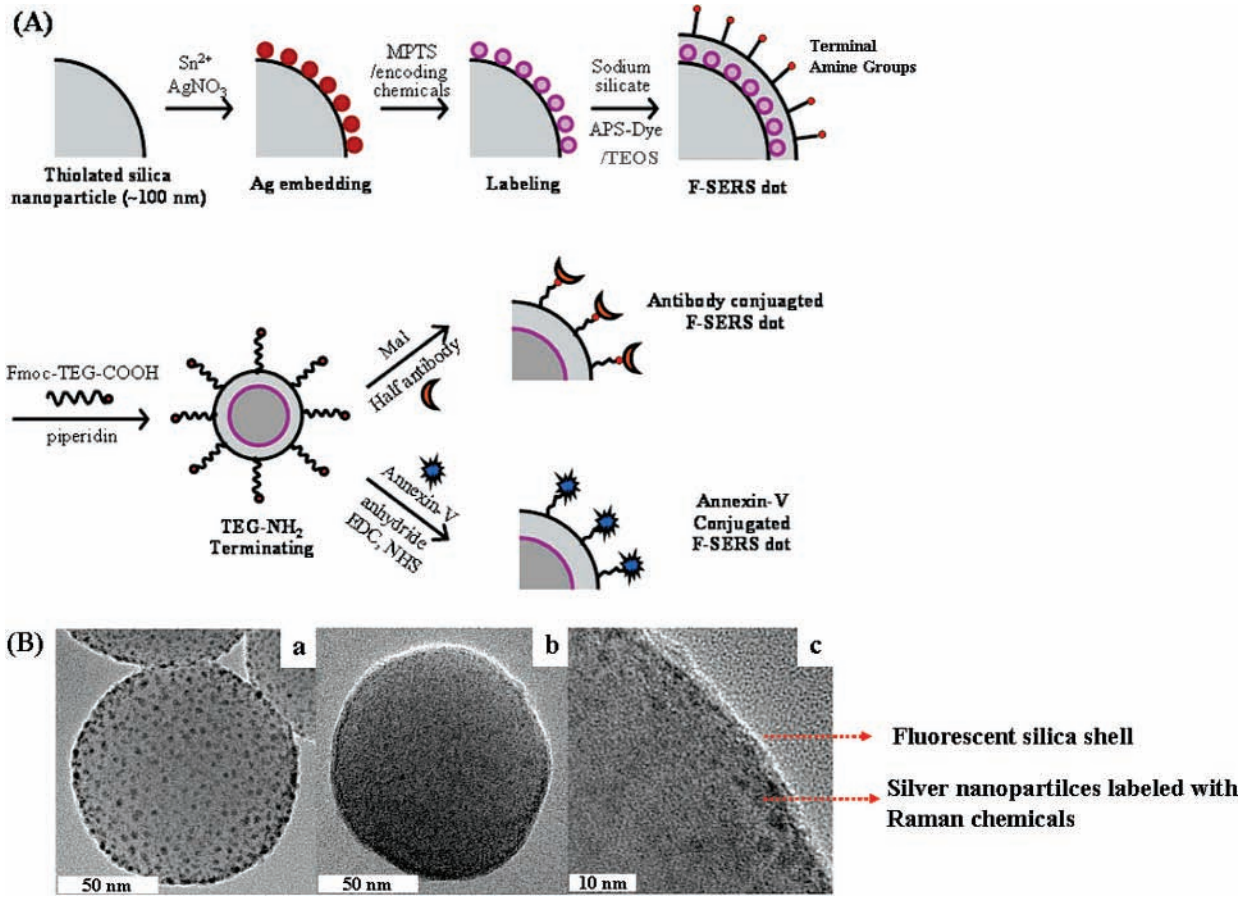

Figure 1. Synthetic scheme of F-SERS dots. Preparation of fluorescent Raman active silica nanoparticle and surface modification of the F-SERS dots with antibody or Annexin V (A). HR-TEM images of silica nanoparticles embedded with silver nanoparticles by Sn^{2+}-reduction method (B-a), after silica shell encapsulation, and then amino-functionalized F-SERS dots labeled with ATP and FITC (B-b) and high-magnification image (B-c).

conjugated F-SERS dots were employed to detect the translocation of phosphatidylserine residues from the inner layer to the outer layer of the plasma membrane. Briefly, cells were grown on chamber slides (Nalge Nunc, Naperville, IL) and treated with STS for 24 h. Then, Annexin V-conjugated F-SERS dots were added and then incubated for 6 h. Slides were then washed with PBS and fixed in 4% paraformaldehyde for 10 min. The slides were examined using a confocal laser scanning microscope (CLSM, Nikon, Tokyo, Japan).

Detection of Apoptosis in Murine Lung Cancer Tissues. Apoptosis study on tissue with the F-SERS dots was carried out onto PAC-1 treated murine lung cancer tissues. Our previous works demonstrated that PAC-1 induced apoptosis significantly through activation of procaspase-3 to caspase-3 in the lungs from mice carrying lung cancer (*17*). Therefore, we adopted the lung samples for current study. The immunohistochemistry on lung tissue was performed with BAX and BAD antibodies with a slightly modified method from Jin et al. (*18*). For the immunoassay with antibody-conjugated F-SERS dots, sample slides were processed according to the same procedures of immunohistochemistry until the blocking process. At the blocking step, F-SERS dots diluted in PBS were added into tissue slides. The slides were incubated for 24 h under dark condition. After incubation, the site of apoptosis was initially identified by fluorescence signals, and then, multiplex targeting was characterized by Raman analysis using a confocal Raman system (LabRam 300, JY-Horiba, Edison, NJ) equipped with an optical microscope (Olympus, Tokyo, Japan). In this system, the Raman scattering signals were collected in a 180° scattering geometry and detected by a spectrometer equipped with a thermoelectrically cooled CCD detector. A 514.5 nm laser line from Ar ion laser (35-MAP-321, Melles Griot, Carlsbad, CA) was used as an excitation source. The strong Rayleigh line was eliminated by a holographic notch filter placed in the collection path. Raman scattered light was collected with a 100× objective microscope (0.95 NA, Olympus). Approximately less than 1 mW of laser irradiation was used to excite samples for Raman measurements. The signal collection time was 30 s.

RESULTS

Synthesis of Annexin V-Conjugated F-SERS Dots. The silica nanoparticles (*ca.*120 nm) as a supporting material were successfully synthesized (Figure 1A). As shown, silver nanoparticles were produced by the Sn^{2+}-reduction method and embedded onto the silica nanoparticles, which were fabricated with Raman chemicals such as ATP or MT and MPTS. The Ag nanoparticle-embedded silica nanoparticles, which contained Raman chemicals, were overcoated with silica shell. The nanoparticles were then treated with APS−organic dye (FITC or AF647)/TEOS under basic conditions to form F-SERS dots. In order to conjugate F-SERS dots with half-fragmented antibody (BAD and BAX), the surface of F-SERS dots was modified with hydrophilic spacer (Fmoc-TEG-COOH). The half-antibodies were prepared by reducing disulfide bonds of the antibody heavy chain using MEA. Also, in the case of Annexin V conjugation for specific targeting to phosphatidylserine, the F-SERS dots were further treated with APS for amine termination and then coupled with the carboxylic group of Annexin V

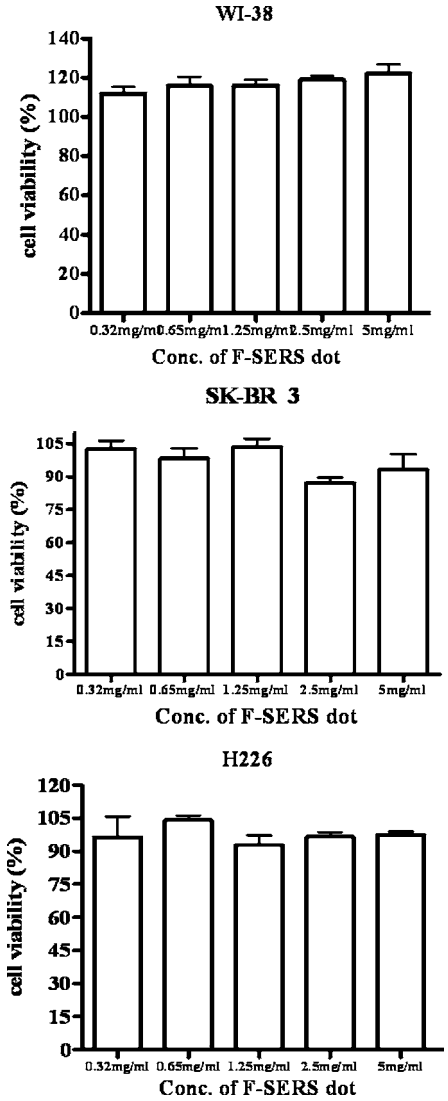

Figure 2. Cell viability assay for potential cytotoxicity of F-SERS dots in various cell lines (WI-38, SK-BR3, and H226). Each cell seeded at 5×10^4 cells/cm^2 was treated with F-SERS dots at different concentrations and incubated for 24 h. All cell viability was expressed as a percentage of viable cells with untreated control cells set at 100%.

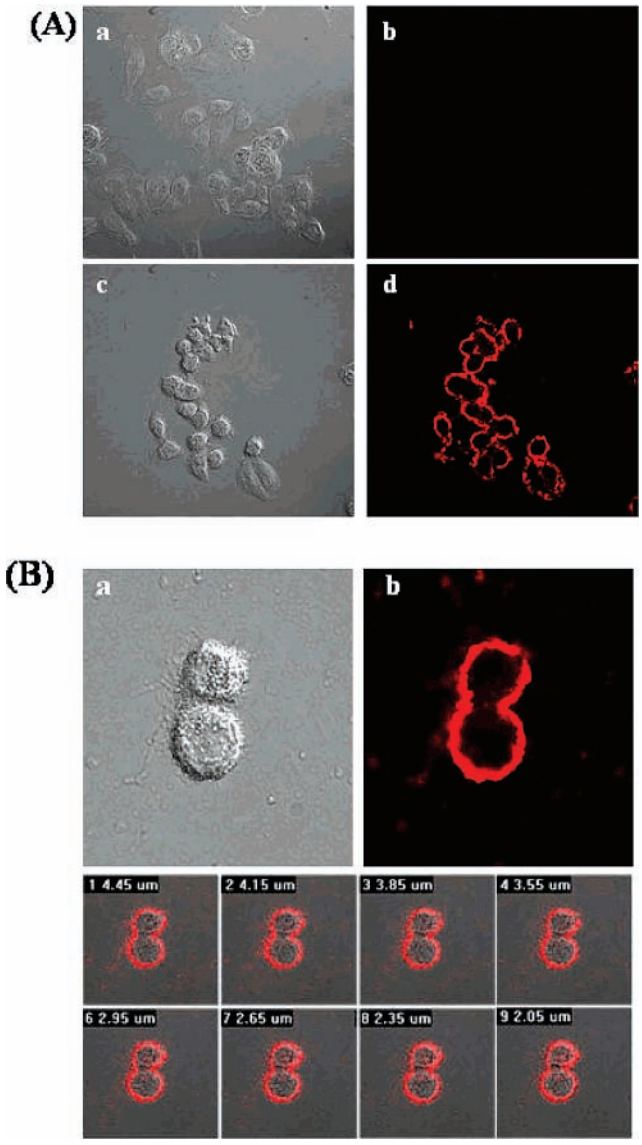

Figure 3. CLSM analysis of specific phosphatidylserine targeting with Annexin-V conjugated F-SERS dots in SK-BR3 cells. (A-a,b) Normal untreated cell. (A-c,d) STS treated cell. (B-a,b) High-magnification images (600×) from apoptotic cell. (B, bottom) *z*-Section images of apoptosis cells (scanned interval of 0.3 μm). A-a, A-c, and B-a are bright field images; A-b, A-d, and B-b are fluorescence images.

leading to amide bond formation. Figure 1B exhibited that the silver nanoparticles were successfully embedded and overcoated with silica shell. The thickness of overcoated silica shell was about 3 nm by high-resolution transmission electron microscope (HR-TEM).

Cytotoxicity Study of F-SERS Dots. The cytotoxicity of the F-SERS dots in various cell lines such as WI-38, SK-BR3, and H226 cells was evaluated (Figure 2). All cell lines were incubated for 24 h at 37 °C, 5% CO_2, and the F-SERS dots containing media were discarded for CCK-8 assay. Our data strongly suggest that F-SERS dots fabricated in this study are not toxic, because cell viabilities remained over 90%.

Specific Targeting with Annexin V-Conjugated F-SERS Dots in the Apoptotic Cells. To demonstrate the specific targeting of phosphatidylserine with Annexin V-conjugated F-SERS dots which were tagged with ATP as Raman chemical and anchored with AF647 (red color), we performed an assay with the cells pretreated with STS. At first, in order to confirm the specific targeting ability, FITC (green color) labeled Annexin V was monitored within STS-treated SK-BR3 cells by CLSM and FACS (see the Supporting Information, SI-Figure 1). We confirmed that FITC-labeled Annexin V could target the apoptosis successfully, because green color was only found in the outer cell membrane (SI-Figure 1A-c), while such staining was not observed in control cells (SI-Figure 1A-a). Such apoptosis was also confirmed by flow cytometry analysis (SI-Figure 1B), thus suggesting that used STS was sufficient to induce apoptosis. Figure 3A showed that the Annexin V-conjugated F-SERS dots could recognize the apoptosis in outer plasma membrane where Annexin V bound to phosphatidylserine selectively. In comparison to STS-treated cells (Figure 3A-d), such red signals were not observed in control cells (Figure 3A-b). Please note that the red fluorescence from F-SERS dots was detected at most of the apoptotic cells. In Figure 3B, high-magnification *z*-section images of cells exhibited clear evidence of reddish nanoparticle location at the outer cell membrane. In contrast, F-SERS dots without Annexin V were internalized into the cells, and such uptake of nonmodified F-SERS dots into the cells was clearly observed in the study

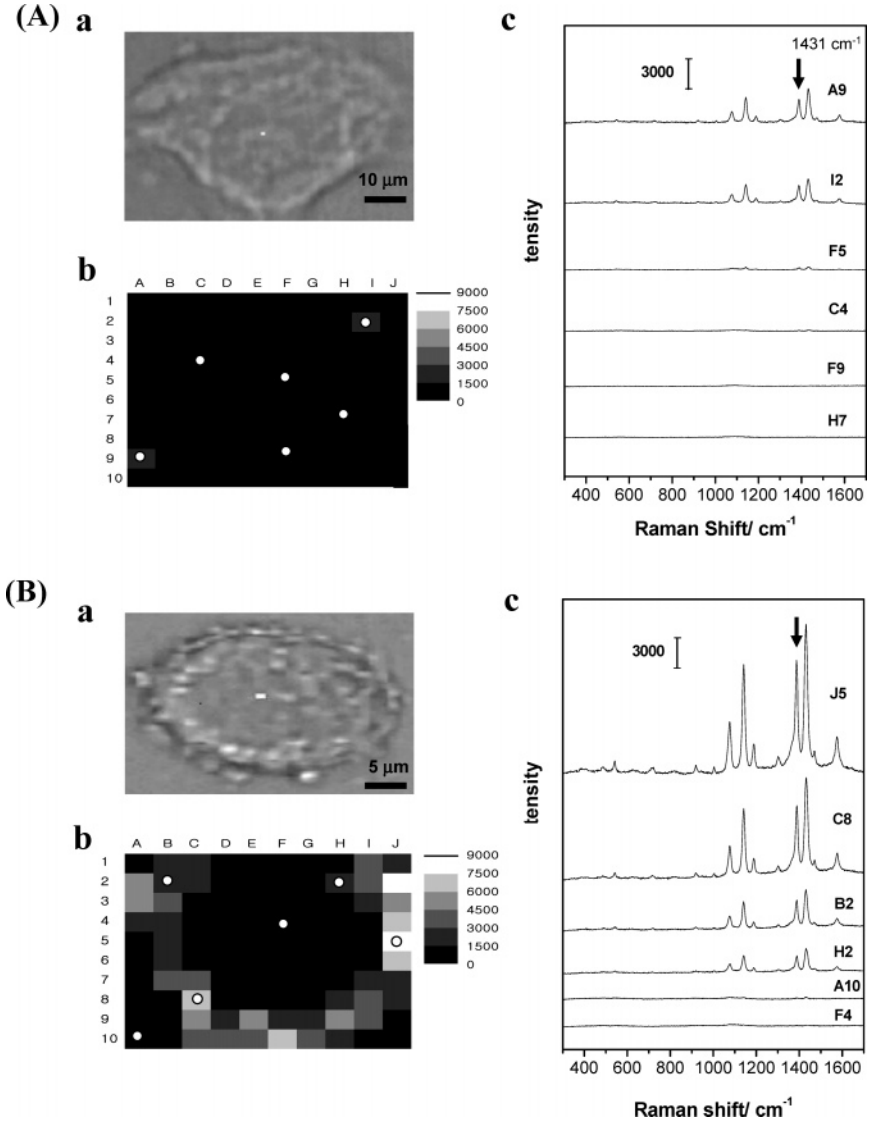

Figure 4. SERS analysis of specific phosphatidylserine targeting with Annexin V conjugated F-SERS dots. A and B represent a control normal cell and a STS-treated cell, respectively. A-a and B-a are bright field optical images of normal and treated cells, respectively. A-b and B-b are SERS intensity maps for 1431 cm^{-1} Raman band, and A-c and B-c depict SERS spectra at several positions indicated as white dots in parts A-b and B-b, respectively. The whole area was scanned by 10 × 10 steps, and Raman signals were collected for 30 s each step.

by CLSM and Raman analysis (SI-Figure 2). According to *z*-section scanning of CLSM, we knew that the internalized F-SERS dots were primarily located at the cytoplasm of the cells. The F-SERS dots were not present in the nucleus, which was confirmed by nucleus staining with DAPI (SI-Figure 2A). Raman spectra were detected in all areas of fluorescence (SI-Figure 2B). Together, F-SERS dots with Annexin V could detect the apoptosis effectively through specific binding to phosphatidylserine in outer plasma membrane.

Since the fluorescence and SERS spectra of F-SERS dots were spectrally well-separated, we could obtain the SERS spectra from cells emitting fluorescence lights (Figure 4). When the cells were not treated with STS, the SERS signals from the F-SERS dots were not detected in most of cell region (Figure 4A). On the other hand, the SERS signals were clearly observed in the cells treated with STS (Figure 4B). Figure 4A-b,B-b demonstrated the SERS intensity maps for the 1431 cm^{-1} Raman band of ATP corresponding to the regions shown in Figure 4A-a,B-a images, respectively. The same scales of the brightness for both SERS intensity maps were used to visualize their different intensities. White blocks represent stronger SERS signals compared to black blocks. Selected SERS spectra for cells with and without STS treatment are shown in Figure 4A-c and B-c, respectively. Most regions of the cell without STS exhibited no SERS signals, but some parts depicted SERS signals with very weak intensity, such as at A9 and I2 positions in Figure 4A-b reflecting a noncorrelated distribution with cell morphology presumably due to nonspecifically bound F-SERS dots. However, the cell treated with STS exhibited a highly correlated distribution of strong intensity with cell morphology as well as strong SERS spectra as shown in Figure 4B-c.

Detection of Multiple Targets of Apoptosis in the Murine Lung Tissues with F-SERS Dots at once. In order to locate the expressed sites of BAX and BAD proteins on the tumor tissue, an immunoassay with F-SERS dots was performed in the murine lung cancer tissues adopted from previous study (*17*). Please note that brown color indicates the apoptotic proteins such as BAX (Figure 5A upper left (×200), lower left (×400)) and BAD (Figure 5A upper right (×200), lower right (×400)). The white arrows are position markers in sequential slices. On the basis of the effective searching the sites of apoptosis by fluorescence signals (representative white square in Figure 5), we tried to characterize the apoptosis through Raman scattering. The green blocks in Figure 6a indicate the SERS intensity of

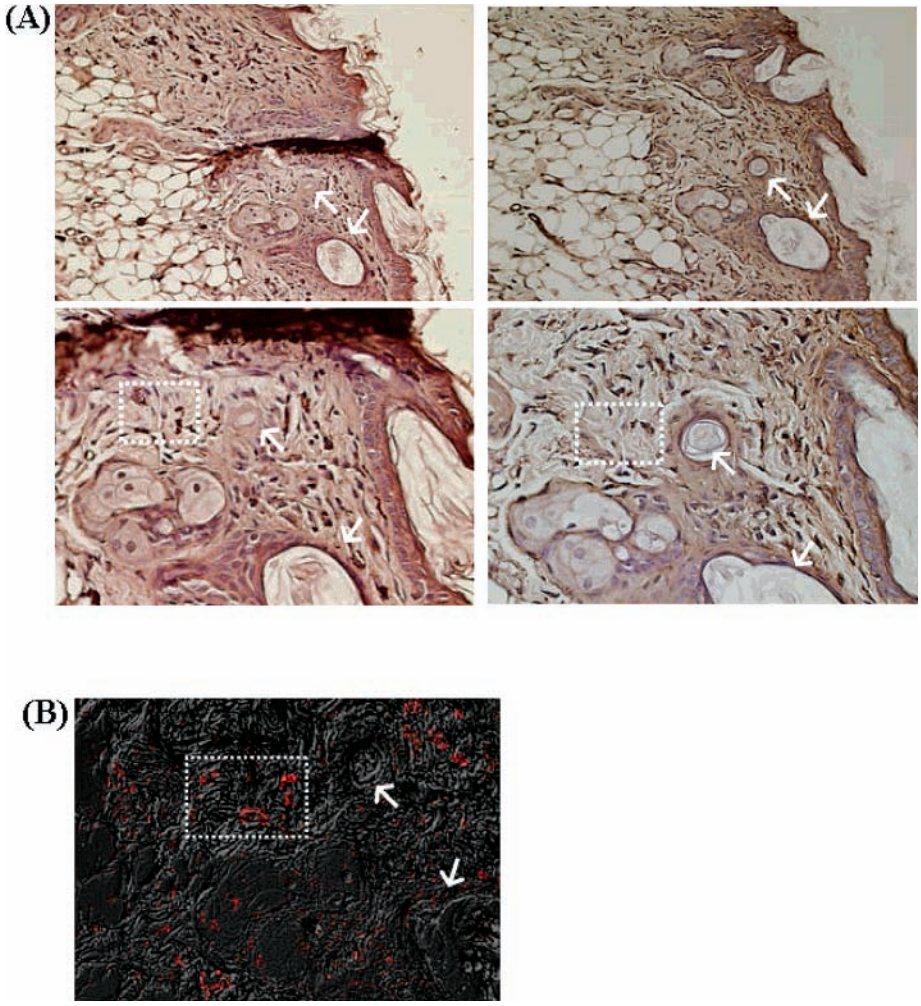

Figure 5. Immunohistochemistry and CLSM image of BAX/BAD protein on PAC-1 induced apoptosis in murine lung tissue. (A) Immunohistochemistry images of BAX (left)/BAD (right) and low magnification (up, 200×)/high magnification (down, 400×). (B) Fluorescent images of F-SERS dots (400×). White square indicates the same areas scanned by Raman analysis. White arrows are the position markers.

the 384 cm^{-1} Raman band of MT (signal of BAX), and the red blocks in Figure 6b indicate the SERS intensity of the 1431 cm^{-1} Raman band of ATP (signal of BAD). Figure 6c is a merged image of both images to illustrate the distributions of BAX and BAD proteins in the tissue. In most parts, occurrences of BAX and BAD were similarly distributed with some exceptions such as positions C and D marked in Figure 6c. The representative SERS spectra from the tissue are depicted in Figure 6d. As illustrated, F-SERS dots were able to detect the multiple targets of apoptosis in the murine lung cancer tissue at once.

DISCUSSION

Nanotechnology has been applied to various biological areas such as specific targeting, cell sorting, and fluorescent or magnetic imaging. The increased application of nanotechnology can, however, be either positive or negative or a mix of both (*19*). Therefore, the biocompatibility of nanomaterials is a very important factor. In this regard, we performed a cytotoxicity study of F-SERS dots on several cell lines (Figure 2). On the basis of our results, F-SERS dots seemed to be nontoxic, thus suggesting that F-SERS dots may be used as a biocompatible tool.

Analysis of current literature suggests that combining several biomarkers improves sensitivity and specificity of many diseases dramatically (*20*). Therefore, a multimarker approach for detection and monitoring of disease status should have a great potential in the future (*21*). In this regard, several research groups have successfully linked fluorescent nanoparticles to peptides, proteins, and oligonucleotides (*22*). Quantum dots are fluorescent nanoparticles and emit narrow symmetrical emission peaks with minimum overlap between spectra, thus allowing unique resolution of their spectra. These key advantages make it possible to label molecular targets by quantum dots both *in vitro* and *in vivo* (*23*). However, the use of quantum dots may be limited by the difficulty in surface modification and the potential toxic effects of the heavy metal core (*24*). The use of organic fluorescent molecules as tags for the probe of interest also has some limitations such as influence on fluorescence intensity from environmental molecules, broad emission profiles, and photobleaching problems (*25*).

SERS has gaining attention because it is another sensitive method for spectroscopic detection of multiple targets in aqueous and solid samples (*26*). The benefit of SERS and nanoparticles in terms of sensitivity, specificity, and selectivity has been previously proven by our previous works (*2*). In this study, F-SERS dots were successfully synthesized by the well-established procedure, and the size and the shape were well-characterized by TEM (Figure 1). Moreover, the modified F-SERS dots could provide a rapid and specific way to monitor the apoptosis in both cells and tissues by simultaneous use of

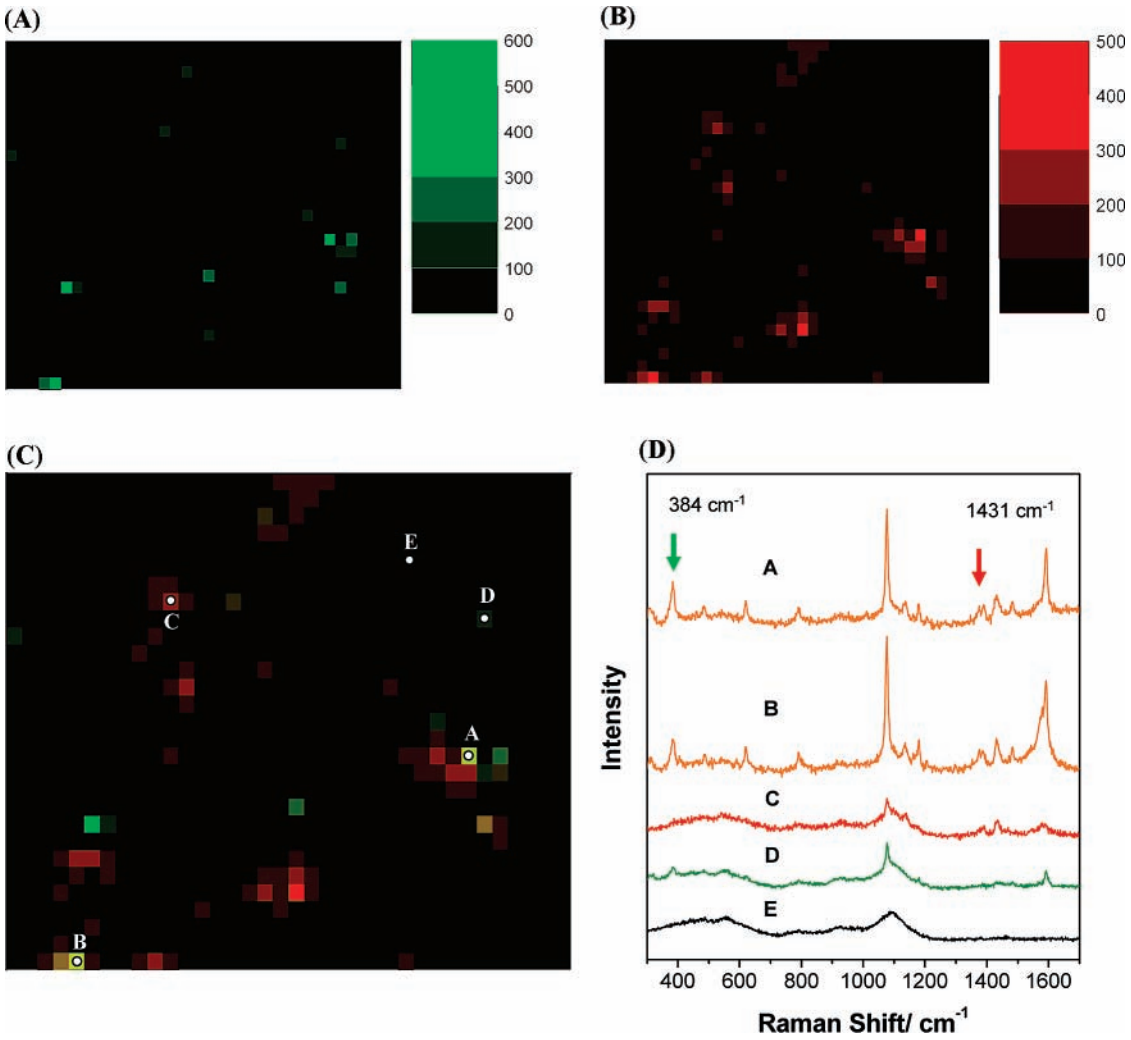

Figure 6. SERS intensity maps indicating distribution of BAX and BAD proteins on the tumor tissue. The maps were produced using the baseline-corrected intensities of the 384 cm^{-1} Raman band of MT corresponding to BAX proteins (a) and the 1431 cm^{-1} Raman band of ATP corresponding to BAD proteins (b), respectively. Part c represents the merged figure of parts a and b to illustrate the distribution of both apoptotic proteins.

fluorescence and Raman signals (Figures 3−6). Interestingly, Annexin V-conjugated F-SERS dots remained in the outer plasma membrane due to the selective binding to phosphatidylserine (*27*), while F-SERS dots without Annexin V were translocated into the cells; thus, we could confirm the specificity and selectivity of F-SERS dots (Figure 3, and Supporting Information). Furthermore, multiplex targeting under the guide of tracking and imaging of F-SERS dots were clearly demonstrated in the study done with murine lung cancer tissue samples. In a classical study of immunohistochemistry, it is difficult to detect multiple targets in one time process. Moreover, immunohistochemistry takes a relatively long time (more than 72 h). In contrast to such time-consuming immunohistochemistry, however, multiplex targeting of BAX/BAD protein expression by F-SERS dots with different encoding chemicals was simple, accurate, effective, and reproducible (Figures 5 and 6). Immunoassay with F-SERS dots just requires one sample due to the multifunction of fluorescence and Raman signals. Taken together, the simplicity and specificity of F-SERS dots for the simultaneous multidetection of apoptosis at cells or tissues were proven clearly. In conclusion, our results strongly demonstrate that F-SERS dots may be applicable to multiplex analysis of diverse cellular/molecular events important for maintaining cell/tissue homeostasis in the future.

Synthesis of Poly(amidoamine) Dendron-Bearing Lipids with Poly(ethylene glycol) Grafts and Their Use for Stabilization of Nonviral Gene Vectors

Toshinari Takahashi, Jun Hirose, Chie Kojima, Atsushi Harada, and Kenji Kono*

Department of Applied Chemistry, Graduate School of Engineering, Osaka Prefecture University, 1-1 Gakuen-cho, Naka-ku, Sakai, Osaka 599-8531, Japan. Received January 16, 2007; Revised Manuscript Received April 10, 2007

Recently, we developed a new type of cationic lipid that consists of an amine-terminated poly(amidoamine) dendron and two long alkyl groups. These dendron-bearing lipids achieved efficient gene transfection of cells through synergetic action of the proton sponge effect and membrane fusion in combination with fusogenic lipid dioleoylphosphatidylethanolamine. Using those dendron-bearing lipids as a base material, we developed in this study a functional component of gene vectors that stabilizes lipoplexes by multiple PEG chains and promotes gene transfection through the proton sponge effect. We combined a poly(ethylene glycol) (PEG, 550 Da) graft to each of four chain ends of the G2 dendron-bearing lipid (P4-DL). An analogous molecule having single PEG graft was also synthesized using the G0 dendron-bearing lipid (P1-DL). Inclusion of P4-DL decreased the size of the G3 dendron-bearing lipid-based lipoplexes more efficiently than P1-DL. In addition, P4-DL-containing lipoplexes exhibited two-orders-higher transfection efficiency than P1-DL-containing lipoplexes with the same PEG graft density. These results indicate the superiority of multiple attachments of PEG graft chains to a lipid for heightened ability to increase colloidal stability of lipoplexes while retaining their transfection activity. The lipoplexes stabilized by P4-DL were small, around 250 nm, and achieved efficient transfection in the presence of serum. Therefore, P4-DL and its analogues will form the basis for production of efficient nonviral vectors for *in vivo* use.

INTRODUCTION

Development of nonviral vector systems that deliver therapeutic genes to targets cells is an important step for gene therapy. Cationic lipids are the most extensively studied among nonviral vectors. These lipids can associate with DNA and form complexes, which are termed lipoplexes (*1*, *2*). Lipoplexes are widely used because of their low immunogenic nature, ability to deliver large pieces of DNA, and ease of handling and preparation. However, lipoplexes also pose inherent problems. They are generally heterogeneous, often aggregating and exhibiting transfection activities that vary from sample to sample. Furthermore, despite demonstrating reasonable transfection activity *in vitro*, their large size and overall positive charge engenders rapid clearance by the cells of the reticuloendothelial system (RES) and to nonspecific association with the extracellular matrix *in vivo*; therefore, the highest levels of transfection activity are apparent in the first-pass organs such as the lung, liver, and spleen (*3*−*7*). The instability of lipoplexes limits their use for systemic injection *in vivo*.

To overcome such drawbacks, lipoplexes can be coated with highly hydrophilic and flexible polymers such as poly(ethylene glycol) (PEG), which forms a steric barrier on the surface (*8*−*10*). In fact, various lipoplexes modified with PEG-modified lipids exhibit prolonged circulation in blood (*10*, *11*). Moreover, PEG lipids can inhibit intensive aggregation and fusion during complexation with DNA, engendering formation of small lipoplexes with high stability (*8*, *11*). However, incorporation of PEG chains onto the lipoplex surface often induces a marked reduction of its transfection activity because PEG chains cover its surface and suppress direct contact with cell membranes. For that reason, it is desired to develop a PEGylation methodology that provides high colloidal stability and high transfection activity.

In general, PEG-modified lipids used for stabilization of lipoplexes have a structure in which a single PEG chain is conjugated to the head group of phospholipids. However, considering that conformation of PEG chains grafted onto the lipoplex membranes and distribution of the PEG chains in the lipoplex membrane might affect the ability of PEG to stabilize lipoplex particles and interaction between the lipoplex and a cell, the use of PEG-modified lipids that have multiple PEG chains might be of interest.

In a previous study, we developed a novel type of cationic lipid that consists of two dodecyl or octadecyl groups and a poly(amidoamine) (PAMAM) dendron as a head group (*12*, *13*). The PAMAM dendron possesses many tertiary amines, which become protonated under weakly acidic conditions (*14*−*16*). Those amines suppress the lowering of pH in endosomes and lysosomes by adsorbing protons and prohibiting degradation of DNA in the lysosome. In addition, the endosome buffering ability of PAMAM dendron is believed to induce osmotic swelling of the endosome interior, thereby engendering rupture of the endosome and the subsequent release of DNA into the cytoplasm (*17*). Such a function of these tertiary amine groups of PAMAM dendron, the so-called proton sponge effect, is considered to contribute to their high transfection activity (*18*).

As a new type of PEG-bearing lipid, we prepared in this study a PAMAM dendron-bearing lipid having four PEG chains at the dendron chain ends, which is termed P4-DL. Such a PEG-modified dendron lipid can efficiently increase the colloidal stability of lipoplexes by multiple PEG chains and enhance gene transfection of cells through the proton sponge effect (Figure 1). As a control, DL-G0-2C_{18} having a single PEG chain at its chain terminal, so-called P1-DL, was also synthesized (Figure 1). We examined advantages using a lipid having multiple PEG

chains to obtain lipoplexes with increased colloidal stability and enhanced transfection activity.

EXPERIMENTAL PROCEDURES

General Methods. PEG with the number average molecular weights of 550 [PEG-(550)] was purchased from Aldrich Chemical (Milwaukee, WI). 4-Nitrophenyl chloroformate was obtained from Tokyo Kasei Kogyo (Tokyo, Japan). Tris-(hydroxymethyl)aminomethane (Tris), triethylamine (TEA), tetrahydrofuran (THF), and dimethyl sulfoxide (DMSO) were supplied from Kishida Chemical (Osaka, Japan). Ethidium bromide was supplied from Wako Pure Chemical Industries (Osaka, Japan). Fetal calf serum (FCS) was obtained from PAA Laboratories GmbH (Pasching, Austria). Dulbecco's modified Eagle's medium (DMEM) was from Nissui Pharmaceutical (Tokyo, Japan). Agarose was purchased from Nacalai Tesque (Kyoto, Japan). DOPE was kindly donated by Nippon Oil and Fats Co. (Tokyo, Japan).

DL-G0-2C_{18}, DL-G2-2C_{18}, and DL-G3-2C_{12} were synthesized by the method previously reported (*12*, *13*). Plasmid DNA pCMV-Luc, which contains the cDNA of firefly luciferase driven by a human cytomegalovirus immediate-early promoter, was a gift from Dr. Kazuo Maruyama, Teikyo University, and amplified in the *E. coli*, isolated, and purified using a QIAGEN plasmid Maxi Kit.

Synthesis of PEG-Attached Dendron-Bearing Lipids. The PEG-attached DL-G2-2C_{18} (P4-DL) and PEG-attached DL-G0-2C_{18} (P1-DL) were synthesized via the procedure shown in Scheme 1 as reported by Kojima et al. (*19*).

PEG 4-Nitrophenyl Carbonate. PEG-(550) (1.1 mmol) was dissolved in THF (12 mL). To the solution were added 4-nitrophenyl chloroformate (4.3 mmol) and TEA (4.3 mmol),

followed by stirring for 24 h at room temperature. PEG 4-nitrophenyl carbonate was recovered by evaporation of the reaction mixture and purified using a Sephadex LH-20 column with methanol as the eluent. Yeild. 82%; ^{1}H NMR ($CDCl_3$): δ 3.38 (s, OCH_3), δ 3.54−3.83 (m, CH_2CH_2O), δ 4.44 (m, $OCOOCH_2$), δ 7.40 (d, aromatic), δ 8.28 (d, aromatic).

PEG-Attached Dendron-Bearing Lipids. The PEG-attached DL-G2-2C_{18} (P4-DL) was synthesized via the procedure shown in Scheme 1. To a solution of the DL-G2-2C_{18} (38 μmol) in DMSO (12 mL) was added PEG 4-nitrophenyl carbonate (0.76 mmol), and the solution was stirred for 5 days at room temperature. The solution was diluted with distilled water and dialyzed using a dialysis bag (molecular weight 1000 cut off) against distilled water for 24 h. The crude compound was lyophilized and then purified by a Sephadex LH-20 column using methanol as the eluent. In the case of PEG-attached DL-G0-2C_{18} (P1-DL), to a solution of the DL-G0-2C_{18} (63 μmol) in chloroform (6 mL) was added PEG 4-nitrophenyl carbonate (0.32 mmol), and the solution was stirred for 5 days at room temperature. The obtained material was chromatographed on silica gel using chloroform−methanol (95/5, v/v) and then chloroform−methanol (90/10, v/v) as eluent. The solution was diluted with distilled water and dialyzed using a dialysis bag (molecular weight 1000 cut off) against distilled water for 24 h. The P1-DL was recovered by lyophilization. Yields of P4-DL and P1-DL were 49 and 89%, respectively. ^{1}H NMR for P4-DL ($CDCl_3$): δ_{Alkyl} 0.88 (m, $CH_3(CH_2)_{15}$), δ_{Alkyl} 1.25 (s, $CH_3(CH_2)_{15}$), δ_{Alkyl} 1.53 (br, CH_2CH_2N), $\delta_{Alkyl/PAMAM}$ 2.37 (br, CH_2N, CH_2CONH), δ_{PAMAM} 2.53 (br, $CONHCH_2CH_2$), δ_{PAMAM} 2.72 (br, CH_2CH_2CONH), δ_{PAMAM} 3.28−3.33 (br, $CONHCH_2$, CH_2NHCOO), δ_{PEG} 3.38 (s, OCH_3), δ_{PEG} 3.54−3.82 (m, CH_2CH_2O), δ_{PEG} 4.18 (br, $NHCOOCH_2$). ^{1}H NMR for P1-DL ($CDCl_3$): δ_{Alkyl} 0.88 (m, $CH_3(CH_2)_{15}$), δ_{Alkyl} 1.26 (s, $CH_3(CH_2)_{15}$), δ_{Alkyl} 1.43 (br, CH_2CH_2N), δ_{PAMAM} 2.35 (m, CH_2CONH), δ_{Alkyl} 2.44 (m, CH_2N), δ_{PAMAM} 2.67 (br, CH_2CH_2CONH), δ_{PAMAM} 3.28−3.34 (m, $CONHCH_2$, CH_2NHCOO), δ_{PEG} 3.38 (s, OCH_3), δ_{PEG} 3.54−3.82 (m, CH_2CH_2O), δ_{PEG} 4.20 (br, $NHCOOCH_2$).

Preparation of Lipoplexes. The composition of basic components for the lipoplex, namely, DL-G3-2C_{12} and DOPE, was fixed at the ratio of 1/10 (mol/mol) throughout the experiment. To a dry thin membrane of a mixture of the DL-G3-2C_{12}, DOPE and a given amount of PEG-attached dendron-bearing lipids (P4-DL or P1-DL), phosphate-buffered saline (PBS) was added and sonicated for 2 min using a bath-type sonicator to afford a lipid suspension. Plasmid DNA (1 μg) was dissolved in 20 mM Tris-HCl buffer (pH7.4, 50 μL), mixed with the lipid suspension (50 μL), and incubated for 30 min at room temperature to afford a lipoplex with a ratio of primary amine of DL-G3-2C_{12} to DNA phosphate (N/P ratio) of 4.

Agarose Gel Electrophoresis. The lipoplexes with a given amount of PEG-attached dendron-bearing lipids were prepared by mixing plasmid DNA (1 μg) dissolved in 20 mM Tris-HCl buffer (5 μL) and lipid suspension (5 μL). After 30 min incubation at room temperature, the samples (10 μL) were electrophoresed on 0.6 wt % agarose gel in 40 mM Tris, 20 mM sodium acetate, and 2 mM EDTA buffer (pH 8.0) containing 1 μg/mL ethidium bromide at 100 V for 30 min. The ethidium bromide-stained bands were visualized using a LAS-1000UVmini (Fujifilm, Japan) and analyzed with Science Lab 2003 Multi Gauge software (Fujifilm, Japan).

Zeta Potential Measurement. The zeta potential values were determined by a Nicomp PSS ZW380 instrument (Santa Barbara, CA). Lipoplexes with a given amount of PEG-attached dendron-bearing lipids were prepared by mixing plasmid DNA (20 μg) and the lipid suspension and incubated for 30 min as described above. The measurement was performed in triplicate.

Dynamic Light Scattering (DLS) Measurement. To estimate the hydrodynamic diameters of lipoplexes, dynamic light scattering (DLS) was analyzed using an electrophoretic light scattering spectrometer ELS-8000F (Otsuka Electronics Co, Ltd., Japan). Lipoplexes with a given amount of PEG-attached dendron-bearing lipids were prepared by mixing plasmid DNA (20 μg) and the lipid suspension and incubated for 30 min as described above. The data obtained at a detection angle of 90° at 25 °C were analyzed by the cumulant method to obtain the hydrodynamic diameters of the lipoplexes.

Atomic Force Microscopy (AFM). AFM measurements were performed by SPI3800 probe station and SPA400 unit system of the scanning probe microscopy system (Seiko Instruments Inc, Japan). The cantilever was made of silicon (SI-DF40; Seiko Instruments Inc, Japan), and its spring constant was 38 N/m. Lipoplexes were formed at a total of 100 μg/mL of plasmid DNA concentration. Lipoplexes containing 0.5 μg of plasmid DNA were applied to freshly cleaved mica and incubated on the mica for 5 min. After incubation, excess fluid was dried under air flow. The measurements were performed in a dynamic force mode (noncontact mode). Raw AFM images have been processed only for background removal (flattening) using the microscope manufacturer's image-processing software.

Transfection. Transfection of HepG2 cells was done according to the following procedures unless otherwise noted in the text. The cells were seeded in 0.5 mL of DMEM supplemented with 10% FCS in 24-well culture plates at 5.0×10^4 cells per well the 2 days before transfection. The cells were washed with PBS containing 0.36 mM $CaCl_2$ and 0.42 mM $MgCl_2$ [PBS(+)] and then covered with DMEM supplemented with a given amount of FCS (1 mL). The lipoplexes containing plasmid DNA were added gently to the cells and incubated for 24 h at 37 °C. Then, the cells were rinsed with PBS(+), covered with DMEM containing 10% FCS, and incubated at 37 °C. After 24 h, the cells were lysed by adding 50 μL of Luc-PGC-50 detergent (Toyo Ink, Japan). A 20 μL aliquot from each dish was used for one luciferase assay using a kit (Toyo Ink) and a Lumat LB9507 luminometer (Berthold, Bad Wildbad, Germany). The protein content of the lysate was measured by Coomassie Protein Assay Reagent (Pierce, IL) using bovine serum albumin as the standard.

RESULTS AND DISCUSSION

Design and Synthesis of PEG-Attached Dendron-Bearing Lipids. In a previous study, we developed a new type of cationic lipid consisting of two dodecyl or octadecyl groups and PAMAM dendron of varying generations (*12*, *13*, *20*).

We examined conjugation of PEG chains to amino groups at chain ends of the PAMAM G2 and G0 dendron-bearing lipids (DL-G2-2C_{18} and DL-G0-2C_{18}) through urethane bonds (Scheme 1). We showed that PEG chains are attachable to terminal amino groups of the PAMAM dendrimers using 4-nitrophenyl chloroformate (*19*). In this study, we combined PEG chains with the PAMAM dendron chain ends using the same method. We synthesized DL-G2-2C_{18}, which has four PEG grafts at chain terminals; it is called P4-DL. As a control lipid, DL-G0-2C_{18} was also synthesized; it has a single PEG graft at its chain terminal, and is termed P1-DL. Characterization using ^{1}H NMR showed good correspondence between the theoretically expected and experimentally obtained values for the synthesized products, as described in the Experimental section.

Evaluation of Complex Formation with Plasmid DNA. In a previous study, we established the composition of a lipoplex comprising DL-G3-2C_{12}, DOPE, and plasmid DNA with high transfection activity in the presence and in the absence of serum. Specifically, we showed that a lipoplex with an N/P ratio of 4 and DL-G3-2C_{12}/DOPE ratio of 1/10 exhibited the highest

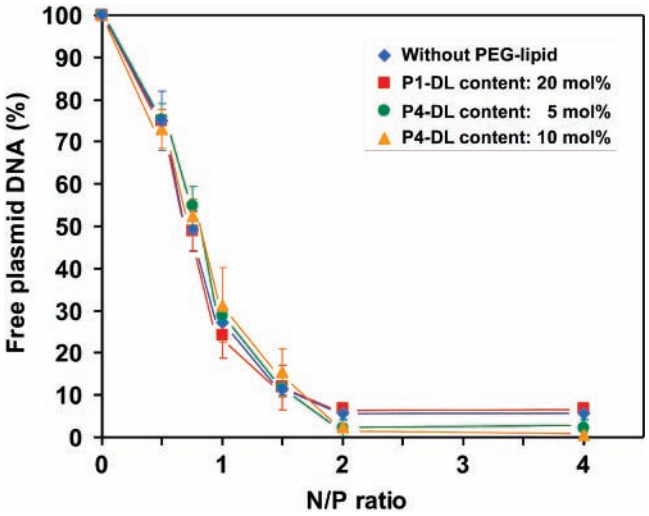

Figure 2. Complexation between DL-G3-2C_{12}−DOPE mixtures containing varying amounts of P1-DL or P4-DL and plasmid DNA. Percent of free plasmid DNA after the complexation was estimated using gel electrophoresis and plotted against N/P ratio of DL-G3-2C_{12} to plasmid DNA. Each point represents the mean ± SD (n = 3).

activity (*20*). Suspensions of a mixture of DL-G3-2C_{12} and DOPE with that composition can form complexes efficiently with plasmid DNA through electrostatic interaction between protonated primary amines of the DL-G3-2C_{12} and negatively charged phosphate groups of DNA (*20*). Nevertheless, addition of the dendron-bearing lipid with hydrophilic PEG chains to the mixture of DL-G3-2C_{12} and DOPE might affect their complex formation with plasmid DNA. For that reason, we examined complexation among DL-G3-2C_{12}–DOPE mixtures containing varying amounts of PEG-bearing lipids with plasmid DNA.

The plasmid DNA (1 μg) was incubated with suspensions of DL-G3-2C_{12}−DOPE mixtures containing varying amounts of P4-DL or P1-DL at varying N/P ratios for 30 min and electrophoresed on an agarose gel. Figure 2 shows the formation of lipoplexes of the DL-G3-2C_{12}−DOPE mixtures containing varying amounts of the PEG-lipids with plasmid DNA. Irrespective of the type of PEG-lipids and their contents, there is essentially no difference among them. Free DNA was not detected at the N/P ratio of 2 for complexation with these mixtures. All plasmid DNA molecules were associated with mixtures at this N/P ratio. Therefore, influence of these PEG-grafted lipids could be only slight for the complex formation of the DL-G3-2C_{12}-DOPE mixture with DNA.

Effects of PEG-Modified Dendron-Bearing Lipids on Lipoplex Characteristics. Figure 3A presents zeta potentials of the lipoplexes containing varying amounts of PEG-attached dendron-bearing lipids. The DL-G3-2C_{12}−DOPE lipoplex without the PEG-modified lipid exhibited zeta potentials of about 10 mV. However, their zeta potentials decreased with increasing amounts of P4-DL or P1-DL and reached a constant value of about 3−4 mV at P4-DL contents above 2 mol % or P1-DL contents above 20 mol %. The lipoplex containing 2 mol % of P4-DL and that containing 8 mol % of P1-DL have the same PEG density on the surface, which suggests that the P4-DL has greater ability to cover the lipoplex surface and shield its positive charge.

Effects of inclusion of the PEG-modified dendron-bearing lipids on the lipoplex size were examined using DLS. As shown in Figure 3B, the lipoplex without the PEG-modified lipids exhibited an 800-nm diameter. However, the lipoplexes containing the PEG-modified dendron-bearing lipids showed much smaller diameters. Their size decreased markedly with increasing PEG-attached dendron-bearing lipid contents and reached

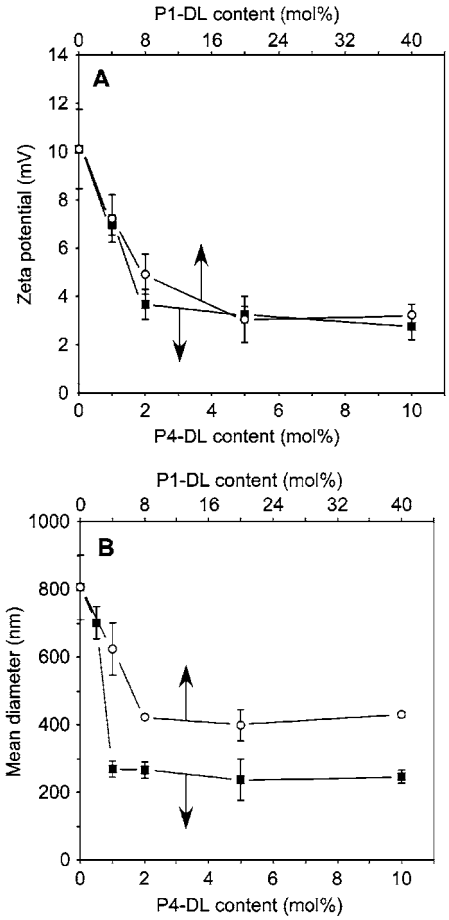

Figure 3. Zeta potentials (A) and mean diameters (B) of lipoplexes with varying P4-DL (■) and P1-DL (○) contents. Each lipoplex was prepared at N/P ratio of 4 and DOPE/DL-G3-2C_{12} ratio of 10. Each point represents the mean ± SD (n = 3).

constant values of 250 nm for lipoplexes containing P4-DL greater than 1 mol % and 400 nm for lipoplexes containing P1-DL greater than 8 mol %. This result is indicative that the lipid with multiple PEG chains has greater ability to decrease the lipoplexes' particle size.

The lipoplexes were further characterized using AFM. For lipoplexes that did not contain the PEG-modified dendron-bearing lipid, particles with irregular shapes and wide size distribution were observed, implying that these particles were formed by aggregation and fusion of smaller lipoplexes (Figure 4A). In contrast, lipoplexes containing 5 mol % of the P4-DL showed spherical particles with much smaller diameter and more uniform particle size of about 200 nm (Figure 4B) compared to the plain lipoplex. For lipoplexes containing P1-DL content of 20 mol %, spherical particles with a wider size distribution between 250 and 500 nm were observed. These particles were smaller than those of the plain lipoplex, but more heterogeneous than those of the lipoplex containing P4-DL (Figure 4C). These results indicate that lipids having multiple PEG chains to the lipid are more effective to stabilize lipoplex than those having a single PEG chain. We confirmed that the lipoplexes with P4-DL contents greater than 1 mol % were highly stable and that their size did not change over a period of more than 10 days in saline (see Supporting Information).

Transfection Activity of Lipoplexes Containing PEG-Modified Dendron-Bearing Lipids. Lipoplexes are known to lose their transfection activity readily in the presence of serum because negatively charged serum proteins bind to the lipoplexes and induce their destabilization and/or aggregation (*21, 22*). Modification of lipoplexes with PEG-lipids might increase the

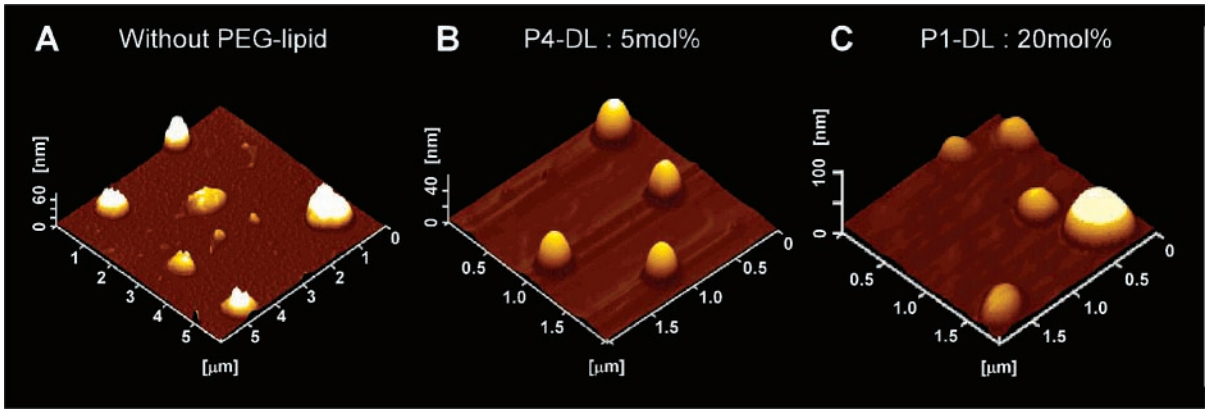

Figure 4. AFM images of plain (A), P4-DL-containing (B), and P1-DL-containing (C) DL-G3-2C_{12}–DOPE lipoplexes. Contents of P4-DL (B) and P1-DL (C) were 5 and 20 mol %, respectively. N/P and DOPE/DL-G3-2C_{12} ratios of lipoplexes were 4 and 10, respectively.

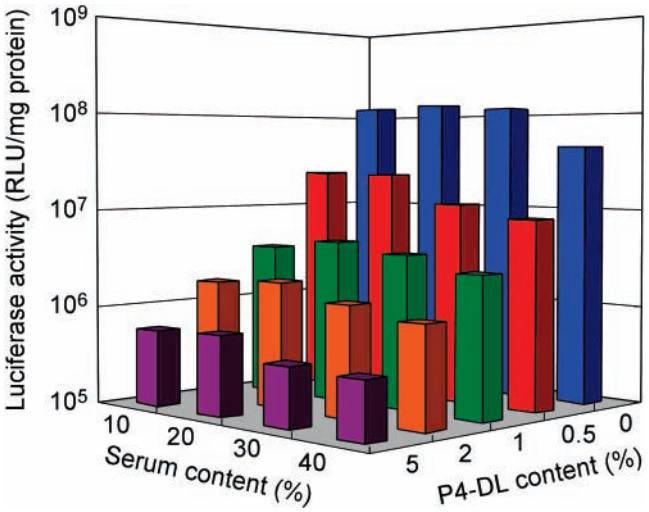

Figure 5. Luciferase activities of HepG2 cells treated with lipoplexes containing varying amounts of P4-DL. N/P and DOPE/DL-G3-2C_{12} ratios of lipoplexes were 4 and 10, respectively. The cells (5×10^4) were treated with the lipoplexes containing 1μg plasmid DNA in the medium with varying contents of FCS. Each bar represents the mean ($n = 5$).

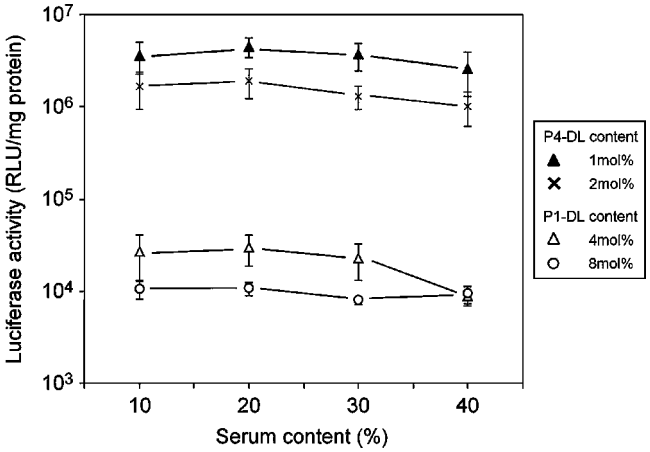

Figure 6. Comparison of transfection activity of lipoplexes containing varying amounts of P4-DL or P1-DL. N/P and DOPE/DL-G3-2C_{12} ratios of lipoplexes were 4 and 10, respectively. The cells (5×10^4) were treated with the lipoplexes containing 1 μg plasmid DNA in the medium with varying contents of FCS. Each point represents the mean $\pm$ SD ($n = 5$).

colloidal stability of lipoplexes because highly hydrated PEG chains shield the positively charged surface of lipoplexes. However, incorporation of PEG chains onto lipoplex surfaces often substantially reduces their transfection activity because PEG chains suppress interaction with cell membranes simultaneously (*23*−*25*). Therefore, PEGylation that increases colloidal stability of the lipoplexes without a concomitant decrease in transfection activity is desired to obtain nonviral vectors for use in biological fluids.

As described above, P4-DL increased colloidal stability of the dendron-bearing lipid-based lipoplexes more efficiently than P1-DL. Consequently, the influence of inclusion of P4-DL on transfection activity of the lipoplexes was examined in a medium with varying serum contents. The HepG2 cells were treated with the P4-DL-modified lipoplexes containing luciferase gene. As shown in Figure 5, transfection activity of the lipoplexes decreased gradually with increasing P4-DL content in the lipoplexes, probably because hydrophilic PEG chains suppress their interaction with the cell membrane. However, these lipoplexes exhibited excellent serum resistance: their transfection activity decreased only slightly with increasing serum content.

Next, we examined the influence of multiple attachments of PEG chains to the dendron-bearing lipid by comparing transfection of lipoplexes containing either P4-DL or P1-DL. Figure 6 shows the dramatic difference observed in their transfection efficiencies. Despite the same PEG chain density in the lipoplex surfaces, the lipoplexes with the P1-DL content of 4 mol % induced production of luciferase that was 2 orders of magnitude less than the lipoplex containing 1 mol % of P4-DL. A similar situation was observed when the transfection efficiency of the lipoplexes containing 2 mol % of P4-DL and that of the lipoplex containing 8 mol % of P1-DL were compared.

In this study, we compared stability and transfection activity of the PEG-modified dendron-bearing lipid based lipoplexes and showed the superiority of multiple attachments of PEG chains to the lipid head group for production of lipoplexes with high colloidal stability and high transfection activity. The distance between neighboring polymer chains is known to affect their conformation (*26*). Thus, PEG chains grafted to lipid membrane surface change their configuration from a hydrated mushroom structure to a more stretched brush structure, depending on their density in the lipid membrane. For example, Bartucci et al. reported that PEG (350 Da) chain grafted to a dipalmitoylphosphatidylcholine (DPPC) membrane converts its configuration from a mushroom-like structure to a more stretched brush-like structure at mole fractions greater than 0.07 in the DPPC membrane (*27*). Therefore, it is possible that multiple attachments of PEG (550 Da) chains to a lipid head group induced a more extended conformation than the case of single attachment of PEG chain. The extended PEG chains tethered to the lipoplex

surface can form a thicker hydration layer and increase the colloidal stability of the lipoplexes.

Hydrophobic chains of the PEG-grafted lipid might be another means to modify the lipoplexes' properties. In general, lipids with unsaturated alkyl chains, such as DOPE, are used as a helper lipid for preparation of potent lipoplexes because these lipids increase the fusion ability of the lipoplexes (*28*, *29*). However, inclusion of a large amount of PEG-modified lipid with saturated alkyl chains might induce alteration of physical properties of the lipoplex and decrease its transfection activity. In fact, efficient stabilization of the lipoplexes was obtained at P1-DL contents above 8 mol %, whereas the same PEG chain density is attainable at 2 mol % of PEG-grafted lipid using P4-DL (Figure 3B). Furthermore, tertiary amines of the dendron contained in P4-DL might help retain the ability of the dendron-bearing lipid based lipoplexes to induce the proton sponge effect, although the contribution might not be important, considering the content of P4-DL in the lipoplexes.

In this study, we prepared a new type of a functional PEG-grafted lipid, P4-DL, by PEGylation of a PAMAM dendron-bearing lipid DL-G2. When included in the DL-G3-based lipoplexes, this PEG-grafted lipid increased the colloidal stability of the dendron-based lipoplexes more efficiently than P1-DL, which has a single PEG chain, as do PEG-lipids of the conventional type generally used for lipoplex stabilization. The lipoplexes stabilized with P4-DL displayed a small particle size with narrow size distribution and much higher transfection activity than the lipoplexes stabilized with P1-DL. The results demonstrate the superiority of multiple attachments of PEG chains to a lipid molecule for production of PEG-stabilized lipoplexes with high transfection activity in the presence of serum. Indeed, optimizations of the number and length of PEG chains are necessary. However, information obtained through this study will be useful for production of highly potent gene vectors.

ACKNOWLEDGMENT

This work was partly supported by a Grant-in-aid for Scientific Research from the Ministry of Education, Science, Sports, and Culture in Japan. T. Takahashi thanks the Research Fellowships of the Japan Society for the Promotion of Science for Young Scientists.

A useful property of optical imaging is the potential to modulate the detectable signal to improve target/nontarget ratios. When administered as a dimer of a fluorophore- and a quencher-conjugated duplex arranged to inhibit fluorescence but designed to dissociate only in the presence of its target, the fluorescence signal should in principle appear only in the target. This laboratory has demonstrated the feasibility of this approach by using a duplex consisting of a linear oligomer conjugated with Cy5.5 (emitter) hybridized to another linear oligomer conjugated with Iowa Black (quencher) in a pretargeting optical study. Now eight duplexes consisting of combinations of 18 mer linear phosphodiester (PO) and phosphorothioate (PS) DNAs and phosphorodiamidate morpholinos (MORFs) conjugated with Cy5.5 (emitter) and Iowa Black (quencher) were variously screened for in vitro duplex stability. The MORF/PO duplex was selected for further study based on evidence of stability in 37 °C serum. Simultaneously, the kinetics of quenching were investigated in vitro and in vivo in mice. Thereafter, mice were implanted in one thigh with MORF/PO Cy 5.5 microspheres and the complementary PS Iowa Black administered iv to measure the extent and kinetics of duplex formation in the target. While all duplexes were stable in buffer, only the MORF/PO duplexes and possibly all PS containing duplexes were stable in 37 °C serum for at least 4 h. The kinetics of quenching were found to be rapid in vitro, with a 80−90% decrease in Cy5.5 fluorescence immediately following formation of a PS/PS homoduplex, and in vivo, with a 27 to 38% decrease in target thigh/nontarget ratio within 1 h following administration of the complementary PS Iowa Black complementary DNA but not the random control DNA to mice implanted with MORF/PO Cy5.5 microspheres. This investigation has provided additional evidence that Cy5.5 may be efficiently and rapidly quenched by Iowa Black when both are conjugated to complementary oligomers and that the resulting inhibition of fluorescence is sufficiently persistent for imaging.

INTRODUCTION

While nuclear imaging offers many advantages including high sensitivity of detection, quantitation accuracy, and the availability of numerous contrast agents, the physics involved does not permit varying the nuclear emissions. By contrast, a property of optical imaging unique among most molecular imaging modalities is the potential to modulate the detectable signal in the target. By bringing into close proximity a fluorophore and its quencher, it is possible to inhibit fluorescence by contact fluorescence inhibition (*1*). This laboratory is investigating antisense and pretargeting of tumor and other applications of radiolabeled oligomers (*2*−*4*). In the course of these investigations, it became apparent that the hybridization properties of oligomers may have applications in optical imaging as well. When properly designed, it should be possible with fluorophore-conjugated linear duplexes to limit fluorescence in a living subject except at the target site presenting a complementary oligomer capable of dissociating the duplex. Molecular beacons consisting of DNAs in the form of hairpins with two fluorophores or a fluorophore and a quencher on opposite ends are already in use in a similar manner for in vitro assays and for in vivo studies as well (*5*−*11*). Possible applications include antisense targeting in which the target mRNA serves as the complementary oligomer and pretargeting in which the complementary oligomer is localized in the target by a preliminary administration. This laboratory has recently reported on a poof of concept study of optical pretargeting showing that a linear fluorophore/quencher-conjugated oligomer duplex may be designed to dissociate in its target with the release of fluorescence inhibition (*12*). The further development of optical imaging using linear duplexes will require additional investigations of imaging sensitivity, duplex stability, and the kinetics of fluorescent inhibition.

We report herein on the screening of duplexes consisting of phosphodiester (PO) and phosphorothioate (PS) DNAs and/or phosphodiamidate morpholinos (MORFs) conjugated with Cy5.5 as emitter and Iowa Black as quencher to evaluate duplex stability in vitro and in vivo and to measure the pharmacokinetic and optical imaging properties of a stable duplex in a mouse microsphere model. The results of these measurements will be required to select duplexes for future investigations.

EXPERIMENTAL PROCEDURES

All oligomers were either uniform PO, PS, or MORF throughout their length. All DNAs, fluorophore/quencher conjugated or native, were purchased HPLC purified (Integrated DNA Technologies, Inc., Coralville, IA) as were the MORFs, biotin conjugated, or native (GeneTools, Philomath, OR). The DNAs were purchased with the fluorophore/quenchers attached directly while the biotin was attached to the MORF via a six-

Table 1. Base Sequences of the PO and PS DNAs and MORF of this Investigation[a]

oligomer type	base sequence	modifications
MORF1, 18 mer	5′-TCT-TCT-ACT-TCA-CAA-CTA	native or 3′ biotin conjugated
PO DNA1, 18 mer	5′-TCT-TCT-ACT-TCA-CAA-CTA	native only
PO cc′DNA 36 mer	5′-TAG-TTG-TGA-AGT-AGA-AGA-GGT-GTA-GGA-GTC-GGT-GTT	native and 3′ Cy5.5 conjugated
PS DNA1 18 mer	5′-TCT-TCT-ACT-TCA-CAA-CTA	native and 3′ Iowa Black conjugated
PS cDNA1 18 mer	5′-TAG-TTG-TGA-AGT-AGA-AGA	5′ Cy5.5 conjugated
PS random rDNA1 18 mer	5′-AGA-ATG-ATG-GTT-ATA-AGG	5′ Cy5.5 conjugated
PS random rDNA2 18 mer	5′-ATA-CCA-ACC-GCC-TCC-ACA	5′ Iowa Black conjugated
PS DNA2 18 mer	5′-AAC-ACC-GAC-TCC-TAC-ACC	5′ Iowa Black conjugated
PS cc′DNA 36 mer	5′-TAG-TTG-TGA-AGT-AGA-AGA-GGT-GTA-GGA-GTC-GGT-GTT	native

[a] Complementary DNAs identified as cDNAs, random DNAs identified as rDNAs, DNAs with two complementary regions identified as cc′DNAs.

carbon linker. The oligomer base sequences of this investigation are shown in Table 1. For convenience, the 18 mer sequence was selected as the standard sequence of ongoing pretargeting studies in this laboratory (*13*). The calculated melting temperatures of PO homoduplexes with the 18 mer standard sequence and with the new sequence of this investigation are above 43 °C. The melting temperatures of the PS and MORF duplexes of this investigation are also expected to exceed 37 °C whether native or with fluorophore/quencher attached (*14, 15*). Complementary sequences are designated herein as cDNA or c′DNA and random sequences are designated as rDNAs. The base sequence of both the 36 mer PO and PS DNAs consisted of two complementary regions, an 18 mer sequence complementary to the above standard sequence (i.e., cDNA1) and an additional 18 mer new sequence (i.e., c′DNA2) complementary to that of a new 18 mer PS DNA2 sequence. Therefore, in this article, both the 36 mer PO and PS DNAs are represented as cc′DNAs to illustrate this structure. The new sequence was selected to avoid hairpin formation and to bring the fluorophore/quencher into the proper configuration for quenching after hybridization (Scitools OligoAnalyzer 3.0, Integrated DNA Technologies). The control PS rDNA1 and PS rDNA2 were also 18 mer but with randomized sequences. The 1.0 μm streptavidin-coated polystyrene microspheres had a 3.5 μg/mL biotin binding capacity (Polysciences, Inc., Warrington, PA).

All centrifuge tubes, pipet tips, and PBS buffers were autoclaved before use. The Cy5.5 fluorophore was selected because its emission maximum is at 694 nm and therefore in the near-infrared where light absorbance in tissue reaches a minimum. The Cy5.5 fluorescence can therefore be detected in vivo at subnanomolar concentrations and at depths sufficient for experimental studies in small animals and possibly in patients (*16*−*19*). The Iowa Black RQ dye was selected because it has a broad absorbance spectrum ranging from 500 to 700 nm with peak absorbance at 656 nm and therefore that overlaps the emission spectrum of Cy5.5 such that the emissions of Cy5.5−DNA may be efficiently inhibited (quenched). The Cy5.5 fluorescence was detected using a 615−665 nm excitation filter combined with a 695−770 nm emission bandpass filter on a IVIS 100 optical camera (Xenogen, Alameda, CA). Regions of interest were set and data were analyzed with Living Image software (Xenogen). To reduce autofluorescence, the animals were hairless male SKH-1 (Charles River Breeding Labs, Wilmington, MA) and were fed on a chlorophyll-free diet (AIN-93G Purified Diet, Harlan Teklad, Madison, WI).

Duplex Stability Studies by PAGE. All oligomers for the duplex stability studies were native rather than fluorophore/quencher conjugated and all were prepared at 10 μM concentration. The PAGE Ready Gel 15% TBE gel was purchased (Bio-Rad, Richmond, CA) and run in 1 ×TBE (Tris-borate buffer) at 87 v for 1 h then stained with ethidium bromide (0.5 mg/mL in 1× Tris-borate buffer). The following four duplexes were prepared: PO DNA1/PO cc′DNA; MORF1/PO cc′DNA; MORF1/PS cc′DNA; and PO DNA1/PS cc′DNA. All duplexes were first formed by heating at 90 °C for 10 min before cooling to room temperature. Samples were then incubated in PBS at 37 °C for 2, 4, or 9 h before analysis. For analysis, 1 μL was added to each well. Samples were also incubated in fresh mouse serum by adding 10 μL of each sample to 30 μL of serum followed by incubation at 37 °C for 2 or 4 h before analysis. For analysis, 4 μL was added to each well except for serum alone in which 3 μL was added.

Confirmation of Fluorescence Hybridization Quenching in Vitro. The 18 mer PS Cy5.5 cDNA1 was first added in triplicate to Costar 96 well black polystyrene flat bottom assay plates (Corning Incorporated, Corning, NY) at concentrations of 1, 2, or 5 μM in room-temperature 50 μL PBS (pH 7.4) or 75% fresh mouse serum followed immediately by the addition of the 18 mer PS Iowa Black DNA1 to the wells at different cDNA1:DNA1 molar ratios. Fluorescence intensity was measured over 1.5 h thereafter on the IVIS camera. As control, the identical study was repeated with the random control PS Cy5.5 rDNA1 in place of the study PS Cy5.5 cDNA1. The kinetics of quenching was also measured in 75% fresh mouse serum in wells containing 5 μM PS Cy5.5 cDNA1 to which the PS Iowa Black DNA1 was added at a 1:1 molar ratio.

Before performing imaging studies on animals implanted with microspheres, the ability of PS Iowa Black DNA2 to quench the fluorescence of PO Cy5.5 cc′DNA immobilized on microspheres was established. Streptavidin-coated microspheres (100 μL) were added to a solution of 0.8 nmol of the duplex formed previously between biotin-MORF1 and PO cc′DNA and incubated at room temperature for 30 min. Thereafter the microspheres were separated by centrifugation and washed in PBS/BSA binding buffer three times.

Approximately 20 μL of these microspheres (Cy5.5 concentration 2 μM) were added to each well of the flat bottom assay plate and suspended in 50 μL of PBS/BSA binding buffer. Thereafter, the PS Iowa Black DNA2 was added at different cc′DNA:DNA2 molar ratios followed by agitation to suspend the microspheres. The fluorescence intensity was measured at room-temperature 20 and 60 min later on the IVIS camera, and the results were analyzed by Living Image software as before.

Animal Studies. All animal studies were performed with the approval of the UMMS Institutional Animal Care and Use Committee. For in vivo studies, the identical illumination settings (lamp voltage, filters) were used for all images, and fluorescence emission was normalized to photons per second per centimeter squared per steradian (p/s/cm^2/sr). All data were processed by Living Image 2.50 software (Xenogen). Prior to performing the imaging studies on microsphere implanted animals, the stoichiometry and kinetics of fluorescence hybridization quenching was studied in vivo. In groups of 3 to 4, male SKH-1 mice were injected via a tail vein with either 0.3 nmol (2 μg) or 0.8 nmol (5 μg) of the PS Cy5.5 cDNA1 in 0.1 mL, and thereafter each received via a tail vein either 0.3 nmol, 0.8 nmol or 2.4 nmol of PS Iowa Black DNA1. The molar ratios of Iowa Black DNA1 to Cy5.5 cDNA1 were either 1:1 or 3:1. The animals were then anesthetized using ketamine (90 mg/kg) and xylazine (10 mg/kg) and imaged on the IVIS camera

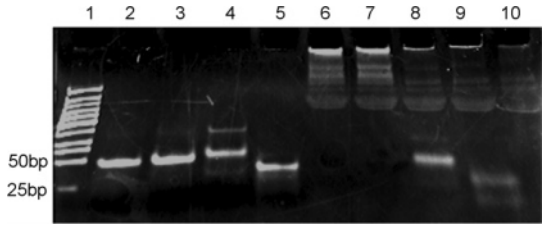

Figure 1. PAGE gel photograph presenting results of stability measurements after 2 h of incubation at 37 °C. Lane 1, low molecular weight DNA ladder; lane 2, PBS incubation of PO DNA1/PS cc′DNA; lane 3, PBS incubation of MORF1/PS cc′DNA; lane 4, PBS incubation of MORF1/PO cc′DNA; lane 5, PBS incubation of PO DNA1/PO cc′DNA; lane 6, serum incubation of PO DNA1/PS cc′DNA; lane 7, serum incubation of MORF1/PS cc′DNA; lane 8, serum incubation of MORF1/PO cc′DNA; lane 9, serum incubation of PO DNA1/PO cc′DNA; lane 10, serum alone.

both in the ventral and dorsal views at various times postinjection while under continuous sedation. All images were acquired with 1 s exposure (f/stop = 2). A large region of interest was set about the whole animal for quantitation.

Approximately 30 μL of the microspheres prepared as described and carrying 0.06 nmol of Cy5.5 were implanted intramuscularly in one thigh of each SKH-1 mice. After 15 min, each animal received either 0.06 nmol ($N = 2$), 0.6 nmol ($N = 2$) or 6.0 nmol ($N = 4$) of the PS Iowa Black DNA2 by iv administration and was imaged in both the dorsal and ventral view immediately thereafter. The fluorescence intensity in a region of interest about both thighs was recorded, and target to nontarget ratios were compared before and after the administration of PS Iowa Black DNA2 with any decrease defined as the quenching efficiency. As a control, one implanted animal received 6.0 nmol of the random Iowa Black rDNA2.

Although the amount of microspheres implanted was identical, the depth of intramuscular implantation varied from animal to animal and resulted in differences in the fluorescence intensity. To correct for absorption and scatter, the fluorescence intensity of all mice but one with implanted PO Cy5.5 cc′DNA microspheres were measured before the PS Iowa Black DNA2 was administrated. The remaining mouse left as a further control did not receive PS Iowa Black DNA2.

RESULTS

Duplex Stability Studies by PAGE. Figure 1 presents a photograph of the 2 h gel showing a molecular weight ladder in lane 1, the results of incubating at 37 °C in PBS in lanes 2 to 5, the results of incubating in serum in lanes 6 to 9 and serum alone in lane 10. The gels obtained in the 4 h incubations in PBS and serum and the 9 h incubation in PBS show the identical trends (data not presented).

As shown, all four duplexes with either the PS or PO cc′DNAs are stable in 37 °C PBS (lanes 2 to 5). In each case, one intense band at about 50 base pairs appears for both homoduplexes and the MORF1/PS cc′DNA heteroduplex. The two weaker bands in the case of the MORF1/PO cc′DNA heteroduplex (lane 4) appeared consistently in all gels.

However, also as shown in the figure, duplex stability in serum compared to PBS is obviously very different. Of the four duplexes, only the MORF1/PO cc′DNA duplex showed evidence of stability at the earliest time point at 2 h (lane 8). This band was weaker although still readily apparent at 4 h. The 9 h gels were equivocal as regards duplex stability (data not presented). The weak bands at low molecular weight in the case of the PO DNA1/PO cc′DNA (lane 9) are probably the result of the nuclease instability of this DNA. Finally, a band is apparent at the loading point in all serum samples, including that of serum alone. However, this band is much more intense in the case of the PS cc′DNA duplexes (lanes 6 and 7) presumably because of the protein binding affinity of this DNA. This analysis therefore cannot exclude the possibility that the duplexes with PS cc′DNA were also stable in serum but remained at the loading point.

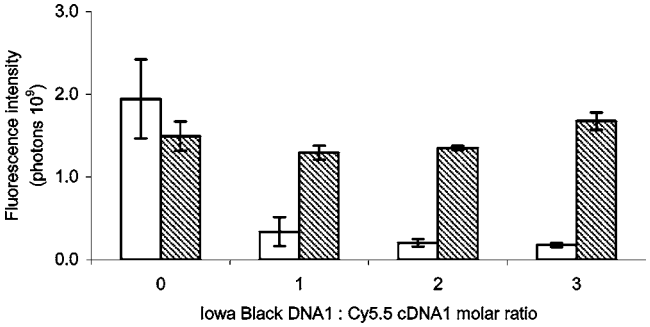

Figure 2. Fluorescence intensity of wells containing 5 μM of the study PS Cy5.5 cDNA1 (open bars) and control PS Cy5.5 rDNA (closed bars) 30 min after the addition of PS Iowa Black DNA1 at different DNA1:cDNA1 molar ratios from 0:1 to 3:1 in PBS buffer. Error bars represent one SD ($N = 3$).

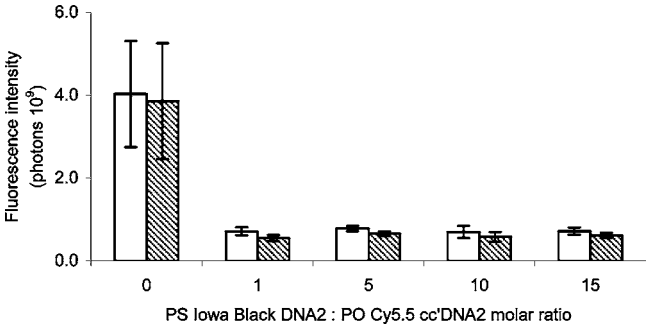

Figure 3. Fluorescence intensity of wells with MORF1/PO Cy5.5 cc′DNA microspheres at 20 min (open bars) and 60 min (hatched bars) following addition of PS Iowa Black DNA2 at 0 to 15 fold molar excess to PO Cy5.5 cc′DNA in PBS/BSA binding buffer. Error bars represent one SD ($N = 3$).

An additional four 18 mer duplexes were also investigated in buffer and in serum: MORF1/PO cDNA1; MORF1/PS cDNA1; PO DNA1/PO cDNA1; PO DNA1/PS cDNA1 (data not presented). The results show once again that at 2 and 4 h of incubation, the MORF1/PO cDNA is stable in serum.

It is possible to conclude from these duplex stability studies that the PO DNA homoduplex with overhang is unstable as expected due to the recognized instability to nucleases of a single chain PO DNAs (*20*, *21*). However nuclease attack on PO DNA, including the single chain overhang, appears to be less effective when hybridized to MORF.

The bead studies described below require streptavidin microspheres to which Cy5.5-conjugated oligomer are bound. Since neither a PO or PS DNA derivitized with both Cy5.5 and a biotin group on opposite ends were commercially available, the results of the above PAGE study provided confidence that microspheres prepared by the addition of biotinylated MORF1 first to the beads followed by addition of PO cc′DNA-conjugated Cy5.5 would be stable.

Confirmation of Fluorescence Hybridization Quenching in Vitro. The histograms of Figure 2 show that the fluorescence in PBS buffer of the PS Cy5.5 cDNA1 was reduced by more than 80% following addition of the PS Iowa Black DNA1 even at the lowest 1:1 cDNA1:DNA1 molar ratio and more than 90% at cDNA1:DNA1 molar ratios 1:2 or higher. This quenching of Cy5.5 fluorescence was not apparent when the Iowa Black was added to the control nonspecific PS Cy5.5 rDNA. The figure

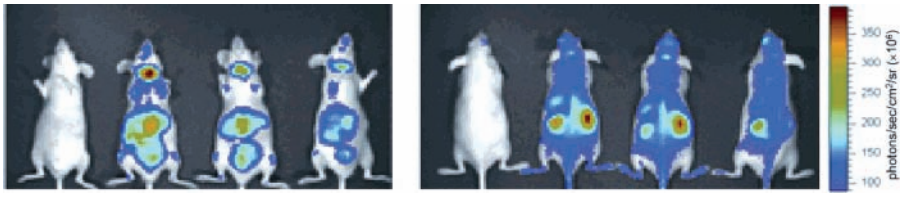

Figure 4. Whole body ventral (left panel) and dorsal (right panel) fluorescent images of SKH-1 mice. From left to right in both panels: blank control, Cy5.5 cDNA1 alone, 1:1 and 3:1 molar ratios of Iowa Black DNA1 to Cy5.5 cDNA1 with 10 min between administrations. Images at 30 min.

presents results ($N = 3$) obtained at 30 min and at the 5 μM concentration of PS Cy5.5 cDNA1.

The kinetics of quenching in wells ($N = 3$) with 5 μM PS Cy5.5 cDNA1 following addition of PS Iowa Black DNA1 at three cDNA1:DNA1 molar ratios from 1:1 to 1:3 showed that under the conditions of this in vitro study, quenching occurred extremely rapidly, reaching more than 80% within 5 min even at cDNA1:DNA1 molar ratio of 1:1 and greater than 90% at higher molar ratios. The quenching was persistent thereafter at least until the end of observation at 90 min. The quenching was found to be equally rapid in serum as well as in buffer (data not presented). Specifically compared to the fluorescence of wells without the Iowa Black, the fluorescence intensity in wells containing 5 μM PS Cy5.5 cDNA1 in 75% serum fell by 73% immediately upon addition of the PS Iowa Black DNA1 at 1:1 molar ratio at room temperature and rose only slightly to 77% and 83% at 8 and 57 min, respectively. However, the quenching efficiency was somewhat reduced in serum over the 80% achieved in buffer under essentially identical experimental conditions.

Figure 3 presents histograms showing that Cy5.5 on the 3′ end of the 36 mer PO cc′ DNA even when tethered via MORF1 to streptavidin-coated microspheres loses 82% of its fluorescence by the addition of Iowa Black DNA2 in PBS/BSA buffer within 20 min at room-temperature even at a 1:1 molar ratio with little change at higher molar ratios or at 60 min ($N = 3$).

Animal Studies. Camera sensitivity was sufficient to provide an acceptable fluorescence image within 10 min following the administration of 0.3 nmol of PS Cy5.5 cDNA1 alone. However following administration of PS Iowa Black DNA1, image quality was markedly superior when 0.8 nmol of PS Cy5.5 cDNA1 was initially administered. Accordingly, the 0.8 nmol dosage of Cy5.5 was selected for subsequent studies.

Figure 4 presents the images obtained in the study of the stoichiometry and kinetics of fluorescence hybridization quenching in vivo and shows both the ventral (left panel) and dorsal (right panel) whole body fluorescence images in animals receiving from left to right: nothing, PS Cy5.5 cDNA1 alone (0.8 nmol), and PS Cy5.5 cDNA1 followed by PS Iowa Black DNA1 at a 1 and 3 fold molar excess 10 min later and imaged 30 min thereafter. The figure shows obvious quenching in both the ventral and dorsal views of PS Cy5.5 cDNA1 fluorescence following administration of PS Iowa Black DNA1. As expected, the quenching is more pronounced following administration of PS Iowa Black DNA1 at a 3-fold molar excess. Fluorescence intensity in these hairless animals fed on a chlorophyll-free diet appears to be concentrated in the kidneys as evident in the dorsal view and in the GI tract and possibly the thyroid as evident in the ventral view. The fluorescence from these and other tissues tended to change over time (data not presented).

The quenching efficiency was determined by subtracting from unity the ratio obtained by dividing the whole body fluorescence intensity of the mice receiving both PS Cy5.5 cDNA1 and PS Iowa Black DNA1 by the fluorescence intensity of the mice receive PS Cy5.5 cDNA1 alone. As shown in Figure 5, when measured in this manner, the quenching efficiency at 20 min postadministration ($N = 3$ in all cases) at a 3 fold molar excess

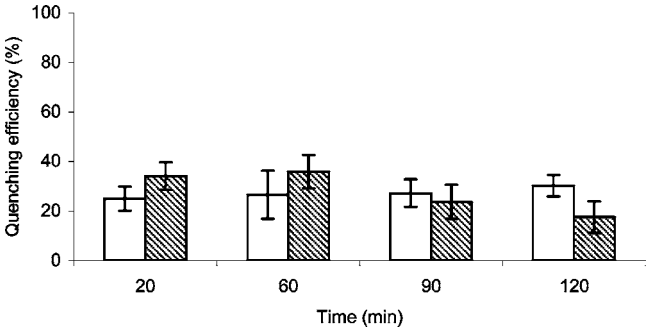

Figure 5. Histograms showing the quenching efficiency in SKH-1 mice receiving iv 0.8 nmol of PS Cy5.5 cDNA1 followed by a 3-fold molar excess of PS Iowa Black DNA1 10 min later. Results presented for both the dorsal view (open bars) and ventral view (hatched bars) obtained between 20 and 120 min thereafter. Error bars represent one SD ($N = 3$).

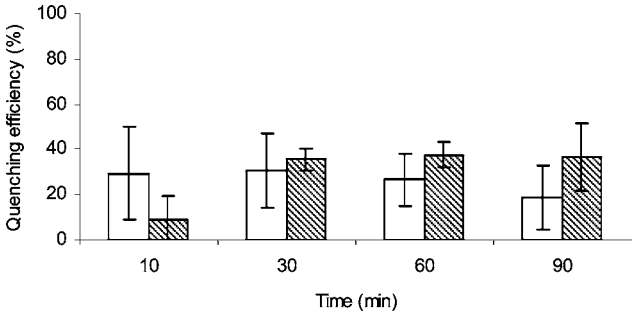

Figure 6. The quenching efficiency 10 to 90 min after iv administration of 6.0 nmol of PS Iowa Black DNA2 in SKH-1 mice implanted with 0.06 nmol PO Cy5.5 cc′DNA microspheres. Results presented for both dorsal view (open bars) and ventral view (hatched bars). Error bars represent one SD ($N = 4$).

of PS Iowa Black DNA1 was 25.0 ± 4.8% (dorsal view) and 34.1 ± 5.6% (ventral view) with little change at 60 min (26.6 ± 9.6% and 35.9 ± 6.7%, respectively).

Thereafter, the streptavidin microspheres carrying 0.06 nmol of biotinylated MORF1/PO Cy5.5 cc′DNA were implanted intramuscularly in one thigh of SKH-1 mice and, after 15 min, each animal received either 0.06 nmol ($N = 2$), 0.6 nmol ($N = 2$), or 6.0 nmol ($N = 4$) of the PS Iowa Black DNA2 by iv administration. One mouse received 6.0 nmol of the random PS Iowa Black rDNA2 as control. The animals were imaged in both the dorsal and ventral view immediately thereafter. The fluorescence intensity of the implanted thigh compared to that of the contralateral thigh was measured, and the decrease in this ratio after administration of the Iowa Black was defined as the percent quenching efficiency as before. Figure 6 presents the results obtained over 90 min in mice receiving 6.0 nmol of the PS Iowa Black DNA2 at a 100-fold molar excess over the PO Cy5.5 ($N = 4$). Lower dosage of Iowa Black DNA2 (10 and 1 fold molar excess) gave an unremarkable quenching effect.

Specifically mice implanted with streptavidin beads binding the 36 mer PO Cy5.5 cc′DNA showed a decrease in target/

nontarget ratio of 27% ± 12% (dorsal view) and 38% ± 6% (ventral view) within 1 h of administration of the 18 mer PS Iowa Black DNA2 but not the Iowa Black rDNA2 random control. When administered at a 100-fold molar excess, the target/nontarget ratio was *increased* 20% (dorsal view) and 14% (ventral view) at 40 min postadministration of the random Iowa Black rDNA2 control. Therefore, despite the barriers to in vivo hybridization including rapid clearance and poor access, the quenching of the tethered Cy5.5 fluorescence was remarkably effective following intravenous administration of the Iowa Black DNA2.

DISCUSSION

To the best of our knowledge, pretargeting and similar applications of optical imaging have not been previously considered especially with linear oligomers. This laboratory recently completed a optical pretargeting study in which microspheres with a 25 mer cMORF were implanted in mice that subsequently received a duplex consisting of a 25 mer Cy5.5-MORF hybridized with a 18 mer BHQ3-PS DNA (*12*). The results of that study confirm that fluorescent conjugated duplexes may be designed to dissociate rapidly in the presence of its target. We report herein on an investigation of the vivo stability of novel duplexes, the sensitivity of detection, the kinetics of hybridization and the pharmacokinetics of in vivo quenching. While these measurements are not directly related to pretargeting and similar applications of optical imaging, the results described herein will be required in the further development of optical imaging with linear duplexes.

Of the eight duplexes between PO DNA, PS DNA, and MORF, gel electrophoresis showed stability only for the MORF/PO DNA and possibly the MORF/PS DNA duplexes following incubations in 37 °C serum for 2 h (Figure 1) and 4 h (data not presented). To measure the kinetics of quenching, the fluorescence intensity of a Cy5.5 conjugated PS DNA was measured in vitro following addition of various molar ratios of Iowa Black conjugated complementary PS cDNA. The quenching was initially found to be essentially completed within 30 min (Figure 2) while a more focused study of kinetics indicated that quenching was completed within several minutes. By contrast no queching was observed if the study Cy5.5 cDNA was replaced with the control Cy5.5 rDNA. Quenching in vivo in mice was also found to be rapid and essentially completed within 20 min (Figure 5).

The most plausible mechanism to explain the fluorescence inhibition of a Cy5.5 conjugated PS DNA following addition of the Iowa Black complementary but not random control DNA is contact fluorescence inhibition following duplex formation. That the quenching and therefore hybidization is rapid is encouraging since rapid kinetics will be required for the in vivo applications contemplated. Rapid hybridization was previously observed in this laboratory by surface plasmon resonance in which a 25 mer Cy5.5 MORF duplexed with an 18 mer BHQ3 DNA was allowed to flow over an immobilized 18 mer PS DNA complementary to the MORF (*12*). Dissociation of the duplex with capture of the MORF was completed in less than 1 min.

Figure 4 presents whole body optical images of mice showing fluorescence inhibition at 30 min after the iv administration of Cy5.5-cDNA1 to mice administered iv Iowa Black-DNA1 10 min earlier. The results presented in Figure 5 show that at 20 min postadministration of Iowa Black DNA1, the quenching efficiency was 25 to 34% depending upon the view, with little change thereafter.

Fluorescence was apparent at all dosages in hairless SKH-1 mice administered iv Cy5.5 cDNA1 alone; however, the administration of 0.8 nmol (5 μg) of the Cy5.5 cDNA1 provided the most intense image. We conclude from these studies that the 0.8 nmol of Cy5.5 cDNA1 fluorescence may be detected with sufficient sensitivity and that the iv administration of 2.4 nmol of Iowa Black DNA1 (i.e., a 3 fold molar excess) provided obvious inhibition, superior to an equamolar administration and superior to the initial administration of 0.3 nmol of Cy5.5 cDNA1. The results confirm that a 0.8 nmol dosage of Cy5.5 cDNA1 provides sufficient fluorescence intensity for subsequent in vivo measurements with the camera used in this investigation, that fluorescence intensity is stable over at least 1 h, and that in vivo quenching of fluorescence occurs rapidly, consistent with the earliest practical times between administrations and imaging.

Having thus established that rapid fluorescence quenching follows hybridization in solution both in vitro and in vivo, we found it necessary to ensure that immobilization does not adversely influence these properties. Since MORF/PO DNA duplexes are stable in serum, an 18 mer PO immobilized microsphere was constructed, consisting of a biotinylated MORF1 added first to the streptavidin-coated bead followed by addition of the 36 mer PO Cy5.5 DNA with two 18 mer complementary regions, one against the standard sequence (i.e., cDNA1) and one against a new sequence (i.e., c′DNA2). Thereafter, the PS conjugated Iowa Black DNA2 quencher complementary to the 18 mer PO overhang of the bead duplex was administered, and the fluorescence intensity was measured. As shown in Figure 3, quenching inhibition in buffer was completed in 20 min or less and with about 82% inhibition at the lowest 1:1 molar ratio despite the immobilization.

Finally, as shown in Figure 6, in mice implanted with the 36 mer PO Cy5.5 cc′DNA microspheres showed a decrease in target/nontarget ratio of 27% (dorsal view) and 38% (ventral view) within 1 h of administration of the 18 mer PS Iowa Black DNA2 but not the Iowa Black rDNA2 random control. The quenching efficiency was therefore remarkable despite the rapid clearance from circulation of the PS Iowa Black DNA2 and the poor accessibility of the subcutaneous microspheres from the circulation.

In conclusion, the results of this proof of concept study show that duplexes of a fluorophore- and a quencher-conjugated linear oligomer can be designed to be sufficiently stable for use in vivo, that fluorescence quenching follows duplex hybridization of Cy 5.5 and Iowa Black conjugated oligomers and that this can be detected in mice at reasonable concentrations, that the hybridization and therefore quenching is rapid whether free or immobilized, and that the quenching is persistent. Future studies will apply the results of this investigation of fluorescent quenching to applications such as optical antisense and pretargeting imaging.

Functionalization of atomic force microscope (AFM) tips with bioligands converts them into monomolecular biosensors which can detect complementary receptor molecules on the sample surface. Flexible PEG tethers are preferred because the bioligand can freely reorient and locally palpate the sample surface while the AFM tip is moved along. In a well-established coupling scheme [Hinterdorfer et al. (1996) *Proc. Natl. Acad. Sci. U.S.A. 93*, 3477−3481], a heterobifunctional PEG linker is used to tether thiol-containing bioligands to amino-functionalized AFM tips. Since antibodies contain no free thiol residues, prederivatization with *N*-succinimidyl 3-(acetylthio)-propionate (SATP) is needed which causes a relatively high demand for antibody. The present study offers a convenient alternative with minimal protein consumption (e.g., 5 μg of protein in 50 μL of buffer) and no prederivatization, using a new heterobifunctional cross-linker that has two different amino-reactive functions. One end is an activated carboxyl (*N*-hydroxysuccinimide ester) which is much faster to react with the amino groups of the tips than the benzaldehyde function on its other end. The reactivity of the latter is sufficient, however, to covalently bind lysine residues of proteins via Schiff base formation. The method has been critically examined, using biotinylated IgG as bioligand on the tip and mica-bound avidin as complementary receptor. These experiments were well reproduced on amino-functionalized silicon nitride chips where the number of specifically bound IgG molecules ($\sim$2000 per μm^2) was estimated from the amount of specifically bound ExtrAvidin-peroxidase conjugate. For a bioscientific application, human rhinovirus particles were tethered to the tip, very-low-density lipoprotein receptor fragments were tethered to mica, and the specific interaction was studied by force microscopy.

INTRODUCTION

Atomic force microscopy (AFM[1]) can operate in aqueous solution under physiological conditions (*1*) and reveal fine details not resolved by electron microscopy (*2*). AFM is thus well suited for structural analysis of biomolecules and their assemblies (*1, 3*). In addition, the AFM tip can be upgraded into a monomolecular biosensor by coupling of a "ligand" molecule which is moved over the sample surface and recognized by complementary "receptor" molecules on the sample surface, yielding a map of recognition sites (*3, 4*). Binding is detected as a rupture event which is sensed by a vertically oscillated cantilever (*5*), preferably under simultaneous monitoring of sample topography (*6*−*8*). Moreover, fine biophysical and structural details of biomolecular interactions are obtained when measuring the unbinding forces at different force loading rates (*9*), interaction time before dissociation (*10*), biochemical modifications, and coassociation of third components (*11*), or with different mutants or truncated forms of the participating proteins (*12*).

Linear PEG chains have frequently been used to attach one or few sensor molecules to an AFM tip because the PEG itself is chemically and physically inert and it allows for rapid and free reorientation of the sensor molecule when the AFM tip approaches the surface (*6*−*8, 10*−*31*). Thus, even a single sensor molecule on the tip can recognize its cognate molecule on the target surface with up to 25% probability in one force−distance cycle with 100−800 nm vertical range and 1 s cycle time (*26*). Moreover, the nonlinear stretching behavior of the PEG tether helps to discriminate biospecific interactions from nonspecific tip−sample adhesion (*19, 21, 26*).

Small ligand molecules (exemplified by biotin or fluorescein) are usually first attached to the PEG linker before the ligand−PEG conjugate is attached to an amino-functionalized AFM tip (*8, 15, 26, 28, 32*). Flexible tethering of proteins to AFM tips, however, has always been performed by a three-step procedure, in which (i) reactive amino groups (*15, 25, 26, 33*) or thiol functions (*12, 18, 27*) are generated on the tip surface, (ii)

these are reacted with one end of the PEG linker, and (iii) the protein is coupled to the free PEG end (*6, 7, 10−14, 16−27, 30, 31*).

The heterobifunctional cross-linker most widely used for tip−PEG−protein linking is PDP-PEG-NHS (*6, 7, 10, 13, 16, 17, 19−24, 30, 31*). Its NHS ester function forms a stable amide bond with an amino group on the AFM tip and subsequently its pyridyldithiopropionyl (PDP) group reacts with a protein thiol, resulting in a disulfide linkage between PEG and protein (see Figure 6S in the Supporting Information). Use of this method is appropriate if the protein of interest contains a free thiol group (e.g., in case of $F_{ab'}$ or half antibodies, see ref 24). Most extracellular proteins (e.g., antibodies), however, possess no free thiol group, requiring artificial thiol functions to be introduced, e.g., with SATP (see Figure 6S in the Supporting Information). The procedure for SATP derivatization is quick and simple, however, unreacted SATP must rigorously be removed to ensure coupling of SATP-derivatized antibody, rather than of free SATP, to the AFM tip (*19*). Consequently, gel filtration must be used for removal of free SATP which cannot be done at a small scale such that 0.2−0.5 mg of antibody are required per batch. Moreover, refreezing of the modified protein is undesirable because of its low concentration after gel filtration.

The need for prederivatization of nonthiol proteins is eliminated if the tip is grafted with PEG chains carrying amino-reactive functions at their free ends. This allows for reaction with lysine residues which are abundant in most proteins. As an example, human antibodies have been shown to contain 80−90 lysines (*34*). Two different methods have been reported in which the tip-bound PEG still carries an NHS-ester function that can couple lysine residues. In the first method, the tip is prefunctionalized with a critically adjusted low density of amino groups which ensures that NHS-PEG-NHS (i.e., the bis-NHS ester of a PEG dicarboxylic acid) cannot form loops with two adjacent amino groups, thereby sparing one of the two NHS ester functions for protein coupling (*25, 35*). In the second method, a tip with a high area density of thiol functions is reacted with maleimide-PEG-NHS, expecting thioether formation between thiol and maleimide to predominate over thioester formation between thiol and NHS ester for kinetic reasons (*12, 18*). In this respect it is fortunate that maleimide−thiol coupling is exceptionally fast ($k \leq 10^5$ M^{-1} min^{-1}, see ref 36) because thiol groups are prone to react not only with maleimides but with the NHS ester functions as well, being much better nucleophiles than amino groups which are the typical targets of NHS esters. Probably the high lateral density of thiol groups on the tip ensured that a sufficient number of PEG linkers was unilaterally bound with the maleimide function only, even if a sizable fraction of PEGs may have been bound via both end groups.

The two above-described methods (with NHS-PEG-NHS or maleimide-PEG-NHS) have in common that both ends of the cross-linker have a considerable reactivity for the reactive groups on the tip surface (amine or thiol, respectively) and that the relative extent of desired univalent coupling as compared to undesired bivalent coupling of PEG on the tip is dependent on the lateral density of reactive groups on the tip, as well as on the length of the chosen PEG linker. Such interdependence of the experimental parameters is avoided if only one end of the PEG linker can react with the reactive groups on the tip surface. This requirement seems particularly difficult to fulfill if the PEG tether should react with amino groups on the tip surface and with amino functions on the protein. Nevertheless this situation is quite typical because most tip functionalization methods utilize amino groups (*8, 15, 26, 28, 32*) and because lysines are the most general coupling functions on proteins.

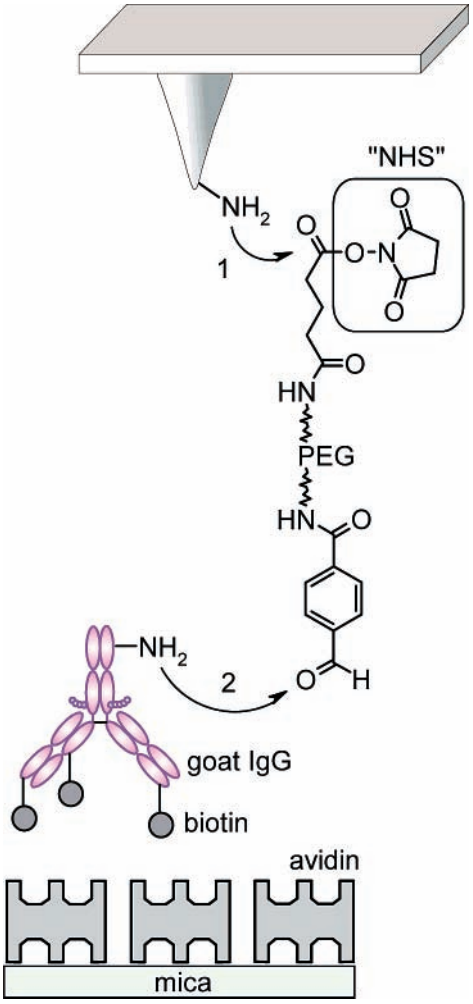

Figure 1. Schematic representation of the testing system for tip−antibody linking via lysine−aldehyde coupling. In the first step (in organic solvent), the NHS-ester of aldehyde-PEG-NHS reacts with the amino groups on the tip, while in the second step (in aqueous buffer), one of the antibody's lysines forms a Schiff base with the aldehyde function on the free end of the cross-linker. The Schiff base is reduced by $NaCNBH_3$ to form an irreversible bond (not shown). When brought into contact with avidin-covered mica, the biotin residues on the model antibody show reversible binding to, and unbinding from, immobilized avidin.

The present study ventured to solve this nontrivial problem by a newly synthesized heterobifunctional PEG linker (aldehyde-PEG-NHS, see Figure 1). Its NHS ester function has a much higher reactivity for amino groups than its benzaldehyde terminus, as previously observed with the short homologue (the NHS ester of formylbenzoic acid, see ref 37). Consequently, the reaction of aldehyde-PEG-NHS with an amino-functionalized tip yields a high number of tip-bound PEGs with intact benzaldehyde functions. The latter provide for easy and robust coupling of unmodified nonthiol proteins, as demonstrated below by quantitative analysis of AFM test experiments, as well as of surface functionalization performed on silicon nitride chips.

EXPERIMENTAL PROCEDURES

Materials. Analytical grade materials were used as long as they were commercially available. The starting materials were of highest available purity. NH_2-PEG-COOH was synthesized as described (*27*). *N*-Succinimidyl 4-formylbenzoate was synthesized similarly as described (*37*) (see Supporting Information). As shown in Figure 2, aldehyde-PEG-NHS was synthesized by reaction of *N*-succinimidyl 4-formylbenzoate with NH_2-PEG-COOH, followed by conversion of the terminal carboxyl

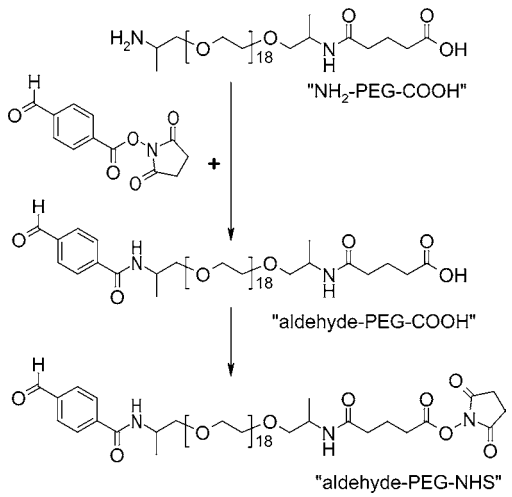

Figure 2. Synthesis of aldehyde-PEG-NHS. In the first step, NH_2-PEG-COOH (*27*) was reacted with *N*-succinimidyl 4-formylbenzoate in chloroform/triethylamine. In the second step, the terminal carboxyl was activated with TSTU in DMF/pyridine (*26*). The PEG chain length was not uniform but the chain length distribution was relatively narrow ($n = 18 \pm 2$), as determined by mass spectrometry (*26*).

function into an NHS ester (see Supporting Information). Muscovite mica sheets were supplied by Christiane Gröpl (Austria). Si_3N_4 measuring tips were bought from Veeco (Santa Barbara, CA) and Si_3N_4 chips from Wacker-Chemitronic GmbH (Germany). Biotin−IgG and biotin−IgG−SATP were prepared by derivatization of goat IgG with biotin−cap-NHS (and SATP), as described before (*19*). HRV2 viral particles (in HBS, 150 mM NaCl, 25 mM HEPES−NaOH, pH 7.4) were prepared by a published procedure (*38*). VLDLR1-8, an extracellular fragment of the human VLDL receptor, fused to MBP on the N-terminus and to His_6 peptide on the C-terminus, was produced as reported before (*39*). The latter was dialyzed to exchange TBS-Ca (150 mM NaCl, 2 mM $CaCl_2$, 25 mM Tris-HCl, pH 7.4) for HBS-Ca (150 mM NaCl, 2 mM $CaCl_2$, 25 mM HEPES−NaOH, pH 7.4) and thus to avoid the undesired reaction of Tris base with surface-bound aldehyde linkers.

Functionalization of AFM Tips with PEG Linkers and Antibodies or Virus Particles. AFM tips (Si_3N_4) were amino-functionalized as described before (*26*), using the room-temperature method for reaction with ethanolamine hydrochloride (see also Supporting Information). Attachment of aldehyde-PEG-NHS was performed by incubating the tip for 2 h in 0.5 mL of chloroform containing 6.6 mg/ mL of aldehyde-PEG-NHS and 0.5% (v/v) of triethylamine. After rinsing with chloroform, the tip was stored in an argon-filled desiccator for less than 5 days. For coupling of antibody, 40 μL of biotin−IgG (2.2 mg/mL) was mixed with 380 μL of buffer A (100 mM NaCl, 50 mM NaH_2PO_4, 1 mM EDTA, pH 7.5, adjusted with NaOH) and 8 μL of 1 M $NaCNBH_3$ (freshly prepared by dissolving 32 mg of $NaCNBH_3$ in 500 μL of 10 mM NaOH). Tips with aldehyde-PEG linkers were immersed in this solution for 1 h, washed in buffer A (2 ×) and PBS (2 ×), and stored in PBS at 4 °C until used (up to 3 days). The procedure for covalent binding of virus particles to the aldehyde termini of tip-linked PEG chains was similar (see Supporting Information for details).

Monitoring of Single Unbinding Events between Tip-Bound Biotin−IgG and Mica-Bound Avidin by AFM. Avidin (1 mg/mL in PBS, 150 mM NaCl, 5 mM NaH_2PO_4, pH 7.4, adjusted with NaOH) was diluted with 9 volumes of water and adsorbed to freshly cleaved mica. After 15 min, the substrate was extensively rinsed (25 ×) with a 1/9 mixture of PBS and water and imaged in PBS. Force measurements with biotin−IgG-functionalized AFM tips were performed in the fluid cell of a commercial AFM (Pico-SPM, Molecular Imaging, Phoenix, AZ) using a Nanoscope IIIA controller (Digital Instruments, Santa Barbara, CA). Force−distance cycles were recorded at a 1 Hz vertical scan rate and 300 nm *z*-amplitude. The measurements were done in PBS at a constant trace and retrace velocity of 600 nm/s. The spring constants of the levers were determined by the thermal noise method (*40, 41*).

Functionalization of Silicon Nitride Chips with Amines, PEG Linkers, and Biotin−IgG−SATP, and Quantitative Assay for Chip-Bound Biotin−IgG−SATP. Silicon nitride chips were precut, weighed for calculation of the effective surface area, precleaned, and amino-functionalized in a DMSO solution of ethanolamine hydrochloride (16 h), using the room-temperature method (*26*). After washing in DMSO (3×) and ethanol (3×), the chips were dried with nitrogen gas and derivatized with aldehyde-PEG-NHS exactly as described above for AFM tips. After binding of the PEG linkers, the chips were washed in chloroform (3 ×), dried with nitrogen, and placed in a polystyrene petri dish. Biotin−IgG (3.2 mg/mL) was mixed with buffer A and with 1 M $NaCNBH_3$ reagent (see above) to adjust to final concentrations of 0.5 mg/mL for biotin−IgG and of 20 mM for $NaCNBH_3$. A 50 μL aliquot of this solution was pipetted onto the surface of each chip. The petri dishes were covered with lids and incubated at room temperature for 60 min. The chips were removed and washed in buffer A (3 × 10 min) and PBS (3 × 10 min). The surface density of biotin−IgG bound to the silicon nitride chips was determined by specific binding of ExtrAvidin-peroxidase, as described before (*19, 26*).

Monitoring of Single Unbinding Events between Tip-Bound Virus Particles and Mica-Bound VLDL Receptor Fragments. Mica was treated with ethanolamine hydrochloride in DMSO to introduce amino functions (*42*). All further steps (reaction with aldehyde-PEG-NHS and coupling of VLDLR1-8) were analogous to the functionalization of AFM tips with aldehyde-PEG-NHS and biotin−IgG (see above) or virus particles (see Supporting Information for details). Unbinding events were measured in HBS-Ca. The specific interaction between virus and receptor protein was blocked by perfusion of the AFM measuring cell with HBS containing 1 mM EGTA instead of 2 mM $CaCl_2$.

RESULTS AND DISCUSSION

Synthesis of Aldehyde-PEG-NHS. The synthesis of aldehyde-PEG-NHS was analogous to that of other AFM-related cross-linkers (*26, 27*). The general precursor NH_2-PEG-COOH was first acylated with *N*-succinimidyl 4-formylbenzoate, yielding "aldehyde-PEG-COOH" (see Figure 2). Fortunately, the main product was indeed the amide conjugate shown in Figure 2 and not a Schiff base adduct of the formyl group with the amino group of NH_2-PEG-COOH. From this we conclude that under the reaction conditions (i.e., in chloroform/triethylamine) the kinetics of amide bond formation was much faster than that of Schiff base formation. Admittedly, the latter may also have occurred to a minor extent, since small amounts of side products were formed which could not be removed by gel filtration, neither in water (on Sephadex G-25) nor in organic solvent (on Sephadex LH-20). These were removed by a multistep extraction procedure (see Supporting Information). Subsequently, the carboxyl of aldehyde-PEG-COOH was activated as NHS ester to give the heterobifunctional cross-linker aldehyde-PEG-NHS (see Figure 2).

Recognition Force Spectroscopy with AFM Tip-Bound Biotin−IgG and Mica-Bound Avidin. In a preceding study, tip−PEG−protein linking via PDP-PEG-NHS was studied in detail, using biotinylated IgG in place of a specific antibody and avidin in place of an antigen (*19*). As a consequence, we could take advantage of the well-known rupture force of the

Table 1. Critical Test for the Specific Role of the Biotin Residues on TIP-Bound IgG[a]

tip number	tip functionalization	recognition, %
1	biotin−IgG	4
2	biotin−IgG	13
3	biotin−IgG	15
4	IgG	0
5	IgG	1
6	IgG	2

[a] Three measuring tips were functionalized with ethanolamine hydrochloride, aldehyde-PEG-NHS, and biotin−IgG as depicted in Figure 1. For control purposes, another three tips were functionalized in the same way, except for using unlabeled goat IgG in the third step. All tips were subsequently tested in the AFM for specific recognition of avidin on mica. Each tip was tested in five different locations, performing 999 force−distance cycles on each site. The fraction of force−distance cycles containing specific unbinding events was calculated for each tip. AFM experiments and data evaluation were done by a person not knowing which tip carried biotin−IgG or unlabeled IgG.

avidin−biotin bond (*15, 19, 26, 43−45*), of specific block with minute concentrations of D-biotin, and of the ease of avidin immobilization on bare mica (*8, 19, 26*). Biotin−IgG was prepared by statistic labeling with ∼5 biotin residues per IgG, and in addition ∼5 protected thiol groups were attached per IgG to provide for disulfide coupling to tip-bound PEG (see Figure 6S in the Supporting Information). In the present study, the same model system as before (*19*) was used to establish tip−PEG−protein coupling via aldehyde-PEG-NHS (see Figure 1); the essential difference was the omission of SATP for prederivatization of biotin−IgG.

Biotin−IgG was covalently tethered to AFM tips via aldehyde-PEG-NHS, as shown in Figure 1. The procedure consisted of three steps. First, amino groups were introduced as usual, i.e., by reaction of surface silanol groups with ethanolamine hydrochloride (*26*). Second, these amino groups were reacted with aldehyde-PEG-NHS, expecting to form amide bonds between an amino group on the tip and the "carboxy termini" of the PEG linkers while avoiding the undesired reaction of the aldehyde functions with the amino groups on the AFM tip. This reaction was analogous to the reaction of *N*-succinimidyl 4-formylbenzoate with NH_2-PEG-COOH (also in chloroform/triethylamine, first step in Figure 2) which had mainly resulted in the amide conjugate. Such analogy alone, however, was regarded insufficient to ensure complete suppression of Schiff base formation with amino groups on AFM tips. We were afraid that the free aldehyde end of the initially formed product ("aldehyde-PEG-CO-NH-tip") might still react with an adjacent amino group on the tip, forming a bivalently bound PEG linker that would have been refractive to further conjugation of protein. In order to minimize the extent of such PEG loop formation on the surface, we applied a much higher PEG linker concentration (6.6 mg/mL) than with PDP-PEG-NHS (1 mg/mL) in order to speed up surface grafting by amide bond formation as compared to loop formation. This notion was supported by the finding that tip functionalization with 1 mg/mL of aldehyde-PEG-NHS gave unsatisfactory results (data not shown) while, after reaction at 6.6 mg/mL, amino-functionalized AFM tips and silicon nitride chips were regularly seen to couple protein (*14*), as exemplified in Tables 1 and 2 (see below).

Tips with such PEG-linked biotin−IgG were tested for function by repeated approach to, and retraction from, a dense monolayer of avidin on mica (see Figure 1) while measuring the repulsive and attractive forces, as described in detail in our preceding studies (*19, 26, 27*). Typical results are shown in Figure 3. Panel A shows a force−distance cycle with a small adhesion event (at ∼1 nm tip−mica distance) and a specific unbinding event (at ∼20 nm tip−mica distance), exhibiting unbinding forces of ∼33 pN and ∼52 pN. The gradual downward deflection of the cantilever within $2 < x < 20$ nm and the sudden cantilever relaxation at $x > 20$ nm obviously reflect specific binding of tip-tethered biotin−IgG to mica-bound avidin, for the following reasons: (i) The nonlinear force−distance profile is very characteristic for the nonlinear elasticity of the PEG tether between tip and biotin−IgG (*21*). (ii) The tip−mica distance of ∼20 nm at the moment of rupture is explained by the length of the PEG tether (6−8 nm, see ref 26), the length of IgG (∼15 nm), and the height of avidin (∼4 nm), taking into account that the position of PEG attachment on IgG and on the tip is not defined and not known. (iii) The unbinding force of ∼52 pN is in good agreement with the values previously measured at similar force loading rates (*15, 19, 26, 43−45*). (iv) When the avidin molecules on the mica surface were blocked with D-biotin (0.1 mg/mL), the chance of observing traces like that in panel A was dramatically reduced (see below). Instead, almost all traces were as shown in panel B. Panel C shows the unbinding force distributions measured in absence (solid line) or presence of D-biotin (dotted line). In the absence of D-biotin, 131 out of 990 force−distance cycles showed typical avidin−biotin unbinding events (analogous to the virus−receptor unbinding event in Figure 5B, see below) corresponding to a binding probability of 13.2%. The force distribution of these avidin−biotin bond ruptures shows force maxima at ∼50, ∼100, and ∼150 pN. The same phenomenon had previously been observed when biotin−IgG−SATP had been tethered to AFM tips via PDP-PEG-NHS (*19*), and it obviously reflects the simultaneous binding/unbinding of one, two, or three biotin residues which are covalently linked to a single IgG molecule (see ref *19*).

Table 1 shows a comprehensive data set acquired with six different cantilevers functionalized as depicted in Figure 1. Three of the cantilevers were functionalized with biotin−IgG and assigned the numbers 1−3, the other three with unlabeled IgG and assigned the numbers 4−6 (see first two columns of Table 1). Each tip was tested for specific recognition by performing 999 force−distance cycles each on five different locations of avidin-covered mica, and the number of force−distance cycles containing a typical unbinding event was evaluated as described (*46*). As can be seen from Table 1, the tips with biotin−IgG showed much higher binding probabilities than the control tips which had been functionalized with unlabeled goat IgG. This finding agrees with the conclusion from Figure 2 that the large majority of unbinding curves derived from specific avidin−biotin interactions, as previously seen after tip functionalization with biotin−PEG-NHS (*26*) or PDP-PEG-NHS plus biotin−IgG−SATP (*19*).

Imitation of AFM Tip Functionalization by Functionalization of Silicon Nitride Chips for Semiquantitative Analysis of Efficiency. In our preceding model study on the sequential functionalization of AFM tips with ethanolamine, PDP-PEG-NHS, and biotin−IgG−SATP (see Figure 6S in the Supporting Information for illustration), the AFM data were complemented with parallel macroscopic experiments in which silicon nitride chips (same material as the tips) were functionalized by the same three-step protocol (*19*). The chip-bound biotin−IgG molecules were then quantified with the help of a conjugate between avidin and a marker enzyme (ExtrAvidin-peroxidase), similar as in other solid-phase assays such as ELISA. By analogy, we have now reacted amino-functionalized silicon nitride chips with aldehyde-PEG-NHS and subsequently coupled biotin−IgG via Schiff base formation, thereby simulating AFM tip functionalization (see Figure 1) on a macroscopic scale (see Figure 7S in the Supporting Information for a schematic illustration of these steps, as well as of the quantitation of bound IgG).

The number of covalently bound probe molecules (biotin−IgG) per μm^2 was estimated from the number of subsequently

Table 2. Tethering of Antibodies to Silicon Nitride Chips via PEG Linkers[a]

linker type	[linker] (mg/mL)	antibody	total sites (μm^{-2})	nonspecific sites (μm^{-2})	specific sites (μm^{-2})
PDP-PEG-NHS	1	biotin−IgG−SATP	2100 ± 300	130	2000 ± 400
PDP-PEG-NHS	1	biotin−IgG	130 ± 40	120	0 ± 100
aldehyde-PEG-NH S	1	biotin−IgG	2000 ± 200	190	1800 ± 300

[a] The chip surface was amino-functionalized with ethanolamine hydrochloride (room-temperature method, see ref 26) and reacted with the NHS-ester function of PDP-PEG-NHS (see Figure 6S in the Supporting Information) or of aldehyde-PEG-NHS (see Figure 1). For coupling of protein, the chips were incubated in aqueous solutions of biotin−IgG−SATP (pretreated with 50 mM hydroxylamine to unmask the protected thiol functions) or biotin−IgG (in presence of 20 mM $NaCNBH_3$) and washed. the number of biotinylated IgG molecules per μm^2 surface was estimated from the amount of bound ExtrAvidin-peroxidase, measured in the absence (total sites) or presence (nonspecific sites) of free D-biotin.

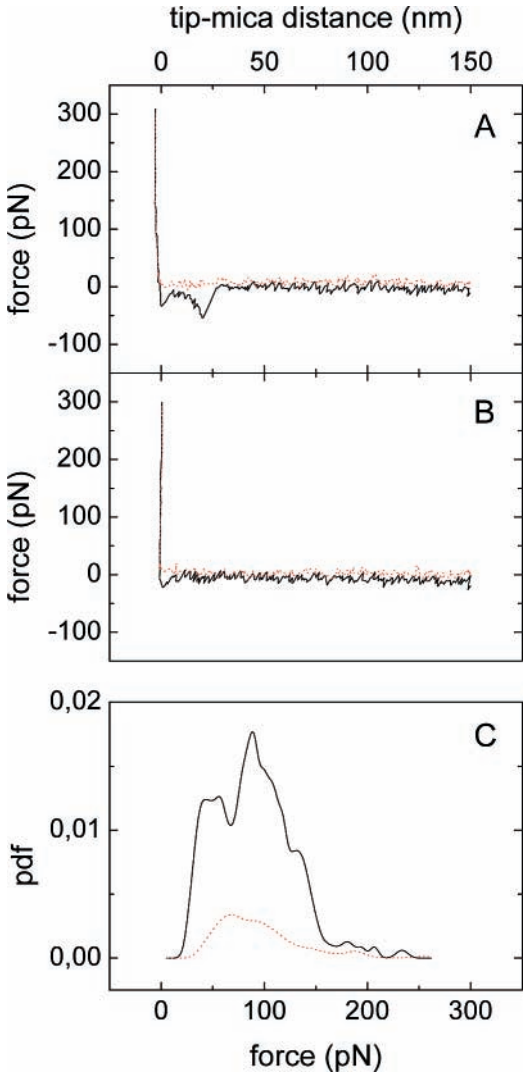

Figure 3. Force measurements of single avidin−biotin interactions. The amino-functionalized tip was derivatized with aldehyde-PEG-NHS and biotin−IgG, and avidin was irreversibly adsorbed to mica, as shown in Figure 1. The piezo movement in the approach-and-retraction cycles was ± 300 nm in 1 s, the force constant of the cantilever was 45 pN/nm, and the loading rate at unbinding was calculated as 2.7 nN/s, taking into account PEG elasticity at 50−100 pN pulling force (*21*). (A) Example of a force−distance cycle showing specific avidin−biotin unbinding in the absence of d-biotin. Unbinding occurred at a rupture force of 52 pN and at a tip−mica distance of 20 nm. (B) Example of a force−distance cycle performed in the presence of free D-biotin (0.1 mg/mL). (C) Probability density function (pdf) of the unbinding forces observed in 174 out of 705 force−distance cycles (solid line, 24.6% binding probability). In the presence of free D-biotin, only 80 out of 1767 force−distance cycles appeared to reflect specific binding (dotted line, 4.5% binding probability).

bound ExtrAvidin-peroxidase molecules, determined and calculated as described in detail in the previous study (*19*). Parallel controls were performed in which ExtrAvidin-peroxidase was blocked with excess of D-biotin in order to determine nonspecific adsorption of ExtrAvidin-peroxidase to the chip surface. As can be seen in Table 2, the extent of nonspecific adsorption (column 5) was very low in comparison to total binding in absence of D-biotin (column 4); thus, the number of specific binding sites (last column) could be estimated with confidence.

The data set in Table 2 was obtained with one batch of chips that had been amino-functionalized together in the same beaker to ensure the same amino group surface density. In addition, further reaction of all chips in lines 1 and 2 of Table 2 with PDP-PEG-NHS was done in a single batch, and the same applies to reaction with aldehyde-PEG-NHS in line 3. In this way the differences between line 1 and line 2 (∼2000 versus ∼0 IgG molecules per μm^2) are clearly attributed to the presence or absence of *S*-acetyl thiopropionyl residues on IgG (see Figure 6S for illustration); in other words, PDP-terminated PEG can only couple proteins which carry free thiol residues. In contrast, chips functionalized with aldehyde-PEG-NHS (see Figure 1) were able to couple biotin−IgG that had not been prederivatized with SATP, i.e., proteins without free thiol residues.

Mechanism of Schiff Base Formation between Protein and Aldehydes on PEG Tethers. The aldehyde function on the free termini of surface-linked PEG chains showed the same coupling efficiency with biotin−IgG as did surface-linked PEG-PDP tentacles with biotin−IgG−SATP (see last column in Table 2). In our preceding study we have shown that the observed efficiency of biotin−IgG−SATP coupling can only be understood by invoking preadsorption of IgG molecules next to surface-bound PEG-PDP chains because in absence of such preadsorption the disulfide coupling step should have taken several months, rather than the actually observed 1−2 h when working at <1 μM biotin−IgG−SATP (*19*). Preadsorption of one protein next to the surface-bound PEG has been estimated to result in a formal protein concentration of 3 mM within the volume that can be reached by the outer end of the 6−8 nm long PEG chain (*19*). Since Schiff base formation is known to be rather slow (*47*), the same preadsorption phenomenon must have helped in this study to achieve efficient AFM tip functionalization at micromolar biotin−IgG concentration.

On the basis of the preadsorption hypothesis, care must be taken to avoid components (e.g., detergents or high concentrations of glycerol) that could weaken the nonspecific adsorption of proteins to the AFM tip. Other forbidden additives are primary amines (e.g., Tris base) which would react with the benzaldehyde function of the PEG linker and de-activate it before protein is coupled. Azide is also likely to inhibit coupling because it is chemically similar to cyanide which is known to react with aldehyde functions. Microdialysis should suffice to eliminate all these components because minute traces of these components left after dialysis are not expected to have a significant effect.

A hitherto unaddressed aspect concerns the simultaneous inclusion of ∼20 mM $NaCNBH_3$ for immediate reduction of the initially formed Schiff bases. It is based on the finding that this concentration of $NaCNBH_3$ reduces only Schiff bases but not the aldehydes themselves (*47*). Moreover, this fixation reagent not only ensures irreversibility of coupling but also

enhances the yield of immobilization when added together with protein, rather than after aldehyde−protein coupling (*48*).

Lateral Density of Antibody Molecules on the Chip and Tip Surface. Table 1 indicates that ∼2000 ExtrAvidin-peroxidase molecules were bound per μm^2 of chip surface. This number is a crude estimate of the number of surface-bound biotinylated IgG molecules per μm^2, as explained before (*26*). With this uncertainty in mind, one can translate the area density of biotin−IgG from the chip assay into a number of functional biotin−IgG molecules per AFM tip. A lateral density of 2000 μm^{-2} corresponds to an average area of 500 nm^2 per biotin−IgG. Based on the nominal tip radii (10−20 nm), the foremost hemispheres of AFM tips should have areas between 600 and 2500 nm^2 and thus carry 1−5 biotin−IgG molecules. In order to be functional, one of the IgG-bound biotin residues must be able to reach beyond the apex of the tip in order to be recognized by mica-bound avidin (see Figure 1). Consequently, the grafting site of the PEG tether must not be higher up on the tip than the total length of the PEG tether (6−8 nm) plus the IgG molecule. In practice, only grafting sites in the lowest 10 nm region of the tip will provide for good functionality because the benzaldehyde terminus of PEG may often bind in the F_{ab} region of the antibody, rather than in the F_c region (as shown for simplicity in Figure 1). In conclusion, the data from the chip assay predict that roughly one functional biotin−IgG molecule should be found on one AFM tip when using the protocol in Figure 1. Taking into account that the chip assay tends to somewhat underestimate the number of surface-tethered biotin−IgG (*26*), the prediction should be modified to "one or several". This prediction has regularly been confirmed in our AFM studies (*10, 14, 16, 17, 19−24, 27*), whether antibodies had been tethered via aldehyde-PEG-NHS (Figure 1) or PDP-PEG-NHS (Figure 6S).

Tethering of Whole Virus Particles to Amino-Functionalized AFM Cantilevers via Aldehyde-PEG-NHS. The tethering of virus particles (human rhinovirus serotype 2, HRV2) to the surface of silicon nitride cantilevers is visualized in Figure 4. The cantilever shown in panel A had been amino-functionalized, reacted with aldehyde-PEG-NHS, and incubated with virus particles (0.1 mg/mL, with 20 mM $NaCNBH_3$) by a similar protocol as described above (for details see Supporting Information), resulting in a high density of virus particles that remained on the cantilever surface after washing. In order to check whether the viral particles had indeed been bound via Schiff base bonds, another cantilever was treated with ethanolamine to block the benzaldehyde residues before exposure to virus. As shown in panel B, a much lower number of virus particles remained on this cantilever surface after washing. The pronounced difference between panel A and panel B provides clear evidence that most virus particles had indeed been immobilized via Schiff base-type bonds.

Measurement of Interaction Forces between Virus Particles on AFM Tips and Virus Receptors on Mica Surfaces. Figure 4A is an image of the top surface of a cantilever densely covered with virus particles, most of which had been covalently tethered to the surface via aldehyde-PEG-NHS. Because of the high density of viral particles it was very likely that the measuring tip of the cantilever also carried at least one virus particle (15 nm radius) on the apex of the tip (10−20 nm radius). The virus-functionalized tip could thus be used to study specific binding to, and unbinding from, a virus-specific receptor protein. VLDLR1-8, a soluble fragment of the very-low-density lipoprotein receptor encompassing the entire ligand binding domain was chosen as the receptor protein. It contains 8 repeats many of which contribute to specific binding of HRV2 (*49*). VLDLR1-8 was tethered to amino-functionalized mica (*42*) via aldehyde-PEG-NHS by the usual protocol used in the present

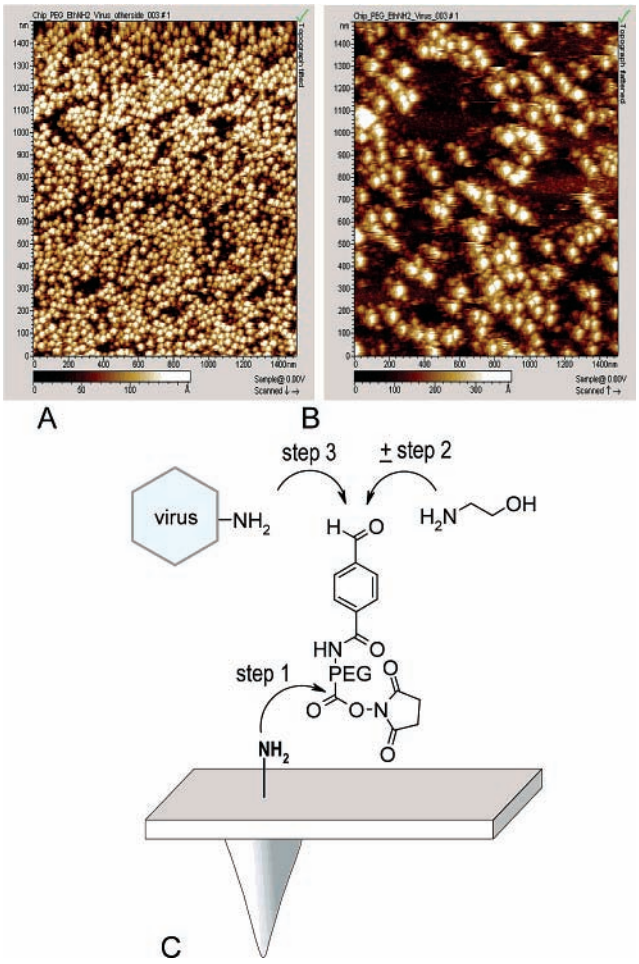

Figure 4. Quantitative study on the tethering of virus particles to the top side of two different silicon nitride cantilevers. This experiment served to characterize the preparation of virus-functionalized tips used for studying virus−receptor interactions as shown in Figure 5. Cantilevers A and B were functionalized with ethanolamine hydrochloride (not shown) and aldehyde-PEG-NHS (step 1 in panel C). On cantilever A, the virus particles were immediately added (step 3 in panel C), together with $NaCNBH_3$, incubated, and washed, and the top side of the cantilever was imaged with an unmodified cantilever (see panel A). On cantilever B, the free benzaldehyde groups on the outer end of the PEG linkers were blocked with ethanolamine and $NaCNBH_3$ (step 2 in panel C) before virus particles were added (step 3 in panel C), incubated, washed, and imaged with an unmodified cantilever (see panel B). In the latter panel, the virus particle look larger (i) because they were not as immobile as in panel A and (ii) because of the tip broadening effect. The latter effect was absent in panel A because the close proximity of the particles prevented the tip to reach the supporting surface in most places.

study, taking care to keep VLDLR1-8 native by inclusion of 2 mM Ca^{2+} (see Supporting Information).

The specific interaction of tip-tethered HRV2 and mica-bound VLDLR1-8 (see Figure 5A) was studied by performing force−distance cycles in which the cantilever base was repeatedly lowered and raised by 400 nm within 1 s while simultaneously recording cantilever bending. The latter was converted into force values (*y*-axis in Figure 5B and 5C) according to Hooke's law, based on the known force constant of the cantilever (23 pN/nm). In the presence of 2 mM Ca^{2+}, 118 out of 999 force distance cycles showed specific recognition events (as exemplified in Figure 5B). In the absence of free Ca^{2+} (1 mM EGTA), however, only 24 out of 999 measuring cycles exhibited some nonspecific recognition event (not shown), and all others were event-free, as shown in Figure 5C. The reduction in binding probability from 11.8% in 2 mM Ca^{2+} to 2.4% in Ca^{2+}-free

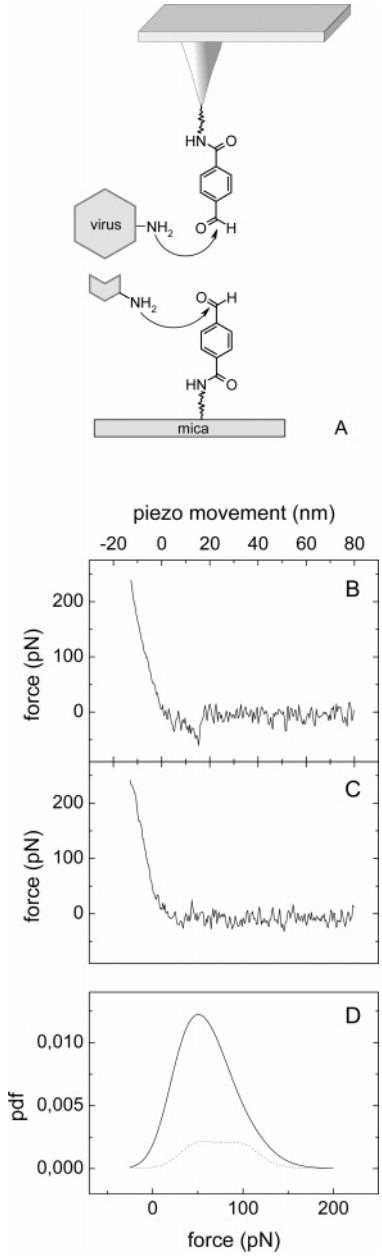

Figure 5. Force measurements between tip-linked virus particles (HRV2) and mica-bound virus receptor protein (VLDLR1-8, the extracellular fragment of human VLDL receptor). (A) Tip and mica were functionalized with ethanolamine hydrochloride and aldehyde-PEG-NHS (compare Figure 1) before virus and receptor were bound to the free aldehyde ends on tip and mica, respectively, and fixed by simultaneous application of $NaCNBH_3$. The piezo movement in the approach-and-retraction cycles was ±400 nm in 1 s, the force constant of the cantilever was 23 pN/nm, and the effective loading rate was 1.7 nN/s. (B) Example of a force−distance cycle showing specific virus−receptor unbinding. Unbinding occurred at a rupture force of 51 ± 18 pN. (C) Example of a force−distance cycle performed in the absence of Ca^{2+}, i.e. in Ca-free buffer containing 1 mM EGTA). (D) Probability density function (pdf) of the unbinding forces observed in 118 out of 999 force−distance cycles (11.8%, solid line). In the absence of Ca^{2+} (dotted line), only 24 out of 999 force−distance cycles (2.4%) appeared to reflect specific unbinding. The integrals of the two pdf curves were scaled to be proportional to the binding probabilities.

buffer indicates the specificity of virus−receptor interaction in the force distance cycles (*49*).

The rupture force distribution of the 118 specific unbinding events is shown in Figure 5D (solid line). The histogram peaks at a force of 50 pN, reflecting the well defined interaction of HRV2 particles with the VLDL receptor fragment. In contrast, the force distribution of the 24 unbinding events observed in EGTA buffer had no distinct maximum (Figure 5D, dotted line), providing further evidence that nonspecific adhesion caused very few apparent unbinding events only and most of the 118 events measured in presence of Ca^{2+} must have been specific in nature.

Meanwhile, promising experiments with other receptor constructs are under way which are expected to elucidate the contributions of the individual repeats to virus−receptor interaction (Rankl et al., manuscript in preparation). Moreover, tip functionalization with aldehyde-PEG-NHS has successfully been used for tethering of cytochrome C to the AFM tip in order to study its biospecific interaction of cytochrome C with azurin that had been immobilized on an ultraflat gold surface (*14*).

CONCLUSIONS

Force measurements of biospecific interactions between isolated purified molecules require linking of the interacting molecules to the AFM tip and to the sample surface. Long flexible linkers such as PEG chains are preferred because they allow for reorientation and local mobility of "receptor" and/or "ligand" molecule. The present study offers a straightforward method for the tethering of proteins via one of their many lysine residues, eliminating the need for endogenous or artificially introduced thiol groups. Minute amounts of protein (e.g., 5 μg in 50 μL of physiological buffer) are required to functionalize one AFM cantilever within 1−2 h incubation time.

Porphyrin−Retinamides: Synthesis and Cellular Studies

Martha Sibrian-Vazquez, Timothy J. Jensen, and M. Graça H. Vicente*

Department of Chemistry, Louisiana State University, Baton Rouge, Louisiana 70803. Received February 2, 2007; Revised Manuscript Received March 14, 2007

A series of four porphyrin−retinamides containing either all-trans- or 13-cis-retinoid acid residues, directly linked to the para-phenyl position of *meso*-tetraphenylporphyrin or via a low-molecular-weight PEG spacer, have been synthesized. The biological properties of these conjugates were evaluated in a model cell line, human HEp2, and in neuroblastoma SK-N-DZ cells, which exhibit moderate expression of retinoic acid receptors and retinoic acid-induced differentiation. The directly linked porphyrin−retinamides were taken up by a greater extent (20−50% more) in SK-N-DZ than in HEp2 cells. However, the PEG-containing conjugates accumulated maximally within both cell lines and approximately by the same amount, probably due to their increased amphiphilicity. Among all conjugates, the porphyrin-PEG-13-cis-retinamide accumulated the most in both cell lines (about 5 times more than the non-pegylated conjugates). None of the porphyrin−retinamide conjugates were toxic toward HEp2 cells at concentrations up to 100 μM, and only the hydrophobic non-pegylated conjugates were moderately toxic to SK-N-DZ cells [IC_{50} (dark) = 56−92 μM, and IC_{50} (at 1 J/cm^2) = 6−8 μM]. All conjugates preferentially localized within cellular vesicles that correlated well to the lysosomes and, in addition, the PEG-containing porphyrin−retinamides were also found in the ER.

INTRODUCTION

The receptor-mediated transport of drugs into targeted cells and sensitive intracellular sites is a valuable approach aimed at increasing the specificity of drugs for diseased tissue (*1*−*4*). Photodynamic therapy (PDT) is a binary modality for the treatment of cancer based on the activation of a tumor-accumulated photosensitizer with light of a wavelength, suitable for the excitation of the photosensitizer and for maximum tissue penetration (*5, 6*). The excited photosensitizer reacts with molecular oxygen and other surrounding molecules, generating radicals and reactive oxygen species (such as $^1O_2$) that cause irreversible photodamage to tumor tissues. Since $^1O_2$, the main cytotoxic agent generated in PDT, has a very short lifetime in biological systems and a very limited range in tissues (<0.05 μm), the site of photodamage is also the site of its generation. A particularly sensitive intracellular site is the cell nucleus, and DNA photodamage has been reported to occur in PDT (*7*−*10*), although porphyrin-based photosensitizers do not usually localize within cell nuclei (*11*). Therefore, the targeting of nuclear receptors by PDT photosensitizers might lead to increased therapeutic efficacy. Nuclear receptors consist of a vast family of proteins composed of steroid receptors, nonsteroidal receptors, thyroid hormone receptors, and retinoic acid receptors, all of which play a major role in intracellular signaling and carcinogenesis (*12, 13*). Among these, the retinoic acid receptor (RAR[1]) and the retinoic X receptor (RXR) belong to a large family of proteins that activate transcription in the presence of retinoic acids, the biologically active metabolites of vitamin A (retinol) and its active derivatives (*14, 15*). The use of retinoids to suppress tumor development has been evaluated in animal models of carcinogenesis including skin, breast, oral cavity, lung, hepatic, gastrointestinal, prostate, and bladder cancers (*16*−*18*). In these studies, all-trans retinoic acid derivatives have demonstrated chemopreventive activity both in vitro and in vivo (*19*−*25*). However, there are some disadvantages associated with the use of retinoids for cancer treatment, including retinoid-induced toxicity, resistance, and long-term side effects. As a result, the use of retinoids has been proposed only in an advanced disease state in order to enhance tumor sensitivity toward cytotoxic agents (*26*−*28*). It is possible that the combined use of retinoids and porphyrin-based photosensitizers might induce synergistic or additive effects that can lead to higher PDT therapeutic efficacy. We envisioned that the conjugation of a porphyrin photosensitizer to a retinoic acid might result in nucleus import of the resulting conjugate upon ligand recognition by the nuclear receptor, thus improving the biological efficacy of the photosensitizer while reducing the toxic effects of the retinoic acid moiety. Porphyrin-retinoid derivatives have been previously prepared, comprising either a *meso*-tetraphenylporphyrin (*29*) or a deuteroporphyrin-IX (*30*) macrocycle and aromatic derivatives of retinoic acid differing in the length of the conjugated side chains. However, only the energy transfer and primary charge separation characteristics of these conjugates were reported, and their biological properties were not investigated. Herein, we report the synthesis and in vitro biological evaluation of a series of new porphyrin−retinamides of the natural occurring all-trans- and 13-cis-retinoic acids, using both human carcinoma HEp2 and neuroblastoma SK-N-DZ cell lines. We studied the effects of (i) a low-molecular-weight PEG spacer between the porphyrin and retinoic acid moieties, (ii) the all-trans- vs 13-cis-retinoic acid moieties, and (iii) the use of a cell line (SK-N-DZ) known to respond to retinoic acid, on the cellular uptake, toxicity, and intracellular localization of the new porphyrin−retinamides.

EXPERIMENTAL PROCEDURES

Synthesis. Unless otherwise indicated, all commercially available starting materials were used directly without further

purification. All reactions were monitored by TLC using Sorbent Technologies 0.25 mm silica gel plates with UV indicator (60F-254). Silica gel Sorbent Technologies 32−63 μm was used for flash column chromatography. NMR spectra were obtained on a ARX-300 Bruker or Bruker DPX 400 spectrometer. Chemical shifts (δ) are given in parts per million (ppm) relative to $CDCl_3$ (7.26 ppm, ^{1}H) unless otherwise indicated. Electronic absorption spectra were measured on a Perkin-Elmer Lambda 35 UV−vis spectrophotometer. Fluorescence spectra were measured on either a Perkin-Elmer LS55 spectrometer or a Florolog 3 Spectrofluorimeter. Mass spectra were obtained on a Bruker ProFLEX III MALDI-TOF mass spectrometer using CCA as the matrix.

Porphyrin−Retinamide 2. To a solution of all-trans-retinoic acid (0.0119 g, 0.0397 mmol) in DMF (500 μL) was added DIEA (0.0154 g, 0.119 mmol), followed by HOBt (0.006 g, 0.0397 mmol) and TBTU (0.0127 g, 0.0397 mmol). The reaction mixture was stirred 5 min, and then aminoporphyrin **1** (0.025 g, 0.0397 mmol) was added in one portion. The reaction mixture was stirred at room temperature for 24 h and then diluted with 50 mL of ethyl acetate. The organic phase was washed with saturated $NaHCO_3$ (100 mL) and water (100 mL), dried over Na_2SO_4, filtered, and the solvent evaporated under vacuum. The title compound was purified by flash chromatography on silica gel using CH_2Cl_2 for elution. Yield: 0.019 g, 51%. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.89 (8H, s, β-H), 8.27 (6H, s, ArH), 8.19 (2H, d, J = 8.17 Hz, ArH), 7.92 (2H, d, J = 7.0 Hz, ArH), 7.81 (9H, s, ArH), 7.49 (1H, s, NHCO), 7.13 (1H, t, J = 14.68 Hz, =CH), 6.40 (1H, t, J = 15.56 Hz, =CH), 6.15−6.22 (3H, m, =CH), 5.98 (1H, s, =CH), 2.60 (3H, s, CH_3), 2.10 (5H, s, CH_3, CH_2), 1.8 (3H, s, CH_3), 1.69−1.75 (2H, m, CH_2), 1.59 (2H, s, CH_2), 1.11 (6H, s, CH_3), −2.71 (2H, s, NH). UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 421 (618 000), 516 (19 000), 552 (10 600), 591 (6200), 647 (5100). LRMS (MALDI) *m*/*z* 911.75 (M^+).

Porphyrin−Retinamide 3. The title compound was synthesized as described above using 13-cis-retinoic acid. Yield: 0.0179 g, 49%. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.87 (8H, s, β-H), 8.04−8.22 (8H, m, ArH), 7.87 (1H, d, J = 6.16 Hz, =CH), 7.77 (9H, s, ArH), 7.45 (1H, s, NHCO), 7.07 (1H, t, J = 13.73 Hz, =CH), 6.13−6.39 (3H, m, =CH), 5.79 (1H, s, =CH), 2.18 (3H, s, CH_3), 2.06 (5H, s, CH_3, CH_2), 1.74 (2H, s, CH_3), 1.63 (2H, s, CH_2), 1.49−1.54 (2H, m, CH_2), 1.06 (6H, s, CH_3), −2.73 (2H, s, NH). UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 421 (605 000), 516 (18 000), 552 (10 000), 591 (5900), 647 (5900). LRMS (MALDI) *m*/*z* 911.76 (M^+).

Porphyrin−Retinamide 4. The monoaminoporphyrin (**1**) reacted with glycolic anhydride to give a carboxylic acid-terminated porphyrin, as previously described (*31*). To a solution of this porphyrin (0.100 g, 0.134 mmol) in DMF (2 mL) was added DIEA (0.1039 g, 0.8044 mmol), followed by HOBt (0.0205 g, 0.1348 mmol) and TBTU (0.043 g, 0.134 mmol). After 5 min, the monoprotected $NH_2CH_2CH_2(OCH_2CH_2)_6OCH_2CH_2NH^tBoc$ (0.0628 g, 0.134 mmol) was added and the mixture stirred at room temperature for 48 h. The reaction mixture was diluted with ethyl acetate (100 mL), the organic phase was treated as described above for the synthesis of compound **2**, and the ^{t}Boc-protected porphyrin−PEG was purified by flash chromatography using $CHCl_3/CH_3OH$ 9:1 for elution. Yield: 0.133 g, 83%. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.87−8.90 (8H, m, β-H), 8.21−8.25 (8H, m, ArH), 8.22 (2H, d, J = 7.98 Hz, ArH), 7.57 (1H, s, NHCO), 7.78−7.85 (9H, m, ArH), 4.39 (2H, s, CH_2O), 4.32 (2H, s, CH_2O), 3.58−3.69 (26H, m, PEG-CH_2O), 3.49−3.55 (4H, m, CH_2NH, CH_2O), 3.30−3.31 (2H, m, CH_2-NH), 1.44 (9H, s, CH_3), −2.73 (2H, s, NH). UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 420 (460 000), 516 (16 800), 552 (8300), 591 (5200), 646 (4500). LRMS (MALDI) *m*/*z* 1195.99 (M^+). The ^{t}Boc-protected porphyrin−PEG (0.133 g, 0.126 mmol) was dissolved in a 1:1 mixture of $CHCl_3$/TFA (2 mL) and stirred at room temperature for 4 h. After the solvent was evaporated under vacuum, the green residue was triturated with ethyl ether and then dried again under vacuum to give the free amino porphyrin−PEG in quantitative yield. ^{1}H NMR ($CDCl_3$, d-TFA, 300 MHz): δ 8.84−8.57 (18H, m, ArH), 7.97 (10H, s, ArH), 4.39 (2H, s, CH_2O), 4.33 (2H, s, CH_2O), 3.62−3.81 (30H, m, PEG-CH_2O), 3.30 (2H, s, CH_2NH), 0.38−0.48 (4H, br, NH^+). UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 420 (670 000), 516 (16 100), 551(8100), 590 (5300), 646 (4100). LRMS (MALDI) *m*/*z* 1095.62 (M^+). Conjugation of this pegylated porphyrin intermediate (0.033 g, 0.03 mmol) to all-trans-retinoic acid amino (0.009 g, 0.03 mmol) was performed as described above for compound **2**. The title compound was purified by flash chromatography on silica gel using $CHCl_3/CH_3OH$ 9:1 for elution. Yield: 0.032 g, 78%. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.85−8.89 (8H, m, β-H), 8.18−8.23 (8H, m, ArH), 8.11 (2H, d, J = 8.22 Hz, ArH), 7.86 (1H, s, NHCO), 7.75−7.77 (9H, m, ArH), 6.88 (1H, t, J = 11.34 Hz, =CH), 6.52−6.58 (1H, m, =CH), 6.03−6.05 (3H, m, =CH), 5.68 (1H, s, =CH), 4.37 (2H, s, CH_2O), 4.31 (2H, s, CH_2O), 3.44−3.66 (32H, m, PEG-CH_2O), 2.34 (3H, s, CH_3), 1.95 (3H, s, CH_3,CH_2), 1.65 (2H, s, CH_3), 1.43 (2H, s, CH_2), 1.26 (2H, s, CH_2), 0.98 (6H, s, CH_3), −2.65 (2H, s, NH). UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 420 (670 000), 516 (17 900), 551 (9100), 590 (5900), 646 (4700). LRMS (MALDI) *m*/*z* 1377.57 (M^+).

Porphyrin−Retinamide 5. This compound was synthesized and isolated as described above for porphyrin−retinamide **4**, using 13-cis-retinoic acid amino (0.009 g, 0.03 mmol) and the same pegylated porphyrin intermediate (0.033 g, 0.03 mmol). Yield: 0.025 g, 60%. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.87 (8H, s, β-H), 8.18−8.23 (8H, m, ArH), 8.10 (2H, d, J = 7.98 Hz, ArH), 7.85−7.90 (1H, m, =CH), 7.77 (9H, s, ArH), 6.80−6.95 (1H, m, =CH), 6.54 (1H, br, =CH), 6.07−6.28 (2H, m, =CH), 5.56 (1H, s, =CH), 4.37 (2H, s, CH_2O), 4.30 (2H, s, CH_2O), 3.45−3.36 (32H, m, PEG-CH_2O), 1.90−1.94 (8H, m, CH_3,CH_2), 1.68 (3H, s, CH_3), 1.59 (2H, s, CH_2), 1.45 (2H, s, CH_2), 1.00 (6H, s, CH_3), −2.77 (2H, s, NH). UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 420 (528 000), 516 (17 300), 551 (8800), 590 (5800), 646 (4600). LRMS (MALDI) *m*/*z* 1377.50 (M^+).

Fluorescence Quantum Yields. All absorption spectra were acquired using 10 mm path length quartz cuvettes and the corresponding solvents as reference solutions. The optical density of the solutions used for the emission studies was below 0.05 at the excitation wavelength to eliminate inner filter effects. All the measurements were performed within 3 h of preparation of the solutions. Stock solutions (10 mM) of porphyrins **1**−**5** were prepared in DMSO. The quantum yields were calculated using a secondary standard method (*32*, *33*). Methylene blue, a dye with an established quantum yield, was used as a secondary standard. Using this method, the integrated fluorescence intensities of the analyte (I) and standard (I_R), the optical densities of the analyte (OD) and the standard (OD_R), and the refractive indexes of analyte solvent (n) and standard solvent (n_R) are related to the quantum yield of the analyte (Q) as follows:

$$Q = Q_R \frac{I}{I_R} \frac{OD_R}{OD} \frac{n^2}{n_R^2}$$

where Q_R is the quantum yield of the reference standard (0.03 for methylene blue). To account for incomplete spectra, the bands were extrapolated using appropriate fitting models whenever necessary.

Computer Simulations. The Gasteiger−Huckel computational model and the Tripos Force Field parameters incorporated into the software package *SYBYL 7.0* (Tripos St. Louis, USA)

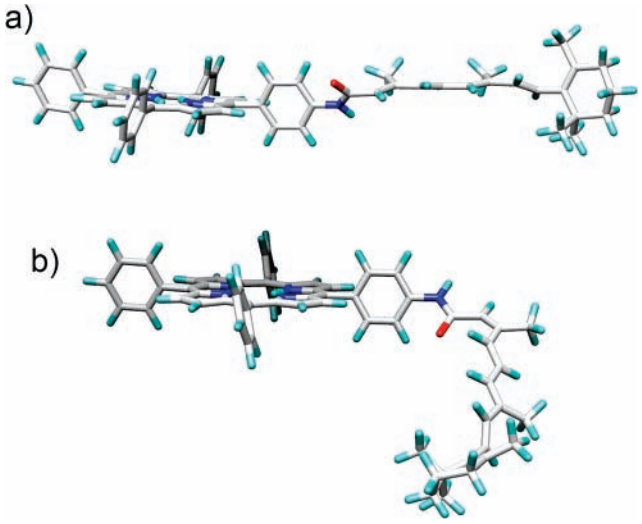

Figure 1. Energy-minimized conformations for conjugates (a) **2** and (b) **3** using the Gasteiger-Huckel model and the Tripos Force Field parameters incorporated into the software package *SYBYL 7.0*.

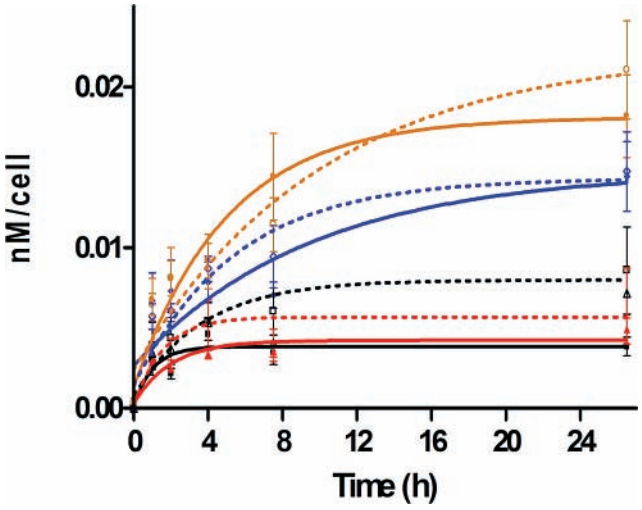

Figure 2. Time-dependent uptake of porphyrin−retinamides **2** (black), **3** (red), **4** (blue), and **5** (brown) at 10 μM by HEp2 cells (solid line) and SK-N-DZ cells (dashed line).

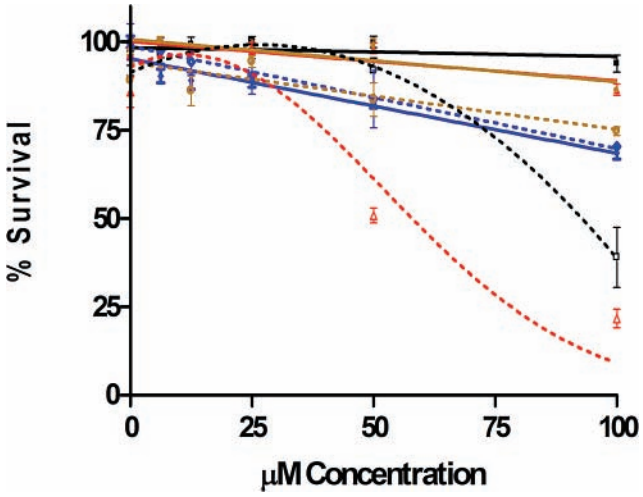

Figure 3. Dark toxicity of porphyrin−retinamides **2** (black), **3** (red), **4** (blue), and **5** (brown) toward HEp2 cells (solid line) and SK-N-DZ cells (dashed line) after 24 h, using the Cell Titer Blue assay.

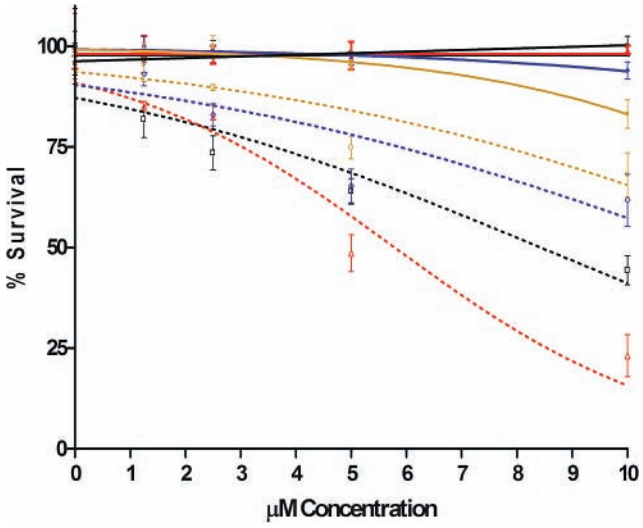

Figure 4. Phototoxicity of porphyrin−retinamides **2** (black), **3** (red), **4** (blue), and **5** (brown) toward HEp2 cells (solid line) and SK-N-DZ cells (dashed line) using 1 J/cm^2 light dose.

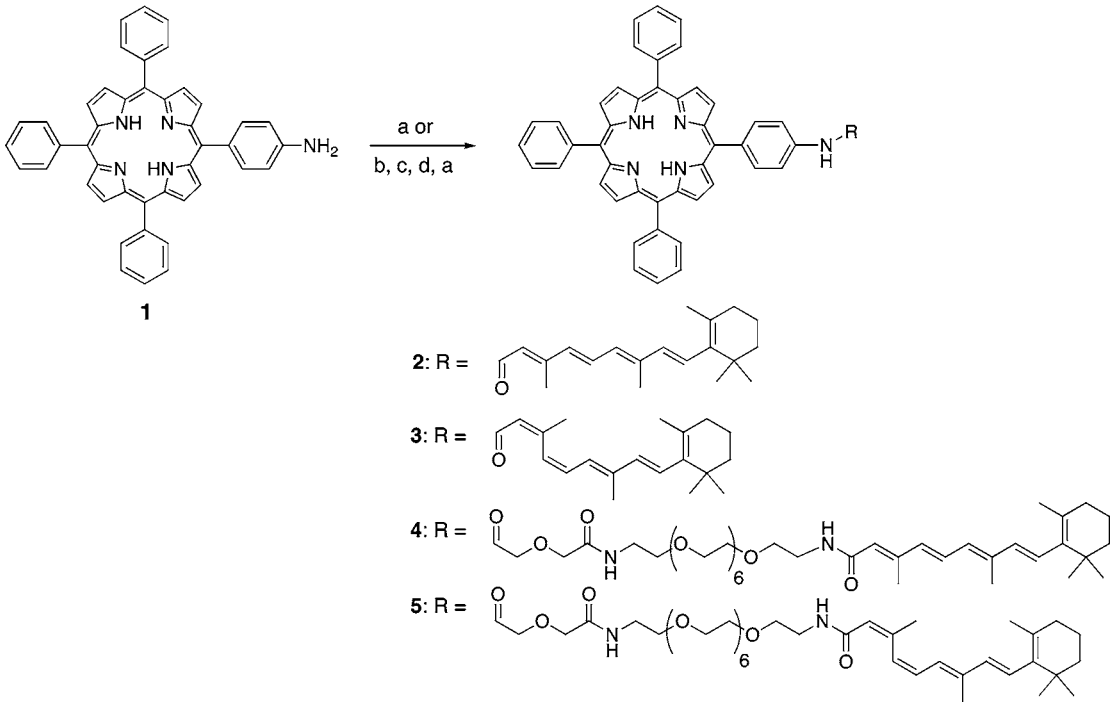
were used for the energy minimization calculations. After initial minimization for each molecule, a dynamics evaluation was performed by heating the molecules to 300 K and then cooling to 0 K over a period of 1000 fs.



Cell Culture. All tissue culture media and reagents were obtained from Invitrogen. Human cervical carcinoma HEp2 and neuroblastoma SK-N-DZ cells were obtained from ATCC and maintained in a 50:50 mixture of DMEM/Advanced MEM containing 5% FBS. The cells were subcultured biweekly to maintain subconfluent stocks. The results shown in Figures 2−4 for the uptake and toxicity experiments are the average of three independent experiments, each performed in triplicate (i.e., nine wells per point).

Time-Dependent Cellular Uptake. HEp2 cells were plated at 10 000 per well and SK-N-DZ cells were plated at 50 000 per well in a Costar 96 well plate and allowed to grow 36−48 h. Porphyrin stocks were prepared in DMSO at a concentration of 10 mM and then diluted into medium to final working concentrations. The cells were exposed to 10 μM of each conjugate for 0, 1, 2, 4, 8, and 26.5 h. At the end of the incubation time, the loading medium was removed and the cells were washed with PBS. The cells were solubilized upon addition of 100 μL of 0.25% Triton X-100 (Calbiochem) in PBS. To determine the conjugate concentration, fluorescence emission was read at 410/650 nm (excitation/emission) using a BMG FLUOstar plate reader. The cell numbers were quantified using the CyQuant reagent (Molecular Probes).

Dark Cytotoxicity. The HEp2 cells and SK-N-DZ cells were plated as described above and allowed 36−48 h to attach. The cells were exposed to increasing concentrations of conjugate up to 100 μM and incubated for 24 h. The loading medium was then removed, and new medium containing Cell Titer Blue (Promega) was added as per manufacturer's instructions. Cell toxicity was then measured by reading the fluorescence at 520/584 nm using a BMG FLUOstar plate reader. The signal was normalized to 100% viable (untreated) cells and 0% viable (treated with 0.2% saponin) cells.

Phototoxicity. The HEp2 cells and SK-N-DZ cells were prepared as described above for the dark cytotoxicity assay and treated with conjugate concentrations of 0, 0.625, 1.25, 2.5, 5, and 10 μM. After compound loading, the medium was removed and replaced with medium containing 50 mM HEPES pH 7.4. The cells were then placed on ice and exposed to light from a 100 W halogen lamp filtered through a 610 nm long-pass filter (Chroma) for 20 min. An inverted plate lid filled with water to a depth of 5 mm acted as an IR filter. The total light dose was approximately 1 J/cm^2. The cells were returned to the incubator

[a]Conditions: (a) HOBt/TBTU/DIEA/DMF, 13-cis- or all-trans-retinoic acid, rt, 24 h (49−78%). (b) Glycolic anhydride/DMF, rt, 24 h, quantitative yield. (c) HOBt/TBTU/DIEA/DMF, $NH_2CH_2CH_2(OCH_2CH_2)_6OCH_2CH_2NH^tBoc$, rt, 48 h (83%). (d) $CHCl_3$/TFA 1/1, rt, 4 h, quantitative yield.

overnight and assayed for viability as described above for the dark cytotoxicity experiment.

Microscopy. The HEp2 cells were plated on LabTek 2 chamber coverslips and incubated overnight, before being exposed to 10 μM of conjugate for 24 h. For the colocalization experiments, the cells were incubated for 18 h concurrently with conjugate and one of the following organelle tracers, for 30 min: MitoTracker Green (Molecular Probes) 250 nM, LysoSensor Green (Molecular Probes) 50 nM, BODIPY FLC_5-Ceramide (Molecular Probes) 50 nM, and $DiOC_6$ (Molecular Probes) 5 μg/mL. The slides were washed three times with growth medium, and new medium containing 50 mM HEPES pH 7.4 was added. Fluorescent microscopy was performed using a Zeiss Axiovert 200M inverted fluorescent microscope fitted with standard FITC and Texas Red filter sets (Chroma). The images were aquired with a Zeiss Axiocam MRM CCD camera fitted to the microscope.

RESULTS

Synthesis. The new series of porphyrin conjugates to either all trans- or 13-cis-retinoic acids were prepared from monoaminoporphyrin **1** (*34*), as shown in Scheme 1, via amide bond formation. The retinoic acids were first activated as the hydroxybenzotriazole esters and then coupled to either aminoporphyrin **1** or to a pegylated monoaminoporphyrin using TBTU in the presence of DIEA, in 49−78% overall yields. The pegylated conjugates were also prepared from monoaminoporphyrin **1**, first by reaction with glycolic anhydride to afford a carboxyl-terminated porphyrin, followed by coupling to $NH_2CH_2CH_2(OCH_2CH_2)_6OCH_2CH_2NH^tBoc$ and deprotection using TFA in $CHCl_3$ (*31*). Conjugates **2** and **3** bearing a direct linkage between the retinoic acid moiety and the para-phenyl porphyrin position are highly hydrophobic, soluble only in organic solvents, such as hexane, dichloromethane, chloroform, and DMSO. In contrast, conjugates **4** and **5**, containing a low-molecular-weight PEG spacer between the porphyrin and the retinoid moiety, showed amphiphilic properties, being soluble in both organic and protic solvents, such as hexane, methanol, acetonitrile, and DMSO, and partially soluble in water. Furthermore, we anticipated that the PEG spacer would favor an extended conformation for conjugates **4** and **5**, which we believe is crucial for receptor binding (*31*). Indeed, we used computer calculations to determine the minimum-energy conformations for porphyrin−retinamides **2**−**5**. While the conformations of the PEG-containing conjugates were similarly extended (results not shown), those for the non-pegylated conjugates **2** and **3** were very different, as shown in Figure 1. The all-trans-retinoic acid conjugate **2** shows a planar conformation, while the 13-cis-retinoic acid conjugate **3** adopts a bend conformation. The structures of the new porphyrin−retinamide conjugates **2**−**5** were confirmed by MS, ^{1}H NMR, UV−vis, and fluorescence spectrophotometry. The UV−vis spectra of porphyrin−retinamides **2**−**5** show characteristic etio-type porphyrin spectra with a shoulder on the Soret band due to the presence of the retinoic acid moiety; retinoic acids typically have a broad absorption band at 390 nm (see Figure 1 of the Supporting Information). The emission spectra of aminoporphyrin **1** and of porphyrin−retinamides **2**−**5** in DMSO can be seen in Figure 2 of the Supporting Information. The fluorescence quantum yields determined for porphyrins **1**−**5** are shown in Table 1.

Cell Studies. The time-dependent cellular uptake of porphyrin−retinoid conjugates **2**−**5** was evaluated in both human carcinoma HEp2 and neuroblastoma SK-N-DZ cells at a concentration of 10 μM, and the results are shown in Figure 2. The HEp2 cell line is a convenient model for the evaluation of porphyrin-based in vitro biological properties (*31, 35*−*37*), while the SK-N-DZ cell line is known to respond to retinoic acid and

4	0.037
5	0.038

to retinoic acid-induced differentiation (*38*−*41*). Indeed, conjugates **2** and **3** bearing a direct linkage between the porphyrin and either all-trans- (**2**) or 13-cis-retinoic acid (**3**) were taken up to a greater extent (20−50%) by SK-N-DZ than HEp2 cells (Figure 2). However, conjugates **4** and **5**, containing a PEG spacer between the porphyrin and retinoic acid moieties, accumulated the most and approximately by the same extent within both cell lines. The PEG-containing 13-cis-retinoic acid conjugate **5** was the most taken up by both cell lines, at all time points studied, indicating that both the PEG and the nature of the retinoic acid moiety influence the cellular uptake of these conjugates. In contrast, the non-PEG-containing hydrophobic conjugates **2** and **3** were taken up similarly by HEp2 cells and the all-trans-retinamide **2** accumulated preferentially in SK-N-DZ cells. All conjugates exhibited similar uptake kinetics in both cell lines at short time points (within the first 1−2 h), but while the uptake of the hydrophobic conjugates **2** and **3** reached a plateau after 4 h, that of PEG-containing conjugates **4** and **5** continued to steadily increase over the 26.5 h period investigated.

The dark toxicity and phototoxicity of the porphyrin−retinamides **2**−**5** were investigated in both HEp2 and SK-N-DZ cells exposed to increasing concentrations of each conjugate, up to 100 μM for 24 h, and the results are shown in Figures 3 and 4, respectively. While none of the conjugates were found to be toxic toward HEp2 cells, both **2** and **3** showed low dark toxicity (IC_{50} = 92 and 56 μM, respectively) and moderate phototoxicity (IC_{50} = 8.4 and 5.8 μM, respectively, at 1 J/cm^2) toward SK-N-DZ cells.

The porphyrin-retinamides **2**−**5** showed similar fluorescence patterns in HEp2 and SK-N-DZ cells when investigated by fluorescence microscopy. Figures 5−8 show the fluorescence observed within HEp2 cells for retinoid conjugates **2**−**5**, respectively, and their overlay with the organelle specific fluorescent probes BODIPY Ceramide (Golgi network), $DiOC_6$ (ER), LysoSensor Green (lysosomes), and Mitotracker Green (mitochondria). The preferential sites of subcellular localization for conjugates **2** and **3** were found to be cellular vesicles that correlated well with the lysosomes, while conjugates **4** and **5** localized preferentially in both the lysosomes and the ER. Similar results (not shown) were observed in SK-N-DZ cells.

DISCUSSION

The new porphyrin−retinoic acid conjugates were designed to contain either a all-trans retinoic acid moiety, due to its documented biological activity, or a 13-cis retinoic acid moiety, a naturally occurring metabolite also with reported biological activity (*19*−*25*). Ester and amide derivatives of retinoic acid have been previously prepared in low to moderate yields by the reaction of alcohols or amines with activated retinoic acids, for instance, as acid chlorides, retinoyl fluorides, or retinoyl imidazolides, and DCC as the coupling reagent (*29, 30, 42*−*44*). In our new synthesis of porphyrin−retinamides **2**−**5** (Scheme 1), the retinoic acids were activated as the hydroxybenzotriazole esters and subsequently coupled to monoaminoporphyrin **1** or to a pegylated porphyrin using TBTU as the coupling agent, in reproducibly high yields (49−78%). We have previously used this synthetic strategy for the conjugation of peptides and other molecules to porphyrin macrocycles (*31, 35, 36*). Conjugates **2** and **3**, with the retinoic acid moiety directly linked to the porphyrin para-phenyl position, are highly hydrophobic and not soluble in water. The all-trans-retinamide conjugate **2** has a planar conformation, while the 13-cis-retinamide conjugate **3** adopts a bent conformation (Figure 1), which might in part explain its preferential accumulation in SK-N-DZ cells in comparison with **3**. Furthermore, in comparison to all-trans-retinoic acid, 13-cis-retinoic acid exhibits lower binding affinity for nuclear retinoid receptors (*45, 46*). On the other hand, conjugates **4** and **5** containing a low-molecular-weight PEG linkage between the porphyrin and the retinoic acid moiety are amphiphilic, and thus soluble in polar and nonpolar organic solvents, as well as partially soluble in water. The PEG spacer was introduced not only to increase the water solubility and to decrease both inter- and intramolecular interactions, but also to favor an extended vs bent conformation of the conjugates, which is believed to be crucial for efficient binding to nuclear receptors. A low-molecular-weight PEG was chosen over a high-molecular-weight PEG in order to avoid the formation of mixtures due to the polydispersity of the high-molecular-weight PEGs (*47*−*49*).

The fluorescence quantum yields observed for porphyrin−retinamides **2**−**5** (Table 1) were significantly higher than that for the nonconjugated aminoporphyrin **1** and depended on the

presence of the PEG linker. Our results are in agreement with previous studies showing that the fluorescence of porphyrin macrocycles increases upon conjugation to carotenoids and other aromatic retinoid moieties (*29*). Porphyrin−retinamides **2** and **3** bearing the retinoid moiety directly linked to the porphyrin phenyl group showed the highest quantum yields of this series. In agreement with previous reports, the introduction of a PEG linker between the porphyrin and the retinoid moiety, as in conjugates **4** and **5**, decreases the fluorescence quantum yields (*50*).

The biological efficacy of the new porphyrin−retinamides was evaluated in a model cancer cell line, human carcinoma HEp2 cells, and in neuroblastoma SK-N-DZ cells, which are known to respond to retinoic acid (*38*−*41*). The cellular uptake of the porphyrin−retinamides was dependent on both the nature of the retinoid moiety (all-trans or 13-cis) and the presence of a PEG linker between the porphyrin and the retinoic acid. Among all conjugates, porphyrin−retinamide **5** bearing a PEG linker to a 13-cis-retinoid moiety accumulated the most within both cell lines, which indicates that the 13-cis-retinoid residue might be a better ligand for promoting conjugate translocation across the plasma membrane. Indeed, the PEG-containing conjugates **4** and **5** exhibited up to five times higher uptake than the non-PEG-containing retinamides **2** and **3** in both cell lines, probably because the PEG confers amphiphilic character to the otherwise highly hydrophobic conjugates, and it also favors an extended over a bent conformation of the conjugates, which might be required for receptor binding and efficient translocation across cellular membranes. While the PEG-containing conjugates **4** and **5** showed similar uptake in both cell lines, the hydrophobic conjugates **2** and **3** accumulated preferentially in SK-N-DZ rather than in HEp2 cells, probably due to the slightly higher expression of retinoic acid receptors in the SK-N-DZ cells. Furthermore, of the hydrophobic porphyrin−retinamides, the all-trans-retinoic acid conjugate **2**

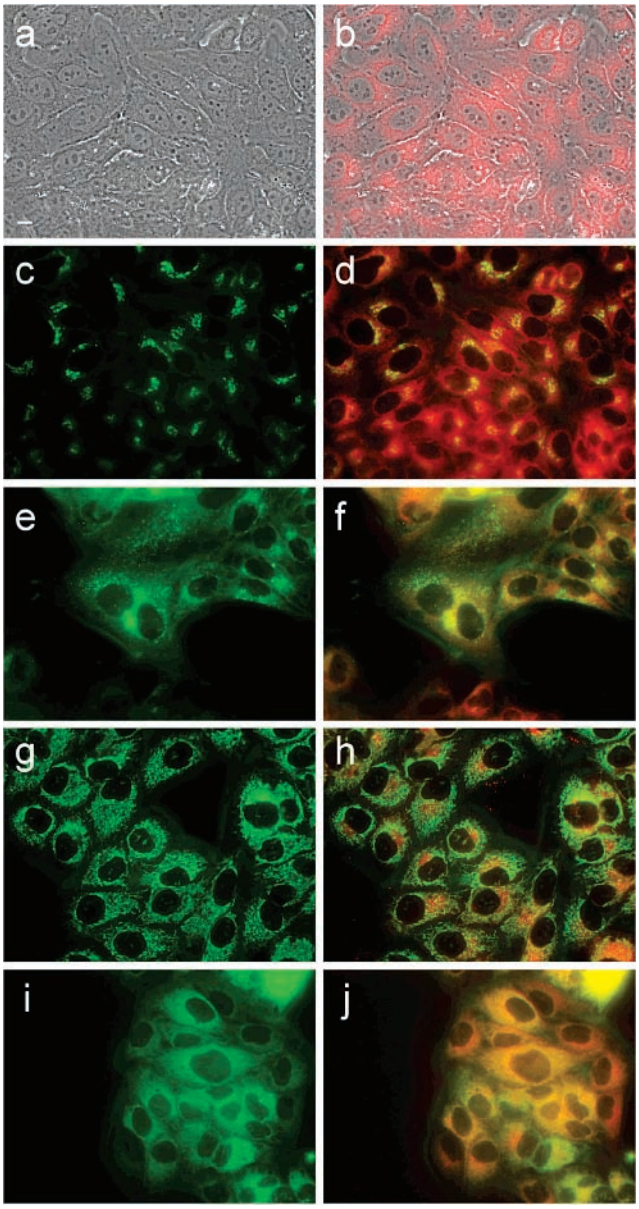

Figure 8. Subcellular localization of porphyrin−retinamide **5** in HEp2 cells at 10 μM for 24 h. (a) Phase contrast, (b) overlay of **5** fluorescence and phase contrast, (c) BODIPY ceramide fluorescence, (e) LysoSensor green fluorescence, (g) MitoTracker green fluorescence, (i) $DiOC_6$ fluorescence, (d,f,h,j) overlays of organelle tracers with **5** fluorescence. accumulated to a slightly higher extent within SK-N-DZ cells than the 13-cis-retinoid analog **3**, probably because of its more favored planar conformation for receptor binding. Previously reported SAR studies in ligand−nuclear receptor binding suggest distinct levels of tolerance among receptors for alterations in ligand structure (*51*, *52*). Structural analysis of LBD−ligand complexes suggest a common ligand-binding mode for the nuclear-receptor family, the preferred ligands being small and hydrophobic, and falling within a narrow range of molecular volumes (250−350 Å^3) (*53*). For example, the all-trans-retinoic acid fits snugly into the hydrophobic pocket of the RAR ligand-binding domain, not leaving enough room for alternative geometries of the ligand. It has also been reported that 13-cis-retinoic acid exhibits lower binding affinity for cellular retinoic acid binding proteins (CRABPs) and retinoid receptors than all-trans-retinoic acid (*45*, *46*).

All porphyrin−retinamides **2**−**5** showed low phototoxicity (IC_{50} > 50 μM) toward HEp2 cells, and only the hydrophobic conjugates **2** and **3** showed moderate phototoxicity toward SK-N-DZ cells (IC_{50} = 8.4 and 5.8 μM, respectively, at 1 J/cm^2). Indeed, the 13-cis-retinoic acid-containing conjugate **3** was the most phototoxic of all conjugates studied. In agreement with our results, it was previously reported that 13-cis-retinoid acid is toxic to neuroblastoma SK-N-DZ cells in the concentration range 0.001−10 μM for 6 to 14 days (*38*). The higher phototoxicity observed for porphyrin−retinamides **2** and **3** which accumulated to a significantly smaller extent within cells than conjugates **4** and **5**, and in addition localized mainly within the cell lysosomes, while **4** and **5** were also found in the more sensitive ER, suggests that these porphyrin−retinamides induce cell death via different mechanisms. Previous studies have shown that retinoids are capable of mediating apoptosis, although the biological mechanisms leading to retinoid-induced cell death are poorly understood (*14*, *15*). It is possible that, upon light exposure, the lysosomal content is released into the cytoplasm where the hydrophobic porphyrin−retinamides **2** and **3** preferentially bind the CRABPs proteins in comparison with the more hydrophilic conjugates **4** and **5**. The CRABPs function as transport proteins to the nucleus and are also reported to facilitate the metabolic degradation of retinoic acids (*54*). Although we observed no nuclear localization of the porphyrin−retinamides, probably because of the large volume of these molecules (800−1200 Å^3) due to the porphyrin macrocycle, our studies show that there is a synergistic effect in the hydrophobic porphyrin−retinamides that leads to their increased phototoxicity in SK-N-DZ cells expressing retinoid receptors.

Angelo, via Cintia, 4, I-80126 Napoli, Italy. Received February 23, 2007; Revised Manuscript Received April 19, 2007

Oligodeoxyribonucleotides of sequence d($^{5'}$TGGGAG$^{3'}$) carrying bulky aromatic groups at the 5′ end were found to exhibit potent anti-HIV activity [Hotoda, H., et al. (1998) *J. Med. Chem. 41,* 3655−3663 and references therein]. Structure−activity relationship investigations indicated that G-quadruplex formation, as well as the presence of large aromatic substituents at the 5′-end, were both essential for their antiviral activity. In this work, we synthesized some representative examples of the anti-HIV active Hotoda's 6-mers and analyzed the resulting G-quadruplexes by CD, DSC, and molecular modeling studies, in comparison with the unmodified oligonucleotide. In the case of the sequence carrying the 3,4-dibenzyloxybenzyl (DBB) group, identified as the best candidate for further drug optimization, we developed an alternative protocol to synthesize the 5′-DBB-thymidine phosphoramidite building block in higher yields. The thermodynamic and kinetic parameters for the association/dissociation processes of the 5′-conjugated quadruplexes, determined with respect to the unmodified one, were discussed in light of the molecular modeling studies. The aromatic groups at the 5′ position of d($^{5'}$TGGGAG$^{3'}$) dramatically enhance both the equilibrium and the rate of formation of the quadruplex complexes. The overall stability of the investigated quadruplexes was found to correlate with the reported IC_{50} values, thus furnishing quantitative evidence for the hypothesis that the G-quadruplex structures are the ultimate active species, effectively responsible for the biological activity.

INTRODUCTION

In the past decade, many synthetic oligonucleotides (ODNs) have been found to be potent antiviral agents, and a number of modified ODNs have been selected as promising drug candidates against HIV (*1*−*3*). The mechanisms of action of synthetic ODNs as antivirals are based on the inhibition and/or interference with the viral cycle at different levels, including HIV binding to target cells. Recently, Hotoda and co-workers demonstrated that various G-rich oligonucleotides, bearing aromatic moieties as the 4,4′-dimethoxytriphenylmethyl (DMT) group at their 5′-end, are non-antisense anti-HIV active compounds (*4*−*7*). Particularly, they identified the lead sequence $^{5'}$d(TGGGAG)$^{3'}$, active against HIV-1 only when conjugated at the 5′ position with large aromatic groups. The 6-mer bearing the 3,4-dibenzyloxybenzyl (3,4-DBB) group at the 5′-end and the 2-hydroxyethylphosphate group at the 3′-end (R-95288) showed the most potent activity and the least cytotoxicity among the synthesized analogues. This specific anti-HIV activity was correlated with the ability of G-rich sequences to form stable quadruplex structures (*8, 9*), postulated to be the ultimate active species, directly interacting with the *in vivo* targets. Evidence for quadruplex formation in 5′-substituted d($^{5'}$TGGGAG$^{3'}$) sequences was obtained by CD spectra, showing a large positive band at 263 nm, diagnostic of parallel, tetramolecular G-quadruplex structures (*4*). The hypothesized mechanism of action of these 5′-conjugated G-rich ODNs is based on the interference/inhibition of both cell-to-cell transmission and virus-to-cell transmission of HIV-1 by interaction with both the V3 loop and the CD4 binding site on viral gp120, in analogy with the behavior proposed for the phosphorothioate oligonucleotides d($^{5'}$TTGGGGTT$^{3'}$) (*10*) and d($^{5'}$GGGTTTTGGG$^{3'}$) (*11*), forming, respectively, tetramolecular and bimolecular G-quadruplex complexes.

Other examples of G-rich oligonucleotides folding into highly stable quadruplexes, found to be potent inhibitors of HIV replication in cell culture, are also known from the literature (*12, 13*). In particular, a recent study (*14*) has identified the 16-mer guanine-rich sequence d(GGGGTGGGAGGAGGGT), designated *93del*, which inhibits both the processing and strand transfer functions of HIV-1 integrase at nanomolar concentrations; and the NMR-based solution structure of this aptamer, adopting an unusually stable dimeric quadruplex architecture, has been described in detail (*15*).

Interestingly, Hotoda's unmodified d($^{5'}$TGGGAG$^{3'}$) showed no antiviral effects; no specific antiviral activity was also found when a relatively small aromatic residue, as the benzyl group, was inserted at the 5′ position of the same sequence. The antiviral activity of 5′-modified ODNs was therefore attributed to the presence of large aromatic groups at the 5′-end of the native ODN backbone, which could produce hydrophobic effects stabilizing quadruplex structures. CD spectra of the investigated ODNs were in agreement with the hypothesized relationship between G-quadruplex formation and antiviral activity, but no successive data appeared in the literature to analyze these G-quadruplex forming systems in a quantitative manner or to shed light on their conformational differences.

The final conclusion of the authors is that *both* the G-quadruplex forming ODN backbone *and* the cluster of 5′-end substituents contribute to the interaction of the 6-mers with viral gp120. These results can also be correlated to a previous study on the 20-mer phosphorothioate d($^{5'}$TGGGGCTTACCTTG-CGAACA$^{3'}$) carrying covalently attached cholesteryl tails (*16*).

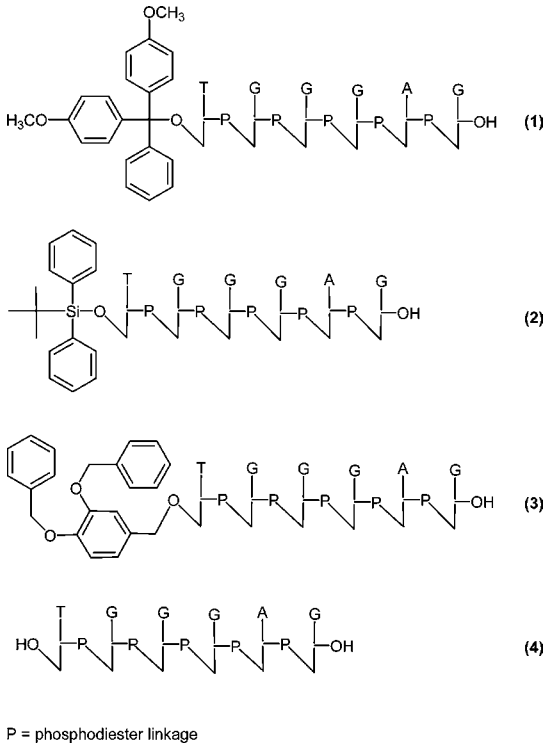

Figure 1. Oligonucleotides used.

In this work, the 3′-conjugated oligomer was showed to form a stable quadruplex aggregate; conversely, the corresponding 5′-conjugate was essentially present as a single strand, which was explained as a consequence of negative steric effects impeding efficient G-quartet formation.

Aiming at the design of novel, more efficient oligonucleotide-based antivirals, we focused our attention on Hotoda's 5′-conjugated d($^{5'}$TGGGAG$^{3'}$) sequences, chosen as model compounds, to determine the main physicochemical parameters of the corresponding quadruplex structures, presumably present also in physiological conditions. In this paper, we intend to explore possible direct relationships between the specific effects induced by the terminal groups and the thermodynamic and kinetic aspects of quadruplex formation. To this purpose, we have selected a set of 5′-substituted Hotoda's ODNs, among the ones showing the highest antiviral activity (*4*), *i.e.*, 5′-DMT, 5′-*tert*-butyldiphenylsilyl (TBDPS), and 5′-DBB-ether modified 6-mers (**1**, **2**, and **3**, Figure 1 and Table 1), and compared them to the natural sequence (**4**, Figure 1). In the case of ODN **3**, an alternative and more efficient procedure has been developed (*17*) for the synthesis of 5′-DBB-thymidine-phosphoramidite building block **13** (Scheme 2), used in the last coupling step of the automated ODN chain assembly.

In all the studied cases, a detailed CD investigation for the analysis of the conformational behavior, as well as a DSC analysis, have been carried out for the complete description of the thermodynamic and kinetic parameters governing the tetraplex formation processes in solution. The obtained experimental data have been examined in light of the molecular models, generated to directly investigate the main conformational differences of the quadruplex structures formed by 5′-conjugated ODNs **1**−**3** (here described, respectively, as Q-DMT, Q-TBDPS, and Q-DBB), in comparison to the quadruplex obtained by unmodified ODN **4** (Q-TGGGAG).

EXPERIMENTAL PROCEDURES

Synthesis and Characterization of Oligonucleotides 1−**4.** Phosphoramidite building blocks **6** and **13** were synthesized following the reactions described respectively in Schemes 1 and 2. In the case of 5′-*O*-*tert*-butyldiphenylsilylthymidine-3′-*O*-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite **6**, known procedures were essentially followed (*18*). An alternative, more efficient procedure was developed for the synthesis of 5′-DBB oligomer **3**, based on the usage of novel building block **13** (*17*). A full description of the synthetic procedures adopted for the preparation of 5′-modified thymidine phosphoramidites **6** and **13**, of the NMR and ESI-MS characterization for all the nucleoside intermediates and final compounds, and of the general experimental procedures are reported in the Supporting Information.

Oligonucleotides **1**−**4** were synthesized using standard solid-phase β-cyanoethyl phosphoramidite chemistry on a 15 μmol scale. In the case of oligomers **1** and **4**, starting from 100 mg of functionalized CPG[1]-dG support with 0.10 mequiv/g initial loading, the sequence $^{5'}$d(TG$_3$AG)$^{3'}$ was assembled by exploiting standard commercially available 3′-phosphoramidite 2′-deoxynucleoside monomers, respectively adopting the DMT-on, for oligomer **1**, and the DMT-off protocol, for oligomer **4**. Analogously, the solid-phase assembly of oligomers **2** and **3** was carried out starting from 100 mg of functionalized CPG-dG support with 0.10 mequiv/g initial loading, using, respectively, 5′-TBDPS- and 5′-DBB-thymidine phosphoramidite (**6**, Scheme 1; and **13**, Scheme 2) in the last coupling step of the chain assembly. Oligomers **1**, **2**, and **4** were detached from the solid support and deprotected by standard treatment with conc aq ammonia at 55 °C for 12 h. In the case of oligomer **3**, detachment from the solid support and full oligonucleotide deprotection, including complete thymidine unmasking, was successfully achieved by an overnight treatment at 50 °C with a 0.1 M NaOH solution.

The combined filtrates and washings were concentrated under reduced pressure, redissolved in H_2O, and analyzed and purified by HPLC on a Nucleosil RP18 column (Supelco, 100−5, C18, 4.6 × 250 mm, 7 μm), using a linear gradient from 20% to 100% of CH_3CN in 0.1 M TEAB in 20 min, flow rate 0.8 mL/min, and detection at λ = 260 nm. The isolated oligomers had the following retention times: **1** = 17.5 min; **2** = 14.0 min; **3** = 11.5 min. After HPLC purification, the oligonucleotide samples were desalted on a Sephadex G25 column eluted with H_2O/EtOH (4:1, v/v). The isolated oligomers proved to be more than 98% pure by ^{1}H NMR and RP-HPLC analysis and were characterized by ESI-MS and/or MALDI-TOF mass spectrometry.

Purification of the crude natural oligomer **4** was carried out on an analytical anion exchange Nucleogel SAX column (Macherey−Nagel, 1000−8/46, 4.6 × 50 mm, 5 μm), adopting the following eluents: buffer A, 20 mM KH_2PO_4/K_2HPO_4 aq solution (pH 7.0), containing 20% (v/v) CH_3CN; buffer B, 1 M KCl, 20 mM KH_2PO_4/K_2HPO_4 aq solution (pH 7.0), containing 20% (v/v) CH_3CN. Using a linear gradient from 0% to 100% B in 40 min, flow rate 0.8 mL/min, and detection at λ = 260 nm, two main peaks were observed, with retention times 15.5 min and 26.7 min. As also reported by Hotoda (*4*), in all the purification attempts on an anionic exchange HPLC column, the fastest eluting peak, attributed to the single-strand 6-mer, was always accompanied by a major peak, having a higher retention time. This additional peak was attributed to a G-quadruplex structure generated under HPLC elution conditions. In fact, by reinjecting on HPLC the isolated and desalted fastest

Quadruplex Preparation. The quadruplex complexes were formed by dissolving the lyophilized compound in the appropriate buffer and annealed by heating at 95 °C for 5 min and slowly

cooling to room temperature. The buffer used was 10 mM potassium phosphate, 200 mM KCl, 0.1 mM EDTA at pH = 7.0. The concentrations of the dissolved oligonucleotides **1**−**3** were determined by UV measurements at 260 nm and at 95 °C, using, as the molar extinction coefficients, the values calculated by the nearest-neighbor model (*19*) for the sequence $^{5'}$GGGAG$^{3'}$, to which the ϵ coefficient determined for the corresponding 5′-conjugated thymidylic acid residue (9100, 8900, and 9000 cm^{-1} M^{-1}, respectively, for 5′-DMT, 5′-TBDPS, and 5′-DBB-thymidine-3′-monophosphate derivatives; for the synthesis of these nucleotides, see Supporting Information) was added.

Thermal Dissociation and Reassociation. Thermal dissociation and reassociation of the different quadruplexes were monitored by recording the CD spectra as a function of the temperature. The molar ellipticity was calculated from the equation $[\vartheta] = 100\vartheta/cl$, where ϑ is the ellipticity value, c is the concentration of the single strand (2.0×10^{-4} M), and l is the path length of the cell in centimeters. The temperature was increased or decreased at a rate of 1.0 °C/min. The melting and annealing profiles were not superimposable, indicating that the dissociation/reassociation reactions were not in thermodynamic equilibrium. Since the heating curves are not equilibrium curves, the melting temperatures obtained from these experiments were indicated as $T_{1/2}$ to distinguish them from the thermodynamic melting temperatures (indicated as T_m).

Dissociation Kinetics. The quadruplex dissociation kinetics were measured by rapidly increasing the temperature and following the change with time of the CD signal at 263 nm. All the experiments were performed at 2.0×10^{-4} M single-strand concentration and in 60−80 °C temperature range, conditions under which the reassociation reaction can be neglected. The kinetic constants were obtained by fitting the recorded time-dependent decrease in CD signal with a single-exponential function.

Isothermal Kinetic Analysis for Association. The association of single strands into a well-defined quadruplex structure was monitored for each sequence in the buffer 10 mM potassium phosphate, 200 mM KCl, 0.1 mM EDTA at pH = 7.0. The experiments were carried out at various strand concentrations (between 5×10^{-6} and 2×10^{-4} M single-strand concentration), depending on the kinetics. The samples were incubated at 90 °C for 5 min to allow for dissociation. The structural transition from the single strands to the tetramolecular quadruplex was monitored in the temperature range 10−30 °C by recording the CD spectra as a function of time. Assuming that the dissociation is negligible, the single-strand concentration at any time is given by

$$[S]_t^{1-n} - [S]_0^{1-n} = 4(n-1)k_{on}t \qquad (1)$$

where $[S]_t$ is the single-strand concentration at time t, $[S]_0$ is the initial single-strand concentration, n is the order of the reaction with respect to the single-strand concentration, and k_{on} is the rate constant for the single-strand disappearance. As previously described (*20*), the changes in CD spectra at a given time t can be related with the single-strand concentration according to the equation

$$\Theta_t = \Theta_\infty - [(\Theta_\infty - \Theta_0)^{1-n} + (n-1)k't]^{1/1-n} \qquad (2)$$

where Θ_∞ and Θ_0 correspond to the ellipticity of the final and initial state, respectively. Θ_t is the ellipticity at time t, and $k' = 4(\Theta_\infty - \Theta_0/[S]_0)^{1-n}k_{on}$.

The association rate constants and the reaction orders were obtained by fitting the ellipticity at 263 nm as a function of time by means of eq 2 using *Origin 7.5* software.

DSC Experiments. Differential scanning calorimetry measurements were carried out on a third-generation Setaram Micro-DSC. The excess heat capacity function $\langle \Delta C_P \rangle$ was obtained after baseline subtraction, assuming that the baseline is given by the linear temperature dependence of the native-state heat capacity (*21*). No baseline difference was observed before and after the transition, indicating a negligible heat capacity difference between the initial and final states. The transition enthalpies, ΔH°_{cal}, were obtained by integrating the area under the heat capacity vs temperature curves. The enthalpy change values are the averages of at least three different heating experiments. The reported errors are the standard deviations of the mean from the multiple determinations.

Molecular Modeling. The conformational features of the quadruplexes generated by modified ODNs **1**−**3** have been explored by means of molecular modeling studies. All the calculations were performed on a personal computer running the *HyperChem 7.5* suite of programs. To build the $[d(TG_3AG)]_4$ quadruplex, the T and dG nucleotide residues were generated by using the coordinates of the corresponding residues in a previously reported quadruplex structure (*22*), whereas the A-tetrad was generated by using the coordinates of the dA residues in the reported structure of the $[d(TTAG_3T)]_4$ (*23*).

The DMT, DBB, and TBDPS groups were generated using the *HyperChem 7.5* building tool. Partial charges for all the atoms in the DMT, DBB, and TBDPS moieties were assigned using the Gasteiger-Marsili algorithm (*24*) implemented in the QSAR module of the HyperChem suite. The Q-DMT, Q-DBB, and Q-TBDPS quadruplexes were then built by linking the appropriate groups to the 5′-ends of the unmodified quadruplex. The resulting coordinates of the modified quadruplexes were energy-minimized in vacuum for 500 steps of the steepest-descent method, keeping the DNA residues in fixed position, allowing only the DMT, DBB, and TBDPS atoms to relax. Potassium ions were positioned in the central channel between the G-tetrads to allow for coordination, for each potassium ion, with the eight carbonyl oxygen atoms of the two adjacent G-quartets completing the octahedral coordination sphere. The remaining potassium counterions were added to give electrical neutrality, and then the neutralized systems were solvated in a preequilibrated box of TIP3P water (*25*). The water molecules within a 2.6 Å radius from any solute atoms were removed. The Amber force field was used (*26*). A simulated annealing was performed on the modified T residues before the energy structure minimization. During the simulated annealing, the DNA coordinates were kept fixed, and only the modified T residues and the solvent (water molecules and ions) were allowed to move. The initial conformation was first heated to 500 K over 10 ps, simulated at 500 K for 70 ps, and finally cooled to 10 K for 20 ps. Then, the whole system was minimized using 1000 cycles of the steepest-descent method followed by the conjugate gradient method until convergence to an rms gradient of 0.1 kcal mol^{-1} $Å^{-1}$.

The contributions of the DBB, TBDPS, and DMT groups to the total solvent-accessible surface area (SASA) were calculated using the grid method (*27*) implemented in the QSAR module of the HyperChem suite. The SASA was obtained for each aromatic group both in the quadruplex ($SASA^{quadruplex}$) and in the dissociated single strand ($SASA^{single\ strand}$). The $SASA^{quadruplex}$ values were calculated using the minimized quadruplex structures, whereas the $SASA^{single\ strand}$ values were obtained under the assumption that the aromatic groups in the single strands are completely exposed to the solvent. The difference $\Delta(SASA) = SASA^{quadruplex} - (4 \times SASA^{single\ strand})$ represents the relative reduction of the solvent-accessible surface area of the 5′-aromatic substituents that occurs upon quadruplex formation.

RESULTS

For a detailed investigation of the structural and biophysical properties of 5′-modified d(5′TGGGAG3′) sequences, the preparation of the model oligonucleotides in the 3−5 mg scale was a prerequisite. The 5′-modified oligomer **1** could be easily achieved by standard ODN chain assembly procedures, simply involving a DMT-on synthetic routine to preserve the 4,4′-dimethoxytriphenylmethyl group at the 5′-end of the oligonucleotide. On the other hand, for the preparation of ODNs **2** and **3** special protocols were required. In their papers, Hotoda and co-workers synthesized the 5′-modified oligonucleotides by means of standard phosphoramidite chemistry (*28*) using tailored 5′-substituted thymidine derivatives as the 5′-terminal residues. 5′-*O*-TBDPS-thymidine derivative **6** was synthesized in two steps, starting from thymidine, with 46% overall yields. 5′-*O*-(3,4-dibenzyloxy)benzylthymidine-3′-*O*-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidite was obtained in three steps and 20% overall yields starting from 3′-*O*-*tert*-butyldimethylsilylthymidine (3′-*O*-TBDMS-thymidine), which in turn can be typically prepared from thymidine in three straightforward, high-yielding reactions (*18*).

In our hands, the preparation of phosphoramidite **6** was successfully achieved with 88% overall yields. Conversely, we always failed in the synthesis of 6-mer **3** following Hotoda's procedure, particularly at the crucial stage of the insertion of the 3,4-DBB group at the 5′-OH of the thymidine monomer. In Hotoda's protocol, the 5′-DBB-ether was synthesized by reacting, in the presence of NaH, DBB bromide (*29*) with 3′-*O*-TBDMS-thymidine in THF. The 5′-alkylated compound, recovered by the authors in very modest yields (23%), after TBDMS removal, was then phosphitylated in 87% yields to give the corresponding 3′-phosphoramidite derivative, used as the last addition monomer in the oligonucleotide chain growth. Following the same alkylation procedure, with the sole difference of using the commercially available DBB chloride in lieu of the bromide, we could exclusively isolate from the reaction mixtures the undesired N3-alkylation product, even when varying several experimental conditions. When further forcing the reaction, two compounds, identified after column chromatography as the N3, O-bis-alkylated derivatives, were observed. In fact, as also reported by Kobe et al. (*30*), starting from 3′-*O*-TBDMS-thymidine the concomitant formation, in almost 1:1 ratio, of both the N3, O-5′- and the N3, O-3′-bis-alkylated derivative occurred, as a result of the hydride-mediated migration of the TBDMS group from the 3′- to the 5′-position. These results led us to develop an alternative protection strategy for the thymidine moieties to more efficiently obtain the 5′-alkylated nucleoside, based on (i) protection of the 3′-OH function with a group completely stable under basic conditions and reluctant to migrate to the 5′-OH and (ii) protection of the thymine base.

Having discarded the silyl ethers as the 3′-OH protecting groups, we moved to the DMT group, completely stable even to harsh basic media, and searched for a suitable heterocycle protection. A novel, two-stage protecting group, namely, the 2-(phenylthio)ethyl group, proved to be useful to our purposes, preventing otherwise predominant N-alkylation of thymine (*17*). The phenylthioethyl residue proved to be completely stable onto the heterocycle as such, but after oxidation of the tioether to sulfone, the resulting group could be easily removed *via* a β-elimination reaction. Treatment with a 0.1 M NaOH solution at 50 °C allowed complete thymine deblocking after 12 h, *i.e.*, under conditions usually adopted also for oligonucleotide deprotection and detachment from the solid support.

We therefore synthesized 5′-*O*-TBDMS-3′-*O*-DMT-thymidine **7** as the starting material and reacted it with 2-(phenylthio)-ethanol under standard Mitsunobu conditions (Scheme 2). Following this protocol, the N3-alkylated nucleoside **8** was obtained in 85% yields for the three steps. Subsequent standard triethylammonium fluoride treatment yielded the 5′-OH derivative **9** in almost quantitative yields, which was next reacted with DBBCl and NaH with cat. NaI, to give the desired 5′-DBB adduct **10** in 70% yields. After oxidation with mCPBA of the thioether function to sulfone **11**, addition of 3% TFA in CH_2Cl_2 led to **12**, which was finally phosphitylated to give desired **13**. Starting from 5′-*O*-TBDMS-3′-*O*-DMT-thymidine, 3′-phosphoramidite building block **13** was obtained in six straightforward steps and 48% overall yields (46% overall yields starting from thymidine).

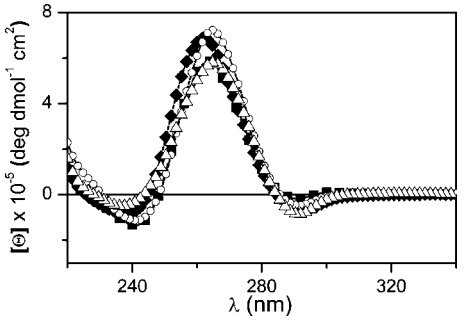

Figure 2. CD spectra of the Q-TGGGAG (squares), Q-DBB (open triangles), Q-TBDPS (open circles), and Q-DMT (diamonds). The spectra were recorded at 10 °C in a 10 mM potassium phosphate buffer (pH 7.0) supplemented with 200 mM KCl.

The assembly of oligomers **1**−**4** was then achieved on an automated DNA synthesizer by exploiting classical phosphoramidite chemistry, using a standard DMT-on protocol for 5′-conjugated **1**−**3**. In the case of the synthesis of **2** and **3**, the last coupling was carried out, respectively, using the building block 5′-TBDPS-thymidine phosphoramidite **6** or 5′-DBB-thymidine phosphoramidite **13**. Once the assembly of the desired sequence was completed, detachment from the solid support and full deprotection of the 5′-conjugated oligomer, including thymine protecting group removal for oligomer **3**, were achieved by an overnight treatment with 0.1 M NaOH.

Purification of the detached oligomers was carried out by HPLC on an analytical anionic exchange column in the case of **4** and on an analytical RP18 column for **1**−**3** (see Experimental Procedures). The isolated products, desalted on a Sephadex G25 column, were checked for purity by HPLC and characterized by mass analysis (Table 1).

The dissociation and reassociation of the tetramolecular quadruplexes were followed by circular dichroism. The CD spectra at 10 °C for all the studied sequences showed a positive band at 263 nm and a negative band at 243 nm (Figure 2), diagnostic of parallel-stranded tetramolecular quadruplex structures (*4*, *31*). In Figure 3, the melting and annealing CD profiles are shown for all the samples at the heating and cooling rate of 1.0 °C/min. All the quadruplexes show hysteresis between the melting and annealing profiles, which indicates that the association/dissociation reaction is not at thermodynamic equilibrium during the heating and cooling experiments (*32*, *33*). The melting temperatures obtained at 1.0 °C/min scan rate are very similar for the modified quadruplexes. Particularly, the $T_{1/2}$ values are 89 °C for the Q-TBDPS, 86 °C for the Q-DMT, and 83 °C for the Q-DBB, whereas the $T_{1/2}$ for the unmodified quadruplex is 60 °C. Q-DBB and Q-TBDPS show less pronounced hysteresis between melting and annealing curves than Q-DMT. In addition, almost no reassociation of the unmodified strands (Figure 3) was observed during the cooling curve. These findings suggest that Q-TBDPS and Q-DBB complexes are formed faster than Q-DMT and that all the modified strands associate faster than the unmodified strands. In the case of Q-DMT, the melting and annealing profiles were

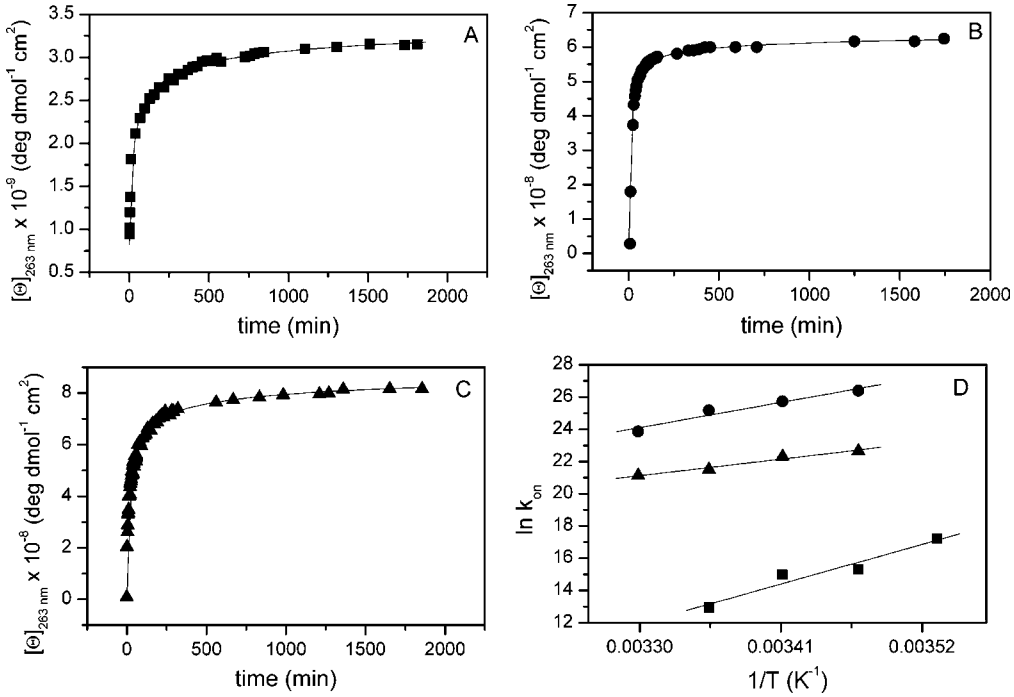

Figure 4. Kinetics of the quadruplex formation. Association profiles for **4** (A), **2** (B), and **3** (C) at 15 °C. Single-strand concentrations used: 2×10^{-5} M for **2**, 4.4×10^{-5} M for **3**, and 4.4×10^{-4} M for **4**. Quadruplex formation leads to an increase of molar ellipticity at 263 nm. Mathematical fits are shown in solid line. (D) Arrhenius plots for the association of **4** (squares), **2** (circles), and **3** (triangles). All the experiments were performed in a 10 mM potassium phosphate buffer (pH 7.0) supplemented with 200 mM KCl.

always found to be not fully reproducible (data not shown). This behavior was not completely unexpected, since the prolonged exposition to high temperatures is well-known to cause partial 5′-deprotection of 5′-DMT-oligonucleotides. To confirm this hypothesis, the Q-DMT samples were analyzed for integrity by RP HPLC after each heating experiment, resulting in a mixture of **1** and **4**. For this reason, the Q-DMT system could not be investigated in detail, and our efforts were then concentrated on more chemically stable ODNs **2**−**4**.

The kinetics of Q-DBB, Q-TBDPS, and Q-TGGGAG quadruplex association was directly measured. The rate of the association reaction was studied by monitoring the ellipticity at 263 nm as a function of time after heating the sample at 95 °C for 5 min and cooling rapidly. Representative molar ellipticity vs time profiles at 15 °C are shown in Figure 4. Similar profiles were obtained at the other investigated temperatures (see Figures S1−S3 in the Supporting Information).

The experimental curves were fitted by means of eq 2. All the data for the studied sequences were fitted well by reaction order of 4.0. The kinetic constants (k_{on}) for the studied sequences are compared in Table 2. The rate of quadruplex association follows the order Q-TBDPS > Q-DBB > Q-TGGGAG. The association rate constants at 25 °C were 8.6×10^{10} M^{-3} s^{-1} and 2.2×10^{9} M^{-3} s^{-1} for Q-TBDPS and Q-DBB, respectively. The corresponding value found for the unmodified sequence at the same temperature is 4.1×10^{5} M^{-3} s^{-1}.

The kinetic experiments were performed over the temperature range 10−30 °C. For all the sequences, the association rate

decreases upon increasing the temperature, and this effect is more pronounced for the unmodified sequence. From the slope of the Arrhenius plots (Figure 4D), the activation energies (E_{on}) could be derived (Table 2). We found negative activation energies for all the sequences, as already reported in the literature for other quadruplexes and attributed to the existence of a rapid preequilibrium step involving intermediate species (*20*, *32*, *34*, *35*).

The kinetics of quadruplex dissociation was also investigated by performing temperature-jump experiments. In each experiment, the temperature of the sample was rapidly increased, and the rate of quadruplex dissociation was monitored by following the change of CD signal with time. Representative kinetic profiles obtained at 65 °C are shown in Figure 5. Similar profiles were obtained at the other investigated temperatures (see Figures S4−S6 in the Supporting Information). The dissociation rate constants were obtained by fitting these kinetic profiles with a single-exponential curve. The kinetic constants were then used to construct the Arrhenius plots (Figure 5D), so allowing the determination of the corresponding activation energies. The kinetic parameters for quadruplexes dissociation are summarized in Table 3. Both Q-TBDPS and Q-DBB have k_{off} values 10−100 times smaller than the corresponding value of Q-TGGGAG at the same temperature. Analogously, the modified quadruplexes have higher activation energies in comparison with the unmodified one. The values found for Q-TBDPS and Q-DBB are about 100 kJ mol^{-1} higher than the one found for Q-TGGGAG, proving that the presence of the aromatic groups significantly stabilizes the quadruplex structure. The kinetically most stable complex is Q-TBDPS, with a half-life of 591 days at 37 °C, whereas at the same temperature, the half-life for the unmodified quadruplex is 69 min.

Differential scanning calorimetry (DSC) experiments were performed on each quadruplex, and the corresponding calorimetric profiles at scan rate of 1.0 °C/min are shown in Figure 6. The calorimetric profiles and melting temperatures were influenced by the scan rate (Figure 7), indicating nonequilibrium conditions, analogous to the results already found in the CD-monitored melting experiments. Although the ΔS°, ΔG°, and T_m values cannot be derived from these measurements as they are not at equilibrium, the enthalpy changes measured can be correctly attributed to the quadruplex−single-strand transition, provided that the oligonucleotides are 100% structured in the quadruplex form at the starting temperature of the DSC scan. To ensure complete quadruplex formation, before DSC experiments, each sequence was annealed by heating at 95 °C for 5 min and slowly cooling to room temperature, and then incubated at low temperature for an appropriate time, depending on the known association kinetics. The enthalpy changes for all the quadruplexes are reported in Table 4. Note, however, that the value obtained here for Q-DMT is assumed to be less precise; in fact, it cannot be excluded that partial detritylation occurred when the sample was exposed to high temperatures. This event was indeed directly analyzed in the case of the samples prepared for the CD-monitored melting investigations.

The thermodynamic parameters for the dissociation of the quadruplexes were calculated from the rate constants and the activation energies (*35*, *36*). These kinetically derived thermodynamic parameters are reported in Table 4. There is a good agreement between the calorimetric $\Delta H^\circ_{cal}\Delta$ values and the kinetically derived values ($\Delta H^\circ = E_{on} - E_{off}$). It is noteworthy that all the modified quadruplexes show an equilibrium melting temperature (T_m) much higher than 37 °C, whereas the unmodified quadruplex show a lower equilibrium T_m (26 °C). The ΔS° and ΔG° values were calculated using the more accurate ΔH°_{cal} values.

The ΔH°_{cal} value for the unmodified quadruplex is 310 kJ mol^{-1}, which accounts for the formation of four G-tetrads (*31*, *37*, *38*) and suggests that both the dA and dG nucleotide at the 3′-ends of the ODN strand participate in the overall quadruplex stabilization. All the modified quadruplexes have higher enthalpic terms in comparison with the unmodified quadruplex. Particularly, the ΔH°_{cal} values of the modified quadruplexes follow the order Q-TBDPS > Q-DMT > Q-DBB. The same trend was observed for the ΔS° values of Q-TBDPS and Q-DBB, thus counterbalancing the contribution given by the ΔH°_{cal} and leading to comparable data for the T_m and free energy values for Q-TBDPS and Q-DBB.

We used molecular modeling to explore the main conformational differences induced by the presence of the DBB, DMT, and TBDPS groups at the 5′-end of the d(5′TGGGAG3′) quadruplex structures. In Figure 8, the minimized structures of the three modified quadruplexes are shown. In the top view, the central channel of the quadruplex structure is clearly visible for Q-TBDPS and Q-DMT, whereas in Q-DBB, it is hidden by the DBB groups, suggesting that only this moiety is able to span the distance between the 5′-ends of nonadjacent strands.

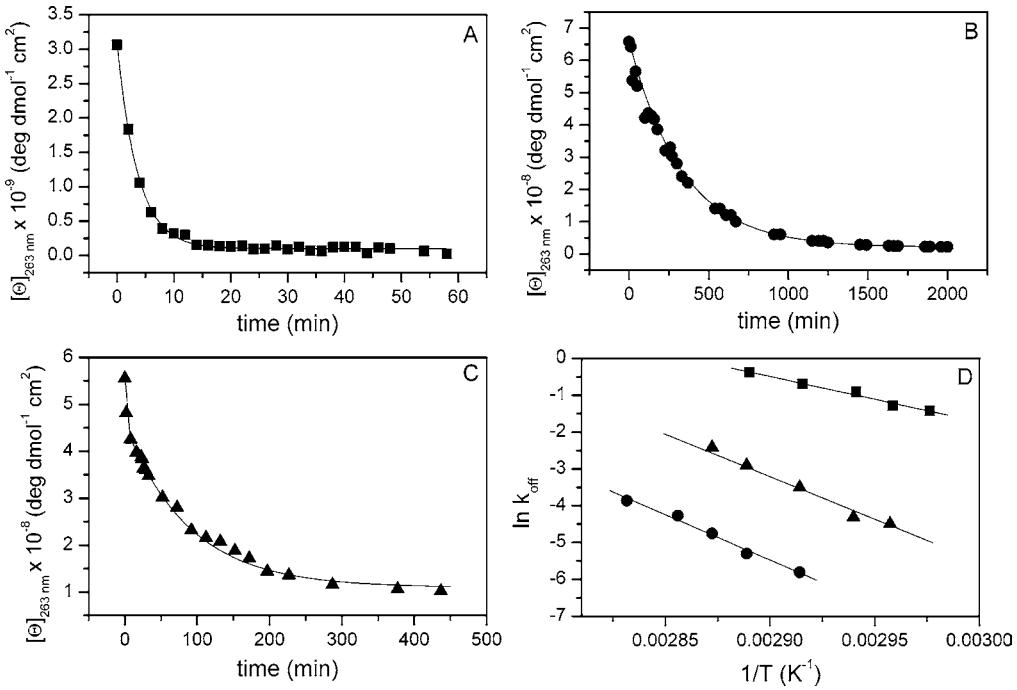

Figure 5. Kinetics of the quadruplex dissociation. Dissociation profiles for Q-TGGGAG (A) and Q-DBB (C), measured at 65 °C, and for Q-TBDPS (B) measured at 70 °C. Quadruplex dissociation leads to a decrease of the molar ellipticity at 263 nm. Mathematical fits are shown in solid line. (D) Arrhenius plots for the dissociation of the Q-TGGGAG (squares), Q-TBDPS (circles), and Q-DBB (triangles). All the experiments were performed in 10 mM potassium phosphate buffer (pH 7.0) supplemented with 200 mM KCl.

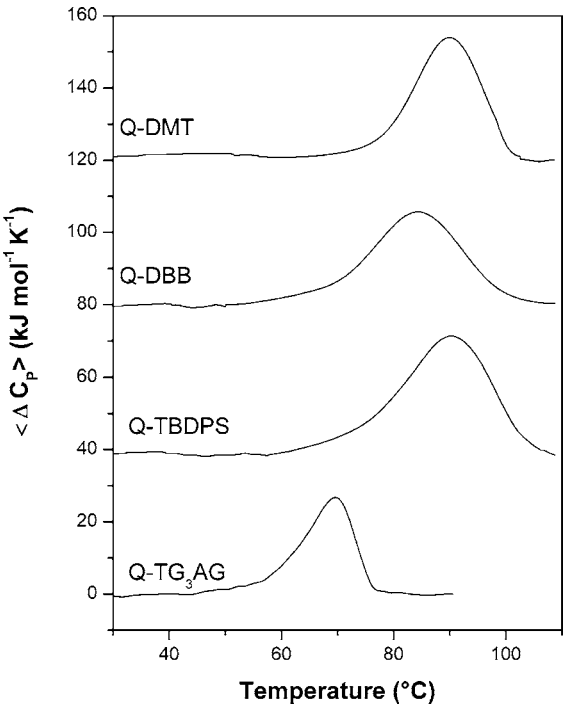

Figure 6. Calorimetric heat capacity vs temperature profiles at 1 °C/min for the studied quadruplexes. Excess capacity values have been shifted along the *y*-axis for ease of presentation. All the experiments were performed in a 10 mM potassium phosphate buffer (pH 7.0) supplemented with 200 mM KCl.

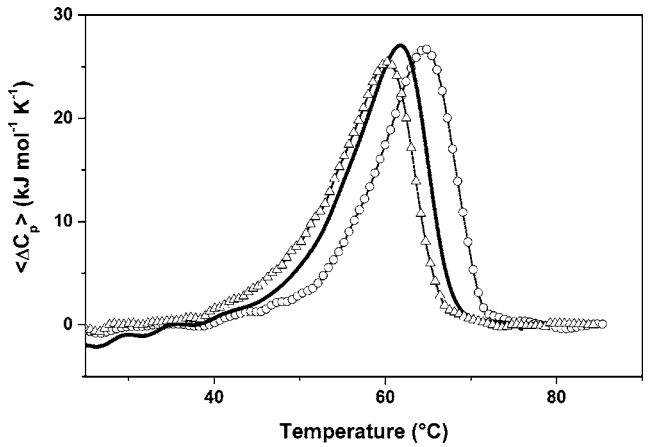

Figure 7. Calorimetric heat capacity vs temperature profiles at different scan rate 0.3 °C/min (open triangles), 0.5 °C/min (solid line), and 1 °C/min (open circles) for the Q-TGGGAG. All the experiments were performed in a 10 mM potassium phosphate buffer (pH 7.0) supplemented with 200 mM KCl.

Close inspection of the models reveals that the DBB aromatic rings form a network of noncovalent face-to-face and face-to-edge (T-shaped) aromatic interactions, so that the planar four thymines at the 5′-end of the strands are not exposed to the solvent.

Still being isomers, the DBB and the DMT groups confer different properties to the resulting quadruplex complexes. In the DBB group, the three phenyl rings are spaced by the flexible O−CH_2− linkers and can adopt different relative orientations, whereas in the DMT group, the three phenyl residues, being attached to the same carbon atom, show a significantly reduced flexibility and, to avoid steric crowding, are obliged to be approximately perpendicular to each other. In Q-DMT, the DMT group does not stack over the surface formed by the four thymine bases, with the three phenyl rings largely projected away from the helix axis, to minimize mutual steric hindrance interactions. However, in Q-DMT, a certain number of van der Waals contacts were observed between the aromatic groups of adjacent strands.

In Q-TBDPS, the TBDPS groups are not large enough to directly interact with each other over the quadruplex surface at the 5′-end and only show stacking interactions with the adjacent thymine base.

To compare the relative contributions of the modified groups to the hydrophobic interactions involved in the quadruplex

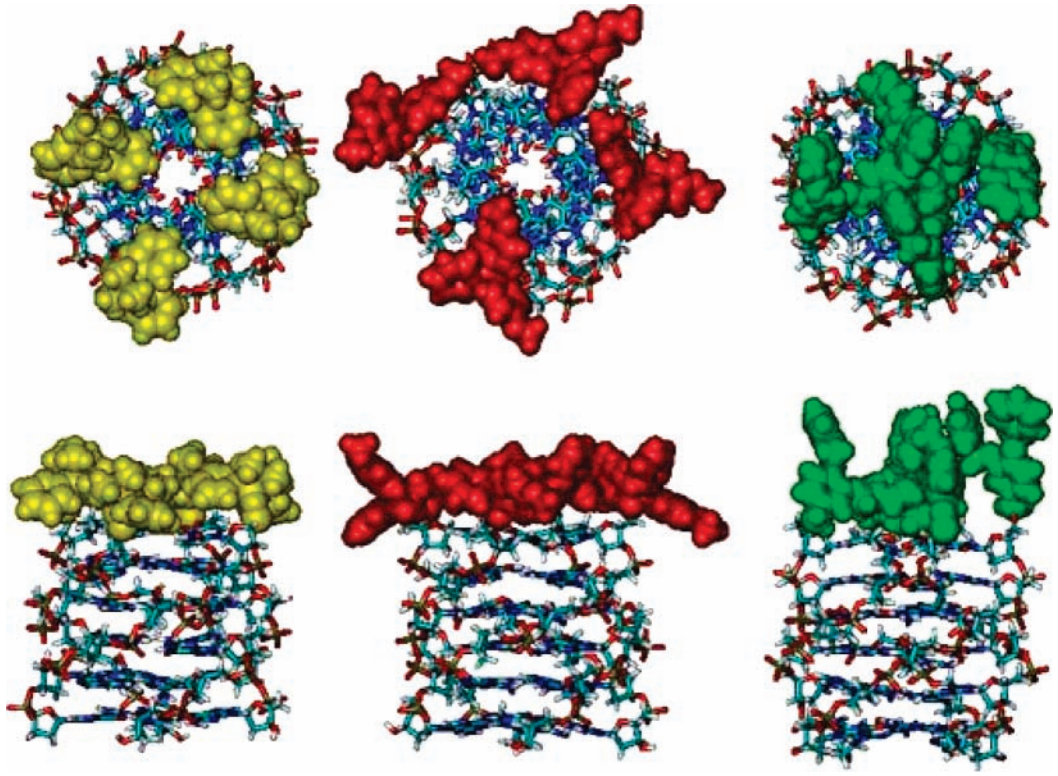

Figure 8. Top and lateral views of the molecular models of Q-TBDPS (left), Q-DMT (middle), and Q-DBB (right). The 5′-aromatic groups are shown with a space-filling representation.

Table 5. Contributions of the 5′-Aromatic Groups to the Total Solvent-Accessible Surface Area (SASA)

5′-aromatic groups	$SASA^{quadruplex}$ (Å^2)	$SASA^{single\ strand}$ (Å^2)	$\Delta(SASA)^a$ (Å^2)
DBB	1245	520	−835
TBDPS	1251	442	−517
DMT	1826	541	−338

^{a} $\Delta(SASA) = SASA^{quadruplex} - (4 \times SASA^{single\ strand})$.

formation, we calculated the relative decrease in the solvent-accessible surface area (SASA) for the DBB, TBDPS, and DMT groups in the quadruplex structure ($SASA^{quadruplex}$) with respect to the dissociated single strands ($SASA^{single\ strand}$). Inspection of the $\Delta(SASA)$ values (Table 5) reveals that the highest reduction in the solvent-accessible surface area upon quadruplex formation is observed in the case of the DBB group. This result suggests that the hydrophobic interactions play a major role in the Q-DBB quadruplex formation with respect to the other two modified quadruplexes.

DISCUSSION

In this work, we synthesized and characterized a set of 5′-substituted Hotoda's ODNs, among the ones showing the highest antiviral activity (*4*), *i.e.*, 5′-DMT, 5′-TBDPS, and 5′-DBB-ether modified 6-mers (**1**, **2**, and **3**, Figure 1 and Table 1). These ODNs were compared to the unmodified sequence, which showed no antiviral effects, in an attempt to put on a quantitative basis the hypothesized correlation between biological activity and physicochemical properties of these G-quadruplex-forming ODNs. Our results point out remarkable physicochemical differences between the Hotoda's 5′-substituted ODNs and the natural sequence. The insertion of large aromatic groups, as DMT, DBB, or TBDPS, at the 5′-end of the d($^{5'}$TGGGAG$^{3'}$) sequence has dramatic effects on the kinetics and thermodynamics of quadruplex formation. All the 5′-modified quadruplexes, showing comparable thermal stability, are far more stable than the natural quadruplex. Inspection of Table 4 reveals that the higher thermodynamic stability of Q-DBB and Q-TBDPS with respect to the natural quadruplex complex has different thermodynamic origins. Indeed, Q-DBB is entropically stabilized, whereas Q-TBDPS is mainly enthalpically stabilized in comparison with Q-TGGGAG. The low entropic term observed for the dissociation of the Q-DBB quadruplex can be due to a decrease of the solvation entropy of the DBB groups after the quadruplex dissociation. This hypothesis is supported by our molecular modeling results, revealing a significant increase of the solvent-accessible surface area (ΔSASA) of the DBB groups when they are not involved in the quadruplex structure. On the other hand, the formation of structured DBB groups in the Q-DBB quadruplex very weakly affects the overall enthalpic change involved in quadruplex formation, with this being the result of two opposite contributions: a positive contribution, due to hydrophobic factors, and a negative contribution, due to increased stacking and van der Waals interactions between the DBB groups. As a consequence, the enthalpic change for Q-DBB formation is very similar to the one measured for Q-TGGGAG.

Conversely, the higher thermodynamic stability of Q-TBDPS in comparison with the natural quadruplex is essentially due to the increased enthalpic term, suggesting that the hydrophobic effects play a minor role in this case, when compared to Q-DBB. This result is in agreement with the smaller $\Delta(SASA)$ value estimated from the molecular models (Table 5). Further, the stacking interactions between the TBDPS groups and the adjacent thymine bases, observed in the molecular models, can account for the higher enthalpic term measured in comparison with the natural quadruplex. In addition, in both Q-DBB and Q-TBDPS complexes, high activation energies were measured for the dissociation processes, consistent with the additional stacking and van der Waals interactions induced by the aromatic groups in these modified quadruplexes.

Another striking result of our study is that the introduction of the aromatic groups deeply affects the rate of quadruplex

formation. Under the same conditions, Q-TBDPS is assembled 10^5 times faster than Q-TGGGAG. The faster association kinetics of the modified single strand is probably due to hydrophobic interactions, which is consistent with the higher activation energies (hydrophobic interactions give a positive contribution to the total E_{on} value) measured for the modified strands with respect to the unmodified sequence.

Taken together, our data show that all the modified d(5′-TGGGAG3′) sequences are able to adopt stable G-quadruplex structures. On the contrary, the unmodified sequence forms a weak complex, with a T_m of 26 °C under the investigated conditions. Large aromatic groups at the 5′-end of the oligonucleotide chain dramatically stabilize the resulting G-quadruplex complexes on both a kinetic and a thermodynamic basis, with hydrophobic contributions on one side and additional stacking and van der Waals interactions on the other side playing major roles in the quadruplex formation processes. T_m values higher than 70 °C were found for Q-DBB and Q-TBDPS; similar indications were obtained also for Q-DMT from ΔH°_{cal} as obtained by DSC experiments, even if the latter case could not be further investigated in detail due to the intrinsic instability to high temperatures of the DMT ether linkage. High thermal stability, associated with a very fast association and slow dissociation, account for the 5′-modified ODNs fully structured in the form of quadruplex complexes; on the contrary, only a very small percentage of the unmodified oligomer is present in the aggregated form under physiological conditions. Since the physicochemical parameters for quadruplex stability reflect well the trend observed for the anti-HIV activity (see IC_{50} data reported in Table 1), our data can furnish indirect evidence that 5′-conjugated d(5′TGGGAG3′) oligomers interact with the HIV-1 gp120 target only if structured in the quadruplex form.

In conclusion, a systematic physicochemical characterization by DSC and CD analyses has been carried out on a representative set of 5′-modified d(5′TGGGAG3′) sequences, able to adopt stable G-quadruplex structures, to better understand the subtle features involved in the formation and stability of these complexes. The present results demonstrate that the large aromatic groups at the 5′-position of d(5′TGGGAG3′) play a decisive role in favoring the quadruplex formation processes. The unmodified sequence is indeed able to adopt a G-quadruplex structure, though it is not thermodynamically stable at physiological temperature and its formation is, in addition, very slow. Conversely, the 5′-modified quadruplexes are formed faster and, once formed, are very thermodynamically stable, with T_m values higher than 70 °C. These findings suggest a correlation between stability and rate of formation of the G-quadruplex structures on one side and anti-HIV activity of 5′-modified ODNs on the other side.

These results are useful not only to gain a critical insight into the biological behavior of Hotoda's 6-mers, but also to develop a general frame to better understand and, ultimately, roughly predict the effective potential as drugs of quadruplex-forming oligonucleotides. The very slow kinetics of quadruplex formation is one of the main drawbacks limiting efficient pharmacological applications of aptamers based on tetramolecular quadruplex structures. For this reason, it is highly desirable that, in a drug optimization process, most research efforts are concentrated on the rational search for well-tailored modifications to be inserted within the oligonucleotide backbone. Large aromatic groups may indeed be regarded as suitable appendages to enhance the biological activity of G-rich, quadruplex-forming ODNs, positively affecting both stability and rate of formation of quadruplex complexes.

This study, developed in the more general frame of the search for novel ODN analogues suitable for therapeutic applications, adds a further contribution to the research of biologically active quadruplex forming oligonucleotides, showing kinetic aspects as relevant as thermodynamic parameters in influencing the overall quadruplex formation process and therefore in affecting their biological role within the cell.

ACKNOWLEDGMENT

We acknowledge MIUR (PRIN) and Regione Campania (L5) for grants in support of this investigation. We also thank C.I.M.C.F., Università degli Studi di Napoli "Federico II", for the NMR, MS, and CD facilities.

Supporting Information Available: Synthetic procedures and characterization of phosphoramidite building blocks **6** and **13** and general experimental procedures and synthetic methods for the preparation of the 5′-DMT, 5′-TBDPS, and 5′-DBB nucleoside-3′-monophosphates for the ϵ calculation are reported. Kinetic profiles for the association process and for the dissociation process of Q-DBB, Q-TBDPS, and Q-TGGGAG at different temperatures are also available. Targeted radiopharmaceuticals offer the possibility of improved tumor imaging and radiotherapy, with reduced side effects. A variety of monoclonal antibodies and antibody fragments have previously been successfully radiolabeled and used in diagnostic imaging and targeted radiotherapy of cancer. Many such antibodies have been shown to recognize the well-characterized MUC1 tumor marker and have recently been in clinical trials. Furthermore, a number of chelators have been synthesized and are currently used as radiopharmaceuticals for imaging and therapy. We now report the synthesis of a novel, cyclen-based ligand with a sulfur-containing arm that offers increased stability of the ligand−metal complex. We have coupled this ligand with previously selected aptamers to the MUC1 tumor marker to generate a novel targeted radiopharmaceutical with improved properties. We have tested the complex against known, commercially available chelators such as MAG3 in model breast cancer systems. To improve the pharmacokinetic properties of the aptamer-based targeted radiopharmaceutical, we have generated multi-aptamer complexes around a central chelator. Such multi-aptamer complexes have increased retention of the complex in circulation, without affecting the lack of immunogenicity of the complex or altering its superior tumor penetration properties.

INTRODUCTION

MUC1 (*1*) is a large cell-surface mucin glycoprotein expressed in the extracellular matrix by most glandular and ductal epithelial cells and some hematopoietic cell lineages (*2, 3*). It is highly expressed by the majority of human adenocarcinomas and has been associated with poor clinical prognosis (*4*). MUC1 is found shed in the bloodstream of adenocarcinoma patients (*5*) and is the antigen in commercial serum tumor marker assays (CA15−3, Truquant-Br, CASA, CA549, MCA) (*6*−*11*).

The extracellular presentation of MUC1, its elongated structure, and characteristic under-glycosylation patterns allow the protein core to be exposed in neoplastic cells, thus making it a suitable target for immunotherapeutic and targeted radiotherapy approaches. These characteristics have been explored in immunotherapies, including radiolabeled antibodies (Abs) against breast (*12*−*14*) and bladder (*15*−*19*) cancers, with encouraging results that led to various clinical trials (*20, 21*). However, radiolabeled Abs are limited to modest amounts of activity (mCi), since with their long circulation time, bone marrow toxicity becomes a problem. Furthermore, a major problem is the antibodies' immunogenicity and poor tumor penetration. We have attempted to overcome such problems using aptamers as binding ligands to MUC1. Aptamers (*22*) are short (<100 bases) oligonucleotides selected from a pool of 10^{14}−10^{16} randomized sequences by binding to a target molecule. The strongest binders are amplified after the removal of the nonbinding sequences. Repetition of the selection-amplification procedure (typically 6−20 times) results in a small number of strongly binding oligonucleotides (*23*). Aptamers have been shown to present reduced immunogenecity and toxicity compared to other biological therapeutics, increased thermal stability and reproducibility compared to Abs, and the possibility of production using solid-phase synthesis (*24*−*26*). Furthermore, the radiolabeling of aptamers has been previously reported (*27*−*29*), raising the possibility of such targeting moieties being used in γ-camera imaging and targeted radiotherapy. In a recent example, aptamers selected against Tenascin-C were used in an *in vivo* preclinical targeting study, investigating the biodistribution of a radiolabeled anti-Tenascin-C aptamer in nude mice bearing either U251 glioblastoma or MDA-MB-435 breast tumor xenografts (*30*). The Tenascin-C targeting aptamer was radiolabeled with ^{99m}Tc using mercaptoacetyl glycine (MAG_2) and DTPA. Imaging studies of the complex demonstrated rapid blood clearance with a half-life of less than 10 min and rapid tumor penetration (6% injected dose per gram) at 10 min.

The chelators used in this study are shown in Chart 1. Macrocyclic chelates, such as DOTA and **MetCyc**, provide a more stable coordination environment compared to open-chain analogues by virtue of the "macrocyclic effect" (*31*). The addition of soft donor atoms, such as sulfur in MAG3 and **MetCyc**, also enhance the stability of the resulting complexes, since both technetium and rhenium prefer softer nitrogen and sulfur donors to harder oxygen in their coordination sphere. Thus, the ligand **MetCyc** combines the features of both commercially available DOTA and MAG3. The development and *in vitro* characterization of the aptamers have been described

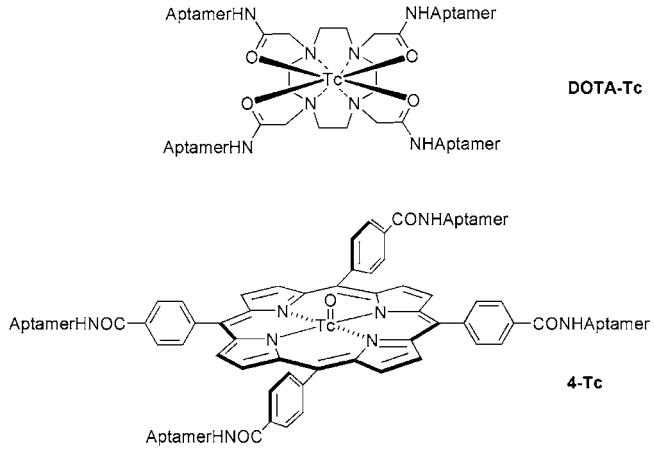
previously (*32*). We now report the synthesis of the novel, cyclen-based bifunctional chelator **MetCyc**, the complexation of technetium-99m with **MetCyc** to generate the radioactive complex **Tc-MetCyc**, and the conjugation of **Tc-MetCyc** to an amino-modified aptamer to furnish conjugate **Tc-MetCyc-Apt**. Conjugate **Tc-MetCyc-Apt** has been compared with an analogous aptamer bioconjugate **Tc-MAG3-Apt**, prepared using the commercially available ligand MAG3 for metal binding.

As aptamers are known to have rapid clearance from the system due to their increased hydrophilicity and low molecular weight (*33*, *34*), we have generated multi-aptamer complexes around a central tetravalent chelator (DOTA and **4**), by reacting 1 equiv of the chelator with 4 equiv of aptamer in the presence of the water-soluble coupling reagent EDCI. The four aptamer molecules are attached via amide bonds formed between the carboxylic acids of the chelators and the 5′-amino group of the modified oligonucleotide. Apart from the stoichiometry, the conditions were identical to those used in the synthesis of the monomeric aptamers. The tetrameric conjugates are shown in Chart 2. These conjugates have approximately four times the molecular weight of a single aptamer and were expected to display increased retention in the circulation compared to the monomeric conjugates **Tc-MetCyc-Apt** and **Tc-MAG3-Apt**. They also have the ability to carry multiple ligands and radionuclides (Chart 3, M_1 and M_2), thus increasing the radioactive load delivered to the tumor site. Finally, the multi-aptamer complex offers potentially increased affinity for the MUC1 tumor marker, as the complex can bind to more than one target molecule on the surface of the tumor cell, as well as increased stability from nuclease degradation.

EXPERIMENTAL SECTION

General Procedures. $NaReO_4$, $NaBH_4$, DOTA, and MAG3 were purchased from Sigma Aldrich, UK. Porphyrin **4** was obtained from Strem Chemicals (UK). All other chemicals were purchased from Acros Organics and were used as received. Triethylamine (TEA) was distilled from CaH_2 under argon and

Chart 2



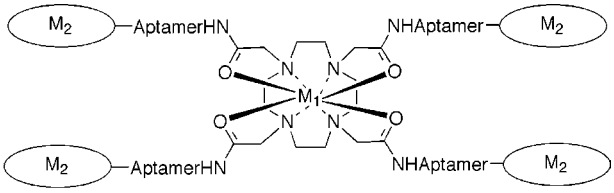


Chart 3

stored over molecular sieves. All other solvents were used as purchased from Fluka. Methionine ethyl ester was synthesized following standard literature procedures (*35*). Thin-layer chromatography was performed on Merck fluorescent silica or on Fluka fluorescent alumina plates with iodine, $KMnO_4$, or UV visualization. ^{1}H NMR (300 MHz) and ^{13}C NMR (75 MHz) spectra were recorded in $CDCl_3$ unless noted otherwise. ESI-MS (positive-ion mode) was performed on a VG Quattro 2 equipment. Samples were introduced by direct infusion of methanolic or aqueous solutions. UV−vis absorption spectra were recorded on a Uvikon XL (Bio-Tek Instruments) spectrometer.

Radioactive $NaTcO_4$ solution in saline was obtained from a Mo-99-Tc-99m generator (Shering, CIS bio international, Burgess Hill, Sussex, UK), with typical activity values being 2000−6000 MBq in 1−2 mL volume. Aptamers were selected as described previously (*32*), and modified aptamers were purchased from Sigma Gensys, UK. The radiolabeled aptamers were purified by size exclusion chromatography on NAP-10 SEC columns (Amersham Biosciences) by elution with sterile saline. Three-week-old nude female mice with MCF-7 xenografts in the left flank were supplied by the Cancer Studies Unit, Nottingham University, for imaging at the γ-camera facilities of the Department of Academic Medical Physics, University of Nottingham, Nottingham, UK. The animal experiments were conducted according to ethical committee approved protocols and regulations.

2. A mixture of DL-methionine ethyl ester (**1**, 0.18 g, 1.00 mmol) in CH_2Cl_2 (10 mL) and chloroacetic acid (0.18 g, 1.90 mmol) was treated with EDCI (0.38 g, 2.00 mmol). Stirring was continued at room temperature for 24 h. The sample was diluted with CH_2Cl_2 and water. The phases were separated, and the aqueous layer was extracted with CH_2Cl_2. The combined organic phases were washed with water, dilute acid (1 M HCl), and dilute base (1 M NaOH). The organic layer was dried ($MgSO_4$). Evaporation of the solvent afforded a colorless solid (0.24 g, 95%). ^{1}H NMR δ 1.16−1.26 (t, 3H, CH_3), 1.92−2.20 (m, 2H, CH_2), 2.02 (s, 3H, S−CH_3), 2.40−2.49 (t, 2H, CH_2), 2.78 (s, 1H, NH), 4.02 (s, 2H, $ClCH_2$), 4.60−4.67 (m, 1H, CH). ^{13}C NMR δ 14.09, 15.44, 29.81, 31.40, 42.41, 51.89, 61.87, 165.89, 171.18.

3. 1,4,7,10-Tetraazadodecane (cyclen, 4.71 g, 27.4 mmol) in 100% ethanol (25 mL) was treated with TEA (0.70 mL, 5.54 g, 54.9 mmol) for 10 min. A sample of **2** (4.64 g, 18.3 mmol) was added. The resulting solution was refluxed under an Ar atmosphere for 24 h. The sample was concentrated. The oily residue was dissolved in a mixture of CH_2Cl_2 and water. The phases were separated, and the aqueous phase was extracted with CH_2Cl_2. The organic layer was washed with water and dried ($MgSO_4$). Chromatography [basic alumina (pH 9.5), CH_2Cl_2/MeOH (0.2 → 4%)] afforded a colorless solid (0.96 g, 13.5%). ^{1}H NMR δ 1.21 (t, J = 7.2 Hz, 3H, CH_3), 1.87−2.15 (m, 2H, CH_2), 2.04 (s, 3H, SCH_3), 2.45−3.01 (m, 18H, CH_2), 3.15 (dd, J_1 = 17.4 Hz, J_2 = 12.5 Hz, 2H, CH_2), 4.11 (q, J = 7.2 Hz, 2H, CH_2), 4.57−5.65 (m, 1H, CH), 8.76 (d, J = 8.4 Hz, 1H, NH). ^{13}C NMR δ 14.07, 15.40, 30.37, 31.55, 45.84, 46.23, 47.19, 51.23, 53.43, 58.99, 61.32, 172.37.

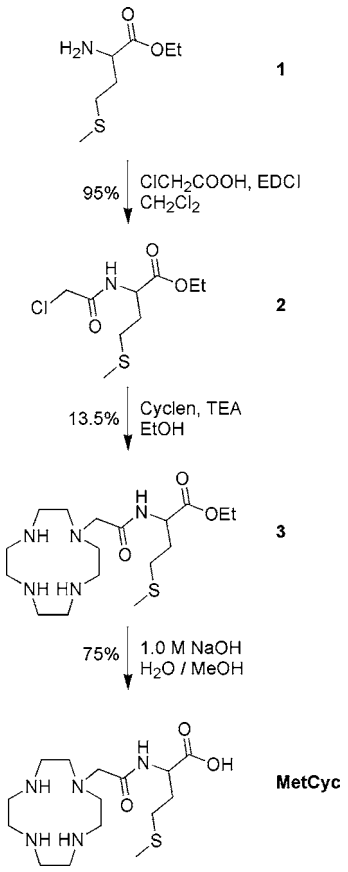
MetCyc [4-Methylsulfanyl-2-(2−1,4,7,10-tetraaza-cyclododec-1-yl-acetylamino)-butyric acid]. A stirred sample of **3** (0.80 g, 2.06 mmol) in methanol (10 mL) was treated with aqueous NaOH (2 M, 10 mL). Stirring was continued at room temperature for 12 h. The pH of the solution was adjusted to 7.0 with dilute HCl (2 M). The sample was concentrated. The residue was suspended in a mixture of CH_2Cl_2 and MeOH (9:1). Filtration and concentration of the resulting solution afforded an off-white solid (0.56 g, 75%). ^{1}H NMR (CD_3OD) δ 1.77−2.23 (m, 5H, CH_2 + SCH_3), 2.08 (s, 3H, SCH_3), 2.45−3.76 (m, 21H, CH_2 + CH). ^{13}C NMR δ 14.02, 14.83, 24.85, 30.17, 52.65, 55.73, 128.94. ESI-MS obsd 361 $(M + H)^+$, 381 $(M + NH_4)^+$, calcd (361.2).

Digestion of MUC1 Aptamers by Blood Nuclease. Approximately 10 pmol of DNA MUC1 aptamers were suspended in 40 μL of fresh human serum (Sigma, UK). The serum was incubated at simulated body temperature for a series of times (5, 10, 20, 40, 80, and 160 min, and 6 and 12 h). Plasma was obtained by centrifugation (13 000× rpm for 30 min) and analyzed on a 2.5% agarose gel for 25 bp inserts.

Digestion of MUC1 Aptamers by Urine Nuclease. Approximately 10 pmol of MUC1 aptamers were suspended in 40 μL of fresh urine sample. The urine was incubated at simulated body temperature for a series of times (5, 10, 20, 40, 80, and 160 min, and 6 and 12 h). Constituents were separated by centrifugation (13 000× rpm for 30 min). Urine was analyzed on a 2.5% agarose gel for 25 bp inserts.

Tc-MetCyc and Re-MetCyc. Metastable sodium pertechnetate in saline (0.2 mL) or sodium perrhenate (25 mg, 0.10 mmol in 2 mL methanol) was treated with small portions of sodium borohydride (4 mg, 0.1 mmol). Stirring was continued for 10 min. A sample of **MetCyc** (36 mg, 0.1 mmol) in HPLC-grade methanol (2 mL) was added, and the reaction mixture was heated to reflux. The reaction was allowed to continue for 12 h. The mixture was allowed to cool back to room temperature, and the sample was filtered through a plug of cotton wool into ice-cold diethyl ether (5 mL). A white precipitate formed. The sample was centrifuged, and the solvents were decanted from the resulting pellet. The solid was dissolved in water, filtered, and freeze-dried to give an off-white solid [14% (**Tc-MetCyc**), 25% (**Re-MetCyc**)]: ESI-MS: 361 (**MetCyc** + H)$^+$.

Tc-MetCyc-Apt. Sodium pertechnetate in saline (1 mL, varying activity) was incubated with sodium borohydryde (4 mg, 0.11 mmol) at room temperature for 10 min. A sample of **MetCyc** (36 mg, 0.1 mmol) was added, and the solution was heated to approximately 60 °C for 30 min. The solution was allowed to cool back to room temperature and was used without further purification for the labeling of the amino-modified aptamers. Aptamer (25-mer, 5′-amino-3′-inverse thymine-modified, 11 mg) and EDCI (19 mg, 0.1 mmol) were added to the solution of the technetium complex, and the reaction was allowed to proceed for 45 min at room temperature. The reaction volume was adjusted to 3 mL with sterile distilled water, and the sample was applied onto a PD-10 SEC column. Elution with sterile deionized water yielded the labeled aptamer in the second, third, and fourth fractions, as indicated by UV−vis absorption spectroscopy (260 nm). The activity of the samples was measured, confirming the presence of the technetium in the bioconjugates. The complexed but unconjugated technetium eluted in fractions 5 to 8. Fraction 4, containing the highest concentration of labeled conjugate **Tc-MetCyc-Apt**, was used for the animal studies without further purification.



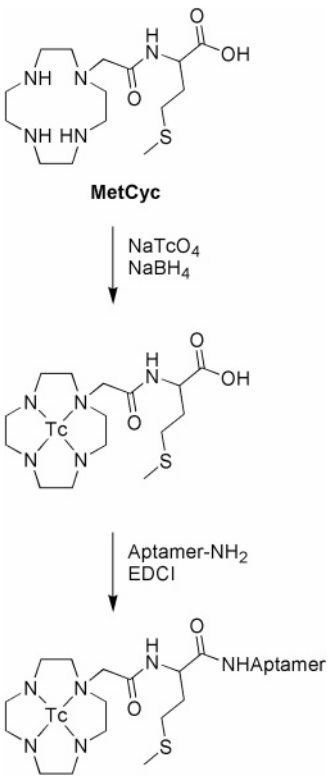
DOTA-Tc and 4-Tc. A mixture of aptamer (25-mer, 5′-amino-3′-inverse thymine-modified, 40 mg)/EDCI/chelator (DOTA or porphyrin **4**) in a 4:4:1 ratio in sodium bicarbonate buffer (1 M $NaHCO_3$, pH 8.3) was prepared, and the reaction was allowed to proceed overnight at room temperature. The crude product was analyzed on an acrylamide nondenaturing gel (15%). The band of interest (∼40 kDa) was excised and purified either by RP-HPLC using a C18 column or by precipitation with ethanol. The products were redissolved in a solution of reduced technetium (approximately 1 mL, prepared as before) and were allowed to react for 45 min at 60 °C. The labeled conjugates were purified by SEC on NAP-10 columns by elution with PBS. Fractions were analyzed as described for the monomeric conjugates **Tc-MetCyc-Apt** and **Tc-MAG3-Apt.**

RESULTS AND DISCUSSION

Aptamer Development and Modification. The development of the aptamers against MUC1 antigen has been previously reported (*32*). Briefly, libraries containing a variable region of 25 bases, flanked by primers on either side were designed and used for the selection of aptamers against synthetic MUC1 peptides of the variable tandem repeat sequence of this well-characterized tumor marker. MUC1 peptides were immobilized on an activated sepharose matrix in an affinity chromatography column. The aptamer library was added to the column and was allowed to interact with the peptides for 1 h at 37 °C. Unbound aptamers were washed away, and bound species were eluted using 3 M NaSCN or 1.5 M NaCl. Eluted aptamers were desalted, lyophilized, and PCR amplified using unidirectional PCR, to be returned to the chromatography column for subsequent rounds of selection and amplification. After 10 rounds of selection, aptamers were cloned and sequenced, resulting in a pool of selected aptamers with high affinity for the target peptides. Selected aptamers were synthesized bearing modifications in both the 5′ and 3′ ends of the aptamer. The NH_2 modification was selected at the 5′ end to facilitate coupling of the aptamer to the metal chelator, whereas an inverted thymine base has been selected for the 3′ end to confer additional nuclease resistance to the aptamer. Modified aptamers were characterized for nuclease degradation by both blood and urine nucleases and were found to be stable, with no indication of degradation for 12 h, as deemed by gel electrophoresis.

Ligand Synthesis and Aptamer Labeling. *Monomeric Conjugates.* A bifunctional chelator **MetCyc** was prepared in three steps from cyclen and methionine ethyl ester chloroacetamide as shown in Scheme 1. DL-Methionine was esterified in a standard procedure (*35*) with ethanol in the presence of 1.1 equiv of $TsOH\cdot H_2O$. The resulting **1** was acetylated with chloroacetic acid in CH_2Cl_2 in the presence of EDCI to furnish **2** in excellent yield as a colorless solid. An excess of cyclen in a refluxing mixture of absolute ethanol and TEA was treated with **2** under an inert atmosphere. The monoalkylated derivative **3** was isolated by conventional aqueous−organic workup, followed by column chromatography on basic alumina (pH 9.5). Hydrolysis of the ethyl ester with 1 M sodium hydroxide in

Scheme 1



methanol/water (1:1), followed by recrystallization from methanol, afforded the bifunctional chelator **MetCyc**. The synthesis can be scaled up to provide up to 500 mg of **MetCyc** without significant decrease in yield. The methionine arm provides both the point of attachment of the targeting aptamer via the carboxylic acid group and an additional stabilizing sulfur donor which can coordinate to the central metal. In this respect, it is analogous to the lariat crown ethers (*36*) where the addition of a simple pendant arm or tail provided enhanced stability for the complex.

Ligand **MetCyc** was complexed with both rhenium and technetium. Both metals have isotopes relevant in radioimaging and/or -therapy (^{99m}Tc and ^{186}Re/^{188}Re) (*37*). To prepare **Re-MetCyc**, sodium perrhenate was reduced in a methanolic suspension with sodium borohydride, followed by treatment with a slight excess of **MetCyc** (*38*). The product was isolated by precipitation from cold diethyl ether, followed by freeze-drying from water. The non-radioactive technetium chelate **Tc-MetCyc** was prepared in a similar manner, with a slight modification (Scheme 2). Sodium pertechnetate was available as a solution in saline by allowing radioactive samples obtained from a Mo−Tc generator to decay over 1 week. Therefore, the reduction of pertechnetate with sodium borohydride was carried out in an aqueous medium. Complexation was carried out by the addition of a methanolic solution of **MetCyc** to the reduced sample. Yields were low to moderate (14% and 25% for **Tc-MetCyc** and **Re-MetCyc**, respectively). Upon ESI-MS analysis of the products, the protonated molecule ion peak corresponding to **MetCyc** (*m*/*z* 361) was observed. This is presumably due to the instability of the complexes under the analysis conditions, as TLC did not indicate the presence of free **MetCyc**.

The radioactive **Tc-MetCyc-Apt** conjugate was prepared by the reduction of an aqueous solution of sodium pertechnetate by sodium borohydride and heating the solution to 60 °C for 45 min (*39*). After cooling the sample back to room temperature,

Scheme 2

the complex was conjugated to the aptamer without isolation. After 1 h, the radiolabeled aptamer was isolated by size exclusion column chromatography on NAP-10 columns by elution with sterile deionized water. Characterization of the product (**Tc-MetCyc-Apt**) was possible by absorption spectroscopy (260 nm) and by measuring the activities of the isolated fraction with a scintillation counter. In an analogous reaction, technetium was complexed with the commercially available **MAG3** ligand, and this complex was attached to the aptamer. This enabled the comparison of the novel ligand to an already established label. Fractions 1−4 contained the labeled aptamer, while the uncomplexed salt eluted in fractions 5−8, as determined by absorption spectroscopy. The labeling efficiency, based on the number of aptamer molecules, was >90%. Using the conjugates, triplicate experiments with approximately 5 MBq activity in 0.1−0.2 mL volume were carried out *in vivo*.

Tetrameric Conjugates. It has been previously observed (*33*, *34*) that aptamers, due to their small size and high hydrophilicity, are rapidly cleared from the system through renal clearance and excreted in the urine, and appropriate modifications can improve their pharmacokinetic properties. To slow down renal clearance of the conjugates, two tetrameric conjugates were synthesized by the attachment of four aptamers to a central chelator. DOTA and the porphyrin ligand **4** were chosen for their commercial availability, known chelating properties and relative small size, as well as the presence of four arms bearing carboxyl groups available for coupling to the amino-modified aptamer. Syntheses of the tetrameric radiolabeled conjugates **DOTA-Tc** and **4-Tc** were carried out by allowing the stoichiometric mixtures of the aptamers, chelators (DOTA or **4**), and EDCI to react overnight, and separating the desired product from the excess starting material and the lower-substituted conjugates, followed by labeling with reduced technetium. The reversal of the complexation−conjugation sequence was necessary to minimize the decay of the technetium. As aptamers are known to retain their 3D structure even after prolonged heating, this was not expected to result in loss of binding affinity.

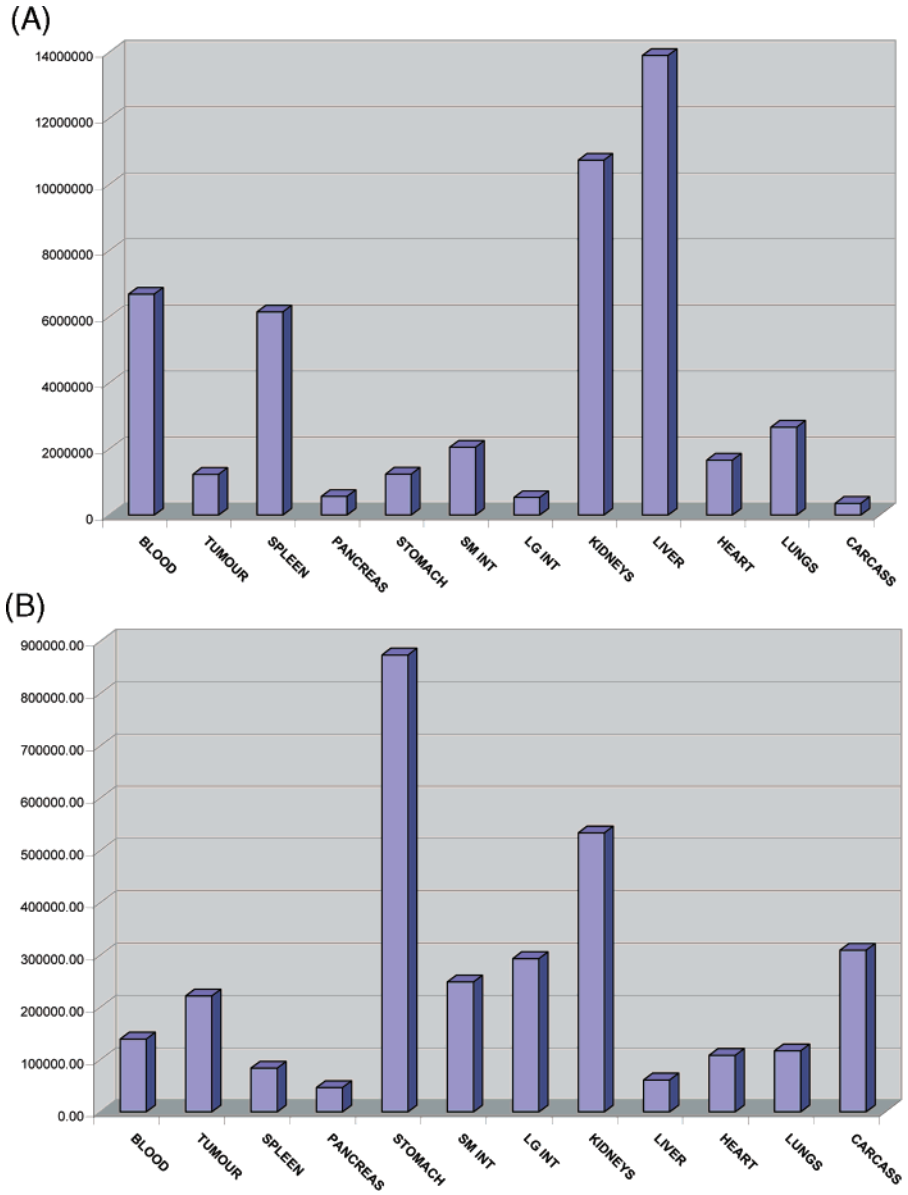


Figure 1. A. The biodistribution data using the monoaptamer labeled with ^{99m}Tc-**MAG3**. B. The biodistribution data using the monoaptamer labeled with the cyclen-ligand, ^{99m}Tc-**MetCyc**.

***In Vivo* Evaluation of the Radioactive Aptamer Complexes.** Radiolabeled aptamers were injected intravenously into nude mice bearing xenografted MCF7 breast cancer cell line tumors. Biodistribution data are shown in Figures 1 and 2. All biodistribution data are presented in counts/gram.

Both **MetCyc** and **MAG3** were labeled with more than 90% efficiency to generate conjugates **Tc-MetCyc-Apt** and **Tc-MAG3-Apt**, respectively, which were subsequently used in the biodistribution studies. The conjugate **Tc-MAG3-Apt** displayed high liver and kidney uptake. However, the kidney uptake was shown to be mainly excreted in the urine, rather than retained in the kidneys. Significant amounts of the conjugate were also observed in the liver. Although nearly 90% of the conjugate was rapidly eliminated through the kidneys in the first few minutes, the remaining conjugate was present in circulation for a long time, with high levels found after 6 h, at which point the animals were sacrificed and the activity was measured (Figure 1a).

Conjugate **Tc-MetCyc-Apt** gave very different biodistribution data from the **Tc-MAG3-Apt** complex. The overall labeling efficiency was somewhat lower than with the **Tc-MAG3-Apt**, presumably due to less efficient complexation of the technetium. This was also indicated by the high activity measured in the stomach, which is associated with the presence of free pertechnetate (*40*), rather than aptamer uptake. However, there was very little liver uptake, and the kidney uptake was smaller than with either of the other ligands (see below). This resulted in a perceptibly higher presence of the aptamer in the tumor at the 6 h study. The biodistribution data for **Tc-MetCyc-Apt** are shown in Figure 1b.

Both the DOTA and the porphyrin-based ligand **4** formed labile technetium complexes, resulting in the release of free technetium, as shown by TLC, and by the uncomplexed technetium found in the stomach and large intestine during the biodistribution studies. Furthermore, both conjugates, but in particular the porphyrin-based one **Tc-4**, gave high liver uptake, although it was hoped that the presence of the porphyrin would assist the conjugate in localizing preferentially in the tumor (*41*). The conjugate **Tc-DOTA** had smaller liver uptake than **Tc-4**, with higher excretion through the kidneys and into the urine. As before, up to 95% of the kidney radiation was actually shown to be in the urine and excreted from the system, which would

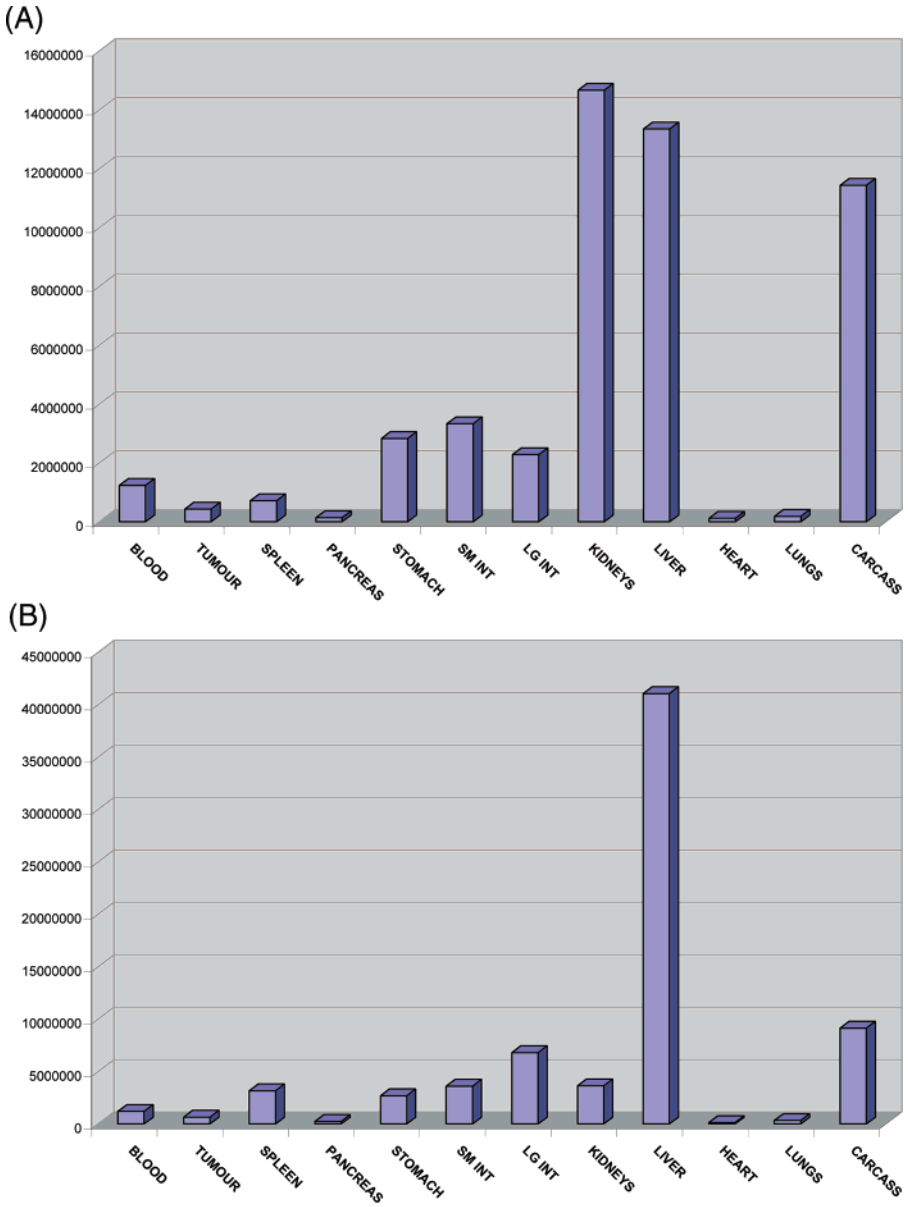

Figure 2. A. The biodistribution data using the tetra-aptamer labeled with ^{99m}Tc-DOTA. B. The biodistribution data using the tetra-aptamer labeled with the ^{99m}Tc-**4**.

indicate that no renal radioprotection would be necessary when the labeled aptamers are used as radiopharmaceuticals. Biodistribution data for **Tc-DOTA** and **Tc-4** are shown in Figure 2a,b, respectively.

Our studies, similarly to previous aptamer-related pharmacokinetic studies, indicate that aptamers alone are cleared rapidly through the kidneys and excreted through the urine, with the ability to localize in the tumor. The high radioactivity counts in the liver and stomach when the labeled aptamers were studied were most likely due to the label that increased the lipophilicity of the molecule, thus altering its pharmacokinetic properties and enabling liver uptake, or due to the presence of labeled unconjugated MAG3 that coeluted with the aptamer conjugate in the PD10 column. The stomach count is usually identified as free technetium in the system. The amount of aptamer in the kidneys was identified as excreted in the urine, again in accordance with other aptamer-related studies.

Electronic Direct β-Autoradiography. Electronic direct β-autoradiography or digital autoradiography combines high sensitivity with good spatial resolution ($<100\ \mu$m). The detector is based on proximity registration of β particles by radioisotope-free low-noise microchannel plates (MCPs) developed for photon counting of the X-ray emissions from active galactic nuclei (*42*). Recently, this technology has been applied in several applications for biological and medicinal research (*43*). The detectors can be used to monitor the uptake of radioactive-labeled material with emitted β radiation in tumors and other tissues (*44*) and has been used in this study to demonstrate the degree of tumor penetration. The tumors from mice numbers 1 and 2 were used to investigate the tumor penetration of the tetrameric carboxyporphyrin aptamer complexes. The tumor section was cut across the largest diameter, and 10 μm thin slices were cut using a cryosectioning manual machine, and two slices were wet-mounted onto a microscope slide. Exposure was measured over a period of 3 h in the electronic β autoradiography apparatus. After 3 h of exposure, and with more than half the life of the radionuclide having decayed (past 6 h), bright images of tumor perfusion and penetration across the tumor were observed (Figure 3). The images demonstrated the potential of these molecules in penetrating solid tumors, in a manner far superior to that observed with antibodies, thus indicating the

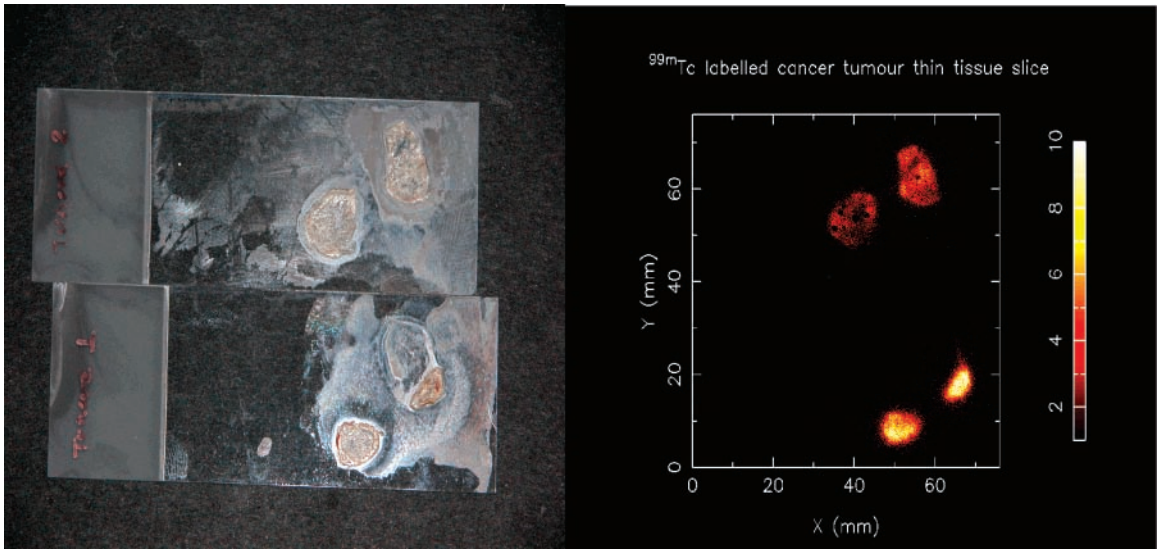

Figure 3. Microscope slides of wet-mounted MCF-7 tumor slices from nude mice numbers 1 and 2 used in biodistribution study (left). The same tumor slices presented on the left were imaged by electronic direct beta autoradiography courtesy of Dr. J. Lees, University of Leicester, UK, for radioactive load of ^{99m}Tc-labeled carboxyporphyrin aptamer.

great potential of aptamers in tumor radiotherapy (*44*). Furthermore, this study allowed us to observe that, once the aptamer molecules bind to the MUC1 on the surface of the tumor molecules, degradation by nucleases no longer occurs, allowing local irradiation to proceed for a longer time. We can thus demonstrate the ability of the aptamer to bind to the MUC1 tumor marker and its ability to penetrate the tumor mass for improved tumor imaging and molecular targeted radiotherapy.

CONCLUSIONS

A series of aptamers targeting MUC1 have been developed using the SELEX procedure. Chemical modifications, aimed at increasing the *in vivo* stability of the aptamers, have been introduced, including an inverted base at the 3′ end of the aptamer, as well as a 5′-amino group, to enable facile bioconjugation of radioactive and fluorescent labels. A novel, cyclen-based ligand for the complexation of Tc and Re has been designed. The synthesis of **MetCyc** can be accomplished using commercially available starting materials in three straightforward steps. The ligand **MetCyc** forms stable Tc and Re chelates owing to its cyclic tetraaza binding site, with its additional sulfur-containing arm. Furthermore, it contains a reactive carboxylic acid moiety, enabling bioconjugation to amino group-containing molecules, such as antibodies, peptides, or in this case the amino-modified aptamers.

Both monomeric and tetrameric aptamer conjugates (based on monovalent and tetravalent bifunctional chelators, respectively) were synthesized and tested *in vitro* and *in vivo*. The tetrameric aptamers displayed improved tumor-retention and pharmacokinetic properties compared to the monomers, due to their larger size, although the ligands were not ideal for metal binding, and additional ligands would need to be explored. The development of other multimeric aptamer bioconjugates with increased *in vivo* complex stability are currently underway in our laboratories, as well as the investigation of alternative ways to increase the molecular weight and further improve the pharmacokinetic properties of the radiolabeled aptamer as diagnostic imaging agents and targeted radiopharmaceuticals.

ACKNOWLEDGMENT

The authors would like to thank Dr. J. E. Lees of the Biomedical Imaging Unit at the Space Research Centre, University of Leicester, UK, for assistance with the autoradiographic studies. This work was supported by The Open University. KEB would like to thank Universities UK for an ORS Award.

Supporting Information Available: ^{1}H and ^{13}C NMR spectra for compounds **2**−**3**, and **MetCyc**. This material is available free of charge via the Internet at http://pubs.acs.org.

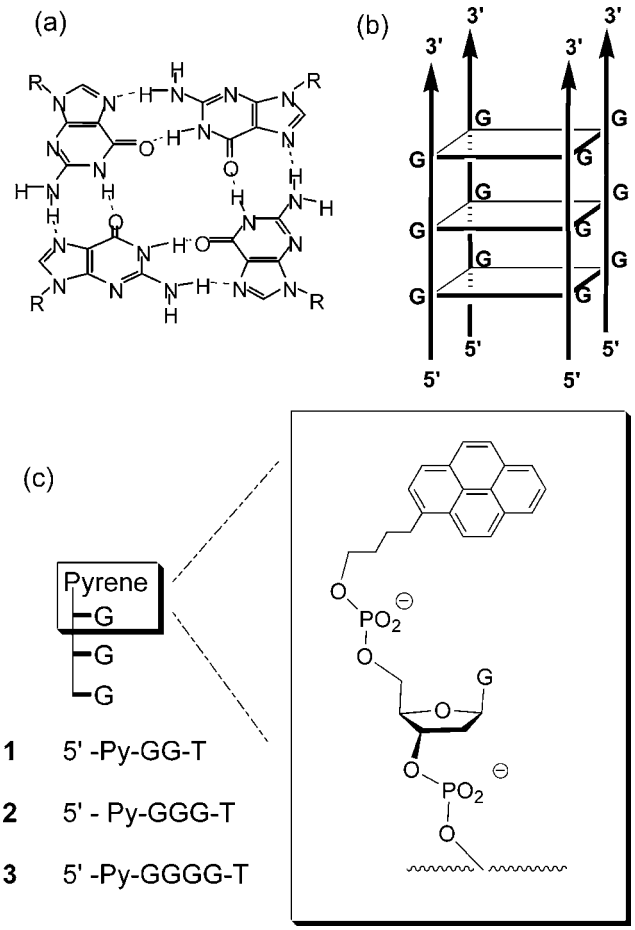
Pyrene Excimer Fluorescence as a Probe for Parallel G-Quadruplex Formation

Huihe Zhu and Frederick D. Lewis*

Department of Chemistry, Northwestern University, Evanston, Illinois 60208. Received September 8, 2006; Revised Manuscript Received February 16, 2007



The formation and properties of G-quadruplex structures from short single-strand oligonucleotide conjugates possessing two to four guanines and a 5′-terminal pyrenebutanol are reported. The 4-G conjugate forms a stable G-quadruplex under low or high potassium ion concentrations, whereas the 3-G conjugate forms a stable G-quadruplex only in the presence of high potassium. The 2-G conjugate fails to form a stable G-quadruplex even at low temperature and high potassium concentration. Both pyrene monomer and excimer fluorescence are observed for the G-quadruplex structures, whereas only monomer fluorescence is observed for the single-strand conjugates. Thus, pyrene excimer fluorescence can be used as a probe for the formation of G-quadruplex structures. The excimer/monomer intensity ratios for the G-quadruplex structures are dependent upon both the temperature and potassium or lithium salt concentration. The salt effect is attributed to a change in the structure of the hydrophobic pyrene chromophores, which are assembled on the 5′-face of the G-quadruplex as a consequence of electrostriction.

INTRODUCTION

Pyrene excimer fluorescence has been widely employed as a probe for the structure of biopolymers possessing covalently attached pyrene chromophores in aqueous solution (*1*). Complementary oligodeoxynucleotides (ODNs) possessing pendant pyrene chromophores or pyrene-derived base surogates in both strands display either monomer or excimer fluorescence, depending upon the proximity of the pyrenes (*2*−*5*). ODNs possessing a single 5′- or 3′-terminal pyrene have been used to investigate the strand polarity (parallel vs antiparallel) of duplex and triplex structures (*6*, *7*). ODNs possessing bases modified with covalently attached pyrene groups have also been prepared and the fluorescence of their duplex structures studied (*2*, *8*−*12*). These studies have established that the proximity of two pyrenes is a necessary but not sufficient condition for the observation of excimer fluorescence. Ground-state conformations which disfavor the formation of a sandwich-type excimer structure for the electronically excited pyrene dimer give rise to monomer or broadened monomer fluorescence rather than excimer fluorescence (*1*). The pyrene excimer/monomer ratio in oligomeric pyrene-containing C-nucleosides increases with the length of the oligomer (*13*).

Guanine-rich ODNs can assemble to form G-quadruplex structures based on stacked arrays of G-quartets connected by Hoogsteen-type base pairing (Scheme 1a) (*14*, *15*). G-quadruplexes can be formed by the association of four ODNs possessing a single poly(dG) domain, dimerization of ODNs possessing two poly(dG) domains, or intramolecular folding of ODNs possessing four poly(dG) domains. Quadruplexes formed via intermolecular association in the presence of potassium generally have parallel structures (*16*, *17*), whereas hairpin dimers and intramolecular quadruplexes are highly polymorphic (*18*). Merkina and Fox (*19*) have recently reported the formation and kinetic stability of intermolecular G-quadruplex structures formed by the conjugate 5′-d(TGGGG)-FL (FL = fluorescein), which possess a covalently attached FL dye. Reduction in the FL fluorescence intensity of these ODNs upon quadruplex formation is attributed to self-quenching of the four dye molecules when assembled on the same face of the G-quadruplex structure (Scheme 1b); however, FL self-quenching

Scheme 1 [a]

does not result excimer fluorescence (*13*). It occurred to us that replacement of FL with pyrene might result in the formation of quadruplex structures with high excimer/monomer fluorescence ratios.

We report here the study of intermolecular G-quadruplex formation using short poly(dG) sequences possessing a 5′-pyrenebutanol fluorescent probe (Scheme 1c, **1**−**3**). Whereas the single-strand ODNs display structured monomer fluorescence, the quadruplex structures display a mixture of monomer and excimer fluorescence, both of which are assigned to parallel quadruplex structures. Thus, the appearance of excimer fluorescence can be used as a probe for parallel G-quadruplex formation. The ratio of excimer/monomer fluorescence intensity is dependent upon both the temperature and salt concentration. These observations are consistent with the presence of a mixture of pyrene geometries which either favor or disfavor excimer formation. Increased excimer fluorescence at high salt concentrations is attributed to a hydrophobic salt effect on the pyrene chromophore ground state-geometry.

EXPERIMENTAL PROCEDURES

Materials. 1-Pyrenebutanol was converted to its phosphoramidite by reaction with 2-cyanoethyl diisopropyl chlorophosphoramidite in tetrahydrofuran in the presence of diisopropylethylamine. The conjugates **1**−**3** were prepared by means of conventional phosphoramidite chemistry using a Millipore Expedite oligonucleotide synthesizer and reagents obtained from Glenn Research following the procedure of Letsinger and Wu (*20*) as implemented by Lewis et al. (*21*). Following synthesis, conjugates **1**−**3** were isolated by reverse phase (RP) HPLC and repurified as needed. HPLC analyses and purifications were performed using a Phenomenex HyperClone column (250 × 4.6 mm). Molecular weights were determined by means of MALDI-TOF mass spectrometry using a Perseptive Biosystems Voyager Pro DE spectrometer with a 2,4,6-trihydroxyacetophenone (THAP)/ammonium citrate matrix.

ODN **1**: calcd. 1236.96; found: 1239.21.
ODN **2**: calcd. 1566.17; found: 1568.73.
ODN **3**: calcd. 1895.37; found: 1897.37.

Electronic Spectra. UV spectra were performed with a Perkin-Elmer Lambda-2 UV spectrophotometer equipped with a Peltier temperature programmer to automatically increase the temperature at the rate of 0.5 °C/min. Fluorescent spectra were obtained using a Spex FluoroMax Fluorometer with temperature control provided by a Quantum Northwest TC 125 Peltier controller. Fluorescent spectra were collected after samples were deoxygenated by purging with dry nitrogen gas for 15 min. The spectra were excited at 336 nm and monitored from 360 to 600 nm. The integration time was 0.1 s, and slits for both excitation and emission were 5.0 nm. Temperature-dependent fluorescent spectra were collected with heating or cooling rate of 40 °C/h. All spectra were obtained on freshly prepared samples within 30 min of preparation. The concentration of single-strand sequences was determined from the extinction coefficient of 1-pyrenebutanol ($\epsilon_{340\ nm} = (5.0 \pm 0.04) \times 10^4\ M^{-1}\ cm^{-1}$ in THF solution).

CD Experiments. Circular dichroism (CD) spectra and thermal denaturation experiments were recorded using a Jasco J-715 circular dichroism spectrometer equipped with a Jasco Peltier temperature controller. Spectra were recorded at room temperature approximately 30 min after sample preparation in a 1 cm path length cuvette using either 1.0×10^{-6} or 5.0×10^{-6} M single-strand concentration. Spectra were obtained from the sum of five scans over the 200−400 nm wavelength range with a scan rate of 100 nm m^{-1}, a bandwidth of 2.0 nm, and a response time of 2 s. The spectra were normalized by subtraction of the background scan obtained with buffer solution. Temperature-dependent experiments were performed in the range 10−90 °C with a heating rate of 40 °C/h, monitoring the CD value (mdeg) at 265 nm.

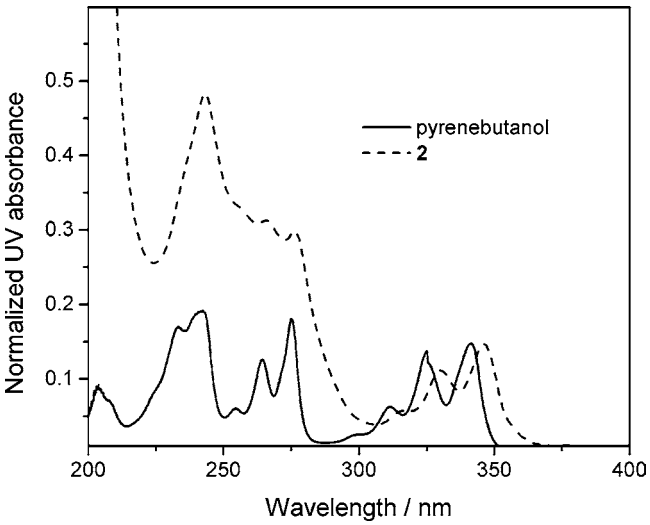

Figure 1. Absorption spectra of the pyrenebutanol in methanol solution and conjugate **2** in aqueous 0.1 M KCl, 10 mM potassium phosphate.

Electrophoresis. Samples for gel electrophoresis were equilibrated for 1 day at 4 °C prior to electrophoresis for 2 h at 150 V at 4 °C using a 15% nondenaturing polyacrylamide gel (PAGE) that contained 100 mM KCl in 1 × TBE, 10 mM potassium phosphate electrophoresis buffer. The fluorescence of the gel was observed over a UV transilluminator (312 nm), and then the gel was stained with Stains-All (Sigma).

RESULTS

The synthesis, purification, and characterization of conjugates **1**−**3** are described in the Experimental Procedures. The UV spectra of pyrenebutanol in methanol and conjugate **2** in aqueous buffer with 0.1 M KCl are shown in Figure 1. The spectrum of **2** in water is similar to that obtained in buffer. The long-wavelength π,π^* band of pyrenebutanol is red-shifted and broadened in the conjugate spectrum. The short-wavelength bands of the conjugate are assigned to overlapping absorption of the bases and pyrene. The spectra of **1** and **3** have band structures similar to that of **2**, but differ in the ratio of band intensities, as a consequence of the different number of dG bases.

The CD spectra of **1**−**3** in water and in 0.01 M phosphate with 0.1 M KCl at room temperature are shown in Figure 2. No CD peaks are observed for **1**, either with or without KCl at room temperature or at 5 °C. The CD spectrum of **2** in water is weaker than that with salt, whereas added salt has little effect on the CD spectrum of **3**. In addition to the short-wavelength bands characteristic of the parallel G-quadruplex structure at 265 and 240 nm, weaker long-wavelength CD bands having vibrational structure similar to that for pyrene UV absorption (Figure 1) are observed for **2** and **3** (Figure 2b). The intensity of the pyrene CD band for **2** increases as the salt concentration is increased from 0.1 to 0.5 M KCl (data not shown). The temperature dependence of the CD spectra of **2** (0.1 M KCl) and **3** (no added salt) are shown in Figure 3. The spectra of **3** are independent of temperature, whereas those of **2** display a marked decrease in CD intensity between 60 and 70 °C, which is largely reversible upon cooling (data not shown).

The fluorescence spectra of **1**−**3** in water and in 0.1 M KCl are shown in Figure 4. The spectra of **2** and **3** with salt and of **3** without salt display a mixture of structured pyrene monomer fluorescence and broad, red-shifted pyrene excimer fluorescence. Only monomer fluorescence is observed for conjugates **1** and

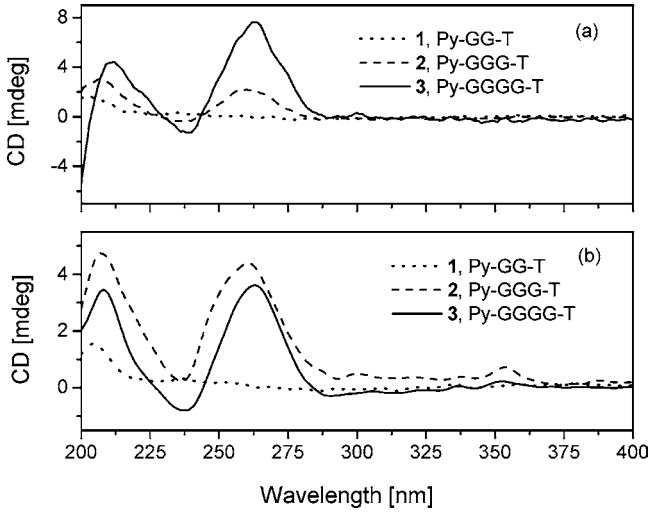

Figure 2. Circular dichroism spectra of 1×10^{-6} M conjugates **1**−**3** in (a) in water and (b) in 10 mM potassium phosphate with 0.1 M KCl.

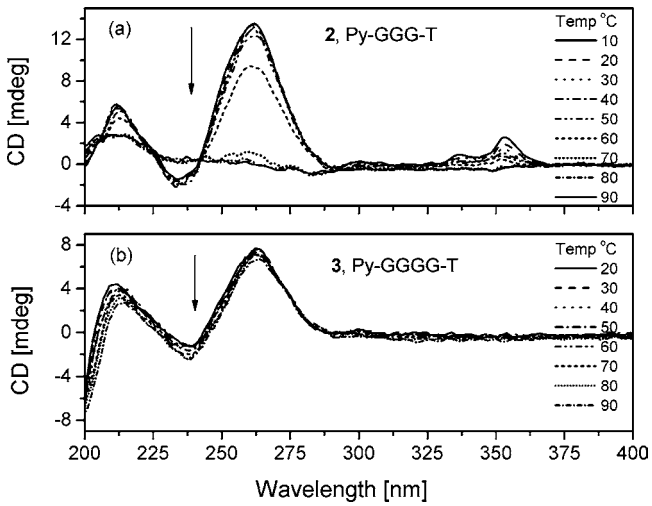

Figure 3. Temperature-dependent circular dichroism spectra of conjugates **2** and **3**. Heating rate: 1.5 min/°C. (a) 5×10^{-6} M conjugate **2** in 10 mM potassium phosphate with 0.1 M KCl and (b) 1×10^{-6} M conjugate **3** in water.

2 in water. The effect of added KCl and LiCl salts on the ratio of excimer to monomer fluorescence intensity for conjugate **2** is shown in Figure 5. The ratio I_{ex}/I_m increases with added KCl to a value of 1.4 at 0.2 M KCl but does not increase further at higher KCl concentrations. The I_{ex}/I_m ratio also increases upon addition of LiCl to a solution of **2** in 0.1 M KCl. Addition of LiCl results in values of I_{ex}/I_m somewhat smaller than that for 0.2 M KCl.

The effects of increasing temperature on the total fluorescence of **2** (with salt) and **3** (in buffer) are shown in Figure 6. The I_{ex}/I_m ratios obtained for both heating and cooling are shown in Figure 7. Heating of **2** results in a decrease in both monomer and excimer fluorescence intensity (Figure 6a). The ratio I_{ex}/I_m remains fairly constant up to ca. 50 °C but decreases at higher temperatures (Figure 7a). Cooling to 0 °C is necessary for recovery of the I_{ex}/I_m ratio. Heating of **3** results in a larger decrease in I_m than I_{ex} (Figure 6b), resulting in an increase in I_{ex}/I_m with increasing temperature (Figure 7b). Cooling results in lower values of I_{ex}/I_m than those observed at the same temperatures in the heating cycle.

Excimer fluorescence can also be used to visually detect G-aggregate formation using nondenaturing PAGE under a UV transilluminator, the eye being more sensitive to pyrene excimer vs monomer fluorescence. Electrophoresis of conjugates **2** and **3** (3.5×10^{-5} M or 0.3 mM in 0.1 M KCl) yields a single strongly fluorescence band, the band for **2** having a higher migration rate. In contrast, the faster-moving band from **1** cannot be detected visually without the addition of a staining agent (data not shown).

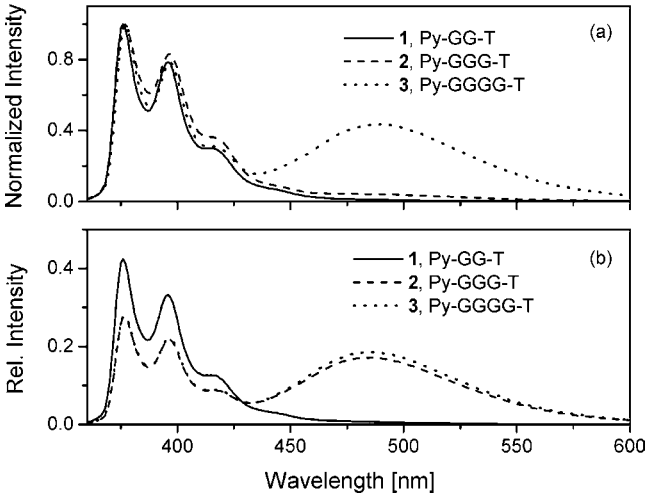

Figure 4. Room-temperature fluorescence spectra of 1×10^{-6} M conjugates **1**−**3** in different salt conditions: (a) in water and (b) in 0.1 M KCl, 10 mM potassium phosphate.

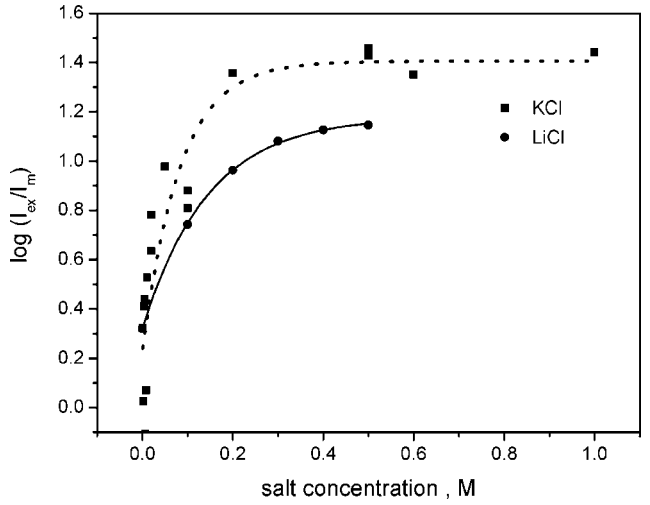

Figure 5. Salt concentration dependence of the pyrene excimer/monomer fluorescence intensity ratio for conjugate **2** (LiCl added to a solution containing 0.1 M KCl).

DISCUSSION

The ODNs d(TGGGT) and d(TGGGGT) are known to form stable parallel G-quadruplex structures in the presence of potassium ions (*17*, *22*). Parallel quadruplex formation has not been reported for d(TGGT); however, hairpin dimer and intramolecular G-quadruplex structures possessing only two G-quartets have been reported (*14*, *23*). The presence of the terminal thymines in the d(TG$_n$T) ODNs inhibits the formation of higher aggregates. The conjugates **1**−**3** are derived from these ODNs by replacement of the 5′-dT by pyrenebutanol (Scheme 1b,c). The 200−300 nm region of the CD spectra of **2** and **3** in the presence of KCl (Figure 2b) are identical, respectively, to those reported for d(TGGGT)$_4$ and for a G-quadruplex in which the 3′-thymines are connected by a branched linker which enforces a parallel structure (*24*, *25*).

The structure of **3** is similar to that of the conjugate d(TGGGG)-FL (FL = fluorescein) recently studied by Merkina

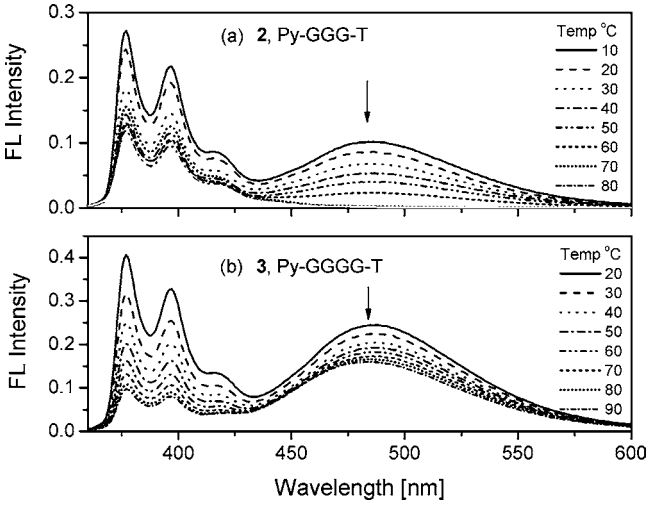

Figure 6. Temperature-dependent fluorescent spectra of conjugates **2** and **3**. Heating rate: 1.5 min/°C. (a) 5×10^{-6} M **2** in 10 mM potassium phosphate with 0.1 M KCl and (b) 1×10^{-6} M **3** in 10 mM potassium phosphate.

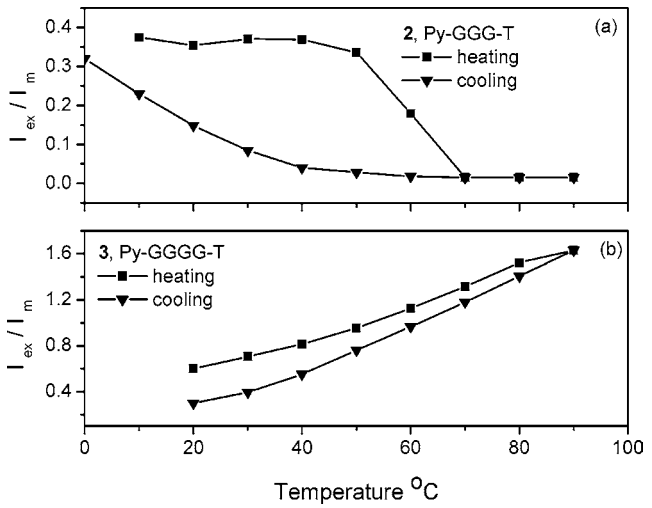

Figure 7. Excimer/monomer fluorescence intensity ratios for conjugates **2** and **3**. Heating and cooling rate: 1.5 min/°C. (a) 5×10^{-6} M **2** in 10 mM potassium phosphate with 0.1 M KCl and (b) 1×10^{-6} M **3** in 10 mM potassium phosphate.

and Fox (*19*). They report that the quadruplex formed by this conjugate is resistant to melting in the presence of 5 mM potassium. Stabilization of the FL-labeled quadruplex in sodium buffer when compared to an unlabeled quadruplex was attributed to stacking of the fluorophore on the exposed face of the terminal G-quartet, as observed for the complexes formed between G-quadruplexes and other planar hydrophobic organic molecules (*26*). We observe no change in the CD spectrum of **3** upon heating to 90 °C in the presence or absence of 10 mM potassium (Figure 3b), in accord with the high thermal stability observed for d(TGGGGT) or d(TGGGG)-FL (*13*, *17*). The failure of **2** to form a stable quadruplex structure under in water (Figure 2a) and the observation of "melting" of the high salt CD spectrum at ca. 60 °C (Figure 3a) is consistent with previous reports of the diminished stability of d(TGGGT) vs d(TGGGGT) (*17*). The failure of **1** to form a G-quadruplex structure even at high salt concentrations indicates that the hydrophobic association of four pyrenes is not sufficient to stabilize an intermolecular G-quadruplex structure possessing only two G-quartets.

The fluorescence spectra of **2** and **3** (Figure 4) consist of mixtures of monomer and excimer fluorescence, even though the CD spectra (Figure 2) are indicative of the formation of stable parallel G-quadruplex structures. It is possible that monomer and excimer fluorescence arise from different structures. However, PAGE gels for **2** and **3** display a single band, as visualized using pyrene excimer fluorescence. Low pyrene excimer/monomer fluorescence ratios have previously been observed upon duplex and triplex formation with pyrene end-labeled ODNs (*6*, *7*). A high excimer/monomer fluorescence ratio has been observed for oligomeric pyrene-containing C-nucleosides (*13*) and for an intramolecular G-quadruplex having pyrenes attached to the 3′- and 5′-ends of the sequence d(GGTTGGTGTGGTTGG) (*27*). However, only broadened monomer emission is observed for several duplexes bearing pyrenes as pendant groups on multiple adjacent dU bases (*9*, *10*). Studies of the fluorescence of conformationally constrained pyrene cyclophanes indicate that a full sandwich-like structure is required for the observation of long-wavelength excimer fluorescence, whereas structures with restricted overlap display small shifts or only broadened monomer emission (*1*, *28*).

We assume that the four pyrene chromophores occupy the 5′-face of the G-quartets formed by **2** and **3**, so as to minimize hydrophobic interactions of both the G-quartet and pyrenes with water. However, it is likely that some of the pyrene chromophores have ground-state geometries that disfavor formation of a sandwich excimer with a neighboring pyrene upon electronic excitation. Evidence for the clustering of pyrenes on a single face of the G-quadruplex is provided by the effect of added salts on the excimer/monomer fluorescence ratio (Figure 5). Both added KCl and LiCl cause an increase in the I_{ex}/I_m ratio, even though 0.01 M KCl is sufficient to effect G-quadruplex formation, as evidenced by the CD spectra. Since LiCl is unable to stabilize G-quadruplex structures (*29*, *30*), its influence on I_{ex}/I_m most likely is a consequence of a hydrophobic salt effect on the structure of the assembled pyrenes. LiCl and KCl have similar hydrophobic effects on the solubility of nonpolar molecules such as benzene in aqueous solution (*31*). Solvation of small ions by water results in collapse of the water molecules around the ions (*32*). This phenomenon, known as electrostriction, increases the energy required for creation of a space for a hydrophobic molecule such as pyrene and would force the four pyrenes attached to the quadruplex to occupy a smaller volume, plausibly favoring excimer formation.

In summary, evidence based on circular dichroism spectra indicates that both **2** and **3** form parallel quadruplex structures in which the appended pyrenes occupy the 5′-face of the quadruplex. Conjugate **1** fails to form a stable quadruplex structure even at low temperature in the presence of KCl. Conjugate **3**, which possesses a GGGG sequence, forms a stable quadruplex even in the absence of added salt and does not dissociate upon heating to 90 °C. In the presence of KCl, conjugate **2** forms a quadruplex structure that is stable at room temperature but undergoes thermal dissociation above 60 °C.

The fluorescence spectra of the quadruplexes formed by conjugates **2** and **3** display both monomer and excimer bands, whereas single-strand conjugates display only monomer fluorescence. Thus, excimer fluorescence can be used as a probe for intermolecular quadruplex formation, both in solution and in visualizing PAGE gels. Upon heating, the excimer/monomer band ratio for **2** deceases sharply above 50 °C, concomitant with thermal dissociation of the quadruplex. In contrast, the excimer/monomer ratio for **3** increases with temperature, indicative of a change in pyrene aggregate structure in a manner that favors the face-to-face geometry required for pyrene excimer fluorescence. The effect of added salts (KCl or LiCl) on the pyrene excimer/monomer ratio is attributed to electrostriction, which confines the hydrophobic pyrenes to a small volume.

An Acetal-Based PEGylation Reagent for pH-Sensitive Shielding of DNA Polyplexes

Veronika Knorr,[†] Lars Allmendinger,[‡] Greg F. Walker,[†] Franz F. Paintner,[‡] and Ernst Wagner*[,†]

Pharmaceutical Biology−Biotechnology and Pharmaceutical Chemistry, Department of Pharmacy Ludwig-Maximilians-Universität München, Butenandtstr. 5-13, D-81377 Munich, Germany. Received October 19, 2006; Revised Manuscript Received February 23, 2007

p-Piperazinobenzaldehyde methoxy poly(ethylene glycol) (mPEG, 5 kDa) acetal was synthesized by the Buchwald-Hartwig coupling reaction from piperazine and *p*-bromobenzaldehyde mPEG acetal. Introduction of a maleimide moiety yielded a novel acetal-based PEGylation reagent (PEG−acetal−MAL) for pH-sensitive conjugation of PEG to thiol-functionalized biomolecules. For reversible shielding of polyplexes, PEG−acetal−MAL was conjugated to polyethylenimine (PEI). At 37 °C, the PEG−acetal−PEI conjugate had a half-life of 3 min at endosomal pH 5.5 and 2 h at physiological pH 7.4, respectively. PEI polyplexes containing PEG−acetal−PEI had a ζ potential of +3 mV and were stable to salt-induced aggregation for 2 h at pH 7.4. In contrast, at endosomal pH, the particles were deshielded and aggregated within 0.5 h. Epidermal growth factor or transferrin receptor-targeted polyplexes shielded with the pH-sensitive PEG−acetal mediated enhanced luciferase gene expression in receptor-expressing target cells (Renca-EGFR or K562) as compared to stably shielded control polyplexes. Thus, the novel PEG−acetal−MAL reagent may present a versatile tool for drug and gene delivery formulations when pH-sensitive PEGylation is preferred.

INTRODUCTION

Nonviral vectors are receiving increasing attention due to their higher biosafety, compound stability, ease of chemical modification, and low cost compared to viral systems. In comparison with viruses, however, they suffer from lower gene transfer efficiency. Polyplexes belong to a subclass of nonviral vectors consisting of negatively charged DNA complexed with cationic polymers (*1*−*4*). Among the cationic polymers, polyethylenimine (PEI[1]) offers the advantage of efficient endosomal release due to its high pH-buffering capacity (*5*−*7*). An excess of PEI over DNA is usually required for high gene transfer activity (*8*), resulting in PEI polyplexes with a net positive surface charge. This charge, however, triggers nonspecific interactions with negatively charged physiological compounds. Systemic application of such polyplexes results in significant toxicity and/or poor efficiency due to binding to plasma proteins or blood cells and complement activation (*9*, *10*). The side effects can be reduced by surface neutralization by PEGylation, i.e., the modification with the hydrophilic polymer poly(ethylene glycol) (PEG). PEGylation covering the polyplex surface, however, reduces not only undesired interactions but also the desired binding to the negatively charged cell membrane (*11*). A reduced association and uptake into the cell can be overcome by the chemical attachment of a targeting ligand to the polyplex for receptor-mediated uptake. PEI polyplexes containing PEG and cell-targeting ligands have been successfully applied in vitro and in vivo (*11*−*17*).

Extensive PEGylation, though beneficial for systemic circulation, appears to negatively affect intracellular release of the delivered nucleic acid. Lipoplexes and polyplexes with a pH-sensitive PEG shield which can be removed upon endosomal acidification have been found to mediate enhanced gene transfer efficiency (*18*−*20*). In our previous work (*20*), reversible shielding of PEI polyplexes was achieved in an indirect manner by the conjugation of PEG to polylysine via a hydrazone bond. The chemistry was not applicable for direct conjugation of PEG to PEI because of insufficient stability of the resulting PEI conjugate. In their synthesis of bio-inspired polymeric carriers, Murthy et al. (*21*, *22*) synthesized hydrophobic, membrane-disruptive methacrylate polymers onto which hydrophilic PEG chains have been grafted through acid-degradable acetal linkages; a *p*-aminobenzaldehyde acetal linkage demonstrated a suitable hydrolysis profile at endosomal pH.

In our current work, a new PEGylation reagent was synthesized containing *p*-piperazinobenzaldehyde acetal linkage and a maleimide moiety which can be coupled to thiol-functionalized compounds. As a first application of this pH-sensitive PEGylation reagent, PEI conjugates were synthesized and used for shielding targeted PEI polyplexes. pH-triggered deshielding and higher gene transfer efficiency in comparison to analogous stable shielded polyplexes was demonstrated.

EXPERIMENTAL PROCEDURES

General Information. All chemical procedures were carried out in oven-dried glassware under a nitrogen atmosphere unless stated otherwise. Compound **6** was dried in a drying tube (KOH,

vacuum) for 3 days prior to use. Unless otherwise specified, all reagents were purchased from commercial suppliers and used without further purification. Toluene and tetrahydrofuran (THF) were distilled from sodium benzophenone ketyl radical; dimethyl sufoxide (DMSO) was distilled and stored over molecular sieves 4 Å under nitrogen. Ethyl acetate (EtOAc), chloroform, *n*-hexane, dichloromethane, diethyl ether, methanol, and *N*-ethyldimethylamine were distilled prior to use. Diethyl ether was stored over KOH. Methoxy poly(ethylene glycol)maleimide (PEG−MAL, average molecular weight of 5 kDa) was purchased from Nektar Therapeutics (Huntsville Alabama). Poly(ethylene glycol) 5 kDa monomethyl ether (mPEG) was purchased from Fluka Chemie GmbH (CH-9471 Buchs) and dried by heating to reflux (water separator) in toluene at an oil bath temperature of 170 °C for 20 h prior to use. Branched PEI with an average molecular weight of 25 kDa (PEI25) was purchased from Sigma-Aldrich (Steinheim, Germany). Linear PEI of 22 kDa (PEI22) was synthesized by acid-catalyzed deprotection of poly(2-ethyl-2-oxazoline) (50 kDa, Aldrich) in analogous form as described (*23*). It is also available from Polyplus Transfections (Strasbourg, France). Targeting conjugates (EGF−PEI and Tf−PEI) contain the ligands EGF or Tf linked with branched PEI 25 kDa by a heterobifunctional 3.4 kDa PEG linker and were synthesized as described previously (*13*−*24*). Succinimidyl 3-(2-pyridyldithio)propionate (SPDP) was purchased from Fluka (Steinheim, Germany). Tris-(dibenzylideneacetone)dipalladium ($Pd_2(dba)_3$) was a gift from Prof. Dr. Lorenz, LMU (Munich, Germany). Cell culture media, antibiotics, and fetal calf serum (FCS) were purchased from Life Technologies (Karlsruhe, Germany). Plasmid pCMVLuc (*Photinus pyralis* luciferase under control of the CMV enhancer/promoter) described in Plank et al. (*25*) was purified with the EndoFree Plasmid Kit from Qiagen (Hilden, Germany).

Column chromatography was performed on Merck silica gel 60 (40−63 μm). Gel filtration was performed on a Sephadex G-25 superfine, HR 10/30 column (Pharmacia, Sweden) in a 20 mM Hepes buffer pH 7.4 with 0.25 M NaCl, at a flow rate of 1 mL/min. Cation exchange was performed on a HR 10/10 column (BioRad, Munich, Germany) filled with Macro-prep High S. Infrared spectra were recorded on a Perkin-Elmer FT-IR Spectrometer Paragon 1000. ^{1}H NMR spectra were recorded on a Jeol JNMR-GX400 (400 MHz) or on a Jeol JNMR-GX500 (500 MHz) spectrometer. Chemical shifts are reported in parts per million (ppm) and refer to the solvent as internal standard (CH_2Cl_2 at 5.32 ppm). Data are reported as s = singulet, d = doublet, t = triplet, m = multiplet; coupling constants in hertz (Hz); integration. ^{13}C NMR spectra were recorded on a Jeol JNMR-GX500 (125 MHz) spectrometer. Chemical shifts are reported in ppm using solvent as an internal standard (CD_2Cl_2 at 53.8 ppm). Mass spectra were obtained on a Hewlett-Packard 5989A MS Engine with 59980B particle beam and on a Jeol MStation JMS-700. UV absorption and UV spectra were recorded on a GENESYS 10 Series Spectrometer.

Syntheses. *1-(4-Bromobenzene)-1-{bis[monomethoxypoly-(ethylenoxy)]}methane (**6**).* *p*-Bromobenzaldehyde (5.5506 g, 30 mmol) and *p*-TsOH·H_2O (19 mg, 0.1 mmol) were added to dried mPEG5kDa (10.0 g, 2 mmol) in toluene (50 mL), and the stirred reaction mixture was heated for 22 h at 170 °C (oil bath temperature). K_2CO_3 (276 mg, 2 mmol) was added, and after 45 min of stirring at room temperature (rt), the solidified reaction mixture was diluted with with CH_2Cl_2, filtered, and evaporated. For purification, the crude product was powdered, washed with Et_2O (7×), and finally dried under vacuum to afford **6** as a white powder (9.860 g, 97%).

^{1}H NMR (500 MHz, CD_2Cl_2): δ = 3.32 (s, CH_3 PEG5kDa), 3.37−3.79 (m, CH_2 PEG5kDa), 5.56 (s, 1 H), 7.34−7.40 (m, 2 H), 7.45−7.52 (m, 2 H).

*2-Trimethylsilylethyl 4-[4-(1{bis[monomethoxypoly(ethylenoxy)]}-methyl)phenyl]piperazine-1-carboxylate (**7**).* The following synthesis steps were carried out under an argon atmosphere. KO*t*Bu (19.1 mg, 0.17 mmol), $Pd_2(dba)_3$ (4.6 mg, 0.005 mmol), 2-(dicyclohexylphosphino)biphenyl, and dried **6** (1.0167 g, 0.1 mmol) were suspended in toluene (1 mL). A solution of 2-trimethylsilylethyl piperazine-1-carboxylate (**2**, Supporting Information) (34.5 mg, 0.15 mmol) in toluene (1 mL) was added, and the reaction mixture was stirred for 45 h at 90 °C. After cooling to rt, the mixture was treated with a saturated solution of $NaHCO_3$ (20 mL). The aqueous solution was extracted with CH_2Cl_2 (7 × 15 mL), and the combined organic layers were dried ($MgSO_4$), filtered, and evaporated under reduced pressure. To remove impurities, the resulting crude product was powdered and extracted with Et_2O (5×) to give **7** as a fawn powder (918 mg, 90%). The ^{1}H NMR shows this product contained about 82% of **7** and 18% of unreacted **6**, which could not be eliminated but also did not interfere in the following synthesis steps.

^{1}H NMR (500 MHz, CD_2Cl_2): δ = 0.04 (s, 9 H), 0.98−1.03 (m, 2 H), 3.13 (t, J = 5.0 Hz, 4 H), 3.32 (s, CH_3 PEG5kDa), 3.42−3.75 (m, CH_2 PEG5kDa, 4 H), 4.13−4.20 (m, 2 H), 5.50 (s, 1 H), 6.87−6.92 (m, 2 H), 7.31−7.36 (m, 2 H).

*1-[4-(1-{Bis[monomethoxypoly(ethylenoxy)]}methyl)phenyl]-piperazine (**8**).* To a suspension of **7** (310 mg, 0.03 mmol) in THF (1 mL), a solution of tetrabutylammonium fluoride trihydrate (TBAF·3H_2O) in THF (1 mL) was added dropwise. After slightly warming the reaction mixture, it was stirred at rt for 20 h. The mixture was then treated with a saturated solution of $NaHCO_3$ (5 mL). The aqueous solution was extracted with CH_2Cl_2 (5×), and the combined organic layers were dried ($MgSO_4$), filtered, and evaporated under reduced pressure. The resulting solid was powdered and washed with Et_2O (5 × 10 mL) to afford **8** as a beige powder (275.5 mg, 90%).

^{1}H NMR (500 MHz, CD_2Cl_2): δ = 2.94−2.99 (m, 4 H), 3.07−3.12 (m, 4 H), 3.33 (s, CH_3 PEG5kDa), 3.42−3.76 (m, CH_2 PEG5kDa), 5.49 (s, 1 H), 6.84−6.90 (m, 2 H), 7.28−7.33 (m, 2 H).

*N-(3-{4-[4-(1-{Bis[monomethoxypoly(ethylenoxy)]}methyl)-phenyl]piperazinyl-3-oxopropyl)maleimide (**9**).* *N*-Methylmorpholine (11 μL, 0.1 mmol) and *N*-succinimidyl-3-maleimidopropionate (13 mg, 0.05 mmol) were added subsequently to a suspension of **8** (101.9 mg, 0.01 mmol) in DMSO (0.5 mL) and stirred at rt for 30 min. The reaction mixture was then treated with phosphate buffer pH 7.4 [3 mL; KH_2PO_4 (250.0 mL, 0.2 M) + NaOH (393.4 mL, 0.1 M)] and extracted with CH_2Cl_2 (5 × 5 mL). The combined organic layers were dried ($MgSO_4$), filtered, and evaporated. The resulting beige solid was aliquoted into two portions of about 50 mg, dissolved in 20 mM Hepes buffer pH 7.4 with 0.25 M NaCl (2 mL) and purified by gel filtration chromatography. The fractions containing the desired product were extracted with CH_2Cl_2 (5 × 5 mL). The combined organic layers were dried ($MgSO_4$), filtered, and evaporated under reduced pressure to give **9** as a pale yellow solid (73.5 mg, 71%).

^{1}H NMR (500 MHz, CD_2Cl_2): δ = 2.63−2.70 (m, 2 H), 3.11−3.20 (m, 2 H), 3.32 (s, 6 H), 3.42−3.82 (m, CH_2 PEG5kDa, 4 H), 5.50 (s, 1 H), 6.69 (s, 2 H), 6.86−6.91 (m, 2 H), 7.32−7.36 (m, 2 H).

Thiolation of Branched Polyethylenimine. PEI25 (6 mg, 0.24 μmol) in 0.1 M Hepes buffer pH 7.4 (0.4 mL) was mixed with 0.6 μmol SPDP from a stock solution at 3 mg mL^{-1} in DMSO. The reaction was mixed overnight at rt, and the resulting product was purified by G-25 superfine gel filtration (*26*, *27*). The dithiopyridyl groups of the product were reduced with 50 mol equiv of DTT for 10 min, and the resulting thiol-modified PEI was purified by G-25 superfine gel filtration equilibrated in 20 mM Hepes pH 7.4 containing 0.25 M NaCl under argon.

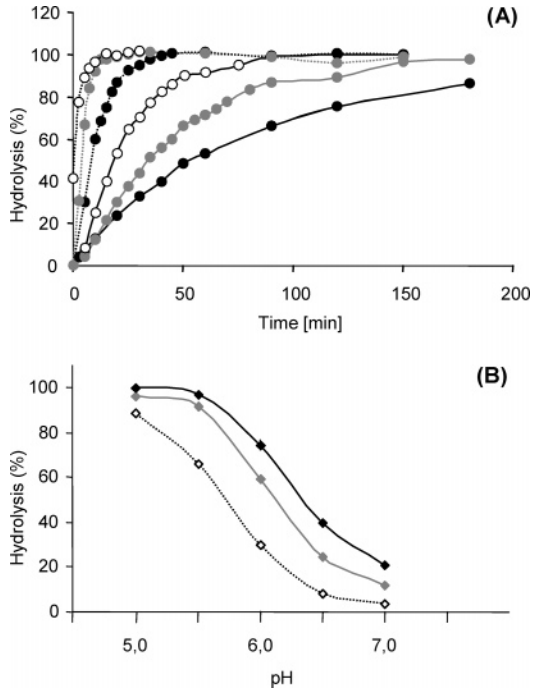

Figure 1. Time course of the cleavage of PEG−acetal−MAL **9** and formation of the corresponding aldehyde at 37 °C at different pH values (pH 7.4,−●−; pH 7.0, gray circles/solid lines; pH 6.5, −○−; pH 6.0, ···●···; pH 5.5, gray circles/dotted lines; pH 5.0, ···○···). (A). Hydrolysis rate of PEG−acetal−MAL **9** as a function of pH shown for different time points at 37 °C (5 min, ···◇···; 10 min, gray diamond/solid line; 15 min, −♦−) (B). Values are shown as duplicate.

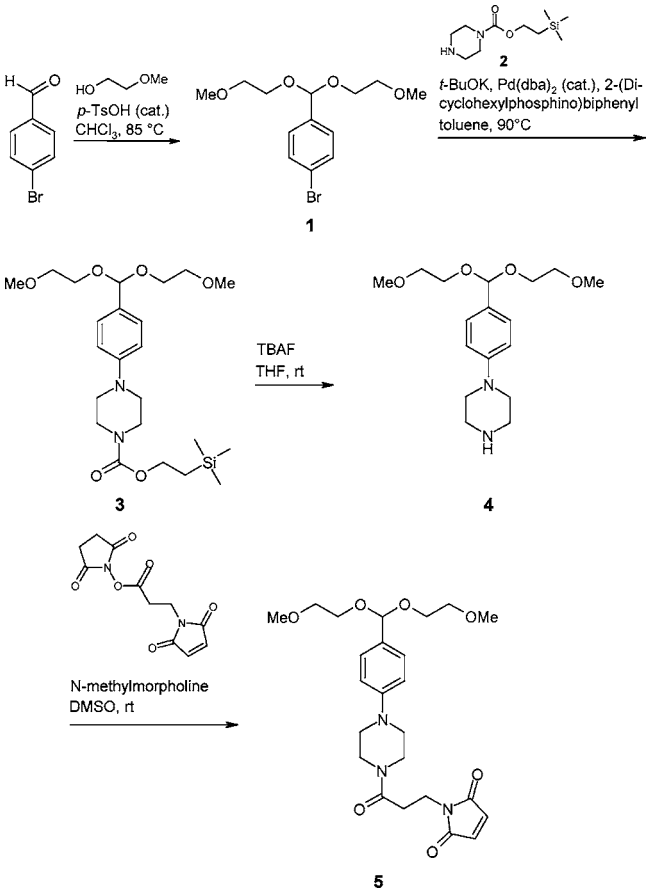
The product was snap-frozen in liquid nitrogen and stored at −80 °C. PEI was quantified by the 2,4,6-trinitrobenzenesulfonic acid (TNBS) assay (*28*), and the amount of free mercapto groups was determined by the Ellman assay (*29*).

Poly(ethylene)glycol−polyethylenimine Conjugates. PEG−acetal−MAL **9** (0.2 mL, 0.12 μmol) or PEG−MAL (0.1 mL, 0.2 μmol) was dissolved in degassed 20 mM Hepes buffer pH 7.4 containing 0.25 M NaCl by brief sonication. PEG−acetal−MAL or PEG−MAL was mixed with PEI25-SH at 0.03 or 0.02 μmol (PEI), respectively (total volume 2 mL). After 10 min, the reaction was applied to the cation-exchange column, which was equilibrated in 20 mM Hepes buffer pH 7.4 containing 0.5 M NaCl. The salt concentration was increased with a linear gradient to 3 M NaCl (10 min) and maintained at 3 M NaCl for 15 min with a flow rate of 1 mL/min. The PEI product was eluted as a single peak at 3 M NaCl. PEI was quantified by the TNBS assay. PEG conjugation was monitored by measuring unbound PEG (*30*) and by ^{1}H NMR. The purified conjugates (PEG−A−PEI and PEG−S−PEI) were snap-frozen in liquid nitrogen and stored at −80 °C.

Hydrolysis Assay. The PEG−A−PEI conjugate (0.0092 μmol, 0.8 mL) was adjusted to pH 5 by the addition of sodium acetate (0.333 M) to a final concentration of 0.2 M total volume 2 mL and was incubated for 22 h at 37 °C. The reaction was applied to and separated on the cation-exchange column, the unbound PEG fractions were pooled, and the amount of PEG was quantified (*30*). For hydrolysis kinetic measurements in Figure 1, compound **9** was dissolved in the respective buffer (0.2 M Hepes buffer pH 7.4; 0.2 M Hepes buffer pH 7.0; 0.2 M phosphate buffer pH 6.5; 0.2 M phosphate buffer pH 6.0; 0.2 M phosphate buffer pH 5.5; 0.5 M NaOAc buffer pH 5.0) at a concentration of 1.5 mg/mL.

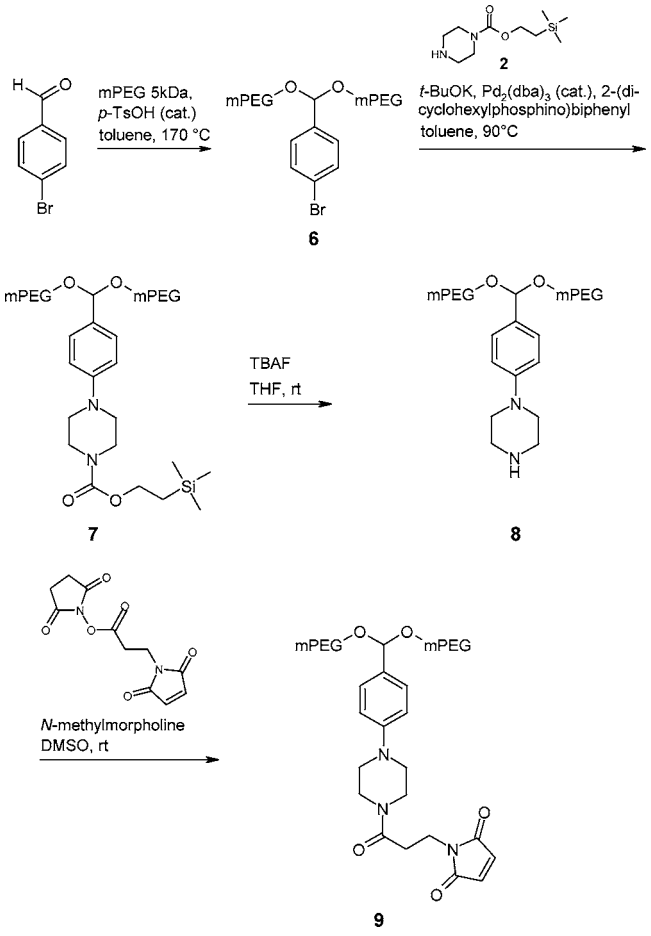
Formation of Polyplexes. DNA was mixed with PEI in HBG; complexes were formed at molar ratios of PEI nitrogen atoms to DNA phosphate (N/P) of 3 and 6. Various PEI derivatives were included in the formulation at the indicated ratios, as unmodified PEI (PEI22 or PEI25), targeting conjugate (EGF−PEI or Tf−PEI), or shielding conjugate (PEG−S−PEI or PEG−A−PEI). The DNA complexes were left at room temperature for 20 min prior to use.

Particle Size and ζ Potential. Particle size of DNA complexes was measured by laser-light scattering using a Malvern Zetasizer 3000HS (Malvern Instruments, Worcestershire, U.K.). For particle sizing, complexes were measured at a final DNA concentration of 10 μg/mL (total volume 1 mL). Measurements at pH 7.4 were performed in 0.5 × HBS pH 7.4, while for pH 5 measurements, a 20 mM NaOAc buffer pH 5.0, containing 75 mM NaCl, was used. For estimation of the surface charge, polyplexes were diluted 5-fold in 10 mM NaCl; ζ potential was measured as previously described (*24*).



Cell Culture and Transfection. Renca-EGFR mouse renal carcinoma cells stably transfected with pLTR-EGFR and pSV2neo (kindly provided by Winfried Wels, Frankfurt am Main, Germany) and K562 suspension cells (ATCC CCL-243) were grown at 37 °C in a 5% CO_2 humidified atmosphere in RPMI-1640 with 4% Glutamax I medium supplemented with 10% FCS and 1% antibiotics (streptomycin, penicillin). Renca-EGFR cells were seeded in 96 well plates with 5×10^3 cells per well 24 h prior to transfection. K562 (2.5×10^5 cells in 0.75 mL) were plated in 24 well plates.

Transfection polyplexes at the indicated amounts of pCMVL plasmid DNA were added to each well. After 4 h incubation at 37 °C, the transfection medium was replaced by fresh culture medium. Luciferase gene expression was measured after 24 h as described (*24*). Values are given as relative light units (RLU) and represent the luciferase activity per 10^4 (Renca) or 2.5×10^5 (K562) cells. Two nanograms of recombinant luciferase (Promega, Mannheim, Germany) corresponds to 10^7 light units.

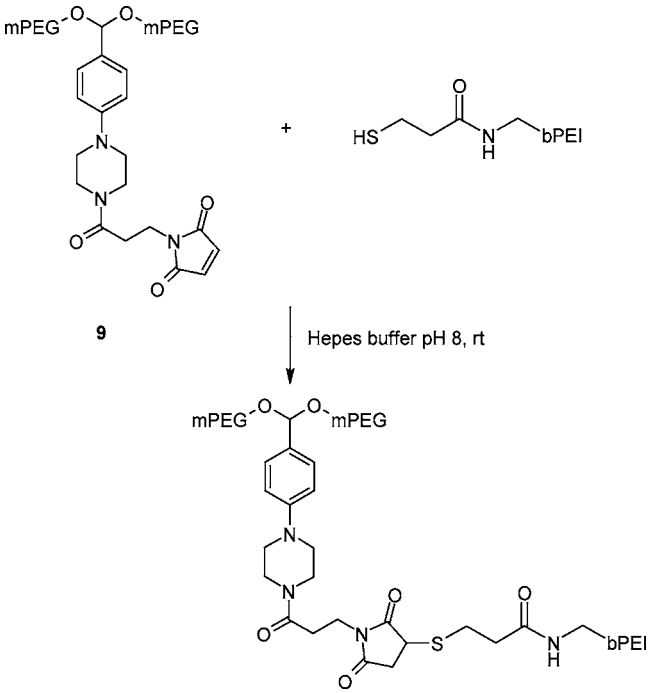


RESULTS

As shown in Scheme 1, the initial synthesis of the acetal linker was developed with 2-methoxyethanol instead of mPEG (see Supporting Information). This was necessary for optimization of the synthesis as well as for the characterization of the linker by NMR, as the PEG signal overlaps several signals of the synthesis intermediates. The synthesis of the methoxyethanol acetal (**5**) was achieved in four reaction steps, each of which was confirmed by NMR analysis. In a similar manner, the PEG acetal linker was synthesized as shown in Scheme 2. In the first step, *p*-bromobenzaldehyde was reacted with mPEG to generate the corresponding acetal (**6**) with a 97% yield. Formation of the acetal was confirmed by ^{1}H NMR, by appearance of a singlet at 5.56 ppm (acetal proton) and the disappearance of a singlet at 9.96 ppm (aldehyde proton). The bromo group of **6** was then substituted with trimethylsilylethyloxocarbonyl piperazine by the Buchwald-Hartwig reaction with 2-trimethylsilylethyl piperazine-1-carboxylate. ^{1}H NMR shows that the product obtained was a mixture of the piperazine-substituted acetal **7** (82%) and the starting material **6** (18%). The signals proving the existence of **7** appear as a singlet at 0.04 ppm belonging to the nine protons of the trimethylsilyl group, a multiplet of the methylene function next to the trimethylsilyl group at 0.98−1.03 ppm, and a triplet from four piperazine protons at 3.13 ppm; while the signal of the other four piperazine protons is overlapped by the PEG signal. For **6**, the acetal proton is represented at 5.56 ppm and the aromatic protons at 7.34−7.40 and 7.45−7.52 ppm. The respective signals for **7** are shifted to 5.50 ppm and to 6.87−6.92 and 7.31−7.36 ppm. The trimethylsilylethyloxocarbonyl protecting group of **7** was removed by reaction with TBAF·$3H_2O$, resulting in a 90% yield. Subsequent ^{1}H NMR analysis of the reaction product **8** showed the deprotection of the amine moiety by the appearance of a signal at 2.94−2.99 ppm which corresponds to the four protons at the carbons next to the

Scheme 1. Synthesis of the Methoxyethanol Acetal−MAL (5)

Scheme 2. Synthesis of PEG−acetal−MAL (9)



secondary amine. A 3-oxopropyl maleimido function was introduced at the deprotected amine by reacting **8** with *N*-succinimidyl-3-maleimidopropionate, resulting in a shift of the ^{1}H NMR signal from 2.94 to 2.99 ppm to lower field, which could not be observed due to the broad, overlapping PEG signal. Furthermore, a singlet appeared at 6.69 ppm, indicating the two methine protons of the maleimido group. In addition, a multiplet emerged at 2.63−2.70 ppm, corresponding to the two protons next to the carboxy group of the new substituent. Product **9**, the PEGylation reagent PEG−acetal−MAL used in the subsequent studies, was obtained with a 71% yield.

To ascertain the pH sensitivity of the linker, hydrolysis of **9** was carried out at pH 5.0, 5.5, 6.0, 6.5, 7.0, and 7.4 respectively. The assay was performed at 37 °C, and the hydrolysis was determined at different time points by measuring the absorbance at 340 nm, the main absorbance of the released aldehyde. Half-life continuously decreased with decreasing pH. At pH 7.4, the acetal hydrolyzed with a half-life of approximately 1 h, while at pH 5, the half-life was less than 3 min. At a pH of 6, which is relevant for PEI-containing endosomes (*6*, *31*), PEG−acetal−MAL degraded with a half-life of less than 10 min (Figure 1A). The curves in Figure 1B show the hydrolysis rates of PEG−acetal−MAL at defined time points as a function of the pH. For pH 5 at all three time points—5, 10, and 15 min—the reagent showed almost complete degradation, while for pH 7.0, between 96% and 80% remained intact during the indicated time periods.

Synthesis of the PEG−A−PEI conjugate was achieved by reacting the maleimide moiety of the PEG acetal linker **9** with mercapto-modified PEI25 (Scheme 3), resulting in a PEG/PEI molar ratio of approximately 3/1, corresponding to approximately 1.5 acetal moieties per PEI25 moiety. The hydrolytic profile of the PEG−A−PEI was measured at 340 nm in a similar manner to that of PEG−acetal−MAL. Figure 2 shows the time course of hydrolysis of the PEG−A−PEI conjugate at either

Scheme 3. Coupling of the PEG−acetal−MAL to Mercaptan-Modified Branched PEI25

pH 7.4 or pH 5.5 at 37 °C. The PEG−A−PEI had a half-life of approximately 3 min at pH 5.5, while the half-life was 2 h at pH 7.4.

To investigate the effect of PEG conjugates on the shielding of polyplexes, particle size and ζ potential were measured.

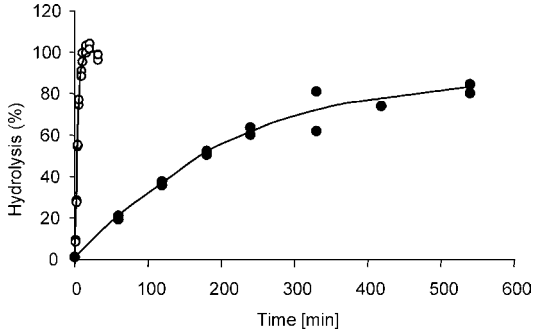


Figure 2. Time course of the cleavage of the acetal PEG−A−PEI25 and formation of the corresponding aldehyde at pH 7.4 (●) and at pH 5.5 (○) at 37 °C. Experiments were performed in duplicate.

[a] Data at the 0 and 2 h time points, pH 7.4. Each value represents the mean of at least three readings. [b] Aggregates with size over 1 μm formed.

Control PEI22 particles at N/P 6 without PEG and targeting ligands have a surface charge of about 30 mV and form aggregates (*24*). Table 1 shows particle sizes and ζ potentials of polyplexes containing targeting conjugate (EGF−PEI25 or Tf−PEI25) with and without PEG shield (PEG−S−PEI or PEG−A−PEI) at pH 7.4 and 37 °C. All PEGylated polyplexes remained shielded and stable for 2 h, whereas non-PEGylated polyplexes formed aggregates. Figure 3 shows the time-dependent changes of PEG−A−PEI shielded polyplexes incubated at either pH 5.0 or pH 7.4 and 37 °C. At pH 5.0, the PEG−A−PEI shielded polyplexes formed aggregates at the 0.5 h time point, indicating PEG removal under these conditions. In contrast, at pH 7.4 polyplexes were stable in size and retained low surface charge for the whole 2 h time period. Even after 4 h at pH 7.4—representing the incubation time of cells with polyplexes—particles remained shielded (data not shown). Different targeting conjugates (EGF in Figure 3A,B; Tf in Figure 3 C,D) did not significantly alter the biophysical properties. Polyplexes containing the nonreversible conjugate PEG−S−PEI did not change in size and remained shielded at both pH values (Table 1 and data not shown).

The transfection efficiency of the various polyplex formulations was tested using a luciferase gene expressing plasmid. EGF-containing polyplexes (*32*, *33*) were applied on Renca-EGFR cells and Tf-containing polyplexes (*24*, *26*) on K562 cells. To avoid extracellular deshielding, transfection medium was replaced after 4 h of incubation by fresh culture medium. All targeted, reversibly shielded polyplex formulations had greater gene transfer activity as compared to the analogous stably shielded formulations (see Figure 4 for Renca-EGFR and Figure 5 for K562). The effect of pH-sensitive PEGylation was most pronounced at a molar PEI nitrogen/DNA phosphate (N/P) ratio of 3 in Renca-EGFR, with a 14-fold enhanced gene expression compared to nonsensitive PEGylation (Figure 4). Analogously, for K562 cells the effect of pH-sensitive PEGylation was most pronounced at a molar N/P ratio of 6 resulting in 8-fold enhancement of gene expression (Figure 5). As polyplexes

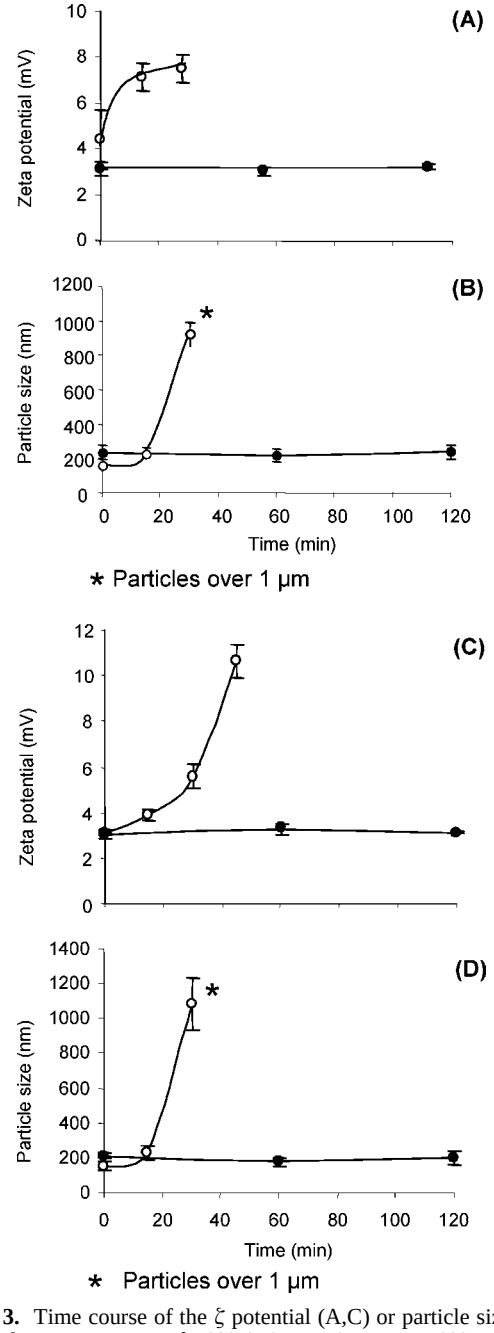

Figure 3. Time course of the ζ potential (A,C) or particle size (B,D) of polyplexes consisting of 70% (w/w; PEI) PEI22, 20% PEG−A−PEI, and 10% EGF−PEI (A,B) or 10% Tf−PEI (C,D) at pH 7.4 (●) and at pH 5.0 (○) at 37 °C. Each point represents the mean ± sd of three experiments.

remained shielded within the incubation time with cells, the higher transfection efficiency of reversibly shielded compared to stably shielded polyplexes is most probably due to intracellular deshielding.

DISCUSSION

Recent strategies for improving drug and gene delivery systems focus on the design of dynamic "stimuli-responsive" formulations (*34*). Similar to viruses in their infection process, these formulations may undergo programmed structural changes (*4*, *22*) which are induced by the particular microenvironment such as an intracellular reductive environment (*35*−*37*), enzymes (*38*), or altered pH (*19*, *22*, *39*), or are introduced externally by physical means (e.g., temperature, light, or magnetic field). The acidification of endosomes has been capitalized to trigger

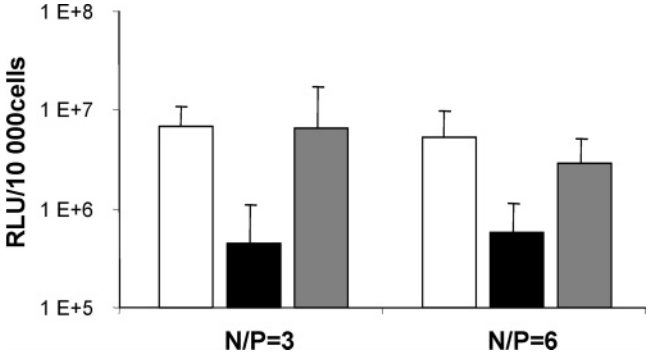

Figure 4. Luciferase gene expression by EGF-receptor-targeted polyplexes on Renca-EGFR cells. The experiments were performed using 200 ng pCMVLuc per well formulated at N/P ratios of 3 and 6. Polyplexes contain 70% PEI22, 10% EGF−PEI, and 20% of either PEI25 (nonshielded polyplexes, white bars), PEG−S−PEI (stably shielded polyplexes, black bars) or PEG−A−PEI (reversibly shielded polyplexes, gray bars). Each bar represents the mean ± sd of four independent experiments, each performed in triplicate.

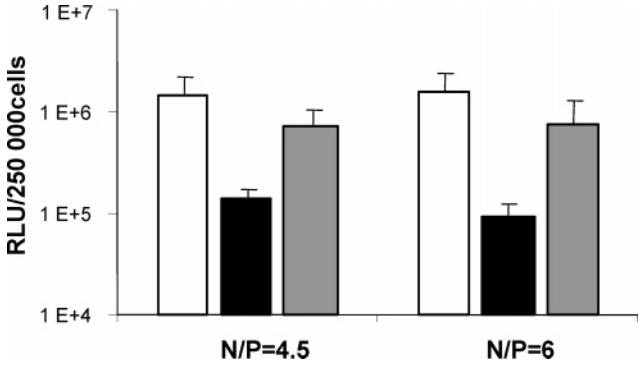

Figure 5. Luciferase gene expression by nonshielded (white bars), stably shielded (black bars), and reversibly shielded (gray bars) Tf-receptor-targeted polyplexes at N/P ratios of 4.5 and 6 on K562 cells. The experiments were performed using a pCMVLuc reporter gene at 2.5 μg per well. The values are mean ± sd of triplicates from a representative experiment out of three.

hydrolysis of acid-labile bonds in drug carriers and conjugates, such as ortho esters (*19*, *40*, *41*), acetals (*21*, *22*, *42*), or hydrazones (*20*, *39*, *43*). Among other applications, this strategy has been used for pH-responsive intracellular deshielding of nonviral gene vectors (*44*). Surface shielding of gene vectors by PEG (*24*) or other hydrophilic polymers (*45*) has been found to be very helpful for systemic circulation and reduced toxicity, but hampers intracellular delivery. Therefore, removal of the shield after delivery of the gene vector to the target cell would be desirable.

The current work describes the synthesis of a new acetal-linked PEGylation reagent that undergoes acidic triggered cleavage and is shown to be advantageous for reversible shielding of gene delivery particles. The novel PEGylation reagent **9** was synthesized following the steps shown in Scheme 2, after synthetic procedures were established using 2-methoxyethanol instead of mPEG. The Buchwald-Hartwig cross-coupling reaction is a powerful method for substitution of aromatic bromines with piperazine (*46*). In this report, the Buchwald-Hartwig amination reaction for substitution of the *p*-bromobenzaldehyde mPEG acetal with the monoprotected piperazine proved to be an efficient procedure affording the desired product with an 82% yield. To our knowledge, it is the first Buchwald-Hartwig cross-coupling reaction with a polymeric compound.

The pH within endosomes varies with the type of endosomal vesicle and the applied formulation (*6*, *31*, *31*). Therefore, hydrolysis studies with PEG−acetal−MAL were performed at several pHs to determine changes in the hydrolysis rate depending on the pH. As shown in Figure 1A, PEG−acetal−MAL hydrolysis revealed a strong pH specificity with a half-life of approximately 1 h at pH 7.4 and less than 3 min at pH 5. At pH 5.5 and 6, approximately the pHs existing in PEI-containing endosomes (*6*, *31*), PEG−acetal−MAL degraded with a half-life of less than 5 and 10 min, respectively (Figure 1A). Figure 1B shows the hydrolysis rates of PEG−acetal−MAL at defined time points as a function of the pH. For pH 5 at all three time points (5, 10, and 15 min), the reagent showed almost complete degradation, while for pH 7.0, between 96% and 80% remained intact during the indicated time periods. These data demonstrate a suitable pH dependence of the degradation rate of PEG−A−MAL.

Since these hydrolytic studies showed the PEG−acetal−MAL linker to be suitable for acid-specific hydrolysis, the reagent was used for PEGylation of the transfection reagent polyethylenimine (PEI) by reaction of the maleimide moiety with mercapto-modified PEI. Kinetic hydrolysis studies on the resulting conjugate PEG−A−PEI showed similar pH specificity (at 37 °C, half-life of about 2 h at pH 7.4 and 3 min at pH 5.5) as for PEG−acetal−MAL. Thus, this conjugate provides sufficient storage stability on one hand and allows polyplex deshielding even in PEI-buffered endosomes of pH 5.5 to 6 on the other hand. This observation was made both for branched PEI 25 kDa (this work) and for linear PEI 22 kDa conjugates (data not shown) and contrasts our previous work with acid-labile hydrazone linkers, where PEI triggers pronounced hydrolysis of the linker also at neutral pH (*20*).

From previous work (*20*, *24*), it is known that for the shielding of polyplexes only part of the polycation has to be replaced by its PEGylated version. The percentage of required PEG conjugate depends on the amount of PEG on the polycation as well as the PEG chain length and type of polycation; therefore, we determined in titration experiments with varying amounts of PEG−A−PEI the optimal amount of shielding conjugate in the formulation. Polyplexes with 20% of the PEG−A−PEI conjugate containing 1.5 acetals, i.e., three PEG chains per PEI were found to be most convenient. With this amount of PEG, polyplexes showed proper and persistent shielding at physiological pH but at the same time were deshielded quickly at the acidic pH of 5. This new acid-labile conjugate PEG−A−PEI was then incorporated into DNA polyplexes to evaluate the effect of pH-specific removal of the PEG shield. For receptor-mediated uptake, targeting conjugates EGF−PEI or Tf−PEI were incorporated into the polyplexes. EGF-containing polyplexes and Tf-containing polyplexes have been previously shown to be efficiently internalized into EGFR-overexpressing Renca cells (*33*, *47*) and transferrin receptor overexpressing K562 cells (*24*, *26*), respectively. To obtain sufficient surface neutralization, the pH-sensitive (PEG−A−PEI) or nonreversible (PEG−S−PEI) shielding conjugate was included in the polyplex at 20% (w/w; PEI), resulting in well-shielded particles with a ζ potential of +3 mV and particle sizes in the range of 200 nm. In order to follow the deshielding process, these particles were incubated at pH 7.4, representing the physiological pH of the blood, or at pH 5, representing endosomal pH. At pH 7.4, all polyplexes maintained their PEG shield for the 2 h time period, after which major receptor-mediated uptake should be completed (*48*). At pH 7.4, additional analysis of the polyplexes after 4 h was performed (data not shown) to ensure stability of the PEG shield during the incubation time in cell culture experiments. Polyplexes did not deshield within this time. Also, the polyplexes containing the nonreversible shielding conjugate PEG−S−PEI did not change their biophysical properties at pH 5 (data not shown). In contrast, the particles containing PEG−A−PEI at pH 5 within 30 min formed aggregates and increased in ζ

potential, indicating deshielding. The reversibly shielded (PEG−A−PEI) polyplexes were found to have approximately 10-fold enhanced gene transfer efficiency than stable shielded polyplexes when tested on the two different cell lines, Renca-EGFR cells and K562 cells. This is consistent also with our previous result using pH-labile hydrazone linkages (*20*).

The novel PEG−acetal−MAL reagent **9** described in this study, however, presents a more versatile tool for pH-sensitive PEGylation. Beyond the branched PEI as applied in this study, other mercapto-modified compounds may be modified for the development of more dynamic, pH-responsive drug and gene delivery systems.

ACKNOWLEDGMENT

We thank Olga Brück for skillful assistance in preparing the manuscript. This work was in part funded by the Deutsche Forschungsgemeinschaft, SFB 486 'Nanoman', excellence cluster NIM, and by the European Community FP6 network project 'GIANT'.

Cancer-targeting biomolecules labeled with ^{211}At must be stable to in vivo deastatination, as control of the ^{211}At distribution is critical due to the highly toxic nature of α-particle emission. Unfortunately, no astatinated aryl conjugates have shown in vivo stability toward deastatination when (relatively) rapidly metabolized proteins, such as monoclonal antibody Fab′ fragments, are labeled. As a means of increasing the in vivo stability of ^{211}At-labeled proteins, we have been investigating antibody conjugates of boron cage moieties. In this investigation, protein-reactive derivatives containing a *nido*-carborane (**2**), a bis-*nido*-carborane derivative (Venus Flytrap Complex, **3**), and four 2-nonahydro-*closo*-decaborate(2-) derivatives (**4**−**7**) were prepared and conjugated with an antibody Fab′ fragment such that subsequent astatination and in vivo tissue distributions could be obtained. To aid in determination of stability toward in vivo deastatination, the Fab′−borane conjugates were also labeled with ^{125}I, and that material was coinjected with the ^{211}At-labeled Fab′. For comparison, direct labeling of the Fab′ with ^{125}I and ^{211}At was conducted. Direct labeling with Na[^{125}I]I and Chloramine-T gave an 89% radiochemical yield. However, direct labeling of the Fab′ with Na[^{211}At]At and Chloramine-T resulted in a yield of <1% after quenching with NaS_2O_5. As another comparison, the same Fab′ was conjugated with *p*-[^{211}At]astatobenzoate NHS ester, [^{211}At]**1c**-Fab′, and (separately) with *p*-[^{125}I]iodobenzoate NHS ester, [^{125}I]**1b**-Fab′. An evaluation in athymic mice demonstrated that [^{211}At]**1c**-Fab′ underwent deastatination. In contrast, the high in vivo stability of [^{125}I]-**1b**-Fab′ allowed it to be used as a tracer control for the natural distribution of Fab′. Although found to be much more stable in vivo than [^{211}At]**1c**-Fab′, the biodistributions of *nido*-carborane conjugated Fab′ ([^{125}I]**2**-Fab′/[^{211}At]**2**-Fab′) and the bis-*nido*-carborane (VFC) ([^{125}I]**3**-Fab′/[^{211}At]**3**-Fab′) had very different in vivo distributions than the control [^{125}I]**1b**-Fab′. Biodistributions of *closo*-decaborate(2-) conjugates ([^{125}I]**4**-Fab′/[^{211}At]**4**-Fab′, [^{125}I]-**6**-Fab′/[^{211}At]**6**-Fab′, and [^{125}I]**7**-Fab′/[^{211}At]**7**-Fab′) demonstrated that they were stable to in vivo deastatination and had distributions similar to that of the control [^{125}I]**1b**-Fab′. In contrast, a benzyl-modified *closo*-decaborate-(2-) derivative evaluated in vivo ([^{125}I]**5**-Fab′/[^{211}At]**5**-Fab′) had a very different tissue distribution from the control. This study has shown that astatinated protein conjugates of *closo*-decaborate(2-) are quite stable to in vivo deastatination and that some derivatives have little effect on the distribution of Fab′. Additionally, direct ^{211}At labeling of Fab′ conjugated with *closo*-decaborate(2-) derivatives provide very high (e.g., 58−75%) radiochemical yields. However, in vivo data also indicate that the *closo*-decaborate(2-) may cause some retention of radioactivity in the liver. Studies to optimize the *closo*-decaborate(2-) conjugates for protein labeling are underway.

INTRODUCTION

The α-particle emitting radionuclide ^{211}At is of interest in targeted radionuclide therapy of cancer (*3*−*7*). Due to its decay properties, it is particulary attractive for therapy of micrometastatic disease (*8*, *9*). To be effective against cancer and to circumvent its high cytotoxicity, it is important to couple ^{211}At to a cancer targeting agent such as a monoclonal antibody (mAb[1]). Indeed, the potential for its use in cancer therapy when coupled to a targeting antibody was suggested over a half-century ago (*10*). However, it became apparent in early studies with ^{211}At that, unlike radioiodine, direct electrophilic labeling of proteins (*11*, *12*) results in a product that is rapidly deastatinated in vivo (*13*, *14*). This problem was circumvented a few years later by the incorporation of ^{211}At into an aromatic diazonium salt-containing compound, which in a second step was conjugated with a protein (*15*−*17*). Many modifications of this labeling approach were subsequently made, including the use of organometallic intermediates for rapid and efficient incorporation of ^{211}At into vinyl and aromatic compounds prior to protein conjugation (*18*−*21*).

A number of studies have shown that stability toward deastatination is not a problem for mAbs labeled with astatobenzoate derivatives when slowly metabolized intact mAbs and

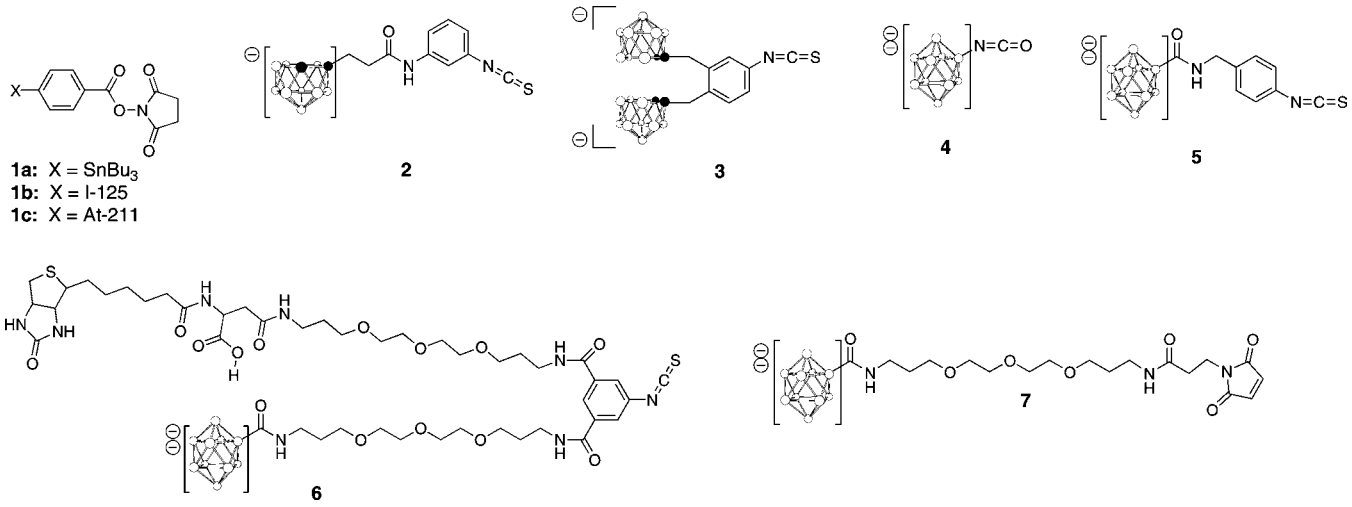

Figure 1. Structures of protein-reactive molecules used for conjugation with 107-1A4 Fab′. In the boron cage structures, white circles represent B or B−H atoms and black circles represent C or C−H atoms. In all conjugation reactions, except with **7**, the Fab′ sulfhydryl group was capped with NEM, and the conjugations were conducted by reaction with lysine amines at pH 8.5. Conjugation of compound **7** was conducted by reaction with the Fab′ sulfhydryl at pH 6.5 with the maleimide.

their $F(ab')_2$ fragments are used (*22*−*26*, *73*). However, when smaller, more rapidly metabolized mAb Fab′ fragments are used, deastatination occurs fairly rapidly. In our studies, the in vivo deastatination was surprising, as the ^{211}At-labeled Fab′ were quite stable to deastatination in vitro. The deastatination process observed for rapidly metabolized proteins is particularly problematic with ^{211}At, as its half-life is only 7.2 h. With such a short half-life, it is anticipated that smaller proteins and peptides will be required to adequately target the cancer before a significant fraction of the injected ^{211}At decays. Therefore, it is of critical importance to develop ^{211}At-labeling methods that circumvent the in vivo stability problem.

We have been investigating alternative methods for attaching ^{211}At to targeting molecules such that they are stable to in vivo deastatination (*27*, *28*). Although other investigators have evaluated a number of different aryl groups for ^{211}At labeling of mAbs (*29*, *30*), stability with the mAb Fab′ fragment has not been demonstrated. Thus, it seemed likely that a completely different approach might be required to obtain in vivo stability of more rapidly metabolized proteins, such as mAb Fab′ fragments, when labeled with ^{211}At. With this in mind, we are studying the use of boron cage moieties as pendant groups for radiolabeling of proteins and peptides with ^{211}At. The rationale behind this approach is that the boron−At bond should be stronger than a carbon−At bond based on the general trend for boron−halogen bond energies, and it may be more resistant to enzymatic reductive or oxidative cleavage. Prior studies involving small borane cage molecules have shown that some were deastatinated in vivo, but other boron cage molecules demonstrated in vivo stability, or the deastatination process was slower than for the aryl conjugates (*28*). An important aspect of using anionic boron cage moieties as pendant groups is that their astatination can be very rapid. This is important, as the alternative method, the two-step benzoate conjugation, is limited by hydrolysis to moderate overall radiochemical yields (40−60%). Therefore, we thought it might be possible to improve the in vivo stability and also improve the radiochemical yields if appropriate borane cage conjugates were used.

In the investigation described herein, the synthesis, conjugation, radiolabeling, and in vivo distribution of mAb Fab′ conjugated with a series of anionic boron cage-containing molecules was conducted. The boron cage molecules contained either a *nido*-carborane, a bis-*nido*-carborane, or *closo*-decaborate(2-) (*74*) cage moiety. The molecules conjugated with Fab′ in the studies are shown in Figure 1. The in vivo ^{211}At stability was assessed by coinjection of the same Fab′ conjugate radiolabeled with ^{125}I. Stability was noted by comparing the concentrations of ^{211}At and ^{125}I in the lung and spleen, tissues that localize ^{211}At but not radioiodine, and in the neck (containing thyroid) and stomach, tissues that localize both radionuclides when present as the halide. The rationale for using the mAb Fab′ in the study rather than another protein was based simply on the fact that prior studies had exhibited in vivo instability when labeled with *p*-[^{211}At]astatobenzoate. For comparison in this study, *p*-[^{211}At]astatobenzoyl- and *p*-[^{125}I]-iodobenzoyl-labeled Fab′ and directly labeled Fab′ were also prepared and evaluated in vivo.

EXPERIMENTAL PROCEDURES

General. Chemicals purchased from commercial sources were analytical grade or better and were used without further purification. 4-Pentynoic acid, **8**, was obtained from Lancaster (Windham, NC) or Farchan Laboratories (Gainesville, FL). Decaborane ($B_{10}H_{14}$) was obtained from Alfa Aesar (Ward Hill, MA). Chloramine-T (ChT) and phosphate buffered saline (PBS) were obtained from Sigma (St. Louis, MO). NHS-3-maleimidoproprionate, **24**, was obtained from Quanta BioDesign (Powell, OH; quantabiodesign.com). Iodobenzoic acid, 4-aminobenzylamine, **15**, 4,7,10-trioxatridecanediamine, **21**, and most other chemicals were obtained from Aldrich Chemical Co. (Milwaukee, WI). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Tetrafluorophenyl trifluoroacetate (TFP-OTFA) was prepared as previously described (*31*). Silica gel chromatography was conducted with 70−230 mesh 60 Å silica gel (Aldrich Chemical Co.). Sephadex G-25 desalting columns (PD-10 and NAP-10) were obtained from Amersham Biosciences (Piscataway, NJ). Centricon-30 centrifugation concentrators were obtained from Amicon (Beverly, MA). Melting points were obtained in open capillary tubes on a Mel-Temp II apparatus with a Fluke 51 K/J electronic thermometer and are uncorrected.

Radioactive Materials. All radioactive materials were handled according to approved protocols at the University of Washington. Standard methods for safely using radionuclides of iodine were employed (*32*). Na[^{125}I]I was purchased from Perkin-Elmer Life Sciences (Billerica, MA) as high concentration/high specific activity radioiodide in 0.1 N NaOH. Measurement of ^{125}I and ^{211}At were conducted on a Capintec CRC-15R Radioisotope Calibrator using calibration numbers 319 and 44, respectively

(designated by Capintec Technical Services). Tissue samples containing ^{211}At and ^{125}I were counted in a Wallac 1480 Wizard gamma counter (Perkin-Elmer Life and Analytical Services, Wellesley, MA). The tissue samples were initially counted to obtain both ^{211}At and ^{125}I counts, then were recounted after 3−5 days (0.1% or less ^{211}At remaining) to obtain ^{125}I counts. Radioactivity counts were imported into an *Excel* spreadsheet (Microsoft Corp., Redmond, WA) where calculations were made. The ^{211}At counts were obtained by subtracting ^{125}I counts from total counts. Individual tissue counts for ^{211}At were corrected for decay from the time of counting the first standard (at the beginning of the tissue counting process).

^{211}At was produced by irradiation of a thin layer (0.003 mm) bismuth metal (99.999%, Aldrich) with 28 MeV α-particles on a Scandatronix MP-50 cyclotron using the conditions previously described (*26*). All handling and processing of the irradiated target was done in a glove box (Innovative Technologies, Inc., radioisotope glove box) which was vented through a charcoal filter. During the study, varying distillation conditions were used. The following was found to provide the highest distillation yields.

Distillation of the ^{211}At from the irradiated target was conducted by first inserting the target into an oven heated to 650−700 °C under slightly negative pressure (vacuum pump on), followed by closure of the distillation apparatus to provide a slight vacuum with a flow of argon gas. The distilled ^{211}At was trapped in a coiled PEEK tube (1 mm i.d. × 35 cm length) which was cooled in a dry ice/$CHCl_3$ trap as previously described (*33*). The distillation process was monitored with a NaI detector by taking readings of the γ-rays emitted from the oven and PEEK tubing. When it was apparent that no additional ^{211}At was being distilled, the PEEK tubing was disconnected and rinsed into a vial with 0.6 mL of $CHCl_3$. Following this, an aliquot of 0.05 N aqueous NaOH (e.g., 0.5 mL) was added, and the mixture was shaken. Then, a portion of the activity in the aqueous layer was removed for use in the labeling experiments. The radioactive sample was tightly sealed, placed in a Ziploc plastic bag, then taken from the glove box and placed in the radiolabeling enclosure within a fume hood.

All radiohalogenation reactions were conducted in a charcoal-filtered Plexiglas enclosure (radioiodine fume hood, 20 × 24 × 36 in^3, Biodex Medical Systems Inc., Shirley, NY) housed within a radiochemical fume hood. The radiohalogenation reactions were conducted in vials capped with Teflon-coated septa and were vented through a 10 mL charcoal filled syringe. Additions of reagents to, or removal of materials from, the radiohalogenation vessel was conducted by passing a syringe needle through the septa.

Spectral Analyses. ^{1}H NMR and ^{11}B NMR spectra were obtained on either a Bruker AV 300 (300 MHz) or Bruker AV 500 (500 MHz) instrument. Proton chemical shifts are expressed as parts per million (ppm) using tetramethylsilane as an internal standard ($\delta = 0.0$ ppm). Boron chemical shifts used $BF_3{\cdot}OEt_2$ as an internal standard. High-resolution mass spectral (HRMS) data were obtained on a Bruker APEX III 47e Fourier transform mass spectrometer using electrospray ionization. For analysis, the samples were dissolved in 50/50 MeOH/H_2O and were introduced by an integral syringe infusion pump (Cole Parmer series 74900). Isothiocyanate derivatives (**5**, **6**) and the bis-TFP ester-containing compound **18** gave erroneous mass data under the conditions studied.

Analytical Chromatography. All synthetic reactions were monitored by HPLC. Samples were assessed on a system that contained a Hewlett-Packard quaternary 1050 gradient pump, a variable-wavelength UV detector (254 nm), and a Varex ELSD MKIII evaporative light-scattering detector. Analyses of HPLC data were conducted using Hewlett-Packard HPLC *ChemStation* software. Reversed-phase HPLC chromatography was carried out on an Alltech Altima C-18 column (5 μm, 250 × 4.5 mm) using a gradient solvent system at a flow rate of 1 mL/min. A gradient of MeOH and H_2O/0.1% HOAc was used. Starting with 40% MeOH, the initial solvent mixture was held for 2 min; then, the gradient was increased to 100% MeOH over the next 10 min and then held at 100% MeOH for 8 min. Retention times (t_R) under these conditions for biotin compounds are provided with the compound experimental.

Size exclusion HPLC (SE-HPLC) separations of the conjugates of Fab′ were obtained on Hewlett-Packard isocratic system consisting of a model 1050 pumping system and a model 1050 multiple wavelength detector (280 nm). Proteins were evaluated on a Protein Pak 300 SW glass size exclusion column (10 μm, 8 mm × 30 cm, Waters Corporation, Milford, MA) run at 1.0 mL/min eluting with 50 mM sodium phosphate buffer (pH 6.8) which contained 300 mM NaCl, 1 mM EDTA, and 1 mM sodium azide. Analyses of the HPLC data were conducted using Hewlett-Packard HPLC *ChemStation* software. Retention times (t_R) for F(ab′)$_2$ were 9.2 min and for Fab′ or its conjugates were ∼10.5 min.

Preparation of the following compounds was conducted as previously described: 4-(tri-*n*-butylstannyl)benzoic acid NHS ester **1a** (*34*); decahydro-*closo*-decaborate(2-) ion, [*closo*-$B_{10}H_{10}]^{2-}$ **13** (*35*); 1-(*N*-biotinyl)-L-aspartyl-4,7,10-trioxatridecane-1,13-diamine (TFA salt), **19** (*36*).

3-(*nido*-carboranyl)-*N*-3-isothiocyanatophenyl)propionamide, 2. This compound was prepared in five synthetic steps from 4-pentynoic acid, **8**, as previously described (*28*).

3,4-Bis-(*nido*-carboranylmethyl)phenylisothiocyanate, 3. The intermediate 3,4-bis(*nido*-carboranylmethyl)aniline **12** was prepared in six synthetic steps as previously described (*26*). A solution of **12** (12.6 mg; 25 μmol) and thiocarbonyldiimidazole (TCDI; 8.9 mg; 50 μmol) in anhydrous DMF (1 mL) was stirred at room temperature for 1 h. Then, the reaction mixture was dropped slowly into 20 mL of ether with stirring at room temperature. The precipitate was filtered and washed with ether to give 13 mg (95%) of **3** as a solid. Mp 114−116 °C. ^{1}H NMR (CD_3CN, 500 MHz): δ −0.37−2.30 (br m, 18H), 1.69 (br s, 4H), 2.73−2.78 (m, 3H), 2.79 (s, 4H), 2.92−2.97 (m, 2H), 5.75 (br s, 9H), 7.09−7.14 (m, 2H), 7.23 (dd, $J = 4.1$, 8.0 Hz, 1H), 7.34 (d, $J = 1.0$ Hz, 3H), 8.32 (s, 2H). ^{11}B NMR (CD_3CN, decoupled, 96.29 MHz): δ −9.5 (2B), −10.7 (2B), −13.2 (2B), −15.6 (2B), −18.7 (4B), −21.1 (2B), −32.7 (2B), −36.2 (2B). LRMS (ES^-) calcd for $C_{13}H_{28}B_{18}NS$ $(M-H)^-$: 428.4. Found: 428.4. HPLC: $t_R = 14.5-14.6$ min.

2-Isocyanatononahydro-*closo*-decaborate(2-) ion, [*closo*-2-$B_{10}H_9$-NCO]$^{2-}$ 4. This compound was prepared by reaction of $[Et_3NH]_2[B_{10}H_{10}]$, **13**, with oxalyl chloride and NaN_3 in acetonitrile as previously described (*37*).

2-Carbonylnonahydro-*closo*-decaborate(2-) ion, [*closo*-2-$B_{10}H_9$-CO]$^{1-}$ 14. This compound was prepared in 92% yield by the method previously described for preparation of the isocyanate **4**, but the NaN_3 addition was omitted (*37*).

2-(4′-Aminobenzyl)amidononahydro-*closo*-decaborate-(2), 16. Et_3N (0.12 mL, 0.86 mmol) was added to a solution containing 4-aminobenzylamine, **15** (0.35 g, 2.86 mmol), $[Et_3NH][B_{10}H_9$-CO], **14** (0.1 g, 0.40 mmol), and anhydrous CH_3CN (10 mL) at room temperature. The resultant solution was heated to reflux for 3 h. After the solution was cooled to room temperature, EtOAc (40 mL) was added to triturate the product. The residue was washed with EtOAc (3 × 20 mL) and dried under vacuum for 16 h to provide 124 mg (92%) of **16** as a tacky brown solid. ^{1}H NMR (500 MHz, DMSO-d_6): δ −0.05−3.49 (m, 9H), 3.66 (s, 2H), 5.04 (br s, 2H), 6.52 (d, $J = 8.4$ Hz, 2H), 7.03 (d, $J = 8.3$ Hz, 2H). ^{11}B NMR (*n*-Bu_4N salt, 160.43 MHz, CD_3CN): δ −0.90 (2B), −23.27 (2B),

−26.05 (2B), −26.85 (4B). LRMS (ES⁻) calcd for $C_8H_{17}B_{10}N_2O$ $(M-H)^-$: 267.2. Found: 267.1. HPLC: t_R = 2.4 min.

2-(4′-Isothiocyanatobenzyl)amidononahydro-*closo*-decaborate(2-), 5. TCDI (50 mg, 0.28 mmol) was added to a solution of compound $[Et_3NH]_2$**16** (100 mg, 0.21 mmol), Et_3N (60 mL, 0.43 mmol), and anhydrous DMF (8 mL) at room temperature, and the resultant solution was stirred for 1 h. EtOAc (30 mL) was added and stirred for another 20 min. The solvents were decanted, and the residue was washed with EtOAc (3 × 20 mL) and dried under vacuum to yield 98 mg (91%) of a tacky brown solid. A portion of the crude product was used directly for conjugation with the Fab′. ^{1}H NMR (500 MHz, DMSO-d_6): δ −0.53−3.47 (m, 9H), 7.94 (s, 4H), 9.16 (s, 2H), 10.71 (br s, 4H). ^{11}B NMR (*n*-Bu_4N salt, 160.43 MHz, CD_3CN): δ −0.84 (2B), −23.26 (2B), −26.03 (2B), −26.90 (4B). HPLC t_R = 2.5 min.

5-Aminoisophthalate Bis-tetrafluorophenyl Ester, 18. To a solution of of 5-aminoisophthalic acid, **17** (1.0 g, 5.52 mmol), and 2,3,5,6-tetrafluorophenol (2.02 g, 12.14 mmol) in 50 mL of anhydrous DMF was added EDC (2.33 g, 12.14 mmol). The reaction mixture was stirred at room temperature for 16 h, then the solution was evaporated to dryness. The crude product was purified by silica gel column (2.5 × 25 cm) eluting with 10% EtOAc/hexanes solution to afford 1.64 g (63%) of a colorless solid, mp 190.2−191.4 °C. ^{1}H NMR 500 MHz (CD_3CN): δ 4.53 (s, 2H), 7.12−7.19 (m, 2H), 7.76 (d, J = 1.4 Hz, 2H), 8.29 (t, J = 1.5 Hz, 1H). HPLC: t_R = 15.0 min.

5-Amino-(3-((15′-((*N*-biotinyl)-*β*-L-Aspartyl)-4,7,10-trioxapentadecanylamino)-isophtalamic Acid 2,3,5,6-tetrafluorophenyl Ester, 20. Biotin-Asp-OH-trioxadiamine TFA salt, **19** (71 mg, 0.11 mmol), and Et_3N (35 μL, 0.25 mmol) in anhydrous DMF (5 mL) was added slowly over 30 min to a solution containing 5-aminoisophthalate diTFP ester **18** (50 mg, 0.11 mmol) and anhydrous DMF (3 mL) at room temperature. The resultant mixture was then stirred at room temperature for an additional 10 min. The volatile materials were removed by rotoevaporation, and the residue was purified by silica gel column (1.5 × 25 cm, 40% MeOH/EtOAc) to yield 65 mg (71%) of **20** as a colorless tacky solid. ^{1}H NMR (CD_3OD, 500 MHz): δ 1.38−1.49 (m, 2H), 1.54−1.60 (m, 1H), 1.65 (t, J = 7.3 Hz, 2H), 1.69−1.74 (m, 3H), 1.87−1.92 (m, 2H), 2.19−2.29 (m, 2H), 2.58 (dd, J = 7.6, 14.8 Hz, 1H), 2.68 (d, J = 13.0 Hz, 1H), 2.75 (dd, J = 5.0, 14.8 Hz, 1H), 2.91 (dd, J = 5.0, 12.6 Hz, 1H), 3.16−3.20 (m, 1H), 3.30−3.31 (m, 2H), 3.23 (t, J = 7.1 Hz, 2H), 3.48 (q, J = 7.1 Hz, 3H), 3.52−3.54 (m, 2H), 3.59−3.66 (m, 7H), 4.30 (dd, J = 4.5, 8.0 Hz, 1H), 4.47 (dd, J = 4.6, 7.9 Hz, 1H), 4.56 (dd, J = 4.8, 7.3 Hz, 1H), 7.44−7.51 (m, 1H), 7.45 (s, 1H), 7.60 (s, 1H), 7.84 (s, 1H). HRMS (ES^+) calcd for $C_{38}H_{48}F_4N_6NaO_{11}S$ $(M+Na)^+$: 895.2936. Found: 895.2923. HPLC: t_R = 12.4 min.

[Et$_3$NH]B$_{10}$H$_9$-CO-trioxadiamine, 22. A reaction solution containing $[Et_3NH][B_{10}H_9-CO]^{1-}$, **14**, (0.50 g, 2.02 mmol) and 4,7,10-trioxa-1,13-tridecanediamine, **21**, (5 mL) was stirred at room temperature for 3 days. The solution was triturated with diethyl ether (15 mL). After solvents were removed, the residue was washed with diethyl ether (5 × 15 mL) and dried under vacuum to afford 0.55 g (68%) of **22** as a tacky light-brown solid, which was used directly for the next step reaction. ^{1}H NMR (CD_3CN, 500 MHz): δ 1.56 (t, J = 7.2 Hz, 18H), 2.24−2.26 (m, 2H), 2.68 (t, 7.1 Hz, 4H), 2.89 (s, 2H), 3.41−3.47 (m, 19H), 3.74 (t, J = 6.1 Hz, 4H), 3.78−3.89 (m, 12H), 3.98 (t, J = 7.2 Hz, 4H), 6.99 (br s, 1H), 7.06 (s, 2H), 7.07 (br s, 1H). ^{11}B NMR (*n*-Bu_4N salt, 160.43 MHz, CD_3CN): δ −0.92 (2B), −23.70 (2B), −27.85 (6B).

3-((15′-(*N*-Biotinyl)-*β*-L-aspartyl-4,7,10-trioxapentadecanylamino)-1-((13-nonahydro-*closo*-decaborate(2-))-4,7,10-trioxatridecanediamine)-aminoisophthalic Acid, 23. [Et_3NH]-$B_{10}H_9$-CO-trioxadiamine **22** (32 mg, 68.7 μmol) in anhydrous DMF (3 mL) was added dropwise to a solution containing **20** (60 mg, 68.7 μmol), Et_3N (20 μL, 0.143 mmol), and anhydrous DMF (5 mL) at room temperature. The resultant solution was stirred at room temperature for 10 min; then, EtOAc (40 mL) was added and stirred for another 10 min. After solvents was decanted, the residue was washed with 10% MeOH/EtOAc (3 × 30 mL) and dried under vacuum to afford 56 mg (76% yield) of **23** as a tacky light-brown solid. ^{1}H NMR (500 MHz, CD_3-OD): δ 1.38−1.47 (m, 2H), 1.52−1.75 (m, 8H), 1.85−1.94 (m, 8H), 2.19−2.30 (m, 2H), 2.63−2.78 (m, 4H), 2.88−2.93 (m, 1H), 3.07−3.11 (m, 2H), 3.15−3.19 (m, 1H), 3.21−3.25 (m, 2H), 3.29−3.31 (m, 2H), 3.45−3.48 (m, 8H), 3.51−3.54 (m, 2H), 3.58−3.67 (m, 24H), 4.29 (dd, J = 4.5, 8.0 Hz, 1H), 4.48 (dd, J = 4.6, 8.1 Hz, 1H), 4.71−4.74 (m, 1H), 7.21−7.23 (m, 2H), 7.43−7.45 (m, 1H). ^{11}B NMR (160.43 MHz, CD_3-OD): δ −0.98 (2B), −23.83 (2B), −28.06 (6B). LRMS (ES^-) calcd for $C_{43}H_{78}B_{10}N_8O_{14}S$ $(M)^-$: 1072.6. Found: 1072.5. HPLC: t_R = 11.4 min.

1-Isothiocyanato-3-((15′-(*N*-biotinyl)-*β*-L-aspartyl-4,7,10-trioxapentadecanylamino)-1-((13-nonahydro-decaborate(2-))-4,7,10-trioxatridecanediamine)-aminoisophthalic Acid, 6. A solution of compound **23** (50 mg, 42.6 mmol), TCDI (10 mg, 56.1 mmol), and anhydrous DMF (6 mL) was stirred at room temperature for 1 h. After the reaction solution was washed 5× with 20 mL 10% EtOAc/hexanes, the residue was dried under vacuum for 3 h to yield 51 mg (98%) of **6** as a tacky light-brown solid. ^{1}H NMR (500 MHz, CD_3OD): δ 1.40−1.47 (m, 2H), 1.54−1.73 (m, 6H), 1.86−1.92 (m, 6H), 2.20−2.30 (m, 2H), 2.62−2.77 (m, 3H), 2.89−2.93 (m, 1H), 3.17−3.24 (m, 4H), 3.29−3.31 (m, 3H), 3.46−3.51 (m, 8H), 3.54−3.65 (m, 18H), 4.31 (dd, J = 4.4, 8.0 Hz, 1H), 4.49 (dd, J = 4.5, 8.1 Hz, 1H), 4.64−4.68 (m, 1H), 7.87 (s, 1H), 8.21 (s, 1H), 8.27 (s, 1H). ^{11}B NMR (160.43 MHz, CD_3OD): δ −1.03 (2B), −23.85 (2B), −28.01 (6B). HPLC: t_R = 12.8 min.

***N*-(15-(Aminoacyldecaborate)-4,7,10-trioxatridecanyl)-3-maleimidopriopionamide, 7.** NHS-3-maleimidopropionate, **24** (70 mg, 0.26 mmol), was added to a solution of [Et_3NH]$B_{10}H_9$-CO-trioxadiamine, **22** (100 mg, 0.18 mmol), Et_3N (45 μL, 0.32 mmol), and anhydrous DMF (5 mL). The resultant solution was stirred at room temperature for 2 h. Then, 20 mL of hexanes/EtOAc (90/10) was added, and the solution was stirred for an additional 30 min at room temperature. The solvents were decanted, and the residue was washed with 20 mL of hexanes/EtOAc (90/10) three times. The residue dried under vacuum for 4 h to yield **7** as a light-yellow tacky solid. Yield 110 mg (87%). ^{1}H NMR (DMSO-d_6): δ 1.18 (t, J = 7.3 Hz, 9H), 1.52−1.66 (m, 6H), 1.72−1.81 (m, 3H), 2.31 (t, J = 7.3 Hz, 4H), 2.80−2.86 (m, 2H), 2.99−3.12 (m, 10H), 3.34−3.62 (m, 14H), 7.01 (s, 2H), 7.90−7.95 (m, 3H). LRMS (ES^-) calcd for $C_{18}H_{35}B_{10}N_3O_7$ $(M-2H)^-$: 515.4. Found: 515.4. HPLC: t_R = 7.0 min.

Preparation of Fab′-S-NEM. The monoclonal antibody 107-1A4, an IgG_1 mAb reactive with the PSMA antigen on prostate cells, was obtained and purified as previously described (*38*). Fragmentation of 107-1A4 was accomplished using pepsin (6.5 μg/mL in 10 mM NaOAc, pH 3.9) at 37 °C for 24 h. The resultant $F(ab')_2$ was purified on a Fractogel TMAE column (EM Science, Gibbstown, NJ). The isolated $F(ab')_2$ was concentrated to 8.4 mg/mL, and aliquots were stored.

To 500 μL of a 8.4 mg/mL solution of 107-1A4 $F(ab')_2$ was added 20 μL of a 100 mM DTT solution in H_2O. The solution was placed on a rotator for 1 h at room temperature. The progress of the reaction was evaluated by HPLC analysis of a small aliquot (e.g., 10 μL). After 1 h, the reaction was complete, so the reaction solution was placed on a Sephadex G-25 (PD-10) column that was equilibrated with 20 mM sodium phosphate, pH 6.5, containing 1 mM EDTA. The column was eluted with

the same buffer, collecting 1 mL fractions. The protein-containing fractions were combined, and protein recovery was evaluated by UV at 280 nm. A recovery of 99% was obtained in 2.2 mL at 1.9 mg/mL.

To 2 mL of a 1.9 mg/mL solution of Fab′ was added 76 μL (50 equiv, 10 mg/mL) of a solution containing *N*-ethylmaleimide (NEM) in DMSO. The reaction was allowed to proceed at room temperature for 30 min. Then, the reaction mixture was placed in a Centricon-30 ultracentifugation filter prewashed with 1 mL 20 mM phosphate buffer, pH 7.2, and centrifuged at 3200 rpm for 15 min to concentrate the solution to 100 μL. The centrifuge retentate was rinsed 4× using 500 μL of the phosphate buffer, reducing the volume to 100 μL each rinse. The final protein concentration was determined by UV as described above and gave 71% recovery (2.7 mg at 3.3 mg/mL).

Fab′-NEM Conjugations with 2, 3, 4, 5, or 6. To 500 μL of 107-1A4 Fab′-NEM (2 mg/mL in 50 mM $NaHCO_3$, pH 8.5) was added 5, 10, or 20 equiv of **2**, **3**, **4**, **5**, or **6** in 20 μL DMSO or 75 μL 10% DMSO in H_2O. The reaction solution was tumbled gently overnight at room temperature. The reaction solution was then placed on a Sephadex G-25 (PD-10) column that had been equilibrated in PBS, pH 7.2, and eluted with the same buffer. Fractions containing protein were combined and concentrated in a Centricon-30 ultracentrifugation unit to give 30−80% recovery.

Fab-SH Conjugation with 7. 107-1A4 Fab′-SH (without NEM capping) was prepared as described above. To 1 mL of a 1.9 mg/mL Fab′ solution was added 54 μL of a 10 mg/mL solution of **7** (20 equiv) in DMF. After 1 h at room temperature, the mixture was eluted on a Sephadex G-25 (PD-10) column that had been equilibrated in PBS, pH 7.2. The fractions containing protein were pooled and concentrated in a Centricon-30 to give a 1 mL volume of a 1.5 mg/mL solution (84% recovery).

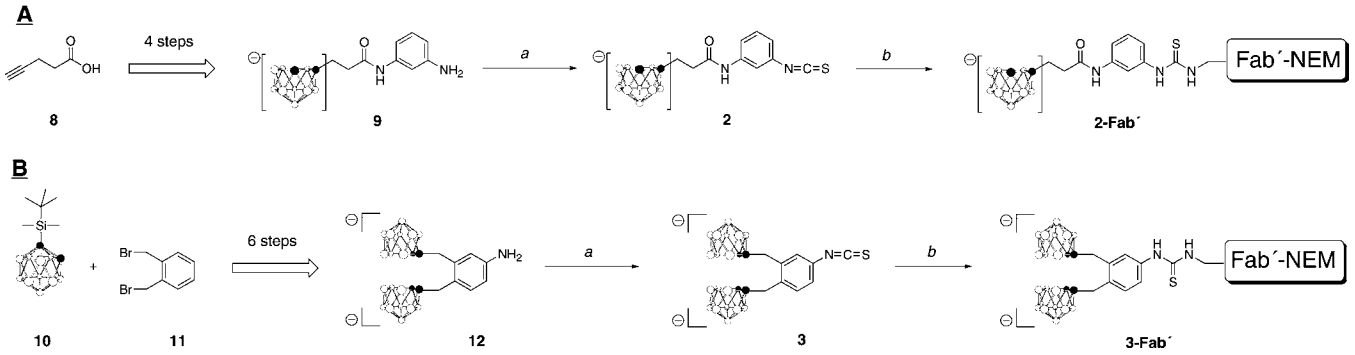
Fab′ Conjugate Characterization. All Fab′ conjugates were evaluated by SE-HPLC as described above. All non-radioactive Fab′ conjugates were also evaluated on isoelectric focusing gels to determine changes in charge (pI) on the molecules as described below. Additional information on the number of conjugates per Fab′ was obtained for the conjugate of **6**, which contained the biotin moiety, by conducting a HABA analysis (*39*) as described below.

Isoelectric Focusing. IEF analyses were conducted on a Novex PowerEase 500 instrument with the XCell II chamber using Invitrogen (Novex) precast gels, pH 3−10 or pH 3−7 (1.0 mm × 12 well), running under the standard IEF program. The protein was stained with GelCode Blue Stain (Pierce). IEF standards were from Serva Electrophoresis GmbH: pH 10.7, cytochrome C; 9.5, ribonuclease A; 8.3, 8.0, 7.8, lectin; 7.4, 6.9, myoglobin; 6.0, carbonic anhydrase; 5.3, 5.2, β-lactoglobulin; 4.5, trypsin inhibitor; 4.2, glucose oxidase; 3.5, amyloglucosidase.

Biotin Quantification. Biotin quantification was accomplished using the HABA-avidin procedure as outlined by the manufacturer (Pierce Biotechnology, Inc., Rockford, IL). Briefly, a 900 μL aliquot of HABA-avidin solution is placed in a cuvette, and the UV absorbance was measured at 500 nm. Following that measurement, 100 μL of the conjugated antibody is added to the cuvette and mixed well. The UV absorbance is again measured at 500 nm, and the value is taken after it stabilizes for at least 15 s. This value is the A_{500} biotin from which the number of mmoles of biotin/mL mixture can be calculated. Once obtained, the calculated mmoles biotin/mL are divided by the mmol antibody/mL solution obtained from the BCA or UV analysis to give the number of conjugates per antibody.

Labeling with *p*-[^{211}At]astatobenzoate NHS Ester and *p*-[^{125}I]iodobenzoate NHS Ester. The *p*-stannylbenzoate NHS ester, **1a**, (100 μg) was dissolved in 100 μL MeOH/5% HOAc. To that solution was added a maximum of 20 μL (500 μCi to 1 mCi) Na[^{211}At]At or Na[^{125}I]I in 0.1 N NaOH, followed by 20 μL of a 1 mg/mL solution of *N*-chlorosuccinimide (NCS) in H_2O. After 5 min at room temperature, 20 μL of a 1 mg/mL solution of $Na_2S_2O_5$ was added. The reaction mixture was then reduced to dryness under a stream of Ar. To the residue was added 0.5−1 mg Fab'-NEM (5 mg/mL in 0.25 M Na Borate, pH 8.5). After 15 min at room temperature, the mixture was eluted with PBS, pH 7.2, over a preequilibrated Sephadex G-25 (PD-10) column. Protein fractions were combined, and the concentration was determined by UV_{280}.

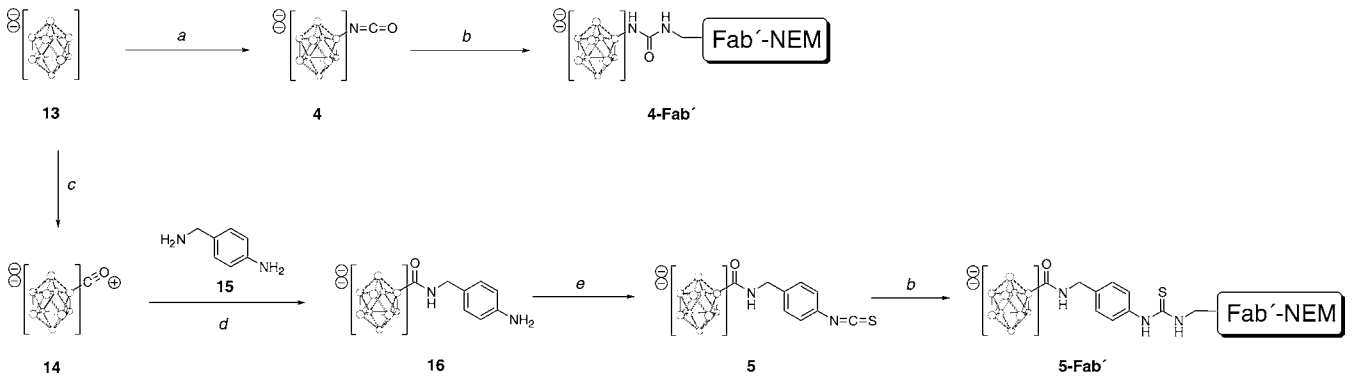
General Method for Radiolabeling Fab′-S-NEM Conjugates of 2, 3, 4, 5, and 6 with Na[^{211}At]At and Na[^{125}I]I. To 500−800 μg of Fab′ conjugate in PBS was added 2−100 μL of Na[^{125}I]I or Na[^{211}At]At, then 20−40 μL of Chloramine-T (1 mg/mL) in H_2O. The reaction was allowed to proceed for 30 s to 2 min; then, 20−40 μL of a 1 mg/mL solution of $Na_2S_2O_5$ in H_2O was added to quench the reaction. The reaction mixture was placed on a NAP-10 column and was eluted with PBS. The amount of activity associated with the protein was measured in a dose calibrator.



Biodistribution Studies. Animal use and procedures were approved by the University of Washington's Institutional Animal Care and Use Committee. All reagents were administered to BALB/c nu/nu mice in a total volume of approximately 100 μL (injectate weighed) via the lateral tail vein. Injections and euthanasia of the animals were done at predetermined times. Blood samples were obtained by cardiac puncture immediately before sacrifice. Urine samples were obtained by syringe bladder tap at the time the tissues were excised. The tissues excised included muscle, lung, kidney, spleen, liver, intestines, neck (with thyroid), and stomach. Excised tissues were blotted free of blood, weighed, and counted. Calculation of the percent injected dose (%ID) and percent injected dose per gram (%ID/g) of radioactivity in the tissues was based on standards containing 1 μL of the injected dose. The ^{211}At counts were corrected for decay. Total blood volume was estimated to be 8% of body weight. The data obtained are provided in Tables S1−S8 in the Supporting Information. The amount of ^{125}I and ^{211}At administered to mice and the average mouse weight in each biodistribution are provided in the table legends.

RESULTS

Synthesis of Protein-Reactive Boron Cage Molecules. The syntheses of the protein-reactive *nido*-carboranyl derivatives **2** and **3** are shown in Scheme 1 (sequences A and B). *N*-(3-Aminophenyl)-3-(*nido*-carboranyl)propionamide **9** was prepared in four synthetic steps as previously described (*28*). Conversion of the aniline amine in **9** to the amine-reactive isothiocyanate **2** was achieved in nearly quantitative yield using thiocarbonyldiimidazole (TCDI) in DMF at room temperature for 30 min. Likewise, 3,4-bis-(*nido*-carboranylmethyl)aniline, **12**, was prepared in six synthetic steps as previously described (*28*). Conversion of the aniline amine in **12** to the amine-reactive isothiocyanate **3** was achieved using the same condition as for **2** to give **3** in 95% yield.



The syntheses of two amine-reactive decaborate(2-) derivatives, **4** and **5**, are shown in Scheme 2. Synthesis of 2-isothiocyanato-nonahydro-*closo*-decaborate(2-) ion [*closo*-2-$B_{10}H_9$-NCO]$^{2-}$, **4**, was accomplished in high yield by reaction of decahydro-*closo*-decaborate(2-) ion [*closo*-2-$B_{10}H_{10}$]$^{2-}$, **13**, with oxalyl chloride and NaN_3 as previously described (*37*). Synthesis of the 2-isocyanatobenzylamidononahydro-*closo*-decaborate(2-) derivative **5** began by reaction of decahydro-*closo*-decaborate(2-) ion [*closo*-2-$B_{10}H_{10}$]$^{2-}$, **13**, and oxalyl chloride to give 92% of 2-carbonylnonahydro-*closo*-decaborate(2-), **14**, as previously

Scheme 1 . Syntheses of Amine-Reactive *nido*-Carboranyl Derivatives 2 and 3 and Conjugation with Fab′-NEM[a]

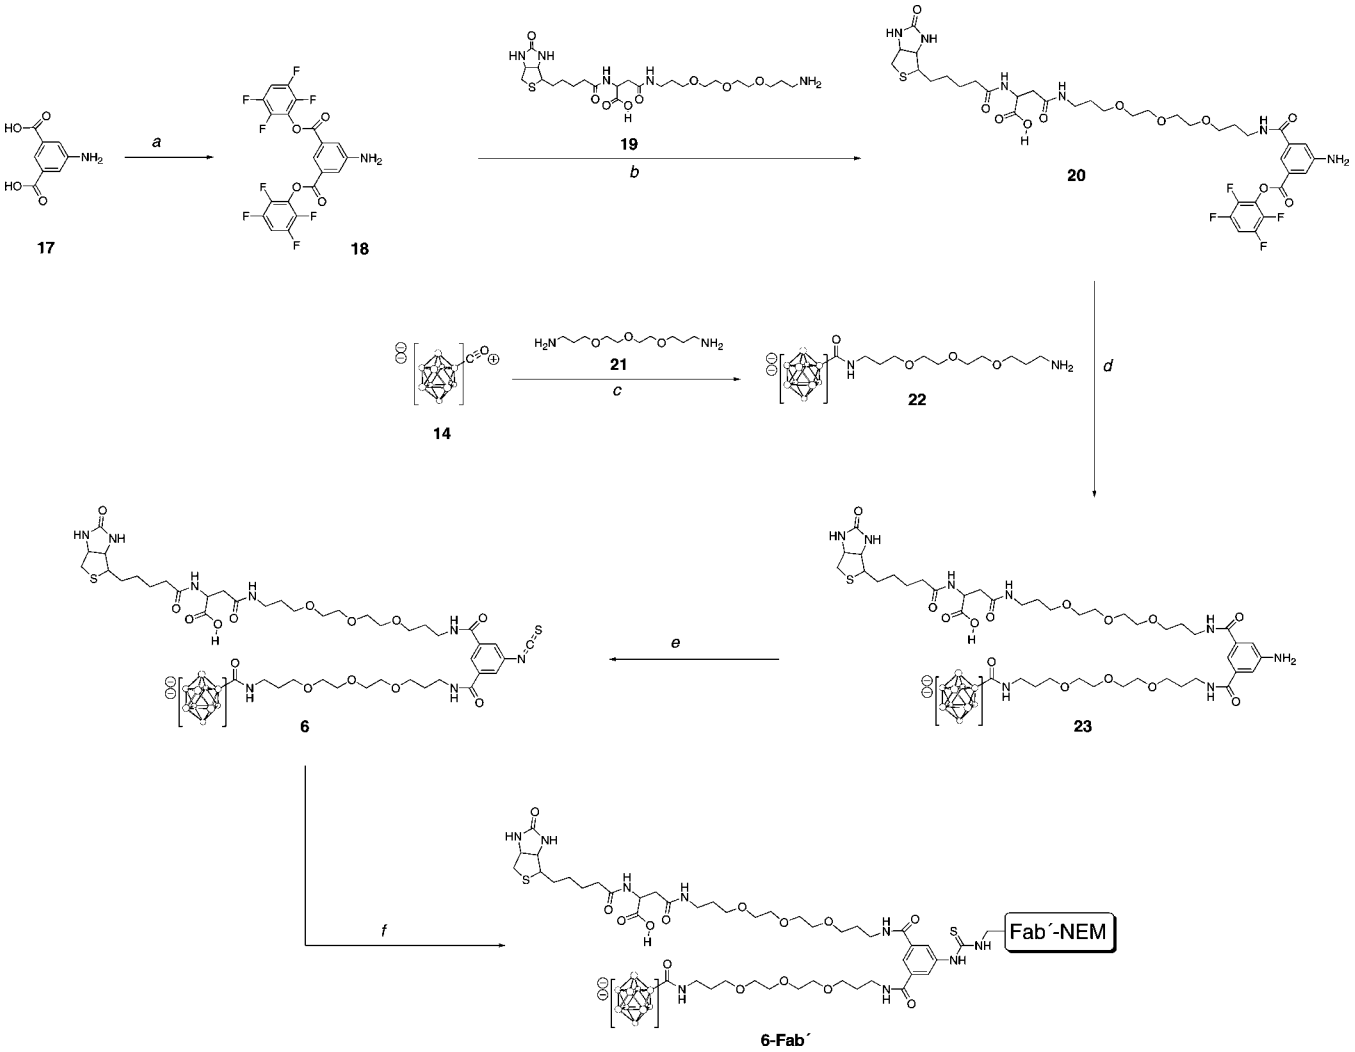
[a] Reagents and conditions: (a) TCDI, DMF, RT, 30 min, 99%; (b) Fab′-NEM, H_2O, $NaHCO_3$, pH 8.5, **2** or **3** in DMSO/H_2O, RT, 16−20 h.

Scheme 2 . Synthesis of Amine-Reactive Decaborate(2-) Derivatives 4 and 5 and Conjugation with Fab′-NEM[a]

[a] Reagents and conditions: (a) ClCOCOCl, NaN_3, CH_3CN, RT, 16−20 h; (b) Fab′-NEM, H_2O, $NaHCO_3$, pH 8.5, **4** or **5** in DMSO/H_2O, RT, 16−20 h; (c) ClCOCOCl, CH_3CN, RT, 16−20 h; (d) **15**, Et_3N, CH_3CN, RT, 3h, 92%; (e) TCDI, DMF, RT, 30 min, 91%.

described (*37*). In the next step, refluxing **14** with 4-aminobenzylamine, **15**, and Et_3N in acetonitrile for 3 h provided the benzylamine adduct **16** in 92% yield. Reaction of **16** with TCDI in DMF at room temperature gave 91% yield of crude **5**.

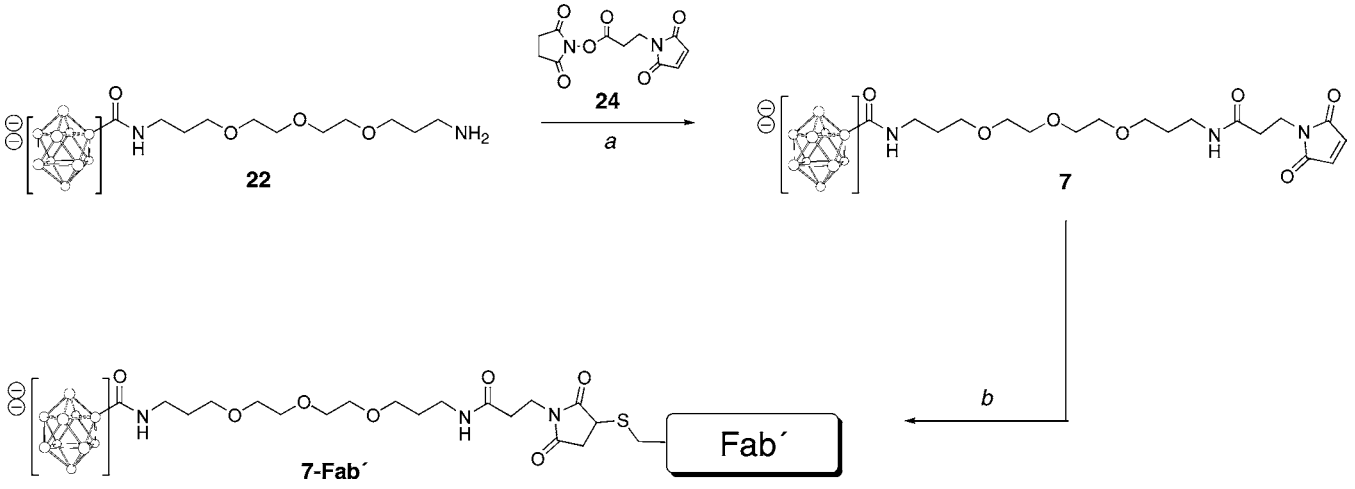
Synthesis of the protein-reactive decaborate(2-) derivative that also contains a biotin moiety, **6**, is shown in Scheme 3. An initial attempt at synthesizing **6** began with N-Boc-protected aminoisophthalic acid (*40*), but deprotection in a later step was problematic. In the successful synthesis, the ditetrafluorophenyl ester, **18**, was prepared in 63% yield by reaction of aminoisophthalic acid, **17**, with tetrafluorophenol (TFP-OH) and EDC in DMF. Reaction of **18** with the biotin derivative **19** and Et_3N in DMF provided **20** in 71% yield. Biotin derivative **19** was prepared as previously described (*36*). The decaborate(2-) derivative **22** was prepared in 68% yield by reaction of 4,7,10-trioxatridecane-1,13-diamine, **21**, with the 2-carbonyl-nonahydro-*closo*-decaborate(2-) ion, **14**. After preparation of **22**, that compound was reacted with **20** and Et_3N in DMF to provide **23** in 76% yield. Reaction of **23** with TCDI in DMF for 1 h provided the protein-reactive **6** in 98% yield.



Synthesis of the protein reactive decaborate(2-) derivative containing a maleimide functionality, **7**, is shown in Scheme 4. The product was obtained in 87% yield by reaction of **22** with the commercially available reagent 3-maleimidopropionate *N*-hydroxysuccinimidyl ester, **24**, and Et_3N in DMF for 2 h.

Protein Conjugation. The protein used in the studies was a Fab′ fragment of the anti-PSMA antibody, 107-1A4 (*38*). To prepare the Fab′ fragment, the intact antibody was digested following standard procedures employing pepsin at 37 °C for 24 h to form the $F(ab')_2$ fragment, then reduced with 4 mM dithiotreitol (DTT) for 1 h at room temperature. For all conjugations, except for the maleimide-containing **7** conjugation, the sulfhydryl on Fab′ was reacted with *N*-ethylmaleimide (NEM) to ensure that it would not be involved in the reactions or reform the $F(ab')_2$. After the conjugation reactions were complete, size exclusion HPLC was run to evaluate the peak shape, rention time, and number of species present. Isoelectric focusing (IEF) gels were run on the isolated conjugates to help assess the extent of the conjugation.

Conjugations of the halobenzoate NHS esters, [^{125}I]**1b** or [^{211}At]**1c**, were conducted in borate buffer, pH 8.5, at room temperature for 15 min. Because the conjugations were conducted with a high specific activity material, very small amounts of the Fab′ were actually modified. Thus, radioHPLC traces look identical to that obtained for Fab′-NEM before conjugation with **1b** or **1c**.



The amine-reactive borane cage compounds **2**, **3**, **4**, **5**, and **6** (Figure 1) were all conjugated with the Fab′-NEM under the same conditions. The conjugations were conducted by reaction of Fab′-NEM with 5, 10, or 20 equiv of the amine-reactive compound in 50 mM $NaHCO_3$ buffer, pH 8.5, for 16 h at room temperature. The conjugation reactions are depicted as the last steps in Schemes 1−3. Conjugation of Fab'-NEM with 20 equiv of **2** caused visible precipitation the Fab′. Conjugations involving lower number of equivalents (e.g., 5 or 10) of **2** with the protein did not cause visible precipitation, but the SE-HPLC chromatograms indicated that the protein properties had changed significantly (i.e., peaks were broadened) and that some higher molecular weight species (eluting before 10 min) were present. The SE-HPLC chromatogram for conjugation with 10 equiv of **2** (Figure 2, panel B) displayed only a small percentage (<5%) of high molecular weight contaminants (t_R = 6.3 min); however, when 20 equiv were reacted, that percentage went up (>30%), and when 50 equiv were reacted, almost all of the soluble protein was found to be high molecular weight species (Figure S1 in Supporting Information). Conjugation of 10 equiv of **3** caused extensive broadening of the chromatographic peak by SE-HPLC

Scheme 3 . Synthesis of Amine-Reactive Decaborate(2-) Derivative 6 and Conjugation with Fab′-NEM[a]

[a] Reagents and conditions: (a) TFP−OH, DMF, EDC, RT, 16 h, 63%; (b) **19**, Et_3N, DMF, RT, 30 min, 71%; (c) **21**, RT, 3 d, 68%; (d) **22**, DMF, RT, 10 min, 76%; (e) TCDI, DMF, RT, 1 h, 98%; (f) Fab′-NEM, H_2O, $NaHCO_3$, pH 8.5, **6** in DMSO/H_2O, RT, 16−20 h, 92% recovered.

Scheme 4. Synthesis of Sulfhydryl-Reactive Decaborate(2-) Derivative 7 and Conjugation with Fab′-SH[a]

[a] Reagents and conditions: (a) **24**, Et_3N, DMF, RT, 2 h, 87%; (b) Fab′-SH, PBS, **7** IN DMF, RT, 1 h, 84% (recovered).

(Figure 2, panel C), but there was no visible precipitation even at 20 equiv reacted.

In contast to the *nido*-carborane derivatives **2** and **3**, the Fab′ conjugates of decaborate(2-) derivatives **4**, **5**, **6**, and **7** did not cause visible precipitation or aggregation of Fab′-NEM, even when 20 equiv or more were offered. The conjugation product Fab′-**4** when analyzed by SE-HPLC (Figure 2, panel D) showed a single peak that was slightly broadened from the starting Fab'. Unfortunately, after the 16 h conjugation period, an IEF gel indicated there was Fab' remaining that was not conjugated with

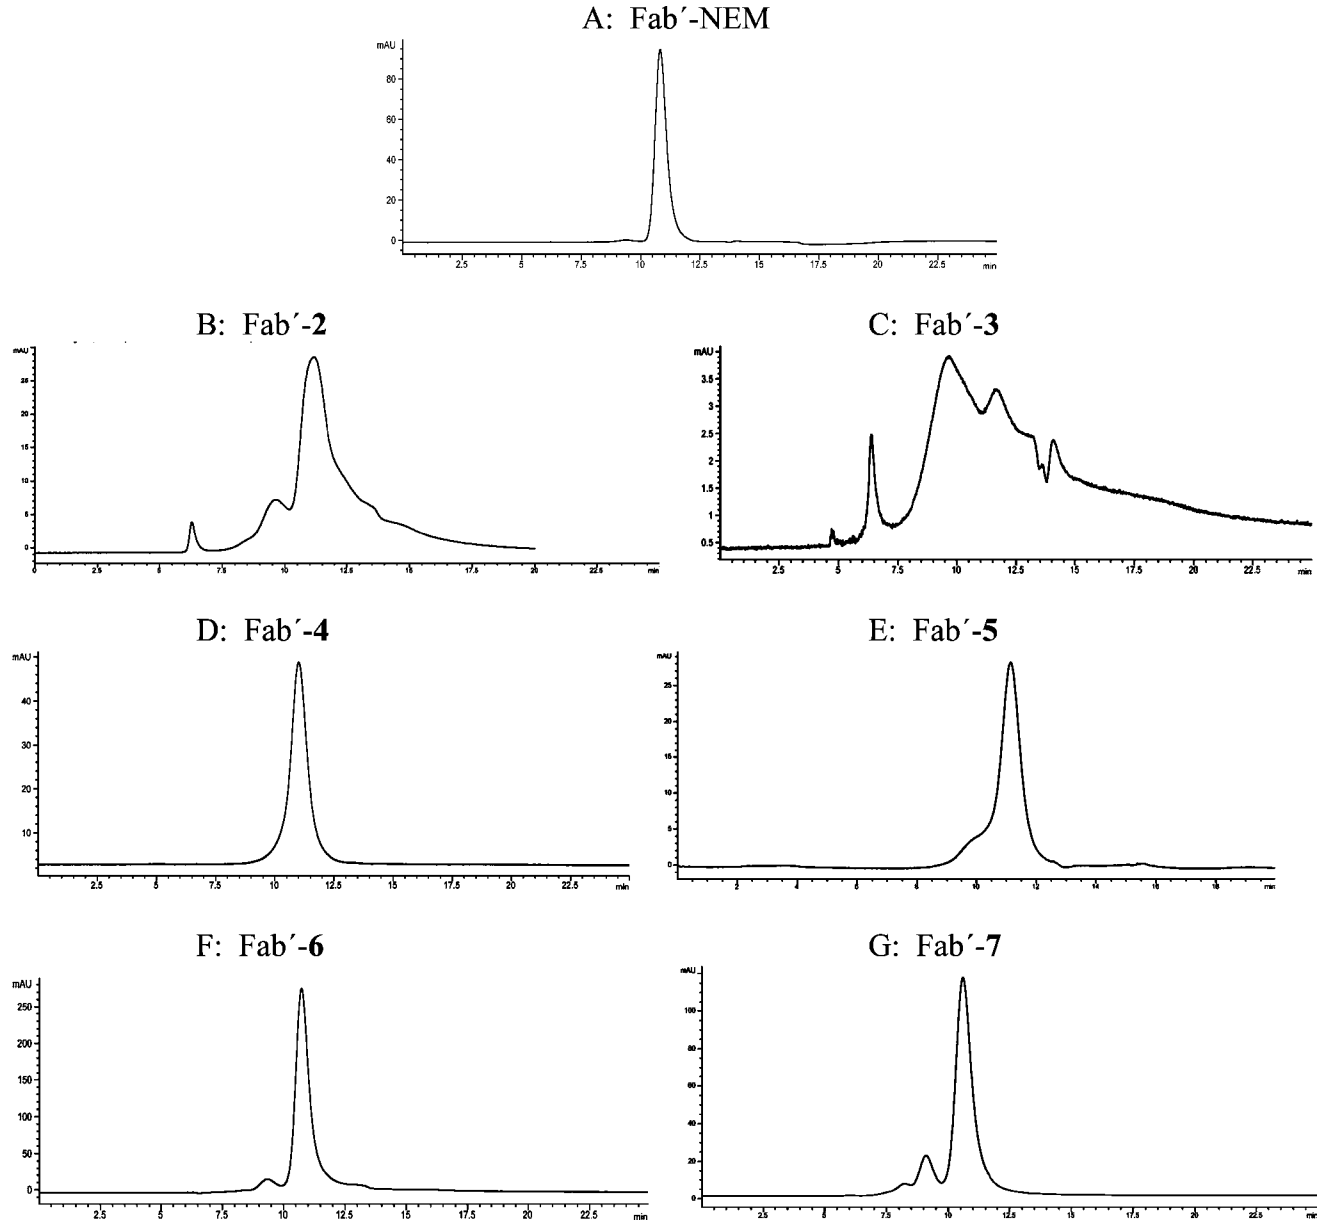


Figure 2. Size-exclusion HPLC chromatograms of 107-1A4 Fab′ conjugates prepared for the study. The conjugate in panel A has the sulfhydryl moiety capped with NEM but contains no borane cage. Chromatograms in panels B−F represent products obtained with 10 equiv of borane-containing reagent (**2**−**6**) offered for conjugation with Fab′-NEM. The chromatogram in panel G is from a conjugation reaction where 20 equiv of **7** were offered for reaction with Fab′-SH.

4. Reactions of **4** with compounds containing primary amines were found to be quite slow compared with other isocyanate derivatives (unreported results), presumably due to conjugation of the isocyanate functionality with the highly anionic borane cage. On the basis of this observation, we became interested in decaborate(2-) derivatives that have a higher reactivity with protein amines. Because we had observed that the carbonyl-substituted decaborate(2-) **14** (Scheme 2) was slightly more reactive than **4**, that compound was conjugated with Fab′-NEM. No aggregation was noted in this reaction, and an IEF gel indicated that a somewhat higher substitution may have been achieved. However, we felt that it was important to be able to have an even more reactive functional group in the conjugation reactions, as some proteins may be sensitive to the reaction conditions and time taken to complete the reactions. Therefore, an isothiocyanate-benzylamine adduct of decaborate(2-), **5**, was prepared and conjugated to the Fab′-NEM. Again, no visible aggregation was observed in the conjugation reactions, and little aggregation was noted by SE-HPLC (Figure 2, panel E). While an IEF gel indicated that conjugation had occurred (e.g., Figure S2, panel B; Supporting Information), it was not possible to quantify the number of conjugates added.

We felt that it was important to have a method for easily assessing the number of decaborate(2-) groups conjugated with the protein. To achieve this, the biotin-containing decaborate-(2-) derivative **6** was prepared and conjugated with Fab′-NEM. The inclusion of a biotin in the structure permits the use of the well-established HABA assay (*39*) to determine the number of biotin moieties present. After conjugation of **6** with Fab′-NEM, there was little change in the SE-HPLC (Figure 2, panel F), even at the highest offering of conjugate (20 equiv). Importantly, a dramatic change in the migration on the IEF gel was noted (Figure S1, panel B). Interestingly, the width of the Fab′ peak at half-height was not broadened from the standard (Figure 1, panels A and F), as was the case for conjugates of **4** and **5**. Assessment of the number of biotin derivatives by the HABA assay indicated that, with 10 equiv of **6** offered, 1.5 conjugates/

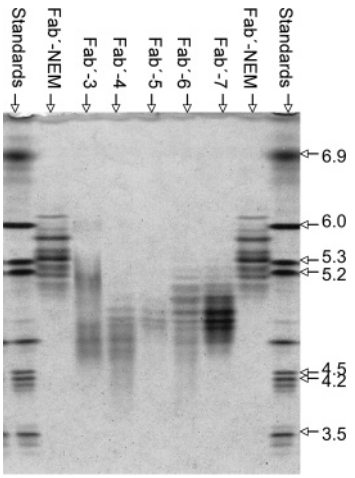

Figure 3. Digitized isoelectric focusing gel containing Fab′ conjugates prepared for the study. Standards are as follows: 6.9, myoglobin; 6.0, carbonic anhydrase; 5.3, 5.2, β-lactoglobulin; 4.5, trypsin inhibitor; 4.2, glucose oxidase; and 3.5, amyloglucosidase.

Fab′ were obtained. With 20 equiv of **6** offered, 2.1 conjugates/Fab′ were obtained.

In collaborative studies (*41*), a sulfhydryl-reactive decaborate-(2-) was desired, so conjugate **7** was prepared and included in this investigation. Conjugation of Fab′-SH using 20 equiv of **7** did not cause visible aggregation. A representative SE-HPLC (Figure 2, panel G) showed one major peak, but also had a minor peak at ~7.8 min which appears to be some reformation of the $F(ab')_2$. As with **6**, conjugation of **7** appears to have minimal affect on the HPLC profile of the Fab′.

For all except Fab′-**6**, the primary method for determining whether conjugations of the borane cage moieties with Fab′ had occurred was an IEF analysis. As the studies progressed, IEF were obtained on one or two boron-conjugated Fab′ species. In an attempt to obtain a better comparison of the anionic borane cage conjugates, a single IEF analysis was conducted with most of the Fab′ conjugates (all except Fab′-**2**). A digitized scan of that IEF is shown in Figure 3. In the samples examined, all conjugates except Fab′-**3** appear to have at least one conjugate on the protein, as none of the primary bands from the Fab′-NEM remain, indicating that at least one charge unit has been changed from the unmodified Fab′. This result is in constrast to an earlier IEF of Fab′-**4**, which indicated that some of the Fab′-NEM remained. The Fab′-**6** also displayed a different banding from those obtained with earlier samples. The difference is likely due to the fact that the Fab′-**6** sample examined in this IEF only had 1.1 biotins/Fab′. Unfortunately, samples shown in Figure 3 had been stored for varying lengths of time, which made comparisons with earlier IEF data difficult.

Radioiodination and Astatination. A key objective in the studies was to evaluate the use of boron conjugates to provide a method for stable attachment by directly labeling proteins with ^{211}At. Our hypothesis was that direct labeling can provide yields comparable to those obtained with direct radioiodination of a native (nonconjugated) protein. Therefore, examples of direct labeling of Fab'-NEM with Na[^{125}I]I/Na[^{131}I]I and Na[^{211}At]-At using the standard reagents (Chloramine-T) in PBS at pH 6.8 were conducted first. As is the general case with most proteins, very good radioiodine labeling yields were obtained (e.g., 75−89%). In contrast, essentially no (<1%) direct labeling was obtained with Na[^{211}At]At. A more effective method for labeling proteins with ^{211}At is to use ^{211}At-labeled benzoate NHS ester, **1c**, in a conjugation/labeling step. Therefore, for comparison, radiolabeling of the Fab′-NEM was conducted using the *p*-[^{125}I]iodobenzoate NHS ester, [^{125}I]**1b**, and the *p*-[^{211}At]-astatobenzoate NHS ester, [^{211}At]**1c**. The labeling of stannyl-benzoate **1a** was conducted in MeOH/5% HOAc using *N*-chlorosuccinimide as the oxidant and $Na_2S_2O_5$ as the quench. The crude residue, obtained after removal of solvent, was mixed with the Fab′-NEM in borate buffer, pH 8.5. The overall labeling yields 32% and 14% isolated yields of Fab′-[^{125}I]**1b** and Fab′-[^{211}At]**1c** (respectively). The yields are lower than obtained in many similar protein-labeling experiments previously conducted in our laboratory (e.g., usually 40−60% conjugation yields). Radiolabeling of the borane cage-conjugated Fab′ was conducted in H_2O using Chloramine-T as oxidant (pH ~7, rt, 30 s to 2 min) and NaS_2O_5 as quench. The yields obtained for radioiodination and astatination of Fab′ and its conjugates are shown in Table 1. The yields are for single labelings under similar conditions and are not optimized.

Table 1. Radiochemical Yields for Labeling 107-1A4 Fab′ Conjugates with Na[^{125}I]I and Na[^{211}At]At[a,b]

Fab′ conjugate reacted	^{125}I yield (%)	^{211}At yield (%)
Fab′ (direct label)	89[c]	<1
Fab′ + **1**b or **1**c	32	14
2-Fab′	75	28
3-Fab′	51	32
4-Fab′	33	36
5-Fab′	72	60
6-Fab′	70	58
7-Fab′	84	75

[a] Reaction conditions are described in the Experimental Section. Yields are for isolated Fab′ conjugates after radiolabeling reaction, quenching with NaS_2O_5, and PD-10 purification. Labeling yields are not optimized. [b] Fab′ sulfhydryl group is capped with NEM. [c] Na[^{131}I]I was used for labeling.

Biodistributions of Radiolabeled Fab′ Derivatives. Tissue distributions of coadministered ^{125}I- and ^{211}At-labeled conjugates of Fab′ were conducted in athymic mice to assess the stability of the ^{211}At label and to assess changes in the tissue concentrations brought about by the boron-containing conjugate. The data obtained for concentrations (%ID/g) of ^{125}I and ^{211}At in selected tissues at 1 and 4 h postinjection are shown as bar graphs (panels A−H) in Figure 4. The complete data obtained in each biodistribution study, including amounts injected, animal weights, and results of statistical significance (using Student's *t* test) are provided as Tables S1−S8 in the Supporting Information.

Panel A in Figure 4 shows the tissue distribution of Fab′-NEM directly labeled with ^{125}I. These data have been included for comparison with the radiolabeled conjugates. The data clearly show that directly labeled Fab′ releases radioiodine in vivo (as noted by neck and stomach concentrations). Direct labeling with ^{211}At gave a very low yield (<1%), so that material was not evaluated in vivo. Panel B in Figure 4 shows the tissue distribution of Fab′-NEM conjugated with [^{125}I]**1b** and [^{211}At]-**1c**. While catabolism of the directly labeled Fab′ releases iodide, catabolism of Fab′ conjugated with *p*-[^{125}I]iodobenzoate, [^{125}I]-**1b**, does not release radioiodine. For this reason, we use [^{125}I]-**1b** labeling as a control to provide the tissue distribution of the Fab′. The tissue distribution data for [^{125}I]**1b**-Fab′ can be used in comparisons with other radiolabeled Fab′ conjugates to determine whether a paricular conjugate has altered the Fab′ distribution. An important point to note in panel B is that the release of ^{211}At from [^{211}At]**1c**-Fab′ is evident due to higher concentrations of ^{211}At than ^{125}I found in lung, spleen, neck, and stomach tissues. Indeed, there was a significant difference in concentrations for the two radionuclides in all tissues except intestines and urine.

Biodistributions of the radiohalogenated *nido*-carborane-conjugated Fab′ derivatives, [^{125}I]**2**-Fab′/[^{211}At]**2**-Fab′ and [^{125}I]-**3**-Fab′/[^{211}At]**3**-Fab′, are shown graphically in Figure 4, panels C and D, respectively. The tissue distributions are very different from those of the Fab′-NEM when directly labeled (panel A) or labeled with the halobenzoates (panel B), suggesting that the

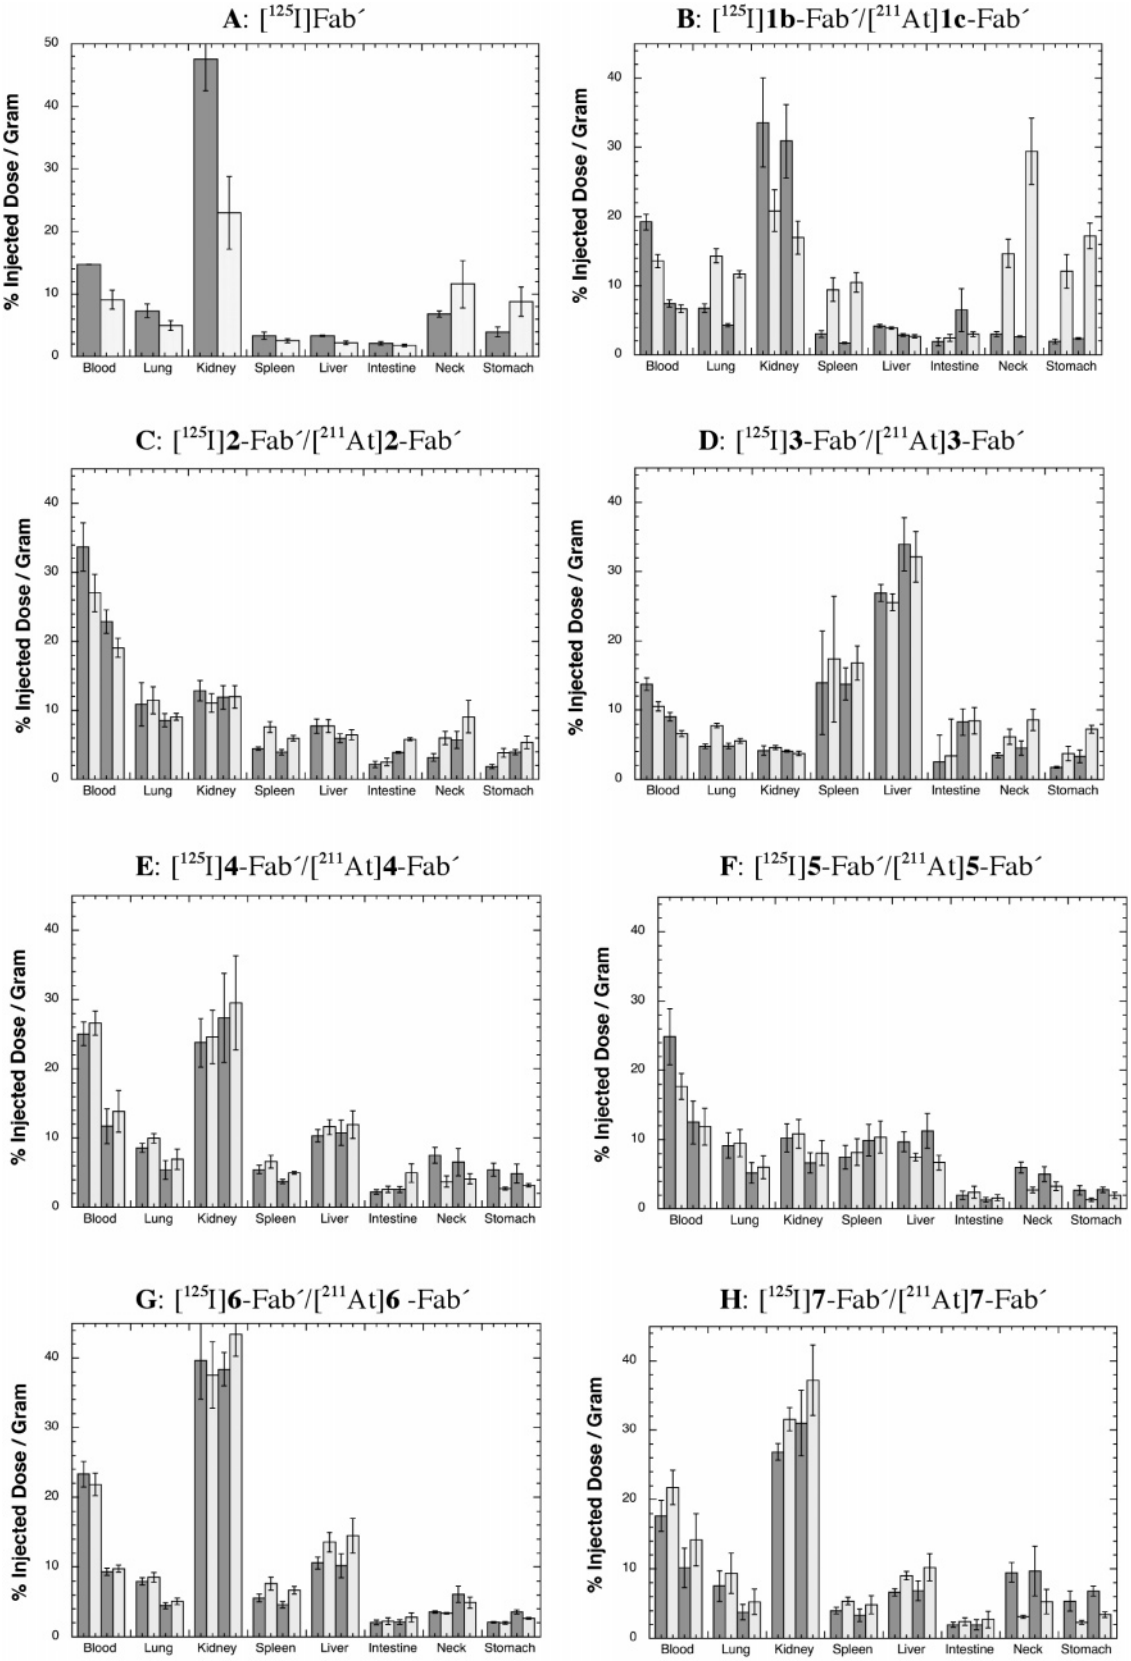

Figure 4. Graphs of tissue distributions of ^{125}I-labeled (dark gray bars) and ^{211}At-labeled (light gray bars) Fab′ and Fab′ conjugates in athymic mice. The heights of the bars (%ID/g) are based on the average %ID/g value obtained in five mice for each tissue, and the error bars are standard deviation of values in each tissue. The first two bars represent values obtained at 1 h postinjection, and the second two bars represent values obtained at 4 h postinjection. In panel A, only the 4 h timepoint is shown. The Fab′ conjugates studied are noted above each bar graph.

nido-carborane conjugates significantly alter the in vivo characteristics of the Fab′. Of particular note in both biodistributions are the low kidney concentrations, suggesting that the material injected aggregated or bound with blood components, resulting in an effective size larger than that of Fab′, causing them to be excluded from the kidney. Both of these conjugates displayed

a high propensity to aggregate during preparation, and additional aggregation may have occurred prior to injection or association with serum proteins occurred after injection. On the basis of the fact that the conjugates of the mono-*nido*-carborane derivative **2** have high concentrations in the blood (compared with the [^{125}I]**1b**-Fab′ standard) and low concentrations in the liver and spleen, it seems likely that this conjugate associates with the serum proteins. Statistical analysis (Student's *t* test) indicated that there were significant differences in the concentrations of radionuclides in blood, spleen, neck, and stomach. Since the concentration of ^{211}At was higher in spleen, neck and stomach, it is likely that some deastatination occurred.

In contrast to Fab′-**2**, blood concentrations are lower than the standard values for the bis-*nido*-carborane derivative **3**, and the concentrations in spleen and liver are higher, suggesting that larger aggregates may have been injected or were formed upon injection of that conjugate. It should be noted that there were small (but significant by Student's *t* test) differences in ^{211}At and ^{125}I concentrations seen in the lung, spleen, neck, and stomach suggesting that there is some instability of the label, but the stability is much higher than that of the astatobenzoate, [^{211}At]**1c**-Fab′ (panel B).

Biodistributions of two radiohalogenated decaborate(2-)-conjugated Fab′ derivatives [^{125}I]**4**-Fab′/[^{211}At]**4**-Fab′ and [^{125}I]-**5**-Fab′/[^{211}At]**5**-Fab′ are shown graphically in Figure 4, panels E and F, respectively. The isocyanato-decaborate(2-) conjugate **4**-Fab′ has a biodistribution that is very similar to the [^{125}I]**1b**-Fab′ standard (darker bars, panel B) indicating that it has minimal affect on the Fab′ distribution. Interestingly, the kidney concentration for the benzamidyldecaborate(2-) conjugate **5**-Fab′ is dramatically lower than expected. Since the liver and intestine concentrations are also relatively low, it seems *unlikely* that the protein is aggregating or the radioactive metabolites are being excreted through the hepatobiliary system rather than the renal system. It should be noted that for both conjugates the concentrations of radioactivity in the liver are higher than observed when the halobenzoates are used, suggesting that some deviation of the distribution or trapping of the radioactivity in the liver has occurred with the decaborate(2-) conjugates. Very small differences can be noted in the concentrations of ^{211}At and ^{125}I in lung and spleen (differences are significant in Fab′-**4**, but not in Fab′-**5**), indicating that the ^{211}At label is fairly stable to in vivo deastatination. It is interesting to note that the concentration of ^{125}I is higher than that of ^{211}At in the neck and stomach. This may be an indication that some of the radioiodine reacted with tyrosine residues on the Fab′ rather than with the decaborate(2-) cage.

Biodistributions of two additional radiohalogenated decaborate-conjugated Fab′ derivatives [^{125}I]**6**-Fab′/[^{211}At]**6**-Fab′ and [^{125}I]**7**-Fab′/[^{211}At]**7**-Fab′ are shown graphically in Figure 4, panels G and H, respectively. As with the isocyanatodecaborate-(2-) conjugate **4**, these more structurally complex decaborate-(2-)-containing conjugates, **6** and **7**, do not appear to significantly alter the in vivo distribution of the Fab′. However, similar to other decaborate(2-) conjugates, the liver concentrations are higher than expected on the basis of those obtained with the iodobenzoyl conjugate, [^{125}I]**1b**-Fab′ (panel B). The small differences in ^{211}At and ^{125}I concentrations in spleen and lung (not significant by Student's *t* test) indicate that the astatinated decaborate(2-) cage is quite stable to in vivo deastatination.

DISCUSSION

The utility of the α-particle-emitting radionuclide ^{211}At for targeted radionuclide therapy will be severely limited unless reagents that provide high in vivo stability toward deastatination are developed. The previously developed protein astatination reagents, such as *meta*-[^{211}At]astatobenzoate NHS ester (*22*) or *para*-[^{211}At]astatobenzoate NHS ester (*25*) are likely to be useful in applications where the protein is slowly metabolized or in applications where the radiolabeled protein is administered to a body compartment (e.g., intraperitoneal, intrathecal, etc.) and remains there during the ^{211}At decay period. One such use is being explored in a clinical study at Duke University. That study involves injection of the astatinated mAb into a resection cavity from brain surgery, similar to the studies being conducted with ^{131}I (*42*). Another potential use under investigation is application of ^{211}At-labeled mAbs for bone marrow conditioning (*43*). In this latter application, all of the astatinated targeting mAb should be bound with hematopoietic cells during the decay of the radionuclide (*44*).

The low in vivo stability toward deastatination of astatobenzene derivatives when used with rapidly metabolized proteins (and other biomolecules) is not their only limitation to their use. They can also be difficult to prepare and can display a low stability toward radiolysis. For example, when labeling with higher quantities of ^{211}At, the two-step preparation and conjugation has inherent problems associated with stability of the activated ester and the stannylbenzoate functionality. In spite of this, studies at Duke University have shown that reproducible clinical-level labelings can be prepared with *m*-[^{211}At]astatobenzoate NHS ester ([^{211}At]**1c**), and clinical studies (noted above) using that agent to label an anti-tenacin mAb (81C6) were initiated (*45*). In their early labeling studies, it was concluded that the labeling chemistry was not affected by radiolysis. More recently, problems with preparing clinical levels of the [^{211}At]astatobenzoate NHS ester were determined to be affected by radiolysis (*46*), particularly when chloroform was used as the solvent (*47*).

Due to the observed instability of ^{211}At-benzoate conjugate on mAb Fab′ fragments, we initiated the investigation using boron cage moieties as alternatives for use in labeling of biomolecules. It is our hypothesis that use of the appropriately functionalized boron cage moieties could provide in vivo stability of the ^{211}At and could also provide a more convenient and robust approach to labeling proteins with ^{211}At. Thus, the primary objective of this investigation was to prepare conjugates of a protein that contained boron cage moieties, such that they could be directly labeled with ^{211}At and evaluated in vivo to determine stability toward deastatination. To assist in determining whether the ^{211}At-labeled protein was stable to in vivo deastatination, it was necessary to also radiolabel the protein conjugates with radioiodine (^{125}I). The inclusion of ^{125}I in the studies made it important to employ boron cage moieties that are highly reactive with radioiodine, such that there is a high likelihood the radioiodine will react with the boron cage moiety in preference to the protein tyrosine residues. On the basis of their highly lipophilic nature and very low reactivity with iodine (*48*−*50*), neutral dicarbon carboranes were not considered appropriate for the studies. In our previous studies, it was noted that anionic *nido*-carboranes reacted much more rapidly with electrophilic iodine than tyrosine (*51*), so this moiety was of interest for the studies. Other boron cage moieties such as anionic monocarbon carboranes were considered nonoptimal due to their low reactivity with iodine (*52*). However, dianionic carborane cage moieties, *closo*-dodecaborate(2-) and *closo*-decaborate(2-), were also of high interest due to their reactivity with halogens (*53*).

In the studies described herein, an antibody Fab′ was chosen as a model system to evaluate the in vivo stability of (relatively) rapidly metabolized astatinated proteins. Prior studies had shown *p*-[^{211}At]astatobenzoyl-labeled A6H Fab′ (*26*) and NRML-05 Fab′ (*25*) underwent rapid deastatination in vivo, most likely after protein degradation. Similar results have been reported for *m*-[^{211}At]astatobenzoyl-labeled 3H11 Fab′ (*54*). As a control,

p-[^{211}At]astatobenzoyl-labeled 107-1A4 Fab′, [^{211}At]**1c**-Fab′, was prepared and evaluated in comparison with coinjected *p*-[^{125}I]iodobenzoyl-labeled 107-1A4 Fab′, [^{125}I]**1b**-Fab′. As in the prior studies, evidence for significant deastatination (Figure 4, panel B; lung, spleen, neck, stomach) was seen even at the 1 h time point.

The studies of boron cage conjugates began by preparation, radiolabeling, and in vivo evaluation of two *nido*-carborane conjugates of 107-1A4 Fab′. In prior studies directed at determining the stability of astatinated boron cage moieties in vivo, it was shown that a diaminobenzene adduct of *nido*-carboranylpropionate derivative, **2**, was more resistant to deastatination than *nido*-carboranylpropionate itself (*28*). Therefore, we chose this protein-reactive derivative **2** for study. In those same prior studies, bis-*nido*-carborane derivatives were shown to be stable to in vivo deastatination, so we chose the isothiocyanate derivative, **3**, for preparation and testing as well. While the studies were not extensive, nor optimized, the results obtained with the *nido*-carboranyl derivatives **2** and **3** indicated that they caused aggregation of the Fab′ when conjugated. Additionally, they also caused dramatic changes in the in vivo behavior of the Fab′. These negative characteristics appear unfavorable for use in astatination of proteins. However, it should be noted that in a series of studies involving a *nido*-carboranylphenyl diazonium salt (*55*) and its corresponding isothiocyanate (*56*, *57*) under optimized conjugation conditions allowed coupling of 12 or more *nido*-carborane moieties with good recovery of protein and retention of immunoreactivity of the antibody. More recently, this same *nido*-carborane derivative was successfully used for radiobromination of the anti-HER/neu/ErbB-2 monoclonal antibody (*58*). Similarly, prior studies demonstrated that the ^{211}At- and ^{125}I-labeled bis-*nido*-carborane derivatives (also referred to as Venus Flytrap Complex, VFC) used in this study localized to liver (*28*). Interestingly, studies with ^{57}Co complexed in a VFC showed no change in protein on conjugation (*59*). These examples tend to suggest that optimization studies might provide better protein conjugates of **2** and **3**, but our initial experience with these agents led us to explore other boron cage moieties for conjugation and astatination.

In prior studies, oxygen- (*60*, *61*), sulfur- (*62*, *63*), and nitrogen-bonded (*64*, *65*) *closo*-dodecaborate(2-) derivatives were prepared by other investigators, and some were conjugated with mAbs for direct labeling with radiobromine, radioiodine, and astatine (*66*−*68*). Our concern with the use of these reagents for direct radiohalogenation was that the dodecaborane(2-) cage moiety is deactivated in aqueous solution by protonation of the heteroatom adjacent to the highly anionic *closo*-dodecaborate-(2-) cage. In fact, some preliminary studies were conducted in this laboratory involving amine- and oxo-bonded *closo*-dodecaborates, and it was found that the iodinations were very much slower than with a *closo*-decaborate(2-) derivative (unreported results). Since it was desirable to directly radioiodinate the Fab' conjugates, we chose to prepare conjugates of the *closo*-decaborate(2-) cage system due to its high reactivity with halogens (*53*). An example of sulfur-bonded derivatives of *closo*-decaborate(2-) has also been previously reported (*69*). As with the *closo*-dodecaborate(2-) derivatives, it is likely that the sulfur is protonated under physiological conditions. Therefore, derivatives that have B-bonded functional groups that are unlikely to be protonated (e.g., amide bond, urea, etc.) were sought.

On the basis of the previously listed considerations, the protein-reactive 2-isocyanato-*closo*-decaborate(2-) derivative, **4**, was initially chosen due to its simple preparation (*37*). Unlike the Fab′ conjugates of *nido*-carborane derivatives **2** and **3**, in vivo evaluation of radiohalogenated Fab′ conjugated with **4** demonstrated that concentrations of ^{211}At and ^{125}I in kidney were similar to the control ([^{125}I]**1b**-Fab′; Figure 4, panel B). Importantly, very small differences in the concentrations of nuclides was seen in lung and spleen, providing evidence that the astatinated *closo*-decaborate(2-) cage was stable to in vivo deastatination. Interestingly, higher concentrations of ^{125}I were noted in the neck and stomach. The reason for this difference is uncertain. However, it might be speculated that some radioiodination occurred on protein tyrosine residues, and that radioactivity was released as free [^{125}I]iodide after catabolism of the protein. Importantly, the radiochemical yield was not as high (36%) as desired (i.e., 50+%) for a direct labeling procedure, so additional derivatives were sought.

The carbonylated decaborate(2-) derivative **14** was also used to prepare Fab′ conjugates. The Fab′ conjugate of 2-carbonyl-*closo*-decaborate(2-) derivative **14** was not astatinated or evaluated in vivo, as it seemed likely that would not be significantly different from Fab′ conjugates of **4**. Subsequently, another *closo*-decaborate(2-) derivative, **5**, which has the protein conjugation functionality a distance from the dianionic cage, was prepared and studied. A significantly improved radiolabeling yield was obtained (60%). Surprisingly, in vivo evaluation of the Fab′ conjugate of **5** provided biodistribution data (Figure 4, panel F) that was significantly different from the control ([^{125}I]**1b**-Fab′; Figure 4, panel B). While the ^{211}At and ^{125}I concentrations in blood, lung, spleen, and liver were not very different, the kidney concentrations were dramatically lower. Although the lower kidney values may be of importance in continued conjugate development, the high variation in tissue concentration from that obtained with [^{125}I]**1b** was not desired in this study, so an alternative *closo*-decaborate(2-) derivative was sought.

Difficulties with assessing the number of *closo*-decaborate-(2-) derivatives conjugated to the protein when **4**-Fab′ and **5**-Fab′ were studied led to the preparation of another *closo*-decaborate-(2-)-containing conjugate, **6**-Fab′. In previous studies, a series of mAb conjugates were prepared, which included a biotin moiety (*70*). The inclusion of a biotin in those conjugates was for its application to extracorporeal affinity absorption techniques (*71*), but it was noted that the presence of biotin also made quantification of the number of conjugates per mAb relatively easy when the "HABA" assay (*39*) was used. Conjugation of Fab′ with **6** provided an appropriate substitution (1.5−2 conjugates/Fab′). Interestingly, in the biodistribution (Figure 4, panel G), the two radionuclides on **6**-Fab′ had almost identical concentrations in most tissues examined, including neck and stomach. The fact that the concentrations of ^{211}At and ^{125}I were very similar in neck and stomach suggests that the radioiodine had reacted with the decaborate cage. However, it should be noted that tissue concentrations of radiolabeled **6**-Fab′ in liver and spleen are significantly higher than for the control ([^{125}I]**1b**-Fab′; Figure 4, panel B). This fact suggests that the protein modification with **6** has an effect, although fairly small, on the biodistribution.

The Fab′ conjugates described thus far were prepared by reaction with the protein lysine residues. A desire to couple the decaborate(2-) moiety to a protein sulfhydryl in a collaborative study (*41*) led to the preparation of a maleimide derivative, **7**. Conjugation of **7** with the sulfhydryl on Fab′ was accomplished at pH 6.5. At this pH, the conjugation would be expected to be highly selective for the thiol group. The yields for radioiodination and astatination were the highest obtained in the study (Table 1). This high yield may in part be due to having a thioether bond rather than a thiourea bond in the conjugate. Previous studies have provided data that suggest that radiohalogenations can be negatively affected in the presence of a thiourea functionality (*72*). The biodistribution data obtained from **7**-Fab′ is fairly consistent with data obtained with other decaborate(2-) conjugates.

CONCLUSION

The preparation, characterization, astatination, and in vivo characteristics of 107-1A4 Fab′ conjugated with a series of *nido*-carborane and *closo*-decaborate(2-) derivatives has been described. The primary goal of the studies was to obtain at least one astatinated protein conjugate that is both stable to in vivo deastatination and has a minimal affect on the in vivo characteristics of the protein. This goal was achieved, and studies involving conjugation and astatination of other proteins with the amine-reactive and sulfhydryl-reactive *closo*-decaborate(2-) derivatives **6** and **7** are planned. *We believe this report provides the first examples of direct labeling of proteins with ^{211}At which do not undergo deastatination in vivo.* A secondary goal of the studies was to simplify the protein astatination reactions and improve the radiochemical yields obtained. This goal was also achieved. *The radiochemical yields for Fab′ conjugates of **6** and **7** were similar to those obtained in direct radioiodination reactions,* and higher than previously attained with the two-step ^{211}At labeling procedures. Despite these very important steps forward, the results also indicate that *closo*-decaborate-(2-) conjugates are not optimal. It is apparent that concentrations of the radionuclides in some tissues (e.g., liver) are higher than obtained with unconjugated Fab′. The reason for the higher concentrations is not known, but it is likely that the dianionic nature of the *closo*-decaborate(2-) cage contributes to a longer residence time in those tissues. Therefore, studies are underway to chemically modify the *closo*-decaborate(2-) cage conjugates to improve their in vivo properties.

ACKNOWLEDGMENT

We thank Janna Quinn, Austin Odman, and Nicole Lavoie for their assistance in the animal biodistributions studies. We thank Quanta Biodesign (Powell, Ohio) for the gift of NHS-3-maleimidoproprionate. We thank the Department of Energy, Office of Isotope Programs (ANMI-DE-FG01-00NE22740), Department of Energy, Medical Applications and Biophysical Research Division, OHER, (DE-FG03-98-ER62572), and NIH (1 RO1 CA113431) for funding the studies described.

Supporting Information Available: SE-HPLC chromatograms for conjugation of varying quantities (10, 20, and 50 equiv) of **2** with Fab′-NEM are provided is Figure S1; digitized IEF gels run on some Fab′ conjugates is provided in Figure S2; and complete tissue distribution data for all in vivo studies are provided in Tables S1−S8. This material is available free of charge via the Internet at http://pubs.acs.org/BC.

Received November 9, 2006; Revised Manuscript Received April 16, 2007

A novel sensing method based on surface plasmon resonance (SPR) was developed for the highly sensitive quantification of low molecular weight (LMW) analytes (colloidal Au replacement assay). Gold nanoparticles (diameter = 20 nm) functionalized with lactosyl-poly(ethylene glycol) (PEG) were prepared and were specifically adsorbed onto a *Ricinus communis* agglutinin (RCA_{120})-immobilized SPR sensor chip surface. Subsequent injection of free D-galactose elicited the elution of the preadsorbed lactosyl-PEGylated gold nanoparticles in a manner proportional to the galactose concentration, achieving a substantial and quantitative analysis over a wide range of galactose concentrations (0.1−50 ppm). This method of D-galactose sensing through the substituted elution of preadsorbed nanoparticles from the sensor chip surface would be applicable for the highly sensitive SPR quantification of various LMW analytes, which are known to be difficult to detect by the conventional SPR sensing regime.

1. INTRODUCTION

The surface plasmon resonance (SPR) technique has been widely used in the real-time assay of biomolecular interactions (*1*−*4*). SPR is based on a change in the reflection of laser light from a metal−liquid surface, induced by a variation in the dielectric constant due to the adsorption of analyte molecules. Because this change is extremely sensitive and is correlated with the amount of adsorbed analytes, quantitative experiments with SPR are feasible for the monitoring of various biomacromolecules, including proteins, carbohydrates, and nucleic acid compounds. Nevertheless, the sensing of low molecular weight (LMW) compounds by SPR is generally difficult, mainly due to the inherently low response of analytes with a limited mass. An available method for the amplification of the SPR signal is the augmentation of the apparent mass of the analyte molecules. In this regard, gold nanoparticles modified with analytes were employed for the enhancement of the SPR signal (*5*−*7*). The amplification mechanisms of colloidal Au enhanced SPR are (i) the increased apparent mass of the analytes immobilized on gold nanoparticles and (ii) a coupling of the localized surface plasmon of gold nanoparticles with the propagating plasmon on the SPR gold surface. The colloidal Au enhanced SPR achieved the highly sensitive detection of the antigen−antibody interaction and DNA hybridization (*5*, *6*), but, as far as we know, this has not been applied to a direct quantitative assay of low molecular weight (LMW) analytes in sample solutions.

We now report a novel SPR method for the quantitative assay of LMW analytes (colloidal Au replacement assay) based on the elution of preadsorbed gold nanoparticles on the sensor chip surface induced by the injection of LMW analytes. In this method, it is crucial to minimize the nonspecific adsorption between the gold nanoparticles and the sensor chip surface. PEGylated gold nanoparticles possessing lactose moieties, as a ligand, at the distal end were then prepared by covering the nanoparticle with a densely tethered layer of a thiolated heterobifunctional PEG (*8*). Note that the hydrophilic PEG layer with a strong steric-repulsive property serves to minimize the nonspecific adsorption and agglomeration of gold nanoparticles in an aqueous medium (*9*). Eventually, the highly sensitive quantification of the label-free LMW compound, galactose, by SPR was achieved by monitoring the competitive elution of the lactosyl-PEGylated gold nanoparticles from a *Ricinus communis* agglutinin (RCA_{120}; a bivalent galactose-binding lectin)-immobilized sensor chip upon the injection of the sample solution containing a definite concentration of free galactose.

2. EXPERIMENTAL PROCEDURES

2.1. Materials. Gold nanoparticles (diameter = 20 nm) were purchased from British Biocell International (Cardiff, U.K.). Bovine serum albumin (BSA), lactosyl-albumin (lac-BSA), and NA3 glycan ($[Gal\text{-}GlcNAc]_3\text{-}Man_3\text{-}GlcNAc_2$, FW = 2006) were purchased from the Sigma-Aldrich Co. (St. Louis, MO). *Ricinus communis* agglutinin (RCA_{120}) was purchased from the Honen Co. (Tokyo, Japan). D-Galactose was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). The CM3 sensor chip, acetate buffer (pH 5.5), and amine coupling kit were purchased from Biacore AB (Uppsala, Sweden). All reagents were used as received. The phosphate buffered saline (PBS, 150 mM, pH 7.4) was prepared using Dulbecco's PBS from the Dainippon-Sumitomo Pharma Co. (Osaka, Japan). Water was purified using a Milli-Q instrument (Millipore, Bedford, MA).

2.2 Preparation of PEGylated Gold Nanoparticles Possessing Varying Lactose Functionalities. PEGylated gold nanoparticles with varying lactose functionalities on the surface

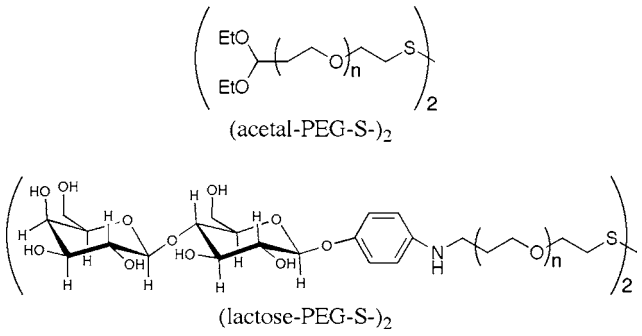

Figure 1. Chemical structures of (acetal-PEG-S-)$_2$ and (lactose-PEG-S-)$_2$.

were fabricated as previously reported (*10*). Briefly, a mixture of (acetal-PEG-S-)$_2$ (M_n = 12 100, Figure 1) and (lactose-PEG-S-)$_2$ (M_n = 12 200, Figure 1; the lactose functionality is 50%) of different molar ratios was added to the gold nanoparticle (diameter = 20 nm) solution (pH = 6.5) at room temperature. Lactose content on the gold nanoparticles was regulated by varying the feed molar ratio of (lactose-PEG-S-)$_2$ with (acetal-PEG-S-)$_2$ in the reaction mixtures. Since the reactivity of the disulfide group toward the surface of gold nanoparticles is likely to be equal between (lactose-PEG-S-)$_2$ and (acetal-PEG-S-)$_2$ because of their identical molecular weight with only a subtle change in the chain ends, the ratio of the lactose moieties on the gold surface is assumed to be equal to the feed ratio. Accordingly, the mol % of (lactose-PEG-S-)$_2$ in the feed was utilized to express the lactose functionalities (the fraction of tethered PEG having a lactosyl ligand at the distal end) on the PEGylated gold nanoparticles. Here, PEGylated gold nanoparticles with 0%, 25%, and 50% functionalities were prepared and abbreviated as lac0, lac25, and lac50, respectively. After 15 h of stirring, repetitive centrifugation and redispersion were carried out twice to remove any excess polymer from the solution. Finally, the nanoparticles were resuspended in PBS containing 0.01 wt % bovine serum albumin (BSA). The final concentration of the resuspended PEGylated gold nanoparticles was calculated from the absorbance at 523 nm using a UV−visible spectrophotometer (V-550 UV/vis spectrophotometer, JASCO, Japan). The calibration curve was prepared on the basis of the absorbance of the bare gold nanoparticles, because the UV−visible spectra revealed no substantial change even after the PEGylation of the gold nanoparticles (Supporting Information Figure S1).

2.3. Surface Plasmon Resonance Measurements. The SPR experiments were done using a Biacore 3000 instrument (Biacore AB, Uppsala, Sweden). RCA_{120} was immobilized on the surface of a CM3 carboxymethyl-dextran sensor chip using an amine coupling kit and 20 μg/mL RCA_{120} in 10 mM acetate buffer (pH 5.5) at the rate of 10 μL/min. Namely, carboxyl groups on the chip surface were activated by a mixture of succinimide (NHS) and carbodiimide (EDC) to form active esters, which then spontaneously react with the amino groups of RCA_{120}. Subsequently, excess ethanolamine was injected to deactivate the remaining active esters. The amount of the immobilized RCA_{120} was 1500 resonance units (RU) in all the experiments. A 0.1° SPR angle shift corresponds to 1000 RU, which is calibrated to be ca. 1 ng/mm^2, as provided by the manufacturer (Biacore) (*11*). Given that the molecular weight of RCA_{120} is ~120 000, it follows that 1500 RU = 1500 pg/mm^2 = 1.25×10^{-14} mol/mm^2 = 7.52×10^9 proteins/mm^2 = 7.52×10^{-3} proteins/nm^2. A similar procedure was carried out for a reference flow cell, for which the RCA_{120} injection is replaced with a blank injection of the buffer.

The lactosyl-PEGylated gold nanoparticles were then continuously injected over the flow cell modified with RCA_{120} and the unmodified flow cell at 25 °C. PBS containing 0.01 wt % BSA was used as the running buffer. All the data were obtained by signal subtraction of the blank flow cell injection from the RCA_{120}-immobilized flow cell, in order to remove any adverse contribution from the refractive index noise due to the bulk contribution of the sample injection. To assess the kinetic parameters, a global analysis of six concentrations of samples was performed using a 1:1 Langmuir model and bivalent model by *Biaevaluation 3.1* software.

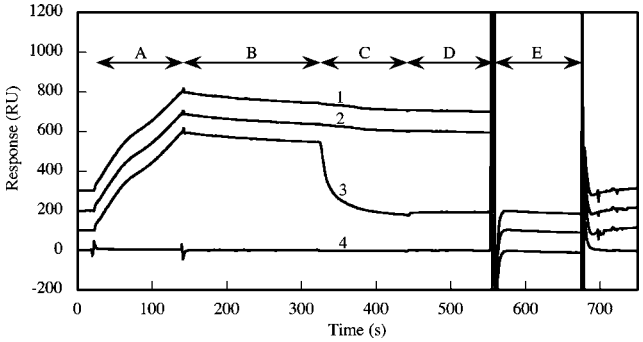

Figure 2. Sensorgrams for the interaction of PEGylated gold nanoparticles with RCA_{120} immobilized on the CM3 sensor chip. (region A): Injection of lac50 (lines 1−3) and lac0 (line 4). (region B): Flowing of running buffer (lines 1−4). (region C): Injection of running buffer (lines 1, 4), 100 μg/mL of glucose solution (line 2), and 100 μg/mL of galactose solution (line 3). (region D): Flowing of running buffer (lines 1−4). (region E): Injection of excess galactose (100 mg/mL, lines 1−4). All of these experiments were carried out at the flow rate of 5 μL/min.

2.4. Colloidal Au Replacement Assay. Lac25 and lac50 (15 nM and 5.2 nM particle concentrations, respectively) were injected over 1500 RU of an RCA_{120}-immobilized sensor chip at 10 μL/min for 5 and 3 min, respectively, producing a 900−1300 RU increase in the response. Subsequently, 0−100 ppm of galactose was injected for 5 min to elute the preadsorbed gold nanoparticles. In the elution sensorgram, the response level was normalized by the amount of the preadsorbed PEGylated gold nanoparticles (*12*, *13*). The dissociation rate constant (k_d) of the galactose-induced dissociation of lac25 and lac50 was calculated by a separate fitting against the first 15 s of the dissociation curves using a Langmuir model of the *Biaevaluation 3.1* software.

3. RESULTS AND DISCUSSION

3.1. Specificity of the Binding. Injection of lac50 (15 nM particle concentration) onto an RCA_{120}-immobilized CM3 sensor chip induced an obvious increase in the SPR signal (ca. 500 RU), in which lac0 was used as the control and conveyed low response (region A, Figure 2). The subsequent injection of 100 μg/mL galactose allowed a fast dissociation of the adsorbing lac50, whereas the same concentration of glucose did not trigger such a dissociation, and almost the same curve as the sensorgram recorded under the buffer injection was observed (region C, Figure 2), indicating the specific interaction of RCA_{120} with the lactose moieties on the PEGylated gold nanoparticles. The injection of a large excess of galactose (100 mg/mL) to the lac50-adsorbed sensor chip allowed the complete dissociation of the lac50, and eventually led to a regeneration of the sensor chip (region E, Figure 2).

3.2. SPR Response of PEGylated Gold Nanoparticles with Varying Lactose Surface Densities. Figure 3 shows the signal changes induced by the injection of the gold nanoparticles possessing various lactose densities (lac25, lac50) into a flow cell equipped with an RCA_{120}-immobilized sensor chip. Data for lac-BSA and NA3 glycan are also shown as controls. Obviously, the lactose-functionalized gold nanoparticles displayed a much higher response compared to the controls,

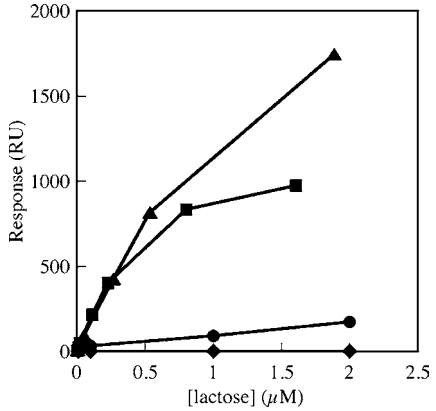

Figure 3. Binding response of various lactosylated substances onto an RCA_{120}-immobilized CM3 sensor chip (square, lac25; triangle, lac50; circle, lac-BSA; diamond, NA3 glycan). The samples were injected for 10 min at the flow rate of 5 μL/min.

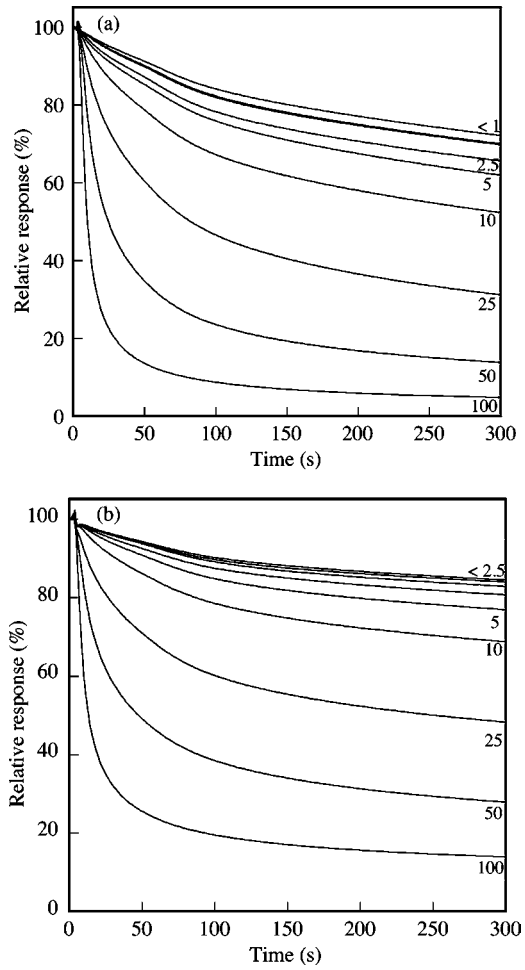

Figure 4. The elution profiles of preadsorbed lac25 (a) and lac50 (b) from an RCA_{120}-immobilized CM3 sensor chip induced by the injection of galactose. Lac25 and lac50 were injected over the sensor chip at the flow rate of 10 μL/min for 5 and 3 min, respectively. The elution of the preadsorbed nanoparticles was done by the injection of 0.1−100 ppm of galactose for 5 min. The magnitude of the net response increase from the baseline at the beginning of the elution phase was taken as 100% for each sensorgram for data normalization. The values indicated in each of the sensorgrams represent the injected galactose concentration (ppm).

indicating that the enhancement of the SPR signal based on the gold nanoparticles effectively worked. This is considered to be due to the large apparent mass and the coupling effect between the gold nanoparticles and gold surface on the sensor chip (*5*, *6*). Interestingly, the lac50 system revealed a more effective signal enhancement than the lac25 system at the same lactose concentration, even where the former has a particle concentration that is half of the latter, suggesting that the former has a higher binding affinity to the immobilized RCA_{120} than the latter.

Table 1. Kinetic Parameters for lac25-RCA_{120} and lac50-RCA_{120} Systems Determined from SPR Analysis

sample	k_a ($M^{-1}\,s^{-1}$)	k_d (s^{-1})	K_D (M)	χ^2
lac25	1.56×10^5	9.88×10^{-4}	6.34×10^{-9}	1.21
lac50	2.41×10^5	4.97×10^{-4}	2.06×10^{-9}	3.88

3.3. Kinetic Evaluations. To quantitatively assess the affinity of lac25 and lac50 to RCA_{120}, a kinetic analysis was carried out. A series of different concentrations of the samples was injected at the flow rate of 20 μL/min for 2 min, followed by the flowing of running buffer for 5 min to observe the dissociation phase of the samples (Figures S2 and S3). As shown in Table 1, the equilibrium dissociation constants (K_D) of the lac25-RCA_{120} and lac50-RCA_{120} systems were calculated to be 6.34×10^{-9} and 2.06×10^{-9} M, respectively, using global fitting of a Langmuir model. On the other hand, the K_D of a single lactose molecule with RCA_{120} was reported to be 3.7×10^{-3} M (*14*). It is notable that the lactosyl gold nanoparticles-RCA_{120} system has a K_D that is 6 orders smaller than the lactose-RCA_{120} system. In our previous report, lactose-installed polymeric micelles behave as a multivalent ligand for an RCA_{120}-immobilized sensor chip with a decrease in the K_D of the same order of magnitude as this system with respect to a monovalent interaction (*15*). Considering this previous report of multivalent interactions and several other references about multivalent glyconanoparticles (*16*, *17*), all of which showed that multivalency causes the nonlinear increase in the affinity, it is reasonable to also assume in this case the multivalent interactions: multiple lactose ligands on a single particle would bind with several lectin molecules on a sensor chip. In fact, in the global fitting of the sensorgrams of lac25 and lac50 using a bivalent model, a sufficiently low χ^2, a measure of the accuracy of the fitting, was obtained (1.26 and 4.03, respectively), making this fit acceptable by Biacore standards ($\chi^2 < 10$).

To gain insight into the multivalent interaction of lactose molecules on the gold nanoparticles with RCA_{120} on the sensor chip, the inter-lactose distance on the gold nanoparticles as well as the distance between two RCA_{120} molecules on the sensor chip were calculated on the basis of the following three assumptions; (i) uniform distribution of lactose molecules on the gold nanoparticles as well as of RCA_{120} molecules on the sensor chip, (ii) reduced apparent valency of an immobilized RCA_{120} molecule on the sensor chip from bivalent to monovalent against lactose molecules on the gold nanoparticles due to a steric restriction, and (iii) all of the lactose ligands accessible to the binding site of RCA_{120}, neglecting the possible decrease in the number of available lactose molecules due to the concealment of the chain end into the flexible PEG coils. As previously reported (*10*), the diameter including the PEG layer of the PEGylated gold nanoparticles was evaluated to be 33.3 nm from SEM, and the number of PEG chains on a single gold nanoparticle was estimated to be 520 chains/particle from a thermogravimetric analysis. Accordingly, the number of lactose molecules and the inter-lactose distance on lac25 and lac50 were calculated and summarized in Table 2 . Alternatively, on the basis of the RCA_{120} density described in the Experimental Section 2.3 (7.52×10^{-3} proteins/nm^2), the area occupied by a single RCA_{120} molecule on the sensor chip was calculated to be $(7.52 \times 10^{-3})^{-1} = 133$ nm^2/protein. Consequently, the average distance between RCA_{120} on the sensor chip surface is approximated to be $133^{0.5} = 11.5$ nm. It may be reasonable to then assume at least a bivalent interaction, because the inter-lactose distance on lac25 and lac50 is calculated to be less than

Table 2. Number of Lactose Molecules and Lactose Density on Gold Nanoparticles

	lac25	lac50
number of lactose molecules on a single particle[a]	130	260
area occupied by a single lactose molecule (nm^2)[b]	26.8	13.4
average distance between lactose moieties (nm)[c]	5.18	3.66

[a] Calculated from the number of PEG chains on a single gold nanoparticle (520 chains/particle) and the lactose functionality. [b] The surface area of PEGylated gold nanoparticles [$4\pi \times (33.3/2)^2 = 3.48 \times 10^3$ nm^2] was divided by the number of lactose molecules on a single gold nanoparticle. [c] Square root of the area occupied by one lactose molecule.

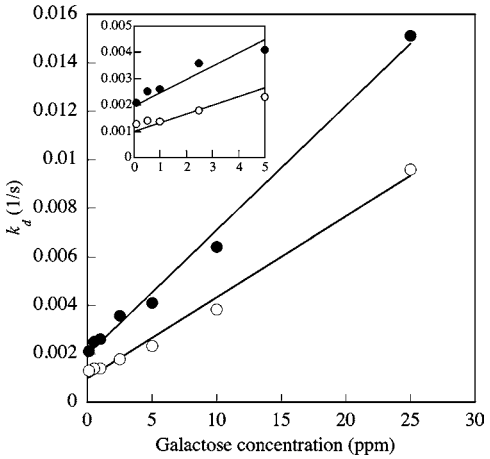

Figure 5. The relationship of the dissociation rate constant (k_d) to the injected galactose concentration. The k_d was obtained by curve fitting of the sensorgrams in Figure 4 as described in the Experimental Section. Closed circles indicate k_d of lac25 ($R^2 = 0.9924$, $\chi^2 = 3.83$), and open circles indicate k_d of lac50 ($R^2 = 0.9895$, $\chi^2 = 1.95$). The insert is the expanded figure in the range 0−5 ppm galactose.

half of the average distance between two RCA_{120} molecules on the sensor chip surface.

3.4. Colloidal Au Replacement Assay. The SPR signal enhancement by the lactosyl-PEGylated gold nanoparticles was then applied to the direct and quantitative detection of the LMW analyte, galactose. The novel method developed here (colloidal Au replacement assay) is based on the elution of the preadsorbed lactosyl-PEGylated gold nanoparticles from the sensor chip surface due to the substitution with galactose in the solution. A practical advantage of this method is that it does not require any labeling of the LMW analytes. The lactosyl-PEGylated gold nanoparticles (ca. 900−1300 RU) were initially adsorbed on the RCA_{120}-immobilized CM3 sensor chip. Free galactose, in varying concentrations (0.1−100 ppm), was then injected into the flow cell. During the elution phase of each sensorgram, the response level was normalized by the amount of the preadsorbed PEGylated gold nanoparticles as shown in Figure 4 (relative response) (*12*, *13*). Obviously, the elution of the gold nanoparticles correlated with the galactose concentration. To quantify the degree of galactose-induced dissociation, the dissociation rate constant (k_d) was calculated by curve fitting against the dissociation sensorgrams. Notably, the k_d has a linear relationship in the 0.1−25 ppm galactose concentration range for both lac25 and lac50 (Figure 5), thus permitting the quantitative analysis of galactose. Moreover, a decrease in the relative response fits nicely to a linear relationship with the galactose concentration for both lac25 (Figure 6A) and lac50 (Figure 6B) measured at several time points. As seen in the inserts of Figure 6A,B, a quantitative analysis is feasible from 0.1 to 50 ppm, indicating the significantly high sensitivity of this method. It is also noted that the linearity was valid for an appreciably wide

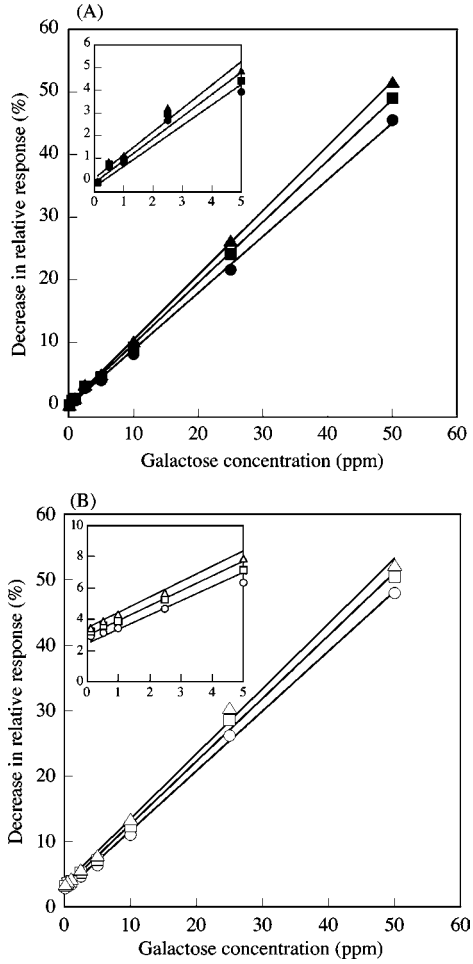

Figure 6. Relationship of the decrease in the relative response vs injected galactose concentration. All the plots in these figures were obtained by the subtraction of the relative response recorded under galactose-induced dissociation from the relative response recorded under only the running buffer. A linear response to the galactose concentration (0.1−50 ppm) was observed in all the plots ($R^2 > 0.997$). The inserts are the expanded figures in the range 0−5 ppm galactose. (A) Closed circles, squares, and triangles are the data corresponding to the time points at 25, 30, and 35 s in the sensorgrams of the lac25 elution (Figure 4a), respectively. (B) Open circles, squares, and triangles are the data points corresponding to the times of 50, 60, and 70 s in the sensorgrams of the lac50 elution (Figure 4b), respectively.

range of response times: 20−30 s for lac25 and 50−70 s for lac50. This linearity in the decrease of the relative response reveals a practical advantage of the colloidal Au replacement assay. Note that the colloidal Au replacement assay achieves a sensitivity comparable to that of ELISA in a much shorter operating time (∼5 min) without any cumbersome processes of multiple washing and separation steps, which are necessary for the ELISA assay.

This method may be applicable for the quantitative sensing of various LMW compounds of practical interest, including sugars (*18*, *19*), by utilizing an appropriate combination of analyte-installed PEGylated gold nanoparticles and immobilized ligands to construct a high-throughput screening system.

4. CONCLUSION

PEGylated gold nanoparticles with different lactose functionalities (0−50%) on the distal end of PEG were prepared in order to construct a novel method for the quantitative assay of LMW analytes by SPR (colloidal Au replacement assay). The lactosyl-PEGylated gold nanoparticles showed a specific adsorption on the sensor chip surface bearing the RCA_{120} lectin,

dependent on the lactose functionality on the surface of the gold nanoparticles due to the multivalent interaction of the nanoparticles with RCA_{120} immobilized on the sensor chip. Interestingly, preadsorbed lactosyl-PEGylated gold nanoparticles on the RCA_{120}-immobilized sensor chip were eluted from the sensor chip by the injection of galactose, in a manner proportional to the galactose concentration. Eventually, this method allowed for the quantitative assay over a wide range of galactose concentrations (0.1−50 ppm) within a short operating time (∼5 min). This concept of colloidal Au replacement assay would be applicable to the highly sensitive SPR quantification of various LMW analytes.

ACKNOWLEDGMENT

The authors acknowledge Dr. Eduardo Jule, the University of Tokyo, for his advice about the SPR experiments. This study was financially supported by Special Coordination Funds for Promoting Science and Technology from the Ministry of Education, Culture, Sports, Science and Technology of Japan (MEXT) as well as by the Core Research for Evolutional Science and Technology (CREST) from the Japan Science and Technology Agency (JST) and also by a Grant for the 21st Century COE Program "Human-Friendly Materials based on Chemistry" from MEXT. S.T. would like to express his special gratitude for the scholarship from the Asahi Glass Scholarship Foundation.

Selective Fluorescence Probes for Dipeptidyl Peptidase Activity—Fibroblast Activation Protein and Dipeptidyl Peptidase IV

Koon Siew Lai,[†,§] Nan-Hui Ho,[†,§] Jonathan D. Cheng,[‡] and Ching-Hsuan Tung*[,†]

Center of Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, Charlestown, Massachusetts 02129, and Department of Medical Oncology, Fox Chase Cancer Center, Philadelphia, Pennsylvania 19111. Received November 16, 2006; Revised Manuscript Received March 15, 2007

Development of suitable tools to assess enzyme activity directly from their complex cellular environment has a dramatic impact on understanding the functional roles of proteins as well as on the discovery of new drugs. In this study, a novel fluorescence-based chemosensor strategy for the direct readout of dipeptidase activities within intact living cells is described. Selective activity-based probes were designed to sense two important type II transmembrane serine proteases, fibroblast activation protein (FAP) and dipeptidyl peptidase IV (DPP-IV). These serine proteases have been implicated in diverse cellular activities, including blood coagulation, digestion, immune responses, wound healing, tumor growth, tumor invasion, and metastasis. Here, we validated that Ac-GPGP-2SBPO and GPGP-2SBPO probes are excellent reporters of both proteolytic activities. Furthermore, the novel probes can differentiate between FAP and DPP-IV proteolytic activities in cellular assay. Potentially, this assay platform is immediately useful for novel drug discovery.

INTRODUCTION

Fibroblast activation protein (FAP; EC: 3.4.21.B28) and dipeptidyl peptidase IV (DPP-IV; EC: 3.4.14.5) belong to a type II transmembrane serine protease family, and are capable of cleaving N-terminal dipeptides after a proline residue (*1*, *2*). Structurally, both proteases have a short cytoplasmic tail, a transmembrane domain, and a large C-terminal extracellular domain (ECD). The ECD domain consists of two characteristic subdomains, a β-propeller subdomain with several sites of N-linked glycosylation at the N-terminus and an α/β-hydrolase subdomain with the catalytic triad of serine, aspartate, and histidine residues at the C-terminus. The human FAP gene maps on chromosome 2 at 2q23, and the DPP-IV gene maps on the same chromosome at 2q24.3. Although FAP and DPP-IV share a high sequence identity and may have arisen by gene duplication, it was reported that each has a distinct enzyme activity profile. Apart from having prolyl exopeptidase activity like its DPP-IV homologue, FAP also functions as a prolyl endopeptidase (*3*, *4*) and has a collagenolytic activity capable of degrading gelatin and type I collagen (*5*, *6*).

In terms of expression, FAP is selectively expressed on reactive stromal fibroblasts in over 90% of common human epithelial cancers, such as colorectal, breast, and lung cancers (*7*). Expression of FAP is not detected in fibroblasts of benign epithelial tumors or normal adult tissues. High expression of FAP in tumors correlates with increased FAP activity relative to normal tissues (*4*, *8*, *9*). It has been suggested that FAP promotes tumor growth and proliferation (*10*). Currently, FAP inhibitor PT-100 (Val-boroPro) (*11*) is being tested in clinical trials to evaluate its efficacy to treat non-small-cell lung and other cancers (*12*). In contrast to FAP, DPP-IV is ubiquitously expressed in normal epithelial cells and melanocytes. It was originally identified as a protein expressed on the surface of T cells, and its expression is lost in various cancers (*13*−*15*). These suggest the involvement of DPP-IV in immunology, oncology, and other areas. DPP-IV has been recently validated as a therapeutic target for type 2 diabetics with the approval of the DPP-IV inhibitor sitagliptin phosphate (*16*). The proteolytic functions of these two proteins and their distinct expression distribution make them promising and attractive targets for new indications (*8*, *17*−*21*).

Protease-targeted fluorogenic substrates using 7-amino-4-methylcoumarin (AMC) or 7-amino-4-trifluoromethylcoumarin (AFC) as a reporter have commonly been used for detecting protease activity in vitro (*4*−*6*). The fluorescence property of the coumarin reporters is masked by the peptide amide linkage. Upon proteolytic conversion of the probes, the reporters are released as fluorescent free dyes. This type of probes has been widely used in cell-free assays; however, it cannot be directly applied to complex cellular environments. Limitations of these probes are attributed to two major factors. First, high autofluorescence background can be caused by the illumination of cells. Second, the poor aqueous solubility of the fluorophores often required DMSO as a cosolvent, which could lead to reduced enzymatic activity (*22*).

To develop methods that allow more direct and reliable assessment of enzyme activity in vivo, a water-soluble and far-red fluorescence-based probe having emission maxima between 650 and 900 nm is preferred. We recently validated the use of a new water-soluble far-red fluorogenic dye containing a disulfonated benzo[*a*]phenoxazine (2SBPO) scaffold for enzyme sensing (*23*). 2SBPO conjugated to a GPGP tetrapeptide is weakly fluorescent but displays strong fluorescence emission at 670 nm upon cleavage by DPP-IV. Here, we further demonstrate that the distinct proteolytic activities between FAP and DPP-IV could be assessed using preselected probes. The sensitivity and selectivity of these fluorescence-based chemosensors are sufficient to measure the prolyl-endopeptidase activities of FAP and the prolyl-exopeptidase activity of DPP-IV in living cells.

MATERIALS AND METHODS

Synthesis of the Fluorescence-Based Chemosensors. The parent dye, 9-di-3-sulfonylpropylaminobenzo[*a*]phenoxazonium perchlorate (2SBPO), was synthesized as previously described (*24*). Amino acids were purchased from Novabiochem (San Diego, CA). All peptide substrates were prepared by solution-phase synthesis using N-Boc-protected amino acids and Ac-glycine for the acetyl-protected peptides using the same procedure as described for GPGP-2SBPO (*23*). The peptide substrates were purified on a C-18 Sep-Pak cartridge. Electrospray mass spectra were obtained on a Platform LCT mass spectrometer (Micromass, Beverly, MA), and MALDI mass spectra were measured on a Voyager linear mass spectrometer (Applied Biosystems; Framingham, MA). GPGP-2SBPO: HRMS (ES+/TOF) calcd for $C_{36}H_{44}N_7O_{11}S_2$ $(M)^+$ 814.2540, found 814.2538. Ac-GPGP-2SBPO: HRMS (ES+/TOF) calcd for $C_{38}H_{46}N_7O_{12}S_2$ $(M)^+$ 856.2640, found 856.2530. APAP-2SBPO: HRMS (ES+/TOF) calcd for $C_{38}H_{48}N_7O_{11}S_2$ $(M)^+$ 842.2848, found 842.2856. Ac-GP-2SBPO: MS (MALDI-TOF) calcd for $C_{31}H_{36}N_5O_{10}S_2$ $(M)^+$ 702.2, found 701.9. TSGP-2SBPO: MS (MALDI-TOF) calcd for $C_{36}H_{45}N_6O_{14}S_2$ $(M)^+$ 702.2, found 701.9.

Cell Lines. HT-29, human colon cancer cell line was obtained from American Type Culture Collection (Rockville, MD). To detect the FAP activity in culture assay, human embryonic kidney cell line, HEK293, stably transfected with full-length wild-type murine FAP (HEK-FAP) was used, and HEK293 cells stably transfected with empty vector alone (HEK-vector) were used as a control cell line (*9*). For recombinant murine FAP preparation, HEK293 stably transfected with murine FAP-ECD cDNA was used (HEK-FAP-ECD) (*9*, *10*). All cell lines were maintained in DMEM medium with 10% FBS.

In Vitro and Cell-Based Enzymatic Assay. Recombinant murine DPP-IV was purchased from R&D Systems (Minneapolis, MN), while murine FAP was purified from HEK-FAP-ECD cells as previously described (*9*, *10*). Purification of the FAP protein was confirmed by SDS-PAGE electrophoresis and staining with Gelcode blue stain reagent (Pierce, Rockford, IL). Concentration of the FAP protein was determined by using a BCA protein assay kit (Pierce, Rockford, IL).

All of the enzymatic assays were performed in triplicate on 96-well assay plates (Corning Inc., NY). Various substrates at 50 μM were tested in vitro with 10 nM of the respective recombinant murine DPP-IV and FAP enzymes under physiological conditions. A total of 200 μL of 10 mM PBS (pH 7.4) with substrate and enzyme, or with substrate alone as control, was incubated in the 96-well plate at 37 °C for 2 h. Fluorescence emission at 670 nm and excitation at 630 nm were measured by a fully modular monochromator-based plate reader (Safire2, Tecan, San Jose, CA). For cell-based enzymatic assays, the cells were first seeded at 50,000 cells/well in the 96-well assay plate. A day later, the serum-containing medium was removed and changed to 10 mM PBS (pH 7.4) with 20 μM of the substrate. Cells were then incubated with substrates at 37 °C for 3 to 5 h prior to fluorescence measurement.

Western Blot Analyses. HEK-vector, HEK-FAP, and HT-29 cells were lysed with M-PER mammalian protein extraction reagent (Pierce, Rockford, IL). Cell debris was removed by centrifugation, and clear cell lysates were transferred to new microfuge tubes. The protein concentrations were determined by using Bradford reagent (Sigma-Aldrich, St, Louis, MO). The cell lysates (50 μg) were loaded onto 10% SDS-PAGE gels and transferred to Immun-blot PVDF membranes (Bio-Rad, Hercules, CA). Anti-murine FAP monoclonal antibody (6E1) (*9*) was custom-made and used at a 1:100 dilution with 5% nonfat milk in PBS + 0.1% Tween. Anti-human DPP-IV polyclonal antibody was purchased from EM Biosciences (San Diego, CA) and used at a 1:1000 dilution. As a control for protein loading, actin antibody (C-11) from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA), was used at a 1:1000 dilution. All immunoblots were analyzed by using the ECL detection system (Amersham Biosciences, U.K.).

Cell Proliferation Assay. MTS tetrazolium compound from Promega (Madison, WI) was used as a colorimetric indicator for determining the number of viable cells in proliferation or cytotoxicity assays. Assays were performed by adding 20 μL of MTS compound to each well containing the cells in 100 μL of assay medium. Absorbance at 490 nm was recorded after 1 h incubation at 37 °C in a humidified chamber with 5% CO_2.

RESULTS AND DISCUSSION

Fluorogenic Substrate Design. Recent study in substrate development has indicated that glycylprolyl dipeptide is an excellent substrate for DPP-IV; unfortunately, it can also be recognized by FAP (*3*). The result from a systematic screening of the proline-containing dipeptide library has suggested a broad substrate exopeptidase selectivity of these two proteases, especially DPP-IV (*5*). The best, maybe the only, approach to distinguish these two proteases is by measuring the exopeptidase and endopeptidase activity of DPP-IV and FAP, respectively (*6*).

A water-soluble DPP-IV sensitive probe, GPGP-2SBPO, was previously synthesized to measure dipeptidyl peptidase activity (*23*). The rationale of having a tetrapeptide to report the dipeptidase activity was the instability of the dipeptide and fluorogenic dye conjugate. GP-2SBPO underwent spontaneous nonenzymatic hydrolysis via intramolecular cyclization to give cyclo[Gly-Pro] and free 2SBPO in physiological conditions. To overcome the problem of this unexpected nonenzymatic hydrolysis, a second glycylprolyl dipeptide was added to the N-terminus of GP-2SBPO to generate the tetrapeptide substrate, GPGP-2SBPO, which was subsequently proven to be useful for DPP-IV sensing. On the basis of this finding, several tetrapeptide substrates were synthesized to detect exo and endo dipeptidyl protease activity (Figure 1).

Substrate Selectivity and in Vitro Enzymatic Activity. To evaluate the selectivity of these fluorogenic probes, recombinant murine FAP and DPP-IV enzymes were assayed for proteolytic activity in vitro. GPGP-2SBPO and APAP-2SBPO were used to compare the specific exopeptidase activity of FAP with DPP-IV. Fluorescence signals released from the substrates upon activation by their respective enzyme were monitored simultaneously in a 96-well assay plate. The fluorescence of the control referred to the background signal where no enzyme was added. Although both proteases exhibit exopeptidase activity, as shown in Figure 2A, FAP preferred the APAP-2SBPO substrate but showed no activity with the GPGP-2SBPO substrate. In contrast, DPP-IV readily cleaved both substrates (Figure 2B), and a greater than 6-fold increase in fluorescence signal was observed with GPGP-2SBPO. These results are consistent with the published data indicating that DPP-IV has broader substrate specificity for prolyl exopeptidase activity (*5*).

It has been reported that FAP, but not DPP-IV, possesses endopeptidase activity (*3*, *5*, *6*). To confirm the endopeptidase specificity of the protease, we assayed FAP and DPP-IV against TSGP-2SPO, Ac-GP-2SBPO, and Ac-GPGP-2SBPO (Figure 2). As expected, DPP-IV showed no activity against any of these substrates (Figure 2B). However, FAP showed a greater catalytic efficiency for Ac-GPGP-2SBPO than for Ac-GP-2SBPO and TSGP-2SBPO under the same assay reaction conditions.

Ac-GPGP-2SBPO was the most efficient substrate for FAP activation. Its cleavage yielded a 7-fold increase in fluorescence signal (Figure 2). Similar to our previous finding (*23*), following the specific FAP endopeptidase cleavage between the Pro and

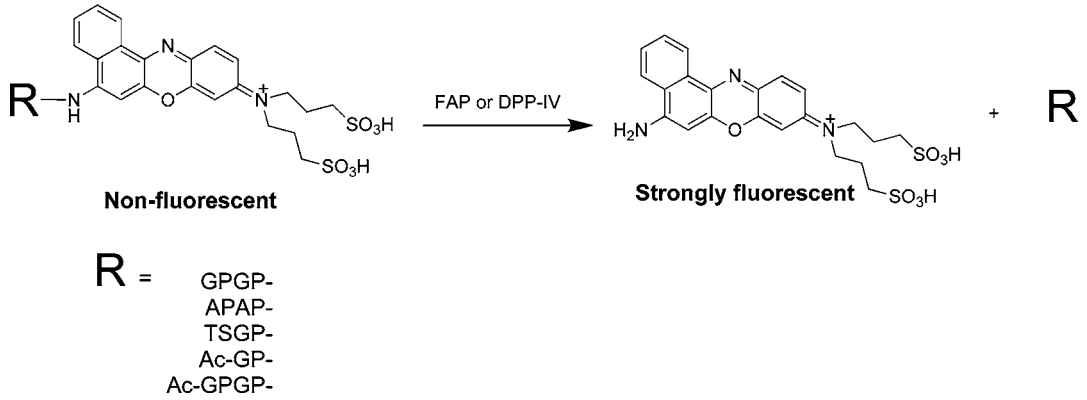

Figure 1. Structure and sequences of the synthesized fluorogenic probes.

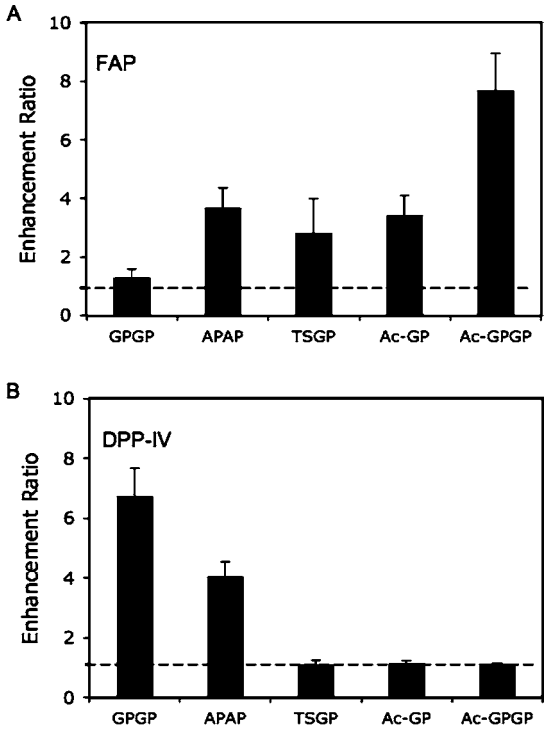

Figure 2. Substrate selectivity of FAP (A) and DPP-IV (B). The substrates (50 μM) were incubated with either protease (10 nM) in 10 mM PBS (pH 7.4) for 2 h. The measurement was collected with 630 nm excitation and 670 nm emission. The dotted lines indicate the background signal.

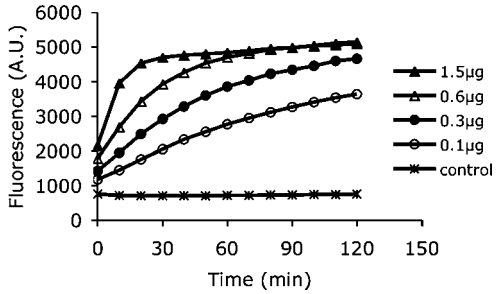

Figure 3. Dose response of fluorescence signal. The fluorescence signal was measured at various times with five different concentrations of FAP and a single Ac-GPGP-2SBPO substrate concentration at 10 uM in PBS. The increase in fluorescence emission was found to be enzyme concentration dependent. The fluorescence of the control referred to the background signal where no enzyme was added.

Gly residues, a spontaneous nonenzymatic hydrolysis of the resulting GP-2SBPO happened to free 2SBPO and emit fluorescence. In contrast, the smaller increases in fluorescence signal for Ac-GP-2SBPO and TSGP-2SBPO may be attributable to sequence preference.

To demonstrate the dose response of FAP enzymatic activity, 10 μM Ac-GPGP-2SBPO substrate was mixed with four different concentrations of FAP enzyme, and fluorescence signals were measured over a period of 2 h. The reaction progress curves, shown in Figure 3, approach a similar maximum plateau fluorescence value. This is an indication that FAP enzyme remains stable under the conditions tested. A nearly linear dose response ($R^2 = 0.98$) was observed in the first 10 min. These curves were also used to define the amount of FAP enzyme that was needed to maintain initial velocity conditions.

Cell-Based Enzymatic Studies. Having identified Ac-GPGP-2SBPO and GPGP-2SBPO probes as excellent reporter substrates of FAP and DPP-IV, respectively, we were interested to know whether these probes permit a direct and simple readout of the enzyme activity in intact mammalian cells. Three cell lines, i.e., (i) human colon cancer cells HT-29, (ii) human embryonic kidney HEK293 cells stably transfected with full length wild-type murine FAP (HEK-FAP), and (iii) HEK293 cells stably transfected with empty vector (HEK-vector), were used to monitor the selectivity of these two fluorogenic probes.

According to Western blot analyses, the HT-29 cell line expresses DPP-IV but not FAP (Figure 4A). On the other hand, HEK-FAP transfected cells show exogenous expression of FAP. For the HEK-vector control cell line, FAP expression is undetectable. It is also noteworthy that neither of these HEK cell lines express DPP-IV, as seen in the blot. Although FAP is not expressed in the HEK-vector control cell line, interestingly we observed an increase in fluorescence signal when Ac-GPGP-2SBPO substrates were directly incubated with HEK-vector cells in the growth medium which contains 10% fetal bovine serum (data not shown). Recent studies have reported the identification of soluble forms of FAP from human blood and bovine serum (*25*, *26*). In order to eliminate the interference and be able to monitor the transmembrane proteases in intact cells directly, a phosphate-buffered solution (10 mM) at pH 7.4 was used for subsequent cellular assays.

As shown in Figure 4B,C, the Ac-GPGP-2SBPO probe showed a 4-fold increase in fluorescence after direct incubation with HEK-FAP cells for 5 h at 37 °C. This result demonstrated that Ac-GPGP-2SBPO possesses significant selectivity for FAP in HEK-FAP cells as compared with HEK-vector control cells and HT-29 cells. In the case of GPGP-2SBPO, the substrate was selectively cleaved by the endogenous DPP-IV in HT-29 living cells and showed an approximately 3-fold increase in fluorescence in 5 h. The smaller increase in fluorescence may suggest that the level of activity corresponds to its lower expression level of DPP-IV within the cells, as supported by Western blot expression data.

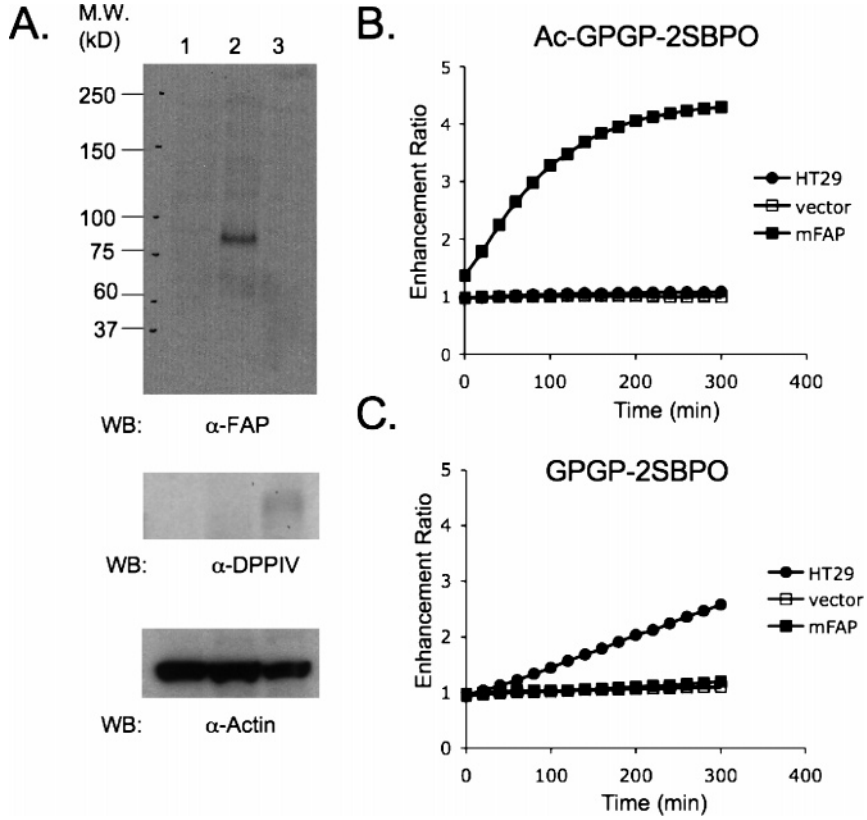

Figure 4. Western blot analysis and detection of dipeptidase activity by cell-based assays. (A) Western blots of cell lysates collected from HEK-vector (column 1), HEK-FAP (column 2), and HT-29 (column 3). (B) Activation of Ac-GPGP-2SBPO in 5 h. Only HEK-FAP was able to activate the probe. (C) Activation of GPGP-2SBPO in 5 h. Only HT-29 was able to activate the probe.

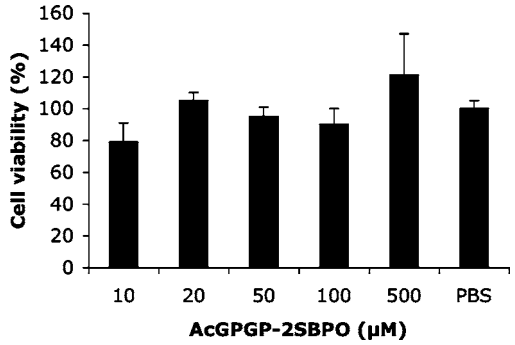

Figure 5. Effects of Ac-GPGP-2SBPO on cell toxicity. HEK-FAP cells were incubated with different concentrations of Ac-GPGP-2SBPO at 37 °C for 1 h. Experiments were performed in triplicate, mean ± SE.

Cell proliferation MTS assay was further performed to ensure that the probes are nontoxic to cells. HEK-FAP cells were treated with various concentrations of Ac-GPGP-2SBPO for 5 h. Then, MTS assay medium was added into each well and incubated for another 1 h. The absorbance readings at 490 nm showed no significant difference, suggesting that 2SBPO fluorogenic dye is nontoxic under the experimental condition (Figure 5).

CONCLUSIONS

In summary, a novel near-infrared optical probe has been developed to detect specific FAP endopeptidase activity by either in vitro or in cellular assays. Ac-GPGP-2SBPO is a water-soluble acetylated tetrapeptide fluorescent substrate with the excitation wavelength at 630 nm and emission wavelength at 670 nm. It contains the Gly-Pro dipeptide motif for the FAP-selective endopeptidase cleavage site. We also validated that Ac-GPGP-2SBPO and GPGP-2SBPO probes are excellent reporters for studying FAP and DPP-IV prolyl aminopeptidase activities in cell culture and can be readily adapted for a high-throughput drug screening format.

ACKNOWLEDGMENT

From Phage Display to Magnetophage, a New Tool for Magnetic Resonance Molecular Imaging

Jérôme Segers,[§] Catherine Laumonier, Carmen Burtea, Sophie Laurent, Luce Vander Elst, and Robert N. Muller*

Department of General, Organic and Biomedical Chemistry, NMR and Molecular Imaging Laboratory, University of Mons-Hainaut, 24 Avenue du Champ de Mars, Mons B-7000, Belgium. Received December 7, 2006; Revised Manuscript Received March 23, 2007

Phage display, an extremely promising technology in the context of molecular imaging, allows for the selection of peptides interacting with virtually any target from a heterogeneous mixture of bacteriophages. In this work, we propose the concept of magnetophages, obtained by covalent coupling of ultrasmall particles of iron oxide (USPIO) to the proteins of the phage wall. To validate magnetophages as a magnetic resonance imaging contrast agent (MRI), we have used as a prototype the clone E3 because of its specific affinity for phosphatidylserine, a marker of apoptosis. Enzyme-linked immunosorbent assay showed that E3 magnetophages incubated with phosphatidylserine retained the properties of the nonmagnetically labeled phages. The usefulness of magnetophages as an MRI contrast agent was estimated by incubation with phosphatidylcholine and phosphatidylserine or with apoptotic and control cells. Under these conditions, E3 magnetophages allow the discrimination of phosphatidylserine from phosphatidylcholine and of apoptotic cells from control ones. Injected *in vivo*, magnetophages are rapidly cleared from the blood stream and internalized by the phagocytic cells of the liver. To abrogate this problem, USPIO were pegylated to obtain stealthy E3-PEG-magnetophages, invisible to phagocytic cells, which were successfully targeted to apoptotic liver. If this feature demonstrated for E3 magnetophages can be extrapolated to other phage display selected entities, magnetophages become an original system which allows validation of the candidate binding peptides before their synthesis is considered. The concept of the magnetophage could be extended to other imaging modalities by replacing USPIO with an adequate reporter (i.e., radiolabeled phages).

INTRODUCTION

Molecular imaging, a concept that has recently emerged, aims at visualizing molecules expressed in pathological conditions. It has therefore the potential of playing an important role in the early detection of pathologies and understanding their molecular mechanisms (*1*). Molecular imaging relies on the use of vectorized reporters acting as contrast agents. In magnetic resonance imaging (MRI), contrast agents are made of a magnetic center responsible for the modulation of the recorded signal, which is coupled to a targeting structure.

Phage-display technology is a powerful strategy for the selection and identification of peptidic sequences interacting with a target of interest (receptor, protein, etc.). It is based on the use of a phage library which is a heterogeneous mixture of phage clones, each carrying a different foreign DNA insert and therefore displaying a different peptide on its surface (*2*−*8*). The identification of binders specific to a target requires several rounds of selection and amplification during which the phage population is gradually enriched in high affinity binders, to finally obtain a population of phages specific for the target. Subsequent coupling of the selected peptide to a magnetic, optical, or radioactive reporter gives specific probes for molecular imaging.

We have previously applied this methodology to the design of a MRI contrast agent specific for apoptosis (*9*). In this study, we propose an alternative strategy: the direct use of the selected phages themselves as vectors of the contrast agent. The conjugation of ultrasmall particles of iron oxide (USPIO) to the phages generates a system that we have called "magnetophages". USPIO are indeed efficient magnetic reporters for MRI (*10, 11*), made of nanocrystals containing 2000 to 3000 Fe^{3+} atoms coated with dextran.

The aim of this work was to design, characterize, and evaluate the potential application of magnetophages as markers for magnetic resonance molecular imaging (MRMI). To evaluate this concept, phages displaying the peptide TLVSSL (corresponding to phage clone E3) identified in our previous work as a specific binder for phosphatidylserine (PS) (*9*), a biomarker of apoptosis (*12, 13*), were turned into magnetic labeled phages (magnetophages E3). Phages E3 and magnetophages E3 were used as prototypes.

EXPERIMENTAL PROCEDURES

The *in vivo* protocols of the experiments fulfill the prescriptions of the ethics committee of our institution.

Phage Display Library, Phage, and Bacterial Strains. A random linear hexapeptide library (fUSE5 vector) was used. The inserts are spliced into the gene corresponding to the minor coat protein pIII (*3*). In addition, the phages of this library contain a gene that confers resistance to tetracycline (Tc) to the infected bacteria. This library was kindly provided by Dr. Hans Ullrichts (KULAK, Kortrijk, Belgium). Nonselected phages, from the initial library, and a clone (E3), specific for phosphatidylserine (PS), were used to produce the corresponding magnetophages. The clone E3 was selected using the phage-display selection procedure carried out in a previous work (*9*). Bacteria used in this work belong to the enterobacterium *Escherichia coli* strain K91BluKAN provided by Dr. H. Ullrichts (KULAK, Kortrijk, Belgium). These bacteria contain the kanamycine (Kan) resistance gene.

Phage Amplification and Precipitation. Phages were amplified by infecting *E. coli* host strain K91BluKan. A culture flask

containing LB (Luria−Bertani) medium supplemented with 100 μg/mL Kan was inoculated with a single bacteria colony. Bacteria were allowed to grow overnight at 37 °C with vigorous rotational shaking. The culture was then diluted 100 times in 100 mL LB medium supplemented with 100 μg/mL Kan and allowed to grow until bacteria reached the midlog phase ($OD_{600} \sim 0.8-0.9$). At that time, an amount of 2×10^{11} phages was added to the culture medium that was completed with 10 μg/mL Tc. The culture was allowed to grow overnight. During this phase, phages are secreted in the medium by infected bacteria.

Amplified phages were recovered by precipitation with poly(ethylene glycol) (PEG). Briefly, the culture was centrifuged at 10 000 rpm and 4 °C for 15 min. The supernatant was transferred to a new flask and 1/5 volume/volume PEG/NaCl was added (20% PEG 6000, 2.5 M NaCl). Phages were precipitated for 2 h at 4 °C and were then retrieved by centrifugation at 4 °C and 3200 rpm for 20 min. The phage pellet was suspended in 1 mL Tris-buffered saline (TBS, 50 mM Tris-HCl, 150 mM NaCl, pH 7.5), 200 μL PEG/NaCl was added, and a new precipitation was carried out for 1 h at 4 °C. A final centrifugation at 4 °C and 13 000 rpm for 5 min allowed the isolation of a pellet that was finally suspended in TBS at the suitable phage concentration.

Synthesis of Magnetophages. Magnetophages were obtained by reacting phages with activated USPIO obtained by pretreating USPIO with epichlorhydrin (Sigma, Bornem, Belgium).

A 1.5 mL amount of USPIO (30 mg of 22 nm Fe particles coated with dextran) was diluted in 5 mL of water and treated with 5 mL of 5 M NaOH and 2 mL of epichlorhydrin. The mixture was stirred for 24 h at 40 °C in the darkness and then dialyzed in a 5 mM citrate solution, pH = 8 (membrane cutoff: 12000−14000) to remove unreacted epichlorhydrin (*14*). A 400 μL amount of activated USPIO (150 mM Fe) was added to 600 μL of phage suspension in water at a concentration of 4×10^{12} phages per mL and incubated 24 h at 37 °C. Magnetophages were recovered by PEG-precipitation as described above. This process was repeated three times to ensure total elimination of free USPIO. The magnetophages were finally suspended in 500 μL of water.

Estimation of Apparent Affinity Constant $K_{a,app}$. The $K_{a,app}$ of E3 magnetophages for PS was determined by saturation experiments performed by enzyme-linked immunosorbent assay (ELISA). PS (1,2-dipalmitoyl-sn-glycero-3-phospho-L-serine, Genzyme Pharmaceuticals-Sygena Facility, Liestal, Switzerland) was dissolved in ethanol and immobilized on microplates (Greiner Gmbh, Frichenhausen, Germany) by overnight evaporation of the ethanol at room temperature. Plates were blocked with 200 μL of a blocking solution [4% milk powder in phosphate-buffered saline (PBS, 137 mM NaCl, 3.2 mM KCl, 6.4 mM Na_2HPO_4, 1.5 mM KH_2PO_4, pH 7.2−7.5)] for 2 h at room temperature. After rinsing three times with washing buffer (PBS completed with 0.1% Tween 20) using a microplate washer (Adil Instruments, Schiltigheim, France), serial magnetophage dilutions ranging from $\sim 10^{-8}$ to $\sim 10^{-16}$ M were prepared in a calcium buffer (2 mM $CaCl_2$, 150 mM NaCl, 10 mM HEPES, 3 mM NaN_3, pH 7.4). PS-coated plates were incubated with 200 μL of each dilution for 2 h at 37 °C. Plates were then rinsed six times with washing buffer. Bound phages were detected using the horseradish peroxidase (HRP)-conjugated anti-M13 antibody (HRP anti-M13, Amersham Pharmacia Biotech, Roosendaal, The Netherlands). The peroxidase staining reaction was performed with HRP substrate solution containing 100 mM citric acid pH 2, 200 mM Na_2HPO_4, 30% H_2O_2 (8 μL for 20 mL of substrate solution) and OPD (o-phenylenediamine dihydrochloride, ICN, Asse-Relegem, Belgium). After incubation with the substrate for 30 min, the reaction was stopped by addition of 50 μL/well of 4 M H_2SO_4. OD_{450} values were determined with Stat Fax-2100 ELISA plate reader (Awareness Technology, Palm City, FL). Titration curves were obtained by plotting OD_{450}, which reflects the number of phages bound to PS, against the logarithmic concentration of total magnetophages, expressed in mol/L. Curves were fitted according to a sigmoidal model. The phage concentration at half-saturation corresponds to $1/K_{a,app}$ (*7*).

Competition Experiments with Annexin V. Annexin V, a protein interacting specifically with PS (*15*), was used as competitor for E3 magnetophages. Serial dilutions from 6×10^{-4} to 10^{-10} M of annexin V (33 kDa from human placenta, Sigma-Aldrich, Bornem, Belgium) were prepared in calcium buffer. PS-coated plates were incubated with each dilution of annexin V during 30 min at 37 °C. E3 magnetophages were then added at the concentration yielding half-saturation and incubated for 90 min at 37 °C. The subsequent protocol was identical to that used in the previous section. The competition curve was obtained by plotting OD_{450} against the logarithmic concentration of total annexin V input, expressed in M.

Nuclear Magnetic Resonance Dispersion Profiles. Nuclear magnetic resonance dispersion (NMRD) profiles represent the relaxivity of the contrast agent as a function of the proton Larmor frequencies. Longitudinal relaxivities r_1 and transverse relaxivities r_2 were obtained respectively from longitudinal relaxation rate R_1 and the transverse relaxation rate R_2 at each field as described below. R_1 and R_2 are the reciprocals of the measured longitudinal relaxation time T_1 and the transverse relaxation time T_2 of water protons respectively, expressed in seconds. The relaxivity reflects the efficiency of a MRI contrast agent: the higher the relaxivity, the lower the amount of contrast agent needed to produce a given contrast enhancement in MRI. Relaxivity (r_1 or r_2, expressed in s^{-1} $mmol^{-1}$ L) is defined as the increase of relaxation rate (R_1 and R_2) produced by 1 mmol per liter of contrast agent. The r_1 and r_2 are the main physicochemical parameters that are considered in the development of an effective magnetic label. They depend essentially on the size and chemical structure of the magnetic center as well as on its accessibility to water molecules. The MRI contrast agents are indirect agents because they are not visible by themselves contrary to the situation encountered in other imaging modalities. Indeed, they enhance the difference between healthy and diseased tissues by modifying their intrinsic parameters, mainly the longitudinal, T_1, or transverse, T_2, relaxation times of the tissues water protons. Relaxivities and observed relaxation rates are linked by the following formula:

$$R_{i(obs)} = \frac{1}{T_{i(obs)}} = \frac{1}{T_{i(diam)}} + r_i C; \qquad i = 1 \text{ or } 2 \qquad (1)$$

where: $R_{i(obs)}$ and $1/T_{i(obs)}$ = global relaxation rate of the tissue (s^{-1}), $T_{i(diam)}$ = relaxation time of the tissue before the addition of the contrast agents, C = the concentration of the paramagnetic center (mmol L^{-1}), and r_i = the relaxivity (s^{-1} $mmol^{-1}$ L).

Iron concentration was determined as follows. Magnetophage samples were mineralized in nitric acid/hydrogen peroxide 3:1 volume/volume by microwave treatment (Milestone, Analis, Namur, Belgium). Fe content was then determined by inductively coupled plasma atomic emission spectrometry (ICP-AES, Jobin Yvon JY70+, Longjumeau, France). The iron concentration of mineralized samples was also estimated by relaxometry at 20 MHz from the known relaxivity of the Fe^{3+} ion in acidic solution.

R_1 and R_2 were recorded with different systems. For proton Larmor frequencies ranging between 0.01 and 15 MHz, R_1 was measured on a fast field cycling NMR relaxometer (Stelar spa, Mede, Italy). For 20 and 60 MHz, R_1 and R_2 were measured on

minispecs (PC-20 and mq-60, Bruker, Karlsruhe, Germany). At 200 MHz, R_1 and R_2 were estimated by image analysis on an Avance-200 vertical magnet spectrometer (Bruker, Karlsruhe, Germany). For R_1 determination, an inversion−recovery sequence was used [repetition time (TR)/echo time (TE) = 2004/8.1 ms, slice thickness = 1.5 mm, field of view (FOV) = 5 cm, matrix = 64]. R_1 was calculated by fitting the intensities observed for different inversion times (TI) with the equation

$$M_z(T_1) = M_z(0)[1 - (1 - \alpha) \times \exp^{TI/T_1}] \quad (2)$$

R_2 was obtained by a spin−echo T_2 sequence (TR/TE = 2062/6.6 ms, echo number (NE) = 24, slice thickness = 1 mm, FOV = 5 cm, matrix = 64). R_2 was calculated by fitting the curve representing the image intensities as a function of echo time according to the equation

$$M_{xy}(\mathrm{TE}) = A + C \times \exp^{TE/T_2} \quad (3)$$

MaLISA and C-MaLISA. MaLISA (magnetic-linked immunosorbent assay) is the MRI equivalent of ELISA (*16*). PS or phosphatidylcholine (PC, 1,2-dipalmitoyl-sn-glycero-3-phospho-L-choline, Genzyme Pharmaceuticals-Sygena Facility, Liestal, Switzerland) were adsorbed on a microtiter plate by overnight evaporation of a phospholipid solution (concentration: 25 mg/30 mL ethanol). Phospholipid-coated plates were then blocked by incubation with 200 μL of blocking solution (5 mg/mL BSA in PBS) for 90 min at 4 °C. After washing three times with 0.1% Tween 20 in PBS, serial magnetophage dilutions ranging from $\sim 10^{-8}$ to $\sim 10^{-16}$ M were prepared in calcium buffer. A 100 μL amount of each magnetophage dilution was added to the wells and incubated at 37 °C during 90 min. After washing six times with 0.1% Tween 20 in PBS, 100 μL of 0.2 M glycine-HCl (pH2.2) was added and a 10 min incubation was carried out in order to eluate bound magnetophages. This resuspension is necessary to obtain a homogeneous solution of magnetophage required for MRI measurements. As acidic solution can alter phages and digest iron particles, the pH was neutralized with 25 μL of 1 M Tris pH 8. Magnetophages were then detected by MRI using an Avance-200 imaging system equipped with a vertical magnet (Bruker, Karlsruhe, Germany). Images were acquired using the following parameters: TR/TE = 3000/20 ms, NE = 40, number of acquisitions (NA) = 2, slice thickness = 1.5 mm, FOV = 5 cm, matrix 256 × 256.

C-MaLISA, for cellular magnetic-linked immunosorbent assay, was performed with apoptotic and control Jurkat cells. Jurkat cells (contribution from Prof. Oberdan Leo, Free University of Brussels, IBMM, Belgium) were grown in RPMI-1640 medium (Sigma-Adrich, Bornem, Belgium) supplemented with 10% FCS (Fetal calf-serum, Gibco, Paisley, UK), and 1% antimycotic−antibiotic solution (Gibco, Paisley, UK). Apoptosis was induced with 1 mM campthotecin (ICN, Asse-Relegem, Belgium) (*17*). Cells were fixed in 0.5% formalin (37% formaldehyde solution, Sigma-Adrich, Bornem, Belgium) in PBS at a final concentration of 10^7 cells/mL. Wells were coated by evaporating 200 μL of the cell suspension at 37 °C (*18*). After blocking for 90 min at 4 °C with 200 μL/well of 5 mg/mL BSA in PBS, plates were washed three times with 0.1% Tween 20 in PBS. A 100 μL amount of each magnetophage dilution was incubated during 90 min at 37 °C. The subsequent steps of the protocol are the same as described above. Competition with annexin V was carried out at a final concentration of the competitor equal to 0.3 mM.

Stealthy Magnetophages. Stealthy magnetophages were obtained by covalent attachment of pegylated USPIO to the proteins of the phage wall using the protocol already described. USPIO were modified by monoamine polyethylene glycol 2000 (PEG, Shearwater Corporation, Huntsville, AL) as follows: 100 mg of PEG 2000 was incubated with 0.8 mL of activated USPIO (100 mM Fe) for 24 h at room temperature. Particles were dialyzed (membrane cut off: 12000−14000) and the resulting PEG-derivatized USPIO were again treated with epichlorydrin. These particles were finally incubated with phages to obtain stealthy magnetophages.

***In Vivo* Evaluation of Magnetophages.** Magnetophages (stealthy or not) were injected to Balb/c mice (5−6 weeks old, Universal Limited Hull, UK) in the caudal vein. The injected amount was 65 μL at an iron concentration of 2.4 mM. Animals were anesthetized by intraperitoneal injection of 60 mg/kg Nembutal (sodium pentobarbital, CEVA, Sanofi Santé Animale, Benelux). Apoptosis of hepatic cells was induced by intravenous injection of 10 μg anti-Fas antibody (Becton-Dickinson, Erembodeghem, Belgium) (*19*). TUNEL staining (terminal deoxynucleotidyl-transferase-mediated UTP end labeling) demonstrated that 70% of hepatocytes were apoptotic 2 h after treatment (results not shown).

Magnetic resonance images were acquired on a 4.7 T Avance-200 imaging system. Acquisition parameters were: TR = 2000 ms, TE = 20 ms, matrix = 128, slice thickness = 2.5 mm, FOV = 6 cm.

As explained above, the MRI contrast agent enhances the relaxations rates R_1 and R_2 of the water protons. The modification of the relaxation rates are reflected on the MR image by a local modification of the image intensity. The MRI signal was expressed as relative postcontrast enhancement (RE%), i.e., the signal modification related to the precontrast image. RE% is calculated by the following formula:

$$RE(\%) = \frac{\dfrac{I_i}{I_{ref,i}} - \dfrac{I_0}{I_{ref,0}}}{\dfrac{I_0}{I_{ref,0}}} \times 100 \quad (4)$$

where RE(%) is the relative enhancement expressed as a percentage, I_0 and $I_{ref,0}$ are respectively the image intensity measured in the liver and in the reference (tube containing an USPIO solution of 0.1 mM Fe) before administration of the contrast agent, and I_i and $I_{ref,i}$ are respectively the signal intensity in the liver and in the reference after the contrast agent administration. A decrease of the image intensity (negative enhancement, darkening of the image) or the increase of the image intensity (positive enhancement, brightening of the image) are respectively reflected by negative or positive RE(%). Intensities were measured in circular ROI (region of interest) drawn in the liver or in the external reference.

Statistics. Data are given as the mean ± SEM (standard error of the mean). Comparison between groups was performed with the Student *t* test and differences were considered to be significant for $p \leq 0.05$ and highly significant for $p \leq 0.01$.

RESULTS

Synthesis of Magnetophages. Magnetophages were obtained by linking of iron particles pretreated with epichlorhydrin directly to the amino functions of the phage proteins. We used previously similar experimental procedure to graft small peptides on USPIO, and we could estimate that less than five peptides were grafted on each particle (see ref 16, Burtea et al.). We can thus expect that each USPIO activated with epichlorydrin has only a few amine reactive sites and that the risk of cross-linking virions is low. Moreover, the water solubility of the synthesized magnetophages confirms the absence of considerable cross-linking of the virions.

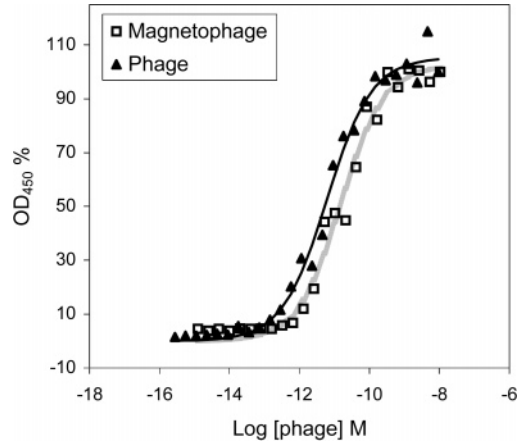

Figure 1. Estimation of $K_{a,app}$. OD_{450}% is the percentage ratio of OD_{450} related to OD_{450} measured for the maximal concentration. OD_{450} measured for magnetophages at maximal concentration was 1.3.

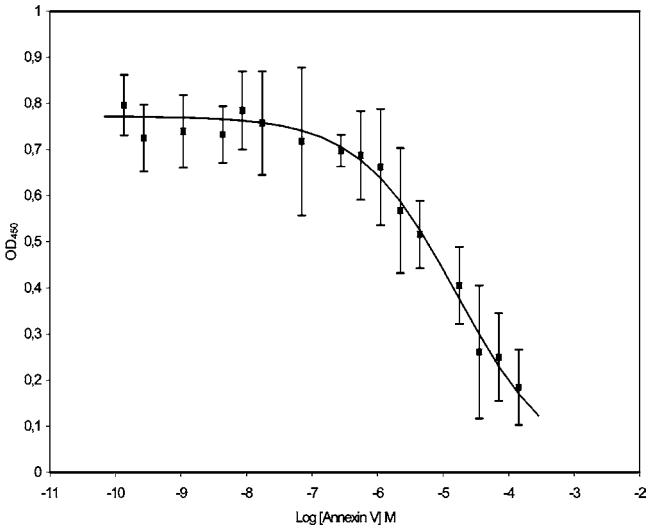

Figure 2. Competition between annexin V and E3 magnetophages for PS. Each value represents the mean of three measurements.

From the magnetophage concentration and the iron concentration (determined by ICP-AES), we evaluate the average number of USPIO per phage at 80 (160 000 to 240 000 iron atoms per virion) assuming that each USPIO contains 2000−3000 iron atoms.

Determination of $K_{a,app}$. The apparent association constant $K_{a,app}$ of E3 magnetophages for PS was compared to that of the nonmagnetically labeled E3 clone, previously determined (*9*), in order to evaluate the capacity of magnetophages to recognize their target. Figure 1 shows that the titration curve of magnetophages is shifted to the right, meaning that their $K_{a,app}$ is slightly decreased as compared to that of the nonmagnetically labeled phages. $K_{a,app}$ is equal to 1.6×10^{11} and 6.55×10^{10} M for phages E3 and magnetophages E3, respectively.

Specificity of the Interaction with Phosphatidylserine. To confirm the specific interaction between E3 magnetophages and PS, annexin V, known to bind PS with high affinity (*15*), was used in a competitive binding assay with E3 magnetophages. The amount of magnetophages bound to PS, as expressed by the OD_{450} value, decreased when the concentration of competitor was increased (Figure 2). These results confirmed that E3 magnetophages selectively interact with PS and not with other structures exposed during the ELISA experiments, such as polystyrene or blocking buffer.

Determination of Relaxivity. NMRD profiles reflect the relaxation rate as a function of field strength and allow for the determination of relaxivity at the magnetic field of interest. These profiles are largely used to characterize contrast agents because they reflect the efficacy of a MRI contrast agent and are very sensitive to the agents' structural modifications (*20*). They can be seen as a fingerprint of the MRI contrast agents. The NMRD profiles of the three magnetophage samples (Figure 3), synthesized under identical experimental conditions, were compared to those of the original USPIO (represented by black squares). Although small differences exist at lower magnetic fields, the three profiles corresponding to the three magnetophage samples mainly overlap above 5 MHz, confirming the reproducibility of our protocol. The low field r_1 and the high field r_2 are higher than those observed for the USPIO not conjugated to virion and are characteristic of some clustering of the magnetic centers as shown by Roch et al. (*21*). As compared to that of free USPIO, the high field r_2 of magnetophages (about 160 $s^{-1}mM^{-1}$ at 60 MHz) is indeed four times higher than that of unconjugated USPIO (about 40 $s^{-1}mM^{-1}$ at 60 MHz). As a result, a similar MRI contrast enhancement will be obtained with a four times lower amount of iron than with nonconjugated USPIO.

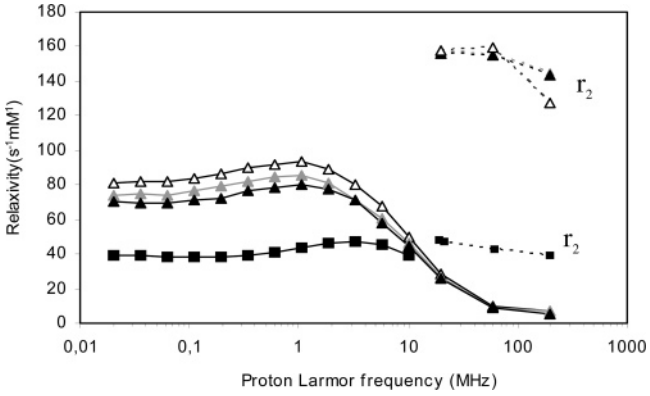

Figure 3. NMRD relaxivity profiles of magnetophages and USPIO. Black squares: USPIO. Black, gray, and white triangles: different samples of magnetophages. r_1 relaxivity: plain lines; r_2 relaxivity: dashed lines.

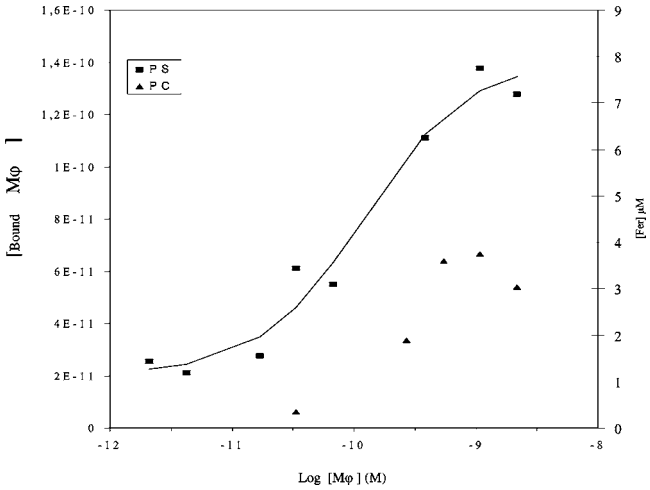

Figure 4. Titration curves obtained by MaLISA. They were obtained after incubation of E3 magnetophages (Mφ) with phosphatidylserine (PS) and phosphatidylcholine (PC).

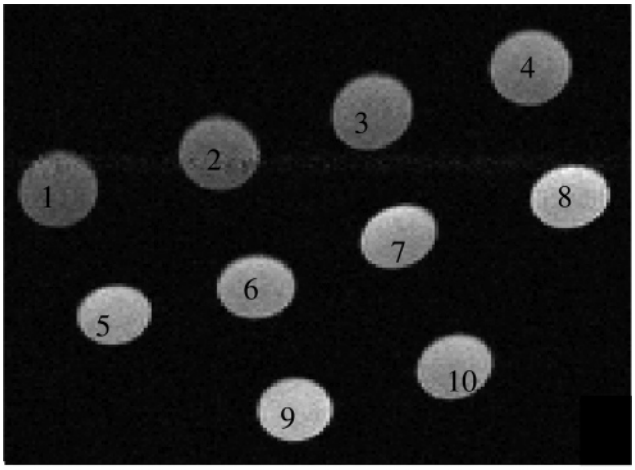
MaLISA. Titration curves like those obtained by ELISA, which represent the amount of magnetophages bound to the target, can be obtained by MaLISA where the colorimetric evaluation is replaced by the measurement of signal intensity by MRI. The amount of bound magnetophages was determined from a calibration curve obtained from the MRI measurement of the transverse relaxation time T_2 as a function of iron

Table 1. T_2 (ms) Obtained in C-MaLISA after Incubation of E3 Magnetophages (Initial Concentration $\sim 10^{-8}$ M) with Apoptotic and Control Jurkat Cells in the Absence and in the Presence of the Competitor Annexin V[a]

[magnetophages], M	JURKAT apoptotic	JURKAT control	competition with annexin V
10^{-8} M	296	335	353
5×10^{-9} M	295	329	336
2.5×10^{-9} M	316	362	361
1.25×10^{-9} M	326	353	367

[a] E3 magnetophages (10^{-8} M corresponding to 6×10^{12} magnetophages/mL) were diluted, and each dilution was incubated with the cells.

concentration. The fixation curves for PS and PC obtained by MaLISA are represented in Figure 4. The fixation curve for PC is shifted to the right, suggesting that the affinity for PS of E3 magnetophages is much higher than for PC. The fitting of the fixation curve for PS gave a $K_{a,app}$ equal to 8.3×10^9 M.



The same MaLISA protocol was used to validate the potential of magnetophages as an MRI contrast agent. The acquired image is represented in Figure 5. Signal intensities are lower and therefore T_2 values shorter in the wells coated with PS than in those coated with PC, confirming the selective binding of the E3 magnetophages. These results confirm that magnetophages are able to discriminate between PS and PC.

C-MaLISA. E3 magnetophages were incubated with apoptotic and control Jurkat cells by a C-MaLISA protocol. The T_2 values are given in Table 1. In the case of apoptotic Jurkat cells, E3 magnetophages induced a higher decrease of intensity than in the case of control Jurkat cells. Competition with annexin V weakened this interaction, confirming a specific interaction of E3 magnetophages with phosphatidylserine. These results corroborate the conclusion that magnetophages are able to discriminate apoptotic and normal structures at the cellular level.

***In Vivo* MRI Evaluation of Magnetophages: Stealthy Magnetophages.** Magnetophages, specific or not to PS, are rapidly sequestered by the liver (healthy or apoptotic) when they are injected in mice and induce a decrease of the relative enhancement (RE%) (Figure 6). As shown on Figure 7, stealthy nonspecific magnetophages, produced from the native phage display library, are not sequestrated by the liver, contrary to their nonstealthy analogs. Figure 7 shows that stealthy magnetophages specific to PS induce a decrease of RE% only in apoptotic livers, and not in healthy ones. These results are conceivably correlated with the specific accumulation of stealthy magnetophages specific to PS in apoptotic livers. The reasons for the increase of the signal intensity in the case of healthy mice treated with specific or nonspecific stealthy magnetophages remains to be explored. It could be attributed to a very low concentration of magnetic nanoparticles in the liver caused by an absence of immobilization and a rapid diffusion in the hepatic vascular tree (*22*).

DISCUSSION

The coupling of target-specific peptides identified by phage display technology with an appropriate reporter is a powerful strategy in the context of molecular imaging. This approach defines the new rationale in the design of novel MRI contrast agents pursued by our laboratory. However, the behavior of the peptide isolated from its phage carrier cannot be predicted after *in vivo* injection, since it could potentially interact less with its target and show unspecific binding with other structures. This is a consequence of a different spatial conformation of the target when immobilized on a solid support or from lower target concentration in an *in vivo* environment (*2*). To avoid these problems, and because phage production is more economical than peptide synthesis, we propose an alternative system, designated with the generic name "magnetophages", obtained by conjugation of USPIO to the phage clone presenting the highest affinity for the target.

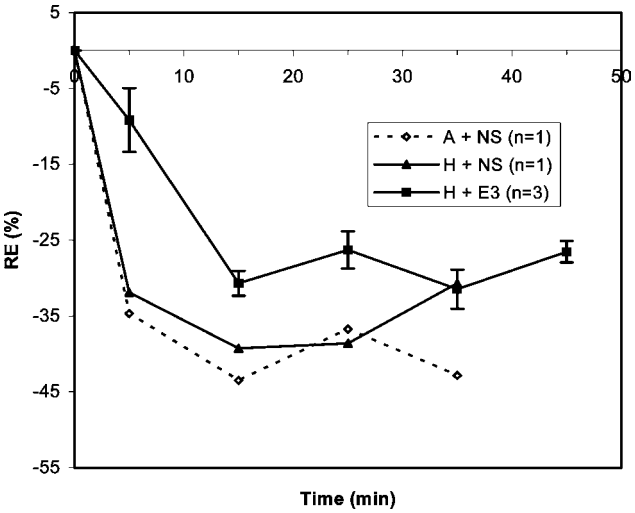

Figure 6. Relative enhancement of the NMR signal in apoptotic (A) or healthy (H) mouse liver after intravenous injection of nonspecific magnetophages (NS) or magnetophage E3 (E3). A + NS: injection of nonspecific magnetophage to apoptotic liver bearing mouse, H + NS: injection of nonspecific magnetophages to healthy liver bearing mouse, H + E3: injection of magnetophages carrying the peptide E3 specific for PS to mice with normal liver.

Magnetophages would be inoperative if the linkage of USPIO to the phage proteins would alter their capacity to interact with their target, an attribute conferred by the displayed peptide. To characterize magnetophages, and subsequently to evaluate them as a contrast agent, we synthesized magnetophages from the

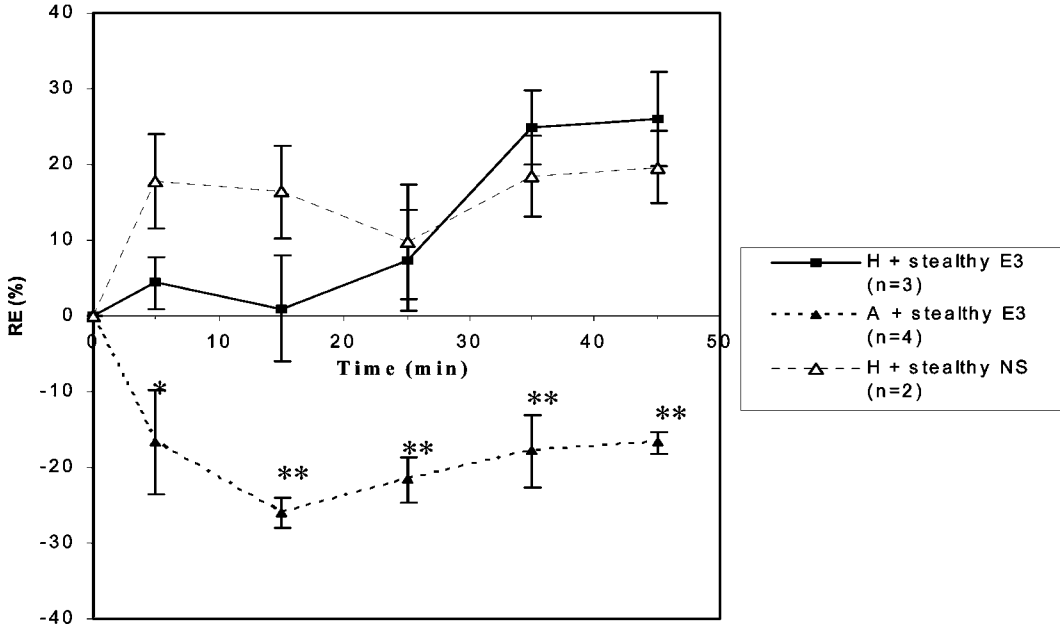

Figure 7. Relative enhancement of the NMR signal in healthy (H) or apoptotic (A) mouse liver (A) after intravenous injection of stealthy magnetophages carrying the peptide specific to PS (stealthy E3) or nonspecific stealthy magnetophages (NS). H + stealthy E3: injection of magnetophage E3 to mice with healthy liver, A + stealthy E3: injection of magnetophages E3 to mice with apoptotic liver, H + stealthy NS: injection of nonspecific magnetophages to mice with healthy liver. *: statistically significant ($p < 0.05$); **: highly statistically significant ($p < 0.01$).

phage clone E3 obtained in our laboratory to target PS. The titration curve of E3 magnetophages showed that the peptide ability to link to PS is maintained after the conjugation with USPIO to create magnetophages, although with a slightly decreased K_a. The specific interaction was further demonstrated by a competition experiment with annexin V, where the extent of PS binding decreased as a function of the competitor's concentration. These results suggest that USPIO do not significantly alter the potential of peptide displayed by magnetophages to interact with the target.

Relaxivity is a measure of the contrast agent efficiency and a way of characterization. NMRD profiles (Figure 3) showed that our protocol of synthesis gives magnetophages with reproducible magnetic properties. The relaxivity r_1 is similar for the three magnetophage batches and approaches 0 with increasing magnetic fields. As usual, this suggests that the T_1 effect of magnetophages at 200 MHz (4.7 T) would be very weak. However, at 20, 60, and 200 MHz, the r_2 relaxivity is constant and four times higher than that of USPIO. This suggests a strong T_2 effect at 200 MHz. Thus, magnetophages would act as a superparamagnetic contrast agent locally, disturbing the homogeneity of the magnetic field and inducing a subsequent suppression of the NMR signal. It has to be emphasized that these modifications of the NMRD profiles as compared to USPIO are characteristic of clustered systems and confirms the multiple USPIO attachment to each virion. This conclusion agrees with the determination of the number of USPIO particles per virion, based on the determination of the concentration of phages and of iron (calculation of 80 USPIO per virion, see above). Results obtained from the *in vitro* characterization of magnetophages encourage their use as a new kind of contrast agent for MRMI. In this context, two different *in vitro* protocols were used to evaluate magnetophages. These protocols basically rely on the ELISA technique and were adapted as an MRI application for biomedical research and clinical diagnosis. Under these conditions, immobilized targets (MaLISA) or intact cells (C-MaLISA) are detected with specifically targeted contrast agents. Hence, the ligand itself (e.g., phages) is labeled with a superparamagnetic moiety (USPIO), which directly reports on the interaction with the specific reporter. MaLISA and C-MaLISA revealed that E3 magnetophages interacted with apoptotic Jurkat cells at a higher level than with control cells and that this interaction was specific for phosphatidylserine, as confirmed by the competition experiment. In addition, it was possible to estimate the constant describing the interaction with the phospholipid by MaLISA. In these experiments, E3 magnetophages were able to discriminate PS from PC and apoptotic cells from nonapoptotic ones. They suggest that magnetophages can be used as contrast agents *in vitro*, playing the role of a reporter for the expression of cellular receptors in any type of biomedical screening. In our protocol of C-MaLISA, we have assumed that PS was not exposed (or was exposed at a lesser extent) in control samples as suggested by the lower level of magnetophage binding on control cells compared to apoptotic cells. Still, binding on controls could have been lower if cells would not have been fixed. However, our rationale was to propose a protocol for high-throughput MRI screening by using magnetophages instead of more complicated, expensive, and time-consuming ELISA protocols which use several antibodies to measure ligand−receptor interaction.

In the vascular system of a mammal, magnetophages are processed by the host's defense system, i.e., the immunologic response and the pathway of endocytosis by the phagocytic cells of the reticuloendothelial system (RES), such as Kupffer cells of the liver. It has been shown that circulating bacteriophages are rapidly sequestered by the RES (*23*). On the other hand, USPIO used to produce magnetophages are coated by dextran that adsorbs plasma proteins such as albumin, transferrin, and immunoglobulins. These proteins act as opsonins, facilitating endocytosis by Kupffer cells (*22*, *24*, *25*). Parameters like the size or the charge of USPIO favor the internalization by the cells of RES (*10*). The accumulation of magnetophages in the RES with a subsequent reduction of their bioavailability was confirmed by experiments summarized in Figure 6, where nonspecific magnetophages and E3 magnetophages (carrying a PS-specific peptide) were rapidly and nonspecifically taken up by healthy or apoptotic livers.

Stealthy nanoparticles have two characteristics: they are invisible to the RES, meaning a decrease of their capture by phagocytic cells, and they have a long vascular circulating time,

making them available to interact with the target (*26, 27*). As a consequence, these particles can act efficiently as biocarriers and are used in molecular targeting for both therapy and molecular imaging (*27, 28*). These properties are conferred by grafting PEG onto particles to prevent the absorption of the proteins and to reduce the phagocytosis. This is because of the fact that PEG is neutral and allows a relatively strong binding of water molecules around the polymer chain that induces high steric exclusion. In addition, pegylated surfaces are biocompatible and not immunogenic nor antigenic (*26, 29*−*32*). This approach has already been applied to liposomes and superparamagnetic nanoparticles, reducing their capture by Kupffer cells (*33, 34*). We employed the same procedure with magnetophages to fashion stealthy magnetophages. Stealthy E3 magnetophages (carrying a peptide specific for PS) were injected into healthy mice and into mice with apoptotic liver. The absence of signal depression in the liver on MR images of healthy mice and the negative signal enhancement of apoptotic livers (decrease of RE(%), Figure 7) confirm that these magnetophages were not internalized by the RES of healthy mice but are retained by apoptotic livers. These results are convincing arguments that stealthy E3 magnetophages can discriminate between apoptotic and normal livers.

CONCLUSIONS

E3 magnetophages selected for their affinity for apoptotic structures were able to discriminate apoptotic from normal cells and between PS and PC *in vitro*, while stealthy E3 magnetophages targeted *in vivo* apoptotic liver. If this feature demonstrated for E3 magnetophages can be extrapolated to other phage display selected entities, magnetophages become an original system which allows validation of the candidate binding peptide before their synthesis is considered. This means that the targeting peptide discovered by phage display can be investigated without having to incorporate those peptides into more conventional molecular imaging probes. Furthermore, magnetophages themselves can be used as an MRI contrast agent. Finally, the concept of magnetophage could be extended to other imaging modalities by replacing USPIO with an adequate reporter (i.e., radiolabeled phages).

ACKNOWLEDGMENT

The financial supports of the FNRS (Fonds National de la Recherche Scientifique), of the French Community of Belgium ARC (Concerted Research Action), of Region of Wallonia, of the NOMADE program, and of EU (EMIL Network of Excellency, FP6) are acknowledged. Mrs. Patricia De Francisco is thanked for her help in preparing the manuscript.

NOTE ADDED AFTER ASAP PUBLICATION

This manuscript was released ASAP on May 24, 2007 with a typographical error in Figure 5. The corrected version was posted on July 2, 2007.

Identification of an Orthogonal Peptide Binding Motif for Biarsenical Multiuse Affinity Probes

Baowei Chen, Haishi Cao, Ping Yan, M. Uljana Mayer, and Thomas C. Squier*

Cell Biology and Biochemistry Group, Biological Sciences Division, Pacific Northwest National Laboratory, P.O. Box 999, Richland, Washington 99352. Received December 18, 2006; Revised Manuscript Received April 5, 2007

Biarsenical multiuse affinity probes (MAPs) complexed with ethanedithiol (EDT) permit the selective cellular labeling of proteins engineered with tetracysteine motifs, but are limited by the availability of a single binding motif (i.e., CCPGCC or PG tag) that prevents the differential labeling of coexpressed proteins. To overcome this problem, we have used a high-throughput peptide screen to identify an alternate binding motif (i.e., CCKACC or KA tag), which has a similar brightness to the classical sequence upon MAP binding, but displays altered rates and affinities of association that permit the differential labeling of these peptide sequences by the red probe 4,5-bis(1,3,2-dithiarsolan-2-yl)-resorufin (ReAsH-EDT_2) or its green cognate 4′,5′-bis(1,3,2-dithoarsolan-2-yl)-fluorescein (FLAsH-EDT_2). The utility of this labeling strategy was demonstrated following the expression of PG- and KA-tagged subunits of RNA polymerase in *E. coli*. Specific labeling of two subunits of RNA polymerase in cellular lysates was achieved, whereby ReAsH-EDT_2 is shown to selectively label the PG-tag on RNA polymerase α-subunit prior to the labeling of the KA-tag sequence of the β-subunit of RNA polymerase with FlAsH-EDT_2. These results demonstrate the ability to selectively label multiple individual proteins with orthogonal sequence tags in complex cellular lystates with spectroscopically distinct MAPs, and indicate the absolute specificity of ReAsH to target expressed proteins with essentially no nonspecific binding interactions.

INTRODUCTION

Biarsenical multiuse affinity probes (MAPs[1]) based on a xanthene scaffold permit the selective labeling of expressed proteins that contain a tetracysteine motif and have been used for the affinity isolation of individual proteins and associated complexes, for the biophysical characterization of protein structure and binding interactions, and for cellular imaging and turnover measurements of protein expression (*1*−*10*). Specific labeling is accomplished through the chelation of each arsenic with a pair of vicinal cysteines within a tetracysteine tag sequence, which is uncommon within endogenously expressed proteins (*4*). Important to these applications has been (*1*) the ability to stabilize the arsenics through their reversible association with ethanedithiol (EDT) in order to enhance membrane permeability, decrease nonspecific binding, and protect the arsenic from oxidation and polymerization, and (*2*) the identification of an optimal 9−12 amino acid high-affinity binding motif involving a tetracoordinate linkage between the biarsenical and the vicinal thiols associated with a PG-tag sequence (i.e., a CCPGCC tag) (*11*, *12*). The commercially available red probe 4,5-bis(1,3,2-dithiarsolan-2-yl)-resorufin (ReAsH-EDT_2) and its green cognate 4′,5′-bis(1,3,2-dithoarsolan-2-yl)fluorescein (FlAsH-EDT_2) both bind with high affinity to the PG-tag sequence, permitting the use of competing dithiol reducing agents to minimize nonspecific binding (*12*).

To date, only a single high-affinity peptide motif has been identified, preventing the simultaneous use of ReAsH-EDT_2 and FlAsH-EDT_2 to label multiple tag sequences for structural measurements of protein dynamics or cellular colocalization. In fact, current approaches involve the pairing of a tetracysteine tag with a cyanofluorescent protein (CFP) derived from the jellyfish *Aequorea victoria* (*13*), whose relatively large size and slow folding kinetics have the potential to perturb both protein structure and cellular localization. ReAsH and FlAsH are synthesized as ethanedithiol adducts in order to protect the arsenic from oxidation and polymerization. In the initial study of the binding kinetics, the starting material was not this commercial form, but rather the arsenoxide (*11*). Since the reaction does not involve the thiol exchange necessary for the binding of the EDT chelates, the reported binding rates may overestimate the rates of reaction using the stable ReAsH-EDT_2 and FlAsH-EDT_2 compounds. Furthermore, it is commonly suggested that addition of 1,2-dithiol antidotes such as 1,2-ethanedithiol (EDT) or 2,3-dimercaptopropanol (BAL) into the reaction mixture can facilitate the reduction of nonspecific binding to endogenous cysteine-rich proteins (*12*, *14*), but the binding kinetics under conditions of competing dithiol ligand have not been reported.

To extend the applicability of MAPs, we have used a surface-bound peptide library to identify useful protein-encoded tags in addition to CCPGCC that would permit the specific labeling of distinct tag sequences with both ReAsH-EDT_2 and FlAsH-EDT_2. Through one round of selection, in which the two amino acids between the vicinal cysteines were substituted combinatorially, we identified an alternate binding sequence with the amino acids KA located between two pairs of vicinal cysteines (i.e., KA-tag), which has a similar brightness to the classical sequence upon MAP binding, but displays altered rates and affinities of association that permit the differential labeling of these peptide sequences engineered into the α- and β-subunits

of RNA polymerase by the red probe ReAsH-EDT_2 and its green cognate FlAsH-EDT_2.

EXPERIMENTAL PROCEDURES

Materials. 4,5-Bis(1,3,2-dithiarsolan-2-yl)-resorufin (ReAsH-EDT_2 or Lumio Red) and 4′,5′-bis(1,3,2-dithoarsolan-2-yl)-fluorescein (FLAsH-EDT_2 or Lumio Green) were synthesized as previously described (*3*, *11*) or, in the case of FlAsH-EDT_2, obtained commercially under the trade name Lumio Green (Invitrogen, Carlsbad, CA), *N*-(2-Hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid) (HEPES) and tris(carboxyethyl)phosphine (TCEP) were obtained from Sigma (St. Louis, MO). 2-Mercaptoethanol (β-ME) and 1,2-ethanedithiol (EDT) were obtained from Aldrich (Milwaukee, WI). The peptides, AR-EACCPGCCK-$CONH_2$ (peptide PG) and AREACCKACCK-$CONH_2$ (peptide KA) were obtained from SynPep Corporation (Dublin, CA). The concentration of tetracysteine-containing peptide was measured as previously described (*15*). All other chemicals were the purest grade commercially available.

Peptide Arrays. The peptide library was from Sigma-Genosys (The Woodlands, Texas), which contained 208 different 15 amino acid acetylated peptides (5 nmol per spotted peptide) that were immobilized on a cellulose membrane through the C-terminus with the basic structure Ac-YYYYWDCCXXCC-KAA. The YYYY sequence at the N-terminus was constrained to be GGGG, AAAA, or the originally proposed AREA sequence (*11*), while XX was systematically varied. High-affinity binding sequences were identified following overnight incubation with FlAsH-EDT_2 (5 nmol). Sequences of each peptide and identified peptides that became very bright upon binding FlAsH-EDT_2 are provided in the Supporting Information.

Peptide-Tag Labeling. Peptide tags (1 μM) were placed in 50 mM HEPES (pH 7.5), 140 mM KCl, 1 mM β-ME, and 1 mM TCEP at room temperature for 1 h to reduce any disulfide bonds prior to incubation at 4 °C with either ReAsH-EDT_2 or FLAsH-EDT_2. Fluorescence emission spectra of ReAsH-peptide or FlAsH-peptide complexes were measured using a Fluoro Max-2 fluorometer (SPEX, Edison, NJ), with excitation and emission slits set at 5 nm. In all cases, the sample temperature was 25 °C. Apparent rate constants were calculated from the second-order reaction

$$\frac{F_t}{[\mathrm{L}]_{t=0} \times (F_{\max} - F_t)} = kt \quad (1)$$

where F_{max} is the fluorescence maximum, F_t is the fluorescence at time t, $[L]_{t=0}$ is the concentration of fluorescent probe at time zero, k is the second-order rate constant, and t is the time of reaction. For equilibrium binding measurements, the extent of labeling was assessed following 24 h, and the concentration of peptide that is in association with the fluorescent probe, i.e., $[FP]_{bound,}$ can be calculated such that

$$[\mathrm{FP}] = \frac{\Delta F}{\Delta F_{\max}} \times [\mathrm{F}]_{\mathrm{total}} = \left[\frac{|(F - F_0)|}{|(F_{\max} - F_0)|}\right] \times [\mathrm{F}]_{\mathrm{total}} \quad (2)$$

where F_0 is the initial fluorescence, F_{max} is the fluorescence observed in the presence of saturating concentrations of peptide, and F is the observed fluorescence at a particular peptide concentration. $[F]_{total}$ is the concentration of FlAsH-EDT_2 or ReAsH-EDT_2 in solution. Determination of the binding affinities assumes a ligand exchange mechanism whereby the binding of the vicinal cysteines within the target peptides to the two arsenics on the MAPs involves the displacement of the bound EDT, as described by the following equilibrium.

$$\mathrm{MAP} + \text{Peptide Tag} \rightarrow \text{MAP-Peptide complex} + 2\ \mathrm{EDT} \quad (3)$$

The dissociation constant, K_d, can be described as

$$K_{\mathrm{d}} = \frac{[\mathrm{F}][\mathrm{P}]}{[\mathrm{FP}][\mathrm{EDT}]^2} \quad (4)$$

where [F] and [P] represent the concentration of free dye and free peptide, respectively. [EDT] represents the concentration of ethanedithiol, which must be in large excess of the dye or peptide concentrations in order to calculate an apparent dissociation constant, K_{app}, as given by

$$K_{\mathrm{app}} = K_{\mathrm{d}}[\mathrm{EDT}]^2 = [\mathrm{F}][\mathrm{P}]/[\mathrm{FP}] \quad (5)$$

When the reaction is at equilibrium, then

$$[\mathrm{F}]_{\mathrm{total}} = [\mathrm{F}] + [\mathrm{FP}] \quad (6)$$

$$[\mathrm{P}]_{\mathrm{total}} = [\mathrm{P}] + [\mathrm{FP}] \quad (7)$$

where $[P]_{total}$ is the concentration of added peptide. After rearranging, the concentration of the dye−peptide complex [FP] can be solved, where

$$[\mathrm{FP}]^2 - ([\mathrm{F}]_{\mathrm{total}} + [\mathrm{P}]_{\mathrm{total}} + K_{\mathrm{app}})[\mathrm{FP}] + [\mathrm{F}]_{\mathrm{total}}[\mathrm{P}]_{\mathrm{total}} = 0 \quad (8)$$

$$[\mathrm{FP}] = \{([\mathrm{F}]_{\mathrm{total}} + [\mathrm{P}]_{\mathrm{total}} + K_{\mathrm{app}}) - [([\mathrm{F}]_{\mathrm{total}} + [\mathrm{P}]_{\mathrm{total}} + K_{\mathrm{app}})^2 - 4[\mathrm{F}]_{\mathrm{total}}[\mathrm{P}]_{\mathrm{total}}]^{1/2}\}/2 \quad (9)$$

Substitution of [FP] (see eq 2) yields

$$\Delta F = \Delta F_{\max}\{([\mathrm{F}]_{\mathrm{total}} + [\mathrm{P}]_{\mathrm{total}} + K_{\mathrm{app}}) - [([\mathrm{F}]_{\mathrm{total}} + [\mathrm{P}]_{\mathrm{total}} + K_{\mathrm{app}})^2 - 4[\mathrm{F}]_{\mathrm{total}}[\mathrm{P}]_{\mathrm{total}}]^{1/2}\}/2[\mathrm{F}]_{\mathrm{total}} \quad (10)$$

Cloning and Expression of RNA Polymerase Subunits. A C-terminus 52 amino acid sequence was appended onto the α- or β-subunit of RNA polymerase (SO0256 or SO0257) from *Shewanella oneidensis* cloned into the pBAD/DTOPO 202 vector (Invitrogen) containing in the following order a tetracysteine tag (either AREACCPGCCK or AREACCKACCK) adjacent to a V5 epitope (KGGRADPAFLYKVVINSKLEGK PIPNPLLGL) and His_6 sequence at the C-terminus, as previously described (*5*). The pBAD-TOPO expression system contains the promoter of the *araBAD* (arabinose) operon, which can be upregulated by arabinose and downregulated by glucose to permit optimal expression. Plasmids were maintained by addition of 20 μg/mL kanamycin.

Following transformation of *E. coli*, cells were grown in flasks in standard Luria-Bertani growth media. Cells were grown until the optical density was 0.4−0.6, and PG-tagged α- or KA-tagged β-subunits were expressed near native levels (about 0.5 pM). Following overnight growth at 30 °C, cells were collected by centrifugation and lysed. Cell lysates (5 mg/mL) in 50 mM HEPES (pH 7.5), 140 mM NaCl, 2 mM β-ME, and 5 mM TCEP were labeled in the dark (due to the photoinstability of ReAsH; see Figure S1 in Supporting Information) with either FlAsH-EDT_2 or ReAsH-EDT_2 (5 μM) for 20 min. Alternatively, equal amounts of lysate expressing either the PG-tagged α- or KA-tagged β-subunits were mixed prior to their sequential labeling, which involved first addition of ReAsH-EDT_2 (5 μM) for 20 min followed by the addition of FlAsH-EDT_2 (5 μM) for an additional 20 min. Proteins were then separated by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-

Maximal fluorescence intensities (left panel) and selected emission spectra (right panel) for FlAsH-EDT$_2$ (1 μM) in the presence of indicated thiol reagents (500 μM) or tetracysteine-containing peptide motifs (1 μM) in 50 mM HEPES (pH 7.5), 140 mM KCl, 1.0 mM EGTA, 1.0 mM β-ME, and 1.0 mM TCEP. Inset shows dependence of emission spectra on added DTT. Excitation was at 500 nm.

PAGE) and protein bands were visualized with GELCode Blue stain reagent (Pierce, Rockford, IL); the fluorescence was observed by Kodak IS2000MM illuminator with selected filters for excitation and emission.

RESULTS

Identification and Fluorescence Properties of Multiuse Affinity Probes Bound to Target Peptide. Currently, two commercially available biarsenical dyes, i.e., ReAsH-EDT$_2$ and FlAsH-EDT$_2$, permit the labeling of tagged proteins in cells, but cannot be used in multicolor experiments due to the current limitation of a single class of tetracysteine peptide motifs that bind these probes with similar affinities. To circumvent this problem, we have used a combinatorial peptide screen to identify new peptide motifs that differentially bind these commercially available MAPs. Briefly, this involved selection of a cellulose-derivatized peptide library containing 208 different peptide motifs for optimal candidate sequences that preferentially bind FlAsH-EDT$_2$ to form a highly fluorescent complex. Following overnight incubation with limiting amounts of FlAsH-EDT$_2$, 18 very bright peptides were identified that fall into 2 sequence classes corresponding to the previously identified CCPGCC motif (PG-peptide) (*11*, *12*) and a motif with a basic amino acid at the first position between the vicinal cysteines (i.e., KA-peptide) (see Supporting Information). Following identification of these candidate peptides, we have measured the binding kinetics and affinities of ReAsH-EDT$_2$ and FlAsH-EDT$_2$ to these two peptide motifs. Since all prior measurements of MAP binding to target peptides involved unchelated MAP (i.e., no bound EDT), we have also measured the apparent affinities and reaction rates for both FlAsH-EDT$_2$ and ReAsH-EDT$_2$ against both the classical PG-peptide and the newly introduced KA-peptide in the presence of both EDT (suggested to enhance labeling specificity) and other thiols that are either present within cells or have previously been suggested to reduce nonspecific binding (*9*).

As previously described (*4*, *11*), there is a large (i.e., >20-fold) increase in the fluorescence of FlAsH-EDT$_2$ or ReAsH-EDT$_2$ upon binding the PG-peptide (Figure 1) (see Supporting Information for photostability data). In the presence of a large excess of 1,2-ethanedithiol (EDT), 2,3-dimercapto-1-propanesulfonic acid (DMPS), cysteine, or glutathione, there is little change in the fluorescence. A similar large increase in fluorescence is observed upon binding to the KA-peptide or the dithiol DTT (albeit with a substantially reduced affinity; $K_d = 0.1$ mM; Figure 1), whose intensities are approximately 91% and 38% of that associated with binding to the PG-peptide. These latter results indicate that DTT cannot be used as a reducing agent in the application of biarsenical dyes due to substantially higher background fluorescence. A much smaller increase is observed in the presence of β-mercaptoethanol (β-ME), which has been suggested to reduce nonspecific binding in cell imaging measurements with reduced toxicity in comparison to the application of EDT (*9*).

The fluorescence enhancement upon binding to DTT further suggests the possible structural underpinning associated with the large fluorescence enhancements associated with binding to target peptides in comparison to other thiols. Our results suggest a relationship between the ring size between the arsenic atoms in FlAsH and the sulfur ligands. On the basis of the structure of thiol reagents, EDT and DMPS can form a complex with the arsenic in FlAsH to form a rigid five-membered ring that has a very low fluorescence. In contrast, following derivatization with DTT, a seven-membered ring is formed that has an intermediate fluorescence. Upon liganding to either PG-tag or KA-tag sequences, a nine-membered ring can form that is associated with the large fluorescence enhancement (Figure 1). Consistent with this model, there is a small increase in fluorescence for FlAsH in the presence of 0.5 mM β-ME that is significantly higher than observed in the presence of either EDT or DMPS. These results are consistent with the known hydrogen bonding character between proximal β-ME that can form upon the liganding of two β-ME with the arsenic atoms of FlAsH to form a transient nine-membered ring. Thus, our results demonstrate that binding of the small mono- and dithiols (i.e., β-ME and DTT) to FlAsH result in an enhanced fluorescence that, in the case of DTT, is comparable to that following peptide tag binding and correlates strongly with increases in ring size. We suggest that arsenic is capable of quenching fluorescein fluorescence, and that ability, in turn, is modulated by the ring strain induced by the arsenic liganding. This is in contrast to prior suggestions that attributed the low fluorescence of FlAsH-EDT$_2$ in comparison to the peptide bound dye to the greater mobility of the arsenic atoms bound to the small ligands that would act to "quench the fluorescence of fluorescein" (http://www.invitrogen.com/content/sfs/manuals/ lumiogreen-detection_man.pdf).

Rates of ReAsH− or FlAsH−Peptide Complex Formation. Under conditions in which there is a large molar excess of PG- or KA-peptide tag relative to ReAsH-EDT$_2$ or FlAsH-EDT$_2$, there is a linear relationship between the pseudo-first-order constant associated with fluorescent probe binding and the concentration of peptide, which is indicative of a reaction mechanism involving second-order kinetics (data not shown). Using equimolar stoichiometries of fluorescent probes and peptides, we find that ReAsH-EDT$_2$ preferentially binds to the PG-peptide with a nearly 50% rate enhancement in comparison to the KA-peptide (Figure 2; Table 1). In comparison, the rates of FlAsH-EDT$_2$ binding to these peptide tags are very similar. These results indicate that ReAsH-EDT$_2$ labeling is sensitive to the conformation of the peptide binding motif in a manner that is not possible for the bigger FlAsH-EDT$_2$ moiety.

Binding of Tetracysteine-Containing Peptides with ReAsH-EDT$_2$ and FlAsH-EDT$_2$. Peptide binding to ReAsH-EDT$_2$ or FlAsH-EDT$_2$ was measured using associated increases in the fluorescence intensity upon formation of the dye−peptide complex in the absence and presence of excess amounts of the competing dithiol EDT, whose presence diminishes the apparent affinity and permits an accurate determination of an apparent binding affinity (see eq 3 in Experimental Procedures). In all cases, it is apparent that FlAsH-EDT$_2$ binds to all peptide sequences with a higher affinity than ReAsH-EDT$_2$, and that the presence of EDT results in a reduction in the apparent affinity. In the absence of unliganded EDT, binding to both the

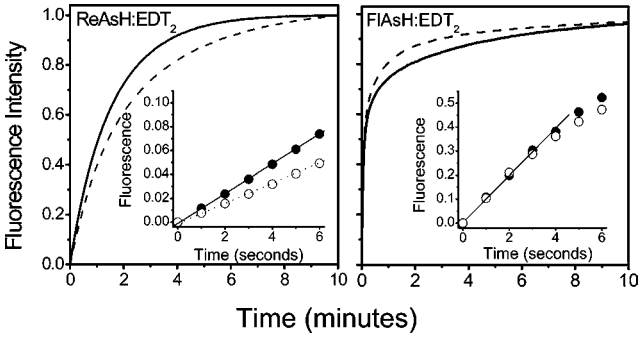

Figure 2. Binding kinetics of ReAsH-EDT_2 or FlAsH-EDT_2 (1 μM) to peptides (1 μM) AREACCPGCCK-$CONH_2$ (peptide PG) (solid line; closed circles) or AREACCKACCK-$CONH_2$ (peptide KA) (dashed line; open circles). In all cases, the reaction mixture contained 50 mM HEPES (pH 7.5), 140 mM KCl, 1.0 mM EGTA, 1.0 mM β-ME, and 1.0 mM TCEP. Lines represent fits to eq 1, where for ReAsH-binding to PG and KA peptides, $k = 12.5 \pm 0.1 \times 10^3\ M^{-1}\ s^{-1}$ and $8.47 \pm 0.07 \times 10^3\ M^{-1}\ s^{-1}$. For FlAsH-binding to PG and KA peptides, $k = 124 \pm 8 \times 10^3\ M^{-1}\ s^{-1}$ and $k = 143 \pm 8 \times 10^3\ M^{-1}\ s^{-1}$ (KA peptide). Fluorescence was measured at 530 and 608 nm with excitation at 500 and 593 nm for FlAsH and ReAsH, respectively.

Table 1. Binding Rates and Apparent Affinities of FlAsH-EDT_2 and ReAsH-EDT_2 to Peptide Tags

complex	k ($M^{-1}\ s^{-1}$)[a]	K_{app} (μM)[b]
ReAsH-Peptide PG	12 500 ± 1000	1.3 ± 0.2
ReAsH-Peptide KA	8470 ± 700	3.3 ± 1.2
FlAsH-Peptide PG	124 000 ± 8000	0.24 ± 0.09
FlAsH-Peptide KA	143 000 ± 8000	0.85 ± 0.23

[a] The second-order rate constant obtained from fitting the data in Figure 2 using eq 1 in Experimental Procedures. [b] Apparent dissociation constant in presence of 200 μM EDT obtained from fitting data in Figure 3 to eq 10 in Experimental Procedures, where $K_d = K_{app}/[EDT]^2$.

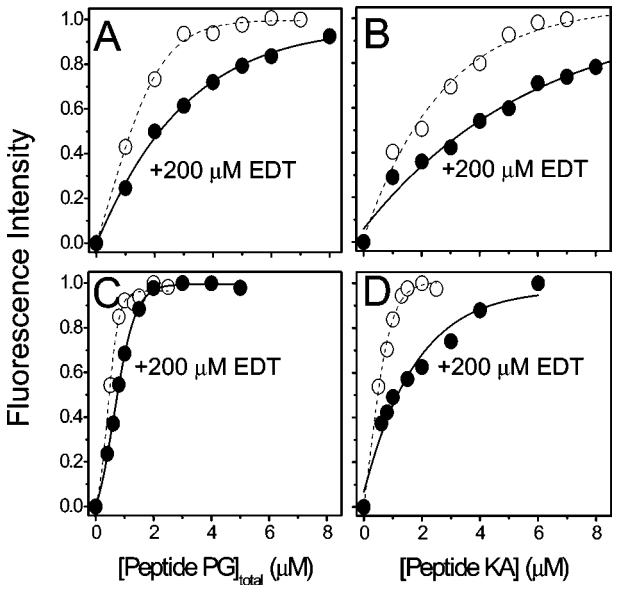

Figure 3. Equilibrium binding of ReAsH-EDT_2 (A, B) or FlAsH-EDT_2 (C, D) to peptides AREACCPGCCK-$CONH_2$ (peptide PG) or AREACCKACCK-$CONH_2$ (peptide KA) in the absence (○) or presence (●) of 200 μM EDT. Buffer contained 50 mM HEPES (pH 7.5), 140 mM KCl, 1.0 mM EGTA, 1.0 mM β-ME, and 1.0 mM TCEP at 25 °C. Dashed and solid lines represent fits to eq 10 in Experimental Procedures, assuming that respective concentrations of unliganded EDT in solution are negligible and 200 μM.

PG- and KA-peptide is essentially complete in the presence of equimolar amounts of FlAsH-EDT_2 and either peptide (Figure 3), consistent with prior estimates regarding the high-affinity binding of the unliganded bis-arsenoxide FlAsH probe to this peptide, whose K_d has been estimated to be approximately 10 pM (*11*).

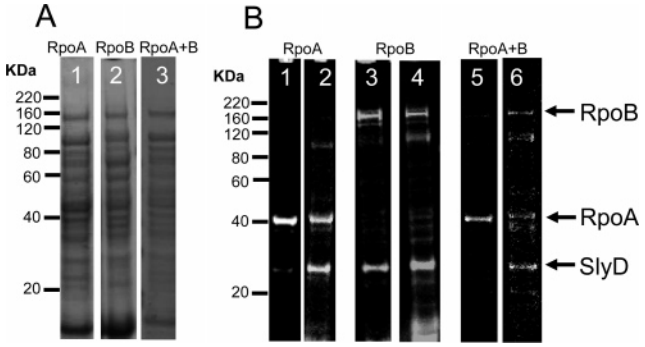

Figure 4. SDS-PAGE of cellular lysates corresponding to total protein gel-code blue protein stain (A) or fluorescence signals (B) associated with ReAsH (lanes 1, 3, and 5; $\lambda_{ex} = 555$ nm, $\lambda_{em} = 600$ nm) or FlAsH-labeling (lanes 2, 4, and 6; $\lambda_{ex} = 465$ nm, $\lambda_{em} = 535$ nm) of cellular lysates containing the α-subunit of RNA polymerase containing an engineered PG-tag (i.e., RpoA), the β-subunit of RNA polymerase containing an engineered KA-tag (i.e., RpoB), or equimolar amounts of both tagged proteins (i.e., RpoA+B). Labeling protocols are fully described in Experimental Procedures. Relative mobilities of molecular mass standards shown at left, and positions of RpoA, RpoB, and SlyD on SDS-PAGE obtained from authentic standards are indicated.

A quantitative determination of differences in binding affinities is possible in the presence of excess EDT, as the presence of EDT reduces the apparent dissociation constant (i.e., $K_{app} = K_d \times [EDT]^2$). The reduction in the apparent dissociation constant (K_{app}) in the presence of EDT permits the accurate measurement of differences in binding affinities for the different peptides, and in the presence of excess EDT, apparent dissociation constants can be obtained (Table 1). In the presence of 200 μM EDT, differences in FlAsH-EDT_2 binding to the PG- and KA-peptides are revealed, where complete binding of FlAsH-EDT_2 requires a 2- and 6-fold molar excess of the PG- and KA-peptide (Figure 3). Likewise, complete binding of ReAsH-EDT_2 is observed in the presence of an 8- and 20-fold molar excess of the PG- and KA-peptides (data not shown for the KA-peptide). These differences reflect 3−4-fold differences in binding affinities (Table 1), and suggest a strategy to selectively label these peptide motifs with these complementary dyes.

Selective Labeling of Tagged Subunits in RNA Polymerase. Tagged α- and β-subunits of RNA polymerase (RNAP) complex were respectively expressed in *E. coli* with the PG- and KA-tags located near their C-termini at nearly native levels of expression (about 0.5 pM), essentially as previously described (*5*, *16*). The specificity of ReAsH-EDT_2 and FlAsH-EDT_2 binding to individual proteins was determined following expression of either the PG-tagged α-subunit (RpoA) or KA-tagged β-subunit (RpoB) of RNA polymerase (Figure 4). Prior to labeling, cell lysates (5 mg protein/mL) were incubated with either ReAsH-EDT_2 or FlAsH-EDT_2 (5 μM) in buffer containing 50 mM HEPES (pH 7.5), 140 mM NaCl, 2 mM β-mercaptoethanol, and 5 mM TCEP for 20 min prior to separation and visualization of labeling specificity using SDS-PAGE.

ReAsH-EDT_2 and FlAsH-EDT_2 both label RpoA tagged with the PG-tag, which migrates as a 40 kDa band on SDS-PAGE (Figure 4). However, while ReAsH-EDT_2 specifically labels RpoA, we find that FlAsH-EDT_2 binds to a number of additional proteins, with apparent molecular masses 28 kDa, 39 kDa, and 100 kDa. These results indicate that both ReAsH-EDT_2 and FlAsH-EDT_2 permit the labeling of expressed proteins in cellular lysates, but that ReAsH-EDT_2 has the required affinity and selectivity for applications involving the fluorescent labeling of low abundance proteins. Complementary measurements

assessed the ability of both ReAsH-EDT_2 and FlAsH-EDT_2 to bind the KA-peptide tag engineered onto the β-subunit of RNA polymerase (RpoB). Consistent with measurements using the PG-tag on RpoA, we find that ReAsH-EDT_2 and FlAsH-EDT_2 both label RpoB, which migrates with an apparent mass of about 160 kDa (Figure 4). However, in this application, ReAsH-EDT_2 and FlAsH-EDT_2 bind several additional proteins, including the prominent band at about 28 kDa corresponding to the thiol-rich chaperone SlyD protein (*17*).

Multicolor Labeling of RNA Polymerase Subunits. Differences in the affinities and kinetics of ReAsH-EDT_2 binding to the PG- and KA-peptides suggest a strategy to differentially label subunits of RNA polymerase. As a proof of principle, lysate expressing PG-tagged α- and KA-tagged β-subunits of RNA polymerase (i.e., RpoA and RpoB) were mixed, and the α- and β-subunits were then sequentially labeled. First, ReAsH-EDT_2 (5 μM) is used to modify the PG-tag sequence on the α-subunit of RNA polymerase (RpoA), which is possible due to the 50% rate enhancement and 3-fold increase in binding affinity (i.e., $1/K_{app}$) of the PG-tag in comparison to the KA-tag (Table 1). Second, following the selective labeling of the PG-tag sequence, FlAsH-EDT_2 (5 μM) was used to selectively label the KA-tag sequence on the β-subunit of RNA polymerase (RpoB). Using this strategy, specific labeling of two subunits of RNA polymerase in cellular lysates from *E. coli* was achieved (Figure 4), whereby ReAsH-EDT_2 specifically labels the RNA polymerase α-subunit RpoA engineered with a PG-tag in the presence of an equimolar mixture of RpoA and RpoB (engineered with the KA-tag). Following labeling of RpoA, the KA-tag sequence of the RNA polymerase β-subunit RpoB can then be labeled with FlAsH-EDT_2. These results demonstrate the ability to differentially label multiple proteins engineered with orthogonal sequence tags in complex cellular lysates with spectroscopically distinct MAPs.

DISCUSSION

Summary of Results. Using a combinatorial approach involving a peptide array, we have identified an orthogonal peptide tag sequence (i.e., CCKACCK-$CONH_2$ or KA-tag) that in combination with the classical PG-tag sequence permits the use of the commercially available cell permeable MAPs ReAsH-EDT_2 (Lumio Red) and FlAsH-EDT_2 (Lumio Green) for multicolor measurements in which different proteins engineered with either tag can be differentially labeled. Upon binding to either peptide-tag, similar levels of brightness are observed (Figure 1). In addition, we have for the first time characterized the affinities and rates of binding of the commercially available and stable forms of these dyes. As expected, the chelation of ReASH or FlAsH with EDT reduces the rates of protein modification, where complete labeling requires approximately 10 min (Figure 2). Further, the commonly suggested inclusion of EDT to reduce nonspecific labeling (*12*) results in a substantial reduction in the apparent binding affinity (Figure 3). Indeed, in our hands, labeling of tagged proteins in cellular lysates is minimal in the presence of amounts of EDT suggested to be necessary to reduce nonspecific binding. Rather, we find that optimal amounts and specificities of labeling are observed in the presence of both 2 mM β-ME and 5 mM TCEP (but no competing EDT) (Figure 4). Under the latter conditions, we have demonstrated the ability to specifically modify a PG-tagged α-subunit of RNA polymerase (i.e., RpoA) with ReAsH-EDT_2 in the presence of an equimolar amount of the β-subunit of RNA polymerase engineered with the KA-tag (see lane 5 in Figure 4). This specificity of labeling permits the subsequent modification of the KA-tag on the β-subunit using FlAsH-EDT_2 for multicolor measurements.

Genetic Tagging and Cell Permeable Multiuse Affinity Probes. To understand the expression, localization, and fate of proteins in live cells, current approaches emphasize the engineering of GFP mutants with improved properties and altered colors that provide the basic tools to investigate more complex processes in live cells (*18*−*20*). However, because of the large size of GFP and its slow folding kinetics, it has the potential to alter the function, binding interactions, and localization of tagged proteins (*21*). Furthermore, in bacteria GFP labels are often incompatible with cellular export systems associated with the trafficking of proteins into the periplasm. The development of small molecular probes, i.e., the biarsenical dyes FlAsH and ReAsH, have largely overcome these prior limitations (*3*, *4*, *11*, *22*, *23*). The specific ligand for the labeling reaction is the small tetracysteine binding motif (i.e., CCXXCC), whose sequence is readily engineered within the gene encoding the protein of interest. Indeed, the small tag can be placed within the protein of interest to minimize the physical interference associated with N- or C-terminal tags, and to allow direct functional measurements of protein conformational change and binding interactions (*1*, *2*, *4*).

Recent improvements in the brightness and selectivity of FlAsH-EDT_2 analogs offer the potential to image low-abundance proteins in living cells (*24*, *25*). Nevertheless, the prior recognition of only a single binding motif has limited the application of multiuse affinity probes to imaging the cellular locations or turnover of individual proteins (*8*, *20*), while the identification of protein−protein interactions requires the use of Aequorea-derived fluorescent proteins such as YFP (*13*). In this respect, the identification of orthogonal tags using a combinatorial screen that permit the simultaneous use of both commercially available MAPS (i.e., ReAsH-EDT and FlAsH-EDT_2) to selectively modify the α- and β-subunits of RNA polymerase tagged, respectively, with PG- and KA-tags extends the range of possible applications of these cell-permeable reagents to selectively label multiple proteins to assess protein−protein interactions using, for example, fluorescence resonance energy transfer or colocalization single-molecule measurements in cell lysates. This strategy permits the validation of protein−protein interactions identified using high-throughput screens and mass spectrometry, when specific pairwise interactions are not certain. Thus, upon tagging multiple proteins, their association in a protein complex can be directly assessed using, for example, single-molecule methods that measure the association between tagged proteins to validate their interactions without the need to try to purify specific binding partners. In addition, these reagents permit fluorophore-assisted light inactivation (FALI) to selectively knock-out targeted protein activities to aid in the identification of their functions as well as the modulation of metabolic networks (*26*−*28*). However, additional specificity for cellular measurements will require the introduction of new biarsenical probes with different spacings between the arsenic ligands, providing greater labeling specificity.

Practical Considerations. Observed rates of binding for the commercially available and more stable reagents ReAsH-EDT_2 or FlAsH-EDT_2 to tag sequences are substantially slower than reported for the unliganded probes, which bind to peptide tags on the time scale of seconds, and require approximately 10 min for stoichiometric labeling due to the requirement for ligand exchange (Figure 2). Furthermore, the high-affinity association of the unliganded dyes with peptide tags (K_d = 10 pM) is substantially reduced in the presence of added EDT (Figure 3) (*11*). In the presence of 200 μM EDT, which has previously been suggested to minimize nonspecific binding (*12*), we find that apparent binding affinities are in the micromolar range (Table 1). Indeed, under the latter conditions, we observe low stoichiometries of peptide-tag modification in cellular lysates

(data not shown), limiting the ability of these reagents to image highly abundant proteins. In contrast, using other reducing reagents (e.g., β-mercaptoethanol and TCEP), we are able to selectively modify tagged proteins with nearly equimolar stoichiometries of either ReAsH-EDT_2 or FlAsH-EDT_2, permitting both enhanced detection of low-abundance proteins and multicolor experiments involving the differential labeling of PG- and KA-tags engineered onto different proteins. In this application, we take advantage of the substantially larger rates of labeling and binding affinity of ReAsH-EDT_2 binding against the PG-peptide tag in comparison to the KA-tag (Figure 4). Following the stoichiometric labeling of PG-tagged protein (RpoA) with ReAsH-EDT_2, it is then possible to label the KA-tagged protein (RpoB) with the higher-affinity FlAsH-EDT_2 probe with minimal cross-reactivity.

Conclusions and Future Directions. The identification of orthogonal peptide tags permits the simultaneous application of the commercially available and stable biarsenical dyes ReAsH-EDT_2 and FlAsH-EDT_2 to differentially label multiple proteins, providing a path forward for their use in multicolor measurements relating to protein associations and colocalization. Specificity of labeling is dependent on the reduction of peptide tags with the cell-permeant reducing agents β-mercaptoethanol and tris(carboxyethyl)phosphine (TCEP), which act to enhance binding to peptide tags without significantly affecting the binding affinity. These differences in binding specificities were demonstrated using a single peptide scaffold in which vicinal cysteines were separated by two amino acids whose sequence was altered, indicating that modest conformational differences in the binding sequence of the peptide tag can promote differences in binding specificity. These results suggest that further variation of the scaffold to vary the spatial separation between the biarsenical linkages within the probes will provide the required specificity to allow the generation of a family of cell-permeant affinity probes that permit simultaneous labeling and isolation of multiple tagged proteins, using peptide tags with variable spacing between the vicinal cysteine binding ligands.

Received January 2, 2007; Revised Manuscript Received May 1, 2007

The integrin receptor $\alpha_v\beta_3$ is overexpressed on the endothelial cells of growing tumors and on some tumor cells themselves. A radiolabeled $\alpha_v\beta_3$ antagonists belonging to the quinolin-4-one class of peptidomimetics (**TA138**) was previously shown to exhibit high affinity for integrin $\alpha_v\beta_3$ and high selectivity versus other integrin receptors. ^{111}In-**TA138** exhibited high tumor uptake in the c-neu Oncomouse mammary adenocarcinoma model and produced excellent scintigraphic images. This study describes the synthesis of eight divalent versions of **TA138** and their evaluation as potential tumor radiotherapeutic agents. The two main variables in this study were the length of the spacer bridging the biotargeting moieties and the total negative charge of the molecules imparted by the cysteic acid pharmacokinetic modifiers. Receptor affinity was evaluated in a panel of integrin receptor affinity assays, and biodistribution studies using the ^{111}In-labeled derivatives were carried out in the c-neu Oncomouse model. All divalent agents maintained the high receptor affinity and selectivity of **TA138**, and six of the eight ^{111}In derivatives exhibited blood clearance that was faster than ^{111}In-**TA138** at 24 h postinjection (PI). All divalent agents exhibited tumor uptake and retention at 24 h PI that was higher than ^{111}In-**TA138**. Tumor/organ ratios were improved for most of the divalent agents at 24 h PI in critical nontarget organs marrow, kidney, and liver, with the agents having intermediate-length spacers (29−43 Å) showing the largest improvement. As an example, ^{111}In-**15** showed tumor uptake of 14.3% ID/g at 24 h PI and tumor/organ ratios as follows: marrow, 3.24; kidney, 7.29; liver, 8.51. A comparison of therapeutic indices for ^{90}Y-**TA138** and ^{177}Lu-**15** indicate an improved therapeutic index for the divalent agent. The implications for radiotherapeutic applications and the mechanism of this multivalent effect are discussed.

INTRODUCTION

Integrins are a large family of transmembrane heterodimeric glycoprotein cell surface receptors formed by associations between α and β subunits. Integrins are important facilitators of cell−cell and cell−matrix interactions, and are also involved in cell signaling events (*1*). This has made integrins an important area of study in cancer metastasis and angiogenesis research (*2*−*5*). The integrin $\alpha_v\beta_3$ (vitronectin receptor or VnR) is generally expressed at low levels on normal tissues and quiescent blood vessels, but is significantly upregulated on the neovasculature found in tumors and in wound repair (*6*−*9*) and is also present on certain tumor cells, including melanoma, kidney, breast, and prostate, and squamous cell carcinoma (*10*−*13*). This differential expression has made the vitronectin receptor a promising target in anti-angiogenic research (*14*, *15*). For example, antagonists of integrin $\alpha_v\beta_3$ have been demonstrated to inhibit tumor angiogenesis and disrupt metastasis in a number of models (*16*−*19*).

We and others have utilized integrin $\alpha_v\beta_3$ antagonists for selective localization of diagnostic and therapeutic radionuclides in the vicinity of malignant tumors. Cyclic RGD peptides labeled with ^{18}F and ^{64}Cu for PET imaging (*20*−*22*) and with ^{99m}Tc and ^{111}In for SPECT imaging (*23*−*26*) have been shown to exhibit selective tumor uptake in a variety of murine tumor models, and a ^{18}F-labeled RGD peptide has recently been evaluated in 19 human patients with solid tumors (*27*). The use of radiolabeled peptides to image tumor angiogenesis has recently been reviewed (*28*−*30*). Our goal in this area was the development of an integrin $\alpha_v\beta_3$ antagonist platform that could be utilized to deliver both imaging and radiotherapeutic isotopes to tumors. While many radiolabeled RGD peptides have demonstrated potential as tumor imaging agents, none have been able to combine the high tumor uptake and retention and low uptake in critical nontarget tissues required of a radiotherapeutic agent (*29*). We reasoned that peptidomimetics having high affinity and selectivity for integrin $\alpha_v\beta_3$ offered the best opportunity to deliver diagnostically and therapeutically useful quantities of radionuclides to tumors while minimizing dose to nontarget organs. We recently described the synthesis and evaluation of a series of peptidomimetic antagonists to integrin $\alpha_v\beta_3$ based on a substituted quinolin-4-one ring system (*31*, *32*). The agent providing the best combination of tumor uptake and tumor/organ ratios was ^{111}In-**TA138** (Figure 1). This agent uses 2-aminoimidazole and a 2,3-diaminopropionate (DAP) arylsulfonamide as mimics of the guanidine and carboxylate groups of the RGD sequence, respectively. Macrocyclic chelator DOTA allows for chelation to both imaging (^{111}In) and therapeutic (^{90}Y, ^{177}Lu) radionuclides, and is conjugated to the aryl sulfonamide group through a short spacer that includes cysteic acid as a pharmacokinetic modifier (PKM). ^{111}In-**TA138** was evaluated in the c-neu Oncomouse model, providing tumor uptake of 9.39% ID/g at 2 h postinjection (PI) and selected tumor/organ ratios at 2 h PI as follows: blood, 17.5; muscle, 17.1; liver,

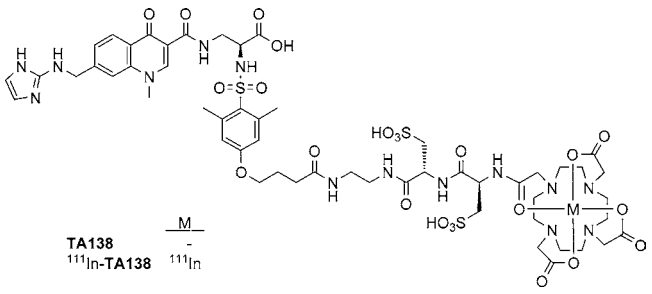

Figure 1. Structures of monovalent parent **TA138** and ^{111}In-**TA138**.

4.83; kidney, 4.04; bone 6.01. ^{111}In-**TA138** exhibited slow washout from the tumors, decreasing to 3.46% ID/g at 24 h PI.

These are excellent biodistribution properties from the viewpoint of an imaging agent, but they leave room for improvement for a radiotherapeutic agent. We were especially interested in a further slowing of tumor washout and in improving the tumor/organ ratios for critical nontarget organs such as kidneys and bone marrow. One technique that is commonly employed to improve receptor affinity and retention is polyvalency. Our early work with cyclic RGD peptides has shown that in the c-neu Oncomouse model (*33*), and in the OVCAR-3 xenograft model (*23*, *24*), divalent cyclic RGD peptide $\alpha_v\beta_3$ antagonists give superior tumor uptake and retention compared to the cyclic monovalent peptides. This polyvalency effect has also been noted by others for cyclic RGD peptides (*34*−*36*), for α-MSH receptor peptides (*37*), and for Tuftsin antagonist peptides (*38*). Herein, we report the complete details of the synthesis of eight divalent analogues of **TA138**, along with receptor affinity and biodistribution data of the ^{111}In-radiolabeled analogues. The general structures of these compounds are shown in Figure 2. The length of the spacer between the two biotargeting groups was varied over a wide range by the number and position of the cysteic acid PKMs and by the number of repeating PEG units, as shown in Table 1. Varying the total number of cysteic acid groups also provided control of the total charge on the molecule.

Table 1. Structural Features of Divalent Agents Shown in Scheme 1

EXPERIMENTAL SECTION

General Experimental. All reactions were carried out under a dry nitrogen atmosphere at ambient temperatures, unless otherwise noted. All chemicals and solvents (reagent grade) were used as supplied from the vendors cited without further purification, unless otherwise noted. Solutions were concentrated under reduced pressure on a rotary evaporator, with final drying, if required, under high vacuum (<0.5 mmHg). Boc-Glu(OTfp)-OTfp was synthesized according to a previously published procedure (*39*). 3-((*tert*-Butoxy)carbonylamino)propyl bromide and 4,7,10-trioxa-1,13-tridecanediamine were purchased from Fluka. *tert*-Butyloxycarbonyl (Boc) amino acids and other starting amino acids were obtained from Bachem Inc., Bachem Biosciences Inc. (Philadelphia, PA), or Advanced ChemTech (Louisville, KY). 2-(1*H*-Benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) and benzotriazol-1-yloxy-tris-pyrrolidinophosphonium hexafluorophosphate (PyBOP) were purchased from Advanced ChemTech. Ethyl acetate, chloroform ($CHCl_3$), methanol (MeOH), acetonitrile (ACN), dichloromethane (DCM), ethyl ether, acetone, and hydrochloric acid (HCl) were obtained from Baker. Anhydrous dimethylformamide (DMF), *N*-methylpyrrolidinone (NMP), acetonitrile (ACN), pyridine, triethylamine (TEA), and diisopropylethylamine (DIEA) were obtained from Aldrich in SureSeal bottles. Absolute ethanol was obtained from Quantum Chemical Corp. Merck silica gel, grade 9385, 230−400 mesh, 60 Å was used for flash chromatography. DOTA(O*t*-Bu)$_3$OH was obtained from Macrocyclics, Dallas, TX. Other reagents were obtained from Lancaster Synthesis, Inc., Aldrich Chemical Co, or Fluka Chemical Corp.

^{1}H NMR spectra were recorded on a Bruker Avance DRX (600 MHz) spectrometer. Chemical shifts are reported in parts per million (ppm) from tetramethylsilane with the residual

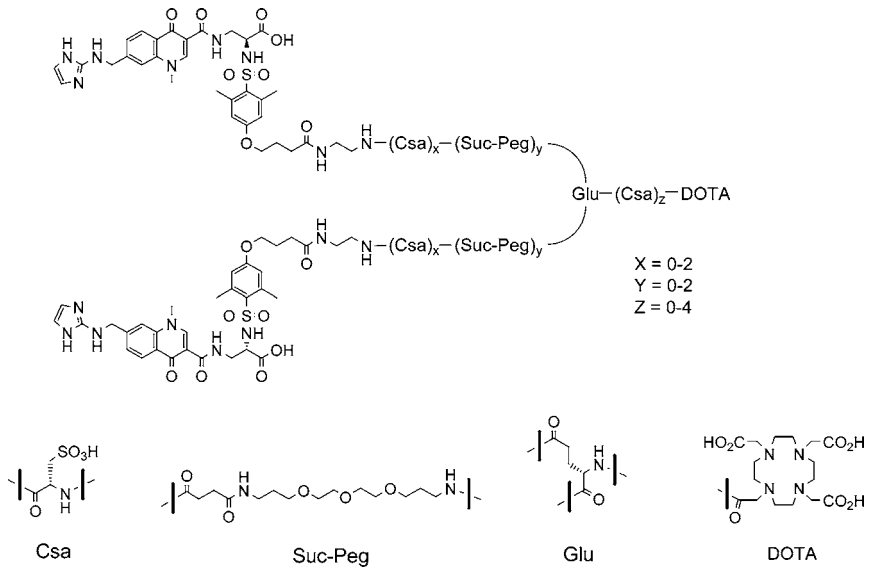

Figure 2. General structure of divalent integrin $\alpha_v\beta_3$ receptor antagonists of this study.

solvent resonance resulting from incomplete deuteration as the internal standard ($CDCl_3$, δ 7.25 ppm; ACN-d_3, δ 1.95 ppm; DMSO-d_6, δ 2.50 ppm). Data are reported as follows: chemical shift, multiplicity (s = singlet, d = doublet, t = triplet, q = quartet, quin = quintet, b = broad, m = multiplet), coupling constants, and integration. ^{13}C NMR spectra were recorded on a Bruker Avance DRX (150 MHz) with complete proton decoupling. Chemical shifts are reported in ppm from tetramethylsilane with the solvent as the internal reference ($CDCl_3$, δ 77.0 ppm; ACN-d_3, δ 118.1 ppm; DMSO-d_6, δ 39.5 ppm). Low-resolution mass spectra were recorded on an Agilent Technologies 1100 series LC/MS ESI-MS and are reported as *m/z*, fragment identification (C_4H_8 = isobutylene, Boc = isobutylene + CO_2, Trt = triphenylmethane), and percent relative abundance. High-resolution mass spectrometry was performed on an Ionspec Ultima FTMS; ESI-MS (positive mode). Chiral amino acid purity was determined according to a published GC-MS method (*40*). Melting points were determined using a Thomas-Hoover melting point apparatus and are uncorrected.

(VnR Antagonist)$_2$Glu-(Csa)2-DOTA (13). *Part A. Synthesis of (Trt-VnR Antagonist)$_2$Glu-H (**4**).* A solution of (*S*)-2-(4-(4-(2-aminoethylamino)-4-oxobutoxy)-2,6-dimethylphenylsulfonamido)-3-(1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)-propanoic acid (1) (*41*) (1.41 g, 1.50 mmol) and DIEA (0.52 mL, 3.00 mmol) in DMF (14 mL) was treated with Boc-Glu-(OTfp)-OTfp (0.41 g, 0.75 mmol) and stirred for 18 h. The solution was concentrated, and the oily residue was triturated with EtOAc (2 × 25 mL) to give a dry, off-white solid. MS (ESI) *m/z* 1847.6 (M + H − Trt, 47), 1604.6 (M + H − 2Trt, 20), 1045.4 (M + 2H, 100), 924.0 (M + 2H − Trt, 42). The above solid was treated with 1:1 TFA/DCM (20 mL) and stirred for 1 h. The solution was concentrated, and the resulting red oil was triturated with diethyl ether (2 × 40 mL) to give a yellow solid. This crude product was divided into three portions, and these were individually purified by preparative HPLC on a Vydac C18 Pharmaceutical column (50 × 250 mm) using a 0.90%/min gradient of 22.5−72% ACN containing 1.65% TFA at a flow rate of 80 mL/min. The main product peak eluting at 15 min was collected and lyophilized to give the TFA salt of **4** as a colorless solid (1.36 g, 43%). MS (ESI) *m/z* 1989.6 (M + H, 40), 1747.6 (M + H − Trt, 45), 1626.5 (M + H − 2Trt, 10), 995.3 (M + 2H, 80).

*Part B. Synthesis of (Trt-VnR Antagonist)$_2$Glu-(Csa)$_2$-H (**9**).* A solution of Boc−L-cysteic acid (176 mg, 0.402 mmol), DIEA (640 μL, 3.68 mmol), and PyBOP (251 mg, 0.402 mmol) in DMF (15 mL) was stirred for 15 min and added to a previously prepared solution of **4** (800 mg, 0.380 mmol) and DIEA (365 μL, 2.09 mmol) in DMF (15 mL). The solution was stirred for 30 min and concentrated to an amber oil. The oil was triturated with EtOAc (2 × 25 mL) to give the Boc−cysteic acid conjugate as a dry, tan solid (884 mg). MS (ESI) *m/z* 2240.7 (M + H, 37), 1997.6 (M + H − Trt, 25), 1756.4 (M + H − 2Trt, 8), 1494.8 (2M + 3H, 8), 1120.8 (M + 2H, 75), 999.6 (M + 2H-Trt, 12). The above solid (884 mg) was dissolved in 1:1 TFA/DCM (20 mL), stirred for 45 min, and concentrated. The resulting oily residue was triturated with ether (2 × 50 mL) to give the amine TFA salt as a dry, off-white solid (865 mg). MS (ESI) *m/z* 1898.6 (M + H − Trt, 37), 1655.4 (M + H − 2Trt, 20), 1070.9 (M + 2H, 53), 949.4 (M + 2H − Trt, 25). A solution of Boc−L-cysteic acid (263 mg, 0.904 mmol), DIEA (315 μL, 1.81 mmol), and PyBOP (376 mg, 0.724 mmol) in DMF (15 mL) was stirred for 10 min and added to a previously prepared solution of the above amine salt (860 mg, 0.380 mmol). The solution was stirred for 30 min and concentrated to an oily yellow solid. Trituration of the solid with EtOAc (2 × 25 mL) gave a dry, pale yellow solid, which was divided into two portions, and these were individually purified by preparative HPLC on a Vydac C18 Pharmaceutical column (50 × 250 mm) using a 1.2%/min gradient of 31.5−67.5% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 18 min was collected and lyophilized to give the protected bis-cysteic acid conjugate as a colorless solid (670 mg, 74% from **4**). MS (ESI) *m/z* 1906.4 (M + H − 2Trt, 10), 1595.7 (2M + 3H, 12), 1196.2 (M + 2H, 45), 1074.9 (M + 2H − Trt, 30). A solution of this solid (670 mg, 0.280 mmol) in 1:1 TFA/DCM (20 mL) was stirred for 10 min and concentrated to give a yellow, oily solid. This solid was triturated with ether (2 × 50 mL) to give **9** as a pale yellow, dry solid (523 mg, 81%). MS (ESI) *m/z* 2050.4 (M + H − Trt, 19), 1806.4 (M + H − 2Trt, 10), 1146.3 (M + 2H, 42), 1024.8 (M + 2H − Trt, 28).

*Part C. Synthesis of **13**.* A solution of DOTA(O*t*-Bu)$_3$OH (210 mg, 0.366 mmol), DIEA (128 μL, 0.732 mmol), and HBTU (104 mg, 0.275 mmol) in DMF (15 mL) was stirred for 15 min and added to a previously prepared solution of the product from part B (520 mg, 0.227 mmol) and DIEA (192 μL, 1.10 mmol) in DMF (10 mL). The solution was stirred for 2.5 h and concentrated to a yellow solid, which was divided into two portions, and these were individually purified by preparative HPLC on a Vydac C18 Pharmaceutical column (50 × 250 mL) using a 1.20%/min gradient of 31.5−67.5% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 15 min was collected and lyophilized to give the TFA salt of the DOTA conjugate as a colorless solid (600 mg, 89%). MS (ESI) *m/z* 1898.1 (2M + 3H, 11), 1423.5 (M + 2H, 52), 1302.6 (M + 2H − Trt, 87), 1181.5 (M + 2H − 2Trt, 20). A solution of the DOTA conjugate (600 mg, 0.203 mmol) in 97:3 TFA/Et_3SiH (20 mL) was heated at 70 °C for 45 min and concentrated to an oily solid. The solid was partitioned between 10:90 ACN/H_2O (4.0 mL) and diethyl ether (2.0 mL). The aqueous phase was washed with additional diethyl ether (2 × 2 mL) and divided into two portions, and the portions were individually purified by preparative HPLC on a Vydac C18 Pharmaceutical column (50 × 250 mL) using a 0.75%/min gradient of 0.9−31.5% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 15 min was collected and lyophilized to give **13** (158 mg, 35%). MS (ESI) *m/z* 2193.4 (M + H, 6), 1463.0 (2M + 3H, 12), 1097.3 (M + 2H, 90), 731.8 (M + 3H, 100), 549.3 (M + 4H, 8). Amino acid analysis: L-Csa, 99.3%; L-Glu, 99.7%; L-DAP, 98.4%.

(VnR Antagonist)$_2$Glu-(Csa)$_4$-DOTA (14). *Part A. Synthesis of (Trt-VnR Antagonist)$_2$Glu-(Csa)$_4$-H (**10**).* A solution of Boc−L-cysteic acid (24 mg, 0.082 mmol), DIEA (64 μL, 0.368 mmol), and PyBOP (34 mg, 0.065 mmol) in DMF (5 mL) was stirred for 10 min and added to a previously prepared solution of **9** (130 mg, 0.054 mmol) and DIEA (98 μL, 0.57 mmol) in DMF (3.0 mL). The solution was stirred for 30 min and concentrated, and the resulting residue was triturated with EtOAc (2 × 25 mL) to give the Boc-protected conjugate as an off-white solid. MS (ESI) *m/z* 2301.3 (M + H − Trt, 13), 2057.4 (M + H − 2Trt, 9), 1695.5 (2M + 3H, 8), 1272.0 (M + 2H, 55), 1150.4 (M + 2H − Trt, 30). The solid was dissolved in 1:1 TFA/DCM (10 mL), stirred for 10 min, and concentrated to give **(Trt-VnR Antagonist)$_2$Glu-(Csa)$_3$-H**. MS (ESI) *m/z* 2200.4 (M + H − Trt, 9), 1958.2 (M + H − 2Trt, 10), 1548.3 (2M + 3H − Trt, 7), 1222.2 (M + 2H, 13), 1100.7 (M + 2H − Trt, 30). A solution of Boc−L-cysteic acid (36 mg, 0.123 mmol), DIEA (43 μL, 0.25 mmol), and PyBOP (51 mg, 0.098 mmol) in DMF (10 mL) was stirred for 10 min and added to a previously prepared solution of the tris-cysteic acid conjugate. The resulting solution was stirred for 30 min and concentrated, and the resulting residue was triturated with EtOAc (2 × 25 mL) to give a dry, off-white solid. The solid was purified by preparative

HPLC on a Vydac C18 Pharmaceutical column (21 × 250 mL) using a 0.9%/min gradient of 0−36% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 29 min was collected and lyophilized to give the Boc-protected tetra-cysteic acid conjugate as a colorless solid (80 mg, 55% over three reactions). MS (ESI) *m/z* 1347.3 (M + 2H, 24), 1226.2 (M + 2H − Trt, 17). A solution of the above solid (43 mg, 0.016 mmol) in 1:1 TFA/DCM (10 mL) was stirred for 10 min and concentrated to give **9** as a colorless solid. MS (ESI) *m/z* 2351.2 (M + H − Trt, 7), 2108.3 (M + H − 2Trt, 11), 1648.9 (2M + 3H − Trt, 10), 1297.3 (M + 2H, 12), 1176.3 (M + 2H − Trt, 36).

*Part B. Synthesis of **14**.* A solution of DOTA(O*t*-Bu)$_3$OH (18 mg, 0.032 mmol), DIEA (11 μL, 0.064 mmol), and HBTU (9.1 mg, 0.024 mmol) in DMF (10 mL) was stirred for 15 min and added to a previously prepared solution of the product from part A and DIEA (34 μL, 0.20 mmol) in DMF (5.0 mL). The resulting solution was stirred for 45 min and concentrated, and the resulting residue was triturated with EtOAc (2 × 10 mL) to give the protected DOTA conjugate as an off-white solid. MS (ESI) *m/z* 1574.7 (M + 2H, 12), 1454.4 (M + 2H − Trt, 32), 1332.9 (M + 2H − 2Trt, 13), 1050.2 (M + 3H, 10). A solution of the above solid in 97:3 TFA/Et_3SiH (10 mL) was heated at 70 °C for 1 h and concentrated to an oily solid. The solid was partitioned between 1:9 ACN/H_2O and diethyl ether, and the aqueous layer was purified by preparative HPLC on a Higgins Clipeus C18 column (20 × 250 mL) using a 0.22%/min gradient of 13.5−22.5% ACN containing 0.1% TFA at a flow rate of 15 mL/min. The main product peak eluting at 34 min was collected and lyophilized to give slightly impure product. The product was repurified on the same column using a 0.64%/min gradient of 9−31.5% ACN containing 0.1% formic acid at a flow rate of 15 mL/min. The main product peak eluting at 21 min was collected and lyophilized to give **14** (5.0 mg, 12% over three reactions). MS (ESI) *m/z* 2495.9 (M + H, 7), 1664.3 (2M + 3H, 10), 1248.8 M + 2H, 40), 832.7 (M + 3H, 100). Amino acid analysis: L-Csa, 99.6%; L-Glu, 99.7%; L-DAP, 98.9%.

(VnR Antagonist-Csa)$_2$Glu-DOTA (15). *Part A. Synthesis of (Trt-VnR Antagonist-Csa)$_2$Glu-H (**5**).* A solution of the TFA salt of (*S*)-2-(4-(4-(2-((*R*)-2-amino-3-sulfopropanamido)ethylamino)-4-oxobutoxy)-2,6-dimethylphenylsulfonamido)-3-(1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)propanoic acid (**2**) (*41*) (317 mg, 0.264 mmol), HOAt (36 mg, 0.264 mmol), and DIEA (230 μL, 1.32 mmol) in DMF (5.0 mL) was treated with Boc-Glu-(OTfp)-OTfp (65 mg, 0.12 mmol) and stirred for 3.5 h. The reaction solution was concentrated, and the resulting amber oil was triturated with EtOAc (2 × 5 mL) to give a tan solid, which was purified by preparative HPLC on a Vydac C18 Pharmaceutical column (50 × 250 mm) using a 0.34%/min gradient of 32−49% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 36 min was collected and lyophilized to give the Boc-protected dimer as a colorless powder (212 mg, 74%). MS (ESI): *m/z* 2392.9 (M + H, 9), 2149.4 (M + H − Trt, 21), 1196.4 (M + 2H, 48). A solution of the above solid (212 mg, 0.0886 mmol) in 1:1 TFA/DCM (15 mL) was stirred for 10 min and concentrated under vacuum to give a pale yellow, glassy solid. The solid was dissolved in 1:1 ACN/H_2O and lyophilized to give amine **5** as an off-white solid (231 mg). MS (ESI): *m/z* 2049.5 (M + H − Trt, 19), 1806.4 (M + H − 2Trt, 12), 1146.1 (M + 2H, 17).

*Part B. Synthesis of **15**.* A solution of DOTA(O*t*-Bu)$_3$OH (26 mg, 0.045 mmol), DIEA (10 μL, 0.06 mmol), and HBTU (14 mg, 0.0375 mmol) in DMF (0.5 mL) was stirred for 20 min and added to a previously prepared solution of the product from part A (72 mg, 0.030 mmol) and DIEA (31 μL, 0.18 mmol) in DMF (2.0 mL). Additional DIEA (10 μL, 0.06 mmol) was added after 15 min to maintain a strongly basic solution. The solution was stirred for 3 h and concentrated to an amber oil. This oil was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.68%/min gradient of 31.5−58.5% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 20 min was collected and lyophilized to give the protected DOTA conjugate as a colorless solid (37 mg, 46%). MS (ESI): *m/z* 2604.9 (M + H − Trt), 1423.6 (M + 2H, 100), 1302.7 (M + 2H − Trt, 53), 1181.4 (M + 2H − 2Trt, 17). HRMS: Calcd for $C_{141}H_{174}N_{23}O_{33}S_4$ (M + H), 2846.1606; found, 2846.1580. A solution of the protected DOTA conjugate (35 mg, 0.0123 mmol) in 97:3 TFA/Et_3SiH (4.0 mL) was heated at 70 °C for 70 min. The solution was concentrated, and the resulting residue was purified by preparative HPLC on a Higgins C-18 Clipeus column (20 × 250 mm) using a 0.45%/min gradient of 9−27% ACN containing 0.1% TFA at a flow rate of 15 mL/min. The main product peak eluting at 29 min was collected and lyophilized to give **15** as a colorless solid (27 mg, 91%). MS (ESI): *m/z* 2193.9 (M + H, 8), 1462.4 (2M + 3H, 5), 1096.9 (M + 2H, 57), 731.8 (M + 3H, 100). HRMS: Calcd for $C_{91}H_{122}N_{23}O_{33}S_4$ (M + H), 2192.7458; found, 2192.7430. Amino acid analysis: L-Csa, 99.3%; L-Glu, 99.1%; L-DAP, 99.3%.

(VnR Antagonist-Csa)$_2$Glu-Csa-DOTA (16). *Part A. Synthesis of (Trt-VnR Antagonist-Csa)$_2$Glu-Csa-H (**11**).* A solution of Boc−L-cysteic acid (29 mg, 0.100 mmol), DIEA (23 μL, 0.134 mmol), and HBTU (32 mg, 0.0836 mmol) in DMF (1.0 mL) was stirred for 20 min and added to a previously prepared solution of 5 (161 mg, 0.0669 mmol) and DIEA (69 μL, 0.401 mmol) in DMF (2.5 mL). Additional DIEA (23 μL, 0.134 mmol) was added after 60 min to maintain a strongly basic solution. The solution was stirred a total of 3.5 h and concentrated under vacuum to a viscous amber oil. This oil was triturated with ether to give a dry solid (234 mg). MS (ESI): *m/z* 2300.6 (M + H − Trt, 14), 1271.8 (M + 2H, 50), 1150.5 (M + 2H − Trt, 23). The solid was dissolved in 1:1 TFA/DCM (6.0 mL) for 10 min and concentrated to give an amber oil. Trituration with ether gave **11** as an off-white solid (210 mg, 93%). MS (ESI): *m/z* 2201.1 (M + H − Trt, 8), 1958.3 (M + H − 2Trt, 9), 1221.7 (M + 2H, 17), 1100.9 (M + 2H − Trt, 19).

*Part B. Synthesis of **16**.* A solution of DOTA(O*t*-Bu)$_3$OH (37 mg, 0.065 mmol), DIEA (9.4 μL, 0.054 mmol), and HBTU (15 mg, 0.0405 mmol) in DMF (1.0 mL) was stirred for 20 min and added to a previously prepared solution of the product of part A (66 mg, 0.027 mmol) and DIEA (28 μL, 0.162 mmol) in DMF (1.3 mL). The solution was stirred for 2 h and concentrated to an amber oil. This oil was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.36%/min gradient of 36−54% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 23 min was collected and lyophilized to give the protected DOTA conjugate as a colorless solid (24 mg, 29%). MS (ESI): *m/z* 1499.4 (M + 2H, 30), 1377.9 (M + 2H − Trt, 38). The DOTA conjugate (22 mg, 0.00707 mmol) was dissolved in 97:3 TFA/Et_3SiH (6.0 mL) and heated at 70 °C for 1 h. The solution was concentrated, and the residue was purified by preparative HPLC on a Higgins Clipeus C-18 column (20 × 250 mm) using a 0.21%/min gradient of 10.8−22.5% ACN containing 0.1% TFA at a flow rate of 15 mL/min. The main product peak eluting at 48 min was collected and lyophilized to give **16** as a colorless solid (13 mg, 75%). MS (ESI) *m/z* 2345.3 (M + H, 7), 1173.3 (M + 2H, 45), 782.3 (M + 3H, 100). Amino acid analysis: L-Csa, 99.7%; L-Glu, 99.5%; L-DAP, 98.8%.

(VnR Antagonist-Csa)$_2$Glu-(Csa)$_2$-DOTA (17). *Part A. Synthesis of (Trt-VnR Antagonist-Csa)$_2$Glu-(Csa)$_2$-H (**12**).* A solution of Boc−L-cysteic acid (42 mg, 0.143 mmol), DIEA

(40 μL, 0.229 mmol), and HBTU (43 mg, 0.115 mmol) in DMF (1.5 mL) was stirred for 20 min and added to a previously prepared solution of **11** (140 mg, 0.0573 mmol) and DIEA (40 μL, 0.229 mmol) in DMF (2.5 mL). The solution was stirred for 4 h and concentrated to give a viscous amber oil. The oil was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.60%/min gradient of 18−54% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 54 min was collected and lyophilized to give the cysteic acid conjugate as a colorless solid (83 mg, 53%). MS (ESI) *m*/*z* 1347.1 (M + 2H), 1226.4 (M + 2H − Trt), 1176.8 (M + 2H − Boc − Trt), 1104.9 (M + 2H − 2Trt), 1055.5 (M + 2H − Boc − 2Trt). The solid (82 mg, 0.0305 mmol) was dissolved in 1:1 TFA/DCM (10 mL) for 15 min and concentrated to an amber oil. This oil was lyophilized from 1:1 ACN/H_2O to give **12** as colorless solid (79 mg, 100%). MS (ESI) *m*/*z* 2351.4 (M + H − Trt, 7), 2109.4 (M + H − 2Trt, 10), 1297.8 (M + 2H, 11), 1176.3 (M + 2H − Trt, 25).

*Part B. Synthesis of **17**.* A solution of DOTA(O*t*-Bu)$_3$OH (42 mg, 0.0734 mmol), DIEA (11 μL, 0.062 mmol), and HBTU (18 mg, 0.0462 mmol) in DMF (1.0 mL) was stirred for 20 min and added to a previously prepared solution of the product of part A (80 mg, 0.0308 mmol) and DIEA (44 μL, 0.208 mmol) in DMF (1.8 mL). The solution was stirred for 2 h and concentrated to give an amber oil, which was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.36%/min gradient of 36−54% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 40 min was collected and lyophilized to give the protected DOTA conjugate as a colorless solid (56 mg, 58%). MS (ESI) *m*/*z* 1572.2 (M + 2H, 16), 1453.9 (M + 2H − Trt, 32). A solution of this solid (54 mg, 0.0172 mg) in 97:3 TFA/Et_3SiH (5.0 mL) was heated at 70 °C for 1 h and concentrated to an oily, yellow solid. This solid was purified by preparative HPLC on a Higgins Clipeus C-18 column (20 × 250 mm) using a 0.24%/min gradient of 9−22.5% ACN containing 0.1% TFA at a flow rate of 15 mL/min. The main product peak eluting at 45 min was collected and lyophilized to give **17** (33 mg, 77%) as a colorless solid. MS (ESI) *m*/*z* 2496.1 (M + H, 14), 1664.7 (2M + 3H, 27), 1248.3 (M + 2H, 44), 832.5 (M + 3H, 100). Amino acid analysis: L-Csa, 99.2%; L-Glu, 98.9%; L-DAP, 98.8%.

(VnR Antagonist-(Csa)$_2$)$_2$Glu -DOTA (18). *Part A. Synthesis of (Trt-VnR Antagonist-(Csa)$_2$)$_2$Glu-H (**6**).* A solution of (*S*)-2-(4-(4-(2-((*R*)-2-((*R*)-2-amino-3-sulfopropanamido)-3-sulfopropanamido)ethylamino)-4-oxobutoxy)-2,6-dimethylphenylsulfonamido)-3-(1-methyl-4-oxo-7-((1-trityl-1*H*-imidazol-2-ylamino)methyl)-1,4-dihydroquinoline-3-carboxamido)propanoic acid (**3**) (*41*) (136 mg, 0.110 mmol) and DIEA (76 μL, 0.44 mmol) in DMF (3.0 mL) was treated with Boc-Glu(OTfp)-OTfp (27 mg, 0.050 mmol) and stirred for 7 h. The solution was concentrated, and the resulting amber oil was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.45%/min gradient of 45−63% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 16 min was collected and lyophilized to give the Boc-protected bis-conjugate as a colorless solid (129 mg, 96%). MS (ESI) *m*/*z* 1347.3 (M + 2H, 9), 1226.4 (M + 2H − Trt, 12), 1176.5 (M + 2H − Trt − Boc, 12). The above solid (95 mg, 0.0353 mmol) was dissolved in 1:1 TFA/DCM (20 mL), stirred for 20 min, and concentrated. The resulting solid was taken up in 1:1 ACN/H_2O and lyophilized to give **6** as a pale yellow solid (89 mg, 97%). MS (ESI) *m*/*z* 2351.9 (M + H − Trt, 6), 2110.2 (M + H − 2Trt, 7), 1298.0 (M + 2H, 16), 1176.4 (M + 2H − Trt, 18).

*Part B. Synthesis of **18**.* A solution of DOTA(O*t*-Bu)$_3$OH (63 mg, 0.110 mmol), DIEA (48 μL, 0.270 mmol), and HBTU (20 mg, 0.0514 mmol) in DMF (2.0 mL) was stirred for 20 min and added to a previously prepared solution of the product of part A (88 mg, 0.0340 mmol) and DIEA (48 μL, 0.270 mmol) in DMF (3.0 mL). The solution was stirred for 3 h. The solution was concentrated, and the resulting residue was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.36%/min gradient of 36−54% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 41 min was collected and lyophilized to give the protected DOTA conjugate as a colorless solid (42 mg, 39%). MS (ESI) *m*/*z* 1575.7 (M + 2H, 10), 1454.4 (M + 2H − Trt, 50). The above DOTA conjugate was dissolved in 97:3 TFA/Et_3SiH (5.0 mL) and heated at 70 °C for 45 min. The solution was concentrated, and the oily solid was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.68%/min gradient of 0−27% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 34 min was collected and lyophilized to give **18** as a colorless solid (23 mg, 73%). MS (ESI) *m*/*z* 2496.6 (M + H, 5), 1664.5 (2M + 3H, 10), 1248.2 (M + 2H, 25), 832.4 (M + 3H, 100). Amino acid analysis: L-Csa, 99.8%; L-Glu, 99.6%; L-DAP, 99.1%.

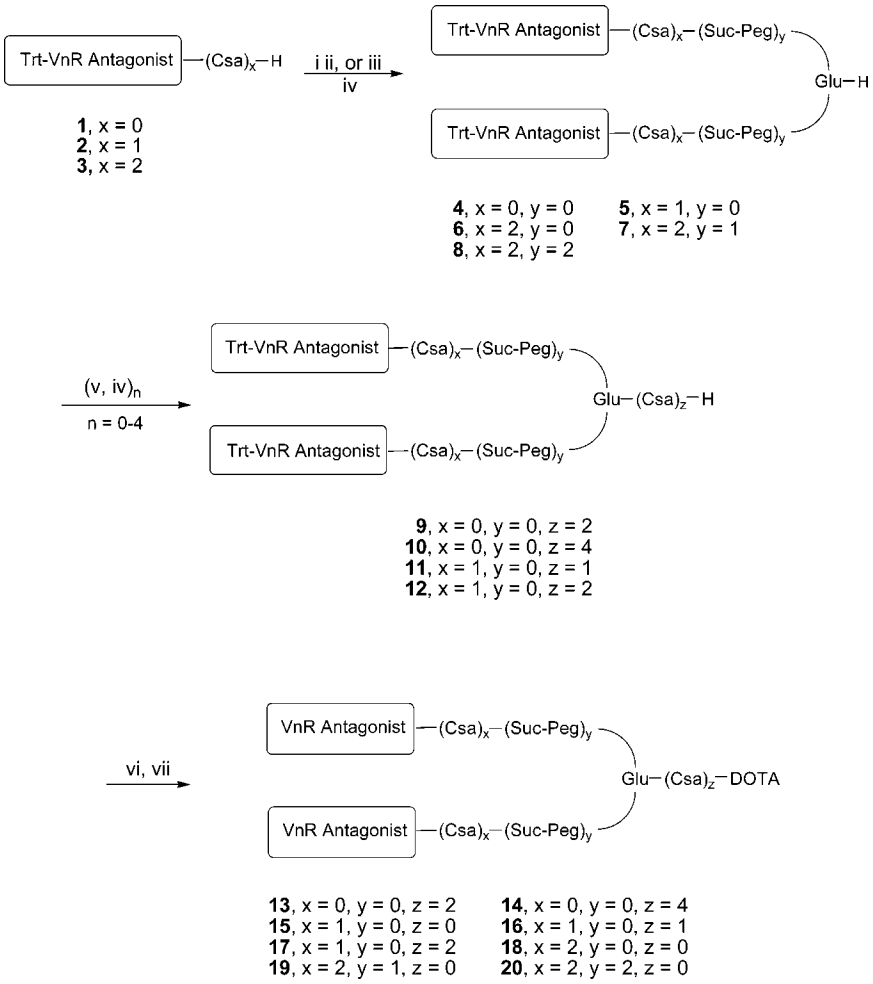
(VnR Antagonist-(Csa)$_2$-Suc-Peg)$_2$-Glu-DOTA (19). *Part A. Synthesis of (S)-tert-butyl 1,33-diamino-15,19-dioxo-4,7,10,-24,27,30-hexaoxa-14,20-diazatritriacontan-16-ylcarbamate ((H-Peg)$_2$Glu-Boc).* A solution of benzyl 3-(2-(2-(3-aminopropoxy)-ethoxy)ethoxy)propylcarbamate (*41*) (3.55 g, 10.0 mmol), Boc-Glu-OH (1.00 g, 4.05 mmol), DIEA (2.00 mL, 11.5 mmol), and PyBOP (8.00 g, 15.4 mmol) in NMP (45 mL) was stirred for 1 h and partitioned between EtOAc (175 mL) and 0.5 N HCl/NaCl (150 mL). The organic phase was washed consecutively with 0.5 N HCl/NaCl (3 × 50 mL), H_2O (50 mL), saturated $NaHCO_3$ (25 mL), and H_2O (25 mL). The aqueous phases were back-extracted with EtOAc (6 × 25 mL). The combined organic layers were dried (Na_2SO_4) and concentrated to give a pale yellow oil. This oil was purified by flash chromatography on SiO_2 (100 g) using a step gradient consisting of EtOAc (400 mL), 3:1 EtOAc/acetone (200 mL), 1:1 EtOAc/acetone (200 mL), 1:3 EtOAc/ acetone (200 mL), and acetone. Product fractions were combined and concentrated to give impure product as a colorless oil (4.30 g). This oil was repurified by flash chromatography using the above conditions to give pure bis-conjugate as a waxy solid (3.30 g, 88%). ^{1}H NMR ($CDCl_3$): δ 7.33−7.28 (m, 10H), 7.08 (bs, 1H), 6.69 (bs, 1H), 5.89 (bs, 1H), 5.59 (bs, 2H), 5.08 (s, 4H), 4.12−2.04 (m, 2H), 3.68−3.48 (m, 24H), 3.37−3.24 (m, 8H), 2.29−2.17 (m, 2H), 2.04−1.96 (m, 1H), 1.95−1.83 (m, 1H), 1.80−1.68 (m, 8H), 1.42 (s, 9H). ^{13}C NMR ($CDCl_3$): δ 172.69, 171.81, 156.52, 155.75, 136.66, 128.32, 127.92, 127.86, 79.57, 70.23, 70.20, 69.89, 69.86, 69.75, 69.46, 69.29, 69.17, 66.31, 38.80, 37.50, 37.21, 32.44, 29.31, 28.90, 28.74, 28.21. MS (ESI) *m*/*z* 920.5 (M + H, 100). The above solid (920 mg, 1.00 mmol) was dissolved in MeOH (25 mL) and hydrogenolyzed over 10% Pd/C (140 mg) at 60 psi for 6 h. The catalyst was removed by filtration through Celite, and the filtrate was concentrated to give a quantitative yield of (H-Peg)$_2$Glu-Boc. ^{1}H NMR ($CDCl_3$): δ 8.04 (bs, 1H), 7.67 (bs, 1H), 6.34 (bs, 1H), 4.08 (bs, 1H), 3.67−3.50 (m, 24H), 3.37−3.26 (m, 4H), 3.09 (t, J = 6.4 Hz, 4H), 2.28 (t, J = 7.0 Hz, 2H), 2.10−1.88 (m, 10H), 1.77 (quin, J = 6.2 Hz, 4H), 1.42 (s, 9H). ^{13}C NMR ($CDCl_3$): δ 173.17, 172.48, 155.02, 79.45, 70.28, 69.88, 69.86, 69.71, 69.68, 69.64, 69.45, 68.82, 68.63, 54.10, 38.70, 36.85, 36.67, 32.47, 29.18, 29.06, 29.02, 28.26, 27.12. MS (ESI) *m*/*z* 652.5 (M + H, 43), 326.8 (M + 2H, 100), 298.8 (M + 2H − C_4H_8, 20), 276.7 (M + 2H − Boc, 90).

*Part B. Synthesis of (H-Suc-Peg)$_2$-Glu-Boc (**22a**).* A solution of the product of part A (650 mg, 1.00 mmol) and succinic anhydride (226 mg, 2.26 mmol) in pyridine (10 mL) was

sonicated briefly to dissolve all solids and then stirred for 20 h. The solution was concentrated, and the residue was triturated with toluene (4 × 50 mL). The remaining residue was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.56%/min gradient of 13.5−36% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product fractions were collected and lyophilized to give **22a** as a colorless solid (650 mg, 76%). ^{1}H NMR ($CDCl_3$): δ 7.70 (bs, 1H), 7.43 (bs, 1H), 7.05 (bs, 2H), 6.04 (bs, 1H), 4.11 (bs, 1H), 3.71−3.52 (m, 24H), 3.37−3.28 (m, 8H), 2.67 (t, J = 6.5 Hz, 4H), 2.51, (t, J = 6.6 Hz, 4H), 2.34−2.27 (m, 2H), 2.12−2.04 (m, 1H), 1.96−1.87 (m, 1H), 1.79−1.70 (m, 8H), 1.42 (s, 9H). MS (ESI) *m*/*z* 852.4 (M + H, 100), 376.8 (M + 2H − Boc, 50).

*Part C. Synthesis of (Trt-VnR Antagonist-(Csa)$_2$-Suc-Peg)$_2$-Glu-H (**7**).* A solution of the product of part B (20 mg, 0.024 mmol), DIEA (50 μL, 0.285 mmol), and HBTU (17 mg, 0.044 mmol) in DMF (0.5 mL) was stirred for 5 min and treated sequentially with 3 (*38*) (61 mg, 0.049 mmol), DIEA (42 μL, 0.240 mmol), and DMF (0.7 mL). The solution was stirred for 20 min and concentrated. The resulting residue was purified by preparative HPLC on a Vydac C-18 column (21 × 250 mm) using a 0.56%/min gradient of 22.5−45% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 35 min was collected and lyophilized to give the Boc-protected bis-conjugate as a colorless solid (35 mg, 50%). MS (ESI) *m*/*z* 1648.7 (M + 2H, 35), 1099.5 (M + 3H, 15). The above solid (35 mg, 0.011 mmol) was dissolved in 1:1 TFA/DCM (2.0 mL) and stirred for 15 min. The solution was concentrated, and the residue was taken up in 1:1 ACN/H_2O and lyophilized to give **7** as a colorless solid (34 mg, 100%). MS (ESI) *m*/*z* 1600.1 (M + 2H, 40), 1478.9 (M + 2H − Trt, 50).

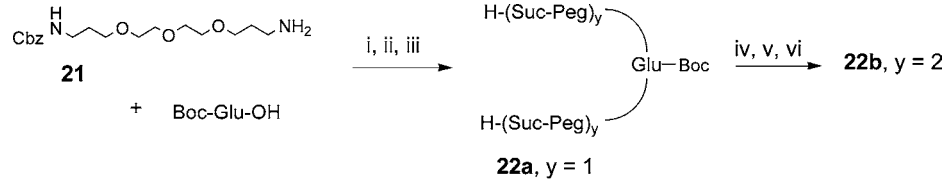
*Part D. Synthesis of **19**.* A solution of DOTA(O*t*-Bu)$_3$OH (24 mg, 0.042 mmol), DIEA (43 μL, 0.247 mmol), and HBTU (12 mg, 0.032 mmol) in DMF (1.0 mL) was stirred for 15 min and treated sequentially with the product of part C (34 mg, 0.011 mmol), DIEA (20 μL, 0.115 mmol), and DMF (0.4 mL). The solution was stirred for 30 min and concentrated to an amber oil. This oil was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.68%/min gradient of 27−54% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 27 min was collected and lyophilized to give the protected DOTA conjugate as a colorless solid (16 mg, 40%). MS (ESI) *m*/*z* 1877.2 (M + 2H, 70), 1756.2 (M + 2H − Trt, 70), 1635.1 (M + 2H − 2Trt, 40), 1251.8 (M + 3H, 60), 1171.2 (M + 3H − Trt, 50). The above solid (12 mg, 0.0032 mmol) was dissolved in 97:3 TFA/Et_3SiH (1.3 mL), heated at 65 °C for 90 min, and concentrated to an oily solid. The solid was dissolved in 10:90 ACN/H_2O (3.0 mL) and washed with diethyl ether (2 × 4 mL) to remove triphenylmethane. The product in the aqueous layer was purified by preparative HPLC by direct injection of the solution on a Vydac C-18 column (21 × 250 mm) using a 0.36%/min gradient of 9−27% ACN containing 0.1% TFA at a flow rate of 20 mL/min. The main product peak eluting at 31 min was collected and lyophilized to give **19** as a colorless solid (7.4 mg, 75%). MS (ESI) *m*/*z* 1550.6 (M + 2H, 40), 1034.2 (M + 3H, 100), 775.8 (M + 4H, 90), 620.9 (M + 5H, 35). HRMS: Calcd for $C_{125}H_{186}N_{29}O_{51}S_6$ (M + 3H), 1034.0398; found 1034.0394. Amino acid analysis: L-Csa, 99.1%; L-Glu, 99.7%; L-DAP, 97.9%.



(VnR Antagonist-Csa-Csa-Suc-Peg-Suc-Peg)$_2$-Glu-DOTA (20). *Part A. Synthesis of (H-Peg-Suc-Peg)$_2$-Glu-Boc.* A solution of **22a** (850 mg, 1.00 mmol), DIEA (0.85 mL, 5.0 mmol), and HBTU (1.00 g, 2.60 mmol) in DMF (25 mL) was stirred for 5 min and treated with benzyl 3-(2-(2-(3-aminopropoxy)ethoxy)-ethoxy)propylcarbamate (1.00 g, 2.80 mmol). The solution was stirred for 1 h and concentrated to a red oil, which was triturated with H_2O (3 × 15 mL) and dissolved in DCM. The DCM solution was filtered, and the filtrate was concentrated to give a red−orange oil. This oil was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.90%/min gradient of 31.5−67.5% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product fractions were collected and lyophilized to give the bis-conjugate as a colorless oil (1.282 g, 84%). MS (ESI) *m*/*z* 1524.7 (M + H, 32), 763.0 (M + 2H, 100). The above oil (1.20 g, 7.90 mmol) was hydrogenolyzed over 10% Pd/C (200 mg) in MeOH (25 mL) at 50 psi for 2 h. The catalyst was removed by filtration through Celite, and the filtrate was concentrated to give a quantitative yield of (H-Peg-Suc-Peg)$_2$-Glu-Boc. MS (ESI) *m*/*z* 1256.7 (M + H, 10), 629.0 (M + 2H, 100), 386.4 (M + 3H-Boc, 92).

*Part B. Synthesis of (H-(Suc-Peg)$_2$)$_2$-Glu-Boc (**22b**).* A solution of the product of part A (942 mg, 0.75 mmol) and succinic anhydride (250 mg, 2.50 mmol) in pyridine (10 mL) was sonicated briefly to dissolve solids and then stirred for 18 h. The solution was concentrated, and the resulting residue was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.90%/min gradient of 31.5−67.5% ACN containing 0.1% TFA at a flow rate of 80 mL/min. It was necessary to take fine heart cuts in order to remove closely eluting impurities. The pure product fractions were collected and lyophilized to give the **22b** (206 mg, 14%) as a colorless viscous oil. MS (ESI) *m*/*z* 1456.8 (M + H, 60), 729.0 (M + 2H, 100), 453.0 (M + 3H − Boc, 48).

*Part C. Synthesis of (Trt-VnR Antagonist-(Csa)$_2$-(Suc-Peg)$_2$)$_2$-Glu-H (**8**).* A solution of the product of part B (77 mg, 0.053 mmol), DIEA (52 μL, 0.30 mmol), and HBTU (38 mg, 0.100 mmol) in DMF (1.0 mL) was stirred for 10 min and treated sequentially with **3** (*38*) (142 mg, 0.112 mmol), DIEA (100 μL, 0.574 mmol), and DMF (0.5 mL). The solution was stirred for 2 h and concentrated. The resulting residue was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.60%/min gradient of 45−63% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting as a broad peak from 16−20 min was collected and lyophilized to give the bis-conjugate as a colorless solid (104 mg, 53%). MS (ESI) *m*/*z* 1952.3 (M + 2H, 32), 1831.3 (M + 2H − Trt, 55), 1709.3 (M + 2H − 2Trt, 34), 1302.2 (M + 3H, 72), 1221.2 (M + 3H − Trt, 58), 1140.8 (M + 3H − 2Trt, 22). A solution of the above solid (100 mg, 0.026 mmol) in 1:2 TFA/DCM (2.4 mL) was stirred for 25 min and concentrated. The resulting oil was taken up in 1:1 ACN/H_2O (40 mL) and lyophilized to give **8** as a colorless solid (99 mg, 100%). MS (ESI) *m*/*z* 1902.2 (M + 2H, 55), 1780.6 (M + 2H − Trt, 60), 1659.9 (M + 2H − 2Trt, 45), 1268.6 (M + 3H, 85), 1187.6 (M + 3H − Trt, 70).



*Part D. Synthesis of **20**.* A solution of DOTA(O*t*-Bu)$_3$OH (24 mg, 0.042 mmol), DIEA (43 μL, 0.247 mmol), and HBTU (12 mg, 0.032 mmol) in DMF (1.0 mL) was stirred for 10 min and treated sequentially with the product of part C (97 mg, 0.0255 mmol) and DIEA (65 μL, 0.37 mmol). The resulting solution was stirred for 45 min and concentrated to an amber oil. This oil was purified by preparative HPLC on a Vydac C-18 column (50 × 250 mm) using a 0.54%/min gradient of 27−54% ACN containing 0.1% TFA at a flow rate of 80 mL/min. The main product peak eluting at 42 min was lyophilized to give the protected DOTA conjugate as a colorless solid (60 mg, 54%). MS (ESI) *m*/*z* 2179.6 (M + 2H, 30), 2058.1 (M + 2H − Trt, 30), 1936.8 (M + 2H − 2Trt, 25), 1453.4 (M + 3H, 70), 1372.8 (M + 3H − Trt, 100), 1241.6 (M + 3H − 2Trt, 60). A solution of the DOTA conjugate in 80:20 TFA/Et_3SiH (2.5 mL) was stirred at 60 °C for 95 min and concentrated to an oily solid. This solid was purified by preparative HPLC on a Vydac

Receptor Binding Assays. Affinity assays toward four integrin receptors were carried out according to previously published procedures (*31*, *43*) and are included in the Supporting Information.

Radiolabeling. ^{111}In-DOTA complexes used in this study were prepared in >95% radiochemical purity according to a previously published procedure (*41*). This procedure is included in the Supporting Information. ^{177}Lu-**15** was prepared in >95% radiochemical purity according to a previously published procedure (*42*). This procedure is included in the Supporting Information.

In Vivo Biodistribution Study. Biodistribution in the c-neu Oncomouse mammary adenocarcinoma model was carried out according to a previously published procedure (*41*) as described in the Supporting Information.

Scintigraphic Image Study. Scintigraphic images of ^{111}In-**TA138** and ^{111}In-**15** in the c-Neu Oncomouse model were acquired according to a previously published procedure (*31*). This procedure is reproduced in the Supporting Information.

RESULTS

Synthesis of Divalent $\alpha_v\beta_3$ Antagonists. The syntheses of vitronectin receptor antagonists **1**, **2**, and **3**, having zero, one, and two cysteic acid PKMs, respectively, were described previously (*41*). The general synthetic route from these three

starting materials to the divalent radiopharmaceuticals reported here is shown in Schemes 1 and 2. Conjugation of **1**, **2**, and **3**, with 0.5 molar equiv of Boc-Glu(OTfp)-OTfp in DMF gave the bis-conjugates in good to excellent yields. Treatment of these conjugates with 1:1 TFA/DCM removed the Boc protecting group from the glutamyl residue, while leaving intact the trityl protecting group on the imidazole rings, to give **4**, **5**, and **6** in purified yields of 43%, 74%, and 94%, respectively. Compound **4** was used to synthesize DOTA conjugates **13** and **14**, having two and four cysteic acid PKMs, respectively. These compounds are related in that the cysteic acids are conjugated to the glutamic acid α-amine, between the glutamic acid branch point and DOTA. Thus, the compounds have identical spacing between the two biotargeting groups but differ in their lipophilicity and charge. The cysteic acids were added in stepwise fashion using Boc−L-cysteic acid and PyBOP in DMF for the conjugation reactions and 1:1 TFA/DCM for Boc removal. Two coupling/deprotection cycles gave compound **9** in 60% yield over four reactions. Triturations were used to remove impurities in three of the four synthetic steps, with one HPLC purification used for final purification prior to DOTA conjugation. In a similar fashion, **9** was converted to tetra-cysteic acid derivative **10** in 55% overall yield. Conjugation of the bis- and tetra-cysteic acid derivatives to DOTA(O*t*-Bu)$_3$-OH was accomplished using HBTU in DMF. Global deprotection using 97:3 TFA/Et_3SiH at 70 °C gave final products **13** and **14** in 31% and 12% yield, respectively. The low yields for these final two steps were due in large part to very challenging HPLC purifications that necessitated taking small heart cuts from the product peaks.

Compound **5** was used to synthesize a trio of DOTA conjugates, **15**, **16**, and **17**, having a total of two, three, or four cysteic acid PKMs, respectively. All three of these compounds have a single cysteic acid PKM on each arm of the spacer, and either zero, one, or two cysteic acid PKMs conjugated to the glutamic acid α-amine. As a group, they have identical spacing between the biotargeting groups but differ in their lipophilicity and charge. Placing cysteic acids in the chain linking the biotargeting groups adds a total of six atoms to the spacer length. Conjugation of DOTA(O*t*-Bu)$_3$-OH directly to **5** followed by global deprotection gave **15** in 42% yield. Reaction of **5** with Boc−cysteic acid and HBTU, followed by removal of Boc using TFA/DCM, gave **11** in 93% yield. Addition of a second cysteic acid PKM to **11** using the same chemistry gave **12** in 53% yield. Compounds **11** and **12** were converted to DOTA conjugates **16** and **17** in 22% and 45% purified yields, respectively. Conjugation of DOTA(O*t*-Bu)$_3$-OH directly to **6** followed by global deprotection gave **18** in 28% yield.

The final two compounds of this study utilized Suc-PEG spacers to provide a large additional increase in the distance between the biotargeting groups. The spacer groups were added to Boc−glutamic acid in stepwise fashion as shown in Scheme 2. Conjugation of Boc−glutamic acid with 2 equiv of Cbz-protected PEG diamine **21**, followed by catalytic hydrogenolysis, and reaction of the resulting amine with succinic anhydride gave dicarboxylic acid **22a** in 67% overall yield. A second Suc-PEG spacer was added to each arm of **22a** using the same sequence of reactions to give **22b** in 12% overall yield. Conjugation of **22a** and **22b** with bis-cysteic acid $\alpha_v\beta_3$ receptor antagonist **3**, followed by removal of the Boc protecting groups, gave divalent antagonists **7** and **8** in 50% and 55% yields, respectively. HBTU-mediated conjugation of **7** and **8** to DOTA(O*t*-Bu)$_3$-OH followed by global deprotection gave **19** and **29** in 30% and 40% yields, respectively.

Receptor Binding Assays. Affinity assays toward four integrin receptors were used to measure the potency and selectivity of the divalent $\alpha_v\beta_3$ antagonist described here and to compare them to **TA138**. Our principle receptor $\alpha_v\beta_3$ assay was the 293β_3-fibrinogen ($\alpha_v\beta_3$-mediated) adhesion assay (*43*). Receptor selectivity was measured using the platelet aggregation $\alpha_{IIb}\beta_3$ assay (*43*), the human SKBR3 cell-vitronectin ($\alpha_v\beta_5$-mediated) adhesion assay (*31*), and the human lymphocyte (Jurkat)-fibronectin ($\alpha_5\beta_1$-mediated) adhesion assay (*31*). The affinity data in Table 2 show that all compounds have high affinity toward receptor $\alpha_v\beta_3$, with IC_{50} values of 6−58 nM in the 293β_3 assay. They also show good to excellent selectivity versus receptors $\alpha_{IIb}\beta_3$, $\alpha_v\beta_5$, and $\alpha_5\beta_1$.

Table 2. In Vitro Receptor Affinity of Quinolin-4-one DOTA Conjugates

Radiolabeling. All DOTA conjugates of this study formed stable complexes with ^{111}In. The complexes were prepared according to a previously published procedure and isolated in >95% radiochemical purity (*41*).

In Vivo Biodistribution Study. The biodistribution properties of the compounds in this study were evaluated in the c-neu Oncomouse mammary adenocarcinoma model according to a previously published procedure (*41*). Compounds were evaluated as the ^{111}In complexes and administered at 2 mCi/Kg of body weight. Mice were euthanized and dissected at 2 and 24 h postinjection (PI), and activity in the organs and tumors was counted on a gamma counter. The biodistribution data are presented in Figures 3 and 4, expressed as % of injected dose/gram of tissue (%ID/g). All biodistribution data are decay-corrected. Tumor uptake was rapid for all divalent agents, ranging from 4.81% ID/g at 2 h PI for ^{111}In-**20** to 9.99% ID/g at 2 h PI for ^{111}In-**17**. The parent monovalent agent, ^{111}In-**TA138**, displayed slow washout from the tumor, decreasing from 9.39% ID/g at 2 h PI to 3.46% ID/g at 24 h PI. In contrast, tumor uptake for the divalent agents either remained constant or increased between 2 and 24 h, with ^{111}In-**15** showing the highest uptake at 14.3% ID/g at 24 h PI. This continuous uptake was also apparent in the colon and uterus, where the majority of divalent agents displayed increased uptake between 2 and 24 h. As shown in Figures 3 and 4, uptake in the kidneys, marrow, and liver decreased over 24 h for all agents. Uptake in organs not shown in the figures was low for all agents as follows at 24 h PI: eyes, muscle, heart, and bile, <1% ID/g; spleen, lung, and bone (excluding marrow), < 2% ID/g. Complete biodistribution data at 2 and 24 h PI for all of these organs, plus stomach, blood, and urine is available in the Supporting Information. All agents were excreted primarily through the kidneys. Blood clearance was fast for all agents, with seven of the eight divalent agents decreasing to lower levels than parent monovalent agent ^{111}In-**TA138** over a 2 h period, and six of the eight remaining below ^{111}In-**TA138** at 24 h PI (Figure 5).

DISCUSSION

Many interactions in biological systems are polyvalent in nature, including the DNA helix, carbohydrate interactions, and virus−cell wall interactions. However, the idea of using multiple, simultaneous interactions as a strategy in drug discovery and development is a relatively recent phenomenon.

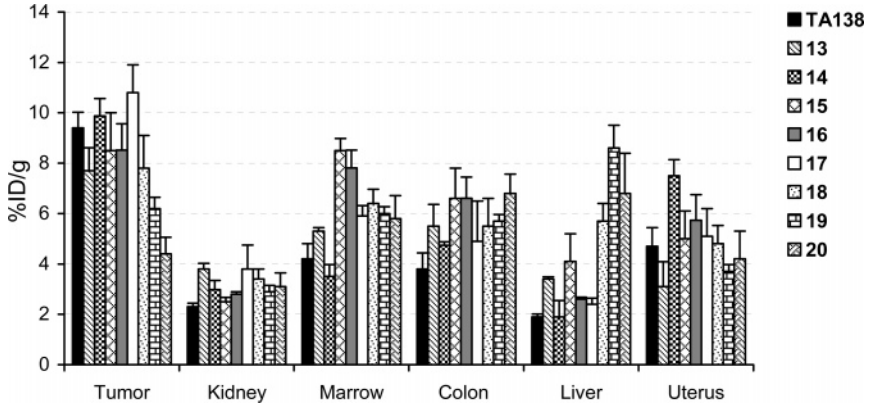

Figure 3. Biodistribution of the ^{111}In complexes of **TA138** and the eight divalent agents described in the text 2 h PI in the c-neu Oncomouse model at 2 mCi/Kg. Values are the average of three animals. The radiolabeling and biodistribution procedures were described in ref 41.

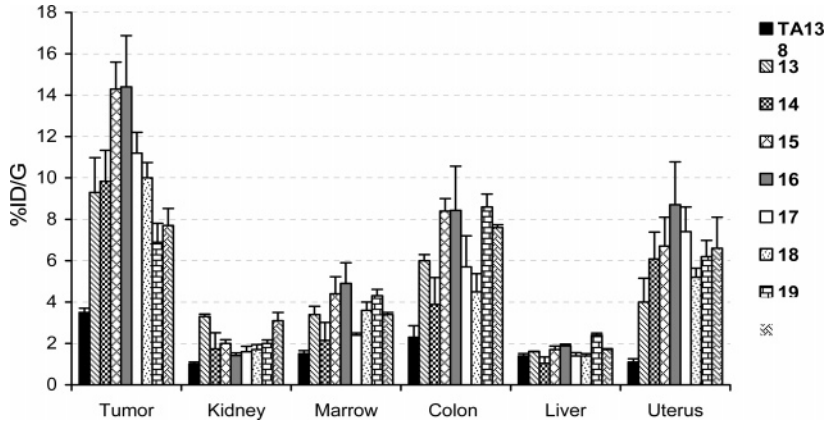

Figure 4. Biodistribution of the ^{111}In complexes of **TA138** and the eight divalent agents described in the text 24 h PI in the c-neu Oncomouse model at 2 mCi/Kg. Values are the average of three animals. The radiolabeling and biodistribution procedures are described in ref 41.

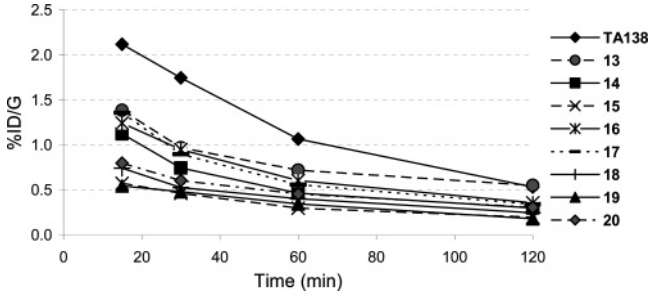

Figure 5. Blood clearance of the ^{111}In complexes of **TA138** and the eight divalent agents described in the text in the c-neu Oncomouse model at 2 mCi/Kg. Values are the average of three animals. The radiolabeling and biodistribution procedures are described in ref 41.

Polyvalency is a complex phenomenon, and the reader is referred to two recent reviews for an in-depth discussion (*44*, *45*). Past efforts by us and others to simultaneously achieve high tumor uptake and retention and favorable tumor/organ ratios for critical nontarget organs using polyvalent radiolabeled cyclic RGD peptide antagonists to receptor $\alpha_v\beta_3$ have led either to high tumor uptake or to improved tumor/organ ratios, but not both (*23*, *35*, *46*). Our main goal in this work was to determine whether polyvalency in peptidomimetic $\alpha_v\beta_3$ antagonists could be used as a means of improving tumor uptake and retention, and tumor/organ ratios for radiotherapeutic applications, where the radiation dose to nontarget organs, especially kidneys and bone marrow, becomes critically important.

We were also interested in understanding the nature of the polyvalent effect in $\alpha_v\beta_3$ antagonists, including the question of whether a polyvalent ligand can simultaneously bind to two or more $\alpha_v\beta_3$ receptors. The minimum spacer length required for homogeneous divalent association can be inferred from structural studies carried out on integrin receptors. Integrin $\alpha_v\beta_5$, which also recognizes the RGD binding motif, is an internalization receptor for adenovirus. Cryomicroscopy and difference map analyses of adenovirus complexed with an $\alpha_v\beta_5$ cluster were used to derive a 3D map of the extracellular domain of $\alpha_v\beta_5$ (*47*). Five integrin molecules form an integrin cluster and bind to the penton base of adenovirus. The penton base of adenovirus has five surface protrusions, which are believed to be the five RGD-containing surface loops that bind to the integrin cluster. The distance between any two adjacent loops was estimated to be 60 Å, suggesting a minimum length requirement of a spacer in order to achieve homogeneous divalent binding. The multivalent nature of the adenovirus−integrin cluster interaction was confirmed by kinetic analyses, which indicated 4.2 integrin molecules bound to each adenovirus penton base at close to saturation conditions. Additional structural information comes from the recently determined crystal structure of the extracellular segment of integrin $\alpha_v\beta_3$ in its activated state (*48*). The α and β subunits of $\alpha_v\beta_3$ assemble into an ovoid head having lateral dimensions of 60 Å by 90 Å. The putative $\alpha_v\beta_3$ binding site is centrally located on top of the head in the cleft between subunits. Below the integrin head, each subunit forms a thin cylindrical tail ~20 Å in diameter. Thus, the head dimensions determine the closest approach distance of two receptors and suggest that homogeneous bridging of adjacent receptors requires a minimum spacer length of 60−90 Å, depending on orientation of the two receptors.

All reported examples of the polyvalent effect in divalent cyclic RGD peptides have spacer lengths that fall far short of that required to simultaneously bridge the primary binding sites of adjacent integrin receptors (*23*, *24*, *33*−*36*). What, then, is

the source of the observed polyvalent effect? One explanation is the statistical effect, where increased affinity or retention is the result of increased effective local concentration of the binding moiety. Detachment of the ligand from the receptor is more likely to be followed by reattachment if there are multiple copies of the binding moiety near the receptor, effectively reducing the off-rate. Another possibility is the existence of secondary binding sites. A portion of the spacer or a portion of the second ligand may bind to what is commonly referred to as a subsite or exosite. These secondary binding sites are typically on the same receptor as the primary binding site and thus require a relatively short spacer for simultaneous attachment.

Given these previous studies, it was our expectation that we would observe a polyvalent effect with the quinolin-4-one vitronectin receptor antagonists using relatively short spacer lengths. The study design therefore consisted of a series of divalent structures having relatively short spacer lengths, which would not be predicted to bridge the primary binding sites of adjacent receptors but would be expected to produce a polyvalent effect by the statistical and/or exosite modes of binding. In addition, we synthesized and tested two divalent structures with spacer lengths greater than the estimated 60−90 Å required for simultaneous binding to the primary binding sites of adjacent receptors. To our knowledge, this is the first reported instance of divalent small molecule receptor $\alpha_v\beta_3$ antagonists having spacers that, in theory, are long enough to show true homogeneous divalent interactions. Such homogeneous divalent interactions would be evidenced by an increase in receptor affinity and target uptake when compared to those divalent agents binding by statistical and/or exosite divalent interactions. The structural features of all the divalent compounds in the study (structures **13**−**20**) are shown in Scheme 1 and in Table 1. The table also shows the length of the spacer groups as a function of the number of atoms in the spacers and as the maximum achievable length of the spacer in angstroms.

The structure of the spacer linking receptor-binding moieties plays an important role in the polyvalent process. The spacer must be of sufficient length to span the closest approach distance of the receptors, allow the pharmacophores to adopt the proper orientation to the receptors, and not interfere with binding. For short distances, we used spacers consisting of the ethylenediamine 4-oxobutyramide tether attached to the arylsulfonamide group of monomer **TA138**, plus cysteic acid PKMs (see structures **13**−**18**, Scheme 1 and Figure 2). For the longer distances (e.g., **19** and **20**), we added short diamino PEG units derivatized on one end with succinic acid (Suc-PEG in Figure 2). We reasoned that this PEG spacer should be neutral in its effect on the hydrophilic nature of the antagonist molecules. This spacer is also very flexible and will allow the molecules to acquire the necessary orientation for binding. Unfortunately, such extreme flexibility carries a thermodynamic penalty due to the increased entropy associated with divalent association. Entropy would be reduced with a rigid spacer of correct length and conformation. However, little is known about the optimum distance and conformation required for simultaneous binding to two $\alpha_v\beta_3$ receptors, and the flexible spacer approach was judged to be best in this instance.

The divalent compounds of this study can be grouped into two main series. The larger series consists of five compounds (**14** and **17**−**20**) having spacer lengths of 29−134 Å. These compounds have four cysteic acid PKMs and therefore have the same overall charge. The shortest spacers (compounds **14** and **17**) required a relocation of cysteic acid PKMs to a position between the glutamic acid branch point and DOTA. The lipophilicities of these five compounds are similar as judged by their elution properties on reverse-phase HPLC, where all compounds elute from a C18 column at 20−22% ACN under acidic mobile phase conditions. The principal variable in this series is therefore spacer length, and it was felt the biodistribution data would reveal information on the optimum spacer length and on the mechanism of the expected divalent effect in these molecules. The second series consists of three compounds (**15**, **16**, and **17**) having the same 36 Å spacer length, but having a total of either two, three, or four cysteic acid PKMs. This series was intended to reveal information on the role of charge and lipophilicity.

Receptor Affinity and Selectivity. Receptor affinity and selectivity of our divalent agents were measured in a panel of four integrin binding assays, as shown in Table 2. The affinity data for monovalent parent agent **TA138** are shown in line 1 of the table, with divalent agents following in order of increasing spacer length. Refer to Table 1 for spacer length data. The data show that all agents have high affinity toward the vitronectin receptor in the 293β_3-fibrinogen ($\alpha_v\beta_3$-mediated) adhesion assay, with IC_{50} values of 6−58 nM. There is no trend in the numbers that would suggest an optimum spacer length. For example, parent **TA138** has essentially the same affinity (IC_{50} = 12 nM) as **15** with a 36 Å spacer (IC_{50} = 9 nM) and **19** with a 89 Å spacer (IC_{50} = 6 nM). Receptor selectivities against receptors $\alpha_{IIb}\beta_3$, $\alpha_v\beta_5$, and $\alpha_5\beta_1$ are good for all agents. There are some minor differences, but no consistent pattern. For example, in the $\alpha_{IIb}\beta_3$ assay, the agents having intermediate-length spacers showed a slight reduction in selectivity, while in the $\alpha_5\beta_1$ assay, the shorter and longer spacers gave a slight reduction in selectivity. All compounds showed high selectivity in the $\alpha_v\beta_5$ assay. The two compounds with spacers long enough to simultaneously bind adjacent vitronectin receptors (**19** and **20**) have some of the best $\alpha_v\beta_3$ affinity numbers (IC_{50} = 6 and 15 nM, respectively), but the numbers are not orders of magnitude better than monomer **TA138**, as might be expected of a homogeneous divalent interaction. Thus, the receptor affinity data do not suggest simultaneous binding to two vitronectin receptors for compounds **19** and **20**. With regard to the effect of total charge of the molecules, there is no correlation between the negative charge imparted by the cysteic acid PKMs and affinity for $\alpha_v\beta_3$. These latter data support our earlier conclusion that the close proximity of the negatively charged cysteic acid PKM to the receptor does not negatively influence affinity for integrin $\alpha_v\beta_3$ (*41*). It is interesting that there is no correlation between affinity for $\alpha_v\beta_3$ and the tumor uptake of these agents (discussion to follow). It must be remembered that receptor affinity is only one of many variables that affect tissue uptake. Among these variables are protein binding, uptake and release by nontarget tissues, and blood clearance rates, and the role play by these variables will not be revealed by a simple in vitro affinity study.

In Vivo Biodistribution. We have previously shown that the ^{90}Y and ^{111}In complexes of **TA138** are biologically equivalent (*49*). We therefore assume that the ^{111}In complexes of these divalent antagonists can serve as reasonable surrogates for the corresponding therapeutic analogs. The ideal biodistribution and pharmacokinetic profile for a therapeutic radiopharmaceutical is one of rapid, high, and prolonged uptake in the target tissue, followed by rapid clearance from nontarget tissues and renal excretion. An agent with such a profile minimizes the radiation burden to the patient while maximizing the radiation dose to the target. Monovalent agent ^{111}In-**TA138** shows rapid tumor uptake in the c-neu Oncomouse model (9.39% ID/g at 2 h PI) with slow tumor washout (3.46% ID/g at 24 h PI), rapid blood clearance (Figure 5), and primarily renal excretion. Our principal goal in this study was to further reduce the already slow tumor washout shown by ^{111}In-**TA138**. This would allow us to take full advantage of the long half-life of therapeutic radionuclides such as ^{90}Y ($t_{1/2}$ = 64.1 h, 2.3 MeV β^- particle) and ^{177}Lu ($t_{1/2}$

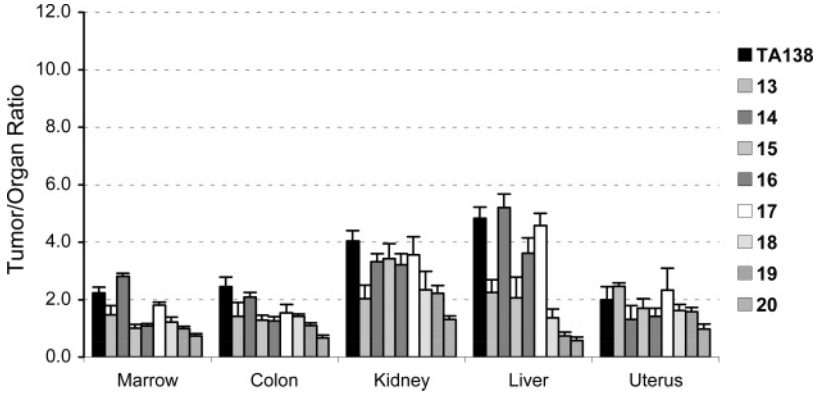

Figure 6. Tumor/organ ratios of the ^{111}In complexes of **TA138** and the eight divalent agents described in the text 2 h PI in the c-neu Oncomouse model at 2 mCi/Kg. Values are the average of three animals. The radiolabeling and biodistribution procedures are described in ref 41.

= 6.65 d, 0.48 MeV β^- particle). This goal has been achieved by all of the divalent agents of the study. The ^{111}In complexes of compounds **14**−**17** have tumor uptake at 2 h PI that is approximately equal to ^{111}In-**TA138**. But while ^{111}In-**TA138** washes out of tumors beyond 2 h PI, seven out of the eight divalent agents continue to accumulate in tumors, and by 24 h PI, all divalent agents display tumor uptake significantly higher than that of ^{111}In-**TA138** (Figure 4). It is interesting that the agents delivering the highest tumor uptake (^{111}In-**15**, ^{111}In-**16**, and ^{111}In-**17** with 14.3%, 11.1%, and 11.2% ID/g at 24 h PI, respectively) have the same intermediate-length spacers (36 Å). On the basis of the integrin structural studies discussed above, a 36 Å spacer is insufficient to provide simultaneous binding to two adjacent integrins. In contrast, the two agents having spacers sufficiently long to bridge the gap between adjacent integrins (^{111}In-**19** and ^{111}In-**20**) gave the lowest tumor uptake of the divalent agents at both 2 h PI (6.04% and 4.81% ID/g, respectively) and 24 h PI (6.87% and 7.69% ID/g, respectively). These data strongly suggest that ^{111}In-**19** and ^{111}In-**20** are also binding primarily by the statistical and/or exosite modes of polyvalent interaction, and the fact that they show the lowest tumor uptake of the divalent agents implies a thermodynamic penalty is being paid for having spacers longer than that required by the operative binding mechanism. Thus, while divalency has improved on the tumor uptake and retention of ^{111}In-**TA138** for all of the divalent agents, the data suggest that this is due in all cases to the statistical and/or exosite modes of polyvalent interaction rather than the simultaneous binding to two receptors.

Our calculations of organ doses from ^{111}In-**TA138** suggested that for a therapeutic version of **TA138** the kidneys and bone marrow would be the critical nontarget organs. The tumor/kidney ratios (Figures 6 and 7) for ^{111}In-**TA138** were 4.04 and 3.27 at 2 and 24 h PI, respectively, while the tumor/marrow ratios were constant at 2.30 from 2 to 24 h PI. The majority of divalent agents showed improved tumor/marrow and tumor/kidney ratios. The tumor/kidney ratios showed the largest improvement, with ^{111}In-**15**, ^{111}In-**16**, and ^{111}In-**17**, all with 36 Å spacers, having ratios of 3.42, 3.21, and 3.55 at 2 h PI, and increasing to 7.29, 8.51, and 6.82 at 24 h PI. The tumor/liver ratios showed a similar profile of improvement across the divalent agents, with the intermediate-length spacers providing the largest ratios. A much smaller improvement was observed for bone marrow, with ^{111}In-**14** and ^{111}In-**17** having nearly identical tumor/marrow ratios of 4.57 and 4.66 at 24 h PI. The colon and uterus displayed a pattern of uptake and retention noticeably different from other organs. Both showed uptake for all divalent agents at 24 h PI (Figure 4) that was significantly higher than ^{111}In-**TA138**, and the pattern of uptake was similar to that observed in the tumors. For example, from 2 to 24 h PI there was increased uterus uptake for seven of the eight divalent agents and increased colon uptake for four of the eight divalent

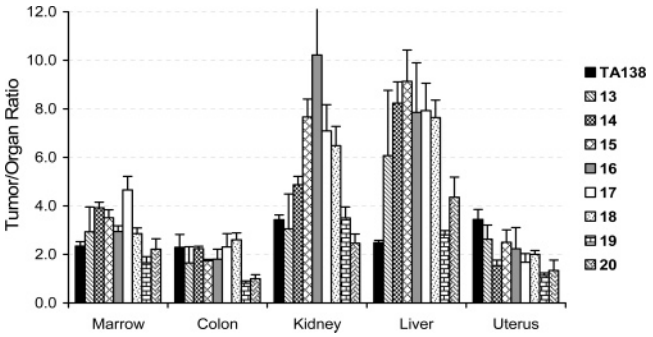

Figure 7. Tumor/organ ratios of the ^{111}In complexes of **TA138** and the eight divalent agents described in the text 24 h PI in the c-neu Oncomouse model at 2 mCi/Kg. Values are the average of three animals. The radiolabeling and biodistribution procedures are described in ref 41.

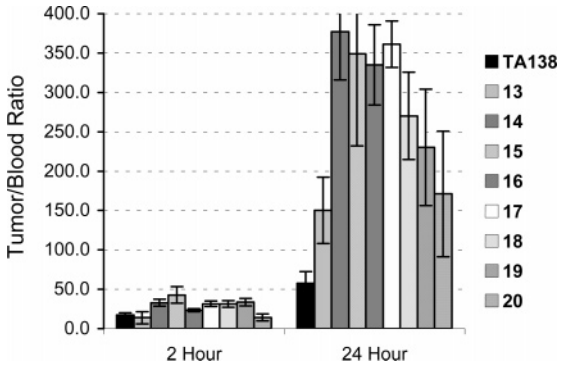

Figure 8. Tumor/blood ratios of the ^{111}In complexes of **TA138** and the eight divalent agents described in the text at 2 and 24 h PI in the c-neu Oncomouse model at 2 mCi/Kg. Values are the average of three animals. The radiolabeling and biodistribution procedures are described in ref 41.

agents. These findings are consistent with our previously reported competition studies with ^{111}In-**TA138**, which showed that uptake in colon and uterus was blocked to exactly the same degree as in tumors (*31*). It is our belief that uptake in these two organs is in large part receptor-mediated rather than the result of nonspecific binding. The rapid blood clearance and high tumor uptake provide very high tumor/blood ratios for all agents in the study (Figure 8).

The spacer that links the different binding moieties of a multivalent system is of paramount importance because it is responsible for the orientation that the binding ligands present to the biological target. The spacer must be of sufficient length to bridge the closest approach distance between receptors and

have a certain degree of flexibility to adjust to the changing conformation of the cellular surface. A spacer that is longer and more flexible than necessary will have increased conformational entropy and reduce the ability of all binding ligands to find their respective receptors. The current understanding of the optimum length and conformation required for simultaneous binding to two or more vitronectin receptors is very imprecise, and the divalent agents of this study were therefore joined by very flexible spacers. The increased thermodynamic penalty of the longest spacers presented here (i.e., ^{111}In-**19** and ^{111}In-**20**) is the most likely reason these agents did not display clear evidence of homogeneous divalent interaction with two vitronectin receptors. However, all of the divalent agents of this study displayed increased retention in tumors out to 24 h PI. Both the statistical and exosite binding modes are consistent with the observed results. While ^{111}In-**15**, ^{111}In-**16**, and ^{111}In-**17**, all with 36 Å spacers, gave the highest tumor uptake at 24 h PI, one must be careful about generalizing these results to other systems. The optimum spacer length will depend on a multitude of variables, including the receptor antagonist structure, spacer conformation, spacer rigidity, lipophilicity, protein binding, and so forth. The other variable in this study, the number of cysteic acid PKMs, appears to have little effect on the biodistribution properties of these divalent agents. Here again, one must be careful not to overanalyze these data, since the two series where cysteic acid is the only variable consist of only two and three compounds (**13** and **14**, and **15**−**17**). ^{111}In-**15** gave the best combination of tumor uptake and tumor/organ ratios for critical nontarget organs, and the ^{177}Lu analogue was used in the tissue residence time study below.

Tissue Residence Time Study. Of the readily available therapeutic radionuclides that form stable complexes with DOTA, ^{90}Y best fits the uptake and washout characteristics of ^{111}In-**TA138**. It has a relatively short $t_{1/2}$ of 64.1 h and decays to produce a very energetic 2.3 MeV β^- particle. One disadvantage of ^{90}Y is the relatively long 95% energy range (~5 mm in water), which means that a significant fraction of the decay energy escapes the tumor and is deposited in surrounding tissues. This fraction of lost energy increases as the size of the tumor decreases. The defining characteristic of the divalent agents in this study is the high and continuous tumor uptake in the c-neu Oncomouse model out to 24 h PI. This difference in tumor retention is more pronounced at later time points. For example, ^{111}In-**TA138** has a tumor uptake of 3.46% ID/g at 24 h PI, decreasing to 0.94% ID/g at 144 h PI, while divalent agent ^{111}In-**15** has a tumor uptake of 14.3% ID/g at 24 h PI, decreasing only slightly to 12.2% ID/g at 144 h PI. Complete biodistribution data for ^{111}In-**TA138** and ^{111}In-**15** from 2 to 144 h are provided in the Supporting Information. This prolonged tumor retention, coupled with the improved tumor/kidney and tumor/marrow ratios at later time points for the majority of divalent agents, suggested that they should exhibit an improved therapeutic index with radionuclides having relatively long half-lives, such as ^{177}Lu ($t_{1/2}$ = 6.65 d, 0.48 MeV β^- particle). The longer half-life of ^{177}Lu translates into a lower dose to nontarget organs at early time points while excess agent is clearing from the body, and the shorter 95% energy range (~0.8 mm in water) of the lower-energy β^- particle translates into less energy deposited outside the tumor. We therefore attempted to quantify this by comparing the therapeutic indices of monovalent agent ^{90}Y-**TA138** and divalent agent ^{177}Lu-**15** in our c-neu Oncomouse model. The biodistribution data of ^{90}Y-**TA138** used for these calculations has been reported previously (*49*). Biodistribution data for ^{177}Lu-**15** in critical nontarget organs are shown in Table 3 from 2 to 168 h PI. Complete biodistribution data are provided in the Supporting Information. The relative therapeutic indices of radiotherapeutic agents can be calculated by comparing the agent's tissue residence times. The tissue residence times of ^{90}Y-**TA138** and ^{177}Lu-**15** were compared after correcting for the difference in the energy released and retained between ^{90}Y and ^{177}Lu. Figure 9 shows the residence times (total disintegrations per unit injected dose per gram of tissue) for ^{90}Y-**TA138** and ^{177}Lu-**15** from 15 min PI to 168 h PI and extrapolated to infinity. The values are corrected using the ratio of the self-dose *S*-values for each organ. The *S*-value correction for the tumor was derived from thymus, which is similar in size to the tumors of this study. All *S*-values were taken from OLINDA/EXM (*50*). Relative to ^{90}Y-**TA138**, the residence time for ^{177}Lu-**15** decreases in the liver and kidney, is identical in the spleen, and increases in marrow, colon, and tumor. The tumor/organ residence time ratios (Figure 10) give a clearer picture of the relative radiation dose delivered to each organ. The tumor/organ residence time ratios for ^{177}Lu-**15** in the marrow and colon are identical to those for ^{90}Y-**TA138**, while the ratios in the liver, kidney, and spleen are considerably higher for ^{177}Lu-**15**, confirming the improved therapeutic index for this divalent $\alpha_v\beta_3$ antagonist.

Table 3. Biodistribution of ^{177}Lu-15 from 2−168 h PI, c-neu Oncomouse Mammary Adenocarcinoma Model

	organ uptake expressed as % ID/g (± SEM)[a]			
organ	2 h PI	24 h PI	48 h PI	168 h PI
liver	1.256 (0.108)	0.904 (0.071)	0.751 (0.047)	0.447 (0.022)
kidney	2.390 (0.223)	1.458 (0.169)	1.004 (0.073)	0.484 (0.027)
spleen	1.380 (0.148)	0.547 (0.037)	0.477 (0.042)	0.359 (0.028)
colon	2.677 (0.298)	3.160 (0.199)	3.179 (0.442)	0.746 (0.059)
marrow	2.527 (0.375)	1.356 (0.232)	0.913 (0.138)	1.119 (0.227)
tumor	6.867 (0.720)	7.285 (0.873)	7.165 (0.682)	8.048 (1.302)

[a] Values are the average of three animals. Test agents were administered at 2 mCi/Kg.

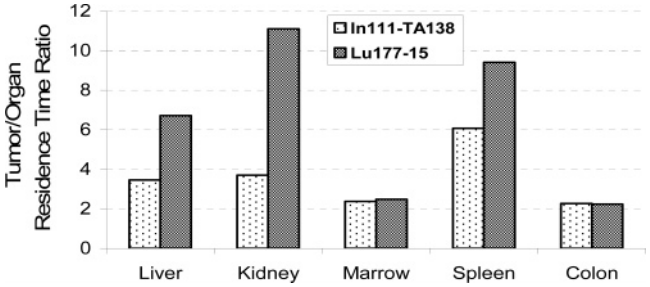

Figure 10. Tumor/organ residence time ratios for ^{90}Y-**TA138** and ^{177}Lu-**15** in the c-neu Oncomouse model at 2 mCi/Kg. Values are the average of three animals. The radiolabeling and biodistribution procedures are described in ref 41.

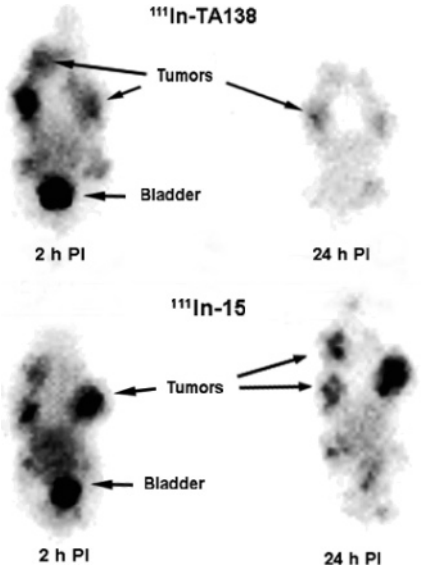

Figure 11. Representative scintigraphic images of ^{111}In-**TA138** and ^{111}In-**15** in the c-neu Oncomouse model at 2 mCi/Kg at 2 and 24 h PI.

Scintigraphic Image Study. As stated in the introduction, the primary goal of this study was the evaluation of these divalent agents as potential oncology radiotherapeutic agents. A secondary goal was their evaluation as potential imaging agents for detecting the overexpression of the vitronectin receptor. An examination of the tumor/organ ratios at 2 h PI (Figure 6) and 24 h PI (Figure 7) suggests that monovalent agent **TA138** should be the superior imaging agent at early time points due to rapid tumor uptake and relatively low nontarget uptake. At later time points, several of the divalent agents should be superior due to their continued tumor uptake and clearance from the majority of nontarget organs. This impression was confirmed in an imaging study comparing ^{111}In-**TA138** and ^{111}In-**15** in the c-neu Oncomouse model as shown in Figure 11. The excellent biodistribution properties of both agents are confirmed visually in the scintigraphic images. Both agents are able to clearly visualize tumors at 2 h PI, but ^{111}In-**TA138** gives a cleaner image with less background signal in the abdominal region. At 24 h PI, the ^{111}In-**TA138** image shows considerable washout from the tumors, making it difficult to clearly visualize the smaller tumors. In contrast, the image obtained with divalent agent ^{111}In-**15** very clearly shows even the smallest tumors. In addition, there is generally low background signal from the general musculature and abdomen. These data raise an interesting question: What is the optimum time postinjection required to obtain the ideal image with these divalent agents? The experiments required to answer that question were outside the scope of this study and will have to await further work.

CONCLUSIONS

In the present work, we have described synthetic methodology for the preparation of divalent versions of the quinolin-4-one class of receptor $\alpha_v\beta_3$ antagonists. A panel of integrin receptor affinity assays have shown that all of these agents have high affinity for receptor $\alpha_v\beta_3$ and good selectivity versus three other integrin receptors. Biodistribution studies in the c-neu Oncomouse revealed that compounds with intermediate-length spacers (29−43 Å) provide the highest tumor uptake and the best tumor/organ ratios. These data suggest that the primary mechanism for enhanced tumor uptake and retention is either the statistical effect or the subsite effect, rather than divalent homogeneous binding with two vitronectin receptors. The compound giving the best combination of tumor uptake and tumor/organ ratios for critical nontarget organs was ^{111}In-**15**, with a 36 Å spacer. A comparison of tissue residence times for ^{90}Y-**TA138** and ^{177}Lu-**15** show an improved therapeutic index for ^{177}Lu-**15** and suggest the potential application of these divalent vitronectin receptor antagonists as radiotherapeutic antitumor agents.

Oligodeoxynucleotides containing unmethylated CpG sequences (CpG DNAs) activate the vertebrate innate immune system via toll-like receptor 9 (TLR-9). Although CpG DNA is a promising immunotherapeutic agent, its short circulation time in biological fluids due to nuclease is the major drawback. This paper proposes that a natural polysaccharide called schizophyllan (SPG) can be used as an effective CpG DNA carrier because SPG can complex with CpG DNA and the resultant complex shows the nuclease resistance of the bound DNA. In order to increase cellular uptake in vitro, we chemically attached spermine, cholesterol, arginine octamer, or RGD peptide to SPG. The complexes made of the chemically modified SPG and CpG DNA having a phosphorothioate (PS) or phosphodiester (PO) backbone led to increased secretion of cytokines of about 4- to 15-fold, compared with the uncomplexed dose. Furthermore, when PO CpG DNA was complexed with unmodified SPG, the IL-12 level increased by almost 3- to 11-fold compared with the naked dose. The PO CpG DNA/unmodified SPG complex data suggested that unmodified SPG might effectively deliver PO in vivo due to the electrically neutral nature of unmodified SPG. When the complexed CpG DNAs were injected intraperitoneally, a large amount of IL-12 production was observed compared with the uncomplexed material. Both in vivo and vitro assays indicated that the SPG complex may be of use for CpG DNA therapy.

INTRODUCTION

Oligodeoxynucleotides containing unmethylated CpG sequences (CpG DNAs) can activate the vertebrate immune system (*1*−*3*). The initial step of this event is cellular uptake of CpG DNAs by antigen-presenting cells (APCs), particularly dendritic cells, macrophages, and B-cells. Subsequently, CpG DNAs are transported through the endocytosis pathway, and during the transport they are recognized by a pattern recognition receptor called toll-like receptor 9 (TLR-9) in endosome vesicles (*4*). The recognition by TLR-9 triggers the secretion of cytokines, including IL-6, TNF-α, IFN-γ, and IL-12. These cytokines activate natural killer (NK) cells and dendric cells (DC) (*5*−*8*) and finally control adaptive immune responses toward Th1- and IgG2a-secreting B cell inductions. Therefore, the interaction between CpG DNAs and TLR-9 effectively bridges the innate and adaptive immune systems.

Recently, clinical trials have demonstrated that CpG DNAs can be useful as adjuvants for vaccines against infectious pathogens, cancer antigens, and allergens (*9*, *10*). However, there is a serious drawback in CpG DNA therapy. Generally, once naked DNAs are exposed to biological liquids, they are quickly eliminated by nuclease-mediated degradation and nonspecific binding with plasma proteins. To translate CpG DNAs to practical therapy, it is essentially important to deliver CpG DNAs to their target cells while avoiding these unfavorable interactions. Phosphorothioate (PS) DNA, an analogue of the natural type phosphodiester (PO) DNA, has relatively strong antinuclease capability, so that PS DNAs are used in clinical trials. Some recent studies pointed out the cytotoxicity of PS and unexpected biological responses, for example, inducing a nonspecific response from a complement system (*11*, *12*). These side effects can be ascribed to nonspecific binding to serum proteins and antigen nature of PS. It would be better if we can use PO by effectively protecting it from nuclease-mediated degradation and nonspecific binding.

Recent studies categorized CpG DNAs into at least two types of structurally and functionally different classes (*10*, *13*−*15*). One is denoted as K-type, which contains TCGT or TCGA motifs and activates plasmacytoid DCs to produce IL-6 and IL-12, but very little IFN-α or IFN-γ. K-type also stimulates B cells to proliferate and recreate IL-6 and IgM. The PS analogues of K-type show almost the same activity as native phosphodiesters. The other is called D-type. The structural distinction of D-type is an unmethylated CpG dinucleotide flanked by a palindromic sequence and G quartet attached to the 3′ end to increase the cellular uptake (*16*). D-type activates plasmacytoid DCs to secrete a large amount of IFN-α, causing stimulation of NK-cells to produce IFN-γ and differentiate monocytes into myeloid DCs (*14*). D-type does not stimulate B-cells and other subsets of DCs. Ballas et al. recently reported that D-type for immunotherapy of cancer was more effective than K-type in the therapy of murine melanoma (*17*). Verthelyi et al. also

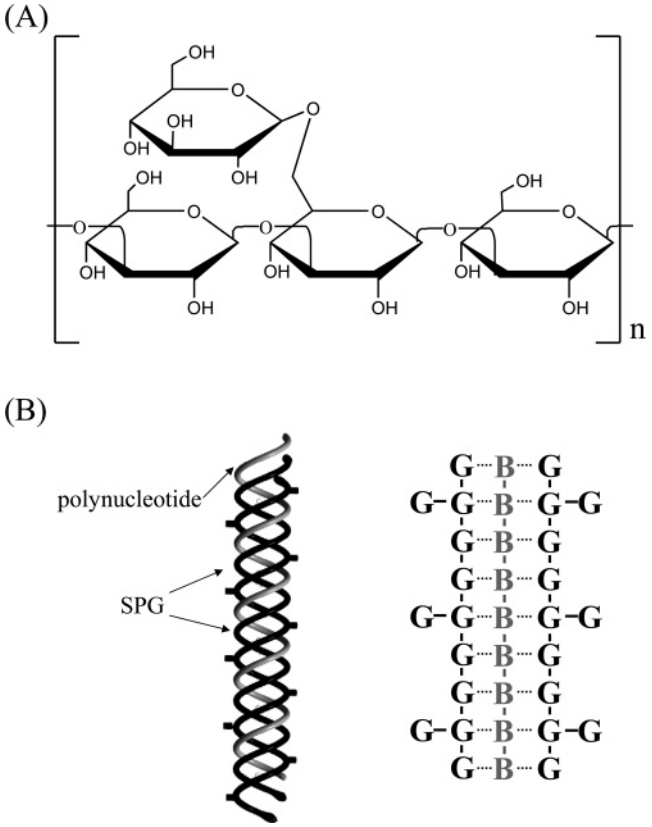

Figure 1. (A) Repeating unit of SPG, and (B) the structural model of the complex consisting of one polynucleotide and two SPG chains (*21*). The chemical modifications were carried out by the selective cleavage of the 1,2-diol group of the glycosyl side chain with periodate, leading to formyl group formation, and then subsequently introducing a chemical group (*27*). As presented in B, the complex forms a triple helix. The black lines and gray lines indicate SPG and polynucleotide, respectively (left). Two main-chain glucoses of SPG interact with one base of nucleotide. Capital letters of G and B indicate the glucoses of SPG and the base of polynucleotides (right).

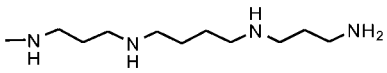
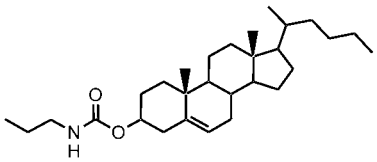
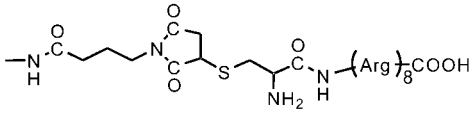
reported that D-type as an adjuvant was superior to K-type in the magnitude of elicited antibody response by coadministered heat-killed *Leishmania* vaccine (*18*). Delivery system for D-type is required to protect against nuclease because the essential sequence of D-type cannot be replaced by PS (*13*).

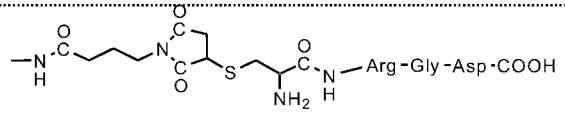
There is a natural polysaccharide called schizophyllan (SPG) (Figure 1A), whose main chain consists of β-(1→3)-D-glucan and one β-(1→6)-D-glycosyl side chain links to the main chain at every three glucose residues (*19*). We found that SPG forms a novel complex with single-stranded homo polynucleotides (Figure 1B), and the fundamental properties of the complex have been examined by our group (*20*−*23*). Recently, we started to apply this complex to DNA delivery. Our communication preceding this paper showed a possibility to apply this complex to a CpG DNA carrier, showing that the complex can protect the bound DNA against unfavorable interactions with proteins and thus increase cytokine secretion (*24*, *25*). The previous paper used a classical K-type PS DNA and delivered it to macrophage-like cell lines (*24*). The promising results in the excellent antinuclease resistance of the complex compelled us to expand this research. This study utilized CpG DNA, having a PO backbone instead of a cytotoxic PS, spleen primary cells in vitro, and a preliminary in vivo assay.

MATERIALS AND METHODS









Materials. Mitsui Sugar Co., Ltd. (Japan) kindly supplied the SPG sample. The weight-average molecular weight (M_w) and the number of repeating units were found to be 1.5×10^5 and 231, respectively. We used this SPG sample unless mentioned. Additionally, two SPG samples with M_w of 2.5×10^6 and 2.5×10^4 were used to study the M_w dependence of the cytokine secretion. The molecular weight control of SPG and purification were described elsewhere (*26*). The cellular uptake efficiency of SPG itself was not significant *in vitro*; therefore, we modified SPG with a functional group that can induce passive cellular uptake. In this work, we introduced spermine (SP), arginine-glycine-aspartic acid tripeptide (RGD), octaarginine (R8), and cholesterol (Chol) (see Table 1). The experimental details and characterization for the modified SPG are described in our previous papers (*24*, *27*)

As a CpG DNA and its negative control, we adopted the two sequences of 5′-TCC ATG ACG TTC CTG ATG-3′ and 5′-TCC ATG AGC TTC CTG AGT-3′ (key sequence is underlined), respectively. To bind these sequences with SPG, we had to attach a poly(dA)$_{40}$ tail at the 3′ ends (*23*). In the present work, 5′-TCC ATG ACG TTC CTG ATG -(dA)$_{40}$-3′ and 5′-TCC ATG AGC TTC CTG ATG -(dA)$_{40}$-3′ were used and denoted by CpG DNA and non-CpG DNA, respectively. In addition to this classical sequence, we used typical K- and D-type DNAs, which were 5′-(dA)$_{40}$-ATC GAC TCT CGA GCG TTC TC-3′ ((dA)$_{40}$-K3) and 5′-(dA)$_{40}$-GGT GCA TCG ATG CAG GGG GG ((dA)$_{40}$-D35). PS analogues for the CpG DNA and non-CpG DNA were used to compare with PO. The sequences of the CpG DNA used in this work are summarized in Table 2. All DNAs were synthesized at Hokkaido System Science (Hokkaido, Japan) and purified with high-pressure liquid chromatography. The fetal bovine serum (FBS) and penicillin/streptomycin were purchased from Gibco/BRL. Dulbecco's modified Eagle's medium (DMEM) and RPMI1640 were obtained from Nissui Pharmaceutical Co., Ltd.

Complex Preparation. A 2 mg amount of PO CpG DNA or PS CpG DNA was dissolved in 10 mM Tris buffer solution (pH = 7.8) (1 mL). An appropriate concentration of unmodified or modified SPG/DMSO solution was added to the DNA solution so that the water volume fraction was always adjusted to be 0.9 after mixing. The molar ratio (M_{SPG}/M_{DNA}) was controlled to be 1.5, where M_{SPG} and M_{DNA} are the repeating molar concentration of SPG and DNA, respectively. After the DNA and SPG mixture was kept at 5 °C for 1 night to complete the complexation, DMSO was removed by ultrafiltration. After the filtration, the final concentration of DNA was determined by measuring the ultraviolet absorbance.

Mice and Cells. Seven- to eight-week-old female BALB/c or C57/B6 mice were purchased from Kyudo Co., Ltd., and CLEA, respectively. TLR-9 deficient mice were generated as previously described (*4*). Single spleen cell suspensions were prepared in RMPI1640 medium/10% FBS, 2 mM L-glutamine, 10 mM HEPES, and 0.11 mg/mL sodium pyruvate. Bone marrow dendric cells (BMDCs) were prepared as the established method (*28*). Flt3 ligand (Flt3L)-induced BMDCs (1×10^5 cells/well) were generated by culturing bone marrow cells with Flt3 ligand (100 ng/mL; PeproTech) for 8−9 days in DMEM medium containing 10% FBS. Murine macrophage-like cells (J774.A1) were cultured in DMEM containing 10% FBS and 1 wt % penicillin/streptomycin mixture. BALB/c spleen cells were maintained in RPMI1640 supplemented with 10% FBS. All medium contains a 1 wt % penicillin/streptomycin mixture. The cells were cultured at 37 °C in a 5% CO_2 incubator. Cells were stimulated in the presence of the indicated stimuli, and supernatants were collected for cytokine ELISA. For the in vivo assay, C57/B6 mice were injected intraperitoneally with 50 μg of CpG DNAs or the complex per mouse. Serum was collected in hours. The amount of IL-12p40 in serum was determined by ELISA.

Table 1. Sample Codes and the Introduced Chemical Groups

Sample code	Chemical group	Modification level [a]
SP-SPG		4.6 ±0.3 mol%
Chol-SPG		6.9 ±1.0 mol%
R8-SPG		0.5 ±0.1 mol%
RGD-SPG		1.3 ±0.3 mol%

[a] The key sequences are indicated as underlined text. All backbones of $(dA)_{40}$-K3 and $(dA)_{40}$-D35 are composed of phosphodiester.

ELISA. Spleen cells were plated in 48-well dishes using 2.5 $\times$ 10^6 cells/mL (1 well/1 mL) and were incubated 2 h at 37 °C. Naked CpG DNA or SPG/CpG DNA complexes were added to the cells. The cells were incubated at 37 °C for 24 h, and the supernatants were collected for ELISA assays (n = 4). The secretion of IL-6 and total IL-12 was determined using commercially available ELISA kits according to the instructions of the manufacturer (Endogen). For the experiments using BMDCs and in vivo experiments, IL-12 p40 and IFN-α (PBL Biomedical Laboratories) were measured either from the supernatants or the serum by ELISA according to the manufacturer's instructions (n = 4). R-848 and LPS were added to the cells at the concentration of 1 μM and 1 μg/mL, respectively. J774.A1 cells were plated in 48-well dishes using 1 $\times$ 10^6 cells/mL (1 well/200 μL) and were incubated 5 h at 37 °C, and then samples were added to the cells. The cells were incubated at 37 °C for 24 h, and the supernatants were collected for ELISA assays (n = 4). For all assays, each experiment was repeated at least twice.

RESULTS AND DISCUSSION

Comparison of the Cytokine Secretion between Phosphorothioate and Phosphodiester. Figure 2 shows the cytokine secretions from the spleen cells when PS CpG DNA (left panels) and PS non-CpG DNA (right panels) were administered. When naked CpG DNA was exposed at a concentration of 25 μg/mL, the secretion levels of IL-12 and IL-6 were 2.2 and 2.5 ng/mL, respectively. When the amount of dose was doubled, the secretion became almost 2-fold, 3.7 ± 0.5 ng/mL for IL-12 and 3.7 ± 0.4 ng/mL for IL-6. When CpG DNA was complexed with unmodified SPG, the secretions were increased to ~15% compared with the naked dose for IL-12 and IL-6. This increment can be ascribed to the fact that the complex can

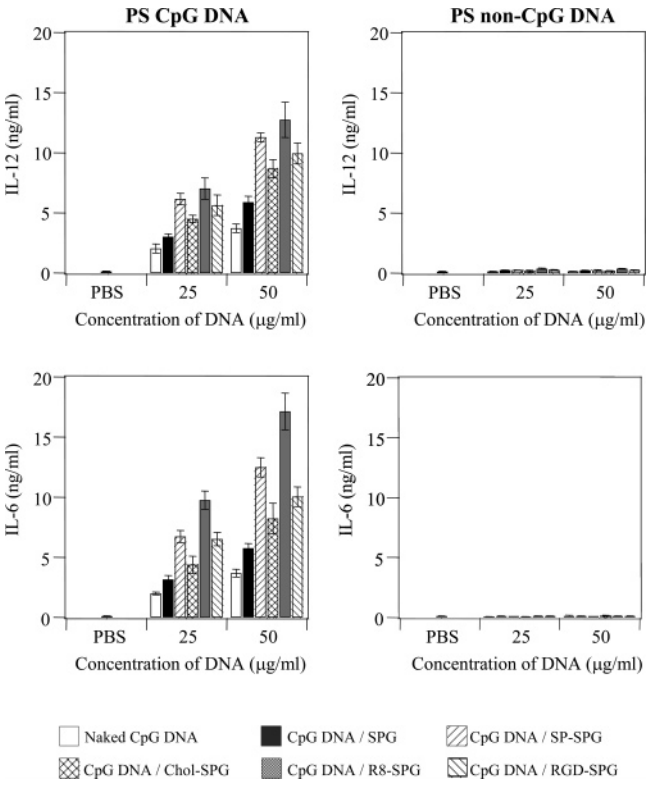

Figure 2. The cytokine secretions by various SPG/CpG DNA complexes when PS CpG was used. The spleen cells were stimulated with various concentrations of CpG DNA. The amount of secretions was determined with ELISA kits, after incubation of the cells in the presence of CpG DNA or its complex for 24 h. The molar ratio (M_{SPG}/M_{DNA}) is fixed at 1.5. Data represent the average ± SD (n = 4).

stabilize the bound DNA in the culturing medium, and thus it increases the population of CpG DNA that can reach the cell surface. The stabilization is effective even for PS, because BSA contained in the culturing medium tends to bind to PS to eliminate the activity (*29*). We carried out the control experiments using naked non-CpG DNA and complexed non-CpG DNA with SPG. Some results are presented in the right panels, showing essentially no secretions for all of the cytokines.

When we used the modified SPG samples, all of them increased the amount of secretions for IL-12 and IL-6 2- to

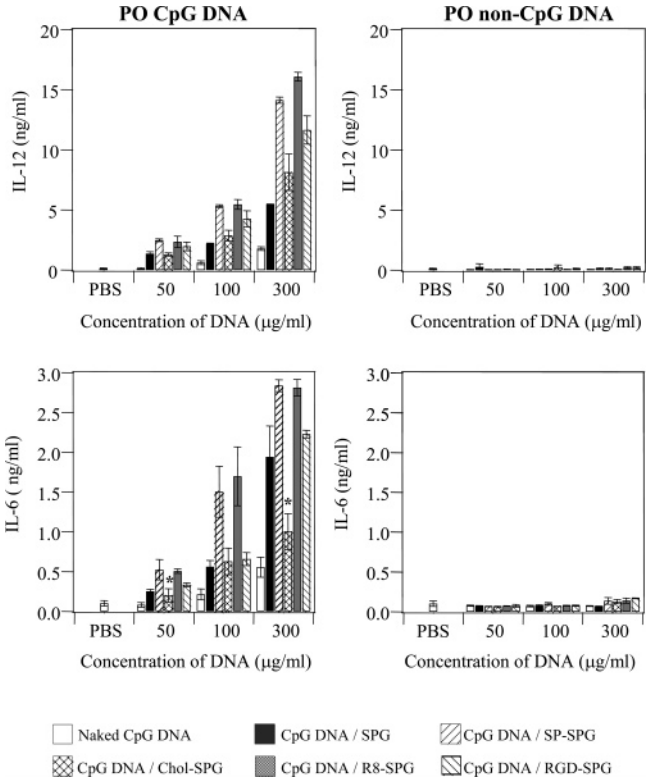

Figure 3. The cytokine secretions by various SPG/CpG DNA complexes when PO CpG was used. The spleen cells were stimulated with various concentrations of CpG DNA. The amount of secretions was determined with ELISA kits, after incubation of the cells in the presence of CpG DNA or its complex for 24 h. The molar ratio (M_{SPG}/M_{DNA}) is fixed at 1.5. Data represent the average ± SD ($n = 4$), *$p <$ 0.05 for naked PO CpG DNA dose.

4-fold, confirming the previous results obtained for the murine macrophage-like cells J774.A1 (*24*). The carriers themselves did not show any increment in the cytokines (data not shown). The increments in Figure 2 are ascribed to the increased cellular uptake mediated by the functional groups. Similar to the previous data, the R8−SPG complex was superior to the others. RGD−SPG, SP−SPG, and Chol−SPG ranked second, and RGD−SPG follows. According to previous work, the cellular uptake for the RGD, SP, and Chol complexes can be ascribed to normal endocytosis (*30*, *31*). On the other hand, the R8 complex is seemingly ingested by an endocytosis pathway different from the other functional groups, although there is still controversy over how R8 and its analogues are ingested by cells (*32*−*34*). R8 binds to heparan sulfate proteoglycan which is a sulfated polysaccharide anchored to the cell surface (*35*). The anchored heparan sulfate may release R8 and its cargo during the endocytosis transport (*36*). Since R8 has cationic charge, it can be ingested by normal electrostatic interactions similar to the other functional groups. The enhanced secretion for the R8−SPG complex may be caused by a combination of all of the endocytosis pathways.

Figure 3 shows the cytokine secretions when PO CpG DNAs were administered; here all the assays were carried out with the same conditions as those in Figure 2, except for using PO instead of PS. In contrast to the PS doses, naked PO CpG DNA did not show significant secretions unless the dose was increased over 100 μg/mL (PS showed appreciable secretion even at 25 μg/mL dose). This difference between PS and PO can be ascribed to two factors: PS is more stable against nuclease degradation than PO, and PS itself can be positively ingested by cells with an unidentified pathway (*37*). When PO CpG DNA was complexed with unmodified SPG, IL-12 level increased almost 11-fold at 50 μg/mL, 3.6-fold at 100 μg/mL, and 3.1-fold at 300 μg/mL, compared with the naked dose, respectively. In the case of PS, the complex with unmodified SPG increased the secretion level by 1.5-fold at most. The complexation increased the secretion level more efficiently in the PO system than in the PS system. This feature can be ascribed to the antinuclease protection effect of the complex (*25*) because naked PO DNAs should be more easily degraded than PS DNAs.

The modified SPG samples showed that the amount of secretions for IL-12 and IL-6 increased 4- to 15-fold, compared with the naked ones, similar to the PS results while the order of the superiority was different. R8−SPG and SP−SPG showed the highest increment, and RGD−SPG and Chol−SPG ranked second. Comparison between Figures 2 and 3 offers valuable insight. When we compared PO and PS at the same dose level, the complexed PO did not show the equivalent secretion with those of the complexed PS. For IL-12, we needed to increase the dose level to about 6 times to obtain the same secretion level (e.g., PS CpG DNA/SPG induced 5.5 ng/mL at 50 μg/mL dose, while PO CpG DNA/SPG induced 5.8 ng/mL at 300 μg/mL dose. Compare the black bars between Figures 2 and 3). This is because PS is positively introduced into cells but PO is not, and the complexation does not perfectly protect the bound PO from degradation. For IL-6, the secretion due to PO was much lower than that of PS (e.g., PS CpG DNA/R8 induced 17 ng/mL at 50 μg/mL dose, while PO CpG DNA/R8 induced 2.8 ng/mL at 300 μg/mL dose. Compare the gray bars between Figure 2 and 3). This difference in IL-6 secretion is due to the intrinsic difference between PS and PO reported by previous papers (*38*, *39*). A large amount of IL-6 secretion induces unfavorable side effects,(*40*) as in the case of TNF-α. Therefore, the lower induction of IL-6 from PO CpG DNA/SPG complexes can be an advantage as an adjuvant.

It is interesting that the complex of unmodified SPG showed a comparable effect with that of Chol−SPG and probably with that of RGD−SPG for IL-6. These results suggest that we can use unmodified SPG for CpG DNA carriers. A neutral or slightly anionic nature is favorable for the delivery in vivo, providing prolonged circulation time (*41*). This is because cations are generally easily absorbed by anionic proteins or the cellular surface and thus eliminated and/or inactivated in short period. Additionally, polycations can indeed induce side effects in the case of frequent doses, such as activation of complement, erythrocyte aggregation, and hemolysis. This is the main reason that the carriers with neutral and negative charge show good performance in vivo. On the basis of these facts, we decided to use unmodified SPG. An additional advantage to using unmodified SPG is that recent immunology (*42*, *43*) and our data (*44*) showed that SPG and other β-(1→3)-d-glucans can be recognized by dectin-I and thus ingested by APCs. This means that the unmodified SPG complex has the ability to deliver its cargo to APCs in vivo, where the target TLR-9 is present.

Many RGD-attached molecules have been studied as drug carriers to target to tumor cells in vivo (*45*−*47*), because the RGD motif can bind to integrin on the surface of the tumor cells (*48*) and also bind to newly formed endothelial cells (*49*). CpG DNA is required for uptake by APCs. This is why we did not use RGD−SPG.

SPG Molecular Weight Dependence of the Secretion. The M_w of SPG used in the above experiments was 1.5×10^5, which means 230 repeating units in one molecule. The stoichiometric number of the complex shows that two repeating units of SPG and three bases are interacting with each other; that is to say, two main-chain glucoses and one base are interacting (Figure 1B) (*21*). CpG DNA consists of 58 bases; therefore, one complex contains at least 11 CpG DNA molecules. [In this calculation, we assumed that the hetero sequence of CpG DNA

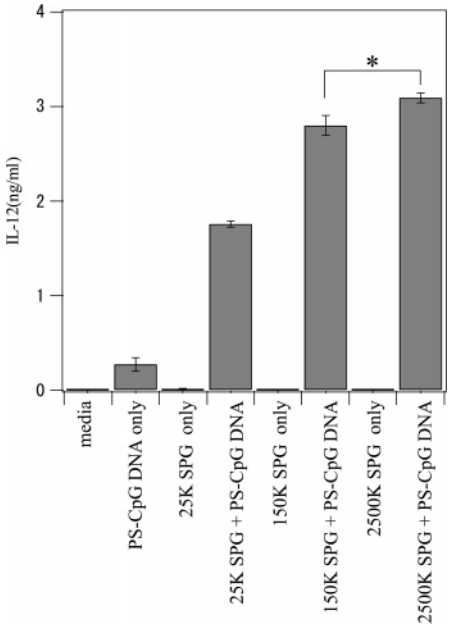

Figure 4. SPG molecular weight dependence of the secretion. J774.A1 (1×10^6 cells/mL, 200 μL) was stimulated with 25 μg/mL of PS CpG DNA and its SPG complex for 24 h. Data represent the average ± SD ($n = 4$), *$p < 0.001$.

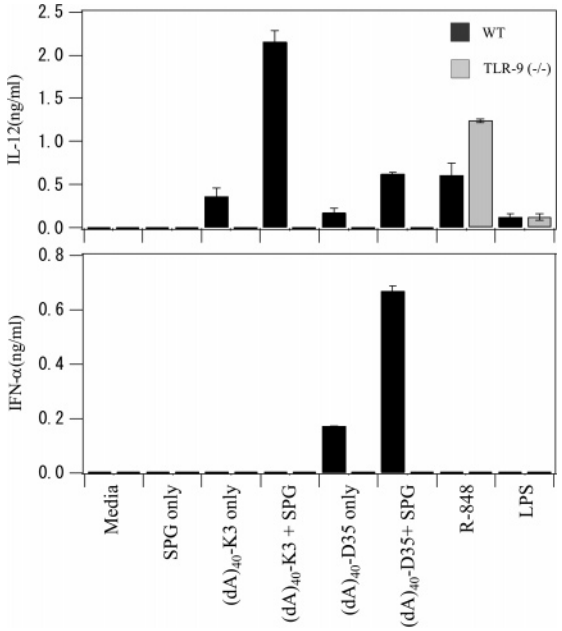

Figure 5. Difference of the cytokine secretions between K-type and D-type DNA with unmodified SPG. Flt3L-induced BMDCs were stimulated with CpG DNAs (30 μg/mL), R-848 (1 μM), or LPS (1 mg/mL) for 24 h. WT and TLR-9 (−/−) denote BMDCs obtained from wild type and TLR-9 knockout mice, respectively. Data represent the average ± SD ($n = 4$), *$p < 0.001$.

is complexed with SPG and one SPG chain is involved in one complex. In ref 23, we attached the $(dA)_{40}$ tail to a hetero sequence at the 3′ or 5′ end, where $(dA)_{40}$ can form a complex but the hetero sequence itself does not. After complexation with SPG, we compared the hydrolysis rate between the 3′- and 5′-$(dA)_{40}$ tailed hetero sequences using exonuclease I (hydrolyzes DNA from the 3′ end). We found that the hydrolysis rate was dramatically reduced for both 3′- and 5′-$(dA)_{40}$ tailed hetero sequences and there was no appreciable difference between them. This result implies that the hetero part is protected, suggesting that the complexation of the $(dA)_{40}$ part triggers additional complexation between the hetero part and SPG. If the hetero part is not involved in the complexation, 17 CpG DNA molecules are present in the complex.] We prepared two additional SPG samples with different M_w: 2.5×10^4 and 2.5×10^6. The same calculation shows that 2 and 200 CpG DNA molecules can be present in one complex, respectively. Figure 4 shows M_w dependence of the cytokine secretion for IL-12. The secretion was increased with increasing M_w. These results imply that the more CpG DNA molecules contained in the complex, the more cytokine secretion can be induced. A recent study reported the dramatic enhancement of cytokine secretion in the case of multiple CpG pairs in one DNA (*50*). Their results can be rationalized with the "cluster effect", which is normally termed for the case that branched oligosaccharides are bound much more tightly to receptors than monosaccharides or single chain oligosaccharides. We presume that the multiple CpG DNA pairs in one sequence can play the same role as the multiple oligosaccharides. A more recent study, by Wu et al., reported that the aggregation of CpG DNA due to the polymerization of G-quartet and palindrome enhanced the IL-12 secretion (*51*). This result can be explained with the cluster effect of CpG pairs. Our results in Figure 4 can be understood in the same framework as these two studies.

With increasing M_w, the size of the complex increases. Our dynamic light scattering determined the hydrodynamic diameter of the complexes using SPG with $M_w = 1.5 \times 10^4$ to be 100−300 nm and with $M_w = 2.5 \times 10^6$ to be 1000 nm, respectively (data not shown). Since SPG is internalized by dectin-I-mediated phagocytosis, such a large size of complex may not hinder the cellular uptake.

Distinct Cytokine Secretion with K-Type and D-Type CpG DNAs in Vitro. A distinctive difference between K- and D-type in the immunological response for the Flt3L-induced BMDCs can be determined by whether the secretion of IFN-α is induced. The resultant BMDCs contain $CD11c^+/B220^+$ and $CD11c^+/B220^-$ cells (*52*). K-type leads both cells to secrete IL-12; on the other hand, D-type leads to IFN-α secretion from $CD11c^+/B220^+$ and to IL-12 secretion from $CD11c^+/B220^-$. Therefore, when K-type is administered to the Flt3L-induced BMDCs, only IL-12 should be observed and the secretion level of IL-12 should be higher than that of D-type. On the other hand, both IL-12 and IFN-α should be secreted from the D-type administration.

The upper panel of Figure 5 shows the IL-12 secretion comparing $(dA)_{40}$-K3 and $(dA)_{40}$-D35, when the wild type and TLR-9-knockout (TLR-9 −/−) BMDCs were used. The IL-12 secretion was dramatically increased when $(dA)_{40}$-K3 was complexed. The increment due to the complexation was also observed for the case of $(dA)_{40}$-D35; however, the amount of the secretion was much smaller than those of $(dA)_{40}$-K3. These features are consistent with the difference between K- and D-types. The control experiment used with TLR-9 −/− BMDCs did not secret IL-12 at all for both $(dA)_{40}$-K3 and $(dA)_{40}$-D35 systems, while it showed a large amount of IL-12 for R848 and LPS doses, which are recognized by TLR-7 and TLR-4, respectively (*53*). This result indicates that the IL-12 productions by treatments of complex of both $(dA)_{40}$-K3 and $(dA)_{40}$-D35 are ascribed to the signal induced by TLR-9. The lower panel shows the IFN-α secretions. As in the case of IL-12, the advantage of the complexation is evidently demonstrated. The K-type did not show any secretion; on the other hand, the D-type clearly showed the secretion and the complex increased the secretion. The present IFN-α assay clarifies the advantage of using the SPG complex for the CpG DNA delivery.

IL-12 Secretion Induced by the Complex in Vivo. Figure 6 shows IL-12 p40 secretion of unmodified SPG/CpG DNA complex in vivo. IL-12 secretion was hardly observed by injection of unmodified SPG and naked CpG DNAs. On the other hand, injection of the complexes clearly exhibited 2−9 fold increase in IL-12 productions compared with those of naked

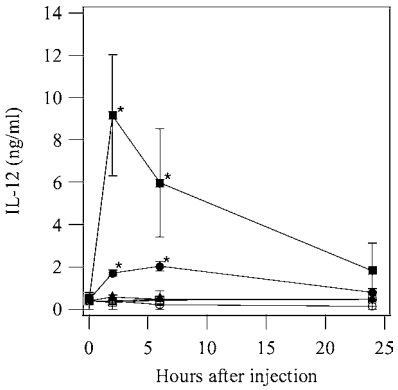

Figure 6. Time course of IL-12 p40 secretion in vivo, when CpG DNAs (50 μg) were intraperitoneally injected to C57/B6 mouse. Results represent the average ± SD of three mice per group. *$p < 0.05$ when compared with naked DNAs at each time. Naked $(dA)_{40}$-K3 and its SPG complex are indicated with unfilled and filled squares, respectively. Naked $(dA)_{40}$-D35 and its complex are indicated with unfilled and filled circles, respectively. PBS alone and SPG alone are indicated with open triangles and filled triangles, respectively.

doses. Maximum secretions appeared at 2−4 h. These enhancements can be ascribed to the stabilization due to the complex. Moreover, the complex with $(dA)_{40}$-K3 produced a large amount of IL-12 than that with $(dA)_{40}$-D35. This result agrees with in vitro study (Figure 5).

CONCLUSIONS

This paper showed that a natural polysaccharide called schizophyllan (SPG) can be used as a CpG DNA carrier. K- and D-type of phosphodiester CpG DNA were administered to Flt3L-induced BMDCs. K-type induced a large amount of IL-12 secretion; on the other hand, D-type led to the secretion of both IL-12 and IFN-α. The complexation increased the secretion in both cases, showing that the difference between K- and D-type was further enhanced. When CpG DNA was complexed with SPG and intraperitoneally injected to mouse, the maximum value of IL-12 for $(dA)_{40}$-K3 was 9-fold that of the naked dose. On the basis of these promising findings, the present paper proposes a new delivery method of CpG DNA and could lead to development of this therapy.

Received February 6, 2007; Revised Manuscript Received April 12, 2007

A new class of lipids, containing the *closo*-dodecaborate cluster, has been synthesized. Two lipids, *S*-(*N*, *N*-(2-dimyristoyloxyethyl)acetamido)thioundecahydro-*closo*-dodecaborate (2-) (**B-6−14**) and *S*-(*N*, *N*-(2-dipalmitoyloxyethyl)acetamido)thioundecahydro-*closo*-dodecaborate (2-) (**B-6−16**) are described. Both of them have a double-tailed lipophilic part and a headgroup carrying two negative charges. Differential scanning calorimetry shows that **B-6−14** and **B-6−16** bilayers have main phase transition temperatures of 18.8 and 37.9 °C, respectively. Above the transition temperature of 18.8 °C, **B-6−14** can form liposomal vesicles, representing the first boron-containing lipid with this capability. Upon cooling below the transition temperature, stiff bilayers are formed. When incorporated into liposomal formulations with equimolar amounts of distearoyl phosphatidylcholine (DSPC) and cholesterol, stable liposomes are obtained. The ζ-potential measurements indicate that both **B-6−14-** and **B-6−16**-containing vesicles are negatively charged, with the most negative potential described of any liposome so far. The liposomes are of high potential value as transporters of boron to tumor cells in treatments based on boron neutron capture therapy (BNCT). Liposomes prepared from **B-6−14** were slightly less toxic in V79 Chinese hamster cells (IC50 5.6 mM) than unformulated $Na_2B_{12}H_{11}SH$ (IC_{50} 3.9 mM), while liposomes prepared from **B-6−16** were not toxic even at 30 mM.

INTRODUCTION

In boron neutron capture therapy of tumors (BNCT[1]), successful treatment requires a selective delivery of boron-10 to tumor tissues to maximize damage to the tumor and to minimize damage to surrounding normal tissue (*1*). However, relatively large intracellular accumulations of boron (approximately 20−30 μg of boron-10 per gram of tumor) are necessary to produce cell death (*2*). Several means of selective targeting of boron-10 to tumors have been investigated. In 1964, Soloway suggested that antibodies might be used for delivering boron-10 to cancer cells (*3*). Assuming an antigen site density of 10^6 per tumor cell, this would require approximately 1000 boron-10 atoms per antibody molecule to attain 10^9 boron atoms per cell (approximately 20−50 μg boron-10/gram of tumor). The structures formed by linking 1000 boron atoms to an antibody molecule fail, however, to find their antigenic target (*4*). The increased rate of mitosis of malignant cells has inspired the synthesis of boron-containing nucleic acid precursors (*5*). Further, porphyrin derivatives that contain boron have been synthesized as capture agents for BNCT (*6*). However, significant normal tissue uptake of the boronated porphyrins (*7*, *8*) may limit their use in BNCT.

Liposomes show selective localization in tumors (*9*, *10*). The lipid carriers extravasate through the highly permeable microvessels of the tumors and remain locked in the interstitial fluid compartment due to a lack of functional lymphatic drainage (*11*). Liposomes might therefore be useful vehicles for transporting boron to the tumor site.

Two approaches are possible when using liposomes in boron delivery: encapsulation of boron compounds in the aqueous core of theliposome, and incorporation of boron-containing lipids in theliposome bilayer. Encapsulation of a boron compound in liposomes has been described by, e.g., Hawthorne, (*12*), Mehta (*13*), Johnsson (*14*), Maruyama (*15*), and Lee (*16*). Problems might arise by the encapsulation of these compounds into the liposomes through, e.g., low encapsulation efficiency and changes in the physical−chemical behavior through the presence of the boron compounds, and leakage upon storage and in contact with serum. The amount of boron which can be encapsulated in liposomes depends on the maximal concentration of the boron compound which is compatible with stability. For liposomes of 100 nm diameter, the encapsulated volume is about 2.5 L per mol lipid (*17*). With concentrations of the encapsulated agent of 0.1 M, about 0.25 mol can be encapsulated per mol of lipid. The alternative approach, incorporation of boron-containing amphiphilic molecules into liposomes, has been described by, e.g., Hawthorne (*18*), Nakamura (*19*), Tjarks (*20*), and Rossi (*21*, *22*). Many of the problems encountered in the encapsulation approach can be avoided by using the latter strategy. It is, in principle, not even necessary to prepare closed vesicles, as long as tumor accumulation is possible.

Boron-containing lipids constitute very interesting building blocks for the construction of boron-containing liposomes. A few approaches toward the synthesis of such lipids intended for incorporation into liposomes have been described in the literature.

Synthesis of a nido-carborane lipid with a one-tailed moiety (Figure 1, compound **1**) has been described, and the liposomal boron delivery using this compound and DSPC has been

examined in mice (*18*, *23*). Later, Nakamura designed a nido-carborane lipid with a double-tailed moiety for the purposes of high boron accumulation into liposomes (*19*) (Figure 1, compound **2a**). More recently, Hawthorne et al. described a very similar lipid (differing only in the number of methylene groups of the side chain) and investigated the in vivo toxicity of liposomes formed from the boron-containing lipid and helper lipids (distearoylphosphatidylcholine (DSPC), cholesterol (CHO)). They found that the liposomes were very toxic already at dosages of 6 mg boron per kg body weight (*24*). Nidocarborane lipids might therefore be problematic as agents for boron delivery in BNCT. A first dodecaborate-containing ether lipid (Figure **1**, compound **2b**) was recently described by Nakamura (*25*).

Our target was the preparation of $(B_{12}H_{11}S)^{2-}$-containing lipids, since mercaptoundecahydrododecaborate ($B_{12}H_{11}SH^{2-}$, BSH) is the only acceptable boron cluster compound that can be used at the present time in clinical trials in Japan, Europe, or the USA. Other suitable target species are under rapid development, but $B_{12}H_{11}SH^{2-}$ will probably remain as the baseline compound for clinical studies conducted in the immediate future (*26*). Soloway found that $B_{12}H_{11}SH^{2-}$ was sufficiently nontoxic ($LD_{50} = 73 \pm 4$ mg of boron per kg body weight in male CD1 Swiss mice by intraperitoneal injection) to be used clinically (*27*). Absence of toxicity in patients has later been proven in clinical trials (*28*). The boron compounds that are used as capture agents for BNCT should be nontoxic when administered in amounts required to obtain sufficient tumor concentrations and thus sustain a lethal $^{10}B(n,\alpha)^{7}Li$ reaction.

EXPERIMENTAL PROCEDURES

General. NMR spectra were recorded on a Bruker DPX 200 spectrometer. IR spectra of KBr pellet were collected on a BioRad FTS 155 spectrometer. Electrospray mass spectra were measured with a Bruker Esquire spectrometer. Charge was determined through isotope satellite peaks. For B-containing compounds, the peak with highest intensity is given. The peak multiplicity for B-containing compounds was compared to the theoretical pattern and found to agree for all B-containing compounds prepared. Melting points were measured on a Büchi 512 melting point apparatus.

Chemistry. *N,N-Bis-(2-dimyristoyloxyethyl)-2-chloracetamide (**4a**).* *N,N*-Bis-(2-myristoyloxyethyl)amine (**3a**) (5.23 g, 0.01 mol) and (1.11 g, 0.011 mol) triethylamine were dissolved in $CHCl_3$ (50 mL) and cooled to −10 °C. While stirring, chloroacetylchloride (1.24 g, 0.011mol) was added dropwise. After stirring the reaction mixture for 2−3 h, hexane was added until a precipitate (triethylamine hydrochloride) formed. The precipitate was removed by filtration, acetone (50 mL) was added, and the solution was kept at +4 °C overnight, whereupon the product precipitated. It was filtered off, dried, and recrystallized from $CHCl_3$. Yield 5.11 g (85%), mp 52−54 °C. IR (KBr): ν = 2956−2850 (C−H), 1732 (C═O), 1661 (-N−C═O), 1179 (C−O), 720 cm^{-1} (C−Cl). ^{1}H-NMR (200 MHz, $[D_1]$-$CDCl_3$, 25 °C, TMS): δ = 0.89 (t, *J*(H, H) = 3.0 Hz, 6H, C*H*$_3$−CH$_2$-), 1.27 (s, 40H, CH$_3$−(C*H*$_2$)$_{10}$−CH$_2$-), 1.51−1.69 (m, 4H, -CO−CH$_2$−C*H*$_2$-), 2.23−2.38 (m, 4H, -CO−C*H*$_2$-), 3.57−3.76 (m, 4H, -O−C*H*$_2$-), 4.19 (s, 2H, Cl−C*H*$_2$−CO-), 4.12−4.32 ppm (m, 4H, -N−C*H*$_2$-). MS (ESI, methanol, *m*/*z*): negative 636 $[M + Cl^-]^-$; positive 624 $[M + Na^+]^+$, 640 $[M + K^+]^+$.

*N,N-Bis-(2-dipalmitoyloxyethyl)-2-chloracetamide (**4b**).* Similar to **4a**. Yield 5.72 g (87%), mp 80−82 °C (hexane). IR (KBr): ν = 2917−2851 (C−H), 1732 (C═O), 1661 (−N−C═O), 1179 (C−O), 720 cm^{-1} (C−Cl). ^{1}H-NMR (200 MHz, $[D_1]CDCl_3$, 25 °C, TMS): δ = 0.89 (t, *J*(H, H) = 3.0 Hz, 6H, C*H*$_3$−CH$_2$-), 1.26 (s, 48H, CH$_3$−(C*H*$_2$)$_{12}$−CH$_2$-), 1.52−1.67 (m, 4H, -CO−CH$_2$−C*H*$_2$-), 2.26−2.37 (m, 4H, -CO−C*H*$_2$-), 3.60−3.73 (m, 4H, -O−C*H*$_2$-), 4.17 (s, 2H, Cl−C*H*$_2$−CO-), 4.23−4.33 ppm (m, 4H, -N−C*H*$_2$-). MS (ESI, methanol, *m*/*z*): negative 692 $[M + Cl^-]^-$; positive 680 $[M + Na^+]^+$, 696 $[M + K^+]^+$.

*S-(2-Cyanoethyl)-S-(N,N-(2-dimyristoyloxyethyl)acetamido)-sulfonioundecahydro-closo-dodecaborate (1-) Tetramethylammonium Salt (**5a**).* Bis-tetramethylammonium 2-cyanoethyl-thioundecahydro-*closo*-dodecaborate (2-) (**10**) (0.375 g, 1.0 mmol) and (1.2 g, 2.0 mmol) *N,N*-bis-(2-dimyristoyloxyethyl)-2-chloracetamide (**4a**) were suspended in acetonitrile (40 mL) for 24 h and then heated to 70 °C for 3 h. The mixture was cooled, and the solid was removed by filtration. The solvent was evaporated, and the product was dried at the oil pump. Yield 0.485 g (56%). IR (KBr): ν = 2923−2853 (C−H), 2487 (B−H), 1739 (C═O), 1651 (−N−C═O), 1175 cm^{-1} (C−O). ^{1}H-NMR (200 MHz, $[D_3]CD_3CN$, 25 °C, TMS): δ = 0.88 (t, *J*(H, H) = 3.2 Hz, 6H, C*H*$_3$−CH$_2$-), 1.27 (s, 40H, CH$_3$−(C*H*$_2$)$_{10}$−CH$_2$-), 1.48−1.63 (m, 4H, -CO−CH$_2$−C*H*$_2$-), 2.21−2.38 (m, 4H, -CO−C*H*$_2$-), 2.96−3.48 (m, 2H, -S−C*H*$_2$-), 3.12 (s, 12H, (C*H*$_3$)$_4$N), 3.24−3.37 (m, 2H, -C*H*$_2$−CN), 3.52−3.64 (m, 4H, -O−C*H*$_2$-), 4.12−4.20 (m, 4H, -N−C*H*$_2$-), 4.25 (s, 2H, S−C*H*$_2$−CO), 0.1−2.3 ppm (m, 11H, B-*H*). ^{11}B-NMR (200 MHz, $[D_6]$-DMSO, 25 °C): δ = −5.86 (1B), −14.56 ppm (11B). MS (ESI, acetonitrile, *m*/z): negative 794 $[A]^-$; positive 74 $[Kat]^+$, 942 $[A^- + 2Kat^+]^+$.

*S-(N,N-(2-Dimyristoyloxyethyl)acetamido)thioundecahydro-closo-dodecaborate (2-) Ditetramethylammonium Salt (**B-6**−**14**).* Method A. To a solution of **5a** (0.867 g, 1.0 mmol) in acetone, 1 equiv of a 25% solution of tetramethylammonium hydroxyde in methanol was added dropwise. The white precipitate of the product formed immediately. The precipitate was filtered off and dried. Yield 0.434 g (49%), mp 165 °C (decomp.). IR (KBr): ν = 2922−2853 (C−H), 2487 (B−H), 1739 (C═O), 1651 (−N−C═O), 1175 cm^{-1} (C−O). ^{1}H-NMR (200 MHz, $[D_3]CD_3CN$, 25 °C, TMS): δ = 0.85 (t, *J*(H, H) = 3.2 Hz, 6H, C*H*$_3$−CH$_2$-), 1.25 (s, 40H, CH$_3$−(C*H*$_2$)$_{10}$−CH$_2$-), 1.44−1.61 (m, 4H, -CO−CH$_2$−C*H*$_2$-), 2.21−2.37 (m, 4H, -CO−C*H*$_2$-), 3.11 (s, 24H, (C*H*$_3$)$_4$N), 3.16 (s, 2H, S−C*H*$_2$−CO), 3.38−3.62 (m, 4H, -O−C*H*$_2$-), 4.10−4.27 (m, 4H, -N−C*H*$_2$-), 0.2−2.3 ppm (m, 11H, B-*H*). ^{11}B-NMR (200 MHz, $[D_6]$DMSO, 25 °C): δ = −8.70 (1B), −13.23 (5B), −15.31 (5B), −18.80 ppm (1B). ^{13}C-NMR (400 MHz, $[D_3]CD_3CN$, 25 °C, TMS): δ = 174.16, 64.18, 62.39, 56.25, 56.19, 56.13, 48.80, 46.24, 36.25, 34.72, 34.66, 32.59, 30.31, 30.17, 30.03, 29.77, 27.59, 23.32, 14.33 ppm. MS (ESI, acetonitrile, *m*/*z*): negative 738 $[A^- - H^\bullet + H^+]^-$; positive 74 $[Kat]^+$, 963 $[A^{2-} + 3Kat^+]^+$.

Method B. To a solution of **9** (0.331 g 0.7 mmol) in dry CH_3-CN (30 mL), a 60% suspension of NaH in mineral oil (0.051 g, 1.8 mmol) was added. The mixture was stirred under N_2 for 30 min at RT, then for 30 min at 70 °C, and cooled to 25 °C. To the stirred mixture, myristoyl chloride (0.493 g, 2.0 mmol) was added dropwise at RT and stirred for 24 h. The solvent

was evaporated. The remaining oil was crystallized from 2−3 mL acetone. Yield 0.48 g (76%).

*S-(2-Cyanoethyl)-S-(N,N-(2-dipalmitoyloxyethyl)acetamido)-sulfonioundecahydro-closo-dodecaborate (1-) Tetramethylammonium Salt (**5b**).* Similar to **5a**. Yield 0.554 g (60%). IR (KBr): ν = 2935−2887 (C−H), 2491 (B−H), 1732 (C=O), 1651 (−N−C=O), 1175 cm^{-1} (C−O). ^{1}H-NMR (200 MHz, [D_3]CD_3CN, 25 °C, TMS): δ = 0.88 (t, J(H, H) = 3.1 Hz, 6H, CH_3−CH_2-), 1.27 (s, 48H, CH_3−(CH_2)$_{12}$−CH_2-), 1.45−1.62 (m, 4H, -CO−CH_2−CH_2-), 2.23−2.35 (m, 4H, -CO−CH_2-), 2.93−3.04 (m, 2H, -S−CH_2-), 3.07 (s, 12H, (CH_3)$_4$N), 3.22−3.36 (m, 2H, -CH_2−CN), 3.57−3.63 (m, 4H, -O−CH_2-), 4.12−4.20 (m, 4H, -N−CH_2-), 4.25 (s, 2H, S−CH_2−CO), 0.1−2.3 ppm (m, 11H, B-*H*). ^{11}B-NMR (200 MHz, [D_6]DMSO, 25 °C): δ = −5.86 (1B), −14.56 ppm (11B). MS (ESI, acetonitrile, *m*/*z*): negative 850 $[A]^-$; positive 74 $[Kat]^+$.

*S-(N,N-(2-Dipalmitoyloxyethyl)acetamido)thioundecahydro-closo-dodecaborate (2-) Ditetramethylammonium Salt (**B-6**−**16**).* Similar to **B-6**−**14**. Method A. Yield 0.518 g (55%), mp 179 °C (decomp). IR (KBr): ν = 2935−2867 (C−H), 2487 (B−H), 1732 (C=O), 1651 (−N−C=O), 1175 cm^{-1} (C−O). ^{1}H-NMR (200 MHz, [D_3]CD_3CN, 25 °C, TMS): δ = 0.88 (t, J(H, H) = 3.1 Hz, 6H, CH_3−CH_2-), 1.27 (s, 48H, CH_3−(CH_2)$_{12}$−CH_2-), 1.47−1.63 (m, 4H, -CO−CH_2−CH_2-), 2.23−2.33 (m, 4H, -CO−CH_2-), 3.10 (s, 24H, (CH_3)$_4$N), 3.16 (s, 2H, S−CH_2−CO), 3.47 (t, J(H, H) = 3.1 Hz, 2H, -N−CH_2-), 3.79 (t, J(H, H) = 2.8 Hz, 2H, -N−CH_2-), 4.08 (t, J(H, H) = 3.1, 2H, -O−CH_2-), 4.22 (t, J(H, H) = 2.8 Hz, 2H, -O−CH_2-), 0.2−2.3 ppm (m, 11H, B-*H*). ^{11}B-NMR (200 MHz, [D_6]DMSO, 25 °C): δ = −8.70 (1B), −13.23 (5B), −15.31 (5B), −18.80 ppm (1B). ^{13}C-NMR (400 MHz, [D_3]CD_3CN, 25 °C, TMS): δ = 174.60, 166.63, 64.63, 62.80, 56.57, 56.51, 49.20, 46.69, 36.68, 35.15, 35.06, 33.03, 30.78, 30.63, 30.48, 30.21, 26.02, 23.77, 14.78 ppm. MS (ESI, acetonitrile, *m*/*z*): negative 796 $[A^{2-} - H^{\bullet} + H^+]^-$; positive 74 $[Kat]^+$.

*N,N-Bis-(2-trimethylsilyloxyethyl)-2-chloracetamide (**8**).* A mixture of *N*,*N*-Bis-(2-trimethylsilyloxyethyl)amine **7** (23.23 g, 0.093 mol) (prepared by reacting diethanolamine with 1 equiv of bis(trimethylsilyl)disilazan without solvent) and triethylamine (13.0 mL, 0.093 mol) in THF (125 mL) was added dropwise to a solution of chloroacetylchloride (7.42 mL, 0.093 mol) in THF (60 mL) at −20 °C. The precipitated triethylammonium chloride was removed by filtration, and the solvent was evaporated. The remaining oil was distilled in vacuo at $1.4 \cdot 10^{-2}$ mbar (130−131 °C). Yield 28.5 g (94%). IR (KBr): ν = 2959−2875 (C−H), 1651 (C=O), 655 cm^{-1} (C−Cl). ^{1}H-NMR (200 MHz, [D_1]$CDCl_3$, 25 °C, TMS): δ = 0.087 (s, 18H, CH_3−Si-), 3.43 (t, J(H, H) = 2.9 Hz, 2H, N−CH_2), 3.52 (t, J(H, H) = 2.9 Hz, 2H, N−CH_2-), 3.57−3.73 (m, 4H, -O−CH_2-), 4.21 ppm (s, 2H, Cl−CH_2−CO-). MS (70 eV, EI, *m*/*z*): 325 [M].

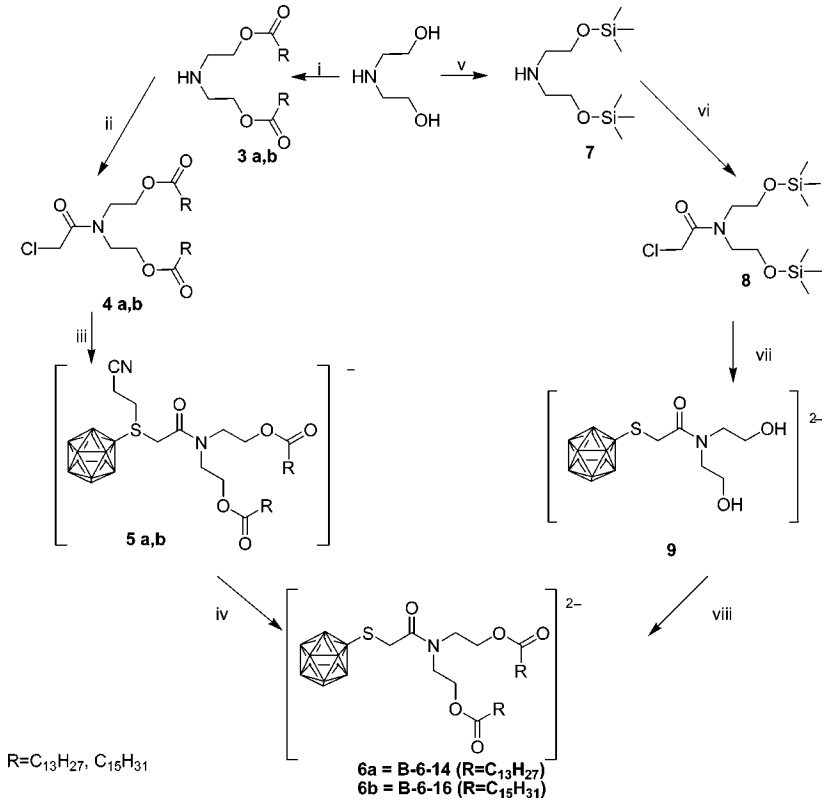
*S-(N,N-(2-Dihydroxyethyl)acetamido)thioundecahydro-closo-dodecaborate (2-) Ditetramethylammonium Salt (**9**).* **10** (1.87 g 5.0 mmol) and **8** (2.44 g 7.5 mmol) were stirred in CH_3CN (40 mL) at RT and then heated to 70 °C for 2 h. The mixture was cooled, and tetramethylammonium chloride was removed by filtration. The solvent was evaporated. The residue was dissolved in acetone and treated with 1 equiv of a 25% solution of tetramethylammonium hydroxide in MeOH. The precipitate of **9** which formed immediately was removed by filtration and dried. Yield 1.5 g (65%). IR (KBr): ν = 3400 (O−H), 3036−2875 (C−H), 2484 (B−H), 1622 cm^{-1} (C=O). ^{1}H-NMR (200 MHz, [d_6]DMSO, 25 °C, TMS): δ = 2.99 ppm (s, 2H, S−CH_2-), 3.08 (s, 24H, (CH_3)$_4$N), 3.19−3.32 (m, 2H, -N−CH_2-), 3.33−3.44 (m, 2H, -N−CH_2-), 3.45−3.57 (m, 4H, -O−CH_2-), 4.50−4.90 (m, 2H, -CH_2−O*H*), 0.2−2.3 ppm (m, 11H, B-*H*). ^{11}B-NMR (200 MHz, [d_6]DMSO-d_6, 25 °C): δ = −8.70 (1B), −13.23 (5B), −15.31 (5B), −18.80 ppm (1B). MS (ESI, acetonitrile, *m*/*z*): negative 160 $[A]^{2-}$; positive 74 $[Kat]^+$, 542 $[A^{2-} + 3Kat^+]^+$.

Preparation of Liposomes. Each lipid mixture was dissolved in a mixture of acetonitrile and chloroform (2:1). The solution was dried to a thin film in a round-bottom flask. The dried lipid film was then hydrated and dispersed by vortexing in 10 mM HEPES buffer saline, pH 7.4 (150 mM NaCl, 10 mM HEPES buffer), to achieve a lipid concentration of 10 mg/mL. The resulting suspension was subjected to 10 cycles of freezing and thawing, then extruded through a polycarbonate membrane with a pore diameter of 100 nm (Avestin, Mannheim, Germany) at a temperature of 50 °C.

For preparation of liposomes in the absence of helper lipids, 20 mg of lipid was dissolved in acetonitrile and dried to a film. The film was then hydrated with 4 mL of 10 mM HEPES buffer saline, pH 7.4. The lipid suspension was subjected to 10 freeze−thaw cycles and then extruded as described previously.

Lipid contents was measured by the Stewart assay (*29*), using appropriate standard curves for the individual lipids.

Cryotransmission Electron Microscopy (cryo-TEM). The liposomal suspension was applied to a polymer-coated grid either at room temperature or (in the case of Figure 3a) at 30 °C. The sample was shock-frozen in liquid ethane. The vitrified sample was mounted and examined in a Zeiss EM 902 A electron microscope, operating at an accelerating voltage of 80 keV in filtered bright field image mode at ΔE = 0 eV. The stage temperature was kept below 108 K, and images were recorded at defocus settings between 1 and 3 μm. A large number of areas were examined in order to ensure the reproducibility of the results (*30*).



ζ-Potential and Size Measurements. ζ-potential and size were measured at 25 °C using a Malvern Zetasizer Nano ZS, Malvern Instruments Ltd., Malvern, U.K. The liposomes were diluted to a concentration of about 1 mg lipid per mL with 1 mM HEPES buffer (pH 7.4). For ζ-potential measurements, fifteen individual determinations were averaged. For size measurements, ten individual determinations were averaged.

Differential Scanning Calorimetry Measurements. Differential scanning calorimetry (DSC) measurements were carried out on a VP−DSC microcalorimeter from Microcal (Northampton, MA), using a lipid concentration of 5 mM. Samples were degassed under vacuum prior to the measurements. The upscans and downscans were recorded at a temperature range between 10 and 60 °C, a scan rate of 90 °C/h, and a filtering period of 2 s. A background scan collected with buffer in both cells was subtracted from each scan. For data analysis, the software package *ORIGIN* (Microcal) was used.

Cytotoxicity Determinations. The cytotoxicity of the boron-containing liposomes was assessed using the WST-1 assay (using the conversion of 4-[3-(4-iodophenyl)-2-(4-nitrophenyl)-2*H*-5-tetrazolio]-1,3-benzene disulfonate to a formazan) which is a colorimetric quantification of cell proliferation and cell viability. The WST-1 reagent was 4× diluted with 10 mM phosphate buffered saline pH 6.9 and then 1:10 diluted with the culture medium.

F10 medium supplemented with 10% newborn calf serum was used for V79 Chinese hamster cells (obtained from ATCC). The cells were harvested by trypsinization and plated at 11 000 cells/well in a 96 well plate and grown in a humidified atmosphere at 37 °C under 5% CO_2. Different concentrations of the liposomes were incubated with the cells for 24 h. At the end of the incubation time, the old medium was removed, and 100 μL of the diluted WST solution was added and allowed to react for 4 h in the incubator at 37 °C and 5% CO_2. The absorbance was measured at 450 and 620 nm using a Wallac 1420 Multilabel counter from Perkin-Elmer. A subtraction analysis of the dual wavelength measurement was performed

to increase the accuracy of the measurement. Controls were set to 100%. Experiments were run in three wells for each concentration and repeated once. As the data appeared essentially identical, they were pooled, and the pooled data (6 data points per concentration) were used to calculate the average survival and its standard deviation.

RESULTS

Chemistry. In this work, two different dodecaborate cluster-containing lipids, **B-6−14** and **B-6−16**, were synthesized according to Scheme 1. The structures are similar to those of **DC-6−14** (*O,O′*-ditetradecanoyl-*N*-(α-trimethylammonioacetyl)-diethanolamine chloride, described by Almofti et al. (*31*)) and are named accordingly. The synthesis followed either the work of Trowbridge and Falk (method A) (*32*) or through the *O*-protected diethanolamine (method B). The introduction of the boron cluster was achieved by alkylation with *S*-cyanoethylmercaptoundecahydrododecaborate **10** and subsequent alkaline removal of the cyanoethyl protecting group (*33*).

In method A, 2 equiv of the chloroanhydride of the fatty acids was allowed to react with diethanolamine. The resulting products *N,N*-(2-dimyristoyloxyethyl)- and *N,N*-(2-dipalmitoyloxyethyl)-amine **3a**,**b** were reacted with chloroacetylchloride in the presence of triethylamine to obtain **4a**,**b** in 87% yield. The reaction between the chloroacetamides **4a**,**b** and the tetramethylammonium salt of 2-cyanoethylmercaptoundecahydro-*closo*-dodecaborate (2-) produced sulfonium salts **5a**,**b** in 60% yield. The end products **B-6−14** and **B-6−16** were obtained from the reaction of sulfonium salts **5a**,**b** with tetramethylammonium hydroxide in acetone. The yield of lipids **B-6−14** and **B-6−16** is 48−55% (overall yield from diethanolamine 25−28%).

The lipids can also be obtained through method B. Here, the introduction of the fatty acid chain occurs later, and the intermediate **9** is therefore a suitable synthon when aiming at a variety of fatty acid derivatives. Two equivalents of chlorotrimethylsilane are reacted with diethanolamine in the presence of triethylamine. The trimethylsilyloxy derivative **7** is reacted with chloroacetylchloride in the presence of triethylamine to give **8** in 84% yield. **8** can react in analogy to path 1 with *S*-cyanoethylmercaptuundecahydrododecaborate. Starting from **9**, the yield of **B-6−14** was 76% (overall yield from diethanolamine 46%).

The synthesized compounds have two negative charges due to the presence of the undecahydro-*closo*-dodecaborate (2-) cluster in the head group. They are one of the examples of amphiphilic lipids which carry two negative charges in the part that would be in direct contact with water when incorporated into mixed lipid films, with phosphatidylglycerol lipids being another example.

Physical Characterization and Liposome Preparation. DSC results demonstrated that **B-6−14** and **B-6−16** alone exhibit a main phase transition at 18.8 and 37.9 °C, respectively (Figure 2). These temperatures are quite comparable to the transition temperatures of dimyristoyl- and dipalmitoylphosphatidylcholine (DMPC and DPPC, respectively), which are 24.3 and 41 °C, respectively (*34*). Phase transition data for the lead structure **DC-6−14** are not reported in the literature. Liposomes containing 33.3 mol % of either **B-6−14** or **B-6−16**, as well as the same mol % of DSPC and CHO, exhibit broad phase transitions, and the enthalpy of transition was low (data not shown), in accordance with literature observations (*35*, *36*).

Liposomes from pure **B-6−14** can be prepared by lipid film hydration and extrusion above the phase transition temperature

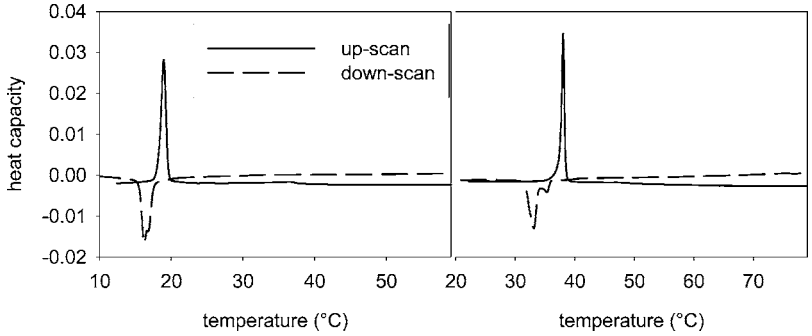

Figure 2. DSC of pure films of **B-6−14** (left) and **B-6−16** (right) (the first upscan and the first downscan are shown). Lipid concentration 5 mM.

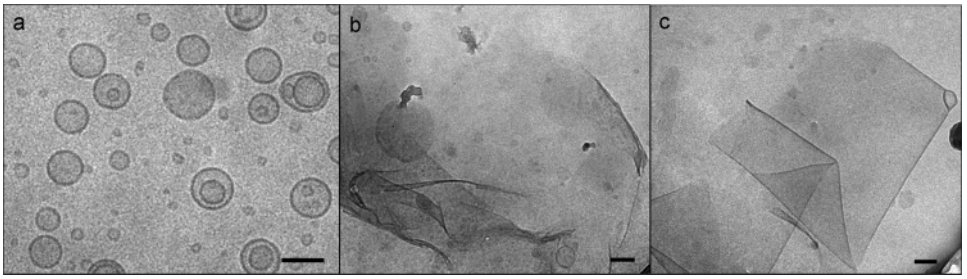

Figure 3. Cryo-TEM pictures of a preparation of **B-6−14** prepared by extrusion at 50 °C and vitrification from 30 °C (a), prepared by extrusion at 50 °C, storage at 4 °C for 1 week and vitrification from 25 °C (b) and **B-6−16** prepared as sample b (c). Scale bare 100 nm.

18.8 °C (Figure 3a). The liposomes are heterogeneous in size, and many have diameters well below the 100 nm size of the extrusion membrane. Important structural rearrangements take place upon cooling of the samples to temperatures below the phase transition temperature. As shown in Figure 3b, the liposomes transform into large open bilayer sheets when stored for some time at 4 °C. The equipment used for cryo-TEM in the present study did not allow vitrification from temperatures safely above the phase transition temperature for **B-6−16** (37.6 °C), and therefore, the possible formation of liposomes could not be verified for this lipid. As already observed for **B-6−14**, open bilayers are obtained when the sample is stored for some time at 4 °C (Figure 3c). Some of the large bilayer sheets of both lipids covered more than one of the holes in the supporting polymer net.

Nakamura et al. have previously shown that it is possible to prepare liposomes from the ether lipid **2a** (*19*). **B-6−14** represents, however, the first dodecaborate-containing lipid which has been proven to form liposomes without the addition of helper lipids.

From X-ray crystal analysis (see, e.g., (*37*)), the van der Waals radius of the dodecaborate cluster can be determined to be approximately 4 Å, giving an unsolvated cross section area of the head group of about 0.5 nm^2. This is close to the 0.6 nm^2 area occupied by lipids with saturated fatty acid chains in the gel phase (*34*).

Liposomes consisting of either a mixture of 33.3 mol % **B-6−14**, 33.3 mol % DSPC, and 33.3 mol % CHO or a mixture of 33.3 mol % **B-6−16**, 33.3 mol % DSPC, and 33.3 mol % CHO were successfully prepared (Figure 3) by thin film hydration and extrusion.

The mean diameters of the liposomes containing **B-6−14** and **B-6−16** in combination with DSPC and CHO were found to be 135 and 123 nm, respectively, when measured by dynamic light scattering. This value is corroborated by the results from cryo-TEM (see below). The liposomes containing 33.3 mol % of either **B-6−14** or **B-6−16** had ζ potentials of −67 and −63 mV, respectively, reflecting the double negative charge of the headgroup. Liposomes prepared by extrusion from neat **B-6−14** at 50 °C and analyzed at 30 °C had a ζ potential of −63 mV and showed a broad size distribution centered at 129 nm.

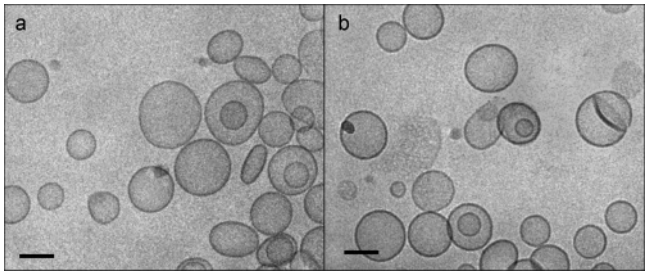

Figure 4. Cryo-TEM pictures of liposomes prepared from an equimolar mixture of DSPC, CHO and **B-6−14** (a), or **B-6−16** (b), respectively. Scale bar 100 nm.

The pictures obtained from cryo-TEM (Figure 4) showed formation of boron cluster-containing liposomes when an equimolar mixture of the boron lipid, DSPC, and CHO was used for liposome preparation. The micrographs confirm a size distribution centered around 100 nm as measured by dynamic light scattering. Cryo-TEM also revealed a certain degree of heterogeneity in the preparation. A few open structures were observed (see Figure 4b), but most of the material was present in the form of closed liposomes.

It has been shown before that liposomes composed of DSPC/CHO (60/40 molar ratio) and prepared by extrusion through 100 nm filters have a tendency to aggregate (*38*). As a consequence of the attractive interaction, the liposomes adapt a nonspherical, more elongated shape. The spherical shape of the liposomes displayed in Figure 4 is likely due to the presence of the boron-containing lipid and the repulsion caused by the negatively charged headgroups.

Cytotoxicity. We found that 5.6 mM of **B-6−14**-containing liposomes was required to inhibit cell growth by 50% (Figure 5. This value should be compared to the IC_{50} value of BSH in the same cell assay system, which is 3.9 mM. **B-6−16**-containing liposomes were added at different concentrations ranging from 0.5 to 30 mM. In this case, cell growth and activity was only weakly affected even at the highest concentration used, and accordingly, we could not determine an IC_{50} value.

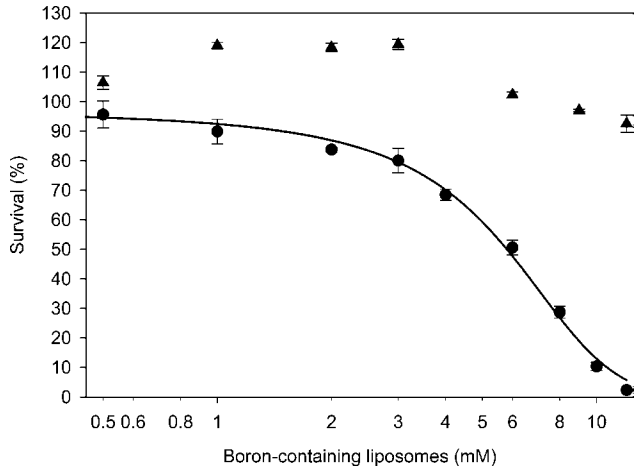

Figure 5. Survival of V79 Chinese hamster cells exposed to **B-6−14** (circles) and **B-6−16** (triangles), respectively. The solid line is the fitted curve from which the IC_{50} value was calculated.

DISCUSSION

Synthesis of two *closo*-dodecaborate cluster-containing lipids was achieved. Cryo-TEM results show that liposomesthat are stable above the transition temperature of the boron lipid can be prepared from pure **B-6−14**,. Although no evidence was collected in the present study, it is plausible that also **B-6−16** is capable of forming liposomes at temperatures above the phase transition temperature. Liposomes that are stable below the phase transition temperature can be prepared from mixtures containing equimolar amounts of the boron lipid, DSPC, and CHO. The liposomes containing the pure lipid are among the most boron-rich units prepared to date for BNCT. The structure of the liposomes provides two modes of delivery: encapsulation of boron and transport of boron-containing lipids. Previously, liposomes have been used to encapsulate concentrated aqueous solutions of water-soluble polyhedral borane anion salts (*12*, *13*, *15*) or to incorporate lipophilic boron-containing moieties embedded within the bilayer membrane (*18*, *19*, *21*, *23*, *24*).

The use of a boron-containing lipid circumvents problems with possible leakage of encapsulated material. The liposomes prepared here can most probably be tagged with tumor-seeking entities (*16*, *39*), and thereby, it should be possible to achieve selective tumor accumulation. Due to their high contents of boron, their relative lack of toxicity, and the known procedures by which liposomes can be targeted, they appear to be of great potential value for BNCT.

Successful BNCT is considered to require between 10 and 30 ppm boron in the target tissue, which corresponds to around $(1-3)\cdot10^9$ boron atoms for an average mammalian cell (*41*). Assuming an area per lipid molecule of 0.6 nm^2 (*34*), the bilayer of a unilamellar liposome with a diameter of 100 nm (and thus an area of $31\cdot10^3$ nm^2) contains about 10^5 lipid molecules. If composed purely of **B-6−14** or **B-6−16**, one such liposome will contain $1.2\cdot10^6$ boron atoms. Thus, the binding of 800−2500 liposomes would suffice to accumulate therapeutic amounts of boron. Naturally, the amount of boron carried by each liposome becomes lower if helper lipids, such as cholesterol and DSPC, are used in the preparation. The effective area per lipid molecule in bilayers containing DPPC and 33 mol % cholesterol is about 0.39 nm^2 (*41*), and a similar value may be assumed for bilayers based on DSPC and cholesterol. A 100 nm liposome will in this case contain approximately $1.6\cdot10^5$ lipid molecules. Assuming that the area per lipid remains close to 0.39 nm^2 when half the DSPC molecules are exchanged for boron lipids, a liposome composed of equimolar amounts of DSPC, cholesterol and boron lipid will contain about $6.5\cdot10^5$ boron atoms. This may be compared to the $3.8\cdot10^5$ boron atoms per liposome obtained when a water-soluble dodecaborate is encapsulated at a concentration of 0.1 M in 100 nm liposomes (assuming a volume per liposome of $5.2\cdot10^6$ nm^3) (see, e.g., (*15*)). In the latter case, leakage of the encapsulated compound might reduce the boron content even further, thus making the use of liposomes prepared from boron-containing lipids very attractive for BNCT.

Reconstitution of Modular PDK1 Functions on Trans-Splicing of the Regulatory PH and Catalytic Kinase Domains

Hassan Al-Ali, Timothy J. Ragan, Xinxin Gao, and Thomas K. Harris*

Department of Biochemistry and Molecular Biology, Miller School of Medicine, University of Miami, P.O. Box 016129, Miami, Florida 33101-6129. Received February 16, 2007; Revised Manuscript Received March 29, 2007

The serine-threonine protein kinases PDK1 and PKB each contain a pleckstrin homology (PH) domain that binds the membrane-bound phosphatidylinositol 3,4,5-triphosphate [PI(3,4,5)P_3] second messenger and is required for PDK1-catalyzed phosphorylation and activation of PKB. While X-ray structures have been reported for the individual regulatory PH and catalytic kinase domain constructs of both PDK1 and PKB, diffraction quality crystals of full length constructs have yet to be obtained, likely due to conformational heterogeneity. In developing alternative approaches to understanding the potential role of conformational dynamics in regulating PKB phosphorylation by PDK1, an efficient in vitro method for protein trans-splicing was developed, which utilizes the N- and C-terminal split inteins of the gene *dnaE* from *Nostoc punctiforme* [(N)*Npu*DnaE] and *Synechocystis* sp. strain PCC6803 [(C)SspDnaE], respectively. For conjugating the regulatory PH domain to the catalytic kinase domain of PDK1, the recombinant trans-splicing fusion constructs KINASE(AEY)-(N)*Npu*DnaE-His_6 and GST-His_6-(C)*Ssp*DnaE-(CMN)PH were designed, PCR assembled, overexpressed, and affinity purified. The cross-reacting (N)*Npu*DnaE and (C)*Ssp*DnaE inteins generated full length spliced-PDK1 with $k_{obs} = (2.8 \pm 0.3) \times 10^{-5}$ s^{-1} and with ≤5% of any competing trans-cleavage reactions. Spliced-PDK1 was efficiently purified to ≥95% homogeneity from the reaction mixture by subsequent His_6 affinity and ion exchange chromatography steps. In vitro kinase assays and phosphopeptide mapping studies confirmed that spliced-PDK1 retained the ability to colocalize and selectively phosphorylate Thr-309 of PKBβ in a PI(3,4,5)P_3-dependent manner. The high-level production and reconstitution of functional spliced-PDK1 establishes the feasibility of incorporating domain-specific biophysical probes for spectroscopic studies of regulatory PH domain mediated catalytic specificity.

INTRODUCTION

Protein kinases comprise the largest enzyme family, with ~518 being encoded by the human genome (*1*). The large number of serine-threonine protein kinases (~80% of total protein kinases) reflects the large number of intracellular signal transduction pathways required in regulating proper cellular growth, survival, and proliferation. The complexity in elucidating intracellular signaling networks is compounded by analyses, indicating that individual protein kinases may target and phosphorylate numerous different protein substrates (*2*, *3*). Further complexities arise in the observation that individual protein kinases can be intricately regulated by multiple phosphorylation events catalyzed by numerous upstream kinases, as well as autocatalytically. On review of protein kinase sequence alignments, it becomes readily apparent that signaling complexity can be largely accounted for by a distinguishingly diverse arrangement of regulatory domains, which may exist contiguously N- or C-terminal to an otherwise structurally homologous catalytic kinase domain (*4*). Often such domains may serve in proper localization, but many have been shown to play direct roles in regulating kinase activity either intrinsically or through participation in docking-based substrate recognition.

While the functions of various regulatory domains of different protein kinases are steadily being recognized, progress toward molecular understanding of conformational interactions within full length multidomain kinases remains hampered. To date, no three-dimensional structure has been reported for any full length monomeric multidomain serine-threonine protein kinase. Rather for example, X-ray structures have been reported for the isolated catalytic kinase domains of multidomain AGC kinases including PDK1[1] (*5*), PKBβ (*6*, *7*), PKCθ (*8*), and PKCι (*9*); multidomain MAP kinases including B-RAF (*10*), MEK1,2 (*11*), MK2 (*12*), and MSK1 (*13*); and multidomain cell-cycle related kinases including CHK1 (*14*), Aurora A (*15*), and Aurora B (*16*). Likewise, X-ray or NMR structures have been reported for corresponding isolated regulatory domain constructs including the PH domains of PDK1 (*17*), PKBα (*18*), and PKBβ (*19*); the C1 domain of PKCγ (*20*); the *C*2 domains of PKCα (*21*, *22*), PKCβ (*23*), PKCδ (*24*, *25*), and PKCϵ (*26*); the CR1 domain of RAF1 (*27*); the FHA domain of CHK2 (*28*); and the PBD domain of PLK1 (*29*, *30*). The observation that suitable crystals for X-ray diffraction studies of full length multidomain monomeric protein kinases have not been obtained suggests an important role for intra-domain−domain conformational dynamics. Thus, alternative methodologies will be required for advanced understanding of such processes.

One very promising approach toward better understanding conformational interactions within full length multidomain kinases involves the use of intein-based technologies to generate a native peptide bond between given pairs of contiguous regulatory and catalytic kinase domains (*31*−*34*). Successful peptide conjugation would facilitate domain-specific incorporation of biophysical probes (e.g., fluorophores and paramagnetic spin labels) and stable isotopes (e.g., ^{15}N and ^{13}C), enabling spectroscopic characterization of intra-domain−domain conformational dynamics in solution. While a large number of small C-terminal peptides have been successfully ligated to their cognate proteins, few cases have been reported in which two large functional domains have been conjugated to reconstitute regulatory function in a monomeric multidomain native enzyme (*34*). To begin addressing the possibility that intein-based technologies may be used to reconstitute a monomeric multidomain protein kinase for spectroscopic functional studies, we selected the human serine-threonine AGC protein kinase, PDK1, for which X-ray structures are known for both the N-terminal catalytic kinase (*5*) and the C-terminal PH domains (*17*). The C-terminal PH domain is required for PI(3,4,5)P_3-dependent colocalization and phosphoryaltion of PKB (*35*).

In this paper, we report efficient protein trans-splicing of the regulatory PH and catalytic kinase domains of human PDK1 by using naturally split DnaE inteins from two different organisms. In addition, spliced-PDK1 is shown to retain the ability to colocalize and selectively phosphorylate Thr-309 of PKBβ in a PI(3,4,5)P_3-dependent manner. The high-level production and reconstitution of functional spliced-PDK1 establishes the feasibility of generating full length PDK1 with either (i) segmental ^{15}N-isotopic labeling of the PH domain for NMR studies or (ii) simultaneous site-directed modifications of the PH and kinase domains with small molecule donor and acceptor fluorophores for FRET-based studies of conformational transitions related to docking-based catalytic specificity.

EXPERIMENTAL PROCEDURES

Materials. PDK1-Tide (acetyl-KTFCTGTPEYLAPEVRRE-PRILSEEEQEMFRDYIAD-WC) and Crosstide (acetyl-GR-PRTSSFAEG) were from 21st Century Biochemicals, Inc. (Marlboro, MA). [γ-^{32}P]ATP was from MP-Biomedical (Irvine, CA). 1,2-Dioleoyl-*sn*-glycerol-3-phosphocholine (PC), 1,2-dioleoyl-*sn*-glycerol-3-phospho-L-serine (PS), and *sn*-1-stearoyl-2-arachidonyl D-phosphatidylinositol-(3,4,5)-triphosphate [PI(3,4,5)P_3] were from Echelon Biosciences (Salt Lake City, UT). Full length His_6-PKBβ and His_6-PDK1 (residues 51−556) were expressed using the Bac-to-Bac Baculovirus Expression System (Invitrogen, Carlbad, CA) and His_6 affinity purified as described (*36*). Affinity-purified His_6-PKBβ was fully dephosphorylated by treatment with lambda protein phosphatase (λPP) as described (*36*).

PDK1 Trans-Splicing Strategy. Figure 1 shows the protein engineering strategy designed for trans-splicing of the regulatory PH and catalytic kinase domains of human PDK1. This strategy derives from recent reporting of the highly efficient in vivo cross trans-splicing reaction catalyzed between the N-terminal DnaE intein from *Nostoc punctiforme* [(N)*Npu*DnaE] and the C-terminal DnaE intein from *Synechocystis* sp. strain PCC6803 [(C)*Ssp*DnaE] (*37*). One additional advantage of utilizing (N)-*Npu*DnaE is that it has been demonstrated to be more tolerant of amino acid substitutions at the at the C-terminal side of the splice junction (*37*). Since three-dimensional structures have been reported for the N-terminal catalytic kinase domain (residues 51−359) (*5*) and the C-terminal regulatory PH domain (residues 409−556) (*17*), C385 was chosen as the optimal site of conjugation. In utilizing the (N)*Npu*DnaE and (C)*Ssp*DnaE cross trans-splicing intein pair, ^{382}QFG^{384} at the N-terminal side of the splice junction was replaced with ^{382}AEY^{384}. In addition, a conservative Q387N mutation gave ^{385}CMN^{387} residues at the C-terminal side of the splice junction, which has been shown to be equally effective as the native CFN sequence required for trans-splicing with the native (N/C)*Ssp*DnaE pair (*37*). In order to facilitate purification of spliced-PDK1 from cleaved and uncleaved DnaE intein containing fragments, His_6 affinity tags were joined to the corresponding DnaE inteins. Addition of GST significantly increased the overall protein yield and solubility over that obtained by expression of the His_6-(C)SspDnaE-(CMN)PH construct.

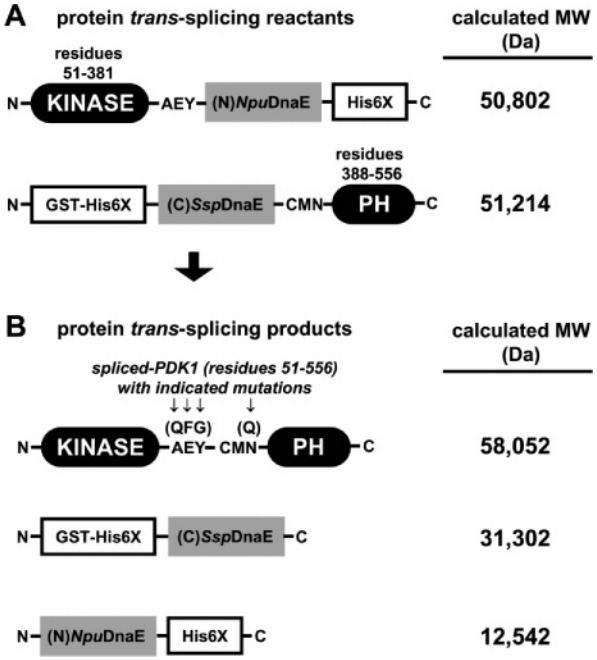

Figure 1. (A) Protein trans-splicing reactants. The N-terminal kinase domain of PDK1 (residues 51−381, black oval) is fused to the (N)-*Npu*DnaE trans-splicing intein (gray square) with a C-terminal His_6 affinity tag (open square). The N-terminal three residues flanking the splice junction (Q382, F383, and G384) were mutated to the preferred AEY sequence required in trans-splicing. The C-terminal PH domain of PDK1 (residues 388−556, black oval) is fused to the (C)*Ssp*DnaE trans-splicing intein (gray square) with an N-terminal GST-His_6 tag (open square). Whereas the His_6 tag was used for affinity purification, the GST tag significantly improved both expression yield and solution stability. For the native C-terminal three residues flanking the splice junction (C385, M386, and Q387), only Q387 was mutated to yield the preferred CMN sequence optimal for cross trans-splicing of the (C)*Ssp*DnaE intein with the (N)*Npu*DnaE intein. The (N)*Npu*DnaE and (C)*Ssp*DnaE split inteins associate with high affinity and catalyze trans-splicing of the regulatory PH and catalytic kinase domains by forming a native peptide bond between Tyr-384 and Cys-385. (B) Protein trans-splicing products. The primary domain arrangement of PDK1 is regenerated, which contains the Q382A, F383E, G384Y, and Q387N mutations that flank the spice junction. The affinity tagged trans-splicing inteins are indicated. Spliced-PDK1 is separated from the cleaved (N)-*Npu*DnaE-His_6 and GST-His_6-(C)*Ssp*DnaE split inteins, as well as any uncleaved intein fusion constructs by His_6 affinity purification. The calculated molecular weights (MW) of each trans-splicing reactant and product are indicated.

Baculovirus-Mediated Expression of KINASE(AEY)-(N)*Ssp*DnaE-His_6. Experimental procedures describing PCR engineering to generate an *EcoR*I-*Xba*I cDNA fragment containing the KINASE(AEY)-(N)*Npu*DnaE-His_6 fusion construct are given as described (Supporting Information). A sequence verified *EcoR*I-*Xba*I fragment containing the KINASE(AEY)-(N)*Npu*DnaE-His_6 construct (Figure 1) was removed from the pCR-Blunt II-TOPO cloning vector and ligated into pFastBac1 vector (Invitrogen) to generate recombinant baculovirus using the Bac-to-Bac Baculovirus Expression System (Invitrogen).

Recombinant P2 viral stocks were used to infect 200 mL spinner flask cultures of Sf9 cells in the midlogarithmic phase of growth (2×10^6 cells/mL) at a multiplicity of infection (MOI) of two viral particles/cell. The infected cells were incubated at 27 °C for 72 h and harvested by centrifugation for 10 min at 4 °C at 3000 rpm in a Beckman tabletop centrifuge. The cells were resuspended in 50 mL of buffer (50 mM Tris-HCl, pH 7.5, 300 mM NaCl, 50 mM imidazole, 1 mM 2-mercaptoethanol, 1 mM benzamidine, and 0.2 mM PMSF) and were immediately stored at −80 °C. The resuspended frozen cells were allowed to thaw on ice for 1 h, which resulted in efficient cell lysis. Cell debris was pelleted by centrifugation for 30 min at 4 °C at 12 000 rpm. The supernatants containing the soluble components of the cell lysate were collected, and the KINASE(AEY)-(N)-*Npu*DnaE-His_6 construct was His_6-affinity purified from the soluble lysate as described below.

Bacterial Expression of GST-His_6-(C)*Ssp*DnaE-(CMN)-PH. Experimental procedures describing PCR engineering to generate the *Sac*II-*Kpn*I fragment containing the (C)*Ssp*DnaE-(CMN)PH fusion construct are given as described (Supporting Information). A sequence-verified *Sac*II-*Kpn*I fragment containing the (C)*Ssp*DnaE-(CMN)PH construct was removed from the pCR-Blunt II-TOPO cloning vector and ligated into the pET-41b protein expression vector (Novagen), which provided N-terminal dual GST-His_6 affinity tags to yield the GST-His_6-(C)*Ssp*DnaE-(CMN)PH construct (Figure 1). The protein expression vector was transformed into the Rosetta (DE3) protein expression strain of *E. coli*. Cells were grown in 1 L of Luria Broth (LB) containing kanamycin (50 μg/mL) and chloramphenicol (37 μg/mL) at 37 °C until an OD of 0.4. Then the cell culture was transferred to 15 °C and grown until an OD of 0.8 before induction with 0.5 mM isopropyl β-D-thiogalactopyranoside (IPTG) for 16 h. The cells were harvested by centrifugation at 3500*g* for 20 min and then resuspended in 3 mL of PBS buffer per gram of cells (10 mM Na_2HPO_4 and 1.8 mM KH_2PO_4, pH 7.3, 140 mM NaCl, 2.7 mM KCl, 2 mM dithiothreitol, 1 mM benzamidine, and 0.2 mM PMSF). The cells were lysed using the EmulsiFlex-C3 high-pressure homogenizer (Avestin, Inc.), and particulates were removed from the lysate by centrifugation for 20 min at 14 000 rpm in the SS-34 Sorvall rotor. The GST-His_6-(C)*Ssp*DnaE-(CMN)PH construct was GST-affinity purified from the soluble lysate as described below.

His_6- and GST-Affinity Purification. The soluble Sf9 insect cell lysate containing the KINASE(AEY)-(N)*Npu*DnaE-His_6 recombinant fusion construct (Figure 1) was directly loaded by FPLC (1 mL/min) onto a 5 mL size Ni^{2+} Sepharose HiTrap HP affinity column (Amersham) equilibrated at 4 °C in 50 mM Tris-HCl, pH 7.5, 500 mM NaCl, 50 mM imidazole, 1 mM 2-mercaptoethanol. The soluble *E. coli* lysate containing the GST-His_6-(C)*Ssp*DnaE-(CMN)PH recombinant fusion construct (Figure 1) was directly loaded by FPLC (1 mL/min) onto a 5 mL size GST HiTrap HP affinity column (Amersham) equilibrated at 4 °C in PBS buffer (10 mM Na_2HPO_4 and 1.8 mM KH_2PO_4, pH 7.3, 140 mM NaCl, 2.7 mM KCl, and 2 mM dithiothreitol). The columns were subsequently washed until the absorbances at 260 and 280 nm returned to baseline. The KINASE(AEY)-(N)*Npu*DnaE-His_6 construct was eluted by linear increasing of the imidazole concentration from 50 to 500 mM at 1 mL/min for 30 min. The GST-His_6-(C)*Ssp*DnaE-(CMN)PH construct was eluted with buffer containing 50 mM Tris-HCl, pH 8.0, 2 mM dithiothreitol, and 20 mM glutathione. Chromatographic fractions (1 mL) containing the designated fusion protein were detected by absorbance at 280 nm and analyzed by SDS-PAGE. Fractions containing recombinant protein were pooled and subjected to gel exclusion chromatography for exchange to the protein trans-splicing buffer (50 mM Tris-HCl, pH 7.5, 500 mM NaCl, 0.5 mM TCEP, 0.5 mM EGTA, 1 mM EDTA, and 5% (v/v) glycerol). Protein was concentrated using a VivaSpin 20, 6, or 2 mL ultrafiltration concentrator (10 kDa molecular weight cutoff, VivaScience). Protein concentrations were determined by BioRad protein assay. Protease inhibitors (0.5 mM benzamidine and 0.1 mM PMSF) were added to each purified protein construct. A ~40 μM stock solution of the KINASE(AEY)-(N)*Npu*DnaE-His_6 construct was prepared using ~2 mg/mL total protein with ≥95% purity. A ~40 μM stock solution of the GST-His_6-(C)-*Ssp*Dna-(CMN)PH construct was prepared using ~2.8 mg/mL total protein with ≥60% purity. These solutions were stored at −80 °C.

PDK1 Trans-Splicing. Frozen aliquots containing ~40 μM of either the KINASE(AEY)-(N)*Npu*DnaE-His_6 or the GST-His_6-(C)*Ssp*Dna-(CMN)PH trans-splicing constructs were thawed at 21 °C. After 10 min microcentrifugation of each tube, the reaction was initiated by combining the clarified supernatants to yield ~20 μM of each construct. The reaction tube was incubated either at 4 °C or 21 °C, and at varying times (0, 1, 3, 6, 9, 12, and 18 h) 9 μL aliquots containing ~18−20 μg of total protein were removed and quenched by addition to 9 μL of 2× SDS sample buffer, heated at 95 °C for 2 min, and placed on ice for SDS-PAGE analysis of trans-splicing progress. At the end of the time course, the reaction mixture was buffer exchanged by gel exclusion chromatography to 50 mM Tris-HCl, pH 7.5, 500 mM NaCl, 50 mM imidazole, and 1 mM 2-mercaptoethanol, the equilibration buffer for His_6 affinity chromatography. The cleaved (N)*Npu*DnaE-His_6 and GST-His_6-(C)*Ssp*Dna products and any uncleaved KINASE(AEY)-(N)-*Npu*DnaE-His_6 and GST-His_6-(C)*Ssp*Dna-(CMN)PH reactants were removed by passage over a 5 mL size Ni^{2+} Sepharose HiTrap HP affinity column (Amersham). The column was subsequently washed until the absorbances at 260 and 280 nm returned to baseline. Flow-through fractions containing spliced-PDK1 were desalted and directly loaded by FPLC (0.5 mL/min) onto a Tricorn Mono Q 5/50 GL anion exchange column (Amersham) equilibrated at 4 °C in Tris-HCl buffer, pH 7.5, containing 2 mM 2-mercaptoethanol. Upon linear increasing of the NaCl concentration from 0 to 1 M at 1 mL/min for 1 h, ≥95% purified spliced-PDK1 eluted between 0.1 and 0.2 M NaCl. Fractions containing purified spliced-PDK1 (~35 μM or ~2 mg/mL) were combined, and protease inhibitors (0.5 mM benzamidine and 0.1 mM PMSF) were added before storage of either 50 μL or 1 mL aliquots at −80 °C.

SDS-PAGE and Western Analysis. Protein samples in SDS sample buffer were heated at 95 °C for 2 min and cooled on ice. Analytical SDS-PAGE was performed on 4−20% gradient polyacrylamide gels (GradiPore) developed at 150 V (constant) for 1 h or until the tracking dye reached the bottom of the slab. Coomassie staining was used to visualize total protein. Densitometric analysis was performed using the ImageQuant software (Molecular Dynamics). For Western analyses, protein was transferred from the gel to Nitrocellulose Membrane Filter Paper Sandwich (Invitrogen) in a semidry blotting apparatus using 0.7% (v/v) acetic acid as transferring solution. According to the manufacturer's instructions, purified KINASE(AEY)-(N)-*Npu*DnaE-His_6 was probed with phospho-PDK1 (Ser241) polyclonal rabbit antibody (Cell Signaling Technology), and His_6-PKBβ was probed with either phospho-PKB (Thr-308) or phospho-PKB (Ser473) polyclonal rabbit antibodies (Cell Signaling Technology). Detection of all immunoprotein complexes was carried out using secondary anti-rabbit antibody conjugated to horseradish peroxidase (HRP) and LumiGLO chemiluminescent reagent and peroxide.

Kinetic Assays and Phosphopeptide Mapping. V_{max} and K_m values at 30 °C and percent inactivation over time of purified 20 μM KINASE(AEY)-(N)*Npu*DnaE-His_6 in protein trans-

splicing buffer at 21 °C were measured by quantifying transfer of ^{32}P-radiolabel from [γ-^{32}P]ATP to the model PDK1-Tide substrate as described (*36*). PI(3,4,5)P_3-dependent phosphorylation of His$_6$-PKBβ by spliced-PDK1 and measurement of the resulting increase in His$_6$-PKBβ-catalyzed transfer of ^{32}P-radiolabel from [γ-^{32}P]ATP (100 μM) to the model Crosstide substrate (50 μM) was carried out as described (*36*). For both assays, one unit of activity was defined as the amount of enzyme required to catalyze phosphorylation of 1 nmol of peptide substrate in 1 min.

The ability of spliced-PDK1 to *selectively* phosphorylate Thr-309 in the activation loop of His$_6$-PKBβ was tested in a 1 mL reaction mixture containing 2 μM of each enzyme (60 μg or 1 nmol) in 50 mM Tris-HCl buffer, pH 7.5, 1 mM 2-mercaptoethanol, 10 mM $MgCl_2$, 0.2 mM sodium vanadate, and PC/PS/PI(3,4,5)P_3 vesicles. The reaction was initiated by addition of 100 μM [γ-^{32}P]ATP (~500 cpm/pmol) and allowed to proceed with continuous shaking at 30 °C for 40 min. The reaction was quenched by addition of urea to 6 M. Control assays were carried out in parallel in which either spliced-PDK1, PI(3,4,5)P_3 in the phospholipid vesicles, or both were omitted.

^{32}P-Radiolabeled His$_6$-PKBβ was affinity-purified from the quenched reaction mixture by addition of 200 μL of Ni-NTA agarose resin and shaking overnight at room temperature. After low-speed centrifugation, the supernatant was removed and the resin was washed twice with 1 mL of 50 mM Tris-HCl, pH 7.5, containing 6 M urea, 50 mM imidazole, 300 mM NaCl, and 1 mM 2-mercaptoethanol. ^{32}P-Radiolabeled His$_6$-PKBβ was eluted from the Ni-NTA agarose resin pellet with 100 μL of 50 mM Tris-HCl, pH 7.5, containing 6 M urea, 500 mM imidazole, 300 mM NaCl, and 1 mM 2-mercaptoethanol, and approximately 40−50% of enzyme (400−500 pmol) was recovered in the 100 μL elute. First, protein concentration was determined with the Bio-Rad protein assay kit, using 10 μL of the eluted enzyme. Second, the specific radioactivity of the ^{32}P-radiolabeled His$_6$-PKBβ construct ($SA^{PKB\beta}$, cpm/pmol) was determined from radioactivity detected by scintillation counting of the known amount of enzyme (~40−50 pmol) in 10 μL of the eluted enzyme. The mole fraction of total phosphorylated sites ($f_{mol}{}^{tot}$) was calculated according to $f_{mol}{}^{tot} = SA^{PKB\beta}/SA^{ATP}$.

To determine site-specific phosphorylation, the remaining amount (~80 μL with ~320−400 pmol) of affinity-purified His$_6$-PKBβ was used for trypsin digestion and HPLC resolution of ^{32}P-radiolabeled peptides. First, cysteine residues were reduced by addition of 0.5 mL of 50 mM Tris-HCl, pH 7.5, containing 20 mM 2-mercaptoethanol. Free cysteines were protected from reoxidation by subsequent addition of 50 μL of 500 mM iodoacetamide incubation in the dark at room temperature for 20 min. Excess unreacted iodoacetamide was depleted from the reaction mixture by further addition of 30 μL of 500 mM 2-mercaptoethanol and incubation at room temperature for 5 min. Proteolytic digestion was carried out by addition of 1 μg of trypsin and incubation at 37 °C for 5 h, followed by subsequent addition of 1 μg of trypsin and incubation at 37 °C overnight. The individual reaction mixtures (~200 μL) containing digested ^{32}P-radiolabeled His$_6$-PKBβ constructs were diluted to 1 mL with solvent A [0.1% (v/v) trifluoroacetic acid in water]. The 1 mL samples were directly loaded by HPLC (0.5 mL/min) onto a μRPC *C*2/C18 column (Amersham) equilibrated in 100% solvent A. The column was subsequently washed in this buffer for 5 min, and the peptides were eluted by linear increasing solvent B [80% acetonitrile and 0.07% (v/v) trifluoroacetic acid in water] from 0% to 50% in 1 h at a flow rate of 0.4 mL/min, while 300 μL was collected for each fraction. ^{32}P-Radiolabeled peptides were detected by scintillation counting of 30 μL of each chromatographic fraction.

The identity of the ^{32}P-radiolabeled peptide was confirmed by MALDI-TOF mass spectrometric analysis. The 300 μL fraction containing the ^{32}P-radiolabeled peptide was evaporated to dryness and resuspended in a small volume (10−30 μL) of 50% acetonitrile to yield a ^{32}P-peptide concentration of 10 pmol/μL, as indicated by the amount of radioactivity; 1 μL of saturated 2,5-dihydroxybenzoic acid (2,5-DHB) was added to 1 μL of the concentrated ^{32}P-peptide, and 1 μL of this mixture containing ~5 pmol of the ^{32}P-peptide was placed on a stainless steel MALDI-TOF target plate and allowed to dry. MALDI-TOF mass spectra were acquired on a Biflex IV MALDI-TOF mass spectrometer (Bruker Daltronics) in either linear (larger peptides) or reflectron (smaller peptides) mode. A N_2 laser was used to desorb/ionize the matrix/analyte material. Calibration was performed using angiotensin II (monoisotopic mass [MH^+] 1046.5423 Da), angiotensin I (monoisotopic mass [MH^+] 1296.6900 Da), bombesin (monoisotopic mass [MH^+] 1619.8229 Da), and adrenocorticotropic hormone clip 18−39 (monoisotopic mass [MH^+] 2465.2027 Da) (Sigma-Aldrich, St. Louis, MO).

RESULTS AND DISCUSSION

Development of PDK1 Cross Trans-Splicing Strategy. It has been underreported but overestablished that a majority of human protein kinases are poorly expressed and purified as inclusion bodies from both bacterial and yeast protein expression strains under a wide variety of growth and induction conditions. In addition, such kinase preparations have proven difficult to resolubilize into stable and active conformations. To date, baculovirus-mediated protein expression in either Sf9 or Sf21 insect cells has been the most effective method for generating high levels of soluble and active human protein kinases (*36*). Although the reason is not entirely clear, we observed that high production of the catalytic kinase domain constructs of PDK1, S6K1, and PKBβ, typically achieved by baculovirus-mediated expression in Sf9 insect cells, was severely attenuated when these constructs were fused with a C-terminal *active* intein (e.g., *Mxe* GyrA or VMA inteins available from New England Biolabs, Inc.) (unpublished results). In addition, the small amounts of expressed fusion protein (≤0.5 mg/200 mL Sf9 insect cell culture) were observed to be ≥80% hydrolyzed. Therefore, only very small quantities of N-kinase-intein fusion protein (≤0.1 mg/200 mL Sf9 insect cell culture) were available for thiolysis of the intein to generate the C-terminal thioester required for chemical ligation to the N-terminal cysteine residue of a C-terminal peptide fragment. Thus, we reasoned that high-level baculovirus-mediated expression in Sf9 insect cells of human catalytic kinase domains for engineered ligation could be better achieved if fused to an *inactive* intein fragment of a protein trans-splicing intein pair.

To date, the naturally occurring split *Ssp* DnaE intein (*38*−*40*) and the artificially split *Ssp* DnaB and *Sce* VMA inteins (*41*, *42*) have been best characterized with regard to achieving protein trans-splicing activity in the absence of protein refolding routines typically required of artificially split inteins. However, in all these cases, protein trans-splicing under native conditions has been compromised by competing cleavage of the protein trans-splicing reactants upon mixing, resulting in typical yields of only 40−50% spliced protein product. Encouragingly, highly efficient protein trans-splicing (≥98%) of two B1 domains of the IgG binding protein (GB1) was recently demonstrated when the His$_6$-GB1-(N)*Npu*DnaE and (C)*Ssp*DnaE-GB1 cross reacting trans-splicing constructs were coexpressed in *E. coli* (*37*). Since it is difficult to access contributions of endogenous chaperones and the reducing environment to the observed high splicing efficiency in *E. coli*, it became of immediate interest whether this highly efficient in vivo 'cross' trans-splicing strategy would translate to in vitro conditions.

Table 1. Purification of Recombinant KINASE(AEY)-(N)*Npu*DnaE-His$_6$ from Sf9 Insect Cells[a]

purification (step)	volume (mL)	concn (mg/mL)	yield (mg)	purification (fold)
crude lysate	50	2.2 ± 0.2	110 ± 10	N/A
Ni Sepharose	10	1.0 ± 0.2	10 ± 2	11

[a] All values are reported for purification from initial infection of 200 mL of insect Sf9 cells (2×10^6 cells/L) with recombinant baculovirus.

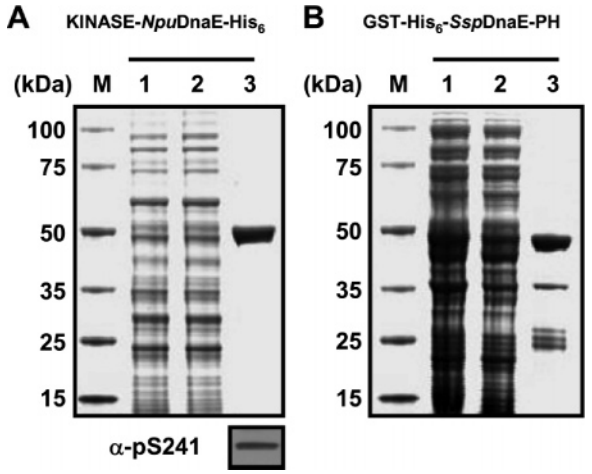

Figure 2. SDS-PAGE analysis of purification of protein trans-splicing reactants. (A) KINASE(AEY)-(N)*Npu*DnaE-His$_6$ was His$_6$ affinity purified from Sf9 insect cell lysate. (B) GST-His$_6$-(C)*Ssp*DnaE-(CMN)-PH was GST affinity purified from *E. coli* lysate. Lane 1 shows the total lysate; lane 2 shows protein species that were not retained by the affinity column, and lane 3 shows the affinity-purified recombinant protein trans-splicing construct. Molecular weight markers are indicated. Proteins were visualized by Coomassie staining.

Preparation of Cross Trans-Splicing Constructs. The KINASE(AEY)-(N)*Npu*DnaE-His$_6$ fusion construct of PDK1 (Figure 1) was generated by PCR and subcloned into the pFastBac1 vector for generation of recombinant baculovirus using the Bac-to-Bac Baculovirus Expression System (Invitrogen). Using MOI = 2 and a time of harvest 72 h after post infection, KINASE(AEY)-(N)*Npu*DnaE-His$_6$ was overexpressed and His$_6$ affinity purified, typically yielding 10 ± 2 mg from initial infection of 4×10^8 total Sf9 insect cells (Table 1). Figure 2A shows that the KINASE(AEY)-(N)*Npu*DnaE-His$_6$ was efficiently purified to ≥95% homogeneity (lane 3), as judged by Coomassie blue staining of 4−20% SDS-PAGE. Purified KINASE(AEY)-(N)*Npu*DnaE-His$_6$ migrates with an apparent molecular weight of 51 kDa, which agrees with its calculated molecular mass of 50 802 Da. Similar to the recombinant catalytic domain construct of PDK1 [His$_6$-PDK1(ΔPH), residues 51−359] (*5*), Western analysis showed that the KINASE(AEY)-(N)*Npu*DnaE-His$_6$ construct was purified in its Ser-241 phosphorylated and catalytically active form (Figure 2A, lower panel). The values of V_{max} = 200 ± 15 U/mg and $^{Tide}K_m$ = 70 ± 10 μM measured for KINASE(AEY)-(N)*Npu*DnaE-His$_6$-catalyzed phosphorylation of the model PDK1-Tide substrate were in the same range as those measured for native His$_6$-PDK1 (*36*).

The (C)*Ssp*DnaE-(CMN)PH fusion construct was cloned into pET-41b vector downstream of a GST-His$_6$ tag, yielding the coding sequence for the GST-His$_6$-(C)*Ssp*DnaE-(CMN)PH fusion protein (Figure 1). Recombinant protein expression of cell cultures (OD of 0.8) were induced with 0.5 mM IPTG for 16 h at 15 °C. Cell lysate from 1 L of culture was collected by homogenization, and GST affinity purification typically yielded 17 ± 3 mg total protein (Table 2). Figure 2B shows that the GST-His$_6$-(C)*Ssp*DnaE-(CMN)PH construct was purified to ∼60% homogeneity (lane 3), as judged by Coomassie blue staining of 4−20% SDS-PAGE. Affinity-purified GST-His$_6$-(C)*Ssp*DnaE-(CMN)PH showed anomalous slightly faster migration corresponding to an apparent molecular weight of 49 kDa compared with its calculated molecular mass of 51 214 Da. The ∼40% impurities retained after GST affinity purification of GST-His$_6$-(C)*Ssp*DnaE-(CMN)PH from the *E. coli* are primarily composed of a mixture of four protein species that migrate with apparent molecular weights of approximately 24, 25, 26, and 37 kDa, which were efficiently removed in subsequent chromatographic steps used to purify spliced-PDK1 from the trans-splicing reaction (see below).

Table 2. Purification of GST-His$_6$-(C)*Ssp*DnaE-(CMN)PH from *E. coli*[a]

purification (step)	volume (mL)	concn (mg/mL)	yield (mg)	purification (fold)
crude lysate	25	14 ± 2	350 ± 50	N/A
Ni Sepharose	10	1.7 ± 0.3	17 ± 3	21

[a] All values are reported for purification from expression in 1 L of *E. coli*.

PDK1 Cross Trans-Splicing Kinetics and Yield. Figure 3A shows the progress of protein trans-splicing that occurs over 12 h. The 10 mL protein trans-splicing reaction (21 °C) was initiated by combining 2 mmol of each of the protein trans-splicing reactants, KINASE(AEY)-(N)*Npu*DnaE-His$_6$ (species I) and GST-His$_6$-(C)*Ssp*Dna-(CMN)PH (species II) (∼20 μM each). SDS-PAGE with Coomassie staining shows decreasing band intensities corresponding to consumption of the trans-splicing reactants (species I and II) with a concomitant increasing band intensity corresponding to formation of full length spliced-PDK1 (species III). In addition, increasing band intensities were observed for formation of the cleaved affinity tagged intein constructs, GST-His$_6$-(C)*Ssp*Dna (species IV) and (N)-*Npu*DnaE-His$_6$ (species V). Densitometric analysis of multiple reaction gels indicated that PDK1 trans-splicing follows apparent first-order kinetics with $k_{obs} = (2.8 \pm 0.3) \times 10^{-5}$ s^{-1} (Figure 3B). This rate is approximately 10-fold slower than the $k_{obs} = (3.0 \pm 0.4) \times 10^{-5}$ s^{-1} reported for trans-splicing of the maltose binding protein and thioredoxin utilizing the native (N/C)-*Ssp*DnaE intein pair, which was also performed at room temperature (*40*). However, the fit of the kinetic data (Figure 3B) also indicated that the cross trans-splicing strategy facilitates a limiting reaction extent approaching 90 ± 10%. This is corroborated by observation of the faint band intensity indicated for KINASE(AEY) (species VI ≤ 5%), which results from trans-cleavage or hydrolysis of KINASE(AEY)-(N)*Npu*DnaE-His$_6$. The extent of the competing trans-cleavage reaction is significantly lower than those typically reported for the native (N/C)-*Ssp*Dna intein pair (*38*−*40*). Disappointingly, the trans-splicing reaction was much less efficient when performed at 4 °C.

Although the cross trans-splicing reaction at 21 °C should approach 90% yield, it was not reasonable to allow the reaction to proceed to such limits, as a $k_{obs} = (4.4 \pm 0.4) \times 10^{-6}$ s^{-1} was determined for KINASE(AEY)-(N)*Npu*DnaE-His$_6$ inactivation at 21 °C (Figure 3B). Thus, a reaction time of 18 h was selected as an optimal time for maximizing the yield of spliced-PDK1, while retaining significant enzyme stability and function (Figure 3C, lane 2). The reaction mixture was then buffer exchanged and subjected to His$_6$ affinity chromatography. Figure 3C (lane 3) shows that the cleaved affinity tagged intein constructs, GST-His$_6$-(C)*Ssp*Dna (species IV) and (N)*Npu*DnaE-His$_6$ (species V), as well as the remaining uncleaved KINASE-(AEY)-(N)*Npu*DnaE-His$_6$ and GST-His$_6$-(C)*Ssp*Dna-(CMN)PH reactants, were effectively retained by the column. In addition, three of the four contaminating protein impurities (24, 25, and 26 kDa) that copurified with GST-His$_6$-(C)*Ssp*Dna-(CMN)PH

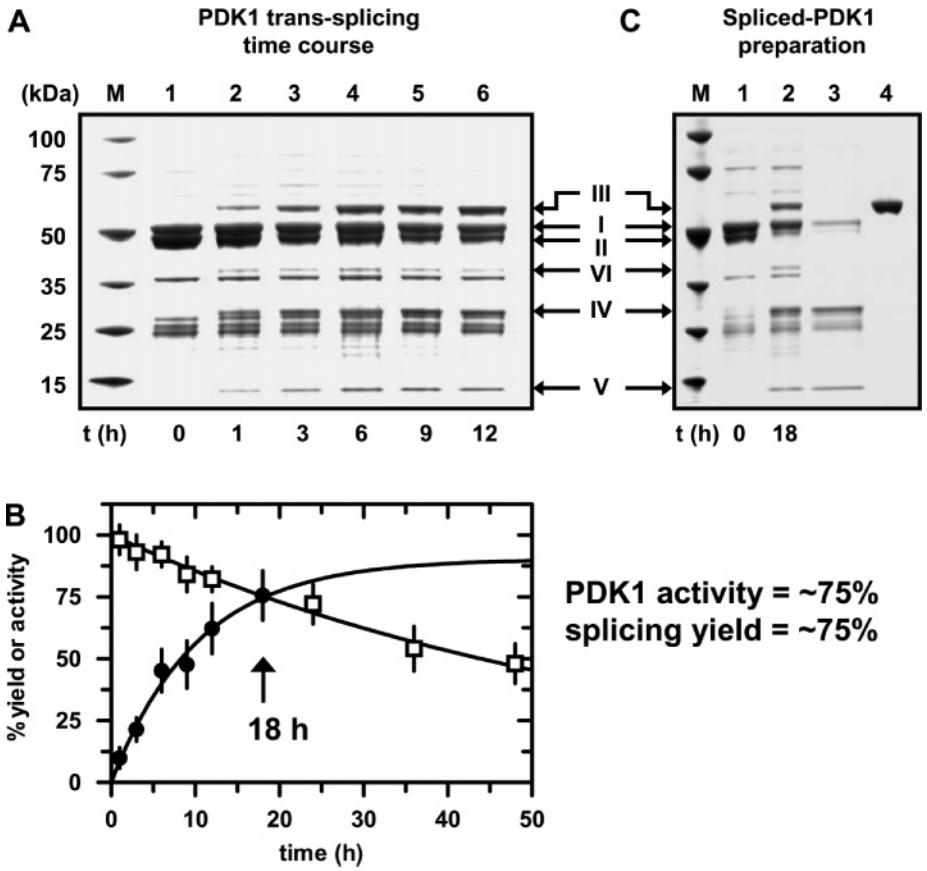

Figure 3. (A) Progress of PDK1 trans-splicing. Affinity-purified KINASE(AEY)-(N)*Npu*DnaE-His_6 and GST-His_6-(C)*Ssp*DnaE-(CMN)PH protein trans-splicing reactants were mixed and allowed to react at 21 °C. Aliquots of the reaction mixture were removed and analyzed by SDS-PAGE, which indicates the distribution of reactants and products at varying times of 0 h (lane 1), 1 h (lane 2), 3 h (lane 3), 6 h (lane 4), 9 h (lane 5), and 12 h (lane 6). (B) Time courses for KINASE(AEY)-(N)*Npu*DnaE-His_6 inactivation (□) and yield of spliced-PDK1 (●) at 21 °C. (C) Preparative amounts of trans-splicing reactants were mixed (lane 1) and allowed to react at 21 °C for 18 h (lane 2). Lane 3 shows the protein species in the reaction mixture that were retained by His_6 affinity chromatography. Lane 4 shows purified spliced-PDK1 (≥95%), which was resolved by MonoQ ion exchange chromatography from trace amounts of protein species that were not retained by His_6 affinity chromatography.

(Figure 3C, lane 3) were retained, suggesting that these may likely result from proteolytic degradation prior to cell lysis. Spliced-PDK1, the contaminating species (37 kDa), and the small amount of trans-cleaved KINASE(AEY), which were not retained by the His_6 affinity column were readily resolved by MonoQ ion exchange chromatography. Figure 3C (lane 4) shows that spliced-PDK1 is purified to ≥95% homogeneity. For this optimized preparative procedure, ∼1 mmol of purified spliced-PDK1 could be readily obtained from 2 mmol of each of the starting reactants.

PI(3,4,5)P_3-Dependent Phosphorylation of PKBβ by Spliced-PDK1. The best characterized function of the C-terminal PH domain of PDK1 is its ability to bind the PI(3,4,5)P_3 second messenger, causing its membrane colocalization with PKB, which also contains a PH domain that selectively binds PI(3,4,5)P_3 (*43*−*53*). At the membrane, PDK1 catalyzes phosphorylation of the critical residue in the activation loop of PKB, which is required for downstream PKB signaling activity. For the three known isoforms of PKB, the phosphorylation sites correspond to Thr-308, Thr-309, and Thr-305 in PKBα, PKBβ, and PKBγ, respectively. In vitro characterization of PDK1-catalyzed site-specific phosphorylation of PKB isoforms, which utilize phosphoinositide-containing vesicles, demonstrated an absolute requirement for PI(3,4,5)P_3-containing vesicles, as well as functional PH domains in both PDK1 and PKB (*45*, *46*, *50*). Since protein trans-splicing of the regulatory PH and catalytic kinase domains of PDK1 required mutation of ^{382}QFG^{384} to ^{382}AEY^{384} at the N-terminal side of the splice junction, as well as the Q387N mutation to give ^{385}CMN^{387} at the C-terminal side of the splice junction (Figure 1), it was very important to assess whether spliced-PDK1 retained the characteristic ability to specifically phosphorylate and activate PKB in a PI(3,4,5)P_3-dependent manner.

First, full length His_6-PKBβ was obtained by baculovirus-mediated expression and purification from Sf9 insect cells (*36*). As we have previously demonstrated, His_6-PKBβ purifies with minimal catalytic activity to the Crosstide substrate (∼0.3 U/mg) and displays very small but detectable amounts of both Thr-309 and Ser-474 phosphorylation, as detected by Western analysis (Figure 4A, lane 1). Previous isoelectric focusing studies, as well as ion exchange chromatography, could not resolve the phosphorylated isoforms, suggesting that the small detectable amount of phosphorylated His_6-PKBβ likely consists of a mixture of enzyme monophosphorylated either at Thr-309 or Ser-474 (*36*). Nevertheless, homogeneous unphosphorylated His_6-PKBβ with slightly lower Crosstide activity (∼0.2 U/mg) was readily generated by treatment with λPP (Figure 4A, lane 2). Western analysis further showed that λPP-treated unphosphorylated His_6-PKBβ did not catalyze autophosphorylation at either Thr-309 or Ser-474 when incubated in autophosphorylation reaction mixtures either in the absence (Figure 4A, lane 3) or presence of PI(3,4,5)P_3-containing vesicles (Figure 4A, lane 4). Most importantly, Western analysis detected significant Thr-309 phosphorylation of His_6-PKBβ only when incubated with spliced-PDK1 in the presence of PI(3,4,5)P_3-containing vesicles, and His_6-PKBβ catalytic activity to Crosstide increased ∼10-fold (Figure 4A, lanes 5 and 6). Affinity purification and phosphopeptide mapping of His_6-PKBβ from the phosphorylation reaction mixture containing both spliced-PDK1 and PI(3,4,5)P_3-containing vesicles (Figure 4A, lane 6) confirmed that

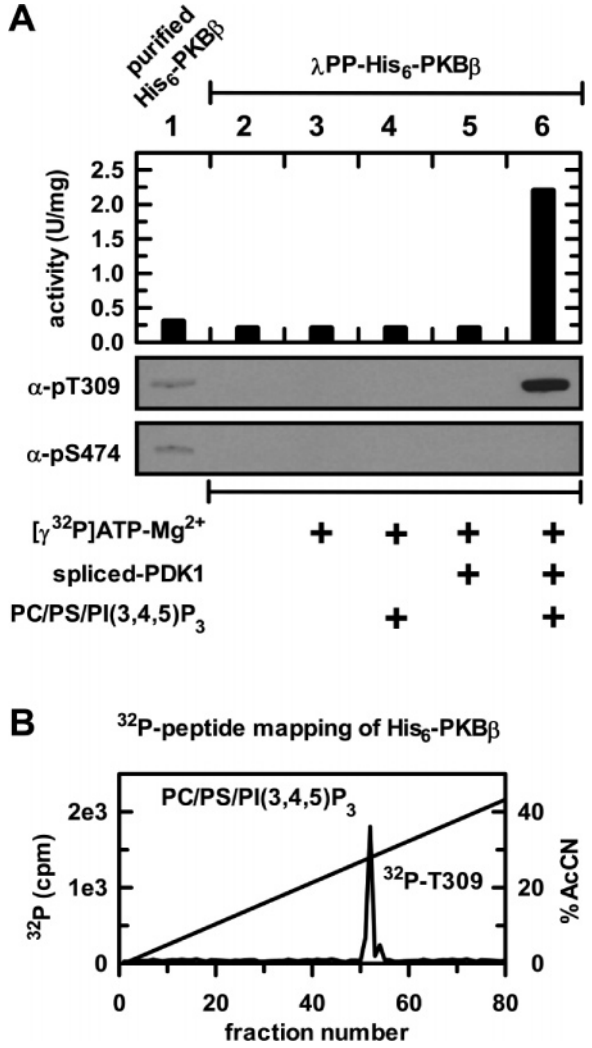

Figure 4. Site-specific Thr-309 phosphorylation by spliced-PDK1. (A) Preparation of His_6-PKBβ (lane 1), preparation of λPP-treated unphosphorylated His_6-PKBβ (lane 2), and affinity-purified λPP-treated His_6-PKBβ after 40 min incubation at 30 °C in phosphorylation reaction mixtures containing [γ-^{32}P]ATP-Mg^{2+} (lane 3), [γ-^{32}P]ATP-Mg^{2+} in the presence of PC/PS/PI(3,4,5)P_3 vesicles (lane 4), [γ-^{32}P]ATP-Mg^{2+} in the presence of spliced-PDK1 (lane 5), and [γ-^{32}P]ATP-Mg^{2+} in the presence of both spliced-PDK1 and PC/PS/PI(3,4,5)P_3 vesicles (lane 6). SDS-PAGE and Western analysis were used to visualize Thr-309 and Ser-474 phosphorylated His_6-PKBβ. Activities were determined for His_6-PKBβ-catalyzed phosphorylation of 100 μM of Crosstide (Ψ). (B) After 40 min incubation at 30 °C in the phosphorylation reaction mixture containing [γ-^{32}P]ATP-Mg^{2+}, affinity-purified λPP-treated His_6-PKBβ was digested with trypsin and subjected to reversed-phase HPLC. Scintillation counting of the individual fractions detected the ^{32}P-radiolabeled peptide that eluted near 28% acetonitrile, which was identified by MALDI-TOF (m/z = 2469.6) to be the monophosphorylated tryptic peptide containing Thr-309 (^{309}pTFCGTPEYLAPEVLEDNDYGR^{329}).

spliced-PDK1 catalyzed site-specific Thr-309 phosphorylation of His_6-PKBβ (Figure 4B), as no other ^{32}P-radiolabeled peptides were detected. The mole fraction of total phosphorylated sites (f_{mol}^{tot}) was calculated to be 0.65 ± 0.15, in agreement with previous reports (*50*).

PROSPECTIVE AND SUMMARY

Large efforts are being directed toward design of potent and selective inhibitors of well-established protein kinase drug targets (*54*, *55*). Since the overwhelming majority of protein kinase inhibitors bind in or near the ATP binding pocket shared by the structurally homologous catalytic domain shared by all kinases, very few serine-threonine protein kinase inhibitors have been clinically approved due to their broad specificity and overall high toxicity (*56*−*58*). Therefore, we are developing the hypothesis that serine-threonine protein kinase inhibitor selectivity may be better achieved by designing compounds that target interfacial clefts and crevices formed between contiguous regulatory and catalytic kinase domains, thereby 'allosterically' stabilizing inactive or autoinhibited conformations of multidomain protein kinases (*59*). In fact, validation of this hypothesis is exemplified by the recent discovery of the small molecule inhibitors, Akt-I-1 and Akt-I-1,2, which showed remarkable isozyme specificity toward PKB/Akt isozymes and did not significantly inhibit other closely related kinases (*60*). Most importantly, only the full length PKB/Akt isozymes containing the regulatory PH domain were sensitive to inhibition, suggesting an 'allosteric' mechanism in which high selectivity results from inhibitor binding at a site that stabilizes a PH domain-mediated autoinhibited form of the kinase.

The inability to obtain diffraction quality crystals for full length constructs of any of the large number of multidomain serine-threonine protein kinase drug targets suggests a large degree of conformational heterogeneity, which likely results from changes in relative orientations of contiguous regulatory and catalytic kinase domains. In order to better facilitate structure-based discovery or design of highly selective inhibitors (e.g., Akt-I-1 and Akt-I,2), development of alternative methodologies will be required to better understand autoinhibitory contiguous domain−domain interactions, and domain-specific incorporation of biophysical probes would greatly facilitate spectroscopic studies of these interactions in solution. Disappointingly, the use of intein-mediated chemical ligation for such purposes is largely precluded, as we found it difficult to purify from Sf9 insect cells adequate quantities of a number of protein kinases when fused with *active* inteins (e.g., *Mxe* GyrA and VMA). While the use of naturally [e.g., (N/C)*Ssp*DnaE] or artificially split intein pairs [e.g., (N/C)*Ssp*DnaB] circumvents decreased protein stability and intein self-cleavage issues during baculovirus-mediated expression in Sf9 insect cells, only 40−50% protein trans-splicing yields are typically achieved. On the basis of the recently reported highly efficient in vivo protein trans-splicing (≥98%) catalyzed between split DnaE inteins from two different organisms (*37*), we implemented and demonstrated that the 'cross' trans-splicing strategy was optimal for in vitro ligation of the regulatory PH and catalytic kinase domains of PDK1, and spliced-PDK1 was shown to retain the ability to specifically phosphorylate Thr-309 and activate PKBβ in a PI-(3,4,5)P_3-dependent manner. This bioconjugation strategy may prove useful for design of spectroscopic experiments to detect and characterize the elusive frontier of potential allosteric drug targeting sites, which may exist at interfacial clefts and crevices in flexible multidomain monomeric protein kinases.

Received January 23, 2007; Revised Manuscript Received May 13, 2007

In this paper, we describe the synthesis and the photophysical properties of two novel near-infrared (NIR) cyanine dyes (**NIR5.5-2** and **NIR7.0-2**) which are water soluble potential substitutes of the commercially available Cy 5.5 and Cy 7.0 fluorescent labels respectively. For each one of these cyanine dyes, the synthetic strategy relies on the postsynthetic derivatization of a cyanine precursor in order to introduce the key functionalities required for bioconjugation of these NIR fluorophores. For **NIR5.5-2**, a reactive amino group was acylated with an original trisulfonated linker for water solubility. For **NIR7.0-2**, a vinylic chlorine atom was derivatized through a $S_{RN}1$ reaction for the introduction of a monoreactive carboxyl group for labeling purposes. Unexpectedly, when these two fluorophores were closely associated within a peptidic architecture, mutual fluorescence quenching between **NIR5.5-2** and **NIR7.0-2** was observed both at 705 (**NIR5.5-2**) and 798 nm (**NIR7.0-2**). On the basis of this property, a novel internally quenched caspase-3-sensitive NIR fluorescent probe was prepared.

INTRODUCTION

During the past decade, intensive research efforts have been devoted to the design and synthesis of novel water-soluble fluorescent organic dyes for life science applications (*1*). Indeed, despite the multitude of commercially available fluorophores, new fluorophoric systems, especially those with spectral properties in the near-infrared (NIR) region, are hotly sought for emerging and more challenging biotechnology and biomedical applications such as genetic analysis, DNA sequencing, *in vivo* imaging, and proteomics (*2*, *3*). Thus, numerous long-wavelength fluorophores belonging to the BODIPY (*4*), rhodamine (*5*, *6*), oxazine (*7*), or cyanine dyes (*8*−*10*) have been recently reported. Because of their large molar extinction coefficients, moderate-to-high fluorescence quantum yields, and a broad wavelength tunability, cyanine dyes have received considerable attention and can be considered as the main class of NIR fluorescent probes for biological applications at present (*11*, *12*). Cy 5.5 **1** and Cy 7.0 **2** (Figure 1) are two of these NIR fluorescent cyanine dyes, widely used for such bioanalytical purposes and commercially available from GE Healthcare (formerly Amersham-Biosciences). Despite its good optical properties in the NIR range, the sulfobenzoindocyanine **1** is prepared through a low-yield (15% as described) and poorly reproducible synthetic route using 6-amino-1,3-naphthalenedisulfonic acid as starting material (*13*). Major synthetic difficulties are related to the poor solubility of this latter amino-naphthalene derivative in organic media. This synthetic bottleneck and the drastic reaction conditions required explain why only two bioconjugatable derivatives (i.e., amine-reactive succinimidyl ester and thiol-reactive maleimide) of this fluorescent marker are available at present. As far as the heptamethine cyanine dye **2** (*14*) is concerned, its poor chemical stability restrains its use as fluorescent marker in numerous site-specific biolabeling strategies, especially those requiring additional purification steps by RP-HPLC. To overcome this limitation, numerous studies have shown that incorporating a rigid cyclohexenyl (or cyclopentenyl) ring in the polymethine chain increases the stability of the resulting Cy 7.0 analogue (*15*−*17*). Furthermore, the central cyclohexenyl (or cyclopentenyl) group offers a reactive site for labeling biomolecules *via* substitution of its *meso*-chlorine atom by nucleophiles (metal alcoholates, amines, and thiols) bearing an additional functional group (amine or carboxylic acid) through a $S_{RN}1$ mechanism. Thus, a variety of water-soluble heptamethine cyanine dyes containing aryl-ether, aryl-thioether and alkyl-ether linkages have been prepared using this route (*18*−*21*). However, the susceptibility of most of these dyes to form nonfluorescent aggregates (*18*) limits their use as probes in biological analysis.

With the goal in mind to develop new bright, monofunctional, water-soluble NIR fluorophores suitable for bioconjugation and easily accessible through high-yielding synthetic routes, we have explored an original approach to prepare Cy 5.5 and Cy 7.0 analogues based on the postsynthetic derivatization of cyanine precursors ("convertible cyanine dyes") readily available through standard cyanine synthesis protocols. This synthetic methodology has been already applied to the chemical derivatization of heptamethine cyanine dyes but never extended to cyanine dyes bearing a shorter polyene chain. We thought that the introduction of the key functionalities of a bioconjugatable NIR fluorophore (for instance hydrophilic moieties for water solubility or functional reactive groups for covalent attachment to biomolecules) in the last step of the synthetic process should improve its synthesis because the time-consuming handling and RP-HPLC purification of highly polar materials will be reduced only to the final dye product. Furthermore, both the level of byproducts resulting from interference of the functional reactive groups with the reagents currently used to achieve the condensa-

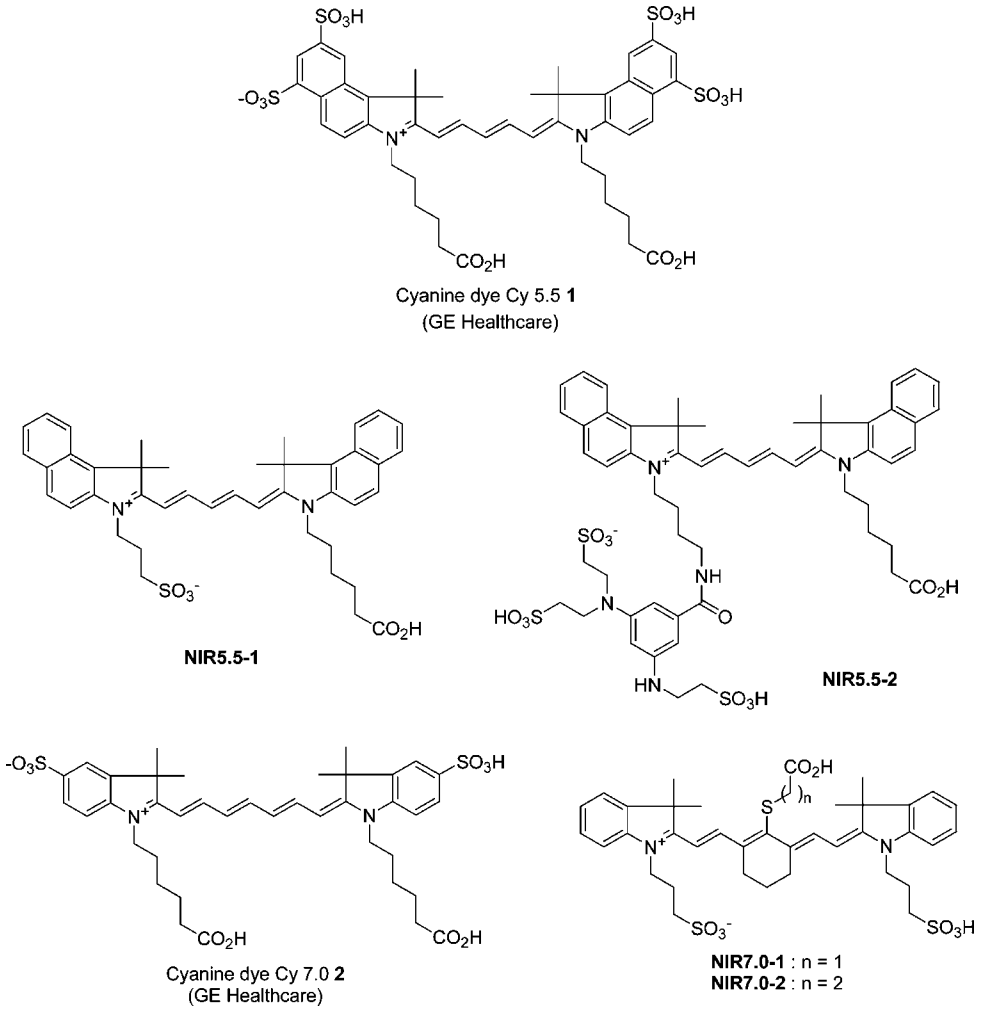

Figure 1. Structures of cyanine dyes Cy 5.5 and Cy 7.0 and their novel analogues studied in this work. An unsymmetrical derivative of cyanine dye Cy 5.5 **1** bearing the ethyl and carboxypentyl substituents is also commercially available, but its synthesis is not described in the literature.

tion reaction leading to the cyanine dye, and the limitation associated with drastic reaction conditions on those fragile polyconjugated scaffolds, should be minimized and consequently the overall yield of the synthesis significantly improved.

We describe here the synthesis and properties of two such novel NIR cyanine fluorophores **NIR5.5-2** and **NIR7.0-2** which are analogues of Cy 5.5 **1** and Cy 7.0 **2**, respectively. These two dyes display absorption and emission maxima in the NIR region, large extinction coefficients, excellent solubility, and no tendency to self-aggregate in aqueous solutions. Their conversion into thiol- and amine-reactive derivatives is also described. The utility of these latter fluorescent labeling reagents is illustrated by the preparation of an internally quenched fluorescent probe of caspase-3 protease.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. Column chromatography was performed on silica gel (40−63 μm) from SdS. Reversed-phase column flash-chromatography was performed on octadecyl-functionalized silica gel (mean pore size 60 Å) from Aldrich or Whatmann. TLC was carried out on Merck DC Kieselgel 60 F-254 aluminum sheets and visualized by employing a short wavelength UV lamp (i.e., λ = 254 nm). DMF was dried by distillation over BaO. DIEA, pyridine, and triethylamine were distilled from CaH_2 and stored over BaO. Chloro-substituted heptamethine sulfocyanine dye **12** was prepared from 2,3,3-trimethyl-3*H*-indole by using the multistep synthetic procedure developed by Strekowski et al. (*20*). Cyanine-based amino acid **6** was prepared in five steps from 1,1,2-trimethyl-1*H*-benz[*e*]-indole by using the convergent synthetic scheme recently reported by us (*22*, *23*). Malonaldehyde dianilido hydrochloride, sodium 2-bromoethanesulfonate, *N*-succinimidyl[4-iodoacetyl]-aminobenzoate (SIAB), sulfocyanine dye Cy 5.0, 1,1,2-trimethyl-1*H*-benz[*e*]indole and its derivatives *N*-(3-sulfonatopropyl)-1,1,2-trimethylbenzindolinium, inner salt **3**, and *N*-(γ-carboxypentyl)-1,1,2-trimethylbenzindolinium, bromine salt **4**, were prepared by using literature procedures (*14*, *24*−*29*). Hexapeptide Ac-Cys(StBu)-Asp-Glu-Val-Asp-Lys-NH_2 **16** was synthesized on an automated peptide synthesizer (ABI 433A, Applied Biosystems) using the stepwise solid-phase synthesis method and Fmoc amino acids, as previously described (*30*). Indocyanine green (ICG or IR-125, laser grade) was purchased from Acros. Recombinant human caspase-3 enzyme (5.52 U/mg) and Bovine Serum Albumin (BSA, ≥98%) were purchased from Sigma. The HPLC grade solvents (CH_3CN and MeOH) were obtained from Acros. Aqueous buffers for HPLC were prepared using water purified with a Milli-Q system. Triethylammonium acetate (1.0 M) (TEAA) and triethylammonium bicarbonate (1.0 M) (TEAB) buffers were prepared from distilled triethylamine and glacial acetic acid or CO_2 gas.

Instruments. ^1H and ^{13}C NMR spectra were recorded on a Bruker DPX 300 (Bruker, Wissembourg, France). Chemical shifts are expressed in parts per million (ppm) from D_2O (δ_H = 4.79) or DMSO-d_6 (δ_H = 2.54, δ_C = 40.45) (*31*). *J* values are expressed in Hz. Analytical HPLC was performed on a Thermo Electron Surveyor instrument equipped with a PDA

detector. Semipreparative HPLC was performed on a Finnigan SpectraSYSTEM liquid chromatography system equipped with a UV-Visible 2000 detector. UV−visible spectra were obtained on a Varian Cary 50 scan spectrophotometer. Fluorescence spectroscopic studies were performed either in a semi-micro fluorescence cell (Hellma, 104F-QS, 10 × 4 mm, 1400 μL) or in an ultra-micro fluorescence cell (Hellma, 105.51-QS, 3 × 3 mm, 45 μL) with a Varian Cary Eclipse spectrophotometer. Mass spectra were obtained with a Finnigan LCQ Advantage MAX (ion trap) apparatus equipped with an electrospray source. The purified peptides were characterized by MALDI-TOF mass spectrometry on a Voyager DE PRO in the reflector mode with CHCA as a matrix.

HPLC Separations. Several chromatographic systems were used for the analytical experiments and the purification steps. Each one of these systems was optimized in order to improve separation conditions.

System A: RP-HPLC (Thermo Hypersil GOLD C_{18} column, 5 μm, 4.6 × 150 mm) with CH_3CN and 0.1% aq trifluoroacetic acid (aq TFA, 0.1%, v/v, pH 2.0) as eluents, at a flow rate of 1 mL/min, with the following gradients:

A1: [80% TFA (5 min), linear gradient from 20 to 40% (5 min) and 40 to 100% (50 min) of CH_3CN]. Triple UV-visible detection was achieved at 260, 650, and 675 nm.

A2: [80% TFA (5 min), linear gradient from 20 to 30% (5 min) and 10 to 90% (50 min) of CH_3CN]. Triple UV-visible detection was achieved at 260, 650, and 675 nm.

A3: [80% TFA (5 min), linear gradient from 20 to 60% (30 min) of CH_3CN]. Dual UV-visible detection was achieved at 260 and 750 nm.

A4: [100% TFA (5 min), linear gradient from 0 to 60% (40 min) of CH_3CN]. Dual UV-visible detection was achieved at 260 and 750 nm.

System B: RP-HPLC (Thermo Hypersil GOLD C_{18} column, 5 μm, 4.6 × 150 mm) with CH_3CN and aq triethylammonium acetate buffer (TEAA, 0.1 M, pH 7.0) as eluents [100% TEAA (10 min), linear gradient from 0 to 60% (30 min) of CH_3CN] at a flow rate of 1 mL/min. Dual UV detection was achieved at 260 and 330 nm.

System C: RP-HPLC (Varian Kromasil C_{18} column, 10 μm, 21.2 × 250 mm) with CH_3CN and aq triethylammonium bicarbonate buffer (TEAB, 50 mM, pH 7.5) as eluents [100% TEAB (20 min), linear gradient from 0 to 30% (60 min) of CH_3CN] at a flow rate of 20 mL/min. Dual UV detection was achieved at 255 and 335 nm.

System D: RP-HPLC (Thermo Hypersil GOLD C_{18} column, 5 μm, 10 × 250 mm) with CH_3CN and 0.1% aq trifluoroacetic acid (aq TFA, 0.1%, v/v, pH 2.0) as eluents, at a flow rate of 5 mL/min, with the following gradients:

D1: [90% TFA (5 min), linear gradient from 10 to 30% (10 min) and 30 to 70% (55 min) of CH_3CN]. UV detection was achieved at 260 nm.

D2: [90% TFA (5 min), linear gradient from 10 to 40% (15 min) and 40 to 70% (40 min) of CH_3CN]. UV detection was achieved at 260 nm.

System E: RP-HPLC (Varian Kromasil C_{18} column, 10 μm, 21.2 × 250 mm) with CH_3CN and 0.1% aq TFA as eluents [95% TFA (5 min), linear gradient from 5 to 25% (5 min) and 5 to 75% (70 min) of CH_3CN] at a flow rate of 20 mL/min. UV-visible detection was achieved at 780 nm.

System F: RP-HPLC (Waters XTerra MS C_{18} column, 5 μm, 7.8 × 100 mm) with CH_3CN and 0.1% aq TFA as eluents, at a flow rate of 2.5 mL/min, with the following gradients:

F1: [100% TFA (5 min), linear gradient from 0 to 36% (18 min) and 36 to 60% (24 min) of CH_3CN]. UV detection was achieved at 260 nm.

F2: [100% TFA (5 min), linear gradient from 0 to 30% (15 min) and 30 to 60% (60 min) of CH_3CN]. Triple UV-visible detection was achieved at 260, 675 and 778 nm.

F3: [100% TFA (5 min), linear gradient from 0 to 30% (15 min), 30 to 35% (10 min) and 35 to 60% (125 min) of CH_3CN]. Dual UV-visible detection was achieved at 675 and 778 nm.

Preparation of NIR5.5-1. *(a) Hemicyanine Intermediate 5*. A solution of *N*-(3-sulfonatopropyl)-1,1,2-trimethylbenzindolinium, inner salt **3** (1 g, 3.0 mmol) and malonaldehyde dianilido hydrochloride (0.88 g, 3.42 mmol) in a mixture of acetic acid (5 mL) and acetic anhydride (5 mL) was heated under reflux. The reaction was checked for completion by UV-visible spectroscopy (the absorption maximum of **3** at $\lambda = 380$ nm has declined whereas the absorption maximum of hemicyanine intermediate **5** has appeared at $\lambda = 455$ nm). After 90 min, the reaction mixture was evaporated under reduced pressure without heating above 40 °C (to avoid the formation of some symmetrical dye). The resulting residue was dissolved in water and lyophilized. The crude hemicyanine intermediate was used without further purification in the next reaction.

(b) Preparation of Cyanine Dye. A solution of crude hemicyanine intermediate **5** (1.44 g, 2.77 mmol) and *N*-(γ-carboxypentyl)-1,1,2-trimethylbenzindolinium, bromine salt **4** (1.11 g, 2.77 mmol) in a mixture of acetic anhydride (5 mL) and dry pyridine (5 mL) was heated under reflux for 30 min. The reaction was checked for completion by UV-visible spectroscopy (the absorption maximum of **5** at $\lambda = 455$ nm has disappeared whereas the absorption maximum of cyanine dye **NIR5.5-1** has appeared at $\lambda = 679$ nm). The reaction mixture was evaporated under reduced pressure, dissolved in water, and lyophilized to give a blue solid (2.86 g). One gram of this crude product was purified by chromatography on a silica gel column (40 g) with a step gradient of MeOH (0−5%) in dichloromethane as the mobile phase. After drying under vacuum, **NIR5.5-1** was obtained as a blue solid (0.67 g, 0.97 mmol, yield 80%). $R_f = 0.35$ (CH_2Cl_2/MeOH 9/1, v/v). ^{1}H NMR (300 MHz, DMSO-d_6): δ 8.52 (t, 2H, $J = 13.2$ Hz), 8.29 (d, 2H, $J = 8.7$ Hz), 8.11 (m, 4H), 7.86 (d, 1H, $J = 9.0$ Hz), 7.77 (d, 1H, $J = 9.0$ Hz), 7.71 (t, 2H, $J = 7.5$ Hz), 7.54 (t, 2H, $J = 7.5$ Hz), 7.32 (s, 1H, NH), 7.15 (s, 1H, NH), 6.98 (s, 1H, NH), 6.65 (t, 1H, $J = 12.4$ Hz), 6.55 (d, 1H, $J = 13.9$ Hz), 6.41 (d, 1H, $J = 13.6$ Hz), 4.43 (m, 2H), 4.27 (m, 2H), 2.67 (t, 2H, $J = 6.4$ Hz), 2.25 (t, 2H, $J = 6.8$ Hz), 2.11−2.05 (m, 2H), 2.01 (s, 6H, Me), 1.99 (s, 6H, Me), 1.81−1.46 (m, 6H). HPLC (system A1): $t_R = 20.5$ min, purity >95%. UV-visible (DMSO, 25 °C): $\lambda_{max} = 688$ nm (147 000 M^{-1} cm^{-1}). UV-visible (EtOH, 25 °C): $\lambda_{max} = 681$ nm (156 000 M^{-1} cm^{-1}). Φ_F (DMSO, 25 °C): 0.27. Φ_F (EtOH, 25 °C): 0.17. MS (ESI, positive mode): *m/z* 691.40 $[M + H]^+$, 713.47 $[M + Na]^+$, 1381.40 $[2M + H]^+$, 1404.53 $[2M + Na]^+$, calcd exact mass for $C_{42}H_{46}N_2O_5S$ 690.91.

Trisulfonated Linker (9). A mixture of 3,5-diaminobenzoic acid (0.25 g, 1.6 mmol), sodium 2-bromoethanesulfonate (1.39 g, 6.6 mmol), KI (0.29 g, 1.8 mmol), and NaOH (64 mg, 1.6 mmol) in deionized water (3 mL) was heated under reflux for 4 days. After 24 and 48 h, further amounts of sodium bromoethanesulfonate (2 × 1.34 g, 2 × 6.4 mmol) and NaOH (2 × 0.64 mL of an aq 5 N solution, 2 × 3.2 mmol) were added. The reaction was checked for completion by RP-HPLC (system B) and purified by RP-HPLC (system C, 12 injections). The product-containing fractions were twice lyophilized (to remove excess of TEAB salts) to give **9** as a highly hygroscopic white powder (yield 36%). ^{1}H NMR (300 MHz, D_2O): δ 6.78 (s, 1H), 6.71 (s, 1H), 6.32 (s, 1H), 3.77 (m, 6H, N−CH_2−CH_2-SO_3^-), 3.11 (m, 30H, TEA & N$CH_2CH_2SO_3^-$), 1.21 (t, 36H, TEA, $J = 7.2$ Hz). ^{13}C NMR (75.5 MHz, D_2O): δ 175.1, 148.8, 147.7, 138.7, 104.9, 104.2, 100.8, 49.8 (2C), 48.3 (4C),

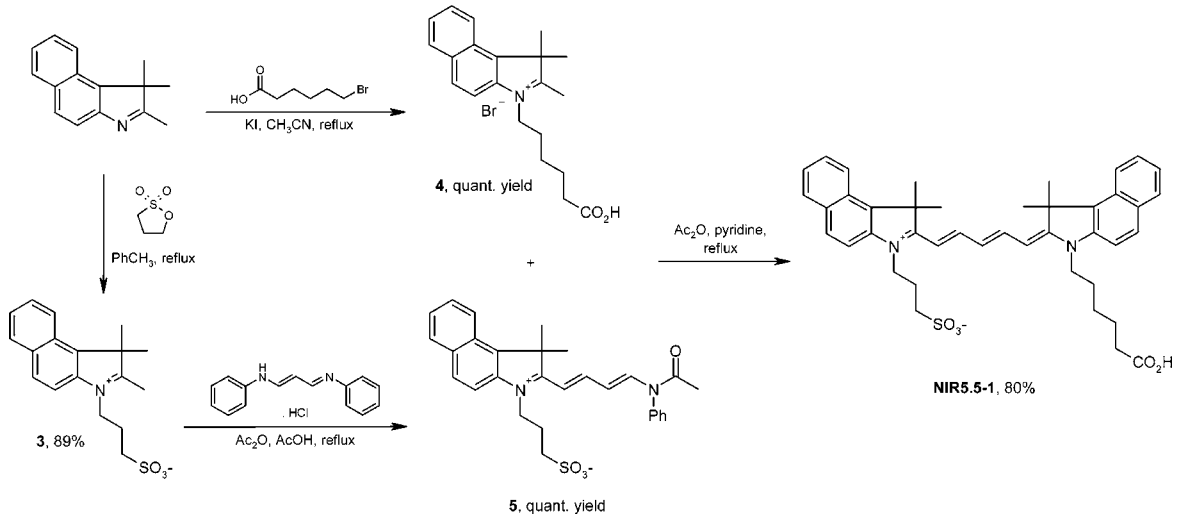
48.1 (4C), 46.9 (12C), 39.9 (2C), 8.5 (12C). HPLC (system B): $t_R = 7.0$ min. MS (ESI, negative mode): *m/z* 157.93 $[M - 3H]^{3-}$, 237.33 $[M - 2H]^{2-}$, 475.20 $[M - H]^-$, calcd for $C_{13}H_{20}N_2O_{11}S_3$ (acid form) 476.50.

Preparation of Trisulfonated Linker, Succinimidyl Ester (10). A mixture of trisulfonated linker **9** (50 mg, 56.7 μmol) and *N*-hydroxysuccinimide (7.2 mg, 62.0 μmol) was dissolved in dry DMF (100 μL). DCC (12.8 mg, 62.0 μmol) was added, and the resulting reaction mixture was stirred at room temperature for 20 h. After 3 h, further amounts of *N*-hydroxysuccinimide (5.8 mg, 50.8 μmol) and DCC (10.7 mg, 50.8 μmol) were added. The reaction was checked for completion by RP-HPLC (system B), and the resulting succinimidyl ester **10** was used without further purification. HPLC (system B): $t_R = 17.8$ and 18.6 min (broad peak, compared to $t_R = 7.0$ min for the free acid **9**). Two peaks are observed due to a counterion effect with the triethylammonium cations of HPLC eluent.

NIR5.5-2. A solution of cyanine-based amino acid **6** (39.5 mg, 45.5 μmol) in dry NMP (1 mL) was added to the solution of crude succinimidyl ester **10** (56.7 μmol) and DIEA (57.6 μL, 330 μmol). The resulting reaction mixture was protected from light and stirred at room temperature for 24 h. The reaction was checked for completion by RP-HPLC (system A1). Finally, the reaction mixture was quenched by dilution with aq TFA 0.1% and purified by RP-HPLC (system D1, 6 injections). Two products identified as the Cy 5.5 analogue **NIR5.5-2** (t_R = 27.0−28.8 min) and its corresponding succinimidyl ester **11** (29.4−31.2 min) were isolated. The product-containing fractions were lyophilized to give **NIR5.5-2** and **11** as blue amorphous powders (combined yield 70%). ^{1}H NMR (300 MHz, DMSO-d_6 + TFA): δ 8.56 (m, 2H), 8.47 (t, 1H, $J = 12.8$ Hz), 8.27 (m, 2H), 8.11 (m, 4H), 7.84−7.68 (m, 4H), 7.53 (m, 2H), 7.28 (bs, NH), 7.07 (bs, 1H, NH), 7.01 (bs, 1H, NH), 6.89 (bs, 1H, NH), 6.72 (t, 1H, $J = 12.5$ Hz), 6.44 (dd, 2H), 4.28 (m, 4H), 3.75 (m, 6H, $NCH_2CH_2SO_3^-$), 2.83 (m, 2H), 2.72 (m, 6H, $NCH_2CH_2SO_3^-$), 2.24 (t, 2H, $J = 7.2$ Hz), 1.99 (s, 12H), 1.83−1.01 (m, 10H). All spectroscopic characterizations are reported only for the free acid **NIR5.5-2** except for the HPLC and MS analyses. HPLC (system A1): $t_R = 17.8$ min (**NIR5.5-2**), 18.9 min (**11**). UV-visible (PBS, pH 7.4, 25 °C): $\lambda_{max} = 680$ nm (197 000 M^{-1} cm^{-1}). UV-visible (DMSO, 25 °C): $\lambda_{max} = 688$ nm (147 000 M^{-1} cm^{-1}). Φ_F (PBS, pH 7.4, 25 °C): 0.05. Φ_F (DMSO, 25 °C): 0.05. MS (MALDI-TOF, positive mode, CHCA matrix): *m/z* 1098.89 $[M + H]^+$. MS (ESI, negative mode): *m/z* 400.93 $[M - 3H+TEA]^{3-}$, 601.87 $[M - 2H+TEA]^{2-}$, calcd for $C_{56}H_{66}N_5O_{12}S_3$ (**NIR5.5-2**, acid form) 1097.37. MS (MALDI-TOF, positive mode, CHCA matrix): *m/z* 1195.93 $[M + H]^+$, calcd for $C_{60}H_{70}N_6O_{14}S_3$ (**11**, acid form) 1195.45.

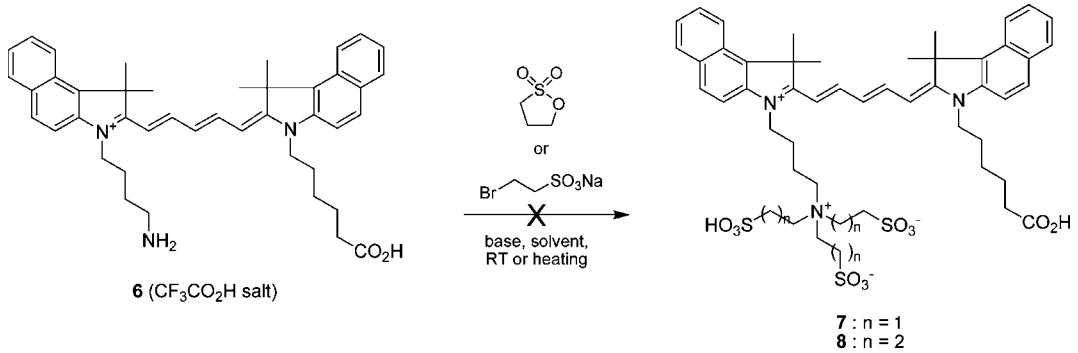
Preparation of Thiol-Reactive NIR5.5-2 Derivative (15). *(a) Preparation of **NIR5.5-2** Carboxylic Acid, Succinimidyl Ester **11**.* Free carboxylic acid dye **NIR5.5-2** (10.5 mg, 9.6 μmol) was introduced into a Reacti-Vial and dissolved in 140 μL of dry NMP. A 20 μL amount of a solution of TSTU reagent in dry NMP (2.88 mg, 9.6 μmol) and 11.7 μL of DIEA (67.2 μmol) were added, and the resulting reaction mixture was protected from light and stirred at room temperature for 1 h. The reaction was checked for completion by RP-HPLC (system A1) and the resulting succinimidyl ester **11** was used without further purification. HPLC (system A1): t_R = 18.8 min (compared to $t_R = 17.8$ min for **NIR5.5-2** carboxylic acid, *vide supra*).

*(b) Synthesis of **NIR5.5-2** Amine **14**.* Ethylenediamine dihydrochloride (150 mg, 1.152 mmol) was dissolved in a mixture of deionized water (0.9 mL) and DMF (10 mL). The crude reaction mixture containing the succinimidyl ester **11** and a 10% solution of DIEA in DMF (0.9 mL, 537 μmol) were sequentially added, and the resulting reaction mixture was protected from light and stirred at room temperature for 1 h. The reaction was checked for completion by RP-HPLC (system A1), and the mixture was evaporated to dryness. The resulting residue was purified by RP-HPLC (system D2, 2 injections). The product-containing fractions were lyophilized to give the **NIR5.5-2** amine **14** as a blue amorphous powder (8.0 mg, yield 73%). HPLC (system A1): $t_R = 16.6$ min, purity >95%. MS (MALDI-TOF, positive mode, CHCA matrix): *m/z* 1140.98 $[M + H]^+$, calcd exact mass for $C_{58}H_{73}N_7O_{11}S_3$ 1140.46.



*(c) Preparation of **NIR5.5-2** SIAB Derivative **15**.* **NIR5.5-2** amine **14** (3.3 μmol) was dissolved in NMP (200 μL). $NaHCO_3$ (2.7 mg, 32.1 μmol) and a solution of SIAB reagent (2.5 mg, 6.3 μmol) in NMP (200 μL) were sequentially added. Thereafter, 0.1 M $NaHCO_3$ buffer (pH 8.5, 1 mL) was added, and the resulting reaction mixture was protected from light and stirred at room temperature for 2 h. The reaction was checked for completion by RP-HPLC (system A2). Finally, the reaction mixture was quenched by dilution with aq TFA 0.1% and purified by RP-HPLC (system D2, 2 injections). The product-containing fractions were lyophilized to give the thiol-reactive **NIR5.5-2** derivative **15** as a blue amorphous powder (3.8 mg, yield 80%). HPLC (system A2): $t_R = 23.2$ min (broad peak). Φ_F (PBS, pH 7.4, 25 °C): 0.056. Φ_F (DMSO, 25 °C): 0.145. MS (MALDI-TOF, positive mode, CHCA matrix): *m/z* 1299.96 $[(M - I)+H]^+$, 1427.85 $[M + H]^+$, calcd exact mass for $C_{67}H_{79}IN_8O_{13}S_3$ 1427.52.

NIR7.0-2. A mixture of crude chloro-substituted heptamethine sulfocyanine dye **12** (220 mg, 0.31 mmol) and 3-mercaptopropionic acid (107 μL, 1.22 mmol) in dry DMF (15 mL) was heated under reflux for 40 min. The reaction was checked for completion by RP-HPLC (system A3), and the mixture was evaporated to dryness. The resulting residue was purified by RP-HPLC (system E, three injections, t_R = 24.5−26.5 min). The product-containing fractions were lyophilized to give **NIR7.0-2** as a green amorphous powder (187 mg, 0.24 mmol, yield 80%). ^{1}H NMR (300 MHz, DMSO-d_6 + TFA-d_1): δ 8.70 (d, 2H, $J = 13.9$ Hz), 7.58 (d, 2H, $J = 7.5$ Hz), 7.49−7.37 (m, 4H), 7.24 (t, 2H, $J = 7.5$ Hz), 6.48 (d, 2H, $J = 13.9$ Hz), 4.34 (bt, 4H, $N^+CH_2CH_2CH_2SO_3^-$), 2.99 (t, 2H, $J = 6.8$ Hz), 2.66−2.49 (m, 10H), 2.05−1.80 (m, 6H), 1.68 (s, 12H). HPLC (system A3): $t_R = 20.6$ min, purity > 95%. HPLC (system A4): t_R = 34.6 min, purity >95%. UV-visible (PBS, pH 7.4, 25 °C): λ_{max} = 777 nm (120 000 M^{-1} cm^{-1}). UV-visible (DMSO, 25 °C): $\lambda_{max} = 802$ nm (146 000 M^{-1} cm^{-1}). UV-visible (EtOH, 25 °C): $\lambda_{max} = 790$ nm (171 000 M^{-1} cm^{-1}). Φ_F (PBS, pH 7.4, 25 °C): 0.025. Φ_F (DMSO, 25 °C): 0.092. MS (ESI, positive mode): *m/z* 769.60 $[M + H]^+$, MS (ESI, negative mode): *m/z* 767.80 $[M - H]^-$, calcd exact mass for $C_{39}H_{48}N_2O_8S_3$ 769.02.

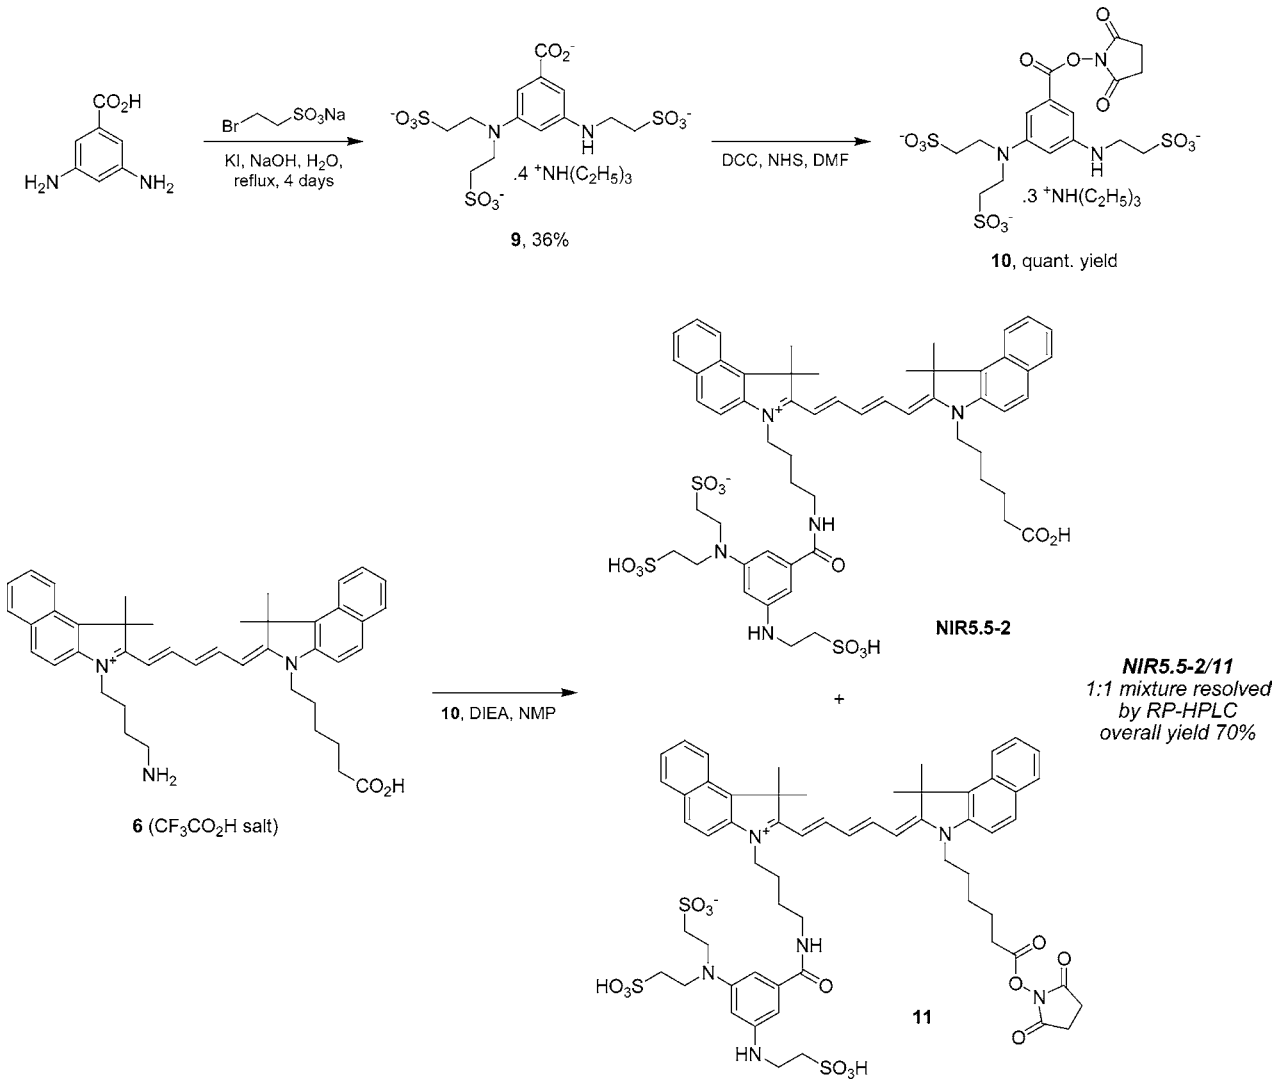


Preparation of NIR7.0-2 Carboxylic Acid, Succinimidyl Ester (13). NIR7.0-2 carboxylic acid (4.12 mg, 5.36 μmol) was introduced into a Reacti-Vial and dissolved in 50 μL of dry NMP. A 50 μL amount of a solution of TSTU reagent in dry NMP (1.94 mg, 6.45 μmol) and 1.86 μL of DIEA (10.72 μmol) were added, and the resulting reaction mixture was protected from light and stirred at room temperature for 35 min. The reaction was checked for completion by RP-HPLC (system A4), and the resulting succinimidyl ester **13** was used without further purification. HPLC (system A4): $t_R = 35.6$ min (compared to $t_R = 34.6$ min for **NIR7.0-2** carboxylic acid, *vide supra*).

Synthesis of Ac-Cys(StBu)-Asp-Glu-Val-Asp-Lys(NIR7.0-2)-NH_2(17). A 5.66 mg amount of crude peptide Ac-Cys(StBu)-Asp-Glu-Val-Asp-Lys-NH_2 **16** (5.95 μmol, weighed in a 1.0 mL Eppendorf tube) was dissolved in 100 μL of dry NMP, and 4.14 μL of DIEA (23.76 μmol) was added. After complete solubilization by vortexing, the resulting solution was added to the crude reaction mixture containing the succinimidyl ester of

Scheme 1

Scheme 2



NIR7.0-2. The resulting reaction mixture was protected from light and stirred at room temperature for 1 h. The reaction was checked for completion by RP-HPLC (system A4). Finally, the reaction mixture was quenched by dilution with 1 mL of aq TFA 0.1% and purified by RP-HPLC (system F1, 2 injections, t_R = 27.0−28.5 min). The product-containing fractions were lyophilized to give the peptide-**NIR7.0-2** conjugate **17** as a green amorphous powder. Quantification was achieved by UV-visible measurements at λ_{max} = 777 nm of **NIR7.0-2** by using the ϵ value 120 000 M^{-1} cm^{-1} (yield estimated after RP-HPLC purification: 60%). HPLC (system A4): t_R = 35.0 min, purity 91%. MS (MALDI-TOF, positive mode, CHCA matrix): *m/z* 796.78 $[M + 2H]^{2+}$, 1590.03, $[M + H]^+$, 1625.99 $[M + K]^+$. MS (ESI, positive mode): *m/z* 825.00 $[M + Na + K]^{2+}$, 1609.60 $[M + Na]^+$, 1625.67 $[M + K]^+$, calcd exact mass for $C_{72}H_{102}N_{10}O_{20}S_5$ 1587.99.

Removal of *tert*-butylthio Group. Peptide Ac-Cys(StBu)-Asp-Glu-Val-Asp-Lys(**NIR7.0-2**)-NH_2 **17** (5.7 mg, 3.6 μmol) was introduced into a Reacti-Vial and dissolved in 0.1 M $NaHCO_3$ buffer (pH 8.5, 250 μL). A solution of DTT (8.03 mg in 500 μL, 52.1 μmol) in 0.1 M $NaHCO_3$ buffer (pH 8.5) was added. The reaction mixture was protected from light and stirred at room temperature for 2 h. The reaction was checked for completion by RP-HPLC (system A4). Finally, the reaction mixture was quenched by dilution with aq TFA 0.1% (1 mL) and purified by RP-HPLC (system F1, 2 injections, t_R = 26.5−27.5 min). The product-containing fractions were lyophilized to give the free sulfhydryl containing peptide-**NIR7.0-2** conjugate **18** as a green amorphous powder. Quantification was achieved by UV-visible measurements at λ_{max} = 777 nm of **NIR7.0-2** by using the ϵ value 120 000 M^{-1} cm^{-1} (estimated quantitative yield after RP-HPLC purification). HPLC (system A4): t_R = 33.8 min, purity >95%. MS (ESI, positive mode): *m/z* 752.13 $[M + 2H]^{2+}$, 1502.67 $[M + H]^+$; MS (ESI, negative mode): *m/z* 1500.60 $[M - H]^-$, calcd exact mass for $C_{68}H_{94}N_{10}O_{20}S_4$ 1499.82.

Synthesis of Ac-Cys(NIR5.5-2)-Asp-Glu-Val-Asp-Lys-(NIR7.0-2)-NH_2 (19). Peptide Ac-Cys-Asp-Glu-Val-Asp-Lys-(**NIR7.0-2**)-NH_2 **18** (2.3 mg, 1.56 μmol) was introduced into a Reacti-Vial and dissolved in 0.1 M $NaHCO_3$ buffer (pH 8.5, 200 μL). A 300 μL amount of a solution of iodoacetyl derivative **15** (0.75 mg, 0.52 μmol) in 0.1 M $NaHCO_3$ buffer (pH 8.5) was added. The reaction mixture was protected from light and stirred at room temperature for 2 h. The reaction was checked for completion by RP-HPLC (system F2). Finally, the reaction mixture was quenched by dilution with aq TFA 0.1% (1 mL) and purified by RP-HPLC (system F3, 2 injections, t_R = 45.0−46 min). Because of the small difference in polarity between the peptide **19** and iodoacetamido derivative **15**, it is essential to use a slow linear gradient of increasing acetonitrile (0.2%/min) in aq TFA to get peptide **19** in a pure form. The product-containing fractions were lyophilized to give the peptide Ac-Cys(**NIR5.5-2**)-Asp-Glu-Val-Asp-Lys(**NIR7.0-2**)-NH_2 **19** as a blue-green amorphous powder. Stock solution of this fluorogenic caspase-3 substrate was prepared in HPLC grade water and UV-visible quantification was achieved in DMSO at λ_{max} of **NIR7.0-2** by using the ϵ value 146 000 M^{-1} cm^{-1} (yield after RP-HPLC purification: 25%). HPLC (system F2): t_R = 39.9 min, purity >95%. UV-visible (water, 25 °C): λ_{max} = 649, 676 and 800 nm. UV-visible (DMSO, 25 °C): λ_{max} = 689 and 799 nm. MS (ESI, positive mode): *m/z* 1059.20 $[M + 2H]^{2+}$; calcd exact mass for $C_{99}H_{130}N_{16}O_{28}S_4$ 2120.49.

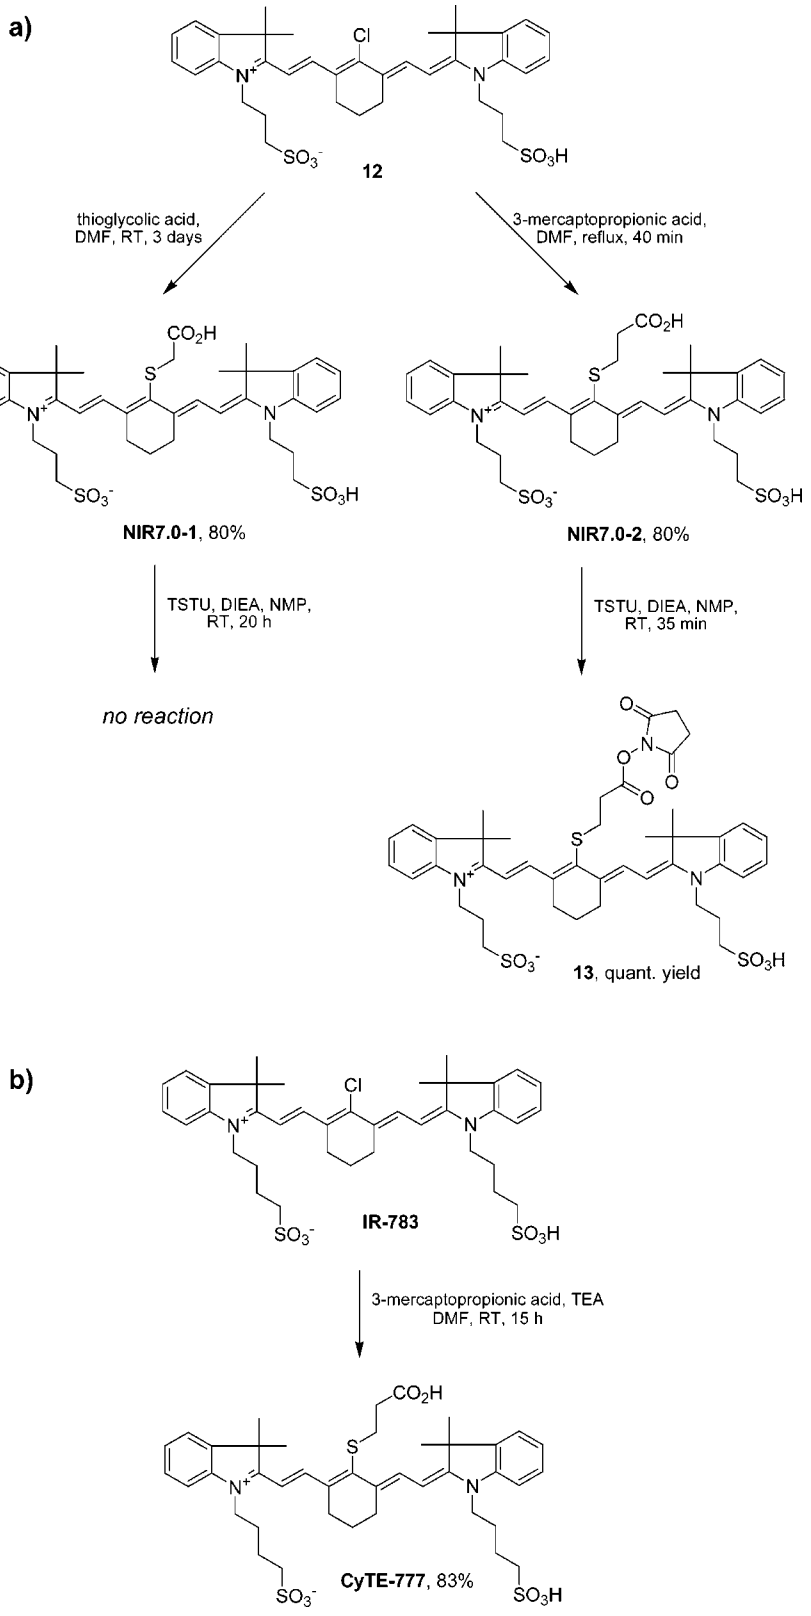
Optical Properties of Water-Soluble NIR Cyanine Dyes. The absorption spectra of NIR cyanine dyes **NIR5.5-1**, **NIR5.5-2**, and **NIR7.0-2** were recorded (220−900 nm) in deionized

Scheme 3

water, DMSO, and PBS (concentration: 1.0−5.0 μM) at 25 °C. Emission spectra were recorded under the same conditions after excitation at a wavelength 10 nm below the corresponding λ_{max} (excitation and emission slit = 5 nm). Relative quantum yields were measured in DMSO and/or PBS at 25 °C by a relative method using either sulfocyanine dye Cy 5.0 (for **NIR5.5-1** and **NIR5.5-2**, $\Phi_F = 0.20$ in PBS (*14*)) or ICG (for **NIR7.0-2**, $\Phi_F = 0.106$ in DMSO (*32*)) as a standard.

Steady-State Fluorescence Quenching Experiments of NIR5.5-2 SIAB Derivative 15 by NIR7.0-2. A Stern−Volmer plot for **NIR7.0-2** was obtained at 25 °C as follows. A solution of **NIR5.5-2** SIAB derivative **15** in PBS (0.72 μM) was treated with an increased amount of **NIR7.0-2** from 0 to 7.2 μM in PBS. The integrated fluorescence intensity F (area under the corrected emission curve in the range 670−900 nm after excitation at λ = 660 nm) was measured, and the relative fluorescence intensity F_0/F was plotted versus **NIR7.0-2** concentration. A straight line was obtained in the concentration range. The following equation was used to derive the Stern−Volmer quenching constant:

$$F_0/F = 1 + K_{sv}[\textbf{NIR7.0-2}]$$



where F_0 is the integrated unquenched fluorescence intensity of **15** and K_{sv} is the static Stern−Volmer quenching constant (K_{sv} = 67500 M^{-1}, R^2 = 0.983).

***In Vitro* Peptide Cleavage by Recombinant Human Caspase-3.** A 1.0 μM solution of peptide **19** was prepared in 50 μL of caspase-3 buffer (100 mM NaCl, 40 mM HEPES, 10 mM DTT, 1 mM EDTA, 10% (w/v) sucrose and 0.1% (w/v) CHAPS, pH 7.4) and transferred into an ultra-micro fluorescence cell. A 2 μL amount of human recombinant caspase-3 (3.2×10^{-3} U) was added, and the resulting mixture was incubated at 37 °C. After excitation at 670 and 775 nm (excitation slit = 5 nm), fluorescence emission at 705 and 805 nm (emission slit = 5 nm) was monitored over time with measurements recorded every 5 s. Control experiment with BSA was performed under the same conditions by adding 2 μL of 1% (w/v) aq solution of this protein.

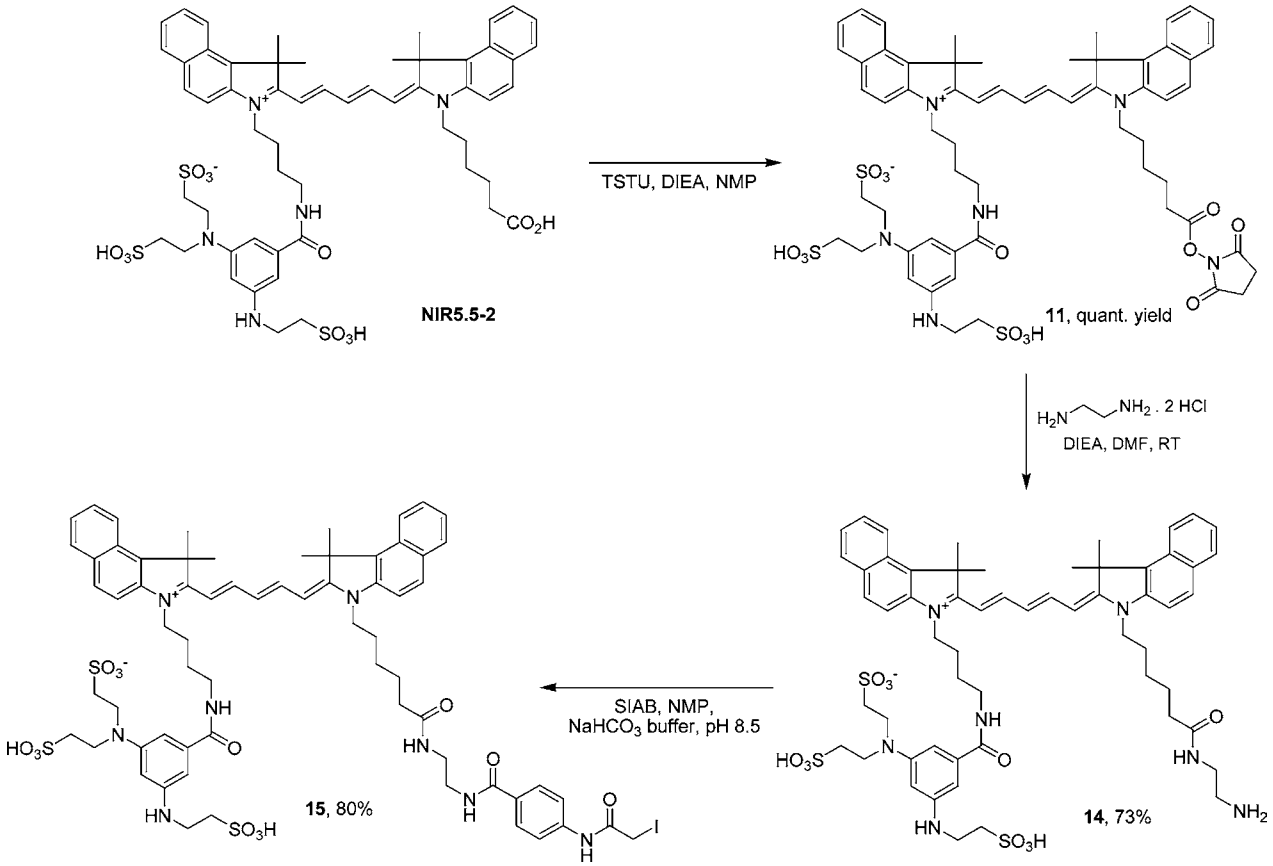
RESULTS AND DISCUSSION

Synthesis of the Cy 5.5 Analogues. Sulfobenzoindocyanine dye Cy 5.5 **1** is probably one of the most widely used NIR dyes as fluorescent reporter group in numerous molecular probes designed to facilitate the detection of molecular processes in solutions and living tissues (*33*−*36*). Indeed, this compound fulfils the most requirements expected for an ideal biomarker (i.e., narrow excitation and emission peaks in the NIR range, high quantum yield, high chemical and photostability, reasonable aqueous solubility, and a reactive carboxyl functional group for bioconjugation). However, as mentioned in Introduction, the multistep synthesis reported in 1996 by Mujumdar et al. (*13*) is not suitable for a convenient preparation of Cy 5.5 dye at a

Scheme 4

gram scale in good yields. We started the study related to the development of improved methods for the synthesis of cyanine dyes in our laboratory with the preparation of the Cy 5.5 analogue **NIR5.5-1**. Despite the presence of a single water-solubilizing sulfonated group on the cyanine core, we thought that the covalent association of **NIR5.5-1** with some biomolecules could lead to NIR fluorescent molecular probes suitable for various biomedical applications. Although this dye is commercially available (FEW Chemicals GmBH (www.few.de)), there is no detailed experimental procedure for its efficient synthesis. Thus, we have developed a practical high-yield synthesis of **NIR5.5-1** from relatively inexpensive precursors (Scheme 1). The nitrogen atom of 2,3,3-trimethyl-3*H*-indole was alkylated with propanesultone in dry toluene under reflux for 24 h to afford compound **3** in 89% yield, which was treated with malonaldehyde dianilido hydrochloride in a 1:1 mixture

Scheme 5



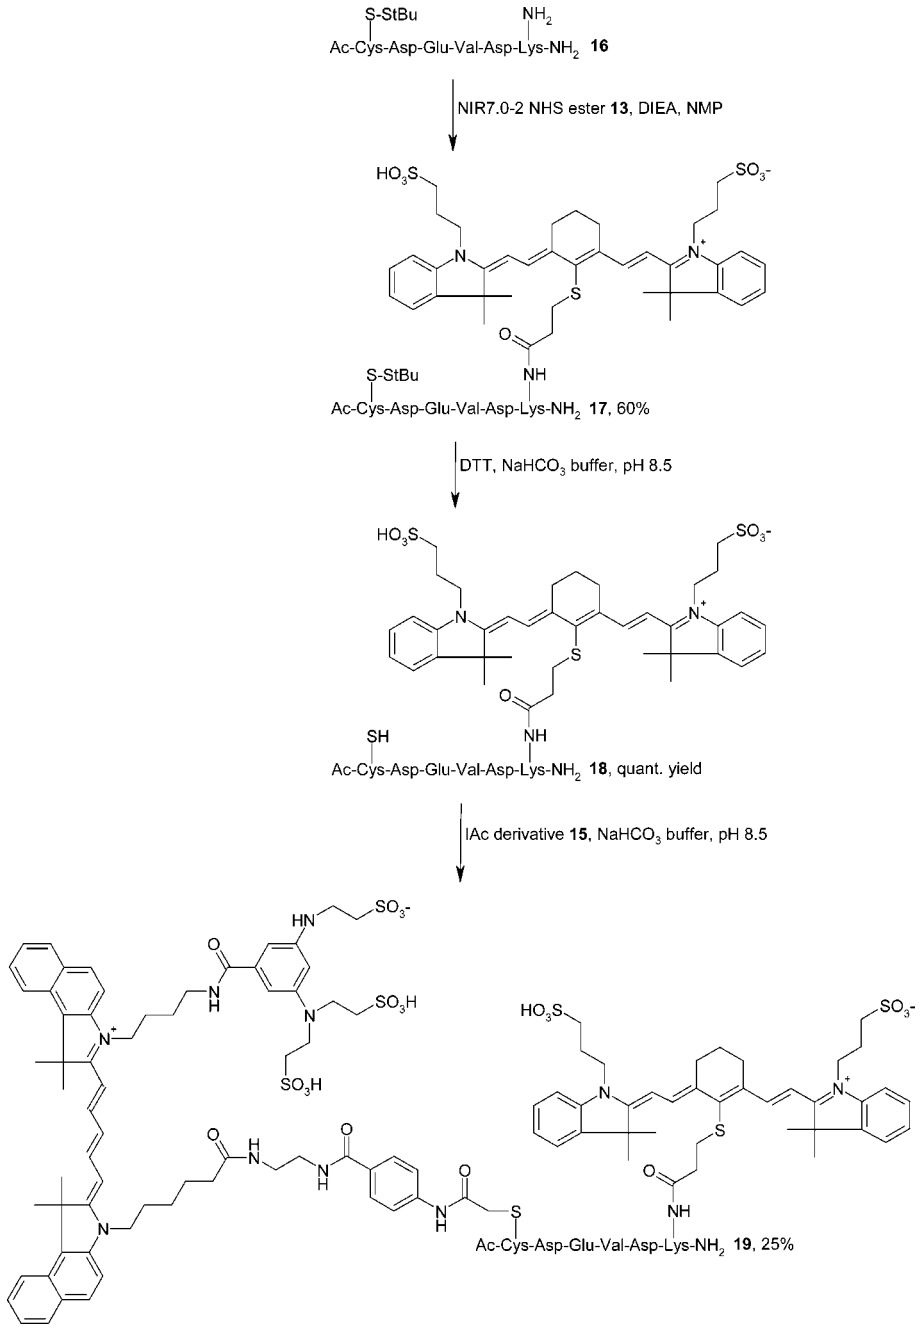


Table 1. Optical Properties of NIR Cyanine Dyes

compound	solvent	$\lambda_{max,abs}$ (nm)	$\lambda_{max,em}$ (nm)	Stokes shift (nm)	ϵ (M^{-1} cm^{-1})	Φ_F [b]

NIR7.0-2	PBS	777	798	21	120 000	0.025

[a] Values reported by Mujumdar et al. (*13*, *14*). [b] Determined at 25 °C by using either sulfocyanine dye Cy 5.0 (for **NIR5.5-1** and **NIR5.5-2**, $\Phi_F = 0.20$ in PBS (*14*)) or ICG (for **NIR7.0-2**, $\Phi_F = 0.106$ in DMSO (*32*)) as a standard.

of acetic acid and acetic anhydride under reflux for 90 min to obtain hemicyanine intermediate **5** in a quantitative yield. Reaction of **5** with the carboxypentyl indole derivative **4** in a 1:1 mixture of acetic anhydride and pyridine under reflux for 30 min furnished **NIR5.5-1** which was isolated in good yield (80%) by silica gel chromatography. All spectroscopic data, especially NMR and mass spectrometry, were in agreement with the structure assigned. However, preliminary experiments on bioconjugation of **NIR5.5-1** to hydrophilic peptides have shown that the resulting fluorescent conjugates are poorly soluble in water and related aqueous buffers (see Supporting Information). We wished to improve the water solubility of this Cy 5.5 analogue by increasing the number of sulfonated groups on the backbone and to be able to modulate this solubility by varying the nature and the number of solubilizing moieties. Yet possibilities offered for such a further modification of **NIR5.5-1** dye were limited, and modulation of the solubility required starting again the synthesis from the beginning. In an effort to develop an improved and flexible synthetic methodology enabling an easy access to numerous analogues of this NIR fluorophore, we have explored the postsynthetic derivatization of the cyanine-based amino acid **6** (*22*, *23*). This amino acid offers two amenable groups; thus, the derivatization could be undertaken either on the amino group (for instance through selective acylation reactions) or on the carboxylic acid, and derivatizations or bioconjugations could be led successively on the two reactive functions. Moreover, the introduction of water-solubilizing groups after completion of the cyanine synthesis seems to be an interesting approach because it avoids the use of a highly polar naphthalene derivative (for instance, as described for the synthesis of Cy 5.5 itself, 6-amino-1,3-naphthalenedisulfonic acid) as starting material whose the restricted solubility in organic solvents made synthesis and purification of cyanine dye and its intermediates tricky. The backbone of this fluorescent amino acid **6** (two naphthalene rings and a pentamethine chain) has been chosen to get the same spectral properties as that of cyanine dye Cy 5.5. Furthermore, it is conveniently prepared using a five-step reaction (overall yield 42%) and could be purified by flash-chromatography on RP-C_{18} silica gel column at gram quantities. Therefore, we first tried to directly convert **6** into the sulfonated derivatives **7** and **8** by successive alkylations of the amino group with 1,3-propanesultone or sodium 2-bromoethanesulfonate. As described in a preliminary report (*22*, *23*), all our attempts to get **7** or **8** failed (Scheme 2). The amino acid **6** is either completely recovered or converted into decomposition products which were not characterized. Since the sulfonation of aniline derivatives is well described in the literature (*37*, *38*), we have explored the synthesis of an original polysulfonated linker derived from cheap, commercially available 3,5-diaminobenzoic acid and its subsequent covalent attachment to the aminobutyl arm of **6** (Scheme 3). Reaction of 3,5-diaminobenzoic acid with a large excess of sodium 2-bromoethanesulfonate and KI in aq NaOH under reflux for 4 days gave the trisulfonated derivative **9** as the major compound. This highly polar linker was purified by semipreparative RP-HPLC. For this latter chromatographic

Scheme 6

purification, it was essential to use a volatile aqueous buffer such as triethylammonium bicarbonate buffer (TEAB, 50 mM, pH 7.5) as eluent both (1) to get a good separation between **9** and the other residual sulfonated species and (2) to avoid after lyophilization its contamination with salts which may further react with the reagents used for the conversion into active ester in the next steps. Thereafter, benzoic acid **9** was quantitatively converted into the corresponding *N*-hydroxysuccinimidyl ester **10** by treatment with DCC and *N*-hydroxysuccinimide (NHS) in dry DMF. This reaction was found to be very slow (20 h) and required the use of an excess of reagents (2 equiv) to go to completion. Finally, acylation of amino acid **6** with this crude active ester **10** in near stoichiometric amounts in dry NMP in the presence of DIEA (7 equiv) gave a 1:1 mixture of dye **NIR5.5-2** and its NHS ester **11** which was readily purified by semipreparative RP-HPLC (overall yield 70%). Their structures were confirmed by detailed measurements, including MALDI-TOF mass spectrometry and NMR analyses. As expected, **NIR5.5-2** was found to be perfectly soluble in water and related aqueous buffers in the concentration range (1 μM to 5 mM) suitable for biomolecular labeling applications.

Synthesis of the Cy 7.0 Analogue. A variety of water-soluble Cy 7.0 analogues with a functional reactive group at cyclohexenyl bridge included in the heptamethine chain have been already reported in the literature (*15*−*20*). Most of them have been obtained from readily available chloro cyanine dye **12**. However, most of these dyes are not optimal for applications as biological markers. Although they are water-soluble, cyanine dyes containing an additional aryl group in the meso position through an ether or a thioether bridge show an increased tendency to aggregate in aqueous solution (*18*), and the aryl-(thio)ether linkage in some of these fluorophores is fragile and thus susceptible to cleavage (*39*). To circumvent these problems and further optimize the chemical and photochemical properties of these NIR fluorophores, Lee et al. have recently reported the preparation of heptamethine cyanine dyes with a robust C−C bond at the central position of the chromophore by an efficient Suzuki−Miyaura palladium-catalyzed cross-coupling reaction

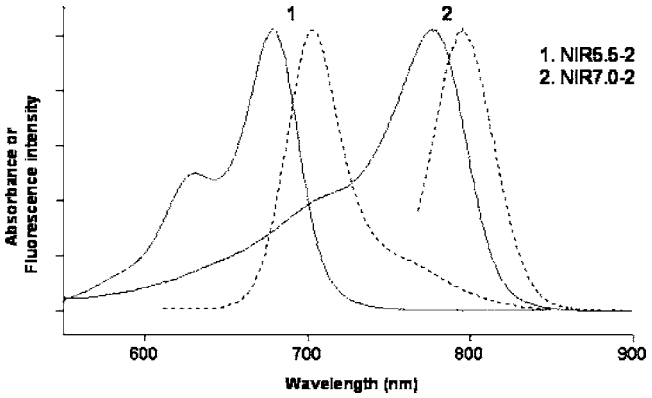

Figure 2. Normalized absorption (—) and emission (---) spectra of **NIR5.5-2** (Ex. $\lambda = 600$ nm) and **NIR7.0-2** (Ex. $\lambda = 760$ nm) in PBS at 25 °C.

(*40*). However, their spectral properties were investigated in MeOH or 20% aq DMSO, and no data about the fluorescence efficiency and aggregation tendency under physiological conditions are reported. Alternately, we have explored the postsynthetic derivatization of the precursor chloro cyanine dye **12** with a mercaptoalkyl carboxylic acid through an effective $S_{RN}1$ reaction of its *meso*-chlorine atom (Scheme 4a). Indeed, the introduction of a short alkyl linker between the reactive carboxyl group and the heptamethine chain should prevent the $\pi-\pi$ stacking interactions observed with the aryl linkers and so lead to fluorescent derivatives that are less likely to aggregate in aqueous solutions than their aryl-thioether congeners. As a starting point, we have developed a synthetic procedure that allows for the facile synthesis of dye **NIR7.0-1**. Reaction of the chloro-substituted heptamethine sulfocyanine dye **12** (*20*) with an excess of thioglycolic acid (3 equiv) in dry DMF gave the carboxylic acid functionalized **NIR7.0-1** in nearly quantitative yield. However, this dye proved to not be suitable for bioconjugation applications since its conversion into the *N*-hydroxysuccinimidyl ester or its direct activation with various peptide coupling reagents (i.e., phosphonium and uronium reagents) failed. Therefore, we have turned our attention to the carboxylic acid dye **NIR7.0-2** bearing a propanoic acid-based linker. [The Cy 7.0 analogue bearing an hexanoic acid based-based linker has also been also synthesized (by $S_{RN}1$ reaction between **12** and 6-mercaptohexanoic acid). These optical properties and its bioconjugation efficiency are similar to those reported for **NIR7.0-2**.] The synthesis of this new derivative was achieved by using the same synthetic procedure but required an additional heating of the reaction mixture (i.e., **12** and 3-mercaptopropionic acid in dry DMF) under reflux. Pure **NIR7.0-2** was obtained by RP-HPLC in 80% yield; its structure was confirmed by detailed measurements, including ESI mass spectrometry and NMR analyses. In addition to these characterizations, we have checked the reactivity of the free carboxylic acid functional group. Its activation was accomplished by treatment of **NIR7.0-2** with TSTU uronium salt in the presence of DIEA. Complete conversion to the *N*-hydroxysuccinimidyl ester **13** was observed by RP-HPLC. It is important to note that during the course of our work, a similar monofunctional NIR fluorophore namely **CyTE-777** was reported by Hilderbrand et al. (*10*). **CyTE-777** was obtained by postsynthetic derivatization of the commercially available dye IR-783 through the same $S_{RN}1$ reaction with 3-mercaptopropionic acid as described above (Scheme 4b). However, in this case, the use of a stoichiometric amount of triethylamine has enabled us to perform this reaction at room temperature.

Optical Properties. As expected, the two novel water-soluble cyanine fluorophores **NIR5.5-2** and **NIR7.0-2** display wavelength absorption and emission bands in the NIR range. The optical properties of these dyes are summarized in Table 1, and their absorption and emission spectra are displayed in Figure 2. **NIR5.5-2** has absorption and emission bands that match closely those of Cy 5.5 in PBS, which has an absorption maximum of 674 nm. There is no indication for dye−dye aggregation in PBS, which would manifest itself as a second absorption band at approximately 50 nm shorter wavelength (*13*). Indeed, the short wavelength shoulder visible in the absorption spectrum of **NIR5.5-2** is typical of cyanines and related polymethine dyes and attributed to transitions from different vibrational levels of the excited-state of fluorophore (i.e., vibronic shoulder) (*14*). The formation of dye−dye dimers and other aggregates is detrimental, because they frequently result in intermolecular quenching fluorescence emission. Thus, it appears that the three sulfonate groups introduced onto the 3,5-diaminobenzoic acid linker are sufficient to prevent dye−dye aggregation. The quantum yield of **NIR5.5-2** is significantly lower than that reported for Cy 5.5. This lower value may be explained by the presence of the trisulfonated aryl linker **9** because aromatic amines are known to quench the excited-state of some fluorophores through the photoinduced electron transfer (PET) process (*41*, *42*). This explanation was supported by the higher value of quantum yield determined for the Cy 5.5 analogue **NIR5.5-1**. Indeed, this dye contains a single sulfonatopropyl substituent which has no electron-donating ability for such PET to occur. However, the brightness or fluorescence intensity per dye molecule (i.e., the product of the fluorescence quantum yield and molar absorptivity) of **NIR5.5-2** is compatible with its use as a donor in NIR molecular probes relying on the fluorescence resonance energy transfer (FRET) process (*43*). Concerning the long wavelength dye **NIR7.0-2**, its absorption spectrum shows a characteristic band broadening, which is typical of heptamethine dyes with the absorption maxima in the range of 770−800 nm. As with **NIR5.5-2**, the Cy 7.0 analogue **NIR7.0-2** does not show any tendency to aggregate in aqueous solution. This indotricarbocyanine dye has a 20 nm Stokes shift of the fluorescence emission maximum and a quantum yield of 0.025 in PBS and 0.09 in DMSO. These latter values are comparable to those recently reported for other heptamethine cyanine dye derivatives (*17*, *40*, *44*). Furthermore, as illustrated in Figure 2, there is a good spectral overlap between the absorption of **NIR7.0-2** and emission of **NIR5.5-2**. Thus, **NIR7.0-2** might serve as an efficient acceptor for the fluorophores with emission around 700 nm in a FRET configuration.

Peptide Labeling. To demonstrate the general applicability of these novel water-soluble NIR cyanine dyes, **NIR5.5-2** and **NIR7.0-2** were converted into thiol- and amine-reactive derivatives for use in peptide labeling. As these two NIR fluorophores may act as an efficient FRET pair, their sequential and selective introduction within the same peptide architecture seems to be an interesting way to validate the labeling strategy leading to original NIR molecular probes relies on FRET process. We thus chose to couple our FRET pair to the caspase-3 cleavable peptide substrate Ac-Cys-Asp-Glu-Val-Asp-Lys-NH_2 **16** (cleavage site after the aspartic acid residue at the C-terminal side). Caspases are Cysteine-ASpartic-acid-ProteASES that play a critical role as mediators for apoptotic cell death (*45*). Caspase-3 has been specifically identified as being a key mediator of apoptosis in mammalian cells (*46*): activation of caspase-3 indicates that the apoptotic pathway has progressed to an irreversible stage. There is thus a growing interest in identifying caspase inhibitors to minimize cell death in pathological conditions (neurodegenerative diseases for instance) but also for inducing caspase activation in cancer cells (*47*, *48*). In addition, caspase-3 is widely used for monitoring apoptosis induction for general cytotoxicity screening. This interest for

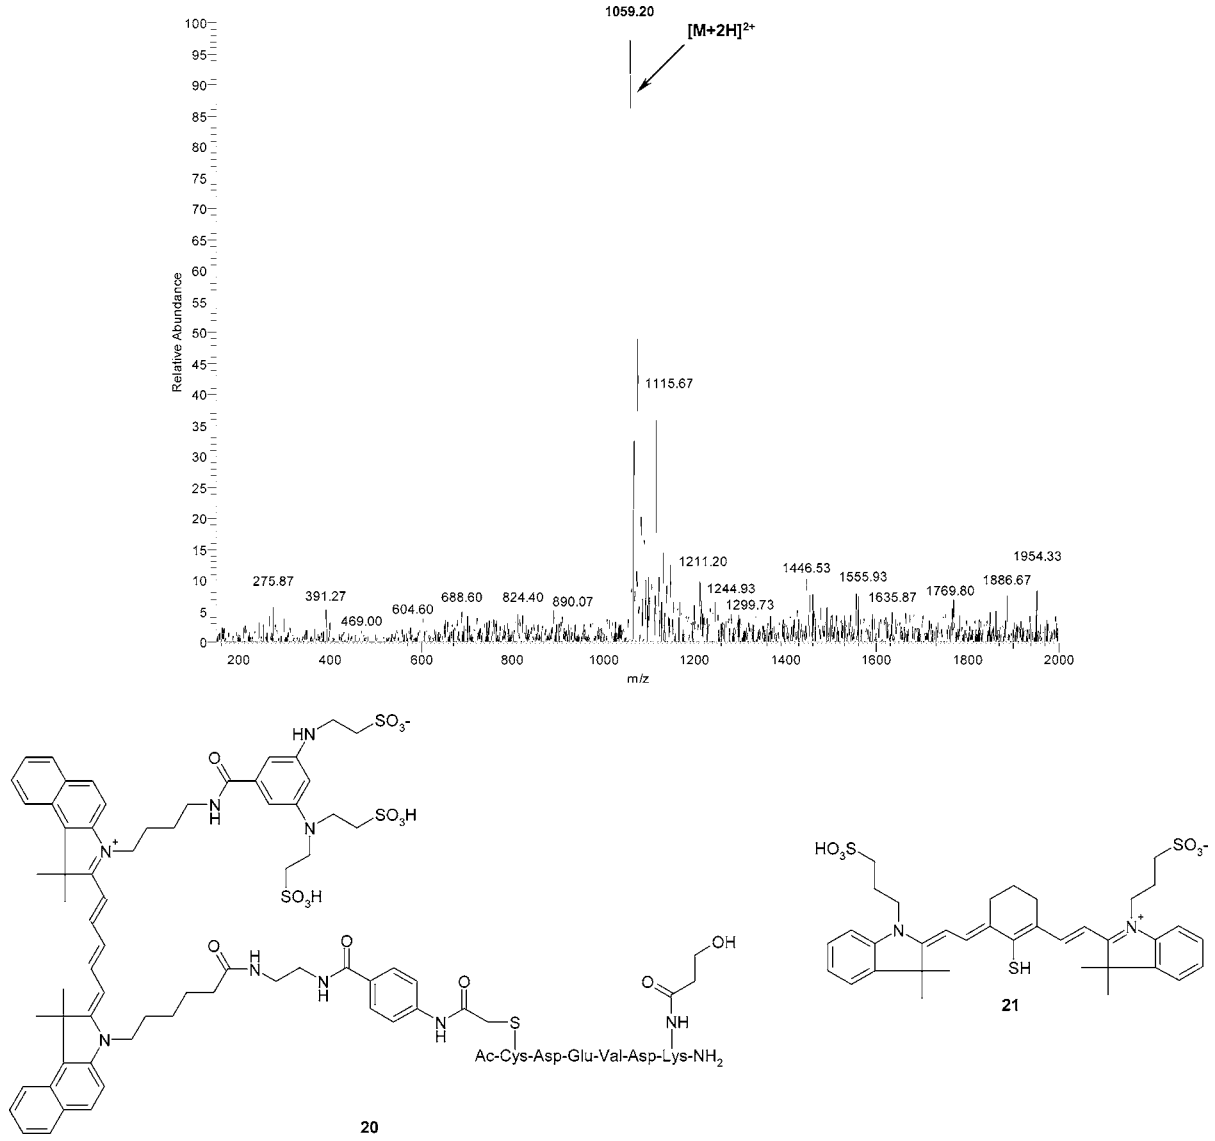

Figure 3. ESI mass spectrum of the fluorogenic substrate of caspase-3 protease **19**, in the positive mode, $[M + 2H]^{2+}$: m/z: calcd for $C_{99}H_{130}N_{16}O_{28}S_4$: 1061.24, found 1059.20. Loss of thiol NIR dye **21** occurred during the ionization process. Structures of peptide **20** and thiol NIR dye **21**.

caspase-3 resulted in the development of several assays using a variety of formats and amenable to high throughput screening (*49*−*54*). Hexapeptide **16** has thus been chosen as a suitable target in order to get a novel fluorogenic substrate useful for detecting apoptosis in whole cells and for cell-based high throughput screening assays for apoptosis inhibitors or inducers.(- For other examples of FRET-based probes used for caspase-3 detection, see refs 55−58.) To the core caspase-3 substrate sequence, cysteine and lysine residues were incorporated at N- and C-termini, respectively, as handles for the attachment of fluorophores. The use of a cysteine side-chain protecting group removable under mild reducing conditions (i.e., *tert*-butylthio group, StBu) has enabled the selective introduction of the two fluorescent labels within this peptide, thus obtaining the target FRET substrate through an efficient solution-phase labeling method.

First, **NIR5.5-2** was converted into the thiol-reactive iodoacetyl derivative **15** using a conventional three-step method (Scheme 5). **NIR5.5-2** *N*-hydroxysuccinimidyl ester **11**, generated by reaction with TSTU/ DIEA in dry NMP, was reacted with ethylenediamine under the conditions reported by Gruber et al. (*59*) to give **NIR5.5-2** amine **14** in 73% yield. Finally, acylation of the primary amino group of **14** with the heterobifunctional cross-linker reagent succinimidyl 4-[(iodoacetyl)-amino]benzoate (i.e., SIAB) in a mixture of NMP and aq sodium bicarbonate buffer (pH 8.5) provided, after RP-HPLC purification, the thiol-reactive Cy 5.5 analogue **15** (yield 80%). Its structure was confirmed by ESI mass spectrometry. Site-specific fluorescent labeling of caspase-3-cleavable peptide substrate started with the reaction between Ac-Cys(StBu)-Asp-Glu-Val-Asp-Lys-NH_2 **16** and the *N*-hydroxysuccinimidyl ester of **NIR7.0-2 13** in dry NMP in the presence of DIEA (Scheme 6). Purification by RP-HPLC provided the **NIR7.0-2**-labeled peptide Ac-Cys(StBu)-Asp-Glu-Val-Asp-Lys(**NIR7.0-2**)-NH_2 **17** in 60% yield. The removal of the StBu protecting group from the cysteine residue was achieved by treatment with an excess of dithiothreitol (DTT) in aq sodium bicarbonate buffer (pH 8.5). Purification of the free sulfhydryl-containing peptide−**NIR7.0-2** conjugate **18** was achieved by RP-HPLC. Finally, iodoacetamido-activated **NIR5.5-2 15** was attached on the free cysteine of peptide **18** by using a 3:1 molar excess (**18**/**15**) in aq sodium bicarbonate buffer (pH 8.5). The caspase-3 substrate **19** was obtained in a pure form after purification by RP-HPLC (yield 25%, purity >95%). When this fluorogenic substrate was analyzed by ESI mass spectrometry (Figure 3), the expected molecular ion $[M + H]^+$ around *m*/*z* 2800.00 Da was not observed. The mass spectrum shows a single peak at *m*/*z* 1059.20 Da corresponding to the positive ion $[M + 2H]^{2+}$ of

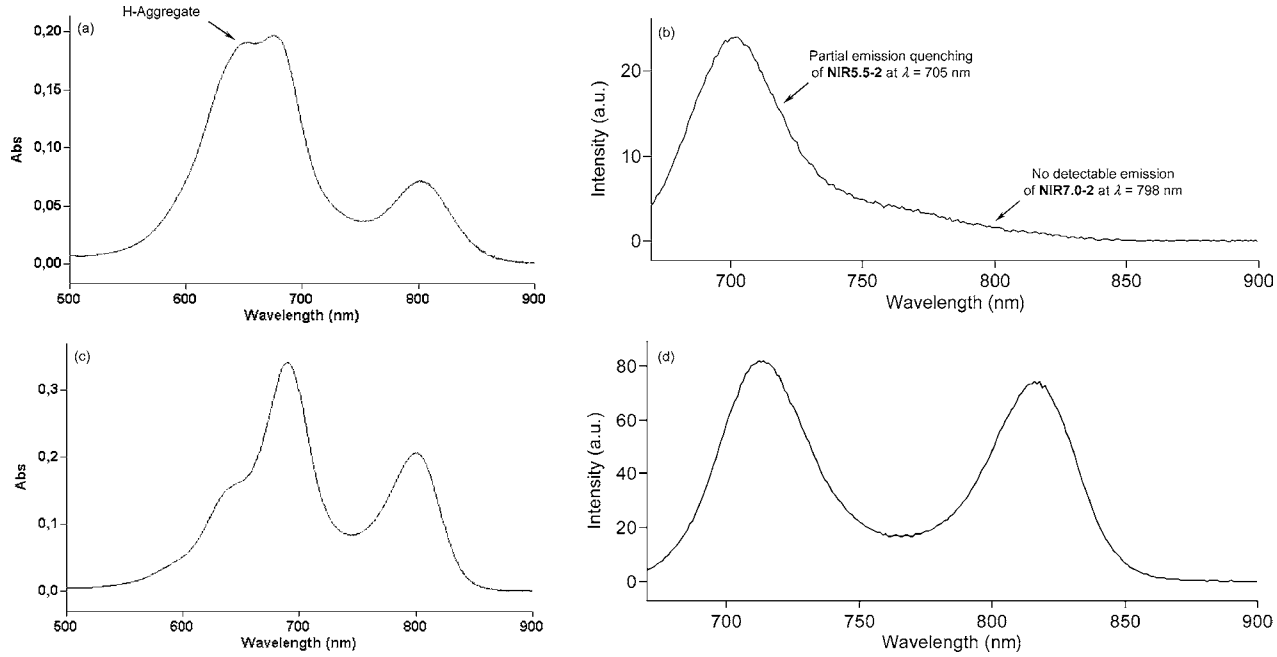

Figure 4. Absorption and emission (Ex. $\lambda = 660$ nm) spectra of probe **19** at 25 °C (concentration 2.6 μM). (a,b) In PBS. (c,d) In DMSO. The efficiency of this energy transfer (E) is typically measured using the relative fluorescence intensity of the donor (**NIR5.5-2**), in the absence (F_D) and presence (F_{DA}) of acceptor (**NIR7.0-2**): $E = 1 - (F_{DA}/F_D)$. For our fluorescent probe, this was accomplished by comparing the **NIR5.5-2** emission (i.e., area under the corrected emission curve in the range 670−760 nm after excitation at $\lambda = 660$ nm) for the iodoacetyl derivative **15** and peptide **19**. From these emission spectra, a value of F_{DA}/F_D close to 0.45 was found.

NIR5.5-2 derivative **20**. The formation of this single fluorescently labeled peptide was explained by the elimination of thiol **NIR7.0-2** derivative **21** (i.e., retro-Michael reaction) followed by the 1,4-addition of a water molecule onto the newly formed Michael olefin. This fragmentation pathway was also observed when the fluorogenic probe was subjected to a MALDI-TOF mass spectrometry analysis and observed with other FRET probes bearing the same NIR cyanine dye as energy acceptor (see Supporting Information). Furthermore, as the photophysical characterization (see below) has confirmed the presence and integrity of the two fluorophores **NIR5.5-2** and **NIR7.0-2** within the hexapeptide, the hydrolytic release of **21** obviously occurs during the ionization process.

Photophysical Characterization and *in Vitro* Cleavage by Caspase-3 of the Fluorogenic Peptide. The absorption and emission spectra of the probe **19** recorded in PBS and DMSO are shown in Figure 4. In DMSO, two major absorption peaks at 689 and 800 nm, indicating the presence of **NIR5.5-2** and **NIR7.0-2**, respectively, were observed. Surprisingly, a new peak at 649 nm, which is blue-shifted by about 30 nm from the absorption peak of the free **NIR5.5-2** dye, was observed for the probe dissolved in aqueous buffered solution. As the absorption peak of **NIR7.0-2** dye is also red-shifted by about 20 nm, it is clear that this probe displays significant dye−dye-aggregation leading to the formation of an intramolecular heterodimer (*60*). Further evidence for the formation of an H-aggregate within the dual-labeled peptide **19** was given by the fluorescence emission spectrum (recorded after excitation of the donor **NIR5.5-2** at 660 nm). Indeed, no significant emission at 798 nm corresponding to the **NIR7.0-2** fluorescence (see Supporting Information) or a minor emission at 705 nm (diminished by 3 times compared to the fluorescence of free **NIR5.5-2** dye at the same concentration) corresponding to the remaining untransferred **NIR5.5-2** fluorescence was observed. This quenching was not observed in the fluorescence emission spectrum recorded in DMSO, where an energy transfer efficiency close to 55% was found. Thus, **NIR7.0-2** acts as an efficient quencher for **NIR5.5-2**. As this quenching effect is also observed with the probe bearing the less polar Cy 5.5 analogue **NIR5.5-1** as donor (see Supporting Information) but not observed with the fluorogenic Cy 5.0/**NIR7.0-2** hexapeptide, dye−dye aggregation may result from strong $\pi-\pi$ stacking interactions between the benz[*e*]indole and indole units. To assess the quenching efficiency of the **NIR5.5-2**/**NIR7.0-2** pair, a Stern−Volmer plot was obtained from steady-state fluorescence intensity measurements of the donor **NIR5.5-2** with or without the acceptor **NIR7.0-2** (Figure 5). Since the structural features of the linker connecting the Cy 5.5 analogue to the peptide core may influence the quenching, this study was performed with iodoacetyl derivative **15** instead of the free carboxylic acid dye. The Stern−Volmer plot displays an upward curvature; this positive deviation from linearity with increasing **NIR7.0-2** concentrations indicates that static quenching is much higher than expected for a diffusion-controlled bimolecular reaction. This strongly supports the idea of the formation of a nonfluorescent ground-state complex between the two NIR cyanine dyes in aqueous solutions (*61*).

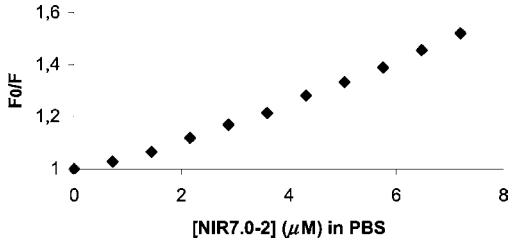

Figure 5. Static bimolecular Stern−Volmer plot for determining quenching efficiency of **NIR7.0-2** toward the idoacetyl derivative of **NIR5.5-2** in PBS. F_0 and F are fluorescence intensity of **15** (0.72 μM) in the absence and in the presence of **NIR7.0-2**, respectively.

Interestingly, a comprehensive study of the optical properties of the thiol-reactive Cy 5.5 analogue **15** has revealed that the chemical derivatization of **NIR5.5-2** with the SIAB cross-linker significantly increases the quantum yield of our Cy 5.5 analogue especially in DMSO ($\Phi_F = 0.145$ compared to $\Phi_F = 0.05$ for **NIR5.5-2**). We presume that this increase of fluorescence in **15** as compared with **NIR5.5-2** is due to the longer distance between the cyanine core and the aniline nitrogen atoms of the

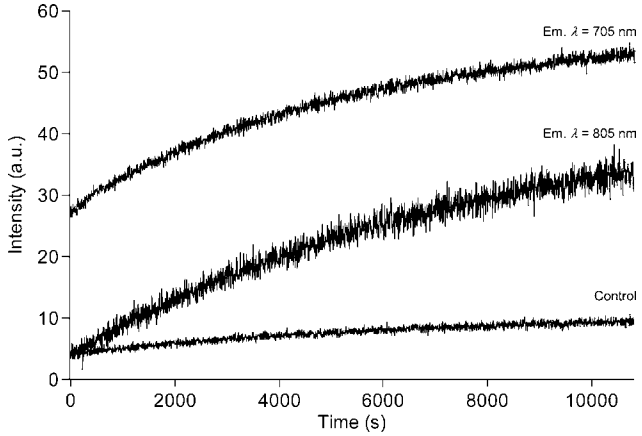

Figure 6. Fluorescence emission time course of probe **19** (concentration 1.0 μM) with recombinant human caspase-3 (3.2 10^{-3} U, incubation time 180 min) in caspase assay buffer (100 mM NaCl, 40 mM HEPES, 10 mM DTT, 1 mM EDTA, 10% (w/v) sucrose, and 0.1% (w/v) CHAPS, pH 7.2, 37 °C) at 705 nm (Ex. $\lambda = 670$ nm) and 805 nm (Ex. $\lambda = 770$ nm). To avoid overloading of this figure, only the emission at 805 nm (Ex. $\lambda = 770$ nm) is shown for the control reaction without caspase-3. The same straight line was obtained for the emission at 705 nm but at a fluorescence level around 25 a.u.

hydrophilic linker which acts as a quencher (see above). Indeed, strong $\pi-\pi$ stacking interactions between the benzene rings of trisulfonated linker **9** and SIAB cross-linker may favor a conformation in which the quencher−fluorophore distance is significantly increased. Thus, this conformational change would reduce the rate of the PET-based quenching process, thereby enhancing the fluorescence emission.

With this interesting tool in hand, the internally quenched fluorescent probe **19** was assayed against recombinant human caspase-3. Within 180 min, the fluorescence emission of **19** at 705 and 805 nm has increased about 2- and 8-fold, respectively, while no activation was observed when the peptide **19** was incubated only with the caspase-3 buffer (Figure 6). Furthermore, no fluorescence enhancement was obtained after prolonged incubation of **19** with BSA protein (see Supporting Information). This latter observation asserts that an hypothetical nonspecific binding between peptide **19** and protein (such as caspase-3) cannot induce the fluorescence revealing of both NIR dyes through conformational changes of the probe. Overall, these results confirm that the fluorogenic peptide-based probe **19** is a substrate for recombinant caspase-3 protease. However, fluorescence recovery was significantly lower than expected if complete proteolytic cleavage of **19** had occurred. One possible explanation for this result is the low accessibility of the enzyme cleavage site within the peptide backbone. As the enzyme activity and substrate recognition are usually extremely sensitive to peptide conformation, the formation of the intramolecular heterodimer has probably significantly modified the shape of the peptide recognition unit, and the activity rate was dramatically decreased.

CONCLUSION

In this paper, we have described the synthesis and photophysical properties of two novel water-soluble NIR cyanine dyes **NIR5.5-2** and **NIR 7.0-2** which are potential substitutes of the commercially available Cy 5.5 and Cy 7.0 labels. They are easily prepared in good yields by postsynthetic derivatization of an amino or a chloro cyanine precursor through an efficient acylation and a $S_{RN}1$ reaction respectively. These two derivatives display absorption and emission maxima in the NIR range and do not self-aggregate in aqueous solution, and their fluorescence efficiency is compatible with their use in a wide variety of optical imaging applications and NIR fluorescence studies. However, further efforts are required in order to improve the quantum yield of **NIR5.5-2** especially by introducing a polysulfonated aminoalkyl linker as water-solubilizing moiety onto the cyanine precursor. Efficient synthetic protocols were also found for conversion of **NIR5.5-2** and **NIR7.0-2** into thiol- and amine-reactive derivatives **13** and **15**. These novel fluorescent labeling reagents have been successfully used in solution-phase peptide labeling to provide an original peptide-based NIR probe of caspase-3 protease. Efficient quenching effect between **NIR5.5-2** and **NIR7.0-2** at 705 and 798 nm was demonstrated. In the caspase-3 model, the probe is able to release fluorescence signal by 8-fold at 805 nm after enzymatic degradation. However, enzyme activity is dramatically decreased compared with other fluorogenic FRET-based probes previously reported by us (*30*, *62*). Thus, further studies aimed at re-engineering the placement of the NIR dye labels and their covalent attachment, such that dimer formation will not alter the hexapeptide secondary structure, are necessary to get an internally quenched fluorescent probe suitable to assay caspase-3 activity both *in vitro* and *in vivo*. Yet, the observation of an efficient formation of an intramolecular heterodimer yielding a nonfluorescent ground-state complex between the two NIR cyanine dyes in aqueous solutions, even with a very short peptide which is unlikely to fold, opens the door to the use of this efficiently quenched fluorophore pair using coil-containing longer peptidic backbones.

ACKNOWLEDGMENT

The contribution of Dr. Jérôme Leprince (U 413 INSERM/IFRMP 23) to MALDI-TOF mass spectrometry measurements and solid-phase synthesis of hexapeptide **16** is greatly acknowledged. We thank Dr. Xavier Franck for helpful discussions concerning the sulfonation reactions of amines. The financial support of the "Région Haute Normandie" is gratefully acknowledged.

Development of a Small Peptide Tag for Covalent Labeling of Proteins

Fujie Tanaka,* Roberta Fuller, Lily Asawapornmongkol, Axel Warsinke, Sarah Gobuty, and Carlos F. Barbas, III*

The Departments of Molecular Biology and Chemistry and The Skaggs Institute for Chemical Biology, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, California 92037. Received March 8, 2007; Revised Manuscript Received May 11, 2007

A 21-mer peptide that can be used to covalently introduce synthetic molecules into proteins has been developed. Phage-displayed peptide libraries were subjected to reaction-based selection with 1,3-diketones. The peptide was further evolved by addition of a randomized region and reselection for improved binding. The resulting 21-mer peptide had a reactive amino group that formed an enaminone with 1,3-diketone and was used as a tag for labeling of maltose binding protein. Using this peptide tag and 1,3-diketone derivatives, a variety of molecules such as reporter probes and functionalities may be covalently introduced into proteins of interest.

INTRODUCTION

Development of systems for labeling of proteins with synthetic molecules or small molecules is of considerable interest (*1*), because labeling systems can be used to address fundamental biological questions and can be used for the preparation of novel therapeutics. For example, labeling of proteins with fluorescent molecules allows tracking of the proteins within native environs (*2*−*4*). Whereas GFP variants have a given fluorescence, use of a tag-fusion protein allows for labeling with a variety of synthetic fluorescent molecules that differ in fluorescence. In addition, modifications to a tag-fusion protein are not limited to introduction of fluorescent molecules; other molecules can be introduced to the tag-fusion protein. Proteins conjugated with carbohydrates or lipids are tools for exploring interactions among these biomolecules on the cell surface and inside cells (*5*). Drug−protein conjugates, including antibody conjugates with cytotoxic molecules or radioisotopes, are often safer and more effective therapeutics than drug or protein alone (*6*−*9*). Proteins labeled with polymers are more stable than the corresponding unlabeled proteins in serum and are useful for therapeutic applications (*10*). Labeling reactions of proteins with synthetic molecules can also be used for covalently attaching proteins to the surfaces of microchips or microarrays (*11*−*13*).

In order to label a protein of interest selectively and specifically, several strategies and methods have been developed. For example, using a tag protein or peptide (either enzyme-derived or designed) that selectively reacts with designed synthetic molecules provides selective and specific labeling. Methods using a covalently modifiable tag fusion include labeling of O^6-alkylguanine-DNA alkyltransferase with O^6-benzylguanine derivatives (*3*, *14*), Sfp phosphopantetheinyl transferase-catalyzed labeling of a peptide excised from a nonribosomal peptide synthetase with an adenosine 3′-monophosphate derivative (*11*, *15*), phosphopantetheine transferase-catalyzed labeling of the acyl carrier protein with an adenosine 3′-monophosphate derivative (*4*), biotin ligase-catalyzed labeling of the acceptor peptide with a biotin-mimic derivative (*16*), labeling of a serine esterase cutinase with phosphate derivatives (*13*), and labeling of a tetracysteine α-helix motif with biarsenical ligands (*17*, *18*). Other useful covalent labeling methods include intein-mediated labeling (*19*−*21*), incorporation of an unnatural amino acid into a protein and labeling of the unnatural amino acid (*5*), and introduction of a N-terminal cysteine and its labeling with aldehyde derivatives (*22*). When serine or threonine is introduced at the N-terminus of a protein, oxidation of the N-terminal serine or threonine to form an aldehyde group followed by oxime or hydrazone formation reaction is another useful chemical modification method (*23*−*25*). Labeling of fusion proteins with noncovalent, but tight-binding compounds has also been reported. Examples include labeling of a dihydrofolate reductase (DHFR)-fusion with methotrexate conjugates (*26*, *27*), labeling of an FKBP12 mutant (F36V)-fusion with its ligand derivatives (*28*), labeling of a single chain antibody fusion with its hapten-conjugated molecules (*29*), and labeling of avidin fusion with biotin conjugates (*30*).

For labeling of fusion proteins, a smaller peptide tag is preferred as the fusion partner because a larger protein tag may affect the function of the protein of interest and because production of larger proteins is often more difficult. When multiple labeling of a protein of interest with different molecules is required, one convenient solution is the introduction of different tags into the protein at the same time followed by specific labeling of each tag of the fusion. For multiple labels, smaller fusion partners allow for the fusion protein to be of reasonable size. When small peptides are used, noncovalent binding is unlikely to provide sufficient hydrogen bonds and/or charge and hydrophobic interactions for tight binding. In contrast, a covalent bond is sufficient to retain the label and numerous noncovalent interactions are not necessary. Thus small peptides that form covalent bonds with designed compounds should be suitable for conjugation of the fusion proteins with synthetic molecules. In addition, it is preferred that labeling methods do not require additional catalysts or toxic metal reagents. Here we report the development of a small 21-mer peptide that forms an enaminone with 1,3-diketone derivatives. We have demonstrated that when fused to a protein of interest, the peptide can be used to introduce synthetic molecules into the fusion protein without the requirement of additional catalysts or reagents.

EXPERIMENTAL PROCEDURES

Selection of Peptides from Initial Libraries. Ph.D.-C7C, Ph.D.-7, and Ph.D.-12 phage display peptide libraries (New England Biolabs, NEB) were used for the selection. Wells of a microtiter plate (Costar 3690) were coated with **1**−bovine serum albumin conjugate (**1**−BSA) (2 μg/PBS 25 μL/well) at 4 °C

overnight, washed with H_2O two times, and blocked with 3% BSA/PBS (170 μL/well) at room temperature for 1.5 h (PBS is 10 mM Na_2HPO_4, 1.8 mM KH_2PO_4, 137 mM NaCl, 2.7 mM KCl, pH 7.4). Blocking solution was removed, and the library phage were added. After 2 h, the wells were washed 10 times with 0.5% Tween 20/PBS (PBST) to remove unbound phage. The bound phage were eluted by trypsin digestion (Difco Trypsin 1:250, 10 mg/mL in TBS, 50 μL/well) at 37 °C for 30 min, added to *E. coli* 2537 cells in LB medium, and grown using the procedures recommended by NEB. After four rounds of selection using each phage-displayed peptide library separately, panned libraries were combined and an additional three rounds of selection were performed. The DNA sequences of the clones from the seventh round were analyzed using procedures recommended by NEB. Individual clones were analyzed by ELISA for binding to **1**−BSA immobilized on wells of a microtiter plate using anti-M13 antibody−horseradish peroxidase conjugate (Amersham) and the peroxidase substrates 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) and hydrogen peroxide.

Construction of the Second and Third Libraries and Peptide Selections. The synthesized oligonucleotide library was amplified by PCR using 5′-primer SfiI-f (5′-GAGGAGGAG-GAGGCCCAGGCGGCC-3′) and 3′-primer SfiI-b (5′-GAG-GAGGAGGAGGCCGGCCTGGCC-3′). The PCR conditions as were follows: SfiI-f, 1 μg; SfiI-b, 1 μg; oligonucleotide library, 50 ng; 0.2 mM each dNTP; 10 μL of 10x PCR buffer; 2.5 units of Ampli Taq DNA polymerase (Roche) in a total volume of 100 μL. A program of 94 °C 1 min; 94 °C 15 s, 52 °C 15 s, 72 °C 30 s (25 times); 72 °C 10 min was used for amplification. The PCR products were purified, digested with *Sfi*I, and ligated to *Sfi*I-digested pComb3X using T4 DNA ligase (NEB). The following oligonucleotides were used (N = A, C, G, or T; K = G or T): PhD-C7C-NNK6 (5′-GGCCCAGGCGGCCTGTCAT-AATCATCAGAAGGCTACGTGCNNKNNKN NKNNKNN-KNNKGGCCAGGCCGGCC-3′), PhD7−2-NNK6-f (5′-GGCC-CAGGCGGCCGCTGCTGTGGCTAAGCCGCCGNNKNNKNN-KNNKNN KNNKGGCCAGGCCGGCC-3′), NNK6-PhD7-2-f (5′-GGCCCAGGCGGCCNNKNNKNNKNNKNNKNNKG-CTGCTGTGGCTAAGC CGCCGGGCCAGGCCGGCC-3′), PhD7-6-NNK6-f (5′-GGCCCAGGCGGCCGTGTCGGTGCA-GACTAAGTATNNKNNKNNKNNK NNKNNKGGCCAG-GCCGGCC-3′), NNK6-PhD7−6-f (5′-GGCCCAGGCGGCC-NNKNNKNNKNNKNNKNNKGTGTCGGTGCAGAC TAAG-TATGGCCAGGCCGGCC-3′), PhD7-14-NNK6-f (5′-GGCCCA-GGCGGCCAATCCGCTGGGTGCTAAGTTGNNKNNKNN-KNNK NNKNNKGGCCAGGCCGGCC-3′), NNK6-PhD7-14-f (5′-GGCCCAGGCGGCCNNKNNKNNKNNKNNKNNKAA-TCCGCTGGGTGCTAAGTTGGGCCAGGCCGGCC-3′), PhD12-3-NNK6-f (5′-GGCCCAGGCGGCCGCTGCTATGGATG-CTAAGAATTCTCCTGCTTCTGC TNNKNNKNNKNNKN-NKNNKGGCCAGGCCGGCC-3′), NNK6−PhD12−3-f (5′-GGCCCAGGCGGCCNNKNNKNNKNNKNNKNNKGCTGC-TATGGATGCT AAGAATTCTCCTGCTTCTGCTGGCCAG-GCCGGCC-3′), PhD12-9-NNK6-f (5′-GGCCCAGGCGGC-CGATTTGCCTATTCCTACTACGAAGCTTGGGCGGTCTNN-KNNKNNKNNKNNKNNKGGCCAGGCCGGCC-3′), and NNK6-PhD12-9-f (5′-GGCCCAGGCGGCCNNKNNKNNKNN-KNNKNNKGATTTGCCTATTCCTACTACGAAGCTTGGGCG-GTCTGGCCAGGCCGGCC-3′).

Construction of the third libraries was performed using the same procedures as used for construction of the second libraries. The following oligonucleotides were used: PhD-C7C-1319-NNK6 (5′-GGCCCAGGCGGCCTGTCATAATCATCAGAA-GGCTACGTGCACGGCGCAG GCGCAGAGTNNKNNKNN-KNNKNNKNNKGGCCAGGCCGGCC-3′), PhD-C7C-1320-NNK6 (5′-GGCCCAGGCGGCCTGTCATAATCATCA-GAAGGCTACGTGCCGGAGGATG CGGTCTAGGNNKNN-KNNKNNKNNKNNKGGCCAGGCCGGCC-3′), PhD-C7C-1322-NNK6(5′-GGCCCAGGCGGCCTGTCATAATCATCAGAA-GGCTACGTGCTCGTGGGTT CTTGTGCCGNNKNNKNN-KNNKNNKNNKGGCCAGGCCGGCC-3′), PhD-C7C-1326-NNK6 (5′-GGCCCAGGCGGCCTGTCATAATCATCAGA-AGGCTACGTGCCCGAGGGAT AGGCATGGGNNKNN-KNNKNNKNNKNNKGGCCAGGCCGGCC-3′), PhD7-14-2-NNK6 (5′-GGCCCAGGCGGCCAATCCGCTGGGTGCTA-AGTTGGCGGGTGTGTTTTGG TGGNNKNNKNNKNNK-NNKNNKGGCCAGGCCGGCC-3′), and PhD7-14-10-NNK6 (5′-GGCCCAGGCGGCCAATCCGCTGGGT-GCTAAGTTGGCTATGGCTATGTGG GGGNNKNNKNN-KNNKNNKNNKGGCCAGGCCGGCC-3′). The library size of the second and third libraries was between 2.3×10^7 and 3.1×10^8.

Ligation mixtures were ethanol precipitated and transformed into *E. coli* ER 2537 cells by electroporation. Immediately after transformation, 5 mL of SOC (2% trypton, 0.5% yeast extract, 0.05% NaCl, 2.5 mM KCl, 10 mM $MgCl_2$, 20 mM glucose) was added to each reaction, and the cells were grown at 37 °C. After 1 h, 10 mL of super broth (SB, 3% trypton, 2% yeast extract, 1% Mops) and carbenicillin (to 20 μg/mL) were added. After 1 h, additional carbenicillin was added to increase the final concentration to 50 μg/mL. After 1 h, helper phage VCS-M13 ($\sim 10^{13}$ pfu) were added, and the culture volume was increased to 100 mL by the addition of SB including carbenicillin (at 50 μg/mL). After 1.5 h, kanamycin (for a final concentration of 70 μg/mL) was added, and the culture was incubated at 37 °C over night. The cells were removed by centrifugation (4000 rpm, 30 min). Phage were purified by precipitation: Poly(ethylene glycol) 8000 (final concentration 4% w/v) and NaCl (final concentration 3% w/v) were added to the supernatant, and, after 30 min on ice, the mixture was centrifuged at 9000 rpm for 20 min. The phage precipitate was resuspended in 1% BSA/PBS (2 mL) and filtered (0.2 μm).

Selection was performed using **1**−BSA immobilized on wells in a microtiter plate as described above. The bound phage eluted by trypsin were added to *E. coli* ER2537 cells (20 mL in SB), and the culture was shaken at 37 °C. After 15 min, carbenicillin (for a final concentration of 20 μg/mL) was added. After 45 min, helper phage VCS-M13 ($\sim 10^{12}$ pfu) was added, and the culture was diluted to the total volume 100 mL with SB containing carbenicillin (50 μg/mL). After 1.5 h, kanamycin (final concentration of 70 μg/mL) was added, and the culture was incubated at the same temperature overnight. Phage were purified as described above and were used for further panning.

An enzyme-linked immunosorbent assay (ELISA) of individual clones against **1**−BSA immobilized on wells of a microtiter plate was performed using anti-decapeptide antibody−alkaline phosphatase conjugate (Pierce) and *p*-nitrophenyl phosphate.

Preparation rpf1368-MBP. The *Sfi*I-digested fragment of rpf1368 was ligated to *Sfi*I-digested pComb3-MBP vector (see below) with T4 DNA ligase. The ligation mixture was transformed into *E. coli* XL1-Blue cells (Stratagene) by electroporation. After transformation, SOC (2 mL) was immediately added, and the cells were grown at 37 °C. After 1 h, the culture (100, 10, and 1.0 μL) was plated on LB agar containing carbenicillin (100 μg/mL). Individual colonies were picked from the plates and grown in SB (5 mL) containing carbenicillin (50 μg/mL) at 37 °C for overnight. The culture was diluted 1:10 in SB containing 0.2% glucose and carbenicillin (50 μg/mL) and was grown for 2 h at 37 °C. Expression of the rpf1368-MBP genes was induced by addition of IPTG (1 mM), and the culture was incubated for additional 3 h. The culture was centrifuged

(3500 rpm) for 20 min, and the cells were resuspended in PBS (500 μL) and then freeze-thawed five times in a dry ice−ethanol bath and water bath. The lysate sample was spun in a microcentrifuge at maximum speed for 20 min, and the supernatant was used for the ELISA with **1**−BSA (see below). The sequence of rpf1368-MBP was confirmed by DNA sequencing of peptide rpf1368 region using primer Mal-B (5′-GAATTTCTCTTCCAGTTTATCCG-3′) as well as the positive signal in ELISA with **1**−BSA.

For large-scale production of rpf1368-MBP, the following procedures were used: The colony was picked from a plate and grown in SB (5 mL) containing carbenicillin (50 μg/mL) at 37 °C for overnight. A 1 mL aliquot of the culture was added into each of two flasks containing 100 mL of SB containing 0.2% glucose, 20 mM $MgCl_2$, and carbenicillin (50 μg/mL) and was grown for 7 h at 37 °C. Expression of the rpf1368-MBP genes was induced by addition of IPTG (1 mM), and the culture was incubated overnight. The culture was centrifuged (3500 rpm) for 20 min at 4 °C, and the cells were resuspended in amylose column buffer (5 mL) composed of 20 mM Tris-HCl, 200 mM NaCl, 1 mM EDTA, and 1 mM PMSF. The cells were sonicated on ice using Tekmer Sonic Disrupter. The lysate sample was centrifuged (3500 rpm) for 15 min at 4 °C, and the supernatant was filtered. The filtrate was applied to the amylose resin column (pre-equilibrated with the amylose column buffer). The column was washed with the column buffer and rpf1368-MBP was eluted with 10 mM maltose in column buffer. The combined eluted fractions were concentrated, and the buffer was changed to PBS using Centriprep-10 (Millipore). The protein purity was judged to be >95% by in gel electrophoresis.

Construction of pComb3-MBP. Cloning of the *Sfi*I-digested fragment from the pComb3X (*31*) into pComb3-MBP allowed the production of the MBP-fusion. Vector pComb3-MBP produces N-terminal MBP-fusion (protein/peptide of interest fused at the N-terminus of MBP), and the N-terminal sequence of protein/peptide of the MBP fusion is identical to that produced from the pComb3X system. Vector pComb3-MBP was prepared by replacing gene III of pComb3X with the MBP gene from pMAL-pIII (*32*).

PCR was performed using (i) primers Bseq (5′-GTGAGC-GAGGAAGCGGAAGAG-3′) and TT-SfiI-b (5′-CATCTGGC-CGGCCTGGCCACTAG-3′) and template pComb3X containing anti-tetanus toxoid Fab p313 gene (*33*) between the *Sfi*I sites, and (ii) primers SfiI-MBP-f (5′-GGCCAGGCCGGCCAGAT-GAAAATCGAAGAAGGTAAACTG-3′) and MBP-NotI-b (5′-GAGGAGGAGAAGCGGCCGCTTAAATTAATTAGCTA-GCTTAAGAGGAT CCAAATTCTGAAATCC-3′) which included a silent mutation to destroy an intrinsic *Eco*RI site in MBP (indicated by underlining) and template pMAL-pIII. The PCR fragments were fused using primers Bseq and MBP-NotI-b. The resulting PCR product was digested with *Eco*RI and *Not*I and purified. The fragment was ligated to *Eco*RI/*Not*I-digested pComb3X. The correct vector pComb3-MBP was identified by the production of anti-tetanus toxoid Fab fused to MBP and by ELISA against tetanus toxoid using detection of MBP. When the gene of a protein is cloned by the *Sfi*I sites into this vector and the protein is overproduced, the protein is delivered into the periplasm. Thus in this system disulfide bonds that are conformationally reasonable can form automatically in the periplasm when the protein is produced in *E. coli* cells.

ELISA of rpf1368-MBP. Wells of a microtiter plate (Costar 3690) were coated with **1**−BSA (1 μg/PBS 25 μL/well) at 37 °C for 1 h, washed with H_2O two times, and blocked with 3% BSA/PBS (170 μL/well) at 37 °C for 1 h. Blocking solution was removed, and ELISA sample (cell lysate or purified protein) was added (25 μL/well). After 2 h of incubation at room temperature, the wells were washed 10 times with water. The bound rpf1368-MBP was detected using mouse anti-MBP antibody clone MBP-17 (Sigma), goat anti-mouse antibody-alkaline phosphatase conjugate (Pierce), and the phosphatase substrate *p*-nitrophenyl phosphate. The resulting yellow color was measured at 405 nm. For the control MBP, MBP2* protein (NEB) was used.

For the ELISA using **1**−biotin (Figure 2b), wells of a microtiter plate (Costar 3690) were coated with NeutrAvidin (Pierce) (10 μg/PBS 25 μL/well) at 37 °C for 1 h and washed with H_2O two times, and **1**−biotin (80 μM/PBS, 25 μL) was added. After 2 h incubation at room temperature, the wells were washed with H_2O two times and were blocked with 3% BSA/PBS (170 μL/well) at room temperature for 1 h. Blocking solution was removed, and ELISA sample was added. The same procedure was then followed as described for the ELISA with **1**−BSA. For background ELISA, the same procedures were used except that **1**−biotin was added (i.e., wells coated with NeutrAvidin were used for background binding studies).

Whereas **1**−BSA possessed ∼30 diketone moieties per BSA molecule, each subunit of NeutrAvidin binds one molecule of biotin. Therefore, ELISA using **1**−BSA afforded greater signal (absorption at 405 nm) than that using **1**−biotin/NeutrAvidin. Because of the difference in the numbers of the diketone moieties presented on well surfaces, the ELISA signal difference between binding to **1**−BSA and to BSA (background) were also greater than that between binding to **1**−biotin/NeutrAvidin and to NeutrAvidin (background).

Reaction of rpf1368-MBP with 2,4-Pentanedione. Reactions were initiated by adding 2 μL of 2,4-pentanedione (20 mM in CH_3CN) to 78 μL of rpf1368-MBP solution in PBS at 25 °C. The final conditions were [rpf1368-MBP] 2 μM, [2,4-pentanedione] 500 μM in 2.5% CH_3CN/PBS (total volume 80 μL). Enaminone formation was measured by the increase in absorption at 318 nm using a spectrophotometer.

Peptide rpf1368. Peptide rpf1368 was synthesized on a peptide synthesizer using standard Fmoc solid-phase peptide synthesis chemistry, purified by HPLC to >95% purity, and characterized by mass spectrometry. An intramolecular S−S bond was formed when the peptide was stored in buffer under air at room temperature overnight or during the reaction with diketones. The cyclized form of the peptide was also characterized by mass analysis.

Mass Analysis for the Reaction of Peptide rpf1368 with Diketone 2. Reactions were initiated by adding 2.5 μL of diketone **2** (20 mM in CH_3CN) to a mixture of 47 μL of 50 mM Na phosphate, pH 7.0, and 0.5 μL of peptide rpf1368 (10 mM in H_2O). The final conditions were [rpf1368] 100 μM, [**2**] 1 mM in 5% CH_3CN−47 mM Na phosphate, pH 7.0 (total volume 50 μL). After 1 day, MALDI-TOF analysis was performed.

Synthesis of 1−Biotin. See Supporting Information. A mixture of EZ-Link Biotin PEO-LC-Amine (Pierce) (11.2 mg, 0.027 mmol) and diketone *N*-hydroxysuccinimide ester (*N*-hydroxysuccinimide ester rather than BSA amide in the structure of **1**−BSA shown in Figure 1; 9.3 mg, 0.022 mmol) in CH_3CN (0.2 mL)−MeOH (0.2 mL) was stirred at room temperature for 3 h. The mixture was purified by flash silica gel chromatography (EtOAc/MeOH = 4:1 to 2:1) to afford **1**−biotin (7.4 mg, 46%). ^{1}H NMR (500 MHz, CD_3OD) δ 7.50 (d, J = 8.5 Hz, 2H), 7.19 (d, J = 8.5 Hz, 2H), 4.52 (m, 1H), 4.33 (m, 1H), 3.70−3.62 (m, 8H), 3.59 (t, J = 5.5 Hz, 2H), 3.56 (t, J = 5.5 Hz, 2H), 3.41 (t, J = 5.5 Hz, 2H), 3.38 (t, J = 5.5 Hz, 2H), 3.24 (m, 1H), 2.99−2.86 (m, 2H), 2.92 (t, J = 7.4 Hz, 2H × 0.5), 2.74 (m, 1H), 2.63 (t, J = 7.4 Hz, 2H × 0.5), 2.44 (t, J = 7.4 Hz, 2H), 2.33 (t, J = 7.4 Hz, 2H), 2.25 (t, J = 7.4 Hz, 2H), 2.05 (s,

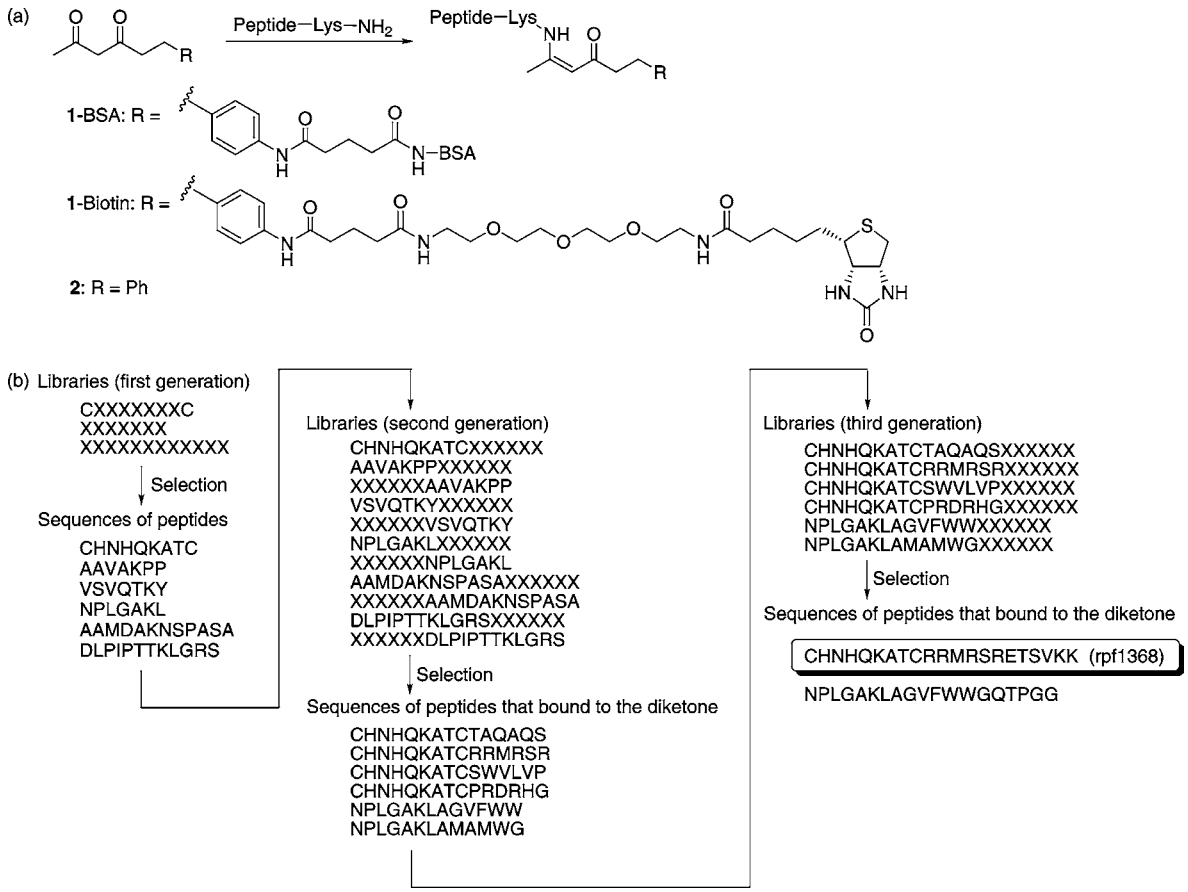

Figure 1. Selection of peptides that form enaminones with diketones. (a) 1,3-Diketones and enaminone formation. (b) Peptide libraries and selected peptide sequences. Selection implies selection using phage display with **1**−BSA immobilized on wells in a microtiter plate.

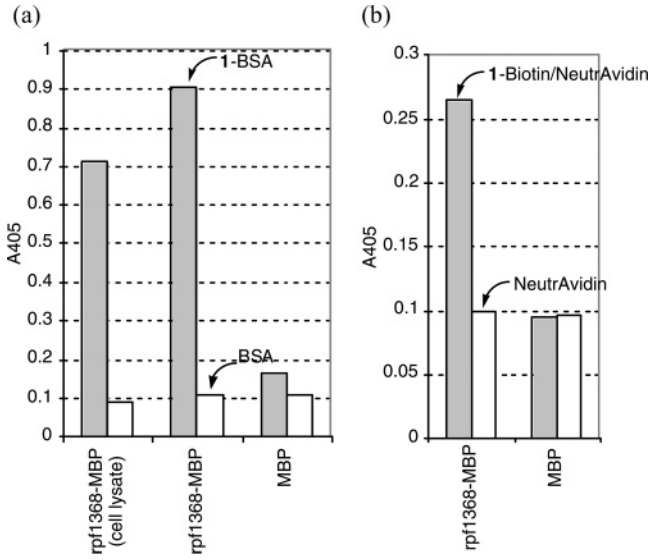

Figure 2. Binding assays of rpf1368-MBP to diketones. (a) ELISA with **1**−BSA. The cell lysate of *E. coli* cells expressing the fusion protein (labeled as cell lysate) was evaluated, as were purified proteins. Data of binding to **1**−BSA and to BSA (background) are shown: **1**−BSA (gray), BSA (white). Deviations were within ±10% of the indicated values. (b) ELISA with **1**−biotin. Data of binding to **1**−biotin supported on NeutrAvidin and to NeutrAvidin (background) are shown: **1**−biotin/NeutrAvidin (gray), NeutrAvidin (white). Deviations were within ±10% of the indicated values.

RESULTS AND DISCUSSION

Design of Labeling System Using Enaminone Formation and Selection of Peptides. Lysine ϵ-amino groups and N-terminal amino groups in proteins and peptides are not typically nucleophilic enough to form enaminones with 1,3-diketones at neutral pH, but certain enzymes have nucleophilic lysine ϵ-amino groups that are essential for catalysis (*34*, *35*). 1,3-Diketones act as inhibitors of such enzymes by formation of enaminones with the nucleophilic amino groups (*36*). Because of the π-conjugation, enaminones are very stable (*34*, *36*, *37*). In order for an amino group to be nucleophilic enough to allow for formation of an enaminone with diketones, the amino group must either have an electrostatic interaction with a positively charged residue or be present within a hydrophobic microenvironment (*35*, *38*, *39*). Only proteins and peptides that can provide such interactions/microenvironments can form enaminones with 1,3-diketones. Thus a small peptide that forms an enaminone with a 1,3-diketone derivative should provide selective and stable labeling of a protein of interest through the enaminone formation reaction with a diketone-labeling molecule conjugate.

Although peptides possessing lysine residues in α-helical structures whose lysine ϵ-amino groups are nucleophilic have also been developed by design (*40*, *41*−*43*), design of peptides that form an enaminone with 1,3-diketones is generally a difficult task. To efficiently develop proteins and peptides that have nucleophilic amino group(s), we have used selections from libraries based on formation of enaminones with 1,3-diketones. Using the enaminone formation reaction-based selections with 1,3-diketone derivatives from antibody libaries, we have previously developed catalytic antibodies that possess a nucleophilic lysine ϵ-amino group for catalysis (*33*, *34*, *44*). We have also demonstrated that peptides with improved activities for enamine

catalysis can be generated by the reaction-based selection with 1,3-diketones using phage displayed peptide libraries (*45*, *46*) and developed an RNase S-peptide-derived small peptide that forms an enaminone, upon interaction with RNase S-protein (*47*).

Here we have explored reaction-based selection with 1,3-diketone derivatives using peptide libraries that did not initially include helix or sheet structures. Peptide libraries composed of randomized amino acids that are not part of other folded proteins were previously used to identify peptides that noncovalently bind to small molecules (*48*). Although selections starting from a completely randomized 80-mer protein library have been performed to select ATP binding proteins (*49*), current methods allow for only a small portion of such libraries to be probed. Further, the results obtained from such libraries have not superseded results obtained with smaller peptide libraries. Thus, we started our selection using peptides containing seven to twelve randomized amino acids displayed on phage. Initially selected peptides were improved by extending their structure through the attachment of libraries composed of six randomized amino acids followed by the same reaction-based selections. Multiple rounds of peptide growth and selection were performed to access functional peptides without resorting to a longer peptide library where the theoretically diversity of the library would far exceed that examined in the actual experiment.

First, phage-displayed peptide libraries that contained seven randomized amino acids flanked by a pair of cysteine residues (CX_7C, X = any of the natural 20 amino acids), linear seven-mer peptides (X_7), and linear 12-mer peptides (X_{12}) fused via a short spacer to the N-terminus of a minor coat protein (pIII) of the filamentous bacteriophage M13 phage were screened in a covalent selection with a 1,3-diketone derivative (Figure 1). Four rounds of binding selection of each peptide-phage library were performed against diketone **1**−bovine serum albumin conjugate (**1**−BSA) (*34*) immobilized on wells in a microtiter plate. Phage from each of the selected libraries were combined, and three additional rounds of selection were performed. After the final round of selection from the first libraries, individual clones were examined for binding to the diketone in an enzyme-linked immunosorbent assay (ELISA) using **1**−BSA. The amino acid sequences of the 20 individual clones that showed positive signals, including those with borderline signals (the ELISA signal was above the background but less than 2-fold of the background) in the ELISA, were determined, and six different peptides (total 10 out of the 20) had at least one lysine residue. Since we were more interested in peptides that formed enaminones through lysine ϵ-amino groups than through the N-terminal amino group, these six peptide sequences were used as the starting points for further improvement. The peptides were elongated to evolve their activity by attachment of six randomized amino acid residues of each of the natural 20 amino acids. The resulting libraries (the second generation libraries) were selected against **1**−BSA for four rounds using the monovalent phage display system pComb3X (*31*). ELISA identified individual clones, from the final round of selection from the second-generation libraries, that bound to **1**−BSA, and the amino acid sequences of the bound clones were determined. These peptides were further elongated by attachment of six randomized amino acid residues, and the same phage selection procedure was used. After the selection from the third generation libraries, a peptide that showed a relatively strong ELISA signal (more than 5-fold of the background) against **1**−BSA, named rpf1368 (Figure 1b), was obtained, and this peptide was further characterized.

Preparation of the Fusion Protein and Evaluation of Diketone Labeling. In order to examine whether peptide rpf1368 could be used to label a protein, a fusion of this peptide with maltose binding protein (MBP) was prepared, and labeling

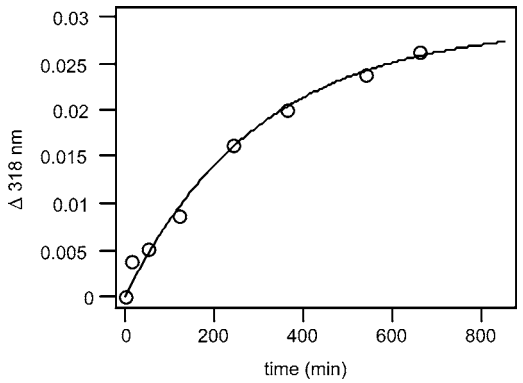

Figure 3. Time course of enaminone formation of rpf1368-MBP with 2,4-pentanedione. Increase in absorption at 318 nm, characteristic of the enaminone, was monitored. Conditions: [rpf1368-MBP] 2 μM and [2,4-pentanedione] 500 μM in 2.5% CH_3CN/PBS. The second-order rate constant k in this reaction {V (M/min) = k[2,4-pentanedione (M)][peptide rpf1368 (M)]} was 6.0 M^{-1} min^{-1}.

was analyzed by ELISA with **1**−BSA. The culture supernatant and lysates of *E. coli* cells that produced fusion protein rpf1368-MBP showed a positive signal in the ELISA, while the culture supernatant and lysate of *E. coli* cells that did not produce rpf1368-MBP or that produced only MBP were negative in the same ELISA. The ELISA results concerning these cell lysate experiments and those performed with the purified protein are shown in Figure 2a. Both the cell lysate containing rpf1368-MBP and the purified fusion protein rpf1368-MBP bound to the diketone conjugate **1**−BSA significantly better than to BSA. These results indicate that rpf1368 tagged protein can be labeled with diketone derivatives. Since MBP that was not fused to peptide rpf1368 did not bind to **1**−BSA, the peptide rpf1368 portion of rpf1368-MBP is essential for binding to the diketone. Note that MBP has 34 lysine residues per molecule. The ELISA results indicate that peptide rpf1368 has a different chemical reactivity with the 1,3-diketone and is selectively labeled.

Labeling of protein rpf1368-MBP was also analyzed using diketone−biotin conjugate **1**−biotin in ELISA experiments. Fusion protein rpf1368-MBP bound to **1**−biotin supported on a NeutrAvidin, but native MBP did not (Figure 2b). Biotin was introduced into rpf1368-MBP without requirements of the addition of any second catalysts or reagents. These results indicate that peptide rpf1368 functions as a fusion protein and that this peptide can be used as a tag for proteins to introduce compounds conjugated with the diketone.

Formation of enaminones can be monitored through the UV absorption characteristic of the enaminone at 318 nm (*34*), so enaminone formation of rpf1368-MBP was analyzed by monitoring this UV absorption band. When rpf1368-MBP was mixed with 2,4-pentanedione, the smallest compound containing the diketone structure, at pH 7.4, an increase in UV absorption at 318 nm was observed, indicating that rpf1368-MBP covalently bound to this diketone through formation of an enaminone linkage. When 500 μM of 2,4-pentanedione and 2 μM of rpf1368-MBP were mixed in buffer at pH 7.4, the enaminone formation reaction took approximately 10 h to reach >90% modification as shown in Figure 3. This reaction rate for enaminone formation between rpf1368 and 2,4-pentanedione should be acceptable for labeling. Fusion protein rpf1368-MBP was labeled at a low protein concentration (2 μM). When we studied our previously developed 24-mer peptide FT-YLK3 (*46*) that possesses nucleophilic lysine residues in a helical structure upon dimerization or oligomerization was fused to MBP, the labeling of FT-YLK3-MBP fusion with 1,3-diketones was not detected at 2 μM fusion protein concentration. At a high concentration, FT-YLK3-MBP formed oligomers, possibly based on oligomerization of the FT-YLK3 portion. Such

oligomerization typically is not suitable for many uses of labeled fusion proteins. Thus, as a labeling tag, peptide rpf1368 is superior to our previously developed small peptides containing helical structures where self-association is key for the conformation necessary to provide enaminone forming amino groups.

Characterization of the Labeling Reaction Using Synthetic Peptides. In order to characterize the peptide in more detail, the 21-mer peptide rpf1368 was chemically synthesized (with a C-terminal amide, in cyclic form due to the formation of a disulfide bond between cysteines) and evaluated. This synthesized peptide also showed an increase in UV absorption at 318 nm upon addition of 2,4-pentanedione, characteristic of enaminone formation. Enaminone formation was also confirmed by MALDI-TOF mass analysis. A mixture of peptide rpf1368 and diketone **2** gave isotopic mass *m*/*z* MH^+ of 2725 whereas peptide rpf1368 alone had isotopic mass *m*/*z* MH^+ of 2553 (see Supporting Information). One molecule of diketone **2** (MW 190) was incorporated per peptide rpf1368 and one molecule of H_2O (MW 18) was released, indicating the formation of the enaminone through an amino group of the peptide. Only one amino group of rpf1368 was nucleophilic. Another possible covalent modification, formation of the pyrimidine derivative with a guanidyl group of an arginine, was excluded by the mass analysis: If a guanidyl group reacted with diketone **2** and formed a derivative of pyrimidine (*50*), the mass MH^+ should be 2707 because two molecules of H_2O are released in the formation of pyrimidine. Unrelated peptides possessing lysine residue(s), ELLELDKWASLWNC, ELKDKWASLWNWFNIT, ELDKWASLWNWFDITGGC, and CDEKSKLQEIYQELTQLKAAVGEL, did not form an enaminone with 2,4-pentanedione; no changes in absorption at 318 nm were observed in the presence of 2,4-pentanedione for these peptides. The single reactive site within peptide rpf1368 is in contrast to our previously developed 24-mer and 35-mer peptides possessing a helical structure (*46*, *51*). Although multiple lysine groups are present in peptide rpf1368, only one amino group was nucleophilic enough to form the enaminone.

The conformation of peptide rpf1368 was critical for the reactivity. An intramolecular disulfide bond between the two cysteines of the peptide formed spontaneously in buffer under air at room temperature. The uncyclized peptide (prior to disulfide bond formation) did not react with 2,4-pentanedione. The cyclic constraint of rpf1368 by the disulfide bond provided for the formation of favorable electrostatic interactions or a microenvironment that tuned the reactivity of the amino group.

CONCLUSION

We have developed a small 21-mer peptide that possesses a single reactive amino group using a reaction-based selection with a 1,3-diketone derivative and phage-displayed peptide libraries. The libraries did not contain designed helix or sheet structures. We have demonstrated that the peptide can be used as a tag for a protein of interest to covalently label the protein with a synthetic molecule through enaminone formation. No enzyme and no additional reagents were necessary for the labeling of the peptide−protein fusion with the diketone derivatives. Although the reactivity of peptide rpf1368 is still moderate compared to existing covalent labeling tags that are derivatives of natural proteins, this peptide is the smallest peptide tag for covalent labeling with designed synthetic molecules without the requirement of additional catalysts or toxic metal reagents. We have demonstrated that small peptides that covalently react with designer synthetic molecules can be generated. Further improvement of this peptide should provide better small peptide tags for covalent labeling. Using these tags, a variety of molecules such as reporter probes and other functionalities may be conveniently and covalently introduced into proteins of interest.

AVI BioPharma, Inc., Corvallis, Oregon. Received February 22, 2007; Revised Manuscript Received April 27, 2007

Objective: Conjugation of arginine-rich cell-penetrating peptide (CPP) to phosphorodiamidate morpholino oligomers (PMO) has been shown to enhance cytosolic and nuclear delivery of PMO. However, the *in vivo* disposition of CPP−PMO is largely unknown. In this study, we investigated the pharmacokinetics, tissue distribution, stability, and safety profile of an anti-c-*myc* PMO conjugated to the CPP, $(RXR)_4$ (X = 6-aminohexanoic acid) in rats. Methods: The PMO and CPP−PMO were administrated intravenously into rats. The concentrations of the PMO and the CPP−PMO in plasma and tissues were monitored by HPLC. The stability of the CPP portion of the CPP−PMO conjugate in rat plasma and tissue lysates was determined by mass spectrometry. The safety profile of the CPP−PMO was assessed by body weight changes, serum chemistry, and animal behavior. Results: CPP conjugation improved the kinetic behavior of PMO with a 2-fold increase in the estimated elimination half-life, a 4-fold increase in volume of distribution, and increased area under the plasma concentration vs time curve. Consistent with the improved pharmacokinetic profile, conjugation to CPP increased the uptake of PMO in all tissues except brain, varied between organ type with greater uptake enhancement occurring in liver, spleen, and lungs. The CPP−PMO conjugate had greater tissue retention than the corresponding PMO. Mass spectrometry data indicated no observable degradation of the PMO portion, while there was identifiable degradation of the CPP portion. Time-dependent CPP degradation was observed in plasma and tissue lysates, with the degradation in plasma being more rapid. The pattern of degraded products differed between the plasma and lysates. Safety evaluation data showed that the CPP−PMO was well-tolerated at the dose of 15 mg/kg with no apparent signs of toxicity. In contrast, at the dose of 150 mg/kg, adverse events such as lethargy, weight loss, and elevated BUN ($p < 0.01$) and serum creatinine ($p < 0.001$) levels were recorded. Supplementation with free L-arginine *ad libitum* showed improved clearance of serum creatinine ($p < 0.05$) and BUN ($p < 0.01$) at the toxicological dose, suggesting that the CPP caused toxicity in kidney. Conclusion: This study demonstrates that conjugation of CPP to PMO enhances the PMO pharmacokinetic profile, tissue uptake, and subsequent retention. Therefore, when dosed at ≤15 mg/kg, CPP is a promising transporter for enhancing PMO delivery in therapeutic settings.

INTRODUCTION

Phosphorodiamidate morpholino oligomers (PMO[1]) are uncharged steric-blocking antisense compounds that can interfere with protein translation, pre-mRNA splicing, and RNA synthesis (*1*−*5*). The structure of PMO differs from DNA, with two major structural changes in the phosphorodiester internucleoside linkages and the five-membered ring of the deoxyribose sugar of DNA, as shown in Figure 1. Several animal models have demonstrated the antisense specificity and efficacy of PMOs against their targets (*6*−*15*). Like many macromolecules, the cellular uptake of PMOs is limited. Recently, several studies have reported success using arginine-rich cell-penetrating peptides (CPPs) to improve cytosolic and nuclear delivery of PMO in cell culture and *in vivo*. For instance, conjugation of CPPs to PMOs enhanced the ability of PMOs to inhibit replication of various viruses in cell culture (*3*, *16*−*22*) and *in vivo* (*19*, *23*), as well as to alter pre-mRNA splicing (*24*−*27*). The internalization of CPP−PMO conjugates may be through an endocytosis mechanism involving binding of cell surface proteoglycans through electrostatic interactions between cationic charges of the CPP and anionic charges of the proteoglycans (*28*).

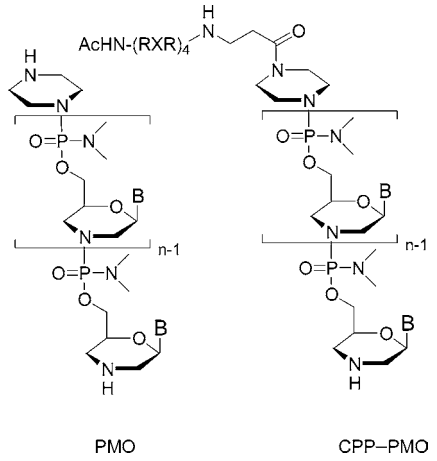

Figure 1. Structures of PMO and CPP−PMO.

These successes point to the potential of CPPs for the intracellular delivery of therapeutic PMO; however, there are no reports on the *in vivo* disposition of any CPP−PMO. Information regarding pharmacokinetics (PK), tissue distribution, dosing, and the safety profile of a CPP−PMO would be useful in designing animal experiments for various disease models.

Therefore, the objective of this study was to evaluate the *in vivo* disposition of a PMO conjugated to a CPP having the $(RXR)_4XB$ sequence (X = 6-aminohexanoic acid, B = β-alanine, R = L-arginine). We chose this CPP for our study on the basis of the following. First, this CPP demonstrated greater serum stability compared to CPPs such as Tat and an oligoarginine (*29*). Second, PMO conjugated to this CPP had greater antisense activity than PMO conjugated to Tat and the oligoarginine CPP (*28*). Last, this CPP has been shown to successfully deliver PMO and caused specific antisense activities in several virus models (*3*, *17*, *18*, *23*) and in pre-mRNA splicing models (*24*, *25*, *28*). Here, we report the PK, tissue distribution, biological stability, and safety profile of the $(RXR)_4XB$−PMO conjugate (CPP−PMO) following intravenous injection in rats.

EXPERIMENTAL PROCEDURES

Synthesis of PMO, CPP, and CPP−PMO Conjugate. The PMO, CPP, and CPP−PMO conjugates were synthesized by AVI BioPharma (Corvallis, OR). The PMO with sequence 5′-ACGTTGAIIIGCATCGTCGC-3′ (I = inosine) was synthesized and purified to >90% by the previously described method (*1*, *30*). The peptide was synthesized and purified to >95% purity using the standard FMOC chemistry and HPLC method. The CPP−PMO conjugate was synthesized and purified according to a method described previously (*28*). The purity of the final conjugate was >90%.

PMO Quantitation. The concentration of PMO in tissue homogenates and plasma from the treated animals was evaluated by HPLC as described previously (*8*). An extra trypsin-digestion step was performed for the samples harvested from CPP−PMO treated rats. The trypsin-digestion step was used for removal of the CPP portion of the conjugate (*31*) and left the PMO portion for quantification. Briefly, a 100 μL aliquot of the plasma or tissue homogenate was mixed with 100 μL of trypsin solution (1.0 mg/mL in 1× PBS; Sigma Aldrich, St Louis, MO). The mixture was then incubated in a water bath at 37 °C overnight to facilitate the removal of the peptide from the CPP−PMO conjugate.

Animals and Husbandry. Experimentally naïve catheterized male Sprague−Dawley rats (Zivic Laboratories, Zelienople, PA) were used for this study. At the time of the experiment, the rats were 9−11 weeks old and weighed 200−250 g. On arrival, the animals were individually housed in stainless steel cages during the acclimatization and treatment periods in the laboratory animal resource center at Oregon State University (OSU), Corvallis, OR. The animals were exposed to a 12 h light/dark cycle in a temperature- and humidity-controlled environment and allowed access to commercially available rodent diet and city-supplied tap water. Temperature was maintained at 18−26 °C. The light/dark cycle was allowed to be interrupted for study-related activities. The animal studies were used in accordance with the guidelines established in the *Guide for the Care and the Use of Laboratory Animals of National Research Council* and was monitored by the institutional animal care and use committee, of OSU.

Treatments. Animals were randomly assigned to each treatment group. Each animal received intravenous (iv) bolus injection at 15, 30, and 150 mg/kg dosing levels of the CPP−PMO or PMO via an installed jugular vein catheter. In this study, the 150 mg/kg dose was chosen for toxicological evaluation. Blood samples were collected via the installed catheter at 0.2, 0.5, 1, 2, 4, 8, 12, and 24 h time points following a single dose for plasma PK evaluation. For the tissue uptake study, the animals were injected with a daily dose of 15 or 30 mg/kg for 5 days. The animals were euthanized 24 h or 5 days after the last injection by 100% carbon dioxide inhalation (in a plexiglass chamber). The liver, kidney, spleen, heart, brain, and lungs of the animals were harvested to assess the tissue distributions of the PMO and CPP−PMO.

Pharmacokinetic Evaluation. PK was characterized by compartmental analysis from the blood samples collected at different time points following the first administration. Plasma concentration versus time profiles were fitted into a two-compartmental open model with bolus intravenous input using the PK Solutions Software (Summit Research Services, Montrose, CO). The fitted PK parameters include the apparent elimination half-life ($T_{1/2}\beta$), plasma clearance (CL), volume of distribution (Vd), and the area under the concentration versus time curve (AUC). The AUC was estimated using the log-linear trapezoidal method. The plasma data were fitted to eq 1

$$C(t) = A\,e^{-\alpha t} + B\,e^{-\beta t} \quad (1)$$

where $C(t)$ is plasma concentration at time t; A and B are intercept terms; α is distribution rate constant; and β is elimination rate constant.

Biological Stability of CPP in Plasma and Tissues. Stability of the CPP−PMO was examined in the rat plasma and lysates of the liver, heart, and kidney. The tissue lysates were prepared as previously described (*32*). The CPP−PMO was incubated in the lysates or plasma at 37 °C for 1, 6, and 24 h periods. The PMO were extracted and subsequently analyzed by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) using a method described previously (*29*).

Safety Assessment. The safety of the CPP−PMO or PMO was evaluated on the basis of mortality as well as changes in physical appearance, behavior by cage-side observations, in-life body weight, and serum biochemistry profile. LD_{50} of the CPP−PMO was determined by iv administration of a single dose of the compound at the doses ranging from 1.2 to 400 mg/kg. The following serum components were monitored as part of the toxicological evaluation following administration of the CPP−PMO or PMO: serum alanine aminotransferase (ALT), lactate dehydrogenase (LDH), alkaline phosphatase, total bilirubin, albumin, total protein, glucose, cholesterol, blood urea nitrogen (BUN), and serum creatinine. All samples were evaluated by the analytical laboratory at OSU college of Veterinary Medicine.

Statistical Analysis. Data were analyzed using the statistical program *GraphPad Prism* v 4.01 (GraphPad Software, San Diego, CA). Statistical differences among compared groups were analyzed by one-way nonparametric ANOVA, and Tukey's multiple comparison post-test analysis with a p value less than 0.05 was considered statistically significant. Comparison of two dosage levels was conducted using the Student's t test. A two tailed p value less than 0.05 was considered statistically significant.

RESULTS

Plasma Pharmacokinetics. Conjugation of PMO to the CPP improved kinetic behavior of the PMO. Pharmacokinetic (PK) analysis was based on plasma data following a single intravenous injection. The plasma concentration data was described by a two-compartment PK model describing both the distribution and elimination phases. The plasma concentration vs time curves and the PK parameters of the CPP−PMO and PMO are presented in Figure 2 and Table 1 respectively. The plasma PK for the CPP−PMO was characterized by rapid distribution from the vascular space to tissues with an initial distribution half-life ($T_{1/2}\alpha$) ranging from 0.40 to 1.56 h. The CPP−PMO showed a prolonged elimination half-life ($T_{1/2}\beta$) ranging from 3.80 to 8.23 h, representing a 2-fold increase compared to the PMO at all three doses. Also, we observed a 4-fold increase in the

volume of distribution (Vd) (12.10−15.22 L/kg body weight) at the 15 and 30 mg/kg doses following conjugation of the CPP to the PMO. There was a small but statistically significant increase in the area under the plasma concentration vs time curve (AUC) at the 30 mg/kg dose and a larger increase in AUC for the 150 mg/kg dose.

Tissue Distribution. Conjugation of PMO to the CPP increased the tissue uptake and retention of the PMO. The liver, kidney, spleen, heart, brain, and lungs of the animals were harvested 24 h following five single daily injections of 15 and 30 mg/kg PMO or CPP−PMO, to assess the tissue distribution of the PMO. The tissue recovery at the 15 mg/kg dose following a 5 day washout period was also evaluated. The data is presented in Figure 3A−C. The CPP−PMO showed a broad tissue distribution with the kidney and liver as the primary sites of accumulation. Relatively lower concentrations were detected in spleen, lungs, heart, and brain. At equivalent dose, the tissue recovery data showed that conjugation of the CPP improved tissue uptake of the PMO in all of these tissues except brain, with the liver, spleen, and lungs showing greater increases at compared to PMO both dosing levels. In addition, tissue concentrations of the CPP−PMO treated samples were greater than the PMO treated samples 5 days postdose (Figure 3C), indicating that CPP conjugation prolongs the duration of tissue retention.

Biological Stability of CPP−PMOs. The stability study found no evidence of PMO degradation, while the observed degradation of the CPP portion of CPP−PMO depended on time and tissue type. The degradation pattern varied among the tissue types and between tissue and plasma. The stability of the conjugate was examined in the plasma and the lysates of rat liver, heart, and kidney. The CPP−PMO was incubated with tissue lysates or plasma at 37 °C for 1, 6, and 24 h. The extracted materials were then analyzed by MALDI-TOF MS (*29*). The CPP portion of the conjugate degraded, more rapidly in plasma than in tissues (Figure 4). The intact CPP−PMO was observable in the plasma up to 6 h. A 24 h treatment resulted in complete degradation of the intact conjugate from $(RXR)_4XB$−PMO to RXRXB−PMO. However, degradation of CPP was slower in tissue homogenates, with no apparent degradation at 6 h but much degradation at 24 h. Unlike the heart and kidney, some intact CPP was detectable in the liver at the 24 h time point. Therefore, the biological stability of the CPP was ranked in the order of liver > heart = kidney > plasma. In the plasma, cleavage appeared to occur between adjacent L-arginine residues with the appearance of an m/z peak corresponding to RXR, which is consistent with the data observed in human serum (*29*). Comparatively, in the liver and kidney, degradation was observed to occur between adjacent L-arginine and 6-amino-hexanoic acid residues with m/z peaks corresponding to XR-(RXR) and $XR(RXR)_2$. CPP degradation in the heart homogenate reflected a combination of the degradation patterns observed for plasma, liver, and kidney.

Safety Assessment. Animals were observed for changes in behavior, appearance, or eating and drinking habits during the course of the study. Body weight measurements and serum chemistry were also used for the safety evaluation as shown in Table 2. The CPP−PMO conjugate did not cause detectable toxicity at the 15 mg/kg dose. It was well-tolerated, with no

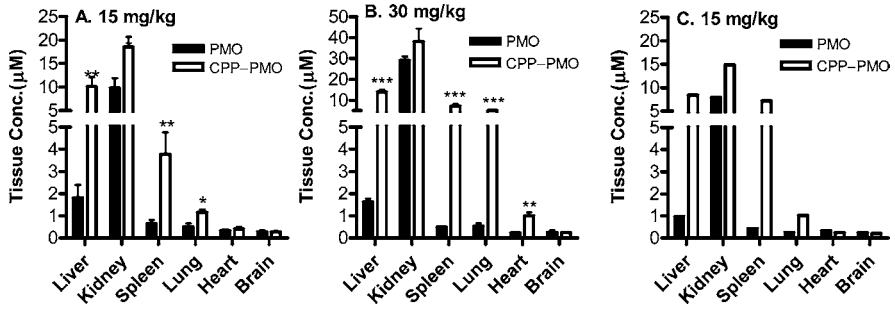

Figure 3. PMO concentration detected in tissue lysates. Rats were administrated with the PMO or the CPP−PMO at 15 mg/kg (A) and 30 mg/kg (B) with single daily iv injection for 5 days, and tissues were harvested 24 h after the last administration. Each data point represents mean ± SD of replicate values ($N = 5$). (C) Rats were administrated with the PMO or the CPP−PMO at 15 mg/kg with single daily iv injection for 5 days, and the tissue were harvested 5 days after the last administration. The lower limit of quantitation (LLOQ) of the HPLC method was 0.075 μM. *p < 0.05, **p < 0.01, ***p < 0.001 (Student's t test).

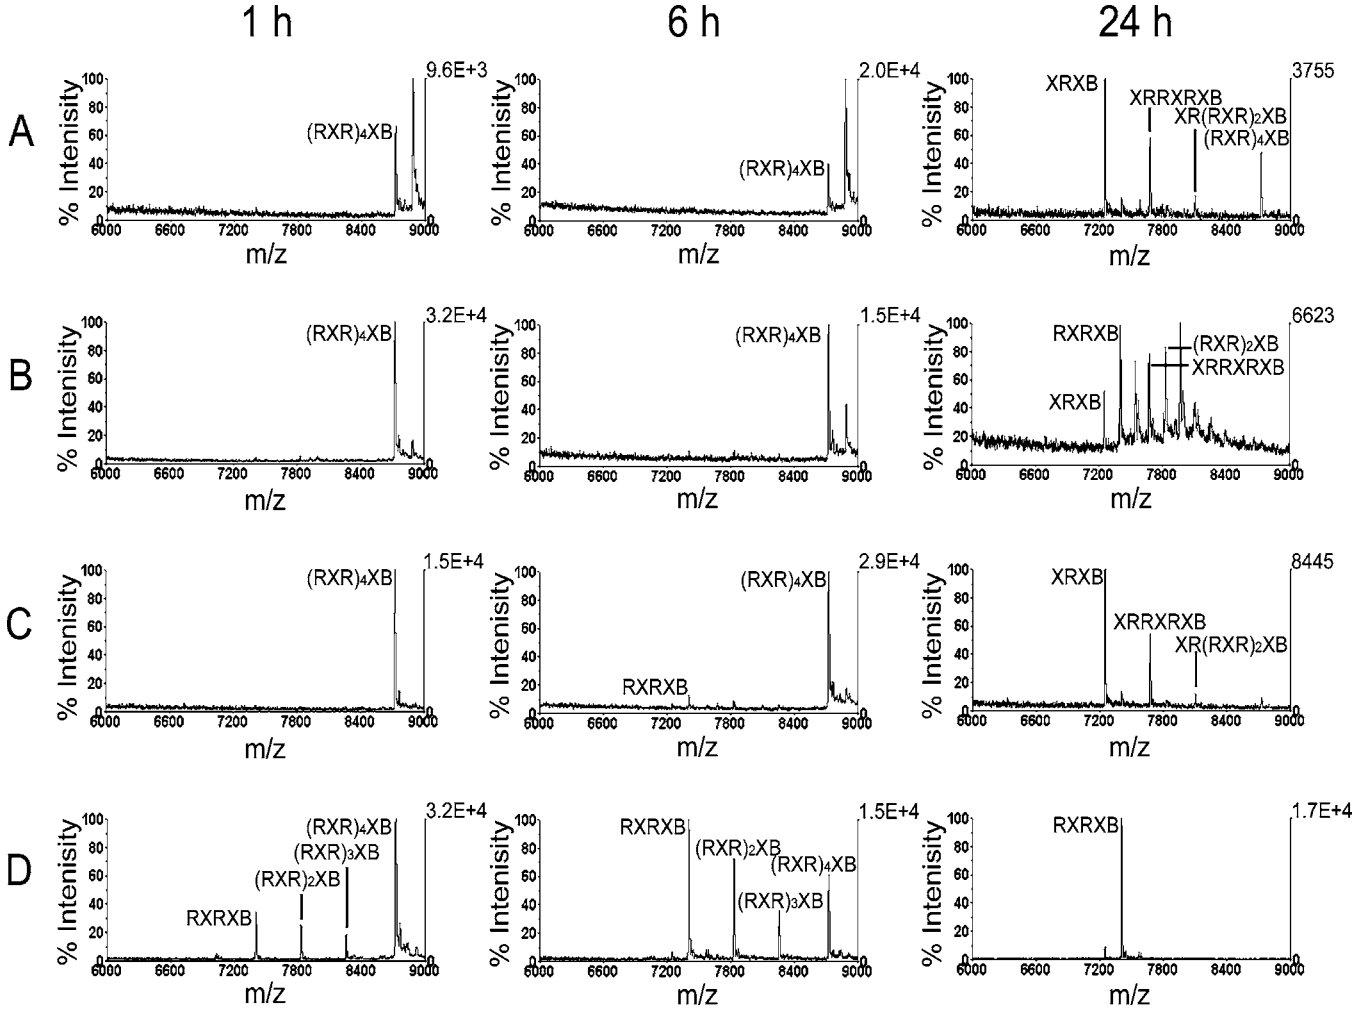

Figure 4. Biological stability of the peptide portion of the CPP−PMO conjugate in the rat tissue lysate or plasma. The mass spectrometry spectra of the samples are shown. Rat liver lysate (A), heart lysate (B), kidney lysate (C), and plasma (D) were treated with conjugate at 34 μM for 1, 6, and 24 h at 37 °C. The extracted materials were then analyzed by MALDI-TOF MS.

apparent adverse events. At 30 mg/kg, there was a decrease in body weight and a slight elevation in BUN levels but not creatinine. At 150 mg/kg, there was a greater decrease in body weight and a greater increase in BUN ($p < 0.05$) and serum creatinine ($p < 0.001$) levels. Animals appeared to be lethargic within minutes after the injection of 150 mg/kg of the conjugate. No changes were observed in albumin, total protein, glucose billirubin, cholesterol, electrolytes, as well as formed elements of blood (including red cells, neutrophils, and platelets) or serum enzymes such as LDH, or ALT (data not shown) at any dose level.

Free L-arginine was administered *ad libitum* in an attempt to restore BUN and serum creatinine to the normal plasma levels alongside treatment with CPP−PMO at a dose of 150 mg/kg. This was based on earlier reports demonstrating L-arginine to be effective against renal toxic or ischemic injury (*33*−*39*). L-Arginine supplementation significantly improved BUN ($p < 0.01$)) and serum creatinine ($p < 0.05$) clearance, as shown in Figure 5A and B, respectively.

The data in Figure 6 show that the LD_{50} of the conjugate administered iv in rats was between 210 and 250 mg/kg. Death was observed at 3 h postdose at 400 mg/kg and was preceded

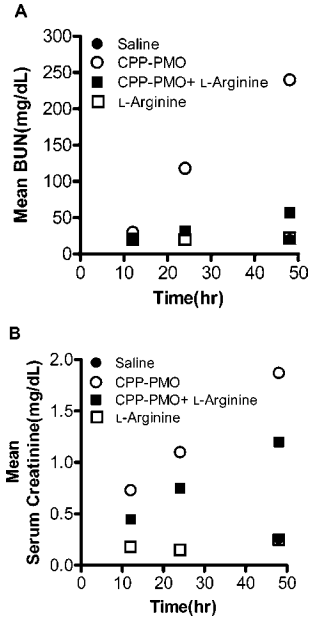

Figure 5. Coadministration of L-arginine reduced serum BUN and creatinine levels. Mean serum creatinine and BUN levels vs time following iv administration of the CPP−PMO at a single 150 mg/kg dose and 0.5 g/animal L-arginine administered *ad libitum*. Serum creatinine and BUN following CPP−PMO + L-arginine treatment were significantly lower than the CPP−PMO alone, $p < 0.05$ and $p < 0.01$, respectively (one-way ANOVA, Tukey's multiple comparison test).

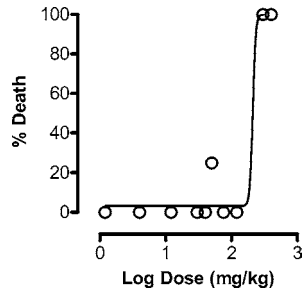

Figure 6. Percent animal death vs log dose of the CPP−PMO following a single iv injection in rats.

by mild to severe lethargy, decreased food and water consumption, and ruffled fur.

DISCUSSION

PMOs have been shown to have good biological stability (*29*), RNA binding affinity and specificity (*2, 31*), efficacy, and safety profiles (*7, 13, 40*). In spite of these qualities, delivery of PMOs into cells is limited. The arginine-rich cell-penentrating peptides, Tat, oligoarginine, and $(RXR)_4$, have been shown to enhance the cytosolic and nuclear delivery of PMO (*3, 23, 26*−*28*). The $(RXR)_4$ peptide has been found to be more efficacious (*28*) and more stable (*29*) than the Tat and oligoarginine peptides, and may have the potential to deliver therapeutic PMO. Therefore, evaluation of the PK, tissue distribution, biological stability, and safety of the $(RXR)_4$−PMO conjugate is an important step for its therapeutic development.

Conjugation of PMO to the $(RXR)_4$ CPP improved kinetic behavior of the PMO as reflected by prolonged elimination half-life, increased AUC, and volume of distribution (Vd). Since the AUC and Vd are directly related to bioavailability and tissue uptake, respectively, it is expected that increases in these pharmacokinetic parameters will lead to increased tissue uptake. Indeed, the CPP−PMO demonstrated broad tissue distribution with increased uptake compared to PMO alone in all tissues except brain. This is in agreement with an earlier study which demonstrated enhanced tissue uptake of a Tat-protein-conjugated PMO compared to the same PMO in a nonconjugated form (*41*). Kidney and liver were the sites of the highest accumulation of CPP−PMO in our study, with relatively lower concentrations observed in the lungs, spleen, heart, and brain. The broad distribution of the PMO is therapeutically valuable, because it is targeted to c-*myc* which is ubiquitously expressed in nearly all replicating cells. c-*myc* is expressed in the process of liver regeneration following partial hepatectomy, polycystic kidney disease, and other cell proliferation disorders. Therefore, the observed accumulation of the CPP−PMO in tissues such as the liver and kidney may be therapeutically valuable. Once delivered to the tissues, CPP−PMO showed extensive retention time as shown by the tissue concentration of the compound detected 5 days after the last injection as shown in Figure 3C. This observation further goes to demonstrate a slow efflux of the compound from tissues back to the vascular space, which is vital in determining the dosing schedule in future clinical studies.

Electrostatic interaction between the positively charged conjugate and cell surface proteoglycans is one of the factors that account for increased tissue uptake of CPP−PMO compared to PMO. The exact mechanism by which conjugated CPPs facilitate PMO delivery into the cytosolic and nuclear compartments of cells is not fully understood, although proteoglycan-involved endocytosis has been suggested (*28*).

The CPP had moderate biological stability with intact CPP detectable up to 6 h in plasma. This, along with the CPP−PMO having an estimated distribution half-life ($T_{1/2}\alpha$) range from 0.4 to 1.56 h, suggests that CPP−PMO will likely have sufficient time for distribution from plasma to peripheral tissues before the CPP component is completely degraded. Once the CPP−PMO reached the tissues, it had a high degree of stability, with the majority of the conjugate still intact up to 6 h in all three tissue types examined. It is interesting that the rate and pattern of CPP degradation differed among the tissues. No detectable intact conjugate was found in heart and kidney after 24 h incubation, but the intact conjugate was still detectable in liver.

Safety was assessed on the basis of changes in the animals' physical appearance and activity, food and water consumption, in-life body weight, and serum biochemistry. The CPP−PMO conjugate was well-tolerated at 15 and 30 mg/kg doses, with no evidence of clinical abnormalities. This observation further emphasizes the therapeutic utility of this CPP−PMO conjugate, since the effective dose has been shown in previous studies to be several fold less than the lowest dose used in this study (*13, 42*). However, the 150 mg/kg dose caused adverse events such as lethargy and elevated BUN and serum creatinine levels. It must be noted that the 150 mg/kg dose was chosen to exclusively examine the toxicological profile of the CPP−PMO conjugate and therefore has no therapeutic relevance. BUN and creatinine are cleared from the plasma mainly by the kidneys, and a decrease in renal output leads to a simultaneous elevation of BUN and creatinine in plasma. We note that L-arginine is a known precursor for urea and creatinine biosynthesis in the liver and kidneys (*43*−*46*). It is therefore possible that the elevated BUN and serum creatinine levels could be due in part to the CPP degradants. However, the degree of elevation of serum creatinine and BUN levels appear to be significant and may not have been generated from the CPP portion of the CPP−PMO. Therefore, we hypothesize that the observed simultaneous increase in serum creatinine and BUN concentrations is a result of reduced renal output.

To test this hypothesis, L-arginine was administered *ad libitum* in an attempt to rescue the animals from the apparent peptide-induced renal failure. Like other cationic amino acids, L-arginine is transported into cells and tissues via the Na^+-independent cationic amino acid transporter system y^+, which is encoded

by the *Cat* gene (*47*−*52*). We speculate that the delivery peptide which is arginine-rich utilizes the y^+ system for transport into the kidney but with lower affinity compared to L-arginine. Therefore, L-arginine may be expected to displace the CPP−PMO conjugate from the transporter, thereby reducing the delivery of the CPP−PMO to the kidney cells. Displacement of the CPP−PMO conjugate from the transporter by L-arginine may lead to reduced kidney exposure, and hence, the effect of the CPP−PMO on the kidney could be reduced. Also, L-arginine has been shown to increase renal glomerular filtration rate (GFR) either via nitric oxide (NO) production or stimulation of glucagon secretion (*33*−*39*). Indeed, our results showed improved renal clearance of creatinine and BUN following L-arginine supplementation.

In conclusion, pharmacokinetic, tissue distribution, biological stability, and safety profiles of a CPP−PMO have been established by this study. CPP conjugation improved the kinetic behavior and tissue uptake of PMO. The CPP component has moderate stability in plasma and tissues. At ≤15 mg/kg, CPP−PMO appeared to be nontoxic. Hence, the data from this study provide useful information when designing future CPP−PMO *in vivo* efficacy studies.

ACKNOWLEDGMENT

The authors thank the chemistry team at AVI BioPharma for the synthesis and purification and analysis of the PMO and CPP−PMO used in this study and the technical assistance provided by Oregon State University laboratory animal resource center (LARC) and Ariel Eberle. Also, we would like to thank Dave A. Stein for the critical reading of this manuscript.

Received September 23, 2006; Revised Manuscript Received January 20, 2007

^{99m}Tc(CO)$_3$-15-[*N*-(Acetyloxy)-2-picolylamino]pentadecanoic acid (**1a**) was prepared by incorporating [^{99m}Tc(CO)$_3$]$^+$ into 15-[*N*-(hydroxycarbonylmethyl)-2-picolylamino]pentadecanoic acid (**2a**). The overall radiochemical yield of **1a** after HPLC purification was 60−63%. Radiotracer **1a** was found to be chemically stable when incubated in human plasma for 4 h at 37 °C. Tissue distribution studies showed that high radioactivity accumulated in the heart with rapid clearance. The maximum heart-to-blood uptake ratio was 1.87 at 5 min after a tail-vein injection. Radioactive metabolites were analyzed in urine samples of mice and corresponded to a 9.3:1 ratio of ^{99m}Tc(CO)$_3$-5-[*N*-(acetyloxy)-2-picolylamino]pentanoic acid (**1b**) to ^{99m}Tc(CO)$_3$-3-[*N*-(acetyloxy)-2-picolylamino]-propionic acid (**1c**), indicating that **1a** is mainly metabolized to **1b** via β-oxidation in the body. These results suggest that **1a** is a promising radiotracer for evaluation of fatty acid metabolism in myocardium.

INTRODUCTION

Fatty acids are important substrates for adenosine triphosphate (ATP) production in myocardium. In the fasting state, fatty acid oxidation is enhanced and anaerobic glycolysis is suppressed, whereas in the nonfasting state, fatty acid oxidation decreases and glucose is utilized as an energy source (*1*). In myocardium, long-chain fatty acids are usually metabolized via β-oxidation, which degrades fatty acids by removing two-carbon units, and only a small fraction of the fatty acids is stored in the intracellular lipid pool as triglyceride (*2*−*4*). Disturbances in fatty acid metabolism often reflect myocardial damage, such as myocardial ischemia and cardiomyopathy; for example, fatty acid metabolism is impaired due to a reduced oxygen supply during myocardial ischemia (*1*, *5*).

Therefore, radiolabeled fatty acid analogs have been investigated for evaluating fatty acid metabolism in myocardium using single-photon emission computed tomography (SPECT) and positron emission tomography (PET). 1-[^{11}C]Palmitate, which reflects the metabolism of its natural counterpart, showed biexponential clearance, indicating rapid washout resulting from β-oxidation and slow washout due to slow turnover of the intracellular lipid pool (*5*, *6*). ω-[^{11}C]Palmitate showed greater heart uptake than 1-[^{11}C]palmitate due to its reduced metabolism (*7*). Several ^{123}I-labeled fatty acid analogs have been extensively studied, i.e., 17-[^{123}I]iodoheptadecanoic acid, 15-(*p*-[^{123}I]iodophenyl)pentadecanoic acid (IPPA), 15-(*p*-[^{123}I]iodophenyl)-3-methylpentadecanoic acid (BMIPP), and 15-(*p*-[^{123}I]iodophenyl)-3,3-dimethylpentadecanoic acid (DMIPP) (*8*−*10*). [^{123}I]BMIPP and [^{123}I]DMIPP showed prolonged myocardial retention versus [^{123}I]IPPA, because methyl branching slowed their myocardial metabolism. Due to its lower liver uptake than [^{123}I]DMIPP, [^{123}I]BMIPP showed promise for the diagnosis of various myocardial diseases (*11*). 16-[^{18}F]Fluoropalmitic acid (FPA) and methyl-branched ω-[^{18}F]fluoroheptadecanoic acids at C3 (3-MFHA) or C5 (5-MFHA) have also been investigated, and 5-MFHA showed an initial myocardial uptake and a retention intermediate between those of FPA and 3-MFHA (*12*). 14-[^{18}F]Fluoro-6-thiaheptadecanoic acid, which was designed for prolonged myocardial retention, was found to be similar to [^{123}I]BMIPP in terms of myocardial uptake and retention (*13*, *14*).

^{99m}Tc-labeled fatty acid analogs are attractive due to ready availability and the nearly ideal physical properties of ^{99m}Tc (141 keV, $t_{1/2}$ = 6 h) (*15*, *16*). Early attempts to develop ^{99m}Tc-labeled long-chain fatty acid analogs included the preparation of ^{99m}Tc-labeled fatty acid analogs containing a strong chelating group, such as DTPA or EDTA (*17*, *18*). However, poor accumulation of these radiotracers in myocardium initiated the developments of more specific radiotracers for in vivo studies of fatty acid metabolism. During these developments, ^{99m}Tc cores were successfully coordinated to the ω-positions of fatty acid analogs, but radiolabeled fatty acid analogs showed poor myocardial uptake (*18*−*21*). Recently, the Magata group found that [^{99m}Tc]MAMA-hexadecanoic acid (HDA) shows high initial heart uptake and subsequent rapid clearance, and that it is metabolized to [^{99m}Tc]MAMA-butyric acid via β-oxidation in the body (*22*). Over the past decade, small ^{99m}Tc cores have been developed, including ^{99m}Tc(CO)$_3$-(cyclopentadienyl) (*23*−*25*), ^{99m}Tc(CO)$_3$-[*N*,*N*-(diacetyloxy)amino], ^{99m}Tc(CO)$_3$-[N^{α}-(histidinyl)], ^{99m}Tc(CO)$_3$-[*N*-(acetyloxy)-2-picolylamino] cores, and others (*26*−*28*). [^{99m}Tc(CO)$_3$(H$_2$O)$_3$]$^+$ is an attractive precursor for the introduction of the small [^{99m}Tc(CO)$_3$]$^+$ into biomolecules (*26*, *27*, *29*). As part of a strategy to develop ^{99m}Tc(CO)$_3$-labeled long-chain fatty acid analogs, the *N*-(hy-

droxycarbonylmethyl)-2-picolylamino group can be labeled with $[^{99m}Tc(CO)_3(H_2O)_3]^+$ to form a $^{99m}Tc(CO)_3$-[*N*-(acetyloxy)-2-picolylamino] core, an ideal tridentate chelator.

In this work, we prepared $^{99m}Tc(CO)_3$-[*N*-(acetyloxy)-2-picolylamino]pentadecanoic acid (**1a**) by the facile incorporation of $[^{99m}Tc(CO)_3]^+$ into a *N*-(hydroxycarbonylmethyl)-2-picolylamino fatty acid analog and evaluated its potential as a substrate for fatty acid metabolism. The β-oxidation products of **1a** were compared with the proposed radioactive metabolite standards, $^{99m}Tc(CO)_3$-5-[*N*-(acetyloxy)-2-picolylamino]pentanoic acid (**1b**) and $^{99m}Tc(CO)_3$-3-[*N*-(acetyloxy)-2-picolylamino]propionic acid (**1c**).

EXPERIMENTAL SECTION

Materials and Methods. Chemicals and solvents were obtained from Sigma-Aldrich (St. Louis, MO), and HPLC solvents were obtained from J. T. Baker (Phillipsburg, NJ). ^1H NMR spectra were obtained using a Varian Unity Inova 500NB (500 MHz) spectrometer (Palo Alto, CA) at the Cooperative Center for Research Facilities, Sungkyunkwan University (Suwon, Korea), and a Varian Gemini-400 (Palo Alto, CA) at Inha University, and ^{13}C NMR spectra were obtained at 100 MHz. Chemical shifts (δ) are reported as parts per million (ppm) downfield of an internal tetramethylsilane standard. Fast atom bombardment (FAB) mass spectra were obtained using a JMS-700 Mstation (JEOL, Ltd., Tokyo, Japan) at the Korea Basic Science Institute (Seoul, Korea). HPLC was carried out using a Thermo Separation Products System (Fremont, CA) equipped with a semipreparative column (Alltech Econosil silica gel, 10 μ, 10 × 250 mm) or an analytical column (YMC-Pack C18, 5 μ, 4.6 × 250 mm). Eluant was simultaneously monitored using a UV detector (254 nm) and a NaI(Tl) radioactivity detector. TLC was performed on Merck F_{254} silica plates, which were analyzed using a Bioscan radio-TLC scanner (Washington, DC). $Na^{99m}TcO_4$ was eluted on a daily basis from a $^{99}Mo/^{99m}Tc$ generator (Samyoung Unitech, Co., Ltd., DuPont Pharmaceuticals Co., and Daiichi Radioisotope Labs). Radioactivity was measured in a dose calibrator (Biodex Medical Systems, Shirley, NY) and tissue radioactivity in a Wallac automated γ counter (Boston, MA). All animal experiments were performed in compliance with the rules of the Samsung Medical Center Laboratory Animal Care, which comply with NIH guidelines.

Synthesis of *tert*-Butyl 2-Picolylamino-*N*-acetate (3). 2-Picolylamine (946 μL, 9.25 mmol) was added to *tert*-butyl bromoacetate (1.7 mL, 12.03 mmol) in CH_3CN (10 mL). The reaction mixture was then stirred under N_2 at room temperature overnight. At the end of the reaction, solvent was removed in vacuo, and residue was extracted with dichloromethane (30 mL × 3), washed with water, and dried over anhydrous Na_2SO_4. Flash column chromatography (2:1 hexane−ethyl acetate) gave **3** (1.48 g) as a yellow oil in 72% yield: ^1H NMR ($CDCl_3$, 500 MHz) δ 8.57 (d, 1H, J = 5.0 Hz), 7.68−7.65 (m, 1H), 7.35 (d, 1H, J = 5.5 Hz), 7.19−7.17 (m, 1H), 3.96 (s, 2H), 3.39 (s, 2H), 1.48 (s, 9H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 171.2, 159.2, 149.1, 136.2, 121.8, 121.7, 80.8, 54.4, 51.0, 27.8; MS (FAB) *m*/*z* 223 (M^+ + H); HRMS calcd for $C_{12}H_{19}N_2O_2$ 223.1447, found 223.1451.

Synthesis of Methyl 15-[*N*-(*tert*-Butyloxycarbonylmethyl)-2-picolylamino]pentadecanoate (4a). Compound **3** (300 mg, 1.35 mmol) was dissolved in CH_3CN (12 mL), and to this solution was added DIEA (1.18 mL, 6.75 mmol). After stirring for 30 min at room temperature, methyl 15-bromopentadecanoate (543 mg, 1.62 mmol) was added dropwise. The reaction mixture was then stirred at 75 °C overnight, extracted with dichloromethane (30 mL × 3), washed with water, and dried over anhydrous Na_2SO_4. Flash column chromatography (4:1 hexane−ethyl acetate) afforded **4a** (521 mg) as a light yellow oil in 81% yield: ^1H NMR ($CDCl_3$, 400 MHz) δ 8.52 (dd, 1H, J = 2.0, 1.6 Hz), 7.65 (t, 1H, J = 8.0 Hz), 7.54 (d, 1H, J = 7.6 Hz), 7.14 (t, 1H, J = 6.0 Hz), 3.90 (s, 2H), 3.66 (t, 3H, J = 7.6 Hz), 3.29 (s, 2H), 2.62 (t, 2H, J = 7.6 Hz), 2.30 (t, 2H, J = 7.6 Hz), 1.64−1.58 (m, 2H), 1.51−1.41 (m, 9H), 1.31−1.18 (m, 22H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 174.0, 170.1, 160.0, 148.8, 136.1, 122.7, 121.6, 80.4, 60.3, 55.9, 54.1, 51.1, 33.9, 29.4; MS (FAB) *m*/*z* 477 (M^+ + H); HRMS calcd for $C_{28}H_{49}N_2O_4$ 477.3693, found 477.3697.

Synthesis of Methyl 5-[*N*-(*tert*-Butyloxycarbonylmethyl)-2-picolylamino]pentanoate (4b). Compound **3** (250 mg, 1.12 mmol) was dissolved in CH_3CN (7 mL), and to this solution was added DIEA (980 μL, 5.63 mmol). After stirring for 30 min at room temperature, methyl 5-bromopentanoate (240 μL, 1.69 mmol) was added dropwise. The remainder of the procedure was as described above. Flash column chromatography (2:1 hexane−ethyl acetate) gave **4b** (280 mg) as a light yellow oil in 74% yield: ^1H NMR ($CDCl_3$, 500 MHz) δ 8.55−8.53 (m, 1H), 7.67 (td, 1H, J = 8.0, 2.0 Hz), 7.55 (d, 1H, J = 7.6 Hz), 7.18−7.15 (m, 1H), 3.93 (s, 2H), 3.66 (s, 3H), 3.31 (s, 2H), 2.68 (t, 2H, J = 7.6 Hz), 2.30 (t, 2H, J = 7.6 Hz), 1.68−1.62 (m, 2H), 1.56−1.50 (m, 2H), 1.48 (s, 9H); MS (FAB) *m*/*z* 337 (M^+ + H); HRMS calcd for $C_{18}H_{29}N_2O_4$ 337.2128, found 337.2132.

Synthesis of Methyl 3-[*N*-(*tert*-Butyloxycarbonylmethyl)-2-picolylamino]propionate (4c). Compound **3** (400 mg, 1.75 mmol) was dissolved in CH_3CN (12 mL), and to this solution was added $NaHCO_3$ (453.6 mg, 5.40 mmol). After stirring for 30 min at room temperature, methyl 3-bromopropionate (257 μL, 2.34 mmol) was added dropwise. The mixture was then stirred at 60 °C overnight. Solvent was removed in vacuo, and the residue was extracted with dichloromethane (30 mL × 3), washed with water (30 mL × 3), and dried over anhydrous Na_2SO_4. Flash column chromatography (1:1 hexane−ethyl acetate) gave **4c** (320 mg) as a yellow oil in 58% yield: ^1H NMR ($CDCl_3$, 500 MHz) δ 8.55−8.54 (m, 1H), 7.67 (td, 1H, J = 8.0, 2.0 Hz), 7.50 (d, 1H, J = 8.0 Hz), 7.19−7.16 (m, 1H), 3.99 (s, 2H), 3.66 (s, 3H), 3.57 (s, 2H), 3.08 (t, 2H, J = 5.0 Hz), 2.53 (t, 2H, J = 7.0 Hz), 1.48 (s, 9H); MS (FAB) *m*/*z* 309 (M^+ + H); HRMS calcd for $C_{16}H_{25}N_2O_4$ 309.1815, found 309.1806.

Synthesis of Methyl 15-[*N*-(Hydroxycarbonylmethyl)-2-picolylamino]pentadecanoate (5a). Trifluoroacetic acid (2 mL) was added to **4a** (250 mg, 0.52 mmol) in dichloromethane (2 mL), and the reaction mixture was stirred for 2 h at room temperature. At the end of the reaction, solvent was removed in vacuo, and the residue was extracted with dichloromethane (30 mL × 3), washed with water, and dried over anhydrous Na_2SO_4. Flash column chromatography (15:1 dichloromethane−methanol) gave **5a** (188 mg) as a light yellow oil in 85% yield. Compounds **5b** and **5c** were synthesized in 79% and 62% yields, respectively, using the same procedure described for **5a**.

5a. ^1H NMR (CD_3OD, 500 MHz) δ 8.67−8.66 (m, 1H), 7.91 (td, 1H, J = 8.0, 1.5 Hz), 7.53 (d, 1H, J = 8.0 Hz), 7.47−7.44 (m, 1H), 4.56 (s, 2H), 3.76 (s, 2H), 3.66 (s, 3H), 3.27−3.23 (m, 2H), 2.32 (t, 2H, J = 7.0 Hz), 1.80−1.75 (m, 2H), 1.63−1.60 (m, 2H), 1.30 (s, 20H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 174.0, 170.1, 160.0, 148.8, 136.1, 122.7, 121.6, 80.4, 60.3, 55.9, 54.1, 51.1, 33.9, 29.4, 27.98, 27.4, 24.7; MS (FAB) *m*/*z* 421 (M^+ + H); HRMS calcd for $C_{24}H_{41}N_2O_4$ 421.3066, found 421.3066.

5b. ^1H NMR (CD_3OD, 500 MHz) δ 8.67−8.65 (m, 1H), 7.92 (td, 1H, J = 7.8, 2.0 Hz), 7.54 (d, 1H, J = 8.0 Hz), 7.53−7.45 (m, 1H), 4.55 (s, 2H), 3.78 (s, 2H), 3.67 (s, 3H), 3.27−3.24 (m, 2H), 2.38 (t, 2H, J = 2.0 Hz), 1.83−1.79 (m, 2H), 1.69−1.66 (m, 2H); MS (FAB) *m*/*z* 281 (M^+ + H); HRMS calcd for $C_{14}H_{21}N_2O_4$ 281.1502, found 281.1495.

5c. ^{1}H NMR (CD_3OD, 500 MHz) δ 8.62 (d, 1H, J = 4.0 Hz), 7.92 (td, 1H, J = 7.5, 1.5 Hz), 7.57 (d, 1H, J = 8.0 Hz), 7.46−7.44 (m, 1H), 4.43 (s, 2H), 3.70 (s, 2H), 3.42−3.39 (m, 2H), 3.36 (s, 3H), 2.76−2.74 (m, 2H); MS (FAB) m/z 253 (M^+ + H); HRMS calcd for $C_{12}H_{17}N_2O_4$ 253.1189, found 253.1192.

Synthesis of 15-[*N*-(Hydroxycarbonylmethyl)-2-picolylamino]pentadecanoic Acid (2a). Compound **5a** (40 mg, 0.10 mmol) was dissolved in a 1:1 mixture of 0.4 N NaOH and MeOH (3 mL) and stirred for 4 h at 70 °C. The solution was then cooled and neutralized with 1.5 mL of 0.1 N HCl in an ice bath. The reaction mixture was then extracted with dichloromethane, and the organic layer was dried over anhydrous Na_2SO_4 and concentrated. Flash column chromatography (9:1 CH_2Cl_2−MeOH) gave **2a** (22 mg) as light yellow solid in 54% yield. Compound **2b** was prepared in 46% yield using the procedure described for **2a** and C-18 Sep-Pak purification.

2a. ^{1}H NMR (CD_3OD, 500 MHz) δ 8.55 (d, 1H, J = 4.5 Hz), 7.84 (td, 1H, J = 7.8, 1.0 Hz), 7.61 (d, 1H, J = 7.5 Hz), 7.37−7.34 (m, 1H), 4.10 (s, 2H), 3.36 (s, 2H), 2.79 (t, 2H, J = 7.0 Hz), 2.17 (t, 2H, J = 7.5 Hz), 1.62−1.59 (m, 4H), 1.28 (s, 20H); MS (FAB) m/z 429 (M^+ + Na); HRMS calcd for $C_{23}H_{38}N_2O_4Na$ 429.2732, found 429.2729.

2b. ^{1}H NMR (CD_3OD, 500 MHz) δ 8.69−8.68 (m, 1H), 8.01−7.97 (m, 1H), 7.59−7.57 (m, 1H), 7.54−7.51 (m, 1H), 4.59 (d, 2H, J = 3.0 Hz), 4.06 (d, 2H, J = 6.0 Hz), 3.67−3.66 (m, 2H), 2.40−2.34 (m, 2H), 1.89−1.77 (m, 2H), 1.69−1.64 (m, 2H); MS (FAB) m/z 289 (M^+ + Na); HRMS calcd for $C_{13}H_{18}N_2O_4Na$ 289.1167, found 289.1169.

Synthesis of Re(CO)$_3$-15-[*N*-(Acetyloxy)-2-picolylamino]-pentadecanoic Acid (6a). $(NEt_4)_2[Re(CO)_3Br_3]$ was prepared as described in the literature (*30*). $(NEt_4)_2[Re(CO)_3Br_3]$ (187 mg, 0.24 mmol) was added to **2a** (60 mg, 0.16 mmol) in MeOH (1 mL) and stirred for 2 h at 65 °C. After reaction, solvent was removed in vacuo, and the resulting oily residue was purified by flash column chromatography (10:1 CH_2Cl_2−MeOH) to give **6a** (57 mg) as a light yellow solid in 53% yield. Compound **6b** was synthesized in 51% yield using the procedure described for **6a**.

6a. mp 221−225 °C; ^{1}H NMR ($CDCl_3$, 500 MHz) δ 8.85 (d, 1H, J = 5.5 Hz), 7.95 (td, 1H, J = 8.0, 1.5 Hz), 7.51 (d, 1H, J = 7.5 Hz), 7.44 (t, 1H, J = 6.0 Hz), 4.51−4.48 (m, 2H), 4.37−4.34 (m, 2H), 3.74−3.70 (m, 2H), 3.58−3.54 (m, 2H), 2.36−2.33 (m, 2H), 1.61−1.59 (m, 2H), 1.27 (s, 20H); MS (FAB) m/z 677 (M^+ + H); HRMS calcd for $C_{26}H_{38}N_2O_7{}^{187}Re$ 677.2237, found 677.2245.

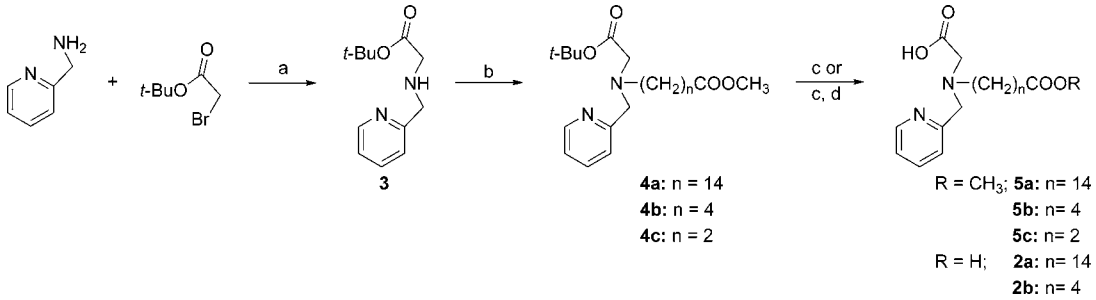
6b. mp 237−240 °C; ^{1}H NMR (CD_3OD, 500 MHz) δ 8.83 (d, 1H, J = 5.5 Hz), 8.10 (td, 1H, J = 8.2, 1.0 Hz), 7.72 (d, 1H, J = 8.0 Hz), 7.55 (t, 1H, J = 6.0 Hz), 4.75−4.72 (m, 2H), 4.57−4.54 (m, 2H), 3.95−3.91 (m, 2H), 3.64−3.62 (m, 2H), 2.42 (t, 2H, J = 7.0 Hz), 1.71−1.69 (m, 2H); MS (FAB) m/z 537 (M^+ + H); HRMS calcd for $C_{16}H_{18}N_2O_7{}^{187}Re$ 537.0672, found 537.0668.

Synthesis of Re(CO)$_3$-3-[*N*-(Acetyloxy)-2-picolylamino]-propionic Acid (6c). $(NEt_4)_2[Re(CO)_3Br_3]$ (187 mg, 0.24 mmol) was added to **5c** (50 mg, 0.16 mmol) in MeOH (3 mL) and stirred for 2 h at 65 °C. After reaction, solvent was removed in vacuo, and the resulting oily residue was purified by flash column chromatography (20:1 CH_2Cl_2−MeOH) to give Re coordinated methyl ester (38 mg) as a light yellow solid in 46% yield: mp 187−192 °C; ^{1}H NMR ($CDCl_3$, 500 MHz) δ 8.86 (d, 1H, J = 5.0 Hz), 7.96 (td, 1H, J = 8.0, 1.5 Hz), 7.51 (d, 1H, J = 8.0 Hz), 7.46 (t, 1H, J = 6.5 Hz), 4.44−4.36 (m, 2H), 3.94−3.91 (m, 2H), 3.80 (s, 3H), 3.39−3.36 (m, 2H), 2.87 (t, 2H, J = 7.0 Hz); MS (FAB) m/z 523 (M^+ + H); HRMS calcd for $C_{15}H_{16}N_2O_7{}^{187}Re$ 523.0516, found 523.0522.

The methyl ester (30 mg, 0.057 mmol) was dissolved in a 1:1 mixture of 0.4 N NaOH and MeOH (1.5 mL) and stirred for 4 h at 70 °C. The solution was then cooled and neutralized with 1 mL of 0.1 N HCl in an ice bath. The reaction mixture was then extracted with dichloromethane, and the organic layer was dried over anhydrous Na_2SO_4 and concentrated. Sold-phase purification (C18 Sep-Pak cartridge) gave **6c** (9.3 mg) as a light yellow solid in 32% yield: mp 257−259 °C; ^{1}H NMR (CD_3OD, 500 MHz) δ 8.83 (d, 1H, J = 6.0 Hz), 8.10 (td, 1H, J = 8.0, 1.5 Hz), 7.72 (d, 1H, J = 8.0 Hz), 7.56 (t, 1H, J = 5.5 Hz), 4.84−4.76 (m, 2H), 4.58−4.55 (m, 2H), 3.93−3.90 (m, 2H), 2.92−2.87 (m, 2H); MS (FAB) m/z 509 (M^+ + H); HRMS calcd for $C_{14}H_{14}N_2O_7{}^{187}Re$ 509.0359, found 509.0359.

Radiochemical Synthesis of ^{99m}Tc(CO)$_3$-15-[*N*-(Acetyloxy)-2-picolylamino]pentadecanoic Acid (1a). *Kit Preparation of* $[^{99m}Tc(CO)_3(H_2O)_3]^+$. $^{99m}TcO_4^-$ (740 MBq, 300 μL) was added to a 10 mL sealed kit vial containing a lyophilized formulation (IsoLink). The vial was then shaken vigorously and placed in an oil bath for 30 min at 75 °C. It was then cooled to room temperature, and the mixture was neutralized with 0.1 N HCl (180 μL). The radio−TLC yield of $[^{99m}Tc(CO)_3(H_2O)_3]^+$ was greater than 95%.

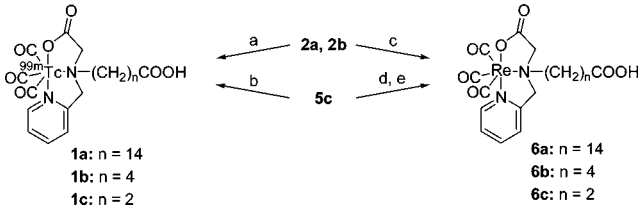
In-House Preparation of $[^{99m}Tc(CO)_3(H_2O)_3]^+$. A mixture of Na_2CO_3 (4 mg, 38 μmol), NaK tartrate tetrahydrate (2 mg), and $NaBH_4$ (5 mg, 130 μmol) was placed in a 10 mL reaction vial and dissolved in water (500 μL), and the vial was then sealed. After bubbling CO in this solution for 10 min, $^{99m}TcO_4^-$ (370 MBq, 200 μL) was added, and the resulting solution was stirred for 30 min at 75 °C, cooled to room temperature, and then neutralized with 0.1 N HCl (180 μL). Radio−TLC yield was greater than 95%.



Radiochemical Synthesis of 1a. Compound **2a** (1.1 mg, 2.7 μmol) was dissolved in a 4:1 mixture of methanol and water (300 μL), and to this solution was added $[^{99m}Tc(CO)_3(H_2O)^3]^+$ (370 MBq, 250 μL). The reaction mixture was then stirred in a sealed vial for 30 min at 75 °C. The crude mixture was loaded onto a C18 Sep-Pak cartridge, which was washed with water (10 mL) and then with methanol (2 mL). The methanol layer was concentrated under N_2 and purified by HPLC using a 8:92 mixture of hexane and dichloromethane−2-propanol−acetic acid (88:12:0.3) at 4 mL/min. The desired fraction (t_R = 21.5−23.5 min) was collected, and solvents were removed under N_2. The residue was then passed through a C18 Sep-Pak cartridge that was washed with water (10 mL) and then with MeOH (2 mL). Methanol removal gave **1a** in 60−63% yield. Radiotracer **1b** was prepared in an identical manner and purified using a C18 Sep-Pak cartridge at yields of 48%.

In preparation of **1c**, methyl ester **5c** (1.3 mg, 4.64 μmol) was labeled with $[^{99m}Tc(CO)_3(H_2O)^3]^+$ (37 MBq, 25 μL) for 30 min at 75 °C. After solid-phase purification, the residue was redissolved in methanol (300 μL) and treated with 0.4 N NaOH (aq, 100 μL) for 10 min at 65 °C. The reaction mixture was then cooled, neutralized with 1 N HCl (40 μL), and purified using a C18 Sep-Pak cartridge and methanol as the eluant, which gave **1c** in 34% yield.

In Vitro Stability. An aliquot (9.7 MBq) of **1a** in saline was added to human plasma (1 mL) and incubated for 4 h at 37 °C, and the resulting solution was analyzed by radio−TLC using dichloromethane-methanol (9:1).



Tissue Distribution in Normal Mice. Radiotracer **1a** was dissolved in saline containing 1% bovine serum albumin (BSA) and 10% ethanol at 40 °C. ICR mice (male, 25−30 g, four mice per time point) were fasted for 12 h before injecting **1a** (1.11 MBq/mouse) via a tail vein. At the indicated time points (0.5, 1, 5, and 30 min), mice were sacrificed by cervical dislocation, and samples of blood were immediately obtained from the myocardial tissue via a syringe, and samples of whole organ (heart) and tissue (lung, liver, kidney, and

Scheme 1 [a]

stomach) were also removed, weighed, and counted. Data are expressed as the percent injected dose per gram of tissue (% ID/g).

Analysis of Metabolites. Radiotracer **1a** (18.5 MBq/mouse) was injected via a tail vein into 12 h-fasted ICR mice. At 30 min after injection, mice were sacrificed by cervical dislocation, and samples of the urine were collected, filtered through a membrane filter, and analyzed by HPLC at a flow rate of 1 mL/min using a combination of solution A (0.1% TFA−water) and solution B (methanol) and a linear gradient program from 60:40 A−B to 40:60 A−B over 20 min, followed by 40:60 A−B to 0:100 A−B over 20 min. A major radioactive metabolite was recovered from the HPLC column at a recovery efficiency of 71%. Radiotracers **1a**, **1b**, and **1c** were analyzed by HPLC using the same conditions.

RESULTS AND DISCUSSION

Chemistry. The precursor **2a** for $[^{99m}Tc(CO)_3]^+$ labeling was synthesized by reacting *tert*-butyl bromoacetate with 2-picolylamine, reacting the resulting compound **3** with methyl 15-bromopentadecanoate, and the subsequent removal of the *tert*-butyl group and the methyl ester group (Scheme 1). Reaction conditions for the synthesis of **4a**−**4c** depended on carbon chain length. Compound **2b** was synthesized using the procedure described for **2a**. Methyl ester **5c** was prepared from deprotection of *tert*-butyl group of **4c** and used directly for $[^{99m}Tc(CO)_3]^+$ labeling.

Radiotracer **1a** was prepared by labeling the precursor **2a** with $[^{99m}Tc(CO)_3(H_2O)_3]^+$ for 30 min at 75 °C (Scheme 2). Hydrolysis can be carried out after $[^{99m}Tc(CO)_3]^+$ labeling of methyl ester precursors **5a**−**5c**. This was the case for $[^{99m}Tc(CO)_3]^+$ labeling of methyl ester **5c**, due to limited isolation of its polar hydrolyzed product, 3-[*N*-(hydroxycarbonylmethyl)-2-picolylamino]propionic acid. No significant difference in the yields of $[^{99m}Tc(CO)_3(H_2O)_3]^+$ was apparent for kit and in-house preparations. The predicted β-oxidation metabolites, **1b** and **1c**, were prepared as shown in Scheme 2 and purified using a C-18 Sep-Pak cartridge.

Table 1. Tissue Distribution of 1a in Normal Mice[a]

	% ID/g			
tissue	0.5 min	1 min	5 min	30 min
blood	18.28 ± 3.32	7.54 ± 1.46	0.39 ± 0.14	0.17 ± 0.03
heart	12.67 ± 1.48	6.38 ± 0.69	0.73 ± 0.37	0.28 ± 0.08
lung	23.58 ± 1.16	15.98 ± 3.32	6.82 ± 1.77	1.36 ± 0.21
liver	27.60 ± 5.31	31.88 ± 2.51	30.33 ± 6.05	13.06 ± 3.24
kidney	16.06 ± 1.82	13.86 ± 2.24	6.63 ± 0.98	6.53 ± 0.90

[a] Values are given as mean ± SD for groups of four mice.

Re standards were also prepared using $(NH_4)_2[Re(CO)_3Br_3]$ as described for the synthesis of ^{99m}Tc-labeled fatty acids. ^{99m}Tc-fatty acid analogs had retention times that were similar to the Re standards on HPLC: 35.9 min vs 35.2 min, 16.7 min vs 15.7, and 11.8 min vs 11.3 min for **1a**−**1c** vs **6a**−**6c**. Although ^{99m}Tc and Re-fatty acid analogs were not coeluted on HPLC, the formers were identified on the basis of the similar chemical properties of ^{99m}Tc and Re complexes. The different HPLC retention times of ^{99m}Tc and Re complexes have also been reported for other cases (*24*, *25*).

In Vitro Stability. Radiotracer **1a** was incubated in human plasma for 4 h at 37 °C and analyzed by radio−TLC. The results showed that 97% of **1a** remained intact after 2 h and over 87% remained after 4 h, demonstrating its high chemical stability.

Tissue Distribution Studies. Since fatty acids are predominantly metabolized in the fasting state, mice were fasted for 12 h prior to experiments. High radioactivity accumulated in blood, heart, lung, liver, and kidneys, and the radioactivity washed out rapidly with time from all tissues except for liver and kidneys (Table 1). Heart uptake of **1a** (6.38% ID/g at 1 min and 0.73% ID/g at 5 min postinjection) was comparable to those of ^{99m}Tc-MAMA-HDA (5.46% ID/g at 2 min and 2.40% ID/g at 5 min postinjection) (*22*). ^{99m}Tc-BAT-pentadecanoic acid and HDA were evaluated in rats, and the results were expressed as % ID/organ (0.31−0.46% ID/organ at 5 min postinjection) (*19*). The maximum heart-to-blood uptake ratio of **1a** was 1.87 at 5 min postinjection, which appears higher than those obtained for other ^{99m}Tc-labeled fatty acid analogs (Table 2). Heart-to-liver uptake ratios of **1a** were similar to those of ^{99m}Tc-MAMA-HDA. ^{99m}Tc-[9,10-bis[*N*-(2′-methyl-2′-mercapto)propyl]aminooctadecanoic acid and ^{99m}Tc-[7,10-bis(2-mercapto-2-methyl)propyl]-7,10-diazapentadecanoic acid showed high heart-to-blood and heart-to-liver uptake ratios in rats (Table 2), probably due to the branching effect of the fatty acid analogs (*20*, *21*). Although direct comparisons in % ID/g of radiotracers may not be appropriate, due to different experiment conditions and animal species used for the studies, **1a** may be superior to other ^{99m}Tc-labeled fatty acid analogs in terms of its facile conjugation of $[^{99m}Tc(CO)_3]^+$ to a fatty acid analog, high heart uptake, and high heart-to-blood ratios. No significant uptake was observed

Table 2. Comparison of in Vivo Data of ^{99m}Tc-Labeled Fatty Acid Analogs[d]

radiotracer	heart	heart/blood[a]	heart/liver[a]	animal	metabolites

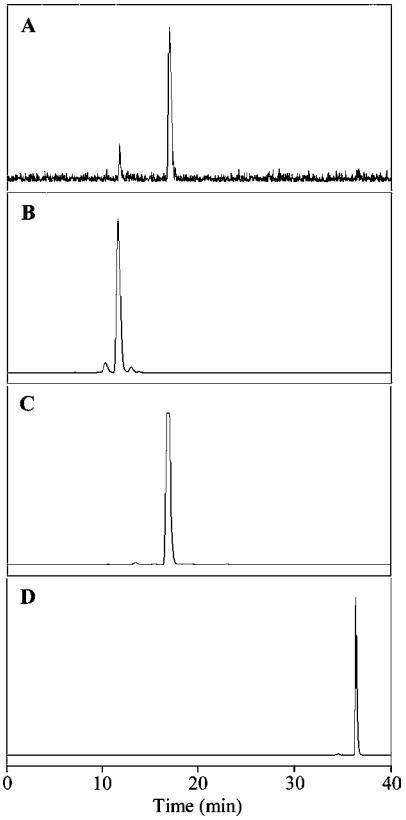

Figure 1. HPLC analysis of 30 min urine samples from mice injected via a tail vein with **1a** (A). HPLC profiles of radioactive metabolite standards: t_R = 11.8 min (**1c**) (B), t_R = 16.7 min (**1b**) (C), and t_R = 35.9 min (**1a**) (D). HPLC analysis was conducted using an analytical column (YMC-Pack C18, 5 μ, 4.6 × 250 mm) and a NaI(T1) radioactivity detector.

by the stomach, indicating that ^{99m}Tc pertechnetate was not regenerated during the study.

Analysis of Metabolites. When samples of urine were analyzed by HPLC, a 9.3:1 ratio of the radioactive metabolites at the retentions times of 16.7 and 11.8 min was observed, which were identified as **1b** and **1c**, respectively (Figure 1). Radioactive metabolite **1b**, which is produced by five cycles of **1a** β-oxidation, was the major metabolite (Figure 1A,C), which indicated that **1a** was metabolized to **1b** via β-oxidation and excreted to the kidneys. Although the metabolites were not analyzed in a time-dependent manner, it is believed that **1b** would be further metabolized to **1c** in time on the basis of the presence of a small portion of **1c** at 30 min postinjection on HPLC (Figure 1A). The metabolism of **1a** is similar to that of ^{99m}Tc-MAMA-HDA, which is metabolized to ^{99m}Tc-MAMA-butyric acid (BA) after six cycles of β-oxidation in rats (Table 2) (*22*). Although the metabolism of **1a** appears to be slower than ^{99m}Tc-MAMA-HDA, it is probable that metabolic rates are species-dependent (mice vs rats). Metabolite analysis has not been carried out for other ^{99m}Tc-labeled fatty acid analogs (Table 2).

CONCLUSION

A ^{99m}Tc-labeled fatty acid analog, **1a**, was prepared in high yield by incorporating $[^{99m}Tc(CO)_3]^+$ into a fatty acid analog, **2a**. An in vivo evaluation of **1a** demonstrated that high radioactivity accumulated in the heart and that the radiotracer is mainly metabolized to **1b** via β-oxidation in the body. Taken together, **1a** may be useful for evaluating the β-oxidation of fatty acids in myocardium.

ACKNOWLEDGMENT

We thank Hyun Jung Jeon for performing the tissue distribution studies and Iljung Lee and Byung Ho Ahn for their technical assistance. IsoLink kits were generous gifts from Mallinckrodt Medical B.V. (Petten, The Netherlands). This work was supported by the Korea Research Foundation Grant (MOEHRD) (KRF-2006-521-E00092).

Objective: Carriers are increasingly now viewed as helpful or even essential to improve cellular uptake in connection with antisense tumor targeting and other applications requiring transmembrane delivery of oligomers. Evaluation of many of the large number of available and potentially useful carriers is limited only by the complexities of preparing the oligomer/carriers by covalent conjugation. However, using streptavidin as a linker between biotinylated carriers and biotinylated antisense oligomers would require only simple mixing for preparation. The goal of this study was to evaluate the preparation and cell accumulation in culture of carrier/streptavidin nanoparticle of an antisense phosphorodiamide morpholino (MORF) oligomer. Methods: The model carriers were cholesterol, a 10 mer HIV-tat peptide, and a 10 mer polyarginine, each having been reported elsewhere to improve cellular delivery of oligomers. The model antisense oligomer was the 25 mer MORF targeting the survivin mRNA. The accumulations of the antisense MORF/carrier nanoparticle were compared to the sense MORF/carrier, to the carrier-free nanoparticles, and to the naked antisense MORF in the survivin-expressing MCF-7 cells. The MORFs and peptides were purchased biotinylated, while the cholesterol was biotinylated in-house. In all cases, the ^{99m}Tc radiolabel was placed on the oligomers. Cell studies were performed at low nM concentration as required for antisense imaging applications and at 37 °C primarily in 1% FBS. Results: Each radiolabeled oligomer/streptavidin/carrier nanoparticle was successfully prepared by careful mixing at a 1:1 molar ratio. As evidence of carrier participation, the radiolabeled MORF showed increased accumulation in cells when incubated as the nanoparticle compared to the carrier-free nanoparticle and by as much as a factor of 11. Accumulation of the antisense MORF/streptavidin/tat nanoparticle was significantly higher than the sense MORF/streptavidin/tat nanoparticle as evidence of specific antisense targeting. Conclusions: The preparation of oligomer/carrier nanoparticles was greatly simplified over covalent conjugations by using streptavidin as a linker. Furthermore, our results suggest that the addition of streptavidin did not interfere with the cellular delivery function of the tat, polyarginine, or cholesterol carriers nor with the specific antisense mRNA binding function of the MORF oligomer.

INTRODUCTION

The results of recent investigations from these laboratories and elsewhere suggest that radiolabeled DNAs and other oligomers for in vivo antisense targeting of tumor may require carriers for improved transmembrane delivery. Fortunately, a large number of potential carriers have been identified primarily for use in cell culture but with increasing reports of successful in vivo use as well (*1*). However, many of the potentially useful carriers can only now be attached to oligomers by covalent conjugation usually requiring involved synthesis, a process that can be challenging (*2*). Two recent reports have described the use of streptavidin to alter the pharmacokinetics of the tat peptide (*3*) and an antisense peptide nucleic acid (PNA) (*4*). We considered that streptavidin could be used in this manner as a linker for radiolabeled antisense oligomer/carrier nanoparticles (*5*). A similar approach was recently described to improve RNA cellular transport in connection with RNAi (*6*). A large number of potential carriers are already available commercially with biotin groups attached, and others with primary amines may be readily biotinylated. In addition to a greatly simplified preparation stabilized by the high binding affinity of biotin for streptavidin, the advantages include the possibility of attaching up to four carriers or oligomers in any combination, since streptavidin possesses four biotin binding sites. This property is illustrated in the artist's conception presented as Figure 1. Toxicities, whether of the streptavidin, oligomer, or carrier, are unlikely to be evident given the low dosages that will be administered in connection with radioimaging, our application of interest. The potential disadvantages include the possibility that streptavidin may interfere with the transmembrane delivery properties of certain carriers and may encourage entrapment of the antisense oligomer in vesicles, thereby restricting its mRNA binding function. In addition, the possibility exists that the addition of streptavidin may unfavorably alter the pharmacokinetics of the oligomer. The goals of this investigation were first to evaluate the preparation of the 1:1 streptavidin nanoparticles and second to address the first two of the above concerns, namely, whether the presence of streptavidin in the nanoparticle will interfere with the ability of carriers to improve cellular accumulations and whether the presence of streptavidin interferes with target mRNA binding by an antisense mechanism.

The three model carriers selected for this initial investigation have each been reported to successfully increase cell membrane permeation in culture. The tat and polyarginine peptides are short cationic peptides with recognized effectiveness as carriers. The tat peptide is the 48−57 residues of the tat protein of HIV-1

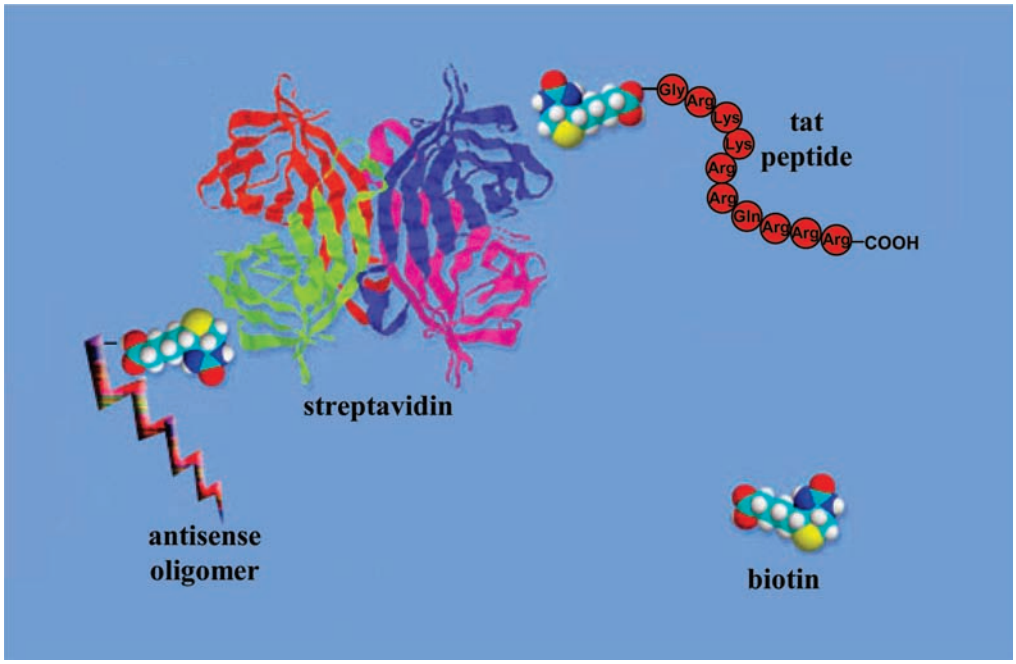

Figure 1. Artist's conception illustrating the composition of the nanoparticle in which the tat peptide and the antisense oligomer have been linked via streptavidin (modified from http://www.arrayit.com/Products/Substrates/SuperStreptavidin/superstreptavidin.html).

with the property of improving accumulations in possibly all cell types by an as yet unknown mechanism (*7*). It has been used as a delivery peptide for the intracellular transduction of large molecules such as proteins, peptides, and MRI contrast agents (*8*), as well as oligomers (*9*, *10*). A polyarginine peptide with similar properties to that of tat was included in this research because of recent reports of effectiveness (*11*−*14*). Finally, the charge neutral cholesterol was selected as a third carrier also because of recent reports of effectiveness (*15*). The model oligomers were both phosphorodiamide morpholinos (MORFs). The study MORF had a base sequence antisense to the 6−30 nucleotides within the survivin mRNA, while the control MORF had the sense sequence.

The influence of the carriers was evaluated by comparing the cell accumulations of the nanoparticle to the carrier-free nanoparticle and to the naked MORF (i.e., without the carrier or the streptavidin).

Determining the antisense properties of the nanoparticle in this investigation requires comment. Since the interest of these laboratories is in antisense imaging, the incubation concentration was fixed at low nanomolarity to avoid target mRNA saturation. While nanomolar concentrations of short double-stranded RNAs can decrease protein expression by RNAi mechanisms (*6*), concentrations in the micromolar range are generally required to decrease protein expression with antisense MORFs and other oligomers (*16*). Accordingly, in this investigation, evidence of antisense targeting was evaluated by comparing cellular accumulations of the antisense to the sense nanoparticles rather than by measurement of survivin protein concentration.

EXPERIMENTAL PROCEDURES

Chemicals and Oligomers. The 25 mer antisense MORF (5′-CCA-ACG-GGT-CCC-GCG-ATT-CAA-ATC-T) and the sense control MORF were obtained with a biotin group on the 3′ equivalent end via a 6-aminohexanoic acid linker and a primary amine on the opposite end (GeneTools, Philomath, OR). The S-acetyl NHS−MAG3 was synthesized in-house (*17*) and its structure confirmed by elemental analysis, proton nuclear magnetic resonance, and mass spectroscopy. The tat (biotin-linker-G-R-K-K-R-R-Q-R-R-R) and polyarginine peptide were both 10 mer and were purchased HPLC purified as the native L-isomer with the biotin attached to the amine end via a 6-aminohexanoic acid linker (21st Century Biochemicals, Marlboro, MA). The biotinylated cholesterol was synthesized by reacting biotinyl-3,6-dioxaoctanediamine (Pierce, Rockford, IL) with cholesteryl choloroformate (Aldrich, Milwaukee, WI). The human breast cancer cell line MCF-7 was a gift from Dr. Dario C. Altieri (Cancer Biology, University of Massachusetts Medical School). This cell line is reported to be a high-level expressor of the survivin mRNA (*18*), and the expression of the survivin mRNA was confirmed by RT-PCR (*19*). Standard chemicals were obtained from various suppliers and used without purification. The ^{99m}Tc-pertechnetate was eluted from a ^{99}Mo−^{99m}Tc generator (Bristol-Myers Squibb Medical Imaging Inc., North Billerica, MA).

Oligomer Conjugation and Radiolabeling. All oligomers were conjugated with S-acetyl NHS-MAG3 via the derivatized amine as previously described (*20*). A solution of 1 mg of oligomer in 200 μL of 0.3 M pH 8.0 HEPES buffer was added to a vial containing 0.7−1.0 mg S-acetyl NHS-MAG3. The vial was vortexed immediately to a clear solution and incubated for 1 h at room temperature. Thereafter, to the solution was added in order 50 μL of 2 M ammonium acetate, 120 μL of freshly prepared 20 mg/mL $SnCl_2 \cdot 2H_2O$/tartrate solution (100 mg/mL sodium tartrate in 0.5 M ammonium bicarbonate, 0.25 M ammonium acetate, and 0.18 M ammonium hydroxide, pH 9.2) with agitation. After heating at 100 °C for 25 min, the mixture was allowed to cool, and absolute ethanol was added to a concentration of 20% (v/v); then, the mixture was purified on a 1 × 20 cm P4 column (Bio-Rad, Hercules, CA) using 0.25 M ammonium acetate as eluant. The peak fractions were pooled and the oligomer concentration quantitated by UV absorbance at 265 nm according to the manufacturer's instructions. The purified samples were stored at refrigerator temperatures. All solutions were passed through a 0.22 μm filter to ensure sterility.

Radiolabeling of each oligomer was achieved by introducing about 0.5 to 1 mCi (20 μL) of ^{99m}Tc-pertechnetate generator eluant into a combined solution consisting of about 15 μL MAG3-conjugated oligomer (10 μg) in 0.25 M NH_4OAc, 45 μL of 0.25 M ammonium acetate, 15 μL of 50 μg/μL Na_2tartrate$\cdot 2H_2O$ in the pH 8.7 buffer, and 5 μL of fresh 4 μg/μL $SnCl_2 \cdot 2H_2O$ in 10 mM HCl containing 1 mg/mL ascorbate

(*20*). The final pH was about 8.5. After vortexing and then heating for 20 min in boiling water, the labeling was confirmed by size exclusion HPLC, or by C18 Sep-Pak (Waters, Milford, MA) in which the first elution with 0.2 M ammonium acetate removes radiolabeled pertechnetate and tartrate, the second elution with 40% acetonitrile removes radiolabeled oligomer while radiolabeled colloids are retained on the Sep-Pak.

Synthesis of Biotinylated Cholesterol. While both the tat and polyarginine peptides were biotinylated by the manufacturer, the biotinylated cholesterol was prepared in-house for this investigation. Briefly, 12 mg of cholesteryl choloroformate (26.7 μmol) in 60 μL anhydrous chloroform was added to a 1.5 mL microfuge tube containing 12 mg (32 μmol) biotinyl-3,6-dioxaoctanediamine in 200 μL anhydrous 1-methyl-2-pyrrolidinone (NMP). The mixture was vortexed to a clear solution. After adding 4 μL diisopropylethylamine (DIEA), the solution was agitated and placed at room temperature for 16 h. The raw product was precipitated as a white powder by addition of 1 mL ethyl ether. The white powder was dissolved in 200 μL NMP and reprecipitated by addition of ethyl ether two more times to remove diisopropylethylamine (DIEA) and unreacted cholesteryl choloroformate. The white powder was dissolved in 400 μL chloroform and washed with 400 μL 0.1 ammonium acetate four times to remove unreacted biotinyl-3,6-dioxaoctanediamine. The chloroform solution was collected, the solvent removed by evaporation over nitrogen, and the product lyophilized at a high vacuum to remove any remained ammonium acetate.

Nanoparticle Preparation and Testing. The streptavidin/tat was prepared by adding very slowly and with vigorous agitation 11.6 μL of tat at 0.5 μg/μL to 20 μL of streptavidin at 10.0 μg/μL both dissolved in 0.5 M NaCl and 0.2 M ammonium acetate solution (molar ratio 1:1). Although the addition was equimolar, the formation of significant concentrations of the 1:2 streptavidin/tat nanoparticle is possible. That the product was free of higher-order tat nanoparticles, i.e., two to four tat peptides per nanoparticle, was confirmed by adding tracer levels of ^{99m}Tc-labeled biotinylated tat peptide to the tat solution before the addition to streptavidin and analyzing the product by size exclusion HPLC with in-line UV and radioactivity detection using 20% acetonitrile in 1 M NaCl, 0.1 M ammonium acetate as eluant at a flow rate 0.6 mL/min. The appearance of a single peak in the UV trace at 280 nm corresponding to a single peak in the radioactivity trace was evidence of complete complexation, since this assay is capable of resolving 1:2 and higher-order nanoparticles (data not presented). Thereafter, the ^{99m}Tc-labeled biotinylated MORF was added to the streptavidin/tat nanoparticle in the identical fashion.

To confirm that the final product was also free of higher-order MORF nanoparticles, i.e., two or three MORFs per streptavidin/tat nanoparticle, the identical preparation was repeated with unlabeled antisense MORF and to the final product was added at tracer levels the complementary DNA (without biotin) radiolabeled with ^{99m}Tc. As before, the appearance by size exclusion HPLC of a single peak in the UV trace at 265 nm was evidence of a successful preparation. As further evidence against higher-order nanoparticles, the nanoparticle was intentionally prepared at a 1:1 tat/streptavidin molar ratio but at a 2:1 MORF/streptavidin molar ratio followed by agarose gel electrophoresis analysis. The complementary phosphodiester DNA was added to each nanoparticle before analysis so that ethidium bromide could be used for detection.

Both the radiolabeled polyarginine and cholesterol nanoparticles were prepared and tested in the identical fashion as was the carrier-free MORF/streptavidin nanoparticle. Radioactivity recoveries were routinely measured in all HPLC analyses and were in all cases 90% or better.

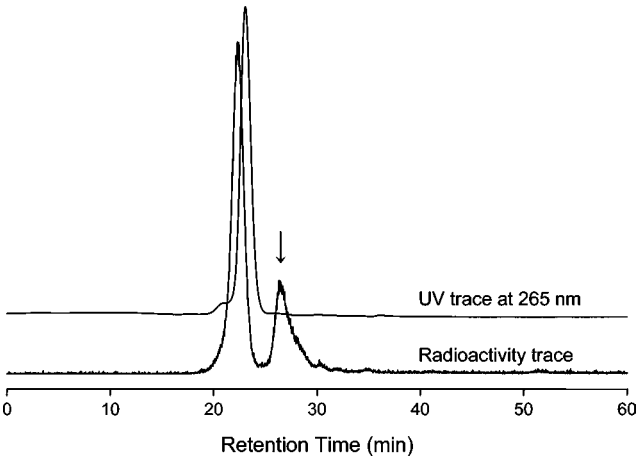

Figure 2. Size exclusion UV trace (265 nm) and radioactivity trace of the antisense MORF/streptavidin/tat nanoparticle radiolabeled by addition of trace ^{99m}Tc-sense DNA (without biotin). The smaller radioactivity peak (arrow) is due to free MORF in the nanoparticle preparation. The small difference in retention time between the UV and radioactivity traces is due to the hybridization of the sense DNA.

Cellular Accumulation Studies. The MCF-7 cells growing in monolayers were expected to be in log phase at the time of the study. Cells were seeded at $(3-4) \times 10^5$ cells per well in 12-well plates. In quadruplet, 1.0 mL of the ^{99m}Tc-labeled oligomer dissolved in 1% FBS DMEM medium was added to each well and the cells incubated at 37 °C in humidified 5% carbon dioxide for different times. The concentration of oligomer was at all times 8 nM to avoid mRNA saturation. The cells were harvested by lysis with 0.2 M NaOH and 1% SDS after removing the medium and washing twice with PBS.

RESULTS

Nanoparticle Preparation and Testing. Figure 2 presents both the UV (265 nm) and radioactivity traces obtained by size exclusion HPLC of the antisense MORF/streptavidin/tat nanoparticle to which trace ^{99m}Tc-labeled sense DNA (without biotin) was added. The radiolabeled sense DNA will hybridize with the antisense MORF in each of its forms and provide a radioactivity peak for each. As shown, only one peak corresponding to the antisense MORF/streptavidin/tat nanoparticles appears in the radioactivity profile and corresponds to the UV trace. Therefore, the result confirms the absence of higher-order MORF/streptavidin/tat nanoparticles. As shown in the figure, a second radioactivity peak is present with about 15% of the radioactivity. This peak is due to free antisense MORF in the preparation resulting from the absence of biotin on a fraction of the MORF provided by the manufacturer. Accordingly, the antisense MORF/streptavidin/tat nanoparticles also showed the same 15% impurity. Since the cellular accumulation of the uncharged naked MORFs is negligible (see below and ref 21), the accumulation of this radiocontaminant will lower the percent accumulations but may otherwise be ignored in the cell accumulations studies. By the same analysis method, biotin was missing on about 20% of the sense MORF.

Figure 3 presents the results of agarose gel electrophoresis of four nanoparticles prepared at 1- and 2-fold molar excess of MORF. The complementary phosphodiester DNA was added to each nanoparticle before analysis so that ethidium bromide could be used for visualization (thus, the nanoparticle with a 2-fold molar excess of MORF will also have twice the DNA therefore twice the charge). The obvious difference in migration of the nanoparticle with two MORFs per streptavidin compared to one (lanes 4 versus 2 without tat and lanes 5 versus 3 with tat) shows that preparation at an intentional 2-fold molar excess

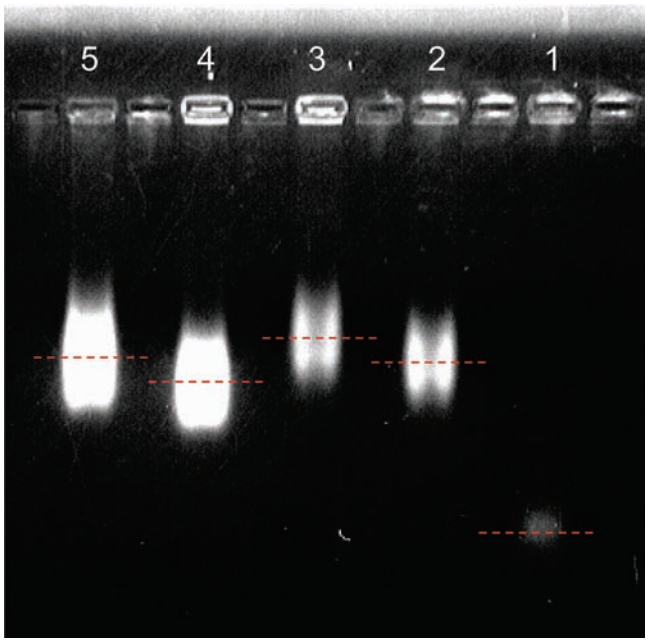

Figure 3. Agarose gel showing the relative positions of naked MORF (lane 1), MORF/streptavidin nanoparticle prepared at a 1:1 molar ratio (lane 2), MORF/streptavidin/tat prepared at a 1:1:1 molar ratio (lane 3), MORF/streptavidin prepared at a 2:1 molar ratio (lane 4), and MORF/streptavidin/tat prepared at a 2:1:1 molar ratio (lane 5). The dotted line in each lane defines the center of each band.

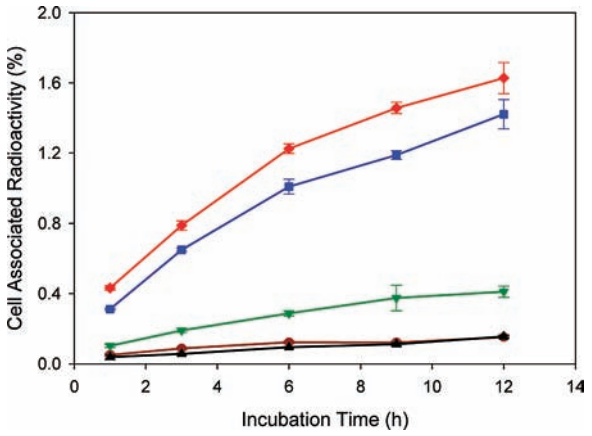

Figure 4. Percent accumulations in MCF-7 cells over time of radiolabeled antisense MORF when incubated as the tat (squares, ■), polyarginine (diamonds, ♦), or cholesterol (inverted triangles, ▼) streptavidin nanoparticles and as the carrier-free nanoparticle (circles, ●) and naked MORF (triangles, ▲) controls. ($N = 4$; error bars indicate one standard deviation).

provides a nanoparticle of higher order compared to nanoparticles prepared under the conditions of this investigation.

MORF Cellular Accumulation Studies. No evidence of cellular toxicity by growth delay was observed in any cell study of this investigation. Results are presented in Figure 4 as the average percent accumulation ($N = 4$) for each of three study MORF nanoparticles and both the carrier-free streptavidin nanoparticle and naked MORF controls in MCF-7 cells at 1, 3, 6, 9, and 12 h of incubation. As shown, adding the carrier increases the accumulations over controls by about 9-fold for tat and 11-fold for polyarginine and somewhat less for cholesterol. The identical accumulations for the MORF/streptavidin nanoparticle compared to the naked MORF suggest that the streptavidin was not responsible for these improved accumulations.

Figure 5 present accumulations in MCF-7 cells over time of the antisense and the sense control MORF/streptavidin/tat

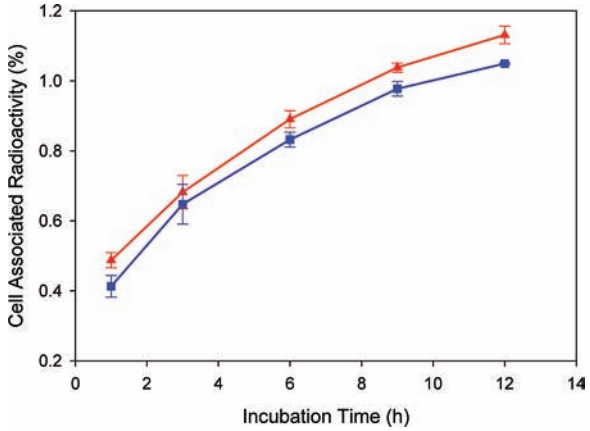

Figure 5. Percent accumulations over time of the antisense MORF/streptavidin/tat nanoparticle (triangles, ▲) compared to that of the control sense MORF/streptavidin/tat nanoparticle (squares, ■). The difference is significant (Student's t test, $p < 0.05$) at all times other than 3 h, providing evidence for specific binding to target mRNA of the nanoparticle and therefore escape from entrapment. ($N = 4$; error bars indicate one standard deviation).

nanoparticles. The differences are significant (Student's t test, $p < 0.05$) at all times other than 3 h, providing evidence for preserved antisense binding function of the nanoparticle and therefore escape from entrapment.

DISCUSSION

In general, all in vivo applications of radiolabeled DNAs and their analogues such as MORFs (collectively: oligomers) are currently characterized to varying degree by the same limitation: poor pharmacokinetic delivery to the target following intravenous administration and, in the case of applications with intracellular targets, poor delivery through cell membranes (*22*). Attempts to increase delivery are now often focused on the use of oligomer/carrier constructs in which the carrier is intended to improve pharmacokinetics, for example, by adding an antitumor antibody to direct the nanoparticle to its target, or more commonly, adding a carrier intended to improve cellular accumulations by chaperoning the oligomer through cellular membranes primarily in vitro but increasingly now in vivo as well.

Charged oligomers such as the DNAs have the advantage that they may be complexed to charged carriers such as cationic peptides or liposomes simply by electrostatic binding (*23*, *24*). While a number of cationic carriers for DNAs are commercially available, the vast majority of these have been designed for in vitro delivery in cell culture and are not recommended by the manufacturers for use in serum environments such as those experienced in vivo. We have achieved largely unfavorable in vivo results using two commercially available cationic carriers with DNAs prepared simply by electrostatic binding (*25*). In cases of uncharged oligomers such as peptide nucleic acids (PNAs) and MORFs, covalent conjugation is necessary at present for carrier attachment, and the synthesis of these nanoparticles can prove difficult (*2*). Even the solid-phase synthesis of PNA/peptide carrier nanoparticles is not without its own difficulties and in our hands has led to products of questionable quality.

In this investigation, the use of streptavidin to prepare the carrier and oligomer nanoparticles performed as anticipated. As shown in Figure 1, the slow addition at a 1:1 molar ratio with continuous agitation, first of the biotinylated carrier to streptavidin, and subsequently of the biotinylated MORF to the streptavidin/carrier, provided a product free of both 1:2 com-

plexes. Since the nanoparticle is expected to dissociate in situ, in all cases, the radiolabel was on the MORF rather than the carrier or streptavidin.

One potential drawback to the use of streptavidin as linker may be a susceptibility to dissociation by endogenous biotin. However, we do not expect endogenous biotin to interfere by displacing biotinylated agents from streptavidin. In preliminary studies, D-biotin at 56 mM was incubated with the streptavidin/tat or streptavidin/MORF used in this investigation at 0.028 mM for 1 h in 37 °C PBS with no evidence of displacement. Since the serum concentration of endogenous biotin in a mouse is about 10 nM (*26*), the displacement from streptavidin by endogenous biotin should be negligable for tat or other biotinylated agents.

In addition to evaluating the ease with which carriers and antisense oligomers may be joined via streptavidin as a convenient linker, a goal of this investigation was to evaluate whether the function of the carrier and the function of the antisense MORF was adversely influenced by the presence of the streptavidin. As shown in Figure 4, the presence of each of the carriers and the streptavidin significantly increased accumulations compared to that of both the naked MORF and the carrier-free nanoparticle and by as much as a factor of 11. Therefore, the streptavidin may not have adversely influenced the function of the carrier to increase cell permeation. As shown in Figure 5, the accumulation of the antisense MORF was statistically higher than the accumulation of the control sense MORF when both were incubated with the MCF-7 cells as the streptavidin/tat nanoparticles. Therefore, the streptavidin may not have adversely influenced the antisense binding properties of the MORF for its mRNA target.

This study is a more extensive evaluation of the use of streptavidin as a linker between biotinylated oligomers and carriers than earlier work from this laboratory (*5*). Recently, Chu et al. described their use of streptavidin as a bridge between a double-stranded siRNA and an RNA aptamer functioning as a cellular delivery agent (*6*). The streptavidin was found by PCR to have little or no effect on the ability of the siRNA to inhibit gene expression. Thus, both by gene expression analysis and by radioactivity accumulations in two difference cells in culture, the evidence is against an adverse influence of streptavidin on function.

CONCLUSION

In conclusion, an advantage to the use of streptavidin as linker is in the simplicity of nanoparticle preparation and therefore the ease with which different nanoparticles may be made and tested in contrast to covalent conjugation. Obviously, the same approach may be used to link tumor targeting agents such as antitumor antibodies as well as antitumor peptides to antisense oligomers with or without carriers. Finally, no evidence was obtained in this investigation that the presence of streptavidin in the nanoparticle interferes with the ability of carriers to improve cell membrane permeation nor with the antisense properties of the oligomers. Taken together, the results of this investigation suggest that further studies in tumored animals are justified to address the issue of whether the streptavidin adversely influences the pharmacokinetic properties of the oligomers.

ACKNOWLEDGMENT

The authors wish to thank Dr. Dario C. Altieri (Cancer Biology, University of Massachusetts Medical School, Massachusetts) for providing the MCF-7 cell line. Simple One-Pot Preparation of Water-Soluble, Cysteine-Reactive Cyanine and Merocyanine Dyes for Biological Imaging

Alexei Toutchkine,*,† Dan-Vinh Nguyen, and Klaus M. Hahn*

Department of Pharmacology and Lineberger Cancer Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599. Received December 3, 2006; Revised Manuscript Received February 16, 2007

A simple one-pot-procedure for preparation of protein-reactive, water-soluble merocyanine and cyanine dyes has been developed. The 1-(3-ammoniopropyl)-2,3,3-trimethyl-3*H*-indolium-5-sulfonate bromide **(1)** was used as a common starting intermediate. The method allows easy preparation of dyes with chloro- and iodoacetamide side chains for covalent attachment to cysteine. By placing a sulfonato group directly on the dye fluorophore system, dyes with high fluorescence quantum yields in water were generated. Both iodo- and chloroacetamido derivatives were shown to be useful in protein labeling. Less reactive chloroacetamides will be preferential for selective labeling of the most reactive cysteines.

INTRODUCTION

Cyanine and merocyanine dyes have been useful as fluorescent labels of proteins in many biological applications, because they have excellent photophysical properties, including high fluorescence quantum yields and extinction coefficients, photostability, and long fluorescence wavelengths that minimally overlap cellular autofluorescence (*1*). These dyes have been used in single molecule spectroscopy (*2*, *3*), in protein profiling (*4*), and for quantifying protein conformational changes in living cells (*5*, *6*). Site-specific protein labeling in these applications was accomplished through reaction with cysteine, introduced into proteins at the desired protein sites using molecular biology approaches.

Multiple different approaches have been used to prepare water-soluble, cysteine-reactive cyanine and merocyanine dyes. Gruber et al. produced cysteine-reactive cyanines by linking the succinimidyl ester of the lysine-reactive dyes to chains bearing different thiol-reactive groups (*7*). The dyes used as starting materials for this approach are expensive and available only in small quantities. In methods published by Wagoner et al. (*8*) and by our group (*9*), the unstable intermediate chloro- or iodoacetamido-indolenine is prepared and then condensed with the appropriate anyl to form the final dye (*9*). Alternately, our published synthesis of cysteine-reactive merocyanine dyes uses Fmoc-protection to mask amino functionality in the intermediate indolium or benzthiozolium salts. In the final steps of the synthesis, after assembling the fluorophore structure, the Fmoc group is removed and the amine linked to an iodoacetamido group (*6*).

Here we report a short synthesis of water-soluble, cysteine-reactive merocyanine and cyanine dyes from the same key intermediate, using a facile, one-pot reaction (Scheme 1). The reaction introduces chloroacetamido side chains into the dyes, which are shown to be cleanly converted into more reactive iodoacetamide derivates. Novel, highly fluorescent merocyanines and cyanine dyes are produced and their chloroacetamide and iodoacetamide derivates are used for protein derivatization.

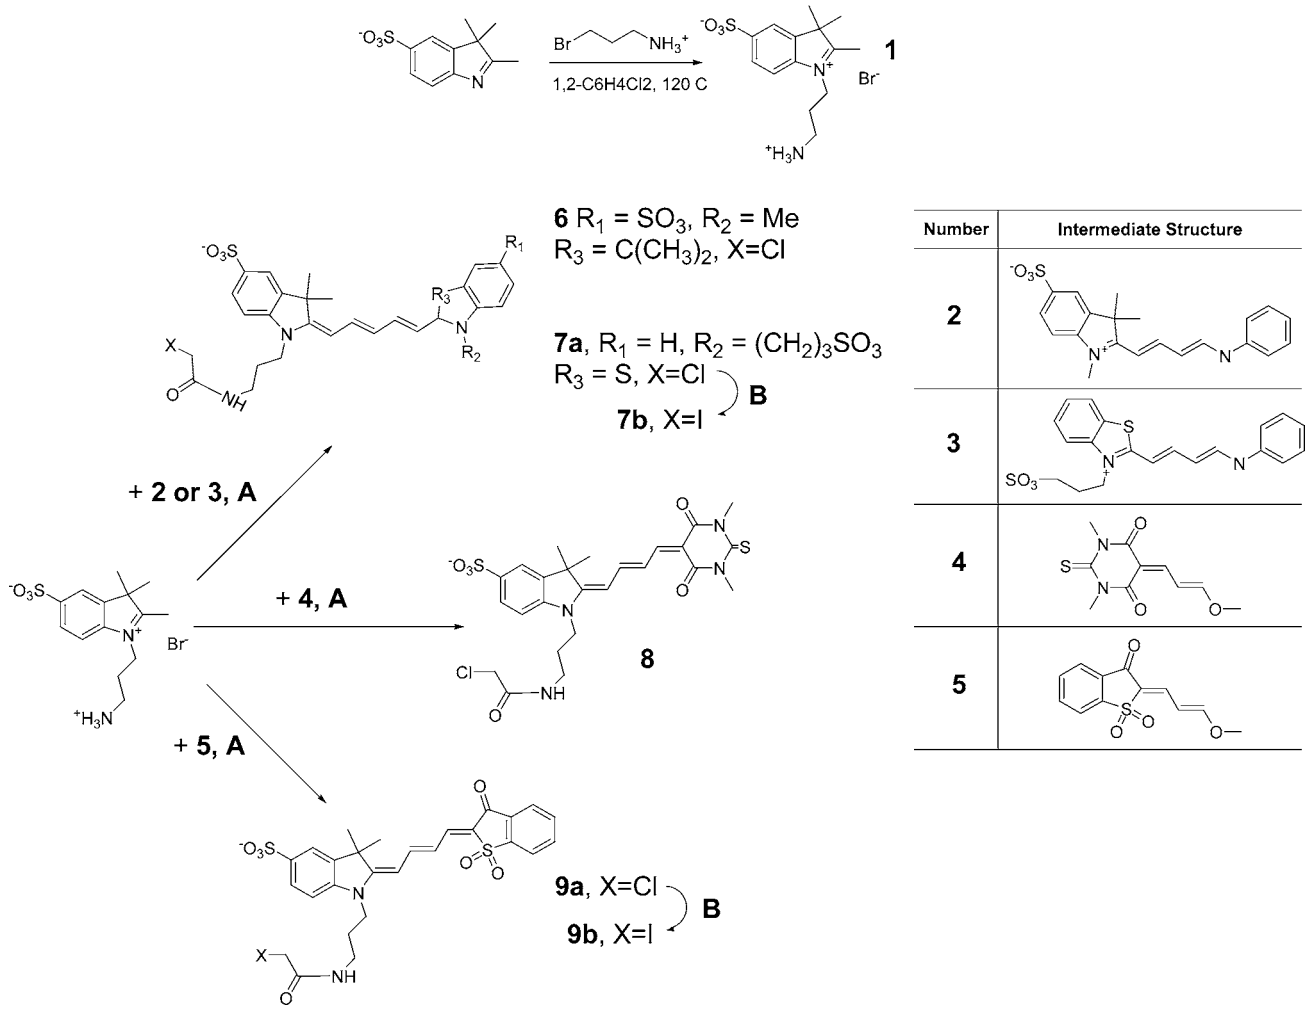
EXPERIMENTAL PROCEDURES

Methods include preparation of the key intermediate 1-(3-ammoniopropyl)-2,3,3-trimethyl-3*H*-indolium-5-sulfonate **1** and its conversion to merocyanine and cyanine dyes. The reaction of this intermediate with hemicyanine **2** (*8*) or 3-methoxyprop-2-enyl-1-idene-2-thiobarbituric acid **3** (*6*) in dimethylformamide in the presence of sodium acetate and chloroacetic acid anhydride (CAA) gave the cyanine or merocyanine dyes, respectively. The pure dyes were obtained by chromatography of crude reaction mixtures on silica gel using acetone−methanol as eluent (Scheme 1). The chloroacetamides were cleanly converted into more reactive iodoacetamides by reaction with sodium iodide in methanol−chloroform.



Materials. Analytical grade reagents were purchased from Sigma-Aldrich Co. Potassium 2,3,3-trimethyl-3*H*-indole-5-sulfonate (*10*), 3-{2-[(1*E*,3*E*)-4-anilinobuta-1,3-dien-1-yl]-1,3-benzothiazol-3-ium-3-yl}propane-1-sulfonate (**3**) (*11*), (2*Z*)-2-[(2*E*)-3-methoxyprop-2-en-1-ylidene]-1-benzothiophen-3(2*H*)-one 1,1-dioxide (**5**) (*6*), and 5-[(2*E*)-3-methoxyprop-2-en-1-ylidene]-1,3-dimethyl-2-thioxodihydropyrimidine-4,6(1*H*,5*H*)-dione (**4**) (*6*) were prepared as previously described.

Methods. Absorption spectra were recorded on a Hewlett-Packard UV−vis spectrophotometer, and fluorescence measurements were taken on a Spex Fluorolog 2 spectrofluorometer. NMR spectra were obtained on Varian Mercury 300 MHz or on a Bruker 500 MHz DRX 500 spectrometer. Mass spectra were obtained on a Hewlett-Packard 5890 gas chromatograph equipped with a 5971A mass selective detector (MS-EI). Quantum yields were measured using merocyanine 540 (*12*) or Cy5 (*7*) as an internal standards (*13*).

*Synthesis of Intermediate **1**: 1-(3-Ammoniopropyl)-2,3,3-trimethyl-3H-indolium-5-sulfonate Bromide (**1**).* To a suspension of 2.77 g of potassium 2,3,3-trimethyl-3*H*-indole-5-sulfonate in dichlorobenzene was added 2.18 g of 3-bromopropylamine hydrobromide. The mixture was stirred at 130 °C under nitrogen for 12 h. It was then cooled and the solid was filtered. The solid was stirred with 50 mL of hot methanol for 10 min, filtered, and dried. The yield was 2.45 g (65%). NMR (400 MHz, D_2O−DMSO-d_6) 1.48 (s, 6H, 2 × CH_3), 2.13 (p, $^3J_{H-H}$ = 6.2 Hz, 2H, $CH_2-CH_2CH_2$), 3.00 (t, $^3J_{H-H}$ = 6.2 Hz, 2H, $CH_2CH_2NH_3^+$), 4.45 (t, $^3J_{H-H}$ = 6.2 Hz, 2H, CH_2N), 7.81−7.87 (m, 2H), 7.94 (s, 1H). ESI-MS: 297 (M^+, positive ion detection).

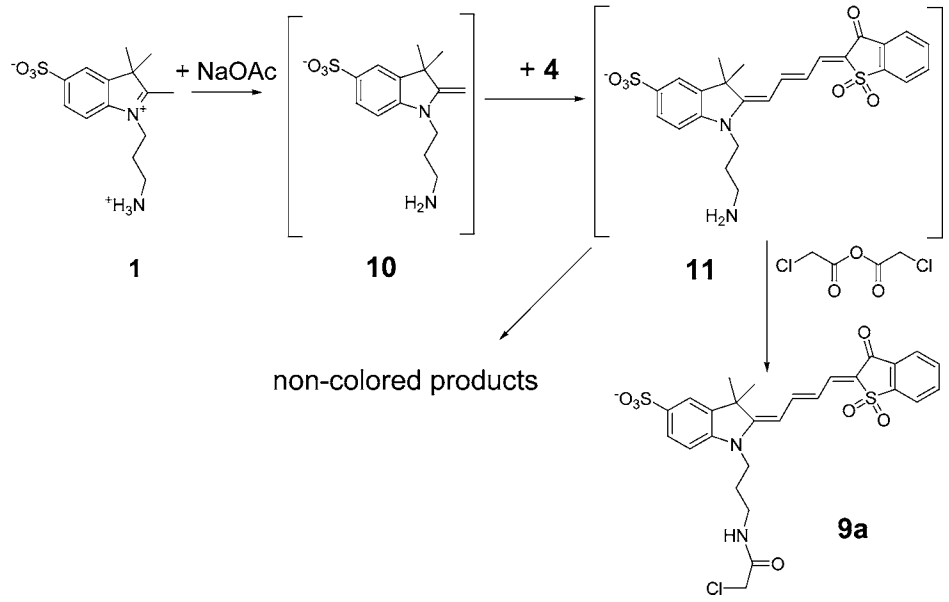
Scheme 1. Synthesis of Water-Soluble Dyes with Chloro- or Iodoacetamido Reactive Groups[a]

[a] Reagents and conditions: A. Chloroacetic anhydride, sodium acetate, DMF, rt, 1 h. B. NaI, MeOH−$CHCl_3$, reflux, 24 h.

General Method for the Preparation of the Chloroacetamido-Substituted Dyes. To a stirred suspension of 377 mg (1.00 mmol) of **1** in 10 mL of DMF were added 425 mg (2.50 mmol) chloroacetic anhydride (CAA), 1.20 mmol of acceptor intermediate (**2, 3, 4**, or **5**), and 200 mg (2.50 mmol) of sodium acetate. The mixture was stirred at room temperature for 1 h. The DMF was removed under vacuum, and the residue was purified by column chromatography on silica gel using acetone−methanol as eluent.



*Sodium (2-((1E,3E,5E)-5-(1-(3-(2-Chloroacetamido)propyl)-3,3-dimethyl-5-sulfonatoindolin-2-ylidene)penta-1,3-dienyl)-1,3,3-trimethyl-3H-indolium-5-sulfonate) or Cy5-CAA (**6**).* The yield was 369 mg (54%). NMR (300 MHz, DMSO-d_6): δ 1.69 (s, 12H, 4 × CH_3), 1.85 (p, $^3J_{H-H}$ = 6.8 Hz, 2H, CH_2CH_2-CH_2), 3.21 (q, $^3J_{H-H}$ = 6.8 Hz, 2H, CH_2CH_2NH), 3.61 (s, 3H, NCH_3), 4.08 (m, 4H, CH_2N and CH_2Cl), 6.27 (m, 2H), 6.54 (t, $^3J_{H-H}$ = 12.3 Hz, 1H), 7.30 (d, $^3J_{H-H}$ = 8.4 Hz, 1H), 7.33 (d, $^3J_{H-H}$ = 8.4 Hz, 1H), 7.60−7.66 (m, 2H), 7.80 (d, $^3J_{H-H}$ = 1.5 Hz, 1H), 7.82 (d, $^3J_{H-H}$ = 1.5 Hz, 1H), 8.30−8.41 (m, 3H). ESI-MS: 660 ((M − Na)$^-$, negative ion detection).

*(2-((1E,3E,5E)-5-(1-(3-(2-Chloroacetamido)propyl)-3,3-dimethyl-5-sulfonatoindolin-2-ylidene)penta-1,3-dienyl)-3-ethylbenzo-[d]thiazol-3-ium-6-sulfonate) or Cy5S-CAA (**7a**).* The yield was 369 mg (63%). NMR (300 MHz, DMSO-d_6): δ 1.64 (s, 6H, 2 × CH_3), 1.87 (p, $^3J_{H-H}$ = 6.8 Hz, 2H, $CH_2CH_2CH_2$), 2.03 (p, $^3J_{H-H}$ = 6.8 Hz, 2H, $CH_2CH_2CH_2$), 2.60 (t, $^3J_{H-H}$ = 6.8 Hz, 2H, CH_2SO_3) 3.25 (q, $^3J_{H-H}$ = 6.8 Hz, 2H, CH_2CH_2NH), 3.96 (t, $^3J_{H-H}$ = 6.8 Hz, 2H, CH_2N), 4.06 (2H, CH_2N, CH_2Cl), 4.67 (t, $^3J_{H-H}$ = 6.8 Hz, 2H, CH_2N), 6.07 (d, $^3J_{H-H}$ = 13.0 Hz, 1H), 6.51 (t, $^3J_{H-H}$ = 13.0 Hz, 1H), 6.98 (d, $^3J_{H-H}$ = 13.0 Hz, 1H), 7.15 (d, $^3J_{H-H}$ = 8.1 Hz, 1H), 7.50−7.70 (m, 4H), 7.98−8.15 (m, 4H), 8.42 (t, $^3J_{H-H}$ = 6.0 Hz, 1H, NH). ESI-MS: 678 ((M−Na)$^-$, negative ion detection).

*Sodium (E)-1-(3-(2-Chloroacetamido)propyl)-2-((E)-4-(1,3-dimethyl-4,6-dioxo-2-thioxotetrahydropyrimidin-5(6H)-ylidene)-but-2-enylidene)-3,3-dimethylindoline-5-sulfonate or I-TBA-CAA (**8**).* The yield was 308 mg (51%). NMR (500 MHz, DMSO-d_6): δ 1.64 (s, 6H, 2 × CH_3), 1.82 (p, $^3J_{H-H}$ = 7.0 Hz, 2H, $CH_2-CH_2CH_2$), 3.24 (q, 2H, $^3J_{H-H}$ = 7.0 Hz, CH_2CH_2NH), 3.60 (s, 6H, 2 × CH_3), 4.06 (s, 2H, CH_2Cl), 4.12 (t, $^3J_{H-H}$ = 7.0 Hz, 2H, CH_2N), 6.40 (d, $^3J_{H-H}$ = 14 Hz, 1H), 7.31 (d, $^3J_{H-H}$ = 8.5 Hz, 1H), 7.58 (d, $^3J_{H-H}$ = 8.5 Hz, 1H), 7.73 (d, $^3J_{H-H}$ = 1.5 Hz, 1H), 7.81 (t, $^3J_{H-H}$ = 13.0 Hz, 1H), 8.19 (d, $^3J_{H-H}$ = 13.5 Hz, 1H), 8.27 (t, $^3J_{H-H}$ = 13.5 Hz, 1H), 8.39 (t, $^3J_{H-H}$ = 6.0 Hz, 1H, NH). ESI-MS: 579 ((M − Na)$^-$, negative ion detection).

*Sodium (E)-1-(3-(2-Chloroacetamido)propyl)-3,3-dimethyl-2-((2E,4Z)-4-(3-oxobenzo[b]thiophen-1,1-dioxide-2(3H)-ylidene)-but-2-enylidene)indoline-5-sulfonate or I-SO-CAA (**9a**).* The yield was 313 mg (55%). NMR (300 MHz, DMSO-d_6): δ 1.64 (s, 6H, 2 × CH_3), 1.83 (p, $^3J_{H-H}$ = 6.5 Hz, 2H, $CH_2CH_2CH_2$), 3.24 (q, $^3J_{H-H}$ = 6.5 Hz, 2H, CH_2CH_2NH), 4.03 (t, $^3J_{H-H}$ = 6.5 Hz, 2H, CH_2N), 4.06 (s, 2H, CH_2Cl), 6.32 (d, 1H, $^3J_{H-H}$ = 13 Hz), 6.68 (t, 1H, $^3J_{H-H}$ = 13 Hz), 7.21 (d, 1H, $^3J_{H-H}$ = 8.5 Hz), 7.58 (d, 1H, $^3J_{H-H}$ = 8.5 Hz), 7.69 (s, 1H), 7.70−8.05

Scheme 2. Mechanism of One-Pot Dye Synthesis

(m, 5H), 8.25 (t, 1H, $^3J_{H-H}$ = 13 Hz), 8.39 (t, 1H, $^3J_{H-H}$ = 5.5 Hz, NH). ESI-MS: 589 ((M − Na)$^-$, negative ion detection).

General Method for the Preparation of the Iodoacetamido-Substituted Dyes. A solution of 0.5 mmol of chloro-substituted dye and 1 g of sodium iodide in 10 mL of 1:1 methanol−chloroform mixture was refluxed for 24 h under nitrogen. The mixture was filtered and evaporated. The iodoacetamides were purified on HPLC using a C18 column (VydacTP152022) with a water-acetonitrile gradient.

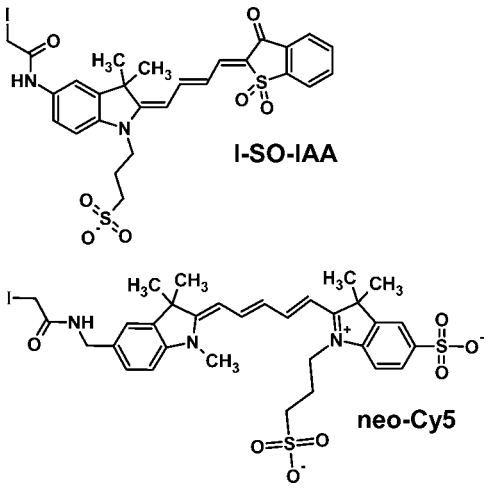
*Sodium (E)-1-(3-(2-Chloroacetamido)propyl)-3,3-dimethyl-2-((2E,4Z)-4-(3-oxobenzo[b]thiophen-1,1-dioxide-2(3H)-ylidene)-but-2-enylidene)indoline-5-sulfonate or I-SO-IAA (**9b**).* The yield was 211 mg (60%). NMR (300 MHz, DMSO-d_6): δ 1.64 (s, 6H, 2 × CH_3), 1.79 (p, $^3J_{H-H}$ = 6.5 Hz, 2H, $CH_2CH_2CH_2$), 3.21 (q, $^3J_{H-H}$ = 6.5 Hz, 2H, CH_2CH_2NH), 3.64 (s, 2H, CH_2I), 4.02 (t, $^3J_{H-H}$ = 6.5 Hz, 2H, CH_2N), 6.31 (d, $^3J_{H-H}$ = 13 Hz, 1H), 6.69 (t, $^3J_{H-H}$ = 13 Hz, 1H), 7.21 (d, $^3J_{H-H}$ = 8.5 Hz, 1H), 7.58 (d, $^3J_{H-H}$ = 8.5 Hz, 1H), 7.69 (s, 1H), 7.70−8.05 (m, 5H), 8.25 (t, $^3J_{H-H}$ = 13 Hz, 1H), 8.39 (t, $^3J_{H-H}$ = 5.5 Hz, 1H, NH). ESI-MS: 681 ((M−Na)$^-$, negative ion detection).

*(2-((1E,3E,5E)-5-(1-(3-(2-Iodooacetamido)propyl)-3,3-dimethyl-5-sulfonatoindolin-2-ylidene)penta-1,3-dienyl)-3-ethylbenzo[d]thiazol-3-ium-6-sulfonate) or Cy5S-IAA (**7b**).* The yield was 258 mg (76%). NMR (300 MHz, DMSO-d_6): δ 1.64 (s, 6H, 2 × CH_3), 1.85 (p, $^3J_{H-H}$ = 6.8 Hz, 2H, $CH_2CH_2CH_2$), 2.07 (p, $^3J_{H-H}$ = 6.8 Hz, 2H, $CH_2CH_2CH_2$), 2.60 (t, $^3J_{H-H}$ = 6.8 Hz, 2H, CH_2SO_3) 3.20 (q, $^3J_{H-H}$ = 6.8 Hz, 2H, CH_2CH_2-NH), 3.65 (2H, CH_2N, CH_2I), 3.96 (t, $^3J_{H-H}$ = 6.8 Hz, 2H, CH_2N), 4.67 (t, $^3J_{H-H}$ = 6.8 Hz, 2H, CH_2N), 6.07 (d, $^3J_{H-H}$ = 13.0 Hz, 1H), 6.51 (t, $^3J_{H-H}$ = 13.0 Hz, 1H), 6.98 (d, $^3J_{H-H}$ = 13.0 Hz, 1H), 7.15 (d, $^3J_{H-H}$ = 8.1 Hz, 1H), 7.50−7.70 (m, 4H), 7.98−8.15 (m, 4H), 8.42 (t, $^3J_{H-H}$ = 6.0 Hz, 1H, NH). ESI-MS: 770 ((M − Na)$^-$, negative ion detection).

Protein Labeling. A fusion protein of enhanced green fluorescent protein and extracellular regulated kinase 2 (EGFP-Erk2) was incubated with a 10-fold molar ratio of the **9a** or **9b** dye (Scheme 1) in 25 mM HEPES (pH 7.4), 50 mM NaCl (0.15 mL 20 μM EGFP-Erk2). To this protein solution was added 13.5 μL of 2 mM dye stock solution in DMSO. The mixture was incubated at room temperature with gentle agitation for 2 h and then was spun at 11750*g* (Eppendorf 5415C centrifuge) for 1 min to remove any precipitate that might have formed during labeling. The supernatant was then purified using a G25 sepharose gel filtration column, pre-equilibrated with 25 mM HEPES (pH 7.4). The dye−protein adduct was clearly separated from free dye during gel filtration. Purity of the conjugates was confirmed by SDS-PAGE electrophoresis. No free dye was seen in the purified protein conjugates. Control samples of free dye were clearly visible on the gel at lower MW than protein. Conjugates formed single, higly colored fluorescent protein bands with molecular weight corresponding to EGFP-Erk2. The degree of labeling D/P (dye-to-protein ratio) was calculated using the following formula:

$$\mathrm{D/P} = (A_{dye}/\epsilon_{dye})/(A_{prot}/\epsilon_{prot})$$

where A_{dye} is the absorbance at the absorption maximum of the dye, A_{prot} is the absorbance at the absorption maximum of EGFP (490 nm), ϵ_{dye} is the extinction coefficient of the dye in H_2O, and ϵ_{prot} is the extinction coefficient of EGFP (61000).



RESULTS AND DISCUSSION

Synthesis. As shown in Scheme 1, cyanine and merocyanine dyes were prepared using a facile one-pot procedure from the key intermediate, 1-(3-ammoniopropyl)-2,3,3-trimethyl-3*H*-indolium-5-sulfonate (intermediate **1**). This intermediate was prepared by reaction of potassium 2,3,3-trimethyl-3*H*-indole-5-sulfonate with 3-bromopropylamine hydrobromide in dichlorobenzene at 130 C. The intermediate **1** precipitates during the reaction and can be easily purified from unreacted starting compounds by simple washing with hot methanol, as the intermediate is practically insoluble in that solvent. The reaction of intermediate **1** with 3-methoxyprop-2-enyl-1-idene-2-thiobarbituric acid **4** or with 3-methoxyprop-2-enyl-1-idene-2-benzothiophen-3-one 1,1-dioxide **5** in the presence of sodium acetate and chloroacetic acid anhydride (CAA) resulted in the formation of merocyanine dyes bearing chloroacetamido reactive groups. Use of the same reaction conditions with hemicyanines **2** or **3** produced the cyanine dyes shown. The dyes were purified by chromatography of crude reaction mixtures on silica gel using acetone−methanol as an eluent. Iodoacetamides were prepared by the reaction of chloroacetamides with sodium iodide in methanol−chloroform mixture. The yields of both merocyanine and cyanine chloroacetamido dyes were in the range of 50−65%, and the substitution of iodide for chloride occurred with 60−80% yield.

The reaction mechanism likely proceeds by deprotonation of **1** by sodium acetate with formation of enamine **10** (Scheme 2).

The enamine then reacts with 3-methoxyprop-2-enyl-1-idene-2-benzothiophen-3-one 1,1-dioxide **4** to give amino-substituted dye **11**. The dye **11** is not stable, and its solution rapidly loses color, as Michael addition of the free amino group to the polymethine chain destroys the dye fluorophore system. In the presence of chloroacetic anhydride, the free amine is quickly trapped as the chloroacetamide (Scheme 2). This mechanism is supported by trapping of unstable dye intermediate **10** with amino-reactive compounds, including acetic anhydride or acetic acid succinimidyl ester.

Absorption and Fluorescence Properties. These reactions generated novel, bright merocyanine and cyanine dyes (Table 1). They had high extinction coefficients, in the range of 120,000−215,000 and moderate fluorescence quantum yields of 0.1−0.4. The absorption characteristics of dyes **6** and **9a** were very similar to those of the published analogues neoCy5 (*9*) and I-SO-IAA (*6*). Substitution with a sulfonato group ($-SO_3$) at the aromatic ring in the new merocyanine dye **9a** and in the new cyanine dye **6** significantly increased the fluorescence quantum yields in polar solvents (H_2O, MeOH) compared to I-SO-IAA and neo-Cy5. For the cyanine, the quantum yield in water more than doubled, and for the merocyanine it increased 5-fold. Similar increases in dye fluorescence upon ring-substitution with sulfonato-groups have been reported for rhodamines (*14*) and cyanines (*15*). Previously, it was thought that dye aggregation is the main reason for the significant drop in dye fluorescence quantum yields in aqueous solutions (*14*, *15*). The I-SO-IAA dye does not form H-aggregates (*6*), and its fluorescence is still significantly lower in water than the fluorescence of the dye **9a**. Although the mechanism of fluorescence quenching of I-SO-IAA in water is not clear, it likely includes either dynamic quenching of excited dye molecules through collision with dye in the ground state (*16*) or static quenching through association (other than H-aggregation) of ground state dye molecules (*17*). In both cases placement of negatively charged sulfonato groups directly on the dye fluorophore system (dyes **6**, **9a** in present study) rather than on alkyl side chains (I-SO-IAA and neoCy5) will reduce dye−dye interactions in water because of Coulombic repulsion and will lead to higher fluorescence quantum yields. Brightness in polar solvents is especially valuable for imaging applications, where dyes are conjugated to proteins and exposed to water.

Protein Labeling. The reactivity of the chloroacetamido and iodoacetamido derivates was compared by covalent derivatization of EGFP-Erk2 with the chloro- and iodoacetamido derivates of I-SO dye (**9a** and **9b)**. Chloroacetamido-reactive groups are not used in protein labeling because of their much lower reactivity toward thiols. In previous studies, chloroacetamides have been about 300 times less reactive than iodoacetamides

Table 1. Absoprption and Fluorescence Data for Merocyanine and Cyanine Dyes

in reaction with mercaptoacetic acid (*18*). When EGFP-Erk2 was labeled with **9a** and **9b** under identical conditions (10:1 dye to protein ratio, 2 h, room temperature), the iodoacetamide **9b** produced conjugates with an average dye/protein (D/P) of 1.25, while labeling with chloroacetamide **9a** produced conjugates with D/P of 0.2 (Figure 1).

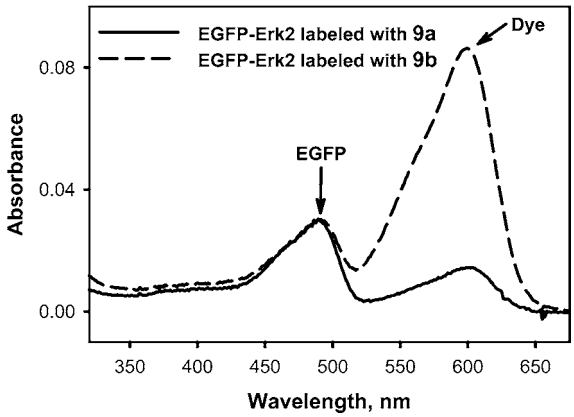

Figure 1. Labeling of EGFP-Erk2 with dyes **9a** and **9b**.

This protein has a total of nine free cysteines (two in EGFP and seven in Erk2) that can potentially react with halogenacetamido groups. The relatively low D/P produced by iodoacetamide labeling implies that there is only one reactive cysteine in EGFP-Erk2. Surprisingly, the reactivity of chloroacetamido-substituted dye was only six times lower than that of the iodoacetamido dye. The diminished difference between the two derivatives may be explained by a two-step reaction mechanism, in which slow formation of the dye−protein complex is followed by rapid reaction with a thiol group. In such a process the reactivity of the substrate will be determined by the rate of dye−protein complex formation, which should be similar for dyes with chloroacetamido and iodoacetamido side chains.

SUMMARY

A simple one-pot procedure for preparation of protein-reactive, water-soluble merocyanine and cyanine dyes has been developed. The method allows easy preparation of dyes with chloro- and iodoacetamide side chains for covalent attachement to cysteine. Novel bright dyes were generated, and both iodo-

and chloroacetamido derivatives were shown to be useful in protein labeling.

ACKNOWLEDGMENT

Financial support from the NIH (Grants GM57464 and GM64346) is gratefully acknowledged. We thank Dr. Frederique Gaits for assistance with EGFP-Erk2 expression and purification.

Alkyl Chain Moieties of Polyamidoamine Dendron-Bearing Lipids Influence Their Function as a Nonviral Gene Vector

Toshinari Takahashi, Chie Kojima, Atsushi Harada, and Kenji Kono*

Department of Applied Chemistry, Graduate School of Engineering, Osaka Prefecture University, 1-1 Gakuen-cho, Naka-ku, Sakai, Osaka 599-8531, Japan. Received October 6, 2006; Revised Manuscript Received February 21, 2007

We recently developed a novel family of cationic lipids consisting of a polyamidoamine (PAMAM) dendron and two dodecyl chains. Their transfection activity increases with increasing generation of the dendron moiety [Takahashi et al. (2003) *Bioconjugate Chem*. *14*, 764−773]. In the present study, to elucidate the effect of hydrophobic tail moieties of the dendron-bearing lipids, two kinds of PAMAM G3 dendron-bearing lipids were synthesized with different alkyl lengths, DL-G3-2C_{18} and DL-G3-2C_{12}. Their functions as gene vectors were compared. Irrespective of their different alkyl chain lengths, these dendron-bearing lipids formed complexes with plasmid DNA with similar efficiency. However, their complex sizes differed markedly: DL-G3-2C_{18} lipoplexes exhibited much smaller diameters than DL-G3-2C_{12} lipoplexes. Interaction of the lipoplexes with heparin revealed that the DL-G3-2C_{18} lipoplexes required more heparin than DL-G3-2C_{12} lipoplexes to cause dissociation of plasmid DNA from the lipoplexes. Although the DL-G3-2C_{12} lipoplexes and DL-G3-2C_{18} lipoplexes transfected CV1 cells with similar efficiency in the absence of serum, only the latter retained high transfection activity in the presence of serum. These results indicate that hydrophobic interaction of alkyl chain moieties plays an important role in the increment of stability and the serum-resistant transfection activity for dendron-bearing lipid lipoplexes.

INTRODUCTION

Preparation of nonviral vectors that deliver therapeutic genes to target cells has been demanded for efficient and safe gene therapy. Among these nonviral vectors, various types of cationic lipids have been studied intensively, but their activity requires improvement. These vectors can associate with plasmid DNA and form complexes, which are termed lipoplexes (*1*, *2*). Lipoplexes bind to the cell surface through electrostatic interactions and are taken up by cells mainly via endocytosis. Subsequently, some parts of plasmid DNA contained in the complexes reach the nucleus, where gene transcription occurs. Nevertheless, most complexes are likely to be trapped in the endosome and be eventually degraded in the lysosome. Therefore, avoidance of plasmid DNA degradation in the lysosome and its transfer into cytosol is considered to be a key process for efficient transfection (*3*).

Cationic polymers are another type of nonviral vector that has been studied intensively (*2*). Polyamidoamine (PAMAM) dendrimers have been shown to achieve efficient gene transfection of cells among cationic polymers: PAMAM dendrimers possess many tertiary amine groups, which become protonated under weakly acidic conditions (*4*−*6*). Those amine groups suppress the lowering of pH in endosomes and lysosomes by adsorbing protons and prohibiting degradation of DNA in the lysosome. In addition, the endosome buffering ability of PAMAM dendrimers is thought to induce osmotic swelling of the endosome interior, engendering rupture of the endosome and the subsequent release of DNA into the cytoplasm (*7*). Such a function of these tertiary amine groups of PAMAM dendrimers, the so-called proton sponge effect, is considered to contribute to their high transfection activity (*8*).

In a previous study (*9*), we developed a novel type of cationic lipid that consists of two dodecyl groups and a PAMAM dendron as a head group and showed that these dendron-bearing lipids are promising as a potent nonviral vector that exhibits higher transfection activity than the PAMAM dendrimer of the same generation. Their molecular structure, e.g., that of the head group of the dendron moiety and the tail moieties of alkyl chains, will influence their transfection activity. We showed in a previous study that their transfection activity increases concomitant with increasing generation of the head moiety (*9*). Nevertheless, it remains unclear how alkyl chains affect their transfection activity.

In this study, we synthesized the PAMAM dendron-bearing lipid with two octadecyl chains DL-G3-2C_{18} and compared its capability as a gene vector to that of DL-G3-2C_{12} (Figure 1). The importance of the alkyl chain moiety for stability and transfection activity of the dendron-bearing lipid lipoplexes is described.

EXPERIMENTAL PROCEDURES

General Methods. Dioctadecylamine was purchased from Fluka (Tokyo, Japan). Methyl acrylate, ethylenediamine, and tris(hydroxymethyl)aminomethane (Tris) were obtained from Kishida Chemical (Osaka, Japan). Sodium cyanide and ethidium bromide were supplied from Wako Pure Chemical Industries (Osaka, Japan). Merck Kieselgel 60 (230−400 mesh) was used for silica gel chromatography. Fetal calf serum (FCS) was obtained from PAA Laboratories GmbH (Pasching, Austria). Dulbecco's modified Eagle's medium (DMEM) was from Nissui Pharmaceutical (Tokyo, Japan). Heparin sodium salt was purchased from Sigma (St. Louis, MO). Agarose was purchased from nacalai tesque (Kyoto, Japan). DL-G3-2C_{12} was synthesized by the method previously reported (*9*). Plasmid DNA pCMV-Luc, which contains the cDNA of firefly luciferase driven by a human cytomegalovirus immediate-early promoter, was a gift from Dr. Kazuo Maruyama, Teikyo University, and amplified in *E. coli*, isolated, and purified using a QIAGEN plasmid Maxi Kit.

Synthesis of Dendron-Bearing Lipids. DL-G3-2C_{18} was synthesized by repetition of exhaustive Michael addition with

methyl acrylate using dioctadecylamine as the core material and subsequent exhaustive amidation with ethylenediamine.

DL-G-0.5-2C_{18}. Dioctadecylamine (2.0 g, 3.8 mmol) was dissolved in methyl acrylate (35 mL, 0.39 mol), and the resultant solution was refluxed under nitrogen. After 18 h, unreacted methyl acrylate was removed under vacuum and the residue was chromatographed on silica gel using petroleum ether−diethyl ether (2/1, v/v) as eluent. Yield: 87.9%. ^{1}H NMR ($CDCl_3$): δ 0.88 (m, C*H*$_3$(CH$_2$)$_{15}$-), δ 1.26 (s, CH$_3$(C*H*$_2$)$_{15}$-), δ 1.41 (br, -C*H*$_2$CH$_2$N-), δ 2.35−2.46 (m, -C*H*$_2$COOCH$_3$, -C*H*$_2$N), δ 2.77 (t, -C*H*$_2$CH$_2$COOCH$_3$), δ 3.66 (s, -OC*H*$_3$).

DL-G0-2C_{18}. DL-G-0.5-2C_{18} (2.0 g, 3.4 mmol) was dissolved in methanol (40 mL). The resultant solution was added dropwise to distilled ethylenediamine (70 mL, 1.05 mol) containing sodium cyanide (33 mg, 0.67 mmol) and stirred at 50 °C under nitrogen. After 1 week, methanol and unreacted ethylenediamine were removed from the reaction mixture under vacuum. The obtained DL-G0-2C_{18} was chromatographed on silica gel using chloroform−methanol−water (60/35/5, v/v/v) as eluent. Yield: 53.2%. ^{1}H NMR ($CDCl_3$): δ 0.88 (m, C*H*$_3$(CH$_2$)$_{15}$-), δ 1.26 (s, CH$_3$(C*H*$_2$)$_{15}$-), δ 1.44 (br, -C*H*$_2$CH$_2$N-), δ 2.33−2.45 (m, -C*H*$_2$CONH-, -C*H*$_2$N-), δ 2.65 (t, -C*H*$_2$CH$_2$CONH-), δ 2.79 (t, -C*H*$_2$NH$_2$), δ 3.28 (q, -C*H*$_2$CH$_2$NH$_2$), δ 8.65 (m, -CON*H*-CONH). MALDI-TOF-MS *m*/*z* 636.5 ([M + H]$^+$).

DL-G0.5-2C_{18}. DL-G0-2C_{18} (1.2 g, 1.9 mmol) was dissolved in methanol (20 mL) and added to methyl acrylate (34 mL, 0.38 mol). The mixed solution was stirred at 35 °C for 50 h under nitrogen. The obtained material was chromatographed on silica gel using petroleum ether−diethyl ether (2/1, v/v) and then chloroform−methanol (9/1, v/v) as eluent. Yield: 97.7%. ^{1}H NMR ($CDCl_3$): δ 0.88 (m, C*H*$_3$(CH$_2$)$_{15}$-), δ 1.26 (s, CH$_3$-(C*H*$_2$)$_{15}$-), δ 1.44 (br, -C*H*$_2$CH$_2$N-), δ 2.35 (m, -C*H*$_2$CONH-), δ 2.43 (m, -C*H*$_2$COOCH$_3$, -C*H*$_2$N-), δ 2.54 (t, -CONHCH$_2$C*H*$_2$), δ 2.69−2.80 (m, -C*H*$_2$CH$_2$CONH-, -C*H*$_2$CH$_2$COOCH$_3$), δ 3.29 (q, -CONHC*H*$_2$-), δ 3.67 (s, -OC*H*$_3$), δ 7.76 (br, -CON*H*).

DL-G1-2C_{18}. DL-G0.5-2C_{18} (1.5 g, 1.8 mmol) was dissolved in methanol (50 mL) and added to ethylenediamine (65 mL, 0.92 mol) containing sodium cyanide (18 mg, 0.37 mmol). The mixed solution was stirred at 45 °C for 60 h under nitrogen. The obtained DL-G1-2C_{18} was purified with a Sephadex LH-20 column using chloroform as eluent. Yield: 94.3%. ^{1}H NMR ($CDCl_3$): δ 0.88 (m, C*H*$_3$(CH$_2$)$_{15}$-), δ 1.26 (s, CH$_3$(C*H*$_2$)$_{15}$-), δ 1.42 (br, -C*H*$_2$CH$_2$N-), δ 2.31 (m, -C*H*$_2$CONH-), δ 2.35−2.43 (m, -C*H*$_2$CONHCH$_2$CH$_2$NH$_2$, -C*H*$_2$N-), δ 2.51 (t, -CONHCH$_2$C*H*$_2$), δ 2.67 (t, -C*H*$_2$CH$_2$CONH-), δ 2.75 (t, -C*H*$_2$CH$_2$CONHCH$_2$-CH$_2$NH$_2$), δ 2.83 (t, -C*H*$_2$NH$_2$), δ 3.24−3.31 (m, -CONHC*H*$_2$), δ 7.37 and 8.65 (br, -CON*H*-). MALDI-TOF-MS *m*/*z* 862.9 ([M + H]$^+$).

DL-G1.5-2C_{18}. DL-G1-2C_{18} (1.3 g, 1.5 mmol) was dissolved in methanol (60 mL) and added to methyl acrylate (110 mL, 1.23 mol). The mixed solution was stirred at 35 °C for 52 h under nitrogen. The obtained material was chromatographed on silica gel using chloroform and then chloroform−methanol (9/1, v/v) as eluent. Yield: 71.9%. ^{1}H NMR ($CDCl_3$): δ 0.88 (m, C*H*$_3$(CH$_2$)$_{15}$-), δ 1.25 (s, CH$_3$(C*H*$_2$)$_{15}$-), δ 1.43 (br, -C*H*$_2$CH$_2$N), δ 2.37 (t, -C*H*$_2$CONH-), δ 2.43 (t, -C*H*$_2$COOCH$_3$, -C*H*$_2$N-), δ 2.52−2.58 (m, -CONHCH$_2$C*H*$_2$-), δ 2.75 (t, -C*H*$_2$CH$_2$CONH-, -C*H*$_2$CH$_2$COOCH$_3$), δ 2.82 (t, -C*H*$_2$CH$_2$CONH-), δ 3.30 (m, -CONHC*H*$_2$-), δ 3.68 (s, -OC*H*$_3$), δ 7.00 and 8.07 (br, -CON*H*).

DL-G2-2C_{18}. DL-G1.5-2C_{18} (1.3 g, 1.1 mmol) was dissolved in methanol (30 mL) and added to ethylenediamine (95 mL, 1.42 mol) containing sodium cyanide (21 mg, 0.43 mmol). The mixed solution was stirred at 45 °C for 50 h under nitrogen. The obtained DL-G2-2C_{18} was purified with a Sephadex LH-20 column using methanol as eluent. Yield: 92.2%. ^{1}H NMR ($CDCl_3$): δ 0.88 (m, C*H*$_3$(CH$_2$)$_{15}$-), δ 1.25 (s, CH$_3$(C*H*$_2$)$_{15}$-), δ 1.42 (br, -C*H*$_2$CH$_2$N-), δ 2.32−2.42 (m, -C*H*$_2$CONHCH$_2$CH$_2$-NH$_2$, -C*H*$_2$CONH-, -C*H*$_2$N-), δ 2.52 (m, -CONHCH$_2$C*H*$_2$-), δ 2.73 (m, -C*H*$_2$CH$_2$CONH-, -C*H*$_2$CH$_2$CONHCH$_2$CH$_2$NH$_2$), δ 2.83 (t, -C*H*$_2$NH$_2$), δ 3.25−3.30 (m, -CONHC*H*$_2$-), δ 7.73, 7.93, and 8.58 (br, -CON*H*-). MALDI-TOF-MS *m*/*z* 1320.6 ([M + H]$^+$).

DL-G2.5-2C_{18}. DL-G2-2C_{18} (0.94 g, 0.71 mmol) dissolved in methanol (60 mL) was added to methyl acrylate (55 mL, 0.61 mol). The mixed solution was stirred at 30 °C for 50 h under nitrogen. The obtained material was chromatographed on silica gel using chloroform−methanol (95/5 and then 8/2, v/v) as eluent. Yield: 67.4%. ^{1}H NMR ($CDCl_3$): δ 0.88 (m, C*H*$_3$-(CH$_2$)$_{15}$-), δ 1.25 (s, CH$_3$(C*H*$_2$)$_{15}$-), δ 1.47 (br, -C*H*$_2$CH$_2$N-), δ 2.37 (m, -C*H*$_2$CONH-), δ 2.44 (m, -C*H*$_2$COOCH$_3$, -C*H*$_2$N-), δ 2.55 (m, -CONHCH$_2$C*H*$_2$-), δ 2.74−2.81 (m, -C*H*$_2$CH$_2$CONH-, -C*H*$_2$CH$_2$COOCH$_3$), δ 3.29 (m, -CONHC*H*$_2$-), δ 3.67 (s, -OC*H*$_3$), δ 7.10, 7.65, and 8.09 (br, -CON*H*-).

DL-G3-2C_{18}. DL-G2.5-2C_{18} (0.92 g, 0.46 mmol) was dissolved in methanol (40 mL) and added to ethylenediamine (60 mL, 0.9 mol) containing sodium cyanide (8.9 mg, 0.18 mmol). The mixed solution was stirred at 45 °C for 55 h under nitrogen. The obtained DL-G3-2C_{18} was purified with a Sephadex LH-20 column using methanol as eluent. Yield: 90.7%. ^{1}H NMR ($CDCl_3$): δ 0.88 (m, C*H*$_3$(CH$_2$)$_{15}$-), δ 1.25 (s, CH$_3$(C*H*$_2$)$_{15}$-), δ 1.42 (br, -C*H*$_2$CH$_2$N-), δ 2.32−2.37 (m, -C*H*$_2$CONHCH$_2$CH$_2$-NH$_2$, -C*H*$_2$CONH-, -C*H*$_2$N-), δ 2.53 (m, -CONHCH$_2$C*H*$_2$-), δ 2.73 (br, -C*H*$_2$CH$_2$CONH-, -C*H*$_2$CH$_2$CONHCH$_2$CH$_2$NH$_2$), δ 2.83 (t, -C*H*$_2$NH$_2$), δ 3.24−3.30 (m, -CONHC*H*$_2$-), δ 7.82, 8.02, and 8.52 (br, -CON*H*-). MALDI-TOF-MS *m*/*z* 2234.3 ([M + H]$^+$).

Preparation of Lipoplexes. To a dry thin membrane of the dendron-bearing lipid, phosphate-buffered saline (PBS) was added and sonicated for 2 min using a bath-type sonicator to afford a lipid suspension. Plasmid DNA (1 μg) was dissolved in 20 mM Tris−HCl buffer (pH 7.4, 50 μL), mixed with the lipid suspension (50 μL), and incubated for 30 min at room temperature to afford a lipoplex with a given ratio of primary amine of DL-G3 to DNA phosphate (N/P ratio).

Agarose Gel Electrophoresis. The dendron-bearing lipid−DNA complexes with varying N/P ratios were prepared by mixing plasmid DNA (1 μg) dissolved in 20 mM Tris−HCl buffer (5 μL) and lipid suspension (5 μL). After 30 min incubation at room temperature, the samples (10 μL) were electrophoresed on 0.6 wt % agarose gel in 40 mM Tris, 20 mM sodium acetate, and 2 mM EDTA buffer (pH 8.0) containing 1 μg/mL ethidium bromide at 100 V for 30 min. The ethidium bromide stained bands were visualized using a

LAS-1000UVmini (Fujifilm, Tokyo, Japan) and analyzed with Science Lab 2003 Multi Gauge software (Fujifilm, Tokyo, Japan).

Dynamic Light Scattering (DLS) Measurement. The diameters of lipoplexes were estimated by DLS using an electrophoretic light scattering spectrometer ELS-8000F (Otuka Electronics Co, Ltd., Osaka, Japan). Lipoplexes with various N/P ratios were prepared by mixing plasmid DNA (20 μg) and a given amount of the dendron-bearing lipid and incubated for 30 min as described above. The data were obtained at a detection angle of 90° at 25 °C and were analyzed by the cumulant method.

Atomic Force Microscopy (AFM). AFM measurements were performed by SPI3800 probe station and SPA400 unit system of the scanning probe microscopy system (Seiko Instruments Inc., Chiba, Japan). The cantilever was made of silicon (SI-DF20; Seiko Instruments Inc., Chiba, Japan), and its spring constant was 14 N/m. Lipoplexes were formed at a total of 100 μg/mL of plasmid DNA concentration with N/P ratio of 4. Lipoplexes containing 0.5 μg of plasmid DNA were applied to freshly cleaved mica and incubated on it for 5 min. After incubation, excess fluid was dried under air flow. The measurements were performed in a dynamic force mode (noncontact mode). Raw AFM images have been processed only for background removal (flattening) using the microscope manufacturer's image-processing software.

Interaction of Lipoplexes with Heparin. The dendron-bearing lipid−DNA lipoplexes were prepared by mixing plasmid DNA (1 μg) dissolved in 20 mM Tris−HCl buffer (2.5 μL) and lipid suspension (2.5 μL). After 30 min incubation at room temperature, the lipoplexes were added to a given amount (0−2 μg) of heparin dissolved in PBS (5 μL) and incubated for 30 min at room temperature. The samples (10 μL) were electrophoresed on 0.6 wt % agarose gel in 40 mM Tris, 20 mM sodium acetate, and 2 mM EDTA buffer (pH 8.0) containing 1 μg/mL ethidium bromide at 100 V for 30 min. The ethidium bromide stained bands were visualized using a LAS-1000UVmini (Fujifilm, Tokyo, Japan) and analyzed with Science Lab 2003 Multi Gauge software (Fujifilm, Tokyo, Japan).

Transfection. Transfection of CV1 cells was done according to the following procedures unless otherwise noted in the text. The cells were seeded in 0.5 mL of DMEM supplemented with 10% FCS in 24-well culture plates at 5.0×10^4 cells per well the day before transfection. The cells were washed with PBS containing 0.36 mM $CaCl_2$ and 0.42 mM $MgCl_2$ [PBS(+)] and then covered with DMEM in the presence or absence of 10% FCS (1 mL). The lipoplexes containing plasmid DNA were added gently to the cells and incubated for 4 h at 37 °C. Then, the cells were rinsed with PBS(+), covered with DMEM containing 10% FCS, and incubated at 37 °C. After 40 h, the cells were lysed by adding 50 μL of Luc-PGC-50 detergent (Toyo Ink, Tokyo, Japan). A 20 μL aliquot was taken from each dish and used for one luciferase assay using a kit (Toyo Ink) and a Lumat LB9507 luminometer (Berthold, Bad Wildbad, Germany). The protein content of the lysate was measured by Coomassie protein assay reagent (Pierce, IL) using bovine serum albumin as the standard.

RESULTS AND DISCUSSION

Synthesis of Dendron-Bearing Lipid with Two Octadecyl Groups. In a previous study, we developed a new type of cationic lipids consisting of two dodecyl groups and PAMAM dendron of varying generations (*9*). Transfection activity of these dendron-bearing lipids was shown to increase with increasing dendron generation, demonstrating the importance of the head moiety of the dendron-bearing lipids. To elucidate the effect of the hydrophobic tail moiety of the lipids, a PAMAM G3 dendron-bearing lipid with two octadecyl chains DL-G3-2C_{18} was designed in this study (Figure 1). This lipid was synthesized through repetition of exhaustive Michael addition with methyl acrylate using dioctadecylamine as the core material and subsequent exhaustive amidation with ethylenediamine, as reported by Tomalia et al. (*10*−*12*). Characterization using ^{1}H NMR showed good correspondence between the theoretically expected and experimentally obtained values for the synthesized products, as shown in the Experimental Section.

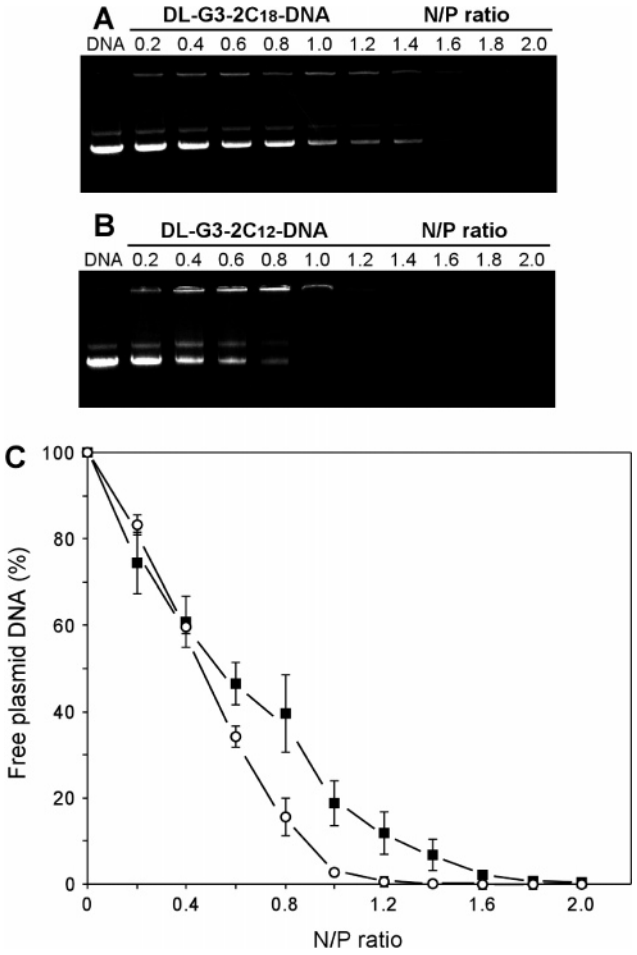

Figure 2. Agarose gel electrophoretic analysis for complexation of DL-G3-2C_{18} (A) and DL-G3-2C_{12} (B) with plasmid DNA at varying N/P ratios. Percent of free plasmid DNA was evaluated and plotted against N/P ratio (C) for complexation of DL-G3-2C_{18} (■) and DL-G3-2C_{12} (○) with plasmid DNA. Each point represents the mean ± SD ($n = 3$).

Lipoplex Formation with Plasmid DNA. The ability of the dendron-bearing lipid to form a lipoplex with plasmid DNA was investigated using gel retardation assay. The plasmid DNA (1 μg) was incubated with varying amounts of DL-G3-2C_{18} or DL-G3-2C_{12} for 30 min and electrophoresed on an agarose gel. Figure 2 shows that the amount of free plasmid DNA decreased with increasing N/P ratio, indicating that these lipids can form a lipoplex with plasmid DNA. In the case of DL-G3-2C_{18}, migration of plasmid DNA band was not observed for N/P ratios greater than 1.6 (Figure 2A), whereas migration of plasmid DNA was inhibited at N/P ratios greater than 1.0 for DL-G3-2C_{12} (Figure 2B). This result indicates that DL-G3-2C_{12} can form a lipoplex with plasmid DNA more efficiently than DL-G3-2C_{18}, even though their abilities of lipoplex formation are not markedly different. Their complex formation is driven by electrostatic interaction between the dendron moiety and DNA. Therefore, the difference of alkyl chains of these dendron-bearing lipids might only slightly affect their lipoplex formation.

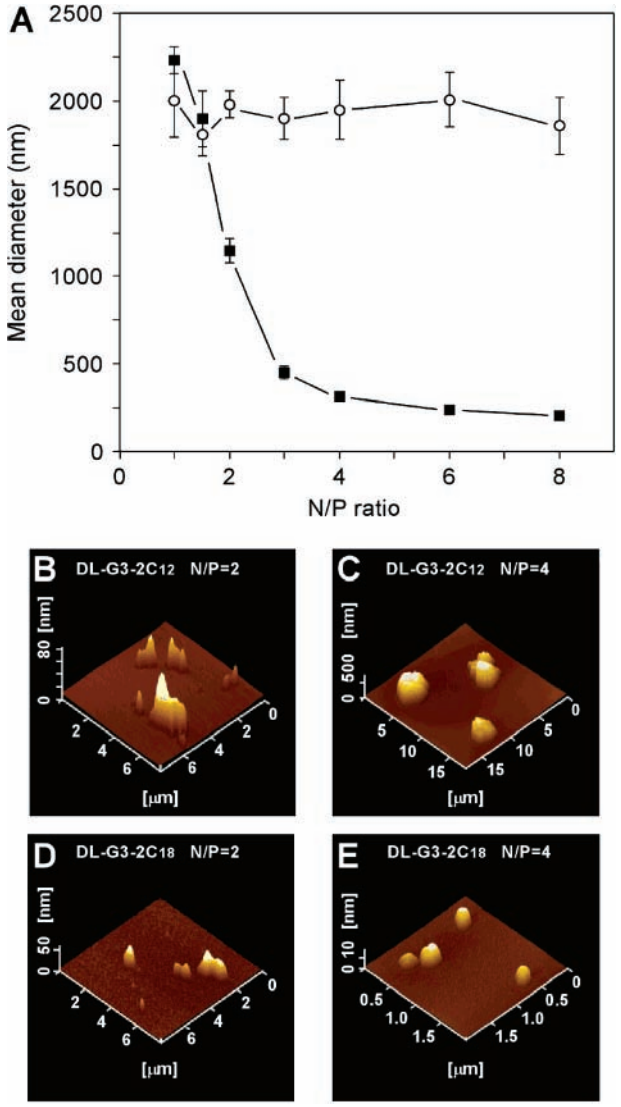

Figure 3. (A) Mean diameters of DL-G3-2C_{18} (■) and DL-G3-2C_{12} lipoplexes (○) as a function of N/P ratio. Mean diameters were estimated using DLS. Each point represents the mean ± SD (n = 3). AFM images of DL-G3-2C_{12} lipoplexes with N/P ratios of 2 (B) and 4 (C), and DL-G3-2C_{18} lipoplexes with N/P ratios of 2 (D) and 4 (E).

Particle Size and Morphology of Lipoplexes. Influence of the alkyl chain length of the dendron-bearing lipids on their lipoplex size was investigated using DLS. Figure 3A shows that the DL-G3-2C_{12} lipoplexes showed roughly the same diameter of about 2 μm, irrespective of the N/P ratio. In contrast, particle sizes of the DL-G3-2C_{18} lipoplexes depended greatly on the N/P ratio. Large particles of about 2 μm were observed at the N/P ratio of 1.0, but the lipoplex size decreased sharply with an increasing N/P ratio from 1 to 4 and became constant around 250 nm.

The lipoplexes particles were further characterized using AFM. Figure 3B,C shows that large particles with a diameter greater than 2 μm were observed for DL-G3-2C_{12} lipoplexes with N/P ratios of 2 and 4. These particles have irregular shapes and rough surfaces. Therefore, it seems that they might be formed by aggregation of smaller particles of the lipid−DNA complexes. Particles with similar morphology and diameter of ca. 1 μm were visible in the AFM image of the DL-G3-2C_{18} lipoplexes with the N/P ratio of 2 (Figure 3D). However, in the image of the DL-G3-2C_{18} lipoplexes with the N/P ratio of 4, spherical particles with 200−300 nm diameter were observed (Figure 3E). These sizes of lipoplexes, which were observed by AFM, were consistent with the DLS results (Figure 3A).

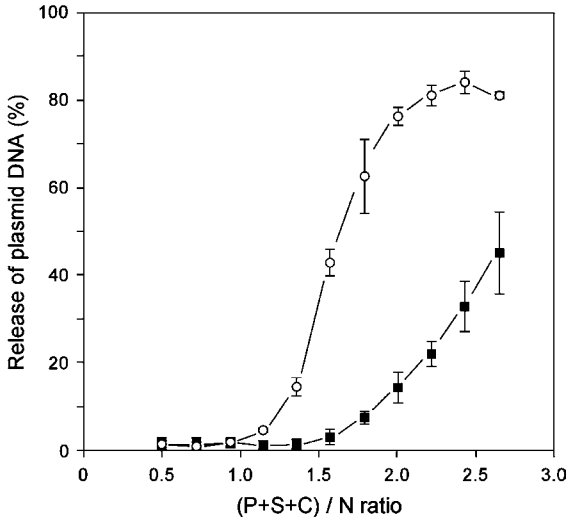

Figure 4. Release of plasmid DNA from DL-G3-2C_{18} (■) and DL-G3-2C_{12} (○) lipoplexes induced by the addition of heparin. Percent release of DNA was determined by agarose gel electrophoresis of DL-G3 lipoplexes with N/P ratio of 2 in the presence of varying amounts of heparin, and plotted against the charge ratio of phosphate (P) groups of DNA and sulfonate (S) and carboxylate (C) groups of heparin to primary amine groups (N) of dendron-bearing lipid. Each point represents the mean ± SD (n = 3).

Charge-neutralized lipoplexes with an N/P ratio around 1 are well-known to tend to form large aggregates because of their hydrophobic interaction (*13*). Therefore, both dendron-bearing lipids might form large lipoplexes at N/P ratio of 2, at which ratio their charge density was low. In contrast, at the N/P ratio of 4, the lipoplexes might possess sufficient net charge to suppress aggregation of small lipoplexes. In fact, we observed small particles with a diameter of 200−300 nm for the DL-G3-2C_{18} lipoplex. However, much larger particles appeared for the DL-G3-2C_{12} lipoplex with the N/P ratio of 4, although both lipoplexes possess the same charge density. Because of strong hydrophobic interaction of the long alkyl chains, the DL-G3-2C_{18} lipoplex particles might have a tightly packed interior and a positively charged surface, prohibiting aggregation and fusion of lipoplexes. However, because the DL-G3-2C_{12} has shorter alkyl chains, its lipoplex particles might be less stabilized than the DL-G3-2C_{18} lipoplex. Such low stability of the lipoplex particles might induce their aggregation and fusion, thereby generating larger particles.

Estimation of Lipoplex Stability. Some polyanions, such as heparin, are known to induce dissociation of DNA from lipoplexes by binding to cationic lipids of lipoplexes through electrostatic interaction (*14*, *15*). These polyanions have been used to estimate the lipoplexes' stability (*16*). Therefore, we examined the effect of addition of heparin on dissociation of plasmid DNA from the DL-G3-2C_{18} and DL-G3-2C_{12} lipoplexes to evaluate their stability. Lipoplexes with an N/P ratio of 2 were incubated for 30 min with various amounts of heparin; the amount of the liberated plasmid DNA was estimated using agarose gel electrophoresis.

Figure 4 shows the percentage of plasmid DNA released from the lipoplexes as a function of the charge balance of the lipoplex and added heparin, which is expressed as the ratio of negative charges of phosphate of DNA and sulfate and carboxylate of heparin and positive charges of primary amines of the dendron-bearing lipid [(P + S + C)/N]. The negative charges of heparin were calculated by assuming the structure of heparin as repeats of (1 → 4)-O-(α-L-idopyranosyluronic acid 2-sulfate)-(1→ 4)-(2-deoxyl-2-sulfamino-α-D-glucopyranosyl 6-sulfate) (*17*, *18*). Figure 4 shows that release of plasmid DNA from the DL-G3-2C_{12} lipoplex occurred at −/+ charge ratios greater than 1.15,

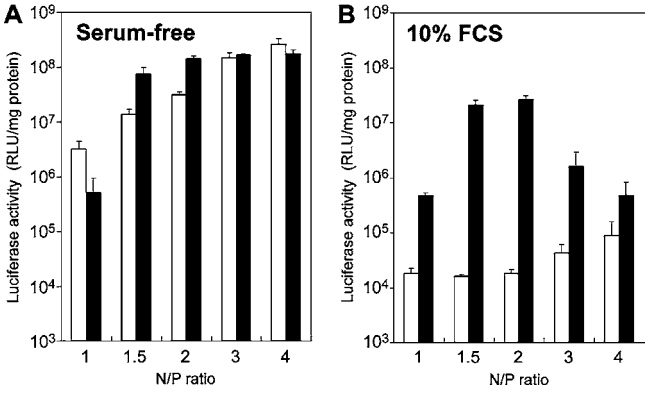

Figure 5. Luciferase activities of CV1 cells treated with DL-G3-2C_{12} lipoplexes (open bars) and DL-G3-2C_{18} lipoplexes (closed bars) in the absence (A) and presence (B) of 10% FCS. Each bar represents the mean ± SD (n = 3).

whereas the release of plasmid DNA was observed at −/+ charge ratios greater than 1.58 for the DL-G3-2C_{18} lipoplex, which indicates that 1.7 times more heparin was necessary to dissociate plasmid DNA from the DL-G3-2C_{18} lipoplexes than in the case of the DL-G3-2C_{12} lipoplex with the same N/P ratio. This result indicates clearly that hydrophobic interaction between the longer alkyl chains of DL-G3-2C_{18} increases the stability of the complex formed with plasmid DNA.

Transfection Activity of Dendron-Bearing Lipid-DNA Lipoplexes. Finally, we investigated the influence of the alkyl chain length of dendron-bearing lipids on their transfection activity. The transfection activity of lipoplexes varies depending on their N/P ratio (*19*). For that reason, we prepared lipoplexes consisting of the dendron-bearing lipid, DL-G3-2C_{12} or DL-G3-2C_{18}, and plasmid DNA containing luciferase gene at various N/P ratios and examined transfection of CV1 cells using these lipoplexes.

Figure 5A represents the expression of luciferase in the cells treated with these lipoplexes in the absence of serum. The transfection activity of these lipoplexes increased with increasing N/P ratio from 1 to 2 and reached an approximately constant level at N/P ratios greater than 2. Although the DL-G3-2C_{18} lipoplexes with the low N/P ratios seem to have a slightly higher activity than DL-G3-2C_{12} lipoplexes with the same N/P ratios, both lipoplexes exhibited similarly high transfection activities at higher N/P ratios.

However, marked differences were apparent when the transfection was performed in the presence of serum. Figure 5B shows that the DL-G3-2C_{12} lipoplexes with N/P ratios of 1−4 did not induce expression of luciferase in CV1 cells in the presence of FCS. In contrast, the DL-G3-2C_{18} lipoplexes caused transfection of CV1 cells efficiently. Especially, DL-G3-2C_{18} lipoplexes with N/P ratios of 1.5 and 2 induced a high level of luciferase expression, which is comparable to the level of transfection in the absence of serum (Figure 5A). In addition, we observed that viability of cells treated with the DL-G3-2C_{18} lipoplexes was about 100% under the experimental conditions, indicating that these lipoplexes were able to achieve efficient transfection without cellular damage (see Supporting Information).

Many studies have indicated that the transfection activity of lipoplexes is reduced dramatically in the presence of serum (*20*−*23*). As shown in Figure 5B, the DL-G3-2C_{12} lipoplexes also abolished their transfection activity in the presence of serum. It is likely that the DL-G3-2C_{12} lipoplexes are decomposed through strong interaction with serum proteins because these lipoplexes might be stabilized weakly by short alkyl chains. In contrast, the DL-G3-2C_{18} lipoplexes retained high transfection activity even in the presence of serum. Hydrophobic interaction of the long alkyl chains of DL-G3-2C_{18} might greatly improve the stability of the lipoplexes and impart a high serum-resistant property to them. In fact, we observed better stability of the DL-G3-2C_{18} lipoplex against interaction with heparin than that of the DL-G3-2C_{12} lipoplex (Figure 4). These results indicate the importance of hydrophobic tail moieties of the dendron-bearing lipid for retention of their high transfection activity in the presence of serum.

In conclusion, we demonstrated the importance of the hydrophobic tail moieties of dendron-bearing lipids for their lipoplex formation with plasmid DNA and their transfection activity. The newly synthesized dendron-bearing lipid DL-G3-2C_{18} produced highly potent, small lipoplexes with high transfection activity in the presence of serum. In a previous study, we showed that addition of dioleoylphosphatidylethanolamine, which increases fusion ability of lipoplexes, enhanced the transfection activity of the DL-G3-2C_{12} lipoplexes (*9*, *16*). Therefore, inclusion of this fusogenic lipid might further elevate transfection activity of the DL-G3-2C_{18} lipoplexes. For that reason, the DL-G3-2C_{18} might be a promising gene vector. We are currently examining the influence of addition of dioleoylphosphatidylethanolamine on transfection activity of the DL-G3-2C_{18} lipoplexes.

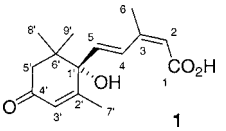
Function and Stability of Abscisic Acid Acyl Hydrazone Conjugates by LC-MS^2 of ex Vivo Samples

Timothy R. Smith,[†] Andrew J. Clark,[†] Richard Napier,[‡] Paul C. Taylor,[†] Andrew J. Thompson,[‡] and Andrew Marsh*[,†]

Department of Chemistry, University of Warwick, Coventry CV4 7AL, U.K., Warwick HRI, University of Warwick, Wellesbourne, Warwick, CV35 9EF, U.K. Received February 28, 2007; Revised Manuscript Received May 1, 2007



We prepare a biotinylated conjugate of the ubiquitous plant hormone (*S*)-(+)-abscisic acid via an acyl hydrazone linkage at the C4′ position and demonstrate in vivo cleavage of the otherwise stable acyl hydrazone linkage using LC-MS^2. As part of a wider chemical genomic study, biological activity of the conjugate was assessed using standard epidermal peel and gravimetric transpiration assays, showing significant activity but at a level lower than the unconjugated hormone. When deuterated samples of the conjugate were fed to the plant, however, it was apparent by LC-MS^2 experiments that significant levels of hydrolysis of the acyl hydrazone had taken place, contrary to in vitro stability assays in artificial sap. We conclude that abscisic acid is liberated in sufficient quantities to account for the observed physiological response and that LC-MS^2 monitoring of conjugates is a simple and practical method by which such events may be assessed, whether in plants or other organisms.

INTRODUCTION

The search for the biological targets of the ubiquitous plant hormone abscisic acid (ABA[1]) **1** (Figure 1) (*1*) has produced many sophisticated strategies for the preparation of analogues and conjugates (*2*). One favored tactic has been the use of bioconjugates such as 4′-hydrazones **2**−**5** (Figure 2) in order to identify anti-idiotypic monoclonal antibodies (*3*), to provide *in vivo* fluorophore reagents (*4*), and as ligands in affinity chromatography (*5*). Each relies on the bioconjugate or derived protein exhibiting demonstrable activity in order to be relevant to the process under investigation. An example of the bioconjugate strategy working well is the use of novel aromatic annelated abscisic acid derivatives (*6*) in order to identify the first (*7*) of two recently confirmed receptors (*8*). Conjugates that retain some activity but at a lower level may still offer useful material, because binding may occur, but with lower affinity. Reliable assays for both biological activity and chemical composition are hence critical components in the design of successful experiments using such bioconjugates. In this Technical Note, we demonstrate the use of LC-MS^2 on *in vitro* and *ex vivo* samples in conjunction with biological assays to determine the stability and biological activity of an acyl hydrazone conjugate of ABA. Significantly, we show that *in vivo* degradation of the conjugate released low levels of ABA that were sufficient to explain the apparent activity of our conjugate.

EXPERIMENTAL PROCEDURES

General Experimental. Unless otherwise noted, all materials were obtained from commercial sources and used without further purification. *S*-(+)-Abscisic acid (98%: purity confirmed by microanalysis) was purchased from Sichuan Lomon Bio Corporation, Chengdu Sichuan, China. Column chromatography was performed on Merck silica gel 60 H (230−400 mesh). Melting points were recorded on a Gallenkamp melting point apparatus and are uncorrected. Optical rotations (given in 10^{-1} deg cm^2 g^{-1}) were measured on an Optical Activity AA-1000 polarimeter. IR spectra were recorded on a Perkin-Elmer Paragon 1000 FT-IR instrument. ^{1}H and ^{13}C NMR spectra were recorded using a Bruker DPX300 at 300 and 75 MHz, respectively. NMR spectra were recorded in the indicated solvent, and chemical shifts (δ) are reported in parts per million (ppm) relative to residual nondeuterated solvent as an internal standard. *J* values are given in hertz (Hz). ^{2}D NMR spectra were recorded using a Bruker DRX500 at 77 MHz. LSIMS mass spectrometry was performed on a Micromass Autospec mass spectrometer. ESI mass spectrometry was performed on a Bruker micrOTOF instrument.

Figure 1. (*S*)-(+)-Abscisic acid with formal atom numbering.

Epidermal Peel Assay. Abaxial epidermal peels from *Commelina communis* L. were incubated at 25 °C under continuous white light (30 μmol m^{-2} s^{-1}) in Petri dishes containing aqueous buffer solution (25 mL) consisting of 8 mmol dm^{-3} MES·KOH pH 6.15 and 50 mmol dm^{-3} KCl. A needle inserted through the lid of the Petri dish allowed CO_2-free air to be bubbled through the buffer solution (100 cm^3 min^{-1}). After 2 h, the stomata were fully open. Solutions of ABA or conjugate were added and incubation continued for a further 2 h. The epidermal peels were then mounted on microscope slides, and stomatal aperture was immediately recorded digitally at 500× magnification. For each treatment, mean apertures were determined from 30 measurements made from 2 independent epidermal peels. Stomatal apertures were measured across the widest part of the opening and expressed as a percentage of an untreated control.

Gravimetric Transpiration Assay. Tomato (*Solanum lycoperiscum* L. cv Ailsa Craig) plants were grown in a glass house in 10 dm^3 pots of Levington M2 compost (Levington, Ipswich, U.K.), until they had produced approximately eight leaves. The youngest fully expanded leaf was cut from the plant, and the

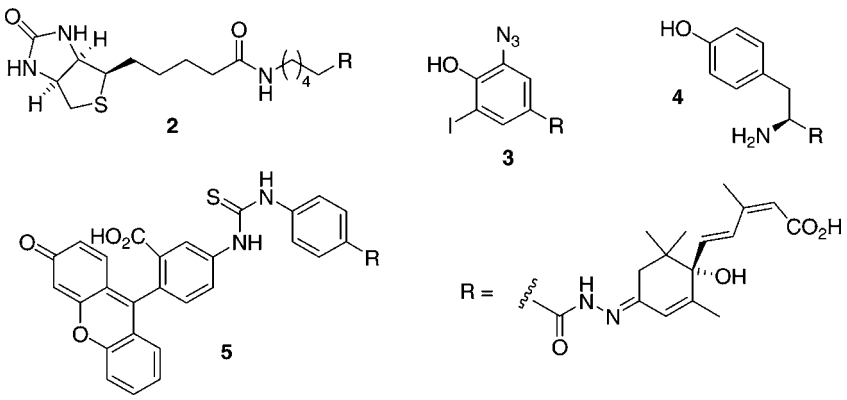

Figure 2. 4′-Acyl hydrazone conjugates of abscisic acid: biotinylated **2** (*9*), radio-iodinated **3** (*5*), tyrosyl **4** (*10*), and fluorescent **5** (*4*).

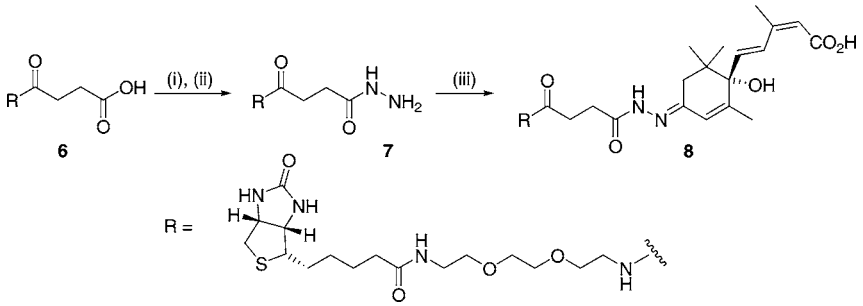
petiole was recut under degassed distilled water to avoid embolization and then immediately transferred to a 2.5 cm^3 glass vial containing 2 cm^3 of artificial sap (AS) consisting of 1.0 mmol dm^{-3} KH_2PO_4, 1.0 mmol dm^{-3} K_2HPO_4, 1.0 mmol dm^{-3} $CaCl_2$, 0.1 mmol dm^{-3} $MgSO_4$, 3.0 mmol dm^{-3} KNO_3, and 0.1 mmol dm^{-3} $MnSO_4$ (*11*). The sap was adjusted to pH 6.0 with aqueous HCl. Laboratory film was used to seal the petiole in the vial to reduce evaporation. Prepared leaf sets were randomized and placed on a laboratory bench under fluorescent lighting (37 μmol m^{-2} s^{-1}). Each vial was weighed every 20 min for 2 h to establish an untreated transpiration rate. After 30−90 min, the rate of transpiration was seen to reach a plateau. Each leaf set was then transferred to a new vial containing the same amount of AS in addition to the specified amount of either ABA or conjugate. The rate of transpiration was determined by weighing the vial every 20 min for 2 h and expressed as a percentage of the initial transpiration rate. Up to six replicates were performed for each assay at five different concentrations of ABA and conjugate.



LC-MS^2 Analysis. *Sample Preparation.* On completion of the gravimetric transpiration assay, leaves fed with the most concentrated solution of conjugate were separated from the petiole and immediately homogenized in liquid nitrogen, lyophilized, and stored at −80 °C until required. Untreated leaves were collected and processed in a similar manner but were spiked with conjugate (75 μg) prior to homogenization as a control. Leaf material (100 mg) was extracted with 1 cm^3 of water by agitation on a whirly mix for 5 min. The sample was centrifuged (2880 g, 10 min at 4 °C) and the supernatant collected and filtered through a plug of glass wool into a centrifuge filter (Vivascience Vivaspin 2, 3000 MWCO). After centrifuging (2880 g, 30 min at 4 °C), the supernatant was collected and analyzed immediately.

LC-MS^2 Procedure. ESI mass spectrometry was performed on a Bruker HCTplus ion trap instrument. Parameters were optimized by direct infusion of d_6-abscisic acid (1 mg dm^{-3}) in water (70%), acetonitrile (30%), and formic acid (0.01%). The optimized conditions were as follows: negative ion polarity, trap drive 34.7 (arbitrary units), octopole RF amplitude 193.4 Vpp, capillary exit −111.5 V, HV capillary 4.5 kV, drying gas (N_2) temperature 320 °C, drying gas flow 9 dm^3 min^{-1}, and nebulizer 30 psi. Fragmentation parameters were handled automatically by the SmartFrag function. LC separation was performed on an Alltech Alltimer C18 column (100 mm × 2 mm, 3 μm) fitted with an Alltech C18 guard column (7.5 mm × 3.0 mm, 5 μm). For each run, 20 μL of the crude plant extract was injected onto the column. The sample was eluted using a binary solvent system comprising 0.01% formic acid in water (A) and 0.01% formic acid in acetonitrile (B). Solvents were mixed and delivered to the column by an integrated HPLC pump and autosampler (Agilent 1100 series) at a flow rate of 0.2 cm^3 min^{-1}. The sample was separated by gradient elution starting at 74% A and 26% B and changed linearly over a 15 min period to 70% A and 30% B.

Preparation of *N*-Succinamidylhydrazono-*N*′-biotinyl-3,6-dioxaoctane-1,8-diamine, 7. A solution of *N*-succinamidyl-*N*′-biotinyl-3,6-dioxaoctane-1,8-diamine **6** (*12*) (173 mg, 0.36 mmol, 1 equiv) in methanol (2 mL) was added dropwise to an ice-cooled solution of thionyl chloride (131 mg, 1.1 mmol, 3 equiv) in methanol (2 mL). The reaction was allowed to warm to room temperature and stirred for 24 h. The solvent was removed under reduced pressure before addition of a further portion of methanol (15 mL). This was removed once more under reduced pressure to yield a brown residue, which was dissolved in methanol (4 mL) and treated with hydrazine monohydrate (183 mg, 3.6 mmol, 10 equiv). The mixture was stirred at room temperature for 24 h, filtered, and then concentrated under reduced pressure. The crude product was purified by column chromatography (silica, 30% MeOH, and 3% concentrated aqueous ammonia solution in EtOAc) to yield a pale yellow solid (100 mg, 56%); R_f 0.10 (30% MeOH and 3% concentrated aqueous ammonia solution in EtOAc); mp 135−138 °C (EtOAc); $[\alpha]^{20}_D$ = +12.3 (*c* 0.65, DMSO); υ_{max}(solid) 3285, 2924, 1698, 1637, 1550, 1461, 1120 cm^{-1}; δ_H (300 MHz, DMSO-d_6) 1.22−1.37 (m, 2H), 1.40−1.69 (m, 4H), 2.06 (t, J = 7.4, 2H), 2.22−2.24 (m, 2H), 2.28−2.31 (m, 2H), 2.57 (d, J = 12.2, 1H), 2.82 (dd, J = 5.1, 12.2, 1H), 3.08−3.10 (m, 1H), 3.17−3.18 (m, 4H), 3.36−3.38 (m, 4H), 3.50 (s, 4H), 3.98 (s, 2H), 4.10−4.14 (m, 1H), 4.28−4.33 (m, 1H), 6.37 (s, 1H), 6.44 (s, 1H), 7.86 (t, J = 5.5, 1H), 7.92 (t, J = 5.3, 1H), 8.96 (s, 1H); δ_C (75 MHz, DMSO-d_6) 25.6 (CH_2), 28.6 (2 × CH_2), 29.3 (CH_2), 31.0 (CH_2), 35.4 (CH_2), 39.0 (2 × CH_2), 40.7 (CH_2), 55.7 (CH), 59.5 (CH), 61.4 (CH), 69.5 (2 × CH_2), 69.9 (2 × CH_2), 163.1 (C), 171.2 (C), 171.6 (C), 172.5 (C); HRMS (ESI): *m*/*z* requires ($C_{20}H_{37}N_6O_6S$) 489.2490, found 489.2489, 57% $[M + H]^+$.

Preparation of *S*-(+)-Abscisic acid 4′-(*N*-Succinamidyl acyl hydrazide-*N*′-biotinyl-3,6-dioxaoctane-1,8 diamine), 8. *N*-Succinamidylhydrazono-*N*′-biotinyl-3,6-dioxaoctane-1,8-diamine, **7**, (190 mg, 0.39 mmol, 1 equiv) and *S*-(+)-abscisic acid (206 mg, 0.78 mmol, 2 equiv) were dissolved in methanol (10 mL). Glacial acetic acid (50 μL) and crushed 4 Å molecular sieves (100 mg) were added and the reaction stirred in darkness at room temperature under a nitrogen atmosphere for 4 days. The mixture was filtered through Celite and the solvent removed under reduced pressure. The product was purified by preparative thin-layer chromatography (silica, 15% MeOH in DCM) to yield a pale yellow solid (177 mg, 62%); R_f 0.15 (15% MeOH in DCM); $[\alpha]^{20}_D$ = +267.2 (*c* 0.25, MeOH); υ_{max}(solid) 3266, 2929, 1653, 1546, 1400, 1119, 1026 cm^{-1}; δ_H (300 MHz, CD_3-OD) 1.06 (s, 3H), 1.09 (s, 3H), 1.40−1.56 (m, 2H), 1.58−1.83 (m, 4H), 1.87 (s, 3H), 2.06 (s, 3H), 2.26 (t, J = 7.4, 2H), 2.47−

Scheme 1. Preparation of Biotinylated Acyl Hydrazone-Linked Abscisic Acid[a]

[a] Reagents and conditions: (i) $SOCl_2$, MeOH, then (ii) hydrazine, MeOH, 56%, (iii) (*S*)-(+)-abscisic acid, AcOH, MeOH, 62%.

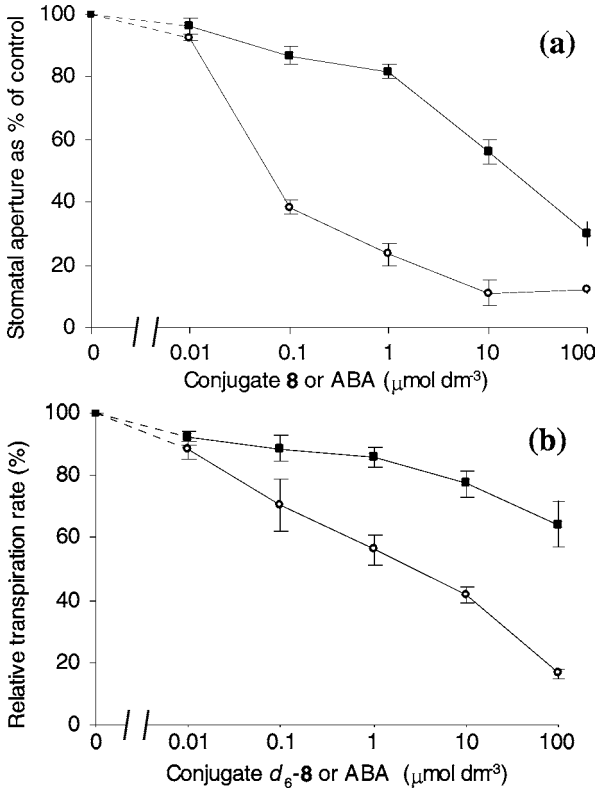


Figure 3. (a) The biological activity of conjugate **8** (■) compared to (*S*)-(+)-abscisic acid (○) in the stomatal closure of epidermal peels. Results are displayed as a percentage of the control with fully open stomata at 100%. Error bars indicate SE of means ($n = 10$). (b) The effect of feeding detached tomato leaves with AS containing conjugate d_6-**8** (■) or (*S*)-(+)-abscisic acid (○) on gravimetric transpiration. Results are displayed as a percentage of the transpiration rate of leaves that received AS alone. Error bars indicate SE of means ($n = 3$).

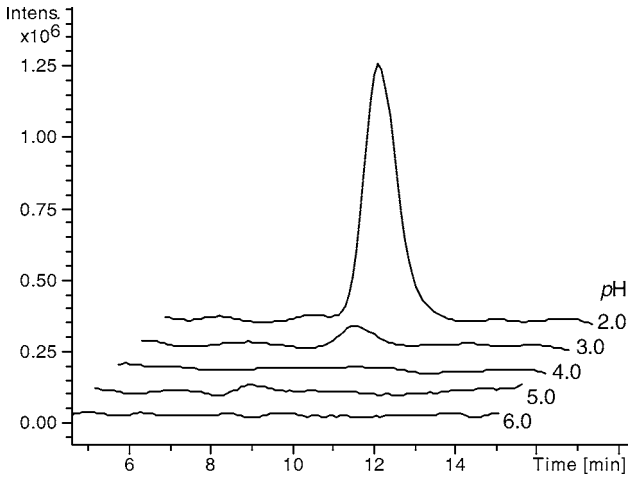

Figure 4. A 100 μmol dm^{-3} solution of d_6-**8** in artificial sap was acidified with HCl (aq) to a specific pH. The mixture was allowed to stand for 2 h, then immediately analyzed using LC-MS^2. Hydrolysis of d_6-**8** releases d_6-abscisic acid indicated by a peak at RT = 9.83 min. Chromatograms are offset.

Preparation of *S*-(+)-d_6-Abscisic acid 4′-(*N*-Succinamidyl acyl hydrazide-*N*′-biotinyl-3,6-dioxaoctane-1,8 diamine), d_6-8. *S*-(+)-d_6-Abscisic acid, prepared from two successive rounds of deuterium exchange (*13*), was reacted with *N*-succinamidyl-hydrazono-*N*′-biotinyl-3,6-dioxaoctane-1,8-diamine **7**, in an identical manner to the preparation of **8**, yielding the title product (154 mg, 53%) as a pale yellow solid; $[\alpha]^{20}_D = +272.0$ (*c* 0.30, MeOH); υ_{max}(solid) 3282, 2933, 1655, 1534, 1458, 1127, 1026 cm^{-1}; δ_H (300 MHz, CD_3OD) 1.01 (s, 3H), 1.05 (s, 3H), 1.42−1.47 (m, 2H), 1.54−1.76 (m, 4H), 1.97 (s, 3H), 2.22 (t, $J = 7.6$, 2H), 2.58 (d, $J = 5.4$, 2H), 2.63 (d, $J = 5.4$, 2H), 2.70 (d, $J = 12.8$, 1H), 2.88 (dd, $J = 5.0$, 12.8, 1H), 3.17−3.23 (m, 1H), 3.36−3.38 (m, 4H), 3.54−3.56 (m, 4H), 3.63 (s, 4H), 4.29−4.32 (m, 1H), 4.48−4.51 (m, 1H), 5.75 (s, 1H), 6.05 (d, $J = 16.0$, 1H), 7.60 (d, $J = 16.0$, 1H); δ_D (77 MHz, CH_3OH) 0.88 (s, br, 3D), 1.63 (s, br, 2D), 7.71 (s, 1D); δ_C (125 MHz, CD_3OD) 19.4 (CH_3), 22.9 (CH_3), 23.6 (CH_3), 26.5 (CH_2), 28.5 (CH_2), 28.8 (CH_2), 29.7 (CH_2), 30.9 (CH_2), 36.0 (CH_2), 38.9 (C), 39.1 (CH_2), 39.3 (CH_2), 40.1 (CH_2), 56.0 (CH), 60.6 (CH), 62.4 (CH), 69.60 (CH_2), 69.63 (CH_2), 70.31 (CH_2), 70.34 (CH_2), 79.3 (C), 122.0 (CH), 128.4 (CH), 136.4 (CH), 146.4 (C), 150.0 (C), 154.4 (C), 165.1 (C), 170.7 (C), 170.8 (C), 173.7 (C), 175.2 (C); HRMS (ESI): *m*/*z* requires ($C_{35}H_{48}N_6O_9SD_6Na$) 763.3942, found 763.3957, 100% $[M + Na]^+$.

RESULTS AND DISCUSSION

Acyl hydrazones including **2**−**5** have been previously reported (*4*, *5*, *9*, *10*) and used in bioassays; hence, as part of a chemical genomic study on the action of abscisic acid requiring well-defined conjugates, related acyl hydrazone **8** was prepared (Scheme 1). A flexible and hydrophilic linker derived from 2-(2-(2-aminoethoxy)ethoxy)ethanamine was used for conjugating D-biotin to *S*-(+)-abscisic acid. Biotin hydrazide **7** was prepared from previously reported acid **6** (*12*) and then coupled to commercial *S*-(+)-abscisic acid, yielding **8** through a modifica-

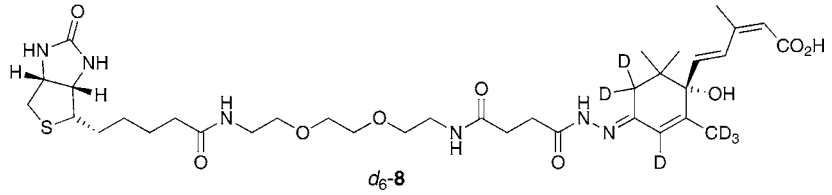

Figure 5. Deuterated ABA conjugate d_6-**8**.

tion of the method reported by Kohler et al. (*5*). Biological activity of this conjugate was observed in a stomatal aperture assay (Figure 3) and shows similar levels of activity to the biotinylated abscisic acid conjugate **2** reported by Yamazaki et al. (*9*). Conflicting reports concerning the stability of acyl hydrazones to hydrolysis led us to assay the purity of our new hydrazone by LC-MS before and after *in vitro* storage under a variety of conditions including in artificial sap (AS) (*11*) at a range of pH values (Figure 4), in addition to the usual methods used to confirm identity (see Experimental Section).

This data clearly showed that the acyl hydrazone was stable in acidic medium at pH ≥ 4.0, thus validating its use in the relatively less acidic *in vivo* plant environment but in line with a general acid-catalyzed hydrolysis mechanism, decomposed at pH ≤ 3.0. It has been proposed that acyl hydrazone conjugates of abscisic acid may hydrolyze *in vivo* (*14*), but this hypothesis has not been fully tested, so we extended this work to the study of their stabilities *in vivo* using a modification of the LC-MS^2 technique described by Gómez-Cadenas and co-workers (*15*). The detection of ABA in plant extracts by LC-MS^2 has been rigorously studied (*16*−*18*) and provides a rapid means of assessing whether *in vivo* hydrolysis has taken place. The labeled conjugate d_6-**8** (Figure 5) was prepared analogously to **8** using d_6-ABA, which allows the conjugated ABA to be distinguished from endogenous ABA in the plant. We were able to enrich the total deuterium content of our d_6-ABA to about 94% (determined by ^{1}H NMR) by submitting *S*-(+)-ABA to two successive rounds of deuterium exchange as described by Hirai and co-workers (*13*). The same authors demonstrated that the deuterium labels in this d_6-ABA were sufficiently stable for use as an internal standard for quantitative analysis. The deuterium content of conjugate d_6-**8** was similarly assessed and estimated at 92%. If *in vivo* hydrolysis of the deuterated biotinylated conjugate d_6-**8** occurs, then free abscisic acid would be released, indicating an apparent biological activity erroneously attributed to the conjugate. In the absence of *in vivo* hydrolysis, it is reasonable to assume that the intact conjugate is active.

ABA and the deuterated conjugate d_6-**8** was fed to detached tomato leaves in a solution of AS. The rate of uptake of the AS was determined gravimetrically and compared to the rate of untreated leaves. Since ABA and our nondeuterated conjugate reduce transpiration by effecting stomatal closure, the rate of AS uptake was, as expected, reduced (Figure 3).

The tomato leaves treated with d_6-**8** were homogenized, lyophilized, extracted with water, and immediately submitted to LC-MS^2 analysis. Although extraction of abscisic acid using water has been validated in previous work (*15*), it should be noted that these conditions may not be optimal for isolation of conjugate d_6-**8**. Spectrometric analysis of the extract was performed in negative-mode ESI to detect the well-characterized (*15*, *18*) fragmentation pattern of abscisic acid (263−153 Da) and our d_6-abscisic acid (269−159 Da). Multiple reaction monitoring (MRM) of the fragmentation to secondary ion peaks together with comparison of retention times of known samples provides unequivocal confirmation of the presence of these compounds. The ESI mass spectrometry parameters were optimized for d_6-abscisic acid by direct infusion of pure samples; however, a low level of d_6-**8** could also be detected. A pure sample of d_6-**8** gave fragments from 739 Da, $[M]^-$ to 455 and 409 Da. The exact nature of the latter fragment is unknown, but the 455 Da species is consistent with the elemental composition $C_{20}H_{31}N_4O_6S$, which we postulate to be the deprotonated ion of the structure shown in Figure 6. This fragment was the most intense, so we chose to monitor the 739−455 Da fragmentation as part of our MRM settings.

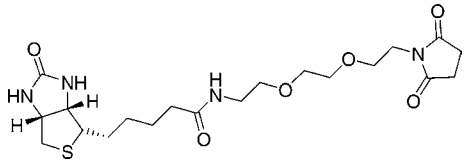

Figure 6.

The results (Figure 7) show the presence of a large peak representing endogenous abscisic acid and a small peak for the conjugate d_6-**8**. Crucially, d_6-abscisic acid was also detected with a peak area of about 15% of the endogenous abscisic acid (we found that d_6-abscisic acid and its fragments have similar ion intensity to those of nondeuterated abscisic acid, allowing comparison of these two peak areas). This result was observed in two biological replicates. A control experiment was performed to ensure that hydrolysis of d_6-**8** had not occurred in sample preparation or during the LC-MS^2 run. Plant cuttings were fed untreated AS, then prior to homogenization were spiked with d_6-**8**. After processing these cuttings in the manner described above, the plant extract was analyzed by LC-MS^2. Only endogenous abscisic acid and d_6-**8** were detected (data not shown), showing that decomposition of d_6-**8** had indeed occurred inside the living plant.

We conclude that the hydrolysis of acyl hydrazone conjugates takes place in living plant tissue at a rate sufficient to account for observed biological activity, although the mechanism and site of decomposition are presently unknown. The data support earlier reports of the inactivity of 4′-carbonyl conjugates (*14*, *19*). The exogenous ABA from the hydrolysis of d_6-**8** will be rapidly metabolized, making an accurate quantitative analysis

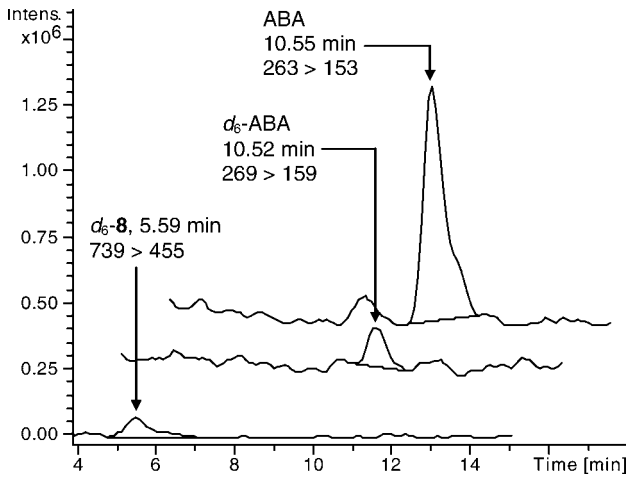

Figure 7. LC-MS^2 chromatograms of a plant extract from tomato leaves fed with conjugate d_6-**8** (100 μmol dm^{-3}) showing endogenous ABA (10.55 min), d_6-abscisic acid (10.52 min), and d_6-**8** (5.59 min). Chromatograms are offset.

of the extent of hydrolysis problematic. Quantification of deuterated ABA catabolites phaseic acid, dihydrophaseic acid, and abscisic acid glucose ester would need to be incorporated into any final quantitative analysis. Exogenous ABA is also likely to trigger increased biosynthesis and metabolism of endogenous ABA (*20*). In summary, knowledge of the *in vivo* stability of bioconjugates is important to the assessment of bioactivity: LC-MS^2 is widely available and ideally suited to such evaluations.

ACKNOWLEDGMENT

We thank the BBSRC for a BMS Committee Studentship (T.R.S.), and thank Dr. A. J. Clarke, Mr. J. C. Bickerton for technical assistance with NMR, mass spectrometry, respectively, and Dr. C. Corre for assistance with LC-MS experiments. We thank the reviewers for helpful comments.

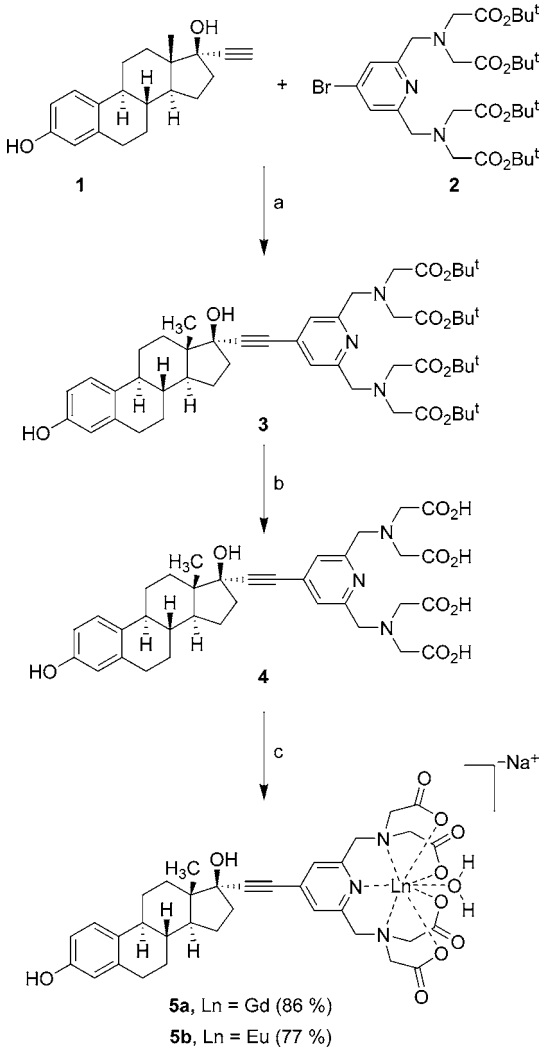
Novel estrogen-conjugated pyridine-containing Gd(III) and Eu(III) contrast agents (EPTA-Gd/Eu) were designed and effectively synthesized. Convenient to administration and MRI experiments, both EPTA-Gd and EPTA-Eu are soluble in water. The EPTA-Gd selectively binds with a micromolar affinity to the estrogen receptor and induces proliferation of human breast cancer cells. The EPTA-Gd is not lethal and does not cause any adverse effects when administrated intravenously. It enhances T_1 and T_2 nuclear relaxation rates of water and serves as a selective contrast agent for localizing the estrogen receptor by MRI.



Targeting the delivery of hormones and drugs with a specific molecular recognition site and simultaneously monitoring their distribution and localization in the body is an important goal in pharmacology and medicinal chemistry, as well as in diagnostic molecular imaging. One such example (*1*) is targeting organs and tissues responsive to estrogen using a selective estrogen receptor modulator (SERM) that can be monitored *in vivo*. Estrogens are steroids that function as the primary sex hormones in females, regulating an assortment of activity in the female reproductive organs and the development and function of the mammary gland. 17β-Estradiol (E2), estriol, and estrone are the three naturally occurring estrogens, with the former being the most potent one. Estrogens enter freely the cells and bind with a very high affinity to nuclear estrogen receptors (ERs), α or β, which act as potent transcription factors regulating many cellular functions (*2*, *3*). The interaction of estrogen with its receptor also elicits ER degradation responsible for its cyclic activity (*2*). In breast cancer, specifically, evaluation of the ER level is a major and well-established tool for assessment of prognosis and for predicting response to endocrine therapy with antiestrogens such as tamoxifen (*4*, *5*). The levels of ERα in human breast cancer biopsies span a broad range reaching 1000 fmol/mg cytosol protein (*6*). However, the current clinical methods for determining ERα are semiquantitative and suffer from technical difficulties and analytical variations which may lead to inconsistent results (*7*). Furthermore, these techniques measure the level in a small fraction of the tumor, which may not reflect the actual distribution in the entire tumor.

Previous attempts to image ER *in vivo* were based on using positron emission tomography or single-photon emission computed tomography of $_{18}$F- or $_{123}$I-labeled ER ligands, respectively

Scheme 1. Synthesis of EPTA and EPTA−Lanthanide Complexes[a]

[a] Conditions: (a) *trans*-$PdCl_2(PPh_3)_2$, CuI, dry $^iPr_2NH$/THF, rt, 60 h, 89%. (b) CF_3CO_2H, rt, 3 h, 92%; (c) (i) pH 5−7, $GdCl_3{\cdot}3H_2O$, rt, 3 h, 86%; (ii) pH 5−7, $EuCl_3{\cdot}6H_2O$, rt, 3 h, 77%.

(*8*−*10*). Although the high-spin gadolinium(III) ion is extremely toxic for living cells, when complexed with suitable chelates it provides useful agents, for magnetic resonance imaging (MRI) (*11*, *12*). Potential target-directed contrast agents developed recently increase the scope of MRI experiments (*13*−*15*). We envision a novel method to detect ER in cancer patients using MRI by a new contrast agent derived from E2. As reported, upon introduction of bulky substituents at the 17α position of E2, a high affinity to ER was retained (*16*−*18*). Herein, we delineate the synthesis of a novel water-soluble, MRI contrast agent integrated SERM which binds to the estrogen receptor with high affinity and induces hormonal activity as well as contrast enhancement in human breast cancer cells.

The Pd-catalyzed reaction of 17α-ethynyl estradiol (**1**) with compound **2** (*19*, *20*) yielded E2-embedded pyridine tetracarboxylate **3**, which on ester deprotection provided the desired ligand, [estradiol-17α-ylethynyl(pyridin-2,6-diyl)bis(methylenenitrilo)] tetrakis(aceticacid) EPTA) **4** (Scheme 1). Complexation of **4** with hydrated $GdCl_3$ resulted in the formation of gadolinium chelate **5a**, EPTA-Gd, in 86% yield. The structure of EPTA-Gd was confirmed by HR/MS, ES/MS, IR, magnetic moment, and XPS studies (*21*). EPTA-Gd displays paramagnetic properties without any hysteresis phenomenon. The Curie constant *C* and effective magnetic moment *p* (for instance, for AC frequency $f = 74$ Hz and temperature $2\ K < T < 22\ K$, $C = 6.93(1)$ emu*K/mol and $p = 7.44\ \mu_B$/molecule; for DC ($2\ K < T < 300\ K$) FC, $C = 6.640(4)$ emu/mol*K and $p = 7.29\ \mu_B$/molecule) were well in accordance with the literature values (*22*). Complexation of **4** with $EuCl_3{\cdot}6H_2O$ provided EPTA-Eu **5b** in 77% yield (*21*).

Table 1. ERα Competitive Binding Affinities of EPTA and EPTA-Gd with 17β-Estradiol and Relaxivities (*24*) of EPTA-Gd[a]

compound	K_i, μM	r_1 (mM·s)$^{-1}$	r_2 (mM·s)$^{-1}$
EPTA (**4**)	0.40 ± 0.13	-	-
EPTA-Gd (**5a**)	0.97 ± 0.07	6.8 ± 0.05	25 ± 1.0

[a] K_i values were calculated using a dissociation constant for 17α-estradiol binding to ERα of 0.2 nM.

Binding affinities of EPTA **4** and EPTA-Gd **5a** to ER were determined by performing competitive radiometric binding assays using tritiated 17β-estradiol and human recombinant ER. Table 1 summarizes the values obtained for the competition constant, K_i (defined as the equilibrium concentration of the competing ligand that binds half of the ER binding sites) of both the metal-free ligand EPTA and the EPTA-Gd. Although the affinities of both EPTA and EPTA-Gd were about 3 orders of magnitude lower than that of 17β-estradiol, their effective concentration required for ER binding was within the micromolar range (*8*, *23*). The effectiveness of EPTA-Gd as a nuclear relaxation agent was demonstrated by the measurement of water proton T_1 and T_2 relaxivities (r_1 and r_2, respectively) at 4.7 T (Table 1).

The cellular hormonal-induced activities of both EPTA and EPTA-Gd were tested in ER+ MCF7 and T47D human breast cancer cells. Time- and dose-dependent growth curves of both cell lines in the presence of EPTA and EPTA-Gd proved a stimulating growth effect similar to that of E2 (Figure 1A). This stimulation was specific to the presence of ER in the cells, as neither EPTA nor EPTA-Gd exerted an effect on the growth of ER-negative MDA-MB-231 human breast cancer cells. In addition, EPTA and EPTA-Gd, like E2, induced ER degradation in the ER+ cells in a similar manner to that of E2, albeit at a slower rate, indicating their binding to ER (Figure 1B).

The ability of EPTA-Gd to specifically bind to the nuclear ER in living cells and consequently enhance the MRI signal in a distinct manner was tested in MDA-MB-231 human breast cancer cells, engineered to express ERα under tetracycline. Cells cultivated with a medium containing tetracycline (tet on) expressed high levels of ERα (ER+), as determined by Western blots, and served to detect the enhancement due to the binding of EPTA-Gd with this receptor. The same cells treated with tetracycline-free medium (tet off) did not express ERα (ER− control cells), as determined by Western blots, and served to determine the effect of nonspecific binding of EPTA-Gd to the cells and of possible decomposition of the contrast agent inside the cells (*25*). To maintain their viability throughout the experiments, the cells were cultivated on Biosilon beads to a density of ∼40 million cells/mL beads (Figure 1C). Enhancement and T_1 measurements by means of microscopic MRI of the cells on beads in the presence and absence of EPTA-Gd (6 μM) and after washout of EPTA-Gd indicated higher enhancement and difference in T_1 relaxation rates, ΔR_1, between EPTA-Gd-treated ER+ cells and the control ER+ cells as compared to the EPTA-Gd-treated ER− cells and the ER− control cells, specifically after removal of the free and nonbound EPTA-Gd from the cell system by washing with standard medium (Figure 1D). Macroscopic enhancement and T_1 measurements of the same cell systems in wells, in the presence and after washout of EPTA-Gd (Figure 1E), confirmed the above results obtained by microscopic MRI (Figure 1F). Although one expects a null ΔR_1 between EPTA-Gd-treated ER− cells and ER− control

The difference in T_1 relaxation rate of water (ΔR_1): +EPTA-Gd designates ΔR_1 between EPTA-Gd treated ER+ cells (incubated for 3 h with 6 μM EPTA-Gd) and ER+ control cells (incubated in standard medium) as compared to ΔR_1 between EPTA-Gd treated ER− cells (incubated for 3 h with 6 μM EPTA-Gd) and ER− control cells (incubated in standard medium); after wash designates ΔR_1 between EPTA-Gd treated ER+ cells (incubated for 3 h with 6 μM) after washout with standard medium and ER+ control cells as compared to ΔR_1 between EPTA-Gd treated ER− cells (incubated for 3 h with 6 μM EPTA-Gd) after washout with standard medium and ER− control cells. E. Low-resolution images of ER+ and ER− MDA-MB-231 cells cultivated on Biosilon beads using standard medium, in the presence of 6 μM EPTA-Gd, and after washout of EPTA-Gd with standard medium (spin echo with TE/TR = 15/300 ms). F. ΔR_1 obtained from experiments demonstrated in E with ΔR_1 defined as in D.

cells after washout, we found a small measurable value for this ΔR_1 (Figure 1D,F) but significantly lower than the comparable ΔR_1 for ER+ cells (Figure 1D,F) suggesting some nonspecific absorption of EPTA-Gd inside the cells. Thus, the difference between ΔR_1 of the ER+ cells and that of the ER− cells reflects the change due to the specific EPTA-Gd binding to ER in the ER+ cells.

Overall, targeting EPTA-Gd to ER in living breast cancer cells enabled us to detect differences in the intensity of T_1-weighted MR images, as well as in the T_1 relaxation rates between ER+ and ER− breast cancer cells. In general, the amount of ER in cells is controlled by a balance between its synthesis and degradation and is influenced by the nature of the bound ligand. For example, as shown in Figure 1A,B, estrogen induction of ER proliferating activity is strongly associated with its proteasomal degradation, leading to a marked decrease in ER within few hours. Temporal changes in ER level can therefore reflect the functional state of ER as well as the

presence or absence of SERMs. Hence, there is a strong scientific need to develop an *in vivo* imaging method that will provide us with knowledge of the ER signaling function and monitor temporal changes of receptor down-regulation and desensitization in the different estrogen-responsive organs.

The assessment of ER function is particularly important for the management of breast cancer. It has been well-established that the estrogen receptor has a pivotal role in prevention and treatment of breast cancer. Specifically, the ER level serves to select patients for adjuvant endocrine therapy, and together with the progesterone receptor, they serve as major prognostic factors predicting the likelihood of recurrence and survival. Assessment of the ER status in breast cancer patients by means of MRI is specifically advantageous, as it can be integrated with the unique diagnostic capabilities of MRI to record anatomical images, as well as produce parametric images that characterize tumor physiological and metabolic properties (*26*, *27*). In order to extend the *in vitro* measurements to *in vivo* conditions, several key experimental criteria must be reached: nontoxicity; high-affinity for ER; reasonable pharmacodynamics; ability to penetrate vascular walls, interstitial spaces, and cell membrane; and sufficient MRI sensitivity. The above *in vitro* results and preliminary *in vivo* experiments in rodents (not shown) have indicated that-indeed EPTA-Gd meets these criteria, particularly, it is not lethal and does not cause any adverse effects when administered intravenously even at a high dose. However, in order to achieve MRI sensitivity it is necessary to design protocols that overcome the heterogeneity of tumors. Further studies of breast cancer xenografts implanted in mice are underway to find out whether utilization of EPTA-Gd provides sufficient MRI sensitivity for the detection of ER down-regulation in the same tumor.

In conclusion, the first estrogen-conjugated Gd(III) contrast agent (EPTA-Gd) has been designed and synthesized. EPTA-Gd competes with E2 on binding to ERα, with a competition equilibrium constant $K_i = 0.97\ \mu M$, demonstrates like estrogens induced cell proliferation and down-regulation of ER level in ER+ breast cancer cells *in vitro*, both requiring binding to ER. Free EPTA-Gd displays a ∼50% higher relaxivity than the common Gd-based contrast agents and increases the T_1 relaxation rates of ER+ cells as compared to these rates in the same cells with null ER indicating a specific enhancement due to the binding to the ER. Structural modification studies aimed at enhancement of binding affinity are currently underway.

Biomimetic Glycoliposomes as Nanocarriers for Targeting P-Selectin on Activated Platelets

Junmin Zhu,[†] Jie Xue,[‡] Zhongwu Guo,*[,‡] Linda Zhang,[†] and Roger E. Marchant*[,†]

Department of Biomedical Engineering, Case Western Reserve University, 10900 Euclid Avenue, Cleveland, Ohio 44106, and Department of Chemistry, Wayne State University, 5101 Cass Avenue, Detroit, Michigan 48202. Received June 14, 2007; Revised Manuscript Received July 2, 2007

The cell glycocalyx is an attractive model for surface modification of liposomes with the objectives of tissue targeting and prolonged circulation time. Here, we reported on glycocalyx-mimicking liposomes, prepared by incorporating a glycolipid of 3′-sulfo-Lewis a (SuLe^a)-PEG-DSPE with a headgroup of SuLe^a and a spacer of poly(ethylene glycol) (PEG) linked to two hydrophobic tails. This PEG spaced structure is used to mimic the extended structure of P-selectin glycoprotein ligand 1 (PSGL-1) on activated leukocytes, in order to facilitate the specific binding of liposomes to the receptor of P-selectin expressed on activated platelets. Our results indicate that SuLe^a-PEG-DSPE can form stable, narrowly distributed liposomes with 1,2-distearoyl-*sn*-glycero-3-phosphocholine (DSPC) and cholesterol, with a vesicle size of 113.3 nm. The resultant SuLe^a-PEG-liposomes can facilitate their binding to the receptor of P-selectin 22 times higher than SuLe^a-liposomes without a PEG spacer. Further studies by fluorescence microscopy show that SuLe^a-PEG-liposomes can bind to activated platelets *in vitro* effectively. It suggests that biomimetic SuLe^a-PEG-liposomes may be used as nanocarriers to target activated platelets for drug delivery to the injury sites of cardiovascular diseases.

The glycocalyx of cells like endothelial cells and erythrocytes is a membrane-bound carbohydrate-rich layer consisting of various glycoproteins, proteoglycans, and glycosaminoglycans. This carbohydrate-rich layer plays an important role in mediating cell-specific interactions and preventing nonspecific protein adsorption (*1*, *2*). Therefore, the cell glycocalyx is an attractive model for surface modification of liposomes with the objectives of tissue targeting and prolonged circulation time. Here, we report on glycocalyx-mimicking glycoliposomes, as shown in Figure 1, prepared by 1,2-distearoyl-*sn*-glycero-3-phosphocholine (DSPC) and cholesterol with incorporation of a glycolipid with a headgroup of 3′-sulfo-Lewis a (SuLe^a) and a spacer of poly(ethylene glycol) (PEG) linked to two hydrophobic tails. This PEG spaced structure is supposed to mimic the extended structure of P-selectin glycoprotein ligand 1 (PSGL-1) on activated leukocytes, in order to facilitate the specific binding of liposomes to the receptor of P-selectin expressed on activated platelets in the processes of thrombosis, inflammation, and atherosclerosis.

Platelets play a central role in thrombosis and atherosclerotic lesions (*3*−*5*), including angina, coronary artery disease, myocardial infarction, and ischemic stroke, which are main causes of death and disability in the Western countries (*6*, *7*). Platelets can be activated upon adhesion to extracellular matrix proteins in the vascular injury region, foreign material surface, or by thrombin generated in the coagulation process (*8*). A number of receptors have been recognized on activated platelets (*9*), including GPIIb/IIIa, GPIb, P-selectin, CD9, CD36, and CD63. P-selectin is one of the important receptors expressed on activated platelets with about 10 000 copies/cell (*10*). It is a member of the selectin family of adhesion molecules, which includes E-, L-, and P-selectin (*11*). P-selectin is stored in platelet α-granules, as well as endothelial Weibel−Palade bodies. After the activation of platelets, P-selectin is expressed on the platelet surface, which can bind to its receptor of PSGL-1, a dimeric membrane mucin on circulating leukocytes (*12*), as shown in Figure 2. P-selectin on activated platelets has a crucial function in the early phases of inflammation regulating

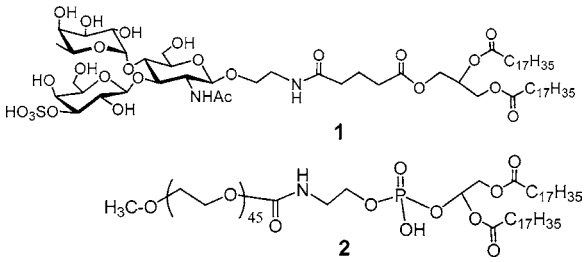

Figure 3. Structures of SuLe^a-DSGA (**1**) and PEG-DSPE (**2**, with PEG Mw of 2000).

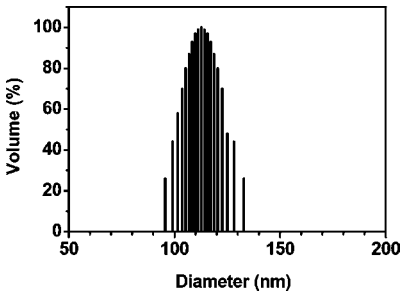

Figure 4. Vesicle size and distribution of liposomes with 5 mol % incorporation of SuLe^a-PEG-DSPE.

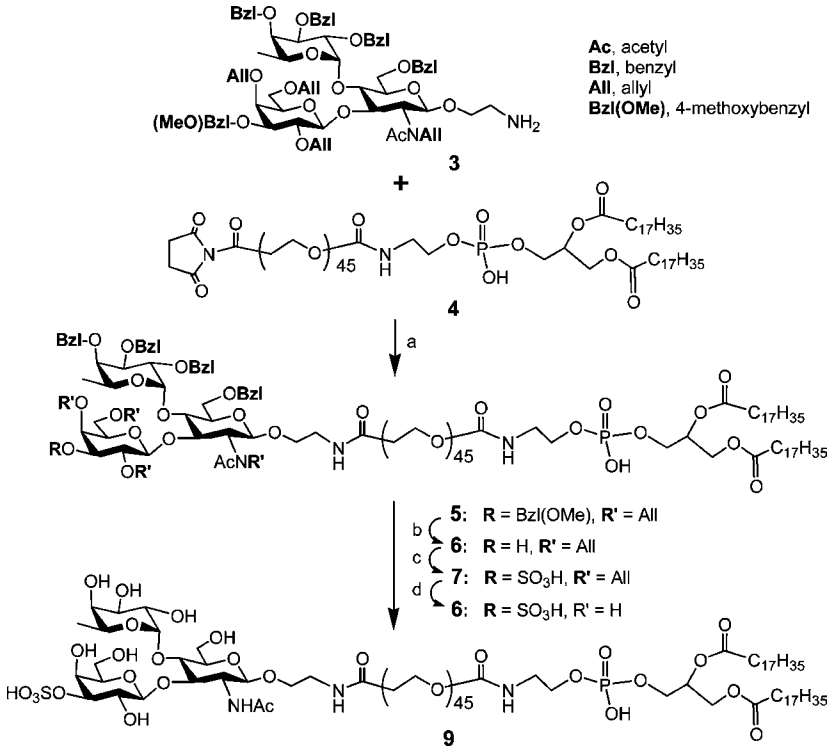

leukocyte−platelet interactions and mediating the recruitment of leukocytes and platelets to the sites of vascular injury (*13*−*15*). Therefore, P-selectin on activated platelets is an attractive candidate for targeted drug delivery to the sites of vascular injury.

P-selectin binds with high affinity to the extreme N-terminal extracellular region of mature PSGL-1, which begins at residue 42 (*12*). Specifically, tyrosine sulfate (Sulfo-Tyr) residues and sialylated O-glycans within this region have been considered essential for P-selectin binding (Figure 2). Much effort has been directed at identifying their carbohydrate mimetics as P-selectin ligands (*16*). One of the most important is Lewis x/a (Le$^{x/a}$) antigens, including sialyl Le$^{x/a}$ (SLe$^{x/a}$) (*17*), and sulfo-Le$^{x/a}$ (SuLe^{axa}) as found on epithelial mucins (*18*). To explore new therapeutic strategies for inflammatory diseases based on using biomimetic glycoliposomes, we have synthesized a SuLe^a glycolipid **1** (designated as SuLe^a-DSGA, Figure 3) by conjugating SuLe^a with 1,2-distearoyl-*rac*-glyceroglutaric acid (DSGA). SuLe^a-DSGA has been incorporated into liposomes for studying vesicle size and stability (*19*, *20*). However, PSGL-1 is a thin, highly extended molecule with an average length of 54 nm. From the natural interaction between PSGL-1 and P-selectin, the binding site for P-selectin is at the N-terminus of PSGL-1, which is about 50 nm away from the leukocyte surface (Figure 2) (*21*, *22*). Therefore, we propose that a spacer between SuLe^a and the liposome surfaces may better mimic the native PSGL-1 structure with enhanced binding affinity to P-selectin, compared with SuLe^a-liposomes without a spacer.

PEG is a good candidate for using as this kind of spacer due to its flexibility and biocompatibility (*23*). Also, it has another advantage to control the spacer length through adjusting its molecular weight. Here, we choose PEG with Mw of 2000 because it has been widely used for surface modification of liposomes (*24*, *25*). For example, PEG-1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine (DSPE) (**2**, with PEG Mw of 2000) (Figure 3) has been incorporated into liposomes to enhance the circulation time of vesicles *in vivo*. Thus, a glycolipid, SuLe^a-PEG-DSPE **9** was designed and synthesized with a PEG spacer (Mw 2000) inserted between the headgoup of SuLe^a and two hydrophobic tails, as shown in Scheme 1.

The synthesis of **9** was based on the conjugation of our previously developed intermediate, a protected amino derivative of SuLe^a **3** with DSPE-PEG-NHS **4** (with PEG Mw of 2000 and an activated carboxylic group by *N*-hydroxylsuccinimide), followed by deprotection of *p*-methoxybenzyl [Bzl(OMe)] groups, 3′-sulfatation, and deprotection of allyl (All) and benzyl (Bzl) groups (*19*, *20*). In the natural form, Lewis antigens are attached through their reducing ends to lipids and/or proteins. If Lewis antigen conjugates have the lipids attached to the

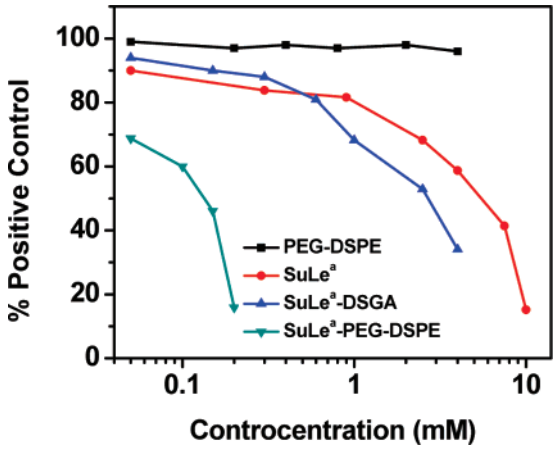

Figure 5. Inhibition of sPSGL-1 binding to recombinant rat P-selectin-IgG coated on plates by liposomes or carbohydrates.

2-amino group of the glucosamine residue with the reducing end capped by an unreactive group, it may affect the conformation of the antigen and their binding to selectins (*26*). SuLe^a-PEG-DSPE was synthesized with the lipid attachment through the reducing end of SuLe^a. Therefore, it has the advantage of stability under physiological conditions due to the lower susceptibility of the glycosyl ether linkage to glycosidases, compared with natural O-glycosides with reducing ends.

SuLe^a-PEG-DSPE (5 mol %) was used with DSPC (55 mol %) and cholesterol (40 mol %) to prepare glycoliposomes using a freeze−thraw and extrusion method through 100 nm membranes (*27*). The vesicle size and distribution was determined by photon correlation spectroscopy (PCS), as shown in Figure 4. The mean vesicle size for SuLe^a-PEG-liposomes is 113.3 nm after extrusion, which is close to the vesicle size of SuLe^a-liposomes (105.8 nm) and PEG-liposomes (108.5 nm) with 5 mol % incorporation of SuLe^a-DSGA **1** and PEG-DSPE **2** (with PEG Mw of 2000, Figure 3), respectively, as listed in Table 1. In addition, the vesicles of SuLe^a-PEG-liposomes were narrowly distributed with a polydispersity index (PDI) of 0.03, maybe due to the steric stabilization from PEG and the electrostatic effect from the charged head group of SuLe^a.

Zeta (ζ)-potential was measured to verify whether the negatively charged SuLe^a groups are on the liposome surface. The results (Table 1) show that the ζ-potential of SuLe^a-PEG-liposomes was −5.66 mV, which is comparable to that of SuLe^a-liposomes (−8.46 mV). It indicates that SuLe^a-PEG-DSPE was successfully incorporated into liposomes and the negatively charged headgroup of SuLe^a was present on the liposome surface. The stability of liposomes was determined by measuring the vesicle size change over time at room temperature. SuLe^a-PEG-liposomes with 5% of glycolipid incorporation maintained their vesicle size in the same range in storage over a 1 month period, comparable with results for PEG-liposomes. It demonstrates that SuLe^a-PEG-liposomes is stable enough for practical uses, and may maintain vesicle integrity while in the circulation.

Enzyme-linked immunosorbent assay (ELISA) was carried out to determine the binding affinity of the surface-modified liposomes to P-selectin. Briefly, recombinant rat P-selectin-IgG was coated on plates, followed by addition of human-soluble PSGL-1 (sPSGL-1) and glycoliposomes or carbohydrate ligands. After incubation, the plates were rinsed and the adherent sPSGL-1 was linked with horseradish peroxidase (HRP) through biotin−steptavidin interactions, followed by incubation with a substrate solution of tetramethylbenzidine (TMD). The absorbance of developed color was measured at 450 nm. The inhibition of sPSGL-1 binding to P-selectin by liposomes or carbohydrate ligands was expressed as the percentage of the sPSGL-1 control in the absence of any inhibitors, as shown in Figure 5. SuLe^a-PEG-liposomes show significant inhibition of sPSGL binding to P-selectin, while PEG-liposome shows no inhibition.

IC_{50} was used to compare the binding ability of liposomes, which was the concentration of carbohydrate ligands that inhibited sPSGL-1 binding to P-selectin by 50%. The IC_{50} values were obtained from Figure 5, as listed in Table 1. The results show that the free SuLe^a saccharide has an IC_{50} of 5.61 mM (Figure 4), but IC_{50} of SuLe^a-liposomes was 2.92 mM. The IC_{50} of SuLe^a-PEG-liposomes was 0.13 mM. That means the binding ability of the ligands on SuLe^a-PEG-liposomes was increased 43 and 22 times, compared to the free SuLe^a ligand and SuLe^a-liposomes, respectively. Therefore, the PEG spacer can increase the mobility of the ligands, and thereafter increase the binding ability.

To further confirm and visualize the specific binding of SuLe^a-PEG liposomes with P-selectin, liposomes were labeled by incorporating 1 mol % of nitrobenzodiazole-modified phosphatidylcholine (NBD−PC), and human platelets were activated and adsorbed on collagen-coated glass coverslips. The binding was studied by the fluorescence microscopy method (*28*). It was observed that the SuLe^a-PEG-liposomes had much higher binding to activated platelets (Figure 6b) than the control of PEG-liposomes (Figure 6a). The significantly increased binding of the former to activated platelets is attributed to the specific interactions between SuLe^a on the glycoliposome and the P-selectin on activated platelets.

In summary, we reported on novel glycocalyx-mimicking liposomes, SuLe^a-PEG-liposomes from a glycolipid, SuLe^a-PEG-DSPE with a headgroup of SuLe^a and a PEG spacer linked to two hydrophobic tails. Our results indicate that SuLe^a-PEG-

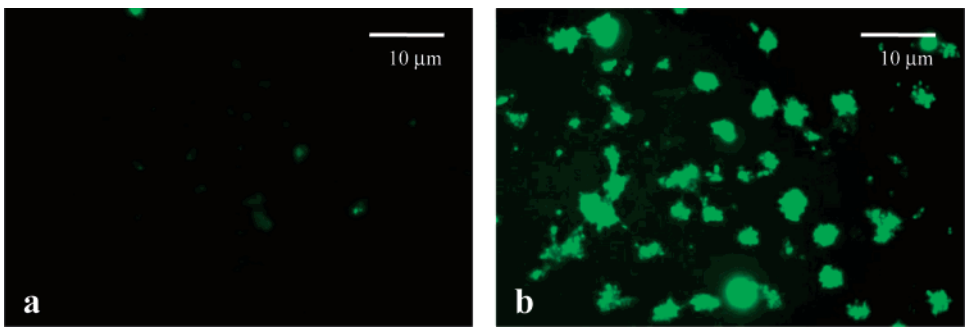

Figure 6. Fluorescence micrographs of platelet binding with NBD-labeled liposomes from PEG-DSPE (a) and SuLe^a-PEG-DSPE (b).

DSPE can form stable, narrowly distributed liposomes with DSPC and cholesterol, with a vesicle size of 113.3 nm. The resultant SuLe^a-PEG-liposomes can mimic the extended structure of PSGL-1 on activated leukocytes and facilitate their binding to the receptor of P-selectin 22 times higher than SuLe^a-liposomes without a PEG spacer. Further studies by fluorescence microscopy show that SuLe^a-PEG-liposomes can bind to activated platelets *in vitro* effectively. It suggests that biomimetic SuLe^a-PEG-liposomes may be used as nanocarriers to target activated platelets for drug delivery to the injury sites of cardiovascular diseases.

Received April 18, 2007; Revised Manuscript Received August 9, 2007

Two stable and water-soluble organometallic carbonyl cluster derivatives have been prepared and shown to enter the cell with ease. The CO stretching vibrations afford strong mid-infrared signals which have been demonstrated, for the first time, to be of utility in cell imaging via an IR microscope.

INTRODUCTION

The most highly developed imaging techniques currently employed in biological studies are probably those based on fluorescence spectroscopy. In comparison, there are far fewer reports on the IR and Raman imaging of cells (*1*−*4*). The use of IR-tagged molecules has been scant, and these have employed molecules absorbing in the near-IR (*5*−*8*). Part of the reason for the comparative scarcity of IR imaging is the high sensitivity that is achievable with current fluorescent detectors. However, IR imaging has its own advantages, which include narrower line-widths (which is important if it is to be used as a probe of the environment about the molecule) and lower energy content (hence less potential damage to the cell).

Organometallic carbonyl compounds show strong C═O stretching absorptions in the 2200−1650 cm^{-1} region, which is relatively devoid of interference from any functional groups in the cell. They can thus potentially be useful as spectroscopic tags for imaging in living systems. Organometallic compounds have already been employed in applications (*9*, *10*) such as the labeling of peptides (*11*−*15*) and enzymes (*16*) and in immunoassays (*17*−*23*). However, their use as spectroscopic imaging agents in cells appears to have been unexplored, although related work on the localization of organometallic compounds inside cells using XRF (*24*), fluorescence (*25*), and AAS (*26*) has been carried out. The organometallic clusters of osmium, in particular, offer the distinct advantages of relative inertness toward air and water and the availability of multiple sites for the attachment of various ligands as property modifiers.

EXPERIMENTAL PROCEDURES

Synthesis and Characterization of Compounds. Solvents were of AR grade, dried over the appropriate drying agents, distilled under nitrogen, and stored in containers fitted with a Teflon valve prior to use. All other starting materials were purchased from Aldrich. All synthetic steps were carried out under an atmosphere of nitrogen using standard Schlenk techniques. ^{1}H NMR spectra were recorded on a Bruker ACF300 NMR spectrometer as $CDCl_3$ solutions unless otherwise stated; chemical shifts reported are referenced against the residual proton signals of the solvents. Routine infrared spectra were recorded on a Shimadzu Prestige-21 FTIR spectrometer. All elemental analyses were performed by the microanalytical laboratory at NUS. The cluster $Os_3(CO)_{10}(\mu\text{-H})[\mu\text{-S}(CH_2)_{10}\text{COO}]$Na, **1**, its parent acid **1a** (*27*), and the monobenzylated triol $HOCH_2CH(OH)CH_2OBz$ were prepared according to the literature methods (*28*). All other reagents were from commercial sources and used without further purification.

Synthesis of $BzOCH_2CHCH_2$*-1,2-*$\{Os_3(CO)_{10}(\mu\text{-H})[\mu\text{-S}(CH_2)_{10}COO]\}_2$, ***3***. Cluster **1** (0.5734 g, 0.5399 mmol) was placed in a Carius tube, followed by dichloromethane (7 mL) and DCC (0.3251 g, 1.578 mmol). After stirring at room temperature for 24 h, DMAP (0.2241 g, 1.836 mmol) and $HOCH_2CH(OH)CH_2OBz$ (0.0491 g, 0.2699 mmol) were added and the mixture stirred for another 24 h. The white precipitate formed was removed by filtration; the filtrate was concentrated by rotary evaporation and then purified by preparative TLC (eluant 1:9 ethyl acetate/hexane, v/v). The third of four bands ($R_f = 0.56$) was identified as $BzOCH_2CHCH_2$-1,2-$\{Os_3(CO)_{10}(\mu\text{-H})[\mu\text{-S}(CH_2)_{10}COO]\}_2$, **3**. Yield = 0.3039 g (53%). IR (KBr): ν_{CO} 2110(s), 2062(s), 2031(s), 2015(s), 1973(s), 1700(s) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 1.27−1.62 (m, 32H, $CH_2(CH_2)_8CH_2$), 2.35 (m, 8H, CH_2S and $COCH_2$), 3.50−3.83 (m, 4H, $CH_2CH(O)CH_2$), 4.0 (m, 1H, CH_2CHCH_2), 4.55 (s, 2H, $OCH_2C_6H_5$), 7.22−7.36 (m, 5H, $CH_2C_6H_5$), −17.41(s, 2H, OsHOs). ^{13}C NMR ($CDCl_3$): δ 24.75, 24.78, 28.30, 29.53, 29.67, 29.72, 29.72, 29.83, 33.83, 33.96, 34.11, 55.33, 65.82, 68.23, 70.40, 73.56, 126.56, 126.56, 128.89, 129.12, 129.12, 136.86, 169.89, 170.86, 173.25, 173.68, 173.96, 176.53, 179.86, 180.12.

Deprotection of ***3***. Cluster **3** (46.1 mg, 19.9 μmol) was placed into a two-necked round-bottom flask. Absolute ethanol (15 mL) and 10% palladium on carbon (100 mg) were then added. The suspension was stirred at room temperature for 12 h with hydrogen gas bubbled through. The catalyst was then removed by filtration, and the solvent removed using a rotary evaporator. The crude product was purified by preparative TLC (eluant ethyl acetate/hexane, 2:8, v/v). The first of two bands ($R_f = 0.35$) was identified as $HOCH_2CHCH_2$-1,2-$\{Os_3(CO)_{10}(\mu\text{-H})[\mu\text{-S}(CH_2)_{10}COO]\}_2$, **4**. Yield = 13.8 mg (30%). IR (KBr): ν_{CO} 2110(s), 2062(s), 2031(s), 2015(s), 1973(s), 1700(s) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 1.25−1.59 (m, 32H, $CH_2(CH_2)_8CH_2$), 2.30 (m, 8H, CH_2S and $COCH_2$), 3.48−3.82 (m, 4H, CH_2CHCH_2), 4.0 (m, 1H, CH_2CHCH_2), −17.41(s, 2H, OsHOs). ^{13}C NMR ($CDCl_3$): δ 24.55, 24.68, 27.26, 28.56, 28.98, 29.23, 29.92, 33.32, 33.83, 33.83, 55.56, 62.28, 63.12, 70.56, 73.56, 169.90, 170.92, 173.28, 173.66, 173.82, 177.03, 180.02, 180.96.

*Synthesis of **6***. To a thoroughly stirred solution of phosphorus oxychloride (2.0 g, 0.013 mol) in DCM (50 mL) was added 2-bromoethanol (0.95 g, 7.6 mmol) via a pressure-equalizing dropping funnel. A continuous stream of nitrogen was directed through the reaction mixture to remove the hydrogen chloride formed. After stirring for 12 h, toluene (50 mL) was added and the mixture rotary-evaporated to dryness with warming in a water bath set at 40 °C. The residue which contains bromoethylphosphoric acid dichloride was used without further purification. To a DCM (60 mL) solution of bromoethylphosphoric acid dichloride (4.86 g, 20.1 mmol) cooled in an ice bath was added triethylamine (8.30 mL, 82.1 mmol). With continuous stirring, a solution of cluster **4** (44.3 mg, 20.1 μmol) in DCM (30 mL) was added dropwise. The reaction was monitored by TLC, and was completed after 1 h. Toluene (120 mL) was added to the reaction mixture, and the precipitated triethylammonium chloride was removed by filtration. The filtrate was evaporated to dryness, the residue redissolved in THF (100 mL) and then hydrolyzed by stirring with aqueous sodium carbonate (0.5 M, 100 mL, pH 8.5) for 6 to 8 h. The pH of the solution was adjusted to 9.0 by the addition of aqueous sodium hydroxide, and then extracted with diisopropylether (100 mL); methanol (20−40 mL) was also added to facilitate phase separation. The ether phase was evaporated to dryness and then recrystallized from chloroform (20 mL) and acetone (200 mL). The crude precipitate of **5** (23.5 mg, 9.8 μmol) was dissolved in chloroform/2-propanol/ dimethylformamide (130 mL, 3:5:5, v/v/v), heated at 50 °C, and a solution of trimethylamine in water (70 mL, 40%, v/v) added. The reaction was completed after 4−6 h. Volatiles were removed by evaporation at 40 °C, and the residual water/dimethylformamide mixture was extracted with a chloroform/methanol (1:1, v/v) solvent mixture. The combined extracts were evaporated and the residue purified by silica gel chromatography to afford **6**. $R_f = 0.13$. Yield = 6.9 mg (15%). Cell Studies. *Cell Culture and Viability Assay*. Cell culture medium, L-glutamine, and trypsin were purchased from Sigma-Aldrich. Phosphate buffered saline (PBS) was purchased from Fisher Scientific. Oral mucosa cells were scratched from the oral mucosa surface and washed twice in pure water before use. HL-60 cell lines were purchased from American Type Culture Collection (ATCC).

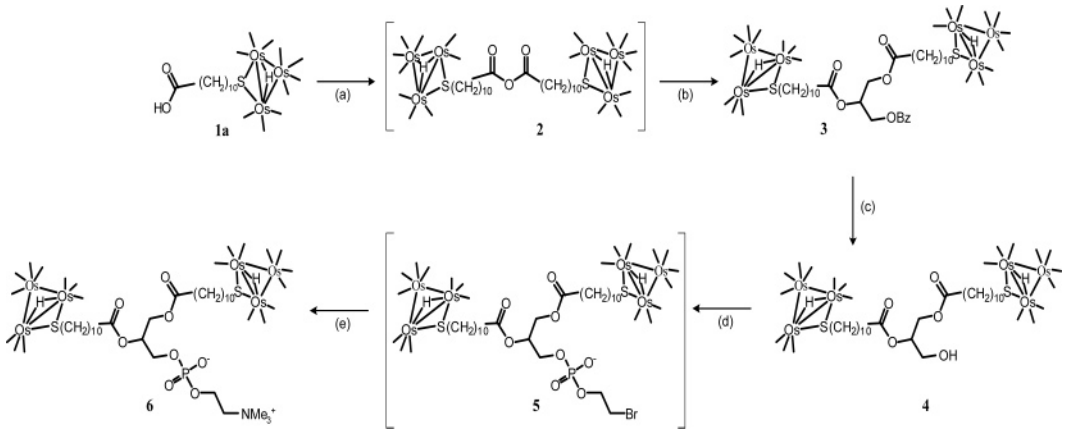
Cell viability under experimental conditions was assessed by the mitochondria-dependent reduction of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) to formazan. HL-60 cells were treated with an equal amount of freshly prepared MTT solution (2−5 mg MTT reagent dissolved in plain media) per sample in triplicate in a 96-well plate. The plate was incubated for 2 h at 37 °C in the dark. After incubation, the plate was spun at 2000 rpm for 5 min. The supernatant was removed, and the crystals were dissolved in 200 μL of DMSO plus 10 μL of Sorenson's glycine buffer. The plate was then read at 570 nm using an ELISA plate reader. Group comparisons were made using the unpaired *t* test and *p*-values less than 0.05 were considered significant.

FT-IR Imaging Experiments. The IR mapping experiments were carried out with a Varian 7000 FT-IR spectrometer fitted with a Stingray infrared microscope and equipped with a 64 × 64 MCT focal plane array (FPA) detector. Oral mucosa cells were incubated using 0.32 mM stock solutions of the compounds for 24 h; the final concentration of the solutions used in the incubation was 0.032 mM. After incubation, the cells were washed with cool buffer solution, quickly transferred onto CaF_2 windows, and then dried under a flow of nitrogen or argon, before imaging. During infrared imaging, the average spatial resolution probed by each FPA pixel is ca. 5.5 μm, amounting to an average spatial field of view of 350 × 350 μm^2 for the entire 64 × 64 pixels of infrared image. FT-IR imaging was performed using 16 scans for co-add at 4 cm^{-1} resolution, and the acquisition time for each FT-IR image was ca. 2 min.

For single-point IR spectral acquisition of cells and cellular material, a Shimadzu Prestige-21 FTIR spectrometer equipped with an AIM-8800 IR microscope was used, with the aperture set to 10 × 10 μm^2 size and the resolution at 4 cm^{-1}.

Cell Fractional Assay. A Chemicon compartment separation kit was used for cell compartment separation. HL-60 cells were grown in culture flasks with modified IMDM containing 10% FBS in a 5% CO_2 incubator. The HL-60 cells were treated with compounds **1** or **6** (0.032 mM) for 24 h at 37 °C, and were then homogenized in sucrose gradient buffer at moderate speed and centrifuged at 20 000 × *g* at 4 °C for 20 min. The supernatant was saved as the cytoplasmic fraction. The pellet was washed with cold sucrose gradient buffer and centrifuged again as above. The supernatant was saved as the nuclear fraction. The procedure was repeated, and the supernatant now contained the membrane fraction, while the pellet contained organelles, granules and cytoskeleton, which was labeled the organelles fraction. Finally, all samples were characterized at a spectral resolution of 4 cm^{-1} as dry films on CaF_2 windows.

TEM Imaging. TEM images and the EDX spectra were recorded on a JEOL JEM 3010 transmission electron microscope at an accelerating voltage of 300 kV; a drop of the cells suspended in water was placed onto a carbon-coated Cu grid.



Washout Studies. HL-60 cells were treated with compound **1** or **6** (0.032 mM) for 24 h at 37 °C. At the end of the incubation period, the cells were rinsed in triplicate with medium at ambient temperature. The removed medium was digested with nitric acid and analyzed for osmium content using ICP−MS. Rinsing of the cells was then repeated as above.

ICP−MS Analysis. ICP−MS analyses were carried out on an ELAN 6100 instrument. Mucosa cells (total of 1000 cells each) were treated with an aqueous solution of **1** or **6** (0.032 mM) for 24 h at 37 °C. At the end of the incubation period, the cells were rinsed with buffer solution at ambient temperature. Mineralization was carried out with 65% HNO_3 at 120 °C, and the dried digested material was redissolved in 2% HNO_3. The osmium content was then determined by ICP−MS.

*Stability of **1** in Vivo*. A solution of **1** was incubated with HL-60 cells at 37 °C for 12, 24, and 48 h, respectively. After centrifugation, the cell pellets were place on CaF_2 and dried under nitrogen. The cells were characterized at a spectral resolution of 4 cm^{-1} on CaF_2 windows, and the stability was assessed by IR spectroscopy.

*Stability of **6** in Vivo*. A culture of (5−7) × 10^6 cells was incubated in a solution of **6** for 24 h. The cells were then collected by centrifugation (1500 rpm, 5 min), the media aspirated off, washed with PBS, then suspended in chloroform/methanol (3 mL, 1:2, v/v) and agitated until an even suspension was attained. Water (0.8 mL) was added, and the cells were transferred to a 15 mL tube and allowed to settle (30 min). The cellular debris was separated by centrifugation (3000 rpm, 5 min), chloroform (1 mL) and water (1 mL) were added to the

liquid material, and the suspension vortexed. Phase separation was obtained by allowing the mixture to stand for 15−30 min, followed by centrifuging (3000 rpm, 5 min); the lower organic phase was collected and then the solvent removed by evaporation. TLC analysis (silica gel, $CHCl_3/CH_3OH$, 3:1, v/v) of the residue showed the presence of only **6** but no **1** or **1a**.

Estimation of Cell Size. Mucosa cells were scratched from the oral mucosa surface, washed twice in pure water, and then quickly transferred onto CaF_2 windows. Cell surface area measurements of the dry cells were performed using the View program of the Shimadzu AIM 8800 microscope. The mucosa cells selected for measurements were flat in shape. The average cell surface area for 20 mucosa cells was measured, and the average cell volume estimated by assuming an average cell thickness of 2 μm. The average cell volume obtained was 1.78×10^{-11} L.

RESULTS AND DISCUSSION

We have recently synthesized the water-soluble cluster, $[Os_3(CO)_{10}(\mu\text{-H})(\mu\text{-S}(CH_2)_{10}COO)]Na$, **1** (*27*), which is essentially an inorganic salt of a fatty acid tagged with an organometallic cluster. This was also elaborated (via the acid precursor, **1a**) to a phosphotidylcholine analogue, **6** (Scheme 1). The synthetic route to **6** utilized synthetic steps similar to those employed in the synthesis of the related organic fragment (*29*−*34*).

Compounds **1** and **6** are air- and water-stable, so that no special handling is required. Cytotoxicity studies carried out showed that **1** does not significantly affect viability of an HL-60 leukemia cell line (89% of the control for 10−30 μM concentrations), although the viability of cells exposed to 30 μM of **6** showed a slight reduction (77% of the control) in viability (Supporting Information Figure S1). Thus, at the doses studied, the labeling method poses only a small effect on the viability of cells. For our chemical imaging, oral mucosa cells were incubated with aqueous solutions (0.032 mM) of **1** or **6** for 24 h, washed with cool buffer solution, quickly transferred onto CaF_2 windows, and dried under argon or nitrogen flow. Oral mucosa cells have been reported to have an average size of up to 100×100 μm^2 (*35*); in our case, we have found them to be closer to 60×60 μm^2. Typical (single-point) IR spectra of the treated and untreated cells are shown in Figure 1. The usual absorption bands due to the cell contents are clearly visible. They do not show unusual broadening and absence of a narrow band at 1730 cm^{-1} due to ester carbonyl groups, both of which have been reported to be associated with necrosis (*36*). There is a significant difference between the spectra for the treated and untreated cells in the 1900−2100 cm^{-1} region, which is due to the carbonyl (CO) stretching vibrations of the organometallic fragments. An EDX (energy-dispersive X-ray)

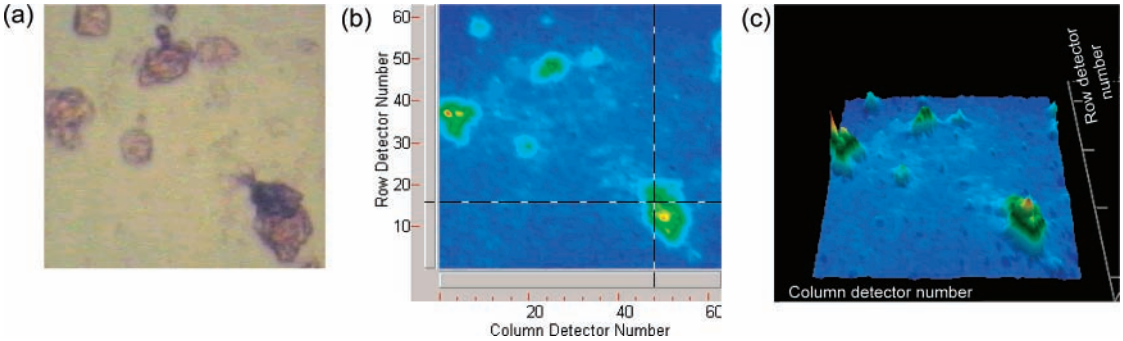

Figure 2. (a) Normal optical image; (b) false-color infrared image; (c) 3-D display of the image, of oral mucosa cells treated with **1**, taken at 2013 cm^{-1}.

spectrum taken of one of the cells treated with **1** also clearly showed the presence of osmium (Supporting Information Figure S2).

Figure 2 shows (a) a normal optical image, (b) a false-color infrared image, and (c) a 3-D display of the image of the oral mucosa cells treated with **1**, taken at 2013 cm^{-1}: one of the carbonyl vibration bands. The infrared images were obtained with a 64 × 64 pixel image plate detector; aperture size was set at 5.5 × 5.5 μm^2 and the signals were averaged over 16 scans. The chemical mapping images are closely correlated with the optical image. Similar images were obtained when different carbonyl vibrational bands, as well as some typical cellular vibrations (such as the amide I band, Supporting Information Figure S3) were chosen; the same was observed with **6** (Supporting Information Figure S4).

Cells that were soaked in an aqueous solution of **1** for different periods of time (*37*) showed a concentration profile of **1** which reached a plateau after ∼7 h of soaking time (Supporting Information Figure S5), consistent with internalization of **1** (*38*), since adsorption onto the outer surface of the cells would be expected to exhibit a profile that is more or less independent of the length of time that the cells were soaked. The profile also suggested delivery through passive diffusion; washout studies on both **1** and **6** support this and are consistent with studies on other modified phospholipids (*39*, *40*). Internalization of both **1** and **6** was confirmed by the fractionation of HL-60 cells incubated for 24 h with solutions of the compounds. Four major fractions (nuclear, cytoplasmic, organelles, and membrane) were obtained, and the IR spectra of the dried fractions clearly showed the presence of the compounds in the organelles and the membrane fractions, albeit with different distributions, but not in the other two (Supporting Information Figure S6).

While it may have been anticipated that the fatty acid-like **1** would stay in the cytoplasm and the more lipid-like **6** in the membrane, previous studies on labeled lipids have shown that they do accumulate in the internal apparatus, forming granules in the cell, or adsorb onto the cell membrane (*41*, *42*). The possible hydrolysis of **6** in the cell was also ruled out, as chromatographic analysis of the cell contents after 24 h incubation with **6** showed that there was no detectable amount of its hydrolysis product, *viz*., the fatty acid **1a**. This is also consistent with previous studies on modified phospholipids, which suggest that they are resistant to hydrolysis or metabolism by the cells (*42*). Thus, both compounds have indeed translocated into the cells and adsorbed onto the internal surface of the cell membrane. The IR spectra of HL-60 cells after incubation in a solution of **1** for various periods of time (up to 48 h) showed that **1** does not decompose to any spectroscopically detectable extent; any decomposition affecting the cluster core would show up clearly as a shift in the pattern of the carbonyl stretching region, and complete loss of carbonyl ligands in osmium clusters at ambient temperature is unknown.

The absorbance across a single mucosa cell showed similar intensities and profiles for both **1** and **6** (Supporting Information Figure S7). The extinction coefficients for the 2013 cm^{-1} bands of **1** and **6** in aqueous solutions have been determined to be 8.3 × 10^4 and 1.75 × 10^5 L mol^{-1} cm^{-1}, respectively. We have estimated the average volume of a mucosa cell to be 1.78 × 10^{-11} L, and together with an assumed cell thickness of 1 μm and an observed IR absorbance of ∼0.04, the osmium content in the cells was estimated to be ∼3 × 10^{-13} mol per cell; this is comparable to the 6 or 2 × 10^{-13} mol per cell obtained from ICP−MS on mucosa cells treated with **1** and **6**, respectively. Conversely, the ICP and IR results could be used to arrive at an estimated cell thickness of ∼0.4−1.3 μm. These values are quite close to the 1−2 μm reported (*35*).

CONCLUSION

This work serves to illustrate, for the first time, that bioimaging in the mid-infrared is possible and that it can be carried out with stable, water-soluble organometallic carbonyl compounds such as **1** and **6**.

Osteotropic Peptide That Differentiates Functional Domains of the Skeleton

HPMA copolymer−D-aspartic acid octapeptide (D-Asp$_8$) conjugates have been found to target the entire skeleton after systemic administration. In a recent study using the ovariectomized rat model of osteoporosis, we surprisingly discovered that D-Asp$_8$ would favorably recognize resorption sites in skeletal tissues, while another bone-targeting moiety, alendronate (ALN), directs the delivery system to both formation and resorption sites. Atomic force microscopy (AFM) analyses reveal that ALN has a stronger binding force to hydroxyapatite (HA) than D-Asp$_8$. *In vitro* HA binding studies indicate that D-Asp$_8$ is more sensitive to change of HA crystallinity than ALN. Because the bone apatite in the newly formed bone (formation sites) usually has lower crystallinity than the resorption sites (mainly mature bone), we believe that the favorable recognition of D-Asp$_8$ to the bone resorption sites could be attributed to its relatively weak binding to apatite, when compared to bisphosphonates, and the different levels of crystallinity of bone apatite at different functional domains of the skeleton.

Bone is a specialized connective tissue, which provides mechanical support and participates in calcium homeostasis. It is continuously being resorbed and rebuilt to maintain its normal function. Disturbances of this resorption/formation balance are characteristic of most bone diseases (*1*−*3*). With ever-increasing understanding of bone biology, many new therapeutic agents have been identified for the treatment of bone diseases (*4*−*15*). However, most of them do not have tissue specificity to the skeleton (osteotropicity), which hampers their clinical application due to the side effects.

In order to overcome this problem, we have developed bone-targeting water-soluble polymeric drug delivery systems. In the initial study, alendronate and D-Asp$_8$ were used as the bone-targeting moieties and conjugated to fluorescein isothiocyanate (FITC)-labeled *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymers (Figure 1A). The administration of these polymers to young growing balb/c mice led to their strong deposition to the skeleton, especially at high turnover sites in bone as determined histologically (*16*). A later pharmacokinetics and biodistribution study confirmed that HPMA copolymer using D-Asp$_8$ as the bone-targeting moiety could recognize the skeleton, especially the high bone turnover sites, such as tibia and femur heads, lumbar vertebrae, and mandibular bone (*17*). To investigate whether the delivery system could deliver model drugs to the osteopenic skeleton, FITC-labeled HPMA copolymer−alendronate conjugate (P-ALN-FITC) and FITC-labeled HPMA copolymer−D-Asp$_8$ conjugate (P-D-Asp$_8$-FITC) were administered intravenously to ovariectomized (OVX) rats, a common model of postmenopausal osteoporosis. To allow the development of osteopenia, the OVX procedure was performed 3 months prior to the beginning of the study. To assist in the identification of different functional domains on bone surfaces, tetracycline (a fluorochrome marker of bone formation) (*18*) was administered intraperitoneally (20 mg/kg) 3 days prior to the administration of the conjugates. Twenty-four hours after administration of the conjugates, the OVX rats (three/group) were euthanized. Tibias, femurs, fifth lumbar vertebra, and mandibles were isolated, fixed, and processed for undecalcified histomorphometric analyses.

As shown in Figure 1B and C, both conjugates were found to bind well to some bone surfaces in the OVX rats, which agrees with a previous study using young balb/c mice (*16*). The tetracycline marker labeled bone formation surfaces permitted easier identification of both bone formation and bone resorption sites. The presence of osteoclasts on the resorption surface and osteoblasts on the formation surfaces was confirmed by histology. Surprisingly, P-D-Asp$_8$-FITC was found to preferentially bind to resorption surfaces, while P-ALN-FITC appeared to bind well at both formation and resorption surfaces. Such a result has never been reported before. As we examine the zone of dentine calcification, the binding of the P-ALN-FITC appeared to be stronger than P-D-Asp$_8$-FITC (Figure 1D and E) in the continuously erupting incisor in the mandible.

Because of this intriguing observation, we hypothesized that the binding strength of D-Asp$_8$ to bone apatite (a poorly crystallized, CO_3-containing, Ca-deficient hydroxyapatite analog) (*19*) may be weaker than that of alendronate. Therefore, it could be sensitive to the crystallinity of bone apatite. It is known that certain pathophysiological conditions such as Paget's disease (*20*) and osteoporosis (*21*) can result in changes of the size of hydroxyapatite crystals. It is also understood that the crystallinity of newly formed bone mineral at active bone

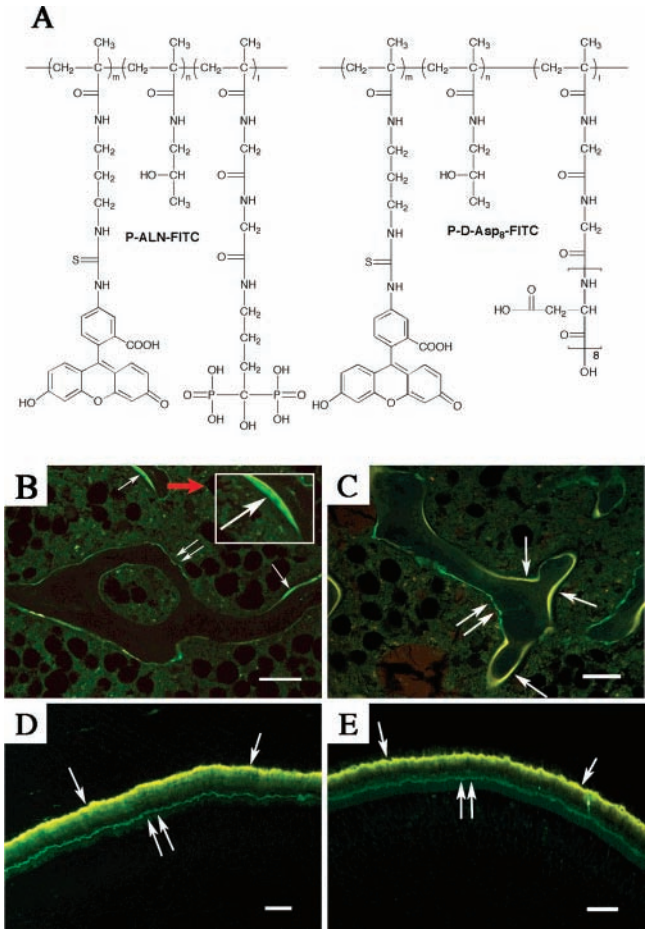

Figure 1. Different *in vivo* bone-binding abilities of HPMA copolymers conjugated with alendronate (P-ALN-FITC) and D-aspartic acid octapeptide (P-D-Asp$_8$-FITC). (A) Chemical structures of the osteotropic polymer conjugates. (B) Cancellous bone from an ovariectomized (OVX) rat injected with the bone formation marker tetracycline (TC) and the P-ALN-FITC. Both tetracycline (TC, yellow) and P-ALN-FITC (green) are seen on some surfaces (arrows) indicating uptake on bone-forming surfaces. A selected area is magnified (×2, insert) to show the double label of TC and P-ALN-FITC. P-ALN-FITC is also evident on some resorption surfaces (double arrows). Bar = 100 μm. (C) Cancellous bone from an OVX rat injected with TC and the P-D-Asp$_8$-FITC. Uptake of TC but little of P-D-Asp$_8$-FITC is evident on bone formation surfaces (arrows). P-D-Asp$_8$-FITC is evident on bone resorption surfaces (double arrows). Bar = 100 μm. (D) Cross sections of the forming mandibular incisor illustrating the uptake of the P-ALN-FITC. Bar = 50 μm. (E) Cross sections of the forming mandibular incisor illustrating the uptake of the P−D-Asp$_8$-FITC. Bar = 50 μm. The TC label (yellow) is clearly evident in both sections (arrows). There is more apparent uptake of P-ALN-FITC (green label, double arrows) in the mineralizing dentin than uptake of P-D-Asp$_8$-FITC.

formation sites is lower than that at the more mature sites where resorption occurs (*20*). This may help to explain the observed preferential binding of P-D-Asp$_8$-FITC to resorption surfaces in skeletal tissues.

To test this hypothesis, we employed force spectroscopy to directly measure the interaction of alendronate and D-Asp$_8$ with hydroxyapatite. Since the AFM force measurement requires a rather flat substrate, we chose tooth enamel (Figure 2) as a model of hydroxyapatite surface. Alendronate or D-Asp$_8$ was covalently attached to the AFM probes via glutaraldehyde cross-links (*22*−*24*). Force−distance measurements were performed in PBS buffer at room temperature at identical experimental conditions. Force curves were taken at various random locations on the surface in order to account for any heterogeneity on the surface. Although both modified tips clearly indicated the tip−surface interaction (Figure 3A and B), the most frequent force−

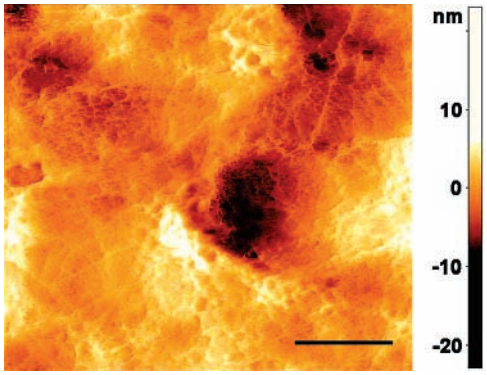

Figure 2. AFM amplitude image of tooth enamel surface taken in PBS buffer using nonmodified tip. Bar = 2 μm.

distance curves were different for alendronate and D-Asp$_8$. The force distance curves for the D-Asp$_8$-modified tip more often showed a single adhesion peak, whereas the alendronate-modified tip often had two clear peaks, including adhesion. Each individual force plot was analyzed one at a time. The rupture force and the distance for each peak were also measured. The results obtained for a series of measurements of adhesion forces for the tips modified with alendronate and D-Asp$_8$, respectively, are shown as histograms in Figure 3C and D. Both histograms demonstrate the interaction of modified tips with the tooth enamel surface, but they are clearly different. For alendronate, the distribution of forces is wide with majority of the forces recorded around 190 pN. For D-Asp$_8$, the distribution is narrower with the majority of the forces recorded around 105 pN. In addition to the analyses of adhesion forces at zero distances, secondary peaks at distances away from the adhesion peak were also analyzed and shown in Figure 3E and F. Clearly, the data reveal a more pronounced difference in the interaction patterns for alendronate and D-Asp$_8$. First, the number of secondary events was considerably larger for alendronate compared to D-Asp$_8$. Second, the values for rupture forces were higher for alendronate than for D-Asp$_8$. An additional difference was the position of the secondary peak. This effect is graphically illustrated in Figure 3G and H, on which the histograms for the distance distribution are plotted for alendronate and D-Asp$_8$, respectively. The positions for the secondary rupture events are centered around 40 nm for alendronate, whereas the secondary peaks for D-Asp$_8$ are scattered but with the majority of the events at distances of ∼10 nm. In spite of the heterogeneity in chemical composition and roughness of the enamel surface (Figure 2), which may widen the histograms for the interaction forces and distances, these AFM data strongly suggest that alendronate interacts more efficiently with the tooth enamel surface and has less sensitivity to the surface topography in comparison with D-Asp$_8$.

To further test the possibility that alendronate and D-Asp$_8$ will bind differently to hydroxyapatite with different crystallinity, we synthesized two hydroxyapatites (HA$_a$, high crystallinity, and HA$_b$, low crystallinity; Table 1) (*25*, *26*) for the *in vitro* binding test. Solubility studies and X-ray diffraction evaluation of these hydroxyapatites indicate that the lattice disorder of the bulk mineral phase (which is reflected by the crystallite microstrain parameter value) correlates well with the lattice disorder at the crystal-solution interface (to be published). So, it would be reasonable to expect that the binding behavior of molecules to apatite surfaces can be dependent upon the lattice disorder of the bulk mineral phase. PBS solutions of P-ALN-FITC and P-D-Asp$_8$-FITC were incubated with HA$_a$ and HA$_b$. After removal of HA powders from the solutions, the percentage of the FITC-labeled conjugates bound to HAs was calculated from the decreased UV absorbance of the polymer solutions. As shown in Figure 4, the higher absolute binding

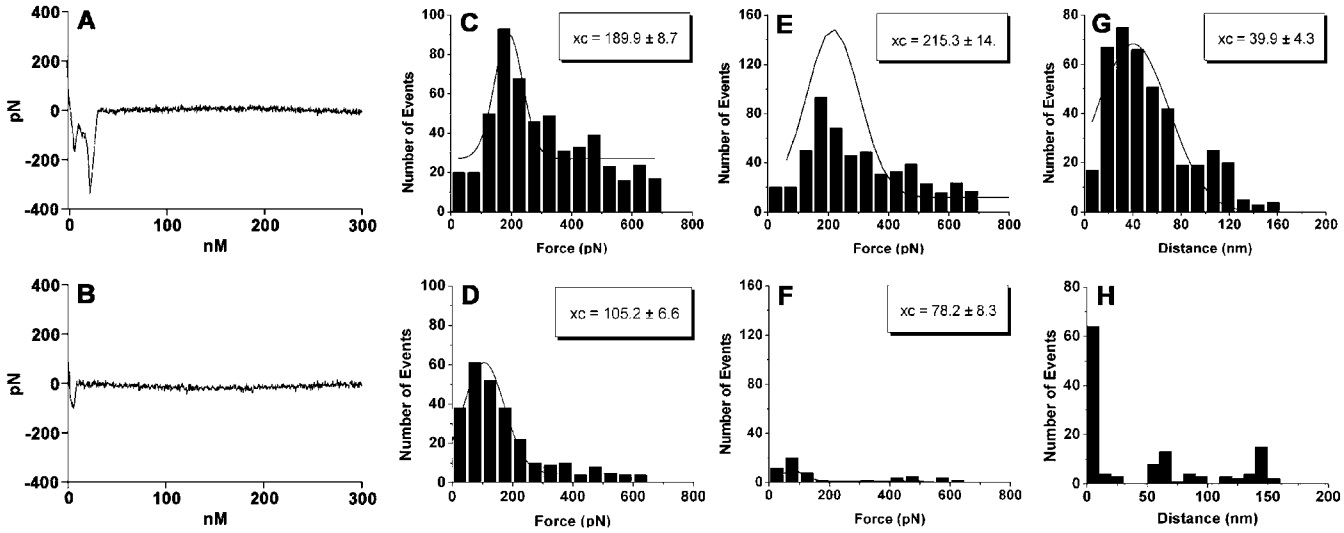

Figure 3. AFM analyses of different interaction between osteotropic compounds (alendronate and D-Asp$_8$) and tooth enamel surface. (A) Typical force−distance curve shows the interaction between alendronate modified tip and tooth enamel surface. (B) Typical force−distance curve shows the interaction between D-Asp$_8$ modified tip and tooth enamel surface. (C) Histogram for rupture forces obtained for the force spectroscopy measurements with the tips functionalized with alendronate. (D) Histogram for rupture forces obtained for the force spectroscopy measurements with the tips functionalized with D-Asp$_8$. (E) Histogram of the secondary rupture force events of Alendronate. (F) Histogram of the secondary rupture force events of D-Asp$_8$. (G) Histogram of the rupture events for all distances except at zero for alendronate. (H) Histogram of the rupture events for all distances except at zero for D-Asp$_8$. The most probable values obtained from the Gaussian fit for the histograms, which combine the analyses for more than 300 events are indicated in the inserts. No Gaussian fit could be obtained for (H).

Table 1. Characterization of Synthetic Hydroxyapatite with Different Crystallinity

sample	CO_3^{2-} (wt %)	PO_4^{3-} (wt %)	Ca^{2+} (wt %)	Na^+ (wt %)[a]	Ca/P	crystallite microstrain parameter (X)	specific surface area (m^2/g)
HA_a	0.5	53.9	38.1	0.23	1.68	0.17	26.7
HA_b	8.7	45.4	37.3	0.58	1.95	0.61	30.0

[a] The remaining contents in HA_a and Ha_b are mainly water, hydroxide, and trace elements (*27*).

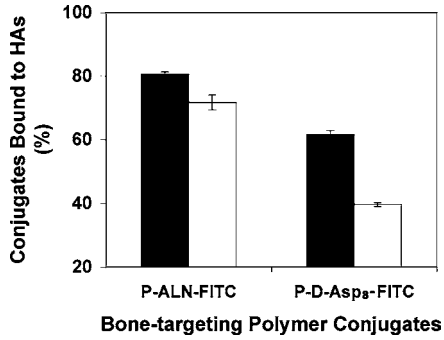

Figure 4. Binding ability of P-ALN-FITC and P-D-Asp$_8$-FITC to hydroxyapatites with different crystallinity. [ALN] = 3.2×10^{-5} mol/g for P-ALN-FITC; [D-Asp$_8$] = 7.0×10^{-5} mol/g for P-D-Asp$_8$-FITC. HA_a (■): microstrain = 0.05 ± 0.03 (high crystallinity). HA_b (□): microstrain = 0.61 ± 0.03 (low crystallinity). The different crystallinity of hydroxyapatites caused 9% difference in binding for P-ALN-FITC and 22% difference for P-D-Asp$_8$-FITC.

percentage of P-ALN-FITC to HAs, when compared to P-D-Asp$_8$-FITC, is probably confirming the stronger binding force of alendronate than D-Asp$_8$. Nevertheless, the binding of P-ALN-FITC to HAs is less sensitive to the change of apatite crystallinity compared to P-D-Asp$_8$-FITC.

Evidently, the AFM study suggests that alendronate has stronger binding to hydroxyapatite than D-Asp$_8$. Such differences in their ability to bind to hydroxyapatite coupled with their differences in binding with changes in apatite crystallinity would provide an explanation for the preferential binding of D-Asp$_8$ to hydroxyapatite with higher crystallinity. Though these experiments were not performed on bone apatite, the data support the hypothesis that it is the weak binding ability of D-Asp$_8$ to apatite that causes its *in vivo* selectivity to the bone resorption surface (containing bone apatite with relatively higher crystallinity) over formation surfaces (mainly amorphous calcium phosphate) (*19*). Incorporation of molecular structures (e.g., tetracycline, D-Asp$_8$) that could recognize different subtissue functional domains (osteolytic and osteoblastic) (*18*) into the new drug design and osteotropic drug delivery systems would greatly enhance the therapeutic index by delivering the drug directly to the desired cells and molecular targets.

On−Off Regulation of ^{19}F Magnetic Resonance Signals Based on pH-Sensitive PEGylated Nanogels for Potential Tumor-Specific Smart ^{19}F MRI Probes

Received June 17, 2007; Revised Manuscript Received August 11, 2007

The pH-sensitive PEGylated nanogels constructed from tethered PEG chains and a polyamine gel core containing ^{19}F compounds showed remarkable on−off regulation of ^{19}F MR (magnetic resonance) signals in response to the extracellular pH (6.5) of the tumor environment, even in the presence of 90% fetal bovine serum, due to the increase in the molecular motion of the ^{19}F compounds through the hydrophilic−hydrophobic (volume-phase) transition of the polyamine gel core. Eventually, an appreciably enhanced ^{19}F MR signal at an extremely low ^{19}F compound concentration (∼55 μM) was achieved, demonstrating the utility of these nanogels as solid tumor-specific smart ^{19}F MRI probes.

Magnetic resonance imaging (MRI[1]) based on ^{1}H has been recognized as a powerful and noninvasive methodology for cancer diagnosis (*1*, *2*). Nevertheless, the intense proton background causes insufficient discrimination of tumor tissues from normal tissues. An important advancement in this field is the ^{19}F MRI technique (*3*), which may be capable of producing high-contrast *in vivo* images, since there is no endogenous ^{19}F in the body that might be a source of background noise. Note that ^{19}F is 100% naturally abundant and has an MR (magnetic resonance) sensitivity nearly as high as that of protons. A variety of stimuli-sensitive ^{19}F probes have been developed so far; however, the tumor diagnostic value of such probes under *in vivo* conditions is still controversial due to their nonspecific accumulation in normal tissues, preferential renal clearance, and low sensitivity of the ^{19}F MR chemical shift ($\Delta\delta$) to tumor environments. Thus, nonspecific interaction between the ^{19}F probe and biological components such as serum proteins and cells often leads to a moderate chemical-shift imaging resolution (*4*). A major key to the success of cancer diagnosis is believed to be the development of nanosized (<100 nm) and nonfouling ^{19}F probes capable of complete on−off regulation of the ^{19}F MR signal in response to the tumor environment, enabling ^{19}F MR signal intensity imaging after smooth accumulation in solid tumor tissues through the enhanced permeability and retention (EPR) effect (*5*).

In this regard, we newly designed and prepared for the first time nanosized and pH-sensitive ("smart") ^{19}F probes based on PEGylated nanogels constructed from a cross-linked polyamine gel core containing ^{19}F compounds and tethered PEG chains bearing an acetal group as a platform moiety to install ligand molecules. Because of the core−shell structure of the nanogels, the pH-sensitive PEGylated nanogels (*6*, *7*) exhibited excellent solubility in aqueous media, minimum interaction with biological components, and significant hydrophilic−hydrophobic (volume-phase) transition of the polyamine gel core in response to the extracellular pH of solid tumor tissues where the pH is 0.4−1.0 units lower than the physiological pH of ∼7.4 (*8*, *9*). A unique finding, which we would like to describe here, is the remarkable on−off regulation of the ^{19}F MR signal based on the molecular motion of the ^{19}F compounds synchronizing with the hydrophilic−hydrophobic transition of the polyamine gel core of the pH-sensitive PEGylated nanogels (Figure 1a), thus achieving appreciably enhanced ^{19}F MR signal at an extremely low ^{19}F probe concentration and at the intracellular pH typical of tumor environments.

Our strategy of formulating pH-sensitive PEGylated nanogels as smart ^{19}F MRI probes is based on the emulsion copolymerization of 2-(*N*,*N*-diethylamino)ethyl methacrylate (DEAMA: pH-sensitive component) and 2,2,2-trifluoroethyl methacrylate (TFEMA: ^{19}F compound) at various molar ratios in the presence of heterobifunctional PEG bearing an acetal group (ligand installation moiety) at the α-end and a 4-vinylbenzyl group at the ω-end (acetal-PEG−Ph−CH=CH$_2$: M_n = 5030, M_w/M_n = 1.04), potassium persulfate (KPS: initiator), and 1.0 mol % of ethylene glycol dimethacrylate (EGDMA: cross-linker) (Figure 1b). The compositions of the PEGylated nanogels were determined as the feed ratio, since the polymerization proceeded smoothly with complete consumption of the DEAMA and TFEMA within 1 h (100% conversion). Figure 2a shows the pH dependency of the diameters of the PEGylated nanogels containing various amounts of TFEMA. As the TFEMA mol % increased in the nanogel, the size variation of the PEGylated nanogels with unimodal size distribution ($\mu_2/\Gamma^2 < 0.155$) became small due to the increase in hydrophobic and non-ionizable PTFEMA segment, leading to a decrease in the ion osmotic pressure of the PDEAMA-*co*-PTFEMA gel core. Note that pH-sensitive PEGylated nanogels containing TFEMA showed volume phase transition points in the pH range 7.3−6.8, strongly suggesting that the swelling of PEGylated nanogels will occur

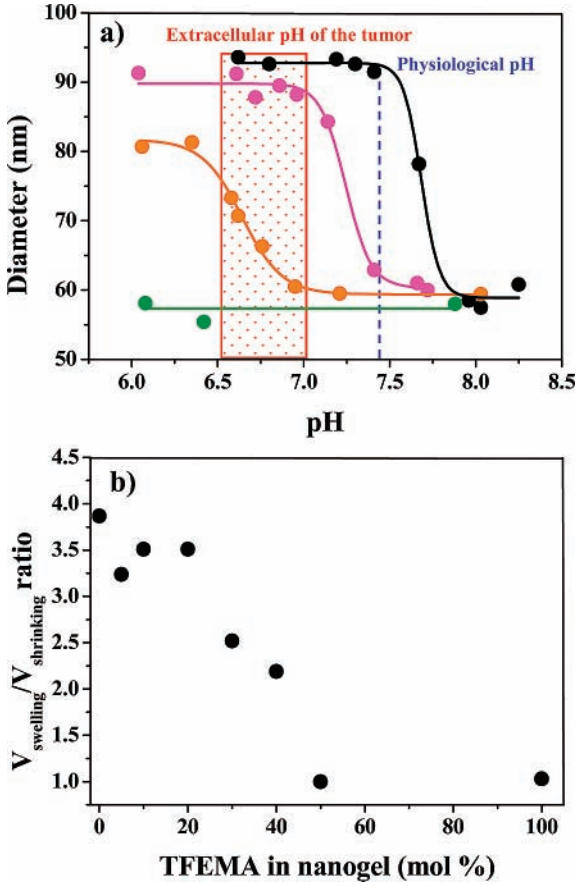

Figure 2. (a) pH dependency of the diameters of the PEGylated nanogels containing 0 (black), 10 (pink), 30 (orange), and 50 (green) mol % of TFEMA. (b) $V_{sweeling}/V_{shrinking}$ ratio of the PEGylated nanogels containing various amounts of TFEMA. (DLS measurement: angle, 90°; temperature, 37 °C; 10 mM phosphate buffer with 0.15 M NaCl).

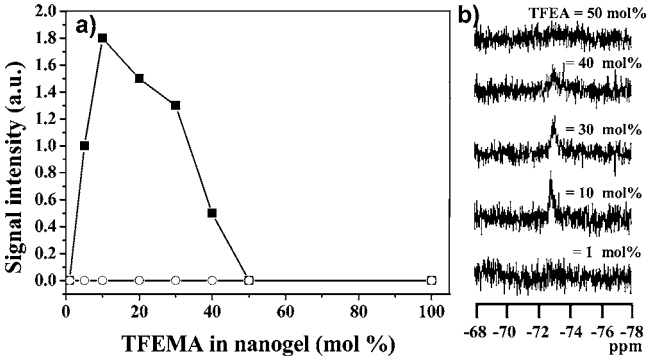

Figure 3. (a) Intensity of the ^{19}F MR signals of the PEGylated nanogels containing various amounts of TFEMA at pH 6.5 (■) and 7.4 (○). (b) ^{19}F NMR spectra of the pH-sensitive PEGylated nanogels containing various amounts of TFEMA at pH 6.5.

only at the extracellular pH of tumor tissues (7.0−6.5). In addition, there was a negligible change in the diameter (ca. 58 nm) of the PEGylated nanogels, because their highly hydrophobic core contains a TFEMA concentration of more than 50 mol %. The $V_{swelling}/V_{shrinking}$ ratio denotes the extent of hydrodynamic volume change at the volume phase transition point. Indeed, the $V_{swelling}/V_{shrinking}$ ratio for PEGylated nanogels containing the TFEMA component in the gel core was smaller than that of PEGylated nanogels without the TFEMA component (TFEMA = 0 mol %: $V_{swelling}/V_{shrinking}$ = 3.9), as shown in Figure 2b.

Figure 3a shows the intensity of the ^{19}F MR signal (ca. −73 ppm) from the ^{19}F compounds in the PEGylated nanogels (450 μg/mL), as measured by ^{19}F NMR spectroscopy at both the physiological pH (7.4) and the extracellular pH (6.5) of tumor environments. Note that almost no ^{19}F MR signal (background level) was observed at physiological pH (7.4), where the PDEAMA-*co*-PTFEMA gel core was hydrophobic owing to the deprotonation of the amino groups, *viz.*, the absence of ^{19}F MR signals is most likely due to the broadening effect caused by the limited molecular motion of the ^{19}F compounds in the hydrophobic (solid-state) gel core (*10*). In sharp contrast, the PEGylated nanogels in the TFEMA range 5−40 mol % showed

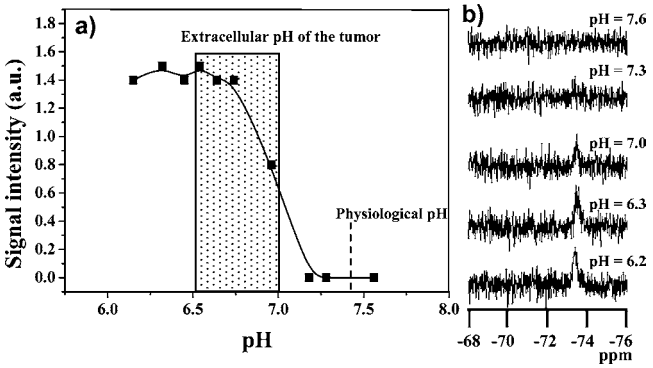

Figure 4. (a) pH dependency of the intensity of the ^{19}F MR signal from the PEGylated nanogel containing 10 mol % of TFEMA. (b) ^{19}F NMR spectra of the pH-sensitive PEGylated nanogels containing 10 mol % of TFEMA at various pH values.

clear ^{19}F MR signals at the extracellular pH (6.5) of tumor environments (Figure 3b). This complete on−off regulation of the ^{19}F MR signal by the pH-sensitive PEGylated nanogels is a remarkable characteristic of the tumor-specific ^{19}F MRI probe. Worth noting is that the signal intensity of the PEGylated nanogels in the TFEMA range 10−50 mol % is almost consistent with the $V_{swelling}/V_{shrinking}$ ratio of the PEGylated nanogels, as shown in Figure 2b. It should also be noted that the intensity of the ^{19}F MR signal of the PEGylated nanogels increased with decreasing TFEMA, *viz.*, the highest intensity of the ^{19}F MR signal was observed at TFEMA = 10 mol %. These findings strongly suggest that the PEGylated nanogels with a high $V_{swelling}/V_{shrinking}$ ratio have a more hydrophilic core and higher mobility than those with a low $V_{swelling}/V_{shrinking}$ ratio. On the other hand, the intensity of the ^{19}F MR signal of the PEGylated nanogels containing less than TFEMA = 5 mol % significantly decreased even though the $V_{swelling}/V_{shrinking}$ ratio was almost similar to that of PEGylated nanogels containing TFEMA = 10 mol %. This is most likely due to a lower TFEMA concentration ([TFEMA] = 83 μM) than that of PEGylated nanogel containing TFEMA = 10 mol % ([TFEMA] = 166 μM), because the weight concentration of all PEGylated nanogels was constant (450 μg/mL). Notably, the pH-sensitive PEGylated nanogel containing TFEMA = 10 mol % showed an increase in the intensity of the ^{19}F MR signal in synchronization with the decreasing pH as shown in Figure 4a,b; thus, this behavior is almost consistent with both the pH-dependent volume phase transition (Figure 2a) and the α/pH curve (Supporting Information Figure S2) of the PEGylated nanogel, indicating that the molecular motion of the ^{19}F compounds in the gel core plays a crucial role in the intensity of the ^{19}F MR signal in ^{19}F NMR spectroscopy.

The intensity of the ^{19}F MR signal of the pH-sensitive PEGylated nanogel containing TFEMA = 10 mol % was linearly correlated to the [TFEMA] concentration (in a dose-dependent manner) at the extracellular pH (=6.5) of tumor environments (Figure 5a), which could be related to the nanogel number, suggesting that it could be quantified by means of ^{19}F MRI *in vivo*. Notably, ^{19}F MR signal from the ^{19}F compounds in the PEGylated nanogel was observed at TFEMA concentration as low as ~55 μM. This finding is also remarkable because the ^{19}F probes (*11*) for ^{19}F MRI generally require concentrations in the millimolar range (~1 mM) in the buffer solution. Worth noting is that the pH-sensitive PEGylated nanogel containing TFEMA = 10 mol % was able to retain the on−off regulation of the ^{19}F MR signal even in the presence of 90% fetal bovine serum (FBS) (Figure 5b,c), which means that it can be used for *in vivo* applications.

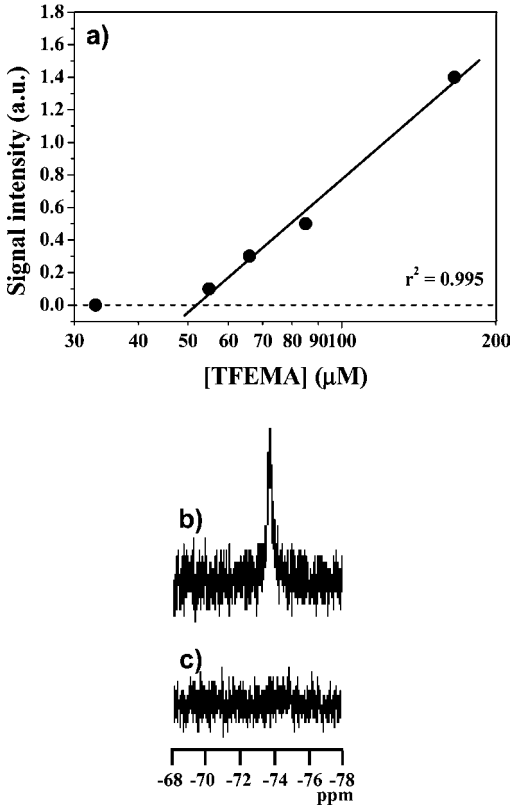

Figure 5. (a) Linear correlation of the intensity of the ^{19}F MR signal versus dilutions of the pH-sensitive PEGylated nanogel containing 10 mol % of TFEMA. ^{19}F NMR spectra of the pH-sensitive PEGylated nanogels containing 10 mol % of TFEMA in the presence of 90% FBS at (b) pH 6.5 and (c) pH 7.4. ([TEFMA] = 553 μM, at 37 °C; number of scans = 64).

In conclusion, the pH-sensitive PEGylated nanogels composed of a PDEAMA-*co*-PTFEMA gel core and tethered PEG chains exhibited significant ^{19}F MR signals at extremely low ^{19}F compound concentrations in response to the extracellular pH of tumor environments under ^{19}F NMR spectroscopy. Therefore, the construction of pH-sensitive PEGylated nanogel with appropriate ^{19}F compounds is a promising approach to the creation of tumor-specific smart ^{19}F MRI systems to be used *in vivo*. Furthermore, pH-sensitive PEGylated nanogels can also be utilized as pH-sensitive carriers in the anticancer drug delivery systems (*12*), *viz.*, the pH-sensitive PEGylated nanogel acts as a theranostic (therapeutic and diagnostic) nanodevice.

ARTICLES

Development of Poly(amino ester glycol urethane)/siRNA Polyplexes for Gene Silencing

S-ja Tseng and Shiue-Cheng Tang*

Department of Chemical Engineering, National Tsing Hua University, 101, Sec. 2, Kuang Fu Road, Hsinchu 300, Taiwan

Received December 11, 2006; Revised Manuscript Received April 2, 2007

Nonviral vectors, with their low immunogenicity and lack of pathogenicity, offer significant promise for siRNA therapy with fewer safety concerns. Nonviral vectors were also preferred in most transient siRNA delivery due to their ease of preparation. Previously, we incorporated tertiary amines and polyethylene glycol (PEG) into poly(ester urethane) to synthesize a soluble poly(amino ester glycol urethane), PaE_GU, as a novel DNA transfection reagent for transgene delivery. The aim of this study was to develop PaE_GU/siRNA polyplexes for gene silencing. We characterized the properties of PaE_GU/siRNA polyplexes and compared them with those of PaE_GU/DNA polyplexes. Using the Alexa Fluor 488-labeled, nonsilencing control siRNA as the reporter, we visualized cellular uptake of PaE_GU/siRNA polyplexes and optimized the mass ratio of PaE_GU/siRNA for delivery at 80/1. At this ratio, the average diameter of polyplexes was 540 nm, which was significantly larger than the average diameter of PaE_GU/DNA polyplexes at 155 nm for efficient DNA delivery. Using the optimized PaE_GU/siRNA polyplexes, transient silencing of constitutive luciferase expression (up to 92%) was achieved in our recombinant human HT-1080 fibroblast model via anti-luciferase siRNA delivery. In conclusion, PaE_GU/siRNA polyplexes were developed and optimized for cellular uptake to allow efficient gene silencing. Engineering of soluble biodegradable polymers to incorporate amino, ester, PEG, and urethane units in the backbone constitutes a useful approach for the future design of siRNA carriers.

INTRODUCTION

The emergence of small interfering RNA (siRNA) to inhibit gene expression in a sequence-specific fashion has initiated an industry of manufacturing synthetic RNA. However, a major challenge to the continued development and therapeutic application of siRNA is the design of suitable vectors for its delivery. Nonviral vectors are preferred over viral vectors for most transient studies due to their ease of preparation. More importantly, the low immunogenicity and lack of pathogenicity of nonviral vectors offer promise for siRNA therapy with fewer safety concerns (*1*−*4*).

Transfection reagents formulated by biodegradable polymers are good candidates for delivery of nucleic acids, including siRNA (*5*−*12*). These polymers can be modified with positively charged amine groups for electrostatic interaction with nucleic acids and bridged with hydrolytically unstable linkages, such as ester or urethane linkages, to induce biodegradability and generate nontoxic degraded compounds. In addition, cationic polymers have been shown to provide pH-buffering ability, allowing the formation of a "proton sponge" to assist in the escape of vectors from the endocytosis pathway and improve transfection efficiency (*13*−*15*).

Poly(ester urethane), PEU, is a class of biodegradable polymer that has been applied as a tissue-engineering scaffold with minimal cytotoxicity *in vitro* and *in vivo* (*16*−*20*). Previously, we developed a method of incorporating tertiary amines and polyethylene glycol (PEG) into PEU to synthesize a soluble poly(amino ester glycol urethane), PaE_GU (Figure 1A), as a novel DNA transfection reagent (*21*). Our study showed that PaE_GU exhibited faster hydrolysis kinetics than the control reagent poly(amino ester), half-lives of 19 h and 36 h for PaE_GU and poly(amino ester), respectively, in the phosphate buffer saline at 37 °C, which underscored PaE_GU's unique property of low cytotoxicity.

The aim of this study was to develop PaE_GU/siRNA polyplexes for gene silencing. Our previous results showed that PaE_GU was capable of mediating DNA transfection for transgene expression. For gene silencing, however, it is unclear whether PaE_GU remains effective in mediating siRNA delivery, because no reports have characterized the interaction of PEU-based vectors with siRNA. There are two important differences between siRNA and DNA transfection. First, the size of siRNA (21−23 base pairs) is significantly smaller than that of the gene-encoding DNA molecule by 2 orders of magnitude in molecular weight. Second, unlike the requirement for nuclear delivery in DNA transfection, siRNA is active within the cytoplasm, and therefore polymer/siRNA polyplexes cannot be too stable in withholding the RNA molecules (*6*, *22*). For instance, poly(ethylene imine) (PEI)-mediated siRNA delivery for gene silencing was observed only in a narrow window of conditions (*23*), in comparison to the efficiency and ease of use of PEI-mediated DNA delivery for transgene expression. We characterized and optimized PaE_GU/siRNA polyplexes for cellular uptake in this research. The results on developing PaE_GU/siRNA polyplexes for gene silencing and comparing the properties of PaE_GU/siRNA and PaE_GU/DNA polyplexes are presented and discussed.

EXPERIMENTAL PROCEDURES

Chemicals and siRNA. 2-Diethylaminoethylamine, 2-hydroxyethyl acrylate, dibutyltin dilaurate, tetrahydrofuran (THF), and *N*,*N*-dimethylformamide (DMF) were purchased from Fluka (Buchs, Switzerland) and were dried by passing them over calcium hydride and then distilled before use. Phosphate-buffered saline (PBS, pH 7.4) was purchased from Sigma Co. (St. Louis, MO). Poly(ethylene glycol) acrylate (MW = 375), 1,4-diisocyanatobutane, and poly(ethylene imine) (PEI, MW = 25 000) were purchased from Aldrich (Milwaukee, WI). The siRNA duplexes targeting luciferase (Luciferase GL3 siRNA) and EGFP (GFP-22 siRNA) and the Alexa Fluor 488, 5′-labeled siRNA with control scrambled sequence (Alexa Fluor 488-siRNA) were purchased from Qiagen (Deutschland, Germany). The siRNA sense sequences were luciferase, 5′-CUUACGCUGAGUACUUCGAdTdT-3′ and EGFP, 5′-GCAAGCUGACCCUGAAGUUCAUdTdT-3′; the control scrambled sequence was 5′-UUCUCCGAACGUGUCACGUdTdT-3′.

Cell Culture and Generation of Recombinant HT-1080 Fibroblasts with Constitutive Luciferase and EGFP Expression. Human HT-1080 fibroblasts (ATCC, Manassas, VA) were grown in Dulbecco's modified Eagle's medium (DMEM, Biosource, Rockville, MD) supplemented with 10% fetal bovine serum, 100 U/mL penicillin, and 100 μg/mL streptomycin at 37 °C in a humidified atmosphere of 5% CO_2. The plasmid pAAV−luciferase−EGFP, used to engineer HT-1080 cells into stable luciferase and EGFP expression cells, was constructed as previously described by Tang et al. (*24*). The dual expression cassettes of luciferase (CMV-driven) and EGFP (SV40-driven) are shown in Figure 1B. Plasmid pSV40−Puro, carrying the expression cassette of puromycin-resistant gene as a selection maker (Figure 1C), was constructed by cloning the 0.6-kb cDNA of puromycin-resistant gene (HindIII/XbaI fragment) from pIRESpuro (Clontech, Mountain View, CA) downstream of the SV40 promoter in pGL3-Control (Promega, Madison, WI) to replace the firefly luciferase cDNA and yield pSV40−Puro.

We applied a cotransfection of plasmids pAAV−luciferase−EGFP and pSV40−Puro to generate and select the recombinant HT-1080 fibroblasts which constitutively expressed puromycin, luciferase, and EGFP. When HT-1080 cells reached roughly 60−70% confluency, they were transfected using the FUGENE 6 reagent (Roche, Indianapolis, IN) according to the manufacturer's protocol. Cells were incubated for 24 h in a 40-mm culture dish with the culture medium (without penicillin and streptomycin) containing the plasmid pAAV−luciferase−EGFP (1 μg), plasmid pSV40−Puro (50 ng), and the FUGENE 6 reagent (3 μL). Cells were cultured for an additional 24 h for recovery after transfection. Cells were then trypsinized and split in 1:100 ratio into 100-mm culture dishes. During the selection process, which lasted over three weeks, cells were cultured in the presence of 1 μg/mL puromycin. Surviving cells formed colonies, which could be seen clearly under a microscope. Cells that expressed EGFP were identified, retrieved, and plated into the wells of a 24-well plate for expansion and later for tests of luciferase expression. Only cells that survived under puromycin selection and expressed both EGFP and luciferase were preserved for future use.

Synthesis and Characterization of Poly(amino ester glycol urethane), PaE$_G$U. PaE$_G$U was synthesized as previously described by Tseng and Tang (*21*). Briefly, poly(ethylene glycol) acrylate and 2-diethylaminoethylamine with a C═C/NH_2 molar ratio of 2/1.1 were mixed in anhydrous THF solvent under liquid nitrogen purge inside a reaction flask. The mixture was heated to 50 °C for reaction for 48 h to generate the monomer PEGamine-diol. In the second reaction, the synthesized PEGamine-diol and 1,4-diisocyanatobutane with a OH/NCO molar ratio of 1/1.1 were mixed in anhydrous DMF solvent in a three-necked reaction flask under dry nitrogen purge. The mixture was then heated to 70 °C for reaction for 6 h with 10 wt % dibutyltin dilaurate as the catalyst. An excess amount of methanol was slowly added into the reaction mixtures until no unreacted isocyanate groups were detected. After reaction, PaE$_G$U was precipitated in anhydrous ethyl ether and vacuum-dried at 40 °C.

The designated functional groups and polymer structure were confirmed by the FT-IR and the ^{1}H and ^{13}C NMR spectra. The molecular weight of PaE$_G$U was determined by high-performance liquid chromatography/gel permeation chromatography analysis (HPLC/GPC, Waters model LC-2410). The synthesized PaE$_G$U had a weight-average molecular weight of 17 500 and a polydispersity index of 1.4.

Preparation and Characterization of PaE$_G$U/siRNA Polyplexes. To prepare PaE$_G$U/siRNA polyplexes, 5.0 mg of PaE$_G$U was dissolved in PBS (pH 7.4) and mixed with Alexa Fluor 488-siRNA at mass ratios ranging from 10/1 to 100/1. The PaE$_G$U/siRNA mixture was incubated at room temperature for 30 min to allow self-assembly of polyplexes before further characterization. The hydrodynamic sizes of polyplexes were measured using a Zetasizer Nano ZS (3000HS, Malvern Instruments Ltd., Worcestershire, U.K.). The surface charges of polyplexes were determined by the electrophoretic mobility at 25 °C with a zeta-potential system (Nicomp Instrument, Santa Barbara, CA). The electrostatic interaction between PaE$_G$U and siRNA was evaluated by a gel retardation assay. In this assay, electrophoresis was carried out with different mass ratios of PaE$_G$U/siRNA polyplexes loaded into parallel wells of a 0.7% agarose gel in a Tris-acetate-EDTA (TAE) buffer. Polymer-free siRNA was used as the control. RNA duplexes ladder (Qiagen) with the smallest base pairs at 21 was used as a size reference. Electrophoresis was performed at 100 V for 35 min. The retardation of the polyplexes was visualized by staining with ethidium bromide.

Optimizing PaE$_G$U/siRNA Transfection. Prior to delivering the siRNA of interest for targeted gene silencing, we optimized transfection conditions using the Alexa Fluor 488-siRNA as the reporter. PaE$_G$U/siRNA polyplexes for transfection were prepared by incubating various amounts of PaE$_G$U (in PBS) with 1 μg of siRNA (in DMEM), with PaE$_G$U/siRNA mass ratios ranging from 40/1 to 200/1 for 30 min. In parallel, PEI/siRNA and Lipofectamine RNAiMAX (Lipofectamine, Invitrogen, Carlsbad, CA)/siRNA polyplexes were prepared as controls. PEI/siRNA polyplexes were prepared by incubating various amounts of PEI (in PBS) with 1 μg of siRNA (in DMEM), with PEI/siRNA mass ratios ranging from 0.5/1 to 5/1 for 30 min. Lipofectamine/siRNA polyplexes were prepared by incubating various volumes of Lipofectamine (μL) with 1 μg of siRNA (in DMEM), with Lipofectamine/siRNA ratios ranging from 2.5 μL/1 μg to 7.5 μL/1 μg for 30 min. Culture medium (without antibiotics) was then added to the mixture for adjusting the final volume to 1100 μL. Transfection was carried out by exposing cells on the 40-mm dish to the 1100-μL transfection cocktail. Approximately 24 h later, 2 mL of complete DMEM medium was added to the culture without removing the polymer/siRNA polyplexes, and cells were incubated for an additional 24 h before flow cytometry analysis.

Flow cytometry analysis of Alexa Fluor-488 positive cells was carried out using the FACSCalibur (Becton Dickinson) benchtop flow cytometer equipped with an argon laser at 488 nm excitation and a band-pass filter at 505−530 nm to detect the Alexa Fluor 488-labeled cells. Untransfected cells were used as the control. The cells were appropriately gated by forward and side scatters and 10 000 events per sample were collected. Additionally, transfected fibroblast monolayers were imaged by the Nikon ECLIPSE TS100-F fluorescence microscope for Alexa Fluor 488 detection with a Nikon GFP-L filter set (EX 480/40, DM 505, BA 510).

Silencing Luciferase and EGFP Expression. Recombinant HT-1080 cells, with constitutive luciferase and EGFP expression, were seeded in the wells of a 12-well plate overnight prior to transfection. Cells at various numbers, ranging from 2×10^4 to 5×10^5, were then treated with PaE$_G$U/siRNA (Luciferase GL3, Qiagen) polyplexes at 80/1 (μg/μg), PEI/siRNA polyplexes at 2/1 (μg/μg), or Lipofectamine/siRNA polyplexes at 5/1 (μL/μg) for silencing luciferase expression. At time = 0, 12, 24, 36, and 48 h, luciferase activity in transfected cells was measured with the luciferase assay system (Promega) according to the manufacturer's protocol and with a 20/20^n luminometer (Turner Biosystems, Sunnyvale, CA).

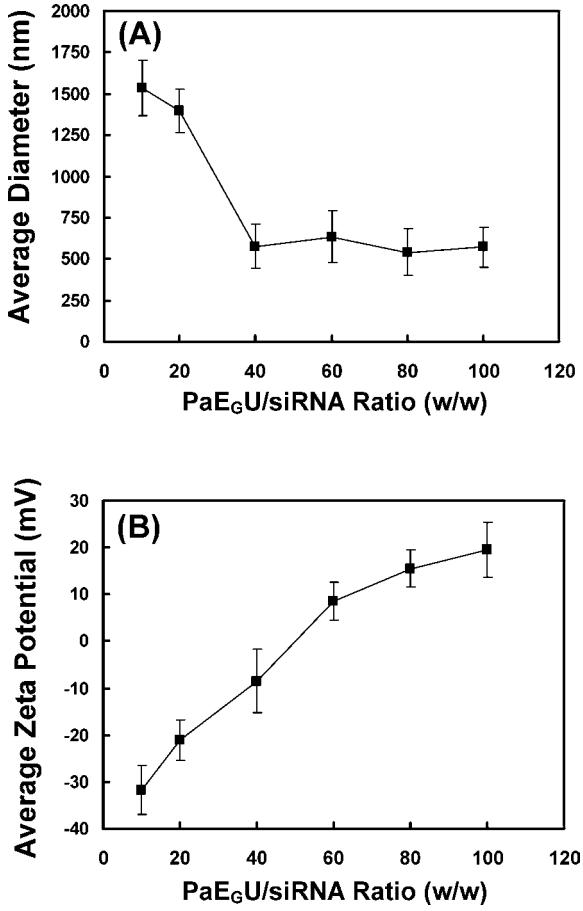

Figure 2. Size (A) and zeta-potential (B) of PaE$_G$U/siRNA polyplexes at different PaE$_G$U/siRNA mass ratios (w/w). Results are presented as mean ± standard deviation (n = 3).

We also evaluated the dose-dependent effect of PaE$_G$U/siRNA polyplexes on silencing luciferase expression. A half-million cells in each well of a 12-well plate were transfected with PaE$_G$U/siRNA polyplexes at different concentrations but at a fixed ratio of 80/1 (w/w). Luciferase activity was analyzed 36 h posttransfection. Silencing of EGFP using PaE$_G$U/GFP-22 siRNA polyplexes was performed in parallel with silencing of luciferase. The decrease in EGFP expression was visualized by the Nikon ECLIPSE TS100-F fluorescence microscope using the same settings as those for Alexa Fluor 488 detection. Untreated recombinant HT-1080 cells were used as the control.

Evaluation of PaE$_G$U/siRNA Cytotoxicity. The mitochondrial activity of PaE$_G$U/siRNA treated cells was measured using the CellTiter 96 AQueous one solution cell proliferation assay system (an MTS assay, Promega) according to the manufacturer's protocol. In this cell viability/proliferation assay, cells were treated with PaE$_G$U/siRNA or PEI/siRNA (control) polyplexes at various polymer/siRNA ratios for 36 h prior to the MTS assay. To compare the cytotoxicity of PaE$_G$U/siRNA (88 μg/1.1 μg) and Lipofectamine/siRNA polyplexes (3.3 μL/1 μg, following manufacturer's recommended dose), HT-1080 cells in 40-mm dishes were treated with polymer/siRNA polyplexes for 6 h and then replaced with polyplexes-free medium for another 30 h (a total of 36 h), or cells were treated with polyplexes for 36 h prior to the MTS assay. The methoxyphenyltetrazolium salt (MTS) compound was reduced by viable cells to form a colored formazan product, which was quantified colorimetrically at 490 nm using a spectrofluorometer (Sunrise/Tedan, Austria). GFP-22 siRNA (Qiagen) was used in this cytotoxicity experiment. Untreated HT-1080 cells were used as the control.

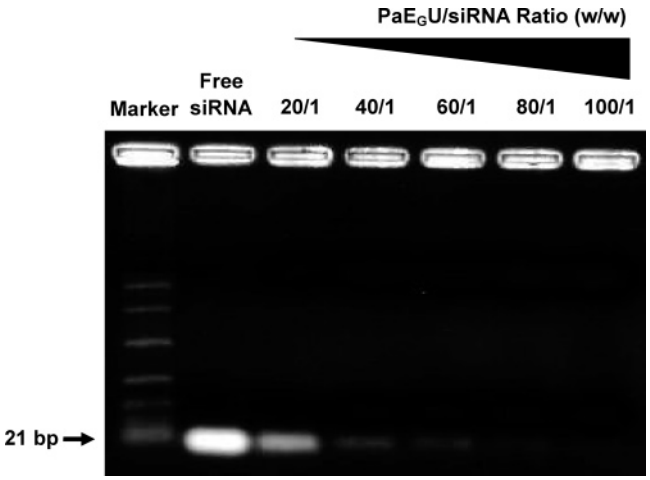

Figure 3. Gel retardation analysis of the PaE_GU/siRNA polyplexes. Migration of the PaE_GU/siRNA polyplexes in agarose gel at mass ratios varying from 20/1 to 100/1.

Dissociation Kinetics of Polymer/siRNA Polyplexes. Dissociation of polymer/siRNA polyplexes over time was assessed by measuring the fluorescence intensity generated from the Alexa Fluor 488-siRNA in PBS solution (pH 7.4) at 37 °C. PaE_GU/siRNA and PEI/siRNA polyplexes were prepared 80/1 (w/w) and 2/1 (w/w), respectively, and diluted to yield a concentration of 1-μg siRNA in a 200-μL solution. The 200-μL solution was then transferred to each well of an opaque black 96-well plate for analysis. The change of fluorescence intensity over time was recorded using the kinetic mode of the Molecular Devices SpectraMax M2^e microplate spectrofluorometer (Sunnyvale, CA) with settings of excitation wavelength at 485 nm and emission filter at 515 nm. Free Alexa Fluor 488-siRNA was used as the control.

RESULTS AND DISCUSSION

Characterization of PaE_GU/siRNA Polyplexes. We have previously developed PaE_GU/DNA polyplexes carrying the EGFP or β-galactosidase reporter gene for transfection (*21*). The sizes of DNA molecules were 5.4 and 7.8 kilobase pairs for EGFP and β-galactosidase-encoding genes, respectively, which were significantly larger than the size of siRNA at 21−23 base pairs by >230-fold in molecular weight. It was unclear whether siRNA would mimic DNA in forming polyplexes with PaE_GU in a similar fashion. We thus sought to characterize the particle size and zeta-potential of PaE_GU/siRNA polyplexes, and we compared them with those of PaE_GU/DNA polyplexes.

Figure 2A shows that the particle size decreased following an increase in the PaE_GU/siRNA (Alexa Fluor 488-labeled, nonsilencing control siRNA) mass ratio and reached a plateau when the ratio was larger than 40/1. We have previously observed a similar change in the size of PaE_GU/DNA polyplexes following an increase in the PaE_GU/DNA mass ratio (*21*). However, at the same PaE_GU/nucleic acids mass ratio, the sizes of PaE_GU/siRNA polyplexes were 3.4−6.5-fold larger than those of PaE_GU/DNA polyplexes in general. Figure 2B shows the zeta potential values of PaE_GU/siRNA polyplexes at the mass ratios ranging from 10/1 to 100/1 (w/w). The zeta potential steadily changed toward positive values associated with an increase in mass ratio. The values became larger than zero when the mass ratio was ≥60/1. Positively charged polyplexes were expected to bind to cellular membranes and to be taken up into cells by endocytosis.

We next studied the electrostatic interaction between PaE_GU and siRNA in the gel retardation assay. Figure 3 shows that the PaE_GU was able to partially retard siRNA in the agarose gel at the PaE_GU/siRNA mass ratio of 20/1 (lane 3) and efficiently retard siRNA at mass ratios ≥ 40/1 (lane 4), indicating that strong binding occurred between the negatively charged siRNA and the cationic PaE_GU and confirming the formation of PaE_GU/siRNA polyplexes.

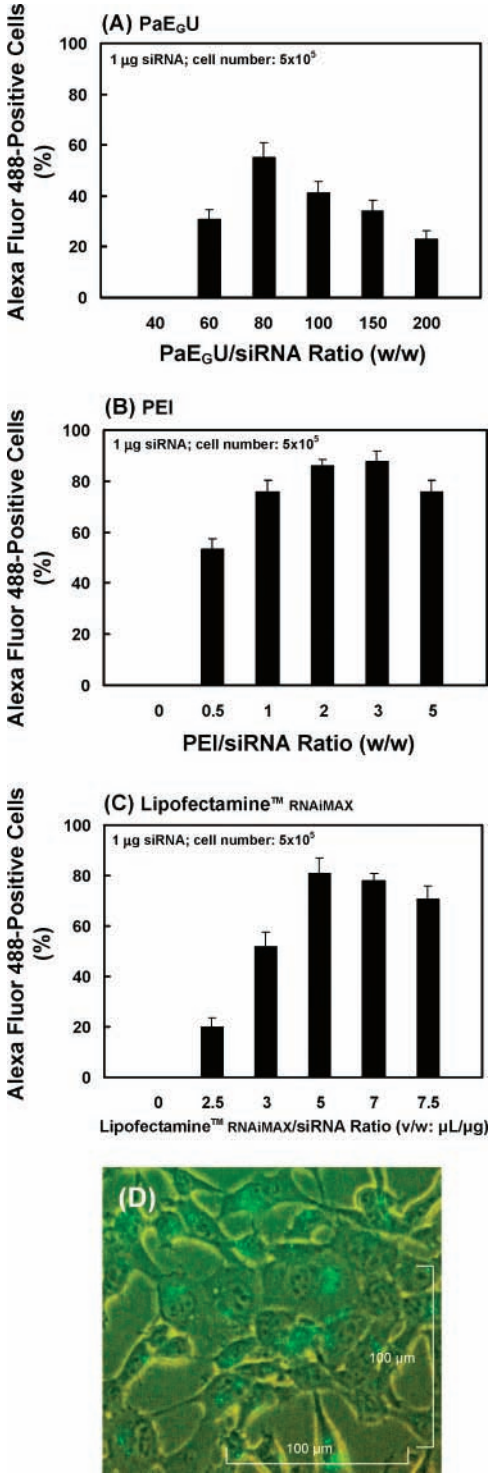

Figure 4. Alexa Fluor 488-positive cells (%) of PaE_GU (A), PEI (B), and Lipofectamine RNAiMAX (C)-mediated transfections. PEI and Lipofectamine transfections were used as controls. The percentage of positive cells was analyzed by fluorescence-activated flow cytometry. Results are presented as mean ± standard deviation (n = 3). control siRNA as the reporter to optimize the mass ratio of PaE$_G$U/siRNA for transfection and visualize the cellular uptake of polyplexes. Human HT-1080 fibroblasts grown as monolayers were transfected at various PaE$_G$U/siRNA mass ratios. Shortly after transfection (2−3 h), small amounts of Alexa Fluor 488-positive cells could be identified under the fluorescence microscope; six to 7 h after transfection, a significant number of fluorescent cells could be seen.

Fluorescence-activated flow cytometry was applied 48 h after transfection to quantify the percentage of fluorescence-positive cells, which can be considered as the average transfection efficiency (Figure 4A). The highest efficiency of PaE$_G$U-mediated transfection occurred at the polymer/siRNA mass ratio of 80/1, which generated 55% of Alexa Fluor 488-positive cells. In parallel, we applied PEI/siRNA and Lipofectamine/siRNA polyplexes as controls. Among the test conditions, the highest efficiency of PEI/siRNA and Lipofectamine/siRNA transfection generated 87% and 81% of fluorescence-positive cells (Figures 4B and 4C), respectively, indicating that PaE$_G$U was less efficient as a siRNA carrier in comparison to PEI and Lipofectamine.

Figure 4D shows a typical fluorescence micrograph of PaE$_G$U/siRNA (80/1) transfected cells 12 h posttransfection. A diffuse distribution of fluorescence-positive cells indicated a successful delivery of PaE$_G$U/siRNA polyplexes. The cellular uptake of PaE$_G$U/siRNA can be attributed to the polyplexes' positive surface charge (Figure 2B, when the mass ratio was ≥60/1), which facilitated their interaction with the negatively charged cellular membrane. On the other hand, when the surface charge

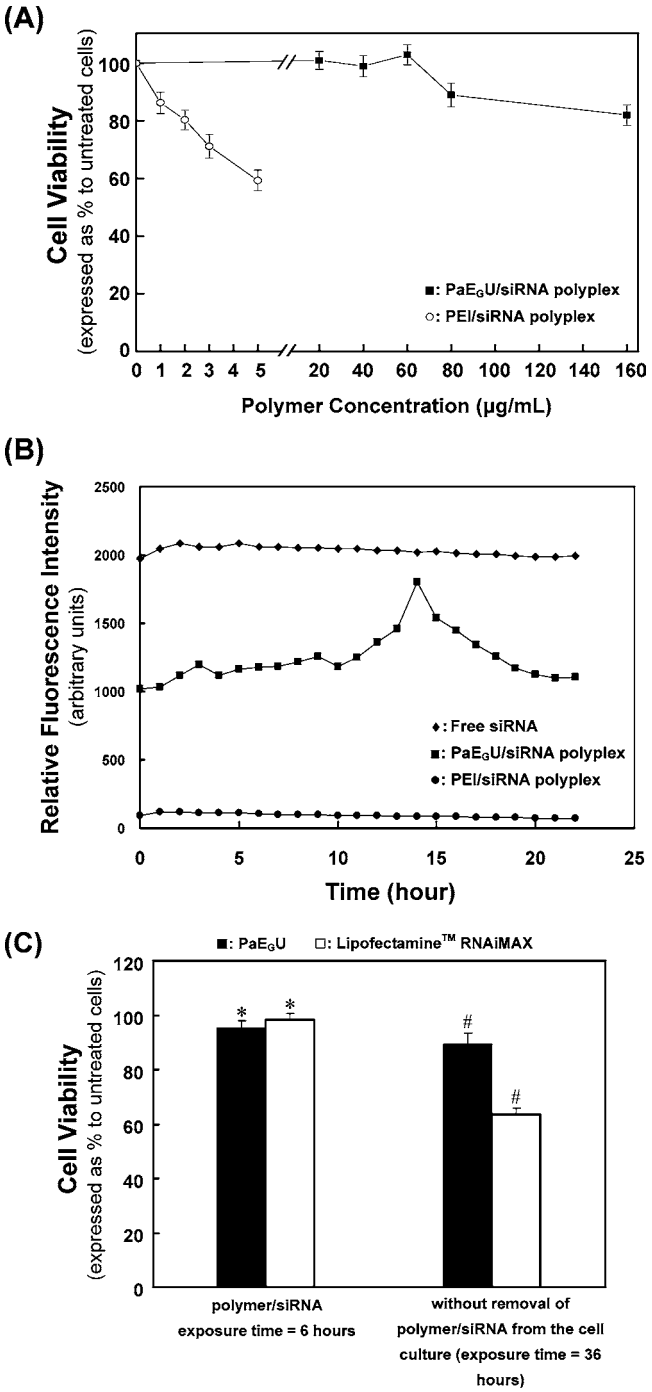

Figure 7. (A) Assessment of cell viability (MTS assay) after treatment with PaE_GU/siRNA or PEI/siRNA polyplexes. The viability of untreated HT-1080 cells was assigned a value of 100. Results are presented as mean ± standard deviation ($n = 3$). (B) Dissociation kinetics of PaE_GU/siRNA and PEI/siRNA polyplexes in PBS at 37 °C. The Alexa Fluor 488-siRNA was used as the reporter. Free Alexa Fluor 488-siRNA was used as the control. (C) Comparative cytotoxicity of PaE_GU/siRNA and Lipofectamine RNAiMAX/siRNA polyplexes. The viability of untreated HT-1080 cells was assigned a value of 100. ∗indicates $P = 0.18$. # indicates P value <0.002. P values were calculated using a two-tailed t test, assuming unequal variances. Results are presented as mean ± standard deviation ($n = 3$).

of PaE_GU/siRNA polyplexes was negative at the mass ratio of 40/1 (Figure 2B), the efficiency of siRNA delivery was zero (Figure 4A).

Interestingly, at the optimized ratio (80/1) for siRNA delivery, the average diameter of polyplexes was 540 nm (Figure 2A), which was 3.5-fold larger than the average diameter of PaE_GU/DNA polyplexes at 155 nm for efficient DNA delivery (*21*). Similar uptake of large fluorescent particles with an average size of 900 nm in diameter has been applied for endosomal labeling of mesenchymal stem cells, suggesting that PaE_GU/siRNA polyplexes could follow a similar endocytic pathway (*25*, *26*).

Gene Silencing via PaE_GU/siRNA Polyplexes Delivery. Cellular uptake of the labeled siRNA did not necessarily indicate that the internalized siRNA would be incorporated into the RNA-induced silencing complexes (RISCs) and in turn inhibit the target gene expression. Therefore, we sought to investigate RNA interference of endogenous protein expression. We created a model recombinant human HT-1080 fibroblast line, which stably expressed both luciferase and EGFP reporters, to evaluate target gene silencing. Detailed procedures were described in Experimental Procedures.

A transient suppression profile of luciferase expression was observed (Figure 5A) after the recombinant HT-1080 cells were transfected with PaE_GU/anti-luciferase siRNA polyplexes at the mass ratio of 80/1. The efficiency of gene silencing depended on the number of the targeted cells; the lower the cell number, the higher the siRNA dose per cell and the stronger the suppression. Among our test conditions, the highest efficiency of gene silencing occurred when 2×10^4 cells were transfected with PaE_GU/siRNA (80 μg/1 μg) for 12 h; in this situation, 92% of luciferase expression was suppressed relative to that in the untransfected recombinant HT-1080 cells. Under the same conditions, a similar efficiency of gene silencing, 88% and 84% for PEI/siRNA (2 μg/1 μg) and Lipofectamine/siRNA (5 μL/1 μg) transfections, were observed (Figures 5B and 5C) at 12 h posttransfection, respectively. However, unlike the mild PaE_GU transfection, PEI and Lipofectamine transfections were cytotoxic, especially toward the culture with fewer cell numbers. Thus, to avoid cell death, fresh culture media were used to replace the PEI and Lipofectamine transfection cocktails 12 h after the kinetics study. Figure 5D shows a dose-dependent suppression of PaE_GU-mediated siRNA delivery. Approximately 50% suppression of luciferase expression was achieved when 5×10^5 cells were transfected with the polyplexes consisting of 88 μg PaE_GU and 1.1 μg siRNA at the mass ratio of 80/1.

A similar result of gene silencing via PaE_GU/anti-EGFP siRNA delivery is illustrated in Figure 6, where the decrease in reporter EGFP expression was revealed by fluorescence micrographs. Figure 6A shows a typical fluorescence micrograph of EGFP expression in our model recombinant HT-1080 cells. Thirty-six hours after transfection, a decrease in fluorescence intensity of the transfected recombinant HT-1080 cells was observed (Figure 6B), in comparison to that of the untransfected control cells (Figure 6A). However, the turn-off of fluorescence from the recombinant cells was incomplete. This incomplete fluorescence suppression could be due to the long half-life of EGFP (>24 h, in comparison to 2 h for luciferase) leading to continuous emission of fluorescence from the residual EGFP molecules in the transfected cells, even when the EGFP mRNA was silenced by the anti-EGFP siRNA delivery (*27*, *28*).

Cytotoxicity of PaE_GU/siRNA Polyplexes. The cytotoxicity of PaE_GU/siRNA polyplexes was accessed in the HT-1080 cell culture by analyzing the mitochondrial activity (an MTS assay). As shown in Figure 7A, the cell viability of HT-1080 cells was at 89% when the PaE_GU concentration was at 80 μg/mL, after cells were incubated with PaE_GU/siRNA (80/1, w/w) for 36 h. Even when the concentration of PaE_GU reached 160 μg/mL, the cell viability was still approximately 82%, in contrast to 59% for 5 μg/mL of PEI (complexed with siRNA, 2/1, w/w), one of the commonly used cationic polymers for DNA and siRNA delivery (*29*−*33*).

Figure 7B shows the dissociation kinetics of polymer/siRNA polyplexes. The fluorescence intensity of PEI/Alexa Fluor 488-

siRNA polyplexes was low (1/20 of the intensity of free siRNA) and steady in PBS at 37 °C over a period of 22 h, suggesting a very stable PEI/siRNA structure. Cellular accumulation of nondegradable cationic polymer, such as PEI, could cause severe cytotoxicity, as indicated in Figure 7A and in other reports (*34*). On the other hand, the fluorescence intensity of PaE_GU/Alexa Fluor 488-siRNA polyplexes was higher than that of the PEI/siRNA polyplexes by 10-fold at time = 0 (1/2 of the intensity of free siRNA) and continuously increased and peaked at time = 14 h. This result suggested an unstable structure of the PaE_GU/siRNA polyplexes, underscoring the degradability of PaE_GU and its low cytotoxicity (*21*). The decline in fluorescence intensity after the peak could arise from the reassociation of Alexa Fluor 488-siRNA with the degraded PaE_GU to shed the absorption and/or emission of photons in the assay.

Figure 7C compares PaE_GU with the siRNA transfection reagent Lipofectamine in cytotoxicity. When cells were treated with polymer/siRNA for 6 h and then followed by reagent removal and another 30 h of cultivation in fresh medium, the viabilities of PaE_GU/siRNA (88 μg/1.1 μg)- and Lipofectamine/siRNA (3.3 μL/1 μg, recommended dose)-treated cells in 40-mm culture dishes were at 95% and 98%, respectively, and had no significant difference between them ($n = 3$; $P = 0.18$). However, when the administered polymer/siRNA polyplexes were left in the culture medium, mimicking an irretrievable situation of *in vivo* administration, the viability of Lipofectamine/siRNA-treated cells dropped to 63% from 98%, or by 35%. By contrast, PaE_GU/siRNA marginally decreased the viability to 89% from 95%, or by 6%, indicating that PaE_GU/siRNA was mild and exhibited little toxicity toward the target cells.

CONCLUSIONS

The present study constitutes an important step toward using poly(ester urethane (PEU)-based polymers to develop siRNA carriers while eliciting minimal cytotoxicity. We have demonstrated that PaE_GU, an engineered PEU with amine and PEG units in the backbone, was able to associate with siRNA through electrostatic interaction and led to self-assembly of polyplexes. Despite the average diameters of PaE_GU/siRNA polyplexes at 540 nm, 3.5-fold larger than the average diameters of PaE_GU/DNA polyplexes at 155 nm, efficient cellular uptake of PaE_GU/siRNA polyplexes was identified at the optimized PaE_GU/siRNA mass ratio of 80/1. At this ratio, transient silencing of constitutive luciferase expression (up to 92%) was achieved in the model recombinant human HT-1080 fibroblast line via anti-luciferase siRNA delivery. Our work thus provides a unique, PEU-based siRNA polyplex system for gene silencing, which is expected to be useful for the future design of siRNA carriers.

Treatment of human diseases such as cancer generally involves the sequential use of diagnostic tools and therapeutic modalities. Multifunctional platforms combining therapeutic and diagnostic imaging functions in a single vehicle promise to change this paradigm. in particular, nanoparticle-based multifunctional platforms offer the potential to improve the pharmacokinetics of drug formulations, while providing attachment sites for diagnostic imaging and disease targeting features. We have applied these principles to the delivery of small interfering RNA (siRNA) therapeutics, where systemic delivery is hampered by rapid excretion and nontargeted tissue distribution. Using a PEGlyated quantum dot (QD) core as a scaffold, siRNA and tumor-homing peptides (F3) were conjugated to functional groups on the particle's surface. We found that the homing peptide was required for targeted internalization by tumor cells, and that siRNA cargo could be coattached without affecting the function of the peptide. Using an EGFP model system, the role of conjugation chemistry was investigated, with siRNA attached to the particle by disulfide cross-linkers showing greater silencing efficiency than when attached by a nonreducible thioether linkage. Since each particle contains a limited number of attachment sites, we further explored the tradeoff between number of F3 peptides and the number of siRNA per particle, leading to an optimized formulation. Delivery of these F3/siRNA−QDs to EGFP-transfected HeLa cells and release from their endosomal entrapment led to significant knockdown of EGFP signal. By designing the siRNA sequence against a therapeutic target (e.g., oncogene) instead of EGFP, this technology may be ultimately adapted to simultaneously treat and image metastatic cancer.

INTRODUCTION

The development of multifunctional nanoparticles for treatment of focal disease is attractive for several reasons: they exhibit unique pharmacokinetics including minimal renal filtration, they have high surface to volume ratios enabling modification with surface functional groups that can be used to specifically target the delivery of therapeutic agents to sites of disease, and they can serve as vehicles for integration of diagnostic imaging and therapeutic drug delivery, a potentially transformative clinical paradigm. Use of a nanoparticle imaging core that is decorated with functional moieties provides a strategy that is particularly amenable to modular design of a multifunctional nanoparticle where features may be interchanged or combined to tailor formulations for a plethora of applications. In an attempt to move toward this goal, we have previously combined peptides derived from phage display- a powerful biological screening technique- with fluorescent semiconductor quantum dots to target multivalent nanoparticles to tumors (*1*). In this report, we further explore the feasibility of incorporating an oligonucleotide-based therapeutic cargo, siRNA. Short, double-stranded small-interfering-RNAs (siRNA) are one manifestation of a phenomenon known as RNA interference whereby translation of a target protein is inhibited. This type of therapeutic cargo is of particular interest in recent years because it has the potential to modulate so-called 'nondruggable' targets (*2*, *3*).

The *untargeted*, systemic delivery of siRNA has been explored by conglomeration of duplexes into nanosized complexes that reduce their renal filtration rates, extending the circulation half-life well beyond the ∼6 min observed for unmodified siRNA (*4*). For example, cholesterol−siRNA conjugates bind serum albumin after intravenous injection, forming long-circulating "natural" nanoparticles (*4*). Similarly, siRNA−carrier complexes can be formed ex vivo, prior to injection, by condensing the nucleic acid with a cationic protein (e.g., protamine (*5*)) or polymer (e.g., poly(ethylene imine) (PEI) (*6*), cyclodextrin-containing polycations (*7*), or PEG-based block catiomer (*8*)). In addition, targeted delivery of such agents has the potential to limit collateral toxicity and 'off-target' effects. Targeting has been explored through use of through the attachment of antibodies (*5*), small molecules (e.g., transferrin (*7*)), aptamers (*9*, *10*), or well-established peptide ligands (*6*)); however, these approaches are typically not modular nor multifunctional (i.e., do not incorporate imaging moieties). Addition of a nanoparticle-based imaging agent to siRNA delivery strategies may be particularly advantageous as protein knockdown by RNAi is delayed (>48 h or more after administration), and many fluorescent dyes are not stable for monitoring delivery over extended periods of time in vivo. In vitro, co-delivery of fluorescent reporter plasmid along with the siRNA is often utilized; however, this is unlikely to be used clinically given the potential risks associated with integration into host DNA.

Quantum dots offer the potential to serve as photostable beacons to track siRNA delivery. We have previously explored their utility for monitoring siRNA delivery in vitro by co-complexing QDs with cationic liposomes and siRNA (*11*, *12*); however, this approach is not amenable to either systemic delivery, because of their relatively large size and rapid uptake

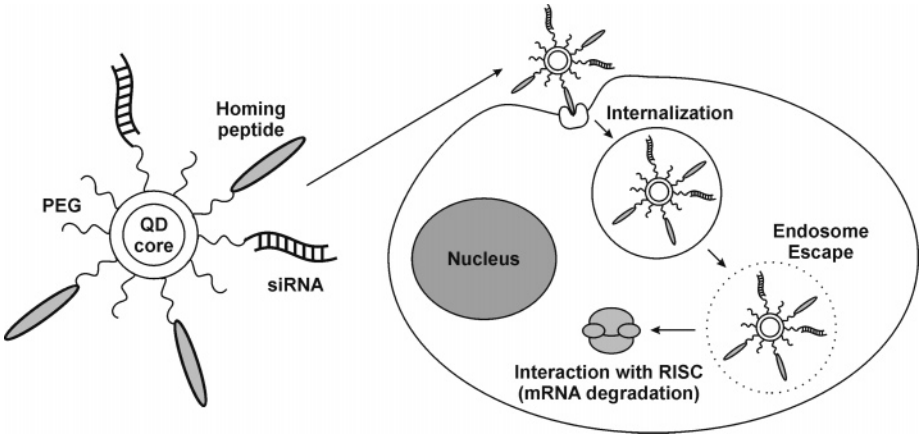

Figure 1. Design of a multifunctional nanoparticle for siRNA delivery. Because of their photostable fluorescence and multivalency, QDs are suitable vehicles for ferrying siRNA into live cells in vitro and in vivo. Conjugation of homing peptides (along with the siRNA cargo) to the QD surface allows targeted internalization in tumor cells. Once internalized, these particles must escape the endolysomal pathway and reach the cytoplasm to interact with the RNA-induced silencing complex (RISC), which leads to degradation of mRNA homologous to the siRNA sequence.

by macrophages, or targeted delivery, as they are ubiquitously internalized. In this report, we sought to generate multifunctional conjugates of a size compatible with eventual systemic delivery ($5 < d < 200$ nm) upon a quantum dot core that presented both targeting peptides and siRNA (Figure 1). A QD core with emission in the near-infrared (NIR) was chosen to allow greater imaging depth in tissue than that achieved with visible wavelengths. The siRNA was attached to the surface with a chemical cross-linker, rather than the electrostatic interactions used in many schemes. This strategy grants a smaller overall size than polymer-based particles, which may carry advantages in evading uptake by the reticuloendothelial system (*13*). As a proof-of-concept, the attached siRNA was designed against the enhanced green fluorescent protein (EGFP) gene, and complexes were delivered to EGFP-transfected HeLa cells in vitro. A tumor-homing peptide (F3), targeting cell-surface nucleolin (*14*), was attached to achieve cell uptake. F3 peptide has been shown to target tumor cells in vitro and in vivo when administered as a free peptide and also when coconjugated with poly(ethylene glycol) to quantum dots delivered systemically in mice bearing xenograft tumors(*15*).

Combining these components onto a single particle brings several engineering requirements and constraints that affect their design and fabrication. Accordingly, in this report we first investigate whether the attachment of the peptide is necessary and sufficient to achieve cell internalization. As particle surface area is limited (~100 surface amines on these QDs), the actual copy numbers of targeting peptide and siRNA required are also quantified. Increasing the number of peptides on the QDs lowers the siRNA dose per particle and vice versa. Next, because conjugation of siRNA to the particles must be stable in cell media yet also allow the duplex to interact with the RNA-induced silencing complex (RISC) in the cytosol, we test the efficacy of two different cross-linkers for this task. While RISC binding may be possible with the duplex attached to the particle, release of the siRNA from the particle's surface upon internalization proved advantageous to knockdown efficacy. Finally, cytoplasmic delivery, free of endosomes, is essential to allow siRNA to interact with cellular silencing machinery. While fluorophore-labeled F3 peptide has been shown to reach the nuclei of tumor cells (*15*), internalization of particles generally follows the endolysosomal pathway. In this report, the addition of endosome-disrupting agents was required to aid escape and increase siRNA-mediated knockdown.

EXPERIMENTAL SECTION

Materials. Quantum dots with emission maxima of 655 or 705 nm and modified with PEG and amino groups were obtained from Quantum Dot Corporation (ITK amino). QD concentrations were measured by optical absorbance at 595 nm, using extinction coefficients provided by the supplier. Cross-linkers used were sulfo-LC-SPDP (sulfosuccinimidyl 6-(3′-[2-pyridyldithio]-propionamido)hexanoate) (Pierce) and sulfo-SMCC (sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate) (Sigma). Synthetic RNA duplexes directed against the EGFP mRNA were synthesized, with the sense strand modified to contain a 5′ thiol group (Dharmacon) (sense: 5′-Th-$(CH_2)_6$-GGC UAC GUC CAG GAG CGC ACC; antisense: 5′-UGC GCU CCU GGA CGU AGC CUU). The F3 peptide was synthesized with an aminohexanoic acid (Ahx) spacer and cysteine residue added for conjugation (final sequence: C[Ahx]-AKVK DEPQR RSARL SAKPA PPKPE PKPKK APAKK). A FITC-labeled F3 peptide was also synthesized, along with KAREC (Lys-Ala-Arg-Glu-Cys), a five amino acid control peptide. All peptides were synthesized by *N*-(9-fluorenylmethoxycarbonyl)-L-amino acid chemistry with a solid-phase synthesizer and purified by HPLC. The composition of the peptides was confirmed by MS.

Conjugation of Peptides and Nucleic Acid to QDs. Amino-modified QDs were conjugated to thiol-containing siRNA and peptides using sulfo-LC-SPDP and sulfo-SMCC cross-linkers. QDs were resuspended in 50 mM sodium phosphate, 150 mM sodium chloride, pH 7.2, using Amicon Ultra-4 (100 kDa cutoff) filters. Cross-linker (1000-fold excess) was added to QDs and allowed to react for 1 h. Samples were filtered on a NAP-5 gravity column (to remove excess cross-linker) into similar buffer supplemented with 10 mM EDTA. siRNA was treated with 0.1 M DTT for 1 h and filtered on a NAP-5 column into EDTA-containing buffer. Peptides were typically used from lyophilized powder. Peptide and/or siRNA was added to filtered QDs and allowed to react overnight at 4 °C. Using three Amicon filters, product was filtered twice with Dulbecco's phosphate-buffered saline (PBS), twice with a high salt buffer (1.0 M sodium chloride, 100 mM sodium citrate, pH 7.2), and twice again with PBS. High salt washes were required to remove electrostatically bound siRNA and peptide, which was not removed with PBS washes alone.

For siRNA−QDs, a 10-fold excess of siRNA was typically used for both cross-linkers. In the case of sulfo-LC-SPDP, the amount of conjugated siRNA was assayed using gel electro-

phoresis (20% TBE gel, Invitrogen), staining with SYBR Gold (Invitrogen). To confirm that similar amounts of siRNA (approximately two per QD) were conjugated to QDs using sulfo-SMCC, particles were stained with SYBR Gold and measured with a fluorimeter (SpectraMax Gemini XS, Molecular Devices).

For F3/siRNA−QDs and KAREC/siRNA−QDs, a molar ratio of 15:70:1 (siRNA:peptide:QDs) was found to be optimum, though a variety of ratios were attempted (Figure 4A). These conditions yielded approximately 20 F3 peptides and 1 siRNA duplex per particle.

Cell Culture. Internalization and knockdown experiments were performed using a HeLa cell line transfected with destabilized EGFP with a half-life of 1 h (courtesy of Phillip Sharp, MIT). Growth media was Dulbecco's modified Eagle's medium (DMEM) containing 4.5 g/L glucose and supplemented with 10% FBS, 100 units/mL penicillin, 100 ug/mL streptomycin, and 292 ug/mL L-glutamine. Cells were passaged into 24-well plates and used at 50−80% confluency for internalization experiments and 20−40% confluency for knockdown experiments.

For internalization experiments (Figure 2), QDs were added to cell monolayers in media without serum at a final concentration of 50 nM. After 4 h, cells were washed with media, treated with trypsin (0.25%) and EDTA, and resuspended in 1% BSA (in PBS) for flow cytometry (BD FACSort, FL1 for EGFP signal and FL3 for QD signal). Fluorescence data on 10 000 cells was collected for each sample, and the geometric mean of intensity was reported.

For knockdown experiments in Figure 3, siRNA−QDs (in 50 uL serum/antibiotic-free media) were added to Lipofectamine 2000 (1 μL in 50 μL media, Invitrogen) and allowed to complex for 20 min. Cell media was changed to 400 μL of serum/antibiotic-free per well, and QD solutions (100 μL) were added dropwise. Complete media was added 12−18 h later, and 48 h after the QD were added, cells were trypsinized and assayed for fluorescence by flow cytometry.

To assess EGFP knockdown, 50 nM or 10 nM concentrations of F3/siRNA−QDs or KAREC/siRNA−QDs were added to cell monolayers (20−40% confluent) in media with serum/antibiotics. To demonstrate specificity, irrelevant siRNA (designed against the Lamin A/C gene, as described in ref 12) was conjugated to QDs along with F3 and also delivered to cells. Four hours later, cells were washed with similar media. Some samples were then treated with 1 μL of Lipofectamine per well (added dropwise in 100 μL media) either immediately after washing or after a 90 min incubation at 37 °C (to allow membrane recycling). For all samples, media was changed to complete DMEM with serum/antibiotics ~16 h after the addition of QDs and assayed by flow cytometry 48 h from the start of the experiment. For imaging, cells were initially seeded on glass-bottom dishes (Mat-Tek) and observed 48 h after the addition of QDs using a 60× oil immersion objective. Images were captured with a SPOT camera mounted on a Nikon TE200 inverted epifluorescence microscope.

RESULTS AND DISCUSSION

Taking a modular approach, particle internalization and siRNA attachment were investigated separately before these functions were combined in a single particle. First, peptides were conjugated to QDs to improve tumor cell uptake. Addition of as-purchased PEGlyated QDs to HeLa cell monolayers led to minimal cell uptake, as quantified with flow cytometry (Figure 2A). Conjugation of siRNA or a control pentapeptide (KAREC) did not increase QD internalization, but addition of F3 peptide to the QDs improved the uptake significantly (2 orders of magnitude). To confirm the specificity of F3 uptake, free F3 peptide was added to cells along with 50 nM F3−QDs (Figure 2B). Dose-dependent inhibition of uptake was observed with F3 peptide concentrations from 1 μM to 1 mM. Inhibition of uptake by an irrelevant peptide, free KAREC, was minimal by comparison. The large excess of free peptide required for inhibition may be due to multiple copies of the F3 peptide on each QD and improved receptor binding as a result of multivalency.

To quantify the number of peptides added per particle, FITC-labeled F3 peptide was synthesized and attached to QDs using

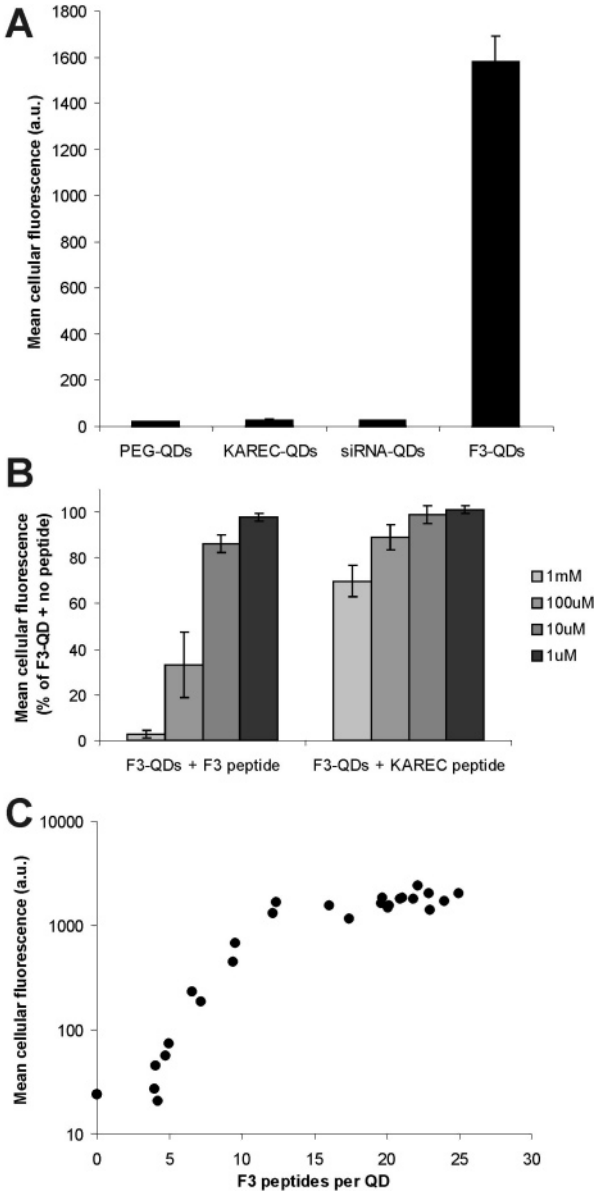

Figure 2. Attachment of F3 peptide leads to QD internalization in HeLa cells. Thiolated peptides (F3 and KAREC control) and siRNA were conjugated to PEG-amino QD705 particles using sulfo-SMCC. Particles were filtered to remove excess peptide or siRNA and incubated with HeLa cell monolayers for 4 h. Flow cytometry indicated the F3 peptide is required for cell entry (A). The addition of free F3 peptide inhibits F3−QD uptake, while KAREC peptide does not, suggesting the F3 peptide and F3-labeled particles target the same receptor (B). In part C, the relationship between the number of F3 peptides per QD and cell uptake was examined. In these experiments, FITC-labeled peptide was conjugated to QDs using sulfo-LC-SPDP. For each formulation (black circles), peptide:QD ratio was determined by measuring the QD concentration by absorbance and then treating the conjugate with 2-mercaptoethanol, filtering out the QDs, and measuring the FITC fluorescence. Cell uptake increases dramatically with peptide number but appears to saturate around 10−15 F3s per QD.

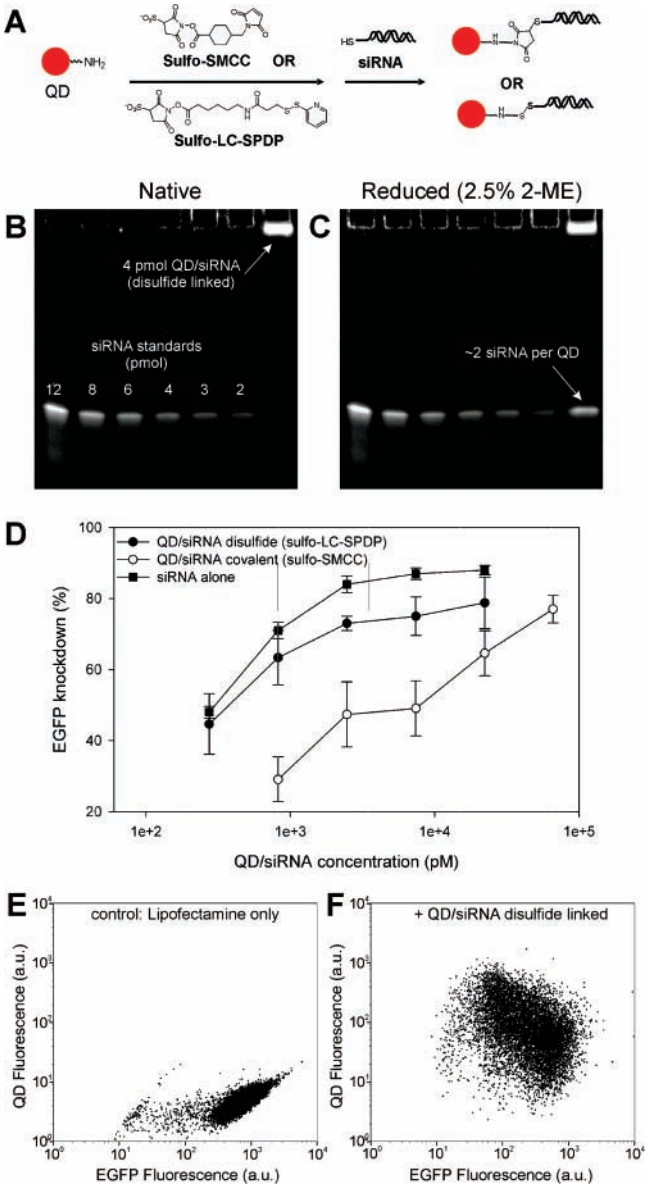

Figure 3. Conjugation of siRNA to QDs with cleavable or noncleavable cross-linkers. Thiol-modified siRNA was attached to PEG-amino QDs using the water-soluble heterobifunctional cross-linkers sulfo-SMCC and sulfo-LC-SPDP (A). The cross-link produced by SPDP is cleavable with 2-mercaptoethanol (2-ME), while SMCC yields a nonreducible linkage. Gel electrophoresis of the disulfide-linked conjugates indicated that no siRNA are electrostatically bound to the conjugate (B). Upon treatment with 2-ME, the QD/siRNA cross-link is reduced and the siRNA migrated down the gel alongside siRNA standards (C). QD/siRNA conjugates (or siRNA alone) were delivered to EGFP-expressing HeLa cells using Lipofectamine 2000 (cationic liposome reagent). Cells were trypsinized and assayed by flow cytometry 48 h later. Comparison with control cells (treated with Lipofectamine alone) indicated the disulfide bond leads to superior EGFP knockdown (% reduction in geometric mean fluorescence) (D). Comparing a dot-plot of cells treated with Lipofectamine alone (E) or disulfide-linked QD/siRNA (F) revealed a negative correlation between QD uptake and EGFP signal. Thus, the QD label can serve as a means of quantifying siRNA delivery and thus knockdown.

a cleavable cross-linker (sulfo-LC-SPDP). After unreacted peptide was removed by filtration, 2-mercaptoethanol (2-ME) was added to reduce the disulfide bond between peptide and QD. Using a 100 kDa cutoff filter, F3-FITC peptide was separated from the QDs and quantified by fluorescence. Several reactions were performed with various amounts of FITC-F3 and siRNA as reactants. For each formulation, the cellular uptake was quantified by flow cytometry and F3 number measured (Figure 2C, each point indicates a separate formulation). Attachment of a small number of peptides (0−5) did not lead to significant uptake (less than 10% of maximum). Uptake increases with peptide number but begins to saturate around 15 copies per QD.

The use of cleavable (sulfo-LC-SPDP) or noncleavable (sulfo-SMCC) cross-linkers for the attachment of F3 peptide did not significantly affect cell uptake. The choice of cross-linker, however, may affect the ability of the siRNA cargo to interact with RISC. The interior of the cell is a reducing environment, which would lead to cleavage of the disulfide bond generated by sulfo-LC-SPDP, freeing the siRNA. On the other hand, the amide bond produced by sulfo-SMCC is unaffected by reducing conditions (confirmed by treating the conjugates with 2.5% 2-ME for 30 min), leaving the intracellular QD/siRNA conjugate intact. We compared the efficiency of QD/siRNA conjugates prepared with both cross-linkers using an EGFP model system. Delivery of the conjugates to EGFP-labeled HeLa cells was performed by first complexing the particles with a cationic liposome transfection reagent (Lipofectamine 2000), to satisfy the functions of cell internalization and endosome escape, and knockdown efficiency was quantified by a reduction in EGFP fluorescence over controls (Lipofectamine only).

Using gel electrophoresis, the amount of siRNA conjugated per particle was quantified relative to double-stranded RNA standards. Particles conjugated using sulfo-LC-SPDP were first introduced under native (nonreduced) conditions (Figure 3B). The absence of a siRNA band in the QD/siRNA lanes indicates that no siRNA is noncovalently bound to the particles. Exposing the particles to 2-ME for 30 min led to the appearance of a siRNA band in the SPDP lane, which was quantified with RNA standards and ImageQuant software. Using this approach, approximately two siRNA duplexes were conjugated per QD under these conditions (Figure 3C). Cellular fluorescence was quantified 48 h after incubation with HeLa cells using flow cytometry. As hypothesized, the QD/siRNA formulation produced with the disulfide bond (using sulfo-LC-SPDP) led to greater EGFP knockdown (Figure 3D). The level of knockdown attained with disulfide-linked QD/siRNA, however, was less than observed when an equal concentration of free siRNA was delivered with Lipofectamine. On the basis of previous observations(*12*), one potential cause may be the limited surface area of the cationic liposomes, which is shared by QDs and siRNA. Additionally, the presence of the QDs in the endosome may reduce the efficiency of escape, or reduction of the disulfide bond may be incomplete, resulting in less efficient complexation with RISC.

The F3:siRNA reaction ratio was varied with the goal of generating a formulation capable of high cell uptake as well as the ability to carry a significant payload of siRNA. The cleavable cross-linker allowed the removal and quantification of both species after F3 peptide and siRNA coattachment. The results indicate a tradeoff between one siRNA per particle with high uptake (>15 peptides) and two duplexes but lower uptake (<10 peptides) (Figure 4A). Negatively charged siRNA may be electrostatically adsorbing to the surface of the aminated QDs, preventing the attachment of additional F3 peptides. Potentially, performing the reaction in high salt conditions, or in the presence of a surfactant, may allow higher loading. Since both high uptake efficiency and siRNA number are required for knockdown, particles with ~20 F3s and a single siRNA duplex were further investigated in cell studies.

When incubated with cells, these 20-F3/1−siRNA−QDs were shown to internalize significantly but did not lead to reduction in EGFP fluorescence 48 h later. Fluorescence microscopy revealed that the particles were intracellular, but they colocalized with an endosomal marker (LysoSensor, Molecular Probes).

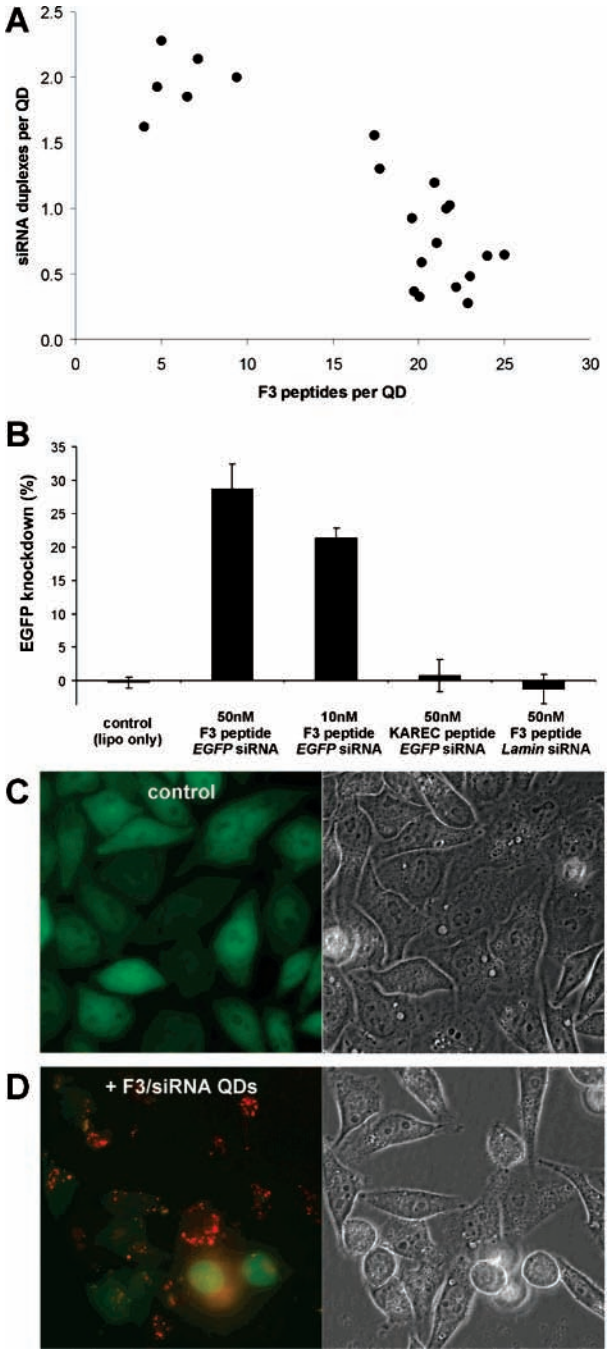

Figure 4. Co-attachment of F3 peptide and siRNA cargo allows EGFP knockdown upon delivery and endosome escape. Because of a limited number of attachment sites on the QDs, the goal of coattachment was to maximize siRNA loading while conjugating sufficient F3 peptides to allow internalization (>15). Varying the F3:siRNA ratio resulted in a number of QD formulations (black circles, A). We chose a formulation containing ~20 F3 peptides and ~1 siRNA per QD for knockdown studies in cell monolayers (B−D). EGFP-expressing HeLa cells were treated with 50 nM F3/siRNA−QDs for 4 h and then washed with cell media. When assayed for green fluorescence 48 h later, no knockdown was observed ("control", B). When these cells were treated with cationic liposomes (Lipofectamine 2000) immediately after removing the QDs and washing, a ~29% reduction in EGFP was observed. A lower concentration of QDs (10 nM) is less effective (21% knockdown). Incubation with KAREC-labeled particles followed by cationic liposomes leads to minimal particle internalization and thus no knockdown. Attachment of an irrelevant siRNA (directed against Lamin A/C) to QDs along with F3 peptide also results in no knockdown when delivered to cells followed by lipofectamine. Fluorescence imaging of cells incubated with F3/siRNA QDs (red dots) showed a reduced green fluorescence (D), compared with control cells incubated with Lipofectamine alone (C).

Addition of an endosome escape agent, therefore, was required to achieve knockdown. Specifically, after incubation of cells with F3/siRNA−QDs and washing, cationic liposomes were added for 12 h. Although cationic liposomes and polymers are typically used to form complexes with nucleic acids or particles, thereby ferrying the payload inside cells, in this case the reagent leads to endosomal escape of previously internalized QDs. We hypothesize that the cationic liposomes are internalized into new endosomes, which fuse with the endosomes carrying the QDs. As the pH of the vesicle is lowered by the cell, osmotic lysis leads to the release of both species into the cytoplasm. To assess the importance of the targeting ligand, particles carrying siRNA and a control peptide (KAREC) were used. These KAREC/siRNA particles were not internalized, and no EGFP knockdown was observed, despite endosome disruption. The specificity of knockdown was verified by delivery of F3/siRNA QDs containing an irrelevant siRNA (directed against Lamin A/C). Additionally, a time lag of 90 min between washing the cells free of QDs and cationic liposome addition did not lead to significant reduction in efficiency, indicating that endosomal degradation of the siRNA is not an issue on this time scale.

In addition to cationic liposomes, some chemotherapeutics, such as chloroquine have been shown to be capable of endosomal escape (*16*). While an endosome escape step could be a realistic part of a treatment regimen, there is also potential that this function could be built into each particle. Addition of fusogenic moieties to the QD surface, for example, may further improve delivery of the multifunctional particles described (*17*).

CONCLUSIONS

Decorating the surface of a fluorescent quantum dot with both a targeting ligand and siRNA duplex requires a tradeoff in the number of each species but can be used to generate a conjugate capable of knockdown in vitro. We found that multiple copies of the F3 targeting peptide were required for QD uptake, but that siRNA cargo could be co-attached without affecting the function of the peptide. Disulfide (sulfo-LC-SPDP) and covalent (sulfo-SMCC) cross-linkers were investigated for the attachment of siRNA to the particle, with the disulfide bond showing greater silencing efficiency. Finally, after delivery to cells and release from their endosomal entrapment, F3/siRNA−QDs produced significant knockdown of EGFP signal. By designing the siRNA sequence against a therapeutic target (e.g., oncogene) instead of EGFP, the technology explored in this study may be adapted to treat and image diseases such as cancer. This technology could also be readily adapted to other nanoparticle platforms, such as iron oxide or gold cores, which allow image contrast on magnetic resonance or X-ray imaging, respectively, and may therefore mitigate concerns over QD cytotoxicity and the limited tissue penetration of light. QDs, however, remain an attractive tool for in vitro and animal testing, where fluorescence is the most accessible and common imaging modality.

Received December 20, 2006; Revised Manuscript Received July 17, 2007

The aim of this work was to develop new fluorescent probes for the localization and function of the peripheral benzodiazepine receptor (PBR). This receptor is primarily expressed on the mitochondria, and it is overexpressed in a variety of different states including glioma, breast cancer, Alzeheimer's disease, and activated microglia. For the mentioned purpose, imidazopyridine and imidazopyrimidine compounds **5**−**20** were synthesized, and their affinity for PBR was determined. Although some intrinsically fluorescent imidazopyrimidine compounds **12**−**20** possess good binding affinity, they cannot be used for visualizing PBR due to their unfavorable fluorescence characteristics. Among the imidazopyridine−7-nitrofurazan conjugates **5**−**11**, compound **10** was the most active, and it was found to stain live Ra2 microglial cells effectively. An in vivo biodistribution study carried out on compound **10** showed that this imidazopyridine derivative, injected in the carotid artery, is able to penetrate to liver parenchyma, whereas fluorescein isothiocyanate labeled dextran (FITC-dextran), used as a control dye, hardly penetrated from blood vessels to tissues. On the other hand, as for the distribution to brain, the patterns of staining with **10** and FITC-dextran are similar, indicating that both of them hardly penetrate into the brain because of the existence of the blood−brain barrier. The obtained results indicate that compound **10** represents a new useful fluorescent probe for visualization of activated microglia and PBR.

INTRODUCTION

The peripheral benzodiazepine receptor (PBR) is pharmacologically distinct from the central benzodiazepine receptor (CBR), which is coupled to GABA-regulated chloride channels in the central nervous system (CNS). CBR mediates the classical sedative, anxiolytic, anticonvulsant, and muscle relaxant properties of the benzodiazepines. On the other hand, the 18 kDa protein PBR, located in the outer mitochondrial membrane (*1*) and for which the name "translocator protein" has recently been proposed (*2*), plays an important role in stimulating the neurosteroids synthesis in glial cells, and it is involved in various neurological diseases such as Alzheimer's disease, Huntington's disease, and multiple sclerosis (*3*−*7*). In this regard, one useful index in delineating areas of active disease in the brain is the presence of activated microglia. In normal brain parenchyma, microglia are in a down-regulated state, but during disease or injury the microglia are activated and the expression of PBR in vivo is increased (*8*). Thus, the visualization of activated microglia is of relevant diagnostic value and suitable for monitoring of disease progression in the brain (*8*). There is also evidence showing that PBR expression is selectively increased in a wide variety of human tumors, including cancers of the colon, breast, ovary, liver, and especially the brain (*9*−*11*). Moreover, it has also been shown that PBR-specific ligands induce apoptosis and cell cycle arrest in cancer cells (*12*−*14*) and that appropriate PBR ligand−drug conjugates characterized by PBR affinity can be used as diagnostic imaging agents of solid tumors or to selectively release the linked anticancer drug to the target by a receptor-mediated mechanism (*15*−*18*). The synthesis and biological activity of compound **1** (Chart 1) have been reported by Kozikowski et al. (*19*), and this compound represents the first example of a fluorescent probe for PBR. Compound **1** was obtained by linking a fluorogenic 7-nitro-2,1,3-benzoxadiazol-4-yl moiety to the 2-phenylindole-3-acetic acid through a hexamethylenediamine spacer, and **1** was found to possess biological activity like other indoleacetamide PBR ligands at nanomolar levels (*19*). Moreover, by conjugation of different trifunctional lanthanide chelates to the isoquinoline PBR ligand PK11195 analogue, two conjugate compounds of general formula **2** (Chart 1) were prepared (*20*). For these conjugates, which may provide an optical or magnetic resonance (MR) signature depending on the involved lanthanide ion M (i.e., Eu^{3+} for optical or Gd^{3+} for MR), no affinity or selectivity data for PBR were provided. Subsequently, the same research group developed the molecular imaging agent **3** by conjugation of a PK11195 analogue with Lissamine−Rhodamine B dye, and the K_d of this conjugate to PBR was 1 μM (*21*). Chen et al. also reported that pyropheophorbides and their metal complexes **4** [M = In(III), Ni (II), and Zn(II)], characterized by PBR binding values at nano−micromolar levels, could be promising candidates as fluorescent probes for PBR and may have great potential as fluorophores to replace radioactive PBR probes (*22*). Further studies demonstrated that in addition to 2-phenylindole-3-acetic acid and isoquinoline derivatives (*23*, *24*), PBR binds with high affinity to other classes of compounds such as

benzodiazepines (*25*) and *N*-phenoxyphenyl-*N*-isopropoxybenzyl-acetamides such as DAA1097 (*26*). We have shown that some 2-phenyl-imidazo[1,2-*a*]pyridine-3-acetamides (Chart 1) are potent and selective ligands for PBR and stimulate steroidogenesis both in the brain and at the periphery (*27*−29).

As part of our research program aimed at developing new probes for the localization and function of PBR in different tissues, we report the synthesis and biological evaluation of compounds **5**−**11** and **12**−**20** (Table 1). Compounds of the former set are characterized by a 7-nitro-2,1,3-benzoxadiazol-4-yl fluorophore linked through a diamine spacer to 2-phenylimidazo[1,2-*a*]pyridine-3-acyl moiety, whereas the other compounds may also be of interest because they are characterized by an imidazopyrimidine nucleus, which is intrinsically fluorescent (*30*) and are also analogues of imidazopyridine-3-acetamides with affinity and selectivity for PBR. Because the insertion of a bulky fluorescent group on a ligand is known to reduce binding affinity for the receptor, one might expect that compounds **12**−**20** would interact better than the conjugated compounds **5**−**11**. In this paper, the synthesis, binding data, fluorescence characteristics, and cell biology of these imidazopyridine and imidazopyrimidine compounds **5**−**20** are reported and discussed.

EXPERIMENTAL PROCEDURES

Chemistry. Melting points were determined in open capillary tubes with a Buchi apparatus and are uncorrected. IR spectra were obtained on a Perkin-Elmer 283 spectrophotometer (KBr pellets for solid or nujol for liquid). ^{1}H NMR spectra were determined on a Varian 390 or Bruker 300 MHz instrument. Chemical shifts are given in δ values downfield from Me_4Si as an internal standard. Mass spectra were recorded on a Hewlett-Packard 5995c GC-MS low-resolution spectrometer. All compounds showed appropriate IR, ^{1}H NMR, and mass spectra. Elemental analyses were performed on a Hewlett-Packard 185 C, H, N analyzer and agreed with theoretical values within ±0.40%. Silica gel 60 (Merck 70−230 mesh) was used for column chromatography. The starting 2-aminopyrimidine compounds, 4-chloro-7-nitrobenzofurazan (NBD chloride), alkyl-

endiamines, triethylamine (TEA), ethyl 1,2-dihydro-2-ethoxy-1-quinolinecarboxylate (EEDQ), and anhydrous tetrahydrofuran (THF) were purchased from Sigma-Aldrich (Milan, Italy).

General Procedure for the Preparation of 2-Phenylimidazo[1,2-*a*]pyridineacetamide *N*-Alkylcarbamates 23a−g. To a stirred solution of the required imidazo[1,2-*a*]pyridin-3-acetic acid **21** (1 mmol) in anhydrous THF (20 mL) were added EEDQ (1.2 mmol), the appropriate mono-Boc-protected polymethylendiamine **22a−f** (1.1 mmol), and TEA (1.3 mmol) successively. Stirring was prolonged at room temperature for 6−12 h, and the resulting reaction mixture was poured into 20 mL of water (pH ∼4.5) and extracted with ethyl acetate (3 × 30 mL). The organic layer was separated, washed with water and brine, and dried over Na_2SO_4. Solvent was evaporated under reduced pressure, and the resulting residue was purified by silica gel column chromatography [light petroleum ether/ethyl acetate 6:4 (v/v) as eluent)] to give the corresponding compounds **23a−g**.

General Procedure for the Preparation of Benzooxadiazole-imidazopyridine Acetamides 5−11. To a stirred and ice-cooled solution of the appropriate compound **24a−g** (0.5 mmol) in anhydrous THF (20 mL) were added a solution of NBD chloride (0.5 mmol) in anhydrous THF (2 mL) and then TEA (0.7 mmol). Stirring was prolonged at room temperature for 1 h, and the resulting mixture was poured into 20 mL of water and then extracted with chloroform (3 × 30 mL). The organic layer was washed with water and brine and successively dried over Na_2SO_4. Solvent was evaporated under reduced pressure, and the resulting residue was purified by silica gel column chromatography [light petroleum ether/ethyl acetate 4:6 (v/v) as eluent)] to give the corresponding compounds **5−11**.

*2-(6,8-Dichloro-2-(4-chlorophenyl)imidazo[1,2-a]pyridin-3-yl)-N-(2-(7-nitrobenzo[c](1,2,5)oxadiazol-4-ylamino)ethyl)acetamide (**5**):* IR (KBr) 3250, 1656 cm^{-1}; ^1H NMR (acetone-d_6) δ 3.6−3.8 (m, 4H, NCH_2CH_2N), 4.18 (s, 2H, CH_2CO), 6.44 (d, $J = 8.8$ Hz, 1H, C(5)H NBD moiety), 7.4−7.5 (m, 3H, Ar), 7.87 (d, $J = 8.5$ Hz, 2H, Ar), 8.45 (d, $J = 8.8$ Hz, 1H, C(6)H of NBD moiety), 8.51 (d, $J = 1.6$ Hz 1H, Ar); MS (ESI) *m/z* 562 $(M + H)^+$. Stability Studies on Compound 10. *Chemical Hydrolysis.* Stability studies were carried out at controlled temperature (37 ± 0.2 °C) in a water bath shaken at 150 rpm. The hydrolysis of compound **10** was studied at pH 7.4 in isotonic 0.05 M phosphate buffer. The experiments were carried out by adding 35 μL of a stock solution in DMSO (1.0 mg/mL) to 1 mL of the buffer solution preheated at 37 °C. The final concentration of the resulting solutions was 50 μM. The test solutions were vortexed and maintained in a shaker water bath at a constant temperature of 37 ± 0.2 °C. At appropriate intervals, aliquots of 20 μL were removed and immediately analyzed by high-performance liquid chromatography (HPLC). Pseudo-first-order rate constants for the hydrolysis of the derivatives were determined from the slopes of linear plots of the logarithms of residual compound against time. HPLC analyses were performed with a Waters Associates model 600 pump equipped with a Waters 990 variable wavelength UV detector and a 20 μL loop injection valve. A reversed phase Symmetry C18 (25 cm × 3.9 mm; 5 μm particles) column in conjunction with a precolumn (Sentry Guard Symmetry C18, 20 × 3.9 mm) was eluted with mixtures of methanol/water 80:20 (v/v). The injected volume was 20 μL. The flow rate of 0.8 mL/min was maintained, and the column effluent was monitored continuously at 254 nm. The compounds were estimated by measuring the peak areas or peak heights in relation to those of standards chromatographed under the same conditions.

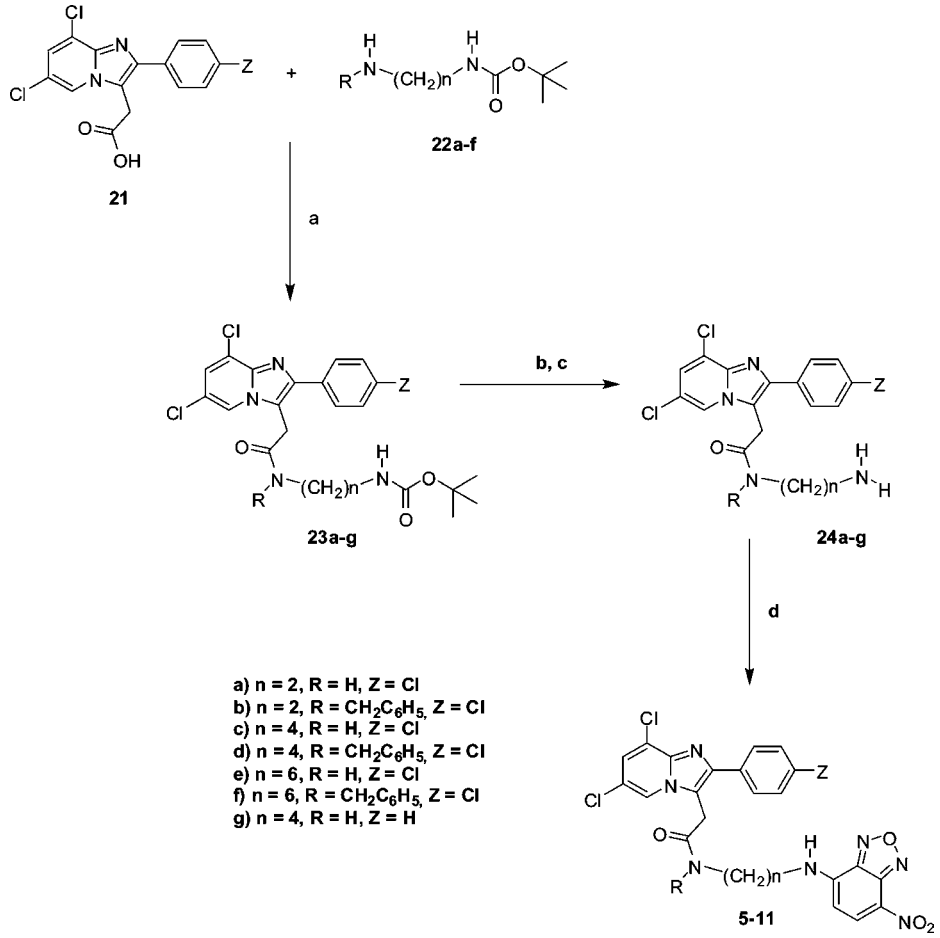
Stability in Physiological Medium. The stability of compound **10** in physiological medium was studied at 37 °C in 0.05 M phosphate buffer saline (0.14 M NaCl) at pH 7.4, containing 50% v/v of rat serum. The final concentration was 50 μM. The resulting test solution was maintained at 37 ± 0.2 °C in a shaking water bath. Aliquots of 100 μL were withdrawn at appropriate intervals and treated with 500 μL of cold acetonitrile to precipitate the serum proteins. After mixing and centrifugation for 5 min at 13200 rpm, the clear supernatant was analyzed by HPLC as described above.



Biological Methods and Materials. Adult male or female Sprague−Dawley CD rats (Charles River, Como, Italy) with body masses of 200−250 g at the beginning of the experiments were maintained under an artificial 12-h light/dark cycle (light on from 8:00 a.m. to 8:00 p.m.) at a constant temperature of 23 ± 2 °C and 65% humidity. Food and water were freely available, and the animals were acclimated for >7 days before use. Experiments were performed between 8:00 a.m. and 2:00 p.m. Animal care and handling throughout the experimental procedure were performed in accordance with the European Communities Council Directive of 24 November 1986 (86/609/EEC). The experimental protocols were approved by the Animal Ethical Committee of the University of Cagliari.

In Vitro Receptor Binding Assays. After sacrifice, the brain was rapidly removed and the cerebral cortex was dissected; tissues were stored at −80 °C until assay.

[^{3}H]Flunitrazepam Binding. The tissues were thawed and homogenized with a Polytron PT 10 in 50 volumes of ice-cold 50 mM Tris-HCl buffer (pH 7.4) and centrifuged twice at 20000*g* for 10 min. The pellet was reconstituted in 50 volumes of Tris-HCl buffer and was used for the binding assay. Aliquots of 400 μL of tissue homogenate (0.4−0.5 mg of protein) were incubated in the presence of [^{3}H]flunitrazepam at a final concentration of 0.5 nM, in a total incubation volume of 1000 μL. The drugs were added in 100 μL aliquots. After a 60 min incubation at 0 °C, the assay was determined by rapid filtration through glass-fiber filter strips (Whatman GF/B). The filters were rinsed with 2−4 mL portions of ice-cold Tris-HCl buffer as described above. Radioactivity bound to the filters was quantitated by liquid scintillation spectrometry. Nonspecific binding was determined as binding in the presence of 5 μM diazepam and represented about 10% of total binding.

[^{3}H]PK11195 Binding. The tissues were thawed and homogenized in 50 volumes of Dulbecco's phosphate-buffered saline (PBS; pH 7.4) at 4 °C with a Polytron PT 10 (setting 5, for 20 s). The homogenate was centrifuged at 40000*g* for 30 min, and the pellet was resuspended in 50 volumes of PBS and recentrifuged. The new pellet was resuspended in 20 volumes of PBS and used for the assay. [^{3}H]PK11195 binding was determined in a final volume of 1000 μL of tissue homogenate (0.15−0.20 mg of protein), 100 μL of [^{3}H]PK11195 (specific activity = 85.5 Ci/mmol, New England Nuclear) at a final assay concentration of 1 nM, 5 μL of drug solution or solvent, and 795 μL

Scheme 1 [a]

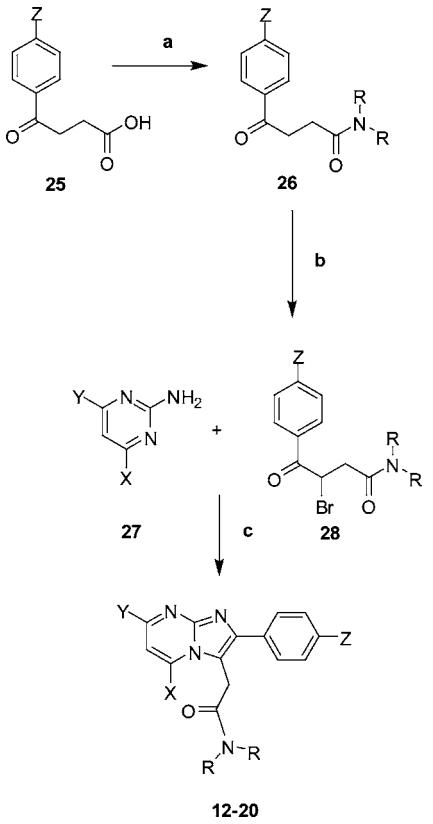
of PBS buffer (pH 7.4 at 25 °C). Incubations (25 °C) were initiated by the addition of membranes and were terminated 90 min later by rapid filtration through glass-fiber filter strips (Wathaman GF/B), which were rinsed five times with 4 mL of ice-cold PBS buffer using a Cell Harvester filtration manifold (Brandel). Filter-bound radioactivity was quantitated by liquid scintillation spectrometry. Nonspecific binding was defined as binding in the presence of 10 μM unlabeled PK11195 (Sigma-Aldrich, St. Louis, MO).

Cell Cultures. Ra2, an immortalized microglial clone, was established from a mouse primary microglial culture and maintained in Eagle's minimum essential medium (MEM) supplemented with 10% calf serum, 5 μg/mL bovine insulin, 0.2% glucose, and 1 ng/mL recombinant mouse granulocyte-macrophage colony stimulating factor (Genzyme, Cambridge, MA), which is essential for Ra2 growth in culture.

Ra2 cells were seeded at a density of 6500 cells/cm^2 on a glass cover slip and then cultured for 16 h. Compound **10** was added to the Ra2 culture at a final concentration of 1 μM followed by the addition of Mito Tracker Red after 10 min (a dye useful for staining mitochondria in live cells) (Molecular Probes, Eugene, OR) and was then incubated at 37 °C for 1 h. After treatment, Ra2 cells were observed by a fluorescent microscope and photographed. The Ra2 cells were then incubated for 24 h with 1 μg/mL lipopolysaccharide (LPS) (Sigma-Aldrich), which is an endotoxin from *Escherichia coli* and a potent activator of microglia.



In Vivo Biodistribution Study on Compound 10. Adult male C57BL/6 mice were deeply anesthetized with sodium pentobarbital (25 mg/kg, ip) before surgery and remained under anesthesia throughout the entire procedure. When spinal reflexes were absent, a transverse incision was made and then the right carotid artery was exposed and dissected free of surrounding tissues. After the temporary occlusion of proximal site of the carotid artery with an aneurysm clip, a small hole was made in the distal site of the artery with a 27-gauge needle, and a polyethylene tube (Becton Dickinson) was inserted into the proximal site of the artery from the pole. After the aneurysm clip was released, 0.2 mL of compound **10** solution (1 μM in the final concentration) or the same volume of fluorescein isothiocyanate labeled dextran (FITC-dextran) (Sigma-Aldrich, average molecular weight over 250 000; 5 μM in the final concentration) were injected as a bolus over 30 s into the recipient's carotid artery through the polyethylene tube. The solution of compound **10** for injection was obtained from a stock solution (2.9 mM) in dimethyl sulfoxide in turn diluted to 1.0 μM with phosphate-buffered solution (pH 7.2).

Sampling for Fluorescence Observation. At 30 min after injection, animals were additionally anesthetized, and their blood was washed out by transcardial perfusion of isotonic saline solution. Then brains and livers were removed, frozen in liquid nitrogen, and embedded in OTC compound (Tissue Tek, Elkhart, IN). Coronal sections (8 μm) were cut in a cryostat and mounted on slides and dried. Then sections were fixed by 4% paraformaldehyde. Fluorescent observation was performed with a fluorescence microscope (Olympus BX50).

RESULTS AND DISCUSSION

The synthesis of compounds **5**−**11** was accomplished according to the procedure shown in Scheme 1. Synthesis involved the condensation of the suitably substituted imidazopyridineace-

Scheme 2 [a]

[a] Reagents: (a) R_2NH, TEA, EEDQ, THF; (b) Br_2/CCl_4; (c) DMF reflux.

tic acids **21** (*17*) with the appropriate mono-*N*-Boc-protected diamine compounds **22a**−**f** (*32, 33*) in anhydrous THF and in the presence of EEDQ to give the corresponding amides **23a**−**g**. The Boc deprotection of these last compounds yielded the corresponding compounds **24a**−**g**, which, in turn, by condensation with 7-nitro-2-oxa-1,3-diazole chloride (NBD-Cl) in anhydrous THF and in the presence of TEA afforded the desired compounds **5**−**11**. The synthesis of the imidazo[1,2-*a*]pyrimidines **12**−**20** was carried out as outlined in Scheme 2. Condensation of suitably substituted 2-aminopyrimidine **27** with the appropriate bromoketoamide **28** in refluxing DMF gave compounds **12**−**20** in moderate to good yield. In principle, by using 2-amino-4-methylpyrimidine in the condensation reaction, two regioisomeric compounds **14** and **14′** or **16** and **16′**, respectively, may be produced. The structural assignment of the isolated compounds is based on the analysis of 2D NOESY ^{1}H NMR spectra, which showed the presence of cross-peaks between the proton linked at C(5) and the protons of the methylene group at C(3) of the imidazopyrimidine nucleus, being consistent with the **14** and **16** structures only. The starting 2-aminopyrimidine **27** was commercially available, whereas compound **28** was prepared according to a two-step procedure and summarized in Scheme 2 (*28, 29*). This involved the condensation of the commercially available 3-benzoylpropionic acid **25** with the required dialkylamines in the presence of EEDQ as a dehydrating agent. Treatment of the resulting amide **26** with bromine in carbon tetrachloride afforded compound **28**. All compounds were fully characterized by IR, ^{1}H NMR, mass spectra, and elemental analyses. The yields and physical data for the final compounds are reported in Table 1.

Radioligand Binding Assays. The affinity of compounds **5**−**20** for CBR and PBR was assessed by measuring their ability to displace [^{3}H]flunitrazepam and [^{3}H]PK11195, respectively, from binding to membrane preparations from the cerebral cortex.

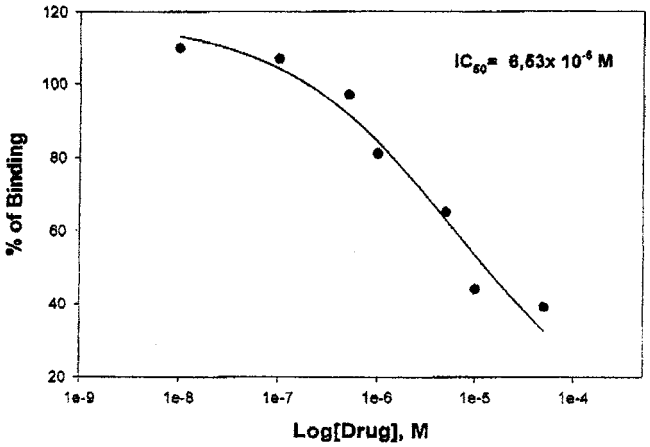

Figure 1. Inhibition of [^{3}H]PK11195 binding to rat cerebrocortical membranes by compound **10**.

Their effects were compared with those of unlabeled PK11195, and the results of these analyses are shown in Table 2. Compounds **5**−**11**, including both monoalkyl- and dialkylamides with *n* varying from 2 to 6, generally showed low affinity and selectivity for PBR. However, dialkylamides were more active and selective than monoalkylamides, and significant improvement in affinity and selectivity was observed by increasing the spacer chain length. In this subset of compounds, **10** ($n = 6$, R $= CH_2C_6H_5$) seemed to be the most interesting one, showing an IC_{50} value of 6.7 μM. Figure 1 shows the inhibition of [^{3}H]-PK11195 binding to rat cerebrocortical membranes by compound **10**. Analysis of the present binding data clearly demonstrates that imidazopyridine PBR ligands linked via a fluorogenic 7-nitro-2,1,3-benzoxadiazol- 4-yl spacer group give rise to new ligands with reduced affinity for the receptor, whereas this was not observed when the same fluorogenic group and spacer were linked to 2-phenylindole-3-acetic acid to give compound **1** (*19*). Thus, for example, compound **8** showed affinity and selectivity for PBR much lower than those of the previously described PBR ligand *N*-benzyl-*N*-*n*-butyl-(2-phenyl-6,8-dichloroimidazo[1,2-*a*]pyridin-3-yl)acetamide (*29*) (i.e., 18% of [^{3}H]PK11195 inhibition at 10^{-5} M versus IC_{50} 14 nM, respectively).

On the other hand, compounds **12**−**20** showed different affinities for the PBR ranging from the moderate (i.e., in the

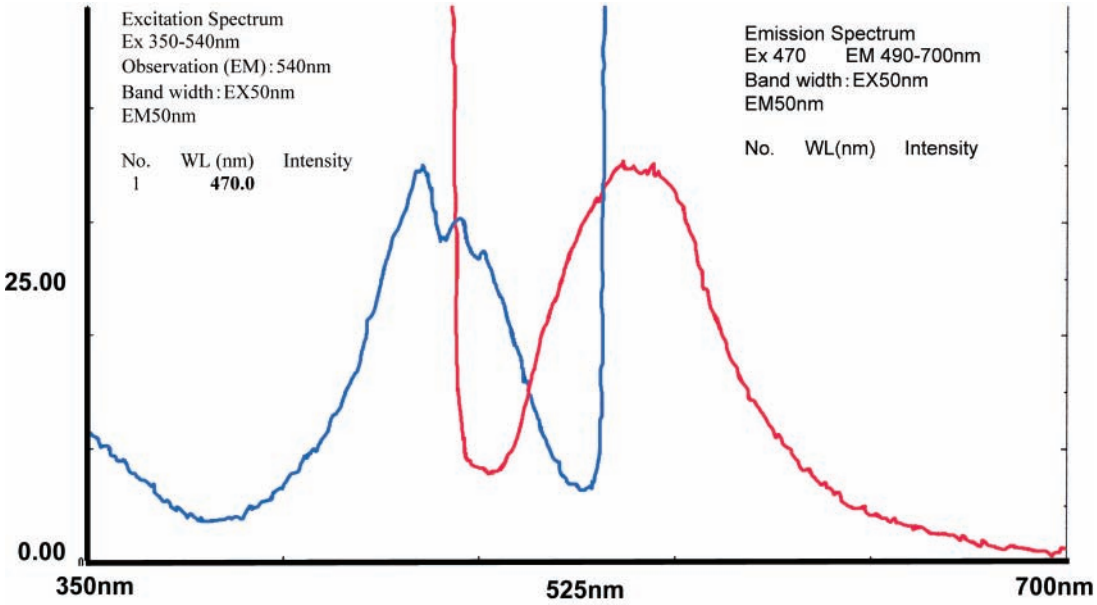

Figure 2. Fluorescence spectrum of compound **10** (excitation at λ 470 and 483 nm) recorded in phosphate-buffered saline (pH 7.2). Compound **10** in dimethyl sulfoxide at 10 mM was diluted to 100 nM in phosphate-buffered saline (pH 7.2) and then the fluorescence spectrum measured by fluorescent spectrophotometer (Shimadzu RF-5300, Shimadzu Co., Kyoto, Japan).

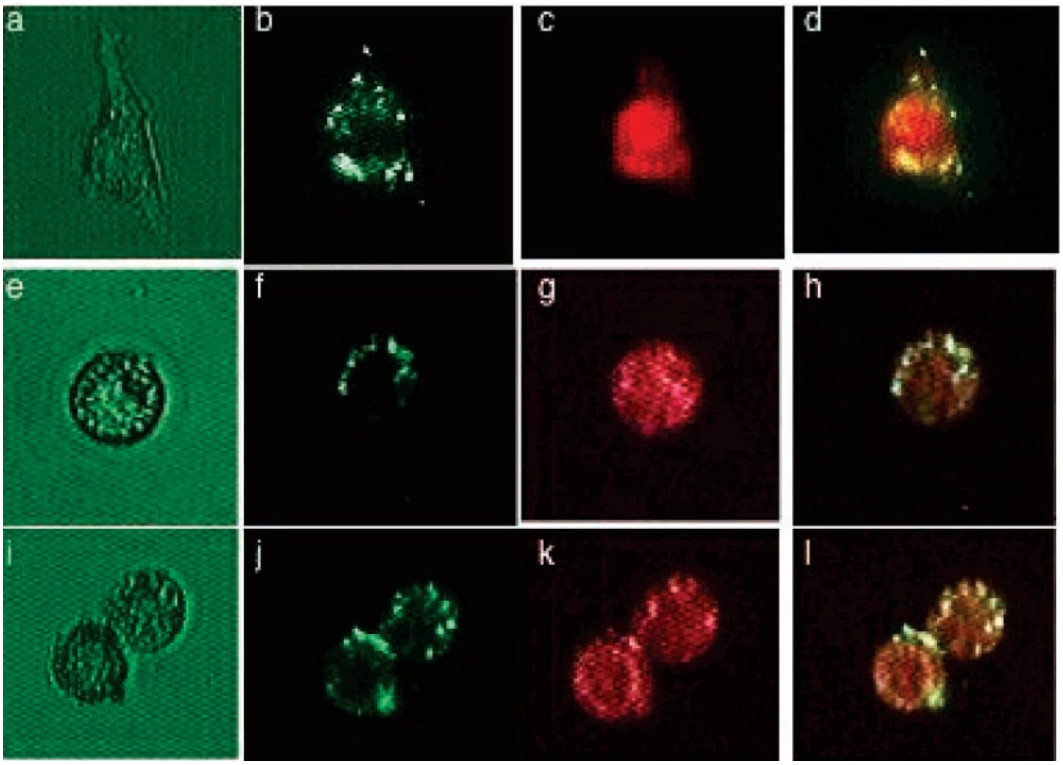

Figure 3. Fluorescent images of Ra2 microglia stimulated with (e−l) or without (a−d) LPS: (a, e, i) phase optics; (b, f, j) fluorescent optics of microglia stained with compound **10**; (c, g, k) fluorescent optics of microglia stained with Mito Tracker Red; (d, h, l) merged optics of fluorescence images of green (compound **10**) and red (Mito Tracker Red).

micromolar range, **12**, **19**, **20**) to high affinity (i.e., in the nanomolar range, **13**, **15**−**18**). Among the compounds of this subset, **17** and **18** were the most active and selective for the PBR, with selectivity indices (defined as the ratio IC_{50} CBR/IC_{50} PBR) of 278 and 546, respectively. From a structure−affinity relationship point of view, it can be pointed out in this subset that alkyl substituents of optimum length on the carboxamide nitrogen and substitution at the para position of the phenyl ring at C(2) of the imidazopyrimidine nucleus with a chlorine atom are crucial for high affinity and selectivity (compare the binding affinities of **15** and **16** as well as **18** and **19**, respectively).

Fluorescence Characteristics of Compounds 5−**20.** All of the examined compounds **5**−**20** showed a visible fluorescence, and the optimum excitation and emission wavelengths are summarized in Table 2. The data were recorded in methanol as solvent by using a Kontron UV−vis spectrometer and a Perkin-Elmer LS-50B spectrofluorometer. As can be seen from Table 2, the intrinsically fluorescent compounds **12**−**20** exhibited fluorescence emission maxima in the range of 260−350 nm,

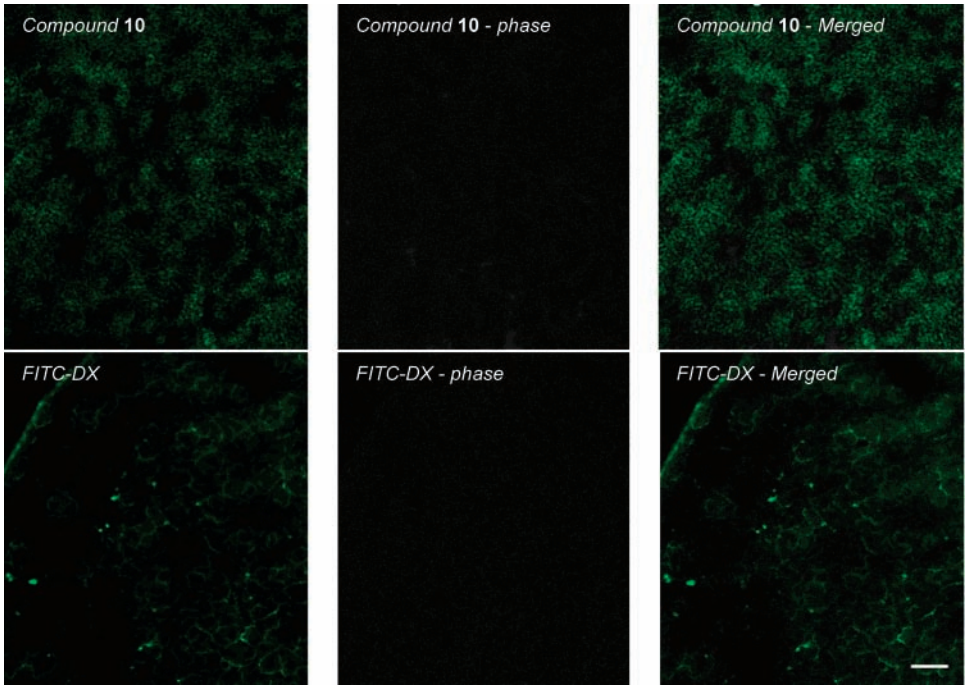

Figure 4. In vivo distribution of compound **10** and FITC-dextran in liver. Liver sections from mouse injected with **10** (upper panels) or FITC-dextran (lower panels) were observed with green fluorescence (left panels) and phase contrast (center panels). Right panels indicate the merged optics of green fluorescence and phase contrast. Bar = 20 μm.

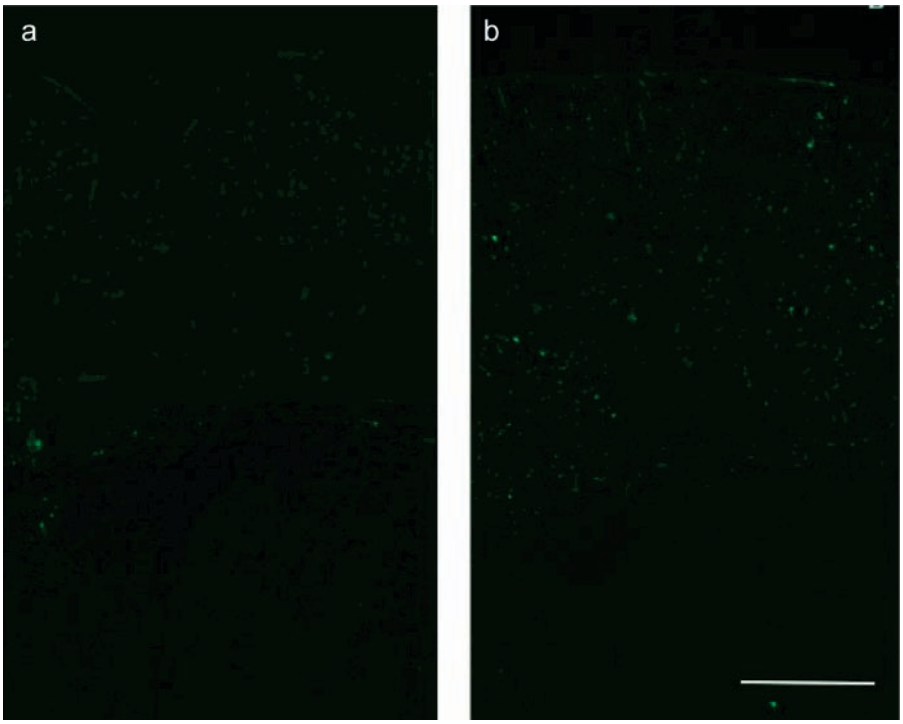

Figure 5. In vivo distribution of compound **10** and FITC-dextran in brain. Brain sections from mouse injected with **10** (a) or FITC-dextran (b) were observed with green fluorescence. Bar = 50 μm.

and thereby their use to successfully visualize PBR is restricted because these wavelengths correspond to those at which many cells and tissues autofluoresce. In contrast, compounds **5**−**11**, bearing the 7-nitrobenzofurazan probe, showed fluorescence emission at longer wavelengths (520−541 nm) and, hence, might be useful for visual imaging of PBR. Thus, in this subset, compound **10** as the most active and selective ligand for PBR was used in fluorescence microscopy studies. Figure 2 shows the fluorescence spectrum of compound **10** with the principal excitation and emission wavelengths at 470, 473, and 541 nm, respectively. Although compound **10** is characterized by a micromolar binding affinity to PBR, literature reports suggest (*21*, *22*) it still can be useful for cellular targeting applications.

Cell Biology, Fluorescence Microscopy, and in Vivo Biodistribution Study on Compound 10. Compound **10** was found to stain live Ra2 microglial cells effectively. Intense fluorescence was observed as a deposit-like pattern mainly distributed in cytosol. Some of the fluorescent deposits were observed to associate with the plasma membrane. Many compound **10**-positive deposits were also stained with Mito Tracker Red, suggesting that compound **10** binding sites may

exist on mitochondria. Large deposits that were not stained with Mito Tracker Red were sometimes observed.

Compound **10**-positive fluorescent deposits were translocated from cytosol to the plasma membrane by LPS stimulation. Some of the deposits were still positive for Mito Tracker Red staining (Figure 3).

The experiments showed that intracellular fluorescent labeling was obtained by using a concentration of 1 μM **10**, that is, a concentration about one-sixth lower than its IC_{50} value.

Compound **10** was used in a biodistribution study to evaluate its utility as a targeting moiety in vivo. Preliminarily, the stability of compound **10** was studied both in 0.05 M phosphate buffer at pH 7.4 and in diluted rat serum solution at 37 °C. Pseudo-first-order kinetics were always observed, and the half-lives were found to be >3 h.

After injection in the carotid artery of adult male C57BL/6 mice of compound **10** and FITC-dextran, used as a control dye, and successive brain and liver removal, it was found that in liver sections compound **10** penetrates to liver parenchyma and stains hepatocytes, whereas FITC-dextran was observed to remain in blood vessels (Figure 4). On the other hand, as for the distribution to brain, the patterns of staining with **10** and FITC-dextran are similar, indicating that both of them hardly penetrate into the brain because of the existence of the blood−brain barrier (BBB) (Figure 5).

In conclusion, some fluorescent imidazopyridine and imidazopyrimidine compounds **5**−**20** were synthesized, and their affinity for PBR was determined. Although members of the subset **12**−**20** possess good PBR binding affinity, they are characterized by a fluoroscence emission wavelength that prevents their use in successfully visualizing PBR. In contrast, compounds **5**−**11** fluoresce at a longer wavelength but possess a low to moderate affinity for PBR. Compound **10** was shown to be the most active derivative and represents a new fluorescent probe for visualization of activated microglia and PBR. It may have some significant advantages (structural simplicity, cost-effective, easy to handle) over the fluorescent or radioactive probes for PBR currently used. In particular, a comparison with compounds **1** [Kozikowski's compound, utilizing the same fluorophore (NBD)] and **3**, both characterized by simple structure and involving no linkages with transition metals, reveals that compound **10** should possess better BBB penetration properties on the basis of its log C_{brain}/C_{blood} (log BB) value (−0.54 compared with −1.06 of **1** and −1.78 of **3**) as estimated by using Clark's model (*34*), which relates log BB to polar surface area. This last descriptor was computed with a fragment-based approach, known as the topological PSA (TPSA) approach (*35*). It is generally accepted that compounds with log BB > 0.3 cross the BBB readily, whereas compounds with log BB < −1.0 are poorly distributed to the brain. On the basis of the predicted log BB values, compound **10** should be able to cross the BBB, whereas compounds **1** and **3** as such should be unable to. The observed in vivo poor BBB penetration of **10** might be due to the possibility that this compound is a substrate of Pglyco efflux protein (Pgp) or to extensive binding to serum proteins. From the results of cell culture and in vivo injection, it can be stated that compound **10** is a new useful tool of bioimaging for PBR and has potential to generate new information on the pathological role of this receptor in vivo. Further studies are in progress to synthesize additional compounds, particularly those that combine high affinity and selectivity for PBR and fluorescence emission at long wavelengths as well as good BBB penetration properties.

ACKNOWLEDGMENT

This work was supported by a grant from Ministero dell'Istruzione dell'Università e dellaRicerca (COFIN 2004 MIUR to G.T.). We thank Giovanni Dipinto for skillful technical assistance in recording mass spectra and determining microanalytical data. We also thank Dr. Kelly Desino (The University of Kansas) for helpful discussion.

PMMA Isocyanate-Modified Digital Discs as a Support for Oligonucleotide-Based Assays

María-José Bañuls, Victoria González-Pedro, Rosa Puchades, and Ángel Maquieira*

Instituto de Química Molecular Aplicada, Departamento de Química, Universidad Politécnica de Valencia, Camino de Vera s/n, Valencia, Spain. Received May 30, 2007; Revised Manuscript Received July 10, 2007

A mild chemical procedure for the derivatization of PMMA as the isocyanate on rigid supports is described. The proposal is based on spin-coating the support with a hydroxy-modified PMMA polymer, followed by treatment with (3-isocyanatopropyl)triethoxysilane, developing an isocyanate-ended PMMA. Oligonucleotide hybridization assays performed on this surface demonstrate that the process is simple and highly effective and agree with the results of other modified materials, including aminated PMMA, gold, and glass. As a demonstration, it has been applied to covalently attached aminated oligonucleotides on a modified audio−video compact disc (CD) surface to perform DNA probe hybridization assays. Measurements were carried out with a CD player, by detecting the solid microspots precipitated from an enzymatic reaction (HRP-TMB). This new approach, being a competitive technique, opens a broad horizon of applications for point of care or *in situ* needs.

INTRODUCTION

The concept of hybrid systems has become an active area of research. In them, a molecular event is detected by its ability to alter the transmission of a digital sequence; a true interaction between digits and molecules occurs (*1*).
