

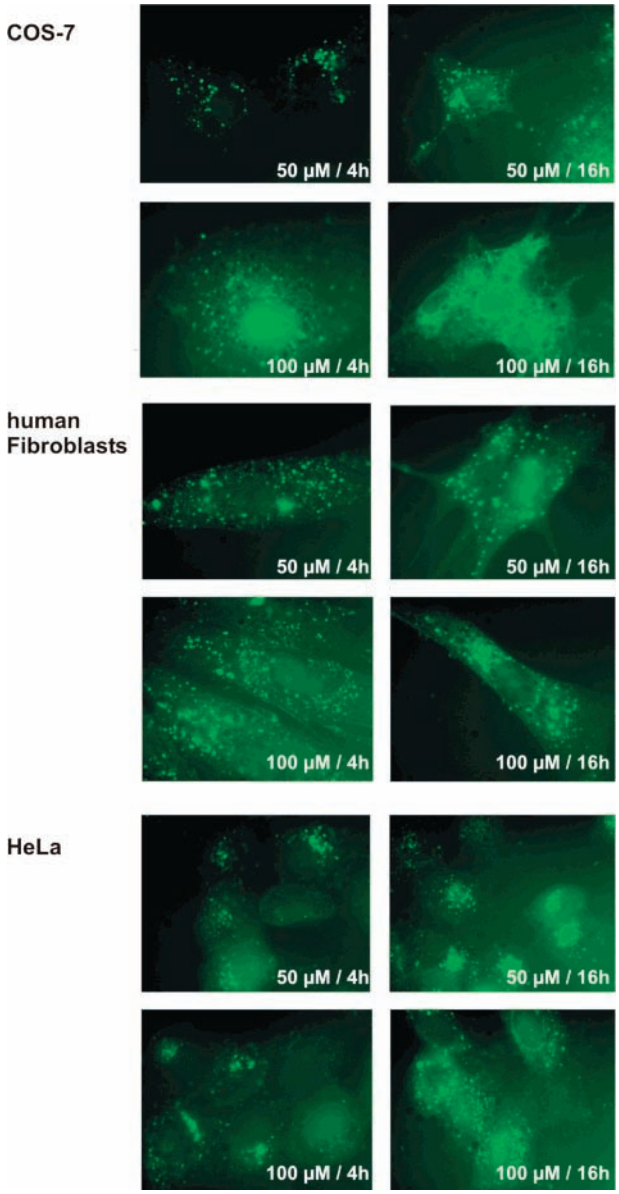

Figure 13. Treatment of COS7, human fibroblasts, and HeLa cells with the fluorescein-labeled hexameric peptoid with alternating C4 and C8 side chains **Fluo**-{**8,4,8,4,8,4**}-NH_2. In all cells, fluorescence was concentrated in vesicular structures, but a diffuse cytosol staining in the cells was also observed.

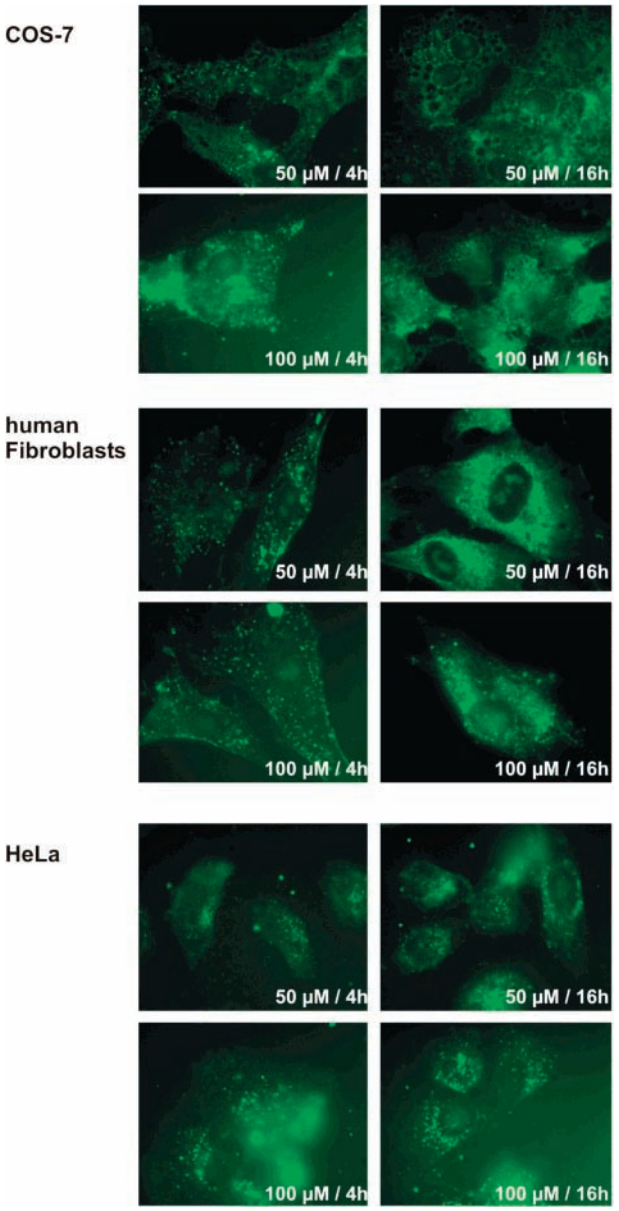

Figure 14. Treatment of COS7, human fibroblasts, and HeLa cells with the fluorescein-labeled octameric peptoid **Fluo**-{**8,4,8,4,8,4,8,4**}-NH_2. In all cell types, fluorescence was localized to vesicular structures and nuclear staining was observed. The main region of the nucleus was precluded from staining.

octameric compound **Fluo**-{**8,4,8,4,8,4,8,4**}-NH_2 exhibited the highest amount of putative cytosolic staining, while vesicular fluorescence decreased in cells with a high degree of diffuse staining. Fluorescence was weak in the nuclei. After overnight incubation, vesicular structures were found to aggregate in the perinuclear region (Figure 14).

In summary, the cytosolic stain was stronger for peptoids with longer backbones. The chimeric compound appeared to be trapped in vesicular structures with markedly less diffused fluorescence within the cytosol. With an increase in incubation time, vesicular structures redistributed their proximity from the plasma membrane to the nucleus. This tendency was markedly less pronounced for the hexamer with alternating side chain lengths than for the homohexamer. The results are summarized in Table 1.

To further examine the influence of side chain length and backbone length, three fluorescein-labeled peptoids and three rhodamine-labeled peptoids of varying side chain and backbone lengths were tested: **Fluo**-{**4,4,4,4**}-NH_2, **Rhod**-{**8,8,8,8**}-NH_2, **Rhod**-{**4,4,4,4,4,4**}-NH_2, **Fluo**-{**6,6,6,6,6,6**}-NH_2, **Rhod**-{**6,6,6,6,6,6,6,6**}-NH_2, and **Fluo**{**8,8,8,8,8,8,8,8**}-NH_2, respectively. Tests were performed in primary human fibroblasts with incubation times of 8, 24, and 48 h, respectively.

As in prior experiments, the transporter molecules were found to accumulate in vesicular structures. In general, transporters with shorter backbones exhibited a weaker uptake than those with a long backbone. The weakest uptake was observed for the tetramer **Fluo**-{**4,4,4,4**}-NH_2, while the octamers **Rhod**-{**6,6,6,6,6,6,6,6**}-NH_2 and **Fluo**{**8,8,8,8,8,8,8,8**}-NH_2 exhibited the highest uptake efficiency but are not as efficient for cytosolic and nuclear staining. Comparison with their relatives containing alternating side chains revealed a higher uptake rate of the nonalternating peptoids in the tested cell cultures.

To prove that this kind of peptoids can be used as shuttles for other cargos than fluorophores, the different peptoid building blocks were covalently coupled to 5-(4-carboxyphenyl)-10,15,-20-triundecyl-21*H*,23*H*-porphyrin (**12**) (carboxyporphyrin) (*37*)

Table 1. Comparison of Cellular Uptake of Different Peptoids

			intracellular localization			
	compound	uptake rate % of cells	vesicular	perinuclear	cytosolic	nuclear
tetramer	**Fluo**-{**4,4,4,4**}-NH_2	100	++	++	+	-
	Fluo-{**6,6,6,6**}-NH_2	100	++	++	+	++ (high conc.)
	Rhod-{**8,8,8,8**}-NH_2	100	++	++	+	-
pentamer	**Fluo**-{**6,1*,6,1*,6**}-NH_2	100	+++	+++	+	+
hexamer	**Rhod**-{**4,4,4,4,4,4**}-NH_2	100	+++	+++	++	+
	Fluo-{**6,6,6,6,6,6**}-NH_2	100	+++	+++	++	+
	Fluo-{**8,4,8,4,8,4**}-NH_2	100	+++	++	++	++ (high conc.)

(Figure 4) via a peptide bond. It is well-known that porphyrin derivatives are photosensitizers that are administered in photopdynamic therapy (PDT) to initiate a light-activated destruction of a variety of cell types, especially in tumors. Porphyrins have the ability to generate reactive oxygen species (ROS) after illumination with visible light, which leads to the destruction of all kinds of double bonds in biomacromolecules such as unsaturated lipids, DNA, RNA, and many more. However, most of the porphyrin derivatives are insoluble in polar solvents such as water, DMSO, or methanol making them unsuitable for *in vivo* applications. If the porphyrins can be carried into tumor cells, those can be destroyed by illumination. Therefore, the following peptoids **Porph**-{**4,4,4,4,4,4**}-NH_2, **Porph**-{**6,6,6,6,6,6,**}-NH_2, and **Porph**-{**8,8,8,8,8,8**}-NH_2 were synthesized by using building blocks **5a**{**4**}, **5a**{**6**}, and **5a**{**8**} (Scheme 1) and carboxyporphyrin **12** (*37*, see Supporting Information) to investigate whether the peptoid moiety is able to enhance the water solubility and the cellular uptake of the porphyrin. The cellular uptake of **Porph**-{**4,4,4,4,4,4**}-NH_2, **Porph**-{**6,6,6,6,6,6,**}-NH_2, and **Porph**-{**8,8,8,8,8,8**}-NH_2 was tested in primary fibroblasts and several tumor cell lines such as HeLa, COS-7, and neuroblastoma cells at a concentration of

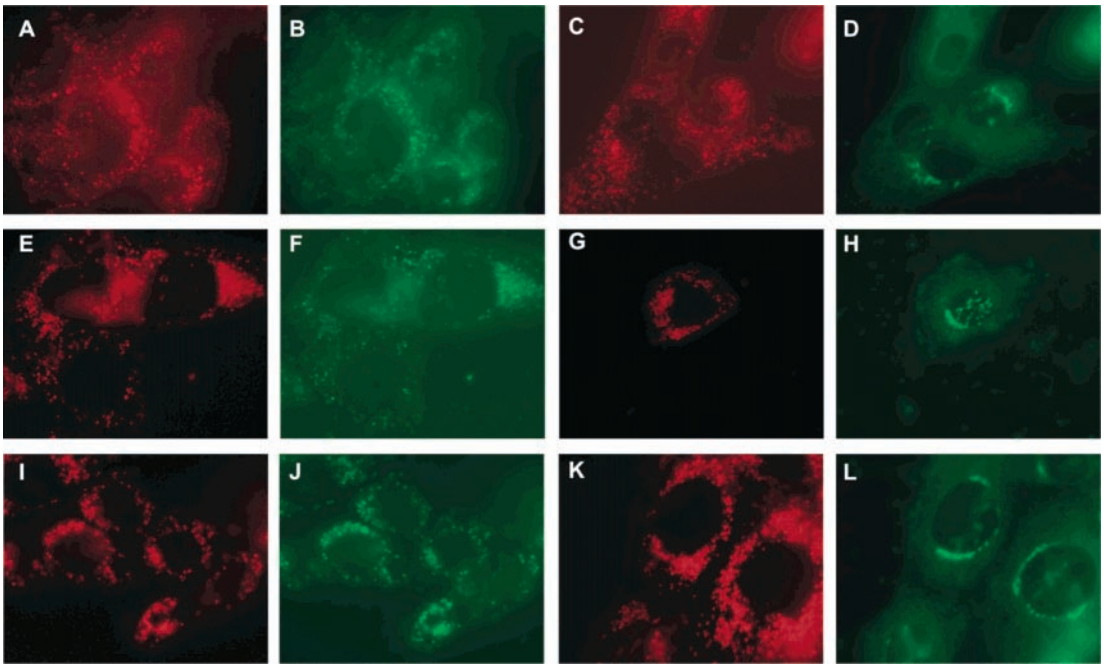

Figure 16. Confocal images of living primary fibroblasts treated as follows: A, **Porph**-{**4,4,4,4,4,4**}-NH_2, 1 μM, 24 h; B, labeling of A with Lysotracker for endosome and lysosome staining; C, **Porph**-{**4,4,4,4,4,4**}-NH_2, 1 μM, 24 h; D, labeling of C with NBD-C6-Ceramide for Golgi staining; E, **Porph**-{**6,6,6,6,6,6**}-NH_2, 1 μM, 24 h; F, labeling of E with Lysotracker; G, **Porph**-{**6,6,6,6,6,6**}-NH_2, 1 μM, 24 h; H, labeling of G with NBD-C6-Ceramide; I, **Porph**{**8,8,8,8,8,8**}-NH_2, 1 μM, 24 h; J, labeling of I with Lysotracker; K, **Porph**-{**8,8,8,8,8,8**}-NH_2, 1 μM, 24 h; L, labeling of K with NBD-C6-Ceramide.

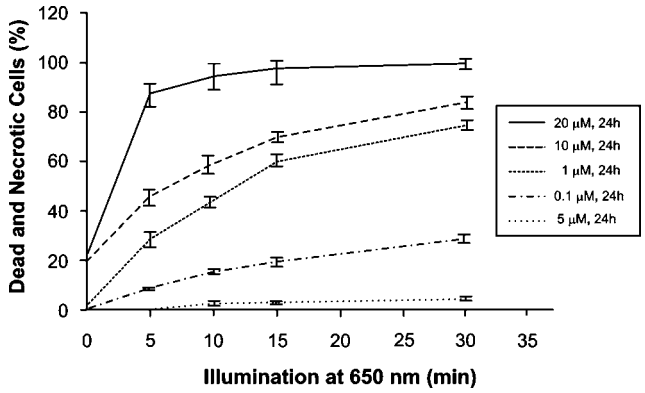

Figure 17. Quantification of the phototoxic effect of **Porph-{8,8,8,8,8,8}-NH$_2$** on primary fibroblasts. Cells were incubated with 0.1, 1, 10, and 20 μM **Porph-{8,8,8,8,8,8}-NH$_2$** and 5 μM carboxyporphyrin **12** for 24 h. Eventually, the cells were illuminated with 650 nm light for various times. Quantification of dead and necrotic cells from five independent experiments was performed after staining with propidium iodide and trypan blue. The illumination of cells in the absence of photosensitizers revealed no significant necrosis. The cells were counted in 3 × 4 random fields framed with the *Axiovision* software, and the readout was evaluated by the Student's *t* test. SD was calculated from the $n = 5$ experiments.

1−10 μM. Figure 15 shows the intracellular localization and the successful cellular uptake of all porphyrin-coupled peptoids while the unmodified carboxyporphyrin **12** was not taken up by the cells. As shown in Figure 16, **Porph-{4,4,4,4,4,4}-NH$_2$**, **Porph-{6,6,6,6,6,6,}-NH$_2$**, and **Porph-{8,8,8,8,8,8}-NH$_2$** colocalize with the endosomal compartment but with neither the Golgi apparatus nor the nucleus. After longer incubation with the *Lysotracker Green* and a chase of the lysosomal marker into the lysosomes, colocalization is not longer detectable (data not shown), revealing an endosomal accumulation.

Besides the measurement of the cellular uptake, the phototoxic effect was determined after illumination of the cells with light of 650 nm. The cells were incubated with different concentrations of **Porph-{8,8,8,8,8,8}-NH$_2$** for 24 h. A phototoxicity was already seen after 5 min of illumination, and necrosis of the cells was clearly dependent on the concentration of **Porph-{8,8,8,8,8,8}-NH$_2$** during the treatment (Figure 17). When cells are treated with 20 μM of **Porph-{8,8,8,8,8,8}-NH$_2$**, about 85% of the cells already showed severe necrosis after 5 min, while almost no cells survived the treatment for 15−30 min. Likewise, incubation with 10 μM of **Porph-{8,8,8,8,8,8}-NH$_2$** yielded 80% dead cells after 30 min.

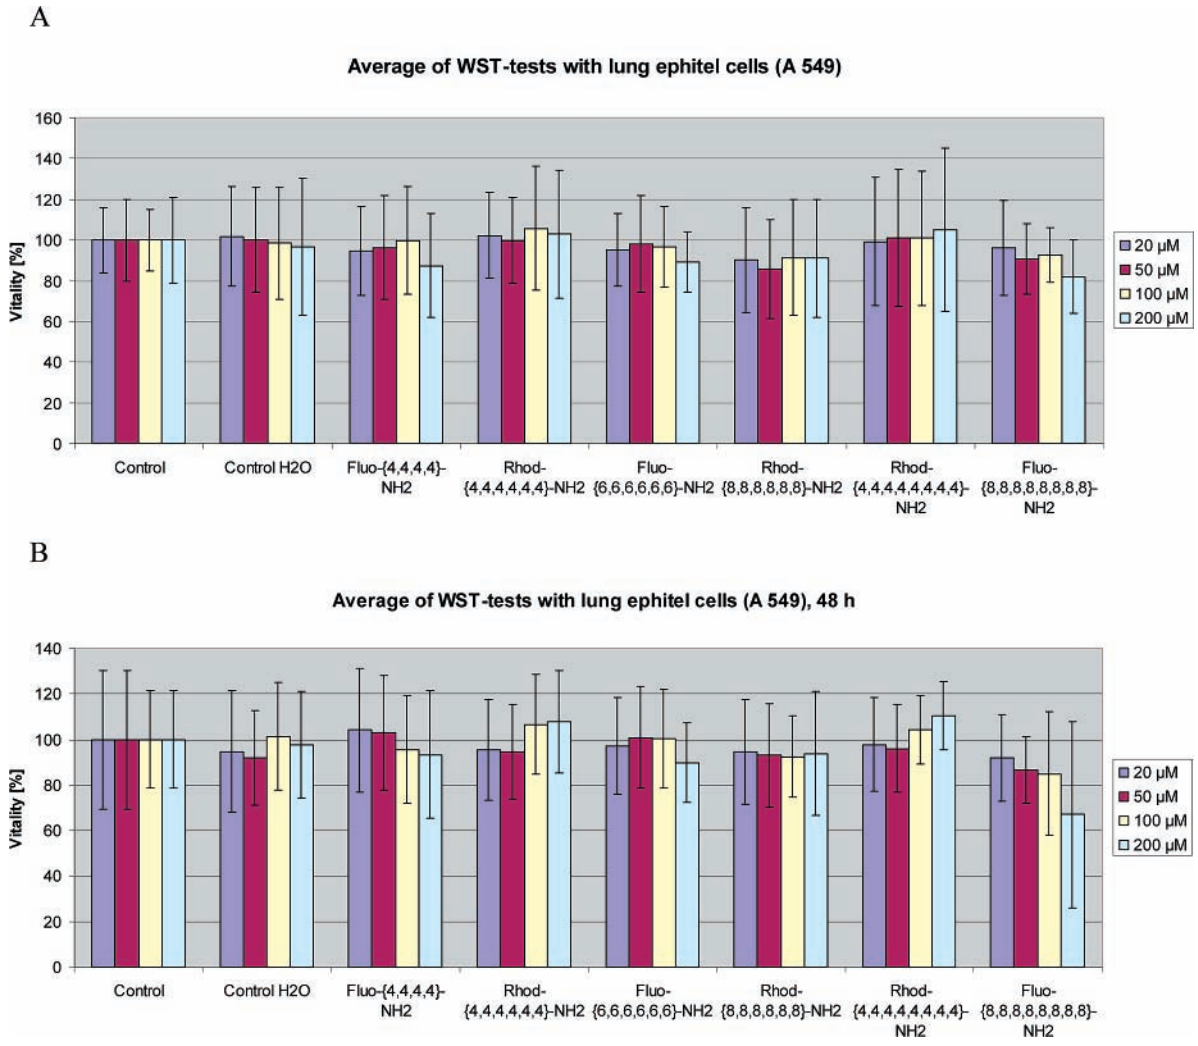

Figure 18. WST test. A. For each viability test, human epithelial lung cancer cells (A549) were grown to confluence in 96 MicroWell plates from Nunc and treated with 20, 50, 100, and 200 μM of the peptoids for 24 h at 37 °C. All experiments were carried out two to three times in quadruplicate. After incubation, the formed dyes were quantified at 450 nm by using a scanning multiwell spectrophotometer (ELISA reader). For every time point, the test was carried out twice. Untreated cells are used as positive control (100% viable), and all values from the experiment are correlated with this set of data. B. Average from WST test after incubation with the above-described peptoid concentration for 48 h.

Toxicological Tests. To verify that the synthesized peptoids could be used for in vivo applications, it is important to gain information about their toxicity toward mammalian cells. Therefore, six of the ten peptoids were tested in different cytotoxicity assays. The effects of the peptoids were investigated with the adherent human epithelial lung cancer cell line A549.

To confirm the results, three tests with different outcome or procedures were carried out. Two of the tests, MTT and WST-1, detect the viable cells by examination of the intracellular reduction potential, while the third, the LDH test, detects dead cells.

The MTT assay, which is usually used to measure cell proliferation of cancer cells, is based on the reduction of the yellow tetrazolium salt MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) by actively growing cells to produce a blue formazan product.

The positive charge of MTT is responsible for its cellular uptake. Within the cell, the reduced pyridine nucleotide cofactor, NADH, is responsible for most MTT reduction to the blue formazan. This reduction is associated not only with mitochondria, but also with the cytoplasm and with the endosomal/lysosomal compartment and the plasma membrane (*38*). This bioreduction occurs intracellularly in viable cells only. Eventually, it can be extracted and photometrically quantified at 550 nm. The amount of formazan dye formed directly correlates to the number of metabolically active cells in the culture.

The WST-1 assay uses second-generation tetrazolium dyes that form water-soluble formazans and require an intermediate electron acceptor for reduction. The WST-1 assay is more sensitive than the MTT assay, and the results are depicted in Figure 18. WST-1, a sodium salt of 4-[3-(4-iodophenyl)-2-(4-nitrophenyl)-2*H*-5-tetrazolio]-1,3-benzene disulfonate, is oppositely charged from MTT and cannot be taken up by the cells. It was suggested that its reduction occurs at the extracellular side of the plasma membrane via trans-plasma membrane electron transport (*38*, *39*). In contrast to MTT−formazan from the MTT assay, the resulting WST-1-formazan is water-soluble and can be photometrically quantified at 450 nm. This bioreduction is largely dependent on the glycolytic production of NAD(P)H in viable cells and is thus directly correlated to the number of metabolically active cells.

In contrast the lactate dehydrogenase (LDH) assay is a marker for membrane integrity. The test is based on the measurement of cytoplasmic enzyme activity found in the supernatant of damaged cells. Lactate dehydrogenase (LDH) is a stable cytoplasmic enzyme that is present in all cells. It is rapidly released into the cell culture supernatant when the plasma membrane is damaged. It is freely floating in the cytosol, and upon membrane damage, it is released into the extracellular space, where it can reduce the tetrazolium salt INT (2-(4-iodophenyl)-3-(4-nitrophenyl)-5-phenyl-2*H*-tetrazolium chloride) to another formazan dye (*40*). LDH enzyme activity in the culture supernatant increases with the number of dead cells. The increase in supernatant LDH activity directly correlates to the amount of formed formazan.

The cells were tested in cell proliferation and viability assays according to the protocols described previously (*40*). The data shown in Figure 18 representing the results from the WST-1 test could be reproduced by the two other tests (data not shown). As shown by all viability tests, the viability of A549 cells treated with up to 200 μM of any one of the six peptoids did not differ significantly and did not increase or decrease in comparison to wild-type cells over the time period observed. This makes the peptoids suitable for the first in vivo assays.

DISCUSSION

Ten peptoids labeled with a fluorescent dye and three carriers, bioconjugated with porphyrins, were efficiently prepared using solid-phase syntheses and tested for cellular uptake in three different mammalian cell types (COS7, HeLa, human fibroblasts). Peptoids with short backbones were shown to exhibit a weaker uptake than those with long backbone lengths, with the highest ratio between uptake efficiency and cytosolic/nuclear localization being found for hexameric peptoids. In addition, a relatively short peptoid with chiral side chains also exhibited good cellular properties. Nevertheless, all carrier peptoids had cell-penetrating abilities, making these efficient structures promising transporter candidates for drug delivery.

As it is shown, no acute toxicity of the peptoids could be detected in the WST-1 assay. The results of the MTT and LDH assays (data not shown) supported this conclusion. For these tests, lung cells were taken to observe whether the transporters could be used as aerosols as well. The uptake rate was 100%.

ACKNOWLEDGMENT

This work has been performed as part of the project E1.1 of the DFG Research Center for Functional Nanostructures (CFN). Further support provided by a grant from the Ministry of Science, Research, and the Arts of Baden-Württemberg (Az: 7713.14−300). K. Schmitz was supported by the Fond der Chemischen Industrie. A special thank-you goes to Dr. Johannes Köbberling, Bayer Health Care AG, Germany, for donation of modified resins. We thank Dr. Frank Lauterwasser for supply of the monomer **5**{**1***} and Sylvia Vanderheiden for the dedicated experimental help.

Supporting Information Available: Spectroscopic and analytical data for all products not described in the text (e.g., building blocks). This material is available free of charge via the Internet at http://pubs.acs.org.

Received July 22, 2006; Revised Manuscript Received November 15, 2006

Ultrathin poly(methyl methacrylate) (PMMA) stereocomplex films with macromolecularly double-stranded regular nanostructures were prepared by layer-by-layer assembly of isotactic and syndiotactic PMMAs on solid surfaces. Antibodies were immobilized through the Fc region-capturing protein A, which had been physically adsorbed on the complex film, and the binding of antigens to immobilized antibodies was quantitatively investigated by the quartz crystal microbalance technique. Greater amounts of protein A with native forms were adsorbed on the complex film than those on conventional single-component PMMA films. Antibodies with high target-binding activities were also immobilized on the complex film. A greater amount of antigens could be detected on the complex film. The activity of protein A was maintained on the complex for a long time even within a dried state. The mechanism for the preservation of protein native forms on the complex surface was speculated by analyzing the physical adsorption of proteins with various secondary structures. Stereocomplex films can be utilized as novel coating nanomaterials for efficiently detecting protein−protein interactions.

INTRODUCTION

Efficient and reproducible observations of the interaction between proteins and biomolecules including target proteins, peptides, DNAs, and sugars on solid material surfaces are essential to develop reliable immunoassay (*1*−*3*) and high-throughput microarray/chip (*4*, *5*) systems. The first step for the observation is the immobilization of proteins on material surfaces. Covalent or noncovalent linkages based on site-specific or nonspecific interactions between proteins and surfaces have been used to stably immobilize proteins on material surfaces (*6*). The suitable immobilization method is selected on the basis of protein species and surface chemical compositions. The key technology among these methods is the maintenance of protein active forms after the immobilization on solid surfaces.

The detection of antigen−antibody interactions on material surfaces is one of the important requirements for immunoassay and microarray/chip. For these applications, antibodies have to be immobilized on surfaces, as those can bind efficiently to antigens. In this case, antigen-binding sites of antibodies should be oriented ideally to outside of the surface. For the simple noncovalent immobilization, physical adsorption of antigens or antibodies on nitrocellulose membrane (*7*), polystyrene surfaces, polylysine- or nitrocellurose-modified glass slides (*8*), and ω-functionalized self-assembled monolayers (*9*) have been employed. However, these methods lack defined orientations of proteins. In order to overcome this problem, site-specific protein A (PA) (or protein G)-Fc interactions (*10*−*15*), avidin−biotin interactions (biotinylated antibody) (*10*, *16*), duplex formation of DNAs (*17*), metal coordination (*18*), and other interactions (*19*, *20*) have been utilized for protein immobilization.

We originally developed ultrathin polymer films composed of double-stranded helical stereocomplexes (SCs) (*21*−*26*), in which isotactic (it) poly(methyl methacrylate) (PMMA) is surrounded by twice the length of syndiotactic (st) PMMA (*27*, *28*). Layer-by-layer (LbL) assembly (*29*, *30*) of stereoregular polymers of methacrylates on material surfaces resulted in the stepwise formation of SCs on surfaces, thus fabricating ultrathin complex films with regular nanostructures at macromolecular level. Since LbL assembly is simply and readily demonstrated in wet processes, ultrathin SC films with controllable thicknesses can be fabricated on various material surfaces, when substrates never dissolve into acetonitrile, a typical assembly solvent for the complex.

Our previous papers quantitatively analyzed physical adsorption of proteins such as bovine serum albumin (*31*), human serum albumin (HSA), fibrinogen, and lysozyme (*32*) on PMMA films and revealed that (1) greater amounts of proteins adsorbed on the SC film surface than those on conventionally prepared spin-coated films composed of a single PMMA component, (2) apparent adsorption constants of proteins on the complex surface were smaller than those on the conventional film, and (3) denaturation of physically adsorbed proteins might be suppressed on the complex surface, although the mechanism for the interaction between the complex surface and proteins has not been discussed. Furthermore, interactions of human whole blood with the complex surface supported un-denaturing of serum proteins adsorbed (*33*). These observations indicated that the protein adsorption property on polymer films is strongly dependent on surface-assembly structures of polymers. Note that the static contact angle of the complex surface is located between it- and st-PMMA films, thereby indicating that the film's

hydrophobicity cannot interpret these observations (*21*). Since the complex film can be fabricated not only on inorganic surfaces such as glass and gold but also on organic surfaces such as polystyrene and poly(ethylene terephthalate), the complex film surface has the potential for novel platforms that efficiently detect antigen−antibody interactions, when suitable target-capturing proteins are utilized for the direct immobilization on the complex surface.

In this study, we analyzed the detection of antigens using antibodies immobilized on PA, which had been physically adsorbed on ultrathin SC films composed of stereoregular PMMA. A combination of HSA and anti-HSA rabbit polyclonal antibody (Ab) was selected as a typical model. The results were compared to conventionally prepared spin-coated films composed of a single stereoregular PMMA and a gold surface. On the basis of amounts of HSA detected on Ab-immobilized PA surfaces with other spectral and surface topological data, PA denaturing and Ab orientation were discussed. It was suggested that the physical adsorption of PA with native forms on the complex film surface is the key step for favorable oriented immobilization of antibodies through PA and subsequent antigen detection. Other antigen−antibody combinations supported the advantage of the complex surface. In order to reveal the mechanism, other proteins were adsorbed on PMMA films, and effects of the secondary structure were analyzed. Our system is schematically shown in Figure 1.

MATERIALS AND METHODS

Film Fabrication. PA adsorption, antibodies immobilization, and antigen detection were quantitatively analyzed by a 9 MHz quartz crystal microbalance (QCM) substrate with gold electrodes (4.5 mm diameter), which estimates the mass of proteins (Δm) from frequency decreases ($-\Delta F$) as follows: $-\Delta m$ [ng] $= 0.87 \times \Delta F$ [Hz] (*34*). The potential of the QCM method for the detection of antigen−antibody interactions has already been demonstrated (*15*). PMMA SC films were prepared by the alternate immersion of substrates into acetonitrile solutions of it-PMMA (M_n 19 000, M_w/M_n 1.10, >98% isotacticity) (Polymer Source) and st-PMMA (M_n 18 600, M_w/M_n 1.23, >85% syndiotacticity) (Polymer Source) at 1.7 mg mL^{-1} for 5 min each at ambient temperature, following methods previously reported (*21*). After the 14 step assembly (7 steps for each PMMA), the mean film thickness was estimated to be 4.8 nm. Atactic (at) PMMA (M_n 22 500, M_w/M_n 1.03) was purchased from Polysciences. Single-component films with 7 nm thickness were prepared by a conventional spin-casting method using a chloroform solvent (1.7 mg mL^{-1}, 2000 rpm).

Antigen−Antibody Interaction. On the film surface, PA (42 kDa, *Staphylococcus aureus*, ICN Pharmaceutical) was physically adsorbed at 1 μM in PBS (pH 7.4) for 1 h at 37 °C, and Ab (160 kDa, Sigma-Aldrich) was immobilized at 1 μM in PBS for 1 h at 37 °C. Subsequently, specific HSA (69 kDa, human serum, fatty acid and globulin free, Sigma-Aldrich) or nonspecific bovine serum albumin (66 kDa, bovine serum, fatty acid and globulin free, Sigma-Aldrich; BSA) was bound from PBS solutions for 1 h at 37 °C to immobilized antibodies and analyzed for suitable concentrations. After immersion of substrates into protein solutions, substrates were rinsed with PBS and ultrapure water and dried with nitrogen gas. Then, frequencies were measured in air, so as not to weigh solvents. PA amounts were measured in air in all experiments, since Ab were successfully immobilized in the following steps. However, antigen amounts were measured without drying (and measuring ΔF) at Ab steps, so as not to lose Ab activities (in fact, Ab in dried state did not detect antigens). Therefore, antigen amounts were estimated by the difference of total Ab immobilized plus antigen detected amounts, and Ab immobilized amounts (see Table 1). For other antigen−antibody combinations, fibrinogen (Fib) (EMD Bioscience)/anti-Fib goat antibody (Rockland Immunochemicals), avidin (Av) (Zymed Laboratories)/anti-Av rabbit antibody (Polysciences), and human chorionic gonadotropin (hCG) (Cell Sciences)/anti-hCG rabbit polyclonal antibody (Rohto Pharmaceutical) were used. The antibodies were similarly immobilized on PA-coated films at 1 μM at 37 °C, and then the antigens were detected.

Characterization Methods. The surface topology at each step was analyzed by a tapping-mode atomic force microscope (AFM) (SPM-9500J3, Shimadzu) in air at ambient temperature. The mean roughness (R_a) of each surface was estimated. The apparent binding constant between antibodies and antigens on surfaces was estimated using the following equation:

$$A = \frac{K_{app} A_{max}}{1 + K_{app}[\mathrm{HSA}]}[\mathrm{HSA}]$$

where A is the amount of HSA bound, A_{max} is the maximum A, K_{app} is the apparent binding constant. Apparent adsorption constants of PA on polymer surfaces were similarly estimated by using the aforementioned equation, as shown in previous studies. (*31, 32*) Attenuated total reflection (ATR) spectra of PA adsorbed were obtained using the refractive surface of 100 nm thick gold-coated poly(ethylene terephthalate) substrates (Tanaka Precious Metals, Japan) with a Perkin-Elmer Spectrum One (U.S.A.) in air at ambient temperature. Interferograms were co-added 50 times and Fourier transformed at a resolution of 4 cm^{-1}. Experiments were repeated three times. Note that *S*/*N* ratios of spectra obtained from the substrate were smaller than those directly obtained from the QCM gold surface.

Physical Adsorption of Proteins. Physical adsorption of HSA, citrate synthase (52 kDa, porcine heart, Sigma-Aldrich; cit. synth), horseradish peroxidase (44 kDa, horseradish, Sigma-Aldrich; HRP), cytochrome c (12 kDa, horse heart, Sigma-Aldrich; cyto. c), alkaline phosphatase (94 kDa, *E. coli*, Wako; ALP), carbonic unhydrase (30 kDa, bovine erythrocytes, Sigma-Aldrich; CA), α-chymotrypsin (25 kDa, bovine pancreas, Wako; α-CTP), green fluorescent protein (27 kDa, aeqorea victoria, prepared by our group; GFP), avidin (67 kDa, egg white, nacalai tesque), and superoxide dismutase (62 kDa, bovine erythrocytes, Sigma-Aldrich; sup. dismut) at 1 μM in PBS (except for ALP and β-Gal) at 37 °C was similarly analyzed by using the QCM method. ALP was dissolved in 50 mM Tris-HCl (pH 9.0), and β-Gal was dissolved in 50 mM phosphate buffer (pH 7.4) containing 1 mM $MgCl_2$, because the enzymatic activity will be analyzed using these solutions in the near future. Although we have already analyzed the physical adsorption of HSA on the SC film (*32*), it was analyzed again because of the difference in polymer sources. The secondary structures of these proteins were obtained from the web site of Protein Data Bank (PDB, http://www.rcsb.org/pdb/home/home.do). Experiments were repeated at least three times.

RESULTS AND DISCUSSION

Protein A Adsorption on Surfaces. Direct immobilization of antibodies on polymer films is the simplest way for detecting antigens on surfaces. Since the SC film has the potential to suppress the antibody denaturing by physical adsorption, we expected efficient detection of antigens using the antibody-immobilized complex film. Therefore, the antibody immobilization on PMMA films based on physical adsorption and antigen detected was investigated as the first system. However, antigens did not bind to the antibodies (a level of nonspecific adsorption), indicating that directed orientation of antibodies could not be realized by the simple adsorption on solid PMMA films (data not shown). Accordingly, we selected PA, which specifically binds to the Fc region of IgG, as an antibody-capturing protein, and PA was physically adsorbed on PMMA films, following previous studies (*10*−*15*). In this case, the amount and activity of immobilized PA is crucial for antibody immobilization and subsequent antigen detection.

The amounts of PA physically adsorbed on SC film surfaces, each component film, at-PMMA, and the bare gold of the QCM substrate are summarized in Table 1. These amounts were almost saturated at 1 μM and are reasonable when we consider monolayer adsorption of proteins (*35, 36*). Greater amounts of PA adsorbed on the complex film at the same PA concentration when compared to other PMMA films. The aforementioned observation is consistent with our previous results, in which greater amounts of serum proteins tend to adsorb on complex surfaces (*31, 32*). The amounts of PA on the gold surface were the same as those of the complex, within experimental error. Accordingly, the amount of PA adsorbed was strongly dependent on the film surface component.

Antibody Immobilization on Protein A-Coated Surfaces. The amounts of Ab immobilized on PA-coated surfaces and the percent of PA used for the Ab immobilization are shown in Table 1 (the percentage was estimated by assuming 1:1 binding between PA and Ab). The component obviously affected the amount of immobilized antibodies. The greatest amount of Ab was immobilized on the complex film coated with PA. The amount of Ab immobilized on the complex was 1.5 times greater than the amount observed on other PMMA films. In addition, the Ab amount on gold was clearly smaller than the amount on the complex, suggesting that certain amounts of PA adsorbed on gold were functionally denatured (this is also supported by spectral data; see below). Surface coverages of IgG were estimated to be 550 ng cm^{-2} and 200 ng cm^{-2} for all "end-on" (Fc closer to the surface) and "side-on" orientations, respectively (*37*). Therefore, it is suggested that the present surfaces are covered by Ab monolayer with different orientations. These observations indicate that the PMMA surface composed of the double-stranded SC is suitable to immobilize greater amounts of Ab through the physically adsorbed PA underlayer at the same protein concentrations.

It is noted that all PA adsorbed on polymer film surfaces are not necessary to interact with Ab, because the molecular size of PA (M_w 42 kDa) is much smaller than that of Ab (M_w 160 kDa), as schematically drawn in Figure 1. When we compare the percent of PA used for the Ab immobilization between the complex and gold surfaces, the former was estimated to be 60% and the latter was 46%, indicating that greater percents of PA adsorbed on the complex were used for the Ab immobilization. Since Ab immobilized on the complex more efficiently detects HSA than those on gold (see the percent Ab used for HSA detection in Table 1, as discussed below), favorable immobilization of Ab was not realized on gold. This means that the specific interaction between PA and the Fc region might not occur due to PA denaturing, followed by the fact that antigen HSA cannot access the binding site of Ab immobilized on PA-coated gold surfaces. On other homogeneous PMMA surfaces, greater percents of PA captured Ab in comparison to that on the complex. This observation is possibly due to the reduced steric hindrance during Ab immobilization, because the amount of PA adsorbed was smaller than that on the complex. However, the percents of Ab used for capturing HSA on homogeneous films were similarly smaller than that on the complex, thus suggesting unfavorable Ab orientation.

Antigen Detection Using Antibody-Immobilized Surfaces. Detecting amounts of antigen HSA at the same concentration (1 μM) and the percent Ab used for the HSA detection, which was estimated by assuming that a single Ab can capture a single HSA due to steric hindrance (although Ab has two sites for antigens), is also summarized in Table 1. Significantly, 2 to 3 times greater total amounts of HSA could be detected on the complex, which is significant when compared to other PMMA films and gold. Detected amounts were clearly greater than those of nonspecifically adsorbed BSA (approximately 23 ng cm^{-2}), thereby indicating that HSA interacted specifically with surface-immobilized Ab. The PA underlayer was used to immobilize Ab, and then it possibly blocked nonspecific protein adsorption. On the complex, the percent of Ab used for HSA detection was greatest in all surfaces. These observations indicate that greater amounts of Ab were immobilized on the complex, and that complex-immobilized Ab worked efficiently. Accordingly, the amount of HSA detected on the complex was maximal, even though the polymers had the same chemical structure.

In order to obtain surface topographic data of the present stepwise process, the surfaces were observed by AFM, as shown in Figure 2. AFM images revealed that the mean roughness of surfaces of the QCM, SC-coated, PA-adsorbed, Ab-immobilized,

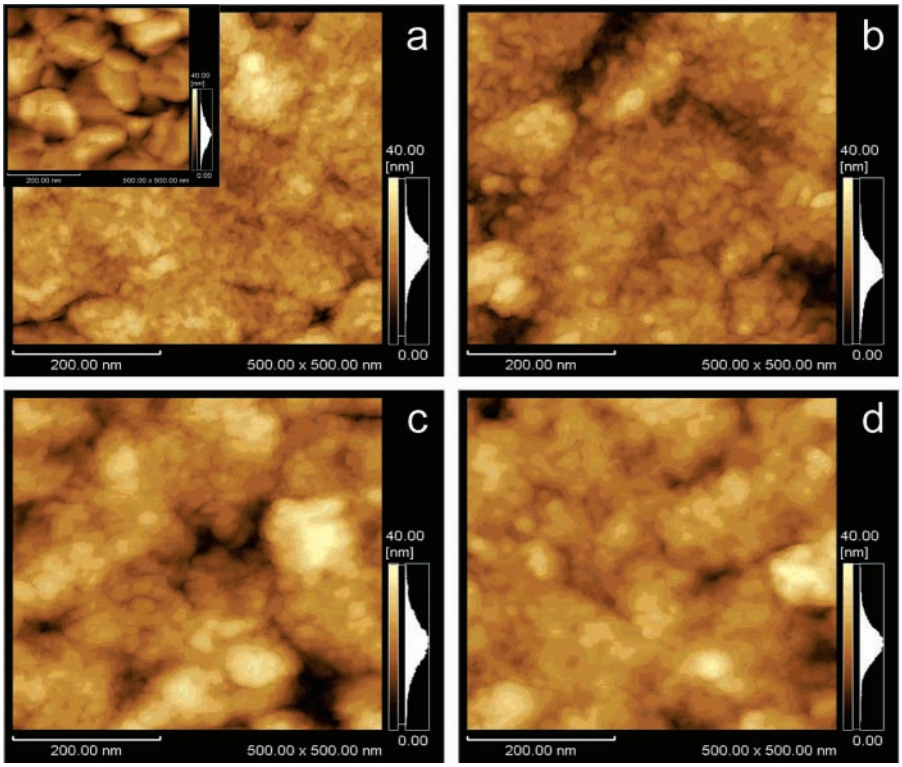

Figure 2. AFM images of (a) the SC surface, (b) the PA-adsorbed surface, (c) the Ab-immobilized surface, and (d) the surface after HSA detection. The inset in (a) shows the bare QCM surface.

and HSA (1 μM)-detected substrates were 5.6, 3.6, 3.7, 4.7, and 3.5 nm, respectively. The roughness of the gold QCM surface was diminished by the SC coating. The adsorption of PA increased the roughness of 0.1 nm. Then, the immobilization of Ab resulted in the roughness increase of 1.0 nm. Since Ab has a nonspherical extremely distorted shape, this roughness increase suggested the Ab coverage. The HSA binding regenerated the smooth surface, which is reasonable when we consider that smaller HSA covered the Ab-immobilized surface based on antigen−antibody interactions. These observations strongly suggest layer-by-layer monolayer immobilization and detection of proteins.

The dependence of HSA detected against the HSA concentration was analyzed to understand the potential for antigen detection on the SC surface, as shown in Figure 3. The dependences for all surfaces were saturated against the HSA concentration. It is obvious that detected values on the complex are greater than those detected on other conventional surfaces. Assuming a Langmuirian-type adsorption, data were fitted to obtain the apparent binding constant (K_{app}) and the maximum detecting amount (A_{max}), which can be converted to the maximum percent Ab used for HSA detection. The coefficient of variation of the fitting for the complex was 0.93. K_{app} was estimated to be 2.02×10^7 M^{-1}, which would be reasonable for the present antigen−antibody combinations. A_{max} was also estimated to be 128 ng cm^{-2}, which corresponds to the maximum percent to be 64%. On the contrary, the coefficients of variation for it-PMMA and gold were 0.66 and 0.54, respectively, Since these fittings for it-PMMA and gold seemed to be unreliable, parameters were not discussed.

The SC surface has the unique potential for maintaining protein functions. The activity of PA was surprisingly maintained even though complex films coated with PA were stored for 10 days under a dried state, as shown in Figure 4. Even after 10 days in a silica gel box at ambient temperature, Ab was similarly immobilized and detected HSA as freshly prepared. However, as expected, the detected amounts on it-

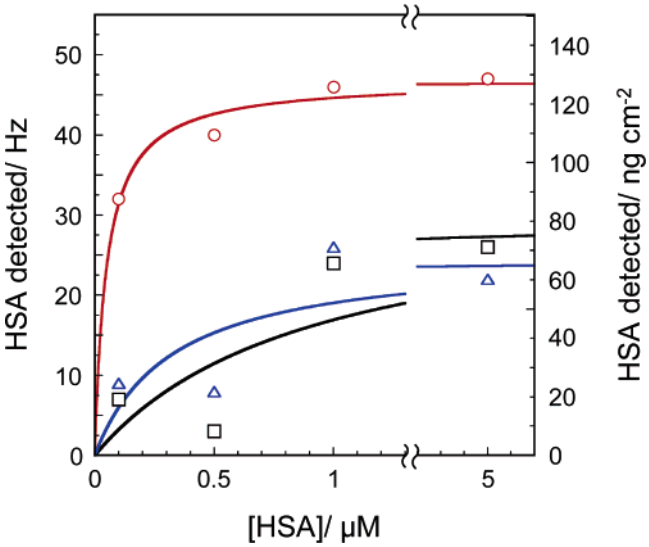

Figure 3. Dependences of the HSA concentration against HSA detected on the SC (red), it-PMMA (black), and the QCM gold (blue) surfaces. Lines show the fitting to a Langmuir isotherm.

PMMA and gold decreased to 25% and 54%, respectively. These observations mean that PA denaturation after drying was suppressed on the complex. Accordingly, the SC surface has the potential for maintaining the activity of physically adsorbed proteins. It is important to maintain the activity of proteins adsorbed on substrates for the long-term preservation of diagnostic materials and other biorelated materials. These stabilizing activities of the complex surface will be caused by the fact that PA with native forms adsorbed on the complex, as shown below. The denaturing of proteins that initially adsorbed with denatured forms on other surfaces might be accelerated in air atmosphere. ATR spectra at the amide I region of PA adsorbed on the complex hardly changed after 10 days storage (see below), supporting the maintenance of PA functions. More

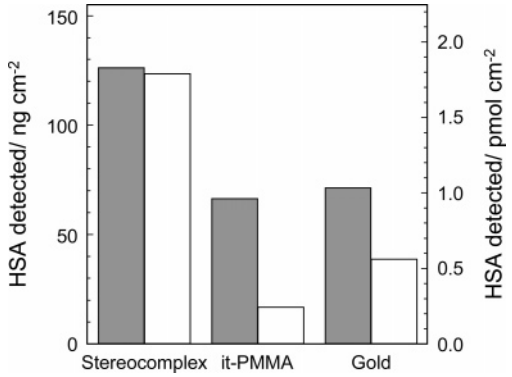

Figure 4. Amounts of detected HSA on each surfaces after adsorbed PA was maintained for 10 days in air. Gray and open bars show the detections as prepared and after 10 days, respectively.

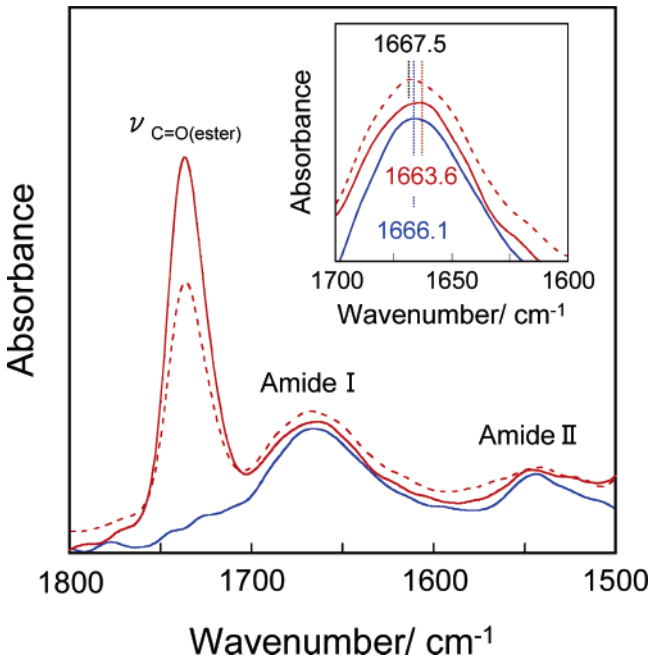

Figure 5. ATR spectra of PA adsorbed on the SC (red) and the gold QCM surface (blue), and denatured PA adsorbed on the SC (dotted).

details regarding the aforementioned dry storage of adsorbed proteins will be investigated in the near future.

Other antigens such as Fib, Av, and hCG (0.5 μM) were similarly detected using corresponding antibodies immobilized on PA-coated SC and it-PMMA surfaces. Detecting amounts on the former surface were analyzed to be 328, 129, and 148 ng cm^{-2}, while those on the latter surface were analyzed to be 252, 85, and 47 ng cm^{-2}, respectively. In all combinations, detecting amounts on the complex were clearly greater than those on it-PMMA. Accordingly, we found that the SC surface is generally valuable to detect antigen−antibody interactions.

Structural Analysis of Protein A Adsorbed on Solid Surfaces. The biological activity of the SC should be derived from the non-denaturing of PA adsorbed on complex surfaces. The long-term maintenance of PA activity is also thought to be derived from the initial non-denaturing adsorption. Therefore, the denaturing of adsorbed PA was analyzed by using ATR spectra, following previous studies (*38*−*40*). ATR spectra at the amide I region (1600−1700 cm^{-1}) of PA also supported the non-denaturation of PA on the complex, as shown in Figure 5. The peak position on the complex was observed at 1663.6 ± 0.9 cm^{-1}. On the other hand, that on gold was observed at 1667.1 ± 1.2 cm^{-1} and was the same as that for denatured PA adsorbed on the complex (1667.8 ± 0.4 cm^{-1}) and gold (1667.4 ± 1.8 cm^{-1}), respectively, within experimental error (PA was denatured in an acidic solution of pH 1 for 5 min). Previous studies suggest that peak positions for an ordered α-helix could be observed at a relatively smaller wavenumber than those for unordered α-helices and random coils (*41*−*43*). Accordingly, the aforementioned observations strongly suggest that PA on gold was relatively denatured compared to that on the complex. A greater amount of ordered α-helices in PA might be maintained on the complex.

The amide I peak position of PA on the complex after 10 days storage (1662.9 ± 1.1 cm^{-1}) was the same as that as prepared within experimental error, suggesting that changes in the ordered structure were not detected. This observation is consistent with the aforementioned maintenance of PA activities. It is noted that the decrease in PA activities on gold after storage was not supported by amide I peak shifts, possibly because of the detection limitation of protein structural changes with ATR spectra. As a consequence, ATR spectra suggested that PA native forms were maintained after the immobilization on the complex surface.

Amide I peak positions from adsorbed PA spectra obtained by an ATR method were relatively shifted to higher wavenumbers, compared to those from native PA powder (1652.6 ± 0.2 cm^{-1}). This observation is possibly due to changes in hydration states of PA on surfaces, as similarly shown in a previous study (*44*). In fact, the amide I peak position of denatured PA powder was adequately observed at 1655.4 ± 0.6 cm^{-1} and was slightly greater than that from native PA. Therefore, the aforementioned discussion about relative peak shifts for denatured PA on surfaces would be reliable.

Mechanistic Speculation of Unique Protein Adsorption on the Stereocomplex Surface. It is necessary to speculate the reason that proteins are comfortable on the complex surface. Since the hydrophobicity of the complex surface ranges between it- and st-PMMAs (*22*, *45*), the hydrophobicity must be negligible. Furthermore, since amounts of physically adsorbed proteins such as BSA (*31*), HSA, fibrinogen, lysozyme (*32*), and the present PA, which are composed of different amino acid sequences, have been ordinarily greater on the SC surface than homogeneous films; therefore, specific functional groups on protein surfaces (as well as on film surfaces) that are related to protein physical adsorption can also be negligible. On the other hand, it has been observed that apparent adsorption constants of serum proteins for the complex were ordinarily smaller than those for homogeneous films (*31*, *32*). The adsorption isotherms of PA for the complex and it-PMMA are shown in Figure 6 and were fitted to the Langmuirian adsorption to obtain adsorption constants, following our previous studies (*31*, *32*). In fact, the adsorption constant of PA for the complex was estimated to be 4.8 × 10^7 M^{-1} (coefficient of variation, 0.84) and was also smaller than 7.5 × 10^7 M^{-1} for it-PMMA (coefficient of variation, 0.94). Since adsorption constants are composed of the sum of individual interactions such as hydrogen bonding, hydrophobic, and van der Waals interactions of proteins against PMMAs, the greater numbers of contacting points are necessary for greater adsorption constants.

To interpret these interfacial phenomena, we focus on the difference in regular conformations of the film surface and proteins. The quantitative QCM analysis as well as other analytical data supported that almost all it-PMMAs on the film surface formed the SC with st-PMMAs, thus forming a 9/1 double-stranded helical assembly (*21*, *28*). On the contrary, homogeneous films simply prepared by spin-casting without thermal treatment possibly have disordered surface structures, although it- and st-PMMAs partially have 10/1 or 5/1-helical and planer zigzag or glide-plane structures, respectively (*46*). To adsorb proteins with greater adsorption constants on the

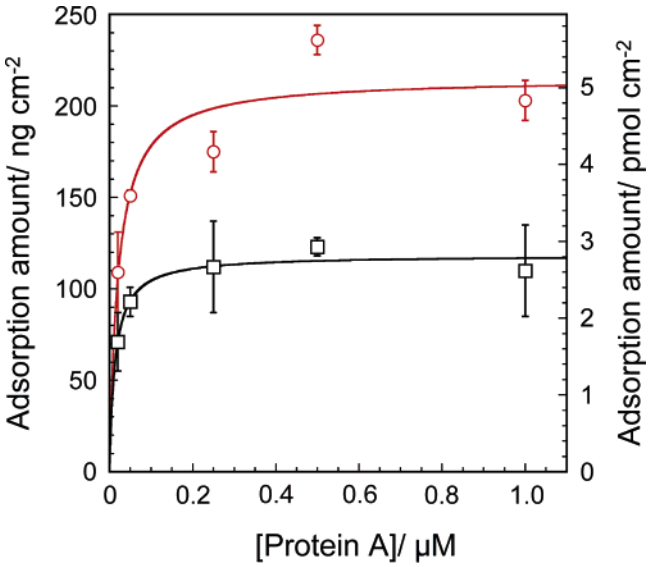

Figure 6. Adsorption isotherms for PA on the SC (red) and it-PMMA (black) surfaces.

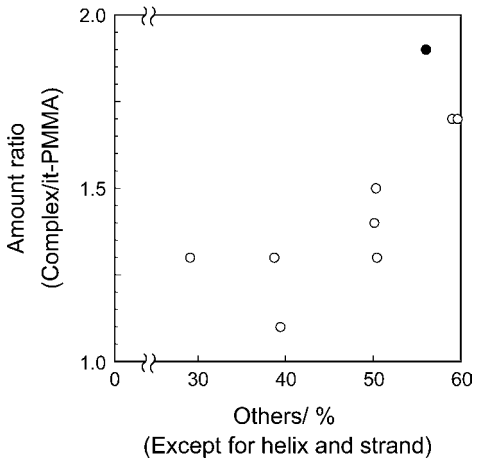

Figure 7. Dependence of the ratio of protein amounts adsorbed on the SC and it-PMMA surfaces. To estimate the ratio, the adsorption amount on the complex was divided by that on it-PMMA. Closed symbol shows the ratio of PA.

disordered surface, multiple interactions are necessary. Therefore, entropic disadvantages of the surface polymer for protein adsorption have to be compensated by enthalpy gain through the multiple interactions. The greater numbers of the interaction between the surface and PA should result in denaturing of PA native forms, followed by unfavorable Ab orientation and smaller percent of Ab used for HSA detection. In fact, the amount of PA adsorbed on gold, which has an ordered surface structure, was almost the same as that on the complex. This observation also supports the regular conformation effect of the surface on protein physical adsorption. It is, however, noted that PA adsorbed on gold was denatured by strong electrostatic interactions with free electrons on gold surfaces.

The secondary structure of proteins is the other parameter for discussing protein physical adsorption. In order to understand effects of the secondary structure on the difference in adsorption amounts on the complex and it-PMMA surfaces, we selected ten proteins (HSA (*47*), cit. synth (*48*), HRP (*49*), cyto. c (*50*), ALP (*51*), CA (*52*), α-CTP (*53*), GFP (*54*), avidin (*55*), and sup. dismut (*56*)) with different secondary structures for adsorption experiments. Amounts of proteins adsorbed at 1 μM with secondary structures, molecular weights, shapes assuming a rectangular parallelepiped, and expected adsorption amounts assuming monolayer coverage were summarized in Table 2. Except for cyto. c and α-CTP, which were ignored because they adsorbed with multilayers (the adsorption amounts on it-PMMA and the complex exceeded expected monolayer full coverage, respectively), adsorption amounts of proteins were greater on the complex than it-PMMA. These results revealed that the ratio of the amounts of adsorbed proteins on the complex and it-PMMA was independent of the secondary structure of the helix and sheet, molecular weights, and shapes. On the contrary, the ratio tended to increase with an increase in other structures such as random coil and turn, as shown in Figure 7. It is obvious that random coil is a disordered structure in proteins. Although it is difficult to conclude that the use of bulk secondary structures is reasonable to discuss protein physical adsorption, Figure 7 clearly demonstrated the relationship between the ratio and the other structure. It is noted that PA contains 56% other structures (*57*). In fact, the ratio was estimated to be 1.9, confirming the relationship. Accordingly, disordered conformation effects of protein structures as well as polymer surfaces were observed. The aforementioned advantage of the complex surface, which has regular conformations compared to conventional polymer film surfaces, was also supported.

CONCLUSIONS

Stepwise processes comprising the fabrication of functional ultrathin films, PA adsorption, Ab immobilization, and antigen detection were quantitatively monitored by the QCM method. We newly developed the SC platform for efficiently detecting antigen−antibody interactions. Amounts of adsorbed PA, immobilized antibodies, and detected antigens were greatest on the complex film surface. Percent PA and antibodies used for antibody immobilization and antigen detection, respectively, were discussed quantitatively. It was found that the greatest percents of antibodies were used for antigen detection on the complex surface. The activity of PA adsorbed on the complex surface was maintained for a long time even in air atmosphere. Unique activities were derived from the nondenaturing adsorp-

[a] Adsorption amounts on the SC surface were divided by those on the it-PMMA surface. [b] From previous papers (see text). [c] Expected adsorption amounts when assumed the monolayer full coverage. For estimation, the substrate area was divided by the cross section of proteins. [d] From PDB.

tion of PA. The mechanism for the protein adsorption on the complex surface was speculated on the basis of previous observations (*31*, *32*) and physical adsorption data of various proteins. Since the SC film can be easily prepared on solid material surfaces, the present observation will help to fabricate novel immunoassay materials and high-throughput microarray/chips and will lead to other protein-conjugated materials such as enzyme immobilization (*58*). Even though certain polymer materials have the same chemical structure, the assembly nanostructure that provides regular conformations might be one of the essential factors to regulate interactions with proteins with variable secondary structures. SC surfaces might be helpful leads to develop a new category of bioconjugated nanomaterials.

ACKNOWLEDGMENT

The authors thank Prof. M. Chikira (Chuo University) for helpful discussion on all experiments and Mr. M. Matsuda and Mr. A. Kogure (Shimadzu) for AFM measurement. This work is financially supported in part by Grant-in-Aid for Scientific Research (no. 16710089) from the Ministry of Education, Culture, Sports, Science and Technology, Japan, and by PRESTO from JST.

Design, Synthesis, and Characterization of pH-Sensitive PEG−PE Conjugates for Stimuli-Sensitive Pharmaceutical Nanocarriers: The Effect of Substitutes at the Hydrazone Linkage on the pH Stability of PEG−PE Conjugates

Amit A. Kale and Vladimir P. Torchilin*

Department of Pharmaceutical Sciences and Center for Pharmaceutical Biotechnology and Nanomedicine, Northeastern University, Boston, Massachusetts 02115. Received July 24, 2006; Revised Manuscript Received November 8, 2006

A set of aliphatic and aromatic aldehyde-derived hydrazone (HZ)-based acid-sensitive polyethylene glycol−phosphatidylethanolamine (PEG−PE) conjugates was synthesized and evaluated for their hydrolytic stability at neutral and slightly acidic pH values. The micelles formed by aliphatic aldehyde-based PEG−HZ−PE conjugates were found to be highly sensitive to mildly acidic pH and reasonably stable at physiologic pH, while those derived from aromatic aldehydes were highly stable at both pH values. The pH-sensitive PEG−PE conjugates with controlled pH sensitivity may find applications in biological stimuli-mediated drug targeting for building pharmaceutical nanocarriers capable of specific release of their cargo at certain pathological sites in the body (tumors, infarcts) or intracellular compartments (endosomes, cytoplasm) demonstrating decreased pH.

INTRODUCTION

The development of an optimal drug delivery systems has the utmost importance in contemporary medicine (*1*). The ultimate goal in drug delivery is to achieve therapeutic concentrations of the drug at the target site while drug concentrations at other tissues are kept in safe levels. This has particular importance in the case of cancer treatment, where the challenge is to selectively destroy the tumor without damaging normal tissues. Disease (tumor) site-specific targeting of drugs and drug carriers may, at least partially, solve the problem. The issue, however, remains how to achieve fast and effective drug release from the pharmaceutical carrier when it has already reached its target, such as a tumor (*2*−*4*). This issue is equally important when long-circulating PEGylated drug delivery systems are used (*5*−*7*), since PEG prevents normal interaction of the carrier with cells and other destabilizing factors, or when the drug carrier is intended for intracellular penetration (*8*, *9*) and a properly scheduled cytoplasmic release of the active drug is expected to prevent its degradation in lysosomes (*10*).

There are several approaches to this problem including the use of stimuli-sensitive pharmaceutical nanocarriers, which is based on the fact that many pathological sites including tumors demonstrate hyperthermia or acidification (*11*−*13*). In general, environmentally sensitive carriers exhibit dramatic changes in their swelling behavior, network structure, permeability, or stability in response to changes in the pH or ionic strength of the surrounding fluid or temperature (*14*). Such systems, for example, may include certain pH-sensitive linkages allowing for drug release, protective "coat" removal, or new functional appearance because of their fast degradation in acidified pathological sites (*15*−*17*). Different approaches have been employed to develop pH-responsive carriers, with one being the incorporation of acid-sensitive linkages between drug and ligand or into the molecules of the carrier-forming components. These include cis-aconityls (*18*, *19*), electron-rich trityls (*20*), polyketals (*21*), acetals (*22*, *23*), vinyl ethers (*24*, *25*), hydrazones (*26*−*28*), poly(ortho esters) (*29*), and thiopropionates (*30*). Such constructs may turn out to be useful for the site-specific delivery of drugs at the tumor sites (*12*), infarcts (*31*), inflammation zones (*32*), or cell cytoplasm or endosomes (*33*), since at these "acidic" sites, pH drops from the normal physiologic value of pH 7.4 to pH 6.0 and below.

We have recently demonstrated the utility of highly pH-sensitive hydrazone bond-based PEG−PE conjugates in preparing double-targeted stimuli-sensitive pharmaceutical nanocarriers (*34*). This proof-of-principle study did not, however, address an important issue of the proper coordination between two important temporal characteristics of such carriers, which are expected to demonstrate a sufficiently long lifetime under normal physiological conditions allowing for their efficient accumulation in the target, and sufficiently fast destabilization within the acidic target providing better drug penetration into the target cells. Since real practical tasks may require different times for such carriers to stay in the blood and to release their contents (or "develop" an additional function) inside the target, the need is evident to have a set of pH-sensitive conjugates capable of serving as components of stimuli-sensitive pharmaceutical nanocarriers and demonstrating variable stabilities at normal and acidic pH values.

With this in mind, we have synthesized a series of PEG−HZ−PE conjugates with different substituents at the hydrazone bond and evaluated their hydrolytic stability at normal and slightly acidic pH values. These conjugates differ from each other with respect to the exact structure of groups forming the hydrazone linkage between phospholipid and PEG. The characterization of the in vitro behavior of these conjugates has provided important information useful for future design and development of pH-sensitive nanocarriers with desired properties.

MATERIALS

1,2-Dioleoyl-*sn*-glycero-3-phosphoethanolamine, DOPE[1]; 1,2-dipalmitoyl-*sn*-glycero-3-phosphothioethanolamine (sodium salt), DPPE-SH; and 1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) ammonium salt, Rh-PE, were purchased from Avanti Polar Lipids, Alabaster (AL); (*N*-ϵ-maleimidocaproic acid) hydrazide, EMCH; 4-(4-*N*-male-

imidophenyl)butyric acid hydrazide hydrochloride, MPBH; *N*-(κ-maleimidoundecanoic acid) hydrazide, KMUH; succinimidyl 4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate, SMCC, were purchased from Pierce Biotechnology, Inc., Rockford, IL. 2-Acetamido-4-mercaptobutanoic acid hydrazide, AMBH, was purchased from Molecular Probes (Invitrogen, Carlsbad, CA); methoxy poly(ethylene) glycol butyraldehyde (MW 2000) and mPEG-SH (MW 2000) were purchased from Nektar Therapeutics (Huntsville, AL). Triethylamine was purchased from Aldrich Chemicals. 4-Succinimidyl formylbenzoate (SFB) was purchased from Molbio (Boulder, Colorado). All solvents were purchased from Fisher Scientific (HPLC grade) and used without further purification.

SYNTHESES

All reactions were monitored by TLC using 0.25 mm × 7.5 cm silica plates with UV indicator (Merck 60F-254) and mobile phase of chloroform/methanol (80:20% v/v). Phospholipid and PEG alone or their conjugates were visualized by iodine, phosphomolybdic acid, and Dragendorff spray reagents (Figure 1). Silica gel (240−360 μm) and size exclusion media, Sepharose CL4B (40−165 μm) and Sephadex G25 m (Sigma-Aldrich), were used for silica column chromatography and size exclusion chromatography, respectively.

^{1}H NMR spectra were obtained on Varian Unity AS500 instrument (500 MHz). Chemical shifts (δ) were given in ppm relative to TMS.

Hydrazide-Activated Phospholipids (3a, 3b, 3c). 22 μmol of phosphatidylthioethanolamine, **2**, were mixed with 1.5 molar excess of each acyl hydrazide linker (Table 1) in 3 mL anhydrous methanol containing 5 molar excess of triethylamine over lipid (Scheme 1). The reaction was performed at 25 °C under argon for 8 h. Solvent was removed under reduced pressure, and the residue was dissolved in chloroform and applied to a 5 mL silica gel column which had been activated (150 °C overnight) and prewashed with 20 mL of chloroform. The column was equilibrated with an additional 15 mL of chloroform followed by 5 mL of each of the chloroform/methanol mixtures, 4:0.25, 4:0.5, 4:0.75, 4:1, and 4:2, and, finally, with 6 mL of 4:3 v/v. The phosphate-containing fractions eluting in 4:l, 4:2, and 4:3 chloroform/methanol (v/v) were pooled and concentrated under reduced pressure. The yields of **3a**, **3b**, and **3c** were 65.7%, 71.9%, and 68%, respectively. The products were stored in glass ampoules as chloroform solutions under argon at −80 °C.

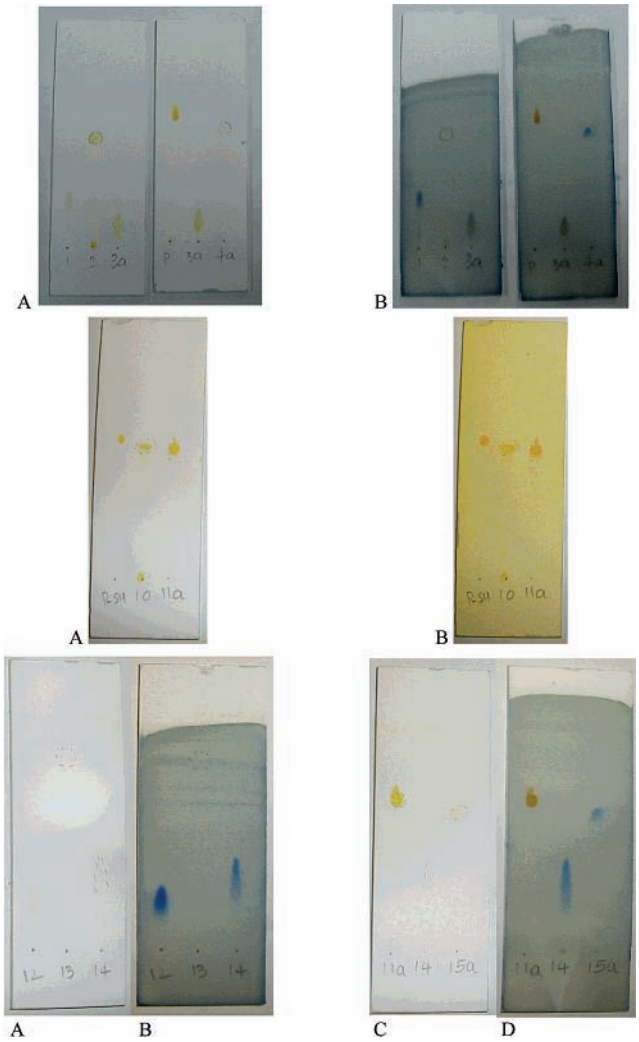
For the activation of phospholipid with AMBH, a maleimide derivative of phosphatidylethanolamine (PE), **7**, was prepared using SMCC (Scheme 3). In brief, PE, **6**, in chloroform was reacted with 1.5 molar excess of SMCC, **5**, over lipid in the presence of 5 molar excess of TEA under argon for 5 h. The maleimide derivative was separated from excess SMCC on silica gel column using chloroform/methanol (4:0.2 v/v) mobile phase. The elution fractions containing ninhydrin-negative and phosphorus-positive fractions were pooled and concentrated under reduced pressure. The yield of the product was 65.7%.

DOPE−maleimide was further used to synthesize the AMBH-activated derivative of phospholipid, **8**, by reacting with 1.5 molar excess of AMBH using TEA as catalyst (Scheme 4).

^{1}H NMR Spectroscopy. EMCH-Activated Phospholipid Derivative (**3a**). ^{1}H NMR (500 MHz, $CDCl_3$): δ 0.85−0.87 (t, 6H, 20), 1.25−1.32 (m, 46H), 1.39 (d, 2H, 35), 1.56−1.64 (m, 8H), 2.25 (m, 12H), 3.06−3.08 (m, 5H), 3.48 (m, 3H), 7.12−7.19 (d, 2H, 35), 7.32 (s, 3H).

MPBH-Activated Phopsholipid Derivative (**3b**). ^{1}H NMR (500 MHz, $CDCl_3$): δ 0.85−0.89 (t, 6H, 20), 1.11 (s, 5H), 1.18 (s, 12H), 1.25−1.30 (m, 44H), 1.56−1.60 (m, 8H), 2.26 (m, 4H), 3.49 (s, 1H), 7.12 (s, 1H), 7.19 (s, 2H), 7.32 (s, 4H).

KMUH-Activated Phospholipid Derivative (**3c**). ^{1}H NMR (500 MHz, $CDCl_3$): δ 0.85−0.89 (t, 6H, 20), 1.11 (s, 3H), 1.25−1.30 (m, 52H), 1.30−1.35 (m, 4H), 1.57−1.60 (m, 4H),



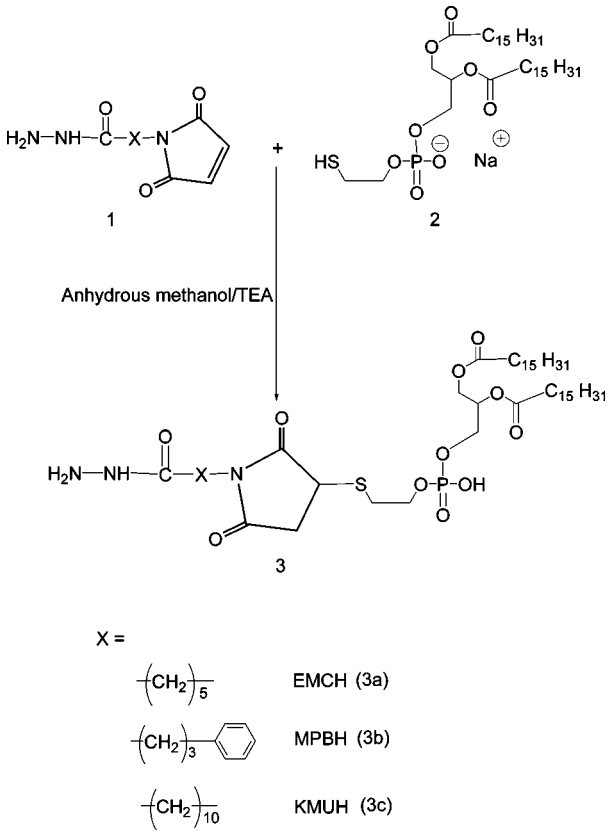


Figure 1. Representative TLC patterns of different reactants and purified products. Upper row: For Schemes 1 and 2 with iodine (A) or phosphomolybdenum spray (B) visualization. (**1**, DPPE−SH; **2**, EMCH linker; **3a**, EMCH-activated phospholipid; P, PEG-butyraldehyde; **4a**, PEG−HZ−PE conjugate). Middle row: For Scheme 6 with iodine (A) or Dragendorff spray (B) visualization. (P−SH, PEG−SH; **10**, EMCH linker; **11a**, EMCH-activated PEG). Bottom row: For Schemes 7 and 8 with iodine (A,C) or phosphomolybdenum spray (B,D) visualization. (**11a**, EMCH-activated PEG; **12**, DOPE; **13**, SFB; **14**, SFB-activated DOPE; **15a**, PEG−HZ−PE).

Table 1. Acyl Hydrazide Linkers Used in This Study

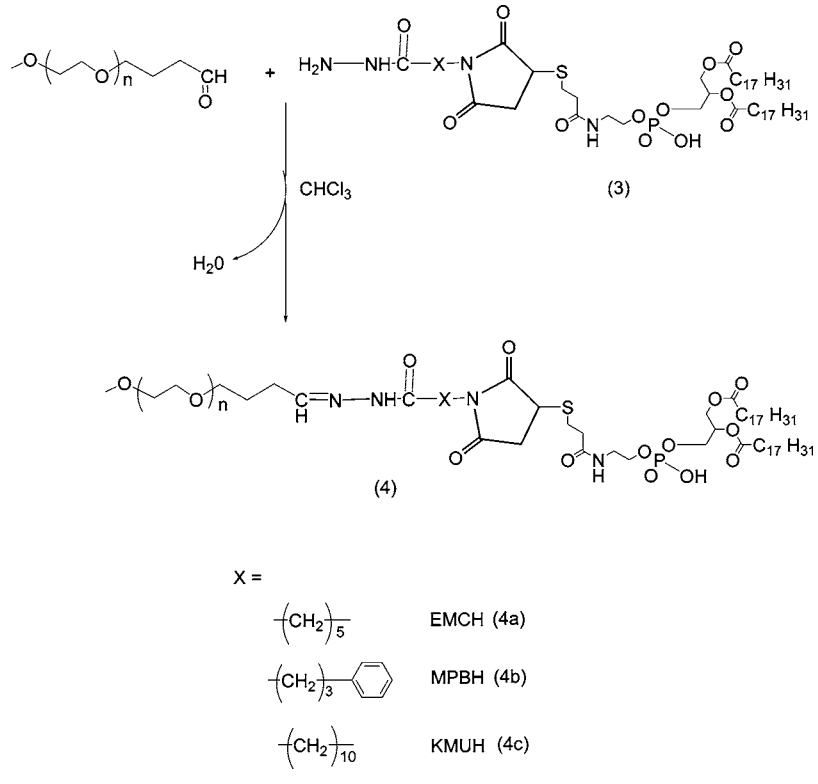
linker (X)	mol. wt.	length of spacer arm
AMBH 2-acetamido−4-mercaptobutanoic acid hydrazide	191.25	−
EMCH (*N*-ϵ-maleimidocaproic acid) hydrazide	225.24	11.8 Å
MPBH 4-(4-*N*-maleimidophenyl)butyric acid hydrazide	309.5	17.9 Å
KMUH *N*-(κ-maleimido undecanoic acid) hydrazide	295.8	19.0 Å

[1] Abbreviations: Phosphotidylethanolamine, PE; 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine, DOPE; 1,2-dipalmitoyl-*sn*-glycero-3-phosphothioethanolamine (sodium salt), DPPE-SH; methoxy(polyethylene)glycol, PEG; hydrazone, HZ.

Scheme 1. Synthesis of Acyl Hydrazide-Activated Phospholipids

2.13−2.29 (m, 6H), 3.08−3.11 (m, 8H), 3.48 (m, 3H), 3.90−3.96 (m, 5H), 7.19 (s, 1H), 7.32 (s, 2H).

AMBH-Activated Phospholipid Derivative (**8**). ^{1}H NMR (500 MHz, $CDCl_3$): δ 0.85−0.90 (t, 6H, 25), 1.26−1.29 (m, 41H), 1.57 (s, 8H), 1.80−1.84 (m, 5H), 2.01 (m, 19H), 2.17 (d, 6H, 2.5), 2.27−2.29 (d, 5H, 10), 2.69 (s, 2H), 3.37−3.40 (m, 3H), 3.86−3.88 (m, 4H), 4.09−4.11 (m, 1H), 5.3 (m, 3H)



PEG−HZ−PE Conjugates (4a, 4b, 4c, 9). 21 μmol of $mPEG_{2000}$−butyraldehyde were reacted with 14 μmol of linker-activated phospholipid in 2 mL chloroform at 25 °C in a tightly closed reaction vessel (Schemes 2 and 5). After overnight stirring, chloroform was evaporated under vacuum in a rotary evaporator. The excess $mPEG_{2000}$−butyraldehyde was separated from PEG−HZ−PE conjugates using gel filtration chromatography. The gel filtration chromatography was performed using Sepharose-CL4B equilibrated overnight in pH 9−10 degassed ultrapure water (elution medium) in a 1.5 × 30 cm glass column. The thin film formed in the round-bottom flask after evaporating chloroform was hydrated with the elution medium and applied to the column. The micelles formed by PEG−HZ−PE conjugate were the first to elute from the column. Micelle-containing fractions were identified by Dragendorff spray reagent, pooled together, and kept in the freezer at −80 °C overnight before subjecting to freeze-drying. The freeze-dried PEG−HZ−PE conjugates were weighed and stored at −80 °C as chloroform solutions. The yields of **4a**, **4b**, **4c**, and **9** were 55.1%, 57.4%, 53.5%, and 61.0%, respectively.

^{1}H NMR Spectroscopy. PEG−HZ−PE Conjugate with EMCH Cross-Linker (**4a**). ^{1}H NMR (500 MHz, $CDCl_3$): δ 0.85−0.88 (t, 6H, 15), 1.25−1.27 (m, 44H), 1.55−1.60 (m, 9H), 2.12−2.20 (m, 106H), 2.68 (s, 22H), 3.37 (s, 3H), 3.49−3.59 (m, 240H), 3.90−3.92 (m, 9H), 4.2 (s, 6H), 4.67−4.7 (m, 1H), 5.31−5.33 (m, 2H).

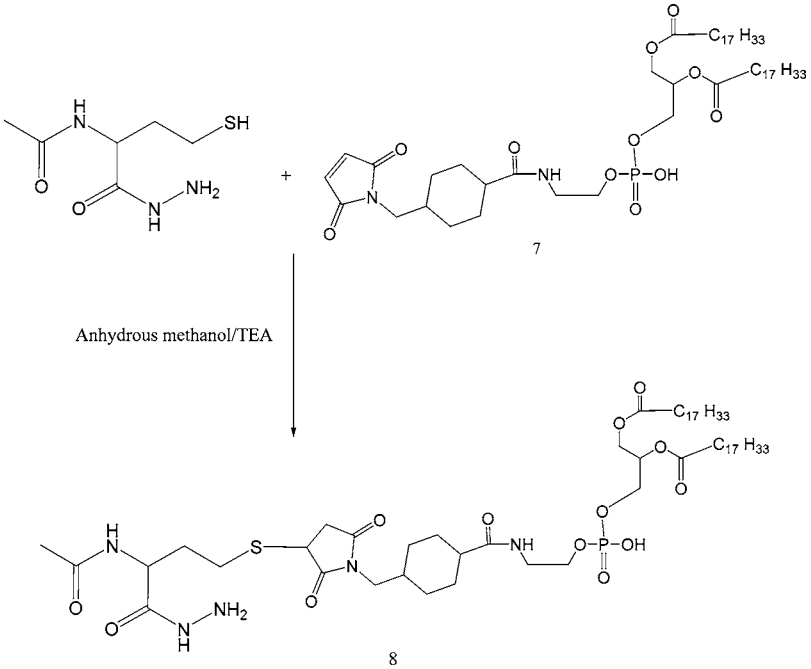
Hydrazide-Activated PEG Derivatives (11a, 11b, 11c). 40 μmol of mPEG−SH in chloroform were mixed with 2 molar excess of acyl hydrazide cross-linkers: EMCH (**10a**), MPBH (**10b**), and KMUH (**10c**) presence of 5 molar excess of triethylamine over lipid. The excess EMCH was separated from the product by size exclusion chromatography using Sephadex G25m media. The acyl hydrazide derivatives of PEG (**11a**, **11b**, **11c**) were freeze-dried, weighed (yields 80.3%, 80.5%, 84%, respectively) and stored as chloroform solutions at −80 °C.

EMCH-Activated PEG Derivative (**11a**). ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.21 (s, 1H), 1.3 (s, 1H), 1.6 (m, 2H), 1.78 (s, 1H), 1.86 (s, 1H) 1.96 (s, 1H), 2.09−2.11 (m, 29H), 2.42−2.46 (m, 3H), 2.57−2.64 (m, 2H), 3.07−3.14 (m, 1H), 3.34 (s, 3H), 3.45−3.51 (m, 8H), 3.54−3.62 (m, 236H), 3.68−3.71 (t, 2H, 15), 3.73−3.75 (t, 1H, 10), 7.01−7.11 (m, 1H).

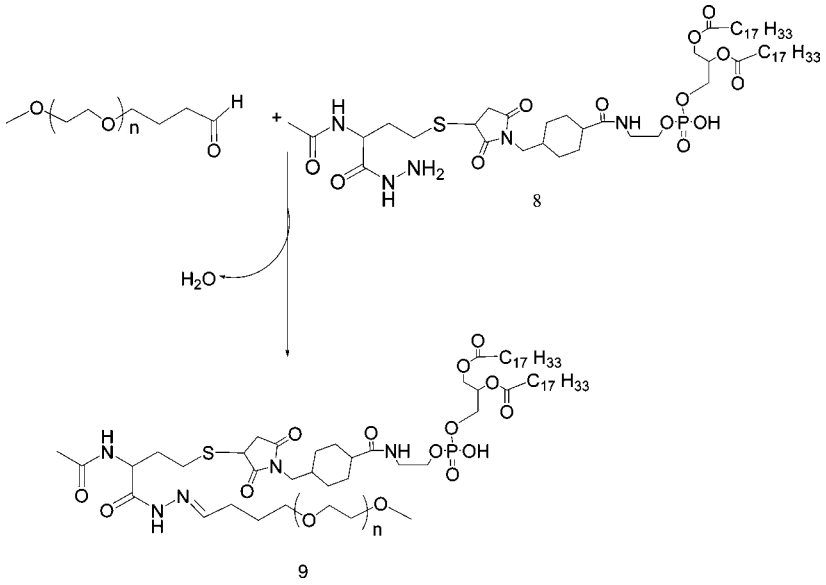
MPBH-Activated PEG Derivative (**11b**). ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.25 (s, 1H), 1.71−1.8 (d, 19H, 45), 1.98 (s, 2H), 2.16−2.17 (d, 18H, 5), 2.48 (m, 1H), 2.64−2.73 (m, 2H), 3.37 (s, 3H), 3.53−3.69 (m, 183H), 7.18−7.20 (d, 1H, 10), 7.31−7.32 (d, 1H, 5).

KMUH-Activated PEG Derivative (**11c**). ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.27−1.33 (m, 18H), 1.53−1.56 (m, 3H), 1.18 (s, 3H), 1.96−2.03 (m, 25H), 2.16 (m, 43H), 2.45−2.49 (m, 5H), 2.60−2.63 (t, 2H, 5), 3.11−3.17 (m, 2H), 3.37 (s, 3H), 3.48−3.68 (m, 236H).



4-Succinimidylformyl Benzoate (SFB) Activated Phospholipid (14). 35 μmol of phosphatidylethanolamine, DOPE-NH_2, **12**, in chloroform were mixed with 2 molar excess of 4-succinimidylformyl benzoate, **13**, in the presence of 3 molar excess triethylamine over lipid. After stirring for 3 h, solvent was evaporated, residue was redissolved in chloroform, and product was separated on a silica gel column using acetonitrile/methanol mobile phases 4:0, 4:0.25, 4:0.5, 4:0.75, and 4:1 v/v. The fractions containing the product were identified by TLC analysis, pooled, and concentrated. The yield was 73%. The product was stored as chloroform solution at −80 °C.

^{1}H NMR Spectroscopy. SFB-Activated Phospholipid (**14**). ^{1}H NMR (500 MHz, $CDCl_3$): δ 0.85 (t, 6H, 15), 1.21−1.29 (m, 45H), 1.5 (s, 4H), 1.96 (d, 8H, 10), 2.19 (d, 4H, 25), 2.6 (s, 2H), 3.0 (m, 1H), 3.64 (m, 2H), 3.9−4.04 (m, 4H), 5.30−5.34 (m, 4H), 7.84−7.87 (t, 3H, 15), 8.05−8.13 (m, 3H), 9.98−10.05 (d, 1H, 35).



PEG−HZ−PE Conjugates (**15a**, **15b**, **15c**). 1.5 molar excess of SFB-activated phospholipid, **14**, was reacted with acyl hydrazide-derivatized PEGs, **11a**, **11b**, and **11c**, respectively, in chloroform at room temperature. After overnight stirring, chloroform was evaporated under reduced pressure. The PEG−HZ−PE conjugate was purified using size exclusion chromatography using Sepharose CL4B as described before. The yields of the conjugates **15a**, **15b**, and **15c** were 57.8%, 65.4%, and 62%, respectively.

PEG−HZ−PE Conjugate with KMUH-Activated PEG (**15c**). ^{1}H NMR (500 MHz, $CDCl_3$): δ 0.86−0.88 (t, 6H, 10), 1.26−1.28 (m, 62H), 1.55−1.65 (m, 56H), 1.99−2.00 (d, 20H, 5), 2.04 (s, 6H), 2.12 (s, 16H), 2.16 (m, 40H), 2.20 (m, 11H), 2.27−2.29 (m, 12H), 3.37 (s, 3H), 3.54−3.67 (m, 248H), 5.33 (m, 7H).

Micelle Size Measurement. The micelle size (hydrodynamic diameter) was measured by the dynamic light scattering (DLS) using a N4 Plus Submicron Particle System (Coulter Corporation, Miami, FL) at PEG−PE concentration of 10 mM.

In Vitro pH-Dependent Degradation Of PEG−HZ−PE Conjugates. The time-dependent degradation of PEG−HZ−PE micelles incubated in buffer solutions (phosphate buffered saline, pH 7.4 and pH 5.5) maintained at 37 °C was followed by HPLC using Shodex KW-804 size exclusion column as described in ref 34. In brief, the elution buffer used was pH 7.0, phosphate buffer (100 mM phosphate, 150 mM sodium sulfate), run at 1.0 mL/min. For fluorescent detection (Ex 550 nm/Em 590 nm) of micelle peak, Rh−PE (1 mol % of PEG−PE) was added to the PEG−PE conjugate in chloroform. A film was prepared by evaporating the chloroform under an argon stream and hydrated with the phosphate buffered saline, pH 7.4 or 5.5 (adjusted by precalculated quantity of 1 N HCl). A peak that represents micelle the population appeared at the retention

Scheme 8. Synthesis of PEG−HZ−PE Conjugate

time between 9 and 10 min. The degradation kinetics of micelles was assessed by following the area under the micelle curve.

DISCUSSION

Synthesis of Hydrazone-Based PEG−PE Conjugates. The success of hydrazones as pH-sensitive linkages derives from the fact that their hydrolytic stability is governed by the nature of hydrazone bond formed. Hydrazones are much more stable than imines as a result of the delocalization of the π-electrons in the former. In fact, parent hydrazones are too stable for the application in drug delivery systems, and an electron withdrawing group has to be introduced to moderate the stability by somewhat disfavoring electron delocalization throughout the molecule as compared to the parent hydrazone. Hydrazones can be prepared from aldehydes or ketones and hydrazides under very mild conditions including aqueous solutions. Hydrazone bond formation can take place even in vivo from separate fragments which self-assemble under physiological conditions (*35*).

In this work, we have applied different synthetic methods based on the use of various aldehydes that can produce the hydrazone linkage between PEG and PE. We have also conducted studies to check hydrolytic stability of hydrazones derived from aliphatic and aromatic aldehydes and different acyl hydrazides. Synthesis of aliphatic aldehyde-derived hydrazone containing PEG−PE conjugate was pursued in two steps. First, phospholipid was activated with four different acyl hydrazides. The sulfhydryl reactive group of phosphatidylthioethanolamine was reacted with maleimide end of maleimido acyl hydrazides (refer to Table 1) through Michael addition, thus providing acyl hydrazide-activated PE. mPEG−butyraldehyde, an aliphatic aldehyde, was then reacted with acyl hydrazide-activated PE to get a hydrazone-based PEG−PE conjugate. ^{1}H NMR analysis was performed on synthesized conjugates using comparisons with both starting materials.

To synthesize aromatic aldehyde-derived hydrazone, an aromatic aldehyde moiety was introduced into the phospholipid by reacting succinimidyl 4-formylbenzoate (SFB) with PE under mild alkaline conditions. The acyl hydrazide−PEG derivatives were synthesized using mPEG−SH and maleimido acyl hydrazides (EMCH, MPBH, and KMUH). The SFB-activated phospholipid was then reacted with acyl hydrazide-derivatized PEG. The identity of aromatic aldehyde derived PEG−HZ−PE conjugates was confirmed by ^{1}H NMR.

Particle Size Measurement. All synthesized conjugates spontaneously self-assemble into micelles in aqueous solutions. The typical size distribution pattern of the micelles assembles from the representative PEG−HZ−PE conjugate, **15a**, is presented in Figure 2. As the measurements indicate, **15a** exhibited the size of 8−24 nm that is characteristic for typical PEG−PE micelles (*36*, *37*). All synthesized PEG−HZ−PE conjugates followed similar micelle size and distribution pattern.

In Vitro pH-Dependent Degradation of PEG−HZ−PE Conjugates. The stability of hydrazone-based PEG−PE conjugates incubated at physiological pH 7.4 and acidic pH 5.5 in buffer solutions maintained at 37 °C was investigated by HPLC. For this purpose, the area under the micelle peak of PEG−HZ−PE (R_t = 9−10 min) was observed over a period of time. PEG−HZ−PE conjugates were derived from an aliphatic aldehyde, and different acyl hydrazides were found to be highly unstable under acidic conditions, with the micelle peak completely disappearing within 2 min incubation at pH 5.5. At the

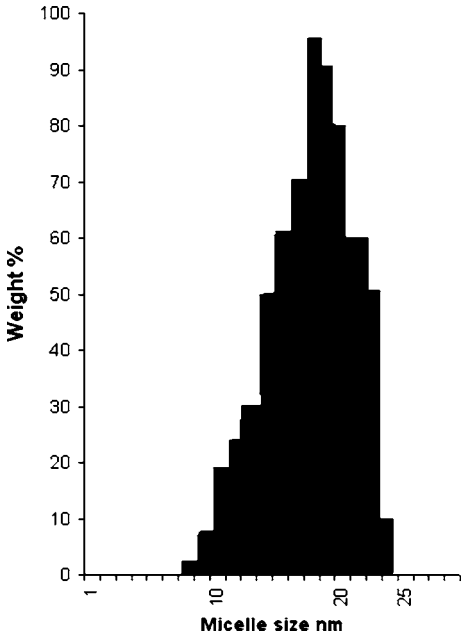

Figure 2. Typical particle size distribution pattern for PEG−HZ−PE conjugate miceles (compound **15a**).

Table 2. Half-Lives of Aliphatic Aldehyde-Based Hydrazone-Derived mPEG−HZ−PE Conjugates[a]

	half-life (min)	
mPEG−HZ−PE conjugate	pH 7.4	pH 5.5
4a	120	<2
4b	90	<2
4c	20	<2
9	150	<2

[a] In phosphate buffered saline, pH 7.4 or 5.5, at 37 °C.

Table 3. Half-Lives of Aromatic Aldehyde-Based Hydrazone-Derived mPEG−HZ−PE Conjugates[a]

	half-life (h)	
mPEG−HZ−PE conjugate	pH 7.4	pH 5.5
15a	>72 h	>48 h
15b	>72 h	>48 h
15c	>72 h	>48 h

[a] In phosphate buffered saline, pH 7.4 or 5.5, at 37 °C.

same time, these conjugates were relatively stable at physiological pH: the PEG−HZ−PE conjugate, **9**, with AMBH as cross-linker showed a half-life of 150 min, followed by EMCH, **4a**, (120 min), MPBH, **4b**, (90 min), and KMUH, **4c**, (20 min) (Table 2). The hydrolysis rate of the aliphatic aldehyde-derived hydrazone-based PEG−PE conjugates (**4a**, **4b**, **4c**, and **9**) at pH 7.4 seems to be dependent on the carbon chain length of acyl hydrazide. The increase in the number of carbon atoms in acyl hydrazide led to an increase in the rate of hydrolysis (PEG−PE conjugate **4c**, acyl hydrazide with 10 C atoms > **4a**, acyl hydrazide with 5 C atoms > **9**, acyl hydrazide with 3 C atoms). Introducing aromatic character within the carbon chain of acyl hydrazide led to an increase in the hydrolysis rate as observed in cases of **4b** and **4a** (the rate of hydrolysis of **4b** > **4a**). One has to note the precipitate (lipid) formation as hydrolysis of the hydrazone bond proceeds.

Alternatively, the PEG−HZ−PE conjugates derived from an aromatic aldehyde and acyl hydrazides were found to be highly stable at pH 7.4 and 5.5 (Table 3). The half-life values were not attained at either of those pH values even at the end of the incubation periods of 72 h at pH 7.4 and 48 h at pH 5.5 in buffer solutions maintained at 37 °C. The resistance to hydrolysis exhibited by hydrazones derived from aromatic aldehydes can be attributed to the conjugation of the π bonds of the −C═N− bond of the hydrazone with the π-bonding benzene ring. This observation supports the finding that hydrazones formed from aromatic aldehydes are more stable to acidic hydrolysis than those formed from aliphatic ones (*38*, *39*). The hydrazone hydrolysis involves the protonation of the −C═N nitrogen followed by the nucleophilic attack of water and cleavage of C−N bond of the tetrahedran intermediate (*40*). Any of these steps are determining and dependent on the pH. The substituents on the carbonyl reaction partner influence the rate of hydrolysis by altering the pK_a of the hydrazone with electron donating substituents facilitating protonation of the −C═N nitrogen (*41*). It is important to note here that "direct" PEG−PE conjugates with no HZ linkage between PEG and PE moieties used by us as controls in this study and others (*34*, *36*, *37*) do not demonstrate any hydrolysis at tested pH values over extended periods of time.

This would support the fact that PEG−HZ−PE conjugates containing a hydrazone bond derived from the aliphatic aldehyde are more prone to hydrolytic degradation. The aromatic aldehyde-derived hydrazone bond is too stable for the purpose of pH-triggered drug release. Careful selection of an aldehyde and an acyl hydrazide would be necessary for the application of the hydrazone-based chemistry for the development of pH-sensitive pharmaceutical nanocarriers with required stabilities/instabilities at normal and acidic pH values. Additional studies on the synthesis of aromatic and aliphatic ketone-derived hydrazone-based PEG−PE conjugates are currently underway in our laboratory.

ACKNOWLEDGMENT

This work was supported by NIH grant R01 EB001961 to Vladimir P. Torchilin. Authors thank Vijay S. Boddapathi and Dr. Ganesh Thakur for the technical assistance with ^{1}H NMR studies.

Synthetic PEGylated Glycoproteins and Their Utility in Gene Delivery

Chang-po Chen, Ji-seon Kim, Dijie Liu, Garrett R. Rettig, Marie A. McAnuff, Molly E. Martin, and Kevin G. Rice*

Division of Medicinal and Natural Products Chemistry, College of Pharmacy, University of Iowa, Iowa City, Iowa 52242.
Received July 24, 2006; Revised Manuscript Received November 13, 2006

PEGylated glycoproteins (PGPs) were synthesized by copolymerizing a Cys-terminated PEG−peptide, glycopeptide, and melittin peptide. Compositionally unique PGPs were prepared by varying the ratio of PEG−peptide (20−90%) and melittin (0−70%) with a constant amount of glycopeptide (10%). The PGPs were purified by RP-HPLC, and characterized for molecular weight and polydispersity by GPC-HPLC and SDS-PAGE and for composition by RP-HPLC following reduction to form monomeric peptides. PGPs formed DNA condensates of 200−300 nm in diameter that were administered to mice via the tail vein. Biodistribution studies confirmed their primary targeting to liver hepatocytes with a DNA metabolic half-life of 1 h. Upon stimulation by hydrodynamic dosing with saline, PGP DNA (5 μg) mediated luciferase expression in the liver detected by bioluminescence imaging (BLI) after 24 h. The level of gene expression mediated by PGP DNA was 5000-fold less than direct hydrodynamic dosing of an equivalent amount of DNA and was independent of the mol percent of melittin incorporated into the polymer, but dependent on the presence of galactose on PGP. The results establish the ability to prepare three-component gene delivery polymers that function in vivo. Further design improvements in fusogenic peptides for gene delivery and for the simultaneous use of a nuclear targeting strategy will be necessary to approach levels of expression mediated by the direct hydrodynamic dosing of DNA.

INTRODUCTION

Glycoproteins are a class of biological molecules composed of a protein backbone modified with N or O-glycans (*1*). Their functions are quite varied and often involve the interaction of the terminal sugars on the glycan with endogenous lectins on mammalian cell surfaces (*2*).

One of the earliest nonviral gene delivery systems was able to target DNA to internalize into hepatocytes via the asialoglycoprotein receptor (*3*, *4*). This delivery system was composed of an asialoglycoprotein covalently linked to polylysine. Refinement of this delivery system has been ongoing by many groups since this first demonstration. The ligand has been simplified by utilization of a cluster of the monosaccharide galactose (*5*−*7*), neoglycopeptides (*8*), or purified N-glycans (*9*−*11*). Polylysine has been substituted by PEI (*12*), chitosan (*13*), dendrimers (*14*), and synthetic peptides (*10*, *15*−*18*) containing clusters of Lys or Arg residues. In many cases, the polymers have been modified by poly(ethylene glycol) (PEG) (*10*, *19*−*22*) to render them more biocompatible for use as in vivo gene delivery agents. In all, these refinements have led to more sophisticated nonviral gene delivery systems that are smaller, more homogeneous, more modular, and better equipped to achieve subcellular targeting than their predecessors.

Two key steps to enhancing the expression of a receptor-mediated nonviral gene delivery system in vivo are (1) DNA escape from the endosome (*23*−*26*) and (2) nuclear targeting (*27*). Several studies have reported the utility of fusogenic peptides to enhance endosomal escape and gene expression in vitro (*21*, *25*, *28*), but fewer studies have reported their use in vivo (*29*, *30*), and none have reported the use of melittin in vivo. In part, the difficulty in demonstrating the utility of fusogenic peptides in vivo relates to the synthetic challenge in incorporating these into the gene delivery system so that they can be properly released within the endosomal compartment of the target cell. A further complication with testing the efficacy of fusogenic peptides in vivo is the need to simultaneously achieve efficient targeted delivery of DNA to cells and nuclear targeting of DNA, to observe appreciable gene expression in animals.

Ongoing studies from our lab have reported the development of peptides possessing terminal Cys residues that bind DNA and polymerize through disulfide bond formation (*31*, *32*). The resulting polypeptide DNA condensates mediate enhanced in vitro gene transfer, presumably by triggered release of the DNA following intracellular reduction of disulfide bonds (*33*). To test the utility of this approach in vivo, we have reported the use of a Cys-terminated glycopeptide and PEG−peptide that copolymerize on DNA, direct its biodistribution through receptor-mediated targeting to hepatocytes in mice, and produce measurable but low-level gene expression in vivo (*11*, *22*).

In the present study, we have advanced this delivery system to generate ternary peptide copolymers composed of PEG−peptide, glycopeptide, and a fusogenic melittin peptide. A detailed account of the polymerizable melittin peptide used in this study was recently reported (*34*). The resulting PEGylated glycoproteins (PGPs) are prepared with a precise stoichiometry of peptide components and have the ability to bind to DNA and mediate targeted gene delivery in vivo. Entry into hepatocytes requires careful control over the particle size of DNA condensates (*35*). Once inside the cell, the reduction of disulfide bonds should lead to the rapid dissociation of the carrier from the DNA and release of melittin in the endosome where it can function to facilitate DNA escape to the cytosol.

However, without the ability to target DNA to the nucleus, endocytosed DNA remains largely in the cytosol where it is incapable of mediating significant gene expression in quiescent hepatocytes. To stimulate gene expression, we report the utility of hydrodynamic dosing (*36*) of saline 5 min after a conventional dose of formulated DNA. This approach has allowed us to utilize bioluminescence imaging (BLI) to compare the efficiency of

PGP DNA relative to the direct hydrodynamic dosing of an equivalent amount of DNA.

MATERIALS AND METHODS

General Methods. Substituted Wang resin for peptide synthesis, N-terminal Fmoc-protected amino acids, 9-hydroxybenzotriazole, and diisopropylethylamine were obtained from Advanced ChemTech (Lexington, KY). *N*,*N*-Dimethylformamide, trifluoroacetic acid (TFA), acetic acid anhydride, acetonitrile, and piperidine were purchased from Fisher Scientific (Pittsburgh, PA). Tris(2-carboxyethyl)phosphine hydrochloride (TCEP), thiazole orange, poly(lysine) of varying molecular weight, and bovine testes β-galactosidase (EC 3.2.1.23) were obtained from Sigma Aldrich Co. (St Louis, MO). PEG standards were purchased from Tosoh Corp. (Tokyo, Japan). D-Luciferin and luciferase from *Photinus pyralis* were purchased from Roche Applied Science (Indianapolis, IN). Inactivated "qualified" fetal bovine serum (FBS) and Seeblue prestained peptide standard were from Invitrogen Co. (Carlsbad, CA). BCA assay kit, Blocker BSA in TBS (10×), and 1-Step NBT/BCIP were from Pierce (Rockford, IL). Precast 4−15% gradient SDS-PAGE gels (Ready Gel) were purchased from BioRad (Hercules, CA). GS-1 lectin was from EY Laboratories, Inc. (San Mateo, CA). Protran (pure nitrocellulose transfer and immobilization membrane, 0.2 μm) was from Schleicher and Schuell BioScience (Basel, Germany). pGL3 control vector, a 5.3 kb luciferase plasmid containing a SV40 promoter and enhancer, was obtained from Promega (Madison, WI). pDNA was amplified in a DH5α strain of *Escherichia coli* and purified on an endotoxin-free Qiagen megaprep column (Valencia, CA) according to the manufacturer's instructions.

Peptide Synthesis. Peptide synthesis was carried out on an Apex 396 from Advanced Chem Tech (Louisville, KY). Peptide purification was performed using a semipreparative (10 μm) C_{18} RP-HPLC column from Vydac (Hesperia, CA). Preparative HPLC was performed using a computer-interfaced HPLC and fraction collector from ISCO (Lincoln, NE). Electrospray mass spectrometry (ES-MS) was performed using an Agilent 1100 LC-MS system.

Cys-terminated melittin peptide, (**M1**) CKKKIGAVLKVLTTG LPALISWIKRKRQQKKKC, was synthesized using standard Fmoc procedures as described previously (*34*).

DNA binding peptide (**P1**) (Acm)CKKKKKKKKCKKKKKKKKKWC(Acm) (acetamidomethyl) was synthesized using standard Fmoc procedures starting from Fmoc-Cys(Acm)-Wang resin, except that N-capping with diisopropylethylamine and acetic anhydride was included after each coupling cycle to avoid truncated sequences. The peptide was cleaved from the resin and deprotected (except for the Acm protecting groups on cysteines) in 95% TFA. The peptide was then purified to homogeneity by injecting 1 μmol onto a semipreparative RP-HPLC column (2 × 25 cm) eluted at 10 mL/min with 0.1% (v/v) TFA and a gradient of acetonitrile (5−25% over 30 min) while monitoring tryptophan absorbance at 280 nm. The major peak eluting at 22 min was collected and pooled from multiple injections, concentrated by rotary evaporation, lyophilized, and stored dry at −20 °C. The purified peptides were reconstituted in 0.1% TFA, quantified by tryptophan absorbance ($\epsilon_{280\ nm}$ = 5600 M^{-1} cm^{-1}) and characterized on an Agilent 1100 LC-MS resulting in *m*/*z*: 2706.6/2706.1 (found/calculated).

An Acm-protected PEG−peptide was synthesized by reacting **P1** with PEG−maleimide (molar ratio 1:1.5) in 0.1 M sodium phosphate buffer (pH 7.0) at RT for 3 h. The PEG−peptide was purified by injection of 2 μmol onto semipreparative RP-HPLC (2 × 25 cm) eluted at 10 mL/min with 0.1% TFA and a gradient of acetonitrile (5−65% over 30 min) while detecting $Abs_{280\ nm}$. Final deprotection was accomplished by dissolving 5 μmol in 1 mL of cold TFA followed by the addition of silver tetrafluoroborate (20 mol equiv per Acm group) and anisol (10 equiv per Acm group) followed by reaction at 4 °C for 1 h with stirring. The deprotected PEG−peptide was precipitated as the silver salt in 60% (v/v) diethyl ether. The precipitate was centrifuged, then redissolved in 0.1 M acetic acid containing DTT (40 equiv per Acm group) and reacted at RT for 3 h. Following centrifugation to remove insolubles, the deprotected PEG−peptide was purified on a semipreparative RP-HPLC eluted as described above. The isolated PEG−peptide was freeze-dried and reconstituted in 0.1% TFA and reanalyzed by analytical HPLC to determine purity. The PEG−peptide was characterized by MALDI-TOF by spotting 1 μL (1 nmol) in α-cyano-4-hydroxycinnamic acid (30 mg/mL) on the target. A broad peak with an average mass of 8077 *m*/*z* was observed, consistent with the anticipated mass of the conjugate.

Acm-protected glycopeptide was synthesized by conjugating iodoacetamide triantennary *N*-glycan (*37*) and **P1** at a molar ratio of 1:1.25 in 0.2 M Tris buffer (pH 8.0) for 12 h at RT. The resulting glycopeptide was purified by a semipreparative RP-HPLC column (2 × 25 cm) eluted at 10 mL/min with 0.1% TFA and a gradient of 5−20% acetonitrile over 30 min. The peak corresponding to the glycopeptides was pooled and lyophilized. Final deprotection of the Acm groups was performed as described above. After purification on semipreparative RP-HPLC, the glycopeptide was concentrated, lyophilized, and reconstituted in 0.1% TFA, then quantified by $Abs_{280\ nm}$ ($\epsilon_{280\ nm}$ = 6930 M^{-1} cm^{-1}) and characterized by LC-MS resulting in *m*/*z*: 4773.5/4775.0 (found/calculated).

Synthesis of PGPs. Cys-terminated melittin peptide, glycopeptide, and PEG−peptide were combined in a predetermined ratio resulting in 200 nmol of total peptide in 200 μL of 0.1% TFA. The peptides were vortexed and freeze-dried, then dissolved in 16 μL of 0.1 M sodium phosphate pH 8 containing 4 μL of DMSO and reacted at RT for 48 h.

The progress of the polymerization was monitored using Ellman's method (*38*) to monitor free thiols. An aliquot (2 μL) was combined with 1 mL of DTNB solution (10 mM DTNB in 100 mM sodium phosphate pH 7.3 containing 0.5 mM EDTA) at times ranging from 1 min to 48 h. The absorbance was determined at 412 nm relative to a blank of DTNB solution.

PGPs were purified on a semipreparative RP-HPLC column (2 × 25 cm) eluted at 10 mL/min with 0.1% TFA and a gradient of 20−55% acetonitrile over 30 min. The primary peak was collected, concentrated by freeze drying, dissolved in water, and quantified by $Abs_{280\ nm}$ (ϵ = 6900 M^{-1} cm^{-1}). Agalatosyl PGP was prepared by treating the PGP 3 with β-galactosidase as reported previously (*22*). The agalactosyl PGP 3* was characterized by compositional analysis as describe below, during which LC-MS verified the complete removal of galactose from the glycopeptide.

RP-HPLC-purified PGPs (10 nmol) were prepared in 100 μL of 50 mM Tris pH 7.5 to which 50 nmol equiv of TCP was added in 10 μL of water and reacted for 3 h at RT. The product was chromatographed on analytical RP-HPLC eluted 1 mL/min with 0.1% TFA and 5−65% gradient of acetonitrile over 30 min. The glycopeptide, PEG−peptide, and melittin peptide were quantified against primary standards of each peptide to allow calculation of the peptide composition of each PGP.

The molecular weight of each PGP was determined GPC−HPLC on an Agilent 1100 HPLC system equipped with a refractive index detector and a Shodex OH Pak SB-800 HQ column (7.8 × 300 mm). Freeze-dried PGPs were dissolved in the mobile phase (10 v/v % methanol in water prepared in 0.5 M sodium chloride and 50 mM sodium phosphate pH 7), and 100 μL (10 nmol) was applied to the column. The average molecular weight (MW) was calculated relative to the elution

time of polylysine standards of 3.5, 20.4, 27.4, 66.7, and 84.0 kDa and PEG standards of 24, 50, 107, and 140 kDa.

PGPs (8 nmol) were dissolved in nondenaturing sample loading buffer containing 8 M urea, then loaded onto a 4−15% gradient SDS-PAGE without a stacking gel and run for 1.5 h at 90 V. PGPs bands were visualized by staining with coumassie followed by destaining. PGPs were also stained for PEG using Dragendorff's method (*39*). PGPs were likewise stained for galactose following transfer onto a nitrocellulose membrane in transfer buffer (10 mM $NaHCO_3$, 9.9 mM Na_2CO_3, 0.1% SDS; pH 9.9). The membrane was blocked overnight in 2.5% BSA in TBS (50 mM Tris-HCl, pH 7.4, 150 mM sodium chloride), washed three times with TBST (0.1% Tween 20 in TBS), and washed once with lectin buffer I (1 mM $CaCl_2$ and 1 mM $MgSO_4$ in TBS). The membrane was then incubated with 1 mL of alkaline phosphatase-conjugated GS-1 lectin (1 μg/mL) for 1.5 h. The unbound lectin was removed by washing with TBST three times, and the membrane was treated with 5 mL of lectin buffer II containing 100 μg/mL of nitro blue tetrazolium and 200 μg/mL of 5-bromo-4-chloro-3-indolyl phosphate.

DNA Formulation, Biodistribution, and Gene Expression. PGP binding to DNA was monitored by a fluorophore exclusion assay (*17*). PGP DNA condensates (2.5 μg in 50 μL) were prepared at 0, 0.1, 0.15, 0.3, 0.6, and 1.2 nmol of peptide monomer per μg of DNA then added to 950 μL of HBM (0.27 M mannitol, 5 mM Hepes; pH 7.5) containing 0.1 μM thiazole orange. The fluorescence of the intercalator dye was measured using an LS50B fluorometer (Perkin-Elmer, U.K.) by exciting at 500 nm while monitoring emission at 530 nm with the slit width set at 15 and 20 nm, respectively. Fluorescence blanks were subtracted from all values before data analysis.

The particle sizes of peptide DNA condensates were determined by quasi-elastic light scattering at a scatter angle of 90° on a Brookhaven ZetaPlus particle sizer. Condensates were prepared at a DNA concentration of 50 μg/mL in 400 μL of HBM at a stoichiometry of 0.3 nmol of peptide per μg of DNA corresponding to a charge ratio of approximately 2:1 for each. The mean diameter and population distribution were computed from the diffusion coefficient using a unimodal cumulate analysis supplied by the manufacturer. The zeta potential was determined as the mean of ten measurements in 5 mM Hepes pH 7.4.

Plasmid DNA was radiolabeled with ^{125}I as described previously (*40*), resulting in ^{125}I-DNA with a specific activity of 250 nCi/μg. PGP DNA biodistribution studies were conducted in ICR mice. Mice were anesthetized, and ^{125}I-DNA (2.5 μg, 0.75 μCi) condensed with 0.8 nmol PGP in 50 μL of HBM were dosed i.v. via the tail vein. After 5, 15, 30, 60, 120, 240, 360, and 480 min, mice were sacrificed by cervical dislocation; and the major organs (liver, lung, spleen, stomach, kidney, heart, large intestine, and small intestine) were harvested, rinsed with saline, and weighed. The radioactivity in each organ was determined by direct γ-counting and expressed as the percent of the dose in the target organ (*10*). The distribution of liver-targeted DNA between hepatocytes and Kupffer cells was determined following collagenase perfusion as described previously (*10*).

PGP DNA condensates were prepared for in vivo gene expression by combining 15 μg of pGL3 in 150 μL of HBM (0.27 M mannitol, 5 mM Hepes; pH 7.5) with 4.5 nmol of PGP in 150 μL of HBM while vortexing, resulting in DNA condensates possessing a calculated charge ratio (NH_4^+/PO_4^-) of 2. Triplicate mice (20 g) were administered a 100 μL tail vein dose (5 μg of DNA, 1.5 nmol of PGP), and after 5 min, a 1.8 mL dose of PBS was hydrodynamically delivered (*36*) via the tail vein to stimulate gene expression. After 24 h, the mice were dosed i.p. with 80 μL (2.4 mg) of D-luciferin, then anesthetized with isoflorane gas and imaged after 4 min on an IVIS Imaging System (Xenogen, Alameda, CA). The luminescence in the liver was quantified (photons/s/cm^2/seradian) by *Living Image* software and is presented with a pseudo-color overlay of luminescence intensity on grayscale images. The photon intensity in the liver was converted into pg of luciferase via a standard curve that was reported previously (*41*).

RESULTS

The present study prepared three Cys-terminated peptides used as monomers to polymerize into PEGylated glycoproteins (PGPs) with utility for gene transfer. This strategy would allow polymeric peptides to undergo reduction into their monomeric components after cellular internalization (*42*). We have previously utilized DNA as a template to polymerize either one or two Cys-terminated peptides into polymers (*22*, *31*). However, template polymerization becomes inherently more difficult as the number of peptide components increase. This is especially true if each peptide component possesses a different binding affinity for DNA. Thus, when preparing polymers that possess a PEG−peptide, glycopeptide, and a melittin peptide, it became desirable to polymerize, purify, and characterize the resulting PGPs prior to the formation of DNA condensates. The component PEG−peptide, glycopeptide, and melittin peptide utilized in this study and the resulting PGPs are illustrated in Figure 1.

To establish optimal polymerization conditions for multicomponent PGPs, a model peptide ($CWK_{17}C$) was used (*31*). The results obtained were similar to those reported by Seymour and colleagues using a single peptide (*43*). The polymerization reaction was monitored by RP-HPLC with the full-length polymer eluting later relative to monomeric and intermediate-length peptides. The polymerization progressed further toward completion when the peptide was concentrated to 10 mM in 100 mM sodium phosphate buffer pH 8. More dilute peptide solutions polymerized more slowly and to a lesser degree of completion. Lowering the pH to 7 or 6 caused the reaction to slow, whereas raising the pH to 9 or 10 did not increase the rate. Likewise, phosphate buffer concentrations higher than 0.1 M did not influence the rate of reaction. When applying the polymerization conditions described above to a two- or three-component polymerization to form PGPs, the same trends were observed except that the limiting solubility of the melittin peptide (**M1**) necessitated the addition of 20 v/v % DMSO, which also facilitated oxidation to form cystines.

The time course of the optimized reaction to form PGPs was monitored by Ellman's reaction to detect residual thiols (Figure 2). The results indicate that the reaction was >95% complete after 48 h at RT. Analysis of the reaction by RP-HPLC established that the glycopeptide, PEG−peptide, and melittin peptide were consumed during the 48 h of reaction with the formation of a major peak (Figure 3). PGPs were preparatively purified to remove minor earlier- or later-eluting shoulder peaks.

A calibrated GPC-HPLC was used as the primary means to measure the approximate size of each PGP. Each purified PGP appeared as single peak on a Shodex column eluted with 10% methanol and 0.5 M sodium chloride (Figure 4A−E). When using commercially available poly(lysine)s as calibrants, the average molecular weights of PGPs 1−4 were determined to be 83−106 kDa (Table 1). The average molecular weight of PGP 5 was significantly lower (35 kDa) than those of the other PGPs, most likely due to the larger ratio of **M1** in the polymer (Table 1). The average molecular weights of PGPs 1−4 were estimated to be approximately 50 kDa when using PEG standard to calibrate the GPC-HPLC (Table 1). On the basis of the monomer composition and molecular weight of each monomer, the average degree of polymerization (dp) for PGPs 1−4 was found to be 10−13 monomer peptides based on poly(lysine) standards or dp 5−6 based on PEG standards.

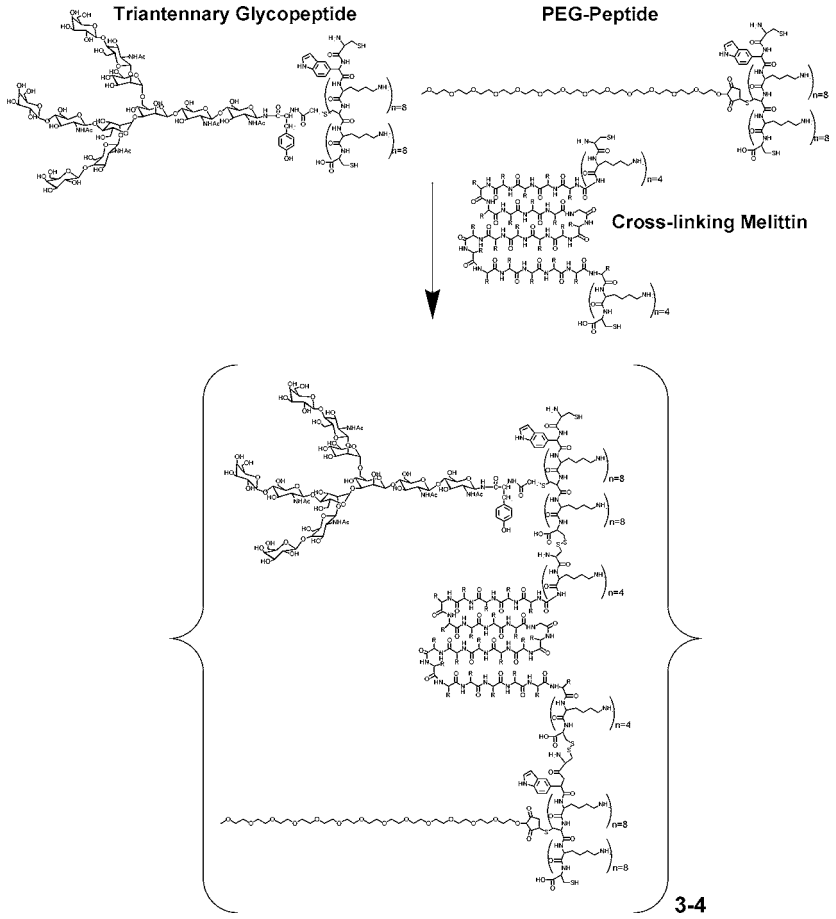

Figure 1. Structure of Cys-terminated peptides and PEGs. The structures of Cys-terminated glycopeptide, PEG−peptide, and melittin peptide are shown. Following polymerization for 48 h, the resulting PGPs, illustrated as a representative structure, were isolated by RP-HPLC and characterized for composition and molecular weight. R represents the side chains of melittin amino acids (*34*).

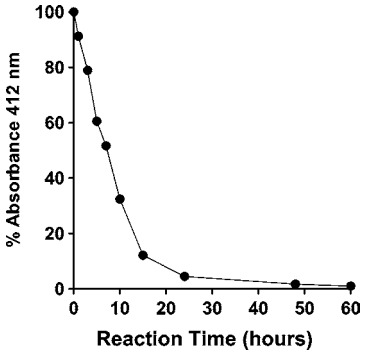

Figure 2. Kinetic analysis of polymerization reaction. The time course of the PGP polymerization reaction was measured by monitoring the number of residual thiols by Ellman's reaction. The results indicated that the reaction was >95% complete after 48 h.

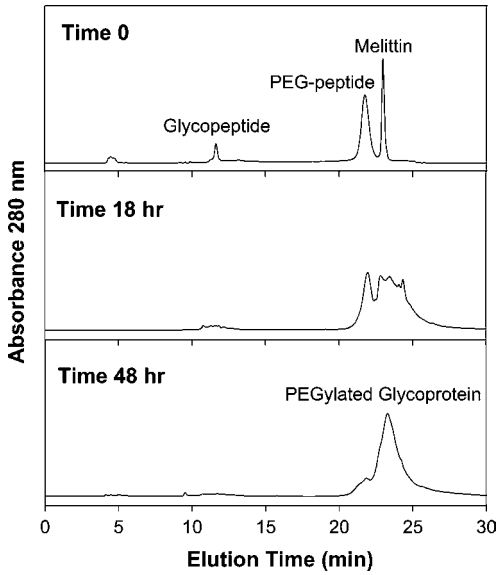

Figure 3. RP-HPLC analysis of PGP formation. The time courses of polymerization of Cys-terminated glycopeptide, PEG−peptide, and melittin peptide were monitored by RP-HPLC. The results indicate that PGPs elute slightly later than the monomeric components on RP-HPLC eluted with a gradient.

Gradient SDS-PAGE was used as a secondary measure of molecular size. As illustrated in Figure 4, PGPs 1−4 each showed a high molecular weight band of greater than 250 kDa based on protein standards stained with coumassie (Figure 4, lanes A−E), as well as Dragendorff's stain (lanes F−J) for PEG and by lectin overlay (lanes K−O) to detect for galactose-terminated N-glycans. Although the PAGE analysis established that each PGP is polymeric and contains both PEG and N-glycan, the molecular weight by PAGE appears to be overestimated. As with GPC-HPLC, the PAGE analysis of PGP 5 established that it is substantially less polymeric than the other PGPs (Figure 4, lanes E,J,O).

Each purified PGP was also characterized for the precise composition of Cys-terminated peptide in the polymer. Reduction of each PGP followed by RP-HPLC analysis led to the quantitative analysis of each peptide component (Figure 5A−E′). The results summarized in Table 1 indicate that melittin peptide was slightly overincorporated and the glycopeptide slightly underincorporated relative to the input ratio. However,

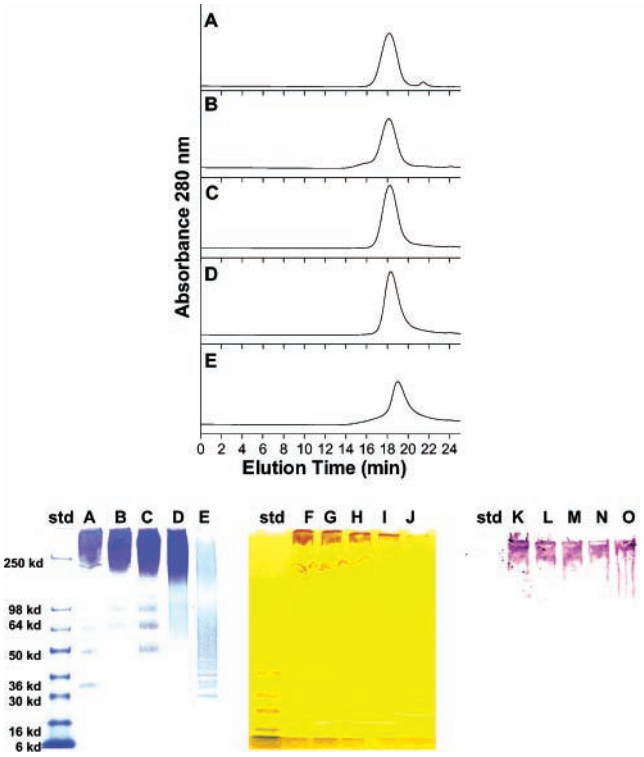

Figure 4. Molecular weight characterization of PGPs. The average molecular weight of each PGP was determined by GPC−HPLC and estimated by gradient SDS-PAGE. Panels A−E (upper) and lanes A−O (lower) represent (A,F,K) PGP 1, 90% PEG−peptide/10% glycopeptide; (B,G,L) PGP 2, 80% PEG−peptide/10% glycopeptide/10% melittin; (C,H,M) PGP 3, 70% PEG−peptide/10% glycopeptide/20% melittin; (D,I,N) PGP 4, 40% PEG−peptide/10% glycopeptide/50% melittin; (E,J,O) PGP 5, 20% PEG−peptide/10% glycopeptide/70% melittin. The gradient SDS-PAGE gel was stained with coumassie to detect protein (lanes A−E), with iodobismuthate to detect PEG (lanes F−J), and with lectin overlay to detect N-glycan (lanes K−O).

these results clearly indicate the potential to manipulate the PGP composition.

PGPs were individually combined with plasmid DNA, and the binding stoichiometry was measured by fluorophore displacement assay (not shown). On the basis of this experiment, the PGP to DNA stoichiometry was set at 0.3 nmol (based on peptide monomer) per μg of DNA, corresponding to approximately a 2:1 N/P ratio. The particle size of each PGP DNA condensate ranged from 200 to 300 nm, whereas the zeta potential was +0.5−6 mV (Table 1).

The biodistribution of tail vein dosed PGP−^{125}I-DNA revealed that each targeted the liver as the primary target site (Figure 6). Nearly 50% of the dose accumulated in the liver within 5 min following i.v. dosing. Control experiments reported previously (*10*) established that naked ^{125}I-DNA also accumulates with 50% of the dose recovered in the liver after 5 min but is rapidly metabolized and eliminated from the liver with a half-life of 30 min. Likewise, previously published biodistribution studies also established that 65% of the liver-targeted dose of naked ^{125}I-DNA was recovered from Kupffer cells and only 35% recovered from hepatocytes (*10*). In contrast, each PGP−^{125}I-DNA resulted in a slightly longer liver metabolic half-life of 1 h (Table 1). Detailed analysis of the liver targeting established that PGP DNA condensates mediated specific targeting with 60% of the dose recovered with hepatocytes and only 40% with Kupffer cells (Table 1). A control PGP that lacked galactose (PGP 3*) was deficient in specific targeting, resulting in the recovery of 62% of the dose from Kupffer cells and 38% from hepatocytes (Table 1).

To determine the influence of melittin concentration on gene transfer efficiency, each PGP DNA sample was dosed i.v. via the tail vein in mice. A conventional dose of 5 μg of DNA administered in 100 μL failed to produce luciferase gene expression after 24 h as measured by a Xenogen CCD camera (not shown). In contrast, a hydrodynamic dose of 5 μg of naked plasmid DNA in 1.8 mL of normal saline delivered via the tail vein in 5 s to 20 g mice produced 1×10^{10} light units in triplicate mice at 24 h post-DNA administration (Figure 7).

To evaluate if hydrodynamic dosing could stimulate the gene expression from DNA delivered by a conventional dose, a hydrodynamic dose of 1.8 mL of normal saline was administered in 5 s via the tail vein at 5 min post-conventional dose administration. Luciferase expression was then measured by a Xenogen CCD camera at 24 h post-administration of DNA. The results indicate that PGP DNA gained access to the liver cells and that upon stimulation by hydrodynamic dose the DNA gained access to the nucleus. A control experiment of conventionally dosed naked DNA followed by a hydrodynamic dose of saline established the complete absence of gene expression (Figure 7, Con1). This result suggests that a conventional dose of PGP DNA results in hepatocyte internalization and perhaps endosomal release, with the nuclear localization of DNA stimulated by a hydrodynamic dose of saline. Likewise, a control experiment that utilized PGP 3*, which was devoid of galactose, failed to mediate specific targeting of plasmid DNA to hepatocytes (Table 1) and greatly diminished the influence of the hydrodynamic dose of saline to stimulate gene expression (Figure 7, PGP 3*).

The magnitude of expression mediated by PGPs 1−5 DNA was approximately 5000-fold less than direct hydrodynamic dosing of an equivalent amount of DNA (5 μg). Surprisingly, the level of expression mediated by PGP DNA was independent of the amount of melittin incorporated into the PGP. The expression mediated by PGP 1, which was a copolymer of PEG−peptide and glycopeptide, was indistinguishable from that mediated by PGPs 2−5.

DISCUSSION

Receptor-mediated gene delivery holds promise as being a safe and efficient means of targeting DNA into specific cells following i.v. dosing. For nonviral gene delivery to reach its full potential, many biological barriers must be overcome from the point of dosing to crossing the nuclear membrane of the target cell. We have systematically studied receptor-mediated gene delivery aimed at targeting the liver and, in particular, hepatocytes as a model system to discover solutions to the barriers that exist for all receptor-mediated gene delivery systems. To this end, the asialoglycoprotein receptor on hepatocytes has been useful, since its cell trafficking and ligand specificity are well-understood (*44*, *45*).

We have previously demonstrated specific targeting to hepatocytes in mice via the asialoglycoprotein receptor mediated by a triantennary glycopeptide (*10*). We have also demonstrated the necessity for PEG to block protein binding and the recognition of DNA condensates by the reticuloendothelial system (*10*, *22*, *46*). Binary peptide copolymers were prepared from glycopeptides and PEG−peptides using plasmid DNA to conduct a template polymerization (*22*). One of the primary advantages of this approach is the triggered release of DNA upon reduction of the disulfide bonds within the cell. In order to cause endosomal escape, we have recently reported the design of synthetic Cys-terminated melittin peptides that bind and polymerize on DNA and mediate gene transfer in vitro (*34*). In the present study, we have selected a melittin analogue that mediated potent gene expression in vitro to incorporate into a copolymeric gene delivery system in an attempt to enhance gene expression in vivo.

Table 1. Structure, Biological, and Formulation Properties of PGP DNA

structure	monomer composition[a] (mol %)	measured composition[b] (mol %)	molecular weight (PLL),[c] (PEO)[d]	particle size[e]	zeta potential[f]	$t_{1/2}$ [g] hr	PC/NPC[h]
PGP 1	0:90:10	0:91.7:8.3	106 kDa, 50 kDa	221 ± 8	+0.5	1.1	60:40
PGP 2	10:80:10	12.8:82.5:4.7	109 kDa, 51 kDa	210 ± 13	+5	1.2	59:41
PGP 3	20:70:10	24.4:70.3:5.3	99 kDa, 47 kDa	227 ± 11	+6	1.2	65:35
PGP 4	40:50:10	44.8:46.4:8.8	83 kDa, 46 kDa	232 ± 1	+6	1.3	60:40
PGP 5	70:20:10	73.2:19.8:7.0	35 kDa, 21 kDa	295 ± 7	+5	1.1	63:37
PGP 3*[i]	20:70:10	12.6:80.9:6.5	99 kDa, 47 kDa	227 ± 11	+6	1.0	38:62

[a] Represents the input mol ratio of Cys-terminated melittin, PEG−peptide, and glycopeptide. [b] Represents the measured mol ratio of Cys-terminated melittin, PEG−peptide, and glycopeptide for each purified PGP. [c] Values are the calculated MW based on polylysine standards. [d] Values are the calculated MW based on PEG standards. [e] The mean particle size determined at a stoichiometry of 0.3 nmol of PGP per μg of DNA. The value represents the mean diameter (nm) based on unimodal analysis. [f] The zeta potential of PGP DNA condensates at a stoichiometry of 0.3 nmol of PGP per μg of DNA. [g] The metabolic half-life of PGP ^{125}I-DNA in triplicate mice. The results are derived from Figure 6. [h] The PC/NPC ratio of DNA-targeted liver. [i] Represents a control PGP 3 in which galactose has been removed.

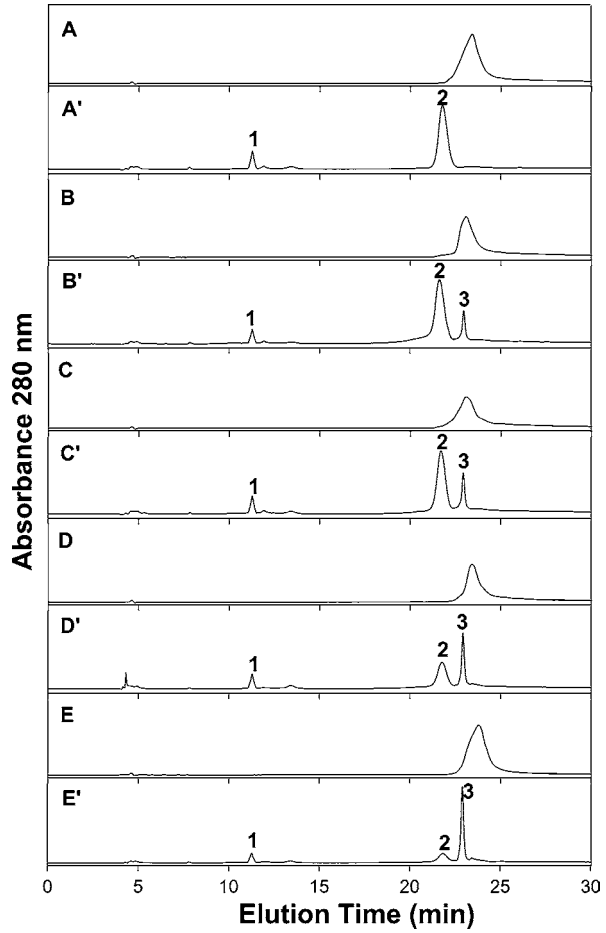

Figure 5. Compositional analysis of PGPs. The composition of each PGP was determined by RP-HPLC following reduction of the polymer with TCEP. Panels A−E illustrate the purified PEGylated glycoprotein prepared with mol composition of (A) PGP 1, 90% PEG−peptide/10% glycopeptide; (B) PGP 2, 80% PEG−peptide/10% glycopeptide/10% melittin; (C) PGP 3, 70% PEG−peptide/10% glycopeptide/20% melittin; (D) PGP 4, 40% PEG−peptide/10% glycopeptide/50% melittin; (E) PGP 5, 20% PEG−peptide/10% glycopeptide/70% melittin. Panels A′−E′ illustrate the recovery of the three peptide components from reduction with TCP. The precise compositions determined relative to standard curves are indicated in Table 1.

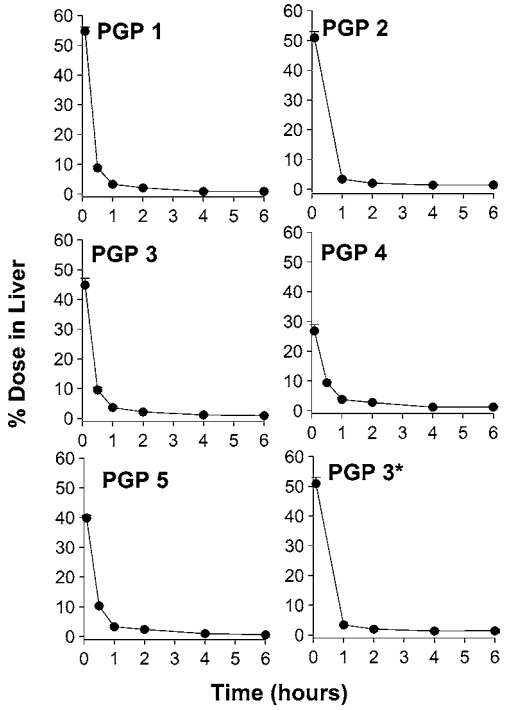

Figure 6. Biodistribution analysis of PGP DNA. The biodistribution analysis of each PGP−^{125}I-DNA condensate is compared following tail vein dosing in triplicate mice. The results establish the liver as the major target site. The liver metabolic half-life of PGP DNA is approximately 1 h, whereas naked ^{125}I-DNA dosed via the tail vein produced a similar targeting efficiency to liver but only a 0.5 h half-life. Each formulation demonstrated specific targeting to hepatocytes as indicated in Table 1, whereas a control formulation where galactose had been removed produced much lower targeting to hepatocytes.

To incorporate all three peptide components into a polymer and control their mol ratio, we found it most efficient to copolymerize concentrated mixtures of monomeric peptides followed by RP-HPLC purification of the resulting PGPs. The advantages of this approach over template polymerization are that it is not necessary that each monomer possesses DNA binding affinity, the resulting polymer can be characterized for size and composition, and more than three peptide components can be copolymerized to further increase the efficiency of gene delivery.

The de novo synthesis of PGPs 1−5 is a significant advancement toward more sophisticated gene delivery carriers that not only achieve primary targeting in vivo, but may potentially achieve secondary targeting by lysing endosomes and releasing DNA intracellularly. The molecular weight and compositional analysis of each PGP demonstrates that the polymerization results in the incorporation of 6−13 monomer peptides and the input ratio of monomer peptides closely reflects the ratio of peptides incorporated into the PGPs. At low melittin ratios, PGPs are higher molecular weight and somewhat more homogeneous, whereas at high melittin ratios, the opposite is observed. Still, each PGP was able to bind to plasmid DNA and form condensates that were of sufficiently small size to mediate specific targeting to the liver.

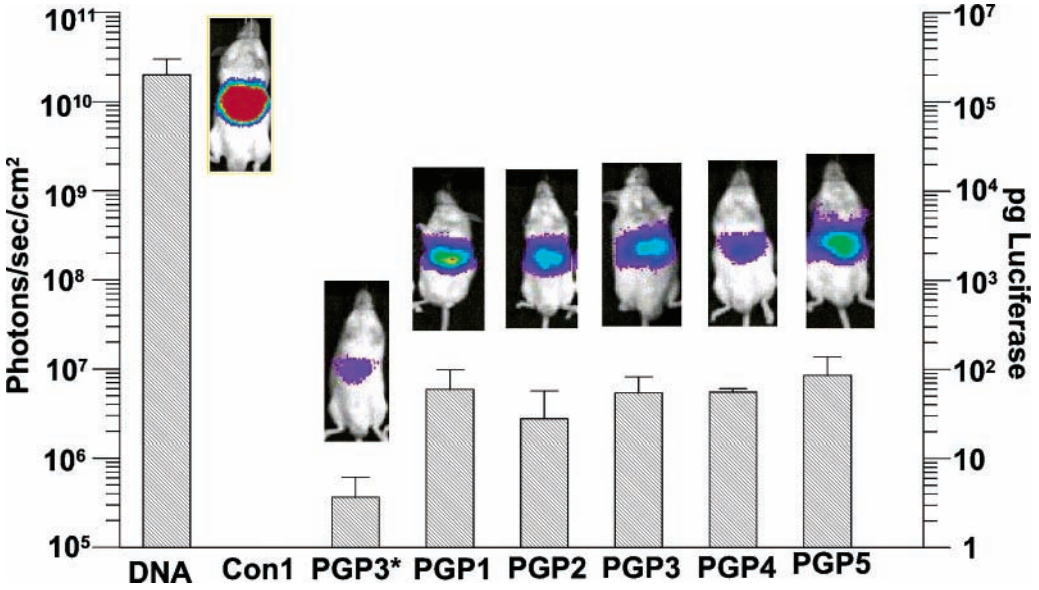

Figure 7. In vivo gene expression of PGP DNA condensates. Luciferase expression was measured by BLI 24 h following an i.v. tail vein dose of PGP DNA (5 μg) in 100 μL in triplicate mice and a subsequent hydrodynamic dose of 1.8 mL of saline administered 5 min later to stimulate nuclear uptake and gene expression. The insets illustrate representative BLI images for each treatment group. Control 1 illustrates the result of tail vein dose dosing of 5 μg of DNA in 100 μL of saline followed 5 min later by a hydrodynamic stimulation dose, resulting in no detectable luciferase expression. Likewise, PGP 3* has been modified to remove galactose, greatly reducing the specific targeting and the liver mediated gene expression. Alternatively, PGPs 1−5 demonstrate that the gene expression is independent of the amount of melittin incorporated into the PGP.

One of the difficulties in developing and testing targeted gene delivery systems in vivo is that, even if cell-type specific targeting is achieved, appreciable gene expression will not be observed unless the DNA gains access to the nucleus. This is indeed the case for PGP DNA, which fails to mediate measurable gene expression relative to direct hydrodynamic dosing of identical amounts of DNA (Figure 7).

Since hydrodynamic dosing is able to deliver a small fraction of a 5 μg DNA dose to the nucleus of mouse hepatocytes, resulting in a high level of gene expression (*36*), we rationalized that it may also stimulate the movement of cytosolic DNA to the nucleus. We tested this by measuring the luciferase gene expression after administering the PGP DNA by conventional small-volume dosing (100 μL), followed after 5 min by a hydrodynamic dose of saline that occurred after the DNA condensate had time to bind and perhaps internalize into hepatocytes via receptor-mediated endocytosis. We found that a delay 15 or 30 min prior to hydrodynamic stimulation resulted in unreliable stimulation of gene expression. The resulting expression profiles clearly establish that some of the hepatocyte-targeted DNA could be stimulated to enter the nucleus, resulting in its expression. The mechanism by which this occurs is unknown and could be similar to that by which hydrodynamic dosing delivers DNA to the nucleus (*47*), although the overall magnitude of gene expression still does not compare with direct hydrodynamic dosing.

Despite finding that hydrodynamic dosing could stimulate gene expression, we found that there was no correlation between the amount of melittin in PGPs and the magnitude of gene expression. This could result from the inability of melittin to release from the polymers during reduction or that this particular melittin analogue is not fully active in endosomal lysis in hepatocytes when entering via receptor-mediated endocytosis. In fact, the melittin analogue used in this study was found to maintain nearly full hemolytic potency at pH 7 relative to natural melittin but lost most of this activity at pH 4 (*34*). It is also possible that the lack of correlation may result from the use of hydrodynamic stimulation, which could mask the influence of melittin in vivo.

In conclusion, we have developed a modular gene delivery system by generating PGPs that function to deliver 5 μg of DNA in vivo leading to measurable gene expression in liver following hydrodynamic stimulation. However, given that hydrodynamic stimulation was essential to observe gene expression in vivo, the results point toward the need to develop more sophisticated delivery systems that are able to deliver the cytosolic DNA to the nucleus in vivo without the need for artificial intervention.

Peptide-Based Pharmacomodulation of a Cancer-Targeted Optical Imaging and Photodynamic Therapy Agent

Klara Stefflova,[†] Hui Li,[‡] Juan Chen,[‡,§] and Gang Zheng*[,‡,§,||]

Departments of Chemistry and Radiology, University of Pennsylvania, Philadelphia, Pennsylvania 19104, and Ontario Cancer Institute, University of Toronto, MaRS Center, TMDT 5-363, 101 College Street, Toronto, Ontario M5G 1L7, Canada. Received August 18, 2006; Revised Manuscript Received November 20, 2006

We designed and synthesized a folate receptor-targeted, water-soluble, and pharmacomodulated photodynamic therapy (PDT) agent that selectively detects and destroys the targeted cancer cells while sparing normal tissue. This was achieved by minimizing the normal organ uptake (e.g., liver and spleen) and by discriminating between tumors with different levels of folate receptor (FR) expression. This construct (Pyro−peptide−Folate, PPF) is composed of three components: (1) pyropheophorbide a (Pyro) as an imaging and therapeutic agent, (2) peptide sequence as a stable linker and modulator improving the delivery efficiency, and (3) Folate as a homing molecule targeting FR-expressing cancer cells. We observed an enhanced accumulation of PPF in KB cancer cells (FR+) compared to HT 1080 cancer cells (FR−), resulting in a more effective post-PDT killing of KB cells over HT 1080 or normal CHO cells. The accumulation of PPF in KB cells can be up to 70% inhibited by an excess of free folic acid. The effect of Folate on preferential accumulation of PPF in KB tumors (KB vs HT 1080 tumors 2.5:1) was also confirmed in vivo. In contrast to that, no significant difference between the KB and HT 1080 tumor was observed in case of the untargeted probe (Pyro−peptide, PP), eliminating the potential influence of Pyro's own nonspecific affinity to cancer cells. More importantly, we found that incorporating a short peptide sequence considerably improved the delivery efficiency of the probe—a process we attributed to a possible peptide-based pharmacomodulation—as was demonstrated by a 50-fold reduction in PPF accumulation in liver and spleen when compared to a peptide-lacking probe (Pyro−K−Folate, PKF). This approach could potentially be generalized to improve the delivery efficiency of other targeted molecular imaging and photodynamic therapy agents.

INTRODUCTION

When a porphyrin-like molecule is activated by light, it relaxes to its ground state in three ways: through nonradiative decay, by emitting a photon, or transferring the energy, producing reactive oxygen species, mainly singlet oxygen (*1*). The detectable outcomes are fluorescence (*2*) and phototoxicity (*3*), making the porphyrin-based photosensitizer (PS[1]) a perfect candidate for image-guided therapy.

Curing cancer is a complicated goal, and the success of treatment is often short-term owing to the difficulty in clearing out all the cancer cells. Being able to clearly identify the cancer cells shortly before or during the treatment would most likely increase the success of the therapy, making imaging and therapy a beneficial union (*4*−*7*). We have utilized the natural connection of near-infrared (NIR) fluorescence imaging, a sensitive and accessible means of in vivo cancer detection (*2*, *8*, *9*), with photodynamic therapy (PDT), a promising cancer therapy using a laser to excite a tumor-associated photosensitizer that produces short-lived cytotoxic singlet oxygen (*10*, *11*). Although many target-specific NIR imaging and PDT agents are being developed, the common limit remains: these agents are mostly lost in organs involved in drug clearance, generating an unwanted toxicity and elevated background (*12*). Here, we propose a novel construct designed for improving the delivery efficiency of NIR imaging and PDT agents to the desired cancer cell targets with reduced normal tissue retention. It is composed of three functional modules (Scheme 1). The first is a fluorescent photosensitizer pyropheophorbide a (Pyro) for NIR imaging (with a long-wavelength absorption at 665 nm and emission at 675 and 720 nm) and PDT (over 50% singlet oxygen yield) (*13*, *14*). This semisynthetic photosensitizer, obtained by three steps from *Spirulina* algae, has minimal dark toxicity, and its derivative Photochlor is in phase I/II clinical trial (*15*).

The second component is a folate moiety, serving as a tumor-homing molecule that guides the photosensitizer into folate receptor (FR)-overexpressing cancer cells (*16*, *17*) via receptor-mediated endocytosis (*18*). FRs are mainly overexpressed on ovary, breast, colon, lung, nose, prostate, and brain cancer cells and activated macrophages (*19*) but have limited expression on normal cells (e.g., kidney, intestine, lung) with restricted accessibility for blood-circulating drugs (*20*).

The third component is a short peptide sequence GDEVDGSGK inserted between the photosensitizer and folate. It serves multiple purposes: (A) it is a stable and hydrophilic linker that prevents the separation of folate and Pyro and enhances water solubility, (B) it separates the Pyro from the Folate to avoid the hindrance of FR-targeting (*20*), (C) it serves as a pharmacomodulator for better delivery efficiency and decreased normal

Pyro−GDEVDGSGK−Folate Comprises Three Principal Components: (1) Fluorescent Photosensitizer Pyropheophorbide a, an Imaging and Therapeutic Agent; (2) Peptide Sequence Is a Stable and Pharmacomodulating Linker That Can Be Exchanged with Any Organelle-Targeting Sequence; and (3) Folate, Serving as a Cancer-Specific Delivery Vehicle

tissue toxicity, and (D) it is possible to exchange it with other peptide sequences for targeting subcellular organelles (*21*−*23*).

There have been many attempts to enhance the photosensitizer's efficacy by targeting "cancer fingerprints" (*24*) through association with various vehicles (*25*, *26*) like proteins (e.g., BSA targeting scavenger receptors on macrophages (*27*), transferrin (*28*), or LDL (*29*)), tumor-selective monoclonal antibodies (*30*), saccharides (*31*), aptamers (*32*), or other small molecule ligands (e.g., short peptides or peptidomimetics) (*22*, *33*−*35*). By attaching Pyro to Folate, an easy-to-conjugate, small, soluble, and nonimmunogenic tumor homing molecule (*20*) targeting cancer cells overexpressing FR (*9*, *36*, *37*), we expected to enhance the cancer specificity of Pyro. To potentiate this specificity, we have inserted a short peptide sequence to serve as a spacer, a solubilizer, and a pharmacomodulator (*38*). As a spacer, it makes the Folate more accessible to FR and, being small and hydrophilic, it decreases its retention in the excretion organs, making it more suitable for in vivo applications.

In this paper, we describe the synthesis and characterization of such agent, Pyro−GDEVDGSGK−Folate (PPF, Figure 1). We have demonstrated, both in vitro and in vivo, that all three functional modules act in synergy and thus significantly improve the delivery efficiency, reducing the potential toxicity of the probe.

MATERIALS AND METHODS

The coupling reagents HOBt (1-hydroxybenzotriazole) and HBTU (*O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate) were purchased from ACROS and Fluka, respectively. KB cells (human epidermal cancer cells; folate receptor positive), HT 1080 cells (human fibrosarcoma cells; folate receptor negative), and CHO (chinese hamster ovary cells; folate receptor negative) were purchased from ATCC. "Complete MEM" (for HT 1080 and KB cells) consists of 85% Minimum Essential Medium (MEM), 10% fetal bovine serum, 2% of 1.5 g/L sodium bicarbonate, 1% of 200 mM L-glutamine, 1% of 0.1 mM nonessential amino acids, and 1% of 1 mM sodium pyruvate; and "MEM containing 0.8% BSA" consists of MEM supplemented with 8 g/L of bovine serum albumin. "Complete F12K" (for CHO cells) consists of 85% Ham's F12K medium (F12K), 10% fetal bovine serum, 2% of 1.5 g/L sodium bicarbonate, and 1% of 200 mM L-glutamine; and "F12K containing 0.8% BSA" consists of F12K supplemented with 8 g/L of bovine serum albumin. Compounds **3** (PP), **4** (PPF), and Pyro−K−Folate (PKF) prepared for in vivo experiments were dissolved in 1 μL DMSO and 20 μL PBS, filtered through a 0.22 μm filter and further diluted with saline to the 120−150 μL volume. For the in vitro experiments, compound **4** (PPF) and Pyro−K−Folate (PKF) were first dissolved in DMSO (no more than 0.5% of total volume), then diluted with 0.1% Tween-80 in DNA−water, filtered through a 0.22 μm filter, and further diluted with MEM containing 0.8% BSA (HT 1080 and KB cells) or F12K containing 0.8% BSA (CHO cells).

All compounds were purified by HPLC (Waters 600 controller with a 2996 photodiode array detector). The eluents were A = 0.1 M TEAA (pH 7) and B = acetonitrile, and the method used for all injections was 90% of A and 10% of B to 100% of B in 45 min with flow 1.5 mL/min on a Zorbax 300SB-C3 column. MALDI-ToF was measured on an Applied Biosystems Voyager DE mass spectrometer, and fluorescence was measured on a Perkin-Elmer LS50B luminescence spectrometer. We acquired confocal images using a Leica TCS SP2 confocal microscope and Xenogen images at the Bioluminescence Molecular Imaging Core facility at UPenn on an IVIS Xenogen Imager. The laser for PDT treatment was tuned to 670 nm with a fluence rate of 20 mW/cm^2. Mice were euthanized according to guidelines established by the Institutional Animal Care and Use Committee of the University of Pennsylvania.

Synthesis of PPF. The peptide Fmoc-GD(O-2-PhiPr)E(O-2-PhiPr)VD(O-2-PhiPr)GS(Trt)GK(Mtt) (**1**) was synthesized by manual SPPS using commercially available Fmoc amine-protected amino acids as building blocks and Sieber resin (cleavable by 2% TFA) as a solid phase, all purchased from Novabiochem. After the last Fmoc group cleavage, the resin was washed with NMP, and Pyro acid was coupled to the N-terminal glycine to give Pyro-GD(O-2-PhiPr)E(O-2-PhiPr)-VD(O-2-PhiPr)GS(Trt)GK(Mtt)-Sieber resin (**2**). The molar ratio of Pyro/HOBt/HBTU to the peptide (**1**) was 3/3/3:1, and the reaction was done in a shaker flask with a 12 h coupling time using dry NMP as a solvent. The resin was then washed with NMP, capped by 0.3 M acetylimidazol in NMP for 15 min, and washed again by an excess of NMP, DCM, and dry methanol, transferred from the shaker flask, and dried. Compound **2** (37.7 mg, 11.5 μmol) was cleaved from the resin and deprotected in one step by 2% TFA/5% TIS/DCM for 1 h to yield Pyro-GDEVDGSGK(NH_2) (**3**) with the ε-NH_2 group of the C-terminal lysine exposed. The compound was precipitated from the cleavage solution by dry ether and prepurified by a few cycles of ether precipitation−DMSO dissolving. Compound **3** (10.9 mg, 6.8 μmol) was dried under high vacuum and, without further purification, used in the next reaction. For in vivo experiments, compound **3** (PP) was purified by HPLC. The structure was confirmed by MALDI-ToF (Supporting information Figure 1A; mass calculated 1377.64, found 1377.95). Crude PP (9.3 mg, 5.8 μmol) was dissolved in 100 μL of dry 1% DIPEA/DMSO and reacted for 2 h with Folate−NHS (4.7 mg, 6 μmol) dissolved in 100 μL of dry DMSO to give Pyro−GDEVDGSGK−Folate (**4**, PPF). The reaction was concentrated by precipitation with ether and directly separated by HPLC. Purified compound **4** (11.7 mg, 5.5 μmol) was dried under high vacuum and stored at −20 °C. The purity was checked by HPLC and MALDI-ToF (mass calculated 1800.76, found 1799.79).

Synthesis of PKF. The Fmoc−Lys was coupled to the Sieber resin after activation with HOBt/HBTU in the ratio 1/1/1:3 (Fmoc−Lys/HOBt/HBTU:Sieber resin) in NMP. After the Fmoc group cleavage, the resin was washed with NMP, and Pyro−acid was coupled to the N-terminus to give Pyro−K(Mtt)−Sieber resin. The molar ratio of Pyro/HOBt/HBTU to the NH_2−K(Mtt)−Sieber resin was 3/3/3:1, and the reaction was done in a shaker flask with a 12 h coupling time using dry NMP as a solvent. The resin was then washed with NMP, capped by 0.3 M acetylimidazol in NMP for 15 min, and washed again

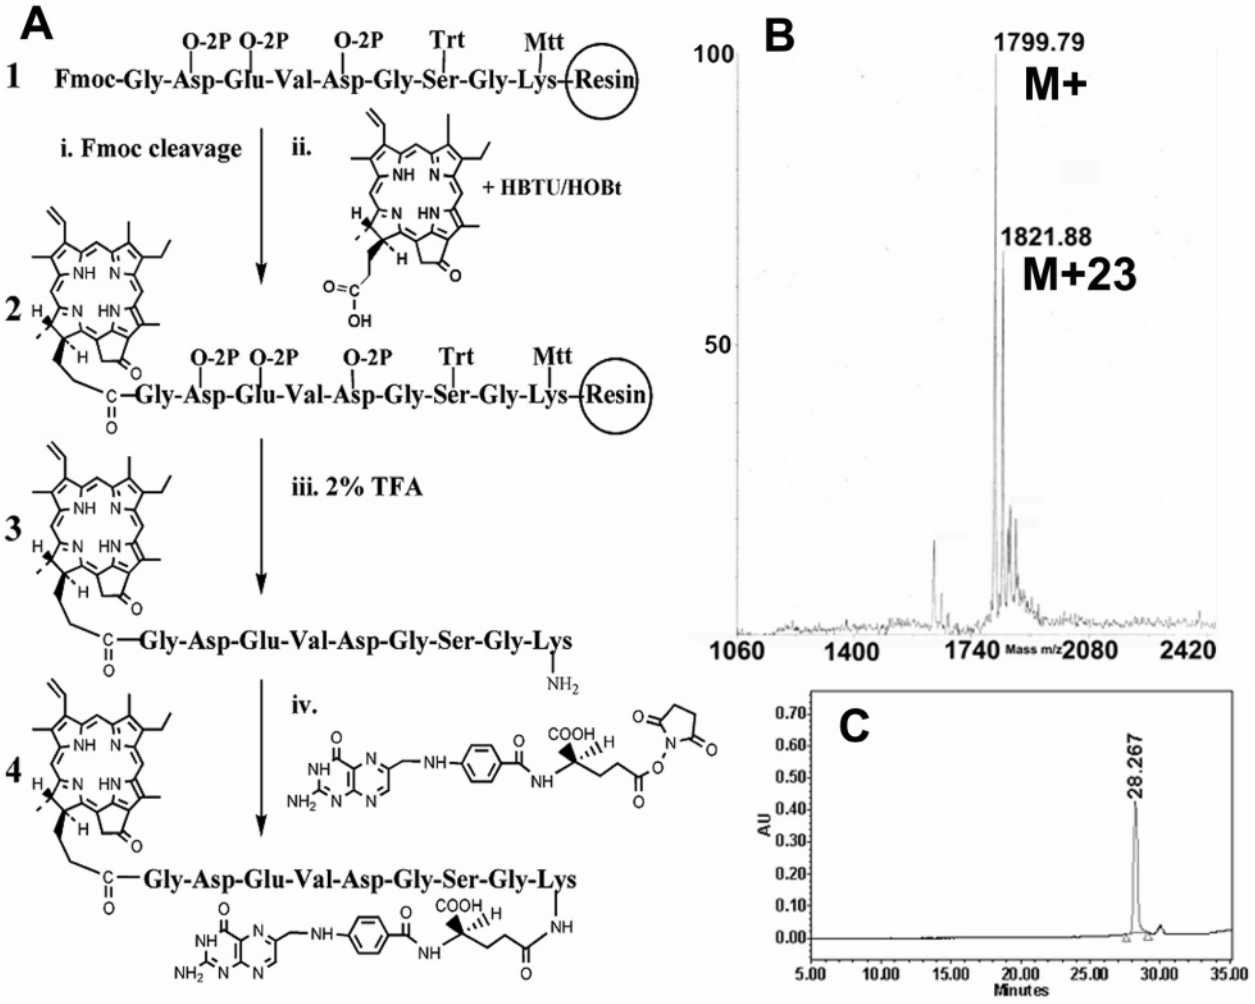

Figure 1. Synthesis (A), MALDI-ToF (B, mass calculated 1800.76, found 1799.79) and HPLC (C, absorbance at 410 nm) of Pyro−GDEVDGSGK−Folate.

by an excess of NMP, DCM, and dry methanol, transferred from the shaker flask, and dried. Pyro−K(Mtt)−Sieber resin was cleaved from the resin and the Mtt group deprotected in one step by 2% TFA/5% TIS/DCM for 1 h to yield Pyro−K−ϵNH$_2$. The compound was precipitated from the cleavage solution by dry ether and dried under high vacuum. This crude compound (21 mg, 31.7 μmol) was dissolved in 300 μL of dry 1% DIPEA/DMSO and reacted for 2 h with Folate−NHS (31.3 mg, 40 μmol) dissolved in 200 μL of dry DMSO to give Pyro−K−Folate (PKF). The reaction was concentrated and directly separated by HPLC. Purified PKF (29.8 mg, 27.5 μmol) was dried, and the purity was checked by HPLC and MALDI-ToF (Supporting information Figure 1B; mass calculated 1084.50, found 1084.18).

Confocal Microscopy. KB and HT 1080 cells were grown in 4-well Lab-Tek chamber slides (Naperville, Illinois) at a density of 50 000 cells/well and grown for 24 h in complete MEM, then rinsed with HBSS (Hank's balanced salt solution) and incubated with 50 μM PPF in 300 μL of MEM containing 0.8% BSA at 37 °C for 5 h. Cells were repeatedly rinsed with HBSS after the incubation and fixed by 1% formaldehyde in PBS for 20 min prior to scanning with confocal microscopy. The settings for confocal microscopy were as follows: 640−800 nm detector slit for detection of Pyro fluorescence, with zoom = 2, expander = 3, resolution 512 × 512, 633 nm excitation wavelength, 40× objective, 100% power, 851.1 gain, and −28.5 offset.

Flow Cytometry Experiments. KB, HT 1080, and CHO cells were seeded in T25 flasks (each flask 10^6 cells) and grown for 1 day in complete MEM (KB cells and HT 1080 cells) or complete F12K (CHO cells) medium. The cells were incubated for 12 h with 5 μM PPF or PKF in MEM containing 0.8% BSA (KB and HT 1080 cells) or F12K containing 0.8% BSA (CHO cells) 1.3 mL/flask alone or with 5 mM folic acid added, and at the end of incubation, the medium was aspirated and cells washed 3 times with 2 mL of PBS. The cells were detached by 0.25% trypsin−EDTA, fixed by 1% formaldehyde (methanol-free) in PBS, resuspended in 1 mL of PBS, and immediately analyzed on a BD LSRII machine at the Flow Cytometry Laboratory, Abramson Cancer Center, at the University of Pennsylvania focusing on Pyro fluorescence (exc. 633 nm, em. 695 nm). The gain was constant for all three samples and set so that the control cells had a fluorescent intensity between 1 and 100 AU.

Cell Viability (MTT) Assay. KB, HT 1080, and CHO cells were seeded in clear 96-well plates at a density of 50 000 cells/well in 250 μL of complete MEM (KB and HT 1080 cells) or complete F12K (CHO cells) and grown for 24 h at 37 °C. Cells were subsequently rinsed with HBSS and incubated with no or 0.5, 5, or 15 μM PPF in MEM containing 0.8% BSA (KB and HT 1080 cells) or F12K containing 0.8% BSA (CHO cells) for 24 h. Cells were then rinsed with HBSS, 100 μL/well of complete MEM was added, and the cells were either kept in the dark or treated with different light doses (5 or 10 J/cm^2) by a 670 nm laser with a 20 mW/cm^2 fluence rate. After incubation for 24 h at 37 °C, the cells were incubated for 2 h with a 0.5 mg/mL solution of MTT in complete MEM/complete F12K, that was disposed afterward and replaced with 100 μL of equal

parts of DMSO and 70% isopropanol in 0.1 M HCl. Absorbance at 570 nm was measured. Data shown are based on three different experiments, and the results were expressed as mean ± standard error.

In Vivo Imaging. Nude mice were inoculated subcutaneously with 10^7 KB cells above the right leg and 10^7 HT 1080 cells above the left leg, and the tumors were grown for about 7 days. First, three mice were initially scanned with a Xenogen IVIS imager with a Cy 5.5 filter (λ_{exc} = 615−665 nm, λ_{em} = 695−770 nm) and then intravenously injected with 50 nmol (left), 100 nmol (middle), and 150 nmol (right mouse) of PPF 60−180 μL/mouse into the tail vein. The mice were imaged 5 min, 6 h, and 24 h after injection. In order to compare the biodistribution of PP and PPF, two double tumor mice were intravenously injected with 30 nmol of PPF or 30 nmol of PP and imaged. These mice were sacrificed 26−30 h after the injection, and the organs (KB tumor, HT 1080 tumor, muscle, heart, adrenal, kidney, spleen, and liver) were imaged directly after dissection and used for biodistribution. In order to compare the biodistribution of PP, PPF, and PKF, the first mouse was injected with 30 nmol of PPF, the second with 30 nmol of PP, and the third with 15 nmol of PKF in two different experiments. The Xenogen images were obtained with the same settings (small binning, 2 s exposure time) and were compared using max = 20 000, min = 3000 for PPF and PP and max = 10 000, min = 1500 for PKF. The mice were sacrificed 26−30 h after iv, the organs were scanned by Xenogen and used for biodistribution.

Semiquantitative ex Vivo Organ Biodistribution. The mice were euthanized 26−30 h after drug injection, and the dissected organs were washed in PBS and scanned by Xenogen in a clear 24-well plate. The organs were weighed and disintegrated in DMSO/MeOH (2/3). After settling, the fluorescence was measured (excitation 650 nm, emission 670 nm) and divided by weight for each organ. This ratio of fluorescence vs weight was normalized with respect to muscle, and these semiquantitative values plotted in graphs comparing either PP and PPF (these data are based on three different experiments and the results expressed as mean ± standard error) or PP, PPF, and PKF. Statistically significant differences between KB tumor and other organs of PPF mouse are indicated with an asterisk ($P < 0.05$).

RESULTS AND DISCUSSION

Synthesis and Characterization of Pyro−GDEVDGSGK−Folate (PPF). First, Fmoc−GDEVDGSGK was synthesized according the standard solid-phase peptide synthesis (SPPS) protocol using a Sieber resin as a solid phase (**1**). The photosensitizer Pyro acid was then coupled to the N-terminus of the immobilized peptide (Figure 1A) to give Pyro−GDEVDGSGK−Sieber resin (**2**), which was cleaved from the solid phase and deprotected with 2% TFA. The folate−NHS was then coupled in a solution reaction to the ϵ-NH_2 group of C-terminal lysine of Pyro−GDEVDGSGK (PP, **3**), and the product Pyro−GDEVDGSGK−(Folate) (PPF, **4**) was characterized by MALDI-ToF (mass calculated 1800.76, found 1799.79; Figure 1B) after purification by HPLC (Figure 1C, absorbance at 410 nm).

Accumulation of Pyro−GDEVDGSGK−Folate (PPF) inside FR-Positive and -Negative Cells Monitored by Confocal Microscopy and Flow Cytometry. To confirm the preferential uptake of PPF by folate receptor-overexpressing tumor cells, KB cells (human epidermal cancer cells; folate receptor positive, FR+) and HT 1080 cells (human fibrosarcoma cells; folate receptor negative, FR−) were incubated with 50 μM PPF for 5 h, and the fluorescence of fixed cells was then monitored by confocal microscopy (Figure 2). By comparing

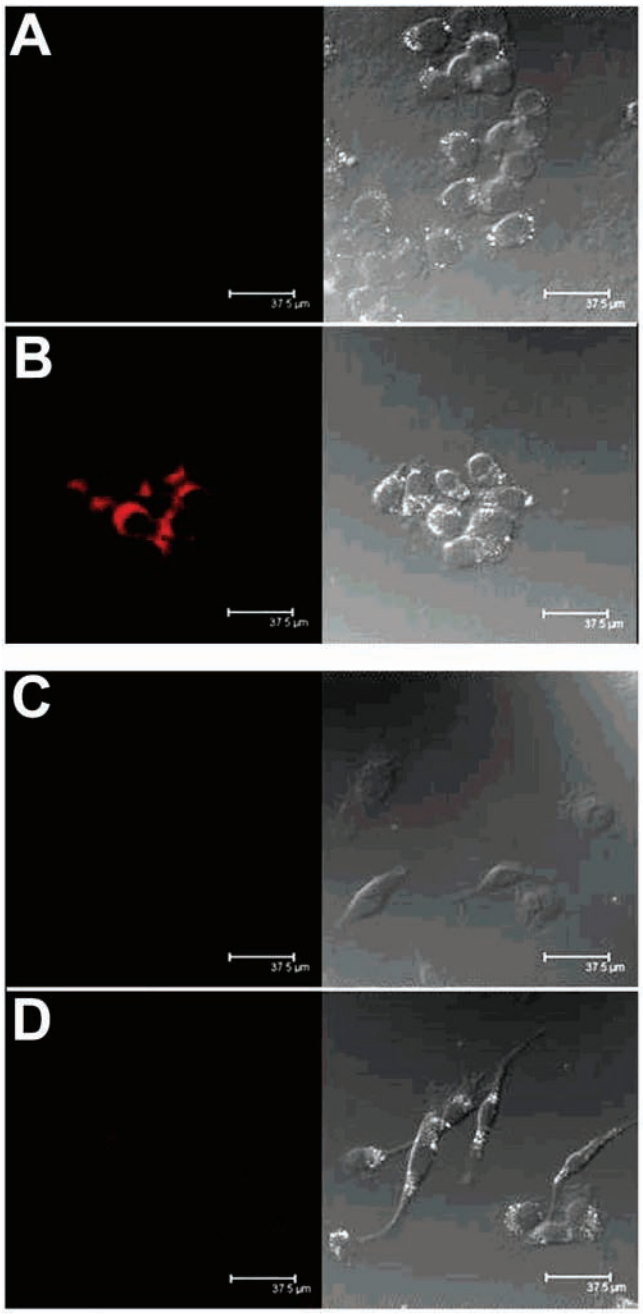

Figure 2. Accumulation of Pyro−GDEVDGSGK−Folate (PPF) in KB (FR+) vs HT 1080 (FR−) cells. (A) KB cells alone, (B) KB cells incubated with 50 μM PPF for 5 h, (C) HT 1080 cells alone, (D) HT 1080 cells incubated with 50 μM PPF for 5 h. PPF accumulates preferentially in KB cells. The scale bar represents 37.5 μm.

Figure 2B andD, it is clear that PPF accumulates more in KB cells (FR+) (Figure 2B) than in HT 1080 cells (FR−) (Figure 2D).

In order to establish the FR delivery pathway as the main uptake mechanism for PPF, the inhibition of PPF uptake was monitored by flow cytometry using an excess of free folic acid in KB, HT 1080, and CHO (chinese hamster ovary) cells. As expected, there is a minimal influence of folic acid on the uptake of PPF into HT 1080 and CHO cells (both FR−) in contrast to KB cells, where the uptake was inhibited up to 70% (Figure 3). These results suggest that (A) the main delivery pathway for PPF into the FR+ cells is via folate receptor-mediated endocytosis, (B) PPF's uptake can be inhibited up to 70% by folic acid in the case of KB cells (FR+), and (C) the remaining

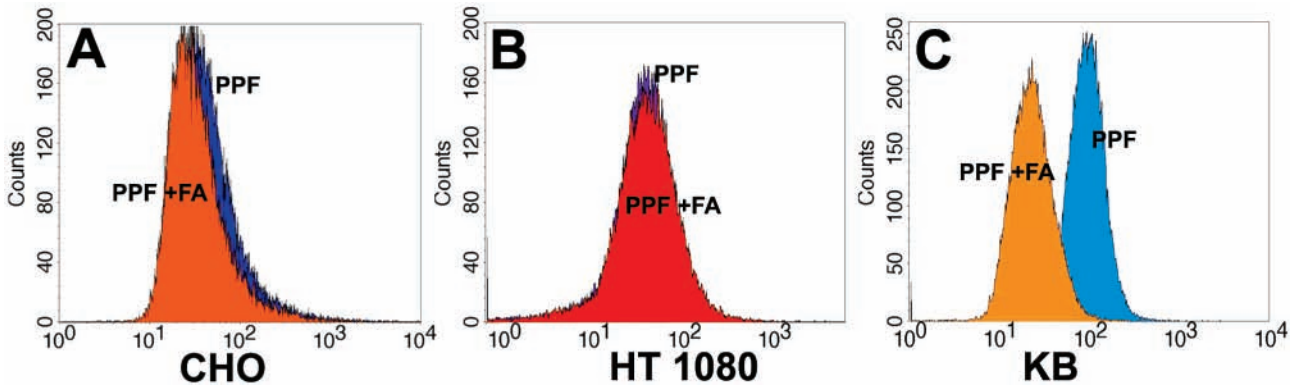

Figure 3. Monitoring the accumulation of PPF (Pyro−GDEVDGSGK−Folate) in CHO (FR−), HT 1080 (FR−), and KB (FR+) cells using flow cytometry and inhibition of this uptake with free folic acid. CHO cells (A) and HT 1080 cells (B) incubated with 5 μM PPF (blue) or 5 μM PPF and 5 mM folic acid (orange/red) show very similar uptake of PPF (695 nm fluorescence) with or without inhibition (PPF + FA vs PPF). Only KB cells (C) show significant (70%) reduction in PPF uptake when incubated with 5 μM PPF and 5 mM Folic acid (PPF, blue; vs PPF + FA, orange), suggesting that folate receptor-mediated endocytosis is the main delivery pathway for KB, but not for CHO and HT 1080 cells.

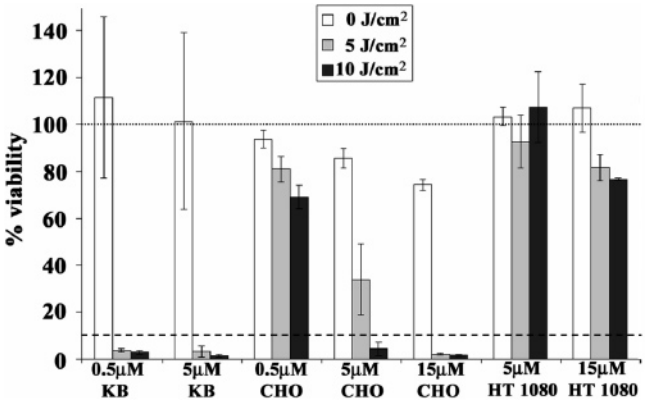

Figure 4. Viability of KB cells (FR+, cancer cells), HT 1080 cells (FR−, cancer cells), and CHO cells (FR−, normal cells) incubated with 0.5, 5, and 15 μM PPF and treated with light (5 or 10 J/cm^2) or kept in the dark (0 J/cm^2). KB cells have viability reduced below 10% when incubated with the lowest drug dose (0.5 μM) and treated with 5 J/cm^2. CHO cells reach this level of cell death for the same concentration (5 μM) only when treated with the highest light dose (10 J/cm^2), and in case of HT 1080, even the highest drug dose (15 μM) and light dose (10 J/cm^2) did not reduce their viability below 10%.

uptake of PPF to KB cells and the lower uptake of PPF to the HT 1080 and CHO cells can be attributed to the nonspecific tumor affinity of the Pyro moiety.

Selective PDT-Induced Cell Killing as a Result of FR Targeting. To compare the post-PDT viability reduction for cell lines with different levels of FR expression, KB tumor cells (FR+), HT 1080 tumor cells (FR−), and normal CHO cells (FR−) were incubated with 0.5, 5, and 15 μM **PPF** for 24 h and were then either kept in the dark or treated by PDT with 5 or 10 J/cm^2 light doses using a 670 nm tunable laser with a fluence rate of 20 mW/cm^2. The MTT study (Figure 4) shows that the viability of KB cells drops below 10% when incubated with 0.5 μM **PPF** and treated with a 5 J/cm^2 light dose. Achieving the same cell viability reduction in CHO cells requires both a 10-fold concentration (5 μM) in combination with a 2-fold light dose (10 J/cm^2). Interestingly, using the combination of the highest drug dose (15 μM) and light dose (10 J/cm^2) does not effectively kill the HT 1080 cells, suggesting an even lower accumulation of PPF or a possible PDT resistance of the HT1080 cells. This study further supports the FR-mediated PDT activity of PPF toward FR+ cancer cells.

In Vivo Discrimination between KB (FR+) and HT 1080 (FR−) Tumors. To validate the FR-targeting specificity of PPF in vivo, nude mice bearing an HT 1080 tumor (FR−) on the left flank and a KB tumor (FR+) on the right flank were used for in vivo imaging studies. Three double tumor mice were intravenously injected with 50, 100, and 150 nmol of PPF and scanned by Xenogen imager (Figure 5, using a Cy 5.5 filter) before the drug injection (prescan, Figure 5A) and after the drug injection at three different time points (5 min, 6 h, and 24 h). Five minutes after injection (Figure 5B), PPF is distributed rapidly throughout the body, carried by the blood stream. At 6 h postinjection (Figure 5C), KB tumor accumulates significantly more PPF than HT 1080, and accumulation in normal organs is considerably reduced. At 24 h postinjection (Figure 5D), the uptake of PPF in normal organs as well as the HT1080 (FR−) tumor for "50 nmol" and "100 nmol" mouse drops almost to the prescan level in contrast to a high fluorescent signal that remains in the KB tumor. These in vivo imaging studies clearly show that (A) PPF accumulates preferentially in KB tumor with respect to HT1080 tumor and other normal organs, (B) it is clear from the saturated image of the "150 nmol" mouse (Figure 5D) that PPF also accumulates in HT 1080 tumor, and (C) PPF is not toxic at the 150 nmol drug dose and is cleared quickly out of normal tissues.

The Role of Folate and Peptide Modules in Targeted Delivery of PPF. In order to examine the impact of each module on delivery efficiency and target specificity, two analogues of PPF were synthesized. One is Pyro−GDEVDGSGK (PP) that lacks the folate moiety; the other is Pyro−K−Folate (PKF) with one lysine residue replacing the short peptide sequence (Figure 6).

A. The Role of Folate Attachment for Target-Specific Delivery of PPF in Vivo. Since Pyro itself can serve as a delivery molecule (albeit with poor specificity), the in vivo imaging and biodistribution of the nontargeting Pyro−GDEVDGSGK (PP) can help to assess the true influence of folate as a tumor homing molecule. Thus, two double tumor-bearing mice in each experiment were injected with 30 nmol of PPF or with 30 nmol of PP (n = 3). The image in Figure 7 (upper left) shows that, around 6.5 h after injection of PPF (left) and PP (right), PPF accumulates significantly more in KB tumors than in HT1080 tumors, whereas PP accumulates comparably in both KB and HT 1080 tumors (see also Figure 8). The animals were sacrificed 26−30 h after injection, and the dissected organs were first imaged (Figure 7, lower left) and then homogenized. The images of the organs showed stronger fluorescence in the KB tumor from the PPF mouse, a weaker signal coming mainly from kidneys and livers of both the PPF and the PP mouse, and almost no signal from other organs.

The uptake of PPF and PP was determined by extracting the homogenized organs with DMSO/MeOH, measuring the fluorescence at 670 nm, and correcting the signal for weight (Figure

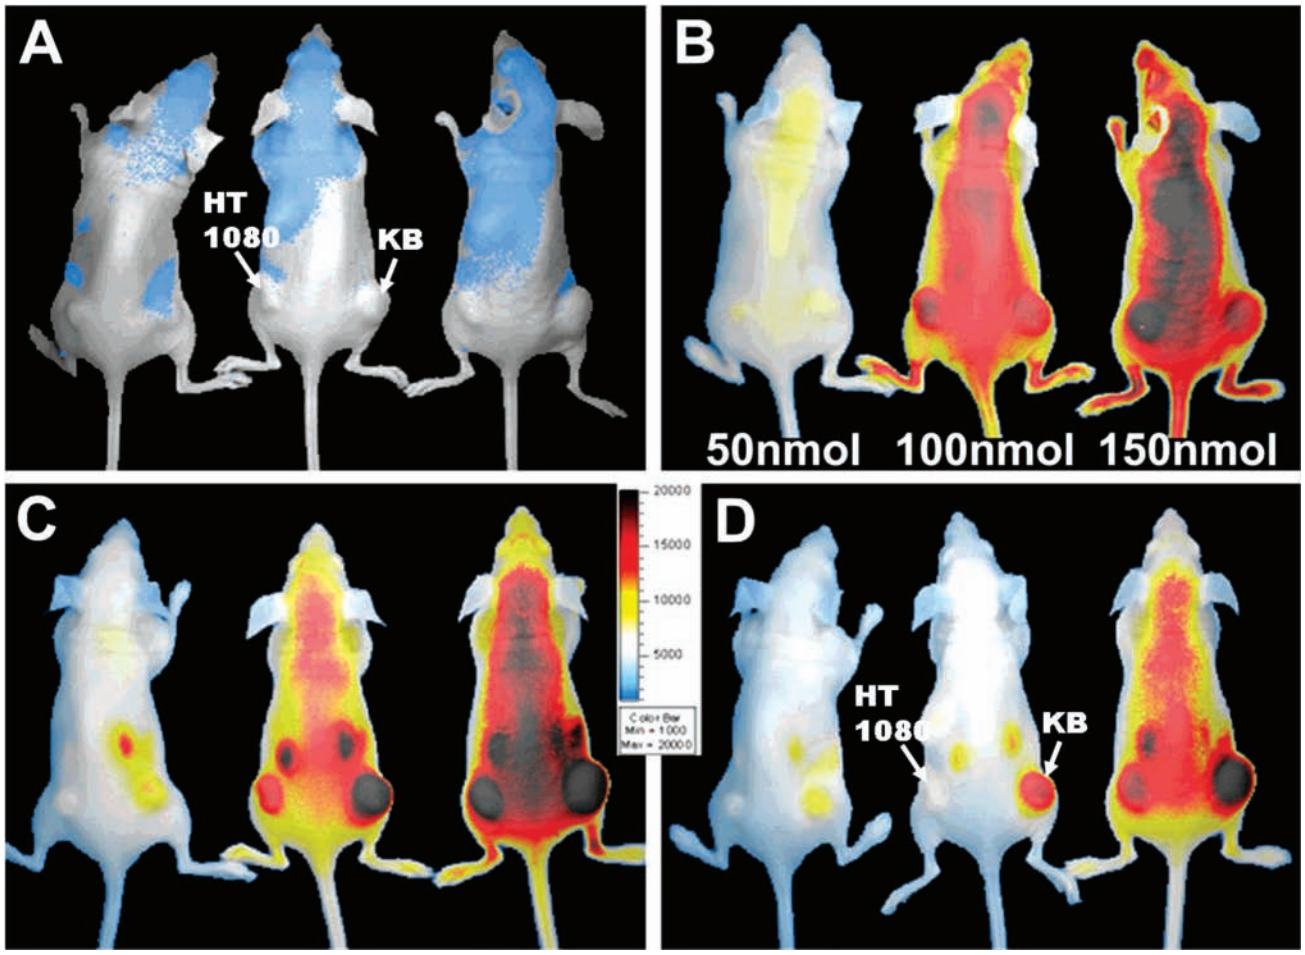

Figure 5. Monitoring fluorescence signal distribution after intravenous injection of three different doses of PPF to double tumor-bearing mice that have a KB tumor (FR+) on the right side and an HT 1080 tumor (FR−) on the left side, using a Xenogen imager. (A) Prescan, (B) 5 min after injection of 50 nmol (left mouse), 100 nmol (middle mouse) and 150 nmol (right mouse) of PPF, (C) 6 h after injection, and (D) 24 h after injection. At this point, it is clear that PPF preferentially accumulates in the KB tumor.

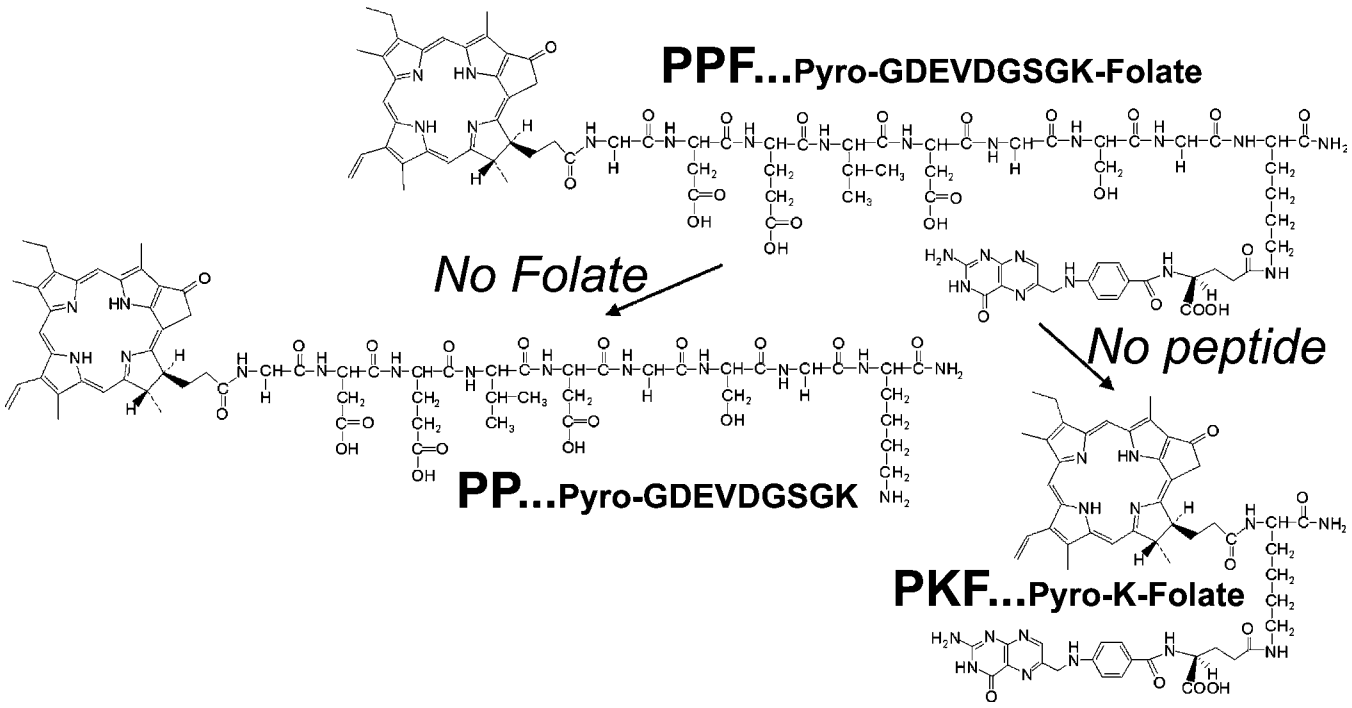

Figure 6. Structure of PPF (both peptide and folate modulation), PP (lacking the folate), and PKF (lacking the peptide module).

7, right). By examining the biodistribution of PPF after normalizing with respect to muscle, the highest fluorescence signal was found in the KB tumor. This signal is only comparable to the signal from kidney, which is known as the

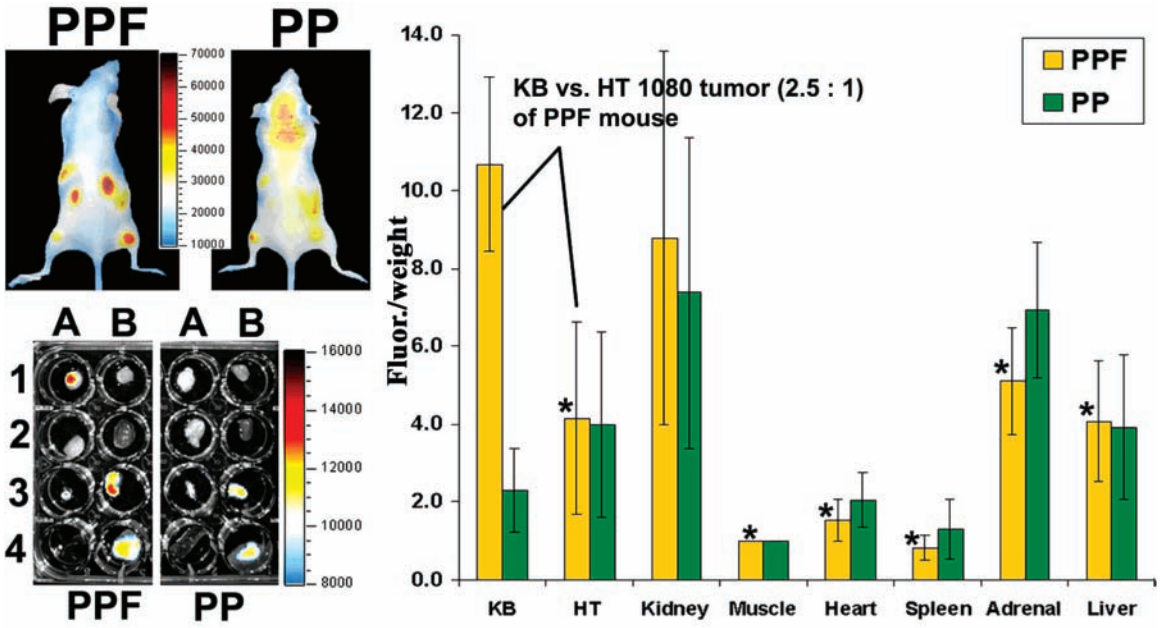

Figure 7. In vivo and ex vivo distribution of iv injected Pyro−GDEVDGSGK−Folate (PPF, targeting FR+ KB tumor) and Pyro−GDEVDGSGK (PP, no targeting). Xenogen images of double tumor mice (HT 1080 tumor left, KB tumor right) injected with PPF (left) or PP (right) at 6.5 h after injection (upper left corner) shows higher accumulation of PPF in the KB tumor. This was confirmed by images of the dissected organs (lower left corner): 1A, KB tumor; 1B, HT 1080 tumor; 2A, muscle; 2B, heart; 3A, adrenal; 3B, kidney; 4A, spleen; 4B, liver (left, PPF; and right, PP). Fluorescence from homogenized organs (right: PPF, orange; PP, green), corrected for weight and expressed as a ratio of the signal of muscle (=1), shows a significantly higher accumulation of PPF in the KB tumor than in the HT 1080 tumor but a similar distribution of nontargeting PP in both tumors. The asterisk identifies those organs of the PPF mouse whose relative fluorescence is significantly ($P < 0.05$, $n = 3$) different from that of the KB tumor, showing that the KB tumor has the highest accumulation of PPF, comparable only with kidney, while the HT 1080 tumor has an average signal that is 2.5 times lower.

major clearance pathway for folate bioconjugates. Moreover, the fluorescence signals in HT 1080 and other normal organs (adrenal, liver, heart, and spleen) were significantly lower (*$P < 0.05$) with the ratio of KB to HT 1080 on average 2.5:1. In contrast, the biodistribution of PP shows no significant difference between the HT 1080 tumors and KB tumors (or the rest of the organs), confirming the minimal role of Pyro on the PPF tumor selectivity and thus validating the importance of folate as a tumor homing molecule.

B. The Role of Peptide Modulation in Targeted Delivery of PPF. In order to clarify the role of peptide in the targeted delivery of PPF, Pyro−K−Folate (PKF) was synthesized by replacing the nine amino acid peptide sequence in PPF with a single lysine residue. The following investigations revealed the consequences of removing the peptide module. First, PKF showed the increased hydrophobicity and decreased water solubility when compared to PPF (HPLC, Supporting information Figure 2). Next, the accessibility of the folate moiety to FR in PKF vs PPF was also investigated in vitro using flow cytometry. KB, HT 1080, and CHO cells were incubated with the same concentration (5 μM) of PKF or PPF. It was observed that both PPF and PKF accumulate in HT 1080 and CHO cells (both FR−) with similar efficiency, whereas in KB cells (FR+), the efficiency of PKF uptake drops almost to 50% compared to that of PPF (Supporting information Figure 3). This indicates that the nine amino acid linker in PPF increases the efficiency of the FR-mediated uptake probably by making the folate more accessible (Supporting information Figure 4).

Perhaps the most profound effect of peptide modulation on the targeted delivery of PPF was its role in the biodistribution pattern of PPF as depicted in Figure 8 and Supporting information Figure 5. As expected, when we compare the in vivo biodistribution of PPF with that of PP, the difference in KB and HT 1080 tumor accumulation of PPF is visible at 1.5 h (Figure 8, column C) and is much more distinguishable at 6.5 h (Figure 8, column D) postinjection. This is clearly due to the effect of FR targeting by the folate moiety, which facilitates the preferential accumulation of PPF in the KB tumor (FR+), since folate-lacking PP does not distinguish between the FR+ and FR− tumors. However, what is notable is the common biodistribution pattern showing a low retention in the organs responsible for drug clearance for both PPF and PP. We attribute this finding to the peptide-based pharmacomodulation, meaning that the presence of a short peptide sequence significantly alters the pharmacokinetics and pharmacodynamics of the parent molecule. Such modulation becomes more obvious when we compare the biodistribution pattern of PPF with that of PKF (Figure 8, row 3, and Supporting information Figure 5). Even though PKF immediately after the injection (Figure 8, 3B) displays a distribution pattern very similar to that of PPF and PP (Figure 8, 1B and 2B), this pattern is drastically changed only 1.5 h postinjection (Figure 8, column C). At 6.5 h, it is clear that most PKF is retained by the excretion organs and exhibits extremely low tumor accumulation (Figure 8, 3D). In contrast, both PPF and PP are delivered to the tumors with much higher efficiency even though there is a difference in FR-targeting specificity.

The ex vivo organ biodistribution corrected for weight and normalized for muscle (Supporting information Figure 5) further confirmed this accumulation pattern. It identifies liver and spleen (followed by adrenal and kidney) as the organs accumulating most of the PKF, and when comparing the relative fluorescence intensity with both that of PPF and PP, this accumulation is approximately 50-fold higher for PKF. This pharmacomodulation highlights the positive impact of the peptide sequence on the targeted delivery of PPF by minimizing the nonspecific uptake by liver, spleen, and other organs.

Future Perspective. In principle, the target-specific, peptide-based pharmacomodulation approach described here could be applicable for improving the delivery efficiency of other cancer diagnostics and therapeutics. The versatility of this approach lies in its modular design in which any module could be easily

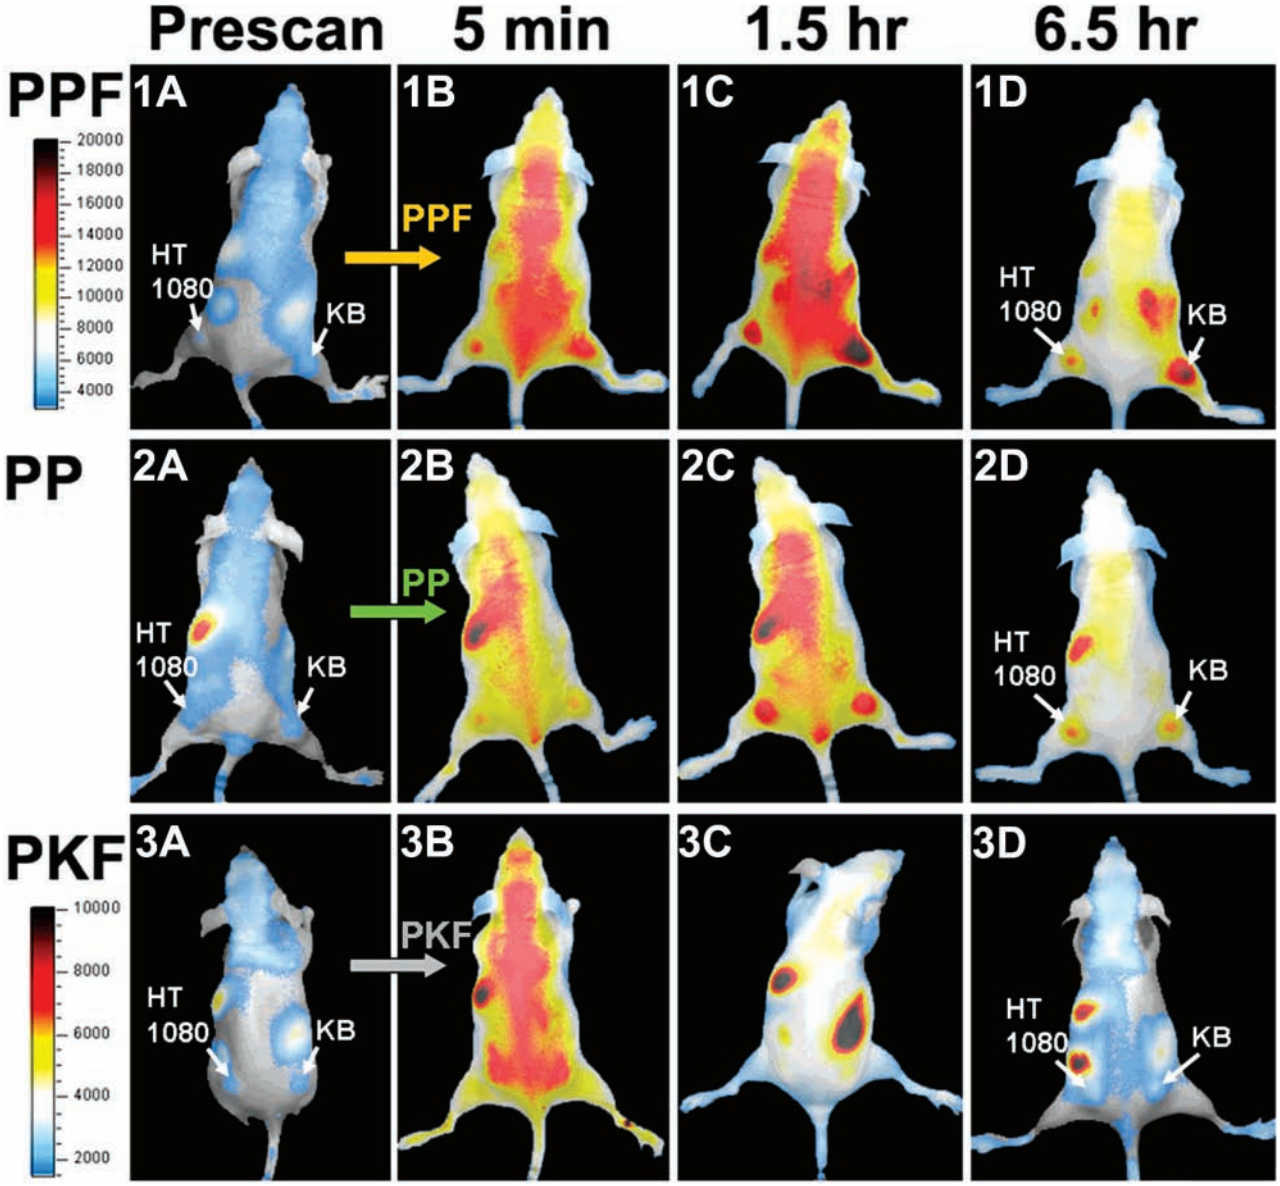

Figure 8. Double tumor mice (HT 1080 tumor, left; KB tumor, right) injected with Pyro−GDEVDGSGK−Folate (PPF, row 1), Pyro−GDEVDGSGK (PP, row 2), or Pyro−K−Folate (PKF, row 3) and imaged before the injection (Prescan, A) and 5 min (B), 1.5 h (C), and 6.5 h (D) after the drug injection. It is clear that 6.5 h after the injection PPF accumulates mostly in the KB tumor (1D) and PP equally in both tumors (2D), demonstrating the folate-introduced cancer specificity. This is in contrast to PKF (3D) that has minimal tumor accumulation and is retained in organs responsible for drug clearance, clearly identifying the peptide as the pharmacomodulating component.

replaced for a different purpose. For example, the Pyro moiety could be replaced with another photosensitizer that is active at a longer-wavelength absorption (e.g., bacteriochlorophylls (*39*) or naphthalocyanines (*40*)) or even a chemotherapeutic agent (e.g., docetaxel, etc.). The target specificity can also be modulated by exchanging the folate moiety for any small molecule ligand targeting other cancer signatures. Finally, the length and the sequence of the peptide linker could be fine-tuned to optimize the pharmacomodulation, improving not only the solubility and the target accessibility, but most importantly, also the delivery efficiency. In the future, the peptide linker could also serve as an subcellular organelle specific delivery vehicle when exchanged for different sequences.

SUMMARY

We synthesized, characterized, and evaluated a target-specific NIR imaging and PDT agent with improved target specificity and delivery efficiency. This agent is composed of three modules: a fluorescent photosensitizer Pyro for NIR imaging and PDT, folate for selective delivery, and a short peptide linker for pharmacomodulation. Although there were several previous attempts to link a dye (*9*) or a photosensitizer (*9*, *37*) to a folate moiety in order to specifically deliver the agent to cancer cells overexpressing FR, they were limited either to use in vitro or only to the imaging purposes. Here, we report a novel, modular approach using the combination of a folate-mediated targeting and a peptide-based pharmacomodulation to improve the efficiency of targeted delivery of NIR imaging and PDT agents. This study created a fluorescent photosensitizer with an excellent biodistribution pattern (folate receptor-specific tumor uptake and low accumulation in normal tissues), a crucial step toward lowering the toxicity and background signal, thus making it potentially applicable for detecting and treating cancers in patients.

ACKNOWLEDGMENT

We thank André E. X. Brown for critical comments and suggestions on the manuscript. This work was supported by the

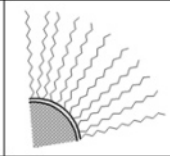
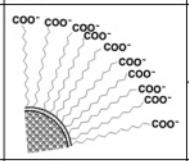
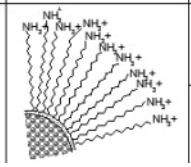
We demonstrate that quantum dots injected into two model tumors rapidly migrate to sentinel lymph nodes. PEG-coated quantum dots having terminal carboxyl, amino, or methoxyl groups all migrated from the tumor to surrounding lymph nodes similarly. Passage from the tumor through lymphatics to adjacent nodes could be visualized dynamically through the skin; at least two nodes could usually be defined. Imaging during necropsy confirmed confinement of the quantum dots to the lymphatic system and demonstrated easy tagging of sentinel lymph nodes for pathology. Examination of the sentinel nodes identified by quantum dot localization showed that at least some contained metastatic tumor foci.

INTRODUCTION







Mapping the reticuloendothelial system (RES) and locating draining lymph nodes were among the first uses of quantum dots *in vivo* (*1*−*3*). Fluorescence imaging should allow a simple optical readout, as well as higher resolution and a wider dynamic range than dye absorption or scintigraphy. For exposed tissues, the localization capability and sensitivity are potentially better than given by either visible dyes or radioactives, especially when using near-infrared emission, because of good tissue penetration and lowered background in the infrared (*3*−*5*).

Frangioni and colleagues (*3*, *6*−*9*) as well as others (*10*−*16*) have published studies showing mapping of draining lymph nodes by injection of fluorophores or fluorescently labeled macromolecules and particulates into various normal tissues. However, to our knowledge this is the first study that uses quantum dots injected into tumors to map sentinel nodes. In this paper, we also investigate whether changing the surface of PEG-conjugated quantum dots influences migration to sentinel nodes. We would expect binding and retention in lymph nodes to be influenced by surface charge, but simple drainage from the tumor volume would not.

MATERIALS AND METHODS

Quantum Dots were provided by Quantum Dot Corporation (now a division of Invitrogen). For the experiments reported here, we used 655 nm emitting ZnS−CdSe and 800 nm emitting ZnS−CdSe−CdTe core−shell quantum dots having a primary amphiphilic polymer coating (amp (*17*)), which yields highly fluorescent quantum dots with a high density of carboxyl groups on the surface. These amp-coated QDs were further substituted using poly(ethylene glycol) polymers having terminal methoxy, carboxy, or amino termini (*2*) (see Table 1). Thus, PEG-conjugated quantum dots having terminal neutral, positively charged, or negatively charged PEG surfaces could be compared as to their ability to access sentinel nodes after injection into a tumor.

Table 1. Quantum Dot Surfaces Used in this Report

Surface	Diagram	Emission wavelength, nm	Quantum yield	Hydrodynamic diameter, nm*
Methoxy-PEG		655	71%	22.6
		800	19%	*
Carboxy-PEG		655	44%	30.4
		800	17%	*
Amino-PEG		655	70%	41.2
		800	19%	*

*Measured in 0.01 M sodium borate buffer, pH 8.5. It was not possible to perform fluorescence correlation spectroscopy on the 800 nm quantum dots using our apparatus, which uses an 800 nm emitting laser for two-photon excitation. We expect the hydrodynamic diameters to be roughly similar to those of the 655 nm quantum dots.

Properties of the quantum dots are summarized in Table 1. Quantum yields were determined as described (*2*), using Rhodamine 101 as a standard, and with excitation at 530 nm. Hydrodynamic diameters were determined in 0.01 M sodium borate buffer, pH 8.5, using two-photon fluorescence correlation spectroscopy (*18*, *19*).

To minimize aggregation, all quantum dots were kept in 0.01 M sodiuim borate, pH 8.5. Just before use, the quantum dots were filtered through a 0.2 μm filter and made up to normal tonicity by addition of $^1/_9$ volume of 1.5 M NaCl, then adjusted to the desired volume by adding Dulbecco's phosphate-buffered saline (PBS).

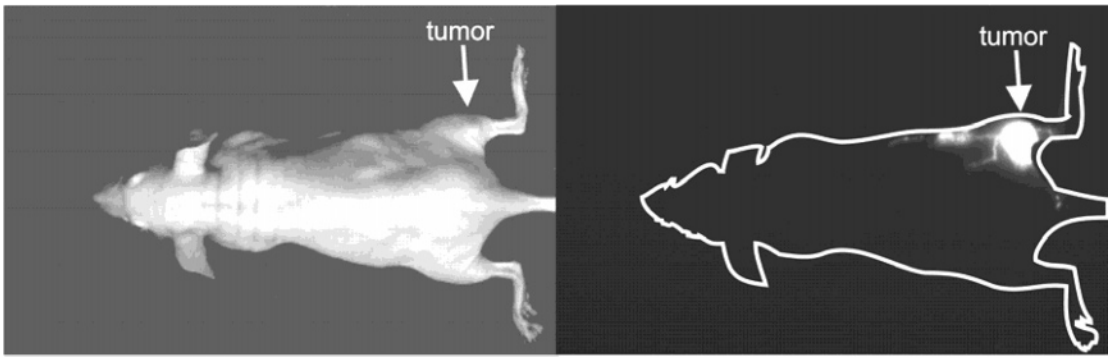

Figure 1. Nude mouse bearing M21 melanoma, dorsal view 3 min after injection into the tumor using 655 nm PEG 5k−COOH quantum dots. Left, visible light; right, fluorescence at 655 nm. Migration toward the inguinal node is already apparent.

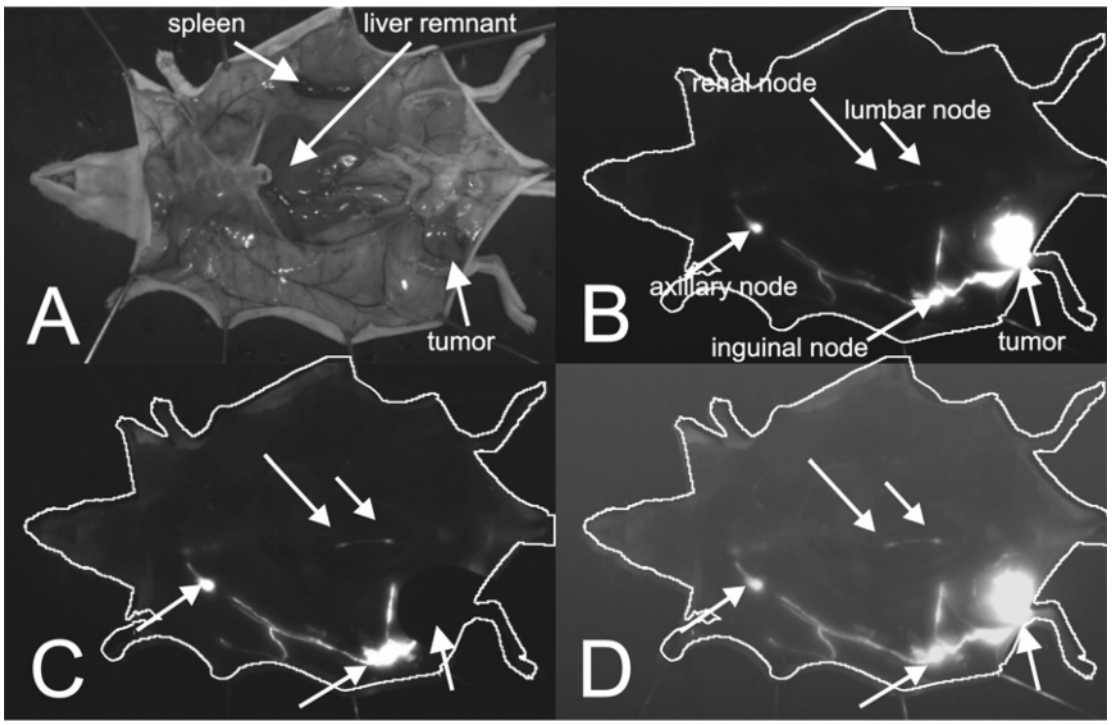

Figure 2. Same mouse as Figure 1, dissected at 40 min postinjection; ventral view. (A) Visible light. (B) Fluorescence at 655 nm. (C) Same as B, but with tumor masked. (D) Same as B, log-transformed image. Both C and D allow better display of the less bright lymphatics and smaller lymph nodes. Note drainage from tumor into lymphatics, accumulation in right inguinal, axillary, lumbar, and renal lymph nodes, but no fluorescence in the general circulation or in lymph nodes on the left side of the body. Arrows in C and D as in B; captions are omitted for clarity. We use the term "axillary" to describe lymph nodes often termed brachial (or "proper axillary") nodes as well as axillary (or "accessory axillary") nodes; in our preparations, these nodes are often not well separated (compare ref 48).

Table 2. Quantum Dot Combinations Used in This Report[a]

study	Qdot 1 surface	Qdot 1 emission	Qdot 2 surface	Qdot 2 emission
1	PEG 5k-OMe	800 nm	PEG 6k-NH2	655 nm
2	PEG 6k-NH2	655 nm	PEG 5k-OMe	800 nm
3	PEG 5k-OMe	800 nm	PEG 5k-COOH	655 nm
4	PEG 5k-COOH	655 nm	PEG 5k-OMe	800 nm

[a] Three mice were injected using each mixture.

Animals. Athymic nude mice were obtained from Harlan Sprague Dawley and were used at ages from 6 weeks to 3 months. All operations involving animals were performed in accord with institutional animal use and care regulations.

Tumors. Two tumor models were used, the M21 human melanoma (*20*, *21*) and the MH-15 mouse teratocarcinoma (*22*). For each tumor model, the tumor was grown subcutaneously in the right thigh; this location drains to the inguinal lymph node. Because the inguinal node is large and superficial, a rapid, reproducible assessment of quantum dot migration by noninvasive imaging was possible. After tumor growth to a suitable size (usually 2−4 mm diameter, 1−2 mm thick), mice were anesthetized using pentobarbital ip to effect (typically 62.5 mg/kg). Quantum dots were injected into tumors using a volume of 5−25 μL of a quantum dot preparation containing 25−100 pmol of quantum dots. The volume was adjusted to avoid noticeably inflating the tumors. In all cases, we attempted to inject directly into tumors and not into surrounding tissue. In two cases, we removed the skin over the tumor, then injected the visible tumor; no significant leakage was observed. Migration of fluorescence to the lymph nodes was identical to that reported in this paper (data not shown). We cannot exclude the possibility that a small amount of material may have leaked into subcutaneous space in some instances, but any significant

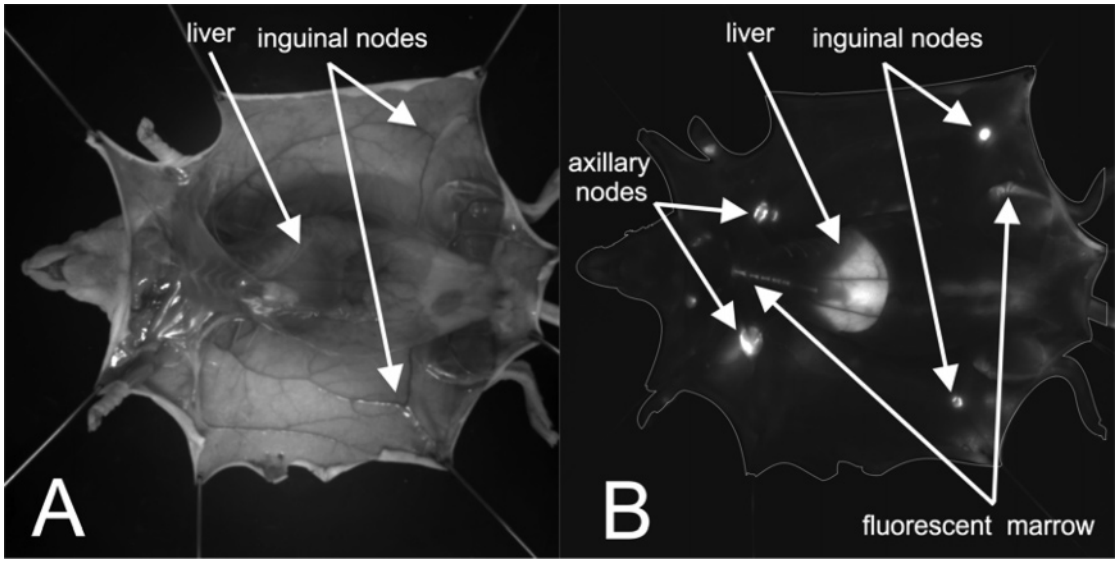

Figure 3. Mouse bearing M21 melanoma, injected sequentially in the tail vein first using 655 nm PEG 5k−COOH quantum dots, followed 20 min later by injection into the tumor using 800 nm PEG 5k−OMe quantum dots. Necropsy 90 min after tail vein injection. (A) Visible light image. (B) General labeling by IV-injected quantum dots, 655 nm window. Bone marrow, lymph nodes, and liver are prominent in the 655 window.

amount would have been detected by imaging immediately after injection. Tail vein injection was as described (*2*). Quantum dot doses given by tail vein were typically 300 pmol in 200 μL of normal saline.

Imaging. Tumors were imaged using an Andor DU 434-BR−DD cooled CCD camera (Andor Technology, South Windsor, CT 06074) equipped with a 50 mm AF Nikkor lens and any of several interference filters fitted between the lens and the CCD (filters were supplied by Chroma Technologies, Brattleboro, VT 05301). Mice were illuminated using four 450 nm emitting 5 W LEDs (Luxeon Royal Blue LXHL-MRRC, Lumileds Lighting, San Jose, CA 95131); 655 nm emitting quantum dots were imaged using a 654 nm × 24 nm interference filter. 800 nm emitting quantum dots were normally imaged using an 820 nm × 40 nm interference filter. Where the two different emitters were used together, to eliminate any residual spillover from 655 nm emitting quantum dots, 800 nm emitters were illuminated using a 250 W fiberoptic equipped halogen illuminator (Cuda Products, Jacksonville, FL 32217) filtered through a 750 nm × 30 nm interference filter, and emission was observed using an 840 nm × 20 nm filter. This resulted in much less observed emission from the 800 nm quantum dots and a higher background, but eliminated completely a small spillover (∼2%) from the 655 nm emitting quantum dots seen using the 450 nm LED illuminators and the 820 nm × 40 nm interference filter. There was no spillover from 800 nm quantum dots into the 655 nm channel.

A difficulty in displaying lymph nodes in the same image as the tumor is caused by the much greater brightness of the tumor. Either a logarithmic transform of the image or masking the tumor permits the display of small lymph nodes or faint lymphatics in the same image as the tumor. Where a log-transformed image is used, we display the original and transformed images together.

To demonstrate that transfer of quantum dots from tumors occurred through the lymphatics, lymph nodes were labeled generally by injecting animals in the tail vein, followed by injection in the tumor using a different wavelength quantum dot. This allowed us to assess whether any trapping of quantum dots had occurred by leakage from the tumor into the vascular compartment, followed by uptake into lymph nodes. In only 2 cases of a total of 27 mice examined, including the 12 mice reported in this paper, was there any indication of such leakage. Both cases involved large tumors having significant necrotic areas.

To compare the effects of surface charge on migration to sentinel nodes, a mixture of quantum dots having a methoxy−PEG surface and either a carboxy−PEG or amino−PEG surface was injected, and images were made in two different spectral windows corresponding to the neutral or charged quantum dots; the reciprocal combination was also injected. The tested combinations of emission wavelengths and surfaces are summarized in Table 2. For the results given in this paper, three mice were labeled using each combination.

Microscopy. Lymph nodes were removed at necropsy and subjected to normal paraffin embedding and staining procedures. Examination by a veterinary pathologist confirmed the presence or absence of tumor in lymph nodes. Where necessary, paraffin sections were stained using tumor-binding monoclonal antibodies: anti-SSEA-1 for the MH-15 teratocarcinoma (*22*) or 9.2.27 for the M21 melanoma (*20*).

RESULTS

In most cases, injection of quantum dots into the tumor yielded rapid transfer of fluorescence into adjacent lymph nodes, visible through the skin. Figure 1 shows that movement out of the tumor to adjacent lymphatics is rapid. Drainage toward the inguinal node can be seen through the skin almost immediately after injection. Figure 2 shows the same animal as in Figure 1, necropsied 40 min after injection. Drainage through the lymphatics to the right inguinal and axillary lymph nodes is clearly apparent. Migration of quantum dots to the right lumbar and renal nodes is also detectable. There is no labeling of the lymph nodes on the left side of the mouse. Note that Figure 1 shows a dorsal view, while all the other figures show ventral views. The tumors were always on the dorsal side of the thigh, so the tumor in the ventral images is partly obscured by the mouse thigh.

Figures 3 and 4 show that drainage to adjacent lymph nodes is not caused by any difference in ability to trap quantum dots between nodes adjacent to the tumor and more distant lymph nodes. All lymph nodes were labeled by the 655 nm PEG 5k−COOH quantum dots that were tail-vein injected; only nodes close to the tumor were labeled by the 800 nm PEG 5k−OMe quantum dots injected into the tumor. (Carboxy-terminal quantum dots were used for general labeling to ensure rapid uptake by lymph nodes (*1*, *2*).)

To determine the effect of terminal charged groups on migration from tumors to lymph nodes, neutral PEG 5k−OMe

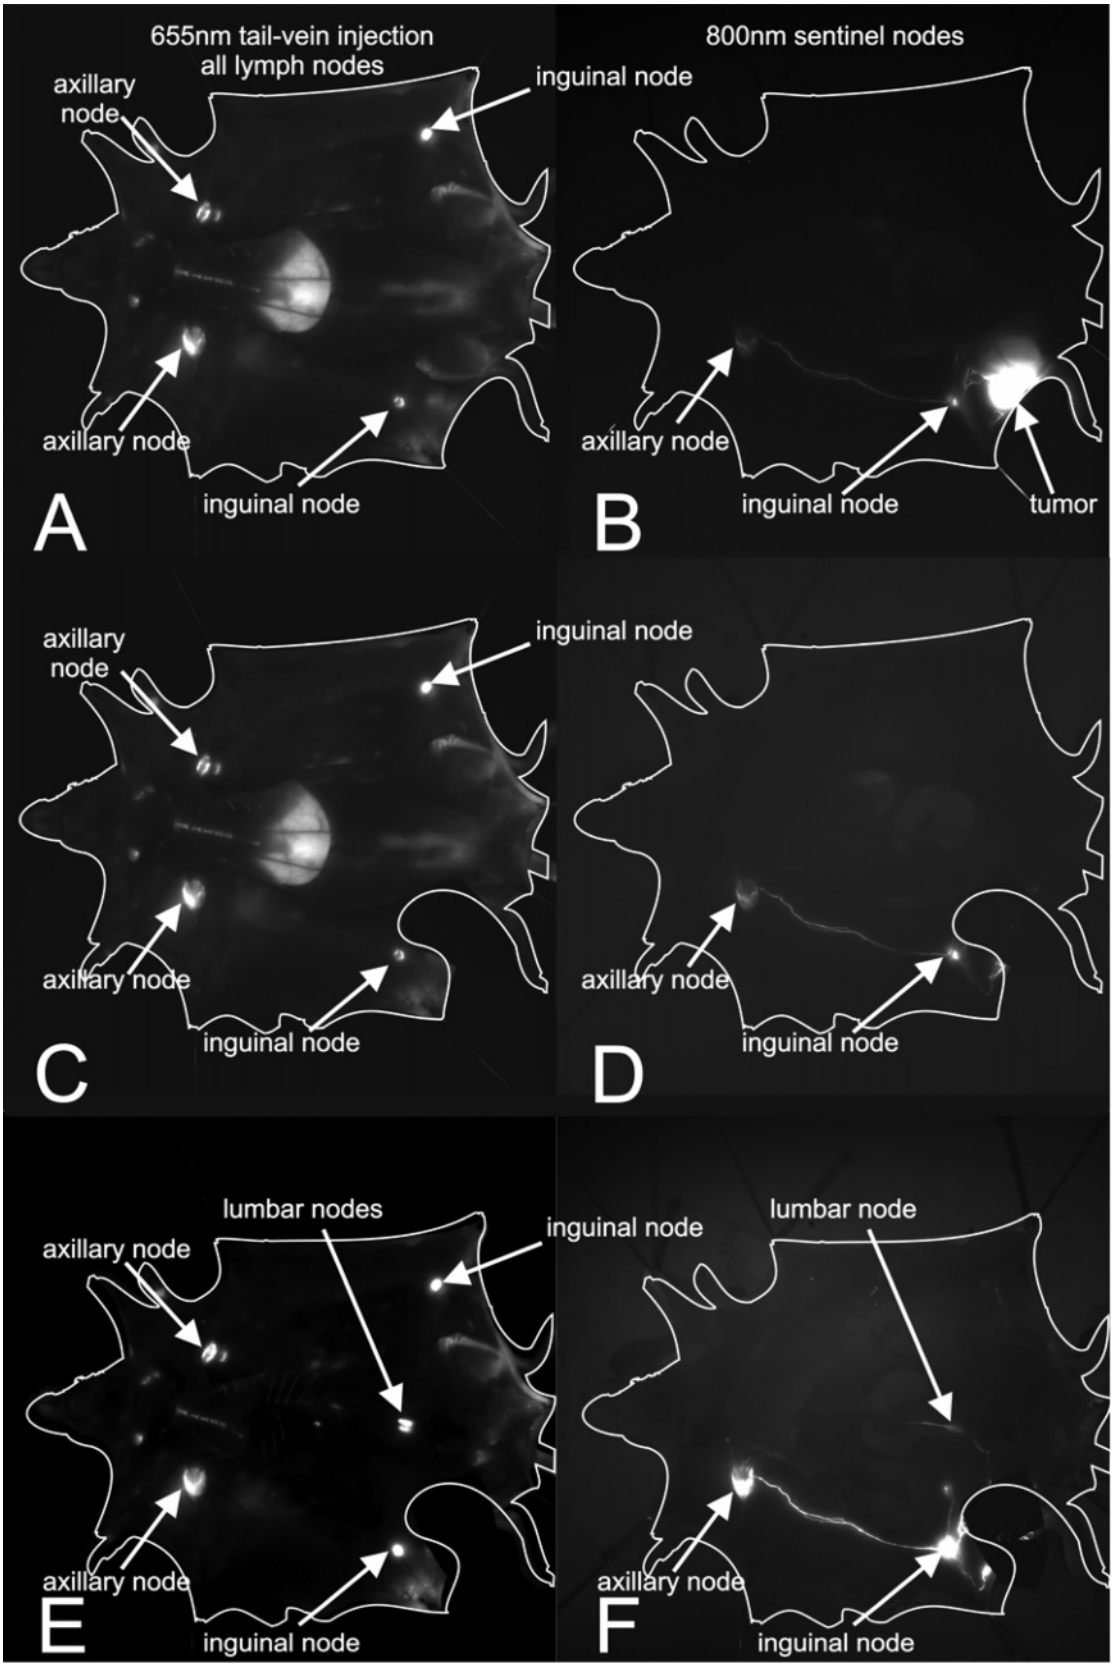

Figure 4. Same mouse as Figure 3, visualized in 655 nm window (left; A,C,E; tail-vein injection, 655 nm PEG 5k−COOH) and 800 nm window (right; B,D,F; intratumoral injection, 800 nm PEG 5k−OMe). Internal organs are removed to display all lymph nodes. (A,B) Superficial skin removed, but peritoneum intact. (A) Fluorescence of peripheral lymph nodes and liver. (B) Unilateral fluorescence of lymph nodes adjacent to tumor, no staining of liver. (C,D) Same as A,B, but with tumor masked. The lymphatic drainage from the tumor is more easily seen in D. (E,F) Most internal organs removed. Bilateral staining of lumbar and renal nodes visible in E, but only unilateral staining is visible in F.

quantum dots were injected together with either PEG 5k−COOH or PEG 6k−NH_2 quantum dots (Table 2; coprecipitation rules out injecting amino− and carboxy−PEG mixtures). Figures 5 and 6 (reciprocal combination) show that migration to sentinel nodes was similar when mixed methoxy- and carboxy-terminated PEG substituents were used. Results were also similar

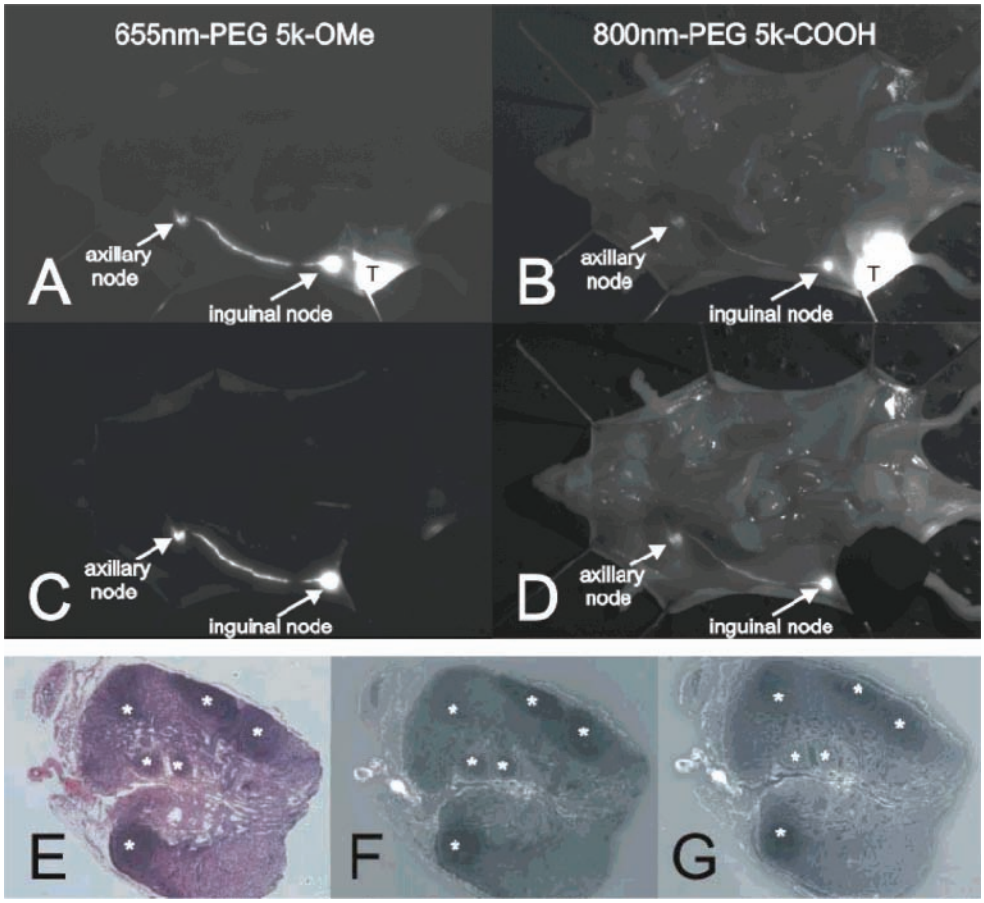

Figure 5. Quantum dots having either carboxy or methoxy surfaces migrate similarly. A mixture of 655 nm PEG 5k−OMe and 800 nm PEG 5k−COOH was injected into the tumor. Necropsy at 40 min after injection. (A) 655 nm window, tumor visible. (B) 800 nm window, tumor visible. (C) 655 nm window, tumor masked. (D) 800 nm window, tumor masked. Visibility of tumor through the leg is better using 800 nm quantum dots, but signal is lower and background is higher in B,D due to long-wavelength illumination (750 nm); however, no spillover from 655 nm quantum dots is possible. (E−G) Lymph node from mouse in Figure 5. The node was removed, fixed in buffered formalin, paraffin-embedded, and then stained using conventional hematoxylin and eosin. (E) Bright-field color image; note germinal centers (asterisks). (F) 655 nm fluorescence image (PEG 5k−OMe quantum dots). (G) 800 nm fluorescence image (PEG 5k−COOH quantum dots.) Fluorescence is confined to lymphatic vessels and sinuses.

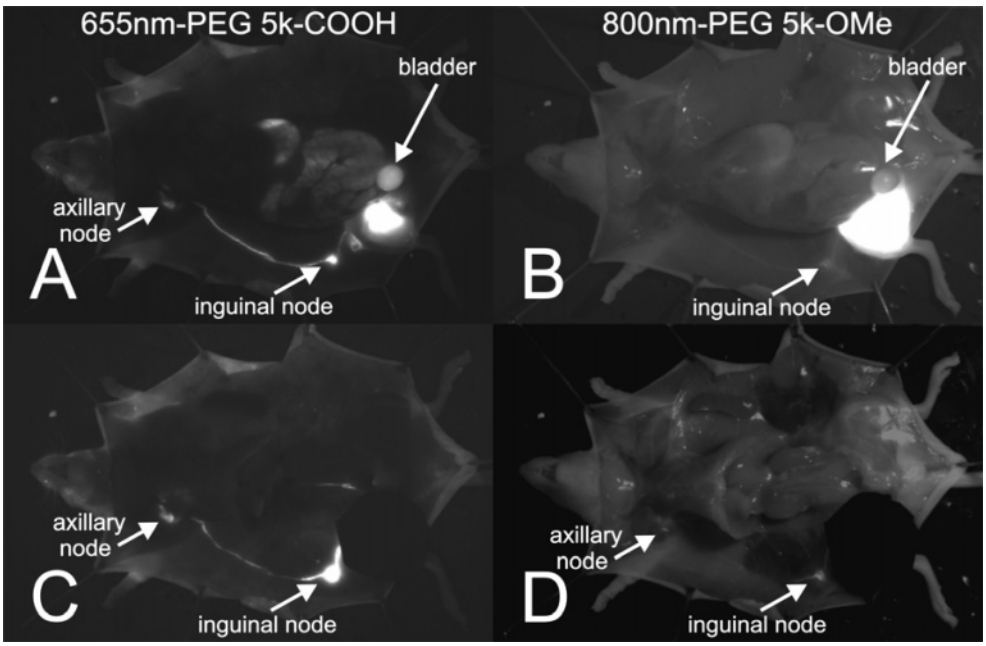

Figure 6. A mixture of 655 nm PEG 5k−COOH and 800 nm PEG 5k−OMe quantum dots was used, reciprocal to that of Figure 5. Necropsy and imaging were similar to those of Figure 5. (A) 655 nm window, tumor visible. (B) 800 nm window, tumor visible. (C) 655 nm window, tumor masked. (D) 800 nm window, tumor masked.

when injections of mixed amino- and methoxy-PEG-terminated quantum dots were used (Figure 7). Reciprocal combinations of emission wavelength and surface (Table 2) all gave similar results, so the nature of the core−shell material was unimportant.

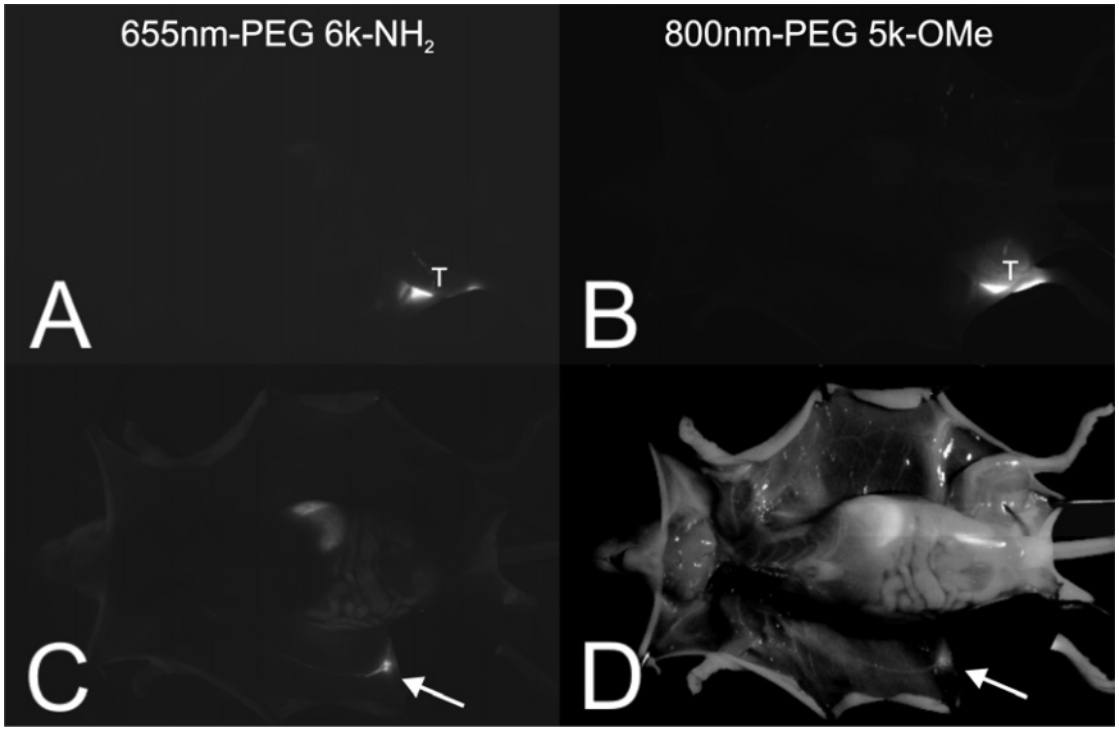

Figure 7. A mixture of 655 nm PEG 6k−NH_2 and 800 nm PEG 5k−OMe quantum dots was used. Necropsy 40 min after intratumoral injection into M21 melanoma. (A) 655 nm window, tumor visible. (B) 800 nm window, tumor visible. (C) 655 nm window, tumor masked. (D) 800 nm window, tumor masked. Quantum dots having either surface migrate similarly to adjacent inguinal node (arrows). T, tumor.

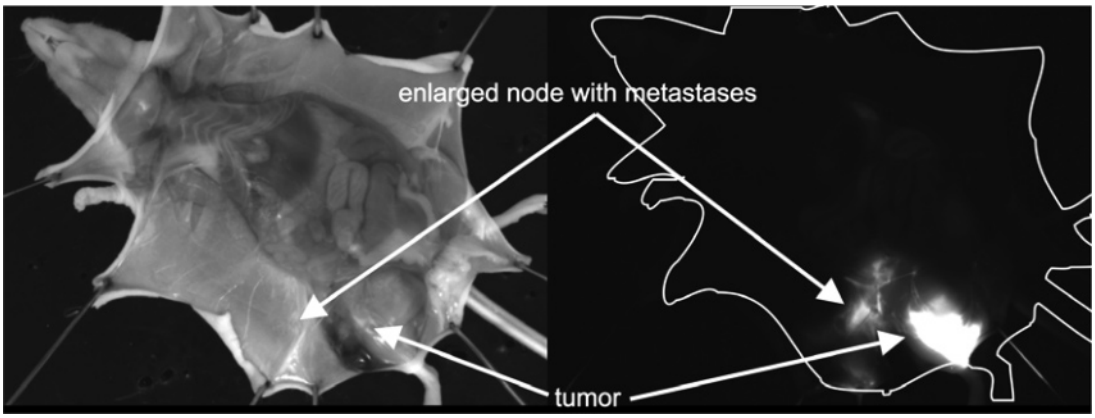

Figure 8. Nude mouse having large (~0.5 g) MH-15 teratocarcinoma, main growth dorsal to the right thigh, injected using 655 nm PEG 5k−OMe quantum dots. Ventral view. Left, visible light; right, 655 nm fluorescence. The thigh muscle has been infiltrated by the tumor, and there are local metastases to the adjacent tissue, including the right inguinal lymph node. Image taken 24 h postinjection.

Figure 8 shows the result of injecting a large MH-15 teratocarcinoma with neutral PEG-surfaced quantum dots. In this case, only the adjacent inguinal lymph node showed uptake of the quantum dots.

DISCUSSION

We have demonstrated that quantum dots define sentinel lymph nodes in mice after injection into tumors. Our results indicate that, for tumors in mice, terminal charged groups on PEG-conjugated quantum dots have little or no effect on drainage to surrounding lymph nodes. These results were surprising, since we expected that, as with whole-body imaging after intravenous injection, charged surfaces on quantum dots would increase lymph node uptake (*1*, *2*).

Our results also show that quantum dots having significantly different hydrodynamic diameters migrate similarly to lymph nodes. We would expect significant binding of intersitital tissue fluid components to the quantum dots, including enhanced binding to charged surfaces as compared to neutral PEG; this makes the results we observed even more remarkable and reinforces our belief that we are following mostly fluid flow from the tumors. On the time scale of these experiments, it is unlikely that any significant selective uptake by the lymph node occurs. Figure 5 shows that quantum dots in sentinel lymph nodes are found only on vessel boundaries and not in monocytes surrounding the germinal centers.

For visualization of superficial lymph nodes and lymphatics, or for parts of the lymphatic system exposed during necropsy, there was little difference in visibility between 655 nm emitting and 800 nm emitting quantum dots. For imaging deeper nodes or visualizing tumors through the thigh, we found 800 nm emitting quantum dots to be superior, as expected (*1*, *23*).

Frangioni and colleagues proposed the use of NIR-emitting quantum dots for sentinel lymph node mapping and demonstrated migration of quantum dots to lymph nodes when injected into normal tissues in mice. They also demonstrated that quantum dots can be used for lymph node mapping in a large animal model (pig) at centimeter depths (*3*). In subsequent

papers, this group has shown quantum dot fluorescence imaging of lymph nodes draining the lungs (*6*, *9*) and esophagus (*8*). Recently, Zimmer et al. (*24*) demonstrated that sufficiently small InAs−ZnSe quantum dots, coated using PEG−DHLA, localized in sentinel lymph nodes when injected into normal tissues. A sequence of draining lymph nodes could be labeled using these quantum dots; the authors attributed passage through the first draining lymph node to the small size of their quantum dots (>10 nm hydrodynamic diameter). In our hands, a sequence of lymph nodes was labeled using much larger, polymer-coated quantum dots; however, the bypass route through mouse lymph nodes (*25*) likely accounts for our results.

Other fluorophores used for sentinel lymph node imaging include free indocyanine green (*11*, *26*), indocyanine green adsorbed to albumin (*26*), free IRDye800CW (*26*), albumin conjugated to IRDye78 (*7*) or IRDye800CW (*8*, *26*), albumin colloid conjugated to IRDye800CW (*26*), fluorescent polystyrene microspheres (*14*, *15*), and two targeted conjugates, Cy5−vitamin B12 ("Cobalofluor") (*13*) and MECA-78, a cyanine-conjugated IgM antibody (*11*). Finally, enzyme-specific dequenching of a Cy5.5 conjugated polymer has been used to define lymph nodes (*16*, *27*). Frangioni and colleagues directly compared quantum dots to human serum albumin conjugates (*8*, *26*) and to isosulfan blue (*9*). Both quantum dots and organic fluorochromes imaged sentinel lymph nodes successfully; the quantum dots, probably because of their relatively large sizes (10−30 nm), normally targeted only the first draining lymph node, while organic dyes and smaller conjugates continued further to more distant lymph nodes (*26*) (but see ref 3.)

As compared to other methods of sentinel node location, fluorescence imaging offers improved sensitivity and greater speed, at least for lymph nodes that are close enough to the surface to be imaged or are revealed during surgery. Combining quantum dot fluorescence imaging with other noninvasive techniques (e.g., scintigraphy, MRI, or PET) would allow mapping of deep nodes; after exposure during surgery, fluorescence would then give more precise, detailed localization, potentially including microscopic levels (*3*, *28*). Alternatively, fluorescence endoscopic examination could be used during minimally invasive surgery (*8*, *13*). The equipment required for near-infrared imaging is relatively cheap and readily available, and a color video−NIR combined system has been described (*9*, *29*). Easy visualization of transport through lymphatics and accumulation in lymph nodes should be helpful for understanding the pattern of flow in the vicinity of tumors.

The ability to use multiple fluorescent emission colors may be useful in tumor diagnosis; ideally, sentinel nodes might be labeled using nonspecific quantum dots, while quantum dots conjugated to appropriate ligands and fluorescing at a different wavelength might be used to localize metastases in lymph nodes.

The advantages of quantum dots remain: very high brightness, wide range of fluorescence emission wavelengths, excitation at any wavelength below the emission wavelength, and extraordinary photostability. No organic fluorophore matches this set of advantages. Moreover, the long fluorescence lifetimes of quantum dots potentially allow nearly zero background imaging by time-gating (*30*). The difficulties remain also: relatively large size caused by the coats required for stability in aqueous solution; and potential toxicity, due either to heavy metal toxicity from dissolution of the quantum dots or to the size and surface characteristics of the nanoparticles. Several recent articles have discussed both actual and potential toxicity of quantum dots (*31*−*39*). Both major concerns are being addressed; new quantum dot compositions and coats should yield nanoparticles that are both smaller and less toxic (*24*, *40*−*47*). Molecules or particulates multiply substituted with organic dyes are good alternatives that have been demonstrated to function well for sentinel node location (*7*, *8*, *26*); however, the NIR organic fluorophores themselves may also be toxic. In our hands, the toxicity of amp-coated CdSe−ZnS quantum dots is minimal or nonexistant, as assessed by pathological examination of animals injected with quantum dots and kept for long periods (now over 2 years.) Even after this time, at least some of the quantum dots retain their fluorescence, suggesting that they remain intact ((*1*) and in preparation). We therefore believe that the clinical use of existing quantum dots, suitably purified and at low doses relevant to sentinel lymph node detection, would result in minimal toxicity, though less toxic compositions and surfaces will be welcome.

ACKNOWLEDGMENT

The authors are grateful for assistance with quantum dot manufacture by Joseph Treadway (present address Invitrogen, 29851 Willow Creek Road, Eugene OR 97402) and to B. Christoffer Lagerholm (present address Memphys, Physics Department, University of Southern Denmark, Campusvej 55, 5230 Odense M, Denmark) for assistance in infrared imaging. We are grateful to Newell R. Washburn (Department of Chemistry, Carnegie Mellon University) for use of the FCS apparatus. We also thank Lisa McGaw (Department of Biological Sciences, Carnegie Mellon University) for assistance with animal handling. This work was supported by NIH grant no. R01 EB 000364. The work at Quantum Dot Corporation was partly funded by NIST-ATP 70NANB0H3000.

A New Optical and Nuclear Dual-Labeled Imaging Agent Targeting Interleukin 11 Receptor Alpha-Chain

Wei Wang,* Shi Ke, Sunkuk Kwon, Sasidhar Yallampalli, Arlin G. Cameron, Kristen E. Adams, Michel E. Mawad, and Eva M. Sevick-Muraca

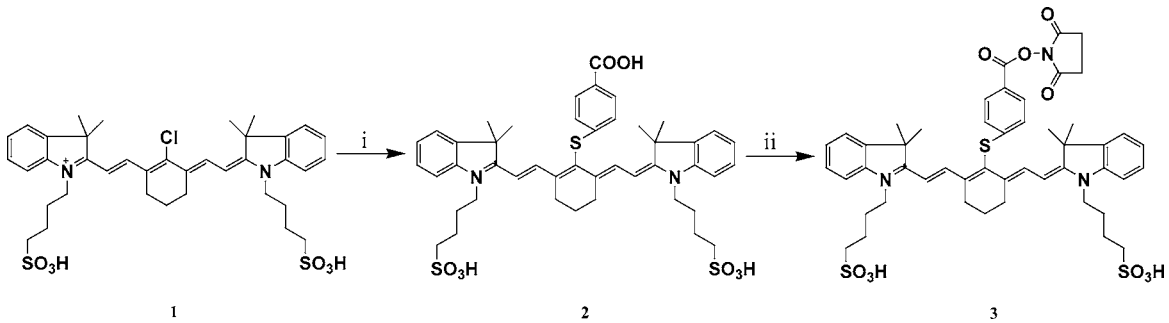
Received August 30, 2006; Revised Manuscript Received January 5, 2007

Optical imaging has great potential for studying molecular recognitions both *in vivo* and *in vitro*, yet nuclear imaging is the most effective clinical molecular imaging modality. The combination of optical and nuclear imaging modalities may provide complementary information for improving diagnosis and management of diseases. In this study we developed an optical and nuclear dual-labeled imaging agent, ^{111}In-DTPA-Bz-NH-SA-K(IR-783-S-Ph-CO)-c(CGRRAGGSC)NH_2, called DLIA-IL11Rα. ^{111}In-DTPA-Bz-NH-SA is the radiotracer moiety; a near-infrared dye IR-783-S-Ph-COOH serves as the fluorescent emitter; and the cyclic peptide c(CGRRAGGSC), which is known to target interleukin 11 receptor alpha-chain (IL-11Rα), delivers the desired imaging agent to its target. Experiments revealed that the cyclic peptide c(CGRRAGGSC) continued to possess the targeting capability to IL-11Rα after the conjugation of the optical and nuclear tracers. Furthermore, the presence of the metal isotope chelator did not cause quenching of fluorescence emission. The cross validation and direct comparison of optical and nuclear imaging of a tumor was achieved using a single injection, and the preliminary results show the conjugate has tumor targeting capabilities *in vivo*.

INTRODUCTION

Near-infrared (NIR) fluorescence imaging is an active and promising area for noninvasive, *in vivo* molecular imaging (*1*−*4*). It is used to probe the expression of disease-associated biomarkers in small animals and provide real-time information about molecular events. In the wavelength range of 700−900 nm, NIR light causes minimal autofluorescence and is minimally absorbed by hemoglobin (the principal absorber of visible light) as well as by water and lipids (the principal absorbers of infrared light). Furthermore, since stable fluorophores can be reactivated by propagating excitation light, as many as 10^9 photons per second per molecule can be generated from a fluorophore with a fluorescent lifetime of one nanosecond. The sensitivity of fluorescence in microscopy is well established, and the correlation between medical imaging and pathology may be offered by optical imaging (*5*, *6*).

On the other hand, nuclear imaging techniques such as positron emission tomography (PET) and single photon emission tomography (SPECT) are currently the most effective clinical molecular imaging modalities due to their intrinsically high sensitivity at deep tissue sites and capability of quantitation. However, radionuclide imaging may suffer from low photon counts requiring long scan times as well as from a finite half-life and radiation dosage preventing longitudinal imaging in patients (*7*).



Considering the importance and advantages of both nuclear and fluorescence imaging, a combination of these two techniques provides an attractive approach for enhancing the imaging accuracy and providing complementary information for improving diagnosis and management of diseases. The strategy to achieve this goal is to develop an optical and nuclear dual-labeled imaging agent. Although NIR fluorophores and radiotracers possess excellent photophysical properties, none are tumor specific. To address this problem, a targeting moiety must be introduced to specifically deliver a dual-labeled imaging agent to diseased sites. Dual-labeled targeting imaging agents, such as the one described herein, allow cross validation and direct comparison between nuclear and fluorescence optical imaging (*8*−*10*). By combining optical imaging for enhanced photon signal count without agent half-life concerns and gamma imaging for high sensitivity at deep tissue detection, dual-labeled imaging agents could allow a comprehensive picture of the imaging agent distribution and provide a rapid and efficient imaging method for basic research and clinical diagnosis.

Small peptides represent a class of potential targeting unit candidates (*11*), since they are structurally well defined, easily synthesized, and possess faster circulatory clearance when employed in imaging agents compared to larger antibodies or proteins. Interleukin-11 (IL-11) is a multifunctional cytokine involved in various pathways in blood cells, their precursors, and many other cell types both *in vitro* and *in vivo*. The effects of IL-11 are largely mediated by the IL-11 receptor alpha-chain (IL-11Rα), which is a member of the gp130-dependent receptor group that has been associated with various unique biological actions. Experimental evidence has shown that interleukin (IL-11) and its receptor (IL-11Rα) are related to breast cancer development and progression and may play a significant role in the bone metastasis of human breast cancer (*12*−*14*). IL-11 may also be a predictor of poor prognosis in human breast cancer (*15*). Consequently, targeting of IL-11Rα positive tumors could be a useful strategy for noninvasive imaging. Using phage display technique, Arap et al. (*16*, *17*) identified the cyclic nonapeptide c(CGRRAGGSC), as a mimic motif of IL-11 and showed that it bound specifically to IL-11Rα. Herein, we report the development of a new dual-labeled imaging agent, called DLIA-IL11Rα [^{111}In-DTPA-Bz-NH-SA-K(IR-783-S−Ph−CO)-c(CGRRAGGSC)NH_2] targeting IL-11Rα based upon this cyclic nonapeptide. The radioisotope ^{111}In complexes with DTPA-Bz-NH-SA to form a radiotracer and the NIR dye (IR-783-S-Ph-CO) functions as an optical signal generator. Both are conjugated via amino functional groups of lysine to the

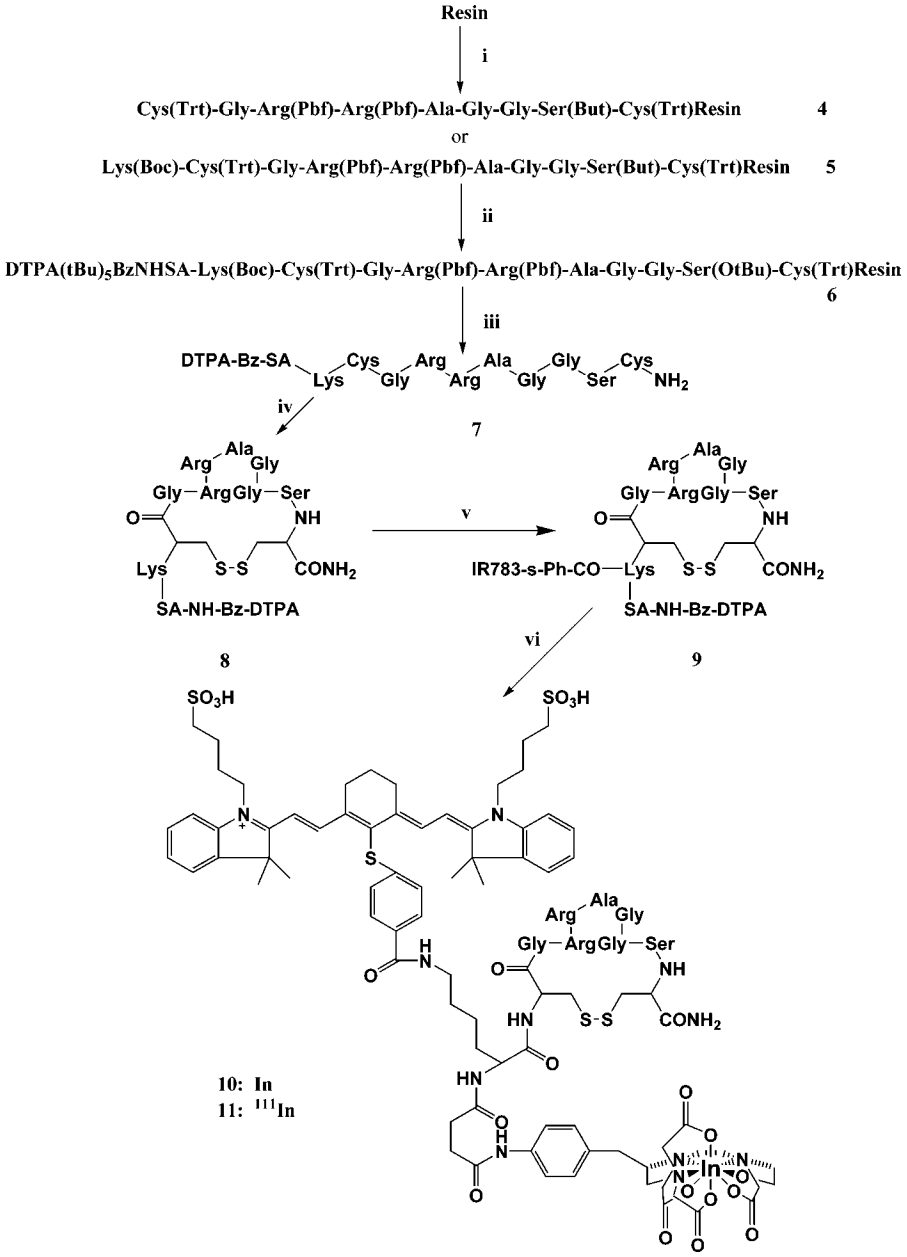
cyclic peptide K-c(CGRRAGGSC)NH_2. The use of this probe enables us to image the interaction between a targeting ligand and an IL-11Rα positive tumor in mice by both conventional nuclear imaging and fluorescence-enhanced optical imaging techniques. Herein, we present the chemistry, *in vitro* cell binding, and *in vivo* imaging of DLIA-IL11Rα.

EXPERIMENTAL PROCEDURES

Materials. All Fmoc-amino acids, benzotriazol-1-yl-oxy-tris-pyrrolidino-phosphonium hexafluorophosphate (PyBOP), *O*-benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyl-uronium-hexafluoro-phosphate (HBTU), dimethylaminopyridine (DMAP), 1-hydroxybenzotriazole (HOBt), *N*-hydroxysuccinimide (HOSu), and Fmoc rink linker were purchased from Novabiochem (San Diego, CA); PL-DMA resin was purchased from Polymer Laboratories (Amherst, MA); piperidine, *N*,*N*-diisopropylethylamine (DIPEA), ethylenediamine, triethylsilane (TES), 1,3-diisopropylcarbodiimide (DIC), IR-783 and succinic anhydride were purchased from Sigma-Aldrich Chemical (St. Louis, MO); *p*-aminobenzyl-diethylenetriamine-penta-(acetic acid-*t*-butyl ester) was purchased from Macrocyclics (Dallas, TX); trifluoroacetic acid (TFA), *N*-methylmorpholine (NMM), indium chloride, and all other solvents were purchased from VWR (San Dimas, CA); indium^{111} chloride ($^{111}InCl_3$) was purchased from Perkin-Elmer (Billerica, MA). 10% serum was purchased from Invitrogen Corporate (Carlsbad, CA). Mouse whole blood was purchased from Pel-Freez Biological (Fayetteville, AR).

Analyses. Analytical high-performance liquid chromatography (HPLC) was performed on an Agilent 1100 HPLC system equipped with a Varian reverse phase C-18 analytical column (R0086200CG) at a flow rate of 1 mL/min. Samples were eluted with H_2O/acetonitrile containing 0.1% TFA varying from three linear gradients (A: 0−40% in 30 min; B: 10−80% in 30 min; C: 30−100% in 30 min). Preparative HPLC was performed on a Varian Prostar 210 HPLC equipped with a 25 × 2.5-cm Varian reverse phase C-18 preparative column (R0080220CB). Matrix-assisted laser desorption ionization mass spectrometry (MALDI) and electrospray ionization mass spectrometry (ESI) were performed by the Protein Chemistry Core Laboratory at Baylor College of Medicine. Fluorescence properties were measured on a Spex Fluorolog III spectrophotometer from HORIBA Jobin Yvon, Inc. (Edison, NJ).



Synthesis of *p*-Succinamidobenzyl-diethylenetriamine-penta-(acetic acid-*t*-butyl ester) [DTPA(OtBu)5-Bz-NH-SA]. Synthesis of DTPA(OtBu)5-Bz-NH-SA was conducted according to previously published procedures (*18*). DTPA(OtBu)5-Bz-NH_2(1.0 mmol) was dissolved in 10 mL of DMF/DCM (1/5). Succinic anhydride (1.0 mmol) and DIPEA (0.2 mL) were added to the solution. The mixture was stirred at room temperature for 4 h. After evaporation of the solvents under vacuum, the residue was dissolved in ethyl acetate, washed with 2% $KHSO_4$ and brine, and then dried over $MgSO_4$. After filtration, ethyl acetate was removed to yield a white powder. ESI for $C_{45}H_{74}N_4O_{13}$ calcd. $[M + H]^+$ 879. 53; found 879. 4; HPLC (gradient C) retention time 23.98 min.

Synthesis of 2-(2-(2-(4-Carboxyphenylthio)-3-(2-(3,3-dimethyl-1-(4-sulfobutyl)indolin-2-ylidene)ethylidene)cyclohex-1-enyl)vinyl)-3,3-dimethyl-1-(4-sulfobutyl)-3H-indolium [IR-783-S-Ph-COOH] (*2*) (Scheme 1). IR-783 (**1**) (250 mg, 0.33 mmol) and 4-mercaptobenzoic acid (156 mg, 1 mmol) were dissolved in 5 mL of DMF and stirred overnight at room temperature. After the solvent was removed, the residue was dissolved in MeOH and then precipitated in ether. The solid was filtered out and further purified with flash chromatography with ethyl acetate and methanol. MALDI for $C_{45}H_{53}N_2O_8S_3^+$ calcd. $[M]^+$ 845. 30; found 845. 30; HPLC (gradient B) retention time 18.56 min; Ex/Em 794/810 in MeOH.

Synthesis of 2-(2-(3-(2-(3,3-dimethyl-1-(4-sulfobutyl)indolin-2-ylidene)ethylidene)-2-(4-((2,5-dioxopyrrolidin-1-yloxy)-carbonyl)-phenylthio)cyclohex-1-enyl)vinyl)-3,3-dimethyl-1-(4-sulfobutyl)-3H-indolium [IR-783-S-Ph-CO-NHS] (*3*) (Scheme 1). IR-783-S-Ph-COOH (**2**) (200 mg, 0.24 mmol), DIC (56 μL, 0.36 mmol), HOSu (42 mg, 0.36 mmol), and DMAP (15 mg, 0.12 mmol) were dissolved in 5 mL of DMF and stirred overnight at room temperature. After the solvent was removed, the residue was dissolved in MeOH and then precipitated in ether. The solid was filtered out and purified with reverse phase HPLC. MALDI for $C_{49}H_{56}N_3O_{10}S_3^+$ calcd. $[M]^+$ 942. 31; found 942. 30; HPLC (gradient B) retention time 20.27 min.

Synthesis of cyclic peptide c(Cys-Gly-Arg-Arg-Ala-Gly-Gly-Ser-Cys)NH_2 (*4*) and its DTPA chelating conjugate DTPA-Bz-NH-SA-Lys-c(Cys-Gly-Arg-Arg-Ala-Gly-Gly-Ser-Cys)NH_2 (*8*) (Scheme 2). First, Fmoc-rink linker was attached to PL-DMA resin, which had been treated with ethylenediamine overnight. The linear peptide Cys-Gly-Arg-Arg-Ala-Gly-Gly-Ser-Cys-NH_2 and its conjugate DTPA-Bz-SA-Lys-Cys-Gly-Arg-Arg-Ala-Gly-Gly-Ser-Cys-NH_2 were synthesized using Symphony synthesizer from Protein Technologies, Inc. (Tucson, AZ) following Fmoc standard procedure. The protecting groups of amino acid side chains were t-butyloxycarbonyl (Boc) for Lys, trityl (Trt) for Cys, 2,2,4,6,7-pentamethyl-dihydrobenzofurane-5-sulfonyl (Pbf) for Arg, t-butyl (tBu) for Ser and t-butoxy (tBuO) for DTPA. Each amino acid was sequentially coupled on solid support using HBTU, HOBt, and NMM as coupling reagents. The conjugation of DTPA$(OtBu)_5$-Bz-NH-SA to the linear peptide Lys(Boc)-Cys(Trt)-Gly-Arg(Pbf)-Arg(Pbf)-Ala-Gly-Gly-Ser(But)-Cys(Trt)-resin was achieved in the presence of PyBOP, HOBt, and DIPEA. Cyclization between Cys−Cys for peptide **4** and **8** was achieved in NH_4OH solution (pH 9. 5) after linear peptides were cleaved from the support using TFA/H_2O/TES (94/2/4). The products were purified by reverse phase HPLC. MALDI for c(CGRRAGGSC)NH_2 (*4*) ($C_{30}H_{54}N_{16}O_{10}S_2$) calcd. $[M + H]^+$ 863. 37; found 863. 37; HPLC (gradient A) retention time 8.71 min. MALDI for DTPA-Bz-NH-SA-K-

c(CGRRAGGSC)NH$_2$ (*8*) ($C_{61}H_{98}N_{22}O_{23}S_2$) calcd [M + H]$^+$ 1571. 66; found 1571. 70; HPLC (gradient A) retention time 13.24 min.

Synthesis of DTPA-Bz-NH-SA-K(IR783-S-Ph-CO)-c(CGRRAGGSC)NH$_2$ (*9*) (Scheme 2). Conjugation of IR783-S-Ph-CONHS (**3**) to ω-NH$_2$ of Lys in DTPA-Bz-NH-SA-K-c(CGRRAGGSC)NH$_2$ was carried out in DIPEA/DMF(1/9) solution overnight. After the solvent was removed, the residue was washed with ether several times. The product was purified by reversed phase HPLC. MALDI for $C_{106}H_{149}N_{24}O_{30}S_5$ calcd. [M]$^+$ 2397. 95; found 2397. 94; HPLC (gradient B) retention time 18.19 min; Ex/Em 794/810 in MeOH.

Cold and Radioactive Indium Labeling of DTPA-Bz-NH-SA-Lys(IR783-S-Ph-CO)-c(CGRRAGGSC)NH$_2$ to Yield DLIA-IL11Rα (*10, 11*) (Scheme 2). DTPA-Bz-NH-SA-K(IR-783-S-Ph-CO)-c(CGRRAGGSC)NH$_2$ (9) in 0.1 N sodium acetate solution was mixed with an aqueous solution of cold $InCl_3$ or radioactive $^{111}InCl_3$ for 30 min. The purity of the labeled compound was analyzed using an HPLC system equipped with a radiometric detector from Bioscan (Washington, DC). MALDI for $C_{106}H_{146}InN_{24}O_{30}S_5$ calcd. [M]$^+$ 2509. 83; found 2509.9; HPLC (gradient B) retention time 17.39 min; Ex/Em 794/810 in MeOH.

Peptide Stability Test in Serum. DTPA-Bz-NH-SA-K-c(CGRRAGGSC)NH$_2$ (**8**) (1 mg) was incubated in 1 mL of culture medium containing 10% of fetal serum albumin at 37 °C. At various time intervals, 50 μL aliquot was injected into an HPLC system. The samples were eluted with water and acetonitrile containing 0.1% TFA varying from 0 to 40% over 30 min and detected with a diode array UV/vis detector at 230 and 275 nm.

Peptide Stability Test in Mouse Whole Blood. DTPA-Bz-NH-SA-K-c(CGRRAGGSC)-NH$_2$ (**8**) (1 mg) was incubated in 200 μL of mouse whole blood at 37 °C. At various time intervals, 20 μL of the mixture was added into 100 μL of PBS and then centrifuged. 50 μL of the supernatant was injected

into an HPLC system. The samples were eluted with water and acetonitrile containing 0.1% TFA varying from 0 to 40% over 30 min and detected with a diode array UV/vis detector at 230 and 275 nm.

Cell Binding Study of Imaging Agent. Human breast cancer that expresses IL-11Rα (MDA-MB-231) was purchased from American Type Culture Collection (Manassas, VA). A highly metastatic subline MDA-MB-231 (1833) was a kindly donated by Dr. Massaque at the Memorial Sloan-Kettering Cancer Center. The cells were cultured in MDEM DMEM/F12 (Invitrogen, Carlsbad, CA) with 10% FBS (Hyclone, Logan, UT) in a humidified incubator maintained at 37 °C with 5% CO_2. In vitro cell binding was performed on both cell lines. A solution (1 μM) of dual-labeled imaging agent was incubated with cells for 10 min at 37 °C. The cells were fixed and stained with 1 μM of Sytox Green in 95% ethanol for 15 min at 4 °C. Images were recorded by a Leica fluorescent microscope (Model: DM6000 B, Leica Microsystems GmbH, Ernst-Leitz-Strasse, Germany) equipped with 100 W xenon lamp and fluorescent filters.

Autocrine Stimulation. MDA-MB-231 cells that express IL-11 Rα were first co-incubated and stimulated by 0.5 mg/mL of IL-11 (Neumega, Oprelvekin, Wyeth Pharmaceuticals Inc. Philadelphia, PA) for 18 h. DLIA-IL11Rα was then added to achieve a final concentration of 1 μM for 10 min at 37 C. Cells were washed 3 times with PBS. The autocrine stimulatory effect of IL-11 was determined by measuring the intensity of bound DLIA-IL11Rα normalized by cell number for both stimulated and untreated cells. Statistical analysis was performed using SAS software version 9.0 (SAS Institute Inc., Cary, NC) for Microsoft Windows. The difference between normalized intensities of stimulated and unstimulated cells was compared using the one-way ANOVA. The significant value (p) was set at 0.5.

***In Vivo* NIR Optical and Nuclear Imaging Studies of Imaging Agent.** Human breast cancer xenografts were injected s.c. with 1×10^6 MDA-MB-231 cells on the hindlimb. Tumor growth occurred over 3−4 weeks reaching 7−8 mm in diameter. At this size, 2 nmol of DLIA-IL11Rα was injected intravenously into the tail vein of the mice. Mice were imaged on a Siemens Preclinical microCAT II for SPECT/CT. The integration time for SPECT was 20 min and CT required 8 min. *In vivo* fluorescence-based optical imaging was accomplished by illuminating the animal with light from a laser diode (80 mW at 785 nm light) expanded to an approximately 8-cm-diameter circular area. The re-emitted fluorescent light was collected by an electron-multiplying charge-coupled device (EMCCD) camera (model PhotoMAX:512B, Princeton Instruments, Trenton, NJ). The resolution of the EMCCD camera was 16×16 μm in a 512×512 pixels square frame-transfer format. Filter sets used in this study included a bandpass filter (830 nm center wavelength) to transmit fluorescent emission and holographic filter (785 nm center wavelength) to reject reflected excitation light. Image acquisition was accomplished using V++ software from Digital Optics (Auckland, New Zealand). Data processing and analysis were accomplished using Matlab software from The MathWorks, Inc. (Natick, MA). The integration time for each image was 800 ms. The whole body images were taken at 24 h after the injection and 48 h after the injection, mice were sacrificed and images of the excised organs were taken. Three-dimension SPECT/CT and images/movies were reconstructed by Amira (version 3.1, Konrad-Zuse-Zentrum fur Informationstechnik Berlin, Germany).

RESULTS AND DISCUSSION

Chemistry. In this study, the cyclic nonapeptide c(CGRRAGGSC)NH_2 was selected as targeting molecule. To develop an optical and nuclear dual-labeled targeting imaging agent based upon this targeting molecule, it is necessary to introduce a fluorophore, which serves as an optical imaging component, and to select a suitable bifunctional chelator, which is able to be coupled to a targeting compound and capable of forming a stable complex with a radiometal ion.

Cyanine dyes are most commonly used as NIR fluorophores. IR-783-S-Ph-CONHS (**3**) was selected as NIR fluorescence reaction agent for this study, due to its increased chemical stability over IR-783-S-(CH2)2-CONHS (*19*). Compound **3** was prepared from a commercially available cyanine dye IR-783 (**1**). First, the chlorine on IR-783 was replaced with S-Ph-COOH (Scheme 1) using a similar method as Strekowski et al. described (*20*) to form compound **2**. Next, the reaction of compound **2** with HOSu yielded the desired compound **3**, which can be directly applied for conjugation with an amino functional group.

Diethylenetriaminepenta-acetic acid (DTPA) is one of the well-known radiometal chelating agents for such radionuclides as ^{111}In and ^{90}Y. The DTPA derivative DTPA$(OtBu)_5$-Bz-NH-SA (*18*) was selected as a chelating compound. The advantage of this reagent is that it can be easily conjugated to peptides on a solid support and still possesses five carboxylates for radiometal chelation.

The reaction scheme and the structure of dual-labeled targeting imaging agent [In-DTPA-Bz-NH-SA-K(IR-783-S-Ph-CO)-c(CGRRAGGSC)NH_2] are summarized in Scheme 2. The synthesis procedure can be divided into six major parts. The first three parts were carried out on solid support. The latter three parts were performed in solution phase. The linear protective peptides on resin, Cys(Trt)-Gly-Arg(Pbf)-Arg(Pbf)-Ala-Gly-Gly-Ser(But)-Cys(Trt)-resin (**4**) and Lys(Boc)-Cys(Trt)-Gly-Arg(Pbf)-Arg(Pbf)-Ala-Gly-Gly-Ser(But)-Cys(Trt)-resin (**5**), were synthesized using Fmoc solid-phase chemistry (part 1). DTPA$(OtBu)_5$-Bz-NH-SA was coupled to the linear peptide Lys(Boc)-Cys(Trt)-Gly-Arg(Pbf)-Arg(Pbf)-Ala-Gly-Gly-Ser-(But)-Cys(Trt)-resin (**6**) through α-amino functional group of lysine (part 2). After deprotection and cleavage of the compounds from the solid support (part 3), the side chain−side chain cyclization between cysteine and cysteine of peptide CGRRAGGSCNH_2 or its conjugate DTPA-Bz-NH-SA-K-CGRRAGGSCNH_2 (**8**) was achieved through disulfide bridge formation (part 4).

An important consideration in selecting cyclic peptide c(CGRRAGGSC)NH_2 as the targeting agent to IL-11Rα was the peptide stability, since it may be degraded by enzymes in vivo. Consequently, the stability test of DTPA-Bz-SA-K-c(CGRRAGGSC)NH_2 (**8**) was carried out in two different media: 10% fetal serum albumin serum and mouse whole blood. The peak areas from HPLC analysis of the conjugate (**8**) were quantified, and the stability was expressed as a percentage of individual peak area at different incubation times divided by the peak area at the initial incubation time. The results indicated that compound **8** was 20% degraded when incubated in a serum-containing culture medium at 37 °C over 24 h, while 50% degradation was observed when incubated in mouse whole blood. Although modification of the peptide can be carried out later to improve the stability, the data demonstrated that the stability of the peptide chelator complex is sufficient for this study, since imaging was to be accomplished within 24 h.

After validating the stability of DTPA-Bz-SA-K-c(CGRRAGGSC)NH_2, conjugation of dye (IR-783-S-Ph-CO-NHS) to compound **8** through ε-amino functional group of lysine was performed in a basic solution (part 5). In the last step (part 6), DTPA-Bz-SA-K(IRdye783-S-Ph-CO)-c(CGRRAGGSC)NH_2 (**9**) was separately labeled with cold indium or with radioactive isotope. The non-radioactive compound **10** was selected for

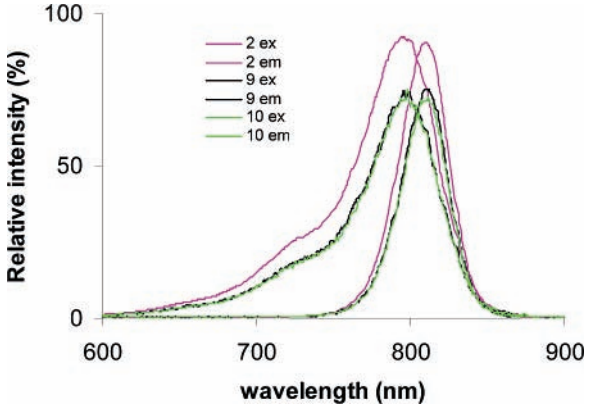

Figure 1. Excitation and emission fluorescence spectra of compound **2** (IR-783-S−Ph-COOH), compound **9** [DTPA-Bz-SA-K(IR-783-S-Ph-CO)-c(CGRRAGGGSC)NH_2] and compound **10** [In-DTPA-Bz-SA-K(IR-783-S-Ph-CO)-c(CGRRAGGSC)NH_2] at 1 μM in MeOH at wavelength Ex/Em 795/810 nm.

examination of fluorescence properties and cell studies, while the radiolabeled conjugate **11** was used for the *in vivo* imaging study.

The fluorescence properties of compounds IR783-S-Ph-COOH (**2**), DTPA-Bz-NH-SA-Lys(IR783-S-Ph-CO)-c(CGRRAGGSC)NH_2 (**9**) and In-DTPA-Bz-NH-SA-Lys(IR783-S-Ph-CO)-c(CGRRAGGSC)NH_2 (**10**) were evaluated. Upon comparing compounds **2** and **9**, we found that the excitation and emission spectra of conjugate **9** remained unchanged (Figure 1). However, after the conjugation of dye to DTPA-cyclopeptide the signal intensity was reduced to 84%. Nevertheless, the spectra in Figure 1 demonstrate that the metal chelation of compound **9** to form compound **10** did not impact fluorescence spectra.

Cell Binding Study of Imaging Agent. To evaluate DLIA-IL11Rα as a potential targeting molecule for *in vivo* imaging, the binding ability to IL-11 receptor was examined *in vitro*. Figure 2 illustrates cell binding of the imaging agent **10** to IL-11Rα positive MDA MB-231 and its subline 1833. The cell nuclei were stained with Sytox green, while the red halo arose from the imaging agent associated with the membrane expression of IL-11Rα. Furthermore, cell stimulation study was carried out using the MDA-MB-231 cell line (*21*). The results show that conjugate **10** binding to stimulated cells was statistically significant higher than binding to nonstimulated cells. These preliminary data reveal that the targeting ability of cyclic peptide c(CGRRAGGSC)NH_2 to IL-11Rα was retained after introducing the nuclear and optical tracers.

***In Vivo* NIR Optical and Nuclear Imaging.** Further demonstration of the targeting feasibility of DLIA-IL11Rα as an imaging agent was performed *in vivo*. Figure 3 demonstrates white light, SPECT/CT, and NIR optical images of the same mouse bearing subcutaneous MDA-MB-231 tumor 24 h after administration of the imaging agent. The white light shows the location of the tumor in the hind leg of the animal. The SPECT/CT and NIR optical imaging illustrate the uptake of the imaging agent in the region of the tumor. In addition, each of the images display uptake of the agent in the abdominal area, presumably within the kidneys as indicated from the NIR planar imaging. It is important to note that the NIR imaging is not tomographic and therefore is directly comparable to the gamma scintigraphy. SPECT/CT on the other hand provides the three-dimensional image of the location of the imaging agent based upon the indium signature. The tomographic SPECT/CT has resolution on the order of 2 mm and consequently may not provide the same information as the NIR images. Furthermore, since light is attenuated in blood born tissues such as the liver, the NIR

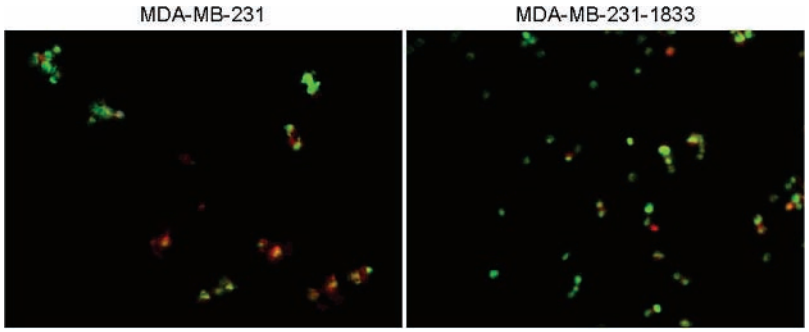

Figure 2. Cell binding study: Two human breast cancer cell lines (MDA-MB-231 and MDA-MB-231-1833) that express IL-11Rα receptor were incubated with 1 μM of DLIA-IL11Rα. Green (Sytox green) represents cell nuclei, and red (NIR imaging agent) represents conjugate bound to the cells.

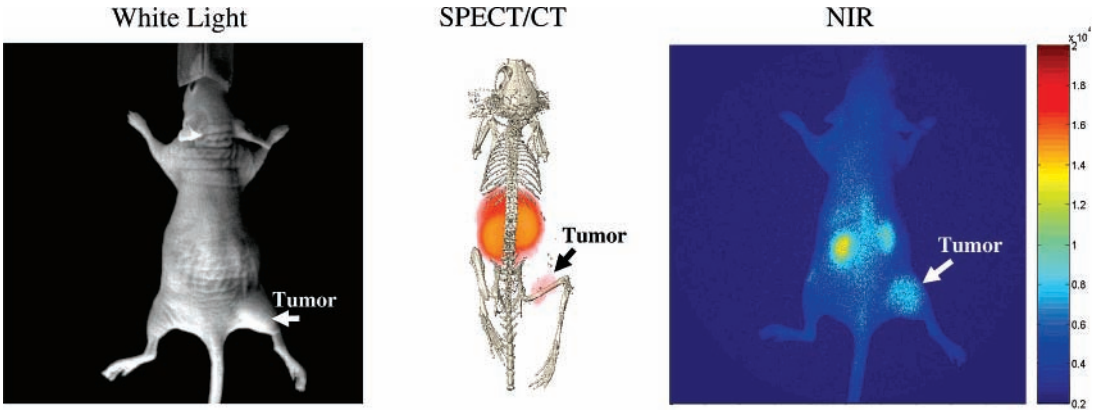

Figure 3. SPECT/CT and NIR imaging. Mice bearing human breast cancer xenograft (MDA-MB-231) were injected with 2 nmol of the conjugate DLIA-IL-11Rα i.v. Representative images show results 24 h after injection. Tumors (arrows) show more conjugate uptake than muscle in both SPECT/CT and NIR images. High signal intensity in kidneys showed the excretion route of this agent even at very low injection dose.

imaging may not provide the same depth specificity of the indium label. When tissues are excised and counted for gamma emission, we found that the tumor to muscle, liver to muscle, and kidney to muscle ratios were 2.12, 2.62, 10.42. To date, we have not conducted biodistribution or pharmacological studies to determine the optimal dose or timing for imaging. The high kidney signal counts may reflect excretion routes and therefore suggest that a lower dose/longer post administration imaging time is warranted. While these *in vitro* scintigraphy counts provide an absolute measure of the deposition of the imaging agent within the body, there is no validated method for quantifying the uptake on the basis of NIR fluorescence. Development of quantitative methods for NIR imaging and tomography depend upon the development of dual-labeled imaging agents to further improve optical imaging techniques.

CONCLUSION

We successfully developed and deployed a new optical and nuclear dual-labeled targeting imaging agent DLIA-IL11Rα [In-DTPA-Bz-NH-SA-K(IR-783-S-Ph-CO)c(CGRRAGGSC)-NH_2] against IL-11Rα expressed in cancer as well as in other processes associated with disease. Our data indicate that the cyclic peptide c(CGRRAGGSC)NH_2 is a feasible targeting agent of IL-11Rα for diagnostic cancer imaging. As shown in our in vitro cell study, introduction of two imaging tracers to cyclic peptide c(CGRRAGGSC)NH_2 did not alter the targeting capability of the peptide to IL-11Rα. Furthermore, indium isotope chelation did not cause any quenching on fluorescence emission of imaging agent **10** relative to the nonchelated compound **9**. Even through peptides usually have lower binding affinity than antibodies, we found that injection of 2 nmol of DLIA-IL11Rα was sufficient to observe specific binding in tumor region. Furthermore, we found that the preliminary *in vivo* imaging by optical and radionuclear methods were consistent. Before DLIA-IL11Rα can be validated as a potential imaging agent, the optimal dose and biodistribution remain to be determined.

Novel biocompatible macromolecular vectors were developed that not only enable transport of bioactive cargo across the cell membrane but also control the delivery into defined intracellular compartments. This work describes the synthesis and design of two non-peptidic fluorescently labeled Newkome-type dendrimers, differentiated over a varied alkyl spacer with guanidine end moieties. The internalization of the fluorescein-labeled molecular transporter into mammalian cells showed strong subcellular localizations, evident with both live cells and fixed cells costained with DAPI, a nuclear stain. We observed that the subcellular distribution of these vectors varied significantly, as one of the vectors concentrates in the nucleus (**FD-1**) while the other (**FD-2**) concentrates in the cytosol. All experiments performed with NIH-3T3 fibroblasts and human microvascular endothelial cells (HMEC) showed similar results. The differential localization patterns of the two molecular transporters can be controlled through the variation of alkyl spacer length at the terminal generation of the dendrimer. Intracellular delivery of bioactive entities into specific subcellular locations, utilizing this practical approach, might overcome limitations in drug delivery and pioneer future technologies in drug transport.

INTRODUCTION

The development of novel approaches that facilitate cellular uptake of a variety of physiologically and therapeutically active agents relies on the elucidation of new molecular transporter/translocator molecules and methodologies. In the past several years, strategies to overcome the limiting uptake of the plasma membrane have included cell-permeable peptide vectors (*1*−*4*), such as Tat peptide and other various arginine-rich oligopeptides (*5*−*9*). HIV−Tat peptide (R_{49}KKRRQRRR$_{57}$) and its arginine-rich derivatives have been given much attention, primarily due to their high efficiency, short sequence, and capabilities of transporting various types of molecular structures, such as small molecular weight compounds, oligonucleotides, magnetic beads, plasmid DNA, and even a full 129 kDa protein, across the membranes of most cell types (*10*−*16*). In particular, uptake assays of oligoarginines identified nona-arginines as being superior over traditional Tat peptides. The subcellular localization profile of synthetic oligoarginine peptides appeared to be in both the cytoplasm and nucleus, which is similar to that of HIV−Tat (49−57) (*7*, *13*, *17*−*19*). However, our goal is to develop novel therapeutic strategies to deliver drugs directly to intracellular sites such as the nucleus or the cytosol, in order to limit unwanted intracellular probe metabolism and transport and reduce nonspecific effects, toxicity and dosage levels. Alternative delivery tools for drug delivery, gene therapy, and vaccine delivery are in high demand to overcome current limitations.

One attempt to develop transport vectors has been the investigation of selected lysine−arginine-rich human-derived peptide vectors (*20*). It was found that these peptides, once inside the cell, enable accumulation of therapeutic molecules in the cytoplasm or nucleus, depending on the specific vector used. However, these peptide or peptoid-based molecular transporters are limited again by high cost, scalability, solubility, and stability.

We sought to exploit non-peptidic branched architectures based on the reported observation that branched-chain arginine peptides resulted in different patterns of cellular localization (*21*). Dendritic structures have been recognized to be ideal building blocks for biomedical applications because of their monodispersity, high loading capacity, large-scale production, and bioconjugation capability (*22*−*24*). Despite numerous reports about the importance of guanidinium groups in the peptidic backbone of oligoarginines, relatively few attempts have been made using guanidine groups in branched dendritic scaffolds (*25*, *26*). For example, a recent paper by Wender et al. (*26*) employs the use of triamine-based diamino acids to form a series of octa-arginine dendrimers that show differences in uptake efficiency related to the structural flexibility of the dendritic architecture. In contrast to this study, we directed our efforts to develop dendritic structures which mimic features of branched polyarginines but provide means to target and control intracellular delivery. We investigated intracellular distributions and the time course of uptake in vivo with two different mammalian cell lines using confocal microscopy.

We proposed that for a molecular transporter to possess the aforementioned features the constitution of the dendritic backbone had to be one of the most compact, highly branched, and biocompatible structures possible. Through mimicking a regular peptidic backbone, by the implementation of highly symmetric macromolecular peripheries, the critical presentation of the guanidino groups to the biological systems are controlled by the length of the alkyl spacer. We focused on these parameters for two main reasons. One, the length and flexibility of the spacer in dendritic transporter have thus far been connected with enhanced and rapid cellular uptake, and two, factors for

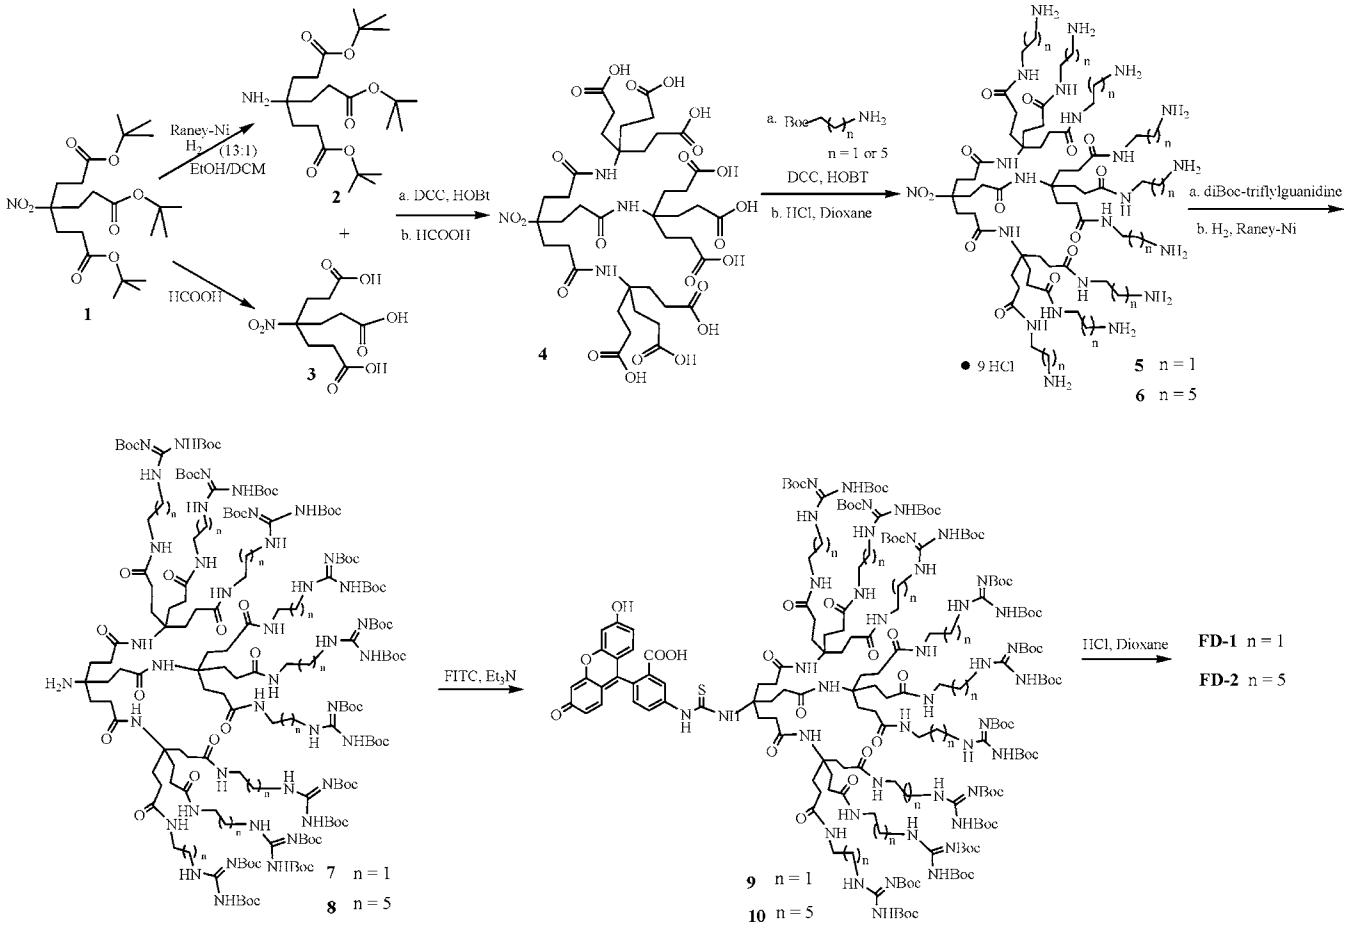
Scheme 1. Structures of FD-1 and FD-2

regulating intracellular specification have been unclear. Therefore, we sought to design and synthesize macromolecules with a differentiated flexible spacer to the guanidine functionality, but with a high-density arrangement on a symmetric and compact dendritic macromolecule.

In this study, we utilized the classic Newkome-type dendrimer as the structural building block, a compact yet highly branched structure in which the necessary nine end functionalities can be achieved in just one generation of dendritic growth (*11*, *27*). We report the design and synthesis of Newkome-type probe transporters, functionalized with guanidine end moieties and differentiated over a varied alkyl spacer to the scaffold, with a fluorophore conjugated to the focal point as the sample cargo molecule. We demonstrate the cell-penetrating capabilities of two new fluorescent macromolecular conjugates, FITC−dendrimer 1 (**FD-1**) and FITC−dendrimer 2 (**FD-2**), shown in Scheme 1. Interestingly, while these molecules feature similar, high levels of cellular uptake, they differ considerably in their subcellular localization (cytoplasm vs nucleus). There is a high potential for these molecular transporter molecules in both basic biomedical research and the clinical setting, as they could be used for the highly targeted delivery of a variety of bioactive molecules, thereby avoiding some of the common caveats of other drug delivery approaches, such as toxicity and limited cargo delivery (*16*).

EXPERIMENTAL PROCEDURES



Materials and Methods. All reagents and solvents were purchased from commercial sources and were used as received, unless otherwise stated. Spectra/Por Biotech cellulose ester and regenerated cellulose dialysis membranes were purchased from Spectrum Laboratories, Inc. Di-*tert*-butyl-4-[2-(*tert*-butoxycarbonyl)ethyl]-4-nitroheptanedicarboxylate **1** and 4-nitro-4-[2-(carboxyethyl)]heptanediacid **3** (Scheme 2) were prepared using a previously described method (*27*). Analytical TLC was carried out on Merck 250 μM silica gel 60 F_{254} plates, and spots were located by UV light or treatment with iodine. Column chromatography was conducted by silica gel (60−200 mesh) from Fisher Scientific. All NMR spectra were measured on a 400 MHz Bruker FT−NMR spectrometer. MALDI-MS were carried out on a Perspective Biosystems Voyager-DE STR (Framingham, MA) equipped with delayed extraction technology operating in linear mode (MALDI-MS data of known compounds not shown). 2′,4′,6′-Trihydroxyacetophenone (THAP) or 2,5-dihydroxybenzoic acid (DHBA) was used as the matrix with a matrix/analyte ratio of 1000:1. Reverse-phase high-performance liquid chromatography (RP-HPLC) was carried out with a Varian Prostar 210/215 HPLC using either an analytical column (Vydak, C18, 150 × 4.6 mm) or a preparative column (Alltec Alltima, C18, 250 × 22 mm). The products were eluted using a solvent gradient (solvent A = 0.05% TFA/H_2O; solvent B = 0.05% TFA/CH_3CN).

Synthesis of Di-*tert*-butyl-4-[2-(*tert*-butoxycarbonyl)ethyl]-4-aminoheptanedicarboxylate, "Behera's Amine" 2 (*27*). A solution of nitrotriester **1** (6.00 g, 0.0135 mol) in ethanol/dichloromethane (13:1, 140 mL) in a Parr hydrogenation bottle with 4 g of Raney-Nickel was stirred at 60 psi for 24 h at room temperature. The suspension was carefully filtered through Celite, and the removal of the solvent under reduced pressure gave the crude product. The residue was dissolved in dichloromethane (120 mL), and the resulting organic solution was washed sequentially with saturated $NaHCO_3$ (120 mL) and water (120 mL) and dried over anhydrous Na_2SO_4. The solvent was evaporated under reduced pressure to yield aminotriester **2** (5.2 g, 93%). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.44 (s, CH_3, 27H), 1.95 (t, CH_2, 6H), 2.43 (t, CH_2, 6H). ^{13}C NMR (400 MHz, $CDCl_3$): δ = 27.98 (*C*H_3), 29.46 (*C*H_2CO), 31.47 (C*C*H_2), 56.99 (*C*NH_2), 80.96 (*C*CH_3), 172.30 (*C*O_2).

Synthesis of 9 Cascade:nitromethane [3]:(2-aza-3-oxopenylidyne):propionic acid 4 (*27*). To a solution of nitrotriacid **3** (0.65 g, 2.35 mmol) in dry THF (50 mL), 1-hydrobenzotriazole (HOBt) (0.96 g, 7.10 mmol), DCC (1.46 g, 7.10 mmol), and aminotriester **2** (3.54 g, 8.5 mmol) were added sequentially. The solution was stirred at room temperature for 40 h, then filtered and concentrated under reduced pressure. The crude product was purified by flash column chromatography, eluting with hexane/ethyl acetate (3:2) to yield the desired denron (3.00 g, 86%). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.44 (m, CH_3, 81H), 1.95 (m, CH_2, 18H), 2.21 (m, CH_2, 30H), 6.20 (s, N*H*, 3H). ^{13}C NMR (400 MHz, $CDCl_3$): δ = 28.04, 29.74, 29.85, 31.28, 57.56, 80.69, 92.47, 170.46, 172.76. The dendron (1.47 g, 1 mmol) was stirred in 15 mL of formic acid overnight at room temperature. After the solvent was evaporated under reduced pressure, toluene was added and concentrated in vacuo to remove any residue of formic acid to give a white nona-acid **4** (0.95 g, 100%). ^{1}H NMR (400 MHz, DMSO): δ = 1.81 (m, CH_2, 18H), 2.11 (m, CH_2, 30H), 7.29 (s, N*H*, 3H), 12.10 (br, COO*H*). ^{13}C NMR (400 MHz, DMSO): δ = 28.03, 29.03, 30.08, 56.41, 93.31, 170.43, 174.42.

Synthesis of 9 Cascade:nitromethane [3]:(2-aza-3-oxopenylidyne):[propionic acid-(2-aminoethyl)amide] HCl Salt 5. To a solution of nona-acid **4** (2.12 g, 0.0022 mol) in DMF (30 mL), HOBt (2.68 g, 0.0198 mol) and DCC (4.09 g, 0.0198 mol) were added, and the solution was cooled to 0 °C. *N*-Boc-ethylenediamine (3.49 g, 0.0218 mol) in DMF (5 mL) was added dropwise, and the mixture was stirred for 48 h at room temperature, filtered, and concentrated under reduced pressure. The residue was dissolved in dichloromethane (100 mL), and the resulting organic solution was washed sequentially with 1 N HCl (100 mL), saturated $NaHCO_3$ (100 mL), and water (100 mL) and dried over anhydrous Na_2SO_4. The solvent was evaporated under reduced pressure, and the crude residue was purified by flash column chromatography eluting with 2% methanol in dichloromethane and gradually increasing to 10% methanol in dichloromethane to yield a white solid (2.5 g, 51%). ^{1}H NMR (400 MHz, CD_3OD): δ = 1.44 (m, CH_3, 81H), 1.80−2.10 (m, CH_2, 48H), 3.0−3.2 (m, CH_2, 36H), 6.20 (m, N*H*, 3H), 6.46 (m, N*H*, 8H), 7.71 (m, N*H*, 8H). ^{13}C NMR (400 MHz, CD_3OD): δ = 28.40, 31.24, 31.44, 31.80, 32.09, 40.66, 40.97, 59.14, 80.13, 94.42, 158.48, 173.48, 175.91. MALDI MS: calculated for $C_{103}H_{187}N_{22}O_{32}$ (M + Na^+), 2268.9; found, 2270.5. The resulting solid was dissolved in 1,4-dioxane (40 mL), the solution was cooled to 0 °C, and 4 M HCl in dioxane (40 mL) was added and stirred for 1 h at room temperature. Removal of the solvent under reduced pressure gave **5** as a white

Scheme 2. Synthetic Scheme for FITC−Dendrimer Conjugates

solid (1.86 g, 100%). ^{1}H NMR (400 MHz, D_2O/CD_3OD): δ = 1.70−2.15 (m, CH_2, 48H), 3.30 (m, CH_2, 18H), 3.36 (m, CH_2, 18H). ^{13}C NMR (400 MHz, D_2O/CD_3OD): δ = 27.61, 27.98, 28.86, 35.11, 37.41, 56.29, 92.01, 171.84, 174.98. MALDI MS: calculated for $C_{58}H_{124}Cl_9N_{22}O_{14}$ ($M + H^+$), 1673.9; found, 1674.8.

Synthesis of 9 Cascade:nitromethane [3]:(2-aza-3-oxopenylidyne):[propionic acid-(6-aminohexyl)amide] HCl Salt 6. To a solution of nona-acid **4** (1.2 g, 0.0012 mol) in DMF (20 mL), HOBt (1.514 g, 0.0112 mol) and DCC (2.311 g, 0.0112 mol) were added and the solution cooled to 0 °C. *N*-Boc-1,6-diaminohexane (2.66 g, 0.0123 mol) in DMF (5 mL) was added dropwise, and the mixture was stirred for 48 h at room temperature, filtered, and concentrated under reduced pressure to give the crude product. The residue was dissolved in dichloromethane (80 mL), and the solution was washed with 1 N HCl (80 mL), saturated $NaHCO_3$ (80 mL), and water (80 mL) and dried over anhydrous Na_2SO_4. The solution was concentrated under reduced pressure, and the crude product was purified by flash column chromatography eluting with 2% methanol in dichloromethane and gradually increasing to 10% methanol in dichloromethane to yield a white solid (1.68 g, 49%). ^{1}H NMR (400 MHz, CD_3OD): δ = 1.2−1.6 (m, CH_3, CH_2, 153H), 1.80−2.10 (m, CH_2, 48H), 3.0−3.2 (m, CH_2, 36H). ^{13}C NMR (400 MHz, CD_3OD): δ = 27.54, 28.85, 30.37, 30.90, 31.28, 31.60, 32.14, 40.58, 41.24, 59.13, 79.30, 94.30, 158.49, 173.50, 175.56. MALDI MS: calculated for $C_{139}H_{259}N_{22}O_{32}$ ($M + H^+$) 2750.7; found, 2784.03. The product was then dissolved in 1,4-dioxane (40 mL) and the solution cooled to 0 °C; 4 M HCl in dioxane (40 mL) was added and stirred for 1 h at room temperature. Removal of the solvent under reduced pressure gave **6** as a white solid (1.32 g, 100%). ^{1}H NMR (400 MHz, D_2O/CD_3OD): δ = 1.10−1.60 (m, CH_2, 72H), 1.7−2.2 (m, CH_2, 48H), 3.30 (m, CH_2, 18H), 3.36 (m, CH_2, 18H). ^{13}C NMR (400 MHz, D_2O/CD_3OD): δ = 26.89, 27.42, 28.21, 28.90, 35.03, 37.68, 56.28, 91.89, 172.3, 175.50. MALDI MS: calculated for $C_{94}H_{196}Cl_9N_{22}O_{14}$ ($M + H^+$), 2177.8; found, 2177.6.

Synthesis of 9 Cascade:nitromethane [3]:(2-aza-3-oxopenylidyne):propionic acid-(2-(1,3-bis-(*tert*-butoxycarboyl)guanidino)ethyl)amide 7. The resulting HCl salt of **5** (1.53 g, 0.92 mmol) was dissolved in methanol (80 mL), and the solution was cooled to 0 °C. Et_3N (3.5 mL) was added, followed by *N*,*N*′-diBoc-*N*′′-triflylguanidine (4.2 g, 10.73 mmol), and the mixture was stirred for 24 h at room temperature. After the solvent was evaporated under reduced pressure, the residue was dissolved in dichloromethane (100 mL), and the solution was washed with 1 N HCl (100 mL), water (100 mL), and dried over anhydrous Na_2SO_4. After removal of the solvent under reduced pressure, the crude product was purified by flash column chromatography starting with 2% methanol in dichloromethane and gradually increasing to 10% methanol in dichloromethane to yield a white solid (2.88 g, 90%). ^{1}H NMR (400 MHz, CD_3OD): δ = 1.45 (m, CH_3, 81H), 1.51 (m, CH_3, 81H), 1.90−2.25 (m, CH_2, 48H), 3.30−3.52 (m, CH_2, 36H). ^{13}C NMR (400 MHz, CD_3OD): δ = 28.37, 28.67, 31.32, 31.67, 32.06, 39.74, 41.24, 59.02, 80.23, 84.35, 94.31, 153.91, 157.737, 164.38, 173.33, 175.87. MALDI MS: calculated for $C_{157}H_{278}N_{40}O_{48}$ (M^+), 3524.1; found, 3573.4. The resulting white solid (0.352 g, 0.10 mmol) was dissolved in ethanol (40 mL) and transferred into a hydrogenation vessel containing Raney-Nickel catalyst (5 g), and the suspension was stirred at 65 psi for 48 h at room temperature. After filtration through Celite, the solvent was removed under reduced presssure to give a **7** as a white solid (0.28 g, 80%). ^{1}H NMR of **7** (400 MHz, CD_3OD): δ = 1.46 (m, CH_3, 81H), 1.51 (m, CH_3, 81H), 1.90−2.25 (m, CH_2, 48H), 3.30−3.55 (m, CH_2, 36H). ^{13}C NMR (400 MHz, CD_3OD): δ

= 28.37, 28.67, 31.40, 31.76, 39.76, 41.27, 54.0, 58.86, 80.32, 84.37, 153.97, 157.81, 164.4, 175.61, 176.02. MALDI MS: calculated for $C_{157}H_{278}N_{40}O_{48}$ ($M + H^+$), 3495.1; found, 3496.3.

Synthesis of 9 Cascade:nitromethane [3]:(2-aza-3-oxopenylidyne):propionic acid-(6-(1,3-bis-(*tert*-butoxycarboyl)guanidino)hexyl)amide 8. The resulting HCl salt **6** (0.838 g, 0.385 mmol) was dissolved in methanol (50 mL), and the solution was cooled to 0 °C. Et_3N (1.45 mL) was added, followed by *N*,*N*′-diBoc-*N*′′-triflylguanidine (1.765 g, 4.51 mmol), and the solution was stirred at room temperature for 24 h and the solvent evaporated under reduced pressure. The crude product was purified by flash column chromatography eluting with 2% methanol in dichloromethane and gradually increasing to 10% methanol in dichloromethane to give a white solid (1.40 g, 91%). ^{1}H NMR (400 MHz, CD_3OD): δ = 1.15−1.55 (m, 234H), 1.70−2.15 (m, C*H*$_2$, 48H), 3.29−3.30 (m, C*H*$_2$, 36H). ^{13}C NMR (400 MHz, CD_3OD): δ = 27.70, 27.62, 28.33, 28.67, 30.08, 30.33, 31.30, 31.60, 40.48, 40.62, 41.27, 54.5, 59.14, 80.25, 84.40, 154.22, 157.49, 164.53, 173.50, 175.53. MALDI MS: calculated for $C_{193}H_{349}N_{40}O_{50}$ ($M + H^+$), 4030.1; found, 4031.8. The white solid (0.40 g, 0.10 mmol) was dissolved in ethanol (40 mL) and transferred into a hydrogenation bottle containing Raney-Nickel catalyst (5 g), and the suspension was stirred at 65 psi for 72 h at room temperature. After filtration through Celite, the solution was evaporated to under reduced pressure to give a white solid **8** (0.32 g, 80%). ^{1}H NMR of **8** (400 MHz, CD_3OD): δ = 1.46 (m, C*H*$_3$, 81H), 1.51 (m, C*H*$_3$, 81H), 1.90−2.25 (m, C*H*$_2$, 48H), 3.30−3.55 (m, C*H*$_2$, 36H). ^{13}C NMR (400 MHz, CD_3OD): δ = 28.37, 28.67, 31.40, 31.76, 39.76, 41.27, 54.0, 58.86, 80.32, 84.37, 153.97, 157.81, 164.4, 175.61, 176.02. MALDI MS: calculated for $C_{193}H_{350}N_{40}O_{48}$ ($M + H^+$), 4000.1; found, 4007.8.

Synthesis of 9 Cascade:fluoresceinylmethane [3]:(2-aza-3-oxopenylidyne):propionic acid-(2-guanidino)ethyl)amide HCl Salt FD-1. Fluorescein isothiocyanate (FITC, 0.14 g, 0.36 mmol) in DMF (1 mL) was added to a 1:1 mixture of DMF/dichloromethane (10 mL) containing dendron **7** (0.23 g, 0.066 mmol). The mixture was cooled to 0 °C, Et_3N (0.092 mL, 0.66 mmol) was added, and the solution was stirred overnight at room temperature. After removal of the solvent under reduced pressure, the residue was dissolved in dichloromethane (15 mL), and the resulting solution was washed with 1 N HCl (15 mL) and water (15 mL) and dried over anhydrous Na_2SO_4. The solution was concentrated under reduced pressure to afford the yellow solid of 9 cascade:fluoresceinylmethane[3]:(2-aza-3-oxopenylidyne):propionic acid−(2-(1,3-bis-(*tert*-butoxycarboyl)-guanidino)ethyl)amide **9** (0.23 g, 91%). ^{1}H NMR (400 MHz, CD_3OD): δ = 1.46 (m, C*H*$_3$, 81H), 1.51 (m, C*H*$_3$, 81H), 1.90−2.25 (m, C*H*$_2$, 48H), 3.30−3.55 (m, C*H*$_2$, 36H), 6.52−6.72 (br, 4H), 7.15 (br, 1H), 7.5 (br, 2H), 7.72 (br, 1H), 8.4 (br, 1H). MALDI MS: calculated for $C_{179}H_{294}N_{41}O_{53}S$, ($M + H^+$), 3899.5; found, 3901.9. The resulting yellow solid (200 mg, 0.052 mmol) was dissolved in 1,4-dioxane (10 mL), and the solution was cooled to 0 °C. 4 M HCl in dioxane (10 mL) was added, and the mixture was stirred overnight at room temperature. After removal of the solvent under reduced pressure, the residue was dissolved in water, the insoluble precipitate was filtered off, and the filtrate was concentrated under reduced pressure. The crude product was purified by RP-HPLC using a solvent gradient (solvent A = 0.05% TFA/H_2O; solvent B = 0.05% TFA/CH_3CN) to give water-soluble **FD-1** (50 mg, 44%). Alternatively, the crude product could be purified by dialysis, as described for FD-2, to give a pure compound. ^{1}H NMR (400 MHz, D_2O): δ = 1.85−2.30 (m, C*H*$_2$, 48H), 3.10−3.30 (m, C*H*$_2$, 36H), 6.9 (br, 2H), 7.10−7.2 (m, 3H), 7.4 (s, 2H), 7.5 (br, 1H), 8.1 (s, 1H). MALDI MS: calculated for $C_{89}H_{157}Cl_9N_{41}O_{17}S$, ($M + H^+$), 2425.6; found, 2427.20.

Synthesis of 9 Cascade:fluoresceinylmethane [3]:(2-aza-3-oxopenylidyne):propionic acid-(6-guanidino)hexyl)amide HCl Salt FD-2. FITC (0.096 g, 0.2256 mmol) in DMF (1 mL) was added to 1:1 mixture of DMF/dichloromethane (10 mL) containing nona-(Boc-guanidinohexyl) dendron amine **8** (0.300 g, 0.075 mmol). The mixture was cooled to 0 °C, Et_3N (72 μL) was added, and the solution was stirred overnight at room temperature. After removal of the solvent under reduced pressure, the residue was dissolved in dichloromethane (15 mL), and the resulting solution was washed with 1 N HCl (15 mL) and water (15 mL) and dried over anhydrous Na_2SO_4. The solvent was evaporated at reduced pressure, and the crude product was dissolved in methanol and purified by dialysis against methanol with SpectraPor Biotech regenerated cellulose membranes (MWCO = 3500) for 24 h. Removal of the methanol in vacuo gave a yellow solid of 9 cascade:fluoresceinylmethane[3]:(2-aza-3-oxopenylidyne):propionic acid−(6-(1,3-bis-(*tert*-butoxycarboyl)guanidino)hexyl)amide **10** (290 mg, 88%). ^{1}H NMR (400 MHz, CD_3OD): δ = 1.20−1.7 (m, C*H*$_3$, C*H*$_2$, 234H), 1.89−2.30 (m, C*H*$_2$, 48H), 3.10−3.40 (m, C*H*$_2$, 36H), 6.52−6.72 (br, 4H), 7.15 (br, 1H), 7.5−7.72 (br, 3H), 8.1 (br, 1H). MALDI MS: calculated for $C_{215}H_{366}N_{41}O_{53}S$, ($M + H^+$), 4405.5; found, 4406.7. The resulting yellow solid (200 mg, 0.052 mmol) was dissolved in 1,4-dioxane (10 mL) and the solution cooled to 0 °C; 4 M HCl in dioxane (10 mL) was added and the solution stirred overnight at room temperature. The precipitate was filtered off and dried to give the crude product. The solid was redissolved in water, insoluble precipitate was filtered off, and the filtrate was dialyzed against water with SpectraPor Biotech cellulose ester membranes (MWCO = 1000) for 48 h and lyophilized to yield water-soluble **FD-2** (127 mg, 96%). ^{1}H NMR (400 MHz, D_2O): δ = 1.1−1.50 (m, C*H*$_2$, 72H), 1.50−2.20 (m, C*H*$_2$, 48H), 3.10−3.30 (m, C*H*$_2$, 36H), 6.5−6.7 (br, 6H), 7.10 (m, 1H), 7.5 (br, 3H). MALDI MS: calculated for $C_{124}H_{226}Cl_9N_{41}O_{17}S$ (M^+), 2914.5; found, 2914.6.

Uptake Experiment Protocol. Fluorescent dendrimer uptake by mammalian cells was assessed using NIH-3T3 cells (American Type Culture Collection) and HMEC (human microvascular endothelial cells—Centers for Disease Control) grown on gelatin-coated coverslips and a Zeiss LSM 510 confocal microscope. NIH-3T3 cells were grown in DMEM (Invitrogen) supplemented with 10% FBS (Invitrogen), and HMEC were grown in MCDB-131 media (Mediatech) supplemented with 5% FBS (Invitrogen) and 2 mM L-glutamine (Invitrogen). A time course of fluorescent dendrimer entry into NIH-3T3 cells and HMEC was completed in triplicate as previously described for Tat peptides (*21*). Briefly, the cells were treated with the dendrimer molecules for the series of incubation times, washed three times with PBS, fixed with 3% paraformaldehyde at room temperature for 10 min, and analyzed using confocal microscopy. In order to confirm the data, these experiments were also completed without fixing the cells. These experiments were completed through the use of the VUMC Cell Imaging Resource (supported by CA68485 and DK20593).

DAPI Staining. NIH-3T3 cells grown on gelatin-coated coverslips were treated with **FD-1** (10 μM), **FD-2** (10 μM), or vehicle (water) for 60 min at 37 °C, washed, and fixed as previously described above (*21*). After the cells were permeabilized with 0.1% Triton X-100 and washed twice with PBS, they were incubated with 0.5 μg/mL of 4′,6-diamidino-2-phenylindole (DAPI—Invitrogen) for 30 min at room temperature in the dark. The coverslips were then washed twice with PBS and mounted. A Nikon fluorescent microscope with a UV filter was then used to image the samples.

TUNEL Assay. NIH-3T3 cells grown on gelatin-coated coverslips were treated with **FD-1** or **FD-2** (10 μM), vehicle (water), or 50% methanol (positive control for apoptosis) for

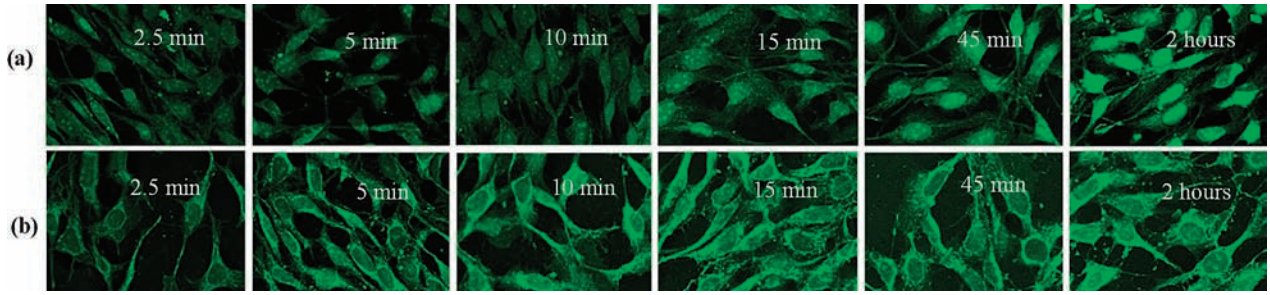


Figure 1. Time course of internalization of (a) **FD-1** and (b) **FD-2** into NIH-3T3 cells (fixed) at 37 °C. The conjugate concentration was 10 μM.

1 h at 37 °C and washed and fixed as previously described (*28*). An additional positive control involved the addition of DNAseI (New England BioLabs) to vehicle-treated cells that had been permeabilized with 0.1% Triton X-100 (Sigma). In order to label apoptotic nuclei, an in situ cell death detection kit with tetramethyl rhodamine (TMR-red) labeled dUTP (Roche Diagnostics) was used. The number of apoptotic nuclei in the **FD-1** and **FD-2** treated samples as compared to the positive and negative controls were measured with a Zeiss LSM-510 Confocal Microscope.

RESULTS AND DISCUSSION

In developing a new molecular transporter for targeted subcellular delivery of cargo molecules, we were drawn to the Newkome-type dendrimers, which are typically 1→3 C-branched polyamide macromolecules. These molecules are built from a "Behera's amine" monomer or its derivatives, that can be easily attached to a great variety of starting cores, surfaces, and polymers. Although the Newkome-type dendrimer is well-known, one of the drawbacks for a broader application is the elaborate synthesis of the monomer **2**. We efficiently synthesized the amine monomer **2** through improved hydrogenation of nitroester **1** and workup procedures of known literature methods (*27*). The synthesis of the dendron scaffold began with nitro-triacid monomer **3** reacting with "Behara's amine" monomer **2**, achieving the necessary nine end functionalities in only one generation of dendritic growth (Scheme 2). After the *t*-butyl groups were removed, the [G-1] nona-acid scaffold **4** was obtained in high yields. In order to introduce the guanidinium groups to the periphery of the dendrimer and provide diversity in the presentation of the guanidine groups to biological membranes, the carboxylic acid groups were first converted into Boc-protected amine groups. This was completed by reaction with a short alkyl linker (*N*-Boc-ethylendiamine) or a longer alkyl linker (*N*-Boc-1,6-diaminehexane), through established amide coupling reactions. After removal of the Boc groups, the nine free amines **5** or **6** were reacted with the guandinylating reagent (*29*) to give the guanidinylated dendritic scaffold in high yield (Scheme 2).

For preliminary uptake studies, a fluorescent probe was conjugated to the focal point of the molecular transporter, which served also as the test cargo molecule. The attachment of the fluorescein isothiocyanate (FITC) moiety to the guanidinylated scaffold started with a successful reduction of the nitro group at the focal point to an amino group via hydrogenation at room temperature in quantitative yields to form **7** or **8**. The free amino group was then directly reacted with FITC to form the Boc-protected FITC-labeled guanidino dendrimers **9** or **10**. After deprotection of the Boc-protected guanidine groups, FITC-labeled dendritic molecules were obtained and further purified by dialysis or HPLC, yielding pure **FD-1** and **FD-2**.

The two FITC−dendrimer conjugates were found to be highly water-soluble and were investigated for their capability to translocate through cell membranes. Internalization of **FD-1** and **FD-2** in mammalian cells was assessed using two different

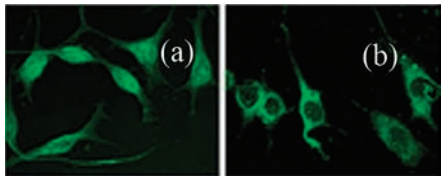

Figure 2. Confocal microscopy of (a) **FD-1** and (b) **FD-2** into unfixed NIH-3T3 cells at 37 °C. The conjugate concentration was 10 μM.

mammalian cell lines, NIH-3T3 fibroblasts and human microvascular endothelial cells (HMEC). Figure 1 shows the time course of uptake of **FD-1** and **FD-2** into NIH-3T3 fibroblasts at 37 °C. In this time course, the cells were treated with **FD-1** or **FD-2** for the series of time points shown, then washed, fixed with paraformaldehyde, and analyzed using confocal microscopy. The fluorescence was clearly observed within the cells 2.5 min after the addition of conjugates to the medium, which is comparable to the uptake rate of Tat−peptide (*13*, *21*). Furthermore, the extent of internalization increased in an incubation time-dependent manner, and the fluorescence intensity of cells treated with **FD-2** was near saturation after 10 min. However, the fluorescence intensity of cells treated with **FD-1** did not approach saturation until longer time points (45 min to 2 h). Interestingly, **FD-1** and **FD-2** exhibited differential patterns of subcellular localization, as **FD-1** appeared to concentrate in the nucleus with punctuated patterns similar to that of HIV Tat peptide, whereas **FD-2** appeared to concentrate in the cytosol. These data suggest that guanidine-rich **FD-1** and **FD-2,** bearing dendritic backbones, are internalized into cells in a similar manner to Tat peptides, but the length of the spacer at the terminal generation of the dendrimer not only controls the uptake rate (*30*), it also regulates the subcellular localization of the molecule and its putative cargo. For instance, the uptake levels of **FD-2** appeared to be generally higher than those of **FD-1** after the same incubation time at the same concentration. Therefore, the dendrimer with a hexyl spacer seems to cross the cell membrane faster than the molecule with an ethyl chain. As pointed out before, **FD-1** with the short spacer appeared to be localized mainly in the nucleus, whereas **FD-2**, with its longer spacer, was observed to reside mainly in the cytosol.

Fixed cells are usually used for confocal microscopy to obtain clear images, but recent studies indicate that cell fixation might lead to the artifactual redistribution of highly charged peptides (*31*, *32*). For this reason, the intracellular localization of **FD-1** and **FD-2** were also assessed using unfixed NIH-3T3 fibroblasts. In these experiments, the cells were treated with **FD-1** or **FD-2**, washed, and analyzed using confocal microscopy. The confocal images (Figure 2) showed that the distribution pattern of the fluorescent conjugates was consistent with that seen in fixed cells: **FD-1** with the short spacer appeared to be highly concentrated in the nucleus; while **FD-2**, with its longer spacer, was observed mainly in the cytosol. These experimental results strengthen the hypothesis that the cellular localization of **FD-1** and **FD-2** by fibroblasts is dominated to a high extent by the

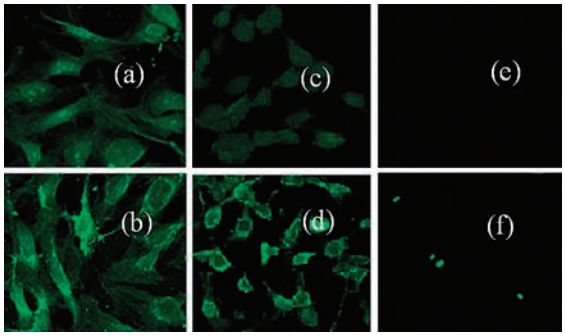

Figure 3. Confocal microscopy of human microvascular endothelial cells (HMEC) treated with (a) 10 μM of **FD-1** for 10 min at 37 °C; (b) 10 μM of **FD-2** for 10 min at 37 °C; (c) 10 μM of **FD-1** for 10 min at 4 °C; (d) 10 μM of **FD-2** for 10 min at 4 °C; (e) fluorescein isothiocyanate (FITC) for 1 h at 37 °C; (f) 10 μM of Boc-protected guanidinylated **FD-2** for 1 h.

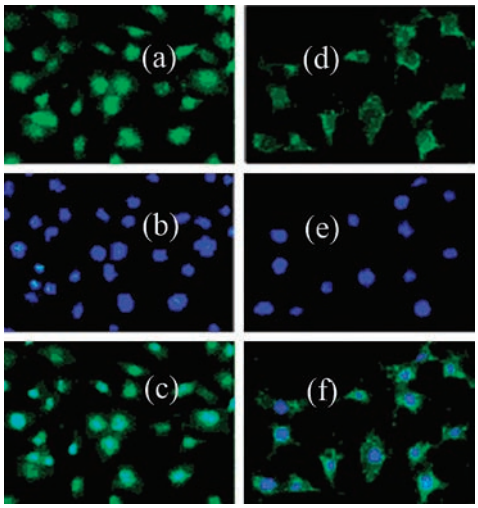

Figure 4. (a−f) NIH-3T3 cells were treated with **FD-1** (10 μM), **FD-2** (10 μM), or vehicle (water) for 60 min at 37 °C. Then, the cells were incubated with 0.5 μg/mL of 4′,6-diamidino-2-phenylindole (DAPI) for 30 min at room temperature in the dark.

length of the linker between the guanidine headgroups and the dendritic backbone. These results were confirmed with HMEC cells (Figure 3a,b).

The subcellular localization of **FD-1** and **FD-2** was further assessed by determining colocalization with the DAPI DNA stain. The 3T3 cells were treated with **FD-1** or **FD-2** and the nuclei were stained with DAPI, followed by the imaging of the cells with a fluorescent microscope equipped with a UV filter. **FD-1** colocalizes with DAPI (Figure 4a−c) to a much greater extent than **FD-2** (Figure 4d−f). These data provide solid evidence of the disparate subcelluar localization of the synthesized carriers, with **FD-1** concentrated mainly in the nucleus and **FD-2** concentrated in the cytosol.

In order to evaluate the effect of the guanidinium groups and the macromolecular dendritic structure on cellular uptake, control experiments were performed. HMEC were treated with free FITC and Boc-protected guanidinylated **FD-2**-dendrimer **10**. In the same time course of cellular uptake corresponding to the experiments of **FD-1** and **FD-2,** we observed extremely weak or no fluorescence for both compounds, as shown in Figure 3e,f. These observations suggest that the nanoscale hole formation mechanism (*33*), as previously proposed for the PAMAM dendrimer uptake mechanism, could be excluded and that the guanidino groups play a critical role in the cell permeability.

Additionally, we assessed the effect of temperature on the internalization of **FD-1** and **FD-2.** Figure 3c,d shows that the

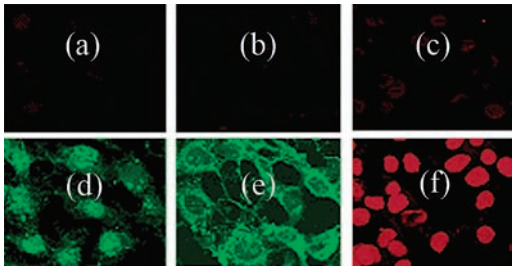

Figure 5. (a) **FD-1** + TMR − dUTP (red filter). (b) **FD-2** + TMR− dUTP (red filter). (c) Vehicle (water) + TMR − dUTP = negative control (red filter). (d) **FD-1** + TMR − dUTP (green filter). (e) **FD-2** + TMR − dUTP (green filter). (f) 50% Methanol + TMR− dUTP = positive control (red filter).

two conjugates are able to internalize into cells not only at 37 °C, but also at 4 °C, and no significant decrease in fluorescence intensity was observed. Although the exact translocation mechanism of guanidinylated peptides such as Tat and its derivatives remains controversial, these experiments suggest that active transport across the membrane is not needed and demonstrate that the internalization mechanism of the dendrimer carriers is similar to that of Tat and its derivatives.

The cytotoxicity of **FD-1** and **FD-2** was assessed using a well-characterized TUNEL assay and confocal microscopy to ensure the biocompatibility for further utilization. Neither **FD-1** nor **FD-2** caused 3T3 cell apoptosis in the dose range tested, with the highest dose being 10 μM for 60 min (Figure 5d,e), as only background staining of the nuclei (Figure 5a **FD-1**, red channel; Figure 5b, **FD-2**, red channel) similar to that of the negative control samples (Figure 5c) occurred. DNAse I (data not shown) and 50% methanol (Figure 5e) were used as the positive control treatments, as both cause nicks in the genomic DNA, and the nuclei of these cells were highly apoptotic as denoted by their strong staining pattern. Additionally, HMEC treated with 10 μM **FD-1** or **FD-2** for 60 min had no defect in intracellular calcium mobilization, as measured by the flex station, upon thrombin receptor stimulation when compared to HMEC treated with water (data not shown). These data suggest that **FD-1** and **FD-2**, at the experimental conditions tested, are not cytotoxic and are therefore ideal molecular carriers for the transport of putative bioactive cargo molecules.

CONCLUSION

In this report, we have described the synthesis of two novel dendritic molecular transporters, **FD-1** and **FD-2**, and investigated their uptake rate and intracellular distribution in mammalian cell lines using confocal microscopy. The design features of this macromolecule display a compact, biocompatible Newkome dendrimer scaffold with guanidine groups differentiated over an alkyl spacer. The combination of flexible spacer units conjugated to a highly symmetric dendritic backbone affords an increased density presentation of critical guanidine groups on the scaffold, without neglecting the necessity of structural flexibility for cellular uptake. We observed that the shorter alkyl spacer of **FD-1** directed the uptake of the transporter mainly into the nucleus, while **FD-2**, with the longer alkyl spacer, concentrated its fluorescent cargo in the cytosol. The critical role of the length of the hydrophobic alkyspacer, in this particular macromolecular design, has never been shown and allows for the directed subcellular delivery of bioactive cargo molecules utilizing scalable, biocompatible macromolecular carriers. Our results suggest that the synthetic approach of these molecular transporters and their unique targeting abilities will advance the development of novel vaccine vectors and drug delivery systems to overcome the limitations of current technologies.

Synthesis and Properties of Cell-Targeted Zn(II)−Phthalocyanine−Peptide Conjugates

Martha Sibrian-Vazquez,[†] Javier Ortiz,[‡] Irina V. Nesterova,[†] Fernando Fernández-Lázaro,[‡] Angela Sastre-Santos,*[,‡] Steven A. Soper,*[,†] and M. Graça H. Vicente*[,†]

Department of Chemistry, Louisiana State University, Baton Rouge, Louisiana 70803, and División de Química Orgánica, Instituto de Bioingeniería, Universidad Miguel Hernández, 03202 Elche, Spain. Received September 22, 2006; Revised Manuscript Received November 29, 2006

Two Zn−Pc−peptide conjugates bearing either a short linker or a long PEG−linker between the macrocycle and a bifunctional peptide containing the nucleoplasmin and HIV-1 Tat 48−60 sequences have been synthesized in order to increase the Pc cell-targeting ability and to evaluate the effect of the linker. The presence of the peptide chain increased the water solubility of the Pc macrocycle and, consequently, its fluorescence in aqueous solutions. The highest fluorescence quantum yields were observed at low pH (5.0) for both conjugates and were always higher for the conjugate bearing the short linker. Both conjugates were found to have low dark cytotoxicity toward human HEp2 cells ($IC_{50} > 77\ \mu M$) but were highly phototoxic ($IC_{50} < 2\ \mu M$ at 1 J cm^{-2}). The conjugate bearing the long PEG−linker accumulated the most within cells (26 times more than the unconjugated Zn−Pc), followed by the short linker conjugate (17 times more than the unconjugated Zn−Pc). Both conjugates were found to localized preferentially within the cell lysosomes.

INTRODUCTION

Photodynamic therapy (PDT) is a binary modality for cancer treatment that involves the activation of photosensitizer-containing tissue with light (*1*). Since neither the photosensitizer nor the light has a toxic effect when used alone, PDT has the potential for being highly selective for tumor tissue. Phthalocyanines (Pcs[1]) are promising photosensitizers for use in PDT because they typically exhibit strong light absorptions in the near-infrared (650−750 nm) and often have high quantum yields of singlet oxygen formation (*2*, *3*). These characteristics are important, because red light penetrates significantly deeper into tissues than visible light and singlet oxygen is considered a key species in PDT-induced cell death. Nevertheless, the biological efficacy of a photosensitizer is often determined by its subcellular distribution within cancer cells, which in turn depends on the structural characteristics and physicochemical properties of the photosensitizer (*4*). Therefore, depending on the nature of the peripheric substituents, the centrally chelated metal ion, the overall molecular charge, and the formulation vehicle, Pc-based sensitizers can be localized within certain compartments of cells, such as in the lysosomes, mitochondria, ER, or the Golgi complex (*5*). A significant disadvantage of Pc-based photosensitizers is their strong tendency for aggregation in solution, especially in water and other polar solvents, due to the hydrophobic nature of the Pc macrocycle. Phthalocyanine aggregation not only reduces their solubility in aqueous solutions, but also decreases their fluorescence and singlet oxygen quantum yields and consequently their photosensitizing activity (*6*).

In order to reduce Pc aggregation and to increase their solubility and biological efficacy, hydrophilic groups have been introduced at the Pc macrocycle periphery, for example, multiple carboxylic acids (*7*), sulfonic acids (*8*), or polyoxyethylene groups (*9*). Another strategy involves the conjugation of Pc macrocycles to biomolecules, such as oligonucleotides (*10*, *11*), antibodies (*12*−*15*), proteins (*16*−*19*), cyclodextrins (*20*), and epidermal growth factors (EGF) (*21*). Although improved biological efficiency has been achieved with some of the above Pc conjugates, the use of peptide signaling sequences, with the exception of EGF peptides, to direct the delivery of Pc-based photosensitizers within cancer cells and into sensitive organelles has not been fully explored. This strategy is based on the natural ability of certain proteins and peptide sequences for crossing cellular membranes and specifically targets sensitive organelles, such as the mitochondria, ER, and cell nuclei. Examples of desirable peptide signaling sequences to be conjugated to Pc macrocycles include fusogenic or cell-penetrating peptides, nuclear localization sequences (NLS), and bifunctional signaling sequences (*22*−*26*). Among these, the bifunctional peptides contain a minimum sequence for translocation across cellular membranes and a signaling sequence to direct the movement of the molecule from the cytoplasm to a target organelle, for example, containing both a fusogenic and an NLS peptide sequences. We have recently shown that porphyrin−peptide conjugates bearing either NLS, fusogenic, or bifunctional peptides exhibit increased cellular uptake and improved biological efficacy in cells in culture (*27*). We now report the synthesis and photophysical and biological evaluation of two cationic Pcs and two new Pc conjugates to a bifunctional peptide containing the bipartite NLS nucleoplasmin (*28*) and the fusogenic peptide sequence corresponding to the human

Syntheses. Unless otherwise indicated, all commercially available starting materials were used directly without further purification. All reactions were monitored by TLC using Sorbent Technologies 0.25 mm silica gel plates with or without UV indicator (60F-254). Silica gel Sorbent Technologies 32−63 μm was used for flash column chromatography. ^{1}H NMR spectra were obtained on either an ARX-300 Bruker spectrometer or a Bruker AVANCE DRX-500. Chemical shifts (δ) are given in ppm. Electronic absorption spectra were measured on either a Perkin-Elmer Lambda 35 UV−vis spectrophotometer or a Helios Gamma spectrophotometer. IR spectra were recorded with a Nicolet Impact 400D spectrophotometer. Mass spectra were obtained on either a MAT 900 (Finnigan-MAT Gmbh, Bremen Instrument, FAB-MS) spectrometer or a Bruker ProFlex III MALDI-TOF mass spectrometer using CCA or dithranol as the matrix. Elemental analyses were performed on a Thermo Finnigan Flash 1112 CHN elemental analyzer. HPLC analyses were carried out on a Dionex system containing a P680 pump and a UVD340U detector. Semipreparative HPLC was carried out using a Luna C_{18} 100 Å, 5 μm, 10 × 250 mm (Phenomenex, U.S.A.) column and a stepwise gradient; analytical HPLC was carried out using a Delta Pak C_{18} 300 Å, 5 μm, 3.9 × 150 mm (Waters, U.S.A.) column and a stepwise gradient.

Peptide Synthesis. The peptide sequence KRPAATKK-AGQAKKKLEDPRKKRRQRRRPPQG was prepared on an automated peptide synthesizer (Applied Biosystems Pioneer, Peptide Synthesis System, U.S.A.) on a 0.2 mmol scale using the Fmoc strategy of solid-phase peptide synthesis. A 4-fold excess of the Fmoc-protected amino acids were coupled to the PAL−PEG−PS resin using PyBOP/TBTU as the activating agents. After the final coupling and the successive removal of the Fmoc group, the resin was washed with DMF and isopropanol and then dried under vacuum. The dried resin containing the protected peptide sequence was used in the coupling reaction to the Pc derivatives.

Zn−Pc 1. A mixture of 4-(2-*tert*-butoxycarbonylaminoethoxy)phthalonitrile (50 mg, 0.174 mmol), $Zn(CH_3CO_2)_2{\cdot}2H_2O$ (19.3 mg, 0.087 mmol), DMAE (0.2 mL), and a drop of DBN was refluxed for 5 h under argon. The green solution obtained was cooled, then methanol (4 mL) was added and the solvents were evaporated. The crude product was purified by column chromatography (methanol/CH_2Cl_2 3/97) affording 30 mg of pure **1**. Yield: 57%. UV−vis (DMF), λ_{max} (log ϵ): 354 (4.76), 612 (4.42), 679 (5.10). IR (KBr): 3361, 2976, 2931, 1705, 1609, 1491, 1392, 1241, 1171, 1095, 747 cm^{-1}. ^{1}H NMR (DMF-d_7): δ = 1.48−1.50 (m, 36H, $(CH_3)_3C$), 3.80 (m, 8H, CH_2N), 4.64−4.72 (m, 8H, CH_2O), 7.32 (broad s, 4H, NH), 7.80−7.87 (m, 4H, ArH), 8.95−9.01 (m, 4H, ArH), 9.30−9.37 (m, 4H, ArH). FAB-MS (3-NOBA) *m*/*z* 1212 (M^+). Calcd for $C_{60}H_{68}N_{12}O_{12}Zn{\cdot}2H_2O$: C, 57.62%; H, 5.80%; N, 13.44%. Found: C, 57.70%; H, 6.02%; N, 13.11%.

Zn−Pc 2. Phthalocyanine **1** (25 mg, 0.022 mmol) was dissolved in a mixture of CH_2Cl_2 (0.3 mL) and TFA (0.3 mL) at 0 °C and then room temperature for 2 h. The solvent was removed at reduced pressure, and the residue was treated with 2 M NaOH, extracted with ethyl acetate (3 × 5 mL), and dried over magnesium sulfate. After evaporating the solvent, the tetramino-subtituted Pc was obtained as a blue powder. This compound was dissolved in 2 M HCl (2 mL), the solvent was removed by azeotropic distillation with toluene, and the residue was dried under vacuum to obtain Pc **2** as a green powder. Yield: 11 mg, 52%. UV−vis (DMF), λ_{max} (log ϵ): 354 (4.79), 631 (4.54), 683 (4.91). IR (KBr): 3600−2000, 1606, 1482, 1335, 1242, 1120, 1009 cm^{-1}. ^{1}H NMR (TFA-d_1): δ = 4.04 (m, 8H, CH_2O), 4.95 (m, 8H, CH_2N), 7.97 (m, 4H, ArH), 9.09 (m, 4H, ArH), 9.46 (m, 4H, ArH). MALDI-TOF MS (dithranol) *m*/*z* 813 $(M + H)^+$. HR MALDI-TOF *m*/*z* 812.22693 (M^+), calcd for $C_{40}H_{36}N_{12}O_4Zn$ 812.22685.

Zn−Pc 3. Phthalocyanine **3** was prepared by statistical condensation of 4-*tert*-butylphthalonitrile (385 mg, 2.09 mmol) and 4-(2-*tert*-butoxycarbonylaminoethoxy)phthalonitrile (200 mg, 0.696 mmol) in the presence of $Zn(CH_3CO_2)_2{\cdot}2H_2O$ (306 mg, 1.39 mmol), DMAE (3.2 mL), and two drops of DBN. The crude phthalocyanine was purified by column chromatography using hexane/ethyl acetate 4:1 for elution affording 58 mg (9%) of protected Zn−Pc. This compound (30 mg, 0.033 mmol) was stirred at 0 °C for 2 h in a mixture of CH_2Cl_2 (0.3 mL) and TFA (0.3 mL). The solvent was removed, and the resulting residue was treated with 2 M NaOH, extracted with ethyl acetate, and washed with water, affording 22 mg of Zn−Pc **3a**. To this compound, an equivalent of HCl and diethyl ether (2 mL) were added. The mixture was sonicated and the solvents removed, yielding 18 mg of Zn−Pc **3b** (67%). UV−vis (DMF), λ_{max} (log ϵ): 677 (5.34), 610 (4.58), 350 (4.88). IR (KBr): 3399, 2957, 2904, 2866, 1611, 1489, 1328, 1229, 1090, 1047, 748 cm^{-1}. ^{1}H NMR (TFA-d_1): δ = 1.80 (s, 27H, $(CH_3)_3C$), 4.04 (m, 2H, CH_2O), 4.96 (m, 2H, CH_2N), 8.00 (m, 1H, ArH), 8.59−8.64 (m, 3H, ArH), 9.15−9.18 (m, 1H, ArH), 9.42−9.50 (m, 4H, ArH), 9.58−9.67 (m, 3H, ArH). MALDI-TOF (dithranol) *m*/*z* 804 $(M + H)^+$.

Zn−Pc 4. Diglycolic anhydride (2 mg, 0.0186 mmol) was added to a solution of Pc **3a** (10 mg, 0.0124 mmol) in DMF (100 μL), and the solution stirred overnight at room temperature. The reaction mixture was diluted with CH_2Cl_2 (1 mL) and hexanes (2 mL) until precipitation occurred. The dark green solid was washed with hexanes (3 × 2 mL) and warm water until neutral pH. The solid residue was dissolved in $CHCl_3$, dried over Na_2SO_4, the solvent evaporated, and the solid residue dried under vacuum to yield 11 mg (97%) of Pc **4**. ^{1}H NMR (DMF-d_7, 250 MHz): δ =1.77 (s, 27H, $(CH_3)_3C$), 3.95 (s, 2H, CH_2), 4.32 (s, 2H, CH_2O), 4.54 (s, 2H, CH_2N), 4.69 (s, 2H, CH_2O), 7.78−7.95 (m, 2H, ArH), 8.35−8.44 (m, 4H, ArH), 9.05 (d, 1H, J = 8.30 Hz, ArH), 9.33−9.43 (m, 4H, ArH), 9.53−9.57 (m, 3H, ArH). MALDI-TOF MS *m*/*z* 920.409 ($M + H^+$), calcd for $C_{50}H_{50}N_9O_5Zn$ 920.315.

Zn−Pc Conjugate 5. Peptidyl resin (0.0032 mmol) was introduced into a glass synthesizer, swelled in DMF for 1 h, and then washed with DMF (2 × 5 mL). To the peptidyl resin was added 300 μL of a solution containing 0.0064 mmol of Pc **4**, 0.193 mmol of DIEA, 0.0064 mmol of HOBt, and 0.0064 mmol of TBTU. The reaction mixture was shaken overnight at room temperature and then filtered to give a blue resin. The resin was washed to remove unreacted Pc, first with DMF until the filtrate was colorless, then with CH_2Cl_2 and methanol, before being dried under vacuum. Cleavage and deprotection was carried out by treatment of the dried resin with 2 mL of a mixture of TFA/phenol/TIS/H_2O, 88/5/2/5, at room temperature for 4 h. The resin was filtered, washed with TFA (3 × 2 mL), and the filtrates combined and evaporated under vacuum to give a blue residue. Addition of cold Et_2O yielded a blue−green precipitate, which was washed repeatedly with Et_2O and dried under vacuum. The purification of the Pc−peptide conjugate was achieved by reverse-phase HPLC on a Luna C_{18} semi-preparative column (10 × 250 mm, 5 μm) (Phenomenex, U.S.A.) using a solvent system of water and acetonitrile both containing 0.1% TFA, with a stepwise gradient from 50% to 95%. The fraction containing the conjugate was collected and lyophilized to yield pure conjugate. The purity of the Pc−peptide conjugate was >95% as obtained by HPLC on an analytical Delta Pak C_{18} (3.9 × 150 mm, 5 μm) column. Yield: 12.3 mg,

57%. HPLC, $t_r = 16.04$ min. MALDI-TOF MS *m/z* 4670.643 ($M + H^+$), calcd for $C_{210}H_{339}N_{74}O_{44}Zn$ 4669.592.

Zn−Pc Conjugate 6. To a solution of Pc **4** (15 mg, 0.0167 mmol) in 200 μL of DMF was added DIEA (13 mg, 0.1 mmol), followed by the addition of HOBt (2.5 mg, 0.0167 mmol) and TBTU (5 mg, 0.0167 mmol). The reaction mixture was stirred for 2 min, and then $NH_2CH_2CH_2(OCH_2CH_2)_5OCH_2CO_2{}^tBu$ (6.6 mg, 0.0167 mmol) was added in one portion. Stirring was continued for 24 h at room temperature and then the reaction mixture diluted with ethyl acetate (25 mL). The organic phase was washed with water (100 mL), saturated aqueous $NaHCO_3$ (100 mL), water (100 mL), then dried over Na_2SO_4, filtered, and the solvent evaporated under vacuum to leave a blue residue. The Pc conjugate was isolated by flash chromatography on silica gel using ethyl acetate followed by $CHCl_3$/MeOH 9/1. Yield 8.6 mg, 40%. MALDI-TOF MS *m/z* 1242.518 ($M - C_4H_9$), calcd for $C_{64}H_{76}N_{10}O_{12}Zn$ 1242.738. The protected Pc conjugate was dissolved in 1 mL of $CHCl_3$/TFA 1/1 and stirred at room temperature for 4 h. The solvent was evaporated, and the dark blue residue was triturated with cold Et_2O. The dark blue residue was dried under vacuum to give 8.2 mg, quantitative yield of the title conjugate. MALDI-TOF MS *m/z* 1242.618 (M^+), calcd for $C_{64}H_{76}N_{10}O_{12}Zn$ 1242.738. Conjugation to the peptide sequence was performed on the solid phase as described above. Because this conjugate was sensitive to acid conditions, after separation by reverse-phase HPLC, the fraction corresponding to the Pc conjugate was neutralized with triethylamine. After lyophilization, the blue residue was redissolved in water, and any excess of Et_3N or $Et_3NH^+CF_3COO^-$ salt was removed by gel filtration on Sephadex G-25 (PD-10 desalting column, GE) using water as the eluent. The fraction containing the Pc conjugate was lyophilized to yield the pure conjugate as a blue solid (6.6 mg, 42%). HPLC, $t_r = 12.50$ min. MALDI-TOF MS *m/z* 4995.527 ($M + Na^+$), calcd for $C_{224}H_{365}N_{75}O_{50}ZnNa$ 4996.7577.

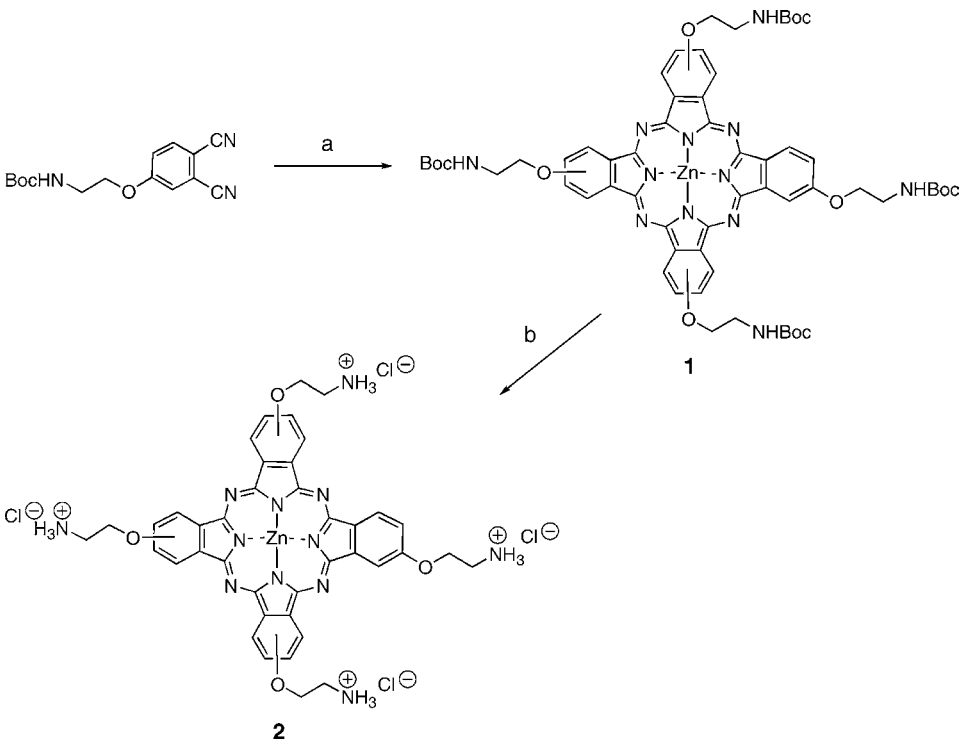
CD Studies. The CD measurements were carried out on a AVIV 620S Circular Dichroism Spectrometer, at a scan speed of 10 nm/min using quartz cells with 1 mm path length. 20 μM Pc−peptide conjugate solutions were prepared in water/TFE 9/1, and the pH adjusted to 7.0 using 0.1 M NaOH. All spectra correspond to an average of three separate experiments. All spectra were corrected by the baseline obtained for Pc−peptide conjugate free solutions.

Photophysical studies. All absorption spectra were acquired using a Perkin-Elmer Lambda 25 UV−vis spectrophotometer with 10 mm path length quartz cuvettes. Corresponding diluents were utilized as reference solutions. Emission spectra were obtained using a Fluorolog 3 spectrofluorometer. The optical density of solutions used for emission studies was below 0.05 at the excitation wavelength to eliminate inner filter effects. All the measurements were performed within 3 h of solution preparation. Anhydrous DMSO (Biotech grade) was purchased from Sigma-Aldrich and sodium phosphate from EMD. Milli-Q water (resistance 18 MΩ) was prepared in-house. Stock solutions (10 mM) of Pcs **2** and **3b** and conjugates **5** and **6** were prepared in DMSO The aqueous solutions were prepared by spiking 1.5−2 μL of the corresponding stock solutions into 1 mL of phosphate buffer. Phosphate buffers (100 mM) were prepared by dissolving appropriate amounts of the dibasic sodium phosphate in H_2O and adjusting pH using HCl and/or NaOH.

Calculations. The quantum yields were calculated using a secondary standard approach (*29*, *30*) with methylene blue, a dye with excitation/emission wavelengths similar to Pcs, and an established quantum yield. According to this approach, the integrated fluorescence intensity of the analyte (I) and standard (I_R), the optical density of the analyte (OD) and the standard (OD_R), and the refractive index of analyte solvent (n) and standard solvent (n_R) are related to the quantum yield of the analyte (Q) as

$$Q = Q_R \frac{I}{I_R} \frac{OD_R}{OD} \frac{n^2}{{n_R}^2}$$

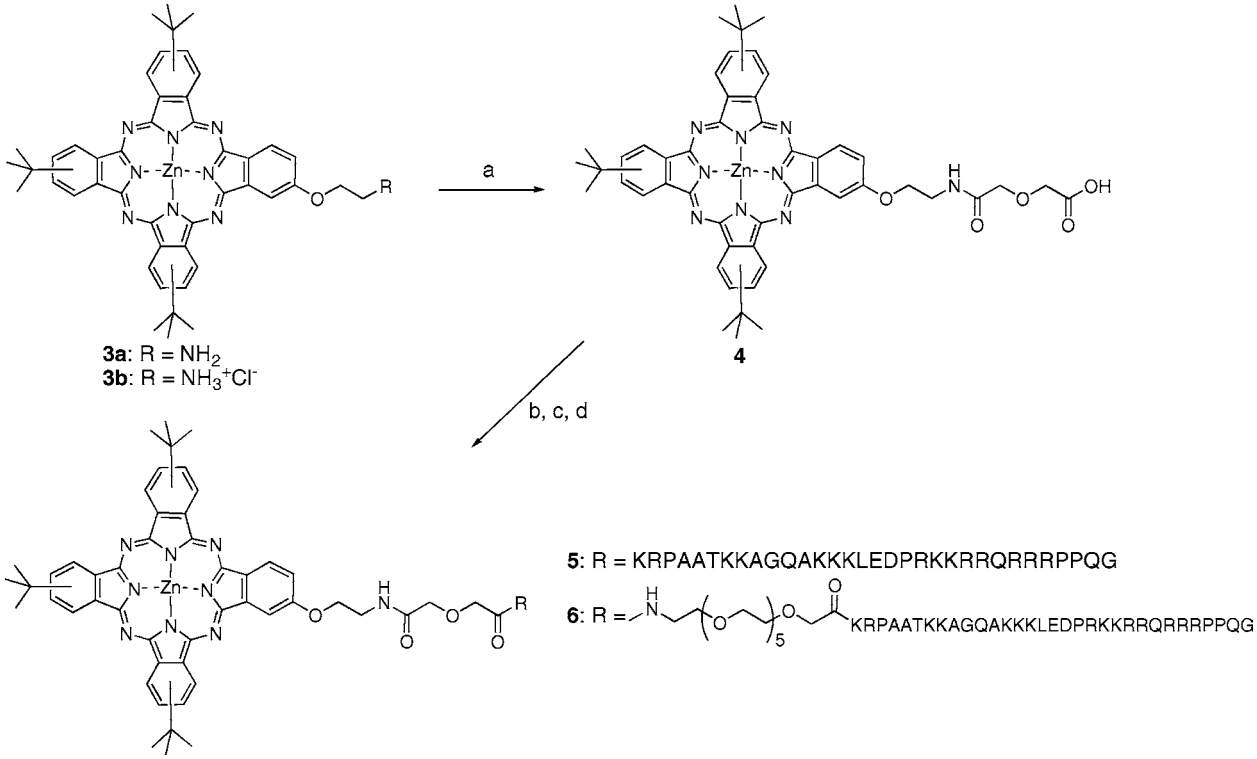
where Q_R is a quantum yield of the reference standard (0.03 for methylene blue). To account for incomplete spectra, the bands were extrapolated using appropriate fitting models whenever necessary.



Cell Culture. All tissue culture media and reagents were obtained from Invitrogen. Human HEp2 cells were obtained from ATCC and maintained in a 50:50 mixture of DMEM/advanced MEM containing 5% FBS. The cells were subcultured biweekly to maintain subconfluent stocks.

Time-Dependent Cellular Uptake. HEp2 cells were plated at 10 000 per well in a Costar 96 well plate and allowed to grow 36 h. Conjugate stocks of Pcs **2** and **3b** were prepared in DMSO, and Pc conjugates **5** and **6** were prepared in water at a concentration of 10 mM and then diluted into medium to final working concentrations. The cells were exposed to 10 μM of each conjugate for 0, 1, 2, 4, 8, and 24 h. At the end of the incubation period, the loading medium was removed and the cells were washed with 200 μL of PBS. Cells were solubilized upon addition of 100 μL of 0.25% Triton X-100 (Calbiochem) in PBS. To determine the Pc concentrations, fluorescence emission was read at 690/710 nm (excitation/emission) using a BMG FLUOstar plate reader. The cell numbers were quantified using the CyQuant reagent (Molecular Probes).

Cytotoxicity. The HEp2 cells were plated as described above and allowed 36−48 h to attach. For the dark cytotoxicity experiments, the cells were exposed to increasing concentrations of Pc conjugate up to 100 μM and incubated for 24 h. The loading medium was then removed, and medium containing Cell Titer Blue (Promega) was added to the cells as per manufacturer's instructions. The dark cell toxicity was then measured by reading the fluorescence at 520/584 nm using a BMG FLUOstar plate reader. The signal was normalized to 100% viable (untreated) cells and 0% viable (treated with 0.2% saponin from Sigma) cells. For the phototoxicity experiments, the HEp2 cells were prepared as described above, treated with Pc conjugate concentrations of 0, 0.625, 1.25, 2.5, 5, and 10 μM and incubated for 24 h. After compound loading, the medium was removed and replaced with medium containing 50 mM HEPES (pH 7.4). The cells were then placed on ice and exposed to light from a 100 W halogen lamp filtered through a 610 nm long pass filter (Chroma) for 20 min. An inverted plate lid filled with water to a depth of 5 mm acted as an IR filter. The total light dose was approximately 1 J cm^{-2}. The cells were returned to the incubator overnight and assayed for toxicity as described above.



Microscopy. The HEp2 cells were plated on LabTek 2 chamber coverslips and incubated for 36 h before being exposed to 10 μM of Pc and incubated for 24 h. For the colocalization experiments, the cells were incubated for 24 h concurrently with Pc and one of the following organelle tracers for 30 min: MitoTracker Green at 250 nM (mitochondria), LysoSensor Green at 50 nM (lysosomes), $DiOC_6$ at 5 μg/mL (ER), and BODIPY FL C_5-ceramide at 50 nM (Golgi network). The slides were washed three times with growth medium, and new medium containing 50 mM HEPES (pH 7.4) was added. Fluorescent microscopy was performed using a Zeiss Axiovert 200M inverted fluorescence microscope fitted with standard FITC and Texas Red filter sets (Chroma). The images were aquired with a Zeiss Axiocam MRM CCD camera fitted to the microscope.

Scheme 1 [a]

[a] Conditions: (a) $Zn(OAc)_2 \cdot 2H_2O$, DBN, DMAE (57%); (b) TFA/CH_2Cl_2 rt/2h, then NaOH followed by HCl (52%).

Scheme 2 [a]

[a] Conditions: (a) diglycolic anhydride/DMF rt/24 h (97%); (b) HOBt/TBTU/DIEA/peptidyl-PEG-PAL resin/DMF 24 h, then TFA/H_2O/phenol/TIS 88/5/5/2 (42−57%); (c) HOBt/TBTU/DIEA/$NH_2CH_2CH_2(OCH_2CH_2)_5OCH_2CO_2{}^tBu$/DMF, rt/24 h (40%); (d) $TFA/CHCl_3$ 1/1, 4 h/rt, quantitative yield.

RESULTS

Synthesis. The synthetic route to water-soluble Zn−Pc **2** is shown in Scheme 1. Zn−Pc **2** was prepared in good yield from Zn−Pc **1** by deprotection of the Boc groups using TFA, followed by neutralization with NaOH to afford the tetra-amino-substituted Pc and final treatment with HCl. The tetraBoc-protected Zn−Pc **1** was synthesized in 57% yield by tetramerization of 4-(2-*tert*-butoxycarbonylaminoethoxy)phthalonitrile using zinc acetate as the template, DMAE as the solvent, and DBN as the catalyst, following a standard procedure for the synthesis of Pcs (*31*). Zn−Pc **3**, containing either a single amino group (**3a**) or quaternary ammonium salt (**3b**) (upon acidifica-

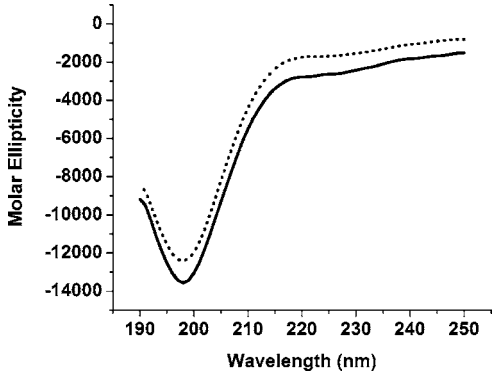


Figure 1. Pc conjugates **5** (full line) and **6** (dotted line) in TFE/H_2O 1/9 at pH 7.0 and 20 μM concentration. The molar ellipticity is given in deg cm^2 dmol^{-1}, cell path was 0.1 cm, and the temperature 25 °C.

tion), was also prepared following a known methodology (*31*). Two Pc−peptide conjugates were prepared from amino-Pc **3a** as shown in Scheme 2 in order to improve its water solubility and to reduce Pc aggregation in aqueous media. Conjugates **5** and **6** were designed to contain a bifunctional peptide bearing both an NLS and cell-penetrating peptide sequences attached to the Pc via either a short (9 atom) or long (30 atom) linker. The NLS corresponding to nucleoplasmin (*32*) and the HIV-1 Tat 48−60 cell-penetrating sequence (*24*) were chosen in order to obtain amphiphilic Pc conjugates **5** and **6** with higher cell-penetrating ability and improved biological activity. This bifunctional nucleoplasmin−HIV-1 Tat peptide sequence, KRPAATKKAGQAKKKLEDPRKKRRQRRRPPQG, was synthesized using Fmoc solid-phase synthesis methodology (*33*), and the heterofunctional PEG linker $^tBuO_2CCH_2O(CH_2CH_2O)_5CH_2CH_2NH_2$ was prepared as previously described in the literature (*34*). The reaction of Pc **3a** with diglycolic anhydride in DMF gave Pc **4** in 97% yield (Scheme 2), thus providing a free carboxylic acid group for conjugation to either the peptide or the Boc-protected PEG linker. The coupling of the hydroxybenzotriazole ester of Pc **4** with $^tBuO_2CCH_2O(CH_2CH_2O)_5CH_2CH_2NH_2$ in solution using TBTU as the coupling agent gave the corresponding Boc-protected PEG−Pc in 40% yield after purification by flash chromatography on silica gel. The deprotection of the Boc group in $CHCl_3$/TFA 1:1 was achieved in quantitative yield. The solid-phase conjugation of the carboxylate-functionalized Pcs to the bifunctional peptide produced conjugates **5** and **6**, respectively, bearing either a short or a PEG-containing long linker between the peptide and the Pc moieties. The carboxylates were initially converted to the corresponding reactive hydroxybenzotriazole esters and then coupled to the peptidyl−PAL−PEG−PS resin using TBTU as the coupling agent; after cleavage and deprotection from the solid support using TFA/phenol/TIS/H_2O, 88/5/2/5, the water-soluble Pc conjugates **5** and **6** were isolated by reverse-phase HPLC in 57% and 42% yield, respectively.

The structures of the Pc conjugates **5** and **6** were confirmed by MS, NMR, CD, and UV−vis and fluorescence spectrophotometry (vide infra). CD was used to determine the secondary structure of the peptide sequences on the Pc conjugates in solution. The CD spectra of conjugates **5** and **6** in water/TFE 9/1 at pH 7.00 were measured in the amide region (190−250 nm). As shown in Figure 1, both conjugates show negative Cotton effects; for Pc **5**, $[\Phi]_{MRW} = -13\,560$ deg cm^2 dmol^{-1} at 198 nm, and for Pc **6**, $[\Phi]_{MRW} = -12\,416$ deg cm^2 dmol^{-1} at 198 nm. These CD spectra indicate that the peptide sequences conjugated to the Pc macrocycle by either the short or long linkage adopt random coil conformations under the conditions studied; peptides adopting a random coil structure usually exhibit a single negative Cotton effect at 198 nm (for example, for polylysine at pH 7, $[\Phi]_{MRW} = -41\,900$ deg cm^2 dmol^{-1} at 197 nm (*35*)).

Photophysical Studies. The spectral characteristics observed for Zn−Pcs **2** and **3b** and conjugates **5** and **6** in DMSO and water at different pH values are summarized in Table 1. The absorption and emission properties for the Pcs and conjugates studied were found to be strongly dependent on their structure and aggregation state. With the exception of Pc **2**, where partial aggregation was observed in DMSO as noted from the relatively strong absorption band appearing at 628 nm (Supporting Information Figure S3), no evidence of aggregation was observed in DMSO for Pc **3b** or the Pc conjugates **5** and **6** (Supporting Informatio Figures S4−S6). However, in buffered aqueous solutions, both Pcs **2** and **3b** were strongly aggregated as evidenced in the broadening of the Q-band absorption and bathochromic and hypsochromic shifts (Supporting Information Figures S3 and S4). Pc **3b** did not exhibit fluorescence at any of the pH values investigated (5.0, 6.0, 7.0, 7.4, and 8.0), while Pc **2** fluoresced only at pH 5.0 but with a very small quantum yield (0.00011; see Table 1). In DMSO, the fluorescence quantum yield determined for Pc **3b** was 10 times higher than that of Pc **2**, although the observed Stokes shift was smaller for **3b** (see Table 1). The absorption spectra for Pc conjugates

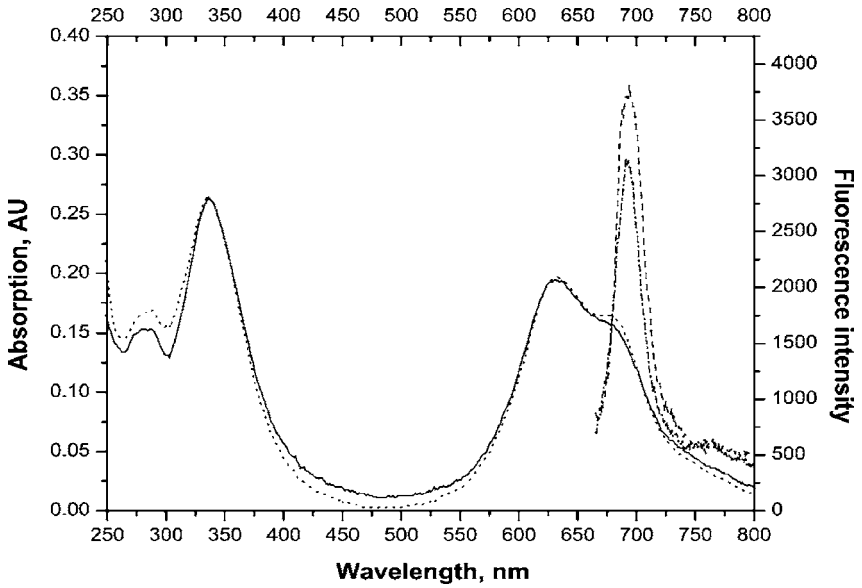

Figure 2. Absorption and emission spectra of Pcs **5** and **6** in 100 mM phosphate buffer, pH 7.4: absorption of **5** (dot line), absorption of **6** (solid line), emission of **5** (dash line), emission of **6** (dash−dot line).

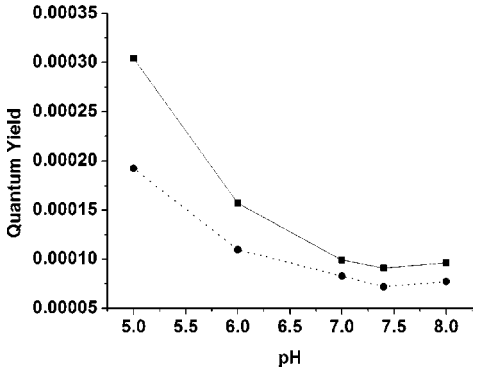

Figure 3. Fluorescence quantum yields in 100 mM phosphate buffer at different pH values of Pc conjugate **5** (full line) and Pc conjugate **6** (dot line).

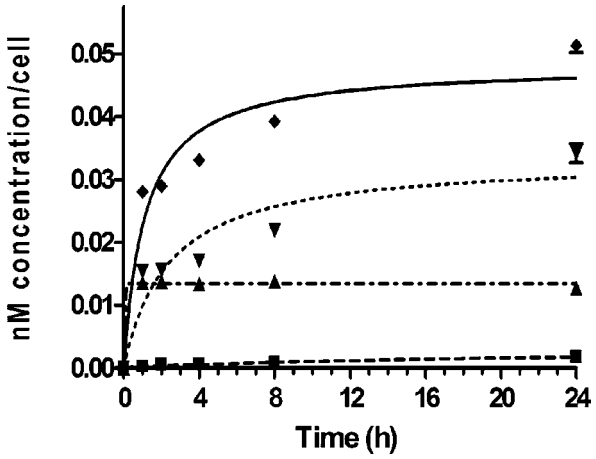

Figure 4. Time-dependent uptake of Pcs **2** (dash−dot−dash), **3b** (dash), conjugate **5** (dot), and conjugate **6** (full line) at 10 μM by HEp2 cells.

5 and **6** in aqueous solutions (Figure 2 and Supporting Information Figures S5 and S6) also showed evidence of ground-state aggregation as indicated by the blue-shifted and broad Q bands. No significant effect of the pH on the position and shape of the absorption bands was observed within the range studied for Pc conjugates **5** and **6** (Supporting Information Figures S3 and S4). Nevertheless, both Pc conjugates **5** and **6** fluoresced in aqueous solutions at all pH values studied (Figure 2 and Supporting Information Figures S5 and S6). The fluorescence quantum yields for Pc conjugates **5** and **6** were found to be 0.14 and 0.17 in DMSO, respectively, and these compounds also displayed measured fluorescence in all the pH values investigated but were generally found to increase as the pH value was decreased (see Figure 3). Pc conjugate **5** exhibited a higher quantum yield at all pH values studied compared to Pc conjugate **6**.

Cellular Studies. The results obtained for the time-dependent uptake of Zn−Pcs **2** and **3b** and conjugates **5** and **6** at a concentration of 10 μM in human HEp2 cells are shown in Figure 4. As expected, Pc conjugates **5** and **6** bearing the bifunctional peptide nucleoplasmin-HIV-1 Tat 48−60 accumulated to a significantly higher extent within cells than Pcs **2** and **3b**. The extent of conjugate uptake was dependent on the nature of the linker between the Pc and the peptide moieties; conjugate **6** containing a long PEG−linker was taken up by cells to a higher extent than conjugate **5**, which possesses a short linker. On the other hand, the cellular uptake of the unconjugated Zn−Pcs **2** and **3b** depended significantly on the number of quaternary ammonium groups at the Pc periphery, i.e., Zn−Pc **2** exhibited higher uptake than Zn−Pc **3b**, bearing only one quaternary ammonium group. Similar uptake kinetics were observed for Pc conjugates **5** and **6**; both conjugates accumulated rapidly in the first 2 h, and from 2 to 24 h, their uptake was considerably slower. Zn−Pc **2** also accumulated within cells very rapidly in the first 30 min, and after this time, a plateau was reached. On the other hand, Zn−Pc **3b** accumulated steadily over time during the 24 h period studied but at a much lower extent when compared with Pcs **2**, **5**, and **6**.

The dark and phototoxicity of Pcs **2**, **3b**, **5**, and **6** were evaluated in human HEp2 cells exposed to increasing concentrations of each Pc for 24 h as shown in Figures 5 and 6, respectively. Pc **3b**, the least accumulated within cells (see Figure 4), showed no toxicity in the dark at concentrations up to 100 μM. On the other hand, Pc **2** and conjugates **5** and **6** exhibited low dark toxicity with determined IC_{50} = 70.9, 77.6, and 87.3 μM, respectively (see Figure 5). Upon exposure to a low light dose (1 J cm^{-2}), conjugates **5** and **6** were the most phototoxic to the HEp2 cells, with IC_{50} = 1.44 and 1.87 μM, respectively. Zn−Pc **3b**, bearing only one quaternary ammonium

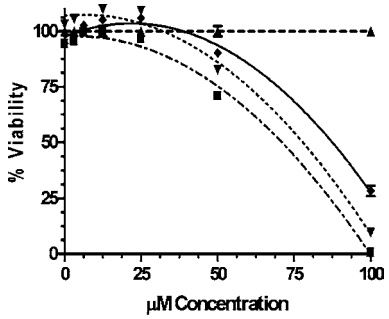

Figure 5. Dark toxicity of Pcs **2** (dash−dot−dash), **3b** (dash), conjugate **5** (dot), and conjugate **6** (full line) toward HEp2 cells using the Cell Titer Blue assay, after 24 h incubation time.

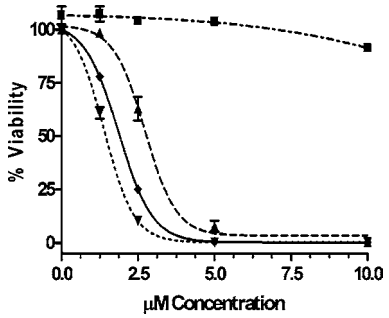

Figure 6. Phototoxicity of Pcs **2** (dash−dot−dash), **3b** (dash), conjugate **5** (dot), and conjugate **6** (full line) toward HEp2 cells using 1 J/cm^2 dose light, after 24 h incubation time.

group, also exhibited high phototoxicity, with $IC_{50} = 2.78\ \mu M$ (see Figure 6).

The subcellular localization of Pcs **3b**, **5**, and **6** was investigated in HEp2 cells using fluorescence microscopy. Figures 7−9 show the fluorescent images observed for Pcs **3b**, **5**, and **6** after 24 h incubation time, and their overlay with the organelle-specific fluorescent probes LysoSensor Green (lysosomes), Mitotracker Green (mitochondria), $DiOC_6$ (ER), and BODIPY Ceramide (Golgi). Due to the low fluorescence signal observed for Zn−Pc **2** as a result of its aggregation under the experimental conditions, the main sites of subcellular distribution of this Pc were not determined. Pcs **3b**, **5**, and **6** all showed a punctuate fluorescence pattern in the cytoplasm. While Pc **3b** was observed in both the lysosomes and the Golgi, the preferential sites of intracellular localization for Pc conjugates **5** and **6** were found to be the lysosomes.

DISCUSSION

Pc conjugates **5** and **6** were prepared from mono-amino Pc **3a** (Scheme 2) and their photophysical and cellular properties investigated and compared with those of Pcs **2** (Scheme 1) and **3b** containing, respectively, 4 and 1 quaternary ammonium groups. Conjugates **5** and **6** were designed to contain a bifunctional peptide sequence bearing NLS and cell-penetrating peptides attached to the Pc via either a short or a long (PEG-containing) linker. The conjugation of drugs to fusogenic and/or organelle-directing peptides is a strategy often used to improve their water solubility, cellular uptake, and biological efficacy (*22*−*28*, *36*). Since aggregation in aqueous media of Pc-type compounds is known to deeply influence their photosensitizing properties (*37*), we conjugated Zn−Pc **3a** to a bifunctional peptide and investigated the effect of a short (9 atom) and a long (30 atom) PEG-containing linker between the Pc and peptide moieties. The low molecular weight PEG linker was used to minimize possible intramolecular interactions between the Pc and the peptide chain, as we have previously observed with short linkers in porphyrin−peptide conjugates

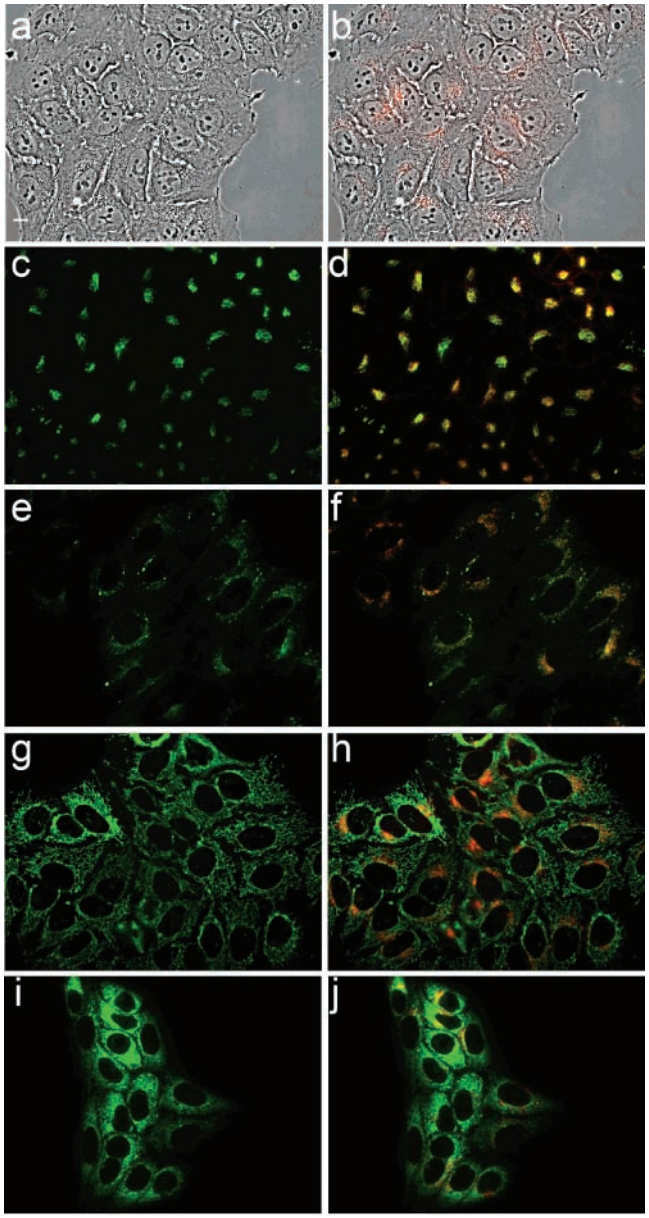

Figure 7. Subcellular localization of Pc **3b** in HEp2 cells at 10 μM after 24 h: (a) phase contrast, (b) overlay of Pc **3b** fluorescence and phase contrast, (c) BODIPY Ceramide fluorescence, (e) LysoSensor Green fluorescence, (g) MitoTracker Green fluorescence, (i) $DiOC_6$ fluorescence, (d,f,h,j) overlays of organelle tracers with Pc **3b** fluorescence. Scale bar: 10 μm.

(*38*), and to enhance the water solubility of the conjugate. The pegylation of drugs to improve their pharmacokinetic properties has been extensively used, and it is known that PEG−drug conjugates display enhanced water solubility, serum life, and tumor accumulation (*39*). A low molecular weight PEG was chosen over a high molecular weight PEG in order to avoid the formation of mixtures due to the polydispersity of the high molecular weight PEG (*40*). The synthesis of the amino−Pcs **2** and **3** followed a known methodology for the preparation of Pc macrocycles (*31*), involving the tetramerization of phthalonitriles under basic conditions.

The CD spectra for Pc conjugates **5** and **6** were obtained in aqueous TFE at pH 7.0, thus mimicking the cell membrane environment, in order to investigate the preferred conformation of the peptide chains. The peptide conformation is known to influence the mode of translocation of the Pc conjugates across membranes and their binding to biomolecules for trafficking within the cell. Our CD studies (see Figure 1) indicate that the

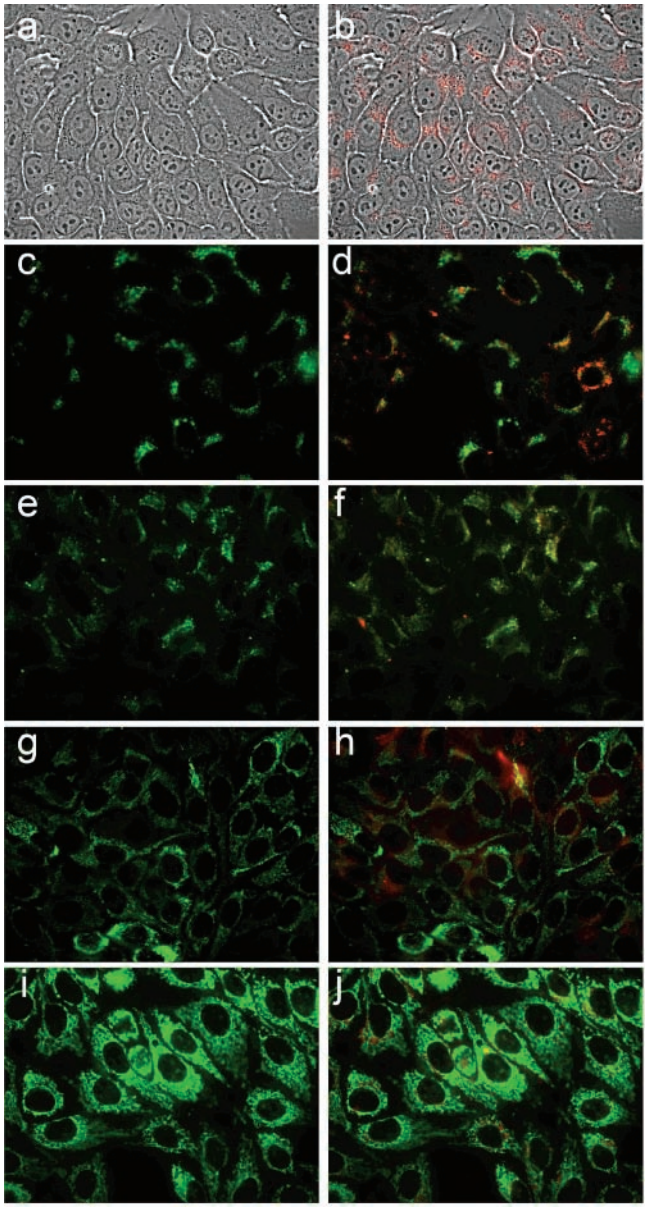

Figure 8. Subcellular localization of Pc cnjugate **5** in HEp2 cells at 10 μM after 24 h: (a) phase contrast, (b) overlay of Pc **5** fluorescence and phase contrast, (c) BODIPY Ceramide fluorescence, (e) LysoSensor Green fluorescence, (g) MitoTracker Green fluorescence, (i) $DiOC_6$ fluorescence, (d,f,h,j) overlays of organelle tracers with Pc **5** fluorescence. Scale bar: 10 μm.

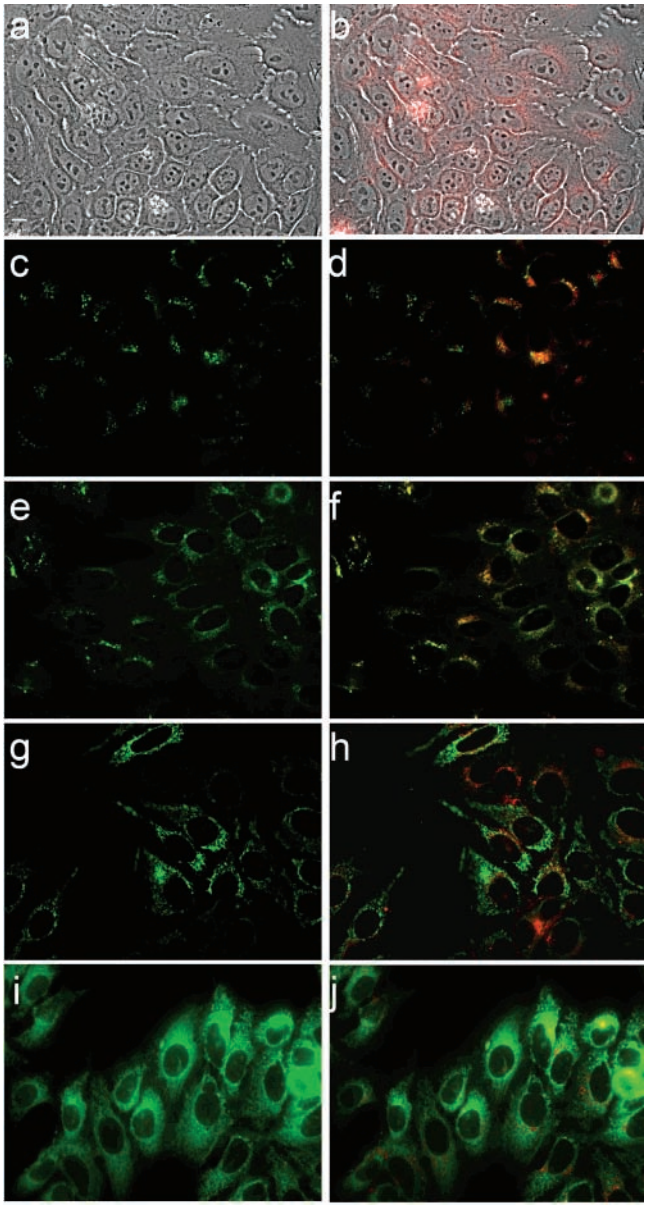

Figure 9. Subcellular localization of Pc conjugate **6** in HEp2 cells at 10 μM after 24 h: (a) phase contrast, (b) overlay of Pc **6** fluorescence and phase contrast, (c) BODIPY Ceramide fluorescence, (e) LysoSensor Green fluorescence, (g) MitoTracker Green fluorescence, (i) $DiOC_6$ fluorescence, (d,f,h,j) overlays of organelle tracers with Pc **6** fluorescence. Scale bar: 10 μm.

peptides conjugated to the Pc macrocycle in **5** and **6** adopt random coil rather than helix conformations under the conditions tested. These results are in agreement with the crystal structure reported for the complex importin α/nucleoplasmin (155−170, KRPAATKKAGQAKKKK), a protein involved in nuclear import (*41*). In this complex, the nucleoplasmin 155−170 sequence in an extended conformation binds at the minor and major binding sites of importin α. On the other hand, previous CD studies reported for the Tat protein have shown that the highly basic region from 48 to 60 (i.e., RKKRRQRRRRPPQ) forms part of the N-terminus domain of the coat protein that is located toward the interior of the virus (*42*). This stretch of basic residues adopts an extended conformation due to the electrostatic repulsion between the positively charged side groups.

The fluorescence quantum yields determined in DMSO for Zn−Pcs **2**, **3b**, and conjugates **5** and **6** (see Table 1) are in agreement with previous values reported for Zn−Pcs (*43*). Inspection of the electronic absorption spectra in aqueous solutions indicated that Pc **2** showed minimal aggregation effects at low pH due to protonation of the amino groups, while Pc **3b** and conjugates **5** and **6** did not display significant changes in their electronic spectra at different pH values, indicating no significant change in their aggregation states. Because cells display marked heterogeneity in local pH and tumor cells usually exhibit lower pH than normal cells, we investigated the pH dependence on the spectral properties of the Pcs included in this study (*44*). We observed that, while Pc **3b** did not exhibit fluorescence in any of the aqueous solutions (pH = 5.0−8.0), Pc **2** fluoresced only at pH 5.0, possibly due to reduced aggregation. This supposition is supported by the ground-state spectrum at pH = 5.0, which showed partial restoration of the Q band at this pH value. Zn−Pcs usually form aggregates in aqueous solutions, and these species typically display reduced fluorescence (*45*). Interestingly, Pc conjugates **5** and **6** showed fluorescence at all pH values with slightly higher quantum yields at pH = 5.0 even though their electronic spectra were relatively

unaffected by the solution pH. Pc conjugate **5**, bearing a short linker to the bifunctional peptide, exhibited higher fluorescence quantum yields at all pH values studied and a larger Stokes shift compared to Pc conjugate **6**. The difference in quantum yields observed for conjugates **5** and **6** may be attributed to the nature of the linker between the Pc and the peptide chain. The long PEG-containing linker is more flexible and therefore may adopt multiple conformations in aqueous solutions due to its amphiphilic character (*46*). Furthermore, the association of PEG chains to water molecules (approximately 2−3 water molecules per ethylene oxide unit) might lower the fluorescence quantum yield of conjugate **6** as compared with that of **5**.

The cellular uptake of all Pcs studied is dependent on the nature of the groups at the Pc periphery and on the overall molecular charge. Pc conjugates **5** and **6** bearing the bifunctional peptide nucleoplasmin-HIV-1 Tat 48−60 accumulated within cells to a significantly higher extent than Pcs **2** and **3b**. The high cellular uptake of the conjugates might be due to the presence of the guanidinium groups on the HIV-1 Tat sequence and the ammonium groups on the nucleoplasmin sequence, which can form hydrogen bonds with membrane phosphate groups (*26*, *47*), thus promoting endocytosis. Zn−Pc **2** bearing four quaternary ammonium groups at physiologic pH also exhibited significantly higher uptake than Pc **3b**, which only possesses one quaternary ammonium group. These results are in agreement with previous studies showing that the overall molecular charge and its distribution at the Pc periphery play an important role on the cellular uptake of these photosensitizers (*48*). Pc **3b**, the least accumulated within cells, showed no toxicity at concentrations up to 100 μM in the dark. On the other hand, Pc **2** and conjugates **5** and **6** exhibited $IC_{50} = 70.9$, 77.6, and 87.3 μM, respectively. Upon exposure to low light dose (1 J cm^{-2}), conjugates **5** and **6** bearing the peptide chain were the most phototoxic to cells ($IC_{50} = 1.4$ and 1.9 μM, respectively). Surprisingly, Pc **3b**, which showed the lowest cellular uptake and no dark cytotoxicity up to 100 μM concentration, exhibited high phototoxicity (IC_{50} of 2.8 μM). This result may be attributed to (a) its subcellular localization within more sensitive cell compartments (lysosomes and Golgi), (b) its possible relocalization after light irradiation, and/or (c) the decrease in aggregation (and consequently higher fluorescence) within the cell due to interaction with lipid membranes and/or change in pH. The reactive oxygen species produced in PDT can induce apoptosis through the Golgi network (*49*), and the cell lysosomes are also an important PDT target (*50*). Our results indicate, as has been previously reported (*4*), that not only the amount of photosensitizer within the cell, but also its subcellular distribution, determines its biological efficacy. Whereas Pc **3b** localized preferentially within the cell lysosomes and Golgi, conjugates **5** and **6** were observed mainly in the lysosomes, possibly due to their favored endocytic uptake. Although both Pc conjugates **5** and **6** contain an NLS nucleoplasmin sequence, the cell nucleus is not their main localization site; however, it is possible that after light exposure conjugates **5** and **6** could be released from the lysosomes and relocalize within more sensitive organelles, such as the nuclei, ER, and Golgi, as has been previously observed for Zn−Pcs (*7b*, *48*).

ACKNOWLEDGMENT

The authors thank Ms. Martha Juban for peptide synthesis. This work was supported by the National Science Foundation, grant numbers CHE-304833 and EPS-0346411, the State of Louisiana Board of Regents, the Spanish Government (CICYT grant no. MAT2005-07369-C03-02), and the Spanish Generalitat Valenciana (grant no. ACOMP06/054-2005).

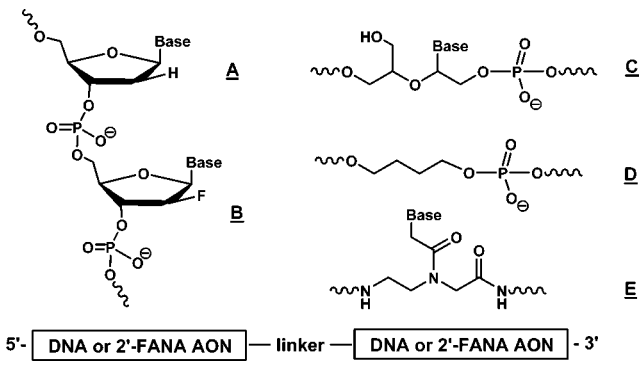
Induction of RNase H Activity by Arabinose−Peptide Nucleic Acid Chimeras

Bénédicte M. Pâtureau,[†] Robert H. E. Hudson,*[,‡] and Masad J. Damha*[,†]



Department of Chemistry, McGill University, Montreal, Quebec, Canada H3A 2K6, and Department of Chemistry, The University of Western Ontario, Ontario, Canada N6A 5B7. Received September 25, 2006; Revised Manuscript Received November 27, 2006

We report the syntheses of chimeras of peptide nucleic acid (PNA) with DNA and 2′-deoxy 2′-fluoroarabinonucleic acid (2′-FANA). Chimeric oligomers possessing a single central PNA insert were capable of forming hybrid duplexes with complementary RNA, although with diminished thermal stability in comparison to the unmodified oligomers. We subsequently determined the ability of the DNA and 2′-FANA oligomers of mixed-base composition to elicit human RNase H1 degradation of complementary RNA that was either unstructured or as a hairpin. In the case of the more rigid FANA strand, a PNA insert led to a higher ability of the chimera to direct the degradation of both types of RNA targets. Generally, the enhancement observed was greater for a butanediol linker than for a more rigid PNA linker. Along with previous work, these studies suggest that the general flexibility associated with an acyclic insert (e.g., butyl vs PNA)—and not necessarily the presence of local structural imperfections in the heteroduplex—is beneficial for RNase H1 activity. As well, there are implications to the charge nature of non-nucleotide inserts (neutral vs negative) and their ability to maintain RNase H activity that may serve to direct further design considerations. Together, these studies support the notion that flexibility of antisense oligonucleotide (AON)/RNA hybrids is essential for high RNase H catalysis, in which an enzyme-induced altered trajectory of the bound AON/RNA substrate could facilitate optimal interaction with the catalytic site of RNase H.

INTRODUCTION

The ability of antisense oligonucleotides (AONs) to specifically bind to a single-stranded RNA via Watson−Crick complementary hybridization represents an attractive and increasingly important practical strategy for inhibition of gene expression. AONs are short, chemically modified oligonucleotide sequences designed to possess good exo- and endonuclease resistance, sufficient cell penetration, and good affinity for the target mRNA (*1*). An attractive mechanism for suppression of gene expression involves specific mRNA hydrolysis via activation of the ubiquitous intracellular enzyme RNase H (*2*). Although the origins of the substrate specificity of RNase H are not well-defined yet, structural analysis of modified AONs capable of eliciting this enzyme highlights a common feature: an O4′-*endo* sugar pucker that leads to the formation of a helical conformation intermediate between pure A- and B-forms (*3*, *4*). The discovery that [3.3.0]*bc*-ANA satisfies the conformational requirement for RNase H recognition and cleavage, without activating this enzyme, revealed the importance of flexibility within the AON strand (*3*, *5*). We therefore hypothesized that both preorganization and flexibility are two important criteria for the ability of an AON to elicit RNase H activity and thus for their therapeutic potential (*6*). This prompted us to examine the properties of known RNase H-active AONs such as DNA and 2′-FANA containing acyclic 2′,3′-secouridine (Chart 1**C**) or butanediol (**D**) linkers (*6*). 2′-FANA AONs incorporating a butyl linker showed RNase H induction with comparable efficiency to the native DNA strands, a result that is further supported by the present study. Unfortunately, a substantial decrease in the thermal stability imparted by the flexible, abasic linker, reduces its practical utility in AONs.

Chart 1[a]

[a] Top: Chemical structure of modified oligonucleotides. **A**, DNA; **B**, 2′-FANA; **C**, 2′,5′-secouridine residue; **D**, butanediol linker; **E**, peptide nucleic acid. Bottom: AON design.

Thus, we next turned our attention to a peptide nucleic acid (PNA) linker (Chart 1**E**) (*7*), which, due to the presence of an amide bond, is rendered comparably less flexible than the hydrocarbon linkers previously examined by our group (*6*), and conceivably more likely to engage in interactions with the opposing RNA residue of the formed heteroduplex. As a PNA insert also possesses an acyclic structure, and therefore some inherent flexibility relative to the native furanose framework, we surmised that its introduction in place of an aliphatic linker within the AON strand might also result in elevated RNase H activity. In the present work, we evaluate the affinity of DNA and 2′-FANA oligonucleotides containing one or three PNA inserts toward complementary DNA and RNA and compare their ability to elicit RNase H1 to native and butyl-modified AON oligonucleotides. This allowed us to assess the charge nature of non-nucleotide inserts (neutral vs negative) and their impact on RNase H activity.

Scheme 1[a]

[a] Reagents: (a) $ClCH_2CO_2H$, $NaOH/H_2O$, Reflux (85%); (b) $ClCH_2CO_2H$, 4 °C, (51%, 2 Steps); (c) MMT−Cl, CH_2Cl_2, $NEt(i\text{-}Pr)_2$, Overnight (50%, after Chromatography); (d) DCC, 24 h (65%); (e) 1M NaOH, 0 °C, (75%).

Scheme 2[a]

[a] Reagents: (a) PPh_3, NaN_3, CBr_4, Dry DMF, Overnight (80%); (b) PPh_3, Pyridine, H_2O, 3 h; (c) MMT−Cl, 4-DMAP Pyridine, Overnight (30% over Two Steps); (d) $Cl-P(OCE)N(i\text{-}Pr)_2$, DIPEA, THF, 2.5 h (80%).

EXPERIMENTAL PROCEDURES

Synthesis of Monomers. The *N*-(2-aminoethyl)glycine-based thymine PNA monomer was prepared according to literature precedent with minor modifications to the procedures (Scheme 1) (*8*−*12*). 2′-FANA phosphoramidites were synthesized according to established procedures (*13*) and DNA phosphoramidites purchased from ChemGenes Corp. (Ashland, MA) were used as received. The 5′-amino-dC derivative required for the PNA insertion was synthesized as described in Scheme 2). All standard 5′-*O*-dimethoxytrityl-3′-*O*-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidites of the various 2′-deoxy- and ribonucleosides, 5′-monomethoxytritylamino-2′,5′-dideoxythymidine-3′-phosphoramidite, and the phosphitylation reagent used for derivatization [*β*-cyanoethyl-(*N*,*N*-diisopropylamino) phosphorchloridite] were purchased from ChemGenes Corp. (Ashland, MA).

Synthesis of Thymin-1-yl Acetic Acid (1). Thymin-1-yl acetic acid was prepared as previously described (*8*). Briefly, thymine (10.0 g, 79.0 mmol) was dissolved in 100 mL of water, by heating to reflux, which contained 9.0 g (160 mmol) of KOH. To this solution was slowly added chloroacetic acid (7.6 g, 80 mmol) dissolved in 25 mL of water. The pH was maintained at approximately 10 while the solution was refluxed for 2 h. Upon acidification with concd HCl, the acid (**1**) precipitated (12.4 g, 85%) and was subsequently carefully recrystallized from water. Mp 260−262 °C. EI MS: calcd 184.15, found 184 (M^+, 40%), 140 ($-CO_2$, 50%), 96 (100%).^{1}H NMR (400 MHz, DMSO-d_6): 13.10 (br s, 1H), 11.33 (s, 1H), 7.49 (s, 1H), 4.35 (s, 2H), 1.74 (s, 3H). ^{13}C NMR (100 MHz, DMSO-d_6): 169.9, 164.6, 151.3, 142.2, 142.0, 108.6, 48.7.

Methyl *N*-(2-Aminoethylglycinate)dihydrochloride (2). *N*-(2-Aminoethyl)glycine was prepared according to the method of Heimer et al. (*9*). Neat ethylenediamine (500 mL, 7.5 mol) was rapidly stirred while being cooled in an ice bath (4 °C). Solid chloroacetic acid (75 g, 0.79 mol) was added in ten portions allowing for complete dissolution between each addition. The reaction mixture was then stirred overnight at room temperature. The unreacted ethylenediamine was removed by evaporation under vacuum and later recycled. The remaining paste was triturated with DMSO and then filtered, and the solid cake was washed with DMSO and then diethyl ether. The white solid was of sufficient purity to carry on to the next step without recrystallization (51 g, 55%). Recrystallization may be done in methanol to give white plates, mp 159−161 °C. ^{1}H NMR (400 MHz, D_2O): 3.03 (s, 2H), 2.79 (app t, J = 6.5 Hz, 2H), 2.66 (app t, J = 6.5 Hz, 2H). ^{13}C NMR (100 MHz, D_2O): 177.9, 51.3, 46.2, 38.3. Compound **2** was prepared by Fischer esterification of the parent acid (*11*). *N*-(2-Aminoethyl)glycine (15.0 g, 127 mmol) was suspended in 700 mL of methanol that was saturated with gaseous, dry HCl. The mixture was refluxed for 12 h, and the product was collected at room temperature. Subsequent crops were obtained by cooling the mother liquor to −20 °C and again by reducing the volume and cooling. Yield: 24 g, 92%. Mp 190−192 °C. ^{1}H NMR (400 MHz, DMSO-d_6): 8.58 (br s, 3H), 4.05 (s, 2H), 3.68 (s, 3H), 3.26 (m, 2H), 3.18 (m, 2H). ^{13}C NMR (100 MHz, DMSO-d_6): 166.9, 52.8, 46.7, 44.0, 35.0.

Methyl *N*-(2-Monomethoxytritylaminoethylglycinate) (3) (*10*, *11*). Methyl *N*-(2-aminoethylglycinate) dihydrochloride (1.0 g, 4.9 mmol) was stirred in 20 mL of CH_2Cl_2 containing 1 mL of Hünig's base while being cooled in an ice bath (4 °C). To this slurry was dropwise added a solution of 1.2 equiv of monomethoxytrityl chloride (1.8 g, 5.8 mmol) in CH_2Cl_2. The mixture was stirred for 12 h at room temperature, after which the reaction was quenched by the addition of 5 mL CH_3OH, diluted with 100 mL of CH_2Cl_2 and was extracted (3 × 100 mL sat $NaHCO_3$, 3 × 100 mL brine), dried (anhydrous sodium sulfate), and the solvent was evaporated to yield a sticky off-white foam. TLC analysis (2:1 diethyl ether, hexanes with 1% NEt_3) was done with silica gel plates that had been pretreated with eluent and indicated the presence of monomethoxytritanol and methyl monomethoxytrityl ether, as well as unreacted started material as likely impurities. The desired product was visualized by UV shadowing, staining with HCl vapor and ninhydrin. R_f = 0.16. Isocratic silica gel column chromatography was done (60:30:1 diethyl ether/hexanes/triethylamine) to yield a viscous yellow oil (50%), as previously reported (*11*). ^{1}H NMR (400 MHz, $CDCl_3$): 7.47−6.79 (m, 14H), 3.77 (s, 3H), 3.71 (s, 3H), 3.48 (s, 2H), 2.73 (t, J = 5.6 Hz, 2H), 2.27 (t, J = 5.6 Hz, 2H), 1.89 (br s, 2H).

Methyl *N*-(2-Monomethoxytritylaminoethyl)-*N*-(thymin-1-yl) Glycinate (4). Compounds **1** and **3** were condensed to give the PNA monomer ester. Equimolar amounts of **1** (166 mg, 0.9 mmol), DCC, and HOBt were dissolved in dry DMF (3 mL) and stirred for 30 min. After the appearance of a heavy white precipitate (DCU), a solution of **3** (125 mg, 0.3 mmol) in 2 mL of DMF which contained a catalytic amount of 4-DMAP was added dropwise. The suspension was stirred for 1 h; then, 2 equiv Hünig's base was added, and stirring was continued for an additional 12 h, after which time TLC analysis (as above) indicated complete consumption of **3**. The mixture was then filtered to remove the DCU and diluted with 100 mL of CH_2Cl_2 and extracted (3 × 100 mL sat $NaHCO_3$, 2 × 100 mL brine). After drying (Na_2SO_4), removal of the solvent by evaporation gave a crude product that was purified, without chromatography, by precipitation of an ethereal solution with hexanes (65% yield). Two rotamers were observed: major (ma.) and minor (mi.). ^{1}H NMR (400 MHz, DMSO-d_6): 11.32 (br s, 1H), 7.41−6.84 (m, 15H), 4.84 (ma.) and 4.53 (mi.) (s, 2H),

4.46 (mi.) and 4.09 (ma.) (s, 2H), 3.72 (s, 3H), 3.69 (mi.) and 3.58 (ma.) (s, 3H), 3.49 (ma.) and 3.37 (mi.) (m, 2H), 2.15 (ma.) and 2.08 (mi.) (m, 2H), 1.76 (s, 3H).

***N*-(2-Monomethoxytritylaminoethyl)-*N*-(thymin-1-yl)-glycine (5)** (*12*). Compound **4** was hydrolyzed to the free acid by treatment for 1 h with equal volumes of 2 M NaOH and methanol at 4 °C. The pH of the solution was then adjusted to 4−5 by dropwise addition of aqueous NaH_2PO_4 and the title compound isolated by repeated extraction into ethyl acetate. The organic fractions were pooled, dried over anhydrous sodium sulfate, and the solvent was removed by evaporation to yield a white solid. The crude product was purified by repeated trituration with diethyl ether, and the purified product was consistent with previous reports and isolated in 75% yield (*12*). Two rotamers were observed: major (ma.) and minor (mi.). ^{1}H NMR (400 MHz, DMSO-d_6): 11.31 (s, 1H), 6.8−7.4 (m, 15H), 4.81 (ma.) and 4.50 (mi.) (s, 2H), 4.30 (mi.) and 3.92 (ma.) (s, 2H), 3.71 (s, 3H), 3.33 (ma.) and 3.15 (mi.) (m, 2H), 2.15 (ma.) and 2.09 (mi.) (m, 2H), 1.74 (s, 3H). Alternatively, the triethylammonium salt was prepared by saponification with 2 M aqueous NEt_3, 48 h at room temperature. The water was removed by evaporation under vacuum with gentle warming, and the excess triethylamine was removed by repeated coevaporation with absolute ethanol, ethyl acetate, and then dichloromethane.

Synthesis of 5′-Azido-2′,5′-dideoxy-N^4-benzoylcytidine (6) (*14*). N^4-Benzoyl-2′-deoxycytidine (1.0 g, 3.02 mmol), PPh_3 (80 mg, 3.08 mmol), NaN_3 (33 mg, 5.13 mmol), and CBr_4 (1.02 g, 3.08 mmol) were separately dried in a vacuum desiccator over P_2O_5 overnight. The following were then combined and dissolved in 15 mL of anhydrous DMF: N^4-benzoyl-2′-deoxycytidine, PPh_3, and NaN_3. CBr_4 was promptly added, and the reaction was stirred under a nitrogen atmosphere for 26 h at room temperature. The reaction was quenched by the addition of 3 mL of MeOH, and stirring was continued for 1 h. The solvent was then removed under vacuum, and the crude material was flash purified by silica gel chromatography using 5% methanol/dichloromethane to afford the desired product **1** as a white foam with a yield of 70% (0.75 g). TLC: $R_f = 0.43$ in 9:1 (v/v) dichloromethane/methanol. FAB-MS (NBA matrix): calcd [M + Na$^+$] 379.34, found 379. ^{1}H NMR (400 MHz, DMSO-d_6) of 5′-azido-2′,5′-dideoxy-N^4-benzoylcytidine: 11.3 (s, 1H, N−H), 8.2 (d, 1H, $J_{5,6} = 7.7$ Hz, H-6), 8.0 to 7.4 (m, 6H, H-5 and Bz), 6.2 (dd, 1H, $J_{1',2'} = 6.7$ Hz, $J_{1',2''} = 6.4$ Hz, H-1), 5.5 (d, 1H, $J_{OH,3'} = 4.2$ Hz, OH), 4.2 (m, 1H, H-3′), 4.0 (m, 1H, H-4′), 3.6 (m, 2H, H-5′ and H-5″), 2.3 (m, 1H, H-2′), 2.2 (m, 1H, H-2″).

Synthesis of 5′-Amino-2′,5′−dideoxy-N^4-benzoylcytidine (7) (*15*). Dry 5′-azido-2′,5′-dideoxy-N^4-benzoylcytidine (**6**; 356 mg, 1.0 mmol) was dissolved in 5 mL of anhydrous pyridine, and to the stirred solution was added 0.3 g PPh_3. After 3 h, 1 mL of water was added and stirring was continued for 2 h, at which time another 1 mL aliquot of water was added and the resulting precipitate was filtered, removing the PPh_3 and $Ph_3P{=}O$. The water/pyridine solution was extracted three times with 5 mL ethyl acetate, and the aqueous solution lyophilized to afford crude **7**. For characterization purposes, the N^4-benzoyl group was removed as follows (*16*). A small amount of **7** (220 mg, 0.6 mmol) was dissolved in a mixture containing 2.5 mL of pyridine and 2.5 mL of concentrated NH_4OH, and stirred overnight at 60 °C, after which the solution was cooled on ice and evaporated. The residue was partitioned between 15 mL of H_2O and 1.5 mL of EtOAc. The aqueous layer was extracted, washed with Et_2O (3 × 3 mL) and EtOAc/Et_2O (1:2 v/v, 2 × 5 mL), and lyophilized to afford 5′-amino-2′,5′-dideoxycytidine in 98% yield (190 mg). FAB-MS (NBA-matrix): calcd [M + Na$^+$] 249.22, found 249.0. ^{1}H NMR (270 MHz, DMSO-d_6) of 5′-amino-2′,5′-dideoxycytidine: 7.7 (d, 1H, $J_{5,6} = 7.4$ Hz, H-6), 7.15 (br s, 1H, NH_2), 6.1 (t, 1H, $J_{1',2'} = 7.17$ Hz, $J_{1',2''} = 6.43$ Hz, H-1′), 5.7(d, 1H, $J_{5,6} = 7.17$ Hz, H-5), 5.2 (br s, 3H, NH_2 and OH), 4.1 (m, 1H, H-3′), 3.7 (m, 1H, H-4′), 2.7 (m, 2H, H-5′ and H-5″), 2.1 (m, 1H, H-2′), 2.0 (m, 1H, H-2″).

Synthesis of 5′-MMTNH-2′,5′-dideoxycytidine-N^4-benzoylcytidine (8) (*8*). Compound **7** (226 mg, 1 mmol) was coevaporated twice with 20 mL dry pyridine and dissolved in 5 mL dry pyridine. MMT−Cl (460 mg, 1.5 mmol) was added and the reaction stirred overnight. When the reaction appeared complete by TLC ($R_f = 0.6$ in 1:9 v/v MeOH/CH_2Cl_2), the mixture was diluted with 50 mL dichloromethane, washed with 50 mL brine, and the organic layer dried (sodium sulfate), filtered, and evaporated to obtain the crude product. The crude product was dissolved in a minimal amount of dichloromethane and purified by flash silica gel chromatography (eluant: dichloromethane, then 19:1 (v/v) dichloromethane/methanol with 3−5 drops of TEA to prevent removal of the trityl group due to acidity of the silica) to afford the desired product **8** as white foam with a yield of 30% (180 mg). FAB-MS (NBA matrix): calcd [M + Na$^+$] 625.68, found 625.3. ^{1}H NMR (400 MHz, DMSO-d_6) of 5′-MMTNH-2′,5′-dideoxycytidine-N^4-benzoylcytidine: 11.5 (s, 1H, N−H), 8.1 to 7.1 (m, 16H, H-6, H-5 and MMTr), 6.1 (t, 1H, $J_{1',2'} = 6.4$ Hz, $J_{1',2''} = 6$ Hz, H-1′), 5.2 (d, 1H, $J_{OH,3'} = 4.8$ Hz), 4.1 (m, 1H, H-3′), 3.9 (m, 1H, H-4′), 3.7 (s, 3H, CH_3O−), 2.7 (t, 2H, $J_{NH,5'} = 8$ Hz, $J_{NH,5''} = 8$ Hz), 2.4 (m, 1H, H-5″), 2.2 (m, 2H, H-5′ and H-2″), 2.0 (m, 1H, H-2′).

Synthesis of 5′-MMTNH-2′,5′-dideoxycytidine-N^4-benzoylcytidine phosphoramidite (9). Compound **8** (73.2 mg, 0.12 mmol) was dissolved in 2 mL of anhydrous THF and the flask purged with argon. While stirring, 0.076 mL (0.44 mmol) double-distilled *N*-ethyl-*N*,*N*-diisopropylamine (DIPEA) was added, followed by the slow addition of 0.03 mL (0.14 mmol) 2-cyanoethyl-*N*,*N*-diisopropylchlorophosphoramidite. The reaction mixture was stirred until complete consumption of starting material was observed (2.5 h). The reaction progression was monitored by silica plate TLC which employed 1:19 (v/v) methanol/dichloromethane as the mobile phase. TLC: $R_f = 0.4$ and 0.47 (corresponding to two isomers). After evaporating the mixture to dryness, the crude material was dissolved in a minimum amount of dichloromethane. The chromatography column was preconditioned with 20:80 (v/v) dichloromethane/hexane and 1% TEA, and the pure compound was eluted following a stepwise gradient of dichloromethane/hexane until a 1:1 ratio was reached. The pure fractions of the two isomers were combined, concentrated on a rotatory evaporator, and dried under high vacuum to obtain a stable foam following coevaporation with diethyl ether. FAB-MS (NBA matrix): [M + Na$^+$] calcd 825.9, found 825. ^{31}P NMR (270 MHz, acetone-d_6): 153.9 and 153.8.

Oligonucleotide Synthesis. DNA and 2′-FANA oligonucleotides containing PNA inserts were prepared as previously described (*17*−*19*), purified by PAGE or anion exchange HPLC, and characterized by MALDI-TOF mass spectrometry (Kratos MS25RFA instrument) (Table 1). Sequences of all the oligonucleotides studied are listed in Table 2.

UV Thermal Denaturation Measurements. Thermal denaturation profiles were obtained on a Varian CARY 300 UV−vis spectrophotometer. Prior to experiments, equimolar solutions of AON and target DNA or RNA oligonucleotides were mixed in a buffer consisting of 140 mM KCl, 1 mM $MgCl_2$, and 5 mM Na_2HPO_4 (pH 7.2). The duplex concentration was close to 2 μM. Samples were heated at 95 °C for 10 min and then cooled slowly to room temperature and finally stored overnight at 4 °C to permit annealing. The solutions were gradually heated (0.5 °C/min) and the UV absorbance measured at 260 nm after

temperature stabilization. T_m values were calculated using the baseline method and have an uncertainty of ±0.5 °C.

RNase H assays. RNase H1 degradation assays were carried out to monitor the efficiencies of modified duplexes to elicit activity. The temperature at which the assays were run was usually chosen to be 10 °C lower than the determined thermal melting temperature of the least stable hybrid in the series. Whenever possible, assays were performed at 37 °C to simulate intracellular conditions. Generally, 150 pmol of antisense oligonucleotide were mixed with 50 pmol of 5′-^{32}P-labeled RNA in buffer containing 60 mM Tris-HCl (pH 7.8), 60 mM KCl, 2.5 mM $MgCl_2$, and 2 mM dithiothreitol (500 μL final volume). Samples were heated at 90 °C for 10 min and slowly cooled to room temperature to allow the duplexes to form. They were then transferred to a Plexiglass sample holder and left overnight in a freezer at −20 °C. 9 μL aliquots of the solutions were placed in sterile microtube vials and incubated at the assay temperature for at least 1 h prior to initiating enzymatic cleavage reactions.

Determination of Relative Enzyme Acceleration Profiles. Optimal conditions for enzymatic assays were evaluated from a series of preliminary RNase H dilution assays that were prepared as follows: 1 μL aliquot of purified stock enzyme solution was transferred to a microtube and diluted with varying amounts of double-distilled water. When assays were done at suboptimal temperatures (i.e., T < 37 °C), less dilution of the enzyme was necessary. Reactions were initiated in parallel at the specified temperature by addition of purified human RNase H1 (1 μL) in sterile double-distilled water. The resulting mixture was gently mixed by pipeting action and centrifuged to ensure reaction homogeneity and consistency between vials. The enzyme was handled over ice to avoid any loss of activity. Trial runs were performed on two representative test substrates, usually the first and last points (e.g., 5 and 30 min) in the presence of three enzyme dilutions. At the end of the incubation time, samples were quenched with an equal volume of denaturing loading buffer (98% deionized formamide, 10 mM EDTA, 1 mg/mL bromophenol blue (BPB), and 1 mg/mL xylene cyanole (XC)) and vortexed to mix the contents and ensure complete deactivation of the enzyme. The samples were then heated at 90 °C for 5 min to denature the strands and were subsequently loaded onto a 16% polyacrylamide sequencing gel containing 7 M ultrapure urea. Cleavage patterns were analyzed by autoradiography as described below.

Assays were done with the optimized enzyme concentration as determined above. Duplex substrate solutions were made of a 3-fold excess of AON relative to the target RNA strand. Assays were conducted in parallel for a given series. Reactions were initiated by addition of 5 μL of a freshly prepared solution of human RNase H1 in sterile water (diluted as explained above) to each test substrate (45 μL final volume: 4 time points + 1 extra = 5 × 9 μL). 9 μL of the 0 min time point were prepared in a different vial. 10 μL aliquots were taken at five defined times (0, 5, 10, 20, and 30 min) and quenched with an equal volume of loading buffer, followed by heating at 90 °C for 5

min. For Ha-*ras* sequences, reactions were initiated by the addition of 25 μL of freshly prepared human RNase H1 in sterile water (diluted as explained above) to each test substrate (30 μL final volume). 9 μL of the control solution (time = 0 min) were prepared in a different Eppendorf tube. 10 μL aliquots were taken at six defined times (0, 2, 5, 10, 20, and 30 min) and quenched with an equal volume of loading buffer, followed by heating at 90 °C for 5 min. At the completion of the experiment, the samples were heated and then quickly cooled on ice before electrophoretic analysis (16% denaturing PAGE, 1.5−2 h, 2000 V). Gels were prerun for 20 min at 1500 V before loading the samples. Degradation profiles were analyzed by autoradiography and further quantified by densitometric analysis after autoradiography. Quantification of the remaining full-length ^{32}P-RNA signal was obtained by *UN-Scan-It* digitizing software (Silk Scientific, Inc.).

RESULTS AND DISCUSSION

Duplexation Studies. For the homopolymeric sequences shown in Table 2, thermal melting experiments were performed at two wavelengths, 260 and 284 nm, corresponding to the absorbance of duplexes and triplexes, respectively. In the latter case, data obtained at the longer wavelength was primarily undertaken to rule out the existence of triple-helical species in solution (data not shown), which are favored for poly(thymine) PNA oligomers (*7*). Indeed, no transitions characteristic of triple-helical species were observed. T_m data indicative of duplex formation were thus obtained for the modified oligomers at 260 nm (**I**−**III**) and summarized in Table 2.

In assessing the thermal profiles of unmodified and PNA-containing AONs, we observed a significant drop in duplex stability for all modified oligonucleotides investigated. As expected, all oligomers (**I**, **II**, and **III**) showed greater affinity toward dA_{18} than rA_{18}. Surprisingly, we found that the stability of duplexes formed with rA_{18} appear sensitive to the site of modification, whereas the complexes formed with dA_{18} were not. For instance, whether a PNA unit substitutes a nucleotide at position 13 or 9 (numbered from the 5′-end, entries **II** and **III**, Table 2), the destabilization is the same ($\Delta T_m = \sim -10$ °C) when associating with a DNA complement. However, when hybridized with rA_{18} targets, AON **III** (substituted in the middle at position 9) is 4 °C more stable than AON **II** in which the point of substitution is closer to the 3′-end (position 13).

We next turned our attention toward mixed sequences (A/T/C) in order to do a comparative study of duplex stability of oligomers containing either a butanediol (sequence **X**, Table 2) or a PNA linker at position 10 (**VI**, Table 2). We were also interested to see if there was any beneficial additive effect upon the thermal stability of the duplex following the incorporation of three contiguous PNA residues (**VII**). In accord with the observation for homopolymeric sequence **III**, sequence **VI** showed greater destabilization with its complementary DNA target ($\Delta T_m = -13$ °C) as compared to the hybrid formed with RNA ($\Delta T_m = -10.5$ °C). Similar results have been observed by Bergman et al. (*20*). who introduced a single PNA building block in a mixed sequence DNA 13-mer. For the same RNA target, the PNA insertion (**VI**, $\Delta T_m = -10.5$ °C) was less tolerated than a butyl linker (**X**, $\Delta T_m = -5$ °C) (*6*). However, the destabilizing effect was not additive upon incorporation of three contiguous PNA residues (**VII**). In fact, the same decrease was observed for one or three insertions ($\Delta T_m \approx -10$ °C). This is not surprising since PNA−DNA chimeras are known to form stable hybrid duplexes with complementary DNA or RNA (*21*). The stability is dependent upon the overall composition and placement of DNA versus PNA (*22*), such that higher thermal stability is to be expected upon increasing the number of consecutive PNA residues. It is also interesting to note that the selectivity for the RNA complement increased with the insertion of a PNA triad. In fact, AON **VII** binds to its DNA complement very weakly at best (T_m ca. 15 °C, broad transition).

Table 3. Melting Temperatures (T_m) of (PNA)T-G Mismatch Experiments

	target strand[a]		
	RNA (ΔT_m, °C)		DNA (ΔT_m, °C)
AON strand[b]	single mismatch	triple mismatch	single mismatch
VI (single PNA insert)	39 (+1)[c]	n.a.	34 (−0.5)
VII (triple PNA insert)	n.a.	27 °C (−11.5 °C)	n.a.

[a] Target sequences correspond to RNA, in uppercase lettering, single mismatch underlined: 5′-GGG AAA GAG AAA AUA UAA-3′. RNA triple mismatch underlined: 5′- GGG AAA GAG GGA AUA UAA-3′. DNA, in lowercase, single mismatch underlined: 5′-ggg aaa gag aaa ata taa−3′. Aqueous solutions of $\sim 2 \times 10^{-6}$ M of each oligonucleotide, 140 mM KCl, 1 mM $MgCl_2$, 5 mM Na_2HPO_4 buffer (pH 7.2); uncertainty of ±0.5 °C for T_m; n.a. − not applicable. [b] See Table 2. [c] ΔT_m: the difference between the melting temperature of the perfectly matched PNA-containing AON and the hybrids containing one or three mismatches.

To gain further insight into the effect of replacing nucleotides with PNA units and the role of base pairing on the stability of the complexes, we undertook T_m studies with sequences containing one or three base mismatches either opposite or in place of PNA in the duplex (sequences **VI**−**IX**, Tables 2 and 3). First, introduction of a single mismatch in the DNA or RNA target strand opposite the PNA insert in sequence **VI** to yield a duplex with a (PNA)T-G mismatch gave a T_m which was the same as the perfectly matched sequence (Tables 2 and 3). Thus, there is no deleterious effect for a mismatch across from the single PNA insert, and both resulted in the same destabilization of the hybrid relative to the non-PNA-containing strands.

This result implies that the nucleobase of the PNA residue does not contribute to binding in this sequence context, or its base pair is worth no more energetically than the wobble pair available in (PNA)T-G mismatched strand. A possible explanation for lack of base pairing may be that the rigidity of the PNA insert does not permit it to adopt a geometry that allows interstrand hydrogen bonding with the opposing nucleobase in the complementary strand. Interestingly, a single C−A mismatch ($\Delta T_m = -11$ °C) in the mixed sequence **VIII** is less destabilizing than a putative matching PNA insert (**VI**, $\Delta T_m = -13$ °C), which supports the observation that the presence of an amide bond at the PNA−DNA junction is destabilizing (*19*, *23*). Sequence **VII**, which contains three contiguous PNA inserts, demonstrates a large destabilization when hybridized to a complement RNA to give three (PNA)T-G mismatches. The magnitude of the depression of the T_m is similar to that observed for three (DNA)C-A mismatches ($\Delta T_m = -20$ °C, Table 2), when hybridized to an RNA target. This change in T_m is much larger than when **VII** hybridizes to a matched RNA sequence ($\Delta T_m = -11.5$ °C, Table 3), thus indicating that the three PNA nucleobases partially participate to binding with the RNA target. This may be understood on the basis that the insertion of a PNA triad is sufficient to nucleate a structural perturbation that can accommodate nucleobase pairing, whereas a single residue insertion is not. This notion is supported by the similarity in CD spectra of the unmodified DNA/RNA heteroduplex (**V** and complementary RNA) to the spectra of **VI** and **VII** with the same complementary RNA. In addition, the global conformation of either the homopolymeric sequence or 2′-FANA sequence is largely unperturbed by insertion of a single PNA residue, as shown by the CD spectra of these complexes. Only the introduction of a triple PNA(T)-G mismatch showed a strong disruption of the overall morphology evidenced by a dramatic change in the CD spectra.

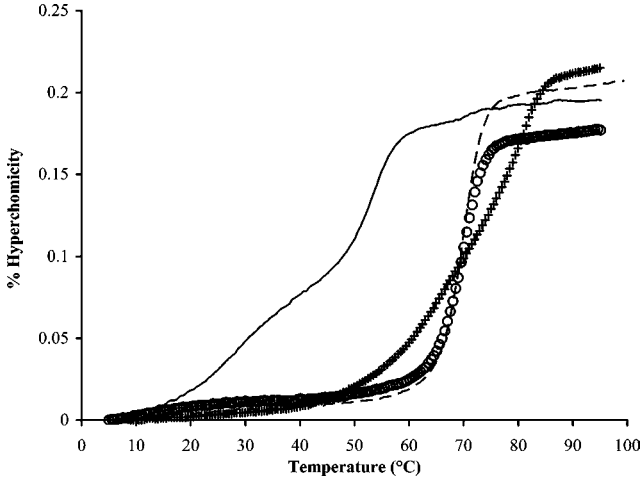

Figure 1. UV thermal melting profiles of 2′-FANA and DNA backbones containing a PNA insert complexed with Ha-*ras* 18-mer RNA. Solid line, **XII**; crosses, **XIV**; dashed line, **XI**; open circles, **XV**.

Finally, we analyzed the impact of the presence of one PNA insert in a more rigid 2′-fluoroarabinonucleic acid (2′-FANA) backbone (**XV**), using the all-DNA sequence for comparison. As expected, 2′-FANA sequence **XIV** showed a greater T_m than the unmodified DNA **XI** (Table 2) that is rationalized on the basis of greater strand preorganization that entropically favors double helix formation (*17*, *24*, *25*). The greater rigidity of the 2′-FANA scaffold may also explain the smaller destabilization that is caused ($\Delta T_m = -9.5$ °C) by a single PNA insert in the middle of the sequence (**XV**) as compared to the DNA analog **XII** ($\Delta T_m = -17$ °C). Furthermore, in contrast with the 2′-FANA counterpart, the melting curve of sequence **XII** presents two clearly distinct melting transitions (Figure 1).

The reason for the biphasic nature of this transition could lie in the fact that 2′-deoxynucleotides are more flexible than 2′-FANA residues and would be more likely to experience greater intrahelical disorder around the PNA domain. The PNA residue possibly creates distortions that prevent one-half of the strand from binding efficiently to the target. Further experiments are needed to investigate this hypothesis. Interestingly, while flanking deoxynucleotides in the AON tolerate PNA inserts poorly in comparison to a butyl linker (sequences **XII** and **XIII**, Table 2, $\Delta T_m = -17$ °C vs -12 °C), 2′-FANA sequences exhibit the same destabilization with either type of insert (**XV** and **XVI**, $\Delta T_m = -9.5$ and -10 °C).

RNase H Assays. The ability of the modified oligonucleotides to elicit human RNase H1 activity when targeted to a structured RNA (e.g., hairpin) or unstructured RNA (random coil) was next evaluated. We first examined the activity of homopolymeric AON **II** and **III** in conjunction with DNA control (**I**) and the sequence containing a butyl insert in position 10 (**IV**). The presence of a PNA linker within the AON strand increases RNase H1 activity compared to control DNA but to a smaller extent than observed with **IV**, which may be attributed to the loss of flexibility imparted by the rigid amide bond. The noted order of RNA degradation within this series is **IV** > **III** > **II** > **I** (Figure 2). Interestingly, sequences **II** and **III**—although relatively less efficient at activating RNase H with respect to central butyl-modified AON **IV**—nonetheless confer the same accelerating trends to their relevant AON−RNA substrates as those described in previous work comparing central vs 3′-terminal butyl insertions on RNase H activity (*6*).

Next, we turned our attention toward mixed sequences with DNA (**V**) as the control and the butyl-containing AON **X** for comparison. As PNA inserts induce some flexibility in the AON strand, and given the previous result with the poly(T) sequences, we expected **VI** to have greater RNase H activity than the DNA

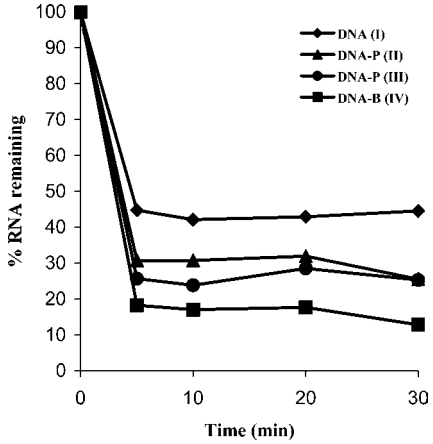

Figure 2. Time course of RNase H1-mediated cleavage of hybrids containing polypyrimidine sequences **I**−**IV** (see Table 1).

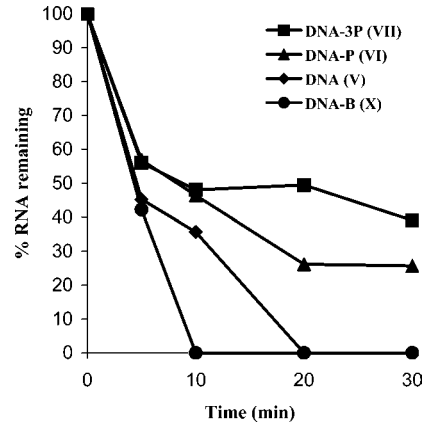

Figure 3. Time course of RNase H1-mediated cleavage of hybrids containing mixed sequences (Table 1).

control. However, hybrids of **VI** with RNA were found to be much less reactive as substrates for RNase H1 than control DNA/RNA. This effect is emphasized in comparison to the control DNA, because this sequence context is inherently a better substrate for RNase H1. Thus, for this sequence, the activity of the control DNA is enhanced by incorporation of a flexible butyl linker and diminished by incorporation of one or three PNA residues. A possible explanation may be that the PNA insert creates a greater local distortion within this duplex, as compared to the butyl linker, and becomes a less acceptable substrate for the enzyme. This idea is supported by the observation that complexes of **VI** with complementary RNA have a lower T_m than their butyl counterpart **X**. However, the thermal destabilizations associated with these two AON sequences likely have different thermodynamic origins, with diminished RNA binding likely owing to the absence of a base pairing partner in the case of butyl inserts, and to an incompatible local conformation in the case of a PNA insert. This effect may also be sequence-dependent, since it was not observed in other studies. Oligonucleotide **VII** is the least reactive of all AONs tested, which is not surprising if we consider that this oligonucleotide tends to adopt the profile of a PNA−DNA chimera, with the latter being less reactive than pure DNA, and first synthesized with the goal of introducing an RNase H-active backbone to the nonreactive PNA domain (*22*). The RNase H1 efficiency observed for each AON is the following: **X** > **V** > **VI** > **VII**; Figure 3.

Finally, we used an in vitro Ha-*ras* model system to evaluate the ability of the DNA−PNA chimera to elicit RNase H1 activity. This RNA species and its associated structure is of particular interest, since hyperactivated forms of point mutant

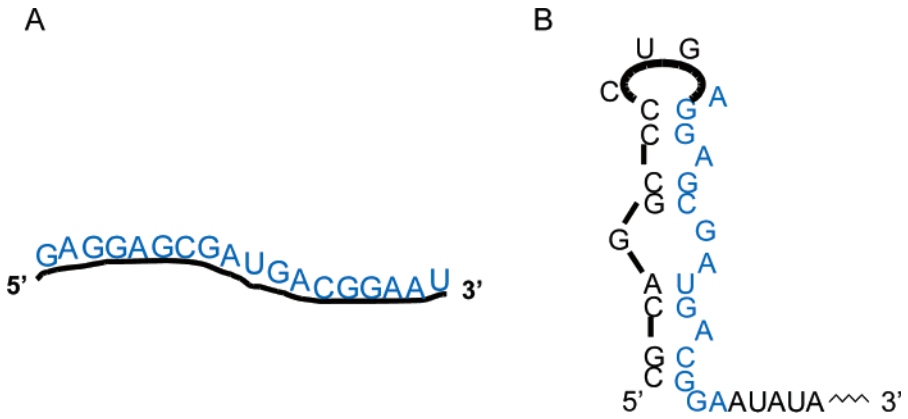

Figure 4. Secondary structures presumably adopted by (A) 18-mer and (B) 40-mer Ha-*ras* RNA. AON binding region is in blue.

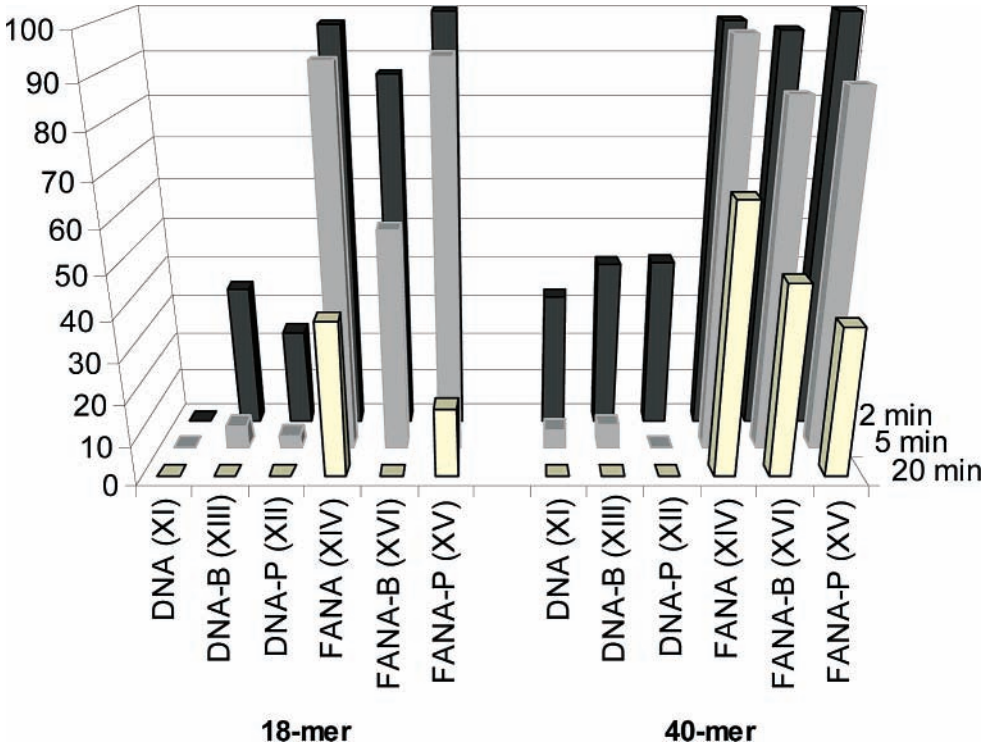

Figure 5. Quantification of the remaining full-length ^{32}P-RNA signal at two time points (20 and 30 min) for the Ha-*ras* RNA targets. For convenience, AONs are identified on the basis of the single inserts wherein B = butyl and P = peptide nucleic acid.

and nonmutated mammalian *ras* protooncogenes are responsible for various human cancers (*26*−*29*), and hence represent a potential therapeutic target. Furthermore, we wished to compare the rate and extent of reactivity of both structured and unstructured RNA targets. As is common in the antisense approach, we believe that RNA cleavage should also depend on the structure, length, and base composition of the target RNA. For this purpose, two oligomers were investigated: an 18-mer and a 40-mer, both of which are complementary to an internal nucleotide region encompassing the translation initiation site of the *ras* gene and corresponding, respectively, to residues −8 to +10 and −19 to +21 of the full-length transcript. The apparent secondary structures of both targets have previously been determined (*6*) using the MFOLD program (*30*, *31*) and supported by UV thermal profiles. No intramolecular association was observed for the 18-mer target, whereas the 40-mer was capable of self-associating into a stable 25 nucleotide hairpin structure (*6*) (Figure 4).

The ability of PNA-containing Ha-*ras* sequences (**XII**) to activate human RNase H1 was evaluated in conjunction with butyl-containing Ha-*ras*-DNA (**XIII**) and 2′-FANA sequences (**XV**, **XVI**), as well as DNA (**XI**) and 2′-FANA (**IX**) control AONs (Figure 5). The linker-containing DNA AON (**XIII**) did not enhance target degradation, which is consistent with the work of other groups (*32*, *33*).

Obviously, target accessibility is an important determinant in the ability of the AONs studied to elicit RNase-H-mediated cleavage of the RNA. For the 18-mer unstructured RNA target, complete disappearance was observed after 20 min when in the presence of complementary DNA or the butyl linker containing 2′-FANA (**XVI**), whereas the structured 40-mer target was ∼30% intact when treated with the most active oligomers **XVI** or **XV** (Figure 6). In fact, all the FANA AONs were less effective at mediating RNase H1 directed destruction of the structured RNA target as compared to the same oligomers tested against the 18-mer unstructured target. The best modified AON for the 18-mer target was the 2′-FANA possessing a butyl linker (**XVI**), whereas the PNA-containing oligomer was more efficient at eliciting the cleavage of the 40-mer target.

For 2′-FANA-based AONs, the order of enzyme efficiency is roughly the same for both the 18- and 40-mer targets: **XVI** ≈ **XV** > **XIV**. This is similar to the trend we observed earlier (**IV** > **III**, **II** > **I**) and likely correlates with a gradual decrease in the flexibility of the AON strand. In other words, the all-

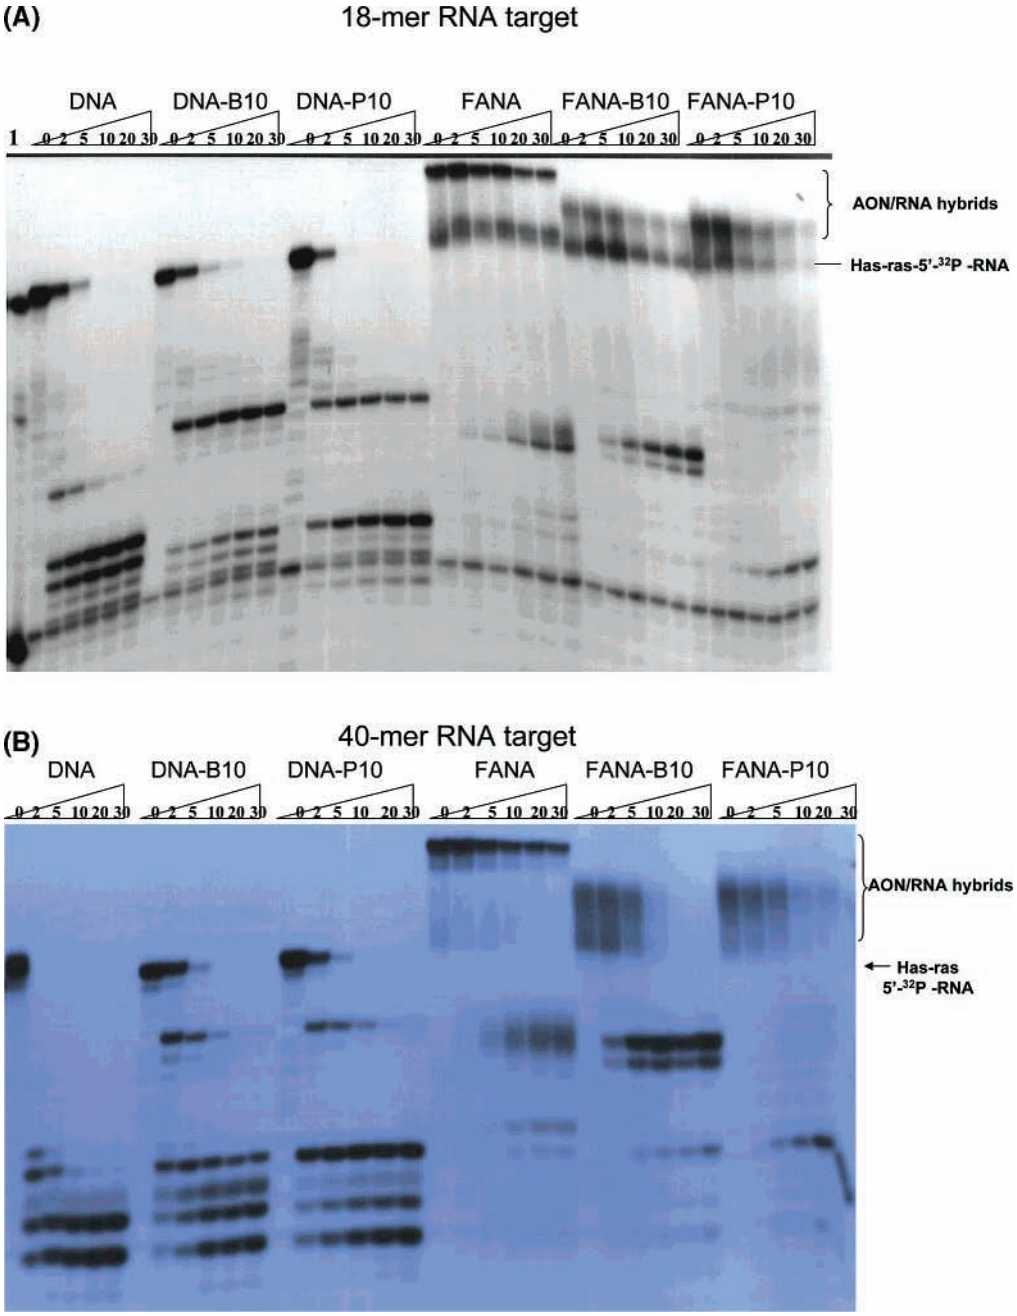

Figure 6. Degradation patterns of Ha-*ras*-RNA (A) 18-mer and (B) 40-mer hybridized with various AONs. See experimental procedures for details. $T = 37$ °C; time points: 0, 2, 5, 10, 20, and 30 min. The slowly migrating band observed for **XIV**, **XVI**, and **XV** hybridized to the 18-nt and 40-nt RNA targets corresponds to the duplexed species that does not dissociate despite heating of the sample prior to loading and the denaturing conditions of the gel electrophoresis, due to high T_m.

FANA strand **XIV** likely does not present enough flexibility to the enzyme, which would therefore require greater energy to adjust the hybrid to adopt the correct conformation for hydrolysis.

Polyacrylamide electropherograms can be inspected to qualitatively assess the effect of a non-nucleotide insert into DNA or 2′-FANA on the pattern of RNase-H-directed RNA hydrolysis. Figure 6 shows the gel from which the data presented in Figure 5 was obtained. For both the 18-mer and 40-mer targets, the DNA oligomer **XI** causes a predominance of short hydrolysis products, likely a result of multiple cleavage events. For the modified oligomers, there is a specific hydrolysis more central in the targeted RNA resulting in a slower moving band. This is clearly seen in the linker-modified DNA oligomers regardless of the identity of the linker, that is, both the butyl- and PNA-linked DNA oligomers produce similar cleavage patterns. Interestingly, the nature of the linker in a 2′-FANA sequence appears to affect the pattern of cleavage. The 2′-FANA oligomer (**XIV**) directs a central cleavage, assumed to be a primary hydrolysis event, as does the butyl linker-modified 2′-FANA (**XVI**). In contrast, the PNA-modified 2′-FANA (**XV)** presents a different cleavage pattern, with a product resulting from central hydrolysis being absent. We interpret this observation as being a result of the structural perturbation that a single PNA insert causes as well as the relative stiffness of the amide backbone, as compared to a butyl insert, which makes it a less suitable enzyme substrate.

CONCLUSIONS

Oligonucleotide analogs capable of recruiting RNase H for the destruction of mRNA have potential use as artificial regulators of gene expression. Our previous work has shown

that the ability of 2′-FANA to direct the RNase-H-mediated hydrolysis of RNA is dramatically improved by incorporation of a flexible non-nucleotide butyl linker. This modification has the deleterious effect of reducing the thermal stability of the complexes formed with complementary nucleic acids. The current study has investigated the incorporation of a neutral peptide nucleic acid linker, which we have found diminishes the thermal stability of complexes formed with complementary oligonucleotides. Although this is presumably due to some degree of structural changes at the PNA−DNA or PNA−FANA junctions in the chimeras, this was not found by comparative examination of the complexes by CD spectroscopy (data not shown).

In general, PNA-modified oligonucleotides did not lead to a substantial improvement in induction of RNase H1 activity as compared to butyl derivatized oligonucleotides. However, homopolymeric DNA sequences containing a PNA insert were more efficient at eliciting RNase H1 activity relative to the unmodified homopolymeric DNA presumably due to added flexibility. Nevertheless, the greater rigidity imparted to the oligonucleotide strand by the PNA unit as compared to the butyl linker is believed to be accountable, at least in part, for the decrease in enzymatic activity. Another effect that cannot be ruled out from the present study is a partial loss of key enzyme interactions due to the uncharged nature of the amide backbone at the insertion junction. Nonetheless, it is clear that PNA-modified substrates can still support elevated cleavage over unmodified (i.e., all-DNA or all-FANA) strands in certain sequence contexts, especially given the general inability of PNA to activate RNase H. These trends thus corroborate our previous claims on substrate flexibility as a crucial element for high RNase H activity, and also illustrate the versatility with which a non-nucleotide residue, when strategically placed in the antisense oligonucleotide, can still maintain appreciable RNase H activation. Conversely, AON sequences containing three PNA inserts were less efficient at recruiting RNase H activity due to the increasing degree of PNA character to the oligomer and associated topological consequences on overall helix architecture.

Together, these and other studies reinforce the hypothesis that local flexible sites within AON/RNA hybrids are essential for high RNase H catalysis, (*6*, *34*−*36*) in which an enzyme-induced altered trajectory of the bound substrate (*37*, *38*) could facilitate optimal interaction with the catalytic site of RNase H1.

ACKNOWLEDGMENT

The authors (M.J.D., R.H.E.H.) gratefully acknowledge the Natural Science and Engineering Research Council of Canada and the Canadian Institutes of Health Research (M.J.D.) for funding. This work was also supported by a scholarship award from the Chemical Biology Strategic Training Initiative of the Canadian Institutes of Health Research to B.P. We thank Dr. M. M. Mangos for several helpful discussions, encouragement, and assistance with the writing of this manuscript.

Received October 4, 2006; Revised Manuscript Received November 29, 2006

DNA interstrand cross-links are formed by chemotherapy drugs as well as by products of normal oxidative metabolism. Despite their importance, the pathways of cross-link metabolism are poorly understood. Laser confocal microscopy has become a powerful tool for studying the repair of DNA lesions that can be detected by immunofluorescent reagents. In order to apply this approach to cross-link repair, we have synthesized conjugates of 4,5′,8-trimethylpsoralen (TMP) and easily detected compounds such as Lissamine rhodamine B sulfonyl chloride (LRB-SC), biotin, and digoxigenin. These conjugates are activated by UVA, and we have analyzed the intracellular localization of DNA damage and DNA reactivity by confocal and immunofluorescence microscopy. The LRB-SC−TMP conjugate **2** appeared mainly in the mitochondria, while the biotin−TMP conjugate **4** preferentially localized in the cytoplasm. Adducts formed by UVA and digoxigenin conjugates of TMP **7a** and 4,5′-dimethylangelicin (DMA) **7b**, which forms only monoadducts, were largely localized to the nucleus. Exposure of cells incubated with **7a** and **7b** to a 364 nm UV laser directed toward defined nuclear regions of interest resulted in localized adduct formation which could be visualized by immunofluorescence. Repair-proficient cells were able to remove the photoadducts, while repair-deficient cells were unable to repair the damage. The results indicated that the digoxigenin−TMP conjugate **7a** and digoxigenin−DMA conjugate **7b** can be used for studying the repair of laser localized DNA monoadducts and cross-links.

INTRODUCTION

Genomic instability resulting from chemical or radiation damage to DNA is linked to many human disorders, including cancer. Instability is also believed to contribute to the deterioration of cellular and organ function during aging (*1*). As a consequence, the elucidation of pathways for the repair of chemical and radiation damage in DNA has been the subject of considerable research effort employing a variety of experimental approaches. In recent years, immunofluorescence microscopy has become an important tool in the study of the proteins and enzymes involved in DNA repair. One of the most powerful applications of this technology involves the introduction of localized damage by exposure of a discrete area in a cell nucleus to light from a laser. The energy from the laser activates endogenous or exogenous compounds, which in turn react with DNA. The best-known example is the activation of Hoechst dye by a 390 nm laser. Radicals released by the dye attack DNA, resulting in various damage products, including double-strand breaks. These are marked by the rapid appearance of a phosphorylated form of histone γ-H2AX in the chromatin in the vicinity of the break. Immunofluorescent staining of the phospho-histone yields a pattern that illuminates the region exposed to the laser (*2*). This approach has been used by a number of groups to characterize the dynamics of double-strand break repair (*3*, *4*). More recently, the localized laser strategy has been extended to studies on the repair of single-strand breaks and guanine oxidation products (*5*, *6*).

Although the study of localized damage has been quite productive, it is necessarily limited to the analysis of DNA lesions whose presence can be verified. This may be by the appearance of a protein specific for the DNA lesion, such as phosphorylated γ-H2AX, or by immunostaining of treated cells with antibodies against specific DNA adducts (*6*). If appropriate immunological reagents are unavailable, then it can be difficult, perhaps impossible, to verify the presence of the adduct of interest. Furthermore, it would not be possible to follow the removal of an adduct by DNA repair functions. This can be a major limitation.

We are interested in the metabolism of interstrand DNA cross-links. These are formed by lipid peroxidation products (*7*, *8*) and chemotherapy reagents such as cisplatin, nitrogen mustards, and the photoactive psoralens (*9*). They are absolute blocks to transcription and replication and cannot be accumulated in proliferating cells. In light of the clinical significance and biological implications, cross-link repair is the subject of much current research (*10*−*12*). The requirement for photoactivation would suggest that psoralens would be ideal reagents for the study of repair dynamics of localized genomic cross-links. However, there are no commercial immunological reagents available for the detection of psoralen adducts in genomic DNA. Psoralen has been chemically linked to molecular tags, such as biotin, which can be detected with fluorescent avidin or streptavidin. These have been used as hybridization probes but have not been applied to live cells. In this report, we describe the synthesis and immunofluorescence studies of 4,5′,8-trimethylpsoralen (TMP), a psoralen derivative, linked to easily detected compounds such as Lissamine rhodamine B sulfonyl chloride (LRB-SC), biotin, and digoxigenin. In live cell experiments, we find that the first two conjugates have limited utility for studies of repair of genomic interstrand cross-links, while the digoxigenin−TMP conjugate can be used to cross-link

nuclear DNA in global and localized reaction protocols. Repair-proficient cells were able to remove the tagged psoralen adducts, while repair-deficient cells were not.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. LRB-SC (Acros Organics), *N*-hydroxysuccinimidyl-D-biotinyl-15-amido-4,7,10,13-tetraoxapentadecylate, biotin−NHS ester (Quanta Biodesign, Ohio), and digoxigenin-3-*O*-methylcarbonyl-ϵ-aminocaproic acid-*N*-hydroxysuccinimidyl ester, dig-NHS ester (Roche Applied Science, Indianapolis) were used as received. All other reagents were purchased from Sigma-Aldrich and used without further purification. The starting materials methylaminodiethoxyethanemethylaminomethyltrimethylpsoralen (**1**) (*13*), 4′-aminomethyl-4,5′,8-trimethylpsoralen (**3**) (mp 190−192 °C), 4′-chloromethyl-4,5′,8-trimethylpsoralen (**5a**) (mp 215−217 °C) (*14*), and 4′-chloromethyl-4,5′-dimethylangelicin (**5b**) (mp 211−213 °C) (*15*) were prepared by following the reported procedures. Thin-layer chromatography was performed on silica gel 60 F_{254} plates (0.2 mm) (E. Merck, Gibbstown, NJ), column chromatography on silica gel (100−230 mesh, Natland International Corporation, NC), and preparative thin layer chromatography on precoated silica gel (Analtech, Inc., Uniplate, layer thickness 500 μm).

Instruments. Melting points (uncorrected) were measured on a Fisher-Johns melting point apparatus. NMR was recorded on a Bruker (Bellevica, MA) AC-300 spectrometer with tetramethylsilane as an internal standard. Mass was recorded on a Micromass Q-TOF1 mass spectrometer (Micromass, Beverely, MA) in the ESI mode.

Preparation of LRB-SC−TMP Conjugate 2. To a solution of **1** (25 mg, 0.06 mmol) and triethylamine (6 μL) in 15 mL of chloroform, LRB-SC (25 mg, 0.04 mmol) was added in small portions over a period of 10 min while the reaction mixture was stirred at 0 °C. The reaction mixture was stirred at room temperature for 12 h, and the solvent was distilled off under reduced pressure to obtain a residue which was chromatographed over silica gel. Elution of the column with a mixture (1:9) of methanol and chloroform gave 34 mg (60%) of **2**, mp 145−148 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C) δ ppm: 1.29 (t, J = 7.0 Hz, 12H), 2.27 (s, 3H), 2.47 (s, 3H), 2.51 (s, 3H), 2.55 (s, 3H), 2.7 (t, J = 5.3 Hz, 2H), 2.97 (s, 3H), 3.39 (t, 5.9 Hz, 2H), 3.7−3.5 (m, 18H), 6.6 (s, 2H), 6.7 (d, J = 9.4 Hz, 2H), 7.18−7.25 (m, 4H), 7.6 (s, 1H), 7.8 (d, J = 7.9 Hz, 1H), 8.7 (s, 1H). Molecular weight calculated for $C_{50}H_{60}N_4O_{11}S_2$ was 957.16, found 957.52 ($M + H^+$).

Preparation of Biotin−TMP Conjugate 4. A solution of 4′-aminomethyl-4,5′,8-trimethylpsoralen (**3**) (15 mg, 0.06 mmol) and biotin−NHS ester (25 mg, 0.04 mmol) in dichloromethane (10 mL) was stirred at room temperature for 12 h. The solvent was distilled off under reduced pressure to obtain a residue which was chromatographed over silica gel. Elution of the column with a mixture (1:9) of methanol and chloroform gave 35 mg (50%) of the conjugate **4,** mp 103−106 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C) δ ppm: 1.35−1.42 (m, 2H), 1.55−1.73 (m, 4H), 2.16−2.21 (t, J = 7.4 Hz, 2H), 2.47−2.53 (m, 11H), 2.67−3.15 (m, 4H), 3.39−3.55 (m, 16 H), 3.73 (t, J = 6.0 Hz, 2H), 4.25−4.29 (m, 1H), 4.44−4.50 (m, 3H), 6.21 (d, J = 1.0 Hz, 1H), 6.28 (s, 1H), 6.8 (t, J = 5.4 Hz, 1H), 7.17 (t, J = 5.5 Hz, 1H), 7.66 (s, 1H). Molecular weight calculated for $C_{36}H_{50}N_4O_{10}S$ was 730.86, found 731.22 ($M + H^+$).

Preparation of Digoxigenin−TMP Conjugate 7a and Digoxigenin−DMA Conjugate 7b. *Preparation of 4′-[N-(13-amino-4,7,10-trioxatrideca)]aminomethyl-4,5′,8-trimethylpsoralen (**6a**).* A mixture of 4′-chloromethyl-4,5′,8-trimethylpsoralen (**5a**) (50 mg, 0.18 mmol) and 4,7,10-trioxa-1,13-tridecanediamine (590 mg, 2.7 mmol) in toluene (10 mL) was refluxed for 12 h. The solvent was removed under reduced pressure, and the residue obtained was chromatographed over silica gel. Elution of the column with a mixture of chloroform, methanol, and 28% ammonia solution (9:1:0.5) gave 50 mg (60%) of **6a** as a pale yellow viscous liquid. ^{1}H NMR (300 MHz, $CDCl_3$ + DMSO-d_6 (4:1), 25 °C) δ ppm: 1.96 (m, 2H), 2.17 (m, 2H), 2.53 (s, 3H), 2.63 (s, 6H), 3.05 (t, J = 6.4 Hz, 2H), 3.17 (t, J = 7.3 Hz, 2H), 3.55−3.64 (m, 12 H), 4.33 (s, 2H), 6.2 (s, 1H), 8.35 (s, 1H). ^{13}C NMR ($CDCl_3$ + DMSO-d_6 (4:1), 25 °C) δ ppm: 8.29, 12.80, 19.75, 25.89, 26.52, 38.46, 45.06, 67.98, 68.94, 69.45, 69.62, 69.66, 69.94, 104.67, 106.38, 108.24, 112.24, 113.95, 116.21, 123.74, 149.06, 154.19, 154.47, 158.09, 160.84. Molecular weight calculated for $C_{25}H_{36}N_2O_6$ was 460.56, found 461.29 ($M + H^+$).

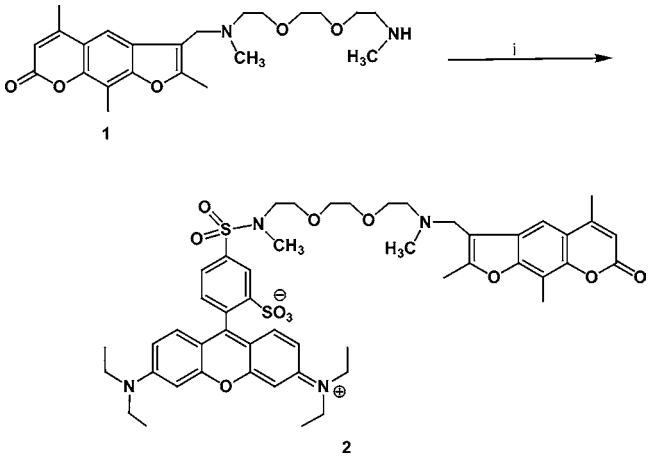
*Preparation of 4′-[N-(13-amino-4,7,10-trioxatrideca)]aminomethyl-4,5′-dimethylangelicin (**6b**).* Similarly, 4′-chloromethyl-4,5′-dimethylangelicin (**5b**) (50 mg, 0.19 mmol) and 4,7,10-trioxa-1,13-tridecanediamine (612 mg, 2.8 mmol) gave 47 mg (55%) of **6b** as a pale yellow viscous liquid. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C) δ ppm: 1.73 (m, 2H), 1.85 (m, 2H), 2.47 (s, 3H), 2.48 (s, 3H), 2.76−2.85 (m, 4H), 3.51−3.59 (m, 12H), 3.99 (s, 2H), 6.23 (s, 1H), 7.33 (d, J = 8.6 Hz, 1H), 7.41 (d, J = 8.6 Hz, 1H). ^{13}C NMR ($CDCl_3$, 25 °C) δ ppm: 12.01, 19.25, 24.54, 26.22, 36.91, 38.45, 45.16, 66.58, 67.54, 68.45, 68.42, 68.32, 68.96, 108.52, 112.81, 113.51, 115.26, 115.66, 120.56, 147.76, 154.25, 155.26, 155.76, 160.31. Molecular weight calculated for $C_{24}H_{34}N_2O_6$ was 446.53, found 447.05 ($M + H^+$).

*Preparation of **7a**.* To a solution of **6a** (5.5 mg, 0.012 mmol) and dig-NHS ester (5 mg, 0.008 mmol) in anhydrous DMF (0.5 mL), triethylamine (3.4 μL) was added. The reaction was stirred at 50 °C for 18 h and the solvent removed under reduced pressure. The residue obtained was purified directly by preparative thin layer chromatography, eluting with $CHCl_3$−MeOH−28% NH_4OH (8:1:0.1) to give 3.8 mg (50%) of the conjugate **7a**, mp 68−71 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C) δ ppm: 0.80 (s, 3H), 0.94 (s, 3H), 1.25−2.13 (m, 34H), 2.48 (s, 3H), 2.51 (s, 3H), 2.57 (s, 3H), 2.76 (t, 2H), 3.27−3.74 (m, 19H), 3.86 (s, 2H), 3.88 (s, 2H), 4.78−4.93 (m, 2H), 5.94 (s, 1H), 6.24−6.29 (m, 2H), 6.62 (t, 1H), 7.65 (s, 1H). Molecular weight calculated for $C_{56}H_{81}N_3O_{13}$ was 1004.25, found 1004.76 ($M + H^+$).

*Preparation of **7b**.* Similarly, **6b** (5.4 mg, 0.012 mmol) and dig-NHS ester (5 mg, 0.008 mmol) gave 4 mg (53%) of the conjugate **7b**, mp 75−78 °C. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C) δ ppm: 0.79 (s, 3H), 0.95 (s, 3H), 1.19−2.17 (m, 34H), 2.48 (s, 3H), 2.49 (s, 3H), 2.79 (t, J = 6.9 Hz, 2H), 3.26−3.67 (m, 19H), 3.87 (s, 2H), 3.99 (s, 2H), 4.77−4.92 (m, 2H), 5.92 (s, 1H), 6.23 (s, 1H), 6.40 (t, 1H), 6.62 (t, 1H), 7.34 (d, J = 8.7 Hz, 1H), 7.43 (d, J = 8.7 Hz, 1H). Molecular weight calculated for $C_{55}H_{79}N_3O_{13}$ was 990.56, found 990.62 ($M + H^+$).

Detection of Cross-Link Formation by HPLC. TMP, **7a**, and **7b** were incubated with duplex DNA and exposed to UVA (365 nm) for 10 min on ice. The irradiated samples were applied to a DIONEX DNAPac ion exchange column on a Shimadzu HPLC system (LC-10ADvp) with a dual wavelength detector (SPD-10ADvp) and an autoinjector (SIL-10AVvp). A solution of 25 mM NaOH (mobile phase A) and 1 M NaCl in 25 mM NaOH (mobile phase B) was used for the separation. A gradient of 2 min 10−50% B, 20 min 50−90% B, and 21 min 90−100% B was employed with a flow rate of 1.5 mL/min.

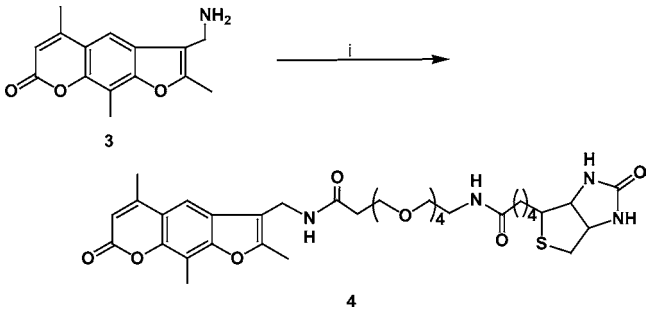
Cell Culture. Chinese hamster wild-type AA8 and ERCC1[1] deficient 727 cells were grown in culture dishes or glass coverslips to 80% confluency in α-MEM (Gibco) supplemented with 10% fetal bovine serum, 1 mM L-glutamine, and 1% antibiotics. HeLa cells were cultured in DMEM (Gibco), supplemented with 10% fetal bovine serum, 1 mM L-glutamine, and 1% antibotics.



Immunofluorescence Labeling of DNA Conjugates. Cells were incubated with **7a** and **7b** at appropriate concentrations in serum and phenol red free culture medium for 30 min and then exposed to UVA for 5 min. Irradiated cells were washed three times with PBS, fixed with 4% formaldehyde at room temperature for 10 min, and lysed on ice for 15 min (1% BSA, 0.1% Triton X-100, 100 mM Glycine, 0.2 mg/mL EDTA). Cells were again rinsed three times with PBS, incubated in TE buffer (10 mM Tris base, 1 mM EDTA, pH 8) containing RNase A at 37 °C for 30 min, and blocked with PBS containing 20% fetal bovine serum at 37 °C for 1 h. The cells were then incubated with antibodies for 1 h at 37 °C and rinsed three times with washing buffer (0.05% Tween 20 in PBS), followed by incubation with secondary antibodies for 30 min at 37 °C. After washing, cells were mounted in Prolong Gold mounting medium containing DAPI as a DNA counter stain (both from Molecular Probes). Visualization of the cells treated with LRB-SC−TMP conjugate **2** did not require staining with antibodies. Cells treated with biotin−TMP conjugate **4** were stained with streptavidin−fluorescein (1 ng/mL, Vector Laboratories). Samples required for DNase I treatment were incubated with PBS containing DNase I (1 μg/mL) and $MgCl_2$ (100 μM) for 30 min at 37 °C prior to antibody staining.

Microscopy. Fluorescence images were obtained with a Zeiss Axiovert 200M microscope equipped with appropriate filters for FITC, DAPI, and Cy3/Texas red. Digital images were captured with a CCD camera and processed with the *Axio Vision* software packages (Zeiss, Germany).

Antibodies. The primary antibodies used in this study were sheep IgG polyclonal anti-digoxigenin (1.5 ng/mL, Roche Bioscience). The secondary antibody utilized in this study was donkey anti-sheep IgG conjugated with Alexa 488 (1:1000, Molecular Probes).



Localized Photoactivated Cross-Link Damage by UV Laser. HeLa cells or Chinese hamster AA8 cells were seeded on glass-bottom dishes (MatTek) at 2×10^5 cells per dish and incubated with 20 μM **7a** or **7b** for 1 h at 37 °C in α-MEM free of serum, antibiotics, and phenol red. Cells were kept in the dark from this point on. A Zeiss 510 Meta laser scanning confocal microscope equipped with a multiline (351 and 364 nm) 80 mW argon ion UV laser (Coherent Enterprise II) was employed in this study. We used the 364 nm emission of the UV laser at 19.8 A output to deliver a continuous beam via a quad (375/488/543/633) primary dichroic in the LSM system and through a Plan Apochromat 100X/1.4 Oil DIC objective at 20% transmission and 6.4 μs per pixel. Cell nuclei were imaged with a 633 nm HeNe laser that has no effect on the treated cells. A small region within the nucleus of each cell (6.5 μm^2 or 6 × 30 pixels) received laser energy of 80 nJ/μm^2, as measured using a light meter equipped with a 364 nm UV-optimized probe placed on the objective (International Light model IL 1400A). Laser-irradiated cells were immediately washed and incubated with complete medium at 37 °C for the times indicated and then processed for immunofluorescence imaging as described previously. Images were processed using the LSM browser software package (Zeiss).

[a] Reagents: (i) biotin−NHS ester, dichloromethane, rt, 12 h.

RESULTS

Synthesis and Cellular Localization of LRB-SC−TMP Conjugate and Biotin−TMP Conjugate. Conjugates of LRB-SC and biotin with TMP were prepared as shown in Schemes 1 and 2, respectively. Briefly, methylaminodiethoxyethanemethylaminomethyltrimethylpsoralen (**1**) was reacted with LRB-SC to give the conjugate **2,** while the reaction between the *N*-hydroxysuccinimidyl ester of a biotin derivative with 4′-aminomethyl-4,5′,8-trimethylpsoralen (**3**) afforded the biotin−TMP conjugate **4**. LRB-SC was coupled to TMP on the anticipation that it would allow direct visualization of cross-linked sites in cells. The coupling to biotin was prompted by the ready availability of reagents for detection. The cellular localization of each compound has been well-characterized. Rhodamines are known to concentrate in mitochondria (*16*), while biotin distributes throughout the cell, with a strong presence in the cytoplasm, including in the mitochondria (*17*). Psoralens are DNA intercalators which interact with all DNA, nuclear as well as mitochondrial. Thus, we were curious as to know which component of the conjugates would dominate the cellular distribution. Cells were incubated with each conjugate and exposed to UVA to photoactivate the psoralen. The cells were then washed, fixed, and either viewed directly (those treated with the conjugate **2**) or incubated with a fluorescent streptavidin prior to analysis. The results with the conjugate **2**

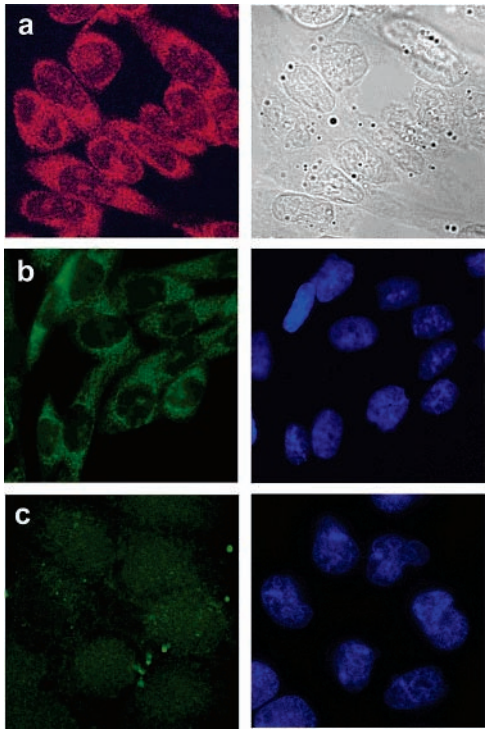

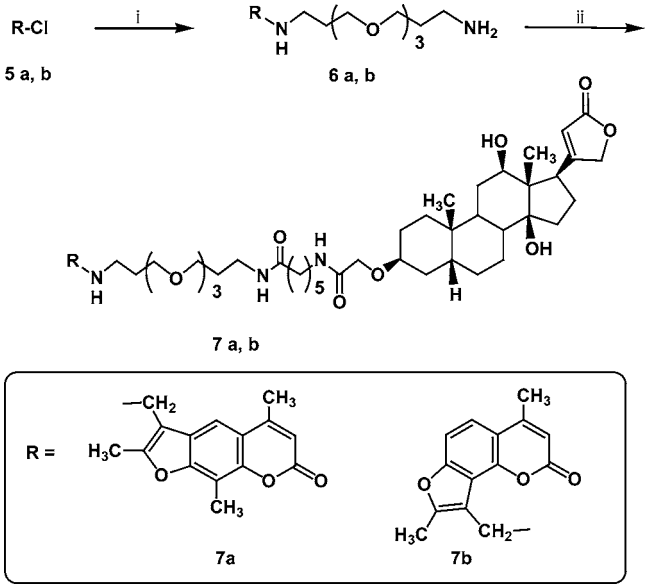

Figure 1. Fluorescence microscope images of Chinese hamster AA8 cells incubated with (a) LRB-SC−TMP conjugate **2** (30 μM), (b) biotin−TMP conjugate **4** (50 μM), (c) biotin−TMP conjugate **4** (200 μM), and free biotin (1 mM). Cells treated with conjugate **4** were stained with fluorescein−streptavidin. Corresponding bright field and DAPI images are also shown.

(Figure 1a) showed that the location of the psoralen cross-links was dictated by the properties of the LRB-SC. The adducts of conjugate **2** were found in the mitochondria. Control experiments showed the requirement for UVA treatment and that DNase I digestion of the fixed cells eliminated the LRB-SC signal (not shown). Cells incubated with conjugate **4** showed an extensive cytoplasmic presence (Figure 1b). Coincubation of cells with conjugate **4** and free biotin, to block biotin binding sites, resulted in a much greater proportion of the signal appearing in the nucleus (Figure 1c). Control experiments again showed the requirement for UVA and the sensitivity of the signal to DNase I (not shown). Although the combination of free biotin and conjugate **4** did yield a nuclear signal, high concentrations of both compounds were required. Furthermore, since biotin is a cofactor for many enzymes, we were concerned about the influence of the high levels of biotin on the cellular physiology. In light of these limitations for the LRB-SC−TMP and biotin−TMP conjugates **2** and **4**, we turned to the examination of digoxigenin as a tag for psoralen in live cell experiments.

Synthesis of Digoxigenin−TMP and −DMA Conjugates. We prepared digoxigenin conjugates of TMP and also 4,5′-dimethylangelicin (DMA), which can only form monoadducts (*18*) (Scheme 3). The latter compound was synthesized to permit analysis of cellular responses to monoadducts generated under the same conditions as the cross-links formed by TMP. Chloromethylation of TMP as well as DMA with chloromethylmethylether followed by the reaction with 4,7,10-trioxa-1,-13-tridecanediamine gave the corresponding TMP and DMA-glycol amines **6a** and **b** which were further reacted with NHS ester of digoxigenin to give the corresponding digoxigenin conjugates of TMP (**7a**) and DMA (**7b**). The poly(ethylene glycol) linker was used to enhance the water solubility of the individual conjugates.

Scheme 3. Synthesis of Digoxigenin−TMP and Digoxigenin−DMA Conjugates 7a and 7b[a]

[a] Reagents: (i) 4,7,10-trioxa-1,13-tridecanediamine, toluene, reflux, 12 h. (ii) Dig-NHS ester, DMF, 50 °C, 18 h.

Reaction of 7a and 7b with Duplex Oligonucleotides. Conjugates **7a** and **7b** were incubated with a duplex oligonucleotide containing multiple 5′ TA steps, appropriate for psoralen cross-linking. In our initial experiments with TMP, we examined the reaction products by electrophoresis on denaturing polyacrylamide gels, which resolved cross-linked from non-cross-linked oligonucleotides. However, we found that linkage to digoxigenin obscured the distinction between single-stranded and cross-linked duplex DNA (not shown). Consequently, we resolved single-strand and cross-linked duplex DNA by HPLC. Following exposure to UVA, the oligonucleotides were examined by HPLC on an ionic exchange column eluted with a NaCl gradient in 25 mM NaOH. In control reactions, the duplex oligonucleotide was incubated with varying amounts of TMP. The individual single strands had retention times of 13.3 and 13.6 min. Similarly, the non-cross-linked duplex sample showed the presence of the same two peaks (Figure 2a). In the sample incubated with the TMP, there was an additional peak of cross-linked oligonucleotide, with increased retention time (Figure 2b). Treatment of the duplex oligonucleotide with **7a** produced a peak with the same retention time as that formed in the reaction with the unconjugated TMP (Figure 2c). The samples treated with the corresponding angelicin conjugate **7b** did not show a peak in this region, although there was a broadening of the peaks in the single-strand positions (Figure 2d). We interpreted these results as demonstrating the cross-linking activity of the **7a** and the absence of that activity with the angelicin derivative **7b**. Comparison of the activity of **7a** with unconjugated TMP demonstrated that the conjugation had reduced the activity by about 10-fold.

Immunofluorescence of Cells Treated with 7a and Whole Cell UVA. Cells were grown on glass coverslips and incubated with 50 μM **7a** for 30 min, followed by exposure to UVA. The slides were fixed and incubated with sheep anti-digoxigenin antibody and then with secondary antibody covalently modified with Alexa 488. Cells treated with **7a** but no UVA showed barely detectable fluorescence (Figure 3a). However, cells treated with **7a**/UVA showed a largely nuclear fluorescence (Figure 3b). These results, which contrasted with those shown in Figure 1, indicated that the conjugate **7a** could be used to cross-link nuclear DNA in living cells.

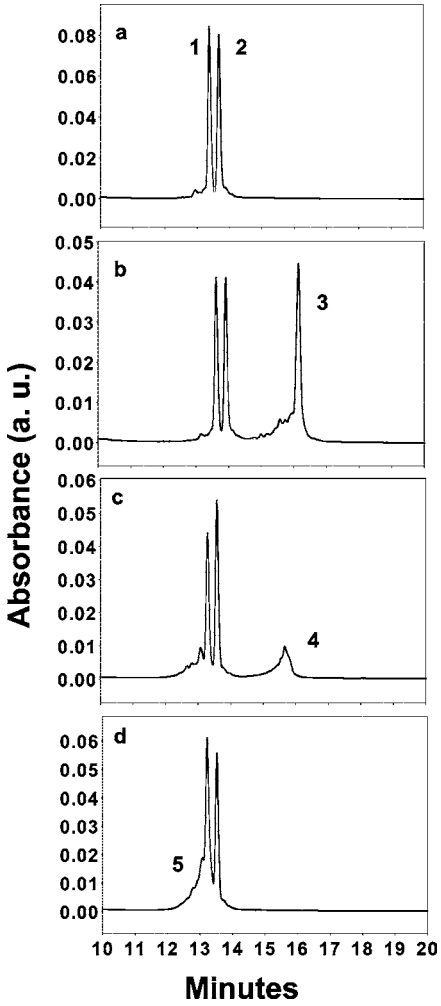

Figure 2. HPLC trace for the separation of the interstrand cross-link reaction mixtures. (a) Traces 1 and 2 represent unreacted oligos 1 and 2. (b) Trace 3 indicates the oligos 1 and 2 cross-linked by TMP. (c) Trace 4 indicates the oligos 1 and 2 cross-linked by digoxigenin−TMP conjugate **7a**. (d) Trace 5 indicates the monoadducts formed between oligos 1 and 2 and digoxigenin−DMA conjugate **7b**.

Since the intended application of the digoxigenin−TMP conjugate was to examine the repair of cross-links in treated cells, it was important to show that the cells were capable of removing the photoadducts formed between DNA and the conjugate. Accordingly, the cells were treated with **7a**/UVA, washed, returned to complete medium without **7a**, and incubated for 6 h at 37 °C. When these cells were fixed and immunostained, we observed a decline in fluorescence intensity to near-background levels (Figure 3c).

Although we interpreted the loss of the immunofluorescence signal in the cells shown in Figure 3c as due to DNA repair, it was also possible that it could have been due to a degradation of the digoxigenin tag, unrelated to DNA repair. In order to test this, we used a cell line lacking the ERCC1 gene. The protein encoded by this gene is a member of a heterodimeric protein complex (with the XPF protein) which is a component of the nucleotide excision repair pathway. It is a structure-specific endonuclease and has been shown to be critical for the repair of interstrand cross-links (*19*, *20*). ERCC1-deficient cells were treated with **7a**/UVA, fixed, and stained immediately or after 6 h of incubation at 37 °C. Figure 4 shows the fluorescent microscopy images of cells treated with **7a**/UVA. As seen from these figures, the fluorescence intensities of the cells stained immediately after treatment (Figure 4a) or after 6 h of incubation (Figure 4b) were quite similar. In a second experiment, we

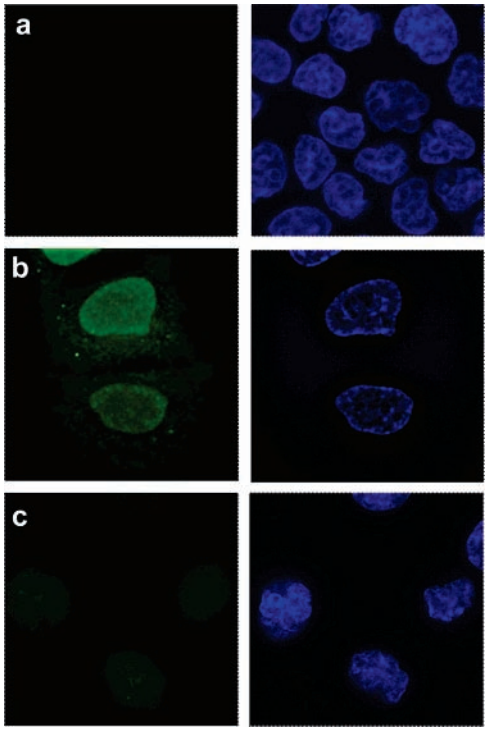

Figure 3. Fluorescence microscopy images of Chinese hamster AA8 cells incubated with digoxigenin−TMP conjugate **7a** (50 μM): (a) Cells without UVA treatment. (b) Cells irradiated with UVA and fixed immediately. (c) Cells irradiated with UVA and fixed after 6 h. Cells were stained with sheep anti-digoxigenin antibody and anti-sheep Alexa 488 antibody. Right panel shows the corresponding images of the same cells counter stained with DAPI.

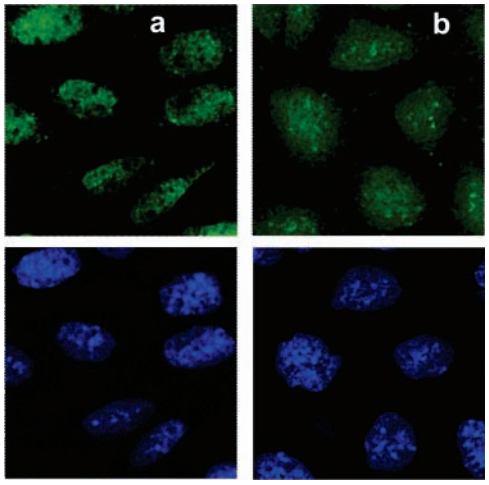

Figure 4. Fluorescence microscope images of ERCC1 (−/−) cells (727) incubated with 50 μM of digoxigenin−TMP conjugate **7a**: (a) Cells irradiated with UVA and fixed immediately. (b) Cells irradiated with UVA and fixed after 6 h. Cells were stained with sheep anti-digoxigenin antibody and anti-sheep Alexa 488 antibody. Lower panel shows the corresponding images of the same cells counter stained with DAPI.

incubated ERCC1-deficient cells overnight with **7a** prior to exposure to UVA. The signal intensity from these cells was indistinguishable from cells that were incubated for only 30 min with **7a** prior to UVA and immunostaining (not shown). These experiments demonstrated that the digoxigenin tag was stable during incubation in a cellular environment and also as part of a genomic DNA interstrand cross-link in living cells.

Localized Cross-Linking via Laser Photoactivation. In the past few years, the energy from focused laser light has been used to introduce DNA damage in defined regions of living

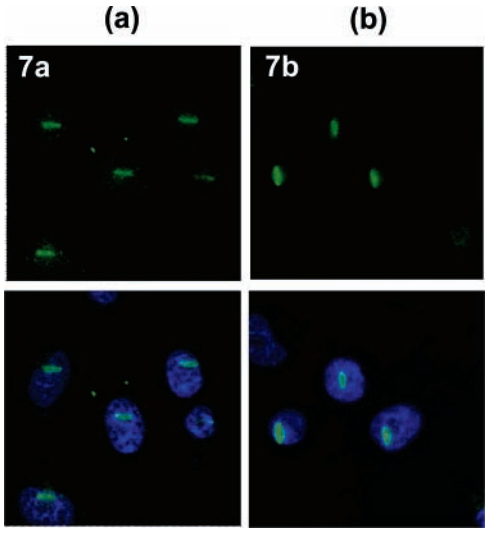

Figure 5. Confocal microscope images of HeLa cells treated with digoxigenin−TMP conjugate **7a** (20 μM) and digoxigenin−DMA conjugate **7b** (50 μM) and locally exposed to UV laser. (a) Cells with localized DNA cross-links induced by **7a** (green fluorescence). (b) Cells with localized DNA monoadducts induced by **7b** (green fluorescence). Cells were stained with sheep anti-digoxigenin antibody and anti-sheep Alexa 488 antibody. Lower panel represents the corresponding merged images of the same cells counter stained with DAPI.

cells (*3*, *6*). We applied this approach to cells incubated with digoxigenin−TMP conjugate **7a**. The cells were viewed in a confocal microscope, and **7a** was photoactivated by exposure of rectangular regions of interest (ROI) in individual cells to the 364 nm emission from a UV laser. The focus was set at the plane of the intersection of a cell nucleus and the adjacent cytoplasm. This was done to place the damage within the interior of the nucleus. The cells were then fixed and immmunostained for the covalently bound conjugate **7a**. Areas of the nucleus outside the ROI as well as cells not exposed to the localized laser served as controls for nonspecific binding of the immunodetection reagents. The results indicated that the conjugate **7a** could be used in conjunction with laser photoactivation to introduce localized genomic cross-links (Figure 5a). Similar experiments were carried out with digoxigenin−DMA conjugate **7b**, which can form only monoadducts. Figure 5b shows the immunofluorescent stripes obtained by the localized laser photoactivation of cells treated with **7b**.

The positive cells were subjected to confocal analysis to determine the extent of reaction within the nucleus. Z-stack images of multiple focal planes were capture with 0.5 μm between each section. As shown in Figure 6, the stain due to conjugate **7a** was clearly visible only in the third section (1 μm), but not in the first two sections or the last z-stack image. This result indicated that the adducts could be precisely induced in three dimensions within the nucleus.

We then asked if cells could repair the laser-induced localized cross-links. Defined regions of cross-links were introduced into repair-proficient cells with **7a**. Cells were either fixed and immunostained immediately or incubated for 6 h prior to fixing and immunostaining. The results (Figure 7) were similar to those seen in the whole-cell experiment shown in Figure 3. There was a reduction in signal to the levels seen in untreated controls. These data indicated that cells could repair the cross-links introduced by laser photoactivation of the conjugate **7a**.

DISCUSSION

Psoralens linked to detectable tags have been used for several years as hybridization probes for use on fixed cells and purified DNA (*21*, *22*). Given the current interest in repair of localized

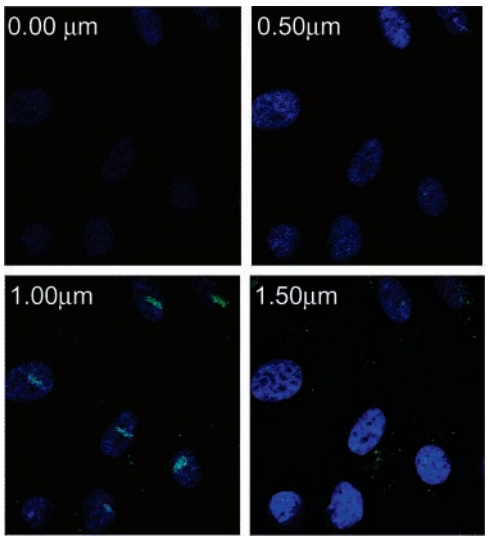

Figure 6. Merged Z stack images of HeLa cells with localized DNA cross-links induced by digoxigenin−TMP conjugate **7a** (20 μM) and UV laser. Cells were stained with sheep anti-digoxigenin antibody and anti-sheep Alexa 488 antibody and counter stained with DAPI.

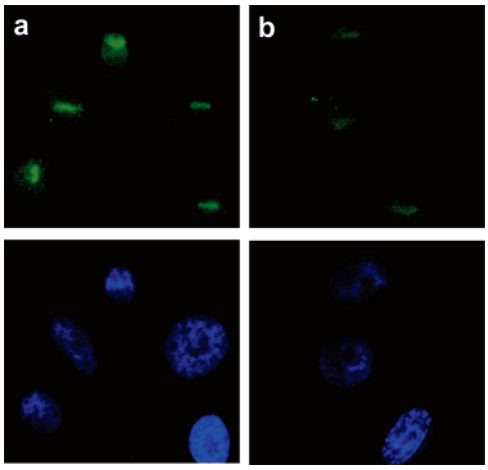

Figure 7. Confocal microscope images of repair proficient HeLa cells treated with digoxigenin−TMP conjugate **7a** (20 μM) and locally exposed to UV laser: (a) Cells with localized DNA cross-links were fixed immediately; (b) after 6 h. Cells were stained with sheep anti-digoxigenin antibody and anti-sheep Alexa 488 antibody. Lower panels represent the corresponding merged images of the same cells counter stained with DAPI.

DNA damage, it seemed reasonable to examine the utility of some of these for examining the repair of DNA cross-links in live cells. Fluorescent derivatives have an obvious appeal, however; as shown in Figure 1a, we found that conjugate **2** localized almost completely to the mitochondria. We also synthesized an Oregon Green derivative. While this compound could be used for nuclear labeling, we found that it was unstable on storage and rapidly bleached during imaging (not shown). The biotin conjugate **4** localized largely to the cytoplasm, and while nuclear labeling could be forced by coadministration of high concentrations of free biotin, we were concerned that this might influence the cellular physiology. The limitations of these compounds led us to synthesize the digoxigenin-linked psoralens. Like the other derivatives, versions of these conjugates have been used for preparing hybridization probes (*23*, *24*). However, as far as we know, they have received no application in living cells. Our results suggest that the digoxigenin−TMP conjugate can be used for studies of repair of localized cross-links in mammalian cells. The digoxigenin tag is stable in cells for extended periods prior to, and following, photoactivation.

Furthermore, we observed no cellular toxicity in the presence of these conjugates.

A key concern was that the cells survive the treatment protocol and be able to repair the DNA damage. Interpretation of repair experiments would be obviously compromised if the cells were killed by the DNA damage treatment. Our observation of repair of the cross-links, caused by conjugate **7a** activated by UVA, in repair-proficient cells appears to allay these concerns. It should now be possible to use the conjugate **7a** to follow the dynamics of repair and the recruitment of repair proteins of laser-induced localized cross-links in mammalian cells.

Integrin $\alpha_v\beta_3$ plays a critical role in tumor angiogenesis and metastasis. Radiolabeled RGD peptides that are integrin $\alpha_v\beta_3$-specific are very useful for noninvasive imaging of integrin expression in rapidly growing and metastatic tumors. In this study, we determined the binding affinity of E{E[c(RGDfK)]$_2$}$_2$ (tetramer) and its 6-hydrazinonicotinamide conjugate (HYNIC-tetramer) against the binding of ^{125}I-echistatin to the integrin $\alpha_v\beta_3$-positive MDA-MB-435 breast cancer cells. The athymic nude mice bearing MDA-MB-435 xenografts were used to evaluate the potential of ternary ligand complex [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] (TPPTS = trisodium triphenylphosphine-3,3′,3″-trisulfonate) as a new radiotracer for imaging breast cancer integrin $\alpha_v\beta_3$ expression by single photon emission computed tomography (SPECT). It was found that the binding affinity of tetramer ($IC_{50} = 51 \pm 11$ nM) was slightly higher than that of its dimeric analogue ($IC_{50} = 78 \pm 27$ nM) and is comparable to that of the HYNIC-tetramer conjugate ($IC_{50} = 55 \pm 11$ nM) within the experimental error. Biodistribution data showed that [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] had a rapid blood clearance (4.61 ± 0.81 %ID/g at 5 min postinjection (p.i.) and 0.56 ± 0.12 %ID/g at 120 min p.i.) and was excreted mainly via the renal route. [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] had high tumor uptake with a long tumor retention (5.60 ± 0.87 %ID/g and 7.30 ± 1.32 %ID/g at 5 and 120 min p.i., respectively). The integrin $\alpha_v\beta_3$-specificity was demonstrated by co-injection of excess E[c(RGDfK)]$_2$, which resulted in a significant reduction in tumor uptake of the radiotracer. The metabolic stability of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] was determined by analyzing urine and feces samples from the tumor-bearing mice at 120 min p.i. In the urine, about 20% of [^{99m}Tc(HYNIC-tetramer)(tricine)-(TPPTS)] remained intact while only ∼15% metabolized species was detected in feces. SPECT images displayed significant radiotracer localization in tumor with good contrast as early as 1 h p.i. The high tumor uptake and fast renal excretion make [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] a promising radiotracer for noninvasive imaging of the integrin $\alpha_v\beta_3$-positive tumors by SPECT.

INTRODUCTION

Angiogenesis is a requirement for tumor growth and metastasis (*1*−*5*). Without the neovasculature to provide oxygen and nutrients, tumors cannot grow beyond 1−2 mm in size. Once vascularized, previously dormant tumors begin to grow rapidly and their volumes increase exponentially. Angiogenic process depends on vascular endothelial cell migration and invasion and is regulated by cell adhesion receptors. Integrins are such a family of proteins that facilitate cellular adhesion to and migration on extracellular matrix proteins found in intercellular spaces and basement membranes and regulate cellular entry and withdrawl from the cell cycle (*4*−*7*). Integrin $\alpha_v\beta_3$ is a receptor for the extracellular matrix proteins with an exposed arginine-glycine-aspartic (RGD) tripeptide sequence (*5*, *6*). Integrin $\alpha_v\beta_3$ is normally expressed at low levels on epithelial cells and mature endothelial cells but it is highly expressed on the activated endothelial cells in the neovasculature of tumors, including osteosarcomas, glioblastomas, melanomas, lung carcinomas, and breast cancer (*8*−*14*). It has been demonstrated that integrin $\alpha_v\beta_3$ is overexpressed on both endothelial and tumor cells in human breast cancer xenografts (*14*). The integrin $\alpha_v\beta_3$ expression correlates well with tumor progression and invasiveness of melanoma, glioma, and breast cancers (*8*, *9*, *13*). The highly restricted expression of integrin $\alpha_v\beta_3$ during tumor growth, invasion, and metastasis present an interesting molecular target for early detection of rapidly growing and metastatic tumors (*15*−*22*).

We and others have been using multimeric cyclic RGD peptides to develop the integrin $\alpha_v\beta_3$-targeted radiotracers to image rapidly growing and metastatic tumors (*23*−*32*). The RGD peptides serve as targeting biomolecules to carry radionuclide (e.g., ^{99m}Tc and ^{64}Cu) to the integrin $\alpha_v\beta_3$ overexpressed on tumor cells and endothelial cells of tumor neovasculature. Recently, we reported ^{64}Cu-DOTA−E{E[c(RGDfK)]$_2$}$_2$ as a positron emission tomography (PET) radiotracer to image glioma integrin $\alpha_v\beta_3$ expression (*26*). Results from the in vitro assay showed that the tetramer, E{E[c(RGDfK)]$_2$}$_2$, had a higher integrin $\alpha_v\beta_3$ binding affinity than the dimer, E[c(RGDfK)]$_2$, against ^{125}I-echistatin due to increased peptide valency. As a result, ^{64}Cu-DOTA−E{E[c(RGDfK)]$_2$}$_2$ showed very high tumor uptake and a long tumor retention (9.93 ± 1.05 %ID/g at 30 min and 4.56 ± 0.51 %ID/g at 24 h p.i.). To further illustrate the advantage of the tetramer, three DOTA conjugates (DOTA−E-c(RGDfK), DOTA−E[c(RGDfK)]$_2$, DOTA−E{E[c(RGDfK)]$_2$}$_2$) and their ^{111}In complexes were prepared (*32*). Figure 1. Schematic structure of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] (tetramer = E{E[c(RGDfK)]$_2$}$_2$; TPPTS = trisodium triphenylphosphine-3,3′,3″-trisulfonate).

^{111}In-DOTA−E-c(RGDfK), ^{111}In-DOTA−E-[c(RGDfK)]$_2$, and ^{111}In-DOTA−E{E[c(RGDfK)]$_2$}$_2$ were performed in athymic nude mice bearing subcutaneous SK-RC-52 tumors. At 8 h p.i, ^{111}In-DOTA−E{E[c(RGDfK)]$_2$}$_2$ showed a much higher tumor uptake (7.40 ± 1.12 %ID/g) than the monomer (2.30 ± 0.34 %ID/g) and the dimer (5.17 ± 1.22 %ID/g). It was concluded that the tetramer E{E[c(RGDfK)]$_2$}$_2$ is the best targeting biomolecule with respect to radiotracer tumor uptake and tumor-to-background (T/B) ratios (*32*). These promising results led us to prepare the 6-hydrazinonicotinamide-conjugated tetramer (HYNIC-tetramer) and its ^{99m}Tc complex [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] (Figure 1: TPPTS = trisodium triphenylphosphine-3,3′,3″-trisulfonate). ^{99m}Tc is the ideal radionuclide for SPECT imaging due to its optimal nuclear properties ($t_{1/2}$ = 6.02 h and E_{max} = 142 KeV) and easy availability at low cost. HYNIC is used as bifunctional coupling agent for the ^{99m}Tc-labeling. TPPTS is used as the coligand because of its three negative charges and the high solution stability of its ^{99m}Tc complexes (*33*).

We now report the evaluation of [^{99m}Tc(HYNIC-tetramer)-(tricine)(TPPTS)] as a SPECT radiotracer to image the integrin $\alpha_v\beta_3$ expression in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts. The objective is to explore the impact of peptide multiplicity on biodistribution characteristics and metabolism of the ^{99m}Tc-labeled multimeric cyclic RGDfK peptides. The results from this study will allow us to further demonstrate the superiority of the cyclic RGDfK tetramer over its dimeric and monomeric analogues with respect to tumor-targeting capability and in vivo kinetics.

MATERIALS AND METHODS

Trisodium triphenylphosphine-3,3′,3″-trisulfonate (TPPTS) and tricine were purchased from Sigma-Aldrich. E{E[c(RGDfK)]$_2$}$_2$ was prepared using the reported procedure (*26*). Sodium succinimidyl 6-(2-(2-sulfonatobenzaldehyde)hydrazono)-nicotinate (HYNIC-NHS) was prepared according to literature method (*34*). Na^{99m}TcO$_4$ was obtained from a commercial DuPont Pharma ^{99}Mo/^{99m}Tc generator, N. Billerica, MA. Mass spectral data were collected on a Finnigan LCQ classic mass spectrometer, School of Pharmacy, Purdue University. HPLC Method 1 used a LabAlliance semiprep HPLC system equipped with a UV−vis detector (λ = 254 nm) and Zorbax C_{18} semiprep column (9.4 mm × 250 mm, 100 Å pore size). The flow rate was 2.5 mL/min. The mobile phase was isocratic with 90% solvent A (0.1% acetic acid in water) and 10% solvent B (0.1% acetic acid in acetonitrile) at 0−5 min, followed by a gradient mobile phase going from 90% solvent A and 10% solvent B at 5 min to 60% solvent A and 40% solvent B at 20 min. The radio-HPLC method (Method 2) used the LabAlliance HPLC system equipped with a β-ram IN-US detector and Zorbax C_{18} column (4.6 mm × 250 mm, 300 Å pore size). The flow rate was 1 mL/min. The mobile phase was isocratic with 90% solvent A (25 mM ammonium acetate buffer, pH = 5.0) and 10% solvent B (acetonitrile) at 0−2 min, followed by a gradient mobile phase going from 10% solvent B at 2 min to 15% solvent B at 5 min and to 20% solvent B at 20 min.

Synthesis of HYNIC-E{E[c(RGDfK)]$_2$}$_2$ (HYNIC-tetramer). HYNIC-NHS (4.17 mg, 10 μmol) and E{E[c(RGDfK)]$_2$}$_2$

(14.0 mg, 10.6 μmol) were dissolved in a mixture of DMF and water (50:50 = v:v). The pH was adjusted to 8.5−9.0 with 0.1 N NaOH. The mixture was incubated overnight at room temperature. The product was purified by HPLC (Method 1). The peak of interest at ~14 min was collected. The collected fractions were combined, and lyophilized to give a pale yellow powder. The yield was 11 mg (~65%) with the purity >95% by HPLC. ESI-MS: $C_{136}H_{188}N_{42}O_{38}S$, calculated 3051.30, observed 3050.93 ($[M + H]^+$).

Synthesis of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)]. To a vial filled with a 1.0 mL solution (pH = 4.8) containing 5 mg of TPPTS, 6.5 mg of tricine, 40 mg of mannitol, 38.5 mg of disodium succinate hexahydrate, and 12.7 mg of succinic acid were added 0.2 mL of HYNIC-tetramer solution (100 μg/mL in water) and 0.3 mL of Na[$^{99m}TcO_4$] solution (370−1850 MBq/mL). The vial was heated at 100 °C for 20−25 min in a lead-shielded water bath. After heating, the vial was placed back into the lead pig and allowed to stand at room temperature for ~10 min. A sample of the resulting solution was analyzed by the radio-HPLC. The radiochemical purity (RCP) was >95%. The HPLC retention time was ~15.5 min (Method 2). For biodistribution study, the radiotracer was first prepared and then purified by HPLC. Volatiles in the mobile phases were completely removed under vacuum. Doses were prepared by dissolving the HPLC-purified radiotracer in saline to a concentration of ~100 μCi/mL. For the blocking experiment, E[c(RGDfK)]$_2$ was dissolved in the solution containing the radiotracer (~100 μCi/mL) to give a concentration of 7.5 mg/mL. The resulting solution was filtered with a 0.20 μm Millex-LG filter to remove any particles before being injected into animals. Each tumor-bearing mouse was injected with 0.1 mL of solution.

Solution Stability. For the stability in kit matrix, samples of the reaction mixture containing the radiotracer were analyzed by HPLC at 0, 2, 4, and 6 h postlabeling. For the cysteine challenging experiment, the solution containing the radiotracer was mixed with an equal volume of a cysteine solution (1 mg/mL). Samples were analyzed by radio-HPLC at 0, 2, 4, and 6 h. For the solution stability after HPLC purification, the radiotracer was purified by HPLC (Method 2). Volatiles were removed under vacuum. The residue was dissolved in saline. Samples of the resulting solution were analyzed by HPLC at 0, 2, 4, and 6 h postlabeling.

Partition Coefficient. The log *P* value of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] was determined using the following procedure: the radiotracer was purified by HPLC. Volatiles were removed under vacuum. The residue was dissolved in a mixture of equal volume (3 mL:3 mL) n-octanol and 25 mM phosphate buffer (pH = 7.4). After being stirred vigorously for at least 20 min, the mixture was centrifuged at a speed of 8000 rpm for 5 min. Samples (in triplicates) from both n-octanol and aqueous layers were counted in a gamma counter (Beckman Gama 8000). The partition coefficients were calculated. The log *P* value was measured three different times and reported as an average of three different measurements plus the standard deviation.

Cell Integrin Receptor Binding Assay. The in vitro integrin-binding affinity and specificity of HYNIC-tetramer were assessed via displacement cell-binding assays using ^{125}I-echistatin as the integrin-specific radioligand. Experiments were performed on MDA-MB-435 human breast cancer cell line by slight modification of a method previously described (*26*). In brief, MDA-MB-435 cells were grown in Gibco's Dulbecco's medium supplemented with 10% fetal bovine serum (FBS), 100 IU/mL penicillin, and 100 μg/mL streptomycin (Invitrogen Co, Carlsbad, CA), at 37 °C in humidified atmosphere containing 5% CO_2. Filter multiscreen DV plates were seeded with 10^5 cells in binding buffer and incubated with ^{125}I-echistatin in the presence of increasing concentrations of different RGD peptide analogues. After the unlabeled ^{125}I-echistatin was removed, hydrophilic PVDF filters were collected and the radioactivity was determined using a gamma counter (Packard, Meriden, CT). The IC_{50} values were calculated by fitting the data by nonlinear regression using GraphPad Prism (GraphPad Software, Inc., San Diego, CA). Experiments were carried out twice with triplicate samples. The IC_{50} values are reported as an average of these samples plus the standard deviation.

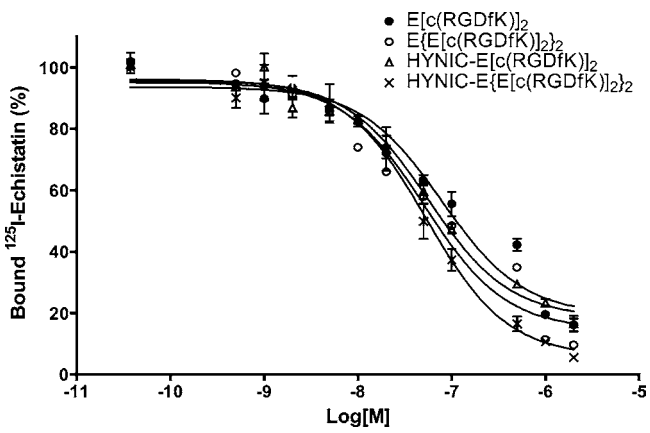

Figure 2. In vitro inhibition of ^{125}I-echistatin binding to $\alpha_v\beta_3$ integrin on MDA-MB-435 human breast cancer cells by E[c(RGDfK)]$_2$ (●), E{E[c(RGDfK)]$_2$}$_2$ (○), HYNIC-E[c(RGDfK)]$_2$ (△), and HYNIC-E{E-[c(RGDfK)]$_2$}$_2$ (×).

Breast Cancer Xenograft Model. Biodistribution, imaging, and metabolism studies were performed using athymic nude mice bearing MDA-MB-435 human breast cancer xenografts in compliance with NIH animal experiment guidelines (*Principles of Laboratory Animal Care*, NIH Publication No. 86-23, revised 1985). The animal protocols were approved by the Purdue University Animal Care and Use Committee (PACUC). Female athymic nude (nu/nu) mice were purchased from Harlan (Indianapolis, IN) at 4−5 weeks of age. The mice were implanted with 5×10^6 cells of MDA-MB-435 estrogen receptor-negative human breast cancer cells into the mammary fat pad. When tumors reached 0.4−0.6 cm in mean diameter, the tumor-bearing mice were used to biodistribution and imaging studies.

Biodistribution Protocol. Sixteen tumor-bearing mice (20−25 g) were anesthetized by intraperitoneal (i.p.) injection of ketamine (40−100 mg/kg) and xylazine (2−5 mg/kg). Once the animal was in surgical plane of anesthesia, as noted by lack of response to pain, the radiotracer (~1 μCi) dissolved in saline was administered via tail vein. Four tumor-bearing mice were sacrificed by exsanguinations and opening of the thoracic cavity at 5, 30, 60, and 120 min postinjection (p.i.). Blood was withdrawn from the heart through a syringe. Organs of interest (such as tumor, brain, eyes, heart, intestine, kidneys, liver, lungs, muscle, and spleen) were excised, washed with saline, dried with tissue, weighed, and counted on a γ-counter (Beckman RD8000). The organ uptake was calculated as a percentage of the injected dose per gram of wet tissue (%ID/g). For the blocking experiment, four tumor-bearing nude mice (20−25 g) were used, and each animal was administered 0.1 mL saline solution containing ~1 μCi of the test agent along with ~750 μg (~ 30 mg/kg) of E[c(RGDfK)]$_2$. At 1 h p.i., all four animals were sacrificed for organ biodistribution using the same procedure above.

Metabolism. Each tumor-bearing mouse was administered with the radiotracer (~100 μCi/mouse). The urine samples were collected at 2 h p.i. by manual void and were mixed with equal volume of acetonitrile. The mixture was centrifuged at 8000 rpm. The supernatant was collected and filtered through a 0.20 μm Millex-LG syringe filter unit. The filtrate was analyzed by

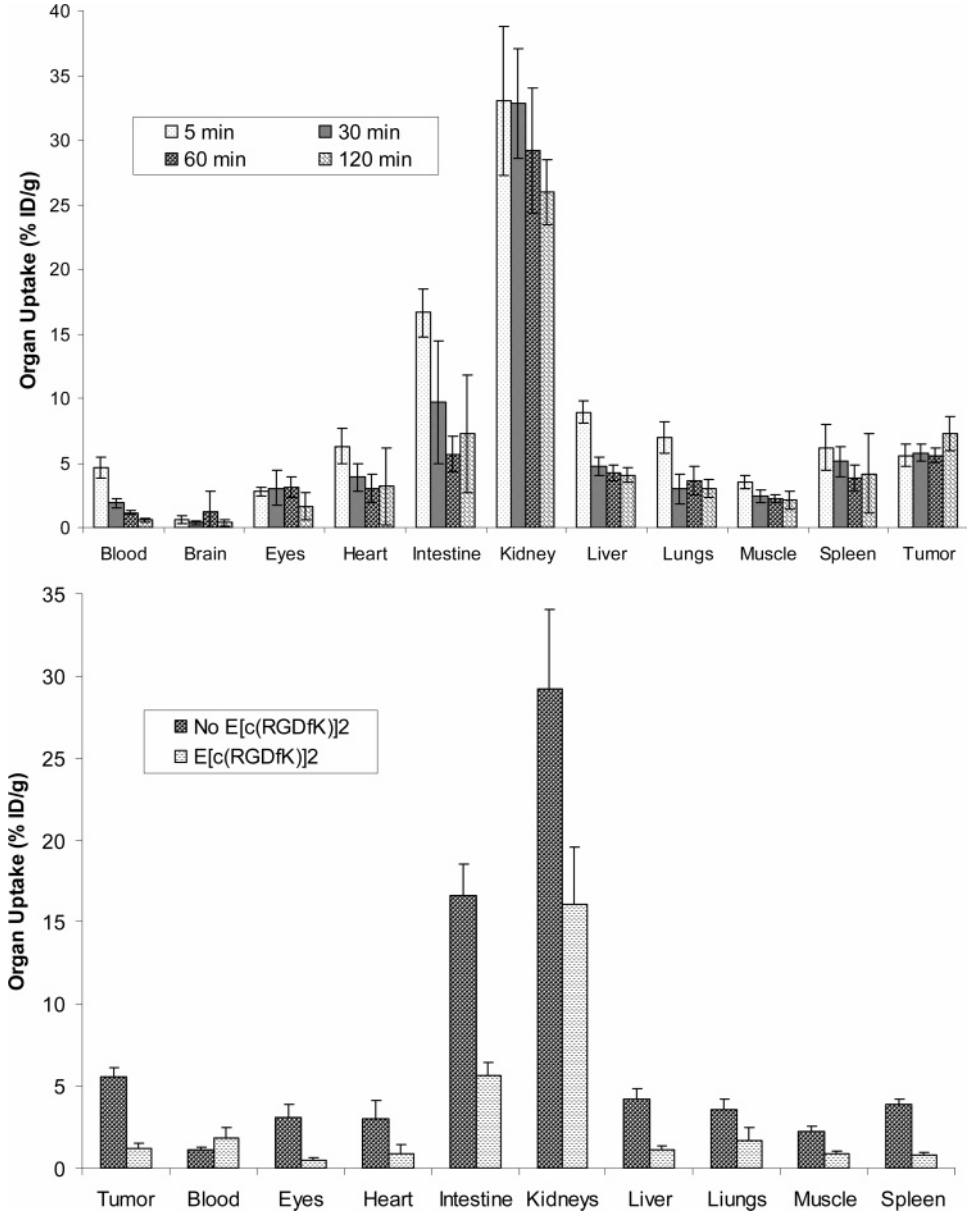

Figure 3. Top: Biodistribution data for [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] at 5, 30, 60, and 120 min p.i. in nude mice bearing the MDA-MB-435 human breast cancer xenografts; Bottom: Comparison of the organ uptake (% ID/g) for [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] at 60 min p.i. in the absence/presence of excess E[c(RGDfK)]$_2$. Each data point represents an average of biodistribution data in four animals.

radio-HPLC (Method 2). The feces samples were collected at 2 h p.i. and suspended in a mixture of 50% acetonitrile aqueous solution, and the resulting mixture was vortexed for 5−10 min. After centrifugation at 8000 rpm for 5 min, the supernatant was collected and passed through a 0.20 μm Millex-LG syringe driven filter unit. The filtrate was analyzed by radio-HPLC. Two tumor-bearing mice were used for the metabolism study.

SPECT Imaging. Imaging studies were performed by Dr. Wang's group using athymic nude mice bearing MDA-MB-435 breast cancer xenografts in accordance with guidelines of Peking University Health Science Center Animal Care and Use Committee. Animals were anesthetized with i.p. injection of sodium pentobarbital at a dose of 45.0 mg/kg. Each animal was administered ~400 μCi of the radiotracer in 0.2 mL of saline. Animals were placed prone on a dual head γ-camera (Siemens, E. CAM) equipped with a parallel-hole, low-energy, and high-resolution collimator. Anterior static images were acquired at 1, 2, and 4 h p.i. and were stored digitally in a 128 × 128 matrix. The acquisition count limits were set at 1000 K. After completion of imaging, animals were sacrificed by cervical dislocation.

Statistical Analysis. The biodistribution data and T/B ratios were reported as an average plus the standard variation based on the results from four animals for each time point. Comparison between two different radiotracers was also made using the one-way ANOVA test. The level of significance was set at $P < 0.05$.

RESULTS

Synthesis of HYNIC-Tetramer. The HYNIC-tetramer conjugate was prepared by coupling E{E[c(RGDfK)]$_2$}$_2$ with HYNIC-NHS under slightly basic condition (pH = 8.5−9.0) in a mixture of water and DMF (50:50 = v:v). It was purified by HPLC (Method 1). Its identity has been confirmed by ESI-MS data (m/z = 3050.93 for $[M + H]^+$ and 1526.89 for $[M + 2H]^{2+}$).

Integrin $\alpha_v\beta_3$ Binding. The integrin $\alpha_v\beta_3$-positive MDA-MB-435 breast cancer cells were used for the in vitro binding affinity studies instead of the immobilized integrin $\alpha_v\beta_3$. We compared the integrin $\alpha_v\beta_3$ binding affinity of HYNIC-tetramer, HYNIC-dimer, E[c(RGDfK)]$_2$, and E{E[c(RGDfK)]$_2$}$_2$ by

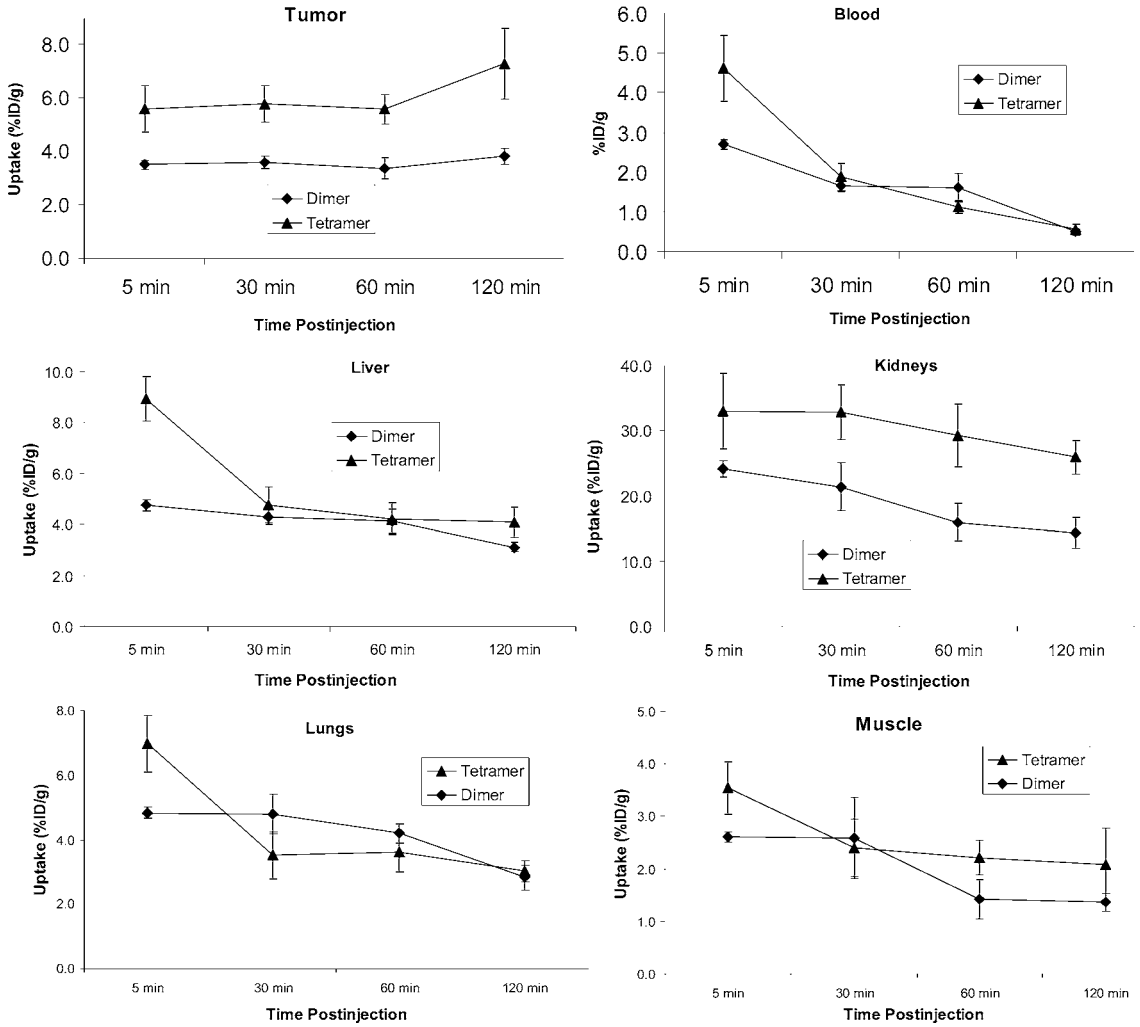

Figure 4. Direct comparison of organ uptake (% ID/g) between [^{99m}Tc(HYNIC-dimer)(tricine)(TPPTS)]) and [^{99m}Tc(HYNIC-tetramer)(tricine)-(TPPTS)]) in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts.

competitive displacement of ^{125}I-echistatin. Both cyclic RGDfK peptides and their HYNIC conjugates inhibited the binding of ^{125}I-echistatin to MDA-MB-435 breast cancer cells (Figure 2). The IC_{50} values for $E\{E[c(RGDfK)]_2\}_2$ and $E[c(RGDfK)]_2$ were 51 ± 11 nM and 78 ± 27 nM, respectively. IC_{50} values for HYNIC-tetramer and HYNIC-dimer were 55 ± 11 nM and 52 ± 9 nM under the same condition. $E\{E[c(RGDfK)]_2\}_2$ has a slightly higher integrin $\alpha_v\beta_3$ binding affinity than $E[c(RGDfK)]_2$. There was no significant difference in the integrin $\alpha_v\beta_3$ binding affinity between their HYNIC conjugates within the experimental error. Attachment of HYNIC did not alter the binding affinity of the tetramer $E\{E[c(RGDfK)]_2\}_2$.

Radiochemistry. [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] was prepared using a non-stannous formulation since TPPTS is a strong reducing agent for Na[$^{99m}TcO_4$] (*33*). The RCP was >95% with less than 0.5% of [^{99m}Tc]colloid. [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] was analyzed using a reversed phase radio-HPLC method (Method 2). The log *P* value for [^{99m}Tc-(HYNIC-tetramer)(tricine)(TPPTS)] was −3.29 ± 0.22 in a mixture of n-octanol and 25 mM phosphate buffer, pH = 7.4. This value is lower than that (−2.66 ± 0.25) of its dimeric analogue [^{99m}Tc(HYNIC-dimer)(tricine)(TPPTS)], suggesting that increasing the peptide multiplicity decreases lipophilicity of the ^{99m}Tc-labeled cyclic RGDfK peptides. The solution stability of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] was monitored by radio-HPLC (Method 2). It was found that it remained stable in the kit matrix and in presence of cysteine challenge (1 mg/mL) for >12 h. It was also stable for >6 h after purification.

Biodistribution. [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] was purified by HPLC to remove the "unlabeled" HYNIC-tetramer. Biodistribution was performed using the athymic nude mice bearing MDA-MB-435 human breast cancer xenografts. Figure 3 showed its biodistribution data in the selected organs with/without the co-injection of excess $E[c(RGDfK)]_2$. The organ uptake was expressed as %ID/g. Each data point represents an average in four animals. Figures 4 and 5 illustrate the comparison of organ uptake and T/B ratios between [^{99m}-Tc(HYNIC-tetramer)(tricine)(TPPTS)] and [^{99m}Tc(HYNIC-dimer)(tricine)(TPPTS)] in several selected organs, such as tumor, blood, liver, lungs, and kidneys. Biodistribution data and T/B ratios of [^{99m}Tc(HYNIC-dimer)(tricine)(TPPTS)] were obtained from our previous study (*24*).

In general, [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] displayed a rapid clearance predominantly via renal route. The tumor uptake of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] (5.60 ± 0.87 %ID/g and 7.30 ± 1.32 %ID/g at 5 and 120 min p.i., respectively) was significantly higher than that of [^{99m}Tc-(HYNIC-dimer)(tricine)(TPPTS)] (3.50 ± 0.18 %ID/g and 3.82 ± 0.32 %ID/g at 5 and 120 min p.i., respectively) over the 2 h study period. The kidney uptake of [^{99m}Tc(HYNIC-tetramer)-(tricine)(TPPTS)] (33.05 ± 5.75 %ID/g and 25.93 ± 2.52 %ID/g at 5 and 120 min p.i., respectively) was much higher than that of [^{99m}Tc(HYNIC-dimer)(tricine)(TPPTS)] (24.15 ± 1.23 %ID/g and 14.33 ± 2.39 %ID/g at 5 and 120 min p.i., respectively) during the same study period. The blood radioactivity level for [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)]

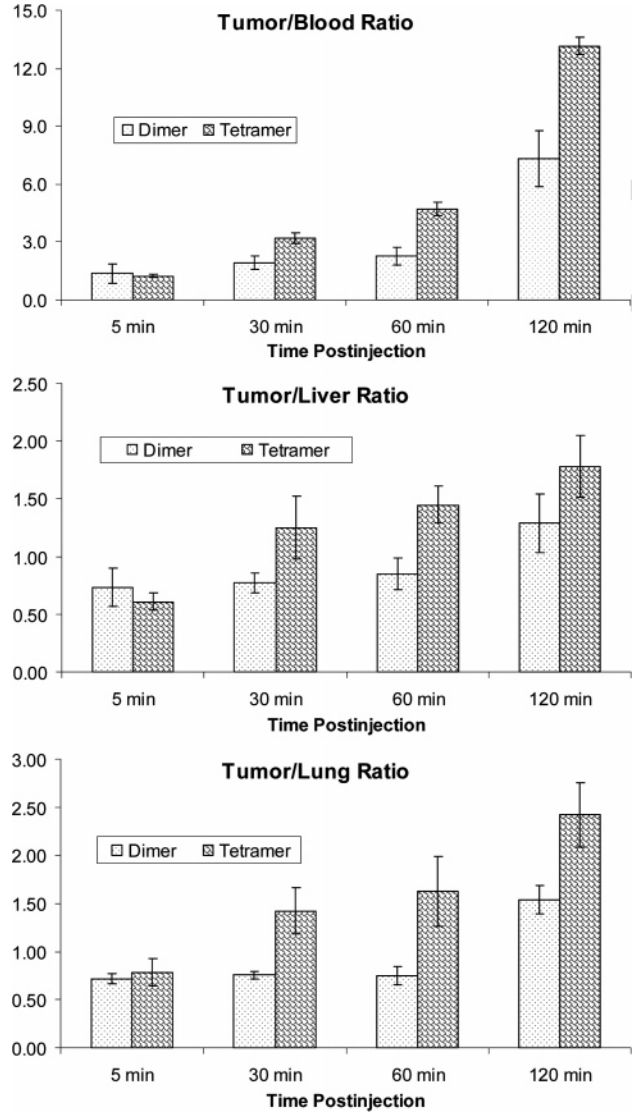

Figure 5. Direct comparison of T/B ratios between [^{99m}Tc(HYNIC-dimer)(tricine)(TPPTS)]) and [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)]) in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts.

(4.61 ± 0.82 %ID/g) was significantly ($p < 0.01$) higher than that of [^{99m}Tc(HYNIC-dimer)(tricine)(TPPTS)] (2.70 ± 0.12 %ID/g) at 5 min p.i.; but this difference disappeared at 30−120 min p.i. (Figure 4). A similar trend was observed for their liver uptake. As a result, [^{99m}Tc(HYNIC-tetramer)-(tricine)(TPPTS)] has the tumor/blood, tumor/liver and tumor/lung ratios that are significantly better ($p < 0.05$) than those of [^{99m}Tc(HYNIC-dimer)(tricine)(TPPTS)] at 30−120 min p.i. (Figure 5).

Blocking Experiment. In this experiment, E[c(RGDfK)]$_2$ (IC_{50} = 78.27 ± 27.59 nM against ^{125}I-echistatin binding to the integrin $\alpha_v\beta_3$-positive MDA-MB-435 breast cancer cells) was used as the blocking agent at a dose of ∼30 mg/kg (∼750 μg per mouse). Such a high dose was used to make sure that the integrin $\alpha_v\beta_3$ is almost completely blocked. It was found that co-injection of a large excess of E[c(RGDfK)]$_2$ resulted in a significant reduction of the uptake of [^{99m}Tc(HYNIC-tetramer))(tricine)(TPPTS)] in the tumor. In addition, there was also substantial decrease of the uptake for [^{99m}Tc(HYNIC-tetramer))(tricine)(TPPTS)] in lungs, liver, spleen, and intestine (Figure 3). The muscle and kidney uptake was also inhibited (to a lesser degree). The blood activity in the presence of E[c(RGDfK)]$_2$ was higher than that without E[c(RGDfK)]$_2$.

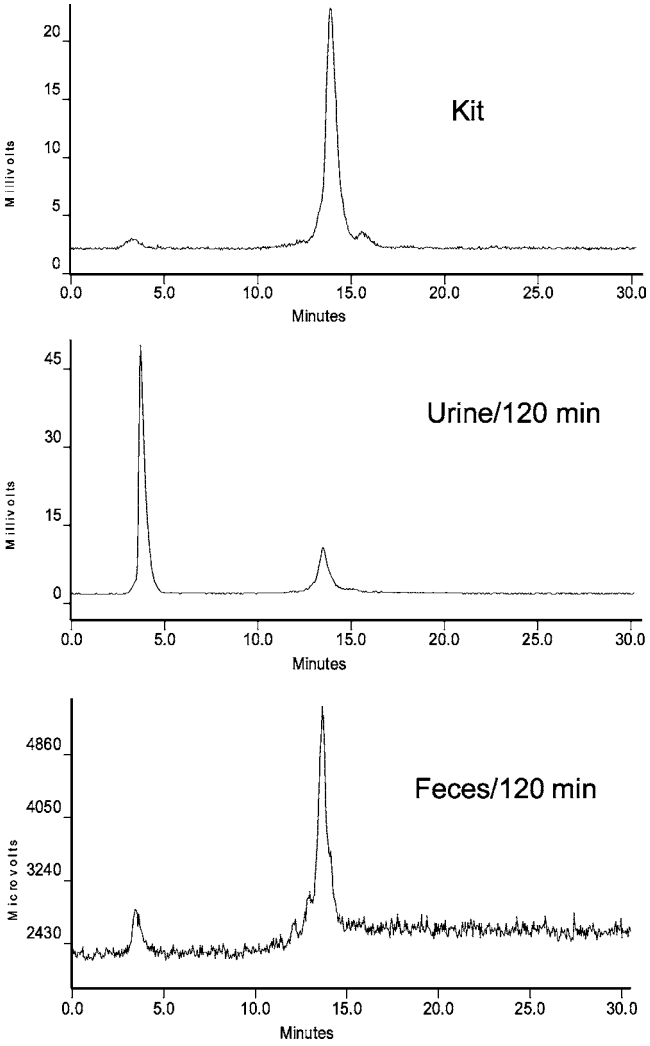

Figure 6. Radio-HPLC chromatograms of [^{99m}Tc(HYNIC-dimer)-(tricine)(TPPTS)] in the kit matrix before injection, in urine and feces at 120 min p.i. Each tumor-bearing mouse was administered with ∼3.7 MBq of radiotracer.

Metabolism. The metabolism study on [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] was performed using the tumor-bearing mice. Since it is excreted via both renal and hepatobiliary routes, we collected samples from urine and feces to determine if they are able to retain their chemical integrity at 2 h postinjection. Figure 6 sowed typical radio-HPLC chromatograms of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] in the kit matrix, urine, and feces at 120 min postinjection. About 80% metabolite of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] was found in the urine while only ∼15% metabolism was detected in the feces sample at 2 h p.i. No efforts have been made to identify the metabolite(s).

SPECT Imaging. Figure 7 illustrated the selected SPECT images of tumor-bearing mice administered with ∼15 MBq of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] at 1, 2, and 4 h postinjection. Tumors were clearly visualized in all three SPECT images. The activity level in the abdominal region (particularly liver and lungs) was very low, which agreed well with the ex vivo biodistribution data at the same time point (Figure 4).

DISCUSSION

The in vivo distribution pattern of a ^{99m}Tc-based radiotracer is determined by several factors, including binding affinity of the targeting biomolecule, internalization of the radiotracer, Tc chelate, molecular charge, lipophilicity, and metabolic stability.

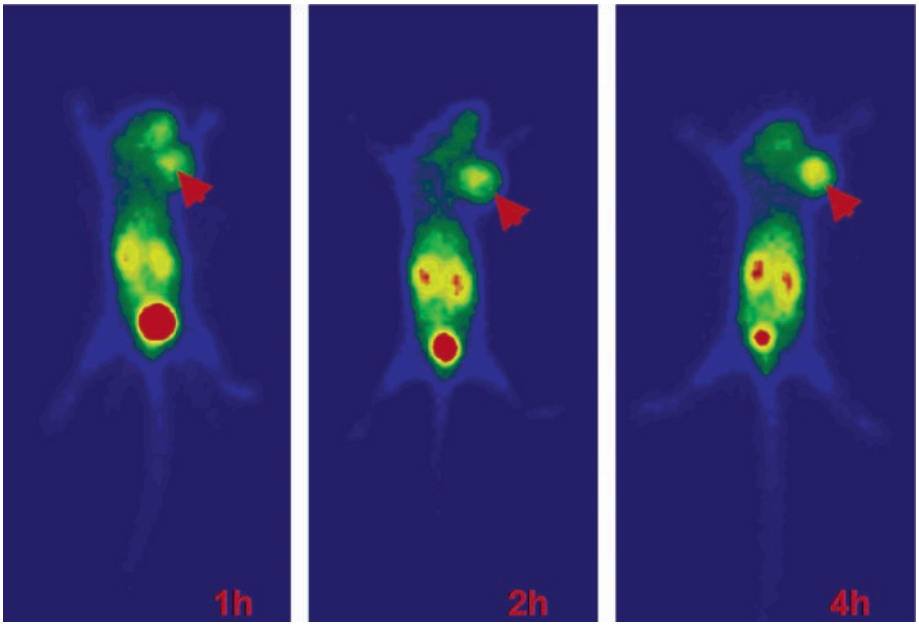

Figure 7. Representative static SPECT images of the tumor-bearing mice administered with ~15 MBq of [^{99m}Tc(HYNIC-tetramer)(tricine)-(TPPTS)] and at 1, 2, and 4 h p.i. Arrows indicate the presence of tumors.

Since the natural mode of interactions between integrin $\alpha_v\beta_3$ and RGD-containing proteins may involve multivalent binding sites, the idea to improve integrin $\alpha_v\beta_3$ binding affinity with multivalent RGD peptides could provide more effective antagonists with better targeting capability and higher cellular uptake through the integrin-dependent endocytosis pathway (*35*). Several groups applied the multivalent concept to develop integrin $\alpha_v\beta_3$-targeted radiotracers. Rajopadhye et al. were the first to use cyclic RGD peptide dimers, such as E[c(RGDfK)]$_2$, as targeting biomolecules for development of diagnostic (^{99m}Tc and ^{111}In) and therapeutic (^{90}Y) radiotracers (*37*, *38*). We also used E[c(RGDyK)]$_2$ to prepare ^{64}Cu-based PET radiotracers (*26*). Kessler et al. reported the hexaethylene glycolic acid (HEG) and poly(lysine)-tethered cyclic RGDfE dimers and tetramers with better integrin $\alpha_v\beta_3$ binding affinity than its monomeric analogues (*30*, *31*). The HEG and poly-(lysine) linkers were used to increase the distance between RGD motifs. It was found that the minimum distance is about 3.5 nm (~25 bond distances) for simultaneous binding of two RGD motifs in the immobilized integrin $\alpha_v\beta_3$ assay (*30*, *31*).

The success of E[c(RGDfK)]$_2$ and E[c(RGDyK)]$_2$ as targeting biomolecules for the integrin $\alpha_v\beta_3$ radiotracers is very intriguing. Given the short distance between two cyclic RGD motifs, it is unlikely that they would bind to the adjacent integrin $\alpha_v\beta_3$ receptors simultaneously. However, the binding of one RGD motif to integrin $\alpha_v\beta_3$ will significantly increase "local concentration" of the second RGD motif in the vicinity of receptor site. This might lead to the enhanced integrin $\alpha_v\beta_3$ binding rate or reduced dissociation rate of RGD peptide from integrin $\alpha_v\beta_3$. The high "local RGD peptide concentration" may explain the higher tumor uptake and longer tumor retention times of the radiolabeled (^{99m}Tc, ^{111}In, and ^{64}Cu) cyclic RGD dimers as compared to their monomeric analogues (*26*, *37*, *38*).

The longest distance between RGD motifs of E{E[c(RG-DfK)]$_2$}$_2$ is ~30 bond lengths. Its integrin $\alpha_v\beta_3$ binding affinity (IC_{50} = 15 ± 1 nM) is higher than that of E[c(RGDfK)]$_2$ (IC_{50} = 32 ± 2 nM) against ^{125}I-echistatin in binding to the integrin $\alpha_v\beta_3$-positive U87MG glioma cancer cells (*27*). In this study, the integrin $\alpha_v\beta_3$ binding affinity of E{E[c(RGDfK)]$_2$}$_2$ (IC_{50} = 51 ± 11 nM) is only slightly higher than that of E[c(RGDfK)]$_2$ (IC_{50} = 78 ± 27 nM) against ^{125}I-echistatin binding to the integrin $\alpha_v\beta_3$-positive MDA-MB-435 breast cancer cells. There is no significant difference in IC_{50} values between HYNIC-tetramer (55 ± 11 nM) and HYNIC-dimer (52 ± 9 nM). We believe that the different results obtained from two in vitro assays might be related to the integrin $\alpha_v\beta_3$ expression level on tumor cells (glioma versus breast cancer). Recently, we have demonstrated that the integrin $\alpha_v\beta_3$ density on MDA-MB-435 breast cancer cells was not as high as that on U87MG glioma cancer cells (*39*). Therefore, the distance between the two neighboring integrin $\alpha_v\beta_3$ receptors would be longer, which makes it more difficult for two RGD motifs in E{E[c(RGDfK)]$_2$}$_2$ and E[c(RGDfK)]$_2$ to bind to the adjacent integrin $\alpha_v\beta_3$ simultaneously. This might explain the fact that the IC_{50} of HYNIC-tetramer (55 ± 11 nM) using MDA-MB-435 breast cancer cells is more than 3-fold higher than that (15 ± 1 nM) using U87MG glioma cancer cells. This may also explain why the IC_{50} values for RGD peptides (monomers, dimers, and tetramers) obtained with the immobilized integrin $\alpha_v\beta_3$ assay (*26*−*29*) are always much lower that those obtained using the whole-cell integrin $\alpha_v\beta_3$-binding assay (*30*, *31*).

The in vivo tumor targeting capability of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] was evaluated in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts. It was found to have a much higher tumor uptake than its dimeric analogue over the 2 h study period, even though HYNIC-tetramer has the IC_{50} (55 ± 11 nM) similar to that of HYNIC-dimer (52 ± 9 nM). Among the radiotracers evaluated in this animal model (*24*, *25*), [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] has the highest tumor uptake (7.30 ± 1.32 %ID/g) at 2 h p.i. One might argue that the enhanced tumor uptake is related to higher molecular weight of the cyclic RGDfK tetramer, resulting in longer blood circulation time. However, there is no significant difference in the blood activity levels and the liver uptake between [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] and [^{99m}Tc(HYNIC-dimer)(tricine)(TPPTS)] at 30−120 min p.i. The tumor/blood ratio of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] (13.15 ± 1.45) is almost twice of that of [^{99m}Tc(HYNIC-dimer)-(tricine)(TPPTS)] (7.32 ± 0.44) at 120 min p.i. (Figure 5). The tumor/liver and tumor/lung ratios of [^{99m}Tc(HYNIC-tetramer)-(tricine)(TPPTS)] are also significantly better ($p < 0.05$) than those of [^{99m}Tc(HYNIC-dimer)(tricine)(TPPTS)] at 30−120 min

p.i. Clearly, the tetramer E{E[c(RGDfK)]$_2$}$_2$ is a better integrin $\alpha_v\beta_3$-targeting biomolecule than its monomeric and dimeric analogues.

The kidney uptake of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] is significantly higher than that of its dimeric analogue at all four time points (Figure 4). Small peptides in blood plasma are filtered through glomerular capillaries in the kidneys and subsequently reabsorbed by proximal tubular cells by carrier-mediated endocytosis. Membranes of renal tabular cells contain negatively charged sites to which the positively charged groups, such as guanidine moieties in cyclic RGD peptides, are expected to bind. In this respect, one might suggest that different charges of E{E[c(RGDfK)]$_2$}$_2$ and E[c(RGDfK)]$_2$ could cause the difference in kidney uptake of [^{99m}Tc(HYNIC-tetramer)(tricine)-(TPPTS)] and [^{99m}Tc(HYNIC-dimer)(tricine)(TPPTS)] because E{E[c(RGDfK)]$_2$}$_2$ has more positively charged R-residues under physiological conditions. It has been shown that positively charged peptides are more efficiently reabsorbed by the proximal renal tubular cell than neutral peptides (*40*). The high kidney uptake and prolonged kidney retention has also been attributed to positively charged K residues of ^{99m}Tc-DKCK-c(RGDfK), in which one K residue is part of the Tc chelate and one is used as a linker between c(RGDfK) and the Tc chelate in addition to the K residue in c(RGDfK) (*40*). However, this explanation cannot account for the fact that the kidney uptake of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] can be partially blocked by excess E[c(RGDfK)]$_2$ (Figure 3). Therefore, the high kidney uptake and prolonged kidney retention of [^{99m}Tc-(HYNIC-tetramer)(tricine)(TPPTS)] is probably caused by several factors, including the ^{99m}Tc chelate (^{99m}Tc-HYNIC-tricine-TPPTS), presence of more R-residues, integrin $\alpha_v\beta_3$-binding, high molecular weight of E{E[c(RGDfK)]$_2$}$_2$.

The tumor-specificity of [^{99m}Tc(HYNIC-tetramer)(tricine)-(TPPTS)] was demonstrated by co-injecting excess E[c(RGD-fK)]$_2$, which resulted in significant reduction in the tumor uptake of [^{99m}Tc(HYNIC-tetramer))(tricine)(TPPTS)]. Since the integrin $\alpha_v\beta_3$ expression in lungs and liver of rats has been documented (*41*), it is not surprising to see a high uptake in liver and lungs of tumor-bearing mice. The blood activity of [^{99m}Tc(HYNIC-tetramer))(tricine)(TPPTS)] with excess E[c(RGDfK)]$_2$ was higher than that without E[c(RGDfK)]$_2$, is probably caused by its saturation effect. Similar results were obtained for [^{99m}Tc-(HYNIC-dimer)(tricine)(TPPTS)] and ^{111}In-DOTA−E[c(RGD-fK)]$_2$ in the BALB/c mice bearing ovarian carcinoma (*28*, *29*), ^{64}Cu-DOTA−E[c(RGDfK)]$_2$ in nude mice bearing the MDA-MB-435 breast cancer xenografts (*26*), and ^{64}Cu-DOTA−E{E-[c(RGDfK)]$_2$}$_2$ in nude mice bearing UG87MG glioma xenografts (*27*).

Radiolabeled cyclic RGD peptides (monomers, dimers, and tetramers) often accumulate in kidneys. Extensive metabolism has been detected for the ^{99m}Tc-labeled RGDfK monomer (*39*) and ^{64}Cu-labeled cyclic RGDfK tetramer in kidneys and urine samples (*27*). In this study, only 20% of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] remained intact in urine at 120 min p.i. Similar results were observed for [^{99m}Tc(HYNIC-dimer)-(tricine)(TPPTS)] (*24*). Surprisingly, >85% of [^{99m}Tc(HYNIC-tetramer)(tricine)(TPPTS)] remains intact in the feces sample at 2 h p.i. It is possible that the metabolized species can be reabsorbed and then excreted via renal system.

CONCLUSION

In summary, we studied biodistribution properties of the ^{99m}Tc-labeled RGD tetramer, [^{99m}Tc(HYNIC-tetramer)(tricine)-(TPPTS)], in athymic nude mice bearing MDA-MB-435 human breast cancer xenografts. The key finding of this study is that the tetramer is a much better integrin $\alpha_v\beta_3$-targeting biomolecule than its monomeric and dimeric analogues. The peptide multiplicity has a significant impact on biodistribution characteristics and metabolic patterns of ^{99m}Tc-labeled cyclic RGD peptides. On the basis of tumor uptake and T/B (particularly tumor/liver and tumor/lung) ratios, we believe that [^{99m}Tc-(HYNIC-tetramer)(tricine)(TPPTS)] is a promising new radiotracer for noninvasive imaging of the integrin $\alpha_v\beta_3$-positive tumors by SPECT.

Delivery of monoclonal antibody therapeutics across the blood−brain barrier is an obstacle to the diagnosis or therapy of CNS disease with antibody drugs. The immune therapy of Alzheimer's disease attempts to disaggregate the amyloid plaque of Alzheimer's disease with an anti-Aβ monoclonal antibody. The present work is based on a three-step model of immune therapy of Alzheimer's disease: (1) influx of the anti-Aβ monoclonal antibody across the blood−brain barrier in the blood to brain direction, (2) binding and disaggregation of Aβ fibrils in brain, and (3) efflux of the anti-Aβ monoclonal antibody across the blood−brain barrier in the brain to blood direction. This is accomplished with the genetic engineering of a trifunctional fusion antibody that binds (1) the human insulin receptor, which mediates the influx from blood to brain across the blood−brain barrier, (2) the Aβ fibril to disaggregate amyloid plaque, and (3) the Fc receptor, which mediates the efflux from brain to blood across the blood−brain barrier. This fusion protein is a new antibody-based therapeutic for Alzheimer's disease that is specifically engineered to cross the human blood−brain barrier in both directions.

INTRODUCTION

Monoclonal antibodies (MAb) have the potential to be new pharmaceutical agents for the diagnosis or therapy of brain disease. However, MAb's are large-molecule drugs that do not cross the blood−brain barrier (BBB). The immune therapy of Alzheimer's disease (AD) began with the active immunization of mice against the 40 amino acid amyloid Aβ peptide of AD (*1*). It was found that certain anti-Aβ antibodies could clear the brain of amyloid plaque following active immunization (*1*), which correlated with in vitro studies showing that certain anti-Aβ antibodies disaggregated preformed Aβ amyloid fibrils (*2*, *3*). The intracerebral injection of anti-Aβ antibodies in AD transgenic mice results in the rapid clearance of pre-existing plaque (*4*−*6*) and repair of dystrophic neurites (*4*, *6*). However, if anti-Aβ antibodies in the blood are to disaggregate the Aβ amyloid in the brain, there must be a mechanism for circulating antibodies to cross the BBB and enter the brain from blood. In active immunization, the mice were immunized with Complete Freund's adjuvant (*1*), which enabled circulating anti-Aβ antibodies to enter the brain from blood, because Complete Freund's adjuvant, and anti-mannan antibodies, cause BBB disruption (*7*, *8*). BBB disruption causes neuropathologic changes in the brain microvasculature (*9*) and in the brain (*10*). What is needed is an anti-Aβ MAb that is engineered to cross the BBB without the requirement for BBB disruption.

Large-molecule drugs, such as antibody therapeutics, can cross the BBB, if the molecule is able to access specific receptor-mediated transport (RMT) systems within the BBB, such as the BBB insulin receptor or BBB transferrin receptor (*11*). A protein drug that is not a ligand for a BBB RMT system can still undergo transport across the BBB, if the MAb is conjugated to a BBB molecular Trojan horse. The latter is an endogenous ligand or peptidomimetic MAb that crosses the BBB via the endogenous RMT systems. Moreover, for certain brain diseases such as AD, there must also be a mechanism for efflux from brain back to blood of the complex of the therapeutic antibody and the Aβ peptide. Otherwise, there would be no net clearance of the Aβ amyloid peptide from AD brain. Therefore, an antibody therapeutic for AD must be engineered to enable transport across the BBB in both directions.

The present work describes the genetic engineering, expression, and validation of an anti-Aβ fusion antibody that is engineered to cross the BBB in both the blood to brain and the brain to blood directions. The immune therapy of AD is viewed as a three-step process (Figure 1): (a) influx of the anti-Aβ antibody from blood to brain across the BBB, (b) binding to and disaggregation of Aβ fibrils behind the BBB, and (c) efflux of the Aβ-antibody complex from brain back to blood. The present studies describe the genetic engineering of a fusion antibody that is a trifunctional molecule. As shown in Figure 2, the "head" of the fusion antibody binds the human insulin receptor (HIR). The insulin receptor is highly expressed at the human BBB (*12*) and mediates the brain uptake of circulating insulin (*13*). In addition, the BBB insulin receptor mediates the brain uptake of certain peptidomimetic monoclonal antibodies (MAb) to the insulin receptor (*14*). The genetic engineering of either a chimeric or a humanized MAb to the HIR has been described previously (*15*, *16*), and both HIRMAbs are rapidly transported from blood to brain across the BBB of the rhesus monkey in vivo. The "tail" of the fusion antibody (Figure 2) is composed of a single-chain Fv (ScFv) antibody directed against the amino-terminal portion of the Aβ peptide. The bivalent nature of the anti-Aβ MAb is restored when each ScFv monomer is fused to the carboxyl terminus of the heavy chain of the HIRMAb, as depicted in Figure 2. The "midsection" of the fusion antibody contains the CH_2-CH_3 interface of the human IgG constant region, which is the binding site for the neonatal Fc receptor or FcRn (*17*). Unlike plasma proteins such as albumin, IgG molecules are rapidly exported unidirectionally from brain to blood across the BBB via a FcR (*18*). Confocal

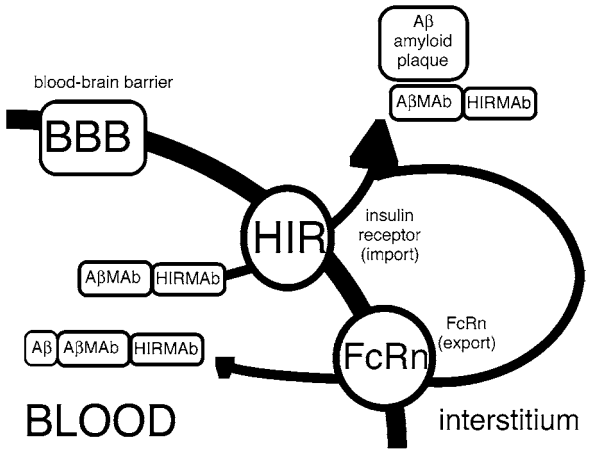

Figure 1. Import−export model of Aβ antibody therapeutics. The fusion antibody clears amyloid from brain in AD via three sequential steps, and each of these three sequential steps uses separate parts of the fusion antibody molecule. Step 1 is the influx of the fusion antibody from blood to brain across the BBB, which is mediated by binding of the fusion antibody to the BBB HIR. Step 2 is binding of the fusion antibody to the amyloid plaque in AD, which promotes disaggregation of the amyloid plaque, and this binding to the plaque is mediated by the anti-Aβ ScFv part of the fusion antibody. Step 3 is the efflux of the fusion antibody from brain to blood across the BBB, which is mediated by binding of the fusion antibody to the BBB FcRn at the CH_2-CH_3 interface of the Fc region of the fusion antibody.

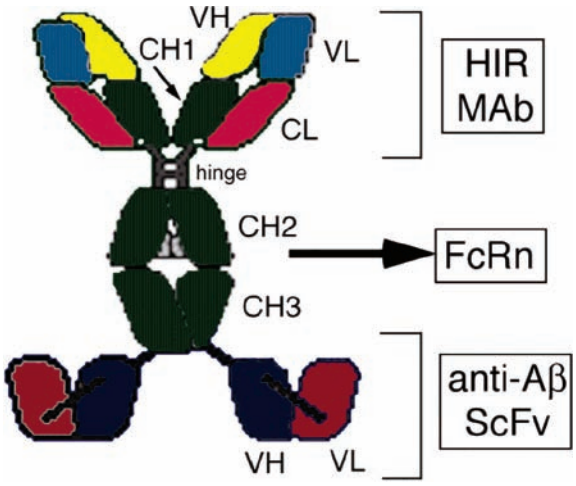

Figure 2. Antibody fusion protein with three functional domains. The first domain, the HIRMAb, binds the BBB HIR to trigger influx across the BBB. The second domain, the CH_2/CH_3 interface of the Fc region, binds to the BBB FcRn to trigger efflux from brain back to blood. The third domain, the anti-Aβ ScFv fused to the CH_3 region, binds to the Aβ amyloid peptide of AD to cause disaggregation of amyloid in brain.

microscopy studies shows the principle BBB FcR isoform is the FcRn (*19*). The FcRn is an Fc receptor that is distinct from classical Fc receptors and is responsible for transcytosis of IgG molecules in peripheral tissues (*20*). Following administration of the fusion antibody into the blood stream, the protein is enabled to cross the BBB in the blood to brain direction, bind and disaggregate Aβ fibrils in the brain of AD, and undergo efflux from brain back to blood (Figure 1).

EXPERIMENTAL PROCEDURES

Genetic Engineering. The variable region of the heavy chain (VH) and the variable region of the light chain (VL) of the murine anti-Aβ ScFv were cloned by PCR using a cDNA template derived from VH- and VL-specific primers described previously (*21*) and poly A+ RNA isolated from the murine hybridoma cell line. Following PCR and agarose gel electrophoresis, the expected major cDNA bands corresponding to the PCR amplified ~0.4 kilobase (kb) VL cDNA and ~0.4 kb VH cDNA were obtained. The VH and VL bands were isolated from the agarose gels and subcloned into a ScFv vector to link the VH and VL genes aside a gene encoding a 17 amino acid linker; the VL gene was followed by a sequence that encoded the 10 amino acid c-myc epitope (EQKLISEEDL) of the 9E10 MAb, as described previously (*21*). The anti-Aβ ScFv cDNA was subcloned into the pcDNA3.1 vector to produce the pCD−ScFv plasmid.

The engineering of the gene encoding the heavy chain of the fusion antibody was done in two steps: (a) PCR cloning of the anti-Aβ ScFv and (b) insertion of this cDNA into the universal chimeric HIRMAb heavy-chain expression vector, pCD−UHC, to form the pCD−HC−ScFv plasmid. The pCD−UHC expresses the cDNA encoding for the intronless heavy chain (HC) of the chimeric HIRMAb (*16*) and has a single HpaI site at the end of the HIRMAb HC open reading frame (orf) for insertion of genes of interest and expression of HIRMAb HC fusion proteins. For the PCR cloning of the mature anti-Aβ ScFv, the mature ScFv PCR forward oligodeoxynucleotide (ODN) was designed, so as to delete the human IgG peptide leader sequence from the anti-Aβ ScFv cDNA while maintaining the orf at the CH_3 region of the HIRMAb heavy chain of the pCD−UHC. This results in the insertion of a Ser−Ser linker between the end of the CH_3 region of the HIRMAb and the amino-terminal part of the ScFv. The anti-Aβ ScFv reverse PCR ODN was designed to delete the c-myc tag and to introduce a stop codon, TAA. Both PCR primers were 5′-phosphorylated for direct ligation into the pCD−UHC at the HpaI site. The PCR cloning of the mature anti-Aβ ScFv cDNA was done using the pCD−ScFv DNA as template. Agarose gel electrophoresis of the PCR products showed the expected single band of ~0.8 kb corresponding to the mature anti-Aβ ScFv cDNA. The engineered ScFv was ligated at the HpaI site in pCD−UHC to form the pCD−HC−ScFv expression vector. The pCD−HC−ScFv clone was validated by DNA sequencing. The deduced amino acid sequence showed that the HC of the fusion antibody was composed of 708 amino acids and included a 18 amino acid signal peptide, a 113 amino acid HIRMAb VH, a 330 amino acid human IgG1 constant region, a 2 amino acid linker, a 114 amino acid anti-Aβ ScFv VH, a 17 amino acid linker, and a 113 amino acid anti-Aβ ScFv VL. The predicted molecular weight of the fusion antibody heavy chain, minus the signal peptide, was 75 594 Da, and the predicted isoelectric point (pI) was 8.81. This pI was experimentally confirmed by isoelectric focusing.

Binding of Anti-Aβ ScFv to Aβ^{1-40} and Aβ Plaque. COS cells were transfected with the pCD−ScFv plasmid with lipofectamine 2000, and conditioned medium was tested in an ELISA. Soluble Aβ^{1-40} peptide was adsorbed to 96 well plates, and COS cell conditioned medium was added. The primary antibody was a murine 9E10 to the c-myc epitope, and 9E10 binding to the ScFv was detected with an anti-mouse IgG−peroxidase conjugate. This format was also used in Western blotting. Concentrated COS cell medium was applied to a 12% SDS-PAGE gel, and the proteins were electroblotted to nitrocellulose. The primary antibody was the 9E10 antibody, and the secondary antibody was an anti-mouse IgG−peroxidase conjugate. Frozen sections (20 um) of AD brain were incubated with COS cell medium, and ScFv binding to plaque was detected with the 9E10 antibody.

Expression of Intact Fusion Antibody in COS Cells. COS cells were dual-transfected with pCD−HC−ScFv and pCD−LC, which is the chimeric HIRMAb LC expression plasmid (*16*), and conditioned medium was collected at 3 and 6 days. The fusion antibody was purified by protein A affinity chromatog-

raphy, and the purity was assessed with both 12% SDS-PAGE followed by Coomasie blue staining and Western blotting using an anti-human IgG primary antibody.

Binding of Fusion Antibody to Aβ and to HIR. The binding of the fusion antibody to soluble Aβ^{1-40} was measured with an immunoradiometric assay described previously (*22*). The Aβ^{1-40} is plated in a 96 well format, and the binding of [^{125}I]-murine anti-Aβ MAb to the solid-phase Aβ^{1-40} is quantitated. The percent displacement of this binding is measured in the presence of increasing concentrations of either unlabeled murine anti-Aβ MAb or the fusion antibody. Binding to the HIR extracellular domain (ECD) was measured as described previously (*15*). HIR ECD was affinity purified from conditioned medium obtained from CHO cells permanently transfected with the HIR ECD. The HIR ECD was plated in a 96 well format, and binding of the HIRMAb was measured with an anti-human IgG primary antibody and a peroxidase-based ELISA. The binding of the fusion antibody or human IgG1 to the HIR ECD was measured in parallel. Binding isotherms were generated by nonlinear regression analysis using the PAR subroutine of the BMDP Statistical Software.

Blood to Brain Transport in the Primate in Vivo. The fusion antibody was iodinated with [^{125}I]-iodine and chloramine T. In parallel, the murine anti-Aβ MAb was tritiated with [^{3}H]-*N*-succinimidyl proprionate. An eight-year-old female rhesus monkey, weighing 10.2 kg, was administered by a single intravenous injection a dose of 777 μCi of [^{125}I]-fusion antibody and 888 uCi of [^{3}H]-murine anti-Aβ MAb. Serum was collected at multiple time points over a 180 min period. The serum removed from the anesthetized rhesus monkey was analyzed for total radioactivity, and expressed as a percent of injected dose (I.D.) per milliliter of serum. The ^{125}I radioactivity was counted in a γ counter, and the ^{3}H radioactivity was counted in a liquid scintillation counter; the ^{125}I isotope emits radioactivity in the ^{3}H window, and standard curves were prepared to account for ^{125}I emission in the ^{3}H channel. The serum concentration profile for the [^{125}I]-fusion antibody was fit to a two-compartment pharmacokinetic model described previously (*14*) to yield the pharmacokinetic parameters. At 180 min after drug injection, the animal was euthanized, and brain radioactivity was analyzed with the capillary depletion method, as described previously (*23*). This method separates brain homogenate into a capillary pellet and a post-vascular supernatant. If the volume of distribution (VD) of the antibody in the post-vascular supernatant is high, then this is evidence that the antibody has crossed the BBB and entered into the brain interstitial and intracellular spaces. The VD has units of μL/g brain and is the ratio of the concentration of the antibody in brain (DPM/g) divided by the concentration of the antibody in serum (DPM/uL) at the 180 min terminal time point. The primate brain was divided into frontal, midsection, and caudal parts, and coronal slabs were snap-frozen in pulverized dry ice, and 20 um frozen sections were prepared on a cryostat. The sections were exposed to Biomax X-ray film for 7−10 days, and the film was scanned, and the grayscale image was colorized with *NIH Image* software.

Brain to Blood Transport in the Rat in Vivo. Human IgG is recognized by the rat BBB Fc receptor (FcR) (*18*) and by the rodent FcRn (*24*). The [^{125}I]-fusion antibody (0.03 μCi in 0.3 μL) was injected into the cortex of the brain of the anesthetized adult rat under stereotaxic guidance per the standard protocol of the brain efflux index (BEI) technique (*18*). The fusion antibody was injected in the par2 region of the parietal cortex of brain, with the following stereotaxic coordinates: 0.2 mm anterior to bregma; 5.5 mm lateral to bregma; 4.5 mm deep from the dural surface. This region is far removed from the cerebrospinal fluid tracts, and efflux of radioactivity from the brain over time can only occur via efflux across the BBB from brain to blood. The labeled fusion antibody was injected with either 0 or 1.5 μg human Fc fragments, as described previously (*18*). The rate of efflux of the [^{125}I]-fusion antibody from rat brain was followed over 90 min.

Binding and in Vitro Disaggregation of Aβ Fibrils by Fusion Antibody. Aβ fibrils were formed after incubating Aβ^{1-40} peptide (Bachem) in an orbital shaker at 37 °C for 6 days (*25*), and the plaque was collected by centrifugation. An affinity-purified rabbit polyclonal antibody against the carboxyl terminus (CT) of the Aβ^{1-40} peptide (Signet Laboratories, catalog number 9130-005) was plated in 96 well dishes. In parallel, the preformed Aβ fibrils were incubated for either 1 or 4 h at 37 °C with the fusion antibody, human IgG1 (hIgG1), and phosphate buffered saline (PBS), or with the mouse anti-Aβ MAb and mouse IgG (mIgG), or PBS. The Aβ aggregate/fusion antibody or Aβ aggregate/mouse anti-Aβ MAb complex was then added in increasing doses (10, 30, 100 μL, which is equivalent to 100, 300, 1000 ng/mL) to the immobilized anti-CT antibody. The anti-Aβ ScFv part of the fusion antibody or the mouse anti-Aβ MAb binds an epitope on the Aβ^{1-40} peptide near the amino terminus (NT). Therefore, if Aβ fibrils are present, then a complex will form with anti-CT antibody, the Aβ fibril, the fusion antibody, and a secondary antibody coupled to peroxidase for detection of anti-Aβ antibody binding to Aβ fibril by ELISA (*2*, *3*). The secondary antibodies used for the fusion antibody and the murine anti-Aβ MAb were anti-human and anti-mouse IgG conjugates of alkaline phosphatase, respectively.

In Vivo Disaggregation of Aβ Plaque by Fusion Antibody in Transgenic Mice. APPswe/PSEN1(dE9) double transgenic (*26*) male mice were obtained from The Jackson Laboratory (Bar Harbor, ME) and investigated at 15 months of age. Following approval by the UCLA Animal Research Committee, mice were anesthetized with ketamine/xylazine, and the fusion antibody (20 pmol in 2 μL) or saline (2 μL) was injected with a mouse stereotaxis apparatus into the cortex and hippocampus on the right side of the brain with the following coordinates: 1.5 mm anterior, 2.0 mm lateral, and 2.0 mm deep relative to bregma and the dural surface for the frontal cortex; and 2.7 mm posterior, 2.5 mm lateral, and 2.5 mm deep relative to bregma and the dural surface for the hippocampus. The mice were euthanized 48 h later, and the brain was removed, and coronal slabs around the cortex and hippocampal injection sites were immersion-fixed 24 h at 4 °C in 4% paraformaldehyde in PBS, and cryoprotected successively in 10%, 20%, and 30% sucrose. The cortex or the hippocampus slab was frozen in embedding medium, and 40 consecutive 20 μm frozen sections were prepared on a Mikron cryostat at −15 °C. The slides were stained with either 4% thioflavine-S for confocal microscopy or 1% potassium ferrocyanide in 1% HCl for Prussian blue light microscopy. For examination of microhemorrhage, every eighth section was stained for Prussian blue deposits. For quantitation of amyloid plaque, every fifth section was examined by confocal microscopy using a Zeiss confocal microscope and Zeiss LSM software (*LSM 5 PASCAL*, version 3.2) for digitizing the area of amyloid plaque, relative to the field area, which was 52 642 μm^2. For each of the eight sections, eight separate fields were quantified and averaged for both the injected side and noninjected side of brain. The difference in amyloid content in the injected brain versus the contralateral, noninjected brain, for the animals injected either with fusion antibody or with saline was assessed with the Student's *t* test.

RESULTS

The cDNAs encoding the variable region of the heavy chain (VH) and variable region of the light chain (VL) were cloned following reverse transcription of RNA isolated from a mouse

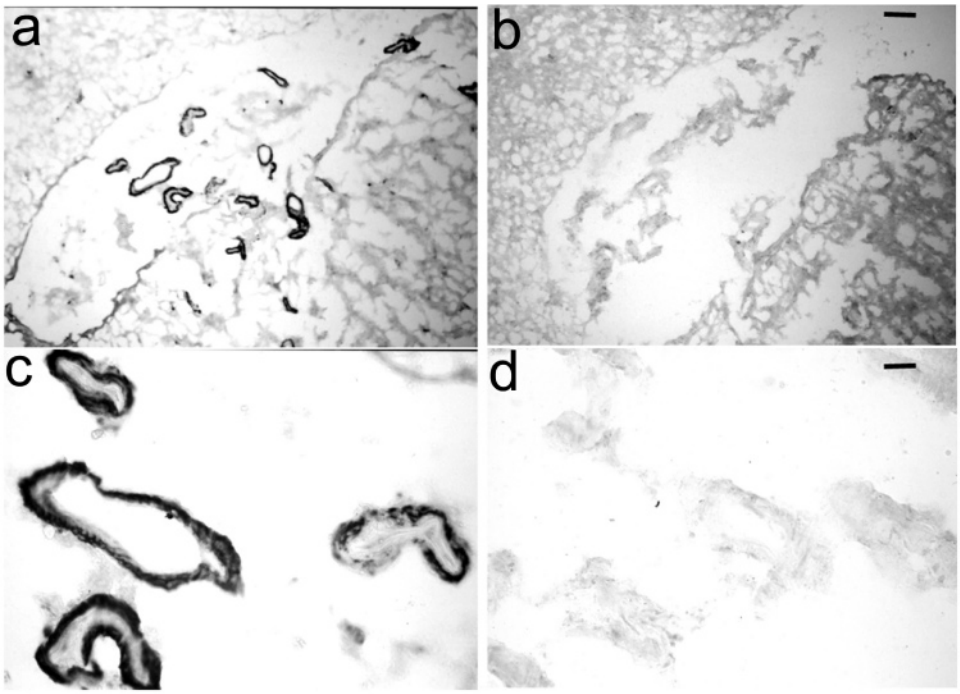

Figure 3. Immunocytochemistry of frozen sections of AD autopsy brain. The brain sections were immune stained with medium conditioned by COS cells that were transfected with pCD-ScFv (a,c), with medium conditioned by COS cells which were exposed only to lipofectamine 2000 (b), or with the mouse IgG1 isotype control antibody (d). Magnification in panels a and b is the same, and the magnification bar in panel b is 88 um; magnification in panels c and d is the same and the magnification bar in panel d is 35 um.

hybridoma secreting a MAb directed against the Aβ^{1-28} peptide. The VH and VL were joined by a 17 amino acid linker to produce a ScFv. The 10 amino acid c-myc epitope of the 9E10 MAb was fused to the carboxyl terminus of the ScFv, followed by insertion in a eukaryotic expression plasmid, designated pCD−ScFv (Methods section). Following transfection of COS cells, the reactivity of the engineered anti-Aβ ScFv against the Aβ peptide was tested with three assays: Western blot, ELISA, and immunocytochemistry of AD brain. Western blotting with the 9E10 antibody showed that a 31 kDa immunoreactive protein was selectively secreted to the medium in COS cells transfected with pCD−ScFv. The anti-Aβ ScFv secreted by transfected COS cells bound soluble Aβ^{1-40} as demonstrated with a 9E10 antibody-based ELISA (Methods section). Immunocytochemistry of frozen sections of AD autopsied brain showed the anti-Aβ ScFv specifically bound to vascular amyloid plaque (Figure 3a,c), whereas medium conditioned by COS cells exposed only to lipofectamine 2000 (Figure 3b) or the mouse IgG isotype control antibody (Figure 3d) showed no specific staining of AD brain.

The cDNA encoding the anti-Aβ ScFv was fused at the 3′ end of the cDNA encoding the heavy chain (HC) of the genetically engineered HIRMAb, and this heavy chain fusion antibody expression vector is designated pCD−HC−ScFv. A separate expression vector, designated pCD−LC, encodes the light chain of the HIRMAb (*15*, *16*). COS cells were dual transfected with pCD−HC−ScFv and pCD−LC, and the fusion antibody secreted into the medium was purified by protein A affinity chromatography. Following SDS-PAGE and Coomasie blue staining, the size of the HC of the fusion antibody was 82 kDa, whereas the size of the HC of HIRMAb was 55 kDa; the difference, 27 kDa, is equal to the size of the ScFv, minus the 9E10 epitope. The size of the light chain (LC) of either the HIRMAb or the fusion antibody is identical at 28 kDa (Figure 4a). The same sizes of the HC and LC of the fusion antibody and the HIRMAb were detected with a Western blot using a primary antibody against human IgG (Figure 4b).

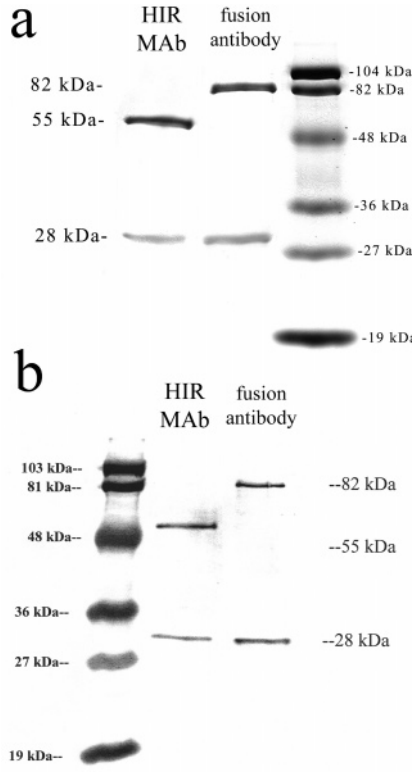

Figure 4. SDS-PAGE and Western blotting of fusion antibody. (a) SDS-PAGE and Coomasie blue staining shows correct processing of intact fusion antibody by transfected COS cells. (b) Western blotting with an anti-human IgG primary antibody. The HIRMAb and the fusion antibody are composed of the same light chain, which is 28 kDa. The size of the heavy chain of the HIRMAb is 55 kDa, whereas the size of the heavy chain of fusion antibody is 82 kDa. The heavy chain of the fusion antibody includes the 55 kDa heavy chain of the HIRMAb fused to the 27 kDa anti-Aβ ScFv.

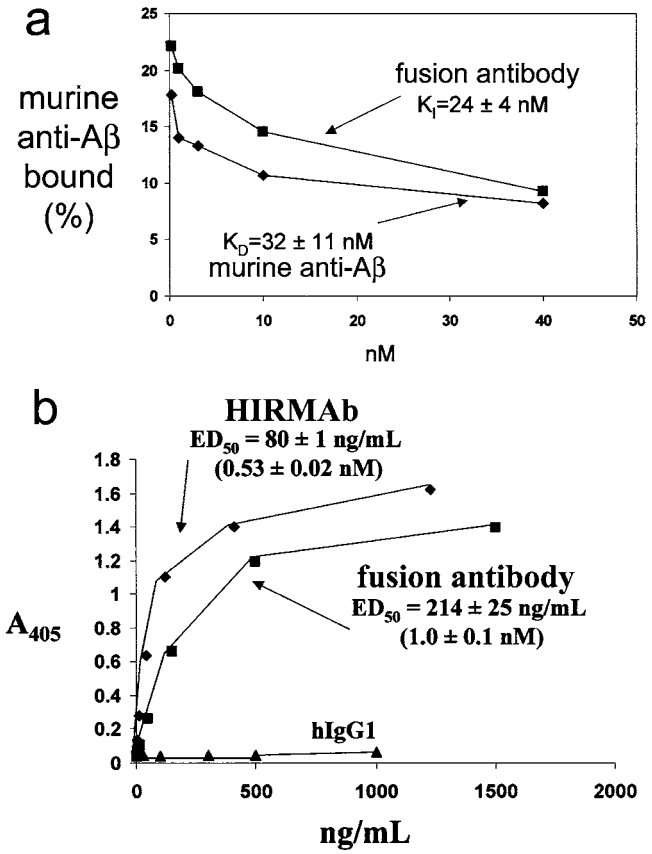

Figure 5. Bifunctional binding of fusion antibody both to Aβ and to the human insulin receptor. (a) The binding of [^{125}I]-murine anti-Aβ MAb to Aβ^{1-40} is competitively inhibited by either unlabeled murine anti-Aβ MAb or by the fusion antibody. The binding affinity of the fusion antibody is not significantly different from the affinity of the murine anti-Aβ MAb. (b) Binding of the genetically engineered HIRMAb or the fusion antibody to the HIR extracellular domain is measured with an ELISA. There is no binding of human IgG1 to the HIR ECD. The affinity of the fusion antibody for the HIR ECD is >50% of the affinity of the HIRMAb.

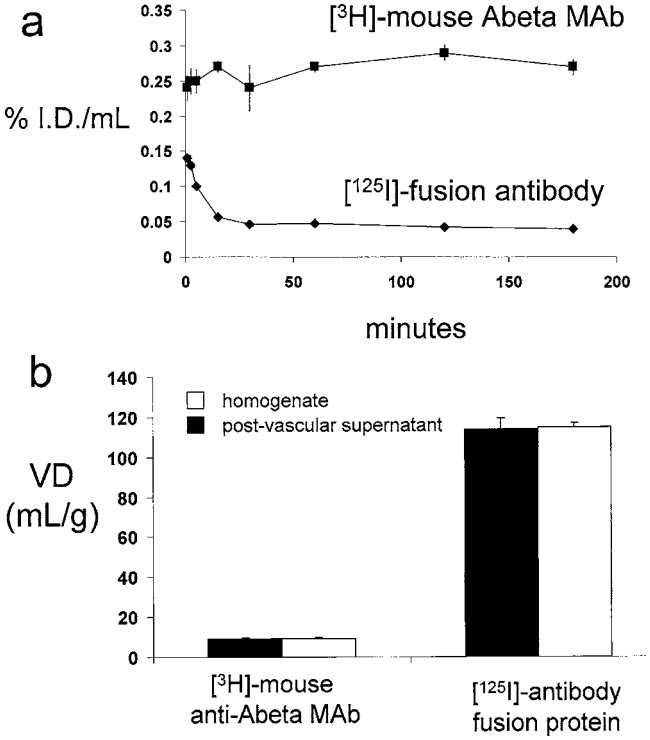

Figure 6. Blood to brain transport of fusion antibody in the primate. (a) The [^{125}I]-fusion antibody and the [^{3}H]-mouse anti-Aβ antibody were injected intravenously into the adult rhesus monkey, and serum concentrations [% of injected dose (I.D.)/mL] were determined over a 3 h period. There is no measurable clearance from blood of the [^{3}H]-mouse anti-Aβ antibody during this time period, whereas the fusion antibody is rapidly cleared from blood, owing to uptake via the insulin receptor. (b) Brain volume of distribution (VD) of the [^{3}H]-mouse anti-Aβ antibody and the [^{125}I]-fusion antibody in the rhesus monkey brain at 3 h after a single intravenous injection. The VD values for the homogenate and the post-vascular supernatant are shown. The VD for the [^{3}H]-mouse anti-Aβ antibody, 10 uL/g, is equal to the brain arterial blood volume, which indicates this antibody is not transported across the primate BBB in vivo in the blood to brain direction. The VD for the [^{125}I]-fusion antibody is >100 uL/g in both the brain homogenate and the post-vascular supernatant, which indicates the [^{125}I]-fusion antibody is transported across the BBB.

The fusion antibody bound with high affinity to soluble Aβ^{1-40}, as determined by an immunoradiometric assay (Methods section). The dissociation constant (K_D) of the original murine anti-Aβ tetrameric MAb was 32 ±11 nM, and the dissociation constant of fusion antibody binding to soluble Aβ^{1-40} was 24 ± 4 nM (Figure 5a). The fusion antibody retained high-affinity binding for the HIR based on an ELISA (Methods section) using affinity-purified HIR extracellular domain (ECD). The concentration of HIRMAb that gives 50% binding to HIR ECD is 0.53 ± 0.02 nM, whereas the ED_{50} of fusion antibody binding to the HIR ECD is 1.0 ± 0.1 nM (Figure 5b).

The fusion antibody was radiolabeled with 125-iodine, the hybridoma-derived mouse anti-Aβ MAb was tritiated, and the labeled antibodies were coinjected intravenously into an anesthetized adult female rhesus monkey. In the first 3 h after injection, there was no measurable decrease in the blood concentration of the [^{3}H]-mouse Aβ MAb, whereas there was an immediate clearance of the [^{125}I]-fusion antibody from blood in the primate (Figure 6a). The extensive distribution of the fusion antibody into the primate brain is shown by the 3 h brain scan (Figure 7). There is global uptake of the fusion antibody in all parts of the brain with a preferential uptake in gray matter relative to white matter. Brain radioactivity at 3 h after intravenous injection was measured with the capillary depletion technique, which demonstrated a high volume distribution (VD), >100 μL/g, of the [^{125}I]-fusion antibody (Figure 6b). In contrast, the brain VD for the [^{3}H]-mouse anti-Aβ MAb is 10 μL/g brain. This VD is equal to the arterial blood volume of brain (*27*) and indicates that the mouse anti-Aβ MAb does not cross the BBB in the blood to brain direction. The VD of the fusion antibody was high in the postvascular supernatant, indicating that the fusion antibody is transcytosed across the BBB into the postcapillary compartment of brain (Figure 6b).

The influx of the fusion antibody from blood to brain in vivo could not be tested in rodents, because the HIRMAb does not recognize the rodent insulin receptor. However, the rat FcRn does recognize human IgG and mediates efflux of human IgG across the BBB from brain to blood in the rat (*18*). Therefore, the transport of the fusion antibody across the BBB in the brain to blood direction was measured with the brain efflux index (BEI) method in the adult rat (Methods section). Following stereotaxic injection into the cortex of rat brain, the fusion antibody rapidly effluxed from the brain to blood and was >50% eliminated from brain at 90 min after injection. The efflux of the fusion antibody from brain was >90% blocked by human Fc fragments (Figure 8).

The binding of the fusion antibody to Aβ fibrils in vitro is demonstrated with the double-antibody ELISA outlined in Figure 9a. The fusion antibody bound to the Aβ fibrils in a dose-dependent manner following a 1 h incubation of the fusion antibody with the Aβ fibrils (Figure 9b). Following a 4 h incubation of the fusion antibody and the Aβ fibrils, most of

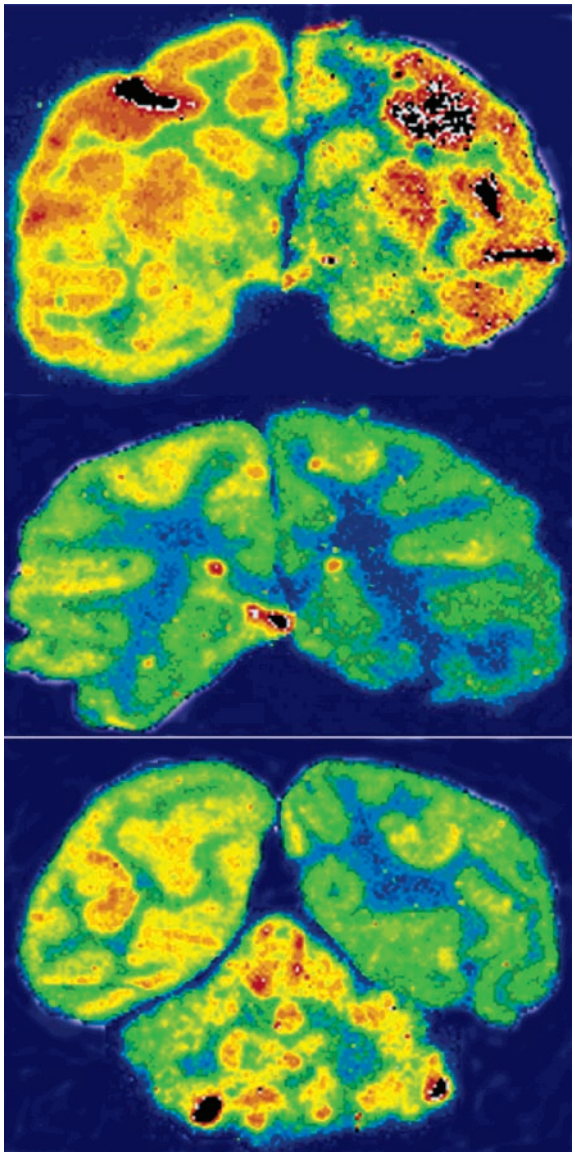

Figure 7. Global distribution of fusion antibody to primate brain. Brain scans of adult rhesus monkey at 3 h after the intravenous administration of the [^{125}I]-fusion antibody demonstrates widespread distribution of the fusion antibody into the primate brain in vivo from blood. The top scan is the most frontal part of brain, and the bottom scan is the most caudal part of brain and includes the cerebellum.

the fibrils were disaggregated (Figure 9b). A comparable binding/disaggregation of Aβ fibrils was observed with the original murine anti-Aβ MAb. The fusion antibody also disaggregates Aβ amyloid in vivo in transgenic mouse brain. The APPswe/PS1dE9 double transgenic mouse develops amyloid plaque as shown by thioflavin-S staining (Figure 9c). Quantitation of the percent of either frontal cortex or hippocampus occupied by the amyloid plaque showed that approximately 5% of the brain was amyloid. A single intracerebral injection of the fusion antibody into the hippocampus or the frontal cortex caused a 39 $\pm$ 3% and 38 $\pm$ 2% decrease, respectively, in the Aβ amyloid burden in the brain in vivo at 48 h after injection in the side ipsilateral to the injection, relative to the amyloid burden in the contralateral hippocampus or frontal cortex (Figure 9d). Conversely, the intracerebral injection of saline in either the cortex or hippocampus of the transgenic mice caused no decrease in amyloid burden in the brain (Figure 9d). Intracerebral injection of the fusion antibody caused no microhemorrhage in the brain, as demonstrated by Prussian blue staining of serial sections of cortex or hippocampus (Methods section).

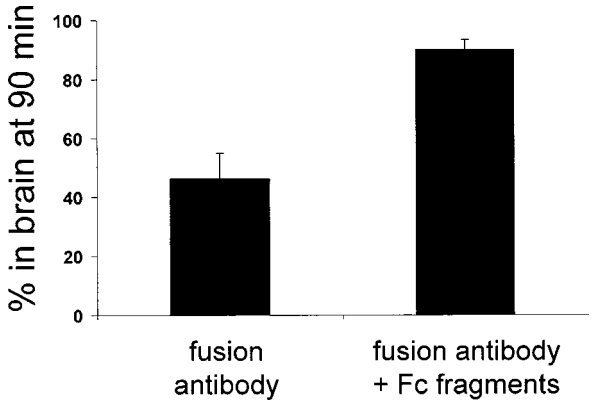

Figure 8. Brain to blood transport of fusion antibody in the rat. The [^{125}I]-fusion antibody was injected into the cortex under stereotaxic guidance, and the efflux of the fusion antibody from brain across the BBB was measured at 90 min after the injection. At this time, nearly 60% of the injected fusion antibody has effluxed from brain. This efflux was >90% blocked ($p < 0.01$) by the coinjection of human Fc fragments, which indicates that the efflux is mediated by an Fc receptor at the BBB. Data are mean $\pm$ S.E. ($n = 4$ rats per point).

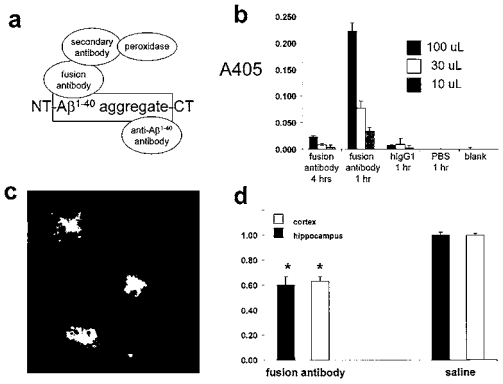

Figure 9. Fusion antibody disaggregates Aβ amyloid fibrils in vitro and in vivo. (a) Outline of Aβ plaque disaggregation assay. The Aβ fibrils are sandwiched by an anti-Aβ antibody that binds the carboxyl terminus (CT) of Aβ, and by the fusion antibody, or the murine anti-Aβ MAb, which binds the amino terminus (NT) of Aβ. (b) Disaggregation of Aβ fibrils in vitro by the fusion antibody. Aβ^{1-40} aggregates were formed over 6 days, followed by incubation with the fusion antibody, with human IgG1 (hIgG1) or with phosphate buffered saline (PBS) for either 1 or 4 h at 37 °C. The antibody that binds to the carboxyl terminal region of the Aβ^{1-40} peptide was plated in 96 well plates. The anti-Aβ ScFv portion of the fusion antibody binds to the amino terminal part of Aβ.$^{1-40}$ A positive ELISA signal is generated only if Aβ fibrils are present. The data show that the fusion antibody binds to Aβ^{1-40} plaque and that this binding causes fibril disaggregation over a 4 h period. (c) Amyloid plaque in brain of double transgenic APPswe/PS1dE9 mice stained with thioflavine-S. (d) The percent of brain occupied by amyloid plaque in either the frontal cortex or the hippocampus in the transgenic mice was quantitated with confocal microscopy. Amyloid was measured at 48 h after the intracerebral injection of 20 pmol of fusion antibody into the frontal cortex and the hippocampus on one side of the brain. The amyloid burden in the brain is expressed as a ratio of the % brain amyloid in the side ipsilateral to the injection relative to the % amyloid content in the contralateral frontal cortex or hippocampus, in the animals injected either with the fusion body or with saline. Data are mean $\pm$ SE ($n = 3$ mice for each treatment group). The decrease in amyloid content in either the frontal cortex or the hippocampus on the side of the fusion antibody injection, relative to the saline control, is statistically significant ($*p < 0.01$).

DISCUSSION

The results of these studies are consistent with the following conclusions. First, a ScFv directed against the amino-terminal portion of the Aβ peptide has been cloned, expressed, and shown to bind both soluble Aβ and Aβ fibrils (Results section and Figure 3). Second, a fusion antibody has been engineered

whereby the anti-Aβ ScFv is fused to the carboxyl terminus of the Fc region of a genetically engineered HIRMAb (Figures 2 and 4); the fusion antibody retains high-affinity binding for the HIR (Figure 5b), as well as for soluble Aβ (Figure 5a) and for Aβ fibrils (Figure 9b). Third, the fusion antibody crosses the BBB bidirectionally; the fusion antibody undergoes rapid influx from blood to brain across the rhesus monkey BBB in vivo (Figure 7); the fusion antibody undergoes receptor-mediated efflux from brain to blood across the BBB via a mechanism that is inhibited by Fc fragments (Figure 8). Fourth, the fusion antibody (Figure 2) is a trifunctional protein with three domains that are all biologically active. The first domain, which targets the HIR, enables receptor-mediated transport across the BBB in the blood to brain direction. The second domain binds to Aβ to cause disaggregation of Aβ fibrils. The third domain binds the Fc receptor to enable receptor-mediated transport of the fusion antibody from brain back to blood across the BBB.

The availability of the cDNA encoding the anti-Aβ ScFv and the cDNA encoding the heavy chain of the chimeric HIRMAb enabled the genetic engineering of a fusion antibody with dual specificities. The fusion antibody binds both the HIR and Aβ (Figure 2). There are multiple approaches to the genetic engineering of fusion antibodies (*28*−*31*). The approach taken in the present investigation was to fuse the ScFv at the carboxyl terminus of the CH_3 region of the HIRMAb heavy chain (Figure 2). Prior work has shown that the fusion of a ScFv to the carboxyl terminus of the CH_3 region of another IgG results in an approximate 10-fold reduction in binding affinity for the ScFv-targeted antigen (*28*, *32*). This was not observed in the present investigation, as the affinity of the fusion antibody for Aβ is unchanged as compared to the original murine anti-Aβ MAb (Figure 5a). The advantage of fusing the ScFv to the carboxyl terminus of the Fc region of the HIRMAb is that this configuration converts the monovalency of ScFv binding of antigen to the original bivalency of antibody binding of antigen (Figure 2).

COS cells were dual transfected with a heavy chain expression vector, pCD−HC−ScFv, and an expression vector, pCD−LC, which produces the light chain of the genetically engineered HIRMAb. Medium was concentrated, and the fusion antibody was purified by protein A affinity chromatography. SDS-PAGE and Western blotting showed that the fusion antibody was correctly processed in COS cells. The size of the light chain of the fusion antibody is identical to the size of the light chain of the HIRMAb (Figure 4), which is expected, since both the fusion antibody and the HIRMAb are composed of the same light chain. The size of the heavy chain of the fusion antibody, 82 kDa, is 27 kDa greater than the size of the heavy chain of the HIRMAb, which is 55 kDa (Figure 4). The difference between the size of the heavy chain of the fusion antibody and the size of the HIRMAb, 27 kDa, is equal to the predicted molecular weight of the ScFv. The bifunctionalilty of the fusion antibody was demonstrated by separate binding assays targeting either the HIR ECD or soluble Aβ^{1-40}. The fusion antibody binds soluble Aβ^{1-40} with a K_D of 24 $\pm$ 4 nM, and this is not significantly different from the K_D, 32 $\pm$ 11 nM, of the binding to Aβ^{1-40} of the original murine anti-Aβ MAb (Figure 5a). The 50% binding of the HIRMAb to the HIR ECD is observed at 0.53 $\pm$ 0.02 nM, and there is a > 50% retention of affinity of the fusion antibody for the HIR ECD (Figure 5b). There is no binding of human IgG1 to the HIR (Figure 5b). The fusion antibody binds soluble Aβ^{1-40} (Figure 5a) and also binds Aβ fibrils (Figure 9b). After a 4 h incubation with Aβ fibrils, the fusion antibody causes a time-dependent disaggregation of Aβ fibrils (Figure 9b). The fusion antibody also causes disaggregation of amyloid plaque in vivo in double transgenic APPswe/PS1dE9 mice (Figure 9d). A single intracerebral injection of 20 pmol of fusion antibody into either the frontal cortex or the hippocampus causes a 38−39% reduction in brain amyloid burden at 48 h after fusion antibody administration (Figure 9d). In contrast, the injection of saline into the frontal cortex or hippocampus caused no decrease in brain amyloid burden (Figure 9d). The mechanism of fusion antibody diaggregation of preformed Aβ plaque is assumed to involve binding of the antibody to amino-terminal epitopes on the Aβ peptide within the fibril, which induces progressive release of Aβ monomers and/or oligomers from the fibril (*2*, *3*).

The purpose of this investigation was to genetically engineer an anti-Aβ antibody that can also cross the BBB in both the blood to brain and brain to blood directions. Therefore, an anti-Aβ ScFv antibody was fused to the heavy chain of the genetically engineered HIRMAb to enable receptor-mediated transport in the blood to brain direction across the BBB via transport on the endogenous insulin receptor. The HIRMAb is not recognized by the rodent insulin receptor, but is recognized by the insulin receptor of Old World primates such as rhesus monkeys but not New World primates such as squirrel monkeys (*14*). The selective transport of the fusion antibody across the primate BBB relative to the murine anti-Aβ MAb is demonstrated in Figure 6b. There is no measurable clearance of the murine anti-Aβ MAb from primate blood at 3 h after intravenous administration (Figure 6a), because this antibody, which is a mouse IgG1, does not recognize any receptor that would mediate selective exodus from the blood compartment. The human FcRn, and presumably the primate FcRn, does not recognize mouse IgG1 (*24*). However, the lack of recognition of the murine anti-Aβ MAb by the primate FcRn cannot explain the lack of influx of this MAb from blood to brain. The BBB FcRn is an asymmetric transporter and mediates only the efflux of IgG from brain to blood but not the influx of IgG from blood to brain (*18*). In contrast to the slow clearance of the murine anti-Aβ MAb from the blood, the fusion antibody is rapidly removed from the blood (Figure 6a), owing to uptake via tissues such as liver, spleen, and brain that express vascular insulin receptor (*14*). This rapid removal of fusion antibody is likely mediated by the insulin receptor, since the rate of removal of the fusion antibody from the blood compartment of the rhesus monkey is virtually identical to the rate of removal of the genetically engineered HIRMAb reported previously (*15*, *16*). The systemic clearance of the [^{111}In]-chimeric HIRMAb, 0.22 $\pm$ 0.08 mL/min/kg (*15*), is not significantly different from the systemic clearance of the [^{125}I]-fusion antibody, 0.18 $\pm$ 0.05 mL/min/kg. The 3 h brain scan of the primate shows global distribution of the fusion antibody in the primate brain in vivo with a greater uptake in gray matter relative to white matter (Figure 7). This pattern of uptake reflects the approximate 3-fold greater vascular density in gray matter relative to white matter and thus 3-fold greater density of microvascular insulin receptor in gray matter as compared to white matter (*14*). The rapid transport of fusion antibody across the primate BBB in vivo is confirmed by measurements of brain VD (Figure 6b). The brain VD of the murine anti-Aβ MAb, 10 μL/g (Figure 6b), is equal to the cerebral arterial blood volume (*27*), which indicates that the murine anti-Aβ MAb does not cross the BBB in vivo in the blood to brain direction. In contrast, the brain VD for the fusion antibody is >100 μL/g brain (Figure 6b). Capillary depletion analysis shows that the fusion antibody undergoes transcytosis across the BBB and penetrates into the postvascular volume of the brain (Figure 6b). Once inside the brain, an anti-Aβ antibody may bind amyloid and cause disaggregation of the amyloid plaque.

In addition to influx from blood to brain, an Aβ antibody therapeutic must also be enabled to efflux from the brain back to blood. Otherwise, there would be no net clearance of amyloid

from the brain. Large-molecule efflux across the BBB may be quantitated with the brain efflux index method (*18*). Prior work shows that during a 90 min period after intracerebral injection, the amount of 70 kDa [^{3}H]-dextran in rat brain is 93 ± 3%, which means that the efflux from the brain via bulk flow is minimal during this time period. Therefore, the only pathway for efflux from the brain is direct transport across the BBB. Unlike other large molecules such as dextran or albumin, IgG molecules rapidly efflux from the brain to blood via a BBB Fc receptor (*18*). Previous confocal microscopy studies have shown that the neonatal FcR, also called the FcRn, is highly expressed at the brain microvascular endothelium (*19*). The FcRn binding site for IgG molecules is at the CH_2-CH_3 interface (*17*), and the FcRn binds deglycosylated IgG (*33*). Therefore, the fusion antibody was engineered to have an intact CH_2-CH_3 interface to enable binding and transport via the BBB FcRn (Figure 2). After the complex of Aβ and the fusion antibody efflux from brain to blood, the fusion antibody is rapidly cleared from blood by tissues such as liver or spleen, which express high levels of microvascular insulin receptor (*14*).

The potential immunogenicity of the fusion antibody in humans is not known until clinical trials are performed. The fusion antibody is derived from chimeric anti-HIR and anti-Aβ antibodies, and both chimeric monoclonal antibodies and antibody fusion proteins are FDA-approved products, which are given repeatedly to humans without immunologic reactions (*34*). Any underlying immunogenicity of the fusion antibody in humans could be reduced by "humanization" of either or both parts of the fusion antibody. A humanized HIRMAb has been genetically engineered and crosses the primate BBB at rates comparable to the chimeric HIRMAb (*16*).

The genetic engineering of the fusion antibody shown in Figure 2 could be replicated with other monoclonal antibody based therapeutics for multiple CNS diseases. Monoclonal antibody based therapeutics have significant potential as neurotherapeutics if the problem of BBB delivery is solved. The present work shows that antibody-based therapeutics can be delivered to brain as fusion proteins with molecular Trojan horses that cross the BBB.

Physicochemical and Biological Characterization of Targeted, Nucleic Acid-Containing Nanoparticles

Derek W. Bartlett and Mark E. Davis*

Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received November 9, 2006; Revised Manuscript Received January 11, 2007

Nucleic acid-based therapeutics have the potential to provide potent and highly specific treatments for a variety of human ailments. However, systemic delivery continues to be a significant hurdle to success. Multifunctional nanoparticles are being investigated as systemic, nonviral delivery systems, and here, we describe the physicochemical and biological characterization of cyclodextrin-containing polycations (CDP) and their nanoparticles formed with nucleic acids including plasmid DNA (pDNA) and small interfering RNA (siRNA). These polycation/nucleic acid complexes can be tuned by formulation conditions to yield particles with sizes ranging from 60 to 150 nm, ζ potentials from 10 to 30 mV, and molecular weights from $\sim 7 \times 10^7$ to 1×10^9 g mol^{-1} as determined by light scattering techniques. Inclusion complexes formed between adamantane (AD)-containing molecules and the β-cyclodextrin molecules enable the modular attachment of poly(ethylene glycol) (AD−PEG) conjugates for steric stabilization and targeting ligands (AD−PEG−transferrin) for cell-specific targeting. A 70 nm particle can contain ~10 000 CDP polymer chains, ~2000 siRNA molecules, ~4000 AD−PEG_{5000} molecules, and ~100 AD−PEG_{5000}−Tf molecules; this represents a significant payload of siRNA and a large ratio of siRNA to targeting ligand (20:1). The particles protect the nucleic acid payload from nuclease degradation, do not aggregate at physiological salt concentrations, and cause minimal erythrocyte aggregation and complement fixation at the concentrations typically used for in vivo application. Uptake of the nucleic acid-containing particles by HeLa cells is measured by flow cytometry and visualized by confocal microscopy. Competitive uptake experiments show that the transferrin-targeted particles display enhanced affinity for the transferrin receptor through avidity effects (multiligand binding). Functional efficacy of the delivered pDNA and siRNA is demonstrated through luciferase reporter protein expression and knockdown, respectively. The analysis of the CDP delivery vehicle provides insights that can be applied to the design of targeted nucleic acid delivery vehicles in general.

INTRODUCTION

Nucleic acid-based therapeutics are envisioned to play a significant role in the next generation of treatments for a variety of diseases such as cancer. In addition to the classic gene therapy approach of delivering DNA to replace mutated or absent genes, nucleic acid molecules can also be used to regulate the production of disease-associated proteins at both the transcriptional and translational levels. These nucleic acid-based drugs have received significant attention as promising new therapeutics, yet their application in vivo has been largely limited by the challenge of delivery; this has been particularly true for systemic delivery.

Naked nucleic acid molecules are rapidly degraded by ubiquitous nucleases present in the bloodstream. Double-stranded nucleic acid molecules ranging in size from small-interfering RNAs (siRNAs) to plasmids (pDNA) have a half-life of less than 1 h in serum (*1*−*3*). Selective chemical modification of nucleic acids can increase nuclease resistance and enable systemic delivery of naked siRNA molecules with functional efficacy in vivo (*1*, *4*). However, even nuclease-stabilized nucleic acids must still overcome other elimination barriers such as renal clearance that severely limit the efficacy of systemically delivered, small nucleic acid therapeutics (*5*). Attachment of specific targeting ligands can induce binding to protein carriers or uptake by the desired population of cells to be treated. Bioconjugates of the nucleic acid therapeutics covalently attached directly to targeting ligands such as cholesterol and antibodies have shown efficacy both in vitro and in vivo (*4*, *6*). While these methods for nuclease stabilization and covalent attachment of targeting ligands are promising for small nucleic acid therapeutics, the use of lipid- or polymer-based delivery vehicles is an approach for systemic delivery that can provide functions not achievable with naked nucleic acids or their covalent attachment to targeting moieties.

Carrier-mediated delivery has several advantages over the delivery of individual nucleic acid molecules. Encapsulation of the payload within a lipid bilayer or through electrostatic interactions is nonspecific, so these delivery vehicles can be used for generalized nucleic acid delivery. The use of a carrier enables delivery of many nucleic acid molecules per uptake event (this is especially important if the uptake involves highly specific cell surface receptors, since they are typically low in number), and isolation from exposure to the systemic environment can permit the use of unmodified nucleic acids (*7*). Modularly designed delivery vehicles can also take advantage of covalent or noncovalent attachment of hydrophilic polymers for steric stabilization and/or targeting ligands for cell-specific delivery, two critical features for systemic delivery (*7*, *8*). Such modifications can affect the resulting biodistribution of delivery vehicles through passive and/or active targeting (*7*−*10*).

Passive targeting occurs as a result of the intrinsic physicochemical properties of the delivery vehicle. For example, the charge and size of the delivery vehicle alone can bias its biodistribution. The charge of the delivery vehicle significantly impacts its interaction with components of the bloodstream; highly charged particles can lead to complement activation, while near-neutral particles exhibit reduced phagocytic uptake (*11*, *12*). Specifically, cationic polymers such as (poly)lysine and (poly)ethylenimine have been shown to activate the complement

system, and increasing polycation length and surface charge density lead to higher complement activation (*11*). Rapid binding of charged molecules by complement proteins or other opsonins can lead to immune stimulation and rapid clearance of the delivery vehicles from the bloodstream. The size of the delivery vehicle also matters for systemic delivery. On the basis of measured sieving coefficients for the glomerular capillary wall, it is estimated that the threshold for first-pass elimination by the kidneys is approximately 10 nm (diameter) (*13*), placing a lower size limit on the assembled delivery vehicles. On the other end of the size spectrum, macromolecular complexes preferentially accumulate in tumors through the enhanced permeability and retention (EPR) effect. However, large macromolecules or delivery vehicles exhibit limited diffusion in the extracellular space, such as the tumor interstitium, and in the complex intracellular environment (*14*); in both situations, restricted movement will severely limit efficacy by preventing uptake by a sufficient number of cells or hindering the ability of the delivered particles to localize to intracellular compartments such as the nucleus. Other restrictions limiting the maximum size of delivery vehicles can also be imposed by the selectivity of receptors on certain cell types. For example, a study by Rensen et al. demonstrated that particles larger than 70 nm in diameter were not recognized by the asialoglycoprotein receptor (ASGPR) (*15*), placing an upper size limit on the particles that can be delivered to hepatocytes through this receptor.

Recent efforts toward targeted delivery have focused on decorating the surface of delivery vehicles with cell surface receptor-specific targeting ligands as a means of active targeting. Hydrophilic polymers, such as poly(ethylene glycol) (PEG), can be attached to the surface of the delivery vehicles to mask surface charge and prevent nonspecific interactions, helping to prevent unwanted binding to components of the bloodstream, slow uptake by the reticuloendothelial system (RES), and alter the cellular uptake patterns (*8*, *16*). Further addition of entities that can interact with cell surface receptors such as the receptors' natural ligands, antibodies, or antibody fragments allows the delivery vehicle to target particular cell types and undergo receptor-mediated endocytosis upon binding to the surface receptor (*7*, *8*, *15*).

In light of these considerations, a successful delivery vehicle must be engineered to have the following characteristics: (i) be small enough to extravasate and exhibit adequate tissue penetration, yet avoid rapid renal clearance; (ii) minimize nonspecific interactions and opsonization while providing specific targeting to a given cell; and (iii) protect the nucleic acid from degradation, but willingly release it upon arrival at the proper site. Over the past few years, we have been developing a synthetic delivery system based on a cyclodextrin-containing polycation (CDP) that has demonstrated some success in delivering nucleic acid payloads that include pDNA, siRNA, and DNAzymes (*7*, *17*−*20*). This delivery system is the first to be de novo designed for systemic delivery of nucleic acids and completely formulated by self-assembly (*17*). Here, we describe the physicochemical and biological characterization of the cyclodextrin-containing polycation delivery system and its formulation with nucleic acids. We illustrate issues of importance when designing any polycation composite with nucleic acids through the use of the CDP and point out when the conclusions are specific to this system only.

EXPERIMENTAL PROCEDURES

Formulation of Nucleic Acid Particles. The chemical structure of the cyclodextrin-containing polycation is shown in Figure 1A. This short, linear polycation can be synthesized with (CDP−Im) or without (CDP) the imidazole groups on the terminal amines (*17*, *18*). A schematic showing particle formation using CDP−Im and nucleic acid is shown in Figure 1B; particles are formed by mixing equal volumes of CDP−Im and nucleic acid. The ratio of positive (+) charges (2 mol of positive charge per CDP−Im monomer, denoted β-CD) to negative (−) charges (1 mol of negative charge per nucleotide) is defined as the formulation charge ratio (±). Poly(ethylene glycol) (PEG) molecules containing adamantane (AD) on the proximal end and either methoxy (AD−PEG) or a targeting ligand such as transferrin (AD−PEG−Tf) on the distal end can be attached to the surface of the particles via inclusion complex formation between adamantane and the β-CD molecules on the polycation backbone (*16*, *17*). The molecular weight of the PEG chain is typically 5000 Da (PEG_{5000}).

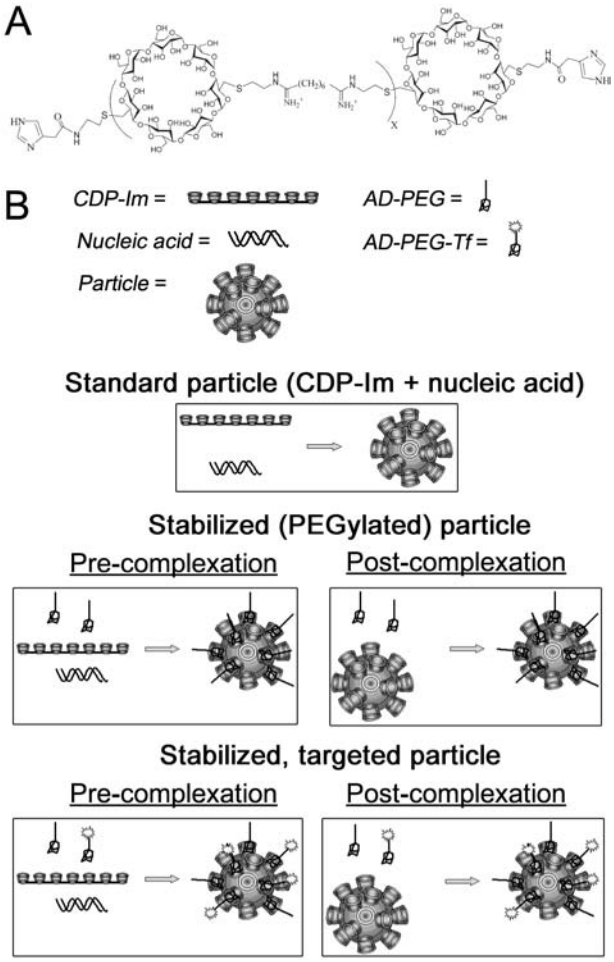

Figure 1. Formation of nucleic acid-containing particles using CDP−Im. (A) Schematic of the chemical structure of CDP−Im. (B) Schematic of particle assembly.

Formulation of PEGylated/Targeted Nucleic Acid Particles. *Pre-complexation (self-assembly).* Before addition to the nucleic acid, the CDP or CDP−Im was mixed with an AD−PEG conjugate at a 1:1 AD−PEG/β-CD (mol/mol) ratio in water. Targeted particles also require the addition of ligand-modified AD−PEG−X (e.g., AD−PEG−Tf (*7*, *19*, *20*)) as a percentage of the total AD−PEG in the mixture. For example, 1 mol % AD−PEG−Tf particles contain 0.01 mol AD−PEG−Tf for every 0.99 mol AD−PEG. The mixture of CDP (or CDP−Im), AD−PEG, and AD−PEG−ligand in water was then added to an equal volume of nucleic acid in water such that the ratio of positive charges from CDP or CDP−Im to negative charges from the nucleic acid was equal to the desired charge ratio. A schematic of this assembly process is shown in Figure 1B. Unless specified otherwise, all PEGylated or targeted nucleic acid particles used in this manuscript were prepared through the pre-complexation method.

Post-complexation. Particles were initially formulated in water by mixing equal volumes of nucleic acid and the cyclodextrin-containing polycation. After particles had formed, the AD−PEG and AD−PEG−Tf conjugates were added directly to the formulation mixture at the desired ratio of AD−PEG/β-CD (mol/mol). A schematic of this assembly process is shown in Figure 1B.

Electrophoretic Mobility Shift Assay. siRNA-containing particles were formulated at different charge ratios by changing the amount of CDP added to 1 μg of siRNA. CDP was first dissolved in 10 μL water and then added to an equal volume of water containing 1 μg of nucleic acid. After a 30 min incubation at room temperature, 10 μL of each formulation was run on a 1% agarose gel and visualized by ethidium bromide staining.

Individual Particle Charge Ratio. siRNA particles were formulated in 40 μL water at charge ratios from 5 to 30 ($\pm$). After formulation, the particles were separated from the free components by addition of 400 μL PBS, to cause particle aggregation, followed by centrifugation to pellet the aggregated particles. Since the CDP is terminated by primary amines, quantitation of polycation content was accomplished by measuring the amount of primary amines as follows. 400 μL of the supernatant was removed and combined with 200 μL of 0.01% w/v 2,4,6-trinitrobenzenesulfonic acid (Sigma). After incubating these samples for 2 h at 37 °C, 200 μL 10% sodium dodecyl sulfate (SDS) and 100 μL 1 N HCl were added to each sample before measuring the absorbance at 335 nm with a spectrophotometer. The amount of CDP in each sample was determined by comparison to a standard curve of CDP. The total positive charge present in each sample was calculated from the mass of CDP present using the fixed charge density of 0.0014 mol "+" per gram. This gave the number of unbound "+" charges present, so the number of bound "+" charges in the particles could be determined by subtracting the number unbound from the total "+" charges added during formulation. Assuming 100% incorporation of the nucleic acid into the particles at a formulation charge ratio of 3 ($\pm$) (based on the electrophoretic mobility shift assays; see Results section), the ratio of CDP to nucleic acid within each particle is equal to the number of bound "+" charges divided by the total number of "−" charges from the nucleic acid.

Serum Stability. Particles were formulated in water at a charge ratio of 3 ($\pm$) with an siRNA concentration of 0.05 g L^{-1}. 10 μL of 100% mouse serum (Sigma) were added to 10 μL of the particle formulation and subsequently incubated for 4 h at 37 °C and 5% CO_2. 0.25 μg naked siRNA in 5 μL water were added to 5 μL of 100% mouse serum and also incubated for 4 h at 37 °C and 5% CO_2. For comparison to the $t = 4$ h samples, identical amounts of naked siRNA or siRNA particles were exposed to 50% mouse serum immediately before gel loading ($t = 0$ h). 10 μL of each sample (containing 0.25 μg siRNA) were loaded per well of a 1% agarose gel. Displacement of the nucleic acid from the particles was achieved by adding 1% SDS to the sample immediately prior to gel loading. Gel electrophoresis was performed by applying 100 V for 30 min, and the bands were visualized by ethidium bromide staining.

Dynamic Light Scattering (DLS). Particle formulations were diluted to a volume of 1.4 mL, placed in a cuvette, and inserted into a ZetaPALS (Brookhaven Instruments Corporation) instrument to measure both the size and ζ potential. Reported effective hydrodynamic diameters represent the average values from a total of 5−10 runs of 30 s each, while ζ potentials represent the average of 10 runs each.

Transmission Electron Microscopy (TEM). Particles containing CDP−Im and siRNA (0.1 g L^{-1}) and PEGylated particles containing CDP−Im, AD−PEG (1:1 AD−PEG/β-CD mole ratio), and siRNA (0.5 g L^{-1}) were formulated in water at a charge ratio of 3 ($\pm$). Samples were stained with 2% uranyl acetate and then examined with an EM201C electron microscope (Philips).

Atomic Force Microscopy (AFM). Particles containing CDP−Im and siRNA (0.1 g L^{-1}) and PEGylated particles containing CDP−Im, AD−PEG (1:1 AD−PEG/β-CD mole ratio), and siRNA (0.5 g L^{-1}) were formulated in water at a charge ratio of 3 ($\pm$). 20 μL of each formulation solution were dropped on a freshly cleaved mica disc (Ted Pella, Inc.) and dried with pressurized air. Images were acquired with a Digital Instruments MultiMode AFM with a Nanoscope IV controller in tapping mode at a scan rate of 1 Hz using a BS Multi75 probe (BudgetSensors) with a resonant frequency of 75 kHz and a force constant of 3 N m^{-1}. Height images were flattened and processed for visualization with the derivative matrix convolution filter using *WSxM* scanning probe microscopy software (Nanotec Electronica).

Isothermal Titration Calorimetry (ITC). A MicroCal MCS titration calorimeter was used to investigate the thermodynamic properties of the interaction between AD−PEG conjugates and the β-cyclodextrin molecules on the CDP−Im backbone. CDP−Im (free or in particles) at 0.22 mM total β-CD in water was placed in the sample cell of the instrument. The reference cell contained water alone without CDP−Im. Small amounts of an AD−PEG stock solution at a concentration of 2.2 mM in water were titrated into the sample cell in 25 separate 10 μL increments. Titrations were performed at 30 °C. The measured parameters were δn, the number of moles of ligand (AD−PEG) added to the sample cell, and q, the amount of heat released or absorbed. The Simplex algorithm in the *Origin* data analysis software was used to determine the following parameters: K, the equilibrium binding constant; n, the number of available binding sites; and ΔH, the change in enthalpy. A more in-depth description of the thermodynamic analysis applied to ITC is provided by Blandamer et al. (*21*).

Percentage of AD−PEG$_{5000}$ Bound after Formulation. The small molecule, lactose (Lac), was attached to the end of AD−PEG$_{5000}$ to enable quantification using the Amplex Red Galactose Oxidase Assay Kit (Molecular Probes). Particles were formulated in a total volume of 100 μL water by adding a 50 μL solution containing CDP−Im and AD−PEG$_{5000}$−Lac (1:1 mole ratio of AD−PEG$_{5000}$−Lac/β-CD) in water to a 50 μL solution of siRNA in water. Control formulations were created by mixing CDP−Im and AD−PEG$_{5000}$−Lac without siRNA in 100 μL water. Particles and control formulations were filtered with Biomax (Millipore) centrifugal filtration devices with a 50 kDa MWCO to separate free and bound components. The Amplex Red Galactose Oxidase Assay Kit (Molecular Probes) was used to quantify the amount of AD−PEG$_{5000}$−Lac in the filtrate and retentate of all samples. Concentrations were determined by comparison to a standard curve of AD−PEG$_{5000}$−Lac. The percentage of AD−PEG$_{5000}$−Lac bound to the particles was determined by subtracting the fraction of recovered AD−PEG$_{5000}$−Lac in the filtrate of the particle samples from the fraction of recovered AD−PEG$_{5000}$−Lac in the filtrate of the control samples.

Percentage of AD−PEG$_{5000}$−Tf Bound after Formulation. Tf-targeted particles were formulated in a total volume of 100 μL water by adding a 50 μL solution of CDP−Im, AD−PEG$_{5000}$, and AD−PEG$_{5000}$−Tf (1:1 mole ratio of AD−PEG$_{5000}$−X/β-CD where AD−PEG$_{5000}$−X was composed of either 1 mol % or 5 mol % AD−PEG$_{5000}$−Tf and the remainder AD−PEG$_{5000}$) in water to a 50 μL solution of siRNA in water. Control formulations were created by mixing CDP−Im, AD−PEG$_{5000}$, and AD−PEG$_{5000}$−Tf without siRNA in 100 μL water. Particles and control formulations were filtered with Nanosep (Millipore) centrifugal filtration devices with a 300 kDa MWCO

to separate free and bound components. Total protein content in the filtrate (unbound AD−PEG_{5000}−Tf) and retentate (bound AD−PEG_{5000}−Tf) was determined using the BioRad DC protein assay. The percentage of AD−PEG_{5000}−Tf bound to the particles was determined by subtracting the fraction of recovered AD−PEG_{5000}−Tf in the filtrate of the particle samples from the fraction of recovered AD−PEG_{5000}−Tf in the filtrate of the control samples.

Multiangle Light Scattering (MALS). Particle formulations were loaded into a 10-mL syringe connected to a syringe pump to control the flow rate into a Dawn EOS (Wyatt Technology) multiangle light scattering instrument. The typical flow rate used was 1 mL min^{-1}. Data were fit by the *Astra* software to the Debye model with a detector fit degree of 2. The d*n*/d*c* value for the particles was determined to be 0.14 mL g^{-1}, and the mass concentration used in the calculations was determined from the total amount of CDP−Im and nucleic acid incorporated into the particles assuming an individual particle charge ratio of 1.1 (±) and complete incorporation of the nucleic acid added during formulation.

Individual Particle Stoichiometry. An estimate for the stoichiometry of each particle (i.e., number of CDP, nucleic acid, AD−PEG, and AD−PEG−Tf molecules) can be calculated from the following equations:

$$MW_{part} = \#NA \times \#bp \times MW_{bp} + \#CDP \times MW_{CDP} + \#PEG \times MW_{PEG} + \#Tf \times MW_{Tf} \quad (1)$$

$$CR = \frac{\#CDP}{\#NA \times \#bp} \quad (2)$$

$$\#PEG = f_{PEG} \times (100\% - \%Tf) \times \#CDP \times PR \times \frac{FR}{CR} \quad (3)$$

$$\#Tf = f_{Tf} \times \%Tf \times \#CDP \times PR \times \frac{FR}{CR} \quad (4)$$

where #NA is the number of nucleic acid molecules in the particle, #CDP is the number of CDP monomers (β-CD) in the particle, #PEG is the number of AD−PEG molecules in the particle, #Tf is the number of AD−PEG−Tf molecules in the particle, MW_{part} is the molecular weight of an individual particle (determined by MALS), #bp is the number of base pairs per nucleic acid molecule (e.g., 21 for siRNA), MW_{bp} is the average molecular weight of each nucleic acid base pair (~650 Da as an approximation), MW_{CDP} is the molecular weight of each CDP monomer (~1460 Da), MW_{PEG} is the molecular weight of each AD−PEG molecule (~5200 Da for AD−PEG_{5000}), MW_{Tf} is the molecular weight of each AD−PEG−Tf molecule (~85 000 Da for AD−PEG_{5000}−Tf), f_{PEG} is the fraction of the AD−PEG molecules that bind to particles during formulation, PR is the mole ratio of AD−PEG to β-CD during formulation, FR is the formulation charge ratio (±), CR is the charge ratio (± = 1.1) of each individual particle, f_{Tf} is the fraction of the AD−PEG−Tf molecules that bind to particles during formulation, and %Tf is the mole percent AD−PEG−Tf during formulation.

Salt Stability. Particle formulations were diluted to a volume of 1260 μL, placed in a cuvette, and inserted into a ZetaPALS (Brookhaven Instruments Corporation) instrument. Kinetic studies of aggregation were performed by recording the effective diameters at 1 min intervals after the addition of 1/10 volume 10× PBS to achieve a final concentration of 1× PBS, corresponding to physiological salt concentration.

Erythrocyte Aggregation. Erythrocytes were obtained from whole bovine calf blood (Rockland Immunochemicals, Inc.) by multiple rounds of centrifugation at 700 *g* and 4 °C for 10 min followed by removal of the supernatant and resuspension of the pellet of erythrocytes in cold PBS (Cellgro) until the supernatant became clear. Finally, the erythrocytes were resuspended at a concentration of 1% (v/v). The free polycations or formulated particles were added to a 24-well plate and diluted with PBS to a volume of 100 μL. Subsequently, 100 μL of the erythrocyte suspension were added to each well, and the plate was incubated for 1 h at 37 °C. Images were taken of each well using a CCD−IRIS/RGB (Sony) video camera attached to an Eclipse TE-300 (Nikon) inverted microscope to visually determine the degree of aggregation.

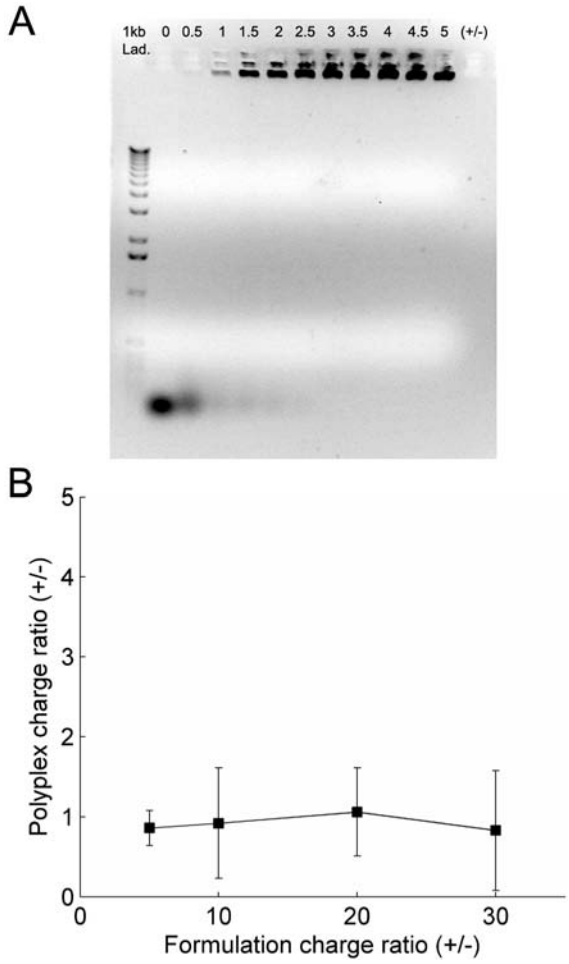

Figure 2. Effect of formulation charge ratio (±). (A) Electrophoretic gel mobility shift assay demonstrating the effect of formulation charge ratio on siRNA particle formation. (B) Individual particle charge ratio as a function of formulation charge ratio.

Complement Fixation. To test the complement fixation by polycations or CDP-based particles, antibody-sensitized sheep erythrocytes were used in a CH50 assay modified from Plank et al. (*11*). 25 μL human complement sera (Sigma) in gelatin veronal buffer (Sigma) were added in a 1:1.5 dilution series across a row of wells in a 96-well plate. To this same row of wells were added 25 μL of the desired concentration of polycation in its free form or complexed with calf thymus DNA (CT-DNA). A different concentration of the polycations or particles was added to each row of wells. After a 30-min incubation at 37 °C, 1.25×10^7 antibody-sensitized sheep erythrocytes (Sigma) were added to each well, and the plate was incubated with shaking for 1 h at 37 °C. Finally, the plate was centrifuged at 2000 rpm for 10 min, 100 μL of the supernatant from each well was transferred to a new 96-well plate, and the absorbance at 410 nm was determined using a SpectraMax 190 (Molecular Devices) microplate reader. This wavelength corresponds to an absorbance peak for the hemoglobin that is released after lysis of the erythrocytes. The CH50

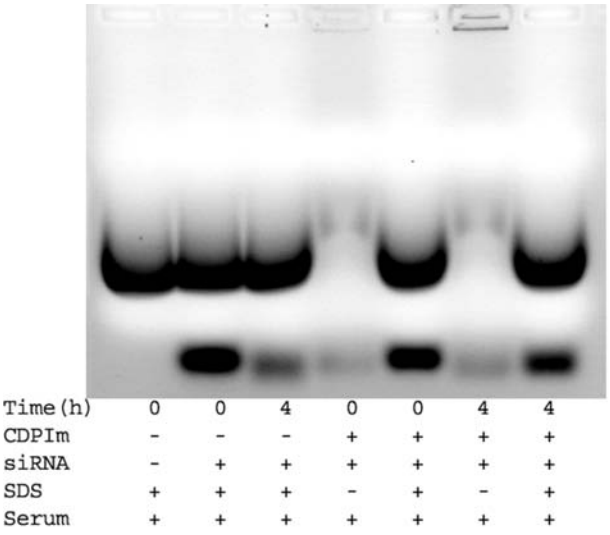

Figure 3. Nuclease stability of siRNA encapsulated within particles. For the $t = 4$ lanes, naked siRNA or siRNA within CDP−Im particles (3 (±)) was incubated in 50% mouse serum for 4 h at 37 °C and 5% CO_2. For the $t = 0$ lanes, serum was added to an equivalent amount of naked siRNA or siRNA within CDP−Im particles immediately before loading into the gel. Addition of 1% SDS was used to displace the siRNA from the particles to visualize the amount of intact siRNA remaining. The first lane demonstrates that the upper bands are nonspecific bands resulting from the interaction between SDS, serum, and the ethidium bromide stain, while the lower bands correspond to the free siRNA.

unit is used to define the serum dilution required to achieve 50% lysis of the antibody-sensitized sheep erythrocytes. If the substance being tested binds complement proteins to an appreciable degree, it will sequester these complement proteins and prevent them from binding to and lysing the erythrocytes. As a result, a lower serum dilution (CH50) will be required to achieve 50% erythrocyte lysis under these conditions. The reported %CH50max represents the ratio of the CH50 for the substance being tested to the CH50 determined for the complement sera alone (CH50max).

Cellular Uptake. *Method 1: Flow Cytometry*. A FACSCalibur (BD Biosciences) flow cytometer was used to detect the uptake of FL−siRNA (fluorescein attached to the 5′ end of the sense strand) delivered with or without the CDP−Im delivery vehicle. HeLa cells were seeded at 2×10^4 cells per well in 24-well plates 2−3 days prior to transfection and grown in medium supplemented with 10% fetal bovine serum (FBS) and antibiotics (penicillin/streptomycin). The growth medium was removed from each well and replaced with 200 μL Opti-MEM I (Invitrogen) alone, 200 μL Opti-MEM I with 100 nM FL−siRNA, or 200 μL Opti-MEM I with 100 nM FL−siRNA formulated into CDP−Im particles at a charge ratio of 3 (±). After incubation for 2 h at 37 °C and 5% CO_2, the transfection medium was removed and the cells were trypsinized and resuspended in Hanks Balanced Salt Solution (HBSS) with 1% bovine serum albumin (BSA) and 10 μg mL^{-1} propidium iodide to detect cell viability.

Method 2: Confocal Microscopy. HeLa cells were seeded at 2×10^4 cells per well in a LabTek II Chamber Slide 2 days prior to transfection and grown in medium supplemented with 10% FBS and antibiotics (penicillin/streptomycin). The growth medium was removed from each well and replaced with 200 μL Opti-MEM I containing 100 nM FL−siRNA formulated into CDP−Im particles at a charge ratio of 3 (±). After incubation for 2 h at 37 °C and 5% CO_2, cells were fixed for 15 min at room temperature using 4% paraformaldehyde in PBS. F-actin was stained with rhodamine phalloidin (Invitrogen) according to manufacturer's instructions. Cells were mounted with Biomeda Gel/Mount according to manufacturer's instructions, and the coverslips were subsequently sealed using nail polish. Fluorescent images were acquired using a Zeiss LSM 510 Meta laser scanning confocal microscope with a 40× water-immersion objective.

Competitive Uptake. Competitive uptake studies were conducted to determine the impact of free holo-transferrin (holo-

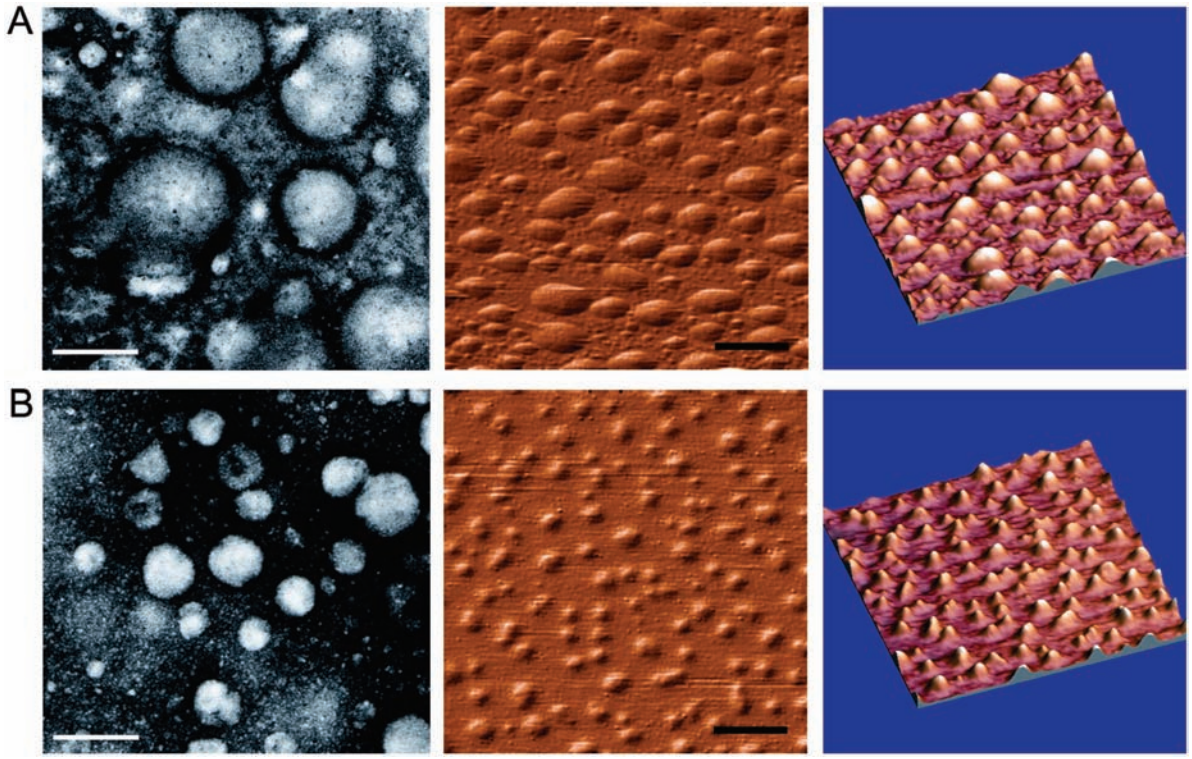

Figure 4. Transmission electron microscopy (left panels) and atomic force microscopy (center and right panels) images of (A) unPEGylated and (B) PEGylated siRNA particles formulated at a charge ratio of 3 (±). Scale bar = 100 nm (left panels) and 200 nm (center and right panels).

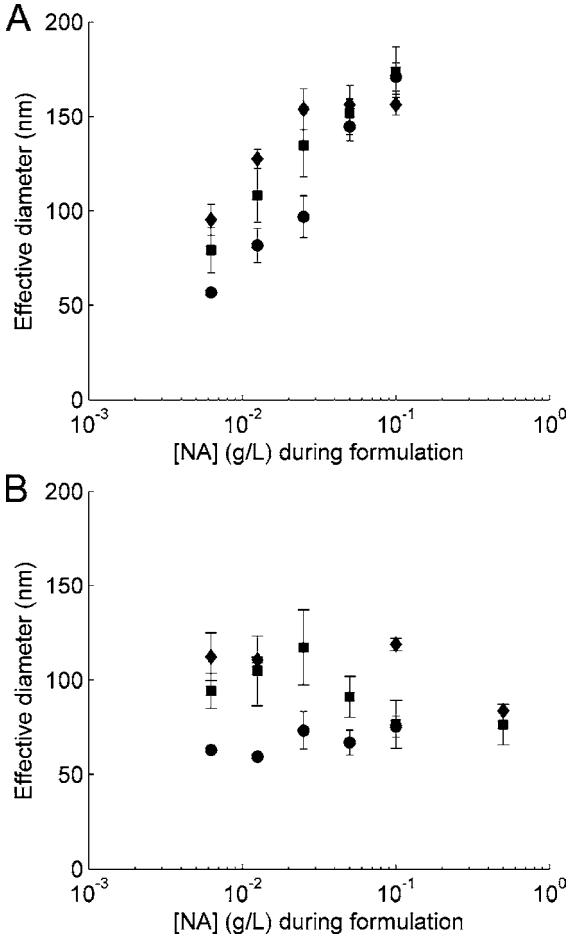

Figure 5. Effect of nucleic acid concentration ([NA]) during formulation on the size of (A) unPEGylated or (B) PEGylated particles. Particles were formulated at a charge ratio of 3 (±) using CDP−Im and either siRNA, pDNA, or CT-DNA (calf thymus DNA). PEGylated particles were formulated by adding a 1:1 mole ratio of AD−PEG_{5000}/β-CD. Particle effective diameter was determined using dynamic light scattering. Squares = CDP−Im/siRNA particles; circles = CDP−Im/pDNA particles; diamonds = CDP−Im/CT-DNA particles.

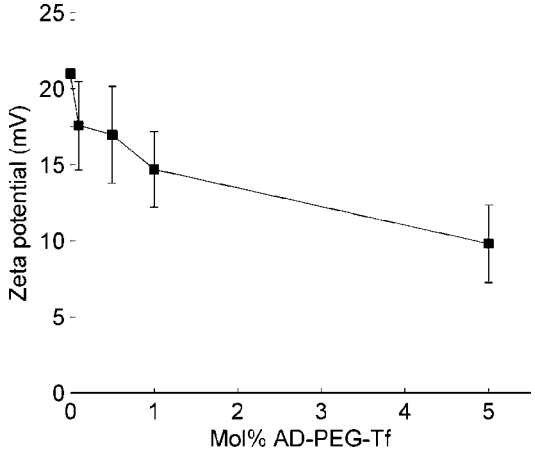

Figure 6. Particle ζ potential as a function of AD−PEG_{5000}−Tf ligand concentration during formulation. Particles were formulated at a charge ratio of 3 (±) using CDP−Im and siRNA, and the AD−PEG_{5000} or AD−PEG_{5000}−Tf molecules were added after particle formation (post-complexation). The total number of moles of AD−PEG_{5000}−X (AD−PEG_{5000} and AD−PEG_{5000}−Tf) was equal to the number of moles of β-CD, and the mixture of AD−PEG_{5000} and AD−PEG_{5000}−Tf is defined by the % AD−PEG_{5000}−Tf.

Table 1. Measured ITC Parameters for the Binding between AD−PEG_{5000} and β-CD Alone, Polycation Alone (CDP−Im), or CDP−Im/siRNA Particles Formulated at Charge Ratios from 3 (±) to 15 (±)[a]

	β-CD + Adamantane Carboxylate		
	n	*K* (M^{-1})	Δ***H*** (cal M^{-1})
β-CD	1	42000	−4440
	β-CD + AD−PEG_{5000}		
	n	*K* (M^{-1})	Δ***H*** (cal M^{-1})
β-CD	1.1	30600	−7358
	siRNA Particle + AD−PEG_{5000}		
	n	*K* (M^{-1})	Δ***H*** (cal M^{-1})
3 (±)	0.34 ± 0.09	5110 ± 730	−15200 ± 4090
5 (±)	0.38 ± 0.04	6320 ± 330	−12600 ± 570
10 (±)	0.48 ± 0.02	8090 ± 620	−10100 ± 520
15 (±)	0.49 ± 0.01	8050 ± 800	−10600 ± 450
CDP−Im	0.54 ± 0.04	8380 ± 940	−9460 ± 1490

[a] For comparison, literature values are provided for the binding between β-CD alone and adamantane carboxylate (*22*).

Tf) on the relative uptake of transferrin-targeted (containing 1 mol % AD−PEG_{5000}−Tf) or nontargeted particles. By formulating the particles with Cy3−siRNA (Cy3 attached to the 5′ end of the sense strand), a Tecan SPECTRAFluorPlus plate reader could be used to measure the total cell-associated fluorescence after transfection. Cells were seeded at 2×10^4 cells per well in 24-well plates 2−3 days prior to transfection and grown in medium supplemented with 10% FBS and antibiotics (penicillin/streptomycin). The growth medium was removed from each well and replaced with 200 μL Opti-MEM I containing 100 nM Cy3−siRNA formulated in particles. After incubation for 30 min at 37 °C and 5% CO_2, the transfection medium was removed, and the cells were lysed in 100 μL cell lysate buffer (Promega). Total fluorescence in the 100 μL lysate per well was measured with the SPECTRAFluorPlus plate reader, and the number of siRNA molecules was estimated from a standard curve of Cy3−siRNA. Cells in two wells that were not transfected were trypsinized and counted to provide an estimate for the average number of cells per well.

Avidity Effects. *Method 1: Competitive Cell Surface Transferrin Receptor (TfR) Binding Assay.* Competitive uptake experiments were performed using flow cytometry to detect the uptake of fluorescently labeled holo-Tf. Unlabeled holo-Tf, Tf conjugates (AD−PEG_{5000}−Tf), or Tf-targeted siRNA particles (1 mol % AD−PEG_{5000}−Tf) were used to compete for uptake by the transferrin receptors on the surface of HeLa cells. Cells were seeded at 2×10^4 cells per well in 24-well plates 2−3 days prior to transfection and grown in medium supplemented with 10% FBS and antibiotics (penicillin/streptomycin). The growth medium was removed from each well and replaced with 200 μL Opti-MEM I containing 1% BSA, 20 nM AlexaFluor488-labeled holo-Tf (AF488-Tf), and the desired unlabeled Tf competitor. After incubation for 1 h at 37 °C and 5% CO_2, the transfection medium was removed, and the cells were trypsinized and resuspended in HBSS with 1% BSA and 10 μg mL^{-1} propidium iodide to detect cell viability. To enable direct comparison of the effects of avidity, the total amount of Tf was kept constant whether it was in its free form, as AD−PEG_{5000}−Tf, or as AD−PEG_{5000}−Tf on the siRNA particles. The relative uptake under each condition is reported as the ratio of the mean fluorescence of the wells with unlabeled competitor to the mean fluorescence of the wells with AF488−Tf alone.

Method 2: Live-Cell Binding Assay. A live-cell binding assay was used to measure the relative binding of transferrin-targeted siRNA particles. 3×10^5 HeLa cells were resuspended in 100 μL PBS in individual microcentrifuge tubes and cooled on ice. To each microcentrifuge tube was added 100 μL PBS containing

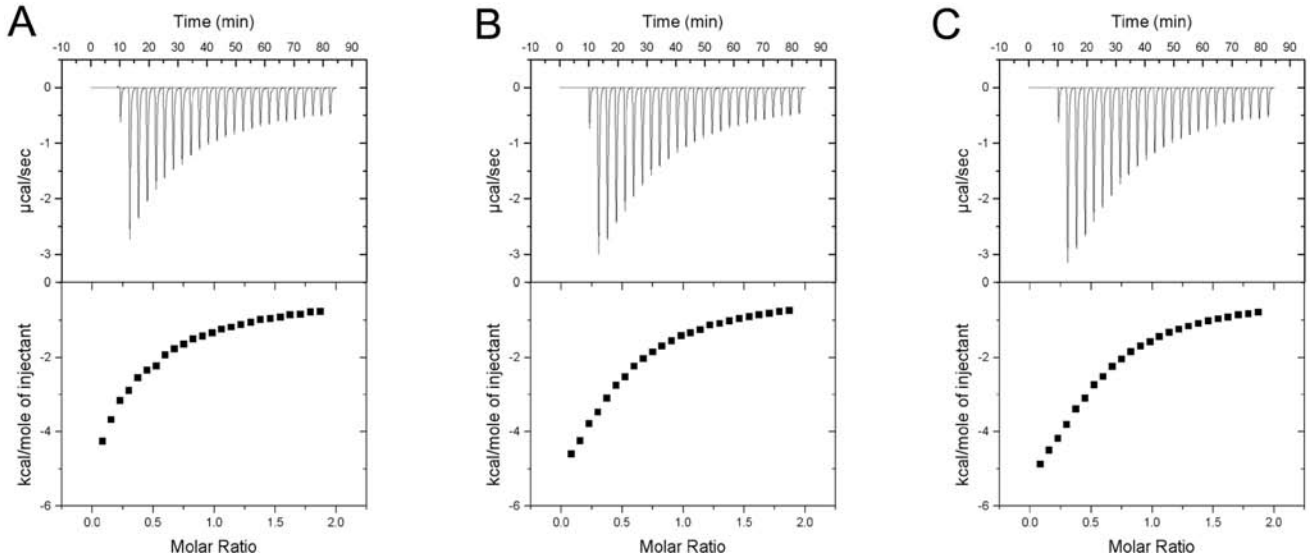

Figure 7. Isothermal titration calorimetry (ITC) plots characterizing the binding between AD−PEG_{5000} molecules and free CDP−Im or siRNA particles. (A) CDP−Im/siRNA particle (3 (±)) and AD−PEG_{5000}; (B) CDP−Im/siRNA particle (10 (±)) and AD−PEG_{5000}; (C) CDP−Im and AD−PEG_{5000}.

PEGylated or Tf-targeted particles formulated with Cy3-labeled siRNA such that the final Cy3-siRNA concentration was 100 nM. After incubating for 30 min on ice, the microcentrifuge tubes were centrifuged for 5 min at 200 *g* to pellet the cells. 100 μL of the supernatant from each microcentrifuge tube was added to a well in a black 96-well plate, and the Cy3 fluorescence was measured using a Tecan Safire plate reader. Comparison to a standard curve of Cy3−siRNA particles allowed quantification of the amount of Cy3−siRNA in each well, and the percent bound (fraction associated with the cell pellet) was determined by subtracting the fluorescence remaining in the supernatant from the initial amount added.

Luciferase Knockdown after siRNA Transfection. Functional efficacy of pDNA and siRNA delivered by CDP−Im particles was demonstrated in HeLa cells by cotransfecting the pGL3−CV vector (Promega) containing the firefly luciferase gene and a nontargeting control siRNA (siCON1) synthesized by Dharmacon or a luciferase-targeting siRNA (siLuc) synthesized by Integrated DNA Technologies. The sequence of the siCON1 siRNA is UAGCGACUAAACACAUCAAUU (sense) and UUGAUGUGUUUAGUCGCUAUU (antisense). The sequence of the siLuc siRNA is GUGCCAGAGUCCUUCGAUAdTdT (sense) and UAUCGAAGGACUCUGGCACdTdT (antisense). The Promega Luciferase Assay System was then used to quantify the relative luciferase expression in cells that had been transfected with 1 μg pGL3−CV alone, 1 μg pGL3−CV and 100 nM siCON1, or 1 μg pGL3−CV and 100 nM siLuc. HeLa cells were seeded at 2×10^4 cells per well in 24-well plates 2−3 days prior to transfection and grown in medium supplemented with 10% FBS and antibiotics (penicillin/streptomycin). CDP−Im particles were formulated to contain 1 μg pGL3−CV vector and 100 nM siRNA in 200 μL Opti-MEM I. The growth medium was removed from each well and replaced with 200 μL Opti-MEM I containing the formulated particles. After incubation for 5 h at 37 °C and 5% CO_2, 800 μL complete growth medium was added to each well. 48 h later, the cells were lysed in 100 μL 1X Luciferase Cell Culture Lysis Reagent (Promega). 10 μL of the cell lysate was added to 90 μL of the luciferase substrate, and bioluminescence was measured using a MonoLight (Pharmingen) luminometer. 5 μL of the cell lysate was used in a BioRad DC protein assay to determine the protein concentration in each lysate sample. Luciferase activities are reported as relative light units per milligram protein.

RESULTS AND DISCUSSION

Particle Formation Requires a Slight Excess of Positive Charge and Protects siRNA from Degradation in Serum. Results from an electrophoretic mobility shift assay (EMSA) demonstrate that siRNA particles completely form at charge ratios (±) greater than ~1 to 1.5 (Figure 2A). At sufficiently high charge ratios, the band corresponding to the free nucleic acid becomes undetectable, since the nucleic acid remains associated with the particles that have greatly reduced electrophoretic mobility. To determine what portion of the polycations (CDP) added during formulation actually are incorporated into the particles, the free polycations were separated from the particles after formulation. Regardless of the formulation charge ratio up to 30 (±), the charge ratio of individual particles remains ~1 (±) (Figure 2B). This is consistent with the results shown in Figure 2A where charge ratios slightly greater than 1 were required to achieve complete particle formation. A nuclease stability assay was conducted to determine if the formation of particles could protect the nucleic acid payload from degradation by nucleases present in serum. While naked siRNA degrades rapidly in serum, siRNA within particles is protected from significant degradation even after 4 h in 50% mouse serum (Figure 3). Additionally, the data given in Figure 3 show that (i) there is essentially complete encapsulation of the siRNA by the particles, and (ii) when the particles exposed to serum are disrupted with SDS, the nucleic acids released are still intact siRNA duplexes.

Formulation Conditions Affect Particle Size and ζ Potential. Transmission electron microscopy (TEM) and atomic force microscopy (AFM) were used to visualize the siRNA particles formulated at a charge ratio of 3 (±). The images in Figure 4 demonstrate that the siRNA particles assume a roughly spherical shape, but the unPEGylated particles display more variability in size and adopt a slightly oblong shape relative to the PEGylated particles when they are visualized by AFM on the mica surface. While a large fraction of the unPEGylated particles (0.1 g L^{-1} siRNA) have diameters that exceed 100 nm, PEGylated particles (0.5 g L^{-1} siRNA) formulated with a 1:1 mole ratio of AD−PEG_{5000}/β-CD consistently have diameters of <100 nm and are approximately 60−80 nm.

To further investigate the effects of formulation conditions, dynamic light scattering was used to measure the effective hydrodynamic diameter and ζ potential of the particles. Con-

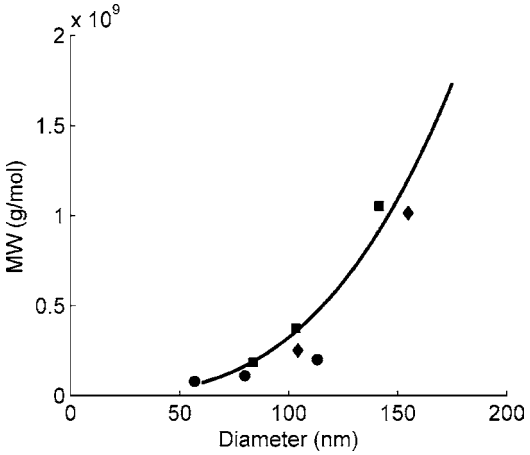

Figure 8. Relationship between particle size and molecular weight (MW) as determined by dynamic and multiangle light scattering. Particles were formulated at a charge ratio of 3 (±) using CDP−Im and either siRNA, pDNA, or CT-DNA. Effective diameters were measured using dynamic light scattering, and molecular weights were determined using multiangle light scattering. Squares = CDP−Im/siRNA particles; circles = CDP−Im/pDNA particles; diamonds = CDP−Im/CT-DNA particles; solid line = r^3 scaling dependence of the MW of particles starting with a MW of 7×10^7 g mol^{-1} for a 60 nm particle.

sistent with the TEM and AFM images, the results shown in Figure 5A reveal that the nucleic acid concentration during formulation affects the size of the particles. Particles formulated with siRNA, pDNA, and calf thymus (CT-DNA) show nearly identical trends of increased size with higher nucleic acid concentration. However, particles that are formulated in the presence of AD−PEG$_{5000}$ (PEGylated particles formed by the pre-complexation method) do not exhibit such a dependence on formulation conditions (Figure 5B). These properties allow the delivery vehicles to be fine-tuned with respect to size by altering the formulation conditions accordingly (i.e., PEGylation through the pre- or post-complexation method). The ζ potential of unPEGylated particles ranges from 10 (particles ∼60 nm in diameter) to 30 mV (particles ∼150 nm in diameter), while that of PEGylated particles ranges from 10 to 20 mV for similarly sized particles. This positive ζ potential implies that the charge ratio of the individual particles is slightly greater than 1 (±). The AD−PEG$_{5000}$ conjugates can be further modified to contain targeting ligands on the distal end of the PEG chain. For example, transferrin can be conjugated to the AD−PEG$_{5000}$ molecules to yield AD−PEG$_{5000}$−Tf (*19*). Because the transferrin protein is negatively charged, inclusion of AD−PEG$_{5000}$−Tf molecules during particle formulation reduces the ζ potential of siRNA particles in a concentration-dependent manner (Figure 6). Bellocq et al. reported a similar trend using particles made with pDNA (*19*).

AD−PEG Conjugates Bind to the Surface of Particles Through Inclusion Complex Formation. An important property of the cyclodextrin-containing polycations is their ability to form inclusion complexes with hydrophobic molecules. This provides the opportunity for modular attachment of different stabilizing molecules or targeting ligands through coupling to an adamantane (AD) molecule that forms inclusion complexes with the β-cyclodextrin molecules. Isothermal titration calorimetry was used to investigate the thermodynamics of the interaction between AD−PEG molecules and CDP−Im either in its free form or within siRNA-containing particles (Table 1). Figure 7 shows representative ITC data plots for binding between AD−PEG$_{5000}$ and CDP−Im formulated with siRNA at a charge ratio of 3 (±), CDP−Im formulated with siRNA at a charge ratio of 10 (±), and CDP−Im alone. As the charge ratio increases, the measured binding parameters approach those

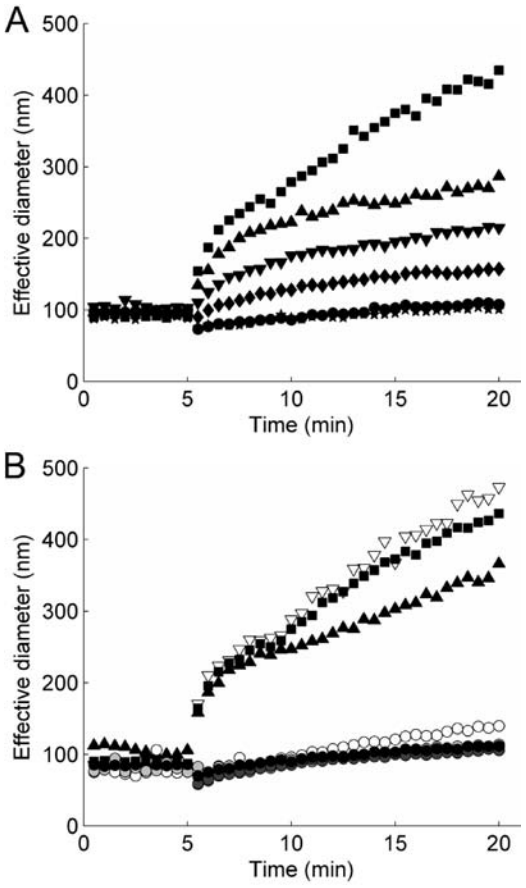

Figure 9. Aggregation of siRNA particles in physiological salt solutions. 140 μL of a 10× PBS solution were added to 1260 μL of the particles in water after 5 min, and dynamic light scattering was used to follow the formation of aggregates with time. (A) Effect of the ratio of AD−PEG$_{5000}$/β-CD on particle stability. CDP−Im/siRNA (3 (±)) particles were formulated without AD−PEG$_{5000}$ (black squares) or through the post-complexation method with an AD−PEG$_{5000}$/β-CD mole ratio of 0.25:1 (black triangles), 0.5:1 (inverted black triangles), 0.75:1 (black diamonds), 1:1 (black circles), or 2:1 (black stars). (B) Effect of PEG chain length, adamantane conjugation, and Tf targeting ligand density on particle stability. CDP−Im/siRNA (3 (±)) particles were formulated without AD−PEG$_{5000}$ (black squares), with a PEG$_{5000}$ (no adamantane)/β-CD mole ratio of 1:1 (open inverted triangles), with an AD−PEG$_{500}$/β-CD mole ratio of 1:1 (black triangles), with an AD−PEG$_{5000}$/β-CD mole ratio of 1:1 (black circles), or with a 1:1 mole ratio of AD−PEG$_{5000}$-X/β-CD where AD−PEG$_{5000}$−X was composed of 0.1 wt % AD−PEG$_{5000}$−Tf (dark gray circles), 0.1 mol % AD−PEG$_{5000}$−Tf (gray circles), 1 mol % AD−PEG$_{5000}$−Tf (light gray circles), or 5 mol % AD−PEG$_{5000}$−Tf (open circles) and the remainder AD−PEG$_{5000}$.

of free CDP−Im as expected. Given the previous results showing that the actual particle charge ratio is slightly greater than 1 (±), this is consistent with the presence of excess free CDP−Im at charge ratios of >1.

The value of *n* represents the fraction of the β-CD molecules available for inclusion complex formation with the AD−PEG molecules. Each β-CD cup can interact with a single adamantane molecule, as previous reports have shown a 1:1 binding stoichiometry between adamantane molecules and β-CD (*22*). While binding between individual β-cyclodextrins and AD−PEG$_{5000}$ conjugates gives the expected *n* value of ∼1, binding between CDP−Im and AD−PEG$_{5000}$ exhibits an *n* value of ∼0.5. When the AD−PEG$_{5000}$ molecule containing a 5000 Da PEG chain binds to a β-CD cup on the CDP−Im polymer, it likely provides steric hindrance that impedes binding between other AD−PEG$_{5000}$ molecules and nearby β-CD molecules. Support for this hypothesis comes from the observation that the *n* value for binding between CDP−Im and AD−PEG$_{500}$

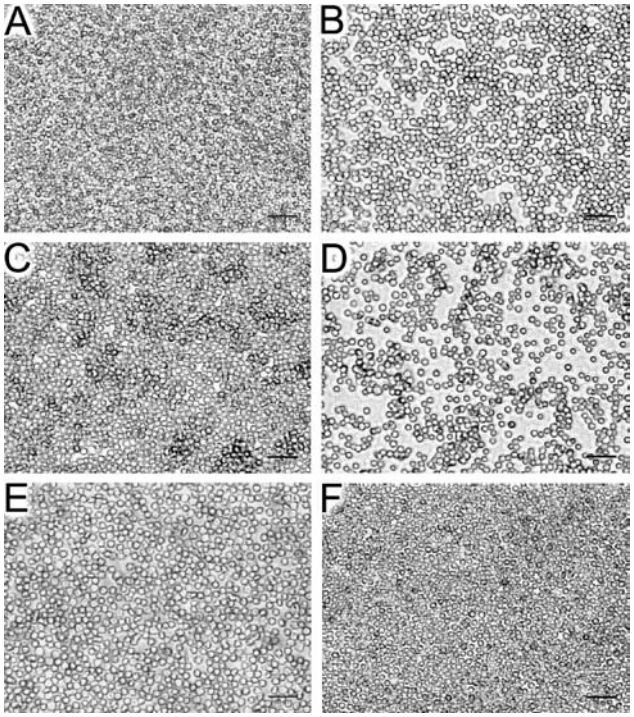

Figure 10. Erythrocyte aggregation: (A) 0.2 g L^{-1} CDP, (B) 2 g L^{-1} CDP, (C) 0.2 g L^{-1} CDP−Im, (D) 2 g L^{-1} CDP−Im, (E) CDP−Im/siRNA (3 (±)) particles at 0.2 g L^{-1} CDP−Im formulated with a 1:1 mole ratio of AD−PEG_{5000}/β-CD, (F) PBS alone. Scale bar = 20 μm.

molecules containing short 500 Da PEG chains is 0.92 ± 0.05, likely indicating that the shorter PEG chains do not interfere to as great an extent with the binding of AD−PEG_{500} to neighboring β-CD molecules.

Another interesting pattern is observed with the ΔH values, representing the change in enthalpy that results from binding between an AD−PEG molecule and a β-CD cup. These values are all negative, indicating that energy is released upon binding due to the favorable interaction between the hydrophobic adamantane and the β-CD cup. Notably, ΔH is more negative for AD−PEG_{5000} binding to the siRNA particles than it is for AD−PEG_{5000} binding to free CDP−Im. We hypothesize that this increased stabilization energy, in addition to the inclusion complex formation, is a result of favorable interactions between the PEG chains themselves when they are grouped together on the surface of an siRNA particle.

Particle Molecular Weight Can Be Used to Estimate Individual Particle Stoichiometry. Determining the individual component stoichiometry of the particles provides important insights into their functional properties. Centrifugal filtration was used to separate unbound components from those bound to the particles. As discussed previously, it was determined that the individual particle charge ratio (i.e., the ratio of positive charges from the CDP−Im to negative charges from the nucleic acid) is slightly greater than 1; we used 1.1 (±) for the calculations. The percent of the total AD−PEG_{5000} or AD−PEG_{5000}−Tf added to the formulation mixture that remains free was determined by quantifying the AD−PEG_{5000} (experiment actually used AD−PEG_{5000}−Lac, and we assumed that the value for AD−PEG_{5000} would be approximately the same) or AD−PEG_{5000}−Tf recovered in the filtrate versus the retentate after centrifugal filtration. The results of these measurements indicated that approximately 3% of the total AD−PEG_{5000} and 10% of the total AD−PEG_{5000}−Tf added during formulation remained associated with the particles. The greater degree of binding measured for the AD−PEG_{5000}−Tf conjugates may be partly due to charge interactions between the negatively charged

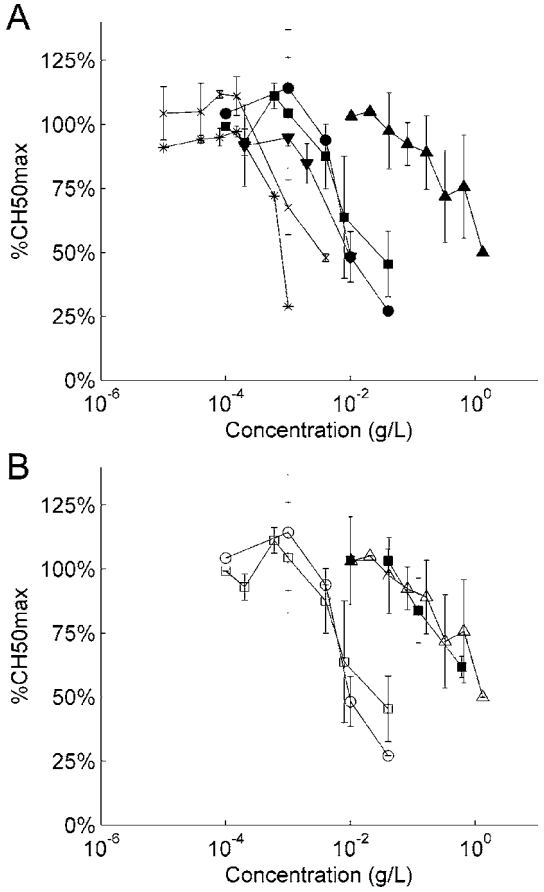

Figure 11. Complement fixation. (A) Complement fixation by free polycations. *, branched PEI; ×, linear PEI; ▲, pentalysine; ▼, polylysine (36-mer); ■, CDP; ●, CDP−Im. (B) Complement fixation by CDP/CT-DNA (3 (±)) particles formulated with a 1:1 mole ratio of AD−PEG_{5000}/β-CD (■). The curves for CDP (□), CDP-Im (○), and pentalysine (△) are shown again for comparison.

transferrin proteins and the positively charged particles. The final piece of data needed to estimate the individual particle stoichiometry is the molecular weight of the particles. This was determined using multiangle light scattering. The results in Figure 8 show that the molecular weight of particles formulated with siRNA, pDNA, or calf thymus (CT-DNA) scales approximately as r^3, where r is the radius of the particle determined by DLS. This similarity among all three types of particles is consistent with the trends observed in Figure 5, further supporting the interesting result that formulation with a variety of nucleic acids leads to particles with similar physical properties. An unPEGylated particle with a diameter of 70 nm is expected to have a molecular weight around 1×10^8 g mol^{-1} from data given in Figure 8. Inserting this molecular weight and an individual particle charge ratio of 1.1 (±) into eqs 1 and 2 yields 48 800 CDP monomers (or 9750 CDP chains with a degree of polymerization of 5) and 2110 siRNA molecules (with 21 bp per siRNA) per particle. For the sake of calculation, we can then use this value for #CDP to estimate the number of AD−PEG_{5000} and AD−PEG_{5000}−Tf molecules per particle using eqs 3 and 4. For example, a 70 nm siRNA particle with a molecular weight of 1.3×10^8 g mol^{-1} (accounting for the added mass from the PEG conjugates) formulated at a charge ratio of 3 (±) with 1 mol % AD−PEG_{5000}−Tf is calculated to contain 9750 CDP chains, 2110 siRNA molecules, 3950 AD−PEG_{5000} molecules, and 133 AD−PEG_{5000}−Tf molecules. The corresponding surface density for this number of AD−PEG_{5000} chains on a 70 nm particle is ~43 pmol cm^{-2} or 0.26 chains nm^{-2}. The calculated average distance between PEG_{5000} molecules at this surface density is ~2.0 nm, while the Flory radius is

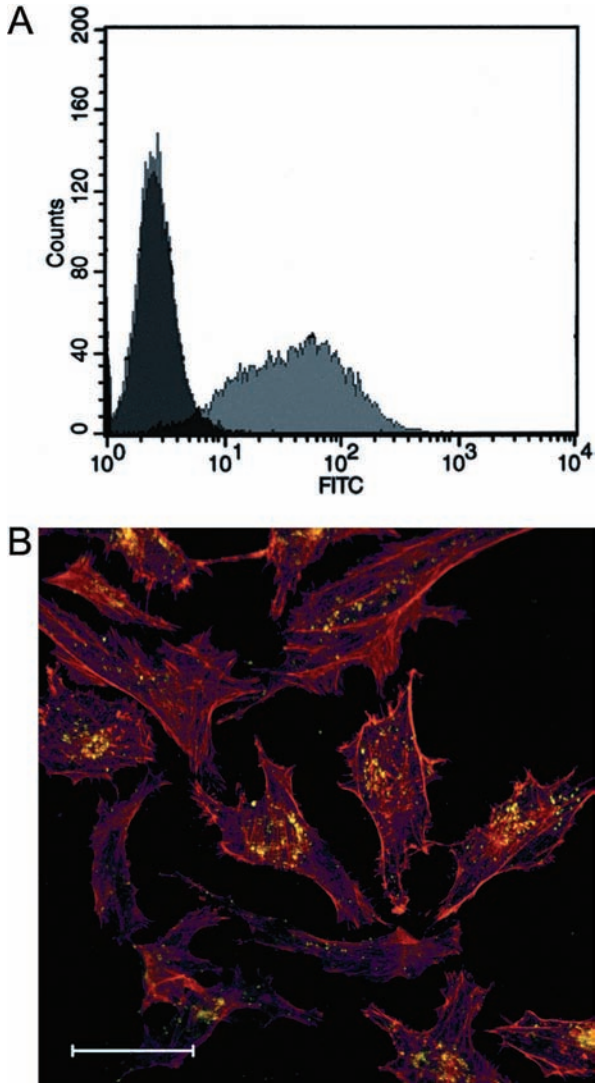

Figure 12. Uptake of CDP−Im particles containing fluorescein (FL)-labeled siRNA by HeLa cells. (A) Histogram of cell-associated fluorescence measured by flow cytometry. The left-most peaks correspond to the overlapping peaks for HeLa cells incubated with either Opti-MEM I alone or 100 nM naked FL−siRNA, while the right-most peak represents the cell-associated fluorescence after transfection with CDP−Im/FL−siRNA particles. (B) Confocal fluorescence microscopy image of HeLa cells after transfection with CDP−Im/FL−siRNA particles (green) and rhodamine phalloidin staining of F-actin (red). Scale bar = 50 μm.

~6 nm. Since the distance between PEG_{5000} molecules is much less than the Flory radius, the PEG_{5000} chains are expected to interact laterally and extend out from the surface in a dense brush layer with an estimated thickness of ~12.5 nm. Hansen et al. further examined the brush scaling laws for poly(ethylene glycol)s and predicted that PEG_{5000} solutions must have monomer volume fractions, ϕ, greater than 0.07−0.09 to be in the brush regime (*23*). This is satisfied when the PEG_{5000} surface density exceeds ~26−28 pmol cm^{-2}, again indicating that the PEG_{5000} chains on the particles are in the brush regime.

PEGylation Provides Steric Stabilization to the Particles and Reduces Nonspecific Interactions. DLS-based kinetic studies of aggregation were performed to determine whether the inclusion of AD−PEG conjugates could help to stabilize the particles against aggregation at physiological salt concentrations. First, the ratio of AD−PEG_{5000}/β-CD (mol/mol) was varied from 0 to 2 to investigate how the surface density of AD−PEG_{5000} affects the steric stability of siRNA particles formulated through the post-complexation method (Figure 9A). Particles formulated with AD−PEG_{5000}/β-CD (mol/mol) ratios of >1 do not exhibit observable aggregation after 15 min in 1× PBS. At ratios of <1, aggregation increases as the ratio of AD−PEG_{5000}/β-CD (mol/mol) decreases. These results with siRNA-containing particles are consistent with those observed by Pun et al. using particles made with pDNA (*24*). The length of the PEG molecule in the AD−PEG conjugate also impacts its ability to confer steric stabilization to the particles. As shown in Figure 9B, the stabilization effects increase with the length of the PEG chain, with AD−PEG_{500} (AD−PEG_{500}/β-CD = 1) only slightly slowing the aggregation, while AD−PEG_{5000} (AD−PEG_{5000}/β-CD = 1) prevents detectable aggregation up to 15 min after salt addition. If the AD−PEG_{500} chains, like the AD−PEG_{5000} chains, also achieve a surface density of ~43 pmol cm^{-2} (AD−PEG_{500}/β-CD = 1), then the average distance between PEG_{500} chains remains ~2.0 nm. However, since this is not less than the Flory radius for a PEG_{500} molecule (~1.5 nm), the PEG_{500} molecules are not expected to form the brushlike layer on the particle surface that is needed for steric stabilization. Furthermore, modification of up to 1 mol % of the AD−PEG_{5000} chains with Tf (AD−PEG_{5000}−Tf) leads to minimal perturbations in the salt stability of the particles. However, at 5 mol % AD−PEG_{5000}−Tf, gradual particle aggregation becomes apparent during the 15 min incubation in 1× PBS.

Besides providing steric stabilization to the particles, PEGylation can help to reduce nonspecific interactions. Specifically, experiments were performed to study the interaction between the polycations (or particles) and erythrocytes (Figure 10). Significant erythrocyte binding will lead to aggregation that can be observed by visual inspection using a light microscope. While the free CDP or CDP−Im showed negligible aggregation at 0.2 g L^{-1}, some aggregation was observed as the concentration increased to 2 g L^{-1} (Figure 10A−D). Erythrocyte aggregation was also measured after incubation with siRNA particles that were formulated with CDP−Im and a 1:1 mole ratio of AD−PEG_{5000}/CDP−Im (Figure 10E). The results demonstrate that PEGylated particles do not lead to any observable aggregation at a total CDP−Im concentration of 0.2 g L^{-1}, corresponding to the expected concentration after systemic delivery in vivo (*7*).

PEGylated Particles Show Minimal Complement Fixation. Complement fixation by poly(ethylenimine) and poly(lysine) was compared to that of CDP or CDP−Im. The CDP and CDP−Im molecules do not show as much complement fixation as PEI (branched or linear) or a 36-mer of poly(lysine), but they do exhibit higher complement fixation than a 5-mer of poly(lysine) (Figure 11A). This is consistent with the notion that polycation length and charge density can augment complement activation (*11*).

Because complement fixation was observed at the physiologically relevant concentration of 0.2 g L^{-1}, corresponding to the typical concentration of polycations in the bloodstream after delivery of nucleic acids at a dose of 2.5 mg kg^{-1} (a typical dose used for in vivo siRNA delivery (*7*)), experiments were performed to test particles formulated with calf thymus DNA and stabilized by PEGylation (Figure 11B). Notably, these formulations showed minimal complement fixation at polymer concentrations of 0.2 g L^{-1}.

Particles Achieve Intracellular Delivery of siRNA in Vitro. The uptake of particles containing fluorescently labeled siRNA was assessed using flow cytometry and confocal fluorescence microscopy. While naked siRNAs do not achieve measurable levels of cellular uptake, formulation into particles with CDP−Im dramatically increases the amount of cell-associated siRNA as measured by flow cytometry (Figure 12A). To confirm that the siRNA was being delivered to the interior of cells, confocal

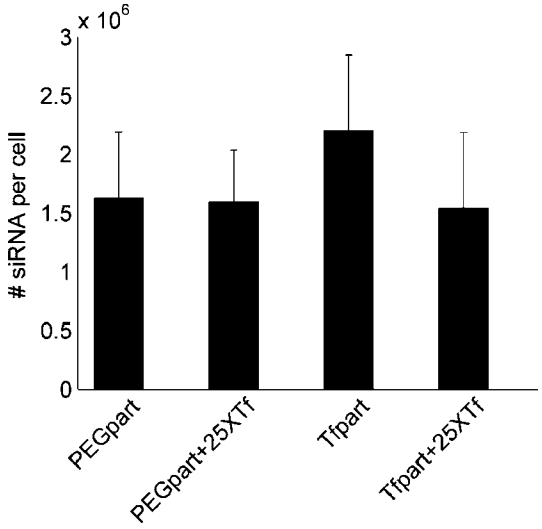

Figure 13. Uptake of PEGylated and Tf-targeted particles in the presence of holo-Tf competitor. Particles were formulated at a charge ratio of 3 (±) using CDP−Im and siRNA. PEGylated particles (PEGpart) were formulated with a 1:1 mole ratio of AD−PEG_{5000}/β-CD and Tf-targeted particles (Tfpart) were formulated with a 1:1 mole ratio of AD−PEG_{5000}−X/β-CD where AD−PEG_{5000}−X was composed of 99 mol % AD−PEG_{5000} and 1 mol % AD−PEG_{5000}−Tf. Particles containing 100 nM siRNA were added to HeLa cells in 200 μL Opti-MEM I in the absence or presence of a 25-fold (moles holo-Tf/moles AD−PEG_{5000}−Tf) excess of holo-Tf competitor.

fluorescence microscopy was used to visualize cells transfected with particles containing fluorescently labeled siRNA (Figure 12B). The internalized particles exhibited a punctate staining and were eventually observed to accumulate in the perinuclear region.

Targeting Ligands Enhance Cellular Uptake of PEGylated Particles. To verify that attachment of AD−PEG_{5000}−Tf can lead to uptake through transferrin receptor (TfR)-mediated endocytosis, the uptake of stabilized (PEGylated) particles was measured in the presence or absence of free holo-Tf. While the uptake of PEGylated particles without AD−PEG_{5000}−Tf was not affected by the presence of free holo-Tf, the uptake of Tf-targeted particles was reduced as a result of competition with free holo-Tf (Figure 13). Because the particles can be internalized simultaneously by numerous mechanisms including simple pinocytosis, there is still significant uptake even without TfR-mediated internalization under these conditions.

Targeted Particles Exhibit Increased Affinity through Avidity Effects. If multiple receptor/ligand interactions can occur simultaneously, then the effective affinity of the binding interaction can be enhanced through avidity effects. Antibodies or divalent antibody fragments are excellent examples of molecules whose binding affinities are enhanced through avidity effects. Their divalent interactions allow single antibodies to bind two separate receptors, leading to a stronger apparent affinity than exhibited by the monovalent antibody fragment (*25*). Targeted delivery vehicles that contain multiple targeting ligands on the surface should also display these avidity effects if multiple targeting ligands can simultaneously interact with the receptors. A typical cancer cell may contain thousands of receptors on its surface (*26*, *27*), and the Tf-targeted delivery vehicles can contain tens or even hundreds of Tf ligands (depending on the percent of the AD−PEG_{5000} molecules with Tf molecules attached to the distal end of the flexible PEG_{5000} chains) decorating each particle surface. This arrangement should enable multiple Tf molecules to bind to TfR on the surface of the cells. To test whether these avidity effects increase the apparent affinity of the Tf-targeted particles for the TfR on the cell surface, a competitive uptake assay was performed using

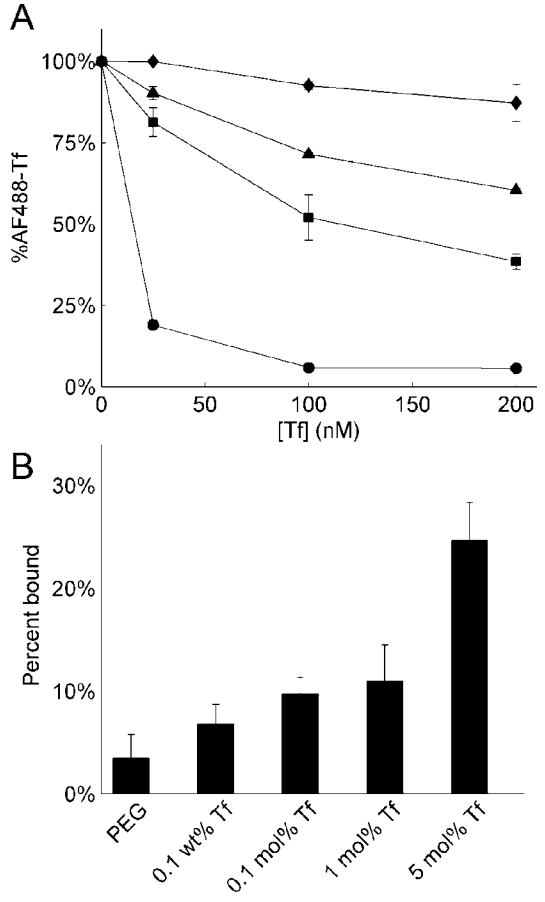

Figure 14. Effect of transferrin targeting ligand density on relative binding affinity. (A) Competitive TfR binding by free holo-Tf (circles), free AD−PEG_{5000}−Tf (triangles), Tf-targeted CDP−Im/siRNA (3 (±), 1 mol % AD−PEG_{5000}−Tf) particles (squares), and PEGylated CDP−Im/siRNA (3 (±)) particles (diamonds) in the presence of 20 nM AlexaFluor488-labeled holo-Tf. As a control, the PEGylated particles were formulated identically to the Tf-targeted particles at each concentration except without the addition of AD−PEG_{5000}−Tf during formulation. (B) Live-cell binding assay. Particles were formulated at a charge ratio of 3 (±) using CDP−Im and Cy3-labeled siRNA. PEGylated particles (PEGpart) were formulated with a 1:1 mole ratio of AD−PEG_{5000}/β-CD and Tf-targeted particles (Tfpart) were formulated with a 1:1 mole ratio of AD−PEG_{5000}−X/β-CD where AD−PEG_{5000}−X was composed of the stated % AD−PEG_{5000}−Tf and the remainder AD−PEG_{5000}. Particles containing 100 nM Cy3−siRNA were added to HeLa cells in 200 μL PBS and incubated on ice for 30 min. The "percent bound" represents the fraction of particles associated with the cell pellet after centrifugation.

flow cytometry. The results shown in Figure 14A demonstrate that the Tf-targeted particles possess enhanced affinity for the TfR relative to individual AD−PEG_{5000}−Tf molecules. Additionally, particles without the Tf targeting ligand had a minimal impact on the uptake of the fluorescently labeled holo-Tf. To determine how targeting ligand density affects particle binding to cell surface TfR, particles were incubated with HeLa cells in PBS at 4 °C to measure the amount of binding in the absence of internalization. The results shown in Figure 14B show that Tf targeting increases the amount of cell-associated particles under these conditions, and the amount of binding increases with the targeting ligand density.

Particles Deliver Functional pDNA and siRNA to Cells in Vitro. In addition to achieving intracellular delivery of the nucleic acid-containing particles, the particles need to release their nucleic acid payload intracellularly to allow it to function. Co-delivery of a luciferase-expressing plasmid and either a control or luciferase-targeting siRNA was used to demonstrate the ability of the particles to deliver functional pDNA and

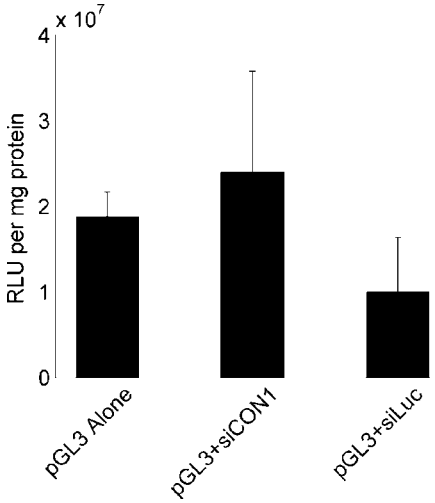

Figure 15. Luciferase expression 48 h after cotransfection of HeLa cells with particles containing pDNA and siRNA. Particles were formulated at a charge ratio of 3 (±) by combining CDP−Im with pGL3−CV (pGL3 alone), pGL3−CV and a control siRNA (pGL3+siCON1), or pGL3−CV and an siRNA against luciferase (pGL3+siLuc).

siRNA. The luciferase activity in cell lysates was quantified using a luminometer, and relative light units (RLU) were normalized to total cellular protein levels. As shown in Figure 15, cells that received CDP−Im particles containing the plasmid and siRNA against luciferase (siLuc) had luciferase activity that was ∼50% lower than cells that received CDP−Im particles with either the plasmid alone or the plasmid plus a control siRNA (siCON1).

Nanoparticles Are Multifunctional, Integrated Systems for Nucleic Acid Delivery. The results presented here highlight the importance of creating a nanoparticle that consists of multiple components that function together as a system, and control over size, surface modification, payload protection, and targeting ligand to payload ratio are key parameters to consider when designing nucleic acid delivery vehicles for in vivo systemic use. These parameters also represent some of the major advantages of nanoparticle composites for delivery of nucleic acids instead of using carrier-free delivery methods. Nucleic acid delivery vehicles can help reduce renal clearance while adding features such as stabilization against nuclease degradation, cell-specific targeting, and large payload delivery. These features make them well-suited for the systemic delivery of nucleic acids in general, and we have shown that the system investigated here can deliver pDNA, siRNA, and DNAzymes in vitro and in vivo (*7*, *17*, *19*, *20*).

The capability to fine-tune the delivery vehicle's properties combined with an understanding of how those properties affect its function in biological systems represent two key factors necessary for optimization of nucleic acid delivery vehicles. This study demonstrates the importance of a rational approach in delivery vehicle design and lays a foundation for further in vivo studies to understand the relationships between the properties of nanoparticle delivery systems and their biological function. The approach to designing nanoparticle delivery vehicles that is outlined here can be used for other synthetic materials and is thus not limited to the cyclodextrin polymer-based system illustrated.

Sortase A as a Novel Molecular "Stapler" for Sequence-Specific Protein Conjugation

Ranganath Parthasarathy,[†] Shyamsundar Subramanian,[†] and Eric T. Boder*[,†,‡]

Departments of Chemical and Biomolecular Engineering and Bioengineering, University of Pennsylvania, Philadelphia, Pennsylvania 19104. Received October 28, 2006; Revised Manuscript Received January 6, 2007

The Sortase family of transpeptidase enzymes catalyzes sequence-specific ligation of proteins to the cell wall of Gram-positive bacteria. Here, we describe the application of recombinant *Staphylococcus aureus* Sortase A to attach a tagged model protein substrate (green fluorescent protein) to polystyrene beads chemically modified with either alkylamine or the in vivo Sortase A ligand, Gly-Gly-Gly, on their surfaces. Furthermore, we show that Sortase A can be used to sequence-specifically ligate eGFP to amino-terminated poly(ethylene glycol) and to generate protein oligomers and cyclized monomers using suitably tagged eGFP. We find that an alkylamine can substitute for the natural Gly_3 substrate, which suggests the possibility of using the enzyme in materials applications. The highly specific and mild Sortase A-catalyzed reaction, based on small recognition tags unlikely to interfere with protein expression, thus represents a useful addition to the protein immobilization and modification tool kit.

INTRODUCTION

The immobilization of proteins on surfaces continues to be an active area of research driven by widespread interest in protein−protein interactions and protein-based sensors, among others. Numerous immobilization techniques have been described in the literature (*1*−*9*). The older chemical approaches, where reactive functional groups (such as −COOH, $-NH_2$, or −S) present on a protein are covalently bonded to complementary groups on a surface, are subject to a lack of specificity (*1*); in addition, these methods can occasionally require the use of harsh reaction conditions, which may negatively impact activity of the immobilized protein. The lack of specificity stems from the presence of many solvent-accessible functional groups on a given protein that can react with a surface. This may result in multiple immobilized conformations or impaired activity due to the modification of a critical amino acid. Furthermore, several proteins may have similar functional groups, which would render chemical ligation approaches useless in selectively immobilizing a specific protein from a complex mixture (e.g., biological fluids or unpurified cellular lysates).

Another approach to immobilization is to biotinylate the protein of interest for subsequent binding to an avidin-covered surface using the strong and specific biotin−avidin interaction (*3*). The protein can be biotinylated enzymatically (which can be quite specific (*10*)) or chemically. Immobilizing a specific protein from a mixture of proteins would of course require that the target protein be biotinylated selectively.

Enzyme-directed efforts have circumvented many of these problems (*4*, *5*). In one embodiment of this concept, the protein of interest is fused to an enzyme. An irreversible inhibitor of the enzyme is covalently ligated to the target surface. Incubation of the fusion protein with the modified surface leads to specific and relatively rapid covalent bonding between the two. The disadvantages of this approach are the need to fuse relatively large proteins (22 kDa for cutinase (*5*) or O^6-alkylguanine−DNA alkyltransferase (*4*)) to the protein of interest and the need to synthesize complex substrates on an ad hoc basis (different for different enzymes) for use as surface tags. Large fusion partners can reduce yields in recombinant expression and the manipulation of reaction rates or reaction extents is not easy, since the substrate-to-enzyme stoichiometry is locked in from the outset. A further potential problem is the presence of the enzyme in the eventual fusion. This last issue is neatly avoided by the use of intein-based splicing (*1*, *8*), although this method also has the disadvantages of (a) requiring the fusion of a relatively large protein (123 residues in one case (*1*)) to the protein of interest and ligating a complementary protein to the surface with a specific orientation and (b) fixing intein−protein stoichiometry, which makes reaction conditions difficult to manipulate. However, enzyme-mediated and intein-based approaches both are very specific, which is especially relevant to the immobilization of a specific protein from a complex mixture (*1*).

An enzyme that catalyzes the ligation of two substrates through specific tags can be used to attach proteins to surfaces if the tags can be fused to the protein and surface. If the tags are small, this approach avoids the fusion of large proteins to the target protein or surface of interest while potentially retaining the specificity of enzymatic reactions. Furthermore, using the enzyme as a catalyst rather than a substrate of the immobilization reaction permits the easy optimization of reaction rates and extents by changing enzyme concentrations. High enzyme concentrations and the resulting rapid reactions could be very useful in capturing transient species or species at relatively low concentrations.

Microbial transglutaminases (mTGs) are bacterial enzymes that catalyze the formation of an amide link between the amide group of glutamine and the ϵ-NH_2 group of a lysine, thereby creating inter- or intramolecular cross-links (*11*). mTGs are also known to catalyze the reaction between an alkylamine (in place of lysine) and glutamine (*12*), but the enzymes have not been extensively investigated as a protein immobilization tool partly because specificity determinants for the reaction are not well-understood. In contrast, the bacterial transpeptidase Sortase A

is an extensively studied enzyme with known substrate specificity. Sortase A is used by Gram-positive bacteria to anchor surface proteins to the cell wall through a condensation reaction between a C-terminal −LPXTG tag on the former and a poly(glycine) bridge in the latter (*13*). The enzyme cleaves the LPXTG at the amide bond between the threonine and the glycine to form an acyl−enzyme intermediate. Nucleophilic attack by the amino group of the tris(Gly) on the intermediate results in the formation of an LPXT−GGG bond and the liberation of the free enzyme. It has been shown that LPETG is the optimal isoform of the tag (*14*).

In a paper highlighting the in vitro applications of Sortase A to protein conjugation, Mao and co-workers (*15*) were the first to show that this easily purified enzyme could be used to ligate model proteins (enhanced green fluorescent protein, eGFP) or peptides together if the reactants had −LPETG−COOH, or $-NH_2-$GGG, tags. In one example, a protein-transfection domain was ligated to eGFP, thereby enhancing eGFP transfer into mammalian cells (*15*). Our work furthers these in vitro applications of Sortase A by showing that (a) the tris(Gly) group can participate as a nucleophile in the reaction even when covalently bonded to a surface or a non-protein species such as poly(ethylene glycol) (PEG), and not merely in solution at a protein terminus, (b) alkylamine bound to a surface or PEG can function as a nucleophile, albeit less efficiently than tris(Gly), (c) tris(Gly) surfaces can be used to capture −LPETG-tagged proteins from crude cell lysates, and (d) the transpeptidation reaction can be used to make cyclic proteins and protein oligomers with specifically designed tagged proteins.

EXPERIMENTAL PROCEDURES

Protein Expression. Sortase A was expressed from plasmid pHTT27 (a gift from Dr. Olaf Schneewind, University of Chicago) that encodes a 159 amino acid N-terminal truncation with activity very similar to that of the full-length enzyme. eGFP variants were expressed by subcloning the gene with the desired flanking tags into the pET23-derived vector pBamUK (gift of Dr. Greg Vanduyne , University of Pennsylvania) between the *Nde I* and *Xho I* sites to add a C-terminal 6×His tag for purification. We have included the Avitag sequence GLNDIFEAQKIEWHE (*10*), which is the consensus sequence for biotinylation by bacterial biotin ligase (BirA), amino to the eGFP sequence for future use. Standard molecular biology techniques were used, and sequencing services were provided by the Central Sequencing Facility of the School of Medicine at the University of Pennsylvania. eGFP and Sortase A were expressed in BL21-DE3 *E. coli* (Invitrogen, Carlsbad, CA). Cultures were allowed to reach an OD_{600} of 0.7 before induction of expression by the addition of 1 mM isopropyl thioglucoside (IPTG, Fisher, Pittsburgh, PA). After 3 h of further growth at 37 °C, the cultures were pelleted by centrifugation and the pellets were frozen overnight at −20 °C. B-per solution (Pierce, Rockford, IL) was added to the thawed pellet to solubilize the cells, and the manufacturer's protocol was followed closely to isolate soluble protein. Nearly all of the fluorescence of the cell pellet was extracted by B-per, confirming that the eGFP remained soluble despite the presence of the added tags. Protein purification using the 6×His tag followed the procedure outlined by either Qiagen (Ni-NTA resin) or Clontech (TALON resin). Protein-enriched 0.5 mL fractions were combined and dialyzed against 50 mM Tris, 150 mM NaCl, pH 8, using a Slide-A-Lyzer dialysis cassette (Pierce) with a MWCO of 10 kDa for 48−60 h with at least one buffer change.

Conjugation of Gly_3 to Beads. Amine-terminated beads 3 μm in diameter were purchased from Polysciences (Warrington, PA). 100 μL of the beads (approximately 10^8 beads) were pelleted and washed twice in 0.1 M 2-morpholinoethane sulfonic acid (MES), pH 4.8. Fmoc-protected Gly_3 (Sigma, St Louis, MO) was dissolved in dimethylformamide and added at a final concentration of 0.8 mM to 200 μL of 0.1 M MES (pH 4.8) containing the washed beads. 1-ethyl-3-[3-dimethylaminopropyl]-carbodiimide hydrochloride (EDC, Pierce, Rockford, IL) was then added in aqueous solution to the bead slurry at a final concentration of 8 mM, and the mixture was shaken for 2 h at room temperature. After shaking, the beads were pelleted, washed once with 0.1 M MES, and twice in deionized water. They were suspended in 20% piperidine in water and shaken for 20 min, after which the beads were pelleted, washed twice in water and then twice in 50 mM Tris, 150 mM NaCl, 0.1% Tween-20, and stored in the same buffer. Except for minor, reversible aggregation, Gly_3-conjugated beads are stable for at least 7 weeks at 4 °C.

Conjugation of Gly_3 to PEGamine. Amine-terminated PEG (PEGamine) with a molecular weight of 10 kDa was obtained from Nektar Therapeutics (Huntsville, AL). The polymer terminates in $-CH_2OCH_2CH_2NH_2$. 5 mM PEGamine in 200 μL 0.1 M MES buffer (pH 4.8) was incubated with 5 mM Fmoc−Gly_3 and 25 mM EDC with shaking for 2 h at room temperature. The reaction mixture was then dialyzed against 50 mM Tris, 150 mM NaCl, pH 8, for 24 h using a 3.5 kDa MWCO dialysis cassette (Slide-A-Lyzer, Pierce, Rockford). To ensure the complete cleavage of Fmoc, the contents of the dialysis cassette were withdrawn and shaken with 20% piperidine for a half-hour. The reaction mixture was re-dialyzed for 48 h against the Tris/NaCl buffer. MALDI-TOF/TOF analysis (Proteomics Core Facility, Penn School of Medicine) was used in an effort to gauge the efficacy of polymer modification. The molecular weight of the polymer was found to have increased by 221 Da in place of the expected 172 Da. However, the peak was very broad, and the exact change in molecular weight is therefore uncertain.

Bead Reaction with Purified eGFP. Approximately 5 μL (5×10^6 beads) of a suspension of 3 μm diameter amino-terminated or Gly_3-modified beads was used per reaction. Beads were washed twice in 50 mM Tris, 150 mM NaCl, pH 8, containing 0.1% Tween-20 (the "reaction buffer") and then incubated with Sortase A and eGFP−LPETG in reaction buffer containing, in addition, 6 mM $CaCl_2$ and 3 mM β-mercaptoethanol. Addition of reagents such as BSA or NP-40 to block nonspecific binding did not alter data significantly. The concentrations of eGFP and Sortase A depended on the experiment and are mentioned in the context of specific experiments. The microcentrifuge tube containing the suspension was shaken vigorously. All of the Sortase A-mediated reactions in this work were conducted at 37 °C for 3 h unless otherwise indicated. At the end of this period, the beads were pelleted, washed three times with PBS + 0.1%BSA with careful resuspension of the beads between washes, and used for flow cytometric analysis. Flow cytometry was carried out on FACScan or FACSCalibur machines (BD Biosciences, San Diego, CA) at the Core Facility of the School of Medicine, University of Pennsylvania. Data were analyzed with *CellQuest* software (BD Biosciences, Pharmingen, San Diego, CA).

Bead Reactions with Cellular Lysate. BL21-DE3 *E. coli* cells expressing eGFP−LPETG were frozen overnight and lysed in 50 mM Tris, 150 mM NaCl, 0.1% Tween-20, at pH 8 using freeze−thaw cycles. The concentration of eGFP in the lysate was assayed by spectrophotometry at 488 nm and adjusted to 30 μM. Reaction mixtures containing 15 μM eGFP (pure or in unpurified lysate), 10 μM Sortase A, 3 mM β-mercaptoethanol, and 6 mM $CaCl_2$ were incubated at 37 °C for 3 h with an aliquot of Gly_3-conjugated beads. The beads were prepared for flow cytometric analysis as described above.

Table 1. Monomers for Sortase A-Catalyzed Ligation[a]

amino acid sequence	functional name
M***GGG***LNDIFEAQKIEWHEMVSK------***LPETG***LEHHHHHH	bifunctional eGFP
M***GGG***LNDIFEAQKIEWHEMVSK----------LEHHHHHH	monofunctional, acceptor eGFP
M--AGLNDIFEAQKIEWHEMVSK------***LPETG***LEHHHHHH	monofunctional, donor eGFP

[a] Tags relevant to Sortase A are highlighted. The dashes indicate the portion of the gene conserved among the three monomers.

Homogeneous Solution Reactions. The conditions described above were used with homogeneous reactions as well. When reactions could not be analyzed immediately, 10 mM EDTA was added to the reaction volume, and the microcentrifuge tubes were stored at 4 °C.

Reaction with PEGamine. 20 μM eGFP with a C-terminal LPETG was incubated with 30 μM Gly_3-conjugated PEGamine in the presence of 6 mM $CaCl_2$, 3 mM β-mercaptoethanol, and 10 μM Sortase A and incubated at 37 °C for 6 h.

Protein Electrophoresis and Western Blotting. Samples in LDS buffer (Invitrogen) were denatured by heating at 95 °C for 10 min in the presence of β-mercaptoethanol. Cooled samples were loaded into wells on 10% Bis-Tris NuPage gels with MES as running buffer and run using the XCell Surelock module (Invitrogen). Simply Blue reagent (Invitrogen) was used for staining the gel. For Western blotting, protein was transferred to a 0.2 μm PVDF membrane (Biorad, Hercules, CA) using the XCell II Blot Module (Invitrogen). The membrane was blocked with 5% nonfat milk in TTBS (Tris-buffered saline with 0.1% Tween-20) by shaking overnight at 4 °C, washed with TTBS, and incubated with alkaline phosphatase-conjugated anti-GFP (Rockland Immunochemicals, Gilbertsville, PA) or an anti-His_6 monoclonal antibody (Covance, Berkeley CA). An alkaline phosphatase-conjugated goat anti-mouse polyclonal antibody (Sigma, St Louis, MO) was used in the latter case. The membrane was washed again and incubated with the alkaline phosphatase substrate NBT−BCIP (Sigma, St Louis, MO). Image quantification used ImageJ. To enhance the signal-to-noise ratio for experiments involving quantification of bands, higher concentrations of Sortase A were used than in the other experiments.

RESULTS

Sortase-Mediated Conjugation of eGFP−LPETG to Gly_3-Conjugated Beads. Gly_3-conjugated beads as well as commercial amino-terminated beads were incubated with eGFP−LPETG ("donor" eGFP; Table 1) and Sortase A under conditions described below for each experiment. Flow cytometry using the intrinsic fluorescence of eGFP was employed to assess coupling to the beads. Beads that were incubated with donor eGFP and Sortase A for 3 h were visibly fluorescent to the naked eye. Flow cytograms of beads incubated with Sortase A show that they are considerably more fluorescent than those incubated without Sortase A (Figure 1a,b). The fluorescence intensity on the bead increases approximately 70-fold over the native Gly_3 beads; the ratio for nonspecifically adsorbed eGFP (reaction run in the absence of Sortase A) was about 3-fold (Figure 1b). The enzyme clearly ligates donor eGFP to the Gly_3 bead in Ca^{2+}-dependent fashion, since adding EDTA abrogates the reaction (Figure 1c). A smaller increase in fluorescence can also be seen when eGFP is coupled to amine-terminated beads by Sortase A (Figure 1d,g), with similar background binding in the absence of Sortase A and similar inhibition by EDTA (Figure 1e,f). Addition of 15 mM Gly_3 to amine-terminated bead reactions also inhibited Sortase A-mediated attachment of eGFP (data not shown). Higher concentrations of Sortase A (40 μM) were used in the experiments with the amine beads than with the Gly_3-terminated beads; comparable levels (4 μM Sortase A) yielded much lower yields of immobilized eGFP (data not shown).

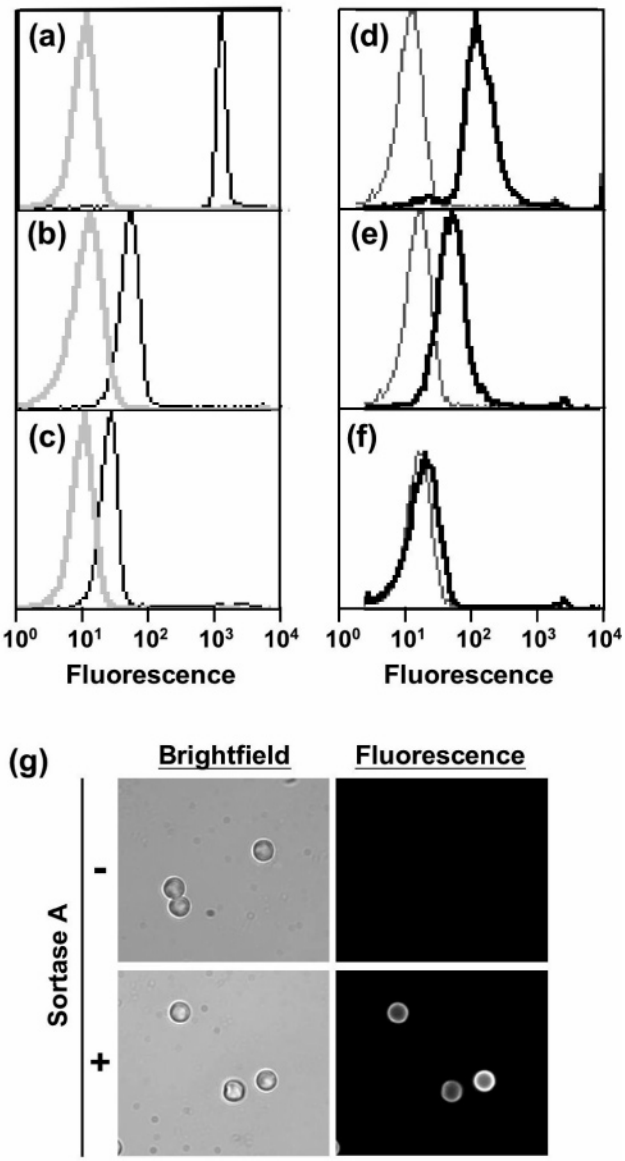

Figure 1. Characterization of GFP-conjugated polystyrene beads. (a−c) Flow cytograms of $(Gly)_3$-terminated beads before (gray lines) and after (black lines) incubation with eGFP−LPETG (a) in the presence of 4 μM Sortase A, (b) in the absence of Sortase A, or (c) in the presence of Sortase A and 10 mM EDTA. (d−f) Flow cytograms of amine-terminated beads incubated with eGFP−LPETG (d) in the presence of 40 μM Sortase A, (e) in the absence of Sortase A, or (f) in the presence of Sortase A and 10 mM EDTA. (g) Micrographs of amine-terminated beads labeled with eGFP−LPETG in the presence or absence of Sortase A.

Evidently, alkylamines can function as Sortase A substrates but with considerably reduced efficiency compared to Gly_3 conjugates.

The effect of varying the concentration of Sortase A on the reaction with the Gly_3 beads was investigated. When the enzyme is present at 40 μM, the reaction reaches steady state within 60 min; at 4 or 10 μM, the reaction reaches 90% of steady state in approximately 2 h (Figure 2a). Exponential fits, where the fluorescence of the beads at time t is given by $a_1[1 - \exp(-$

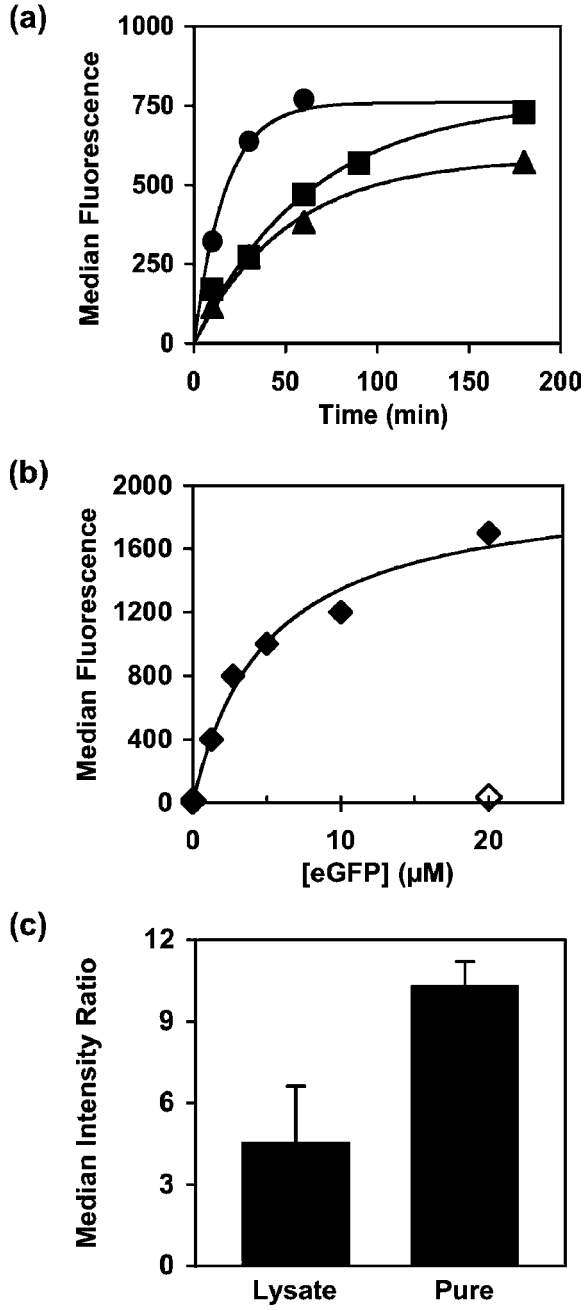

Figure 2. Reaction characteristics of Sortase A-mediated conjugation. (a) Kinetics of 20 μM eGFP coupling to Gly_3-terminated beads mediated by 40 μM (circles), 10 μM (squares), and 4 μM (triangles) Sortase A. The median fluorescence intensity of the bead population was measured by flow cytometry, and exponential functions were fit to the data. (b) eGFP concentration dependence of the median bead fluorescence after a 2 h incubation with 10 μM Sortase A. (c) Comparative activity of Sortase A (10 μM) for attachment of purified eGFP or eGFP in crude bacterial lysates. Median bead fluorescence ratio is relative to beads incubated in the absence of Sortase A.

a_2t)], yielded kinetic parameters a_2 that were very similar (0.019 and 0.016 min^{-1}) at the lowest concentrations of Sortase A, rising to 0.059 min^{-1} for the highest concentration of Sortase A tested. The reaction extent parameter, a_1, ranged from 584 at the lowest enzyme concentration to 750 for the other two concentrations tested—the difference of around 20% may not be meaningful, given that data are collected in log mode, but could arise from a slow, competitive inactivating process. The dependence of bead fluorescence at the 2 h time point on the concentration of eGFP was modeled using the equation a_3-[eGFP]/($K_{1/2}$ + [eGFP]) for a reaction run with 10 μM Sortase

Scheme 1

A, to yield a $K_{1/2}$ of 5 μM (Figure 2b). The fluorescence measured in this experiment is higher than that seen for the same conditions in Figure 2a; however, we note that the fluorescence of the Sortase control was also higher by a factor of 3 in this experiment, so a systematic offset in fluorescence values cannot be ruled out but should not affect our estimate of the half-maximal eGFP concentration. The ligation of donor eGFP to the Gly_3 beads proved to be reversible, since incubating eGFP-ligated beads with 3 mM hydroxylamine and 10 μM Sortase A for 3 h at 37 °C resulted in a 50% reduction in bead fluorescence, while beads incubated without Sortase A maintained fluorescence levels (data not shown). The ability of Sortase A to catalyze immobilization of LPETG-tagged eGFP from crude *E. coli* lysates was also investigated (Figure 2c). The fluorescence ratio of the lysate-incubated beads (+Sortase A) relative to background fluorescence of lysate-incubated beads was approximately half that of beads treated with purified eGFP−LPETG, using 15 μM eGFP (measured spectroscopically) in both cases.

Sortase A Can Engineer Protein−Protein Oligomerization. SDS-PAGE gels of an aliquot of a reaction mixture containing donor eGFP and eGFP tagged with Gly_3 at the N-terminus ("acceptor" eGFP) in the presence of Sortase A for 3 h at 37 °C (see Scheme 1) revealed a band at approximately 63 kDa (Figure 3a), as has also been reported by others (*15*). The band was not found in the absence of the enzyme or when either of the tags was absent, when the -GGG- was protected by a cleavable upstream sequence tag (data not shown), or in

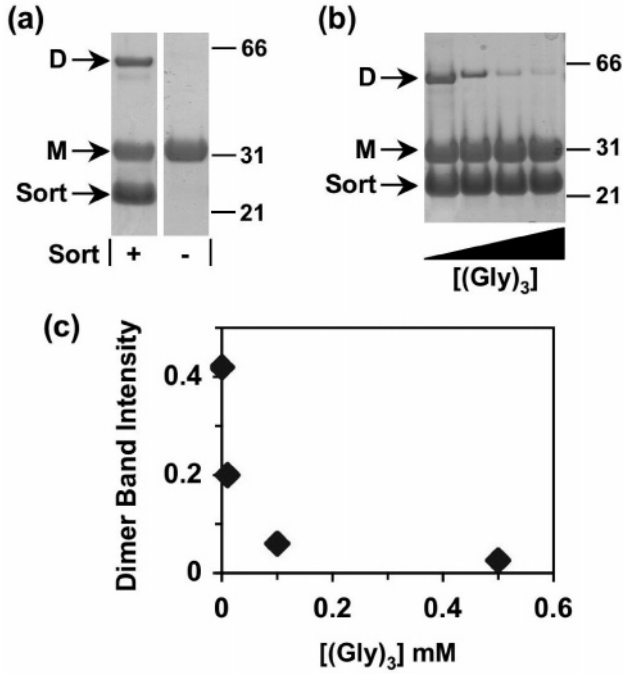

Figure 3. Sortase A-mediated protein ligation. (a) Reactions in 50 mM Tris, 150 mM NaCl, pH 8, between eGFP−LPETG (12 μM) and GGG−eGFP (36 μM) in the presence or absence of 40 μM Sortase A were analyzed by SDS-PAGE. Bands consistent in size with the monomer (M), dimer (D), and Sortase A (Sort) are labeled, and migration distances of molecular weight markers (in kDa) are indicated. (b) The same reaction in the presence of Sortase A and 0, 0.01, 0.1, and 0.5 mM soluble Gly_3. (c) The fractional intensity of the dimer band (normalized to the monomer band) as a function of the concentration of soluble Gly_3.

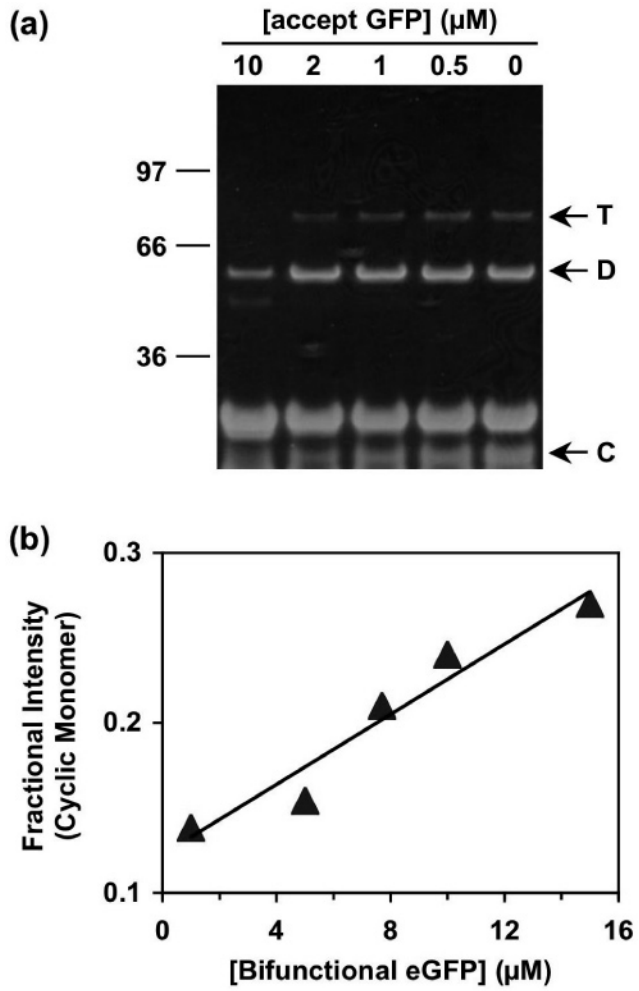

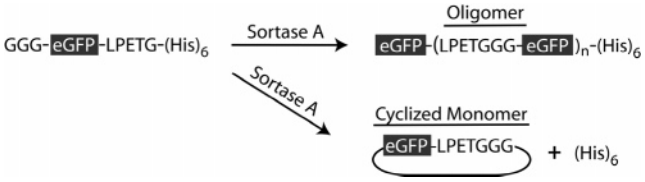

Figure 4. Oligomerization of bifunctional monomer. (a) A series of reactions containing bifunctional and acceptor eGFP in the ratios shown were analyzed by SDS-PAGE. Total amount of eGFP is constant at 15 μM. The reaction mixture included 40 μM Sortase A in 50 mM Tris−HCl and 150 mM NaCl. The scanned gel image was color-inverted for quantification. Bands consistent with expected sizes of a GFP dimer (D) and trimer (T) are marked, along with a band putatively representing a cyclized monomer (C). (b) The gel data was quantified by integrating band intensities. The integrated intensity of the cyclized monomer band relative to the monomer band is shown as a function of the concentration of bifunctional eGFP.

the presence of soluble Gly_3 concentrations above a threshold level (see below). Taking these results together, we conclude that the band represents the dimer formed between acceptor and donor GFPs. The integrated intensity of the dimer band is approximately 40% of that of the monomer band, suggesting that the reaction is approximately 30% complete at the end of 3 h or that ~30% of the monomer is competent for ligation. Increasing the concentration of soluble Gly_3 in the reaction mixture results in a steady weakening of the dimer band (Figure 3b), as the smaller molecule competes effectively with eGFP for the enzyme, confirming that the reaction is catalyzed by Sortase A. Quantification of band intensities shows that inhibition by soluble Gly_3 increases rapidly until the band falls to about one-tenth of control intensity at 0.05 mM, approximating the concentration of GFP (Figure 3c).

In contrast to the monofunctional monomers, a bifunctional monomer (Table 1) reacts in the presence of Sortase A to yield both the dimer and a species that migrates slightly faster than the monomer (Figure 4a, extreme right lane) on a polyacrylamide gel. This band is not seen with the monofunctional GFP's (Figure 3a) or in the control experiments listed above, so we

Scheme 2

conclude that it represents the cyclized monomer (see Scheme 2). The total extent of reaction at the end of 3 h in the case of the bifunctional monomer is around 40% with the putative cyclized GFP being present at 50−75% of dimer.

In a further series of reactions in the presence of Sortase A, the bifunctional eGFP was diluted with monofunctional acceptor eGFP, keeping the total concentration of the eGFP constant at 15 μM. The acceptor eGFP can be regarded as a "capping" monomer in these experiments. Aliquots of the reactions were then analyzed electrophoretically (Figure 4a). The intensity of the putative cyclized monomer band (relative to the total of all bands) increases approximately linearly with bifunctional monomer concentration (Figure 4b) as might be expected (see Discussion section), increasing our confidence in its identification. The intensity of the band representing the dimer decreases noticeably only when the (non-dimerizable) monofunctional monomer is present in substantial excess over the bifunctional monomer and the bifunctional monomer concentration is therefore significantly lower. A weak band from a putative trimer is evident, and its intensity is even more sensitive than that of the dimer band to the presence of the capping monomer.

Reactions with bi- and monofunctional eGFP monomers were also analyzed by Western blotting for eGFP (Figure 5). Considerably more detail is evident in the Western blot than in the Coomassie stained gel (Figure 4a), especially at molecular weights higher than the dimer. A densitometric trace of the lane corresponding to pure bifunctional monomer (Figure 5b) reveals major peaks at molecular weights consistent with the trimer and possibly the tetramer and pentamer (note: high molecular weight species cannot be quantitatively assigned sizes for a 10% gel under these conditions). The origin of the minor peaks in the trace (just below 91 kDa and 67 kDa) is unclear at this point, although they may represent circularized oligomers. The number of higher molecular weight bands seen decreases as the mono-to-bifunctional monomer ratio increases, as would be expected if the bands did in fact arise from higher oligomers whose formation would be limited in the presence of high concentrations of (non-polymerizable) capping monomer.

Although all of the eGFP reactants used in the ligation experiments were 6×His-tagged (Table 1), the tag is excised upon cyclization (Scheme 2). To confirm the identity of the putative cyclized monomer, we therefore used an anti-6×His antibody to probe a blot of Sortase A-mediated ligation of bifunctional eGFP (Figure 5c). The anti-6×His antibody identified bands consistent with the unreacted monomer, dimer, and trimer seen with the anti-GFP blot (Figure 5a) and stained gel (Figure 4a), but no band appears at the expected position of the cyclized monomer.

Conjugation of Donor eGFP to Amine-Terminated Poly(ethylene glycol). Amine-terminated methoxyPEG (PEGamine) with a molecular weight of 10 kDa was reacted with eGFP−LPETG in the presence or absence of Sortase A. Similar reactions were carried out in parallel between Gly_3-terminated PEG and eGFP−LPETG, with a reaction between eGFP−LPETG and GGG−eGFP as a control. Reaction mixtures were analyzed using SDS-PAGE (Figure 6). A band corresponding to a protein migrating slightly faster than the eGFP dimer is observed only in reaction mixtures containing eGFP, Sortase A, and PEGamine or Gly_3−PEG, and we attribute that to the

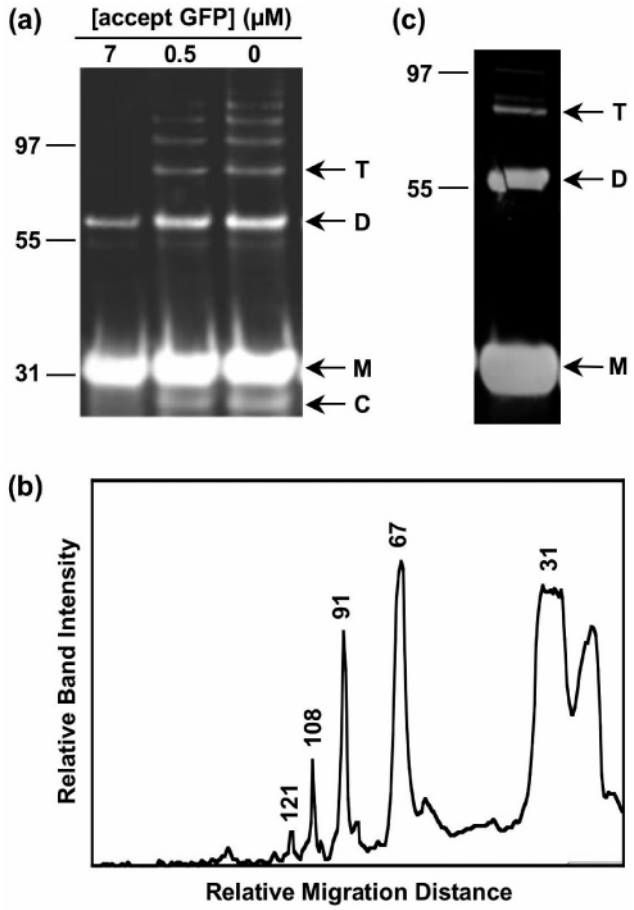

Figure 5. Verification of oligomerization and cyclization. (a) Western blot using anti-GFP antibody of a reaction mixture containing mono- and bifunctional eGFP at the mono- to- bifunctional monomer ratios shown. Bands are labeled as in Figures 3 and 4. (b) Line trace of the 0:1 mono/bifunctional lane of the blot. Peaks are labeled with apparent sizes. Molecular weight markers are shown (in kDa). Reactions contained 4 μM Sortase A and 15 μM eGFP (total). (c) Western blot using anti-His_6 antibody of a reaction mixture containing 20 μM Sortase A and 36 μM bifunctional eGFP. Bands are labeled as in (a).

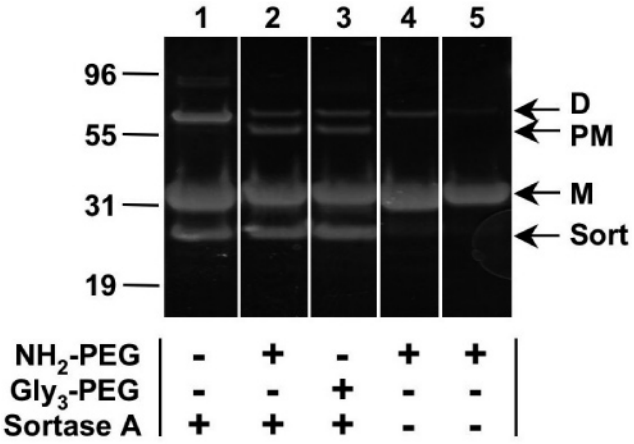

Figure 6. Ligation of PEG to eGFP. SDS-PAGE analysis of reactions between eGFP−LPETG and GGG−eGFP (lane 1) or the indicated modified PEG (lanes 2−5). Reaction mixtures contained 30 μM of each of the eGFP monomers or 30 μM of the PEG monomers, 4 μM Sortase A. The putative PEGylated eGFP monomer is indicated (PM), and molecular weight markers are shown (in kDa).

PEG−eGFP dimer. Surprisingly, both Gly_3−PEG and native PEGamine seem to form roughly similar amounts of PEG−eGFP, since the intensity of the heterodimer band is similar in both cases—approximately half that of the band corresponding to the eGFP−eGFP homodimer. Lanes 4 and 5 are control lanes without Sortase A: lane 4 contains both eGFP proteins, and lane 5 contains donor eGFP and PEGamine. A weak impurity band putatively corresponding to a small quantity of dimeric GFP in the monomer prep is evident in samples lacking Sortase A. A similar control using Gly_3−PEG and lacking Sortase A yielded similar results (data not shown).

DISCUSSION

Immobilizing proteins on surfaces presents many challenges, and development of many alternative techniques is highly desirable, since no single technique is likely to succeed with all proteins of current interest. Many recent approaches require the fusion of a large partner which may (*4*, *5*) or may not (*1*) be retained in the immobilized construct, and the fusion of a molecule (inhibitor or split-intein) to the target surface; in return for this inconvenience, the resulting immobilization is very specific. Very recent work by Neves-Petersen and colleagues (*16*) relies on the photocleavage of a disulfide bond by UV irradiation of a proximal aromatic residue. The activated cleaved bond is now available for reaction with a thiol-sensitive surface, thereby immobilizing the protein. Although this clever approach avoids the introduction of a fusion partner, the requirement that the aromatic residue be within 1 nm of the disulfide bond (and that there be only one such pair) restricts general applicability. Antibodies meet this requirement, but specifically immobilizing one protein from a complex mixture with a "tagless" approach would, in general, be a difficult task.

The approach described here promises wide applicability in that it is specific, rapid, and uses small tags that are unlikely to interfere with the function and expression of the target protein. Sortase A is easily overexpressed; it is soluble, requires no further refolding, and can be readily obtained at yields approaching 10 mg/L in simple shake flask cultures of *E. coli* with no optimization of conditions. Surface preparation for optimal Sortase A reactivity involves simple, well-understood carbodiimide chemistry with commercially available reagents. Starting with an amine-terminated bead, it is thus possible to immobilize a pure protein using Sortase A in less than 5 h.

The mechanism of Sortase A has been studied intensively. Studies on the hydrolysis of the optimal substrate, LPETG (*17*), have shown that diglycine is the optimal nucleophile, with the addition of more glycines having no effect on the reaction rate. Among dipeptide substrates, the enzyme displays a strong preference for glycine in the first position; alanine and valine can apparently substitute for glycine in the second position, although the reaction is not as efficient. However, Sortase A is not an especially efficient enzyme. Its affinity for its Gly-terminated substrates in vitro has been reported to be in the micromolar range (*17*), similar to the half-maximal eGFP concentration we find here; however, the micromolar range appears compatible with the concentrations generally used in protein immobilization work. We found that the reaction with Gly_3-terminated beads reached equilibrium in a period ranging from 30 min to 2 h, depending on Sortase A concentration, suggesting the possibility of using high concentrations of Sortase A to achieve higher reaction rates and shorter reaction times (with especially labile proteins, for example). The rapid approach to equilibrium at the highest Sortase A concentrations may reflect depletion of ligation-competent eGFP, rather than the effect of the reverse reaction, since one of the reactants (the Gly_3 on the bead) is present in considerable excess. The reaction is reversible, and GFP can be released from the bead when GFP-ligated beads are treated with Sortase A and a nucleophile such as hydroxylamine. The ability to separately manipulate enzyme and substrate concentrations to achieve desired rates distinguishes our approach from the ligand-mediated immobilization

techniques pioneered by Johanssen (*4*) and Mrksich (*5*), where the enzyme and target protein are covalently bound in a 1:1 ratio.

The similarity in length between diglycine and hexylamine and the ready availability of hexylamine-terminated surfaces to which protein ligation might be of interest motivated us to examine whether the alkylamine could function as a nucleophile with Sortase A. Schneewind and associates note that transpeptidation in the cell wall context proceeds with the glycines rather than the alkylamine side chain of a lysine (*13*, *18*). In contrast, the lysinyl side chain initiates nucleophilic attack during pilin assembly (*18*). These results can be reconciled if the enzyme−acyl intermediate is less reactive toward an alkylamine than toward Gly_n. Our work with amine-terminated and Gly_3-terminated beads shows that the latter are better substrates for ligation with eGFP−LPETG in the presence of Sortase A and therefore favors this hypothesis. A study of mTGs has also shown that alkylamines can function as surrogates for physiological nucleophiles in transamidation (*19*). Whether Sortase A can be engineered to react as facilely with the alkylamine as with its natural substrate, while retaining a high degree of specificity, will be intriguing to explore. Similar features have been found in subtiligase, which has some properties in common with Sortase A, including specifity requirements even when lysinyl side chains are present (*20*). We believe we are the first to show *direct* enzyme-catalyzed immobilization of proteins onto commercially available synthetic surfaces, certainly the first to use Sortase A for this purpose.

Mao et al. previously demonstrated that Sortase A can be used to form dimers between appropriately tagged monofunctional GFP (*15*), but the formation of oligomers and the cyclized monomer and the interplay between these species remained to be explored. When we reacted eGFP−LPETG with GGG−eGFP in the presence of Sortase A, a dimer was formed, as expected, with formation being increasingly inhibited by soluble Gly_3 at concentrations approximating that of the eGFP monomers. This substantiates the role that the Gly_3 moiety plays in the reaction and points to the specificity of the reaction. When a bifunctional eGFP (GGG−eGFP−LPETG) was incubated with Sortase A at 37 °C, we found evidence for intramolecular cyclization of the monomer: (a) the band does not react with an anti-6×His antibody, the 6×His having been excised in the course of cyclization; (b) its intensity is linearly related to the monomer concentration, consistent with a unimolecular reaction; and (c) the band is reactive with an anti-GFP antibody, confirming that it does not arise from an enzyme-related impurity. Additionally, this band was not observed in any reactions involving monofunctional eGFP, suggesting that it does not arise from cleavage of the protein. Both termini of the GFP molecule are known to lie on the same side of the protein, separated by approximately 19 Å, a distance that can be bridged by about 5−6 amino acids (*21*). The 15-member Avitag, to say nothing of the LPETG and the GGG tags, present here should bridge it readily.

Cyclic GFP has been made previously by other groups, most recently using inteins (*21*). Our approach uses far smaller tags and is therefore likely to cause less disruption should in vivo cyclization (in the presence of coexpressed Sortase A) be desired. Importantly, the approach described here also permits facile purification, since the 6×His tag present in the monomers is excised *only upon cyclization but not upon oligomerization*. One can readily envision an orthogonal purification scheme for cyclized species using a monomer with two different tags: schematically, one would pass the lysate first through, for example, a metal-affinity column to bind all of the 6×His-tagged reactants and noncyclic products. The flow-through would then be passed through an affinity column for the second tag, which would bind the cyclized species with trace amounts of the noncyclized species.

The cyclization of proteins has been suggested as a means to enhance their thermal and proteolytic stability (*22*, *23*). We anticipate that more work, perhaps with therapeutically important proteins, will be carried out if easy strategies for the protein cyclization are made available. Substantial work based on intein-mediated cyclization, oligomerization, and immobilization of proteins has been performed previously. Intein-mediated reactions require in-frame fusion of the splicing partner (at least 100 amino acids in size). These extremely specific approaches have the merit of not introducing extraneous amino acids in the course of the ligation, although a 9 amino acid linker has been intentionally introduced in circularization work (*22*) to avoid straining the protein. The range of inteins that can be used for circularization is limited, since the difficulty of isolating the circular product requires a high-affinity intein. Last, the obligatory fusion of the intein with the target protein could limit soluble expression of the protein in some cases. It certainly makes it impossible to control the reaction by independently varying reactant concentrations. In summary, intein-based approaches have enjoyed great success and are very valuable, but they may not be optimal in all cases.

Having observed that dimers formed readily between appropriately terminated monofunctional eGFP, we conducted reactions with bifunctional eGFP to determine whether higher oligomers could be formed. Small amounts of trimer were indeed found, depending on the amount of bifunctional monomer present. Factors that favor circularization (proximity of the termini, for example) probably limit oligomer formation. Western blotting with an anti-GFP antibody reveals the presence of higher molecular weight bands (putatively tetramers and pentamers), which must be present in small amounts since they are not visible in Coomassie stains (where even the trimer band is barely visible).

This result could be further generalized to amine-terminated PEG, which likewise reacted with LPETG-tagged eGFP. Adding a $(Gly)_3$ group to the amino terminus did not result in substantially different rates or outcomes. The explanation for the similar activity of these substrates, in contrast to our results with modified beads, is unclear at present, although it is possible that the terminal structure of the amine-terminated PEG sufficiently resembles di- or tris-Gly such that further substitution has no effect on the reaction. In any case, our results demonstrate that Sortase A can mediate site-specific PEGylation. The importance of being able to ligate proteins to PEG under mild conditions that would not adversely affect function is difficult to overstate. PEGylation is known to extend the circulation times of therapeutically important species in the blood stream (*24*). Additionally, PEGylated proteins with low levels of PEGylation are very useful as homing signals on drug-loaded liposomes (*25*). In this context, it may be highly desirable to mono-PEGylate proteins as over PEGylation could interfere with intercalation into the liposome. The ability of Sortase A to mono-PEGylate proteins in a manner that need not affect function nor mask a useful epitope makes it highly suited for this application.

On the basis of our results, it seems clear that Sortase A can be used to create intra- and intermolecular attachments among proteins and between proteins and surfaces. Such ligation can be reversed with small nucleophiles (e.g., hydroxylamine (*26*)); initial studies suggest that Gly_3 can also be used for this purpose (data not shown). Enzymes such as mTG's have been explored as reagents for protein ligation as well, and binding sequences needed to enhance the specificity of this enzyme are now becoming known (*27*, *28*). The advantage of Sortase A over mTGs is twofold: (a) it is more specific with a rigorously

defined specificity determinant, and (b) it is easier to overexpress and purify in *E coli*, where (unlike mTG (*29*)) it is produced solubly in large quantities. When used in its native form, Sortase A seems limited to performing ligations at chain termini, whereas mTGs can perform transamidation-based ligations at any point in the chain. This apparent limitation could be useful when only single ligations are desired (e.g., for monoPEGylation). Protein engineering approaches might yield Sortase A mutants suited for a wider range of applications and thereby enhance its usefulness as a reagent in bio- and nanotechnology, perhaps as a reagent for making multivalent inhibitors as therapeutics (*30*). The ability of Sortase A to mediate gentle protein attachment to surfaces, a feature critically important in the creation of protein arrays for proteomic applications (*31*), to mediate site-specific PEGylation, and to potentially provide a simple route to selectively label tagged cell surface proteins (an area of burgeoning interest (*32*, *33*)) underscores the promise of this versatile enzyme.

Dextran is a highly biocompatible molecule with osmotic activity. We synthesized histidine derivatives of dextran, DexH (dextran histidine), to test the feasibility of an IMAC-based controlled release system. DexH was synthesized by the periodate oxidation method. The effect of periodate oxidation and histidine conjugation on osmotic activity was tested. The oxidized intermediate itself exhibited higher osmotic activity than native dextran. Conjugation with histidine further increased the osmotic activity, and the resulting DexH exhibited nine times more osmotic activity than native dextran. A positive correlation was observed between the extent of derivatization with histidine and osmotic activity. Association of DexH was tested on two of the matrices, namely, Cu-IDA−Novarose and Zn-IDA−Novarose. DexH bound to both these matrices, and only partial elution was achieved with stepwise lowering of pH, and complete elution was possible only with EDTA. Interestingly, it was found that DexH in its bound state (DexH−Cu-IDA−Novarose and DexH−Zn-IDA−Novarose) exhibited lesser osmotic activity than the eluted soluble form. The IDA-Cu and IDA-Zn-based solid supports bound strongly to DexH in a species-dependent manner, as the IDA-Zn matrix selectively bound DexH with clustered histidine. Further, this DexH with clustered histidine shows higher osmotic activity. A controlled release system is proposed on the basis of this difference in the osmotic activity between the bound and eluted forms of DexH with EDTA as the external trigger to induce this transition in osmotic activity.

INTRODUCTION

Osmotically active compounds swell in the presence of aqueous solutions as they imbibe water. The rate of swelling has been studied for a large number of synthetic as well as naturally occurring substances, as these compounds find a wide range of biomedical applications that include their usage as monomers in the preparation of hydrogel networks that are used in drug delivery, entrapment of cells, and so forth (*1*−*3*). In their monomeric state, they are used as tablet disintegrants wherein they control the delivery of the pharmaceutical agent in a spatially and temporally controlled manner, resulting in what are known as controlled release systems (*4*). Molecules such as glucose, hydroxyethylcellulose, glycerol, poly(ethylene glycol)s, and dextrans of different molecular weights are extensively employed osmotic agents (*4*−*7*). In controlled release systems, the osmotic agents usually form the expandable core contained within a semipermeable compartment. They expand and bring about a large volume increase in the biological milieu, releasing the pharmaceutical agent held within.

Another interesting application solely based on the ability of these osmotically active agents to bring about large volume changes is illustrated in the patent of ref 8. In the proposed concept, the osmotically active agent forms the expandable core surrounded by a semipermeable membrane in the implanted endoprosthesis. Here, both induction and rate of expansion are controlled using a proposed affinity-based release system.

Dextran is a naturally occurring, osmotically active, high molecular weight polymer. It contains repeating glucose units comprising mainly α-(1−6)-linked D-glucose units and some short α-(1−3)-linked D-glucose branch units. It is water-soluble, inert in biological systems and does not affect cell viability, and hence highly biocompatible. Dextran has been used extensively as an osmotically active colloid in re-establishing the plasmatic volume, in postoperative prophylaxis of thromboembolic risk, for the acute treatment of ischemic cerebral attacks, for the prevention of anaphylactic reactions (*9*, *10*), for other applications.

Several derivatives of dextran, such as carboxymethyldextran, [2-(diethylamino)ethyl]dextran (*11*), dexamethasone succinate dextran (*12*), and lauroyldextran (*13*), have been synthesized and studied for their potential use in tablet formulations. Periodate oxidation is a well-known method for preparation of dextran derivatives such as streptomycin-tagged dextran (*14*), amino dextran, and protein derivation to enhance their half-life (*15*, *16*). We exploited this method to couple the amino acid histidine to dextran. Histidine-containing proteins and peptides have been extensively studied for their metal-binding ability (*17*). Poly(histidine) tags have been used to modify recombinant proteins to aid in their effective purification (*18*, *19*). In view of this, it was proposed that histidine coupled to dextran would act as an anchor that can be effectively retained on the immobilized metal affinity matrix. Also, the presence of histidine groups was found to enhance the osmotic activity of native dextran.

Here, we report the study of a novel histidine derivative of dextran with enhanced osmotic properties along with its retention and release from a metal affinity system. The dextran−histidine (DexH[1]) and its oxidized intermediate were evaluated for their osmotic activity in solution, with reference to native dextran also in solution. In parallel, the binding properties of the DexH derivative to the well-known IDA-Cu and IDA-Zn

matrices were exploited for retaining rather strongly the derivative to these matrices, and then eluted by dissociation with EDTA. The released DexH exhibited tremendous enhancement of osmotic activity. This was measured by the entrapment of the matrix-bound DexH as well as the free eluted form in a semipermeable membrane. On the basis of the differences between the osmotic properties of DexH in its matrix-bound form and freely soluble form, the concept of a novel controlled release system is proposed.

MATERIALS AND METHODS

Dextran, sodium meta periodate, sodium borohydride, potassium iodide, ethylene glycol, histidine, copper sulfate, zinc sulfate, IDA, MOPS, sodium acetate, sodium chloride, sodium hydroxide, and EDTA were obtained from Sigma, Dialysis tubing (10 000 MW cutoff) was from Spectrophor, and AN-69S membranes were from Biospal. Novarose High Act 100/40 was obtained from Inovata. Commercially available epoxy glue Poxymatic Rapide was used to glue the cut AN-69 membranes.

Oxidation of Dextran. The procedure was adopted from Guisan et al. (*20*). Briefly, a 25 mL solution containing 0.5 g of dextran (40 000 Da) in M/Q water was prepared. Then, 1.3 g of sodium periodate was added, and the mixture was allowed to react at room temperature. After 24 h, the solution was dialyzed against 50 volumes of distilled water to eliminate the formaldehyde produced during oxidation.

Oxidation of dextran by periodate was measured by two different methods, viz, by following the consumption of periodate in the reaction mixture and second by measuring the production of formic acid as the reaction byproduct, as a function of time (*16*).

Briefly, for the estimation of periodate, 10 μL aliquots were withdrawn from the reaction mixture at regular intervals and mixed with 500 μL of 1.5% KI solution. The volume was brought up to 1 mL with M/Q water, and absorbance of the resulting solution was measured at 400 nm. Formic acid released was measured by titrating an aliquot of the mixture against 0.1 N NaOH to pH 7.0.

Calculations were based on the hypothesis that each molecule of glucose consumes 2 molecules of periodate to produce a dialdehyde product, in turn releasing 2 molecules of formic acid.

To prepare dextrans of varying degree of oxidation, the reaction was stopped at the end of 1, 2, 3, and 24 h by the addition of ethylene glycol, and aliquots withdrawn were dialyzed to remove unreacted periodate and concentrated by lyophilization.

Synthesis of DexH. To the solution containing 95% oxidized dextran, known concentrations of histidine were added. The amount of ligand added was calculated on the basis of the assumption that each dialdehyde glucose moiety in dextran can potentially bind to one histidine. Thus, on the basis of the extent of derivatization required, histidine is added and allowed to react at 4 °C for 16 h based on the optimized experimental conditions. The pH of the resulting solution is increased to 8.5 with sodium carbonate (100 mM), followed by addition of 1 mg/mL sodium borohydride to reduce the unreacted aldehyde groups as well as to stabilize the aldehyde−amine bonds. The mixture is stirred for 15 min, and the sodium borohydride step is repeated. Finally, the reaction mixture is dialyzed extensively against M/Q water, to remove the unbound ligand and other small molecular weight reactants, and lyophilized.

Concentrations of histidine and dextran in the resulting compound were measured using Pauly's reagent and by the phenol−sulfuric acid method (*21*), respectively.

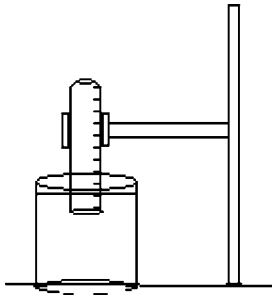

Figure 1. The AN-69 membrane setup used for measuring the osmotic activity.

Measurement of Osmotic Activity. To measure the water-absorbing capacities of different preparations the following setup was used (Figure 1). AN-69 membrane flat sheets were taken out of the hemeodialyser (Biospal, AN69S) and cut in to 5 × 5 cm^2 pieces. They were glued onto the open end of 50 mL Falcon tubes (using the epoxy glue Poxymatic Rapide). The pointed ends of the tubes were cut open to facilitate sample insertion. The tubes with the membranes were stored overnight at 4 °C, and the membrane was further secured with elastic. These tubes were then wetted in water and checked for leaks. For dialysis, the sample was inserted directly onto the membrane from the open conical end of the tube. The tubes were then weighed and positioned into a 1-L glass beaker containing water so that the membrane portion is completely immersed in water. In all the experiments, the volume of the test solution is kept to a minimum so as to maximize the membrane surface area available for exchange. The tubes were taken out at specified time intervals and weighed to measure the volume increase.

Effective volume increase is calculated using the formula

$$\text{EV (effective volume)} = \frac{\text{final weight of the setup} - \text{initial weight of the setup}}{\text{initial weight of the setup}}$$

All the experiments were carried out at least in triplicate, typically yielding an experimental error of less than 5%.

Affinity of DexH to Matrix−IDA. Novarose IDA was prepared as described earlier (*22*). 1 mL of Novarose (Novarose High Act, Inovata, 100/40) matrix coupled to IDA was saturated with Cu^{2+} or Zn^{2+} and was used as the matrix to test the affinity of DexH. The column was equilibrated with 25 mM MOPS-acetate buffer pH 7.0, and a known concentration of DexH was loaded onto the column. Elution was carried out with stepwise lowering of the pH (25 mM MOPS-acetate of pH 6.0, 5.5, 5.0, and 4.0) and finally with 100 mM EDTA. The flow rate was maintained at 0.5 mL/min, and the fractions were analyzed for histidine and dextran content.

Measurement of Water Uptake by DexH in Bound and Free Eluted Forms. A 3 mL Novarose column was packed and equilibrated with copper. From this, 1 mL was removed and kept aside as a negative control. A known concentration of DexH (of specific DexH stoichiometry) was loaded onto the remaining 2 mL column material and extensively washed until DexH was no longer detected in the wash fractions. 1 mL of this gel was used to test the osmotic activity of DexH in its bound form. The gel samples were maintained in 25 mM MOPs-acetate buffer pH 7.0. The remaining 1 mL was washed with 100 mM EDTA to elute all the bound DexH. The eluted fraction was collected and dialyzed initially against water and finally against 25 mM MOPs-acetate buffer pH 7.0 to remove copper ions and 100 mM EDTA, and then tested in comparison with the other two gel fractions for its osmotic activity in the AN-69 setup at different time intervals.

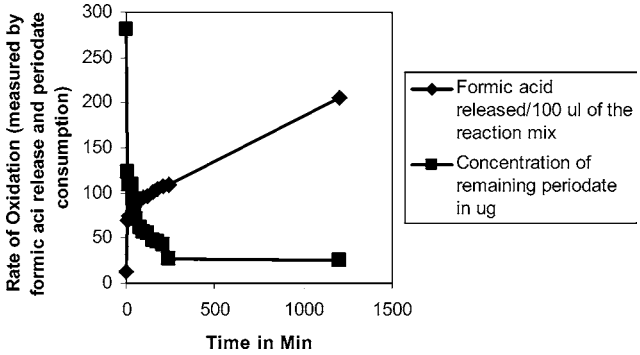

Figure 2. Time course of periodate oxidation. From the reaction mix consisting of 0.5 g of Dex-40000 and 1.3 g of periodate in a total volume of 25 mL of water, 10 and 100 μL aliquots were withdrawn and assayed for periodate consumption and release of formic acid, respectively, as described in Materials and Methods.

Table 1. Effect of Oxidation on the Osmotic Activity of Dextran

oxidation state in % (reaction time in h)	osmotic activity (effective increase in volume in mL)		
	24 h	48 h	72 h
86 (1 h)	4.5	5.5	8.0
89 (2 h)	6.6	8.2	9.0
91 (3 h)	8.1	9.1	9.9
96 (24 h)	10.8	12.0	12.4
0 (0 h)	2.7	4.5	5.0

RESULTS

Oxidation of Dextran. Oxidation of dextrans is usually carried out using the periodate method. The reaction is highly specific and results in the cleavage of the ring structure to form an acyclic backbone with intact glycosidic linkages (*23*, *24*).

The degree of oxidation is correlated to the amount of periodate used in the reaction mixture, which in turn determines the nature of the reaction end product that could be either a monoaldehyde or a dialdehyde. A dialdehyde product is ideally suited for further derivatization with an amino group-containing compound. Also, most of the oxidized dextrans reported in the literature range from 10% to 40% oxidized product based on the estimation of the liberated formic acid as well as consumption of periodate in the reaction mixture (*16*). We followed the oxidation reaction kinetics using both of these methods to obtain dextrans with different degrees of oxidation. These dextrans were tested for their osmotic activity to understand the effect of excess of OH groups generated by oxidation on the osmotic potential. On the basis of this kinetic data, we could also obtain a >90% oxidized product that was further used to obtain optimally derivatized DexH.

As indicated in Figure 2, the reaction profile obtained is in agreement with the earlier reports (*16*). All the estimations were carried out using the phenol−sulfuric acid method (*21*).

Results depicted in Figure 2 show rapid initial kinetics reaching more than 80% completion at the end of 1 h. The reaction was allowed to proceed for a total of 24 h. We could achieve a maximum of 96% oxidation under the conditions employed.

Effect of Oxidation on the Osmotic Activity. The oxidation reaction was stopped at different time intervals with the help of ethylene glycol, and the resulting product was subjected to dialysis and concentrated by lyophilization. The extent of oxidation was estimated, and the results are shown in Table 1. The various oxidized dextrans obtained were dissolved in water (1 wt %/vol) and comparatively analyzed for their osmotic activity with native dextran.

On the basis of the results obtained, it can be inferred that there is a positive correlation between the degree of oxidation and osmotic activity (Table 1). There is more than a twofold increase in the osmotic activity as measured by the increase in volume at the end of 72 h. It is possible that generation of excess OH groups is responsible for this increase. It can also be observed here that oxidation affects the swelling time. Dextrans with lower oxidation levels (<90%) exhibit an almost linear increase in osmotic activity. On the other hand, little or no increase in osmotic activity is observed after 48 h in the case of highly oxidized intermediates, indicating that swelling equilibrium is reached earlier in these intermediates (90%).

Table 2. Analysis of Osmotic Activity of DexH

derivatives tested		increase in volume (mL)		
% oxidation	% histidine derivatization	24 h	48 h	72 h
0[a]	0[a]	2.7	4.5	5.0
96[b]	0[b]	10.8	12.0	12.4
96[c]	70[c]	26.4	33.7	37.0

[a] 0% oxidation and 0% histidine derivatization represents native dextran. [b] 96% oxidation and 0% His derivatization represents the oxidized intermediate. [c] 96% oxidation and 70% derivatization represents the oxidized intermediate wherein 70% of the glucose residues were derivatized with histidine.

Table 3. Effect of Ligand Concentration on the Osmotic Activity

concn of DexH in % (wt/vol)	increase in volume in mL	
	24 h	48 h
1	24.9	32.3
2.5	27.9	34.2
5	33.2	47.8
Native Dextran		
1	2.7	4.5
2.5	4.0	5.3
5	5.2	7.3

Effect of Derivatization of Oxidized Dextran on the Osmotic Activity. It has been shown that the dialdehyde dextran can be efficiently derivatized with an amino group-containing ligand. Histidine coupling to the oxidized dextran was via the NH_2 group, leaving the imidazole free. The dextran-to-histidine ratio was varied to achieve a range of derivatized products. The resulting DexH was analyzed using histidine estimation by Pauly's and dextran estimation by the phenol−sulfuric acid method. Histidine content in the preparation is expressed as % of glucose units derivatized.

A nonoptimized DexH preparation (70% derivatized) was comparatively analyzed with native dextran as well as its oxidized intermediate (96% oxidized) for its osmotic activity.

Results shown in Table 2 indicate clearly that derivatization with histidine produces a large increase in osmotic activity of dextrans. There is about a ninefold increase in osmotic activity on derivatization at the end of 24 h.

Effect of Concentration on the Osmotic Activity of DexH. To understand the osmotic activity of DexH further, different concentrations (of 70% derivatized DexH) were tested for osmotic activity, and the results are shown in Table 3. Here, solutions of varying concentrations (expressed in wt %/vol) were prepared in M/Q water in a final volume of 1 mL and tested using the AN-69 membrane setup as described in Materials and Methods.

Data presented in Table 3 show that there is a positive correlation between concentration and volume increase with DexH. When the data are analyzed further, it can be observed that the correlation between concentration and osmotic activity is linear.

To understand this behavior, the increase was calculated by comparing the volume increase between DexH and native

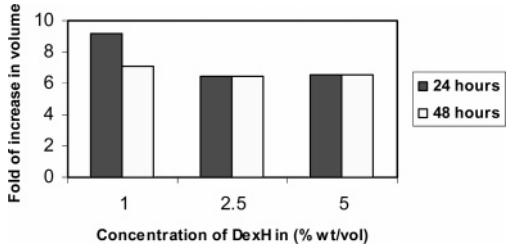

Figure 3. Comparison of increase at different concentrations. Solutions of varying concentrations of 70% derivatized DexH (expressed in wt %/vol) were prepared in M/Q water in a final volume of 1 mL and tested using the AN-69 membrane setup as described in Materials and Methods.

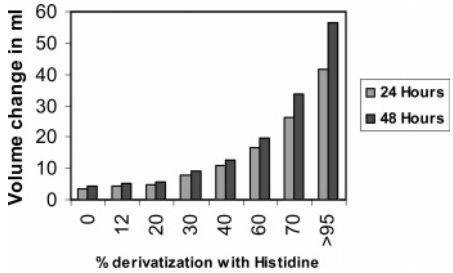

Figure 4. Effect of histidine content on the osmotic activity of DexH. 1% solutions of DexH (with varying concentrations of histidine coupled) were prepared in a final volume of 0.5 mL and tested for 24 and 48 h for their ability to induce volume changes in the AN-69 membrane setup.

Table 4. Effect of Histidine Content on the Osmotic Activity of DexH

derivatives tested		increase in volume (mL)	
% oxidation	% histidine derivatization	24 h	48 h
96	0	3.5	4.6
96	10	4.2	5.3
96	20	4.7	5.6
96	30	7.8	9.3
96	40	10.8	12.8
96	60	16.5	19.8
96	70	26.4	33.7
96	>95	41.8	56.5

dextran. At a concentration of 1%, there is about a ninefold increase, whereas at a concentration of 2.5%, only about a sixfold increase in the activity is seen (Figure 3). No increase in the activity was observed from 2.5% to 5% concentration. This discrepancy could arise from the pressure exerted in the opposite direction by the rising column of water, interfering with the in-flow in the open setup (tube of 50 mL capacity) used for testing, indicating the limitation of the system used. It is possible that the figures indicated here could represent an underestimation of the actual osmotic potential of DexH.

Effect of Concentration of Histidine on the Osmotic Activity of DexH. As can be seen from the data presented so far, the presence of histidine enhances the osmotic activity of dextran, indicating that histidine alters the osmotic property of the native dextran molecule. Thus, to understand the effect of histidine further, dextran was derivatized with varying quantities of histidine, and the volume changes of the resulting preparations were studied.

As indicated in Figure 4 and Table 4, there is a steep increase in the osmotic activity as the percent derivatization with histidine increases.

The correlation between enthalpic changes associated with periodate oxidation have been reported in literature. It is proposed that cleavage of the pyranose ring of dextran due to oxidation removes the enthalpic constraint on the elasticity of the molecule, making it shorter and stiffer (*23*). Due to these changes in the elasticity, the molecules may shift to a more extended conformation with an excess of exposed OH groups that might positively affect the osmotic activity. In conjunction with this, the presence of histidine could increase the repulsion between individual dextran molecules, enhancing the osmotic activity further. Another contributing factor could be the hydrogen-bonding abilities of excessive His groups present on dextran.

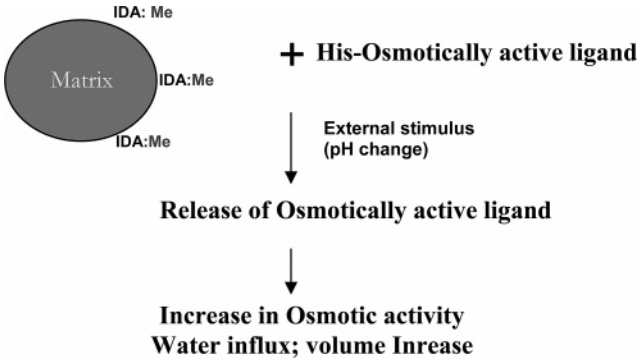

Figure 5. The envisioned affinity-based controlled release system.

Association and Dissociation of DexH to Metal Chelate Affinity Matrix. Once the histidine derivatization was successfully carried out and the resulting compound was found to exhibit a large increase in osmotic activity, due to oxidation as well as an increasing number of histidine groups on the dextran molecule, it was of interest to test the validity of the proposed controlled release systems.

The presently envisioned system would comprise a matrix capable of binding IDA that would in turn bind to the metal ion of interest at very high concentrations. This matrix would anchor DexH. The binding and release of this osmotically active DexH should be controlled by an external trigger such as changes in pH or use of EDTA. The released molecule would produce a change in osmotic activity leading to the influx of water and thereby a volume change. A schematic representation of the envisioned concept is provided below (Figure 5). Such a system would be well-suited either as a controlled release system in tablet formulations or as an affinity-based in vivo expandable system described by Cinquin et al. (*8*).

It is also required that the ligand in its bound form should be osmotically inactive or should exhibit less osmotic activity than the free form so that the system would be inert in the absence of the external trigger. After its release from the matrix in the presence of the trigger, it would bring about a large volume change and thereby behave as an ideal controlled release system. For example, the endoprosthesis would expand only in presence of an external trigger and not on immediate contact with the biological milieu, which would be the case if the osmotically active ligand alone were to be placed instead of the osmotically inactive complex. The extent of volume increase can thus be controlled in a spatial and temporal manner.

Novarose was chosen as the model matrix, as it can be coupled to high IDA and hence IDA-metal concentration. Two of the metal ions were tested for their possible affinity to DexH, viz., Cu and Zn.

Association Studies of DexH with Cu-IDA−Novarose. Association of DexH was tested on Cu-IDA−Novarose as described in Materials and Methods. Elution was initially carried out with stepwise lowering of the pH, followed by elution with 100 mM EDTA.

As indicated in Figure 6, DexH binds to the Cu-IDA matrix rather strongly. Complete elution of the bound material is possible only on treatment with 100 mM EDTA. Small peaks

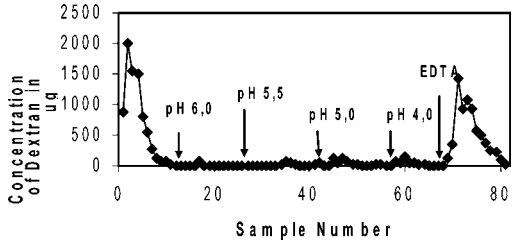

Figure 6. Chromatogram of DexH on Cu-IDA−Novarose. 1 mL of Novarose−IDA-Cu^{2+} was mixed with 25 mM MOPS−acetate buffer pH 7.0 and a known concentration of DexH was loaded onto the column. Elution was carried out with stepwise lowering of pH (25 mM MOPS acetate of pH 6.0, 5.5, 5.0, and 4.0) and finally with 100 mM EDTA. The flow rate was maintained at 0.5 mL/min, and the fractions were analyzed for histidine and dextran content.

Novarose−IDA-Cu−DexH	10.03	14.724
eluted DexH	31.67	42.3

are visible at each of the pH values, possibly indicating heterogeneity in the polymer preparation. 1 mL of the Cu-IDA matrix was found to bind a total of 8−9 mg of DexH (dextran equivalents).

Osmotic Activity of DexH−Cu-IDA Novarose. On the basis of our initial hypothesis, DexH should bind to the matrix of interest at very high concentrations and should be effectively released only on application of an external stimulus. Also, the osmotic effect exhibited by the compound in its bound form should be less than that exhibited in its eluted free form. The following experiment was carried out to test this possibility. DexH was tested bound to Novarose−IDA-Cu as well as in its free soluble from after elution. Novarose−IDA-Cu without any bound DexH was also tested for comparison.

Data represented in Table 6 clearly indicate that DexH exhibits a large activity difference between its bound and eluted soluble form. The Novarose−IDA-Cu complex was also found to contribute to the osmotic activity. The DexH−Cu-IDA−Novarose complex exhibits osmotic activity almost equal to that exhibited by Novarose−IDA-Cu, indicating that DexH has very little osmotic activity in its bound form and fulfils one of the prerequisites of the proposed hypothesis. Also, it should be noted here that 1 mL Novarose−Cu-IDA can effectively bind and release about 8 mg of DexH preparation (Table 5), which should, in principle, exhibit osmotic activity comparable to 1% (wt/vol) DexH solution (Table 3). On the contrary, DexH in its eluted form exhibits activity equivalent to a 5% solution. It could be reasoned that Novarose−Cu-IDA is able to selectively bind DexH with high histidine content from a heterogeneous pool.

Association Studies of DexH with Zn-IDA−Novarose. Zn is relatively less toxic than Cu, and also, histidine binding to Zn-IDA is known to be less strong than that between Cu-IDA (*25*). Thus, we tested the affinity of DexH on an IDA-Zn matrix.

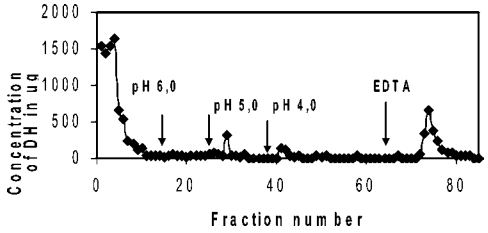

Figure 7. Chromatogram of DexH on Zn-IDA−Novarose. 1 mL of Novarose−IDA-Zn^{2+} was mixed with 25 mM MOPS-acetate buffer pH 7.0 and a known concentration of DexH was loaded onto the column. Elution was carried out with stepwise lowering of pH (25 mM MOPS acetate of pH 6.0, 5.5, 5.0, and 4.0) and finally with 100 mM EDTA. The flow rate was maintained at 0.5 mL/min, and the fractions were analyzed for histidine and dextran content.

Novarose−IDA-Zn-DexH	17.2	19.4
DexH eluted	25.2	40.4

Similar chromatographic conditions were employed as in the case of the Cu-IDA matrix.

The chromatogram obtained with Zn is very similar to that of Cu (Figure 7 and Table 7), with a major elution peak only with 100 mM EDTA. It was also found that Zn exhibits a much lower binding capacity then Cu. 1 mL matrix binds to about 3.8 mg of DexH as against 8 mg in the case of Cu-IDA−Novarose (Tables 7 and 5). This could be attributed to the fact that Zn requires adjacent histidine residues for effective binding (*25*, *26*) and is thus able to bind only a small fraction of DexH molecules from the heterogeneous pool.

Osmotic Activity of DexH−Zn-IDA−Novarose. We tested the osmotic activity of DexH as a complex with Zn-IDA−Novarose under similar conditions as in the case of Cu complexes.

The results shown in Table 8 indicate that Novarose−IDA-Zn exhibits less osmotic activity than Cu-IDA−Novarose, whereas the complex of Novarose−IDA-Zn−DexH exhibits significant osmotic activity. It is of interest to note here that eluted free DexH from the Zn-IDA matrix amounts to only about 0.3% (wt/vol) solution in terms of concentration, but the osmotic activity exhibited is almost equivalent to 5% free DexH preparation. This again indicates that the ability of the Zn-IDA matrix to concentrate DexH with higher histidine content may be due to its ability to bind to adjacent histidines, which is significantly higher when compared to DexH−Cu-IDA−Novarose.

DISCUSSION

We report here a novel derivative of dextran, DexH, that exhibits enhanced osmotic properties. Oxidized intermediates of dextran are prepared using the well-known periodate method and are subsequently derivatized with histidine. An enhancement in osmotic activity is observed at the oxidized intermediate stage

itself. Significant changes are also observed with respect to the swelling time. There seems to be an inverse correlation between the degree of oxidation and the swelling time. This behavior can be explained by taking into account the structural features of native dextran as well as the changes that have been reported to occur during oxidation.

Dextran has, in its structure, a ring-oxygen atom and a bridge-oxygen atom with hydrogen-acceptor properties and a hydroxyl group with hydrogen-donor and -acceptor properties (*27*). Dextrans consists of glucose molecules bonded together mostly by α-(l−6) linkages with about 5% α-(1−3) linkages serving as branch points. The branches are short and are mainly one or two glucose monomers in length (*28*). The behavior of dextran in aqueous solution has been the subject of several investigations (*29*−*32*) Periodate-mediated oxidation is known to break the bond between the third and fourth carbon atoms, leading to formation of the dialdehyde product. This cleaves the pyranose ring, in the process generating an excess of CHO groups. This event increases the elasticity of the molecule as well as the hydrogen-bonding ability, depending on the extent of oxidation. Also, dextran solutions are known to exhibit intermolecular associations (*32*), and periodate oxidation has been shown to decrease these molecular interactions proportionally to the degree of oxidation (*33*). All these structural changes could contribute to the enhanced osmotic activity observed.

Further, the osmotic activity was found to increase on conjugation with histidine. A positive correlation was observed between the extent of derivatization and the osmotic activity. It has previously been documented that, at lower concentrations, the osmotic potential of dextran is comparable to that of albumin. But, at higher concentrations, there is a marked deviation, with dextrans exhibiting a large increase in osmotic potential with increasing concentration. This behavior is attributed to greater interaction between dextran and water, and the properties conferred by the random coil structure. Also, the coiled nature is known to change from a compact one to an expanded coil in aqueous solutions. It is possible that the introduction of a polar group such as histidine enhances the hydrogen-bonding ability of dextran, and the presence of multiple histidines can ease the conformational constraints, further enhancing the hydrodynamic interactions leading to a significant increase in osmotic activity. It would be of interest to test the effect of histidine conjugation on the intermolecular associations of dextran.

Another interesting feature observed is the selectivity observed in the case of Cu- and Zn-bound IDA matrices. When DexH preparations are loaded onto these columns, the eluted soluble fractions exhibit higher osmotic activity. It can be suggested here that the polymer preparation contains a heterogeneous pool of DexH molecules with varying degrees of derivatization with histidine, and both the IMAC systems tested could bind selectively to the DexH species with higher content of histidine. The effect is more pronounced in the case of the Zn-IDA matrix, as eluted DexH at a concentration of 0.38% exhibits a tenfold increase in osmotic activity compared to native dextran tested at a concentration of 1%. It is known that, in the case of proteins, multiplicity, density, and localization of histidine residues on the surface determines the strength of interaction with the metal-IDA matrix (*26*). Also, Cu-IDA is known to efficiently bind proteins even with a single surface histidine, whereas metals in the lower end of the series, such as Zn, bind only when multiple histidines are present on the surface. For example, as reported by Hamden et al., (*26*) myoglobin from two different species exhibits radically different affinities to the Zn-IDA matrix. Dog myoglobin with one histidine exhibits very little affinity, whereas sperm whale myoglobin with two surface histidine exhibits strong binding. Histidines separated by two amino acid residues, forming a part of an α helix, are known to be favorably positioned to form strong coordination with IDA-Zn. The same analogy can be extended to explain the behavior of DexH. Here, in DexH with a high degree of derivatization, histidines possibly exist as clusters and are readily exposed on the surface due to the expanded coil structure. The Zn-IDA matrix is able to selectively bind to these molecules with histidine clusters. Thus, the Zn-IDA matrix can be effectively used to concentrate the DexH species with high osmotic activity.

DexH with its enhanced osmotic properties would find many applications apart from the two discussed in the above sections, such as in contrast enhancers, preparation of novel hydrogels with higher swelling capacity, and so forth. Also, it would be interesting to test the effect of molecular weight on the osmotic activity. It is possible that higher molecular weight dextrans can potentially conjugate with histidine to a larger extent and thus can exhibit more osmotic activity than the one tested in this paper. This approach could also provide a method to engineer DexH with the tailor-made osmotic properties to suit specific requirements.

ACKNOWLEDGMENT

This work was carried out as a part of the project SURGETIQUE 2 within the framework of the National Network of Technology for Health (RNTS) France, from the French Ministry of Industry. We wish to thank RNTS for the financial support. We particularly thank Prof. P. Cinquin and the Societe PRAXIM, for their valuable discussions.

Lipopolythioureas: A New Non-Cationic System for Gene Transfer

Jeanne Leblond, Nathalie Mignet, Céline Largeau, Maria-Vittoria Spanedda, Johanne Seguin, Daniel Scherman, and Jean Herscovici*

Inserm, U640, Paris, F-75006, CNRS, UMR8151, Paris, F-75006, Ecole Nationale Supérieure de Chimie de Paris, Paris, F-75005, Unité de Pharmacologie Chimique et Génétique, France, Université René Descartes, Faculté de Pharmacie, Paris, F-75270 France, and Chimie Moléculaire de Paris Centre, CNRS, FR 2769, Paris, F-75005. Received May 30, 2006; Revised Manuscript Received November 28, 2006

A DNA-transfection protocol has been developed that makes use of thiourea non-cationic synthetic lipid, *N*-[1,3-bis(carbamothioylamino)propan-2-yl]-2-(dialkycarbamoylmethoxy)acetamide. It was found that these new compounds could be formulated without helper lipid and that the N-decanoyl and N-lauryl derivatives transfected B16 cells in the presence of serum with an efficiency at the same level as cationic lipids, under identical conditions. In vivo transfection using intratumoral injection was also investigated. It was found that compounds **18c** and **19** showed an efficiency of the same magnitude as naked DNA and cationic lipid.

INTRODUCTION

Plasmid-based gene medicine (*1*) requires a safe and efficient delivery system to transport DNA to the cell nucleus in order to cure innate or acquired disease. Naked plasmid DNA (*2*) could be directly administrated to the muscle (*3*), liver (*4*), or tumor (*5*), but in most cases, DNA is delivered by systemic injection and, for increased efficiency, should be protected from degradation in the bloodstream. The use of cationic lipid or polymer is one of the main strategies to deliver therapeutic genes or oligonucleotides to the nucleus (*6*−*8*). As compared to viral vectors (*9*), these gene delivery technologies suffer from a lack of efficiency but offer more flexibility and safety. This lack of efficiency is particularly true for in vivo transfection, due to interaction of cationic complexes with blood proteins (*10, 11*). Several strategies have been proposed to solve this drawback, like liposome postgrafting (*12*), polymer shielding (*13, 14*), and anionic liposomal delivery system (*15*). Nonelectrostatic systems have also been worked out that might bind DNA by base stacking (*16, 17*), nucleoside interaction (*18*), or trapping into a saccharidic cluster (*19*). But in these last cases, DNA transfection was seldom observed in vitro except for the glycocluster (*19*), unless the system bore a cationic charge (*20*).

We have previously reported alternative lipids that interact with DNA in a nonelectrostatic fashion (*21*). These lipids are composed of di- or trithiourea functions that bind DNA. Unfortunately, these complexes did not transfect cells efficiently probably because of their high hydrophobic nature and their poor interaction between uncharged lipopolythiourea (LPT) liposomes and the cell membrane. Targeting LPT−DNA particles to membrane receptors seemed to represent the most suitable way to use these new DNA complexing particles for gene transfer. We recently obtained lipopolythiourea liposomes labeled with a fluorescent agent and formulated with a PEG−RGD lipid (*22*). These targeting thiourea lipoplexes were efficiently internalized by the cells displaying $\alpha_v\beta_3$ integrin receptor, as compared to the nontargeting complexes. However, no transfection was achieved by such lipoplexes. This previous study showed that modifications of the lipopolythiourea head from three linear thiourea functions to two branched thiourea functions still allowed efficient DNA compaction. Moreover, we observed that such structural element modification improved the formulation and decreased the hydrophobic properties without destabilizing the lipoplexes.

We therefore concentrated our efforts on decreasing the hydrophobicity of LPT lipids. Log *P* calculation clearly showed that hydrophilicity could be greatly improved by decreasing the length of the hydrophobic anchor. Here, we describe a general synthesis of readily available dithioureas. These derivatives interact with DNA without any helper lipid and exhibit cell transfection properties. These novel delivery agents represent a new example of nonelectrostatic nanosystem with transfecting properties.

EXPERIMENTAL PROCEDURES

Materials and Methods. All solvents were purchased from Carlo Erba-SDS (Peypin France). Dichloromethane was distilled from P_2O_5. DMF was dried over 3 Å molecular sieves and pyridine over KOH. All chemicals were purchased from Sigma-Aldrich-Fluka or Lancaster. Tosyl chloride was recrystallized in petroleum ether, and diglycolic anhydride was dehydrated (P_2O_5) prior to use. Other solvents and products were used without further purification. Reactions were monitored by thin-layer chromatography using Merck precoated 60 F254 silica gel plates. Column chromatography was performed over SDS (Peypin France) 35−70 nm silicagel according to the method of Still, Khan, and Mitra (*23*) or using small column flash chromatography (SFC) according to the following procedure: a plastic syringe was filled with silica gel (product/silica gel 1/5) and connected to a vacuum pump. The column was equilibrated with heptane, and then the sample dissolved in a minimum of dichloromethane was added to the top. The column was eluted by ten fractions of a heptane/ethyl acetate mixture. The volume was equal to the silica gel volume. For each fraction, the amount of ethyl acetate was increased (10% to 100% (v/v) heptane in ethyl acetate). Inverse-phase SPE was performed on Supelco Superclean C8 cartridge using an H_2O/CH_3CN/CH_3OH mixture. ^1H and ^{13}C NMR spectra were recorded on a Bruker Advance DRX-300 spectrometer at 300.13 MHz for ^1H and 75.47 MHz for ^{13}C. NMR spectra were processed using *Xwinnmr* (Bruker) or *SwaN-MR* (*24*). MS were carried out on a Shimazu 2010A LC-MS on ESI mode. High-resolution MS and elemental analysis were carried out by the "Service Central de Micro-analyse du CNRS" Vernaison France.

Dipalmytoylphosphatidylcholine (DPPC) and phosphatidylethanolamine-lissamine rhodamine were purchased from Aventi Polar Lipids (Alabaster Alabama). Log *P* calculations were performed using *MarvinSketch* (Chemaxon, Ltd., Budapest, Hungary) (*25*).

Synthetic Procedures. *tert-Butyl 1,3-Dihydroxypropan-2-ylaminoformate (**2**).* A solution of 2-aminopropane-1,3-diol (**1**) (5 g, 55 mmol) in ethanol (200 mL) was added to a solution di-*tert*-butylcarbonate (12 g, 55 mmol) in ethanol (200 mL). The reaction mixture was stirred for 5 h, then evaporated to dryness to yield a white solid, which was recrystallized in heptane to yield 10 g of **2** (93%). Mp 82 °C. ^{1}H NMR ($CDCl_3$) δ (ppm): 1.45 (s, 9H, CH_3), 3.24 (m, 2H, OH), 3.67−3.83 (m, 5H, CH, CH_2OH), 5.34 (d, 1H, J = 6.6 Hz, NH). ^{13}C NMR ($CDCl_3$) δ (ppm): 28.44 (s, CH_3), 53.31 (s, CH), 63.45 (s, CH_2-OH), 80.07 (s, $C(CH_3)_3$), 156.14 (s, C═O). Anal. Calcd for $C_8H_{17}NO_4$ C, 49.96; H, 8.94; N, 7.32. Found C, 50.25; H, 8.96; N, 7.32.

*tert-Butyl 1,3-Bis(methoxysulfonyloxy)propan-2-ylaminoformate (**3**).* Methanesulfonyl chloride (8.3 mL, 100 mmol) and triethylamine (18.6 mL, 133 mmol) were added to a solution of diol **2** (8.5 g, 44 mmol) in dichloromethane (100 mL). The reaction mixture was stirred for 3 h; then, the solution was diluted (dichloromethane, 500 mL), washed (water, 2 × 150 mL), then dried ($MgSO_4$). After filtration and evaporation of the solvent, 15.5 g of **3** was recovered as a solid (100%). Mp 85 °C. ^{1}H NMR ($CDCl_3$) δ (ppm): 1.43 (s, 9H, CH_3), 3.06 (s, 6H, CH_3), 4.23−4.37 (m, 5H, CH, CH_2OH), 5.07 (d, 1H, J = 7.6 Hz, NH). ^{13}C NMR ($CDCl_3$) δ (ppm): 28.32 (s, CH_3), 37.54 (s, CH_3), 48.69 (s, CH), 67.02 (s, CH_2OH), 80.05 (s, $C(CH_3)_3$), 154.97 (s, C═O). MS (ESI, *m*/*z*) 370 $(M + Na)^+$, 391 $(M + HCOO)^-$. Anal. Calcd C, 34.57; H, 6.09; N, 4.03; S, 18.46. Found C, 32.86; H, 5.98; N, 4.32; S, 19.09.

*tert-Butyl 1,3-Diazidopropan-2-ylaminoformate (**4**).* A solution of dimesyl **3** (1.8 g, 5.1 mmol), sodium azide (2.0 g, 30.6 mmol), and 18-crown-6 (0.14 g, 0.5 mmol) in DMF (25 mL) was refluxed for 20 h. The mixture was coevaporated with toluene and water, then diluted in ethyl acetate, washed three times with brine, dried ($MgSO_4$), and evaporated to yield **4** as a yellow oil that was further used without any purification (1.24 g, 100%). ^{1}H NMR ($CDCl_3$) δ (ppm): 1.43 (s, 9H, CH_3), 3.40 (dd, J = 7.8 Hz, J = 16.6 Hz, CH_2), 3.51 (dd, J = 6.8 Hz, J = 16.6 Hz, CH_2), 3.85 (m, 1H, CH), 4.91 (d, 1H, J = 8.4 Hz, NH). ^{13}C NMR ($CDCl_3$) δ (ppm): 28.36 (s, CH_3), 49.61 (s, CH_2), 51.84 (s, CH), 80.05 (s, $C(CH_3)_3$), 155.19 (s, C═O).

*1,3-Diazidopropan-2-amine (**5**).* A TFA/water mixture (3:1, 80 mL) was added to a solution of diazide **4** (4.7 g, 20 mmol) in dichloromethane (20 mL). The reaction mixture was stirred for 4 h, then poured on solid $NaHCO_3$ and filtered. The aqueous phase was extracted by dichloromethane, adjusted to pH 10 (NaOH 2 N), and then extracted again with dichloromethane. The mixed organic layers were dried ($MgSO_4$), filtered, and then evaporated to dryness to give **4** (2.7 g, 96%) that was used without any purification. ^{1}H NMR ($CDCl_3$) δ (ppm): 1.45 (s, 2H, NH), 3.02 (p, 1H, J = 5.8 Hz, CH), 3.32 (dd, 2H, J = 5.8 Hz, J = 12.0 Hz, CH_2), 3.40 (dd, 2H, J = 5.8 Hz, J = 12.0 Hz, CH_2). ^{13} C NMR ($CDCl_3$) δ (ppm): 50.69 (s, CH), 55.08 (s, CH_2). MS (EI DCI) 142 $(M + H)^+$.

*N′,N′-Ditetradecylsuccinamide (**7**).* Succinic anhydride (10.7 g, 107 mmol) and 4-dimethylaminopyridine (0.48 g, 3.9 mmol) were added to a solution of ditetradecylamine (**6a**) (8g, 21.5 mmol) in a mixture of dry pyridine (32 mL) and dichloromethane (80 mL). The reaction mixture was stirred at RT for 18 h before addition of 1 N hydrochloride (20 mL). The organic layer was extracted, washed with brine, dried ($MgSO_4$), and evaporated to afford **7** as an oil (9.8 g, 98%). ^{1}H NMR ($CDCl_3$) δ (ppm): 0.85 (t, 6H, J = 6.3 Hz, CH_3), 1.23 (m, 44H, $-CH_2-$), 1.48 (m, 2H, $-CH_2-$), 2.64 (s, 4H, CH_2CO), 3.22 (m, 4H, CH_2N). ^{13}C NMR ($CDCl_3$) δ (ppm): 14.08 (s, CH_3), 22.69 (s, $-CH_2-$), 27.74 (s, $-CH_2-$), 28.10 (s, CH_2CO), 28.92 (s, $-CH_2-$), 29.67 (m, $-CH_2-$), 30.07 (s, CH_2CO), 31.96 (s, $-CH_2-$), 46.21 and 47.98 (2s, $-CH_2N$), 171.46 (s, C═O), 176.34 (s, C═O). MS (ESI, *m*/*z*) 511 $(M + H)^+$.

*N-(2-Azido-1-azidomethylethyl)-N′,N′-ditetradecylsuccinamide (**8**).* Diazide **5** (0.074 g, 0.53 mmol) was added to solution of **7** (0.26 g, 0.5 mmol) in dichloromethane (3 mL). The reaction mixture was stirred for 1 h before the addition of a solution of DCC (0.16 g, 0.75 mmol) in dichloromethane (1 mL). After overnight stirring, diethyl ether (5 mL) was added, and the resulting precipitate was filtered through a celite pad. The solvent was evaporated to yield a crude oil that was dissolved in THF (10 mL/mmol). Amberlyst-21 (0.27 g, 4 equiv) was added to remove the acid excess. The resin was removed by filtration, and then the filtrate was evaporated to yield **8** as a yellow oil (0.31 g, 93%). ^{1}H NMR ($CDCl_3$) δ (ppm): 0.87 (t, 6H, J = 6.6 Hz, CH_3), 1.25 (m, 44H, $-CH_2-$), 1.47 (m, 4H, $-CH_2-$), 2.60 (dd, 4H, J = 22 Hz, J = 8 Hz, CH_2CO), 3.23 (dt, 4H, J = 22 Hz, J = 8 Hz, CH_2N), 3.43 (dd, 4H, J = 6.0 Hz, J = 14.4 Hz, CH_2N_3), 4.15 (m, 1H, CH), 7.23 (d, 1H, J = 8 Hz, NH). ^{13}C NMR ($CDCl_3$) δ (ppm): 13.95 (s, CH_3), 22.66 (s, $-CH_2-$), 27.12 (s, $-CH_2-$), 27.84 (s, CH_2CO), 28.97 (s, $-CH_2-$), 29.66 (m, $-CH_2-$), 31.90 (m, $-CH_2-$, CH_2CO), 46.42 and 48.09 (2s, $-CH_2N$), 48.55 (s, CH), 51.62 (s, CH_2N_3), 171.39 (s, C═O), 172.87 (s, C═O). MS (ESI, *m*/*z*) 634 $(M + H)^+$.

*N-(2-Amino-1-aminomethylethyl)-N′,N′-ditetradecylsuccinamide (**9**).* A round-bottom flask equipped with a stirring bar was charged with **8** (0.30 g, 0.48 mmol), ethanol (10 mL), Pd/C (0.06 g), and hydrogen. The suspension was stirred for 19 h at RT; then, the mixture was filtered through a celite pad to yield after evaporation 0.27 g of the diamine **9** (98%) as a colorless oil. ^{1}H NMR ($CDCl_3$) δ (ppm): 0.80 (t, 6H, J = 8.4 Hz, CH_3), 1.25 (m, 44H, $-CH_2-$), 1.49 (m, 4H, $-CH_2-$), 2.43 (m, 2H, CH_2CO), 2.63 (m, 2H, CH_2CO), 2.75 (m, 4H, CH_2NH_2), 2.86 (m, 4H, NH_2), 3.25 (m, 4H, CH_2N), 3.82 (m, 1H, CH), 7.12 (d, 1H, J = 8.4 Hz, NH). ^{13}C NMR ($CDCl_3$) δ (ppm): 14.14 (s, CH_3), 22.73 (s, $-CH_2-$), 27.12 (s, $-CH_2-$), 27.82 (s, $-CH_2-$), 29.40 (s, CH_2CO), 29.66 (m, $-CH_2-$), 31.97 (m, $-CH_2-$, CH_2CO), 43.56 (s, CH_2NH_2), 46.36 and 48.10 (2s, $-CH_2N$), 53.27 (s, CH), 171.39 (s, C═O), 172.87 (s, C═O). MS (ESI, *m*/*z*) 582 $(M + H)^+$, 626 $(M + HCOO)^-$.

*N′-[1,3-Bis(methylthiocarbamoylamino)propan-2-yl]-N,N-ditetradecylbutanediamide (**10**).* Methyl isothiocyanate (11 mg, 0.15 mmol) was added to solution of diamine **9** (58 mg, 0.1 mmol) and triethylamine (14 μL, 0.1 mmol) in dichloromethane (1 mL). The solution was stirred overnight. The solvent was evaporated, and the crude was purified by SFC to yield **11** as an oil (0.046 g, 63%). ^{1}H NMR ($CDCl_3$) δ (ppm): 0.87 (t, 6H, J = 8.4 Hz, CH_3), 1.25 (m, 44H, $-CH_2-$), 1.46 (m, 4H, $-CH_2-$), 2.47 (m, 2H, CH_2CO), 2.66 (d, 2H, CH_2CO), 3.01 (s, 6H, CH_3NCS), 3.22 (m, 4H, CH_2N), 3.75−3.90 (m, 5H, CH, CH_2NCS), 7.59 (m, 5H, NH). ^{13}C NMR ($CDCl_3$) δ (ppm): 14.20 (s, CH_3), 22.79 (s, $-CH_2-$), 27.17 (s, $-CH_2-$), 28.01 (s, $-CH_2-$), 29.02 (s, CH_2CO), 29.66 (m, $-CH_2-$), 31.21 (s, CH_3 NCS), 31.78 (s, CH_2CO), 32.06 (s, $-CH_2-$), 44.75 (s, CH_2-NCS), 46.83 and 48.51 (s, $-CH_2N$), 51.99 (s, CH), 171.88 (s, C═O), 173.67 (s, C═O), 183.61 (s, C═S). HR-ESMS calcd for $C_{39}H_{78}N_6O_2NaS_2$: 749.5525. Found 749.5487.

*N-(2-Isothiocyanato-1-isothiocyanatomethylethyl)-N′,N′-ditetradecylsuccinamide (**11**).* Diisopropylethylamine (0.25 mL, 1.4 mmol) and carbon disulfide (0.11 mL, 1.9 mmol) were successively added to a solution of diamine **9** (0.28 g, 0.5 mmol) in dichloromethane (5 mL). The solution was stirred for 3 h, and then a solution of tosyl chloride (0.18 g, 0.9 mmol) in

dichloromethane was added dropwise. The mixture was stirred for 20 h at RT, diluted with dichloromethane, and washed three times with brine. The organic solution was dried ($MgSO_4$) and evaporated under vacuum. The crude was purified by SFC to yield **11** as a colorless oil (0.07 g, 22%). ^{1}H NMR ($CDCl_3$) δ (ppm): 0.88 (t, 6H, J = 6.6 Hz, CH_3), 1.25 (m, 44H, $-CH_2-$), 1.51 (m, 4H, $-CH_2-$), 2.56 (m, 2H, CH_2CO), 2.69 (m, 2H, CH_2CO), 3.25 (m, 4H, -CH_2N), 3.76 (dd, 4H, J = 6.0 Hz, J = 11.1 Hz, CH_2NCS), 4.28 (m, 1H, CH), 7.51 (d, 1H, J = 8.4 Hz, NH). ^{13}C NMR ($CDCl_3$) δ (ppm): 14.18 (s, CH_3), 22.77 (s, $-CH_2-$), 27.19 (s, $-CH_2-$), 27.87 (s, $-CH_2-$), 29.03 (s, CH_2CO), 29.74 (m, $-CH_2-$), 32.01 (m, $-CH_2-$, CH_2CO), 45.98 and 46.69 (2s, $-CH_2N$), 48.10 (s, CH), 49.04 (s, CH_2-NCS), 171.39 (s, C═O), 172.87 (s, C═O). IR (NaCl) σ (cm^{-1}): 1629 ($\nu_{N-C=O}$), 1675 ($\nu_{NH-C=O}$), 2089 ($\nu_{N=C=S}$), 2852 ($\nu_{=C-H_2}$), 2929 (ν_{CH_2}). Anal. Calcd for $C_{37}H_{68}N_4O_2S_2$: C, 66.82; H, 10.31; N, 8.42. Found C, 66.94; H, 10.70; N, 7.63.

*N′-[1,3-Bis(2,3-dihydroxypropylthiocarbamoylamino)propan-2-yl]-N,N-ditetradecylbutanediamide (**12**).* 3-Amino-1,2-propanediol (40 mg, 0.44 mmol) was added to a solution of **11** (0.073 g, 0.11 mmol) in dry DMF (1.5 mL). The solution was stirred at RT for 2 h, then heated overnight (50 °C). The solvent was evaporated, and then the resulting oil was dissolved in dichloromethane (4 mL) and washed twice with brine (1 mL). The organic layer was dried ($MgSO_4$), filtrated, and evaporated. The crude was first purified by SPE (C8, 100% H_2 O to 100% CH_3CN then to 100% CH_3OH), then by SFC to yield **12** as a colorless oil (23 mg, 25%).^{1}H NMR ($CDCl_3$) δ (ppm): 0.88 (t, 6H, J = 6.6 Hz, CH_3), 1.26 (m, 44H, $-CH_2-$), 1.55 (m, 4H, $-CH_2-$), 2.52 (t, 2H, J = 6.0 Hz, CH_2CO), 2.68 (t, 2H, J = 6.0 Hz, $-CH_2CO$), 3.11 (t, 2H, J = 7.5 Hz, $-CH_2N$), 3.18 (t, 2H, J = 7.5 Hz, $-CH_2N$), 3.21 (m, 2H, CH_2NCS), 3.39 (m, 4H, CH_2NCS), 3.53 (m, 6H, CH_2NCS, CH_2OH), 3.77 (t, 2H, J = 4.5 Hz, CHOH), 3.87 (m, 1H, CH), 6.97 (t, 1H, J = 6.0 Hz, NH). ^{13} C NMR ($CDCl_3$) δ (ppm) 14.05 (s, CH_3), 22.70 (s, $-CH_2-$), 27.02 (s, $-CH_2-$), 27.81 (s, $-CH_2-$), 28.93 (s, $-CH_2CO$), 29.66 (m, $-CH_2-$), 31.68 (s, CH_2CO), 31.91 (s, $-CH_2-$), 44.46 (s, CH_2NCS), 46.18 (s, CH_2NCS), 46.58 and 48.29 (2s, CH_2N), 53.12 (s, CH), 63.44 (s, CH_2OH), 70.93 (s, CHOH), 171.66 (s, C═O), 174.76 (s, C═O).

*Ditetradecylcarbamoylmethoxyacetic Acid (**13a**).* Glycolic anhydride (6.3 g, 53.8 mmol) was added to a solution of ditetradecylamine **6a** (8.8 g, 21.5 mmol) and DMAP (1.3 g, 10.7 mmol) in dichloromethane (200 mL). The solution was stirred for 18 h at RT; then, the reaction mixture was diluted with dichloromethane and washed successively with 1 N HCl (3 times) and brine (3 times), then dried ($MgSO_4$). Acid **13a** was isolated as a white solid after removal of the solvent (11.3 g, 100%). Mp 62 °C. ^{1}H NMR ($CDCl_3$) δ (ppm): 0.87 (t, 6H, J = 6.9 Hz, CH_3), 1.25 (m, 44H, $-CH_2-$), 1.54 (m, 2H, $-CH_2-$), 3.08 (t, 2H, J = 7.5 Hz, $-CH_2N$), 3.34 (t, 2H, J = 7.5 Hz, $-CH_2N$), 4.21 (s, 2H, CH_2CO), 4.38 (s, 2H, CH_2CO). ^{13}C NMR ($CDCl_3$) δ (ppm): 14.13 (s, CH_3), 22.72 (s, $-CH_2-$), 27.01 (s, $-CH_2-$), 28.71 (s, $-CH_2-$), 29.68 (m, $-CH_2-$), 31.97 (s, $-CH_2-$), 46.95 (s, $-CH_2N$), 71.21 (s, CH_2O), 72.87 (s, CH_2O), 170.69 (s, C═O), 172.03 (s, C═O). MS (ESI, m/z) 527 $(M + H)^+$, 95% purity by ELSD.

*Didodecylcarbamoylmethoxyacetic Acid (**13b**).* Glycolic anhydride (1.6 g, 14.1 mmol) was added to a solution of bis-dodecylamine **6b** (8.8 g, 21.5 mmol) and DMAP (0.17 g, 1.4 mmol) in dichloromethane (20 mL). The solution was stirred for 23 h and was treated as for **13a**. SFC purification gave **13b** as a white solid (1.1 g, 84%). Mp 55 °C. ^{1}H NMR ($CDCl_3$) δ (ppm): 0.88 (t, 6H, J = 6.6 Hz, CH_3), 1.26 (m, 36H, $-CH_2-$), 1.55 (t, 2H, J = 6.9 Hz, $-CH_2-$), 3.08 (t, 2H, J = 7.5 Hz, $-CH_2N$), 3.35 (t, 2H, J = 7.5 Hz, $-CH_2N$), 4.21 (s, 2H, CH_2O), 4.38 (s, 2H, CH_2O). ^{13}C NMR ($CDCl_3$) δ (ppm): 14.18 (s, CH_3), 22.76 (s, $-CH_2-$), 27.02 (s, $-CH_2-$), 27.51 (s, $-CH_2-$), 29.70 (m, $-CH_2-$), 31.98 (s, $-CH_2-$), 46.98 (s, $-CH_2N$), 71.32 (s, CH_2O), 73.15 (s, CH_2O), 170.68 (s, C═O), 174.13 (s, C═O). MS (ESI, m/z) 470 $(M + H)^+$, 100% purity by ELSD. Anal. Calcd for $C_{28}H_{56}NO_4$: C, 71.59; H, 11.80; N, 2.98. Found C, 70.26; H, 11.65; N, 2.78.

*Didecylcarbamoylmethoxyacetic Acid (**13c**).* Glycolic anhydride (4.7 g, 40 mmol) was added to a solution of didecylamine **6c** (3.0 g, 10 mmol) and DMAP (0.6 g, 5 mmol) in dichloromethane (100 mL). The solution was stirred for 20 h at RT and was treated as for **13a** to yield **13c** as a white solid (4.14 g, 100%). Mp 55 °C. ^{1}H NMR ($CDCl_3$) δ (ppm): 0.85 (t, 6H, J = 6.0 Hz, CH_3), 1.25 (m, 28H, $-CH_2-$), 1.53 (m, 4H, $-CH_2-$), 3.08 (t, 2H, J = 7.3 Hz, $-CH_2N$), 3.33 (t, 2H, J = 7.3 Hz, $-CH_2N$), 4.19 (s, 2H, CH_2O), 4.39 (s, 2H, CH_2O). ^{13}C NMR ($CDCl_3$) δ (ppm): 14.08 (s, CH_3), 22.69 (s, $-CH_2-$), 26.85 (s, $-CH_2-$), 27.45 (s, $-CH_2-$), 28.67 (s, $-CH_2-$), 29.30 (m, $-CH_2-$), 29.51 (s, $-CH_2-$), 31.89 (s, $-CH_2-$), 46.93 (s, $-CH_2N$), 71.20 (s, $-CH_2O$), 72.78 (s, $-CH_2O$), 170.7 (s, C═O), 171.1 (s, C═O). MS (ESI, m/z) 414 $(M + H)^+$. HPLC purity 100% by ELSD. Anal. Calcd for $C_{24}H_{47}NO_4$: C, 69.69; H, 11.22; N, 3.30. Found C, 69.00; H, 11.35; N, 3.39.

*N,N-Bis(azidomethyl)-2-(ditetradecylcarbamoylmethoxy)acetamide (**14a**).* A solution of DCC (0.16 g, 0.75 mmol) in dichloromethane (1 mL) was added to a solution of **13a** (4.0 g, 7.6 mmol) and **5** (1.1 g, 8 mmol) in dichloromethane (50 mL). The reaction mixture was stirred overnight, and then diethyl ether (70 mL) was added. The resulting suspension was filtered through a celite pad; then, the solvent was evaporated under reduced pressure to yield a crude oil that was first purified by SFC and then dissolved in THF (20 mL/mmol). Amberlyst-21 (4 equiv) was added to remove the acid excess. The resin was removed by filtration, and then the solvent was evaporated under reduced pressure. The amide **14a** was isolated as an oil (4.9 g, 98%). ^{1}H NMR ($CDCl_3$) δ (ppm): 0.87 (t, 6H, J = 6.6 Hz, CH_3), 1.25 (m, 44H, $-CH_2-$), 1.52 (m, 4H, $-CH_2-$), 3.06 (t, 2H, J = 7.5 Hz, $-CH_2N$), 3.31 (t, 2H, J = 7.5 Hz, $-CH_2N$), 3.47 (dd, 4H, J = 6.0 Hz, J = 12.3 Hz, CH_2N_3), 3.55 (dd, 4H, J = 5.7 Hz, J = 12.3 Hz, CH_2N_3), 4.10 (s, 2H, CH_2O), 4.17 (m, 1H, CH), 4.27 (s, 2H, CH_2O), 8.75 (d, 1H, J = 8.4 Hz, NH). ^{13}C NMR ($CDCl_3$) δ (ppm): 14.13 (s, CH_3), 22.73 (s, $-CH_2-$), 27.06 (s, $-CH_2-$), 27.64 (s, $-CH_2-$), 29.70 (m, $-CH_2-$), 31.98 (s, $-CH_2-$), 46.45 and 46.91 (2s, CH_2N), 48.44 (s, CH), 51.54 (s, CH_2N_3), 70.33 (s, CH_2O), 72.68 (s, CH_2O), 168.70 (s, C═O), 170.30 (s, C═O). *N′-[1,3-Bis(methylthiocarbamoylamino)propan-2-yl]-2-(didecylcarbamoylmethoxy)acetamide (**19**).* Methyl isothiocyanate (0.71 mL, 10.3 mmol) was added to solution of diamine **15c** (2.0 mg, 4.1 mmol) and triethylamine (0.58 mL, 4.13 mmol) in dichloromethane (41 mL). The solution was stirred overnight at RT. The solvent was evaporated and the crude was purified by SFC to yield **19** as an oil (2.35 g, 90%). ^1H NMR ($CDCl_3$) δ (ppm): 0.88 (t, 6H, $J = 6.0$ Hz, CH_3), 1.25 (m, 28H, $-CH_2-$), 1.52 (m, 4H, $-CH_2-$), 3.01 (s, 6H, CH_3NCS), 3.08 (t, 2H, $J = 7.3$ Hz, $-CH_2-$), 3.29 (m, 3H, $-CH_2-$), 3.40 (m, 1H, CH), 3.51−3.98 (m, 4H, CH_2NCS), 4.13 (s, 2H, CH_2O), 4.30 (s, 2H, CH_2O), 7.60 (m, 1H, NH), 8.54 (m, 4H, NH). ^{13}C NMR ($CDCl_3$) δ (ppm): 14.88 (s, CH_3), 22.79 (s, $-CH_2-$), 27.22 (s, $-CH_2-$), 27.80 (s, $-CH_2-$), 29.07 (s, $-CH_2-$), 29.44 (m, $-CH_2-$), 29.66 (s, $-CH_2-$), 32.01 (m, $-CH_2-$, CH_3NCS), 41.39 (s, CH_2NCS), 46.63 and 47.15 (2s, CH_2NCO), 50.96 (s, CH), 69.89 (s, CH_2O), 71.97 (s, CH_2O), 168.73 (s, C═O), 171.54 (s, C═O), 184.00 (s, C═S). MS (ESI, *m/z*) 631 $(M + H)^+$, 666 $(M + Cl)^-$, 676 $(M + HCOO)^-$. HPLC purity 98% by ELSD. Anal. Calcd for $C_{31}H_{62}N_6O_3S_2$: C, 59.01; H, 9.90; N, 13.32; S, 10.13. Found C, 59.85; H, 9.79; N, 13.13; S, 8.58.

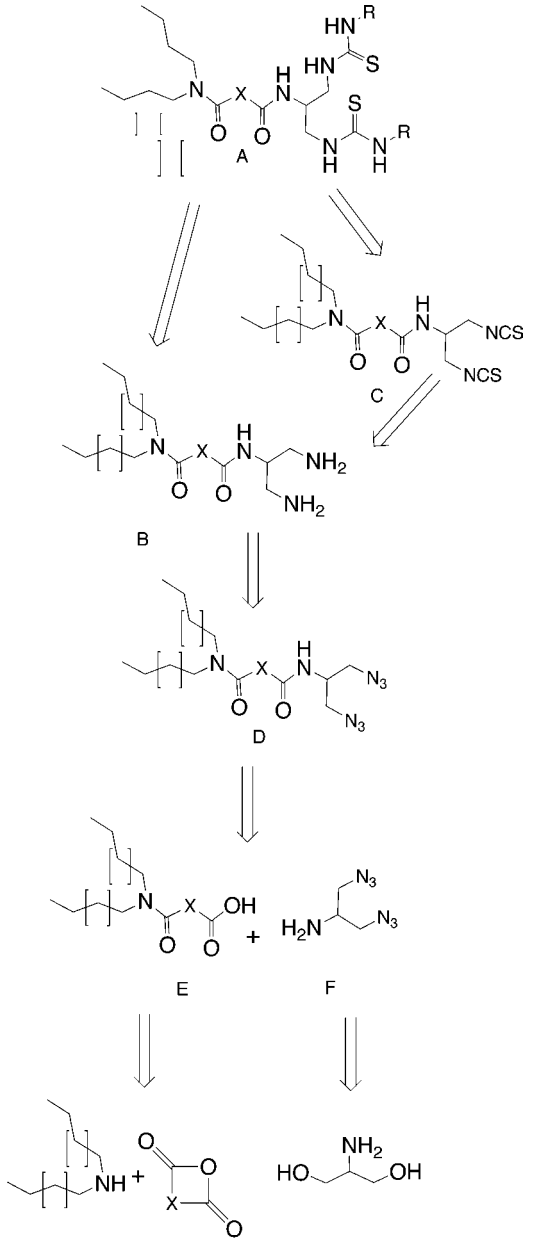
Physicochemistry and Biology. *Liposome Preparation.* Lipids (and colipids if necessary) were dissolved in ethanol and were added dropwise to ten volumes of water under vigorous agitation. The mixture was stirred overnight and then evaporated under reduced pressure at RT to obtain a fairly concentrated solution of liposomes.

As an example, **18c** (5 mg, 6,4 μmol) was dissolved in 500 μL ethanol. This solution was added dropwise into 5 mL of stirred filtered water. The mixture was stirred overnight, then evaporated under reduced pressure at RT to obtain a clear suspension of **18c** (440 μL, 14.5 mM).

Size Measurement. Particle diameter was determined by dynamic light scattering on a Zeta Sizer NanoSeries Malvern (Malvern Instruments, France). Liposome concentration, 0.1 mM in H_2O, from the mean value of three runs is given (1 min equilibration, 3 min run).

Preparation of LPT−DNA Complexes. Plasmid pVax2 was used for transfection experiments. pVax2 is a derivative of the commercial plasmid pVax1 (InVitrogen), which was digested with the restriction enzymes HincII and BamHI to excise the promoter. The plasmid was then blunted with the Klenow fragment, dephosphorylated with alkaline phosphatase, pCM-Vbeta (Clontech), and was digested with EcoR1 and BamHI to excise the CMV promoter. The CMV promoter was blunted with Klenow enzyme and ligated into the blunted pVax1 to give pVax2. The plasmid pXL3031 (*26*) was digested with EcoRI and BamHI and then treated with the Klenow fragment to produce a blunted fragment containing the luciferase cDNA. This fragment was ligated into pVax2 after EcoRV digestion and phosphatase alkaline dephosphorylation to give pVax21−Luc (*27*). Plasmid (100 μL, 0.02 g/L in H_2 O) was added dropwise with constant vortexing to various amounts of LPT liposomes (in 100 μL H_2O) at RT. TU/P indicates the ratio in nanomoles of thiourea function (2 per lipid) versus nanomoles of DNA phosphates.

Gel Retardation Experiments. Samples were described as above (20 μL), and 5 μL of bromophenol blue was added. The mixture was loaded on a 0.8% agarose gel in TBE buffer (1 M Tris, 0.9 M boric acid, 0.01 EDTA) at 80 V/cm. DNA was revealed with ethidium bromide and visualized under UV light.

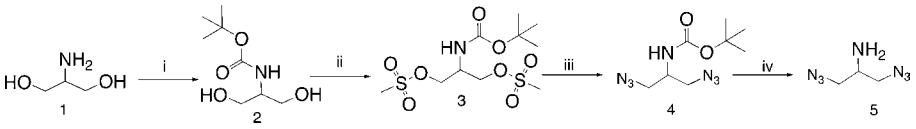


DNA Accessibility. LPT−DNA complexes (corresponding to 40 ng DNA) were loaded on a 96 well plate, and 100 μL of picogreen (diluted 200× in TBE) was added in each well. Fluorescence was measured by a Wallac Victor2 1420 Multilabel Counter Perkin-Elmer. Values are subtracted from the background and are expressed in percentage of the value of free DNA.

DNA Protection. 20 μL of culture medium (MEM with 10% or 50% murine fresh serum) were added on 20 μL of LPT−DNA complexes (0.1 g/L DNA). Samples were incubated at 37 °C. After 6 h, 10 μL of samples were frozen at −20 °C. After 24 h, all the samples were replaced at RT. SDS 2% (5 μL), EDTA (2 μL, 0.5 M), and bromophenol blue (3 μL) were added on each sample (10 μL). The mixture was loaded on agarose gel 1% containing 0.05% SDS at 80 V/cm. After 24 h washing in water, DNA was revealed with ethidium bromide and visualized under UV light.

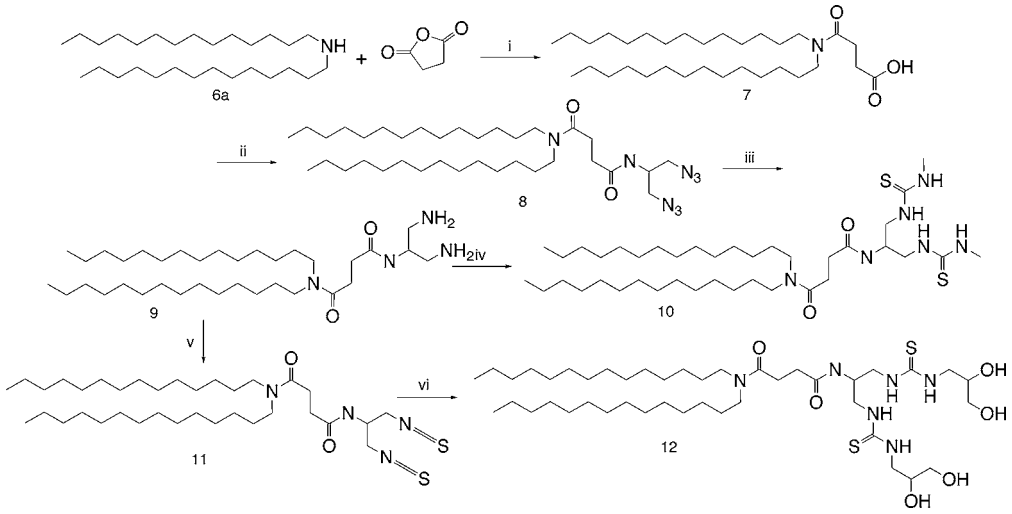
Transfection Method. B16 murine melanoma cells were grown into DMEM supplemented with 10% fetal bovine serum, 1% antibiotics (penicillin and streptomycin), and 1% glutamine. One day before transfection, cells were treated by trypsin and deposited into 24 well plates (45 000 cells/well) and incubated 24 h at 37 °C in DMEM supplemented with 10% fetal bovine serum. 100 μL of LPT−DNA (corresponding to 0.5 μg DNA) complex was loaded on each well, and the plates were incubated at 37 °C for 48 h. Then, the cells were washed twice with PBS and treated with 200 μL of a passive lysis buffer (Promega). After 15 min, the cells were centrifuged for 5 min at 12 000 rpm. 10 μL of supernatant and 10 μL of iodoacetamide were deposited on a 96 well plate, which was incubated at 37 °C for 1 h. Protein quantification was performed with the BCA Protein Assay Kit (Pierce) and reported to the BSA taken as a reference curve. Luciferase activity was quantified using a commercial kit Luciferase Assay System (Promega). On 10 μL of the lysed cells, 50 μL of the luciferin substrate was injected via an injector, and the absorbance was read immediately at 563 nm on a Wallac Victor2 1420 Multilabel Counter from Perkin-Elmer.

Intratumoral Injection. LPT−DNA (40 μL, 10 μg DNA, 40 TU/P) was injected in the tumor of three mice C57BL6 bearing 3LL tumors. Mice were sacrificed 24 h after injection, then tumors were removed, weighed, crushed in 5 mL lysis buffer per tumor, and centrifuged for 10 min (12 000 tr/min, 4 °C). 50 μL of the supernatant was loaded on a 96 well plate, and luciferase activity was quantified using a commercial kit (Protein Assay). The luminescence was read on a Wallac Victor2 1420 Multilabel Counter from Perkin-Elmer.



Scheme 1. Retrosynthetic Analysis of Lipopolythiourea Lipids

RESULTS AND DISCUSSION



Chemistry. As we had previously established that two thiourea groups were enough for the lipid to properly interact with DNA, we kept an identical interacting lipid head, but we modified the linker and the lipid length in order to obtain lipids with a suitable hydrophilic−lipophilic balance. We chose to use a propane triamine scaffold that could be readily prepared from 2-amino-1,3-diazidopropane (*28*). The preparation of these compounds could be envisioned according to the retrosynthetic scheme shown in Scheme 1. Thiourea formation could occur either by the reaction of an isothiocyanate on diamine **B** or by the condensation of an amine on the bis-isothiocyanate **C**. Precursor **B** may be prepared by reduction of diazide **D**. The synthesis of **D** could be easily achieved by coupling acid **E**

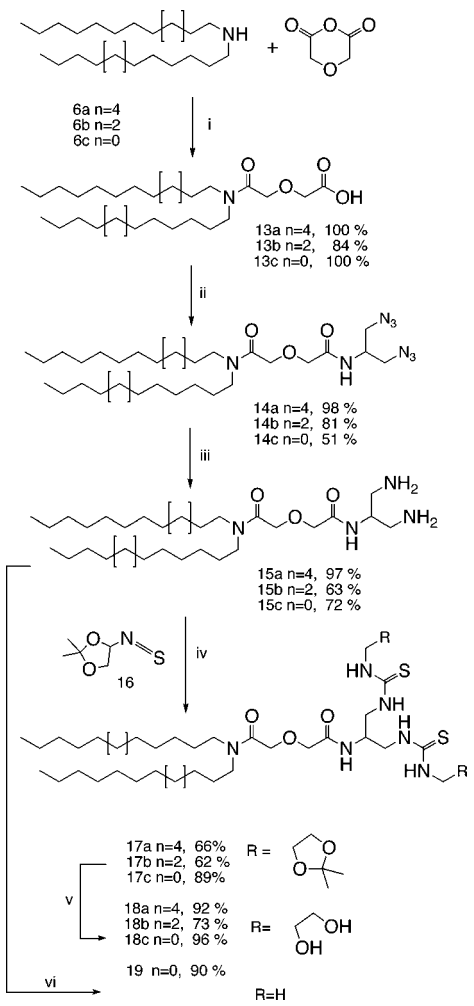
glycolic	methyl	**19**	10 C	4.84	EtOH		108 ± 1	0.158

[a] Polydispersity index.

with the amine **F**. **F** could be obtained in two steps from BOC-protected serinol via a sulfonylation/substitution protocol. Accordingly, disconnection of **E** gives the known dialkylamine and acid anhydride.

Therefore, we began the synthesis with the preparation of diazide **5** (Scheme 2), which was obtained in four steps from serinol.



First, the amine was BOC protected; then, diol **2** was mesylated to yield **3** quantitatively. Substitution of the mesylate using sodium azide in DMF gave the diazide **4** whose BOC-protecting group was cleaved to afford **5** with an excellent global yield (89%). With the diazide **5** in hand, we turned our attention to the preparation of lipopolythioureas (Scheme 3). The synthesis started with the reaction of ditetradecylamine **6a** with succinic anhydride, which provided the acid **7** in 98% yield. Coupling **7** with the diazidoamine **5** was performed using various conditions. Both mixed-anhydride protocol using isobutyl chloroformate (*29*) and in situ preparation of the acid chloride using thionyl chloride and A-21 resin (*30*) afforded the amide **8** in 60% yield. However, DCC coupling offered higher yields (93%), and DCC/NHS was then selected for the syntheses. Catalytic hydrogenation of **8** gave the corresponding amine **9**. The first lipopolythio urea **10** was achieved by reaction of amine **9** with methyl isothiocyanate. Besides, treatment of **9** with carbon disulfide in the presence of tosyl chloride (*31*) afforded the bis-isothiocyanate **11**. The modest yield of this reaction could be explained by an intramolecular process leading to a cyclic thiourea as described by Marmillon et al. (*32*). However, no side product was isolated. Finally reaction of **11** with 1-amino 2,3-propanediol gave the lipopolythiourea **12** in 25% yield.

Concerning the preparation of the glycolic derivatives, the diamides **15a**, **15b**, and **15c** were prepared in three steps from the corresponding diamines similarly to **9** (Scheme 4). Regarding the low yields obtained in the last steps of the synthesis of **12**, a different strategy was used for the LPT formation in order to improve the reaction efficacy. **15a**, **15b**, and **15c** were treated with isothiocyanate **16** to afford the corresponding thioureas in 62% to 89% yields. Deprotection of **17a**, **17b**, and **17c** with 1 N hydrochloric acid in THF led to the tetraols **18a**, **18b**, and **18c** in good yields. In addition, the diamine **15a** was treated with methyl isothiocyanate to give the methyl thiourea **19** in 90% yield.

Formulation Characterization. The ability of lipopolythioureas (LPT) to form micellar or liposomal particles was then evaluated. Previous studies have indicated that LPT hydrophobicity prevents its solubilization in H_2O and particle formation (*22*). For this reason, phosphatidylcholine (DPPC) has been added as an amphiphilic colipid because of its high hydration potency and its zwitterionic nature.

Then, solubility of the LPT lipids in chloroform and ethanol was first evaluated. The aim of this test was to define the way for the lipid to be formulated and the necessity of adding a colipid. Data are reported in Table 1, in parallel to log *P* calculation. Both calculation and solubility were in agreement.

Scheme 4 [a]

[a] (i) DMAP, CH_2Cl_2, RT; (ii) DCC or DCC/NHS, CH_2Cl_2, RT; (iii) H_2, Pd/C, EtOH, RT; (iv) **6**, DIPEA, CH_2Cl_2, RT; (v) HCl, THF, RT; (vi) MeNCS, DIPEA, CH_2Cl_2, RT.

Indeed, the most lipophilic compounds **10** and **12**, bearing a succinic linker, exhibited a good solubility only in $CHCl_3$. Interestingly, comparison of compounds **12** and **18a** that differ only by an oxygen atom within the linker showed that this atom added interesting physicochemical properties despite the very close values of their log *P*. A more dramatic influence on log *P*, as well as solubility, was observed when the lipid length was reduced from myristyl to decanoyl, on the series of glycolic LPTs **18a**, **18b**, and **18c**. The glycolic LPT **19**, bearing a methyl group within the thiourea condensing head, clearly showed a higher log *P* as compared to its tetraol counterpart **18c**.

Next, we investigated the formulation of LPT with or without the use of the colipid DPPC. The formulations were performed using ethanolic injection, a gentle method leading spontaneously to small particles (see Material and Methods section). Data in Table 1 indicate that the formulation was also closely related to the log *P*. All the compounds under log $P = 6.4$ were soluble in ethanol and could be formulated without helper lipid. Above this value, LPT, namely, LPT with succinic linker **10** and **12**, required DPPC. A 1:1 ratio was found to be optimal for **12**, but the more lipophilic compound **10** required a higher amount of DPPC in order to obtain a homogeneous suspension as shown by the polydispersity index value (PDI). Formulation of the LPT led to liposomes with diameters ranging from 70 to 205 nm as measured by dynamic light scattering experiments. It is noteworthy that smaller particles were obtained for compounds **18a**, **18b**, and **18c**. These results clearly showed that structural changes of polar head, linker, and lipidic anchor had a real influence on the formulation properties of the resulting lipid.

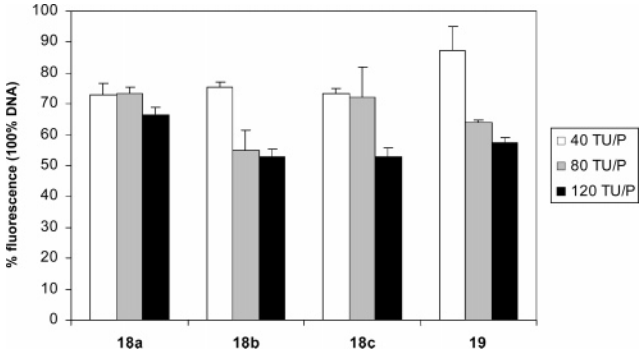


Figure 1. Accessibility of DNA in LPT/DNA complexes measured by picogreen fluorescence. Free DNA corresponds to 100% fluorescence. Measures for the free lipids were taken as the background. TU/P indicates the ratio of thiourea function per DNA phosphate.

LPT−DNA Interaction. The degree of DNA accessibility, once complexed with LPT, was assessed by the double-stranded-DNA-binding reagent picogreen. Fluorescence assays were performed using a fixed DNA amount and increasing the LPT equivalents. As observed in Figure 1, fluorescence decreased when the amount of lipids increased. However, the intensity was only half-reduced in comparison to the intensity observed with free DNA, even with a large excess of lipids (120 TU/P). This experiment means that DNA was still accessible to picogreen despite its interaction with the LPT. To evaluate if DNA was only partly associated to LPT, we loaded the complexes on an agarose gel (Figure 2). We could observe that all prepared LPT possessed the capacity to fully associate with DNA leading to LPT−DNA complexes, the required lipid amount depending on the LPT structure. Hence, lipopolythiourea **19** required more lipids to complex all DNA (40 TU/P) than compounds **18a, 18b**, and **18c**, which required a low ratio TU/P = 15 (Figure 1). From agarose gel retardation experiments, we observed that all prepared LPT totally retained DNA migration at a ratio TU/P = 15. On the other hand, DNA accessibility experiments suggested that LPT interaction with DNA led to a partially compacted structure that left free access for picogreen as previously described for sphingosine (*33*).

Lipoplex Sensitivity to Serum. DNA protection toward serum degradation was investigated in the absence and presence of LPT. After 30 min incubation at 37 °C in 10% serum containing medium, samples were treated by SDS and loaded on agarose gel containing 0.05% SDS (*34*) (Figure 3). In these conditions, free DNA was fully degraded in 24 h (lane 3), while DNA integrity was maintained in 10% serum when associated to LPT (TU/P = 40). Glycolic LPT presented the same capacity as cationic lipopolyamine RPR 209120 (*7*, *35*), taken as reference, to protect DNA (*36*). Same results have been previously found for the lipopolythiourea DTTU (*21*).

The same experiment performed with compound **18c** in 50% serum showed the ability for this lipid, as compared to free DNA, to partially protect DNA in these drastic conditions (data not shown). These data indicate that DNA is partly protected from degradation in serum-containing medium when associated to LPT. This favors the hypothesis of a strong interaction between LPT and DNA that might be mediated not only by the thiourea/phosphate interaction but also by the overall supramolecular lipid structure. These data may also suggest that the LPT−DNA complexes allow accessibility to small molecules like picogreen, but not to large ones, like DNases.

In Vitro Transfection Efficiency. We evaluated the lipids in vitro as a preliminary study for in vivo experiments. In this context, all lipids were tested in serum-containing media, which

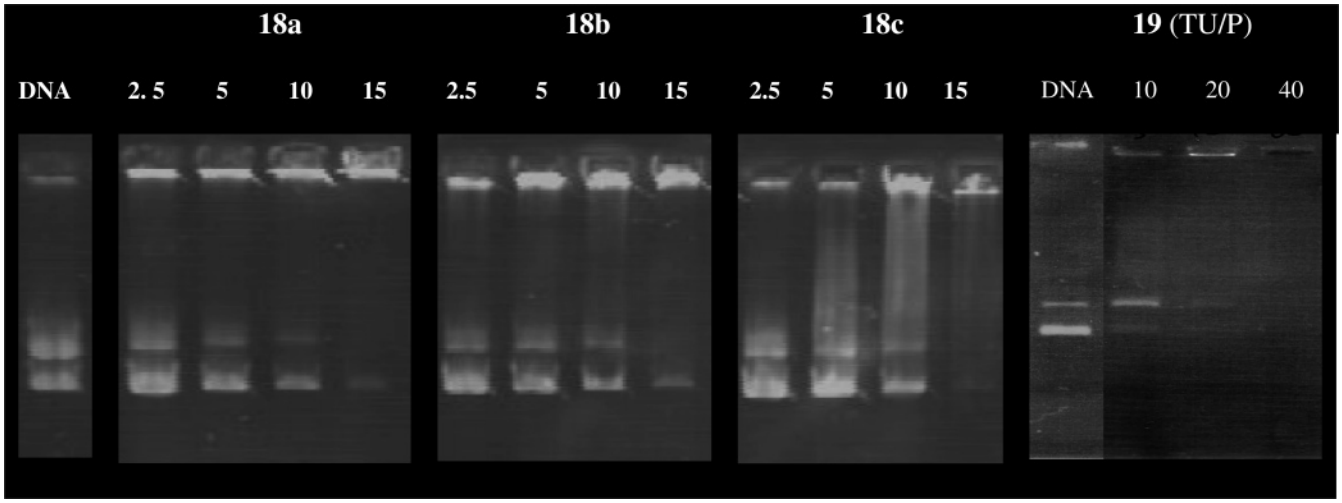

Figure 2. Migration of LPT/DNA complexes (**18a**, **18b**, **18c**, left; **19**, right) on a 0.8% agarose gel in TBE (1×). Complexes were revealed with ethidium bromide staining. From left to right, the lanes correspond to 2.5, 5, 10, and 15 TU/P.

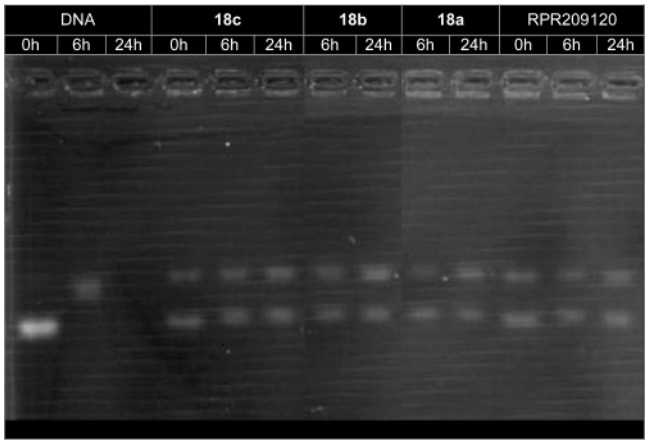

Figure 3. Complexes LPT/DNA (TU/P = 40) were incubated for 0, 6, or 24 h in 10% serum at 37 °C, then treated with SDS 2% and EDTA 0.5 M and loaded on an 1% agarose gel containing in TBE (1×) 0.05% SDS for electrophoresis (80 V/cm).

appears more appropriate (*37*). The lipopolythiourea transfection efficiency was tested on B16 cells at various TU/P ratios. The transfection efficiency of the LPT was compared to those of the cationic lipid and PEI (*38*). Results are presented in Figure 4 as well as the complex size, which might influence the result. Indeed, cationic complexes exhibit higher transfection capacity in serum when precipitated (*39*). Thus, PEI was formulated in NaCl and taken as a positive control. Although lipopolythiourea **18a** showed a poor transfection activity, compounds **18b** and **18c** led to a more significant transfection level. They proved to be comparable to the efficiency of the cationic systems of nanometric scales in these conditions, in particular, the lipoplex RPR209120/DNA, which exhibited a similar size as compared to LPT−DNA complexes. In addition, the transfection level was found to be dose-dependent. Furthermore, LPT **19** displayed the same activity as LPT **18c** with the same hydrophobic anchor. Thus, the length of the chain appeared to be decisive for transfection activity.

In Vivo Transfection Efficiency. Interestingly, intratumoral injection of the more efficient compounds as selected by in vitro experiments showed good transfection ability in vivo as compared to the lipopolyamine RPR209120 (Figure 5). No significant difference could be observed between the four samples, meaning that LPT are able to induce gene expression in vivo as well as in this cationic system.

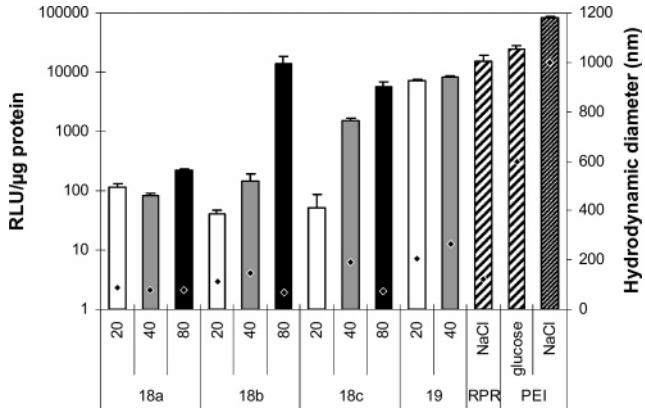

Figure 4. Hydrodynamic diameter (lozenge symbols, right scale) and gene transfection (bars, left scale) measured by luciferase activity of LPT/DNA complexes at 20, 40, and 80 TU/P ratios after 48 h incubation on B16 cells in the presence of serum. LPT/DNA complexes were prepared at 20, 40, and 80 TU/P in H_2O. RPR209120/DOPE/DNA lipoplexes was prepared N/P ratio = 8 in NaCl 150 mM. PEI/DNA polyplexes were prepared at N/P = 15 in glucose 5% or NaCl 150 mM. The complexes were then added to the cells in DMEM + 10% FBS at 37 °C. Results are expressed as the mean of an experiment performed in triplicate errors bars indicating standard error of the mean. Note: **18c** at 20TU/P was found to be precipitated (>1000 nm).

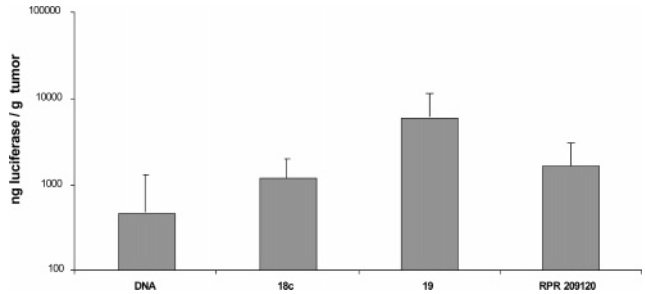

Figure 5. Luciferase activity 24 h after intratumoral injection of **18c**/DNA, **19**/DNA (40 TU/P, 10 μg DNA) and RPR209120/DOPE/DNA (ratio N/P = 5) on three mice previously injected with 3LL carcinoma cells.

CONCLUSION

The presented lipopolythioureas provided new tools for nucleic acid delivery using nonelectrostatic vectors with a transfection level comparable to cationic systems in serum-containing medium. Lipopolythioureas **18a**, **18b**, **18c**, and **19** can be formulated without the use of colipid, leading to small

stable particles. In addition, these compounds showed efficient interaction with plasmid DNA and can protect it from serum degradation during 24 h. The mechanism of LPT−DNA interaction and transfection is now under investigation.

Zn-protoporphyrin (ZnPP) is a promising candidate for cancer therapy. It is known to inhibit heme-oxygenase-1 (HO-1), resulting in suppressed biliverdin/bilirubin production accompanying lowered antioxidative capacity. As a consequence, a significant suppression of tumor growth in vivo was reported. Recent findings also showed that ZnPP efficiently generated reactive singlet oxygen under illumination of visible light. In the present report, we describe the photosensitizing capabilities of water-soluble polymer conjugates of ZnPP as novel compounds for photodynamic therapy against solid tumors. The polymer conjugation made ZnPP water-soluble, thus possible for injection for its aqueous solution. The cellular uptake and photobiological activity of ZnPP derivatives have been tested using a human T-cell leukemia cell line in vitro and demonstrated most potent phototoxic effects of SMA−ZnPP followed by PEG−ZnPP under aerobic conditions.

INTRODUCTION

Metal protoporphyrins (MePP), e.g., Zn protoporphyrin (ZnPP), exhibit many different interesting properties in terms of cancer treatment. While it is well-known that ZnPP is a strong heme oxygenase-1 (HO-1) inhibitor, it also has photosensitizing properties. It is also known that HO-1 is highly up-regulated in many cancer cells (*1*, *2*). HO-1, also known as the heat shock protein 32 (Hsp 32), is induced by various insults such as oxystress, electromagnetic irradiation (UV and X-ray), and nitric oxide, and it is also up-regulated in the inflammatory tissues; thus, it is an inducible enzyme. HO-1 catalyzes the degradation of heme in the presence of oxygen to liberate biliverdin, iron, and CO. Biliverdin is then converted to bilirubin. The hypothesis is that inhibition of HO-1 would result in the inhibition of bilirubin production, which means that suppression and depletion of HO-1 would make cells more vulnerable to oxystress or radiation, since bilirubin is a very potent antioxidative agent. Thus, such tumor cells treated with an inhibitor of HO-1 (e.g., Zn protoporphyrin) would undergo apoptosis readily (*3*).

On the other hand, ZnPP derivatives are known as efficient photosensitizers (*4*). ZnPP absorbs light in the UV−vis region and in turn changes to the first excited singlet state. In doing so, the molecules undergo intersystem crossing that leads to the population of the long-lived first excited triplet state. From this state, the energy is transferred efficiently to molecular oxygen, and thus reactive singlet molecular oxygen [$^1O_2$] (*5*) is generated, that would induce directly or indirectly cell death.

ZnPP has a very low solubility in water at neutral pH, and hence its practical use would be limited as a pharmaceutical agent. For that reason, a water-soluble form of ZnPP was prepared by conjugating it with a poly(ethylene glycol) (PEG) chain (*6*). As a result, the compound became of a macromolecular nature, i.e., apparent molecular size in solution >70Da. In our earlier studies, it was shown that macromolecules tend to accumulate in solid tumors much more extensively, e.g., a 10−30-fold higher amount than low molecular weight drugs due to unique differences in pathophysiology and architecture of tumor blood vessels, as well as overproduction of various vascular mediators at or near the tumor site that further facilitate vascular permeability. This phenomenon was coined the EPR effect (*7*, *8*). Now, the EPR (enhanced permeability and retention) effect is considered to be the key issue to achieve tumor-selective targeting of macromolecular drugs.

On the other hand, using our more recent micellar technology with poly(styrene−maleic acid) copolymer (SMA), it becomes possible to encapsulate varieties of drugs at very high loading levels, as much as 50% (w/w) in the SMA micelle, which releases free drug in a time-dependent manner, and the micellar form of drugs also exhibits this EPR effect (*9*).

The present study is focused on the comparative investigation of SMA−ZnPP micelles and PEG−ZnPP according to their photodynamic activity in vitro. Until now, an antitumor effect for PEG−ZnPP has been reported only in ref 10. In this earlier study, a hypothetical mechanism of antitumor activity of ZnPP was attributed to the inhibition of HO-1 (that suppresses bilirubin generation), and thus enhancement of vulnerability against oxystress (that derived via the host defense system such as macrophages) was envisaged.

The aim of the present study was to investigate the ability of both compounds (PEG−ZnPP and SMA−ZnPP) for intracellular generation of singlet oxygen, that causes photodynamically induced cell death. We assume that the polymer conjugates would benefit from the EPR effect driven tumor accumulation. In this context, antitumor effect is exerted both by HO-1 inhibition and singlet oxygen generated photodynamic activity. Consequently, the antitumor effect will be exhibited in a highly tumor targeted manner. Thus, it would result in a superior therapeutic effect compared to free ZnPP.

MATERIALS AND METHODS

Preparation of Polymeric Zn-Protoporphyrin. PEG−ZnPP conjugate was prepared by conjugation of succinimidyl PEG

(NOF, Tokyo) to bis(ethylenediamino) protoporphyrin and the chelation of zinc into the porphyrin ring afterward. The detailed method is described in ref 7. Poly(styrene-*co*-maleic acid) (SMA) micelles containing ZnPP were prepared similarly to the SMA−pirarubicin micelles as reported previously (*10*, *11*).

Absorption Spectra. The absorption spectra were recorded using a commercial spectrophotometer Shimadzu UV-2501 PC at room temperature. The spectrum of free ZnPP was measured after dissolving it in ethanol. Spectra of PEG−ZnPP and SMA−ZnPP were taken after dissolving in H_2O.

Time-Resolved Singlet Oxygen Luminescence Measurement. Measurements were carried out using a nanosecond Nd:YAG laser (BM Industries, Evry Cedex, France) with an attached optical parametric oscillator (BMI). The singlet oxygen emission was detected using a liquid nitrogen cooled Ge-diode (North Coast, Inc., Santa Rosa, CA). For wavelength selection, a combination of a silicon filter and an interference filter for 1270 nm was placed in front of the diode (*12*). PEG−ZnPP and SMA−ZnPP were dissolved in D_2O. The optical density was adjusted to 0.2 at the excitation wavelength of 550 nm. Rose Bengal served as a reference standard for the determination of singlet oxygen quantum yield ($Q_\Delta = 0.75$) (*13*).

Laser Flash Photolysis. The same equipment as described before was used to excite the samples for triplet−triplet absorption measurements. A continuous wave (cw) test beam was generated using an XBO lamp with the light passed through a monochromator adjusted to 480 nm. The beam traversed through the PEG− and SMA−ZnPP solutions perpendicular to the excitation beam and was detected by an avalanche Si-photodiode with an interference filter for 480 nm. Oxygen was removed by bubbling the samples with N_2 gas for approximately 40 min at room temperature (*14*).

Cell Culture and Incubation Conditions. A T-cell line of human T-lymphocytes (Jurkat cells: clone E 6−1 ATCC, human acute T-cell leukemia) were cultured in 5 mL of RPMI 1640 medium containing Glutamax-I, supplemented with 10% fetal calf serum (FCS), 100 μg/mL streptomycin, and 100 I.E./mL penicillin in 50 mL flasks. Cells were cultured at 37 °C in 100% humidity and 5% CO_2 and subcultured in new medium every 3 days. PEG−ZnPP and SMA−ZnPP were dissolved in PBS. Water-insoluble free ZnPP was dissolved in 0.1 M NaOH. Jurkat cells (2×10^5 cells/mL) were incubated in medium with four different Zn-protoporphyrin concentrations at (0.5, 1.0, 2.5, and 5 μM). All reported concentrations refer to free Zn-protoporphyrin equivalents. Cells without the studied compounds were irradiated with UVA (R/UVA) or kept in the dark (R/D) and used as a reference standard.

Intracellular Uptake. The amount of sensitizer uptaken by Jurkat cells was determined by measuring the fluorescence intensity of cell extracts. Cells were harvested 24 h after incubation, washed twice, and counted using a hemocytometer (Neubauer improved). The cell pellets were stored at −20 °C. Cells were then thawed, and the sensitizer was extracted after centrifugation using ethanol. The fluorescence intensity of cell extracts was measured with a fluorescence microplate reader Gemini EM (Molecular Devices, Germany), using $\lambda_{exc} = 420$ nm and $\lambda_{em} > 650$ nm. Concentration of the sensitizers in the cell extracts was quantified by fluorescence intensity relative to standard curves after disintegration with ethanol in the case of SMA−ZnPP.

UVA Irradiation of Cell Suspensions. Jurkat cells were washed, resuspended in PBS, and placed in a 24-well plate and covered with a quartz glass. A fluorescence lamp (type TLK 40 W, Philips) was used with 99.58% emission in the UVA region (315 and 400 nm) and 0.42% emission in the spectral range below 315 nm. The culture plate was placed under the lamp at 4 cm distance, and cells were irradiated for 5 min. At these conditions, the irradiation received by the cells in the UVA range was 10.68 W/m^2, and the received UVA dose was 0.3 J/cm^2.

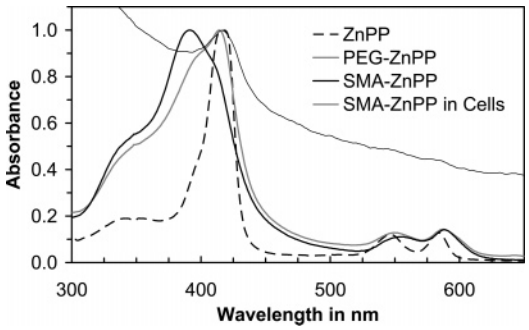

Figure 1. Normalized absorption spectra of PEG−ZnPP (solid gray line) and SMA−ZnPP (solid black line) in H_2O. The absorption of SMA−ZnPP in Jurkat cells (thin black line) exhibits a strong background due to light scattering by the cells. For comparison, the spectrum of ZnPP in ethanol is shown (dashed line).

Cell Survival after UVA Irradiation. The phototoxicity induced by PEG−ZnPP and SMA−ZnPP on Jurkat cells was determined by the XTT test (Roche Diagnostics GmbH, Mannheim, Germany). The assay is based on the conversion of the yellow tetrazolium salt XTT into an orange formazan dye by dehydrogenase in metabolically active cells, which was quantified by absorbance at 492 nm. The reference wavelength was at 650 nm, and the percentage of cell survival was determined as follows: (OD_{sample}/OD_{dark} reference) × 100 (bars; ± standard deviation, $n = 3$).

Caspase 3/7 Activity. Apoptosis was assessed using a fluorimetric assay kit (Apo-ONE Homogeneous Caspase-3/7 Assay, Promega GmbH, Germany), based on caspase 3/7 substrate (Z-DEVD-R110) as a profluorescent substrate. The cleavage and removal of the DEVD peptide by caspase 3 and 7 gives free rhodamine 110 of which the fluorescence intensity is proportional to caspase 3/7 activity. The fluorescence intensity was measured with a fluorescence microplate reader Gemini EM (Molecular Devices, Germany), using $\lambda_{exc} = 485$ nm and $\lambda_{em} > 530$ nm. Cells incubated with 1.5 μM staurosporine (St) at 37 °C were used as a positive control of apoptotic cell death. Caspase 3/7 activity was detected 3−4 h after irradiation. The caspase 3/7 activity of the samples is expressed as a percentage of the positive control values 4 h after stimulation (bars; ± standard deviation, $n = 3$).

RESULTS

In the present study, the photophysical parameters relevant for PDT of two different water-soluble polymeric forms of Zn protoporphyrin (ZnPP), poly(ethylene glycol)-conjugated ZnPP (PEG−ZnPP), and styrene−maleic acid copolymer micelles containing ZnPP (SMA−ZnPP) were compared, and their photodynamic activity was investigated in vitro in comparison with free ZnPP.

Absorption Spectra. The absorption spectrum of free ZnPP resembles that of metal-containing tetrapyrroles consisting of the Soret band and the two Q-band transitions with lower transition dipole moments and therefore lower absorbance (see Figure 1). The Soret band of PEG−ZnPP centered at 414 nm exhibits a hypsochromic shift by about 4 nm compared to that of ZnPP. For SMA−ZnPP, the blue shift is much stronger, about 27 nm. The Q-bands of PEG−ZnPP and SMA−ZnPP are red-shifted by about 3 nm with respect to ZnPP. Moreover, every absorption band is broadened. In the case of SMA−ZnPP, the spectrum is a result of aggregation of many ZnPP molecules, which are tightly enclosed, in the hydrophobic inner core of the micelles. The appearance of spectral shifts may be due to

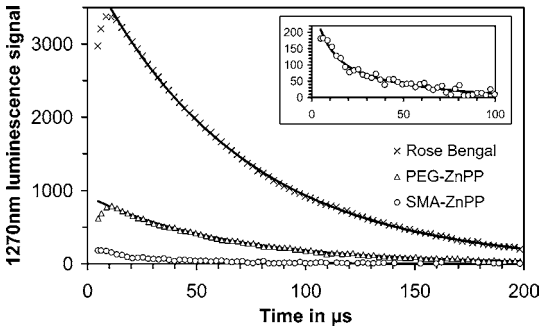

Figure 2. Time-resolved singlet oxygen emission in D_2O photosensitized by PEG−ZnPP and SMA−ZnPP. (Reference: Rose bengal) Inset: Magnification of the two-exponential kinetics of the singlet oxygen emission photosensitized by SMA−ZnPP.

interactions between individual dye (ZnPP) and styrene ring molecules. The absorption spectrum of SMA−ZnPP in Jurkat cells suspended in PBS buffered solution is an overlay of the free ZnPP absorption and a scattering background caused by the cells. Although the Q-band of ZnPP in cells treated with SMA−ZnPP cannot be clearly identified due to the low concentration of the drug in the cells, the peak of the Soret band is now located at the same wavelength as for free ZnPP seen in ethanol. From this observation, it can be concluded that the SMA micelles release free ZnPP molecules from their inner cores after being internalized by the Jurkat cells.

For PEG−ZnPP macromolecules, the situation is quite different. The red shift of the Q-band is less pronounced and is regarded as a result of the covalent attachment of the PEG chain. Attachment of PEG chain to ZnPP does not hinder relatively free rotational and vibronic motion, which corresponds to the observed broadening of the absorption spectrum, a good contrast to SMA−ZnPP.

Singlet Oxygen Measurements. It was found that PEG−ZnPP in D_2O generates singlet molecular oxygen [$^1O_2$] with a quantum yield of 17%; the lifetime was determined to be 61 μs. The last value matches the well-known lifetime of $^1O_2$ in D_2O of 60 μs (*15*). Therefore, the PEG chain does not wrap the ZnPP molecule closely enough to cause efficient quenching of singlet molecular oxygen being generated. In contrast to PEG−ZnPP, the singlet oxygen generation in the case of SMA−ZnPP is very low, and the emission decay shows a two-exponential behavior with lifetimes of 8 μs and 50 μs (see Figure 2). The longer component of the emission is attributed to singlet oxygen, which diffused out of the micelle into the D_2O environment. The shorter lifetime corresponds to singlet oxygen, which is quenched by the densely packed photosensitizer molecules within the micelle and/or the micelle-building polymers. The quantum yield of singlet oxygen generation for SMA−ZnPP was determined to be 5%.

Laser Flash Photolysis. Because of the very short lifetime of singlet oxygen in viable cells, it is very hard to follow its generation via luminescence detection directly. For this reason, we used the method of laser flash photolysis for indirect determination of singlet oxygen formation via triplet lifetime measurement. This is possible because the triplet lifetimes can be related to the singlet oxygen generation. After activation of the first excited singlet state S_1 via light absorption, a part of the molecules undergo transition to the first excited triplet state T_1 with a quantum yield Φ_T. Some of the molecules in the T_1 state are deactivated via phosphorescence (k_{phos}) or nonradiative (k_{nonrad}) transition. The fraction deactivated via interaction with molecular oxygen is referred to as f_T. The energy transfer to molecular oxygen resulting in the generation of singlet molecular oxygen is described by the yield S_Δ. For tetrapyrroles under normal air conditions, this value is nearly unity. Therefore, the

Table 1. First Excited Triplet-State Lifetimes (τ_T) of the Photosensitizers Obtained by Laser Flash Photolysis and Measured Singlet Oxygen Quantum Yield in H_2O

sample	τ_T [μs] under normal air conditions	τ_T [μs] after 40 min N_2 flushing	singlet oxygen quantum yield Φ_Δ
PEG−ZnPP in H_2O	2.5 (±0.2) μs	406 (±40) μs	0.17
PEG−ZnPP in JCS[a]	27 (±3) μs	325 (±30) μs	
SMA−ZnPP in H_2O	1.4 (±0.2) μs	484 (±40) μs	0.05
SMA−ZnPP in JCS[a]	2.4 (±0.2) μs	92 (±11) μs, 1.2 (±0.1) ms	

[a] Jurkat cell suspensions.

singlet oxygen quantum yield (Φ_Δ) can be calculated using the relation

$$\Phi_\Delta = \Phi_T \cdot f_T \cdot S_\Delta = \Phi_T \cdot \left(\frac{k_{O_2}[O_2]}{k_{phos} + k_{nonrad} + k_{O_2}[O_2]} \right) \cdot S_\Delta$$

The triplet lifetime in the presence of oxygen τ_{O_2} is given by $\tau_{O_2} = (k_{phos} + k_{nonrad} + k_{O_2}[O_2])^{-1}$. Bubbling the solution with N_2 removes oxygen and leads to an increase of the triplet lifetime. In this case, the lifetime is calculated by $\tau_{N_2} = (k_{phos} + k_{nonrad})^{-1}$. The value of the singlet oxygen quantum yield can be obtained finally by

$$\Phi_\Delta = \Phi_T \cdot \left(\frac{\tau_{N_2} - \tau_{O_2}}{\tau_{N_2}} \right) \cdot S_\Delta$$

That means that for the calculation of Φ_Δ the value of Φ_T must be known. For ZnPP in ethanol, a high Φ_T value of 0.9 was reported (*16*). In the case of SMA−ZnPP in H_2O, the aforementioned aggregate formation of ZnPP molecules located in the micellar core causes a strong decrease of the triplet quantum yield Φ_T. In cells, the free ZnPP molecules are—at least partly—released from the micelle, and because of the unknown influence of the cellular environment on the aggregation of these molecules, Φ_T is also not known. Therefore, very efficient quenching processes make it difficult to obtain the quantum yield of singlet oxygen generation in cells. On the other hand, because of the fact that S_Δ of tetrapyrroles is about 1, the triplet lifetimes measured in air-liberated and deoxygenated solutions and cell suspensions provide information on the efficiency of such dyes to generate singlet molecular oxygen. For this reason, laser flash experiments were used to compare PEG−ZnPP and SMA−ZnPP according to their ability to generate singlet oxygen.

In the presence of oxygen, the triplet lifetime of PEG−ZnPP in H_2O was measured to $\tau_T = 2.5$ μs and the lifetime of SMA−ZnPP was $\tau_T = 1.4$ μs (Table 1). In an environment with low pO_2, the triplet lifetime of the compounds dissolved in H_2O increased to 406 μs (PEG−ZnPP) and 484 μs (SMA−ZnPP) as seen in Table 1.

In comparison to these findings, the triplet-state lifetime of the two compounds accumulated in Jurkat cells under normal air conditions (aerobic) and under nitrogen (N_2) bubbling of the cell suspensions were investigated. Under normal aerobic conditions, triplet lifetimes of 27 μs (PEG−ZnPP) and 2.4 μs (SMA−ZnPP) were measured (Figure 3). In the case of PEG−ZnPP, the larger value indicates an accumulation in cellular compartments with lower oxygen concentration or a lowered diffusion rate of reactants in regions with higher viscosity (*17*), although the latter possibility is more likely in this case.

For PEG−ZnPP in cells after 40 min N_2 flushing (removing of O_2), a triplet lifetime of 325 μs was obtained (Figure 4) and a bleaching of the triplet state occurred. This can be concluded from the fact that the induced absorbance does not approach

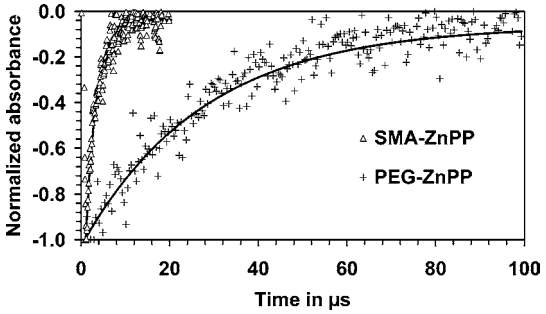

Figure 3. Laser flash photolysis of SMA−ZnPP and PEG−ZnPP in Jurkat cells under normal air conditions. For SMA−ZnPP, the triplet lifetime was obtained to 2.4 μs, whereas for PEG−ZnPP, the fit yielded a value of 27 μs.

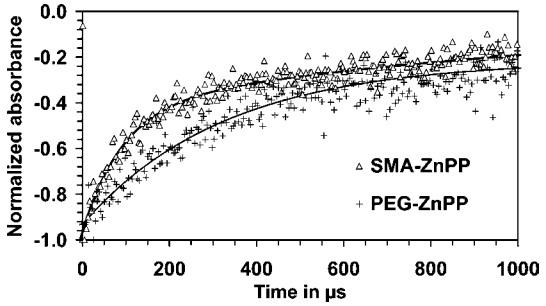

Figure 4. Laser flash photolysis of PEG−ZnPP and SMA−ZnPP in Jurkat cells after 40 min N_2 flushing. The removal of oxygen leads to an increase of the triplet lifetime. The triplet lifetime of PEG−ZnPP was determined to be 325 μs. For SMA−ZnPP, a two-exponential decay was observed consisting of a short component with 92 μs and a long one with approximately 1.2 ms.

the value before excitation. This can be treated as an indication for a chemical change of the photosensitizer, whereas an additional long-lived species could not be identified. The triplet lifetime of PEG−ZnPP is in the range of the value measured in aqueous solution. On the basis of these findings, we suggest that PEG−ZnPP is preserved primarily in its monomeric water-soluble form in cells. It generates singlet oxygen under illumination in cells but with a lower quantum yield than in aqueous solution. The interpretation is consistent with the results obtained from in vitro experiments described below.

For SMA−ZnPP after 40 min N_2 bubbling, a two-exponential triplet decay was observed. The short component with 127 μs is significantly lower than the lifetime in H_2O with oxygen removed. Such a strong reduction of the triplet lifetime may result from close association of the released ZnPP molecules. This type of situation occurs in hydrophobic environments like the lipid bilayer of cell membranes. Similar findings were reported in refs 17 and 18. This effect is due to weak interaction at high local concentrations of the photosensitizer and has to be distinguished from the aggregation of ZnPP observed in the core of SMA micelles. The latter case leads to a strong fluorescence suppression which was observed for SMA−anthracycline micelles (doxorubicin and pirarubicin) as reported previously (*10*, *11*). The longer component of the triplet decay with 1.2 ms is attributed to a bleaching process probably resulting in the formation of long-lived radicals. For SMA−ZnPP in cells, either singlet oxygen mediated phototoxicity (type II) or a free radical destruction mechanism (type I) under low oxygen concentration may occur. This result may reflect its biological effect.

Photodynamic Activity and Cell Killing. First, the intracellular uptake of the two polymeric compounds by Jurkat cells was studied in comparison with free ZnPP at different incubation concentrations (Figure 5). The intracellular uptake of the compounds increased in parallel with the concentration of the

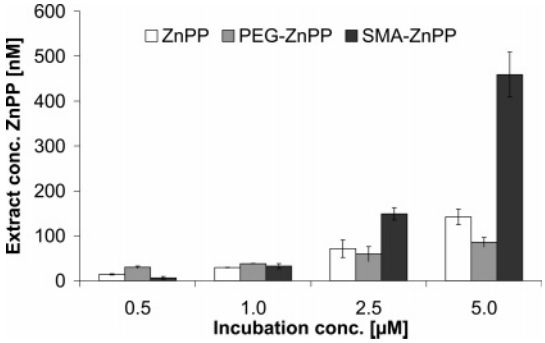

Figure 5. Intracellular uptake of sensitizers by Jurkat cells. Cells were incubated with the investigated compounds at different concentrations (expressed in ZnPP equivalents). The amount of sensitizer uptaken by Jurkat cells was determined by measuring the fluorescence intensity of cell extracts as described in Materials and Methods.

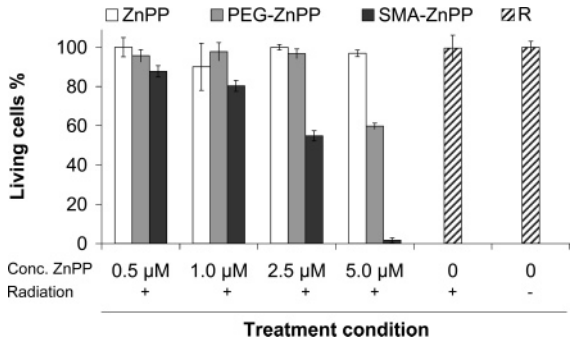

Figure 6. Phototoxicity against Jurkat cells of ZnPP, PEG−ZnPP, and SMA−ZnPP. Cell survival 24 h after irradiation (radiation, +) was measured using the XTT test. Two references (R, streaked bar) were used: cells without test compounds and kept in the dark (radiation, −) and those with radiation at the same dose of UVA.

compounds in the incubation suspension. SMA−ZnPP reached higher intracellular concentrations than PEG−ZnPP and free ZnPP (in terms of ZnPP equivalents). At an incubation concentration of 5 μM, the intracellular concentration of SMA−ZnPP was approximately 5.4 times higher than that of PEG−ZnPP and more than 3.2 times higher than that of free ZnPP. This data can be explained by the fact that the molecular concentration of ZnPP in SMA micelles is much higher (loading of >40% by weight), whereas its content in PEG−ZnPP is about 5%. Both will be internalized by endocytosis.

To investigate the photocytotoxicity of PEG−ZnPP and SMA−ZnPP in comparison with that of free ZnPP, Jurkat cells were incubated for 24 h with different concentrations of the compounds and irradiated at dose of 0.3 J/cm^2 of UVA. Cellular viabilities were estimated by XTT assay 24 h after irradiation. Less than 5% of the reference cells lost their viability after UVA exposure (Figures 6 and 7). No cytotoxic activity by ZnPP without UVA exposure alone may indicate that HO-1 inhibition does not show a significant effect at this dose range (Figure 6), although more oxystressed systems may prove this possibility in vivo. Free ZnPP does not demonstrate a phototoxic effect under illumination. As shown in Figures 6 and 7, significantly enhanced phototoxicity was observed for SMA−ZnPP at incubation concentrations higher than 1 μM. The phototoxicity increased in a concentration-dependent manner with LD_{50} of about 2.5 μM. PEG−ZnPP exerted significant phototoxic activity only at concentration of 5 μM under UVA irradiation (Figure 6).

Caspase 3 and 7 activities were measured 4 h after irradiation to answer the question regarding which cell death mechanism is induced by the uptake of ZnPP (Figure 7). Caspase 3 and 7 activity was detected when treated with both ZnPP compounds,

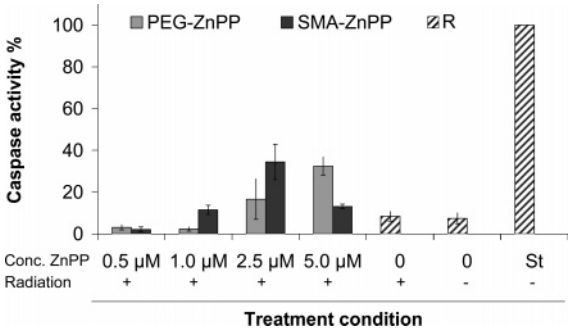

Figure 7. Photoinduction of caspase 3/7 activity on Jurkat cells. Two references (R) were used: cells without test compounds in the dark (radiation, −) and those with radiation at the same dose of UVA (radiation, +). Cells incubated for 4 h with 1.5 μM staurosporine (St) were used as a positive control for caspase activity.

even if only a low percentage of activity (about 30% of the positive control) could be measured and only at concentrations of 5 μM for PEG−ZnPP and 2.5 μM for SMA−ZnPP.

At an incubation concentration of 5 μM, only a low level of caspase activity was measured for SMA−ZnPP, whereas almost no living cells were detected with the XTT test. Thus, the caspases might have already released out of the cells. In concordance with this notion, all these cells showed Trypan blue positive staining (data not shown), indicating disruption of the integrity of cell membrane. These observations showed that cells had also undergone a necrotic cell death pathway to a considerable extent. Namely, cell viability was approximately 60% after irradiation of the cells incubated with 5 μM PEG−ZnPP, and the measurements of caspase 3 and 7 activities showed that approximately 30% of dead cells were caused by an apoptotic mechanism. These results show that SMA−ZnPP is able to initiate cell death via necrosis at higher concentrations, while PEG−ZnPP is mainly inducing the apoptotic cell death pathway.

DISCUSSION

Our experimental results obtained from in vitro studies on Jurkat cell suspensions show that both SMA−ZnPP and PEG−ZnPP exhibit photodynamic activity. SMA−ZnPP causes about five times higher phototoxicity compared to PEG−ZnPP due to the higher uptake of ZnPP by tumor cells. This fact clearly demonstrates the advantage of SMA−ZnPP over PEG−ZnPP for photodynamic therapy. In this context, the polymeric form of ZnPP is better than free ZnPP in addition to its increased water solubility.

The SMA micelle acts as a macromolecular encapsulating container for ZnPP with densely packed ZnPP molecules; it thereby seems to prevent the efficient formation of singlet oxygen to a considerable extent before delivery to tumor cells. Such dense packing of ZnPP would lead to a strong decrease of the triplet quantum yield of the photosensitizer molecules outside of cells. After incorporation into the cells via endocytosis, the SMA micelles release free ZnPP molecules in lysosomal compartments or tend to accumulate in lipophilic regions in the cells at high concentrations. The destruction of the cell membranes under UVA illumination was envisaged, as they became Trypan blue positive, indicative of a necrotic cell death pathway. The phototoxicity of SMA−ZnPP is based primarily on the generation of singlet oxygen, but probably long-lived radicals are formed additionally, especially in the case of lowered oxygen concentration, such as the lipid peroxiradical (ROO$^{\bullet}$) that can also cause DNA breakage and other damage (*19*).

Free ZnPP showed some uptake in the cells (Figure 5) though no cytotoxicity (Figure 6); this may be an arguable point that quantification of ZnPP by fluorometry after ethanol extraction would dismiss the difference of the localization of ZnPP, i.e., one bound on a cell membrane (lipid bilayer) versus endocytotic vesicle (upon endocytosis of SMA−ZnPP). Thus, free ZnPP-treated cells may not contain real intracellular ZnPP.

The comparative study of PEG−ZnPP and SMA−ZnPP shows the possibility of development of more efficient drug delivery systems for photodynamic therapy using macromolecular drug carrier systems such as SMA micelles, which exhibit tumor-selective delivery via the EPR effect, which is far better than free ZnPP or low molecular weight drugs. Moreover, by using these "intelligent" SMA micelles as a carrier system proposed in this paper, it will be possible to make a more efficient delivery system without toxicity in general. The photodynamic activity will be ideal for superficial tumors where light can penetrate, whereas on the other parts of the body, it may work by HO-1 inhibition (Hsp-32), which is considered to be one of the survival proteins of tumor cells.

In addition to the comments of polymeric ZnPP in view of singlet oxygen generation, recent reports show that Zn or ZnPP can affect the signal transduction system involving down-regulation of the oncogene on chronic myelogenous leukemic cells (*20*) or Zn transporter-mediated cytokine modulation (e.g., IL-6, etc.) (*21*). These could be the other alternative mechanisms to the EPR effect/HO-1 inhibition/increased ROS sensitivity in understanding the multiple effects after SMA−ZnPP uptake.

ACKNOWLEDGMENT

The technical assistance of Gisela Wöhlecke and the support of Anneliese Powitz, and Arun Iyer for preparing SMA micelles are greatly appreciated. H.M. thanks the Ministry of Education, Science, Culture and Sports for the Cancer Research Grant for 2005−2010. F.R. and F.B. thank the DFG for financial support (BO 1353/2−2). K.G. thanks JSPS for supporting his research in Japan.

Site-Specific PEGylation for High-Yield Preparation of Lys^{21}-Amine PEGylated Growth Hormone-Releasing Factor (GRF) (1−29) using a GRF(1−29) Derivative FMOC-Protected at Tyr^1 and Lys^{12}

Yu Seok Youn and Kang Choon Lee*

Drug Targeting Laboratory, College of Pharmacy, SungKyunKwan University, 300 Chonchon-dong, Jangan-ku, Suwon City 440-746, Korea. Received June 18, 2006; Revised Manuscript Received October 23, 2006

PEGylation has been viewed as an effective means of overcoming the therapeutic restriction of growth hormone-releasing factor (1−29) (GRF(1−29)) due to its short biological lifetime caused by severe proteolysis and rapid glomerular filtration. Of three isomers according to the PEGylation sites (Tyr^1, Lys^{12}, or Lys^{21}), PEGylated GRF-(1−29) at Lys^{21}-amine (Lys^{21}-PEG-GRF(1−29)) was shown to have the highest bioactivity. In this report, we propose a unique two-step site-specific PEGylation method capable of producing only Lys^{21}-PEG-GRF(1−29) with a single composition in high yield using a GRF(1−29) derivative protected at Tyr^1 and Lys^{12} and remained available at Lys^{21} ($FMOC^{1,12}$-GRF(1−29)). The first step of this reaction involved the PEG attachment to $FMOC^{1,12}$-GRF(1−29), and the second step involved the removal of FMOC moieties. This PEGylation process was optimized at the following conditions: 0.2−0.3% (v/v) triethylamine concentration, 5.0−6.0-fold molar amount of PEG, reaction temperature of 25−45 °C, and reaction time of 30 min. Under these conditions, the maximum yield of Lys^{21}-PEG-GRF(1−29) produced was ca. ∼95%, 6.3-fold higher than that by nonspecific PEGylation at pH 8.5. Significantly, this site-specific Lys^{21}-PEG-GRF(1−29) was found to have greatly increased resistance to rat plasma, liver, and kidney homogenates, with 7.0-, 25.4-, and 16.4-fold longer half-lives vs GRF(1−29), respectively. Furthermore, ^{125}I-Lys^{21}-PEG-GRF(1−29) displayed significantly reduced liver and kidney distributions and extended blood presence vs ^{125}I-GRF(1−29) in rats. Due to these benefits, Lys^{21}-PEG-GRF(1−29) displayed an enhanced initial growth hormone release in vivo despite having 15% remaining activity in vitro. This devised PEGylation method using an FMOC-protection/deprotection strategy would provide great usefulness for PEGylating bioactive peptides in terms of improved biological potency, elevated production yield, and a uniform composition.

INTRODUCTION

Growth hormone-releasing factor (GRF) is attracting growing interest because it acts as an alternative treatment to growth hormone (GH) (*1*). GRF has two beneficial therapeutic issues vs GH: first, it induces physiological GH-release mimicking the natural pattern; and second, it can be administered via non-parenteral routes (*2*−*3*) due to its small molecular size. Upon release into the circulation, however, GRF(1−29), the shortest and fully active form of GRF, is rapidly inactivated by proteolysis of dipeptidyl peptidase IV (DPP IV) (*4*) and glomerular filtration, with a short plasma half-life of 10−20 min (*5*). Accordingly, studies previously undertaken on this topic have highlighted the importance of a longer-acting GRF(1−29), and thus PEGylation has been considered to present a means of circumventing these clinical limitations by retarding the rapid turnover (*6*−*7*).

PEGylation, defined as a chemical modification with polyethylene glycol (PEG), improves therapeutic potentials of peptides and proteins by increasing proteolytic resistance, diminishing glomerular filtration, and, thus, extending biological half-life (*8*−*11*). In particular, PEGylated peptides and proteins have been shown to decrease proteolytic sensitivities due to increased steric hindrance (*12*−*14*). PEGylation of a DPP IV-sensitive peptide was found to greatly increase its resistance to this peptidase using this mechanism (*15*−*16*). Similarly, PEGylated GRF(1−29) showed a sustained in vivo GH releasing potency despite a decreased in vitro bioactivity (*6*−*7*).

The relationship between PEGylation site and bioactivity in GRF(1−29) analogs has been studied (*6*, *17*−*18*). The N-terminus region of GRF(1−29) is known to be where receptor binding takes place (*6*). In actuality, both N^{α}(Tyr^1)- and Lys^{12}-PEG_{5K}-[Ala^{15}]-GRF(1−29) analogs were found to have significantly lower bioactivities than its original species (*6*, *17*). On the contrary, PEGylation of GRF(1−29) at Lys^{21}-amine well preserved its bioactivity, tenfold higher than that at Lys^{12}-amine (*6*). Accordingly, it has been required to achieve a site-dependent PEGylation as a key consideration for its biological activity issue. Felix and co-workers developed a solid-phase PEGylation method capable of incorporating PEG into target amino acids (Tyr^1, Lys^{12}, Asp^8, Lys^{21}, or Asp^{25}) during the course of solid-phase peptide synthesis (*19*−*20*). Separately, Esposito and co-workers optimized a solution-phase Lys (Lys^{12} or Lys^{21})-amine PEGylation method of GRF(1−29) for a large laboratory-scale preparation (*6*, *21*). However, the practical use of these previous methods seems to be significantly restricted: the former accompanies the drawback of limited production because of its total synthesis character, and the latter still does not provide a uniform product because of two different compositions.

Site-specific PEGylation of bioactive peptides can be completely achieved by gaining all required factors in terms of improved therapeutic potential, uniform product composition, and increased production yield. On the basis of this, in the present study, we propose a unique site-specific PEGylation method using an FMOC-protected GRF(1−29) system that enables the high-yield production of Lys^{21}-amine PEGylated

GRF(1−29), which is known as an isomer with the most promising GH releasing potential.

EXPERIMENTAL PROCEDURES

Materials. GRF(1−29) and FMOC-protected GRF(1−29) at Tyr^{1}- and Lys^{12}-amines ($FMOC^{1,12}$-GRF(1−29)) were supplied by A&PEP, Inc. (Wolsan, Korea). Succinimidyl propionate monomethoxy poly(ethylene glycol) (SP-$mPEG_{5K}$, MW 5000) was purchased from Nektar Therapeutics (Huntsville, AL). Rat GH radioimmunoassay (RIA) kits were purchased from Amersham Pharmacia Biotech (Uppsala, Sweden). Male Wistar rats (150−200 g), male SD rats (180−200 g), and male ICR mice (weighing 18−22 g) were purchased from the Hanlim Experimental Animal Laboratory (Seoul). All other reagents used, unless otherwise indicated, were of the highest quality commercially available.

Stability Study of $FMOC^{1,12}$-GRF(1−29) in Various Amine Bases. $FMOC^{1,12}$-GRF(1−29) stability in various amine bases with different concentrations was evaluated. An aliquot (5 μL) from the $FMOC^{1,12}$-GRF(1−29) stock solution (5 mg/mL) was mixed with the same volume of various amine base (diisopropylethylamine, DIEA; triethylamine, TEA; 4-dimethylaminopyridine, DMAP; 2,4,6-trimethylpyridine, colidine; 2,6-dimethylpyridine, lutidine; and pyridine)/dimethyl formamide (DMF) solutions, and then left at room temperature. At predetermined times, reactions were terminated by adding 10 μL of a mixture (10:6) of 1% trifluoroacetic acid (TFA) in acetonitrile (ACN) and DMF. A 10 μL aliquot of the resulting mixture was subjected to reversed-phase high-performance liquid chromatography (RP-HPLC) using a LiChrospher 100 RP-18 column (250 × 4.0, 5 μm, Merck, Germany) at ambient temperature. Gradient elution was carried out at a flow rate of 1.0 mL/min using solvent A (0.1% TFA in deionized water (DW)) and solvent B (0.1% TFA in ACN) and a gradient profile of 35% B to 90% B over 10 min.

Site-Specific PEGylation of GRF(1−29) using $FMOC^{1,12}$-GRF(1−29). Site-specific (Lys^{21}) PEGylation of GRF(1−29) was examined by focusing on the four dominant reaction factors: (i) type of amine base; (ii) TEA concentration; (iii) PEG amount; and (iv) reaction temperature. The first part of this reaction involved the conjugation of $FMOC^{1,12}$-GRF(1−29) with PEG, and the second part involved the removal of FMOC (9-fluorenylmethoxycarbonyl) moieties from PEGylated $FMOC^{1,12}$-GRF(1−29) as described in Scheme 1. Briefly, an aliquot (5 μL) of $FMOC^{1,12}$-GRF(1−29) in DMF (10 mg/mL) was mixed with the same volume of SP-$mPEG_{5K}$ in DMF at different concentrations (1.0−8.0-folds), and reactions were initiated by adding 10 μL of various amine bases/DMF with different concentrations at reaction temperatures ranging from 25 to 65 °C. At predetermined times, FMOC was removed by adding 1 μL of piperidine at room temperature for 20 min. The overall reaction was quenched by adding 20 μL of 50% DW/ACN containing 1% TFA with thorough shaking. The resulting mixtures were analyzed by RP-HPLC (gradient profile: 34% B to 48% B over 20 min). Production yields (%) were expressed as a percentage of the peak area of Lys^{21}-PEG-GRF(1−29) produced vs the peak area of initial GRF(1−29).

Nonspecific PEGylation of GRF(1−29). Conventional nonspecific GRF(1−29) PEGylation was performed, as previously described (*22*). Briefly, 6.0 mg of SP-$mPEG_{5K}$ was added to 1 mL of GRF(1−29) (2 mg/mL) in 50 mM phosphate buffer solutions (pH 6.5, 7.0, 7.5, 8.0, and 8.5) (molar ratio of GRF-

(1−29) to PEG = 1:2). Mixtures were gently shaken at room temperature for 60 min, and reactions were quenched by adjusting the pH to ∼4.0 with phosphoric acid.

Mass Characterization of GRF(1−29) Derivatives and Their Conjugation Sites. GRF(1−29) and its two derivatives together with their conjugation sites were identified using a modification of a previously described MALDI-TOF MS method (*15*, *22*). Briefly, a 5 μL aliquot of endoproteinase Lys-C solution (20 μg/mL in 50 mM Tris-HCl, pH 8.5) was added to a 10 μL of GRF(1−29) derivatives in the same buffer solution (50 μg/mL); digestion was allowed to continue at 37 °C for 30 min. Samples were subjected to MALDI-TOF MS (Voyager-RP Biospectrometry Workstation, PerSeptive Biosystems, Cambridge, MA).

Proteolytic Stability. Proteolytic stabilities of GRF(1−29) and Lys^{21}-PEG-GRF(1−29) were evaluated in rat plasma, liver, and kidney homogenate solutions using a modification of a previously described method (*12*, *23*−*24*). An aliquot (25 μL) of either GRF(1−29) or Lys^{21}-PEG-GRF(1−29) solution (400 μg/mL) was mixed with the same volume of each biological fluid (pre-incubated at 37 °C for 15 min) and then incubated until predetermined times. Incubations were stopped by adding 200 μL of ice-cold methanol. The resulting mixtures were centrifuged at 12 000 rpm for 5 min, and the supernatants were subjected to RP-HPLC (gradient elution: 34% B to 44% B over 20 min, followed by 100% B for 5 min). Degradation half-lives obtained from time vs residual amount curves were calculated by assuming first-order kinetics.

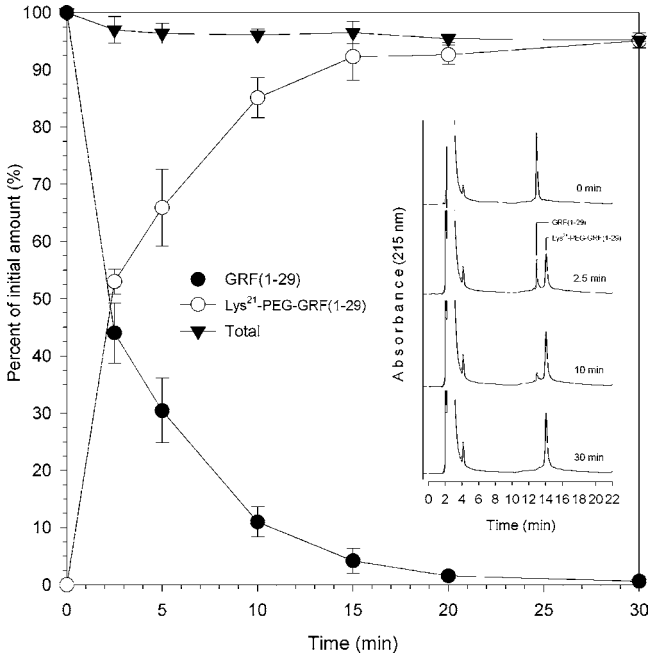

Figure 1. Stoichiometric reaction profiles of Lys^{21}-amine specific PEGylation of GRF(1−29) under optimized conditions, i.e., 0.3% TEA, a 37 °C reaction temperature, and a 5.0-fold PEG molar amount vs GRF(1−29) (inset: RP-HPLC profiles of site-specific PEGylated GRF-(1−29) mixture after FMOC deprotection at each reaction time).

Radioiodination. Radioiodinated GRF(1−29) and Lys^{21}-PEG-GRF(1−29) were prepared using the IODO-GEN method described elsewhere with slight modification (*25*). Briefly, 100 μL of an IODO-GEN (Pierce, Rockford, IL) solution in methylene chloride (1.0 mg/mL) was dispensed into a fresh tube, and the solution was then removed under a nitrogen stream. To such tubes were added 50 μL aliquots of GRF(1−29) or Lys^{21}-PEG-GRF(1−29) (0.4 mg/mL) and 50 μCi of Na^{125}I (Perkin-Elmer, Boston, MA) diluted to 100 mM with PBS (pH 7.0). After allowing reactions at room temperature for 5 min, supernatants were subjected to a C_{18} HPLC column connected to a flow-through radioisotope detector (Ramona 2000, Raytest, Straubenhardt, Germany) (gradient elution: 32% B to 64% B over 20 min). Fractions corresponding to ^{125}I-labeled samples

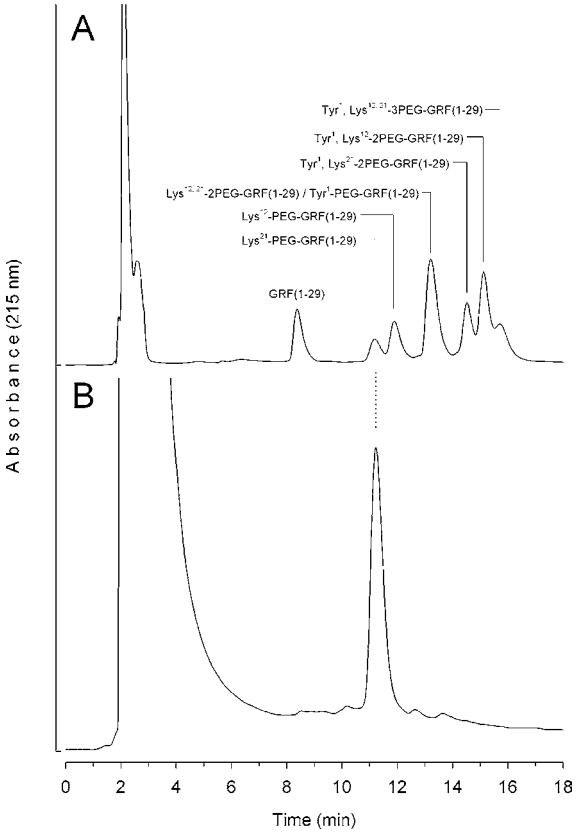

Figure 2. Chromatographic profiles of a conventional non-specific PEGylated GRF(1−29) mixture (A) and of a site-specific PEGylated GRF(1−29) mixture (B). Site-specific PEGylation of GRF(1−29) was achieved at the detailed conditions: 0.3% TEA, a molar ratio of FMOC^{1,12}-GRF(1−29) to PEG = 1:6, a reaction temperature of 37 °C, and a reaction time of 30 min. Nonspecific PEGylation of GRF(1−29) was performed with a 1:2 molar ratio of GRF(1−29) to PEG at pH 7.5 for 60 min.

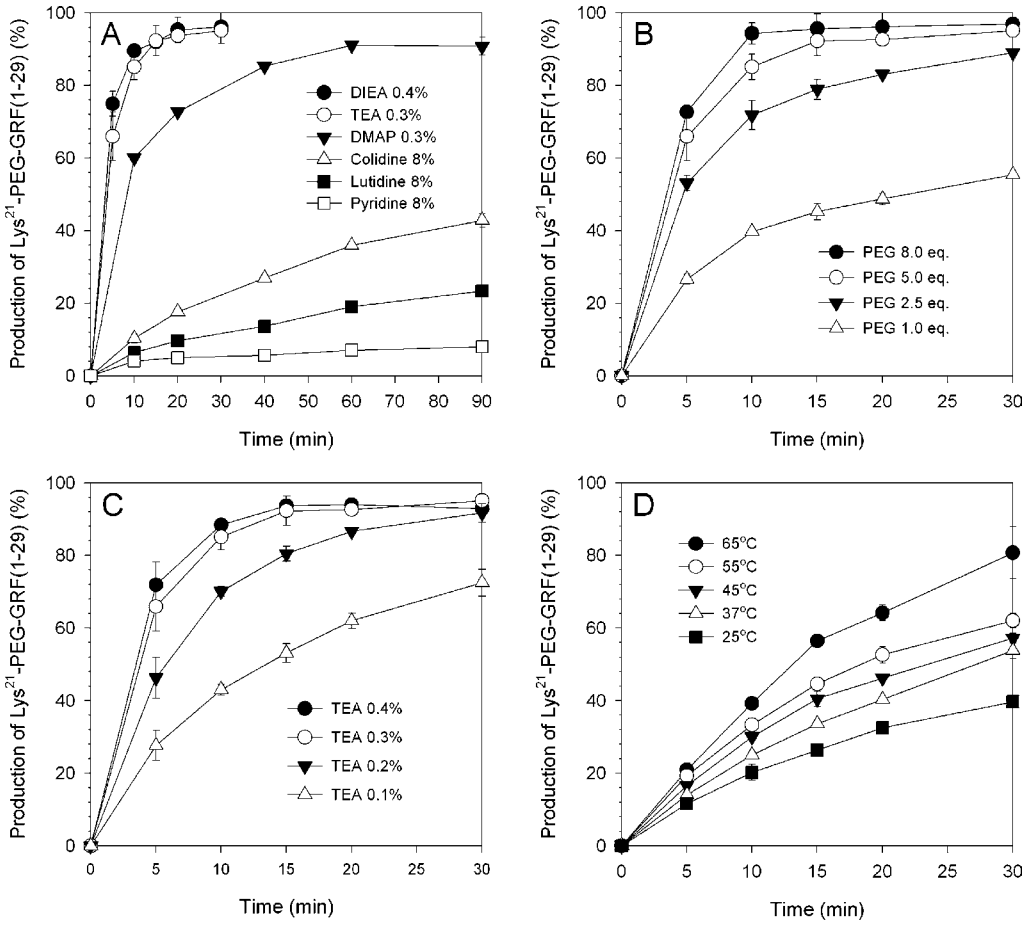

Figure 3. Reaction profiles of site-specific (Lys^{21}) PEGylation of GRF(1−29) according to various reaction factors: (A) type of amine base; (B) molar ratio of $FMOC^{1,12}$-GRF(1−29) to PEG; (C) concentration of TEA; and (D) reaction temperature. Amounts of Lys^{21}-PEG-GRF(1−29) produced were quantified by RP-HPLC, and production yields (%) were expressed as a percentage of the peak area of Lys^{21}-PEG-GRF(1−29) produced vs the peak area of initial GRF(1−29).

were collected, dried under nitrogen, and stored in 10 mM PBS solution (pH 7.4) at 4 °C until required.

Pharmacokinetic Study. Pharmacokinetic dispositions were examined using a modification of a previously described method (*26*). Radioiodinated GRF(1−29) species were administered by subcutaneous (sc) injection (approximately 0.5 μg, 4.1−4.3 × 10^4 cpm) to ICR mice. Mice were sacrificed at predetermined times. Blood samples were obtained by heart puncture, and livers and kidneys were quickly excised and rinsed three times with saline solution. Radioactivities of blood (100 μL) and whole tissue organs were measured by γ-counting (Cobra, Packard Instruments Co., Groningen, The Netherlands). Results were then used to calculate the percentage of injected dose in each organ. In the case of blood, the total blood volume on body weight of ICR mice was assumed to be 70 mL/kg, which is used to calculate the percentage of radioiodinated GRF(1−29) species in whole blood.

In Vitro GH Releasing Activity in Rat Pituitary Cells. Monolayer cultures of anterior pituitary cells obtained from Wistar rats (150−200 g) were performed using a modification of a previously described method (*27*−*28*). Pituitary cells obtained were washed twice with 1 mL of supplemented DMEM and incubated at 37 °C for 30 min. Prior to experimentation, cells were rewashed twice, and the supplemented DMEM medium was replaced with 500 μL of fresh medium containing either GRF(1−29) or Lys^{21}-PEG-GRF(1−29) with different concentrations. The cells were then incubated at 37 °C for 15 min, and media were collected and centrifuged at 10 000 rpm for 10 min. GH concentrations in response to the stimulation of GRF(1−29) species were measured using GH RIA kits (Amersham Pharmacia Biotech, Uppsala, Sweden).

In Vivo GH Releasing Potency in Rats. Male SD rats (180−200 g) were anesthetized (ketamine and xylazine (90/10 mg/kg) i.p.) and cannulated (PE tubing, 0.58 mm i.d., 0.96 mm o.d., Natsume, Tokyo) at the right jugular vein. After a 2 day recovery period, the rats were randomly divided into three groups (4 animals/group), i.e., saline, GRF(1−29), and Lys^{21}-PEG-GRF(1−29). Each sample (100 μg equiv/kg wt) was administered into rats intravenously, and blood samples were collected using the implanted cannulae. Plasma GH levels were measured using GH RIA kits.

RESULTS AND DISCUSSION

Site-specific PEGylation has been considered as an effective way of avoiding the pharmaceutical heterogeneity and pharmacological inefficiency by nonspecific PEGylation, making only biologically necessary PEGylated species (*29*−*31*). Therefore, this enables one to produce the chemically defined PEGylated species with the most bioactivity in terms of uniform composition. Furthermore, if the overall process is robust, site-specific PEGylation can greatly increase the production yield, because it is able to concentrate the reactivity on a single site. On the basis of this concept, we undertook to develop a unique high-yield PEGylation method capable of producing a uniform Lys^{21}-PEG-GRF(1−29) isomer, which has the most preserved bioactivity compared to other isomers.

Initially, we tried to increase the Lys^{21}-amine specificity in GRF(1−29) by either pH control or Lys-amine selectivity in

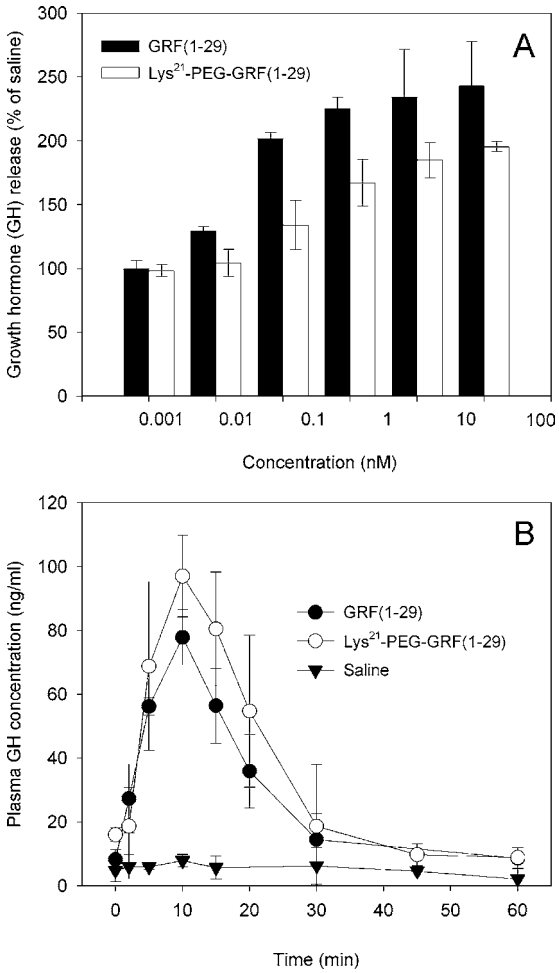

Figure 4. Dose−response curves of GRF(1−29) and Lys^{21}-PEG-GRF(1−29) in terms of stimulated GH release from rat pituitary cells (A). Data were obtained from six individual tests and are presented as means ± SDs. Changes in plasma GH levels following iv administrations of GRF(1−29) and Lys^{21}-PEG-GRF(1−29) (100 μg equiv/kg wt) in rats (B). Data are presented as means ± SDs for four rats/group. AUCs (0−60 min) for GH concentration vs time charts for each group were compared.

the organic phase. However, the Lys^{21}-PEG-GRF(1−29) production seemed to still be restricted by both cases because all GRF(1−29) amines are still open; only 5.3−15.2% (pH 6.5−8.5) and approximately 25% (0.3−1.2% TEA) of Lys^{21}-PEG-GRF(1−29) production were made, respectively (data not shown). Consequently, we confirmed that such methods are ineffective enough for the high-yield preparation of Lys^{21}-PEG-GRF(1−29). Thus, we introduced a unique GRF(1−29) derivative (FMOC^{1,12}-GRF(1−29)), which is FMOC-protected at Tys^{1}- and Lys^{12}-amines but remained available at Lys^{21}-amine.

As summarized in Table 1, this FMOC^{1,12}-GRF(1−29) derivative showed the increased mass of 3803.5 Da by its two FMOC presence (445 Da) vs the observed mass of GRF(1−29) (3358.1 Da). Furthermore, the masses of the Lys-C digested FMOC^{1,12}-GRF(1−29) fragments were determined to be 2845.7 and 974.2 Da, corresponding to the fragments of Tyr^{1}-FMOC−Lys^{12}-FMOC−Lys^{21} (calcd 2846.2) and Leu^{22}-Arg^{29} (calcd 974.2), respectively. These mass spectrometric profiles of FMOC^{1,12}-GRF(1−29) indicated that the FMOC groups are conjugated to the aimed amines (Tyr^{1} and Lys^{12}) of GRF(1−29), and that this protection would provide a much greater opportunity for Lys^{21} amine-specific PEGylation.

Prior to optimizing the site-specific PEGylation process, the stability of the FMOC moiety in FMOC^{1,12}-GRF(1−29) was assessed in DMF solutions containing amine bases. Several amine bases were inevitably added to activate the PEGylation reactivity, because this hydrophobic derivative did not show substitution activity under the aprotic condition of DMF. However, since the amine base addition can result in the potential danger that deteriorates the FMOC^{1,12}-GRF(1−29) integrity because of their strong substitution activity, its chemical stability during the course of PEGylation has become another key consideration for achieving a well-controlled site-specific (Lys^{21}) PEGylation. We tried to investigate the concentration ranges of each amine base for obtaining both good stability and PEGylation reactivity. FMOC stabilities were found to be well-maintained (96.9 ± 0.8% remaining, 37 °C, 90 min) under most conditions, particularly in 0.2−0.4% TEA range with >99.3% remaining over 30 min (Table 2).

On the basis of this stability profile, FMOC^{1,12}-GRF(1−29) could be conjugated with PEG at Lys^{21}-amine without site competition in the presence of various amine bases. After PEGylation, the FMOC moieties were removed via a typical deprotection process using piperidine (5%), and this step did not affect significantly the PEGylation reaction. In this way, Lys^{21}-PEG-GRF(1−29) was two-step produced in high yield using an FMOC protection/deprotection strategy (Scheme 1). Furthermore, this process showed a stoichiometric manner, and thus the amount of FMOC^{1,12}-GRF(1−29) reacted quantitatively matched the amount of Lys^{21}-PEG-GRF(1−29) produced, maintaining the >95.0% level of the total amount (Figure 1). This finding indicates that Lys^{21}-PEG-GRF(1−29) production is completely originated from FMOC^{1,12}-GRF(1−29) without significant side reactions. Figure 2 displays the advantage of this site-specific method in GRF(1−29) PEGylation vs the nonspecific method. The chromatogram of site-specific PEGylated GRF(1−29) mixture shows only Lys^{21}-PEG-GRF(1−29) with trace levels of other products (Figure 2B), whereas a nonspecific PEGylated GRF(1−29) mixture includes a variety of possible isomers of mono-, di-, and tri-PEGylated GRF(1−29)s as reported previously (*22*) (Figure 2A).

The next goal was to determine an optimized reaction condition capable of maximizing the Lys^{21}-PEG-GRF(1−29) production yield. To achieve this, four major reaction factors were examined as follows: (i) type of amine base, (ii) PEG amount (molar ratio of FMOC^{1,12}-GRF(1−29) to PEG), (iii) TEA concentration, and (iv) reaction temperature. First, the type of amine base was considered to be a key factor. As shown in Figure 3A, amine bases of TEA, DIEA, and DMAP displayed effective PEGylation reactivities, whereas other pyridine bases are ineffective (at PEG 5.0 equiv, 37 °C). Despite the similar PEGylation reactivity, we finally chose TEA as a candidate base because it provides an excellent FMOC stability along with a rapid reaction time. Second, the optimum molar ratio of FMOC^{1,12}-GRF(1−29) to PEG was determined to fall in the range of 1:5 to 1:6 (at 0.3% TEA, 37 °C). No significance was observed beyond this range, and no complete reactions occurred below this (Figure 3B). Third, TEA appeared to have good reactivity in the concentration range from 0.2% to 0.4% (v/v) (at PEG 2.5 equiv, 37 °C), but the reactivity was clearly decreased below 0.2% (Figure 3C). Finally, the PEGylation reaction rapidly increased with increasing reaction temperature from 25 to 65 °C (at PEG 1.5 equiv, 0.3% TEA) (Figure 3D). However, the serious instability of the FMOC moiety was observed at reaction temperatures of over 55 °C (data not shown).

Through this careful investigation, the site-specific (Lys^{21}) PEGylation of GRF(1−29) was successfully achieved using the following optimized conditions: 0.2−0.3% TEA, a reaction temperature of 25−45 °C, a reaction time of 30 min, and a 5.0−6.0-fold molar PEG amount. Under this condition, the Lys^{21}-PEG-GRF(1−29) production yield was elevated to ca. 95%,

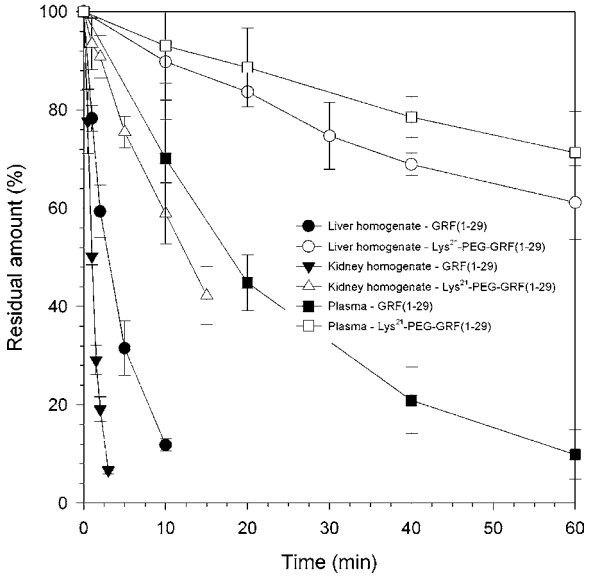

Figure 5. Degradation profiles of GRF(1−29) and Lys^{21}-PEG-GRF-(1−29) incubated with rat plasma or rat liver or kidney homogenates. Samples were analyzed by RP-HPLC. Data are presented as the means ± SDs of three determinations.

which is 6.3- and 3.8-fold greater than the yield by nonspecific PEGylation at pH 8.5 or in 0.3−1.2% TEA/DMSO, respectively. In addition, despite the high concentration (∼15.0 mg/mL) of FMOC^{1,12}-GRF(1−29), the Lys^{21}-PEG-GRF(1−29) production yields were maintained at 92.2−95.0%. Therefore, the devised site-specific PEGylation process requires only a single supporting chromatography step to isolate Lys^{21}-PEG-GRF(1−29) even at larger scale (>150 mg) due to minimal presence of other side products. Finally, the purified Lys^{21}-PEG-GRF(1−29) showed the symmetric mass peaks (M_n = 8813 Da, at a purity of >99.2% by RP-HPLC) together with the appropriate identity for Lys^{21}-amine PEGylation (Table 1).

The biological potential of this site-specific Lys^{21}-PEG-GRF-(1−29) was evaluated by examining its GH releasing activity in vitro and in vivo. First, the effect of Lys^{21}-PEG-GRF(1−29) on GH release was evaluated in rat pituitary cells. Despite the Lys^{21}-amine selection, the remaining GH releasing activity of Lys^{21}-PEG-GRF(1−29) was only 15% that of GRF(1−29) (EC_{50} = 0.219 ± 0.012 and 0.031 ± 0.002 ng/mL, respectively) (Figure 4A), consistent with the previous report (*6*). Contrary to the in vitro result, however, Lys^{21}-PEG-GRF(1−29) displayed a higher GH releasing potency than GRF(1−29) in conscious rats. In an initial GH peak analysis, plasma GH levels peaked at 77.9 ± 8.7 and 97.1 ± 12.8 ng/mL at 10 min following the iv administrations (100 μg equiv/kg wt) of GRF(1−29) and Lys^{21}-PEG-GRF(1−29), respectively (Figure 4B). The area under the curve (AUC) of GH by Lys^{21}-PEG-GRF(1−29) stimulation was greater than that of GRF(1−29) ($AUC_{0\sim60\ min}$= 1992.1 ± 449.1 vs 1626.1 ± 376.5 ng·min/mL). Despite a reduced initial GH release, Lys$^{12/21}$-PEG-GRF(1−29) was reported to have sustained long-acting in vivo GH releasing potency with additional GH release at 3 and 6 h after injection (*6*−*7*). This PEGylation effect is due to the compensation mechanism by the PEGylation advantage in terms of augmented proteolytic stability and extended plasma lifetime in vivo.

Significantly, the proteolytic stabilities of Lys^{21}-PEG-GRF-(1−29) in rat plasma, liver, and kidney homogenates, which are considered to be the representative in vivo enzyme systems containing DPP IV, were improved. GRF(1−29) was rapidly degraded in all systems, with half-lives of 18.0 ± 4.8, 3.3 ± 0.1, and 0.7 ± 0.1 min, respectively (Figure 5). On the contrary, Lys^{21}-PEG-GRF(1−29) displayed greatly increased resistance

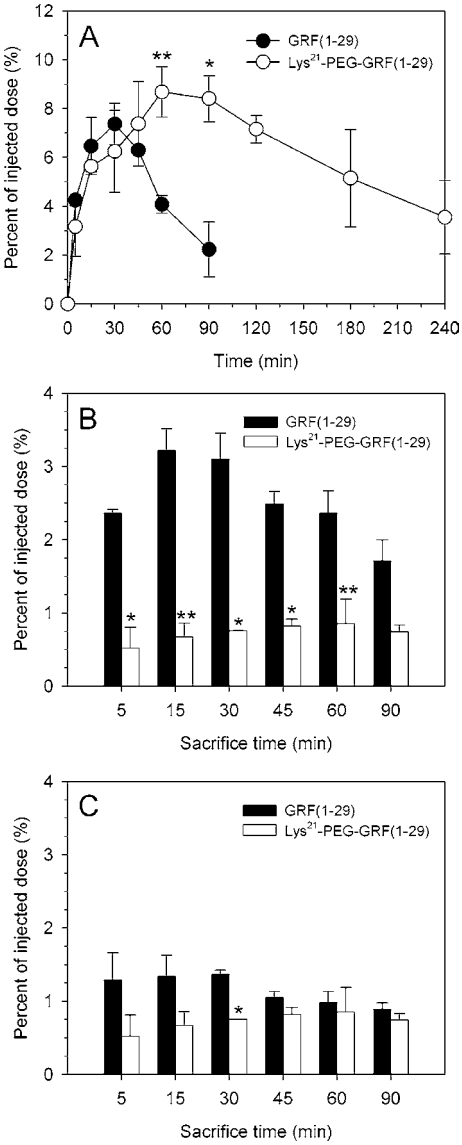

Figure 6. Pharmacokinetic dispositions of ^{125}I-GRF(1−29) and ^{125}I-Lys^{21}-PEG-GRF(1−29) in mouse (A) blood, (B) liver, and (C) kidney following sc administrations. Data are presented as the means ± SDs of three determinations. Significances were determined using the Student's *t* test (*P < 0.006 and **P < 0.03 over GRF(1−29)).

to these enzyme systems, with 7.0-, 25.4-, and 16.4-fold extended half-lives, respectively. Furthermore, the pharmacokinetic profiles of ^{125}I-Lys^{21}-PEG-GRF(1−29) in mice were clearly enhanced vs ^{125}I-GRF(1−29) (Figure 6A). ^{125}I-Lys^{21}-PEG-GRF(1−29) was found to have a 3.8-fold greater AUC_{inf} than that of ^{125}I-GRF(1−29) (2157.0 ± 523.2 vs 566.4 ± 104.5%·min, respectively) in blood (Figure 6B). In addition, PEGylation significantly reduced the liver distribution (5−90 min) of GRF(1−29) by 2.2 times (p < 0.03) and the kidney distribution (5−90 min) of ^{125}I-GRF(1−29) by about 40% (Figure 6C). Accordingly, it is clear that these improved proteolytic resistance and pharmacokinetic dispositions of Lys^{21}-PEG-GRF(1−29) resulted in the GH release potency in vivo, and these may equate to therapeutic potential for the treatment of GH-related disorders.

CONCLUSIONS

We developed a unique two-step site-specific (Lys^{21}) method of PEGylating GRF(1−29) using an FMOC-protected GRF-(1−29) derivative. This method was used to produce the uniform Lys^{21}-PEG-GRF(1−29) in high yield (∼95%), and this conju-

gate was found to have better pharmacokinetic/pharmacological profiles than GRF(1−29). Recently, site-specific PEGylation has often been achieved by using protein mutants or peptide analogs, which have the replaced amino acid sequence to confer site specificity. However, the PEGylation method described here involves no change to the native GRF(1−29) properties, because the FMOC groups are removed by a straightforward deprotection process after PEGylation. We believe that our findings suggest that PEGylation using FMOC-protected peptides has great potential for the mass production of site-specific PEGylated peptides.

Received June 30, 2006; Revised Manuscript Received January 12, 2007

The peroxisome proliferator-activated receptor γ (PPARγ) is an important regulator of lipid metabolism and the differentiation of pre-adipocytes. Thus, imaging PPARγ in vivo using positron-emission tomography (PET) might be useful in assessing lipid metabolism disorders and identifying tumor cell differentiation. A fluorine-substituted PPARγ ligand from tyrosine-benzophenone class, compound **1**, has a very high affinity for PPARγ receptor (K_i = 0.14 nM). To develop this compound as a PPARγ PET imaging agent, we investigated synthetic routes suitable for its labeling with the short-lived PET radionuclide fluorine-18 ($t_{1/2}$ = 110 min). To obtain the high specific activity material needed for receptor imaging with this isotope, reactions need to proceed efficiently, within a short time, starting from fluoride ion at the tracer level. The most promising approach involves introduction of fluorine into a suitable benzophenone precursor, followed by efficient coupling of this intermediate with the heterocyclic tyrosine component using a copper-catalyzed Ullmann-type condensation.

INTRODUCTION

The nuclear hormone receptor, peroxisome proliferator-activated receptor γ (PPARγ) plays critical roles in adipogenesis and insulin-mediated glucose homeostasis, and in liposarcoma, PPARγ ligands can induce cancer cells to stop proliferating, lose their malignant character, and undergo terminal differentiation to adipocytes (*1*−*10*). PPARγ is also expressed in other tumor cells, including several breast cancer cell lines, as well as in animal models for breast cancer derived from primary and metastatic tumors, and recently, a number of laboratories have shown that PPARγ activation alters the growth characteristics of breast cancer cells (*6*, *9*). Thus, PPARγ is an attractive target for in vivo imaging that might be useful in assessing lipid metabolism disorders associated with obesity, type 2 diabetes, atherogenesis, and restenosis (*11*), and in identifying small metastatic tumors.

In previous work, our group has evaluated an initial set of fluorine-18 labeled compounds based on PPARγ ligands of the phenyl propanoic acid class, such as the fluorine-substituted analog of SB 213068 (Chart 1) (*12*). These compounds showed good binding affinities for PPARγ and good binding selectivity relative to the other receptor subtypes, PPARα and PPARδ. Though respectable, the PPARγ affinities of this set of compounds were not as high as would be desirable for imaging.

Since our prior work, ligands that have much higher affinity and selectivity for both PPARγ and PPARα have been discovered, largely through the efforts of researchers at Glaxo SmithKline (GSK) (*13*−*16*). In particular, members of the novel benzophenone-tyrosine class, exemplified by farglitazar (GI 262570), have a very high affinity for PPARγ, and they have high potency in vivo. Our group also recently prepared three fluorine-substituted members of the benzophenone−tyrosine class that retain high affinity and selectivity for PPARγ and thus appear to be attractive compounds to evaluate further as agents to be labeled with the short-lived positron-emitting radionuclide fluorine-18 ($t_{1/2}$ = 110 min) for imaging PPARγ in vivo using positron-emission tomography (PET).

In this work, we have selected one fluorine-substituted analog of farglitazar, namely, compound **1**, which was also previously described by GSK (*13*−*16*), and we have investigated synthetic routes by which it might be labeled with fluorine-18 in a manner that is rapid, efficient, and suitable for starting from fluoride ion at the tracer level, as would be needed to obtain the high specific activity material needed for receptor imaging with this radioisotope.

EXPERIMENTAL SECTION

Materials and Methods. Solvents and reagents were purchased from the following commercial sources: Aldrich, Fisher, or Acros. Anhydrous THF, Et_2O, and CH_2Cl_2 were collected using a solvent dispensing system built by J. C. Meyer based on a design described by Pahgborn (*17*). TLC was performed on Merck F_{254} silica plates. The chemical shifts were reported in parts per million downfield from tetramethylsilane and were referenced to the internal solvent peaks. Coupling constants were reported in hertz. ^{1}H NMR and ^{13}C NMR spectra were recorded on Varian U400 and U500 Instruments (Palo Alto, CA). Melting points were determined using a Thomas-Hoover capillary melting point apparatus (Philadelphia, PA) and are uncorrected. Low-resolution mass spectra (MS) were recorded on a Micromass 70-VSE, Finnigan MAT CH-5 and ZAB-SE spectrometers, respectively. High-resolution mass spectra were obtained on a VG 70-SE-4E spectrometer. Mass spectra were acquired in the positive ion mode under electron impact (EI, 70 eV), fast-atom bombardment mass (FAB), and electrospray ionization (ESI) methods. Microwave-assisted reactions were performed with model 520A Resonance Instruments, Inc. (Skokie, IL). N^{α}-*tert*-Butoxycarbonyl-L--tyrosine *tert*-butyl ester, 2-(5-methyl-2-phe-

nyloxazol-4-yl)ethanol, and compound **11** were prepared according to the literature (*18*−*20*, respectively).

(2*S*)-[2-(4-Fluorobenzoyl)phenylamino]-3-(4-hydroxyphenyl)propionic Acid Methyl Ester (7). To a stirred solution of L--tyrosine methyl ester (1.90 g, 9.74 mmol) in toluene (10 mL) and 1,4-dioxane (10 mL) was added 2-(4-fluorobenzoyl)-cyclohexanone (2.41 g, 10.95 mmol). The reaction mixture was refluxed using a Dean−Stark trap for 12 h under nitrogen atmosphere. The resulting solution was evaporated, and anisole (20 mL) and an excess of 10% Pd/C were added. The reaction mixture was refluxed for 2 h. The resulting solution was evaporated and extracted with EtOAc (100 mL) and washed with H_2O (50 mL) and brine (50 mL). The organic layer was separated and dried with $MgSO_4$. Purification of this material by silica gel flash column chromatography using 20% EtOAc/hexane as eluant afforded 2.47 g (65%) of the title compound **7** as an orange oil: ^{1}H NMR (400 MHz, $CDCl_3$) δ 3.11 (dd, J = 14.0, 7.2 Hz, 1H), 3.18 (dd, J = 14.0, 5.6 Hz, 1H), 3.70 (s, 3H), 4.40 (t, J = 8.0 Hz, 1H), 6.59−6.70 (m, 4H), 7.07−7.13 (m, 4H), 7.33−7.38 (m, 1H), 7.42−7.45 (m, 1H), 7.59−7.63 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 37.84, 52.38, 57.84, 111.94, 115.04, 115.26, 115.53, 118.06, 127.50, 130.31, 131.65, 135.18, 136.02, 149.94, 155.10, 163.15, 165.65, 173.14, 198.14; MS (FAB) *m*/*z* 394 (M + H). HRMS calcd for $C_{23}H_{21}FNO_4$ 394.1455, found 394.1455.

(2*S*)-[2-(4-Nitrobenzoyl)phenylamino]-3-(4-hydroxyphenyl)-propionic Acid Methyl Ester (8). Prepared from L-tyrosine methyl ester and 2-(4-nitrobenzoyl)cyclohexanone by the method used to prepare compound **7** and obtained as an orange oil (10%): ^{1}H NMR (400 MHz, $CDCl_3$) δ 3.13 (dd, J = 14.0, 7.2 Hz, 1H), 3.21 (dd, J = 13.6, 5.6 Hz, 1H), 3.73 (s, 3H), 4.43 (m, 1H), 6.57−6.66 (m, 2H), 6.72 (d, J = 8.4 Hz, 2H), 7.11 (d, J = 8.4 Hz, 2H), 7.30−7.40 (m, 2H), 7.70 (d, J = 8.8 Hz, 2H), 8.29 (d, J = 8.4 Hz, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 37.82, 52.46, 57.62, 112.06, 115.55, 116.95, 123.36, 127.62, 129.58, 130.39, 135.27, 136.05, 145.77, 148.78, 150.58, 154.99, 172.90, 197.13; MS (FAB) *m*/*z* 421 (M + H). HRMS calcd for $C_{23}H_{21}N_2O_6$ 421.1400, found 421.1399.

(2*S*)-[2-(4-Fluorobenzoyl)phenylamino]-3-{4-[2-(5-methyl-2-phenyloxazol-4-yl)ethoxy]phenyl}propionic Acid Methyl Ester (9). A stirred solution of compound **7** (193 mg, 0.49 mmol), 2-(5-methyl-2-phenyloxazol-4-yl)ethanol (100 mg, 0.49 mmol), and triphenylphosphine (129 mg, 0.49 mmol) in THF (30 mL) at room temperature was treated with diethyl azodicarboxylate (77 μL, 0.49 mmol) in THF (5 mL) via dropwise addition. The resulting solution was stirred for 16 h at room temperature, and then the solvent was removed in vacuo. The crude reaction mixture was purified by silica gel flash column chromatography using 30% EtOAc/hexane as eluant to afford 127 mg (45%) of the title compound **9** as a yellow oil: ^{1}H NMR (400 MHz, $CDCl_3$) δ 2.35 (s, 3H), 2.95 (t, J = 4.0 Hz, 2H), 3.11 (dd, J = 13.6, 7.2 Hz, 1H), 3.20 (dd, J = 13.6, 6.0 Hz, 1H), 3.69 (s, 3H), 4.20 (t, J = 4.0 Hz, 2H), 4.39 (m, 1H), 6.57−6.65 (m, 2H), 6.83 (d, J = 8.0 Hz, 2H), 7.10−7.18 (m, 4H), 7.31−7.35 (m, 1H), 7.40−7.45 (m, 4H), 7.61−7.65 (m, 2H), 7.98 (d, J = 8.0 Hz, 2H), 8.79 (d, J = 4.0 Hz, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 10.14, 26.20, 37.96, 52.16, 57.80, 66.48, 111.76, 114.53, 114.92, 115.03 (J = 21.0 Hz), 117.99, 125.80, 127.57, 128.16, 128.57, 129.70, 130.17, 131.53 (J = 8.0 Hz), 132.51, 134.86, 135.02, 136.19 (J = 4.0 Hz), 144.97, 149.97, 157.70, 159.334, 164.29 (J = 250.0 Hz), 172.87, 197.55; MS (FAB) *m*/*z* 579 (M + H). HRMS calcd for $C_{35}H_{32}FN_2O_5$ 579.2295, found 579.2295.

(2*S*)-[2-(4-Nitrobenzoyl)phenylamino]-3-{4-[2-(5-methyl-2-phenyloxazol-4-yl)ethoxy]phenyl}propionic Acid Methyl Ester (10). Prepared from **8** by the method used to prepare **9** and obtained as an orange oil (44%): ^{1}H NMR (500 MHz, $CDCl_3$) δ 2.35 (s, 3H), 2.95 (t, J = 5.0 Hz, 2H), 3.13 (dd, J = 14.0, 7.5 Hz, 1H), 3.22 (dd, J = 14.0, 6.0 Hz, 1H), 3.71 (s, 3H), 4.20 (t, J = 5.0 Hz, 2H), 4.39−4.43 (m, 1H), 6.57 (t, J = 5.0 Hz, 1H), 6.64 (d, J = 10.0 Hz, 1H), 6.84 (d, J = 10.0 Hz, 2H), 7.17 (d, J = 10.0 Hz, 2H), 7.31 (d, J = 10.0 Hz, 2H), 7.34−7.43 (m, 4H), 7.71 (d, J = 10.0 Hz, 2H), 7.97 (d, J = 5.0 Hz, 2H), 8.29 (d, J = 10.0 Hz, 2H), 9.04 (d, J = 5.0 Hz, 1H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 10.13, 26.35, 38.03, 52.21, 57.77, 66.70, 112.13, 114.77, 115.20, 117.14, 123.33, 125.92, 127.81, 128.15, 128.63, 129.62, 129.74, 130.26, 132.71, 135.10, 135.81, 144.96, 145.97, 148.93, 150.67, 158.00, 159.49, 172.65, 196.79; MS (FAB) *m*/*z* 606 (M + H). HRMS calcd for $C_{35}H_{32}N_3O_7$ 606.2240, found 606.2238.

(2*S*)-[2-(4-Fluorobenzoyl)phenylamino]-3-{4-[2-(5-methyl-2-phenyloxazol-4-yl)ethoxy]phenyl}propionic Acid (1). A stirred solution of compound **9** (50 mg, 0.086 mmol) in THF/MeOH (v/v = 3:1, 1.25 mL) was treated with 1.0 M LiOH (172 μL, 0.172 mmol). After the mixture was stirred at room temperature for 6 h, 1 N HCl (200 μL), water (1 mL), and EtOAc (5 mL) were added. The organic layer was separated and dried with sodium sulfate. The obtained organic layers were concentrated and purified by silica gel flash column chromatography using 5% MeOH/CH_2Cl_2 as eluant to afford 47 mg (96%) of the product **1** as a yellow solid: mp 140−145 °C; ^{1}H NMR (400 MHz, CD_3OD) δ 2.30 (s, 3H), 2.90 (t, J = 6.8 Hz, 2H), 3.05 (dd, J = 13.8, 7 Hz, 1H), 3.22 (dd, J = 14, 5.2 Hz, 1H), 4.15 (t, J = 6.4 Hz, 2H), 4.42 (br, 1H), 6.56 (t, J = 7.6 Hz, 1H), 6.73−6.79 (m, 3H), 7.13 (d, J = 8.4 Hz, 2H), 7.18 (t, J = 8.4 Hz, 2H), 7.33−7.37 (m, 2H), 7.44−7.47 (m, 2H), 7.58−7.61 (m 2H), 7.91−7.93 (m, 2H);^{13}C NMR (100 MHz, DMSO-d_6) δ 9.84, 14.11, 25.56, 57.66, 59.79, 65.98, 112.62, 113.96, 115.10, 115.31, 116.84, 125.41, 127.11, 129.04, 130.05, 130.43, 131.36, 131.45, 132.65, 134.40, 134.79, 136.71, 145.05, 150.06, 156.73, 158.32, 162.31, 164.78, 196.24; MS (FAB) *m*/*z* 565 (M + H). HRMS calcd for $C_{34}H_{30}FN_2O_5$ 565.2139, found 565.2139.

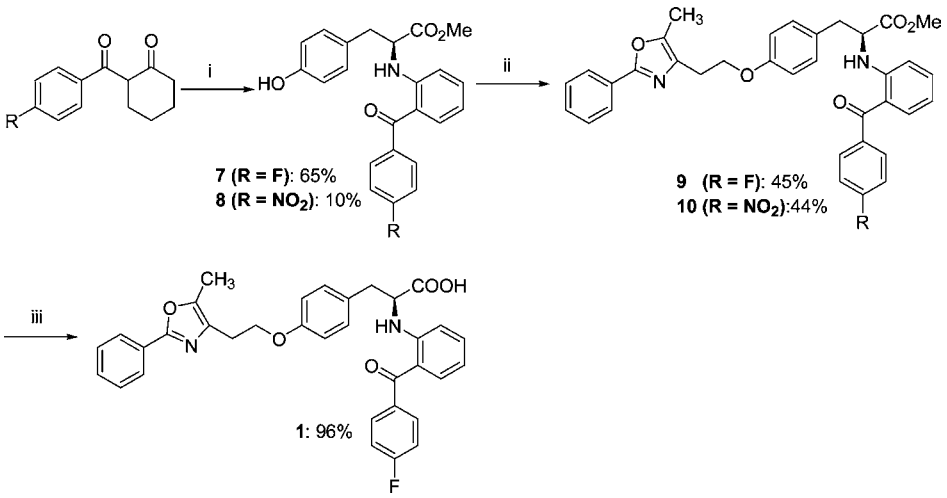
2-Iodo-4′-dimethylaminobenzophenone (12). To a suspension of 2-iodo-*N*-phenyl benzamide **11** in *N*,*N*-dimethylaniline (5.49 mL, 43.33 mmol) was added phosphorus oxychloride (865 μL, 9.28 mmol) dropwise over 30 min at 50 °C. On completion of the addition, the resulting dark solution was heated to 150 °C for 4 h. After the reaction mixture was cooled to room temperature, HCl (8 mL, 50% aq) was added, and the

mixture was refluxed for 2 h. The cooled solution was poured into water (200 mL) and 2 M NaOH (50 mL) and extracted with dichloromethane (50 mL × 3). The organic layer was washed with 0.2 M NaOH (25 mL), 0.2 M HCl (25 mL), and water (25 mL), respectively. The organic layer was dried with sodium sulfate, and the solvent was removed to give the crude benzophenone. Purification of the material by silica gel flash column chromatography using 30% ethyl acetate/hexane as eluant afforded 1.72 g (79%) of the product **12** as a green solid: mp 121−125 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 3.07 (s, 6H), 6.63 (d, J = 9.2 Hz, 2H), 7.10−7.14 (m, 1H), 7.25−7.28 (m, 1H), 7.39−7.42 (m, 1H), 7.56 (d, J = 8.8 Hz, 2H), 7.88 (d, J = 8 Hz, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 39.99, 92.52, 110.62, 123.02, 127.64, 127.94, 130.24, 132.82, 139.23, 145.64, 153.73, 195.38; MS (ESI) *m*/*z* 352 (M + H). HRMS calcd for $C_{15}H_{14}INO$ 352.0198, found 352.0215.

2-Iodo-4′-fluorobenzophenone (13). *Method A.* The flask was charged with $AlCl_3$ (644 mg, 4.82 mmol) and cat. $FeCl_3$ (5 mg, 0.03 mmol) in fluorobenzene (3 mL). The solution was then chilled thoroughly in an ice bath under nitrogen atmosphere. To this solution was added 2-iodobenzoylchloride (1.29 g, 4.82 mmol) in fluorobenzene (3 mL). The reaction mixture was allowed to stir overnight at room temperature. At the end of the reaction, the flask was placed again in an ice bath, and water (2 mL) was slowly added. The resulting two-phase mixture was stirred vigorously for 30 min. The organic layer was dried over anhydrous sodium sulfate, and the solvent was removed in vacuo. Purification of the material by silica gel flash column chromatography using 10% ethyl acetate/hexane as eluant afforded the product **13** (1.39 g, 88%).

Method B. To a solution of compound **14** (100 mg, 0.19 mmol) in acetonirile (2 mL) was added 1 M TBAF in THF solution (210 μL, 0.21 mmol) at room temperature. The reaction mixture was heated at 90 °C for 1 h. The reaction mixture was poured into ethyl acetate (10 mL) and washed with water (10 mL) and brine (10 mL). The organic layer was dried over anhydrous sodium sulfate, and the solvent was removed in vacuo. Purification of the material by silica gel flash column chromatography using 10% ethyl acetate/hexane as eluant afforded the product **13** (59 mg, 96%) as a white solid: mp 50−52 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.11−7.21 (m, 3H), 7.28 (dd, J = 7.6, 2 Hz, 1H), 7.43−7.47 (m, 1H), 7.81−7.85 (m, 2H), 7.92 (dd, J = 8.4, 2 Hz, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 92.05, 115.88 (d, J = 22 Hz), 127.87, 128. 29, 131.20, 131.94 (d, J = 3 Hz), 133.09 (d, J = 9.9 Hz), 139.67, 144.01, 166.07 (d, J = 254.9 Hz), 195.66; MS (EI) *m*/*z* 327 (M + H). HRMS calcd for $C_{13}H_8FIO$ 326.9682, found 326.9676. Registry Number: 138504-31-1.

2-Iodo-4′-*N*,*N*,*N*-trimethylaminobenzophenone Triflate (14). To a solution compound **12** (500 mg, 1.42 mmol) in methylene chloride (10 mL) was added methyl trifluoromethanesulfonate (193 μL, 1.70 mmol) dropwise over 10 min at room temperature under argon atmosphere. Upon completion of the addition, the resulting dark brown solution was stirred at room temperature for 12 h. The reaction mixture was poured into diethyl ether (20 mL) and washed with water (10 mL). The residue was recrystallized from diethyl ether and methylene chloride to afford 380 mg (52%) of the product **14** as a white solid: mp 163−165 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 3.71 (s, 9H), 7.29−7.37 (m, 2H), 7.55−7.58 (m, 1H), 7.98−8.02 (m, 3H), 8.07−8.10 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 57.68, 92.42, 122.18, 123.36, 129.42, 129.63, 132.98, 133.25, 138.45, 141.06, 144.85, 151.97, 196.91; MS (ESI) *m*/*z* 366 (M − OTf). HRMS calcd for $C_{16}H_{17}INO$ 366.0355, found 366.0346.



(*S*)-*tert*-Butoxycarbonylamino-3-{4-[2-(5-methyl-2-phenyloxazol-4-yl)ethoxy]-phenyl}propionic Acid *tert*-Butyl Ester (15). A stirred solution of N^{α}-*tert*-butoxycarbonyl-L-tyrosine *tert*-butyl ester (193 mg, 0.49 mmol), 2-(5-methyl-2-phenyloxazol-4-yl)ethanol (100 mg, 0.49 mmol), and triphenylphosphine (165 mg, 0.49 mmol) in tetrahydrofuran (30 mL) at room temperature was treated with diethyl azodicarboxylate (77 μL, 0.49 mmol) in tetrahydrofuran (5 mL) via dropwise addition. The resulting solution was stirred for 8 h at room temperature under nitrogen, and then the solvent was removed in vacuo. The crude reaction mixture was purified by silica gel flash column chromatography using 30% EtOAc/hexane as eluant to afford 140 mg (55%) of the product **15** as a white solid: mp 50−52 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 1.36 (s, 9H), 1.37 (s, 9H), 2.30 (s, 3H), 2.90−3.00 (m, 4H), 4.17 (t. J = 6.6 Hz, 2H), 4.36 (q, J = 13.6 Hz, 1H), 5.04 (d, J = 8 Hz, 1H), 6.78 (d, J = 8.4 Hz, 2H), 7.02 (d, J = 8.4 Hz, 2H), 7.31−7.38 (m, 3H), 7.93 (d, J = 6.8 Hz, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 9.96, 26.08, 27.70, 28.07, 37.22, 54.73, 66.36, 79.22, 81.54, 114.11, 125.62, 127.47, 128.14, 128.39, 129.51, 130.24, 132.44, 144.72, 154.86, 157.46, 159.17, 170.77; MS (ESI) *m*/*z* 523 (M + H, 100%), 467 (45%). (*S*)-Amino-3-{4-[2-(5-methyl-2-phenyloxazol-4-yl)ethoxy]-phenyl}propionic Acid (16). A solution of (*S*)-*tert*-butoxycarbonylamino-3-{4-[2-(5-methyl-2-phenyloxazol-4-yl)ethoxy]-phenyl}propionic acid *tert*-butyl ester **15** (300 mg, 0.574 mmol) in trifluoroacetic acid and CH_2Cl_2 (v/v = 1:1, 6 mL) was stirred at room temperature for 6 h. The volume was reduced by evaporation of the solvent, whereupon some crystal formation occurred; then, diethyl ether was poured into the concentrated mixture. The white solid was filtered and washed with diethyl ether (5 mL) before being dried in vacuo. The trifluoroacetate was obtained as a white solid **16** (296 mg, 97%): mp 191−193 °C; ^{1}H NMR (400 MHz, CD_3OD) δ 2.39 (s, 3H), 2.97 (t, J = 6.4, 2H), 3.01−3.25 (m, 2H), 4.10 (q, J = 8.0 Hz, 1H), 4.23 (t, J = 6.4 Hz, 2H), 6.92 (d, J = 8.4 Hz, 2H), 7.18 (d, J = 8.4 Hz, 2H), 7.46−7.49 (m, 3H), 7.93−7.96 (m, 2H); ^{13}C NMR (100 MHz, CD_3OD) δ 10.03, 26.94, 36.61, 55.48, 67.62, 116.19, 126.94, 127.65, 128.49, 130.07, 131.51, 131.62, 133.77, 147.12, 159.94, 161.17, 171.60; MS (ESI) *m*/*z* 367 (M + H). HRMS calcd for $C_{21}H_{23}N_2O_4$ 367.1658, found 367.1650.

Ullmann-Type Condensation Procedure for (2*S*)-[2-(4-Fluorobenzoyl)phenylamino]-3-{4-[2-(5-methyl-2-phenyloxazol-4-yl)ethoxy]phenyl}propionic Acid (1). *Method A.* To a solution of compound **16** (73 mg, 0.15 mmol) and 2-iodo-4′-fluorobenzophenone **13** (50 mg, 10.4 μmol) in *N*,*N*-dimethylformamide (DMF, 3 mL) were added potassium carbonate (46 mg, 0.33 mmol), and CuI (3 mg, 0.015 mmol) under a nitrogen atmosphere. After the mixture was stirred at 100 °C for 4 h, the cooled solution was concentrated in vacuo. The residue was dissolved in water and acidified to pH 5 with 1 M HCl. After extraction with ethyl acetate (5 mL), the combined organic layers were dried, concentrated, and purified by silica gel flash column chromatography using 5% MeOH/CH_2Cl_2 as eluant to afford 43 mg (51%) of the product **1**.

Method B. To a solution of trifluoroacetate salt **16** (5.0 mg, 10.4 μmol) in acetonitrile (1 mL) was added tetrabutylammonium hydroxide (40% aq solution, 13 μL, 20.6 μmol). After sonication of the mixture, the clear solution was concentrated under reduced pressure. To the tetrabutylammonium salt were added 2-iodo-4′-fluorobenzophenone **13** (3.4 mg, 10.4 μmol), CuI (1 mg), and DMF (0.5 mL) under a nitrogen atmosphere. After the mixture was stirred at 100 °C for 20 min under nitrogen atmosphere, the cooled solution was concentrated in vacuo. The residue was dissolved in water and acidified to pH 5 with 1 M HCl. After extraction with ethyl acetate (1 mL), the combined organic layers were dried, concentrated, and purified

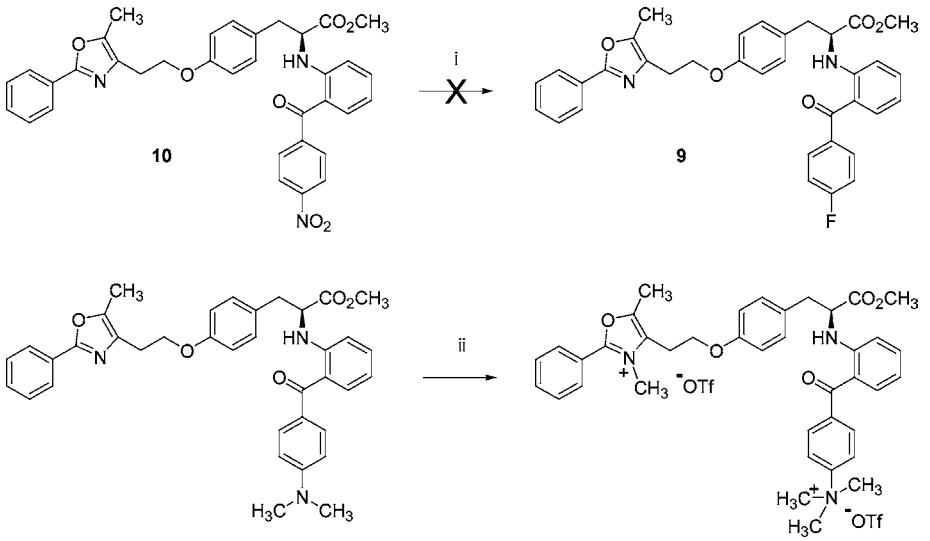
by short silica gel flash column chromatography using 5% MeOH/CH_2Cl_2 as eluant to afford 3.1 mg (53%) of the product **1**.

PPARγ Binding Assay. The binding of compound **1** to PPARγ was evaluated using a scintillation proximity assay (SPA) adapted from the method described by Sun et al. (*21*). Yttrium silicate (Ysi) copper His-Tag SPA beads (Amersham Biosciences, Piscataway, NJ), histidine-tagged human PPARγ ligand-binding domain (amino acids 195−477; Invitrogen, Carlsbad, CA), and the tritium ligand, [^{3}H]-rosiglitazone (American Radiolabeled Chemicals, St. Louis, MO) were obtained from the sources indicated.

[^{3}H]-Rosiglitazone and PPARγ protein were diluted to 23 μCi/mL and 50 ng/mL stock, respectively. Radioligand, protein and test compound at various concentrations (10 nM to 2 μM) were incubated at room temperature for 2 h. SPA beads were diluted and aliquoted into a clear bottom 96-well plate according to the manufacturer's specifications. Test the ligand, [^{3}H]-Rosiglitazone and protein were then added to the assay plate and incubated at room temperature for at least for 1 h before the plate was read by a Packard TopCount plate reader (Perkin-Elmer, Wellesley, MA). GW1929 (Cayman Chemical Co., Ann Arbor, MI), a potent PPARγ agonist, served as a positive control. The initial IC_{50} values of GW1929 and test compound were calculated by the *Prism* program (GraphPad Software, San Diego, CA). The reported compound IC_{50} value of the compound tested was normalized against GW1929 due to the variability of the assay (*22*). The normalized IC_{50} value is 0.14 ± 0.01 nM, which corresponds to a pK_i value of 9.85.

RESULTS AND DISCUSSION

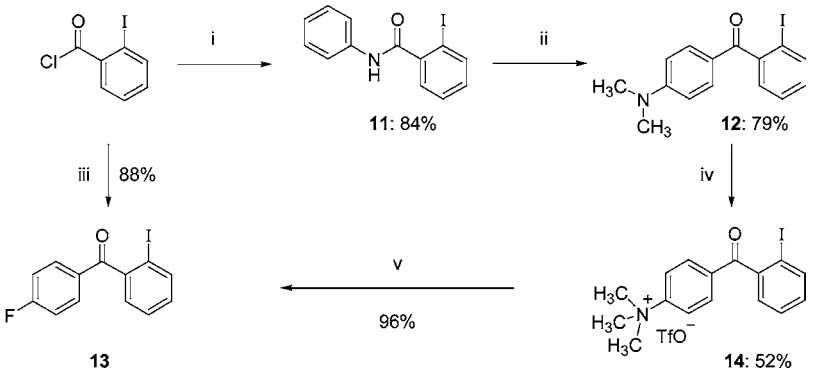
Chemical Synthesis. We designed two synthetic routes to compound **1**, the first for preparation of an authentic sample of this compound and the second designed to proceed through precursor molecules that can be radiolabeled by fluoride ion displacement of a suitable leaving group for the eventual radiolabeling of this compound with fluorine-18.



Synthesis of (2*S*)-[2-(4-fluorobenzoylphenylamino)-3-{4-[2-(5-methyl-2-phenyloxazol-4-yl)ethoxy]phenyl}propionic Acid (1). As shown in Scheme 1, an authentic sample of compound **1** was synthesized in three steps from 2-(4-fluorobenzoyl)-cyclohexanone, using a modification of known methods (*13*−*15*). 2-(4-Fluorobenzoyl)cyclohexanone (*23*) was attached to tyrosine methyl ester by an imine formation−aromatization sequence catalyzed by 10% Pd/C in anisole to produce compounds **7** and **8**. Under Mitsunobu conditions, the phenolic function in compound **7** was coupled to the known heterocyclic alcohol 2-(5-methyl-2-phenyloxazol-4-yl)ethanol (*19*) to provide compound **9**. Hydrolysis of this methyl ester with LiOH proceeded under mild conditions to give the desired fluorine-substituted PPARγ ligand **1**. Because it involves multiple steps following the introduction of the fluorine-containing component, this route is not suitable for labeling with the short-lived radionuclide fluorine-18.

An obvious approach for the direct labeling of compound **1** with fluorine would involve nucleophilic aromatic substitution by fluoride ion on a precursor of the final compound bearing a good leaving group on the para position of the benzophenone unit (i.e., compound **10**, Scheme 2). In many cases, a nitro group can function effectively as a leaving group in nucleophilic aromatic substitutions with fluoride ion, provided the system is adequately activated with electron withdrawing groups situated at ortho and/or para positions (*24*−*26*). Thus, we subjected compound **10**, the nitro analog of compound **1** that we had prepared previously, to various conditions typically used for such substitutions, but we failed to obtain any of the desired fluoro product. Although fluorine substitution of other nitrobenzophenones has been accomplished (*24*), we presume that the lack of reaction of compound **10** is due to the strongly electron donating ortho amino substituent on the other ring that can also hydrogen-bond with the benzophenone carbonyl group.

Our attempts to prepare the more reactive trimethylammonium analog of the nitro compound from the dimethyl amine analog using methyl triflate (Scheme 2) were thwarted by the dominant competitive N-methylation of the more nucleophilic oxazole ring in the tail of the molecule. Initial methylation took place on the heterocycle, so we could only obtain the bis-(ammonium) salt. Because of these difficulties with these direct fluorination approaches, we took an alternative, indirect approach to prepare target compound **1**, as outlined in Scheme 3.



Synthesis of 2-iodo-4′-fluorobenzophenone (13). There is precedent for introducing fluoride ion by nucleophilic aromatic substitution at the para position of certain benzophenones bearing simple o,p′-substituents (*27*). We did not anticipate encountering problems in preparing the reactive p′-trimethylammonium group in the simpler benzophenone precursor **14**, because in this system this benzophenone is not attached to the nucleophilic oxazole. We imagined that fluoride ion substitution in compound **14** would proceed selectively by displacement of the more reactive p′-trimethylammonium leaving group rather

than the o-iodo group (Scheme 3). This would leave as a final step in this approach the attachment of the *o*-iodo-*p*′-[^{18}F]-fluorobenzophenone system to the complex tyrosine unit by the displacement of the iodide using an Ullmann-type condensation (Scheme 4) (*28*, *29*). In this respect, our approach differs from earlier methods for achieving this coupling step, which involved imine formation with an *o*-benzoylcyclohexanone, followed by palladium-catalyzed aromatization (*13*, *15*).

An authentic sample of the o,p′-substituted benzophenone **13** was easily prepared by the Friedel−Crafts acylation of fluorobenzene with 2-iodobenzoyl chloride. The precursor for fluorine labeling, compound **14**, was prepared in three steps. 2-Iodo-4′-dimethylaminobenzophenone **12** was obtained in moderate yield by the Vilsmeier−Haack reaction of *N*,*N*-dimethylaniline with *N*-phenyl 2-iodo-benzamide (**11**), which was derived from the acylation of aniline with 2-iodo-

[f] Isolated yields.

benzoyl chloride using a catalytic amount of DMAP in pyridine (*20*, *30*, *31*). Treatment of the tertiary amine **12** with methyl trifluoromethanesulfonate produced the desired ammonium salt **14**, the key precursor for fluorine substitution. To demonstrate the effectiveness of the ammonium salt **14** as a precursor to the key intermediate **13**, we showed that the conversion of **14** to **13** occurred rapidly and in near quantitative yield when **14** was exposed to tetrabutylammonium fluoride in acetonitrile (Scheme 3).

As shown in Scheme 4, N^{α}-*tert*-butoxycarbonyl-L-tyrosine *tert*-butyl ester (*18*) was coupled to 2-[5-methyl-2-phenyloxazol-4-yl]ethanol under Mitsunobu conditions. Hydrolysis of the *tert*-butyl ester and Boc group in compound **15** with TFA in dichloromethane solution proceeded under mild conditions to give the desired phenyloxazole−tyrosine TFA salt **16**. The target compound **1** was then prepared using an Ullmann-type aryl amination of 2-iodo-4′-fluorobenzophene **13** with the amino group of the tyrosine ether **16** (Scheme 5). It is of note that this conversion can be done with the tyrosine unit **16** in its free acid form, rather than its ester derivative; this is a significant convenience for radiolabeling with short-lived isotopes, because it obviates ester hydrolysis as a final step.

Under conditions typical for Ullmann-type arylations, the conversion of **13** and **16** to **1** proceeded to only 51% yield after a 4 h reaction. We realized that this would be problematic for the synthesis of compound **1** labeled with the short-lived fluorine-18 ($t_{1/2}$ = 110 min), and thus we needed to find conditions for expediting this coupling reaction (Table 1).

While the mechanism of the Ullmann-type coupling reaction is not known, it is presumed to involve the coordination of copper ion with the aryl halide, followed by chelation with the carboxyl and/or amino groups in the coupling partner. The rate-determining step is then the intramolecular nucleophilic substitution of the aromatic ring by the amino group (*28*, *32*). Ullmann condensations typically proceed in higher yields under mild conditions, and we found the reaction yield to be strongly dependent on time. To explore how we might reduce the reaction time, we examined this reaction, when conducted on a micromolar scale (compound **16**, 5 mg, 10.4 μmol), under different conditions and using different reagents (Table 1).

When the phenyloxazole-tyrosine TFA salt **16** was reacted with the o,p′-substituted benzophenone **13** with CuI and K_2CO_3, under general Ullmann-type conditions, the reaction proceeded only slowly, with the yields of product **1** being very low at reaction times that would be applicable to labeling compound **1** with fluorine-18 (Table 1, entries 1−3). We also tried using a palladium/copper cocatalyst with microwave heating, conditions that have promoted other C−N cross couplings (*33*), but the reaction did not appear to be accelerated; yields were very low, and unknown side compounds were generated by the microwave heating (Table 1, entries 4 and 5). We noticed with interest that treatment of amino acid **16** with tetrabutylammonium hydroxide gave a TBA salt that was soluble in DMF (*34*). Interestingly, when this salt/solvent combination was used, the C−N coupling could be carried out in 20 min with 53% yield by heating to 120 °C, as shown in Table 1 (entry 6).

PPARγ Binding Affinity Determination. We retested the binding affinity of compound **1** for PPARγ in a competitive scintillation proximity radiometric binding assay, using a receptor preparation consisting of the ligand binding domain of PPARγ expressed in *E. coli* (*21*, *22*). The K_i value for compound **1** determined in this assay was 0.14 nM ($pK_i = 9.85$), consistent with the binding affinity for this compound reported earlier (*14*).

CONCLUSION

In this study, we have developed a method for introducing fluorine into a fluorine-substituted analog (compound **1**) of the high-affinity PPARγ ligand, farglitazar, that utilizes fluoride ion and that proceeds efficiently and rapidly under conditions suitable for labeling this molecule with the short-lived, positron-emitting radionuclide fluorine-18. The radiochemical synthesis of [^{18}F]compound **1** and an evaluation of its tissue distribution properties will be described in a future publication.

ACKNOWLEDGMENT

Received June 30, 2006; Revised Manuscript Received January 12, 2007

Well-known as an important regulator of lipid metabolism and adipocyte differentiation, the peroxisome proliferator-activated receptor γ (PPARγ) also has potential use as a target for antitumor therapy in certain cancers. To develop agents for radionuclide imaging PPARγ in vivo, we synthesized fluorine, bromine, and iodine-substituted analogs (**1**−**3**) of a high-affinity benzophenone−tyrosine PPARγ ligand; all three analogs retain very high affinity for the PPARγ receptor. In preparation for the synthesis of these PPARγ ligands in radiolabeled form, we have synthesized two types of precursors: (a) an aryltributylstannane (**9**), from which the bromine and iodine-substituted analogs (**2** and **3**) can readily be prepared by electrophilic destannylation, and (b) three diaryliodonium tosylate derivatives (**12a**−**c**), precursors for nucleophilic aromatic fluorination using fluoride ion. Conditions were developed whereby the thiophenyliodonium tosylate (**12c**) underwent nucleophilic aromatic substitution with fluoride ion, efficiently and in short reaction times, to produce the desired fluorine-substituted target compound **1**. These reactions laid the groundwork for producing these three PPARγ ligands in radiolabeled form; in addition, our use of diaryliodonium ion precursors for aromatic fluorination in this series provides an example that should encourage application of this approach for radiofluorination of more complicated radiopharmaceuticals.

INTRODUCTION

The peroxisome proliferator-activated receptors (PPARs) are members of the nuclear receptor superfamily, of which three subtypes are known: PPARα, PPARγ, and PPARδ (*1*−*3*). Each of these subtypes appears to regulate specific aspects of lipid metabolism, glucose homeostasis, inflammation, and cell differentiation (*4*−*6*). PPARγ can also play a critical role in certain cancers (*6*−*15*), and PPARγ ligands can induce liposarcoma cells to stop proliferating, lose their malignant character, and undergo terminal differentiation to adipocytes. In fact, in clinical trials, the PPARγ ligand troglitazone has been shown to induce differentiation of liposarcoma solid tumors in patients with advanced disease (*12*, *14*). PPARγ is also expressed in several breast cancer cell lines and in animal tumor models for breast cancer derived from primary and metastatic breast tumors, and PPARγ activation may alter the growth characteristics of breast cancer cells (*11*, *15*). Thus, PPARγ is an important target for in vivo imaging using positron emission tomography (PET) or single photon emission computed tomography (SPECT) that might be useful in assessing lipid metabolism disorders in obesity, type-2 diabetes, or vascular disease (*16*) or in identifying small metastatic tumors.

With this goal in mind, some time ago our group evaluated as PET imaging agents a set of fluorine-18 labeled PPARγ receptor ligands, based on the known compound SB 213068 (Scheme 1) (*17*). The binding of these fluorine-substituted compounds was selective for PPARγ compared to the PPARα and PPARδ subtypes; however, their affinity for PPARγ, though good, was not in the low nanomolar region as would be desirable for in vivo imaging. Also, one SB 213068 analogue (**5**), prepared in the fluorine-18 labeled form (*17*), did not show evidence of receptor-mediated uptake in tissue distribution studies in brown fat, the most receptor-rich tissue (*18*).

Since then, however, there have been a number of significant advances in the development of PPAR ligands, most notably, the discovery of systems that have much higher affinity and selectivity for both PPARγ and PPARα, largely through efforts of researchers at Glaxo SmithKline (GSK) (*19*−*22*). In particular, members of the novel benzophenone−tyrosine class (farglitazar GI 262570, **4,** Scheme 1) have particularly high affinity for PPARγ, and they show high potency in vivo. In addition, the use of the high-affinity enantiomer of this chiral compound increases its receptor binding affinity and would likely also enhance its target tissue uptake selectivity (*19*, *23*, *24*). Thus, we have selected farglitazar as a parent compound for the development of radiohalogen-labeled PPARγ-based imaging agents.

In this investigation, we have prepared three farglitazar analogues that are substituted at a tolerant aromatic ring position with fluorine, bromine, or iodine (**1**−**3**), which could be labeled, respectively, with fluorine-18, bromine-76, and iodine-124 for PET imaging or with other radionuclides for SPECT imaging. All three farglitazar derivatives retain high binding affinity for PPARγ. In model procedures for radiolabeling, we developed methods by which these three compounds can be produced from suitable precursors by reaction with simple halide species. The bromine and iodine-substituted compounds (**2** and **3**) were readily produced by electrophilic aromatic destannylation of a trialkyltin precursor. The use of electrophilic aromatic halogenation is not suitable for fluorine-18 labeling at the high specific activity needed for imaging receptors, which generally needs to be in the range of 1000 Ci/mmol for nuclear receptors such

Scheme 1. Structure of Synthetic Targets and Known PPARγ Ligands in This Study

as PPARγ, because they are present at only nanomolar concentrations in target tissues (*25*). Preparation of fluorine-18 labeled radiopharmaceuticals at this specific activity level requires the use of fluoride ion as the reagent. The aromatic ring position in question is also not sufficiently activated for conventional nucleophilic aromatic substitution reactions with fluoride ion. To overcome this problem, we synthesized iodonium salts from the same trialkyltin intermediate using various hydroxyl(tosyloxy)iodoarenes (*26*−*29*). Conditions were then optimized to produce the desired fluorine-substituted compound by nucleophilic aromatic substitution by fluoride ion on this highly activated system.

The methods we have developed here lay the groundwork for the synthesis of these three halogen-substituted PPARγ ligands in iodine, bromine, and fluorine radiolabeled form. The last method, using diaryliodonium salts for fluorine labeling, in particular, demonstrates an approach that is effective for introducing fluoride ion into aromatic rings that are not sufficiently activated for conventional nucleophilic aromatic substitution reactions, and it illustrates that this approach should be applicable for the preparation of other complex fluorine-18 labeled radiopharmaceuticals.

EXPERIMENTAL SECTION

Materials and Methods. Solvents and reagents were purchased from the following commercial sources: Aldrich, Fisher, or Acros. Anhydrous THF, Et_2O, and CH_2Cl_2 were collected using a solvent dispensing system built by J. C. Meyer based on a design developed by Pahgborn (*30*). TLC was performed on Merck F_{254} silica plates. The chemical shifts were reported in parts per million downfield from TMA and were referenced to the internal solvent peaks. Coupling constants were reported in hertz. ^{1}H NMR and ^{13}C NMR spectra were recorded on Varian U400 and U500 Instruments (Palo Alto, CA). Melting points were checked using a Thomas-Hoover capillary melting point apparatus (Philadelphia, PA) and are uncorrected. Low-resolution mass spectra (MS) were recorded on a Micromass 70-VSE, Finnigan MAT CH-5, and ZAB-SE spectrometers, respectively. High-resolution mass spectra were obtained on a VG 70-SE-4E spectrometer. Mass spectra were acquired in the positive ion mode under electron impact (EI, 70 eV), fast-atom bombardment mass (FAB), and electrospray ionization (ESI) methods. Methyl 4-bromo-3-oxopentanoate and (2*S*)-2-((2-benzoylphenyl)amino)-3-(4-hydroxyphenyl)-propionic acid methyl ester were prepared according to literature methods (*19*, *20*). Koser's reagent **11a** was purchased from Aldrich. Compounds **10a**, **10b**, and **11c** were prepared according to the literature method (*31*−*33*): Diacetoxyiodo-*p*-methoxybenzene (**10a**) yield 69%, mp 131−135 °C, literature (*31*) mp 133−135 °C; 2-(diacetoxyiodo)thiophene (**10b**) yield 51%, mp 119−125 °C; literature (*32*) mp 120−122 °C (decomp); 2-[hydroxy(tosyloxy)-iodo]thiophene (**11c**) yield 95%, mp 62−66 °C (decomp), literature (*33*) mp 65−68 °C (decomp).

[2-(4-Fluorophenyl)-5-methyloxazol-4-yl]-acetic Acid Methyl Ester (6a). To a solution of 4-fluorobenzamide (1.23 g, 8.85 mmol) in 1,2-dichlorobenzene (50 mL) was added methyl 4-bromo-3-oxopentanoate (1.84 g, 8.85 mmol). The reaction mixture was refluxed using a Dean−Stark trap at 120 °C for 16 h. The resulting dark slurry was cooled to room temperature, diluted with EtOAc (100 mL), and washed with aqueous sodium bicarbonate (100 mL). The organic layer was separated and dried with sodium sulfate, and the solvents were removed in vacuo. Purification of the material by silica gel flash column chromatography using 10% EtOAc/ hexane as eluant afforded the product **6a** (683 mg, 31%) as an oil: ^{1}H NMR (400 MHz, $CDCl_3$) δ 2.35 (s, 3H), 3.56 (s, 2H), 3.73 (s, 3H), 7.10 (m, 2H), 7.97 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 10.25, 31.91, 52.19, 115.77 (J = 22.0 Hz), 123.90 (J = 4.0 Hz), 128.09 (J = 8.4 Hz), 129.35, 145.72, 158.76, 163.77 (J = 249.6 Hz), 170.72; MS (FAB) *m*/*z* 250 (M + H). HRMS calcd for $C_{13}H_{13}FNO_3$ 250.0879, found 250.0878. Registry Number: 196810-28-3.

[2-(4-Bromophenyl)-5-methyloxazol-4-yl]acetic Acid Methyl Ester (6b). Prepared from 4-bromobenzamide by the method used to prepare compound **6a** and afforded the title compound **6b** (35%) as a white solid: mp 58−61 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ 2.33 (s, 3H), 3.55 (s, 2H), 3.71 (s, 3H), 7.52−7.54 (m, 2H), 7.81−7.83 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 10.22, 31.84, 52.16, 124.20, 126.41, 127.42, 129.60, 131.82, 146.00, 158.64, 170.66; MS (ESI) *m*/*z* 310 (M^+). HRMS calcd for $C_{13}H_{13}BrNO_3$ 310.0079, found 310.0082. Registry N591775-29-0.

[2-(4-Iodophenyl)-5-methyloxazol-4-yl]acetic Acid Methyl Ester (6c). Prepared from 4-iodobenzamide by the method used to prepare compound **6a** and afforded the title compound **6c** (37%) as a white solid: mp 90−91 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ 2.35 (s, 3H), 3.56 (s, 2H), 3.73 (s, 3H), 7.69−7.71 (m, 2H), 7.75−7.77 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 10.29, 31.90, 52.22, 96.21, 127.00, 127.52, 129.65, 137.81, 146.09, 158.82, 170.72; MS (ESI) *m*/*z* 358 (M^+). HRMS calcd for $C_{13}H_{13}INO_3$ 357.9940, found 357.9940.

2-[2-(4-Fluorophenyl)-5-methyloxazol-4-yl]ethanol (7a). To a stirred solution of compound **6a** (612 mg, 2.46 mmol) in tetrahydrofuran (10 mL) at 0 °C was added 1.0 M solution of $LiAlH_4$ (2.46 mL, 2.46 mmol) in tetrahydrofuran. The resulting solution was stirred at room temperature for 45 min, then cooled to 0 °C, and quenched by careful addition of a minimum volume of H_2O. The resulting heterogeneous mixture was filtered under vacuum, and the filtrate was concentrated in vacuo. Purification

of this material by silica gel flash column chromatography using 40% EtOAc/hexane as eluant afforded the product **7a** (326 mg, 60%) as a pale yellow solid: mp 102−104 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 2.33 (s, 3H), 2.72 (t, J = 6.0 Hz, 2H), 3.41 (br, 1H), 3.92 (t, J = 6.0 Hz, 2H), 7.10−7.14 (m, 2H), 7.96−7.99 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 10.10, 27.90, 61.77, 115.90 (J = 22.0 Hz), 128.15 (J = 4.0 Hz), 129.35 (J = 8.4 Hz), 133.66, 144.26, 158.69, 165.11 (J = 249.6 Hz); MS (EI) m/z 221 (M^+). HRMS calcd for $C_{12}H_{12}FNO_2$ 221.0852, found 221.0853. Registry Number: 853309-24-7.

2-[2-(4-Bromophenyl)-5-methyloxazol-4-yl]ethanol (7b). To a stirred solution of compound **6b** (465 mg, 1.5 mmol) in methanol (10 mL) at room temperature was added $NaBH_4$ (570 mg, 15.0 mmol) carefully and portionwise over a 3 h period using a spatula. The resulting solution was stirred at room temperature for 6 h, then cooled to 0 °C and quenched by careful addition of H_2O. Methanol was evaporated and diluted with EtOAc (15 mL) and brine (15 mL). The organic layer was separated and dried with sodium sulfate, and the solvents were removed in vacuo. Purification of the material by silica gel flash column chromatography using 40% EtOAc/hexane as eluant afforded the product **7b** (318 mg, 75%) as a white solid: mp 85−91 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 2.29 (s, 3H), 2.70 (t, J = 6 Hz, 2H), 3.23 (br, 1H), 3.89 (t, J = 6.0 Hz, 2H), 7.65−7.68 (m, 2H), 7.73−7.77 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 10.06, 28.12, 61.67, 124.23, 126.29, 127.34, 131.88, 134.07, 144.51, 158.58; MS (EI) m/z 283 (M^+). HRMS calcd for $C_{12}H_{12}BrNO_2$, 283.0031 found 283.0037. Registry Number: 328918-84-9.

2-[2-(4-Iodophenyl)-5-methyloxazol-4-yl]ethanol (7c). Prepared from compound **6c** by the method used to prepare compound **7b** and afforded the title compound **7c** (62%) as a white solid: mp 108−111 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ 2.32 (s, 3H), 2.70 (t, J = 6.0 Hz, 2H), 3.23 (br, 1H), 3.89 (t, J = 6.0 Hz, 2H), 7.65−7.68 (m, 2H), 7.73−7.77 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 10.09, 28.10, 61.68, 96.18, 126.81, 127.38, 134.07, 137.81, 144.56, 158.70; MS (EI) m/z 328 (M^+). HRMS calcd for $C_{13}H_{13}INO_3$ 328.9912, found 328.9907.

(2*S*)-(2-Benzoylphenylamino)-3-(4-{2-[2-(4-fluorophenyl)-5-methyloxazol-4-yl]ethoxy}phenyl)propionic Acid Methyl Ester (8a). To a stirred solution of triphenylphosphine (165 mg, 0.49 mmol) and diethyl azodicarboxylate (77 μL, 0.49 mmol) in tetrahydrofuran (5 mL) at 0 °C was added the mixture of (2*S*)-2-((2-benzoylphenyl)amino)-3-(4-hydroxyphenyl)propionic acid methyl ester (183 mg, 0.49 mmol) and compound **7a** (108 mg, 0.49 mmol) in tetrahydrofuran (2 mL) under nitrogen atmosphere. After the mixture was stirred at 0 °C for 1 h, the resulting solution was stirred for 8 h at room temperature under nitrogen. The solvent was removed in vacuo. The crude reaction mixture was purified by silica gel flash column chromatography using 30% EtOAc/hexane as eluant to afford the product **8a** (140 mg, 55%) as a yellow oil (55%): ^{1}H NMR (400 MHz, $CDCl_3$) δ 2.34 (s, 3H), 2.94 (t, J = 6.8, 2H), 3.11 (dd, J = 13.6, 7.2 Hz, 1H), 3.20 (dd, J = 14.0, 6.0 Hz, 1H), 3.69 (s, 3H), 4.19 (t. J = 6.4 Hz, 2H), 4.38 (m, 1H), 6.56−6.64 (m, 2H), 6.82 (d, J = 8.0 Hz, 2H), 7.09 (m, 2H), 7.17 (d, J = 8.0 Hz, 2H), 7.33 (m, 1H), 7.42−7.53 (m, 4H), 7.60 (d, J = 4.0 Hz, 2H), 7.95−7.98 (m, 2H), 8.91 (d, J = 7.6 Hz, 1H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 10.18, 26.28, 38.06, 52.21, 57.96, 66.52, 111.73, 114.62, 114.95, 115.79 (J = 22. 0 Hz), 118.19, 124.19 (J = 3.6 Hz), 127.95 (J = 8.3 Hz), 128.04, 128.38, 129.09, 130.29, 130.89, 132.71, 134.91, 135.55, 140.28, 145.10, 150.19, 157.80, 158.66, 163.69 (J = 249. 1 Hz), 173.05, 199.30; MS (FAB) m/z 579 (M + H). HRMS cald for $C_{35}H_{32}FN_2O_5$ 579.2295, found 579.2295.

(2*S*)-[2-Benzoylphenylamino]-3-{4-[2-(4-bromophenyloxazol 5-methyl-4-yl)ethoxy]phenyl}propionic Acid Methyl Ester (8b). Prepared from **7b** by the method used to prepare compound **8a** and obtained as a yellow oil (43%): ^{1}H NMR (500 MHz, $CDCl_3$) δ 2.34 (s, 3H), 2.94 (t, J = 6.5, 2H), 3.09−3.22 (m, 2H), 3.69 (s, 3H), 4.18 (t. J = 7.0 Hz, 2H), 4.37 (q, J = 13.5 Hz, 1H), 6.57 (t, J = 8.5 Hz, 1H), 6.63 (d, J = 8.5 Hz, 1H), 6.82 (d, J = 8.5 Hz, 2H), 7.17 (d, J = 8.5 Hz, 2H), 7.31−7.34 (m, 1H), 7.42−7.60 (m, 8H), 7.83 (d, J = 8.5 Hz, 2H), 8.90 (d, J = 7.5 Hz, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 10.21, 26.25, 38.01, 52.21, 57.91, 66.45, 111.70, 114.59, 114.93, 118.15, 124.03, 126.67, 127.36, 128.02, 128.36, 129.07, 130.27, 130.88, 131.87, 132.98, 134.90, 135.54, 140.24, 145.42, 150.16, 157.75, 158.55, 173.03, 199.28; MS (ESI) m/z 639 (M^+). HRMS calcd for $C_{35}H_{31}BrN_2O_5$ 639.1495, found 639.1487.

(2*S*)-[2-Benzoylphenylamino]-3-{4-[2-(4-iodophenyloxazol 5-methyl-4-yl)ethoxy]phenyl}propionic Acid Methyl Ester (8c). Prepared from **7c** by the method used to prepare compound **8a** and obtained as a yellow oil (50%): ^{1}H NMR (400 MHz, $CDCl_3$) δ 2.33 (s, 3H), 2.93 (t, J = 6.8, 2H), 3.09−3.22 (m, 2H), 3.69 (s, 3H), 4.18 (t. J = 6.4 Hz, 2H), 4.38 (q, J = 13.2 Hz, 1H), 6.55−6.59 (m, 1H), 6.63 (d, J = 8.8 Hz, 1H), 6.82 (d, J = 8.8 Hz, 2H), 7.17 (d, J = 8.8 Hz, 2H), 7.31−7.35 (m, 1H), 7.42−7.53 (m, 4H), 7.58−7.60 (m, 2H), 7.69 (d, J = 8.4 Hz, 2H), 7.75 (d, J = 8.8 Hz, 2H), 8.91 (d, J = 7.6 Hz, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 10.18, 26.22, 37.98, 52.17, 57.87, 66.43, 95.92, 111.68, 114.57, 114.90, 118.13, 127.17, 127.37, 127.99, 128.33, 129.04, 130.25, 130.85, 132.97, 134.86, 135.49, 137.77, 140.21, 145.42, 150.12, 157.71, 158.60, 172.98, 199.22; MS (ESI) m/z 687 (M + H). HRMS calcd for $C_{35}H_{32}IN_2O_5$ 687.1356, found 687.1358.

(2*S*)-(2-Benzoylphenylamino)-3-(4-{2-[2-(4-fluorophenyl)-5-methyloxazol-4-yl]ethoxy}phenyl)propionic Acid (1). A stirred solution of compound **8a** (50 mg, 0.086 mmol) in THF/MeOH (v/v = 3:1, 1.25 mL) was treated with 1.0 M LiOH (172 μL, 0.172 mmol). The resulting solution was stirred at room temperature for 4 h. To the reaction mixture was added 1 N HCl (200 uL), and that solution was extracted with EtOAc (5 mL). The organic layer was separated and dried with sodium sulfate. The obtained organic layers were concentrated and purified by silica gel flash column chromatography using 5% MeOH/CH_2Cl_2 as eluant to afford the product **1** (47 mg. 96%) as a yellow solid: mp 95−101 °C; ^{1}H NMR (400 MHz, CD_3OD) δ 2.29 (s, 3H), 2.89 (t, J = 6.4 Hz, 2H), 3.15 (dd, J = 13.8, 7.4 Hz, 1H), 3.23 (dd, J = 13.8, 5 Hz, 1H), 4.14 (t, J = 6.4 Hz, 2H), 4.27−4.30 (m, 1H), 6.49 (t, J = 7.6 Hz, 1H), 6.73 (d, J = 8.8 Hz, 1H), 6.77 (d, J = 8.4 Hz, 2H), 7.15−7.22 (m, 4H), 7.29−7.35 (m 2H), 7.43−7.54 (m, 4H), 7.94−7.97 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 10.19, 26.15, 37.99, 57.90, 66.38, 111.67, 114.54, 114.90, 115.81 (J = 22.0 Hz), 118.09, 127.97, 128.01 (J = 8.0 Hz), 128.29, 129.03, 130.23, 130.85, 132.40, 134.88, 135.50, 140.17, 145.23, 150.09, 157.67, 158.61, 163.71 (J = 249.0 Hz), 172.99, 199.24; MS (FAB) m/z 565 (M + H). HRMS calcd for $C_{34}H_{30}FN_2O_5$ 565.2139, found 565.2139. Registry Number: 196808-49-8.

(2*S*)-(2-Benzoylphenylamino)-3-(4-{2-[2-(4-bromophenyl)-5-methyloxazol-4-yl]ethoxy}phenyl)propionic Acid (2). Prepared from **8b** by the method used to prepare compound **1** and obtained as a yellow solid (98%): mp 102−107 °C; ^{1}H NMR (500 MHz, DMSO-d_6) δ 2.27 (s, 3H), 2.82 (t, J = 6.5 Hz, 2H), 2.97 (dd, J = 13.5, 6.5 Hz, 1H), 3.16 (dd, J = 13.5, 5 Hz, 1H), 4.04 (t, J = 7.0 H, 2H), 4.21 (m, 1H), 6.43 (t, J = 7.0 Hz, 1H), 6.69−6.74 (m, 3H), 7.08 (d, J = 8.5 Hz, 2H), 7.24−7.25 (m, 2H), 7.46−7.55 (m, 5H), 7.66 (d, J = 8.5 Hz, 2H), 7.79 (d, J = 8.0 Hz, 2H), 8.77 (d, J = 7.5 Hz, 1H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 9.84, 25.53, 36.83, 58.06, 65.96, 112.60, 113.23, 113.94, 116.77, 123.42, 126.25, 127.35, 127.84, 128.16, 128.55, 130.45, 130.76, 132.09, 132.97, 134.59, 134.68, 140.21, 145.50,

150.30, 156.66, 157.49, 175.13, 197.59; MS (ESI) *m*/*z* 625(M + H). HRMS calcd for $C_{34}H_{30}BrN_2O_5$ 625.1338, found 625.1335.

(2*S*)-(2-Benzoylphenylamino)-3-(4-{2-[2-(4-iodophenyl)-5-methyloxazol-4-yl]ethoxy}phenyl)propionic Acid (3). Prepared from **8c** by the method used to prepare compound **1** and obtained as a yellow solid (98%): mp 107−110 °C; ^{1}H NMR (500 MHz, DMSO-d_6) δ 2.29 (s, 3H), 2.85 (t, J = 6.5 Hz, 2H), 2.98 (dd, J = 13.5, 6.5 Hz, 1H), 3.13 (dd, J = 13.5, 5 Hz, 1H), 4.10 (t, J = 7.0 H, 2H), 4.42 (m, 1H), 6.54 (t, J = 7.5 Hz, 1H), 6.76 (d, J = 8.5 Hz, 2H), 6.79 (d, J = 8.5 Hz, 1H), 7.09 (d, J = 8.5 Hz, 2H), 7.31 (d, J = 8.0 Hz, 1H), 7.37 (t, J = 7.5 Hz, 1H), 7.47−7.51 (m, 4H), 7.54−7.57 (m 1H), 7.65 (d, J = 8.5 Hz, 2H), 7.84 (d, J = 8.5 Hz, 2H), 8.68 (d, J = 7.5 Hz, 1H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 9.84, 25.50, 36.58, 56.80, 65.96, 96.96, 112.47, 114.14, 117.08, 126.49, 127.23, 128.20, 128.61, 129.18, 130.36, 130.94, 132.92, 134.68, 134.92, 137.88, 139.92, 145.47, 149.91, 156.93, 157.70, 162.30, 173.62, 197.99; MS (ESI) *m*/*z* 673 (M + H), 515 (80%), 257 (100%). HRMS calcd for $C_{34}H_{30}IN_2O_5$ 673.1199, found 673.1190.

(2*S*)-(2-Benzoylphenylamino)-3-(4-{2-[2-(4-tributylstannanyl)-5-methyloxazol-4-yl]ethoxy}phenyl)propionic Acid Methyl Ester (9). To a solution of tetrakis(triphenylphospine)-palladium(0) (22 mg, 5 mol %) and bis(tributyltin) (217 μL, 0.418 mmol) in dry toluene (5 mL) was added (2*S*)-[2-benzoylphenylamino]-3-{4-[2-(4-iodophenyloxazol 5-methyl-4-yl)ethoxy]phenyl}propionic acid methyl ester **8c** (258 mg, 0.38 mmol) in dry toluene (3 mL) at room temperature under nitrogen atmosphere. After addition, the reaction mixture was heated to 120 °C for 6 h. After evaporation of the solvent, the concentrate was filtered through a layer of Celite, and the residue was subjected to flash chromatography using 20% EtOAc/hexane as eluant to afford the product **9** (271 mg, 84%) as a yellow oil: ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.88 (t, J = 7.2 Hz, 9H), 1.08 (t, J = 8.2, 6H), 1.30−1.36 (m, 6H), 1.50−1.58 (m, 6H), 2.35 (s, 3H), 2.95 (t, J = 6.4 Hz, 2H), 3.09−3.22 (m, 2H), 3.69 (s, 3H), 4.19 (t, J = 6.8 Hz, 2H), 4.38 (q, J = 13.2 Hz, 1H), 6.57 (t, J = 7.2 Hz, 1H), 6.63 (d, J = 8.4 Hz, 1H), 6.83 (d, J = 8.4 Hz, 2H), 7.17 (d, J = 8.4 Hz, 2H), 7.31−7.35 (m, 1H), 7.42−7.61 (m, 8H), 7.89 (d, J = 8.4 Hz, 2H), 8.91 (d, J = 7.6 Hz, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 9.58, 10.23, 13.66, 26.33, 27.31, 29.03, 38.09, 52.22, 57.97, 66.61, 111.72, 114.61, 114.91, 118.16, 124.95, 127.19, 128.01, 128.29, 129.07, 130.24, 130.86, 132.58, 134.87, 135.51, 136.66, 140.23, 144.83, 144.97, 150.15, 157.79, 159.73, 173.02, 199.22; MS (ESI) *m*/*z* 851 (M + H, 10%), 625 (10%), 291 (80%), 235 (100%). HRMS calcd for $C_{47}H_{59}N_2O_5Sn$ 851.3446, found 851.3486.

[(Hydroxy)(tosyloxy)iodo]-*m*-methoxybenzene (11b). To a solution of compound **10a** (2 g, 5.68 mmol) was added to solution of *p*-toluenesulfonic acid monohydrate (1.1 g, 5.7 mmol) in acetonitrile (10 mL) at room temperature under nitrogen atmosphere. The mixture was stirred for 12 h at room temperature. After the addition of diethyl ether and EtOAc (v/v = 2:1, 30 mL), the solid was filtered and dried in vacuo to give the product **11b** as a white solid (92%): mp 134−137 °C (decomp); ^{1}H NMR (400 MHz, CD_3OD) δ 1.98 (s, 3H), 3.52 (s, 3H), 6.81 (d, J = 7.5 Hz, 2H), 6.93−6.95 (m, 1H), 7.17 (d, J = 8.0 Hz, 2H), 7.22 (t, J = 8.0 Hz, 1H), 7.45 (d, J = 8.0 Hz, 2H), 7.52−7.53 (m, 1H), 9.47 (br, 1H); ^{13}C NMR (100 MHz, CD_3OD) δ 21.28, 56.53, 114.50, 120.95, 121.95, 126.89, 128.91, 129.84, 133.42, 141.92, 142.94, 162.49.

[(Hydroxy)(tosyloxy)iodo]thiophene (11c). To a solution of compound **10b** (500 mg, 1.52 mmol) was added to solution of *p*-toluenesulfonic acid monohydrate (290 mg, 1.52 mmol) in acetonitrile (10 mL) at room temperature under nitrogen atmosphere. The mixture was stirred for 1 h at room temperature. After the addition of diethyl ether and EtOAc (v/v = 2:1, 30 mL), the solid was filtered and dried in a short time under nitrogen atmosphere to give the product **11c** (95%). Because this product (**11c**) was unstable under air atmosphere and at room temperature, it was used immediately after isolation to prepare the next compound, **12c**: ^{1}H NMR (400 MHz, CD_3OD) δ 2.36 (s, 3H), 4.88 (s, 3H), 7.22 (d, J = 8.0 Hz, 2H), 7.35−7.37 (m, 1H), 7.68 (d, J = 8.4 Hz, 2H), 8.09−8.10 (m, 1H), 8.24−8.25 (m, 1H); ^{13}C NMR (100 MHz, CD_3OD) δ 21.30, 126.95, 129.83, 131.19, 141.39, 141.76, 143.29, 143.38, 145.23.

(2*S*)-[2-Benzoylphenylamino]-3-{4-[2-(4-iodophenyl(phenyl) Oxazol 5-methyl-4-yl)ethoxy]phenyl}propionic Acid Methyl Ester Iodonium Tosylate (12a). To a solution of Koser's reagent **11a** (47 mg, 0.12 mmol) in CH_3CN (3 mL) was added tin compound **9** (100 mg, 0.12 mmol) in CH_3CN (3 mL) at room temperature under nitrogen atmosphere. The reaction mixture was stirred for 12 h at room temperature under nitrogen atmosphere. The solvent was evaporated using a stream of nitrogen. The crude mixture was dissolved a small amount of EtOH (1.5 mL) and transferred to the centrifuge tube to which was added excess diethyl ether (20 mL). After centrifuging, the collected yellow oil was dried in vacuo to give the product **12a** (42 mg, 38%) as a yellow oil: ^{1}H NMR (400 MHz, CD_3OD) δ 2.32 (s, 3H), 2.34 (s, 3H), 2.91 (t, J = 6.4 Hz, 2H), 3.06−3.20 (m, 2H), 3.69 (s, 3H), 4.16 (t. J = 6.0 Hz, 2H), 4.56 (t, J = 6.0 Hz, 1H), 6.56−6.60 (m, 1H), 6.73−6.78 (m, 3H), 7.08 (d, J = 8.8 Hz, 2H), 7.21 (d, J = 8.0 Hz, 2H), 7.34−7.71 (m, 12H), 8.02 (d, J = 8.4 Hz, 2H), 8.18−8.24 (m, 4H); ^{13}C NMR (100 MHz, CD_3OD) δ 10.15, 21.29, 26.88, 38.36, 52.70, 58.29, 67.26, 113.30, 115.61, 116.13, 116.20, 116.59, 119.37, 126.94, 129.19, 129.70, 129.78, 130.00, 131.49, 132.08, 132.20, 133.24, 133.75, 135.04, 136.25, 136.38, 136.56, 137.03, 141.49, 141.59, 143.56, 148.56, 151.25, 158.68, 159.09, 174.37, 200.81; MS (ESI) *m*/*z* 763 (M^+ − OTs, 100%). HRMS calcd for $C_{41}H_{36}IN_2O_5$ 763.1669, found 763.1657.

(2*S*)-[2-Benzoylphenylamino]-3-{4-[2-(4-iodophenyl(3-methoxyphenyl) oxazol 5-methyl-4-yl)ethoxy]phenyl}propionic Acid Methyl Ester Iodonium Tosylate (12b). Prepared from tin precursor **9** and the *m*-methoxyphenyl iodonium salt **11b** by the method used to prepare iodonium salt **12a** and obtained as a yellow oil: ^{1}H NMR (400 MHz, CD_3OD) δ 2.29 (s, 3H), 2.31 (s, 3H), 2.87 (t, J = 6.0 Hz, 2H), 3.03−3.17 (m, 2H), 3.67 (s, 3H), 3.80 (s, 3H), 4.12 (t, J = 6.5 Hz, 2H), 4.53 (t, J = 6.0 Hz, 1H), 6.56 (t, J = 7.0 Hz, 1H), 6.71−6.75 (m, 3H), 7.06 (d, J = 8.5 Hz, 2H), 7.17−7.20 (m, 3H), 7.33−7.49 (m, 8H), 7.66 (d, J = 8.0 Hz, 2H), 7.69−7.71 (m, 1H), 7.79 (t, J = 2.5 Hz, 1H), 7.95 (d, J = 8.5 Hz, 2H), 8.20 (d, J = 8.5 Hz, 2H); ^{13}C NMR (100 MHz, CD_3OD) δ 10.17, 21.33, 26.87, 38.35, 52.75, 56.51, 58.34, 67.27, 113.32, 115.62, 115.95, 116.12, 116.66, 119.39, 119.68, 121.87, 126.94, 126.99, 128.38, 129.25, 129.71, 129.81, 129.85, 130.05, 131.53, 132.12, 132.24, 133.88, 135.07, 136.29, 137.04, 141.55, 141.69, 143.52, 148.62, 151.31, 158.78, 159.15, 162.83, 174.43, 200.90; MS (ESI) *m*/*z* 793 (M^+ − OTs, 100%), 752 (35%). HRMS calcd for $C_{42}H_{38}IN_2O_6$ 793.1775, found 793.1801.

(2*S*)-[2-Benzoylphenylamino]-3-{4-[2-(4-iodophenyl(2-thiophenyl) oxazol 5-methyl-4-yl)ethoxy]phenyl}propionic Acid Methyl Ester Iodonium Tosylate (12c). Prepared from tin precursor **9** and thiophene iodonium salt **11c** by the method used to prepare iodonium salt **12a** and obtained as a yellow oil: ^{1}H NMR (500 MHz, CD_3OD) δ 2.30 (s, 3H), 2.32 (s, 3H), 2.88 (t, J = 6.5 Hz, 2H), 3.04−3.17 (m, 2H), 3.67 (s, 3H), 4.13 (t, J = 6.0 Hz, 2H), 4.54 (t, J = 6.0 Hz, 1H), 6.56 (t, J = 7.5 Hz, 1H), 6.72 (d, J = 8.0 Hz, 1H), 6.75 (d, J = 9.0 Hz, 2H), 7.07 (d, J = 8.5 Hz, 2H), 7.14−7.16 (m, 1H), 7.18 (d, J = 8.0 Hz, 2H), 7.33−7.37 (m, 2H), 7.41−7.44 (m, 2H), 7.48−7.52 (m, 3H), 7.67 (d, J = 8.0 Hz, 2H), 7.86−7.87 (m, 1H), 7.95 (d, J = 9.0 Hz, 2H), 8.01−8.02 (m, 1H), 8.19 (d, J = 8.5

Hz, 2H); ^{13}C NMR (100 MHz, CD_3OD) δ 10.13, 21.29, 26.90, 38.39, 52.70, 58.33, 67.28, 99.20, 113.31, 115.63, 116.13, 119.41, 119.55, 126.95, 129.22, 129.70, 129.79, 130.01, 130.93, 131.50, 132.15, 132.22, 135.08, 136.26, 136.38, 136.41, 138.78, 141.56, 141.65, 142.39, 143.52, 148.66, 151.29, 158.73, 159.12, 174.43, 200.92; MS (ESI) *m*/*z* 769 ($M^+ - OTs$, 100%). HRMS calcd for $C_{39}H_{34}IN_2O_5S$ 769.1233, found 769.1238.

Halodestannylation Reactions with Bromine and Iodine. *Synthesis of (2S)-(2-benzoylphenylamino)-3-(4-{2-[2-(4-bromophenyl)-5-methyloxazol-4-yl]ethoxy}phenyl)propionic Acid (**2**).* To a solution of compound **9** (10 mg, 0.012 mmol) in peracetic acid (500 μL, 0.3% v/v in acetic acid) was added NH_4-Br (1.3 mg, 0.013 mmol) in H_2O (500 μL) at room temperature. The reaction mixture was stirred for 30 min at room temperature, then diluted with 0.5 N NaOH (3 mL) and EtOAc (3 mL). The organic layer was separated and dried with sodium sulfate, and the solvents were removed in vacuo. The crude mixture obtained was dissolved in THF/MeOH (v/v = 3:1, 0.5 mL) and then was treated with 0.1 M LiOH (130 μL, 0.013 mmol). The resulting solution was stirred at room temperature for 1 h. The reaction mixture was then poured into 1 N HCl (20 μL) and extracted with EtOAc. The organic layer was separated and dried with sodium sulfate. The obtained organic layers were concentrated and purified by silica gel flash column chromatography using 5% MeOH/CH_2Cl_2 as eluant to afford the product **2** (7 mg. 91%) as a yellow solid.

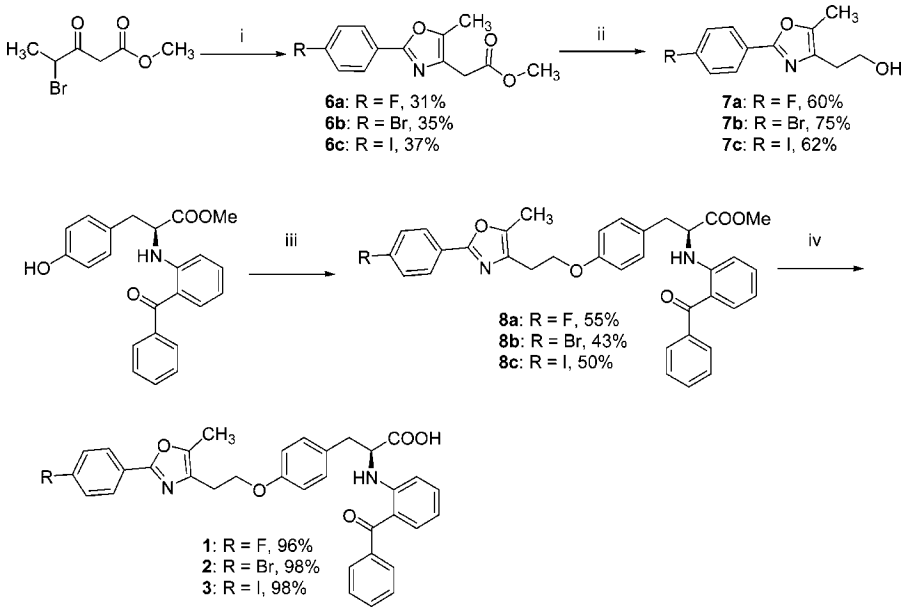
*Synthesis of (2S)-(2-benzoylphenylamino)-3-(4-{2-[2-(4-iodophenyl)-5-methyloxazol-4-yl]ethoxy}phenyl)propionic Acid (**3**).* To a solution of compound **9** (10 mg, 0.012 mmol) in peracetic acid (500 μL, 0.3% v/v in acetic acid) was added NaI (2 mg, 0.013 mmol) in H_2O (500 μL) at room temperature. The reaction mixture was stirred for 30 min at room temperature, then diluted with 0.5 N NaOH (3 mL) and EtOAc (3 mL). The organic layer was separated and dried with sodium sulfate, and the solvents were removed in vacuo. The hydrolysis of methyl ester was performed by the method used for **2** and obtained as a yellow solid (93%).

Fluorination of Iodonium Salts. *Synthesis of (2S)-(2-benzoylphenylamino)-3-(4-{2-[2-(4-fluorophenyl)-5-methyloxazol-4-yl]ethoxy}phenyl)propionic Acid (**1**).* To a solution of compound **12c** (10 mg, 0.011 mmol) in CH_3CN (1 mL) was added CsF (2.5 mg, 0.016 mmol). The reaction mixture was heated at 90 °C for 60 min. After cooling, the solvent was removed in vacuo. Hydrolysis of the methyl ester was performed by the method used to prepare compound **2**. The progress of the reaction and yields were analyzed by HPLC (prep silica gel column, 10 μm, 10 × 250 mm; hexane/isopropanol/methylene chloride/trifluorosulfonic acid = 70:1.5:28:0.03 (v/v): 254 nm; 4 mL/min).

PPARγ Binding Affinity Assays. The binding of compound **1** to PPARγ was evaluated using a scintillation proximity assay (SPA) adapted from the method described by Sun et al. (*34*). Briefly, only the energy emitted from the negatrons of the bead-protein-bound radioligand complex can be absorbed by scintillant-coated SPA beads to produce light, which can be detected in a liquid scintillation counter. The potency of the test compound is assessed by its displacement of a tritium-labeled ligand. Yttrium silicate (Ysi) copper His-Tag SPA beads were purchased from Amersham Biosciences (Piscataway, NJ). A histidine-tagged human PPARγ ligand-binding domain (amino acids 195−477) was acquired from Invitrogen (Carlsbad, CA). The tritium ligand, [^{3}H]-rosiglitazone, which has high affinity and high potency for PPARγ (K_d and EC_{50} ca. 15−20 nM) (*35*), was obtained from American Radiolabeled Chemicals (St. Louis, MO).

[^{3}H]-Rosiglitazone and PPARγ protein were diluted to 23 μCi/mL and 50 ng/mL stock, respectively. Radioligand, protein, and test compound at various concentrations (10 nM to 2 μM) were incubated at room temperature for 2 h. SPA beads were diluted and aliquoted into a clear-bottomed 96-well plate according to the manufacturer's specifications. Test ligand, [^{3}H]-Rosiglitazone, and protein were then added to the assay plate and incubated at room temperature for at least 1 h before the plate was read by a Packard TopCount plate reader (Perkin-Elmer, Wellesley, MA). GW1929 (Cayman Chemical Co., Ann Arbor, MI), a potent PPARγ agonist, served as a positive control. Nonspecific binding was very low. The initial IC_{50} values of GW1929 and test compound were calculated by the *Prism* program (GraphPad Software, San Diego, CA). The reported compound IC_{50} value of the compound tested was normalized against GW1929 due to the variability of the assay (*36*).

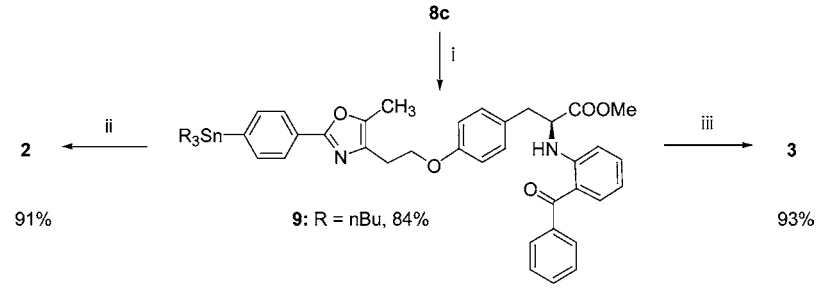
RESULTS AND DISCUSSION



Chemical Synthesis. We prepared compounds **1**−**3** by two approaches: the first (Scheme 2) was to prepare authentic samples of these PPARγ ligands; the second proceeded through precursors from which the halogen could be introduced at a very late step, using a simple halogen reagent (Schemes 3 and 7), as would be needed for labeling these compounds with radiohalogens at high specific activity.

Synthesis of (2*S*)-(2-benzoylphenylamino)-3-(4-{2-[2-(4-halogenophenyl)-5-methyloxazol-4-yl]ethoxy}phenyl)-propionic Acid (1−3). As shown in Scheme 2, the three PPARγ ligands (**1**−**3**) were synthesized in four steps, using a modification of known methods (*19*−*21*). Three halogen-substituted phenyl oxazole rings **6a**−**c** were synthesized directly from a 4-halogen-substituted benzamide and 4-bromo-3-oxopentanoate, followed by reduction of the ester with lithium aluminum hydride or sodium borohydride in tetrahydrofuran to produce the corresponding alcohols **7a**−**c**. Using Mitsunobu conditions, alcohols **7a**−**c** were coupled to (2*S*)-2-((2-benzoylphenyl)-amino)-3-(4-hydroxyphenyl)propionic acid methyl ester. Hydrolysis of the methyl esters **8a**−**c** with LiOH solution proceeded under mild conditions to give the desired fluorine, bromine, and iodine-substituted PPARγ ligands **1**−**3**.

Synthesis of (2*S*)-(2-benzoylphenylamino)-3-(4-{2-[2-(4-tributylstannylphenyl)-5-methyloxazol-4-yl]ethoxy}phenyl)-propionic Acid Methyl Ester (9) and Iodonium Tosylates (12a−c). A different approach is needed for the synthesis of the target compounds **1**−**3** in radiolabeled form. Because the radiohalogens have relatively short half-lives (F-18, 110 min; Br-76, 16.1 h; I-124, 4.2 d), it is best if they can be introduced late in the synthesis, in a rapid and efficient manner, into appropriate precursors using simple halogenating agents that are available in radiolabeled form at high specific activity. The trialkylstannane compound **9**, which can readily be prepared from the iodo compound **8c** in the presence of bis(tributyl)tin and a catalytic quantity of tetrakis(triphenylphosphine)palladium (Scheme 3), is a precursor that could be used to prepare the bromine- and iodine-substituted PPARγ ligands **2** and **3** in labeled form by a halodestannylation reaction. These reactions proceed readily (Scheme 3).



We considered a number of approaches that would be suitable for the preparation of the fluorine-substituted PPARγ ligand (**1**) in F-18 labeled form at the high specific activity required for PET imaging of nuclear receptors. For this type of tracer-level labeling, [^{18}F]fluoride ion is the only practical fluorination reagent. Fluoride ion can be introduced into certain aromatic rings by nucleophilic aromatic substitution of a suitable leaving group, such as nitro or trimethylammonium triflate, provided the ring is sufficiently activated by ortho or para electron withdrawing groups (*37*−*39*). In our system, it was not clear whether the 2-oxazolyl substituent at the para position would provide sufficient activation for fluoride ion substitution.

[a] Reaction conditions: (i) TMAF, DMSO, 130 °C; (ii) $CF_3SO_2OCH_3$, CH_2Cl_2, rt.

As shown in Scheme 4, in studies on a model system, we were unable to effect fluoride ion substitution on the corresponding p-nitro precursor under a variety of conditions. Curiously, we were also unable to prepare the more reactive p-trimethylammonium precursor, because in the final methylation step of the dimethylaniline precursor, the oxazole moiety became N-methylated in preference to the aromatic amine, giving the N-methyloxazolium salt as the only identifiable product. Although alternative routes to reach this precursor were considered, the uncertainty of success with this modestly activated ring system led us to consider different approaches altogether.

It was known that diaryliodonium salts can be used as precursors for fluoroarenes (*27*), and Widdowson showed that these salts are useful, as well, for the introduction of fluorine-18 into arenes (*28*). Mixed functional diaryliodonium tosylates can be prepared by the reaction of aryltrialkylstannanes with hydroxy(tosyloxy)iodobenzene (Koser's reagent, **11a**) under mild conditions (*26*−*29*). To prepare diaryliodonium precursors suitable for introducing fluorine into the PPARγ ligand **1** (Scheme 5), we reacted the tributyltin analog **9** with commercially available Koser's reagent, as well as with two other related and known hydroxy(tosyloxy)iodoarenes (**11b** and **11c**) derived, respectively, from *m*-methoxyphenyl iodide (*m*-io-

doanisole) and 2-iodothiophene (*31*−*33*). These reactions proceeded readily and in good yield under mild conditions.

The diaryliodonium salts were readily prepared from the same tin precursor **9** that was used to prepare the bromo and iodoanalogs (**2** and **3**) by exposure to the three hydroxyl(tosyloxy)iodoarenes **11a**−**c** (Scheme 6). These iodonium salts are liquids that can be easily isolated, but they cannot be rigorous purified. They are sufficiently pure, however, to function as effective precursors for fluorination to produce the final compound **1** (Scheme 7).

In fluorination of mixed functional diaryliodonium salts, steric demand and/or electron deficiency of the aromatic rings determines the site of fluorine substitution (*27*, *28*, *40*, *41*). Because steric effects in the two rings of our systems are essentially equivalent, fluoride anion is expected to attack the more electron deficient ring. Thus, the three salts we have prepared present an interesting situation, where the "dispensable ring" is either phenyl or the two more electron rich rings, *m*-methoxyphenyl or 2-thiophenyl. We avoided the choice of the *p*-methoxyphenyl analog of compound **11b** series, because the reagent required, [hydroxy(tosyloxy)iodo]-*para*-methoxybenzene, is known to be unstable and to decompose violently at room temperature (*42*). The reagent to prepare the thiophene heteroaromatic iodonium salt **12c**, namely, [hydroxy(tosyloxy)iodo]thiophene **11c**, is also somewhat unstable; however, we were able to isolate it and use it immediately to prepare the PPARγ precursor **12c** (*33*).

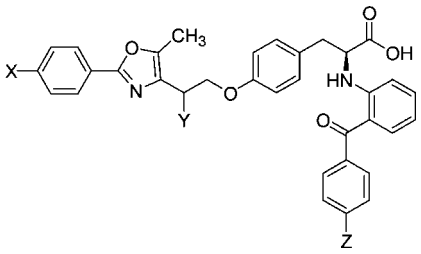
Table 1. Reaction of Fluorination with Iodonium Tosylates

		product ratio (%)[a]			
cmpd no	Ar	**1**	**3**	**4**	yields[b]
12a	phenyl	50	38	9	27%
12b	*m*-anisolyl	34	56	5	28%
12c	2-thiophenyl	68	28	1	35%

[a] Progress of the reaction and yields were analyzed by HPLC (prep. silica gel column, 10 μ, 10 × 250 mm; hexane/isopropanol/methylene chloride/trifluorosulfonic acid = 70:1.5:28.5:0.03 (v/v); 254 nm; 4 mL/min). Ratios represent the areas of the peaks associated with products **1**, **3**, and **4**; the ratios do not add to 100% because small byproduct peaks are also present. [b] Yield of isolated pure product **1**, obtained by preparative column chromatography.



Synthesis of (2*S*)-(2-Benzoylphenylamino)-3-(4-{2-[2-(4-fluorophenyl)-5-methyloxazol-4-yl]ethoxy}phenyl)-propionic Acid (1). Various conditions were explored for the preparation of the fluoride-substituted PPARγ ligand **1** from the three precursors **12a**−**c** (Scheme 7). The results from reactions conditions optimized to give the fluorine-substituted ester (CsF in acetonitrile at 90 °C) and then mild hydrolysis to the acid with LiOH are summarized in Table 1. Reaction products were analyzed by HPLC, and the crude reaction mixture showed the presence of the desired product **1** (t_R = 16.7 min) and two side products (t_R = 13.4 and 18.0 min, Figure 1). These were identified as the iodine-substituted and reduced compounds (**3** and **4**, respectively) by comparison with authentic samples that we had prepared (cf., Scheme 2). Product ratios of **1**, **3**, and **4** were calculated from the peak areas, and the

isolated yield of compound **1** was determined after purification by preparative chromatography.

The desired product, compound **1**, was produced in highest product ratio and highest yield from the 2-thiophenyl iodonium salt (**12c**). This is consistent with the fact that, in this salt, the dispensable ring is a thiophene, the most electropositive ring of the three, and thus it is most effective in directing fluoride ion to attack the other ring, that of the complex aryl system of the PPARγ portion of the salt, as is needed to produce the desired product (**1**). The isolated yields of **1** produced from the other salts, **12a** and **12b** were only somewhat lower than that from **12c**. Notably, the unsubstituted product, **4**, potentially an undesired competitor for binding to PPARγ, is also produced in lowest amounts from the thiophenyl precursor **12c**.

As a matter of practical importance, it is also of note that in this chromatographic system the desired fluorine-substituted compound **1** elutes well behind the iodine-substituted byproduct (**3**), and it also precedes the unsubstituted compound (**4**, farglitazar itself), which in any case is produced in very small amounts. Thus, it should be possible to separate the fluorine-18 labeled product from the two reaction byproducts that have potential for competing for its binding to PPARγ, thus ensuring high effective specific activity.

Binding Affinity Determination. In previous work, we synthesized fluorine-substituted members of the benzophenone−tyrosine class (farglitazar) and demonstrated that they had very high binding affinity and selectivity for PPARγ receptor. The result of PPARγ binding measurements on compounds **1**−**4**, done using a scintillation proximity assay (*34*), and measurements of certain related ligands from other studies are shown in Table 2 (*17*, *20*, Lee, K. C., unpublished results). Fluorine substitution of the phenyl ring or alkyl chain of the 2-phenyloxazole system (compounds **1** and **13**) and fluorine substitution of benzophenone ring (compound **12)** provided higher-affinity and more selective PPARγ ligands (Lee, K. C., unpublished results) than did the fluorine-substituted analog of SB 213068 (**5**) that we prepared earlier (*17*). Among these, compound **1** appears to be an excellent ligand in terms of binding affinity and selectivity, and the pK_i value we obtained in this study is very close to that determined on this compound by a corporate laboratory (Lee, K. C., unpublished results).

In this study, we have also evaluated the effect of substitution of this phenyl ring with other halogen isotopes that could be used for PET or SPECT imaging, and both the bromine and iodine analogs (**2** and **3**) retain very high affinity for PPARγ, comparable to or greater than that of the fluorine-substituted compound **1** and the parent ligand farglitazar **4** (Table 2).

CONCLUSION

PPARγ, a nuclear receptor that plays critical roles in regulating lipid and carbohydrate metabolism and cellular differentiation and has marked effects on certain cancers, is an important target for in vivo imaging with PET. In our effort to develop radiohalogen-labeled ligands suitable for this purpose, we have prepared three homologous halogen-substituted analogues (fluorine, bromine, and iodine) of the selective and high-affinity PPARγ ligand **4** (farglitazar). All members of this benzophenone−tyrosine class retain very high affinity for PPARγ, superior to that of F-18 labeled ligands of the phenylpropanoic acid class that we investigated earlier (*17*). We have also developed methods by which the halogen can be introduced into each of these ligands (**1**−**3**) as the penultimate step: the heavy halogens are introduced by an electrophilic destannylation sequence and the fluorine by nucleophilic substitution on an optimized heteroarylarene iodonium salt. The latter reaction is an example of fluorine substitution on one of the most complex, highly functionalized systems using this approach. These strategies are easily adaptable to radiolabeling with these halogens in radiolabeled form. Further work describing the preparation of these compounds in radiolabeled form and evaluation of their in vivo tissue distribution will be described in forthcoming publications.

ACKNOWLEDGMENT

We are grateful for support of this work by grants from the Department of Energy (FG02 86ER60401 to J.A.K.) and the National Institute of Health (P01 HL13851 to M. J. Welch, P.I.).

Covalent Attachment of Ferrocene to Soybean Peroxidase Glycans: Electron Transfer Mediation to Redox Enzymes

Neil Carolan,[†] Robert J. Forster,[‡] and Ciarán Ó'Fágáin*,[†]

School of Biotechnology, National Centre for Sensors Research, Dublin City University, Dublin 9, and School of Chemical Sciences, National Centre for Sensors Research, Dublin City University, Dublin 9, Ireland. Received July 10, 2006; Revised Manuscript Received October 26, 2006

The electrochemical properties of native soybean peroxidase (SBP) and of SBP modified with covalently attached ferrocene electron-transfer mediators within microcavities etched at the tip of 25 μm radius platinum microelectrodes are reported. The microcavities incorporate approximately 50 fmol of SBP. In the microcavity, native SBP undergoes a relatively fast reduction but a very slow oxidation. Ferrocene mediators have been attached to the SBP glycans (Fc−SBP) (approximately 1.5 ferrocene mediators per SBP molecule). Cyclic voltammetry reveals that these centers are capable of mediating the reduction of oxidized SBP and increase the rate of heterogeneous electron transfer between the enzyme and the electrode by >10-fold. Micromolar concentrations of H_2O_2 chemically oxidize the SBP and Fc−SBP systems leading to an electrocatalytic reduction at approximately −0.1 V. Successive additions of 2.5 μmol of H_2O_2 at a constant applied potential of −0.1 V gave a steady-state constant current of approximately 60 nA within 20 s. The steady-state current increased linearly with peroxide concentration for $2.5 \leq [H_2O_2] \leq 42$ μM. Ferrocene-modified SBP shows an approximately 3-fold increase in the sensitivity of the steady-state current response to successive additions of hydrogen peroxide compared to the native enzyme. This observation indicates increased turnover of the redox enzyme per unit time in the presence of the covalently attached ferrocene mediators.

INTRODUCTION

Peroxidase enzymes (donor: hydrogen peroxide oxidoreductases; EC 1.11.1.7) find widespread use in electrochemical biosensors. They act as sensitive indicators of hydrogen peroxide levels on graphite, glassy carbon, and other electrodes (*1*−*3*). They also act as coupling enzymes with oxidases (e.g., glucose or cholesterol oxidase (*4*)).

Peroxidase from the soybean plant *Glycine max* (SBP[1]; EC 1.11.1.7) has advantages over the well-known horseradish peroxidase (HRP). SBP is more thermostable, has a broader pH−activity profile, and is readily and cheaply isolated from waste soybean hulls (*5*−*7*). It is a glycoprotein of 41 kDa with four disulfides, two structural Ca^{2+} ions, and a prosthetic heme group. Cloning and expression of recombinant SBP has led to determination of its crystal structure (*7*). Its δ-meso heme edge, the site of electron transfer between reducing substrates and the catalytic intermediates compounds **I** and **II**, is much more solvent-accessible than in other plant peroxidases (*7*). Its kinetic properties have been explored using stopped-flow techniques (*8*), and the full amino acid sequence of SBP from the plant has recently been determined (*9*). Despite these key advantages over other peroxidase enzymes, there have only been a few reports on SBP-based biosensors (*1*, *4*, *10*−*13*).

Direct electron transfer from the widely studied horseradish peroxidase (HRP) to carbon-based electrodes has been observed (*14*). However, in seeking to develop enzyme-based biosensors, a key challenge is to improve the dynamics of electron transfer between the electrode and the redox enzyme (*15*). Slow dynamics frequently arise because the enzyme's redox center is encapsulated, thus significantly increasing the electrode-active site separation. A highly successful approach to increasing the electron-transfer rate is to "electrochemically wire" the enzyme by either attaching redox-active mediators, e.g., ferrocene, that have a suitable redox potential, directly to the enzyme or using a redox-conducting polymer that can shuttle electrons to and from the active site.

In this contribution, we report an SBP modification procedure that involves covalent attachment of ferrocene to the sugars of the redox enzyme (18% of its 44 kDa molecular weight), and we compare native and ferrocene-modified SBP in an amperometric microcavity biosensor, specifically, the etched tip of a 25 μm radius platinum microelectrode that is subsequently packed with native or ferrocene-modified SBP. Ferrocene attachment significantly increased the rate of electron transfer between the electrode and the active site, giving improved signal-to-noise responses, lower limits of detection, and increased dynamic range.

EXPERIMENTAL SECTION

Materials and Methods. Ethylene diamine, ferrocene carboxylic acid, *N*-hydroxysuccinimide (NHS), *N*-acetyl-L-lysine, MOPS, Sephadex G-25, sodium *meta*-periodate, $NaCNBH_3$, 3,3′,5,5′-tetramethyl benzidine (TMB), and 2,4,6-trinitrobenzene sulfonic acid (TNBS) were obtained from Sigma-Aldrich and used without further purification. BCA protein estimation kits

and 1-(3-dimethylaminoproypl)-3-ethylcarbodiimide hydrochloride (EDC) were from Pierce. Hydrogen peroxide (30% v/v) and $FeCl_3 \cdot 6H_2O$ were obtained from BDH.

Soybean peroxidase (SBP, food grade, batch S0103261) was a gift from Quest International, Kilnaglery, Carrigaline, County Cork, Ireland. To remove particulate matter, SBP was suspended in 25 mM MOPS pH 7.0 (2.5 mg/mL, 20 mL), mixed for 20 min at room temperature, and centrifuged for 3 min at 1800 rpm (rotor diameter 7.5 cm). The supernatant was removed and stored and the pellet discarded. The concentration of SBP solutions (typical RZ 2.7) was calculated by measuring absorbance at 403 nm (millimolar extinction coefficient 90 $mM^{-1} \cdot cm^{-1}$ (*7*).

Protein determination was via the BCA standard and micro protocols in microtiter plates according to the Pierce kit insert (*16*) using bovine serum albumin (BSA) as standard.

Buffer exchange and removal of unused materials was via overnight dialysis at 4 °C or by centrifugal gel filtration (*17*) through Sephadex G-25 at room temperature.

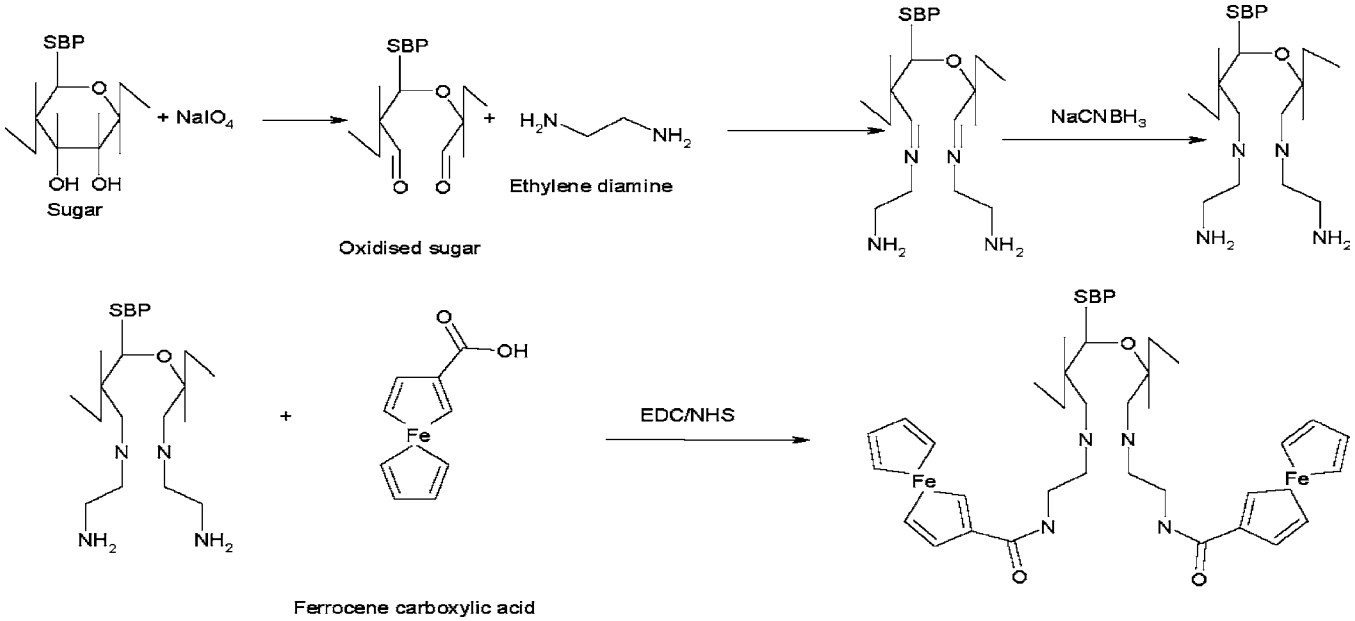
Catalytic activity assay (*18*): TMB (1 mg) was dissolved in 200 μL DMSO (final concentration 2%) and added to 9.8 mL of 100 mM citric acid buffer pH 5.5. Tween 20 (0.002% final concentration) was included in all buffers used in polystyrene microplates to prevent contact denaturation (*19*). Immediately prior to assay, 4 μL H_2O_2 (30% v/v) was added and mixed to give a final concentration of 0.04% H_2O_2. To a 50 μL sample or blank (buffer) in the wells of a 96 well microtiter plate, 150 μL reaction solution was added, mixed, and allowed to react for 150 s. Absorbances of all samples were read in triplicate simultaneously at 620 nm on a Labsystems Multiskan MS microplate reader.

Free amino groups were determined using 2,4,6-trinitrobenzene sulfonic acid (TNBS) (*20*) with α-*N*-acetyl-L-lysine (10−0.05 μM) as standard.

Covalent Attachment of Ferrocene Carboxylic Acid (FCA) to SBP Carbohydrates. An SBP solution (3.5 mg/mL, 20 mL) was prepared in 25 mM MOPS pH 7.0 and mixed with 400 μL 50 mM $NaIO_4$; this mixture was reacted with stirring for 2 h in the dark. Ethylene glycol (95% v/v, 0.6 mL) was added to quench the reaction, mixed, and left for 10 min. Next, 1 M ethylene diamine (0.215 mL) was added and reacted for 90 min, with stirring, at room temperature. The sample was dialyzed overnight into 25 mM MOPS pH 7.0 at 4 °C. To reduce the Schiff bases formed between ethylenediamine and the oxidized SBP carbohydrates to secondary amines, 0.2 mL $NaCNBH_3$ (100 mM in 0.1 M NaOH) was added and the reaction allowed to proceed at room temperature in the dark for 90 min with stirring before overnight dialysis into 25 mM MOPS pH 7.0 at 4 °C. To this aminated SBP preparation was added *N*-hydroxysuccinimide (NHS; 2 mM final concentration) followed 5 min later by 0.15 mL 10 mM FCA/EDC solution, in 25 mM MOPS pH 7.0. The reaction proceeded overnight with stirring at 4 °C and was followed by overnight dialysis into 25 mM MOPS pH 7.0 at 4 °C. A 0.5 mL aliquot was removed for analysis at each stage.

Atomic Absorption Spectroscopy. AAS was conducted using a Perkin-Elmer 3100 atomic absorption spectrometer with an iron hollow cathode lamp (S & J Juniper Co., Essex, England) using standard procedures. Ultrapure water was used to prepare the buffer (25 mM MOPS pH 7.0; used as blank) and standards (2.0−0.0625 mg/L $FeCl_3 \cdot 6H_2O$).

Fabrication of Etched Microelectrode. Platinum microelectrodes of 25 μm radius were fabricated and characterized using previously described procedures (*21*). The microelectrodes were etched in hot aqua regia (75 °C, for up to 20 h) to create a cavity of 2−4 μm depth, and this cavity was subsequently packed as follows. The bottom was removed from a 1.5 mL Eppendorf tube and the electrode inserted through the new bottom opening. SBP solution (0.25 mL; no external mediator) was pipetted into the tube, which was then capped. The electrode and solution were repeatedly inverted to fill the etched cavity with solution. The electrode/tube was kept at 4 °C for 5 h to allow deposition and immobilization of the SBP in the etched cavity.



Cyclic voltammetry was performed using a CH Instruments model 660 Electrochemical Workstation and a conventional three-electrode cell. The electrochemical measurements were carried out at room temperature in a 10 mL buffer solution (25 mM MOPS/NaOH pH 7.0, 20 °C) containing the three-electrode voltammetric cell that comprised the H_2O_2 sensor. All potentials are referenced with respect to the KCl saturated Ag/AgCl reference electrode. All CVs were obtained in O_2-free buffer (*22*, *23*), achieved by purging the system with N_2 or Ar gas for at least 15 min and by maintaining a N_2 atmosphere over the buffer during all assays.

RESULTS AND DISCUSSION

Ferrocene-Modified SBP. Ideally, one would like to attach numerous ferrocenes covalently close to the SBP active site to maximize electron transfer to the underlying electrode without disrupting the catalytic function. However, SBP has few sites that can be chemically modified under mild conditions that avoid deactivation, e.g., it has no free thiol groups because its eight cysteines form disulfides. Most reported chemical modifications of the widely used horseradish peroxidase, HRP, target its glycans or lysine residues, but we have previously demonstrated that only three of HRP's six lysines are reactive under mild conditions (*24*). Comparison of SBP's and HRP's amino acid sequences (refs 9 and 25, respectively) reveals that exactly those three HRP lysines are replaced by other, less reactive residues in the SBP sequence. This leaves only SBP's glycans as potential attachment sites for FCA and necessitated a multistep approach. Scheme 1 shows the approach employed here, namely, periodate oxidation of the vicinal diols of SBP glycans to create free aldehyde groups, followed by addition of the bifunctional amine ethylenediamine. Schiff bases form between amine and the aldehydes of SBP glycans, and these Schiff bases are reduced by addition of $NaCNBH_3$. The primary amine on the opposite end of ethylenediamine is unaffected by this treatment, and the outcome is the addition of new free amino groups to the SBP molecule (aminated SBP). FCA can then be covalently coupled to aminated SBP via a further, carbodiimide-mediated reaction. Recovery of initial SBP activity (TMB assay) is high, due to the mild conditions of each of the reactions in the sequence. Initial FCA-to-SBP couplings were carried out in the presence of EDC alone, but later EDC-mediated modifications included *N*-hydroxysuccinimide (NHS), which stabilizes a reaction intermediate and aids successful FCA attachment to SBP. The procedure is successful, albeit labor-intensive. Note that covalent ferrocene coupling to SBP can be accomplished with a minimally treated commercial enzyme preparation, avoiding the added costs and delays associated with chromatographic purification. Attachment of the mediator to the external SBP glycans overcomes the problems faced by Degani and Heller (*26*) in attaching the mediator to the GO polypeptide via the ϵ-NH_2 of lysines.

Covalent attachment of ferrocene units to SBP oligosaccharides (to improve the electron-transfer dynamics) does not unduly affect the enzyme's catalytic activity. Table 1 shows that the catalytic activity increases by approximately 20%, reproducibly, following amination: this is most likely due to the removal of naturally occurring low molecular weight inhibitors from the SBP enzyme preparation by the two dialysis steps. In contrast, the protein concentration decreases by

Scheme 1. Proposed Mechanism for the Addition of Ferrocene Carboxylic Acid to SBP[a]

[a] The sugars in the SBP glycans are oxidized to produce free aldehyde groups. Next, ethylene diamine is added to the oxidized SBP. $NaCNBH_3$ reduces the Schiff bases (formed between ethylene diamine and SBP) to secondary amines without affecting the primary amine on the opposite end of the bifunctional ethylenediamine. This results in the addition of new free amino groups onto the SBP. Ferrocene carboxylic acid is then added to the aminated SBP in the presence of EDC and NHS, resulting in attachment of ferrocene units to the enzyme.

Table 1. Activity, Protein Concentration, Number of Available Amine Sites, and Iron Content of Native and Ferrocene-Modified SBP[a]

enzyme	activity[b] (%)	protein (μg/mL)	number of free $-NH_2$[c]	iron[d] (ppb)
native SBP	100	439 ± 34.0	3 ± 0.5	49 ± 8
aminated SBP	128.0 ± 14.1	234.3 ± 23.7	35 ± 6.4	52 ± 8
FCA-SBP	66.8 ± 14.3	238.0 ± 38.0	3 ± 0.9	137.5 ± 14

[a] $n = 3$. [b] SBP catalytic activity was determined at 100 μg/L protein. [c] Free $-NH_2$ groups were estimated by TNBS method (*20*). [d] Elemental iron was determined using atomic absorption spectroscopy.

approximately 50%, presumably due to the loss of low molecular weight proteins during the first dialysis step. The amination procedure yielded a 10-fold increase in the number of free amines on the SBP molecule without changing the iron content. Following the FCA−EDC−NHS modification step, catalytic activity decreased by approximately 23% compared to its initial value. The number of free amines also decreased, but the Fe concentration more than doubled, indicating successful modification of SBP by FCA. These data clearly demonstrate that the result of this procedure is the covalent binding of approximately 1.5 ferrocene centers per enzyme without significantly affecting the enzyme's catalytic activity.

Voltammetry in the Microcavity. Figure 1 shows cyclic voltammograms for the unmodified microcavity electrode as well as background corrected voltammograms for the native and ferrocene-modified SBP immobilized within the etched microcavity. The supporting electrolyte was 25 mM MOPS/NaOH, pH 7.0, and the scan rate was 0.01 V s^{-1}. In the absence of enzyme, the background charging current is flat and featureless across the whole potential range investigated. In order to quantify differences in the Faradaic current response between modified and native enzymes, the background current was modeled using a third- or fourth-order polynomial and subtracted from the overall response.

Native Enzyme. Figure 1 shows that the native SBP exhibits a well-defined, irreversible redox response with a reduction peak potential of approximately 0.05 V vs Ag/AgCl. This process corresponds to reduction of the iron center within the native

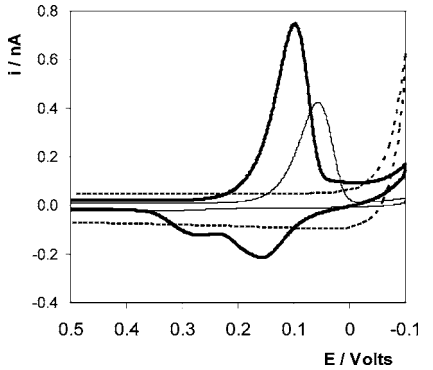


Figure 1. Cyclic voltammograms for unmodified microcavity electrode (dashed line) and native (thin line) and ferrocene-modified SBP (thick line) recorded within a platinum microcavity at a scan rate of 0.01 V s^{-1}. The supporting electrolyte is 25 mM MOPS/NaOH buffer at pH 7.0.

enzyme. No well-defined return peak is observed even at a scan rate of 0.01 V s^{-1}. This behavior could arise from very slow electrochemical reoxidation of the reduced enzyme (slow heterogeneous electron transfer) or because the reduced enzyme undergoes a subsequent chemical reaction. However, experiments involving peroxide in solution, vide infra, indicate that the reduced enzyme can be chemically reoxidized efficiently. This observation suggests that the reduced enzyme undergoes very slow electron transfer with the electrode causing an irreversible response to be observed.

Fc−SBP Response. As illustrated in Figure 1, the ferrocene-modified enzyme also shows a single, well-defined reduction peak which is centered at 0.098 V. The reduction peak potential, E_{pa}, is shifted by approximately +40 mV with respect to the native form, indicating that reduction of the native iron centers and the ferrocene mediators is thermodynamically more facile in the modified form. This behavior most likely arises because of the electron donating properties of the covalently attached ferrocene mediators. Significantly, the peak current and charge increases by a factor of approximately 2 after binding of the ferrocene moieties. While this charge most likely includes contributions from both the endogenous iron centers of the

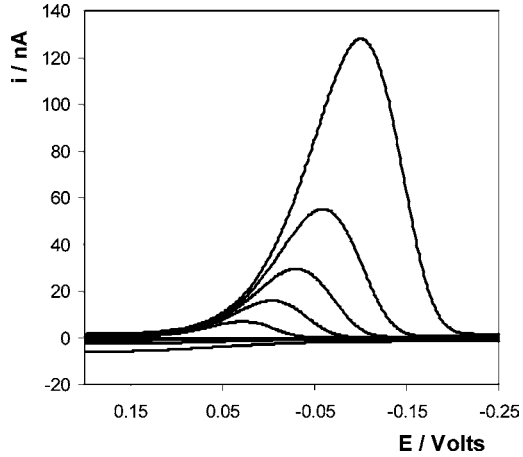

Figure 2. Effect of scan rate on the voltammetric response of native SBP packed within a microcavity electrode. From top to bottom, the scan rates are 0.2, 0.5, 1.0, 2.0, and 5.0 V s^{-1}. The supporting electrolyte is 25 mM MOPS/NaOH buffer at pH 7.0.

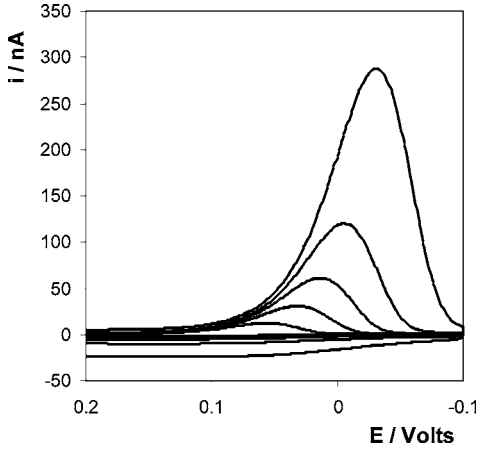

Figure 3. Effect of scan rate on the voltammetric response of ferrocene-modified SBP packed within a microcavity electrode. From top to bottom, the scan rates are 0.2, 0.5, 1.0, 2.0, and 5.0 V s^{-1}. The supporting electrolyte is 25 mM MOPS/NaOH buffer at pH 7.0.

enzyme and the tethered ferrocene centers, the magnitude of the increase in charge passed is consistent with the atomic absorption spectroscopy data presented in Table 1, which indicate that approximately 1.5 ferrocene centers become bound to each enzyme. The peak areas for the native and modified enzymes are 3.1 and 6.0 nC, respectively, and correspond to approximately 50 fmol of enzyme being immobilized within the microcavity. Given the fact that, for the Fc−SBP system, reduction of the enzyme becomes thermodynamically more facile, and the fact that the charge passed increases, it appears that, while the native SBP can undergo direct electron transfer with the electrode, reduction of the heme center within Fc−SBP is mediated by the covalently bound ferrocene centers.

In sharp contrast to the native enzyme, Fc−SBP exhibits a well-defined oxidation process with peak potentials of approximately 0.15 and 0.27 V. This process corresponds to reoxidation of the ferrocene mediators and the heme centers. The observation that the peak areas for the reduction and oxidation processes are not equivalent suggests that the ferrocene centers efficiently mediate the reduction of the heme but not its reoxidation. Significantly, the scan rate impacts dramatically on the ability to observe the ferrocene-based oxidation; e.g., even at scan rates of 0.1 V s^{-1}, the oxidation process does not give rise to a well-defined peak for ferrocene reoxidation. This observation strongly suggests that oxidation of *both* the heme and ferrocene centers at an electrode surface is kinetically very slow even in Fc−SBP.

Electron-Transfer Dynamics. Figure 2 illustrates the effect of scan rate on the voltammetry of the native SBP. A key advantage of microelectrodes is that the small currents observed eliminate any deleterious effects of ohmic drop, and the dynamics of the electrochemical processes can be explored over a wide range of time scales. This figure reveals that the peaks broaden significantly and shift in a negative potential direction with increasing scan rate. This behavior indicates that the dynamics of electron transfer between the electrode and the enzyme influences the response at high scan rate; i.e., the time constant for reduction of the enzyme and the experiment become comparable.

Figure 3 illustrates the scan rate dependence of the voltammetry for the ferrocene modified SBP packed within the microcavity. When compared to the behavior observed for the native enzyme, it is apparent that the peak potential for the ferrocene-modified enzyme is much less sensitive to the scan rate than the native form. For example, when the scan rate is increased from 0.1 to 5 V s^{-1}, E_{pc} shifts by approximately 160 mV for the native but only by 110 mV after ferrocene centers

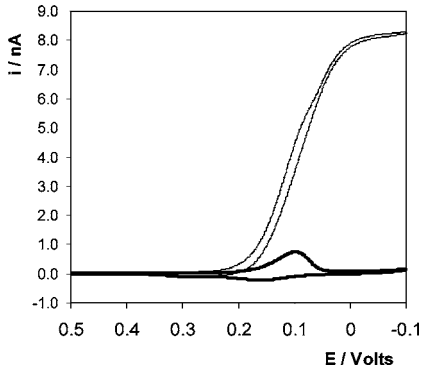

Figure 4. Cyclic voltammograms of Fc−SBP-modified microcavity electrodes at a scan rate of 0.1 V s^{-1}. The curves represent the response in the absence of H_2O_2 (thick line) and in the presence of 100 μM H_2O_2 (thin line).

are covalently bound to the enzyme. This result indicates that the ferrocene centers increase the rate of electron transfer from the electrode to the enzyme. While the results are not shown here, we have successfully simulated the electrochemical response of the native enzyme as an electrochemically irreversible reduction process (*27*). The Fc−SBP response is adequately modeled as an electrochemically irreversible reduction process for the enzyme heme, E_{irr}, and an electrochemically reversible process, E, for the bound ferrocene mediators. This analysis indicates that the rate of electron transfer from the heme centers to the electrode increases by more than an order of magnitude upon binding of the ferrocene centers. The significant increase in the electron-transfer dynamics should lead to a substantial improvement in the analytical performance of these peroxide microsensors.

Analytical Performance. Figure 4 shows cyclic voltammograms of Fc−SBP-modified microcavity electrodes before and after the addition of H_2O_2. This figure shows that adding hydrogen peroxide gives rise to an electrocatalytic reduction current at the same potential as the Fc−SBP reduction process. This result confirms that the Fc−SBP is capable of reducing H_2O_2 and that the oxidized enzyme can then be electrochemically reduced. A key objective is to assess the impact of covalently attaching the ferrocene centers on the electrocatalytic efficiency of the enzyme.

Figure 5 illustrates the microelectrode response to batch injection of 2.5 μmol injections of peroxide in 25 mM MOPS buffer at pH 7.0 (20 μL of 0.125 mol/L peroxide in buffer added to the 10 mL reaction cell) for both the native and FCA−SBP

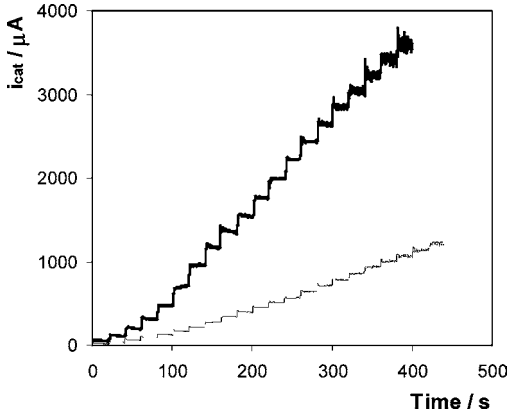

Figure 5. Current response of native (lower curve) and ferrocene-modified SBP-packed microcavity electrodes to successive injections of 2.5 μmol of peroxide. The supporting electrolyte is 25 mM MOPS/NaOH buffer at pH 7.0. The electrode is poised at −0.100 V.

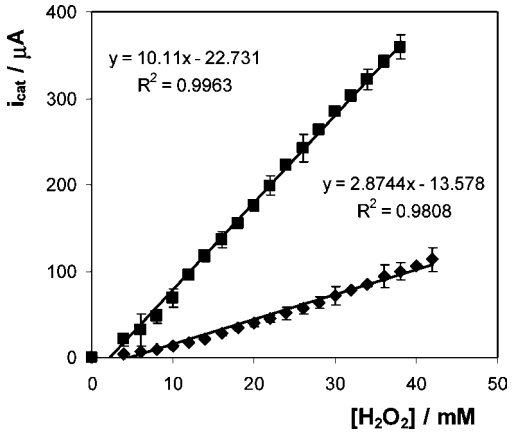

Figure 6. Calibration curve of ΔI, the change in current between successive injections, on the H_2O_2 concentration for native (lower curve) and ferrocene-modified SBP (upper curve).

microcavity biosensors. The electrode potential is poised at −0.100 V. Significantly, the fact that successive H_2O_2 additions generate measurable currents for the native SBP indicates that direct electron transfer takes place between SBP and the Pt electrode at the bottom of the microcavity. This figure shows that a steady-state response is obtained for both sensors within less than 20 s. The steady-state current arises because of the high mass transport rates that are achieved because of the radial diffusion field established at the microelectrodes. This mass transport rate is comparable to that obtained for an electrode rotated at 2500 rpm. The response time is approximately 2-fold faster than that reported by Wang et al. (*2*) based on SBP immobilized within a copolymer mix deposited on a 4 mm glassy carbon electrode. Figure 5 reveals that the response of the ferrocene-modified enzyme microsensor is significantly more sensitive than that of the native SBP with each 2.5 μmol injection of peroxide giving a 220 nA increase in current for ferrocene−SBP compared to 60 nA for the native form.

Figure 6 illustrates calibration curves for both microcavity sensors. There is a notable difference in the calibration curves for native and FCA−SBP, with the slope observed for the ferrocene derivative being approximately 3.5-fold larger. The dynamic range for both SBPs is similar with linear calibration curves being observed for $2.5 \leq [H_2O_2] \leq 42.5$ μM. We ascribe this additional activity to an increased turnover rate of the enzyme through mediated electron transfer via the ferrocene carboxylic acid units covalently attached to the SBP glycans.

CONCLUSION

We have presented a method for covalently binding ferrocene mediators to SBP glycans which is effective even with a crude SBP preparation and offers significant advantage over previously reported approaches. Approximately 1.5 ferrocene mediators are bound per enzyme site. We have also demonstrated for the first time (to the best of our knowledge) that native SBP, a heme protein, is capable of undergoing direct, mediator-free electron transfer when deposited within a microcavity etched at the tip of a platinum microelectrode. FCA−SBP gave notably improved responses over native SBP in our etched Pt electrode with the rate of electron transfer between the enzyme and the electrode increasing by more than 10-fold. The current response to peroxide injection depends linearly on peroxide concentration for both native and modified SBP sensors for $2.5 \leq [H_2O_2] \leq 42.5$ μM. However, the sensitivity of the ferrocene−SBP is approximately 3.5-fold larger than that of the native enzyme. These microcavity sensors have the potential for use in reagentless electrodes for the measurement of H_2O_2 and many other analytes that act as electron donors for peroxidases.

ACKNOWLEDGMENT

The financial support of the National Centre for Sensor Research (NCSR), the School of Biotechnology, DCU, and Science Foundation Ireland under the Biomedical Diagnostics Institute (05/CE3/B754) is deeply appreciated. Mr. Michael Woulfe (Quest International) kindly donated the soybean peroxidase and Dr. Sonia Ramírez-García is thanked for helpful advice.

Received September 5, 2006; Revised Manuscript Received October 16, 2006

Radiolabeled peptides containing the Arg-Gly-Asp amino acid sequence (single letter code = RGD) have been studied extensively to target integrin receptors upregulated on tumor cells and neovasculature. Integrins are cell surface transmembrane glycoproteins that exist as $\alpha\beta$ heterodimers. The $\alpha_v\beta_3$ integrin is known to be overexpressed in many tumor types and is expressed at lower levels in normal tissues. Furthermore, $\alpha_v\beta_3$ and $\alpha_v\beta_5$ subtypes are expressed in neovasculature during angiogenesis. Thus, there is some impetus to image angiogenesis and tumor formation in vivo using RGD-based peptide targeting vectors. In this study, we report the design and development of a new cyclic RGD analogue *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)] (PZ = 3,5-Me_2-pz$(CH_2)_2$N$((CH_2)_3$COOH)-$(CH_2)_2NH_2$) that can be radiolabeled with the $[^{99m}Tc(CO)_3(H_2O)_3]^+$ metal aquaion. Radiochemical evaluation of this new conjugate in vitro indicated a facile radiosynthesis of the new ^{99m}Tc-RGD conjugate with high radiolabeling yields (≥95%) and high specific activities. In vitro internalization and blocking assays in $\alpha_v\beta_3$ receptor-positive, human M21 melanoma cancer cells showed the ability of this conjugate to target the integrin receptor with high specificity and selectivity. In vivo pharmacokinetic studies in normal CF-1 mice showed rapid clearance from blood with excretion primarily via/through the renal−urinary system. In vivo accumulation of radioactivity in mice bearing either $\alpha_v\beta_3$ receptor-positive or negative human melanoma tumors showed receptor specific uptake of tracer with accumulations of 2.50 ± 0.29 and 0.71 ± 0.08% ID/g in $\alpha_v\beta_3$ integrin positive (M21) and negative (M21L) tumors at 1 h postinjection (p.i.), respectively.

INTRODUCTION

Radiolabeled peptides containing the RGD amino acid sequence have been studied extensively to develop site-directed targeting vectors for integrin receptors upregulated on tumor cells and neovasculature (*1*, *2*). The RGD consensus sequence, Arg-Gly-Asp, appears in several proteins of the extracellular matrix, including vitronectin, fibronectin, fibrinogen, von Willebrand factor, thrombospondin, and osteopontin (*3*). Integrin recognition of the canonical RGD sequence plays a prominent role in many cell−cell and cell−extracellular matrix (ECM) interactions. Integrins are cell surface transmembrane glycoproteins that exist as $\alpha\beta$ heterodimers, and at least 24 different combinations of $\alpha\beta$ heterodimers are known (*4*). The integrins of most interest in cancer imaging and therapy contain the α_v subunit, particularly the $\alpha_v\beta_3$ and $\alpha_v\beta_5$ subtypes. The $\alpha_v\beta_3$ integrin is known to be overexpressed in many tumor types and expressed at lower levels in normal tissues (*5*). Both $\alpha_v\beta_3$ and $\alpha_v\beta_5$ subtypes are expressed in neovasculature during angiogenesis (*5*). Therefore, the impetus to image/treat angiogenesis and tumor formation in vivo using RGD-based peptide targeting vectors is of significant interest.

RGD peptide conjugates used to target integrin receptors are generally linear, disulfide-cyclized, or head-to-tail cyclized constructs (*6*−*18*). However, the most extensive class of RGD analogues being studied utilizes the head-to-tail cyclized RGD derivatives. These analogues represent the most promising class of RGD-based imaging agents (*2*). Early investigations into the effect of head-to-tail cyclization on RGD affinity for the $\alpha_v\beta_3$ integrin led to the identification of *cyclo*-(RGDfV) (*19*), an $\alpha_v\beta_3$ antagonist with a low nanomolar IC_{50}. Further characterization led to the observation that a bulky hydrophobic residue was required in position 4 for maximum affinity, while position 5 was tolerant of a range of substitutions (*12*). For example, the insertion of either a D- or L-tyrosine into position 4 or 5 yielded RGD peptide conjugates with available sites for radioiodination. The resulting ^{125}I-labeled peptides were tested in vitro and in vivo to examine the feasibility of using cyclic RGD peptides as in vivo imaging agents (*12*). These conjugates displayed rapid

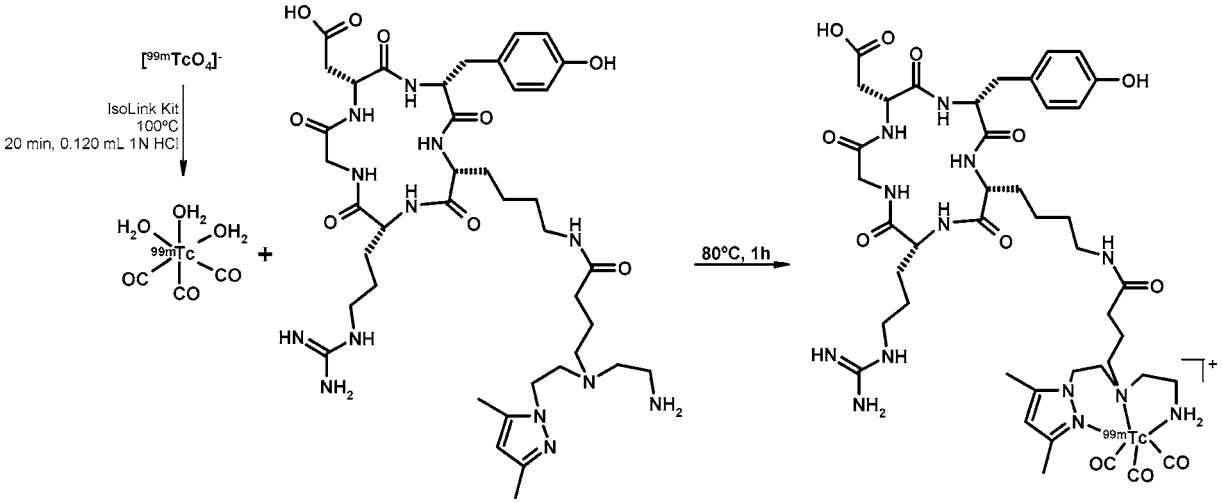
blood clearance through hepatobiliary excretion and tumor uptake at 1 h p.i. (post intravenous administration) of 1.30 ± 0.13 %ID/g in M21 melanoma human tumor xenografts (*12*). Further attempts to improve the pharmacokinetics of these RGD constructs of this type resulted in the synthesis and in vitro/in vivo evaluation of a glycosylated analogue via the attachment of a carbohydrate moiety to the ϵ amino group of Lys5 (*13*). The resulting molecule showed decreased uptake in liver and intestine and increased tumor uptake and residualization, with 2.05 ± 0.55 %ID/g in M21 melanoma human tumor xenografts. Similar results have been reported using an ^{18}F-labeled galacto-RGD analogue, an agent that has already been evaluated in human patients (*14*, *15*).

New and exciting methods of attaching radiometals to specific biomolecular targeting vectors such as RGD continue to be of significant interest. $\alpha_v\beta_3$-Targeted cyclic pentapeptides include a lysine residue in position 5 for the purpose of appending a diverse array of radiolabels. For example, PET tracers have been synthesized by appending a PEG-[^{18}F]fluorobenzoate domain (*16*). Furthermore, metal chelators such as DTPA and DOTA have also been conjugated to RGD via a Lys5 residue to coordinate a wide range of radionuclides useful for imaging and therapy (*17*, *18*). The availability of Isolink for kit preparation of the *fac*-[^{99m}Tc(CO)$_3$(H$_2$O)$_3$]$^+$ synthon (Isolink, Tyco Healthcare, St. Louis, MO) offers a new and exciting approach toward production of ^{99m}Tc-based RGD conjugates. Alberto and co-workers have well-established the macroscopic and tracer level chemistry of Tc(I) and Re(I) tricarbonyl complexes containing the *fac*-[M(CO)$_3$]$^+$ moiety (*20*−*27*). They have demonstrated the effectiveness of using ligand frameworks with a host of donor atoms (i.e., P, S, and N) to effectively stabilize the metal center to produce in vivo stable and kinetically inert complexes (*28*−*34*). Recently, Alves et al. have reported the design of a tridentate metal chelator that effectively coordinates the *fac*-[M(CO)$_3$]$^+$ metal center (M = Tc or Re) (*35*−*39*). This new ligand framework, 3,5-Me$_2$-pz(CH$_2$)$_2$N-((CH$_2$)$_3$COOH)(CH$_2$)$_2$NH$_2$ (PZ), has been shown to produce in vitro and in vivo stable complexes of ^{99m}Tc. Furthermore, ^{99m}Tc-bombesin conjugates of 3,5-Me$_2$-pz(CH$_2$)$_2$N((CH$_2$)$_3$COOH)-(CH$_2$)$_2$NH$_2$ demonstrated high selectivity and affinity for the GRP receptor, subtype 2 (*39*). As part of an International Atomic Energy Agency Co-ordinated Research Project, "Development of ^{99m}Tc-based Small Biomolecules Using Novel ^{99m}Tc Cores", there is some interest in conjugation of new ligand frameworks to Lys5 of cyclic RGD for the design and development of a novel, cyclized ^{99m}Tc-RGD analogue. The participating countries herein report the design and development of a new cyclic RGD analogue, *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)] (PZ = 3,5Me$_2$-pz(CH$_2$)$_2$N((CH2)$_3$COOH)(CH$_2$)$_2$NH$_2$), that can be radiolabeled with the *fac*-M(CO)$_3$ metal center (M = Tc or Re). In this study, we report the synthesis and radiolabeling of *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)], in vitro internalization, and blocking assays of this conjugate in $\alpha_v\beta_3$ receptor-positive, human M21 melanoma cancer cells and in vivo pharmacokinetic studies of this conjugate in normal CF-1 mice. Furthermore, in vivo evaluation of this conjugate in mice bearing either $\alpha_v\beta_3$ receptor-positive or negative human M21 melanoma tumors will be discussed.

EXPERIMENTAL PROCEDURES

Materials. *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)] was synthesized by Biosynthan (Gesellschaft fur Bioorganische Synthese mbH, Berlin, Germany). 3,5Me$_2$-pz(CH$_2$)$_2$N((CH2)$_3$COOH)-(CH$_2$)$_2$NH−BOC was synthesized as previously reported (*38*). All other reagents were purchased from either Fisher Scientific (Chicago, IL) or Sigma-Aldrich (St. Louis, MO) and used without further purification. ^{125}I-Echistatin was purchased from Amersham-Pharmacia Biotech (Vienna, Austria). $\alpha_v\beta_3$ integrin receptors were purchased from Chemicon (Temecula, CA). ^{99m}Tc, in the form of [^{99m}TcO$_4$]$^-$, was eluted from commercially available ^{99}Mo/^{99m}Tc generator systems. Isolink radiolabeling kits were provided by Tyco Healthcare International (Petten, The Netherlands).

Methods. *1. Peptide Synthesis. cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ-BOC)] was synthesized by the reaction of 3,5Me$_2$-pz-(CH$_2$)$_2$N((CH2)$_3$COOH)(CH$_2$)$_2$NH−BOC, (2-(5-norbornene-2,3-dicarboximido)-1,1,3,3-tetramethyluronium tetrafluoroborate (TNTU), and diisopropylethylamine (DIEA) (1:1.2:1.2) in *N*,*N*,-dimethyl formamide (DMF) for 1 h. Two equivalents of the corresponding HONB-ester (hydroxy-5-norbornene-2,3-dicarboxylimide) solution was added to 1 equiv of the unprotected cyclopeptide, *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys], in DMF. The pH of the solution was adjusted to 8 by addition of *N*-methylmorpholine (NMM), and the reaction mixture was allowed to stir at room temperature for 48 h.



The crude, BOC-protected peptide conjugate was purified by preparative reversed phase-high performance liquid chromatography (RP-HPLC) utilizing a Shimadzu LC-8A system equipped with a SPD-6A tunable absorbance detector calibrated to 220 nm. HPLC solvents consisted of H$_2$O containing 0.05% trifluoroacetic acid (TFA, solvent A) and acetonitrile/water (80:20 containing 0.05% trifluoracetic acid (solvent B). An Ultrasep C-18 column (10.0 μm, 100 Å, 20 × 250 mm, SEPSERV GmbH, Berlin) was used with a flow rate of 15.0 mL/min. The HPLC gradient system began with a solvent composition of 95%A and 5%B and followed a linear gradient of 2.5%B/min. MALDI-MS of the BOC protected cyclic peptide was performed confirming the chemical constitution of the purified conjugate (calculated mass: 970.2; experimental mass: 970.4).

The cyclic RGD analogue, *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys-(PZ)], was obtained by reaction of *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ-BOC)] with TFA/water (95:2) for 1 h. Purification by preparative HPLC was performed, and the final purified analogue was analyzed by MALDI-MS (calculated mass: 870.2; experimental mass: 870.1).

2. Radiolabeling of cyclo-[Arg-Gly-Asp-D-Tyr-Lys(PZ)] Conjugate. To 0.2 mL of 2.5 × 10^{-4} M aqueous solution of *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)] was added 0.8 mL of [^{99m}Tc-(H$_2$O)$_3$(CO)$_3$]$^+$ prepared via the Isolink kit (Scheme 1). The solutions were allowed to incubate at 75 °C for 1 h. Quality control (radiochemical yield and radiochemical purity) of the products was determined by RP-HPLC. Analysis of radiolabeled and non-radiolabeled compounds was performed on a Waters 600S controller equipped with a Waters 626 pump, Waters 2487 dual wavelength absorbance detector, an Eppendorf CH-30 column heater, an in-line EG&G ORTEC NaI solid scintillation detector, and a Hewlett-Packard 3395 integrator. HPLC analysis of the new radiolabeled RGD conjugate was performed using an analytical C-18 reversed phase column (Phenomenex, 50 × 4.6 mm, 5 μm). The mobile phase consisted of a linear gradient system, with solvent A corresponding to 100% water with 0.1% trifluoroacetic acid and solvent B corresponding to 100% acetonitrile with 0.1% trifluoroacetic acid. The mobile phase began with solvent compositions of 95%A/5%B. At time = 25 min, the solvent compositions were 30%A/70%B. Solvent compositions of the mobile phase remained at 30%A/70%B for 1 min before being changed to 20%A/80%B. At time = 28 min, the solvent composition was changed to 95%A/5%B for column re-equilibration. The flow rate of the mobile phase was 1.5 mL/min. Product purification and final preparation of the labeled species were performed by collecting the samples off the chromatographic system, removal of solvent via a nitrogen stream, and reconstitution in normal saline.

3. In Vitro Stability in Human Blood. To 1 mL of whole human blood, collected in heparinized polypropylene tubes, was

Scheme 1. Radiosynthesis of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$

added a solution of the [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ conjugate (∼9.25 MBq). This mixture was incubated at 37 °C. Samples were taken at 5 min, 45 min, and 4 h postincubation, and centrifuged for 15 min at 2000 rpm at 4 °C. The plasma was separated and ethanol was added in a 2:1 (v/v) ratio. The samples were centrifuged at 3000 rpm (15 min, 4 °C), filtered through a Millex GV filter (0.22 μm), and the supernatant was analyzed by RP-HPLC. HPLC analyses of the ^{99m}Tc-conjugates were performed on a Shimadzu C-R4A chromatography system equipped with a Berthold - LB 505 gamma detector and a tunable absorption UV detector. Separations were achieved on an analytical C-18 reversed phase column (Nucleosil, 250 × 4.0 mm, 10 μm, 100 Å). The mobile phase consisted of a linear gradient system, with solvent A corresponding to 0.1% trifluoroacetic acid in water and solvent B corresponding to 0.1% trifluoroacetic acid in acetonitrile. The mobile phase (linear gradient) began with solvent compositions of 100%A/0%B. At time = 9 min, the solvent compositions were 75%A/25%B. Solvent compositions were changed linearly to 0%A/100%B at time = 20 min. At time = 22 min, the solvent composition was changed to 100%A/0%B for column re-equilibration. The detection wavelength was 220 nm, and the flow rate was 1 mL/min.

4. Binding Affinity of cyclo-[Arg-Gly-Asp-D-Tyr-Lys(PZ)] to $\alpha_v\beta_3$ Integrin Receptors. The in vitro binding affinity of the pyrazolyl−RGD conjugate was determined and compared directly to *cyclo*-[Arg-Gly-Asp-D-Phe-Val] using ^{125}I-echistatin as the radioligand as described by Orlando and Cheresh (*40*). Briefly, 96-well plates were coated with $\alpha_v\beta_3$ integrin receptors (Chemicon, Temecula, CA) and incubated in the presence of varying amounts of competing ligand (0.05 nM to 50 μM RGD peptide) for 3 h with 370 Bq/well (0.05 nM) ^{125}I-Echistatin (Amersham Biosciences, Piscataway, NJ). After incubation, wells were washed three times with 25 mM Tris-HCl containing 150 mM NaCl, 1 mM $CaCl_2$, 0.5 mM $MgCl_2$, 1 mM $MnCl_2$, pH 7.4, and bound ^{125}I-echistatin was solubilized with hot 2 N NaOH. Radioactivity in the resulting suspension was measured by a γ-counter (Wallac Wizard). IC_{50} values were calculated by fitting the percent inhibition values using ORIGIN software (Northhampton, MA).

5. In Vitro Internalization Analysis of [^{99m}Tc(CO)$_3$−cyclo-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ in $\alpha_v\beta_3$ Positive M21 Melanoma Cells. $\alpha_v\beta_3$ positive M21 or $\alpha_v\beta_3$ negative M21L human melanoma cells (*41*) were grown in culture until a sufficient number of cells were available. For internalization experiments, cells were determined to be at a concentration of 2×10^6 cells/mL in RPMI 1640 containing 1% glutamine and 1% BSA. One milliliter of this solution was pipetted into each separate tube for internalization assays. [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ conjugate (≥100000 cpm, ∼1 nM) was added to the cellular media, and the solutions were incubated at 37 °C for 90 min (n = 3) in presence of either PBS/0.5%BSA buffer (150 μL; regular assay) or 10 μM *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys] (RGDyK) in PBS/0.5%BSA buffer (150 μL; nonspecific binding assay). Following the 90 min incubation period, the solutions were centrifuged, media was removed, and cells rinsed with cold TRIS buffered saline (×2). Thereafter, the cells were twice incubated at ambient temperature in 50 mM acetate buffer (pH = 4.2) for 15 min, a period sufficient to remove membrane bound radioligand. The supernatant was collected (membrane bound radioligand fraction), and the cells were washed with 50 mM acetate buffer. Cells were lysed by treatment in 1 N NaOH, and cell-associated radioactivity was collected (internalized radioligand fraction). Protein content in the NaOH fraction was determined using spectrophotometric techniques according to the Bradford method (*42*). The internalized and non-internalized fractions were determined by measuring radioactivity, and the internalized fraction was expressed as a percent of total activity per milligram of protein.

6. In Vivo Evaluation of [^{99m}Tc(CO)$_3$−cyclo-[Arg-Gly-Asp-D-Tyr-Lys(L)]] in Normal Mouse Models. All animal studies were conducted in accordance with the highest standards of care as outlined in the NIH guide for Care and Use of Laboratory Animals and the Policy and Procedures for Animal Research at the Harry S. Truman Memorial Veterans' Hospital. The animals were fed autoclaved rodent chow (Ralston Purina Company, St. Louis, MO) and water ad libitum. The biodistribution studies of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys-(PZ)]]$^+$ conjugate were determined in normal, CF-1 mice (female, 4−5 weeks old, ∼20 g). The mice were injected with 185 kBq (∼1×10^{-5} μg, specific activity ∼ 5.2×10^8Ci/mol) of HPLC-purified conjugate in 50 μL of isotonic saline via the tail vein. The mice were euthanized by cervical dislocation, and the tissues and organs were excised from the animals following at 1, 4, and 24 h p.i. Subsequently, the tissues and organs were weighed and counted in a NaI well counter, and the percent injected dose (%ID) and %ID/g of each organ or tissue was calculated. The %ID in whole blood was estimated assuming a whole-blood volume of 6.5% the total body weight.

In vivo stability of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ conjugate was determined at 1 h p.i. by assessing aliquots of urine, murine serum, and liver homogenate via RP-HPLC analysis using a method previously described herein (vide infra, in vitro serum stability). Urine: The urine was collected at the time of sacrifice and filtered through a Millex GV filter (0.22 μm), after which RP-HPLC was used to assess the degree

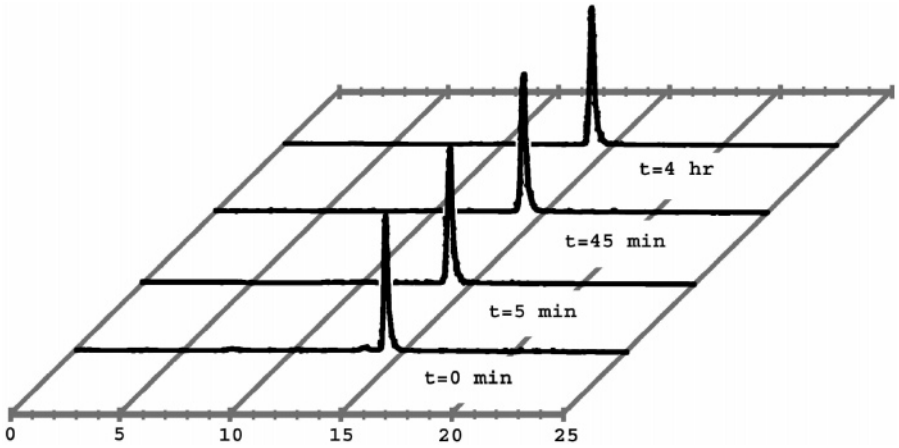


Figure 1. RP-HPLC stability profile of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ in whole blood (t_R = 14.2 min).

of in vivo stability. Serum: Blood collected from mice was immediately centrifuged for 15 min at 3000 rpm at 4 °C, and the serum was separated. Aliquots of 100 μL of serum were treated with 200 μL of ethanol for protein precipitation. Samples were centrifuged at 4000 rpm for 15 min at 4 °C, the supernatant was collected and passed through a Millex GV filter (0.22 μm), and the degree of in vivo stability was assessed by RP-HPLC. Liver homogenate: After radiopharmaceutical administration, animals were kept for 1 h on normal diet ad libitum. Immediately upon sacrifice, the liver was excised, rinsed, and placed in chilled 50 mM TRIS/0.2 M sucrose buffer (pH = 7.4), wherein it was homogenized. The liver homogenate was treated with ethanol in a 2:1 EtOH/homogenate v/v ratio. The sample was then centrifuged at 25 000 rpm for 15 min at 4 °C and filtered through Millex GV filter (0.22 μm), and the activity was measured. Aliquots (in duplicate) of the filtrate were analyzed by RP-HPLC as previously described. Taking into account the radionuclide decay, the recovery of the radioactivity was found to be between 70 and 80% (activity of the filtrate/total liver activity).

7. In Vivo Evaluation of [^{99m}Tc(CO)$_3$−cyclo-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ in $\alpha_v\beta_3$ positive and $\alpha_v\beta_3$ negative M21 Human, Melanoma-Bearing, Nude Mouse Models. All animal experiments were conducted in compliance with the Austrian animal protection laws and with approval of the Austrian Ministry of Science. Tumor uptake studies were performed in nu/nu mice (female, 6−9 weeks old, ∼20 g, Charles River). For the induction of tumor xenografts, M21 and M21L cells were subcutaneously injected into the left and right flanks of the mouse at a concentration of 5×10^6 cells per mouse. Tumors were allowed to grow to sizes of ∼0.3−0.6 cm^3 prior to initiation of the study. Animals were intravenously injected with 100 μL (925 kBq, ∼1 μg of peptide conjugate, specific activity ∼2.6×10^4 Ci/mol) of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ conjugate via the tail vein and were maintained on normal diet ad libitum. The mice were sacrificed by cervical dislocation at 1 and 4 h p.i. Tissues and organs were collected, weighed, and counted in a gamma counter, and the percent injected dose (%ID/organ) and %ID/g of each organ or tissue was calculated. Tumor-to-organ and tumor-to-blood ratios were also determined.

RESULTS

PZ-BOC (3,5Me$_2$-pz(CH$_2$)$_2$N((CH2)$_3$COOH)(CH$_2$)$_2$NH−BOC) was synthesized as previously reported (*35*−*38*) and provided to Biosynthan for conjugation to *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys]. The cyclic peptide, *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys-(PZ)], was synthesized by standard solid-phase synthetic methods, purified by preparative RP-HPLC, and characterized by MALDI-MS (calculated mass: 870.2; experimental mass: 870.1).

[^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ was produced in very high yield (≥90%, specific activity ∼ 6×10^6 Ci/mol) upon addition of [^{99m}Tc(H$_2$O)$_3$(CO)$_3$]$^+$ (prepared via the Isolink radiolabeling kit) to a vial containing 2.5×10^{-4}M *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)] (Scheme 1). The radiochemical yield of the new ^{99m}Tc-conjugate was monitored by RP-HPLC. The HPLC chromatographic profile for [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ is demonstrated in Figure 1. The chromatogram shows a single peak (t_R= 14.2 min) corresponding to the new radiometallated conjugate. Pertechnetate had a retention time of ∼2.9 min under identical HPLC conditions. Nonmetallated *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(L)] eluted as a single species with a retention time of 8.8 min. This allowed for easy separation of metalated from nonmetallated conjugate, making it possible to collect very high specific activity [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys-(PZ)]]$^+$.

To assess the in vitro integrity of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ conjugate, stability assays in human blood were performed. Figure 1 shows the RP-HPLC stability profile of the new conjugate at various timepoints (0 min, 5 min, 45 min, and 4 h) postincubation with human blood. From this study, we can assess that [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ conjugate is ≥98% stable at 4 h postincubation in whole blood.

In vitro binding affinity of cyclo[Arg-Gly-Asp-D-Tyr-Lys-(PZ)] for the $\alpha_v\beta_3$ receptor was assessed by competitive binding assays utilizing ^{125}I-Echistatin as the binding displacement ligand (*40*). *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)] showed very high binding affinity for the $\alpha_v\beta_3$ receptor with an IC$_{50}$ value of 3.01 nM (Figure 2). Comparatively, *cyclo*-[Arg-Gly-Asp-D-Phe-Val] showed an IC$_{50}$ value of 3.68 nM.

To evaluate the biological potential of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ conjugate, the degree of internalization in human, M21 melanoma cells was determined. This study showed approximately 1.0 ± 0.09% cellular uptake/mg of protein of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys-(PZ)]]$^+$ in M21 cells at 90 min postincubation. Blocking studies, in which excess *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys] was incubated concurrently with [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys-(PZ)]]$^+$, demonstrated the in vitro specificity of conjugate for $\alpha_v\beta_3$ receptor-expressing cells. The presence of 10 μM *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys] reduced cellular uptake/mg of protein to 0.34 ± 0.04% for [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ at 90 min postincubation. Comparably, cellular

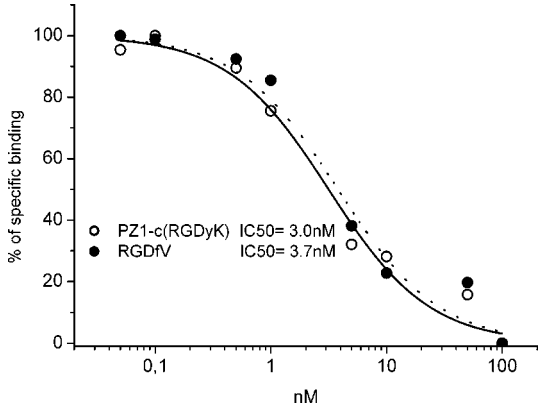

Figure 2. Competitive binding assays of *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)] and *cyclo*-[Arg-Gly-Asp-D-Phe-Val] versus ^{125}I-echistatin in $\alpha_v\beta_3$ integrin receptors. IC_{50}s = 3.01 (*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys-(PZ)]) and 3.68 nM (*cyclo*-[Arg-Gly-Asp-D-Phe-Val]), respectively.

uptake/mg protein of $[^{99m}Tc(CO)_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ in M21L receptor-negative cells was only 0.37 ± 0.11%.

Biodistribution studies in normal CF-1 mice are summarized in Table 1. These studies showed the $[^{99m}Tc(CO)_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ conjugate to be a hydrophilic species that effectively cleared the bloodstream at 1 h p.i. For example, only 0.23 ± 0.06% ID/g of the administered dose remained in whole blood at 1 h p.i. Approximately 75% of the injected dose was excreted at 1 h p.i. via the renal−urinary pathway for this ^{99m}Tc-RGD conjugate. Hepatobiliary uptake and excretion was minimal for this conjugate. For example, only 4.25 ± 0.70 and 2.03 ± 0.20% ID/g of $[^{99m}Tc(CO)_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ accumulated in intestines and liver tissue at 1 h p.i, respectively. Some residualization of radioactivity in normal kidney is evident for the $[^{99m}Tc(CO)_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ conjugate (3.11 ± 0.32% ID/g, 1h p.i.). However, this radioactivity appears to wash out significantly over time. To demonstrate the effective in vivo stability or kinetic inertness of $[^{99m}Tc(CO)_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ conjugate, urine, serum, and liver samples were acquired and analyzed by RP-HPLC at 1 h p.i. The samples were homogenized and reinjected onto the HPLC to verify product integrity. The conjugate showed remarkable in vivo stability as ≥98% of the conjugates were in the form of $[^{99m}Tc(CO)_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ at 1 h post-intravenous administration (Figure 3).

Table 2 summarizes the results of biodistribution studies of $[^{99m}Tc(CO)_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ in nude mice bearing xenografted human, M21, melanoma tumors at 1 and 4 h post-intravenous injection. High tumor uptake and retention of $[^{99m}Tc(CO)_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys-(PZ)]]$^+$ in M21 melanoma tumors demonstrates effective selectivity and affinity of this new RGD conjugate for the $\alpha_v\beta_3$ receptor. For example, accumulation of radioactivity in tumor tissue was 2.50 ± 0.29 and 1.62 ± 0.44% ID/g at 1 and 4 h p.i., respectively. To demonstrate the effectiveness of $[^{99m}Tc(CO)_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ for selectively targeting the $\alpha_v\beta_3$ receptor, biodistribution studies were also performed in nude mice bearing xenografted receptor-negative, M21L, melanoma tumors (Table 2). Accumulation of radioactivity in M21L tumors showed markedly less tumor uptake at 1 h p.i as compared to the receptor-positive M21 cell line. For example, tumor accumulation in this receptor-negative cell line was only 0.71 ± 0.08% ID/g at 1 h p.i. Tumor-to-blood and tumor-to-muscle ratios in the receptor-positive M21 cell line were ∼2.6 and 2.4 at 1 h p.i, respectively. Conversely, these values were only 0.78 and 0.95 in receptor-negative M21L xenografted tumors. In all of these studies (i.e., tumor-bearing and non tumor-bearing mice), there is no significant uptake or retention of radioactivity in the stomach indicating that there is minimal, if any, in vivo dissociation of the ^{99m}Tc metal center from this tridentate ligand framework to produce $[^{99m}TcO_4]^-$.

DISCUSSION

Significant effort into the design and development of specific targeting vectors for imaging angiogenesis have provided valuable insight in identifying structural features that produce kinetically inert conjugates having very high affinity and selectivity for the $\alpha_v\beta_3$ integrin, a mediator of endothelial cell migration during blood vessel formation (*1*). These studies indicate that head-to-tail cyclized derivates of the general type *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys] are easily functionalized for radiolabeling at Lys5 producing antagonistic conjugates with nanomolar affinity for the $\alpha_v\beta_3$ integrin receptor (*6*−*18*). These studies have demonstrated the effectiveness of targeting angiogenesis factors for diagnosis and potential therapy of specific human tumors.

Typically, RGD peptide-based targeting vectors for integrin receptors are either linear, disulfide-cyclized, or head-to-tail cyclized constructs (*6*−*18*). However, increasing attention has recently focused on the development of dimeric or multimeric cyclic RGD peptide constructs. Multimerization is expected to increase the apparent affinity of targeting vectors for their cognate receptors due to avidity effects. In one instance, a dimeric *cyclo*-(RGDfK) construct was synthesized by bridging two lysine ϵ amino groups with a HYNIC-glutamic acid moiety (*43*). This peptide, when labeled with ^{99m}Tc, showed high receptor-mediated tumor uptake of 5.8 ± 0.7%ID/g at 1 h pi in an OVCAR-3/nude mouse in vivo model. The corresponding monomer showed tumor uptake of 5.2 ± 0.6%ID/g. However, at all timepoints, kidney retention of the dimer was significantly higher as compared to the monomer (*43*). In a second study, *cyclo*-(RGDfE) multimers were formed using variable-length PEG spacers linked to a diaminopropionic acid/lysine backbone (*44*). Monomeric, dimeric, and tetrameric forms were synthesized and labeled with ^{18}F. Biodistribution of the dimer was comparable to that of a monomeric, glycosylated ^{18}F-labeled RGD analogue (*44*).

Haubner and co-workers have used a tetrapeptide sequence (H-Asp-Lys-Cys-Lys-OH) as a chelating system for labeling a *cyclo*-RGD derivative (DKCK-RGD) with ^{99m}Tc (*45*). Gamma camera images at 4 h p.i. clearly demonstrated tumor-specific uptake of conjugate. However, there was high concentration of radioactivity in normal kidneys, possibly due to the lysine-containing tetrapeptide used as the chelating sequence (*45*).

Other attempts at targeting $\alpha_v\beta_3$ receptor expression have focused on the labeling of a disulfide-bridged undecapeptide found via a phage display library. In this study, a shortened derivative of RGD-4C ((Cys^1-Cys^9-Cys^3-Cys^7)H-Cys-Asp-Cys-Arg-Gly-Asp-Cys-Phe-Cys-OH) was coupled with HYNIC and radiolabeled with ^{99m}Tc (*11*, *46*). In two murine tumor models, only marginal tumor uptake was observed, presumably due to only modest association of this conjugate for the $\alpha_v\beta_3$ receptor ($K_a = 7 \times 10^6$ M^{-1}) (*11*, *46*).

Recent studies by Psimadas and co-workers and Line and co-workers have led to some interesting developments toward development of new $[^{99m}Tc(CO)_3$-RGD]$^+$ conjugates (*47*, *48*). For example, Psimadas et al., have conjugated picolinamine-*N*,*N*-diacetic acid (PADA) and histidine to the epsilon amine of lysine for coordination to the *fac*-$[M(CO)_3]^+$ metal center. Studies show these new conjugates can be produced in very high yields (∼98%) as single radiochemical products. Furthermore, these new conjugates were stable to histidine and cysteine challenge experiments even at 24 h postincubation with exchange ligand. In vivo evaluation of the biodistribution of

these new conjugates indicated rapid clearance from the blood pool with excretion predominantly the hepatobiliary pathway (*47*, *48*). Studies by Line et al. have conjugated *fac*-$[M(CO)_3]^+$ metal chelator *N*-*ω*-bis(2-pyridyl-methyl)-L-lysine to an *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer with side chains terminated in doubly cyclized, integrin-specific RGD derivative KACDCRGDCFCG (RGD4C) or nonreactive RGE derivative KACDCRGECFCG (RGE4C) (*49*, *50*). In this study, they were able to produce conjugates in very high yield (≥93%) with specific activities ranging from 16.8 to 19.5 MBq/nmol ($4.5-5.3 \times 10^6$ Ci/mol). $[^{99m}Tc(CO)_3$-HPMA-RGD4C] conjugate showed very high uptake in each DU145 and PC-3 prostate tumor xenografts. For example, uptake and retention of activity at 24 h p.i. was determined to be 4.60 ± 1.80% ID/g and 5.92 ± 0.41% ID/g in DU145 and PC-3 prostate tumor models, respectively. Scintigraphic images in SCID mice bearing either DU145 or PC-3 prostate tumor xenografts demonstrated the high affinity and selectivity of these conjugates for $\alpha_v\beta_3$ integrin receptors expressed in these tumor models (*49*, *50*).

In the current study, we have developed a monomeric ^{99m}Tc-radiolabeled cyclic RGD conjugate, *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)] (PZ = 3,5-Me_2-pz$(CH_2)_2$N$((CH_2)_3$COOH$)(CH_2)_2NH_2$), having high affinity for the $\alpha_v\beta_3$ integrin receptor. 3,5-Me_2-pz-$(CH_2)_2$N$((CH_2)_3$COOH$)(CH_2)_2NH_2$ coordinates technetium and rhenium metal centers in tridentate fashion through the pyrazolyl and amine nitrogen donor atoms giving the metal complexes sufficient stability for in vivo radiochemical investigations (*38*, *39*). In this study, we were able to effectively show that the new conjugate *cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)] could be radiolabeled in very high yield upon simple heating with the *fac*-$^{99m}Tc(CO)_3(H_2O)_3$-synthon. Upon simple radiolabeling of conjugate, a specific activity ~ 6×10^6Ci/mol was determined for $[^{99m}Tc(CO)_3-$*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$. This is comparable to other $[^{99m}Tc(CO)_3$-RGD] targeting vectors having very high affinity for the $\alpha_v\beta_3$ integrin receptor. Studies indicated production of a single species even at ligand concentrations of 10^{-5} M, precluding the potential for kit development for radiolabeled conjugates of this type. The new conjugate was stable in human serum for an extended period, demonstrating the ability of the nitrogen-based pyrazolyl chelator to effectively stabilize the metal center against transmetallation reactions to serum-based proteins. For example, $[^{99m}Tc(CO)_3-$*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ was ≥98% stable for periods up to 4 h postincubation as indicated by RP-HPLC.

It is essential to maximize uptake and residualization of radioactivity in human tumor tissue to optimize the diagnostic/therapeutic efficacy of the radiolabeled targeting vector. Results of internalization studies in M21 receptor-positive cells show that most of the radioactivity is not surface bound and is not lost from the cells upon incubation in pH 4.2 buffer. These studies indicate that $[^{99m}Tc(CO)_3-$*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ has high specificity for $\alpha_v\beta_3$ receptor-expressing cells. For example, there was approximately 1.0 ± 0.09% cellular uptake/mg of protein of in M21 cells at 90 min postincubation. Blocking studies indicated reduced cellular uptake/mg of protein for $[^{99m}Tc(CO)_3-$*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ at 90 min postincubation. Only 0.34 ± 0.04% cellular uptake/mg of protein was observed, further demonstrating the selectivity of conjugate for the integrin receptor. Cellular uptake/mg of protein of $[^{99m}Tc(CO)_3-$*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ in M21L receptor-negative cells was only 0.37 ± 0.11%. Uptake of ^{125}I-radiolabeled RGD in each M21 and M21L human melanoma cells showed less than 0.25% cellular uptake/mg of protein comparatively.

In vivo evaluation of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ conjugate demonstrated rapid clearance from the bloodstream and excretion primarily via the renal−urinary pathway. Subsequent stability evaluation of the conjugate in human tissue showed that the conjugate was not readily metabolized in vivo, with 98% of the conjugate remaining intact upon in vivo administration. High tumor uptake and retention of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ in M21 melanoma tumors was observed. For example, accumulation of radioactivity in tumor tissue was 2.50 ± 0.29 and 1.62 ± 0.44% ID/g at 1 and 4 h p.i., respectively. Studies in nude mice bearing xenografted receptor-negative, M21L melanoma tumors further demonstrates high specificity and affinity of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ for the integrin receptor. Tumor accumulation in this receptor-negative cell line was only 0.71 ± 0.08% ID/g at 1 h p.i. These results show some similarity to those studies by Haubner and co-workers in the same tumor model (12−15). Tumor-to-blood and tumor-to-muscle ratios of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ in the receptor-positive M21 cell line were ∼2.6 and 2.4 at 1 h p.i, respectively. The moderately high tumor-to-blood and tumor-to-muscle ratios are a reflection of the high binding affinity of this conjugate for the integrin receptor. These ratios are maintained even at 4 h postinjection (3.3 and 5.2, respectively) demonstrating receptor-mediated transport and subsequent intracellular trapping of this conjugate in M21, $\alpha_v\beta_3$, receptor-expressing cells. Janssen and co-workers have reported $\alpha_v\beta_3$ receptor expression in murine tissues such as the liver and spleen (*51*). In fact, they were able to effectively block uptake in muscle, lung, spleen, and liver indicating localization of their ^{111}In-RGD conjugate to be $\alpha_v\beta_3$ receptor-mediated in these tissues. In the present study, we were not able to effectively block uptake in these specific tissues and therefore cannot conclude that uptake in these organs was $\alpha_v\beta_3$ receptor-mediated.

In conclusion, these studies have demonstrated the potential utility of [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ to image angiogenesis and tumor formation in vivo. The pyrazolyl−RGD conjugate, when radiolabeled with the [^{99m}Tc(H$_2$O)$_3$(CO)$_3$]$^+$ aquaion, provided for kinetically inert complexes of very high specific activity. [^{99m}Tc(CO)$_3$−*cyclo*-[Arg-Gly-Asp-D-Tyr-Lys(PZ)]]$^+$ showed extraordinary stability in vitro and in vivo thereby retaining biological activity with high selectivity for the $\alpha_v\beta_3$ receptor.

ACKNOWLEDGMENT

This material is the result of a collaborative research project between participating countries. This work has been coordinated and partially funded by the International Atomic Energy Agency, Vienna, Austria. Special thanks go to Drs. D. V. S. Narasimhan and M. R. A. Pillai of the Department of Nuclear Sciences and Applications of the IAEA for their considerable effort into the success of this coordinated research project. We would also like to thank D. A. Cheresh, Scripps Institute, La Jolla, CA, for providing the M21 and M21L melanoma cell lines. S.A. would like to thank Fundação para a Ciência e Tecnologia for Ph.D. Grant No. BD/3052/2000. Tyco Healthcare International (Petten, The Netherlands) is also gratefully acknowledged for financial support of this project.

Synthesis and Biological Evaluation of N-Substituted Quinolinimides, as Potential Ligands for in Vivo Imaging Studies of δ-Opioid Receptors

Thomas Bourdier,[†,§] Géraldine Poisnel,[†,§] Martine Dhilly,[†] Jérôme Delamare,[†] Joël Henry,[‡] Danièle Debruyne,*[,†] and Louisa Barré*[,†]

Groupe de Développements Méthodologiques en Tomographie par Emission de Positons, DSV/DRM UMR CEA 2E, Université de Caen Basse Normandie, Centre Cyceron, 15 Boulevard Henri Becquerel, 14074 Caen France, and Laboratoire de Biologie et Biotechnologies Marines, UMR IFREMER 100 Physiologie et Ecophysiologie des Mollusques Marins, Université de Caen Basse-Normandie, 14032 Caen France. Received September 11, 2006; Revised Manuscript Received January 11, 2007

We report here the syntheses of *N*-substituted quinolinimide derivatives displaying sufficient affinity and high selectivity for δ-opioid receptors. Among 9-subsituted derivatives, one showed much higher selectivity for the δ receptor in binding assays than the δ antagonist methylnaltrindole (**6**: $K_i = 42$ nM; μ/δ and $\kappa/\delta > 238$ on rat brain membranes) and antagonist properties. This compound was labeled with carbon-11 ($t_{1/2} = 20.4$ min) as a potential radioligand for the noninvasive assessment of δ opioid receptors in vivo with positron emission tomography (PET). A high yielding radiosynthesis of **[^{11}C]-6**, based on the [^{11}C]methyl introduction on the pyridine moiety by a Stille reaction, was described (radiochemical yield = 60 ± 10%, specific activities = 0.8 to 1.5 Ci/μmol). The in vivo pharmacological profile in rats indicated that the radiotracer crossed the blood−brain barrier but was not stable and underwent rapid degradation in both plasma and brain. No specific binding was consequently revealed.

INTRODUCTION

Opioid receptors are classified into μ, δ, and κ subtypes and belong to the superfamily of G protein-coupled receptors (GPCRs) that produce their effects by activation of intracellular Gi/Go proteins. Most endogenous opioids and synthetic ligands do not possess absolute specificity for a given opioid receptor subtype but interact with more than one specific site. The situation is further complicated by the fact that multiple receptor subtypes coexist within cerebral regions. The molecular cloning of μ-, δ-, and κ-opioid receptors (MOP−R, DOP−R, and KOP−R, respectively) showed that they share a high degree of amino acid sequence similarity (65%), and only 35% confer selectivity (*1*−*3*).

The δ-opioid receptors play an important role in the modulation of nociceptive signaling encountered in animal models of pain (*2*). Moreover, δ agonist administration or DOP−R deficient mice studies confirmed that δ receptors are involved in emotional responses such as depressive-like behavior and anxiety. These receptors are implicated in some aspects of morphine tolerance and dependence (*4*) with limited contribution compared with μ receptors (*2*). δ-Opioid agonists do not display side effects usually observed with κ-opioid agonists such as dysphoria, diuresis, and locomotor impairment. Despite δ-opioid receptor involvement in several clinically relevant diseases and syndromes such as analgesia, addiction, Parkinson's, Alzheimer's, and seizure disorders (*1*−*8*), their precise role in humans is incompletely understood.

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) are unique and complementary imaging techniques for in vivo assessment of drug distribution and interaction with biochemical target systems (*9*). They are well-adapted for the exploration of brain function in healthy and disease conditions and crucial tools for clinical research and diagnosis. PET is a quantitative and very sensitive method, but it requires high-cost facilities due to the use of tracers labeled with cyclotron-produced positron emitters (carbon-11, $t_{1/2} = 20.4$ min; florine-18, $t_{1/2} = 109.7$ min). SPECT has coarser spatial and temporal resolution, reduced sensitivity, and less quantification capability; however, it uses commercially available γ-emitter radionuclides of relatively long half-lives (iodine-123, $t_{1/2} = 13.2$ h; technetium-99m, $t_{1/2} = 6$ h) and thus is routinely employed in nuclear medicine centers.

Among opiate radioligands already available for PET imaging (*5*, *7*, *10*), only the antagonist [^{11}C]-methylnaltrindole ([^{11}C]-MeNTI) allows visualization of δ-opioid receptors in the human brain (*11*, *12*). In vitro, it displays a very high affinity for δ-opioid receptor and moderate affinities for μ and κ receptors, respectively (Chart 1) (*13*, *14*). The most recently selectivities reported by Clayson et al. (*14*) were 81 for δ over μ and 17 for δ over κ and were less attractive than values (700 for δ over μ and >3000 for δ over κ) determined by Portoghese et al. (*13*), who used a nonspecific radioligand ([^{3}H]-DADLE) associated

Chart 1. Opioid Receptor Binding of Naltrindole and Methylnaltrindole[a]

compound	Ki, nM δ	μ	κ	references
methylnaltrindole	0.02	14	65	13
	0.49	39.2	8.33	14
naltrindole	0.03	3.8	332	13
	0.15	27.5	14.3	14

[a] Opioid receptor affinities of naltrindole and methylnaltrindole were determined by displacement of radioligands from guinea pig brain membranes. In Portoghese's study (*13*), binding to δ receptors was evaluated with [^{3}H]-DADLE in the presence of 1 μM DAMGO, to μ receptors with [^{3}H]-DAMGO, and to κ receptors with [^{3}H]-EK in the presence of 1 μM DAMGO; while in Clayson's study (*14*), binding to δ receptors was evaluated with [^{3}H]-DPDPE, to μ receptors with [^{3}H]-DAMGO, and to κ receptors with [^{3}H]-U69,593.

Chart 2. Lead Compound and Target Molecules

to an excess of μ-specific ligand (DAMGO) to approach δ selectivity. In vivo, mice brain studies with [^{11}C]-MeNTI (*15*) established δ selectivity by competition with naltrindole whose binding characteristics are similar to those of MeNTI (Chart 1). Moreover, in behavior assays, the selective κ-opioid receptor antagonist, norbinaltorphimine, inhibited MeNTI antinociceptive effects significantly (*16*). Although this radioligand is metabolically stable and allows visualization of δ sites in the human brain (*5*, *7*, *10*−*12*), ligands with improved selectivity would be desirable for δ-opioid receptor imaging studies.

The development of a unique tracer for PET or SPECT requires the presence, in the same structure, of atoms (C, F, I) that can be substituted for their positron (^{11}C, ^{18}F) or γ (^{123}I)-emitting isotope.

Recently, a new series of N-substituted quinolinimide derivatives has been reported (*19*). They displayed synthetic accessibility, nanomolar affinity, and selectivity (IC_{50} μ > 10 000 and IC_{50} κ > 1000 nM) for δ-opioid receptors much higher than previous synthetic ligands (naltrindole (*13*), TAN 67 (*17*), SNC 80 (*18*)). Among them, compound **1** represents the most promising compound with an affinity of 6 nM (IC_{50} δ) for the cloned human DOP−R. From this new structural class and the associated structure−activity relationship (SAR) studies, we have investigated the incorporation of a halogen atom on the butyl chain and/or on the 2-position of the pyridine ring (Chart 2). The binding characteristics (K_i) of the new synthesized compounds **2**−**10** toward the three μ, δ, and κ receptor subtypes were determined and permitted the selection of the most promising compound **6**. Radiosynthesis of **6** was developed, its δ agonist/antagonist activity was performed using the [^{35}S]-GTPγS binding assay, and its in vivo behavior including metabolism, organ uptake, regional brain distribution, and specific binding were investigated in the rat.

EXPERIMENTAL PROCEDURES

Chemistry. *General Procedure for the Synthesis of **2**, **3**, and **6**−**8**.* A mixture of sulfonamide **13**−**14** and aldehyde **21**−**23** in trifluoroacetic acid (4 mL) was stirred at reflux for 7 h under nitrogen. The reaction mixture was quenched with ice and water (11 mL). The product was extracted with dichloromethane (3 × 10 mL). The combined organic layers were washed with saturated aqueous solution of $NaHCO_3$, dried ($MgSO_4$), and the solvents evaporated.

6-{2-[2-(4-Butylbenzenesulfonyl)-1,2,3,4-tetrahydroisoquinolin-1-yl]-ethyl}-2-chloropyrrolo[3,4-*b*]pyridine-5,7-dione (**2**). Starting from sulfonamide **13** (511 mg, 1.61 mmol) and aldehyde **21** (499 mg, 2.09 mmol), the crude compound was purified by chromatography on silica gel (7:3 heptanes/ethyl acetate) to afford a white solid; mp 84−86 °C; yield 658 mg (76%); ^{1}H NMR ($CDCl_3$) δ 8.09 (d, J = 8.0 Hz, 1H), 7.61 (d, J = 8.0 Hz, 1H), 7.54 (d, J = 8.3 Hz, 2H), 7.10−6.90 (m, 5H), 6.78 (d, J = 7.4 Hz, 1H), 5.06 (dd, J = 5.0 Hz, J = 9.6 Hz, 1H), 4.00−3.80 (m, 3H), 3.65−3.45 (m, 1H), 2.80−2.40 (m, 4H), 2.30−2.00 (m, 2H), 1.44 (qu, J = 7.6 Hz, 2H), 1.19 (sextet, J = 7.2 Hz, 2H), 0.84 (t, J = 7.2 Hz, 3H); ^{13}C NMR ($CDCl_3$) δ 165.2, 165.0, 158.0, 152.2, 148.2, 137.3, 135.4, 133.4, 132.5, 128.95, 128.8, 128.5, 127.0, 126.9, 126.7, 126.3, 126.0, 54.6, 38.9, 36.2, 35.3, 35.0, 33.0, 25.7, 22.0, 13.8; IR (KBr) 1784, 1719, 1336, and 1162 cm^{-1}; MS (EI) *m*/*z* (%) 340 (16), 329 (41), 328 (100), 197 (16), 133 (39), 91 (25); Anal. ($C_{28}H_{28}ClN_3O_4S$) C, H, N.

2-Bromo-6-{2-[2-(4-butylbenzenesulfonyl)-1,2,3,4-tetrahydroisoquinolin-1-yl]-ethyl}-pyrrolo[3,4-*b*]pyridine-5,7-dione (**3**). Starting from sulfonamide **13** (432 mg, 1.36 mmol) and aldehyde **22** (500 mg, 1.76 mmol), the crude compound was purified by chromatography on silica gel (7:3 heptanes/ethyl acetate) to afford a white solid; mp 88−90 °C; yield 607 mg (76%); ^{1}H NMR ($CDCl_3$) δ 7.99 (d, J = 8.0 Hz, 1H), 7.80 (d, J = 8.0 Hz, 1H), 7.57 (d, J = 8.3 Hz, 2H), 7.15−6.90 (m, 5H), 6.80 (d, J = 7.4 Hz, 1H), 5.08 (dd, J = 9.5 Hz, J = 5.1 Hz, 1H), 4.05−3.85 (m, 3H), 3.65−3.50 (m, 1H), 2.60−2.40 (m, 4H), 2.30−2.00 (m, 2H), 1.48 (qu, J = 7.6 Hz, 2H), 1.23 (sextet, J = 7.3 Hz, 2H), 0.87 (t, J = 7.2 Hz, 3H); ^{13}C NMR ($CDCl_3$) δ 165.3, 164.9, 152.4, 149.0, 148.2, 137.4, 135.4, 132.8, 132.6, 132.2, 128.9, 128.8, 127.0, 126.9, 126.7, 126.3, 126.2, 54.6, 38.9, 36.3, 35.3, 35.1, 33.0, 25.7, 22.0, 13.8; IR (KBr) 1784, 1717, 1331, and 1154 cm^{-1}; MS (EI) *m*/*z* (%) 386 (15), 384 (15), 330 (22), 329 (66), 328 (100), 197 (13), 133 (36), 91 (23); Anal. *General Procedure for the Synthesis of **4** and **9***. A mixture of chlorinated sulfonamide **2** or **7** (186 μmol), potassium fluoride (558 μmol), and Kryptofix 222 (186 μmol) in DMSO (820 μL) was heated at 120 °C for 3 h under nitrogen. The reaction mixture was then quenched with water (18 mL). The aqueous phase was thoroughly extracted with ethyl acetate (2 × 24 mL), and the combined organic layers were washed with water (2 × 30 mL), dried ($MgSO_4$), and the solvents evaporated. The crude compound was purified by chromatography on silica gel.

6-{2-[2-(4-Butylbenzenesulfonyl)-1,2,3,4-tetrahydroisoquinolein-1-yl]-ethyl}-2-fluoropyrrolo[3,4-*b*]pyridine-5,7-dione (**4**). Chromatography 3:2 heptanes/ethyl acetate; yield 68 mg (70%) from **2** (100 mg, 186 μmol); white solid; mp 72−74 °C; ^{1}H NMR ($CDCl_3$) δ 8.25 (dd, J = 8.2 Hz, J = 6.7 Hz, 1H), 7.57 (d, J = 8.3 Hz, 2H), 7.24 (dd, J = 8.2 Hz, J = 1.4 Hz, 1H), 7.15−6.95 (m, 5H), 6.81 (d, J = 7.3 Hz, 1H), 5.09 (dd, J = 9.6 Hz, J = 5.0 Hz, 1H), 4.05−3.80 (m, 3H), 3.70−3.50 (m, 1H), 2.60−2.40 (m, 4H), 2.30−2.00 (m, 2H), 1.48 (qu, J = 7.5 Hz, 2H), 1.22 (sextet, J = 7.3 Hz, 2H), 0.87 (t, J = 7.2 Hz, 3H); ^{19}F NMR ($CDCl_3$) δ −58.80; ^{13}C NMR ($CDCl_3$) δ 167.7 (d, J = 253.0 Hz), 165.0, 164.9, 151.4 (d, J = 15.0 Hz), 148.2, 137.4, 136.2 (d, J = 10.0 Hz), 135.4, 132.6, 128.9, 128.9, 127.0, 126.9, 126.7, 126.3, 125.5 (d, J = 4.0 Hz), 114.3 (d, J = 37.0 Hz), 54.6, 38.9, 36.3, 35.3, 35.2, 33.0, 25.8, 22.0, 13.8; IR (KBr) 1782, 1722, 1335, and 1163 cm^{-1}; MS (EI) *m*/*z* (%) 330 (20), 329 (61), 328 (100), 324 (29), 197 (18), 133 (52), 130 (13), 91 (29); Anal. *General Procedure for the Synthesis of **5** and **10***. Method A: To a solution of **2** or **7** (93 μmol) and sodium iodide (279 μmol) in acetonitrile (300 μL) was added chlorotrimethylsilane (96 μmol) under nitrogen. The reaction mixture was stirred at reflux for 3 h, then was quenched with water (3 mL). The aqueous phase was thoroughly extracted with dichloromethane (3 × 3 mL). The combined organic layers were washed with a 0.4 N aqueous solution of sodium hydroxide (5 mL) and water (5 mL), dried ($MgSO_4$), and the solvents evaporated. The crude residue was purified by semipreparative HPLC (μ-BondaPak C18 column, 7.8 × 300 mm, 10 μm; flow rate, 5 mL/min; λ = 254 nm). For **5**: eluent CH_3CN/H_2O (50:50, v/v), t_R = 25.20 min; yield 33 mg, 56% from **2** (50 mg, 93 μmol). For **10**: eluent CH_3CN/H_2O (45:55, v/v) t_R = 22.10 min; yield 34 mg, 58% from **7** (50 mg, 90 μmol).

Method B: A solution of iodine in chloroform (30 mL, 0.1 N, 3 mmol) was added dropwise to a stirred solution of **24** or **25** (1.5 mmol) in chloroform (30 mL). The reaction mixture was stirred for 5 h at room temperature. The reaction mixture was quenched with saturated aqueous solution of $Na_2S_2O_3$ (100 mL), and the product was extracted with chloroform (3 × 50 mL). The combined organic layers were washed with water (100 mL), dried ($MgSO_4$), and the solvents evaporated. The crude residue was purified by chromatography on silica gel. For **5**: eluent 7:3 heptanes/ethyl acetate; yield 445 mg, 46% from **24** (1 g, 1.5 mmol); For **10**: eluent 6:4 heptanes/ethyl acetate; yield 790 mg, 52% from **25** (1.6 g, 2.34 mmol).

6-{2-[2-(4-Butylbenzenesulfonyl)-1,2,3,4-tetrahydroisoquinolin-1-yl]-ethyl}-2-iodopyrrolo[3,4-*b*]pyridine-5,7-dione (**5**). White solid; mp 94−96 °C; ^{1}H NMR ($CDCl_3$) δ 8.04 (d, J = 7.9 Hz, 1H), 7.76 (d, J = 7.9 Hz, 1H), 7.56 (d, J = 8.3 Hz, 2H), 7.10−6.90 (m, 5H), 6.80 (d, J = 7.4 Hz, 1H), 5.07 (dd, J = 9.6 Hz, J = 5.2 Hz, 1H), 4.00−3.80 (m, 3H), 3.65−3.45 (m, 1H), 2.60−2.40 (m, 4H), 2.30−2.00 (m, 2H), 1.47 (qu, J = 7.6 Hz, 2H), 1.20 (sextet, J = 7.2 Hz, 2H), 0.89 (t, J = 7.2 Hz, 3H); ^{13}C NMR ($CDCl_3$) δ 165.5, 164.9, 152.4, 148.2, 138.7, 137.3, 135.3, 132.5, 131.6, 128.9, 128.7, 126.9, 126.8, 126.6, 126.4, 126.2, 125.0, 54.5, 38.8, 36.1, 35.3, 35.0, 32.9, 25.7, 22.9, 13.8; IR (KBr) 1781, 1724, 1334, and 1161 cm^{-1}; MS (EI) *m*/*z* (%) 431 (11), 329 (22), 328 (100), 197 (8), 133 (21), 91 (16); Anal. 6-(2-{2-[4-(4-Fluorobutyl)-benzenesulfonyl]-1,2,3,4-tetrahydroisoquinolin-1-yl}-ethyl)-2-tributylstannanylpyrrolo[3,4-*b*]pyridine-5,7-dione (**26**). Compound **10** (675 mg, 1.04 mmol) and hexabutylditin (1.91 g, 3.12 mmol) were dissolved in dry toluene (12 mL), and a catalytic amount of tetrakis(tripheylphosphine)-palladium (91 mg, 78 μmol) was added. The mixture was refluxed with stirring for 24 h under a nitrogen atmosphere. After cooling, the reaction mixture was filtered through celite. The filtrate was concentrated under reduced pressure. The oily residue was then purified by chromatography on silica gel (8:2 heptanes/ethyl acetate) to afford **26** (340 mg, 40%) as a yellow viscous oil. ^{1}H NMR ($CDCl_3$) δ 7.89 (d, J = 7.4 Hz, 1H), 7.69 (d, J = 7.4 Hz, 1H), 7.62 (d, J = 8.2 Hz, 2H), 7.15−6.95 (m, 5H), 6.81 (d, J = 7.4 Hz, 1H), 5.10 (dd, J = 9.7 Hz, J = 5.0 Hz, 1H), 4.40 (dt, J = 47 Hz, J = 5.7 Hz, 2H), 4.05−3.85 (m, 3H), 3.70−3.50 (m, 1H), 2.60 (t, J = 7.3 Hz, 2H), 2.55−2.45 (m, 4H), 2.30−2.05 (m, 2H), 1.75−1.50 (m, 4H), 1.40−1.15 (m, 12H), 0.87 (t, J = 7.2 Hz, 9H); ^{19}F NMR ($CDCl_3$) δ −218.5; ^{13}C NMR ($CDCl_3$) δ 185.0, 167.4, 167.2, 151.5, 148.1, 138.0, 135.7, 135.1, 132.7, 129.1, 128.9, 127.3, 127.2, 127.0, 126.9, 126.4, 125.8, 83.8 (d, J = 165.0 Hz), 54.8, 39.0, 35.9, 35.5, 35.2, 29.8 (d, J = 19.8 Hz), 29.1, 27.4, 26.7 (d, J = 5.0 Hz), 26.0, 13.8, 10.5; IR (KBr) 1778, 1722, 1337 and 1162 cm^{-1}.

In Vitro Assays. *Membrane Preparations.* Membrane preparations and radioligand binding assays were performed according to a method previously described (*19*). Brain without cerebellum was removed from a male Wistar rat or a Hartley guinea pig and homogenized in 10 volumes (w/v) of ice-cold 50 mM Tris−HCl buffer (pH 7.4 at 4 °C) using an ultra-turax. The homogenate was centrifuged at 45 000 *g* for 15 min at 4 °C. The pellet was resuspended by homogenization in 10 volumes of ice-cold buffer (4 °C). To remove endogenous opioids that might interfere with the radioligand binding assays, the membranes were incubated at 30 °C for 30 min in a shaking water bath, recentrifuged, and resuspended in 10 volumes of ice-cold buffer. Protein concentration was measured according to the method of Bradford (*53*), using bovine serum albumin (BSA) as the standard. Membranes were stored frozen at −80 °C at a final concentration of 1 g/L with 0.1 g/L bacitracin (ICN Biomedicals, U.S.A.).

Binding Assays. Receptor binding assays were performed with crude membranes from rat (μ- and δ-opioid receptors) or guinea pig (κ-opioid receptors) brain homogenates using [^{3}H]-DAMGO as μ-selective radioligand (67 Ci/mmol, Amersham Biosciences, U.K.), [^{3}H]-deltorphin II (33.9 Ci/mmol, Perkin-Elmer Life Sciences, U.S.A.) as δ-selective radioligand and [^{3}H]-U69.593 as κ-selective radioligand (47.5 Ci/mmol, Perkin-Elmer Life Sciences, U.S.A.). The time to reach steady state was previously determined by kinetic studies and stated as 60 min for μ and κ ligands and 90 min for δ ligand. The dissociation constant (K_d) and the maximum number of binding sites (B_{max}) for each tritiated ligand were obtained using preliminary saturation binding experiments. Competitive binding experiments were then carried out on membranes (300 μg of proteins) with a constant concentration of radioligand corresponding to the dissociation rate (K_d) previously measured. Membranes were incubated with 1.9 nM [^{3}H]-DAMGO, 0.6 nM [^{3}H]-deltorphin II, or 2.6 nM [^{3}H]-U69.593 in a total volume of 1 mL incubation buffer containing 50 mM Tris−HCl, pH 7.4, 0.1 g/L bacitracin, and 1 g/L BSA. Various concentrations of test compounds 10^{-12} to 10^{-5} M (naloxone, naltrindole, deltorphin II, DAMGO, or U50.488; SIGMA RBI, U.S.A.) were added separately to incubation medium for 60 min at 25 °C. 10 mM $MgCl_2$, 5 mM EDTA, and 90 min incubation time were necessary for [^{3}H]-deltorphin II. Incubations were stopped by rapid filtration with a Filtermate Universal Harvester (Perkin-Elmer Life Sciences, U.S.A.) through Unifilter-24 GF/B Microplates that were presoaked for at least 60 min in 0.5% polyethylenimine (PEI). Membranes were washed three times with ice-cold 50 mM Tris−HCl, pH 7.4 at 4 °C, and bound radioactivity (dpm) determined using liquid scintillation counting (TopCount NXT Microplate Scintillation, Perkin-Elmer Sciences, U.S.A.). Nonspecific binding was determined for each ligand in the presence of 10 μM naloxone (Sigma RBI, U.S.A.).

Concentration−response curves for each compound were run using data of duplicate samples from at least two independent experiments using curve-fitting procedures in *SigmaPlot* (Jandel Scientific, Germany, 2001). The best nonlinear regression was obtained with a three-parameter logistic equation showing a single set of binding sites. Specific binding was determined by subtracting nonspecific binding from total binding. Percent inhibition of specific binding was determined for each concentration of compounds. The IC_{50} values, defined as the concentration required inhibiting 50% of the specific binding, were obtained from concentration−response curves. The K_i values were calculated using the following equation: $K_i = IC_{50}/(1 + [L]/K_d)$ according to Cheng and Prusoff (*54*).

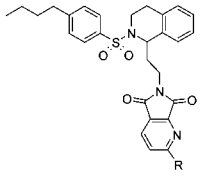
[^{35}S]GTP-γ-S Functional Assay. The [^{35}S]GTP-γ-S binding assays were performed according to the methods previously described with slight modifications (*55*, *56*). Rat brain membranes (10 μg of proteins) were suspended in 1 mL of buffer containing 50 mM Tris−HCl, pH 7.4, 1 mM EGTA, 3 mM $MgCl_2$, 60 μM GDP, 0.05 nM [^{35}S]GTP-γ-S (1250 Ci/mmol, Perkin-Elmer Life Sciences, U.S.A.), and varying concentrations of naltrindole, deltorphin II, and compounds **1** and **6** (10^{-10} to 10^{-5}M). The reaction mixtures were incubated for 60 min at 30 °C (equilibrium). The reactions were terminated by rapid vacuum filtration through Unifilter-24 GF/B microplates previously soaked in ice-cold Tris−HCl, pH 7.4 at 4 °C. The filters

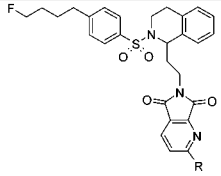
Scheme 1. Syntheses of 2−10[a]

[a] Reagents and conditions: (a) 2-phenylethylamine, pyridine, rt; (b) $SOCl_2$ or AcO_2, reflux; (c) 3-aminopropanol, toluene, NEt_3, reflux; (d) IBX, EtOAc, 80 °C; (e) TFA, reflux; (f) KF, K_{222}, DMSO, 120 °C; (g) TMSCl, NaI, CH_3CN, reflux; (h) Me_6Sn_2, $Pd(PPh_3)_4$, dioxane, reflux; (i) I_2, $CHCl_3$, rt.

were washed three times with ice-cold Tris−HCl, pH 7.4 at 4 °C, and then dried. The radioactivity retained on the filters was measured by liquid scintillation counting using a TopCount NXT Microplate Scintillation (Perkin-Elmer Sciences). Nonspecific binding was determined in the presence of 10 μM GTP-γ-S. Concentration−response curves for each compound were run using data of duplicate samples from at least two independent experiments using curve-fitting procedures in *SigmaPlot*. [^{35}S]-GTP-γ-S binding is expressed as percentage of basal level.

Radiosynthesis of [^{11}C]-6. In a vial (1 mL) purged with nitrogen and containing tris(dibenzylideneacetone)dipalladium-(0) (1.38 mg, 1.5 μmol) and tri-*o*-tolylphosphine (1.88 mg, 6.0 μmol) was added DMF (150 μL). The reactor was cooled at 0 °C, and [^{11}C]methyl iodide was trapped, then the mixture was stirred for 3 min at room temperature. A freshly prepared solution of tin precursor **26** (3.1 mg, 3.75 μmol), potassium carbonate (0.83 mg, 6.0 μmol), and copper(I) chloride (0.60 mg, 6.0 μmol) in DMF (100 μL) was transferred in the vial containing the radioactivity solution. The resulting mixture was stirred vigorously and was heated to 90 °C for 5 min. CH_2Cl_2 (800 μL) was added, and the radioactive solution was transferred into a cartridge (Chromabond PTS phase separation) containing 1 mL of CH_2Cl_2 and 5 mL of water. The isolated organic layer was injected onto semipreparative HPLC (Zorbax RX-SIL column 9.4 × 250 mm; mobile phase CH_2Cl_2/MeOH 99.75/0.25 v/v; flow 5 mL/min; λ = 254 nM). The fraction containing the labeled product **[^{11}C]-6** was collected at 6.30 min, the solvents were evaporated, and the residue was formulated in a sterile water/DMSO (50:50, v/v) solution. The final product was filtered through a 0.22 μm filter into a sterile vial. Routinely, **[^{11}C]-6** was ready for injection in about 40 min in batches of 70−80 mCi. The radiochemical purity and specific activity were determined by reverse-phase analytical HPLC (μ-Bondapak C18 column 4.6 × 250 mm; mobile phase CH_3CN/H_2O 70/30 v/v; flow rate 1 mL/min; λ = 254 nM).

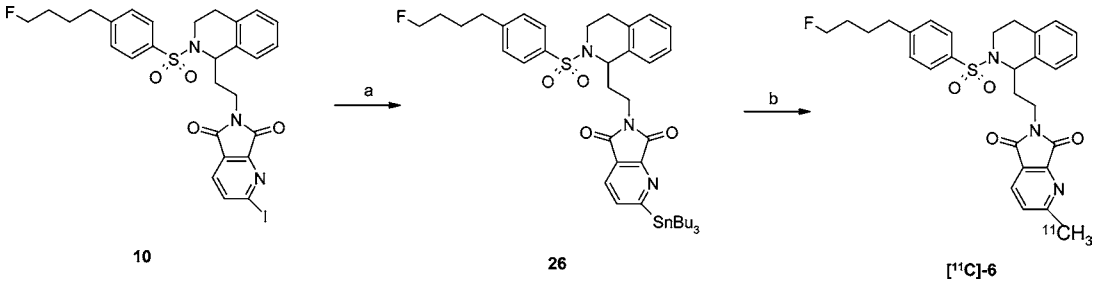




Octanol/Water Partition Coefficient. Apparent drug lipophilicity was determined by a conventional partition method between 1-octanol phase and phosphate-buffered saline (PBS), pH 7.4. Briefly, 1-octanol was mixed into PBS for 20 min, then the labeled compound was added. The tube was sealed and vigorously shaken at room temperature for 40 min. The mixture was then centrifuged at 3000 *g* for 5 min. An aliquot (100 μL) from each phase was removed, and the radioactivity was counted in a γ-counter (Cobra 2 gamma counter, Packard). The log $P_{oct/PBS}$ was calculated as follows: log $P_{oct/PBS}$ = log(radioactivity concentration in the 1-octanol phase/radioactivity concentration in the PBS phase). The reported value represents the mean of six measurements in duplicate.

Ex Vivo Experiments. *Animals.* Sprague−Dawley male rats weighing 250 to 300 g were used in all experiments. The animals were kept at constant temperature (22 °C) and humidity (50%) with 12 h light/dark cycles and were allowed free access to food and water until the time of the experiments. The anesthesia was induced with 5% isoflurane in a gas mixture of nitrous oxide/oxygen (70/30%) and maintained with 1.5−2.5% isoflurane during the entire surgical procedure. Body temperature was monitored rectally and kept close to 37 °C. Catheters were inserted into the femoral vein and artery. Animal experimental procedures were in accordance with the recommendations of the EEC (86/609/EEC), the French National Committee (decret 87/848), for the care and use of laboratory animals and were approved by the Normandy Regional Animal Ethics Committee (saisine 01/04/2005).

Biodistribution Studies. Rats were injected with **[^{11}C]-6** (0.3−0.7 mCi; 0.6−1.4 nmol) in DMSO/water solution (v/v 50/50; 200 μL) and were sacrificed at 3, 5, 10, and 30 min postinjection (n = 3 per time). Whole brain and peripheral organs were quickly dissected at 4 °C. The radioactivity of weighed tissue samples was measured in a γ-counter (Cobra 2 gamma counter, Packard). For the measurements of the cerebral distribution, the animals were decapitated at 3, 10, and 30 min (n = 3 per time) after **[^{11}C]-6** injection (0.7 ± 0.1 mCi, ∼1.4 nmol) in DMSO/water solution (v/v 70/30; 500 μL). Brains were quickly removed and dissected out on an ice-cold plate to obtain the regions of interest. These regions were weighed and counted. For blocking and competition experiments, naloxone (1 mg/ kg) or unlabeled **6** (1.3 mg/ kg) were administrated either 15 min prior to radiotracer or by coinjection, respectively. Data were expressed as the percentage of the injected dose (decay-corrected) per gram of tissue (% ID/g).



Metabolite Analysis from Brain Homogenate and Plasma. Brain radiometabolite analysis was carried out on half-brain crushed in 2.5 mL acetonitrile (UltraTurrax T25, Janke and Kunkel) after injection of **[^{11}C]6**. After centrifugation (4100 *g*, 7 min), supernatants were filtered and injected onto HPLC (reverse-phase μ-Bondapak C18 column 7.8 × 300 mm; mobile phase CH_3CN/H_2O 70:30 v/v; flow rate 5 mL/min; λ = 254 nM). Plasma metabolite analysis was carried out on intracardiac blood samples (1 mL). Following centrifugation (3000 *g*, 5 min), plasma was mixed with an equivalent volume of acetonitrile

Scheme 2. Radiosynthesis of [^{11}C]-6[a]

[a] Reagents and conditions: (a) Bu_6Sn_2, $Pd(PPh_3)_4$, toluene, reflux, 24 h; (b) [^{11}C]CH_3I, Pd_2dba_3:P(*o*-tol)$_3$ (1:4), K_2CO_3, CuCl, DMF, 90 °C, 5 min.

and centrifuged (3000 *g*, 7 min). Supernatants were filtered and injected onto HPLC as described above. The retention times of a [^{11}C] polar metabolite and **[^{11}C]6** were 2.5 and 5.5 min respectively. The [^{11}C] polar metabolite fraction was collected (from three experiments in competition condition) at 30 min and analyzed by a microLC-ESI-MS/MS apparatus. After evaporation of the HPLC solvents, the samples were resuspended in 10 μL of 0.1% formic acid in water and injected onto a C18 Thermo Hypersil column (50 × 0.5 mm, 3 μm) with an acetonitrile linear gradient of 4% per minute in 0.1% formic acid, from 2% to 90%. A split ratio of 30:1 was used to perfuse the column at a flow rate of 10 μL/min. The HPLC column was rinsed with 90% acetonitrile in 0.1% formic acid between each injection. The HPLC Surveyor chain was connected on-line to an orthogonal electrospray source (Deca XP MS-n Thermofinnigan) operated in the positive electrospray ionization mode (ESI+). The ions were focused into an ion trap, capable of MS and MS/MS analyses. The mass spectra were acquired over 35 ms from *m*/*z* 30 to 2000. The capillary exit of the electrospray ion source was set at 70 V, the octapole at 3 V, and the capillary temperature at 200 °C. A counterflow of nitrogen was used as a nebulizing gas. An Xcalibur data system was used to acquire the data, which were further processed with the Turbo Sequest data system.

Data Analysis. **[^{11}C]-6** uptake values in the different experimental conditions were analyzed by two-way ANOVA. When the differences between groups were greater than expected by chance, a multiple comparison Tukey's test or Fisher LSD method was used to isolate the divergent group(s); a value of $p < 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

Chemistry. Syntheses of novel analogues **2**−**10** are shown in Scheme 1. The strategy was based on the Pictet−Spengler cyclization of sulfonamides **13** and **14** with aldehydes **21**−**23**. The sulfonyl chlorides **11** and **12** were achieved by chlorosulfonation of butylbenzene and (4-fluorobutyl)benzene (*20, 21*) with chlorosulfonic acid in chloroform at room temperature (*22, 23*) and were obtained in 91% and 43% yields, respectively; the moderate yield registered for compound **12** was due to a competitive substitution reaction of the fluorine atom by the chlorine atom. The formation of the sulfonamides **13** and **14** was obtained quantitatively by the reaction of sulfonyl chlorides **11** and **12** with 2-phenylethylamine in pyridine at room temperature (*19*, *24*).

Quinolinic acids **15** and **16** were used as starting materials in the syntheses of aldehydes **21**−**23** and were synthesized by oxidation with ruthenium tetraoxide of their corresponding halogenated quinolines (*25*). Dehydration of quinolinic acids **15**−**17** with thionyl chloride (*26*) or acetic anhydride (*27*) into quinolinic anhydrides followed, without purification, by the

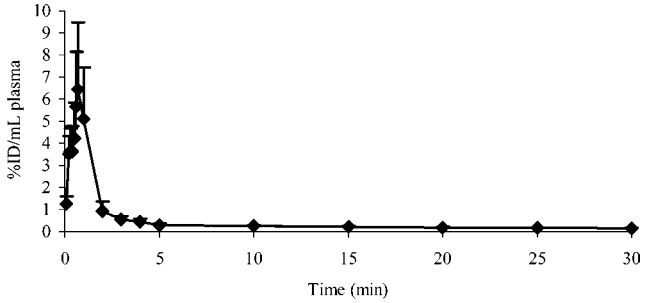

Figure 1. Radioactive kinetics in rat plasma after **[^{11}C]-6** intravenous injection; $n = 3$ at each time, mean ± SEM.

reaction with 3-aminopropanol, in the presence of triethylamine and in toluene at reflux (*28*, *29*), afforded the alcohols **18**−**20** in 46−55% yields. Initially, the aldehyde **21** was synthesized by a Swern oxidation in a poor yield (24%) and a degradation on silica gel column (*30*, *31*). To overcome this drawback, the oxidation of alcohols was performed with *o*-iodoxybenzoic acid (IBX) (*32*, *33*), a mild oxidant, in EtOAc at 80 °C, and the aldehydes **21**−**23** were isolated, without further purification, in excellent yields (95−100%). N-Substituted quinolinimides **2**, **3**, and **6**−**8** were obtained in 70−83% yields by the Pictet−Spengler reaction of sulfonamides **13** and **14** with aldehydes **21**−**23** in trifluoroacetic acid at reflux (*19*, *34*). Syntheses of N-substituted quinolinimides **4**, **5**, **9**, and **10** were undertaken by direct halogen/halogen exchange reaction from chlorinated compounds **2** and **7**. The fluorinated compounds **4** and **9** were prepared in 68−70% yields, using anhydrous potassium fluoride in the presence of Kryptofix in DMSO (*35*). Sodium iodide in acetyl chloride allowed the transformation of chlorinated compound **2** to its iodinated analogue **5** in only a poor yield (18%) (*36*). The reaction conducted with sodium iodide/chlorotrimethylsilane (*37*) was shown to be more efficient, and iodinated compounds **5** and **10** were isolated by HPLC in 56−58% yields. This method was not well adapted to obtain the compounds in large amounts; for this purpose, an alternative synthesis from chlorinated compounds **2** and **7** was used where a stannylation (*38*)/iododestannylation (*39*) reaction sequence permitted isolation of the iodinated compounds **5** and **10** in 28% and 37% overall yields.

In Vitro Studies. *Binding Assays.* In vitro binding studies of quinolinimides **1**−**10** were assessed either from rat brain membranes using [^{3}H]-DAMGO (μ) and [^{3}H]-deltorphin II (δ) or from guinea pig brain membranes using [^{3}H]-U69,593 (κ). The inhibition constants (K_i) were calculated from the IC_{50} values determined on the concentration−response curves. The results are summarized in Table 1. The values were compared with those obtained for five ligands of reference, which are as follows: naloxone, which does not really discriminate between the three opioid receptor subtypes; the selective antagonist naltrindole (δ); and the selective agonists deltorphin II (δ), DAMGO (μ), and U50,488 (κ). In the present experiments, K_i values for ligands chosen as references were found to be in agreement with previoulsy reported data (*1*, *14*, *19*, *40*−*42*).

Previously, the affinity of the lead compound **1** toward δ-opioid receptors was obtained by displacement of [^{3}H]-naltrindole from crude membranes from CHO cells stably expressing the human δ-opioid receptor cDNA (*19*) (IC_{50} δ = 6nM). We chose to evaluate the affinity and the selectivity of this compound using rat brain membranes considering our following in vivo experiment conditions. With this less selective biological material than cloned cells, the K_i value of **1** was 82 ± 9 nM, but its excellent selectivity was confirmed. Data in Table 1 show that the introduction on the lead compound **1** of a halogen instead of a methyl group in the 2-position of the pyridine ring results in a lower δ affinity and selectivity (compounds **2**−**5**). Then, we investigated the effect of the introduction of a fluorine atom on the butyl chain and observed that the affinities of compounds **6** and **8**−**10** were approximately 2-fold greater than those of compounds **1** and **3**−**5** at δ and with a slightly improved selectivity. Considering compounds **5**

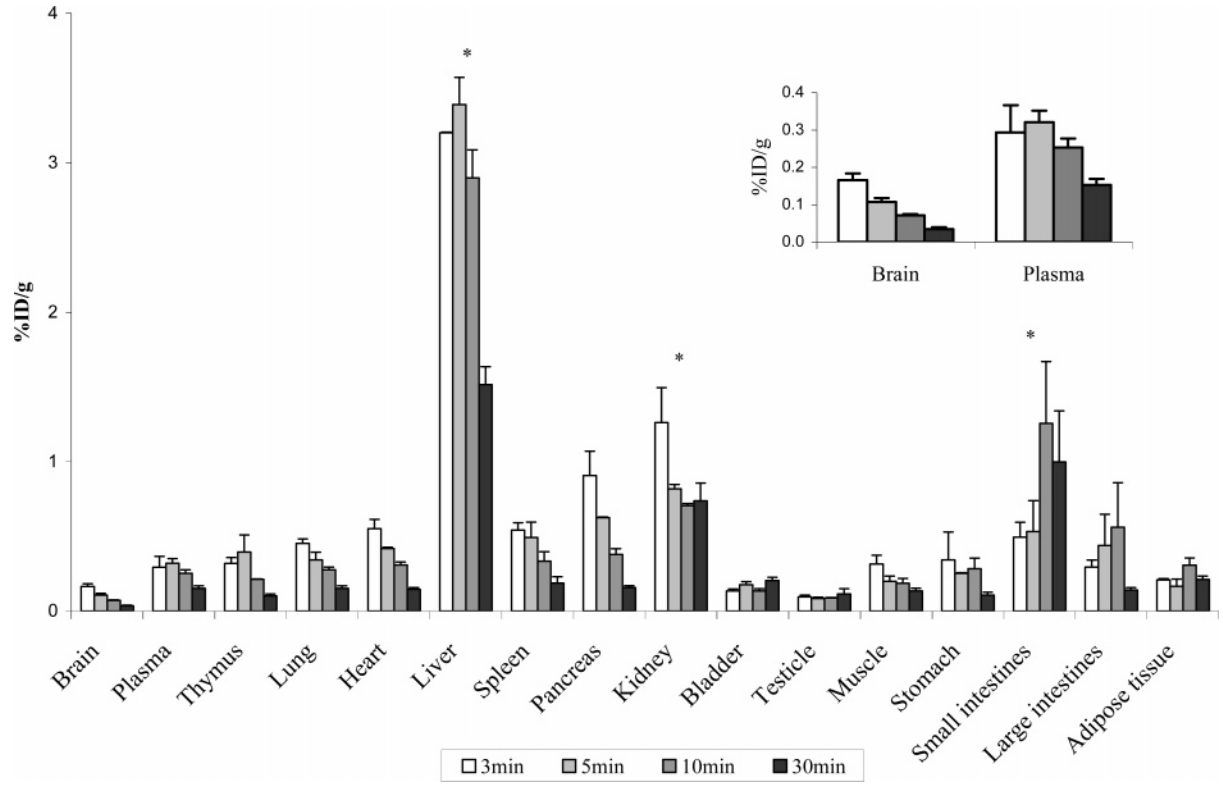

Figure 2. Radioactivity distribution in various tissues after intravenous administration of **[^{11}C]-6** in the rat; $n = 3$, mean ± SEM, * ANOVA $p < 0.001$, and post hoc Tukey's test $p < 0.001$.

Table 2. Percentage of Unchanged [^{11}C]-6 in Rat Brain and Plasma[a]

	3 min	5 min	10 min	30 min
brain	91 ± 3	71 ± 10	62 ± 4	41 ± 4
plasma	61 ± 9	40 ± 10	46 ± 8	22 ± 2

[a] Mean ± SEM; $n = 3$ for each determination.

and **10** possessing an iodine atom that could be substituted by a γ ^{123}I isotope, the low affinities registered ($K_i \approx 112-192$ nM) led us to delay the development of a radioligand for SPECT studies. Compound **6** showed a better selectivity over μ and κ receptors (μ/δ and $\kappa/\delta > 238$) than that described by Clayson (*14*) for methylnaltrindole ($\mu/\delta = 81$ and $\kappa/\delta = 17$) and the best affinity among the series ($K_i = 42 \pm 8$ nM). The lack of very specific PET radioligands for human brain δ opioid receptor imaging led us, in spite of a moderate affinity, to develop **6** as a potential tracer. We considered that a lower affinity could not be a handicap if the injected tracer dose was lower than the δ receptor density in the CNS, and the high selectivity could contribute to an increase of the signal-to-noise ratio. The introduction on this structure of either a carbon-11 isotope via [^{11}C]CH_3I on the pyridine moiety or a fluorine-18 isotope on the butyl chain could be considered.

GTP-γ-S Functional Assays. The relative efficacies of selected compound **6** and lead compound **1** were characterized using the [^{35}S]GTPγS assay. Data show the agonist and antagonist properties of these compounds, together with naltrindole ($E_{max} = 102 \pm 1\%$) and deltorphin II ($E_{max} = 129 \pm 1\%$), in stimulating [^{35}S]GTPγS binding mediated by the δ-opioid receptor on rat brain membranes. Compound **1** produced intermediate maximal stimulation of [^{35}S]GTPγS binding ($E_{max} = 110 \pm 2\%$) that confirmed the weak analgesic activity described by Barn (*19*), while compound **6** produced low maximal stimulation ($E_{max} = 104 \pm 3\%$) similar to that of the antagonist naltrindole.

Radiochemistry. Having in our hands compound **10** which could allow, via a stannane precursor, the introduction of [$^{11}CH_3$]I by a Stille reaction (*43*−*45*), we have developed the labeling of **6** with carbon-11 instead of fluorine-18 with the aim of evaluating **[^{11}C]-6** as a PET tracer (Scheme 2). The tributylstannane **26** was obtained in 40% yield from the corresponding 2-iodo derivative **10** by a palladium-catalyzed cross-coupling reaction using hexabutyltin and a catalytic amount of tetrakis(triphenylphosphine)palladium(0) in toluene (*46*). [^{11}C]Methyl iodide, obtained from the reduction of [^{11}C]-carbon dioxide, was trapped in a vial containing tris(dibenzylideneacetone)dipalladium(0) and tri-*o*-tolylphosphine in DMF; then, a freshly prepared solution of precursor **26**, potassium carbonate, and copper(I) chloride in DMF was added. The vial was heated to 90 °C for 5 min before purification on a semipreparative HPLC column. Typical syntheses provided 70−80 mCi (uncorrected) of **[^{11}C]-6** in an average decay-corrected yield of 60 ± 10% calculated from [^{11}C]methyliodide in a total synthesis time of 40 min, including radioligand formulation for intravenous administration. The radiolabeled product was over 98% radiochemically pure, determined by analytical HPLC, and the specific activity ranged from 0.8 to 1.5 Ci/μmol at EOS.

Lipophilicity. Frequently, the selection of a candidate PET radioligand has been done on the basis of the affinity value and selectivity, leading to poor results when its lipophilicity was too high. On the other hand, it is well-understood that an optimal lipophilicity (log *P* near 2) of a drug is required for good blood−brain barrier permeability. The experimental log *P* of **[^{11}C]-6** was obtained by the octanol/water partition coefficient, as detailed in the Experimental Section, and showed a good log *P* value (2.49 ± 0.03).

Ex Vivo Studies. Male Sprague−Dawley rats served for preliminary in vivo evaluation of pharmacokinetics. The injected dose calculated with the present specific radioactivity was lower than the δ-opioid receptor density described in the rat brain (*47*). Figure 1 depicts the **[^{11}C]-6** plasma kinetics where an early peak was registered (6.5% ID/mL at 1 min), followed by very short distribution ($t_{1/2} \approx 1$ min) and fast elimination ($t_{1/2} = 20$ min) phases. Figure 2 shows the organ distribution of **[^{11}C]-6** between 3 and 30 min postinjection. The accumulation was highest in liver > kidneys > small intestines and lowest in testicles and bladder; the radioactivity levels decreased in all tissues from 3 to 30 min except in small intestines.

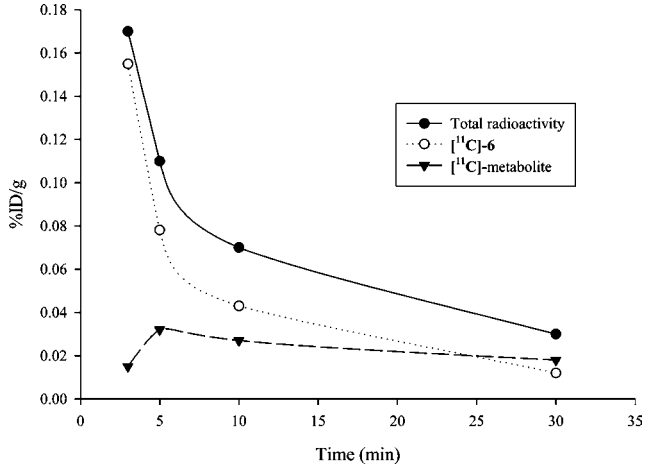

Figure 3. Time course for radioactivity expressed as % ID/g in brain after intravenous injection of **[^{11}C]-6** in rat.

The brain uptake ranged from 0.17 ± 0.02% ID/g at 3 min to 0.04 ± 0.003% ID/g at 30 min. This relatively low uptake does not correlate with the lipophilicity of **[^{11}C]-6**, which predicted a good blood−brain barrier crossing. It could be explained by a strong affinity for plasma proteins, minimizing the drug delivery to the brain. The stability of **[^{11}C]-6** was determined in brain homogenates and plasma samples. The radiochromatograms obtained from HPLC analysis exhibited two radioactive peaks, one corresponding to **[^{11}C]-6** and the other to a polar radioactive compound. Sequential studies revealed the progressive appearance of this labeled metabolite in brain and plasma (Table 2), already present at 3 min and reaching 30 min after tracer injection 59% and 88% of total radioactivity, respectively. These results led to the pharmacokinetic profiles of the parent compound and metabolite shown in Figure 3. The polar radioactive compound identified as a metabolite M1 was isolated and analyzed by LC/MS/MS. Mass spectral analysis revealed an intense protonated molecular ion at *m*/*z* 518.1 ([M + H]$^+$). The MS data tentatively assigned M1 as a structure close to either dehydrated or dehalogenated parent compound **6** (MS = 535.1), which suggested a stability of the parent compound-based structure. The MS/MS analysis of *m*/*z* 518.1 provided informative product ions at *m*/*z* 321, attributed to the phthalimido tetrahydroisoquinolinium moiety, and at *m*/*z* 356, corresponding to the benzenesulfonyl tetrahydroisoquinolinium moiety (Figure 4).

The regional brain distribution was studied at 3, 10, and 30 min. The anatomical regions of interest were selected and identified using the atlas of Paxinos and Watson (*48*), i.e., olfactory tubercles, striatum, frontal cortex, hypothalamus, cerebellum, thalamus, and hippocampus (*49*, *50*). The corpus callosum devoid of receptor was used as an indicator of the nonspecific binding. The uptake values and the region/corpus callosum ratios for selected regions are shown in Table 3. In the control condition, data indicated significant uptake of **[^{11}C]-6** at 3 min, higher in frontal cortex, olfactory tubercles, thalamus, hypothalamus, striatum ($p < 0.05$), and cerebellum ($p < 0.001$) than in corpus callosum. δ-Opioid receptors are known to be

[a] Results are expressed as % ID/g of tissue (mean ± SEM; $n = 3$ for each determination). [b] Coinjection with cold compound **6** (1.3 mg/ kg). [c] Blocking with naloxone (1 mg/ kg).

highly confined in olfactory tubercles, striatum, and frontal cortex (*49*). In the cerebellum, significant levels were observed only in some studies (*50*). In thalamus and hypothalamus, the present results disagreed with published data (*49*). These significant differences between cerebral regions disappeared at 10 and 30 min. These interstructural differences at 3 min could be explained by the influence of the cerebral blood flow on early radiotracer distribution. To address the nonspecific binding of **[^{11}C]-6** in vivo, displacement studies were carried out. Neither preadministration of naloxone (1 mg/kg, 15 min prior to radiotracer) nor coinjection of **[^{11}C]-6** with cold compound **6** (1.3 mg/kg) could significantly alter the tracer distribution. The coadministration of cold compound **6** caused a 5.4-fold increase in radioactivity uptake at 3 min and 3.2-fold at 10 min ($p < 0.001$) and return to baseline at 30 min. These results could be explained by the pharmacological effect of **6** characterized as a δ antagonist influencing the cerebral blood flow. Indeed, it was described that the injection of a high dose of naltrindole produced significant increases in heart rate and mean arterial pressure (*51*).

Kinetics studies of the radiotracer in the rat demonstrated a fast washout of the parent compound in blood as in the brain

mainly due to an extensive metabolism. In spite of the good selectivity of **6** for δ-opioid receptors in vitro and sufficient affinity with regard to δ-opioid receptor density in rat brain (*47*) (see recommended procedure (*52*)), significant specific binding could not be revealed. A possible interference of the [^{11}C] byproduct with other binding sites could contribute to an increase of the nonspecific binding. Further studies, using animal species more close to human relating to qualitative and/or quantitative metabolism pathways, could be envisaged.

CONCLUSION

On the basis of a series of N-substituted quinolinimide derivatives displaying nanomolar affinity on human cloned δ-opioid receptor and high selectivity for δ versus μ and κ opioid receptors, novel compounds possessing a halogen atom on the butyl chain and/or on the 2-position of the pyridine ring were synthesized in order to develop tracers for medical imaging. In vitro assays led us to consider compound **6** which displayed an affinity of 42 nM on rat brain membranes, a >238-fold selectivity for the δ over the μ and κ receptors, respectively, and antagonist properties, as a promising ligand for PET imaging. We reported a high yielding radiosynthesis of **[^{11}C]-6**, based on the [^{11}C]methyl introduction on the pyridine moiety by a Stille reaction. The radiochemical yield was 60 ± 10%, and the radiochemical purity exceeded 98%. In rats, in vivo evaluation clearly indicated that the radiotracer crossed the blood−brain barrier, but was not stable and underwent rapid metabolism in both plasma and brain. No specific binding was consequently revealed. Although the goal of identifying a new potential PET radioligand for δ-opioid receptors was not achieved, the proposed strategy is a starting point for future developments of more stable analogues.

ACKNOWLEDGMENT

This research has been supported through two grants from the CEA and the Conseil Regional de Basse Normandie. The authors wish to thank Mr. Olivier Tirel the cyclotron operator and Mr. Laurent Prieur, Mr. Laurent Chazalviel, and Mr. Ahmed Abbas who skillfully contributed to the in vivo studies.

Supporting Information Available: Additional experimental data on compounds **11**−**23**. This material is available free of charge via the Internet at http://pubs.acs.org/BC.

Received September 18, 2006; Revised Manuscript Received January 25, 2007

Affibody molecules present a new class of affinity proteins, which utilizes a scaffold based on a 58-amino acid domain derived from protein A. The small (7 kDa) Affibody molecule can be selected to bind to cell-surface targets with high affinity. An Affibody molecule ($Z_{HER2:342}$) with a dissociation constant (K_d) of 22 pM for binding to the HER2 receptor has been reported earlier. Preclinical and pilot clinical studies have demonstrated the utility of radiolabeled $Z_{HER2:342}$ in imaging of HER2-expressing tumors. The small size and cysteine-free structure of Affibody molecules enable complete peptide synthesis and direct incorporation of radionuclide chelators. The goal of this study was to evaluate if incorporation of the natural peptide sequences cysteine-diglycine (CGG) and cysteine-triglycine (CGGG) sequences would enable labeling of Affibody molecules with ^{99m}Tc. In a model monomeric form, the chelating sequences were incorporated by peptide synthesis. The HER2-binding affinity was 280 and 250 pM for CGG-$Z_{HER2:342}$ and CGGG-$Z_{HER2:342}$, respectively. Conjugates were directly labeled with ^{99m}Tc with 90% efficiency and preserved the capacity to bind specifically to HER2-expressing cells. The biodistribution in normal mice showed a rapid clearance from the blood and the majority of organs (except kidneys). In the mice bearing SKOV-3 xenografts, tumor uptake of ^{99m}Tc-CGG-$Z_{HER2:342}$ was HER2-specific and a tumor-to-blood ratio of 9.2 was obtained at 6 h postinjection. Gamma-camera imaging with ^{99m}Tc-CGG-$Z_{HER2:342}$ clearly visualized tumors at 6 h postinjection. The results show that the use of a cysteine-based chelator enables ^{99m}Tc-labeling of Affibody molecules for imaging.

INTRODUCTION

In recent years, progress in molecular biology has led to the identification of a number of molecular biomarkers in malignant cells, which can be used as targets for cancer treatment. For example, the elucidation of the role of tyrosine kinase receptors enabled the development of therapy directed to disruption of their signaling (*1*). Apparently, such therapy can be efficient only if a particular biomarker is present or overexpressed in a particular tumor, i.e., this therapy should be personalized. By now, the major way to determine the presence of a biomarker is a biopsy. However, heterogeneity of biomarker expression causes two problems which may lead to false-negative findings, i.e., sampling errors and discordance in the biomarker expression in primary tumors and metastases (*2*). The use of radionuclide imaging may help to avoid these problems by imaging both the whole primary tumor volume and the metastases in a single noninvasive procedure.

The use of peptide receptor ligands or their analogues as targeting agents provided excellent clinical results in the detection, e.g., of overexpression of somatostatin receptors (*3*). This was also a spectacular demonstration of a potential of small, high affinity peptides in radionuclide imaging. However, this approach cannot be applied for imaging of nonreceptor tumor markers, or for receptors for which no naturally occurring ligands have been identified, such as HER2, which signal by heterodimerization with other receptors (*4*). For this kind of target, monoclonal antibodies or their Fab or F(ab′)$_2$ fragments were mainly considered as targeting agents. Intact antibody molecules are large glycoproteins (about 150 kDa), which limits their application in molecular imaging. This is due to their relatively slow clearance from the blood circulation, which leads to a high background radioactivity and to their limited extravasation and diffusion into the tumor (*5*). The use of smaller fragments, e.g., F(ab′)$_2$, has enabled high-contrast imaging of tumors (*6*). The development of even smaller engineered antibody fragments, such as single-chain variable fragments (scFv), has become the mainstream for development of targeting agents for imaging (*7*). Still, a decrease of the targeting agent size below the size of scFv (approximately 27 kDa) would be appealing. To fulfill this goal, the use of nonimmunoglobulin scaffolds for selection of targeting proteins is promising (*8*).

Affibody molecules are an example of nonimmunoglobulin scaffolds, which have been successfully applied for *in vivo* imaging. Affibody molecules are based on a 58-amino acid residue protein domain, derived from the B-domain of staphylococcal protein A (*9*). This low-molecular weight (7 kDa) cysteine-free three-helix bundle protein has become an attractive alternative to antibody-based binding proteins in many applications in biotechnology, separomics, and analysis (see http://www.affibody.com). Recently, a new anti-HER2 targeting agent, named Affibody molecule $Z_{HER2:4}$, has been obtained by selection from an affibody library (*10*). HER2/*neu* (c-*erbB*-2) is a transmembrane receptor tyrosine kinase that mediates the growth, differentiation, and survival of cells (*11*). Overexpres-

sion of HER2 receptors occurs in 25−30% of human breast and ovarian cancer, and its elevated expression is associated with poor prognosis (*12*). Herceptin (trastuzumab; Genentech), a humanized monoclonal antibody, is approved for clinical use for treatment of HER2-positive tumors. For the moment, both the American Association of Clinical Oncology and the European Group on Tumor Markers recommend an evaluation of the HER2 status of each breast cancer in order to select patients who will benefit from Herceptin therapy (*13*, *14*). In radionuclide tumor targeting, the radioiodinated (*15*, *16*) and radiobrominated (*17*) bivalent Affibody ligands $(Z_{HER2:4})_2$ have been reported to be suitable for visualization of HER2-expressing tumors. Affinity maturation of the $Z_{HER2:4}$ Affibody molecule generated a new HER-2 binding clone with a dissociation constant (K_d) of 22 pM for binding to the HER2 receptor, $Z_{HER2:342}$ (*18*). This Affibody molecule labeled with iodine or indium radioisotopes showed an excellent *in vivo* visualization of HER2-expressing tumor xenografts (*18*, *19*). The robust cysteine-free structure and the capability to quick refolding enabled synthetic production of Affibody molecules and incorporation of chelators during peptide synthesis. $Z_{HER2:342}$ with a DOTA chelator introduced at N-terminal was labeled with ^{111}In and ^{68}Ga and was successfully used in a pilot clinical study for imaging of HER2-expession in breast carcinomas (*20*, *21*).

Apparently, the radionuclide technetium-99m would be an attractive label for HER2-targeting Affibody molecules, due to its many favorable features such as low price, high availability, and optimal photon energy (140 keV) for imaging. Besides that, its short half-life ($T_{1/2}$ = 6 h) is a good match to the pharmacokinetics of Affibody molecules, which are characterized by rapid blood clearance. A site-specific technetium labeling of His_6-$(Z_{HER2:4})_2$ with Tc(I)-carbonyl chemistry was investigated (*16*). The radiolabeled conjugate provided good tumor accumulation; yet the liver uptake was too high to make it possible to detect liver metastases. For this reason, we started to investigate alternative labeling strategies. Earlier we have evaluated the incorporation of the mercaptoacetyltriglycyl-containing chelating sequence, maGGG (MAG3), for ^{99m}Tc-labeling of a synthetic variant of $Z_{HER2:342}$ (*22*). This conjugate enables imaging of HER2-expression in LS174T and SKOV-3 xenografts, both at 6 and 24 h pi. However, an appreciable part of the ^{99m}Tc-maGGG-$Z_{HER2:342}$ conjugate was excreted via bile, which might complicate the detection of HER2-expression in, e.g., ovarian carcinomas or in extrahepatic abdominal metastases of other tumors at the day of injection.

The strength of the Affibody technology lies in the capacity to generate multimeric constructs and fusion proteins in order to modify affinity/avidity, modulate *in vivo* kinetics, or introduce a peptide/protein effector function. The use of dimerization to increase apparent affinity has been mentioned above. A fusion with an albumin binding domain (ABD) to the dimeric form of $Z_{HER2:342}$ was used to prolong residence time in the blood and permit radionuclide therapy using ^{177}Lu (*23*). Obviously, such constructs are too large (more than 100 amino acids) to permit peptide synthesis in a cost-efficient way, and recombinant production is therefore required. Although it is possible to couple different chelators to recombinant proteins, this would result in a heterogeneous mixture of conjugates with different modification degree. The use of site-specific labeling would always be preferable, since it provides a more defined targeting agent. It was reported earlier that the introduction of a terminal cysteine in scFv fragments provides a chelating function for ^{99m}Tc-labeling (*24*−*26*). Recent progress in biotechnology, e.g., an introduction of TEV protease (*27*) which tolerates cysteine at +1 position of the cleavage site, has also facilitated the recombinant production of proteins with N-terminal cysteine residues.

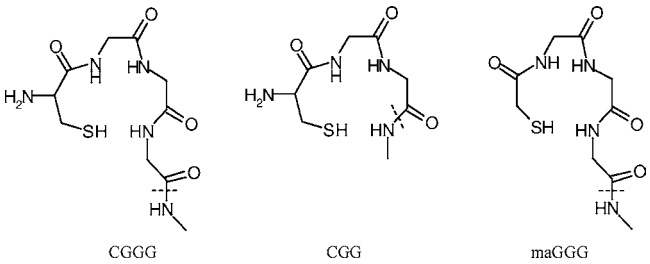

Figure 1. Chelator structures.

We hypothesized that the introduction of the ^{99m}Tc-chelating amino acid sequences cysteine-diglycine (CGG) and cysteine-triglycine (CGGG) (Figure 1) at the N-terminus of Affibody molecules would provide an attachment of ^{99m}Tc to the Affibody, which is stable enough for an *in vivo* application. The aim of the present study was to evaluate the labeling conditions and the *in vitro* and *in vivo* targeting properties of the ^{99m}Tc-labeled CGG- and CGGG-containing $Z_{HER2:342}$ Affibody conjugates.

MATERIALS AND METHODS

Materials. Fmoc-Ala-OH, Fmoc-Arg(Pbf)-OH, Fmoc-Asn-(Trt)-OH, Fmoc-Asp(*t*Bu)-OH, Fmoc-Cys(Trt)-OH, Fmoc-Gln-(Trt)-OH, Fmoc-Glu(*t*Bu)-OH, Fmoc-Gly-OH, Fmoc-Ile-OH, Fmoc-Lys(Boc)-OH, Fmoc-Met-OH, Fmoc-Phe-OH, Fmoc-Pro-OH, Fmoc-Ser(*t*Bu)-OH, Fmoc-Trp(Boc)-OH, Fmoc-Tyr(*t*Bu)-OH, and Fmoc-Val-OH were all from Applied Biosystems (Warrington, U.K.). Fmoc-Leu-OH was from Calbiochem-NovaBiochem (Läufelfingen, Switzerland).

N-Methylpyrrolidone (NMP) and acetic acid were from VWR. Dichloromethane and acetic anhydride were from Applied Biosystems (Warrington, UK). *N*-Ethyldiisopropylamine (DIEA) and piperidine were from Lancaster Synthesis (Morecambe, UK). Triisopropylsilane (TIS), trifluoroacetic acid (TFA), and *tert*-butyl methyl ether were from Merck International. Ethanedithiol (EDT) was from Aldrich Chemical Co. Inc. (Milwaukee, WI). 1-Hydroxybenzotriazole (HOBt) and 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) were from Advanced ChemTech (Louisville, KY).

For use in comparative biodistribution experiments, the synthetic Affibody molecule maGGG-$Z_{HER2:342}$ was labeled with ^{99m}Tc according to a previously published method (*22*). A recombinant Affibody molecule ($Z_{HER2:342}$) was indirectly radioiodinated using a succinimidyl ester of *p*-iodobenzoate according to Orlova and co-workers (*18*) and designated as ^{125}I-PIB-$Z_{HER2:342}$. An Ultra-TechneKow generator from Tyco was eluted with sterile 0.9% sodium chloride (Mallinckrodt Medical BV, Petten, The Netherlands) to obtain ^{99m}Tc as pertechnetate.

Instrumentation. An automated gamma-counter with a 3 in. NaI(Tl) detector (1480 Wizard, Wallac Oy, Turku, Finland) was used to measure the radioactivity. An instant thin layer chromatography analysis was performed using silica gel impregnated glass fiber sheets, ITLC strips (ITLC SG, from Gelman Sciences Inc). The Cyclone Storage Phosphor System and the OptiQuant image analysis software (both from Packard) were used to measure the radioactivity on the ITLC strips. The cells were counted in an electronic cell counter (Beckman Coulter, Fullerton, CA). *In vivo* imaging was performed by a dual-head e. Cam gamma camera (Siemens Medical Systems, Inc.), equipped with a low-energy, high-resolution collimator (LEHR). The acquisition of static images was performed with a 256 × 256 matrix and a zoom factor of 3.2. The energy window settings were 140 keV, 15%.

Peptide Synthesis. $Z_{HER2:342}$ was synthesized using Fmoc-chemistry on a 433A Peptide Synthesizer (Applied Biosystems, Warrington, U.K.) as previously described (*25*). Ten molar equivalents of amino acid were activated with HBTU and HOBt in NMP for each coupling reaction. Fmoc deprotection was performed by treatment with 20% piperidine−NMP. A double coupling procedure was used at 17 selected positions to increase the synthetic yield, and acetic anhydride was used to cap any remaining free amino groups. The peptide sequence is VENK FNKEMRNAYWEIALLPNLNNQQKRAFIRSLYDDPSQSAN-LLAEAKKLNDAQAPK, with double coupled amino acids underlined.

After the automatic assembly of $Z_{HER2:342}$, the N-terminal of the peptide was manually extended with the Tc-chelating sequences CGG and CGGG by coupling each amino acid with 5 mol equiv of amino acid, HBTU, and HOBt and 10 equiv of DIEA in NMP for 20 min. 20% piperidine−NMP was used for removal of the N-terminal Fmoc protecting group. Kaiser tests were performed to evaluate if the acylation and deprotection reactions were successful or had to be repeated. The manual coupling step of the chelators was used, since it is a rapid and easy way to introduce different chelating amino acid residues.

The resin-bound peptide was incubated with TFA/EDT/TIS/H2O (94:2.5:2.5:1) for 2 h to remove permanent protecting groups and liberate the peptide from the solid support. The peptide was extracted in *tert*-butyl methyl ether−H_2O (50:50), filtered, and lyophilized. The crude synthetic product was analyzed by analytical RP-HPLC using a 4.6 × 150 mm polystyrene/divinylbenzene matrix column with a particle size of 5 μm (Amersham Biosciences, Uppsala, Sweden), a 20 min gradient of 20−60% B (A: 0.1% TFA−H_2O, B: 0.1% TFA−CH_3CN) and a flow rate of 1 mL/min. All peptides were purified using a 20 min gradient of 25−45% B. The pure product was lyophilized, and the final peptide concentration was determined by amino acid analysis (Aminosyraanalyscentralen, Uppsala, Sweden). To verify the identity of the peptides, the peptide mass was analyzed on a Q-Tof II mass spectrometer fitted with an ESI source (Waters Corporation, Micromass MS Technologies, Manchester, U.K.). The Maximum Entropy 1 (MaxEnt1) algorithm was used to deconvolute the isotopic and charge state information. For the labeling experiments, the freeze-dried peptides were dissolved in degassed, deionized water to a concentration of 1 mg/mL and were stored at −20 °C

Biophysical Characterization. The melting point of each peptide was determined on a Jasco J-810 spectropolarimeter (JASCO, Tokyo, Japan). The temperature was increased from 20 to 90 °C at a rate of 5 °C/min, and the absorbance was detected at 221 nm. In addition, CD spectra were recorded from 250 to 195 nm at 20 °C before and after melting. The sample concentration was 50 μM in PBS pH 7.4 and the optical path length was 1 mm.

Biosensor Analysis. The binding kinetics of the different peptides were compared by performing a real-time biospecific interaction analysis on a Biacore 2000 instrument (Biacore, Uppsala, Sweden). HBS (10 mM HEPES, 150 mM NaCl, 3.4 mM EDTA, 0.005% Surfactant P20, pH 7.4) was used as running buffer at a flow rate of 50 μL/min, and also for dilution of the samples into the concentration range 0.3−10 nM. 500 RU (response units) of recombinant extracellular domain of HER2 (a generous gift from Prof. Gregory Adams, Fox Chase Cancer Center, Philadelphia, PA) and 900 RU of human serum albumin, HSA (KabiVitrum, Stockholm, Sweden), were immobilized onto a CM5 sensor chip (Biacore, Uppsala, Sweden) from 20 μg/mL solutions in 10 mM NaAc pH 4.5. The association time was 5 min, and the dissociation time was 10 min, followed by regeneration with 20 μL of 20 mM HCl. The BiaEval software (Biacore, Uppsala, Sweden) and the Langmuir 1:1 binding model were used for the kinetic analysis.

Labeling with ^{99m}Tc. The analysis of the labeled Affibody molecules was done by ITLC. To determine labeling yield and stability, ITLC strips were eluted with PBS. Validation experiments showed that pertechnetate, as well as tartrate, glucoheptonate, and cysteine complexes of ^{99m}Tc migrated with the eluent front, while the Affibody remained at the origin in PBS. To determine the presence of reduced hydrolyzed technetium, ITLC was eluted with pyridine:acetic acid:water (5:3:1.5). In this eluent, the technetium colloids remained at the origin, while the radiolabeled Affibody, pertechnetate, and tartrate complexes of ^{99m}Tc migrated with solvent front.

Two variants of labeling procedures were evaluated.

Indirect labeling of CGGG-$Z_{HER2:342}$ was performed according to Winnard et al. (*29*). CGGG-$Z_{HER2:342}$ (20 μL, 1 mg/mL in deionized degassed water) was mixed with 80 μL of PBS and 20 μL of a solution containing Na/K tartrate in 0.5 M $NaHCO_3$ and 0.25 M NH_4OAc. If necessary, 0.15 M NaOH was added to keep the pH of the final mixture at about 11. A fresh ^{99m}Tc-generator eluate (50−350 μL) followed by $SnCl_2 \cdot 2H_2O$ in 0.01 M HCl (10 μL, 1 mg/mL) was added, and the mixture was incubated at room temperature for 60 min.

Direct labeling: 20 μL of CGG-$Z_{HER2:342}$ or CGGG-$Z_{HER2:342}$ (1 mg/mL in deionized degassed water) was mixed with 20 μL of 0.15 M NaOH to obtain a final pH of about 11. A solution of $SnCl_2 \cdot 2H_2O$ in 0.01 M HCl (10 μL, 1 mg/mL) was added to the mixture, followed by 100−200 μL of fresh pertechnetate solution. The mixture was slightly vortexed and incubated at room temperature for 60 min.

After being labeled, ^{99m}Tc-CGG-$Z_{HER2:342}$ and ^{99m}Tc-CGGG-$Z_{HER2:342}$ were isolated from unreacted technetium and other low-molecular weight components using size-exclusion chromatography on disposable NAP-5 columns (Amersham Pharmacia Biotech AB, Uppsala, Sweden) preequilibrated with PBS. The purity of the final product was assessed by analysis with ITLC.

Stability Test. The stability of the labeled Affibody conjugates was tested in PBS and in 300 molar excess of cysteine. After purification, 100 μL of labeled conjugates was added to 500 μL of PBS. The solutions were stored at room temperature for 2 h and were analyzed using ITLC. In the cysteine challenge test, a fresh solution of cysteine was prepared (1 mg/mL in PBS, pH 7.0). The radiolabeled conjugates were added to a final molar ratio of cysteine to peptide of 300:1. The test tubes were incubated for 2 h at 37 °C, and the radiochemical purity was analyzed using ITLC. All experiments were performed in triplicate.

To analyze the serum stability, blood was collected from NMRI mice using a heparinized syringe. The blood was centrifuged at 5000*g*, and serum was collected, divided into 0.5 mL aliquots, and stored frozen before use. Serum samples were unfrozen immediately before the stability test. The test was performed in triplicate. The serum samples (240 μL) were mixed with freshly labeled ^{99m}Tc-CGG- and ^{99m}Tc-CGGG-$Z_{HER2:342}$ (10 μL) to obtain an Affibody molecule concentration similar to their concentration in blood at the moment of injection. The samples were incubated for 1 h at 37 °C. After incubation, the tested samples were analyzed by SDS-PAGE on NuPAGE 4−12% Bis-Tris Gel (Invitogen) in MES buffer (200 V constant, 35 min). To facilitate interpretation of the result, a sample of ^{99m}Tc-pertechnetate was run in parallel with the test sample on the same gel. After the analysis, the gels were dried, and radioactivity distribution along the gels was evaluated using Cyclone Storage Phosphor System.

Cell Culture. The HER2-expressing ovarian carcinoma cell line SKOV-3, displaying approximately 1.2 × 10^6 HER2

Table 1. Peptide Synthesis and Characterization Data

peptide	synthetic yield (%)	theoret mw (Da)	exptl mw (Da)	K_D (pM)	T_m (°C)
$Z_{HER2:342}$	21	6718	6718	80	64

receptors per cell, was used in this study. The cell line was cultured in McCoy's medium (Flow Irvine, UK), supplemented with 10% fetal calf serum (Sigma), 2 mM L-glutamine, and PEST (penicillin 100 U/mL and 100 μg/mL streptomycin), all from Biokrom Kg, Germany. The cells were cultured at 37 °C in a humidified incubator with 5% CO_2 and trypsinized using trypsin−EDTA solution (0.25% trypsin, 0.02% EDTA, Biokrom Kg, Germany). The SKOV-3 cells were cultivated on Petri dishes with a diameter of 3.5 cm to a cell density of 2 to 5 × 10^5 cells per dish.

Binding Specificity of ^{99m}Tc-Labeled Conjugates to HER2-Expressing Cells. Labeled conjugates were added to two groups of Petri dishes (three dishes per group) with a calculated ratio of one labeled Affibody conjugate per one HER2 receptor. One group of dishes was presaturated with a 100-fold excess of nonlabeled Affibody 10 min before the labeled conjugate was added. Cells were incubated for 1 h at 37 °C, and the incubation media was collected. The cell dishes were washed six times with cold serum-free medium and treated with 0.5 mL trypsin−EDTA for 10 min at 37 °C. When the cells were detached, 0.5 mL complete medium was added to each dish and the cells were resuspended. The cell suspension was used for radioactivity measurements.

Cellular Retention after Interrupted Incubation with ^{99m}Tc-Labeled $Z_{HER2:342}$. Labeled conjugate, 0.8 ng/10^5 cells, was added in 1 mL of complete medium to a series of Petri dishes containing SKOV-3 cells. The dishes were incubated for 2 h at 37 °C, and the incubation medium was removed. The cells were washed six times with ice-cold serum-free medium, and after addition of 1 mL of complete medium, the cell dishes were incubated further at 37 °C. At designated times of incubation (0.5, 1, 2, 4, 8, and 24 h), a group of three dishes was analyzed for cell-associated radioactivity. The media were collected in scintillation tubes, and the cells were washed six times with ice-cold serum-free medium and treated with 0.5 mL of trypsin-EDTA solution for 10 min at 37 °C. After addition of 0.5 mL of complete medium, the cells were resuspended and collected in scintillation tubes. The radioactivity content of the samples was measured on an automated gamma-counter.

Antigen Binding Capacity. The SKOV-3 cells were scraped from the surface in order to preserve the receptor expression. After resuspension of scraped cells in medium, the cells were counted in an automated cell counter, and cell pellets containing 6 × 10^6 cells were formed in Eppendorf tubes by gentle centrifugation (2 min at 2500*g*). The analysis was done in triplicate. The supernatant was removed completely, and 1 mL of medium with labeled conjugate (with a ratio of approximately one Affibody molecule per 100 HER2 receptors) was added.

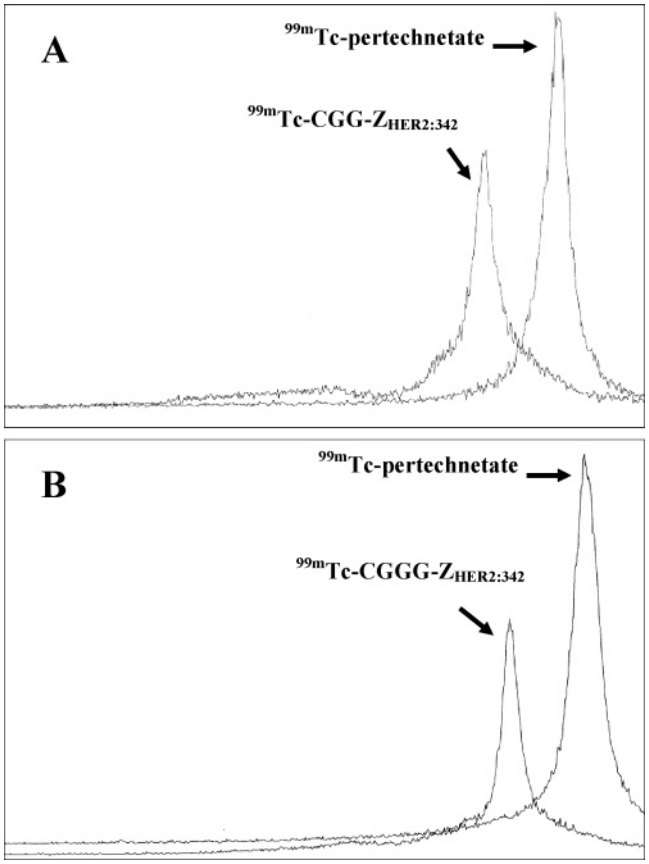

Figure 2. Analysis of ^{99m}Tc-CGG-$Z_{HER2:342}$ (A) and ^{99m}Tc-CGGG-$Z_{HER2:342}$ (B) stability in serum. A sample of each conjugate was incubated in blood serum for 1 h at 37 °C and analyzed using SDS PAGE and radioactivity distribution on the gel was measured using a PhosphorImager.

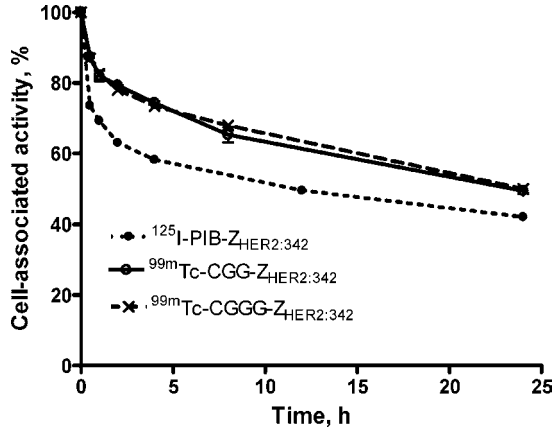

Figure 3. Cell-associated radioactivity as a function of time after interrupted incubation of SKOV-3 cells with radiolabeled $Z_{HER2:342}$. The cell-associated radioactivity at time zero after the interrupted incubation was considered as 100%. Data are presented as mean ± SD (n = 3). Error bars might not be seen, because they are smaller than point symbols.

The cells were gently resuspended and incubated for 4 h at 4 °C under slight shaking. After incubation, the cells were centrifuged (8 min at 7500*g*), and 0.5 mL supernatant medium was taken to a separate Eppendorf tube. The radioactivity was measured on both samples, and the antigen binding capacity (ABC) was calculated as ABC = (A − B)/(A + B) × 100%, where *A* is the radioactivity of the Eppendorf tube containing both the cell pellet and 0.5 mL supernatant, and *B* is the radioactivity of the Eppendorf tube containing 0.5 mL supernatant only.

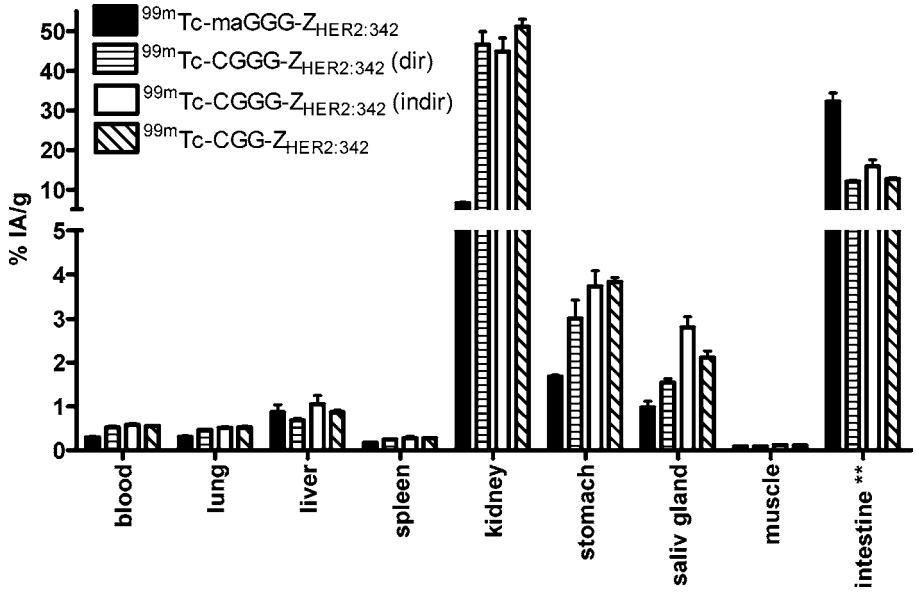

Figure 4. Biodistribution of radiolabeled Affibody molecules in NMRI normal mice 4 h pi. Data are presented as an average from four animals ± SEM. ^{99m}Tc-maGGG-$Z_{HER2:342}$ was included in the experiment for comparison. Uptake in spleen and muscle was less than 0.3% IA/g.

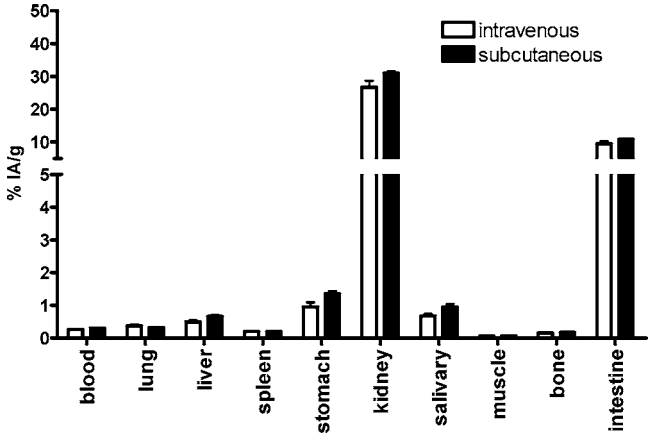

Figure 5. Biodistribution of ^{99m}Tc-CGG-$Z_{HER2:342}$ in NMRI mice after intravenous and subcutaneous injection (4 h pi). Data are presented as an average from four animals ± SEM.

Animal Model. The animal study was approved by the Local Ethics Committee for Animal Research. In comparative biodistribution studies, non-tumor-bearing NMRI mice were used. In tumor targeting and imaging experiments using ^{99m}Tc-CGG-$Z_{HER2:342}$, female Balb/c nu/nu mice were used. The animals (10−12 weeks old at arrival) were acclimatized for one week at the Rudbeck laboratory animal facility using standard diet, bedding, and environment before tumor implantation. The tumor was grafted by subcutaneous (sc) injection of ∼10^7 SKOV-3 cells in the right hind leg. Xenografts were allowed to develop during 2 months.

In all biodistribution studies, the mice were euthanized at predetermined time points with an intraperitoneal injection of Ketalar-Rompun solution (20 μL of solution per gram of body weight: Ketalar [ketamine], 10 mg/mL; Rompun [xylazin], 1 mg/mL). The mice were punctured in the heart with a 1 mL syringe rinsed with diluted heparin (5000 IE/mL, from Leo Pharma, Copenhagen, Denmark). Blood and organ samples were taken and weighed, and their radioactivity was recorded using an automatic gamma-counter with standard ^{99m}Tc protocol. The background was measured for each sample holder in the same way. The tissue uptake values were calculated as percent injected activity per gram tissue (% IA/g).

Comparative Biodistributions in Non-Tumor-Bearing NRMI Mice. Sixteen mice were randomly divided into four groups with four animals each. Each group of mice was injected subcutaneously with 1μg (∼ 100 kBq in 100 μL of PBS) of ^{99m}Tc-CGG-$Z_{HER2:342}$, ^{99m}Tc-CGGG-$Z_{HER2:342}$ (directly labeled), ^{99m}Tc-CGGG-$Z_{HER2:342}$ (indirectly labeled), or ^{99m}Tc-maGGG-$Z_{HER2:342}$, respectively. After 4 h, the mice were euthanized, and samples of blood, lung, liver, kidney, stomach, salivary glands, spleen, muscle, and intestines were collected.

In a separate study, two groups of four animals each were injected with the same batch of ^{99m}Tc-CGG-$Z_{HER2:342}$, but one group was injected intravenously and another subcutaneously. After 4 h, the mice were euthanized and the biodistribution of radioactivity was performed as described above.

Tumor Targeting in Balb/c nu/nu Mice with SKOV-3 Xenografts. Sixteen mice were randomly divided into four groups with four animals each. One group of mice was injected subcutaneously with 0.5 mg of nonlabeled recombinant $Z_{HER2:342}$ in 250 μL of PBS 1 h before radioactive injection. All mice were sc co-injected with ^{99m}Tc-CGG-$Z_{HER2:342}$ and ^{125}I-PIB-$Z_{HER2:342}$ (totally 1μg Affibody ligand, totally ∼100 kBq in 100 μL of PBS). After 1, 4, and 6 h pi, respectively, the mice were euthanized as described earlier. The mice in the blocking group were euthanized 4 h pi. Organ and tissue samples were taken, and their radioactivity uptake was determined as percent injected activity per gram tissue (%IA/g).

Gamma-Camera Imaging of HER2-Expressing Xenografts Using ^{99m}Tc-CGG-$Z_{HER2:342}$. Experimental tumor imaging was performed in two mice bearing SKOV-3 xenografts. The animals were intravenously injected through the tail with 3 MBq (10 μg) ^{99m}Tc-CGG-$Z_{HER2:342}$. Six hours after injection of ^{99m}Tc-CGG-$Z_{HER2:342}$, the animals were killed by overdosing of Rompun/Ketalar. Imaging was performed using a Siemens gamma-camera equipped with a LEHR collimator at the Department of Nuclear Medicine of Uppsala University Hospital. Static images were collected during 10 min, and the images were evaluated with a Hermes system (Nuclear Diagnostic). A quantitative analysis was done by drawing equal regions of interest (ROI) over the tumor and contralateral thigh.

RESULTS

Peptide Synthesis. The Fmoc solid-phase synthesis of $Z_{HER2:342}$ resulted in a yield of 21% of the full-length peptide, as determined by analytical RP-HPLC. The ^{99m}Tc-chelating sequences of CGG or CGGG introduced N-terminally by manual

synthesis, both resulting in total synthetic yields 16% (Table 1). After purification with RP-HPLC, the purity was higher than 90%. ESI-MS was used to verify the molecular weight of the peptides. For the MS analysis, the thiol groups were capped with iodoacetamide, resulting in an additional mass of 57 Da. The data obtained correlated well with the expected masses (Table 1).

Biophysical Characterization. The stability of the secondary structure of the different proteins was studied at variable temperatures. The melting temperatures of the CGG and CGGG-modified peptides were 68 °C (Table 1). The CD spectra were recorded before and after melting of each peptide, and all generated very similar spectra, showing α-helical structure, suggesting that the proteins refold after heating to 90 °C.

Biosensor Analysis. The binding kinetics of the different Tc-chelating proteins were compared in a biospecific interaction analysis on a Biacore 2000 instrument. As shown in Table 1, both conjugates showed similar affinities to surface-immobilized HER2 receptors: 280 pM and 250 pM for CGG-$Z_{HER2:342}$ and CGGG-$Z_{HER2:342}$, respectively.

Radiolabeling. As displayed in Table 2, the efficiency of the direct labeling of cysteine-containing Affibody molecules was much higher than for the indirect labeling method (>90% vs 54%). The isolated yield from size-exclusion chromatography using NAP-5 columns was about 70% from the direct labeling and about 50% from the indirect method. Typically, the radiochemical purity of conjugates after NAP-5 separation was over 98% for both labeling methods. The presence of reduced hydrolyzed technetium was less than 2% in all experiments (data not shown).

Stability and Cell Binding of Labeled Conjugates. The *in vitro* stability of the labeled conjugates was evaluated in PBS and cysteine. The incubation of the labeled Affibody molecules for 2 h in the presence of 300 molar excess of cysteine showed a reasonably high stability. Most of the radioactivity (approximately 70%) of ^{99m}Tc-CGG-$Z_{HER2:342}$ and ^{99m}Tc-CGGG-$Z_{HER2:342}$ was still attached to the labels. The stability in PBS was even higher, especially for ^{99m}Tc-CGG-$Z_{HER2:342}$ with 90% attachment of technetium to the conjugate (Table 2).

The results of plasma stability test (Figure 2) showed that the conjugates were stable during 1 h at 37 °C. No release of radioactive low-molecular-weight products or association with serum proteins was observed. A small amount of radioactivity was associated with proteins bigger than the ^{99m}Tc-CGG-$Z_{HER2:342}$ peak (Figure 2.A), which can indicate some transchelation to blood plasma proteins.

The binding specificity of ^{99m}Tc-CGG-$Z_{HER2:342}$ and ^{99m}Tc-CGGG-$Z_{HER2:342}$ was evaluated in the HER2-expressing ovarian cancer cell line SKOV-3. The binding was specific, since it could be blocked with receptor saturation by 100-fold excess of unlabeled $Z_{HER2:342}$ (data not shown). The antigen binding capacity was estimated to be around 60% for directly labeled ^{99m}Tc-CGG-$Z_{HER2:342}$ and ^{99m}Tc-CGGG-$Z_{HER2:342}$. The difference in antigen binding capacity between directly and indirectly labeled ^{99m}Tc-CGGG-$Z_{HER2:342}$ was not statistically significant. It should be noted that the testing method used in this study provides lower value in comparison with the Lindmo analysis but is much less laborious. We use it for comparison of conjugates, not to obtain a true value for binding to an infinite excess of antigen. The cellular retention for the conjugates is illustrated in Figure 3. ^{99m}Tc-CGG-$Z_{HER2:342}$ and ^{99m}Tc-CGGG-$Z_{HER2:342}$ displayed similar patterns at all time points. For comparison, the retention of a radioiodinated Affibody via a *p*-iodobenzoate linker, ^{125}I-PIB-$Z_{HER2:342}$ (*18*), was also included, and it was found that the ^{99m}Tc-labels exhibited higher retention than the radioiodinated conjugate ($p < 0.001$), with about 50% cell-associated radioactivity 24 h after interrupted incubation, compared to 40% for iodine label.

Comparative Biodistribution in Non-Tumor-Bearing NMRI Mice. Figure 4 presents the biodistribution of the labeled conjugates in normal mice 4 h pi. For comparison, we also included the previously described ^{99m}Tc-maGGG-$Z_{HER2:342}$ (*22*) in the study. The biodistribution studies showed rapid renal excretion with about 50% IA/g trapped in the kidneys for ^{99m}Tc-CGG- and CGGG-$Z_{HER2:342}$ (both directly and indirectly labeled) 4 h pi, while the ^{99m}Tc-maGGG-$Z_{HER2:342}$ displayed much lower uptake, less than 7% IA/g. In the previous study of ^{99m}Tc-maGGG-$Z_{HER2:342}$ (*22*), we found that a high percentage of radioactivity was accumulated in the gastrointestinal tract, likely due to its excretion via the bile. In this study, we observed that the hepatobiliary excretion of the Affibody molecules was reduced with the use of CGG and CGGG chelators. The detected uptake in the intestines with their contents was about 12% IA/whole organ, an almost 3-fold reduction compared to when maGGG was used as chelator (32% IA/whole organ). Low levels of radioactivity were found in blood, lung, liver, stomach, salivary glands, spleen, and muscle for all conjugates.

The influence of injection route (intravenous or subcutaneous) on the biodistribution of ^{99m}Tc-CGG-$Z_{HER2:342}$ was also evaluated. The comparison showed that biodistribution 4 h pi was similar in both cases (Figure 5), with a small but significant increase of radioactivity in liver, stomach, and salivary gland after subcutaneous injection. These results indicate a quick drainage of Affibody-based conjugates by lymphatic system.

Tumor Targeting in Balb/c nu/nu Mice with SKOV-3 Xenografts. The *in vivo* tumor-targeting properties of ^{99m}Tc-CGG-$Z_{HER2:342}$ were evaluated through biodistribution studies on mice bearing HER2-expressing SKOV-3 xenografts, as

summarized in Table 3. In the same animals we also injected ^{125}I-PIB- $Z_{HER2:342}$ to have a reference, as this conjugate had previously demonstrated good targeting properties (*18*). The results showed that the blood level of ^{99m}Tc-CGG-$Z_{HER2:342}$ decreased rapidly, reaching 2.32 ± 0.44 %IA/g 1 h pi and 0.62 ± 0.08 %IA/g 6 h pi. The radioactivity clearance from other organs followed the same pattern. The tumor-to-kidney ratios were 0.050 ± 0.01 (1 h pi), 0.072 ± 0.017 (4 h pi), and 0.147 ± 0.074 (6 h pi) for ^{99m}Tc-CGG-$Z_{HER2:342}$. The tumor uptake of ^{99m}Tc-CGG-$Z_{HER2:342}$ did not differ significantly between the points of time.

To study the binding specificity to HER2-receptors *in vivo*, a group of mice were preinjected with a 1000-fold excess of nonlabeled Affibody molecule before injection of the labeled conjugates. As expected, the tumor uptake of both ^{99m}Tc- and ^{125}I-label in the blocked group was lower ($p < 0.005$), which verified that the uptake was receptor-specific.

An Affibody molecule radioiodinated via a *p*-iodobenzoate linker, ^{125}I-PIB-$Z_{HER2:342}$ (*18*), was used as an internal reference for comparison and was also injected into the same animals in this biodistribution study. As can be seen in Figure 6, the tumor-to-organ ratios were high for both ^{99m}Tc-CGG-$Z_{HER2:342}$ and ^{125}I-PIB-$Z_{HER2:342}$. Generally, the technetium label provided better contrast 1 h pi. The uptake was approximately equal 4 h pi, but 6 h pi, the radioiodine label provided better tumor-to-organ ratios.

Gamma-Camera Imaging of HER2-Expressing Xenografts Using ^{99m}Tc-CGG- $Z_{HER2:342}$. Gamma-camera images in BALB/c nu/nu mice bearing SKOV-3 tumors were acquired after 6 h after administration of ^{99m}Tc-CGG-$Z_{HER2:342}$. The images revealed good radioactivity accumulation in the tumors, which were clearly visualized, as shown in Figure 7. However, the uptake was high in the kidneys and in the abdomen area, which was predicted from the results of biodistribution study. Tumor-to-contralateral thigh was 29 ± 7 (average ± maximum error).

DISCUSSION

Earlier studies demonstrated that the use of solid-phase peptide synthesis can provide monomeric forms of Affibody molecules, capable for binding to target proteins and site-specific attachment of chelators for ^{111}In and ^{99m}Tc (*19*, *22*). However, the present peptide synthesis techniques would be inefficient in production of large multimeric Affibody molecules or fusion proteins. For recombinant production, which would be required in this case, an incorporation of synthetic chelators would be possible only as a separate process. A possible alternative has been proposed earlier for scFv (*24*−*26*), namely an incorporation of a terminal cysteine, which would form N3S chelator together with adjacent amino acids. Still, we had to take into account that direct translation of a labeling technique from one protein to another is not easy in the case of technetium, since the surrounding amino acids influence the stability of the chelate on one hand, and the chelator may affect the biodistribution properties of a targeting protein on the other (*30*, *31*). It is well-known that a change of chelator has a dramatic influence on the pharmacokinetics of short peptides, such as somatostatin analogues (*32*, *33*). It is also known that the biodistribution of antibodies and their fragments is relatively insensitive to the labeling method (*34*). But data concerning the biodistribution of intermediate size (5−10 kDa) molecules are rather scant.

The model Affibody molecule $Z_{HER2:342}$ was synthesized for this study by a solid-phase peptide synthesis with N-terminal extensions of the CGG or CGGG sequences. The final products showed subnanomolar affinities for the HER2 receptor, suggesting no major negative effect of CGG or CGGG attachment on binding properties of $Z_{HER2:342}$ (Table 1).

Initial experiments on labeling of CGGG-$Z_{HER2:342}$ with ^{99m}Tc were performed using tartrate as an intermediate weak chelator, i.e., by an indirect method. The labeling efficiency (Table 2) was 53.8 ± 10.1%, which is lower than obtained for maGGG-containing $Z_{HER2:342}$ conjugate (about 80%) (*22*). George and co-workers (*24*) have reported that labeling of scFv containing the GGGC sequence provided higher labeling yields (about 97%) in an alkaline condition. Alkaline pH is usually favorable for rapid ^{99m}Tc-labeling, probably because of deprotonation of sulfur and nitrogen donor atoms, which facilitates the complexation of technetium (*35*, *36*). The direct labeling method in alkaline solution (0.15 M NaOH, pH ∼ 11) provided a high radiochemical yield (90%), and a stable technetium

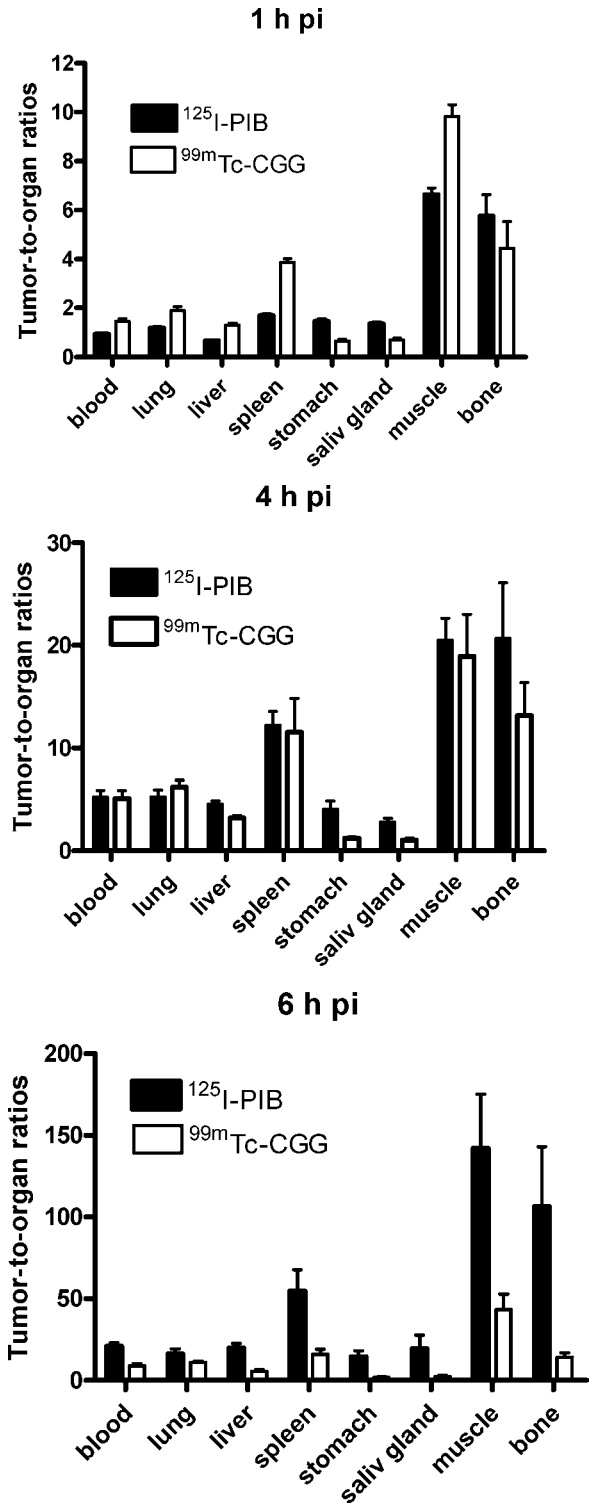

Figure 6. Tumor-to-organ ratios for ^{99m}Tc-CGG-$Z_{HER2:342}$ and ^{125}I-PIB-$Z_{HER2:342}$ in Balb/c nu/nu mice bearing SKOV3 xenografts. Data are presented as average from four animals ± SEM.

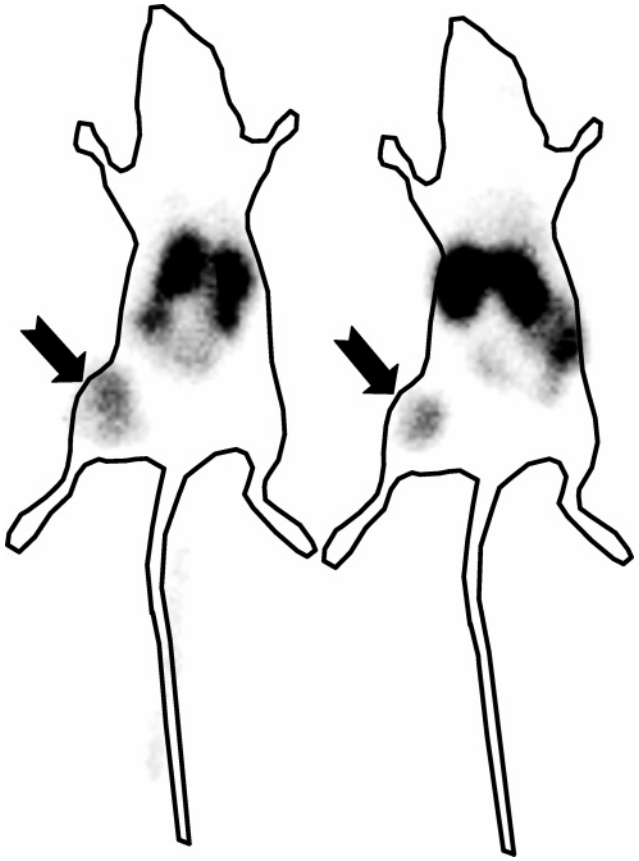

Figure 7. Gamma camera imaging of ^{99m}Tc-CGG-$Z_{HER2:342}$ in Balb/c nu/nu mice bearing SKOV3 xenografts after 6 h pi.

labeling was achieved. The specificity of binding to HER2 *in vitro* after direct labeling was preserved, and the antigen binding capacity did not differ significantly from the capacity after indirect labeling. No significant difference in biodistribution was found between directly and indirectly labeled CGGG-$Z_{HER2:342}$ (Figure 4). For this reason, direct labeling was selected for CGG-$Z_{HER2:342}$ labeling as well. The plasma stability in mouse serum indicated that the labeled conjugates were stable during 1 h. It was found that the retention of radioactivity in malignant SKOV-3 cells was better for ^{99m}Tc-labeled cysteine-containing conjugates than for a radioiodinated counterpart (Figure 3). This can be explained by better intracellular retention of radiocatabolites after internalization and lysosomal degradation of Affibody molecules.

The primary purpose of the development of an imaging agent lies in achieving high tumor-to-organ ratios, giving high contrast images. Therefore, a quick clearance from blood and unspecific compartments and quick tumor localization are essential properties of a targeting conjugate. Comparative biodistribution in normal mice (Figure 4) showed that the labeled conjugates had rather rapid blood clearance, with less than 1% IA/g at 4 h pi. This is in the same range (0.3−1.8% IA/g) as in mice for ^{99m}Tc-labeled somatostatin analogues (*37*) and lower than the blood level reported at that time for ^{99m}Tc-labeled scFv (*38*) or their multimeric constructs (*39*). The low blood radioactivity concentration suggested that, in agreement with the *in vitro* serum stability test, no considerable transchelation to blood plasma proteins occurred. Low levels of radioactivity were detected in liver and lungs, suggesting that no colloids were formed. However, a somewhat elevated radioactivity (in comparison with ^{99m}Tc-maGGG-$Z_{HER2:342}$) in stomach and salivary glands was observed, indicating some release of free pertechnetate. Since the conjugates appeared to be stable in blood plasma, it is likely that the release occurred during the catabolism of the labeled conjugates in kidney, probably due to reoxidation. Furthermore, the ^{99m}Tc-labeled cysteine-based chelators behaved similarly, while the most essential difference between these chelators and the maGGG chelator could be seen in the radioactivity accumulation in intestines. The results showed a 3-fold reduction of hepatobiliary excretion in the case of cysteine-based chelators in comparison with maGGG-$Z_{HER2:342}$. An explanation of this effect could be that the use of cysteine instead of mercaptoacetyl as a thiol group donor increases the overall hydrophilicity of the chelate due to the presence of a charged amino group and shifts excretion pathway from hepatobiliary to renal. A number of studies indicate that the use of more hydrophilic ^{99m}Tc chelates favor renal excretion (*31*, *37*, *40*, *41*). A shift to renal excretion was also indicated in this study by the increase of the kidney uptake of a factor of 7 by exchanging the maGGG chelator to cysteine-based chelators. It might be surprising that an additional charged group caused such profound difference in biodistribution of a 7-kDa protein. However, similar effects were also reported by Zhu and co-workers (*41*) for a neutrophil elastase inhibitor HNE2, which is similar in size (about 7 kDa) to the Affibody molecules. In that study, a variation of a single amino acid (phenylalanine, glycine, or glutamic acid) in the chelator modified the biodistribution of the protein in the same way as in our experiments.

The *in vitro* results showed that both ^{99m}Tc-CGG-$Z_{HER2:342}$ and ^{99m}Tc-CGGG-$Z_{HER2:342}$ provided promising characteristics as targeting agents for HER2. To further evaluate the targeting properties, one of the conjugates (^{99m}Tc-CGG-$Z_{HER2:342}$) was investigated in nude mice carrying SKOV-3 xenografts. Biodistribution data from the blocking experiment of ^{99m}Tc-CGG-$Z_{HER2:342}$ demonstrated that the binding to HER2 receptors in ovarian carcinoma tumors was receptor-specific, since the uptake was blocked by a preinjection of an excess of nonlabeled Affibody ($p < 0.005$). The *in vivo* retention in tumors was constant over time, which corresponded well with the results of the *in vitro* cellular retention study in SKOV-3 cells. Moreover, ^{99m}Tc-CGG-$Z_{HER2:342}$ had a fast blood clearance and low uptake in most organs and was mainly excreted through kidneys, thus providing a low background for imaging. At early time points (1 and 4 h pi), the technetium label provided tumor-to-organ ratios that were similar to or better than those provided by $Z_{HER2:342}$ radioiodinated using *p*-iodobenzoate. At 6 h pi, the radioiodine label was superior, probably due to a different pattern of clearance of radiocatabolites. However, the contrast level provided by the technetium label (e.g., tumor-to-blood ratio of 9.2) is acceptable. For clinical use, the ^{99m}Tc-labeled conjugate might be preferred over the ^{125}I-labeled one, due to the easy labeling (with a potential for a kit formulation), better logistics, and much lower price. Only a clinical study can answer if these factors may overweight the somewhat lower contrast in comparison with the radioiodinated counterpart.

Gamma-camera imaging with ^{99m}Tc-CGG-$Z_{HER2:342}$ at 6 h pi clearly showed the tumors in the mice. Although the accumulation in the intestines was largely reduced in comparison with the use of maGGG-chelator, the amount of radioactivity (10% IA per whole content) could still complicate the detection of extrahepatic metastases in the abdominal area on the day of injection. Nevertheless, the Affibody molecules seem to exhibit as good tumor-to-organ ratios as the other technetium-labeled anti-HER2 conjugates, if not better. For instance, ^{99m}Tc-HYNIC-trastuzumab Fab (*42*) and ^{99m}Tc-scFv barnase barstar constructs (*43*) had tumor-to-blood-ratios of 1.3 at 6 h pi and 10.8 at 24 h pi, respectively, compared to 9.2 at 6 h pi for the ^{99m}Tc-labeled Affibody molecule. This comparison would give some ideas about the *in vivo* properties but should be interpreted with care, as different HER2-xenografts and sampling techniques were used.

In summary, the Affibody molecules containing cysteine-based chelators CGG and CGGG were stably labeled with ^{99m}Tc, rapidly cleared from the blood circulation, and provided specific tumor accumulation (the latter case was for ^{99m}Tc-CGG-$Z_{HER2:342}$). It was evident that ^{99m}Tc-CGG-$Z_{HER2:342}$ clearly showed tumors in mice in the gamma-camera study. Thus, incorporation of cysteine into recombinant Affibody molecules would provide an efficient way for site-specific labeling of these proteins.

ACKNOWLEDGMENT

The authors thank Dr. Lars Abrahmsén, Dr. Joachim Feldwish, and Dr. Anders Wennborg from Affibody AB for intellectual discussions. Thanks to Mrs. Aseel Cherif for providing us with Tc-generator eluate, Mrs. Veronika Eriksson for keeping the cell lab in excellent working conditions, and the staff of the animal department at Rudbeck laboratory. We thank Gustav Sundqvist at KTH for running the ESI-MS analyses. Financial support was provided by the Swedish Cancer Society (Cancerfonden) and the Swedish Research Council (Vetenskapsrådet).

Endotoxin or lipopolysaccharide (LPS) contamination in proteins expressed by Gram-negative bacteria is a major drawback associated with protein expression. Endotoxin intoxication in humans and animals above a certain threshold level can result in a fatal immune response. Reduction in endotoxin levels is therefore essential before proteins can be used in in vivo studies or sold as pharmaceutical products. Affinity chromatography employing the peptide Polymyxin B (PMB) as an affinity ligand is one way in which endotoxin contamination has been addressed; this is, however, a costly process. We describe the synthesis of a novel affinity ligand based on the structure of the drug pentamidine, which can be applied effectively in endotoxin removal. The synthetic route to this ligand is straightforward and inexpensive, while the ligand can be readily immobilized onto activated sepharose beads. Thus, we demonstrate that these pentamidine affinity beads bind endotoxin/LPS with comparable capacity to PMB affinity systems, that the beads can be recycled efficiently and economically without loss of binding capacity, and application of the functionalized beads for endotoxin removal in an authentic contaminated antibody sample.

INTRODUCTION

Endotoxin or lipopolysaccharide (LPS) (Figure 1) is the major constituent of the outer membrane of Gram-negative bacteria, composed of a nontoxic polysaccharide portion and the biologically active portion known as lipid A (*1*). Lipid A is a bisphosphorylated disaccharide bearing several hydrophobic acyl chains (Figure 2). The presence of endotoxin in blood, known as Gram-negative sepsis, is the leading cause of death in intensive care units (*2*). Endotoxin/LPS induces an exaggerated response by the immune system resulting in uncontrolled production of inflammatory mediators, which can lead to fatal shock syndrome and eventually multiple organ failure (*3*).

Proteins expressed by Gram-negative bacteria are often contaminated with endotoxin; this contamination must be reduced sufficiently before a protein can be used in in vivo studies within animal models or sold as pharmaceutical products, for human use, such as vaccines. The FDA recommends that no more than 5.0 EU per kilogram of body weight be introduced parenterally into a human or an animal (10 EU is approximately 1 ng of *E. coli* LPS). Endotoxin removal is an expensive, time-consuming, and laborious part of the protein purification process, which often results in poor recovery of the protein (*4*). Affinity chromatography, whereby a ligand with a high binding affinity for LPS is immobilized on a solid support, is the gold standard for endotoxin removal. Polymyxin B (PMB) is a cyclic lipopeptide produced by *Bacillus polymyxa* that binds LPS with high affinity. Agarose-supported Polymyxin B is used in affinity chromatography for endotoxin removal (Pierce, product no. 20344, Detoxi-Gel AffinityPak Prepacked Columns (5 × 1 mL, currently $95); however, we note that, while this ligand-support system is exceptional for LPS removal, it is also prohibitively expensive. Furthermore, Polymyxin B is a synthetically challenging molecule and is therefore obtained exclusively by bacterial expression.

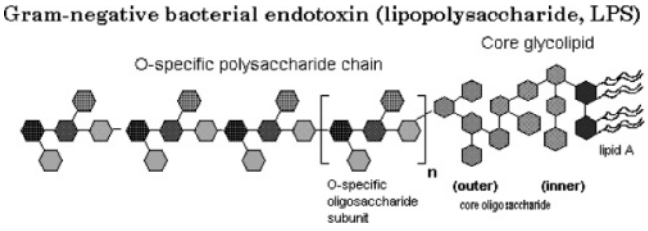

Figure 1. Schematic representation of the structure of bacterial endotoxin/LPS.

The anti-*Pneumocystis carinii* drug, pentamidine (Figure 2), has been reported to bind to lipid A (the toxic constituent of LPS) with a comparable affinity to PMB (*5*, *6*). The high affinity of this drug for lipid A has been attributed to the terminal amidine groups of the drug being an optimal distance apart for their simultaneous interaction with the two anionic phosphate groups of lipid A. We reasoned that a ligand based on the structure of pentamidine could be applied to affinity-based removal of endotoxins. We sought to unveil an economical, synthetically accessible alternative to Polymyxin B which displays similar endotoxin binding ability. Such a molecule could be readily synthesized on a large scale at low cost and would offer a less expensive alternative to the use of PMB in the endotoxin removal process. Herein, we report an efficient, facile synthesis of a tethered derivative of pentamidine that can be immobilized onto a sepharose support. Chemical synthesis of this ligand is straightforward and inexpensive, and we demonstrate that this support can remove endotoxin with comparable effectiveness to PMB affinity systems. The pentamidine-based affinity system can be recycled repeatedly using inexpensive reagents with no significant reduction in performance and results in greater protein recovery than the PMB system.

EXPERIMENTAL PROCEDURES

General Considerations. All synthetic reactions were performed under an atmosphere of Ar or N_2, using anhydrous solvents unless otherwise stated. Reactions were carried out using oven-dried glassware. THF was distilled from sodium/benzophenone, and CH_2Cl_2 and MeOH were distilled from CaH_2. Anydrous DMF, toluene, and ethanol were purchased from Aldrich. Reagents were purchased from commercial sources and used without further purification. ^{1}H NMR and ^{13}C NMR were recorded on Bruker AMX-400, Bruker DRX-500, or Bruker DRX-600 instruments, with chemical shift values being reported in parts per million relative to residual chloroform (δH = 7.27 or δC = 77.2) as an internal standard. High-resolution mass spectrometry was carried out at The Scripps Research Institute using an IonSpec Ultima high-resolution FTMS instrument. Reactions were monitored by thin-layer chromatography (TLC) carried out on 0.25 mm E. Merck silicagel plates (60F-254) visualizing by UV light and $KMnO_4$ stain. Flash chromatography was carried out using Merck silica gel 60 (230−400 mesh). Reagent-grade solvents for chromatography were obtained from Fisher Scientific.

A BODIPY−TR cadaverine probe was purchased from Invitrogen. LPS from *E. coli* 0111:B4, LPS from *E. coli* 0111:B4 FITC conjugate, pentamidine isethionate, Polymyxin B, and agarose-supported Polymyxin B were all purchased from Sigma. The Reacti-Gel CDI support was purchased from Pierce. Fluorescence measurements were carried out on a SpectraMax GeminiEM fluorescence plate reader. Corning nonbinding surface 96-well plates obtained from Fischer were used for all fluorescence assays. 1 mL Detoxi-Gel columns were obtained from Pierce. The *Limulus* Amebocyte Lysate (LAL) QCL-1000 assay kit was purchased from Cambrex bioscience.

Dimethyl 3-(*tert*-Butyldimethylsilyloxy)pentanedioate (1b). To a solution of dimethyl 3-hydroxy-glutarate (**1a**) (2.92 g, 16.6 mmol, 1 equiv) in DMF (10 mL) was added imidazole (1.24 g, 18.3 mmol, 1.1 equiv) and TBSCl (2.74 g, 18.3 mmol, 1.1 equiv). The reaction was allowed to stir at room temperature (rt) for 16 h. The reaction was diluted with 50% EtOAc/Hx and the organic layer washed with H_2O. The organic layer was then dried ($MgSO_4$) and concentrated in vacuo to give dimethyl 3-(*tert*-butyldimethylsilyloxy)pentanedioate (**1b**) (4.80 g, 16.5 mmol, 99.5%) as a clear oil which was used without further purification.

^{1}H NMR ($CDCl_3$, 500 MHz) δ 0.06 (6H, s, (CH_3)$_2$Si), 0.84 (9H, s, (CH_3)$_3$Si)), 2.55 (4H, d, J = 7.0 Hz, 2 × CH_2), 3.69 (6H, s, 2 × CH_3O), 4.55 (1H, t, C*H*O).

^{13}C NMR ($CDCl_3$, 125 MHz) δ −5.00 (2 × *C*H$_3$), 17.9 (*C*(CH$_3$)$_3$), 25.6 (*C*H$_3$)$_3$C), 42.4 (2 × *C*H$_2$), 51.5 (2 × *C*H$_3$O), 66.3 (*C*HO), 171.3 (*C*═O).

MS (ESI-TOF): [M + H]$^+$, $C_{13}H_{27}O_5Si$ requires 291.1622, found 291.1620.

3-(*tert*-Butyldimethylsilyloxy)pentane-1,5-diol (2). To a solution of dimethyl 3-(*tert*-butyldimethylsilyloxy)pentanedioate (**1b**) (7.75 g, 26.7 mmol, 1 equiv) in CH_2Cl_2 (150 mL) at 0 °C was added DIBALH (71 mL of 1.5 M solution in toluene, 106.8 mmol, 4 equiv). The reaction was allowed to stir at 0 °C for 3 h and then quenched with an aq sat solution of potassium sodium tartrate and allowed to stir overnight. The reaction mixture was then extracted several times with $CHCl_3$. Combined organic layers were dried ($MgSO_4$) and concentrated in vacuo to give 3-(*tert*-butyldimethylsilyloxy)pentane-1,5-diol (**2**) (5.78 g, 24.7 mmol, 93%) as a clear oil which was used without further purification.

^{1}H NMR ($CDCl_3$, 600 MHz) δ 0.09 (6H, s, (CH_3)$_2$Si), 0.88 (9H, s, (CH_3)$_3$Si)), 1.57 (2H, broad s, 2 × O*H*), 1.75 (2H, m, CH_2), 1.83 (2H, m, CH_2), 3.71 (2H, m, CH_2O), 3.79 (2H, m, CH_2O), 4.14 (1H, m, C*H*O).

^{13}C NMR ($CDCl_3$, 150 MHz) δ −4.70 (2 × *C*H$_3$), 17.9 (*C*(CH$_3$)$_3$), 25.8((*C*H$_3$)$_3$C), 38.4 (2 × *C*H$_2$), 59.8 (2 × *C*H$_2$O), 69.6 (*C*HO).

MS (ESI-TOF): [M + H]$^+$, $C_{11}H_{27}O_3Si$ requires 235.1724, found 235.1721.

4,4′-(3-(Tert-butyldimethylsilyloxy)pentane-1,5-diyl)bis-(oxy)dibenzonitrile (3a). To a solution of 3-(*tert*-butyldimethylsilyloxy)pentane-1,5-diol (**2**) (5.78 g, 24.7 mmol, 1 equiv) in THF (150 mL) was added 4-hydroxybenzonitrile (8.8 g, 74.1 mmol, 3 equiv), DIAD (19.1 mL, 98.8 mmol, 4 equiv), and PPh_3 (25.8 g, 98.8 g, 4 equiv). The reaction was allowed to stir at rt for 18 h. EtOAc was added, and the reaction mixture was washed with 1 M NaOH, dried ($MgSO_4$), and concentrated in vacuo. The crude product mixture was purified by flash chromatography on silica gel (30% EtOAc/Hx) to give 4,4′-(3-(tert-butyldimethylsilyloxy)pentane-1,5-diyl)bis(oxy)dibenzonitrile (**3a**) together with an impurity derived from DIAD. This mixture was used in the next step without further purification.

^{1}H NMR ($CDCl_3$, 600 MHz) δ −0.01 (6H, s, 2 × CH_3Si), 0.88 (9H, s, (CH_3)$_3$Si), 2.01 (4H, m, 2 × CH_2), 4.10 (4H, t, J = 6.6 Hz, 2 × CH_2O), 4.20 (1H, m, C*H*O), 6.93 (4H, d, J = 9.0 Hz, 4 × Ar*H*), 7.58 (4H, d, J = 9.0 Hz, 4 × Ar*H*).

^{13}C NMR ($CDCl_3$, 150 MHz) δ −4.65 (*C*H$_3$)$_2$Si, 17.9 (*C*(CH$_3$)$_3$), 21.6 (2 × *C*H$_2$), 25.8 ((*C*H$_3$)$_3$Si), 64.5 (*C*H$_2$O), 65.8 (*C*HO), 103.9 (2 × Ar*C*), 115.1 (4 × Ar*C*H), 119.2 (2 × *C*N), 134.0 (4 × Ar*C*H), 162.1 (2 × Ar*C*O).

MS (ESI-TOF): [M + H]$^+$, $C_{25}H_{33}N_2O_3Si$ requires 437.2255, found 437.2255.

4,4′-(3-Hydroxypentane-1,5-diyl)bis(oxy)dibenzonitrile (3b). 4,4′-(3-(tert-butyldimethylsilyloxy)pentane-1,5-diyl)bis(oxy)-dibenzonitrile (**3a**) from the previous step was dissolved in MeOH (250 mL). Conc HCl (6 drops) was added and the reaction allowed to stir at rt for 1 h. The reaction mixture was concentrated in vacuo, and the crude product mixture was purified by flash chromatography on silica gel (30% EtOAc/Hx) to give 4,4′-(3-hydroxypentane-1,5-diyl)bis(oxy)dibenzonitrile (**3b**) (3 g, 9.3 mmol, 38% over 2 steps) as a white solid.

^{1}H NMR ($CDCl_3$, 600 MHz) δ 2.00 (2H, m, CH_2), 2.06 (2H. m, CH_2), 4.18 (3H, m, C*H*O and CH_2O), 4.26 (2H, m, CH_2O), 6.96 (4H, d, J = 9.0 Hz, 4 × Ar*H*), 7.57 (4H, d, J = 9.0 Hz, 4 × Ar*H*).

^{13}C NMR ($CDCl_3$, 150 MHz) δ 36.5 (*C*H_2), 65.5 (*C*H_2O), 66.6 (*C*HO), 104.1 (2 × Ar*C*), 115.1 (4 × Ar*C*H), 119.1 (2 × *C*N), 134.0 (4 × Ar*C*H), 161.9 (2 × Ar*C*O).

MS (ESI-TOF): $[M + H]^+$, $C_{19}H_{19}N_2O_3$ requires 322.1390, found 322.1395.

***tert*-Butyl 2-(1,5-Bis(4-cyanophenoxy)pentan-3-yloxy)acetate (*4*).** To a solution of 4′-(3-hydroxypentane-1,5-diyl)bis(oxy)dibenzonitrile (**3b**) (32 mg, 0.10 mmol, 1 equiv) in toluene (2 mL) was added 25% aq NaOH and tetrabutylammonium hydrogen sulfate (4 mg). The reaction was allowed to stir vigorously at rt for 4 h. The reaction mixture was then extracted with CH_2Cl_2. The combined organic layers were dried ($MgSO_4$) and concentrated in vacuo. The crude product mixture was purified by flash chromatography on silica gel (30% EtOAc/Hx) to give *tert*-butyl 2-(1,5-bis(4-cyanophenoxy)pentan-3-yloxy)acetate (**4**) (34 mg, 0.08 mmol, 77%) as a clear oil.

^{1}H NMR ($CDCl_3$, 600 MHz) δ 1.39 (9H, s, (CH_3)$_3$C), 2.07 (4H, q, J = 7.2 Hz, 2 × CH_2), 3.84 (1H, t, J = 7.2 Hz, C*H*O), 3.97 (2H, s CH_2CO$_2$*t*Bu), 4.14 (2H, m, CH_2O), 4.24 (2H, m, CH_2O), 6.94 (4H, d, J = 8.5 Hz, 4 × Ar*H*), 7.56 (4H, d, J = 9.0 Hz, 4 × Ar*H*).

^{13}C NMR ($CDCl_3$, 150 MHz) δ 28.0 (*C*H_3)$_3$C), 33.7 (2 × *C*H_2), 64.6 (2 × *C*H_2O), 67.7 (*C*HO), 74.8 (*C*H_2CO$_2$*t*Bu), 81.7 (*C*(CH$_3$)$_3$), 104.0 (2 × Ar*C*), 115.2 (4 × Ar*C*H), 119.2 (2 × *C*N), 133.9 (4 × Ar*C*H), 162.0 (2 × Ar*C*O), 169.3 (*C*═O).

Immobilization of Ligand (6) onto Activated Sepharose Beads. Endotoxin-binding ligand *N*-(6-aminohexyl)-2-(1,5-bis-(4-carbamimidoylphenoxy)pentan-3-yloxy)acetamide (**6**) was attached to carbonyldiimidazole-activated Sepharose beads (Reacti-Gel CDI support, Pierce) according to the manufacturer's directions. Briefly, a 5 mg/mL solution of ligand *N*-(6-aminohexyl)-2-(1,5-bis(4-carbamimidoylphenoxy)pentan-3-yloxy)-acetamide in 100 mM borate buffer, pH 9, was prepared. Reacti-Gel beads were added to a polypropylene cartridge, acetone solvent was drained off, and 1 mL of 5 mg/mL ligand solution was added to the cartridge per milliliter of Reacti-Gel beads. The mixture was allowed to shake for 24 h at rt. The solution of ligand was then drained from the beads. 50 mM Tris buffer, pH 9.2, was added (1 mL of buffer per mL of bead volume) and the mixture allowed to shake overnight in order to quench unreacted CDI groups. Finally, excess Tris buffer was drained, and the beads were washed with PBS buffer (pH 7.4) and stored in a suspension of PBS until use. Control beads were prepared analogously by treatment of Reacti-Gel beads with 100 mM borate buffer containing no ligand, followed by blocking reactive groups with Tris buffer.

Fluorescein Displacement Assay for Quantifying Binding Affinity to LPS. The BODIPY-cadaverine (BC) displacement assay was used to quantify the binding affinity of ligand **6** to LPS. This assay was performed according to a published procedure (*7*). Briefly, 10 mM stock of ligand in 50 mM Tris (pH 7.4) was prepared. A stock solution of 5 mg/mL LPS from *E. coli* 0111:B4 (Sigma) in 50 mM Tris (pH 7.4) and a stock solution of 500 μM BC (BODIPY−TR cadaverine, obtained from Invitrogen)−50 mM Tris (pH 7.4) were prepared. 0.1 mL of each of the LPS and BC stocks were mixed and the mixture diluted to a final volume of 10 mL using 50 mM Tris buffer to

give an LPS−BC mixture composed of 50 μg/mL LPS and 5 μM BC. Corning nonbinding surface 96 well plates were used in this assay.

To the first well of a 96 well plate was added 40 μL of 10 mM ligand stock solution and 40 μL of 50 mM Tris buffer. Twofold serial dilution across the plate was carried out, and then 40 μL of Tris was added to each well to give 80 μL volume in each well. 80 μL of LPS−BC (50 μg/mL−5μM) mixture was added to each well. Each experiment was repeated in triplicate. Fluorescence measurements were made at 25 °C on a SpectraMAX GeminiEM fluorescence plate reader. BC excitation wavelength of 580 nm was used; emission was measured at 620 nm.

The K_d(app) values for interaction of ligand **6**, PMB, and pentamidine with LPS were calculated. Curves were fitted to the function $F = F_{max}[L]/(K_d + [L]) + c$ using *WinCurveFit* software. In the case of ligand **6** and pentamidine, fluorescence measurement values used in the curve fit were corrected to account for a concentration-dependent linear background fluorescence effect.

Binding Assays of Sepharose−Ligand 6 Beads with FITC-Labeled LPS. Sepharose−ligand **6** beads were tested for the ability to bind endotoxin using FITC-labeled LPS. A 50 mg/mL concentrated stock solution of *E. coli* 0111:B4 FITC conjugate (purchased from Sigma) in 50 mM Tris buffer, pH 7.4, was prepared. A standard curve of fluorescence at various concentrations of LPS−FITC was prepared (excitation at 495 nm, emission at 525 nm).

Sepharose−ligand **6** beads, control beads, and commercially available agarose-supported Polymyxin B (purchased from Sigma) were tested concurrently for ability to bind LPS−FITC. The experiments were carried out as follows.

100 mg of dried beads was weighed into an Eppendorf tube, and 400 μL of 50 mM Tris buffer, pH 7.4, was added to the tube. A known quantity of concentrated LPS−FITC stock (50 mg/mL) was added to each tube, and the tubes were allowed to shake 30 min. The mixtures were then centrifuged; and 100 μL of the supernatant was removed and placed in a microplate well, and the fluorescence (ex 495 nm, em 525 nm) was measured. Following the fluorescence measurement, the sample was returned to the appropriate Eppendorf tube, and a further aliquot of concentrated LPS−FITC stock was added. This process was repeated until a final LPS−FITC concentration of 8000 μg/mL had been reached. [LPS−FITC] free in the supernatant after incubation was calculated and plotted against the original [LPS−FITC] in the tube.

Curves were fitted to the following function using *Kaleidagraph*:

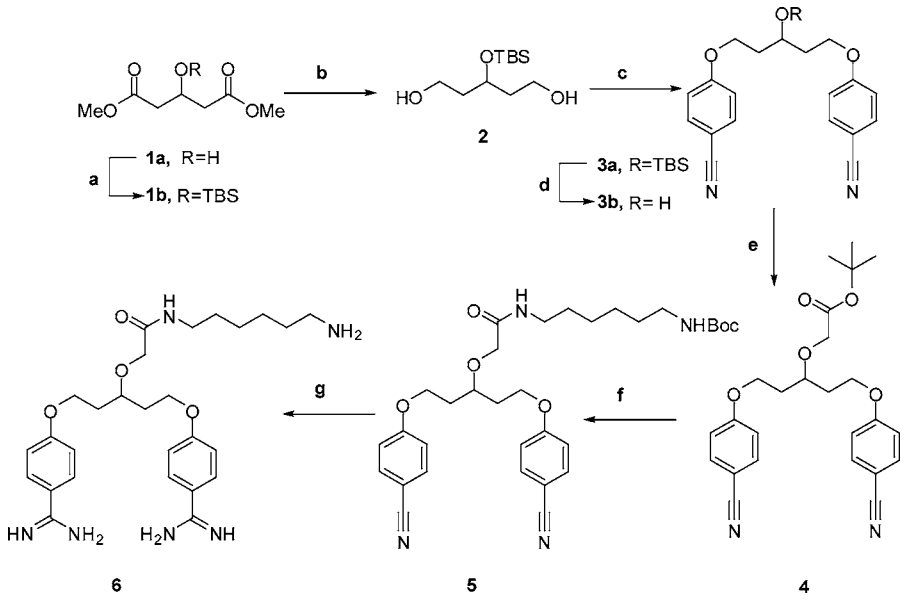
$$LPS_{free} = LPS_{total} - \left[\frac{(LPS_{total} + M_1 + M_2 - \sqrt{(LPS_{total} + M_1 + M_2)^2 - 4LPS_{total}M_2})}{2}\right]$$

where $M_1 = K_d$ and M_2 = total binding sites.

Endotoxin Removal and Protein Loss Following Purification of Samples of Endotoxin-Contaminated Antibody. Sepharose−ligand **6**, control beads, and Pierce Detoxigel beads (agarose-bound PMB) were poured into columns of 1 mL volume. Using pyrogen-free solutions, each column was equilibrated with 3× column volume washes of 1% sodium deoxycholate soln, followed by 5× the column volume of nanopure, filtered water. Solutions of antibody (of known concentration, volume, and endotoxin content) buffered with 0.1−0.5 M NaCl were loaded onto each column. Columns were capped off and allowed to incubate for 1 h. Samples were then eluted from the columns, and the columns were then rinsed with an addition 1 mL of water to clear the void space. Samples were collected, the OD at 280 nm was measured, and the protein concentration was calculated. Endotoxin levels in each sample were then tested using the LAL (*Limulus* Amebocyte Lysate) endotoxin test kit, purchased from Cambrex Bioscience (cat. no. 50-647U).

The LAL endotoxin test uses modified *Limulus* amebocyte lysate and a chromogenic peptide substrate. Bacterial endotoxin catalyzes the conversion of a pro-enzyme in the *Limulus* amebocyte lysate to an active enzyme. The active enzyme then catalyzes the release of *p*-nitroaniline from a colorless peptide substrate. After a given time period, the reaction is stopped by addition of acid, and the *p*-nitroaniline released can be quantitated photometrically by measuring absorbance at 405−410 nm. The amount of *p*-nitroaniline released is proportional to the endotoxin concentration present and can be calculated from a standard curve.

The LAL assay was carried out according to the manufacturer's directions as described in the instruction manual. Briefly, samples were diluted to various strengths, mixed with the lysate reagent supplied in the kit, and incubated at 37 °C for 10 min. The chromogenic peptide substrate was then added and the samples allowed to incubate for a further 6 min. Finally, the reaction was stopped by the addition of 25% glacial acetic acid. Absorbance at 405−410 nm was measured, and these values were used to calculate endotoxin content in the samples.



RESULTS AND DISCUSSION

Synthetic Route to Tethered Pentamidine-Derived Ligand. Synthesis of tethered pentamidine ligand **6** is shown in Scheme 1. The alcohol functionality of commercially available dimethyl 3-hydroxyglutarate **1a** was protected as the TBS ether and the terminal ester groups were subsequently reduced with DIBALH to give diol **2** in good yield. Mitsonobu reaction of diol **2** with 4-hydroxybenzonitrile followed by removal of the silicon protecting group afforded bis-nitrile **3b**. Alkylation of the secondary alcohol in **3b** with *tert*-butyl bromoacetate was achieved under mild conditions using a biphasic system of THF/H_2O in the presence of 25% NaOH and a phase-transfer catalyst to give *tert*-butyl ester **4**. Deprotection of ester **4** by treatment with TFA, followed by BOP coupling of the resulting acid with *N*-Boc-1,6-diaminohexane provided amide **5**. Finally, the nitrile groups were converted into amidines in a two-step process. Bis-nitrile **5** was first treated with hydroxylamine, which had been dried by azeotroping with toluene prior to the reaction. If hydrated hydroxylamine is used in this step, then a significant amount of the nitrile is converted to the corresponding amide. This unwanted byproduct is difficult to separate from the desired bis-amidine **6**, such that HPLC purification is required. However, use of anhydrous hydroxylamine results exclusively in the formation of the desired bis-aldoxime intermediate, which can then be converted to pure bis-amidine in good yield by catalytic hydrogenation. Ultimately, removal of the Boc group from the terminal nitrogen gave pentamidine-derived ligand **6**.

Binding Affinity of Pentamidine-Derived Ligand (6) to LPS. Prior to immobilization of ligand **6** onto sepharose support, we examined its binding affinity to an LPS solution. Although pentamidine itself is reported to bind strongly to lipid A, we felt it was important to confirm that incorporation of a tether functionality did not have a detrimental effect on binding affinity. It has been postulated that modifying the structure of pentamidine such that it incorporates a hydrophobic chain at an appropriate position may indeed improve its affinity for LPS/lipid A due to stabilizing interactions with the acyl chains of lipid A (*6*).

A fluorescent probe displacement assay employing BODIPY−TR cadaverine (BC) was used to test the binding affinity of ligand **6** with LPS, and for comparison, pentamidine and Polymyxin B were also examined (*7*). BC interacts strongly with

Scheme 1. Synthetic Route to Ligand 6[a]

[a] (a) TBSCl, imdazole, DMF, rt, 100%; (b) DIBALH, CH_2Cl_2, 0 °C, 93%; (c) 4-hydroxybenzonitrile, PPh_3, DIAD, THF; (d) HCl, MeOH, 38% over 2 steps; (e) *tert*-butyl-2-bromoacetate, $NaHSO_4$, 25% NaOH, toluene, rt, 77%; (f) 1. 25% TFA in CH_2Cl_2; 2. *N*-Boc-1,6-diaminohexane, BOP, NEt_3, CH_2Cl_2, 75%; (g) 1. $NH_2OH{\cdot}HCl$ (anhydrous), NEt_3, EtOH, sealed tube; 2. LPS, and upon binding, its fluorescence emission intensity at 620 nm is significantly reduced. In the presence of compounds which bind LPS, BC is displaced, and an increase in emission intensity at 620 nm is observed. This assay provides a convenient method of calculating apparent dissociation constants for the binding of molecules to LPS.

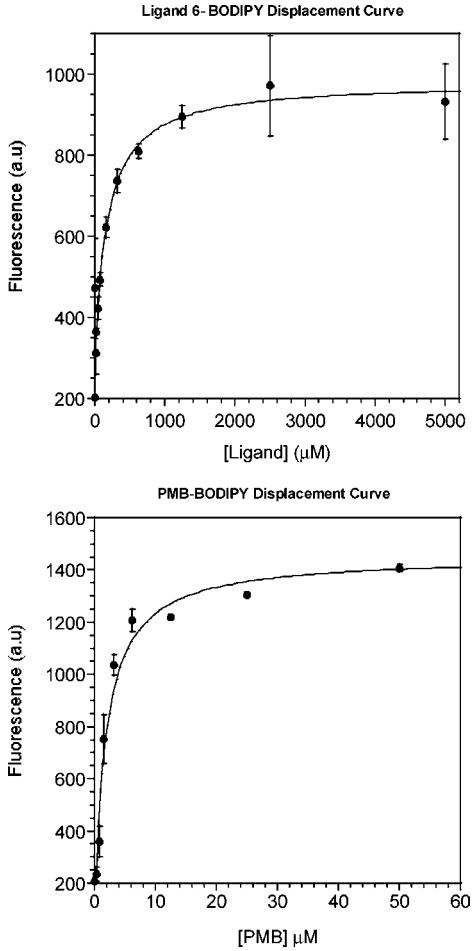
The BODIPY fluorescent displacement assay curves for ligand **6** and for PMB are shown in Figure 3. It was found that ligand **6** binds to LPS with K_d(app) of 180 μM (±60), which is similar to the affinity of pentamidine at 190 μM (±40) (curve not shown). Therefore, it could be concluded that incorporation of a tether group at this position in the molecule does not adversely affect the binding affinity. In our control, K_d(app) of Polymyxin B was found to be 2 μM (±0.6), which is consistent with published results (*8*). It is noteworthy that David et al. have reported PMB and pentamidine to bind lipid A with similar affinities, having K_d(apps) of 0.37 and 0.12 μM, respectively (*5*). In our studies, where we examined relative affinities to LPS, we discovered that PMB has an appreciably greater affinity for LPS than pentamidine. However, the affinity of pentamidine and its derivatives, such as ligand **6**, is still significant in view of the simplicity of their molecular structures.

Immobilization of Ligand 6 onto CDI-Activated Sepharose, Reacti-Gel. Ligand **6** was immobilized onto commercially available carbonyldiimidazole-activated sepharose beads (Reacti-Gel, Pierce) as shown in Scheme 2. Reacti-Gel is an activated form of sepharose particularly suitable for immobilizing small organic molecules and peptides bearing free amino groups. A solution of the ligand in basic aqueous buffer was allowed to react with the Reacti-Gel beads to form a carbamate linkage to the support; unreacted groups were then blocked by incubation with Tris buffer.

Binding Studies of FITC-Labeled LPS with Sepharose-Supported Ligand 6. The ability of our affinity beads to remove LPS from solutions was assessed using LPS from *E. coli* 0111: B4, which had been labeled with fluorescein (LPS−FITC). The change in fluorescence of a solution after incubation with the beads was measured. Thus, modified sepharose beads **7** were filtered to remove excess buffer, and 100 mg samples of **7** were weighed for use. 50 mM Tris buffer (400 μL) was added to **7**, and aliquots of a concentrated LPS−FITC stock (50 mg/mL)



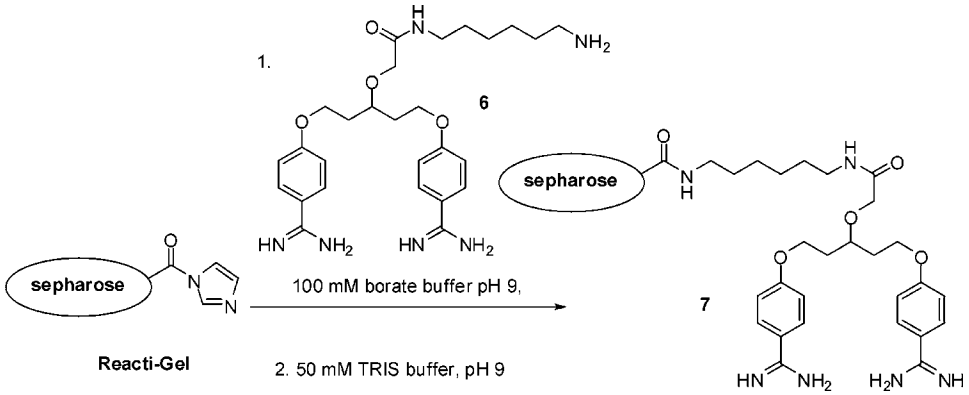


Figure 3. Displacement of LPS bound BC by ligand **6** (top). Displacement of LPS bound BC by Polymyxin B (bottom).

were added successively to the suspension of beads. After the addition of each aliquot, the mixture was allowed to shake for 30 min. Following centrifuging to separate **7** from the LPS−FITC solution, a 100 μL aliquot from the supernatant was

Scheme 2. Immobilization of Ligand 6 onto Reacti-Gel Beads

removed and its fluorescence measured. This experiment was also performed concurrently on control beads (Reacti-Gel which had not been treated with ligand **6** but had been treated with Tris buffer to block reactive groups) and on commercially available agarose-supported Polymyxin B. A standard curve of fluorescence versus concentration of FITC−LPS was prepared ($\lambda_{ex} = 496$ nm and $\lambda_{em} = 525$ nm) and used to calculated free LPS concentration in the supernatant following incubation with each type of bead. Free [LPS−FITC] in the supernatant was plotted against the total [LPS−FITC] for both **7** and agarose−PMB beads and curves fitted to the following function:

$$\mathrm{LPS_{free}} = \mathrm{LPS_{total}} - \left[\frac{(\mathrm{LPS_{total}} + M_1 + M_2 - \sqrt{(\mathrm{LPS_{total}} + M_1 + M_2)^2 - 4\mathrm{LPS_{total}}M_2})}{2}\right]$$

where $M_1 = K_d$ and $M_2 =$ total binding sites. Figure 4 shows the relationships between $[\mathrm{LPS-FITC}]_{free}$ and $[\mathrm{LPS-FITC}]_{total}$. We were surprised to find that both **7** and agarose−PMB beads performed similarly, particularly at lower [LPS−FITC] concentrations. However, we note that the K_d values for both ligands appear to be significantly greater when they are attached to the support than their K_d values in solution. Sepharose-bound ligand **6** displays a K_d of 596 μM ± 120 and agarose-bound PMB shows a K_d of 948 μM ± 340, indicating that the resin-bound versions of both these ligands do not interact as strongly with endotoxin as they do in solution. However, both systems can effectively reduce endotoxin concentration by approximately 50% at the lower concentrations. From this data, we were also able to estimate a maximal binding capacity for both affinity beads. Agarose−PMB resin had a maximal binding capacity of 24 ± 5 μg [LPS−FITC]/mg resin, while resin **7** had a maximal binding capacity of 17 ± 2 μg [LPS−FITC]/mg resin. The apparently higher maximal binding capacity for the agarose−PMB system may account for its improved performance in reducing [LPS−FITC] levels at higher concentrations.

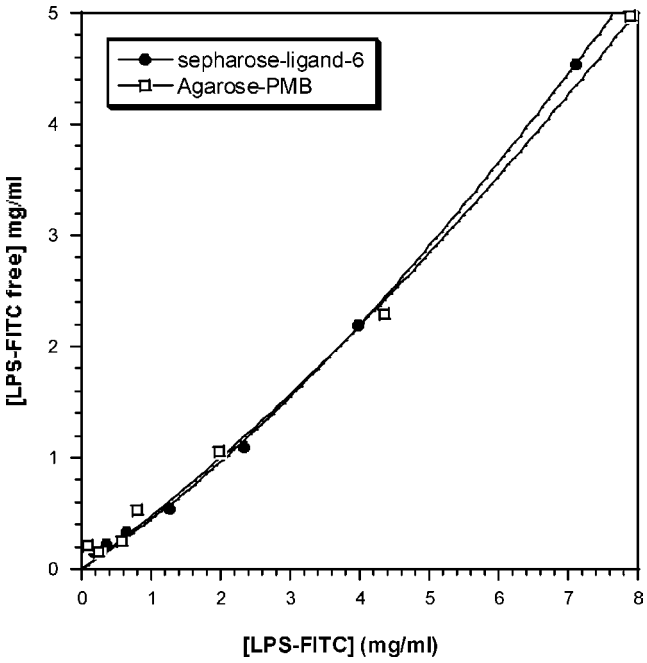

Figure 4. Binding of LPS-FITC by sepharose−ligand **6** and agarose PMB affinity beads.

These results suggested that our affinity system can effectively remove LPS from contaminated solutions. Subsequently, we wanted to assess if this support could be successfully recycled. Table 1 shows the results of recycling with various reagents. Following the incubation of each sample of beads with 500 μg/mL LPS−FITC solution, the beads were washed with a solution of the recycling reagent. The beads were then reincubated with a 500 μg/mL solution of LPS−FITC, and the reduction in LPS−FITC concentration was measured by the fluorescence method described (vide supra). In most cases, the beads could be recycled with only a slight reduction in LPS binding capability after the first round of recycling. We found that 2% Triton X-100 was very effective at restoring LPS binding capability of the beads even after the third round of recycling.

Application of Sepharose-Bound Ligand 6 Beads in Affinity Chromatographic Purification of Endotoxin-Contaminated Antibodies. Finally, we have applied affinity beads **7** in the chromatographic purification of endotoxin-contaminated samples of several different antibody samples of various protein contamination levels and endotoxin contamination levels. Protein loss during affinity-based purification procedures is a significant shortcoming associated with endotoxin removal. We therefore wanted to ensure that our system could effectively reduce endotoxin levels without resulting in unacceptable levels of protein loss. The antibody samples were each passed through a 1 mL column of affinity beads **7**, Pierce Detoxi-Gel beads (i.e.,

Table 2. Endotoxin Removal from Antibody Samples

	Results of LAL Endotoxin Test (EU/ml) affinity column		
antibody	sepharose−ligand **6**	control	agarose−PMB
1 mL of 2.7 mg/mL A7R34 (10-25 EU/mL)[a]	ND[b]	>10	ND[b]
4 mL of 2.7 mg/mL A7R34 (10-25 EU/mL)[a]	ND[b]	>10	ND[b]
4 mL of 3.48 mg/mL KA 417F4 (1.25 EU/mL)[a]	ND[b]	5−10	ND[b]
1.5 mL of 10 mg/mL GNL 23A6 (125-250 EU/mL)[a]	250−500	500−1000	5−10
2 mL of 11 mg/mL FTB 8E9 (500−1000 EU/mL)[a]	50	125−250	25−50

[a] Values in paretheses indicate initial endotoxin contamination level prior to affinity chromatography. [b] ND indicates that endotoxin was not detected; levels were below sensitivity of detection in LAL assay, i.e., ≤0.1 EU/mL.

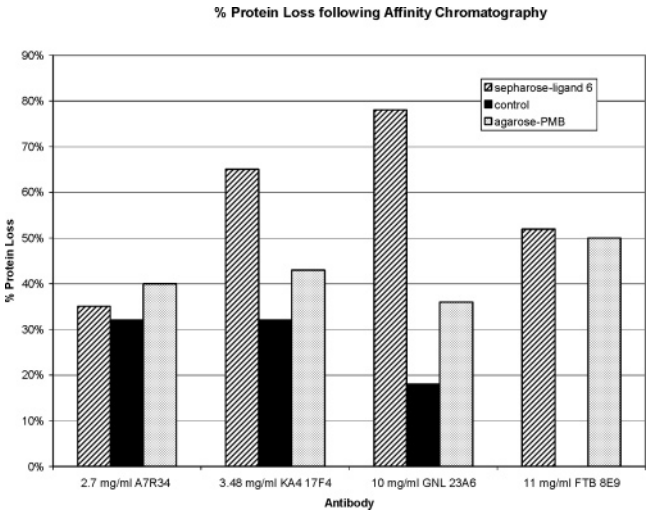

Figure 5. Graph representing % protein loss from samples of antibody following affinity chromatography.

agarose-bound PMB), and control beads. Following elution from the column, the samples were tested for endotoxin concentration using the LAL (*Limulus* Amebocyte Lysate) assay (*9*) and for protein content. The results of the endotoxin testing and protein content tests are shown in Table 2 and Figure 5, respectively.

Table 2 displays the results of LAL endotoxin testing on the antibody samples following affinity chromatography. Antibody A7R34 was contaminated with 10−25 EU/mL prior to affinity chromatography. When a sample loading of 1 mL of A7R34 was applied to 1 mL chromatography columns, both sepharose−ligand **6** and agarose−PMB columns reduced endotoxin levels to a level lower than the detection limit of the LAL assay, while the control column did not reduce endotoxin content. At a higher sample loading volume of 4 mL of A7R34 (and therefore higher endotoxin load), the sepharose−ligand **6** column was also effective in reducing endotoxin level completely. Each affinity column was regenerated, and antibody KA 417F4 contaminated with 1.25 EU/mL was applied. Gratifyingly, the endotoxin level in KA 417F4 was also reduced to a negligible level by the sepharose−ligand **6** affinity system. ELISA studies on purified KA 417F4 against the original BSA−hapten conjugate to which it was raised confirmed that the antigen binding capability of the antibody had not been diminished during the purification process and that no cross contamination had occurred (i.e., that KA 417F4 had not become contaminated with A7R34). Antibodies GNL 23A6 and FTB 8E9 both had considerably higher protein concentrations and endotoxin contamination levels. In both cases, affinity chromatography with the agarose−PMB system was slightly more effective at reducing endotoxin levels. This is possibly due to a greater number of binding sites; however, affinity beads **7** did give a significant reduction in endotoxin level in the case of both antibodies. These results confirmed that sepharose−ligand **6** beads could reduce endotoxin levels as effectively as the agarose−PMB systems at lower endotoxin loadings and that regeneration of the columns was effective and did not result in cross contamination between protein samples.

Figure 5 shows the percentage of protein loss from different antibody samples following chromatography using each type of affinity system. With the exception of antibody GNL 23A6, protein loss following chromatography with the sepharose−ligand **6** system was comparable to that found with the PMB systems. There does not appear to be a strong correlation between antibody concentration and protein loss; for example, 2.7 mg/mL AR734 and 11 mg/mL FTB 8E9 have the most comparable protein loss of any of the antibodies tested despite a large difference in antibody concentration. The differences in percentage of protein loss between the different antibodies may be attributed to the differences in charge on the protein itself. Ansprach (*4*) has reported significant differences between protein recoveries of negatively charged BSA and positively charged lysozyme when endotoxin-contaminated solutions of each of these proteins were subjected to identical endotoxin removal affinity columns. Ansprach proposed that the negatively charged protein competes with endotoxin for ligand binding sites on the affinity column, and thus protein recovery is reduced. It was also observed that different affinity sorbents displayed different degrees of protein loss depending on the degree of specificity of the ligand for endotoxin over the negatively charged protein. The high protein loss on GNL 23A6 for the sepharose−ligand **6** column may be attributed to the charge of the antibody.

CONCLUSION

In conclusion, we have described a simple synthetic route to a novel ligand which binds endotoxin. We have demonstrated that sepharose beads bearing this ligand can be used in affinity chromatography for the removal of endotoxin from contaminated solutions. These affinity beads can be recycled using a variety of simple reagents. In addition, we have verified that this inexpensive system does not result in any greater loss in protein than more expensive commercially available PMB systems. By acknowledging the crucial role of endotoxin removal in protein purification, this system provides an efficient, economical alternative to the PMB systems.

Efficient Sequence-Directed Psoralen Targeting Using Pseudocomplementary Peptide Nucleic Acids

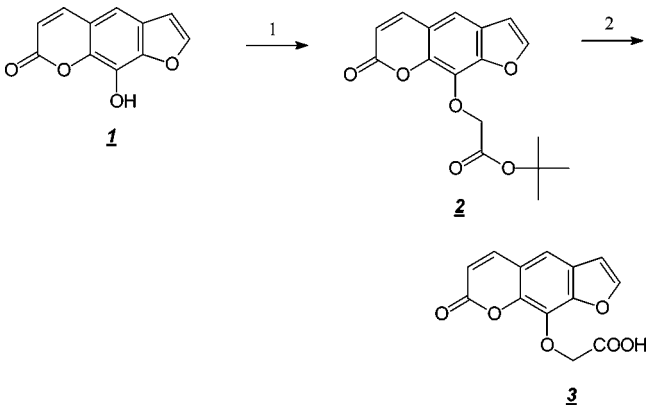
Ki-Hyun Kim,† Xue-Jun Fan, and Peter E. Nielsen*

Department of Cellular and Molecular Medicine, University of Copenhagen, The Panum Institute, Blegdamsvej 3c, 2200 Copenhagen N, Denmark. Received October 14, 2006; Revised Manuscript Received November 21, 2006

A pair of decameric pseudocomplementary PNAs which bind to their mixed purine−pyrimidine sequence target in duplex DNA by double duplex invasion has been synthesized with a derivative of 8-methoxypsoralen conjugated to one of the PNAs. It is shown that this pair of psoralen-conjugated pseudocomplementary PNA oligomers, which target a site in the pBluescriptKS+ vector, upon irradiation with long-wavelength UV light (UVA) with high efficiency and specificity form photoadducts to an adjacent 5′-TA site, and more than 50% of these adducts are DNA interstrand cross-links. Transcription elongation by T7 or T3 RNA polymerase is specifically arrested at the psoralen cross-linking site, yielding more than 90% arrested product. These results emphasize the potential of pseudocomplementary PNA oligomers for highly specific gene targeting, in particular, with respect to sequence-directed psoralen photomodification of double-stranded DNA. Thus, such psoralen−PNA conjugates could be very useful in a range of biology and drug discovery applications.

INTRODUCTION

Design and discovery of chemical agents capable of sequence-specific DNA modification is a challenge with a wide potential for the development of gene knockdown and gene repair technologies in molecular biology and medicine. Many examples of such agents based on DNA minor groove binders (*1*), triple helix forming oligonucleotides (*2*), or zinc-finger DNA binding proteins (*3*) in combination with DNA alkylating reagents (*4*, *5*), photoreactive psoralens (*6*−*9*), or nucleases (*10*, *11*) have been described.



Such reagents may guide the discovery and development of highly specific antigene anticancer drugs and may lead to new techniques for highly specific site-directed mutagenesis in vivo. In particular, sequence-specific repair of targeted genes in somatic cells could eventually have a very significant impact on modalities for the treatment of genetically based diseases. State of the art techniques for the latter typically result in a low percentage (<2%) of repair (*12*−*14*). However, a recent study using Zn-finger−nuclease conjugates indicates that repair efficiencies approaching 20% may be reached when double-stranded DNA breaks are specifically introduced into the target domain (*10*).

We have introduced pseudocomplementary peptide nucleic acids (pcPNAs) as duplex DNA binding agents with only limited sequence constraints (≥50% AT content of the target) (*15*). In these PNAs, adenines and thymines are exchanged with diaminopurine and thiouracil, respectively, thereby strongly reducing the duplex formation of two (pseudo)complementary PNA oligomers (pcPNAs) but essentially not compromising their affinity for a complementary DNA target. Therefore, a pair of such pcPNAs can bind a duplex DNA target by double duplex invasion in which each PNA binds its complementary DNA strand.

It is well-established that psoralen DNA photolesions, in particular interstrand DNA cross-links, cause double-strand breaks in eukaryotic cells (*16*−*19*), and that such cross-links are mutagenic. Therefore, agents that target specifically induce psoralen cross-linking of double-stranded DNA could be of major interest in molecular biology and drug discovery for target-specific mutagenesis and somatic gene repair.

We now report the synthesis of psoralen-conjugated pseudocomplementary PNA oligomers which target a mixed purine−pyrimidine sequence and upon irradiation with long-wavelength UV light (UVA) with high efficiency form photoadducts to an adjacent 5′-TA site.

Scheme 1. Synthesis of the Psoralen Carboxylic Acid Derivative 3[a]

1 *2* *3*

[a] 1: *t*-butyl-2-bromoacatate/K_2CO_3 (92% yield). 2: Trifluoroacetic acid (95% yield).

EXPERIMENTAL SECTION

The psoralen carboxylic acid derivative was synthesized as shown in Scheme 1 (see also ref 20 reporting a psoralen "PNA monomer").

8-(*tert*-Butoxycarbonylmethyleneoxy)psoralen (3). A solution of 8-hydroxypsoralen (*21*) (333 mg, 1.64 mmol), *tert*-butyl-2-bromoacetate (1.28 g, 6.59 mmol), and K_2CO_3 (1.67 g) in dry acetone (50 mL) was refluxed for 2 h. The solid was removed by filtration and the acetone removed in vacuo. The residue was purified by column chromatography (silica gel, CH_2-

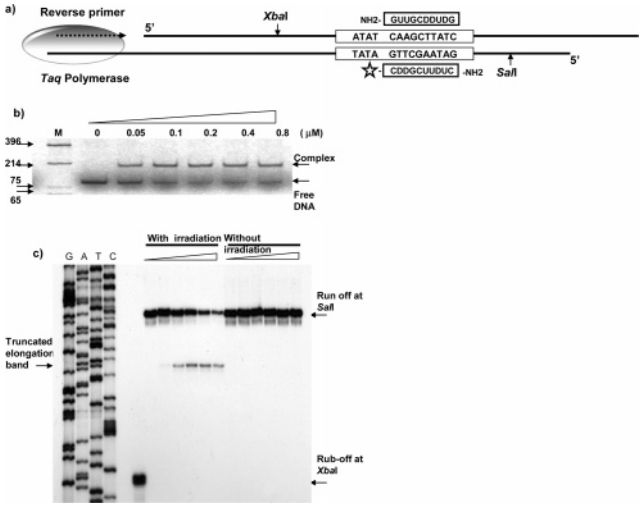

Figure 1. Analysis of photoadducts formed by pseudocomplementary PNA−psoralen conjugates. (A) Schematic drawing of the PNAs, the PNA target DNA, and the position of the primer. (B) Analysis of PNA 2222/2300 binding to *Sal*I-digested linear p260 by gel shift assay. An equimolar mixture of PNA 2222 and PNA 2300 at the indicated concentrations was incubated with *Sal*I-digested p260 in TE buffer in the presence of 10 mM KCl for 4 h at 37 °C. Subsequently, the sample was treated with restriction enzyme *Xba*I and analyzed by electrophoresis in a 10% nondenaturing polyacrylamide gel in TBE buffer. DNA bands were visualized by silver staining. (C) Determination of photoadduct formation site by PCR-based primer extension. PNA 2222/2300−p260 samples incubated as described above were UV-irradiated at 365 nm for 20 min on ice and subjected to PCR-based primer extension analysis. The DNA products were separated on a 10% denaturing polyacrylamide gel containing 7 M urea in TBE buffer and detected by radiography. Nonirradiated controls were also analyzed as well as a primer extension control of *Xba*I-digested p260.

8-(Carboxymethyleneoxy)psoralen (3). Compound *2* (474 mg, 1.5 mmol) in neat TFA was refluxed for 2 h, after which the TFA was removed in vacuo and the product was coevaporated twice from acetonitrile to afford a white foam (330 mg, 95%). mp 204−206 °C. ^{1}H NMR (DMSO, 250 MHz) δ: 8.12 (d, J = 9.6 Hz, 1H), 8.10 (d, J = 2.0 Hz, 1H), 7.62 (s, l H), 7.07 (d, J = 2.0 Hz, 1H), 6.43 (d, J = 9.6 Hz, 1H), 5.12 (s, 2H). ^{13}C NMR (DMSO, 62.9 MHz) δ: 170.15, 159.85, 147.88, 145.89, 145.36, 141.61, 130.52, 126.06, 116.48, 114.36, 113.42, 107.09, 68.33. R_f 0.6 (1-butanol/AcOH/$H_2$0 2:1:1).

Pseudocomplementary PNA Synthesis. In this study, the following pseudocomplementary PNAs were used.

PNA 2222: H-$(Lys)_2$-GDU_S DDG CU_SU_S G-Lys-NH_2.

PNA 2225: Pso-$(eg1)_2$-$(Lys)_2$-CDD CGU_S U_SDU_S C-Lys-NH_2.

PNA 2300: Pso-$(eg1)_2$-$(Lys)_2$-CDD GCU_S U_SDU_S C-Lys-NH_2.

D designates 2.6-diaminopurine and U_s designates 2-thiouracil. Three lysine amino acids were attached for increasing the solubility and the binding affinity to DNA. 8-(carboxymethyleneoxy)psoralen (Pso) was attached to the N-terminal of PNA via two eg1 (8-amino-2,6-dioxaoctanoic acid) flexible linkers on the solid support using standard coupling conditions. The pseudocomplementary PNAs were synthesized and purified as described previously (*16*). The PNAs were homogeneous by HPLC and exhibited one major peak at the expected mass as analyzed by MALDI-TOF mass spectroscopy: PNA 2222 M_w = 3199 (calcd. 3202); PNA 2225 M_w = 3655 (calcd. 3655); PNA 2300 M_w = 3652 (calcd. 3656).

Plasmid Construct. Three plasmids, pBluescriptII SK+ (Stratagene), p206, and pSK1Xpso, were used in this study. Plasmids pSK1Xpso and P206 are simple derivatives of the pBluescriptII KS+ phagemid cloning vector (Stratagene), produced by cloning a synthetic duplex oligonucleotide (5′-GATCTTTCTTTTAAAATTA-3′ and 5′-GATCTAATTTTAA-AAGAAA-3′, or 5′-GATCCGTAGATCACT-3′ and 5′-GATC-CAGTGATCTACG-3′, respectively) into the *Bam*HI site of the polylinker between the promoters for T3 and T7 phage RNA polymerase (neither of these inserts are directly relevant for the experiments described in this paper, as the PNA target is part of the original pBluescriptII SK+ vector). These three plasmids behaved essentially identically with respect to PNA binding and psoralen targeting using the pcPNAs.

Double Duplex Invasion Complex Formation. For the formation of double duplex invasion complexes, a 1:1 mixture of PNA 2222 and PNA 2300 was incubated with 200 ng of *Sal*I-digested pBluescriptII SK+ or p206 (as indicated) in TE buffer (pH 7.4) with 10 mM KCl for 4 h at 37 °C.

Gel Shift Assay for Binding Efficiency of Pseudocomplementary PNA. Double duplex invasion complex was (following desired restriction enzyme treatment) analyzed by gel electrophoresis in 10% native polyacrylamide gels (30:1 acrylamide to bisacrylamide) using TBE buffer (90 mM Tris pH 8.0, 90 mM boric acid, and 2 mM EDTA). DNA bands were visualized by silver staining.

Analysis of Photoadduct Formation by PCR-Based Primer Extension. PNA double duplex invasion complexes were irradiated with long-wavelength UV light (365 nm, 13 J/m^2) for 20 min (or as indicated) on ice. Linear PCR primer extension analysis was performed by incubation in 30 μL PCR mixture (0.4 mM $MgCl_2$, 0.5 mM dNTP (each), 2 pmol ^{32}P-labled M13 reverse primer, and 2.5 unit *Taq* polymerase) for 30 cycles (45 s at 95 °C; 45 s at 56 °C; 80 s at 72 °C), followed by electrophoresis in 10% denaturing polyacrylamide (20:1 acrylamide to bisacrylamide) gels containing 7 M urea in TBE buffer.

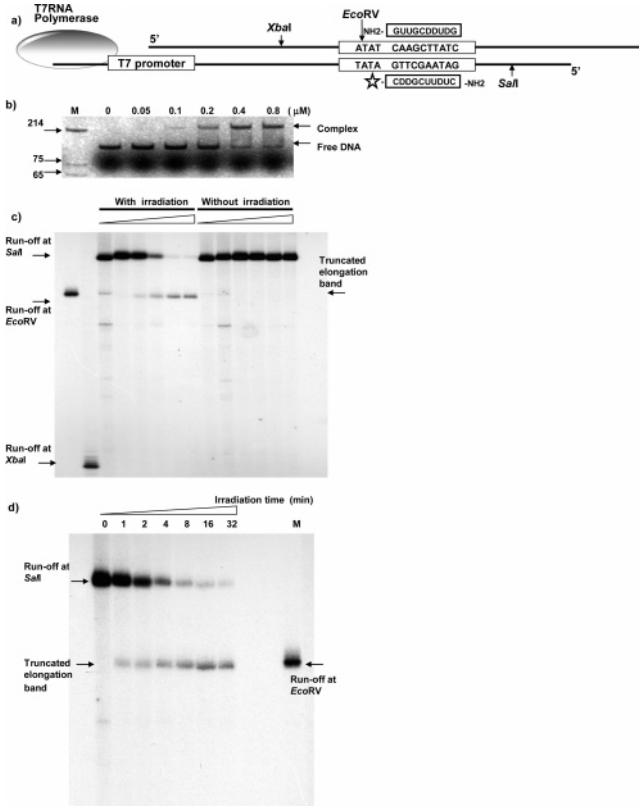

Figure 3. Concentration and UV-dose dependence of transcription elongation inhibition by pseudocomplementary PNA−psoralen conjugates. (A) Schematic drawing of the PNAs, the PNA target DNA, and the position of the T7 promoter. (B) Analysis of the binding of PNA 2222/2300 to *Sal*I-digested linear p206. As in Figure 1B, (C) Concentration dependence (0−0.8 μM as in (B)) of transcription elongation inhibition by photoadduct formation. The T7 RNA polymerase transcription products were analyzed by electrophoresis in 10% denaturing polyacrylamide gel containing 7 M urea in TBE buffer, and autoradiography. As RNA size marker, the runoff products of *Eco*RV- and *Xba*I-digested p206 were included. (D) UV-dose dependence of transcription elongation inhibition by photoadduct formation. The transcription reaction products were analyzed as described in (C).

As a marker, a DNA-sequencing reaction ladder of p260 was used. In parallel, PCR-based primer extension with nonirradiated PNA−plasmid mixture was done as a control. Radioactive bands were visualized by autoradiography using amplifying screen and Agfa Curix RP1 X-ray films exposed at −80 °C for 16 h.

Analysis of Photoadduct Formation by Transcription Elongation Arrest Assay Using T7 or T3 Phage RNA Polymerase. Transcription elongation arrest assay was performed in 30 μL transcription reaction mixture (0.5 mM NTP (except UTP), 0.1 mM UTP, 0.1 MBq [α-^{32}P]-UTP, 5 mM DTT, and 10 unit T7 or T3 RNA polymerase). After incubation at 37 °C for 20 min, the reaction was terminated by adding stop buffer (95% formamide, 20 mM EDTA, 0.05% bromophenol blue, 0.05% xylene cyanol), and the mixture was analyzed by electrophoresis in 10% denaturating polyacrylamide (20:1 acrylamide to bisacrylamide) gel containing 7 M urea in TBE buffer. As a size marker, the reaction mixture of transcription with *Eco*RV-digested and *Xba*I-digested linear p206 was used. Radioactive bands were visualized by autoradiography exposed at −80 °C for 16 h.

Analysis for Psoralen Interstrand Cross-Linking. Double duplex invasion complex was formed by incubating a 3′-^{32}P end-labeled *Xba*I/*Pvu*II DNA fragment of pBluescriptKS+ with PNA 2222 and PNA 2300 (20 nM each) in 120 μL 20 mM sodium phosphate, 1 mM EDTA, pH 6.5, overnight at 37 °C. Subsequently, the samples were UV-irradiated at 365 nm.

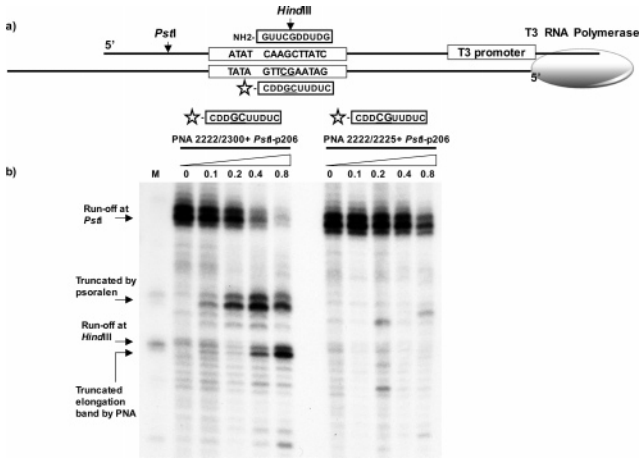

Figure 4. Effect of mismatches on duplex invasion complex formation. (A) Schematic drawing of the PNAs, the PNA target DNA, and the position of the T3 promoter. (B) Analysis of the effect of double duplex invasion complex formation and psoralen cross-linking on transcription elongation using T3 RNA polymerase. Double duplex invasion complex was formed by incubating a mixture of PNA 2222/2300 or PNA 2222/2225 (0 to 0.8 μM) with *Pst*I-cleaved p206 (PNA 2225 is a double mismatch control of PNA 2300). After UV-irradiation at 365 nm for 20 min, transcription was performed, and the transcription products were analyzed by electrophoresis in 10% denaturing polyacrylamide gel containing 7 M urea in TBE buffer. As an RNA size marker, the transcription runoff product of *Hind*III-digested linear p206 was included.

Immediately prior to gel analysis, the samples were heated to 100 °C by boiling (in order to denature the DNA duplexes) and then analyzed by electrophoresis on a 10% native polyacrylamide gel in TBE. Radioactive bands were visualized by autoradiography.

RESULTS AND DISCUSSION

Pseudocomplementary PNAs require 50% AT content for optimal binding to a 10 bp target site (*15*), and 5′-TA sites are optimal for psoralen photoadduct and interstrand cross-link formation (*22*). A combination of these requirements are statistically quite frequent in DNA, and we identified a suitable target (5′-*ATAT*CAAGCTTATC) containing 60% AT at the *Hind*III site in the poly linker of the cloning vector pBluescript SK.

For this target, we synthesized a set of pseudocomplementary PNAs (H-Lys$_2$-GDU$_S$DDGCU$_S$U$_S$G-LysNH$_2$ (PNA 2222) and pso-(eg1)$_2$-Lys$_2$-CDDCGU$_S$U$_S$DU$_S$C-LysNH$_2$ (PNA 2300)) each containing three lysines for improved binding and one of them conjugated to 8-(carboxymethyleneoxy)psoralen through an 18-atom ethylene glycol type linker. Upon binding to the designated target, the psoralen should be positioned optimally for photoreaction with the ATAT target (Figure 1a). Using a gel shift assay, we first demonstrated efficient binding of this set of PNAs at sub-micromolar concentrations (Figure 1b), and by *Taq* DNA−polymerase primer extension runoff analysis (Figure 1c), we observed one and only one premature arrest of the polymerase (for the irradiated samples only) giving rise to a truncated elongation product of a length that corresponds to arrest at the 5′-TA at the psoralen sequence target (Figure 1c). These results clearly demonstrate that the pcPNAs bind their designated target and position the psoralen for photoreaction with the 5′-A*TA*T site. By employing fixed PNA concentration (0.8 μM), a clear irradiation dose response is demonstrated by the experiments presented in Figure 2. From these results, we may also estimate that the efficiency of the photoreaction is close to 100%, as ca. 80% PNA saturation of the binding site (Figure 2a) gives rise to an 80% reduction in the intensity of the runoff elongation product (Figure 2b) after 30 min irradiation.

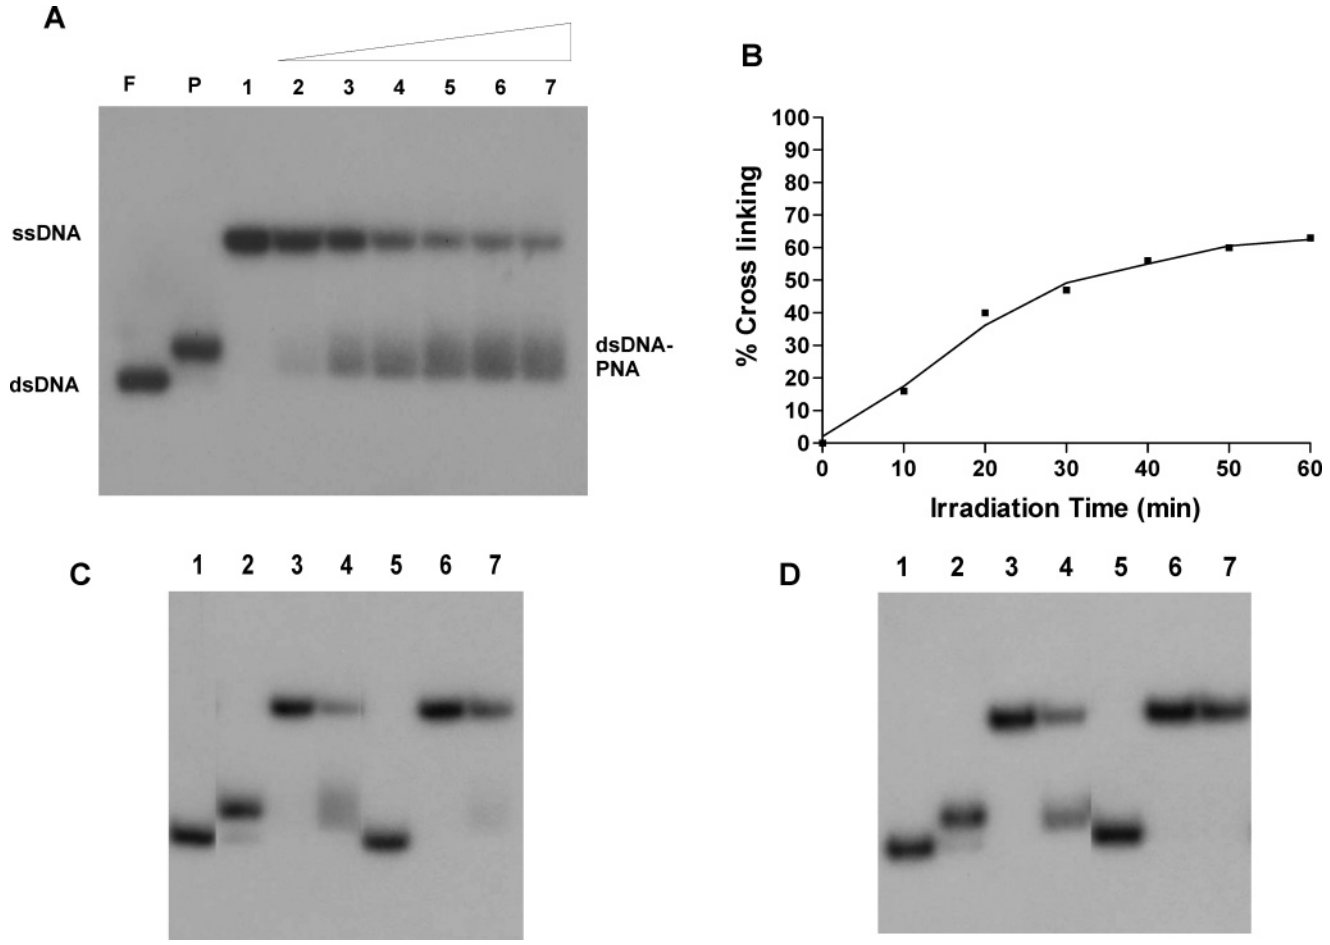

Figure 5. Determination of psoralen interstrand cross-link formation by renaturation analysis. (A) Double duplex invasion complex was formed by incubating PNA 2222/2300 (20 nM each) and a 3′-^{32}P end-labeled *Xba*I/*Pvu*II DNA fragment of pBluescriptKS+ overnight at 37 °C. Subsequently, the samples were UV-irradiated at 365 nm, heated to 100 °C by boiling (in order to denature the DNA duplexes), and analyzed by electrophoresis on a 10% native polyacrylamide gel in TBE (F, free DNA without PNA (without denaturation); P, DNA fragment with bound PNA without denaturation; lanes 1−7: 0, 10, 20, 30, 40, 50, or 60 min irradiation (with subsequent deaturation). (B) The results were quantified by phosphorimager scanning and the relative cross-linking determined as the relative fraction of the dsDNA−PNA band to total amount of DNA. (C) Interstrand cross-linking control using only PNA 2300. Lane 1: control without PNA. Lanes 2−4: PNA 2222 + PNA 2300. Lanes 5−7: PNA 2300. Irradiation was for 30 min (lanes 4 and 7). The samples of lanes 1, 2, and 5 were not denatured prior to gel loading. (D) Same as (C), but the irradiation was performed after addition of KCl to a final concentration of 140 mM.

We have shown that double duplex invasion complexes by decameric pcPNAs do not arrest elongating phage RNA polymerases, such as T7 or T3 RNA polymerases (*15*). The experiment presented in Figure 3 confirms this conclusion using this new set of pcPNAs. However, upon irradiation, the amount of full-length runoff product decreases drastically and a shorter transcript appears, the length of which corresponds to transcription elongation arrest at the psoralen−PNA cross-linking site (Figure 3c). Furthermore, as demonstrated by the experiment presented in Figure 3d, the formation of the truncated transcript (and concomitant disappearance of the full-length transcript) is irradiation dose-dependent and corresponds to practically a 100% yield relative to the PNA binding.

In order to address the target/sequence specificity of the psoralen photoreaction, we introduced a two-base mismatch in the psoralen-conjugated pcPNA by reversing a GC base step (PNA 2225: pso-$(eg1)_2$-Lys_2-CDDCGU$_S$U$_S$DU$_S$C-LysNH_2). This conjugate in combination with PNA 2222 did not photoreact with the target when analyzed by T3 RNA polymerase transcription, whereas the RNA polymerase was arrested by adducts formed by the fully matched set of psoralen−pcPNAs (Figure 4b). Interestingly, in this case as the transcribing polymerase is approaching from the PNA side, the polymerase is also arrested or paused within the PNA target, indicating that the PNA held in place by the psoralen is interfering with transcription elongation.

We also determined the extent of interstrand cross-linking (as opposed to psoralen monoadducts) produced in the system. DNA fragments containing interstrand cross-links will readily renature to a double-stranded structure after heat denaturation, whereas for non-cross-linked fragments, this is a much slower process. The results presented in Figure 5 show that under the conditions used full binding of the PNA is achieved as indicated by migration shifting of the DNA fragment (compare lanes F and P). Upon heat denaturation, the double-stranded fragment (with bound PNA) disappears, and a new band of much slower migration appears (compare lane P and lane 1: 0 min), which is ascribed to the single-stranded product. Upon irradiation of the PNA−dsDNA complex and subsequent denaturation, a (broad) band corresponding to the double-stranded fragment reappears (compare lane 0 min with lanes 2−7: 5−60 min). From the ratio between the amounts of single-stranded and double-stranded DNA molecules, we estimate that the interstrand cross-linking efficiency is over 60% (Figure 5b). As a control, we also made an analogous experiment including only the psoralen-bearing PNA (2300) but not the corresponding pseudocomplementary PNA (2222). The results (Figure 5c, lane 5) show that as expected no complex with dsDNA was formed (as opposed to the situationen when both PNAs were present

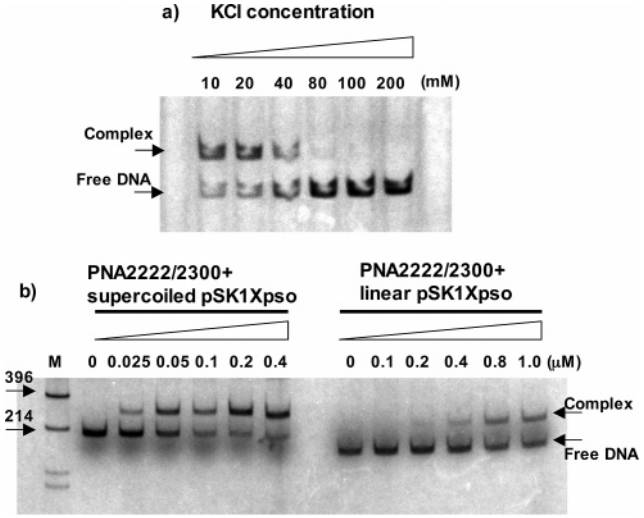

Figure 6. Effect of ionic strength and superhelical density on double duplex invasion complex formation. (A) Effect of KCl on double duplex invasion complex formation. Double duplex invasion complexes were formed by incubating PNA 2222/2300 (0.4 μM) and supercoiled pSK1Xpso in TE buffer (pH 7.4) in the presence of varying KCl concentrations (10 to 200 mM) at 37 °C for 2 h. Subsequently, the samples were treated restriction enzymes *Xba*I and *Sal*I and analyzed by electrophoresis in 10% nondenaturing polyacrylamide gel in TBE buffer (M: DNA size marker). DNA bands were visualized by silver staining. (B) Comparison of the binding efficiency of PNA 2222/2300 to supercoiled and *Xba*I linearized pSK1Xpso. Subsequently, the samples were treated with restriction enzymes *Xba*I and *Sal*I, or *Sal*I only, respectively, and analyzed as described in (A).

(lane 2), which resulted in >90% complex). However, a significant amount of DNA cross-linking took place upon irradiation (Figure 5c, lane 7) in the presence of only PNA 2300. It was noted that the band in the gel was more diffuse, and the cross-linking is ascribed to random cross-linking in the DNA fragment of TA sites by the psoralen−PNA conjugate, which due to the positive charge (+4) has unspecific DNA affinity. This conclusion was supported by the results of a similar experiment performed in 140 mM K^+ (Figure 5d) showing that the cross-linking by PNA 2300 alone is not seen under these conditions (lane 7), while the cross-linking in the presence of both PNAs (2222 and 2300) persists (lane 4), and in addition, the cross-linked band is sharper under these conditions, consistent with target-specific cross-linking. Quantification of the results presented in Figure 5d, lanes 2 and 4) shows that, at 80% binding of the PNA to the target, 47% cross-linking is achieved, giving a cross-linking efficiency of 58%.

It is well-established that helix invasion by PNA oligomers is significantly inhibited by increasing ionic strength (*23*, *24*) and accelerated by DNA negative supercoiling (*25*). The present system exhibits very similar behavior, as binding is negatively affected by 40 mM K^+. However, binding to a supercoiled DNA target is 20-fold more efficient than to a relaxed target (Figure 6b). Therefore, in analogy to dsDNA targeting via triplex invasion complexes (*25*), in vivo dsDNA targeting based on double duplex invasion may also be facilitated by the topological and dynamic state of DNA in vivo.

CONCLUSIONS

The present results clearly emphasize the potential of pseudocomplementary PNA oligomers for highly specific gene targeting, in particular, with respect to sequence-directed psoralen photomodification of double-stranded DNA. It is noteworthy that (at least in the present system) the yield of photomodification is almost stoichiometric and that transcription elongation is effectively arrested by the adducts (while not by the double duplex invasion complexes per se). Thus, such psoralen−PNA conjugates could be very useful in a range of biology and drug discovery applications as already illustrated by the properties of psoralen−TFO conjugates (e.g., *6*−*9*, *26*). Likewise, triplex-forming homopyrimidine bisPNAs−psoralen conjugates have already successfully been used to induce site-directed mutations in cells in culture (*27*). Attempts to exploit pcPNA-directed psoralen photomodification of double-stranded DNA for biological and medically relevant applications are in progress.

TECHNICAL NOTES

Synthesis of a Fluorescent Ganglioside G_{M1} Derivative and Screening of a Synthetic Peptide Library for G_{M1} Binding Sequence Motifs

A ganglioside G_{M1} probe bearing a dark-red fluorescent dye at the sphingosine moiety of the molecule was prepared by a convenient one-pot synthesis. The labeled G_{M1} permitted the detection of the natural ganglioside G_{M1} ligand *Escherichia coli* heat-labile enterotoxin subunit B (EtxB) in picomole quantities on a solid support. When an epitope mapping of several ganglioside binding proteins and protein fragments was performed by screening a cellulose membrane-bound synthetic library of 64 16mer peptides with the new probe, several peptides displaying ganglioside G_{M1} affinity could be identified. We consider the labeled glycolipid described herein a versatile tool for manifold biochemical investigations.

INTRODUCTION

Carbohydrate structures are abundant on cell surfaces and occur in a wide variety, reflecting the diverse functions they exert in biological systems. Carbohydrate moieties have been shown to protect cells, to mediate cell attachment, and to participate in signal transduction pathways (*1*, *2*). Among other possibilities, they can be attached to cell surfaces via linkage to sphingolipids (*3*), thereby forming glycosphingolipids, such as gangliosides.

Glycosphingolipids are composed of two functional units. Their lipid moiety, named ceramide, is responsible for anchoring the molecule in the outer leaflet of the lipid bilayer of the cell membrane. The glycosyl moiety of glycosphingolipids consists of a branched saccharide chain that extends from the membrane surface. The carbohydrate antenna acts as a receptor in intercellular communication processes but may also be exploited by microbial pathogens in order to infect the cells or to manipulate them (*4*). Bacterial toxins of the AB_5-type such as cholera toxin or heat-labile enterotoxin from *Escherichia coli* enter their target cells by binding to ganglioside G_{M1} followed by endocytosis of the complex formed. Once inside, the toxins induce a profound electrolyte and water release which in turn may improve the habitat of the bacteria or facilitate their spread (*5*, *6*).

The multiple and important roles glycosphingolipids are recognized to play has sparked interest in both the development of traceable glycosphingolipid derivatives for studying their cell biology and the use of glycosphingolipid ligands for drug and vaccine targeting purposes. Several ganglioside derivatives carrying fluorescent labels either on their sphingosine or saccharide moiety have been described and used for various applications (*7*−*9*). Their biological behavior seems to be strongly dependent on the site of fluorophore attachment as well as on the structure of the fluorophore itself (*10*), which limits their use in basic studies of glycosphingolipid function. Moreover, none of the fluorescent ganglioside derivatives described so far operates beyond the spectral range where autofluorescence of eukaryotic tissue or membrane supports is observed. Such autofluorescence not only hampers detection of the dye in live cells but may also interfere with fluorescence-based solid-phase assays. Consequently, assays with fluorophore-labeled glycolipids that involve the use of membrane supports or tissue material call for fluorescent dyes which emit light in the far-red to near-infrared region (650−1100 nm), since at these wavelengths, little background fluorescence is usually observed (*11*).

In order to exploit ganglioside G_{M1} as a gateway for drug or vaccine delivery, soluble as well as particulate ganglioside G_{M1} targeting systems have been developed (*12*−*14*). These systems are based on the B subunits of cholera toxin (CTB) or *Escherichia coli* heat-labile enterotoxin (EtxB) and were used, e.g., in mucosal immunizations to target antigens to epithelial cells of the mucosa-associated lymphoid tissue (*13*) or to investigate the accessibility of cell membranes of different intestinal cell types (*15*, *16*). Importantly, the ganglioside binding capability of these proteinaceous ligands may be compromised when they are attached to particulate carriers for use in drug delivery systems (*14*). Thus, small peptides or peptoid structures with high binding affinity to gangliosides would be preferable for these purposes. The identification of such ganglioside ligands, however, requires traceable ganglioside G_{M1} derivatives that can be used without background problems for the screening of solid-phase bound substance libraries and thus must be superior to the currently available compounds.

In the present study, a new fluorescent ganglioside G_{M1} derivative is introduced which meets these requirements. The new probe is characterized regarding its EtxB binding behavior and utilized to identify short ganglioside G_{M1} binding peptides

by screening a solid-phase synthesized library of peptides derived from G_{M1} binding proteins and protein fragments.

EXPERIMENTAL PROCEDURES

Materials. Heat-labile enterotoxin subunit B (EtxB) from *Escherichia coli* was isolated according to a procedure described earlier (*17*). Casein (Hammarsten grade) was obtained from BDH (via VWR International, Darmstadt, Germany), Lyso-ganglioside G_{M1} was from Sigma-Aldrich (Taufkirchen, Germany), and DY650-NHS was from Dyomics (Jena, Germany). PVDF membranes (Westran clear signal membranes, 0.45 μm pore size), nitrocellulose membranes (0.2 μm pore size), cellulose membrane supports (Whatman 540), and a Minifold I 96-well blotting device were from Whatman International (Dassel, Germany). Fmoc amino acid building blocks with side chain protecting groups if required (*t*Bu (serine, threonine, and tyrosine); O*t*Bu (aspartic and glutamic acid); Boc (lysine and tryptophane); Acm (cysteine); Trt (histidine, asparagine, and glutamine), Pbf (arginine)) were obtained from Merck Biosciences (Bad Soden, Germany). Anhydrous hydroxybenzotriazole (HOBt) was from Dojindo Laboratories (Kumamoto, Japan) and dimethylformamide (DMF) from Promochem (Wesel, Germany). *N*-Methylpyrrolidone (NMP; Fluka, Taufkirchen, Germany) was deionized by treatment with ion-exchange mixed bed resin AG501-X8 (Bio Rad Laboratories, München, Germany). All other chemicals and solvents were of analytical grade and purchased from Sigma-Aldrich; they were used without further purification.

HPLC was performed using an Äkta Purifier (GE Healthcare, Freiburg, Germany). Purifications were carried out on a Jupiter (C18, 300 Å, 5 μm, 4.6 × 250 mm) reversed-phase (RP) column (solvents ratio v/v reported) (Phenomenex, Aschaffenburg, Germany). Fourier transform ion cyclotron resonance mass spectrometry was carried out on a Bruker Daltonics (Bremen, Germany) Apex II ESI-FT-MS instrument equipped with a 7 T activity-shielded magnet and an Apollo electrospray ion source in negative detection mode. Fluorescence intensities were quantitated with an Odyssey Infrared Imager running software version 1.2.15 (LI-COR Biosciences, Bad Homburg, Germany). Spatially addressable multiple peptide synthesis was carried out using a pipetting robot ASP 222 (Intavis Bioanalytical Instruments, Köln, Germany).

Synthesis. For preparation of lysoG$_{M1}$-DY650 conjugates (**1**/**2**), lyso-ganglioside G_{M1} was dissolved in dry DMF at a concentration of 2 mg/mL (1.03 mM). 200 μL of this solution was mixed with a solution of DY650-NHS in dry DMF (225 μL, 2 mg/mL), diisopropylethylamine (DIPEA, 7 μL) was added, and the mixture was incubated with shaking under an argon atmosphere at 30 °C. After 36 h, the reaction mixture was analyzed by ESI-MS, the solvent was removed in vacuo, and the residue was redissolved in acetonitrile/water (500 μL, 20% (v/v)). The resulting solution was subjected to HPLC purification on RP-18 silica gel (A = water, B = acetonitrile, 20% B to 100% B, 1 mL/min, 90 mL, retention volume 67 mL), and product fractions were collected. ESI-MS (m/z): fraction 1 1947.95 [M^+] (1947.94 calcd for $C_{95}H_{145}N_5O_{35}S$); fraction 2 1975.98 [M^+] (1975.98 calcd for $C_{97}H_{149}N_5O_{35}S$) (see also Supporting Information).

Peptide libraries were synthesized on cellulose membrane supports following the procedure of Frank (*18*). The cellulose membranes were derivatized with Fmoc-protected β-alanine in DMF (2.5 mL (0.02 mL/cm^2 membrane), 0.2 M Fmoc-β-alanine, 0.2 M methylimidazol, 0.26 M diisopropylcarbodiimide (DIC), 24 h, room temperature (RT)). Excess hydroxyl groups were blocked (capped) with acetic anhydride in DMF (15 mL (0.13 mL/cm^2 membrane), 2% (v/v), 24 h, RT, rocking), and the membranes were washed 3× with DMF (15 mL (0.13 mL/cm^2 membrane)). Fmoc cleavage was performed by incubating the membranes twice with piperidine in DMF (10 mL (0.09 mL/cm^2 membrane), 20% (v/v), 5 min each, RT, rocking). Presence of free amino functions on the cellulose membranes was confirmed with bromophenol blue. For that, membranes were washed 5× with DMF (15 mL (0.13 mL/cm^2 membrane)), stained with bromophenol blue in DMF (15 mL (0.13 mL/cm^2 membrane), 0.01% (w/v), 10 min, RT, rocking), washed 3× with 100% ethanol (15 mL (0.13 mL/cm^2 membrane)), and air-dried.

[a] Linear sequence motif proposed to be responsible for ganglioside G_{M1} binding. Numbering refers to the amino acid positions published in the respective reference. [b] Alphanumeric numbering of the 16mer peptides covering the motif indicated. The numbering refers to their position on the membrane (see Figure 2). [c] Not applicable. [d] Motifs designed rationally from crystal structure data ("linearized discontinuous motif").

The above capping, washing, Fmoc-cleavage and staining steps were repeated between all synthesis cycles from the definition of the synthesis areas (spots) onward, but capping was reduced to 20 min after the third cycle.

For definition of the synthesis areas, 0.1 μL of Fmoc-β-alanine-pentafluorophenyl (Pfp) ester (0.2 M Fmoc-β-alanine-Pfp-ester in NMP) was applied by a pipetting robot on defined membrane areas.

For subsequent synthesis cycles, the amino acids were converted into their corresponding HOBt esters immediately before use by adding 1.25 mol DIC per mole amino acid to a solution containing 0.4 M N-α-Fmoc-protected amino acid and 0.7 M HOBt in NMP (final concentration: 0.2 M amino acid, 0.35 M HOBt, 0.25 M DIC) and allowing the mixture to react for 30 min at RT. Precipitates were removed by a short centrifugation step, and 0.2 μL of these N-α-Fmoc-protected amino acid active esters were applied to the respective synthesis areas. Coupling of each amino acid was repeated three times, and a minimum of 40 min reaction time was allowed in each synthesis cycle. After the last cycle, the peptides were N-terminally acetylated with acetic anhydride in DMF (15 mL (0.13 mL/cm^2 membrane) 2% (v/v), 20 min, RT, rocking).

Side chain protecting groups (except Acm) were removed by immersing the membranes twice in a cleavage cocktail (50% (v/v) trifluoroacetic acid, 3% (v/v) triisobutylsilane, and 2% (v/v) water in dichloromethane (DCM), 10 mL (0.09 mL/cm^2 membrane), 1 h each, RT, rocking). Subsequently, membranes were washed 4× with DCM (15 mL (0.13 mL/cm^2 membrane)), 3× with DMF (15 mL (0.13 mL/cm^2 membrane)), 4× with 1 M acetic acid (15 mL (0.13 mL/cm^2 membrane)), and finally 3× with 100% ethanol (15 mL (0.13 mL/cm^2 membrane)). Membranes were air-dried and desiccated overnight in vacuo and stored in the presence of desiccant at −20 °C. The sequences of the peptides synthesized are compiled in Table 2. The library was prepared in six replicas on a single cellulose membrane.

LysoG$_{M1}$−DY650 Binding to EtxB. EtxB was dissolved in physiological phosphate buffer (10 mM sodium phosphate buffer, 150 mM NaCl, pH 7.5) at a concentration of 5 mg/mL

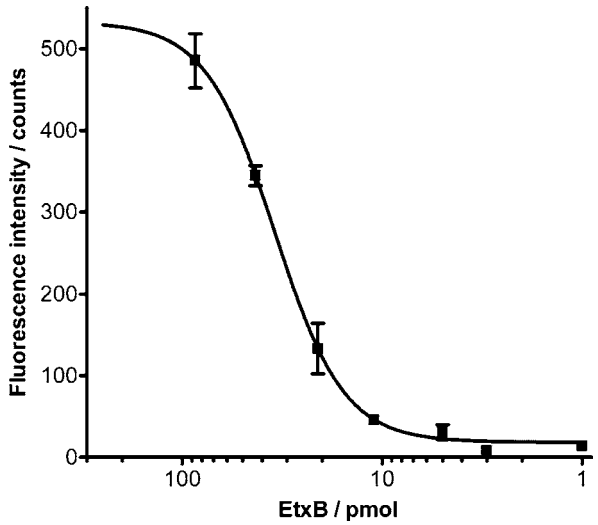
[a] No. indicates the alphanumeric numbering of the respective peptide and refers to its position on the membrane (see Figure 2).

(86 μM), twofold serial dilutions were prepared (concentration range: 5 mg/mL to 80 μg/mL), and 1 μL of each dilution was mixed with 100 μL Dulbecco's phosphate buffered saline (D-PBS; 2.7 mM KCl, 1.5 mM KH_2PO_4, 136 mM NaCl, 8.1 mM Na_2HPO_4, pH 7.4). PVDF membranes were soaked in ethanol for 10 min, washed with water and PBS, and transferred to a 96-well blotting device in the wet state. The EtxB solutions diluted in D-PBS were applied to the membranes under gentle vacuum. Then, the membranes were incubated for 4 h at RT in blocking solution (0.1% (w/v) Tween 20 in D-PBS (PBST)) followed by overnight incubation at RT in a solution of **2** (approximately 10 ng/mL (approximately 5 nM), in 10 mL PBST). They were washed 6× for 10 min with PBST and 2× for 10 min with D-PBS. Fluorescence was measured with an Odyssey infrared imager at 700 nm. Measurements were performed in triplicate; signals are reported as mean fluorescence intensities ± SEM above cutoff. The cutoff was determined according to a method described earlier (*19*).

LysoG_{M1}−DY650 Binding to Peptide Libraries. The cellulose membrane-bound peptide libraries were blocked with casein/PBS (1% casein in D-PBS) for 3 h at RT and incubated overnight at RT with a solution of **2** (approximately 10 ng/mL (approximately 5 nM) in 10 mL casein/PBS). They were washed 6× for 10 min with 10 mL PBST and 2× for 10 min with 10 mL D-PBS, and the bound lysoG_{M1}−DY650 was quantitated on the wet membranes in the Odyssey infrared imager at 700 nm. The experiment was performed in quintuplicate using five identical libraries that had been synthesized in parallel. Signals are reported as mean fluorescence intensities ± SEM above average background outside the spot areas. For all spots, an "average signal" was calculated as the mean of the fluorescence intensities of all spots. From this average signal, the upper and lower cutoff values to classify true binders (signals above upper cutoff) and nonbinders (signals below lower cutoff) was determined using *t*-statistics according to a method described earlier (*19*).



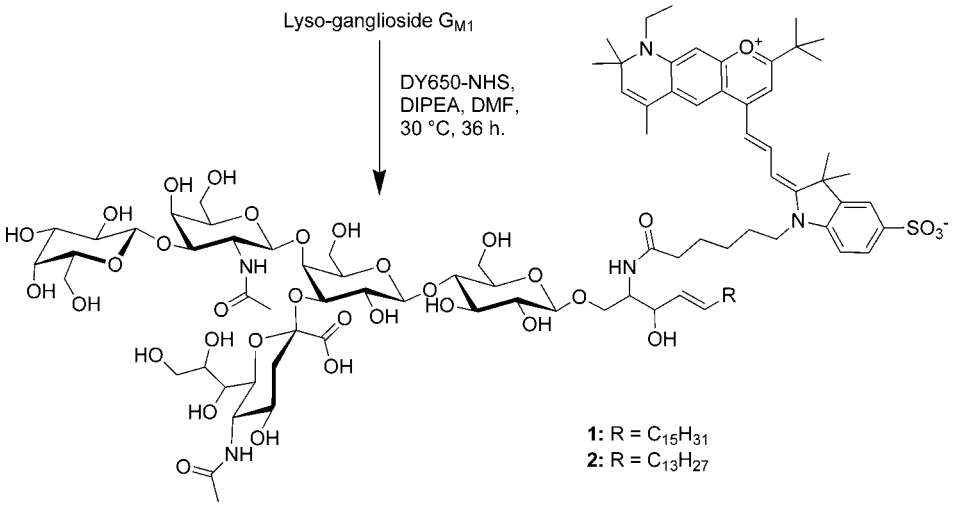


Figure 1. Detection of heat-labile enterotoxin B subunit (EtxB) from *Escherichia coli* by lysoG_{M1}-DY650. Decreasing amounts of EtxB were immobilized on a PVDF membrane and detected with lysoG_{M1}-DY650. Fluorescence emission intensities of bound lysoG_{M1}-DY650 at 700 nm are given in arbitrary units (mean ± SEM of triplicate experiments).

RESULTS AND DISCUSSION

Preparation of a LysoG_{M1}−DY650 Derivative. Since the carbohydrate part of ganglioside G_{M1} is essential for ligand binding, one runs the risk of inactivating the molecule when a bulky group, such as a fluorophore, is attached. The only locale that may be permissive to modification or replacement seems to be the generic fatty acid moiety residing on the amino group of sphingosine. We thus decided to substitute the fatty acid with a dark red fluorescent dye in order to obtain a traceable probe. A G_{M1} derivative that already lacks the fatty acid moiety and contains a free amino function instead is lysoganglioside G_{M1} (lysoG_{M1}) (*20*). Consequently, lysoG_{M1} was chosen as starting material.

As a fluorophore, we selected DY650, a member of the cyanine dye family that carries a lipophilic C-6 spacer and fluoresces at 674 nm after excitation at 653 nm. Due to its emission in the dark red, DY650 should be especially useful in all experiments where autofluorescence is to be expected. Autofluorescence of crude biological samples or organic membrane materials peaks around 550 nm and thus coincides with the emission spectra of popular fluorophores such as Bodipy-FL, which is often used as a label for glycosphingolipids (*10*). In comparison to Bodipy-FL, the DY650 fluorophore shows a twofold higher absorption as well as a doubled Stokes shift, and it is suitable for readout with a variety of fluorescence imagers using red to near-infrared excitation sources. Besides its favorable optical properties, DY650 offers chemical advan-

Scheme 1. Synthesis of Fluorescent Probes 1 and 2

tages, too. The molecular structure of this dye contains no net charge, since the dye's negatively charged sulfo group is compensated by its positively charged aromatic oxonium substructure. Coulomb interactions and hence unspecific binding of DY650 conjugates to charged residues in sample materials should therefore be reduced in comparison to other dyes, which often carry multiple ionic groups in order to increase their solubility in aqueous media.

The preparation of the lysoG$_{M1}$−DY650 conjugate was designed as a one-pot synthesis in which lysoG$_{M1}$ was deprotonated by the sterically hindered base diisopropylethylamine (DIPEA) and reacted with DY650−NHS in dimethylformamide (DMF) in the dark at 30 °C. The reaction was monitored by ESI-MS. It revealed that product formation was slow and came to completion after 36 h only. We attribute this rather low reactivity of the NHS-ester to the fact that the reacting amino function is located at a sterically hindered secondary carbon. Purification of the crude lysoG$_{M1}$−DY650 conjugate was achieved by RP-HPLC, and two product fractions containing the fluorescent glycoconjugates **1** and **2** with molecular weights of 1948 and 1976 were collected (Scheme 1). The occurrence of two different product molecules is due to the fact that the lysoG$_{M1}$, which we used as starting material in the synthesis, is a mixture of two compounds which differ solely in the length of their alkyl chain. The fluorescent G$_{M1}$ derivative **1** carries a C_{15} alkyl chain in its sphingosine moiety, while derivative **2** has a C_{13} alkyl chain in this position. Since fluorescent probe **2** could be enriched to higher purity than **1**, derivative **2** was used in all further experiments.

Binding of LysoG$_{M1}$−DY650 to a G$_{M1}$ Ligand. We first investigated the probe's binding behavior toward a natural G$_{M1}$ binding partner, heat-labile enterotoxin subunit B (EtxB) from *Escherichia coli*, in a dot blot-type assay. Using this setup, a detection limit of 10 pmol EtxB per dot was reached (Figure 1), despite the fact that the probe was excited at a suboptimal wavelength (680 nm) because no laser source for the dye's excitation maximum was available. Even higher sensitivities may be achievable if excitation of the probe is performed at 653 nm, the excitation maximum of DY650. Thus, lysoG$_{M1}$−DY650 was able to bind with high affinity to the natural G$_{M1}$ ligand EtxB, demonstrating that the binding properties of the pentasaccharide moiety were retained in the labeled molecule.

Binding of LysoG$_{M1}$−DY650 to Putative G$_{M1}$ Binding Peptides. We finally wanted to validate the newly developed lysoG$_{M1}$−DY650 derivative as a tool for the detection of molecules which display a high affinity to ganglioside G$_{M1}$. Our ultimate goal is the identification of small ganglioside G$_{M1}$ binding peptides that might be used for drug targeting.

We accomplished an epitope mapping by designing a peptide library consisting of candidate sequences that were taken from known or alleged G$_{M1}$ binding proteins or protein fragments (Table 1) by breaking down the respective sequence motifs into overlapping 16mer peptides (12 to 15 amino acids overlap). We also included three 15mer peptides which had been identified previously as potential G$_{M1}$ ligands in phage display experiments (*21*) and thus could serve as controls. For the sake of comparability, they were extended to 16mers by addition of a C-terminal alanine.

Last, we completed our peptide library with peptides that we deduced from the crystal structure of cholera toxin B-pentamer cocrystallized with bound G$_{M1}$ (*22*). Amino acids that are part of the G$_{M1}$ binding pocket and are involved in G$_{M1}$ binding were selected and assembled sequentially by linear arrangement.

This way, 64 different 16mer peptide sequences were obtained (Table 2) and synthesized on a cellulose membrane support using the SPOT technique (*18*, *23*). With this method, such a high peptide density in each spot of the membrane can be achieved that even weak ligand−peptide interactions are detectable due to multivalency effects. This advantage of SPOT-synthesized peptide libraries is of particular value in our case, as we aimed to detect a carbohydrate−peptide interaction, and this type of interaction is notoriously weak.

Identification of short ganglioside G$_{M1}$ binding peptides was performed by incubating the cellulose membrane-bound library with lysoG$_{M1}$−DY650 and quantitating the fluorescence intensities of the single peptide spots after excitation at 680 nm (Figure 2). Background fluorescence of the membrane support was very low due to the long excitation wavelength used and the blocking of the cellulose membrane with 1% (w/v) casein/PBS. The entire procedure proved highly reproducible, as indicated by the low coefficient of variation that 5 independent screening experiments yielded for each single peptide (mean coefficient of variation for 64 peptides: 11.6%).

The peptides were classified according to their fluorescence intensities into two groups, nonbinders and binders. A peptide was defined as nonbinder if the fluorescence intensity of the respective spot was significantly lower than the "average signal" calculated from the mean fluorescence of all 64 spots (one-tailed t test, $P < 0.05$). Likewise, an upper cutoff value as threshold for significantly higher than average signals was determined. Peptide spots with a fluorescence intensity above this cutoff display better than "average" binding with a probability of ≥99.5% and were hence defined as true binders.

With these discrimination criteria, 25 peptides were classified as nonbinders (Figure 2B, open bars), 15 peptides could not be assigned to either group (Figure 2B, hatched bars), and 24

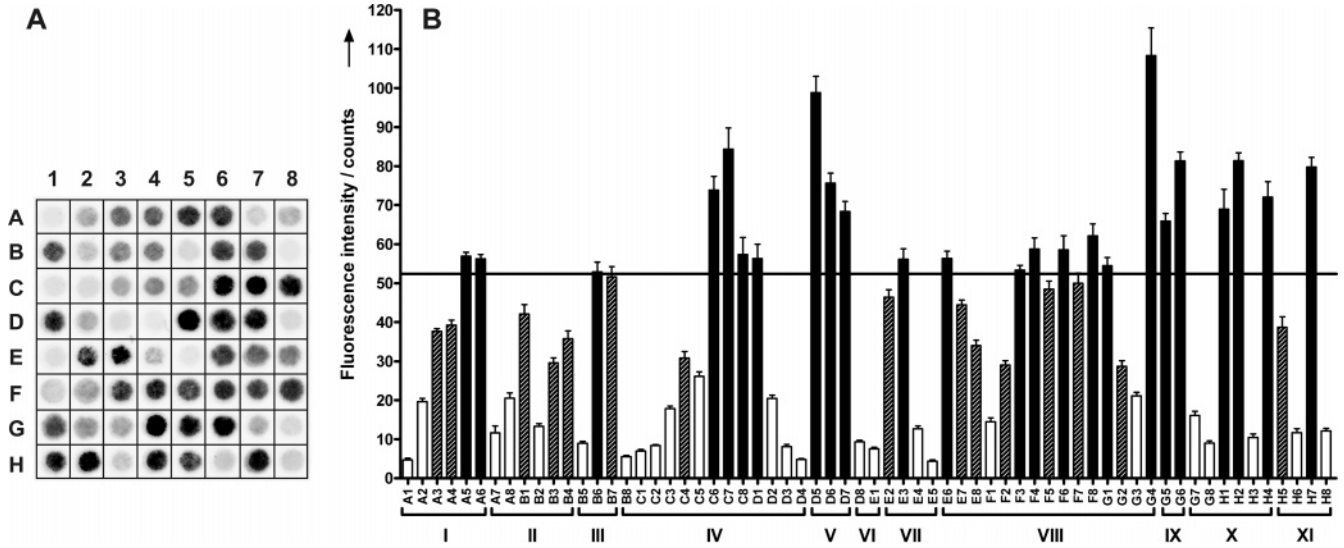

Figure 2. Detection of peptides capable of binding lysoG$_{M1}$-DY650. A library of 64 different peptides was synthesized onto a cellulose membrane support. After blocking, the membrane was incubated with lysoG$_{M1}$-DY650 and fluorescence was measured at 700 nm. (A) Image of the peptide library as generated by the infrared imager depicting the fluorescence signals obtained after incubation of the membrane with lysoG$_{M1}$-DY650. (B) Quantitation of G$_{M1}$ binding to single peptide spots. Filled bars represent signal intensities of peptides assigned to the group of binders; open bars represent nonbinders; hatched bars represent peptides which could not be assigned to either group. Roman numerals indicate the respective set to which the peptides belong (see Table 1). Individual peptides are numbered alphanumerically according to their position on the membrane (for sequences, see Table 2). Fluorescence emission intensities determined for each single spot at 700 nm are shown (mean ± SEM of five experiments). The horizontal line indicates the upper cutoff value used to define true G$_{M1}$ binders.

peptides were found to be binders (Figure 2B, filled bars). All three phage-display-derived, alanine-extended peptides that had been shown to interact with G$_{M1}$ in previous experiments (*24*) (peptide spots D5, D6, and D7 in Figure 2A) belong to the latter group, a finding that we consider a promising preliminary result pertaining to the validation of our screening system. In our assay setup, lysoG$_{M1}$−DY650 showed a stronger interaction with peptide D5 than with peptides D6 and D7 (Figure 2B). This is in conflict with the original report (*21*) where peptide D7 showed the highest inhibition of CTB binding to G$_{M1}$. We reason that these discrepancies are due to the different assay formats used. Originally, the G$_{M1}$ binding performance of the three peptides had been determined in solution, whereas our screening system measures the binding behavior of peptides attached to a solid phase.

The highest fluorescence intensity achieved in our assay resulted from binding of lysoG$_{M1}$−DY650 to peptide G4, which encompasses the C-terminal part of the myelin basic protein fragment. For peptides B8−D4 derived from amyloid β protein, signal intensity peaks at candidate C7, which indicates that the sequence motif of C7 is mainly responsible for the interaction between ganglioside G$_{M1}$ and amyloid β protein (Table 1).

Two linear CTB-derived motifs could be assigned to the group of binders. These peptides, A4 and A5, vary by only one amino acid, an asparagine instead of an aspartic acid, from peptides B3 and B4, but exhibit a much higher fluorescence intensity than the latter. This point mutation originates from a discrepancy in the reported parent sequences (*25*, *26*) and illustrates nicely that the exchange of a single amino acid alone is able to alter the affinity of a peptide ligand to its target. Apparently, a negative charge is highly unfavorable at the respective position. This assumption is supported by the fact that peptide B1 which shares a major part of its sequence with its "neighboring" peptides, B2−B4, but lacks their aspartic acid—and hence the negative charge—displays a similar signal intensity as the other "uncharged" candidate peptides A3−A6. Regardless of the underlying reason for this charge effect, the example emphasizes the value of our assay, which is evidently capable of accurately reflecting the differences in the G$_{M1}$ binding affinities of these closely related peptides.

The peptides derived from the other G$_{M1}$ binding protein fragments exhibited little or no binding to lysoG$_{M1}$−DY650, which suggests that the G$_{M1}$ binding properties of those proteins mainly reside in their three-dimensional structure.

Intriguingly, some of the candidate sequences which we designed on the basis of the structural data of the CTB−G$_{M1}$ complex show rather high fluorescence signals, rendering them true binders (peptides H1, H2, and H4). This demonstrates that rational design may constitute a worthwhile route toward the identification of peptidic ganglioside G$_{M1}$ ligands.

ACKNOWLEDGMENT

We thank Dr. Buko Lindner for performing the mass spectrometrical analyses. This work was funded by the German Federal Ministry of Education and Research (BMBF, grants 13N8473 and 01KO113) and by the German Research Foundation (DFG, grant FR 958/4-1).

Received August 17, 2006; Revised Manuscript Received January 25, 2007

A new convergent synthetic method for the synthesis of PAMAM dendrimers has been developed. The fusion between propargyl-functionalized PAMAM dendrons and azido-functionalized PAMAM dendrons via the Cu(I)-catalyzed Huisgen [2 + 3] dipolar cycloaddition reaction (click chemistry) of an alkyne and an azide leads to the formation of symmetric PAMAM dendrimers in high yields. Furthermore, the coupling reactions between the different generation dendrons afford the size-differentiated unsymmetrical PAMAM dendrimers.

INTRODUCTION

Dendrimers, which are prepared by repetition of a given set of reactions using either divergent or convergent strategies, are highly branched and regular macromolecules with well-defined structures and have served as functional objects in nanotechnology and nanoscience (*1*, *2*). Recent advances in nanomedicine showed that dendrimers are a novel class of nanoscale carriers that can be multifunctionally used for targeting, imaging, and treatment of biological systems (*3*). Especially PAMAM dendrimers, which are nanoscopic spherical macromolecules composed of polyamidoamino units with repeating dendritic branching, have been extensively studied in many fields such as drug, drug and gene delivery, and in magnetic resonance imaging. The interior cavities of PAMAMs are often used to encapsulate hydrophobic or hydrophilic drugs (*4*, *5*). In order to better control the release rate, imaging, and targeting properties of drugs, the terminal groups of PAMAMs have been functionalized with various moieties, such as drugs, biospecific ligands, and fluorescent tags (*6*, *7*). These dendrimer-based nanodevices hold great promise for various biomedical applications. In the future, more expanded applications of PAMAM dendrimers rely on efficient and practical synthetic procedures.

The early synthetic efforts in PAMAM dendrimer synthesis applied the divergent synthesis procedure building the dendrimers from the core by an iterative synthetic procedure (*8*). The convergent approach of dendrimer synthesis introduced by Fréchet and co-workers revolutionized the synthetic approaches to develop monodisperse dendrimers (*9*, *10*). The convergent methodology installs the core in the final step, enabling the incorporation of various functionalities. It provides greater structural control than the divergent approach due to its relatively low number of coupling reactions at each growth step. The ability to prepare well-defined (un)symmetrical dendrimers is the most attractive feature of the convergent synthesis method. Therefore, the synthesis of PAMAM dendrimers via the convergent approach is a significant challenge. However, an example in the convergent synthesis of PAMAM dendrimers by the amide coupling between carboxylic acid and amine is reported (*11*). In continuation of our efforts in the convergent synthesis of dendrimers, we here report the efficient synthesis of symmetric and unsymmetric PAMAM dendrimers by 1,3-dipolar cycloaddition of azide- and alkyne-functionalized PAMAM dendrons.

The reactions employed in the synthesis of dendrimers should be high yielding without any side reactions. Well-known processes, such as Michael reaction, Williamson ether synthesis, amidations, and reductions have been used extensively in the synthesis of dendrimers (*10*). The Cu(I)-catalyzed Huisgen [2 + 3] dipolar cycloaddition reaction between an organic azide and an alkyne (*12*, *13*), the best example of click chemistry (*14*, *15*), is clearly a breakthrough in the synthesis of dendrimers (*16*, *17*). The reaction is characterized by mild and simple reaction conditions, reliable 1,4-regiospecific 1,2,3-triazole formations, and tolerance toward water as well as a wide range of functionalities (*18*). Although many reports have been found in the synthesis of the triazole-mediated dendritic materials using click chemistry (*19*−*26*), there are a few reports that demonstrate the synthesis of the PAMAM dendrimer in spite of its importance for new material design (*27*−*29*).

EXPERIMENTAL PROCEDURES

General. ^{1}H NMR spectra were recorded on a 300 or 500 MHz NMR spectrometer using the residual proton resonance of the solvent as the internal standard. Chemical shifts are reported in parts per million (ppm). When peak multiplicities are given, the following abbreviations are used: s, singlet; d, doublet; t, triplet; q, quartet; quin, quintet; d of d, doublet of a doublet; m, multiplet; br, broad. ^{13}C NMR spectra were proton decoupled and recorded on a 75 or 125 MHz NMR spectrometer using the carbon signal of deuterated solvent as the internal standard. FAB and MALDI mass spectra were obtained from Korea Basic Science Institute (KBSI) in Daegu or Daejeon and POSTECH. Flash chromatography was performed with 37−75 μm silica gel. Analytical thin layer chromatography was performed on silica plates with F_{254} indicator, and the visualization was accomplished by UV lamp or using an iodine chamber. Polydispersity (PDI) of dendrimers was determined by gel permeation chromatography (GPC) analysis relative to polystyrene calibration (Agilent 1100 series GPC, Plgel 5μm

MIXED-C, refractive index detector) in THF solution. All chemicals were obtained from commercial sources and used as received, unless otherwise mentioned. THF was distilled over Na/Ph_2CO ketyl.

General Procedure for the Preparation of Dendrimers 3-Gmn from Propargyl-PAMAM Dendrons 1-Dm and Azido-PAMAM Dendrons 2-Dn. A mixture of propargyl-dendrons **1-Dm** (0.10 mmol) and azido-dendrons **2-Dn** (0.11 mmol) in THF−H_2O (4:1, 1 mL) in the presence of 5 mol % $CuSO_4 \cdot 5H_2O$ with 10 mol % sodium ascorbate was stirred at room temperature for ∼4 h. The reaction mixture was poured into brine (20 mL), and the resulting solution was extracted with EtOAc (20 mL × 4). The combined organic phase was dried with sodium sulfate, concentrated, and purified by column chromatography (EtOAc/methanol system) to afford the desired product.

3-G11. 95% yield; IR 2955, 2840, 1734, 1437, 1258, 1199, 1174, 1044 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$): δ = 2.02 (quintet, J = 6.6 Hz, 2H), 2.39 (t, J = 6.7 Hz, 6H), 2.47 (t, J = 7.0 Hz, 4H), 2.71 (t, J = 6.8 Hz, 4H), 2.77 (t, J = 7.0 Hz, 4H), 3.62 (s, 6H), 3.64 (s, 6H), 3.78 (s, 2H), 4.31 (t, J = 7.0 Hz, 2H), 7.55 (s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 173.3, 173.2, 144.6, 123.4, 52.0, 51.9, 50.8, 49.5, 49.3, 48.9, 48.2, 33.0, 32.8, 28.5; MS (FAB): m/z = 500 [M^+ + H]; HRMS (FAB) calcd for $C_{22}H_{37}N_5O_8$: 499.2642. found: 500.2837 [M^+ + H]. PDI = 1.01.

3-G22. 97% yield; IR 3314, 2952, 2828, 1734, 1663, 1533, 1437, 1357, 1257, 1198, 1176, 1046 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$): δ = 2.02 (m, 2H), 2.34 (m, 4H), 2.41−2.44 (m, 30H), 2.54−2.55(m, 8H), 2.73−2.77 (m, 16H), 3.28 (t, J = 4.7 Hz, 8H), 3.66 (s, 24H), 3.84 (s, 2H), 4.36 (t, J = 6.4 Hz, 2H), 6.97 (br s, 2H), 7.15 (br s, 2H), 7.67 (s, 1H); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 173.4, 172.7, 172.4, 143.8, 123.5, 53.3, 52.0, 50.2, 50.0, 49.6, 49.6, 48.2, 47.8, 37.5, 37.5, 34.2, 33.9, 33.4, 33.0, 28.4; MS (FAB): m/z = 1301 [M^+ + H]; HRMS (FAB) calcd for $C_{58}H_{101}N_{13}O_{20}$: 1299.7286. found: 1300.7364 [M^+ + H]. RESULTS AND DISCUSSION

In the convergent synthesis of the dendrimers, two feasible methods are the fusion of two dendrons and the stitch of multifunctional group with dendrons. We have developed the stitching method for the synthesis of symmetric dendrimers using click chemistry between an alkyne and an azide (*17*, *21*, *22*, *26*). At this time, we are fascinated to utilize the fusion method of two dendrons for the synthesis of symmetric and unsymmetric PAMAM dendrimers. The synthetic strategy for the PAMAM dendrimers **3-Gmn** utilized a fusion of the propargyl-functionalized PAMAM dendrons **1-Dm** and the azido-functionalized PAMAM dendrons **2-Dn** (Figure 1). The propargyl-functionalized PAMAM dendrons **1-Dm** (**m** = 1−4: generation of dendron) and azido-functionalized PAMAM dendrons **2-Dn** (**n** = 1−3: generation of dendron) are synthesized by the divergent approach using propargylamine and azidopropylamine as a focal point, respectively (*27*, *28*). This methodology involves typical stepwise and iterative two-step reaction sequences, consisting of amidation of methyl ester groups with a large excess of ethylenediamine and Michael addition of primary amines with methyl acrylate to produce methyl ester terminal groups.

Stitching together different dendrons effectively and efficiently without any ensuing problems in isolation and purification is a major challenge. The clue was provided by click chemistry due to the high yields and lack of byproducts. Building dendrimers via the fusion approach of dendrons

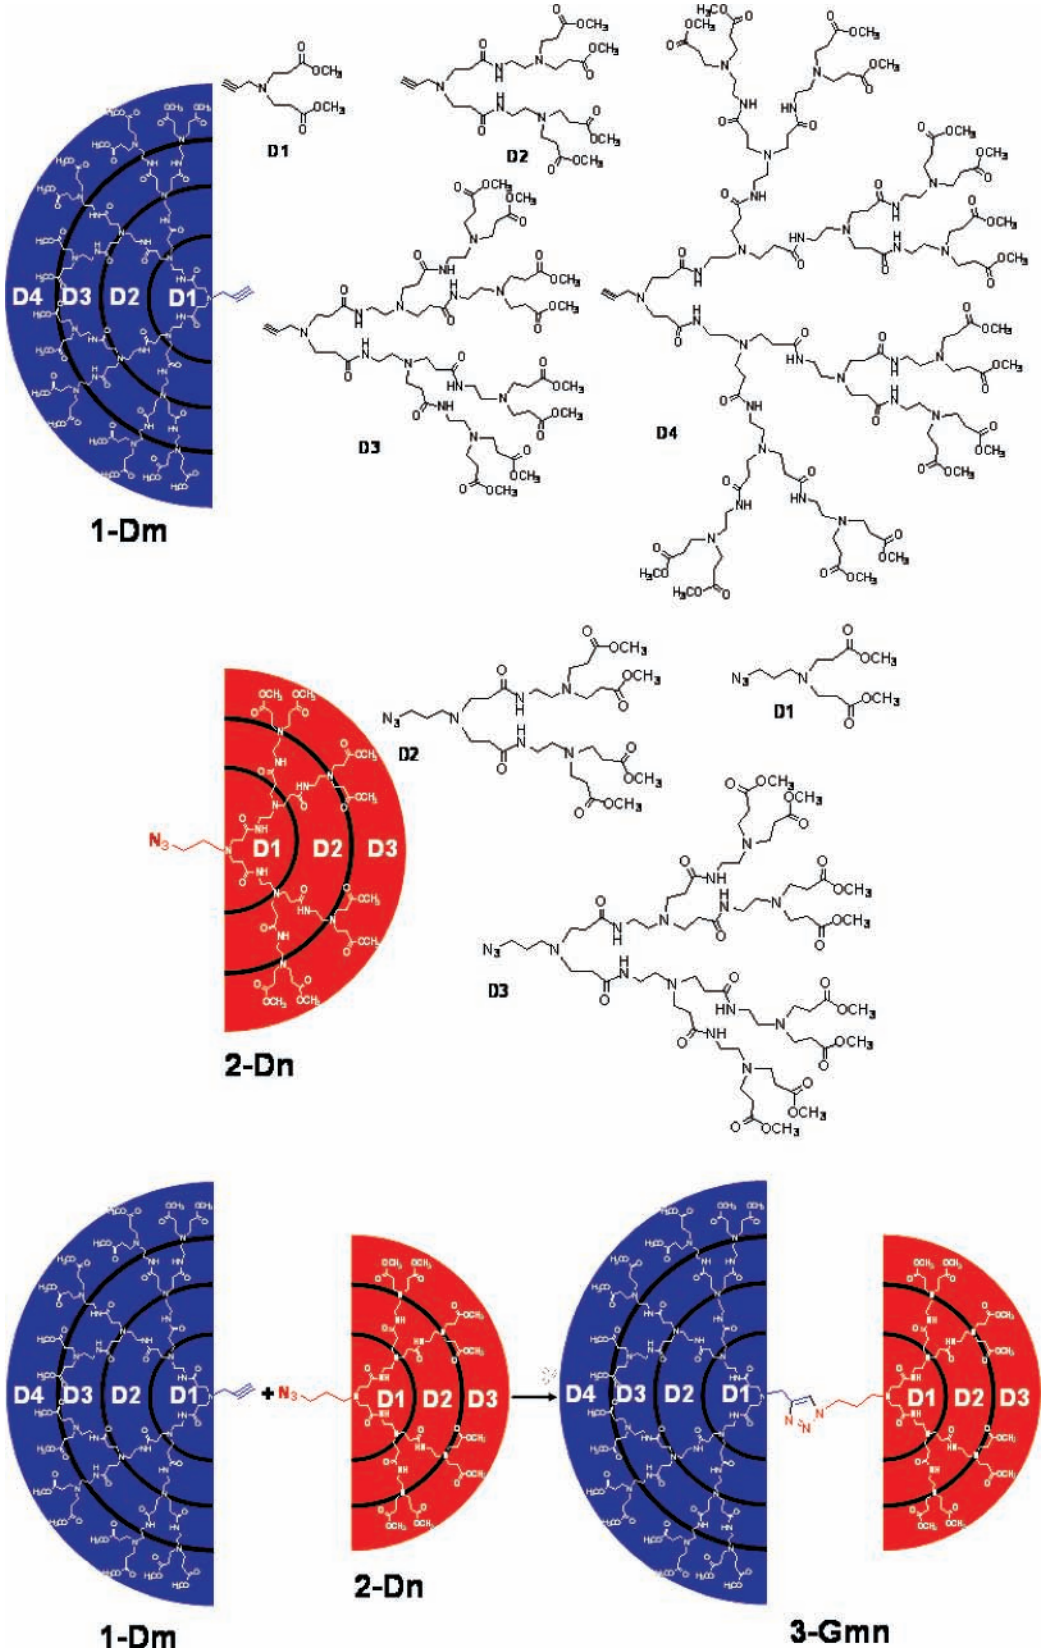

Figure 1. Structures of dendrons **1-Dm** and **2-Dn** and synthetic strategy for PAMAM dendrimers **3-Gmn**.

together allows the synthesis of symmetric and unsymmetrical dendrimers. To efficiently connect the propargyl focal point PAMAM dendrons **1-Dm** with azide-PAMAM dendrons **2-Dn** for the synthesis of PAMAM dendrimer, the click condition using Cu(I) species was selected as synthetic method. The substrate-specificity in the copper-catalyzed cycloaddition reaction between an azide and an alkyne was found to influence at the reaction time. The click reaction of alkyne-PAMAM dendrons **1-Dm**, conducted from the conditions of 5 mol % of $CuSO_4 \cdot 5H_2O$ with 10 mol % of sodium ascorbate, was completed at room temperature within a short time which may potentially be explained by anchimeric assistance due to the amine moiety presented in dendrons (*27*, *30*).

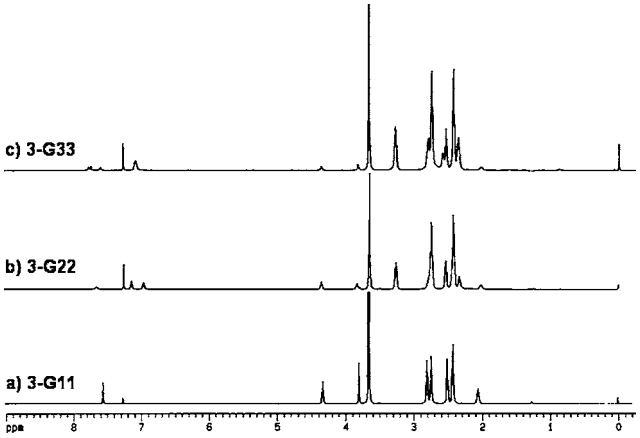

Figure 2. ^{1}H NMR spectra of PAMAM dendrimers (a) **3-G11**, (b) **3-G22**, and (c) **3-G33**.

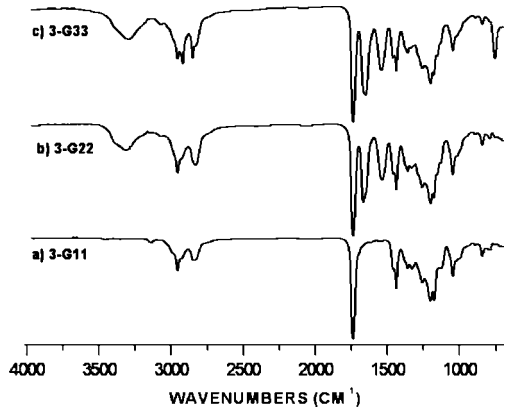

Figure 3. IR spectra of PAMAM dendrimers (a) **3-G11**, (b) **3-G22**, and (c) **3-G33**.

Thus, the reaction of alkyne-dendron **1-D1** and azido-dendrons **2-D1** in 5 mol % $CuSO_4 \cdot 5H_2O$ with 10 mol % sodium ascorbate in a 4:1 solvent ratio of THF to H_2O for 1.5 h at room temperature afforded the desired product **3-G11** in 98% yield. The generation of product and disappearance of the dendrons were monitored by TLC runs of the reaction mixture. Given the success in the synthesis of first generation dendrimer **3-G11**, we expanded this reaction to get higher generation dendrimers. The reactions of **1-D2** with **2-D2** and of **1-D3** with **2-D3** afforded the PAMAM dendrimers **3-G22** and **3-G33** in yields of 97% and 94%, respectively, after 2.5 and 4 h. For completion of the reaction between two dendrons, the higher generation dendrons take slightly longer time than the lower generation dendrons which can be imagined by the simple steric hindrance of dendrons. This result showed that the formation of triazole can be regarded as a new connector to construct the symmetric PAMAM dendrimers from dendrons. The symmetric PAMAM dendrimers were purified by column chromatography, and the structures were confirmed by ^{1}H and ^{13}C NMR spectroscopy, IR spectroscopy, and FAB or MALDI mass spectra.

From the ^{1}H NMR spectra ($CDCl_3$), peaks of the methylene protons adjacent to the carbon of triazole, the triazole proton, and the methylene protons adjacent to the nitrogen of triazole in dendrimers **3-Gmn** were found at 3.78, 7.55, and 4.31 ppm for **3-G11**, 3.84, 7.67, and 4.36 ppm for **3-G22**, 3.82, 7.73, and 4.35 ppm for **3-G33**, respectively (Figure 2). As the dendrimer generation increased, peaks of the triazole proton shifted gradually to downfield which may be influenced by the dendritic effect (*31*). The IR spectra also shows the disappearance of acetylene peak at ~3277 cm^{-1} and the azide peak at ~2096 cm^{-1} in the final dendrimers (Figure 3) while the ^{1}H NMR

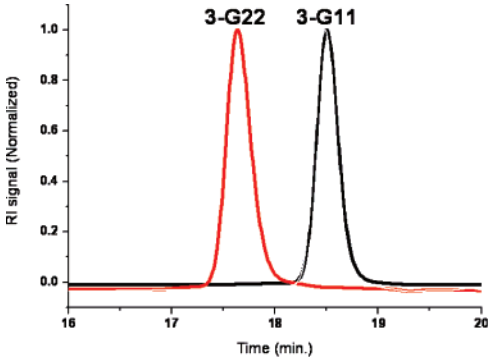

Figure 4. GPC diagrams of dendrimers **3-G11** and **3-G22** obtained from THF eluent.

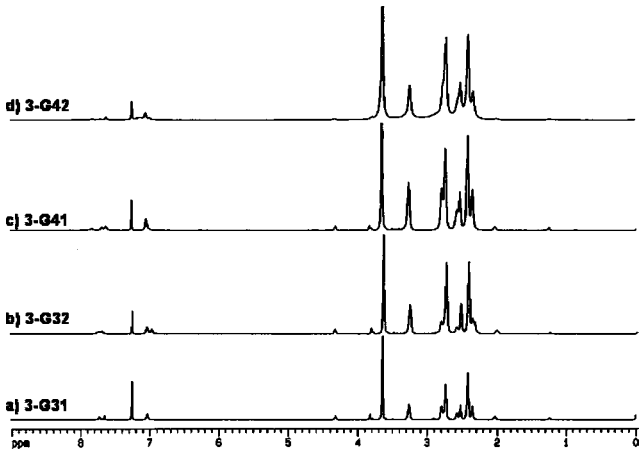

Figure 5. ^{1}H NMR spectra of PAMAM dendrimers (a) **3-G31**, (b) **3-G32**, (c) **3-G41**, and (d) **3-G42**.

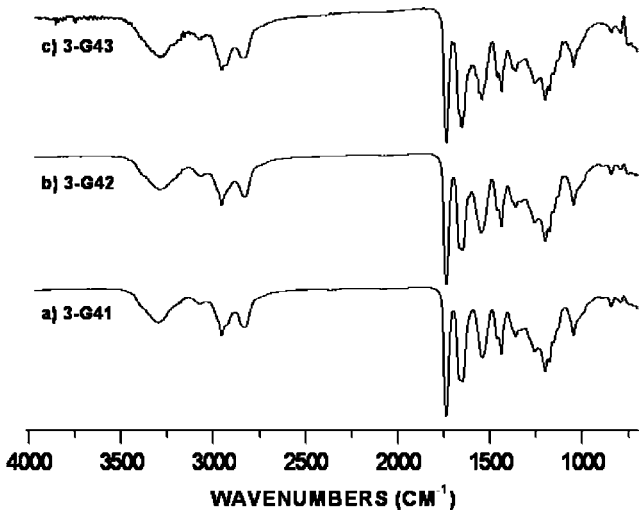

Figure 6. IR spectra of PAMAM dendrimers (a) **3-G41**, (b) **3-G42**, and (c) **3-G43**.

revealed no alkyne peak at around δ 2.46 ppm. Their mass spectra were exhibited very good correlation with the calculated molecular masses. Analysis of the dendrimers by gel-permeation chromatography (GPC) from THF eluent shows very low polydispersity values, PDI = 1.01 and 1.02 for **3-G11** and **3-G22**, respectively (Figure 4). Unfortunately, the PDI value by GPC analysis of **3-G33** could not be obtained due to their poor solubility and aggregation property in THF.

To probe the viability of our approach, we next turned our attention toward the construction of unsymmetrical PAMAM dendrimers. Unsymmetric dendrimers were assembled through the click reactions between different generations of dendrons.

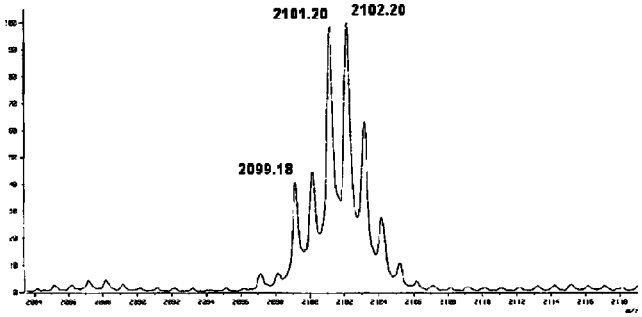

Figure 7. FAB mass spectrum of dendrimer **3-G32**.

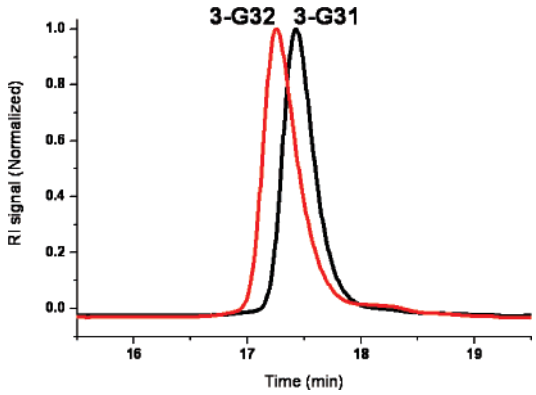

Figure 8. GPC diagrams of dendrimers **3-G31** and **3-G32** obtained from THF eluent.

We used **1-D3** and **1-D4** dendrons as higher generation dendrons for developing unsymmetric dendrimers. The reaction of third generation alkyne-focal dendron **1-D3** with **2-D1** and **2-D2** in the presence of 5 mol % $CuSO_4 \cdot 5H_2O$ with 10 mol % sodium ascorbate in a 4:1 solvent ratio of THF to H_2O afforded the unsymmetrical PAMAM dendrimers **3-G31** and **3-G32** in yields of 92% and 91%, respectively, after 2 h. The reaction of fourth generation alkyne-focal dendron **1-D4** with **2-D1**, **2-D2**, and **2-D3** provided the unsymmetrical PAMAM dendrimers **3-G41**, **3-G42**, and **3-G43** in yields of 95%, 88%, and 76%, respectively, after 2, 2.5, and 4 h. The products were separated by column chromatography. The low yield of **3-G43**, in the absence of any side product(s) as observed by TLC, could be due to significant retention of the polar dendrimer in silica column. To improve the isolated yield of dendrimers, the membrane dialysis could be applied. Therefore, the results showed that the formation of triazole between alkyne-dendrons and azide-dendrons are found to be an efficient connector to construct various unsymmetric dendrimers and may be applied for the synthesis of functional materials. We are currently investigating the synthesis of functional unsymmetric dendrimers using the dendrons peripherally modified with various substituents.

The structures of all unsymmetric PAMAM dendrimers were also confirmed by ^1H and ^{13}C NMR spectroscopy and mass spectra. From the ^1H NMR spectra ($CDCl_3$), we observed that the chemical shifts of the methylene protons adjacent to the carbon of triazole, the triazole proton, and the methylene protons adjacent to the nitrogen of triazole in unsymmetric dendrimers were similar to those in the corresponding dendron(s) of symmetric dendrimers (Figure 5). IR data also confirmed that neither alkyne ($\sim$3277 cm^{-1}) nor azide (2096 cm^{-1}) residues remain in the final dendrimer (Figure 6). Their mass spectra were exhibited very good correlation with the calculated molecular masses (Figure 7). Analysis of the dendrimers by gel-permeation chromatography (GPC) from THF eluent shows very low polydispersity value, PDI = 1.03 for both **3-G31** and **3-G32** (Figure 8). Unfortunately, the PDI value by GPC analysis of other dendrimers also could not be obtained due to their poor solubility and/or aggregation properties in THF.

CONCLUSION

We have demonstrated for the first time that click reaction between the propargyl-functionalized PAMAM dendrons and the azido-functionalized PAMAM dendrons lead to the formation of symmetric PAMAM dendrimers in high yields. Furthermore, the coupling reactions between the different generation dendrons afforded the size-differentiated unsymmetrical PAMAM dendrimers. This method may then provide an insight into designing various (un)symmetrical dendrimers such as amphiphilic dendrimers. We are currently working toward synthesis of various functional dendrimers using this strategy for various applications.

ACKNOWLEDGMENT

This research was supported by the University IT Research Center (ITRC) Project of the Ministry of Information and Communication (J.W.L) and by the Korea Science and Engineering Foundation (KOSEF) grant funded by the Korea government (MOST) (No. M10600000157-06J0000-15710) (S.H.J). We also thank the Korean Ministry of Education (BK 21 Program) for graduate studentships.

Polyhistidine Fusion Proteins Can Nucleate the Growth of CdSe Nanoparticles

Baikuntha P. Aryal and David E. Benson*

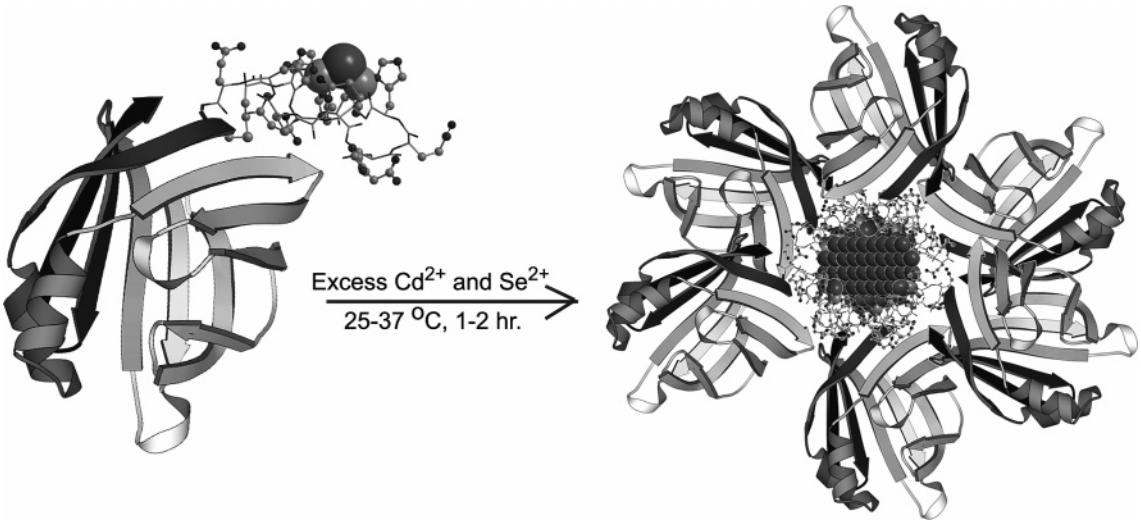
Department of Chemistry, Wayne State University, Detroit, Michigan 48202. Received September 6, 2006; Revised Manuscript Received November 7, 2006

A $(His\text{-}Asn)_6$ domain fused to fatty acid binding protein provides the low-temperature assembly of CdSe nanoparticles starting with common inorganic salt precursors. This observation is significant, since fusion proteins with this protein domain are common for affinity purification. While not optimized, this domain readily provides CdSe nanoparticles from room-temperature solutions. The nanoparticles are soluble and do not precipitate during standard biochemical purification procedures. High-resolution transmission electron microscopy demonstrates that the CdSe nanoparticles are crystalline. Surface defects on these nanoparticles are presumed, as weak emission was observed. This report presents a straightforward method to produce protein-attached semiconducting nanoparticles that can be used for biological assays.

INTRODUCTION

Biomolecular conjugates of nanoparticles are an emerging class of functional smart materials (*1*). Semiconducting nanoparticles have provided visible to near-infrared fluorescence (*2*) and photocatalysis (*3*) to the functions of the attached biomolecules. Semiconducting nanoparticles are typically synthesized through high-temperature synthetic routes to control the distribution of nanoparticle sizes (*4*), followed by biomolecule attachment. Low-temperature biosynthetic routes (*5, 6*) have also been reported. These methods have used peptides (*7*, *8*) or proteins (*9*) known to generate CdS or Fe_3O_4 nanoparticles in vivo. Additional nanoparticulate materials can be generated through using different ionic precursors (*10*) or metathesis reactions (*11*). Nanoparticle diameters can be controlled using protein cages with larger (*12*) or smaller (*13*) diameters. Alternatively, phage-displayed peptides have been selected to bind specific material faces that can also nucleate nanoparticle formation (*5*). The nanomaterials generated by these methods are typically crystalline, but the narrow band gap semiconductor materials do not all have intense fluorescence emission (*14*). Fluorescence of semiconducting nanoparticles is quenched by lattice defects on the nanoparticle surface (*15*), which high-temperature routes (*4*, *16*) minimize by Ostwald ripening (*17*). Low-temperature synthetic methods are currently being developed that maximize nanoparticle surface crystallinity and fluorescence (*18*, *19*). A low-temperature route to protein-semiconducting nanoparticle formation using common inorganic salts and a common fusion protein domain would provide a highly accessible synthetic method. Such a synthetic method would remove the need for high-temperature methods and decrease the high cost currently associated with these bioconjugates. Here, we demonstrate that a NH_3^+-Met-$(His\text{-}Asn)_6$ fusion protein provides CdSe nanoparticle nucleation and attachment at room temperature (Scheme 1). This finding is important, since polyhistidine fusion domains are routinely attached to proteins and used for affinity purification. Such a low-temperature route to semiconducting nanoparticle formation would circumvent high-temperature methods and allow protein-directed growth of nanoparticulate materials. A similar report has just appeared where Au nanoparticles were nucleated by a His_6 fusion domain (*20*). Reduction with $NaBH_4$ was necessary for Au nanoparticle formation, but also degrades many proteins. The significance of the current article is that a low-temperature route that does not require reactive precursors is reported. Polyhistidine domains also bind metal ions, in a coordinatively unsaturated mono- or binuclear fashion (*21*, *22*), and could nucleate CdS or CdSe nanoparticles. Addition of lattice-forming anions (S^{2-} or Se^{2-}) and divalent metal cations for charge neutralization facilitates the nucleation and growth of the nanoparticulate material (*8*). With advances in low-temperature semiconducting nanoparticle synthetic methods (*18*, *19*), this report demonstrates a method for routine biomolecule−nanoparticle assembly from room-temperature aqueous solutions.

EXPERIMENTAL PROCEDURES



All chemicals were purchased from Aldrich and used without further purification, unless otherwise noted. Plasmid DNA encoding rat intestinal fatty acid binding protein (FABP) was a generous gift from Professor Carl Frieden (Washington University, St. Louis). The FABP coding sequence was ligated into the pPROTet expression vector (ClonTech) that encodes a NH_3^+-Met-$(His\text{-}Asn)_6$- domain and an enterokinase binding sequence before the inserted, encoded protein. The FABP conjugate from the pPROTet expression vector is termed $(HN)_6$−FABP. This protein was purified by immobilized metal affinity chromatography to homogeneity, chelated, and desalted. FABP was produced by cleaving the $(HN)_6$ peptide with enterokinase (New England Biolabs 64 pg/μg (protein), 25 °C, 16 h) followed by repurification. Protein concentrations were determined by absorbance ($\epsilon_{280} = 16\,500\ M^{-1}\ cm^{-1}$) or using the Bradford method (*23*).

$(HN)_6$−FABP Mediated Growth of Nanoparticles. $CdCl_2$ and Na_2Se (1 mM each) were added to a 50 μM $(HN)_6$−FABP or bovine serum albumin (BSA, Sigma) in anaerobic aqueous solution (20 mM *N*-morpholinosulfonate [MOPS], pH 7.5). The anaerobicity of solutions was maintained by standard O_2-sensitive techniques for aqueous solutions, and most manipulations were performed in a Coy Laboratories (Grass Lake, MI) inert atmosphere bag. After the reaction, the $(HN)_6$−FABP and BSA solutions were subjected to gel filtration chromatography (molecular weight cut off = 6000 Da, Pharmacia, 10-DG). Protein concentrations after purification were estimated using the Bradford assay (*23*). Centrifugal ultrafiltration (YM-30 or YM 100, Millipore) was performed to estimate protein dissociation from the CdSe nanoparticle surface. Dissociated

Scheme 1. Proposed Method for Protein-Templated CdSe Nanoparticle Synthesis[a]

[a] Left: A $(His\text{-}Asn)_6$ peptide domain modeled to coordinate a $[Cd_2Se]^{2+}$ complex (see experimental, stick only, polypeptide backbone; ball and stick, amino acid side chains; light gray spheres, Cd^{2+} ions; dark gray spheres, Se^{2-} ions) attached to the amino terminus of IFABP (PDB code, 1IFC). Right: a suggested model of CdSe nanoparticle coated with multiple proteins whose stability is maintained through the $(His\text{-}Asn)_6$ domain.

protein was collected in the filtrate and determined by the Bradford assay (*23*). Absorbance and fluorescence spectra were recorded for samples within cuvettes loaded and sealed within the anaerobic bag. Fluorescence emission spectra were recorded with a Horiba Fluoromax-3 (10 nm slit width, 0.8 s integration). Samples were also dried for 36 h at 37 °C on carbon-coated grids and examined by high-resolution transmission electron microscopy (TEM, JEOL FastEM 2010, 200 kV). Formation of $O_2^{\bullet-}$ by nanoparticle photoexcitation was determined by illuminating aerobic nanoparticle-containing solutions, with 100 μM 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO) as a radical trap, in quartz cuvettes with a Xe arc lamp (150 W; water and $\lambda >$ 310 nm filters) for 20 min (*24*). These solutions were loaded into an EPR capillary flow cell (Bruker), and radical production was examined with a Bruker ESP-300 EPR spectrometer (microwave frequency, 9.856 GHz; microwave power, 20 mW; modulation amplitude, 1 G; modulation frequency, 100 kHz). Spectra of the photoilluminated samples were compared with 2,2,6,6-tetramethyl-1-piperidine-1-oxyl (TEMPO) solutions for frequency calibration and spin quantization.

Molecular Modeling of Initial $[Cd_2Se]^{2+}$ Complex. The NH_2-Met-$(His\text{-}Asn)_6$-COOH was modeled in *Chem Draw/Chem 3D* (Cambridge Soft) using the MM2 force field (*25*). The MM2 force field was selected due to the parametrization for both Cd^{2+} and Se^{2-} ions. Initial models of Cd^{2+} ion coordinated conformations were imposed by generating the N,N′,N″-methine (three-coordinate) or N,N′-methylene (two-coordinate) derivatives of the histidine side chains. The stronger C−N bond length force constants, relative to the Cd−N force constants, allowed a pseudo-tetrahedral Cd^{2+} ion coordination geometry to be enforced during geometry minimization by *Chem3D*. Geometry-minimized conformations were examined for maximal solvent exposure and minimal cross-threading of the polypeptide backbone. Once a collection of candidate metal−histidine linkages was selected, the thioether derivative of the N-methylene(ine) groups was formed to constrain the conformation for the $[Cd_2Se]^{2+}$ complex. The bond lengths to the N-methyl groups were elongated to typical $Cd\text{-}N_{imidazole}$ (2.28 Å, Cd-substituted carboxypeptidase) or Cd-(μ-Se) (2.26 Å, from Wurtzite CdSe unit cell parameters) bond lengths and geometry-minimized. The carbon and sulfur atoms were then substituted with trigonal pyramidal or tetrahedral Cd^{2+} ions and bridging Se^{2-} ions and subjected to a final round of geometry minimization. This modeled structure is shown in Scheme 1; Cd_1 coordinated to His2 ($N_{\epsilon 2}$) and His4 ($N_{\epsilon 2}$), Cd_2 coordinated to His8 ($N_{\delta 1}$), His10 ($N_{\delta 1}$), and His12 ($N_{\delta 1}$). Once the $[Cd_2Se]^{2+}$ complex was removed, geometry minimization showed only small backbone movements, suggesting this complex is conformationally accessible.

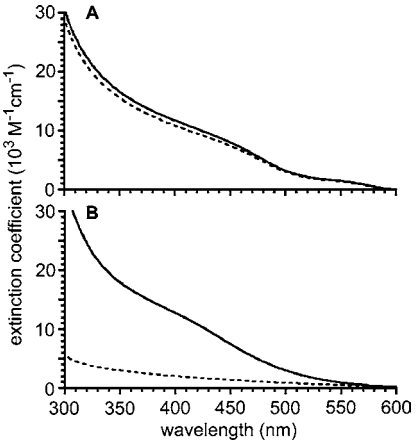

Figure 1. UV−vis spectra of 24 h, 25 °C $CdCl_2/Na_2Se$ (1 mM each) reactions with proteins before (solid line) and after (dashed line) purification by gel filtration: (A) $(HN)_6$-FABP; (B) BSA. Extinction coefficients are calculated on the basis of the protein concentration (50 μM, before purification; 32 μM, after purification).

RESULTS AND DISCUSSION

$(HN)_6$−FABP was used to demonstrate polyhistidine-domain-mediated CdSe nanoparticle nucleation. FABP is a monomeric protein with a mass of 16 KDa that nonspecifically binds hydrophobic molecules. The stability of FABP ($T_M \approx 70$ °C) is high and makes a stable scaffold for developing a biosynthetic method for CdSe nanoparticle production (*26*−*29*). Addition of a 20-fold molar excess $CdCl_2$ and Na_2Se to $(HN)_6$−FABP, FABP, or BSA under anaerobic aqueous conditions at room temperature produced brown solutions. For reactions with $(HN)_6$−FABP, the brown color changed to a red-orange color over a 24 h period (Figure 1A). Reactions with FABP that did not contain the $(HN)_6$ peptide domain produced a brown precipitate after 12 h. This control reaction was important, due to the promiscuous ligand binding of FABP. The brown color persisted for 24 h, with no precipitate, for reactions containing

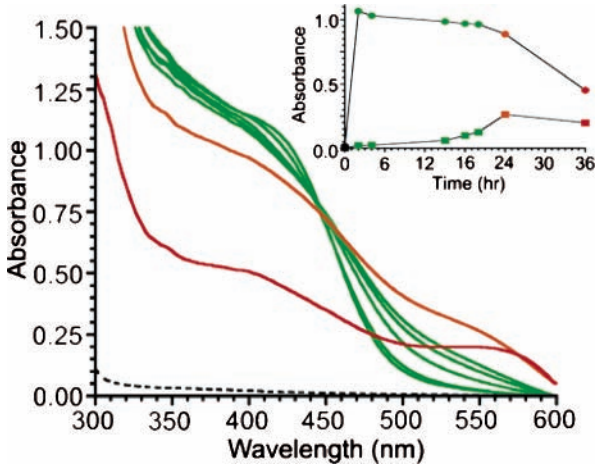

Figure 2. Time-dependent growth of $(HN)_6$-FABP capped CdSe nanoparticles. Absorbance spectra of a 50 μM $(HN)_6$-FABP solution were recorded before (dotted line) and after (solid green lines, 2 h, 4 h, 14 h, 16 h; solid orange line, 24 h; and solid red line, 36 h) the addition of $CdCl_2$ and Na_2Se (1 mM each) under anaerobic conditions (pH 7.5, 20 mM MOPS). Inset: absorbance at 425 nm (circles) and 550 nm (squares) as a function of time (symbol colors refer to line color of main figure).

BSA (Figure 1B). BSA is also known for promiscuous ligand binding (e.g., metal ions, hydrophobic molecules), where the weak Cd^{2+}/Se^{2-} ion-mediated chromophore formation is reflective of these binding events. The colored soluble species in the $(HN)_6$−FABP and BSA reactions were assumed to be due to Cd^{2+} ions and Se^{2-} ions forming a distribution of CdSe nanoparticles. On the basis of absorbance spectra (*30*), the average diameter of the CdSe nanoparticles formed by $(HN)_6$−FABP ranged from 2 to 3 nm. After 24 h at room temperature, the $(HN)_6$−FABP and BSA formed CdSe nanoparticles were isolated by gel filtration chromatography (6000 MW cutoff). Only the isolated $(HN)_6$−FABP fractions maintained the color (red-orange) after gel filtration (Figure 1). Ultrafiltration (30 000 or 100 000 MW cutoff) of the $(HN)_6$−FABP and BSA nucleated CdSe nanoparticle samples, before chromatography, yielded less than 1 μM $(HN)_6$−FABP in the filtrate as opposed to 40 μM BSA in the filtrate. Maltose-binding protein with a C-terminal His_5 domain (MBP−His_5) (*31*, *32*) was used for CdSe nucleation reactions and produced similar spectral and isolation properties to those observed with the $(HN)_6$−FABP samples (Supporting Information). BSA, while functioning as a polyelectrolyte to facilitate CdSe nanoparticle nucleation, had a weak nanoparticle affinity for purification. BSA has been reported previously to nucleate Ag_2S nanoparticles and nanorods (*33*); however, no purification was reported. This finding suggested that $(HN)_6$−FABP and MBP−His_5 can nucleate *and* form a tightly associated complex with CdSe nanoparticles. Such a distinction is important for generating biomolecule-adsorbed nanoparticles for use as soluble fluorophores for biological analysis.

Reactions at 37 °C were examined to decrease the polydispersity of $(HN)_6$−FABP-mediated CdSe nanoparticle sizes. Absorbance measurements (Figure 2) showed the initial formation of a shoulder at 425 nm (average diameter ∼2.0 nm). Weak emission spectra were observed for samples purified after 2 h of reaction (Figure 3) with broad emission maxima observed around 450 nm. The emission maxima shifted ∼5 nm as the excitation wavelengths were varied from 330 to 360 nm, indicating some polydispersity. On the basis of the extinction coefficients for CdSe nanoparticle band gap absorbances (*34*), we estimate that one CdSe nanoparticle is formed per 4−7 $(HN)_6$−FABP (assuming a yield near unity). Using the absorbance-derived CdSe nanoparticle concentration, the quantum

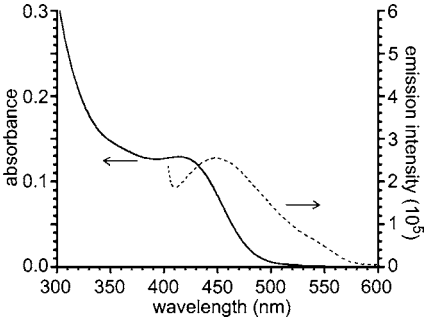

Figure 3. Absorbance (left axis/arrow) and fluorescence emission (right axis/arrow) spectra of $(HN)_6$-FABP-capped CdSe nanoparticles (2 h, 37 °C reaction: $(HN)_6$-FABP (50 μM) with $CdCl_2/Na_2Se$ (1 mM each), purified by gel filtration, diluted 1:10): absorbance, solid line; emission spectrum, dotted line, excited at 340 nm.

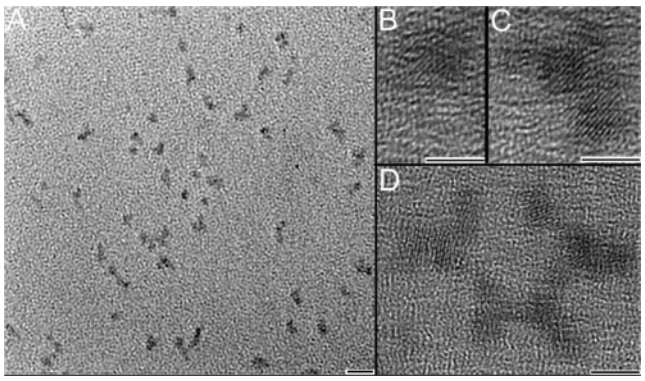

Figure 4. $(HN)_6$-FABP-mediated CdSe nanoparticle nucleation and aggregation: (A) medium resolution transmission electron micrograph (20 nm scale bar) of $(HN)_6$-FABP in the presence of $CdCl_2$ and Na_2Se for 24 h at 37 °C dried on a carbon-coated TEM grid for 36 h; (B−D) High-resolution micrographs (5 nm scale bar) of representative particles/aggregates. Panels B−D were used for lattice spacing determination (d = 3.72 Å). Multiple lines were drawn perpendicular to the lattice fringes and the average d spacing was derived across 10 to 15 lattice fringes per line. A line in panel B is shown as an example which is 52.5 Å over 14 lattice planes (d = 3.75 Å).

yield was estimated as 0.005% compared to 1% for CdSe nanoparticles formed by high-temperature methods. As time progressed, the 425 nm shoulder decreased in intensity (Figure 2 inset), followed by the growth of a shoulder at 550 nm (average diameter ∼3.1 nm). Between 2 and 16 h, the spectra exhibited an isobestic point at 450 nm, suggesting that the small nanoparticles form larger nanoparticles in a concerted fashion. After 40 h, these reactions had a detectable amount of precipitation. The spectral evolution and precipitation suggested initial CdSe nanoparticle nucleation (425 nm shoulder), followed by nanoparticle aggregation (550 nm shoulder), that eventually leads to CdSe precipitation. In contrast, the room-temperature reactions showed both the 425 and 550 nm shoulders, while no precipitation was observed. FABP is thermally stable ($T_M \approx$ 70 °C); however, a reversible transition between 35 and 50 °C has been reported (*35*). The FABP domain with low thermal stability is thought to be the helix−turn−helix mouth of the fatty acid binding pocket (*36*). The conversion of the 425 nm absorbing species to the 550 nm absorbing species, supposedly from nanoparticle aggregation, could be facilitated by thermal denaturation of the FABP helix−turn−helix domain.

TEM analysis confirmed formation and aggregation of hexagonal CdSe nanoparticles. Figure 4 shows a $(HN)_6$−FABP-nucleated, chromatographically purified sample after 24 h at 37 °C that was dried (∼36 h) on a carbon TEM grid. Lower-resolution micrographs showed minimal CdSe macrocrystallite formation, suggesting that the aggregated nucleated CdSe particles were nucleated by $(HN)_6$−FABP. The average nano-

particle diameter was 3.5 nm with a 0.7 nm size distribution (Supporting Information). The broad size distribution by TEM was consistent with the observed broad absorbances (Figures 1−3) and broad emission spectra (Figure 3). However, there were a large number of dimeric and multimeric assemblies of nanoparticles observed (Figure 4). The putative precursor nanoparticle diameters ranged from 2 to 3 nm, consistent with the initial optical nanoparticle size estimates. The majority of nanoparticle interactions were observed as dimeric interactions (Figure 4C). The weak and broad emission observed by these nanoparticles is due to the surface defects from the low-temperature growth conditions. Lattice fringes with *d* spacings of 3.72 Å were observed (Figure 4B−D) for the larger/aggregated particles showing overall that the nucleated CdSe nanoparticles are crystaline. The observed *d* spacing is consistent with the 100 face of hexagonal CdSe. After 72 h at 37 °C, Cd^{2+}/Se^{2-} incubations with $(HN)_6$−FABP showed coalescence of these small nanocrystallites into spherical 60−80 nm hexagonal CdSe nanocrystallites (Supporting Information).

Despite the TEM detected crystalinity of the $(HN)_6$−FABP-nucleated CdSe nanoparticles, the emission quantum yield is low (∼0.005%). Surface defect sites are typically invoked to describe low-emission quantum yields. These defect sites have reduction potentials ranging from the reduction potential of the conduction band ($E° \approx -500$ mV vs NHE (*37*), Se-rich) to the reduction potential of the valence band ($E° \approx +1.7$ V vs NHE (*37*), Cd-rich) (*38*). Defect sites with reduction potentials between the conduction and valence bands can undergo radiative relaxation and cause emission at long wavelengths (deep trap emission). No deep trap emission was observed with the $(HN)_6$−FABP-nucleated CdSe nanoparticles. Se-rich trap states have been suggested as producing superoxide radicals upon prolonged photoillumination (*24*, *39*), which has been suggested to confer CdSe nanoparticle toxicity (*40*). No significant EPR-detected $O_2^{\bullet-}$ production (<0.5 μM) from aerobic O_2 was observed in DMPO-spin-trapped, $(HN)_6$−FABP nucleated CdSe nanoparticle samples that were photoilluminated for 20 min. Under the same conditions, mercaptohexadecanoate-capped CdSe nanoparticles formed from high-temperature methods produced 5 μM $O_2^{\bullet-}$ (*24*). It should be noted that the majority of CdSe materials that are soluble in solution exhibit quantum confinement effects (absorbances at higher energy than bulk CdSe) from estimates of 4−7 proteins per CdSe nanoparticle. The conclusion is that a small number of microcrystallites can be excluded by this statement and suggests that Cd-rich defect sites are responsible for the diminished emission quantum yield of $(HN)_6$−FABP-nuclated CdSe nanoparticles. Such Cd-rich defects could be expected since the role of the $(HN)_6$ domain is to bind Cd^{2+} ions, not Se^{2-} ions. The role of the protein in this process is to arrest CdSe precipitation at a specific size regime, where proteins of different sizes should change the optimal CdSe nanoparticle diameter. Since a common peptide domain used for affinity purification provides this activity, such a correlation could be readily explored.

These observations have two important implications. This finding demonstrates that a protein domain routinely fused to proteins and used for affinity purification provides the ability to bind and nucleate metallic (*20*) and metal sulfide or selenide (chalcogenide) nanoparticles. Due to the similar synthetic preparations of low molecular weight Fe- and Cd-containing chalcogenide clusters (*41*), formation of CdSe nanoparticles could be similar to heterogeneous iron sulfide species formed by low-affinity ferredoxin mimetic peptides (*42*). The work with ferredoxin mimetic peptides has shown that specific conformations must be formed to generate $[Fe_4S_4]^{2+/+}$ clusters. If the proper conformation of ligand side chains are provided, then discrete $[Fe_4S_4]^{2+/+}$ clusters are observed (*43*). In the absence of the proper peptide conformation, a brown and hard-to-purify species forms, more than likely due to a heterogeneous mixture of iron sulfur clusters attached to proteins (*42*). Phytochelatin peptides $(\gamma\text{-Glu-Cys})_n$-Gly are used by bacteria to nucleate CdS nanoparticle growth by coordinating Cd^{2+} ions without sequestering the ions from solvent (*8*). Biogenic sulfide anions assist in forming nanoparticulate CdS materials that are removed from the cell (*7*). The CdSe/$(HN)_6$ domain chemistry could be similar to CdS/phytochelatin chemistry, where peptides that coordinate Cd^{2+} ions with bridging Se^{2-} ligands facilitate the nucleation and growth of CdSe nanoparticles with multiple $(HN)_6$ fusion proteins attached (Scheme 1). The peptide drawn in Scheme 1 is a molecular model of such an initial complex (geometry-minimized, MM2 force field; see Experimental Procedures). This model shows that a conformation of the $(HN)_6$ domain is accessible for coordination and formation of a $[Cd_2Se]^{2+}$ complex ion but does not attempt to address all equilibrium conformations or energetics of the $(HN)_6$ domain. It should be noted that a low molecular weight precursor method has already been reported with $(NMe_4)_4[Cd_{10}Se_4(SPh)_{16}]$-mediated CdSe nanoparticle synthesis (*44*). An important point is that polyhistidine fusion domains both nucleate and stabilize CdSe nanoparticles so that these bioconjugates can be purified by gel filtration chromatography. Toward the rational design of proteins that nucleate and stabilize metal chalcogenide nanoparticles, this report represents a zeroth-order rational design. As low-temperature synthetic methods for crystalline metal chalcogenide nanoparticles are further developed (*18*, *19*), polyhistidine fusion proteins could be used to nucleate, functionalize, and solubilize semiconducting nanoparticles for biological assays. Thus, reagents for fluorescence imaging of small molecule concentrations could be generated by incubating the sensing protein with inorganic salt precursors.

Liposomes have become popular drug delivery vehicles and have more recently also been applied as contrast agents for molecular imaging. Most current methods for functionalization of liposomes with targeting proteins rely on reactions of amine or thiol groups at the protein exterior, which generally result in nonspecific conjugation at multiple sites on the protein. In this study, we present native chemical ligation (NCL) as a general method to covalently couple recombinant proteins in a highly specific and chemoselective way to liposomes containing cysteine-functionalized phospholipids. A cysteine-functionalized phospholipid (Cys−PEG−DSPE) was prepared and shown to readily react with the MESNA thioester of EYFP, which was used as a model protein. Characterization of the EYFP−liposomes using fluorescence spectroscopy showed full retention of the fluorescent properties of conjugated EYFP and provides a lower limit of 120 proteins per liposome. The general applicability of NCL was further tested using CNA35, a collagen-binding protein recently applied in fluorescent imaging of collagen. NCL of CNA35 thioester yielded liposomes containing ∼100 copies of CNA35 per liposome. The CNA35−liposomes were shown to be fully functional and bind collagen with a 150-fold higher affinity compared to CNA35. Our results show that NCL is an attractive addition to existing conjugation methods that allows direct, covalent, and highly specific coupling of recombinant proteins to liposomes and other lipid-based assemblies.

INTRODUCTION

Liposomes and micelles have attracted a lot of interest as drug delivery vehicles (*1*, *2*) and more recently as carriers of contrast agents (MRI, ultrasound) in molecular imaging (*3*−*5*). An important development in these fields has been the introduction of "sterically stabilized" or "stealth" liposomes that have an increased circulation time and altered biodistributions (*6*). These liposomes typically contain ∼5% PEGylated phospholipids resulting in a liposome surface with low immunogenicity and increased liposome stability (*7*−*9*). For applications in molecular imaging and targeted drug delivery, the liposomes also need to be functionalized with targeting ligands, which in most cases are proteins (e.g., antibodies) or peptides. Most current synthetic strategies to covalently couple proteins to liposomes involve either amine or thiol groups at the exterior of the protein (*10*, *11*). Although methods for direct coupling to liposomes have been reported (*12*), amine groups are commonly converted to thiol groups, which are subsequently reacted with phospholipids containing thiol reactive groups such as maleimides, activated disulfides, or iodoacetyl groups (*2*). All of these conjugation methods are nonspecific and result in conjugation at multiple sites on the protein, which sometimes also results in protein inactivation. Due to this lack of control over the conjugation site, protein conjugation is still, to some extent, a process of trial and error. An approach to circumvent the nonspecific modification of proteins is the use of so-called docking proteins as intermediates between the liposome and the targeting protein. Examples include the use of protein G as a docking site for IgG (*13*) and the use of RNase I as a docking site of proteins with a C-peptide tag (*14*−*16*). Although these approaches result in a more homogeneous presentation of targeting ligands on the liposomes, they require additional conjugation steps and depend on a noncovalent bond between targeting ligand and docking protein. To date, no general strategy is available that allows the direct covalent conjugation of liposomes to a single, precisely defined site on a recombinant protein.

Native chemical ligation (NCL) was first reported by Dawson et al. as a unique method to ligate two unprotected peptide fragments to form a native peptide bond, thereby allowing the complete chemical synthesis of large proteins (*17*, *18*). NCL is a chemoselective reaction that occurs spontaneously between a peptide with a C-terminal thioester and a peptide with an N-terminal cysteine under aqueous conditions at neutral pH. The possibilities of NCL have been extended by the development of expression systems that use self-cleavable intein domains to generate recombinant proteins with C-terminal thioester groups (*19*). NCL has been applied to attach synthetic moieties such as fluorescent dyes, biotin, isoprenyl groups, and dendrimers to recombinant proteins, and has also been used in the site-specific immobilization of proteins to surfaces (*20*−*23*). Here, we report on the application of NCL as a method to covalently couple recombinantly expressed proteins in a highly specific and chemoselective way to liposomes containing cysteine-functionalized phospholipids. While this work was in progress, Bertozzi and co-workers reported the novel synthesis of cysteine-functionalized phospholipids for the lipidation of green fluorescent protein (GFP) and subsequent incorporation of the lipidated GFP in supported lipid bilayers (*24*). The focus of our work was to explore the suitability of NCL in the

synthesis of protein−liposome conjugates, however, demonstrating for the first time that protein thioesters can be directly conjugated to cysteine-functionalized phospholipids embedded in liposomes.

EXPERIMENTAL PROCEDURES

General. Unless stated otherwise, all reagents and chemicals were obtained from commercial sources and used without further purification. Dichloromethane (DCM) was obtained by distillation from P_2O_5. 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(poly(ethylene glycol))2000] (NH_2−PEG−DSPE), 1,2-distearoyl-*sn*-glycero-3-phosphocholine (DSPC), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy-(poly(ethylene glycol))2000] (PEG−DSPE), and 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (rhodamine−DPPE) were purchased from Avanti Polar Lipids (Albaster, U.S.A.). Gd−DTPA−bis(stearylamide) was purchased from Gateway Chemical Technology (St. Louis, MO). Trityl-protected cysteine (Tr-Cys(Tr)-OH) was obtained from Bachem (Bubendorf, Switzerland). Trityl-protected succinimidyl-activated cysteine (Tr-Cys(Tr)-OSu) was prepared according to a literature procedure (*20*). UV−vis spectra were recorded on a Shimadzu Multispec 1501 spectrophotometer. Fluorescence spectra were obtained on an Edinburgh Instruments FS920 double-monochromator spectrophotometer. Primers used for all the cloning procedures were supplied by MWG (Ebersberg, Germany).

Synthesis of Cysteine-Functionalized 1,2-Distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(poly(ethylene glycol))2000] (Cys−PEG−DSPE). NH_2−PEG−DSPE (**1**) (100 mg, 35.8 μmol) was dissolved in DCM (1 mL) under an atmosphere of argon. Tr-Cys(Tr)-OSu (30 mg, 43 μmol) and triethylamine (10 μL, 71 μmol) were added to the solution. The reaction proceeded overnight at room temperature. The solution was concentrated under reduced pressure, and the crude product was dissolved in $CHCl_3$ (0.5 mL). The crude product was purified by column chromatography (silica, $CHCl_3$/MeOH, 19:1 v/v → 9:1 v/v), and trityl-protected Cys−PEG−DSPE (**2**) (44 mg, 13 μmol) was obtained in 36% yield. Compound **2** was dissolved in triethyl silane (25 μL, 158 mmol). Subsequently, a solution of trifluoroacetic acid (1 mL) and DCM (1 mL) was added. The obtained solution was stirred for 2 h at room temperature. The solution was concentrated under reduced pressure, and the crude product was precipitated in diethyl ether. The product was filtrated and dried under reduced pressure to give Cys−PEG−DSPE lipid (**3**) (34 mg, 12 μmol, 92%). Compounds **1**−**3** were analyzed in detail with RP-HPLC and MALDI-TOF (see Supporting Information).

Plasmid Constructs. The EYFP gene was amplified by PCR from vector pEYFP-N1 (Clontech) using the primers 5′-GTG GTC ATA TGG TGA GCA AGG GCG AG-3′ and 5′-GTG GTG AAT TCC TTG TAC AGC TCG TCC ATG C-3′. The CNA35 gene was amplified from pQE30CNA35 (a kind gift from Dr. Magnus Höök, Texas A & M University, U.S.A. (*25*)) using the primers 5′-GTG GTC ATA TGG GAT CCG CAC GAG ATA TTT C-3′ and 5′-GTG GTT GCT CTT CCG CAT GCC TTG GTA TCT TTA TCC TGT TTT AAA AC-3′. The PCR products and the pTXB1 vector (IMPACT system, New England Biolabs) were double-digested with the restriction endonucleases *Nde* I and *Sap* I (CNA35) or *Nde* I and *Eco*R I (EYFP) followed by ligation of the amplified DNA fragments in the open plasmids to yield pTXB1−CNA35 and pTXB1−EYFP, respectively. DNA sequencing using T7 promoter and intein-specific reversed primers (New England Biolabs) confirmed the correct in-frame fusion of the proteins with the intein sequence.

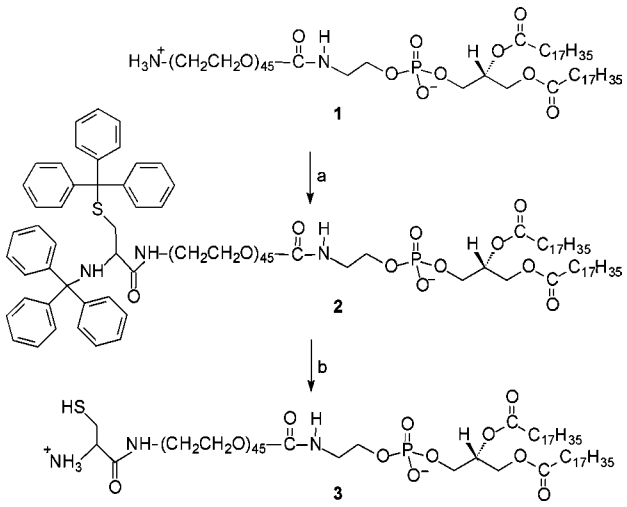
Protein Expression and Purification. The expression plasmids pTXB1−CNA35 and pTXB1−EYFP were transformed into *E. coli* BL21 (DE3) cells. The same expression conditions were used for both proteins. Bacteria were grown in LB medium containing 100 μg/mL ampicillin at 37 °C and 250 rpm to an optical density (OD_{600nm}) between 0.6 and 0.8. Protein expression was induced with 0.5 mM IPTG, and the cultures were incubated overnight at 15 °C. Cells were harvested by centrifugation for 30 min at 8000 *g* at 4 °C. The supernatant was removed, and the cell pellet was resuspended using the BugBuster protocol (Novagen). After incubation for 20 min at room temperature, the cell suspension was centrifuged at 16 000 *g* for 20 min at 4 °C. The supernatant was directly applied to a column of chitin beads and equilibrated with 10 column volumes of column buffer (20 mM sodium phosphate, 0.1 mM EDTA, 0.5 M NaCl, pH 8). The column was washed with 10 volumes of column buffer after which the column was quickly flushed with 3 column volumes of cleavage buffer (20 mM sodium phosphate, 0.1 mM EDTA, 0.5 M NaCl, pH 6) containing 50 mM sodium 2-mercaptoethanesulfonate (MESNA) and incubated overnight at room temperature. Elution fractions were collected and pooled, after which the cleavage step was repeated to gain more thioester-terminated proteins. The proteins were buffer-exchanged into 10 mM HEPES, 135 mM NaCl, pH 8.0 (HBS) using Amicon ultracentrifuge tubes (MWCO 10 kDa). The concentrations of EYFP protein with a C-terminal MESNA thioester (EYFP−MESNA) and CNA35 protein with a C-terminal MESNA thioester (CNA35−MESNA) were determined by UV−vis using $\epsilon_{514nm} = 84\ 000\ M^{-1}\ cm^{-1}$ (*26*) and $\epsilon_{280nm} = 33\ 167\ M^{-1}\ cm^{-1}$, respectively. 1 L *E. coli* culture typically yielded 20 mg of EYFP−MESNA and 40 mg of CNA35−MESNA.

Ligation of EYFP to Pure Cysteine-Functionalized Phospholipids. Cys−PEG−DSPE lipid **3** was dissolved in buffer containing 200 mM sodium phosphate, 200 mM NaCl, pH 7.2. Native chemical ligation reactions were performed in 200 μL with a final concentration of EYFP−COSR of 87 μM. A 10-fold molar excess of compound **3** (final concentration 870 μM) was used. 1% (v/v) benzyl mercaptan and 1% (v/v) thiophenol, or 100 mM MESNA, were added to the ligation mixtures. After overnight incubation at room temperature, the samples were centrifuged to remove precipitate, and the supernatant was analyzed using SDS-PAGE.

Liposome Preparation. Liposomes were prepared by lipid film hydration as described previously (*27*). A mixture of DSPC (37 μmol), Gd−DTPA−bis(stearylamide) (25 μmol), cholesterol (33 μmol), PEG−DSPE (2.5 μmol), rhodamine−DPPE (0.1 μmol), and Cys−PEG−DSPE (2.5 μmol) was dissolved in $CHCl_3$/MeOH 1:1 (v/v) and concentrated under reduced pressure at room temperature. The obtained lipid film was hydrated in HBS buffer (4 mL). This dispersion was extruded five times at 65 °C through polycarbonate membrane filters with pores of 100 or 200 nm. Phospholipid concentrations were determined by phosphate analysis according to Rouser (*28*). The amount of lipids per liposome was calculated using a lipid surface area of 0.6 nm^2 (*29*) and assuming unilamellar liposomes.

Ligation of EYFP to Cysteine−Liposomes. Native chemical ligation of cysteine−liposomes (450 μM Cys−PEG−DSPE) with EYFP−MESNA (33 μM) was performed for 48 h at 20 °C in HBS, pH 8, containing either 100 mM MESNA or 1% (v/v) thiophenol and 1% (v/v) benzyl mercaptan. The coupling efficiency was monitored via SDS-PAGE analysis. The amount of lipidated EYFP was calculated by scanning of the SDS-PAGE gel and integration of the bands of unreacted and reacted protein. The liposome concentration was calculated from the lipid concentration that was determined via phosphate analysis using the assumption of unilamellar liposomes. The number of EYFP proteins per liposome was then obtained by dividing the concentration of lipidated EYFP by the liposome concentration.

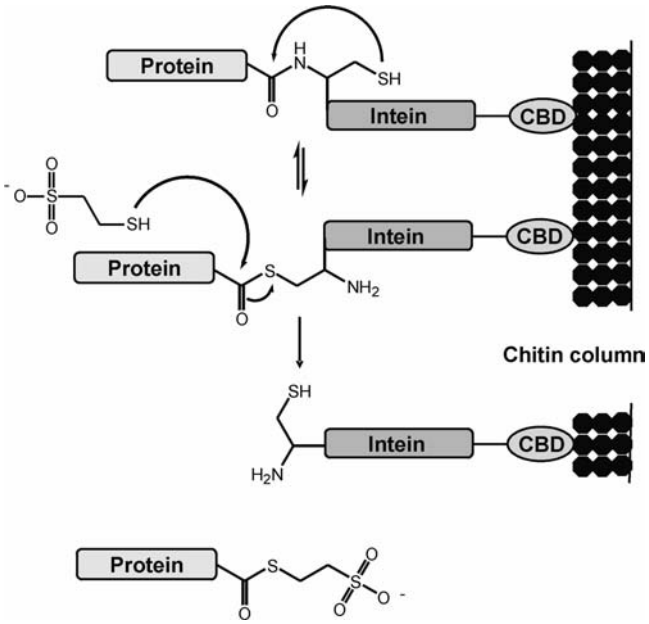
The EYFP−liposomes were ultracentrifuged in a Kontron Centrikon T-2060 ultracentrifuge with a TFT 70.38 rotor for 1 h at 270 000 *g* and 20 °C, after which the liposomal pellet was resuspended in HBS. Pellet and supernatant were analyzed using SDS-PAGE to confirm the separation between reacted and unreacted protein. The incorporation of EYFP was also established using fluorescence spectroscopy. Emission spectra of EYFP−liposomes were measured using an excitation wavelength of 490 nm. The ratio of the EYFP (527 nm) and rhodamine (590 nm) peaks in the emission spectrum was compared to a calibration curve with known molar ratios of EYFP to rhodamine, thus providing an alternative method to determine the amount of EYFP per liposome.



Ligation of CNA35 to Cysteine−Liposomes. Native chemical ligation of cysteine−liposomes (180 μM Cys−PEG−DSPE) with CNA35 thioester (50 μM) was performed for 24 h at 20 °C in HBS, pH 8, containing 100 mM MESNA. The amount of lipidated CNA35 was calculated by scanning the SDS-PAGE gel and integrating the bands of unreacted and reacted protein. The liposome concentration was calculated from the lipid concentration that was determined via phosphate analysis using the assumption of unilamellar liposomes. The amount of lipidated CNA35 was divided over the liposome concentration to determine the number of CNA35 proteins per liposome. Ultracentrifugation of CNA35−liposomes was performed in a Kontron Centrikon T-2060 ultracentrifuge with a TFT 70.38 rotor for 1 h at 270 000 *g* and 20 °C. The obtained liposomal pellet was resuspended in HBS. Pellet and supernatant were analyzed using SDS-PAGE to confirm the separation between reacted and unreacted protein. The concentration of CNA35 in the liposome fraction was determined with the Quant-iT Protein Assay Kit (Invitrogen) according to manufacturer instructions. This amount of lipidated CNA35 was divided by the liposome concentration to determine the number of CNA35 proteins per liposome.

Collagen Binding Assay. 96 well Corning EIA/RIA microplates were coated overnight at 4 °C with 1.4 μg/well (45 μL) rat tail collagen type I (Sigma, C7661) in TBS (50 mM Tris, 150 mM NaCl, pH 7.5). After overnight incubation, the plates were blocked with 100 μL TBS containing 5% (w/v) skim milk powder for 2 h at room temperature. After washing the plates 3 times with 300 μL TBS, the plates were incubated with CNA35−liposomes or nonmodified liposomes in HBS supplemented with 5% (w/v) skim milk powder for 3 h at room temperature. Plates were washed 5 times with 50 mM Tris, 500 mM NaCl, pH 7.5, and subsequently washed 2 times with TBS. The fluorescence of the rhodamine-containing liposomes was measured at 620 nm in triplicate on a Thermo Fluoroskan Ascent FL plate reader after excitation at 578 nm.

RESULTS AND DISCUSSION



In order to use native chemical ligation as a site-specific method to prepare protein−liposomes, the PEG terminus of PEG−DSPE was functionalized with a cysteine containing a free amine group. The introduction of the reactive group at the end of the PEG chain (far removed from the lipid tail) has been reported to enhance ligation efficiencies (*30*) and was also applied in previous work using maleimide-functionalized phospholipids (*27*, *31*). Cys−PEG−DSPE (**3**) was obtained in a two-step synthesis starting from the commercially available 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(poly(ethylene glycol))2000] (**1**) (Scheme 1). In the first step, the amine end group of **1** was reacted with succinimidyl-activated trityl-protected cysteine to yield intermediate **2** in 36% yield. The second step involved deprotection of the cysteine using trifluoroacetic acid (TFA) to give Cys−PEG−DSPE **3** in 92% yield, which was confirmed using RP-HPLC and MALDI-TOF (see Supporting Information).

Scheme 2. Synthesis of Thioester-Terminated Proteins Using Self-Cleavable Intein Domains

Enhanced yellow fluorescent protein (EYFP) was chosen as a model protein to study the performance of Cys−PEG−DSPE in native chemical ligation reactions. The fluorescence of EYFP depends on proper folding of the protein and can thus be used to assess protein stability after ligation. In addition, fluorescence can be used to determine the amount of proteins conjugated per liposome. A C-terminal fusion protein of EYFP with intein and chitin binding domains was expressed in *E. coli* using the IMPACT system. The fusion protein was purified on a chitin resin and treated with 50 mM MESNA to induce the intein-catalyzed cleavage of the fusion protein and the formation of EYFP with a C-terminal MESNA thioester (EYFP−MESNA) (Scheme 2). SDS-PAGE and ESI-MS analysis (see Supporting Information) showed the presence of a single protein with a mass of 27 849 Da that corresponds to the calculated mass of EYFP−MESNA (theoretical mass: 27845.2 Da). We first studied the reaction of pure Cys−PEG−DSPE (not incorporated in a liposome) with EYFP−MESNA in the presence of two different thiol catalysts, thiophenol/benzyl mercaptan and MESNA. Since ligation of Cys−PEG−DSPE to EYFP increases its molecular weight by approximately 3 kDa, the ligation reaction could be monitored

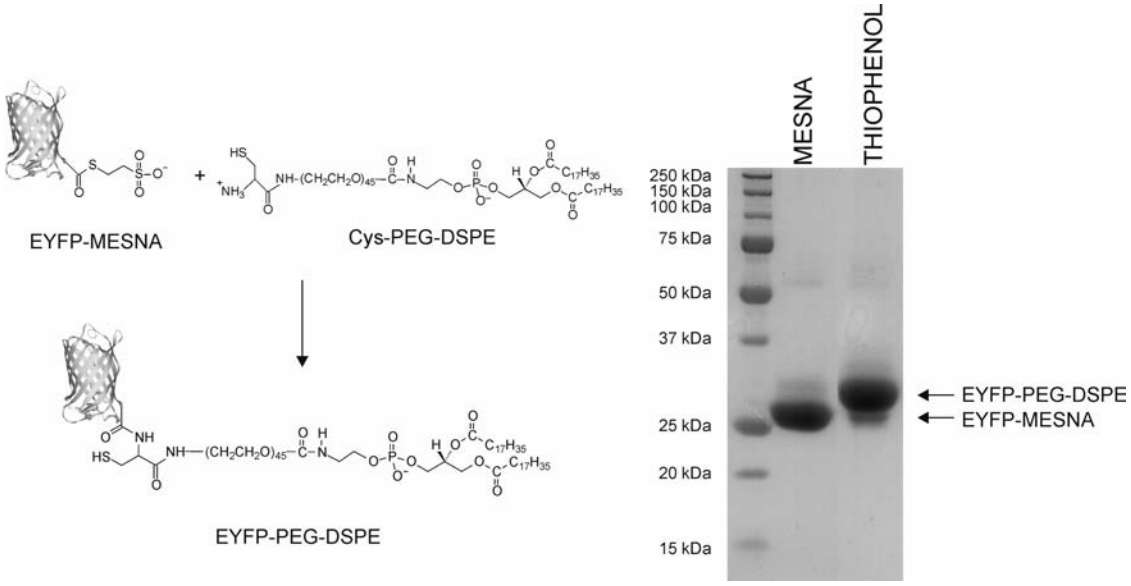

Figure 1. Native chemical ligation of Cys−PEG−DSPE **3** (870 μM) with EYFP−MESNA (87 μM) in 0.2 M sodium phosphate pH 7.2 with either 100 mM MESNA or 1% (v/v) thiophenol + 1% benzyl mercaptan (THIOPHENOL).

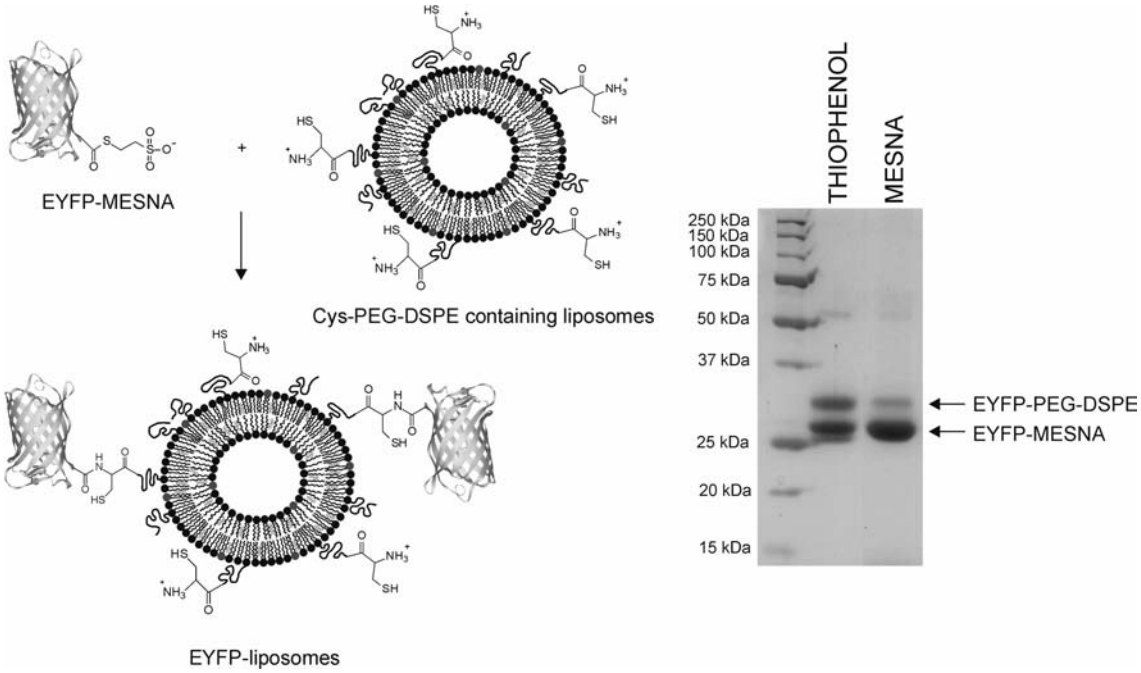

Figure 2. Native chemical ligation of liposomes containing Cys−PEG−DSPE (450 μM cysteine−lipid) with EYFP−MESNA (33 μM) in HBS pH 8 with either 100 mM MESNA or 1% (v/v) thiophenol + 1% benzyl mercaptan (THIOPHENOL).

using SDS-PAGE. Nearly quantitative reaction of EYFP to the lipidated form of EYFP (EYFP−PEG−DSPE) was observed in the presence of thiophenol, whereas a much lower conversion (∼5%) was obtained using MESNA as the catalyst (Figure 1). Since PEGylated phospholipids such as Cys−PEG−DSPE are known to form relatively stable micelles (*32*), the ligation reaction probably resulted in the formation of EYFP micelles. We are currently characterizing the properties of these putative protein micelles.

Having established the suitability of Cys−PEG−DSPE in native chemical ligation reactions, we next tested whether the same native chemical ligation can also be performed when Cys−PEG−DSPE is incorporated into liposomes. Liposomes containing 2.5% of Cys−PEG−DSPE, Gd−DTPA−bis(stearylamide) lipids, and rhodamine-functionalized lipids were prepared by lipid film hydration as described previously (*27*). We again compared thiophenol/benzyl mercaptan and MESNA as catalysts and monitored the reaction using SDS-PAGE. Figure 2 clearly shows the presence of lipidated EYFP proteins upon reaction of 33 μM EYFP−thioester with 450 μM liposome-embedded Cys−PEG−DSPE. To the best of our knowledge, this is the first report that describes the direct coupling of proteins to liposomes via native chemical ligation. Although the ligation reaction is more efficient in the presence of thiophenol/benzyl mercaptan (conversion ≈ 30%) than in the presence of MESNA (conversion ≈ 10%), the use of MESNA has important advantages, in particular, when working with lipid-based systems. Thiophenol and benzyl mercaptan are poorly water soluble and are likely to accumulate in the phospholipid bilayer of liposomes, making it almost impossible to remove these toxic compounds after the ligation reaction. MESNA is a water-soluble thiol with a nonoffensive odor compared to thiophenol and benzyl mercaptan, and is easily removed after ligation via centrifugation.

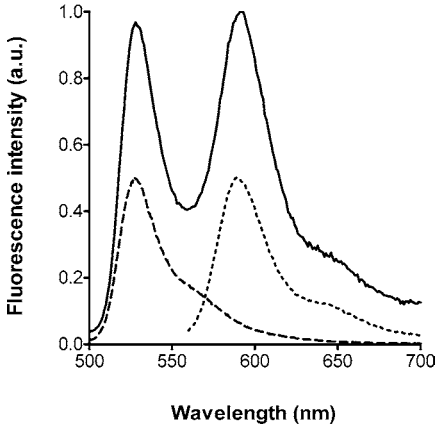

Figure 3. Emission spectrum of EYFP−liposome conjugates using an excitation wavelength of 490 nm (solid line). The emission spectra of EYFP−MESNA (dashed line) and nonmodified rhodamine-containing liposomes (dotted line) are also shown for comparison.

To prove that the lipidated EYFP observed in SDS-PAGE was still attached to the liposomes, liposomes were separated from unreacted EYFP via ultracentrifugation. SDS-PAGE analysis showed that all of the unreacted EYFP was present in the supernatant, whereas most of the lipidated EYFP was found associated with the liposomal pellet (see Supporting Information). Fluorescence spectroscopy was used to determine the number and proper folding of the conjugated EYFP proteins. The fluorescence emission spectrum of the EYFP−liposomes showed peaks at 527 and 590 nm, corresponding to EYFP and rhodamine, respectively (Figure 3). The observation of EYFP fluorescence not only demonstrates that the protein kept its native fold after ligation, but the relative intensity of the EYFP fluorescence compared to the rhodamine fluorescence can also be used to estimate the number of EYFP proteins per liposome. The ratio of EYFP to rhodamine was compared to a calibration curve with known molar ratios of EYFP to rhodamine, yielding approximately 120 proteins per 200 nm liposome. Another method to estimate the number of proteins per liposome is to calculate the amount of lipidated protein from the relative intensities of lipidated and non-lipidated protein bands on the SDS-PAGE gel obtained after NCL, and divide this number by the original liposome concentration. This calculation assumes that all lipidated protein is incorporated into liposomes and yielded 180 EYFP per 200 nm liposome.

Although EYFP is a good model protein to prove that proteins can be conjugated to liposomes via native chemical ligation, we also wanted to use a biomedically relevant protein with a specific binding function. We recently developed a collagen-specific fluorescent probe based on a collagen-binding protein domain (CNA35) from the bacterial adhesion protein of *Staphylococcus aureus* (*33*). Solid-phase binding assays showed a dissociation constant of approximately 0.5 μM for collagen type I. In addition to providing an example of a targeted liposomal contrast agent, we were also interested to see whether attachment of multiple CNA35 proteins to a liposomal scaffold would yield a probe with a higher affinity for collagen due to multivalent interactions between CNA35 and collagen.

The IMPACT expression vector pTXB1 was again used to obtain recombinant CNA35 with a C-terminal MESNA thioester (Scheme 2). An alanine residue was added to the C-terminus of CNA35 during cloning, as this residue is known to enhance the rate of native chemical ligation reactions (*18*). Affinity purification on a chitin column and subsequent cleavage with MESNA yielded CNA35−MESNA in excellent yield. SDS-PAGE analysis typically showed the presence of several smaller bands besides the major band at 35 kDa, which are probably degradation products of CNA35 (Figure 4). ESI-MS showed a single protein peak with a mass of 34 757 Da (theoretical mass: 34774 Da). Collagen-binding assays using fluorescently labeled CNA35−MESNA showed that the modified C-terminus did not affect the collagen-binding properties.

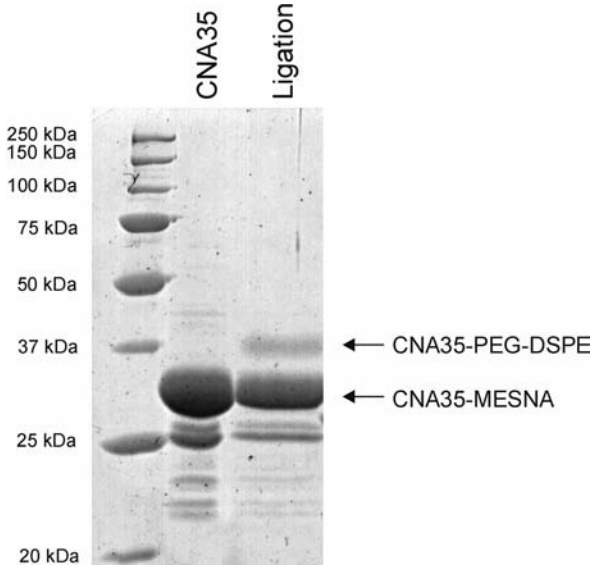

Figure 4. SDS-PAGE analysis of CNA35−MESNA before and after native chemical ligation to liposomes containing Cys−PEG−DSPE.

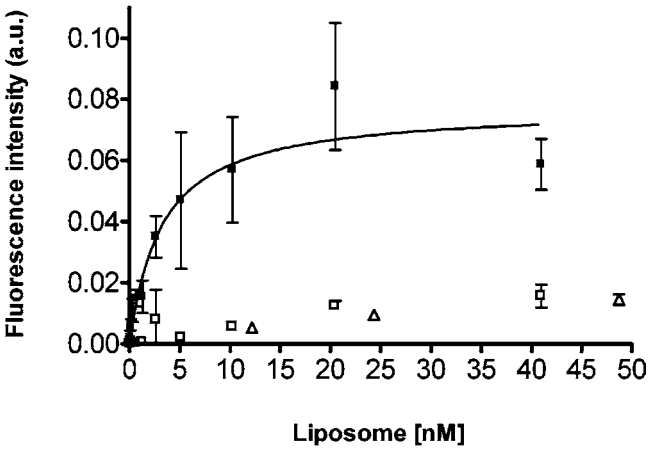

Figure 5. Solid-phase binding assay of CNA35−liposomes to rat tail collagen type I (solid squares). Liposome binding was monitored by measuring the fluorescence of the rhodamine lipids at 620 nm using an excitation of 578 nm. Control experiments using nonmodified liposomes incubated on rat tail collagen type I (open triangle) and CNA35−liposomes incubated on milk-powder blocked well without collagen (open squares) are also shown for comparison. The solid line represents a fit to a 1:1 binding model using a K_d of 3 nM.

CNA35−MESNA was ligated to liposomes using the same procedure as described for EYFP using MESNA as a catalyst. SDS-PAGE analysis again indicated the formation of lipidated protein by the appearance of a new band at approximately 38 kDa (Figure 4). CNA35-modified liposomes were separated from MESNA and unreacted CNA35 by two ultracentrifugation steps (see Supporting Information). A protein quantification assay was used to determine the amount of protein in the liposome fraction. This protein concentration was divided by the known liposome concentration, yielding ~100 proteins per 100 nm liposome. This number is in reasonable agreement with the amount of lipidated CNA35 that was detected by SDS-PAGE analysis immediately after ligation, which gave ~80 CNA35 proteins per 100 nm liposome. The rhodamine fluorescence of the CNA35-functionalized liposomes was used to study their binding to a collagen-coated 96 well plate. Figure 5 shows specific binding of these liposomes to rat tail collagen type I at

low nanomolar concentrations. Control experiments using nonfunctionalized liposomes or plates without collagen did not show a similar signal. A fit of the binding curve using a simple 1:1 binding model yielded a K_d of 3 ± 1 nM, representing a 150-fold increase in affinity compared to the protein itself. These results show that CNA35 conjugated to liposomes via native chemical ligation is fully active in binding collagen. Whether the observed increase in collagen affinity is due to multiple, simultaneous interactions between probe and collagen or mainly a statistical effect due to the presence of ~100 copies of protein per liposome remains to be investigated.

In summary, we have demonstrated that native chemical ligation is an attractive method to directly conjugate recombinantly expressed proteins to sterically stabilized poly(ethylene glycol) liposomes via cysteine-functionalized phospholipids. In contrast to other conjugation methods such as thiol−maleimide reactions, NCL is highly specific and exclusively occurs at the protein's C-terminus, which in most proteins is not important for binding activity. An additional advantage of NCL is that only a single site in the protein is available for conjugation, whereas cross-linking is sometimes observed between liposomes and proteins using classical thiol/amine chemistries (*34*). The strategy reported here for liposomes should be readily applicable to other lipid-based imaging agents such as immunomicelles (*35*), iron oxide nanoparticles (*31*, *36*), and quantum dots with a lipid coating (*37*−*40*).

ACKNOWLEDGMENT

This study was funded by the BSIK program entitled Molecular Imaging of Ischemic Heart Disease (project number BSIK03033). The authors thank Anouk Dirksen for help with the synthesis of the cysteine-functionalized lipid, Marieke Rensen for constructing pTXB1-EYFP, Ingrid van Baal for supplying trityl-protected succinimidyl-activated cysteine, Erik Sanders for providing assistance with liposome preparation and characterization, and Bert Meijer, Klaas Nicolay, and Gustav Strijkers for general support.

Supporting Information Available: Experimental details including the RP-HPLC and MALDI-TOF analysis of the synthesized phospholipids, ESI-MS spectra of EYFP-MESNA and CNA35-MESNA, and SDS-PAGE analysis of the purification of EYFP-MESNA, CNA35-MESNA, EYFP-liposomes, and CNA35-liposomes. This material is available free of charge via the Internet at http://pubs.acs.org/BC.

Convenient Synthesis of Maleimido-Derivatized Lanthanide(III) Chelates and Their Use in Mercapto Group Conjugation

Jari Hovinen

PerkinElmer Life and Analytical Sciences, Turku Site, POB 10, FIN-20101 Turku, Finland. Received September 11, 2006; Revised Manuscript Received December 18, 2006

Simple synthesis of luminescent europium(III) and terbium(III) chelates tethered to a maleimido function (**7**, **8**) is described. The method is based on the following: (i) synthesis of protected ligands tethered to a maleimido function and their purification on silica gel; (ii) deprotection by acidolysis; (iii) conversion of the deprotected ligands to the corresponding lanthanide(III) chelates by passing them through a column of strong cation exchange resin loaded with the appropriate lanthanide(III) ions. According to this procedure, large quantities of mercapto-selective biomolecule-labeling reactants of high purity can be prepared.

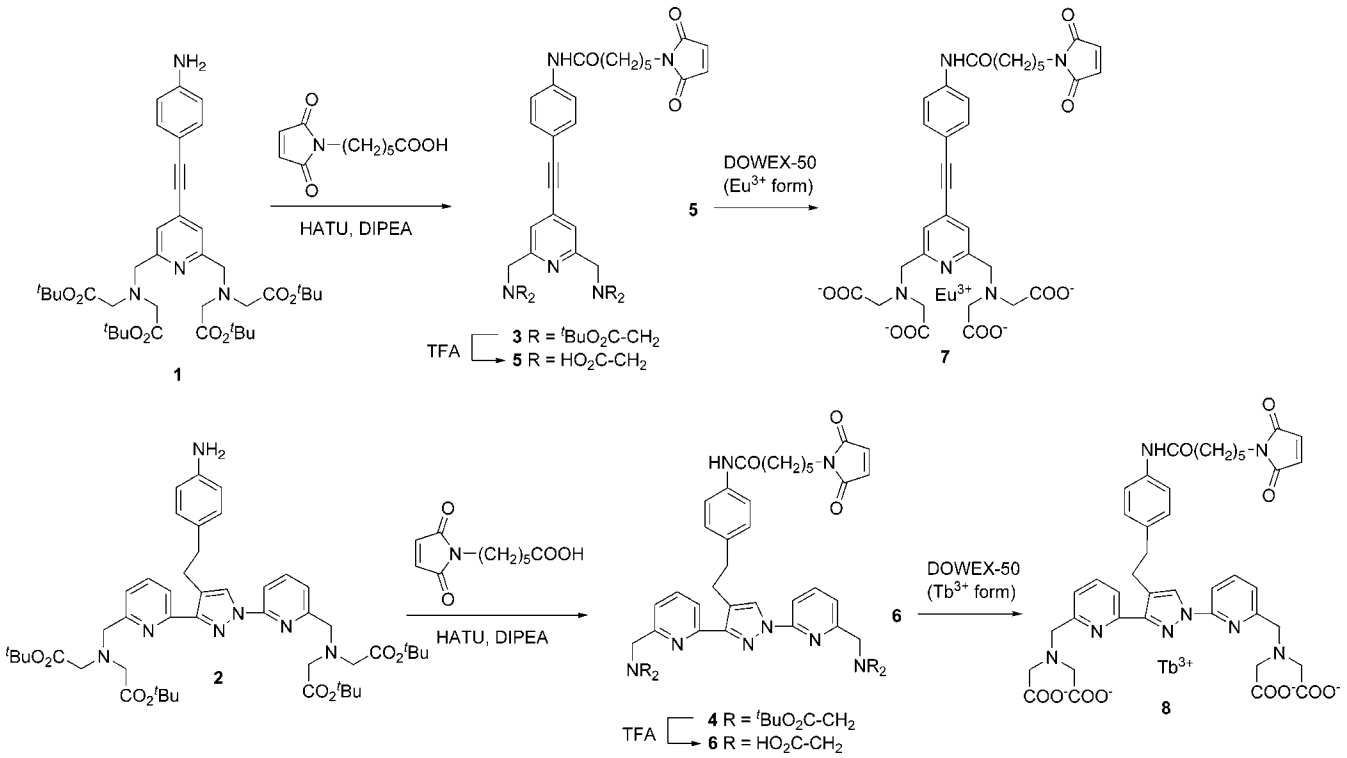
The unique fluorescence properties of lanthanide(III) chelates, such as the long fluorescence delay after excitation of these molecules, very sharp emission lines, and large Stokes shift (i.e., the difference in the chelate's excitation and emission lines) have been widely exploited in assays based on time-resolved fluorescence (*1*−*4*). Indeed, lanthanide(III) chelates have been used in *in vitro* diagnostics over two decades. The excellent fluorescence properties of luminescent lanthanide(III) chelates can be exploited particularily in homogeneous assays, where the use of conventional chromophores causes a very high background signal. The different photochemical properties of europium, terbium, dysprosium, and samarium chelates enable development of multiparametric homogeneous assays. Accordingly, numerous highly luminescent lanthanide(III) chelates have been synthesized and used especially in assays based on fluorescence resonance energy transfer and fluorescence quenching (*5*−*11*).

In order to exploit lanthanide(III) chelates in bioaffinity assays, these molecules have to be linked covalently to bioactive molecules. This can be done in solution by allowing the appropriately activated chelates to react with functional groups of the bioactive molecules (*12*−*16*). Alternatively, the bioactive molecules can be labeled on solid phase using appropriately derivatized building blocks which can be introduced to the biomolecule structure using oligonucleotide (*17*−*19*) and oligopeptide (*20*, *21*) synthesizers.

Although solid-phase labeling has several advantages, solution-phase labeling of large biomolecules such as proteins cannot be avoided. In these cases the labeling reaction has to be as effective and selective as possible.

Thiols are known to react with haloacetamides, maleimides, disulfides and their analogues, mercurials, vinyl sulfones, aryl halides, aziridines, and oxiranes (*22*). For the coupling purposes, the reactions of haloacetamides, maleimides, and disulfides are the most commonly employed. Several mercapto-selective labels are currently commercially available. From them, the haloacetyl derivatives display a wide range of other reactivities, while disulfides are practically completely specific to thiols. The reactivity of maleimides is between them. The problem of the use of disulfides is the lability of the bioconjugate in the presence of reducing agents which are often present in the conjugation reaction. Because of the high reactivity of haloacetamides, the pH of the conjugation reaction has to be carefully controlled. At too low pH, the reaction is slow, while at too high pH, amino functions, often abundantly present in the bioactive molecule to be labeled, compete with the target mercapto function for the label. Furthermore, to avoid oxidation of the mercapto function to be labeled, the labeling reaction has to be performed in the presence of a reducing agent, most commonly tris(carboxyethyl)phosphine (TCEP). The reducing agent, in turn, reacts with the haloacetamido chelate, markedly decreasing the yield of the desired biomolecule conjugate. Accordingly, labeling using maleimido chemistry might be the method of choice.

The known mercapto-selective luminescent lanthanide(III) chelates are haloacetamido or maleimido derivatives (*23*−*25*). They have been synthesized by allowing the corresponding amino chelates or ligands to react with the appropriate activating agents. Since lanthanide(III) chelates are highly hydrophilic molecules, their purification is rather laborious, often including HPLC purifications and various precipitation procedures. Here is described an alternative method for the preparation of lanthanide(III) chelates tethered to a maleimido group. Also their suitability to biomolecule derivation is demonstrated.



EXPERIMENTAL PROCEDURES

General Methods. Adsorption column chromatography was performed on columns packed with silica gel 60 (Merck). HPLC purifications were performed using a Shimadzu LC 10 AT instrument equipped with a diode array detector, a fraction collector, and a reversed phase column (LiChrocart 125-3 Purospher RP-18e 5 μm). Mobile phase (Buffer A): 0.02 M triethylammonium acetate (pH 7.0); (Buffer B): A in 50% (v/v) acetonitrile. Gradient: from 0 to 1 min 95% A, from 1 to 21 min from 95% A to 100% B. Flow rate was 0.6 mL min^{-1}. The cation exchange resin (Dowex 50 × 8, 20−50 mesh, H^+ form) was converted to the Ln^{3+} form by treatment with the approriate lanthanide(III) chloride followed by washing with distilled water until pH of the eluent was neutral. 6-Maleimidocaproic acid and the model peptide (CVEIDK) were purchased from Fluka and Sigma-Genosys, respectively. NMR spectra were recorded on a Bruker 250 spectrometer operating at 250.13 MHz for ^{1}H. TMS was used as an internal reference. Coupling constants are given in hertz. ESI-TOF mass spectra were recorded on an Applied Biosystems Mariner instrument.

2,2′,2″,2‴-{4-(4-(6-Maleimidohexylcarboxamido)phenylethynyl)pyridine-2,6-diyl]bis(methylenenitrilo)}tetrakis-(acetic acid) Europium(III), 7. Compound **3** (50 mg, 0.055 mmol) was dissolved in trifluoroacetic acid (1 mL) and stirred for 2 h at RT before being concentrated *in vacuo*. The residue was triturated with diethyl ether, and the solid material was collected by filtration, washed with diethyl ether, and dried *in vacuo*. It was then dissolved in water (pH adjusted to ca. 7 with Na_2CO_3), and passed through a Dowex-50 resin (Eu^{3+} form) using distilled water as the eluent. Fractions containing the desired chelate were pooled and concentrated to ca. half volume. Precipitation from acetone afforded the title compound as a powder. ESI TOF MS for $C_{33}H_{31}EuN_5O_{11}$ $(M)^-$ calcd, 826,12; obsd, 826.12

2,2′,2″,2‴-{{6,6′-{4″-2-[4-(6-(2,5-Dioxo-2*H*-pyrrol-1(5*H*)-yl)hexyl)carboxamidophenyl)ethyl]pyrazole-1″,3″-diyl}-bis(pyridine)-2,2′-diyl}bis(methylenenitrilo)}tetrakis(acetic acid) Terbium(III), 8. Compound **4** was converted to the title compound as described above but using Dowex 50-resin loaded with Tb^{3+}. ESI TOF MS for $C_{41}H_{40}$ $N_8O_{11}Tb^-$ $(M)^-$ calcd, 979.21, obsd, 979.22.

Labeling of the Oligopeptide with the Europium Chelate 7. The model peptide (Ac-CVEIDK-$CONH_2$) (1 mg, 1.3 μmol) was dissolved in Tris-HCl buffer (1 mL; pH 7). Compound **7** (1 equiv) was added, and the reaction was allowed to proceed for 1 h at RT. Purification on HPLC yielded the desired oligopeptide conjugate. t_R 18.14 min. ESI TOF MS for $C_{64}H_{85}$ $EuN_{13}O_{22}S$ $(M)^-$, calcd, 1572.49; obsd, 1572.67.

RESULTS AND DISCUSSION

Preparation of maleimido-functionalized europium(III) and terbium (III) chelates is shown in Scheme 1. Accordingly, reaction of the amines (**1**, **2**) with preactivated 6-maleimidocaproic acid gave the protected ligands (**3**, **4**) in excellent yield. Purification was easily performed on silica gel column chromatography. It is worth noting that preparation of **3** requires the use of a powerful activator such as *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) due to the low nucleophilicity of the aromatic amino function of **2**. Treatment of the protected ligands (**3**, **4**) with trifluoroacetic acid yielded the corresponding iminoacetic acid derivatives (**5**,

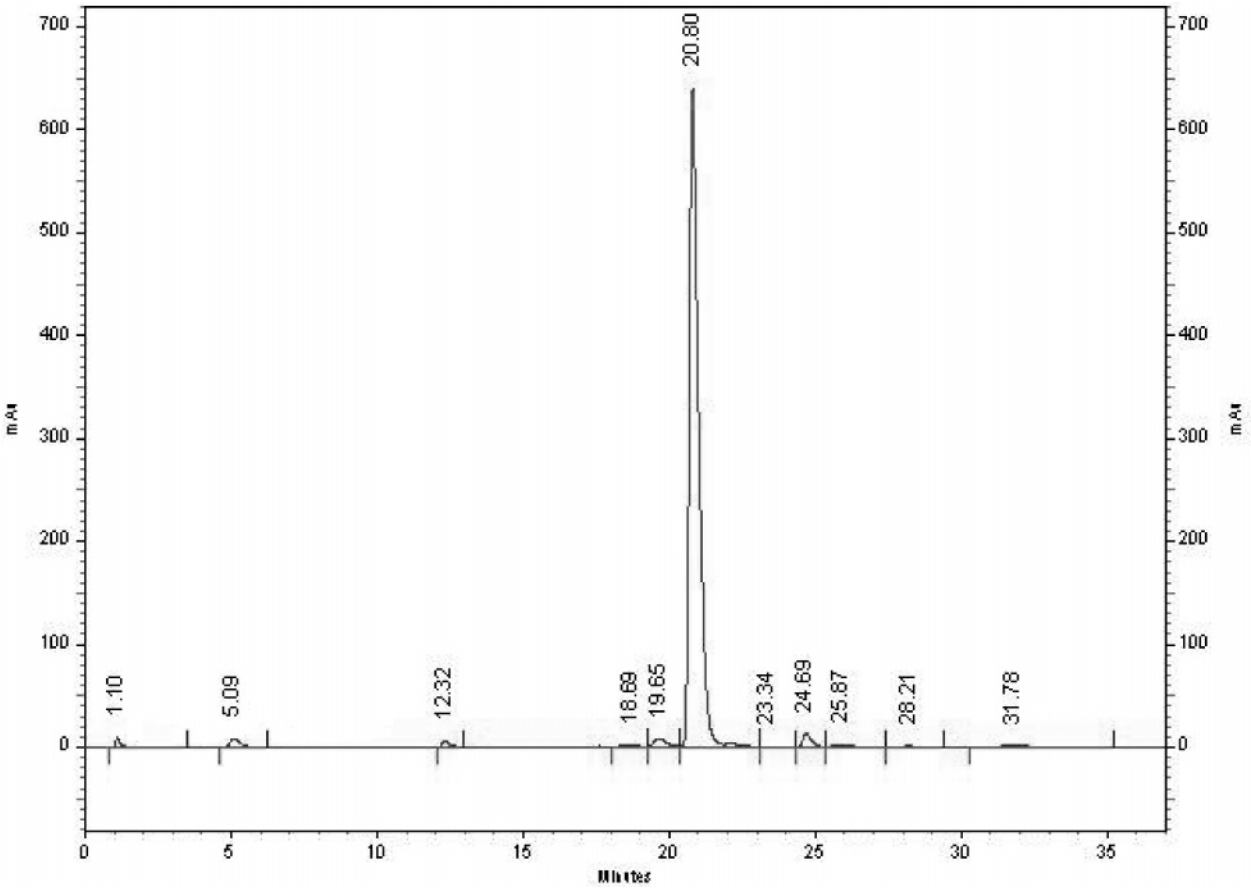

Figure 1. A reversed phase HPLC trace of a luminescent europium(III) chelate tethered to a maleimido group (**7**) synthesized according to the method described, detected at 300 nm. The peak at t_R 20.80 min is the desired product as jugded on ESI-TOF MS. For chromatographic conditions, see Experimental Procedures.

6). As expected (*28*), the maleimido function was completely stable during cleavage of the *tert*-butyl groups.

Lanthanide(III) chelates are most commonly prepared by treatment of the free ligands with a slight excess of lanthanide chloride at pH 6−7. When the chelation is completed, the excess of lanthanide is conveniently removed by increasing pH of the reaction mixture to ca. 11 where the uncomplexed lanthanide precipitates as lanthanide(III) hydroxide. However, this procedure cannot be used in the present case, since the maleimido function is known to hydrolyze in basic conditions (*29*). Here, the ligands were conveniently converted to the corresponding lanthanide(III) chelates (**6**, **7**) simply by passing through a strong cation exchange resin loaded with Eu^{3+} and Tb^{3+} ions for **4** and **5**, respectively. The chelates were analyzed on mass spectrometry, and the observed molecular weights were in accordance with the proposed structures.[1] A typical HPLC trace of the maleimido chelate after treatment with Dowex-50 resin is shown in Figure 1.

In order to demonstrate the suitability of the maleimido-derivatized lanthanide(III) chelates to biomolecule derivatization **7** was allowed to react with Caspase-6 subtrate at pH 6.5. The reaction was completed in a few minutes at ambient temperature. The reaction was clean, and the desired peptide conjugate was purified on reversed-phase HPLC and characterized by ESI-TOF mass spectrometry.

CONCLUSIONS

Here is presented a convenient method for the preparation of maleimido-derivatized lanthanide(III) chelates. The maleimido tether is coupled to protected ligands giving rise to hydrophobic, stable intermediates which can be synthesized in large scale and purified on classical silica gel column chromatography. When desired, the protecting groups can be removed with acidolysis, and the free ligands can be converted to the corresponding lanthanide(III) chelates simply by passing through a cation exchange resin loaded with the appropriate lanthanide(III) ions.

On the Unusual Stability of Succinimidyl Esters in pNIPAm-AAc Microgels

Justin D. Debord and L. Andrew Lyon*

School of Chemistry and Biochemistry & Petit Institute for Bioengineering and Bioscience, Georgia Institute of Technology, Atlanta, Georgia 30332-0400 . Received August 9, 2006; Revised Manuscript Received October 5, 2006

In this contribution, we describe the effects of amide coupling reactions on the physical properties of thermoresponsive hydrogel microparticles (microgels). These microgels, when treated *via* aqueous carbodiimide/sulfo-succinimide coupling protocols, displayed a dramatic modulation of the microgel phase transition thermodynamics. UV spectrophotometry was used to determine that this modulation was due to remarkably stable hydrogel conjugates of sulfo-NHS that resisted degradation under standard hydrolysis protocols. These intermediates result in a shift of the phase transition, along with a large increase in equilibrium microgel swelling degree, due to an increase in chain−chain Coulombic repulsion. Only aggressive hydrolysis protocols resulted in the recovery of the native microgel phase transition, suggesting that an unusually stable succinimidyl ester is formed in the microgel during coupling.

INTRODUCTION

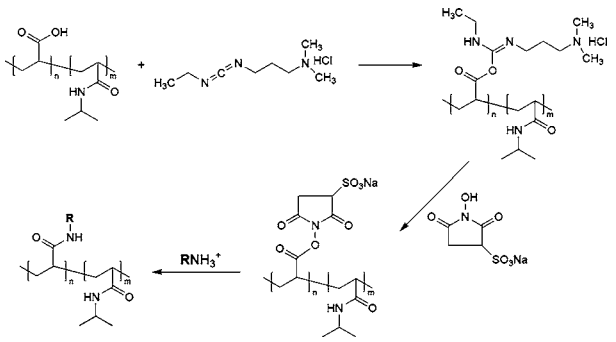
Protein−polymer hybrid materials have been of great interest for some time, especially in the areas of drug delivery (*1*), the modulation of protein:ligand binding (*2*), biosensing (*3*, *4*), and chromatography (*5*). Awareness has also been increasing in the use of thermoresponsive polymers for responsive biomaterials (*6*). Our group has worked extensively on bioconjugates of hydrogel microparticles and nanoparticles (microgels) (*3*, *4*, *6*−*8*) and through the course of these studies has observed unusual phenomena when "standard" amide bond-forming conjugation protocols are used. Therefore, a series of investigations was initiated to more completely study these phenomena. In the course of this investigation it was discovered that the use of *N*-hydroxysulfosuccinimide (sulfo-NHS) in a carbodiimide coupling scheme (*9*) resulted in a dramatic modulation of the microgel phase transition thermodynamics. We report that these effects are due to unusually stable polymer-conjugated succinimidyl ester moieties that persist for many months in aqueous media and are resistant to standard methods of NHS ester hydrolysis. These results may have significant implications for how bioconjugation strategies are developed for complex nanomaterials such as porous, amphiphilic hydrogel particles.

Thermoresponsive microgels such as those composed of poly(*N*-isopropylacrylamide) (pNIPAm) and acrylic acid (AAc) are discussed extensively elsewhere (*10*−*12*). The presence of acrylic acid monomers in the microgels provides a means to form an amide bond with an amine (*9*). Specifically, the water-soluble carbodiimide reagent 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide HCl (EDC) is useful in that it allows for the formation of amide linkages between amine substituents on a molecule (e.g., protein, ligand, fluorescent tag, etc.) and the carboxylic acid incorporated via the acrylic acid in the microgel (*3*, *13*, *14*).

This coupling procedure is essentially the aqueous phase version of the standard amide coupling reaction used for peptide synthesis in organic media. The aqueous phase reaction suffers from significant drawbacks relative to its organic solvent counterpart. Most importantly, the isoacylurea formed by the reaction of EDC and carboxylic acid is quite labile, as water attacks it to regenerate the carboxylic acid (*15*). In order to increase the conjugation efficiency, sulfo-NHS is frequently used, as shown in Scheme 1. This reagent replaces the isoacylurea to form a succinimidyl ester that hydrolyzes at a slower rate (*9*, *16*). The hydrolysis of the NHS ester is shown in Scheme 2. Conjugations such as these are essentially complete after several hours. It is generally accepted that the pH can be raised to quickly hydrolyze any remaining active esters, thereby quenching the reaction (*13*). Alternatively, the conjugated materials can be incubated overnight in PBS buffer (0.01 M, pH 7.4), which will result in hydrolysis of the ester bond.

EXPERIMENTAL PROCEDURES

Materials. All chemicals were obtained from Aldrich unless otherwise noted. The coupling reagents 1-[3-(dimethylamino)-propyl]-3-ethylcarbodiimide HCl (EDC) and *N*-hydroxysulfo-succinimide (sulfo-NHS), as well as phosphate-buffered saline (PBS) were used as received. The buffer component 2-[*N*-morpholino]ethanesulfonic acid (MES) was purchased from Sigma and used as received. Water used in all syntheses was distilled and then purified using a Barnstead E-Pure system. A 0.2 μm filter incorporated into this system removed particulate matter.



Conjugate Preparation. Aqueous carbodiimide coupling is a well-known cross-linking technique (*9*, *13*). Here, 100-μL of pNIPAm-AAc microgel solution (15 g/L) was mixed with 500 μL of MES buffer (0.1 M, pH 5.5). The coupling reagents EDC (4.4 mM final concentration) and sulfo-NHS (7 mM final concentration) are added to the microgel solution. and the prepared microgels are allowed to mix on a shaker table for at least 48−72 h. The microgels are then cleaned of excess reagents and spent reactants by successive centrifugation (5× at 14000*g*) and resuspension in PBS buffer (0.01 M, pH 7.4). Efforts to hydrolyze the active esters included addition of hydroxylamine (0.1 M, 25 μL), as well as various concentrations of NH_4OH. None of these resulted in significant loss of sulfo-NHS over the incubation period. Cleaned microgel conjugate solutions were then stored at 5 °C.

Photon Correlation Spectroscopy (PCS). The radii of the native and EDC/sNHS-treated pNIPAM-AAc microgels were determined in aqueous solution by PCS (Protein Solutions, Inc.). The temperature of the microgel samples was controlled via a Peltier device (±0.1 °C) integrated into the sample holder.

Scheme 1. EDC-NHS Coupling of a Primary Amine to the pNIPAm-AAc Copolymer

Scheme 2. Hydrolysis of the NHS-ester

Microgel samples were thermally equilibrated for 10 min before measurements were taken. The hydrodynamic radii of the particles were calculated from diffusion coefficients using the Stokes−Einstein equation. All correlogram analyses were performed with manufacturer-supplied software (Dynamics v.5.25.44, Protein Solutions, Inc.). The data presented are the averaged values of 20 measurements, with a 10 s integration time for each.

Phase Transition (Cloud-Point) Experiments. Phase transition curves of scattering intensity versus temperature were constructed from experiments performed on a steady-state fluorescence spectrophotometer (Photon Technology International) equipped with a Model 814 PMT photon-counting detector. The instrument was controlled by manufacturer-supplied software (Felix v.1.41, Photon Technology International). In the experimental setup, the λ_{ex} and λ_{em} were set to the same value and the band-pass was adjusted to 2 nm. Light from the instrument impinged on the experimental sample, and the scattered light was collected at a 90° angle. The programmable temperature controller (Linkam Scientific Instruments model PE 60) provides real-time solution temperature data via a temperature probe with accuracy of ±0.1 °C.

UV Analysis. UV data was collected on a Shimadzu UV1601 spectrophotometer. Samples were analyzed by pipetting 100 μL of the centrifuged microgel supernatant into 1 mL of PBS (0.01 M, pH 7.4)

RESULTS AND DISCUSSION

In this study, we treated pNIPAm-co-AAc microgels with EDC and sulfo-NHS under standard conditions (*13*), and the resultant behavior of the treated microgels was investigated. Microgels treated under these conditions were analyzed via light scattering in order to ascertain any change in the phase transition behavior of the microgels. The light scattering data in Figure 1a show a typical phase transition curve for pNIPAm-AAc microgels at pH 3.5 (open circles). The solution scattering intensity increases at the phase transition temperature due to water expulsion from the microgels and concomitant polymer phase separation. The adjacent curve (filled circles) was obtained from microgels that had been treated with EDC and sulfo-NHS, followed by rigorous cleaning by repeated centrifugation/resuspension steps. This sample does not display any evidence of a normal phase transition. Rather, the scattering stays at a

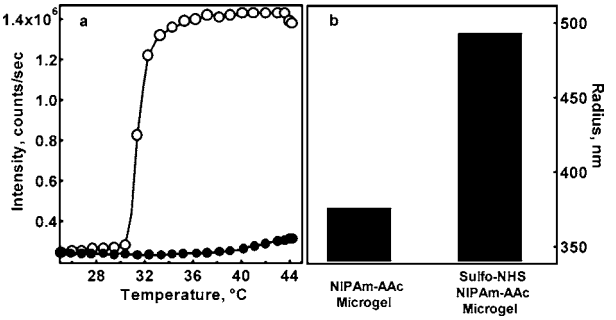

Figure 1. (a) Scattering intensity as a function of temperature for 0.11 mg/mL solutions of native pNIPAm-AAc microgels (open circles) and EDC/sulfo-NHS-treated pNIPAm-AAc microgels (filled circles) in water at pH 3.5. (b) Radii of native and EDC/sulfo-NHS-treated microgels as determined by photon correlation spectroscopy at 25 °C.

relatively low level until ~38 °C at which point the scattering intensity begins to increase gradually. Samples of microgels that were reacted with only EDC or only sulfo-NHS did not show a modulation of the phase transition temperature (see Supporting Information). It has been shown that hydrogels synthesized with anionic monomers exhibit phase transitions at higher temperatures due to Coulombic repulsion between polymer chains (*10*−*12*). The shifted phase transition in Figure 1a may similarly be the result of charge repulsion between sulfo-succinimidyl moieties attached to the microgel via the active ester. Hence, this implies that these active esters conjugated to the microgels are less susceptible to hydrolysis than what is typically observed, where the half-life for the NHS-ester is typically on the order of a few hours (*13*). The photon correlation spectroscopy (PCS) data shown in Figure 1b support the conjecture that sulfo-NHS is still bound to the microgels. At pH 3.5, the microgels treated with EDC and sulfo-NHS show a much larger radius than that of the native microgels. The treated microgels show a size monodispersity similar to the native microgels, ruling out aggregation as a factor in the increased radius. On the other hand, Coulombic repulsion of neighboring charged sulfonate groups would account for this effect, as an expanded polymer network results in larger microgel radii (*17*).

To confirm the presence of sulfo-NHS on the treated microgels, more extreme hydrolysis conditions than that found in simple aqueous media were employed. Such a hydrolysis condition can be achieved via a solution of 95% ethanol−5% PBS (0.01 M, pH 7.4). A small amount of freeze-dried polymer previously treated with EDC/sNHS was added to the solution and heated to 40 °C. The polymer solution was incubated for several hours, cooled to room temperature, and allowed to equilibrate on a shaker table for 72 h. To serve as a control, a microgel sample was mixed with an aliquot of sulfo-NHS (no EDC), cleaned by centrifugation, and carried through the same hydrolysis protocols. Both sets of microgels were then separated from solution via centrifugation. Supernatant was collected before and after hydrolysis treatment and analyzed via UV spectroscopy. Sulfo-NHS ($\epsilon \sim 8500\ M^{-1}\ cm^{-1}$) has a peak in the UV at approximately 268 nm in PBS (0.01 M, pH 7.4). Supernatant from treated microgels preceding the EtOH-PBS treatment resulted in no detectable loss of sulfo-NHS (Figure 2, open circles). However, supernatant from treated microgels incubated in EtOH−PBS showed a small release of sulfo-NHS. No release of sulfo-NHS was detectable from the supernatants of the control sample (data not shown). These data serve to confirm the presence of sulfo-NHS esters on the microgels and also reveal that the ester is hydrolyzing, but apparently at a very slow rate. Following the procedure outlined above, the treated microgels exhibited modestly shifted phase transition temperatures. This shift to a lower phase transition temperature is most likely due to the hydrolysis of a small amount of sulfo-NHS

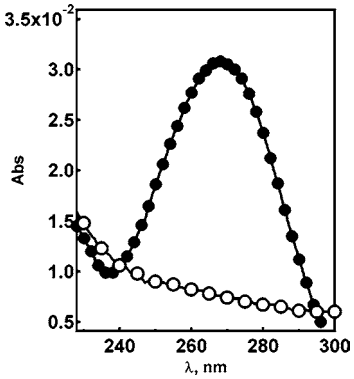

Figure 2. UV spectra of supernatant solutions recovered from EDC-sulfoNHS-modified microgels before EtOH−PBS incubation (open circles) and after 72 h incubation in EtOH−PBS (filled circles). λ_{max} = 268 nm.

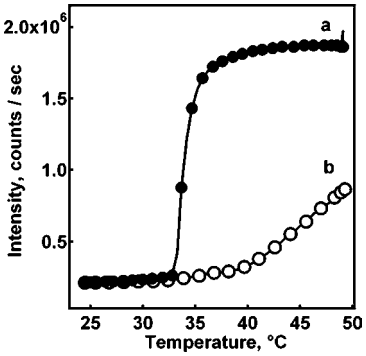

Figure 3. Scattering intensity as a function of temperature for 0.11 mg/mL solutions of (a, filled circles) ethanol−aq NaOH-incubated EDC and sulfo-NHS NIPAm-AAc microgels and (b, open circles) EDC and sulfo-NHS-treated pNIPAm-AAc microgels in water at pH 3.5.

and a resultant decrease in Coulombic repulsion between chains (Supporting Information).

In an effort to completely hydrolyze the succinimidyl ester and recover the native phase transition behavior of the microgels, EDC/sulfo-NHS-treated microgels were dispersed in a more basic solution of EtOH and aq NaOH. The polymer dispersion was heated to 50 °C for 15 min, cooled to room temperature and heated again to 50 °C for 15 min before being incubated for 24−48 h at room temperature. The microgels were separated from the reaction medium by centrifugation and redispersed in water. The results from light scattering experiments on these microgels (Figure 3) reveal that the phase transition temperature changed dramatically. Before incubation (open circles), the microgels exhibited phase transitions around 45−50 °C. The incubated microgels (filled circles) show a phase transition at ∼34 °C. The highly basic ethanolic solution allows for greater hydrolysis of the sulfo-NHS ester moieties and regenerates the original acid sites, resulting in the regeneration of a phase transition typical for native pNIPAm-AAc microgels at pH 3.5. Note that under these conditions, sulfo-NHS itself degrades and is not detectable *via* UV spectroscopy. The above data suggest that the environment of the microgel interior is such that much harsher conditions are necessary for the hydrolysis of sulfo-NHS esters than would be typically expected. The consequence is the long-lived stable esters that affect the solution properties of the microgels themselves.

In addition to the changes in physical properties, these long-lived esters appear to be responsible for decreasing the efficiency of amine conjugation. Experiments with protein, ligand, and fluorophore coupling have resulted in peculiar results, namely, *higher* coupling yields when sulfo-NHS is omitted from the EDC coupling protocols. The data in Figure 4 show an example

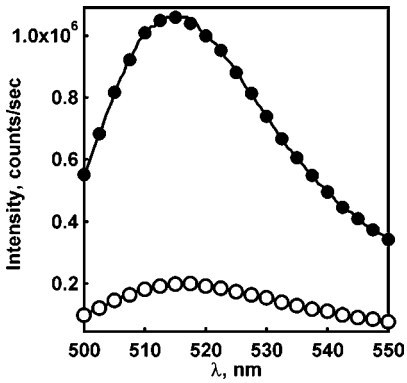

Figure 4. Fluorescence intensity of from a dispersion of microgels conjugated with 1 μL of fluoresceinamine (5.0 mg/mL) *via* EDC (4.4 mM) coupling (filled circles) and microgels conjugated with 1 μL fluoresceinamine (5.0 mg/mL) *via* EDC (4.4 mM) and sulfo-NHS (0.77 mM) coupling (open circles). All microgel solutions conjugated with sulfo-NHS result in lower fluorescence intensity proportional to the amount of sulfo-NHS added, suggesting that the sulfo-NHS competes for sites with the fluorophore by forming a stable ester.

of this effect. Here, the fluorophore fluoresceinamine was EDC coupled to pNIPAM-AAc microgels both with and without sulfo-NHS. When sulfo-NHS is included in the reaction, a dramatically lower yield of fluorophore coupling is observed relative to the EDC-only reaction. Effects such as this have been observed in our lab for proteins (avidin, streptavidin, and various IgGs), ligands (biotin, peptides), and other amine-containing fluorophores. We interpret these results as being due to competition for the chemoligation sites. That is, acid groups that react with sulfo-NHS are not as available for amide coupling as those that do not react with sulfo-NHS.

CONCLUSIONS

In summary, we have shown that treatment of pNIPAm-AAc microgels with the carbodiimide coupling reagents EDC and sulfo-NHS results in microgels containing 'long-lived' sulfo-NHS intermediates, despite the use of standard hydrolysis protocols. These intermediates result in a shift of the phase transition of the microgels to higher temperatures, along with a large increase in equilibrium microgel swelling degree, due to an increase in chain−chain Coulombic repulsion. Despite the typically labile nature of the ester bond in aqueous media, no hydrolysis of the sulfo-NHS ester is observed in standard aqueous solutions, while water/ethanol mixtures allow for hydrolysis rates that are detectable by UV spectroscopy. Extremely aggressive hydrolysis in basic ethanol affords almost complete removal of the sulfo-NHS moieties, thus regenerating the normal microgel phase transition behavior.

While the mechanistic origins of these unusual reactivities are not clear from these studies, it is perhaps not surprising that hydrolysis rates would be perturbed in hydrogel phases, given previous observations of differences in water mobility in microgel networks (*18, 19*). However, the susceptibility of the NHS ester to nucleophilic attack should not necessarily be sensitive to the behavior of water in the network, as water does not directly participate in that reaction. To address this issue, we are currently undertaking more detailed mechanistic studies on model polymers. Regardless of the mechanisms involved in the present study, these results point to the dramatically different reactivity that may be present in complex macromolecular materials such as hydrogels and other novel nanostructures, a point that should be acknowledged when applying "standard" chemoligation strategies to nonstandard materials. In light of the enhanced stabilities of the NHS esters, our group now performs acid−amine chemoligation reactions using EDC only,

as the NHS step obviously decreases the overall yield of the desired coupling reaction.

Peptide Beacons: A New Design for Polypeptide-Based Optical Biosensors

Kenneth J. Oh,[†] Kevin J. Cash,[‡] Verena Hugenberg,[†] and Kevin W. Plaxco*[,†,§]

Department of Chemistry and Biochemistry, Department of Chemical Engineering, and Interdepartmental Program in Biomolecular Science and Engineering, University of California, Santa Barbara, Santa Barbara, California 93106. Received October 11, 2006; Revised Manuscript Received April 3, 2007

Both epitope mapping and other *in vitro* selection techniques produce short polypeptides that tightly and specifically bind to any of a wide range of macromolecular targets. Here, we demonstrate a potentially general means of converting such polypeptides into optical biosensors. The sensing architecture we have developed, termed peptide beacons, is based on the observation that, whereas short peptides are almost invariably unfolded and highly dynamic, they become rigid when complexed to a macromolecular target. Using this effect to segregate a long-lived fluorophore from an electron transfer based, contact quencher (both covalently attached to the peptide), we have produced a robust optical sensor for anti-HIV antibodies. The binding-induced segregation of the fluorophore-quencher pair produces a 6-fold increase in sensor emission, thus allowing us to readily detect as low as ~250 pM of the target antibody. Because the sensor is based on binding-induced folding and a visible-light fluorophore, it is sufficiently selective to work directly in complex, contaminant-ridden samples such as saliva and blood.

INTRODUCTION

Molecular beacons (*1*) (MBs[1]), stem-loop DNAs that undergo a conformational change upon target binding, have proven useful for the optical (*2*) and electronic (*3*) detection of oligonucleotides. In the absence of target, the MB stem holds terminally attached quencher and fluorophore moieties in proximity, reducing emission. Upon target binding, the stem is disrupted, segregating the termini and producing a large, readily measured increase in fluorescence emission (*4*). While sensitive and convenient, however, the generality of the MB approach has proven limited, with only the detection of oligonucleotide-binding targets reported to date. Given the number of analytes, such as antibodies (*5*), better recognized by polypeptides, the development of polypeptide-based MB analogues could thus significantly extend the utility of this promising approach.

The development of polypeptide-based MB analogues has been hampered by the fact that polypeptides do not form stable stem−loop structures (*6*). We have, however, recently demonstrated a solution to this problem in a new class of sensors, termed peptide beacons (PB), that exploit the observation that, while unbound polypeptides are highly dynamic, their structure becomes fixed upon binding to a macromolecular target. Using this effect to segregate pyrene excimers attached to the termini of sensing polypeptides, we have recently extended the MB approach to polypeptide-based detection (*7*).

Pyrene excimer-based peptide beacons achieve sub-nanomolar detection limits and excellent specificity when tested in con-

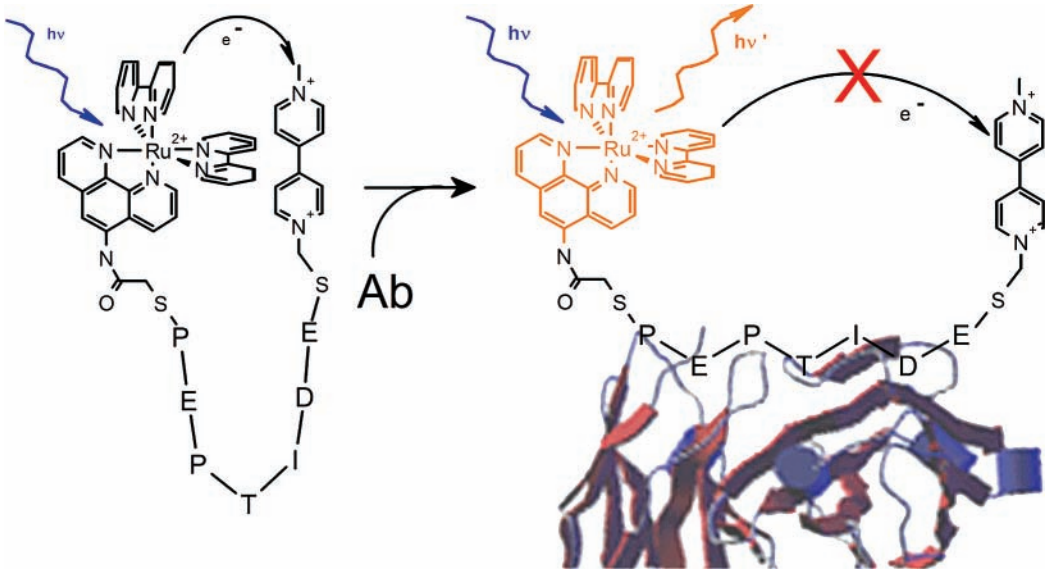

Figure 1. The PB architecture comprises a long-lived fluorophore, an electron-accepting quencher, and a recognition peptide. In the absence of target (left), intramolecular collisions allow for fluorescence quenching. Upon target binding (right), the fluorophore is segregated from the quencher, preventing electron transfer and enhancing fluorescence.

taminant-free buffer. They largely fail, however, when deployed in complex, contaminant ridden samples due to the relatively poor optical characteristics of pyrene: pyrene excitation occurs in the UV, which results in significant background fluorescence, and the signal gain of pyrene-based PBs is only 2-fold (*7*). Here, we describe an alternative PB architecture that, in contrast, is characterized by visible-light excitation and significantly improved signal gain (Figure 1).

RESULTS

We have synthesized a new PB architecture based on a highly antigenic (*8*), six-residue epitope from the HIV protein p17. As is true with almost all unstructured polypeptides, the two ends of the unbound epitope collide on a time scale of <100 ns (*9*). When bound to its target antibody, however, the epitope adopts a rigid, modestly extended conformation (*10*). We also employed a fluorophore, ruthenium(II) bisbipyridine−phenanthroline, that exhibits a ∼800 ns lifetime, exciting in the visible, and exhibiting a 160 nm Stokes shift (*11*). Optimization of the PB signal change upon binding requires that quenching be efficiently halted upon even the smallest binding-induced segregation, requiring in turn that we employ an electron transfer based mechanism that decreases exponentially with distance. To this end, we employed the electron accepting quencher methyl viologen. Our new PB thus consists of a ruthenium/viologen pair conjugated to the termini of the p17 epitope via cysteine linkers (Figure 1).

The emission of our new PB architecture is enhanced 6-fold upon addition of its target antibody (Figure 2). The signal gain and emissivity of the PB allow us to readily quantify the target antibody at concentrations as low as ∼250 pM, close to the 200 pM dissociation constant reported for the unmodified polypeptide (*12*). Finally, the gain of the PB is independent of its concentration (data not shown), indicating that the observed quenching is intramolecular.

The PB mechanism is linked to a binding-specific conformational change, and thus, the sensor should be selective against contaminants. Nevertheless, the background fluorescence present in realistically complex samples generally limits the sensitivity of optical sensors. This problem is minimized here by the use of a visible-light fluorophore with a 160 nm Stokes shift, attributes that allow us to detect the target antibody even in complex, contaminant-ridden samples (such as serum and saliva;

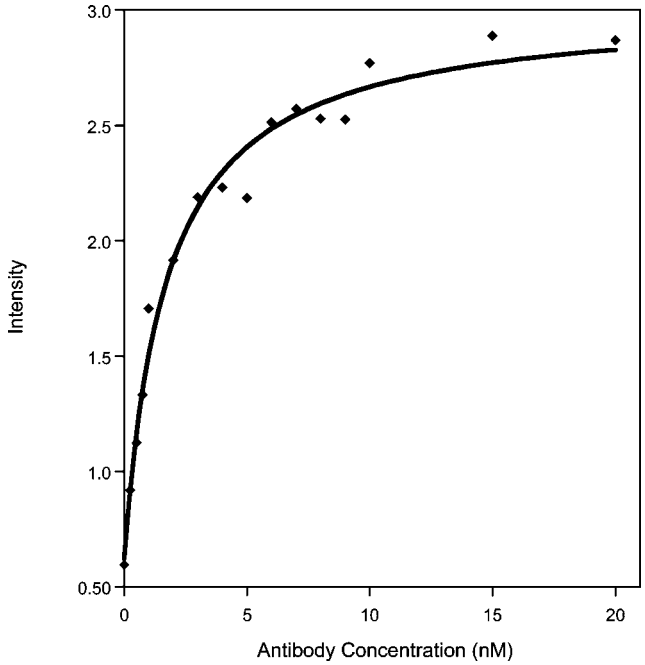

Figure 2. The emission of the PB increases approximately 6-fold upon target binding. Shown are data collected in buffer at a PB concentration of 1 nM.

Figure 3), albeit with poorer detection limits than observed in buffer. Of note, the signal gain observed in serum is similar to that observed in buffer, confirming that the sensor is unaffected by any of the hundreds of proteins contaminating these materials (*13*).

DISCUSSION

Here, we have demonstrated a novel biosensor that is sensitive, operationally convenient, and selective enough to be employed directly in complex, contaminant-ridden samples. The sensitivity of PBs is competitive with absorption-based, label-free sensing approaches, such as surface plasmon resonance and quartz crystal microbalances (*14*). In contrast to these approaches, however, the PB architecture combines this sensitivity with excellent selectivity: because signaling is linked to a specific, binding-induced conformational change, the PB ap-

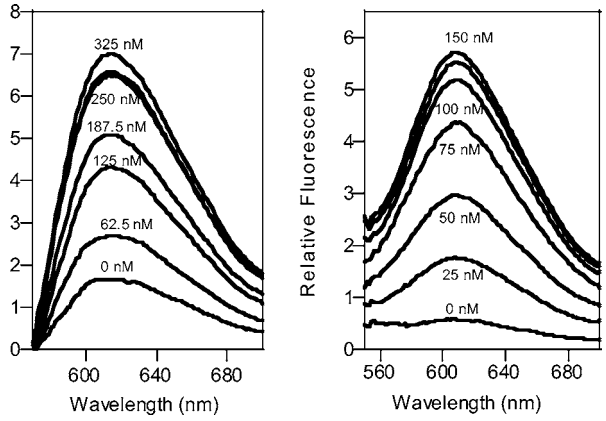

Figure 3. The PB approach is selective to work even in grossly contaminated samples in the background-subtracted spectra of (left) 250 nM PB in 50% serum and (right) 100 nM PB in saliva.

proach is relatively insensitive to the nonspecific binding that typically complicates adsorption-based sensing schemes (*15*). Additionally, the fluorophore we have employed excites in the visible and exhibits a large Stokes shift, reducing background fluorescence and allowing for deployment in clinical samples. The described PB approach also appears to be a more general platform than previous peptide-based optical sensing approaches (*16*, *17*) in that PBs neither require that binding specifically sequester a quencher (*18*) nor rely upon tryptophan fluorescence, which is difficult to monitor in the presence of typical contaminants (*19*). (Of note, we do not observe any significant quenching when tryptophan is titrated against a model ruthenium complex, suggesting that the approach is not limited to tryptophan-free polypeptides—data not shown.) Last, while the described PB does not exhibit the low picomolar-to-femtomolar sensitivities reported for the most highly optimized Western Blot and ELISA assays (*20*, *21*), the approach does not require the cumbersome equipment and batch processing employed by these techniques.

The PB sensing strategy may be general, as its only requirements are that intramolecular collisions in the unbound polypeptide are rapid and intermolecular collisions in the bound state are slow relative to the excited-state lifetime of the fluorophore, that the bound state of the peptide segregates the fluorophore/quencher pair by at least a few ångströms, and that the fluorophore and quencher do not disrupt binding. Given that the majority of small peptides are highly dynamic relative to the lifetime of our ruthenium fluorophore (*9*, *11*), and given the ready elucidation of novel polypeptide-based recognition elements by phage and bacterial display techniques (*22*), it appears that the PB approach described here will be applicable to a wide range of macromolecular targets.

Materials and Methods

Synthesis of the Peptide Beacon.

Synthesis of N-methyl-N'-(2)bromoethyl-4,4'-bipyridinium. To produce N-methyl-4,4'-bipyridinium, 10 g of 4,4'-bipyridine was dissolved in 500 mL of chloroform. Twenty-five mL of iodomethane was added to the reaction, and was allowed to react at room temperature for 48 hours. The product was separated from the starting materials by performing phase extractions with H_2O, three times at 25 mL each. The starting material remained in the chloroform layer. The product was then further purified via HPLC using a gradient of 5% to 25% acetonitrile in H_2O and 0.1% trifluoroacetic acid, and the product eluted at 14 minutes. The product in solution was then lyophilized to a dry powder, and stored at –20˚ C. The product was verified on an Applied Biosystems PE Sciex QSTAR-Pulsar quadrupole orthogonal time-of-flight mass spectrometer fitted with an electrospray source (ESI-MS), m/z = 171. Five g of the product was dissolved in 100 mL acetonitrile and 10 mL of THF to which 15 mL of 1,2-dibromoethane was added. The solution was then allowed to reflux for 8 hours. The solvent mixture was then removed by rotary evaporation. The product was purified from the starting material by reverse-phase HPLC on a Waters Xterra MSC18 column, using gradient of 5% to 25% acetonitrile in H_2O and 0.1% trifluoroacetic acid, and the product eluted at 12 minutes. The reverse-phase mobile phase solvent was then removed by lyophilization, and the dry powder was stored at –20˚ C. The product was verified by ESI-MS, m/z = 278.

Synthesis of Ru(bipy)$_2$phen-5-iodoacetamide (adapted from *11*). Five mg of Ru(bipy)$_2$phen-5-amine (Fluka; diastereomers not determined), was dissolved in 100 mL of acetonitrile followed by the addition

of 100 mg of iodoacetic anhydride (Sigma-Aldrich). The solution was allowed to react for 8 hours at 4˚ C. The solvent was removed by rotary evaporation. The product was separated by reverse-phase HPLC on a 10% to 50% acetonitrile gradient over 60 minutes, the product elutes at 36 minutes. The product was then verified by ESI-MS, m/z = 777.

Conjugation of p17 peptide epitope to Ru(bipy)$_2$phen-5-iodoacetamide. Twenty mg (17 μmol) of the p17 peptide (sequence CEKIRLRC; from Biopeptide, San Diego) was treated with a 10x excess TCEP to reduce any disulfide cross linkages in 100mM TRIS-HCl buffer, pH = 7.5. The peptide was then purified via reverse-phase HPLC, lyophilized, and subsequently resuspended in a 200 mM of argon-degassed TRIS-HCl buffer, pH 7.8. Thirteen mg of Ru(bipy)$_2$phen-5-iodoacetamide was dissolved in the above buffer. The two solutions were mixed and allowed to react for 24 hours at room temperature under argon. The solution was then lyophilized, and purified via reverse-phase HPLC on a 10% to 50% acetonitrile gradient in H_2O and 0.1% trifluoroacetic acid over 60 minutes. The product elutes at 34 minutes. The product was verified using electrospray mass spectrometry, m/z = 1711. Ten mg of the p17 peptide-Ru(bipy)$_2$phen conjugate in 10 mL of 100 mM TRIS-HCl buffer, pH 7.5 was then treated with a 10x excess of TECP to reduce any disulfide cross-links and purified via reverse-phase HPLC to separate it from any unreacted TECP. The reduced p17 peptide-Ru(bipy)$_2$phen conjugate was then lyophilized to a powder, resuspended in 10 mL of 200 mM TRIS-HCl buffer, pH 7.5, degassed with argon. Twenty mg of N-methyl-N'-2-bromoethyl-4,4'-bipyridinium, dissolved in 4 mL of the same buffer, was added and the resulting solution and was allowed to react for 48 hours at room temperature under argon. The solution was then lyophilized, and purified via reverse-phase HPLC on a 10% to 50% acetonitrile gradient in H_2O and 0.1% TFA over 60 minutes. The product elutes at 28 minutes. The product was verified by ESI-MS, m/z = 1910. The resultant product was stored at –20˚ C and exhibits stability over long periods of time as a lyophilized powder. Of note, our PBs are a mixture of constructs in which the fluorophore is on either the amino- or carboxy-end of the

polypeptide, thus simplifying synthesis. Because electron-transfer is highly distance dependent, the orientation of the fluorophore and quencher does not affect the PB signaling.

Spectral Interrogation

Fluorescence Measurements were performed on a Varian Cary Eclipse Fluorimeter. Samples were excited at 450 nm. Titrations were performed with a fixed concentration of PB in a 1 mL quartz cuvette, in 100 mM TRIS buffer, pH 7.8. The anti-p17 antibody (Zeptometrix, Buffalo, New York) clone 32/1.24.89 was aliquoted for the three different titrations of buffer, saliva, and blood serum in increments of 0.25, 0.25 and 0.25 normal equivalents, respectively. After each addition, the solution was allowed to stand for two minutes at 28˚C, and then a measurement was acquired. The reported spectra represent the mean of multiple measurements. All of the reported experiments were conducted in the presence of dissolved oxygen. Experiments with oxygen-free buffers (obtained via purging with argon for 40 minutes) produce only slightly increased fluorescence intensity (data not shown)

Using Luminescent Nanoparticles as Staining Probes for Affymetrix GeneChips

Lin Wang, Charles Lofton, Michael Popp, and Weihong Tan*

Center for Research at the Bio/Nano Interface, Department of Chemistry, Shands Cancer Center and UF Genetics Institute, University of Florida, Gainesville, Florida 32611-7200. Received November 22, 2006; Revised Manuscript Received March 14, 2007

Microarray technology provides efficient access to genetic information using miniaturized, high-density arrays of DNA probes. We investigated the application of luminescent nanoparticles as probes for Affymetrix GeneChips detection without the need for signal amplification. Our goal is to investigate the feasibility of using luminescent nanoparticles as probes in a commercial microarray system without changing its configurations. With the present imaging modality and existing optical excitation and detection systems of the Affymetrix GeneChips, our early results indicate that nanoparticles not only can be used for GeneChip labeling but also are superior to the traditional fluorescent protein streptavidin-phycoerythrin (SAPE). The advantage of the particles lies in a simplified staining procedure, higher photobleaching threshold, and enhanced luminescence signal. The nanoparticles can be used for detection of low-abundance targets without any amplification step. A concentration detection limit of 50 fM has been achieved. This work demonstrates the feasibility of using luminescent nanoparticles as probes for commercial microarray systems, making them less costly, more reproducible, and potentially quantitative.

DNA and oligonucleotide microarrays have revolutionized gene expression profiling by allowing highly parallel and quantitative monitoring of thousands, and in some cases all, of the gene transcripts from an organism (*1*). This greatly increased scale with DNA microarrays has made it possible to tackle qualitatively different questions in biology and medicine. However, despite their extensive profiling and genotyping capability, using microarrays for the assessment of transcripts at low abundance levels remains elusive due to the insufficient detection sensitivity. This can be improved by significant pre-amplification of the starting material (*2*−*3*) which is most often done using a two-round T7/aRNA method. This method, however, has increased noise over the more conventional one-round amplification procedures (*4*−*5*).

Alternatively, microarray sensitivity can potentially be improved by increasing the fluorescence signal of the gene target. Unfortunately, although the new generation of fluorophores such as the Alexa series generate greater signal, their limited sensitivity for microarrays as well as their photostability need further improvement. The rapidly evolving field of bionanotechnology has opened up a promising era in new probe development (*6*−*8*). Gold nanoparticle (NP)-promoted reduction of silver was reported to detect target DNA at a concentration of 50 fM (*6*). The detection, however, relied on coating the gold NP with silver, a complicated process which caused reduced reproducibility. Two-color microarray-based detection has also been demonstrated by using Cy3- and Cy5-doped gold-core/silica-shell NPs in a sandwich hybridization (*7*). Each NP was embedded with ∼100 dye molecules, and the study revealed a detection limit of 1 pM for target DNA. Quantum dots have similarly been used for DNA microarray and achieved a detection limit of 2 nM for target DNA (*8*). So far, however, NP probes have been tested only in proof-of-concept experiments where allele-specific surface-immobilized capture probes and gene-specific oligonucleotide-functionalized NP probes are hybridized to the target sequentially. Under these conditions, only a few genetic markers can be simultaneously detected. Thus far, the use of NPs to analyze genetic information has not yet been demonstrated in a real commercial system.

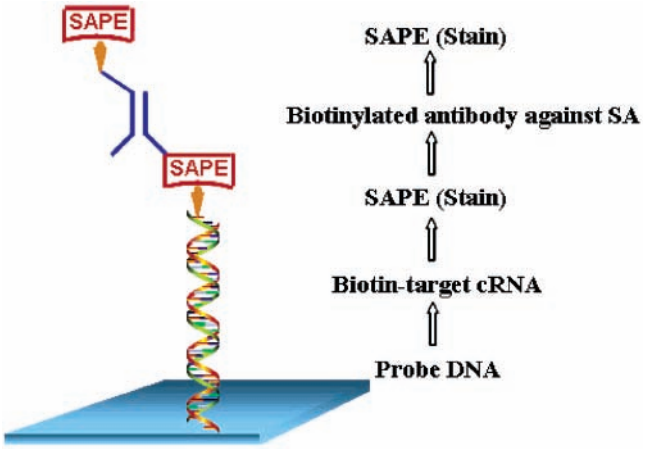

Figure 1. Signal amplification scheme in the Affymetrix system.

Herein, we report the first study using dye-doped silica NPs to visualize the hybridization signal of target RNA binding to probes on Affymetrix GeneChips. Due to their extensive genetic content and the fact that they are supplied ready for use, Affymetrix GeneChip arrays are quickly gaining acceptance as the optimal method for determining transcription profiles. An integral component of the Affymetrix GeneChip technology is probe redundancy. Multiple probes homologous to different regions of the target RNA are designed. This improves the signal-to-noise ratio, increases the dynamic range of detection, and minimizes cross-hybridization effects. An additional level of redundancy comes from the use of mismatch (MM) probes identical to the perfect match (PM) probes except in a single base located in a central position. In the conventional GeneChip labeling strategy (Figure 1), the biotinylated cRNA is fragmented and hybridized to the GeneChip array. After hybridization, the arrays are washed and stained with streptavidin−phycoerythrin (SAPE). The signal is then amplifed by first washing with a solution containing biotinylated anti-streptavidin (goat) antibody

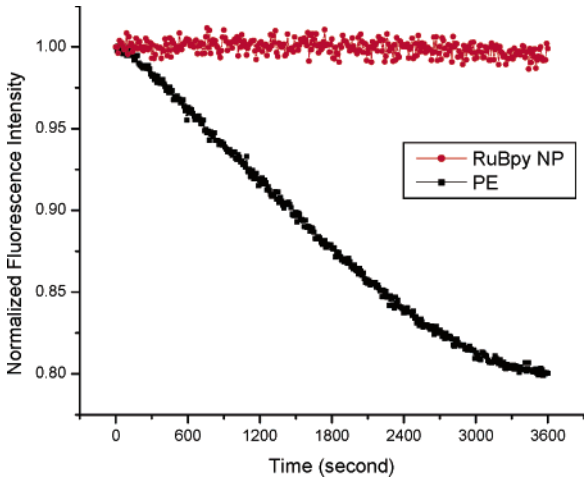

Figure 2. Photostability test of RuBpy-doped silica NPs (top) and PE (bottom) in solution phase under the exposure of a 150 W xenon lamp.

and then a final staining with SAPE. Comparisons of gene expression levels are generated on the basis of the detection of the fluorescence signal emitted from each element on the array. This signal amplification strategy, however, is time-consuming, may generate amplification bias, and disturb the abundance levels of the original transcripts.

Our efforts focused on replacing the conventional SAPE with dye-doped silica NPs (*9*) in an attempt to increase the fluorescence signal and thereby the sensitivity. Each of our dye-doped silica NPs contains a large number of dye molecules, emitting a fluorescence signal more than 10 000 times that of a fluorophore (*10*). This extreme brightness facilitates ultrasensitive determination of trace analytes that are undetectable with existing fluorescence labeling techniques. We aim to investigate whether this new NP reporter technology enhances the commercial microarray performance without either introducing additional amplification bias or requiring a change in the configuration of the commercial system.

The RuBpy dye-doped NPs were spherically uniform with an average diameter of 60 ± 3 nm (RSD = 5%, n = 200). Fluorescence intensity of these NPs was measured, and the effective fluorescence intensity of each particle is equivalent to that of 30 000 RuBpy dye molecules (Supporting Information). Moreover, the silica matrix of the NPs serves as a protective shell or dye isolator; it limits the effect of the outside environment on dye molecules which are otherwise susceptible to photobleaching due to their inherent molecular nature. To compare the photobleaching thresholds of SAPE and NPs, photostability tests were performed on both RuBpy NPs and the PE solutions. Within 1 h of continuous Xenon lamp excitation, no noticeable photobleaching was observed for NPs. However, a significant decrease in fluorescence intensity was observed for the PE solution during the same time period (Figure 2). This observation suggests that the silica matrix isolates the dye molecules from the outside environment and thereby prevents photo-oxidation by oxygen (*11*). Unlike SAPE, which should be kept in the dark either wrapped in foil or stored in an amber tube, the dye-doped NPs can be exposed to room light without interfering with their signaling properties; they are more robust tools for microarray staining. Indeed, after scanning a NP-stained microarray ten times successively, only negligible signal variation was observed. More importantly, the remarkably high photochemical stability of dye-doped NPs allows them to withstand numerous illumination cycles and permits several microarray measurements to be taken at different times. This enables experiment optimization or verification of the measurements by different researchers. Furthermore, this improved photostability would possibly allow for extended integration time, improved signal-to-noise ratios and sensitivity, resulting in overall increased assay reliability.

In order to integrate the dye-doped NPs into the microarray system, our initial idea was to replace the SAPE with streptavidin-labeled NPs. However, considering the effects of strong steric hindrance between the rigid NP and the solid-phase surface, different NP labeling strategies were designed. In addition to direct labeling of SA onto NPs, NHS-PEG-biotin molecules were immobilized onto amine-modified NPs (*13*). These PEG linkers allowed the conjugated biotin molecules to extend out from the NP surface in order to increase binding efficiency. PEG linkers are also well-known for their ability to prevent nonspecific interactions and act as hydrophilic spacers, minimizing any detrimental interactions between the attached biomolecule and the solid surface. To demonstrate the successful immobilization of biotin molecules on the NPs, streptavidin-coated microspheres and biotin-PEG-labeled NPs were mixed (*12*−*13*). The confocal images of the resultant microsphere−NP complexes prove the successful biotinylation of the NPs (Supporting Information).

The Affymetrix GeneChip Test3 arrays (T3 array) were used to compare the performance of different NP staining strategies. The T3 array contains a limited number of probe sets representing genes from various organisms including mammals, plants, and eubacteria. The array also has two inbuilt controls—the B2 oligo, which serves as a positive hybridization control, and four bacterial genes involved in biotin metabolism (bioB, bioC, bioD, creX). These four genes are spiked into the hybridization cocktail in varying molar ratios and are used to evaluate hybridization efficiency. Biotin-labeled cRNA samples from a human lung cancer cell line (A549) were hybridized on the arrays and stained with NPs using three different strategies (Figure 3). The first array was stained with streptavidin-directly labeled NPs (NP-SA); the second array was stained with PEG-biotin-streptavidin-labeled NPs (NP-PEG-biotin-SA); and the third array was first incubated with 1 mg/mL streptavidin, then washed and stained with PEG-biotin-labeled NPs (SA+NP-PEG-biotin) (Figure 4). In this last case, the streptavidin is first bound with biotin tags on the cRNA. Because each streptavidin has four biotin binding sites, it can further bind to biotin tags on the NPs. We found the binding efficiency of the three types of particles as follows: NP-SA < NP-PEG-biotin-SA < SA + NP-PEG-biotin.

This result demonstrates that the PEG linkers improved biomolecule recognition efficiency and reduced NP nonspecific binding. The superiority of the third strategy over the second may be due to better stability and smaller size of biotin-labeled NPs than protein-attached NPs, and the additional washing step. The third strategy was used in all further studies. Using NPs as the staining probe, we found the percentage of genes present on the T3 array to be 21.8%, which is within the range obtained with the normal double SAPE staining (16−25%). The background noise using NP staining probe is at a similar level to the SAPE staining, illustrating minimal nonspecfic binding of NPs on the microarrays.

To demonstrate whether bioconjugated NPs could improve the Affymetrix gene expression analysis by increasing its signal and thereby achieving higher sensitivity, we diluted the stock solution containing four bacterial hybridization control genes (bioB, bioC, bioD, creX) by 100-fold. (It is worth noting that only the concentrations of the commercial stock solutions of these four genes are available, while those in the biological sample (cRNA samples from the cell line) are unknown.) An aliquot of the three diluted hybridization cocktails was hybridized on three arrays in parallel and then stained with different methods. The first was single-stained with SAPE; the second was stained with SAPE, followed by antibody amplification and

Table 1. Control Gene Expression on Test3 Arrays after 100-fold Dilution[a]

final concentrations of control cRNAs	bioB (15 fM)	bioC (50 fM)	bioD (0.25 pM)	Cre (1 pM)
SAPE (one staining)	A	A	A	P
SAPE (two staining)	A	P	P	P
NP (one staining)	A	P	P	P

[a] A = absent; P = present.

second SAPE staining; the third was incubated with streptavidin followed by NP-PEG-biotin staining. After the washing and scanning steps, we found that the detection limit of gene expression with one SAPE staining was 1 pM, with two SAPE stainings, it was 50 fM, and with one RuBpy NP staining, it was 50 fM (Table 1). The NP single staining probe exhibited sensitivity which is 20× higher than the SAPE single staining probe, and comparable to two SAPE stainings.

It should be noted that all the chip signals were scanned on the Affymetrix GC3000 scanner using the optimal excitation/emission wavelengths for PE (Ex 532 nm; Em 570 nm) but not for RuBpy (Ex 460 nm; Em 600 nm). By comparison, the emission signal of RuBpy NPs excited at 532 nm is only 5% as intense as when excited at 460 nm. Even under such unfavorable conditions, the NPs were still more sensitive than one SAPE staining and comparable to two SAPE stainings. Changing the laser excitation diode and scanner filters or synthesizing dye-doped NPs matching the configuration of the scanner would possibly lead to a major enhancement in the signal from the NP-stained microarrays. Another noteworthy issue is the steric crowding effects due to the physical size of the NPs. Each feature (size 11 μm) of the array consists of more than 1 million copies of oligonucleotide probes. Therefore, each probe occupies a square of 11 μm on each side. The NP is around 60 nm in diameter (several times larger than streptavidin−phycoerythrin). This large and bulky size may block some biological binding sites in close proximity. Therefore, some biomolecules were not signaled, leading to lower sensitivity. Reduction of the particle size may address this problem. However, this is not a critical issue at a low target concentration because the distance between hybridized targets will be nearly as large or larger than the diameter of a NP. In that case, the ratio of target molecule to NP will be close to 1.

In conclusion, we used luminescent NPs as staining probes for Affymetrix Genechips and found that they simplified the staining procedure as well as showed enhanced detection sensitivity and photostability when compared to SAPE. As NPs can be used for detection of low-abundance targets without the amplification step, the method is potentially less costly and more quantitative, and the NP probe itself is less photolabile. In order to further improve the performance of dye-doped NPs for gene chips, a few modifications need to be implemented. The single-wavelength laser diodes and the Axon scanner optics need to be optimized for our luminescent NPs or we need to sythesize dye-doped NPs matching the Ex/Em wavelength of PE. The NP size also needs to be optimized to reduce the steric crowding effect. If dye-doped NPs and the optical setup are optimized in the Affymetrix GeneChip array, NP probe could be expected to be more sensitive, less costly, and potentially more reproducible and quantitative, and thereby greatly increses the scope for precise molecular diagnosis in single gene and genetically complex diseases.

ACKNOWLEDGMENT

We thank Dr. Sheng Zhong and Dr. Keith Robertson at UF Medical School for providing us with the biological sample. This work was supported by NSF NIRT and NIH grants. L.W. receives support as an ACS Division of Analytical Chemistry Graduate Student Fellow sponsored by GlaxoSmithKline.

Received April 30, 2006; Revised Manuscript Received February 4, 2007

A high-throughput screening system for analyzing small molecule-induced coactivator (CoA) recruitment by the vitamin D receptor (VDR) has been developed. The vitamin D-induced protein−protein interactions between VDR and fluorophore (Cy3 or Cy5)-labeled TIF2 or SRC-1 were successfully detected by using a new HCHO fixing method of the protein complex on microplates. The results obtained from this screening of our synthetic vitamin D analogues suggest that the CoA-recruiting activities play an important role in determining the biological activity of various vitamin D analogues and explain the discrepancies between the VDR binding affinity and their biological activity.

INTRODUCTION

The superfamily of nuclear receptors (NRs) activates transcription by recruiting coactivators in a ligand-dependent manner to assemble regulatory complexes on target genes (*1*, *2*). The structure of a NR comprises four regions (A/B, C, D, and E/F) including a highly conserved DNA-binding domain and a C-terminal ligand-binding domain (LBD). This C-terminal E/F region contains the activation function-2 (AF-2) motif that mediates ligand-dependent transcriptional activation. The steroid hormones, thyroid hormone, retinoic acids, and 1α,25-dihydroxyvitamin D_3 [1α,25$(OH)_2D_3$] all bind to their respective NRs, which include the androgen receptor, estrogen receptors, retinoic acid receptors, retinoid X receptors, and the vitamin D receptor (VDR). 1α,25$(OH)_2D_3$ (Figure 1A, **1**), the active form of vitamin D, binds specifically to VDR and plays a vital role in calcium homeostasis (*3*, *4*), osteoclastogenesis (*5*, *6*), keratinocyte differentiation (*7*, *8*), phosphate homeostasis (*9*), immune response, cellular proliferation, differentiation, and apoptosis (*10*, *11*).

Crystal structures of the VDR-LBD, alone and in complex with its ligands (*12*), with coactivator peptides (*13*), or as heterodimers, have been reported (*14*). The LBD is generally a three-layered α-helical sandwich of α-helices (H1−H12). When the ligand binds to LBD, H12 moves to seal the ligand-binding cavity, creating the AF-2 motif and a hydrophobic cleft (Figure 1B). This hydrophobic region, together with other surface residues, accommodates the receptor interaction domain (RID) of coactivators (*15*, *16*), such as transcriptional factor 2 (TIF2) (*17*), steroid receptor coactivating factor 1 (SRC-1) (*18*), TRAP220 (*19*), and AIB-1 (*20*) (Figure 1C). The RID includes short helical regions called "NR boxes", which contain the consensus sequence LXXLL (where X is any amino acid). The resulting conformational changes in the VDR lead to the removal of corepressors and the recruitment of various coactivators followed by histone acetylation and target gene promoter activation (*21*).

The active form of vitamin D or its analogues have been used clinically for treating psoriasis (*22*), osteoporosis (*23*, *24*), and secondary hyperparathyroidism (*25*). Furthermore, 1α,25-$(OH)_2D_3$ or its analogues have been shown to inhibit the proliferation of breast, colon, and prostate cancer cells in cultures and tumor cell growth in animal models and stimulate HL-60 cell differentiation. However, the mechanism of interaction between ligand-inducible NRs and cofactor proteins (coactivator, coregulator, and corepressor) remains unknown except in a few cases (*26*, *27*). Such ligand-induced cofactor recruitment has been investigated in cells using a two-hybrid assay and transactivation activity under the expression of a specific coactivator. For direct detection of the complex, a gel shift assay using radio-labeled vitamin D response element and a pull-down assay of radiolabeled coactivator have been used. Other methods using flow cytometry (*28*) and fluorescence resonance energy transfer (*29*, *30*) have also been reported.

A high-throughput system would be extremely useful for examining the correlation between molecular mechanisms and the phenotypes induced by small ligands. Despite the growing success in forward and reverse chemical genetics studies, including protein microarrays, small-molecule microarrays, and cell-based high-throughput assays (*31*, *32*), it remains a key challenge to develop such a system for analyzing ligand-induced interactions between NRs and cofactors. Nishikawa and coworkers reported excellent pioneering work on a high-throughput detection system that used alkaline phosphatase-fused TIF2 on the microplate (*33*). Here we describe a rapid in vitro high-throughput system to examine ligand-induced coactivator (CoA) recruitment using fluorophore-labeled cofactors and a formaldehyde (HCHO)-based fixing method (Figure 2). Moreover, using this system, we are able to explain some of the discrep-

ancies between VDR binding affinity and the biological activity of our original vitamin D_3 analogues.

EXPERIMENTAL PROCEDURES

Preparation of Plasmids. pGEXhVDR$_{4-427}$, which contains GST fused human VDR, was provided by Prof. S. Kato. pGEXhTIF2$_{609-907}$; GST fused at N-terminal a human TIF2 fragment (RID) containing amino acids 609−907 was prepared by subcloning pcDNA3-hTIF2 (full length) plasmid as a template by PCR. This protein also has a flag tag between GST and TIF2 (RID). The primers for PCR are as follows: forward-primer, 5′-GGGGGATCCATGGACTACAAGGACGATGATGACAAGAAGGAAACAAATGAC-3′, reverse-primer, 5′-GGGGAATTCTCAGTTTCTGATTGGTGG-3′. The PCR-amplified DNA fragment was digested with *Bam*HI and *Eco*RI and ligated with pGEX4T-1 expression vector (Pharmacia) digested with *Bam*HI and *Eco*RI to generate pGEXhTIF2$_{609-907}$. pGEXhSRC-1$_{290-567}$; GST fused at N-terminal a human SRC-1 fragment (RID) containing amino acids 290−567 was prepared by subcloning pcDNA3-hSRC-1 plasmid as a template by PCR. This protein also has a flag tag between GST and SRC-1 (RID). The primers for PCR are as follows: forward-primer, 5′-GGGGAATTCATGGACTACAAGGACGATGATGACAAGTCTTCAGGAGGTTCT-3′, reverse-primer, 5′-AGGGCTCGAGTGATCAGTTTCATCTTT-3′. The PCR-amplified DNA fragment was digested with *Eco*RI and *Xho*I and ligated with pGEX4T-1 expression vector (Pharmacia) digested with *Eco*RI and *Xho*I to generate pGEXhSRC-1$_{290-567}$.

Expression and Purification of Recombinant GST-Proteins. *E. coli* strain DH5α serves as a host for pGEXhVDR$_{4-427}$, or pGEXhTIF2$_{609-907}$ and pGEXhSRC-1$_{290-567}$. An overnight plateau phase culture of DH5α was used to inoculate fresh LB medium (Q-BIO gene) containing 50 μg/L ampicillin. Cells were grown at 25 °C to a density of OD_{600} of 0.4−0.6 and induced by 0.1 mM IPTG (isopropyl-1-thio-β-D-galactopyranoside) followed by incubation for an additional 3

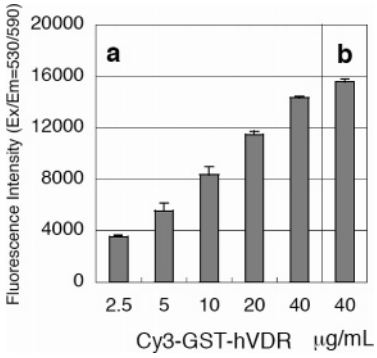

Figure 3. Immobilization of GST-hVDR on the microplate. The relationship between immobilized Cy3-GST-hVDR (Cy3/protein = 2.1) and protein concentration added. a: 2 h incubation, b: overnight incubation. After incubation of various concentrations of Cy3-GST-hVDR, wells were washed and fluorescence intensity was determined.

h at 18 °C. The cells were harvested and were lysed by sonication. The lysate was centrifuged at 37 000 rpm for 30 min at 4 °C. The resulting supernatant was added to prewashed glutathione sepharose 4B beads (Amersham Biosciences) and gentry mixed at 4 °C for 30 min. The beads obtained after centrifugation (3200 rpm, 5 min, at 4 °C) were washed 5 times (1000 rpm, 1 min, at 4 °C) with PBS-Triton X-100 buffer (PBS plus 1% Triton X-100). The recombinant proteins (GST-VDR_{4-427}, GST-$hTIF2_{609-907}$, and GST-$hSRC\text{-}1_{290-567}$) were eluted with 30 mM gluthatione buffer (50 mM Tris·HCl pH 8.8) and then dialyzed against PBS buffer using Slide-A-Lyzer^R Dialysis Cassette (Extra Strength, 10 000 MWCO, 0.5−3 mL capacity; Pierce). The recombinant proteins were estimated to be greater than 90% pure by SDS-PAGE.

Preparation of GST-hVDR Bound Microplate. Typical procedure: Nunc Immobilizer Amino 96 well Plate, white (Nalge Nunc Int., New York) was used for immobilizing GST-hVDR. The microplate wells were incubated with 100 μL of GST-hVDR (100 μg/mL, PBS, or PBS plus 100 mM Na_2CO_3 pH 9.6 buffer) 2 h to overnight at 4 °C. The protein solution was removed, and then each well was washed twice with 200 μL of PBS-Tween buffer (PBST; PBS plus 0.05% Tween 20). To block remaining activated succinimidyl ester units on the well, the wells were incubated for 2 h at room temperature with 100 μL of 10 mM ethanolamine (in 100 mM Na_2CO_3 pH 9.6 buffer) and then washed two times with 200 μL of PBST. The microplate wells were incubated with 100 μL of Cy3-labeled-GST-hVDR in PBS (40 μg/mL, dye/protein = 2.1) overnight at 4 °C. After removal of protein solution, each well was washed twice with 200 μL of PBST and then dried under reduced pressure 2 h to overnight in the dark. For the experiments described in the left five bars of Figure 3A, the microplate wells were incubated with 50 μL of Cy3-GST-hVDR (5, 10, 20, 40 μg/mL, dye/protein = 2.1) for 2 h on ice, whereas b bar in the same panel depicts the wells incubated overnight at 4 °C. The protein solution was removed, and each well was washed twice with 200 μL of PBST followed by drying under reduced pressure overnight. Microplate Reader: Powerscan HT, Dainippon Pharmaceutical Co., LTD, or Fluoroskan Ascent, Thermo Electron Corporation. Cy3; excitation 530 nm, emission 590 nm. Cy5; excitation 590 nm, emission 645 nm.

Detection of GST-hVDR in the Microplate by Anti-hVDR Antibody. We checked immobilized GST-hVDR (without Cy dye) on a well by hVDR antibody (rat monoclonal antibody, NeoMerkers) and Cy3-conjugated secondary antibody (Cy3-anti-rat IgG, Jackson ImmunoResearch Lab. Inc.). After immobilizing GST-hVDR (100 μL of 100 μg/mL, overnight, 4 °C) to a Nunc Immobilizer Amino 96 well Black Plate (Nalge Nunc Int., New York), wells were washed three times with 200 μL of PBST. To block remaining activated surface on the well, wells were incubated for 2 h at room temperature with 200 μL of 10 mM ethanolamine (in 100 mM Na_2CO_3 pH 9.6 buffer). After washing three times with 200 μL of PBST, hVDR antibody in PBS was added to wells and incubated for 1 h at room temperature. After washing three times with 200 μL of PBST, Cy3-conjugated secondary antibody in PBS was added to wells, incubated for 1 h at room temperature, and then washed three times with 200 μL of PBST, dried, and detected by a microplate reader.

Preparation of Cy-Dye-Labeled GST-hVDR (full) or GST-hCoA (RID). The Cy dye-labeled proteins were prepared by mixing of protein in PBS solution with Cy3 or Cy5 bisfunctional dye reagents (succinimidyl ester type; Amersham Biosciences) in DMSO for 1h at 4 °C in the dark. Cy dye solution was made by adding 100 μL of DMSO to 1 vial of Cy dye reagent (Amersham Biosciences) and stored at −20 °C. Usually, 2−4 μL of DMSO solution was added to 1 mL of protein solution (0.4−0.5 mg/mL) in PBS. After incubation, the mixture was directly dialyzed with PBS at 4 °C to remove excess unreacted dye reagents using Slide-A-Lyzer Dialysis Cassette (Extra Strength, 10 000 MWCO, 0.5−3 mL capacity; Pierce). After overnight dialysis, PBS was replaced with fresh PBS and dialyzed for an additional 3 h. The ratio of dye/protein was obtained after the absorption for Cys3 (ϵ 150 000 M^{-1} cm^{-1}), Cys5 (ϵ 250 000 M^{-1} cm^{-1}), and protein were determined at the wavelength 552, 650, and 280 nm, respectively. For Cy dye-labeled CoAs, the buffer was changed to NET-N buffer (20 mM Tris·HCl pH 7.5, 200 mM NaCl, 1 mM EDTA, 0.05% Nonidet P-40) by using Microcon YM-10 (Millipore), before the assay.

Detection of Ligand-Dependent Interaction between VDR and the Cy-Dye-Labeled CoA (RID) on Microplates. To GST-VDR immobilized wells (after ethanolamine blocking) were added 50 μL of Cy3-GST-hTIF2 (RID) or Cy5-GST-hSRC-1 (RID) (100 μg/mL) and 2 μL of 2 mM vitamin D_3 derivative in EtOH solution (final concn 16−160 μM). For background, 2 μL of EtOH was added. After 1 h incubation at room temperature, the VDR-CoA complex with a ligand was fixed by adding 10 μL of 8% formaldehyde (HCHO) aq (final concn 1.3%) and incubated 30 min at room temperature. After removal of the mixture, the wells were washed once with 200 μL of NET-N buffer gently and dried under reduced pressure in the dark 1 h to overnight. The fluorescence intensity was detected by a microplate reader. Usually, the assays were carried out in three individual wells, and the mean value and SD were calculated.

Transactivation Assay. Human MCF-7 breast cancer cells were maintained in Dulbecco's modified Eagle's medium without phenol red (Sigma-Aldrich), supplemented with 5% FBS which had been stripped with dextran-coated charcoal. Cells were transfected with plasmids using Polyfect (QIAGEN) and OPTI-MEM (GIBCO) in 12-well Petri dishes. The following plasmids were used for transfection: a reporter plasmid (2 μg) containing the *GAL4* upstream activation sequence (17-mer [×2], β-globlin promoter, and chloramphenicol acetyltransferase gene [CAT]) was cotransfected with 0.5 μg of pM(GAL4-DBD)-rVDR(DEF) (*26*). As a reference plasmid for normalization, 24 ng of pRL-CMV plasmid (Promega) was used. $1\alpha,25(OH)_2D_3$ (**1**) or vitamin D analogues (**2**α−**4**β) were added to the medium at 6 h after transfection (ligand final concentration: 10^{-8} M). After 18 h, luciferase activity was determined using the Luciferase Assay System (Promega). The mean value and SD of three individual wells were calculated.

Antiproliferative Activity on Prostate Cells. Tritiated thymidine incorporation into DNA was used to determine the effect of vitamin D_3 analogues on the proliferation of PZ-HPV-7 cells, obtained from ATCC (ATCC, Manassas, VA). PZ-HPV-7

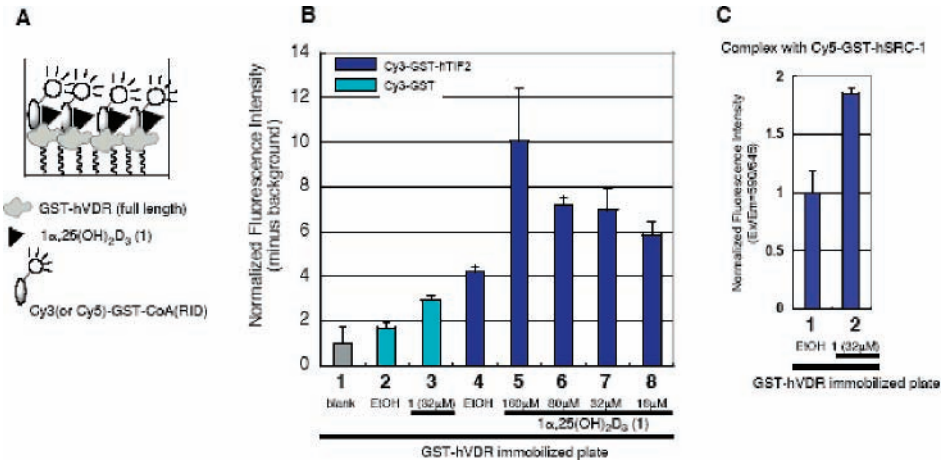

Figure 4. Detection of the ligand-dependent interaction between hVDR (full) and the fluorescent-labeled CoA (RID) on the microplate. Fluorescence intensity with EtOH was normalized to 1. **1**; EtOH with Cy5-SRC-1 (RID). **2**; 32 μM 1α,25(OH)$_2$D$_3$ (**1**) with Cy5-SRC-1 (RID).

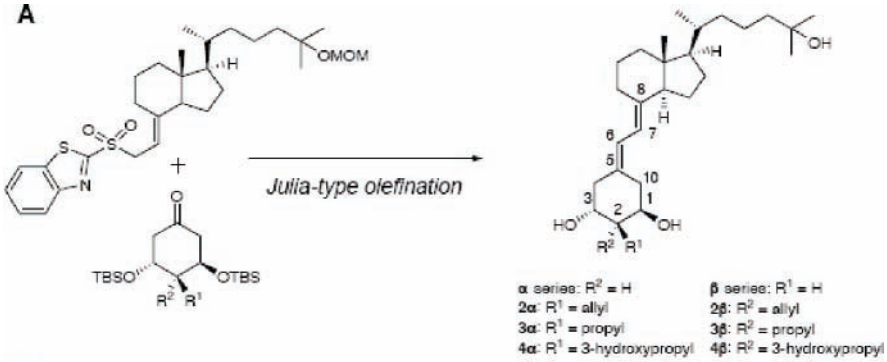
cells were grown on 24-well plates to 70% confluency in normal growth medium (*39*). Cells were then grown in the absence of growth factors for 24 h prior to the treatment with either ethanol vehicle (control), analogues, or 1α,25(OH)$_2$D$_3$ for 18 h (*39*). At the end of incubation, the medium was replaced with 0.5 mL of fresh basal medium containing 1 μCi of [methyl-^{3}H]-thymidine and incubated for 3h at 37 °C. ^{3}H-Thymidine incorporation into DNA was stopped by placing the 24-well plate on ice; unincorporated ^{3}H-thymidine then was removed and cells were washed three times with ice-cold PBS. DNA labeled with ^{3}H-thymidine was extracted by perchloric acid method as previously described (*39*) and counted using a beta-counter.

RESULTS

For preparing the VDR-microplates, glutathione-*S*-transferase-fused-hVDR (GST-hVDR) (full length) was first expressed in *Escherichia coli*, purified with glutathione sepharose 4B (Amersham Biosciences), and then immobilized to a microplate by a chemical linkage (*34*). To optimize a immobilize condition of GST-hVDR proteins, we applied increasing concentrations of Cy3-tagged GST-hVDR to a 96-well microplate (Nunc Immobilizer Amino Plate, Nalge Nunc Int.) (Figure 3) and incubated on ice for 2 h. After the incubation, the plates were washed with buffer and the fluorescence intensity of Cy3 was measured (Figure 3, left five bars). We further compared the length of incubation time. We found that overnight incubation at 4 °C increased immobilization (Figure 3, bar b) and generated more reproducible coating of the proteins (data not shown). We also monitored immobilized GST-hVDR (without Cy dye) by hVDR antibody and Cy3-conjugated secondary antibody. Although an immobilizing method using gluthatione-GST interaction principle was also investigated (*34*), the chemical immobilization method was shown to achieve better reproducibility.



The Cy-dye-labeled CoAs (receptor interaction domain: RID) were prepared by incubating GST-CoAs (RID) with dye reagents (Amersham Biosciences) for 1 h at 4 °C. The buffer, incubation time, temperature, and concentration of CoA for the optimal ligand-induced VDR-CoA interaction were also investigated. It was found that NET-N buffer (20 mM Tris·HCl pH 7.5, 200 mM NaCl, 1 mM EDTA, 0.05% Nonidet P-40), which was used in the pull-down assay, generated a better VDR-CoA interaction. To detect the ligand-induced CoA recruitment by VDR, the dye-labeled GST-CoA (RID) was added to a GST-hVDR-immobilized well with natural hormone 1α,25(OH)$_2$D$_3$ (**1**). After 1 h incubation at room temperature, 10 μL of 8% HCHO (aq) solution (final concn 1.3%) was added to fix the VDR-CoA complex, which was then removed after 30 min incubation. The microplate was washed gently once with 200 μL of NET-N buffer and dried at room temperature under reduced pressure for 1 h in the dark. The fluorescence intensity was then measured using a microplate reader. This assay can also be accomplished with 2 h VDR immobilization. Although the fluorescence intensity of the complex was detectable without HCHO-fixation, the addition of HCHO greatly improved the reproducibility of the fluorescence intensity. HCHO is commonly used to fix animal tissues, presumably by making methylene bridges between proteins.

After Cy3-labeled GST was prepared, we checked the nonspecific interaction between the immobilized GST-hVDR and Cy3-GST under formaldehyde condition. As shown in Figure 4B (**1**−**3**), Cy3-GST did not bind to GST-hVDR specifically. The fluorescence value of **1** (nontreatment with Cy3-protein; blank value), **2** (EtOH), and **3** (1α,25(OH)$_2$D$_3$) were not significantly changed. On the other hand, when Cy3-GST-TIF2 (RID) was used, the significant increasing value was obtained (Figure 4B, **4**−**8**). The complex between GST-hVDR and Cy3-GST-TIF2 (RID), induced by 1α,25(OH)$_2$D$_3$ (**1**), was detected successfully. Because the ligands were prepared as ethanol solution, the solvent effect was investigated in **2** or **4**. Moreover, the relationships between the fluorescence intensity and concentration of 1α,25(OH)$_2$D$_3$ (**1**) was obtained (**5**−**8**). The complex between GST-hVDR and Cy5-GST-SRC-1 (RID), induced by 1α,25(OH)$_2$D$_3$ (**1**), was also detected successfully (Figure 4C).

DISCUSSION

Because vitamin D analogues have many biological properties, a selective activity profile is very important in the development of pharmacological agents. Many vitamin D analogues have been synthesized and their biological activities reported. Among them, 19-nor A-ring derivatives showed a selective activity profile, e.g., a high potency in inducing differentiation of malignant cells with very low or no bone

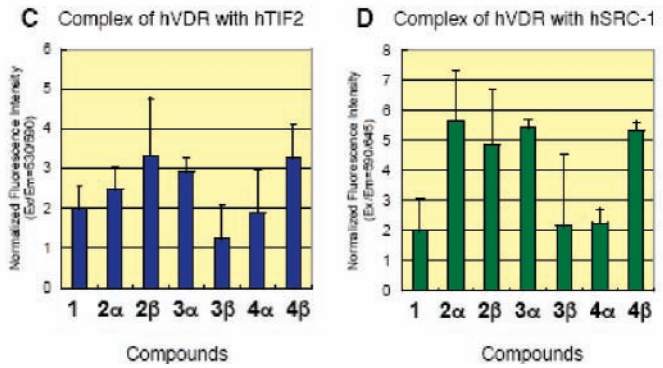

Figure 5. Synthesis and evaluation of 2-substituted-19-norvitamin D_3 derivatives (**2**α-**4**β). (A) Synthesis of 2-substituted-19-norvitamin D_3 derivatives (**2**α−**4**β) by Julia-type olefination (*37*). (B) Relative binding affinity and biological activities of **2**α−**4**β. (C) The recruitment of Cy3-GST-hTIF2 (RID) on GST-hVDR (full) by **2**α−**4**β. (D) The recruitment of Cy3-GST-hSRC-1 (RID) on GST-hVDR (full) by **2**α−**4**β. Cy3-GST-hTIF2 (RID) or Cy5-GST-hSRC-1 (RID) was added to a GST-hVDR (full) immobilized microplate well in the presence of vitamin D ligand (final 32 μM). After incubation at room temperature for 1 h, the GST-VDR (full):GST-CoA (RID) complex was fixed with 1.3% formaldehyde and washed. Background (EtOH) value was subtracted, and fluorescence intensity with 1α,25$(OH)_2D_3$ (**1**) was normalized to 2.

calcification activity (*35*, *36*). Kato et al. have reported the different selectivity of recruiting coactivators with vitamin D derivatives (*26*); however, in most cases, the relationship between biological activity and selectivity is unknown. A high-throughput system would be useful in analyzing this relationship.

We have previously reported efficient syntheses and biological evaluation of new 2-substituted-1α,25-dihydroxy-19-norvitamin D_3 analogues, 2α-allyl- (**2**α), 2β-allyl- (**2**β), 2α-propyl- (**3**α), 2β-propyl- (**3**β), 2α-(3-hydroxypropyl)- (**4**α), and 2β-(3-hydroypropyl)-1α,25-dihydroxy-19-norvitamin D_3 (**4**β), shown in Figure 5A (*37*). The A-ring precursor synthesized from (−)-quinic acid and CD-ring precursor were coupled by using Julia-type olefination to synthesize 19-norvitamin D_3 analogues in high yields. Previously, we have reported that **2**α, **3**α, **2**β, **3**β 19-norvitamin D_3 compounds had negligible VDR binding affinity compared to **1** but showed significant prodifferentiation activity in HL-60 cells. We also reported that **4**α and **4**β had either equivalent or 3% of VDR binding affinity as **1**, however, they respectively showed either 36- or 7-fold higher activity in HL-60 prodifferentiation assay (*37*). Similar discrepancy between VDR binding and antiproliferative activity was observed in prostate cells. For example, **2**α, **3**α, and **3**β had slightly higher antiproliferative activity than **1**, and **2**β, **4**α, and **4**β were 3-, 1000-, and 700-fold more active than **1** in inhibiting prostate cell proliferation (Figure 5B). Furthermore, these analogues were shown to have significantly higher VDR transactivation activity than that induced by the natural hormone **1** (Figure 5B).

Recently, Eelen et al. reported that the superagonists, 14-epi-analogues of 1α,25-dihydroxyvitamin D_3, are more potent inducers of VDR-CoA interactions (*27*). It is likely that our synthetic 19-norvitamin D_3 analogues (**2**α−**4**β) might be more effective inducers of CoAs recruitment by VDR. Therefore, we applied our novel high throughput analyzing system to evaluate the effects of 19-norvitamin D_3 analogues (**2**α−**4**β) on ligand-induced cofactor recruitment by VDR. As shown in Figure 5C, compounds **2**α, **2**β, **3**α, and **4**β showed stronger hTIF-2 recruitment than **1**. Compounds **2**α, **2**β, **3**α, and **4**β showed 2−3-fold stronger hSRC-1 recruitment than **1** (Figure 5D).

Interestingly, even when these derivatives showed low VDR-binding affinity, they had strong CoAs recruitment abilities. This

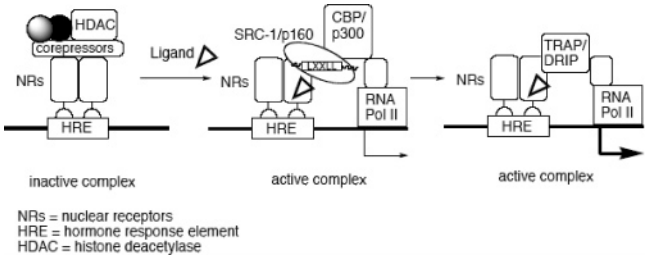

Figure 6. Combinatorial control of gene expression by NRs: Initial binding of ligand causes dissociation of corepressors. Conformational change of NRs makes binding site for SRCs and CBP. SRC and CBP complex results in local acetyltransferase activity and disruption of local nucleosomal structure. TRAP/DRIP directly interacts on the basal transcription machinery to effect transcriptional initiation.

suggests that CoAs recruitment is sensitive to the three-dimensional structure of the VDR; a small difference in conformation caused by change in ligand, and/or differences in the stability of protein−protein interactions, would be sufficient to affect CoAs recruitment ability. Compound **4**α was about 36-fold more potent in the induction of HL-60 cell differentiation than **1**, and even the weaker VDR binding ligand **4**β showed 7-fold higher cell differentiation activity than **1**. Many other cofactors, such as corepressors, HDACs, CBP/p300, and TRAP/DRIP, affect transactivation and combinatorial transcriptional initiation occurs (38 and Figure 6), so the precise molecular mechanism cannot be defined without additional data. However, it is obvious that the biological activity of vitamin D ligands must be influenced not only by VDR-binding activity but also by CoA-recruiting activity and selectivity. We believe that this high-throughput screening system for analyzing small molecule-induced CoA recruitment by VDR has great potential to become a powerful technique for examining the molecular mechanism of biological activities by small molecules.

In this study, we have developed a novel rapid system for analyzing ligand-induced cofactor recruitment by VDR using fluorophore-labeled CoA and HCHO fixation method. The high-throughput screening of small molecules can be utilized to differentiate different ligands that cause NR conformation changes. Moreover, since several different fluorophores (Cy3, Cy5 etc.) can be used, in principle, it will be possible to analyze simultaneously the interactions between the NR and several cofactors, and the cofactor selectivity of each ligand−NR complex. We believe that this method will have broad application for investigating ligand-based cofactor recruitment of NRs in vitro.

ACKNOWLEDGMENT

This study was supported by a Grant-in-Aid for Young Scientists (B) from the Ministry of Education, Culture, Sports, Science and Technology, Japan, (No. 16790027 and 18790012 to M.A.A.) and in part by Grants-in-Aid for Scientific Research (C) from Japan Society for the Promotion of Science (No. 15590021 and 17590012 to A.K.). A.K. also gratefully acknowledges Uehara Memorial Foundation for financial support. This work was also supported in part by a grant from US Army DAMD17-01-0025 (to T.C. Chen). We thank Dr. Yamashita and Dr. Maruyama (Teikyo University) for discussions.

DNA-Directed Assembly of Supramolecular Fluorescent Protein Energy Transfer Systems

Florian Kukolka,[†] Oliver Schoeps,[‡] Ulrike Woggon,*[,‡] and Christof M. Niemeyer*[,†]

Fachbereich Chemie Biologisch-Chemische Mikrostrukturtechnik and Fachbereich Physik, Universität Dortmund, Otto-Hahn Str. 6, D-44227 Dortmund, Germany. Received May 31, 2006; Revised Manuscript Received January 16, 2007

Fluorescent proteins with a wide variety of physicochemical properties have evolved in the past few years. The use of these proteins for applications in biomolecular nanosciences requires their precise positioning at the nanometer length scale. To address this challenge, we report here on the self-organization of DNA-tagged fluorescent probes to construct a set of photofunctional supramolecular complexes which include the enhanced yellow fluorescent protein (EYFP). The optical functionality is based on the strongly distance dependent fluorescence resonance energy transfer (FRET), occurring between the donor (EYFP) and an acceptor fluorophore, i.e., the fluorescent dye Atto647. The photophysical properties of four bimolecular FRET complexes, each possessing a well-defined donor−acceptor distance defined by the length of the interconnecting DNA backbone, are investigated by two-dimensional photoluminescence excitation spectroscopy (2D-PLE).

INTRODUCTION

The major goal of the development and investigation of artificial light-harvesting systems concerns the mimicry of the initial steps of incredibly efficient photon energy uptake and funneling toward a reaction center during photosynthesis. In addition to the general understanding of the fundamental principles of such complex reaction cascades, there is currently also a great interest in the development of photonic energy transfer systems, because such devices hold promise for applications in several research areas of nanotechnology, such as molecular photonics and bioelectronics (*1*). Several organic chromophores have already been used for photon energy uptake in artificial light-harvesting complexes, such as porphyrin derivatives (*2*), polypyridine complexes of d^6 metal ions (*2, 3*), or perylenes (*5*−*8*).

However, in order to fabricate well-defined arrangements of different chromophores, one major problem in the realization of complex superstructures concerns the precise control of the spatial arrangement of the various components within the functional unit (*1*). To address this problem, the biomimetic self-assembly of the individual compounds appears to be straightforward. For example, the extraordinary specific molecular recognition of complementary ssDNA sequences has already been utilized for the spatially defined organization of DNA-tagged molecular and colloidal components (*9*−*14*). The photophysical characterization of such arrangements of synthetic fluorophores assembled along short double-stranded (ds)DNA molecules has been the subject of current research. For example, up to five different organic fluorophores have been organized at the nanometer length scale by means of DNA hybridization to form a photonic wire (*15*−*19*). These systems revealed a unidirectional energy transport based on fluorescence resonance energy transfer (FRET) along an energy cascade.

We have recently suggested utilizing fluorescent proteins for the synthesis and investigation of artificial light-harvesting antennae systems (*20*). The most prominent example of fluorescent proteins is the naturally occurring green fluorescent protein from the north Pacific jellyfish *Aequorea victoria* (*av*GFP), which has been used extensively as a biological marker (*21*). A full range of fluorescent proteins with emission maxima ranging from blue to red are nowadays available. These are either mutants of the *av*GFP or derivatives of similar proteins from other marine organisms (*22*−*25*), and the ongoing discovery of novel proteins with different physicochemical characteristics suggests that the range of these interesting proteins is by far not fully exhausted yet. For example, fluorescent proteins with the ability of being reversibly photoswitched between a fluorescent and a nonfluorescent state have recently attracted attention (*26*−*28*). In addition, proteins, in general, can be tailored with a large variety of synthetic moieties, such as non-natural amino acids (*29*), to modulate their spectral properties and binding capabilities. Hence, one may anticipate that this panel of natural fluorophores should be well-suited as building blocks for artifical supramolecular antennae systems or as components of nanoscaled optical data storage devices. To initiate this novel approach, we recently reported on the synthesis of a semisynthetic covalent DNA−fluorescent protein conjugate, as a first step to the DNA-directed assembly of supramolecular fluorescent protein FRET systems (*20*).

We report here on the assembly and spectroscopic characterization of various unique FRET systems (FS), which were constructed by means of DNA hybridization using the enhanced yellow fluorescent protein (EYFP) as the donor (D) and the organic fluorescent dye Atto647 as the acceptor (A) for energy transfer. In these systems, the interchromophore distance of donor and acceptor can be conveniently changed by variation of the binding sites of the fluorophores at the DNA "carrier" helix. In contrast to another study based on single-molecule spectroscopy, in which donor and acceptor were assembled by hybridization of a DNA−dye and DNA−EYFP conjugate along a complementary DNA scaffold (*30*) to obtain two different complexes, we report here on the assembly of four different FRET systems in a more direct, bimolecular hybridization, thus allowing us to gradually change the distance between A and D.

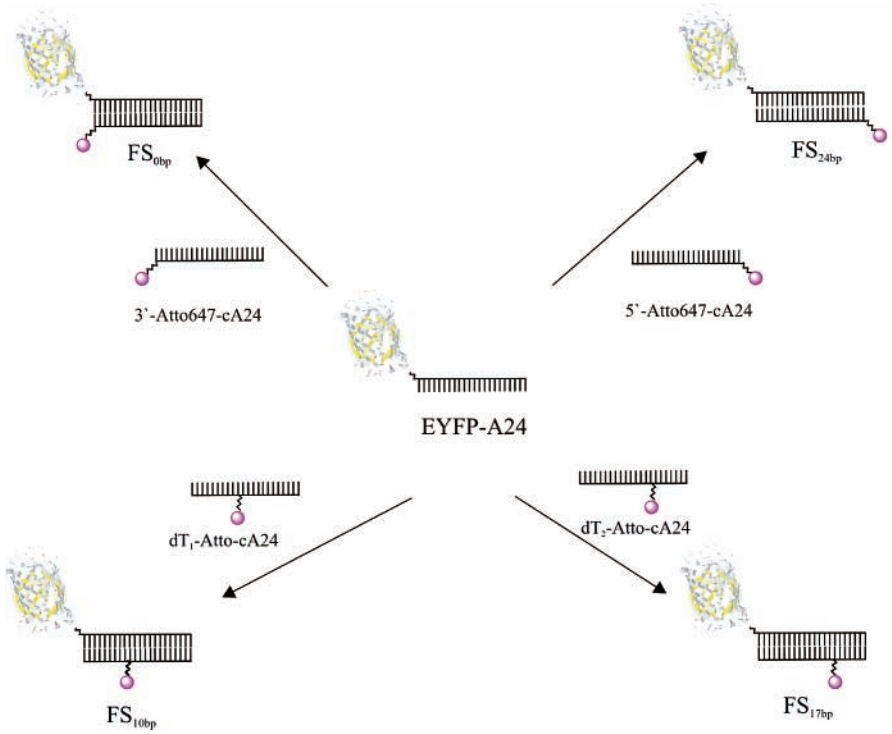
Scheme 1

The different FRET systems were characterized by two-dimensional photoluminescence excitation spectroscopy (2D-PLE). 2D-PLE is a powerful method to study electronic couplings and energy transfer between donor and acceptor states in FRET systems. The emission is monitored over a whole range of wavelengths instead of a narrow detection window, as in conventional, one-dimensional PLE. This enables one to display the full landscape of photoluminescence (PL) intensity as a function of the excitation energy and to analyze energy transfer within a multicomponent system. The mutual correlations between donor and acceptor states can be qualitatively identified from the magnitude of the corresponding off-diagonal signal in the spectrally resolved 2D intensity maps. From the experimental 2D contour plots, we were able to derive energy transfer efficiencies and to calculate the Förster radius R_0 for the EYFP−Atto647 system.

EXPERIMENTAL PROCEDURES



DNA−Chromophore Conjugates. Recombinant ^{Cys}EYFP was covalently coupled to the 5′-end of a 24mer oligonucleotide (sequence A24: 5′-TCC TGT GTG AAA TTG TTA TCC GCT-3′) yielding conjugate ^{Cys}EYFP−A24 similar to the method previously described (*20*). Because the two cystein groups of the native EYFP are not accessible for covalent coupling with DNA oligomers (*20*), a ^{Cys}EYFP mutant was created by site-directed mutagenesis bearing an extra cysteine residue at the C-terminal end, which is located at the protein's surface. The protein was expressed in *E. coli* and purified by affinity chromatography. The amino-modified oligonucleotides were first derivatized with the heterobifunctional cross-linker sulfo-succinimidyl-4-[*N*-maleimidomethyl]-cyclohexane-1-carboxylate (sSMCC), which comprises a maleimide and a N-hydroxy-succinimide (NHS) ester group, that are reactive toward thiols and primary amines, respectively (Scheme 1). The maleimide-containing DNA oligomers were then reacted with the ^{Cys}EYFP, and the conjugates were purified by anion-exchange chromatography and analyzed by UV/vis spectroscopy. The ratio of absorbances measured at 260 and 280 nm, respectively, was found to be 1.50, and this value was in good aggreement with a control solution comprising equimolar amounts of DNA A24 and the EYFP (1.53). In contrast, control samples containing either of the two components in a 2-fold excess, i.e., DNA/EYFP = 2:1 or DNA/EYFP = 1:2, revealed values of 1.61 and 1.41, respectively, thus confirming the 1:1 stoichiometric ration of DNA/EYFP in the ^{Cys}EYFP−A24 conjugate. Moreover, analysis of the ^{Cys}EYFP−A24 conjugate by SDS-PAGE showed a single band with a molecular weight of approximately 39 kDa, which is in good aggreement with the expected mass of a 1:1 conjugate (data not shown). The conjugates were stored in TETBS buffer (20 mM Tris-buffered saline containing 150 mM NaCl, 5 mM EDTA, 0.005% Tween-20, pH 7.5).

Atto647−DNA conjugates were purchased lyophilized from TIB MOLBIOL (Berlin, Germany), dissolved in H_2O at a concentration of 100 μM, and stored at −20 °C until use. In these conjugates, the Atto647−fluorophore is attached through a C_6-linker to the 3′-end, through a C_7-linker to the 5′-end, or through a C_2-linker at two different thymine bases dT (italicized) of the 24mer oligonucleotide cA24 (sequence: 5′-AGC GGA *T*AA CAA T*T*T CAC ACA GGA-3′), which is fully complementary to sequence A24, leading to four different conjugates: 3′-Atto−cA24, 5′-Atto−cA24, dT_1-Atto−cA24, and dT_2-Atto−cA24 (Scheme 2). According to manufacturer's information, the DNA oligomers contained one Atto647 dye per DNA oligomer. Analysis of the Atto-labeled oligonucleotides by MALDI-TOF mass spectrometry indicated the expected molecular weights with slight deviations of less than 2%. The 1:1 stoichiometric ratio was additionally confirmed, on one hand, by quantifying the absorbances of the Atto647−cA24 conjugates at both 260 and 649 nm and the independent calculation of conjugate concentrations. On the other hand, the Atto647−cA24 conjugates were titrated in the course of the assembly of the FRET system with the complementary ^{Cys}EYFP−A24. These titrations showed a maximum in the quenching of the EYFP fluorescence as well as in the FRET-based Atto647 emission at the stoichiometric ratio of 1:1, thus confirming the 1:1 stoichiometry of both conjugates (data not shown).

Assembly of FRET Systems. The four different supramolecular FRET systems with differing numbers of base pair separations ($FS_{0bp-24bp}$, Scheme 2) were assembled by hybridization of ^{Cys}EYFP−A24 with the Atto647-labeled oligomers, such that the variation in donor and acceptor distance should be reflected in different FRET efficiencies. To this end, the ^{Cys}EYFP−A24 conjugate and Atto−oligomers were mixed in TETBS at a final concentration of 0.5 μM. For higher hybridization efficiencies, the samples were heated up to 50 °C for 5 min, slowly cooled to room temperature, and then stored at 4 °C until used in PLE measurements. As controls, the single fluorophore DNA conjugates were hybridized with complementary unlabeled DNA, and an EYFP−DNA conjugate (^{Cys}EYFP−cA24) containing the same DNA sequence as the Atto647−DNA conjugates was incubated with the Atto−oligomer species.

2D-PLE Measurements. For measuring the PLE spectra, the sample was illuminated using a 150 W xenon lamp spectrally filtered by a 1 m monochromator. The collected luminescence was spectrally dispersed in a 0.25 m spectrometer and recorded with an optical multichannel analyzer, yielding spectra over the full visible wavelength range. These spectra were then normalized to the photon flux at the excitation wavelength, which was monitored by a photodiode. The excitation wavelength was scanned over 240 nm with a step size of 1 nm. All signals were corrected with respect to the spectral sensitivity of both the excitation monitoring and the fluorescence detection systems.

Scheme 2

We present the PLE signals of the individual samples as two-dimensional, color-coded plots of the emission intensity, spectrally dispersed along the *x*-axis, while the *y*-axis represents the different excitation wavelengths. The diagonal line, stemming from scattered excitation light, indicates the resonance case of excitation energy being equal to the detection energy.

2D-PLE of the Fluorescent Protein EYFP. In order to establish the major constituent of our FRET system, we initially investigated the internal energy relaxation pathway of the EYFP. An ideal donor system, in general, should emit at a single, homogeneously broadened ground-state energy with intensities proportional to the density and oscillator strength of the absorbing states of the corresponding donor absorption spectrum. The photoluminescence (PL) line width of the emitting state should not be influenced by an internal fine structure of the optical ground state, which would cause inhomogeneous broadening by a superposition of several optically allowed and dark states. Figure 1 shows the measured 2D-PLE intensity map of solely the EYFP−A24 donor conjugate. The excitation wavelength was tuned from short excitation wavelengths/high energies (460 nm/2.694 eV) toward longer wavelengths/lower energies (535 nm/2.316 eV) in steps of 1 nm while recording for each excitation the corresponding emission spectrum within a detection range between 500 and 620 nm. As shown in Figure 1 (left), the EYFP emission has a maximum at 528 nm with an asymmetric line shape showing a long spectral tail toward longer wavelengths, reaching the zero level around 650 nm. The signal on the upper left side of the diagonal line might indicate the presence of excited vibrational degrees of freedom in the sample, that contribute to the complete energy balance for radiative recombination. This observation is not affected by DNA, since it is observed in samples consisting of the fluorophores only. To analyze the PL line shape as a function of excitation energy, we normalized the full emission spectra with respect to the number of exciting photons derived from the absorption strength at the corresponding wavelength measured before in the same experimental setup. The result is shown in Figure 1 (right). It confirms that the shape of the emission spectrum is independent of the excitation energy, thereby ruling out a fine structure that may interfere with an energy transfer signature in the 2D-PLE plot of the combined donor−acceptor system.

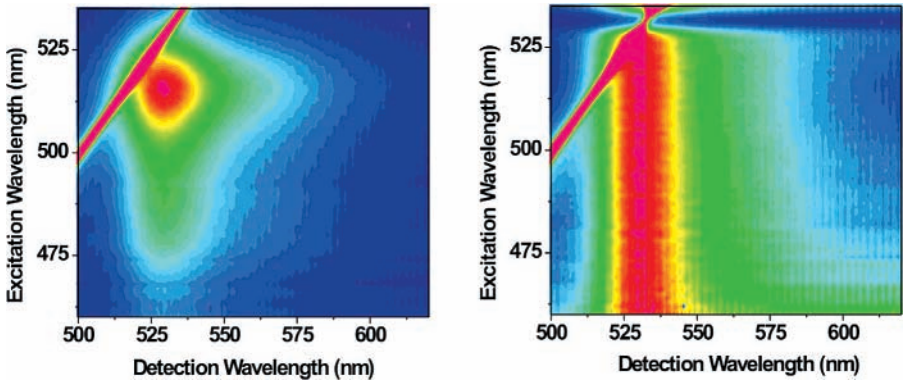


Figure 1. Left: 2D-PLE of the EYFP donor in color-coded (linear) intensities covering a range from 0 (blue) to 50 000 (red) counts. Right: 2D-PLE of the EYFP donor normalized with respect to the number of absorbing states showing an excitation-independent emission line shape and emission maximum. The color-coded (linear) intensity covers a range from 0 (blue) to 1 (red). The intensity which is recorded as the diagonal signal arises from scattered excitation light.

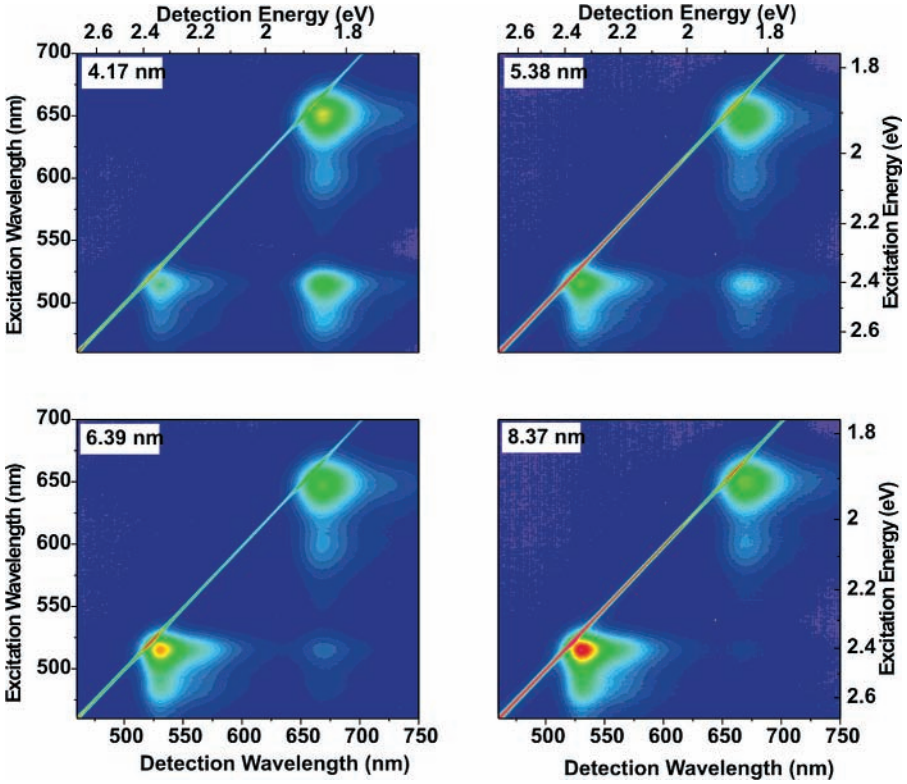

Figure 2. 2D-PLE signals of the different FRET systems FS_{0bp}, FS_{10bp}, FS_{17bp}, and FS_{24bp} with the corresponding donor−acceptor distances. The signature at the upper right corner of each graph arises from the Atto647 acceptor, and the signature at the lower left corner from the EYFP donor. The off-diagonal signature at the acceptor emission energy (lower right corner) shows the emission due to transfer. A distance-dependent quenching of the donor emission is accompanied by an enhanced acceptor PL.

RESULTS AND DISCUSSION

2D-PLE of the Donor−Acceptor System EYFP−Atto647. In the four different supramolecular FRET systems ($FS_{0bp-24bp}$; for a schematic representation of the structures, see Scheme 2), the donor and acceptor distance was increased stepwise from 0 over 10, 17, to 24 base pairs (bp), by varying the binding site of the Atto dye on the DNA in the corresponding Atto647−DNA conjugates. As will be discussed below, these variations in the number of base pairs leads to donor−acceptor distances of 4.17, 5.38, 6.39, and 8.37 nm, respectively. The 2D-PLE spectra of these four different supramolecular FRET systems are shown in Figure 2. In case of a too large donor−acceptor distance, no transfer was expected, and the 2D-PLE signals of donor and acceptor should appear as two independent features, namely, the above-discussed 2D-PLE of the control EYFP−A24 in addition to a similar spectral feature of the acceptor Atto647. Indeed, such a pattern was clearly observed for FS_{24bp}, with a donor−acceptor separation of 8.37 nm. If the donor−acceptor pair is separated by a distance that allows for significant FRET, a third feature should be visible in the PLE plot. It appears as PL intensity at the spectral position of the acceptor's preferential recombination wavelength, while exciting the system at the wavelength of maximum donor absorption (see the 2D-PLE plot for FS_{0bp}; Figure 2). The strength of that off-diagonal signal is considered to be the fingerprint of energy transfer. For a quantitative analysis, the transfer efficiency is extracted from the luminescence intensity F of both emitting species, analyzing either the intensity at the peak positions or the volume under the curve down to 50% of the maximum. The transfer efficiency E is then extracted as $E = [1 + (F_D\eta_A/F_A\eta_D)]^{-1}$. For the FRET systems shown in Figure 2, we obtained values for E of 0.79, 0.53, 0.26, and 0.074 for FS_{0bp}, FS_{10bp}, FS_{17bp}, and FS_{24bp}, respectively.

More obvious information about the energy transfer pathways and the absolute transfer efficiency can be obtained by transforming the PLE signals into a loss/gain statistic by subtracting the intensities of the control samples, i.e., the hybridized samples of the individual fluorophores ^{Cys}EYFP−A24 + bcA24 and Atto647−cA24 + bA24 (see Figure 3).

Figure 3 shows the spectral window of the differential 2D-PLE around the donor absorption. The violet color code indicates fluorescence quenching, while the red color code corresponds to absolute gain. With increasing donor−acceptor distance, the donor emission becomes less quenched while the acceptor gain decreases until the transfer is completely hindered by a too large donor−acceptor separation. In case the EYFP was quenched via another competitive channel without significant transfer to the Atto647 acceptor, we would expect a strong negative (violet) signal at the donor emission in the differential 2D-PLE plot but no (or weak) positive (red) signal at the acceptor energy. Since such a feature and also a significant gain at another spectral position was not observed, we again concluded that the energy of the EYFP donor is directly transferred to the Atto647 acceptor in the FRET systems FS_{0bp}, FS_{10bp}, and FS_{17bp}.

FRET Efficiencies and Determination of the Donor−Acceptor Distance. To estimate the distance between the donor and the acceptor, one has to take into account the helical nature of double-stranded DNA. Under the conditions used in our experiments, we expect the DNA to adopt the regular conformation of the right-handed B-DNA helix. In this conformation, the DNA has a diameter of 2 nm, the increase in height per base pair is 0.34 nm, and ten base pairs comprise one entire helical turn. To confirm the assumption that the DNA in the FRET systems is indeed in the B-form conformation, we measured CD spectra of FS_{0bp} and a sample containing an equimolar mixture of unlabeled A24 and cA24 (Figure 5). Both curves display strong negative and positive cotton effects around 250 and 280 nm, respectively. This pattern is characteristic for B-form DNA and is in agreement with previously reported similar systems (*16*). Since the persistence length of duplex

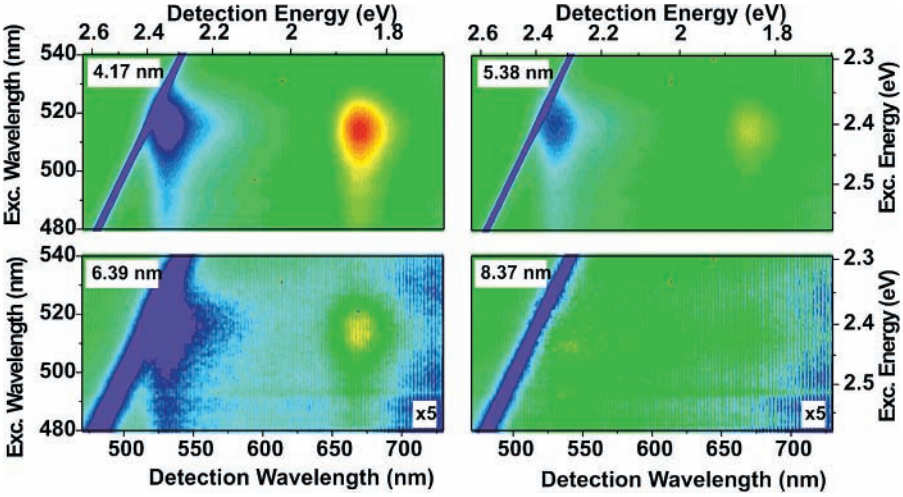

Figure 3. Differential 2D-PLE spectra obtained by subtracting the PLE signals of the control samples (isolated, hybridized donor and acceptor) from the PLE of the FRET systems. The linear color scale shows quenching (violet), enhancement (red), and constancy (green) of the emission intensities on a scale corresponding to −50% to +50% for the top row and −10% to +10% for the bottom row.

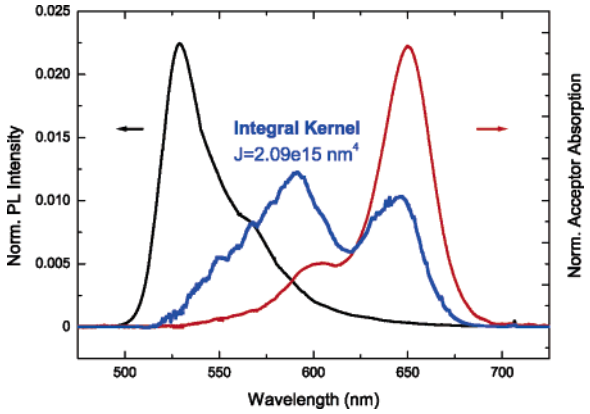

Figure 4. Measured donor emission spectrum (black) and acceptor absorbance (red). The blue curve shows the resulting overlap integral kernel yielding $J = 2.09 \cdot 10^{15}$ nm^4.

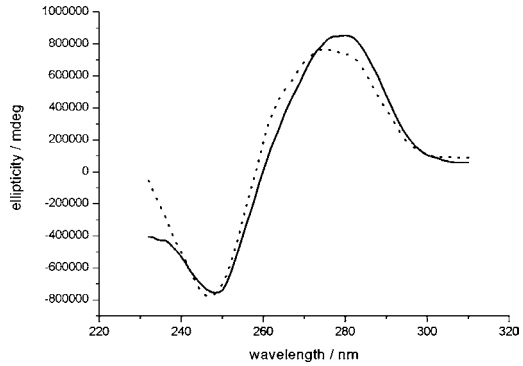

Figure 5. CD spectra of FRET system FS_{0bp} (solid curve) and an equimolar mixture of unlabeled A24 and cA24 (dotted line).

DNA is about 50 nm (*31*), the 24 bp dsDNA system with a nominal length of 8.16 nm studied here can be regarded as a rigid-rod linear system. Donor and acceptor positions were therefore represented as vectors in a cylindrical coordinate system (*32*) with the symmetry axis of the DNA as the *z*-axis and the DNA−donor link defining the direction of the *x*-axis (see schematic representation in Figure 6). The absolute value of the donor and acceptor connecting vector then represents the distance. To calculate the values R_D and R_A for the distances between the *z*-axis and the donor and acceptor, respectively, one first needs to estimate the Förster distance for the donor and acceptor pair. According to Förster theory, the Förster radius R_0 can be calculated by

$$R_0^{\,6} = 8.79 \cdot 10^{-5} \cdot [Q_D \kappa^2 n^{-4} J]$$

yielding R_0 in Å with J in M^{-1} cm^{-1}(nm) (*4*). Q_D is the quantum efficiency of the donor, $\kappa^2 = {}^2/_3$ of the orientational factor, and $n = 1.33$ is the refractive index of the medium. J is the spectral overlap integral, which can be derived from the experimentally obtained absorption and emission spectra. The Förster radius R_0 is the distance at which the energy transfer efficiency is 50%. For the calculation of J, the measured donor emission spectrum was normalized to an area of 1 on a wavelength scale (see Figure 4). It was multiplied by the measured acceptor's extinction, taking into account the optical path length within the cuvette as well as the concentration. After multiplication with the fourth power of the wavelength, the result was numerically integrated to obtain $J = \int f_{Don}(\lambda) \epsilon_{Acc}(\lambda) \lambda^4 \, d\lambda$. Using the experimentally determined J, we find $R_0 = 5.38$ nm as a first estimate for the Förster radius.

Correlation of the cylindrical model with the data measured for the FRET efficiencies (Figure 2) and the calculated R_0 allows one to calculate the values of $R_D = 2.8$ nm and $R_A = 1.38$ nm and to translate the number of base pairs between donor and acceptor into metric values of 4.17, 5.38, 6.39, and 8.37 nm for the $FS_{0bp-24bp}$. To calculate the transfer efficiencies from the maximal emission intensities of donor and acceptor upon donor excitation F_D and F_A, respectively, we took quantum efficiencies of 20% for the Atto647 (according to information of the manufacturer) and 62% for the EYFP (*33*) into account via $E = [1 + (F_D \eta_A / F_A \eta_D)]^{-1}$. The independence of the PL line shape from the excitation wavelength ensures equal results when using peak intensities or volumes under the 2D-PLE intensity plots (not shown).

Figure 6 illustrates the derived change in donor−acceptor distance when increasing the number of base pairs (bp). The closest distance is found for a distance of approximately 5 bp. In this FRET system, the donor would just sit on top of the acceptor, having the same angular coordinates. The minimum distance for 0 bp separation is determined by the diameter of the DNA cylinder and the approximate length of the linking molecules, as well as the distance from the EYFP chromophore inside of the protein structure to the surface. The measured transfer efficiencies in dependence of the donor−acceptor distance is displayed in Figure 7. The data points are in very good agreement with a Förster-type curve for a distance-

dependent energy transfer, proving that DNA−fluorescent protein based supramolecular FRET systems can be rationally designed for generating energy transfer systems with predictable optical properties.

CONCLUSION

We reported here on four supramolecular FRET systems which were obtained by hybridizing the ^{Cys}EYFP−DNA conjugates with the complementary Atto647−cDNA conjugates. The donor−acceptor distance was altered in a controlled way by variation of the number of base pairs separating the donor EYFP and the acceptor dye Atto647. The interchromophore distances were calculated within a cylinder model of the DNA helix yielding 4.17, 5.38, 6.38, and 8.37 nm for the used separations of 0, 10, 17, and 24 base pairs, respectively. For these donor−acceptor distances, the energy transfer was evidenced in 2D-PLE spectra which clearly showed the loss/gain statistics. The calculated values for the FRET efficiencies and the Förster radius are in good agreement with the experimentally obtained values. We anticipate that the molecular construction approach reported here should allow one to rationally assemble more complex, nanoscaled optical systems by taking advantage of the incredibly diverse physicochemical properties of fluorescent proteins.

Fluorescent Fructose Derivatives for Imaging Breast Cancer Cells

Jelena Levi, Zhen Cheng, Olivier Gheysens, Manish Patel, Carmel T. Chan, Yingbing Wang, Mohammad Namavari, and Sanjiv Sam Gambhir*

Molecular Imaging Program at Stanford (MIPS), Departments of Radiology and Bioengineering, Bio-X Program, Stanford University, Stanford, California 94305. Received June 26, 2006; Revised Manuscript Received March 5, 2007

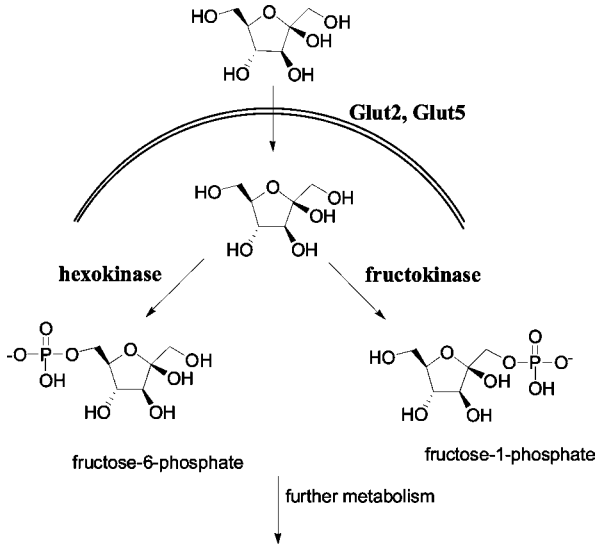
Breast cancer cells are known to overexpress Glut5, a sugar transporter responsible for the transfer of fructose across the cell membrane. Since Glut5 transporter is not significantly expressed in normal breast cells, fructose uptake can potentially be used to differentiate between normal and cancerous cells. Fructose was labeled with two fluorophores at the C-1 position: 7-nitro-1,2,3-benzadiazole (NBD) and Cy5.5. The labeling site was chosen on the basis of the presence and substrate specificity of the key proteins involved in the first steps of fructose metabolism. Using fluorescence microscopy, the uptake of the probes was studied in three breast cancer cell lines: MCF 7, MDA-MB-435, and MDA-MB-231. Both fluorescent fructose derivatives showed a very good uptake in all tested cell lines. The level of uptake was comparable to that of the corresponding glucose analogs, 2-NBDG and Cy5.5-DG. Significant uptake of 1-NBDF derivative was not observed in cells lacking Glut5 transporter, while the uptake of the 1-Cy5.5-DF derivative was independent of the presence of a fructose-specific transporter. While 1-NBDF showed Glut5-specific accumulation, the coupling of a large fluorophore such as Cy5.5 likely introduces big structural and electronic changes, leading to a fructose derivative that does not accurately describe the uptake of fructose in cells.

INTRODUCTION

With an estimated 211 240 diagnosed cases and 40 870 deaths in 2005, breast cancer represents the second leading cause of cancer deaths and one of the most frequently diagnosed malignancies among U.S. women (*1*). When it is detected early, breast cancer patients have a survival rate of 98% (*1*). Despite its limitations (*2*, *3*), screening mammography is still the most widely used method for early detection. Mammography relies on anatomical differences between normal and cancerous tissues, and as such does not provide specific information about the molecular processes and changes at the cellular level. Modalities that offer functional imaging (*4*), such as positron emission tomography (PET[1]), single photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI), are increasingly gaining importance in breast cancer detection (*5*−*8*). Detection using probes that differentiate between cancerous and normal breast cells at a molecular level provides specific information that can potentially be utilized for earlier detection, therapy response assessment, and overall better management of patients, ultimately leading to a better survival rate.

The most common, best-studied example of imaging molecular processes at a cellular level is the use of the glucose analog, 2-[^{18}F] fluoro-2-deoxy glucose (FDG) with PET (*9*). Most cancers overexpress Glut1, a high-affinity glucose transporter, and therefore have an increased capacity for glucose uptake when compared to normal cells (*10*, *11*). Once inside the cell, FDG undergoes the first step of metabolism, phosphorylation by hexokinase. Phosphorylated FDG cannot be further metabolized because it is not a substrate for aldolase, an enzyme involved in the second step of metabolism, nor can it leave the cell due to the charged phosphate. The accumulation of FDG thus describes specific molecular processes: transport by Glut1 and phosphorylation with hexokinase.

Glut transporters are transmembrane proteins responsible for transporting sugars such as glucose, fructose, and galactose through the cell membrane. To date, 13 members of the Glut family have been identified, all having a similar sequence but different tissue expression and substrate specificity (*11*, *12*). To satisfy high-energy needs associated with increased proliferation, cancers commonly overexpress one or more Glut transporters. Breast cancer cells are found to have high levels of Glut5, a fructose-specific transporter, not significantly expressed in normal breast cells (*13*). Fructose can be transported by another member of the Glut family, Glut2, a low-affinity transporter that can also transport glucose. Glut2 is not found to be differentially expressed in normal and breast tumor cells (*13*) and as such does not likely represent a relevant target for detecting molecular changes in breast cancer cells. A recent study (*14*) reported 85% of the 33 tested breast cancer tissues expressing Glut 5. The same study done on 215 different tumor samples has found that, besides the ubiquitous glucose transporter, Glut1, the most commonly expressed transporters in cancer tissues are Glut2 and Glut5, both fructose transporters, suggesting the importance of fructose metabolism not only in breast but also in other cancers.



Molecules tagged with fluorescent labels have found a broad application in imaging as a cheaper and safer alternative to radioactive probes (*15*). Although poor light penetration through tissues makes their utilization in humans difficult, they are successfully applied in preclinical, small animal research (*15*−*18*). For the purpose of developing more specific imaging probes for breast cancer, we have synthesized fructose-based optical probes using two fluorophores as labels: 7-nitro-1,2,3-benzoxadiazole, NBD, and cyanine dye, Cy5.5. NBD fluorophore has

Scheme 1. Transport and Phosphorylation of Fructose[a]

[a] Fructose is transported by Glut2 and Glut5 transporters across the cell membrane. While Glut2 can transport both glucose and fructose, Glut5 is a fructose-specific transporter. Fructose can be phosphorylated by two enzymes: hexokinase that phopsphorylates fructose in C-6 position and fructokinase (ketohexokinase) that phosphorylates fructose in C-6 position.

been used to label glucose at two positions, C-2 and C-6. Fluorescent glucose analog, 2-[*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino]-2-deoxy-D-glucose (2-NBDG) was developed for the viability assessment of *E. coli* (*19*). It has already been shown that it is transported through the cell membrane using the same mechanism as glucose, and that it is a substrate for hexokinase (*19*−*21*). Although transported by the same mechanism, 6-NBDG has a fluorophore at the phosphorylation site and is, therefore, not a substrate for hexokinase (*22*). Cy5.5 dye has better spectral characteristics than NBD, emitting light in the NIR region where there is minimal spectral interference from biological tissues (*23*). In preclinical settings, Cy5.5-labeled tracers have found broad application in tumor detection and drug treatment assessment (*24*−*27*).

In order to choose the labeling position that would allow transport and phosphorylation by the same proteins used by fructose, we looked into substrate specificity of the Glut5 transporter and kinases that can phosphorylate fructose. Fructose can be phosphorylated by two enzymes: hexokinase (HK) and fructokinase (ketohexokinase, KHK). Hexokinase phosphorylates fructose at the C-6 position, while fructokinase phosphorylates it at the C-1 position (Scheme 1). Ideally, we would like to label fructose in such a way to keep both C-1 and C-6 positions available for whichever of the two enzymes might be involved in phosphorylation. However, studies on substrate specificity of Glut5 show bulky groups being tolerated only at C-1 and C-6 positions (*28*, *29*). Furthermore, for fructokinase, C-2, C-3, and C-4 seem to be important for binding and enzyme activity, while groups at C-6 are well-tolerated (*30*, *31*). Similarly, hexokinase allows modification of structure at the C-1 position, the site furthest away from the site of phosphorylation, while hydroxyls at C-3 and C-4 are needed for the productive binding to the enzyme and the subsequent turnover (*32*). Because derivatization at either the C-1 or C-6 position allows phosphorylation by only one of the kinases but prevents enzyme activity of the other, we first wanted to determine the metabolic pathway that fructose takes once inside the cell by looking into the presence and the levels of the two kinases in the breast cancer cell lines. On the basis of the results of the Western analysis and considering substrate specificity of proteins involved in the first steps of fructose metabolism, we chose to label fructose in the C-1 position. Fructose has been labeled at the C-1 position with ^{18}F and evaluated as a PET imaging agent for fibrosarcoma (*33*). Possibly due to the use of fibrosarcoma as a tumor model, for which levels of Glut5 have not been determined, 1-deoxy-1-[^{18}F]fluoro-D-fructose did not show good imaging potential.

Here, we wish to present the syntheses of two fluorescent fructose derivatives, 1-[*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-amino]-1-deoxy-D-fructose (1-NBDF) and 1-Cy5.5-1-deoxy-D-fructose (1-Cy5.5-DF), and evaluation of their possible application as breast cancer imaging probes.

MATERIALS AND METHODS

General. Ketohexokinase (fructokinase) rabbit polyclonal antibody was purchased from Abnova corporation (Taipei, Taiwan). Hexokinase I rabbit polyclonal antibody was purchased from Abgent (San Diego, CA). Hexokinase II rabbit polyclonal antibody was purchased from Chemicon International, Inc. (Temecula, CA). Peroxidase conjugated goat anti-mouse IgG and goat anti-rabbit IgG were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). Enhanced chemiluminescence (ECL) reagents and Cy5.5 *N*-hydroxysuccinimide ester (Cy5.5-NHS) were purchased from Amersham Biosciences (Piscataway, NJ). 2-NBDG was obtained from Molecular Probes (Eugene, OR). 2-Cy5.5-2-deoxy-D-glucose (Cy5.5-DG) was synthesized using the procedure reported earlier (*34*). All other chemicals were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO) and were used without further purification. Glass-bottomed tissue culture dishes were acquired from MatTek Corporation (Ashland, MA). Purification and analysis of the products was performed using the Dionex Summit high-performance liquid chromatography (HPLC) system (Dionex Corporation, Sunnyvale, CA), equipped with a 340U four-channel UV−vis absorbance detector. For the analysis of the products, reverse-phase HPLC column Dionex Acclaim120 (C18, 4.6 mm × 250 mm) was used. Reverse-phase semipreparative HPLC column Zorbax SB (C18, 9.4 mm × 250 mm) was used for purification and isolation of products. The mobile phase was 0.1% trifluoroacetic acid (TFA) in water and 0.1% TFA in acetonitrile (CH_3CN). The flow was 1 mL/min with gradient starting at 5% CH_3CN and ending at 80% CH_3CN at 42 min. UV wavelengths used for detection of NBD-labeled fructose were 218 and 475 nm. For Cy5.5-labeled fructose, detection wavelengths were 218, 280, and 590 nm. Electron spray ionization (ESI) mass spectrometry was done by Vincent Coates Foundation Mass Spectrometry Laboratory, Stanford University. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) was performed by the Protein and Nucleic Acid Biotechnology Facility, Stanford University. All NMR spectra were obtained on a Varian XL-400 (Varian, Palo Alto, CA) at 400 MHz ^1H (100 MHz ^{13}C) .

Cell Lines. Human breast cancer cell lines MCF-7, MDA-MB-435, MDA-MB-231 and human hepatocellular carcinoma cells, HepG2, were obtained from American Type Culture Collection (Manassas, VA). MCF-7 cells were grown in minimum essential medium (Eagle) (MEM, Invitrogen, Carlsbad, CA) supplemented with 0.1 mM nonessential amino acids, 1 mM sodium pyruvate, 1.5 g/L sodium bicarbonate, 0.01 mg/mL bovine insulin, 10% fetal bovine serum (FBS), and 1% penicillin−streptomycin. MDA-MB-435 cells were cultured in Leibovitz's L-15 medium (Invitrogen, Carlsbad, CA) supplemented with 0.01 mg/mL insulin, 10% FBS, and 1% penicillin−streptomycin. MDA-MB-231 cells were cultured in Dulbecco's modified Eagle high glucose medium (DMEM, Invitrogen, Carlsbad, CA) supplemented with 10% FBS and 1% penicillin−streptomycin. HepG2 cells were grown in MEM supplemented with 10% FBS and 1% penicillin−streptomycin.

Ketohexokinase and Hexokinase Western Analysis. Cells were washed with ice-cold phosphate buffered saline (PBS) once and lysed in 1× passive lysis buffer (Promega, Madison, WI) for 10 min on ice. After centrifugation at 13 500 rpm for 15 min at 4 °C, protein content was determined using Bradford assay (Biorad, Hercules, CA). 75 μg of total protein were resolved using the 4−12% NU-PAGE gradient gel (Invitrogen, Carlsbad, CA) and electroblotted onto nitrocellulose membrane (Schleicher & Schuell, Keene, NH). The membrane was first incubated with blocking buffer (5% nonfat dry milk in Tris-buffered saline containing 0.01% Tween 20 (TBST)) for 1 h, and then overnight at 4 °C with an appropriate primary antibody diluted in blocking buffer according to manufacturer's recommendations. The membrane was washed three times with TBST and incubated with appropriate secondary antibodies: peroxidase-conjugated anti-mouse IgG (1:3000 dilution in the blocking buffer) or peroxidase-conjugated anti-rabbit IgG (1:3000 dilution in the blocking buffer) for 1 h. As a loading control, the membrane was incubated with the monoclonal anti-human α-tubulin antibody (1:5000 dilution in the blocking buffer). Enhanced chemiluminescent method was used for visualization of protein bands.

The extraction of mouse liver was performed according to a protocol approved by the Stanford University Administrative Panels on Laboratory Animal Care (A-PLAC). Normal mouse liver was harvested and immediately frozen in dry ice. SDS lysis buffer (50 mM Tris pH 7.4, 2% SDS) containing Complete Mini protease inhibitor (Roche, Palo Alto, CA) was used to lyse the liver. After freezing at −80 °C and thawing at 37 °C three times, liver lysate was centrifuged, and supernatant used for protein detection as described above.

Chemical Syntheses. *1-(Benzylamino)-1-deoxy-D-fructose (**2**).* 1-(Benzylamino)-1-deoxy-D-fructose was synthesized following the published procedure (*35*). Our synthesis starts with D-glucose instead of the D-mannose used in the paper. Briefly, D-glucose (1.8 g, 10 mmol, 1 equiv) was reacted with benzylamine (1.1 mL, 10 mmol, 1 equiv) in boiling absolute ethanol for 5 min. After cooling, the solid was collected and used in the next step without further purification. *N*-Benzyl-β-glucopyranosylamine (1 g, 3.7 mmol, 1 equiv) was heated at 80 °C in the 10:3 mixture of 1,4-dioxane and methanol, in the presence of 0.5 g (5.5 mmol, 1.5 equiv) of oxalic acid for 10 min. The product was collected and recrystallized from isopropanol. ^{1}H NMR (400 MHz, D_2O): 7.28 (5H, m), 4.10 (2H, s), 3.77 (2H, m), 3.66 (1H, dd, J = 3.35 Hz, J = 9.76 Hz), 3.53−3.46 (2H, m), 3.08 (2H, s). ^{13}C NMR (100 MHz, D_2O): 165.55, 130.29, 130.084, 129.88, 129.37, 95.53, 69.69, 69.34, 68.97, 63.97, 52.13, 51.72. ESI$^+$ 270.1. The calculated molecular weight is 269.1 g/mol.

*1-Amino-1-deoxy-D-fructose Oxalate Salt (**3**).* 1-(Benzylamino)-1-deoxy-D-fructose oxalate salt (1 g) was dissolved in 30 mL water. 1 g of Pd/C (10 wt %) was added and the mixture hydrogenated overnight. The catalyst was filtered off and the solvent removed in vacuo. ^{1}H NMR (400 MHz, D_2O): 3.74 (m, 2H), 3.62 (m, 1H), 3.48 (m, 2H), 2.97 (m, 2H). ^{13}C NMR (100 MHz, D_2O): 95.45, 69.62, 69.38, 68.97, 63.91, 45.16. ESI$^+$ 179.9. The calculated molecular weight is 179.1 g/mol.

1-NBDF. 10 mg amino fructose was dissolved in 200 μL 0.3 M $NaHCO_3$ and added to the solution of 10 mg 4-chloro-7-nitrobenzofurazan (NBD chloride) in 400 μL methanol. The mixture was stirred at room temperature for 20 h. Solvents were removed in vacuo, water (400 μL) was added, and the precipitate removed by centrifugation. The filtrate was injected onto the HPLC column. Two major isomers are observed with retention times of 11.5 min and 12.05 min. Both peaks show the same molecular ion in negative ESI 341. Isomers were combined for subsequent uptake studies.

1-Cy5.5-DF. 1 mg Cy5.5-NHS ester was dissolved in 300 μL sodium phosphate buffer (pH 8.5−9). To this solution was added a solution of ∼0.5 mg of 1-amino-1-deoxy-D-fructose in 100 μL phosphate buffer. The mixture was kept at room temperature for 4 h and then directly injected onto HPLC. The 1-Cy5.5-DF fraction was eluted from the column at 15.8 min. MALDI-MS analysis of the collected fraction shows a molecular ion peak of 1077.82. The calculated Mw is found to be 1078.24 g/mol.

Cell Uptake Studies. 1×10^5 MCF-7, MDA-MB-435, MDA-MB-231, and HepG2 cells were plated in 35 mm MatTek glass-bottomed culture dishes 1 day ahead of the imaging study. Cells were washed once with PBS right before incubation with 10 μM probes at 37 °C or 4 °C for 15 min. For the staining of nuclei, after the incubation with 1-Cy5.5-DF, MDA-MB-231 cells were incubated with a solution of Sytox Green (Molecular Probe, Eugene, OR) in 95% ethanol for 15 min. To assess the effect of D-fructose and D-glucose on the uptake of fluorescent-labeled fructose, 1×10^5 MDA-MB-435 cells were coincubated with 10 μM labeled probe and 50 mM D-fructose or 50 mM D-glucose for 15 min at 37 °C. After the incubation, cells were washed three times with cold PBS and imaged using a microscope.

The uptake of 1-NBDF in MCF7 cells was also followed by flow cytometry. Cells (0.1 million) were incubated for 1 h with four different concentrations of 1-NBDF: 10 μM, 7 μM, 5 μM, and 3 μM. After washing two times with 0.5 mL cold PBS, the cells were suspended in 200 μL PBS and analyzed on FACS-Calibur (Becton Dickinson, Franklin Lakes, NJ) using FL-2 channel. The samples were done in triplicate.

Fluorescence Microscopy Studies. Cells were imaged using an Axiovert 200M fluorescence microscope (Carl Zeiss MicroImaging, Inc., Thornwood, NY). To image 1-NBDF in cells and Sytox Green stained nuclei, the eGFP filter set (excitation 450/490 nm, emission 515/565 nm) was used, while for Cy5.5-labeled fructose, the fluorescent signal was recorded using the Cy5 filter set (exciter 640/30 nm; emitter 700/50 nm). An AttoArc HBO 100 W microscopic illuminator was used as a light source. Images were recorded using a thermoelectrically cooled charged-coupled device (CCD) (Micromax, model RTE/CCD-576, Princeton Instruments, Inc., Trenton, NJ) and analyzed using *MetaMorph* software version 6.2r4 (Molecular Devices Corporation, Downingtown, PA).

RESULTS AND DISCUSSION

Fructose can be metabolized via two pathways, one that involves phosphorylation at the C-6 position by hexokinase and the other that starts with phosphorylation at C-1 by fructokinase. Since substrate specificity studies of the proteins involved in transport and phosphorylation point to substitutions at C-1 and C-6 positions as the only ones permissible, the fluorophore labeling site had to be chosen on the basis of the presence and levels of the two kinases that can phosphorylate fructose. That is why we first investigated the expression of hexokinase and fructokinase in the breast cancer cell lines. There are four hexokinase isoforms in mammalian cells. Of those four, two isoforms, hexokinase I and II, are found overexpressed in many cancer cells, hexokinase II being recognized as the key isoform associated with high glycolytic rates (*36*). Among the three breast cancer cell lines studied, MCF7 cell line shows the highest levels of both hexokinase I and II (Figure 1), whereas the other two cell lines, MDA-MB-435 and MDA-MB-231, show considerably lower expression. While Western analysis shows the presence of fructokinase in the liver, the main organ of fructose metabolism, no fructokinase is detected in any of the breast cancer cell lines tested (Figure 1). This suggests that, because only hexokinase is detected in these breast cancer cells, fructose,

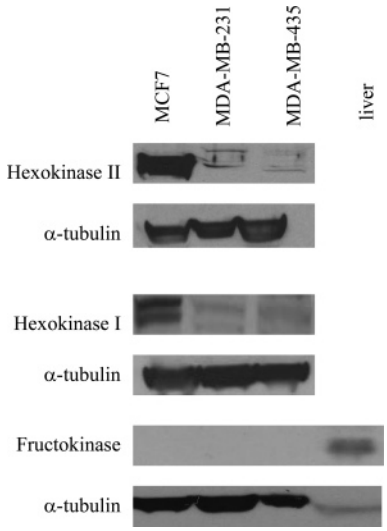

Figure 1. Western blot analysis of hexokinase and fructokinase levels in breast cancer cells and liver. The highest levels of both hexokinase I and II are found in MCF7 cells. Fructokinase was not observed in any of the breast cancer cell lines tested.

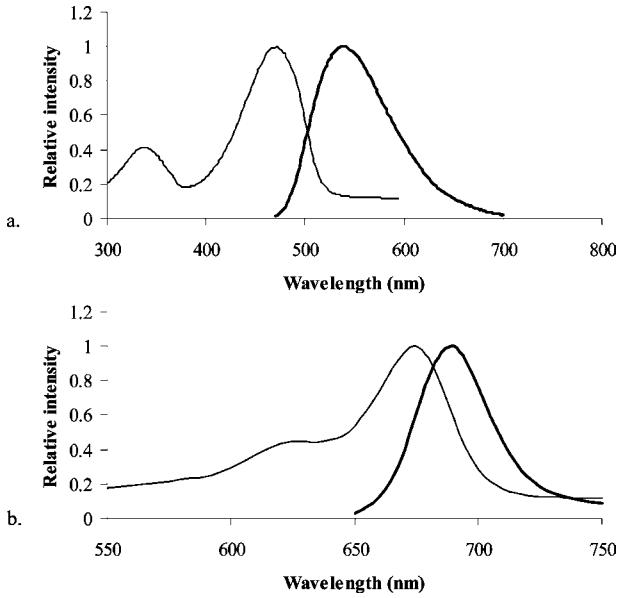

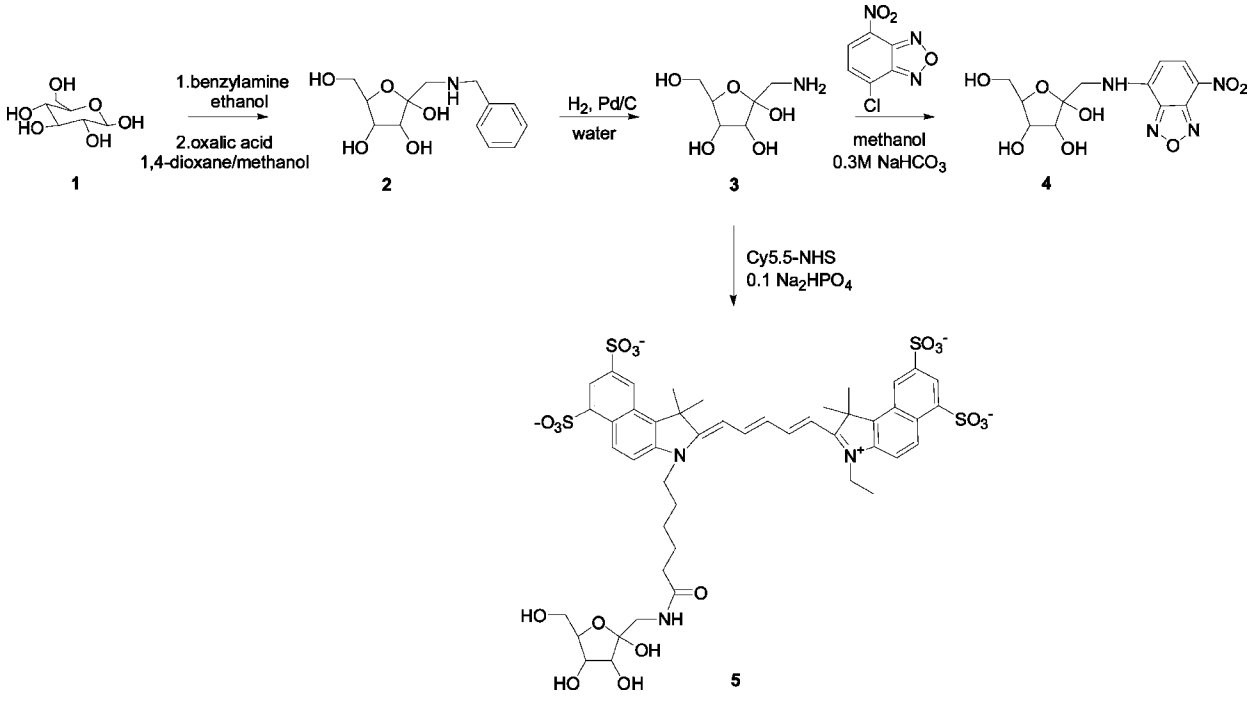

Figure 2. Absorbance (thin line) and fluorescence (thick line) spectra for 1-NBDF (a) and 1-Cy5.5-fructose (b).

once inside the cell, is phosphorylated in the C-6 position. In view of these results, and considering Glut5 and hexokinase substrate specificity, only fructose labeled in the C-1 position should be considered a possible imaging probe—it is expected to be transported by the Glut 5 transporter and trapped in the cells by hexokinase.

Two fluorescent labels were conjugated to fructose in the C-1 position: NBD and Cy5.5. The syntheses of the fluorescent fructose derivatives are shown in Scheme 2. Both syntheses required 1-amino-1-deoxy-D-fructose (**3**), which was prepared by hydrogenation of the Amadori rearrangement product (**2**). 1-NBDF was synthesized by reacting 1-amino-1-deoxy-D-fructose with NBD chloride under basic conditions. The coupling reaction is not very efficient and has a typical yield of only 5%. Two peaks were observed in the HPLC chromatogram, corresponding to different isomers of 1-NBDF. For uptake studies, these isomers were combined, since the Glut5 transporter seems to be accepting all of the four possible fructose isomers, α/*β* fructopyranose and α/*β* fructofuranose (*28*). 1-Cy5.5-DF was synthesized by coupling 1-amino-1-deoxy-D-fructose with Cy5.5-NHS ester. Only one broad peak was observed in the HPLC chromatogram, suggesting closely running 1-Cy5.5-DF isomers.

NBD-chloride is nonfluorescent, but when coupled to the amine group of amino fructose, the NBD group shows fluorescence with the excitation maximum at 472 nm and the emission maximum at 538 nm (Figure 2a). For 1-Cy5.5-DF, the maximum excitation wavelength was found to be 675 nm, while the maximum emission wavelength was at 695 nm (Figure 4b). Cy5.5 dye shows the same spectral characteristics as its fructose conjugate (data not shown). Since the NBD group

Scheme 2. Synthesis of 1-NBDF and 1-Cy5.5-F[a]

[a] Note that fructose exists as a mixture of pyranose and furanose forms but is represented here in the *β*-furanose form for simplicity.

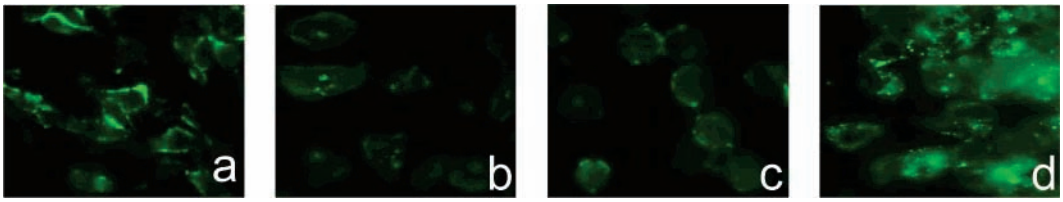

Figure 3. Autofluorescence of MDA-MB-435 (a), MDA-MB-231 (b), MCF7(c), and HepG2 cells (d). Cells were imaged using eGFP filter set, λ_{ex} 450/490 nm, λ_{em} 515/565 nm. All cells showed autofluorescence of low intensity, mostly localized on the cell membrane.

absorbs and emits light in the region where the interference from endogenous fluorophores is expected, it is important to determine the degree of intrinsic fluorescence of the cells. The extent of autofluorescence of different cell lines was investigated by imaging cells, using a fluorescent microscope and appropriate filter sets. Autofluorescence was detected only when using eGFP filter set (λ_{ex} 450/490 nm, λ_{em} 515/565 nm) (Figure 3a−d), while no significant autofluorescence was observed in the NIR region (data not shown). All imaged cell lines showed autofluorescence of very low intensity. Since the observed autofluorescence was limited to the cell membrane and was of relatively small intensity, it is not expected to present a problem in studying the uptake of the 1-NBDF in cell culture.

In order to investigate the tumor targeting ability of the two fluorescent fructose derivatives in cell culture, breast cancer cell lines (MDA-MB-435, MDA-MB-231, and MCF7) were incubated with the probes at 37 °C and imaged using a fluorescent microscope. As a positive control, cells were incubated with the corresponding fluorescent glucose analogs, 2-NBDG and Cy5.5-DG. Good uptake in cancer cells for those two glucose analogs has been previously established (*34*, *37*). Both fructose derivatives were taken up by the breast cancer cells (Figure 4a−f). The level of uptake, as judged by the fluorescence intensity, was comparable to the uptake of the positive probes, 2-NBDG and Cy5.5-DG (Figure 4 g,h). The images suggest a difference in accumulation of the two fructose derivatives. While incubation with 1-NBDF resulted in uniform cell fluorescence, incubation with 1-Cy5.5-DF led to more localized accumulation. In order to investigate localization of 1-Cy5.5-DF, after incubation with the probe, cell nuclei were stained with Sytox Green. The overlay of the images showed cytoplasmic localization of 1-Cy5.5-DF clearly separated from the nucleus (Figure 4i). For the purpose of comparison, cells were also incubated with the Cy5.5-NHS ester. As mentioned earlier, the NBD chloride is nonfluorescent, and as such, its uptake cannot be investigated using the fluorescent microscope. Incubation of cells with the Cy5.5 dye resulted in a cell-associated fluorescence signal (Figure 4j). Although the fluorescence was mostly localized on the cell surface, the uptake of the dye was also observed. Staining of the cell membrane with the Cy5.5 dye alone could be explained by the likely reaction of amine-reactive Cy5.5-NHS ester with many amino groups present on the cell surface. The observed uptake of the dye was likely due to the subsequent endocytosis. The nature of the transport mechanism was investigated by incubating cells with the probes at 4 °C. At low temperature, the uptake of the probes was not observed, indicating an energy-dependent transport (Figure 4k,l).

The uptake of 1-NBDF in MCF 7 cells was further analyzed and quantified using flow cytometry. The amount of probe accumulated clearly correlated with the concentration of the probes that the cells were exposed to (data not shown).

Seeking to explore whether fluorescent fructose probes are specific for the Glut5-expressing cells, we studied their uptake in hepatocarcinoma cells, HepG2, a cell line expressing glucose transporters Glut1−3, while no significant levels of Glut5 transporter are detected (*38*, *39*). The uptake of fructose

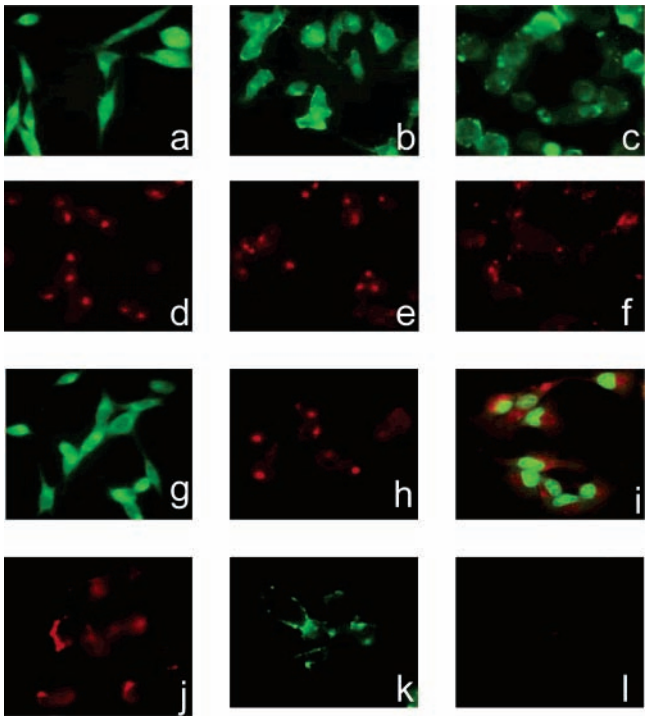

Figure 4. Uptake of fluorescent fructose derivatives in MDA-MB-435 (a,d), MDA-MB-231 (b,e), and MCF-7 cells (c,f). MDA-MB-435 cells incubated with 2-NBDG (g) showed comparable fluorescence intensities to cells incubated with 1-NBDF. Fluorescence of MDA-MB-435 cells incubated with Cy5.5-DG (h) was similar to the fluorescence of cells incubated with 1-Cy5.5-F. Incubation of MDA-MB-231 and MCF7 cells with Cy5.5-DG and NBDG resulted in similar fluorescence intensities as the ones observed after uptake of fluorescent fructose derivatives (data not shown). 1-Cy5.5-DF showed cytoplasmic rather than nuclear accumulation in MDA-MB-435 cells (i). Incubation with Cy5.5-NHS ester results in the staining of MDA-MB-435 cells (j). Incubation of MDA-MB-435 cells with C-1 fructose derivatives at low temperature results in minimal uptake of the probes (k,l).

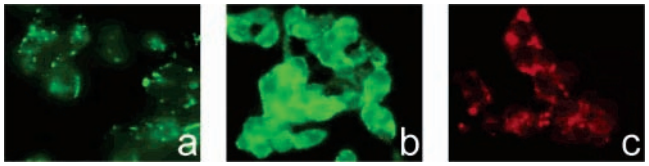

Figure 5. Uptake of 1-NBDF, 2-NBDG, and 1-Cy5.5-DF in HepG2 cells. HepG2 cells lacking Glut5 transporter showed fluorescence of low intensity after incubation with 1-NBDF (a), indicating the absence of the probe transport. 2-NBDG and 1-Cy5.5-F, transported through a different mechanism, were readily taken up by HepG2 cells (b,c).

analogues is not expected in these cells due to the lack of transporter. No significant uptake of 1-NBDF was observed, while glucose analog, 2-NBDG, transported by glucose transporters, showed accumulation in HepG2 cells (Figure 5). These results imply that the uptake of 1-NBDF depends on the presence of the Glut5 transporter and can thus be used to distinguish between the cells expressing and the cells lacking this transporter. In contrast, 1-Cy5.5-DF derivative accumulated

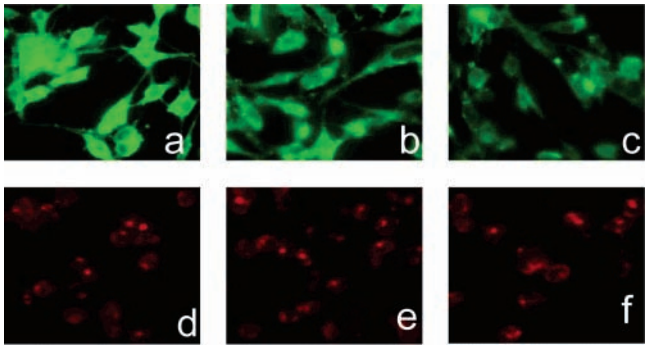

Figure 6. The effect of coincubation with D-fructose and D-glucose on the uptake of the probes in MDA-MB-435 cells. Addition of 50 mM D-fructose (b), as well as addition of 50 mM D-glucose (c) to the incubation medium containing 10 μm 1-NBDF, resulted in decreased fluorescence compared to the cells that have been incubated with 1-NBDF only (a). No effect on the uptake of Cy 5.5-labeled fructose was observed (d,e,f). Analysis of the inhibition by flow cytometry did not show blocking of the transport, indicating that the observed decrease in fluorescence in the cells coincubated with unlabeled fructose and glucose cannot be explained by the inhibitory effect of the sugars on the uptake of 1-NBDF, but rather by the qualitative effect that high concentration of the sugars might have on the fructose transport.

in HepG2 cells, showing that its uptake was not associated with the presence of the Glut 5 transporter.

To further examine the mechanism of transport, MDA-MB-435 cells were coincubated with fluorescent fructose derivatives and unlabeled D-fructose. As judged by the decrease in fluorescence intensity (Figure 6), the uptake of 1-NBDF seems to be diminished by coincubation with D-fructose. The addition of D-glucose has a similar effect, suggesting the inhibition of uptake through the Glut2 transporter, which can transfer both fructose and glucose across the cell membrane. On the other hand, the uptake of 1-Cy5.5-DF was not affected by the addition of either D-fructose or D-glucose, implying that 1-Cy5.5-DF does not use Glut transporters to enter the cell. However, the investigation of the uptake inhibition by flow cytometry failed to show decreased uptake in the cells coincubated with various concentrations of fructose and glucose. The observed decrease in cell fluorescence (Figure 6) could be due to the qualitative rather than quantitative changes that unlabeled fructose and glucose introduce. Other studies report uptake of D-[U-^{14}C]-fructose in cells coincubated with excess cold fructose suggesting that transport is not blocked by cold substrate (*13*, *40*). For the purpose of blocking the transport, the most suitable agents would be substances that bind to the transporter and prevent their function. Cytochalasin B is known to prevent glucose transport by binding to glucose transporters (*41*), but to the best of our knowledge, a molecule preventing the function of Glut5 has not been reported. Fused-ring glyco-1,3-oxazolidin-2-thiones and glyco-1,3-oxazolidin-2-ones have been reported to inhibit the Glut5 transporter, but their specificity and mechanism of action has not been fully evaluated, which limits their current use (*42*).

Although this study suggests uptake of 1-NBDF through Glut5, it remains to be determined whether 1-NBDF gets phosphorylated by hexokinase and at what relative rate compared to glucose. It will also be important for future studies to determine if there is efflux of the probes out of cells, since Glut5 is a bidirectional transporter. On the basis of its behavior in cell culture, it would be interesting to explore the possibility of using 1-NBDF for in vivo studies in small animals. As discussed earlier, 1-NBDF does not have optimal spectral characteristics, but using instruments with multispectral imaging techniques might minimize interference caused by autofluorescence.

In summary, two fluorescent fructose derivatives were synthesized and evaluated in cell culture for their Glut5-detecting ability in breast cancer. Both derivatives show good uptake in breast cancer cells tested. Importantly, we found that the uptake of 1-NBDF appears to correspond with the uptake of fructose in cells. The NBD group is small in size and does not seem to perturb the structure of the fructose to the point at which the labeled analogue is no longer recognized by the Glut5 transporter. In contrast, the coupling of fructose with a very bulky fluorophore such as Cy5.5 results in a derivative that shows nonspecific uptake in breast cancer cells, and as such cannot likely be used in breast cancer imaging.

Received June 28, 2006; Revised Manuscript Received December 12, 2006

New surface-modified iron oxide nanoparticles were developed by precipitation of Fe(II) and Fe(III) salts with ammonium hydroxide according to two methods. In the first method, precipitation was done in the presence of D-mannose solution (in situ coating); the second method involved oxidation of precipitated magnetite with sodium hypochlorite followed by addition of D-mannose solution (postsynthesis coating). Selected nanoparticles were characterized by transmission electron microscopy (TEM), atomic force microscopy (AFM), elemental analysis, dynamic light scattering, infrared (IR), X-ray powder analysis, and ultrasonic spectrometry. While the first preparation method produced very fine nanoparticles ca. 2 nm in diameter, the second one yielded ca. 6 nm particles. Addition of D-mannose after synthesis did not affect the iron oxide particle size. UV−vis spectroscopy suggested that D-mannose suppresses the nonspecific sorption of serum proteins from DMEM culture medium on magnetic nanoparticles. Rat bone marrow stromal cells (rMSCs) were labeled with uncoated and D-mannose-modified iron oxide nanoparticles and with Endorem (Guerbet, France; control). Optical and transmission electron microscopy confirmed the presence of D-mannose-modified iron oxide nanoparticles inside the cells. D-Mannose-modified nanoparticles crossed the cell membranes and were internalized well by the cells. Relaxivity measurements of labeled cells in gelatin revealed very high relaxivities only for postsynthesis D-mannose-coated iron oxide nanoparticles.

INTRODUCTION

Regenerative medicine is a new field in which new treatment strategies are employed. One of the most promising approaches in preclinical research into brain or spinal cord injuries involves the use of cell therapies. After transplantation, the cells integrate into the host environment and respond to intrinsic signals (*1*). Stem cells administered via intravenous infusion migrate to the site of the injury and enter the nervous tissue through a more permeable or opened blood−brain barrier (*2*, *3*).

In the majority of experiments the donor cells are labeled before transplantation (retroviral labeling, bromodeoxyuridine, red fluorescent "cell tracker" PKH 26, green fluorescent protein [GFP]). After a certain time the host organism is sacrificed and evaluation of the position of the transplanted cells is carried out by microscopic analysis. This method, however, does not give data about the dynamics of the process or the movements of the transplanted stem cells in the host organism and requires sacrificing the host organism.

Initial findings confirmed that nanoparticles based on microcrystals of iron oxides could be observed by magnetic resonance imaging (MRI) in brain cells. The first reports (*4*, *5*) of imaging cell transplants labeled by superparamagnetic contrast agents in rat brains appeared in 1992. Different iron oxide nanoparticles coated by dextran were tested, and it was shown that MRI could be used for the dynamic in vivo tracking of labeled cells (*6*, *7*). The greatest progress was achieved with dextran-coated monocrystalline iron oxide nanoparticles (MION) (*8*, *9*), and the migration of MION-labeled oligodendrocyte progenitors was shown (*10*). Dendrimer-encapsulated superparamagnetic iron oxides were used for labeling and in vivo tracking of stem cells (*11*). Recently, immortalized cells from the MHP36 hippocampal cell line labeled in vitro with gadolinium rhodamine dextran were tracked in ischemia-damaged rat hippocampus in perfused brains ex vivo (*12*). Study of embryonic stem cells labeled in vitro with the magnetic resonance (MR) contrast agent Sinerem using a lipofection procedure successfully showed migration of labeled cells into focal cerebral ischemic lesions evoked by middle cerebral artery occlusion (*13*). Another suitable contrast agent for mesenchymal and embryonic stem cells is a commercially available contrast agent based on dextran-coated iron oxide nanoparticles, Endorem (Guerbet, France), which has also been approved as a blood pool agent for human use. Endorem-labeled cells migrated to a cortical photochemical lesion or a spinal cord compression lesion in rats (*14*−*16*).

Our aim is to design new iron oxide nanoparticles for stem cell labeling and investigate and control their surface and morphological characteristics. Surface modification of iron oxide is a key issue for enhancing its permeability through the cell membrane. Biocompatible polymers and targeting agents are therefore attached to the nanoparticle surface to prevent the nanoparticles from agglomeration, make them more biocompatible, and increase their nonspecific intracellular uptake (*17*). Our preliminary experiments with cationic (perchloric acid-stabilized) or anionic (tetramethylammonium hydroxide-stabilized) iron oxides showed that the colloids were unstable in the medium required for cell cultivation and that the particles aggregated. Similarly, dextran-coated iron oxide tended to adhere on the cell surface, while (diethylaminoethyl)dextran-

coated particles hindered cell proliferation. Uptake of (carboxymethyl)dextran-coated ferrofluid by endocytosing cells was too low. In a continuation of the search for a suitable surface modification to enhance nanoparticle transport into the cells, D-mannose was selected as the cell surface is known to possess receptors for this molecule (*18*). Moreover, D-mannose-bound poly(2-hydroxyethyl methacrylate) hydrogels were found to support adhesion of keratinocytes (epidermal cells) and their subsequent cultivation without the presence of feeder cells (*19*).

EXPERIMENTAL SECTION

Materials. $FeCl_2 \cdot 4H_2O$, $FeCl_3 \cdot 6H_2O$, and D-mannose were purchased from Fluka (Buchs, Switzerland), sodium hypochlorite solution (NaClO) from Bochemie (Bohumín, Czech Republic), and sodium citrate dihydrate from Lachema (Brno, Czech Republic). All other reagent-grade chemicals were purchased from Aldrich (Milwaukee, WI) and used as received. The commercial contrast agent Endorem was provided by Guerbet (Roissy, France). Ultrapure Q water ultrafiltered on a Milli-Q Gradient A10 system (Millipore, Molsheim, France) was used for preparation of solutions.

In Situ Precipitation of Iron Oxide in D-Mannose Solution. Molday's procedure (*20*) for coating iron oxide nanoparticles with dextran was modified to prepare iron oxide nanoparticles in D-mannose solution. Briefly, 10 mL of 50 wt % D-mannose aqueous solution was mixed under stirring with 10 mL of a water solution containing 1.51 g of $FeCl_3 \cdot 6\ H_2O$ and 0.64 g of $FeCl_2 \cdot 4\ H_2O$; 15 mL of 7.5% NH_4OH solution was slowly added until pH 12 was reached, and the mixture was heated to 60 °C for 15 min. Large aggregates were destroyed by sonication (Ultrasonic Homogenizer 4710 Series, Cole-Palmer Instruments, at 40% output) for 5 min. To remove unreacted water-soluble salts and excessive D-mannose, particles were washed by dialysis using a Visking membrane (molecular weight cutoff 14 000; Carl Roth GmbH, Karlsruhe, Germany) against 2 L of water for 24 h at room temperature (the water was changed 5 times, 2 L each time) until pH 6 was reached. The volume of water was reduced by evaporation—dry residue: 80 mg of iron oxide/mL of colloid.

Preparation of Iron Oxide Nanoparticles and Postsynthesis Coating with D-Mannose. A solution of $FeCl_2$ (0.2 mol/L) and $FeCl_3$ (0.2 mol/L) in a 1:2 molar ratio was coprecipitated in an excess of 0.5 mol/L NH_4OH. After 15 min, the product was repeatedly separated in a magnetic field and washed with Q-water to reach peptization. The colloid was subsequently sonicated for 5 min (Ultrasonic Homogenizer 4710 Series, Cole-Palmer Instruments, 40% output) and oxidized with 5 wt % NaClO aqueous solution in the presence of 0.1 M sodium citrate solution. Washing and sonication procedures were then repeated. Finally, 20 wt % aqueous D-mannose solution was added to colloidal iron oxide (maghemite, γ-Fe_2O_3). The resulting product was washed three times with 10 mL of water after centrifugation at 14 000 rpm for 3 min (the colloid was so stable that it did not permit magnetic separation).

Characterization. The particle morphology and particle size distribution were examined by transmission electron microscopy (TEM; JEOL JEM 200 CX). An iron oxide nanoparticle dispersion in water was sprayed onto a grid with a carbon membrane. The number-average diameter was determined by measurement of at least 500 particles for each batch from microphotographs using the Atlas program (Tescan, Digital Microscopy Imaging, Brno, Czech Republic). The number-average (D_n) particle diameter was calculated as $D_n = \Sigma N_i D_i / \Sigma N_i$, where N_i is the number of particles with diameter D_i. Polydispersity PDI $= D_w/D_n$, where D_w is the weight-average particle diameter, $D_w = \Sigma N_i D_i^4 / \Sigma N_i D_i^3$. A multimode AFM Nanoscope IIIa (Digital Instruments, Santa Barbara, CA) was used to observe the nanoparticles in situ in tapping mode using OTESPA silicon cantilevers (Veeco Instruments, Dourdan, France) with a radius of 5 nm and oscillating at 245 kHz.

D-Mannose and iron oxide content was calculated from elemental analysis (Perkin-Elmer 2400 CHN) and from the iron content analyzed by atomic adsorption spectrometry (AAS Perkin-Elmer 3110) of an extract from a sample obtained with dilute HCl (1:1) at 80 °C for 1 h.

The hydrodynamic diameter (*z* average) and polydispersity as a measure of the distribution width were obtained by dynamic light scattering (DLS) with an Autosizer Lo-C (Malvern Instruments Ltd., Malvern, Great Britain).

The coating of D-mannose on the surface of the magnetic nanoparticles was investigated using a Fourier transformation infrared (FTIR) spectrometer (NICOLET IMPACT 400) in an H_2O-purged environment with a doped triglycine sulfate (DTGS) detector. The Golden Gate single attenuated total reflection (ATR) system (Specac Ltd., Orpington, Great Britain) was used to measure the spectra of powdered samples by an ATR spectroscopic technique over a wavelength range of 400−4000 cm^{-1}. Typical parameters used were as follows: 256 sample scans, resolution 4 cm^{-1}, Happ-Genzel apodization, KBr beamsplitter.

Differences in ultrasonic velocity between reference (water) and iron oxide colloid were monitored under the slow addition of various concentrations of D-mannose using an Ultrasound Spectrometer HR-US 102 (Ultrasonic Scientific, Dublin, Ireland). In a typical experiment, 1 mL of iron oxide colloid (18 mg of γ-Fe_2O_3/mL) was in the first cell and 1 mL of Q-water in the second cell. D-Mannose solution (1 mg of D-mannose/mL) was then simultaneously added in 10 μL aliquots to both cells with a Hamilton syringe.

X-ray powder diffraction using a Bruker D8 diffractometer (Cu Kα, Sol-X energy-dispersive detector) was used to determine the magnetite phase composition.

In protein adsorption experiments, 1 mL of the colloid with a concentration of 22 mg of iron oxide/mL was mixed with 1 mL of DMEM (Dulbecco's modified Eagle's medium)/10% FBS (fetal bovine serum) medium on a Vortex-T Genie-2 (Scientific Industries, Bohemia, USA) for 1 h; the liquid was separated from the solid by centrifugation and measured on a Perkin-Elmer Lambda 20 UV/vis spectrophotometer. An aqueous solution of DMEM/10% FBS medium (1/1 v/v) served as a standard.

Cell Cultures. To isolate rat bone marrow stromal cells (rMSCs), femurs were dissected from 4-week-old Wistar rats. The ends of the bones were cut, and the marrow was extruded with 5 mL of DMEM with L-glutamine (PAA, Pasching, Austria) using a needle and syringe. Marrow cells were plated in 80 cm^2 tissue culture flasks in DMEM/10% FBS with 100 U/mL penicillin and 100 U/mL streptomycin. After 24 h, the nonadherent cells were removed by replacing the medium. The medium was changed every 2−3 days as the cells grew to confluence. The cells were lifted by incubation with 0.25 wt % trypsin.

Transmission Electron Microscopy of Labeled Cells. For electron microscopic examination, rMSCs were fixed at 4 °C in 2.5% buffered glutaraldehyde for 1 h followed by 1% osmium tetroxide for 2 h. The cells were dehydrated in ascending concentrations of ethanol, immersed in propylene oxide, and embedded in Epon 812 resin (Agar Scientific Ltd., Standsted, England). The samples were cut in ultrathin sections (~60 nm), contrasted with 4% uranyl acetate and Reynold's lead citrate, and examined in a Philips Morgagni 268 electron microscope.

Quantitative Analysis of Labeled Cells. rMSCs were plated in duplicate on uncoated 6-well culture plates at a density of 10^5 cells/mm^2. Endorem or D-mannose-modified nanoparticles

were added to the culture medium (10 μL/mL) for 72 h. After the Endorem was washed out of the culture medium, the cells were fixed with 4% paraformaldehyde in 0.1 M PBS (phosphate-buffered saline) and stained for iron to produce ferric ferrocyanide (Prussian blue). Labeled and unlabeled cells were quantified using an inverted light microscope (Axiovert 200, Zeiss, Jena, Germany) by counting randomly five fields per well and two wells per each run. The cells captured on each image were manually labeled as Prussian blue positive or negative; the labeled cells were then counted, and the staining intensity of Prussian blue positive cells was evaluated using the Image analysis toolbox in Matlab 6.1 (The MathWorks, Natick, USA). Histograms of the intensity of the cytoplasmic staining were constructed.

MR Relaxometry and MR Imaging. Suspensions of contrast agents were prepared together with suspensions of cells labeled by Endorem or D-mannose-modified nanoparticles in 4% gelatin (Sigma, Czech Republic) and subjected to MR relaxometry. T_1 and T_2 relaxation times (which are responsible for contrast in T_1- and T_2-weighted MR images) were measured on a 0.5 T Bruker Minispec relaxometer. Relaxation time values were

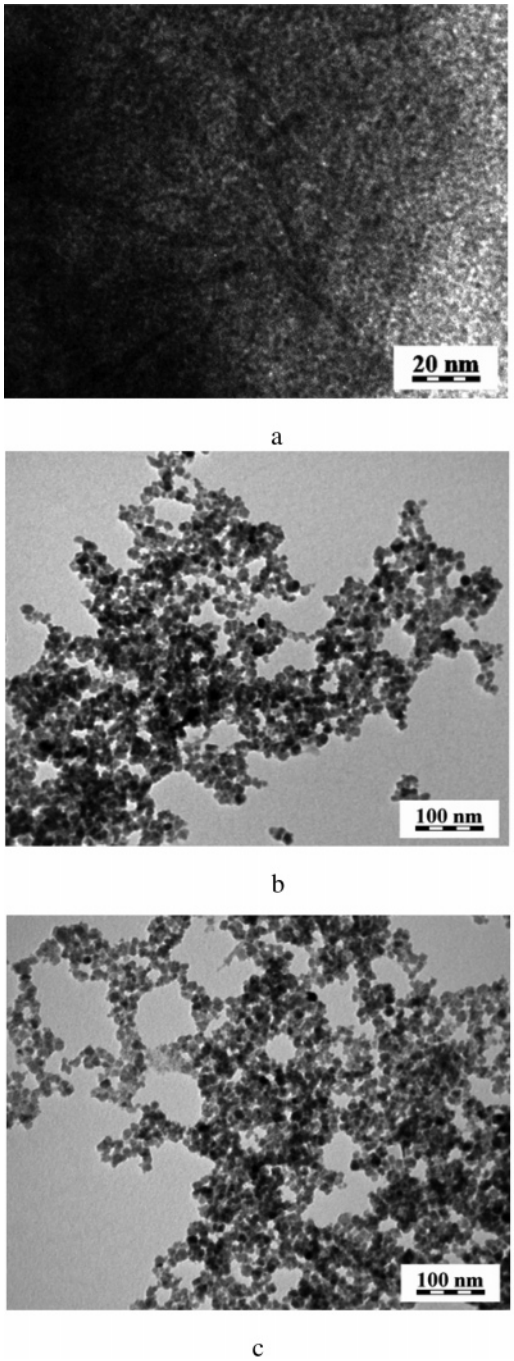

Figure 3. TEM images of in situ D-mannose-coated Fe_3O_4 particles (a; No. 1) and γ-Fe_2O_3 particles before (b; No. 2) and after modification with D-mannose (c; No. 3).

converted to relaxivities and, after deducting the contribution of pure gelatin, related to the actual iron concentration c, i.e., $r_1 = (1/T_1 - 1/T_{1gel})/c$ or $r_2 = (1/T_2 - 1/T_{2gel})/c$ in the case of contrast agent suspensions. In the case of samples containing labeled cells, the relaxivity was related, after deducting the contribution of unlabeled cells, to 10^6 cells in 1 mL.

Samples containing labeled cells (31 100 or 62 200 cells suspended in 0.5 mL of 4% gelatin) underwent MR imaging using a standard T_2-weighted turbospin echo sequence (effective echo time $T_E = 62.7$ ms, repetition time $T_R = 3000$ ms, matrix 256×256, slice thickness 1 mm, FOV = 35 mm). As a control, 62 000 unlabeled cells were suspended in 0.5 mL of 4% gelatin.

Iron Analysis. The amount of iron in the cells after mineralization was determined by spectrophotometry. Cell-containing samples were mineralized by addition of 5 mL of

tro, Littleton, USA) calibrated with a standard Astasol solution (Analytika, Prague, Czech Republic). The measurements were repeated four times, and the average mean value was determined.

RESULTS AND DISCUSSION

Iron oxide colloids were prepared by two methods: (i) coprecipitation of Fe(II) and Fe(III) salts by ammonium in concentrated D-mannose solution (in situ coating) and (ii) precipitation followed by oxidation to maghemite (*21*) and slow addition of D-mannose solution (postsynthesis coating).

In Situ Precipitation of Iron Oxide in D-Mannose Solution. Magnetite was synthesized in a one-step process by alkaline coprecipitation of iron(II) and iron(III) precursors in an aqueous solution of D-mannose. This in situ coating, based on a modified Molday's procedure (*20*), is the easiest way to obtain surface-modified magnetic nanoparticles (run 1 in Table 1). The coating prevents particle aggregation. Elemental analysis of the resulting particles after washing revealed 58.9 wt % iron, 9.3 wt % carbon, and 2.6 wt % hydrogen, suggesting the conjugate contained about 30 wt % of D-mannose. D-Mannose is thought to be bound to the nanoparticles via a well-known coordination bond (chelate) formed between D-mannose and Fe(II) or Fe(III) on the surface of magnetite (*22*). The presence of magnetite

spinel phase was confirmed by X-ray powder analysis (Figure 1). Due to the coating, only the most intense reflections (311 and 440) were observed. Significant broadening of the reflections indicates a very small particle size, in agreement with the TEM and AFM data.

Postsynthesis Iron Oxide Coating with D-Mannose. An iron oxide colloid was also obtained by a two-step procedure involving preparation of iron oxide cores in the first step (run 2 in Table 1) followed by addition of a stabilizer protecting them from aggregation and ensuring other necessary properties. Iron oxide cores were prepared by precipitation of iron salts, in particular $FeCl_2$ and $FeCl_3$, by increasing the pH followed by oxidation of the resulting magnetite with sodium hypochlorite. Oxidation resulted in maghemite (γ-Fe_2O_3), which is chemically stable and does not change its properties. This is in contrast to magnetite, which undergoes uncontrolled oxidation in the presence of oxygen. The conformation of the maghemite phase by Mössbauer spectroscopy and other magnetic properties were described in our previous report (*21*). D-Mannose was used as a stabilizer added to the primary iron oxide nanoparticles. The resulting particles were washed with water and freeze-dried to determine iron content and C and H content. Figure 2 summarizes the adsorption of D-mannose on the particles. At low D-mannose/γ-Fe_2O_3 ratios, the majority of D-mannose adsorbed to the particle surface; with increasing ratios, however, the efficiency of D-mannose adsorption initially decreased, then reached a plateau, and did not change further. It is interesting to note that after freeze drying, the product was rather voluminous without obvious agglomerates, indicating that D-mannose was attached to the iron oxide. Other supporting

evidence for such a claim is presented in the following sections; see the light scattering data, IR, and ultrasonic spectroscopy.

Nanoparticle Size Measurement by TEM, AFM, and DLS. The shapes and sizes of the magnetic nanoparticles obtained both in situ and by postsynthesis coating were observed using TEM. TEM images of the synthesized magnetic particles showed relatively high uniformity in terms of size and spherical shape. The presence of D-mannose during colloid preparation had a profound effect on the precipitation process. A TEM image of the iron oxide nanoparticles from run 1 (Figure 3a), precipitated in a concentrated D-mannose solution, shows their extremely fine size, ca. 2 nm (Table 1). This small size is due to the presence of D-mannose during precipitation, which interferes with the nucleation step of iron oxide formation, resulting in a smaller size compared with the postsynthesis method in which the coating is applied to the existing particles. The orientation of the magnetic particles is visible in Figure 3a. To confirm the TEM results, these particles were also studied by atomic force microscopy (AFM; Figure 4). A D-mannose layer containing iron oxide nanoparticles and many rounded, elevated structures (5−50 nm high) were noticeable in an AFM micrograph of magnetite particles spread across the carbon film on the TEM grid (Figure 4a). The surface structure is even more discernible at double magnification (Figure 4b), especially in the section analysis (Figure 4c). A plane lying 3.4−3.5 nm under the "surface" level can be distinguished in several places in Figure 4b. This plane is thought to be the surface of the carbon film, which is completely smooth as shown by AFM observation. The topography is illustrated in a 3D image of separated magnetite particles (Figure 4d) and in a detailed 3D image of a location where no large particles are present (Figure 4e). It can thus be concluded that the carbon film was covered with a 3.5-nm-thick layer of magnetite nanoparticles, which is in agreement with the TEM results. The layer contained rounded particle clusters 10−80 nm in size and many smaller particles (see the wrinkled surface in Figure 4e), which were otherwise not easily distinguishable. Some spots on the carbon film were not covered by the layer. Individual magnetite particles were not observed, indicating that all the iron oxide nanoparticles were stabilized with D-mannose. The iron oxide crystal growth was obviously retarded due to the unique structure of D-mannose present during precipitation. This is in contrast to the nanoparticles from run 3 (Table 1) obtained by postsynthesis coating of the primary bare colloid with D-mannose. TEM images of such particles (Figure 3c) showed no marked differences in either shape or size from uncoated iron oxide particles (2, Figure 3b). Their average diameter was 6−7 nm, and their polydispersity was PDI 1.3−1.5.

Iron oxide nanoparticle colloids obtained by postsynthesis coating were also investigated by dynamic light scattering measurements. The size calculated from DLS was ca. 10 times larger than that from TEM, mainly due to the effect of large particles on the hydrodynamic diameter. DLS provides the *z* average of the diameter, while TEM gives the number average. Figure 5 shows the dependence of hydrodynamic particle diameter and polydispersity on the D-mannose/γ-Fe_2O_3 ratio at three time points. D-Mannose-modified iron oxide particles were moderately larger than those that were uncoated due to the presence of a D-mannose hydrated shell. Moreover, Figure 5 documents the aging of the samples. Both the size and notably the polydispersity of uncoated iron oxide particles increased with storage time. This indicates aggregation of the particles without D-mannose protection. In contrast, the size and polydispersity of D-mannose-coated iron oxide nanoparticles did not dramatically change with time, implying that the particles do not aggregate (Figure 5). D-Mannose can thus be considered to be an effective stabilizer, preventing particle aggregation.

FTIR Spectra. The surface structure of the magnetic nanoparticles obtained by postsynthesis coating was analyzed by ATR FTIR spectroscopy. The infrared spectra of iron oxide before modification (run No. 2) and after coating with D-mannose (run 4) as well as the spectrum of pure D-mannose are shown in Figure 6a−c. Two broad bands of iron oxide dominate in the spectrum of the magnetic particles before modification (Figure 6a). The typical peaks of the C−H, C−O−H, and C−O−C vibrations of D-mannose (Figure 6c) are clearly distinguishable in the spectrum of the coated magnetic particles (Figure 6b). This indicates that the surface of the γ-Fe_2O_3 nanoparticles is covered with D-mannose (Figure 6). D-Mannose can be attached to iron oxide nanoparticles by the hydroxy group located on the C2 carbon in the axial position (*23*). This is a configuration specific to D-mannose, in contrast to, e.g., glucose and other common sugars that have this hydroxy group only in the equatorial position.

High-Resolution Ultrasonic Spectroscopy. Both uncoated and D-mannose-modified iron oxide nanoparticles were also characterized using high-resolution ultrasonic spectroscopy. Figure 7 shows the dependence of the concentration increment of the ultrasonic velocity on the amount of D-mannose added to the iron oxide. At low D-mannose/γ-Fe_2O_3 ratios, the ultrasonic velocity increased steeply with addition of D-mannose, which results from formation of a more ordered structure than in solution. After exceeding the critical D-mannose concentration, i.e., at a D-mannose/γ-Fe_2O_3 ratio > 0.065, the ultrasonic velocity almost did not change; that is, the excess D-mannose remained in solution. This indicates that until the critical D-mannose/γ-Fe_2O_3 ratio is reached, D-mannose molecules preferentially adsorb on the surface of iron oxide nanoparticles, forming a coat. Binding is obviously achieved via the D-mannose hydroxy group (*23*) at the carbon atom in position C2, possibly C3 and C4.

Protein Adsorption from Culture Medium. Adsorption of proteins from culture medium onto the iron oxide nanoparticles is an important tool for elucidating the transport of iron oxide in cells and also for nanoparticle coagulation. Iron oxide nanoparticles were thus mixed with serum-containing DMEM medium, the liquid separated by centrifugation, and the UV spectra of the supernatant recorded against a standard. The relative concentration decrease of serum proteins was correlated with the D-mannose/iron oxide ratio. Figure 8 indicates that even uncoated iron oxide nanoparticles adsorbed some serum proteins from the culture medium. With increasing D-mannose/iron oxide ratios used in the preparation of the nanoparticles, the amount of adsorbed serum proteins decreased. This is in agreement with published data on suppression of protein adsorption on saccharide-covered surfaces (*24*). The fact that D-mannose suppressed the nonspecific sorption of serum proteins on magnetic nanoparticles provides indirect evidence that the iron oxide particles were indeed coated with D-mannose. Moreover, it indicates that the cellular uptake mechanism of D-mannose-modified nanoparticles differs from that of PLL-modified ones (*25*).

Cell Labeling. Cell labeling with magnetic substances is an increasingly common method for in vivo cell monitoring and separation (*26*), as the labeled cells can be detected by magnetic resonance imaging. First, rat bone marrow stromal cells (rMSCs) labeled with either uncoated or surface-modified iron oxide nanoparticles were observed using an optical microscope. Cell labeling with Endorem served as a control (Figure 9a). Endorem has, however, a tendency to adhere to the surface of the cells, and it also sticks to the bottom of a vessel. Using the Prussian blue reaction, the cellular iron content was measured in rMSCs exposed to the nanoparticles.

Uncoated Iron Oxide. Uncoated iron oxide nanoparticles (No. 2) were used to label cells in order to elucidate the

importance of iron oxide modification/coating in subsequent experiments. Observation using an optical microscope with phase contrast revealed the iron oxide nanoparticles in rMSCs as dark dots. Cells in contact with the nanoparticles proliferated to some extent, and approximately 10% of the cells endocytosed the iron oxide (Figure 9b). Endocytosis might be explained by adsorption of proteins from the culture medium onto the iron oxide surface, subsequently inducing an undesirable partial coagulation of the particles. As the resulting coagulates were of a broad size distribution, only the smaller ones could penetrate the cells, whereas the larger ones were not internalized into the cells. In an attempt to increase the cell labeling, the iron oxide surface was modified with D-mannose.

D-Mannose-Modified Colloid. Modification of the colloid with D-mannose made the situation more complex, and differences were noted when the iron oxide was precipitated in a D-mannose solution compared to adding saccharide to the uncoated iron oxide nanoparticles. Cells in contact with D-mannose-modified nanoparticles No. 1 (prepared by precipitation in a concentrated D-mannose solution) proliferated well. If 10 μL of undiluted D-mannose-modified nanoparticles No. 1 was added to 1 mL of medium containing bone marrow stromal cells (to achieve a concentration of 0.2 mg of iron oxide/mL of medium), the nanoparticles were taken up by the cells (Figure 9c). A large percentage of cells was labeled (more than 80%; Table 1). However, some clumps of particles adhered to the surface of the cells and were difficult to wash out (Figure 9c). Thus, surface-bound iron oxide was indistinguishable from that internalized by the cells when observed by optical microscopy. The colloid was therefore diluted to concentrations of 0.1, 0.05, and 0.02 mg of iron oxide/mL of media. Improved results were already obtained at a concentration of 0.05 mg of iron oxide/mL, and at a concentration of 0.02 mg of iron oxide/mL, the cells were labeled with the nanoparticles without any iron oxide clusters adhering to the cell surface (Figure 9d); the percentage of labeled cells was still greater than 50% (Table 1). Compared with Endorem (0.11 mg of Fe_3O_4/mL), a lower concentration of D-mannose-modified iron oxide nanoparticles No. 1 was sufficient to label the cells. The very good ability of the cells to internalize the colloid can be explained by the extremely small size of the particles. Minimizing particle size was important for the ease of cellular internalization, but it reduced magnetic susceptibility at the same time. Moreover, colloid No. 1 was sensitive to aging; the particles coagulated within several days of storage. Modification by the postsynthesis coating of iron oxide nanoparticles with D-mannose was therefore developed. Table 1 summarizes the results of cell labeling experiments indicating that the degree of cell labeling depended on the D-mannose/γ-Fe_2O_3 ratio. The ratio 2.6/1 (colloid No. 4) can be considered as optimal, with ca. 80% of the cells being labeled. At a higher ratio (4.1/1; run 5) the particles adhered to the cell surface and the uptake of the nanoparticles did not significantly increase. This correlates with the results presented in Figure 2, which also documents that there is a limit to the ability of γ-Fe_2O_3 particles to adsorb D-mannose. Moreover, a high concentration of D-mannose results in an increased viscosity, promoting particle aggregation and adhesion to the cell surface. The mechanism responsible for the cellular internalization of ca. 10 nm nanoparticles is thought to be receptor-mediated endocytosis and/or diffusion through the cell membrane (*27*).

Image analysis tools were used to evaluate not only the percentage of labeled cells but also the intensity of Prussian blue staining. The resulting histograms (Figure 9f) show the distribution of the intensity of Prussian blue staining in rMSCs. In Endorem-labeled cells, the majority of cells (88%) were moderately stained, while in D-mannose-coated iron oxide No. 4 labeled cells, the staining intensity generally (90%) ranged from moderate to strong. These results confirm that the cells labeled with D-mannose-coated nanoparticles No. 4 contained a higher amount of iron per cell than did the cells with dextran-coated iron oxide.

Table 2. r_1 and r_2 Relaxivities of D-mannose-coated Iron Oxide Nanoparticles No. 4 and Endorem and of rMSCs Labeled by These Contrast Agents

	phantoms containing a suspension of pure contrast agent (s^{-1}/mM Fe)		phantoms containing labeled cells (s^{-1}/million of cells/mL)	
	r_1	r_2	r_1	r_2
D-mannose-coated iron oxide nanoparticles	7.31 ± 0.11	140.4 ± 1.4	0.32 ± 0.04	12.1 ± 0.9
Endorem	19.8 ± 1.5	127 ± 9	0.18 ± 0.06	1.24 ± 0.15

Transmission Electron Microscopy of Labeled Cells. Light microscopy revealed that D-mannose-modified nanoparticles were distributed rather randomly in the cytoplasm. To further confirm that D-mannose-coated iron oxide nanoparticles were internalized by the cells rather than simply bound to the surface of the cells and visualize the location of the nanoparticles inside the cells after internalization, TEM images were taken. A TEM image (Figure 10) shows clusters of nanoparticles (No. 4) as black dots scattered in the cell cytoplasm. Cell membrane-bound nanoparticle clusters — as a result of endocytosis — were not detected. Since a highly D-mannose-specific and energy-independent transporter has been found on the surface of the majority of mammalian cells, D-mannose-coated nanoparticles are most likely transported into the cells via this mannose transporter.

MR Relaxometry. MR relaxometry enables quantification of relaxation times (and relaxivities), which are responsible for contrast enhancement in T_1- and T_2-weighted MR images. Table 2 compares the relaxivities of gelatin samples containing suspensions of two contrast agents, D-mannose-coated iron oxide nanoparticles No. 4 and commercially available Endorem, and the relaxivities of gelatin samples containing cells labeled by these contrast agents. A higher r_1 relaxivity was observed for Endorem and a higher r_2 relaxivity for D-mannose-coated iron oxide nanoparticles. Both r_1 and r_2 were higher in the case of D-mannose-coated iron oxide-labeled cells (in the case of r_2 almost 10-fold) than for Endorem-labeled cells. We hypothesize that the higher relaxivity of the D-mannose-coated iron oxide nanoparticles is responsible for not only such a huge increase in relaxivity but also the substantially higher internalization of D-mannose-coated iron oxide nanoparticles as the r_1 relaxivity

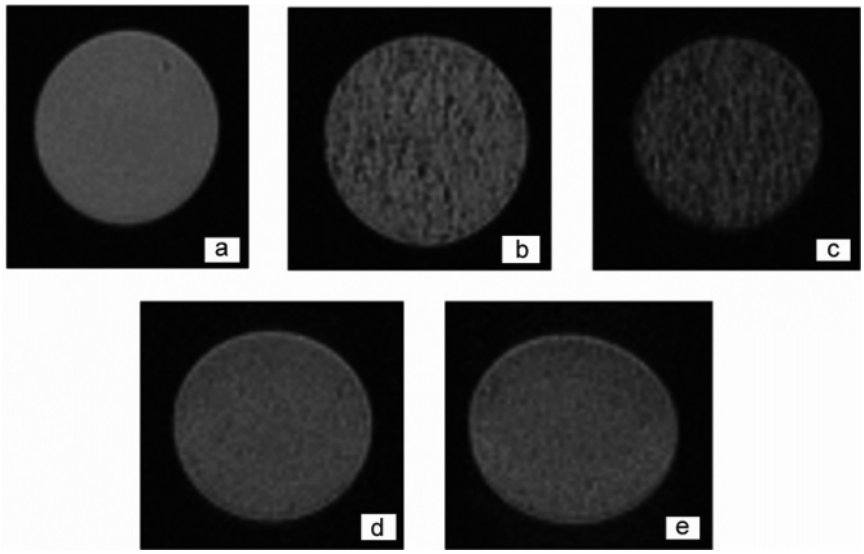

Figure 11. T_2-weighted MR images of gelatin phantoms containing (a) unlabeled cells, (b) 31 100 or (c) 62 200 cells labeled with D-mannose-coated iron oxide nanoparticles, and, for comparison, (d) 31 100 and (e) 62 200 cells labeled with Endorem.

of the D-mannose-coated iron oxide-labeled cells is also higher than the r_1 of Endorem-labeled cells, although D-mannose-coated iron oxide displayed a lower r_1 relaxivity than did Endorem. This hypothesis was confirmed by iron analysis of cell suspensions; the average amount of iron as determined by spectrophotometry after mineralization was 51.7 pg of iron per cell for D-mannose-coated iron oxide nanoparticles and 14.6 pg of iron per cell for Endorem-labeled cells.

These highly promising results were obtained with iron oxide nanoparticles coated by the postsynthesis method. Particles precipitated in situ in D-mannose solution did not display improved relaxivity, probably because they were too small, as reflected by the very low relaxivity of gelatin samples containing labeled cells: $r_2 = 0.114 \pm 0.006\ s^{-1}/10^6$ cells/mL. To mimic signal behavior in the tissue, in vitro imaging of labeled cells was performed. Phantoms with different numbers of rat MSCs labeled by Endorem or by D-mannose-coated iron oxide nanoparticles were prepared and suspended in gelatin. Unlabeled cells (Figure 11a) did not change the signal at all. Cells labeled with D-mannose-coated nanoparticles (Figure 11b,c) produced a visibly greater signal decrease than did Endorem-labeled cells (Figure 11d,e). These detectable changes in the MR signal correspond to 1.17 (Figure 11b,d) or 2.34 (Figure 11c,e) cells per image voxel, depending on the concentration of cells in the phantom. Since it was shown (*14*) that MSCs (300 000 cells in 5 μL) labeled with Endorem and implanted into the rat brain were clearly visible on T_2-weighted images, we believe that use of this novel cellular contrast agent would enable detection of very small numbers of labeled cells.

CONCLUSION

Iron oxide nanoparticles were produced by coprecipitation of Fe(II) and Fe(III) salts in an alkaline medium. The surface of the magnetic nanoparticles was modified by D-mannose, and the particles were characterized by several methods to confirm that D-mannose successfully coated the particles. The intracellular uptake of the D-mannose-coated nanoparticles by rMSCs was confirmed by both optical and transmission electron microscopy. Relaxometric measurements revealed that only postsynthesis-coated nanoparticles possessed very high r_2 relaxivity. D-Mannose-modified iron oxide nanoparticles are a promising tool for labeling living cells, particularly stem cells, for diagnostic and therapeutic applications in cell-based therapies due to their high relaxivities, which are responsible for contrast in MR imaging, and their easy internalization by cells. They can prove useful in human and veterinary medicine, biology, and microbiology for monitoring the fate of cells transplanted into a host organism, including their in vivo migration, localization, and differentiation, by means of noninvasive magnetic resonance.

Received July 8, 2006; Revised Manuscript Received December 9, 2006

Antibodies with high affinity for the surface of a solid material would be advantageous in biomaterial science as a protein device. A human antibody fragment that binds to poly(hydroxybutyrate) (PHB), a biodegradable polymer matter, was generated by a phage display system. Clone PH7-3d3 was isolated after several rounds of selection and prepared as a fragment of immunoglobulin variable regions (Fv). The quartz crystal microbalance technique showed that PH7-3d3 Fv completely inhibited PHB enzymatic degradation by competing with PHB depolymerase. Kinetic analysis based on surface plasmon resonance demonstrated that PH7-3d3 Fv bound to the PHB film with an equilibrium dissociation constant of 14 nM. The three-dimensional structure of PH7-3d3 Fv was resolved to 1.7 Å, revealing that the complementarity determining regions (CDRs) in the Fv fragment form a relatively flat surface on which uncharged polar and aromatic amino acids are distributed in clusters. The structure of PH7-3d3 Fv was similar to that of PHB depolymerase in the orientation of aromatic residues in the binding sites. Alanine scanning mutagenesis demonstrated that these aromatic residues, especially tryptophan residues in CDRs, were critical in the interaction between PH7-3d3 Fv and PHB. Our results suggest the possible selection of an antibody fragment that binds a material surface in a manner similar to protein−ligand interaction.

INTRODUCTION

Although most globular proteins target soluble molecules, some enzymes such as cellulose, chitinase, and PHB[1] depolymerase recognize and bind to a solid-phase biopolymer. Many researchers in the interdisciplinary fields like nanobiotechnology have attempted to exploit these proteins as a specific molecule to solid phase, because they can specifically immobilize the molecules of interest on the support material (*1*, *2*). For technological applications in which proteins serve as recognition devices, understanding the mechanism of recognition between solid surface and protein is necessary. To date, however, only limited information on the molecular recognition mechanism is available for three reasons: (i) few naturally occurring biomolecules that target solid surfaces are available, (ii) there are few efforts to generate such novel proteins de novo, and (iii) the methods for the analysis of the solid surface recognition mechanism are not well developed.

The antibody, which plays a key role in the immune system, is a naturally occurring recognition device that shows excellent binding ability and specificity. To our knowledge, although many antibodies against various antigens, including proteins, haptens, and carbohydrates, have been prepared by means of hybridoma technology, attempts to prepare the antibodies against solid surfaces have been unsuccessful, except the monoclonal antibody against amino acid crystals, because of the poor immunogenic potential of materials and the difficulty in sensitization of the vertebrate immune system by materials.

In contrast, immunization is not required in antibody production based on the in vitro selection method such as the phage display system, thus allowing the preparation of antibodies that recognizes various material surfaces. Although some peptides bound to solid surfaces such as gold (*4*), GaAs (*5*), and ZnS (*6*) were selected using phage display (*1*, *7*, *8*), few studies involve the binding of an antibody to a solid surface, which is capable of showing higher affinity compared with a low molecular weight peptide and being a model for studying the mechanism of molecular recognition between a material surface and a biomacromolecule.

The aim of the present study is to select a human antibody fragment that binds to a solid surface by phage display and to analyze the mechanism of the interaction between the antibody and the solid surface in detail. We use poly(hydroxybutyrate) (PHB), a biodegradable polymer, as a model material surface. PHB, which was found as an insoluble granule in bacteria (*9*), is a polyester of hydroxybutyric acid. The PHB granule serves as a reservoir of non-nitrogenous material under the conditions of insufficient nourishment; therefore, the host bacteria also carry the catabolic enzyme PHB depolymerase. PHB granules are produced in many bacteria, including *Bacillus megaterium* and *Alcaligenes eutrophus*, but also on the plasma membranes of *Escherichia coli* (*10*) and human erythrocytes (*11*). From a practical point of view, the effective combination of a human antibody fragment and a naturally occurring biomaterial would lead to material and medical engineering applications as well

as providing a model for studying specific interactions between proteins and solid-phase surfaces.

EXPERIMENTAL PROCEDURES

Selection of Antibody Fragments. Human antibody fragment libraries were subjected to selection on the basis of Fv fragment stabilization under coexistent antigens as described previously (*12*). Variable regions of light and heavy chains (VL and VH, respectively) were displayed on the filamentous bacteriophage M13. The phage viruses displaying VL chain with affinity for PHB, were first selected from the VL chain library, and then the selection and assay of the phage virus with the VH chain was carried out in the presence of the selected VL chain for stabilizing the VH chain.

PHB purchased from ICI, Inc., was dissolved in chloroform and then dispersed in an amount of hexane to form refined PHB precipitates. Approximately 10^9 phages were mixed with 3 mg of the prepared PHB matter in 1 mL of PBS and 0.1% Tween 20 detergent. The mixture was incubated at room temperature with gentle agitation for 1 h. The residual phage viruses on PHB matter were amplified by directly adding the PHB matter into *E. coli* media after the exclusion of the unbound phage from the phage−PHB solution. After three rounds of selection, random clones were isolated, expressed as soluble fragments, and tested in enzyme-linked immunosorbent assay (ELISA).

ELISA Analysis. PHB was adsorbed on 96-well microtiter plates. Antibody fragments were applied to the plates after nonspecific binding to the plates was blocked by using Super Blocking Buffer (Pierce), and the plates were incubated for 1 h at room temperature. After five washes with PBS, the binding of antibody fragments was detected with Fluoroskan Ascent FL (Labsystems), using ECL Western Blotting Detection Reagent (Amersham Biosciences).

Preparation of Antibody Fragments. The VH and VL genes were inserted into the secretory coexpression vector pRA2; the resulting plasmid was named pRA2FHL. *E. coli* strain BL21 (DE3) was transformed with pRA2FHL and cultured at 28 °C for 18 h in 2 × YT medium containing 100 μg/mL ampicillin. Expression of the Fv fragment under the control of the T7 promoter was induced by adding 1 mM isopropyl β-D-thiogalactopyranoside (IPTG). The harvested cells were centrifuged and suspended in 50 mM Tris−HCl (pH 8.0) buffer with 200 mM NaCl. After sonication, the suspension was centrifuged at 5800 *g* for 30 min at 4 °C. The gene products in the supernatant were refined by means of a metal-chelate chromatography column that interacted with the histidine tag in the expressed VH and VL, after salting out with ammonium sulfate.

Quartz Crystal Microbalance (QCM) Analysis. The apparatus and experimental procedure for QCM analysis were essentially the same as those described previously (*13*). The QCM oscillator in a QCA-917 (SEIKO EG&G) was washed with a freshly prepared piranha solution (H_2SO_4/H_2O_2 = 3/1, v/v), and it was rinsed with distilled water several times. Dissolved PHB in chloroform (1.5 wt %) was cast on one side of the oscillator placed on a spin-coater (MOC Co., Ltd., ME-300) at 4000 rpm under dry air, and then the film was kept at 110 °C for 1 day after the melting treatment at 210 °C for 30 s on a hot stage (Linkam LK-600PM). After stabilization of QCM in a 0.01 M phosphate buffer solution (pH 7.4) for 1 day, the selected Fv fragment was injected into the QCM cell. For the inhibition assay for PHB enzymatic degradation, the selected Fv fragment was injected 4.5 h after the replacement from an enzyme-free solution to a 0.02 μM enzyme solution.

Surface Plasmon Resonance (SPR) Analysis. For the SPR analysis, a sensor chip of Au (Biacore) was ultrasonically cleaned in acetone, soaked in a freshly prepared piranha solution, and rinsed with double-distilled water in advance. PHB dissolved in chloroform (0.25% w/v) was spin-cast onto the chip at 6000 rpm. The chip was melted at 210 °C for 30 s and then kept at 110 °C for 24 h. The SPR resonance angle was confirmed to be within the range needed to detect binding. SPR measurements were performed using Biacore 2000 (Biacore). The running buffer for the experiments was PBS. Kinetic parameters were determined on the basis of a 1:1 Langmuir model by using the data from association phases.

X-ray Crystallography. The soluble Fv was concentrated to 10 mg/mL by using Centricon YM-10 (Millipore). Fv was crystallized in 20% PEG 8000, 100 mM CHES (pH = 9.3). Diffraction data to 1.7 Å were collected at 100 K by using synchrotron radiation on beamline 6A of the Photon Factory (Tsukuba, Japan). The diffraction images were integrated with the *hkl* program *DENZO*, and the intensity data were processed with SCALA in the CCP4 suite (*14*). The crystallographic data and statistics are summarized in Table 2. The structure was determined by a molecular replacement method with the program *Molrep* (*15*) in the CCP4 suite. The coordinates were refined using the programs *REFMAC* (*16*) and *CNS* (*17*). The atomic coordinates and structure factors were deposited in the Protein Data Bank (entry code 2D7T).

Alanine Scanning Mutagenesis. The solvent-exposed amino acid residues in the complementarity determining regions (CDRs) were chosen for mutagenesis analysis. Each site-directed Fv mutant in which an amino acid in CDRs was mutated to alanine residue was performed by overlap extension PCR (Supporting Information). All the Fv mutants were prepared as described in the section of preparation of antibody fragments, and their binding to PHB surfaces were analyzed using SPR.

RESULTS

Selection of a Human Antibody Fragment on PHB Surface. Using a phage-displayed antibody library, the antibody fragments with affinity for PHB were selected. After three rounds of selection, ELISA was used to test the randomly isolated clones for their binding to PHB (Figure 1A). Clone PH7-3d3 showed tight binding to PHB as indicated by its high

chemiluminescence value. The amino acid sequences of the complementary determining regions (CDRs) of the selected clone PH7-3d3 are shown in Figure 1B. The tip of the CDR-H3 loop is composed of four amino acid residues—Gly, Trp, Trp, and Gly—that lie in series, which seems to be the distinctive feature of CDR-H3. The roles of these residues are discussed later. For further analysis, the clone PH7-3d3 was prepared as soluble Fv. SDS polyacrylamide gel electrophoresis verified the purity of samples and confirmed that both chains of the Fv existed in a 1:1 molar ratio. The final yield of Fv was 40 mg per 1 L culture of *E. coli* (data not shown).

QCM Analysis. We assessed the ability of PH7-3d3 Fv to bind to a PHB film by using the QCM technique (*13*). QCM analysis showed that the PH7-3d3 Fv bound tightly to the PHB film, and its binding was detected at the concentration of approximately 40 nM (Figure 2A). We also measured the QCM sensorgram of other Fv fragment with higher chemiluminescence

in ELISA assay than that of the background; however, no frequency changes were observed (data not shown), indicating that only the clone PH7-3d3 has the binding function to the PHB film.

PHB, which is derived from storage materials of bacteria, can be hydrolyzed by PHB depolymerase. Using QCM, we then analyzed how PH7-3d3 Fv altered the biodegradability catalyzed by PHB depolymerase derived from *Alcaligenes faecalis* T1 (Figure 2B). A frequency shift corresponds to a mass change caused by PHB hydrolysis. Enzymatic hydrolysis of PHB film by the depolymerase was completely inhibited by the addition of the Fv (Figure 2B, arrow). A rapid frequency decrease of 80 Hz occurred on the injection of PH7-3d3 Fv, and then the value of this frequency change is nearly equivalent to the shift caused by the Fv binding. The inhibition of hydrolysis is, therefore, attributed to the specific coating of the Fv onto the PHB surface.

Kinetic Study Based on Surface Plasmon Resonance (SPR) Analysis. We then analyzed the binding of PH7-3d3 Fv to the spin-coated PHB film by SPR (Figure 3A). The binding of PH7-3d3 Fv was confirmed, whereas there were no noteworthy responses upon the addition of hen egg-white lysozyme (HEL) and anti-HEL antibody HyHEL10 Fv to the PHB film. PHB, as seen from the structural formula, contains more oxygen atoms than other hydrophobic polymers such as polystyrene, and it is assumed to hydrophobically adsorb less globular protein. The binding of PH7-3d3 Fv to the dextran layer was not detected (Figure 3A).

To examine the recognition mechanism in detail, quantitative analysis from the aspect of kinetics is necessary. Although the kinetic studies based on SPR have been performed for protein−protein interaction to gain insight at the molecular level, we have obtained limited information regarding protein−material surface interaction to date. This difference may be due to protein denaturation on the surface, which influences the dissociation of adsorbed proteins and complicates the fitting analysis using a particular model. Here, we measured the binding affinity of

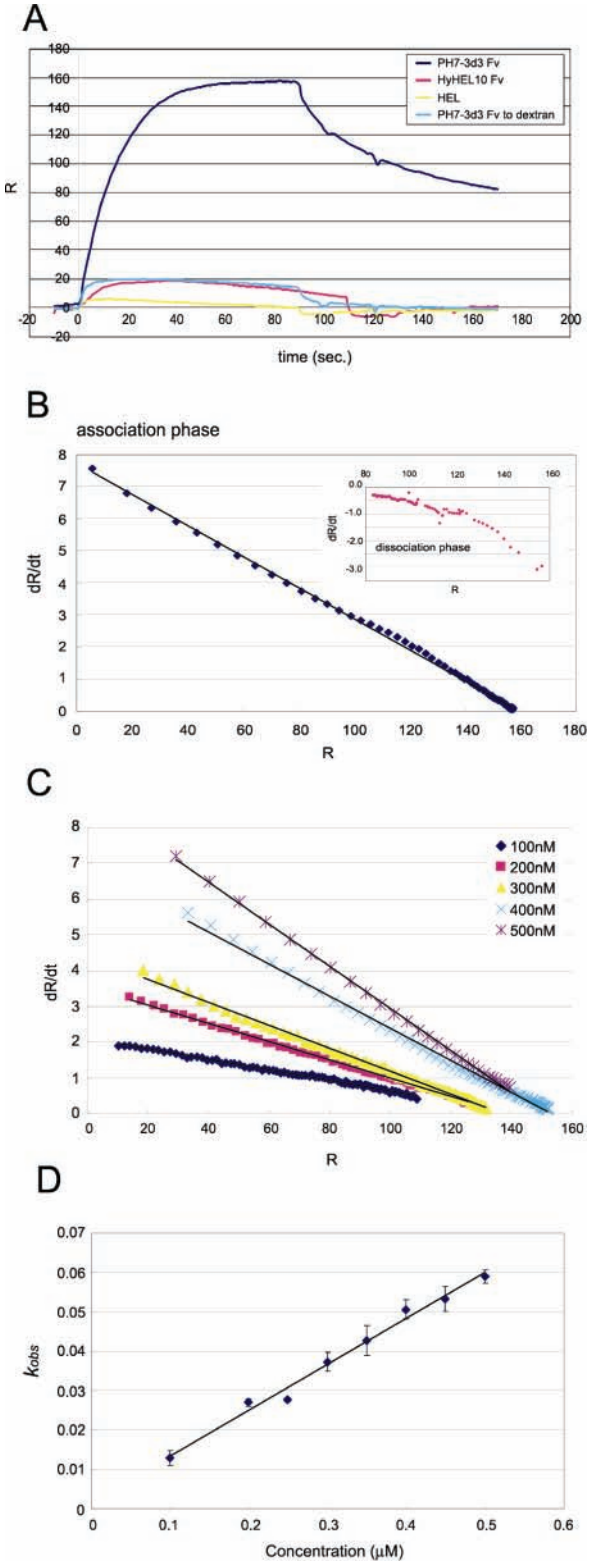

Figure 3. SPR analysis of the binding of PH7-3d3 to the PHB surface. A. Binding behavior of several kinds of protein on the PHB surface. Hen egg-white lysozyme (HEL) and the anti-HEL antibody fragment HyHEL10 Fv were used as control proteins. The binding of PH7-3d3 Fv to a layer of dextran also is shown. The concentration of all samples used in the observation was 200 nM. B. dR/dt vs R plots of the association and dissociation (inset) phases. C. Dose dependency of dR/dt vs R plots. D. The apparent association rate constant (k_{obs}) vs concentration plots. The association rate constant (k_{on}) and dissociation rate constant (k_{off}) were determined from the slope and intercept of the line. The value of the dissociation constant (K_D) was calculated as k_{off}/k_{on}.

PH7-3d3 Fv to the PHB surface according to a 1:1 Langmuir model using only the association phase. As shown in Figure 3B, dR/dt versus R plots for the dissociation phase did not yield a straight line, whereas the association phase showed good agreement with the model.

Figure 3D shows a plot of the apparent association rate constant, k_{obs}, versus concentration and the line's slope and intercept, which are equal to k_{on} and k_{off}, respectively. From these results, the kinetic parameters k_{on}, k_{off}, and K_D were determined to be 1.2×10^5 s^{-1} M^{-1}, 1.7×10^{-3} s^{-1}, and 1.4×10^{-8} M, respectively. The adsorption equilibrium constant of PH7-3d3 was calculated to be $K_e = 2.9$ mL/μg, which is comparable to or larger than those of the substrate binding domains (SBD) of PHB depolymerases as reported by Kasuya et al. (*18*) and Ohura et al. (*19*). In comparison to other depolymerases including cellulases, PH7-3d3 Fv showed a substantially higher affinity for the substrate (Table 1). These results indicate the possibility that in vitro selection enables us to generate human antibody fragments with higher affinities than those of the naturally occurring substrate binding domains.

X-ray Crystallography. Little information on the mechanism of molecular recognition between protein and the material surface is available at the amino acid level. To date, molecular dynamics (MD) simulation or docking studies have been performed for the interactions between solid surfaces and gold binding protein (*20*), carbon nanotube binding peptide (*21*), and amino acid crystal binding antibody (*22*). To gain insight into the interaction between PH7-3d3 and the PHB film surface, we performed X-ray structural analysis of PH7-3d3 Fv. Structural determination of PH7-3d3 Fv was based on the molecular replacement method using various search models (pdb codes 1AD9 for VH, 1DEE for VL) and was refined to an R value of 19.0% ($R_{free} = 21.4\%$).

Figure 4A shows the overall structure of the Fv. The CDR loops, which in general build an antigen binding site, formed a relatively flat surface that resembled those of antibodies against macromolecular antigens like proteins (*23*). Note that the putative antigen binding site lacks a cavity or groove, which typically is seen in those of antibodies for low molecular weight haptens and peptide or carbohydrate antigens (*23*). Although we have not obtained the structural data for any anti-plastic antibodies other than PH7-3d3, a flat binding site is likely to generate a highly complementary binding interface with the planar polymer surface. In addition, we examined the amino acid residues in the binding site for PHB. Polar amino acid residues such as Asn are juxtaposed around a cluster of aromatic amino acid residues (Trp and Tyr). Using *ICM-REBEL* (Molsoft), we calculated the electrostatic potential of the molecular surface around the CDRs (Figure 4B). The molecular surface formed from the CDRs is mainly a noncharged polar surface, which we anticipate is favored in the binding to uncharged plastic.

Alanine Scanning Mutagenesis. On the basis of the three-dimensional structure of PH7-3d3 Fv, we used alanine scanning mutagenesis to identify the amino acid residues critical for interaction. All the solvent-exposed amino acid residues in the CDRs were chosen as target residues for mutation (Figure 4B). We determined the equilibrium dissociation constant (K_D) of the mutants by SPR, and then their Gibbs free energy changes were calculated. The involvement of solvent-exposed residues in antigen binding was represented as relative Gibbs energy changes (Figure 5). Each loss of the binding free energy ($\Delta\Delta G$) due to the point mutation was illustrated in color on a space-filling model of Fv (Figure 4C).

Figure 5 shows that the mutation of aromatic residues to alanine residue tended to affect the interaction more than did the mutation of polar residues. Of all the solvent-exposed residues in the CDRs, the mutation of HN32, HW50, HW100, HW101, and LH92, which are localized in the center of the

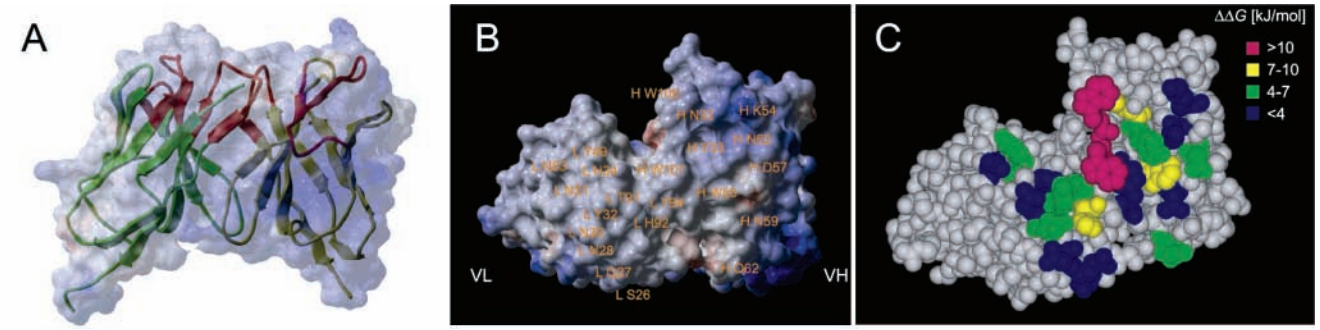

Figure 4. Structural analysis of PH7-3d3 Fv. A. Molecular surface as viewed from the side. The VH domain is shown in yellow; VL is in green. The CDR loops are colored in red in both chains. B. The molecular surface around the CDRs, as viewed from the top. Solvent-exposed amino acid residues in CDRs are annotated. C. Mapping of the amino acid residues critical for the binding of PH7-3d3 to the PHB surface. The resulting decrease in the binding due to alanine substitution was converted to $\Delta\Delta G$ (see Figure 5). The value of $\Delta\Delta G$ in each solvent-exposed residue is color-coded on the model.

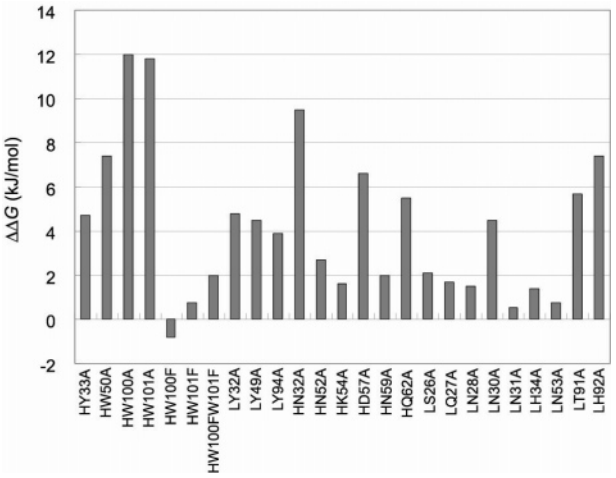

Figure 5. The relative Gibbs free energy changes of the alanine-substituted mutants. The equilibrium dissociation constants (K_D) of each mutant were determined by the same method described in the case of wild type (WT). The Gibbs free energy ΔG was calculated by the equation $\Delta G = RT \ln K_D$. The change in the Gibbs free energy $\Delta\Delta G$ of each mutant was obtained by the subtraction of ΔG of wild type from those of mutants.

CDRs (Figure 4B), resulted in the marked reduction of affinity. Note that the two tryptophan residues HW100 and HW101, which are adjacent to each other in the CDR-H3 loop, have pronounced effects on binding.

Tryptophan residues are known to frequently occur in the binding site critical for protein−protein interactions (*24*). To assess the roles of the tryptophan residues, we made three mutants—HW100F, HW101F, and HW100FW101F—where the tryptophan residues were mutated to phenylalanine. Interestingly, all three mutants bound to the PHB surface with nearly equal affinity (Figure 5), indicating that the binding tolerates the mutation of tryptophan to another aromatic residue.

Three amino acid residues—HN32, HW50, and LH92— were also shown to affect the binding to PHB film. In comparison with HW50 and LH92, the side chain of HN32 is buried and seems to be unable to contact the antigen. The location of HN32 beneath HW100 suggests that HN32 might sustain the orientation of HW100 and stabilize the conformation of the CDR H3 loop to optimally allow it to contact the antigen.

DISCUSSION

PHB, which has been developed as a biodegradable material, is a naturally occurring plastic, and its depolymerases have been isolated from several kinds of bacteria (*18*, *19*). We considered that the comparison of the naturally occurring depolymerases with the in vitro selected antibody and the analogical approach to the antibody−antigen interaction mechanism would contribute to the analysis of the protein−material surface interaction. Yamashita et al. analyzed protein adsorption to PHB film and used QCM to analyze the hydrolysis mechanism (*25*). They reported that PHB hydrolysis was not inhibited by the addition of bovine serum albumin or cellulase, which showed minimal binding of the proteins to PHB. In contrast, a PHB depolymerase mutant entirely lacking the catalytic site completely blocked PHB biodegradation. Therefore, the authors suggested that specific interactions were needed for biodegradation inhibition caused by the exchange of depolymerase for other proteins.

Exchange of proteins on the surface depends not only on the binding site, but also on the binding affinity. Our SPR analysis revealed that PH7-3d3 Fv bound to the PHB surface with higher affinity than PHB depolymerase (Table 1). Therefore, PH7-3d3 Fv is capable of competing with PHB depolymerase, which was also supported by QCM assay (Figure 2B). Kasuya et al. aligned amino acid sequences of substrate binding domains in PHB depolymerases derived from *Alcaligenes faecalis* T1, *Comamonas testosteroni*, *Comamonas* sp., *Streptomyces exfoliates*, *Psuedomonas pickettii*, and *Pseudomonas lemoignei* (*18*). They identified tyrosine and phenylalanine (aromatic residues) and serine, threonine, glutamine, and asparagine (polar residues) as conserved residues in the depolymerases. The driving force for the binding to the PHB surface is not electrically charged, but may be hydrogen bonding, van der Waals contact, or hydrophobic effect; therefore, it is reasonable to consider that all of these residues may be involved in binding. Except for phenylalanine, which does not occur in the tip of CDR loops frequently according to germline gene sequence (*26*), all of the listed residues appear in the CDRs.

The crystal structure of PHB depolymerase from *Penicillium funiculosum* was recently determined by Hisano et al. (*27*). The comparison of the structure of PH7-3d3 Fv with that of the depolymerase revealed that they had some similarities, especially in the distribution of solvent-exposed amino acid residues on the putative binding sites. In the two models, a number of hydrophobic residues on the molecular surface, which contribute to the adsorption to the PHB surface via hydrophobic interaction, and some polar residues around them were aligned in a plane. Some tyrosine and tryptophan residues located in the antigen binding site of PH7-3d3 and the tyrosine residues in the PHB adsorption site of the depolymerase had the same orientation in a way that allowed the aromatic rings to be in face-to-face contact with the PHB surface. The orientation could be effective in adsorption to the surface. The sequential and structural similarities suggest that PH7-3d3 Fv and PHB depolymerases might bind to PHB surface in a similar manner, which is consistent with the results of kinetic analysis and inhibition assay using SPR and QCM.

The alanine scanning mutagenesis studies showed that HN32, HW50, LH92, and especially HW100 and HW101, were critical for the interaction between PH7-3d3 Fv and the PHB film (Figure 5). On the other hand, mutants HW100F, HW101F, and HW100FHW101F, in which tryptophan residues in CDR-H3 were mutated to phenylalanine, have no decrease of binding affinity (Figure 5). This finding indicates that the aromatic ring can compensate for the key interaction between PH7-3d3 and PHB film via the indole ring of Trp, and it strongly suggests that the driving force of the binding is not due to hydrogen bonding but results from other factors such as van der Waals contacts, π electron donors, or hydrophobic effect. Complementarity at the molecular interface becomes particularly important when binding depends on these factors. The planar molecular surface formed by the CDRs of PH7-3d3 Fv suggests that the deletion of the bulky aromatic ring leads to decreased complementarity between binding interfaces.

Bogan et al. statistically identified tryptophan, tyrosine, and arginine as the residues that are apt to be "hot spots" (i.e., that various specific residues play a key role in protein−protein interaction) (*24*). In contrast, the mutation of polar residues surrounding these aromatic residues had less influence on binding. They subsequently proposed a mechanism in which the residues in the center of the binding surface are important as hot spots, and this role originates from being shielded from solvent by the surrounding polar residues. In the case in which those polar residues work as a solvent-shielding ring (referred to as the "O-ring"), single mutation is incapable of decreasing the binding ability. Then, our results (Figure 4) can be discussed in analogy with the concept of hot spots that has been applied to a number of protein−protein interactions, suggesting the possibility of in vitro selection of an antibody that recognizes a material surface in a similar manner to protein−ligand interaction.

CONCLUSION

Few works regarding the proteins that function at the solid−liquid interface have been reported, because only a few natural examples of these kinds of proteins have ever been identified and characterized. The specific mechanism underlying the interaction between a protein and a material surface remains to be revealed. In this study, we focused on a natural antibody repertoire and selected an antibody fragment that binds to PHB from a human antibody library. This is the first report of generating a human antibody fragment with high affinity for a given material surface based on phage display system. Protein engineering of antibodies (i.e., antibody engineering) has generated vast amounts of information and knowledge, including that of macro- and microscopic interaction analysis (*28*−*31*), improvement of functional properties based on site-directed mutagenesis analysis (*32*) or evolutionary engineering approaches (*33*), and construction of multivalent antibody fragments (*34*). The methodology we show here links the knowledge of material engineering with that of antibody engineering. From this practical viewpoint, our current work can be viewed as the generation of a highly regulated protein device that functions on the surface of a material and leads to self-assembly of materials via antibodies targeting solid surfaces.

ACKNOWLEDGMENT

We thank Dr. K. Makabe for helpful discussions. This work was supported in part by the Grant-in-aid for Scientific Research (S) from JSPS, Japan.

MAT B III cells were insonified at ultrasound frequencies of 1.15 and 2.25 MHz in the presence of different ultrasound contrast agents (UCA) and a plasmid encoding for the green fluorescent protein. The transfection efficiency was assessed by flow cytometry, while contrast agent destruction by ultrasound was evaluated using optical and scanning electronic microscopies. It was found that the gas and shell properties of the UCA have an important influence on cell transfection. A good correlation was observed between bubble destruction and transfection rate, and it was demonstrated, for the first time, that hard-shelled contrast agents (gas microcapsules) are promising candidates for ultrasound-mediated gene delivery.

INTRODUCTION

Ultrasound contrast agents (UCA) are widely used in diagnostic applications in medical research and clinical practice. Recently, they have been exploited in ultrasound-mediated gene delivery (*1*−*3*). This new approach uses acoustic cavitation effects of gas microbubbles to induce transient membrane permeabilization (sonoporation) at the cellular level, thereby facilitating the transfer of genetic materials. In comparison to other transfection techniques (viral or nonviral), sonoporation may allow in vivo gene transfer more specifically with high spatial and temporal control, since the site and levels of transfection can be precisely localized and controlled by ultrasound (*4*, *5*). This approach has been applied in vitro (*6*−*9*) and in vivo (*3*, *10*−*12*). It is thought that sonoporation is induced by acoustic cavitation (*13*), which generates microstreaming or microjets in the surrounding medium (*14*−*16*), resulting in permeabilization of the cell membrane.

Most UCA are made of gas microbubbles and are referred to as "soft-shelled" agents, e.g., Albunex, Optison, and Definity (*17*). These UCA have been used in sonoporation as cavitation nuclei (*9*, *18*−*20*). Agents specially designed for gene delivery have also been reported (*21*, *22*), and are generally soft-shelled, comprising phospholipids or proteins with a plasmid-bearing surface and a perfluorocarbon gas core. Hard-shelled UCA (i.e., containing a rigid lipid or polymeric shell) may also be used for ultrasound-mediated gene delivery. These agents, although not yet commercially available, have been extensively studied for diagnostic imaging (*23*−*25*), drug delivery (*26*), acoustic properties (*27*, *28*), and other biophysical applications (*29*). While it is generally believed that UCA destruction at high acoustic pressure is the main cause of sonoporation, there have been few studies in which cell transfection and UCA destruction have been assessed at the same time and then related to the formulation properties of the contrast agent. In the present work, it was hypothesized that the physicochemical parameters of UCA, including bubble size, shell properties, and encapsulated gas, may be modulated to improve the efficiency of gene transfection in sonoporation. Two types of experimental UCA were investigated for in vitro transfection: gas microbubbles, stabilized with phospholipids, and gas-filled microcapsules with a rigid shell made of either triglyceride or polystyrene. Contrast agent destruction was also evaluated and correlated with transfection.

EXPERIMENTAL PROCEDURES

Cell Culture. Rat mammary carcinoma cells (MAT B III) were incubated at 37 °C under 5% CO_2 in 225 cm^2 tissue culture flasks, in a MacCoy's 5A medium containing Glutamax-I (Life Technologie, Switzerland), supplemented with 10% v/v heat-inactivated fetal calf serum (FCS) and 1% v/v antibiotics (initial concentration: 10 000 IU/mL penicillin, 10 000 μg/mL streptomycin, 25 μg/mL fungizone).

Ultrasound Contrast Agents (UCA). UCA were formulated with various shell materials and gases (Table 1). The particle concentration and average number diameter of each agent were determined using a Coulter Multisizer II (Coulter Electronics Limited, Luton, Bedfordshire, England). Table 1 includes the resistance of each UCA to hydrostatic pressure (Pc50, expressed in mmHg), a critical value at which 50% of UCA are destroyed/collapsed. This pressure was determined as described elsewhere (*30*). BR14 and the commercial agent SonoVue are both phospholipid-stabilized gas microbubbles containing, respectively, C_4F_{10} and SF_6. These microbubbles were prepared accordingly to published procedure (*31*). Studies performed using Coulter counter and HPLC analyses confirm that BR14 microbubbles are coated with a monolayer of phospholipid molecules (unpublished results). It is well-known that the thickness of a monolayer of mixed phospholipids spread at a gas−liquid interface is about 2−3 nm (e.g., determined by Langmuir through or Langmuir−Blodgett) (*32*). Figure 1A depicts BR14 microbubbles. Gas-filled microcapsules were prepared by an emulsification procedure according to published protocol (*33*). The characteristics of similar gas-filled microcapsules (also called microballoons) were already reported by Schneider et al. (*23*, *34*, *35*). A comparative study on the behavior of lipid- and polymer-shelled agents (the two agents

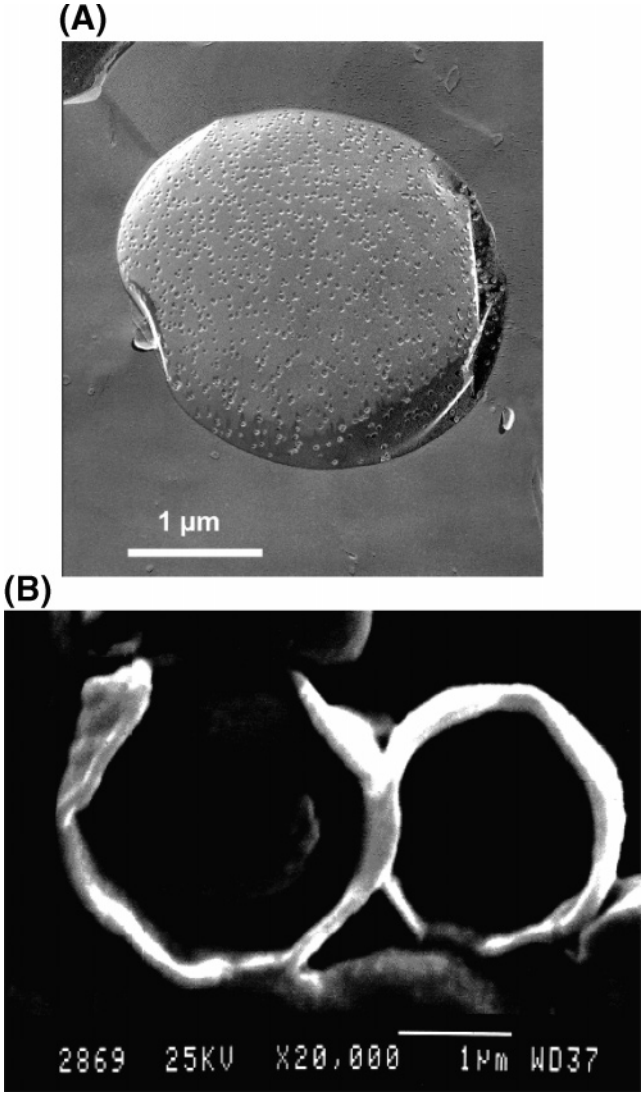

Figure 1. (A) Freeze−fracture electron micrograph of a microbubble (BR14) stabilized by a thin phospholipid film. (B) Scanning electronic micrograph of microcapsules (BG1768)—the shell is made of polystyrene (100 kDa) and has a thickness of about 50−200 nm. The open-shelled structure was obtained after ultrasound exposure of the microcapsules.

used in the present study) in response to acoustic exposure was performed by Bloch et al. (*36*).

For hard-shelled agents, formulated with either triglyceride (Figure 1B) or polystyrene, the estimated shell thickness was 50−200 nm. The soft-shelled agents are hereafter referred to as microbubbles, and the rigid-shelled UCA as microcapsules.

Ultrasound Exposure. A 3 mL polystyrene round-bottom tube was used as an exposure chamber. 500 μL of a cell suspension, at a final concentration of 1×10^6 cells/mL, was mixed with culture medium containing the plasmid gWiz-GFP (5757 base pairs; Aldevron, Fargo, ND), encoding for the green fluorescent protein (GFP). Most sonoporation experiments (except those studying the effects of bubble concentration and size) were performed with a final plasmid concentration of 10 μg/mL and a bubble-to-cell ratio of 30. The tube was mounted in a rotating exposure system and immersed in a water bath at 37 °C. The distance between the transducer and the tube was 7.6 cm. MAT B III cells were insonified for 10 s, using two different transducers (Figure 2). Peak-negative pressures were measured with a membrane hydrophone (Precision Acoustics, Ltd.) for each transducer at a distance of 76 mm (near-field distance for both transducers). The polystyrene tube was cut in half along its axis and was positioned in front of the membrane hydrophone to account for attenuation of the ultrasound beam by the tube. A duty cycle of 20% and a pulse repetition frequency of 100 Hz were applied for all experiments.

After insonification, the mixture was placed in 12-well plates and supplemented with 2 mL of medium containing 10% FCS. Finally, the cells were incubated at 37 °C under a 5% CO_2 atmosphere for 24 h.

Assay of Reporter Gene. GFP-positive cells were analyzed 24 h after ultrasound exposure by flow cytometry (FACS Calibur, Becton Dickinson AG, Switzerland). The cell suspension was placed in 5 mL polystyrene round-bottom tubes and washed twice with phosphate-buffered saline (PBS). The pellet was resuspended with 250−300 μL of PBS, and 20 μL of a propidium iodide (PI) solution (40 μg/mL, Sigma-Aldrich Chemie GmbH, Schnelldorf, Germany) was added to assess cell viability. Results are expressed as a percentage of GFP-positive cells and relative fluorescence intensity (arbitrary units, au), using the software *CellQuest Pro* (Becton Dickinson Bioscience, Binninggerstrasse 94, CH-4123 Allschwill, Switzerland). The percentage of positive cells is calculated on the basis of the total number of cells, including dead cells.

Microbubble Destruction. Microbubbles (12.5×10^6 BR14 bubbles, corresponding to a bubble-to-cell ratio of 25) were suspended in 500 μL of a MAT B III cell suspension (final concentration 1×10^6 cells/mL in medium without FCS) in the sample tube. The suspensions were then exposed to ultrasound using identical parameters to those employed in the transfection experiments. Microbubbles were counted before and after insonification using computer-assisted microscopic analysis (Leica - Program Routine BR20.Q5R, Leica Microsystem AG, Glattbrugg, Switzerland). The percentage of intact bubbles and the bubble size distribution were determined.

Scanning Electron Microscopy (SEM). Microcapsule destruction was assessed using scanning electron microscopy (LEO S470; experiments were performed at Surcotec SA, Plan-les-Ouates, Switzerland). Briefly, 15×10^6 particles were suspended in 500 μL of PBS in a sample tube and exposed to ultrasound as before. After insonification, the suspensions of ten tubes were pooled in a 15 mL polystyrene tube. The microcapsules were then washed twice in distilled water by centrifugation (10 min, 800 g), and the pellet comprising the ruptured microcapsules was collected to be freeze-dried. The washed capsules were then stuck onto an adhesive tape, fitted onto the metal stand of the microscope, and placed under vacuum at room temperature overnight. After gold sputtering, the samples were analyzed at 20 kV acceleration voltages. Microcapsules nonexposed to ultrasound were used as control.

Statistical Analysis. All results are reported and displayed as mean ± standard deviation ($n \geq 6$). Tests of significance were performed using a one-way analysis of variance (*Minitab* software v 13.20, Minitab, Inc., Paris, France), with $p < 0.05$ considered to be statistically significant.

RESULTS

Transfection Efficiency and Cell Viability. Transfection efficiency was assessed as (i) the percentage of transfected cells calculated from the ratio of GFP-positive cells to the total number (including dead cells); (ii) the fluorescence intensity of the cells determined by flow cytometery, relative to average amount of GFP produced per transfected cell; and (iii) the cell viability, expressed as viable cells/total cells and determined by propidium iodide exclusion.

Effect of UCA Concentration and Size. MAT B III cells (1×10^6/mL) were sonoporated using the 1.15 or 2.25 MHz transducer at acoustic pressures of 570 and 207 kPa (peak

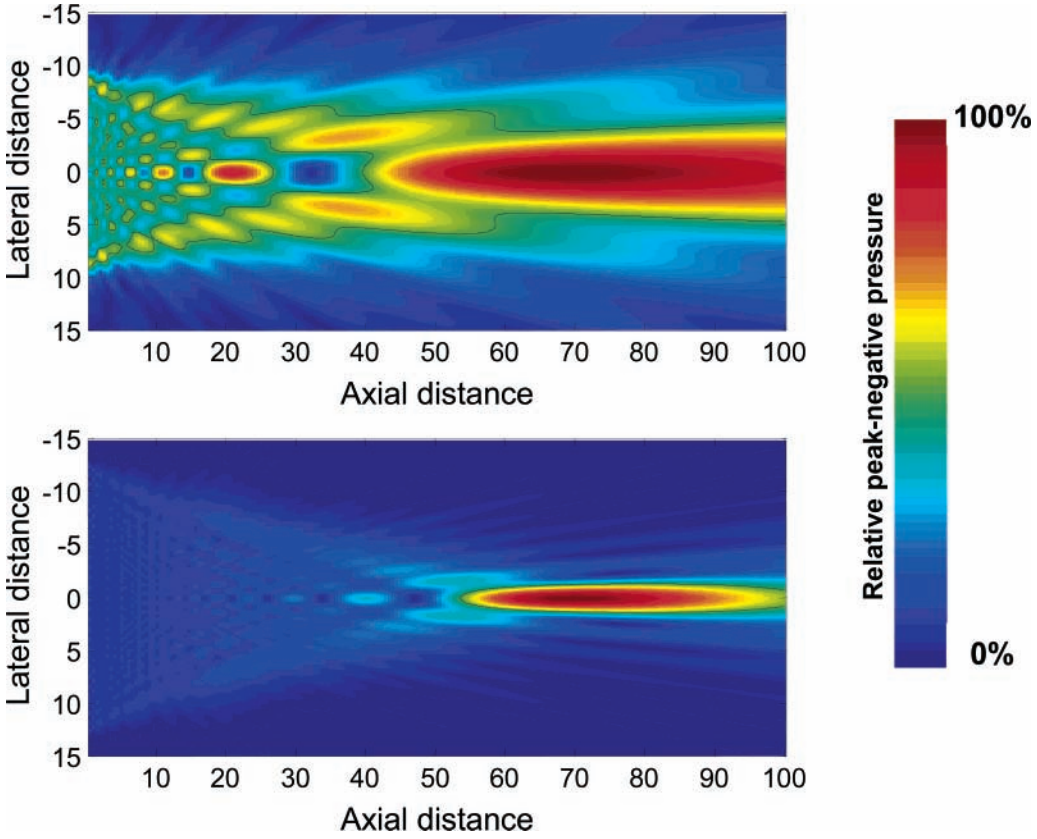

Figure 2. Ultrasound beam simulation for single-element transducers. Upper panel: 1.15 MHz unfocused transducer (Valpey Fisher; Hopkinton, MA); aperture = 0.75 in, narrow band excitation. Lower panel: 2.25 MHz focused transducer (Panametrics; Waltham, MA) (3 in); aperture = 1 in, narrow band excitation. Both plots are normalized to their maximum peak negative pressure in the field. The contours indicate the −6 dB values relative to the maximum.

negative pressure, *P*_), respectively. The exposure duration was 10 s. Perfluorobutane gas microbubbles (BR14) were used as UCA, and the bubble-to-cell ratio was varied from 0 to 150. As shown in Figure 3A, the transfection rate first increased with the bubble-to-cell ratio, peaked at 30 bubbles/cell, and then decreased progressively at higher bubble concentrations. A transfection rate of 8−17% (expressed in % of GFP-positive cells) was obtained depending on the transducer frequency and bubble concentration, with a cell viability varying between 60% and 80% (Figure 3B). Cell viability decreased with bubble-to-cell ratio and reached a plateau at 30 bubbles/cells. Interestingly, both transducers gave similar trends for transfection and cell viability.

Suspensions of BR14-like phospholipid-stabilized microbubbles were fractioned into two narrow-sized populations by decantation. One had a median number diameter, Dn_{50}, of 0.99 μm (BG1126), and for the other, Dn_{50} was 1.9 μm (BG1127). Transfection was performed with these bubble fractions and with the original BR14 bubbles, using different bubble-to-cell ratios. The results are summarized in Table 3 and show that, under the experimental conditions considered, bubble size appeared to have little effect on transfection efficiency (no statistically significant difference between the two decanted samples at $p < 0.05$). The study focused therefore on UCA shell and gas properties.

Effect of UCA Shell Properties. *Microbubbles vs Microcapsules.* The effect of UCA shell properties on MAT B III transfection was first studied using the 2.25 MHz transducer, with an ultrasound exposure of 10 s and an applied peak negative pressure varying from 0 to 800 kPa. MAT B III cells were sonoporated in the presence of plasmid and either soft-shelled microbubbles (BR14) or hard-shelled microcapsules (BG1382) made of triglycerides. Air was the encapsulated gas for both agents.

As shown in Figure 4A, the percentage of GFP-positive cells increased with acoustic pressure and reached a plateau of 16% and 25% at 570 kPa, respectively, for the two agents. An important difference in the cell transfection rate was observed below 570 kPa between the soft-shelled and hard-shelled agents ($p < 0.05$). For instance, at a pressure of 247 kPa, 10% of GFP-

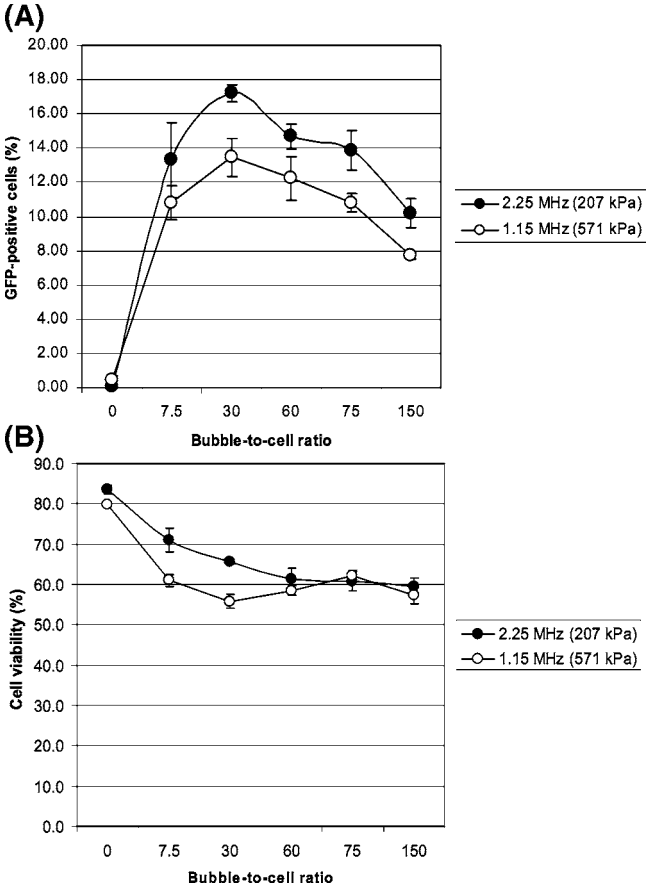

Figure 3. Effect of bubble concentration (bubble-to-cell ratio) on transfection efficiency. MAT B III cells were insonified using C_4F_{10} microbubbles (BR14) at either 1.15 MHz at 571 kPa (−●−) or 2.25 MHz at 207 kPa (−○−). (A) Percentage of transfected cells. (B) Cell viability (%).

positive cells were obtained for microbubbles vs only 0.4% for microcapsules. These results suggest that soft-shelled microbubbles made of phospholipids require a lower pressure to induce acoustic cavitation than microcapsules to facilitate DNA delivery into cells. Microcapsules, being more pressure-resistant, appeared to have a higher cavitation threshold (400−600 kPa for 2.25 MHz), below which only few cells were sonoporated.

The GFP fluorescence from transfected cells is plotted in Figure 4B as a function of ultrasound pressure. Surprisingly, the microcapsules, although showing a lower transfection rate over the entire range of acoustic pressures, gave significantly higher fluorescence (by a factor about 1.5). This means that more plasmid copies per cell were delivered into the cell nucleus in the presence of the hard-shelled agent. Cell viability decreased with increasing ultrasound pressure for both agents with a viability varying from 93% to 72%. The microcapsules resulted in generally lower cell viability as compared to the microbubbles (about 10−15%; data not shown).

A similar experiment was performed using the air-backed transducer with a center frequency of 1.15 MHz and at acoustic pressures varying from 0 to 480 kPa (Figure 4C,D). The same UCAs were compared, except that the encapsulated gas, in this case, was a perfluorocarbon (C_4F_{10}). Transfection rates increased steadily with ultrasound pressure for the two agents. The ultrasound pressure required for maximum transfection was much lower for this frequency; i.e., only about 50% of that required with the 2.25 MHz transducer. This difference in pressure threshold could be due to the beam profile of the two transducers: the 1.15 MHz transducer is unfocused, providing a more homogeneous and a larger insonification field than the 2.25 MHz focused transducer (see Figure 2). In comparison to sonoporation at 2.25 MHz, even higher levels of fluorescence were obtained with the microcapsules (Figure 4D). However, cell viability was 15−25% lower with the capsules (60−79%) than with the microbubbles (85−94%) for the same applied pressure (data not shown).

Microcapsules Made of Different MW Polystyrenes. The shell properties of microcapsules are generally determined by the nature and amount of the materials employed. Three formulations of hard-shelled microcapsules, made with polystyrene of different molecular weights (30, 100, and 300 kDa), were compared. A constant amount of polymer was used in the three preparations, and air was the encapsulated gas core. It was expected that using a polymer, such as polystyrene, would provide a much more rigid shell than that obtained with triglycerides (BG1382, BG1431; see Table 1), particularly when using a high molecular weight polymer of 300 kDa.

MAT B III cells were sonoporated in the presence of polystyrene microcapsules using the focused 2.25 MHz transducer with ultrasound pressure varying from 0 to 809 kPa. The results are summarized in Figure 5. For all three formulations, transfection increased with increasing acoustic pressure from 360 to 570 kPa and reached a plateau of 14−18% GFP-positive cells (Figure 5A). Interestingly, at a pressure of 360 kPa, the transfection rate obtained was significantly higher with the low MW polystyrene: 8% of GFP-positive cells for 30 kDa vs only 2% for the 100 and 300 kDa polymers. The low MW microcapsules also showed a lower acoustic cavitation threshold, similar to that of microbubbles (see Figure 4A). In contrast, the results in Figure 5B showed that the 100 and 300 kDa microcapsules gave significantly higher fluorescence intensities. For example at 364 kPa, these microcapsules, despite their 4-fold lower transfection rates, resulted in 60% more GFP produced per transfected cell as compared to the 30 kDa microcapsules.

Effect of UCA Encapsulated Gas. MAT B III cells were insonified using the 2.25 MHz-focused transducer. Microbubbles used in this experiment were filled with air, perfluoropropane (C_3F_8), or perfluorobutane (C_4F_{10}). As shown in Figure 6A, similar transfection rates were obtained for UCA filled with C_3F_8 and C_4F_{10} and were significantly higher than those for the air-filled microbubbles at all applied acoustic pressures. A small

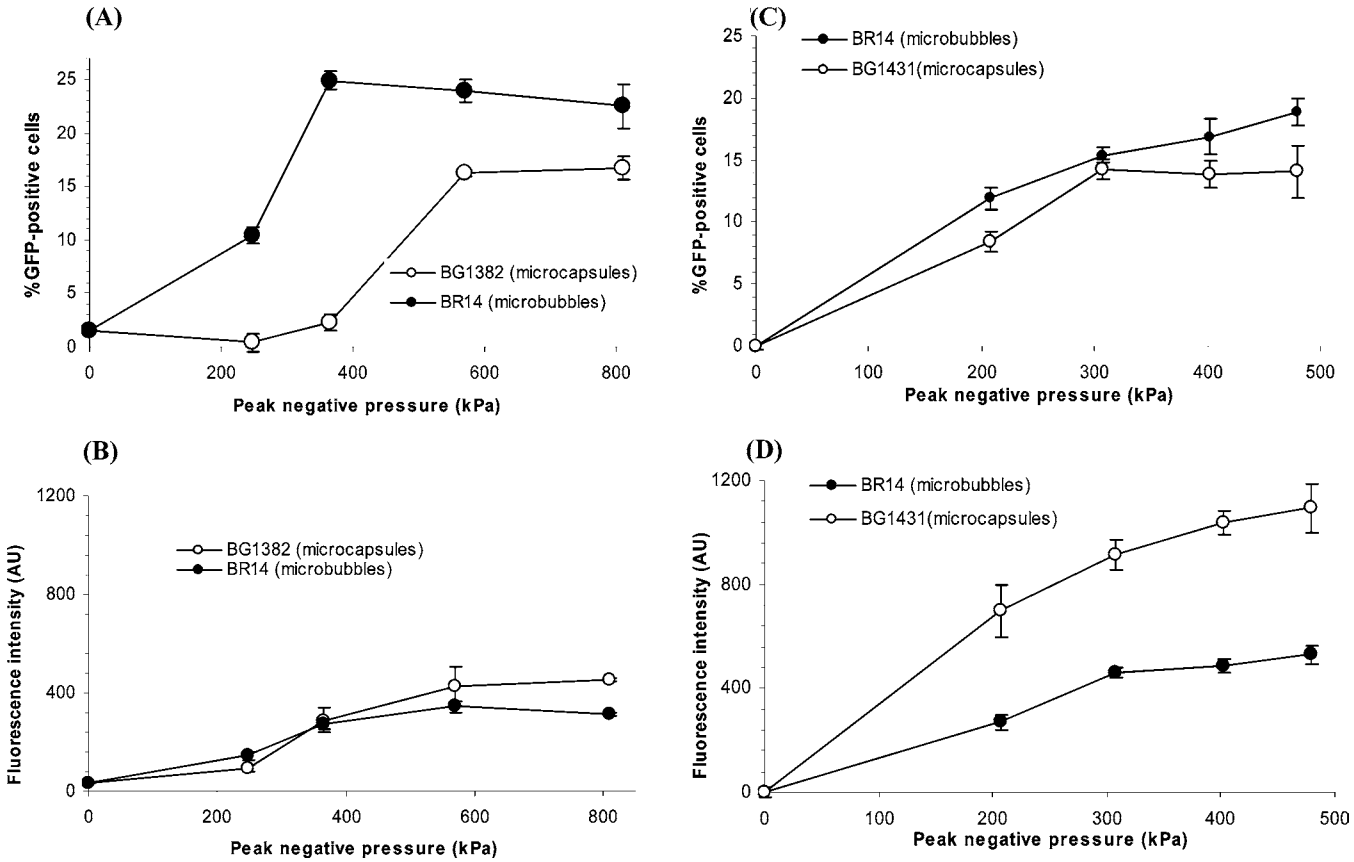

Figure 4. Effect of UCA shell properties on transfection efficiency. MAT B III cells were insonified at various peak negative pressures at 2.25 MHz (A and B) and 1.15 MHz (C and D), in the presence of either a soft-shelled agent, BR14 (−●−), or a hard-shelled agent, BG1766 or BG1382 (−○−). (A,C) Percentage of transfected cells. (B,D) Fluorescence intensity (expressed in arbitrary units (au)). Both UCA contained air as the encapsulated gas.

increase of fluorescence intensity was also observed for the perfluorocarbon gases (Figure 6B).

A similar study was performed with hard-shelled agents (BG1382, 1431) using the 1.15 MHz transducer. The results are in Figure 6. In this case, the encapsulated gas had no impact on transfection (Figure 6A) but significantly improved GFP production (Figure 6B): at pressures above 300 kPa, the fluorescence intensity was almost 2-fold higher with C_4F_{10} compared to air. These results clearly show that, in addition to shell properties, the gas encapsulated in UCA may also play an important role in sonoporation.

Contrast Agent Destruction. It is generally believed that acoustic cavitation and subsequent sonoporation can be enhanced by UCA destruction. It is still unclear, however, whether microbubble or microcapsule destruction is a prerequisite for successful sonoporation and whether there is a relationship between bubble destruction and transfection efficiency. To address these points, microbubbles and microcapsules were insonified using the same ultrasound exposure conditions as described above with the 1.15 and 2.25 MHz transducers. Bubble size distribution was analyzed by optical microscopy before and after ultrasound exposure. As microcapsule destruction could not be directly assessed by optical microscopy or Coulter analysis due to their rigid shells, scanning electron microscopy (SEM) was used to evaluate these agents.

Microbubbles. After a 10 s ultrasound exposure at 1.15 MHz and 402 kPa, more than 90% of gas microbubbles were destroyed (determined using computer-assisted microscopic analysis; data not shown). Figure 7A shows that the bubble size distribution was significantly modified by ultrasound exposure. The bubbles of 4−7 μm seemed to be most sensitive. An increase from 12% to 38% in the large bubble fraction was noted upon ultrasound exposure. This could be explained by the fact that large bubbles (>8 μm) are generally more persistent and less easily destroyed than small ones. The 6 μm bubbles showed the lowest count after insonification; interestingly enough, this diameter roughly corresponds to the calculated resonance diameter for ultrasound at 1.15 MHz.

Bubble destruction and transfection experiments were further performed in parallel using BR14 microbubbles and the focused 2.25 MHz transducer with the acoustic pressure varying from 0 to 809 kPa. As shown in Figure 7B, the 3 μm bubbles appeared most sensitive, and this again correlated well with the calculated resonance diameter of microbubbles for this frequency. Size distribution analysis indicated that 63% to 74% of the bubbles were destroyed during exposure, depending on applied pressure with the 2.25 MHz transducer (Figure 7B). There was a good correlation between transfection rate and bubble destruction as a function of the applied pressure: the higher the pressure, the larger the bubble destruction and the better the transfection (Figure 7C).

Microcapsules. Microcapsules of polystyrene 100 kDa were exposed to 570 kPa ultrasound insonification at 2.25 MHz. Scanning electron microscopy (SEM) revealed the morphology of the microcapsules before (Figure 8A) and after (Figure 8B) ultrasound exposure. Although sample preparation for SEM could alter the appearance of hollow microcapsules (the control microcapsules seemed to be flat rather than spherical in Figure 8A), differences were evident between insonified and control samples. Most ultrasound-treated microcapsules showed an open or deflated structure with a folded shell. In contrast, the control microcapsules presented a regular shape with smooth surfaces

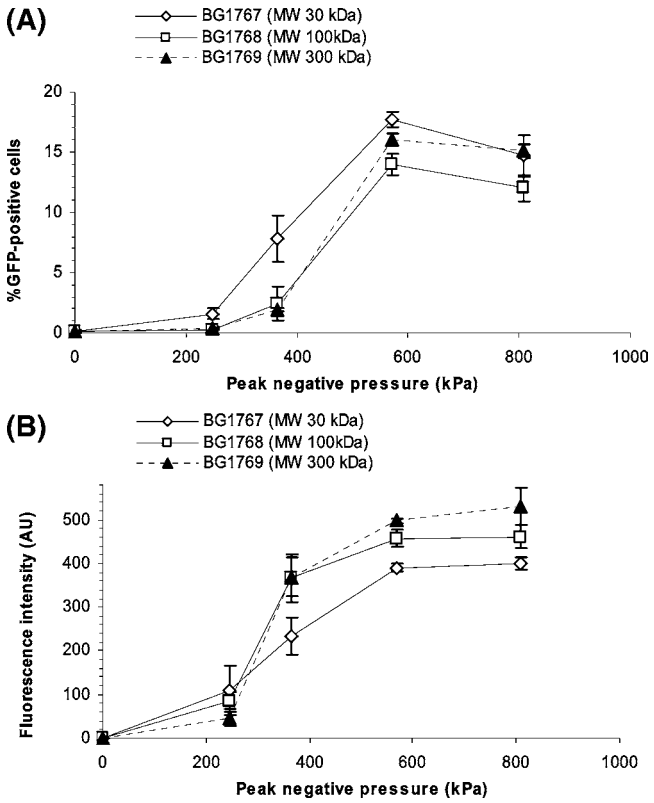

Figure 5. Effect of UCA shell properties on transfection efficiency. Microcapsule shell(s) were polystyrene of different molecular weights: 30 kDa (−×−), 100 kDa (−□−), and 300 kDa (−▲−). MAT B III cells were insonified at various peak negative pressures at 2.25 MHz, in the presence of 30 capsules/cell. (A) Percentage of transfected cells. (B) Fluorescence intensity (expressed in arbitrary units (au)). Both agents contained air as the encapsulated gas.

(Figure 8A). The open or deflated structures were observed for both small and large microcapsules, suggesting that shell properties such as stiffness, thickness, and surface homogeneity may play a more important role in microcapsule destruction than size. The SEM in Figure 8B shows that some microcapsules remained intact (a few had a small hole on the shell surface), but many were broken as a result of ultrasound exposure.

Similar experiments were also performed with the microcapsules of polystyrene 30 and 300 kDa under the same exposure conditions. Generally, the 300 kDa microcapsules were less altered, in terms of their number and shape, than those of 30 kDa (data not shown). It seemed that the shells made of high MW polystyrene were more stable to ultrasound exposure; however, upon destruction, these capsules may collapse more violently, projecting DNA molecules directly toward the cell nucleus. This may explain why fluorescent intensity (GFP production) was higher for these high MW agents (Figure 4D).

DISCUSSION

In vitro sonoporation has been widely investigated. It has been shown that ultrasound exposure parameters, such as acoustic pressure or intensity (*18*, *37*), frequency (*9*, *38*), duration of exposure, pulse-repetition frequency and duty cycle (*37*, *39*), and temperature (*40*, *41*) are important for transfection and delivery of small molecules into cells. Effects of contrast agents and bubble concentration have been also studied (*39*, *42*, *43*). In vitro gene transfection has equally been demonstrated with various cell types, such as rat fibroblasts, chondrocytes (*6*) and cultured Chinese hamster ovary cells (*9*), human cancer cells HeLa, NIH/3T3 C127I (*44*), and prostate cancer cells DU145 (*41*). Other aspects involved in sonoporation have also been evaluated, such as bubble-to-cell ratio or distance (*19*), cell-to-cell heterogeneity of molecular uptake (*37*), ultrasound modalities (*43*), DNA integrity (*41*), and plasmid-attached microbubbles (*21*, *22*, *45*, *46*).

On the other hand, UCA destruction has been evaluated initially for diagnostic imaging purposes (*47*−*51*), before being extended to UCA-induced bioeffects (*52*−*55*) and therapeutic applications (*5*, *56*−*58*). There have been very few studies in which the influence of UCA properties on gene/drug delivery has been systematically assessed, and UCA formulations dedicated to this application have not been optimized in any way. The present study aimed at addressing this issue by assessing, in particular, the effect of UCA size, shell, and gas composition on transfection efficiency. These parameters have been shown to be important in both contrast agent destruction and enhanced acoustic cavitation.

Bubble Concentration and Size. UCA bioeffects on cell lysis appear to decrease with the cubic power of the distance between microbubbles and cells (*19*). A high bubble concentration generally favors cell transfection, but it may also induce strong acoustic attenuation in vitro and in vivo, thereby reducing transfection efficiency. High bubble concentration may also lead to more cell damage, reducing in vitro cell viability and inducing in vivo side effects. For a given sonoporation sample volume, bubble-to-cell distance decreases with both bubble-to-cell ratio and cell density. It was thought that the bubble/cell ratio would be more relevant to assess the effect of UCA concentration on transfection, rather than the number of microbubbles (or microcapsules) alone. In the literature, the use of a UCA dilution factor has also been reported; however, this parameter is meaningful only for a given contrast agent with a defined bubble concentration.

The in vitro results showed a maximum transfection rate with a ratio of 30 bubbles per cell for the two different transducers used in the present study. At this ratio, the bubble/cell distance was ca. 30 μm (*19*). A further increase of the bubble-to-cell ratio tended to reduce transfection rate (Figure 3A). Since the high bubble-to-cell ratios (60, 75, and 150) did not induce more cell damage, this would suggest that the lower percentage of GFP-positive cells obtained was only due to a strong acoustic attenuation caused by microbubbles. These observations are consistent with other studies (*13*, *37*). The high concentration used in this study might yield to secondary effect, such as Bjerknes forces, by which aggregates of bubbles are formed (*59*). Aggregates of bubbles might interact differently with cells compared to individual bubbles. This possible interaction was not taken into account in the study.

It is well-known that bubble size is an important parameter for UCA stability and acoustic response. For instance, contrast agent destruction and its mechanism depend on acoustic pressure and bubble size (*60*). The results obtained in the present study showed little influence of microbubble size on transfection efficiency (Table 3). This lack of effect may be due to heterogeneity of bubble size; indeed, the three bubble samples all had relatively large size distributions: while the median diameters of three preparations were quite different (1.6, 3.9, and 8.9 μm), their Dn values were rather similar: 1.0, 1.4, and 1.9 μm, respectively. Bubbles smaller than 3 μm were predominant: 85% for BR14, 84% for BG1126 (large bubbles), and 99% for BG1127 (small bubbles). The bubble destruction experiment performed at the same frequency and pressure showed that more than 70% of microbubbles were destroyed, in particular, the smaller ones between 1 and 4 μm (see Figure 7A). This is in agreement with a previous report (*50*) which showed that, at a frequency of 2.25 MHz and a peak negative

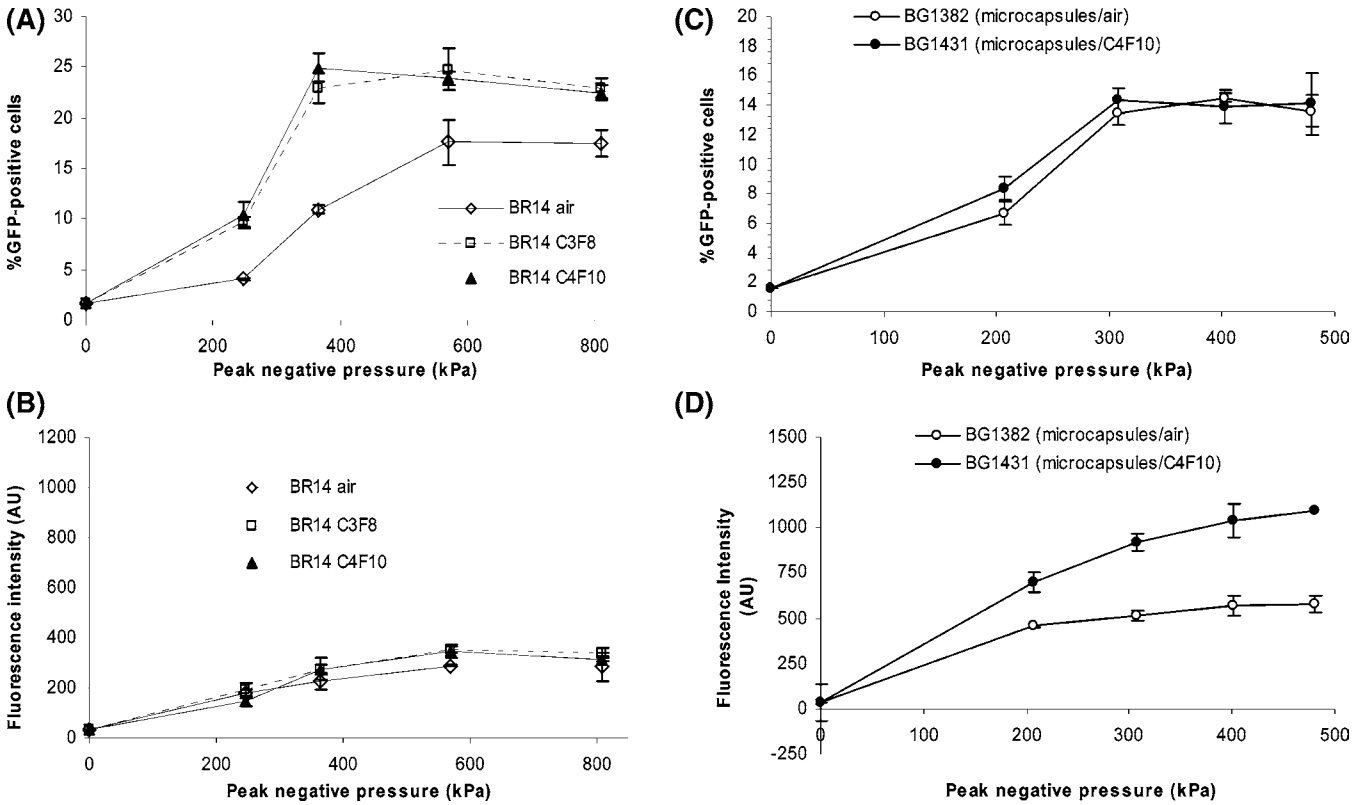

Figure 6. Effect of the encapsulated gas on transfection efficiency. Microbubbles (BR14) were filled with air (−×−), C_3F_8 (−□−), or C_4F_{10} (−▲−) (A,B); and microcapsules were filled with air (−○−) or C_4F_{10} (−●−) (C,D). MAT B III cells were insonified at various peak negative pressures at 2.25 MHz (A,B) or 1.15 MHz (C,D), in the presence of 30 bubbles/cell. (A,C) Percentage of transfected cells. (B,D) Fluorescence intensity (expressed in arbitrary units (au)).

pressure of 800 kPa, small microbubbles (<3 μm) were particularly susceptible to strong size expansion and fragmentation.

These results do not, however, prove that small bubbles are more efficient than large ones in sonoporation. It was not possible to deduce whether transfection was principally induced by stable or inertial (transient) cavitation. It is well-known that very large bubbles (100 μm) can steadily oscillate, inducing microstreaming effects yet remaining intact (*61*). Moreover, small bubbles can also coalesce into larger ones capable of stable cavitation. This raises the following questions. Is stable cavitation sufficient for cell transfection? Is microbubble destruction for a soft-shelled agent necessary to deliver plasmid/drug molecules into cells? When and how does sonoporation occur: below or above the inertial cavitation threshold? A direct and real-time observation of transfection using a high-speed camera would be very useful to clarify these points. To further study the size effect of UCA, microbubbles with a narrow size distribution and low bubble-to-cell ratio should be used to avoid interference from bubbles of different sizes and acoustic attenuation.

Shell Properties. The effects of UCA shell properties on transfection are particularly interesting. Both microbubbles and microcapsules efficiently transfected MAT B III cells at comparable rates. However, the acoustic pressure threshold for transfection was significantly different for these two agents. Higher pressures were required for hard-shelled microcapsules: For example, at 2.25 MHz, an acoustic pressure of 300 kPa was sufficient for microbubbles to transfect 5−10% of the total cells, whereas 400−600 kPa was necessary for microcapsules. This suggests that the cavitation mechanism may not be the same for the two types of agents. On the basis of in-house acoustic characterization (attenuation and backscatter measurements), the triglyceride-based agent is considered as capsules when compared to lipid-shelled microbubbles (e.g., SonoVue) (unpublished data). Bloch et al. (*36*) showed that BR14-like phospholipid-stabilized microbubbles, when insonified at 2.25 MHz, oscillated in response to ultrasound at 180 kPa; in contrast, the polymer-shelled microcapsules remained largely intact at pressures up to 1.5 MPa, and there was no evidence of significant oscillation. However, depending on the molecular weight of the polymer used for the preparation of the microcapsules, they might respond at low acoustic pressure conditions, but in terms of relative wall excursion, it is still substantially lower compared to phospholipid-based agents. Moreover, for destruction, the phospholipid agents are destroyed through fragmentation, whereas for capsules, as used in this study, typically the shell breaks and the contained gas will be released.

Sonoporation with microcapsules resulted in much higher plasmid uptake than with microbubbles. Microcapsule destruction and subsequent gas/shell fragmentation may result in more violent and effective microstreaming or microjets, propelling DNA molecules close to the cell nucleus and thus reducing their cytosolic transfer and degradation (*62*). Higher GFP production obtained with hard-shelled agents could be the result of more intact plasmid being successfully transferred. While the two types of UCA gave similar transfection rates, the microcapsules were destroyed to a lesser extent than the microbubbles (data not shown). This would suggest that, for in vivo applications, where the bubble-to-cell ratio is generally very low, the use of hard-shelled agents and high acoustic intensity would be more effective. However, cell viability was generally 10% lower for rigid microcapsules than for microbubbles; that is, high acoustic pressure with hard-shelled agents might induce more side effects.

The mechanical properties of polymers (including stiffness and shear strength) generally depend upon molecular weight.

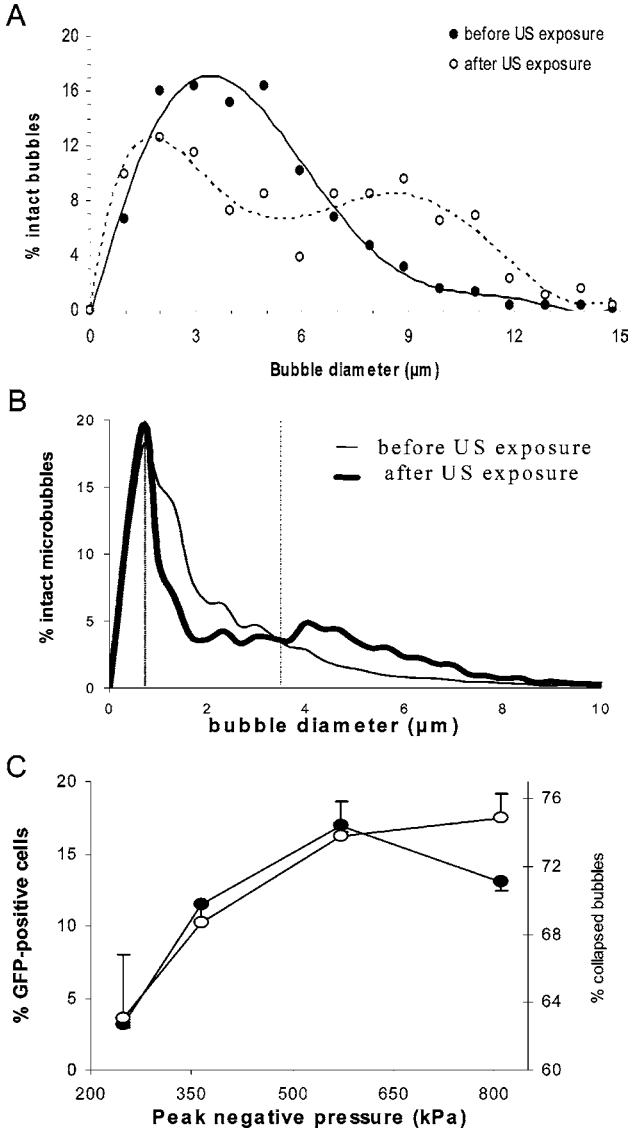

Figure 7. Size distribution of BR14 bubbles before and after insonification. C_4F_{10} microbubbles (BR14, at a concentration of 25 bubbles/cell) were insonified at 1.15 MHz at P_- = 402 kPa (A) 2.25 MHz at a peak negative pressure of 570 kPa (B). (C) Correlation between ultrasound-induced bubble destruction (−○−) and transfection efficiency (−●−). C_4F_{10} microbubbles (BR14, at a concentration of 25 bubbles/cell) were insonified at 2.25 MHz at acoustic pressures varying from 247 to 809 kPa. Size of the microbubbles was determined by computer-assisted microscopy analysis.

It would appear that sonoporation with polymer-shelled agents may be optimized by adjusting this physicochemical parameter. Low MW (30 kDa) polystyrene microcapsules transfected more efficiently at low acoustic pressures, similarly to microbubbles (Figure 5A), but resulted in a lower amount of GFP per cell (low fluorescence intensity). On the other hand, the high MW microcapsules (100 and 300 kDa) required a higher acoustic pressure for transfection, yet resulted in a higher level of GFP per cell.

Encapsulated Gas. The most important difference between first- and second-generation UCA is the encapsulated gas. For example, Albunex, Optison, and PESDA all have shells made of denatured human serum albumin, but Optison and PESDA contain C_3F_8 and perform better than air-filled Albunex, both in diagnostic imaging and in sonoporation (*52, 63, 64*).

This study confirmed that the encapsulated gas can play an important role in sonoporation. For microbubbles, the use of water-insoluble gases, such as C_3F_8 and C_4F_{10}, significantly improved transfection rates compared to air (Figure 6); while for rigid microcapsules, the substitution of air by C_4F_{10} increased the amount of GFP/cell but not the percentage of transfected cells. For microbubbles, destruction and collapse may occur via two distinct mechanisms: (i) acoustically driven gas diffusion at low acoustic pressure and (ii) bubble fragmentation at high pressure (*36, 60*). Dissolution of a free gas bubble of 2 μm in gas-saturated water by static diffusion requires about 8 ms for air, 90 ms for C_3F_8, and 900 ms for C_4F_{10} (*50*). Under ultrasound exposure, the dissolution of a shelled-gas bubble by fragmentation could be very fast, within a few milliseconds. Similar transfection behaviors observed for C_3F_8 and C_4F_{10} microbubbles (Figure 6A) suggest that the destruction of these gas bubbles was essentially driven by acoustic diffusion or fragmentation. Lower transfection with air microbubbles could be due to their instability. These microbubbles have a very low resistance to pressure with a Pc_{50} of only 40−50 mmHg as compared to about 600 mm Hg for C_3F_8 and C_4F_{10} microbubbles (see Table 1).

The effect of the encapsulated gas in microcapsules is rather complex; the pressure stability of microcapsules is primarily determined by the properties of the shell rather than the gas encapsulated inside (Table 1). Since hard-shelled agents do not significantly oscillate in ultrasound, effective microstreaming only occurs when the shell is broken at high acoustic pressure (*36*). This means that the gas cannot have any effect before its release and that the cavitation threshold of microcapsules is determined only by the properties of the shell. The effect of encapsulated gas within the microcapsules on fluorescence intensity was surprising: a twofold increase was obtained with C_4F_{10} compared to air (Figure 6D). After shell rupture, the gas released from hard-shelled microcapsules may generate large, free gas bubbles, which persist for a few milliseconds before dissolving in the surrounding liquid (*28, 29*). The persistence of free gas bubbles depends on bubble size, the gas, and the acoustic intensity. The dissolution rate of free gas bubbles may be important for the uptake of plasmid by sonoporated cells. Longer persistence (or lower dissolution rate) of free C_4F_{10} bubbles may provide more stable cavitation nuclei and stronger microstreaming effects than air. It is quite possible that microcapsule rupture only results in free gas bubbles, whereas that of phospholipid-shelled microbubbles may generate both free and stabilized gas microbubbles. This is due to the unique properties of phospholipids in aqueous media: that is, their capability to instantaneously self-assemble and to repair membrane structure (similar to that occurring at the plasma membrane during sonoporation). As a consequence, the bubble dissolution rate after fragmentation will be determined by the properties of both the shell and the encapsulated gas, and this may explain the lower, and relatively constant, fluorescence intensity obtained for different types of gas microbubbles (Figure 6B).

In summary, the effect of the encapsulated gas on transfection is related to the shell properties of the UCA. For microbubbles, a gas with low water solubility improves bubble cavitation/microstreaming effects and subsequent transfection both before and after bubble fragmentation; in contrast, for microcapsules, the gas properties affect the persistence of the released, free bubbles, only after UCA destruction (shell rupture).

Correlation with UCA Destruction. A good correlation is observed between transfection at 2.25 MHz and UCA destruction (Figure 7C). Recent studies (*36, 50, 65*) showed that bubble destruction, involving initially fast bubble expansion, followed by fragmentation and gas dissolution, can generate very high bubble fragment velocities (about 30 m/s). Even though stable bubble oscillation at low acoustic pressures (e.g., 200 kPa) may be sufficient to induce cell transfection, the high shear stress caused by violent microstreaming or microjets from bubble destruction/fragmentation may explain the maximum transfec-

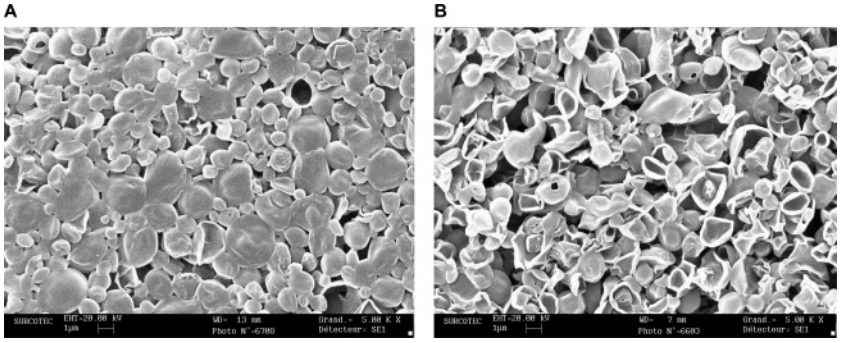

Figure 8. Scanning electron microscopy images of 100 kDa polystyrene (A) before and (B) after ultrasound exposure at 2.25 MHz and $P_- = 570$ kPa.

tion and lowest cell viability obtained at high ultrasound pressure (≥570 kPa at 2.25 MHz) (*15*, *16*).

CONCLUSIONS

The effects of UCA properties on in vitro cell transfection and related contrast agent destruction were investigated. Among different formulation parameters, the shell seemed to play a critical role. Gas bubbles stabilized by a soft shell, a monolayer of phospholipids (BR14), may steadily oscillate under low acoustic pressure and generate cell sonoporation. At a pressure of 200 kPa, significant transfection was obtained (5−10% of total cells) with a cell viability of 80−90%. At higher pressures (>300 kPa, 2.25 MHz), bubble destruction became significant, resulting in a maximum transfection rate (15−25% of GFP-positive cells/total cells) and a lower cell viability (∼70%). Microcapsules, on the other hand, showed only a negligible transfection at this pressure due to the stiffness of their shell. Hard-shelled agents do not significantly respond to ultrasound pressure waves until the shell is destabilized. Consequently, microstreaming effects will be negligible before UCA destruction. This is especially true for microcapsules made of high molecular weight polystyrene (100 and 300 kDa), for which destruction and gene transfection only occurred at pressures approaching 600 kPa (with the 2.25 MHz focused transducer). Transfection rates with microcapsules improved by using the unfocused air-backed transducer at lower frequency (1.15 MHz). The requirement of UCA agent destruction to induce transfection implies that only inertial (transient) cavitation is effective for these agents.

The results in this study also showed that rigid microcapsules generally delivered more DNA molecules into the cell, and subsequently into the cell nucleus, and produced more GFP per cell than microbubbles (by a factor of 1.5 to 2). The exact mechanism involved remains unknown; it is possible that microstreaming/microjets, and subsequent shear stress, caused by destruction/fragmentation of microcapsules, are much stronger due to the large expansion and rapid collapse of the released free gas bubbles. It is interesting to note that the level of GFP/cell can be further improved by combining a hard-shelled agent and a gas with low water solubility such as perfluorobutane (C_4F_{10}). By contrast, for microbubbles, the nature of the entrapped gas had little effect.

While significant progress has been made in both the mechanistic understanding and experimental optimization of sonoporation, more research is required to improve efficacy for in vivo applications. Gene or drug delivery in vivo will be limited by the extremely unfavorable bubble-to-cell ratio, low plasmid concentration, low or nondividing properties of targeted cells, and the accessibility of the cells to the UCA. For instance, at diagnostic imaging doses of UCA, the bubble-to-cell ratio may be lower than 1 ppm. Different approaches have been proposed to tackle these problems (including optimization of ultrasound exposure parameters and settings, exploring new ultrasound modalities, designing novel and dedicated transducers, use of plasmid-loaded microbubbles, targeted UCA and radiation force-assisted targeting, combination of lipofection and sonoporation, etc.). The optimization of UCA formulation parameters will no doubt contribute to the development of this exciting technology.

ACKNOWLEDGMENT

We would like to thank Philippe Bussat for the preparation of the hard-shelled agents.

Preparation of Poly(ethylene glycol)-Attached Dendrimers Encapsulating Photosensitizers for Application to Photodynamic Therapy

Chie Kojima, Yoko Toi, Atsushi Harada, and Kenji Kono*

Graduate School of Engineering, Osaka Prefecture University, Osaka, Japan. Received August 7, 2006; Revised Manuscript Received January 25, 2007

Photodynamic therapy (PDT) is a noninvasive treatment of some diseases including cancer. We have developed poly(ethylene glycol) (PEG)-attached dendrimers as a drug-carrier candidate. In this study, we prepared nanocapsules of photosensitizers using PEG-attached dendrimers for application to PDT. Two PEG-attached dendrimers derived from poly(amido amine) (PAMAM) and poly(propylene imine) (PPI) dendrimers (PEG−PAMAM and PEG−PPI) were synthesized, and rose bengal (RB) and protoporphyrin IX (PpIX) were used as photosensitizers. Results showed that fewer PpIX molecules were encapsulated by both PEG-attached dendrimers than RB, but the complexes were more stable under physiological conditions. Furthermore, we demonstrated that PEG−PPI held photosensitizers in a more stable manner than PEG−PAMAM because of their inner hydrophobicity. We described the cytotoxicity of the complexes of photosensitizers induced by light irradiation in vitro. The complex of PpIX with PEG−PPI exhibited efficient cytotoxicity, compared with free PpIX. It was suggested that the cytotoxicity was caused by the high level of singlet oxygen production and the efficient delivery to mitochondria. Our results suggest that these PEG-attached dendrimers are a promising vehicle for PDT.

INTRODUCTION

Photodynamic therapy (PDT) is a new clinical treatment of superficial tumors and age-related muscular degeneration. This technique involves the systemic administration of a photosensitive drug, by which singlet oxygen is generated after light irradiation, to engender oxidative damage to cells (*1*). This PDT affects only the irradiated areas because singlet oxygen is short-lived, thereby realizing a site-specific and noninvasive treatment. Photosensitizers play a crucial role in generating singlet oxygen in PDT. Porphyrin derivatives have been studied for decades as powerful photosensitizers. One of them, Photofrin, has already been approved for clinical application (*2*). A second generation of photosensitizers for accumulation at affected areas has also been prepared to enhance the potential of PDT, which is achieved using a drug carrier. Liposomes, with their high loading capacity and long circulation properties, are classically used as a drug vehicle that provides less adverse effects. In fact, a liposomal drug for PDT, Visudyne, has been marketed (*3*).

Recently, many researchers have applied dendrimers to drug delivery systems (DDSs). Dendrimers have monodispersed molecular weight, well-defined morphology, and inner space to hold drug molecules. It has been suggested that dendrimer uniformity, along with their chemical and biological reproducibility, is useful for passive targeting to tissues involved in angiogenesis (*4*). Novel photosensitizers made from dendrimers have been reported by some groups. Kataoka et al. studied poly(aryl ether) dendrimers with a porphyrin core: so-called dendrimer porphyrins. They also prepared complexes of dendrimer porphyrins with block polymers containing poly(ethylene glycol) (PEG) as photosensitive biocompatible nanoparticles (*5*). As other types of photosensitive dendrimers, pheophorbide-a and a precursor of porphyrin, 5-aminolevulinic acid (ALA), were bound to the dendrimers in the periphery (*6*). It has also been reported that water-soluble dendrimers having a porphyrin core and other dyes in the periphery create two-photon excitation during low-energy light illumination (*7*). These dendrimers are attached covalently to photosensitizers, so that their photosensitive properties must change from their intrinsic ones. In addition, time and effort are required for synthesis of photosensitive dendrimers. Noncovalent encapsulation of photosensitizers by dendrimers can overcome these obstacles: photosensitizer-encapsulating nanoparticles are applicable to a variety of photosensitizers and are also easily prepared.

We have studied PEG-attached poly(amido amine) (PAMAM) dendrimers (PEG−PAMAM) as drug capsules of anticancer drugs such as adriamycin and methotrexate (*8*, *9*). This kind of dendrimer cannot be removed from blood immediately, because it has been reported that PEG-modified macromolecules and liposomes are efficient at maintaining circulation in blood (*10*). These are applicable as vehicles against diseases involved in angiogenesis because of the enhanced permeability of macromolecules (*4*, *11*). In our previous study, we synthesized several PAMAM dendrimers with different generations of dendrimer and different molecular weights of PEG. Results of that study showed that these dendrimers can encapsulate anticancer drugs. However, the drugs were easily dissociated from PEG-attached dendrimers under isotonic conditions (*8*). Anticancer drugs must be retained until they reach the tumor tissues and must be released to exhibit their action. Therefore, we prepared controlled-release PEG-attached dendrimers (*9*).

In this study, we prepared PEG-attached dendrimers encapsulating photosensitizers on PDT. They can act without release from carriers because reactive oxygen species generated from them, inside dendrimers, can injure cells. Therefore, photosensitizers are good candidates as guest molecules of PEG-attached dendrimers. We synthesized PEG-attached poly(propylene imine) (PPI) dendrimers (PEG−PPI) in addition to PEG−PAMAM, both of which contain many inner tertiary amino groups. Two photosensitizers, rose bengal (RB) and protoporphyrin IX (PpIX), were used because they have acidic moieties

to facilitate interaction with amino groups of dendrimers (Figure 1). We investigated interaction of a couple of photosensitizers with these two PEG-attached dendrimers and compared the complexes' chemical properties for PDT. We examined cytotoxicity of PEG-attached dendrimers encapsulating these photosensitive drugs after irradiation to evaluate the performance of a carrier of photosensitizers. Efficiency of singlet oxygen production by light irradiation and subcellular localization of photosensitizers influence the phototoxicity. Our results suggest that phototoxicity was affected by the stability, singlet oxygen generation, and the cytological behavior of the complex of PEG-modified dendrimers with photosensitizers.

EXPERIMENTAL PROCEDURES

Materials. The PAMAM and PPI dendrimers, poly(ethylene glycol) monomethyl ether, 9,10-anthracene dipropionic acid (ADPA), and PpIX were purchased from Sigma-Aldrich Corp. (St. Louis, MO). From Wako Pure Chemical Industries, Ltd. (Osaka, Japan), RB, 3-(4,5-dimethyl-2-thiazoryl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) and paraformaldehyde were purchased. Also, 4-nitrophenyl chloroformate and 5-(dimethylamino)-1-naphthalenesulfonic acid (DNS) were obtained, respectively, from Tokyo Chemical Industry Co., Ltd. (Tokyo, Japan), and Kanto Chemical Co., Inc. (Tokyo, Japan). MitoTracker Green FM was obtained from Invitrogen Corp. (Carlsbad, CA).

Synthesis of PEG-Attached Dendrimers. We synthesized PEG−PAMAM as described in our previous report (*8*); PEG−PPI was prepared according to our previous report, except the starting material. Briefly, poly(ethylene glycol) monomethyl ether with molecular weight of 2000 was reacted with 4-nitrophenyl chloroformate. It was then bound to PPI dendrimer of generation 5 (G5) with 64 amino groups at the periphery. Also, PEG−PPI was purified using a Sephadex G-75 column (Pharmacia) and dialysis. Yield: 577 mg (57.3%). σ_H (400 MHz, D_2O): 1.68 (br, $CH_2CH_2CH_2N$), 2.83 (br, $CH_2CH_2CH_2N$, $CH_2CH_2CH_2N$), 3.03 (br, $CH_2CH_2CH_2NHCOO$), 3.22 (s, OCH_3), 3.55 (m, CH_2CH_2O), 4.04 (br, $NHCOOCH_2$).

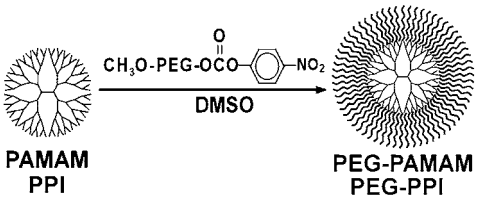
Gel Permeation Chromatography (GPC). The GPC system (Shodex SB-2004; Showa Denko K.K., Japan) had differential refractive index detection (RI-930; Jasco, Inc., Japan). Both PEG−PAMAM and PEG−PPI were eluted with 10 mM phosphate buffer containing 0.2 M sodium sulfate (pH 7.4) at 1.0 mL·min^{-1} at 25 °C.

For complex stability assay, we modified the system except the eluent buffer. The system was equipped with three columns, Shodex SB-803HQ, SB-804HQ (Showa Denko K.K., Japan), and TSK-gel G3000PW (Toso Co., Ltd., Japan), and two detectors, differential refractive index detector (RI-930; Jasco Inc., Japan) and fluorescence detector (λ_{ex} = 400 nm, λ_{em} = 630 nm; FR-2020Plus; Jasco, Inc., Japan). Samples (10 μL) were injected and eluted at 0.5 mL·min^{-1} at 30 °C.

Hydrophobicity of PEG-Attached Dendrimers. PEG−PAMAM or PEG−PPI was added to 1 μM of DNS dissolved in distilled water. The emission spectra excited at 310 nm were examined (*12*).

Encapsulation of Photosensitive Drugs. Encapsulation assay was done according to our previous report (*8*). RB and PEG-attached dendrimers were dissolved in water (first solvent) and incubated for 30 min at 27 °C. The solutions were lyophilized to remove water; then, chloroform (second solvent) was added. After 6 h incubation, the mixtures were centrifuged to remove free RB aggregation. The supernatants were evaporated and dried under vacuum; then, the residues were dissolved in 10 mM phosphate buffer containing 100 mM NaCl (third solvent). The absorbance was measured at 557 nm, an isosbestic point (*9*).

In the case of PpIX, the treatment was almost identical, except for the solvents and UV−vis measurement. The first, second, and third solvents were replaced, respectively, by *N*,*N*′-dimethylformamide (DMF), water, and DMF. The absorbance was measured at 407 nm, the maximum wavelength of PpIX absorption spectra. We confirmed that the spectra in the absence and presence of dendrimers were the same above 350 nm.



Complex Stability with PEG-Attached Dendrimers. The release of photosensitizers from PEG-attached dendrimers was estimated according to our previous report (*8*). Briefly, PEG-attached dendrimers encapsulating RB or PpIX at 10 equiv per dendrimer were dissolved in phosphate buffer saline (PBS) and dialyzed (pore size: 120−140 kDa). The residues in the dialysis bag were monitored by measuring the absorbance at 557 nm (RB) or 407 nm (PpIX). The PpIX solutions sampled in the bag were diluted 20 times by DMF to measure the absorbance. The external solution was changed every 3 h. Free RB solution was analyzed as a control, but free PpIX was not attainable because of its poor water solubility.

For complex stability assay in the presence of fetal bovine serum (FBS), the complexes of PpIX with PEG-attached dendrimers at 1 equiv per dendrimer were incubated in PBS containing various amounts of FBS for 3 h, and the solutions were centrifuged at 21 800 *g* for 20 min. The supernatants were used as samples for GPC analysis.

Generation of Singlet Oxygen. We prepared PBS solutions containing 36 μM of ADPA and 10 μM of RB or PpIX in the absence or presence of PEG-attached dendrimers. These solutions were irradiated using a Xe lamp (400 W·m^{-2}, XEF-152S; San-Ei Electric Co., Ltd.) with a 530 nm filter. Then, the time-dependent absorbance of ADPA was measured at 379 nm (*7*).

Phototoxicity of PEG-Attached Dendrimers Loading PpIX. The HeLa cells (5×10^4 cells) incubated for 1 day in a 24-well plate were added to free photosensitizers and PEG−PAMAM and PEG−PPI loading them at different equivalents at a wide range of concentrations. After 3 h incubation, cells were washed twice with PBS and irradiated using a Xe lamp (400 W·m^{-2}, XEF-152S; San-Ei Electric Co., Ltd.) for 10 min, followed by 24 h incubation (*6b*). Then, surviving cells were evaluated using MTT assay (*13*). Photosensitizers in the absence and presence of dendrimers were dissolved in PBS, except free PpIX. Free PpIX was dissolved in distilled dimethylsulfoxide (DMSO). Under our conditions, neither DMSO nor light irradiation without photosensitive drugs influenced cell viability.

Scheme 1

Subcellular Localization of PpIX with and without PEG-Attached Dendrimers. The HeLa cells (1×10^5 cells) incubated for 1 day in 35 mm glass-bottom dishes were added to 1 μM of free PpIX and PpIX-loading PEG−PAMAM and PEG−PPI at 10 equiv per dendrimer. After 3 h incubation, cells were washed with PBS, fixed with 3.7% paraformaldehyde, and analyzed using laser confocal microscopy with the attached computer software (*LSM 510* v 2.5; Carl Zeiss, Inc.) according to a procedure described in a previous report (*14*).

RESULTS

Synthesis and Characterization of PEG-Attached PAMAM and PPI Dendrimers. PAMAM dendrimer of G4 and PPI dendrimer of G5, each with 64 termini, were reacted with PEG chain (molecular weight: 2000) according to Scheme 1. PEG−PAMAM was already reported (*8*). As for PEG−PPI, the integral ratio of a typical signal of PEG chain (OCH_3) to PPI dendrimer ($NCH_2CH_2CH_2$) of the ^{1}H NMR spectrum indicated that every terminal amino group was attached to PEG chains. In addition, a ninhydrin test of PEG−PPI was negative, indicating that these dendrimers have no primary amino groups.

These dendrimers were characterized by GPC. Figure 2 showed a single peak, suggesting no contamination of noncovalent PEG chains. The elution volumes of PEG−PAMAM and PEG−PPI were almost equal, indicating that the hydrodynamic sizes are similar, even though intact PAMAM dendrimer of G4 was larger than PPI dendrimer of G5 (*15*). This fact suggested that these dendrimers extend to similar sizes because of steric hindrance and PEG chain solubility.

We analyzed emission spectra of DNS to examine the hydrophobicity of the dendrimer interior (*12*). Emission spectrum of DNS is affected by the hydrophobicity of the surroundings. The blue shift of the emission maximum and the increase of fluorescence intensity are observed in the hydrophobic environment. The emission maximum of PEG−PPI was blue-shifted to a greater extent, although that of PEG−PAMAM was blue-shifted only slightly, as shown in Figure 3A. The fluorescence intensity in the presence of PEG−PPI was also higher than that in PEG−PAMAM (Figure 3B). These facts indicate that PPI dendrimer is more hydrophobic than PAMAM dendrimer, as reported previously (*16*). Both PAMAM and PPI dendrimers have equal amounts of amino groups, but PAMAM dendrimer has amide groups. Amide groups of PAMAM dendrimer are expected to contribute to the interior hydrophilicity.

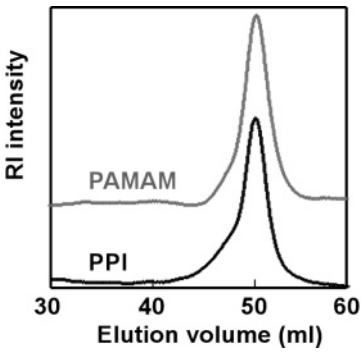


Figure 2. GPC profiles of PEG-attached PAMAM (top) and PPI (bottom) dendrimers. A peak of PEG with 2 kDa is apparent at 58.5 mL.

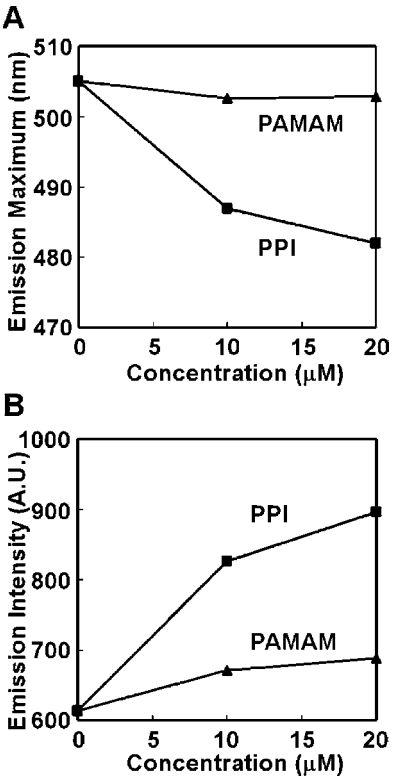

Figure 3. Comparison of the hydrophobicity of PEG−PAMAM (triangles) with that of PEG−PPI (squares). (A) Emission maximum. (B) Fluorescence intensity.

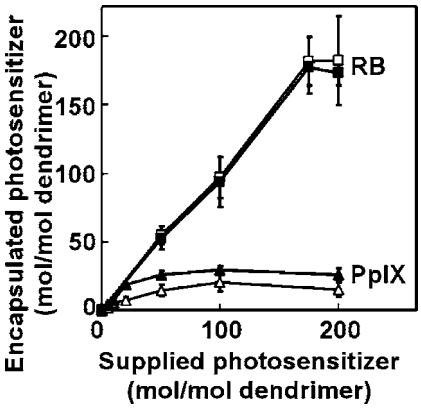

Figure 4. Encapsulation of RB (square) and PpIX (triangles) by PEG−PAMAM (open) and PEG−PPI (closed) dendrimers.

Complex of Photosensitive Drugs with PEG-Attached Dendrimers. To evaluate PEG-attached dendrimers as a drug carrier of photosensitizers, we examined the binding property to photosensitizers such as RB and PpIX. Photosensitizers can be soluble even in a poor solvent, through complexation with dendrimers. We extracted complexes from poor solvents to estimate the numbers of photosensitizers bound to a dendrimer (*8*). We found that 182 and 177 molecules of RB and 20 and 30 molecules of PpIX were bound, respectively, per PEG−PAMAM and PEG−PPI at the maximum (Figure 4). We reported that an important driving force of that binding is the electrostatic interaction between inner amino groups of dendrimers and carboxyl groups of guest molecules (*8*). This fact suggested that carboxyl groups of RB and PpIX interacted with inner tertiary amino groups of PEG−PPI and PEG−PAMAM via electrostatic interaction. Our results indicated that more RB molecules were encapsulated by PEG-attached dendrimers than

by PpIX. Experimental conditions might contribute to this phenomenon: The complexes with RB were extracted using chloroform; PpIX was extracted using water. In a hydrophobic environment, electrostatic interaction between dendrimers and guest molecules is more effective: RB was complexed easily with dendrimers. In water, on the other hand, hydrophobic interaction among guest molecules is efficient; consequently, hydrophobic PpIX tends to interact with other PpIX molecules to engender their aggregation. We also found that PEG−PPI encapsulated more PpIX molecules than PEG−PAMAM. This result suggests that the association of PpIX with dendrimers in water is driven by hydrophobic interaction, consistent with the difference of hydrophobicity of PEG-attached dendrimers (Figure 3).

We next investigated the release behavior of photosensitizers from these dendrimers by dialysis. Free drug molecules are permeable through a dialysis bag, but the complexes are not. Residual photosensitizers in the dialysis bag were detected using UV−vis absorbance (*8*). The RB complexes showed similar profiles to those of free RB, indicating that water-soluble RB molecules were released immediately in PBS solution (Figure 5A). In contrast, more than 50% of hydrophobic PpIX remained in PEG-attached dendrimers after 24 h (Figure 5B). Dialysis assay of PpIX did not obviate the possibility that aggregates of released PpIX remained in the dialysis bag. We performed another release assay to validate this release behavior of PpIX. Absorption of the supernatant of PpIX-loading PEG-attached dendrimers after centrifugation was measured at different time incubations because free PpIX molecules aggregate easily for removal. These results were almost identical to those of the dialysis assay (see Supporting Information). These release experiments suggest that the complexes of PpIX with PEG-attached dendrimers were stable.

Our results indicate that hydrophilic RB was released more rapidly from PEG-attached dendrimers in PBS than hydrophobic PpIX. As described previously, the complex formation was involved in electrostatic and hydrophobic interaction. Electrostatic interaction is suppressed under isotonic conditions. Therefore, hydrophobicity might influence the complexes' stability. Figure 5 also shows that photosensitizers were released more easily from PEG−PAMAM than from PEG−PPI. That result is consistent with our results, which indicated that PEG−PPI is more hydrophobic than PEG−PAMAM (Figure 3). The complex of PpIX with PEG−PPI was the most stable one assessed in this study. Therefore, we suggest that the hydrophobicity of host and guest molecules mainly influenced the complex stability in PBS.

The influence of serum proteins on the complex stability is indispensable for application to PDT. We investigated the complex stability in the presence of serum proteins. The complexes were incubated in the serum-containing PBS for 3 h. Since it is well-known that PpIX molecule binds to serum proteins (*17*), PEG-attached dendrimers were separated from serum proteins using GPC, and then fluorescence intensity of PpIX associated with the PEG-attached dendrimer was measured. We found that serum proteins hardly promoted the dissociation of PpIX from PEG−PPI in the presence of 10% serum. A large fraction of PpIX molecules were still retained in the dendrimer after 3 h incubation in 50% serum. In contrast, PpIX molecules were readily released from the PEG−PAMAM even in the presence of 10% serum (Figure 5C). These results suggest that the complexes with PEG−PPI were much more stable than those with PEG−PAMAM in the presence of serum proteins. This stability difference might be related to the hydrophobicity of their interior: binding of PpIX to PEG−PAMAM was too weak to maintain the complex due to its relatively hydrophilic interior. Therefore, we established stable

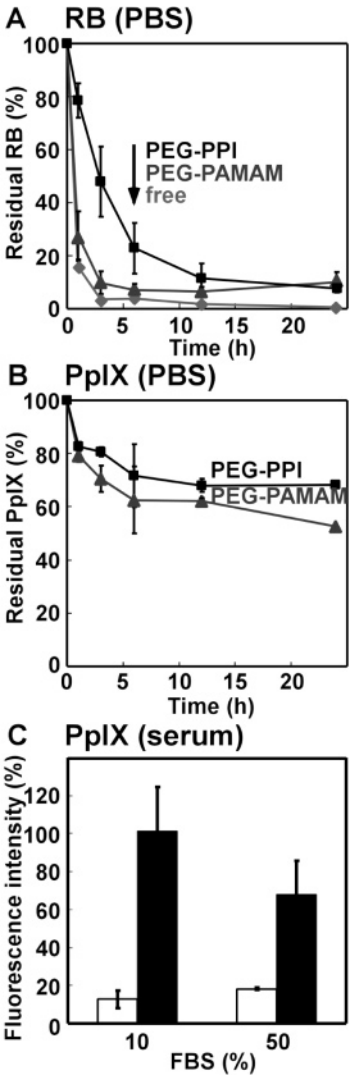

Figure 5. Release of RB (A) and PpIX (B) from PEG−PAMAM (triangles) and PEG−PPI (squares) dendrimers in PBS. Residual photosensitizer (%) was calculated from absorbance of the complex solution in the dialysis bag. Profile for dendrimer-free RB is also shown (rhombi). (C) Effect of serum on release of PpIX from PEG−PAMAM (open) or PEG−PPI (closed). The complexes were incubated in PBS containing 0%, 10%, or 50% FBS for 3 h and were separated using GPC. Relative fluorescence intensity (%) of the complex was calculated by comparison with fluorescence intensity of the complex incubated in serum-free PBS.

complexes under physiological conditions using the combination of hydrophobic PpIX and PEG−PPI with hydrophobic interiors.

Generation of Singlet Oxygen Induced by Light Irradiation. Photosensitive drugs generate singlet oxygen after light irradiation. We examined whether the complex formation affected the photosensitive properties of RB and PpIX using ADPA as a chemical trap. Photobleaching of anthracene moiety of ADPA is useful to monitor singlet oxygen generation (*7*, *18a*). We found that RB encapsulated by PEG-attached dendrimers suppressed the decrease of the absorbance, indicating that the complex formation inhibited the production of singlet oxygen (Figure 6A). RB molecules might be quenched because of high local concentration inside dendrimers (*6a*).

In contrast, free PpIX and the complex with PEG−PAMAM generated less singlet oxygen than the complex with PEG−PPI (Figure 6B). Free PpIX molecules readily aggregate in PBS to impair the ability of photosensitizers, as described in previous reports (*18*). PpIX molecules in the complexes with PEG−PPI, however, are dispersible at the molecular level to maintain the

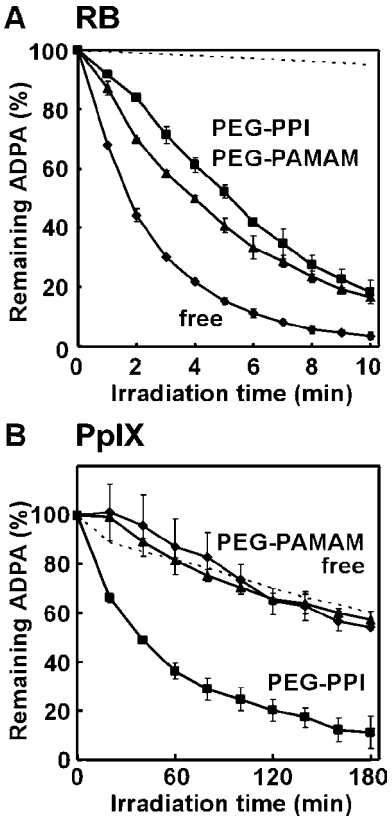

Figure 6. Generation of singlet oxygen induced by RB (A) and PpIX (B) at various irradiation times. The free photosensitizer (rhombi) data and those of complexes with PEG−PAMAM (triangles) or PEG−PPI (squares) at 10 equiv per dendrimer are shown. Degradation of ADPA alone by irradiation is also shown as dotted lines.

photosensitive activity. Figure 6B might indicate that small PpIX aggregates existed in the presence of PEG−PAMAM. It is inferred that PpIX molecules interact with each other, even inside, because PAMAM dendrimers are more hydrophilic than PPI dendrimers (Figure 3). This suggestion is supported by some reports that porphyrin derivatives can aggregate in the complex with PAMAM dendrimers (*19*). We also performed ADPA analysis, by which PEG-attached dendrimers encapsulating PpIX at different equivalents were used. The result showed that greater amounts of PpIX per dendrimer generated less singlet oxygen, which might be attributable to quenching of the PpIX molecules inside dendrimers (see Supporting Information).

Cytotoxicity of the Photosensitizers Encapsulated by PEG-Attached Dendrimers. As an in vitro model of PDT, we examined the cytotoxicity of HeLa cells induced by photosensitizers after light irradiation (*20*). The HeLa cells were treated with photosensitizers encapsulated by PEG-attached PAMAM or PPI dendrimer as well as free ones for 3 h. Both PEG-attached dendrimers themselves exhibited no cytotoxicity under our conditions (data not shown). We found that free RB and the complex with PEG-attached dendrimers exhibited almost equal cytotoxicity to HeLa cells (see Supporting Information). These results are explained using the release profiles that RB molecules were easily released from PEG-attached dendrimers (Figure 5A).

We also examined the cytotoxicity of PpIX in the absence and presence of PEG-attached dendrimers. First, we optimized the equivalent of PpIX molecules per dendrimer for cytotoxicity after light irradiation. As shown in panels A and B of Figure 7, the most effective phototoxicity was obtained for 10 molecules of PpIX encapsulated for each PEG−PAMAM and for each PEG−PPI. That result suggests that the balance of positive and negative factors on complex formation is important to exhibit efficient phototoxicity. The PEG-attached dendrimers with more

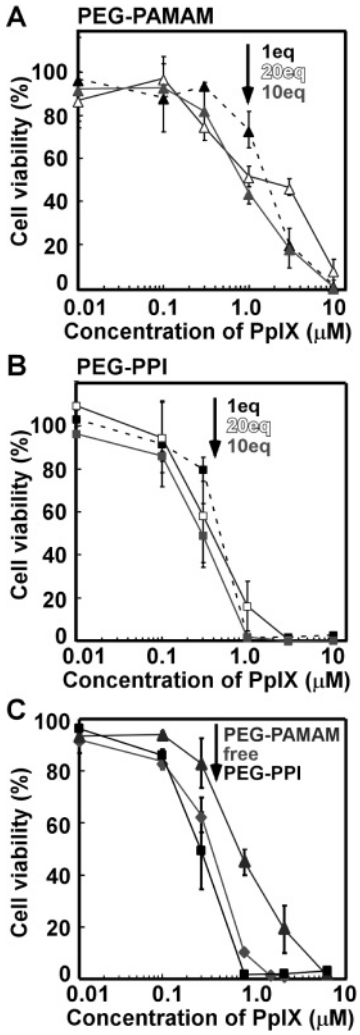

Figure 7. Phototoxicity of PpIX in HeLa cells. The complexes of PpIX with PEG−PAMAM (A) or PEG−PPI (B) were prepared at different equivalents (1 equiv (dash line), 10 equiv (closed), and 20 equiv (open)). The most effective complex with PEG−PAMAM (triangles) or PEG−PPI (squares) dendrimers are shown in panel C. Free photosensitizer (rhombi) was also shown as a control. Cell viability was expressed as the percentage of the untreated control cells.

PpIX were best for the efficient delivery of PpIX into cells. On the other hand, more PpIX per dendrimer induced quenching of PpIX inside dendrimers, thereby suppressing the generation of singlet oxygen (see Supporting Information). Our data indicated that the complex at 10 equiv generated the greatest amount of singlet oxygen in cells.

The most effective PpIX complexes with PEG−PAMAM and PEG−PPI were compared with free PpIX (Figure 7C). Results showed that free PpIX and the complex with PEG−PPI were more cytotoxic than the complex with PEG−PAMAM. The PpIX molecules were complexed stably with PEG-attached dendrimers, different from RB. Especially, 80% of PpIX molecules were still associated with PEG−PPI after 3 h (Figure 5B,C). In addition, PpIX molecules with PEG−PPI can generate more singlet oxygen (Figure 6B), suggesting that the complex with PEG−PPI can function as a photosensitive drug without releasing PpIX.

Toxicity in the dark was also investigated. Without irradiation, 10 μM of RB solutions with and without PEG-attached dendrimers exhibited no toxicity (data not shown). However, PpIX exhibits some cytotoxicity (Table 1) even in the presence of PEG-attached dendrimers, consistent with previous reports (*5a*). For PDT, it is important to reduce cytotoxicity in dark conditions.

Table 1. Viability (%) of Cells Treated with PpIX in the Dark

		complex	
PpIX	free	PEG−PAMAM	PEG−PPI
1 μM	66.1 (±3.9)	75.9 (±5.0)	48.2 (±4.8)
10 μM	27.4 (±1.1)	40.1 (±0.1)	30.5 (±2.4)

Subcellular Localization of PpIX. Intracellular localization of PpIX is a crucial feature of PDT. Singlet oxygen at mitochondria is known to induce apoptotic cell death (*21*). We observed localization to mitochondria in HeLa cells by staining with MitoTracker. As shown in Figure 8, PpIX molecules complexed with PEG−PPI were mostly merged in MitoTracker-positive dots. On the other hand, for free molecules and the complex with PEG−PAMAM, PpIX molecules were partially localized at mitochondria. These data suggest that PpIX was localized to mitochondria efficiently by PEG−PPI.

PpIX, a precursor of heme, is known to localize at mitochondria. However, it was reported that fewer exogenous PpIX molecules localize there in comparison to ALA-mediated endogenous PpIX (*22*). Moreover, few exogenous PpIX were accumulated at mitochondria after 3 h (*23*). It has also been reported that pegylation of a photosensitizer can be efficient for targeting mitochondria (*24*). These observations suggest that stable PpIX complexes with PEG-attached dendrimers were localized to mitochondria, but that free or released PpIX were not. The PpIX molecules complexed with PEG−PPI were more stable than with PEG−PAMAM, as shown in Figure 5B,C. Therefore, PEG−PPI can contribute to localization of PpIX molecules to mitochondria.

DISCUSSION

We used two types of photosensitizers (RB and PpIX) and PEG-attached dendrimers (PEG−PAMAM and PEG−PPI) to produce complexes to apply to PDT. For RB, the complexes with PEG-attached PAMAM and PPI dendrimers were unstable under isotonic conditions. Figure 6A indicated that high local concentrations inside both PEG-attached dendrimers provide less singlet oxygen, suggesting that the photosensitive action is controllable by regulating the release behavior of RB from dendrimers. Therefore, PEG-attached dendrimers with the ability of controlled release by bearing a disulfide and polymer network can be more useful as vehicles of RB for PDT (*9*).

In the case of PpIX, we observed different phototoxicity of free dye from that of the complexes. Figure 7C indicated that the PpIX complex with PEG−PPI is more toxic after light irradiation than the complex with PEG−PAMAM. These results probably arose from the complex stability in serum-containing solutions, the productive rate of singlet oxygen and the subcellular localization of photosensitizers. As shown in Figure 5C, the complexes with PEG−PPI were much more stable than those with PEG−PAMAM in the presence of FBS. Because PpIX molecules were released from PEG−PAMAM during the incubation with cells, encapsulation of PpIX in PEG−PAMAM might not be effective for PDT. Demonstrably, encapsulation in PEG−PPI enhanced the generation of singlet oxygen (Figure 6B) and the localization of PpIX molecules at mitochondria (Figure 8) to engender effective phototoxicity. Although these dendrimers have the same numbers of primary and tertiary amino groups, their properties such as hydrophobicity and complex formation are different. Differences of their properties such as hydrophobicity and pK_a might be attributable to the efficiency for PDT, which remains to be investigated in detail.

The complex with PEG−PPI exhibited almost equal phototoxicity to that of free PpIX. It has already been reported that association of photosensitizers with cells is enhanced by hydrophobicity (*23*). In addition, it is well-understood that PEG chains abrogate the association with many biomolecules. These reports suggest that PEGylation negatively affects association with cells (*10*). Consistent with this notion, we found that the fluorescence intensity of free PpIX in HeLa cells was approximately 2-fold higher than that of the complex with PEG-PPI (data not shown). However, free PpIX molecules generated less singlet oxygen than the complex with PEG−PPI (Figure 6B). In addition, they were not localized efficiently at mito-

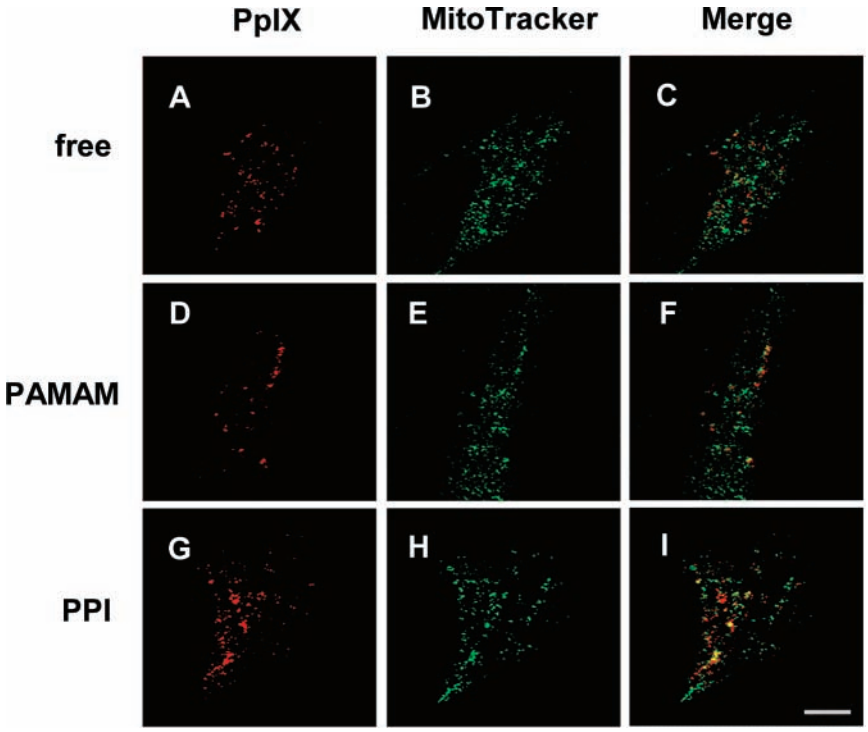

Figure 8. Subcellular localization of free PpIX (A−C) and complexes of PpIX with PEG−PAMAM (D−F) or PEG−PPI (G−I). Here, PpIX is a red fluorescent dye (A,D,G), and mitochondria are labeled using MitoTracker green (B,E,H). Merged images of the left two columns are shown (C,F,I). These are representative images from more than 50 cells examined in each experiment. Bar, 10 μm.

chondria (Figure 8). Taken together, these results suggested that PpIX molecules complexed with PEG−PPI have phototoxicity attributable to the localization at mitochondria, along with more singlet oxygen, in spite of lower amounts of PpIX associated with cells. Although the cytotoxicity of PpIX in dark conditions was observed, toxicity might be reduced using ALA instead of PpIX (*2*, *6b*, *22*, *25*), which remains to be improved.

In conclusion, we synthesized and characterized two PEG-attached dendrimers: PEG−PAMAM and PEG−PPI. We prepared complexes using those dendrimers and photosensitizers such as RB and PpIX. Results showed that PEG−PPI can encapsulate more photosensitizers and hold them inside under physiological conditions. Results also indicated that a hydrophobic photosensitizer, PpIX, can form a stable complex with PEG−PPI under physiological conditions, which suggests that the stable complexes were obtained through hydrophobic interaction rather than electrostatic interaction. Properties of complexes influenced the generation of singlet oxygen, subcellular localization, and the cytotoxic effect. Especially, we demonstrated the efficient phototoxicity of PpIX complexed with PEG−PPI via effective production of singlet oxygen and delivery to mitochondria. We demonstrated photosensitive activity of the complex of PpIX with PEG-attached dendrimers at the same level of free PpIX in vitro. This behavior is important for in vivo application because this kind of nanocapsule can be targeted to the affected tissues. Therefore, we propose that our PEG-attached dendrimers are a promising carrier for PDT.

ACKNOWLEDGMENT

We are grateful to Hisataka Sabe (Osaka Bioscience Institute, Japan) for generous support in microscopic analysis. We thank Yasuhiro Haba for support in synthesis. This work was supported in part by Grants-in-aid from the Ministry of Education, Science, Sports and Culture of Japan, and Grants from Iketani Science and Technology Foundation and Saneyoshi Scholarship Foundation.

Efficient Surface Patterning of Oligonucleotides Inside a Glass Capillary through Oxime Bond Formation

Nabil Dendane,[#,†] Antoine Hoang,[#] Ludovic Guillard,[†] Eric Defrancq,[†,*] Françoise Vinet,[#] and Pascal Dumy[†]

Département de Chimie Moléculaire - UMR CNRS 5250, ICMG FR2607, Université Joseph Fourier, BP 53, 38041 Grenoble Cedex 9, France, and LETI-CEA, 17 rue des Martyrs, 38054 Grenoble Cedex 9, France. Received August 16, 2006; Revised Manuscript Received December 5, 2006

The efficient surface patterning of oligonucleotides was accomplished onto the inner wall of fused-silica capillary tubes as well as on the surface of glass slides through oxime bond formation. The robustness of the method was demonstrated by achieving the surface immobilization of up to three different oligonucleotide sequences inside the same capillary tube. The method involves the preparation of surfaces grafted with reactive aminooxy functionalities masked with the photocleavable protecting group, 2-(2-nitrophenyl) propyloxycarbonyl group (NPPOC). Briefly, NPPOC-aminooxy silane **1** was prepared and used to silanize the glass surfaces. The NPPOC group was cleaved under brief irradiation to unmask the reactive aminooxy group on surfaces. These reactive aminooxy groups were allowed to react with aldehyde-containing oligonucleotides to achieve an efficient surface immobilization. The advantage associated with the present approach is that it combines the high-coupling efficiency of oxime bond formation with the convenience associated with the use of photolabile groups. The present strategy thus offers an alternative approach for the immobilization of biomolecules in the microchannels of "labs on a chip" devices.

INTRODUCTION

The miniaturization of biological assays represents an intensive domain of research especially for the design of high-throughput screening systems. In this context, the microarrays of biomolecules such as DNA, carbohydrates, and peptides have emerged as versatile tools with diverse applications in the areas of genetic analysis, molecular diagnostics, and drug discovery. Similarly, there is a significant interest in the design of microfluidic systems with an objective to achieve integration of synthesis, purification, and analysis steps on a chip. The "lab on a chip" device along with the microarrays technologies would indeed revolutionize the diagnostic field by permitting more rapid, economical, and multiparametric analysis with minimum volumes of samples (*1*, *2*).

The critical step in the preparation of microarrays and/or "lab on a chip" device is the control of surface chemistry. One challenging task is to carry out the surface immobilization of biomolecules (DNA, proteins) without affecting their intrinsic properties. Two major strategies are being currently used for the patterning of biomolecules on planar arrays. The first approach involves surface synthesis (in situ synthesis) whereas the second approach implicates the deposition of prefabricated biomolecules on the surface. The in-situ synthesis, pioneered by Fodor and Coll (*3*) for the preparation of DNA arrays, takes advantage of the photolithography technique for the photochemical addressing of the oligonucleotides on the surface and provides high-density arrays. While very promising, the method suffers from the fact that only short-length oligonucleotide sequences can be synthesized on the surface and the costs incurred are relatively high. Moreover, the procedure becomes arduous when used for the preparation of other microarrays (carbohydrates and peptides for example). On the other hand, the deposition technology involves the attachment (covalent or noncovalent) of prefabricated biomolecules to the surface (*4*). This approach utilizes "spotting techniques" and benefits from the fact that automated robots can be used to immobilize biomolecules on the surface. The major advantage is the fact that biomolecules prepared by chemical or enzymatic methods can be fully purified and characterized prior to spotting. This spotting technology is limited to low complexity arrays only but allows more flexibility. The surface immobilization is mostly achieved by chemical reaction between surface-bound reactive groups and prefunctionalized biomolecules. A large number of combinations of surface/biomolecule functions have been used for this purpose and mostly include maleimide/thiol (*5*), "click chemistry" involving alkyne/azide (*6*, *7*), hydrazide/aldehyde (*8*, *9*), etc. The patterning of biomolecules inside the microchannels used in the design of "lab on a chip" is more complicated due to the closed geometry of this format. To our knowledge, only two methods have been reported to date. The first method involves the photogeneration of surface-bound aldehyde groups for the immobilization of proteins via the formation of a Schiff base (*10*). The second method is based on the photo-cross-linking of surface-bound benzophenone derivatives with biomolecules via C−H insertion (*11*). Consequently, the design and development of alternative chemical approaches for surface immobilization of biomolecules inside the closed space (microchannels) have assumed significant research interest.

The paper describes a new method that allows an efficient immobilization of oligonucleotides (as an example of biomolecules) onto the surface of inner wall of fused-silica capillary tubes as well as of glass slides by utilizing the oxime chemistry. The present approach involves the grafting of aminooxy functionalities protected with a photolabile group on the surface. The photolabile group is then removed by irradiation thereby generating reactive aminooxy functions at predefined positions. This is followed by the deposition of the biomolecule functionalized with an aldehyde group, which reacts with the

aminooxy functions and thus gets immobilized onto the surfaces due to the formation of oxime bond. In order to prove the concept, we have used oligonucleotides as biomolecule and we have first studied all the steps required for the immobilization of oligonucleotides on a planar format. The sensitivity of the arrays prepared by this method for detecting the target sequence was evaluated, and a reasonably high sensitivity of detection (1 nM) was achieved. The potential utility of the present approach for the surface functionalization and immobilization inside the microchannel for "lab on a chip" devices has been further demonstrated by carrying out surface immobilization of three different oligonucleotides sequences onto the inner wall of a same capillary tube and simultaneously monitoring the three hybridization events.

EXPERIMENTAL PROCEDURES

Materials and Methods. All solvents and reagents used were of highest purity available. The complementary labeled oligonucleotides were purchased from MWG Biotech and the hybridization solution from Sigma. Flexible fused-silica capillaries with UV-transparent coating (interior diameter: 100 μm) were obtained from Polymicro Technologies (Phoenix, AZ). The oligonucleotides were characterized by ESI mass spectra on an Esquire 3000 (Bruker) spectrometer. The analysis was performed in negative mode using 50% aqueous acetonitrile as eluent. The oligonucleotides were dissolved in 50% aqueous acetonitrile containing 2% of NEt_3. ^1H, ^{29}Si, and ^{13}C NMR spectra were recorded on Bruker AC 200 and Avance 300 spectrometers. The irradiation experiment on capillaries were performed on an Olympus inverted microscope model IX60, equipped with a 100 W mercury lamp and a 365 nm interference filter. The patterning was performed by irradiation of the focus zone. Hybridization experiments were carried out using a Gentac Scanner (Genomic Solution). The excitation and emission wavelengths employed for different probes are as follows: Fluorescein ($\lambda_{Exc.}$ = 494 nm, $\lambda_{Em.}$ = 518 nm), Cy3 ($\lambda_{Exc.}$ = 550 nm, $\lambda_{Em.}$ = 570 nm), Cy5 ($\lambda_{Exc.}$ = 649 nm, $\lambda_{Em.}$ = 670 nm), Texas Red ($\lambda_{Exc.}$ = 595 nm, $\lambda_{Em.}$ = 615 nm).

Synthesis. The 5′-aldehyde oligonucleotides were prepared as previously reported (*12*). The oligonucleotide sequences employed in the present work are 5′-d-XTTTTTGATAAACCCACTCTA-3′ (**Seq1)**, 5′-d-XTTTTTTGATCATGTTGTTGCTTG-3′ (**Seq2**), 5′-d-XTTTTTTCGGATACCCAAGGA-3′ **(Seq3**) respectively, where X represents the 5′-aldehyde linker.

Compound 2. A solution of *N*-hydroxyphthalimide (3.50 g, 21 mmol) and potassium carbonate (8 g, 41 mmol) in DMF (250 mL) was heated for 1 h at 50 °C under argon. 11-Bromoundecene (5.0 g, 21 mmol) was added, and the reaction mixture was stirred for 3 h at 50 °C. Then the reaction mixture was filtered, and the filtrate was evaporated under vacuum. The residue so obtained was redissolved in CH_2Cl_2 and successively washed with 0.1 N aq NaOH and brine. The organic layer was dried over Na_2SO_4 and evaporated to give compound **2** as a white powder (6.45 g, 97%). Mp 38−40 °C; ^1H NMR ($CDCl_3$) δ 1.20−1.50 (m, 12H; $6CH_2$), 1.78 (m, 2H; CH_2CH_2O), 2.02 (m, 2H; $CH_2CH{=}CH_2$), 4.18 (t, 2H; CH_2O), 4.95 (m, 2H; $CH_2{=}CH$), 5.79 (m, 1H; $CH_2{=}CH$), 7.70−7.85 (m, 4H; Ar−H); ^{13}C NMR ($CDCl_3$) δ 25.66 (CH_2), 28.27 (CH_2), 29.03 (CH_2), 29.20 (CH_2), 29.39 (CH_2), 29.49 (CH_2), 29.52 (CH_2), 33.90 (CH_2), 78.72 (CH_2), 114.22 (CH_2), 123.56 (CH), 129.14 (Cquat), 134.52 (CH), 139.30 (Cquat), 163.75 (Cquat); MS (ESI): M_{calcd} = 315 ($C_{19}H_{25}NO_3$), found (*m/z*): 338 $(M + Na)^+$; Anal. calcd C 72.36 H 7.99 N 4.45, found C 72.21 H 8.13 N 4.40.

Compound 3. Compound **2** (3 g, 9.5 mmol) was dissolved in CH_2Cl_2 (30 mL), and hydrazine hydrate (0,966 g, 19.3 mmol) was added. The solution was refluxed for 2 h and then filtered. The filtrate was evaporated under vacuum. The crude product was purified by silica gel column chromatography using EtOAc/cyclohexane as eluent (1/2, v/v) to obtain **3** as white oil (1.65 g, 94%). ^1H NMR ($CDCl_3$) δ 1.20−1.40 (m, 12H; $6CH_2$), 1.56 (m, 2H; CH_2), 2.03 (m, 2H; CH_2), 3.65 (t, 2H; CH_2O), 4.90−5.02 (m, 2H; $CH{=}CH_2$), 5.74−5.87 (m, 1H; $CH{=}CH_2$); ^{13}C ($CDCl_3$) δ 26.11 (CH_2), 28.51 (CH_2), 29.02 (CH_2), 29.20 (CH_2), 29.51 (CH_2), 29.58 (CH_2), 29.61 (CH_2), 33.89 (CH_2), 76.26 (CH_2), 114.20 (CH_2), 139.25 (CH); MS (ESI): M_{calcd} = 185 ($C_{11}H_{23}NO$), found (*m/z*): 186 $(M + H)^+$.

Compound 4. A solution of 2-(2-nitrophenyl)propyl chloroformate (740 mg, 3 mmol) in CH_2Cl_2 (3 mL) was added dropwise to the solution of compound **3** (470 mg, 2.54 mmol) in pyridine (2 mL). The solution was stirred for 2 h in darkness and filtered, and the filtrate was evaporated under vacuum. The residue so obtained was redissolved in CH_2Cl_2, and the organic layer was washed successively with 10% aq sodium carbonate, 1 N aq HCl, and brine. The organic layer was dried (Na_2SO_4) and evaporated under vacuum. The crude product was purified by silica gel column chromatography using EtOAc/cyclohexane (1/4, v/v) as eluent to obtain compound **4** as an orange oil (873 mg, 87%). ^1H NMR ($CDCl_3$) δ 1.20−1.40 (m, 12H; $6CH_2$), 1.35 (d, 3H; CH_3), 1.56 (m, 2H; CH_2), 2.03 (m, 2H; CH_2), 3.69−3,78 (m, 3H; $CH + CH_2O$), 4.21−4.35 (m, 2H; CH_2OCO), 4.90−5.01 (m, 2H; $CH{=}CH_2$), 5.74−5.87 (m, 1H; $CH{=}CH_2$), 7.34−7.56 (m, 4H, Ar−H); ^{13}C NMR ($CDCl_3$) δ 17.64 (CH_3), 25.86 (CH_2), 27.96 (CH_2), 29.01 (CH_2), 29.19 (CH_2), 29.49 (CH_2), 33.37 (CH), 33.89 (CH_2), 69.35 (CH_2), 77.14 (CH_2), 114.22 (CH_2), 124.20 (CH), 127.57 (CH), 128.21 (CH), 132.74 (CH), 137.14 (Cquat), 139.28 (CH), 150.66 (Cquat), 157.28 (Cquat); MS (ESI): M_{calcd} = 392 ($C_{21}H_{32}N_2O_5$), found (*m/z*): 415 $(M + Na)^+$; Anal. calcd C 64.27 H 8.22 N 7.14, found C 64.16 H 8.48 N 6.88.

Compound 1. Karstedt catalyst (0.1 M platinum(0)-1,3-divinyl-1,1,3,3-tetramethyldisiloxane complex dissolved in poly-(dimethylsiloxane), 15 μL, 0.02 equiv) was added to a solution of compound **4** (663 mg, 1.69 mmol) in triethoxysilane (1.5 mL). The reaction mixture was stirred for 4 h at 60 °C. The solvent was evaporated next under vacuum to obtain compound **1**. This was used in next step without further purification. ^1H NMR (200 MHz, $CDCl_3$) δ 0.6 (m, 2H; $CH_2{-}Si$), 1.10−1.30 (m, 16H; $CH_3 + CH_2$), 1.35 (d, 3H; CH_3), 1.56 (m, 2H; CH_2), 3.65−3.90 (m, 9H; $CH + 4CH_2O$), 4.28 (m, 2H; CH_2OCO), 7.20 (br s, 1H; NH), 7.35−7.75 (m, 4H, Ar−H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 10.9 (CH_2), 18.0 (CH_3), 18.8 (CH_3), 23.2 (CH_2), 23.3 (CH_2), 26.3 (CH_2), 28.4 (CH_2), 29.8 (CH_2), 29.9 (CH_2), 30.0 (CH_2), 30.1 (CH_2), 33.8 (CH), 58.8 (CH_2O), 69.8 (CH_2O), 77.6 (CH_2), 124.6 (CH), 128.0 (CH), 128.6 (CH), 132.2 (CH), 137.0 (Cquat), 150.1 (Cquat), 157.1 (Cquat); ^{29}Si NMR (59 MHz, $CDCl_3$) δ −21.7. IR (NaCl): 3279 (br), 2975, 2926, 2855, 1752, 1728, 1528, 1082 cm^{-1}. MS (ESI): M_{calcd} = 556 ($C_{27}H_{48}N_2O_8Si$), found (*m/z*): 579 $(M + Na)^+$, 595 $(M + K)^+$. Anal. calcd C 58.25 H 8.69 N 5.03, found C 58.62 H 8.57 N 5.05.

Functionalization and Oligonucleotide Immobilization on Glass Surfaces. *Step 1. Hydratation of the Surface:* The glass slides were dipped in an aq ethanolic solution of NaOH (1 g NaOH, 4 mL H_2O, 3 mL EtOH) for 1 h and washed successively with ultrapure H_2O, 0.2 N aq HCl, and H_2O again. The glass slides were then dried under nitrogen.

Step 2. Silanization with 1: The glass slides were dipped in a 5 mM solution of compound **1** in toluene/NEt_3 (97/3, v/v) for overnight storage at room temperature. The slides were washed with toluene followed by EtOH and finally dried under nitrogen. The glass slides were then cured at 110 °C for 3 h.

Step 3. Photodeprotection: An aq pyridine solution (from 5% to 50%) was deposited on the glass slides, and a mask

(containing holes of diameter: 80 μm) was applied on the surface. Irradiation for different time span was carried out by using a mercury lamp (100 W, 24 mW/cm^2). After removal of the mask, the glass slides were washed with H_2O and dried under nitrogen.

Step 4. Immobilization: The glass slides were dipped in a solution of 0.4 M ammonium acetate buffer containing oligonucleotide-5′-aldehyde (**Seq1**, 2−20 μM) for different time durations (30 s−12 h). The glass slides were then successively washed with H_2O, 1% aq SDS solution, and H_2O and finally dried under nitrogen.

Step 5. Hybridization: The glass slides were dipped in the hybridization solution of Cy3 labeled complementary oligonucleotide at different concentrations (0.1−100 nM) for 1 h at 39 °C. The glass slides were washed with 2X SSC buffer and dried under nitrogen. The glass slides were then scanned on a Gentac Scanner (Genomic Solution).

Functionalization and Oligonucleotide Immobilization on Glass Surfaces Inside the Capillary Tubes. *Step 1. Hydratation of the Capillary Tube:* The capillary tube was filled with an aq ethanolic solution of NaOH (1 g NaOH, 4 mL H_2O, 3 mL EtOH) for 1 h and washed successively with ultrapure H_2O, 0.2 N aq HCl, and H_2O. The capillary tube was then dried under nitrogen.

*Step 2. Silanization with **1**:* The capillary tube was filled with a 10 mM solution of compound **1** in trichloroethylene and incubated for overnight at room temperature. The capillary was then washed with trichloroethylene followed by EtOH and dried under nitrogen. Finally, the capillary tube was cured at 110 °C for 3 h.

Step 3. Photodeprotection: The capillary tube was filled with a 5% aq pyridine solution and was mounted on the microscope stage. Irradiation for different time span was carried out by using a mercury lamp (100 W, 24 mW/cm^2). The irradiations were focused at different positions on the capillary. Each irradiation thus corresponded to a separate spot on the capillary array. The capillary was then washed with H_2O and dried under nitrogen.

Step 4. Immobilization: The capillary was filled with a 0.4 M ammonium acetate buffer solution containing oligonucleotide-5′-aldehyde (**Seq1**, 20 μM) for 2 min. A constant reagent flow (0.1−10 μL min^{-1}) was applied by using a syringe pump. The capillary was successively washed with H_2O, 1% aq SDS solution, and H_2O and finally dried under nitrogen.

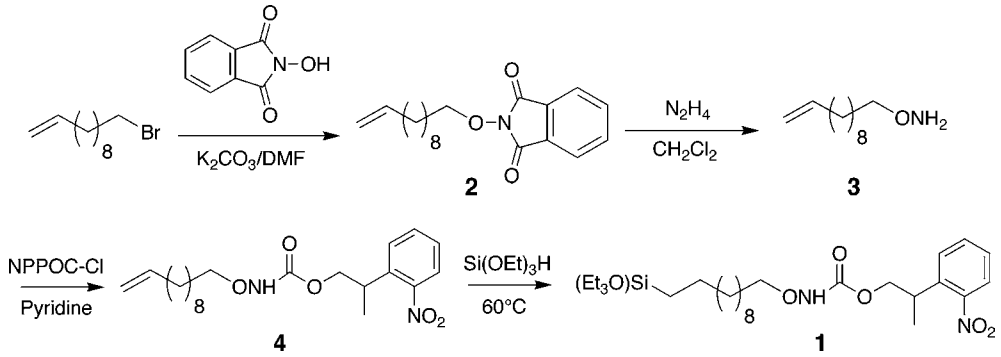
Step 5. Hybridization: The capillary was filled with the hybridization solution of Cy3 labeled complementary oligonucleotide at different concentrations (10−100 nM) for 1 h at 39 °C. A constant flow of hybridization solution (0.1−10 μL.min^{-1}) was maintened by using a syringe pump. The capillary was washed with 2X SSC buffer and then scanned by using a four-color microarray GeneTAC Scanner (Genomic Solutions).

The same procedure as described above was further applied for surface immobilization of three different oligonucleotides inside the same capillary tube (multiple functionalization) by using oligonucleotides **Seq1**, **Seq2**, and **Seq3**. Each immobilization corresponded to a separate spot inside the capillary. The complementary sequences for **Seq1**, **Seq2**, and **Seq3** were labeled with Fluorescein, Cy5, and Texas Red, respectively. These three complementary sequences were used as a mixture in the present case to carry out hybridization experiments.

Specificity of Immobilization Chemistry. In order to investigate the site specificity of the approach, two control experiments were performed: the first one consisted of quenching the aminooxy group liberated during the photodeprotection, the second involved the use during the immobilization step of oligonucleotides, which do not contain the complementary aldehyde reactive group. The first control was carried out in a capillary tube as follows: the first three steps of the functionalization were carried out as before and the capillary tube was then washed with an acetone aqueous solution for 20 min. In this case, the liberated aminooxy functions on the glass surface should be quenched by the acetone by oxime bond formation. Subsequently, the oligonucleotide immobilization and hybridization steps were performed as before and the capillary tube was subjected to laser scanning. For the second control, the immobilization step was carried out by using a 0.4 M ammonium acetate buffer solution containing oligonucleotide-5′-diol (20 μM) for 2 min. Hybridization was then performed using the complementary labeled strand as usual, and the capillary tube was scanned by using a four-color microarray GeneTAC Scanner (Genomic Solutions).

Characterization of the Glass Surfaces. *Contact Angle (θ) Measurements*: The measurements of the contact angle θ of the NPPOC-modified glass surfaces were performed on a Digidrop (GBX) apparatus by using water and diiodomethane solvents. The analysis was done several times by using a series of different slides, and average values of 79° and 42° were found for water and diiodomethane, respectively. By comparison, the contact angle θ of unmodified glass slides was found to be less than 10° using water.

Multireflexion IR (MIR method): 2920 (υ_{CH}), 1725 (υ_{CO}), 1550 (υ_{NO2}) cm^{-1}. The measurements were carried out using a homemade setup placed in the sample compartment of a FTIR Bruker IFS55 spectrometer.



Atomic Force Microscopy: The measurements were carried out on an AFM PicoPlus system (Molecular Imaging) by using acoustic mode (MAC mode). A roughness (rms) of 4 nm was found.

Ellipsometry: Ellipsometric measurements were performed using an imaging ellipsometer EP3-SE from Nanofilm Technology GmbH (Germany). Vase experiments were performed ex situ under air conditions at 20 different wavelengths ranging from 366.3 to 1001.9 nm and at variable angles of incidence ranging from 50° to 80° by steps of 2°. Optical modeling was performed using the EP3View software from Nanofilm Technology GmbH. A four-layer model, Si/SiO_2/Silane/ambient air, was used to fit the data. The optical properties of the bare silicon wafer were previously measured using a three-layer model, Si/SiO_2/ambient air.

RESULTS AND DISCUSSION

An alternative approach for surface patterning of biomolecules was envisioned. The key features of the present approach were the preparation of surfaces grafted with the aminooxy functionality masked with a photocleavable protecting group and surface immobilization of aldehyde-containing oligonucleotides through the formation of oxime bonds. The possibility of a photolabile protecting group was explored because it is more convenient to use. The photolabile group can easily be removed by simple irradiation with light and thus excludes exhaustive deprotection chemistries from the protocol and subsequently associated side-reactions. The oxime bond formation was selected for the surface immobilization because it has been successfully utilized for the preparation of oligonucleotide (*12*−*14*), peptide (*15*), and carbohydrates conjugates (*16*). The advantages associated with the use of oxime bonds are that the reaction is chemoselective and proceeds with high coupling efficiency without any additive. This bond is stable over a large range of pH. Last but not the least, these linkages have been used earlier for the preparation of oligonucleotides (*17*, *18*) and carbohydrates arrays (*19*). It was therefore expected that the present approach would combine the high coupling efficiency of the oxime bond formation with the convenience associated with the use of photolabile protecting groups and will thus aid in achieving an efficient surface patterning.

Scheme 1

The most documented photolabile-protecting group for an amine functionality is undoubtedly the nitroveratryloxycarbonyl group (NVOC). However, the NVOC photocleavage leads to the formation of an aldehyde byproduct that can react with the liberated aminooxy function. Hence, the NVOC was not found to be suitable for the present purpose. It was therefore decided to use the 2-(2-nitrophenyl)propyloxycarbonyl group (NPPOC) instead of NVOC to mask the aminooxy moieties. The NPPOC group has been used earlier for the protection of amines and alcohols for the preparation of peptides and DNA microarrays by in situ synthesis approach (*20*, *21*). It is cleaved under illumination faster than the corresponding NVOC-protected compounds. More importantly, the photocleavage of the NPPOC group leads to an alkene that cannot react with the aminooxy moiety. Thus, NPPOC was thought suitable for the present investigation.

1. Synthesis of the Triethoxysilane Derivative 1. The triethoxysilane derivative **1** was prepared from commercially available 11-bromo-1-undecene in a few simple steps (Scheme 1). The aminooxy group was introduced first by using the dicarboximide derivative in basic conditions, followed by the cleavage of the protecting group with hydrazine. The free aminooxy functionality was protected next by using the photolabile NPPOC chloride derivative. Hydrosilylation was finally carried out using triethoxysilane in presence of Kärstedt's catalyst to obtain silane **1**. The derivatives **1**−**4**, prepared herein, were characterized by satisfactory ^{1}H and ^{13}C NMR and mass spectrometry data.

2. Oligonucleotide Surface Immobilization on Glass Slides. The glass slides were used as a model surface to carefully investigate and standardize the procedure involved in oligonucleotide immobilization before employing it for closed surfaces inside the capillary tubes. The crucial steps involved in the process and evaluated herein were the silanization of surfaces with **1**, the photocleavage of the NPPOC to unmask the aminooxy functionalities, and the immobilization of the aldehyde-containing oligonucleotides and their hybridization with the complementary sequences.

The glass slides were pretreated with sodium hydroxide before silanization. The silane **1** was then chemisorbed from a toluene/NEt_3 solution (97/3) onto the glass slides for overnight storage at room temperature. The silanization step was followed by a curing at 110 °C for 3 h to stabilize the silane layer. This silane coating was found to be stable at least for several months. The characterization of the modified surface was achieved using different techniques. The presence of carbamate function of NPPOC group was detected on the glass slide by multireflexion IR (MIR method). A strong signal for the carbonyl band of the carbamate at 1725 cm^{-1} was observed. Contact angle θ was measured for the modified glass slides using water, and the hydrophobic diiodomethane and θ values of 79° and 42° were found, respectively. On the other hand, the θ value of unmodified glass surfaces was found to be less than 10° using water. These measurements thereby strongly reflect the large increase in the hydrophobicity of the surfaces modified with NPPOC. Last, the thickness of the modified silane layer was evaluated at 5−6 nm by ellipsometry study and the roughness of this silane's layer on the surface was measured at about 4 nm by AFM method (see the Supporting Information).

Following silanization, three crucial steps were performed next to demonstrate the efficiency of the present approach. This included the photocleavage of the protecting group, coupling reaction with oligonucleotide-5′-aldehyde and hybridization with the complementary fluorescent probe. The photocleavage reaction on the glass slide was carried out by irradiation at 365 nm through a mask containing holes with a diameter of 80 μm. The time of irradiation (2−20 s) and solvents (water, water/pyridine, water/ammonia) were varied. It was found that presence of base is required for the photolysis to proceed, as the process in water alone was sluggish. The immobilization of the prefunctionalized oligonucleotides was achieved by dipping the glass slide in a 0.4 M ammonium acetate buffer solution (30 s−12 h) containing the oligonucleotide-5′-aldehyde (**Seq1**) at different concentrations (2−20 μM). The pH of the buffer was adjusted to 4.6 because slightly acidic conditions are known to be conductive for the formation of oxime bonds. As a matter of fact, the use of water alone resulted in lower immobilization efficiencies. Finally, the ability of the surface-bound oligonucleotide arrays to hybridize with the complementary sequence was investigated. The complementary sequences were labeled with Cy3. After hybridization and subsequent washings, the glass slides were scanned under a fluorescent scanner. The signal intensity obtained in this manner directly reflected the efficiency of the method. When the glass slides were irradiated through the mask, a pattern of fluorescent and nonfluorescent areas with the shape of the mask were revealed (Figure 1 shows a representative scanned image from the hybridization experiments). Of the several conditions tested, the best results were achieved using the following conditions: irradiation at 365 nm for 5 s in a 5% aqueous pyridine solution, deposition using a 20 μM solution of aldehydic oligonucleotide in 0.4 M ammonium acetate buffer for 2 min. These conditions mentioned herein represent the best compromise obtained between the times of irradiation and coupling and the quantity of oligonucleotide-5′-aldehyde to be used. The crucial issue of sensitivity was also evaluated. The concentration of the Cy3-labeled complementary sequence was varied (0.1−100 nM) by using the conditions described earlier (Figure 1B). The sensitivity of detection was found to be reasonably high at 1 nM (with a ratio signal/noise S/N close to 6).

3. Oligonucleotide Surface Immobilization Inside the Capillary Tubes. The strategy developed herein was employed for the surface immobilization of oligonucleotides onto the inner wall of capillary tube. The surface immobilization of biomolecules inside the tube is more challenging, and this study has great significance because it may have potential utility in the

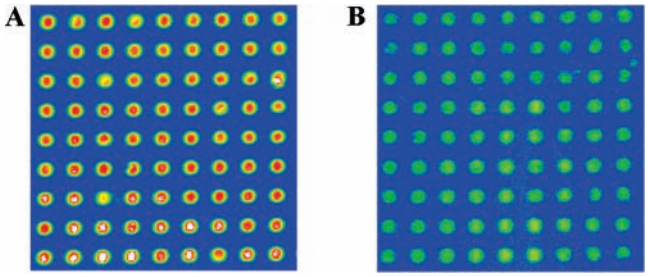


Figure 1. Scanned images of the oligonucleotide arrayed glass slides. The arraying was carrying out by irradiation through a mask (hole diameter: 80 μm) at 365 nm for 5 s in a 5% aqueous pyridine solution, followed by the deposition of a 20 μM solution of aldehydic oligonucleotide (**Seq1**) in 0.4 M ammonium acetate buffer for 2 min. Hybridization was carried out at 39 °C for 1 h using a solution of Cy3-labeled complementary oligonucleotide sequence at different concentrations (0.1−100 nM). A. concentration of the complementary sequence is 100 nM. B. concentration of the complementary sequence is 1 nM. The fluorescence intensities are color-coded, varying from blue (low) to green, yellow, red, and then white (saturation); the gain of the detector was kept constant for comparison of the fluorescence intensity.

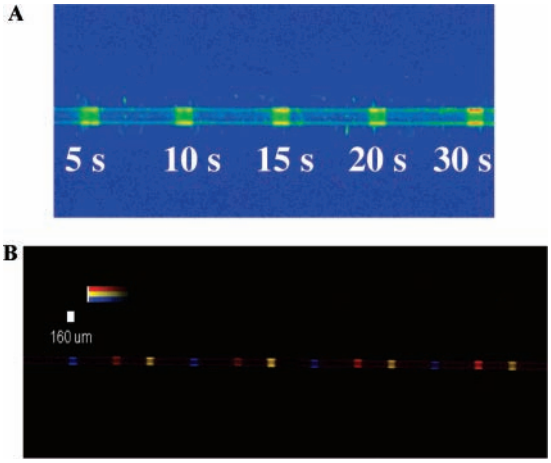

Figure 2. Scanned images of the oligonucleotides arrayed capillary tube. A. Irradiation at 365 nm for various time periods in a 5% aqueous pyridine solution, deposition of a 20 μM solution of aldehydic oligonucleotide (**Seq1**) in 0.4 M ammonium acetate buffer for 2 min and hybridization with the complementary strand labeled with Cy3. B. Multiple deposition of the three oligonucleotides **Seq1**, **Seq2**, and **Seq3** and hybridization with the mixture of corresponding complementary sequences labeled with Fluorescein, Cy5, and Texas Red, respectively. The fluorescence is color-coded: blue for fluorescein, yellow for Cy5, and red for Texas Red.

design of "labs on a chip". Besides, the microfluidic capillary format offers a number of advantages over the planar format, including smaller sample volume and higher surface-to-volume ratio.

The glass capillary tube was silanized with **1** by adapting the procedure described above. Trichloroethylene was used instead of toluene, as the latter caused the degradation of the fused-capillary. The photocleavage of NPPOC was carried out by irradiation at 365 nm for varying time periods on an inverted microscope equipped with a mercury lamp (100 W) and a 365 nm interference filter. The length of the irradiated zone was adjusted at 150 μm by a slit aperture. In this way, irradiation to liberate the surface-bound aminooxy group was performed only at the preselected portions of the tube. The surface immobilization was carried out by dipping the extremity of the capillary tube in a 0.4 M ammonium acetate buffer solution containing the oligonucleotide-5′-aldehyde (**Seq1**). The capillary tube containing the surface-immobilized oligonucleotides was then dipped in the hybridization solution containing the Cy3-labeled complementary sequence for **Seq1**. After several washings with SSC buffer to remove the unhybridized complementary sequences, the capillary tubes were scanned using a fluorescent scanner (Figure 2A). The results from hybridization experiments clearly showed the fluorescence spot localized at the irradiated portion of the capillary tube. The photodeprotection was found to be rapid, as an irradiation time of 2 s was sufficient to give measurable response. It was noted that prolonged irradiation times resulted in some enlargement of the zone compared to the size of the irradiated zone due to light scattering. Two control experiments were performed by using a quencher (acetone) of the aminooxy group liberated during the photodeprotection as well as by using for the immobilization step an oligonucleotide, which does not contain the complementary aldehyde reactive group for oxime bond formation. In these two cases, no significant signal was clearly observed at the irradiated position, thus demonstrating the specificity of the method. Thus, site-selective immobilization of DNA was accomplished even in the closed environment of a capillary tube.

The efficiency and robustness of the process developed herein was next investigated by achieving sequential surface immobilization of three different oligonucleotide sequences inside the same capillary tube. A set of three different aldehyde-containing oligonucleotide sequences, **Seq1**, **Seq2**, and **Seq3**, respectively, were arrayed inside the same capillary tube by repeating the protocol described in the present work. Briefly, the capillary tube was silanized with **1**. The silanized tube was irradiated at certain preselected positions, and this was followed by the surface immobilization of the **Seq1** oligonucleotide sequence. After subsequent washing to remove free oligonucleotides, the process was repeated at certain other preselected positions of the same capillary tube to carry out surface immobilization of oligonucleotide sequences **Seq2** and **Seq3**, respectively. Thus, the surface immobilization of three different oligonucleotides was accomplished inside the same capillary tube. Then a mixture of the three oligonucleotide sequences complementary to **Seq1**, **Seq2**, and **Seq3** was run through the arrayed capillary tube. The three sequences complementary to **Seq1**, **Seq2**, and **Seq3** were labeled with Fluorescein, Cy5, and Texas Red, respectively. The complementary sequences labeled with different fluorescent probes were used to facilitate the simultaneous detection of three hybridization events inside the same capillary tube. The tube was next scanned at different wavelengths corresponding to the three labels on the complementary strand (Figure 2B). The results showed that the complementary labeled sequences were able to hybridize with their targets, as evident from the probe-specific fluorescence emission at predetermined immobilization sites inside the capillary tube (Figure 2B, also see the Supporting Information). These hybridization experiments thus unambiguously demonstrated the selective surface immobilization of different oligonucleotides **Seq1**, **Seq2**, and **Seq3** at the predefined position inside the tube. No side reactions were observed during the repetitive flow of aldehyde-containing oligonucleotide through the capillary tube.

CONCLUSION

Thus, an efficient protocol for surface patterning of oligonucleotides was developed. The efficiency of the present method was demonstrated by carrying out the surface immobilization of oligonucleotides on surfaces of glass slides and inside the capillary tubes. The robustness of the process was further demonstrated by achieving the surface immobilization of up to three different oligonucleotide sequences at predetermined positions inside the same capillary tube. The present method reported herein is simple and convenient. It involves the preparation of surfaces grafted with aminooxy moieties masked with a photocleavable protecting group. A short irradiation at

365 nm cleaves the photocleavable protecting group thereby unmasking the aminooxy functions at preselected positions on the surface. Deposition of aldehyde-containing oligonucleotides on surfaces results in the formation of oxime bonds between aldehyde functionality of the oligonucleotide and the surface-bound aminooxy moieties, thereby leading to an efficient surface immobilization of oligonucleotides. Since the oxime ligation has been used for the preparation of oligonucleotide, peptide, and carbohydrate bioconjugates, it should be possible to extend the present strategy to the preparation of carbohydrate and peptide arrays. Finally, the immobilization protocol reported herein could also be explored as an efficient and alternative approach to design "lab on a chip" devices.

ACKNOWLEDGMENT

This work was supported by the "Centre National de la Recherche Scientifique" (CNRS) and the "Commissariat à l'Energie Atomique" (CEA). We are grateful to NanoBio program for the facilities of the Synthesis and Surface Characterization platforms. We thank Dr. Y. Singh for careful reading of this manuscript and Prof. P. Labbé for help with the surface characterization.

Received August 21, 2006; Revised Manuscript Received December 7, 2006

Tumor-associated glycoprotein-72 (TAG-72) is overexpressed in a high percentage of epithelial cancers and has proven useful as a target for imaging and targeted radiotherapy. Our goal was to express a recombinant Fab (rFab) of the TAG-72 monoclonal antibody CC49 in *Pichia pastoris* and directly compare its tumor and normal tissue uptake and imaging properties with enzymatically generated Fab (eFab). In this study, the genes coding for CC49 Fab were cloned from hybridoma cells and expressed in *P. pastoris*. Fab was purified to homogeneity and its immunoreactivity toward bovine submaxillary mucin (TAG-72) confirmed by ELISA. The tumor and normal tissue localization of ^{123}I-CC49 rFab and eFab were compared in athymic mice bearing s.c. LS174T colon cancer or TAG-72-negative A375 melanoma xenografts. Results showed that pure and immunoreactive rFab of CC49 was produced and labeled with ^{123}I. At 24 h post i.v. injection (p.i.), tumor uptake for ^{123}I-rFab in LS174T xenografts was 6.0% ID/g which was 18-fold higher than in A375 tumors. Tumor-to-normal tissue ratios increased between 2 and 24 h and exceeded 5:1 at 24 h p.i. of ^{123}I-rFab. ^{123}I-rFab exhibited significantly lower liver uptake at 12 h p.i. and lower kidney uptake at 2 h p.i. than ^{123}I-eFab. LS174T tumors were imaged as early as 2 h after administration of ^{123}I-rFab. We conclude that CC49 rFab can be produced in a *P. pastoris* host system and accumulated at comparable levels as eFab in LS174T colon cancer xenografts in mice. The lower liver uptake of ^{123}I-rFab as compared with eFab suggests that it may be more useful for imaging liver lesions. No major effect, except for kidneys and liver, was observed on tumor and normal tissue uptake due to introduction of hexahistidine and FLAG affinity tags or peptide linkers in the scaffold of rFab.

INTRODUCTION

Monoclonal antibodies (mAbs) directed against tumor-associated antigens overexpressed on the surface of tumor cells can deliver radionuclides to tumors for imaging. Small antibody fragments such as Fab or scFv are particularly suitable for this purpose because these fragments extravasate more efficiently, penetrate more deeply into tumor nodules, and clear more rapidly from the body compared with intact IgG, leading to higher tumor-to-normal tissue uptake ratios at early times (*1*−*3*). The utility of antibody fragments in tumor imaging is exemplified by anti-carcinoembryonic antigen (CEA) arcitumomab (CEA-Scan, Immunomedics Inc, Morris Plains NJ), which consists of Fab′ of murine anti-CEA IgG labeled with ^{99m}Tc (*4*). ^{99m}Tc-labeled arcitumomab has been used for imaging colorectal and breast cancers (*5*−*7*).

Tumor-associated glycoprotein-72 (TAG-72) (*8*) is an epithelial mucin overexpressed in a high percentage of colorectal, ovarian, gastric, and breast cancers (*9*). CC49 is a murine high-affinity, second-generation TAG-72 mAb which has been conjugated to radionuclides for radioimmunodetection and radioimmunotherapy in patients with primary and metastatic TAG-72-positive cancers (*10*−*16*). Engineered scFv-based antibody fragments of CC49 have been reported (*17*−*19*). The very fast clearance of these CC49 scFvs from the blood suggested that small antibody fragments are attractive agents for imaging TAG-72-positive tumors. Recombinant scFv-based antibody fragments are technically favored over fragments containing interchain disulfide bonds such as Fab in part because the heterologous expression of scFv is more convenient and the yield is higher. In comparison with scFvs however, Fab is thermodynamically more stable because of the interchain disulfide bond and mutual stabilization between the V_H/V_L and C_H1/C_L interface. In addition, Fab is kinetically more stable than scFv as manifested by a slow unfolding rate, which renders Fab more resistant to denaturation (*20*, *21*). Although murine Fab has the potential to be immunogenic in humans, the incidence of human anti-mouse antibody (HAMA) response reported from several studies in practice is very low (less than 2%) (*2*, *22*).

In this study, we report for the first time the synthesis of recombinant Fab (rFab) of monoclonal antibody CC49 in a heterologous *Pichia pastoris* expression system and their tumor targeting properties compared to enzymatically generated Fab (eFab) produced by proteolytic digestion of CC49 IgG. Our rationale for producing the rFab was several fold. First, we were interested in evaluating the ability of the *P. pastoris* expression system to produce rFab of antitumor antibodies. Second, we were interested in evaluating the effects of affinity tags that are often incorporated into recombinant antibodies (including the

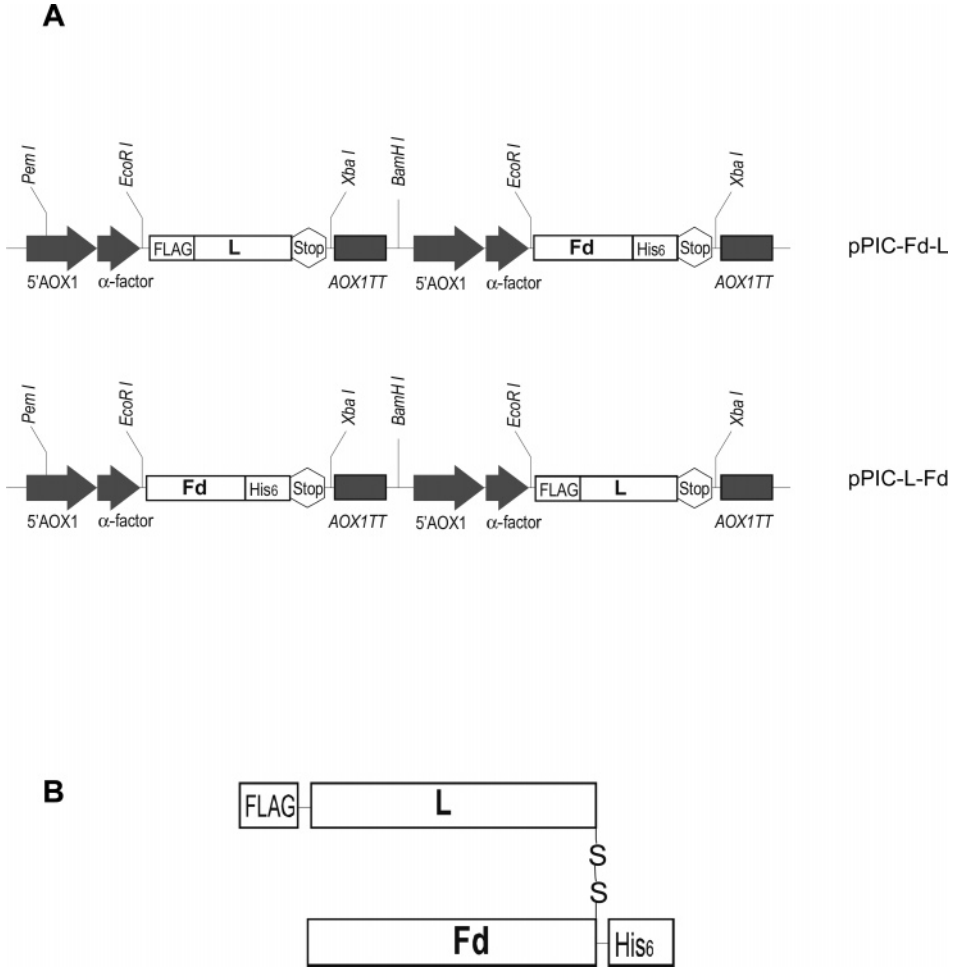

Figure 1. (A) Linear representation of coexpression plasmids pPIC-Fd-L and pPIC-L-Fd. **(B)** Schematic representation of rFab. A FLAG tag (amino acid sequence DYKDDDDK) is fused to the N-terminus of L through a linker sequence (GGGGS); A His_6 tag (amino acid sequence HHHHHH) was fused to the C-terminus of Fd through a GGGGS linker. L and Fd are covalently linked by a disulfide bond.

rFab) on their tumor and normal tissue localization. Third, we were interested in designing a method of producing Fab fragments of CC49 that would be more reproducible than that of enzymatic digestion of IgG, which is fraught with risk for heterogeneous generation of Fab with low molecular weight contaminating peptides as well as smaller fragments and residual intact IgG. Finally, although in the current study the rFab and eFab were radiolabeled with ^{123}I, we speculated that the generation of rFab of CC49 with an incorporated His_6 tag may allow radiolabeling in the future with ^{99m}Tc(I)carbonyl complexes as described by Waibel et al. (*23*).

EXPERIMENTAL PROCEDURES

Materials. The CC49 hybridoma cell line was provided by Dr. J. Schlom at the U.S. National Cancer Institute (Bethesda MD). The hybridoma secretes murine CC49 $IgG_{1,\kappa}$. *E. coli* TOP10F′ (Invitrogen, San Diego, CA) was used for cloning, subcloning, and propagation of plasmids. KM71H (*aox1::ARG4, arg4*) strain of *P. pastoris* was used as the host for protein expression. The pCR 2.1 vector (Invitrogen) was used for cloning the genes encoding the light chain (L) and Fd of the heavy chain from the hybridoma cells; the pPICZαA (Invitrogen) vector containing an α-factor secretion-signal peptide was used to construct coexpression plasmids for rFab expression. *Taq* and *Pfx* DNA polymerases (Invitrogen) were used for polymerase chain reaction (PCR). Restriction enzymes and ligases were from New England Biolabs Ltd. (Beverly, MA). Nickel-nitrilotriacetic acid (Ni-NTA) agarose was from Qiagen Inc. (Valencia, CA). Immobilized Protein-A was from Pierce (Rockford, IL). All oligonucleotide primers for PCR were synthesized by ACGT Corporation (Toronto, ON).

Expression of rFab in *P. pastoris* and Purification. The pPIC-Fd-L or pPIC-L-Fd plasmids (supplemental experimental procedures and Figure S1 in Supporting Information) were linearized at the unique *Pme I* site in the first 5′*AOX1* promoter region before electrotransforming *P. pastoris* KM71H cells using a MicroPulser electroporator (Bio-Rad, Hercules, CA). The transformed KM71H cells were selected for resistance to Zeocin (100 μg/mL) on YPD agar plates (1% yeast extract, 2% peptone, 2% dextrose, and 2% agar). Transformed clones were grown at 30 °C in buffered glycerol-complex medium to an optical density of $OD_{600} = 10$ and then were transferred to buffered methanol-complex medium at a cell density of 15% (w/w, wet cell weight) to induce protein expression. The methanol concentration and induction time were optimized. At the time point of maximum rFab yield determined by ELISA (see Supporting Information), the culture was centrifuged at 3000*g* for 15 min at 4 °C to isolate the supernatant containing secreted rFab.

rFab was precipitated from the culture supernatant by adding ammonium sulfate to 50% saturation at 25 °C (31.3 g ammonium sulfate per 100 mL of supernatant). rFab was purified by affinity chromatography on a Ni-NTA agarose (Qiagen) column. Protein bound to the column was eluted with 100 mM imidazole in 20 mM Tris-HCl and 0.5 M NaCl, pH 8.0. The eluate was buffer-exchanged into PBS, pH 7.0, using Centricon YM-30 ultrafiltration devices (Amicon, Billerica, MA; M_r cutoff 30 kDa).

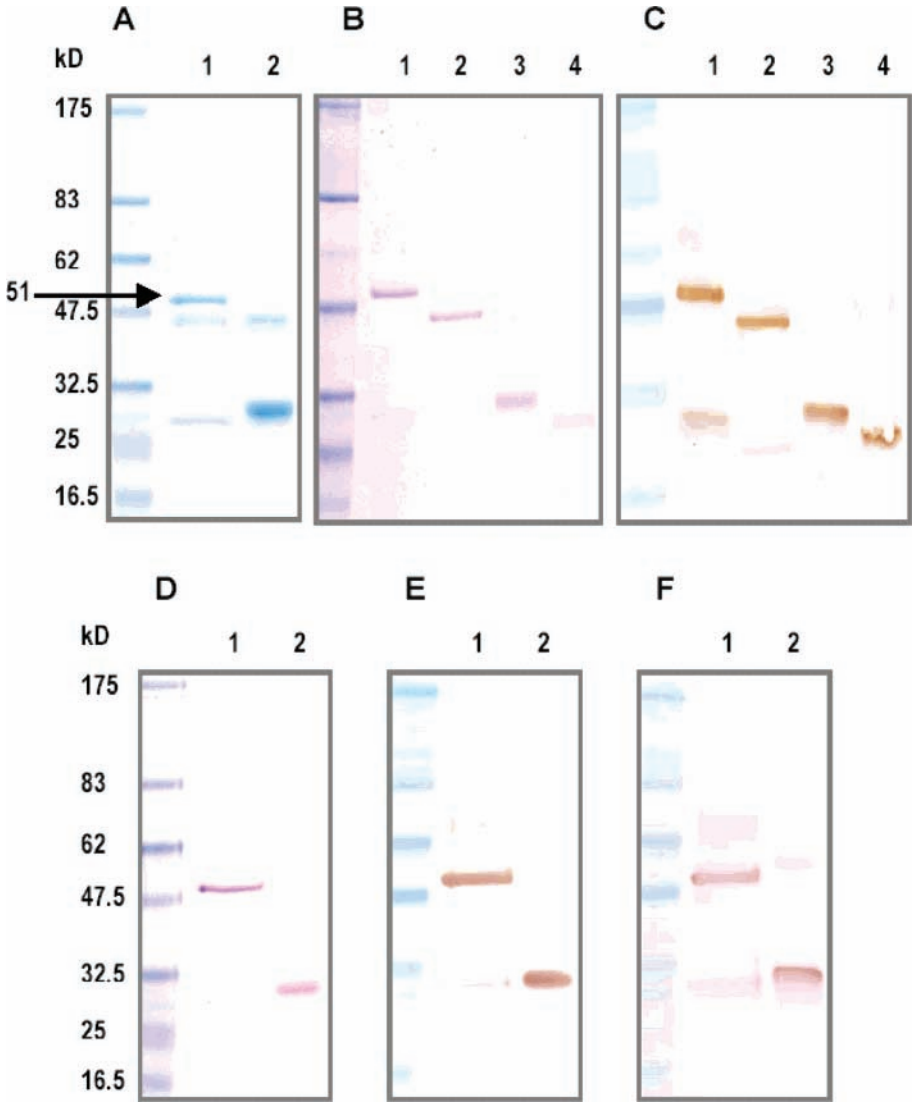

Figure 2. (A) Coomassie-stained SDS-PAGE gel of the crude culture supernatant collected at 48 h after methanol induction. The unpurified sample was concentrated five times and electrophoresed under nonreducing (lane 1) and reducing (β-mercaptoethanol, lane 2) conditions on a 4−20% Tris-HCl gradient gel. **(**B**)** SDS-PAGE comparison of purified rFab (lanes 1 and 3) and papain-produced Fab (lanes 2 and 4) of CC49 under nonreducing (lanes 1 and 2) and reducing (lanes 3 and 4) conditions. **(**C**)** Western blot of purified rFab (lanes 1 and 3) and papain-produced Fab (lanes 2 and 4) of CC49 under nonreducing (lanes 1 and 2) and reducing (lanes 3 and 4) conditions. The proteins were probed with a goat-anti mouse Fab. **(**D**)** Coomassie-stained SDS-PAGE gel of rFab under nonreducing (lane 1) and reducing (lane 2) conditions. **(**E**)** Western blot of purified rFab under nonreducing (lane 1) and reducing (lane 2) conditions. Proteins were probed with tetra-histidine antibody. **(**F**)** Western blot of purified rFab under nonreducing (lane 1) and reducing (lane 2) conditions. Proteins were probed with FLAG M2 antibody.

Enzymatic Preparation of CC49 Fab. Fab fragments of CC49 were prepared by proteolysis of CC49 IgG using immobilized papain (Pierce). After digestion, the supernatant was purified on immobilized Protein-A (Pierce). Purified enzymatically produced Fab (eFab) was buffer-exchanged into PBS, pH 7.0, using Centricon YM-30 ultrafiltration devices.

Analysis of the Purity of rFab. The identity and purity of CC49 rFab was assessed by SDS-PAGE, Western blot, and size-exclusion high performance liquid chromatography (HPLC). For SDS-PAGE, rFab (1−2 μg) was electrophoresed under reducing (β-mercaptoethanol) and nonreducing conditions on a 4−20% Tris-HCl gradient mini-gel (Bio-Rad, Mississauga, ON) stained with Coomassie brilliant blue R-250 (Bio-Rad). Western blot was performed using a panel of horseradish peroxidase (HRP)-conjugated antibodies as probes, including goat anti-mouse Fab (Sigma), anti-tetra-histidine (Qiagen), and anti-FLAG M2 (Sigma). Each antibody was diluted at 1:2000 in PBS/0.5% Tween-20. rFab was also analyzed by size-exclusion HPLC on a BioSep SEC-S2000 column (Phenomenex Inc, Torrance, CA) eluted with 100 mM NaH_2PO_4 buffer, pH 7.0, at a flow rate of 0.8 mL/min using a System Gold Model 125 HPLC interfaced with a Model 166 UV detector (Beckman-Coulter, Mississauga, ON) set at 280 nm.

Protein Concentration. The molar extinction coefficient for rFab at 280 nm [$\epsilon = 75\,560$ cm^{-1} M^{-1}, equivalent to $E = 1.49$ cm^{-1} (mg/mL)$^{-1}$] was calculated (*24*) based on the amino acid sequence for CC49 Fab (*25*−*28*). The protein concentration was measured spectrophotometrically at 280 nm.

Immunoreactivity of CC49 rFab with TAG-72. The ability of rFab or eFab to displace the binding of ^{111}In-labeled CC49 IgG to bovine submaxillary mucin (BSM), a source of TAG-72 (*29*), was measured. CC49 IgG was labeled with ^{111}In (MDS-Nordion, Kanata, ON) to a specific activity of 237 kBq/μg (6.4 μCi/μg) following derivatization with diethylenetriaminepentaacetic acid (DTPA) as previously reported (*30*). Each well of Immulon2 HB strips (Dynex Technologies Inc., Chantilly, VA) was coated with 20 ng of BSM in 100 μL of PBS, pH 7.0, at 4 °C overnight. Nonspecific binding was blocked by 5% BSA in PBS, pH 7.0. rFab or eFab (1.0 or 2.5 μM) in 40 μL of PBS containing 1% BSA was added in duplicate, then ^{111}In-CC49

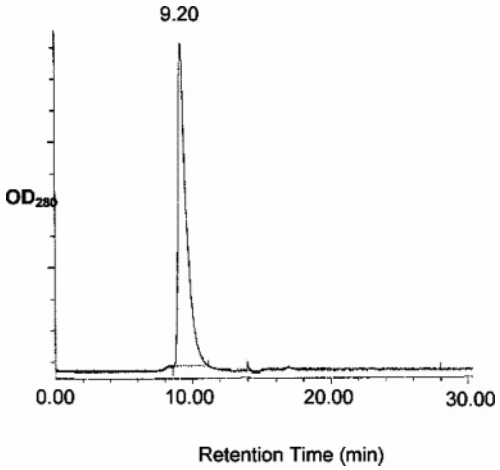

Figure 3. Size-exclusion HPLC of purified rFab of CC49. The solid line represents UV absorbance at 280 nm. rFab was detected as a single peak with a retention time of t_R 9.2 min.

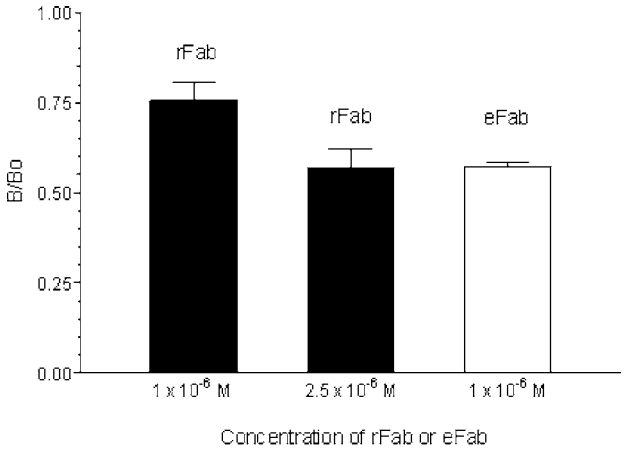

Figure 4. Comparison of the displacement of the binding of ^{111}In-labeled CC49 IgG to bovine submaxillary mucin (a source of TAG-72 antigen) coated onto wells in a microELISA plate by 1.0 or 2.5 $\times$ 10^{-6} M rFab or eFab. B/B_o represents the ratio of radioactivity bound in the presence compared to absence of rFab or eFab

IgG (50 000 CPM) at a final concentration of 5 nM in 40 μL of PBS was added in each well. After incubation at room temperature for 2 h, the wells were rinsed with PBS and the radioactivity bound measured in a γ-counter.

Tissue Distribution and Imaging of TAG-72-Positive Xenografts in Mice. The tumor and normal tissue distribution of ^{123}I-labeled rFab or eFab were evaluated in female athymic mice bearing s.c. LS174T human colon cancer (TAG-72 positive) and A375 human melanoma (TAG-72 negative) xenografts (*17*). Four-week-old BALB/c nu/nu athymic mice (Charles River, Wilmington, MA) were injected s.c. with 1 $\times$ 10^6 LS174T cells in the right flank and with 2 $\times$ 10^6 A375 cells in the left flank. rFab and eFab were labeled with ^{123}I using the Iodogen method (*31*) and then purified on a protein desalting spin column (Pierce). The radiochemical purity (RCP) of ^{123}I-rFab or eFab was >98% by paper chromatography (Whatman No. 1, Maidstone, England) developed in 85% methanol (R_f ^{123}I-Fab: 0.0; R_f ^{123}I- iodide). The specific activity of ^{123}I-rFab and eFab were 37 kBq/μg. At 10−14 days when the implanted tumors reached 5−8 mm in diameter, the mice were injected i.v. (tail vein) with 15 μg of ^{123}I-rFab or eFab (0.5 MBq). The mice received Lugol's iodine solution in their drinking water 2 days prior to radiopharmaceutical injection to attempt to block thyroid accumulation of radioiodine. Groups of three mice were sacrificed at 2, 6, 12, and 24 h postinjection (p.i.). Tumors and samples of normal tissues were collected and weighed, and their radioactivity content was measured in a γ-counter. Radioactivity uptake was expressed as percent injected dose per gram (% ID/g) and as tumor-to-normal tissue (T/NT) ratios. In a separate study, tumor-bearing mice were injected i.v. with 3 MBq (15 μg) of ^{123}I-rFab. Posterior whole body images were obtained up to 24 h p.i. using a small field-of-view gamma-camera fitted with a 4-mm pinhole collimator (ADAC Model TransCam, ADAC Laboratories Inc., Milpitas, CA). The principles of Laboratory Animal Care (NIH Publication No. 86-23, revised 1985) were followed, and animal studies were conducted under a protocol approved by the Animal Care Committee at the University Health Network (No. TG: 00-026) following Canadian Council on Animal Care (CCAC) guidelines.

Statistical Comparisons. Statistical significance was assessed using an unpaired, two-tailed Student's *t*-test or one-way ANOVA ($P < 0.05$).

RESULTS

Construction of Coexpression Plasmids To Express rFab of CC49. The genes coding for the L chain and the Fd chain up to the first cysteine residue in the hinge region of the heavy chain that forms the disulfide bond with the L chain were cloned (supplemental experimental procedures in Supporting Information). A coexpression plasmid based on the *P. pastoris* secretion vector pPICZαA was constructed to coexpress the L and Fd chains of CC49 (Figure 1). In the plasmid (pPIC-L-Fd or pPIC-Fd-L, Figure 1A), the expression of the L and Fd chains was driven individually by a methanol-inducible 5′*AOX1* promoter.

Expression of CC49 rFab in *P. pastoris* in a Shake Flask. CC49 rFab was expressed in *P. pastoris* strain KM71H transformed with plasmid pPIC-L-Fd or pPIC-Fd-L. L and Fd chains were expressed as separate polypeptides, assembled into rFab in the cells through the formation of a disulfide bond between L and Fd peptide chains and then secreted into the culture medium as folded rFab (Figure 1B). Two transformants Clone #24-5 (pPIC-Fd-L) and Clone #5-3 (pPIC-L-Fd) resulted in the greatest rFab expression as measured by ELISA, and a large-scale expression was carried out in a 500 mL Erlenmeyer flask over 48 h induced with 1% methanol added to the culture medium every 12 h. The yield of purified rFab in shake-flask expression was 1−2 mg/L determined by measuring the OD_{280}.

Purity of CC49 rFab. The crude culture supernatant containing expressed rFab was collected after methanol induction. The supernatant was concentrated five times before being electrophoresed under nonreducing (Figure 2A, lane 1) and reducing (β-mercaptoethanol, Figure 2A, lane 2) conditions on a 4−20% Tris-HCl gradient gel. After purification, the SDS-PAGE gel revealed a single band at M_r 51 kDa (Figure 2B, lane 1). This apparent molecular weight (M_r) was consistent with the calculated M_r based on the amino acid sequence of CC49 rFab (*25*−*28*). This band at M_r 51 kDa dissociated into a single band at 30 kDa under reducing conditions (Figure 2B, lane 3). Western blot revealed that both the 51 kDa and 30 kDa bands were reactive with goat anti-mouse Fab antibodies (Figure 2C, lanes 1 and 3). The 51 kDa and 30 kDa bands (Figure 2D) were also reactive with antibodies directed against tetra-histidine (Figure 2E) identifying the His_6 tag at the C-terminus of the Fd chain and were reactive with anti-FLAG antibodies (Figure 2F) identifying the FLAG tag at the N-terminus of the L chain. These results confirmed that the 51 kDa protein was rFab and contained an intermolecular disulfide bond covalently linking the L and Fd chains. For comparison, SDS-PAGE analysis (Figure 2B, lanes 2 and 4) and Western blot (Figure 2C, lanes 2 and 4) of eFab prepared by proteolytic digestion of CC49 IgG using immobilized papain are shown. The slightly greater M_r for rFab compared with eFab (M_r 51 kDa vs 48 kDa) was

[a] Tissue distribution was expressed as % ID /g. T/NT: Tumor (LS174T)-to-normal tissue ratios. Values are mean ± SE ($n = 3$ mice/time point).

expected because the rFab included a His_6 tag, a FLAG tag, and the GGGGS linker (Figure 1B), which contributed 2.8 kDa to the molecular mass. Size-exclusion HPLC (Figure 3) showed a single peak with a retention time (t_R) of 9.2 min corresponding to rFab.

Immunoreactivity of CC49 rFab with TAG-72. rFab competed with ^{111}In-CC49 IgG for binding to BSM, a source of TAG-72 antigen (Figure 4). The specific binding of ^{111}In-CC49 IgG to TAG-72 was reduced to 76 ± 5.1% by 1.0×10^{-6} M rFab and to 57 ± 5.2% by 2.5×10^{-6} M rFab. A 2.5-fold lower concentration of eFab (1.0×10^{-6} M) was required to reduce the binding of ^{111}In-CC49 IgG to 57 ± 1.4% (Figure 4), indicating that the affinity of rFab for TAG-72 was 2- to 3-fold lower than that of rFab.

Tissue Distribution and Imaging of TAG-72-Positive Xenografts in Mice. ^{123}I-rFab accumulated in LS174T xenografts reaching a level of 12.9 ± 2.2% ID/g at 2 h p.i. (Table 1). Tumor retention of ^{123}I-rFab decreased from 10.1 ± 2.1% ID/g at 6 h to 7.4 ± 0.9% ID/g at 12 h p.i. ($P > 0.05$ compared with that at 2 h) and to 6.0 ± 0.3% ID/g at 24 h p.i. ($P = 0.04$ compared with that at 2 h). In contrast, the retention of ^{123}I-rFab in control TAG-72-negative A375 tumors was significantly lower at all time points ($P < 0.05$) and decreased more than 16 fold between 2 and 24 h p.i. ^{123}I-rFab was rapidly eliminated from the blood. By 24 h p.i., the blood concentration decreased 13 fold compared to that at 2 h p.i. (1.1 ± 0.07 vs 14.7 ± 1.73, $P < 0.01$). The greatest tissue uptake occurred in the kidneys at 2 h p.i. (32.3 ± 4.9% ID/g). The specific accumulation of ^{123}I-rFab in LS174T tumors was reflected in the T/NT ratios (Table 1). The ratios of tumor (LS174T) to all tissues including the TAG-72-negative A375 tumors increased from 2 to 24 h p.i. For example, the tumor/blood (T/B) ratio increased from 0.9 ± 0.1 at 2 h p.i. to 5.2 ± 0.1 at 24 h ($P < 0.0001$). At 24 h p.i. the ratio of radioactivity in LS174T to that in A375 tumors was 18.0 ± 1.2. Uptake of ^{123}I-rFab in LS174T tumors (Table 1) was not significantly different than that of ^{123}I-eFab (Table 2; $P > 0.05$). Interestingly, the uptake of ^{123}I-eFab in the kidneys was significantly greater at 2 h than that of ^{123}I-rFab (89.1 ± 4.8 vs 32.3 ± 4.9 %ID/g, $P < 0.01$) but was similar to that of ^{123}I-rFab at later times ($P > 0.05$). T/NT ratios were similar for ^{123}I-rFab and ^{123}I-eFab except for a much higher tumor/kidney ratio at 2 h ($P < 0.001$) as well as greater tumor/liver and tumor/spleen ratios at 12 h after injection ($P < 0.05$) for ^{123}I-rFab. LS174T xenografts were clearly imaged as early as 2 h after injection of ^{123}I-rFab, whereas similarly sized A375 tumor could not be differentiated from the body background (Figure 5).

DISCUSSION

The second-generation, high-affinity TAG-72 monoclonal antibody CC49 has proven to be one of the most clinically useful antitumor antibodies for radioimmunoimaging and radioimmunotherapy of solid tumors (*10*−*17*). In this study, we generated rFab of CC49 using a *P. pastoris* expression system and directly compared its tumor and normal tissue localization properties with those of enzymatically generated CC49 Fab (eFab) in athymic mice implanted s.c. with LS174T human colon cancer xenografts. To our knowledge, such a direct comparison of eFab and rFab of an antitumor monoclonal antibody has never been reported, despite the potential that genetically engineered antibodies may demonstrate altered binding affinities and tissue distribution due to their incorporated affinity tags (e.g., polyhistidine) or other modifications. The CC49 rFab differs from eFab in that rFab contains a His_6 tag, a FLAG tag, and the GGGGS peptide linkers. Despite a 2-to-3-fold lower TAG-72-binding affinity for rFab *in vitro*, both rFab and eFab exhibited a similar pattern of tumor retention and tissue distribution in tumor-bearing mice except in the liver and kidneys.

Kidney retention of ^{123}I-rFab was significantly lower than that of ^{123}I-eFab (32.3 ± 4.9 vs 89.1 ± 4.8% ID/g, $P < 0.01$)

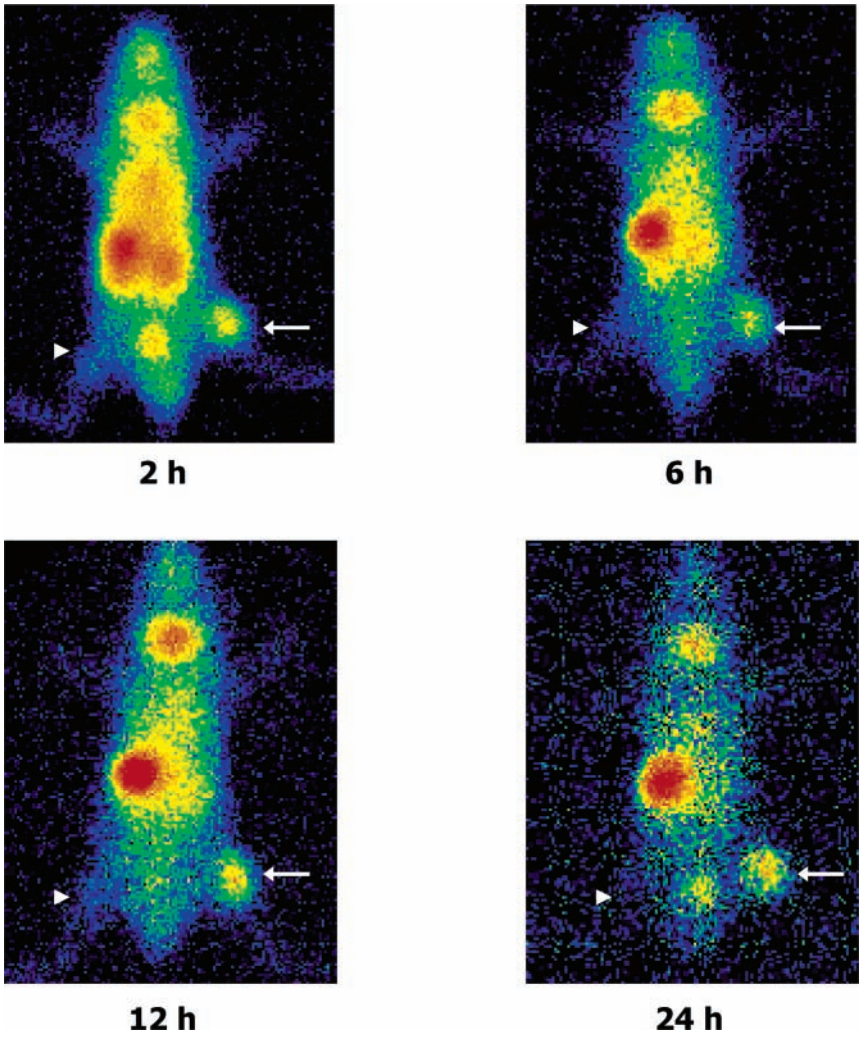

Figure 5. Posterior whole body image of a representative athymic mouse bearing a s.c. TAG-72-overexpressing LS174T human colon cancer xenograft on the right flank (white arrow). A s.c. TAG-72-negative A375 human melanoma xenograft on the left flank (arrowhead only) served as the negative control tumor. Each mouse was injected i.v. with 15 μg of ^{123}I-rFab (3 MBq) and imaged at 2, 6, 12, and 24 h p.i. The series of images were obtained from the same mouse. 250 000, 100 000, 100 000, and 50 000 counts were collected at 2, 6, 12, and 24 h p.i., respectively.

at 2 h p.i., but the difference was not significant at later times, i.e., 6 and 12 h ($P > 0.05$). The reason for the lower initial kidney uptake of ^{123}I-rFab may be related to the net negative charges introduced by the FLAG tag. It was previously reported that introduction of three negatively charged amino acids reduced the kidney retention of radioiodinated CC49 scFv fragments at early time points after administration to mice bearing s.c. LS174T xenografts (*32*). It was proposed that changes in the isoelectric point (pI) could affect kidney uptake. However, the difference in kidney uptake among three CC49 scFv variants, i.e., scFv[pI 8.1], scFv[pI 5.8], and scFv[pI 5.2], was not statistically significant except at 0.5 h p.i. At this time, the scFv with the lowest pI [pI 5.2] showed the highest kidney uptake, whereas scFv with intermediate pI [pI 5.8] had the lowest uptake (*32*). It appears, therefore, that pI did not correlate directly with kidney uptake among the three scFv variants that were studied. The pI values of eFab and rFab were not measured in our study, but the theoretical pI values were calculated using the Swiss-Prot database (*33*) based on the amino acid sequences. These pI values were 6.3 for eFab and 7.6 for rFab. His_6 was also reported to affect the blood clearance and kidney retention of a radioiodinated $(scFv)_2$ of CC49. The blood clearance for the His_6-tagged $(scFv)_2$ was slightly slower while the kidney retention was lower at early time points (20.0 and 14.8 %ID/g at 0.5 and 1 h p.i., respectively) than that for $(scFv)_2$ (41.2 and 24.7 %ID/g at 0.5 and 1 h p.i., respectively) (*18*). In our study, the liver retention of ^{123}I-rFab was lower than that of ^{123}I-eFab and the tumor-to-liver ratio was higher for ^{123}I-rFab at all times examined. The reason for the lower liver uptake of ^{123}I-rFab is not known, but this finding suggests that it could be more useful than ^{123}I-eFab for scintigraphic detection of hepatic lesions.

The blood concentration of ^{123}I-rFab at 12 h was higher than that of ^{123}I-eFab (3.0 ± 0.2 vs 2.1 ± 0.2% ID/g, $P < 0.05$). However, this did not significantly lower the T/B ratio for ^{123}I-rFab compared to ^{123}I-eFab (2.4 ± 0.2 vs 2.8 ± 0.5, respectively, $P > 0.05$) because the tumor uptake for ^{123}I-rFab was higher. In short, the 3-fold lower TAG-72 binding affinity for rFab than eFab *in vitro* failed to translate into any significant difference in tumor accumulation. Consistent with this finding, it was previously noted that a 320-fold decrease in K_d of an anti-HER2/neu scFv resulted in only a 7-fold increase in tumor accumulation in mice (*34*). These and other observations indicate that *in vitro* receptor-binding affinity is not the sole determinant of the accumulation of antibody fragments in tumors (*35*, *36*). Nevertheless, it has been reported that increased avidity by means of engineering bivalent, dimeric $(scFv)_2$ (M_r 54 000) improved tumor retention 2 to 36-fold at 24 h p.i. compared to monovalent scFv (M_r 27 000) in mice (*37*, *38*). T/B ratios between divalent $(scFv)_2$ and monovalent scFv, however, were similar (*37*, *38*). The enhanced tumor retention of divalent

$(scFv)_2$ was likely a combined result of higher avidity, and prolonged residence time as a result of the larger molecular size (*37*, *38*).

Schlom's group and others studied the tumor retention and tissue distribution in mice bearing LS174T xenografts of radioiodinated Fab′ produced by pepsin digestion of CC49 IgG. The tumor retention of radioiodinated Fab′ was 3.9 to 6.2% ID/g at 6 h p.i.; it was 2.9 to 3.7% ID/g at 24 h (*17*, *19*). This level of tumor retention is lower than that observed in our study for ^{123}I-rFab (10.1 ± 2.1% ID/g at 6 h; 6.0 ± 0.3% ID/g at 24 h) or ^{123}I-eFab (8.4 ± 0.2% ID/g at 6 h). It was noted that the size of LS174T tumor xenografts in our study was similar to that previously used by Schlom's group (0.5−0.8 cm diameter) to evaluate the tumor uptake of CC49 Fab′. The blood concentration was also much lower for radioiodinated Fab′ (0.9−1.68 and 0.1 %ID/g at 6 and 24 h, respectively) than observed in our study for ^{123}I-rFab (5.3 and 1.1 %ID/g at 6 and 24 h, respectively) (*17*, *19*). It is unclear whether the slight differences in amino acid sequences between Fab′ and rFab, or between Fab′ and eFab, may be responsible for these disparities in biodistribution and blood clearance, because in our study, mice were injected with a higher dose of rFab or eFab (15 μg/mouse) than previously examined for Fab′ (<10 μg/mouse) (*17*, *19*). Nonlinear, dose-dependent pharmacokinetics have been reported clinically for the HER2/neu monoclonal antibody, trastuzumab (Herceptin). In these studies, there was a decreased rate of serum clearance with increasing doses (*39*).

It has been generally assumed that small affinity tags do not have a major effect on the biological/immunological properties of a biomolecule (*40*). The affinity tags, i.e., His_6 and FLAG, did not appear to yield major differences in the tumor and normal tissue distribution and imaging properties of ^{123}I-labeled CC49 rFab compared to eFab. The safety of the FLAG tag in patients is unknown, but the His_6 tag has been shown to be safe for human administration (*1*). Besides its usefulness for affinity chromatographic purification of rFab, the His_6 tag also presents a site for labeling the rFab with the ^{99m}Tc (I)-tricarbonyl complex (*23*) or with ^{94m}Tc for positron-emission tomography (PET) (*41*). It would also be possible to label the rFab with ^{124}I instead of ^{123}I for PET (*42*, *43*).

CONCLUSIONS

In summary, pure and immunoreactive rFab fragments of the second-generation, high-affinity TAG-72 monoclonal antibody CC49 were generated in *P. pastoris* that have excellent tumor-targeting properties. The specific accumulation of ^{123}I-labeled CC49 rFab in TAG-72-positive LS174T human colon cancer xenografts and its rapid clearance from the blood and most normal tissues suggest that it would be useful for imaging colorectal cancer and other tumors expressing TAG-72. The significantly lower liver accumulation of CC49 rFab compared to eFab observed in this study suggests that CC49 rFab may provide greater sensitivity for the detection of liver lesions. Incorporation of His_6 and FLAG affinity tags did not intefere with tumor targeting, although rFab exhibited a 2−3 fold lower binding affinity for TAG-72.

ACKNOWLEDGMENT

This study was funded by a grant from a Diagnostic and Surgical Breast Imaging award (DAMD17-00-1-0595) to R.M.R., by a predoctoral fellowship (DAMD17-03-1-0372) to Y.T. from the U.S. Army Breast Cancer Research Program, and by a grant from the Ontario Research and Development Challenge Fund. J.G. is supported by the Canadian Breast Cancer Research Alliance. The authors wish to thank Dr. Jeffery Schlom at the U.S. National Cancer Institute (Bethesda, MD) for providing the CC49 hybridoma.

Received August 24, 2006; Revised Manuscript Received January 9, 2007

A novel fluorescent photoprobe for the imaging of endothelin A receptors (ET_AR) was developed. Based on the nonpeptidyl, high-affinity, and selective ET_AR antagonist 3-benzo[1,3]dioxol-5-yl-5-hydroxy-5-(4-methoxyphenyl)-4-(3,4,5-trimethoxybenzyl)-5*H*-furan-2-one (PD 156707), a modification of the lead structure with a PEG-spacer containing an amino moiety was performed. Labeling of this precursor with the fluorescent marker Cy 5.5 NHS-ester was accomplished by adaption of common peptide labeling procedures. The affinity of the Cy 5.5-labeled receptor antagonist was evaluated using human carcinoma cell lines with different degrees of ET_AR expression. Fluorescence microscopy revealed that ET_AR-positive MCF-7 human breast adenocarcinoma and HT-1080 human fibrosarcoma cells effectively bind the photoprobe at very low doses (nM), while ET_AR-negative MDA-MB-435 human breast cancer cells showed no fluorescence signal. Binding specificity of the probe could be demonstrated by predosing with a specific ET_AR antibody or the parent antagonist PD 156707 as a competing inhibitor. The results suggest that the modified photoprobe tightly binds to ET_A receptors and thus may be a possible candidate for the imaging of ET_AR-overexpressing tissues *in vivo*.

INTRODUCTION

Endothelin (ET) was first described by Hickey et al. (*1*) and subsequently isolated by Yanagisawa et al. (*2*) as a 21-amino acid peptide with vasoactive potency. Since their discovery, the role of the endothelins in several diseases, including cardiovascular, inflammatory, and renal diseases, has increasingly been investigated (*3*−*8*). More recently, the role of endothelin as a progression factor in human tumor cell lines has been discussed (*9*−*11*).

ETs and their receptors have been found to contribute to tumorigenesis and tumor progression through autocrine and paracrine pathways. Of the three ET isoforms, ET-1 has been the most extensively studied, and appears to be the most important isoform in cancer pathophysiology. Increased expression of ET-1 has been demonstrated in several human malignancies (*12*−*14*) including breast carcinoma (*15*, *16*). The most important ET-1 binding receptor, the endothelin A receptor (ET_AR), mediates tumorigenesis and tumor progression by activation of tumor proliferation (*13*), invasion (*17*), angiogenesis (*18*), and inhibition of apoptosis (*19*, *20*).

Accordingly, increased ET_AR expression has been demonstrated in various cancers, whereas in normal tissue the endothelin B receptor (ET_BR) subtype predominates (*13*, *14*, *21*). In view of these data, ET_AR has been suggested as a novel target for anticancer therapy in several malignancies with ET dysregulation including breast cancer. In preclinical studies, pharmacological blockade of the ET_A receptor has been shown to inhibit the growth of ovarian and cervix carcinoma cell xenografts (*22*, *23*). Atrasentan (ABT-627, Abbott Laboratories, IL), an orally bioavailable ET_AR antagonist, has been shown to be effective in patients with advanced androgen-refractory prostate carcinoma (*24*, *25*). Moreover, in breast cancer an altered ET system has been described (*15*, *26*) including an overexpression of ET-1, ET_AR, and ET_BR in human breast carcinomas (*16*, *27*), where expression of ET_AR indicated a poor outcome (*16*) as well as chemotherapy resistance (*28*).

In this context, a method for the visualization of ET receptor density in affected tissue would be invaluable for clinical diagnosis and the evaluation of therapy. While radiolabeling of ET receptor agonists and antagonists for the use in single photon emission computed tomography (SPECT) or positron emission tomography (PET) has been reported (*29*−*34*) none of the approaches have been utilized for the imaging of ET receptors in humans *in vivo*.

Varying the labeling strategy to fluorochrome-based molecules is an alternative to scintigraphic imaging techniques since it is relatively inexpensive, free of ionizing radiation and isotope decay, and applicable for tomographic (e.g., fluorescence-mediated tomography, FMT) and surface-weighted (e.g., fluorescence reflectance imaging, FRI) imaging techniques. Optical imaging techniques allow the detection of molecules in picomolar (10^{-12} M) concentrations, which is comparable to conventional scintigraphic imaging techniques and about 6 orders of magnitude more sensitive than MRI. Besides high signal-to-noise ratios (SNRs) imaging in the near-infrared (λ = 650 nm to 950 nm) shows very efficient tissue penetration as the absorption by water and hemoglobin is relatively low ('diagnostic window') (*35*, *36*).

In this study we describe the synthesis of an ET_AR ligand based on PD 156707 (Figure 1, *37*). A polyethylene glycol (PEG) spacer group containing an amino functionality was inserted to enable labeling with fluorescent dyes without changing the ET_A binding domain. The conjugation of the fluorescent dye Cy 5.5 was accomplished by using a recommended labeling procedure (Amersham Biosciences UK Limited, Buckinghamshire, UK). A model compound with a shorter PEG spacer and a phthalimidoyl-protecting group was synthe-

sized and used in a biochemical affinity assay to evaluate the binding potencies of such modified compounds toward ET receptors. PD 156707 was also synthesized and used as a competing ligand and for comparison of the affinity values. The Cy 5.5-labeled ligand was used in *in vitro* binding assays with ET_A-positive MCF-7 human breast adenocarcinoma cells and HT-1080 human fibrosarcoma cells as well as with ET_A-negative MDA-MB-435 human breast cancer cells. An ET_AR-specific antibody and PD 156707 were used to test specific binding of the ET_AR-selective photoprobe.

EXPERIMENTAL SECTION

Materials and Methods. All chemicals, reagents, and solvents for the synthesis of the compounds were analytical grade and purchased from commercial sources. PD 156707 and 2-(1,3-benzodioxol-5-yl)-1-(4-benzyloxyphenyl)-4-oxobutyric acid methyl ester **3** were synthesized as reported (*37*). 2-{2-[2-(2-Azidoethoxy)ethoxy]ethoxy)ethyl methanesulfonate **7** was prepared according to the procedure described by Tahtaoui et al. for the PEG_3 derivative (*38*). Melting points (uncorrected) were determined on a Stuart Scientific SMP3 capillary melting point apparatus. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker ARX 300 or AMX 400 (Bruker BioSpin GmbH, Rheinstetten, Germany) or a Varian 500 MHz INOVA spectrometer (Varian Deutschland GmbH, Darmstadt, Germany), respectively. Mass spectrometry was performed using a Varian MAT 212 (EI = 70 eV, Varian Deutschland GmbH, Darmstadt, Germany), a Bruker MALDI-TOF-MS Reflex IV (matrix: DHB, Bruker Daltonics GmbH, Bremen, Germany), or a QUATTRO LCZ (Waters Micromass, Manchester, UK) spectrometer with a nanospray capillary inlet. Elemental analysis was realized by a Vario EL III analyzer (Elementar Analysensysteme GmbH, Hanau, Germany).

Cell Lines and Reagents. Human breast adenocarcinoma cell line MCF-7 (ATCC-No. HTB-22), MDA-MB-435 human breast carcinoma cells (ATCC-No. HTB-123), and HT-1080 human fibrosarcoma cells (ATCC-No. CCL-121) were cultured in RPMI 1640 (Invitrogen Corporation, San Diego, CA) supplemented with 10% fetal calf serum, penicillin, and streptomycin. Cells were grown routinely in a monolayer culture at 37 °C in a 5% CO_2 humidified air atmosphere. Polyclonal ET_AR antibody (N-15) was purchased from Santa Cruz (Santa Cruz Biotechnology, Santa Cruz, CA).

Synthetic Organic Chemistry. *4,5-Dimethoxy-3-{2-[2-(2-phthalimidoylethoxy)ethoxy]ethoxy}benzaldehyde **2**.* A solution of 500 mg (2.75 mmol) of 4,5-dimethoxy-3-hydroxybenzaldehyde **1** and 860 μL (1.03 g, 5.50 mmol) of 1,2-bis(2-chloroethoxy)ethane in 20 mL of DMF was treated with 2.24 g (6.88 mmol) of cesium carbonate and heated to 55 °C for 20 h. After cooling, the mixture was poured into 100 mL of ice−water and extracted with chloroform. The organic extracts were washed twice with 50 mL water and with brine, dried over sodium sulfate, and evaporated. The resulting yellow oil was flash-chromatographed (petroleum ether/ethyl acetate 2/1) to yield 3-{2-[2-(2-chloroethoxy)ethoxy]ethoxy}-4,5-dimethoxybenzaldehyde (730 mg, 2.20 mmol, 80%), which was directly used for the next synthesis step.

The residue from the above step and 414 mg (2.20 mmol) of phthalimide potassium salt were dissolved in 25 mL of DMF and stirred at 50 °C for 68 h. After hydrolysis with 50 mL of ice−water, the mixture was extracted with chloroform, and the combined organic phases were washed with water and brine and dried over sodium sulfate. Evaporation of the solvent yielded 932 mg of a yellow oil, which was purified by silica gel column chromatography (petroleum ether/ethyl acetate 1/1). The desired product accrued as a colorless oil (595 mg, 1.34 mmol, 61%). ^{1}H NMR ($CDCl_3$) δ = 9.85 (s, 1H), 7.83 (m, 2H), 7.69 (m, 2H), 7.12 (m, 2H), 4.16 (m, 2H), 3.93 (s, 3H), 3.92 (s, 3H), 3.89 (m, 2H), 3.83 (m, 2H), 3.75 (m, 2H), 3.67 (m, 4H) ppm. ^{13}C NMR δ = 190.9, 168.2, 153.8, 152.9, 144.4, 133.9, 132.2, 131.6, 123.2, 109.3, 106.6, 70.8, 70.3, 69.7, 69.0, 68.0, 61.0, 56.4, 37.3 ppm. MS: m/z = 466 $[M + Na]^+$, 443 $[M]^+$. Anal. calcd for $C_{23}H_{25}NO_8$: C 62.30, H 5.68, N 3.16. Found C 61.97, H 5.76, N 3.10.

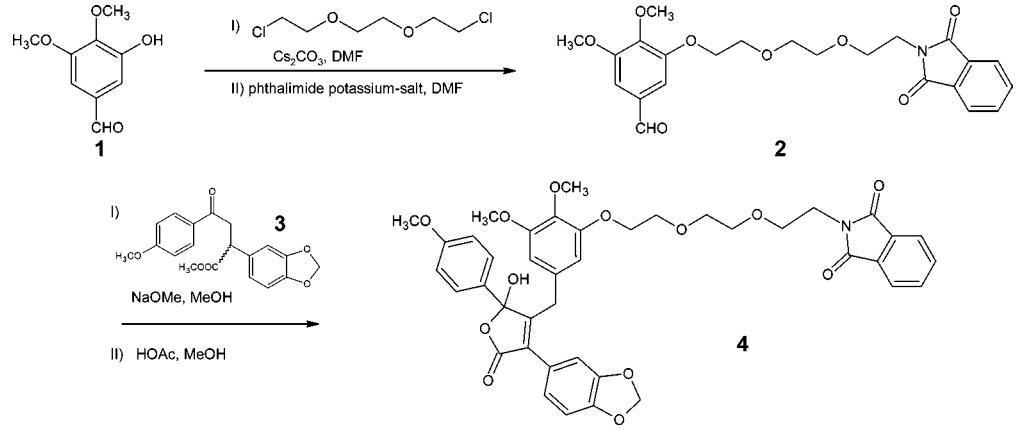
*3-Benzo[1,3]dioxol-5-yl-4-(4,5-dimethoxy-3-{2-[2-(2-phthalimidoylethoxy)ethoxy]ethoxy}benzyl)-5-hydroxy-5-(4-methoxyphenyl)-5H-furan-2-one **4**.* A mixture of 887 mg (2.00 mmol) of 4,5-dimethoxy-3-{2-[2-(2-phthalimidoylethoxy)ethoxy]ethoxy}-benzaldehyde **2**, 689 mg (2.10 mmol) 2-(1,3-benzodioxol-5-yl)-1-(4-methyoxyphenyl)-4-oxobutyric acid methyl ester **3** and 120 mg (2.20 mmol) of sodium methoxide were dissolved in 20 mL of methanol at 0 °C and then heated to reflux for 12 h under an argon atmosphere. Acetic acid was added (1.0 mL), and the mixture was heated to reflux for another 6 h. After cooling to room temperature, the mixture was poured into 50 mL of water and extracted with ethyl acetate. The combined organic extracts were successively washed with water and brine and dried over sodium sulfate. After evaporation of the solvent, a yellow oil remained which was purified by silica gel column chromatography (petroleum ether/ethyl acetate 2/1 > 1/1 > 1/2). Yield: 800 mg (1.06 mmol, 53%). ^{1}H NMR ($CDCl_3$) δ = 7.80 (m, 2H), 7.67 (m, 2H), 7.38 (m, 2H), 6.92 (m, 2H), 6.79 (m, 3H), 6.13 (d, 1H, J = 2.0 Hz), 5.98 (d, 1H, J = 2.0 Hz), 5.94 (s, 2H), 3.87 (m, 4H), 3.77 (s, 3H), 3.73 (m, 2H), 3.71 (s, 3H), 3.69 (m, 2H), 3.64 (m, 2H), 3.62 (s, 3H), 3.61 (s, 4H) ppm. The proton of the butenolide hydroxy group was not detected. ^{13}C NMR δ = 171.1, 168.4, 160.4, 160.3, 153.0, 152.2, 148.1, 147.7, 143.7, 137.3, 134.0, 132.1, 131.8, 129.0, 128.2, 127.5, 123.3, 123.2, 123.1, 113.9, 109.5, 108.4, 108.2, 106.4, 101.3, 70.7, 70.2, 69.8, 68.6, 67.9, 60.7, 55.9, 55.3, 37.4, 32.1 ppm. MS: m/z = 792 $[M + K]^+$, 776 $[M + Na]^+$, 753 $[M]^+$, 736 $[M - OH]^+$. HRMS: Calcd. for $C_{41}H_{39}NO_{13}Na^+$ 776.2314, found 776.2303.

*3-{2-[2-(2-{2-Azidoethoxy}ethoxy)ethoxy]ethoxy}-4,5-dimethoxybenzaldehyde **8**.* A mixture of 5.22 g (17.55 mmol) of 2-{2-[2-(2-azidoethoxy)ethoxy]ethoxy}ethyl methanesulfonate **7**, 3.20 g (17.55 mmol) of 3,4-dimethoxy-5-hydroxybenzaldehyde **1**, and 11.5 g (35.20 mmol) of cesium carbonate in 120 mL of DMF was heated at 50 °C for 17 h. The mixture was poured into 100 mL of saturated aqueous ammonium chloride solution and extracted with methylene chloride. The combined organic layers were washed with water and brine, dried over $MgSO_4$, and evaporated. The residue was purified by silica gel column chromatography (toluene/ethyl acetate 1/1), yielding 4.58 g (11.95 mmol, 68%) of the product as a clear yellow oil. ^{1}H NMR ($CDCl_3$) δ = 9.77 (s, 1H), 7.09 (d, 1H, J = 2.2 Hz), 7.06 (d, 1H, J = 2.2 Hz), 4.17 (m, 2H), 3.88 (s, 3H), 3.85 (s, 3H), 3.83 (m, 2H), 3.66 (m, 2H), 3.60 (m, 8H), 3.30 (t, 2H, J = 5.4 Hz) ppm. ^{13}C NMR δ = 190.7, 153.6, 152.7, 144.2, 131.5, 109.0, 106.4, 70.7, 70.6, 70.5 (2 signals), 69.8, 69.5, 68.8, 60.8,

56.1, 50.5 ppm. MS: m/z = 383 $[M]^+$. Anal. calcd for $C_{17}H_{25}N_3O_7$: C 53.26, H 6.57, N 10.96. Found C 53.15, H 6.66, N 10.99.

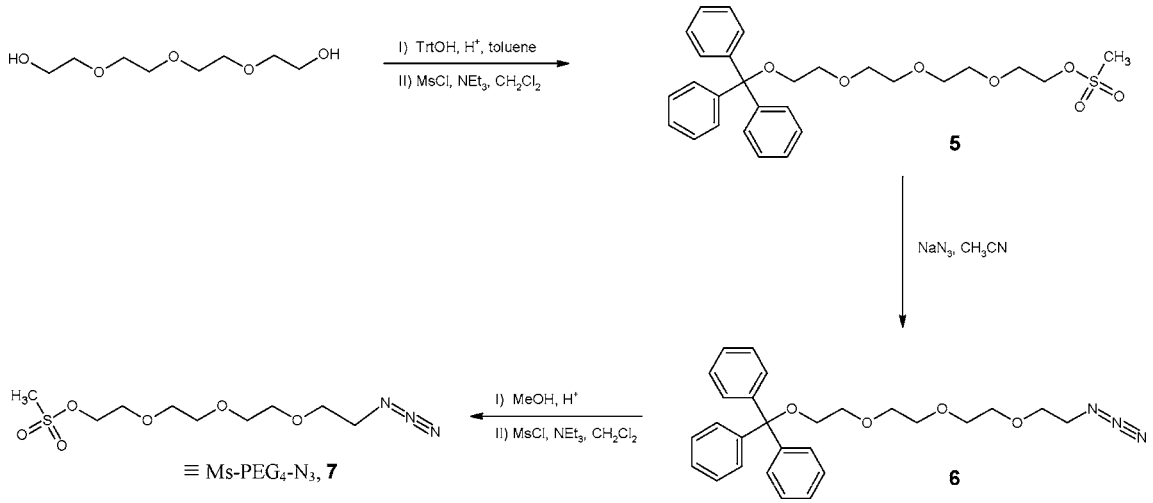
3-Benzo[1,3]dioxol-5-yl-4-(3-(2-{2-[2-(2-azidoethoxy)ethoxy]-ethoxy}ethoxy)-4,5-dimethoxybenzyl)-5-hydroxy-5-(4-methoxy-phenyl)-5H-furan-2-one ***9***. A mixture of 1.16 g (3.00 mmol) of 3-(2-{2-[2-(2-azidoethoxy)ethoxy]ethoxy}ethoxy)-4,5-dimethoxy-benzaldehyde **8**, 1.10 g (3.20 mmol) of 2-(1,3-benzodioxol-5-yl)-1-(4-methoxyphenyl)-4-oxobutyric acid methyl ester **3**, and 216 mg (4.00 mmol) of sodium methoxide in 20 mL of methanol was heated to reflux for 15 h under an argon atmosphere. Acetic acid was added (1.5 mL), and the mixture was heated to reflux for further 5 h. After cooling, the mixture was poured into 50 mL of water and extracted with ethyl acetate. The combined organic extracts were successively washed with water and brine and dried over sodium sulfate. After evaporation of the solvent, a yellow oil remained, which was purified by silica gel column chromatography (diisopropyl ether/acetone 3/1). Yield: 1.49 g (2.15 mmol, 72%). ^{1}H NMR ($CDCl_3$) δ = 7.60 (m, 2H), 7.13, (m, 2H), 7.03 (m, 3H), 6.25 (s, 1H), 6.22 (s, 1H), 6.17 (s, 2H), 4.17 (m, 2H), 4.00 (s, 3H), 3.96 (s, 3H), 3.94−3.80 (m, 17H), 3.57 (m, 2H) ppm. The proton of the butenolide hydroxy group was not detected. ^{13}C NMR δ = 171.0, 160.4, 160.3, 153.0, 152.1, 148.1, 147.7, 137.2, 131.7, 128.9, 128.1, 127.4, 123.1, 123.0, 113.9, 109.4, 108.3, 108.1, 106.3, 105.7, 101.3, 70.6 (2 signals), 70.5, 69.9, 69.7, 68.6, 68.4, 60.7, 55.9, 55.3, 50.6, 32.0 ppm. MS: m/z = 732 $[M + K]^+$, 716 $[M + Na]^+$, 693 $[M]^+$, 676 $[M - OH]^+$, 668 $[M - N_2]^+$. Anal. calcd for $C_{35}H_{39}N_3O_{12}$: C 60.60, H 5.67, N 6.06. Found C 60.50, H 5.90, N 5.69.

3-Benzo[1,3]dioxol-5-yl-4-(3-(2-{2-[2-(2-aminoethoxy)ethoxy]-ethoxy}ethoxy)-4,5-dimethoxybenzyl)-5-hydroxy-5-(4-methoxy-phenyl)-5H-furan-2-one ***10***. A mixture of 1.49 g (2.15 mmol) of 3-benzo[1,3]dioxol-5-yl-4-(3-(2-{2-[2-(2-azidoethoxy)ethoxy]-ethoxy}ethoxy)-4,5-dimethoxybenzyl)-5-hydroxy-5-(4-methoxy-phenyl)-5*H*-furan-2-one **9** and 1.00 g (3.00 mmol) of polymer-bound PPh_3 (polystyrene, 2% DVB, Fluka) was suspended in 10 mL of THF and stirred at room temperature overnight. Water was added (200 μL, ≈10 mmol) and stirring was continued for 3 days. The polymer was removed by filtration and the filtrate was evaporated in vacuo. The remaining oil was purified by silica gel column chromatography (EtOAc/MeOH/NEt_3 5/1/0.3), yielding 246 mg of the product (0.37 mmol, 17%). ^{1}H NMR ($CDCl_3$) δ = 7.32 (d, 2H, J = 8.1 Hz), 6.83, (m, 2H), 6.75 (d, 2H, J = 8.1 Hz), 6.68 (d, 1H, J = 7.7 Hz), 6.14 (s, 1H), 5.91 (s, 1H), 5.85 (s, 2H), 3.88 (m, 2H), 3.70 (s, 4H), 3.64 (s, 3H), 3.59 (m, 4H), 3.54 (s, 3H), 3.48 (m, 4H) 3.37 (m, 2H), 3.15 (m, 2H) ppm. The protons of the butenolide hydroxy group and the amino function were not detected. ^{13}C NMR δ = 171.2, 160.8, 160.1, 152.8, 151.9, 147.9, 147.5, 137.2, 131.8, 129.2, 127.8, 127.4, 123.2, 123.1, 113.7, 109.4, 108.5, 108.2, 106.6, 106.0, 101.2, 70.6, 70.4, 70.3, 70.2, 69.8, 69.7, 68.6, 60.6, 55.8, 55.2, 40.0, 32.0 ppm. MS: m/z = 690 $[M + Na]^+$, 668 $[M + H]^+$. Elemental or HRMS analysis could not be obtained from this product.



2-(3-{2-[2-(2-{2-Azidoethoxy}ethoxy)ethoxy]ethoxy}-4,5-dimethoxyphenyl)-1,3-dioxolane ***11***. A mixture of 4.95 g (12.91 mmol) of 3-{2-[2-(2-{2-azidoethoxy}ethoxy)ethoxy]ethoxy}-4,5-dimethoxybenzaldehyde **8**, 5 mL (5.57 g, 90 mmol) of ethylene glycol, and 200 mg (1.0 mmol) of *p*-toluene sulfonic acid monohydrate was refluxed in 120 mL of toluene for 8 h using a Dean−Stark trap. After cooling to room temperature, the reaction mixture was poured into 200 mL of diluted sodium bicarbonate solution, washed with water and brine, and dried over magnesium sulfate. After removal of the solvent, the residue was purified by silica gel column chromatography (cyclohexane/ethyl acetate 1/1), giving 4.43 g (10.8 mmol, 80%) of the product as a clear oil. ^{1}H NMR ($CDCl_3$) δ = 6.73 (dd, 2H, J = 5.0 Hz, J = 1.8 Hz), 5.72 (s, 1H), 4.19 (m, 2H), 4.11 (m, 2H), 4.03 (m, 2H), 3.87 (s, 3H), 3.84 (s, 3H), 3.76−3.71 (m, 4H), 3.70−3.64 (m, 8H), 3.37 (m, 2H) ppm. ^{13}C NMR δ = 153.3, 152.4, 139.2, 133.1, 105.4, 103.6, 103.4, 70.7, 70.6, 70.5 (2 signals), 69.9, 69.6, 68.7, 65.1, 60.6, 56.0, 50.6 ppm. MS: m/z = 427 $[M]^+$. Anal. calcd for $C_{19}H_{29}N_3O_8$: C 53.39, H 6.84, N 9.83. Found C 52.30, H 6.89, N 9.72.

2-(3-{2-[2-(2-{2-Aminoethoxy}ethoxy)ethoxy]ethoxy}-4,5-dimethoxyphenyl)-1,3-dioxolane ***12***. Fifty milligrams of Pd/C were added to a solution of 7.18 g (16.8 mmol) of 2-(3-{2-[2-(2-{2-azidoethoxy}ethoxy)ethoxy]ethoxy}-4,5-dimethoxyphe-nyl)-1,3-dioxolane **11** in 100 mL of ethanol. The mixture was stirred at ambient temperature under a hydrogen atmosphere overnight, filtered, and purified by silica gel column chroma-tography to give 5.69 g (14.2 mmol, 84%) of the product as a clear oil. ^{1}H NMR ($CDCl_3$) δ = 6.73 (dd, 2H, J = 5.2 Hz, J = 1.7 Hz), 5.72 (s, 1H), 4.19 (m, 2H), 4.11 (m, 2H), 4.02 (m, 2H), 3.86 (s, 3H), 3.84 (s, 3H), 3.87−3.85 (m, 2H), 3.75−3.69 (m, 2H), 3.69−3.59 (m, 6H), 3.57 (t, 1H, J = 5.4 Hz), 3.49 (t, 1H, J = 5.4 Hz), 2.84 (t, 1H, J = 5.2 Hz), 2.79 (t, 1H, J = 5.2 Hz), 1,74 (br, 2H) ppm. ^{13}C NMR δ = 153.2, 152.3, 139.1, 133.0, 105.3, 103.5, 103.3, 73.2, 70.6, 70.5, 70.4, 70.1, 69.5, 68.6, 65.0, 60.5, 55.9, 41.6 ppm. MS: m/z = 424 $[M + Na]^+$, 402 $[M + H]^+$. HRMS: Calcd for $C_{19}H_{32}NO_8^+$ 402.2122, found 402.2122.



N-Boc-2-(3-{2-[2-(2-{2-Aminoethoxy}ethoxy)ethoxy]ethoxy}-4,5-dimethoxyphenyl)-1,3-dioxolane ***13***. A solution of 4.27 g (10.0 mmol) of 2-(3-{2-[2-(2-{2-aminoethoxy}ethoxy)ethoxy]-ethoxy}-4,5-dimethoxyphenyl)-1,3-dioxolane **12** and 1.66 mL (12.0 mmol) of triethylamine in 50 mL of methylene chloride was cooled in an ice bath. A 2.40 g (11.0 mmol) amount of di-*tert*-butyl dicarbonate was dissolved in 20 mL of methylene chloride and added dropwise. The mixture was warmed to room temperature and stirred overnight. After evaporation of the solvent, the residue was purified by silica gel column chroma-tography (cyclohexane/ethyl acetate 1/2), yielding 2.51 g (5.0 mmol, 50%) of the product as a clear oil. ^{1}H NMR ($CDCl_3$) δ = 6.73 (dd, 2H, J = 4.3 Hz, J = 1.7 Hz), 5.73 (s, 1H), 5.07 (br, 1H), 4.20 (m, 2H), 4.12 (m, 2H), 4.03 (m, 2H), 3.87 (s, 3H), 3.84 (s, 3H), 3.74 (m, 2H), 3.70−3.60 (m, 8H), 3.53 (t, 2H, J = 5.3 Hz), 3.30 (m, 2H), 1.44 (s, 9H) ppm. ^{13}C NMR δ = 153.9, 153.2, 152.3, 139.0, 133.0, 105.1, 103.6, 103.4, 79.0, 70.7, 70.5, 70.4, 70.1, 70.0, 69.6, 68.6, 65.1, 60.6, 56.0, 40.3, 28.3 ppm. MS: m/z = 501 $[M]^+$, 444 $[M - C_4H_9]^+$. Anal. calcd for $C_{24}H_{39}NO_{10}$: C 57.47, H 7.84, N 2.79. Found C 57.25, H 7.94, N 2.79.

N-Boc-3-{2-[2-(2-{2-Aminoethoxy}ethoxy)ethoxy]ethoxy}-4,5-dimethoxybenzaldehyde ***14***. A solution of 2.00 g (3.99 mmol) of *N*-Boc-2-(3-{2-[2-(2-{2-aminoethoxy}ethoxy)ethoxy]-ethoxy}-4,5-dimethoxyphenyl)-1,3-dioxolane **13** in 50 mL of acetone was treated with iodine (100 mg, 10% n/n) and stirred at room temperature for 60 min. Acetone was removed and replaced by ethyl acetate. The organic phase was washed with diluted sodium thiosulfate solution, water, and brine and dried over magnesium sulfate. After removal of the solvent, 1.17 g (3.74 mmol, 94%) of a slightly yellow oil remained. ^{1}H NMR ($CDCl_3$) δ = 9.85 (s, 1H), 7.16 (d, 1H, J = 1.8 Hz), 7.13 (d, 1H, J = 1.8 Hz), 5.00 (br, 1H), 4.25 (m, 2H), 3.95 (s, 3H), 3.92 (s, 3H), 3.89 (m, 2H), 3.74 (m, 2H), 3.70−3.59 (m, 6H), 3.53 (t, 2H, J = 5.0 Hz), 3.30 (t, 2H, J = 5.0 Hz), 1.44 (s, 9H) ppm. ^{13}C NMR δ = 190.9, 155.9, 153.7, 152.8, 144.3, 131.6, 109.1, 106.6, 79.1, 70.8, 70.6, 70.5, 70.2, 70.1, 69.6, 69.0, 60.9, 56.2, 40.5, 28.3 ppm. MS: m/z = 480 $[M + Na]^+$, 358 $[M - (COO^tBuH_2)]^+$. HRMS: Calcd. for $C_{22}H_{35}NO_9Na^+$ 480.2204, found 480.2203.

N-Boc-3-Benzo[1,3]dioxol-5-yl-3-(2-{2-[2-(2-aminoethoxy)-ethoxy]ethoxy}ethoxy)-4,5-dimethoxybenzyl)-5-hydroxy-5-(4-methoxyphenyl)-5H-furan-2-one ***15***. A solution of 5.76 g (12.6 mmol) of 3-(2-{2-[2-(2-aminoethoxy)ethoxy]ethoxy}ethoxy)-4,5-dimethoxybenzaldehyde **14**, 4.31 g (12.6 mmol) of 2-(1,3-benzodioxol-5-yl)-1-(4-methoxyphenyl)-4-oxobutyric acid methyl ester **3**, and 756 mg (14.00 mmol) of sodium methoxide were dissolved in 120 mL of methanol at 0 °C and then heated to reflux for 72 h under an argon atmosphere. Acetic acid was added (2.0 mL), and the mixture was heated to reflux for a further 7 h. After evaporation of the solvent, the residue was partitioned between water and ethyl acetate. The organic layer was successively washed with water and brine and dried over sodium sulfate. After evaporation of the solvent a yellow oil remained which was purified by silica gel column chromatography (cyclohexane/ethyl acetate 1/2). Yield: 7.21 g (9.39 mmol, 75%). ^{1}H NMR ($CDCl_3$) δ = 7.74 (d, 2H, J = 8.8 Hz), 6.96−6.91 (m, 2H), 6.83 (d, 2H, J = 8.8 Hz), 6.79 (d, 1H, J = 7.5 Hz), 6.15 (s, 1H), 5.99 (s, 1H), 5.96 (s, 2H), 5.67 (br, 1H), 5.11 (br, 1H), 3.96−3.92 (m, 2H), 3.85−3.80 (m, 2H), 3.79 (s, 3H), 3.74 (s, 3H), 3.71−3.68 (m, 2H), 3.67−3.57 (m, 8H), 3.62 (s, 3H), 3.50 (t, 2H, J = 5.1 Hz), 3.30−3.22 (m, 2H), 1.41 (s, 9H) ppm. ^{13}C NMR δ = 171.0, 160.5, 160.1, 156.1, 152.8, 152.0, 148.0, 147.6, 137.0, 131.8, 129.0, 127.9, 127.4, 123.1, 123.0, 113.8, 109.4, 108.3, 107.9, 106.1, 105.8, 101.2, 79.2, 70.6, 70.5, 70.4, 70.1 (2 signals), 69.7, 68.5, 60.7, 60.4, 55.8, 55.3, 32.1, 28.4 ppm. MS: m/z = 790 [M + Na]$^+$, 668 [M − (COO*t*BuH_2)]$^+$. HRMS: Calcd for $C_{40}H_{49}NO_{14}Na^+$ 790.3045, found 790.3032. Anal. calcd for $C_{40}H_{49}NO_{14}$: C 62.57, H 6.43, N 1.82. 3-Benzo[1,3]dioxol-5-yl-3-(2-{2-[2-(2-aminoethoxy)ethoxy]-ethoxy}ethoxy)-4,5-dimethoxybenzyl)-5-hydroxy-5-(4-methoxy-phenyl)-5H-furan-2-one (TFA salt, ***16****).* A solution of 4.59 g (5.98 mmol) of the Boc-protected butenolide **15** in 25 mL of methylene chloride was cooled in an ice bath. Trifluoroacetic acid (TFA, 8.0 mL, dissolved in 10.0 mL of methylene chloride) was added dropwise over a period of 30 min. Stirring was continued for 30 min at 0 °C and another 60 min at room temperature. The solvent and excess TFA was removed under vacuum. The remaining viscous oil was treated with methanol and water (10 mL, 2/1) and again evaporated to dryness. An off-white foam remained which did not deliquesce if cooled to 4 °C. Yield: 4.66 g (5.97 mmol, 99%). ^{1}H NMR (DMSO-d_6) δ = 8.04 (br, 3H), 7.55 (d, 2H, J = 8.8 Hz), 7.12−7.08 (m, 3H), 7.07 (d, 2H, J = 8.8 Hz), 6.18 (d, 2H, J = 1.5 Hz), 6.15 (s, 1H), 6.13 (s, 1H), 4.00−3.93 (m, 2H), 3.91 (s, 3H), 3.88−3.80 (m, 4H), 3.79−3.74 (m, 6H), 3.73 (s, 3H), 3.70 (s, 3H), 3.64 (s, 4H), 3.15 (q, 2H, J = 5.5 Hz) ppm (the protons of the ammonium and hydroxy functions were not detected). ^{13}C NMR δ = 170.7, 161.4, 159.6, 158.3 (q, $J_{C,F}$ = −35 Hz), 152.2, 151.3, 147.3, 146.9, 135.9, 131.7, 129.1, 127.6, 126.6, 123.3, 123.0, 116.2 (q, $J_{C,F}$ = −295 Hz), 113.6, 109.3, 108.1, 107.2, 106.3, 105.7, 101.2, 69.9, 69.8, 69.7, 69.6, 68.8, 67.8, 66.7, 59.8, 55.4, 55.1, 38.6, 31.4 ppm. ^{19}F NMR δ = −74.4 ppm. HRMS: Calcd. for $C_{35}H_{42}NO_{12}^+$ 668.2702, found 668.2707.

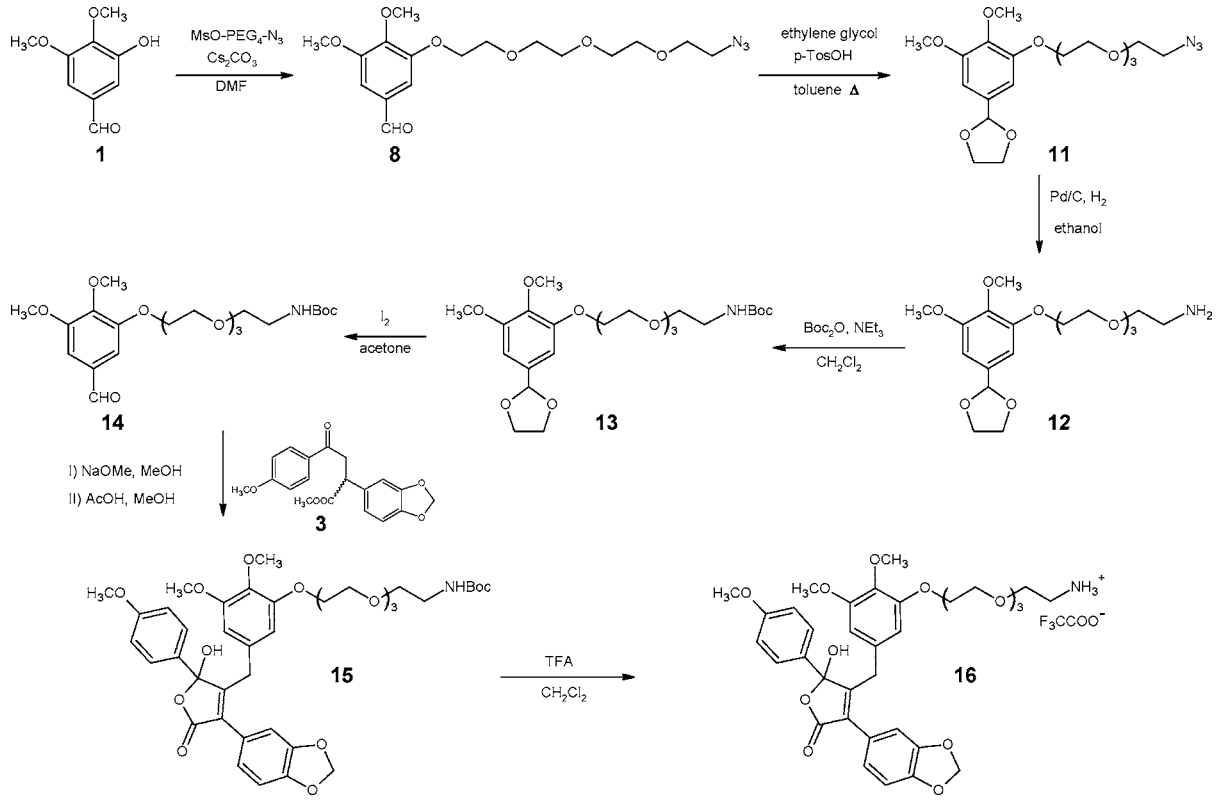
Fluorochrome Conjugation, Compound **17**. The amino-functionalized derivative **16** (1.0 mg, 1.3 μmol) was dissolved in 600 μL of a bicarbonate buffer (0.1 M $NaHCO_3$, pH 8.6). To this was added a solution of Cy 5.5 NHS ester (1.5 mg, 1.3 μmol) in 400 μL of DMSO. The solution was vortexed for 1 h

Scheme 3. Preparation of Amino-Functionalized Target Compound 10 by Staudinger Reaction

at room temperature in the dark. Purification of the Cy 5.5-labeled derivative **17** was performed by gradient HPLC using a Knauer system with two K-1800 pumps, an S-2500 UV detector, and a RP-HPLC Nucleosil 100-5 C18 column (250 mm × 4.6 mm). Eluent A: water (0.1% TFA). Eluent B: Acetonitrile (0.1% TFA). Gradient from 90% A to 40% A over 40 min at a flow rate of 1.5 mL/min, detection at $\lambda = 254$ nm. The appropriate fractions ($t_R = 31$ min) were collected, lyophilized, redissolved in PBS, and finally stored at −20 °C. The average content of **17** was 0.8 ± 0.3 μmol/mL (≈60%) as determined by fluorometer measurements with $\lambda_{abs} = 678$ nm and $\epsilon_{678} = 250000\ M^{-1}\ cm^{-1}$. MS: $m/z = 521.0\ [M]^{3-}$ (100%), 781.9 $[M + H]^{2-}$, 792.8 $[M + Na]^{2-}$, 1564.6 $[M + 2H]^{-}$, 1586.5 $[M + H + Na]^{-}$, 1608.5 $[M + 2Na]^{-}$, 1630.5 $[M - H + 3Na]^{-}$, 1652.5 $[M\text{-}2H + 4Na]^{-}$.

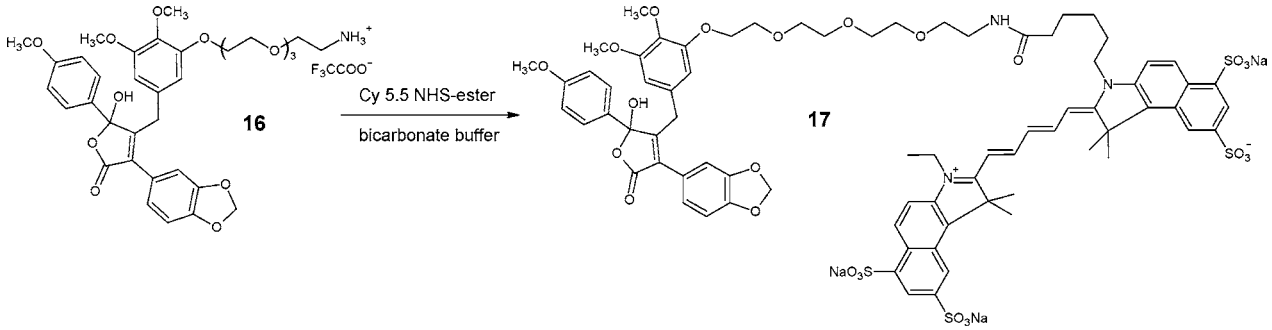
Biology. *Tissue Preparation.* Microsomes were prepared by homogenizing cardiac ventricles from DBA mice at 4 °C for 90 s in 1 mL of buffer A (10 mM EDTA, 10 mM HEPES, 0.1 mM benzamidine, pH 7.4), using a Polytron PT 3000 (Kinematica, Lucerne, Switzerland). Homogenates were centrifuged at $45.000g_{max}$ for 15 min at 4 °C. The pellets were resuspended in 1 mL of buffer B (1 mM EDTA, 10 mM HEPES, 0.1 mM benzamidine, pH 7.4) and recentrifuged at $45.000g_{max}$ for 15 min at 4 °C. The pellets were resuspended in 1 mL of buffer B and centrifuged at $10.000g_{max}$ for 10 min at 4 °C. The supernatants were recentrifuged at $45.000g_{max}$ for 15 min at 4 °C. The pellets, partially enriched ventricular membranes, were resuspended in buffer C (50 mM Tris·HCl, 5 mM $MgCl_2$, pH 7.4) and stored frozen at −80 °C.

Competition Experiments. For competition binding studies, the prepared membranes were resuspended in buffer D (10 mM Tris·HCl, 154 mM NaCl, 0.1 mM ascorbic acid, pH 7.4) at 0 °C. Ten microgram amounts of membranes were incubated with a constant concentration of [^{125}I]ET-1 (Perkin-Elmer Live Sciences Inc., Billerica, MA, 40 pM) and with varying concentrations (10 pM to 100 μM) of ET antagonist **4** and PD 156707 at 37 °C for 4 h. Reactions were stopped by filtering onto Whatman GF/B filters and washed with 0.9% NaCl at 4 °C. The membrane-bound radioactivity was determined in a γ-scintillation counter. Values for the maximum number of binding sites (B_{max}) and the dissociation constant (K_D) were determined using the Scatchard method as described in previous papers (*30*, *39*). Competition binding curves were analyzed by nonlinear regression analysis using the *XMGRACE* program (Linux software).



Cell Binding Assays. Cells (HT-1080 fibrosarcomas, MDA-MB-435 ductal carcinomas, MCF-7 adenocarcinomas, 5×10^4 each) were seeded in four-well plates (Nunc GmbH & Co. KG, Wiesbaden, Germany) and incubated in culture medium (0.5 mL/well) overnight. For binding studies, cells were washed twice with PBS and resuspended in 150 μL of binding buffer (20 mM HEPES in PBS with Ca^{2+}/Mg^{2+}, 0.2% BSA, 0.1% glucose, pH 7.4). Cy 5.5 (final amount 5.0 nmol, 33.3 μM) or Cy 5.5 conjugate **17** (5.0 nmol, 33.3 μM) was added into each well. After an incubation period of 45 min at 4 °C, cells were washed twice with PBS and were resuspended in binding buffer. For competition assays, the parent ET_AR antagonist PD 156707 (final amount 50 nmol, 333 μM) or ET_AR antibody (1.3 μg) was added to each well for 45 min at 4 °C. Cells could be directly visualized by fluorescence microscopy (40× objective, Nikon TE 2000-S, Nikon-Düsseldorf, Germany). The microscope was equipped with a mercury vapor lamp (100 W), 620/775 nm and 545/675 nm (excitation/emission) filters (AHF Analysentechnik, Tübingen, Germany), a Nikon DXM1200F camera, and ACT1/DXM1200F software (Nikon, Japan).

Western Blot Analysis. Confluent (80−100%) HT-1080, MDA-MB-435, and MCF-7 cells were treated with 0.5 mL of trypsin and harvested by scraping in cold PBS. After two centrifugation steps (1500 rpm, 5 min, 4 °C) cells were resuspended in lysis buffer (0.5% Tween 20, 50 mM Tris-HCl pH 8, 250 mM NaCl, 5 mM EDTA pH 8, 50 mM NaF, 0.5 mM Na_3VO_4, 0.9 mg/mL protease inhibitor cocktail, Sigma, St. Louis, MO), and the protein concentration of each sample was determined (Lowry protein assay, total amount 40 μg). To concentrate the protein, a 2-fold volume of cold acetone was added to each sample and placed in −20 °C for 16 h, followed by centrifugation at $10.000g_{max}$ at 4 °C for 30 min. Protein pellets were dissolved in 100 μL of 6× sodium dodecyl sulfate (SDS) sample buffer (New England Biolabs, Beverley, MA). Following precipitation, proteins were electrophoretically separated in nonreducing 10% SDS-PAGE and transferred to PVDF membranes (Millipore Corporation, Bedford, MA). After blocking, immunoblots were incubated with ET_AR polyclonal antibody (N-15, Santa Cruz Biotechnology, Santa Cruz, CA) and with peroxidase-conjugated donkey anti-goat IgG secondary antibody (Sigma, St. Louis, MO). Peroxidase activity was revealed using ECL chemiluminescence (Amersham Biosciences, Freiburg, Germany) and X-ray film, as described by the manufacturers. Human endothelial cell lysate (5 μg, BD Bioscience, San Diego, CA) was used as a positive control.



RESULTS AND DISCUSSION

The objective of this work was the modification of an existing lead structure (PD 156707) with a fluorescent dye, to allow for

Scheme 4. Preparation of Target Compound 16

Scheme 5. Synthesis of Conjugate 17

near-infrared detection of target receptors. Taking into account the size of the dye molecule compared to that of the parent antagonist, we chose a short polyethylene glycol spacer to displace the dye from the ET_AR-binding site and preserve the desired affinity and selectivity.

Chemistry. We synthesized the butenolide compound **4** via the route outlined in Scheme 1. Ketoester **3** was synthesized starting from 4′-methoxyacetophenone and piperonal as described by Doherty et al. (*37*). Benzaldehyde **2** was prepared by reaction of 3,4-dimethoxy-5-hydroxybenzaldehyde **1** with 1,2-bis(2-chloroethoxy)ethane and cesium carbonate in DMF. We found that the use of cesium carbonate instead of potassium carbonate allows us to perform the substitution reactions of these phenolic alcohols with nucleophiles at lower temperature and in shorter reaction times. Reaction with potassium phthalimide in DMF at elevated temperature gives the product **2** in 61% overall yield. To obtain butenolide **4**, condensation of the benzaldehyde with ketoester **3** was arranged. This is carried out by subsequently adding ketoester **3** and aldehyde **2** to a solution of sodium methoxide in methanol at 0 °C and then refluxing the mixture for 12−15 h under an inert atmosphere (argon). Finally, the addition of acetic acid and another 5−6 h reflux is required to obtain the ring-closed butenolide product **4**.

The attempt to obtain amino-functionalized products by hydrazinolysis of phthalimidoyl-modified butenolide derivatives such as **4** failed. The hydrazine not only reacted with the phthalimidoyl group but also inserted into the butenolide ring, giving a pyridazine derivative (data not shown).

The synthesis of benzaldehyde **8** (Schemes 3, 4) began with the preparation of the PEG-spacer. This was achieved in accordance with the procedure described by Tahtaoui et al. for the corresponding PEG_3 derivative and is outlined in Scheme 2 (*38*). Subsequent reaction of triphenylmethanol and methanesulfonyl chloride with tetraethylene glycol yields the trityl-protected, activated PEG derivative **5**, which is converted to the azide **6** by reaction with sodium azide in acetonitrile at reflux. The trityl group is then removed by reaction with *p*-toluenesulfonic acid in methanol, and the free hydroxy function is activated with methanesulfonyl chloride, giving 2-{2-[2-(2-azidoethoxy)ethoxy]ethoxy}ethyl methanesulfonate (MsO-PEG_4-N_3, **7**) in 50% overall yield. The coupling of the so-modified PEG spacer to 3,4-dimethoxy-5-hydroxybenzaldehyde **1** is conducted by reaction of the compounds and cesium carbonate in DMF at 80 °C for 4 h. The final step is the reaction of the ketoester **3** with the corresponding aldehyde **8** to yield butenolide **9**. This is carried out as described above for benzaldehyde **2** (Scheme 1).

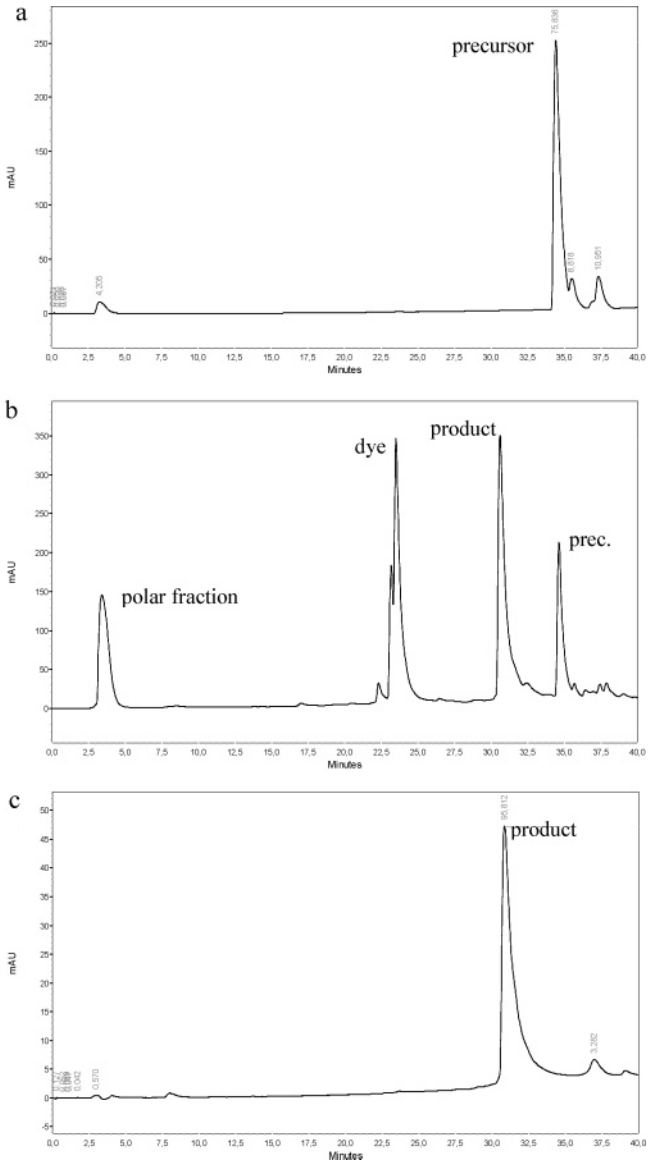


Figure 2. HPLC-chromatograms of precursor **16** (a), a reaction mixture with Cy 5.5 NHS-ester, bicarbonate buffer, and DMSO (b) and the purified sample of conjugate **17** (c).

Compound **9** is then converted to the free amine **10** by Staudinger reaction with triphenylphosphine and water in THF (Scheme 3). Regrettably, the yields in this step were disappointing (<20%), and several byproducts made the purification rather difficult. This was probably due to reaction of the phosphine with one of the oxygen-containing moieties of the butenolide ring structure. To circumvent these difficulties, a second reaction sequence was chosen, in which the amine was generated earlier and then protected for further conversion. This second sequence (Scheme 4) also begins with the reaction of 3,4-dimethoxy-5-hydroxybenzaldehyde **1** with PEG-derivative **7**. The aldehyde function of azide **8** is then protected with ethylene glycol, giving dioxolane **11** in 80% yield after purification. This kind of protection allows subsequent reduction of the azide and BOC protection of the generated amine **12** without the risk of intermolecular imine formation. The dioxolane protecting group of **13** can easily be destroyed by reaction with catalytic amounts of iodine in acetone without affecting the BOC protecting group. The product benzaldehyde **14** and ketoester **3** are then converted to the desired butenolide derivative by the same procedure as described above for the azide functionalized aldehyde **8** (Scheme 3). The product of this rection is the PEG-modified, *N*-Boc-protected butenolide

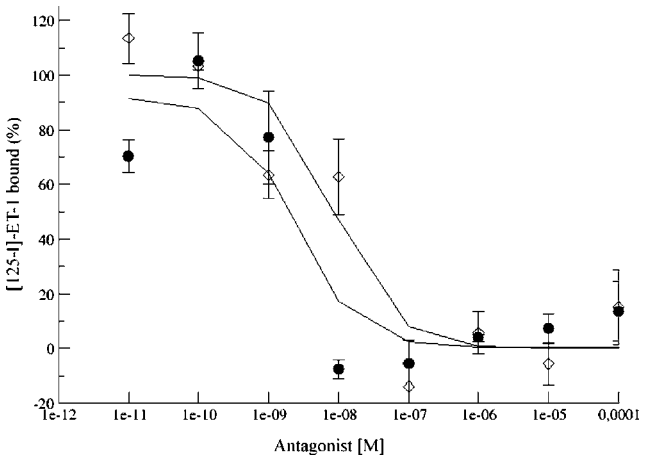

Figure 3. Competition binding study with model compound **4** in comparison to lead structure PD 156707 (● PD 156707, IC_{50} = 2.0 nM, ◇ Compd. **4**, IC_{50} = 9.0 nM).

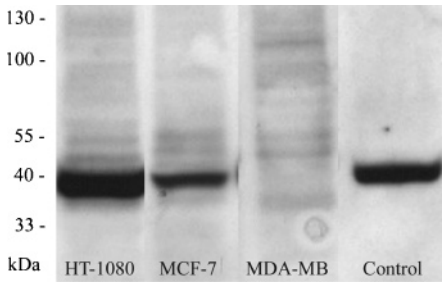

Figure 4. Western blot analysis of the three cell lines HT-1080, MCF-7, and MDA-MB-435 and human endothelial cell lysate as positive control (from left to right). ET_A receptor expression (→ 39 kDa band) was revealed by N15 polyclonal antibody (Santa Cruz) and peroxidase-conjugated donkey anti-goat secondary antibody (Sigma). HT-1080 fibrosarcoma cell show the highes expression level of ET_AR while MCF-7 adenocarcinomas only moderately express the target structure and MDA-MB-435 cells are devoid of the ET_A receptor.

15, which in the final step is deprotected by treatment with trifluoroacetic acid (TFA) in methylene chloride. The final product **16** can be isolated as the TFA salt which can be handled and stored easily at 4 °C.

Fluorochrome Conjugation. The amino-functionalized compound **16** was used for the conjugation of cyanine dye Cy 5.5 (used as the corresponding NHS-ester). The reactions were carried out in accordance with recommended peptide labeling procedures (Amersham Biosciences UK Limited, Buckinghamshire, UK), using an aqueous bicarbonate buffer and DMSO as solvents and reaction conditions of 1 h at room temperature. The conjugate **17** (Scheme 5) was purified by reversed phase HPLC on an analytical column by collection of the appropriate fractions. After lyophilization and redissolving in PBS, the sample showed a purity of >95% (Figure 2). The identification of the labeled ligand was possible by mass spectrometry with the triply negatively charged ion emerging at 100% intensity.

In Vitro Competition Studies. The affinity of the prepared butenolide derivative **4** (Scheme 1) toward ET receptors was determined by competition binding studies using [^{125}I]ET-1 and mouse cardiac ventricular membrane preparations. The binding of [^{125}I]ET-1 to ventricular membranes was specific, saturable, and of high affinity. Scatchard (*39*−*41*) transformation of the saturation data yielded values for the dissociation constant (K_D = 208 ± 2 pM) and the maximum number of binding sites (B_{max} = 300 ± 3 fmol/mg protein). The receptor affinity of butenolide **4** was compared to that of the lead compound PD 156707. We found an IC_{50} value of 8.4 ± 1.7 nM for the

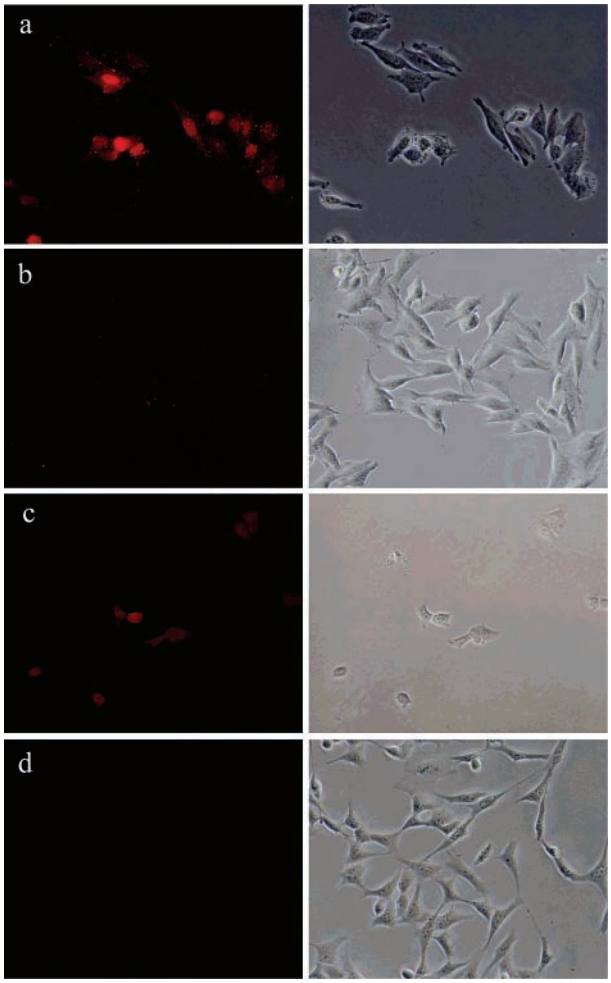

Figure 5. Fluorescence microscopic (left) and phase contrast (right) images of HT-1080 (a), MCF-7 (c), and MDA-MB-435 (d) cells. All cells were incubated with conjugate **17** and subsequently washed with PBS. Note that HT-1080 cells reveal the highest cellular fluorescence (a) while MCF-7 cells show only moderate cellular fluorescence (c) and MDA-MB-435 do not bind the tracer (d). Moreover, predosing of HT-1080 cells with an ET_AR specific antibody resulted in a significant reduction of cellular binding of the probe (b), confirming the binding specificity of Cy 5.5 conjugate **17** (40× objective magnification).

model compound **4** and a value of 2.2 ± 0.5 nM for the lead compound PD 156707 (*37*, 0.3 nM, Figure 3). This result shows that it is possible to modify this small-molecule receptor antagonist with an appropriate spacer group and a relatively large signaling molecule without affecting its receptor binding potencies.

Western Blot Analysis. The cellular expression level of the ET_A receptor was determined by western blot analysis (Figure 4). Using the Santa Cruz polyclonal antibody revealed a low molecular weight band at 39 kDa which corresponds to a proteolytic fragment of the high molecular weight (49 kDa) protein still possessing the ligand binding properties of the receptor (*42*, *43*). The highest amount of protein was found in human fibrosarcoma cells HT-1080, indicated by an intense major band at 39 kDa. A weaker band was found for the human adenocarcinoma cell line MCF-7, indicating a lower amount of ET_A receptor protein while the absence of the 39 kDa band for MDA-MB-435 cells confirmed that these cells were not expressing the ET_A receptor. Therefore, these cell lines providing different levels of target expression were ideally suited to test the conjugate **17** for receptor targeting efficiacy. Human endothelial cell lysate, which shows an intense band at 39 kDa, was used as a positive control (Figure 4).

In Vitro Cell Binding Assays. We tested the specificity of the fluorochrome conjugated ligand **17** for the ET_A receptor using ET_AR-positive MCF-7 human breast adenocarcinoma and HT-1080 human fibrosarcoma cells and ET_AR-negative MDA-MB-435 human breast carcinoma cells. Binding of the labeled antagonist could be directly analyzed by fluorescence microscopy. Negligible signals were detected from the cells when incubated with Cy 5.5 dye alone (5 nmol, data not shown). Incubation of the cells with 2 nmol (33.3 μM) of **17** allowed visualization of the ET_A receptor. The signal was distributed over the cell surface and was membrane-associated (Figure 5). Blocking of the signal was possible with 1.3 μg of the ET_A receptor-specific antibody (Figure 5B) or with a tenfold excess of the unlabeled antagonist PD 156707 (data not shown). The ET_A receptor expressing human fibrosarcoma cells HT-1080 showed a higher fluorescence signal than human breast cancer cell line MCF-7 (Figures 5A,C), while ET_A-negative MDA-MB-435 human breast carcinoma cells showed no accumulation of the ligand (Figure 5D). Thus, these results nicely correlate with the western blot analysis (Figure 4) and confirm target specific binding of the probe.

CONCLUSION

The aim of this work was to develop a nonpeptide, high-affinity ET_A receptor antagonist which is applicable for optical imaging of ET_AR expression. We chose 3-benzo[1,3]dioxol-5-yl-5-hydroxy-5-(4-methoxyphenyl)-4-(3,4,5-trimethoxybenzyl)-5*H*-furan-2-one (PD 156707) as the lead structure and developed a route for the synthesis of an amino-PEG-derivatized compound which can be used for the conjugation of common amino-reactive fluorescent markers. We used Cy 5.5 for conjugation, thus obtaining a near-infrared fluorescent photoprobe for the selective imaging of ET_ARs. The specificity of binding to ET_AR was shown by western blot analysis and *in vitro* cell binding assays. Incubation of human cancer cells with the conjugate lead to the specific visualization of the ET_AR positive cell lines HT-1080 and MCF-7. The signal was distributed over the cell surface and was membrane-associated. Blocking of the signal was possible with the unlabeled ET_AR antagonist PD 156707 or with an ET_AR specific antibody, verifying specific binding to cell surface sites. The ET_AR negative cell line MDA-MB-435 did not show any accumulation of the ligand. The results suggest that the modified photoprobe **17** tightly binds to ET_A receptors, thus representing a potential candidate for the *in vivo* imaging of ET_AR-overexpressing tissues in scientific research and medical diagnosis.

ACKNOWLEDGMENT

Financial support of the Deutsche Forschungsgemeinschaft (SFB 656 A1/A4, Scha 758/5-1) is gratefully acknowledged. We would like to thank Sandra Schröer for the *in vitro* competition experiments and Dr. H. Luftmann at the Organic Chemistry Department of the WWU Münster for mass spectrometry.

Immobilization of Aprotinin to Fibrinogen as a Novel Method for Controlling Degradation of Fibrin Gels

Jason D. Smith,[†,‡] Andrew Chen,[†] Lauren A. Ernst,[‡] Alan S. Waggoner,[‡] and Phil G. Campbell*[,†,‡]

Institute for Complex Engineered Systems and Molecular Biosensor and Imaging Center, Carnegie Mellon University, Pittsburgh, Pennsylvania. Received August 29, 2006; Revised Manuscript Received January 23, 2007

The goal of this work was to demonstrate that aprotinin conjugated to fibrinogen could (1) maintain its function and (2) control fibrin degradation. Using the chick chorioallantoic membrane (CAM) assay, we found that blood vessels did not directly invade fibrin constructs containing immobilized fibroblast growth factor-2. Because the fibrin quickly degraded within approximately 5 days, we hypothesized that controlling fibrinolysis may improve direct blood vessel invasion. Aprotinin, a protease inhibitor typically added to slow fibrinolysis, is a small protein and can diffuse out of the gel resulting in the loss of fibrinolysis protection. Therefore, using a novel synthesis strategy, aprotinin and a fluorescent reporter, Cy3, were chemically conjugated to fibrinogen. In vitro microplate absorbance assays showed that the conjugated aprotinin was able to inhibit plasmin-mediated fibrin degradation and that its activity was comparable to equimolar levels of soluble, nonconjugated aprotinin. Additionally, we found that fibrinolysis rates could be tuned by varying the level of conjugated aprotinin within the gel. The conjugated aprotinin also demonstrated functionality in vivo. In the chick CAM assay, fibrin gels containing conjugated aprotinin were approximately 5 times larger than gels containing soluble aprotinin after 4 days. Also, in support of our hypothesis, we found that immobilized aprotinin within fibrin gels demonstrated substantial blood vessel invasion.

INTRODUCTION

Our laboratory studies the use of fibrin-based constructs for bone tissue engineering applications. Fibrin is the primary provisional extracellular matrix (ECM) protein in wound healing (*1*). Fibrin supports cell adhesion and proliferation (*2*, *3*), can bind a number of growth factors, such as fibroblast growth factor-2 (FGF-2), with high specificity (*4*, *5*), and can be actively remodeled and degraded by cells (*6*−*8*). For these reasons, fibrin is an attractive scaffolding material for tissue engineering applications (*9*−*17*).

One of our laboratory's focus areas is to develop strategies to induce blood vessel ingrowth into such fibrin-based constructs for translation to tissue engineering applications. Our basic in vivo model is the chick chorioallantoic membrane (CAM) assay, a commonly used in vivo angiogenesis assay to study blood vessel development as well as the angiogenic nature of tissue engineered constructs (*9*, *10*, *18*−*28*). However, our initial experiments indicated that the fibrin was completely degraded at the construct/CAM interface as the CAM is invading the construct. Therefore, it appears that vascularization does not directly occur into the construct but is secondary to the invading CAM. Therefore, we asked the following question: Could direct angiogenic invasion be induced into the construct by controlling fibrin degradation?

In vivo, fibrin degradation, or fibrinolysis, occurs primarily through the serine protease plasmin (*8*, *18*, *19*). Aprotinin is a small (58 amino acids), potent competitive inhibitor for the active site of plasmin and is typically added to commercial fibrin glues to slow fibrinolysis (*7*, *20*−*22*). Because of its small size, however, aprotinin can freely diffuse out of the fibrin gel in vivo and is therefore no longer able to protect fibrin from degradation.

To circumvent this problem, we engineered a fused construct, directly linking aprotinin to fibrinogen, to immobilize aprotinin within the construct. Fibrinolysis would still be plasmin-mediated (and thus cell-mediated), but conjugated inhibitor levels would control the degradation rate. In this work, we conjugated aprotinin and a Cy3 fluorescent dye to fibrinogen through the use of a cysteine-based trifunctional cross-linker. Aprotinin was chosen due to its small size (<2% the molecular weight of fibrinogen) and potent plasmin inhibition. The Cy3 fluorescent dye served for quantitation of the conjugated aprotinin as well as a reporter of its localization. The conjugated aprotinin was tested in vitro and in vivo and found to be active in both venues. Additionally, the CAM assay showed that slowing fibrin degradation results in improved direct vascularization within the fibrin construct.

MATERIALS AND METHODS

Reagents. Cystine, diisopropylethylamine (DIPEA), tris(2-carboxyethyl)phosphine hydrochloride (TCEP), recombinant bovine lung aprotinin, EDTA, and sodium *meta*-periodate were obtained from Sigma (St. Louis, MO). Tetraethylammonium hydroxide and *O*-(*N*-succinimidyl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TSTU) were purchased from Fluka (Seelze, Germany). Human fibrinogen was purchased from diaPharma (West Chester, OH). C-18 column media was purchased from Separation Methods Technologies (Newark, DE) and the BioGel P-4 from BioRad (Hercules, CA). 4-(4-*N*-Maleimidophenyl)butyric acid hydrazide hydrochloride (MPBH) was obtained from Pierce (Rockford, IL).

Synthesis Strategy of Aprotinin−Fibrinogen Conjugate Molecule. Cystine was neutralized with tetraethylammonium hydroxide and dried by rotary evaporation. The cystine tetraethylammonium salt (0.7 mg) and 7 mg of monofuctional NHS-

ester Cy3 (synthesized in-house) were dissolved in 1 mL DMF, incubated at room temperature on a rotating rack, and followed by HPLC. Reaction progression ceased after 6 days resulting in a 50% yield. The reaction mixture was diluted with 6 mL ethyl acetate and the precipitate collected by centrifugation and redissolved in 1 mL of 20 mM potassium acetate in methanol. This process was repeated two additional times after which the precipitated material was vacuum-dried at 50 °C for 3 h followed by storage in a desiccator. The dried reaction material was dissolved in 5 mL ddH_2O, loaded on a 10 mL C-18 column, and washed with 20 mL ddH_2O wash. A 2.5% step gradient in acetonitrile was performed (10 mL/step). The 10% acetonitrile step was increased to 20 mL total to collect the band of interest. Appropriate fractions were combined and then dried by rotary evaporation. The bisCy3−cystine product (Figure 1, species I) was shown to be ∼98% pure by HPLC and the structure confirmed by ^{1}H NMR and MALDI mass spectroscopy.

BisCy3−cystine (4.6 mg) and TSTU (3.1 mg) were dissolved in 500 μL DMF containing 0.1% DIPEA. The activation reaction was protected from light and proceeded for 3 days at room temperature with stirring. The dye was precipitated with ethyl acetate, vacuum-dried as above, and stored in a desiccator. Approximately 2.8 mg of activated bisCy3−cystine was recovered (∼60% yield).

Recombinant bovine lung aprotinin (23.4 mg, Sigma) was dissolved in 400 μL deionized formamide + 0.1% DIPEA, added to the activated bisCy3−cystine, and transferred to a round-bottom flask containing a stir bar. The reaction proceeded for 48 h at room temperature, under argon, and protected from light. Progress of the coupling reaction was monitored by the incorporation of Cy3 label into the aprotinin band by SDS-PAGE (Figure 1, species II). The reaction mixture was diluted with 500 μL 200 mM HEPES, pH 7.0, 240 μL 1 mM TCEP, and 660 μL ddH_2O. Disulfide concentration was estimated by the Cy3 concentration (ϵ_{552} = 150 000). EDTA was added to a final concentration of 2 mM. Disulfide reduction was performed for 2 h at room temperature with stirring. MPBH was added to the flask at a 6-fold excess over Cy3 (ϵ_{552} = 150 000) and reacted for an additional 3 h. The product was purified on a 10 mL column containing BioGel P-4 prepared in 20 mM HEPES, 150 mM NaCl, pH 7.4 (Figure 1, species III). Fractions of interest were concentrated using Centricon C3 centrifugation tubes (MWCO ≈ 3000 Da). The final retentate was lyophilized.

Equal volumes of 18.7 mg/mL human fibrinogen and 20 mM sodium *meta*-periodate were mixed and reacted for 30 min at room temperature. The reaction was dialyzed overnight against 20 mM HEPES, pH 7.4, using Pierce Slide-A-Lyzer kits (3500 MWCO). Cy3−cysteine−aprotinin−MPBH was added to the fibrinogen at a 7:1 molar labeling ratio and reacted for 2 h at room temperature followed by separation on a BioGel P-30 size exclusion column equilibrated with 20 mM HEPES, 150 mM NaCl, pH 7.4 (Figure 1, species IV). Fractions were combined, aliquoted, and frozen at −80 °C. Fibrinogen concentration as measured by the Coomassie Plus Assay Kit (Pierce) was 1 mg/mL (2.94 μM), and Cy3 concentration (ϵ_{552} = 150 000) was 14 μM. Since one aprotinin is expected for every Cy3, the theoretical aprotinin concentration was also 14 μM (91 μg/mL), giving an aprotinin/fibrinogen labeling ratio of 4.8:1.

In Vitro Degradation Assay. Microplate-based experiments were similar to those performed by Wolberg et al. (*23*). Solution A contained human fibrinogen, either soluble or fibrinogen-conjugated aprotinin, and HEPES buffer. Solution B contained thrombin (Enzyme Research Labs, South Bend, IN), plasmin (Haematologic Technologies, Inc., Essex Junction, VT), calcium chloride (Sigma), and deionized water. Solutions A and B were mixed directly in the 96 well plate to a total volume of 200 μL/well. The final concentrations were as follows: 1 mg/mL fibrinogen, 5 nM thrombin, 100 nM plasmin, and 5 mM calcium chloride in 20 mM HEPES, 150 mM NaCl, pH 7.4. The concentration of aprotinin varied from 5 nM to 50 nM. Fibrinogen added as a result of the conjugated molecule was less than 0.1% of the gel fibrinogen concentration. Gel absorbance was followed over time at 405 nm and 37 °C at 2.5 min intervals using a Wallac Microplate Reader (Gaithersburg, MD).

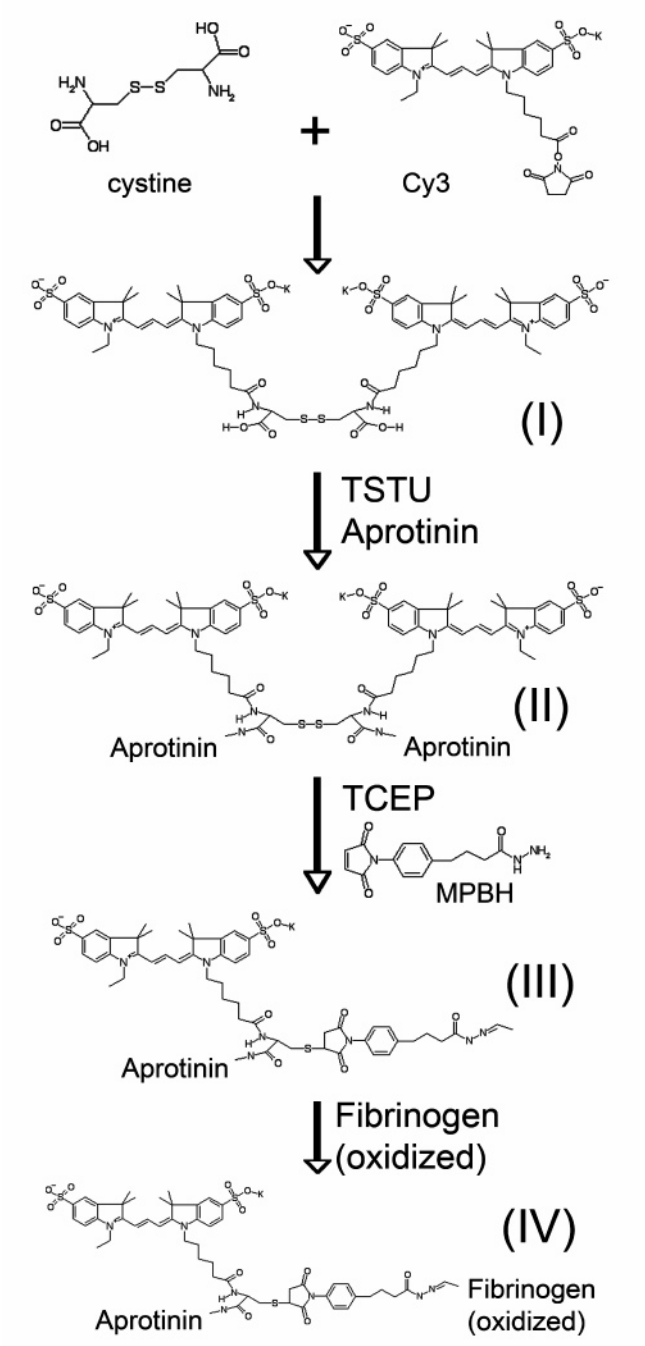

Figure 1. Schematic of aprotinin-fibrinogen conjugate. Cystine was reacted with activated Cy3 dye in DMF and reverse phase column purified. The bisCy3−cystine product (species I) was reacted with TSTU in DMF + 0.1% DIPEA to activate the cystine's carboxylic acid groups. Aprotinin was dissolved in formamide + 0.1% DIPEA and added to the activated bisCy3−cystine compound (species II). In HEPES-buffered saline (HBSS) TCEP was added to species II to reduce cystine disulfide bonds and was followed by the addition of MPBH heterobifunctional crosslinker. The product (species III) was purified by size exclusion chromatography and lyophilized. The product was added to periodate activated fibrinogen to produce the final aprotinin−fibrinogen conjugate (species IV) which was purified by size exclusion using HBSS.

Ex Ovo Chick CAM Assay. Fibrin gels were made in 8 mm × 1 mm cylindrical molds. Final concentrations within the gel are 17 mg/mL fibrinogen, 10 ng/mL fibroblast growth factor-2 (FGF-2) (PeproTech, Inc., Rocky Hill, NJ), 61.7 nM thrombin, and 1 μg/mL of either soluble aprotinin or aprotinin conjugated to fibrinogen. Additional fibrinogen levels due to aprotinin−fibrinogen conjugate addition were less than 0.1% of final fibrinogen levels. White Leghorn eggs were purchased from a local farm and incubated at 38 °C and 70% humidity in a rotating circulated air incubator (G.Q.F. Manufacturing Co., Savanna, GA). On day 3, eggs were cracked into Petri dishes containing 4 mL Dulbecco's Modified Eagles Medium (DMEM) (Gibco, Carslbad, CA) and placed in a 37 °C incubator (Forma Scientific, Waltham, MA). Fibrin gels were placed on the CAM of 10 day old embryos. One gel of each type (soluble and conjugated aprotinin) was placed on each embryo. Fibrin gel images were acquired every 24 h using a M2BIO stereomicroscope (Kramer Scientific, Valley Cottage, NY) with a 1.6× objective (0.075 NA), 0.6× zoom, a Retiga Exi cooled CCD camera (QImaging, Burnaby, BC, Canada), and *QED In Vivo* imaging software v 2.0.39 (Media Cybernetics, Silver Springs, MD). Fibrin gel diameters were measured (in pixels) using *Image J* software (NIH, Bethesda, MD). The relative areas of gels containing conjugated aprotinin to soluble aprotinin were calculated for 12 sets of gels and are reported as the mean ± SEM at each day post-placement on the chick CAM. Using *SYSTAT 9* software (Point Richmond, CA), means were compared using a one-way analysis of variance followed by Tukey's post hoc test. $P \leq 0.05$ was considered significant.
