In order to reconfirm the conjugation of WGA onto the surface of WGA-TFNS, *S. aureus* was used. As can be seen from Figure 5a,b, the WGA-TFNS had agglutinated after *S. aureus* suspension was incubated with WGA-TFNS at 37 °C for 25 min, indicative of the presence of WGA on WGA-TFNS surface. It is the multiple binding sites of WGA that one WGA molecule can at most bind to four *S. aureus* cells, resulting in the agglutination. However, this agglutination phenomenon could not be observed with *Escherichia coli* (Figure 5c,d) because no *N*-acetylglucosamine is present on the *Escherichia coli* surface.

Recognition of Human Prostate Carcinoma DU-145 Cells by WGA-TFNS. The four carbohydrate-binding sites of WGA can recognize sialic acid and *N*-acetylglucosamine. Therefore, WGA can accordingly recognize human prostate carcinoma DU-145 cells because they can express sialic acid and *N*-acetylglucosamine on their surface (*38*). Thus, the recognition of DU-145 cells by WGA-TFNS was expected. Figure 6 shows that, after 30 min incubation with WGA-TFNS and subsequent magnetic isolation, the cells had been collected and separated (Figure 6a,b). Accordingly, the cells captured by WGA-TFNS could fluoresce orange (with a maximum emission wavelength of ca. 580 nm), which came from the WGA-TFNS binding to the cancer cells. Dolichos biflorus agglutinin (DBA) was used for the control, which is a glycoprotein with a molecular weight of about 120 000 and consists of 4 subunits of approximately equal size. This lectin has an isoelectric point of about pH 5.5 and 2 binding sites which are specific for glycoconjugates containing *N*-acetyl-D-galactosamine (GalNAc) in the terminal position (*39*). As reported in the literature (*38*), DBA did not have specificity for DU-145 cells; thus, DBA-TFNS could not capture DU-145 cells as shown in Figure 6c and d. At the same time, COOH-BFNS without WGA cannot recognize DU-145 cells as well (Figure 6e,f). Clearly, WGA-TFNS with WGA on the nanosphere surface can indeed recognize specifically DU-145 cells within 30 min. In particular, the cells captured by WGA-TFNS can be isolated readily with

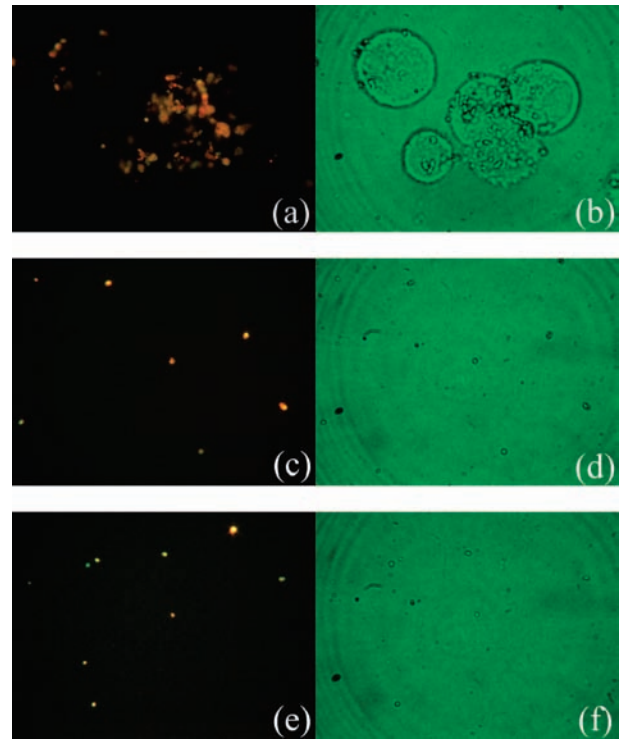

Figure 6. Microscopic images for the recognition of human prostate carcinoma DU-145 cells by WGA-TFNS under an incubation of 30 min with subsequent magnetic scaffold separation (a,b). Control experiment (c–f): DU-145 cells incubated with DBA-TFNS (c,d) and HOOC-BFNS (e,f) for 30 min with magnetic separation. Fluorescence (a,c,e); bright field (b,d,f).

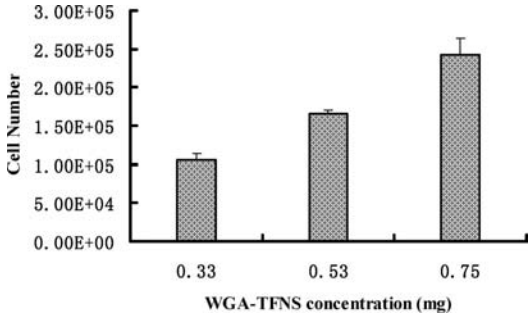

Figure 7. Histogram for capturing capacity of WGA-TFNS.

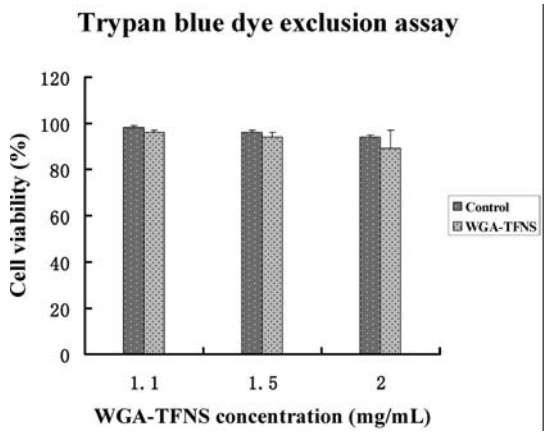

Figure 8. Cytotoxicity of WGA-TFNS examined by Trypan blue dye exclusion assay.

a magnetic scaffold. It is worth pointing out that the magnetic separation is very fast. It only takes tens of seconds to collect the WGA-TFNS-captured cells. The capacity of WGA-TFNS to capture DU-145 cells is shown in Figure 7. About 1.06×10^5 DU-145 cells were captured by only 0.33 mg of WGA-TFNS. By increasing the WGA-TFNS concentration, the number of captured DU-145 cells increased.

The cytotoxicity of WGA-TFNS was examined by Trypan blue dye exclusion assay (*40*). As shown in Figure 8, the cell viability was almost the same both in the presence of WGA-TFNS and in their absence for the control, indicating that WGA-TFNS have scarcely any cytotoxicity on DU-145 cells at WGA concentrations below 2.0 mg/mL and with 30 min incubation.

In general, the relative abundances and branch structures of glycans on the membrane surface of cancer cells are often altered compared with normal cells. These alterations in glycosylation may be indicative of the different stages of the disease, thus being useful for diagnosis. Glycosylation changes in human carcinomas are thought to contribute to the malignant phenotype observed downstream of certain oncogenic events (*41*). Glycans are also the key structures involved in biological processes such as cell attachment, migration, and invasion. Information coded on cell surface glycans is frequently deciphered by proteins, such as lectins, that recognize specific carbohydrate topology (*42*). So, lectins always play an important role in the identification of glycoprotein and the phases of disease, which are very useful for disease diagnosis. Mo and Lim have successfully modified poly(D,L-lactide-*co*-glycolide) particles with WGA to interact with A549 cells (*2*) and made use of lectin receptor-mediated endocytosis for drug release (*5*) based on its capability of binding to membrane-bound carbohydrates. Heinrich et al. (*43*) found that lectin can kill cancer cells, so lectin could be used as a drug candidate for cancer therapy. Hopefully, WGA-TFNS could be used to capture and separate cancer cells, and investigate the mechanism of killing cancer cells by lectin and drug release.

CONCLUSION

A simple and convenient strategy has been put forward to fabricate smart WGA-TFNS with excellent fluorescence, magnetism, and recognition of cancer cells surface-expressed with sialic acid and *N*-acetylglucosamine, which can be easily manipulated, tracked, and conveniently used to capture target cancer cells. WGA-TFNS have the specificity to recognize DU-145 cells, but this is not the case for DBA-TFNS. They have good capture capacity for DU-145 and no cytotoxicity on DU-145 in the present case. The success in capturing DU-145 cells by the WGA-TFNS has opened up a new field: visualizeable and recognizable manipulation and sorting of cells. Alterable functional groups on the BFNS surface such as -NH_2 or -COOH will facilitate their bioconjugation with a variety of biomolecules on demand for the purposes of bioanalysis, biomedical imaging, diagnosis, and combinatorial screening of drugs. Among all the possible applications, simultaneous sorting of different categories of target cells will be the most fascinating, based on multicolor labeling by embedding different sizes and/or types of QDs in different batches of the trifunctional nanospheres.

Synthetic PAMAM–RGD Conjugates Target and Bind To Odontoblast-like MDPC 23 cells and the Predentin in Tooth Organ Cultures

Elliott Hill,*,† Rameshwer Shukla,‡ Steve S. Park,‡ and James R. Baker, Jr.‡

Departments of Biologic and Materials Sciences and Internal Medicine, University of Michigan, Ann Arbor, Michigan. Received January 22, 2007; Revised Manuscript Received July 30, 2007

Screening techniques now allow for the identification of small peptides that bind specifically to molecules like cells. However, despite the enthusiasm for this approach, single peptides often lack the binding affinity to target in vivo and regulate cell function. We took peptides containing the Arg-Gly Asp(RGD) motif that bind to the $\alpha_V\beta_3$ integrin and have shown potential as therapeutics. To improve their binding affinity, we synthesized polyamidoamine (PAMAM) dendrimer–RGD conjugates that that contain 12–13 copies of the peptide. When cultured with human dermal microvessel endothelial cells (HDMEC), human vascular endothelial cells (HUVEC), or odontoblast-like MDPC-23 cells, the PAMAM dendrimer conjugate targets this receptor in a manner that is both time- and dose-dependent. Finally, this conjugate selectively targets RGD binding sites in the predentin of human tooth organ cultures. Taken together, these studies provide proof of principle that synthetic PAMAM–RGD conjugates could prove useful as carriers for the tissue-specific delivery of integrin-targeted therapeutics or imaging agents and could be used to engineer tissue regeneration.

INTRODUCTION

Biologically inductive materials have revolutionized our concept of restorative medicine and reconstructive surgery (*1*). This comes from the recognition of the potential of restoring the form and function of lost tissues by engineering approaches using the identical type of functional tissue that was lost. Though relatively few of these materials have been approved by the Food and Drug Administration (FDA), more than 70 companies are spending a total of $600 million per year to develop new products (*2–5*). In the context of oral facial tissues and dentition, a primary effort involves developing materials that do not elicit an immune response or will camouflage structural deficiencies. While some advances in this area have been made with dental filling materials that release fluoride, or wound dressings that release regenerative growth factors, the molecular cues that enhance and maintain a healthy dental pulp and periodontal ligament are largely unknown.

Extensive numbers of studies have introduced the concept that, in general, tissue health and homeostasis are regulated though the interplay of a variety of signals including insoluble signaling molecules, insoluble ligands, mechanical cues, and cell to cell interaction (*6–8*). Integrin adhesion receptors play a crucial role in regulating interactions between cells and the extracellular matrix (ECM) (*9*). Integrin activation initiates multiple intracellular signaling pathways and results in regulation of cell functions such as motility, proliferation, and differentiation (*10*). One such integrin-binding peptide contains the Arg-Gly Asp (RGD) motif that commonly binds to extracellular matrix proteins. Previous studies have demonstrated that proteins modified with RGD peptides bind with high affinity to $\alpha_v\beta_3$ receptors (*11–13*). The $\alpha_v\beta_3$ integrin is found on the luminal surface of endothelial cells only during angiogenesis (*14*). RGD peptides have been used to deliver doxorubicin (*15*) and proapoptotic peptides (*16*) to the tumor vasculature in targeted chemotherapy. Taken together, these data illustrate the important role RGD plays in regulation of normal cell function. In addition, this important ligand can be potentially utilized to target therapeutic molecules to tissues that express the $\alpha_v\beta_3$ receptor. In this regard, antibody and peptide inhibitors of $\alpha_v\beta_3$ integrins are currently in phase I/II clinical trials for the inhibition of angiogenesis in cancer (*17*).

There also has been growing interest in the use of polymers as nonviral vectors for the delivery of targeting and or therapeutic molecules (*18–22*). One such polymer, polyamidoamine (PAMAM) dendrimers, have been synthesized as building blocks for conjugation to biological molecules, including RGD (*23*). PAMAM dendrimers are water-soluble and biocompatible macromolecules that have been coupled to many biological molecules such as proteins, synthetic drugs, and small molecules. These dendrimers can be coupled to multiple $\alpha_V\beta_3$-selective ligands to target tumor-associated capillary beds and allow the delivery of cytotoxic agents to kill the new vessels (*6, 24, 25*). Also, these dendrimer–RGD conjugates may provide useful building blocks for the creation of new biomaterials in dental applications such as adhesive agents for dental implants or delivery vectors for bone morphogenic proteins and transforming growth factors. In the present work, we describe the synthesis and characterization of a generation 5 dendrimer conjugated to c(RGDyK) labeled with fluorescein. In addition, we examine the binding properties and cellular uptake of this conjugate in endothelial cells, and we report unique binding of the dendrimer–RGD conjugate to the predentin of human tooth organs and dental pulp-like MDPC-23 cells.

EXPERIMENTAL PROCEDURES

General. G5-PAMAM dendrimer was prepared at the Michigan Nanotechnology Institute for Medicine and Biological sciences, University of Michigan, and was analyzed extensively by ^{1}H and ^{13}C NMR, matrix-assisted laser desorption–ionization time-of-flight (MALDI-TOF) mass spectrometry, high-performance liquid chromatography (HPLC), gel-permeation chromatography (GPC), and polyacrylamide gel electrophoresis

(PAGE) (*26*). Prepacked Sephadex G-25 PD-10 columns were purchased from Amersham Pharmacia Biotech (Piscataway, NJ) and equilibrated with degassed eluting buffer before sample introduction.

Synthesis of G5-Ac (1). G5 amine dendrimer (0.265 g, 0.0099 mmol) and triethyl amine (0.088 g, 0.8635 mmol) were dissolved in 30 mL anhydrous MeOH and allowed to stir for 30 min. A solution of acetic anhydride (0.076 g, 0.744 mmol) in anhydrous MeOH (15 mL) was added dropwise while stirring. The reaction mixture was allowed to stir overnight at room temperature. After evaporation of the solvent, the residue was dissolved in H_2O and dialyzed in 10 000 MWCO regenerated cellulose dialysis bags initially against PBS buffer, followed by water. The partially acetylated dendrimer was lyophilized to give a colorless powder (0.270 g, 91.2%). The molecular weight of synthesized G5-PAMAM dendrimer was found to be 26 530 g/mol by GPC, and the average number of primary amino groups was estimated to be 108 by potentiometric titration. The average number of acetyl groups (80) has been determined on the basis of a ^{1}H NMR calibration curve drawn by plotting a ratio of acetyl protons and sum of all methylene protons vs degree of actetylation (*27*). ^{1}H NMR (300 MHz, CDCl3): δ = 1.8 (s, 240H), 2.32–2.38 (m, 499H), 2.51–2.52 (m, 260H), 2.65–2.80 (m, 500H), 3.15 (br m, 62H), 3.4 (s,br, 596H), 3.45 (s, 62H). MS (MALDI): 300 050.

G5-Ac-Fl (2). To G5-Ac (102.05 mg, 3.4 mmol) in DMSO (10 mL) was added FITC (5.8 mg, 15.0 mmol) in DMSO (2 mL) dropwise. The reaction was allowed to stir overnight. The reaction mixture was diluted 1:1 in PBS, and free dye was separated from conjugate by gel filtration on a G-25 Sephadex column. The eluted conjugate was concentrated using a centriprep device (MWCO 10 000) and dialyzed against PBS and H_2O before lyophilization. ^{1}H NMR (300 MHz, CDCl3): δ = 1.8 (s, 240H), 2.32–2.38 (m, 499H), 2.51–2.52 (m, 260H), 2.65–2.80 (m, 500H), 3.15 (br m, 62H), 3.4 (s,br, 596H), 3.45 (s, 62H), 6.25 (br s, 16H), 7.02 (br s, 8H), 7.5 (br s, 8H), 7.71 (br s, 8H). MS (MALDI): 34 470.

G5-Ac-Fl-glutarate (3). Glutaric anhydride (0.0029 g, 0.0257 mmol) dissolved in anhydrous MeOH (2 mL) was added dropwise to a solution of G5-Ac80-Fl4 (0.0203 g, 0.0006 mmol) and TEA (0.0026 g, 0.0257 mmol) in anhydrous MeOH (18 mL) while stirring, and the reaction mixture was allowed to stir for another 24 h at room temperature. The solvent was evaporated in vacuo, and the residual material was dissolved in H_2O, purified by extensive ultrafiltration against PBS and H_2O using a centricon device (10k MWCO), then lyophilized. ^{1}H NMR (300 MHz, CDCl3): δ = 1.8 (s, 240H), 1.7 (m, 56h), 2.32–2.38 (m, 499H), 2.2 (m, 112H), 2.51–2.52 (m, 260H), 2.65–2.80 (m, 500H), 3.15 (br m, 62H), 3.4 (s,br, 596H), 3.45 (s, 62H), 6.25 (br s, 16H), 7.02 (br s, 8H), 7.5 (br s, 8H), 7.71 (br s, 8H). MS (MALDI): 38 370.

G5-Ac-Fl-glutarate-c(RGD) (4). An active ester was prepared by reacting G5-Ac80-Fl4-glutarate (12.26 mg, 0.00036 mmol) in H_2O (2.0 mL) with EDC (1.02 mg, 0.00533 mmol) for 3 h. RGD (0.005 g, 0.0036 mmol) in DMSO (0.5 mL) was added dropwise to the above solution and allowed to stir overnight. The product was purified by extensive ultrafiltration against PBS buffer (pH 7.4) and H_2O using a centricon device (10k MWCO), then lyophilized. ^{1}H NMR (300 MHz, CDCl3): δ = 1.8 (s, 240H), 2.32–2.38 (m, 499H), 2.51–2.52 (m, 260H), 2.65–2.80 (m, 500H), 3.15 (br m, 62H), 3.4 (s,br, 596H), 3.45 (s, 62H), 6.25 (br s, 16H), 7.02 (br s, 8H), 7.27 (br, s, 40H), 7.5 (br s, 8H), 7.71 (br s, 8H). MS (MALDI): 42 416.

Cell Cultures. L1210 cell lines were grown in RPMI medium (with folate), supplemented with 10% FBS, 1% penicillin/streptomycin. and 50 nM L-glutamine. These cells were grown in suspension, and the media were changed every other day. MDPC-23 cell cultures were grown in high-glucose DMEM (Gibco) supplemented with 1% P/S and 10% FBS. HDMEC and HUVEC were grown in EGMV-2 media supplemented with 5% FBS, 1% gentamycin, 1% VEGF, 1% ascorbic acid, 0.5% hydrocortisone, 3% hFGF, 1% IGF, and 1% hEGF. HUVEC, HDMEC, and MDPC-23 cells were incubated as a monolayer at 37 °C and 5% CO_2 and grown in 75 cm^3 flasks until 85% confluent (2×10^6 cells/flask). Approximately 0.5×10^6 cells were seeded onto 6 well culture dishes (MatTek Corp., Ashland, MA) and cultured in 3 mL of medium at least 24 h before the initiation of experimental conditions. Samples were examined quantitatively for G5-conjugate uptake via flow cytometry (Coulter-Epiflow) at time points ranging from 1 h to 7 days normalized to controls that were prepared for each time point.

Cell Targeting and Binding Assay. The cellular uptake of G5-Ac-Fl-RGD conjugate was measured in human dermal microvessel endothelial cells (HDMEC), human vascular endothelial cells (HUVEC), fetal mouse molar papillae derived (MDPC-23) cells, and mouse lymphocytic leukemia cell line (L1210) cells. Endothelial cells were cultured in ECM-2 media supplemented with fetal bovine serum, EGF, VEGF, IGF, and IL-8. All other cell lines were cultured in RPMI media (GIBCO) supplemented with 10% FBS/1% P/S. A time course for G5 (100 nM) binding was done, and results were analyzed via flow cytometric analysis (BectonDickinson FACScan analyzer, Fullerton, CA). The mean fluorescence of 10 000 cells was quantified. Confocal microscopic analysis was performed on HDMEC cells cultured in 35 mm glass-bottomed culture dishes (MatTek Corp., Ashland, MA) using a Carl Ziess confocal microscope. Fluorescence and differential interference contrast (DIC) images were collected simultaneously using an argon laser and *Fluoview* software.

Targeting of Tooth Organ Cultures. Adult human molars were extracted, soft tissue was carefully removed, and teeth were stored in 70% ethanol. One millimeter cross sections of medial and distal roots were made with a diamond wheel saw (South Bay Technology Inc., Temple City, CA) at a point 1 mm apical to the cement–enamel junction. Pulp contents were carefully removed, and the sections were placed in 35 mm glass-bottomed culture dishes (MatTek Corp., Ashland, MA). The targeted binding of G5-Ac-Fl-RGD conjugates was examined by coculturing the conjugate with human molar tooth slice sections under three different conditions: (1) tooth slices cocultured with G5-Ac-Fl-glutarate (with out the targeting RGD moiety), (2) tooth slices cocultured with G5-Ac-Fl-RGD, (3) tooth slices preincubated for 1 h with free RGD peptide and then cocultured with G5-Ac-Fl-RGD conjugate. All cocultures were incubated for 3 h; cultures were rinsed with sterile water (3×) and analyzed via confocal microscopic analysis using a Carl Ziess confocal microscope. Fluorescence and differential interference contrast (DIC) images were collected simultaneously using an argon laser and *Fluoview* software.

RESULTS

The conjugate synthesis and characterization was performed as follows: (1) The synthesis and partial surface modification of G5 dendrimer with acetic anhydride (75 mol %) in the presence of triethylamine (Figure 1) was initiated via the use of 75 molar excess of acetic anhydride. This reaction leaves approximately 25% of the primary amines on the surface for further conjugation. In addition, it prevents aggregation, intermolecular interaction, and problems arising from decreased solubility. The degree of acetylation and the purity of the G5 dendrimer conjugate were analyzed using ^{1}H NMR spectroscopy, which shows a distinct signal for the terminal $NHCOCH_3$ protons of the dendrimer. The degree of acetylation was measured by comparing the ratio of $NHCOCH_3$ protons with

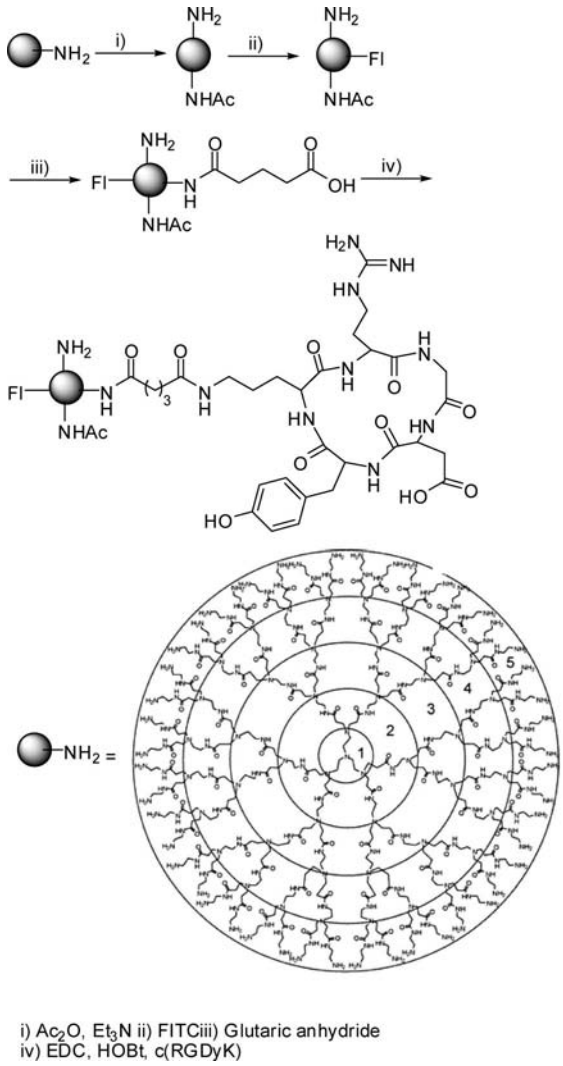

Figure 1. Schematic of PAMAM dendrimer generation 5 (G5)-FL-RGD synthesis.

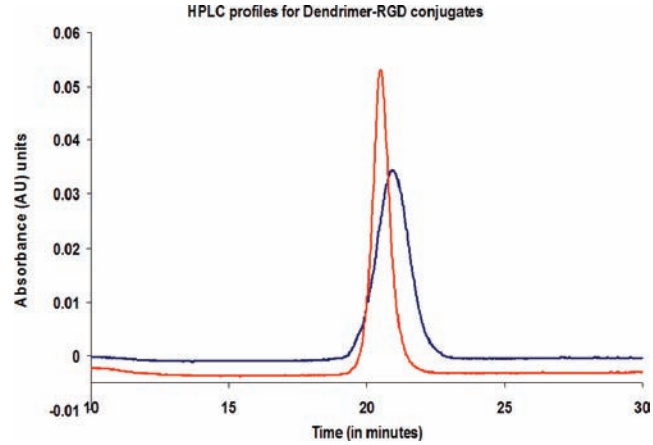

Figure 2. HPLC analysis used to compare G5-FITC to G5-FITC-RGD dendrimer showed a peak typical of a homogeneous peptide conjugate λ max 285 nm. In addition, the difference in retention time between the final conjugate the precursor material gives indirect evidence that RGD peptide conjugation was successful.

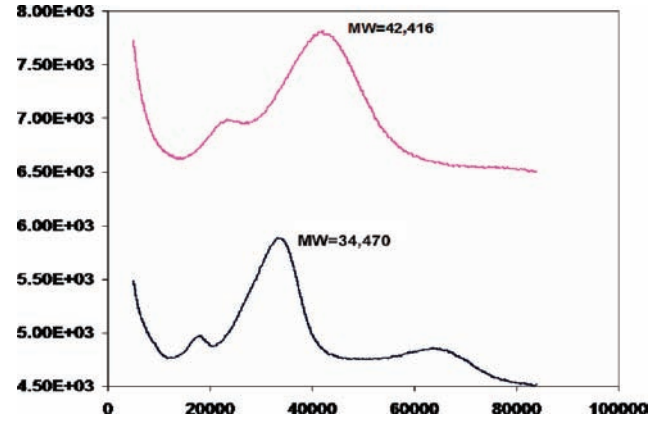

Figure 3. Matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF) analysis of G5-FL conjugate before and after RGD conjugation revealed a difference in mass consistent with the successful conjugation of 13 RGD peptides per G5-FL conjugate.

the sum of all methylene protons in the dendrimer to a calibration curve as described previously (*27*). (2) To detect the conjugate by flow cytometry or for visual imaging via confocal microscopy, a detectable fluorescent probe is required. We labeled the partially acetylated dendrimer with fluorescein isothiocyanate (FITC).

The partially acetylated dendrimer was reacted with 5 mol equiv of FITC dissolved in dimethyl sulfoxide (DMSO). After purification, the conjugate was characterized using ^{1}H NMR spectroscopy and high-performance liquid chromatography (HPLC) (Figure 2). The ^{1}H NMR spectrum of the conjugate shows broad signals in the aromatic region for the FITC (data not shown). The number of dye molecules attached to the dendrimer was calculated to be ~4 based on UV/vis spectroscopy and ^{1}H NMR. (3) Remaining surface amines on the dendrimer were converted to carboxylic acid by reacting with excess glutaric anhydride in MeOH, in the presence of TEA as base. This conversion provides a carboxyl terminal linker while eliminating primary amines that could cause nonspecific charge interactions. The loss of the methylene peaks ($-CH_2CH_2NH_2$) at δ 2.97 and 3.32 ppm and the emergence of the new methylene peaks (-NHCO(CH_2)$_3$COOH) at δ 1.65 and 2.05 ppm indicate complete conversion of the remaining terminal amines to give G5-Ac-Fl-glutarate. (4) Finally, the carboxyl groups were activated by reacting with EDC followed by the addition of 10 equiv of c(RGDyK) to give the dendrimer–RGD conjugate. The dendrimer–RGD conjugate was purified by ultrafiltration and lyophilized. The ^{1}H NMR spectrum of the conjugate shows overlapping signals in the aromatic region for both the FITC and phenyl ring of the peptide apart from the expected aliphatic signals for the dendrimer overlapping with some aliphatic signals from the peptide. The number of peptides was calculated to be 12–13 peptides per dendrimer based on matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry (Figure 3) and ^{1}H NMR.

The cellular uptake of G5Ac-Fl-RGD examined in MDPC-23 odontoblast-like cells, via flow cytometric analysis, revealed time-dependent uptake of G5 conjugate (Figure 4). Measurable binding was observed at 30 min with an increased uptake beginning at 3 h that seemed to become constant at 6 h. The binding was also dose-dependent with a 10-fold increase seen at 300 nM G5RGD as compared to that seen at 30 nM (Figure 4b).

To examine specific binding of G5-Ac-Fl-RGD to HDMEC, HUVEC, and MDPC-23 cells, these cells were cultured with and without preincubation with free RGD peptide and examined via flow cytometry (Figure 5). This approach also demonstrated that when incubated for 6 h at 37 °C the G5 conjugate exhibited RGD-dependent binding to HDMEC, HUVEC, and MDPC-23 cells. The binding effect was not enhanced by longer incubation times, and binding could be completely inhibited when the cells

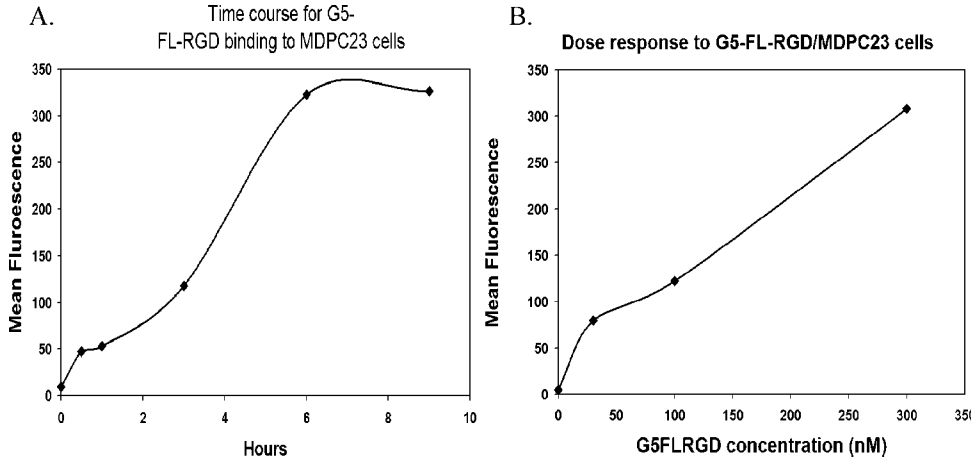

Figure 4. Flow cytometry data of time dependent binding of G5-Ac-Fl-RGD to MDPC-23 (odontoblast like) cells, shows targeted binding after 3 h incubation that increased and stabilized at 6 h (a). The binding demonstrated at 6 h was dose dependent (b).

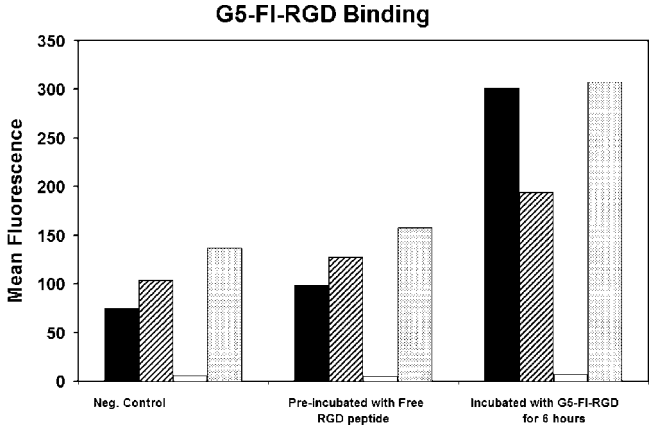

Figure 5. In vitro binding of G5-FL-RGD conjugate to HUVEC (solid block), HDMEC (striped block), or odontoblast-like MDPC-23 (shaded block) cells for 6 h was eliminated by preincubation with free RGD peptide. Negative control L1210 cells exhibited no binding (white block).

were preincubated with free RGD peptide. Finally, no binding was observed when the conjugate was incubated with L1210 cells, cells known to lack RGD binding affinity.

To confirm the flow cytometry data, we repeated the assessment of time-dependent uptake of G5-FL-RGD and its target specific binding to MDPC-23 cells using confocal microscopy. MDPC-23 cells were cultured in 35 cm culture dishes and exposed to 300 nM G5-Fl-RGD conjugate for 30 min, 3 h, or 6 h. The cells demonstrated time-dependent uptake of the conjugate where, at 30 min, the confocal images revealed no apparent internalization of the conjugate (Figure 6a), while after 3 h with the conjugate, the cells showed modest uptake of the G5-FL-RGD (Figure 6b). After 6 h in coculture, the conjugate appears throughout the cytoplasm in a characteristic punctuate pattern (Figure 6c). When HDMEC, HUVEC, and MDPC-23 cells were cultured and exposed to 300 nM G5-FL-RGD with and without preincubation with free RGD peptide, confocal examination confirmed conjugate binding and inhibition by free RGD peptide preincubation (Figure 7).

Finally, when the G5-FL-RGD conjugate was incubated for 3 h in an acellular tooth organ culture, binding to the predentin was clear and robust (Figure 8a–c). This binding was completely eliminated when cultures were preincubated with 300 nM free RGD peptide for 30 min prior to G5 conjugate incubation (Figure 8d–f). Taken together, these data suggest that the G5-FL-RGD conjugate selectively binds to the $\alpha_V\beta_3$ integrin present in the predentin.

DISCUSSION

Tissue engineering is an interdisciplinary field that applies the principles of engineering and the life sciences to the development of biological substitutes that repair, maintain, or improve tissue function that has been lost, impaired, or damaged due to injury, trauma, disease, or cancer (*28*). Currently, in dental medicine, restoration of impaired tooth function depends on materials that share few of the chemical characteristics of natural tooth (*29–31*). About 90% of the organic matrix of tooth structure is type I collagen (*32, 33*). Much work has been done investigating the role of noncollagenous proteins in tooth development (*29, 31, 34, 35*) and pulp biology (*9, 36, 37*). To

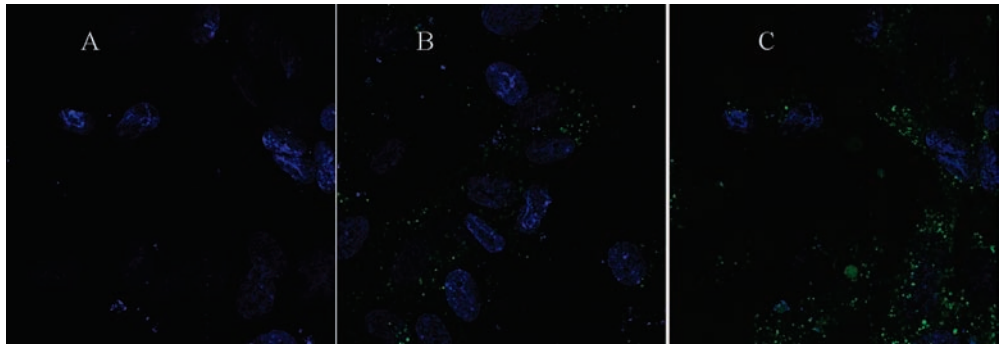

Figure 6. Confocal images of cultured MDPC-23 cells cocultured with G5-Ac-Fl-RGD for 30 min (a), 3 h (b), and 6 h (c) show uptake of this targeted dendrimer in a time-dependent manner.

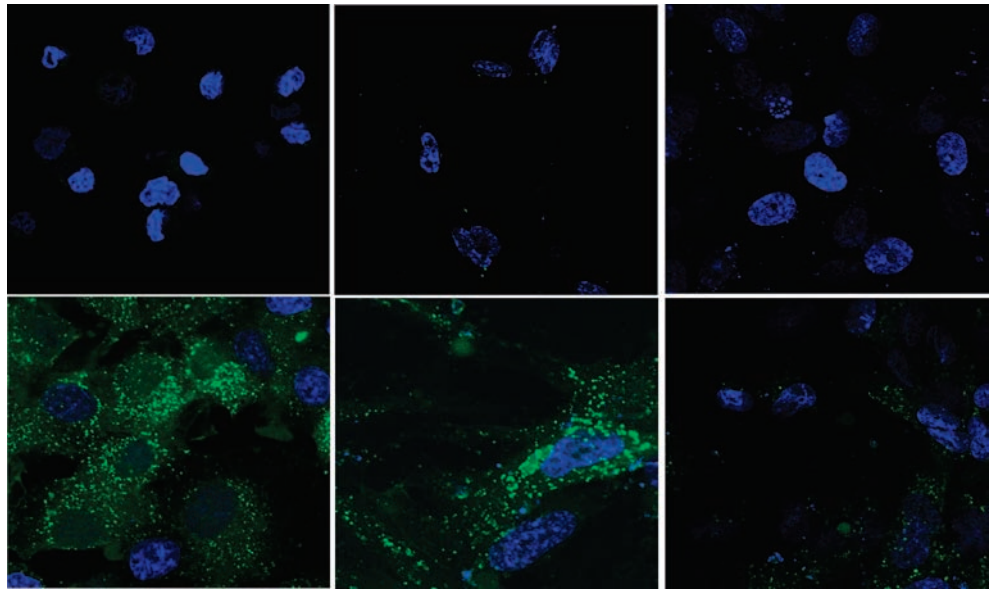

Figure 7. Confocal photomicrographs of odontoblast-like MDPC-23 cells (a,d), human umbilical vein endothelial cells HUVEC (b,e), and human dermal microvascular cells HDMEC (c,f) (60×) show no binding or uptake of G5-Fl-RGD conjugate when cells are preincubated with free RGD peptide (a–c), while binding and uptake of this conjugate are clearly seen in cells not preincubated with free RGD peptide (d–f).

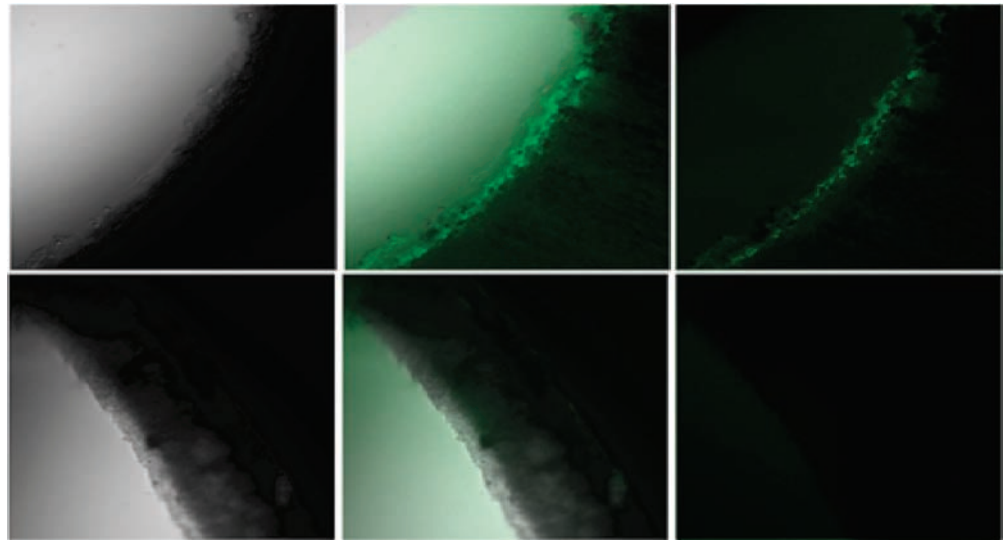

Figure 8. Confocal photomicrographs (20×) of human adult tooth slices (a), when cocultured with RGD targeted G5-Ac-Fl-RGD conjugate (b,c), demonstrate targeted binding of G5-Fl-RGD conjugate to predentin. This effect is not seen in G5-Fl conjugate without the RGD targeting moiety (d,e), and eliminated when coculture of tooth slice and G5-Ac-Fl-RGD was preincubated with free RGD (f) peptide prior to coculture.

build on this work, the present studies examine possible roles for ligands that bind to the organic matrix, specifically the $\alpha_V\beta_3$ integrin.

Integrins constitute a 24-member family of cell adhesion molecules. Each of these molecules consist of two subunits, α and β, which are noncovalently associated (*38*). These subunits bind with specificity to integrin receptors either on extracellular matrix molecules or on the cell surface, thus mediating both cell–cell and cell–matrix interactions (*38*). Strategies focusing on targeting integrin adhesion receptors with short bioadhesive oligopeptides have demonstrated in vitro control of cell adhesion and differentiation. More importantly, these peptides have also demonstrated enhancement of tissue healing responses in vivo including bone formation (*39*), nerve regeneration (*40, 41*) and corneal tissue repair (*42, 43*). Here, we extend this work by showing that synthetic PAMAM–RGD conjugates can be designed to present the RGD motif to cells known to express the $\alpha_V\beta_3$ integrin. By characterizing these conjugates via HPLC, MALDI-TOF, and ^{1}H NMR analysis, we present direct and indirect evidence that RGD peptides were successfully conjugated to a PAMAM-FITC dendrimer platform. In addition, when cultured in vitro with human dermal microvessel endothelial cells (HDMEC), human vascular endothelial cells (HUVEC), and odontoblast-like MDPC-23 cells, we demonstrate both time- and dose-dependent uptake of these conjugates into all three cell types that can be measured quantitatively and visualized via confocal microscopy. We also presented compelling data on the specificity of this binding, which was completely prevented by preincubation with free RGD peptide. Taken together, these data indicate that the G5-FL-RGD conjugate described here selectively binds to cells expressing the $\alpha_V\beta_3$ receptor.

The RGD motif has been widely studied in targeting molecule cancer therapeutics (*11*), and more specifically in targeting the neovasculature of tumor-enhanced angiogenesis (*12, 23, 44*). And, while the role of RGD peptides in angiogenesis is established, the present work is the first study to our knowledge to demonstrate selective binding of a synthetic polymer con-

jugate to the $\alpha_V\beta_3$ integrin binding sites of the predentin matrix of human teeth. The binding, seen via flow cytometry and confirmed by confocal microscopy, suggests robust expression of the $\alpha_V\beta_3$ integrin and uptake of the RGD conjugate in odontoblast-like cells. We further demonstrated that in both the odontoblast-like cells and the predentin of adult tooth organs, this binding is eliminated by preincubation with free RGD peptide. Taken together, these data substantiate a role for this receptor in endothelial cells as well as suggest a possible role in tissue associated with the dental pulp. These data suggest that targeted binding of RGD to tooth predentin may be an important event in pulp biology.

The induction of bone and dentin formation by molecules found in the dental matrix of adult teeth was established several decades ago (*45, 46*). However, the molecular signals responsible for this regenerative response and their signaling pathways are still being studied (*29, 34, 47–50*). In addition, the role of one of the most abundant molecules in the dentin matrix of adult teeth (RGD) is unknown. The current study argues that this often overlooked molecule may play an important role in odontoblast regeneration and/or homeostasis. In addition, we show that synthetic polymers can be used to deliver RGD to both pulplike cells and their mineralized matrix in a way that specifically engages the $\alpha_V\beta_3$ receptor. Since current therapies include mechanical debridment of tooth dentin, diseased via tooth decay or periodontal infection, and this process exposes dentinal tubules and in some cases predentin, the development of functional polymers that can exploit native binding molecules (integrins) for the nonviral delivery of therapeutic drugs makes this therapy a realistic goal for the future.

Ultrasmall Mixed Ferrite Colloids as Multidimensional Magnetic Resonance Imaging, Cell Labeling, and Cell Sorting Agents

Ernest V. Groman,* Jacqueline C. Bouchard, Christopher P. Reinhardt, and Dennis E. Vaccaro

BioPhysics Assay Laboratory, Inc., 80 Webster Street, Worcester, Massachusetts 01603. Received January 22, 2007; Revised Manuscript Received August 30, 2007

One area that has been overlooked in the evolution of magnetic nanoparticle technology is the possibility of introducing informational atoms into the iron oxide core of the coated colloid. Introduction of suitable atoms into the iron oxide core offers an opportunity to produce a quantifiable probe, thereby adding one or more dimensions to the magnetic colloid's informational status. Lanthanide-doped iron oxide nanoparticles have been synthesized to introduce informational atoms through the formation of colloidal mixed ferrites. These colloids are designated ultrasmall mixed ferrite iron oxides (USMIOs). USMIOs containing 5 mol % europium exhibit superparamagnetic behavior with an induced magnetization of 56 emu/g Fe at 1.5 T, a powder X-ray diffraction pattern congruent with magnetite, and R_1 and R_2 relaxivity values of 15.4 $(\text{mM s})^{-1}$ and 33.9 $(\text{mM s})^{-1}$, respectively, in aqueous solution at 37 °C and 0.47 T. USMIO can be detected by five physical methods, combining the magnetic resonance imaging (MRI) qualities of iron with the sensitive and quantitative detection of lanthanide metals by neutron activation analysis (NA), time-resolved fluorescence (TRF), X-ray fluorescence, along with detection by electron microscopy (EM). In addition to quantitative detection using neutron activation analysis, the presence of lanthanides in the iron oxide matrix confers attractive optical properties for long-term multilabeling studies with europium and terbium. These USMIOs offer high photostability, a narrow emission band, and a broad absorption band combining the high sensitivity of time-resolved fluorescence with the high spatial resolution of MRI. USMIO nanoparticles are prepared through modifications of traditional magnetite-based iron oxide colloid synthetic methods. A 5 mol % substitution of ferric iron with trivalent europium yielded a colloid with nearly identical magnetic, physical, and chemical characteristics to its magnetite colloid parent.

INTRODUCTION

Since the initial reports of dextran-coated colloidal magnetic iron oxides (*1*), three principal applications for these materials have been reported: magnetic resonance imaging (*2, 3*), cell labeling and tracking (*4–7*), and cell sorting (*8–11*). In these applications, the use of coated magnetic nanoparticles has been conceptually limited by a focus on the iron oxide's surface, i.e., its coating agent, such as dextran, used to stabilize the iron oxide core and covalently bind probes, antibodies, and binding proteins. One area that has been overlooked in the evolution of magnetic nanoparticle technology is the possibility of introducing informational atoms into the iron oxide core of the (dextran-) coated colloid. Introduction of suitable atoms into the iron oxide core offers an opportunity to produce a quantifiable probe, thereby adding one or more dimensions to the magnetic colloid's informational status.

Among the atoms that carry multiple informational packets are those found in the lanthanide series (*12*). Since the chemistry among the lanthanides is so similar (*13*), one would anticipate that introducing one lanthanide element would serve as a guide, through judicious substitutions, for introducing the entire lanthanide series into the iron oxide core of magnetic nanoparticles. Among the informational properties that lanthanide atoms possess (Table 1) are sensitive and quantitative detection by neutron activation (NA) (*14*), detection by time resolved fluorescence (TRF) (*15*), detection by combined X-ray fluorescence/scanning electron microscopy (EM) (*12*), and applications involving neutron capture therapy (*16–18*).

The question that remains is, Can conditions be found whereby lanthanide atoms can be used to form mixed ferrites that simultaneously (i) allow the formation of stable colloids with magnetic properties similar to colloidal magnetite, (ii) allow the conjugation of labels, drugs, and peptides to the dextran surface as previously reported for iron oxide colloids, and (iii) allow efficient cell labeling? In this report, we successfully address this question and describe the synthesis of a family of dextran-coated colloidal mixed ferrites.

MATERIALS AND METHODS

All materials were obtained from commercial sources unless otherwise indicated.

Synthesis of USPIO and USMIO Colloids. Ultrasmall superparamagnetic iron oxide (USPIO) was prepared as follows: $FeCl_3$ $6H_2O$ (15.8g, 58.6 mmol) and $FeCl_2$ $4H_2O$ (6.24 g, 31.6 mmol) were added to 200 mL distilled water, and the resulting solution was filtered through a 0.2 μm filter. Equal volumes of the metal halide solution and a carbohydrate solution [dextran (60 g, Sigma Chemical Co.) in 120 mL distilled water] were then mixed by stirring at ambient temperature. To this mixture was added dropwise a 30% solution of ammonium hydroxide until the pH of the mixture reached 10. At this stage, the mixture was heated to 90 °C for 15 min. The mixture was cooled, resulting in the formation of a black colloidal iron oxide. The pH was adjusted to 7.2–7.5, and excess dextran was removed by ultrafiltration using a 100 kDa molecular weight cutoff membrane. The ultrafiltered product, obtained with a yield in iron of about 90%, was stored at 4 °C.

New nanoparticles (designated USMIO) were made without change in the above procedure other than the removal of various amounts of ferric chloride from the initial starting materials and

replacement with equivalent moles of lanthanide chloride. Through this procedure, a series of increasing levels of europium containing ferrites was generated from a substitution of 1–100 mol % of ferric iron with trivalent cationic europium. In a second series, replacement of ferric iron was performed using lanthanum, samarium, terbium, and gadolinium. The final product was tested for the presence of ammonia, iron, and dextran. All products tested negative for ammonia. The product was adjusted for total metals concentration (iron plus lanthanide) to 10 mg/mL. Dextran content varied from 1 to 2.5 mg dextran per milligram of iron.

Dry Weight. Dry weight was recorded in mg/mL. Five milliliters of each sample was dried in a tared container at 105 °C for two days until a constant weight was reached.

Dextran. Dextran concentrations were determined by total organic carbon analysis (Galbraith Laboratories, Knoxville, TN).

Ammonia. USMIO colloids were tested for the presence of ammonia using an ammonium test (EMD Chemicals, Gibbstown, NJ).

Iron Content. Total iron was determined using a 2,2′-bipyridyl photometric method (*19*).

Neutron Activation Analysis (NA). Lanthanide concentrations were measured using neutron activation analysis methods as previously reported (*20*). Samples were placed into contaminant-free sample vials (BioPAL, V-0MS02) and dried at 90 °C prior to neutron activation analysis.

X-ray Powder Diffraction. X-ray powder diffraction was performed by H&M Analytical Services, Inc. (Allentown, NJ). Fine powder samples were mounted on a zero-background holder and tested on a Philips PW1800 diffractometer using Cu radiation at 40 kV/30 mA. Scans were run over the range 15–70° with a step size of 0.05° and counting times of 12–24 h. Once the diffraction patterns were obtained, the phases were identified with the aid of the Powder Diffraction File published by the International Centre for Diffraction Data. The mean crystal size was calculated from the diffraction data by H&M Analytical Services, Inc., using the Scherrer formula.

Magnetization Properties. The magnetization of 5 mol % europium USMIO as a function of applied magnetic field was measured with a Quantum Design physical property measurement system equipped with the vibrating sample magnetometer option (Quantum Design, San Diego, CA). The powdered sample consisting of 5.9 mg of USMIO was press-fit into a polypropylene fixture and secured in a brass trough sample holder. Corrections were applied by subtracting the remanant field of the superconducting magnet.

Magnetic Susceptibility. Magnetic susceptibility was measured as volume susceptibility using a Johnson Matthey magnetic susceptibility balance per the instruction manual. Samples were measured at a concentration of 10 mg/mL (total metals).

MR Relaxometry. MR relaxivity measurements (R_1 and R_2) of USMIO colloids were performed in a 0.47 T Bruker Minispectrometer at 37 °C under the direction of Dr. Craig Ferris, Department of Physiology, University of Massachusetts Medical School (Worcester, MA), following standard procedures (*21*, *22*).

Sizing Methods. Colloids were sized by photon correlation spectroscopy using a 90 *Plus* particle size analyzer (Brookhaven Instruments Company). Samples were diluted to a concentration of 1 mg/mL (total metals) in distilled water (unless otherwise indicated), passed through a 0.1 μm filter, and sonicated for one minute in a water-bath sonicator. A count rate between 50 000 and 500 000 counts per second was obtained. Data were collected for 4 cycles of 15 min and the cumulative results combined. Particle size was calculated by assuming refractive indexes of 1 and 0 for the real and imaginary components, respectively. Typical reproducibility for intra- and interassay variability yielded coefficients of variation of less than 6% and 9%, respectively. Nanoparticle sizes were calculated using an intensity-weighted log normal distribution.

Zeta Potential. Zeta potential measurements for representative colloids were provided courtesy of Brookhaven Instruments Company using a Zeta Potential Analyzer version 3.40. Samples were run at a concentration of 1 mg/mL (total metals) in distilled water (pH 7.2–7.5) under the following instrument parameters: Sample count rate $\sim$ 450 kcps, sampling time = 128 μs, current = 150.00 mA, electric field 27.78 V/cm. Data is reported as the mean zeta potential (mV) of nine measurements.

Cross-Linking and Amination of USMIO Colloids. USMIO colloids were reacted with epichlorohydrin followed by amination using methods previously reported for USPIO iron-based colloids (*23*, *24*). Aminated colloids were further reacted with rhodamine isothiocyanate (RITC) or fluorescein isothiocyanate (FITC) in 0.1 M sodium bicarbonate buffer (pH 8.9) and extensively dialyzed against water.

Time-Resolved Fluorescence (TRF). Time resolved fluorescence spectra were measured using a Varian Cary Eclipse fluorescence spectrophotometer. For TRF measurements, the instrument was set for phosphorescence mode. Spectrophotometer settings for both fluorescence and phosphorescence measurements were as follows: scan control, medium; smoothing, moving average factor 5; excitation filter, auto; emission filter, open; PMT detector voltage, 600 V. Settings for TRF were as follows: total decay time, 0.020 s; number of flashes, 1; delay time, 0.2 ms; gate time, 5 ms. Samples were dissolved in 0.1 N HCl, incubated for 5 min, added to 1 mL of development solution (BioPAL), and incubated for 30 min prior to recording spectra. Excitation and emission wavelengths for europium-doped USMIO colloidal particles were 340 and 615 nm, respectively. Dot blots were performed on standard filter paper and developed by overlaying blotted samples with dicarboxyl

pyridine. Blotted samples were dried at room temperature and visualized under black light (254 nm).

Stability of USMIO Colloid to Chelates and Lysosomal Conditions. One milliliter samples of 5 mol % europium USMIO were dialyzed against 10 mL of the following solutions for the indicated times, using a 12–14K MWCO dialysis membrane: 1 mM EDTA pH 7.4 (24 h), 1 mM DTPA pH 7.4 (24 h), 10 mM succinate pH 7.4 (24 h), 10 mM citrate pH 7.4 (24 h), and 10 mM sodium acetate pH 5.0 (1 h, 3 h, 16 h, 2 days, 5 days). A control sample was dialyzed against PBS pH 7.4 for 24 h. Dialyzed USMIO preparations were compared with untreated starting USMIO for europium by time-resolved fluorescence. Samples were prepared and analyzed by time-resolved fluorescence measurements as described above. Results are reported as the percentage of retained europium compared to the untreated USMIO.

Cell Labeling and Electron Microscopy (EM). Cell labeling and electron microscopy studies were conducted at the University of Massachusetts Medical School (Worcester, MA) under the direction of Dr. Gregory M. Hendricks (Manager Core–Electron Microscopy Facility). Normal murine fibroblasts were grown in Petri dishes. USMIO colloids were diluted (1:10) into cell medium and added to the individual dishes. The cells were incubated with the label for 1 h at room temperature. Unincorporated label was washed off with three changes of fresh PBS. The cells were fixed in 2.5% glutaraldehyde in PBS buffer for 1 h. The cells were then washed in three changes of PBS buffer and postfixed in 1% osmium tetroxide for 20 min at room temperature. Following postfixation, the cells were washed in three changes of PBS buffer and transferred into a 1% aqueous solution of uranyl acetate for 20 min and then left in buffer overnight at 4 °C. The next day, the cells were dehydrated through a graded series of ethanol and transferred into a mixture of epoxy resin (SPI-pon 812/araldite) and ethanol (50:50, v/v) and left overnight to infiltrate. The following day, the cells were transferred through three changes of freshly made whole epoxy resin (SPI-pon 812/araldite) and then into the final embedding mixture of the same epoxy resin and flat-embedded in the dishes and allowed to polymerize for 48 h at 68 °C. Once polymerized, the cells embedded in the epoxy resin were removed from the dishes by immersing the dishes into liquid nitrogen, cracking the dish away from the embedded cells. The cells were then oriented and sectioned (cross sections). Electron micrographs were taken on a Philips CM 10 at 80 kV.

Cell Toxicity. Cell toxicity determination was performed with LinCap cells grown to 60% confluence in cell culture media. The cell culture medium was removed. Five mole percent of europium USMIO was diluted into fresh culture medium to either 0.1 or 1 mg/mL (total metals) and added to the cells and incubated at 5% CO_2 and 37 °C for 24 h. The confluence level of the treated cells was then recorded.

RESULTS

Synthesis. USMIO colloids were synthesized and characterized for size and zeta potential using the lanthanides europium, samarium, and lanthanum (Table 2). The synthetic procedures for each of these three lanthanide-enriched USMIO colloids remained unchanged other than the replacement of ferric iron with trivalent europium in the first synthesis, with trivalent samarium in the second, and trivalent lanthanum in the third. The synthetic procedure proved reproducible. To understand the generality of the synthetic process, other trivalent lanthanides not included in Table 2 were substituted for ferric iron. These elements included terbium, ytterbium, and gadolinium. Each preparation appeared visually identical and had similar sizes. Ytterbium- and gadolinium-containing USMIO colloids were not characterized further. Europium, lanthanum, and samarium were chosen for their excellent properties in detection by neutron activation technology. Europium and terbium were chosen because when combined with suitable enhancers, they produce a strong time-resolved fluorescence signal.

Table 2. Effect of Replacement of Ferric Iron with Trivalent Lanthanides on Colloid Size[a]

lanthanide (%)[b]	effective diameter (nm)	zeta potential (mV)
none	23	−1.54
Eu (1%)	30[c]	-
Eu (1%)	22[c]	-
Eu (5%)	37[c]	5.68
Eu (5%)	44[c]	-
Eu (15%)	35	-
Eu (30%)	26	11.87
Eu (50%)	36	8.03
Eu (100%)	90	-
La (30%)	30	-
Sm (30%)	25	-
Eu (5%)-FITC	49[d]	-
Eu (5%)-FITC	49[e]	-

[a] Samples were prepared for sizing by dilution into water to a concentration of 1 mg/ml for total metals and were then passed through a 0.1 μm filter. Less than 2% of colloid was retained on the filter as assessed by metal analysis (lanthanides by neutron activation analysis and iron by the dipyridyl method) and by absorption spectroscopy at 550 nm. Visual examination of the filters showed a minimal amount of staining indicating small amounts of particulate formation. Eu = europium, La = lanthanum, Sm = samarium. [b] Refers to a mol% replacement of ferric chloride with a trivalent lanthanide metal during synthetic procedures. [c] Represents duplicate synthesis. [d] USMIO colloid cross-linked, aminated and labeled with fluorescein. [e] USMIO colloid cross-linked, aminated and labeled with rhodamine.

Physical Properties. *X-ray Powder Diffraction.* MION and 5 mol % europium USMIO X-ray powder diffraction patterns had all the major peaks associated with authentic magnetite. The X-ray powder diffraction pattern for 5 mol % europium USMIO and the position of the major peaks for magnetite are presented in Figure 1. Small miscellaneous peaks were seen in the 5 mol % europium USMIO preparation and are attributed to the large amounts of dextran present in the dry powder. The crystal type for 50 mol % europium USMIO could not be determined due to its small crystal size. The crystal sizes as determined by X-ray powder diffraction of MION, 5 mol % europium USMIO, and 50 mol % europium USMIO were 7.5, 6.6, and <2 nm, respectively. Crystal dimensions of 5 to 15 nm for USPIO magnetite preparations are reported to all be superparamagnetic (*25*), consistent with magnetization measurements performed on 5 mol % europium USMIO.

Magnetization. The magnetization curve for 5 mol % europium USMIO was obtained by varying the applied magnetic field between −3 and +3 Tesla. At room temperature, 5 mol % europium USMIO exhibited superparamagnetic behavior as shown by a single line with no evidence of hysteresis with an induced magnetization of 56 emu/g Fe at 1.5 T (Figure 2). This compares with the literature value of 68 emu/g iron of MION (*22*).

Magnetic Susceptibility. The effect of increasing substitution of europium (+3) for iron (+3) on susceptibility is shown in Figure 3. At levels of 1 and 5 mol % europium, magnetic susceptibility decreased less than 5%. However, at levels of 50 mol % europium, magnetic susceptibility was lowered by greater than 2 orders of magnitude. The relationship between increasing europium content and decreasing magnetic potency exhibited a semilogarithmic relationship. Since the observed magnetic susceptibility is related to the percentage of iron (+3) in the colloid, the observed decrease in magnetic susceptibility with increasing europium content can be attributed to both disruption of the electronic relationship among the ferric iron components

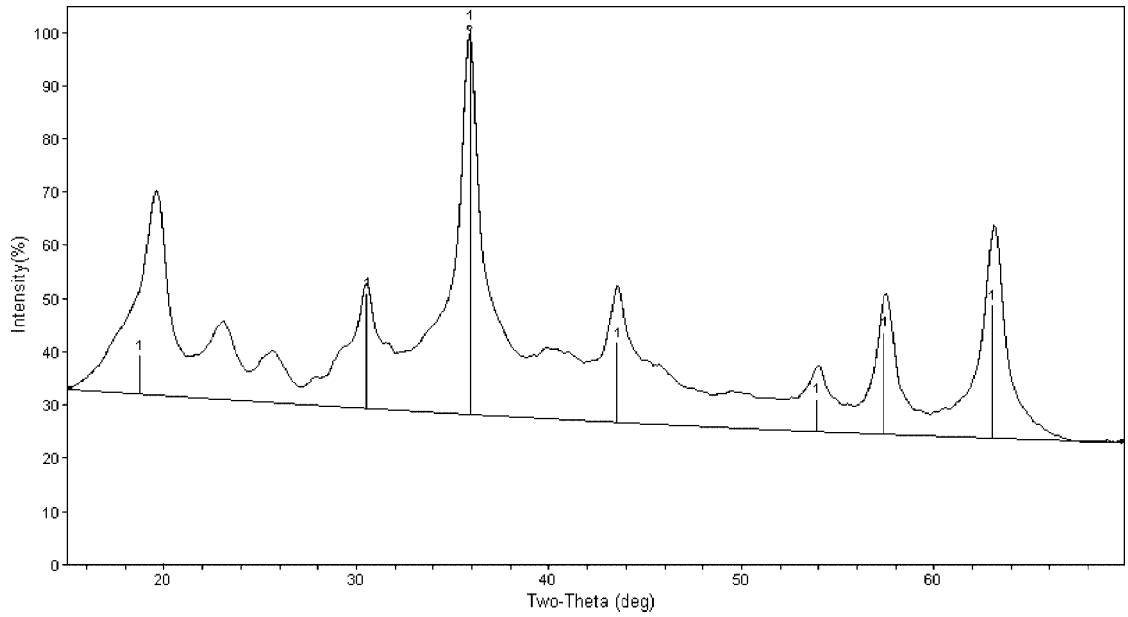

Figure 1. X-ray powder diffraction pattern for 5 mol % europium USMIO. The spectrum was obtained as described in Methods and Materials. The principal peaks for and relative magnitude of magnetite are indicated by the vertical bars labeled 1.

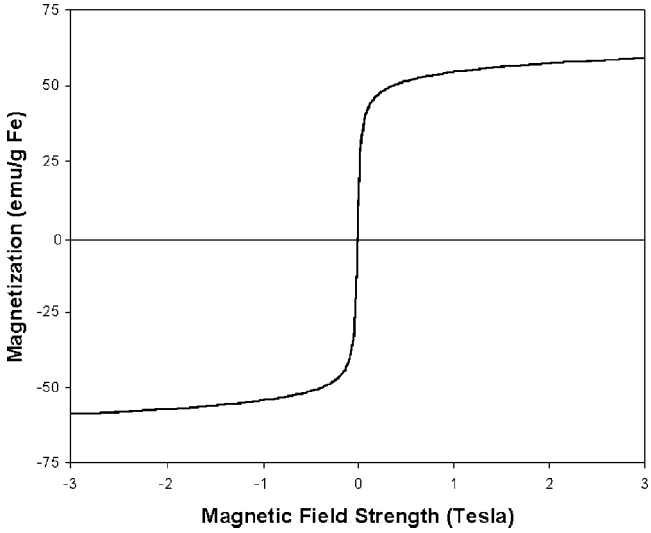

Figure 2. Magnetization vs field strength for 5 mol % europium USMIO at room temperature. The data were acquired between −3 and +3 Tesla and consist of 748 measurements.

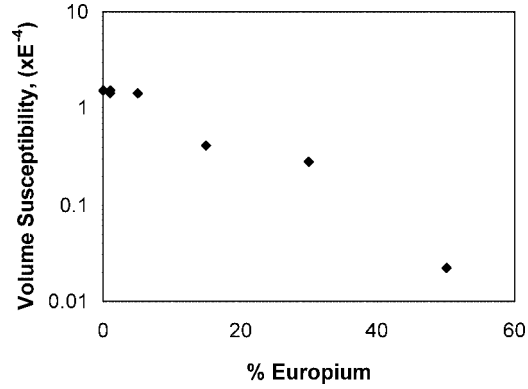

Figure 3. Relationship between magnetic potency (volume susceptibility) and mol % europium replacement of ferric iron in USMIO. Volume susceptibility was determined as described in Methods and Materials section.

in the magnetite crystal (responsible for the generation of the magnetic properties of magnetite (*26*)) and decreasing crystal size associated with the increasing europium content (*26, 27*).

Relaxivity. The relaxation constants R_1 and R_2 were measured at 0.47 T and 37 °C. Values for MION and 5 mol % europium USMIO are presented in Table 3. Literature values for R_1 and R_2 for MION and other iron oxides are included in Table 3 for comparison.

Size and Charge. The substitution of trivalent lanthanide metals for ferric iron in the preparation of colloid had minimal effect on colloid size (Table 2). The effective diameters of most USMIO colloids fell between 20 and 40 nm except for one 5 mol % europium USMIO (44 nm) and the 100 mol% europium USMIO (90 nm). No trend exists between colloid size and increasing europium content, as illustrated by the scatter diagram comparing percent europium (abscissa) versus effective diameter (ordinate) (Figure 4). When europium trichloride completely replaced ferric chloride, the colloid size markedly increased. This size increase was accompanied by formation of particulates as indicated by impaired filtration of the colloid. Substitution of ferric iron with 30 mol % samarium or lanthanum also had no effect on colloid size (Table 2).

The size and size distribution of lanthanide-containing magnetite is very close to that found for similar materials consisting exclusively of ferric and ferrous iron. These materials referred to in the literature as SPIO (Feridex) and USPIO (MION) have sizes between 20 and 100 nm with size distribu-

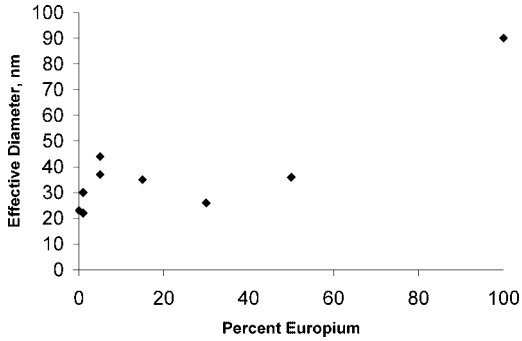

Figure 4. Scattergram of data from Table 2. Percent europium refers to displacement of ferric iron by trivalent europium during synthetic procedures (retention of europium in final colloidal form confirmed by neutron activation analysis; data not shown). The variation in size as a function of increasing lanthanide substitution as illustrated with europium trichloride (through 50 mol % europium) was not statistically significant, as all points fell within 1 standard deviation of the mean effective diameter.

tions that cover a range of a factor of 3 to 4 between the smallest and largest particles (*22*, *28*). USMIO colloid containing 5 mol % europium had an effective diameter of 37 nm with 90% of the particle mass contained between 21 and 64 nm (Figure 5). Similar results were obtained with USMIO colloids containing up to 50 mol % substitution of europium for ferric iron.

The charge of the USMIO colloids was assessed using zeta potential analysis. As shown in Table 2, the zeta potential for colloids containing 0, 5, 30, and 50 mol % europium increases in charge from slightly negative for 0 mol % europium to moderately positive for 50 mol % europium. For comparison, the zeta potential for Feridex, a SPIO, and MION, an USPIO, were measured using the same instrumental system and were −30.97 and −9.16, respectively.

Zeta potentials can vary greatly depending upon the pH and salt concentration. For all zeta potential measurements reported, the samples were diluted 1:10 into distilled water. The pH values of the USMIO, Feridex, and MION were between 7.2 and 7.5. The salt concentration was less than 1 mM. The high negative zeta potential of Feridex can be attributed to its method of synthesis and stabilization with citrate (*29*). The difference in zeta potential between MION and 5 mol % europium USMIO may result from minor variations in synthesis and purification, yielding small differences in binding of chloride and hydroxide ions and loosely associated europium cations to the colloid surface.

Chemical Properties. *Cross-Linking, Amination, and Fluorescence Labeling of USMIO Colloids.* USMIO colloids containing 5 mol % europium were cross-linked with epichlorohydrin. The cross-linking reaction was terminated with ammonia, which introduced amino groups. The presence of amino groups was confirmed by ninhydrin staining. In order to demonstrate the accessibility and reactivity of the amino groups, cross-linked–aminated USMIO was reacted using FITC or RITC as model compounds. Reaction at pH 8.9 led to the covalent attachment of RITC and FITC. In control experiments, RITC and FITC were not retained when incubated with untreated USMIO or cross-linked USMIO not treated with ammonia. Fluorescence of RITC and FITC was clearly apparent in dot blots under black light as well as by detection using conventional instrumental fluorescence detection. The effect of cross-linking, amination, and ligand labeling resulted in a small increase in colloid size consistent with similar reactions reported for colloidal iron oxides. The small size changes strongly indicate that individual colloidal particles do not aggregate during the cross-linking process.

Distinct fluorescence and time-resolved fluorescence spectra were obtained with a cross-linked aminated 5 mol % europium USMIO reacted with RITC (Figure 6). The emission spectrum of rhodamine was clearly apparent when colloid was diluted into either PBS or development solution. The emission spectrum of europium was present only when colloid was diluted into development solution. The absence of an emissions peak for europium (when diluted in PBS) is due to europium's requirement for a chelating antenna in order for its time-resolved properties to be detected (*30*). The fluorescence of rhodamine did not interfere with the acquisition of the time-resolved spectrum for europium for two reasons: (i) Rhodamine does not fluoresce when excited at 340 nm, the excitation wavelength used for europium. (ii) Rhodamine does not yield a signal when excited at 550 nm when its emission spectrum is acquired in phosphorescent mode (time-resolved fluorescence). Therefore, it is possible to acquire the fluorescence spectra of both the organic ligand (rhodamine) and the inorganic element (europium) in the presence of each other without interference from either fluorescent contributor.

USMIO colloids labeled with europium or terbium can be detected by time-resolved fluorescence after treatment with 4,4,4-trifluoro-1-(2-naphthyl)-1,3-butanedione or dicarboxyl pyridine. A representative standard curve is presented in Figure 7 showing the relationship between signal intensity and europium. The minimum level of detection corresponds to about 10^{-14} g of europium.

USMIO colloids labeled with europium or terbium can also be detected using the dot blot technique (Figure 8). Columns 1 and 3 show the visual detection of europium- or terbium-labeled USMIO colloids, which yields a red or green color and a visual detection limit of about 10^{-14} mol. When equal amounts of each USMIO colloid are mixed, a yellow color is obtained (column 2). For comparison, the detection of FITC is shown in column 4, which is minimally visible at 10^{-11} mol.

Europium is Part of the Colloid. The presence of europium in the colloid was demonstrated by passage of europium-containing colloids through a 30K MWCO membrane. Greater than 99% of the europium, as quantified by neutron activation analysis, and 100% of the colloid, as quantified by photon correlation spectroscopy, were retained by the membrane. In a second experiment, after a 10 min treatment of the colloid with 1 mM DTPA (pH 7.4), followed by passage through a 30K MWCO membrane, greater than 98% of the europium was retained by the membrane. As a control experiment, 1 mM europium was treated with 1 mM DTPA (pH 7.4) for 10 min and was found to freely pass through the membrane. In a third experiment using CM-Sephadex (0.01 M Tris buffer pH 7.4) to capture cationic europium, greater than 95% of the europium eluted in the void volume with the colored colloid. In control experiments, cationic europium was quantitatively retained by CM-Sephadex.

In order to additionally demonstrate incorporation of europium into the magnetite crystal structure (fourth experiment), the change in magnetic susceptibility associated with increasing europium substitution for ferric iron in the synthesis of USMIO colloids was examined. A semilogarithmic decline in magnetic potency was associated with increasing europium content consistent with disruption of the crystal structure of the starting magnetite (Figure 3).

In a fifth experiment, the presence of europium in the magnetite crystal was assayed using X-ray powder diffraction. Magnetite samples containing 0 and 5 mol % of europium showed no evidence of europium. This observation was attributed in the 5 mol % europium USMIO to the detection limit of the method. In iron oxide preparations containing 50 mol %

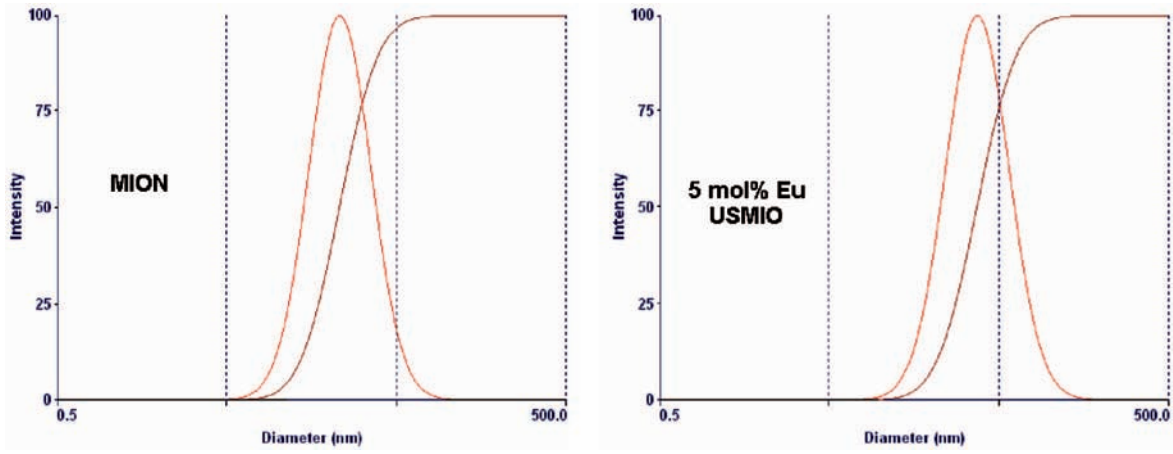

Figure 5. Size distribution of USPIO (MION) colloids and USMIO (5 mol % europium) colloids. MION had an effective diameter of 23 nm and a polydispersity of 0.189. 5 mol % europium USMIO colloids had an effective diameter of 37 nm and a polydispersity of 0.200.

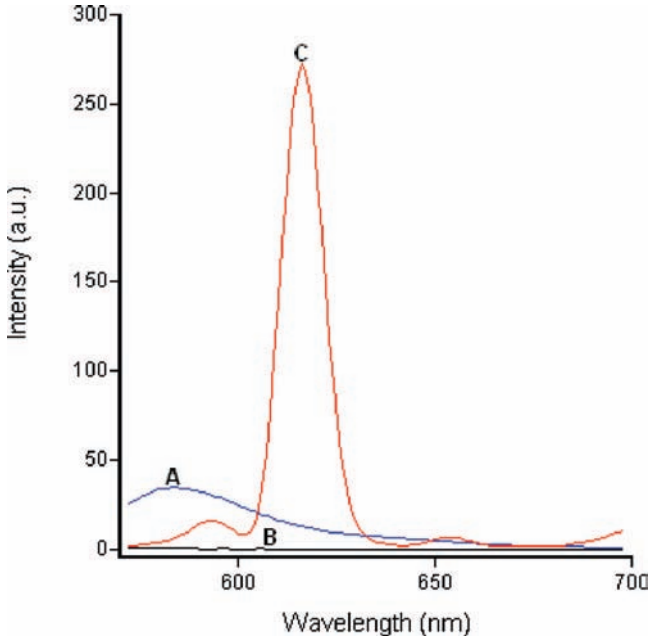

Figure 6. Fluorescence and time-resolved fluorescence spectra of RITC conjugated 5 mol % europium USMIO. USMIO was cross-linked, aminated, and conjugated with RITC. Curve A: Fluorescence of RITC-conjugated USMIO. RITC-conjugated USMIO was diluted 1:10 000 in PBS. The fluorescence spectrum for rhodamine was obtained in fluorescence mode by exciting at 555 nm and scanning emissions between 570 and 700 nm. Curve B: Time-resolved fluorescence of rhodamine-conjugated USMIO without development solution. RITC-conjugated USMIO was diluted 1:10 000 in PBS. Its time-resolved fluorescence spectrum for europium was obtained in phosphorescence mode by exciting at 340 nm and scanning emissions between 570 and 700 nm. Curve C: Time-resolved fluorescence of RITC conjugated USMIO with development solution. RITC-conjugated USMIO was diluted 1:100 into 0.1 N HCl, incubated 5 min, and diluted further 1:100 into development solution. The time-resolved fluorescence spectrum for europium was obtained in phosphorescence mode by exciting at 340 nm and scanning emissions between 570 and 700 nm. Fluorescence spectrum of RITC after acid treatment and incubation in development solution was also obtained in fluorescence mode as described for curve A and presented a nearly identical spectrum to curve A (data not shown).

europium and 100 mol % europium, the presence of characteristic absorption peaks associated with europium oxide were seen.

Stability of USMIO Colloids. The USMIO colloids reported in Table 2 showed no systematic change in size when stored at 4 °C for a period of over a year. Further, 5 mol % europium

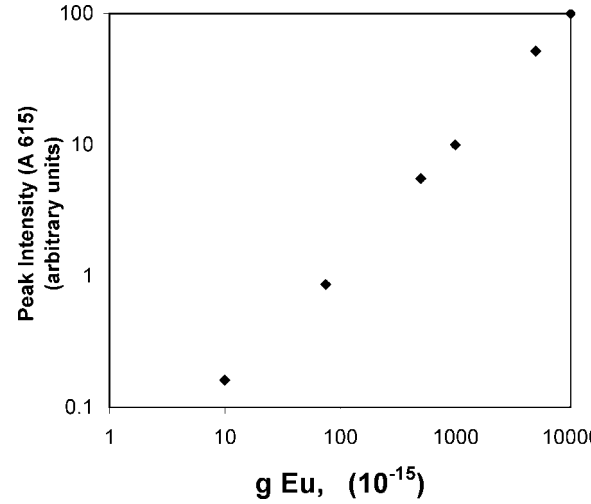

Figure 7. Detection limits for europium in a 5 mol % europium USMIO. Samples were prepared for time-resolved fluorescence measurements as described in Methods and Materials.

USMIO showed no change in size when subjected to autoclaving (121 °C) for 15 min. All colloids reported in Table 2 exhibited no change in size following three freeze–thaw cycles.

The stability of USMIO under physiological conditions between pH 5.0 and 7.4 was studied to simulate stability in serum, cellular cytoplasm, and lysosomal subcompartments (Table 4). At pH 7.4 in the presence of chelating agents (EDTA, DTPA, citrate, succinate), less than 0.2% europium was removed from the colloidal USMIO after 5 days of treatment. This small amount can be attributed to osmotic dilution of the sample during dialysis. At pH 5.0, a time-dependent removal of europium from the colloidal USMIO was observed from 1.40% to 2.04% of total europium. Europium removal plateaued after 2 days, and no additional loss was observed when treatment was extended to 5 days. This small but reproducible loss may be attributed to the removal of surface europium.

Biological Properties. *Cell Labeling with USMIO.* Murine fibroblasts were incubated with 5 mol % europium USMIO suspended in cell medium for 1 h as described in the Methods and Materials section. Cells were then fixed and examined by electron microscopy for the presence of electron dense material. In the image shown in Figure 9, one prominent electron-dense cluster of particles is contained within a vacuole (arrow). Similar electron-dense vacuoles were seen in other fields. In all fields, the particles appeared to be contained within cytoplasmic vacuoles, and no particles were seen adhering to the cell surface.

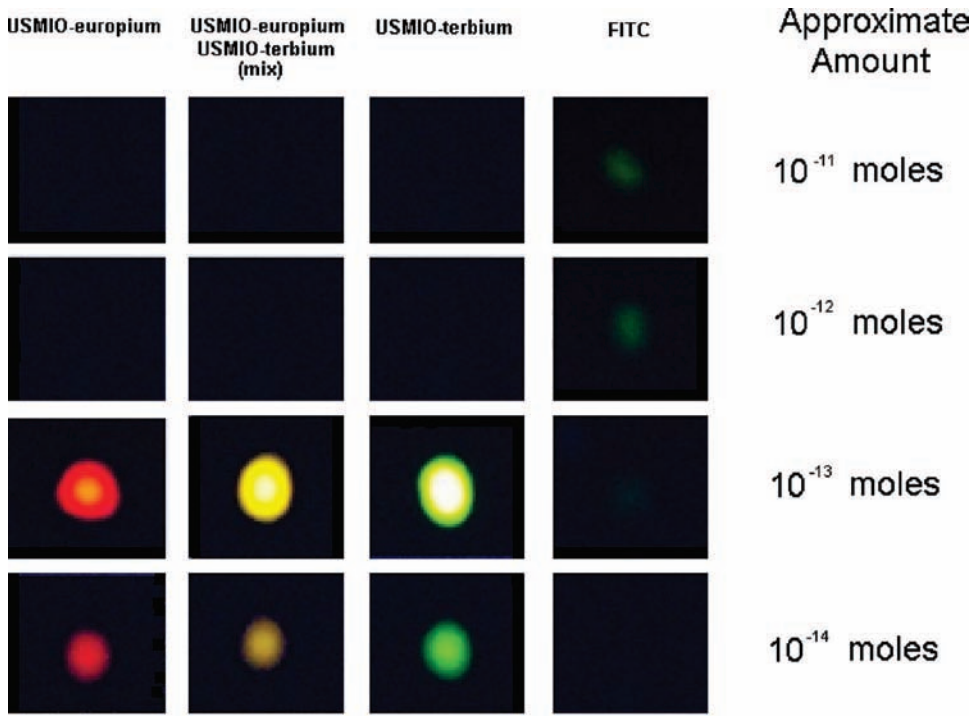

Figure 8. Detection limits and color display of USMIO colloid labeled with europium or terbium. Dot blots of USMIO colloids containing europium and terbium were obtained by pipetting samples containing the indicated amounts of europium or terbium. Samples were dried and then overlaid with dicarboxyl pyridine. No colloid was spotted in rows 1 and 2. Column 4 contains indicated amounts of FITC. Samples were visualized by illumination with a black light set for 254 nm. The approximate amount indicated in the figure represents moles of europium, terbium, or fluorescein contained in the USMIO samples and fluorescein standard, respectively.

Table 4. Stability of USMIO to Chelates and Lysosomal Conditions[a]

dialyzed against:	pH	dialysis (h)	% europium
PBS (control)	7.4	24	99.96
1 mM EDTA	7.4	24	99.91
1 mM DTPA	7.4	24	99.99
10 mM citrate	7.4	24	99.83
10 mM succinate	7.4	24	99.97
10 mM sodium acetate	5.0	1	98.60
10 mM sodium acetate	5.0	3	98.23
10 mM sodium acetate	5.0	16	98.06
10 mM sodium acetate	5.0	48	98.00
10 mM sodium acetate	5.0	120	97.96

[a] 5 mol % europium USMIO was dialyzed against the conditions indicated below. The percent europium retained within the dialysis membrane is shown in column 3.

Close examination of the particle structure reveals multiple groups of smaller irregular shapes that clump together to form the larger particle aggregate. Measurement of the individual "subunits" reveals a size of approximately 4–6 nm consistent with the crystal size measured by X-ray powder diffraction and reported for MION (*22*).

USMIO Cellular Toxicity. There was no suggestion of cell toxicity following a 1 h incubation with USMIO either upon examination of normal murine fibroblasts while in a monolayer or after preparation for electron microscopy (personal communication, Gregory M. Hendricks). Additionally, LinCap cells, when exposed for 24 h to 0.1 and 1 mg/mL (total metals), USMIO showed small declines in confluence falling from a starting level of 60% confluence to 50% and 40% confluence, respectively. The decline in percent confluence may be attributed to cell rounding during the incubation with USMIO.

DISCUSSION

We report the synthesis of a family of mixed ferrite colloidal magnetic iron oxides through the addition of small amounts of non-iron atoms during formation of the iron oxide core. The incorporation of nonferrous atoms to magnetic colloidal iron oxides introduces new reporting properties to these materials while retaining the magnetic potency associated with iron-based MRI contrast agents and cell-sorting magnetic materials. Among the new properties that these atoms confer to the colloidal iron oxides are (i) quantitative detection by neutron activation (Eu, Sm, La, Tb), (ii) quantitative and sensitive detection by time-resolved fluorescence (Eu, Tb), (iii) detection by X-ray fluorescence in conjunction with scanning electron microscopy (all the lanthanides), (iv) simultaneous detection of multiple labeled colloids, e.g., detection of Eu in the presence of La by NA, and (v) applications in neutron capture therapy (Gd). While this report provides data relevant to the incorporation of lanthanides in the ferrite crystal, other elements such as the transition metals scandium, yttrium, cobalt, manganese, and zinc can be introduced using similar synthetic procedures.

Dextran-coated iron oxides containing lanthanides can be prepared using methods that are essentially identical to those used to prepare the analogous iron oxide colloids. Further, these lanthanide-labeled colloids possess nearly identical physical and chemical properties to that of the unlabeled reference material (MION). These properties are manifest in the similarity between the two materials: (i) physical properties including magnetic properties [magnetization (emu/g Fe), superparamagnetism, susceptibility, and relaxivity (R_1 and R_2)], powder X-ray diffraction (crystal size), hydrodynamic size, and size distribution; and (ii) chemical properties including zeta potential (charge), surface chemistry (cross-linking with epichlorohydrin and reaction with low molecular weight ligands), and stability against environmental challenge.

USMIO colloids can be detected by a variety of methods including neutron activation analysis (NA), time-resolved fluorescence (TRF), X-ray fluorescence/scanning electron microscopy (XRF-SEM), and magnetic resonance imaging (MRI). USMIO colloids can be labeled with a number of lanthanides

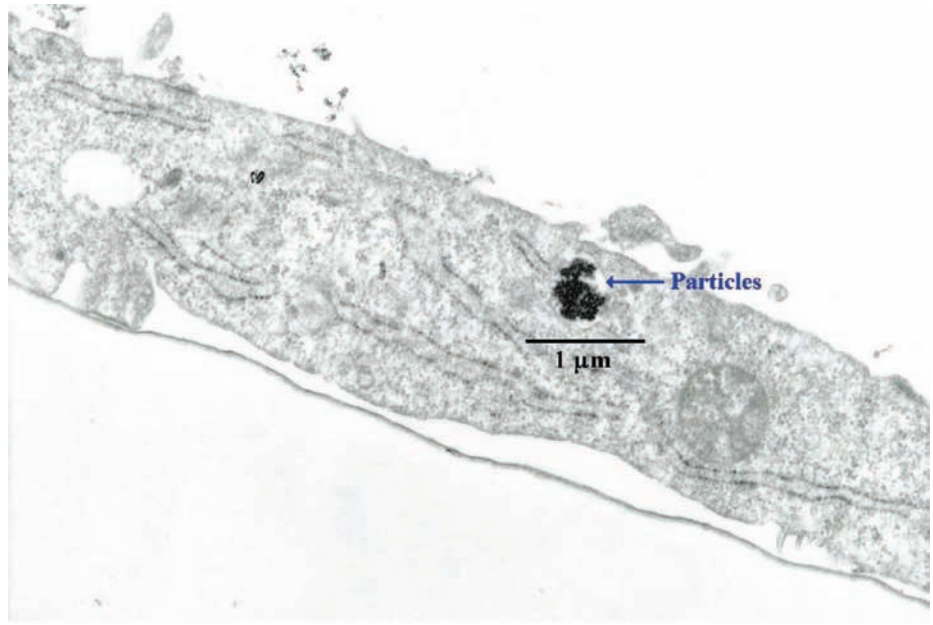

Figure 9. Electron micrograph of 5 mol % europium USMIO in fibroblast cytoplasm. The magnification factor is 25 000.

that can be sensitively detected and quantified by neutron activation analysis (Table 1). The usefulness of any particular lanthanide for NA is determined by its neutron capture cross section of its isotopes, the isotopic abundance of the selected element, and the resulting half-life of the new isotope following neutron capture. On the basis of these requirements, the lanthanides listed in Table 1 have been selected as most useful in neutron activation analysis (*14*).

Neutron activation is a sensitive method of analysis. The limit of detection of europium by NA is 5 ng. Considering the mol % of iron and europium, 95 and 5 mol %, respectively, within an optimized magnetic USMIO colloid, approximately 35 ng of the USMIO colloid can be detected by NA. Similar levels of detection can be achieved with the other lanthanides identified in Table 1.

Neutron activation has the benefits of not requiring sample preparation, correction for differential neutron absorption due to matrix, or processing for quantifying. In addition to labeling iron oxides with europium, other lanthanides can be introduced into the iron oxide core and can be quantified by neutron activation. Since the gamma emission spectra of the various neutron-activated lanthanide elements are both unique and nonoverlapping, these elements can be quantified simultaneously in the presence of other lanthanides. This property allows the design of experiments where similar colloids labeled with different lanthanides are used either sequentially or simultaneously in labeling and tracking cells (*16*).

USMIO colloids labeled with europium or terbium can be detected by time-resolved fluorescence after treatment with 4,4,4-trifluoro-1-(2-naphthyl)-1,3-butanedione or dicarboxyl pyridine. The minimum level of detection corresponds to about 10^{-14} g of europium. USMIO colloids labeled with europium or terbium can also be detected using the dot blot technique with a visual detection limit of about 10^{-14} mol (europium and terbium). The presence of lanthanides in the iron oxide matrix confers attractive optical properties for long-term multilabeling studies with europium and terbium. These USMIOs offer high photostability, a narrow emission band, and a broad absorption band combining the high sensitivity of time-resolved fluorescence with the high spatial resolution of MRI (*15*).

Detection of USMIO colloids using electron microscopy was accomplished after treating cells with colloid added to the cell culture medium. USMIO colloid labeled with 5 mol % europium is strongly magnetic, as indicated from its magnetic susceptibility and magnetization curve. At concentrations of iron equal to approximately 10 mg/mL, the USMIO colloid forms an aqueous ferrofluid consistent with its strong magnetic property. Finally, the USMIO colloid exhibits typical properties of a T2 MRI contrast agent similar to that reported for USPIO (MION) (Table 3) (*21*).

The capability to use neutron activation to quantitate iron oxides and USPIO type materials labeled with lanthanides allows analysis of experimental protocols related to MRI, cell labeling, and cell separation. For instance, when contrast-enhanced MRI experiments are performed with USPIO-type materials labeled with lanthanides, the blood concentration can be followed more accurately and to lower levels of detection than can be achieved using MRI. Further, contrast agent obtained by biopsy, by dissection, or by necropsy can be measured by neutron activation. Similarly, magnetic iron oxides lightly labeled with lanthanides used in cell-sorting experiments can be quantitated to determine the degree of their removal from purified cell preparations. The introduction of gadolinium into USMIO opens the possibility of combining the high spatial resolution of MRI for drug location followed by neutron-capture therapy by exposing the USMIO to thermal neutrons. Therefore, gadolinium-doped USMIO offers an attractive alternative to boron compounds for neutron capture therapy.

Since the initial synthesis of colloidal iron oxides for applications as MR contrast agents, researchers using these materials have arrived at the problem of quantifying the samples containing these colloids in animal models. This problem has been most extreme at low concentrations, particularly in applications of cell labeling and cell tracking. One opportunity to alleviate this difficulty would be to label such colloids with iron-59. However, the use of this isotope in the synthesis of USPIO/USMIO is problematic, especially when the synthesis is performed on the small scale used for trace labeling. A second limitation in using radiolabels is the limited availability of instrumentation suited for quantifying iron-59. Third, a general absence of laboratories prepared to handle iron-59 in the chemical laboratory as well as in animal experimentation has made this solution to quantifying colloidal iron oxides problematic.

We propose a simpler solution to quantifying ferrites as contrast/tracking agents by labeling them with small amounts of stable (nonradioactive) europium. This solution avoids the

introduction of radioactivity into the workplace while minimally affecting the physical and chemical properties of the colloid from that of the unlabeled reference material. Europium can be quantified readily by neutron activation, a well-known and established technique. Neutron activation analysis has several advantages that make it attractive for quantification including sensitive detection, minimal sample preparation, and no quenching of the sample during the activation and counting processes. Further, europium can be sensitively detected by other methods such as time-resolved fluorescence. Thus, through the introduction of europium, USMIO can be quantified by neutron activation, visualized in vivo by MRI, visualized histologically using time-resolved fluorescence, and detected in electron microscopic samples by X-ray fluorescence.

Aequorin-Based Homogeneous Cortisol Immunoassay for Analysis of Saliva Samples

Laura Rowe,[†] Sapna Deo,[‡] Josh Shofner,[†] Mark Ensor,[†] and Sylvia Daunert*[,†]

Department of Chemistry, University of Kentucky, Lexington, Kentucky 40506. Received February 2, 2007; Revised Manuscript Received July 24, 2007

Homogeneous assays are attractive because they are performed in only one phase, namely, the liquid phase, and thus, they do not require separation of phases as their heterogeneous counterparts do. As opposed to heterogeneous assays, the signal generation in a homogeneous assay is a direct result of analyte binding, which allows the multiple washing and incubation steps required in an indirect heterogeneous assay format to be eliminated. Moreover, homogeneous assays are usually fast and amenable to miniaturization and automation. In this article, we describe the development of a homogeneous assay for the hormone cortisol using the bioluminescent photoprotein aequorin as a reporter molecule. A cortisol derivative was chemically conjugated to the lysine residues of a genetically modified aequorin in order to prepare an aequorin–cortisol conjugate capable of binding anticortisol antibodies. The binding of anticortisol antibodies to the aequorin–cortisol conjugate resulted in a linear response reflected in the emission of bioluminescence by aequorin. A competitive binding assay was developed by simultaneously incubating the aequorin–cortisol conjugate, the anticortisol antibodies, and the sample containing free cortisol. Dose–response curves were generated relating the intensity of the bioluminescence signal with the concentration of free cortisol in the sample. The optimized homogeneous immunoassay produced a detection limit of 1×10^{-10} M of free cortisol, with a linear dynamic range spanning from 1×10^{-5} to 1×10^{-9} M. Both serum and salivary levels of cortisol fall well within this assay's linear range (3.0×10^{-7} M to 7.5×10^{-7} M and 1.0×10^{-8} M to 2.5×10^{-8} M, respectively), thereby making this assay attractive for the analysis of this hormone in biological samples. To that end, it was demonstrated that the assay can be reliably used to measure the concentration of free cortisol in saliva without significant pretreatment of the sample.

INTRODUCTION

Homogeneous assays offer the distinct advantage of utilizing relatively simple, "mix and measure" techniques. In a homogeneous assay, the binding of an analyte to its respective binder results in a direct and quantifiable change in signal (*1*). For this reason, homogeneous assays do not require the multiple washing, filtration, and incubation steps that are often required in heterogeneous assays. Therefore, homogeneous assays are more amenable to automation and high-throughput screening adaptation. Traditional enzymatic immunoassays usually do not work in a homogeneous format. Instead, radioisotopic methods, such as scintillation proximity assays, are often employed. However, the use of radioactive substances creates problems in terms of cost, safety, and disposal when dealing with the large reagent volumes necessary for high-throughput screening. In an effort to reduce these problems, there has been a push to increase the availability and practicality of nonisotopic homogeneous assay methods, utilizing techniques such as fluorescence resonance energy transfer (FRET), fluorescence polarization, and fluorescence correlation spectroscopy (*2*).

These homogeneous fluorescence methods have been very successful in reducing the cost and increasing the efficiency of high-throughput drug screening. Problems are encountered, however, as reagent volumes continue to decrease, approaching the sensitivity limit of fluorescence detection. The fluorescent background present in biological fluids can drastically decrease the signal-to-noise ratio when employing fluorescent detection methods in such small sample volumes. In contrast, homogeneous assays based on chemiluminescence or bioluminescence afford the detection limits needed in small volume analysis and are uniquely advantageous in terms of their sensitivity, lack of background noise in biological fluid, and affordability (*3*). Herein, we report the development of such a bioluminescence homogeneous assay for the hormone cortisol employing the recombinant photoprotein aequorin. This assay, in addition to the aforementioned advantages, is also capable of directly detecting cortisol in saliva samples (*4*).

Cortisol is a steroid hormone that is important for the regulation of both metabolic rates and growth rates. Abnormal cortisol levels are indicative of a wide variety of diseases, such as Addison's disease and Cushing's syndrome or the onset of diabetes (*5*). In order to diagnose and properly treat such diseases, a physician must periodically assay a patient's level of free cortisol. However, hormones such as cortisol follow circadian rhythms and require multiple samplings over the course of a day. Noninvasive sampling, such as saliva collection, is therefore preferred over more invasive methods, such as plasma collection. Since the hormone concentration detected in saliva is the nonprotein bound fraction of cortisol, the most important fraction when diagnosing pathological conditions, saliva analysis is as practical as serum analysis for clinical diagnoses (*6*). Another advantage is that the individual concentration of the corticosteroid-binding globulin does not affect the results in salivary cortisol analysis, as it does in serum cortisol analysis. However, the concentration of hormones in saliva is generally 10–50-fold lower than the concentration of hormones in plasma (*7*). For this reason, assays that detect salivary levels of hormones must be more sensitive than the corresponding serum-based assays.

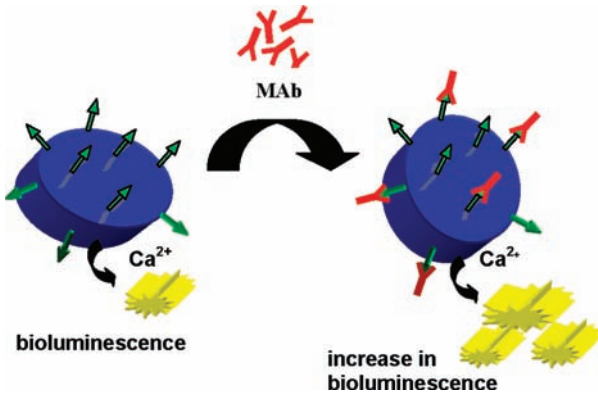

Figure 1. Schematic of how the homogeneous response works in the assay. The bioluminescence intensity of aequorin (blue ball) increases when cortisol Ab (red figures) binds to the cortisol molecules (green arrows) that are conjugated to the aequorin protein via its lysine residues.

In the homogeneous immunoassay described herein, we employed the bioluminescent photoprotein aequorin as a label (Figure 1). Since bioluminescence is a rare phenomenon in terrestrial organisms, there is virtually zero background bioluminescence found in human fluid, and this allows for the highly sensitive detection of the signal emitted by aequorin (*8*). Aequorin is a calcium-activated photoprotein isolated from the jellyfish *Aequorea victoria* that is composed of apoaequorin, coelenterazine, and molecular oxygen (*9*). Coelenterazine, an imdazopyrazinone chromophore, is located in the central, hydrophobic, reaction pocket of apoaequorin. Following the binding of calcium, the protein undergoes a conformational change which leads to the oxidation of coelenterazine to coelenteramide. The relaxation of this excited coelenteramide results in the emission of bioluminescence at 469 nm (*9*). This calcium-induced light emission from aequorin has led to its use as an *in vivo* calcium indicator and as an ultrasensitive label for a variety of immuno- and DNA hybridization assays (*10–19*).

In order to develop a homogeneous assay for cortisol, cortisol-3-*O*-carboxymethyloxime *N*-hydroxysuccinimidyl ester (Cortisol-3-CMO-NHS) was first conjugated to the lysine residues of a cysteine-free aequorin mutant. The cysteine-free mutant of aequorin, in which all three native cysteine residues have been changed to serine residues, was selected on the basis of previous studies performed in our laboratory that demonstrated the higher bioluminescent activity of this mutant, as compared to wild-type aequorin (*20*). Several conjugates were prepared, which differed in their *N*-hydroxysuccinimide cortisol-to-aequorin ratio so that the conjugate that exhibited the largest signal change could be selected for further studies. The conjugate that presented optimal signal generation as well as binding ability to the anticortisol antibody was chosen for the development of the homogeneous assay. The assay was then characterized and optimized in terms of reproducibility, precision, and accuracy in untreated saliva samples in order to establish the analytical performance of the assay. Finally, the assay developed was employed in the determination of cortisol in human saliva samples.

EXPERIMENTAL PROCEDURES

Reagents. Tris (hydroxymethyl) amino methane (Tris) free base, ethylenediaminetetraacetic acid (EDTA) sodium salt, glucose, sodium chloride, calcium chloride, bovine serum albumin, kanamycin, sodium dodecyl sulfate (SDS), and all other reagents were purchased from Sigma (St. Louis, MO). Luria Bertrani (LB) broth was from Gibco BRL (Gaithersberg, MD). Coelenterazine was purchased from Biotium (Hayward, CA). Cortisol-3-CMO-NHS and monoclonal anticortisol antibody were from United States Biological (Swampscott, MA). 96-well polystyrene microtiter plates were purchased from Nunc (Rochester, NY). Bradford assay kits were obtained from Bio-Rad Laboratories (Hercules, CA). The buffers were composed as follows: buffer A, 30 mM Tris, 4 mM EDTA, pH 7.5; buffer B, buffer A with 0.1% Tween-20; buffer C, 30 mM Tris, 100 mM $CaCl_2$, pH:7.5; buffer D, 100 mM $NaHCO_3$, 4 mM EDTA, pH 8.2. Deionized water purified with a Milli-Q System (Waters, Milford, MA) was used to prepare all solutions.

Apparatus. Cell cultures were grown in a Forma Scientific orbital shaker (Marietta, OH), and the optical density was determined using a Milton Roy Spectronic 21D spectrophotometer (Ivyland, PA). Cell cultures were centrifuged using a Beckman J2-M1 centrifuge (Palo Alto, CA). Fractions were lyophilized with a Christ Alpha 2-4 lyophilizer (Osterode am Harz, DE). Triplicate bioluminescence measurements were made on a Dynex MLX Microtiter Plate Luminometer (Vienna, VA). All values reported are the mean of three replicates, which have been background-corrected.

Methods. *Expression and Purification of Apoaequorin.* The plasmid pSD110 was initially constructed in our laboratory to contain the gene for a cysteine-free mutant of apoaequorin in which all three cysteine residues were mutated to serine residues (*19*). This plasmid was transformed into competent *Bacillus subtilis* cells. The cells containing the aequorin gene were then grown to an OD of 0.6, and 1 mM IPTG was added in order to induce the expression of the apoaequorin. The supernatant from the cells was harvested, acid precipitated with glacial acetic acid to a pH of 4.2, and centrifuged for 30 min at 9500 *g*, 4 °C, in order to pelletize the precipitated protein. The protein pellet was resuspended and filtered through a 0.2 μm filter; the pH was then adjusted to 7.5. The resuspended protein was then purified with a HQ ion exchange chromatography column (*18*). Purity of the protein was verified with SDS-PAGE, and concentration was determined with the Bradford Assay.

Conjugation of Aequorin to Cortisol. The apoprotein was dialyzed against buffer D. A solution of cortisol-3-CMO-NHS dissolved in anhydrous dimethyl sulfoxide was then added dropwise to the apoprotein, which was stirring in a 5 mL conical vial, at 4 °C. The reaction was allowed to proceed overnight at 4 °C with slow stirring. The stock solution of the cortisol-3-CMO-NHS in anhydrous dimethyl sulfoxide was prepared immediately prior to use and added to the protein in the following stoichiometric ratios of aequorin/cortisol: 1:1500, 1:2000; 1:2500.

Bioluminescence Emission of the Aequorin–Cortisol Conjugates. The microtiter plate wells for this, and all subsequent experiments, were blocked for nonspecific binding by allowing 300 μL of TE buffer containing 4 mg/mL bovine serum albumin to incubate overnight in the wells at 4 °C. All glass test tubes employed for initial mixing during this, and all subsequent, experiments were also blocked with BSA prior to use in an analogous manner. The wells were then emptied and allowed to air-dry prior to use. The apoaequorin–cortisol conjugates were dialyzed against buffer A and then charged with 100 μg/mL native coelenteraine overnight at 4 °C. Serial dilutions of the conjugates (10^{-8} to 10^{-13} M) were prepared using buffer A. 50 μL of the conjugate dilutions were added to the blocked wells, and signal was collected for 5 s on the luminometer, following the injection of 100 μL of buffer C.

Bioluminescence Half-Life. The conjugates were diluted until total emitted light was less than 5000 RLUs within a 4 s integration time. Ten microliter aliquots of each conjugate were then injected with 100 μL of buffer C, and light measurements were collected every 0.1 s for 4 s on an MGM Optocomp 1 test tube luminometer (Hamden, CT). The linear portion of the decay

kinetics curve was then plotted with time (s) versus ln (intensity). The half-life was then determined using $y = mx + b$, $m = -k$, $t_{1/2} = .697/k$.

Binder Dilution Curves. Anticortisol antibody (330 μg/mL) was serially diluted in buffer A in order to obtain the following dilutions: 33 μg/mL, 3.3 μg/mL, 3.3×10^{-1} μg/mL, 3.3×10^{-2} μg/mL, 3.3×10^{-3} μg/mL, 3.3×10^{-4} μg/mL, 3.3×10^{-5} μg/mL, and 3.3×10^{-6} μg/mL. A volume of 50 μL of the cortisol antibody was incubated with a 50 μL volume of 1×10^{-11} M conjugate (1:1500, 1:2000, 1:2500) for 30 min at room temperature with shaking at 250 rpm. Luminescence measurements were then collected over a 5 s time period following the injection of 100 μL of buffer C.

Dose–Response Curves. A stock solution of 10^{-2} M cortisol was prepared in methanol, and 10^{-3} to 10^{-11} M cortisol dilutions were subsequently made from this stock solution using buffer A. From the binder dilution study, a concentration of 3.3 μg/mL cortisol antibody was selected. A volume of 50 μL of various concentrations of cortisol and a volume of 50 μL cortisol antibody were incubated with 50 μL of the 10^{-11} M 1: 2500 conjugate in blocked microtiter plate wells. The plate was incubated for 30 min at room temperature with shaking at 250 rpm. The luminescence measurements were then collected in a manner identical to the protocol discussed in the binder dilution study. An initial dose–response curve was produced, and the LOD and dynamic range were calculated from this first curve. Subsequent dose–response curves were produced over a period of several days, and these curves were used during the analysis of the saliva samples.

Analysis of Saliva Samples. Saliva samples were collected from six healthy subjects using the following protocol. Subjects rinsed their mouths out with water after they awoke in the morning and collected their saliva 15 min later in two plastic 1.7 mL tubes. Saliva samples were stored at −80 °C until analysis. The samples were thawed and centrifuged at 3000 rpm, 4 °C, just prior to analysis. The supernatant was used for the study. For this study, the buffer used for all dilutions was buffer B. A volume of 50 μL of the 3.3 μg/mL cortisol antibody, 50 μL of the saliva supernatant, and 50 μL of 10^{-11} M 1:2500 conjugate was combined in preblocked wells, incubated at room temperature, with shaking at 250 rpm, for 30 min. Signal was collected from each well for 5 s on the Dynex luminometer following the injection of 100 μL of buffer C. This process was repeated three times, on three separate days, in order to determine the intraassay precision of the salivary cortisol measurements.

Recovery Studies in Saliva. For this study, 1.25 μL of serial dilutions of cortisol standard were added to a pool of saliva (pool 6). Pool 6 refers to the fact that each subject had two separate Eppendorf tubes containing their saliva. The two samples were pooled together to make pool 1 through pool 6. Pool 1 is the combined saliva from subject 1, pool 2 is the combined saliva from subject 2, and so forth. 1.25 μL of 1×10^{-3} to 1×10^{-6} M cortisol standards were added to 250 μL of saliva in order to spike the saliva with 5, 50, 500, and 5000 nmol/L of cortisol. Analysis of the samples was identical to the method detailed in the Analysis of Saliva Samples section.

RESULTS

A cysteine-free mutant of aequorin, in which the cysteines at positions 145, 152, and 180 were all mutated to serine residues, was employed as the label for this assay. This cysteine-free aequorin has been shown to be more active than the wild-type protein. A plasmid was previously constructed in our laboratory that encoded for this apoaequorin mutant (*21*). This plasmid was transformed into *Bacillus subtilis* cells, and the recombinant apoaequorin was then expressed in the cells and purified with ion exchange chromatography. Following purification, the cysteine-free aequorin was chemically conjugated to a cortisol-3-CMO-NHS through the lysine residues of aequorin. Conjugates with aequorin–cortisol derivative initial reaction molar ratios of 1:1500, 1:2000, and 1:2500 were prepared and characterized in terms of their bioluminescent activity and their ability to bind anticortisol antibodies. The bioluminescence of the aequorin–cortisol conjugates was found to be stable for over three months when stored at −80 °C. In order to study the bioluminescent activity of the conjugates, light was collected for 5 s following the addition of a calcium-containing bioluminescence triggering buffer. All three conjugates exhibited acceptable activity, which progressively decreased as the concentration of the cortisol derivative used during conjugation increased. For example, the 1:1500 conjugate exhibited higher activity than the 1:2000 conjugate, and the 1:2000 conjugate was more active than the 1:2500 conjugate. The conjugates were characterized in terms of their half-life to determine whether there were any changes in decay profiles caused by the conjugation. Half-lives were obtained by collecting light for 4 s, at 0.1 s intervals, following the addition of a calcium-containing buffer. The half-life data were analyzed in the same manner as previously described (*12*). The 1:1500, 1:2000, and 1:2500 conjugates gave successively increasing half-lives of 1.48, 1.51, and 1.96 s, respectively.

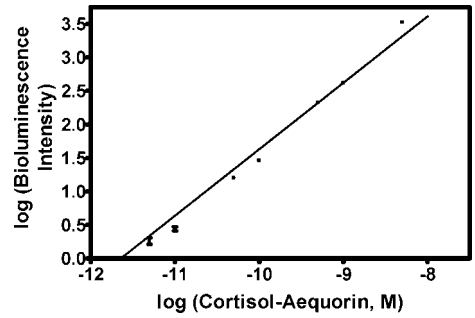

Figure 2. Bioluminescence curve generated by the 1:2500 aequorin–cortisol conjugate. The bioluminescence intensity decreases linearly as the concentration of the conjugate decreases. Data are the mean of three replicates, which have been blank subtracted, ±1 standard deviation.

The aequorin–cortisol conjugates were then characterized in terms of their bioluminescence properties. For that, a curve was generated that related the concentration of the conjugate to the intensity of the bioluminescence signal. From this curve, the lowest possible concentration of the aequorin–cortisol conjugate that could be employed in the development of the assay was determined, i.e., the lowest concentration of conjugate that still exhibited significant bioluminescence emission when compared to a blank control. For this study, the conjugates were first serially diluted with buffer A, and their bioluminescence intensities were then measured over a 5 s time period. From this curve, it was determined that a concentration of 1×10^{-11} M conjugate should be employed in all further studies (Figure 2).

In order to determine the antibody concentration that would produce an optimal change in signal, a binder dilution study was performed employing a 1×10^{-11} M concentration of the aequorin–cortisol conjugate. For this, 50 μL of the conjugate was incubated with 50 μL of different concentrations of anticortisol antibody ranging from 33 to 3.3×10^{-6} μg/mL. Following a 30 min incubation at room temperature with shaking, the bioluminescence intensity of the conjugate–antibody solution was measured over a period of 5 s in a microtiter plate luminometer. Analysis of the binder dilution curve resulted in the selection of the 3.3 μg/mL dilution of anticortisol antibody

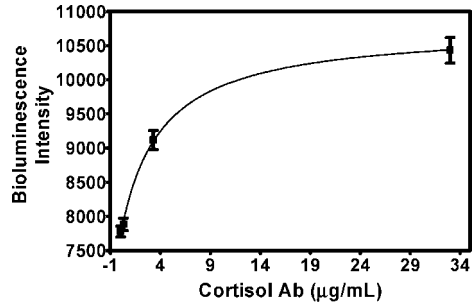

Figure 3. Binder dilution curve for 1:2500 aequorin–cortisol conjugate. The greater the cortisol antibody concentration, the larger the bioluminescent signal from aequorin. Data are the mean of three replicates, which have been blank subtracted, ±1 standard deviation.

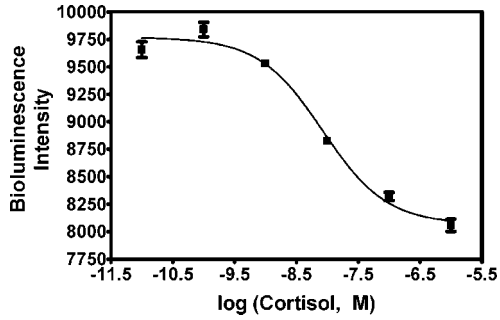

Figure 4. Dose–response curve for cortisol generated using 1:2500 aequorin–cortisol conjugate. Data are the means of three replicates, which have been blank subtracted, ±1 standard deviation.

to be used for the rest of the assay development studies. This concentration was the lowest antibody concentration that caused a significant change in aequorin's signal (Figure 3). Moreover, the results of the binder dilution study indicated that the 1:2500 aequorin–cortisol conjugate yielded the most significant change in signal following anticortisol binding. Therefore, only the 1:2500 aequorin–cortisol conjugate was employed for subsequent dose–response curves and salivary analysis.

Dose–response curves were produced by simultaneously incubating 50 μL of serially diluted cortisol standard, 50 μL of the 1:2500 aequorin–cortisol conjugate, and 50 μL of the anticortisol antibody in a microtiter plate well for 30 min at room temperature, while shaking. Following incubation, light was collected for 5 s after injecting 100 μL of buffer C. The average of three replicates was then plotted (Figure 4). The assay exhibited a sigmoidal response to changing cortisol concentrations with increasing cortisol concentrations resulting in a lower bioluminescence signal. These results corresponded to the data from the binder–dilution curves in that increasing the concentration of anticortisol antibody available to bind the aequorin–cortisol conjugate resulted in an increase in bioluminescent signal. The detection limit for this assay was 1×10^{-10} M of cortisol. The linear dynamic range of the assays spanned over 5 orders of magnitude, from 1×10^{-5} to 1×10^{-9} M of cortisol.

To demonstrate clinical feasibility, we next investigated the ability of this assay to function in untreated biological samples, specifically in human saliva samples. The saliva of six healthy subjects was analyzed, and the concentration of cortisol in the samples fell within, or very close to, the accepted clinical range of morning cortisol saliva levels of 10–25 nmol/L. In order to study the intra-assay precision, the saliva pools of these six subjects were analyzed three times, on subsequent days, and the intra-assay precision was found to be between 0.9% and 6.2% (Table 1). The accuracy of this assay was tested with a percent recovery study. In order to study the performance over a wide range of cortisol concentrations, 5, 50, 500, and 5000 nmol/L samples of cortisol were spiked into the original saliva pool. These spiked samples were then run with the assay, and the results produced an accuracy ranging from 98% to 105% (Table 2).

Table 1. Intra-Assay Precision[a]

saliva pool	observed value 1 (nmol/L)	observed value 2 (nmol/L)	observed value 3 (nmol/L)	mean observed value ± SD (nmol/L)	CV (%)
pool 1	15.6	15.0	15.1	15.2 ± 0.3	2.0
pool 2	5.6	6.0	6.0	5.9 ± 0.2	3.7
pool 3	8.0	7.1	7.7	7.6 ± 0.5	6.2
pool 4	5.3	5.2	5.2	5.3 ± 0.1	1.6
pool 5	7.9	7.8	7.8	7.8 ± 0.1	0.9
pool 6	12.4	11.7	11.7	12.0 ± 0.4	3.5

[a] The saliva of six subjects was analyzed on three subsequent days in order to determine the precision of the assay. Data are the means of three replicates, which have been blank subtracted, ±1 standard deviation.

Table 2. Assay Accuracy[a]

added (nmol/L)	observed value (nmol/L)	expected value (nmol/L)	mean recovery (%)	bias (%)
5.0	18.3 ± 0.2	18.2	100.8 ± 0.9	+ 0.8
50.0	62.0 ± 0.5	63.2	98.1 ± 0.9	− 1.9
500.0	539.4 ± 3.2	513.2	105.1 ± 0.6	+ 5.1
5000.0	5230.5 ± 42.3	5013.2	104.3 ± 0.8	+ 4.3
mean			102.1 ± 0.8	+ 2.1

[a] A saliva pool was spiked with serial dilutions of cortisol standards in order to determine the accuracy of the assay. Data are the means of three replicates, which have been blank subtracted, ±1 standard deviation.

DISCUSSION

In an effort to develop homogeneous assays capable of yielding low detection limits, we selected a bioluminescent photoprotein as the signal-generating label. Other labels commonly employed in these types of assays include enzymes, fluorophores, and radioisotopes. We selected the bioluminescent aequorin over other labeling options because it is nontoxic, very sensitive in biological fluids, does not require long incubation periods, and can be genetically and chemically altered to yield a homogeneous modulation of its bioluminescence signal. The homogeneous, bioluminescence-based assay for cortisol discussed herein represents a distinct advantage over currently available cortisol assays, since it is fast, easy, and has the ability to achieve the very low detection limits that are necessary for salivary analysis.

After conjugating cortisol to aequorin via lysine residues, we determined the decay profile of the conjugates. The results from the activity and half-life studies were similar to the way aequorin responded in previous studies that employed aequorin chemically conjugated to an analyte through its lysine residues (*3*, *10*). In these studies, as in ours, as the molar ratio of analyte to aequorin in the conjugate increased, the bioluminescence activity of the conjugate decreased and the decay half-life of the conjugate increased. We then undertook a calibration study in order to determine the minimum conjugate concentration needed for assay development. From the calibration curves, we selected the 1×10^{-11} M conjugate concentration for a binder dilution study (Figure 2). The binder dilution study was undertaken in order to determine what antibody concentration was optimal for the homogeneous response of the 1×10^{-11} M conjugates. From the binder dilution study, it was determined that a 3.3 μg/mL anticortisol antibody concentration was the minimum antibody concentration required to yield a change in the bioluminescent signal (Figure 3). It was also observed from the binder dilution study that the higher the molar ratio of cortisol

in the conjugate, the more pronounced the homogeneous response following anticortisol antibody binding. In other words, the 1:2000 aequorin–cortisol conjugate gave a better homogeneous response to anticortisol antibodies than the 1:1500 aequorin–cortisol conjugate, and the 1:2500 aequorin–cortisol conjugate exhibited the best homogeneous response, giving the most pronounced change in bioluminescence signal following anticortisol antibody binding. For this reason, the 1:2500 aequorin–cortisol conjugate was selected for the remaining studies, including the dose–response curve and the analysis of saliva samples.

Next, a dose response curve was obtained by incubating the aequorin–cortisol conjugate, the anticortisol antibody, and serially diluted cortisol standards in microtiter plate wells for 30 min. Following incubation, the wells were washed, and the bioluminescence intensity was measured using an automated microtiter plate luminometer. Results of the dose–response curve indicated that decreasing concentrations of cortisol, and corresponding increasing concentrations of free antibody, resulted in an increase in the bioluminescent signal from the conjugate (Figure 4). One may initially assume that increasing the amount of antibody available to bind the conjugate would result in sterically hindering aequorin and, thereby, reduce its bioluminescence, as shown in the homogeneous aequorin-based assay for biotin (*21*). However, a similar homogeneous response to ours, wherein signal increased with increasing antibody concentration, was found by Lewis and colleagues when they studied the response of an aequorin–thyroxine conjugate to increasing concentrations of antithyroxine antibody (*22*). This type of response, seen both here and in Lewis's thyroxine study, is more advantageous than the response found in the biotin assay, since the signal increases as the concentration of free cortisol decreases, thereby allowing a lower detection limit The detection limit of this assay was 1×10^{-10} M cortisol, which is over 1 order of magnitude lower than the detection limit obtained for a heterogeneous bioluminescence aequorin-based cortisol immunoassay, namely, 3.0×10^{-9} M (*4*). The linear range for this assay ranged from 1×10^{-5} M to 1×10^{-9} M, compared to the heterogeneous aequorin-based cortisol assay, whose linear range spanned only 3 orders of magnitude, from 1×10^{-6} to 1×10^{-8} M (*22*). The assay time was 30 min, which is slightly longer than the 18 min time afforded by the Roche Cobas cortisol assay. However, our assay is more sensitive than the Roche assay (0.1 nmol/L vs 0.5 nmol/L) and requires significantly less saliva volume (50 μL vs 500 μL), making our assay more adaptable to miniaturization (*23*). Moreover, the Roche assay utilizes electrochemiluminescence detection, which requires a specialized automated instrument, whereas our assay can be performed using standard luminometers and automated platforms such as Tecan, Hamilton, and so forth.

The low detection limit of the dose–response curve indicated that saliva analysis was possible, due to the fact that salivary levels of free cortisol ranged between 10 and 25 nmol/L. Moreover, salivary cortisol measurements are primarily used to rule out Cushing'syndrome. Cortisol concentrations are very low, generally less than 10 nmol/L, during the standard late-night sampling times used for these Cushing's syndrome tests. Therefore, the 0.1 nmol/L detection limit of this aequorin-based assay suggested that it may be suitable for clinical applications. Also, biological samples generally must be extracted prior to assaying, which is a time-consuming pretreatment. For this assay, the only pretreatment of saliva samples was a brief centrifugation to pellet particulate matter. No extraction or complex pretreatment of biological samples was needed, thereby streamlining the assay. The intra-assay precision with saliva samples was found to be between 0.9% and 6.2%, and the accuracy of the assay was found to be between 98% and 105% using spiked saliva samples. This level of accuracy and precision corresponds to the levels previously reported for cortisol assays, and is a realistic performance for a salivary cortisol assay (*4*).

In summary, we have developed a homogeneous assay using the photoprotein aequorin that can detect physiological levels of cortisol in human saliva. This assay has a dynamic range spanning 5 orders of magnitude and a sub-nanomolar detection limit. Since the level of free cortisol in human saliva ranges from 10 to 25 nmol/L, this assay is also well-suited for real samples, and the analysis of unextracted saliva samples gave acceptable precision and accuracy results. The fact that this homogeneous assay can analyze untreated saliva samples without multiple washing and incubation steps makes it superior to most of the currently commercially available assays for cortisol. Additionally, the low detection limit and long linear range of this assay are sufficient for both serum and saliva analysis. The feasibility of this homogeneous, bioluminescent assay in determining salivary cortisol levels has been clearly demonstrated. However, additional validation methods, such as extensive interference tests, interassay precision, and mass spectrometric confirmation, will be necessary before clinical implementation. However, the speed and simplicity of this homogeneous assay suggests that it may offer a simple alternative for testing salivary cortisol levels in the future, and represent an advance over current technologies by being applicable to both high-throughput screening and on-site monitoring technologies.

Received March 13, 2007; Revised Manuscript Received August 30, 2007

The present study reported proof-of-principle for a kinase assay approach that can detect specific peptide phosphorylation events. The method involves attachment of peptides onto commercial aminosilane and polycarbodiimide-coated glass slides, using a newly developed DNattach linker system that consists of a poly(dT) tail (Nisshinbo Industries Inc.), followed by a detection step using fluorescently labeled antiphosphoamino acid antibodies. The linker-modified peptides are efficiently synthesized by Michael addition between maleimido-modified peptides and thiol-containing DNattach. Specific covalent immobilization of the modified peptides onto aminosilane and poly carbodiimide-coated slides is then achieved by short exposure to UV-light. Highly selective and quantitative recognition by standard antiphosphoamino acid antibodies (antiphosphotyrosine and anti-phosphoGFAP) and kinases (c-Src and PKA) to the corresponding modified peptides on the microarray spots is demonstrated. Furthermore, we found that this immobilization method provides greater signal-to-noise ratio and better discrimination ability of phosphorylated amino acids than does the conventional immobilization technique. The phosphorylation pattern of target sequences, detected using fluorescently labeled antiphosphoamino acid antibodies, revealed that the linker system preference of the kinase is determined by its activity profile.

INTRODUCTION

Kinase-catalyzed phosphorylation of proteins is one of the most important mechanisms for the regulation of cell function. Indeed, it has been estimated that more than one third of all mammalian proteins may be subject to modification by phosphorylation *in vivo* (*1, 2*). To date, however, only a limited number of kinases have been identified and fully characterized. One of the most important features of protein kinases is their substrate specificity, which to a large extent is determined by the primary amino acid sequence around the phosphorylation site of the corresponding target protein. As a result, a number of methods have been developed to identify potential kinase substrates, including combinatorial synthesis of peptide libraries on membranes using SPOT technology, one-bead-one-compound peptide libraries, positional-scaling combinatorial libraries, and peptide libraries using affinity-column selection (*3–6*).

More recently, protein- and peptide-based microarrays have also been developed (*7–11*). In comparison to SPOT technology, a much higher density of spots can be attained using a protein array, making it possible to simultaneously screen tens of thousands of kinase substrates on the solid surface. Unfortunately, however, current peptide and protein chip strategies have several limitations. Chemical strategies leading to the oriented immobilization of a polypeptide chain are ideal because this preserves binding capacity and improves the control and reproducibility of the overall process. However, unwanted adsorption of soluble proteins often results in competition with the detection of protein–substrate interactions, leading to a noisy background (*12*). Usually, only a fraction of the immobilized proteins are competent to participate in binding interactions because many of them are immobilized in inaccessible orientations or are partially denatured (*13*). A consequence of these limitations is that most immobilization procedures are not well suited to quantitative assays of protein–substrate interactions. Several immobilization methodologies that involve the modification of peptides prior to spotting onto the solid surface for specific binding events might circumvent these limitations (*7–10, 14–16*). For example, MacBeath et al. (*14*) and Lesaicherre et al. (*15*) independently used slides treated with maleimide and slides treated with glyoxylic acid as platforms, respectively, for the immobilization of N-terminally Cys-containing peptides. Houseman et al. (*7*) reported the fabrication of a peptide microarray by the Diels–Alder-mediated immobilization of the kinase substrate on a self-assembled monolayer of alkanethiolates on gold. Furthermore, Duburcq et al. (*8*) fabricated the peptide microarray using semicarbazide slides that permitted the immobilization of glyoxylyl peptides. However, current methodologies are time-consuming (in the order of hours) and often require relatively large amounts of peptide (i.e., concentrations between 100 μM and 5 mM) for the immobilization procedure (*7–10, 14–16*). In addition, although appropriate for DNA immobilization, additional surface modifications that would make microarray fabrication a laborious and complex procedure are usually required when peptides or very small proteins are printed on commercial DNA microarray slides, and there are only a few commercial slides for fabricating peptide arrays (*17*). Thus, the increased need for simple, robust, and high throughput assays has led us to develop a novel protocol for preparing peptide and protein microarrays.

Over the past few years, we have been developing polycarbodiimide-coated glass and plastic slides for use with DNA microarray substrates (*18–20*). We found that thymine base(s) of DNA efficiently react with the carbodiimide group under UV irradiation (*20*). On the basis of these findings, we have further developed the patented DNattach system (Nisshinbo Industries

Inc.), which consists of a poly(dT) tail and spacer group, for immobilizing DNA onto various surfaces including polycarbodiimide, nonmodified metal, and plastic surfaces by UV irradiation (*21*, *22*). Using this system, Takahashi et al. (*22*) successfully detected synaptogenesis in the developing mouse cerebellum on a gold surface. As a first step toward the goal of developing an inexpensive, simple, and robust diagnostic tool for assaying kinase activity, we have further expanded this technology.

Here, we describe a novel, simple, and convenient methodology that uses the DNattach immobilization system to site-specifically immobilize peptides onto commercial aminosilane and polycarbodiimide-coated glass slides by UV irradiation in a microarray format. We have found that the technology is also appropriate for attaching peptide to aminosilane and polycarbodiimide-coated slides by UV irradiation. In this detailed quantitative study, we show that the immobilization system is a simple and rapid technique compared to conventional technologies. Furthermore, the methodology provides a uniform environment for kinase assays, resulting from site-specific immobilization onto the solid surface and the use of a selective immobilization chemistry to prepare the chips. The phosphorylation pattern of target sequences, detected using fluorescently labeled antiphosphoamino acid antibodies, revealed that the linker system preference of the kinase is determined by its activity profile.

EXPERIMENTAL PROCEDURE

Materials and General Methods. β-Alanine and maleic anhydride were purchased from Kanto Chemical Company (Tokyo, Japan). $p60^{c\text{-}src}$ kinase was purchased from Oncogene Science (Cambridge, MA). cAMP-dependent protein kinase (PKA) was purchased from New England BioLabs (Ipswich, MA). AG213 was purchased from Calbiochem-Novabiochem International, Inc. (La Jolla, CA). Anti-phosphoGFAP (YC10) and antiphosphotyrosine (PY20) were purchased from Medical & Biochemical Laboratories (Nagano, Japan) and Exalpha Biologicals (Maynard, MA), respectively. NAP5 columns and the Cy3 and Cy5 mAb Labeling Kits were purchased from GE Healthcare Biosciences (Tokyo, Japan). Thiol-modified DNattach was prepared at Nisshinbo Industries Inc. (Chiba, Japan) as follows (*23*). Poly(dT) (DNattach) modified with a 5′-thiol group and a six-carbon spacer was synthesized on an ABI 3900 DNA synthesizer at a 0.2 μmol scale using the standard phosphoramidite method. The thiol-modified DNattach was then purified on a reverse-phase cartridge following a standard procedure and dried *in vacuo*. All of the amino acids of the peptide sequence that were subsequently coupled on a Wang resin, following the standard procedures of Fmoc solid-phase peptide synthesis, were purchased from Operon (Tokyo, Japan). Peptides modified with biotin and the C_4 alkyl spacer group at the *N*-terminus of the amino acid were also synthesized and purified at Operon. All other chemicals were purchased from Wako Pure Chemical (Tokyo, Japan) and used without further purification.

Synthesis of 3-(Maleimido) Propionic Acid. 3-Maleimido propionic acid was synthesized according to a previous report with some modifications (*24*). Briefly, β-alanine (1 g, 11.2 mmol) and maleic anhydride (1.1 g, 11.2 mmol) in acetic acid (40 mL) were stirred at RT for 15 h under a N_2 atmosphere. The resulting suspension was then heated to 150 °C for 8 h. The solvent was removed *in vacuo*, and the residue was purified by silica gel column chromatography ($CHCl_3$/MeOH = 50:1), affording the compound (1.1 g, 57%) as a colorless solid. ^{1}H NMR (400 MHz, $CDCl_3$): δ 10.30 (1 H, br), 6.73 (2 H, s), 3.84 (2 H, t, J = 7.2 Hz), 2.71 (2 H, t, J = 7.2 Hz). MS (MALDI-TOF): *m*/*z* calcd for $C_{11}H_{10}N_2O_6$ $[M + H]^+$, 267.22; found, 266.7. Alternatively, the title compound is commercially available from Wako Pure Chemical.

Synthesis of Maleimide–Peptide. The Fmoc group of the fully protected peptide on the Wang resin (Operon) was first deprotected with 20% piperidine in DMF for 20 min, and 3-(maleimido) propionic acid was then introduced to the *N*-terminus of the amino acid using 3 equivalents of 3-(maleimido) propionic acid, dichlorohexy carbodiimide, and HOBt in DMF for 1 h. Cleavage and deprotection were effected by reaction with TFA/H_2O = 95:5 or thioanisole/H_2O/1,2-ethanedithiol/triisopropylsilane/TFA = 2.5:2.5:2.5:1:91.5 for 2 h. Cold diethyl ether was added to the reaction mixture, and the resulting pellet was purified using a NAP5 column according to the manufacture's procedure.

Synthesis of DNattach Linker–Peptide Conjugate. One nanomole of the thiol-modified DNattach (Nisshinbo Industries Inc.) and 20 nmol of each maleimide–peptide were dissolved in 100 mM phosphate buffer (pH 7.0) (a total 10 μL of solution) and mixed. The reaction mixtures were stirred at RT for 18 h, and progress of the reaction was monitored at 254 nm by HPLC with a μBondasphere C-8 column (Nihon Waters K.K., Tokyo, Japan). A total of 90–95% conjugate was formed as assessed from the relative areas of the thiol-modified DNattach and the conjugate on the HPLC profile. The resulting conjugate was purified by HPLC. We obtained >90% purity of the conjugates as assessed from the relative areas of the conjugate and the other peaks on the HPLC profile. MS (MALDI-TOF): *m*/*z* calcd for Peptide 1 $[M + 6Na]^+$, 7579.2; found, 7576.2; *m*/*z* calcd for Peptide 2 $[M + 3Na]^+$, 7430.0; found, 7427.4; *m*/*z* calcd for Peptide 3 $[M + 3Na]^+$, 7338.3; found 7338.3; *m*/*z* calcd for Peptide 4 $[M + 3Na]^+$, 7947.3; found, 7951.8; *m*/*z* calcd for Peptide 5 $[M + 4Na]^+$, 7890.2; found, 7894.6; and *m*/*z* calcd for Peptide 6 $[M + 4Na]^+$, 7874.2; found, 7768.3.

Fabrication of Aminosilanized and Polycarbodiimide-Coated Arrays. A polycarbodiimide-coated slide (CarboStation) from Nisshinbo Industries Inc. and a SuparAmine slide from Telechem International, Inc. (Sunnyvale, CA) were used in this study. Both nonmodified and linker-modified peptides were spotted on the slide as spots of ~250 μm in diameter with a spot-to-spot distance of 600 μm using a customized microarray robot (*19*).

After printing, the arrays were irradiated (total 0–0.3 J/cm^2) using a UV Stratalinker 2400 (Stratagene, La Jolla, CA), treated with a blocking solution (3% BSA, 0.2 M NaCl, 0.1 M Tris-HCl at pH 7.5, and 0.05% Triton-X100), then washed with TE buffer (pH 7.2) for 5 min, and dried for storage. UV irradiation was carried out within 3 min.

Fabrication of Streptavidin-Coated Arrays. Streptavidin-coated slides from Greiner Bio-One Co., Ltd. (Tokyo, Japan) were also used in this study. The customized microarray robot was also used to print arrays for the biotinylated peptides (Operon) in phosphate-buffered saline (pH 7.4). After printing, the arrays were incubated at RT for 4 h in a humidified chamber, washed, and treated with the blocking solution according to a previously reported method (*11*).

Kinase Reactions. Protein kinase assays were done according to the manufacturer's procedures with some modifications.

$p60^{c\text{-}src}$ Assay. $p60^{c\text{-}src}$ was added to the reaction buffer (50 mM HEPES-HCl at pH 7.5, 30 mM $MgCl_2$, 0.1 mM EDTA, and 0.015% polyoxyethyl (23) lauryl ether) and 150 μM ATP (final concentration of $p60^{c\text{-}src}$ 0–0.1 U/μL in the reaction buffer in a final volume of 30 μL). The reaction mixture was applied to the slide surface, and the reaction was performed at 37 °C for 240 min. The array was briefly washed with EtOH at RT for 5 min, twice with H_2O at RT for 5 min, and then dried.

Table 1. Peptide Sequences To Be Immobilized onto the Solid Surface

peptide	peptide sequence	kinase	remarks
Peptide 1	NH_2-I**Y**(**PO_3**)GEFKKK-COOH		Y-phosphorylated
Peptide 2	NH_2-I**Y**GEFKKK-COOH	c-Src	
Peptide 3	NH_2-I**A**GEFKKK-COOH		A-substituted
Peptide 4	NH_2-RRRVT**S**(**PO_3**)AARRS-COOH		S-phosphorylated
Peptide 5	NH_2-RRRVT**S**AARRS-COOH	PKA	
Peptide 6	NH_2-RRRVT**A**AARRS-COOH		A-substituted

For inhibition experiments, the inhibitor was included in the reaction mixture, and the concentration of DMSO was adjusted to 2%.

PKA Assay. PKA was added to the reaction buffer (25 mM Tris-HCl at pH 7.5, 2.5 mM $MgCl_2$) and 200 μM ATP (final concentration of PKA 0–5 U/μL in the reaction buffer in a final volume of 30 μL). The reaction mixture was applied to the slide surface, and the reaction was performed at 30 °C for 60 min. The array was briefly washed with EtOH at RT for 5 min, twice with H_2O at RT for 5 min, and then dried.

Detection of Phosphorylated Amino Acids Using Fluorescently Labeled Antiphosphoaminoacid Antibodies. Antiphosphotyrosine and anti-phosphoGFAP antibodies were labeled with either Cy3 or Cy5 using Cy3 or Cy5 mAb Labeling Kit (GE Healthcare Biosciences) and then purified using a NAP5 column according to the manufacturer's procedure. Either fluorescently labeled antiphosphotyrosine or anti-phosphoGFAP antibody, dissolved in PBST containing 1% BSA, was then applied to the array. The array was incubated at RT for 1 h, washed with PBST at RT for 5 min, briefly rinsed with PBS, and then air-dried.

Signal Detection and Data Analysis. A ScanArray 4000 (Packard Biochip, Billerica, MA) or FLA-5100 (Fuji Photo Film, Kanagawa, Japan) instrument was used to detect the signals, with equivalent results. Arrays were scanned with variable photo multiplier tube (PMT) settings to obtain optimum signal intensities. The resulting images were used to generate Tiff data files. Data analysis was done using QuantArray (Packard BioChip) or Science Laboratory (Fuji Photo Film) software, and Microsoft Excel (Microsoft Corp., Redmond, WA). Unless stated otherwise, the average signal values were taken from two spots on two slides processed in parallel. The data were further validated by results from more than five experiments.

RESULTS

Effect of UV Irradiation on Aminosilane and Polycarbodiimide-Coated Glass Surfaces. The goal of the current study was to verify a new method of peptide immobilization onto a solid surface by evaluating the DNA–peptide conjugates for peptide microarray applications. To this end, we prepared six different DNA–peptide conjugates (Table 1), which were easily obtained by Michael addition between maleimide–peptides and thiol–DNattach (Figure 1). In all cases, derivatization was carried out after chain assembly by following standard protocols, thus yielding 5′-modified DNattach and peptides with the maleimide group linked to the *N*-terminus (see Materials and General Methods).

The amount of peptide attached to the solid support and the accessibility of enzymes or antibodies to the immobilized peptide are critical factors in microarray analysis, as they determine both the sensitivity and the dynamic range of measurement. To investigate how UV irradiation during immobilization of peptide via the poly(dT) tail on the surface affects the binding affinity and discriminative ability of the antibody, we first immobilized two different DNA–peptide conjugates (Peptides 1 and 2, Table 1) on the polycarbodiimide-coated glass slide. Peptides 1 and 2 both include a tyrosine residue, although only the tyrosine from the former peptide was phosphorylated. The DNA–peptide conjugates were dissolved in 3× SSC at a concentration of 1 μM and applied to the glass slide in quadruplicate.

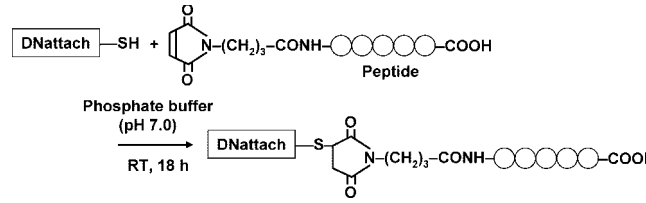

Figure 1. Synthesis of DNattach-induced peptides. The reaction mixture of thiol-modified DNattach and maleimide-modified peptide was incubated at RT for 18 h.

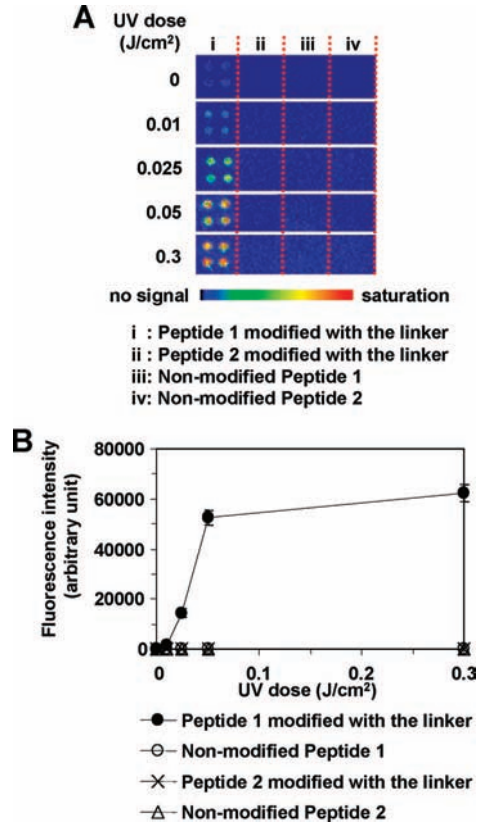

Figure 2. Signal intensities produced upon the interaction of Cy3-labeled antiphosphotyrosine antibody with four different spotted peptides at 0 to 0.3 J/cm^2 of UV irradiation. Peptides 1 and 2 were spotted and immobilized on the polycarbodiimide-coated slide. (A) Spots made with each peptide were present in quadruplicate. (B) The mean signal intensities produced in the experiments are plotted vs UV dose. The error bars indicate standard deviation. Peptide sequences are shown in Table 1. All arrays were scanned with the same PMT setting (600 mV).

In peptide–antibody interaction experiments, Cy3-labeled antiphosphotyrosine antibody, which specifically interacts with the phosphorylated tyrosine in peptide sequences, was used for detection. Figure 2A shows a typical image of fluorescence signal intensities from these experiments. Irrespective of UV dose, peptide–antibody interaction was specific to the phosphorylated tyrosine residue. No signals were obtained from either the non-UV-irradiated arrays or from the UV-irradiated arrays spotted with nonmodified peptides. These results indicate that immobilization of the linker-modified peptide onto the surface by UV irradiation did not originate from residual peptide molecules that were physically absorbed onto the surface. Signal intensities increased with increasing UV dose, whereas non-

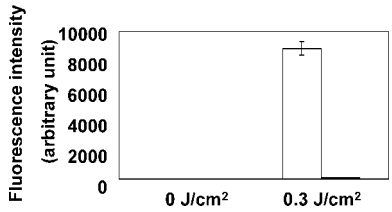

Figure 3. Signal intensities produced upon interaction of Cy5-labeled antiphosphotyrosine antibody with two different spotted peptides at 0 and 0.3 J/cm^2 of UV irradiation. Modified Peptide 1 (white bar) and Peptide 2 (dark bar) at a concentration of 1 μM were spotted and immobilized on the aminosilane slide. The error bars indicate standard deviation. Peptide sequences are shown in Table 1. All arrays were scanned with the same laser power (100%) and PMT setting (50%).

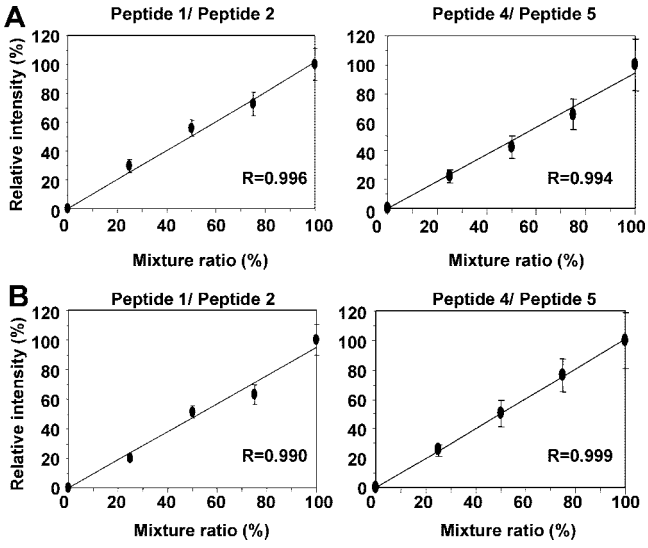

Figure 4. Fluorescent intensity vs amount of phosphorylated substrate. Varied ratios of phosphorylated/nonphosphorylated c-Src (Peptides 1 and 2) and PKA (Peptides 4 and 5) substrates were arrayed onto the polycarbodiimide-coated (A) and aminosilanized (B) slides and probed with the corresponding Cy5-labeled antiphosphoamino acid antibody. The error bars indicate standard deviation. All arrays were scanned with the same laser power (100%) and PMT setting (50%).

specific signals were at background levels. Using a UV dose of up to 0.3 J/cm^2, the signal intensity was 528-fold (Peptide 1) greater for the UV-irradiated array than for the nonirradiated control (Figure 2B). We did not observe an obvious increase in nonspecific signals when the UV dose was increased to 0.3 J/cm^2. A similar trend with the aminosilane slides was also observed (Figure 3).

These results indicate that the modified peptide is immobilized via the poly(dT) attached to the peptide and that the reaction between the DNA–peptide conjugates and polycarbodiimide (aminosilane) on the glass surface is facilitated by UV irradiation.

Detection and Quantification of on-Chip Phosphorylation. We next determined whether the fluorescently labeled antibodies can quantitatively detect phosphorylated peptides on the aminosilanized and polycarbodiimide-coated arrays. Varied ratios of phosphorylated/nonphosphorylated Peptides 1 and 2 (Table 1), with a combined constant concentration (1 μM), were immobilized onto the slide by UV irradiation and then probed with the Cy5-labeled antiphosphotyrosine antibody for 1 h (Figure 4A and B). Figure 4A and B shows that the intensity of the spots increased as the ratio of phosphorylated to nonphosphorylated peptide increased. The graph of fluorescent intensity versus phosphorylated peptide substrate shows a linear correlation for the Peptide 1 ratio, ranging from 0 to 100%, demonstrating the feasibility for on-chip quantification of phosphorylated peptides using this methodology. A similar trend was also observed when we immobilized Peptides 4 and 5 onto the slides by UV irradiation and probed with Cy5-labeled antiphosphoGFAP antibody (Figure 4A and B). Thus, the UV-irradiated DNA–peptide conjugates formed under these conditions are suitable for peptide microarray applications.

Detection Sensitivity. To estimate the detection sensitivity of immunofluorescence detection and laser scanning, modified Peptides 1 and 2 (Table 1) at different concentrations were immobilized onto the aminosilane and polycarbodiimide-coated slides by UV irradiation (0.3 J/cm^2) and then probed with the Cy5-labeled antiphosphotyrosine antibody for 1 h (Figure 5A and B). Figure 5A and B shows that the signal intensity was nearly saturated at a concentration of modified Peptide 1 of only 2.5 μM (carbodiimide) and 5 μM (aminosilane), whereas nonspecific signals were minimal across all DNA–peptide conjugate concentrations. The maximum signal intensity was 1.25-fold (Peptide 1) greater for the carbodiimide slide than for the aminosilane slide. The lowest detection limit was around 0.6 μM, where the signal-to-noise was still around 10 for the aminosilane and 238 for the carbodiimide slide, as shown in Figure 5A and B. These differences most likely arise from different surface conditions, such as loading capacity, charge, hydrophobicity, and efficiency of immobilization and interaction. Further investigation was performed using two different modified peptides (Peptides 4 and 5, Table 1) and the Cy5-labeled anti-phosphoGFAP antibody. A similar trend with these peptides was also observed (Figure 5A and B).

The performance of different attachment chemistry (i.e., most widely used in streptavidin–biotin interaction) was also assessed by testing the detection sensitivity of phosphopeptide, as shown in Figure 5A and B. To this end, we immobilized a total of four different biotinylated peptides (same sequences as those of Peptides 1 and 2, and Peptides 4 and 5 in Table 1) at different concentrations onto streptavidin-coated glass slides and then probed with corresponding Cy5-labeled antiphosphoamino acid antibody (*11*). In our hands, however, we could not detect any signals for the phosphorylated Peptide 1 on the streptavidin slide using interaction and scanning conditions (laser power 100%, PMT 50%) identical to those used in our methodology (data not shown), probably due to the fact that the streptavidin-coated slide has limited peptide binding capacity and/or due to the steric interference of the surface on interaction with the antibody where the phosphorylated tyrosine residue in Peptide 1 is located adjacent to the slide surface (Table 1) (*25*). By contrast, although the streptavidin arrays could discriminate between the phosphorylated Peptide 4 and nonphosphorylated Peptide 5 (the signal intensity for Peptide 4 at a concentration of 5 μM was 17.7-fold greater than that for the Peptide 5 control), quantification revealed lower signals (~9.1-fold) in comparison to those obtained using the poly(dT)-modified peptides and carbodiimide slides (Figure 6).

Thus, we find that DNattach chemistry provides a better substrate for the immobilization of peptides and the interaction with antibody than do conventional biotin–avidine interaction techniques.

Characterization of Kinase Activity. In order to further demonstrate the utility of our methodology for the detection of kinase activity in a microarray format, we next investigated the dose-dependent detection of peptide phosphorylation on a chip. Two different nonphosphorylated substrates at a concentration of 10 μM, Peptide 2 modified with poly(dT) as a substrate for c-Src tyrosine kinase and Peptide 3 modified with poly(dT) as a negative control, were spotted and immobilized onto carbodiimide and aminosilane slides by UV irradiation (Table 1). Nonphosphorylated substrates, Peptide 5 modified with poly(dT) as a substrate of PKA serine kinase and Peptide 6 modified

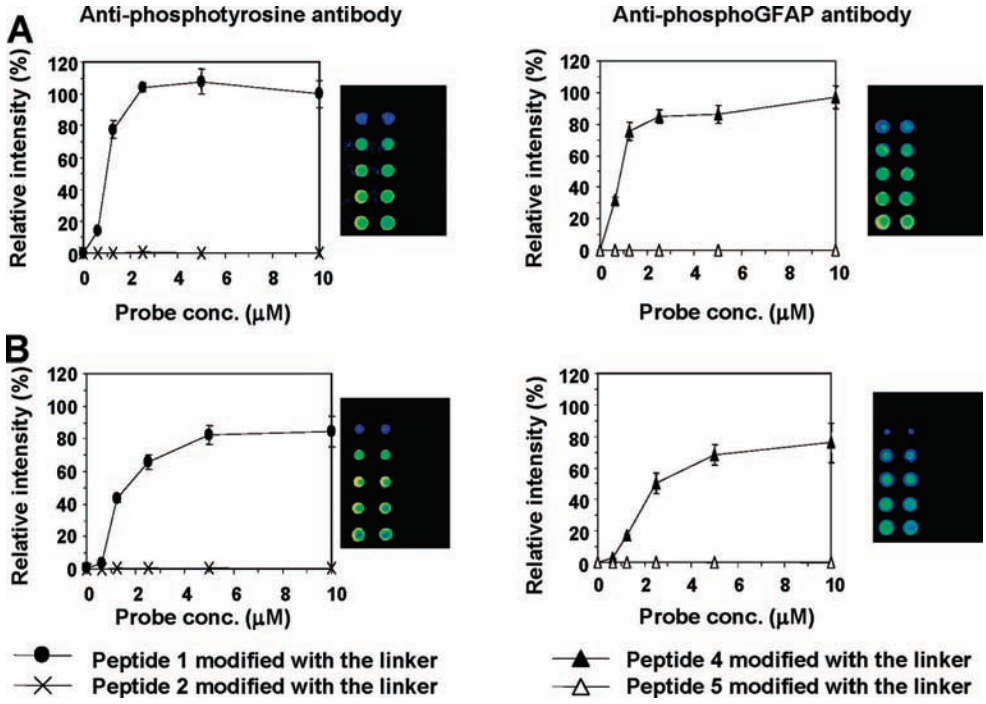

Figure 5. Signal intensities produced upon the interaction of Cy5-labeled antiphosphoaminoacid antibodies. The modified peptides were dissolved in 3× SSC at a concentration of 0–10 μM and spotted on polycarbodiimide (A) and aminosilane (B) in duplicate (see Materials and General Methods). After immobilization, the arrays were probed with the corresponding Cy5-labeled antiphosphoamino acid antibody. Scanned spots and quantitative analysis of spots over interactions with the corresponding antiphosphoamino acid antibody are shown. The error bars indicate standard deviation. All arrays were scanned with the same laser power (100%) and PMT setting (50%). (Note: the maximum mean signal intensity of each specific signal among the different arrays was normalized to 100 (no units); thus, the results represent the relative intensity of the corresponding antiphosphoamino acid antibody.)

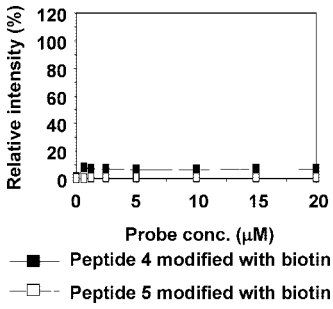

Figure 6. Signal intensities produced upon the interaction of Cy5-labeled anti-phosphoGFAP antibody on the streptavidin arrays. The biotinylated peptides were dissolved in PBS at a concentration of 0–20 μM and spotted on streptavidin slides in duplicate (see Materials and General Methods). After immobilization, the arrays were probed with the Cy5-labeled anti-phosphoGFAP antibody. The error bars indicate standard deviation. All arrays were scanned with the same laser power (100%) and PMT setting (50%). (Note: the maximum mean signal intensity of each specific signal among the different arrays was normalized to 100 (no units) as shown in Figure 5; thus, the results represent the relative intensity of the corresponding antiphosphoamino acid antibody.)

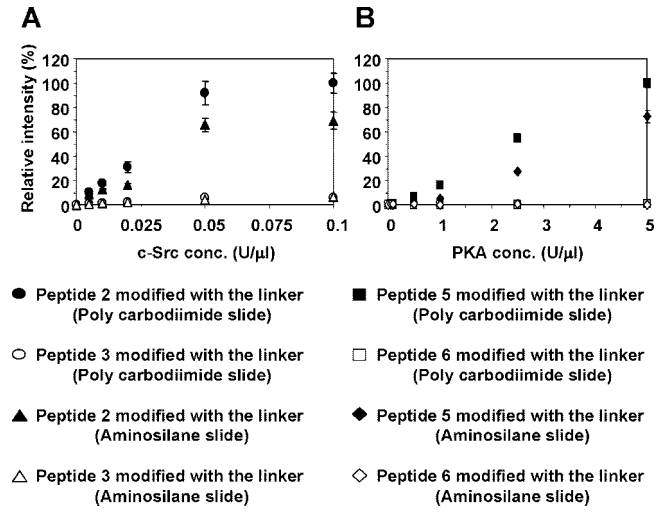

Figure 7. Characterization of c-SRC and PKA kinase activities. The modified Peptide 2, Peptide 3, Peptide 5, and Peptide 6 at the same concentration of 10 μM were immobilized on the slides by UV irradiation (0.3 J/cm^2) and then incubated with (A) c-Src and (B) PKA kinases for 240 or 60 min, respectively. Detection was performed using the corresponding Cy5-labeled antiphosphoamino acid antibody. All arrays were scanned with the same PMT setting (75% and 55% for c-Src and PKA assays, respectively). The error bars indicate standard deviation.

with poly(dT) as a negative control, were also spotted and immobilized onto the same slide (Table 1). The arrays were first incubated with either c-Src or PKA kinase at 5 different kinase concentrations for 240 or 60 min and then incubated with the corresponding fluorescently labeled antiphosphoamino acid antibody for 1 h.

In both cases, Figure 7A and B shows that fluorescent intensities were directly proportional to the concentration of each kinase, whereas nonspecific signals were minimal across all kinase concentrations. In addition, Figure 7A shows that the signal intensity was nearly saturated at a concentration of c-Src kinase of 0.05 U/μL. The CV of intensities for all elements was between 12% and 14% across the entire signal range. As anticipated, the maximum signal intensity was 1.4-fold (Peptide 2) and 1.3-fold (Peptide 5) greater for the carbodiimide slides than for the aminosilane slides (Figure 7A and B). The signal-to-noise ratios for Peptide 2 at a concentration of 0.05 U/μL c-Src kinase were 71.1 (the carbodiimide slide) and 52.5 (the aminsilane slide). In addition, the signal-to-noise ratios for Peptide 5 at a concentration of 5 U/μL PKA kinase were 770

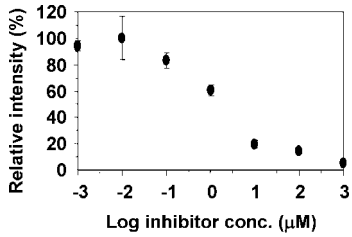

Figure 8. Effect of the AG213 inhibitor upon kinase activity. Modified Peptide 2 was immobilized on the slide by UV irradiation (0.3 J/cm^2) and then incubated with c-Src, ATP, and inhibitor in serial dilutions for 240 min. Detection was performed using the Cy3-labeled antiphosphotyrosine antibody. The error bars indicate standard deviation. All arrays were scanned with the same laser power (100%) and PMT setting (80%).

(the carbodiimide slide) and 678 (the aminsilane slide). These results indicate that, under this immobilization condition, the linker-modified peptide probes are suitable for peptide microarray application.

In order to assess the performance of the different attachment chemistry, again, the biotinytated peptides (Peptides 5 and 6) were spotted and immobilized onto streptavidin slides, and the arrays were incubated with PKA kinase for 60 min and then incubated with the fluorescently labeled anti-phosphoGFAP antibody for 1 h. However, under interaction and scanning conditions (laser power 100%, PMT 55%) identical to those used with the new methodology, we could not detect any signals for the phosphorylation of Peptide 5 (data not shown), probably due to the limited peptide binding capacity on the streptavidin slide and/or due to the steric effect as mentioned above.

Again, we find that DNattach chemistry provides a better substrate for the immobilization of peptides and interaction with kinases than do conventional biotin–avidine interaction techniques.

Evaluation of AG213 Inhibitor of c-Src on the Peptide Arrays. Finally, we used the peptide microarray to evaluate an inhibitor of c-Src, AG213, on substrates. Mixtures containing the kinase, ATP, and inhibitor at concentrations ranging from 1 nM to 1 mM were applied onto the polycarbodiimide surface. After 4 h at 37 °C, the arrays were probed with Cy3-labeled antiphosphotyrosine antibody. When the kinase reactions were performed in the presence of 0.04 U/μL c-Src kinase, an IC_{50} value (1.7 μM) close to the published data in solution-phase assays (8 μM) was obtained (Figure 8) (*7, 26*). The difference observed with this inhibitor may be due to different sources of enzymes or slightly different assay conditions. However, this result is expected since the inhibitor used in this study is known to compete with ATP by binding to the ATP binding site of the kinase (*26*). These results show the feasibility of our methodology for the characterization of inhibitors.

DISCUSSION

The experiments described in this article demonstrate that a combination of modified-peptide and UV irradiation technology can be used to generate an efficient and robust assay for kinases. Nucleases have been studied using peptide–DNA/PNA conjugates by the introduction of a reporter group to investigate DNA–protein interactions (*27–31*). However, this is the first report to demonstrate the utility of UV irradiation of spotted peptides with a poly(dT) tail on commercial aminosilane and polycarbodiimide-coated slides to detect phosphorylation events. The DNA–peptide conjugates are immobilized by UV irradiation to form covalent bonds between the thymidine residues in DNA and the carbodiimide or the amine group on the surface (*20, 32*). On the molecular level, although it is not yet clear how the poly(dT) binds to the substrates by UV irradiation, it can be looked on as any other functional group that is required for efficient immobilization of samples on surfaces (*21, 33, 34*). Polycarbodiimide resin was identified by the presence of absorption at 2145 cm^{-1} in FT-IR assignable to the carbodiimide function. Although the carbodiimide group hydrolyzes very easily at acidic pH around 5 as well as under basic conditions (*18–20, 35*), the polycarbodiimide used in this study was hydrophobic and stable for 12–24 months. In addition, the polycarbodiimide-coated slides can be stored for 6–12 months at room temperature before use (*20*). The presence of carbodiimide groups on the surface was confirmed by X-ray photoelectron spectroscopy. In fact, when fluorescently labeled poly(dT) in 3× SSC were printed on the carbodiimide substrate and the slides were UV-irradiated after 1, 24, 72, and 168 h at RT and then briefly washed, signal intensity from only the slide after 168 h of incubation indicated less signal intensity (1/10-fold) than those obtained from the slides after 1, 24, and 72 h of incubation (data not shown). These results indicate that decomposition of carbodiimide groups on the surface that is involved with the immobilization procedure would dramatically affect immobilization efficiency after 72 h of incubation. The slides should therefore be UV irradiated within 72 h after printing to circumvent this problem. Thus, using this immobilization system, peptides can be reliably and specifically immobilized onto the solid surface. Furthermore, this new immobilization method provides signal intensities greater than those of conventional biotin–avidine interaction techniques. Here, we have demonstrated that this property can be exploited to measure kinase activity. Although the introduction of an additional spacer unit between the biotin and the peptide might avoid steric hindrance and result in facilitating the signal intensity on the streptavidin slide and/or the use of secondary antibody might also facilitate the signal intensity on the streptavidin slide (*25*), the technique described in this study provides three major advantages over those of peptide microarrays that have been reported by other researchers. First, the immobilization reaction involving UV irradiation is both simple and quick, providing a regular, homogeneous environment for immobilized peptide ligands. The peptides therefore have equal activity toward soluble enzyme and are well suited to quantitative assays. Second, a low concentration (up to 10 μM) of modified peptide is sufficient for the kinase assays. By contrast, conventional technologies generally require a peptide concentration of up to 5 mM and a period of several hours for immobilization onto a solid surface (*7–10, 14–16*). Third, using this immobilization method, commercial DNA microarray slides without additional surface modifications can be used for producing peptide microarrays, thereby avoiding making microarray fabrication a laborious and complex procedure.

Mukumoto et al. recently reported that nonmodified DNA could be immobilized onto a carbodiimide-coated gold slide through the covalent bond by a reaction of carbodiimide with the imino moiety of the thymine base in DNA (*35*). Inconsistent with our results, they do not require a UV irradiation procedure for immobilization of DNA. In our studies, however, we could detect only weak signals from Peptide 1 modified with DNattach on non-UV-irradiated slides (Figure 2A and B). These differences may be caused by different surface conditions between our slides treated with polycarbodiimide and their slides treated with the carbodiimide monomer, thereby causing an insufficient amount of immobilized peptides and/or steric effects to detect phosphorylation events on our surface when immobilized peptides on the slides are used in this study without UV irradiation.

One potential drawback of this system is that one has to link the DNattach to the peptides individually followed by multiple purification steps. It might make microarray fabrication a laborious and complex procedure when constructing high-

density peptide microarrays. However, it is possible to synthesize the DNA–peptide conjugates on a solid support and purify the conjugates all together (*36*), and studies to optimize a solid-phase synthesis protocol with DNattach are currently underway. In addition, certain adjustments in the methodology described here will be required if cysteine is to be included in the peptide sequence. The reaction between the free thiol of cysteine and the maleimide group of the peptide conjugate may compete with the reaction between the thiol of DNattach and the maleimide group during the conjugation, yielding side products as a result of Michael additions. To avert the complex mixtures, the conjugate reaction should be carried out using maleimide–peptides with a protected cysteine and followed by unmasking of the thiol group after conjugation. Alternatively, the conjugate reaction may be carried out using 5′-peptide–oligonucleotide conjugates during the conjugation on solid supports as described above (*36*).

In this proof-of-principle study, although we have used a model system consisting of a relatively small number of distinct antiphosphoamino acid antibodies and protein kinases to illustrate the effectiveness of this immobilization methodology, we show that the technique is robust, reliable, and reproducible for generating peptide microarrays. Thus, this method has the potential to provide a key technology for the fabrication of arrays to explore peptides as potential substrates for kinases. This technique might also be applied to high-throughput analysis of various enzyme activity assays and protein expression profiling. In addition, because the linker can be immobilized onto gold surfaces and plastics (*21, 22*), it should be possible to immobilize the modified peptides onto nonmodified gold or plastic surfaces. We are also currently investigating various biological assays, including those for detecting kinase activity, using this system by employing label-free detection methodologies (i.e., SPR and MALDI-TOF Mass). Furthermore, our research group has successfully synthesized poly(dT)-modified carbohydrates and is currently monitoring lectin assays in a carbohydrate microarray format. The results will be reported elsewhere in the near future.

Received March 13, 2007; Revised Manuscript Received July 11, 2007

Designing truly tumor-specific prodrugs remains a challenge in the field of cancer chemotherapy. As a new strategy, we incubated homogenates of a spectrum of human colon tumor xenografts with a fluorogenic positional scanning tetrapeptide library in order to identify peptide sequences that are preferentially cleaved by colon tumors. Our screening experiments at pH 7.4 revealed that Met, Leu, and Lys were preferred amino acids in the position P_1 and Tyr, Phe, and Met in P_2, whereas in P_3 and P_4, the cleavage profiles were less characteristic. However, similar results were obtained when testing breast tumor material and homogenates from healthy murine organs. On the basis of these results, we developed albumin-binding camptothecin (CPT) prodrugs of the general formula EMC-Arg-P_4-P_3-P_2-P_1-Ala-CPT (EMC = 6-maleimidocaproic acid) that incorporated two peptide linkers: H-Arg-Ala-Phe-Met-OH and H-Arg-Phe-Tyr-Met-OH (P_4-P_3-P_2-P_1). The incorporation of two arginine residues rendered the prodrugs water-soluble (>7 mg/mL), while the use of alanine as an amino acid spacer proved to be beneficial for the release of the active agent. Incubation studies with homogenates of HT-29 colon tumor tissue and murine spleen, liver, and kidneys demonstrated cleavage of the peptide linker with CPT–peptide derivatives and CPT being the major cleavage products. Although the peptide sequence is not selectively cleaved in colon tumors, an *in vivo* study in a HT-29 xenograft model showed that the prodrug EMC-Arg-Arg-Ala-Phe-Met-Ala-CPT demonstrated enhanced antitumor efficacy when compared to CPT [(*T*/*C* max: 17% for the prodrug (2 × 12.5 mg/kg CPT equivalents) and 40% for CPT (3 × 12.5 mg/kg)].

INTRODUCTION

One of the major limitations of clinically established anticancer drugs is their lack of tumor selectivity. Cytostatic drugs are evenly distributed in the organism, thus damaging healthy tissue and producing side effects. In order to overcome these drawbacks, a major goal of modern drug development is to provide efficient strategies that enable site-specific delivery of anticancer drugs.

In the past, various low- and high-molecular-weight prodrugs have been evaluated with the aim of improving cancer therapy. Since it has been shown that macromolecules with a molecular weight of >20 kDa accumulate in tumor tissue due to passive targeting almost regardless of their chemical nature (*1*), conjugation of drugs with macromolecules has proved to be a promising and versatile platform technology for tumor targeting (*2*). Typically, the general design of such prodrugs can be formulated as carrier(-spacer-drug)$_n$ wherein *n* describes the number of drugs bound to one carrier molecule.

In the past years, we have developed a macromolecular prodrug concept in which an anticancer agent is functionalized with a thiol-binding maleimide group. After intravenous administration, the prodrug binds rapidly and selectively to the cysteine-34 position of circulating serum albumin, thereby generating a macromolecular transport form of the drug *in situ* (*3–5*). This strategy turned out to be applicable to a number of anticancer drugs such as doxorubicin (*5–8*), carboplatin (*9*), and camptothecin (*10*). These prodrugs demonstrated a lower toxicity combined with a superior *in vivo* efficacy in mice models compared to the respective parent compounds. Our efforts led to the development of DOXO-EMCH, a 6-maleimidocaproic-hydrazone derivative of doxorubicin, which is the first albumin-binding prodrug to enter clinical trials. In animal experiments, DOXO-EMCH was well-tolerated and proved to be superior over doxorubicin in several preclinical tumor models (*3, 4*). In a clinical phase I study, DOXO-EMCH showed promising results (*11*), and a phase II study (with the compound renamed INNO-206) will be initiated at the beginning of 2007.

Although inconspicuously named spacer or linker, the molecule realizing the link between the drug and the carrier plays a crucial role for the prodrug to exert antitumor efficacy. The spacer incorporates a predetermined breaking point and is thus responsible for a site-specific release of the drug after entering tumor cells or tumor tissue, on one hand. On the other hand, the spacer has to ensure the prodrug's stability in the bloodstream and—ideally—healthy tissue. Apparently, a prodrug strategy can only be as effective as its underlying drug release mechanism. It is therefore of special interest to find new release strategies for enhanced tumor specificity and to customize appropriate spacer molecules.

Whereas DOXO-EMCH incorporates an acid-sensitive hydrazone linker that is stable in plasma but is rapidly cleaved after cellular uptake in the acidic environment of endosomes in tumor cells, other strategies for achieving tumor-specific release of drugs are based on the overexpression of certain proteases in tumor tissue. Proteolytic enzymes play a decisive role in metastasis and tumor progression (*12–14*), and elevated levels were reported for cathepsins (*15*), matrix metalloproteases (*16*),

plasmin (*17*), urokinase-type plasminogen activator (uPA) (*17*), and prostate-specific antigen (PSA) (*18*). In our previous work, we developed a number of albumin-binding prodrugs of doxorubicin that were cleaved by uPA (*8*), PSA (*7*), and the matrix metalloproteases 2 and 9 (*6, 19*). Disadvantages of targeting individual enzymes for cleaving the prodrug are their heterogeneous expression in the tumor and their variability among individual tumors, as well as their expression in healthy tissue.

In the present work, we therefore decided not to focus on individual proteases but instead followed a pragmatic approach at attempting to identify those peptide sequences that are most efficiently cleaved by native tumor material irrespective of whether one or more than one enzyme were involved in the cleavage process. For this purpose, we screened tissue homogenates from colon and breast tumor xenografts as well as healthy murine organs with a positional scanning combinatorial tetrapeptide library. On the basis of these results, we selected two tetrapeptide sequences for the development of albumin-binding prodrugs with the anticancer agent camptothecin (CPT), an alkaloid from the chinese tree *Camptotheca acuminata* first isolated by Wall and co-workers, that shows strong cytotoxic activity (*20*), based on the inhibition of DNA-topoisomerase I (*21*). Due to its poor water-solubility (2.5 μg/mL) (*22*), CPT did not gain any clinical importance, whereas the water-soluble derivatives topotecan and irinotecan have meanwhile been approved for the therapy of colorectal, ovarian, and lung cancer (*23, 24*).

By applying this novel approach, we hoped to obtain selective prodrugs for the treatment of colorectal tumors. Herein, we report on the screening experiments using a positional scanning library, the synthesis of the CPT prodrugs, and their cleavage properties and antitumor activity.

MATERIALS AND METHODS

General. Chemicals and solvents were purchased from Sigma-Aldrich, Fluka, Merck, KMF, LGC Promochem and Roth, and were used without further purification. The Fmoc-protected amino acids were purchased from Bachem AG (Switzerland). For the synthesis of the peptide libraries, polystyrol rink-amide AM-resin [Fmoc-RAM-AM, 100–200 mesh, loading (by Fmoc-determination): 0.65 mmol/g] from RAPP Polymere GmbH (Tübingen, FRG) was used. Camptothecin was purchased from Hande Tech Development, Inc. (USA). H-Ala-CPT was synthesized according to a published procedure (*25*). EMC-Arg-Arg-Ala-Phe-Met-OH was custom-made by JPT Peptide Technologies GmbH (Berlin, Germany). Human serum albumin (5% solution) was purchased from Octapharma GmbH that contained approximately 60% free thiol groups as assessed with the Ellmann's test. The buffers used were vacuum-filtered through a 0.2 μm membrane (Sartorius, Germany) and thoroughly degassed with ultrasound or by purging with nitrogen prior to use. Chemical reactions were carried out under a nitrogen atmosphere. Peptide substances were lyophilized with an Alpha 2–4 lyophilizer (Christ, Germany).

Spectral Analyses. Mass spectra were obtained on a Thermoelectron LCQ Advantage with associated MAT SS 200 data system using electron spray ionization. UV/vis spectrophotometry was carried out with a double-beam spectrophotometer U-2000 from Hitachi. LC-MS-pos ESI spectrometry was carried out on a Finnigan LCQ Advantage mass spectrometer (capillary temperature 300 °C; source-induced dissociation voltage 25 V, Thermo Electron) coupled to a Finnigan Surveyor HPLC system (Thermo Electron, Dreieich, FRG) with a Jupiter C_4 column (300–5, 150 × 2 mm; Phenomenex, Aschaffenburg, FRG). Chromatographic conditions are as follows: flow, 300 μL/min; mobile phase A, 1% MeCN, 99% demin H_2O, 0.06% TFA; mobile phase B, 100% MeCN, 0.06% TFA; gradient 15–20 min increase from 10% mobile phase B to 50% mobile phase B; injection volume, 15 μL.

Chromatography. See Supporting Information for chromatography.

Synthesis of the Peptide Library. The peptides were built up on Rink amide resin (RAM-AM). The synthesis of ACC and P_1-loaded ACC resin (H-P_1-ACC-RAM-AM) was carried out according to a published procedure (*26–28*). We used 18 of the 20 standard amino acids (tryptophane and cysteine were omitted), while the published method used 19 amino acids (cysteine was omitted and norleucine was substituted for methionine), and in contrast to the published procedure, we did not use a fixed P_1-position. The capacity of the resin (0.65 mmol/g) was determined by a spectrophotometric Fmoc quantification assay (*29*). For preparation of the P_1-position of the P_1-library, the H-ACC-RAM-AM-resin was divided into 18 reaction columns (1.30 mmol/column) and was suspended in DMF. Consecutively, each of the 18 Fmoc-amino acids (5 equiv), 1,6-collidine (5 equiv), and HATU (5 equiv) were added to the 18 reaction columns. The mixtures were stirred for 16 h and afterwards thoroughly washed with DMF. The yield of the reaction and the loading of the resin was determined via Fmoc quantitative assay (*29*). If the reaction afforded a yield of <50 %, coupling with HATU was repeated. Fmoc-Thr(OtBu)-OH had to be coupled twice, and Fmoc-Arg(Pbf)-OH, Fmoc-Ile-OH, Fmoc-Pro-OH, and Fmoc-Val-OH even three times, whereby a loading of more than 45% was not obtained for Fmoc-Arg(Pbf)-OH and Fmoc-Ile-OH. For the preparation of the P_2-, P_3-, and P_4- libraries, an isokinetic mixture of 18 Fmoc-P_1-ACC-RAM-AM amino acids was used (*30*). Afterwards, the resin was split in the reaction columns (1.30 mmol/column, 18 columns for each library) and DMF was added to solvate the Fmoc-P_1-ACC-RAM-AM resin under gentle stirring for 30 min. Subsequently, the Fmoc protective group was cleaved by replacing the DMF with 20% piperidine in DMF and agitating for 30 min. The piperidine solution was then filtered off, and the resin was washed several times with DMF.

The P_2-library was synthesized first by preactivating the 18 individual Fmoc-amino acids (10 equiv) in separate vials for 10 min with HOBt (10 equiv) and DIPC (10 equiv) in DMF to define the P_2-position. In a second step, an isokinetic mixture of the 18 Fmoc-amino acids (20 mmol per each library, 10 equiv/column) was preactivated with HOBt (20 mmol) and DIPC (20 mmol) in DMF to couple the randomized P_2-amino acids to the P_1-, P_3-, and P_4-libraries. Subsequently, the solution was added to each column for the P_1-, P_3-, and P_4-libraries and stirred for 3 h. The solution was filtered off, and the resin was washed several times with DMF. The installation of the P_3- and P_4-positions was carried out in the same manner.

After synthesis of the P_4-library was completed, the Fmoc protecting group of the P_4-amino acids was cleaved and the resin was washed with DMF. The resin was then subjected to a capping procedure using 3-nitro-1,2,4-triazole (10 equiv), acetic acid (10 equiv), and DIPC (10 equiv), and was agitated for 16 h at room temperature. Afterwards, DIEA (2 equiv) was added, and agitation continued for 1 h before the resin was washed with DMF. For cleavage of the substrates from the resin and of the protecting groups at the side chain of the amino acids, the resin was treated for 1 h with a mixture consisting of TFA/water/diisopropylsilane 95:2.5:2.5 (v/v) (10 mL/column). Subsequently, the resin was filtered off, and the solutions repeatedly evaporated under addition of 10 mL of ethanol and lyophilized out of an acetonitrile–water mixture (1:5). The final libraries were dissolved in DMSO to a concentration of 2 mM with respect to the fluorophor and were kept frozen at 4 °C and thawed prior to use.

Incubation Studies of Different Tissue Homogenates with the Peptide Libraries P_1–P_4. The incubation studies of the P_1-P_4-tetrapeptide library with different colon (HT-29, 5735, 5854, and 5679) and breast (MCF-7, MDA-MB 435, Breast 6661, and Breast 3366) tumor xenograft homogenates and tissue homogenates of healthy organs from nude mice (liver, kidney, and spleen) and human blood plasma were carried out using a 96-well assay. Preparation of the tissue homogenates was carried out according to two different protocols that were previously reported to preserve the activities of cathepsin B (lysosomally active) (*31*) or matrix metalloproteases 8 and 9 (extracellular) (*32*). We assumed that, following the first protocol (pH 5.0), intracellular proteases would primarily be liberated, whereas the second (pH 7.4) would be appropriate for extracting extracellular proteases. All following steps were carried out on ice. The tissues were cut into small pieces, and 200 mg samples were transferred in a 2 mL Eppendorf tube to which was added 800 μL of buffer (50 mM Tris–HCl buffer, pH 7.4, containing 1 mM monothioglycerol or 50 mM sodium acetate buffer, pH 5.0, containing 100 mM sodium chloride, 4 mM EDTA Na_2, and 0.1% Brij 35). Homogenization was carried out with a micro-dismemberator at 3000 rpm for 3 min with the aid of glass balls (diameter: 3 mm). Afterwards, the samples were centrifuged at 5000 rpm for 10 min at 4 °C. The supernatant was aliquoted and kept frozen at −78 °C prior to use.

The tumor homogenates were diluted 1:10 (75 μL + 675 μL) with buffer pH 7.4 (50 mM Tris–HCl buffer, containing 1 mM monothioglycerol) or buffer pH 5.0 (50 mM sodium acetate buffer, containing 100 mM sodium chloride, 4 mM EDTA-2Na, and 0.1% Brij 35). The ACC–tetrapeptide stock solution (2 mM) in DMSO was diluted 1:200 (10 μL + 1990 μL) with the aforementioned buffers. The 96-well plates were filled according to the following pipette scheme: 50 μL buffer, 25 μL tumor homogenate solution (1:10), shaking for 15 s, 25 μL ACC–tetrapeptide solution (1:200), shaking for 15 s. The fluorescence increase (Ex.: 355 nm, Em.: 460 nm) over a 1 h period was determined at room temperature with a Wallac VICTOR V^2 1420 plate reader.

Synthesis of EMC-Arg-Arg-Ala-Phe-Met-Ala-CPT × 2 TFA (1). HATU (24.2 mg, 0.064 mmol) was added under a nitrogen atmosphere to a solution of camptothecin-20-*O*-(L-alaninate) × TFA (30.8 mg, 0.058 mmol), EMC-Arg-Arg-Ala-Phe-Met-OH × 2 TFA (70 mg, 0.064 mmol), and DIEA (39.9 μL, 0.231 mmol) in 1 mL DMF. The solution was stirred for 1 h at room temperature. Subsequently, the product was precipitated with diethyl ether and purified by preparative C_{18}-RP-HPLC chromatography. Preparative chromatography was carried out on a Nucleosil C18 column (100–7, 250 × 21 mm) with precolumn (100–7, 50 × 21 mm) from Macherey-Nagel. Chromatographic conditions are as follows: flow, 10.0 mL/min; mobile phase A, 30% MeCN, 70% demin. H_2O, 0.1% TFA; mobile phase B, 50% MeCN, 50% demin. H_2O, 0.1% TFA; gradient, 0–43 min 0% to 100% mobile phase B; 43–53 min 100% mobile phase B isocrat.; 53–63 min 0% to 100% mobile phase A; injection volume, 500–1000 μL. After lyophilization, 34 mg (39.6%) of the parent compound was obtained as a bright yellow solid.

ESI-MS dir-pos. (5.0 kV, MeOH): *m*/*z* (%) 1274.3 ($[M]^+$, 100), 1275.4 ($[M + H]^+$, 61) (mass spectrum is included as Supporting Information). HPLC purity (λ = 370 nm): >95%.

Synthesis of the EMC-Arg-Arg-Phe-Tyr-Met-OH Linker. The synthesis of the linker was performed on solid phase using methionine-preloaded Wang resin as the solid support. The Fmoc-amino acids were sequentially coupled following a standard Fmoc protocol (*29*). In a final step, 6-maleimidocaproic acid (EMC: 3.01 g, 14.25 mmol) was dissolved in DMF, and 10 equiv of HOBt and 10 equiv of DIPC were added. After preincubation for 2 min, the solution was added to the reaction vessel containing the resin (total volume of DMF: 25 mL). Afterwards, the resin was treated with a mixture of TFA/water 95:5 (v/v) for 2 h. The resin was separated by filtration, and the filtrate was evaporated three times after addition of 10 mL of ethanol before the residue was dried in high vacuum. 1.624 g of a crude product was obtained. The crude product was dissolved in 15 mL of anhydrous methanol and precipitated with 200 mL anhydrous diethylether, then centrifuged and washed with anhydrous diethyl ether. This purification step yielded 600 mg of an off-white solid. Further purification was achieved by preparative C_{18}-RP-HPLC chromatography. Preparative chromatography was carried out on a Nucleosil C18 column (100–7, 250 × 21 mm) with precolumn (100–7, 50 × 21 mm) from Macherey-Nagel. Chromatographic conditions are as follows: flow, 10.0 mL/min (0–26 min) and 15.0 mL/min (26–57 min); mobile phase A, 10% MeCN, 90% demin H_2O, 0.1% TFA; mobile phase B, 40% MeCN, 60% demin H_2O, 0.1% TFA; gradient, 0–26 min, 100% mobile phase A isocrat.; 26–36 min, 0%–100% mobile phase B; 36–46 min, 100% mobile phase B isocrat.; 46–55 min, 0%–100% mobile phase A; 55–57 min, 100% mobile phase A isocrat.; injection volume, 5 mL. After lyophilization, 243 mg of the parent compound was obtained as a white solid.

ESI-MS dir-pos. (2.5 kV, MeOH): *m*/*z* (%) 965.3 ($[M + H]^+$, 100); HPLC purity (λ = 220 nm): ~98%.

Synthesis of EMC-Arg-Arg-Phe-Tyr-Met-Ala-CPT × 2 TFA (2). HATU (15.5 mg, 0.054 mmol) was added under a nitrogen atmosphere to a solution of camptothecin-20-*O*-(L-alaninate) × TFA (19.8 mg, 0.049 mmol), EMC-Arg-Arg-Phe-Tyr-Met-OH × 2 TFA (65 mg, 0.054 mmol) and DIEA (25.5 μL, 0.198 mmol) in 1 mL DMF. The solution was stirred for 1 h at room temperature. Subsequently, the product was precipitated with diethyl ether, and the crude product was purified by preparative chromatography. Preparative chromatography was carried out in analogy to the isolation of **1**. After lyophilization, 26.3 mg (33.7%) of **2** was obtained as a bright yellow solid.

ESI-MS dir-pos (5.0 kV, 30% MeOH): *m*/*z* (%) 1366.4 ($[M]^+$, 100), 1367.4 ($[M + H]^+$, 70) (mass spectrum is included as Supporting Information); HPLC purity (λ = 370 nm): >95%.

Synthesis of the Albumin Conjugates of 1 (HSA-1) and 2 (HSA-2). 1.5 mg of the albumin-binding prodrug was dissolved in 2 mL of a 5% solution of human serum albumin (HSA) (~100 mg of albumin) and incubated under stirring at 37 °C for 1 h after which no free **1** or **2** was detectable. The HPLC method to determine that the reaction was completed is available as Supporting Information. The sample was kept frozen at −20 °C and thawed prior to use.

Incubation Studies of 1 and 2 with Mouse Blood Plasma. 0.75 mg of the albumin-binding prodrugs were dissolved in 100 μL of sterile-filtered glucose–phosphate buffer (10 mM sodium phosphate/5% D-glucose buffer, pH 5.8). 30 μL aliquots of these solutions were added immediately to 570 μL of mouse plasma (gratefully received from Dr. N. Esser, Tumor Biology Center, Freiburg) and incubated at 37 °C. Samples were collected after 5 min, 4 h, 8 h, and 24 h and were analyzed by HPLC. The decrease in the peak area of the conjugates at 370 nm over time was used to determine the half-lives.

Incubation Studies of HSA-1 and HSA-2 with Tissue Homogenates. 300 μL aliquots of the **HSA-1** and **HSA-2** stock solutions (500 μM) were mixed with 150 μL of TEAA buffer (20 mM, pH 7.4 and pH 5.0) and 150 μL of tissue homogenate (pH 7.4 and pH 5.0). The samples were incubated at 37 °C for 5 min, 4 h, and 24 h and were analyzed by HPLC. 150 μL of the 4 h and 24 h HT-29 samples were kept frozen at −20 °C and thawed prior to analysis by LC-MS spectrometry.

***In Vivo* Efficacy of 1.** For the *in vivo* testing of **1** in comparison with its parent compound, female NMRI: nu/nu mice (inhouse breeding) were used. The mice were held in individually ventilaged cages under sterile and standardized environmental conditions (25 ± 2 °C room temperature, 50 ± 10% relative humidity, 12 h light–dark rhythm). They received autoclaved food and bedding (ssniff, Soest, Germany) and acidified (pH 4.0) drinking water *ad libitum*. All animal experiments were performed under the auspices of the German Animal Protection Law.

10^7 cells of HT-29 were transplanted subcutaneously (s.c.) into the left flank region of anaesthetized (40 mg/kg i.p. Radenarkon, Asta Medica, Frankfurt, Germany) mice on day zero. Mice were randomly distributed to the experimental groups (6 mice per group). When the tumors were grown to a palpable size (90–130 mm^3), treatment was initiated. HT-29 xenografted mice were treated intravenously at day 6, 13, and 20 with 10 mM sodium phosphate/5% D-glucose buffer pH 5.8, camptothecin, or **1** (compound was administered as a solution in 10 mM sodium phosphate/5% D-glucose buffer pH 5.8); for doses, see corresponding tables and figures. The volume of administration was 0.20 mL/20 g body weight.

Tumor size was measured twice weekly with a caliper-like instrument in two dimensions. Individual tumor volumes (V) were calculated by the formula $V = (\text{length} + [\text{width}]^2)/2$ and related to the values on the first day of treatment (relative tumor volume, RTV). At each measurement day, treated/control values (T/C) were calculated as percentage for each experimental group; the optimum (lowest) values obtained within four weeks after treatment were used for evaluating the efficacy of the compounds, and optimum T/C values are presented in the respective tables. Statistical analysis was performed with the U-test (Mann and Whitney) with $p < 0.05$. The body weights of mice were determined every 3 to 4 days.

RESULTS

Positional Scanning Library. The first aim of our work was to assess the proteolytic activity and specificity of selected native tumor tissue homogenates. Generally, for analyzing the substrate specificity of proteases, two different combinatorial strategies have been followed in the past:

1. Fluorogenic libraries of resin-bound peptides (one bead—one peptide) are screened with enzymes. Subsequent Edman degradation or mass spectrometry of selected hits provides exact information about the peptide sequence (*33*).

2. Fluorogenic libraries consist of a defined number of nonimmobilized sublibraries, each having one position fixed with one amino acid while all other positions are randomized (positional scanning (PS) libraries). Incubation of sublibraries with proteases and subsequent measuring of fluorescence provides information on the extent to which a single amino acid in a defined position influences the cleavage rate.

Although screening proteases using the first strategy results in exact information, i.e., concrete peptide sequences which are cleaved by the target enzymes, the selection and analysis of hits is extremely time-consuming when assessing combinatorial peptides consisting of more than two amino acids and becomes nearly impossible when the number of amino acids exceeds four. In contrast, positional scanning—once the library is established—can be easily performed with high throughput and low cost. In addition, positional scanning has the advantage that cleavage studies can be carried out in solution, which allows a kinetic determination of proteolytic processes.

Previously, fluorogenic PS-libraries have been successfully employed to explore the substrate specificity of a variety of proteases (*26, 27, 34, 35*). In our work, we synthesized a tetrapeptide PS-library based on 7-amino-4-carbamoylmethylcoumarin (ACC) as the fluorophor in accordance with a published procedure (*27*). Peptides were built up on solid phase (Rink amide resin) in five subsequent coupling steps: first the dye and then four amino acids were bound to the resin following straightforward Fmoc chemistry. For the randomized positions, an isokinetic mixture of Fmoc-protected amino acids was employed to ensure an even distribution (*30*). In order to provide sufficient structural diversity, we employed all standard amino acids except for tryptophane and cysteine. Hence, after cleaving the peptides from the resin, we obtained 4 × 18 sublibraries each having one position fixed. For instance, 18 sublibraries were obtained comprising the general formula *Xxx*-*Yyy*-*Zzz*-P_1-ACC (P_1-library) with P_1 fixed and positions *Xxx*, *Yyy*, and *Zzz* randomized.

Once the bond between the first amino acid (in position P_1) and the ACC dye is cleaved, a significant increase in fluorescence is observed. Therefore, ACC peptides can serve as model compounds for prodrugs in which peptides are bound to drugs via an amide bond.

Incubation Studies of Different Tumor Homogenates and Tissue Homogenates of Healthy Organs with the PS Library. In a first step, the PS-library was used to study the protease specificity of native tumor tissue. For this purpose, tissue material of four different colon tumors (xenografts of HT-29, 5735, 5854, and 5679) was homogenized according to two different protocols (*31, 32*): while homogenization at pH 5.0 was assumed to preserve activity of lysosomal proteases, a workup at pH 7.4 was performed to target extracellular enzymes.

Figure 1A,B shows the relative increase in fluorescence (F_{1h}/F_{0h}) of the peptide libraries P_1–P_4 after a 1 h incubation with the colon tumor homogenates at pH 7.4 and pH 5.0, respectively. On first inspection, all tissue samples exhibited significant proteolytic activity with the homogenates at pH 7.4 being more active than at pH 5.0. Furthermore, the selectivity of the libraries decreased from P_1 to P_4, and for the positions P_3 and P_4 at pH 5.0, it was not possible to identify specific amino acids that have a positive influence on the cleavage rate. Among the tested colon tumor samples, no significant differences in the overall cleavage profiles were noted, but there were differences in the absolute fluorescence values; e.g., HT-29 and 5735 showed a notably stronger increase in fluorescence than the other tested colon tumor samples within the P_3 and P_4 libraries at pH 7.4.

For P_1 and P_2, a clear preference for the following amino acids can be stated at both pH values:

pH 7.4. P_1: methionine, lysine, and leucine. P_2: tyrosine, methionine, and phenylalanine.

pH 5.0. P_1: methionine, leucine, and tyrosine. P_2: methionine.

This selection is based on an increase in the relative fluorescence value of >3 for P_1 and P_2 at pH 7.4 (Figure 1A) and an increase in the relative fluorescence value of >1.5 for P_1 and P_2 at pH 5.0 (Figure 1B) that was defined as to be able to score amino acids that promote cleavage.

For P_3 and P_4, however, the cleavage profiles are less characteristic. While no preferred amino acid can be identified in these positions at pH 5.0, a marginal positive influence on the cleavage rate for tyrosine, phenylalanine, methionine, and alanine for the P_3-position and for arginine, leucine, methionine, tyrosine, and lysine for P_4 is noted at pH 7.4.

In order to discover whether the cleavage profiles are colon tumor specific, the PS-library was additionally incubated with four different breast carcinoma samples (MCF-7, MDA-MB 435, Breast 6661, Breast 3366) at pH 7.4. The results of this experiment are depicted in Figure 2. On the whole, the cleavage profiles obtained from incubation with these homogenates revealed similar amino acid preferences compared to those of colon tumor homogenates.

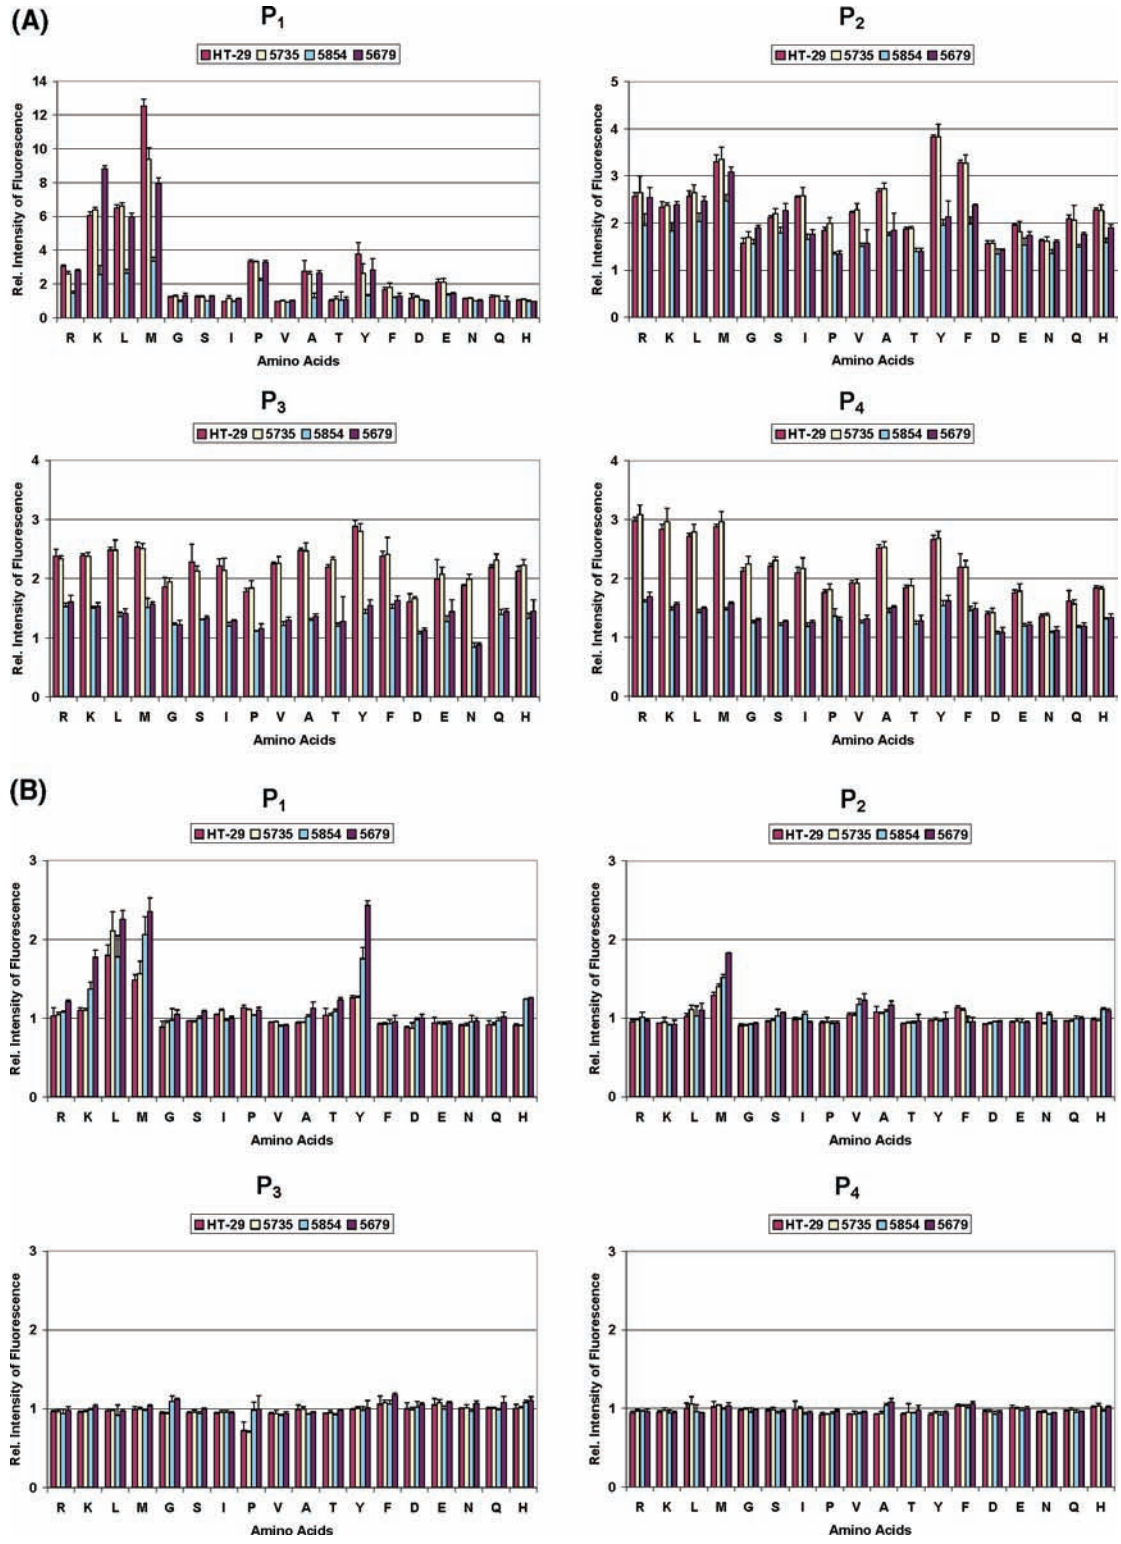

Figure 1. (A) Charts of the P_1–P_4 -libraries incubated with different colon tumor tissue homogenates at pH 7.4. The histograms show the relative increase in fluorescence (F_{1h}/F_{0h}) of the peptide libraries P_1–P_4 after a 1 h incubation with four different colon tumor homogenates at pH 7.4. (number of measurements: $n = 4$). (B) Charts of the P_1–P_4 -libraries incubated with different colon tumor tissue homogenates at pH 5.0. The histograms show the relative increase in fluorescence (F_{1h}/F_{0h}) of the peptide libraries P_1–P_4 after a 1 h incubation with four different colon tumor homogenates at pH 5.0. (number of measurements: $n = 4$.)

To elucidate the ACC–peptides' stability in blood plasma, analogous incubation experiments with the PS libraries P_1–P_4 were carried out using human blood plasma at pH 7.4. The charts in Figure 3 show that no noteworthy increase in fluorescence with human plasma is detected. Hence, in contrast to tumor tissue, the proteolytic activity of plasma seems to be negligible after a 1 h incubation with the library.

Finally, we investigated the proteolytic activity of healthy organs (liver, kidney, and spleen from nude mice). The PS-library was incubated with tissue homogenate samples at pH 5.0 and pH 7.4 (Figures 4 and 5).

At pH 7.4, the cleavage profile was quite similar to that of tumor homogenates with a preference for methionine, lysine, leucine, and additionally alanine in P_1, tyrosine in P_2, and a

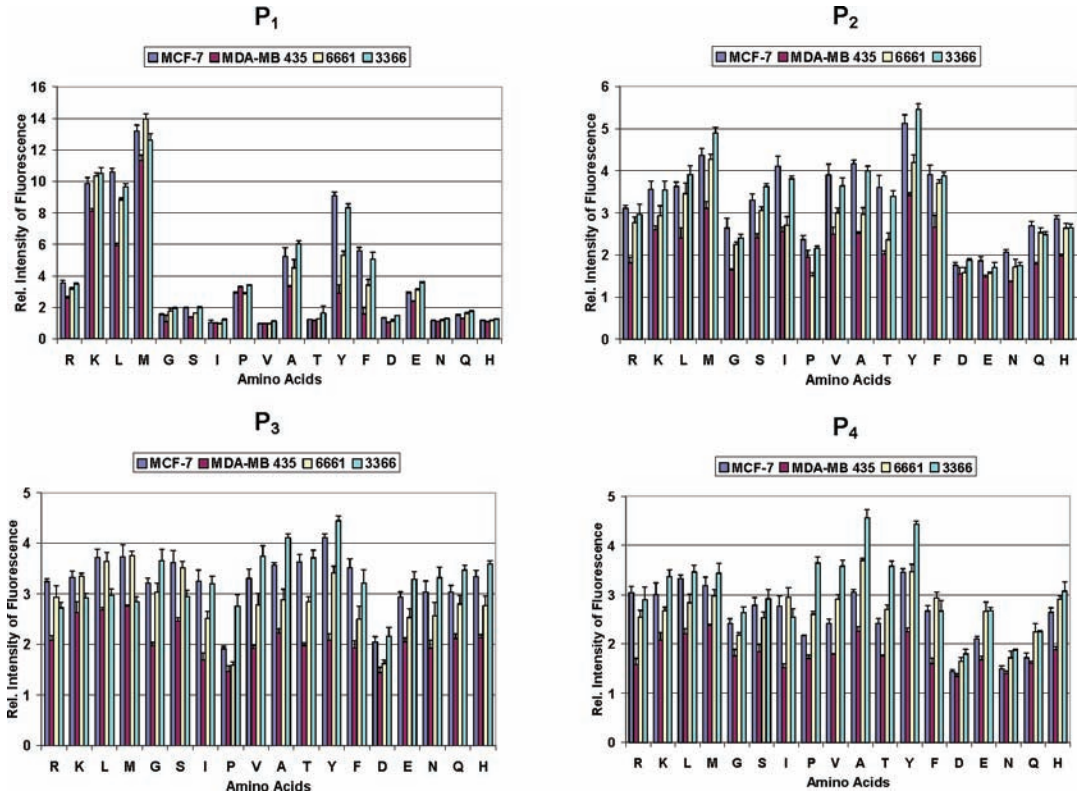

Figure 2. Charts of the P_1–P_4 -libraries incubated with different breast tumor tissue homogenates at pH 7.4. The histograms show the relative increase in fluorescence (F_{1h}/F_{0h}) of the peptide libraries P_1–P_4 after 1 h incubation with four different breast tumor homogenates at pH 7.4. (number of measurements: $n = 4$.)

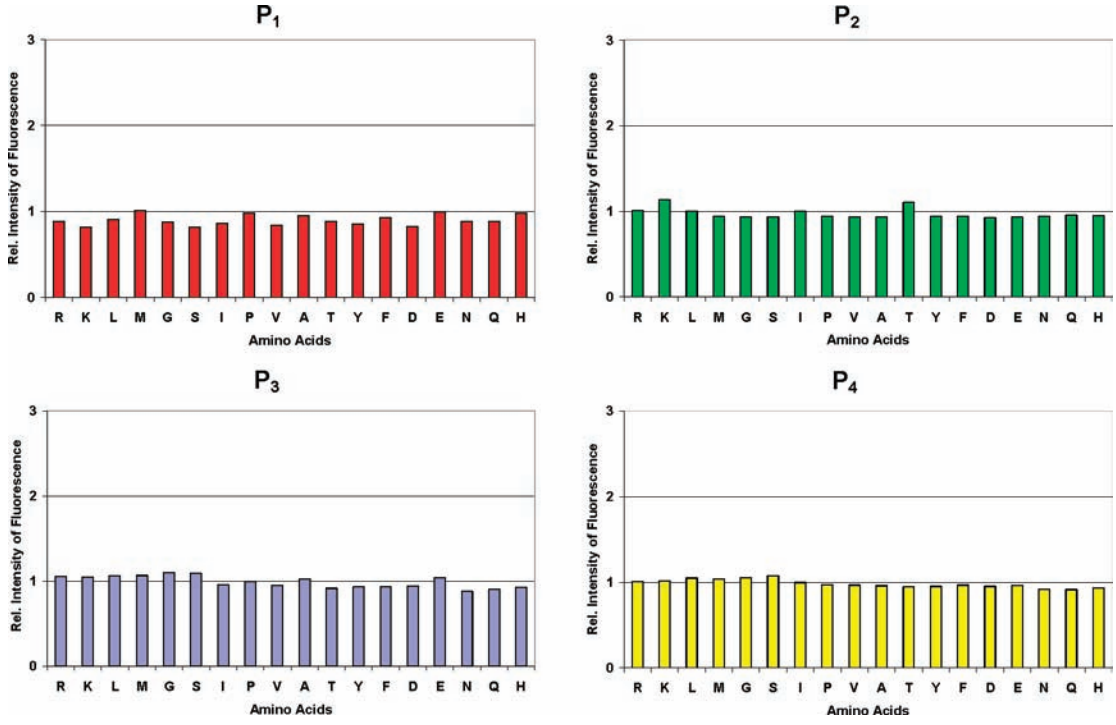

Figure 3. Charts of the P_1–P_4 -library incubated with human blood plasma at pH 7.4. The histograms show the relative increase in fluorescence (F_{1h}/F_{0h}) of the peptide libraries P_1–P_4 after 1 h incubation with human blood plasma at pH 7.4. (number of measurements: $n = 4$.)

less clear picture for P_3 and P_4 (Figure 4). As an exception, the cleavage pattern obtained with kidney homogenate differed markedly from those of liver and spleen. A pronounced cleavage was detected for peptides having arginine, lysine, or glycine in P_1, whereas no clear preference could be seen in P_2–P_4. The overall increase in fluorescence for the P_3- and P_4-libraries was higher in the healthy organs compared to the colon tumor samples.

At pH 5.0, the overall increase in fluorescence was higher in the healthy organs compared to the tumor samples; incubation

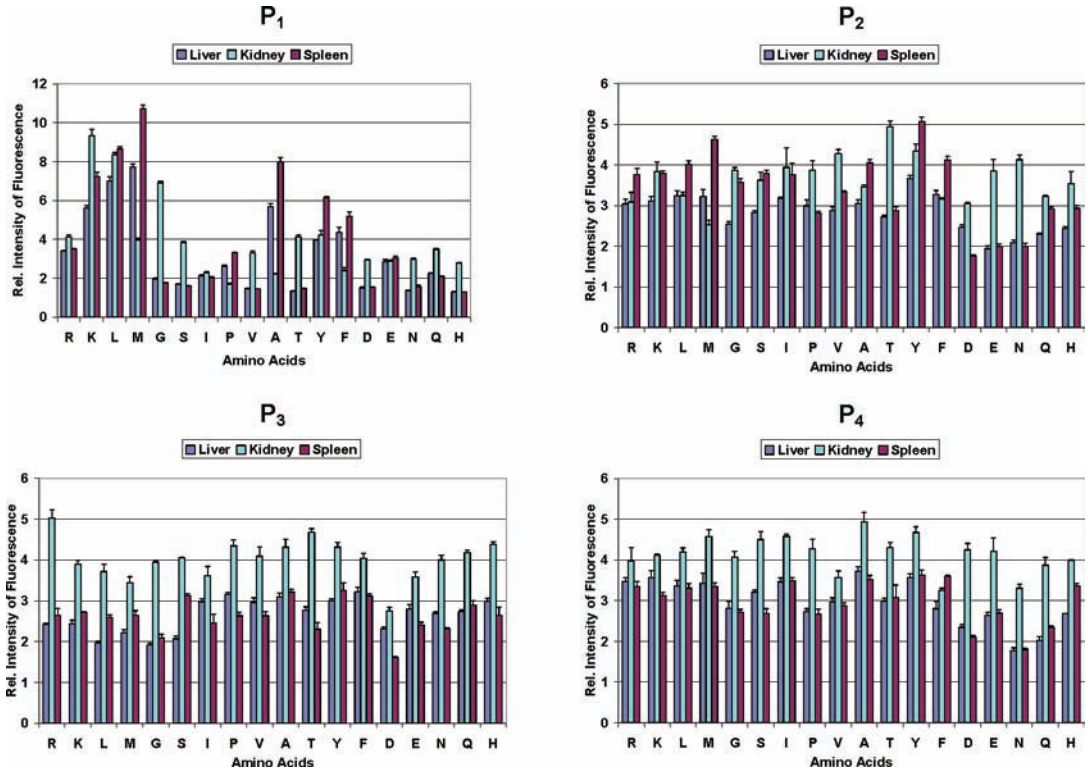

Figure 4. Charts of the P_1–P_4 -library incubated with healthy organs (liver, kidney, and spleen) from nude mice at pH 7.4. The histograms show the relative increase in fluorescence (F_{1h}/F_{0h}) of the peptide libraries P_1–P_4 after 1 h incubation with homogenates of murine healthy organs at pH 7.4. (number of measurements: $n = 4$.)

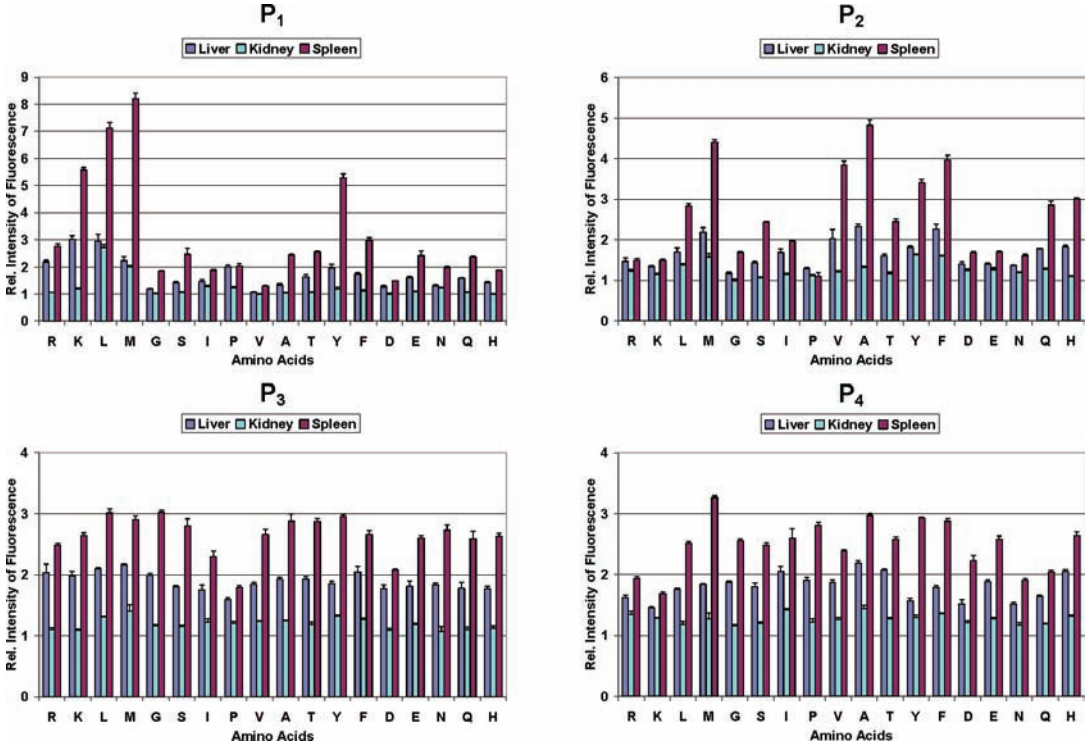

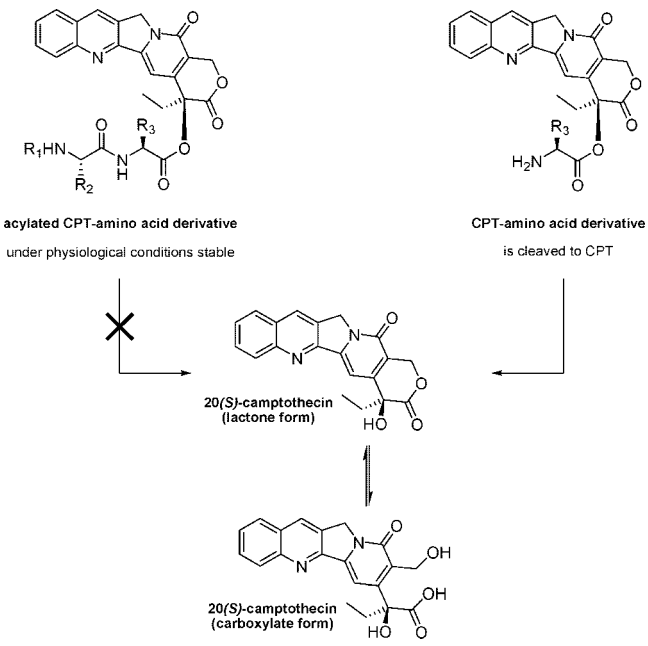

Figure 5. Charts of the P_1–P_4 -library cleaved by healthy organs (liver, kidney, and spleen) from nude mice at pH 5.0. The histograms show the relative increase in fluorescence (F_{1h}/F_{0h}) of the peptide libraries P_1–P_4 after 1 h incubation with homogenates of murine healthy organs at pH 5.0. (number of measurements: $n = 4$.)

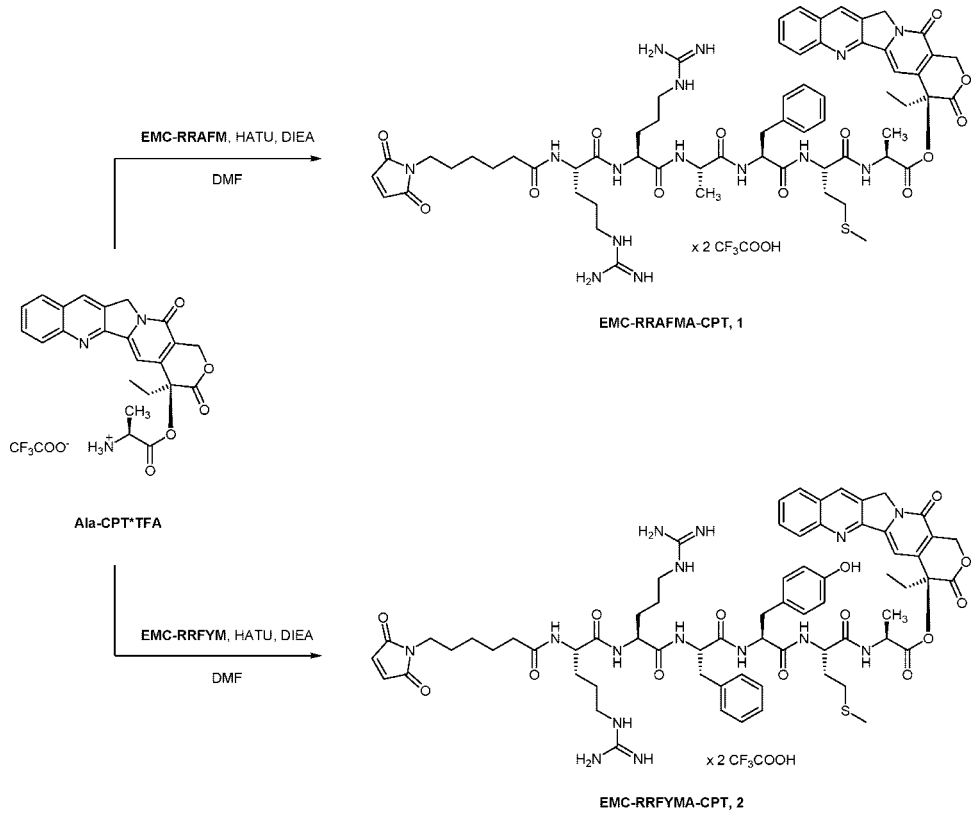
studies with spleen homogenate showed the largest increase in fluorescence. For spleen and liver homogenates, a preference for methionine, lysine, leucine, and tyrosine in P_1 and for methionine, valine, alanine, tyrosine, and phenylalanaine in P_2 can be discerned. Incubation studies with kidney homogenates showed a less characteristic picture.

In summary, the cleavage profiles of homogenates from human breast tumors, human colon tumors, and murine organs

Scheme 1. Release of Camptothecin from CPT–Amino Acid Esters



were generally quite similar; albeit, a noteworthy exception was found after incubation with kidney homogenate at pH 7.4. When selecting a peptide sequence that would act as an efficient protease substrate in the prodrugs, we opted to choose and combine those amino acids with a high increase in fluorescence. This was methionine in the P_1-position, either tyrosine or the related phenylalanine in the P_2-position, alanine or phenylalanine the P_3-position, and arginine in the P_4-position, with the latter being chosen to enhance the water solubility of the prodrugs. The syntheses of two prodrugs with camptothecin incorporating the peptide sequences Arg-Ala-Phe-Met or Arg-Phe-Tyr-Met are described below.

Synthesis of the Camptothecin Prodrugs 1 and 2. Camptothecin (CPT), a pentacyclic alkaloid isolated from a Chinese tree, was chosen for the development of albumin-binding prodrugs incorporating the two aforementioned peptide sequences as enzymatically cleavable spacers. Although highly cytotoxic, CPT has not gained any clinical relevance due to its poor water solubility (2.5 μg/mL) (*22*), whereas the hydrophilic derivatives Topotecan and Irinotecan are meanwhile approved for the treatment of colorectal, lung, and ovarian carcinomas. To improve the water solubility and efficacy of CPT, a poly(ethylene glycol) conjugate of CPT (Prothecan) was developed that is currently undergoing phase II clinical trials (*36*). In this macromolecular prodrug, CPT is bound through an alanine spacer to the polymer. Generally, it could be shown that incorporating amino acids between the carrier and CPT turned out to be beneficial for the following reasons (*37*): (a) The ester bond between the amino acid and CPT is relatively stable under physiological conditions as long as the amino acid remains acylated (Scheme 1) (*38*); (b) once the amide bond between the carrier and the amino acid spacer is cleaved, the ester bond between the amino acid and CPT hydrolyzes spontaneously, liberating CPT in its active and less toxic lactone form. However, this in theory simple reaction proved to be quite complex, as previous mechanistic studies on the hydrolysis of H-Gly CPT revealed (*39, 40*).

In our work, we chose to incorporate an alanine spacer between the peptide linker and the drug. Hence, C-terminal cleavage of the peptides results in the release of H-Ala-CPT, which further decomposes to alanine and the free drug. For the synthesis of the albumin-binding prodrugs **1** and **2**, the maleimide-bearing peptides EMC-Arg-Arg-Ala-Phe-Met-OH and EMC-Arg-Arg-Phe-Tyr-Met-OH were reacted with camptothecin-20-*O*-(L-alaninate) (Scheme 2). The latter was readily prepared by a published two-step procedure, in which the first

Scheme 2. Synthesis of the Albumin-Binding CPT Prodrugs 1and 2

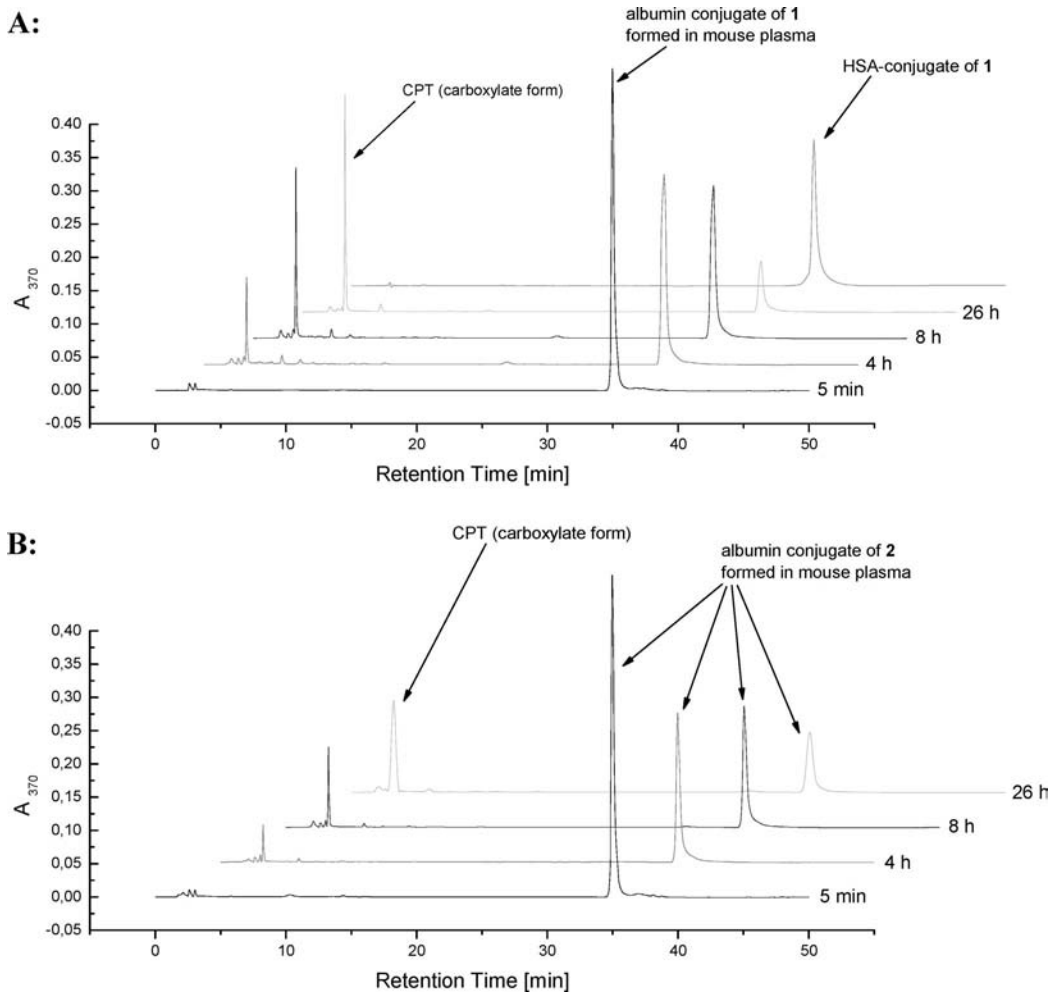


Figure 6. (A,B) Chromatograms of incubation studies of mouse blood plasma after 5 min, 4 h, 8 h, and 26 h with prodrugs **1** (A) and **2** (B) at 37 °C. The chromatograms show the stability of the albumin conjugate of prodrugs **1** and **2** over time, to determine the respective plasma half-lives. In addition, the chromatogram of the HSA-conjugate of **1** is displayed. For chromatographic conditions, see Supporting Information.

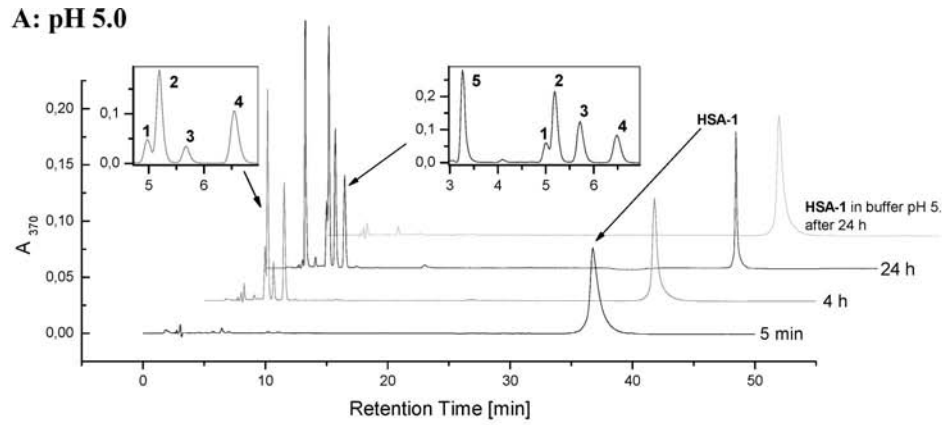
step was a stereoselective acylation of 20-(*S*)-camptothecin (*25*). Condensation of camptothecin-20-*O*-(L-alaninate) with the maleimide-bearing peptides was carried out using HATU as the coupling agent. The two prodrugs EMC-Arg-Arg-Ala-Phe-Met-Ala-CPT (**1**) and EMC-Arg-Arg-Phe-Tyr-Met-Ala-CPT (**2**) were purified by preparative HPLC and characterized by mass spectrometry. The incorporation of two arginine moieties in the peptide chain of the linkers of **1** and **2** resulted in excellent solubility in buffer solution (>7 mg/mL), while the parent compound is almost insoluble (CPT: 2.5 μg/mL).

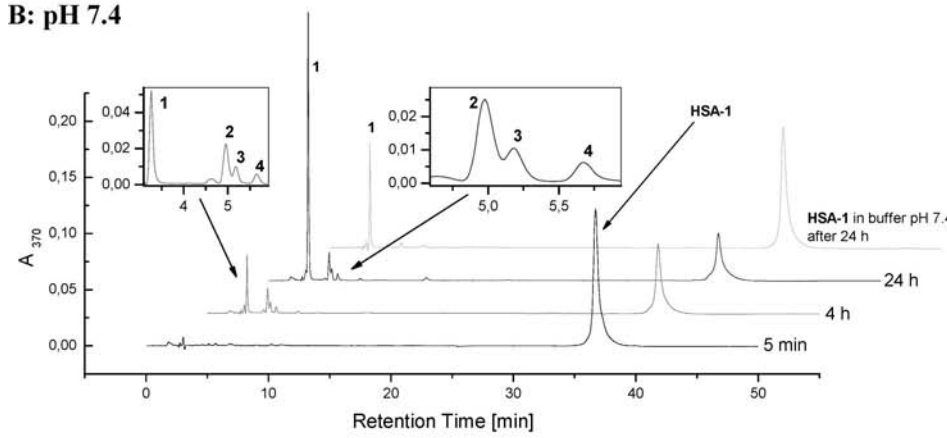
Albumin-Binding Properties and Stability of 1 and 2. In order to show that the prodrugs **1** and **2** bind rapidly and selectively to endogenous serum albumin, incubation with mouse plasma at 37 °C was performed for 5 min and HPLC profiles recorded at $\lambda = 370$ nm, the maximum absorbance of CPT derivatives in the near-UV region.

Figures S1 and S2 in the Supporting Information show the chromatographic profiles of **1** and **2** incubated with mouse blood plasma after 5 min ($\lambda = 370$ nm). While the free prodrugs elute at ~9 min (**1**) and ~11 min (**2**), the signals disappeared almost completely after incubation with mouse plasma, and a single peak eluting at the retention time of mouse serum albumin (MSA) (33–37 min) was observed.



In order to prove that the fast binding results from a Michael addition of the sulfhydryl group of MSA with the maleimide group of the prodrugs, analogous HPLC experiments were carried out in which the cysteine-34 position of MSA was blocked with an excess of ϵ-maleimidocaproic acid (EMC) prior to incubation with **1** and **2** (see Figures S1 and S2 in the Supporting Information). In this case, marginal binding to MSA was observed after incubating plasma with **1** and **2** for 10 min.

This observation is in accordance with our previous work on albumin-binding prodrugs with doxorubicin, camptothecin, and platinum derivatives where we have shown that albumin binding results from a Michael addition between the maleimide group and sulfhydryl group of the cysteine-34 position of serum albumin (*3*, *4*, *8–10*, *41*, *42*).



In order to determine the plasma stability of the compounds **1** and **2** bound to albumin, plasma samples with **1** and **2** were analyzed at further time points (4 h, 8 h, and 26 h) by HPLC (Figure 6A,B) in order to obtain a first estimate of their plasma stability. From the decrease of the peak areas of the albumin conjugates of **1** and **2**, the half-lives were approximately $t_{1/2} \sim$ 26 h (**1**) and $t_{1/2} \sim 25$ h (**2**).

Cleavage of HSA-1 and HSA-2 after Incubation with HT-29 Colon Tumor Homogenate and Tissue Homogenates of Healthy Murine Organs (Liver, Kidney, and Spleen). The cleavage properties of the albumin-bound form of **1** and **2** (**HSA-1** and **HSA-2**) were studied in HT-29 colon tumor homogenates at pH 7.4 and 5.0 (Figure 7A,B and Figure 8A,B).

Additionally, buffer stabilities (TEAA, 20 mM) of the albumin conjugates at pH 7.4 and pH 5.0 over 24 h were assessed, demonstrating that a certain degree of unspecific hydrolysis takes place: degradation at pH 7.4 for **HSA-1** <15% and for **HSA-2** <20%; degradation for **HSA-1** and **HSA-2** at pH 5.0 <5%. However, cleavage of **HSA-1** and **HSA-2** in the

Peak number	Retention time [min]	Observed fragment ions [*m/z*]	Peak assignment

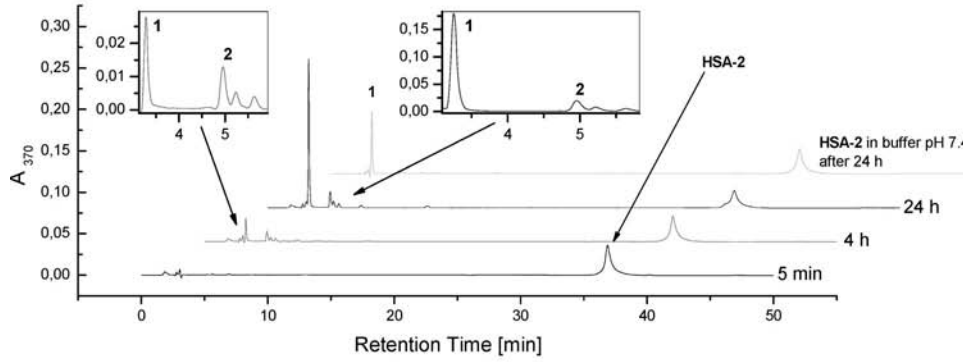
Figure 7. (A,B) Chromatograms of incubation studies of the albumin conjugate of prodrug **1** (**HSA-1**) with HT-29 colon tumor homogenate at pH 5.0 (A) and pH 7.4 (B) after 5 min, 4 h, and 24 h at 37 °C. The chromatograms show the enzymatical degradation of **HSA-1** in colon tumor homogenate. The several clustered peaks are highlighted separately and the cleavage products were analyzed via LC-MS. In addition, the chromatograms of **HSA-1** after 24 h in buffer solution pH 5.0 and pH 7.4, respectively, are displayed.



tumor homogenates is more pronounced and specific (Figures 7A,B and 8A,B). The different cleavage products were identified by LC-MS (Figure S7 in Supporting Information) and by use of CPT and CPT-Ala-OH standards. Unfortunately, the HPLC method used for incubation studies could not be transferred one-to-one to the LC-MS investigations. Therefore, the cleavage products could not be identified by retention times but by their peak areas and by the use of reference compounds. For the cleavage of **HSA-1** at pH 7.4, CPT in its hydroxycarboxylate form (as the main product) and in its lactone form as well as H-Met(O)-Ala-CPT (with oxidized methionine) were identified. In contrast, cleavage with HT-29 colon tumor homogenate at pH 5.0 led to a more complex degradation of the albumin conjugate. The identified cleavage products at pH 5.0 were CPT

Figure 8. (A,B) Chromatograms of incubation studies of the albumin conjugate of **2** (**HSA-2**) with HT-29 colon tumor homogenate at pH 5.0 (A) and pH 7.4 (B) after 5 min, 4 h, and 24 h at 37 °C. The chromatograms show the enzymatical degradation of **HSA-2** in colon tumor homogenate. The several clustered peaks are highlighted separately and the cleavage products were analyzed via LC-MS. In addition, the chromatograms of **HSA-2** after 24 h in buffer solution pH 5.0 and pH 7.4, respectively, are displayed.

in its hydroxycarboxylate form and H-Ala-CPT as the main products, and to a lesser extent CPT in its lactone form, H-Met-Ala-CPT and H-Met(O)-Ala-CPT. Overall, the degradation of **HSA-1** in HT-29 tumor homogenate over 24 h was: pH 7.4 >50% and pH 5.0 >70%.

After incubation of **HSA-2** with HT-29 colon tumor homogenate, a similar cleavage pattern was obtained. At pH 7.4, CPT in the carboxylate form (as the main product) and H-Met(O)-Ala-CPT were detected. Cleavage products at pH 5.0 were CPT in the carboxylate form and H-Ala-CPT as the main products, CPT in the lactone form, H-Met-Ala-CPT, H-Met(O)-Ala-CPT, and additionally H-Tyr-Met-Ala-CPT. For **HSA-2**, the following overall degradation in HT-29 tumor homogenate over 24 h could be determined: pH 7.4 >50%, pH 5.0 ~75%.

Interestingly, the cleavage profiles of both **HSA-1** and **HSA-2** at pH 7.4 showed H-Met-Ala-CPT, as well as H-Met(O)-Ala-CPT in which the thiol group of methionine is oxidized.

Table 1. Antitumor Activity of Prodrug 1 against Human Colorectal Xenografts (HT-29) *in Vivo*

compound	dose[a] [mg/kg]	total mortality	body weight change [%] (days 6–9)	*T*/*C* [%] maximal
CPT	3 × 12.5	0/6	−2	40 (day 22)
1	2 × 12.5	1/6 (day 13)	−1	17[b,c] (day 22)

[a] Dose refers to CPT equivalents. [b] Significant to buffer solution. [c] Significant to camptothecin.

Additional cleavage studies were carried out with **HSA-1** and tissue homogenates of healthy, murine organs (liver, kidney, and spleen) at pH 5.0. The cleavage profiles (see Supporting Information Figures S3, S4, and S5) were compared to those of the incubation study with **HSA-1** and HT-29 colon tumor homogenate at pH 5.0 (Figure 7A). The extent of the cleavage is comparable to the tumor homogenate study (overall degradation over 24 h ~75%). The strongest cleavage was obtained with spleen homogenate. Overall, the cleavage profiles are very similar to those of the tumor homogenate study, with the exception of a lower generation of CPT in the carboxylate form.

***In Vivo* Activity of 1.** The *in vivo* efficacy of **1** and CPT was assessed in xenografted nude mice using a human HT-29 colorectal cell line. CPT was evaluated at a dose of 3 × 12.5 mg/kg (i.v.) which was reported to be the maximum tolerated dose (MTD) for camptothecin in nude mice (*43*) and compared to prodrug **1** at the same dose of 3 × 12.5 mg/kg (i.v.) CPT equivalents. As a result of one toxic death that occurred after the second dose (day 13), a third dose of **1** was not administered. Table 1 and Figure 9 summarize the results of this experiment. Besides an acute toxicity, therapy with **1** produced no significant body weight loss (Figure S6 in Supporting Information). Whereas CPT (3 × 12.5 mg/kg) was moderately active (*T*/*C* max 40%), **1** exhibited superior antitumor activity at a lower dose of 2 × 12.5 mg/kg CPT equivalents (*T*/*C* max 17%).

DISCUSSION

In this work, we set out to discover new peptide sequences for the design of prodrugs that are effectively cleaved within the tumor and, if possible, cleaved tumor-selectively. For this purpose, we screened homogenates of native human tumors and healthy murine organs with a positional scanning library. Positional scanning libraries have previously been used to determine the substrate-specificity of proteases such as plasmin or thrombin (*27*) and more recently of cathepsins (*44*).

Although the number of studied biological samples was limited, a first and somewhat disappointing finding was the fact that the cleavage profiles of samples from human breast carcinoma, human colon carcinoma, and murine spleen, kidney, and liver were quite similar. A noteworthy observation is the preference of methionine in P_1, since this amino acid is mostly omitted in the development of peptide libraries and is not commonly found incorporated as an amino acid in protease substrates for ubiquitous enzymes.

Using positional scanning, we were not able to identify amino acids in P_3 and P_4 that had a significant impact on the cleavage rate. Possible explanations are that these positions are variable or the sensitivity of our assay was too low. In theory, a low sensitivity for P_3 and P_4 can result from a high selectivity for P_1 and P_2 due to the small number of cleavable combinations (percentage of all tetrapeptides with the appropriate P_1 and P_2 combinations). Hence, sensitivity for P_3 and P_4 might be improved by developing a new peptide library with fixed P_1 and P_2.

On the basis of the screening results, the selection of amino acids for developing camptothecin prodrugs was explorative in nature, with preference being given to those amino acids which had a significant impact on the cleavage rate at their respective positions.

The resulting prodrugs EMC-Arg-Arg-Ala-Phe-Met-Ala-CPT (**1**) and EMC-Arg-Arg-Phe-Tyr-Met-Ala-CPT (**2**) showed fast albumin binding, acceptable stability in mouse plasma, and a distinct cleavage profile at pH 5.0 and 7.4. Surprisingly, cleavage of the albumin conjugates of **1** and **2** in HT-29 tumor homogenates was far more pronounced at pH 5.0 than at pH 7.4, considering that the reverse order would have been expected on the basis of the results from the screening experiments with our fluorogenic library. Our incubation studies with tumor homogenate revealed that both peptide sequences were primarily cleaved at the scissile bonds in P_1 and P_2.

Results of in vivo studies in the HT-29 xenograft model were encouraging, since EMC-Arg-Arg-Ala-Phe-Met-Ala-CPT (**1**) showed significantly better antitumor activity than CPT at a lower dose. The incorporated peptide sequence in **1** cannot, however, be regarded as a colon tumor selective protease substrate, because a similar cleavage profile was observed with healthy murine organs.

Reasons for the lack of tumor selectivity are manifold: The most obvious explanation is that there are no relevant differences in the expression pattern of proteases between individual tumors and healthy organs that can be detected with any degree of sensitivity using a positional scanning library. A further reason for the lack of tumor selectivity could be that the overall cleavage profile is determined by ubiquitous proteases that

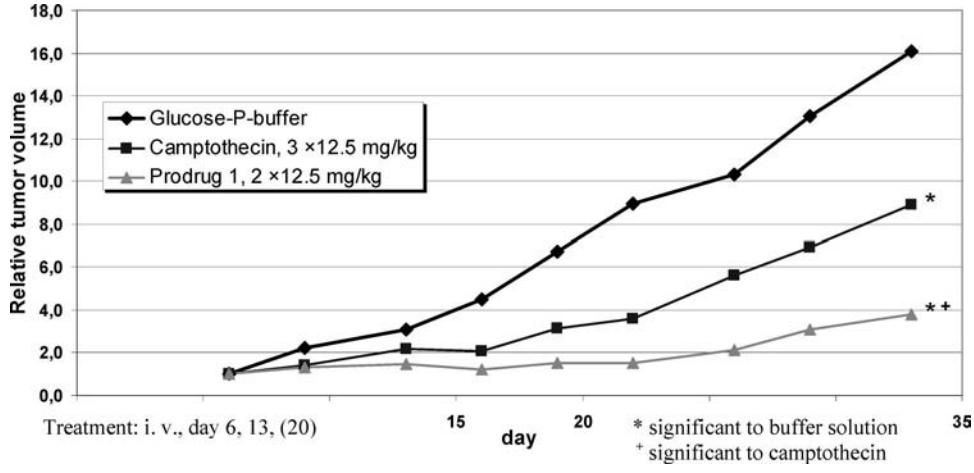

Figure 9. Curves depicting tumor growth inhibition of subcutaneous HT-29 xenografts under therapy with camptothecin and prodrug **1**. The dose of prodrug **1** is given as CPT equivalents. Camptothecin was adminstered at day 6, 13, and 20, whereas prodrug **1** was only administered at day 6 and 13.

overlay finer differences in the expression of proteases in healthy and malignant tissue. Another explanation could be that tumor-associated proteases are deactivated by inhibitors or during homogenate preparation.

An alternative strategy for the evaluation of tumor-selective protease activity would be to consider the cellular pathways for the uptake of macromolecular prodrugs in more detail. In contrast to low-molecular-weight drugs, macromolecular prodrugs are taken up by internalization via the endosomal/lysosomal pathway. As a consequence, assessing the proteolytic activity of pure lysosomal fractions of selected tumors and healthy organs could be an appropriate strategy for future trials in identifying truly tumor-specific peptide sequences.

In summary, we have shown that prodrugs incorporating the peptide sequences Arg-Ala-Phe-Met and Arg-Phe-Tyr-Met that were selected from screening a positional scanning library with colon tumor homogenates were efficiently cleaved in their albumin-bound form after exposure to the initially used colon tumor homogenate. In addition, the antitumor efficacy of prodrug **1** with the Arg-Ala-Phe-Met linker was superior to free camptothecin. However, this sequence is not cleaved selectively in HT-29 colon tumors. It cannot be ruled out that esterases in the acidic milieu of the tumor tissue might be responsible for the cleavage of the ester bond between CPT and the peptide linker and lead to the release of the active compound at the tumor site. The improved activity of the prodrug in comparison to free CPT is presumably based on the much longer circulation of the macromolecular prodrug in the bloodstream due to reduced renal excretion associated with accumulation in the tumor mediated by the EPR effect. Subsequently, the albumin conjugate enters the tumor cell via the endosomal/lysosomal pathway and is presumably enzymatically cleaved to the active lactone form of CPT in the acidic environment of the lysosomes. In contrast, under physiological conditions the major part of free CPT is available in its inactive hydroxycarboxylate form and is rapidly excreted via the kidney.

ACKNOWLEDGMENT

The support of the Wilhelm Sander-Stiftung, Germany, is gratefully acknowledged. We wish to thank Peter Lazar for carrying out the peptide syntheses and Christoph Warth for performing the LC-MS experiments.

Supporting Information Available: Additional experimental data and spectra as described in the text. This material is available free of charge via the Internet at http://pubs.acs.org.

Received March 16, 2007; Revised Manuscript Received July 26, 2007

We have developed efficient synthetic routes to two hydrophobic amino acids, suitably protected for solid-phase peptide synthesis, and have successfully synthesized peptides containing these or other hydrophobic amino acids as spacers between a Lys_{16} moiety and an integrin-targeting motif. These peptides have in turn been used to formulate a range of lipopolyplex vectors with Lipofectin and plasmid DNA. The transfection efficiencies of these vectors and their aggregation behavior in buffers and in serum have been studied. We have shown that vectors containing peptides incorporating long linkers that are entirely hydrophobic are less efficient transfection agents. However, linkers of equivalent length that are in part hydrophobic show improved transfection properties, which is probably due to the improved accessibility of the integrin-binding motif.

INTRODUCTION

The development of gene delivery methods for the treatment of various diseases is still limited by the efficiency, reliability, and safety of the vectors used. Although viral vectors frequently exhibit excellent gene transfer efficiencies, recent concerns about their safety and immunogenicity (*1–3*) have led to renewed interest in the design and synthesis of nonviral gene delivery vectors (*4–6*). We are currently investigating the use of a ternary synthetic lipopolyplex vector, the LID vector, for gene delivery. The first generation of these targeted, self-assembling vector complexes (*7*) consisted of plasmid DNA, a lipid component, Lipofectin (a 1:1 mixture of the cationic lipid DOTMA with a co-lipid DOPE), and a cationic peptide (**1**) (comprising a K_{16} domain which binds to the plasmid DNA, a targeting domain (CRRETAWAC), which binds to $\alpha_5\beta_1$ integrins found on cell surfaces, and a flexible spacer sequence (GA)). LID vectors displayed high transfection efficiency and low toxicity *in vitro* and *in vivo*, transfected nondividing cells efficiently, and were well-tolerated upon repeated administration with low immunogenicity *in vivo* (*7–9*).

Our working hypothesis for the transfection pathway is that the LID complexes bind to the $\alpha_5\beta_1$ integrin and are then internalized by receptor-mediated endocytosis. One factor which might have a major effect on the efficiency of vector binding and internalization, therefore, would be the length and structure of the spacer sequence: longer spacers might position the targeting domain away from the vector surface and therefore render it more accessible. We also hypothesized that the condensed DNA was surrounded by a lipid coat and reasoned that hydrophobic spacers might possess the ability to "stack" within the lipid coating, thus simultaneously increasing the stability of the resulting lipopolyplex vector. We have therefore synthesized peptide **2**, containing ll-aminoundecanoic acid (Aua) as a spacer, and peptide **3**, containing 16-aminohexadecanoic acid (Ahd) as spacer. Furthermore, in an attempt to make the spacer amino acid closer in structure to the unsaturated tail of the lipid DOTMA, we have synthesised the novel amino acid **4** (Fmoc-Laa), and used it to prepare peptide **5**. Finally, we have designed and used peptide **7**, incorporating a spacer containing 6-aminohexanoic acid (Ahx) units. We reasoned that the sequence Ahx-Ser-Ahx would be suitably hydrophobic and act

as a longer spacer, but would not be able to stack within a lipid bilayer so efficiently. In this paper, we report the synthesis of amino acids **4** and **6**, and the synthesis of the peptides; we also describe the effect of these spacers on the transfection efficiencies and biophysical properties of lipopolyplex vectors formulated from peptides **2**, **3**, **5**, and **7**.

EXPERIMENTAL PROCEDURES

General Procedures and Materials. All reagents used for synthesis were purchased from commercial suppliers, with the exception of 9-phenylxanthen-9-ol, which was prepared from xanthone and phenylmagnesium bromide following a literature procedure (*10*). Solvents were purified using standard techniques, with the exception of THF, which was distilled from sodium wire without the use of benzophenone for the synthesis of **13**. NMR spectra were recorded on a Bruker AMX300 spectrometer; chemical shifts (δ) are reported in parts per million (ppm) using residual isotopic solvent as an internal reference. Coupling constants (J) are reported in hertz (Hz). Electrospray mass spectra were recorded on Micromass Quattro LC, Thermo Finnegan MAT 900XP, or VG ZAB 2SE instruments, and fast atom bombardment mass spectra on Thermo Finnegan MAT 900XP or VG ZAB 2SE instruments. IR spectra were recorded on a Shimadzu FT-IR 8700.

Solid-phase peptide synthesis was carried out either manually on a Merrifield bubbler or automatically on a peptide synthesizer (MilliGen 9050Plus PepSynthesiser). All reagents used for either manual or automatic synthesis were purchased from commercial suppliers, with the exception of the Fmoc-protected amino acids **4** (Fmoc-Laa) and **6** (Fmoc-Aua). HIPERSOLV DMF of HPLC grade was used straight from the bottle, while dichloromethane and piperidine were freshly distilled over calcium hydride before use. All peptide syntheses were carried out under nitrogen.

Preparative HPLC was carried out on a Waters 600E instrument with Waters 486 UV detector, using a Vydac 218TP reverse-phase HPLC column (25 × 250 mm). Analytical HPLC was carried out on a Varian ProStar 210 with Varian ProStar 320 UV detector, using a Vydac 218TP reverse-phase HPLC column (2.1 × 250 mm). Water/acetonitrile gradients were used as described, with both water and acetonitrile containing 0.1% trifluoroacetic acid and monitoring at 215 nm.

Synthesis of Fmoc-Laa 4. *6-Bromohexanoic Acid tert-Butyl Ester **8** (11).* To 6-bromohexanoic acid (2.50 g, 12.8 mmol) in dry dichloromethane (50 mL) at 0 °C under nitrogen was added *tert*-butyl alcohol (5.5 mL, 66 mmol, 5 equiv) followed by dimethylaminopyridine (0.156 g, 1.28 mmol, 0.1 equiv). After 5 min, dicyclohexylcarbodiimide (2.90 g, 14.08 mmol, 1.1 equiv) was added to this solution at 0 °C. The solution was then left to warm to room temperature and stirred for 12 h. After 12 h, the reaction was filtered and then partitioned with water (50 mL). The organic fraction was dried over anhydrous $MgSO_4$ and concentrated *in vacuo*. The remaining residue was purified by normal-phase silica gel chromatography, eluting with hexane/ethyl acetate (90:10) to give **8** as a clear oil (2.51 g, 78%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.45 (9H, s, $C(CH_3)_3$), 1.46 (2H, m, $Br(CH_2)_2CH_2$), 1.62 (2H, quintet, J = 7.1 Hz, $Br(CH_2)_3CH_2CH_2$), 1.88 (2H, quintet, J = 7.1 Hz, $BrCH_2CH_2(CH_2)_3$), 2.23 (2H, t, J = 7.3 Hz, $CH_2COOC(CH_3)_3$), 3.41 (2H, t, J = 6.8 Hz, $BrCH_2$); ^{13}C NMR (75 MHz, $CDCl_3$) δ 24.6, 28.0, 28.5, 32.8, 33.8, 35.7, 80.5, 173.2; IR ν_{max}/cm^{-1} (film) 2977, 2936, 1728; $C_{10}H_{19}O_2Br$ (FAB^+) m/z 253 ($M + H^+$ [^{81}Br], 15%), 251 ($M + H^+$ [^{79}Br], 18%), 197 ([$C_6H_{12}O_2$ ^{81}Br]$^+$, 34%), 195 ([$C_6H_{12}O_2$ ^{79}Br]$^+$, 36%), 57 ([C_4H_9]$^+$, 100%).

*6-Iodohexanoic Acid tert-Butyl Ester **9** (12).* To 6-bromohexanoic acid *tert*-butyl ester **8** (2.30 g, 9.20 mmol) in dry acetone (400 mL) under nitrogen was added sodium iodide (41 g, 275 mmol, 30 equiv). The reaction mixture was left to stir in darkness at room temperature for 6 days, after which time it was filtered. The separated solid was then washed with diethyl ether, which was added to the filtrate. The filtrate was concentrated *in vacuo* and then redissolved in diethyl ether (250 mL). This solution was partitioned with 5% aqueous sodium thiosulfate (100 mL) and saturated aqueous sodium chloride (100 mL). The aqueous phase was back-extracted with diethyl ether (150 mL). The organic solutions were combined, dried over anhydrous $MgSO_4$, and concentrated *in vacuo* to give a yellow oil. This oil was purified by silica gel chromatography, eluting with hexane/ethyl acetate (90:10) to give **9** as a yellow oil (2.53 g, 93%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.39–1.49 (2H, m, $I(CH_2)_2CH_2$), 1.45 (9H, s, $C(CH_3)_3$), 1.62 (2H, quintet, J = 7.2 Hz, $I(CH_2)_3CH_2$), 1.84 (2H, quintet, J = 7.2 Hz, ICH_2CH_2), 2.22 (2H, t, J = 7.3 Hz, $CH_2COOC(CH_3)_3$), 3.19 (2H, t, J = 7.0 Hz, $ICH_2(CH_2)_4$); ^{13}C NMR (75 MHz, $CDCl_3$) δ 6.9, 24.4, 28.5, 30.3, 33.6, 35.7, 80.5, 173.2; IR ν_{max}/cm^{-1} (film) 2977, 2933, 1729; $C_{10}H_{19}O_2I$ (FAB^+) m/z 299 ($M + H^+$, 24%), 243 ([$C_6H_{12}O_2I$]$^+$, 55%), 57 ([C_4H_9]$^+$, 100%).

8-Bromooctan-1-ol (13). To 1,8-octanediol (5.96 g, 40.0 mmol) in toluene (350 mL) was added hydrobromic acid (5.25 mL, 48% aq solution). The reaction mixture was heated to reflux for 24 h after which time a further quantity of hydrobromic acid was added (1.5 mL). The reaction mixture was again left to reflux for 24 h. The reaction mixture was then cooled to room temperature, and diethyl ether was added (250 mL). The aqueous hydrobromic acid layer was separated from the organic layer; the organic phase was partitioned with saturated aqueous $NaHCO_3$ (100 mL), then 0.1 M phosphate buffer (pH 7, 100 mL). The aqueous phase was back-extracted with diethyl ether (100 mL); the organic solutions were combined, dried over anhydrous $MgSO_4$, and concentrated *in vacuo* to give a yellow oil (8.56 g). This oil was purified by silica gel chromatography, eluting with hexane/diethyl ether (50:50) to give 8-bromooctan-1-ol as a pale yellow oil (8.29 g, 39.64 mmol, 99%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.33–1.59 (10H, m, $BrCH_2CH_2(CH_2)_5$), 1.86 (2H, quintet, J = 7.1 Hz, $BrCH_2CH_2$), 3.40 (2H, t, J = 6.8 Hz, $BrCH_2(CH_2)_5$), 3.63 (2H, t, J = 6.6 Hz, CH_2OH); ^{13}C NMR (75 MHz, $CDCl_3$) δ 26.0, 28.5, 29.1, 29.6, 33.1, 33.2, 34.3, 63.3; IR ν_{max}/cm^{-1} (film) 3333, 2930, 2855; $C_8H_{15}OBr$ (FAB^+) m/z 211 ($M + H^+$ [^{81}Br], 40%), 209 ($M + H^+$ [^{79}Br], 42%), 69 ([C_5H_9]$^+$, 100%), 55 ([C_4H_7]$^+$, 82 %). HRMS (FAB, NOBA matrix): $C_8H_{16}OBr$ calcd for $[MH]^+$ 209.0541, found 209.0550.

*1-Bromo-8-(9-phenyl-xanthen-9-yloxy)octane **10**.* To 8-bromooctan-1-ol (5.41 g, 25.9 mmol) and 9-phenylxanthen-9-ol (*10*) (7.10 g, 25.9 mmol) was added glacial acetic acid (75 mL). Once complete dissolution had occurred, the solution was concentrated *in vacuo*. A further volume of glacial acetic acid (75 mL) was added, and again the resulting solution was concentrated *in vacuo*. This was repeated a further five times. Once all the glacial acetic acid had been removed for the final time, the remaining oil was redissolved in hexane (250 mL). This solution was partitioned with saturated aqueous $NaHCO_3$ and saturated aqueous NaCl, and the aqueous phase was back-extracted with hexane (100 mL). The organic solutions were combined, dried over anhydrous $MgSO_4$, and concentrated *in vacuo* to give **10** as a yellow oil (12.04 g, 100%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.20–1.42 (8H, m, $BrCH_2CH_2(CH_2)_4$), 1.51 (2H, m, CH_2CH_2OPx), 1.84 (2H, quintet, J = 7.2 Hz, $BrCH_2CH_2$), 2.96 (2H, t, J = 6.2 Hz, CH_2CH_2OPx), 3.40 (2H, t, J = 6.8 Hz, $BrCH_2$), 7.01–7.41 (13H, m, aromatic); ^{13}C NMR (75 MHz, $CDCl_3$) δ 26.5, 28.5, 29.1, 29.5, 30.2, 33.2, 34.3, 63.4, 75.5, 116.5, 123.7, 124.2, 126.8, 126.9, 128.1, 129.2, 130.0, 149.9, 151.7; IR ν_{max}/cm^{-1} (film) 3033, 2932, 2855,

Anal. Calcd for $C_{27}H_{29}O_2Br$: C, 69.68; H, 6.28; Br, 17.16. Found: C, 69.72; H, 6.20; Br, 17.15.

1-Iodo-8-(9-phenylxanthen-9-yloxy)octane ***11***. To 1-bromo-8-(9-phenyl-xanthenyloxy)octane 10 (12.04 g, 25.9 mmol) in dry acetone (500 mL) was added sodium iodide (155.1 g, 1.03 mol, 40 equiv). The reaction was left stirring under nitrogen, in darkness, and at room temperature for seven days. After seven days, the reaction mixture was concentrated *in vacuo*. The remaining solid was dissolved in diethyl ether (400 mL) and saturated aqueous $NaHCO_3$ (400 mL). The organic phase was then partitioned with 5% aqueous sodium thiosulfate (150 mL) and saturated aqueous NaCl (150 mL). The aqueous solutions were combined and back-extracted with diethyl ether (200 mL). The organic solutions were combined, dried over anhydrous $MgSO_4$, and concentrated *in vacuo* to give a dark yellow oil. This oil was purified by normal-phase silica gel chromatography, eluting with chloroform to give **11** as a pale yellow oil (12.9 g, 97%). ^1H NMR (300 MHz, $CDCl_3$) δ 1.22–1.41 (8H, m, $ICH_2CH_2(CH_2)_4$), 1.54 (2H, m, CH_2CH_2OPx), 1.82 (2H, m, ICH_2CH_2), 2.98 (2H, t, $J = 6.3$ Hz, CH_2OPx), 3.2 (2H, t, $J = 7.0$ Hz, ICH_2CH_2), 7.01–7.41 (13H, m, aromatic); ^{13}C NMR (75 MHz, $CDCl_3$) δ 7.5, 26.5, 28.8, 29.5, 30.2, 30.8, 33.9, 63.4, 75.5, 116.5, 123.7, 124.2, 126.8, 126.9, 128.1, 129.2, 130.0, 149.9, 151.7; IR ν_{max}/cm^{-1} (film) 3033, 2932, 2855, 1603, 1574; $C_{27}H_{29}O_2I$ (FAB^+) *m/z* 535 ($M + Na^+$, 3%), 513 ($M + H^+$, 1%), 257 ($[C_{19}H_{13}O]^+$, 100%), 197 ($[C_{13}H_9O_2]^+$, 47%); HRMS (FAB, NOBA matrix): $C_{27}H_{30}O_2I$ calcd for $[MH]^+$513.1291, found 513.1270.

1-(9-Phenylxanthen-9-yloxy)-dec-9-yne ***12***. To lithium acetylide ethylenediamine (11.5 g, 125 mmol, 40 equiv) under nitrogen was added dry tetrahydrofuran (30 mL). This suspension was cooled to −78 °C, and hexamethylphosphoramide (6 mL) was added. A solution of 1-iodo-8-(9-phenyl-xanthen-9-yloxy)octane 11 (12.8 g, 25.0 mmol) in THF (30 mL) was slowly added to the suspension at −78 °C. Once all the solution had been added to the suspension, the reaction was allowed to warm to room temperature and left stirring overnight. After 24 h, the reaction was concentrated *in vacuo*. The remaining oil was dissolved in diethyl ether (350 mL). This solution was filtered and then partitioned with 5% aqueous sodium thiosulfate (150 mL) and saturated aqueous NaCl (150 mL). The aqueous solutions were combined and back-extracted with diethyl ether (100 mL). The organic solutions were combined, dried over anhydrous $MgSO_4$, and concentrated *in vacuo* to give a brown oil. This oil was purified by normal-phase silica gel chromatography, eluting with hexane/chloroform (50:50) with a few drops of triethylamine, to give **12** as a pale yellow oil (10.05 g, 98%). ^1H NMR (300 MHz, $CDCl_3$) δ 1.24–1.63 (12H, m, $HC{\equiv}CCH_2(CH_2)_6$), 1.95 (1H, t, $J = 2.6$ Hz, $HC{\equiv}CCH_2$), 2.27 (2H, dt, $J = 7.0$ Hz and 2.6 Hz, $HC{\equiv}CCH_2$), 2.98 (2H, t, $J = 6.3$ Hz, CH_2OPx), 7.01–7.41 (13H, m, aromatic); ^{13}C NMR (75 MHz, $CDCl_3$) δ 18.8, 26.6, 28.9, 29.1, 29.4, 29.6, 30.3, 63.4, 68.5, 75.5, 85.1, 116.5, 123.7, 124.3, 126.8, 126.9, 128.1, 129.2, 130.0, 149.9, 151.7; IR ν_{max}/cm^{-1} (film) 3304, 3034, 2932, 2856, 2120, 1603, 1575; $C_{29}H_{30}O_2$ (FAB^+) *m/z* 433 ($M + Na^+$, 2%), 411 ($M + H^+$, 2%), 257 ($[C_{19}H_{13}O]^+$, 100%); HRMS (FAB, NOBA matrix): $C_{29}H_{31}O_2$ calcd for $[MH]^+$ 411.2324, found 411.2300.

2-Methylprop-2-yl 16-(9-phenylxanthen-9-yloxy)hexadeca-7-ynoate ***13***. To freshly purified 1-(9-phenyl-xanthen-9-yloxy)-dec-9-yne **11** (2.05 g, 5.00 mmol) in dry THF (30 mL) under N_2 was added HMPA (4 mL). This solution was cooled to −78 °C, and then *n*-butyl lithium (2.6 mL, 2.5 M, 6.5 mmol, 1.3 equiv) was slowly added. The solution was left to stir for 30 min after which time freshly purified iodohexanoic acid *tert*-butyl ester **9** (1.94 g, 6.5 mmol, 1.3 equiv) in THF (25 mL) was added dropwise. Once this was complete, the reaction was allowed to warm to room temperature and was left to stir for 24 h. The reaction was then concentrated *in vacuo* to yield a brown gum, which was dissolved in diethyl ether (300 mL), and the resulting solution was filtered. The filtrate was partitioned with 5% aqueous sodium thiosulfate (150 mL) and saturated aqueous NaCl (150 mL). The aqueous solutions were combined and back-extracted with diethyl ether (150 mL). The organic solutions were combined, dried over anhydrous $MgSO_4$, and concentrated *in vacuo* to give a brown oil. This oil was purified by normal-phase silica gel chromatography, eluting with hexane/chloroform (40:60) with a few drops of triethylamine, to give **13** as a pale yellow oil (2.03 g, 70%). ^1H NMR (300 MHz, $CDCl_3$) δ 1.18–1.68 (18H, m, $PxOCH_2(CH_2)_6CH_2C{\equiv}CCH_2(CH_2)_3$), 1.45 (9H, s, $C(CH_3)_3$), 2.13–2.16 (4H, m, $PxO(CH_2)_7CH_2C{\equiv}CCH_2$), 2.22 (2H, t, $J = 7.4$ Hz, $CH_2COOC(CH_3)_3$), 2.96 (2H, t, $J = 6.3$ Hz, $PxOCH_2$), 6.99–7.39 (13H, m, H aromatic); ^{13}C NMR (75 MHz, $CDCl_3$) δ 19.0, 19.2, 25.1, 26.6, 28.5, 28.7, 29.2, 29.47, 29.55, 29.61, 30.1, 30.3, 35.9, 63.4, 75.4, 80.3, 80.31, 80.8, 116.5, 123.7, 124.3, 126.8, 126.8, 128.1, 129.2, 130.0, 149.9, 151.7, 173.5; IR ν_{max}/cm^{-1} (film) 2931, 2856, 1733, 1603, 1575; $C_{39}H_{48}O_4$ (FAB^+) *m/z* 603 ($M + Na^+$, 5%), 269 ($[C_{16}H_{29}O_3]^+$, 4%), 257 ($[C_{19}H_{13}O]^+$, 100%).

2-Methylprop-2-yl 16-hydroxyhexadeca-7-ynoate ***14***. To 2-methylprop-2-yl 16-(9-phenylxanthen-9-yloxy)hexadeca-7-ynoate **13** (1.39 g, 2.39 mmol) in dichloromethane (50 mL), under nitrogen was added pyrrole (1.65 mL, 1.6 g, 23.9 mmol, 10 equiv) followed by dichloroacetic acid (1.25 mL, 1.95 g, 15.0 mmol). This solution was left to stir for 10 min at room temperature. An excess of saturated aqueous $NaHCO_3$ was then added, and the reaction was stirred vigorously to ensure mixing of aqueous and organic phases. The organic and aqueous phases were separated, and the aqueous phase was partitioned with dichloromethane (100 mL). The organic solutions were combined, partitioned with saturated aqueous NaCl (50 mL), dried over anhydrous $MgSO_4$, and concentrated *in vacuo* to yield a dark brown oil. This oil was purified by normal-phase silica gel chromatography, using only 60 mm in height of silica and eluting with chloroform with a few drops of triethylamine, to give **14** as a clear oil (0.77 g, 95%). ^1H NMR (300 MHz, $CDCl_3$) δ 1.28–1.68 (18H, m, $HOCH_2(CH_2)_6CH_2C{\equiv}CCH_2(CH_2)_3$), 1.45 (9H, s, $C(CH_3)_3$), 2.15–2.18 (4H, m, $HO(CH_2)_7CH_2C{\equiv}CCH_2$), 2.22 (2H, t, $J = 7.5$ Hz, $CH_2COOC(CH_3)_3$), 3.63 (2H, t, $J = 6.6$ Hz, $HOCH_2$); ^{13}C NMR (75 MHz, $CDCl_3$) δ 19.0, 19.01, 25.1, 26.1, 28.5, 28.7, 29.1, 29.2, 29.5, 29.7, 33.2, 35.9, 63.3, 80.3, 80.4, 80.7, 173.5; IR ν_{max}/cm^{-1} (film) 3419 (broad), 2931, 2856, 1732; $C_{20}H_{36}O_3$ (FAB^+) *m/z* 325 ($M + H^+$, 4%), 269 ($[C_{16}H_{29}O_3]^+$, 27%), 57 ($[C_4H_9]^+$, 100%).

(Z)-2-Methylprop-2-yl 16-hydroxyhexadeca-7-enoate ***15***. A suspension of Lindlar catalyst (500 mg) in hexane/methanol (90:10, 20 mL) was prepared under nitrogen. This suspension was connected to a hydrogenation apparatus and exposed to hydrogen at atmospheric pressure at room temperature until no further change in gas volume was detected. 2-Methylprop-2-yl 16-hydroxy-hexadeca-7-ynoate **14** (0.73 g, 2.26 mmol) in hexane (10 mL) was then added to this suspension, and the reaction was left to absorb approximately 58 cm^3 of hydrogen, at room temperature. Once this had occurred, the reaction mixture was dissolved in dichloromethane (80 mL) and filtered. The filtrate was concentrated *in vacuo* to yield **15** as a yellow oil (0.74 g, 100 %). ^1H NMR (300 MHz, $CDCl_3$) δ 1.23–1.68 (18H, m, $HOCH_2(CH_2)_6CH_2CH{=}CHCH_2(CH_2)_3$), 1.45 (9H, s, $C(CH_3)_3$), 2.02 (4H, m, $HO(CH_2)_7CH_2CH{=}CHCH_2$), 2.22 (2H, t, $J = 7.5$ Hz, $CH_2COOC(CH_3)_3$), 3.65 (2H, t, $J = 6.6$ Hz,

This solution was left to stir for 10 min, and then fluorenylmethyl chloroformate (0.73 g, 2.83 mmol, 2 equiv) in dry THF (15 mL) was slowly added. Once addition was complete, the reaction was stirred for a further hour at 0 °C and then left to stir at room temperature overnight. After 24 h, the reaction was concentrated *in vacuo*, redissolved in dichloromethane (150 mL), and filtered. The filtrate was partitioned with 5% aqueous potassium hydrogen sulfate (70 mL) and saturated aqueous NaCl (70 mL). The aqueous solutions were back-extracted with dichloromethane (100 mL). The organic solutions were combined, dried over anhydrous $MgSO_4$, and concentrated *in vacuo* to give a brown solid. This solid was purified by normal-phase silica gel chromatography, eluting with chloroform, to give **18** as a pale brown solid (0.69 g, 89%). ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.20–1.43 (14H, m, $FmocHNCH_2(CH_2)_6CH_2CH$=$CHCH_2(CH_2)_3$), 1.45 (9H, s, $C(CH_3)_3$), 1.57–1.66 (4H, m, $FmocHNCH_2(CH_2)_6CH_2CH$=$CHCH_2(CH_2)_3$), 2.03 (4H, m, $FmocHN(CH_2)_7CH_2CH$=$CHCH_2(CH_2)_4$), 2.21 (2H, t, J = 7.5 Hz, $CH_2COOC(CH_3)_3$), 3.17 (2H, m, J = 6.1 Hz, $FmocHNCH_2$), 4.21 (1H, t, J = 6.7 Hz, $NHCOOCH_2CHC_{12}H_8$), 4.40 (2H, d, J = 6.7 Hz, $NHCOOCH_2C_{13}H_9$), 4.98 (1H, bs, N*H*), 5.37 (2H, m, $FmocHNCH_2(CH_2)_7CH$=CH), 7.31 (2H, t, J = 7.4 Hz, Ar), 7.40 (2H, t, J = 7.4 Hz, Ar), 7.61 (2H, d, J = 7.4 Hz, Ar), 7.77 (2H, d, J = 7.4 Hz, Ar); ^{13}C NMR (75 MHz, $CDCl_3$) δ 25.5, 27.2, 27.5, 27.6, 28.5 ($C(CH_3)_3$), 29.2, 29.6, 29.7, 29.8, 29.9, 30.0, 30.1, 36.0, 41.53, 47.8, 66.9, 80.2 ($C(CH_3)_3$), 120.3, 125.4, 127.4, 128.0, 130.0, 130.4, 141.7, 144.5, 156.9 (*C*=O), 173.6 (*C*=O); IR ν_{max}/cm^{-1} (KBr disc): 3325 (st.), 3005 (wk.), 2926, 2854 (st.), 1730 (st.), 1689 (st.), 1542 (med.), 1266, 1152 (st.); $C_{35}H_{49}O_4N$ (FAB^+) *m/z* 492 ($[C_{31}H_{42}O_4N]^+$, 7%), 270 ($[C_{16}H_{32}O_2N]^+$, 9.6%), 252 ($[C_{16}H_{30}ON]^+$, 5.8%), 179 ($[C_{14}H_{11}]^+$, 100%), 165 ($[C_{13}H_9]^+$, 12%), 57 ($[C_4H_9]^+$, 44.1%); HRMS (FAB, NOBA matrix): $C_{35}H_{49}O_4NNa$ calcd for $[M + Na]^+$ 570.3559, found 570.3580.

(Z) 16-(9-Fluorenylmethyloxycarbonylamido)-hexadeca-7-enoic Acid ***4.*** To (Z)-2-methylprop-2-yl 16-(9-fluorenylmethyloxycarbonylamido)hexadeca-7-enoate **18** (0.75 g, 1.37 mmol) under nitrogen at room temperature was added trifluoroacetic acid/water (95:5, 63 mL). To this solution was immediately added 1,3-propanedithiol (0.693 mL, 0.747 g, 6.9 mmol, 5 equiv). The reaction was left to stir for 1.5 h, after which it was concentrated *in vacuo* to yield a pale brown solid. The solid was purified by normal-phase silica gel chromatography, eluting initially with chloroform (100 %), then gradually changing to chloroform/methanol/acetic acid (92:6:2), to give **4** as an off-white solid (0.64 g, 95 %). ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.27–1.65 (18H, m, $FmocHNCH_2(CH_2)_6CH_2CH$=$CHCH_2(CH_2)_3CH_2CO_2H$), 2.01 (4H, m, $FmocHN(CH_2)_7CH_2CH$=$CHCH_2(CH_2)_4CO_2H$), 2.21 (2H, t, J = 4.9 Hz, -CH_2CO_2H), 3.17 (2H, m, $FmocHNCH_2$), 4.21 (1H, t, J = 6.7 Hz, $NHCOOCH_2CHC_{12}H_8$), 4.40 (2H, d, J = 6.7 Hz, -$NHCOOCH_2C_{13}H_9$), 4.88 (1H, bs, -N*H*-), 5.37 (2H, m, -*CH*=*CH*$(CH_2)_5CO_2H$), 7.31 (2H, dt, J = 7.5 Hz and 0.9 Hz), 7.40 (2H, t, J = 7.4 Hz), 7.61 (2H, d, J = 7.4 Hz), 7.77 (2H, d, J = 7.5 Hz); ^{13}C NMR (75 MHz, $CDCl_3$) δ 25.1, 27.2, 27.4, 27.6, 29.1, 29.6, 29.68, 29.77, 29.83, 30.1, 30.4, 34.5, 41.5, 47.7, 66.9, 120.4, 125.4, 127.4, 128.1, 130.0, 130.1, 141.8, 144.4, 157.0, 179.7; IR ν_{max}/cm^{-1} (KBr) 3325 (st.), 3005 (wk.), 2926, 2854 (st.), 2600–2400 (wk.), 1730 (st.), 1689 (st.), 1542 (med.), 1465 (wk.), 1266, 1152 (st.); $C_{32}H_{41}O_4N$ (FAB^+) *m/z* 492 ($M + H^+$, 3.2%),

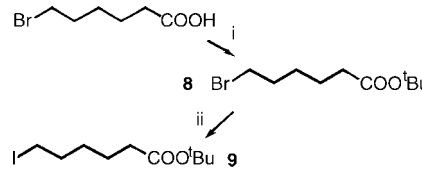
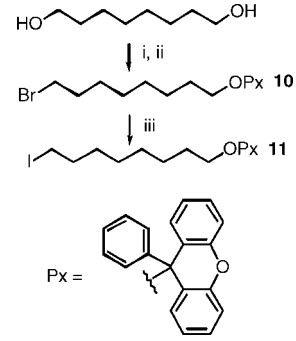
Preparation of Liposomes. Lipopolyplex formulations were prepared by mixing the components in the following order: 50 μL of Lipofectin (InVitrogen Ltd., Paisley, UK: 30 μg/μL in OptiMEM); 70 μL of peptide (at between 0.029 mg/mL and 0.1 mg/mL in OptiMEM, to afford peptide charge ratios of either 4:1 or 1.5:1 (taking into account the TFA counterions associated with each peptide)); followed by 50 μL of the luciferase reporter plasmid pCILux (40 μg/mL in OptiMEM). Plasmid pCILux was prepared by subcloning a luciferase gene from pGL3 Control (Life Technologies, Paisley, UK) into the eukaryotic expression vector pCI (Promega, Southampton, UK). The complex was mixed by pipetting briefly before diluting in OptiMEM to a final volume of 1.57 mL.



Transfection of Cells. The normal human airway epithelial cell line 1HAEo- (*16*) and the cystic fibrosis (CF) cell line 2CFSMEo- (*17*) (D. Gruenert, University of California, San Francisco) were maintained in Eagle's Minimal Essential Medium (MEM) HEPES modification (Sigma, Poole, UK) containing 10% fetal calf serum (FCS), 100 U/mL penicillin, and 100 μg/mL streptomycin and 2 mM L-glutamine, as described previously (*18*). Neuro-2A cells (ATCC) were maintained in Dulbecco's Modified Eagle Medium (DMEM)-Glutamax-1 (Life Technologies, Paisley, UK) containing 10% fetal calf serum (FCS) (Sigma, Poole, UK), 100 IU/mL penicillin, 100 μg/mL streptomycin, 1% sodium pyruvate, and 1% nonessential amino acids (Life Technologies, Paisley, UK). AJ3.1 is a mouse embryonic fibroblast line derived from A/J embryos 13.5 days postcoitum (Barker et al., manuscript in preparation).

The complete growth medium was removed from cells plated at 2×10^4 cells/well overnight in 96-well plates, and 200 μL of complex (0.25 μg of plasmid DNA) was added to each well, leaving minimal time between preparing the complex and adding to the cells. All transfections were carried out in 6 wells each. The cells were incubated with the complexes for 4 h before replacing with normal media for 24 to 48 h, after which reporter gene expression was analyzed by luciferase assay (Promega, Southampton, UK).

Luciferase assays. Cells were washed twice with PBS before the addition of 100 μl of 1 $\times$ Reporter Lysis Buffer (Promega, Southampton, U. K.) to the cells for 20 min at 4 °C before freezing at −20 °C for at least 30 min followed by thawing at room temperature (±20 °C). Twenty μl of the lysate at room temperature was transferred to a white polystyrene 96-well plate (Porvair Sciences Ltd., Shepperton, U. K.) and the luciferase activity was measured using the Luciferase Assay System (Promega) and a Lucy-1 Luminometer (Anthos Ltd., Saltzburg, Austria). The amount of protein present in each transfection lysate was determined with the Bio-Rad protein assay reagent by the manufacturer's instructions, adding 20 μl from the luciferase test to 200 μl of the reagent diluted 1 in 5 and incubating at room temperature for 10 min before comparing the OD_{590} to a range of BSA standards. Luciferase activity was expressed as Relative Light Units (RLU) per mg of protein (RLU/mg).



DLS. The complexes were formulated as described above, but using the PSVβ plasmid (a 6.9 kilobase plasmid). All experiments were conducted at a weight ratio of lipid/peptide/DNA 0.75:4:1. This resulted in a 4:1 charge ratio, when the TFA counterions associated with the peptide are taken into account. The DLS measurements were performed using a Malvern Zetasizer 3000 instrument (Malvern Instruments Ltd., UK) operating at a wavelength of 633 nm and a power output of 5 mW. All experiments were conducted at a constant temperature of 25 °C and a scattering angle of 90°, and spectra were collected every 180 s for at least 30 min. For broad, irregularly shaped distributions, where the method of cumulants was inappropriate, the *CONTIN* "constrained regularization" program (*19, 20*) was used for data analysis.

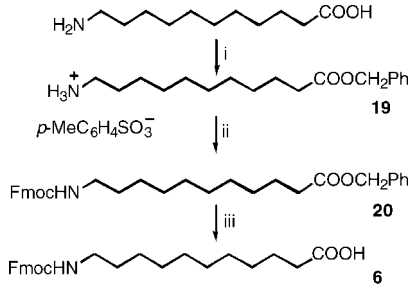
RESULTS

Synthesis of the Lipophilic Amino Acids Fmoc-Laa (4) and Fmoc-Aua (6). 6-Aminohexanoic acid is commonly used as a lipophilic spacer in a variety of applications (*21*) and has been shown to increase the serum stability of some bioconjugates in *in vivo* applications (*22*). However, longer or more structurally complex ω-amino acids have not been extensively investigated as spacers or as conformational constraints. The flexible 11-aminoundecanoic acid (Aua) spacer was recently synthesized by the Campbell group as the Fmoc-protected Pfp ester and incorporated into analogues of atrial natriuretic factor (*15*). The only report of a longer, unsaturated linker being used in bioconjugate applications was the use of cis-alkenyl tethers, derived from alkynyl bis-carboxylic acids, as conformationally restricted cross-linked peptide inhibitors of HIV protease (*23*). In order to prepare peptides containing the long-chain ω-amino acids Aua and Laa using solid-phase peptide synthesis techniques, we had to first synthesize the Fmoc-protected amino acids, **4** and **6**, themselves.



For the cis-alkenyl amino acid Fmoc-Laa **4**, the most efficient synthetic route appeared to be to prepare this from a suitable acetylenic ω-hydroxy acid by selective hydrogenation. This could in turn be synthesized from a protected ω-iodo alcohol, a protected ω-iodo acid, and acetylene. As the other functionality and protecting groups in **4** made it desirable that the protecting group on the ω-iodo acid should not need hydrogenation or base treatment for its removal, we elected to protect the acid as the *tert*-butyl ester. Initial attempts to esterify the available 8-bromohexanoic acid using perchloric acid and *tert*-butyl acetate following a procedure by Jost and Rudinger (*24*) were low-yielding and slow (>5 days), and the low boiling point of the resulting ester **8** made separation from *tert*-butyl acetate difficult. DCC-mediated coupling of *tert*-butyl alcohol (*25*) with the carboxylic acid gave greatly improved yields of the desired ester

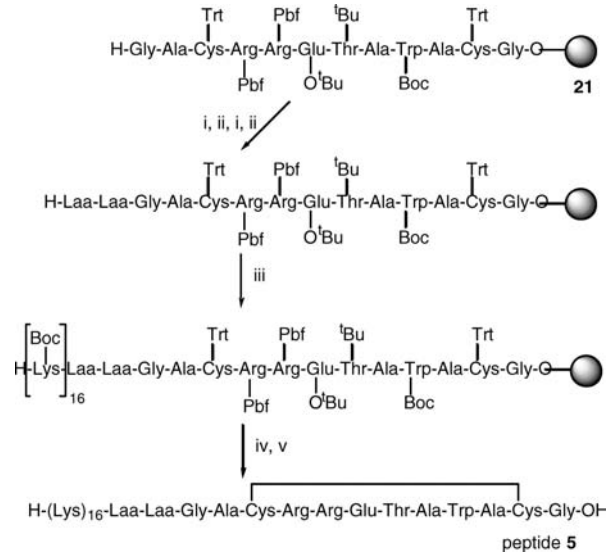
7 within 24 h; this was then converted to the iodide **9** with sodium iodide (*12*) in 93% yield (Scheme 1).

We elected to protect the ω-iodo alcohol with the highly acid-labile 9-(9-phenyl)xanthenyl group (pixyl, Px), as this could be removed under very mild conditions without deprotection of the *tert*-butyl ester. Selective monopixylation of 1,8-octanediol followed by bromination proved to be unsuccessful as, although the monoprotected diol was effectively synthesized, the 9-phenylxanthyl protecting group proved to be unstable to the conditions required to convert the hydroxyl group to a bromo group (CBr_4, PPh_3 in CH_2Cl_2). 8-Bromooctan-1-ol was therefore synthesized first (Scheme 2) using hydrobromic acid (48%) (*26*). The hydroxy group was then protected with 9-phenylxanthen-9-ol, using glacial acetic acid both as a proton source and for azeotroping off water formed in the reaction, following a procedure by Gaffney and Reese (*27*) to give **10**. Treatment with sodium iodide afforded **11** in 97% yield.



To form the required substituted acetylene, **11** was then reacted with lithium acetylide ethylenediamine complex (LAEDA), using a procedure adapted from DeJarlais and Emken (*28*),

to give **12** in excellent yield (Scheme 3). The organolithium derivative of **12** was then prepared by adding *n*-butyl lithium in THF and HMPA at −78 °C; this was followed by addition of **9** to give the desired disubstituted acetylene **13**. Fortuitously, the *tert*-butyl groups of both **13** and **9** appeared to withstand the use of *n*-butyl lithium under the conditions of this reaction. The selective removal of the 9-(9-phenyl)xanthenyl group from **13** was achieved with 0.1 M dichloroacetic acid in dichloromethane using pyrrole as the scavenger (*27*), to give **14**. A small amount (less than 5% by TLC analysis of the crude mixture) of the *tert*-butyl group was removed under these conditions. Catalytic hydrogenation at atmospheric pressure using

Lindlar catalyst in methanol and hexane gave the *cis*-hydroxy compound **15**, which was then mesylated and converted to the azide **16**. Staudinger reduction of **16**, using a procedure originally developed for the synthesis of allylic amines (*29*), gave the amine **17** in 80% yield. A slight modification to the original procedure, adding PPh_3 first and leaving to stir for 5 h before adding water, increased the yield to 93%. Fmoc protection to give **18** (*30*) was followed by removal of the *tert*-butyl

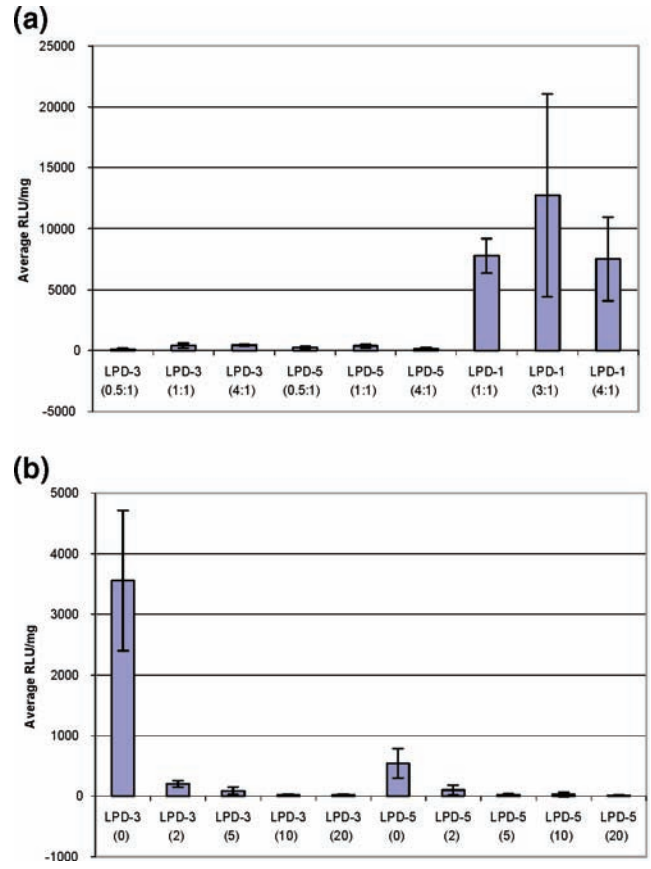

Figure 2. (a) Transfection of 1HAEo- cells with **LPD-3**, **LPD-5**, and **LPD-1** at different charge ratios. (b) Transfection of 1HAEo- cells with **LPD-3** and **LPD-5** at a 4:1 peptide ratio, in varying concentrations of serum.

group (*31*) to give the desired lipophilic amino acid Fmoc-Laa **4** in 46% overall yield from **11**.

For the synthesis of peptide **2**, it was necessary to prepare the Fmoc-derivative of commercially available 11-aminoundecanoic acid. Reaction of the poorly soluble 11-aminoundecanoic acid with fluorenylmethyl chloroformate in water/aqueous sodium hydrogen carbonate failed, and an inseparable mixture of the Fmoc-protected amino acid and the Fmoc-protected dipeptide and tripeptide were recovered. Boumrah et al. (*15*) circumvented the problem of solubility by preparing Fmoc-Aua from 11-(9-fluorenylmethyloxycarbonylamido)undecanoic acid benzyl ester; however, the initial benzyl ester formation was inconvenient because it required the use of dry hydrochloric acid gas. We therefore used a modification (*14*) of a procedure (*32*) for the preparation of amino acid benzyl esters using the less hazardous toluenesulfonic acid to prepare 11-aminoundecanoic acid benzyl ester *p*-toluenesulfonate **19**. Subsequent treatment of **19** with fluorenylmethyl chloroformate in dioxane/aqueous sodium bicarbonate gave 11-(9-fluorenyl-methyloxycarbonylamido)undecanoic acid benzyl ester **20** in 95% yield (Scheme 4). Benzyl deprotection of **20** to give 11-(9-fluorenylmethyloxycarbonylamido)undecanoic acid (Fmoc-Aua, **6**) was accomplished by hydrogenation (*15*) in 88% yield. Thus, **6** was conveniently prepared in three steps in an overall yield of 76%.

Peptide Synthesis. As the integrin-targeting C-terminus is the same for all of the peptides, this sequence was first synthesized on a large scale using automated solid-phase peptide synthesis to give the resin-bound protected peptide **21** (Scheme 5). Incorporation of the lipophilic amino acid Fmoc-Laa **4** using DIC and HOBt in DMF, whether manually or on the peptide synthesizer, was unsuccessful, probably because of the poor

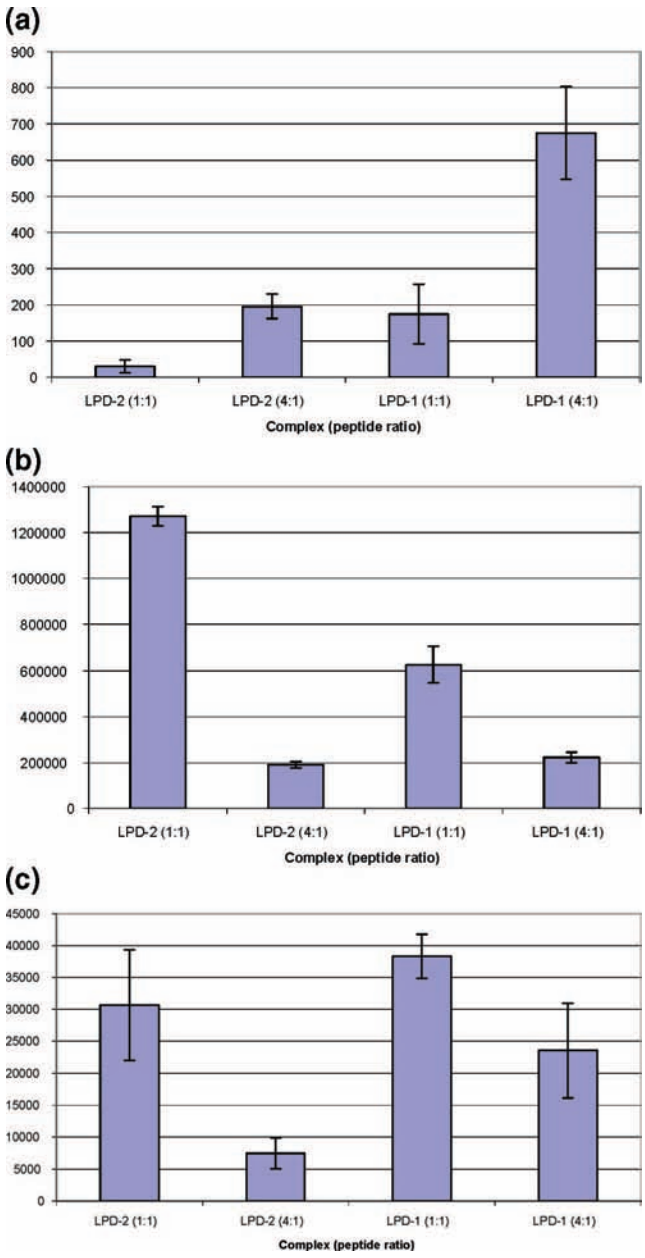

Figure 3. Transfection properties of **LPD-2** and **LPD-1** at 1:1 and 4:1 ratios, in (a) 1HAEo-, (b) N2A, and (c) AJ3.1 cells.

solubility of **4** in DMF. Manual coupling of **4** to **21**, using HATU and HOAt (*33, 34*) in 1:1 CH_2Cl_2/DMF, however, proved successful, and the coupling was confirmed by the Kaiser test and by MS analysis of a cleaved and deprotected sample. As the Laa residue is very hydrophobic, a mixture of DBU and piperidine (*35*) was used for the removal of the Fmoc group. The peptide synthesis was then completed using automated methods to give the resin-bound peptide **22**. Cleavage of **22** from the resin and deprotection, using 85% TFA and thioanisole, phenol, and triethylsilane as scavengers, proved problematic. After purification and MS analysis, it was discovered that reduction of the double bond of Laa had taken place to give peptide **23**, containing the *saturated* Ahd residue. This was surprising, as, although there are instances where double bonds can be reduced with trifluoroacetic acid and an alkylsilane at room temperature, there are very few examples (*36*) of it occurring with nonconjugated alkenes. Aerial oxidiation to form the disulfide bond was then attempted using 0.01 M aqueous ammonium bicarbonate (*37*) or DMSO (*38*). However, both of these methods presented problems in the final HPLC purification

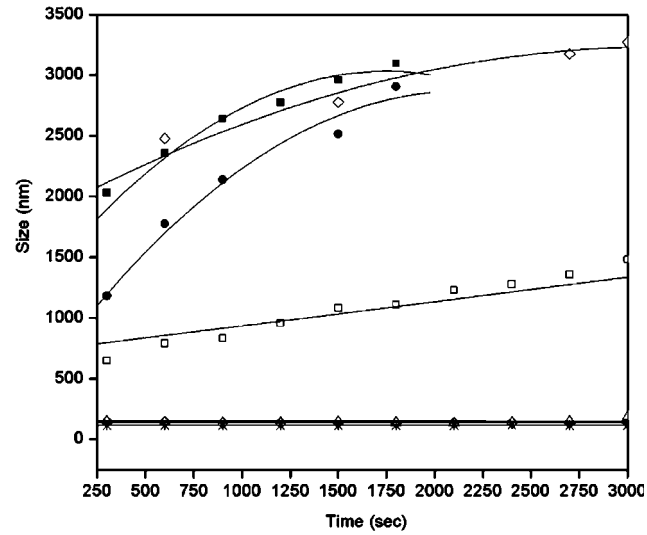

Figure 4. Average aggregate sizes of lipopolyplexes at pH 7.4 as a function of time. Data refer to **LPD-1** in H_2O (♦), **LPD-1** in PBS (■), **LPD-3** in H_2O (△), **LPD-3** in PBS (◇), **LPD-5** in H_2O (*), **LPD-5** in PBS (solid pentagon), **LPD-5** in H_2O + 150 mM NaCl (□). All experiments were conducted at a weight ratio of lipid/peptide/DNA 0.75:4:1 resulting in a +4 charge ratio.

of the peptide, as the excess salts or DMSO led to poor retention of the peptide on the column and hence a very low recovery. The disulfide bond formation was therefore carried out in water at high dilution over 7 days to give complete formation of peptide **3**.

With these observations taken into account, intermediate **21** was then used to prepare peptide **5**. Two Laa residues were incorporated manually using HATU and HOAt, with the Fmoc groups being removed with a mixture of DBU and piperidine. The peptide was completed via automated synthesis and cleaved and deprotected using 85% TFA and thioanisole, phenol, and ethanethiol as scavengers; no reduction of either of the double bonds was detected by MS analysis. Aerial oxidation in water was again carried out to yield peptide **5** (Scheme 6). A similar strategy was used to prepare peptide **2**, using Fmoc-Aua **6** (Scheme 7).

Transfection. A series of lipopolyplexes were formulated, using the previously described procedure (*7*) from Lipofectin, plasmid DNA, and peptides **1**, **2**, **3**, **5**, and **7**, respectively, to give lipopolyplexes **LPD-1** to **LPD-7**. Additionally, each lipopolyplex was formulated at three different peptide/DNA (P/N) charge ratios: 0.5:1; 1:1; and 4:1.

We initially investigated the complex **LPD-7**, with the Ahx-Ser-Ahx spacer. This performed slightly better in transfection than the original LID complex, **LPD-1**, in a range of cell lines (Figure 1). Encouraged by this success, we tested the complexes containing lipid-like spacers, **LPD-3** and **LPD-5**, in 1HAEo- cells (Figure 2). However, the results were disappointing: virtually no transfection was observed with these complexes (Figure 2a) and the complexes showed no stability when placed in even low amounts of serum (Figure 2b).

Peptide **2** contains the 11-aminoundecanoic acid spacer, which is shorter than the other spacer regions but more hydrophobic than the spacer in peptide **7**. The **LPD-2** complexes formulated from this peptide had moderate transfection properties (Figure 3) which were highly dependent on the cell type. In N2A cells, transfection exceeded the original vector (**LPD-1**), whereas in 1HAEo- cells, the transfection was not as good, and in AJ3.1 cells, the transfection was comparable.

Stability Measurements. In order to assess whether the poor transfection results obtained with the lipophilic peptides were

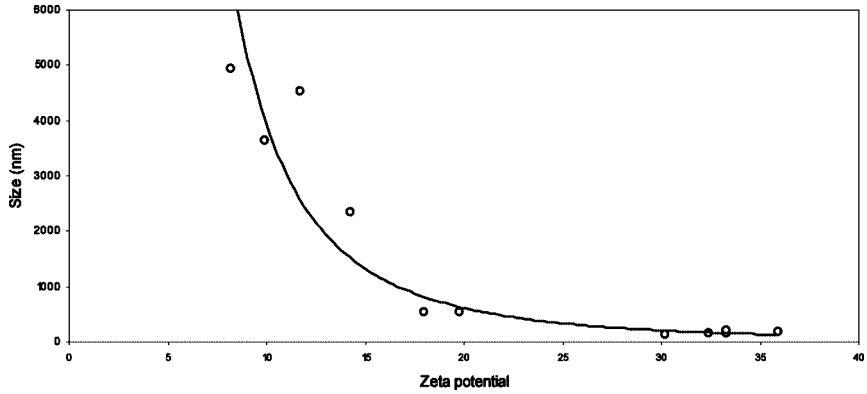

Figure 5. Relationship between zeta potential and particle size. The line represents the Monte Carlo simulation data and the circles the experimental data.

related to aggregation of vector particles, we investigated the aggregation properties of the lipopolyplex complexes containing peptides **3** and **5**. The lipopolyplexes **LPD-1**, **LPD-3**, and **LPD-5** were formulated from Lipofectin, plasmid DNA, and the relevant peptide as described previously (*7*) at 4:1 charge ratios, and the size of the resulting particles measured in water, NaCl solutions, and at different concentrations of phosphate buffered saline (PBS) to mimic physiological conditions. In order to determine the size of the complex, dynamic light scattering (DLS) measurements were made (*39*) and the hydrodynamic radius or diameter of the particles can be calculated (*40*, *41*).

In Figure 4, the changes in size distribution over time of these lipopolyplexes are shown. In water, very little aggregation takes place for any of the complexes; however, when increasing amounts of NaCl are added, the rate of aggregation increases. In PBS, a physiologically relevant buffer, both the original complex and the complexes containing lipophilic spacers aggregate dramatically over time. It is also notable that the starting size of each of the complexes is rather different, with **LPD-3** being the most compact.

DISCUSSION

We have developed efficient routes to two hydrophobic amino acids, suitably protected for solid-phase peptide synthesis. The novel amino acid **4** has been designed to imitate the unsaturated chain of the lipid DOTMA, and we have also developed an improved route to the previously described **6**. We have then successfully synthesized peptides containing these or other hydrophobic amino acids as spacers, for use in nonviral gene delivery studies of targeted ternary lipopolyplex vectors.

Several factors influence the transfection efficiencies of targeted lipopolyplex vectors (*6*). For the present study, three factors could be important. It is probable that a long spacer unit between the DNA-condensation and integrin-targeting moieties of the peptide could lead to better interactions between the vector and the cell surface receptor. We also initially hypothesized that, if these spacer units could be designed to stack within a lipid bilayer, the stability of the vector, and hence its transfection efficiency (*39*), could be enhanced. However, the overall hydrophobicity of the spacer unit will also be important in determining the stability of the resulting vector, and hence the transfection efficiency, as vectors which dissociate rapidly or aggregate in buffer or serum solutions will have greatly reduced transfection efficiencies.

We have previously carried out a theoretical study (*42*) to model the dynamics of vector aggregation. The vectors **LPD-1** and **LPD-3** were studied, using Monte Carlo simulation techniques to model the dynamics of vector aggregation. It was clearly demonstrated, both experimentally and in the simulation, that **LPD-3** aggregated much more rapidly than **LPD-1**. It was shown that the levels of aggregation of vector particles under Brownian motion could be predicted on the basis of the zeta potential of the vector particles. Vector buffer systems with a zeta potential less than 20 mV exhibit significant aggregation (Figure 5).

These results are in agreement with the poor transfection efficiencies of **LPD-3** (Figure 2) and also with the rapid aggregation of **LPD-3** in PBS (Figure 4). The hydrophobicity of the Ahd linker clearly outweighs any beneficial effect of interaction with the hydrophobic portion of either DOTMA or DOPE, although it appears to lead to a structure that is initially more compact than **LPD-1** (Figure 4). Moreover, when two Laa amino acids are used as lipid-like linkers, in peptide **5**, the resulting complex (**LPD-5**) demonstrates equally poor transfection efficiencies (Figure 2) and serum (Figure 2) and buffer (Figure 4) stability. These results suggest three possible alternative hypotheses: either packing of lipid-like linkers within a lipid bilayer is not possible; or it does not result in a more stable vector particle; or ternary lipopolyplex vectors of this type do not have an ordered lipid layer. It is notable that in other, unrelated biological systems where hydrophobic spacers have been employed (*43*) the results have not been as good as with hydrophilic, PEG-based spacers.

In comparison, peptide **7** has a linker sequence of approximately the same length as peptide **5**. However, the transfection efficiency of **LPD-7** is much better than that of **LPD-5**, and also an improvement on the original vector, **LPD-1** (Figures 1 and 2). **LPD-7** is also more efficient than **LPD-2**, with a shorter but equally hydrophobic linker (Figures 1 and 3). We assume that peptide **7** has a spacer unit which is sufficiently long and inflexible to position the integrin targeting motif at the exterior of the vector, rendering it more accessible to cell surface receptors, and that it is the length, rather than the hydrophobicity, of the spacer which is important for efficient transfection. Further biophysical studies into the macromolecular organization and stability properties of ternary targeted lipopolyplex vectors are underway.

Instantaneous Determination via Bimolecular Recognition: Usefulness of FRET in Phosphorylcholine Group Enriched Nanoparticles

Junji Watanabe[†] and Kazuhiko Ishihara*[,‡]

Department of Applied Chemistry and 21st Century COE Program "Center for Integrated Cell and Tissue Regulation", Graduate School of Engineering, Osaka University, 2-1 Yamada-oka, Suita, Osaka 565-0871, Japan, and Department of Materials Engineering, School of Engineering, and Center for NanoBio Integration, The University of Tokyo, 7-3-1 Bunkyo-ku, Hongo, Tokyo 113-8656, Japan. Received March 18, 2007; Revised Manuscript Received July 17, 2007

This paper deals with smart bimolecular recognition for instantaneous determination. In particular, we installed the fluorescence resonance energy transfer (FRET) system in phosphorylcholine (PC) group enriched nanoparticles (NPs). The most favorable characteristics were as follows: (i) the suppression of nonspecific protein adsorption by the PC group enriched surface and (ii) simple bioassay protocol relative to the conventional enzyme-linked immunosorbent assay (ELISA). In the case of immunoassays, nonspecific interaction and complex protocols are known dominant problems. To address these issues, we designed FRET-installed NPs. Agglutination of NPs is a fundamental immunoassay technique; however, it is not quantitative. By evaluating the degree of agglutination based on the fluorescence intensity, the resulting information can be used for diagnosis. Therefore, we installed the FRET system on the surface of the NPs. In this paper, C-reactive protein (CRP) and osteopontin (OPN) were the target biomarkers for instantaneous determination, and the resulting fluorescence intensity correlated well with changes in the concentrations of the target molecules. The immunoassay protocol was quite simple, involving only the mixing of FRET-installed NPs and target molecules, such as CRP and OPN antigens. We successfully evaluated the concentration of the target biomarkers, even when human serum albumin was present as an interference molecule.

INTRODUCTION

Here, we report a new bimolecular recognition system to detect biomarkers using phosphorylcholine (PC) group enriched nanoparticles (NPs). PC group enriched surfaces provide excellent biointerfaces, since they (i) suppress nonspecific protein adsorption (*1–4*) and (ii) stabilize immobilized biomolecules (*5, 6*). PC group enriched surfaces have high hydrophilicities, and the fundamental mechanisms of interactions with proteins are thus investigated in terms of water structure (*7–9*). Therefore, PC group enriched NPs are stable in aqueous solutions without further surface modification. Moreover, PC-introduced polymers have been widely reported using 2-methacryloyloxyethyl phosphorylcholine (MPC) and in hydroxyl group conversions to PC groups via two-step processes. Hilborn et al. reported that PC groups could be incorporated into both terminals of poly(trimethylene carbonate) by using a converting method (*10*). PC-functionalized ionomers showed surface enrichments in PC groups within a few minutes when specimens were soaked in aqueous solutions. Considering these unique properties, PC group enriched surfaces are important materials that form NPs with excellent biointerface properties.

Biomarkers are indicators of biological processes in broad scientific fields, namely, molecular biology; cell biology; and diagnostic, therapeutic, and regenerative medicine. Generally, biomarkers are present in low levels in blood, serum, and cell culture media; thus, amplification and/or highly sensitive methods for detecting trace amounts of biomarkers are major goals when developing immunoassays. Conventional immunosandwich methods, such as enzyme-linked immunosorbent assay (ELISA), are the fundamental protocols for bioassays (*11*). Although the methodology of ELISA is quite simple, unfortunately, it has certain disadvantages in capturing trace biomarker molecules due to the fact that these assays are (i) labor-intensive and time-consuming and (ii) prone to nonspecific protein adsorption. Therefore, to detect low concentrations of biomarkers, assays must be highly sensitive and follow a simple protocol. The latter issue may be improved with the use of PC group enriched surfaces (*1–4*), since nonspecific protein adsorption is suppressed by PC group enriched surfaces that function as blocking biointerfaces. However, even with a decrease in nonspecific protein adsorption, the time-consuming and complicated protocol would continue to be a part of conventional immunoassays. Therefore, instantaneous determination for smart immunoassays is necessary to improve issues regarding complicated protocols.

To improve these issues, we have already proposed a prototype bimolecular recognition system that provides a single protocol that employs fluorescence resonance energy transfer (FRET) on PC group enriched NPs (*12*). The fundamental mechanism of FRET is a distance-dependent interaction between the electronic excited states of two fluorescence molecules in which excitation is transferred from a donor molecule to an acceptor molecule (*13, 14*). Following the capture of a target biomarker by each donor and acceptor molecule-labeled antibody on the NPs, if the FRET phenomenon takes place between donor and acceptor molecules, biomarkers may be detected in the medium. Therefore, we designed dual-bioconjugated NPs covered with PC groups and donor or acceptor molecule labeled antibodies to measure FRET. As a definite plan, each fluorescence molecule was conjugated with a polyclonal antibody, and each fluorescence-labeled antibody was then immobilized onto the PC-covered NPs containing active ester groups for bioconjugation. As a result, the FRET system was installed in the

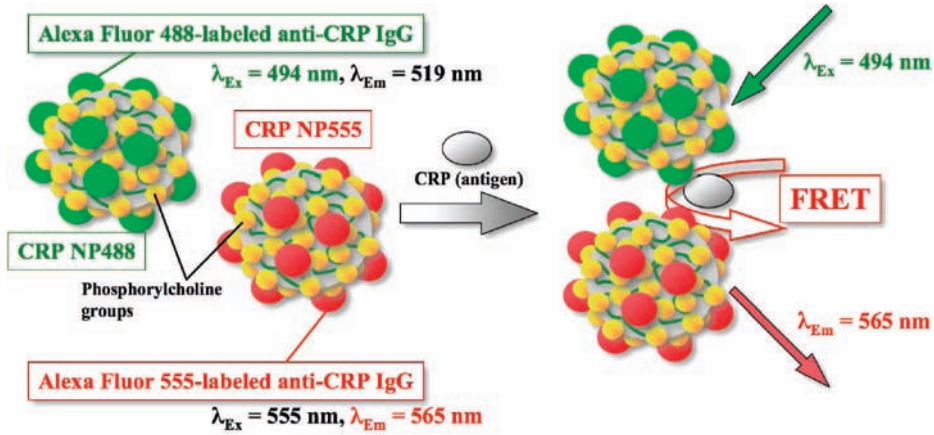

Figure 1. Bimolecular recognition system using PC group enriched NPs by fluorescence resonance energy transfer (FRET). In this illustration, C-reactive protein (CRP) was selected as a target molecule. Two types of NPs could capture the CRP antigen, and FRET was then induced.

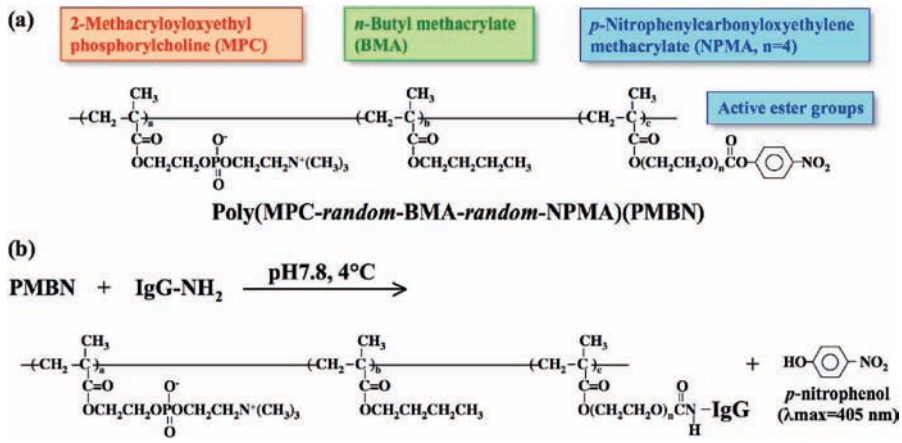

Figure 2. (a) Chemical structure of PC group introduced amphiphilic polymer (PMBN) with active ester groups via oxyethylene spacer (n = 4). (b) Bioconjugation with amino groups in IgG molecule via active ester groups.

bioconjugated PC-covered NPs. Antibody-conjugated NPs could capture specific antigens from sample solutions when the donor and acceptor molecules were in close enough proximity to form antibody–antigen complexes. If FRET occurred by the agglutination of NPs, fluorescence by acceptor molecules would be observed by using a fluorescence spectrometer. The aforementioned reactions are designed to automatically proceed in reaction media when FRET-installed NPs are mixed with blood serum samples. This type of bimolecular recognition system provides a protocol that is rather simple as compared to conventional ELISAs.

Herein, we proposed further improvement of the bimolecular recognition system using FRET-installed NPs and focused on C-reactive protein (CRP) and osteopontin (OPN) as typical target biomarkers for inflammation and differentiation, respectively. Originally, we designed dual-immobilized NPs for bimolecular recognition (*12*). Two types of fluorescence-labeled antibodies were immobilized onto NPs. In the present study, we modified the design of immobilization; mono-immobilized NPs were designed and prepared for bimolecular recognition. Alexa Fluor 488 (donor) and Alexa Fluor 555 (acceptor) were selected as a pair of fluorescence molecules for FRET. Each fluorescent molecule labeled antibody was individually immobilized on the PC group enriched surface (mono-immobilized NPs). For bimolecular recognition using the NPs, the 2 types of mono-immobilized NPs were mixed together, and the addition of an antigen would induce NP agglutination; the FRET phenomenon was then induced quantitatively (Figure 1).

EXPERIMENTAL SECTION

Preparation of PC Group Enriched NPs. PC groups containing polymers (PMBN, Figure 2) for bioconjugation were prepared from MPC, *n*-butyl methacrylate (BMA) (Wako Pure Chemical Co., Ltd., Osaka, Japan), and *p*-nitrophenylcarbonyloxyethylene methacrylate (NPMA). The detailed procedures describing their preparation have been reported elsewhere (*15–17*). PC group enriched NPs were also prepared by a previously reported method (*18*, *19*). The fundamental preparative condition was the solvent evaporation technique via emulsion. PMBN aqueous solution (40 mL, 10 mg/mL) and polystyrene (average molecular weight (MW) = 200 000 g/mol; Kanto Chemicals Co., Ltd., Tokyo, Japan) methylene chloride solution (20 mg, 20 mg/mL) were mixed together. The mixture was treated for 2 min by using a probe-type ultrasonicator (Branson Sonifier 250, Emerson Japan Ltd., Tokyo, Japan). Thus, a finely dispersed emulsion was obtained. After the evaporation of methylene chloride, the resulting NPs were collected using centrifugation. Moreover, the NPs were repeatedly washed by centrifugation and resuspended in ultrapure water. Purified NPs were stored at 4 °C at a concentration of 20 mg/mL until further use.

Preparation of Fluorescence-Labeled Antibodies. For FRET, the distance between the donor and acceptor molecules should be limited, and both must be in close proximity (within 10 nm). The distance at which the energy transfer is 50% efficient is defined by the Förster radius. The magnitude of the radius is dependent on the spectral properties of the donor and

acceptor molecules. In this study, the Förster radius between the Alexa Fluor dye pairs was calculated to be 7 nm (*20*). Antibodies were labeled using the Alexa Fluor labeling kit according to the manufacturer's protocol. In this study, antihuman CRP polyclonal antibodies (CRP-IgG; Oriental Yeast Co., Ltd., Shiga, Japan), recombinant human CRP (Host cell: *Escherichia coli*; Oriental Yeast Co., Ltd.), antimouse OPN polyclonal antibodies (OPN-IgG; R & D Systems, Inc., MN, USA), and recombinant mouse OPN (Host cell: mouse NSO cells; Sigma-Aldrich, Inc., MO, USA) were used without further purification. Alexa Fluor 488 (A-10235, $\lambda_{Ex} = 494$ nm, $\lambda_{Em} = 519$ nm) and Alexa Fluor 555 (A-20174, $\lambda_{Ex} = 555$ nm, $\lambda_{Em} = 565$ nm) labeling kits were purchased from Invitrogen Corp., CA, USA.

In brief, 1 mg CRP-IgG was conjugated with Alexa Fluor 488 dye in sodium bicarbonate buffer (pH 8) for 1 h. To remove the unreacted free dye, the mixture was purified using size-exclusion chromatography (BioGel P-30, Bio-Rad, CA, USA), and Alexa Fluor 488 labeled CRP-IgGs were obtained (CRP IgG488). The resulting conjugates were characterized using UV–vis spectroscopy to calculate the degree of labeling and protein concentration within the samples. The details of the calculation process were referred to from the manufacturer's protocol. OPN-IgG was also labeled with Alexa Fluor dyes, and the samples were referred to as OPN IgG488 and OPN IgG555.

Preparation of Mono-Immobilized NPs. The active ester groups on the NPs could react with the amino groups in IgG (*6*, *16*, *17*, *21*). Therefore, CRP IgG488 (80 μg) solutions were added to NP suspensions (1 mg/mL) using phosphate-buffered saline (PBS, pH 7.8), and the reactions were carried out for 24 h at 4 °C. After the immobilization, the unreacted IgG was removed by centrifugation and re-suspended in ultrapure water. The remaining active ester groups were blocked using glycine for another 24 h at 4 °C. The resulting IgG-immobilized NPs (CRP NP488, concentration of stock solution: 1 mg/mL) were stored at 4 °C until further use. In the same manner, Alexa Fluor 555 dye-labeled anti-CRP IgGs were immobilized to NPs (CRP NP555). Alternatively, OPN NP488 and OPN NP555 were prepared. All the resulting NPs were adjusted to a concentration of 1 mg/mL by using PBS and stored at 4 °C until further use.

Bimolecular Recognition Procedures for Target Biomarkers. The 96-well multiplate for fluorescence measurements (NUNC, Roskilde, Denmark) was used for bimolecular recognition. First, 5 μg each of CRP NP488 and CRP NP555 were simultaneously added to the multiplate, along with 90 μL PBS (pH 7.4) buffer. Basically, the total amount of bioconjugate NPs in each well was adjusted to 10 μg. A target biomarker sample (100 μL), for example, human CRP, was added to each well in various final concentrations ranging from 0.01 to 30 μg/mL. The reaction mixture was mildly rotated for 5 min and maintained at 37 °C for 30 min. Finally, the fluorescence intensity at 590 nm was monitored by excitation at 485 nm by using a multiplate reader (1420 ARVO mx, Perkin Elmer Japan Co. Ltd., Tokyo, Japan).

RESULTS AND DISCUSSION

PC Group Enriched NPs for Bioconjugation. First, we synthesized random copolymers (PMBN) composed of MPC, BMA, and NPMA for bioconjugation as shown in Figure 2b. The monomer composition in the copolymer was determined using ^{1}H nuclear magnetic resonance (^{1}H NMR), and the average molecular weight (Mw) was estimated using gel permeation chromatography (GPC, poly(ethylene glycol) (PEO) standard) as shown in Table 1. Active ester groups on the NPMA units were labile to primary amino groups in biomolecules, and carbamate linkages were produced after the bioconjugation. Interestingly, PMBN was amphiphilic in aqueous solutions, even though the BMA content was approximately 0.43. We believe that hydrophilic PC groups contribute to the amphiphilic property of the molecule. Therefore, PC group enriched NPs could be prepared by a solvent evaporation process using polystyrene (PS), and the resulting NPs were composed of PS cores with PMBN shells (*18*, *19*). Surface elemental analyses on NPs were characterized using X-ray photoelectron spectroscopy (XPS; AXIS-HSi, Shimadzu/Kratos, Kyoto, Japan) (Figure 3). The anode was Mg Kα, and the releasing angle of the photoelectron for each element was fixed at 90°. XPS—an elemental analysis technique—could provide information regarding the outermost surface (within 10 nm). In the case of PC group enriched NPs, O–C–O and C═O peaks from the PMBN were observed at 287.0 and 289.0 eV, respectively. Alternatively, O_{1s} peaks attributed to ether and carbonyl groups were observed at 533.0 and 532.0 eV, respectively. Furthermore, a small broad peak attributed to an aromatic group based on the *p*-nitrophenyl ester group was also observed at 291.5 eV. Additionally, N_{1s} and P_{2p} peaks attributed to trimethyl ammonium (403.0 eV) and phosphate esters (134.0 eV) were observed. We believe that monodispersed NPs covered with PC groups were obtained and that NPs favor the formation of nonspecific interactions with biomolecules. Moreover, the average diameter of the NPs was determined by dynamic light scattering (DLS-7000; Otsuka Electronics Co., Ltd., Tokyo, Japan). On the basis of the Marquadt analysis, the average diameter was approximately 190 nm with a monodispersed size distribution (Figure 4). The average diameter could be changed by altering the PMBN concentration in the feed (*21*). The particle size was crucial in recognizing antigen molecules by using the FRET phenomenon. In the present study, we selected the diameter (190 nm) based on the dispersibility in PBS and its handling of the NPs. The resulting NPs excellently dispersed in PBS due to the hydrophilic surface layer. Moreover, the handling was simple, particularly, the easy sedimentation by

centrifuging when the NPs were rinsed by repeated centrifugation and dispersion.

Mono-Immobilized PC Group Enriched NPs by Fluorescence-Labeled IgGs. In antibody immobilization, antibody-mediated cross-linking may involve the active ester groups on NPs. Moreover, the epitope region may react with the active ester groups, reducing the efficiency of bimolecular recognition. In our previous report, monodispersed antibody-immobilized NPs were observed using a scanning electron microscope (SEM) (*21*). Further, the NPs could form aggregates upon addition of the target antigen, and this aggregation was also observed using the SEM. Considering these reports, the fluorescence molecule labeled antibody was safely immobilized onto NPs without any antibody-mediated cross-linking, and the resulting NPs could capture the target molecule. To estimate the NP conjugation efficiency, the total amount of active ester groups per milligram of NPs was evaluated by a change in the absorbance of *p*-nitrophenol ($\lambda_{max} = 405$ nm) as a leaving group, following the complete hydrolysis of the ester group by treatment with an aqueous solution of NaOH (0.1 mol/L). Active ester groups were located at a concentration of 1.0 nmol/mg NPs. The conjugation efficiency was estimated using peroxidase-labeled antirabbit IgGs (A6154; Sigma-Aldrich, Inc., MO, USA) as model antibodies. Subsequently, 40% active ester groups were consumed, and the 40% conjugation efficiency was approximately equivalent to that of a monolayer of immobilized antibodies (*6*). The total amount of immobilized antibodies was estimated to be 4×10^{-12} mol (2.4×10^{12} molecules) per 10 μg NPs. If 40% conjugation was performed safely, 1 antibody molecule occupied 70 nm^2. The area was larger than that for saturated immobilization (approximately 15 nm^2). Therefore, intramolecular FRET did not occur due to the long distance of each IgG molecule.

To obtain fluorescence-labeled antibodies, each donor and acceptor molecule were conjugated with each antibody. The conjugation efficiency was calculated from the UV–vis spectrum as shown in Table 2. The resulting labeled CRP or labeled OPN antibodies were recovered at concentrations from 8.7×10^{-7} to 4.4×10^{-6} mol/L (Table 2). Each CRP antibody was labeled with an average of 3.2 donor molecules. Similarly, the conjugation efficiencies of acceptor-labeled CRP and OPN antibodies and donor-labeled OPN antibodies were estimated to be approximately 3.5. Gruber et al. reported that multiple fluorescence labeling on antibodies could cause fluorescence quenching (*22*). In the present study, significant quenching of the fluorescence molecules was not observed. Each fluorescence molecule labeled antibody was immobilized onto NPs. The conjugation efficiency was estimated to be approximately 40% from preliminary tests by using peroxidase-labeled antirabbit IgGs. Thereafter, we obtained 4 types of bioconjugate NPs for bioassays via FRET. The following abbreviations were used as shown in the Experimental Section: CRP NP488, CRP NP555, OPN NP488, and OPN NP555.

FRET Observation by Bimolecular Recognition. First, we evaluated the changes in fluorescence intensities by using bare PC-covered NPs. The resulting fluorescence intensities were monitored using a multiplate reader with adequate filters ($\lambda_{EX} = 485$ nm, $\lambda_{EM} = 590$ nm). NP agglutination reactions were carried out in 96-well plates, and final reaction volumes were adjusted to 200 μL in each well. Furthermore, the final NP concentration was 10 μg in each well. The mole concentration of immobilized antibody on 10 μg NPs was estimated to be approximately 4×10^{-12} mol from our previous report (*6*). On the other hand, 0.1 μg CRP and OPN antigens each approximately equaled 4×10^{-12} mol. Therefore, bimolecular recognition was performed using 0.01–10 μg of each antigen. The NP concentration is important, since fluorescence via FRET was induced by NP agglutination. If the NP concentration was very high, the resulting fluorescence might easily decay by a scattering phenomenon. Fortunately, we did not observe any changes in the fluorescence intensity from bare PC group enriched NPs, even after changing the antigen concentration. We believe that NPs are capable of detecting biomarkers via FRET without any interference. In our previous report, CRP antigens were easily captured by anti-CRP IgG-immobilized PC group enriched NPs (*21*) that agglutinated in the solution and caused turbidity changes via changes in the CRP concentration. In this study, we attempted to install a FRET system at the NP surface in order to achieve a higher sensitivity than that achieved in our previous study. Thus, we first checked the preliminary biorecognition using NPs. The FRET phenomenon is clearly related to the CRP concentration. On the basis of the relationship between the fluorescence and the biomarker concentration, the resulting NPs are capable of detecting target molecules, and thus, FRET took place in the multiwell plates.

In this bimolecular recognition system, target biomarkers were sandwiched in NPs, and fluorescence energy transfer was induced between donor and acceptor molecules. Particularly, the distance between donor and acceptor molecules was strongly regulated by the target antigen. In the present study, CRP (30 kDa) and OPN (120 kDa) were used as the target biomarkers, and the molecular sizes were considered to be approximately 4×4 and 4×12 nm^2, respectively. After complex formation, it is assumed that the donor and acceptor molecules would be in close proximity. Energy transfer may be induced between donor-labeled NPs and acceptor-labeled IgGs (free IgG molecules). Thus, we preliminarily examined the process in detail as shown in Figure 5. NPs and free IgG molecules were combined, and the total amount of each IgG molecule was adjusted as appropriate (4×10^{-12} mol). However, the fluorescence intensity did not precisely correlate with the changes in biomarker concentration. Moreover, the final fluorescence intensity of CRP NP488/CRP IgG555 at 565 nm was significantly higher than that of the alternative combination CRP NP555/CRP IgG488. The dominant reason was the free CRP IgG555 molecules in the former combination. The Alexa Fluor 555 molecules on CRP IgG555 could fluoresce to a small extent due to irradiation with excitation light in the absence of FRET.

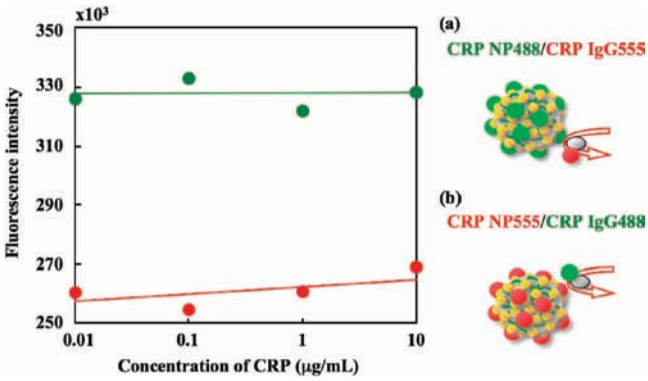

Figure 5. Change in fluorescence intensity by capture of CRP between NPs and free IgG. NPs (10 μg/well) were used: (a) CRP NP488 and CRP IgG555 mixture and (b) CRP NP555 and CRP IgG488 mixture.

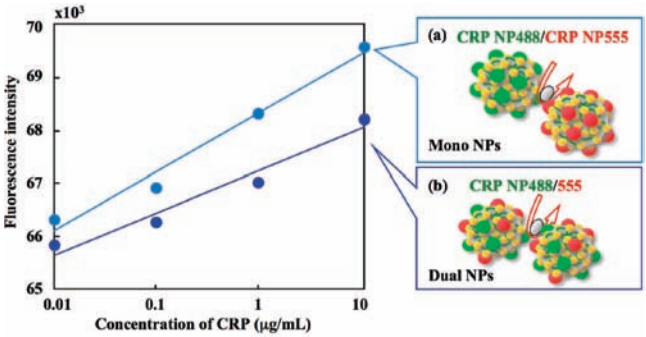

Figure 6. Change in fluorescence intensity. NPs (10 μg/well) were used; (a) mono-immobilized NPs system and (b) dual-immobilized NPs system.

The resulting emission at 590 nm was much higher than that of Alexa Fluor 488 molecules on CRP IgG488. This is the reason for the higher fluorescence intensity of CRP NP488/CRP IgG555. In the case of free IgG, the diffusion coefficient in the solution was very large relative to that of the NPs. Although the fluorescence-labeled IgG might easily capture the target biomarker, the resulting fluorescence intensity did not change. A plausible reason for the insufficient immunoassay is considered to be related to the local concentration of IgG molecules. In the case of bioconjugated NPs, this concentration was quite high relative to the same amount of free IgG molecules in the solution. We have already succeeded in performing a sequential enzymatic reaction on PC group enriched NPs (*6*), and the local concentration is of great importance and governs NP biofunctions. Therefore, target biomarkers should be sandwiched into NPs. Moreover, free IgG molecules interfere with the ideal NP agglutination. Combinations of NPs and free IgG, target molecules were captured in ideal combinations and as products of side reactions. When CRP molecules were sandwiched in CRP NP488 alone, no energy transfer was induced. Furthermore, CRP IgG555 itself could capture CRP molecules, and no FRET was observed. Considering plausible side reactions, target molecules should be captured by a combination of CRP NP488 and CRP NP555.

Optimization of the Bimolecular Recognition System Using NPs. To achieve high-sensitivity bimolecular recognition, two types of bioconjugate NPs were considered, as shown in Figure 6. The fluorescence intensity of mono- or dual-immobilized NPs was lower than that of NPs and free IgG. The NPs and their aggregation by antigen molecules were significantly larger relative to the light source. Therefore, a fair amount of light scattering occurred due to the NPs; the final fluorescence intensity was thus lower relative to the antibody-immobilized NPs and free antibody system. Figure 6a shows mono-immobilized NP bimolecular recognition with donor and acceptor molecules independently immobilized onto NPs. Alternatively, Figure 6b shows both fluorescence molecules immobilized onto NPs (dual-immobilized NP bimolecular recognition). Regarding bimolecular recognition, the question remains whether there is any difference between mono- and dual-immobilized immunoassay systems. To determine whether there was any difference in the dual-immobilized NPs systems, certain experiments were carried out, and the results are summarized in Figure 6. On this basis, it was noted that there was no significant difference in terms of CRP detection. The changes in fluorescence intensity correlated well with CRP concentrations in both bimolecular recognition systems. Moreover, multiparticle clusters may be formed at high concentrations of CRP (*21*). In fact, a mismatched sandwich statistically appeared in the solution. In the case of Figure 6a, the FRET phenomenon was observed only in the sandwich with CRP NP488 and CRP NP555. If the CRP antigen was captured by CRP NP488 alone, the FRET phenomenon could not take place. On the other hand, if the CRP antigen was captured only by the acceptor molecule labeled IgG on CRP NP488/555 (Figure 6b), it was also considered to be a mismatch sandwich (no FRET). The occurrence of these mismatched sandwiches was statistically considered to be 50%. In this mismatch, the FRET phenomenon could not take place; however, the statistical degree of the mismatch was estimated to be 50% in both cases (mono- and dual-immobilized NP immunoassays). Considering these assumptions, there is no difference between both immobilization immunoassay systems. However, the mono-immobilization system is superior to the dual-immobilization system in terms of preparative conditions and storage of NPs. Therefore, the mono-immobilization system was selected for this study.

Diversity of Bimolecular Recognition and Influence of Interference Proteins. The most favorable characteristic of the bimolecular recognition system presented herein is its simplicity, since it involves mixing NPs with sample solutions. A typical simple protocol for the immunoassay is described as follows. First, 5 μL aliquots of CRP NP488 and CRP NP555 are added to the 96-well plate, along with 90 μL PBS (pH 7.4) buffer. A target biomarker, human CRP in this case, is added to each well in various final concentrations ranging from 0.15 to 30 μg/mL. Reaction mixtures are rotated mildly for 5 min by using a plate mixer and maintained at 37 °C for 30 min. After the incubation, the emission fluorescence intensity at 590 nm was monitored by excitation at 485 nm. Excitation and emission wavelengths were regulated using filters. Figure 7a shows the change in the fluorescence intensity by CRP detection. In the reaction medium, NPs covered with donor- or acceptor-labeled CRP antibodies are dispersed. If the CRP antigen was captured by the NPs, the latter could agglutinate within the wells. The antibody is labeled with donor or acceptor molecules, and if the donor and acceptor molecules are close enough to form antigen–antibody complexes, one can observe fluorescence intensity energy transfers. Moreover, the intensity is strongly dependent on the concentration of the target antigen. Therefore, the bioconjugate PC group enriched NPs could specifically detect biomarker molecules. Fortunately, the resulting fluorescence intensity correlated well with the CRP concentration. The aforementioned correlation indicated that ideal agglutination reactions took place when CRP antigen was added to the reaction wells. Additionally, the agglutination was examined using a medium supplemented with protein (4.5 mg/mL human serum albumin (HSA); Sigma-Aldrich Inc.) (Figure 7b). In this study, HSA was added to the reaction media as interference biomolecules. The final result with the HSA-containing system

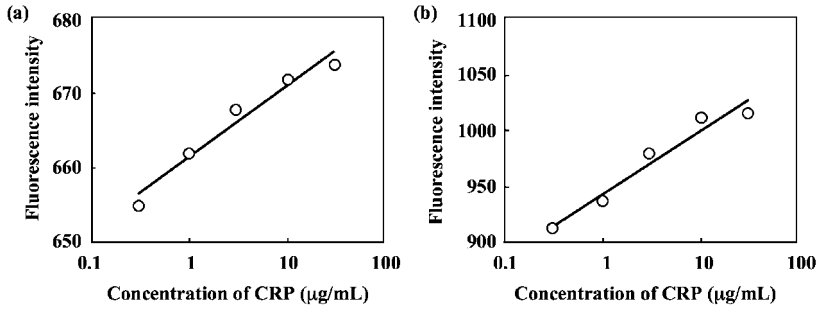

Figure 7. Change in fluorescence intensity by capture of CRP using CRP NP488 and CRP NP555. NPs (each 5 μg/well) were used: (a) without human serum albumin (HSA) and (b) with HSA (4.5 mg/mL).

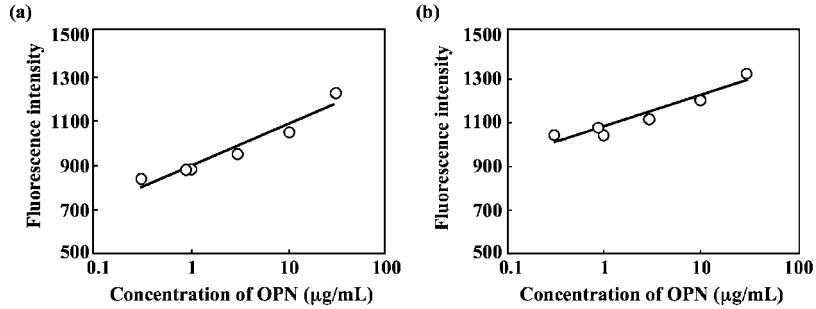

Figure 8. Diversity of immunoassay using FRET system. Change in fluorescence intensity by capture of OPN using OPN NP488 and OPN NP555. NPs (each 5 μg/well) were used: (a) without human serum albumin (HSA) and (b) with HSA (4.5 mg/mL).

correlated with the changes in the CRP concentration. Thus, a FRET system was successfully installed in the bioconjugated PC group enriched NPs, as shown in Figure 1.

OPN was used to obtain more data regarding the diversity of the immunoassay using the FRET system. Figure 8a shows the typical results from the OPN assays using FRET systems. The fluorescence intensity correlates with OPN concentrations ranging from 0.15 to 30 μg/mL. Moreover, the immunoassay was successful even when using HSA-containing media (Figure 8b). Thus, PC group-enriched NPs could capture biomarker molecules on their surfaces without any interference, and fluorescence intensity was observed using FRET. OPN molecules aggregate easily under physiological conditions, because OPN contains dual electric charges due to its cationic and anionic subunits. Therefore, conducting an OPN bioassay by using a conventional ELISA process might be difficult. PC groups contain both electric charges conferred by a trimethylammonium group (cation) and a phosphate group (anion) and show higher free-water contents. Thus, PC group-enriched NPs might easily capture unaggregated OPN molecules. Furthermore, the sensitivity of the present bimolecular recognition was not very high relative to the conventional immunoassay system. However, the recognition protocol was quite easy, and nonspecific protein adsorption was effectively suppressed by the PC group enriched surface. These advantages enable the use of the general methodology in the field of molecular diagnosis.

Our ultimate purpose was to use an immunoassay involving NPs. In particular, a FRET system was used for detection. In this study, target antigens were expected to be captured by NPs. If the antigen was captured only by donor- or acceptor-immobilized NPs, FRET could not take place. However, such specificity was not designed into this NP system. The final result was subject to probability factors. On this basis, we can easily hypothesize that the probability of FRET would be 50%, even when side reactions occurred. With the probability factor taken into account, FRET NPs could precisely read the target antigens. Of course, this immunoassay system is not subject to such types of targets and IgG molecules.

CONCLUSIONS

Improvements in traditional immunoassay systems such as ELISA were designed using PC group-enriched NPs, and these novel bimolecular recognition systems were verified using FRET. Diversity among the target biomarkers was easily designed by changing the fluorescence-labeled antibodies. Additionally, these immunoassays were capable of detecting the existence of interference molecules. Thus, these results suggest that it is possible to tailor the FRET system installed NPs for smart immunoassays as new paradigms.

Fluorescent Diethylcarbamazine Analogues: Sites of Accumulation in *Brugia malayi*

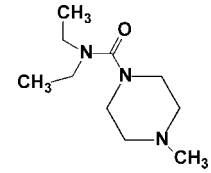
Amy Junnila,[†] D. Scott Bohle,*[,‡] Roger Prichard,*[,†] Inna Perepichka,[‡] and Carla Spina[‡]

Institute of Parasitology and Department of Chemistry, McGill University, 801 Sherbrooke Street West, Montreal, PQ H3A 2K6, Canada. Received March 23, 2007; Revised Manuscript Received July 18, 2007

New fluorescein and rhodamine B-labeled antifilarial drug DEC analogues for use in drug localization studies with confocal microscopy have been prepared by a high-yield three-step synthesis. The resulting β-amine-substituted DEC analogue has a single ethyl substituent which is β-aminated to accommodate the fluorophore of either fluorescein isothiocyananate or rhodamine B. Confocal microscopy is used to show that the drug accumulates in the adult filarial worms in the pharynx, esophagus, and near the nerve ring of all adults, as well as in the uteri and vulva and the testes of the females and males.

INTRODUCTION

Lymphatic filariasis (LF) is a debilitating disease caused by infection with the filarial worms *Wuchereria bancrofti* or *Brugia malayi*. It remains an important disease in tropical areas of Asia, Africa, and the Americas with an estimated 120 million people infected worldwide. LF is caused by the spread of the nematodes by mosquito bites between infected individuals, and its most remarkable symptom is known as elephantiasis which results from the swelling of tissues above infected lymphatic ducts.



Diethylcarbamazine (DEC) has been the drug of choice in treating LF since its discovery in 1947. (*1–3*) It very rapidly kills circulating first-stage larvae (microfilariae, mf) and may also kill or sterilize adult worms. However, there has been relatively little sustained effort with modern tools to understand its localization and drug targets. Furthermore, there are published (*4*) and preliminary reports of a lack of adequate response to DEC treatment, and drug resistance may be developing. In order to understand the possible mechanisms of resistance to a drug, it is critically important to understand how it works. Fluorescent analogues which share the biological activity of the pharmaceutical would be very useful tools for understanding how DEC works.

Early medicinal chemistry studies identified the fundamental importance of the piperazine ring and the 4-*N*-methyl substituent on the ring (Scheme 1). DEC analogues with a range of substituents for the dialkylcarbamyl group show antifilarial activity, but substitution of the methyl and modification of the ring leads to drug inactivity. (*5, 6*)

In this study, we have synthesized new fluorescein and rhodamine B-labeled DEC analogues for use in drug localization studies with confocal microscopy. A high-yield three-step synthesis (Scheme 2) results in the β-amine-substituted DEC analogue **3** in which only a single ethyl substituent is altered, thus preserving the crucial pharmacophore of DEC. (*5, 6*) Compound **3**, by attachment to its reactive amine group, can be readily conjugated to fluorescein isothiocyanate (FITC) to give **4** or rhodamine B (RHB) to give **5** (Scheme 3).

As **3** is the key intermediate of the new fluorescent probes, it was tested for its antifilarial action in Mongolian gerbils (*Meriones unguiculatus*) infected with *B. malayi* prior to use in drug localization experiments. Solutions of compound **3** which would produce dose rates equivalent to standard dosages of DEC had antifilarial activity comparable to that of DEC, so we proceeded to conjugate **3** to FITC and RHB in order to localize drug accumulation in *B. malayi in vitro*.

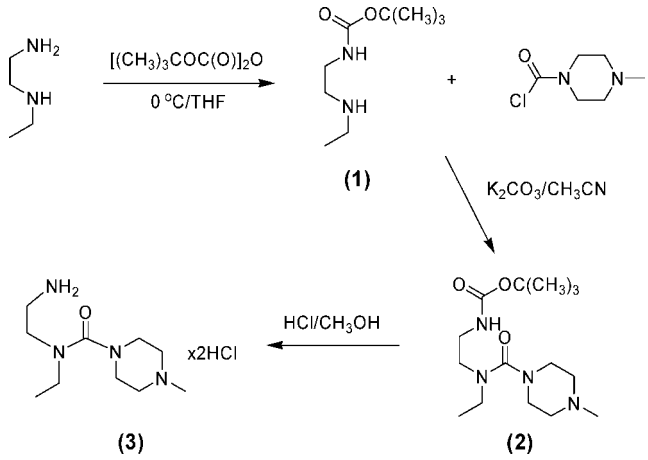
EXPERIMENTAL PROCEDURES



General Experimental. All reagents and solvents were used as supplied commercially, except for tetrahydrofuran (THF) and methylene chloride, which were distilled from Na/Ph_2CO and CaH_2, respectively. *N*-ethylethylenediamine, 4-methyl-1-piperazinecarbonyl chloride hydrochloride, fluorescein isothiocyanate (90%), and rhodamine B isothiocyanate mixture of isomers were purchased from Sigma Chemical Company. ^1H and ^{13}C NMR spectra were measured on a Varian Mercury 300 or 400 MHz spectrometer. All chemical shifts were recorded in δ (ppm) relative to tetramethylsilane (TMS). Melting points were measured with a 2010 differential scanning calorimeter. The IR spectra were taken in KBr disks or as a thin film on a NaCl plate using an ABB Bomem MB Series spectrometer with spectral resolution of 2 cm^{-1}. UV/visible spectra were measured using a Cary 300 Bio UV–visible spectrophotometer from Varian. Fluorescence spectra were recorded on a Varian Cary-Eclipse fluorometer or a FluoroMax 2 (ISA) Jobin Yvon-SPEX spectrofluorometer. The pH values were monitored with Cole Palmer pH meter (model 05669-20) using a Ag/AgCl electrode. The mass spectra analyses were obtained on a Finnigan LCQ-Duo spectrometer operating at 70 eV. Aluminum-backed silica plates with UV indicator and silica gel 60 Å (70–270 mesh) were used in analytical thin-layer chromatography (TLC) and silica gel column chromatography, respectively. Elemental analyses were performed by Quantitative Technologies, Inc.

Synthesis of New DEC Analogues. *tert-Butyl 2-(Ethylamino)ethylcarbamate* **1.** The protected *N*-ethylethylenediamine **1** was prepared by literature methods. (*7*) Recrystallization from pentane with cooling in the freezer led to large crystals of **1**

N-(2-Aminoethyl)-N-ethyl-4-methylpiperzaine-1-carboxamide Dihydrochloride **3.** The *tert*-butoxycarbonyl group of **2** was removed by the following procedure: HCl (2.0 M in methanol, 5 mL) was added to a stirred solution of **2** (1.00 g, 3.19 mmol) in methanol (5 mL) at ambient temperature for an additional 3 h. The solvent was evaporated, yielding oil which crystallized after drying *in vacuo* (0.88 g, 97%). ^{1}H NMR (CH_3OH-d_4, 400 MHz) δ: 1.22 (t, 3H, $J = 7$ Hz), 2.94 (s, 3H), 3.12–3.33 (m, 10H), 3.48–3.52 (m, 4H). ^{13}C NMR ($CDCl_3$, 400 MHz) δ: 13.4, 43.6, 45.4, 46.1, 46.8, 49.7, 54.8, 164.4. The resultant product **3** can be stored, at 4 °C, for at least 3 months without decomposition.

1-(Fluorescein-5-yl)-3-(2-N-ethyl-4-methylpiperzaine-1-carboxamido)ethylthiourea **4.** To a solution of **3** (0.187 g, 0.652 mmol) and triethylamine (0.132 g, 1.30 mmol) in anhydrous dimethylformamide was added FITC (0.127 g, 0.326 mmol). The reaction was stirred at room temperature under nitrogen atmosphere with protection from light overnight. The complete removal of FITC was monitored by TLC (eluent CH_2CL_2/methanol 1:0.3 v/v). The solvent was then removed *in vacuo* and the product was purified by flash column chromatography using CH_2Cl_2/methanol (1:0.3 v/v) as an eluent to give **4**, which is isolated as an intense orange powder (0.12 g, 61%). ^{1}H NMR (DMSO-d_6, 400 MHz) δ: 1.06 (t, 3H, $J = 7$ Hz), 2.12 (s, 3H), 2.24 (t, 3H, $J = 5$ Hz), 3.08–3.19 (m, 10H), 6.47–6.63 (m, 6H), 7.11 (d, 1H, $J = 8$ Hz), 7.62 (d, 1H, $J = 8$ Hz), 8.14 (s, 1H), 10.3 (br s, 2H). IR (KBr, cm^{-1}): 3306br, 3146br, 2984br, 1633s, 1581s, 1565s, 1499m, 1465s, 1424m, 1384m, 1366w, 1319s, 1288s, 1255m, 1208m, 1172w, 1111m, 1030w, 966w, 909w, 843w, 802w, 574w, 484w. MS (ESI) $C_{31}H_{33}O_6N_5S$, 603 g/mol) *m*/*z*: found $[M + H]^+$ 604 (29%), $[M + Na]^+$ 626 (35%). Fluorescence (in water): $\lambda_{exc} = 498$ nm, $\lambda_{em} = 520$ nm.

1-(Rhodamine-5(6)-yl)-3-(2-N-ethyl-4-methylpiperzaine-1-carboxamido)ethylthiourea **5.** To a solution of **3** (0.157 g, 0.548 mmol) and triethylamine (0.06 g, 0.60 mmol) in anhydrous

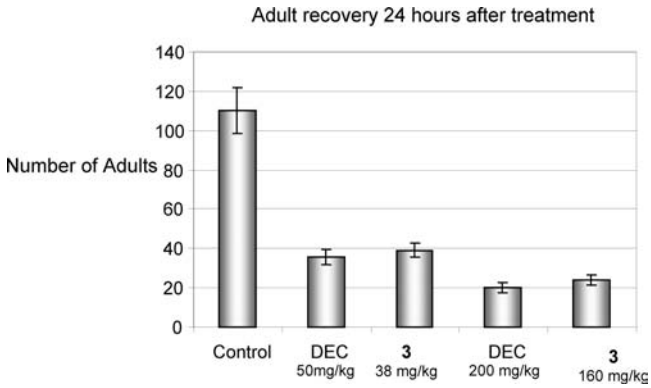

Figure 3. Adult parasite recovery 24 h after treatment. $N = 4$ gerbils per treatment group, with the same dose levels as used in Figures 1 and 2, shown under each column.

dimethylformamide (5 mL) was added rhodamine B isothiocyanate (mixture of isomers, 0.18 g, 0.336 mmol), and the mixture was stirred at room temperature under nitrogen atmosphere with protection from light overnight. Then, the temperature was raised to 70 °C for 10 h (reaction progress was monitored by TLC, eluent CH_2Cl_2/methanol 1:0.3 v/v). The final product **5** was reprecipitated several times from methanol/diethyl ether as a magenta powder (0.11 g, 43.7%) and used without purification for the next analyses. Fluorescence (in methanol): $\lambda_{exc} = 548$ nm, $\lambda_{em} = 570$ nm.

1-(Fluorescein-5-yl)-3-butylthiourea **Control 1.** Under nitrogen, butylamine (0.154 mL, 0.5 M solution in ethanol, 0.077 mmol) was added to a solution of FITC (0.021 g, 0.054 mmol) in dry ethanol (0.1 mL) using a gas-tight microsyringe, and the mixture was stirred at room temperature with protection from light overnight. Progress of the reaction was monitored by TLC (eluent CH_2Cl_2/methanol, 1:0.1 v/v, $R_f = 0.5$). After removal of the solvent, the crude product was purified by column chromatography on silica gel with CH_2Cl_2/methanol (1:0.05 → 1:0.3 v/v) as an eluent to give a deep yellow–orange powder of **control 1** (0.017 g, 68%) ^{1}H NMR (CH_3OH-d_4, 400 MHz) δ: 1.01 (t, 3H, $J = 10$ Hz), 1.44 (m, 2H), 1.67 (m, 2H), 2.03 (s, 1H), 3.63 (m, 2H), 3.98 (s, 1H), 6.72–7.02 (m, 6H), 7.23 (d, 1H, $J = 8$ Hz), 7.86 (d, 1H, $J = 6$ Hz), 8.25 (s, 1H). IR (KBr, cm^{-1}): 3372br, 3253br, 3065br, 2960s, 2929s, 2873m, 2858m, 1685s, 1593s, 1507s, 1465s, 1384s, 1320s, 1261s, 1208s, 1182s, 1112s, 1026w, 995w, 914w, 850s, 804w, 724w, 602w. Fluorescence (in water): $\lambda_{exc} = 505$ nm, $\lambda_{em} = 526$ nm.

1-(Rhodamine-5(6)-yl)-3-butylthiourea **Control 2.** Under nitrogen atmosphere, butylamine (0.106 mL, 0.5 M in EtOH, 0.053 mmol) was added to the solution of Rhodamine B isothiocyanate (21 mg, 0.039 mmol) in dry ethanol (0.1 mL) using a gas-tight microsyringe. The mixture was stirred at room temperature with protection from light overnight, then heated at 70 °C for 6 h. Progress of the reaction was monitored by TLC (eluent CH_2Cl_2/methanol, 4:0.3 v/v). After removal of the solvent, the final product was achieved by reprecipitation of the reaction mixture dissolved in minimal methanol with the addition of diethyl ether to give a deep purple powder of **control 2** (8.3 mg, 35%) ^{1}H NMR (CH_3OH-d_4, 400 MHz) δ: 0.92 (t, 3H, $J = 7$ Hz), 1.30–1.43 (m, 14H), 1.75 (m, 2H), 2.00 (s, 1H), 2.97 (m, 2H), 3.60 (m, 8H), 6.67–6.93 (m, 6H), (d, 7.17 1H, $J = 10$ Hz), (d, 7.47 1H, $J = 10$ Hz), 8.23 (s, 1H). IR (KBr, cm^{-1}): 3422br, 3213br, 2967s, 2936w, 2878w, 2793m, 2527w, 2416w, 1645ws, 1590s, 1528s, 1466s, 1412s, 1338s, 1274s, 1247s, 1181s, 1133s, 1075s, 1012w, 977w, 923w, 825w, 685w. Fluorescence (in water): $\lambda_{exc} = 553$ nm, $\lambda_{em} = 580$ nm.

Parasite Material. Male Mongolian gerbils (*Meriones unguiculatus*) infected intraperitoneally with 400 L3 infective larvae of *B. malayi* were obtained from Dr. J. McCall, University of Georgia. Microfilariae were obtained from the peritoneal cavities of gerbils by lavage with 5 mL phosphate buffered saline; adults were recovered during the subsequent necropsy. Adult worms were washed 3 times in RPMI 1640 containing 20 mM Hepes pH 7.3 to remove any adhering host cells; this was verified by light microscopy. Microfilariae were concentrated by centrifugation of the peritoneal exudates for 5 min at 12 000 rpm; the supernatant was discarded. The pellet containing microfilariae was washed 3 times by adding 1 mL Hepes-buffered RMPI 1640 followed by gentle agitation and centrifugation. Microfilariae were further separated from host cells by the percoll gradient method.

Antifilarial Activity of 3 in Gerbils. Antifilarial activity of the intermediate compound **3** was assessed by *in vivo* comparison with DEC at two dose rates. Gerbils ($N = 4$ for each treatment group) received one of the following combinations: 200 mg/kg or 50 mg/kg DEC in 200 μL normal saline, or 160 mg/kg or 38 mg/kg compound **3** in 200 μL normal saline, or 200 μL normal saline alone for control. All gerbils received

All worms were treated for 8 h, either in medium alone in the case of the controls or with the probe at a concentration of 5 μg/mL.

Scheme 4. Synthesis of FITC-Control and Rhodamine-Control 2 Fluorophores

intraperitoneal injections of the specified dose or control for three consecutive days. After necropsy on the third day, adult worms were counted under a dissecting microscope, and larvae were counted using the hemecytometer method. Means +/− standard deviation were calculated, and the difference between the parasites recovered from the treatment groups and control untreated group was assessed statistically.

Statistical Analysis. Data were analyzed using *SPSS* (version 10.0) statistical package (Chicago, IL). Samples were compared with the Kruskal–Wallis rank test. Significance was assessed at $P \leq 0.05$.

***In vitro* Culture of *Brugia malayi* with Experimental Compounds.** Individual adult worms or groups of approximately 10 microfilariae were incubated in 2 mL of standard medium (without fetal calf serum) as previously described in detail. (*8*) Briefly, RPMI 1640 was supplemented with 25 mM Hepes buffer, 2 mM glutamine, 100 U/mL streptomycin, 100 μg/mL penicillin, and 0.25 μg/mL amphotericin B. Cultures were set up in triplicate, and incubated at 37 °C in a 95% air/5% CO_2 atmosphere. An optimal concentration of **4** or **5** (5 μg/mL) was determined by examining worms incubated in concentrations ranging from 0.1 to 20 μg/mL. The optimal concentration was defined as the concentration in which uptake could be detected with the lowest possible amount of background fluorescence. For all subsequent studies, worms received **4** (5 μg/mL), **5** (5 μg/mL), 5 μg/mL native DEC, 5 μg/mL RHB unconjugated mixed isomers, or unconjugated FITC isomer **1** (5 μg/mL) for 8 h. Live stained worms were then washed for 4 h in standard medium (4 changes—1 every hour). Worms were mounted with pro-long antifade kit (Molecular Probes) according to the manufacturer's instructions.

Confocal Microscopy. Confocal images were taken on a Carl Zeiss LSM 510 Laser Scanning System. Images were processed with Zeiss LSM 5 Image Browser (version 3.1.0.99).

RESULTS

Synthesis of Fluorescent DEC Analogues. The design and synthesis of the DEC fluorescent analogues **4** and **5**, utilized the only site with any flexibility in the molecule, one of the terminal methyls of the diethylamino group. From prior structure–activity studies, it was known that the antifilarial activity of DEC was retained when one of the ethyls was replaced with smaller substituents and the other is larger. (*3*) To build the terminal amino substitutent in **3**, the selective protection of the primary amine with a *t*-boc group was used before condensation with the piperazinecarbonyl chloride to give **2** after two steps. Removal of *t*-boc with acid restored the primary amine, which was then immediately condensed with the fluorescent isothiocyanate FITC or Rhodamine B to give the final fluorescent-labeled DEC analogue **4** or **5**. The four step sequence is shown in Schemes 2 and 32 and 3.

Microfilarial Recovery. Within 24 h after treatment, both concentrations of DEC and **3** resulted in a significant increase of microfilarial levels compared to the control ($P < 0.05$). The low dose rate of both compounds demonstrated a significantly higher microfilarial increase than the high dose rate ($P < 0.05$) (Figure 1).

To determine if **4** and **5** required more time to act on mf, the experiment was carried out again with the sacrifice taking place at 10 days posttreatment instead of 24 h. Ten days after DEC or **3** treatment, microfilarial levels were significantly lower (*P*

Times and probe concentrations used correspond to those used in Figure 4.

< 0.05) in the treated animals compared with the control, for both compounds and dose rates (Figure 2).

Adult Recovery. At 24 h after treatment, DEC and **3**, at both high and low dose rates, showed adulticidal activity, and adult worm numbers were significantly lower than in the control gerbils ($P < 0.05$). The higher dose rate of both compounds was more effective than the lower dose rate of both compounds ($P < 0.05$) (Figure 3). At 10 days posttreatment, there were very few adults alive, and these were difficult to count, as only parts of worms were visible in clusters of nodules. Adult counts at 10 days are not shown.

Confocal Fluorescence Microscopy. Because **3** and DEC behaved similarly, **3** was conjugated to fluorescent molecules FITC and RHB for further use in confocal fluorescence microscopy. The fluorophores FITC and RHB (used unconjugated as controls) were found to be highly reactive, producing bright and nonspecific staining in the parasites (Figure 4) and were therefore unsuitable as controls. The reactive groups of these fluorophores were modified (Scheme 4) to closely resemble the conjugates used in this study. Control worms treated in media alone (8 h) and worms treated with modified control fluorophores (5 μg/mL for 8 h) showed no significant staining.

At the same concentration (5 μg/mL) and incubation time (8 h), **4** and **5** accumulated in the pharynx, esophagus, and near the nerve ring of all adults (Figure 5), uteri and vulva (Figure 6), and testes (Figure 7). When adult worms were examined by confocal microscopy, the intense staining observed in the uterus, testis, and intestine appeared to be localized to the lining (epithelium) of these organs. Additionally, in a few distinct sections of male testis, the contents of this organ were also stained (Figure 7).

Microfilariae accumulated stain in three distinct body areas (Figure 8); area 1 consisted of the excretory pore and the excretory cell, area 2 was the innerbody, and area 3 consisted of the G2, 3, and 4 cells and possibly the anal pore. As well, it appeared that somatic cell nuclei of microfilaria accumulated stain.

DISCUSSION

Conjugation of DEC to fluorescent molecules required a β-amine substitution. It was therefore necessary to determine

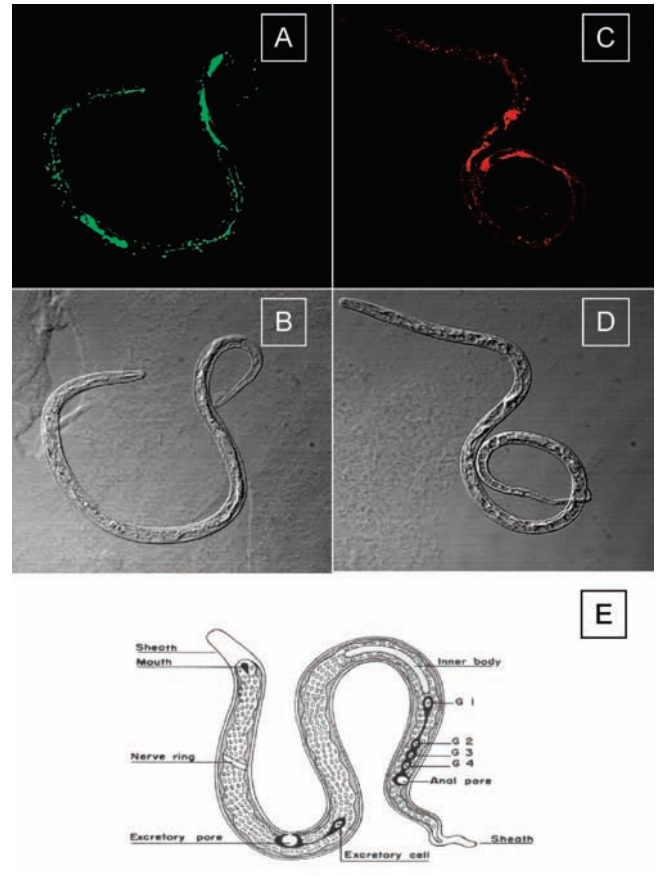

Figure 8. Sites of fluorescent DEC analogue accumulation in microfilariae. (A) Microfilaria stained with **4** DEC-FITC; (B) light microscopy view of A; (C) microfilaria stained with DEC-RHB **5**; (D) light microscopy view of C; (E) reprinted from Noble and Noble (1976) *Parasitology: The Biology of Animal Parasites*, 4th ed., Lea and Febiger, Philadelphia. Times and probe concentrations used correspond to those used in Figure 4.

whether compound **3** would act similarly to DEC in its filaricidal abilities. Similar strategies have been used to determine the subcellular localization of the adrenoceptor inhibitor prazosin when conjugated to BODIPY. (*9*) In survival assays carried out in the gerbil/*Brugia malayi* model, both DEC and **3** caused a surprising initial increase in peritoneal microfilariae 24 h posttreatment. This may be due to toxic effects of these compounds on the adult worms, causing them to release larvae from the uterus. In this particular host/parasite model, DEC and related compounds required several days to effectively reduce microfilariae, so the experiment was carried out again but animals were sacrificed at 10 days posttreatment instead of 24 h. This time, treatment with both DEC and **3** significantly reduced the number of peritoneal microfilariae and further reduced the number of adult worms. In fact, only parts of worms were visible, as they were being broken down in nodules found on the spleen and the liver and free-floating in the peritoneal cavity. Since **3** produced similar antiparasitic activity to DEC, it was conjugated to FITC and RHB for further use in confocal fluorescence microscopy.

In this study, no fluorescence was seen in the muscular system and very little fluorescence was seen in the nervous system (confined only to the area around the anterior nerve ring), which tends to exclude a strictly neuromuscular mode of action of DEC. Adult *Brugia malayi* did, however, strongly accumulate **4** and **5** in the pharynx, esophagus, intestine, and reproductive organs.

The sites of accumulation seen here in adult *Brugia* exposed to the fluorescent DEC analogue together with previous studies

that propose DEC acts by "unmasking previously hidden antigens" could suggest that the drug interferes with either excretion/secretion of a key immunomodulatory factor or with uptake/adsorption of host proteins, for example, serum albumin, which is believed to hide the worms from the immune system. Clearly the drug is accumulating at these sites and this is likely to occur where the drug receptors are localized. What is not observed is a random or diffuse distribution of **3**, which would suggest that it has little specific activity.

Chen and Howells were unable to demonstrate an oral (i.e., pharangeal pumping) uptake *in vitro* of trypan blue, ferritin, or fluorescein conjugated serum proteins by larvae and adults of *Brugia pahangi*. (*10*) It was later demonstrated that the gut of filarial worms is largely nonfunctional and that the cuticle serves as an absorptive as well as excretory surface. (*11*) As no significant fluorescence was detected in the cuticle, it is likely that DEC and DEC analogues are taken up transcuticularly and subsequently accumulate in target tissues.

A study conducted in 1996 provided the first evidence that suggested the existence of an excretory organ in filarial worms in the region of the anterior nerve ring (*12*), and it is believed that the uterus, vas deferens/testis, and intestine are the major organs where excretory proteins, such as superoxide dismutase (*13*) and gluthaione S-transferase (*14*) among others, are synthesized and exported. Our data show fluorescent DEC analogues accumulated in major sites of synthesis of secreted protein (*13*), which lends new evidence to the idea that DEC may be interfering with a key excretory/secretory product.

Microfilariae treated with fluorescent DEC analogues accumulated fluorophore in the inner body, the excretory pore, and the excretory cell, as well as the G-cells. Slight fluorescence was also seen in the pharyngeal thread and some somatic cell nuclei. The microfilariae have a nonfunctional gut (*15, 16*), but they do contain metabolically active sites within the body. (*15*) Feng (1936) demonstrated that the inner body of *Brugia* microfilaria occupies the space that later becomes the intestine in developing larvae. It is interesting to note that DEC analogues accumulate in tissues destined to become those which also accumulate these compounds in the adult worms. The biological significance of these findings is that the drug receptors are most likely localized at the accummulation sites of **3**, and the question we are now determining is the specific protein or receptor target for these drugs.

Advancing knowledge of drug delivery and activity requires an understanding of drug design and drug stability while taking into account the complexities imposed by the biological system (*17*) including cell/tissue penetration, drug-target interaction, and the pharmacodynamic consequences of alterations to native drugs. (*18*) In this study, we developed and synthesized fluorescent drug analogues that helped to address these complexities. The fluorescent DEC analogues synthesized here are small enough to penetrate the filarial cuticle, the crucial pharmacophore is accessible to potential receptors, and the major compound to be attached to the fluorophore **3** retains filaricidal activity.

The use of fluorescent drugs to investigate their targets in cells and tissues continues to expand at a rapid pace. Fluorescence imaging of protein–ligand interactions could provide an important biological context for drugs under study that might be otherwise overlooked by traditional biochemical techniques.

ACKNOWLEDGMENT

The authors gratefully acknowledge support from the FQRNT and the Centre for Host-Parasite Interactions for support in the form of a Centre New Iniative grant. Support from NSERC (to R.P. and D.S.B.) is gratefully acknowledged. In addition, fellowship support for I.P. and C.S. from the CIHR Chemical Biology Traineeship Program is gratefully acknowledged.

Site-Specific Pegylation of G-CSF by Reversible Denaturation

Francesco M. Veronese,*,† Anna Mero,† Francesca Caboi,‡ Mauro Sergi,‡ Christian Marongiu,‡ and Gianfranco Pasut†

Department of Pharmaceutical Science, University of Padua, via Marzolo 5, 35100 Padua, Italy, and Bio-Ker S.r.l., Piscinamanna 09010 Pula (CA), Italy. Received April 13, 2007; Revised Manuscript Received August 3, 2007

A new strategy has been developed for extending the possibility of poly(ethylene glycol) (PEG) modification to accessible thiol groups of biologically active proteins. In particular, thiol-reactive PEGs have been coupled to the cysteine 17 of granulocyte colony stimulating factor (G-CSF), which is known to be partially buried in a hydrophobic protein pocket. The PEG linking was accomplished by partial protein denaturation with 3 M guanidine·HCl in the absence of any reducing agent in order to preserve the native protein's disulfide bridges. PEG coupling occurred also, but at a lower degree, by using a 3 M solution of urea as the denaturing agent. Following the PEGylation, which was carried out in the unfolded state, the conjugated protein was refolded using dialysis or gel filtration chromatography to eliminate the denaturant. Different thiol-reactive PEGs and polymer molecular weights (5, 10, or 20 kDa) were investigated for G-CSF conjugation under denaturation. The secondary structure of the protein in the G-CSF-PEG conjugates, evaluated using circular dichroism and biological activity assay in cell culture, was maintained with respect to the native protein. Unexpectedly, conjugation enhanced the G-CSF tendency to aggregate, a problem that was overcome by a proper formulation.

INTRODUCTION

Granulocyte colony stimulating factor (G-CSF), the major regulator of granulopoiesis in vivo, represents a pharmaceutically useful protein that stimulates proliferation, differentiation, and survival of cells of the granulocyte lineage (*1, 2*). *E. coli* expressed G-CSF differs from the natural material in its lack of glycosylation and the N-terminal methionyl residue incident to bacterial expression (*3, 4*).

Clinical use of G-CSF (reviewed in refs (*5, 6*)), started in 1986 with the first clinical trials in cancer patients treated with chemotherapy (*7*), and it is now widely used to treat neutropenia, a condition that occurs in a wide variety of disease settings, including congenital defects, bone marrow suppression following pharmacological manipulation, infection, and also in cancer patients undergoing cytotoxic chemotherapy.

In 1991, the United States Food and Drug Administration approved Neupogen (Filgrastim, rh-met-huG-CSF) for use by those patients suffering from neutropenia during or after chemotherapy. Treatment with G-CSF can enable a higher-dose-intensity schedule which may allow better antitumor effects (*8*). It was later approved worldwide for use in bone marrow transplantation and more recently for treatment of severe chronic congenital neutropenia. Neupogen has a potential application in mobilizing peripheral blood progenitor cells for transplantation (*9*), but it presents a short in vivo half-life mainly due to two factors: rapid renal clearance and receptor mediated clearance by granulocytes, the last process that provides a self-regulation control on the G-CSF concentration.

To overcome these shortcomings, some methods have been proposed, and PEGylation is among these. PEGylation is intended to be a chemical linking of poly(ethylene glycol) chains to a drug (*10–13*). PEG conjugation masks the protein's surface and increases the hydrodynamic volume of the polypeptide, thus reducing its renal clearance, preventing the approach of antibodies or antigen processing cells, and decreasing the protein degradation by proteolytic enzymes. Finally, PEG conveys to molecules its physicochemical properties and therefore also modifies the biodistribution and solubility of peptide and nonpeptide drugs.

A PEGylation form of G-CSF, Neulasta, was already introduced in the market in 2002; in this case, PEG chains of 20 kDa have been selectively linked to the G-CSF amino terminus (*14*). The derivative presents a better pharmacokinetic profile and increased patient compliance. Interestingly, a recent study has also highlighted that this conjugate has a lower propensity to aggregate than the native G-CSF (*15*). In particular, the pathway of aggregation is not changed with respect to the native G-CSF, but the kinetic rate is slowed by PEGylation. This means that, after a proper time of incubation, both native G-CSF and PEG–G-CSF reach the same level of aggregation (*15*). The process involves first a conformational change that forms an aggregation-prone protein structure (*16*), which then leads to an initial noncovalent aggregation followed by the formation of covalent dimers and oligomers. These covalently linked forms are due to disulfide bridging and shuffling, which are promoted by the lone free cysteine in the G-CSF sequence (*15, 16*). As a confirmation, a G-CSF mutant obtained by switching the Cys17 with an Ala residue still forms aggregates, but only noncovalent ones.

Starting from these data, we tried to combine the beneficial effects obtained with G-CSF PEGylation (*15*), i.e., the reduction in aggregation kinetic rate, and the elimination of the free thiol of Cys17 that promotes the formation of covalent aggregates (*16*). To reach this goal, we performed the PEGylation of G-CSF selectively at the level of Cys17 using thiol-reactive PEGs. The lone free Cys17 in rhG-CSF, the other four being involved in two disulfide bridges (Cys36-Cys42, Cys64-Cys74), is not accessible in the protein native folding. In fact, Arakawa reported that this cysteine cannot be carboxymethylated by a hydrophilic agent, iodoacetic acid, under native conformation, but it becomes fully reactive when rhG-CSF is denatured (*17*). In other experiments, the free thiol has been shown to react very slowly with a

hydrophobic modifying agent, dithiobis-nitrobenzoic acid (DTNB) under nondenaturing conditions. It is postulated that the free cysteine may reside inside a hydrophobic environment of the protein, and therefore, it is inaccessible to chemical modification by hydrophilic agents, whereas it is slightly more accessible to the hydrophobic ones. Conformational studies of G-CSF have also demonstrated that the –SH at position 17 is buried in a cavity of the protein, only partially exposed to solvent.

Therefore, we looked for conditions of specific conjugation between a single chain of PEG and the Cys17 of G-CSF, once this is unmasked by partial denaturation. Furthermore, we tested the different reactivity of three thiol-reactive PEGs: the vinylsulfone–PEG (PEG–VS), the orthopyridyldisulfide–PEG (PEG–OPSS), and the maleimide–PEG (MAL–PEG). Different polymer molecular weights were investigated also.

As a continuation of a preliminary report (*18, 19*), in this paper we describe in more detail the studies involved in the development of this new PEGylation strategy and its application in the preparation of new active PEG–G-CSF conjugates, where only one chain of PEG is bound to the Cys17. Unexpectedly, the obtained conjugates showed a more marked tendency to form soluble aggregates in solution when compared to native G-CSF. Preliminary formulation studies demonstrated that the addition of albumin or β-hydroxypropylcyclodextrin can overcome this aggregation propensity.

MATERIALS AND METHODS

General Methods. A lyophilized powder of rh-G-CSF was supplied by Bioker (Pula, Cagliari, Italy). PEG–OPSS, PEG–VS, and PEG–MAL of different molecular weights were purchased from Nektar (Huntsville, AL). 3-(4,5-Dimethylthiazol)-2-yl-2,5-diphenyl tetrazolium bromide (MTT), 5,5′-dithiobis-(2-nitrobenzoicacid) (DTNB), solvents and denaturing agents, and other chemicals of analytical grade were from Sigma (St. Louis, MO). RPMI medium, fetal bovine serum, and penicillin were from Gibco (Pailey, UK).

Reversed-phase chromatography was performed with a Pharmacia LKB (Gromma, Sweden) analytical HPLC system, using a Vydac C4 column (150 × 4.6 mm, particle size 5 μm) or a Phenomenex C18 column (250 × 4.6 mm, particle size 5 μm). Elution was carried out at a flow rate of 1 mL/min with a linear gradient of acetonitrile in water containing 0.05% (v/v) TFA from 40% to 70% over 25 min. The effluent was monitored by recording the absorbance at 226 nm.

SDS-PAGE was carried out in a vertical slab gel apparatus (Mini-Protean II, Bio-Rad) using an SDS-polyacrylamide gel with a low degree of cross-linking (60% acrylamide, 0.8% bisacrylamide). The gels were stained with Coomassie brilliant blue R-250.

Far-UV circular dichroism (CD) measurements were made at 25 °C on a Jasco J-710 spectropolarimeter (Tokyo, Japan) equipped with a thermostatically controlled cell holder. The instrument was calibrated with D-(+)-10-camphorsulfonic acid. The spectra were recorded in 10 mM acetic acid, 10 mg/mL mannitol, pH 4, at a protein concentration of 0.1 mg/mL, in 1 mm path length quartz cells. Far-UV CD spectra were analyzed in order to estimate the percentage of protein secondary structure from the equation % α-helix = $(\theta_{208\text{nmobs}} - 4000)/(33\,000 - 4000)$ (*20*), where $\theta_{208\ \text{nm,obs}}$ is the observed mean residue ellipticity at 208 nm.

Protein concentrations were determined spectrophotometrically on a Perkin-Elmer Lambda-20 spectrophotometer. The concentrations of stock solutions of G-CSF and G-CSF–PEG conjugates were evaluated from their absorbance at 280 nm. Extinction coefficients at 280 nm for G-CSF (0.88 $mg^{-1}\ cm^2$) were considered unchanged for the G-CSF–PEG conjugates.

Fluorescence emission spectra were recorded at 25 °C on a Perkin-Elmer model LS-50B spectrofluorometer, equipped with a thermostatically controlled cell holder. Spectra were taken in Tris/NaCl buffer, pH 7.5, using 1 cm path length, exciting the samples (1.3 μM) at 295 nm, and recording the emission fluorescence in the wavelength range 303–500 nm, in the presence of different amount of positive (CsCl) and negative (NaI) quenchers.

MALDI Mass Spectrometry. Measurements were performed on a REFLEX time-of-flight instrument (Bruker-Franzen Analytik, Bremen, Germany) equipped with a SCOUT ion source operating in positive linear mode. Ions, formed by a pulsed UV laser beam (nitrogen laser, $\lambda = 337$ nm), were accelerated to 25 kV. Sinapinic acid (saturated solution in acetonitrile/water (50:50 v/v)) was used as a matrix. Samples were dissolved in 0.1% trifluoroacetic acid aqueous solution. Five microliters of the diluted sample solution was mixed with the same volume of matrix solution, and 1 μl of the resulting mixture was deposited on a stainless steel sample holder and allowed to dry before introduction into the mass spectrometer.

Cell Culture. The NSF-60 cell line, which is developed from a mouse myeloblastic leukemia rich in G-CSF receptors, was kindly provided by Dr. William E. Evans St. Jude Children's Research Hospital (USA). Cells were maintained in RPMI medium with 5% fetal bovine serum, 10 U.I./mL penicillin, and 30 U.I./mL Filgrastim at 37 °C, under 5% CO_2 atmosphere.

G-CSF PEGylation under Nondenaturing Conditions. Thiol-reactive PEGs (PEG–OPSS, PEG–VS, or PEG–MAL) were employed. The reactions were carried out in 0.5 M Tris buffer, pH 7.2. At room temperature, one of the active PEGs was added as a powder in a 10-fold molar excess to a rhG-CSF solution (1 mg/mL). The reaction was allowed to proceed for 24 h or in any case until reaching a constant amount of PEG–G-CSF conjugate, which was then analyzed and purified by reverse-phase chromatography according to the conditions reported in Methods and Materials. The purity of the conjugate and the degree of conjugation were determined by SDS-PAGE and DTNB colorimetric assay (*21*).

Control of the Reversibility of G-CSF Denaturation. Solutions of rhG-CSF, at 0.15 mg/mL, were prepared and incubated for 4 h in 2, 3, or 4 M guanidinium chloride (Gu·HCl) in phosphate buffer 0.05 M, pH 7.2. A 5 M solution of urea in the same buffer was also tested as a denaturant. The protein secondary structure recovery was analyzed after dialysis, against sodium acetate 10 mM pH 4.2, to remove the denaturant. The secondary structure was investigated by far-UV CD analysis.

G-CSF PEGylation under Denaturing Conditions. To G-CSF (1.46 mg/mL), dissolved in one of the denaturant solutions reported above, PEG–OPSS (5 kDa), MAL–PEG (5 kDa), or PEG–VS (5 kDa) were added at 10-fold molar excess with respect to the protein. The reaction was allowed to proceed at room temperature, under argon atmosphere, for 4 h. Alternatively, PEG–OPSS at 10 or 20 kDa was used. In this case, the reaction was conducted, under argon atmosphere, for 20 h when using the 10 kDa PEG or at 40 °C for 1 h followed by for 4 h at room temperature when using the 20 kDa PEG.

The reaction mixture was dialyzed against sodium acetate 10 mM pH 4.2, and the conjugate was purified by reverse-phase HPLC using the conditions reported above. The secondary structures of the products were analyzed by far-UV CD.

Evaluation of in Vitro G-CSF Conjugate Activity. NSF-60 cells were seeded in 96 well plates (104 cells/well), and serial dilutions of G-CSF and G-CSF–PEG conjugates were added. The plates were incubated for 67 h at 37 °C before the addition of 20 μL MTT (5 mg/mL in PBS filtered using 0.22 μm filters) to each well. After a further 5 h incubation, the media were removed and optical-grade dimethyl sulfoxide (100 μL) was added to dissolve the formed insoluble formazan dye. Absorbance at 540 nm was measured using an Elisa reader, and the

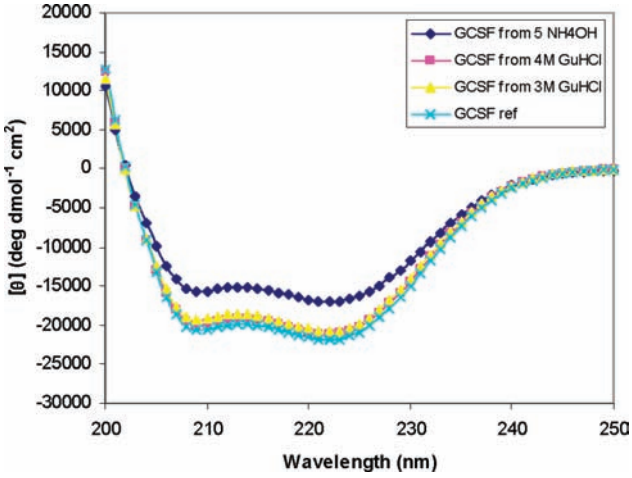

Figure 2. Far-UV CD spectra of native G-CSF in physiological condition (×) and after the denaturation–refolding process. Denaturation was performed using 3 M (▲) or 4 M (■) solutions of guanidine HCI or 5 M (♦) urea. The spectra were obtained at 25 °C in acidic solution at pH 4.2.

cell viability was expressed as a percentage of the viability versus untreated control cells.

RESULTS AND DISCUSSION

G-CSF PEGylation under Nondenaturing Conditions. The direct site-specific conjugation of a linear PEG to the thiol of G-CSF Cys17 was investigated by carrying out the reaction under conditions that maintained the G-CSF tertiary structure. Thiol-reactive PEGs based on double-bond addition (PEG–VS and PEG–MAL) or disulfide exchange (PEG–OPSS) were employed. The reaction was allowed to proceed at room temperature for several hours, until reaching a constant amount of PEG–G-CSF conjugate, as verified by RP-HPLC. In Figure 1 is the RP-HPLC profile of the conjugation mixture of G-CSF and PEG–OPSS (Figure 1A) or PEG–VS (Figure 1B) after 24 h. The degree of conjugation of G-CSF was very limited, thus confirming the difficulty of reaching the buried Cys17. Under these conditions, PEG–OPSS appeared to be slightly more reactive than PEG–VS. PEG–MAL showed a similarly low degree of conjugation (data not shown).

Reversible Denaturation of G-CSF. To overcome the low reactivity of the thiol group of G-CSF in the native state, we studied the conjugation under partially denaturing conditions. For this purpose, urea or Gu·HCl was used as a denaturing agent, while the native protein's disulfide bridges were maintained in order to facilitate the refolding, to prevent PEGylation at unwanted sites, and to avoid S–S scrambling during the refolding.

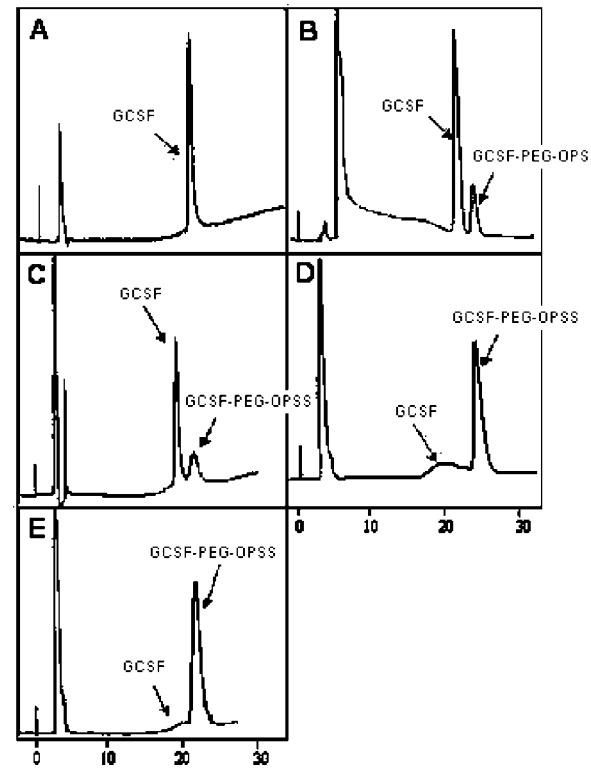

Figure 3. Reaction mixture of G-CSF PEGylated under denaturing conditions. RP-HPLC chromatograms had been obtained using a C4 Vydac column and recorded at 226 nm: (A) native G-CSF; (B) reaction mixture of G-CSF and PEG–OPSS (5 kDa), after 4 h, in the presence of 3 M urea; (C–E) reaction mixture of G-CSF and PEG–OPSS (5 kDa), after 4 h, in the presence of 2, 3, or 4 M guanidine·HCl, respectively.

Table 1. Degree of G-CSF PEGylation after 4 h Using Different PEG Reagents under Different Denaturing Conditions

PEG reagent	percentage of G-CSF conjugation using different denaturing conditions			
	2 M Gu·HCl	3 M Gu·HCl	4 M Gu·HCl	3 M urea
PEG–OPSS (5 kDa)	48	84	95	31
PEG–VS (5 kDa)	15	30	50	11
PEG–MAL (5 kDa)	44	81	91	29

A preliminary study was carried out to evaluate the refolding process of G-CSF after its exposure to different denaturant concentrations. In Figure 2, it is shown that the refolding is complete for concentrations of Gu·HCl up to 4 M. Denaturation using 5 M urea was more critical, and the refolding was incomplete. High salt concentrations interfered with the collection of CD data in the far-UV region. Therefore, spectra of protein samples containing guanidine·HCl could not be obtained below 200 nm.

G-CSF PEGylation under Conditions of Reversible Denaturation. The conjugation of G-CSF by PEG–OPSS 5 kDa, evaluated by reverse-phase HPLC, after 4 h under different denaturing conditions is shown in Figure 3. A fast and high degree of PEGylation at the lone free cysteine residue of G-CSF was successfully reached under the denaturing conditions of 3 or 4 M Gu·HCl. These conjugation data are in good agreement with the cyanylation results of G-CSF Cys17 as a function of Gu·HCl reported by other authors (*16*). PEG linking to denatured G-CSF using a 3 M solution of urea was less effective. Similar results were obtained using PEG–maleimide, while PEG–vinylsulfone had the lowest degree of coupling; in this case, after 4 h only 50% of conjugation was achieved in 4 M

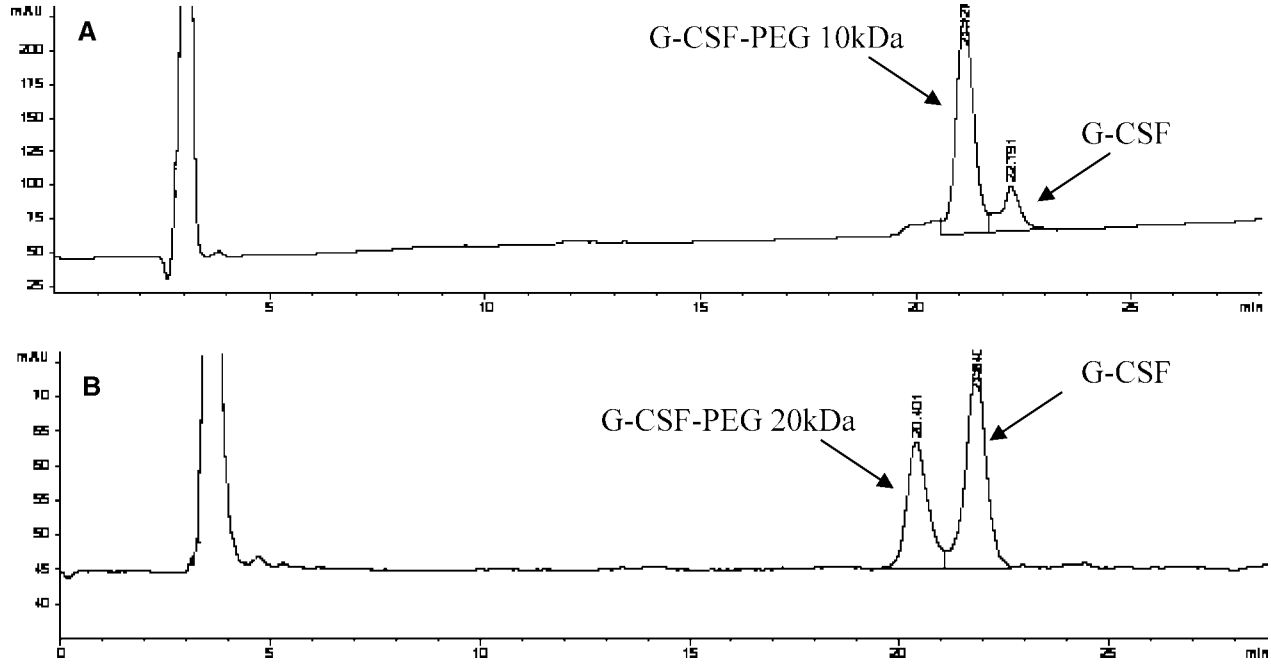

Figure 4. RP-HPLC chromatograms of reaction mixture of G-CSF and PEG–OPSS at different molecular weights, obtained using a C18 Phenomenex column. The spectra were recorded at 280 nm. (A) G-CSF and PEG–OPSS (10 kDa) after 20 h. (B) G-CSF and PEG–OPSS (20 kDa) after 1 h at 40 °C and the following 4 h at room temperature.

of Gu·HCl (Table 1). The denaturant was removed by extensive dialysis towards acetate buffer 10 mM at pH 4.2.

Protein unfolding accompanied by cysteine exposition and reactivity might also be obtained in water/organic solvent solutions. A G-CSF sample dissolved in a 80:20 water/DMSO solution showed a similar reactivity to PEG–OPSS (data not shown). This partial denaturation by DMSO could explain the PEGylation at the level of Cys17 of G-CSF reported by other researchers (*22*).

The conjugation of PEG–OPSS at higher molecular weights, 10 or 20 kDa, was investigated in 4 M guanidinium chloride. Protein modification using these more hindered PEGs was achieved by increasing the reaction time for the 10 kDa polymer and both temperature and time for the 20 kDa PEG. After 4 h at room temperature, the degrees of conjugation were 85% and 45%, respectively (Figure 4A,B). The conjugate G-CSF–PEG (20 kDa), dialyzed and purified as reported above, was characterized by SDS gel electrophoresis (Figure 5). The conjugate appeared as a single band at ∼62 kDa, which does not reflect the sum of G-CSF and polymer molecular weights, because as is known, PEG has a higher hydrodynamic volume than a protein with the same molecular weight (*23*).

The G-CSF–PEG conjugates were further characterized by MALDI-TOF mass spectroscopy, far-UV CD, fluorescence emission and finally by cell proliferative assay.

Structural Characterization of the PEGylated G-CSF. The covalent conjugation was confirmed by MALDI-TOF mass spectroscopy. A broad peak, due to PEG polydispersity, centered at 24 089 kDa, was detected following G-CSF conjugation with PEG 5 kDa. This corresponds to a mono-PEGylated G-CSF (Figure 6A,B).

The near- and far-UV CD spectra of native and PEGylated G-CSF, obtained using mPEG–OPSS 5 kDa, are shown in Figure 7A and B. The observed superimposition of the spectra demonstrates that refolding of PEGylated protein to the native structure took place after PEG linking also. Similar spectra were obtained with G-CSF–PEG–VS and G-CSF–PEG–MAL.

Fluorescence spectra of native and conjugated G-CSF showed a red shift in λ_{max} in the emission spectra, from 344 to 350 nm,

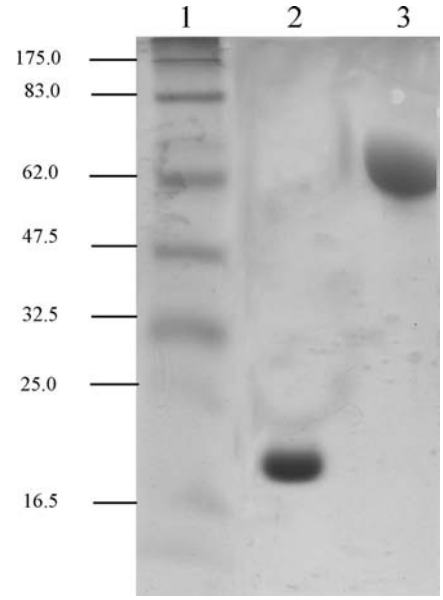

Figure 5. SDS gel electrophoresis of the following: lane 1, low molecular weight standards; lane 2, native G-CSF; lane 3, purified G-CSF–PEG–OPSS (20 kDa).

indicating that tryptophans 58 and 118 are more exposed to solvent in the conjugated protein. These data were confirmed by the tryptophan fluorescence quenching with CsCl and NaI of native G-CSF, G-CSF–PEG–OPSS, and G-CSF–PEG–VS (data not shown). The major solvent exposition of tryptophans in the PEGylated protein can be due to the influence of the highly hydrophilic PEG chain in the surrounding of this amino acid.

In Vitro Cellular Proliferative Activity of G-CSF Conjugates. The activity of conjugated and native G-CSF was evaluated by analyzing the proliferation of a sensitive cell line, which has been developed from a mouse myeloblastic leukemia rich in G-CSF receptors: NFS-60 cells. All of the protein species were found to stimulate cell proliferation, and the final cell

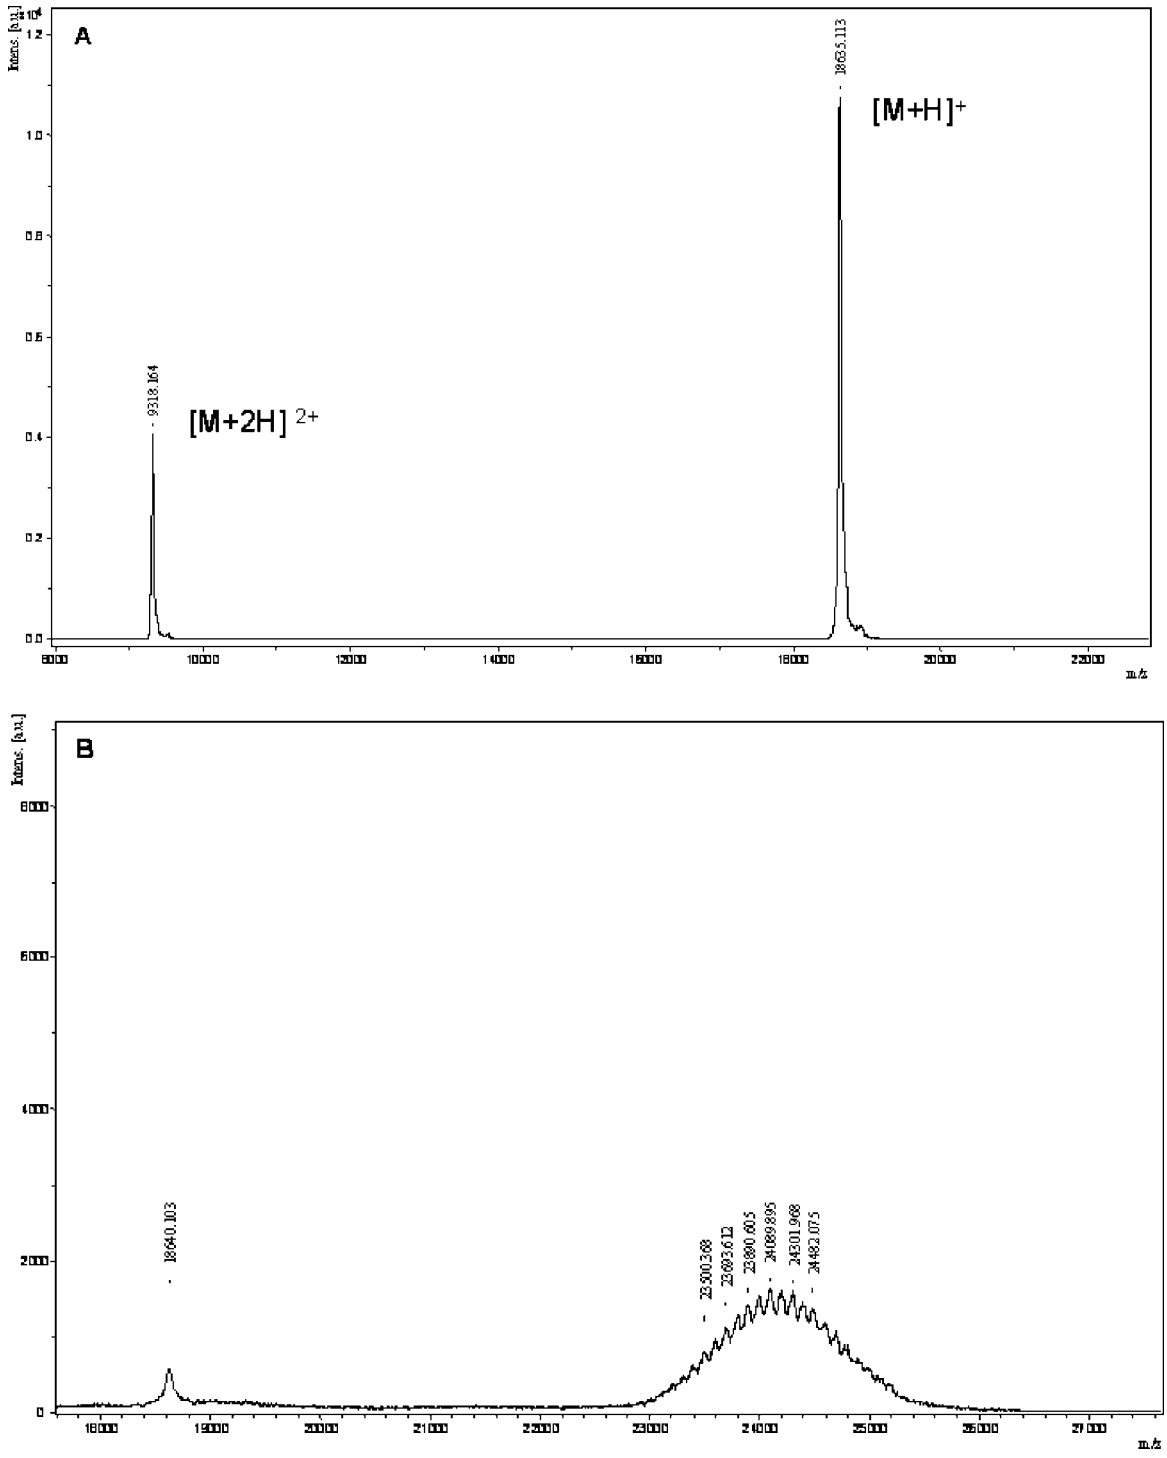

Figure 6. MALDI-TOF mass spectroscopy of (A) native G-CSF; (B) G-CSF–PEG–OPSS (5 kDa); the conjugate was purified from the reaction mixture by RP-HPLC chromatography.

concentration was found to be proportional to the concentration of G-CSF or G-CSF–PEG conjugates present in the cell culture. This allows quantification of the biological potency of G-CSF–PEG conjugates versus a G-CSF reference preparation, applying a dose–reaction ratio.

The IC_{50} values of two G-CSF–PEG conjugates, both prepared using a 5 kDa PEG, are reported in Table 2. The first conjugate was obtained by thiol-exchange reaction using PEG–OPSS and the second by double bond addition using PEG–VS. Both conjugates maintained high biological activity; in particular, the G-CSF–PEG–OPSS was more active than G-CSF–PEG–VS. This may be ascribed to the fact that the more hindered sulfone group of PEG–VS has a negative effect on maintenance of the native protein structure.

Stability of PEGylated G-CSF in Solution. Accelerated stability studies of G-CSF were performed by incubating at 37 °C the PEGylated protein solutions. The aggregation was evaluated on the basis of UV absorption and gel filtration chromatography of the incubated solutions. Figure 8 illustrates that the PEGylated forms unexpectedly undergo more rapid aggregation than the native G-CSF. This result is in contrast to the known drug solubilizing and aggregation prevention properties of PEG. Furthermore, this does not reflect the observations with Neulasta in which PEGylation slowed the rate of aggregate

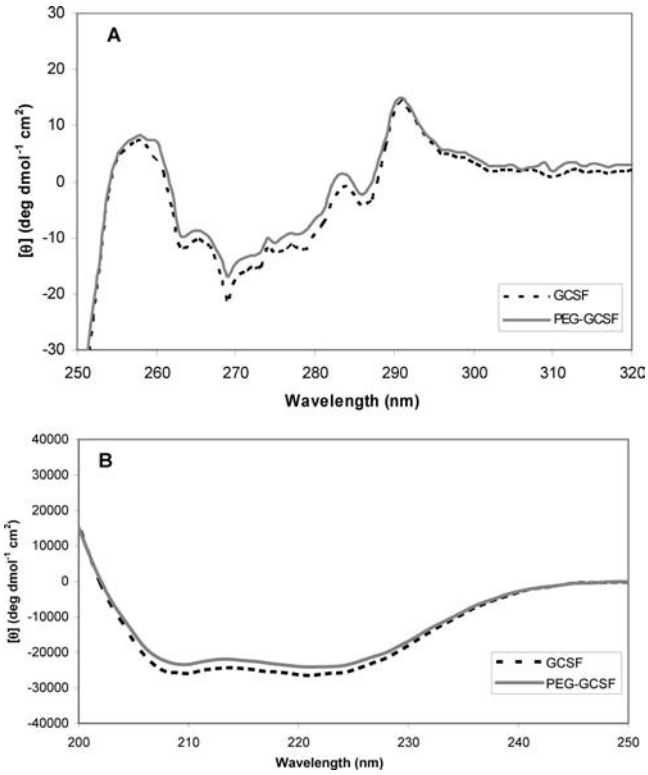

Figure 7. (A) Near-UV CD spectra of native G-CSF, G-CSF–PEG–OPSS (5 kDa). (B) Far-UV CD spectra of native G-CSF, G-CSF–PEG–OPSS (5 kDa). UV-CD spectra were taken at 25 °C in 10 mM acetic acid, 10 mg/mL mannitol, pH 4.2.

Table 2. In Vitro Activity in NSF-60 Cells of Native and Conjugated G-CSF

sample	IC_{50} (pmol/mL)	relative activity
rhG-CSF	0.0096	1
G-CSF–PEG–OPSS (5 kDa)	0.0145	0.66
G-CSF–PEG–VS (5 kDa)	0.039	0.246

formation (*15*). On the other hand, native G-CSF and Neulasta finally lead to covalent aggregates, which are formed as a consequence of disulfide scrambling promoted by the free thiol of Cys17 (*15*). As expected, in our study we did not observe covalent aggregates, since by SDS treatment it was possible to form the monomeric conjugate again. Anyway, preliminary formulation studies demonstrated that it is possible to stabilize the conjugates by adding hydroxypropyl β-cyclodextrin or albumin to G-CSF–PEG solution (Figure 8).

CONCLUSION

We have demonstrated the possibility to get site-specific PEGylation at the level of buried and less-accessible thiol groups of G-CSF cysteine 17. This was achieved by taking advantage of the quantitative reversible G-CSF unfolding by chemical denaturants and maintaining unaltered disulfide bridges to avoid disulfide scrambling. The conjugation was straightforward in the case of 5000 Da PEGs but needed longer time or increased temperature for the higher-molecular-weight PEG (10 and 20 kDa). The structure of the thiol-reactive moiety in the PEG chain plays a role in the biological activity of the final product. In fact, the conjugate G-CSF–PEG–OPSS retains higher activity than the G-CSF–PEG–VS. This may be because PEG, and in particular the steric hindrance of the thiol-reactive moiety, may induce some subtle local changes in the G-CSF three-dimensional structure. This phenomenon was slightly highlighted by fluorescence studies, although it was not evident by CD

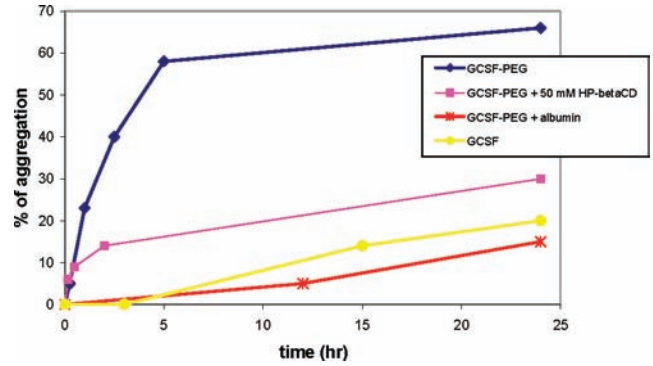

Figure 8. Aggregation profiles of native G-CSF, G-CSF–PEG–OPSS (5 kDa), G-CSF–PEG–OPSS (5 kDa) in 50 mM hydroxypropyl β-cyclodextrin, and G-CSF-PEG-OPSS (5 kDa) in albumin 0.1% (w/v) solution. The samples, all containing 1 mg/mL in G-CSF protein equivalent, were incubated at 37 °C and analyzed at predetermined times by gel filtration chromatography.

analysis. Furthermore, this can be correlated with the increased tendency of PEGylated G-CSF in solution to aggregate with respect to the native protein and the N-terminus PEGylated G-CSF (*15*). The different effect on G-CSF aggregation of this PEGylation strategy can be ascribed to the site of PEG linking. The polymer here is attached to a buried amino acid, and this can cause conformational change that enhances the rate of protein aggregation. We speculate therefore that the faster aggregation may be a consequence of protein hydrophobic residue exposition. In fact, the addition of hydroxypropyl β-cyclodextrin, which is known to mask hydrophobic residues, reduces the aggregation rate (Figure 8). On the other hand, the PEGylation at the level of Cys17 has been performed with the aim of avoiding the formation of covalent aggregates by thiol bridging, a problem faced by both the native and N-terminus PEGylated G-CSF (*15*). As expected, the aggregates, formed by G-CSF PEGylated at the cysteine, are in fact not covalent, and their formation can be totally prevented by a proper formulation by, for instance, using albumin (Figure 8). Therefore, this type of G-CSF–PEG has the advantage of overcoming the problem of covalent aggregation, a drawback presented by both native G-CSF and Neulasta.

This research highlights the possibility of exploiting a protein reversible denaturation for allowing a more selective PEGylation or conjugation of buried residues. Other conditions, which perturb the protein structure, can also enhance the thiol accessibility of G-CSF. In fact, preliminary experiments conducted in our laboratory showed that a complete G-CSF PEGylation at the level of Cys17 could also be achieved by PEG–OPSS during a very short (<30 s) protein exposure to high pH values (~11–12).

The role of protein conformation in influencing the site of PEGylation, as described here, in some way recalls what was done in growth hormone releasing factor (GRF) PEGylation. In this case, structuring solvents allowed a more selective modification, and the change in conformation was exploited to reduce the polymer linking at an unwanted site (*24*).

A final advantage of the procedure reported here is the feasibility of scale-up of the method, as needed for large-scale production of such an important therapeutic protein, because the lone site of modification makes it easier to obtain pure product.

Insulin Receptor Substrate 1 Knockdown in Human MCF7 ER+ Breast Cancer Cells by Nuclease-Resistant *IRS1* siRNA Conjugated To a Disulfide-Bridged D-Peptide Analogue of Insulin-Like Growth Factor 1

Gregory Cesarone,[†] Om Prakash Edupuganti,[†,§] Chang-Po Chen,[†] and Eric Wickstrom*[,‡,†]

Department of Biochemistry and Molecular Biology, and Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, Pennsylvania 19107. Received April 21, 2007; Revised Manuscript Received July 18, 2007

IRS-1 overexpression has been associated with breast cancer development, hormone independence and antiestrogen resistance. IRS-1 is a major downstream signaling protein for insulin and IGF1 receptors, conveying signals to PI-3K/Akt and ERK1/2 pathways. In estrogen-sensitive breast cancer cell lines, the widely used antiestrogen tamoxifen treatment reduces IRS-1 expression and function, thereby inhibiting IRS-1/PI-3K signaling. IRS-1 may serve as an alternative target to overexpressed IGF1R in breast cancer. While siRNA technology has become commonplace in many laboratories for *in vitro* gene knockdown studies, and *in vivo* stability issues are largely solved, its use *in vivo* is limited by an inability to efficiently and specifically deliver it to the intended site of action. We previously reported reduced survival of human MCF7 estrogen receptor positive breast cancer cells treated with a normal *IRS1* siRNA delivered by a cationic lipid, plus an additive effect in combination with tamoxifen. We now report enhanced cellular uptake, relative to the unconjugated serum-stabilized *IRS1* siRNA, of a serum-stabilized *IRS1* siRNA conjugated with our previously characterized peptide mimetic of IGF1, D-(Cys-Ser-Lys-Cys), without the use of cationic lipids or electroporation, in MCF7 cells that overexpress IGF1R. Excess native IGF1 blocked uptake. An *IRS1* siRNA cholesterol conjugate, targeted universally to cell membranes, was taken up by MCF7 cells as much as the peptide mimetic conjugate. *IRS1* mRNA knockdown and IRS-1 protein knockdown were comparable for the IGF1 peptide and cholesterol conjugates. The unconjugated serum-stabilized *IRS1* siRNA control showed negligible effects. Viability assays showed additive effects of siRNA treatment in combination with tamoxifen. In summary, we have taken the first step in converting an siRNA into a pharmacologically active agent for breast cancer.

INTRODUCTION

The crosstalk of ER-α with IGF1R signaling is well-demonstrated and is linked in the proliferation of breast cancer (*1–3*). Estrogens and IGFs act jointly to increase proliferation (*4, 5*); in fact, synergy has been shown between E_2 and IGF-I (*2*). ER-α is able to upregulate the mRNA and protein levels of IGF1R (*6, 7*). These observations illustrate the entwining of signaling between ER-α and IGF1R; yet, in breast cancer, resistance stemming from IGF-IR overexpression and/or prolonged activation leads to protein kinase activation, specifically, by increased pAkt, irrespective of hormone receptor status (*8*).

ER-α has also been shown to enhance the stability of insulin receptor substrate 1 (IRS-1) protein, and to upregulate *IRS1* mRNA (*6, 9, 10*). IRS-1 plays a major role in survival and proliferation signaling as an adaptor of IGF1R, to signal preferentially through the PI3K/Akt pathway for growth, proliferation, and survival (*11*). While IGF1R overexpression on human MCF7 ER+ breast cancer cells does not yield estrogen independence, characterized by reduced estrogen requirements for growth and transformation, IRS-1 seems to play a role in resistance to antiestrogen treatment (*12*). IRS-1 overexpressing MCF7 cells are no longer under ER control; their proliferation is not inhibited by E_2 alone or in combination with IGF1 (*12*). These observations provide a rationale for IRS-1 as the next logical alternative target in attacking breast cancer via a signaling intermediate (*13*). Recently, we reported the ability of *IRS1* siRNA to knock down *IRS1* mRNA, ablate IRS-1 protein, and reduce survival in human MCF7 ER+ breast cancer cells (*14*). siRNA effects were additive with those of tamoxifen (TAM).

Can *IRS1* siRNA, which must be delivered into cells with a cationic lipid, be modified into a pharmacologically active agent for breast cancer? Targeted approaches to therapy in cancer have gained momentum in recent years. The route of delivery for one agent versus another depends on the type or even subtype of cancer targeted (*15*). Recent successes with monoclonal antibody mediated therapy have determined a particular surface receptor to attack, a case of therapeutic agent and delivery vehicle all wrapped into one (*16*). Other solutions represent improvements on more traditional small molecules like taxols with improved delivery schemes to reduce their toxicity (*17*). Perhaps the most simple, yet largely elusive solution, due to delivery issues, is through direct gene targeting with antisense or siRNA.

While a number of reports have described methods of stabilizing these gene-targeting oligonucleotides in serum while retaining their activity (*18*), functionalization for *in vivo* targeted delivery has been a mixed bag. Many attempts have been made to provide siRNAs with the ability to be taken up into cells without the need for liposomal formulations that are fairly toxic *in vivo* but work wonderfully *in vitro*. One example, based on the success of monoclonal antibodies, utilized antibodies against HIV envelope protein and Her2 receptor conjugated to siRNA for cellular uptake *in vitro* and also for *in vivo* mouse studies

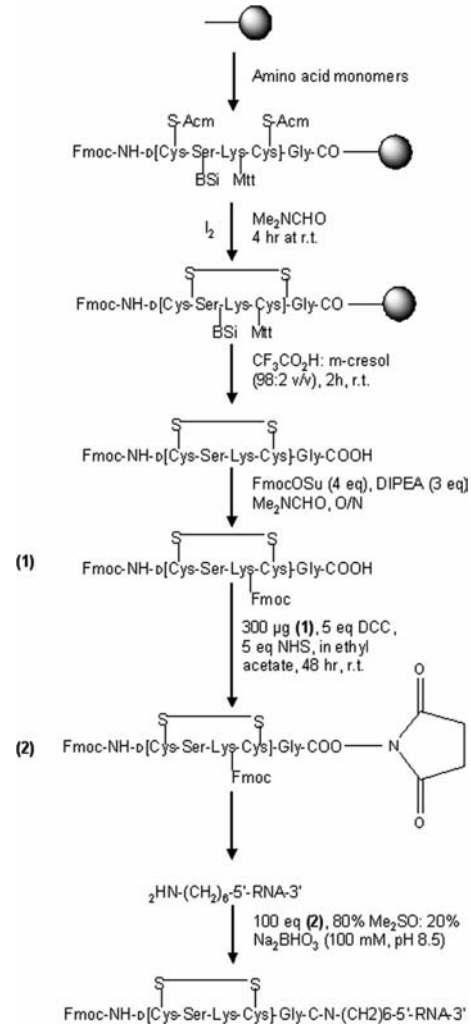
(*19*). A list of other examples, though not exhaustive, includes the use of penetratin (*20*), endogenous *in vivo* knockdown made possible by a cholesterol conjugate (*21*), transportan (*22*), atelocollagen (*23*), and PEG (*24*).



In this work, we tested the hypothesis that a peptide mimetic of IGF1 that has been characterized previously (*25*) would enable *IRS1* siRNA activity, without the need for cationic lipids, in human MCF7 ER+ breast cancer cells that overexpress IGF1R. The Cys-Cys cyclized peptide mimetic D-(Cys-Ser-Lys-Cys) was modeled to emulate an IGF1R binding domain of IGF1 (*25*) and has been used successfully for receptor-mediated endocytosis of peptide nucleic acid (PNA) radiohybridization agents designed to quantitate overexpressed oncogene mRNAs by noninvasive, external imaging *in vivo* (*26*, *27*). We have taken advantage of commercially available modifications to improve the stability of an siRNA that was effective at silencing *IRS1* mRNA in human MCF7 ER+ breast cancer cells (*14*), added a red fluorescent dye to the 3′ end of the antisense siRNA strand to monitor cellular uptake, and added the D-(Cys-Ser-Lys-Cys)-Gly IGF1 peptide analogue to the 5′ end of the sense siRNA strand to enable IGF1R-mediated endocytosis. In MCF7 cells that overexpress IGF1R, we observed enhanced cellular uptake of the serum-stabilized D-(Cys-Ser-Lys-Cys)-Gly-*IRS1* siRNA conjugate, without the use of cationic lipids or electroporation, relative to the unconjugated serum-stabilized *IRS1* siRNA. Excess native IGF1 blocked uptake, implying dependence of uptake on IGF1R. A cholesteryl–*IRS1* siRNA conjugate, targeted universally to cell membranes, displayed similar MCF7 cell uptake. *IRS1* mRNA knockdown and IRS-1 protein knockdown were comparable for the IGF1 peptide and cholesterol conjugates, against a background of minimal effect by the unconjugated serum-stabilized *IRS1* siRNA. Viability assays showed reduced survival of MCF7 cells treated with *IRS1* siRNA-IGF1 peptide conjugate alone or in combination with tamoxifen.

MATERIALS AND METHODS

Solid-Phase Peptide Synthesis of IGF1 Peptide Mimetic. Scheme 1 illustrates our route for solid-phase synthesis of the IGF1 peptide mimetic and its conjugation to the H_2N-Hx-*IRS1* RNA sense strand. The IGF1 mimetic D-(Cys-Ser-Lys-Cys)-Gly (*25*) was synthesized by stepwise Fmoc (9-fluorenylmethoxy carbonyl) coupling of Fmoc-D-Cys(Acm)-OH (Novabiochem, San Diego, CA), Fmoc-D-Lys(Mtt)-OH, and Fmoc-D-Ser(TBDMS)-OH (Bachem, King of Prussia, PA) onto Fmoc-Gly HMP-Tentagel resin (220 μmol/g) (Anaspec, San Jose, CA) using a PS3 peptide synthesizer (Protein Technologies, Phoenix, AZ). Upon completion of coupling, the IGF1 mimetic peptide was cyclized via disulfide bond formation while still on the solid phase support by oxidation with a 10-fold excess of I_2 in $(Me)_2NCHO$ as previously described (*28*). The IGF1 mimetic peptide was then cleaved from its resin using 98% CF_3CO_2H/2% *m*-cresol, followed by reverse-phase HPLC purification on a Microsorb 300 Å pore, 10 μm particle, 10 × 250 mm C_{18} column (Varian, Inc., Palo Alto, CA) eluted with a 40 min gradient from 65% to 100% CH_3CN in aqueous 0.1% CF_3CO_2H at 2 mL/min, at 23 °C, on a SCL-10Avp liquid chromatograph (Shimadzu, Columbia MD) monitored at 260 nm.

The crude product was analyzed by MALDI-TOF mass spectroscopy from an α-cyano-hydroxycinnamic acid matrix excited at 338 nm on a SELDI mass spectrometer (Ciphergen Corp., Fremont, CA) calibrated with porcine neuropeptide Y (Sigma, St. Louis, MO). During cleavage from the resin, the β-TBDMS group of D-Ser(TBDMS) and the ϵ-Mtt group of D-Lys(Mtt) were lost (calculated, 716.8 Da; observed, 716.7 Da). The D-Lys side chain ϵ-NH_2 was then protected again by reaction with FmocOSu (*29*) to yield Fmoc-D-[Cys-Ser-Lys (Fmoc)-Cys]-Gly. Typically, purified Fmoc-D-[Cys-Ser-Lys-Cys]-Gly (1 mg) was dissolved in 50:50 CH_3CN/H_2O (1 mL)

Scheme 1. Synthetic Route to the IGF1 Peptide Mimetic D-(Cys-Ser-Lys-Cys)-Gly and Its Conjugation To the H_2N-Hx-*IRS1* RNA Sense Strand

with 5 equiv FmocOSu (2.35 mg) and 1 equiv iPr_2EtN (0.13 μL). The reaction was followed by subsequent reverse-phase HPLC purification as above to determine the completion time, 15 h. The D-Ser side chain β-OH was not reprotected because it was not likely to compete significantly with the D-Lys side chain ϵ-NH_2 in the succinimidylation reaction.

***IRS1* siRNA.** The *IRS1* siRNA sequence 5′-pCCACGGCGAUCUAGUGCUUUU-3′ was previously found effective and characterized biologically in MCF7 cells (*14*). The three-base mismatch control sequence was 5′-CCACGGCG *GAA* UAGUGCUU-3′. In this study, however, the RNA strands were synthesized with Dharmacon (Lafayette, CO) siSTABLE modifications, which are consistent by MALDI-TOF mass spectroscopy with 2′-O-methyl groups on 11 residues, as well as with 2′-ACE[1] protecting groups to keep the RNA stable until after annealing. The 3′ end of the antisense strand also was modified

to include the red fluorescent dye DY547. Finally, the 5′ end of the sense strand was modified to include an H_2N-Hx linker that would permit conjugation to the IGF1 peptide mimetic. A separate siSTABLE *IRS1* siRNA with 5′-sense strand cholesterol and 3′-antisense DY547 was utilized as a positive control, based on a published study with an *APOB* siRNA cholesterol conjugate (*21*). The *IRS1* siRNA sequence and three-base mismatch sequence were analyzed with the *BLASTn* program and found to have no significant homology to other human genes.

Conjugation of IGF1 Peptide to siRNA. Conjugation of Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly to *IRS1* siRNA was achieved in a two-step reaction. First, the Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly C-terminal carboxylate was converted to an NHS ester with 5 equiv of DCC and 5 equiv of NHS to peptide. Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly (300 μg) was dissolved in EtOAc (150 μL), followed by stepwise addition of DCC (330 μg) and NHS (184 μg) stepwise addition at 0 °C on ice, then allowed to reach room temperature and continuously stirred for 48 h. Following the reaction, a white precipitate of DCU was filtered off; Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS ester was concentrated by centrifugal lyophilization and redissolved in Me_2SO.

The reactivity of the Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS ester was tested by reacting 50 μg dissolved in 8 μL Me_2SO, 2 μL 100 mM Na_2HBO_3, pH 8.5, with the free terminal amine on 500 μg AEEA (100 equiv relative to Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS) at room temperature overnight. The products were analyzed by TLC on silica gel plates developed with 60% hexane/40% EtOAc, imaged with ultraviolet light. The migration standards used were Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS ester (Rf 0.40), Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly (Rf 0.38), and AEEA (Rf 0.10).

A parallel test of H_2N-Hx-*IRS1* RNA (20 μg) reactivity with AlexaFluor-532 NHS ester (40 μg, 40 equiv) was carried out in the same solvent mixture as above at room temperature overnight. Reaction products were analyzed by nondenaturing electrophoresis on a 20% polyacrylamide gel in TBE. Bands were visualized by ultraviolet illumination on a 2000R imaging station (Kodak, Rochester, NY).

Conjugation of sense 5′-H_2N-Hx-*IRS1* RNA and Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS was carried out in 80% Me_2SO/20% H_2O (10 μL) to keep both moieties in solution simultaneously (*30*). Sense 5′-H_2N-Hx-*IRS1* RNA (20 μg) was dried by centrifugal lyophilization prior to reaction and resuspended in 2 μL of 100 mM Na_2HBO_3, pH 8.5. Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS (270 μg, 100 equiv relative to sense 5′-H_2N-Hx-*IRS1* RNA) dissolved in 8 μL Me_2SO was added. The reaction was stirred at room temperature overnight. Fmoc protecting groups on the peptide were then removed by the addition of 40 μL of concentrated (28 M) NH_4OH, bringing the total volume to 50 μL. The mixture was reacted at 23 °C for 1.5 h with continuous stirring, followed immediately by addition of another 100 μL of concentrated (28 M) NH_4OH and another 1.5 h incubation at 23 °C, with continuous stirring. NH_3 was then removed by centrifugal lyophilization. D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* RNA was precipitated by addition of 1.5 μL of 10 mg/mL glycogen stock solution as a carrier, followed by 2.5 volumes of EtOH. The mixture was chilled at −20 °C overnight, then sedimentated at 15 000 *g* for 30 min at 4 °C.

Annealing of purified D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* RNA (25 μM) to the antisense-DY547 strand (25 μM) (or 3 mismatch-DY547 strand) with simultaneous removal of RNA 2′-ACE protecting groups was carried out in 2′-O-deprotection buffer (100 mM TEMED–HOAc, pH 3.8) for 45 min at 60 °C followed by cooling at room temperature for 30 min (Dharmacon RNAi Tech. Ref. & App. Guide). Next, the annealed, deprotected D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* RNA was evaporated to dryness and resuspended in H_2O. Concentration was determined by ultraviolet absorbance at 260 nm. Steps from annealing forward were repeated for an *IRS1* siRNA unconju-

ence; siRNA, short interfering RNA; TAM, tamoxifen; TBE, Tris-borate-EDTA; TBDMS, *t*-butyldimethylsilyl.

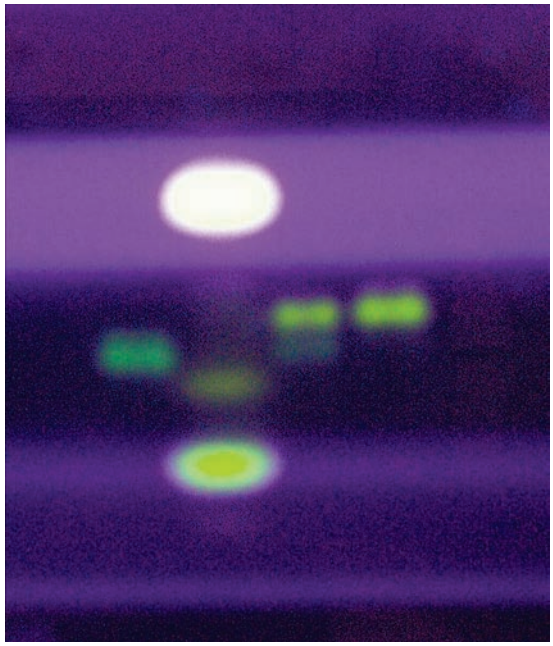

Figure 2. Test of H_2N-Hx-*IRS1* RNA reactivity with AlexaFluor 532-NHS ester. TBE 20% PAGE ran with 250 ng of sample per lane. Lanes from left to right are as follows: 1, H_2N-Hx-*IRS1* RNA alone; 2, AlexaFluor 532-NHS ester alone; 3, H_2N-Hx-*IRS1* RNA reacted with AlexaFluor 532-NHS ester in 80% Me_2SO/20% H_2O with DMAP buffer; 4, H_2N-Hx-*IRS1* RNA reacted with AlexaFluor 532-NHS ester in 80% Me_2SO/20% H_2O with Na_2HBO_3 buffer.

gated control lacking D-(Cys-Ser-Lys-Cys). The extent of annealing was analyzed by native 20% polyacrylamide gel electrophoresis in TBE, followed by staining with Sybr Green II (Molecular Probes, Eugene, OR) and fluorescence observation on a 2000R imaging station (Kodak, Rochester, NY).

Cellular Uptake of siRNA in MCF7 (ER+) Breast Cancer Cells. MCF7 (ATCC, Germantown MD) human breast ER+ epithelial cells were grown in DMEM/F12 medium (Mediatech, Herndon, VA) supplemented with 5% calf serum, 50 U/mL penicillin, 5 μg/mL streptomycin, 2 mM glutamine, and 10 nM 17-β-estradiol under 5% CO_2 in a humidified incubator at 37 °C. MCF7 cells were detached from their flasks with 0.02% EDTA solution (Sigma, St. Louis, MO) and plated 24 h prior to treatment in LabTek 8-well chamber slides (Nalge Nunc International, Naperville, IL) at a concentration of 1.5×10^4 cells/well, such that cells were ~70% confluent at the time of treatment. The cells were then treated for 6 h at 37 °C with D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA-DY547, cholesteryl-*IRS1*siRNA-DY547, or unconjugated *IRS1* siRNA-DY547, premixed at a final concentration of 1 μM in culture medium. For peptide blocking by human recombinant IGF1 (PeproTech, Rocky Hill, NJ), the culture medium was replaced with serum-free DMEM (Life Technologies, Inc.) containing 0.1% bovine serum albumin, 50 μg/mL holo-transferrin 100 U/mL penicillin, 10 μg/mL streptomycin, 2 mM glutamine, and 10 nM 17-β-estradiol to prevent proteolysis of IGF1, which was added to 10 μM. After 10 min of preblocking, D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* RNA was added to 1 μM as above, and also to a nonblocked serum-free control well, followed by incubation for 6 h at 37 °C. At the end of the uptake period, the cells were washed with serum-free medium to remove fluorescent siRNA probes. Cells were then observed on a CK40 fluorescence microscope (Olympus, Center Valley, PA) with a SPOT color digital camera at 600× magnification through a red filter suitable for the DY547 dye. Uptake images were collected in real time and displayed with *Image Pro Plus 4.5*.

Quantitative Real-Time PCR (QRT-PCR). Quantitation of *IRS1* mRNA levels in treated MCF7 cells was carried out as described previously (*14*). The *IRS1* siRNA forward primer was 5′-CTCCACCTCGGATTGTCTCTTC-3′, the reverse primer was 5′-GAAACCGCCATCGCTGG-3′, and the fluorescent probe was 5′-6FAM-CACGGCGATCTAGTGCTTCGGTGTC-TAMRA-3′. The expression of the endogenous control gene GAPDH was assessed using a premade primer probe set (Applied Biosystems, Foster City, CA).

Western Immunoblot Analysis. At 4 days after siRNA administration, plates were lysed in 50 mM HEPES–KOH, pH 7.5, 150 mM NaCl, 1.5 mM $MgCl_2$, 10 mM EGTA, pH 7.5, 10% glycerin, 1% Triton X-100 with a Complete Mini protease inhibitor cocktail tablet (Roche Applied Science, Piscataway, NJ). Cytoplasmic lysates were electrophoresed on NuPAGE 10% Bis–Tris gels (Invitrogen, San Diego, CA). Antibodies used were anti-IRS-1 (Santa Cruz Biotechnology, Santa Cruz, CA) and anti-GAPDH (Ambion, Austin, TX). The substrate for HRP-conjugated secondary antibodies was SuperSignal West Femto (Pierce, Rockford, IL). Detection and quantitation of protein bands were conducted with a 2000R Image Station (Kodak, Rochester, NY).

Cell Viability Assays. Once stained with 0.4% Trypan blue solution (Mediatech, Herndon, VA) to measure viability, the percentage of dead MCF7 cells from pooled adherent and floating cells was determined by direct cell counting using a hemacytometer. At least 400 cells were counted with each experimental condition performed in triplicate. For the MTT viability assay (Chemicon, Temecula, CA), siRNA treatments were scaled for 96-well plates and assayed colorimetrically according to the manufacturer's instructions at 570 nm vs 630 nm using a μQuant plate reader (Bio-Tek, Winooski, VT), with data collected and analyzed by *KCjunior 1.22*.

RESULTS

IGF1 Peptide Mimetic Synthesis and Purification. In order to synthesize the IGF1 peptide mimetic D-(Cys-Ser-Lys-Cys)-Gly, we used solid-phase peptide synthesis carried out from C-terminus to N-terminus. Following coupling, the D-cysteines were cyclized, the peptide was cleaved from the resin, an initial reverse phase HPLC purification and Fmoc reprotection of D-lysine side chain ϵ-NH_2 was completed, and then finally a second round of purification was performed by reverse-phase HPLC. An analytical chromatogram of this final purified peptide is shown in Figure 1A. The mass of the purified Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly was measured by MALDI-TOF mass spectroscopy and is displayed in Figure 1B: calculated 939.4 Da, observed 939.1 Da.

Reactivity of the IGF1 Peptide and of the H_2N-Hx-*IRS1* RNA Sense Strand. The C-terminal carboxyl group of Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly must first be activated in order for the amino terminus of the H_2N-H_2N-Hx-*IRS1* RNA Hx-*IRS1* RNA sense strand to attack the Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys] C-terminal carboxylate (*31*). Therefore, we reacted Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly with DCC and NHS to form a Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS ester that would be stable longer than using a carbodiimide alone for an active intermediate.

Prior to conjugation of Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS ester to the H_2N-Hx-*IRS1* RNA sense strand, the reactivity of each was confirmed independently. We tested the reactivity of the Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS ester with that of the free terminal amine on AEEA. TLC showed no Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS ester or Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly in the reaction mixture lane, compared with known lanes. There was, however, a product with higher mobility (Rf 0.92) consistent with the

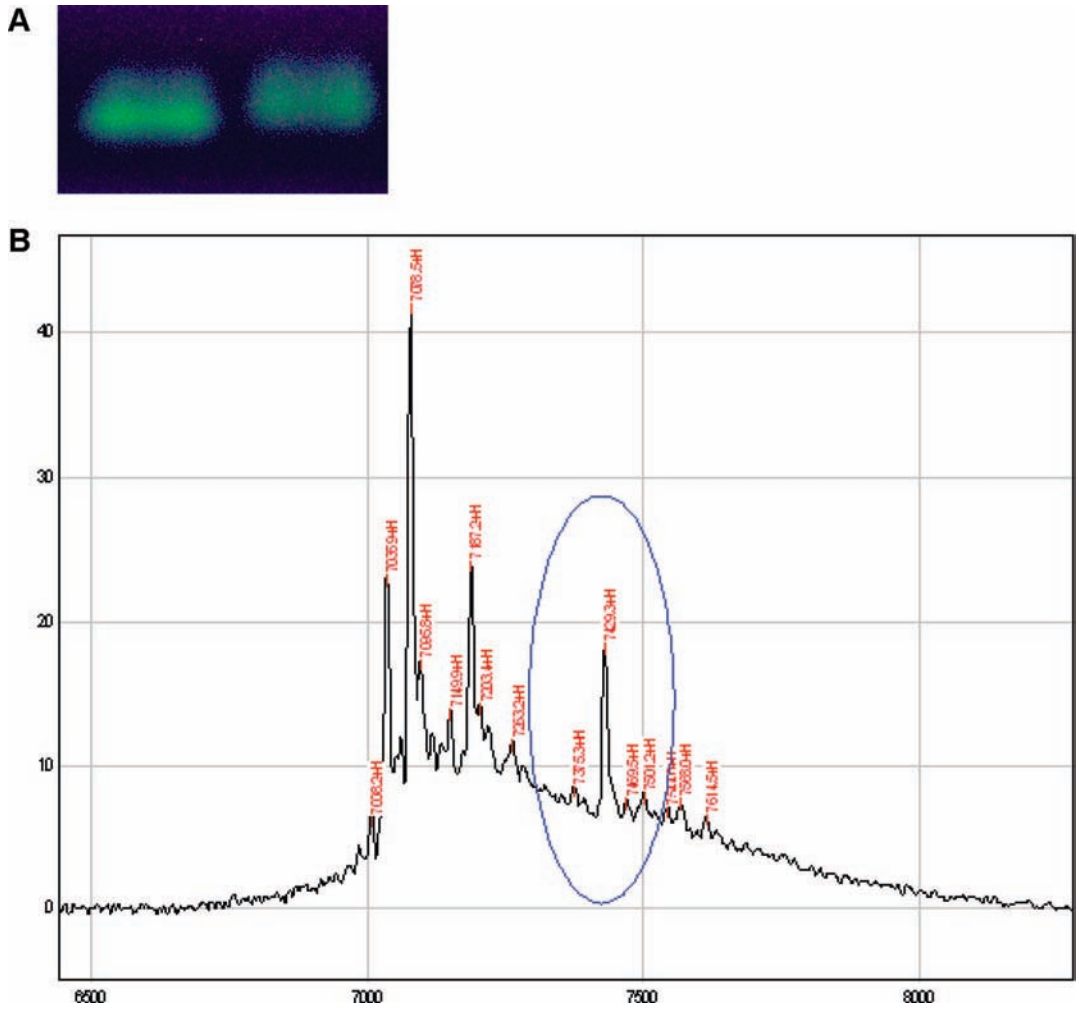

Figure 3. Conjugation of H_2N-Hx-*IRS1* RNA to IGF1 peptide Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly. A. TBE 20% PAGE where left lane is H_2N-Hx-*IRS1* RNA alone unreacted, and right lane is H_2N-Hx-*IRS1* RNA plus Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS ester after reaction and subsequent precipitation. A small shift was observed in the reaction lane as compared to unreacted H_2N-Hx-*IRS1* RNA. B. MALDI-TOF mass spectroscopy of Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly HN-Hx-*IRS1* siRNA. Calculated 7431 Da; observed 7429.3 Da.

predicted Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly AEEA conjugation product, which would be more hydrophobic than either starting material. Because no spots were observed at the Rf of the peptide or peptide–NHS alone, it appeared that all peptide–NHS present in the test reaction was conjugated to peptide–AEEA.

Next, we tested the reactivity of the H_2N-Hx-*IRS1* RNA sense strand with that of a commercially available AlexaFluor 532-NHS ester. Using a fluorescent dye allowed for easy observation of reactivity as well as completeness of reactivity following the reaction due to differential fluorescence intensities and colors upon PAGE analysis (Figure 2). One can observe partial reactivity in the lane where DMAP (pH 8.6) was used as the buffer (orange and green bands) and nearly complete reactivity in the lane where Na_2HBO_3 (pH 8.5) was used as the buffer (orange band only). These separate reactivity tests, plus further optimization trials, formed the basis for optimal conjugation of the Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS ester to the 5′-NH_2-Hx-*IRS1* RNA-3′ sense strand.

Conjugation of IGF1 Peptide to H_2N-Hx-*IRS1* RNA Sense Strand. Following confirmation of individual component reactivities, we then conjugated the H_2N-Hx-*IRS1* RNA sense strand to the Fmoc-D-[Cys-Ser-Lys(Fmoc)-Cys]-Gly NHS ester. A clear upward gel mobility shift of the H_2N-Hx-*IRS1* RNA sense strand band was observed when the reacted RNA was compared to the unreacted RNA by 20% TBE PAGE (Figure 3A). Following the conjugation reaction, cleavage of peptide Fmoc-protecting groups, and precipitation, the molecular mass of the conjugated D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* RNA was measured by MALDI-TOF mass spectroscopy (Figure 3B): calculated 7431.0 Da, observed 7429.3 Da. Annealing yielded only a single significant duplex band upon nondenaturing PAGE (Figure 4), obviating the need for preparative gel electrophoresis.

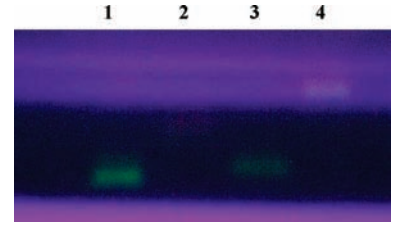

Figure 4. Native 20% polyacrylamide gel electrophoresis in TBE of D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA duplex. 250 ng of RNA was loaded on each lane. Lane 1, H_2N-Hx-*IRS1* sense RNA; lane 2, *IRS1* antisense RNA-DY547; lane 3, D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* sense RNA; lane 4, annealed duplex. Following TBE PAGE, the gel was stained with Sybr Green II and observed on a Kodak 2000R imaging station.

MCF7 Cellular Uptake of Conjugated siRNAs. The cellular uptake of the D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA duplex by human MCF7 ER+ breast cancer cells that express high levels of IGF1R was measured by fluorescence microscopy

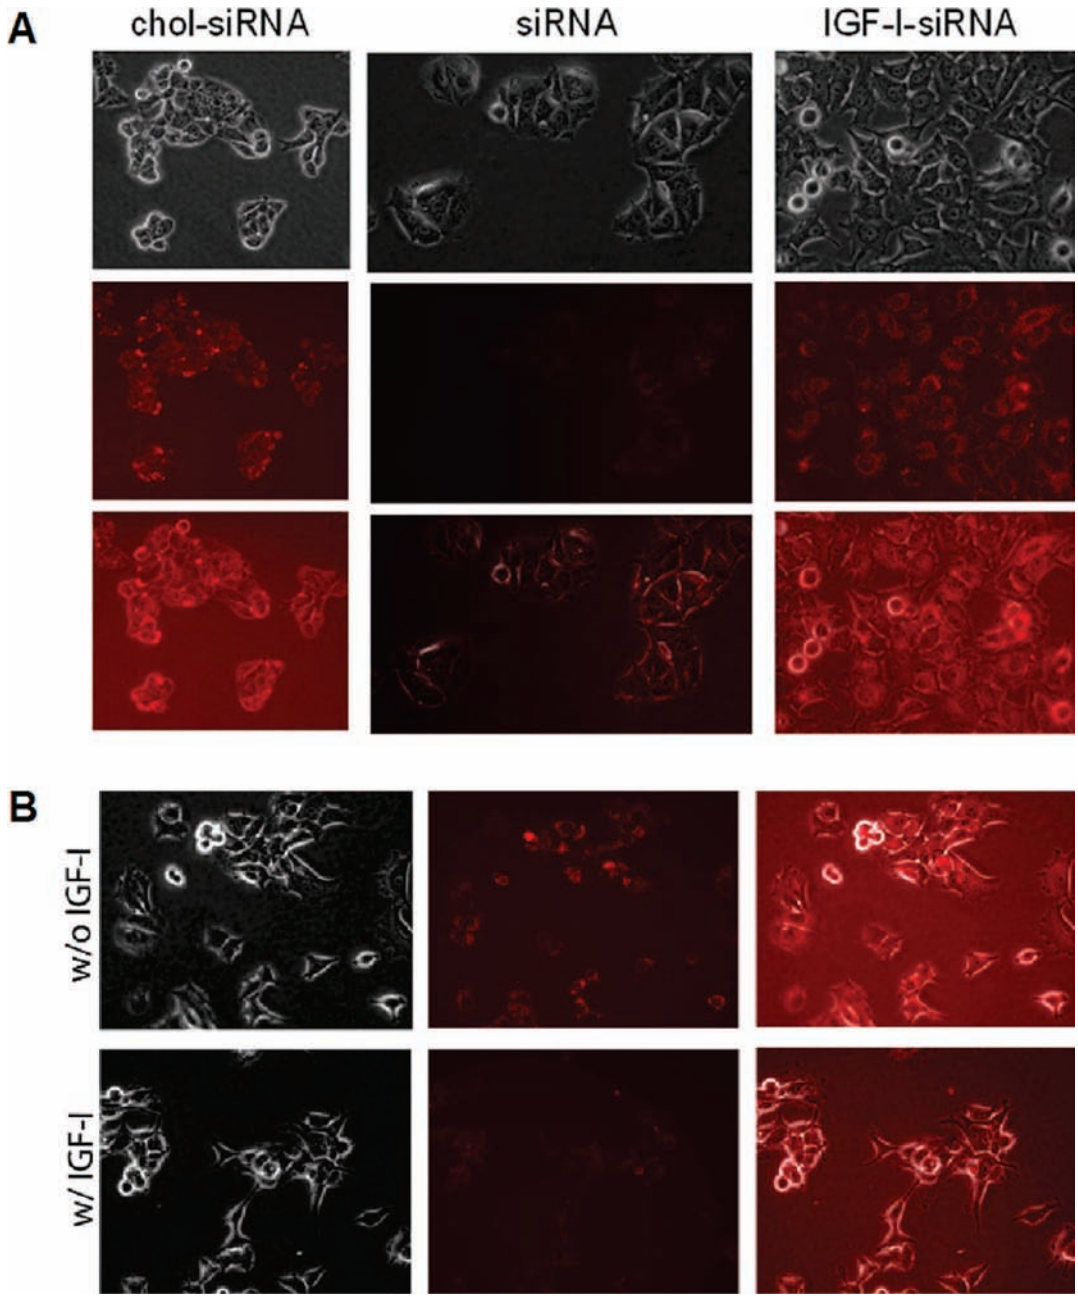

Figure 5. Internalization of siRNA conjugates by human MCF7 ER+ breast cancer cells. A. Cellular uptake of 1 μM cholesteryl–*IRS1* siRNA, D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA, or unconjugated *IRS1* siRNA, after 6 h. B. Cellular uptake in the absence of serum of 1 μM D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA after 4 h with or without exogenous full-size recombinant IGF1, 10 μM, added 10 min prior to siRNA.

after 6 h of incubation (Figure 5A). The D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA and the cholesteryl–*IRS1* siRNA displayed comparable uptake, whereas the unconjugated *IRS1*siRNA was found to have minimal uptake. Preblocking of MCF7 cells with 10 μM full-size IGF1 reduced the uptake of D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA to the level of the unconjugated *IRS1* siRNA (Figure 5B).

Knockdown Efficacy of Conjugated siRNAs. *IRS1* mRNA levels in treated human MCF7 ER+ breast cancer cells were measured by QRT-PCR over a range of siRNA concentrations (100, 150, 200 nM) (Figure 6A). D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-anti-*IRS1* siRNA lowered the level of *IRS1* mRNA significantly, more and more as the dose increased (55.8 $\pm$ 9.3% at 100 nM, 41.4 $\pm$ 5.4% at 150 nM, 35.8 + 12.7% at 200 nM, relative to untreated). The cholesteryl–anti-*IRS1* siRNA, on the other hand, displayed equal knockdown of *IRS1* mRNA at all three doses. The D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-mismatch siRNA control did not lower *IRS1* mRNA (97.9 $\pm$ 2.7%, 92.4 $\pm$ 14%, 103.9 $\pm$ 1.2% relative to untreated), nor did unconjugated *IRS1* siRNA (100.0 $\pm$ 1.0%, 100.5 $\pm$ 12.9%, 107.4 $\pm$ 19.0% relative to untreated). Mock controls where no siRNA was added also showed no change in *IRS1* mRNA.

IRS-1 protein levels in treated human MCF7 ER+ breast cancer cells were measured by Western blotting (Figure 6B), using the highest treatment concentration (200 nM) tested by QRT-PCR, since no apparent cytotoxic effect was observed, based on negligible change by the D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-mismatch siRNA. Significant IRS-1 protein knockdown was observed when MCF7 cells were treated with D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA (57.2 $\pm$ 22.8% relative to untreated) or cholesteryl–*IRS1* siRNA (46.1 $\pm$ 2.6% relative to untreated) as compared to nonsignificant knockdown when cells were treated with D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-mismatch siRNA (92.4 $\pm$ 3.3% relative to untreated) and minimal

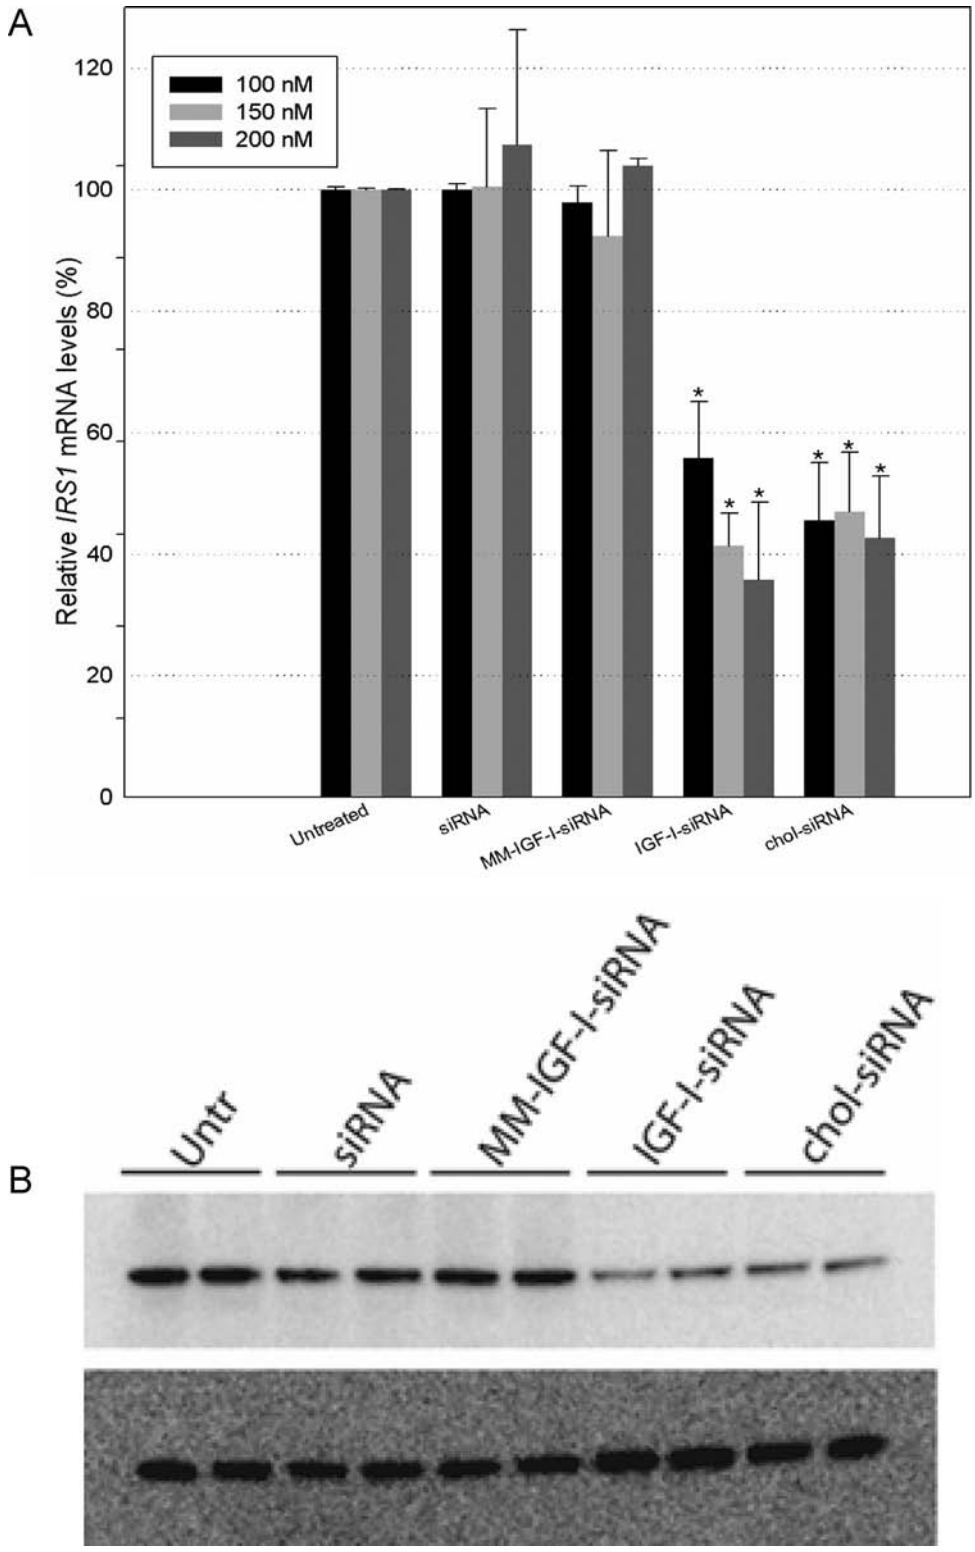

Figure 6. Knockdown efficacy in human MCF7 ER+ breast cancer cells treated with siRNA conjugates. A. QRT-PCR analysis of *IRS1* mRNA levels. Three concentrations of siRNA were tested in MCF7 cells, where total RNA was purified 24 h post-siRNA treatment. Each bar represents the percentage of *IRS1* mRNA expression ± standard deviation relative to untreated cells. * indicates $p < 0.05$ with respect to untreated MCF7 cells. B. Western blot analysis of IRS-1 protein knockdown by 200 nM siRNA of MCF7 cells. Protein was analyzed at a 96 h time point. Expression of IRS-1 was assessed by loading 40 μg of cytoplasmic protein lysate per lane, with the expression of a cytoplasmic enzyme, GAPDH, probed as a loading control following IRS-1 probing and stripping of the blot.

knockdown by unconjugated *IRS1* siRNA (83.6 ± 5.9% relative to untreated).

Viability Following siRNA Treatment Alone or in Combination with TAM. The reasoning behind targeting IRS-1 in breast cancer lies in the previously observed IRS-1 overexpression that correlated with poorer prognosis (*32*) along with estrogen independence (*33*). The IRS-1 phosphorylation level was reduced, causing reduced PI3K activity, with the antiestrogen tamoxifen (*34*). Therefore, we assayed the survival of human MCF7 ER+ breast cancer cells treated with siRNA alone

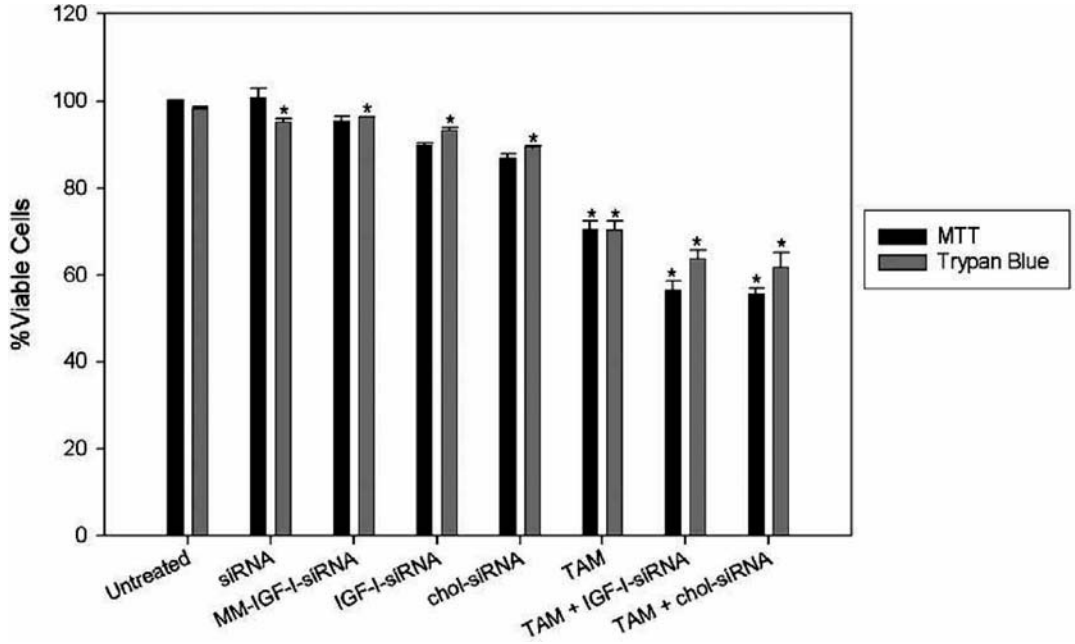

Figure 7. Cell viability of human MCF7 ER+ breast cancer cells following siRNA treatment alone or in combination with the antiestrogen TAM. Percentage of cell death in MCF7 cells after 96 h with a minimum of 400 cells counted for Trypan blue assay. The absorbance was read at 570 nm vs. 630 nm for the MTT assay. Treatment conditions noted on Y-axis. Each bar represents the percentage of viable cells ± standard deviation relative to untreated cells. * indicates $p < 0.05$ with respect to untreated MCF7 cells.

or in combination with TAM, determined by Trypan blue viability staining and the MTT assay (Figure 5B). The decrease in viability for MCF7 cells treated with D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA (7.7 ± 0.6% by Trypan blue; 10.1 ± 0.5% MTT) was observed to be similar but slightly less than for the cholesteryl-*IRS1* siRNA (10.6 ± 0.3% by Trypan blue; 13.0 ± 0.9% by MTT). The measured decreases in viability are greater than twice the control levels for unconjugated *IRS1* siRNA (4.8 ± 0.7% by Trypan blue; 0% by MTT) or D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-mismatch siRNA (3.7 ± 0.1% by Trypan blue; 4.6 ± 1.1% by MTT). The decreases in viability were similar when TAM treatment alone (29.6 ± 2.0% by Trypan blue; 29.4 ± 1.8% by MTT) was combined with D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA (37.1 ± 1.8% by Trypan blue; 43.4 ± 2.2% by MTT) or combined with cholesteryl–*IRS1* siRNA (39.2 ± 3.5% by Trypan blue; 44.3 ± 1.3% by MTT).

DISCUSSION

In this study, we tested the hypothesis that conjugation of an siRNA to a cell-targeting ligand, an IGF1 peptide mimetic, would enable cell-specific, receptor-mediated endocytosis and activity of siRNA, without resorting to cationic lipids or electroporation, or a ligand such as cholesterol that directs siRNA uptake by all cells nonspecifically. Other larger versions of the IGF1 ligand were originally utilized to inhibit cancer cells (*25, 35*). We have utilized a smaller disulfide bridged version, D-(Cys-Ser-Lys-Cys), in previous work with PNA radiohybridization probes (*27*).

In this case, the peptide was extended from an HMP-Tentagel resin in order to yield a free C-terminal carboxylate after cleavage. In order to activate the C-terminal carboxylate of D-(Cys-Ser-Lys-Cys)-Gly for attack by the primary amine of the NH_2-Hx-*IRS1* RNA sense strand, the peptide was converted to an NHS ester. 100-fold excesses of peptide–NHS ester were necessary for complete conjugation of the NH_2-Hx-*IRS1* RNA sense strand. During the conjugation, hydrolysis of the NHS ester occurs simultaneously, leading to the need for more equivalents of peptide–NHS ester, compared to the case of NH_2-Hx-*IRS1* RNA conjugation to AlexaFluor 532-NHS ester. Perhaps the commercially obtained AlexaFluor 532-NHS ester was more stable than our IGF1 peptide–NHS ester. It is possible that electron withdrawal by the peptide from the ester linkage enhanced the partial positive charge on the carbonyl carbon, relative to the corresponding alkyl carbonyl carbon in AlexaFluor 532-NHS ester. In reactions utilizing EDC (aqueous) or DCC (organic) coupling reagents, there is a rate of breakdown of the temporary acid anhydride intermediate back to free carboxylates, as well as the effects of pH controlling the rate of hydrolysis (*31*). In this case, pH must be set to balance base-catalyzed ester hydrolysis vs unprotonated NH_2-Hx-*IRS1* RNA attack on the ester.

Upon biological analysis of the siRNA conjugates, we observed cellular uptake in human MCF7 ER+ breast cancer cells. Uptake of the cholesteryl–*IRS1* siRNA and the D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA was comparable, while unconjugated *IRS1* siRNA showed only a small amount of uptake. siRNA can be taken up into cells independently given ample time, due to the presence of dsRNA-specific receptors, such as TLR3 (*36*). The amount of siRNA taken up in the absence of any other agents was found to be 50 copies per cell when siRNA concentration was 200 nM and cells were incubated with siRNA for 16 h (*37*). If the cellular uptake experiments performed here were extended to a longer time than 6 h, then it may be predicted that the siRNA alone would have been taken up in greater amounts.

When the activity of siRNAs in human MCF7 ER+ breast cancer cells was tested at 100, 150, and 200 nM by QRT-PCR, we observed comparable activity in *IRS1* mRNA knockdown by D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA and cholesteryl–*IRS1* siRNA. Previous observations have shown that there is a limited capacity to assemble RISC on exogenous siRNA, so that increasing amounts of siRNA beyond saturation will not produce a corresponding increase in RISC activity (*38*). Our dose response likely illustrated this phenomenon. Increasing our siRNA treatment concentrations beyond 200 nM would most likely lead to sequence-independent effects (*39, 40*).

Given that the unconjugated *IRS1* siRNA or the D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-mismatch siRNA were observed to show

negligible change up to 200 nM, that concentration was used for protein analysis and the MCF7 cell viability assays. IRS-1 protein knockdown was matched to viability by the Trypan blue exclusion assay. We observed high variability in D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA protein knockdown between independent experiments, which may reflect varied efficiency among separate preparations of D-(Cys-Ser-Lys-Cys)-Gly HN-Hx-*IRS1* siRNA. Separately, an MTT assay was utilized as a second method to detect viability. It was apparent that levels of *IRS1* mRNA and IRS-1 protein knockdown, as well as reduced viability, were not as great compared to our previous work using a cationic lipid transfection reagent at 100 nM *IRS1* siRNA (*14*). Modifications made to stabilize siRNA in the presence of serum, as used here, can reduce silencing efficiency compared to unmodified siRNA (*41*). Therefore, it can be assumed that further improvements in the IGF1 peptide mimetic (*25*) for greater internalization, improvements to the conjugation process, a more potent siRNA sequence, or other RNA stabilization modifications for *in vivo* stability are possible.

Nevertheless, we have taken the first step in converting an siRNA into a pharmacologically active agent designed to be specific for human ER+ breast cancer cells that overexpress IGF1R protein and the IGF1R signaling oncogene *IRS1*. However, there are other types of cancer that show overexpression of IGF1R (*42*) and therefore may also benefit from the use of an siRNA against *IRS1*, or another target oncogene of choice, conjugated to an IGF1 peptide mimetic. Still other cancers could be targeted with siRNAs conjugated to different ligand mimetics that target different overexpressed receptors. The conjugation method described above can be generalized to fit both ligand and siRNA targets of choice.

Synthesis and Biosensor Performance of a Near-IR Thiol-Reactive Fluorophore Based on Benzothiazolium Squaraine

Joseph Thomas,* Douglas B. Sherman, Terry J. Amiss, Sandra A. Andaluz, and J. Bruce Pitner*

BD Technologies, 21 Davis Drive, Research Triangle Park, North Carolina 27709. Received April 24, 2007; Revised Manuscript Received June 29, 2007

Environmentally sensitive near-IR (NIR) dyes are useful fluorophores for various biosensor applications when tissue absorption, scattering, and autofluorescence are a leading concern. Biosensors operating in the NIR region (generally wavelengths >650 nm) would avoid interference from biological media and thereby facilitate relatively interference free sensing. Squaraine dyes are potential candidates to serve as reporter molecules due to their spectral properties in the NIR region, but none is commercially available for site-specific coupling to proteins through native or engineered thiols on cysteine. In this context, we have synthesized a thiol-reactive squaraine that displays fluorescence emission above 650 nm and have coupled the dye site-specifically to various mutants of glucose/galactose binding protein that contained an engineered cysteine for attachment. Mutant E149C/A213R/L238S ISQ GGBP gave a fluorescence change of +50% and a binding constant of 12 mM, which is in the human physiological range for glucose.

INTRODUCTION

Fluorescent dyes that emit in the near-infrared region have been long sought-after for biosensor development due to their specific advantages when operating in biological media. A unique feature that makes the near-IR (NIR) dyes attractive is that their spectral properties are generally independent from biological interferences, such as tissue autofluorescence and scattering. Biological interference is minimized in the 600–900 nm wavelength region (*1–4*). In order for the dye to qualify as a reporter molecule in a fluorescence-based sensor assay, at least one of the fluorescence properties, such as intensity, lifetime, or wavelength, should undergo a significant change in a variety of environments. However, the availability of such dyes is limited for a number of reasons, including poor photostability, solubility, and toxicity. Moreover, the design of these dyes is complicated, since the increased number of conjugated double bonds required to achieve the NIR spectral properties leads to destabilization of the structure.

Squaraines are a class of dyes that could potentially serve as reporter molecules for biosensors in the NIR region. Squaraines are 1,3-disubstituted squaric acid derivatives in which the substituents can be introduced through nucleophilic substitution reactions (*5*). The intense absorption of squaraine dyes arises from charge transfer transitions between the central cyclobutane ring and the oxygen moieties with a minor contribution from the substituents on either side (*6*). Dyes that undergo charge transfer transitions during electronic excitation are generally solvatochromic and environmentally sensitive (*7*). For example, bis(2,4,6-trihydroxy)phenylsquaraine has a fluorescence quantum yield of <0.002 in aqueous media and undergoes a 90-fold enhancement by microencapsulation within β-cyclodextrin (*8*). The fluorescence maximum of squaraine dyes can also be tuned from 550 to 850 nm by the choice of aromatic or heterocyclic substituents (*5, 9–12*). Although the stability of anilinic-type squaraines is limited in water due to reasons not yet identified, the dyes can be stabilized by replacing the anilinic moieties with other heterocycles such as indoles, benzimidazole, benzooxazole, pyrroles, and benzothiazole (*9, 13–16*).

Squaraine dyes are generally not soluble in water; however, they can be made soluble by the introduction of polar functional groups. Moreover, synthetic methods are sufficient to install structural modifications needed for bioconjugation. In a recent study, Oswald et al. modified squaraine dyes with amine-reactive *N*-hydroxysuccinimide (NHS) pendant groups (*1*) and attached these dyes on BSA and HSA proteins. The fluorescence quantum yields of the dyes increased from ca. 0.15 to 0.6–0.7 when attached to protein. The high fluorescence yield of these squaraines allowed measurements in whole blood at detection limits twice as low as alternate assays employing a cyanine-based dye. These studies indicate that squaraines are well-suited for use in implanted fluorescence biosensors.

Periplasmic binding proteins (PBPs) have been the subject of considerable research as reagentless biosensors (*17, 18*). PBPs are composed of two domains that are connected by a hinge, and the proteins undergo a large conformational change at the hinge when they bind their ligands between the two domains (*19, 20*). Attachment of environmentally sensitive fluorophores at engineered cysteines near the binding pocket provides a method to monitor ligand binding as the protein changes from an open, unliganded form to a closed, liganded form (*21–23*). Site-specific attachment also provides greater control of dye placement to maximize the fluorescence response. Nonspecific attachment through amine-reactive groups, such as NHS esters, can result in attachment of multiple dyes to the protein at sites that do not produce a useful response to the binding event (*24*).

We have previously reported the synthesis and biosensor performance of long-wavelength Nile Red derivatives that were conjugated to mutants of maltose binding protein (MBP) (*25*) and to galactose/glucose binding protein (GGBP) (*26*) and displayed fluorescence maxima in the 550–630 nm range. We have also examined the application of a thiol-reactive anilinic squaraine which had a fluorescence maximum near 675 nm when conjugated to GGBP mutants (*27*). Here, we describe the synthesis and biosensor performance of a thiol-reactive derivative of benzothiazolium-based squaraine that demonstrates sensitivity to changes in its environment above 650 nm in the

NIR wavelength range when conjugated to mutants of GGBP containing engineered cysteines.

EXPERIMENTAL PROCEDURES

Materials. Starting materials were products of Sigma-Aldrich unless otherwise indicated. *Eschericia coli* strain Sg13009 was used to prepare GGBP with site-selective cysteine mutations as previously reported (*28*). A Cary 50 Bio UV–vis spectrophotometer was used to record absorption spectra. Fluorescence responses were measured using a PTI QM-4/2003 SE spectrofluorimeter and are uncorrected. A Varian 400 MHz Mercury or Bruker (400 MHz) AMX 400 spectrometer was used to obtain NMR data. A Finnigan-MAT 212 (FAB) or a Sciex 150 Electrospray spectrometer was employed for mass spectral analyses.

Synthesis of ISQ (1). *Intermediate* **1c.** 2-Methylbenzothiazole (1 mM) **1a** and *N*-bromoethylphthalimide **1b** (1 mM) were heated in a round-bottom flask at 100 °C for 24 h. The resultant solids were isolated by filtration and purified by continuous washing with chloroform to obtain the intermediate **1c** in 80% yield. ^{1}H NMR (CD_3OD, TMS) δ ppm: 4.295 (t, CH_2, 2H), 4.871 (s, CH_3, 3H), 5.102 (t, CH_2, 2H), 7.680–7.760 (m, 2H, aromatic), 7.760–7.790 (m, aromatic, 4H), 8.14–8.17 (m, aromatic, 1H), 8.260–8.290 (m, aromatic, 1H). ^{13}C NMR (CD_3OD) δ ppm: 28.091, 35.198, 39.264, 115.946, 123.295, 124.262, 128.607, 129.501, 129.860, 131.574, 134.450, 134.681, 141.656, 168.018. Mol wt calcd for $C_{18}H_{15}N_2O_2S$ is 323 (M+), found 323 (FAB).

Intermediate **1g.** Dibutyl squarate **1e** was reacted with 3-ethyl-2-methyl-benzothiazolium iodide **1d** (1:1 ratio) in ethanol at reflux for 30 min. The reaction mixture was filtered while hot. An orange-colored solid **1f** crystallized out of the filtrate while cooling, which was separated, resuspended in ethanol, and treated with 40% NaOH solution under reflux. After 30 min, the contents were cooled and acidified with 2 N HCl (pH adjusted to 4.0). The product was extracted with chloroform to give intermediate **1g** (97% yield). ^{1}H NMR ($CDCl_3$, TMS) δ ppm: 1.385 (t, CH_3, 3H), 4.150 (q, CH_2, 2H), 5.379 (s, CH, 1H), 7.180–7.200 (m, aromatic, 2H), 7.360–7.400 (m, aromatic, 1H), 7.58–7.595 (d, aromatic, 1H). ^{13}C NMR (CD_3OD) δ ppm: 12.169, 47.836, 48.049, 48.261, 48.466, 48.679, 111.997, 122.958, 123.720, 126.599, 127.684, 141.326, 157.768, 173.967. Mol wt calcd for $C_{14}H_{11}NO_3S$ is 273 (M+), found 273 (FAB).

Intermediate **1h.** Intermediates **1c** and **1g** were reacted in a solvent mixture containing 1:1 (v/v) toluene and *n*-butanol. The reaction mixture was subjected to azeotropic distillation, and the water formed during the reaction was removed using a Dean–Stark trap. After 6 h, the reaction mixture was allowed to cool to room temperature, and the blue product was filtered out. Further purification was carried out using flash column chromatography over silica gel using methanol and chloroform (1:4 ratio) as eluent to obtain dye **1h** in 80% yield. ^{1}H NMR ($CDCl_3$, TMS) δ ppm: 1.439 (t, CH_3, 3H), 4.227 (t, CH_2, 2H), 4.380 (q, CH_2, 2H), 4.581 (t, CH_2, 2H), 6.140 (s, CH, 1H), 6.170 (s, CH, 1H), 7.070–7.823 (m, aromatic, 12H). ^{13}C NMR ($CDCl_3$) δ ppm: 13.122, 35.315, 42.641, 44.495, 104.910, 111.543, 112.686, 122.819, 123.801, 123.918, 124.988, 125.559, 126.424, 126.761, 127.720, 128.006, 128.175, 128.790, 131.648, 131.684, 134.571, 134.674, 134.849, 140.411, 140.550, 140.975, 168.040, 179.242. Mol wt calcd for $C_{32}H_{23}N_3O_4S_2$ is 577 (M+), found 577 (FAB).

Intermediate **1i.** The dye **1h** was dissolved in anhydrous methylene chloride and was treated with hydrazine monohydrate at room temperature. The deprotected squaraine dye precipitated from the reaction mixture and was isolated by filtration, followed by repeated washing with methylene chloride (56% yield). ^{1}H NMR (CD_3OD, TMS) δ ppm: 1.420 (t, CH_3, 3H), 3.780 (t, CH_2, 2H), 4.320 (q, CH_2, 2H), 4.520 (t, CH_2, 2H), 5.924 (s, CH, 1H), 5.964 (s, CH, 1H), 7.200–7.850 (m, aromatic, 8H). Mol wt calcd for $C_{24}H_{21}N_3O_2S_2$ is 447 (M+), found 447 (FAB).

Compound **1.** The intermediate dye **1i** was dissolved in anhydrous methylene chloride, and an equivalent amount of iodoacetic anhydride was added. The mixture was stirred for 3 h at room temperature, and the product was isolated by evaporation of the solvent to obtain the final dye **1**. Purification was carried out by repeated precipitation from hexane/methylene chloride and afforded the product in 48% yield. ^{1}H NMR (CD_3OD, TMS) δ ppm: 1.420 (t, CH_3, 3H), 3.900 (s, CH_2, 2H), 4.300 (q, CH_2, 2H), 4.450 (t, CH_2, 2H), 4.480 (t, CH_2, 2H), 5.820 (s, CH, 1H), 5.980 (s, CH, 1H), 7.200–8.200 (m, aromatic, 8H). Mol wt calcd for $C_{26}H_{22}IN_3O_3S_2$ is 615 (M+), found 615 (FAB).

Preparation of Dye–Protein Conjugates. Dithiothreitol (8 nmol) was added to a solution of GGBP mutant (4 nmol) in PBS (200 uL) in an Eppendorf tube. After mixing for 30 min on a Dynal rotamix (Dynal Inc., New Hyde Park, NY), ISQ (40 nmol) was added from a stock solution of dye in DMSO (approximately 1 mg in 100 uL DMSO). The Eppendorf tube was wrapped in aluminum foil, and mixing continued for 4 h at room temperature. The reaction mixture was purified using a NAP-5 size exclusion column using PBS (pH = 7.4) as the eluent (Amersham-Pharmacia, Uppsula, Sweden). The labeled protein eluted in the second (0.5 mL) fraction. Labeling efficiencies were generally on the order of 20%.

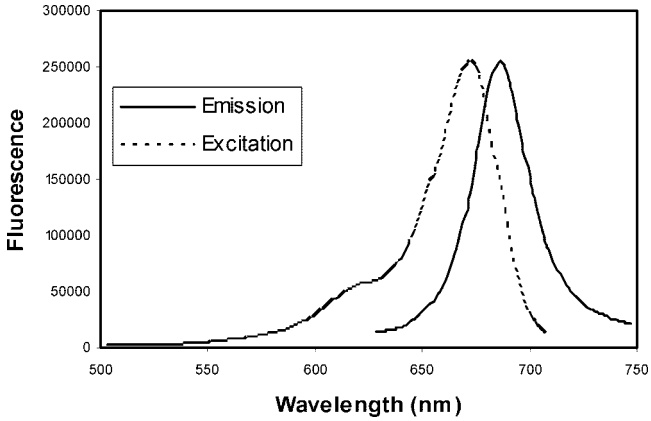
Fluorescence Measurements. The percent change in fluorescence (ΔF) was measured by the relative method using optically dilute solutions of the protein (~2 uM) in the absence and presence of 100 mM glucose unless otherwise noted. Excitation was at 600 nm and emission was measured from 625 to 725 nm. Binding constants were determined using methods as previously described (*26*), which take into account the amounts of labeled and unlabeled protein.

Molecular Modeling. A model of ISQ with methyl groups in place of the ethyl group and the linker was prepared in *Gaussian 98W* (*29*). Geometry optimization was performed using the semiempirical AM1 method, followed by optimization using HF/3-21G and HF/6-31G(d). Following optimization, frequency calculations were performed to confirm that the final geometry was at a stationary point on the potential energy surface. The resulting structure was imported into Sybyl (Tripos, St. Louis, MO) to complete construction of the full dye with linker.

The X-ray crystal structure of closed form *E. coli* GGBP was 2GBP (*30*) taken from the Protein Data Bank (*31*). The open form of GGBP was studied using a homology model created in-house using ribose binding protein (RBP) crystal structure 1URP (*32*) as a template (Sherman et al., unpublished results). The appropriate residues in the GGBP structures were modified to Cys, and the dye was then attached to model the bioconjugate. Genetic algorithm (GA) conformational searches were performed in Sybyl. For ISQ alone, the amide bond was fixed in the trans conformation, and the remaining 7 bonds were defined as rotatable. Default settings in the GA search were generally used with the duplicate window set to 10. For E149C/A213R/L238S ISQ GGBP, the number of rotatable bonds allowed was 14 total (7 in the dye linker, 5 in the A213R side chain, and 2 in the L238S side chain). The population size was increased from 100 to 500, and the number of generations was increased from 5,000 to 15,000. Up to 10 conformers per search were allowed within a 20 kcal/mol energy window.

RESULTS

Synthesis. The synthesis of ISQ (**1**), as shown in Scheme 1, was completed in a total of 6 steps. No base was used for the



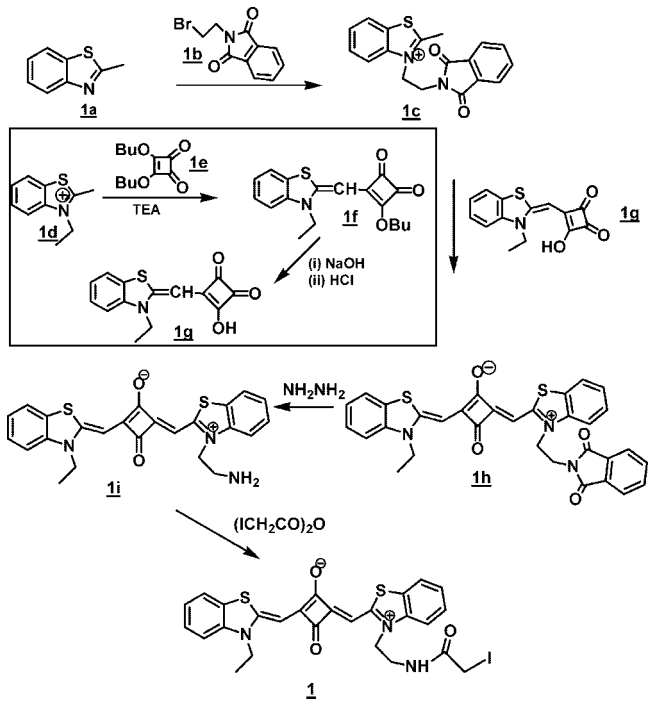


Figure 1. Absorbance and emission spectra of ISQ (**1**) in chloroform.

Scheme 1. Synthesis of ISQ (1)

condensation of **1c** with **1g**, as this reaction takes place spontaneously due to the highly nucleophilic nature of the CH_3 group of **1c**, owing to the presence of the quarternary nitrogen in the ring. The intermediates except for the final dye were purified by flash column chromatography using a mixture of methanol and chloroform with yields of 80% to 97%. The deprotection of the phthalimide group was accomplished using hydrazine in 50% yield. The final thiol-reactive version of the dye was formed under anhydrous conditions using iodoacetic anhydride in the presence of catalytic amounts of pyridine. Purification of the dye was carried out by repeated precipitation using methylene chloride and hexane with a yield of 48%.

Spetrophotometric Properties of ISQ. The excitation and emission spectra of ISQ (**1**) in chloroform is shown in Figure 1. The absorption maximum in chloroform was 680 nm, and it was 652 nm when the dye was attached to E149C GGBP in aqueous medium. The fluorescence maximum was 690 nm in chloroform and 665 nm for the dye–protein conjugate. ISQ (**1**) had a 10 nm Stokes shift in chloroform and a 13 nm shift when attached to the protein. The extinction coefficient was determined to be 51,100 M^{-1} cm^{-1} in chloroform.

Table 1. Summary of the Results for GGBP-NIR Dye Conjugates

GGBP mutation sites	ISQ ΔF^a ($K_d{}^b$, mM)
Y10C	−5
K11C	−5
D14C	−30
V19C	25
K92C	−5
Y107C	−25
T110C	−15
E149C	37 (0.005)
E149C/A213R/L238S	50 (12)
H152C	10
M182C	−14
W183C	17
N211C	−45
D236C	−10

[a] ΔF is the percentage of fluorescence change upon glucose binding by the protein. [b] K_d is the dissociation constant of the binding event expressed in terms of the concentration of glucose.

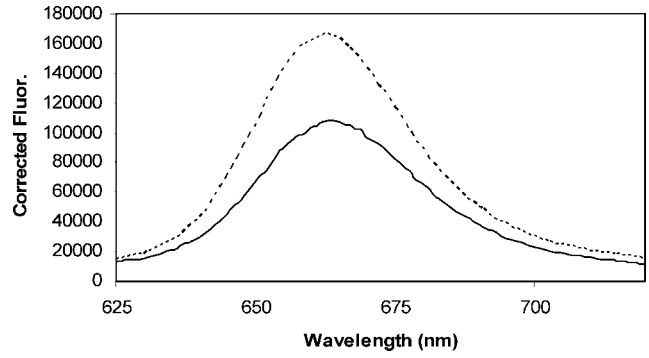

Figure 2. Fluorescence response of E149C/A213R/L238S ISQ GGBP in the absence (solid line) and presence (dotted line) of 200 mM glucose.

Biosensor Responses. ISQ (**1**) was conjugated to GGBP mutants that contained single cysteine mutations at the positions listed in Table 1. The largest changes observed for ISQ (**1**) were with the dye conjugated to D14C (−30%), E149C (37%), E149C/A213R/L238S (50%, Figure 2), and N211C (−45%). Binding constants (K_d) were determined for two of the ISQ-GGBP conjugates. These ranged from 5 uM for E149C-ISQ GGBP to 12 mM for E149C/A213R/L238S ISQ GGBP (Figure 3).

Modeling Analysis. Mutants D14C, K92C, N211C, and E149C/A213R/L238S GGBP were examined by genetic algorithm conformational searches with ISQ conjugated to the cysteine. Searches on the closed forms yielded a single conformation for all protein–dye conjugates except K92C, which produced six conformers that were very similar in dye–protein orientation. ISQ was expelled from the binding pocket and had significant solvent exposure with K92C and N211C (Figure 4a). Only the backbone carbonyl of residue D150 and the side chain of D69 were within 3.7 Å of the dye on K92C-ISQ. Similarly, on N211C-ISQ, only the backbone carbonyl of D13 and the side chain of D184 were within 2 Å of the dye. For D14C, the central four-membered ring of ISQ was within 3.2 Å of the carboxylate group of residue D184. In E149C/A213R/L238S ISQ GGBP (Figure 4c), the dye was parallel to the surface of the N-terminal domain in proximity to the side chains of N43 (3.2 Å), S46 (3.0 Å), D50 (3.8 Å), and T75 (3.5 Å).

The conformational searches on the open forms returned 10 conformers that were within 3 kcal/mol of one another for a given protein–dye conjugate. ISQ was placed inside the open binding pocket in D14C-ISQ approximately 5 Å from the rim of the C-terminal domain. In K92C-ISQ, the dye was solvent-

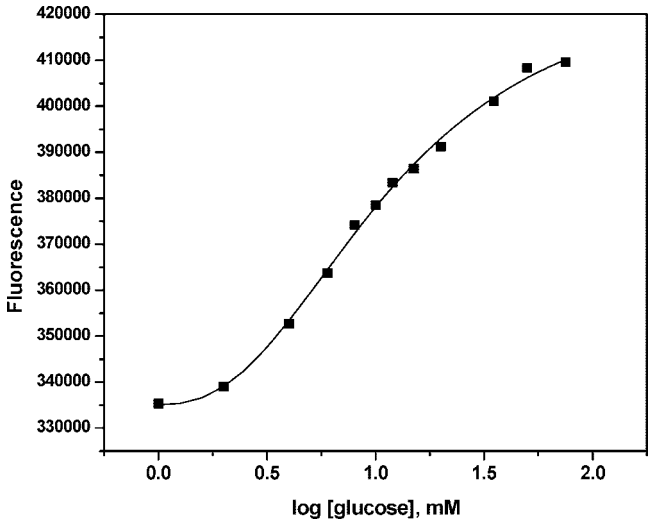

Figure 3. K_d determination for E149C/A213R/L238S ISQ GGBP yielded a 12 mM binding constant.

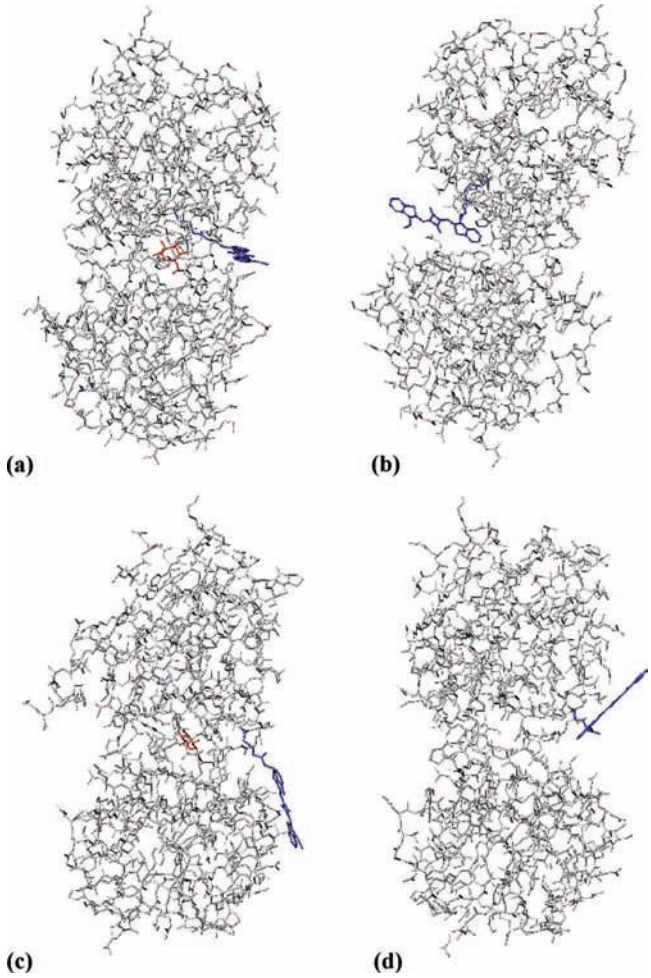

Figure 4. Representative conformers for ISQ attached to N211C GGBP (a and b) and to E149C/A213R/L238S GGBP (c and d). The closed protein conformations are on the left and the open forms on the right. Glucose is in red and the dye is in blue.

exposed or >4 Å from the rim of the binding pocket of the C-terminal domain. For N211C-ISQ, the benothiazolium ring containing the linker was located inside the binding pocket, while the remainder of the dye structure was solvent-exposed (Figure 4b). Finally, the dye in the conformers of E149C/A213R/L238S ISQ GGBP was solvent-exposed with only the side chain of residue Q187 within 3.7 Å of the dye (Figure 4d).

DISCUSSION

The squaraine dye was chosen due to its sharp absorption and fluorescence properties in the >600 nm region, which is highly sensitive to the environment. In general, the synthesis of ISQ (**1**) proceeded smoothly. Deprotection of the phthalimide in **1h** to form **1i** was first attempted using methylamine. This led to a half-protected species as identified by mass spectral and NMR analysis. Using hydrazine in place of methylamine resulted in a cleaner deprotection. In the final step to purify **1**, the high reactivity of the iodoacetamide group prevented purification using column chromatography; thus, the final product was obtained by repeated precipitation from hexane and methylene chloride.

The spectrophotometric properties of ISQ in chloroform and aqueous medium demonstrated the environmental sensitivity of the dye as well as the potential of ISQ for biosensor applications in the NIR region. The dye had Stokes shifts of ≥10 nm, and the absorption maxima in chloroform and aqueous medium were above 650 nm. The fluorescence maxima were also above 665 nm. In addition, ISQ showed remarkable fluorescence properties when conjugated to GGBP, demonstrating that the fluorescence response was significantly affected by the glucose binding event. Of the mutants studied, N211C-ISQ had the largest negative change (−45%). E149C-ISQ had a lower fluorescence change of 37% and a binding constant of 5 uM, which is slightly weaker than the binding constant of wild-type GGBP (0.2 uM) (*33*), but it is consistent with binding constants reported for other dyes (*26*) and bioconjugates (*28*) at this site. As shown in Figure 2, the triple mutant E149C/A213R/L238S ISQ had a larger fluorescence change of +50%, and the binding constant was 12 mM (Figure 3), which is near the midpoint of the human physiological range.

We also wanted to examine molecular models of several dye–protein conjugates to relate the experimental sensor performance to the structures. The chromophoric unit of benzothiazolium squaraine dyes is highly hydrophobic. It tends to be encapsulated within hydrophobic matrices and polymers such as β-cyclodextrin (*8*) and polymers such as polyvinyl pyrrolidone (*34*). Due to this nature, to a first approximation it would be expected that movement of the dye from a more hydrophilic environment to a more hydrophobic environment would result in a positive fluorescence change, whereas movement from a more hydrophobic to a more hydrophilic environment would induce a negative change. Other types of dye–protein interactions, such as hydrogen bonding, can also play an important role in the nature of the fluorescence change (*35*).

Conformational analysis of the dye attached to a number of sites provided qualitative support to this hypothesis. For example, ISQ was solvent-exposed and had very little interaction with the protein in both the open and closed forms of K92C-ISQ, which would be expected to produce little to no change in fluorescence as was observed. D14C-ISQ and N211C-ISQ had significant negative fluorescence changes. For these bioconjugates, the dye was positioned either within the binding pocket near the surface of the C-terminal domain (D14C) or partially buried inside the binding pocket (N211C) of the open form. As with K92C, the dye was solvent-exposed in the closed form for both mutants with only 1 to 2 residues <4 Å from the dye (Figure 4a,c). Such conformational changes would agree with a negative change in fluorescence. In the case of ISQ attached to E149C/A213R/L238S, the dye was solvent-exposed in the open form, but in the closed form, the entire dye was in close proximity to the surface of the N-terminal domain (Figure 4c,d), which agrees qualitatively with the observed positive

change in fluorescence. Thus, the models suggest that the placement of the dye near the protein surface leads to an enhancement in fluorescence by increasing hydrophobic interactions, while increased solvent exposure decreases fluorescence as the dye moves into a hydrophilic environment.

The overall size of the dye may also play a role in the magnitude of the fluorescence response. Greater than 4-fold fluorescence changes have been reported for NBD attached to E149C GGBP (*23*, *36*). NBD is a relatively small molecule that is approximately 6 Å in length. The chromophore of ISQ is approximately 16 Å in length. It is possible that smaller dyes, by virtue of their size, can develop more favorable interactions with the surface of the protein or can enter pockets formed by residue side chains compared to larger dyes such as the squaraines, which in turn would lead to larger fluorescence changes.

In summary, towards the development of reagentless glucose sensors, we have synthesized an NIR fluorescent squaraine dye with a thiol-reactive linker. The dye exhibited fluorescence properties that are highly dependent on the environment. Upon conjugation to glucose binding protein, the fluorescence intensity of the dye underwent significant changes in the presence of glucose. In particular, E149C and E149C/A213R/L238S GGBP showed highly desirable fluorescence intensity changes and could potentially lead to a reagentless glucose monitoring assay. The glucose binding range of ISQ on E149C/A213R/L238S GGBP was in the relevant human physiological range (1–30 mM). Further development of these systems towards a practical glucose sensor is in progress.

ACKNOWLEDGMENT

This work is supported in part by a grant from the Technologies for Metabolic Monitoring (TMM) program, contract number W81XWH-04-1-0076. The authors thank Michael T. Cash (BD Technologies) for obtaining ^{13}C NMR spectra of the compounds and Helen V. Hsieh (BD Technologies) for insightful discussions during the preparation of the manuscript.

Box 9101, HB Nijmegen 6500, The Netherlands. Received April 27, 2007; Revised Manuscript Received August 9, 2007

Arginine–glycine–aspartate (RGD) derivatives were prepared by a combination of solid-phase and solution-phase synthesis for selective targeting of $\alpha_v\beta_3$ integrin expressed in tumors. In order to evaluate the value of a triazole moiety as a proposed amide isostere, the side chain glycosylated cyclic RGD (*c*RGD) peptides were synthesized with either a natural amide linkage or a triazole. Affinity of the *c*RGD constructs for the $\alpha_v\beta_3$ integrin was determined in a solid-phase competitive binding assay, showing strong similarity in binding affinity for each of the compounds under evaluation. Furthermore, the in vivo tumor targeting potential of glycosylated *c*RGD peptides, linked via amide or triazole, was investigated by determining the biodistribution of ^{125}I-labeled derivatives in mice with tumors expressing $\alpha_v\beta_3$. All of the cyclic RGD derivatives showed preferential uptake in the subcutaneous tumors, with the highest tumor-to-blood ratio measured for the triazole-linked glycosylated derivative. The results of the present study are a clear indication of the value of the triazole moiety as a suitable amide isostere in the development of glycosylated peptides as pharmaceuticals.

INTRODUCTION

In a recent communication, we showed (*1*) that the Cu(I)-catalyzed [3 + 2] cycloaddition (*2, 3*) of an organic azide and an acetylene, one of the most reliable click reactions (*4*), could be used for the synthesis of triazole-linked glycoamino acids. The incorporation of a triazole as a bridging moiety in a glycoamino acid is of particular interest because the triazole function has been postulated as a useful amide isostere (*4, 5*) in terms of electronic properties and atom placement, and the resulting cyclic triazolyl RGD peptides may therefore be of value for a variety of biological or medicinal applications. Thus, it was demonstrated by us, and by others (*6*) that subjection of 1-azidosugars with acetylene-containing amino acids to the standard protocol for copper-catalyzed Huisgen addition leads to triazolylglycoamino acids, with a nitrogen-linked sugar (^{N}TGA), in high yields (Figure 1). Similarly, application of the procedure to 1-acetylenosugar and azide-containing amino acid afforded the corresponding carbon-linked triazole-linked glycoamino acids (^{C}TGA).

The applicability of the triazole-linked glycoamino acids for the preparation of glycopeptides isosteres was inter alia demonstrated by us by incorporation of TGAs into a range of glycopeptides either via standard solution-phase peptide coupling protocols or under the influence of alcalase (*7*). In addition we have shown the possibility of preparing 5-bromo-substituted triazolylglycoamino acids by applying a modified procedure of the Cu(I)-catalyzed Huisgen cycloaddition to azides and bromoacetylenes (*8*).

After suitable technology for the preparation of stable glycopeptides isosteres was established, the present study aimed to investigate the biological relevance of a triazole function as an amide isostere. Some precedence for the isosteric value of a triazole has been provided for true peptide analogues (*4, 5, 9*),

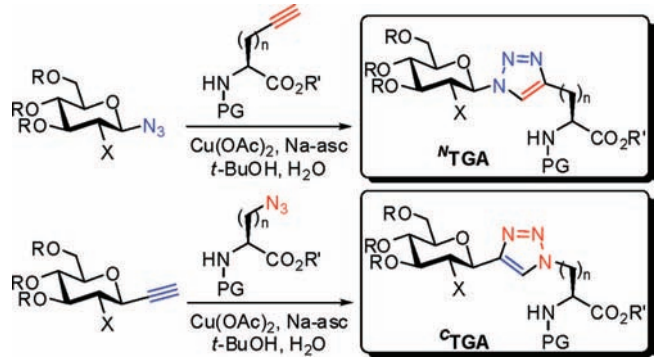

Figure 1. Synthesis of triazolyl glycoamino acids ^{N}TGA and ^{C}TGA.

but the synthesis of triazole-linked glycopeptides with relevant biological activity has hitherto not been reported. Moreover, little was known about the chemical stability of a glycosyl triazole linkage under basic or acidic conditions, with the exception of typical carbohydrate chemistry conditions (*10*). We became intrigued by the covalent attachment of carbohydrates to the so-called arginine–glycine–aspartate (RGD) peptides (*11*), found in proteins of the extracellular matrix such as vitronectin, fibrinogen, and laminin. The RGD motif is specifically recognized by heterodimeric transmembrane proteins called integrins. Integrins link the intracellular cytoskeleton with the extracellular matrix, thereby playing an important role in cell-signaling, cell–cell adhesion, apoptosis, and cell–matrix interactions. More specifically, the $\alpha_v\beta_3$ integrin is expressed on endothelial cells and modulates cell migration and survival during angiogenesis, while the $\alpha_v\beta_3$ integrin expressed on carcinoma cells potentiate metastasis by facilitating extravasation and tissue invasion. As a consequence, the integrin RGD binding site is an attractive pharmaceutical target (*12*) and a large number of RGD analogues have been prepared over the years. For example, Kessler et al. (*13*) showed that cyclo[Arg-Gly-Asp-D-Phe-Val] is one of the most active and selective antagonists for the $\alpha_v\beta_3$

integrin. Later, it was shown that glycosylation of the side chains of the cyclic RGD (*c*RGD) peptides led to significant improvement of the pharmacokinetic properties of lipophilic peptides (*11*, *14*). Various glycosylated *c*RGD peptides were prepared to elucidate the influence of various substitutions on the biological properties (*15*). On the basis of these studies, we hypothesized that triazole isosteres of such cyclic glyco-RGD peptides would display a comparable pharmaceutical profile. Here, we studied the stability of *N*-triazolylglycoamino acids and the preparation of a representative set of "normal" *c*RGD peptides as well as two glycosylated *c*RGD derivatives (Figure 2) synthesized by a combination of solid phase and solution phase techniques. The *in vitro* and *in vivo* $\alpha_v\beta_3$ binding characteristics of these compounds were investigated.

MATERIALS AND METHODS/EXPERIMENTAL PROCEDURES

All chemicals were used as supplied without further purification. The trityl chloride polystyrene (TCP) resin as well as the 9-fluorenylmethoxycarbonyl (Fmoc) amino acids were purchased from NovaBioChem (Bad Soden, Germany). 1-Hydroxybenzotriazole (HOBt) and diisopropylcarbodiimide (DIPCDI) were purchased from Aldrich (Steinheim, Germany). L-Propargylglycine was purchased from Chiralix (Nijmegen, The Netherlands). All other reagents were purchased from Acros (Geel, Belgium). Low-resolution mass spectra (LRMS) were obtained using a Thermo Scientific Advantage LCQ linear iontrap electrospray mass spectrometer (ESI-MS), and high-resolution mass spectra (HRMS) using electrospray ionization time-of-flight (ESI-TOF) were obtained using a JEOL AccuTOF mass spectometer. ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a Varian Inova 400 (400 MHz) or a Bruker DMX300 (300 MHz) spectrometer. The chemical shifts (δ) are given in ppm downfield from tetramethylsilane. Analytical reversed-phase high-performance liquid chromatography (RP-HPLC) was performed on a Merck Hitachi HPLC using an analytical reversed-phase column (Alltech Adsorbosphere C18, 300 Å, 5 μm, 4.6 mm × 250 mm) and a Merck Hitachi (L-4000) UV detector operating at 215 nm. Elution was effected using an appropriate gradient from 0.1% trifluoroacetic acid (TFA) in H_2O/CH_3CN (95/5, v/v) to 0.1% TFA in CH_3CN/H_2O (95/5, v/v). Semipreparative HPLC was performed using an Alltech Adsorbosphere XL C18 column (250 mm × 10 mm, pore size of 100 Å, particle size of 10 μm) at a flow rate of 5.0 mL/min.

Synthesis of Sugar Derivatives (Scheme 1). *2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosylazide (**1**).* The glucopyranosylazide was prepared according to a literature procedure (*16*).

*2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosylamine (**4**).* The glucopyranosylamine was prepared according to a literature procedure (*17*) with slight modification. In an oven-dried Schlenck flask filled with N_2, the azidoglucose **1** (500 mg, 1.3 mmol), Et_3N (140 mg, 1.4 mmol), and Pd/C (14 mg, 0.1 mmol) were suspended in THF (3 mL). Next the Schlenk flask was subjected to a sequence of vacuum and flushing with H_2 (3×), after which it was vigorously stirred while H_2 was bubbled through the solution. After 30 min, the reaction was completed, the slurry was filtered over HyFlo, and THF was evaporated

under reduced pressure to yield **4** as a white solid (99%) sufficiently pure for further reactions.

Synthesis of Fmoc-Protected Glycosidic Amino Acids (Scheme 1). *Fmoc-L-^{N}TGA(Ac)$_4$-OH (2).* The triazole-linked sugar amino acid **2** was prepared according to a procedure reported earlier (*1*). To a solution of glycoside **1** (1 equiv) and Fmoc-protected L-propargylglycine (1 equiv) in *tert*-butanol (0.5 M) was added a solution of $Cu(OAc)_2$ (20 mol %) and sodium ascorbate (40 mol %) in H_2O (0.04 and 0.08 M, respectively). The mixture was stirred overnight, water was added, and the product was extracted with DCM (2×). The combined organic layers were washed with aqueous NaCl, dried over Na_2SO_4, and evaporated in vacuo. The product was purified by flash chromatography using EtOAc/heptane (2/1) to yield a white solid (86%). $R_f = 0.20$ (EtOAc/heptane, 2:1). IR (film): ν 3360, 2950, 2250, 1748, 1221 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.75 (d, J = 7.6 Hz, 1H), 7.70 (s, 1H), 7.61–7.58 (m, 2H), 7.41–7.37 (m, 2H), 7.32–7.28 (m, 2H), 6.00 (d, J = 7.8 Hz, 1H), 5.86–5.83 (m, 1H), 5.48–5.35 (m, 2H), 5.31–5.19 (m, 1H), 4.80–4.67 (m, 1H), 4.38 (d, J = 7.2 Hz, 2H), 4.30 (ABdd, J = 12.6, 5.1 Hz, 1H), 4.23 (t, J = 7.2 Hz, 1H), 4.15–4.09 (m, 1H), 3.99 (ddd, J = 10.2, 4.9, 2.0 Hz, 1H), 3.45–3.30 (m, 2H), 2.10 (s, 3H), 2.07 (s, 3H), 2.02 (s, 3H), 1.84 (s, 3H). ^{13}C NMR (75 MHz, $CDCL_3$) δ 173.2, 170.7, 170.0, 169.8, 169.6, 156.2, 143.9, 143.6, 141.4, 127.9, 127.2, 125.3, 121.4, 120.1, 85.9, 75.4, 72.6, 70.6, 67.9, 67.4, 61.7, 53.4, 47.3, 27.9, 20.8, 20.7, 20.6, 20.2. HRMS (ESI) calculated for $C_{34}H_{37}N_4O_{13}$ $(M + H)^+$ 709.2344, found 709.2357.

^{N}TGA (3). Fmoc-L-^{N}TGA(Ac)$_4$-OH (**2**) (500 mg, 0.70 mmol) was treated with 20% piperidine in DMF (v/v, 5 mL) and stirred for 20 min before concentration of the solvent in vacuo. The crude product was dissolved in MeOH (5 mL), and a catalytic amount of K_2CO_3 was added. The mixture was stirred for 1 h. Purification of the product with a basic ion exchange column (IRA-410) afforded the triazole-linked glycosidic amino acid **3** (125 mg, 56%) as a white solid. IR (film): ν 3309, 2362, 2327, 1623 cm^{-1}. ^{1}H NMR (400 MHz, D_2O) δ 5.01 (d, J = 8.4 Hz, 1H), 4.04 (s, 1H), 3.89 (d, J = 12.2 Hz, 1H), 3.74 (dd, J = 13.0, 4.8 Hz, 1H), 3.46–3.39 (m, 2H), 3.44 (m, 2H), 3.14–2.80 (m, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 172.3, 141.7, 123.3, 86.9, 78.4, 75.4, 71.7, 68.4, 59.9, 53.7, 25.7. HRMS (ESI) calculated for $C_{34}H_{37}N_4O_{13}$ $(M + H)^+$ 709.2357, found 709.2344.

Fmoc-(N-1-Glu(Ac)$_4$-Asn)-OH (6). The triazole-linked sugar amino acid was prepared from glucopyranosylamine **4** and Fmoc-Asp-O^{t}Bu via a procedure reported by van Ameijde et al. (*18*) involving peptide coupling catalyzed by BOP followed by deprotection using TFA/DCM (4 h, room temp) to afford the *N*-glycosylasparagine **6** as a white solid in 71% overall yield. $R_f = 0.12$ (EtOAc/heptane, 2:1). IR (film): ν 3313, 2250, 1740, 1506 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.76 (d, J = 7.5 Hz, 2H), 7.58 (d, J = 7.4 Hz, 2H), 7.40 (t, J = 7.4 Hz, 2H), 7.31 (t, J = 7.4 Hz, 2H), 6.70 (d, J = 8.8 Hz, 1H), 6.16 (d, J = 7.6 Hz, 1H), 5.33 (t, J = 9.5 Hz, 1H), 5.26 (t, J = 9.1 Hz, 1H), 5.08 (t, J = 9.7 Hz, 2H), 4.94 (t, J = 9.5 Hz, 1H), 4.67–4.53 (m, 1H), 4.47–4.34 (m, 2H), 4.30 (dd, J = 12.6, 4.4 Hz, 1H), 4.22 (t, J =7.04 Hz, 1H), 4.08 (dd, J =12.6, 2.0 Hz, 1H), 3.82 (ddd, J =10.1, 4.1, 2.0 Hz, 1H), 2.90 (dd, J =16.3, 2.8 Hz, 1H), 2.76 (dd, J =16.3, 5.2 Hz, 1H), 2.06 (s, 5H), 2.04 (s, 3H), 2.02 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ 176.1, 173.9, 171.4, 170.9, 170.2, 169.8, 156.6, 143.7, 141.3, 127.9, 127.2, 125.3, 120.1, 78.0, 73.8, 272.9, 70.8, 68.2, 67.6, 61.8, 50.5, 47.1, 37.7, 20.8, 20.7, 20.7, 20.6. HRMS (ESI) calculated for $C_{33}H_{36}N_2NaO_{14}$ $(M + Na)^+$ 707.2051, found 707.2064.

N-1-Gluco-Asn (7). Fmoc-(*N*-1-Glu(Ac)$_4$-Asn)-OH (**5**) (500 mg, 0.73 mmol) was treated with 20% piperidine in DMF (v/v, 5 mL) and stirred for 20 min before concentration of the solvent in vacuo. The crude product was dissolved in MeOH (5 mL), and a catalytic amount of K_2CO_3 was added. The mixture was stirred for 1 h. Purification of the product with a basic ion exchange column (IRA-410) afforded the amide-linked glycosidic aspargine **7** (133 mg, 62%) as a white solid. ^{1}H NMR (400 MHz, D_2O) δ 8.14 (s, 1H), 5.77 (d, J = 9.2 Hz, 1H), 4.10 (t, J = 5.0 Hz, 1H), 4.02 (t, J = 9.2 Hz, 1H), 3.93 (d, J = 11.4 Hz, 1H), 3.82–3.71 (m, 3H), 3.64 (t, J = 9.1 Hz, 1H), 3.43–3.34 (m, 1H). HRMS (ESI) calculated for $C_{33}H_{36}N_2O_{14}$ $(M + H)^+$ 707.2064, found 707.2051.

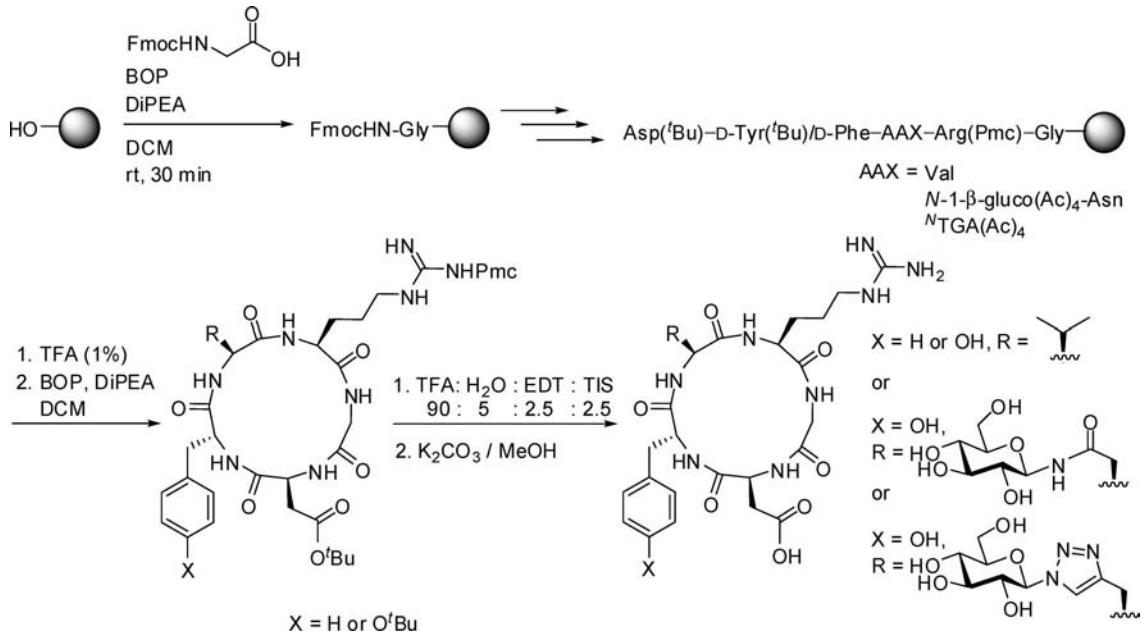
Table 1. Stability Tests for ^{N}TGA and *N*-1-β-Glyco-Asn, Respectively

			stability	
conditions	temperature	time	^{N}T GA (**3**)	*N*-1-β-glyco-Asn (**7**)
2 M HCl (aq)	room temp	3 d	++	++
2 M HCl (aq)	reflux	2 h	++	+
4 M HCl (aq)	reflux	3 h	++	− −
2 M NaOH (aq)	room temp	3 d	++	−
2 M NaOH(aq)	reflux	3 h	++	− −
2.6 M HCl/EtOAc	room temp	3 d	++	+
Et_3N	reflux	3 h	++	+

Stability Tests. ^{N}TGA (**3**) (50 mg, 0.07 mmol) or *N*-1-gluco-Asn (**7**) (50 mg, 0.07 mmol) was dissolved in 3 mL of 2 M HCl (aq), 4 M HCl (aq), 2 M NaOH (aq), 2.6 M HCl/EtOAc, or Et_3N and stirred for the time and temperature indicated in Table 1. The relative stability of the substrates was determined by TLC analysis and integration of the ^{1}H NMR signals of the side products and starting material.

General Procedures for the Preparation of the Cyclic RGD Peptides (Scheme 2). Loading of the trityl resin, synthesis of the pentapeptides, cleavage, subsequent cyclization, and deprotection of the cyclic RGD peptides were carried out following standard Fmoc peptide chemistry protocols. Side chains were protected with 2,2,5,7,8-pentamethylchroman (Pmc) for arginine and *tert*-butyl (^{t}Bu) for aspartic acid and tyrosine.

Removal of the Side Chain Protection of the Peptides. The peptides were treated with a solution of 95% trifluoroacetic acid (TFA), 2.5% water, and 2.5% ethanedithiol (EDT) for 4 h at ambient temperature. Next, the glycopeptides were precipitated in diethyl ether. The crude product was isolated by centrifugation and washed three times with diethyl ether.



Removal of the Acetyl Protections of the Carbohydrate Bearing Peptides. The crude product was dissolved in MeOH. A catalytic amount of K_2CO_3 was added, and the mixture was stirred for 1 h. Ion exchange resin (Amberlyte IR-120) was added until the solution was neutral, and the ion exchange resin was filtered off. A final purification was done via semipreparative RP-HPLC as described above.

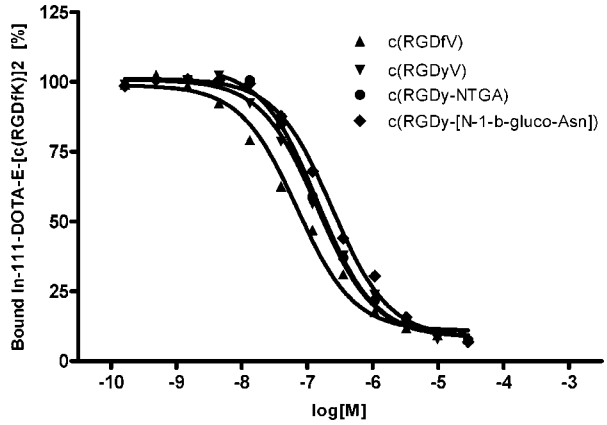
c(RGDfV). Retention time (t_R) (min): 8.1. HRMS (ESI) calculated for $C_{26}H_{39}N_8O_7$ $(M + H)^+$ 575.2914, found 575.2942. For additional data, see ref *14*.

c(RGDyV). t_R (min): 8.2. HRMS (ESI) calculated for $C_{26}H_{39}N_8O_8$ $(M + H)^+$ 591.2891, found 591.2891. For additional data, see ref *19*.

c(RGDy-N-[1-β-gluco(OAc)$_4$]-Asn). t_R (min): 6.3. ^{1}H NMR (400 MHz, MeOD) δ 7.02 (d, J = 8.6 Hz, 2H), 6.70 (d, J = 8.6 Hz, 2H), 5.32 (t, J = 9.5 Hz, 1H), 5.23 (t, J = 9.4 Hz, 1H), 5.04 (t, J = 10.0 Hz, 1H), 4.95 (t, J = 9.5 Hz, 1H), 4.73 (t, J= 6.9 Hz, 1H), 4.57–4.52 (m, 1H), 4.44–4.39 (m, 1H), 4.28–4.23 (m, 3H), 4.11 (dd, J = 12.4, 2.2 Hz, 1H), 3.92 (ddd, J = 10.2, 4.6, 2.4 Hz, 1H), 3.25–3.13 (m, 2H), 3.00–2.95 (m, 1H), 2.86–2.76 (m, 2H), 2.68 (dd, J = 16.1, 6.9 Hz, 1H), 2.57 (dd, J = 16.5, 6.8, 1H), 2.48 (dd, J = 16.1, 5.3 Hz, 1H), 2.03 (s, 3H), 2.03 (s, 3H), 1.99 (s, 3H), 1.98 (s, 3H), 1.98–1.55 (m, 4H). LRMS calculated for $C_{39}H_{54}N_9O_{18}$ $(M + H^+)$ 936.4, found 936.4.

Scheme 2. Preparation of the *c*RGD Peptides

c(RGDy-^{N}TGA(OAc)$_4$). t_R (min): 7.9. ^{1}H NMR (400 MHz, MeOD) δ 7.94 (s, 1H), 6.99 (d, J = 8.5 Hz, 2H), 6.69 (d, J = 8.5 Hz, 2H), 6.09 (d, J = 9.2 Hz, 1H), 5.63 (t, J = 9.4 Hz, 1H), 5.53 (t, J = 9.4 Hz, 1H), 5.27 (t, J = 9.8 Hz, 1H), 4.71 (dd, J = 8.3, 5.7 Hz, 1H), 4.58–4.50 (m, 2H), 4.35–4.24 (m, 3H), 4.17 (dd, J = 12.3, 1.7 Hz, 1 H), 4.13–4.09 (m, 1H), 3.38 (d, J = 15.4 Hz, 1H), 3.26–3.18 (m, 3H), 3.12–3.05 (m, 1H), 2.99–2.94 (m, 1H), 2.84–2.77 (m, 2H), 2.56 (dd, J = 16.6, 5.8 Hz, 1H), 2.06 (s, 3H), 2.00 (s, 3H), 2.00 (s, 3H), 1.83 (s, 3H), 2.00–1.52 (m, 4H). LRMS calculated for $C_{40}H_{54}N_{11}O_{17}$ ($M + H^+$) 960.4, found 960.4.



c(RGDy-N-[1-gluco]-Asn). Removal of the acetyl protecting groups as described above afforded 50 mg (0.06 mmol) of the product, 18% relative to the resin. ^{1}H NMR (400 MHz, D_2O/MeOD) δ 7.01 (d, J = 8.4 Hz, 2H), 6.68 (d, J = 8.2 Hz, 2H), 4.88 (ap d, J = 9.5, 1H), 4.70 (t, J = 7.2 Hz, 1H), 4.50 (dd, J = 6.8, 5.0 Hz, 1H), 4.45–4.38 (m, 2H), 4.24 (d, J = 14.5 Hz, 1H), 3.89 (ap d, J = 11.1 Hz, 1H), 3.74 (dd, J = 12.4, 5.1 Hz, 1H), 3.58 (t, J = 9.2, 1H), 3.53–3.40 (m, 3H), 3.38–3.31 (m, 1H), 3.26–3.15 (m, 2H), 2.98 (dd, J = 13.3, 5.9 Hz, 1H), 2.89–2.83 (m, 2H), 2.77 (dd, J = 16.4, 7.2 Hz, 1H), 2.65 (dd, J = 15.6, 6.5 Hz, 1H), 2.55–2.49 (m, 2H), 1.96–1.87 (m, 1H), 1.76–1.67 (m, 1H), 1.65–1.53 (m, 2H). HRMS (ESI) calculated for $C_{31}H_{46}N_9O_{14}$ $(M + H)^+$ 768.3101, found 768.3164.

c(RGDy-^{N}TGA). Removal of the acetyl protections as described above afforded 39 mg (0.05 mmol) of the product, 14% yield relative to the resin. ^{1}H NMR (400 MHz, D_2O) δ 7.83 (s, 1H), 7.01 (d, J = 8.4 Hz, 2H), 6.68 (d, J =8.4 Hz, 2H), 5.72 (d, J = 9.2 Hz, 1H), 4.68 (t, J =7.1 Hz, 1H), 4.51 (dd, J = 9.9, 5.9 Hz, 1H), 4.43 (t, J = 6.9 Hz, 1H), 4.34 (dd, J = 8.9, 5.6 Hz, 1H), 4.21 (d, J = 14.9 Hz, 1H), 3.99 (t, J = 9.2 Hz, 1H), 3.94 (d, J = 10.4 Hz, 1H), 3.68–3.55 (m, 3H), 3.64 (t, J = 9.3 Hz, 1H), 3.50 (d, J = 14.9 Hz, 1H), 3.09–2.95 (m, 3H), 3.04 (dd, J = 15.3, 6.5 Hz, 1H), 2.94 (dd, J = 13.4, 5.9 Hz, 1H), 2.86 (dd, J = 13.2, 10.2 Hz, 1H), 2.67 (dd, J = 15.8, 7.0 Hz, 1H), 2.53 (dd, J = 15.7, 7.3 Hz, 1H), 1.75–1.63 (m, 1H), 1.55–1.42 (m, 1H), 1.35–1.23 (m, 2H). HRMS (ESI) calculated for $C_{32}H_{46}N_{11}O_{13}$ $(M + H)^+$ 792.3210, found 792.3277.

Solid Phase $\alpha_v\beta_3$ Binding Assay. The affinity of *c*(RGDfV), *c*(RGDyV), *c*(RGDy-[*N*-1-β-gluco-Asn]), and *c*(RGDy-^{N}TGA) for the $\alpha_v\beta_3$ integrin was determined in a competitive binding assay using the dimeric peptide ^{111}In-DOTA-E-[*c*(RGDfK)]$_2$ as a tracer. The ^{111}In-labeled peptide (3 MBq/μg) was prepared as described earlier (*20*). Microtiter 96-well vinyl assay plates (Corning B.V., Schiphol-Rijk, The Netherlands) were coated with 100 μL/well of a solution of purified human integrin $\alpha_v\beta_3$ (150 ng/mL) (Chemicon International, Temecula, CA) in coating buffer (25 mM Tris-HCl, pH 7.4, 150 mM NaCl, 1 mM $CaCl_2$, 0.5 mM $MgCl_2$, and 1 mM $MnCl_2$) for 17 h at 4 °C. The plates were washed twice with binding buffer (0.1% bovine serum albumin (BSA) in coating buffer). The wells were blocked for 2 h with 200 μL of blocking buffer (1% BSA in coating buffer) at room temperature. The plates were washed twice with binding buffer. Then 100 μL of binding buffer containing 11 kBq of ^{111}In-DOTA-E-[*c*(RGDfK)]$_2$ and appropriate dilutions of non-labeled *c*(RGDfV), *c*(RGDyV), *c*(RGDy-[*N*-1-β-gluco-Asn]), and *c*(RGDy-^{N}TGA) in binding buffer were incubated in wells at 37 °C for 1 h. After incubation, the plates were washed three times with binding buffer. The retained radioactivity in each well was determined in a γ-counter. IC_{50} values of the *c*RGD peptides were calculated by nonlinear regression using GraphPad Prism (GraphPad Prism 4.0 software, San Diego, CA). Each data point is the average of three determinations.

Radiolabeling of the *c*RGD Peptides. The peptides containing tyrosine, *c*(RGDyV), *c*(RGDy-[*N*-1-β-gluco-Asn]), and *c*(RGDy-^{N}TGA) were labeled with ^{125}I using the iodogen method. The peptide (10–20 μg) was dissolved in 100 μL of phosphate-buffered saline (PBS) (pH 7.4) in a 1.5 mL polypropylene vial coated with 100 μg of iodogen, and [^{125}I]NaI (37 MBq) was added to the vial. After 10 min, the solution was transferred to another vial to terminate the iodination. A sample of the mixture was analyzed by HPLC. Radiochemical purity was always higher than 98%.

Biodistribution Studies. In the right flank of 6–8 week old female nude BALB/c mice, 0.2 mL of a suspension of 15–10^6 cells/mL SK-RC-52 cells was injected subcutaneously (sc). Two weeks after inoculation of the tumor cells, mice were randomly divided into four groups. Mice were injected with ^{125}I-*c*(RGDfV) (0.5 MBq, 0.5 μg), ^{125}I-*c*(RGDyV) (0.5 MBq, 0.5 μg), ^{125}I-*c*(RGDy-[*N*-1-β-gluco-Asn]) (0.5 MBq, 0.5 μg), or ^{125}I-*c*(RGDy-^{N}TGA) (0.5 MBq, 0.5 μg) via the tail vein. Mice were euthanized by CO_2 asphyxiation 2 h postinjection (pi) (four mice per group). Blood, tumor, and all the major organs and tissues were dissected, weighed, and counted in a well-type γ-counter.

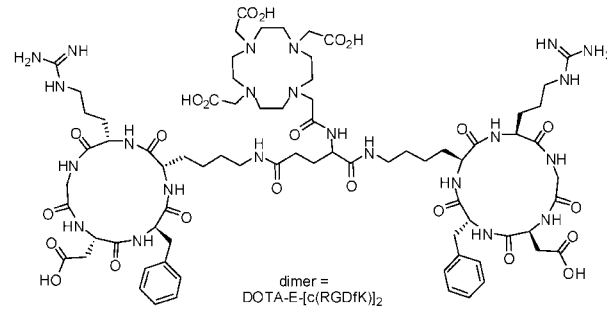


Figure 3. Competition of specific binding of ^{111}In-DOTA-E-[*c*(RGDfK)]$_2$ with *c*(RGDfV) (▲), *c*(RGDyV) (▼), *c*(RGDy-^{N}TGA) (●), and *c*(RGDy-[*N*-1-β-gluco-Asn]) (◆).

The percent injected dose per gram (%ID/g) was determined for each sample. To investigate whether the uptake of each of the four *c*RGD peptides (in the dissected tissues) was $\alpha_v\beta_3$-mediated, a separate group of mice was coinjected with an excess (50 μg) of nonradiolabeled DOTA-E-[*c*(RGDfK)]$_2$ to saturate all the $\alpha_v\beta_3$ integrin receptors, and the biodistribution of the radioiodinated *c*RGD peptide conjugates was determined as described above. All animal experiments were approved by the local animal welfare committee in accordance with the Dutch legislation and carried out in accordance with their guidelines.

RESULTS AND DISCUSSION

Synthesis of Glycoamino Acids. Cyclic RGD peptides represent valuable ligands for selective targeting of $\alpha_v\beta_3$ integrins. Consequently, large numbers of RGD analogues have been prepared (*20–22*) and extensively tested. We have shown that 1-azido sugars and acetylene-modified amino acids readily undergo [3 + 2] cycloaddition via a standard protocol for the copper-catalyzed Huisgen addition to form in high yields triazole isosteres of glycoamino acids (*1*). Although synthetically of interest, here we explored the potential value of triazolyl cyclic glyco-RGD peptides as targeting agents. In this respect, the first relevant question to answer is to what extent the triazole analogues of glycoamino acids have increased stability with respect to the natural compounds. Second, the medicinal value of the triazole compounds as glycoamino acid mimics can only be evaluated by incorporation in biologically active compounds. For this reason, a set of cyclic RGD peptides was chosen to evaluate the binding affinities for $\alpha_v\beta_3$ integrins, including the amide-linked glyco-RGD *c*[RGDy(*N*-1-β-glyco-Asn)], the triazole-linked *c*(RGDy-^{N}TGA) and *c*(RGDyV) and *c*(RGDfV) for reference purposes. D-Tyr was incorporated instead of D-Phe for *c*[RGDy(*N*-1-β-glyco-Asn)], *c*(RGDy-^{N}TGA), and *c*(RGDyV), enabling subsequent iodination for tumor imaging as reported by Haubner et al. (*14*).

The requisite building blocks for solid-phase synthesis, 1-azido-2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose **1** (*16*) was efficiently condensed with Fmoc-L-propargylglycine under the influence of Cu(OAc)$_2$ and sodium ascorbate in a mixture of ^{t}BuOH and H$_2$O to synthesize fully protected *N*-triazolylglycosidic alanine (*2*), which we refer to as Fmoc-L-^{N}TGA(Ac)$_4$-OH, in a 91% yield. The amide-linked glycoamino acid was prepared by hydrogenation of **1** with hydrogen in the presence of Pd/C and Et$_3$N in MeOH to afford 1-aminoglucose derivative **3**. Subsequent coupling to Fmoc-aspartic acid *tert*-butyl ester yielded acetyl and Fmoc protected glycosidic asparagine *tert*-butyl ester **5** in a yield of 87%. Next, the *tert*-butyl ester was treated with TFA in DCM (1/1, v/v) to afford the free acid Fmoc-[*N*-1-β-glyco(Ac)$_4$-Asn](OH) in near-quantitative yield.

Evaluation of Stability. In order to investigate the chemical stability of the substrates ^{N}TGA(Ac)$_4$-OH, as well as *N*-1-glycosyl(Ac)$_4$-Asn(OH), the protected glycoamino acids **2** and **6** were subjected to treatment with 20% piperidine in DMF (v/v) followed by a saponification of the acetyl esters by K$_2$CO$_3$ in MeOH. The resulting glycoamino acids ^{N}TGA (**3**) and *N*-1-β-glyco-Asn (**7**) were subjected to various acidic and basic conditions as summarized in Table 1. The triazole-linked ^{N}TGA was found to be completely compatible with a range of basic and acidic conditions, whereas the natural amide-linked *N*-1-β-glyco-Asn did not withstand some of the conditions tested. From these results, it can be concluded that triazole-linked substrates are versatile building blocks for the preparation of stable analogues of the common asparagine-linked *N*-glycoproteins.

Solid-Phase Synthesis. For the synthesis of the cyclic RGD peptides, a solid-phase strategy was chosen, followed by cleavage from the resin and cyclization. Thus, in order to avoid racemization of the C-terminal amino acid during the last activation step, Fmoc-glycine was elected as the C-terminal amino acid and coupled to trityl resin with DiPEA in DCM. Subsequent elongation of the peptide was executed by application of standard Fmoc chemistry involving HOBt/DIPCDI-mediated coupling followed by piperidine-induced Fmoc deprotection. Both Fmoc-L-^{N}TGA(Ac)$_4$-OH and Fmoc-[*N*-1-β-glyco(Ac)$_4$]-Asn(OH) were compatible with the conditions applied, although the amide-linked glycoamino acid was incorporated at a much slower rate. After completion of the synthesis, the fully protected pentapeptides were cleaved from the resin using a 1% solution of TFA in DCM and purified by silica gel column chromatography. Next, cyclization of the linear RGD peptides was effected under the influence of BOP to give the protected cyclic peptides in good overall yields (14–18%). Finally, protecting groups were removed under basic conditions and the final product was purified by semipreparative RP-HPLC as described above.

Solid-Phase $\alpha_v\beta_3$ Binding Assay. The affinities of *c*(RGDfV), *c*(RGDyV), *c*(RGDy-[*N*-1-β-gluco-Asn]), and *c*(RGDy-^{N}TGA) for the $\alpha_v\beta_3$ integrin as determined in the competitive binding assay are summarized in Figure 3.

From Figure 3, it becomes clear that binding of ^{111}In-DOTA-E-[*c*(RGDfK)]$_2$ (*23*) to $\alpha_v\beta_3$ was inhibited by each compound in a concentration-dependent manner. In fact, only relatively small differences between the different peptides can be observed, with IC$_{50}$ values of 65 nM for *c*(RGDfV), 144 nM for *c*(RGDyV), 238 nM for *c*(RGDy-[*N*-1-β-gluco-Asn]), and 144 nM for *c*(RGDy-^{N}TGA), indicating that side chain modification had only limited effect on the $\alpha_v\beta_3$ binding affinity of the compounds, which is in agreement with earlier reports (*16, 24, 25*).

[a] The organ uptake is expressed as %ID/g.

In addition, these data showed that only a slight difference was noticeable between the carbohydrate containing *c*RGD peptides (*c*[RGDy-^{N}TGA]) and *c*(RGDy-[*N*-1β-gluco-Asn]), which is a first indication that the glycoamino acid binding characteristics are nearly unchanged upon substitution of the amide linkage for a triazole linkage.

Biodistribution Studies. Side chain glycosylation can improve the pharmacological properties of hydrophobic/lipophilic peptides (*26*), which has also been demonstrated for *c*RGD (*14*). In order to validate the potential of the glycoamino acids **3** and **7** for incorporation into glyco-RGD peptides, the biodistribution of ^{125}I-*c*(RGDyV), ^{125}I-*c*(RGDy-[*N*-1-β-gluco-Asn]), and ^{125}I-*c*(RGDy-^{N}TGA) in athymic mice with sc $\alpha_v\beta_3$-expressing tumors was determined (Figure 4). The results of the biodistribution studies of ^{125}I-RGDyV, ^{125}I-*c*(RGDy-[*N*-1-β-gluco-Asn]), and ^{125}I-*c*(RGDy-^{N}TGA) in athymic mice with SK-RC-52 tumors at 2 h pi are summarized in Table 2. In order to determine the nonspecific uptake of the peptides, the biodistribution was also determined in the presence of excess unlabeled *c*RGD compound, i.e., dimeric DOTA-E-[*c*(RGDfK)]$_2$.

All peptides ^{125}I-*c*(RGDyV), ^{125}I-*c*(RGDy-[*N*-1-β-gluco-Asn]), and ^{125}I-*c*(RGDy-^{N}TGA) rapidly cleared from the blood because blood levels at 2 h pi did not exceed 0.3% ID/g. Two hours after injection, the concentration of ^{125}I-*c*(RGDy-[*N*-1-β-gluco-Asn]) and ^{125}I-*c*(RGDy-^{N}TGA in the tumor was the highest of all tissues examined. Coinjection of excess unlabeled DOTA-E-[*c*(RGDfK)]$_2$ (50 μg) along with ^{125}I-*c*(RGDyV), ^{125}I-*c*(RGDy-[*N*-1-β-gluco-Asn]), and ^{125}I-*c*(RGDy-^{N}TGA) indicated that for each of the three compounds, the major part of the uptake in the tumor was $\alpha_v\beta_3$-mediated. In this mouse model, ^{125}I-*c*(RGDy-^{N}TGA) revealed the highest tumor-to-blood ratio (18 at 2 h pi). The carbohydrate-bearing *c*RGD peptides, ^{125}I-*c*(RGDy-[*N*-1-β-gluco-Asn]) and ^{125}I-*c*(RGDy-^{N}TGA), also showed $\alpha_v\beta_3$-mediated uptake in nontarget organs like lung, spleen, and intestine. Specific uptake of *c*RGD analogues in normal tissues has been reported in previous studies and is probably due to $\alpha_v\beta_3$ expression in these tissues (*27, 28*). Furthermore, the conducted studies once more show that tumor uptake is not solely dependent on the binding affinity but relies on many more factors such as blood residence time, molecular weight, structure, charge, etc. These aspects may explain the fact that ^{125}I-*c*(RGDy-[*N*-1-β-gluco-Asn]) displayed the highest tumor uptake while the corresponding monomer failed to provide the highest binding affinity. Although ^{125}I-*c*(RGDy-^{N}TGA) showed the highest tumor-to-blood ratio, it showed a lower tumor uptake than ^{125}I-*c*(RGDy-[*N*-1-β-gluco-Asn]). Therefore, it may be concluded that the high tumor uptake of ^{125}I-*c*(RGDy-[*N*-1-β-gluco-Asn]) can only partially be explained by the presence of the carbohydrate moiety.

CONCLUSION

A high-yielding route for the preparation of Fmoc-L-^{N}TGA(Ac)$_4$-OH starting from azidoglucose and Fmoc-protected propargylglycine is described by application of our technology for the synthesis of triazolylglycoamino acids (*1*). The ^{N}TGA building block was found to display significantly improved chemical stability with respect to the "natural" amide-linked glycoamino acid and is fully compatible with basic and acidic conditions. The incorporation of the Fmoc-

protected ^{N}TGA derivative in an *c*RGD peptide proceeded without incidence, in fact more smoothly than the amide-linked glycoamino acids, with the final yield of the substrate being comparable to the yields of the other cyclic RGD substrates. The solid-phase binding assay revealed no significant differences between the different peptides under evaluation, confirming that modification of the side chain of the cyclic RGD peptide did not affect affinity for $\alpha_v\beta_3$. The ^{125}I-labeled cyclic peptides accumulated specifically in SK-RC-52 tumors. The uptake of the cyclic RGD substrates in the tumor, lung, spleen, and intestine was $\alpha_v\beta_3$-mediated. The biodistribution studies indicated that the side chain glycosylated *c*RGD peptide ^{125}I-*c*(RGDy-^{N}TGA) showed improved pharmacologic properties compared to ^{125}I-*c*(RGDyV), with reduced liver uptake and the highest uptake in the tumor, in accordance with earlier literature reports (*14, 15*) for different glycosylated cyclic RGD peptides. Moreover, the in vitro and in vivo tests indicated that *c*(RGDy-^{N}TGA) to some extent has the same pharmacologic properties as *c*(RGDy-[*N*-1-β-gluco-Asn]), which may be interpreted as one of the first examples of the value of triazoles as amide isosteres. The ease of synthesis of the triazolylglycoamino acids, the improved stability and behavior in solid-phase peptide synthesis, and the similar pharmacologic properties are a demonstration of the potential of ^{N}TGA building blocks as isosteres of amide-linked glycoamino acids for the synthesis of pharmaceutically relevant glycopeptide mimics.

Fabrication of Langmuir–Blodgett Film of a Fullerene Derivative with a Cyclic Peptide as an Anchor

Shigekatsu Fujii, Tomoyuki Morita, and Shunsaku Kimura*

Department of Material Chemistry, Graduate School of Engineering, Kyoto University, Kyoto-Daigaku-Katsura, Nishikyo-ku, Kyoto 615-8510, Japan. Received May 2, 2007; Revised Manuscript Received August 21, 2007

A novel cyclic octapeptide carrying a fullerene unit and poly(ethylene glycol) at the side chain (cyclo8-C_{60} + PEG) was synthesized, and its monolayer formation at the air/water interface and on a substrate was studied. Surface pressure–area per molecule isotherms indicated that cyclo8-C_{60} + PEG formed a stable monolayer at the air/water interface. The cyclo8-C_{60} + PEG monolayers prepared from various spreading volumes (i.e., from various initial areas per molecule) overlapped nicely on a single curve, suggesting that the molecules were uniformly dispersed on the surface without aggregation of the fullerene units. The uniform dispersibility is due to the scaffold effect of the cyclic peptide unit to keep the fullerene units away from each other. The formed monolayer could be quantitatively transferred onto a solid substrate. UV–vis absorption spectroscopy of the Langmuir–Blodgett (LB) monolayer showed that the electronic structure of the fullerene unit was not affected by the formation of the monolayer. Cyclic voltammetry of the LB monolayer in an aqueous solution containing redox species indicated that the LB monolayer was densely packed. Furthermore, reversible redox peaks attributed to the one-electron reduction of the fullerene unit were observed, showing that the redox property of the fullerene unit was also retained in the monolayer. It is thus concluded that the cyclic peptide is a good candidate as a scaffold for stable monolayer formation at the air/water interface and for intact immobilization of the fullerene moiety onto a substrate.

INTRODUCTION

Fullerenes, C_{60} in particular, and their derivatives have attracted much attention because of their special chemical and physical properties (*1–9*). To utilize their unique properties in nanoscale systems, preparation of well-organized thin films of fullerenes on the surface is the first step. So far, monolayers and multilayers have been prepared on various surfaces and their properties have been investigated (*3, 10–15*). The Langmuir–Blodgett (LB) technique has been most widely used as a method for preparation of such ordered thin films. With this technique, a monolayer of organic compounds is first prepared at the air/water interface and the formed monolayer is then transferred onto a solid substrate. However, it is difficult to prepare a stable and uniform monolayer from pristine fullerenes (*16–19*). First, quite low solubility of fullerenes in organic solvents is troublesome in preparation of solutions to be spread on the water surface. Second, even if one finds a good solvent, the fullerene easily self-aggregates at the air/water interface, making the monolayer very stiff and fragile. It is thus hard to transfer the monolayer quantitatively onto a solid substrate. To overcome these problems, chemical modifications of fullerenes are needed. A wide variety of fullerene derivatives have been synthesized by modification with various chemical species such as crown ethers (*12, 20–22*), polyhydroxylates (*23*), oligopeptides (*24, 25*), poly(ethylene glycol)s (*26*), hydrophilic porphyrins (*27, 28*), and so on (*13*). Polymers having fullerenes at the main or side chains (*29, 30*) and dendrimers carrying fullerenes as the dendrons (*31–33*) have been reported as well. In general, attachment of a highly hydrophilic moiety to fullerenes can help the molecule dissolve into solvents and disperse on the surface. Physical prevention of fullerenes from aggregation is also effective. For example, encapsulation of fullerenes by inclusion hosts (e.g., calixarenes (*34–36*) or cyclodextrins (*37, 38*)) has been studied.

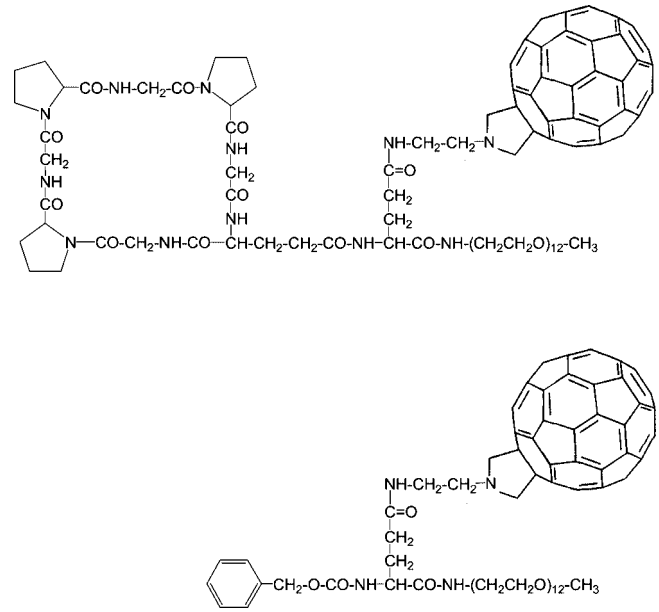

Figure 1. Chemical structures of cyclo8-C_{60}+PEG (top) and C_{60}+PEG (bottom).

In the present study, we synthesized a novel cyclic peptide carrying a fullerene (C_{60}) unit and poly(ethylene glycol) (PEG) chain at the side chain (cyclo8-C_{60} + PEG; Figure 1) for preparation of well-organized monolayers at the air/water interface and on a solid substrate. The PEG chain (the average degree of polymerization is 12) will increase the solubility of the compound to help the C_{60} units disperse in the preparation solution as well as on the water surface. A similar cyclic octapeptide has been shown to have a rigid and flat conformation

and to form a stable monolayer at the air/water interface with horizontal orientation to the surface (*39*). Since the molecular area of the cyclic peptide moiety is larger than that of the C_{60} unit, it is expected that aggregation among the C_{60} units is physically suppressed even when the monolayer is compressed. A compound carrying the same fullerene unit and the PEG chain but without the cyclic peptide scaffold (C_{60} + PEG, Figure 1) was also synthesized and used as a control. The formation of the monolayer at the air/water interface was studied by the surface pressure–area per molecule (π–*A*) isotherm analysis. The monolayer was then transferred onto a solid substrate by the vertical dipping method. The electronic property of the C_{60} unit in the LB monolayer was examined by UV–vis absorption spectroscopy, and the packing of the monolayer and the redox property of the C_{60} unit were studied by cyclic voltammetry.

EXPERIMENTAL PROCEDURES

Materials. cyclo8-C_{60} + PEG and C_{60} + PEG, were synthesized by the liquid-phase synthesis. The details in the synthesis are available in Supporting Information.

Monolayer Measurements. A homemade Langmuir film balance with a trough area of 100 mm × 189 mm was used to prepare a monolayer at the air/water interface and to measure the isotherm of the monolayer under linear compression of the molecules spread on the water surface. The subphase temperature was set to 25.0 ± 1.0 °C. Ultrapure water processed by a Millipore Milli-Q system (resistivity of >18 MΩ cm^{-1}) was used as the water subphase. A chloroform solution of the fullerene derivatives was prepared (0.47 mM for cyclo8-C_{60} + PEG and 0.96 mM for C_{60} + PEG), and the solution was spread by a microsyringe onto the water surface. The solvent was allowed to evaporate for 15 min prior to compression, and then the molecules spread on the surface were compressed at a rate of 10 cm^2/min. The monolayer formation was performed at room temperature. The formed monolayer was then transferred onto a solid substrate by the vertical dipping method at a rate of 10 mm/min. Quartz and gold were used as the substrates for UV–vis absorption spectroscopy and cyclic voltammetry, respectively. The gold substrate was prepared by vacuum deposition with chromium (300 Å) as the underlying adhesive layer and gold (2000 Å) on a glass substrate. The glass substrate was cleaned with sulfonic acid and rinsed thoroughly with distilled water and methanol prior to the deposition.

UV–Visible Absorption Spectroscopy. UV–visible absorption spectra were recorded on a Shimadzu UV-2450PC spectrometer at room temperature. The absorption spectrum of the LB monolayer on quartz was measured with a special attachment to hold substrate samples.

Cyclic Voltammetry. Cyclic voltammetry was carried out on a BAS model 604 voltammetric analyzer in a three-electrode system with the gold substrate as the working electrode, Ag/AgCl in 3 M NaCl as the reference electrode, and a platinum wire as the auxiliary electrode. Ultrapure water was used to prepare aqueous solutions for the measurements. All the solutions were deaerated by passing N_2 gas for 10 min prior to the measurements. All the electric potentials reported here were measured with respect to the reference electrode. The experiment to examine the monolayer packing was performed in a 1 mM $K_4[Fe(CN)_6]$ and 1 M KCl aqueous solution at a scan rate of 0.05 V/s. On the other hand, the redox property of the C_{60} unit was investigated in a 1 M *n*-Bu_4NCl aqueous solution at a scan rate of 0.1 V/s. All the measurements were performed at room temperature.

Computational Modeling of Cyclic Peptide Scaffold. The geometry of a model cyclic peptide, cyclo(Pro-Gly)$_4$, was optimized to estimate the molecular area of the cyclic peptide scaffold. The initial geometry was generated by a Fujitsu CAChe WorkSystem software (version 6.1.1). The dihedral angles of the peptide backbone were set $\omega = 180°$, $\varphi = -98°$, and $\psi = 90°$ for the Pro residues while the dihedral angles were set to $\omega = 180°$, $\varphi = -175°$, and $\psi = 178°$ for the Gly residue according to the literature (*40*). The geometry was then optimized by the Molecular Mechanics 2 (MM2) method and the semiempirical Austin Model 1 (AM1) method in the MOPAC 2002 package in the same program.

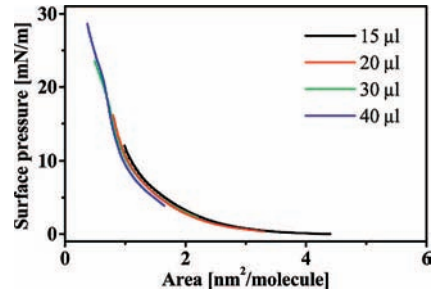

Figure 2. π–*A* isotherms of the cyclo8-C_{60} + PEG monolayer prepared with different spreading volumes.

RESULTS AND DISCUSSION

Monolayer at the Air/Water Interface. The cyclo8-C_{60} + PEG molecule is soluble in many organic solvents because of the modification with the cyclic peptide and the PEG chain. In this study, a chloroform solution of cyclo8-C_{60} + PEG was used for monolayer preparation. The π–*A* isotherms of cyclo8-C_{60} + PEG recorded with various spreading volumes of the solution are shown in Figure 2. With 15 μL of spreading volume (black line), surface pressure was observed at the starting point (~4.5 nm^2/molecule) and increased gradually with compression. Such an expanded isotherm is a typical behavior for monolayers carrying long PEG chains, in which intermolecular interactions among the PEG chains work over a large area (*41–43*). However, since the PEG chain of our compound is relatively short (degree of polymerization is ~12), the behavior at large areas (4–2 nm^2/molecule) might contain the contribution from the interaction among the cyclic peptide moieties. Since the compression ratio is limited to 1/4.5 in our trough, information at smaller areas could not be obtained with this spreading volume. To obtain the information on the C_{60} unit or the cyclic peptide moiety, the spreading volume was increased (Figure 2, red, green, and blue lines). Before the compression, surface pressure more than zero was observed depending on the spreading volume. Despite the separated measurements, the four isotherms overlapped nicely onto one curve; therefore, the behavior of the compound in a wide range of areas can be discussed. This result also suggests that the cyclo8-C_{60} + PEG molecules are uniformly dispersed and the C_{60} units do not aggregate even at small areas. This point will be discussed later. The monolayer did not collapse up to ~30 mN/m, indicating formation of a stable monolayer. The limiting molecular area was estimated to be 1.1 nm^2 by extrapolation of the linear region of the isotherm to the surface pressure of zero. This molecular area is much larger than that of the C_{60} unit (~0.7 nm^2/molecule assuming hexagonal packing of a 0.8 nm diameter sphere). Thus, it should be ascribed to the area of the cyclic peptide moiety. Indeed, a similar cyclic peptide has been reported to form a stable monolayer at the air/water interface. In the case of cyclo[Tyr(X)-Gly-(Pro-Gly)$_3$] (X represents a DR-1 derivative) the molecular area was about 1.0 nm^2 from the π–*A* isotherm (*39*). On the other hand, cyclo(Pro-Gly)$_4$ has a flat square form with a 1.2 nm side estimated by computational geometry optimization. The smaller molecular area of cyclo8-C_{60} + PEG compared with that of cyclo(Pro-Gly)$_4$ suggests that one replacement of the Pro residue in cyclo(Pro-Gly)$_4$ with a Glu

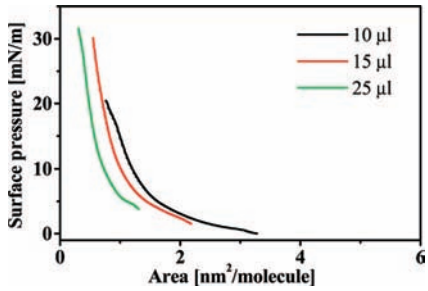

Figure 3. π–A isotherms of the C_{60} + PEG monolayer prepared with different spreading volumes.

or a Tyr derivative should reduce the molecular area because of the reduction of one flat pyrrolidine ring of the Pro residue from the total molecular area. The fact that the limiting molecular area is determined by the cyclic peptide moiety can be interpreted as follows. At large areas, it is unknown whether the C_{60} unit and the cyclic peptide moiety get together or are separated. However, upon compression of the monolayer, the fullerene unit should be physically forced to get on the cyclic peptide moiety because its molecular area is smaller than that of the cyclic peptide moiety with horizontal orientation and the C_{60} unit is hydrophobic. In other words, the cyclic peptide moiety acts as a scaffold to prevent the C_{60} units from aggregation, leading to the formation of a stable monolayer.

To examine the effect of the cyclic peptide moiety on monolayer formation, the control compound without the peptide moiety (C_{60} + PEG) was similarly studied. The isotherms of C_{60} + PEG showed an expanded feature similar to that of cyclo8-C_{60} + PEG (Figure 3). Increase of the surface pressure upon compression is observed even at large areas that can be attributed to the interaction among the PEG chains. However, the dependence on the spreading volume was different. The isotherm is shifted toward the smaller area as the spreading volume is increased. Therefore, the limiting molecular area of C_{60} + PEG could not be obtained. Such behavior is typical for a monolayer composed of molecules with a strong tendency to aggregate (*44*). This result clearly shows that the aggregation among the C_{60} units cannot be suppressed by a PEG chain alone. In other words, the cyclic peptide moiety in the cyclo8-C_{60} + PEG molecule should play an important role as a scaffold to prevent the C_{60} units from the aggregation in a condensed state.

LB Monolayer on a Substrate. The cyclo8-C_{60} + PEG monolayer was transferred onto a solid substrate by the vertical dipping method with the surface pressure maintained at 10 mN/m, resulting in preparation of the LB monolayer on the substrate. Two types of substrates, a quartz substrate and a gold substrate, were used for UV–vis absorption spectroscopy and cyclic voltammety, respectively. The transfer ratio was close to unity at upstroke but nearly zero at downstroke for both substrates. Figure 4 shows the absorption spectra of the cyclo8-C_{60} + PEG LB monolayer and cyclo8-C_{60} + PEG in chloroform. The absorption spectrum in solution shows a typical pattern for fullerene derivatives with four characteristic absorptions at 254, 319, 429, and 699 nm (*45*, *46*). The cyclo8-C_{60} + PEG LB monolayer shows similar absorptions at 252 and 322 nm, but the absorption bands are broadened compared to that in solution. This broadening infers that the C_{60} units electronically interact with each other in a condensed state in the monolayer (*47*). However, the interaction should not be considerable because the peak wavelengths do not shift much. Weak absorption bands at 429 and 699 nm could not be identified because of the lower signal to noise ratio in the monolayer spectrum. It is thus concluded that the electronic structure of the C_{60} unit is not significantly affected upon monolayer formation.

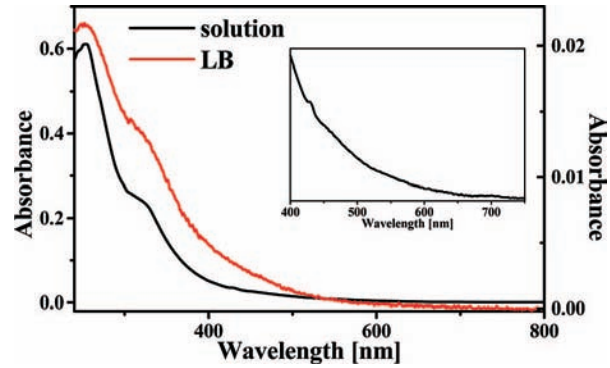

Figure 4. UV–vis absorption spectra of cyclo8-C_{60} + PEG in solution (black) and on a substrate (red). The absorbance of the spectrum in solution is referred to the left vertical axis while that of the LB monolayer to the right axis. The inset shows the magnified view of the spectrum in solution at a wavelength longer than 400 nm.

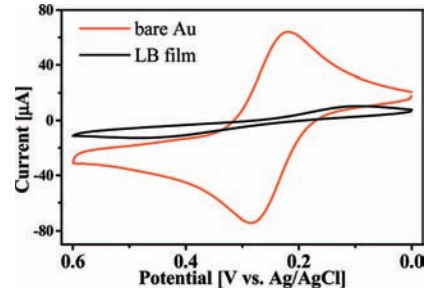

Figure 5. Cyclic voltammograms of a bare gold substrate (red) and the cyclo8-C_{60} + PEG LB monolayer-modified substrate (black) in 1 mM $K_4[Fe(CN)_6]$ and 1 M KCl aqueous solution at a scan rate of 0.05 V/s.

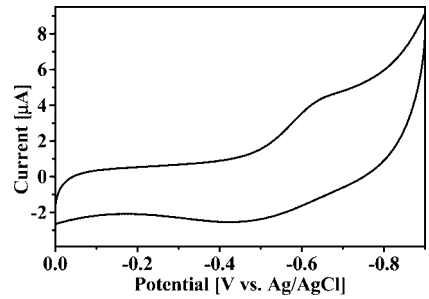

Figure 6. Cyclic voltammogram of the cyclo8-C_{60} + PEG LB monolayer in a 1 M *n*-Bu_4NCl aqueous solution at a scan rate of 0.1 V/s.

To investigate the packing of the cyclo8-C_{60} + PEG LB monolayer, cyclic voltammetry in an aqueous solution containing redox species was carried out using the LB monolayer prepared on a gold substrate. The cyclic voltammograms of a bare gold substrate and the LB monolayer-modified gold substrate in a 1 mM $K_4[Fe(CN)_6]$ solution are shown in Figure 5. Redox peaks of ferrocyanide/ferricyanide were clearly observed in the bare substrate. The peak separation was ~60 mV, showing fast electron transfer at the surface. In contrast, in the cyclo8-C_{60} + PEG LB monolayer, the current of the ferrocyanide/ferricyanide redox reaction was significantly reduced. This result shows that the cyclo8-C_{60} + PEG LB monolayer is well-packed and does not allow the penetration of the redox species to reach the gold surface.

To examine the redox property of the C_{60} unit in the monolayer, cyclic voltammetry in a 1 M *n*-Bu_4NCl aqueous solution was performed (Figure 6). The cyclo8-C_{60} + PEG LB monolayer exhibited reversible redox peaks of one-electron

reduction of the C_{60} unit. The formal potential was −0.53 V (vs Ag/AgCl). The peak separation was relatively large (204 mV), suggesting that the electron transfer between the C_{60} unit and gold is slow. This slow electron transfer can be ascribed to the poor physical contact between the monolayer and gold. Additional reduction peaks typical for C_{60} derivatives were not observed. The surface coverage of the cyclo8-C_{60} + PEG monolayer was estimated to be 0.58×10^{-10} mol cm^{-2} by integration of the area of the reduction peak. This surface coverage is comparable to that of dense C_{60} self-assembled monolayers prepared by covalent linking of molecules to metal ($(0.83–1.6) \times 10^{-10}$ mol cm^{-2}) (*48–50*). It is thus concluded that with modification of C_{60} with a cyclic peptide and PEG, a monolayer with relatively high density of the C_{60} unit can be prepared by the LB method on a surface retaining the C_{60} redox property.

CONCLUSION

In this work, a cyclic peptide carrying a C_{60} unit and a hydrophilic PEG chain at the side chain was synthesized, and its monolayer formation at the air/water interface and on a solid substrate was studied. The molecule formed a stable and uniform monolayer at the air/water interface because of a scaffold effect of the cyclic peptide moiety to prevent the C_{60} units from aggregation. The monolayer at the air/water interface could be successfully transferred onto a solid substrate. Absorption spectroscopy and cyclic voltammetry demonstrated that the electronic and redox properties of the C_{60} unit are preserved even in a condensed state in the monolayer. This method to prepare ordered fullerene thin films will be useful in the development of nanoscale electronics and photonics devices.

Improved probes for amyloid fibril formation are advantageous for the early detection and better understanding of this disease-associated process. Here, we report a comparative study of eight luminescent conjugated polythiophene derivates (LCPs) and their discrimination of a protein (insulin) in the native or amyloid-like fibrillar state. For two of the LCPs, the synthesis is reported. Compared to their monomer-based analogues, trimer-based LCPs showed significantly better optical signal specificity for amyloid-like fibrils, seen from increased quantum yield and spectral shift. The trimer-based LCPs alone were highly quenched and showed little interaction with native insulin, as seen from analytical ultracentrifugation and insignificant spectral differences from the trimer-based LCP in buffered and native protein solution. Hence, the trimer-based LCPs showed enhanced discrimination between the amyloid-like fibrillar state and the corresponding native protein.

INTRODUCTION

Several human disorders, including Alzheimer's disease, are known to be associated with protein misfolding events and amyloidogenesis. Both *in vivo* deposits and *in vitro* formed amyloid fibrils have a β-sheet-rich fibrillar structure. Although no structural or sequential homology of amyloidogenic proteins is present, the amyloid fibril structure appears generic, showing linear filaments with a diameter of approximately 10 nm (*1*).

For early detection and better understanding of the processes involved in amyloid fibril formation, a sensitive method is fundamental. Traditionally, Congo Red (CR) provides the most standardized way of staining amyloid plaques, showing green birefringence in cross-polarized light (*2*). The binding of CR to amyloid is considered specific but requires good control and experience to be reliable (*3*). The specificity of CR binding to *in vitro* amyloid fibrils has, however, been questioned (*4*), where it was demonstrated that Congo red binds to native, partially folded conformations and amyloid fibrils of several proteins. This finding indicates that CR must be used with caution as a diagnostic test for the presence of amyloid fibrils *in vitro*. Thioflavin T (ThT) and the analogue thioflavin S (ThS) are other small molecules well established for use in analysis of aggregated amyloid proteins formed *in vitro*. The binding of ThT to amyloid is somewhat weaker than CR binding, but upon binding, the dye increases its fluorescence more than 1000-fold (*5*). ThT is a bluegreen-emissive dye, causing interference with autofluorescence from tissue, which is a recurring problem. On the basis of the affinity of CR and ThT, several compounds have been synthesized to increase affinity and contrast, and remove metabolic and toxic liabilities for *in vivo* applications as well as increasing blood- brain barrier permeability (*6–9*). A more novel approach to designing an *in vivo* amyloid imaging probe is the synthesis of a dithienylethenyl compound, on the basis of the empirical experiences of dyes with affinity for amyloid structures performed by Nesterov et al. (*8*).

Luminescent, conjugated polymers (LCPs) have been demonstrated as conformational sensitive optical probes to detect conformal changes in synthetic peptides (*10, 11*) and calcium induced conformal changes in calmodulin (*12*). More recently, we have shown that LCPs can be used to monitor amyloid fibril formation *in vitro* (*13, 14*), for the histological labeling of amyloid deposits in *ex vivo* tissue samples (*15*), and conformal mapping of amyloid deposits (*16*). The electronic structure and thereby the optical processes of LCPs is directly correlated to the conformation of the polymer chains and their organization. If the polymer is governed by a biomolecule capable of folding into several possible conformational states or quaternary organizations, then the optical properties of the polymer will be a spectroscopic signature of the state of the biomolecule.

The chain length of π-conjugated polymers is directly correlated with physical properties such as optical absorption maximum or oxidation potential (*17–20*). Regioregular oligomers of well-defined chain length have been used as model compounds to facilitate the interpretation of physical properties in photonic and electronic applications (*18, 20*). Likewise, in biosensing, a defined conjugated oligomer can give a more specific interaction with the biomolecule, and the correlation between this interaction and the optical properties of the conjugated oligomer would be more easily interpreted.

We have reported the use of a number of polythiophenes with diverse side chain funtionalization for biomolecular interactions (*10, 12–16, 21*), and more recently, we have synthesized trimer-based analogues of these. In this work, we demonstrate two examples of the synthesis of thiophene-based LCPs, PTT, and tPTAA (see Figure 1 and Scheme 1). These two LCPs complete a series of eight, which we have used in this study for structure/functionality evaluation of the properties influencing the interaction between LCPs and amyloid-like fibrils. The LCPs were designed to have different hydrophobic/hydrophilic properties as well as alterations in steric congestion. Interaction with native and fibrillar insulin in solution was studied and evaluated

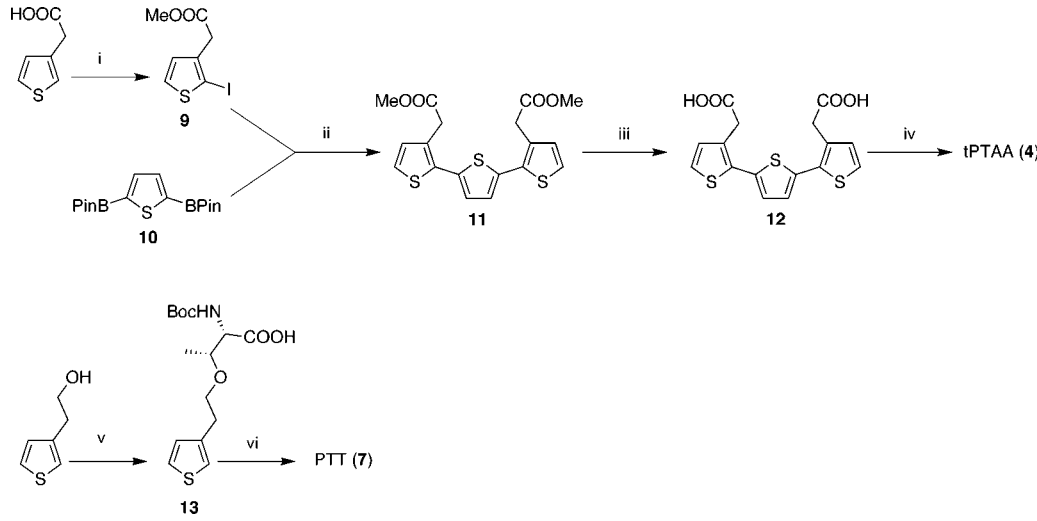
by means of their optical properties. The interaction between native/fibrillar insulin and the well-defined trimer-based tPTAA and tPOWT was investigated in more detail.

EXPERIMENTAL PROCEDURES

Polymer Synthesis. Synthesis of PTAA (*22*), POWT (*23*), POMT (*21*), and tPOWT (*13*) has been described elsewhere, and recently, Nilsson et al. (*16*) reported the synthesis of tPOMT and tPTT.



General Methods. Organic extracts were dried over anhydrous magnesium sulfate, filtered, and concentrated in vacuo at 40 °C. 3-Thiopheneethanol, 3-thiopheneacetic acid, and PEPPSI-IPr are commercially available from Sigma-Aldrich Co. Microwave reactions were carried out on a SmithCreator 482 microwave reactor. NMR-spectra were recorded on a Varian 300 MHz instrument. Chemical shifts are given in ppm relative to TMS in $CDCl_3$ (δ 0.00) for ^{1}H and ^{13}C or CD_3OD (δ 3.31) for ^{1}H and CD_3OD (δ 49.0) for ^{13}C NMR. TLC was carried out on Merck precoated 60 F_{254} plates using UV-light and charring with ethanol/sulfuric acid/*p*-anisaldehyde/acetic acid 90:3:2:1 for visualization. Flash column (FC) chromatography was performed using silica gel 60 (0.040–0.063 mm, Merck). Gradient HPLC-MS was performed on a Gilson system (column, Phenomenex C-18 250 × 15 mm and Phenomenex C-18 150 × 4.6 mm for preparative and analytical runs, respectively; pump, Gilson gradient pump 322; UV/vis-detector, Gilson 155; MS detector, Thermo Finnigan Surveyor MSQ; Gilson Fraction Collector FC204) using acetonitrile with 0.1% formic acid and deionized water with 0.1% formic acid as mobile phase. MALDI-TOF MS was recorded in linear positive mode with α-cyano-4-hydroxycinnamic acid matrix (CHCA) or 2,5-dihydroxy benzoic acid (DHB) as matrix.

*(2-Iodo-thiophen-3-yl)-acetic Acid Methyl Ester (***9***).* Acetyl bromide (11.7 mL, 158 mmol) was added slowly to a solution of 3-thiopheneacetic acid (7.51 g, 52.8 mmol) in methanol (60 mL, 0 °C). After 4 h, the mixture was diluted with chloroform (70 mL) and washed twice with $NaHCO_3$ (100 mL, sat, aq.) and once with H_2O (100 mL). After concentration, the product (6.08 g, 39.0 mmol) was dissolved in chloroform/acetic acid (30 mL, 1:1) and cooled to 0 °C, and *N*-iodosuccinimide (11.0 g, 48.8 mmol) was added. Eighteen hours later, water was added to the reaction, and the organic phase was washed twice with KOH (50 mL, 10%, aq.) and H_2O (50 mL). The crude product was purified by vacuum distillation to afford **9** in 43% yield.

^{13}C-NMR($CDCl_3$) δ: 35.9, 52.4, 123.1, 126.0, 128.6, 139.0, 170.9.

^{1}H-NMR($CDCl_3$) δ: 3.63 (s, 2H), 3.78 (s, 3H), 6.93 (d, 1H, J = 5.48 Hz), 7.57 (d, 1H, J = 5.48 Hz). HRMS calcd. for $C_7H_7IO_2S$: $[M]^+$ 281.9211; Found: 281.9209.

NaOH, H_2O, dioxane; 2. $FeCl_3$, TBA-triflate, chloroform. (iv) 1. p-TsCl, chloroform/pyridine (7:1); 2. N-t-Boc-Thr, K_2CO_3, DMF; (v) 1. TFA, chloroform; 2. $FeCl_3$, TBA-triflate, chloroform.

*(3″-Methoxycarbonylmethyl-[2,2′;5′,2″]terthiophen-3-yl)-acetic Acid Methyl Ester (***11***).* Compounds **9** (0.185 g, 0.656 mmol), **10** (0.113 g, 0.336 mmol), and K_2CO_3 (0.120 g, 0.868 mmol) were dissolved in degassed toluene/methanol (5 mL, 1:1), and Ar (g) was bubbled for 10 min. PEPPSI-IPr (0.006 mg) was added, and the reaction was subjected to microwave conditions for 10 min at 100 °C. The mixture was diluted with toluene (20 mL) and washed with HCl (10 mL, 1 M, aq.) and H_2O (20 mL). The crude product was further purified by FC (toluene → toluene/ethyl acetate (40:1)) to give the trimer (**11**) (87 mg, 66%) as a pale yellow oil.

^{13}C-NMR($CDCl_3$) δ: 34.7, 52.3, 124.9, 127.5, 130.5, 130.6, 133.0, 135.9, 171.5.

^{1}H-NMR($CDCl_3$) δ: 3.72 (s, 6H), 3.79 (s, 4H), 7.05 (d, 2H, $J = 5.21$), 7.14 (s, 2H), 7.25 (d, 2H, $J = 5.21$). HRMS calcd. for $C_{18}H_{16}O_4S_3$: $[M]^+$ 392.0211; Found: 392.0228.

*tPTAA (***4***).* To a solution of the trimer (**11**) (0.086 g, 0.218 mmol) in dioxane (10 mL), NaOH (5.5 mL, 0.1 M, aq.) was added slowly. When no starting material was seen by TLC, the solution was transferred to an extraction flask, and ethyl acetate (30 mL) was added. The organic phase was washed with HCl (50 mL, 1 M, aq.) subjected to normal workup and used directly in the next step. To a solution of the deprotected trimer and tetrabutylammonium-trifluoromethanesulfonate (0.171 g, 0.436 mmol) in chloroform (5 mL, dry), $FeCl_3$ (0.158 g, 0.981 mmol) was added at 0 °C. After 18 h, methanol was added and the product precipitated as red flakes. The red flakes were collected, dissolved in NaOH (3 M, aq.), neutralized with HCl (conc.), and precipitated with methanol to give tPTAA (**4**) as red crystals (17 mg, 20%).

*(2S,3R)-2-tert-Butoxycarbonylamino-3-(2-thiophen-3-yl-ethoxy)-butyric Acid (***12***).* 3-Thiopheneethanol (7.52 g, 58.7 mmol) and *p*-toluenesulfonic chloride (190.7 g, 16.8 mmol) were added to a solution of chloroform/pyridine (80 mL, 7:1) at 0 °C. After one day, the solution was diluted with diethyl ether and washed twice with HCl (2 M, aq.), twice with $NaHCO_3$ (5%, aq.), and once with H_2O. FC (toluene → toluene/ethyl acetate 3:1) and recrystallization from ethyl acetate/hexane afforded 2-(3-thienyl)ethanol tosylate (16.1 g, 97%) as white crystals. The ^{1}H NMR data was in accordance with that previously reported (*24*). The tosylated product (1.38 g, 4.90 mmol), *N*-t-Boc-Thr (2.15 g, 9.81 mmol), and K_2CO_3 (2.03 g, 14.7 mmol) were added to DMF (90 mL) and heated to 40 °C. After one day, the mixture was poured over HCl/ice (2 M, aq. 1:1) and extracted twice with toluene. The combined extracts were washed twice with H_2O and purified twice on FC (toluene/ethyl acetate 4:1 and toluene/ethyl acetate 6:1) to give **12** (1.16 g, 72%).

^{13}C NMR (CD_3OD) δ: 20.3, 28.7, 30.4, 60.8, 66.4, 68.5, 80.8, 122.7, 126.5, 129.3, 139.4, 158.3, 172.7.

^{1}H NMR (CD_3OD) δ: 1.18 (d, 3H, $J = 6.23$ Hz), 1.46 (s, 9H), 3.00 (t, 2H, $J = 6.78$ Hz), 4.11 (d, 1H, $J = 2.93$), 4.22 (dq, 1H, $J = 2.93$, 6.23 Hz), 4.34 (t, 2H, $J = 6.78$), 7.02 (dd, 1H, $J = 1.47$, 4.95 Hz), 7.15 (dd, 1H, $J = 1.47$, 2.93 Hz), 7.33 (dd, 1H, $J = 2.93$, 4.95). HRMS calcd. for $C_{15}H_{24}NO_5S$: $[M + H]^+$ 330.1375; Found: 330.1303.

*PTT (***7***).* Compound **13** (0.818 g, 2.48 mmol) was added to a solution of dichloromethane/TFA (11 mL, 1:1). After 1 h, the solution was quenched with methanol (3 mL) and coevaporated with toluene three times. The deprotected product and tetrabutylammonium-trifluoromethanesulfonate (1.26 g, 3.22 mmol) were dissolved in chloroform (32 mL, dry) at 0 °C under a N_2 atmosphere. $FeCl_3$ (1.81 g, 11.2 mmol) was added to the solution. After one day, the solution was extracted three times with H_2O. The aqueous solution was diluted with acetone, and conc. HCl (4 mL) was added. When the product had precipitated, it was centrifuged (6 min, 3600 rpm). The collected precipitate was dissolved in water (4 mL) and precipitated from acetone/HCl (40 mL, 25:1). The procedure was repeated twice to afford PTT (**7**) (224 mg, 39%) as red crystals.

Bovine Insulin Preparation. Bovine insulin (Sigma-Aldrich) was dissolved in 2 M guanidine hydrochloride and was dialyzed versus three rounds of 25 mM HCl at 4 °C. The insulin stock solutions ($0.5 \leq 2.0$ mM) were stored at 4 °C and were stable for several weeks. Absorbance at 280 nm was employed for concentration determinations using $\varepsilon^{280} = 5840$ M^{-1}cm for insulin.

Amyloid-Like Fibril Formation. A stock solution containing 320 μM bovine insulin in 25 mM HCl was prepared. The solution was placed in a water bath at 65 °C for at least 13 h to induce amyloid fibril formation. The fibrillated samples were ultra sonicated for at least 10 min prior to optical measurements to avoid sedimentation of large fibril aggregates.

Optical Measurements. Stock solutions of each LCP at a concentration of 1 mg/mL in deionized water were prepared. For fluorescence measurements, 2.5 μL of the LCP solution was diluted with the buffer used: 50 mM HCl and 100 mM Na_2CO_3 at pH 10, to a final volume of 912.5 μL. In the samples where

native and fibrillar insulin were studied, 2.5 μL of the LCP solution was mixed 15 μL of the bovine insulin solution (25 mM HCl) diluted with buffer to a final volume of 912.5 μL. In titration experiments, the concentration of LCP was kept constant, and the concentration of sonicated insulin fibrils was varied between 0 and 105 μM. For the absorption measurements, 5 μL of the LCP solution was diluted to a total volume of 200 μL with buffer.

The samples were incubated for 5 min at RT, and the excitation and emission spectra were recorded with an ISA Jobin-Yvon spex FluoroMax-2 apparatus. For the absorption measurements and the titration experiments, a Tecan Saphire^2 plate reader was used.

Analytical Ultracentrifugation. Weight average molecular weights were determined by analytical ultracentrifugation in Beckman Coulter XL-A/XL-I with an An50Ti rotor and a photoelectric scanner. Equilibrium sedimentation experiments were run at 3000, 7000, 11,000, 15,000, 25,000, 32,000, 40,000, and 45,000 rpm until equilibrium was reached at each speed (20 h) at 20 °C. Five microliters of stock LCP solution was mixed with 30 μL of native or fibrillated bovine insulin solution (320 μM in 25 mM HCl) or 30 μL 25 mM HCl and diluted to 200 μL in buffer. Data was collected at 280 and 446 nm and evaluated using the self-association model in the XL-I, XL-A data analysis software. The solvent density was calculated to be 0.99913 g/cm^3 and 1.00915 g/cm^3 for 50 mM HCl and 100 mM Na_2CO_3, respectively. The partial specific volume (ν) of insulin used was 0.735. ν of the LCPs was determined densiometrically in Anton Paar DMAC02 Precision Density Meter.

RESULTS AND DISCUSSION

Synthesis. *PTT.* 3-Thiopheneethanol was tosylated in chloroform/pyridine, and the tosylate was substituted with *N*-t-Boc-Thr in K_2CO_3 and DMF. Interestingly, the substitution of the tosylate with the secondary alcohol *N*-t-Boc-Thr gave a higher yield of **13** (72%) than that with the primary alcohol *N*-t-Boc-Ser previously reported (57%) (*23*) (see Scheme 1). The functionalized thiophene monomer was subsequently deprotected and polymerized to give PTT (**7**) in 39% yield.

*tPTAA (**4**).* Monohalogenated thiophenes are generally hard to separate from the nonhalogenated thiophene and the dihalogenated one using conventional flush chromatography. Therefore 3-thiopheneacetic acid was protected as a methylester in acetyl bromide and methanol before it was iodinated with NIS in chloroform and acetic acid. This product could be purified by distillation to give **9** in 43% over two steps. The diboronic ester (**10**) used to assemble **11** was made from thiophene with a protocol described by Parakka et al. (*25*). The coupling of **9** and **10** was performed under microwave conditions for 10 min at 100 °C using PEPPSI-IPr as catalyst to afford the trimer (**11**) in 66% yield. Finally, the esters were hydrolyzed under basic conditions, and the deprotected trimer was polymerized using iron(III)chloride to give tPTAA in 20% yield.

Matrix Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectroscopy (MALDI-TOF MS). MALDI-TOF MS has become increasingly important as a convenient method to characterize polymers even though the result often does not reliably show the actual chain length distribution (*26*). PTT (0.5 μL, 1 mg/mL) was mixed with CHCA in 0.1% TFA/acetonitrile (0.5 μL, 1:1) as the matrix. The spectra of the product showed polymers mainly in the range 10 to 18 monomer units following ion series corresponding to the monomer unit $[227n]^+$, $[227n + 35]^+$, and $[227n + 70]^+$, where +35 and +70 correspond to covalent end termination of the polymer by one and two chlorines, respectively (see Figure 2A). There are few references (*27*) in the literature to negatively charged polymers characterized by MALDI-TOF MS, and even the tPTAA-analogue PTAA, synthesized some time ago (*28*), has yet to be characterized this way. Therefore, a new protocol had to be used. tPTAA (0.5 μL) was mixed with DHB (0.5 μL, 10 mg/mL in 10% TFA). The spectra showed two main peaks corresponding to [362n]+, where n corresponds to 4 or 5 units (Figure 2B). The chain distribution of the LCPs varies to some extent depending on the chemical structure of the LCP. However, it seems that the trimer-based LCPs (**1**–**4**) generally have the same molecular weight (around 1500 Da) regardless of the substituent (*13*). The same trend can be observed for the monomer-based LCPs (**5**–**7**), but the molecular weight is higher (around 3000 Da) (*21, 29*).

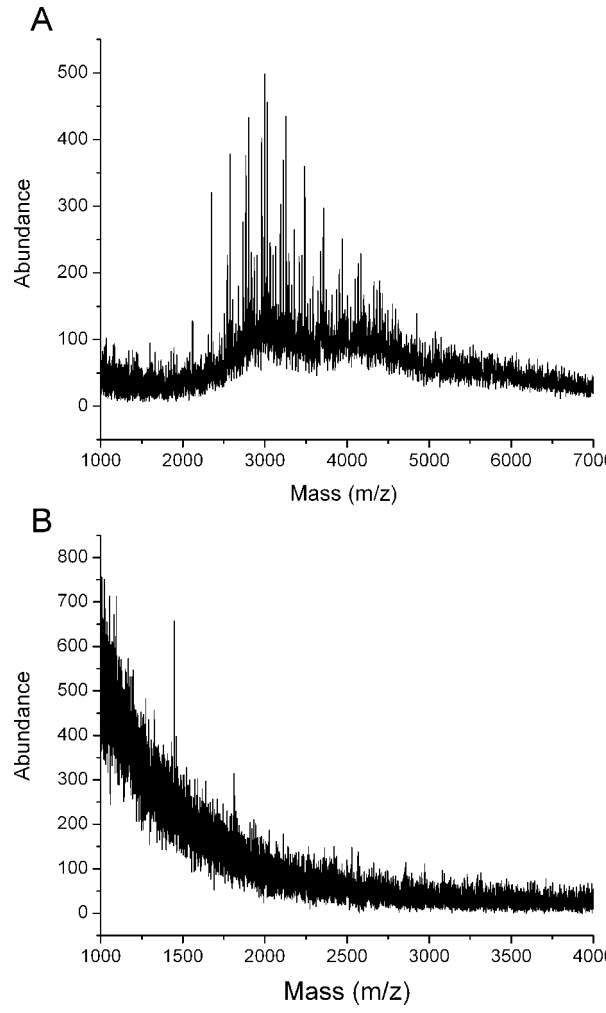

Figure 2. MALDI spectra of (A) PTT and (B) tPTAA.

Optical Characterization of LCPs. The optical properties, measured by absorption, fluorescence, and circular dichroism (CD), of the LCPs in Figure 1 are highly pH-dependent because of the different degree of protonation of the carboxyl and amine groups on the side chains (*13, 30*). The degree of protonation will influence the propensity of the polymer chains to aggregate in water-based solutions. Aggregation will enhance interchain interactions, leading to a red shift in absorption and fluorescence and lower fluorescence intensity due to higher probability of nonradioactive de-excitation pathways. The trimer-based LCPs (compounds **1**–**4**; Figure 1) showed more red-shifted spectra and lower fluorescence intensity (see Table 1 and Figure 1) compared to their monomer-based analogues (compounds **5**–**8**; Figure 1) in the same buffer solution. These differences in optical properties are likely to arise from the lower degree of side-chain substitution along the polymer backbone. The lower

degree of side-chain substitution can enhance interchain backbone interaction and promote aggregation.

Optical Characterization of LCPs Interacting with Native and Fibrillar Insulin. We have shown earlier the characteristic changes in optical properties, in fluorescence–excitation and emission, of LCPs upon interaction with amyloid-like fibrils (*13, 14, 16*), PTAA and tPOWT interacting with insulin fibrils, and PTAA, POMT, tPOMT, and tPTT interacting with fibrils of Aβ 1–42. To further characterize these, we have made a comparison of the monomer- and trimer-based LCPs in fluorescence emission (Figure 3 and Table 1) and fluorescence–excitation spectra of two of the trimer-based LCPs, tPOWT and tPTAA (Figure 4), upon interaction with insulin in native and fibrillar form.

Figure 3 and Table 1 show that there is virtually no difference in the fluorescence emission spectra between buffer and native insulin in the case of the trimer-based LCPs, whereas the monomer-based LCPs show intensity differences and in some cases spectral shifts upon interaction with native insulin. As also seen with fibrillar Aβ (1–42) (*16*), interaction with fibrillar insulin gives a higher quantum yield (QY) for all LCPs, but the relative difference is significantly larger with trimer-based LCPs. All of the emission spectra have been recorded with excitation at 488 nm, which is near the peak maximum of the fluorescence–excitation spectra shown earlier (*16*) and in Figure 4. Also, in these spectra, there is an augmented fluorescence response upon interaction with insulin fibrils. The possibility of exciting these LCPs with 488 nm is advantageous considering that the 488 nm laser line of argon is often used in confocal microscopy. The increased fluorescence emission of the LCPs upon interaction with fibrils was most likely due to polymer chain separation caused by the binding event. Hence, LCPs alone in the corresponding buffer associated into clusters, and notably, the clusters were still in solution. In all cases, except for PTAA, fibril interaction was associated with a blue shift in emission, which is associated with chain separation or an increased twist of the polymer backbone compared to the free LCP cluster.

The spectral discrimination between a LCP in buffered solution, solution with native insulin, or with fibrillar insulin seems to be governed by both the backbone and the side chain of the LCP. It appears important that the backbone is exposed for maximum hydrophobic interaction with fibrillar insulin, while the side chain must remain hydrophilic to ensure water solubility as well as reducing the interaction with native insulin. The six cationic LCPs (**1**–**3** and **5**–**7**) were all buffered at pH 1 and are therefore easily compared with each other. At pH 1, both the LCPs and the protein in its native and fibrillar state were positively charged. Electrostatic repulsion from the charges is likely to occur, and it is reasonable to assume that a trimer-based LCP with every third cationic substituent removed and thereby with a more exposed backbone more easily interacts with the amyloid fibrils. If the three monomer-based cationic LCPs **5**–**7** are compared (Figure 3 and Table 1), there is a relationship between hydrophobicity of the side chain and the spectral discrimination of native and fibrillar insulin. The LCP POWT, substituted with serine, showed a larger shift and higher intensity change than the two methylated species, PTT, methylated at the β-position, and POMT, the methyl ester of serine, when the discrimination between the native and fibrillar state of insulin is compared. Possibly, a more hydrophobic substituent interferes with the fibril/polymer backbone interaction. In the trimer-based LCPs **1**–**3**, the spectral trend as observed with the monomer-based analogues with respect to their side-chain substituents was more pronounced. tPOWT showed almost twice as large a blue-shift and intensity increase as tPOMT and tPTT when comparing spectra from native and fibrillar insulin. Moreover, the spectral difference between the signal of the trimer-based LCPs in buffered solution compared to the signal with native insulin was insignificant. The anionic trimer-based tPTAA (**4**), which was used in a buffered environment at pH 10, shows the same spectral discrepancy as the LCPs **1**–**3**. Compared to the monomer-based **5**–**7**, PTAA showed larger spectral shifts, although not as distinct as for tPTAA. For the application as a probe for amyloid fibril detection, it is clearly advantageous with a low signal toward native protein and buffer. Besides the substitution pattern, there are other differences between the monomer- and trimer-based LCPs that might influence the contrast. The trimer-based LCPs are completely regioregular because of the 2-fold rotational axis in the center thiophene, whereas the monomer-based LCPs do not contain a rotational axis and therefore when polymerized can bind head-to-tail as well as head-to-head. The trimer-based LCPs are also shorter with a more well-defined chain length that could influence the discrimination behavior.

To further evaluate the interaction between LCP and fibrillar insulin, tPTAA and tPOWT were more thoroughly studied. The two LCPs showed the best signal discrepancy and emission enhancement between native and fibrillar insulin. Moreover, tPTAA had so far not been further characterized and was also interesting because of the good tissue staining properties published earlier with its analogue PTAA (*15*).

Titration experiments were performed, where the amount of LCP was kept constant, and the fibril concentration was increased (Figure 5). The titration curve was fitted to a Hill plot cooperative model.

$$Y = B_{max}[X]^{n_H}/(K_{1/2}^{n_H} + [X]^{n_H}) \quad (1)$$

In eq 1, B_{max} is the maximum recorded signal, n_H is the cooperativity value, where a value larger than 1 indicates positive cooperativity, and $K_{1/2}$ is the value where 50% of the maximum signal is reached. At fibril concentration $K_{1/2}$, 50% of the LCP chain population was bound to fibrils.

In the model, tPOWT had a $K_{1/2} = 0.2$ μM and $n = 1.2$, whereas tPTAA had $K_{1/2} = 2.4$ μM and $n = 1$. This indicates that tPTAA (at pH 10) had a lower affinity for fibrils than tPOWT at pH 1. Whether the affinity difference is a side-chain-induced effect or a reduced fibril polymer–backbone interaction at the higher pH is unclear. None of the LCPs showed a clear cooperativity in the interaction event since n was not significantly larger than 1.

To evaluate the interaction between tPTAA and tPOWT with amyloid-like fibrils, we studied the LCP fluorescence response at a constant total protein concentration with increasing fibril content compared to native protein. In Figure 6, the result is presented as the percentage of amyloid-like fibrils in total protein concentration (5.26 μM) as relative change in the fluorescence ratios 550/600 (tPOWT) and 570/670 (tPTAA). Clearly, a small amount of fibrils could be detected in the presence of native protein. The lowest detection level was reached at 0.5% and

(A) POWT and tPOWT in 50 mM HCl, (B) POMT and tPOMT in 50 mM HCl, (C) PTT and tPTT in 50 mM HCl, and (D) PTAA and tPTAA in 100 mM Na_2CO_3.

1.4% fibrils for POWT and tPTAA, respectively, corresponding to a 20% relative change in the signal.

Analytical Ultracentrifugation. Along with the limitations of MALDI-TOF MS (vide supra), it is vital to consider that weakly associated assemblies, for example, linked through hydrogen bonding, can easily break during measurements. Analytical ultracentrifugation (AUC) is a nondisruptive solution-based technique, well known for the characterization of proteins and protein complexes and also synthetic macromolecules (*31*). This makes the technique suitable to study the state of LCPs in solutions and the interaction between LCPs and proteins.

AUC experiments were run in equilibrium sedimentation mode at 9 velocities, and absorption was measured at 280 and 445 nm. tPTAA and tPOWT were studied in buffer and with native insulin and fibrillar insulin. tPTAA and tPOWT in buffer were fitted to a single species self-association model as shown in Figure 7.

The main disadvantages of AUC are related to the difficulty in obtaining accurate partial specific volumes in some cases (*31*). The partial specific volume $\bar{\nu}$; is needed to determine the absolute molar mass (M) from the buoyant mass as follows:

$$M_b = M(1 - \bar{\nu}\rho) \qquad (2)$$

$\bar{\nu}$ of tPTAA and tPOWT was determined densiometrically at the concentration (25 μg/mL) used in the AUC experiments in order to avoid the formation of different states of interchain interactions. The low concentration made the measurement of $\bar{\nu}$; difficult, and the obtained value 0.5 for both tPOWT and tPTAA should be seen as a guideline. To our knowledge, there are no values of $\bar{\nu}$; for polythiophenes in the literature, but our value can be compared with the study of Michaels et al., which determined $\bar{\nu}$; of a polyparaphenylene to 0.62, of a polyfluorene to 0.65, and a polydiphenylenevinylene to 0.55 (*32*).

If the sedimentation curves of tPTAA are fitted to a self-association model, the average buoyant mass (M_b) is 25600 ± 1600 g/mol, which gives an molecular mass (M) of 12700 ± 800 g/mol. tPOWT gives a value of M_b of 24800 ± 4000 g/mol, which corresponds to an M of 12400 ± 2000 g/mol. Interestingly, if we compare these values with the MALDI-TOF spectra reported by us earlier (*13*) and in this publication, we can see clear differences since the majority of the tPOWT chains had a mass value of 1509 g/mol and tPTAA had a corresponding value of 1447 g/mol. These values lead us to the conclusion that the studied free LCPs were in a state of small clusters when present in aqueous solution. On average, a cluster of tPTAA consisted of nine polymer chains, and for tPOWT, this value is 8 ± 1. This result could explain the very low fluorescence signal intensity from tPOWT and tPTAA in acidic and basic buffers, respectively, due to intermolecular quenching.

To evaluate the interaction between native insulin and the LCP, an equilibrium sedimentation experiment was run with 48 μM native insulin and 16.6 (tPOWT, 25 μg/mL) and 17.2 (tPTAA, 25 μg/mL) μM LCP. There was no significant difference between the sedimentation profiles at A_{445nm} of the pure LCP samples and those where insulin was present (Figure S1, Supporting Information). The sedimentation profiles of pure insulin measured at A_{280nm} were fitted to the self-association model and resulted in an average weight in 100 mM Na_2CO_3 at pH 10 and in 50 mM HCl at pH 1 of 5700 g/mol and 11500 g/mol, respectively, corresponding to the monomer and dimer weight of insulin. The association state of insulin is highly dependent on pH, ion concentration, and insulin concentration

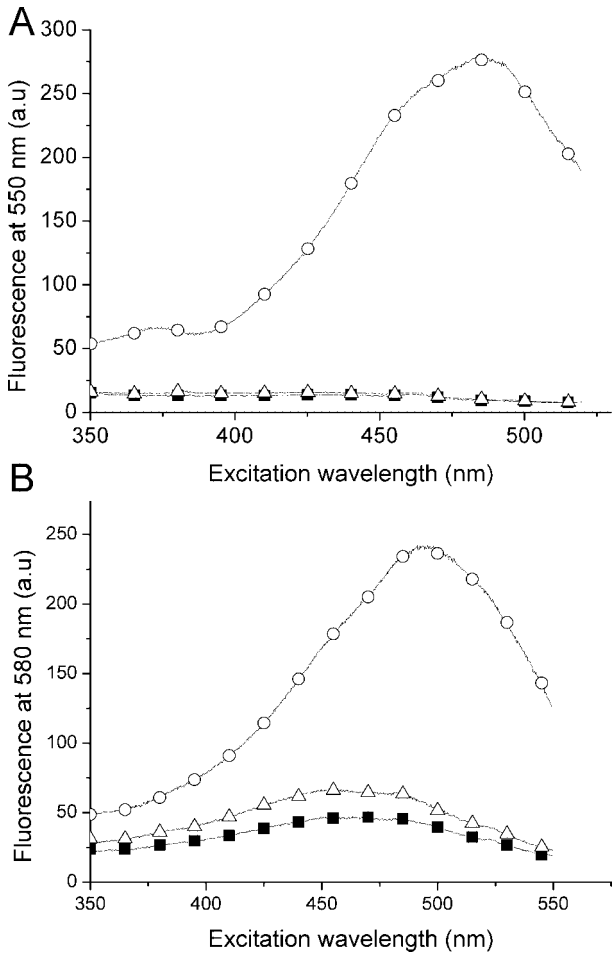

Figure 4. Fluorescence–excitation spectra. (A) Fluorescence emission at 550 nm from 2.7 μg/mL tPOWT in (;■) 50 mM HCl, (;△) 20 mM HCl with 5 μM native insulin, and (○) 50 mM HCl with 5 μM fibrillar insulin. (B) Fluorescence emission at 580 nm from 2.7 μg/mL tPTAA in (;■) 20 mM $NaCaO_3$, (;△) 20 mM $NaCaO_3$ with 5 μM native insulin, and (○) 20 mM $NaCaO_3$ with 5 μM fibrillar insulin.

(*33*). Kadima et al. found that zinc-free insulin was present as monomers at a concentration of 1.9 mg/mL at pH 10.5 (*33*). At an insulin concentration of 2 μM at pH 2.0, Nettleton et al. reported that insulin was to be found mostly in monomeric form but also that dimers were present (*34*). Our results, obtained at pH 1, indicate that the dimerization of insulin increases at lower pH. From the sedimentation curves shown in Figure S1, Supporting Information and the mass determination of native insulin, it can be assumed that the LCPs did not interact with the native protein in the mentioned solution conditions. If one considers the preservation of the fluorescence–excitation and emission properties of the LCP, it is unlikely that the interaction with native insulin led to the disruption of the clusters of LCPs and the formation of a complex of similar mass.

The sedimentation of the ultrasonicated insulin fibrils occurred already before equilibrium at the lowest rotation speed (3000 rpm), indicating that the masses of these fibril fragments are >1000000 g/mol. This result shows that the dissolution of insulin fibrils with aqueous ammonia at pH 10.5 showed by Nilsson et al. (*35*) did not occur in 100 mM Na_2CO_3 at pH 10. In samples with both LCP and sonicated fibrils, the cosedimentation of both species at low rotation speed was obvious, showing interaction between LCP and fibrils.

CONCLUSIONS

From the optical measurements, in absorbance and fluorescence, of the LCP, it was clear that the trimer-based analogues

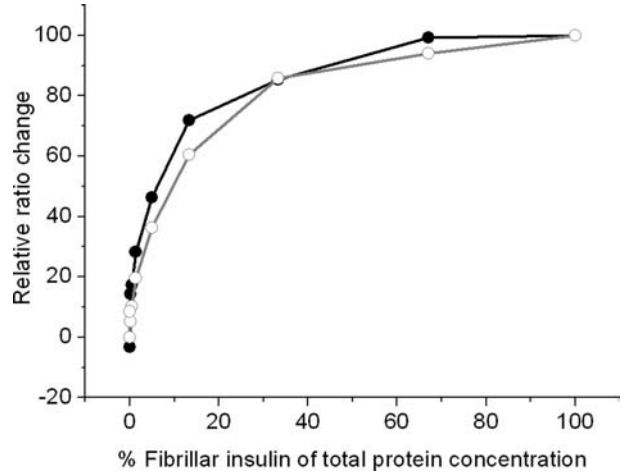

Figure 6. Detection of fibrillar insulin in the presence of native insulin. tPOWT (black) (2.7 μg/mL) in 50 mM HCl. tPTAA (grey) (2.7 μg/mL) in 100 mM Na_2CO_3 at pH 10. The percentage of sonicated fibrillated insulin of the total amount of insulin is shown as the monomer insulin added. Total protein concentration (5.26 μM) was kept constant. Excitation was at 488 nm. The relative change in the emission ratio at 550 nm/600 nm (tPOWT) and 570 nm/670 nm (tPTAA) is shown.

were more quenched in solution, giving lower quantum yields. The trimer-based LCPs showed optical signal specificity for amyloid-like fibrils as seen from increased QY and spectral shift, whereas no spectral changes could be seen with native insulin compared to buffered solution. These results were also supported by the possibility of distinguishing the fibrillar signal in a 70-

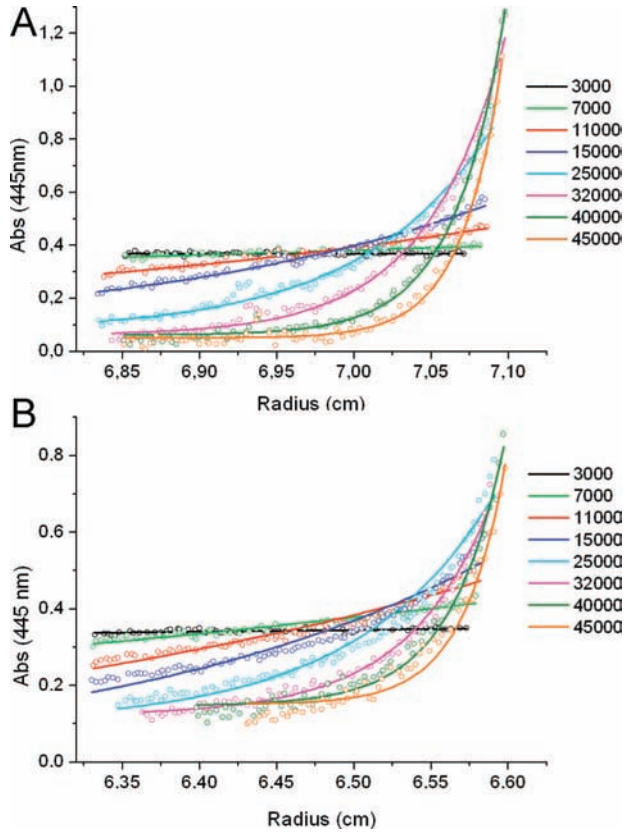

Figure 7. Analytical ultracentrifuge sedimentation curves of absorbance at 445 nm (A) tPOWT (25 μg/mL) in 50 mM HCl. (B) tPTAA (25 μg/mL) in 100 mM Na_2CO_3 at pH 10. Rotation speed in rpm is shown in the legend. Lines are fitted to a self-association model.

fold excess of native insulin. Furthermore, AUC demonstrated that the trimer-based tPTAA and tPOWT showed no interaction with native insulin, whereas they cosediment with fibrils, indicating strong noncovalent binding. We also report that tPTAA and tPOWT form small clusters in solution, likely to avoid exposure of the hydrophobic polythiophene backbone. The LCP/amyloid-like fibril interaction seems to be governed by the backbone of the polymer. If one compare the cationic monomer-based polymers with the trimer-based cationic LCPs, it is apparent that the removal of one out of three side chains and thereby increasing the exposure of the backbone, gave rise to a strong signal enhancement upon interaction with amyloid fibrils compared to monomer-based LCPs. The anionic LCPs PTAA and tPTAA showed the same behavior as their cationic counterparts, even though the pH was changed from acidic to basic. This study verifies our hypothesis that trimer-based LCPs have a better potential than monomer-based LCPs as optical probes for amyloid fibril detection. Moreover, LCPs **2**, **3**, **6**, and **8** have been discussed for use in diagnostics of aggregation proteopathies (*16*), and here, we demonstrate that tPTAA is another potential candidate for these applications.

ACKNOWLEDGMENT

We acknowledge partial funding from VINNOVA and CENANO at LiU (A.H.). Thiolytically Cleavable Dithiobenzyl Urethane-Linked Polymer–Protein Conjugates as Macromolecular Prodrugs: Reversible PEGylation of Proteins

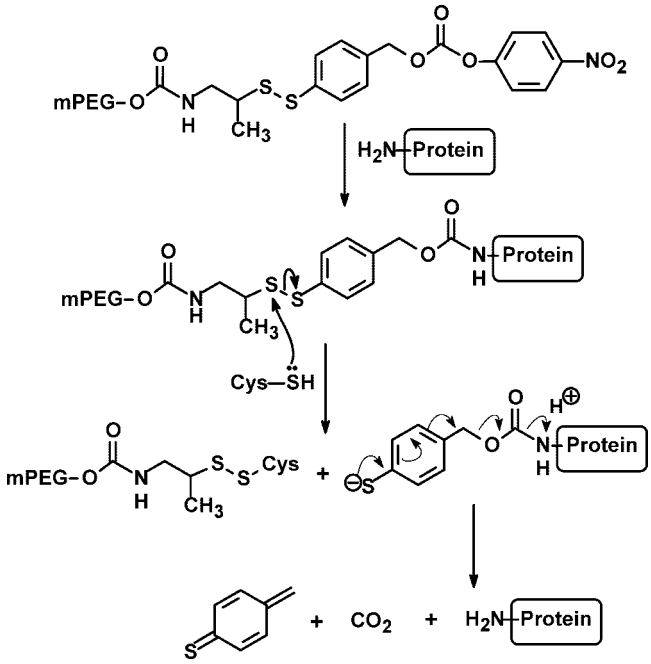
Samuel Zalipsky,* Nasreen Mullah, Charles Engbers, Maria U. Hutchins, and Radwan Kiwan

ALZA Corporation, 1900 Charleston Road, Mountain View, California 94043. Received May 25, 2007; Revised Manuscript Received August 31, 2007

New thiolytically cleavable dithiobenzyl (DTB) urethane-linked conjugates of methoxypoly(ethylene glycol) (mPEG) and a model protein, lysozyme, were prepared and thoroughly characterized. In contrast to our earlier communication [Zalipsky, et al. (1999) *Bioconjugate Chem. 10*, 703], in the current study we used a more sterically hindered form of *para*-DTB urethane linkage containing a methyl group on the α-carbon to the disulfide moiety. The new reagent for covalent attachment of mPEG-DTB to amino groups of proteins was synthesized via a seven-step process. As a result of PEG conjugation, the lysozyme was shown to completely lose its bacterial cell wall-lysing activity. However, activity was almost fully restored upon cysteine-mediated cleavage of the PEG component. The conjugate decomposition process was monitored by RP-HPLC and by ion spray LC-MS, which showed the formation of the *p*-mercaptobenzyl urethane–lysozyme intermediate, and ultimately its conversion to the unmodified lysozyme as the sole protein component. Pharmacokinetic evaluation of ^{125}I-labeled cleavable and noncleavable PEG-lysozyme given intravenously in rats revealed similar clearance patterns; both cleared in a significantly slower manner compared to that of the native protein. However, subcutaneous administration of the same conjugates showed a significantly larger AUC of the cleavable conjugate, indicating that some cleavage of the DTB urethane may have occurred. Although the DTB-linked PEG-lysozyme exhibited almost the same plasma clearance as the noncleavable counterpart, hinting that methyl-DTB linkage might be stable in the bloodstream, SDS–PAGE examination of the conjugate incubated in plasma showed decomposition at least partially mediated by albumin. These results suggest the potential of PEG-DTB-proteins as macromolecular prodrugs capable of generating fully active native proteins under in vivo conditions.

INTRODUCTION

Covalent linking of proteins with water-soluble biocompatible polymers is often used to modulate the properties of the resulting conjugates in order to make them more amenable to in vivo applications (*1–3*). One of the most popular polymers used for this purpose, polyethylene glycol (PEG[1]) (*4–6*), is known to convey a number of useful properties to its conjugates. Among them are prolonged plasma circulation time, reduced immunogenicity and antigenicity, improved solubility, and resistance to proteolytic degradation (*3, 5–7*). Usually, there is a direct relationship between the amount of the linked polymer and the improvement in the above-listed characteristics. However, covalent attachment of PEG strands to a protein, a process often referred to as PEGylation, is at times accompanied by a substantial loss of the functional biological activity. This is a particularly severe problem for proteins acting on macromolecular substrates (*3, 8, 9*). Most receptor-binding proteins, for example, cytokines and chemokines, fall into this category. Three approaches were applied to deal with the problem of the loss of biological activity as a result of PEGylation: (i) site specific PEGylation, sometimes in combination with site-specific mutagenesis (*10–15*); (ii) protection of receptor-binding site during the conjugation (*16, 17*); and (iii) reversible PEGylation (*18–22*). The latter is essentially a prodrug approach in which one or several PEG chains are acting as pro-moieties. Each of these approaches has its merits and can potentially be effective in some specific situations, and each one of them also presents nontrivial technical obstacles.



We recently introduced the new PEGylation chemistry depicted in Scheme 1, which was designed to produce gradual in vivo loss of PEG chains from its conjugates (*21, 23, 24*). It is based on benzyl urethane *para*-substituted with a disulfide, dithiobenzyl (DTB) moiety. The urethane formed between an amino group of a protein and the benzyl is quite a stable linkage. However, reductive or thiolytic scission of the disulfide leads to an unstable *p*-mercaptobenzyl urethane intermediate, which breaks down via 1,6-elimination and decarboxylation, and results in the regeneration of the original amino group. To the best of our knowledge, *p*-aryldisulfanyl-substituted benzyloxycarbonyl mitomycin C described by Senter et al. (*25*) constituted the first disclosure of a DTB-urethane derivative. In our laboratory, we used this linkage to prepare a lipid-based anticancer prodrug (*26, 27*) and also thiolytically cleavable lipopolymers (*21, 28*) that were utilized for liposomal and gene delivery. In addition to the thiolytic recovery of the modified amino group, the relative stability of DTB at neutral pH in the absence of redox agents is important for the convenient formulation and storage of the DTB-based conjugates. This feature offers an advantageous distinction from other published approaches to reversible PEGylation (*18–20, 22*) that are triggered by hydrolysis or pH changes. Since reductive scission of disulfide-linked conjugates is known to occur in various physiological environments (*29, 30*), it was envisioned that similarly under in vivo conditions DTB urethane would be cleaved, for example, by cysteine or glutathione-mediated thiolysis or perhaps by an enzymatic

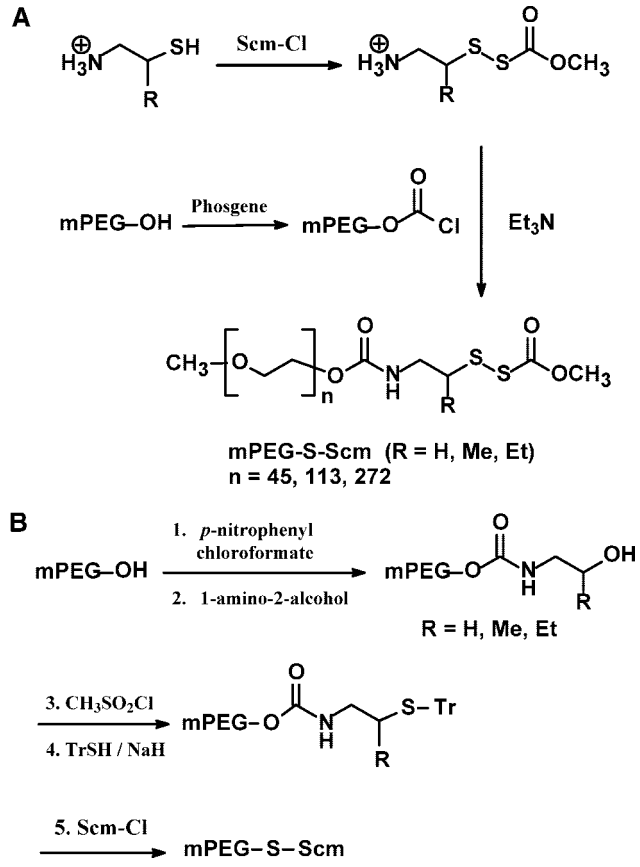
[a] Sterically hindered DTB containing a methyl group adjacent to the disulfide was utilized in the current study. Note that the thiolytic cleavage shown here for cysteine is equally applicable to any biologically relevant thiol, e.g., glutathione, albumin, etc.

Scheme 2. Synthesis of mPEG-DTB-NPC, Reagent for the Attachment of mPEG-DTB Moieties To Amino Groups on Proteins[a]

[a] Note that the size of the R residue (also shown in Scheme 3) affects the hindrance on the adjacent disulfide and, ultimately, the rate of the PEG detachment from the protein conjugates.

reduction. Thus, in vivo PEG would be present in these reversible conjugates only temporarily, improving such characteristics as pharmacokinetics and biodistribution. As a result of the PEG-chain detachment, the original native protein and its activity would ultimately be regenerated. In essence, the system is intended to work as a macromolecular prodrug, where each PEG chain is acting as a promoiety.

We chose lysozyme as a model protein to perform the initial feasibility studies on conjugate preparation and thiol-mediated decomposition, as well as pharmacokinetic properties of the reversible PEG-DTB-proteins. Lysozyme is a readily available, small protein (14.4 kDa) similar in size to various cytokines and chemokines, and its lytic activity is directed toward a very large substrate, the bacterial cell wall peptidoglycan. Therefore, lysozyme represents a suitable model for a small protein, which is acting on a large substrate to exhibit its biological activity. Herein, we report the results of the lysozyme model studies.



RESULTS AND DISCUSSION

A new reactive polymer derivative, mPEG-DTB-NPC, which is required for the preparation of PEG-DTB-protein conjugates, was synthesized as shown in Scheme 2. This synthesis scheme was applied to mPEG derivatives with molecular weights of 2000, 5000, and 12000 Da with equal success, although the mPEG-2000 derivatives were mainly utilized for the preparation of DTB-linked lipopolymers (*21*, *28*). The R residue, which is intended to regulate the steric hindrance on the disulfide bridge of the DTB urethane linkage and ultimately the rate of the cleavage of this linker was varied from hydrogen to more bulky methyl and ethyl groups. Our earlier experiments with PEG-lipids and PEG-liposomes indicated that when R = Me or Et the liposomes containing these DTB-linked lipopolymers exhibited long persistence in the bloodstream characteristic to STEALTH liposomes, while the analogous preparations with R = H did not (*28*). On the basis of these observations, the protein modifications described herein were performed with the former more stable mPEG-DTB form of the linkage containing a methyl substituent on the disulfide adjacent carbon (Scheme 1).

For the formation of the DTB-mixed disulfide, we relied on the reactivity of the *S*-sulfenylcarbomethoxy (S-Scm) functionality (*21*) (Scheme 2). Facile formation of asymmetrical disulfides via fragmentation of sulfenyl thiocarbonates is known to proceed even with weakly nucleophilic aromatic thiols (*31*). The reaction is driven by the release of COS and methanol. The mPEG-S-Scm was assembled from 1-alkyl-substituted 2-aminothiols (*32*), which were first reacted with methoxycarbonylsulfenyl chloride (Scm-Cl) to form the corresponding ammonium hydrochloride sulfenyl thiocarbonates. The latter were purified and then reacted with mPEG-chloroformate, forming stable carbamate attachments (Scheme 3A). An alternative approach to the *S*-sulfenyl thiocarbonates, prepared by treatment of the corresponding PEG-S-trityl with Scm-Cl by a modification of previously published method (*33*), also worked well. The corresponding S-Tr derivative was prepared in a clean manner from mPEG-OH in four steps as depicted in Scheme 3B. The reaction of mPEG-S-Scm with *p*-mercaptobenzyl alcohol was carried out in methanol at ambient temperature, yielding mPEG-DTB-OH. This reaction was considerably faster for the less-hindered Scm derivatives (R = H), but nevertheless, it was driven to completion with excess *p*-mercaptobenzyl alcohol over 24–48 h in the case of the more hindered analogues (R = Me and Et). To enable alkoxycarbonylation of amino groups, the hydroxyl group of mPEG-DTB-OH was converted into a reactive carbonate form by treatment with nitrophenyl choloroformate (Scheme 2).

This new reagent, mPEG-DTB-NPC (Scheme 1), was utilized in a series of lysozyme modification experiments. The aim of these experiments was to prepare lightly PEGylated species and to study their thiolytic decomposition while comparing the properties to those of the noncleavable analogues of the PEG-lysozyme. The latter were prepared with a known alkoxycarbonylating reagent of proteins, mPEG-NPC (*34*). Our lysozyme modification experiments demonstrated that both reagents, mPEG-DTB-NPC and mPEG-NPC, had similar reactivity

Scheme 3. Synthesis of mPEG-S-Scm by Two Different Approaches: (A) Reacting the Aminothiol Compound with Methoxycarbonylsulfenyl Chloride (Scm-Cl), Followed by Coupling To mPEG-Chloroformate, and (B) Generation of mPEG-S-Tr Followed by Its Conversion To mPEG-S-Scm

toward amino groups on proteins and under the same conditions yielded comparable PEGylated lysozyme mixtures with 1–3 polymer chains per protein molecule. We characterized these conjugates by SDS–PAGE, RP-HPLC, and MALDI-TOF-MS (Figures 1, 2 and 3). We purified the PEG-lysozyme conjugates from the unreacted PEG and protein by cation-exchange chromatography. Baseline separations between the reaction mixture components, PEG-lysozyme, unreacted protein, and excess of PEG reagent, were achievable on the CM-HEMA column. Fractionation on the CM-column also allowed us to obtain pure 1:1 PEG-lysozyme conjugates, which proved to be very useful in our mechanistic studies. MALDI-TOF-MS confirmed the expected molecular masses of $(mPEG)_{1-3}$-lysozyme conjugates in the purified samples. It also showed the presence of the unmodified lysozyme present in the mass spectra of the PEG-DTB-conjugates (Figure 3), even though the preparations were free from the native enzyme by RP-HPLC and SDS–PAGE. This is explained by the partial cleavage of the disulfides linkages under the MALDI conditions, which has been previously reported (*21*, *35*). The conjugate derived from both mPEG-5K and -12K (not shown) produced similar patterns of MALDI spectra.

As illustrated in Scheme 1, the reversibility of the DTB-urethane linkage is based on the thiolytic or reductive cleavage of the disulfide bond. Under in vivo conditions, this can occur via a reaction with any of the thiols present in blood plasma or tissues or by an enzymatic reductive scission of the disulfide. Among the low molecular weight thiols present in the physiological milieu, cysteine is the most reactive. Therefore, to examine the PEG detachment reaction, we used cysteine as the cleaving agent. Upon incubation of the $(mPEG\text{-}DTB)_n$-

lysozyme–conjugate mixture with cysteine, gradual decomposition and cleavage of the PEG chains took place. Following the de-PEGylation process with RP-HPLC (Figure 2), it was revealed that the heavier PEG-lysozyme species were converted to lighter ones and ultimately formed a sole protein component. The identity of the regenerated protein showing the same elution time on RP-HPLC as lysozyme was corroborated by ion spray LC-MS. Average spectra taken on the peak eluting at 6.7 min were identical to the spectra of the reference lysozyme (Figure 4A and D). LC-MS also confirmed that the main peak of the conjugate mixture eluting at 14.4 min (Figure 4B) was mPEG5K-DTB-lysozyme (calculated molecular mass of 20

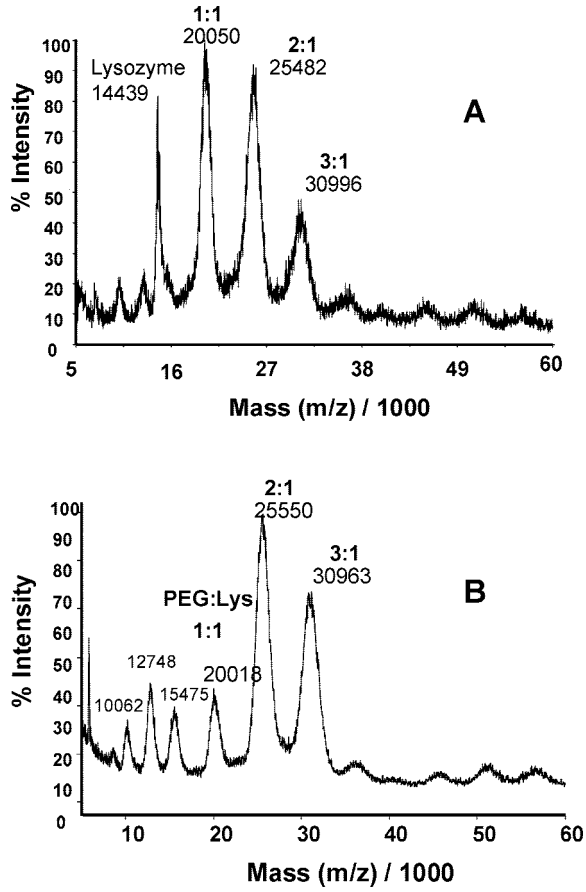

Figure 3. MALDI-TOF spectra of (A) mPEG5K-DTB-lysozyme conjugates and (B) their noncleavable counterparts.

kDa). Two distinct PEG products with bell-shaped distributions centered around 5480 and 5600 Da, differing approximately by the molecular weight of cysteine (121 Da), were observed during the cysteine-mediated cleavage of DTB urethane. The relative amounts of the lighter species (eluting later, less polar mPEG-SH) versus the heavier ones (eluting earlier, more polar mPEG-SS-Cys) increased with the cysteine incubation time, as judged by the ratios of their RP-HPLC peaks (result not shown). This is consistent with the disulfide-linked mPEG-cysteine being the main product (Scheme 1) at the early time points and its conversion to mPEG-thiol with time. For comparison, the ion spray MS of the corresponding mPEG5K-DTB-OH produced a typical bell-shaped distribution of signals centering around 5600 Da. Upon closer examination of the cysteine-mediated de-PEGylation reaction using the 1:1 conjugate of PEG5K-DTB-lysozyme (Figure 5A), we learned that the putative *p*-mercaptobenzyl urethane lysozyme intermediate (confirmed by LC-MS; Figure 4C) was detectable by RP-HPLC. As shown in Figure 5B, the decomposition of this intermediate occurred slower than the initial thiolysis step, which explains why the disappearance of the starting conjugate was faster than the appearance of the free lysozyme product.

One of the characteristics of lysozyme that makes it an excellent model for a large substrate binding protein is the high sensitivity of its cell wall-lysing activity to PEGylation. Consistent with previously reported observations (*36, 37*), we found that attachment of even one PEG chain to lysozyme completely abolishes its enzymatic activity in a *Micrococcus luteus* lysis assay. As illustrated in Figure 6, both cleavable PEG-lysozyme and its noncleavable counterpart showed no activity in this assay. However, in contrast to the noncleavable conjugate, the treatment of PEG-DTB-lysozyme with cysteine restored the lytic activity of the enzyme.

Pharmacokinetic properties of PEG-proteins are mainly governed by the molecular size of the conjugates (*38*). In other words, the results obtained with PEG-lysozyme should be roughly representative of conjugates derived from proteins of size similar to that of lysozyme. We studied the pharmacokinetic properties of the ^{125}I-labeled $(mPEG)_{1-3}$-lysozyme conjugates in rats, comparing the stable urethane analogue to the cleavable DTB-linked counterpart and to the native protein. In order to enhance the contrast between the free protein and its conjugates, we used the higher molecular weight mPEG-12K in these experiments. Following intravenous administration, we observed that both PEG-lysozyme preparations circulated much longer than the native protein (Figure 7A). The DTB-linked conjugate exhibited pharmacokinetic characteristics similar to those of the noncleavable analogue, which hinted at an apparent plasma stability of the DTB-linkage-containing methyl group on the α carbon. This result was consistent with our observations in the liposomal system (*28*), in which the PEG-liposome containing the same sterically hindered DTB linkage also exhibited the same clearance curves as those of the liposome containing the stable urethane-linked lipopolymer analogue. Administration of the same mPEG12K-lysozyme preparations by the subcutaneous route (Figure 7B) resulted in noticeably larger AUC for the DTB-linked conjugate compared to its noncleavable urethane counterpart. Subcutaneous administration is often considered to be a more attractive and less invasive route compared to the intravenous route. Both conjugates exhibited a much longer presence in circulation than the free protein, which rapidly peaked in the bloodstream after subcutaneous administration and also was rapidly cleared. These route-of-administration differences between the results of the two pharmacokinetic experiments and their implications regarding the stability of DTB linker in the relevant environments might be due to the differences in the thiol species and their concentration between plasma and interstitial fluid. It was reported, for example, that the levels of sulfur-containing amino acids are higher in interstitial fluids compared to those in plasma (*39*). However, the albumin concentration in interstitial fluid is significantly lower (*40*) compared to its plasma levels, where it is the most abundant and also the most reactive thiol (*41*).

The latter fact prompted our investigation of the stability of our DTB-linked conjugates in the presence of albumin or plasma. Note that there is a great deal of homology among rat (RSA), human (HSA), and bovine (BSA) albumin, all of which contain a single reactive thiol group, Cys-34. First, we followed the integrity of purified 1:1 PEG5K-lysozyme incubated in BSA solution (4% in PBS, similar to the albumin concentration in plasma) by SDS–PAGE using PEG-sensitive staining. This staining provides information on PEG-containing species, although proteins at high concentrations are also visualized. Conversely, the free lysozyme present at a relatively low concentration was hardly detectable. The results of these experiments are shown in Figure 8. The band of mPEG-DTB-lysozyme completely disappeared from the gel after overnight incubation with albumin (Figure. 8A, lane 9). Under the same conditions, the noncleavable conjugate remained stable (lane 4), excluding the possibility that noncovalent association with albumin was responsible for the disappearance of the cleavable PEG-lysozyme (lane 9). BSA with blocked thiol (pretreated with iodoacetamide) did not react with mPEG-DTB-lysozyme (lane 8), indicating that the thiol group played a role in the decomposition of the conjugate. Finally, when a BSA-decomposed sample of mPEG-DTB-lysozyme was treated with excess DTT, free mPEG5K was readily detectable on the gel (lane 7) to the same extent as cysteine-mediated cleavage product (lane 3). Likewise, mPEG5K-DTB-lysozyme incubations in rat plasma (Figure 8B) produced the same pattern of

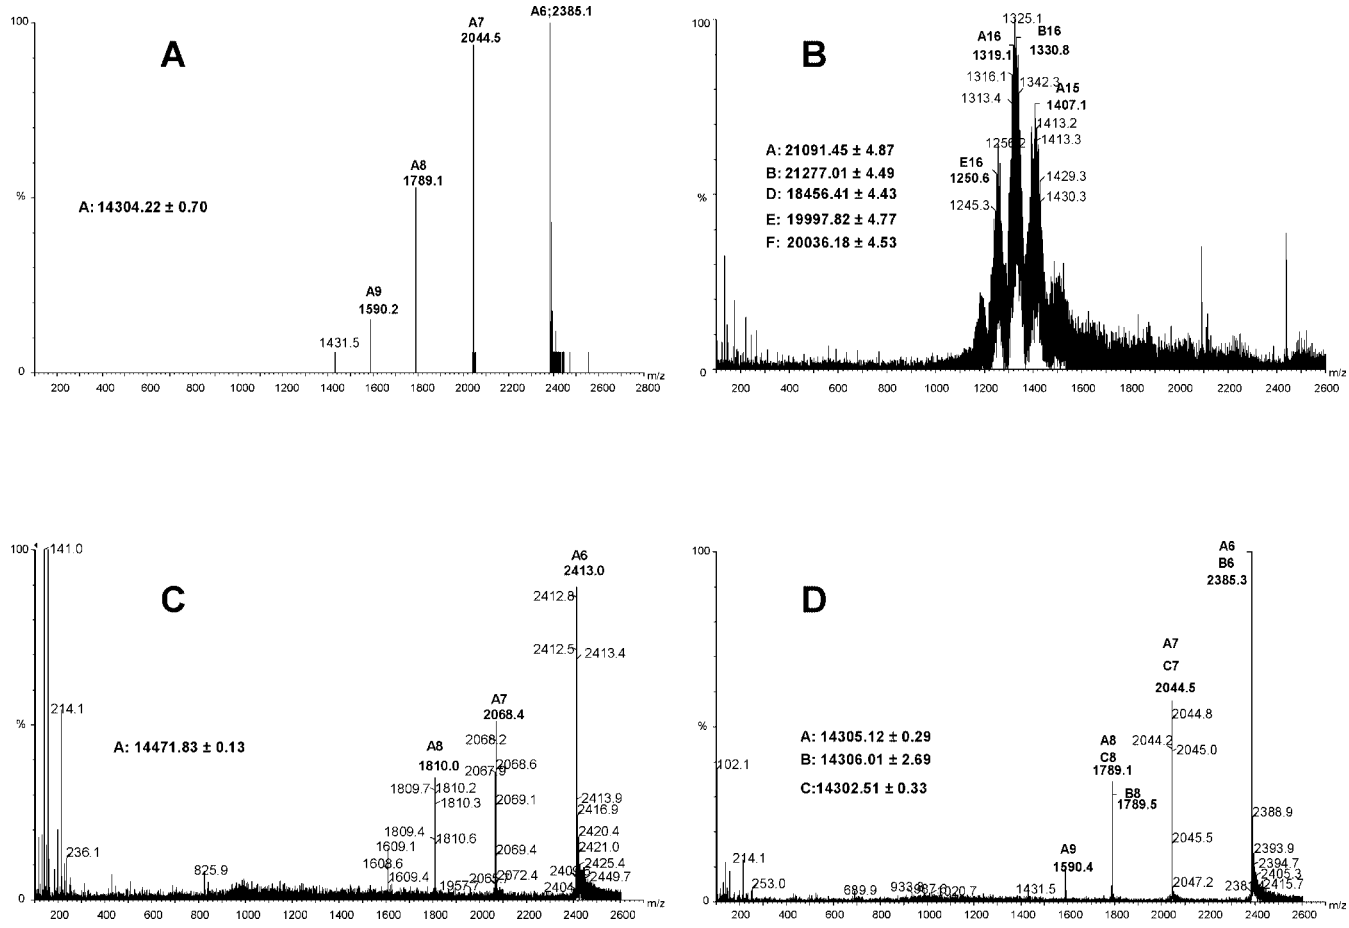

Figure 4. ES-MS spectra of mPEG5K-DTB-lysozyme, the intermediate detected during cysteine-mediated cleavage, and the protein product of this cleavage. decomposition as in the albumin solution. These experiments clearly show that albumin cleaves the DTB linkage, and PEG becomes attached to albumin (or another plasma protein), which can be liberated by the excess low molecular weight thiol (DTT). Because of the high concentration of albumin, its oligomers, and other contaminant proteins in the BSA and plasma preparations that we used, in addition to the relatively small shift affected by mPEG5K, the disulfide-linked PEG-albumin species formed during the DTB cleavage were not distinguishable from the background on these gels. In further corroboration of albumin-mediated cleavage, incubation of a model compound, mPEG12K-DTB-Glycine, in excess of HSA, produced facile cleavage accompanied by a clear SDS–PAGE band of mPEG12K-albumin (approximately 100 kDa on a protein molecular weight scale) readily detectable within a few hours and continuing to increase for up to 96 h (result not shown).

In this article, we demonstrate the synthesis of a new PEG-based reagent for the preparation of thiolytically cleavable PEG-DTB-protein conjugates. Using lysozyme as a model, we show that such conjugates are prepared and characterized as their

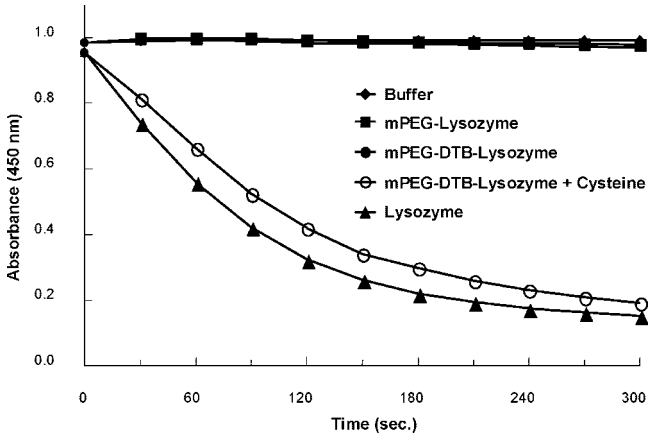

Figure 6. Turbidometric assay of bacterial cell wall lysis of lysozyme and its conjugates. The conjugates and the control samples were treated as described in the Materials and Methods section, under lysozyme activity assay.

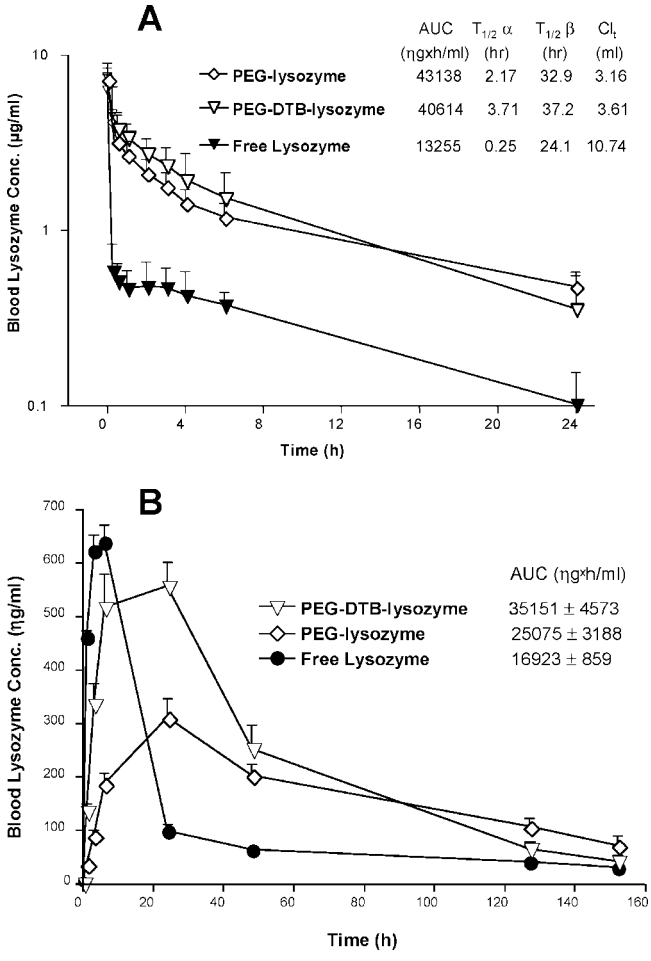

Figure 7. Pharmacokinetics in rats of ^{125}I-labeled mPEG12K-DTB-lysozyme conjugates, its noncleavable analogues, and the free parent protein. Clearance curves were constructed from the radiolabeled detection of ^{125}I after (A) intravenous and (B) subcutaneous administration.

noncleavable counterparts. Thiolytic cleavage occurs under mild conditions achievable in vivo, and most importantly, as expected from a true prodrug, the original native protein is generated as the result. This was demonstrated both by complete recovery of the PEGylation-induced loss of activity and by LC-MS yielding identical spectra of the native and de-PEGylated lysozyme. Furthermore, our studies show that although mPEG12K-DTB-lysozyme exhibited long circulating characteristics similar to its noncleavable counterpart, the DTB linker is clearly vulnerable to both low and high molecular weight biologically relevant thiols, cysteine, and albumin. The latter thiol is the most likely culprit responsible for the decomposition of the conjugate in plasma. The observation of both DTB cleavage and long circulation of mPEG12K-DTB-lysozyme could be the result of a relatively slow breakdown rate; however, alternative explanations are also possible. We investigated, in further detail, the albumin reaction with several PEG-DTB conjugates, and the results as well as the insight into the possible mechanisms involved and the reasons for the long in vivo circulation are presented in a separate paper (Hutchins, M. U., et al., in preparation).

MATERIALS AND METHODS

Lysozyme was obtained from Roche Molecular Biochemicals, Indianapolis, IN. Amino-2-propanethiol hydrochloride (*32*) and 4-mercaptobenzyl alcohol (*42*) were prepared as described elsewhere. All the synthetic procedures below, although written for derivatives of mPEG5K, are equally applicable to the mPEG12K analogues (gifts from Union Carbide and NOF, respectively). All the NMR spectra were acquired in DMSO-d_6/Me_4Si using 360 MHz spectrometer at Acorn NMR, Livermore, CA.

Methoxycarbonyldisulfanyl-2-propylamonium Chloride. The title compound was prepared by reacting methoxycarbonylsulfenyl chloride with an equivalent amount of amino-2-propanethiol hydrochloride according to the previously published procedures (*43*, *44*). Amino-2-propanethiol hydrochloride (1.83 mL, 19.44 mmol) in methanol (15 mL) was added dropwise (~1.0 mL/min) to a cold (4 °C) solution of methoxycarbonylsulfenyl chloride (Scm-Cl, 2.5 g, 19.6 mmol) in methanol (15 mL). The solution was stirred at room temperature for 3 h and then rotary evaporated. The residue was taken up in acetone and then stripped of the solvent two more times, resulting in the formation of a white solid. Silica-C8 (1 g) was added to the product solution in MeOH, which was then evaporated. The product-containing residue was added to the top of the C8-silica column and was eluted with water under N_2 pressure. Fractions containing the pure product were combined, evaporated, and lyophilized from *tert*-butanol (5 mL). It was further dried in vacuo over P_2O_5 to give product as a white solid (2 g, 47% yield). ^{1}H NMR δ: 1.30 (d, C*H*$_3$CH, 3H), 2.94 (br t, C*H*$_2$NH$_3$Cl, 2H), 3.37 (q, CH$_3$C*H*CH$_2$NH$_3$Cl, 1H), 3.88 (s, CH$_3$OCO, 3H), 8.21 (br s, CH$_3$CHCH$_2$N*H*$_3$Cl, 3H) ppm.

MPEG5K-Oxycarbonylaminopropyl-*S*-sulfenylcarbomethoxy (mPEG-S-Scm), Method A. This method is shown in Scheme 3A. mPEG-OH (15 g, 3 mmol) was dried by azeotropic removal of toluene (100 mL). The solution was cooled, diluted with dichloromethane (40 mL), and treated with phosgene (10 mL, 19.3 mmol) at 4 °C. The ice bath was removed, and the reaction was stirred at room temperature overnight and then evaporated to dryness, leaving solid mPEG-chloroformate. Methoxycarbonyldisulfanyl-2-propylamonium chloride (686.7 mg, 3.15 mmol) and then TEA (836.3 μL, 6 mmol) were added to the mPEG-chloroformate in chloroform (30 mL). The reaction mixture was stirred at room temperature overnight and then evaporated. The residue was taken up in warm ethyl acetate (150 mL) and filtered to remove the TEA hydrochloride. The solvent was removed, and the product was purified by recrystallization from ethyl acetate/iso-propanol (100 /100 mL, three times) and dried in vacuo over P_2O_5, yielding a white solid (14.5 g, 93%). ^{1}H NMR δ: 1.18 (d, C*H*$_3$CHSS$_2$, 3H), 3.10 (m, C*H*$_2$NH, 2H), 3.24 (s, CH$_3$O, 3H), 3.50 (s, PEG, ≈520H), 3.86 (s, C*H*$_3$OCOSSCH, 3H), 4.05 (t, OCOC*H*$_2$, 2H), 7.38 (t, OCON*H*, 1H) ppm.

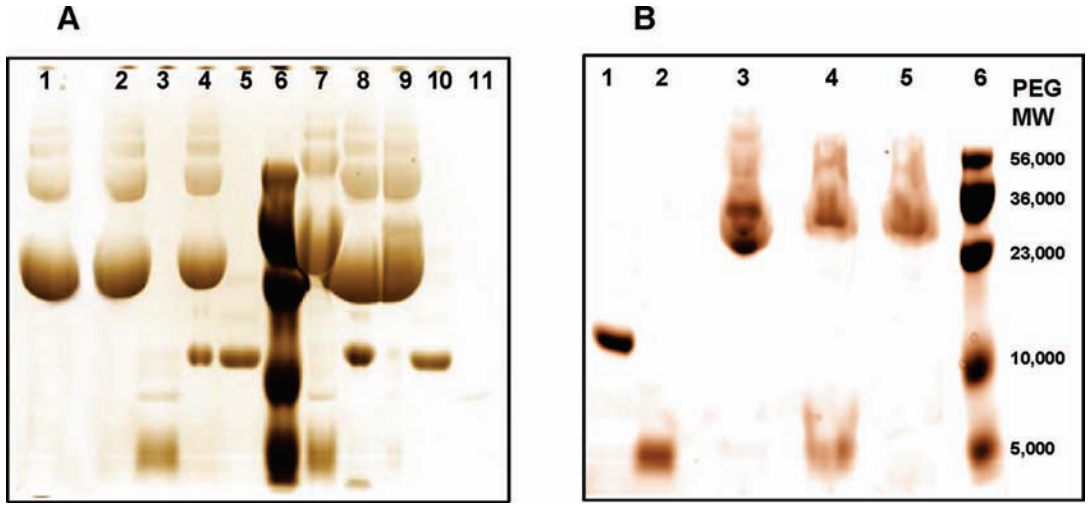

Figure 8. SDS–PAGE gels of samples from an overnight incubation of mPEG5K-DTB-lysozyme and controls in (A) albumin (BSA) solution and in (B) rat plasma. Samples list A: (1) BSA-blocked SH, (2) BSA, (3) mPEG-DTB-lysozyme + cysteine, (4) noncleavable PEG-lysozyme + BSA, (5) noncleavable PEG-lysozyme, (6) PEG MW Markers, (7) mPEG-DTB-lysozyme + BSA, then DTT, (8) mPEG-DTB- lysozyme + BSA-blocked SH, (9) mPEG-DTB-lysozyme + BSA, 16 h, (10) mPEG-DTB-lysozyme, and (11) lysozyme. Samples list B: (1) mPEG-DTB-lysozyme, (2) mPEG-DTB-lysozyme + cysteine, (3) mPEG-DTB-lysozyme in rat plasma, 18 h, (4) mPEG-DTB-lysozyme in rat plasma, then DTT, (5) rat plasma control, and (6) PEG molecular weight markers.

mPEG5K-Nitrophenyl Carbonate (mPEG-NPC). Azeotropically dried mPEG5K-OH (40 g, 8 mmol) in toluene/dichloromethane (20/100 mL) solution was treated with *p*-nitrophenyl chloroformate (2.42 g, 12 mmol) and TEA (3.3 mL, 24 mmol). After the initial cooling (≈15 min) on ice–water during the addition of the reagent, the reaction mixture was stirred at room temperature overnight. The reaction solution was evaporated to dryness, and the residue was taken up in warm ethyl acetate (≈50 °C). TEA hydrochloride was filtered off and washed with a small volume of warm ethyl acetate. The solvent was rotary evaporated, and the residue was recrystallized from iso-propanol twice and then dried in vacuo over P_2O_5, yielding 38.2 g (92%) of white powder. ^{1}H NMR δ: 3.24 (s, CH_3O, 3H), 3.50 (s, PEG, 460H), 4.37 (t, OCOCH_2, 2H), 7.57 (d, C_6H_5, 2H), 8.32 (d, C_6H_5, 2H) ppm.

MPEG5K-Oxycarbonylamino-2-propanol (mPEG-*i*Pr-OH). Amino-2-propanol (1.1 mL, 14.52 mmol) and TEA (2.02 mL, 14.52 mmol) were added to mPEG5K-NPC (25 g, 4.84 mmol) solution in DMF (60 mL) and CH_2Cl_2 (40 mL). The reaction solution turned yellow. It was stirred at room temperature for 30 min. TLC ($CHCl_3$/MeOH = 90:10) showed that the reaction went to completion. Dichloromethane was removed by rotary evaporation, and iso-propanol (250 mL) was added to the concentrated DMF solution. The precipitated product was collected by filtration and further purified by two additional precipitations from iso-propanol. It was then dried in vacuo over P_2O_5, yielding 22.1 g (90%) of white powder. ^{1}H NMR δ: 0.99 (d, CH_3CH, 3H), 2.90 (m, NHCH_2, 2H), 3.24 (s, CH_3O, 3H), 3.50 (s, PEG, ≈480H), 4.04 (t, OCOCH_2, 2H), 4.85 (d, CH_3CHO*H*, 1H), 7.11 (t, NH, 1H) ppm.

MPEG5K-Oxycarbonylamino-2-propyl methanesulfonate (mPEG-OMs). mPEG5K-oxycarbonylamino-2-propanol (22.12 g, 4.34 mmol) was azeotropically dried in its toluene solution (45 mL). The solution was cooled, diluted with dichloromethane (60 mL), and then treated with methanesulfonyl chloride (604.6 μL, 7.81 mmol) and TEA (3.93 mL, 28.21 mmol, 6.5 equiv) while maintaining continuous stirring and cooling (4 °C), and protecting the reaction mixture against air moisture. After 30 min, the cooling bath was removed, and the reaction mixture was stirred at room temperature for 16 h. The solution was rotary evaporated, and the residue was taken up with warm ethyl acetate. TEA salt was removed by filtration. The product was precipitated with iso-propanol and recrystallized with the same solvent two more times, and then dried in vacuo over P_2O_5 yielding 20.27 g (90%) of white powder. ^{1}H NMR δ: 1.28 (d, CH_3CHOMs, 3H), 3.13 (s, CH_3O_2SO, 3H), 3.18 (t, CH_2NH, 2H), 3.24 (s, CH_3O, 3H), 3.50 (s, PEG, ≈480H), 4.08 (t, $OCOCH_2$, 2H), 4.65 (q, C*H*OMs, 1H), 7.51 (t, NH, 1H) ppm.

mPEG5K-Oxycarbonylamino-2-propyl-*S*-triphenylmethane (mPEG-S-Tr). Sodium hydride (60% oil dispersion, 377 mg, 9.4 mmol, 4.75 equiv) was treated with anhydrous toluene (60 mL) at ≈4 °C. Triphenylmethanethiol (3.92 g, 14.6 mmol, 7.15 equiv) was added after 5 min, followed by mPEG-oxycarbonylamino-2-propyl methanesulfone (10.3 g, 1.98 mmol) 10 min later. The reaction turned yellow. After 45 min, acetic acid (440 μL, 7.7 mmol) was added to the reaction mixture to neutralize the excess sodium hydride. A white precipitate was formed. The solution was evaporated to dryness. Warm ethyl acetate (30 mL) and iso-propanol (70 mL) were added to the residue. The solution was filtered while still warm (≈40 °C) and then cooled down to facilitate product precipitation. Then the product was further recrystallized from iso-propanol/tert-butanol (100/20 mL) and dried in vacuo over P_2O_5, yielding 8.87 g (84%) of white powder. ^{1}H NMR δ; 0.75 (d, CH_3CHSTr, 3H), 2.42 (m, CHSTr, 1H); 2.77 (m, CH_2N, 2 H); 3.23 (s, CH_3O, 3H); 3.50 (s, PEG, ≈ 520H), 4.01 (t, OCOCH_2, 2H); 7.24 (t, *p*-H of $SC(C_6H_5)_3$ & NH, 4H); 7.33 (t, *m*-H of $SC(C_6H_5)_3$, 6H); 7.42 (d, *o*-H of $SC(C_6H_5)_3$, 6H) ppm.

MPEG5K-Oxycarbonylaminopropyl-*S*-sulfenylcarbomethoxy (mPEG-S-Scm), Method B. mPEG5K-oxycarbonylamino-2-propyl-*S*-triphenylmethane (8.87 g, 1.65 mmol) was dissolved in TFA/CH_2Cl_2 (10/10 mL) at 4 °C and treated with methoxy carbonylsulfenyl chloride (185.5 μL, 1.99 mmol) while vigorously stirring the solution. The reaction was allowed to proceed at room temperature for 45 min and then evaporated to dryness. The residue was recrystallized with iso-propanol/*tert*-butanol (80/20 mL) twice and then lyophilized from *tert*-butanol (5 mL) and further dried in vacuo over P_2O_5 to yield a white fluffy solid (8.32 g, 97 %). ^{1}H NMR was identical to that of the same derivative obtained in Method A (see above).

MPEG5K-Oxycarbonylaminopropyl-dithiobenzyl Alcohol (mPEG-DTB-OH). mPEG5K-oxycarbonyl-2-(aminopropyl)-*S*-sulfenylcarbomethoxy (8.32 g, 1.6 mmol) was reacted with *p*-mercaptobenzyl alcohol (592 mg, 4 mmol) in methanol/chloroform (25 mL, 90:10) at ambient temperature for 18 h. In

order to drive the reaction to completion, another portion of mercaptobenzyl alcohol (322 mg, 2.2 mmol) was added and allowed to react for 24 h. The reaction solution was evaporated to dryness. The solid residue was recrystallized from ethyl acetate/isopropanol (30/100 mL) three times and then dried in vacuo over P_2O_5, yielding a white powdery material (7.25 g, 94%). ^{1}H NMR δ: 1.17 (d, CH_3CHS$_2$, 3H), 3.02 (m, CH_2NH, 2H), 3.24 (s, CH$_3$O, 3H), 3.50 (s, PEG, ≈470H), 4.05 (br t, CH_2OCO, 2H), 4.48 (d, HOCH_2C$_6$H$_5$, 2H), 5.21 (t, *H*OCH$_2$C$_6$H$_5$, 1H), 7.30(d, C$_6H_5$, 2H), 7.46 (br t, mPEG-OCON*H*, 1H), 7.50 (d, C$_6H_5$, 2H) ppm.

MPEG5K-Oxycarbonylaminopropyl-dithiobenzyl Nitrophenyl Carbonate (mPEG-DTB-NPC). mPEG5K-oxycarbonylamino-2-propyl-dithiobenzyl alcohol (6.75 g, 1.27 mmol) was dissolved in CHCl$_3$ (30 mL) and treated with *p*-nitrophenyl chloroformate (513 mg, 2.54 mmol) and TEA (531 μL, 3.81 mmol) at 4 °C. After 30 min, the ice bath was removed, and the reaction mixture was stirred at room temperature overnight. The reaction solution was rotary evaporated, and the residue was taken up in warm ethyl acetate. TEA hydrochloride was filtered off, and then the solvent was evaporated. The solid residue was recrystallized with ethyl acetate/iso-propanol (30/100 mL) three times and dried in vacuo over P_2O_5, yielding 6.55 g (94%) of white solid. ^{1}H NMR δ: 1.18 (d, CH_3CHSSC$_6$H$_5$, 3H), 3.16 (m, CH$_2$N, 2H), 3.24 (s, CH_3O-PEG, 3H), 3.40 (s, PEG, 180H), 4.03 (br t, OCOCH_2, 2H), 5.28 (s, C$_6$H$_5$CH_2OCO, 2H), 7.45–7.60 (overlapping two types of C$_6$H$_4$ and NH, 7H), 8.31 (d, C$_6$H$_4$NO$_2$, 2H); ^{13}C NMR (DMSO-d_6) δ: 17.5, 45.1, 45.8, 58.0, 63.2, 68.8, 69.7 (PEG), 71.2, 122.5, 125.3, 126.7, 129.3, 137.8, 145.1, 151.9, 155.2, 156.2 ppm.

Preparation and Purification of PEG-Lysozyme Conjugates. Lysozyme (at final concentration of 10 mg/mL) was allowed to react in borate buffer (0.1 M, pH 8.0) at 25 °C for 2–5 h with either mPEG-DTB-NPC or mPEG-NPC, using the feed molar ratio of 3.5 PEG/lysozyme (0.5 PEG/amino group). The conjugation reactions were quenched by the addition of 10-fold excess of glycine.

PEG-lysozyme conjugates were purified on a CM HEMA-IEC Bio 1000 semipreparative HPLC column (7.5 × 150 mm) purchased from Alltech Associates, Deerfield, IL. First, the conjugation reaction was injected into the HPLC column in 10 mM sodium acetate buffer at pH 6. The elution with this buffer was continued until all unreacted PEG was removed. Then, 0.2 M NaCl in 10 mM sodium acetate at pH 6 was applied for 15 min in order to elute the PEGylated-lysozyme. Finally, the native lysozyme was eluted by increasing the salt concentration to 0.5 M NaCl over 20 min. Fractions (1 mL) were collected and assayed for protein and PEG contents. Thus, aliquots (25 μL) of each fraction were reacted with BCA protein assay reagent (200 μL, Pierce Chemical Company, Rockford, IL) in microtiter plate wells at 37 °C for 30 min, and the absorbance was read at 562 nm. Similarly, for PEG determination (*14*), 25 μL aliquots were reacted with 0.1% polymethacrylic acid solution in 1 N HCl (200 μL), in microtiter plate wells, followed by absorbance reading at 400 nm. Fractions containing both protein and PEG were pooled. For the isolation of the PEG-lysozyme containing only one PEG moiety, the same cation-exchange chromatography protocol was repeated and the collected fractions were analyzed by the HPLC reversed-phase assay. Fractions containing the single peak of 1:1 PEG-lysozyme conjugate species were pooled.

SDS–PAGE. Polyacrylamide gel electrophoresis under denaturing conditions was performed for conjugate characterization. Precast 4–12% NuPAGE Bis-Tris gels, MES running buffer, molecular weight protein standards (Mark12), and a Colloidal Coomassie G-250 staining kit, were all obtained from Invitrogen, Carlsbad, CA. In a typical gel, 1 to 3 μg of protein containing sample were loaded per well, then electrophoresed at a constant voltage of 200 mV, and stained for protein according to the manufacturer's instructions. For PEG detection, a duplicate gel was stained with iodine according to Kurfürst (*45*).

Reversed-Phase HPLC Analysis. RP-HPLC separation of PEG-lysozyme conjugates was achieved on a Vydac Protein C4 (4.6 × 150 mm) column eluted at 1 mL/min with an aqueous acetonitrile gradient as follows. Each chromatography run started with mobile phase A (30% acetonitrile, 5% 0.1 M sodium acetate at pH 5, and 65% H_2O) and over a period of 40 min ended with mobile phase B (50% acetonitrile, 50% 0.1 M sodium acetate at pH 5). A UV detector set to 280 nm was used to monitor the chromatography.

De-PEGylation Experiments. A mixture of purified mPEG-DTB-lysozyme conjugates (2 mg/mL protein), containing 1:1, 2:1, and 3:1 conjugate species, was incubated with 1 mM cysteine in 0.1 M sodium phosphate buffer at pH 7.3 containing 5 mM EDTA at 37 °C on a rocking mixer. Aliquots were taken out from the reaction vial at various time points and analyzed by RP-HPLC as described above. These results are shown in Figure 2.

De-PEGylation experiments of the cation-exchange-purified 1:1 PEG-DTB-lysozyme (0.5 mg/mL protein) treated at room temperature with 0.6 mM cysteine (or glutathione (not shown)) were monitored by a modified RP-HPLC method on the same Vydac Protein C4 column and flow rate but under the following elution protocol, which was also suitable for LC-MS. Each chromatography run was conducted with a gradient of 30% to 40% mobile phase B in 18 min. Mobile phase A was composed of 0.1% TFA in 5% acetonitrile and 95% H_2O, while mobile phase B was composed of 0.1% TFA in 95% acetonitrile and 5% H_2O. The fluorescent detector was set at 295 nm excitation and 360 nm emission. The results of these experiments are depicted in Figure 5.

Lysozyme Activity Assay. The enzymatic activity of lysozyme and its conjugates was assessed as previously described (*46*). *Micrococcus luteus* cells were suspended, at 0.3 mg/mL in 0.1 M sodium phosphate buffer at pH 7.3. Test samples were diluted to 0.5 mg/mL (lysozyme equivalent) in the phosphate buffer. Cells suspension and test sample were mixed at a v/v ratio of 1:14 in a 1 cm glass cuvette. Absorbance at 450 nm was immediately recorded for the initial time reading and then for the subsequent 30-s time intervals.

LC-MS. Purified PEG-lysozyme containing only one PEG moiety per lysozyme was treated with 1 mM cysteine, while the reaction was monitored by LC-MS. The HPLC system (HP 1100 LC-102) equipped with the same C4 column as that described above was connected to an electrospray mass spectrometer (Micromass QTOF II), permitting peaks identification by their molecular weights. The sodium acetate in the mobile phase was replaced with ammonium acetate in order to minimize salt interference with electrospray ionization.

Preparation of ^{125}I PEG-Lysozyme. Lysozyme (66 mg in 100 mg/mL in 0.1 M sodium phosphate buffer at pH 7.3) was mixed with 605 μCi of Na^{125}I (ICN Biomedicals, Irvine, CA), in an Iodo-Gen coated tube (Pierce Chemical Company, Rockford, IL), and allowed to react for 1 h at room temperature with mixing at 20 min intervals. The iodination reaction was stopped by removing the free ^{125}I on a Sephadex G-25F gel filtration column (17 mL) and collecting the ^{125}I-lysozyme, which was then reacted with either mPEG-DTB-NPC or mPEG-NPC, and purified by cation exchange chromatography as described above.

Pharmacokinetic Experiments. Male Sprague–Dawley rats (250–330 g each, 3 animals per formulation per experiment) were dosed either by intravenous (via a lateral tail vein) or by

subcutaneous (dorsally above the right rear leg) routes with ^{125}I-labeled lysozyme or its PEG conjugates (0.35 mL, 0.4 mg protein/mL, 4.6×10^6 cpm/mL). Blood samples (0.4 mL) were collected via the retro-orbital sinus. All injections and blood collections were performed while the animals were under inhaled anesthesia (isoflurane/O_2). Samples were collected on heparin into polypropylene tubes and stored on ice for no longer than 1 h before being pipetted in triplicate (0.100 mL) into fresh polypropylene tubes. Blood samples were collected at the following times after dosing (though no single rat had blood collected at all of the following times): 30 s, 15 min, 30 min, and 1, 2, 3, 4, 6, 8, 24, 48, 72, 96, 120, and 168 h post-dose. Note that the last four time points were added for the longer subcutaneous experiments. The samples were then counted for ^{125}I in a Packard 5000 gamma counter. The results are summarized in Figure 7.

ACKNOWLEDGMENT

We would like to thank Union Carbide and NOF Corporation for samples of mPEG5K and mPEG12K, respectively. We are grateful to Katie Zomorodi for her help with processing the pharmacokinetic data and to Bob Suzuki for the acquisition of ES-MS spectra.

Direct Immunofluorescence of Plant Microtubules Based on Semiconductor Nanocrystals

K. Eggenberger,[†] A. Merkulov,[‡] M. Darbandi,[‡] T. Nann,[‡,§] and P. Nick*[,†]

Institut of Botany 1, University of Karlsruhe, Kaiserstrasse 2, D-76128 Karlsruhe, Germany, Freiburg Materials Research Centre, University of Freiburg, Stefan-Meier-Strasse 21, D-79104 Freiburg, Germany, and School of Chemical Sciences and Pharmacy, University of East Anglia (UEA), Norwich NR4 7TJ, U.K. Received May 25, 2007

Fluorescence microscopy in combination with multiple, simultaneous labeling of biomolecules has been a key breakthrough in cell biology. However, the spatiotemporal resolution of this approach is limited by bleaching of the fluorescence label and illegitimate cross-reference of the label. CdSe-based semiconductor nanocrystals with their excellent bleaching stability would be an alternative to overcome this limitation. We therefore explored direct immunofluorescence based on nanocrystal-conjugated antibodies using plant microtubules as model. We compared two strategies of bioconjugation, covalent coupling of antitubulin antibodies to BSA-coated nanocrystals and covalent coupling to nanocrystals that were surrounded by functionalized silica shells. Both nanoparticle–antibody conjugates were used to follow the dynamic reorganization of microtubules through the cell cycle of a tobacco cell culture in double and triple staining with FITC as conventional fluorochrome and Hoechst 33258 as marker for mitotic duplication of DNA. BSA-coated nanocrystals visualized fluorescent dots that decorated the various arrays of microtubules. The specificity of the antibody was maintained after conjugation with the nanocrystals, and the antibodies correctly represented the dynamics of cell-cycle-dependent microtubular reorganization. However, this approach did not yield a contiguous signal. In contrast, silica-shelled nanocrystals visualized contiguous microtubules in the same pattern as found for the conventional fluorochrome FITC and thus can be used as labels for direct immunofluorescence in plant cells.

INTRODUCTION

Luminescent semiconductor nanocrystals with spherical morphology (so called quantum dots or QDs[1]) have attracted enormous interest as labels for bioimaging (for recent reviews, see refs *1* and *2*) because of their increased fluorescence intensity and bleaching resistance. In addition, they can be excited over a broad wavelength range but emit with a narrow band that can be tuned by the size of the particles. Thus, QDs are endowed with optical properties that renders them superior over the organic fluorophores that are used conventionally. However, the application of QDs for cell biology is limited by their potential cytotoxicity (which is discussed controversially (*3–6*)), their large size (*2*), and the challenging task to stabilize those nanoparticles colloidally under the general conditions of biological applications.

To overcome these limitations, QDs have been coated with inert silica shells or, alternatively, by thin layers of organic ligands. The coating protects the QDs from oxidation and prevents the leakage of toxic metal ions, especially Cd^{2+}, that can induce oxidative burst and programmed cell death (*7, 8*). In addition, the coat can be used as platform to generate a surface that is biocompatible and amenable to the coupling with biomolecules of interest.

For biological applications, silica coating has several advantages over alternative coating strategies. Because of the high density of silica, the conjugated particles can be separated easily, during particle preparation and biofunctionalization, from uncoated particles. The silanol groups on the surface decrease hydrophobicity and thus the tendency to agglomerate in aqueous environment. Silica is inert in both aqueous and nonaqueous solvents, which should reduce any noxious effects on the cells hosting the particles as well as microbial degradation (*6*). Silica coats are tighter against leakage of the toxic Cd^{2+} compared to coats made from SH ligands, such as mercaptoacetic acid, 3-mercaptopropionic acid, 11-mercaptoundecanoic acid, or 2-aminoethanethiol. Furthermore, it is possible to introduce specific surface functionalities by modification of surface hydroxyls with amines, thiols, carboxyls, or methacrylate.

The BSA coating provides better electrostatic colloidal stabilization of QDs in water and is more versatile with respect to active groups (i.e., NH_2, COOH, and SH) for the covalent coupling of antibodies to the BSA-coated QDs. Moreover, the coating of QDs with small proteins produces particles of smaller diameter compared to the SiO_2 approach, which improves their suitability for in vivo imaging.

Biology has entered the so-called postgenomic era, where the assignment of gene to function has become a central task. By the use of reverse genetics, expressed sequences of unknown function are analyzed with respect to phenotypes that occur upon overexpression or suppression of the corresponding gene products and with respect to their intracellular localization. Classical light microscopy and electron microscopy have focussed on the visualization of cellular structures. The socalled functional genomics calls for, in addition, reliable information about the molecular nature of these structures. This requirement has stimulated an impressive bloom of fluorescence microscopy that has developed from an exotic technique used by a handful of specialists into a central tool of molecular biology. There are basically three motive forces that drive this development:

in vivo imaging, spatial (and temporal) resolution, and molecular specificity. To achieve these goals, the technological progress on the side of microscopical devices has to be complemented by advances on the side of the fluorescent label, and it is this point where the QDs have stimulated enormous interest of cell biologists.

So far, the use of QDs for in vivo imaging has been biased toward studies on the organismic level, for instance, when derivatized QDs were successfully targeted to cancer cells (*9, 10*) or when they were targeted to the surface of unicellular spores for the detection of the water-borne pathogen *Cryptosporidium* (*11*). Because of their large size, it is very difficult to exploit the potential of QDs for single-molecule tracking within living cells. Even though it has been published that bona fide labeled kinesins could be tracked in HeLa cells (*12*), the potential of QDs for spatiotemporal resolution has been mainly demonstrated during in vitro studies on single-molecule tracking (for a recent review see ref *13*). For instance, the high bleaching resistance of the QDs made it possible to visualize the hand-over-hand processivity of myosin V during in vitro sliding assays (*14*).

To conjugate QDs to proteins of interest, in most cases the strong binding of streptavidin (coupled to the QDs) and biotin (coupled to the target protein) is utilized. For instance, in a pioneering work, actin was visualized in cellula through a biotinylated version of phalloidin (an actin-binding compound) that was detected by streptavidin-coupled QDs (*15*), or microtubules were visualized simultaneously with nuclei through two different streptavidin-coupled QDs that bound to biotinylated secondary antibodies directed against primary antibodies targeted to tubulin and nuclear epitopes (*16*). A similar approach, where the epitope was visualized by a sandwich composed of three layers (primary antibody, secondary antibody conjugated to biotin, streptavidin-conjugated QDs as tertiary component), was used to visualize chloroplasts in maize leaves in comparison to Alexa 488 as a control fluorophore (*17*). However, the poor quality of the obtained images and the optical setup used in this experiment indicate that the signal might in fact be due to the autofluorescence of chlorophyll. A general problem of the biotin–streptavidin conjugation is the illegitimate cross-reference between different QD–streptavidin conjugates in dual-visualization experiments. The streptavidin is expected to bind to the biotin on both primary antibodies such that the label will not be attributable to the respective epitope. This problem can be somewhat reduced by sequential labeling; however, the second label will still be partitioned between both epitopes, obscuring the specificity of the label. Especially for the discrimination of closely related epitopes (such as differentially modified subpopulations of a given protein), this will seriously impair the feasibility of this approach.

Thus, the best option to obtain specific labeling would be a direct fluorescence, where the QD label is linked to the primary antibody itself. The pronounced bleaching stability of QDs and their brightness is predicted to yield reasonable signals even in the absence of signal amplification through a secondary antibody (and a tertiary streptavidin conjugate). Streptavidin is a very robust biomolecule that tolerates even massive manipulations without a loss of function. This has been the major reason for the wide use of streptavidin as conjugation partner to introduce QDs into the realm of cell biology. Most proteins are much more delicate with respect to their functionality, and it is a challenging task to couple them with QDs in a nondestructive manner. In a previous work we have coupled silica-coated semiconductor nanocrystals directly to the cytoskeletal protein tubulin and were able to demonstrate the specific self-assembly of the QD–tubulin into fluorescent microtubules (*18*). In contrast, antibodies tend to lose their activity when directly coupled to nanoparticles. To date, there is no general solution for coupling biomolecules to nanoparticles under preservation of their biological activity. We therefore ventured to generate biocompatible nanoparticles surfaces that are versatile to be amenable for different kinds of nanoparticles and that are flexible regarding the biological problem. We have chosen two alternative strategies, through a biological surface (bovine serum albumine) and through an inorganic surface (silica), to couple QDs to monoclonal antibodies targeted against tubulin. To challenge the feasibility of this approach for cell-biological applications, we have used the QD-labeled antibodies for direct immunofluorescence following the dynamic reorganization of microtubules during the cell cycle. To our knowledge, this is the first report where QDs have been successfully employed to visualize subcellular details in plant cells.

EXPERIMENTAL PROCEDURES

Synthesis of Luminescent Semiconductor Nanocrystals. The luminescent CdSe/ZnS NPs were synthesized as described elsewhere (*19*) and encapsulated in silica using a water-in-oil microemulsion method at room temperature according to our previous protocol (*20*). Typically, 10 mL of cyclohexane (Roth, Karlsruhe, Germany), 1.3 mL of NP-5 as surfactant (Fluka, Taufkirchen, Germany), and 400 μL of the luminescent CdSe/ZnS NCs (8.72×10^{-7} mol/L) in chloroform (Roth, Karlsruhe, Germany) and 80 μL of tetraethyl orthosilicate (Sigma-Aldrich, Taufkirchen, Germany) as a precursor for silica formation were added in a flask under vigorous stirring. Thirty minutes after formation of the microemulsion, an amount of 150 μL of an aqueous ammonia solution (33 w/v %, Roth, Karlsruhe, Germany) was introduced to initiate the encapsulation process. Subsequently, the reaction mixture was incubated for 24 h at room temperature until completion. Subsequently, the nanoparticles were precipitated from the microemulsion using acetone and were centrifuged and the resultant precipitate of the CdSe/ZnS/SiO_2 composite particles was washed in sequence with butanol, propanol, ethanol (Roth, Karlsruhe, Germany), and water to remove any surfactant and unreacted educts. Finally, the composite particles were dispersed in water. Structure, size, and morphology of the resulting nanoparticles were determined by transmission electron microscopy (TEM; Zeiss LEO 912 Omega operating at 120 kV). For the TEM studies, the specimens were prepared by adding drops of the freshly produced suspension onto a carbon film supported on a Cu grid.

Preparation of Antibody Conjugates with Silica-Shelled Nanocrystals. The silica-encapsulated nanoparticles were briefly spun down, and subjected to three cycles of washing with dry DMSO (Roth, Karlsruhe, Germany), followed by precipitation with dry diethyl ether (Roth, Karlsruhe, Germany). Then, they were redispersed in 1 mL of dry DMSO. A small amount (covering the tip of a spatula) of 1,1′-carbonyldiimidazole (CDI, Fluka, Buchs, Switzerland) was added to the mixture that was then incubated overnight at 4 °C. Subsequently, the nanoparticle dispersion was warmed up to room temperature, incubated for an additional 6 h, and finally centrifuged and resuspended in 1 mL of phosphate buffered saline (PBS). An amount of 200 μL of the primary antibodies at a dilution of 1:10 was added and allowed to bind overnight at 4 °C. The final product was centrifuged and dialyzed against PBS. The resulting conjugates were then used without further purification. As antibodies for the coupling, the mouse monoclonal antibodies DM1A (*21*) and ATT (*22*) specific for the α-tubulin subunit were used in this study.

Preparation of Antibody Conjugates with BSA-Coated NPs. The details for preparation and characterization of BSA-coated CdSe/ZnS core–shell particles will be published else-

where (*23*). Briefly, an amount of 1.5 mL of MeOH was added to 500 μL of CdSe/ZnS nanoparticles in $CHCl_3$ (8.72×10^{-7} mol/L), and the nanoparticles were isolated by centrifugation. Subsequently, 500 μL ofDMSO (Roth, Karlsruhe, Germany) and 10 μL of 2-mercaptoethanol (ME) were added and the sample was heated to 60 °C for 3 h. The nanoparticles were reprecipitated again by addition of 1.3 mL of acetone and 0.2 mL of Et_2O and collected by centrifugation. These hydrophilic nanoparticles were suspended in 500 μL of 2 mg/mL BSA in a Tris-glycine buffer (25 mM Tris, 250 mM glycine, pH 8.3). These BSA-coated nanoparticles were purified by agarose electrophoresis, dialyzed against PBS, and coupled with the target antibodies DM1A and ATT by a standard protocol (*24*) using *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC). The resulting conjugates were used without further purification.

Tobacco Cell Cultures. The tobacco cell line BY-2 (*Nicotiana tabacum* L. cv. Bright Yellow 2 (*25*)) was cultivated in liquid medium containing 4.3 g/L Murashige and Skoog salts (Duchefa, Haarlem, The Netherlands), 30 g/L sucrose, 200 mg/L KH_2PO_4, 100 mg/L inositol, 1 mg/L thiamine, and 0.2 mg/L 2,4-dichlorophenoxyacetic acid (2,4-D), pH 5.8. Cells were subcultured weekly, inoculating 1.5–2 mL of stationary cells into 30 mL of fresh medium in 100 mL Erlenmeyer flasks. The cell suspensions were incubated at 25 °C in the dark on an orbital shaker (KS250 basic, IKA Labortechnik, Staufen, Germany) at 150 rpm. Stock BY-2 calli were maintained on media solidified with 0.8% (w/v) agar and subcultured monthly. All experiments were performed 4 days after subcultivation.

Visualization of Microtubules by Indirect Immunofluorescence Using FITC as Label. Microtubules were processed for immunofluorescence in self-made staining chambers using a nylon mesh of 70 μm pore width as published previously (*26*). This allowed fast exchange of media at preventing the loss of cells during the staining. After fixation for 30 min with 3.7% (w/v) paraformaldehyde in microtubule stabilizing buffer (MSB: 50 mM PIPES, 2 mM EGTA, 2 mM $MgSO_4$, 0.1% Triton X-100, pH 6.9), cells were washed in PBS three times for at least 5 min to remove excess paraformaldehyde. Subsequently, the cell wall was digested using 1% (w/v) Macerozym (Duchefa, Haarlem, The Netherlands) and 0.2% (w/v) Pectolyase (Fluka, Taufkirchen, Germany) in MSB for 5 min. Again, excess enzyme was washed out for 5 min with PBS. Unspecific binding sites were blocked for 20 min with 0.5% (w/v) BSA diluted in PBS. Directly after blocking, the cells were transferred into a small volume of the primary antibody. To visualize microtubules, we used a 1:250 dilution in PBS of either DM1A recognizing a conservative epitope near the carboxyterminus of α-tubulin (*21*) or ATT recognizing the carboxyterminal 12 amino acid residues of full-length α-tubulin (*22*), both purchased from Sigma (Taufkirchen, Germany). This primary antibody was allowed to bind overnight at 4 °C. The next day, unbound primary antibody was removed by washing the cells three times for at least 5 min in PBS. The sample was then incubated with a secondary FITC-conjugated antibody targeted against mouse IgG for 1 h at 37 °C in a moist chamber to prevent drying of the specimen. Unbound secondary antibody was removed by washing with PBS, and DNA was stained using 0.1 μg mL^{-1} Hoechst 33258 (2′-(4-hydroxyphenyl)-5-(4-methyl-1-piperazinyl)-2,5′-bi-1*H*-benzimidazole trihydrochloride hydrate) (Sigma, Taufkirchen, Germany).

Visualization of Microtubules by Direct Immunofluorescence Using QDs as Label. The cells were fixed, digested with Macerozyme, blocked, and washed as described above. After the unspecific binding sites were blocked, the cells were incubated overnight at 4 °C with the primary monoclonal antibody against α-tubulin that had been coupled to biofunctionalized, fluorescent CdSe-based semiconductor nanocrystals. The antibody–NC conjugates were adjusted with PBS to a dilution of 1:250 as used in the indirect FITC-based immunofluorescence described above. After unbound particles were washed out the next day, the sample was directly used for the staining of DNA by Hoechst 33258 as described above. To assess the success of bioconjugation for each antibody–NC conjugate batch, a specimen processed in parallel was poststained with a secondary FITC-conjugated antimouse IgG for 1 h at 37 °C and then triple-stained with Hoechst 33258.

Microscopy and Image Analysis. The samples were examined under an AxioImager Z.1 microscope (Zeiss, Jena, Germany) equipped with an ApoTome microscope slider for optical sectioning and a cooled digital CCD camera (AxioCam MRm). For the observation of the QD-antibody conjugates, the filter set 43 HE (excitation at 550 nm, beamsplitter at 570 nm, and emission at 605 nm) was used. The DNA signal and the FITC fluorescence were viewed through filter sets 49 (excitation at 365 nm, beamsplitter at 395 nm, and emission at 445 nm) and 38 HE (excitation at 470 nm, beamsplitter at 495 nm, and emission at 525 nm) (Zeiss, Jena, Germany). A test for potential filter cross-talk, where single-stained samples were viewed with the three filter sets at corresponding exposure conditions, revealed that the filters were tight for the three fluorochromes (data not shown). The images were analyzed using the AxioVision (release 4.5) software and processed for publication using Photoshop (Adobe Systems, San Jose, CA).

RESULTS AND DISCUSSION

Synthesis of CdSe-Based NPs and Their Antibody Conjugates. We used two strategies to prepare the antibody conjugates, which are presented in parts a and b of Figure 1. In the first one the water solubility of NPs has resulted from encapsulation with the hydrophilic SiO_2 layer and the free OH groups on the surface have been used for conjugation of the NPs with tubulin antibody ATT or DM1A via a CDI crosslinker.

In the first strategy (Figure 1a), the CdSe/ZnS nanocrystals were transferred into water by a standard ligand exchange method utilizing 2-mercaptoethanol (ME). In the next step, the product was coated with bovine serum albumine (BSA) to stabilize the nanoparticles against coagulation in water and to provide free chemical groups for improved covalent conjugation (*23*). The covalent coupling between BSA and the antibodies DM1A and ATT occurred via the standard reagent EDC through mutual coupling between free carboxylic and amino side groups on the two respective proteins. The detailed characterization of these particles will be published elsewhere (*23*).

The second strategy (Figure 1b) was based on silica coating as published previously (*20*). Transmission electron micrographs from the resulting CdSe/ZnS nanoparticles and their silica-coated nanocomposites are shown in parts a and b of Figure 2, respectively. Since the electron density of the CdSe/ZnS core is significantly higher than that of silica, the darker and lighter parts of the particles in Figure 2b correspond to the CdSe/ZnS core and the silica shell, respectively. The size distributions of the CdSe/ZnS core particles (Figure 3a), and the CdSe/ZnS/SiO_2 nanocomposites (Figure 3b) were calculated from the micrograph over several hundred individuals. The average diameter of the CdSe/ZnS core particles was 5.8 nm, and the diameter of the silica-coated nanoparticles was 41.6 nm.

The particles obtained by the two approaches were coupled to the monoclonal antitubulin antibodies ATT and DM1A as described in detail in Experimental Procedures. Because of the high affinity and specificity of these antibodies, they are used at highly diluted preparations such that it was not feasible to

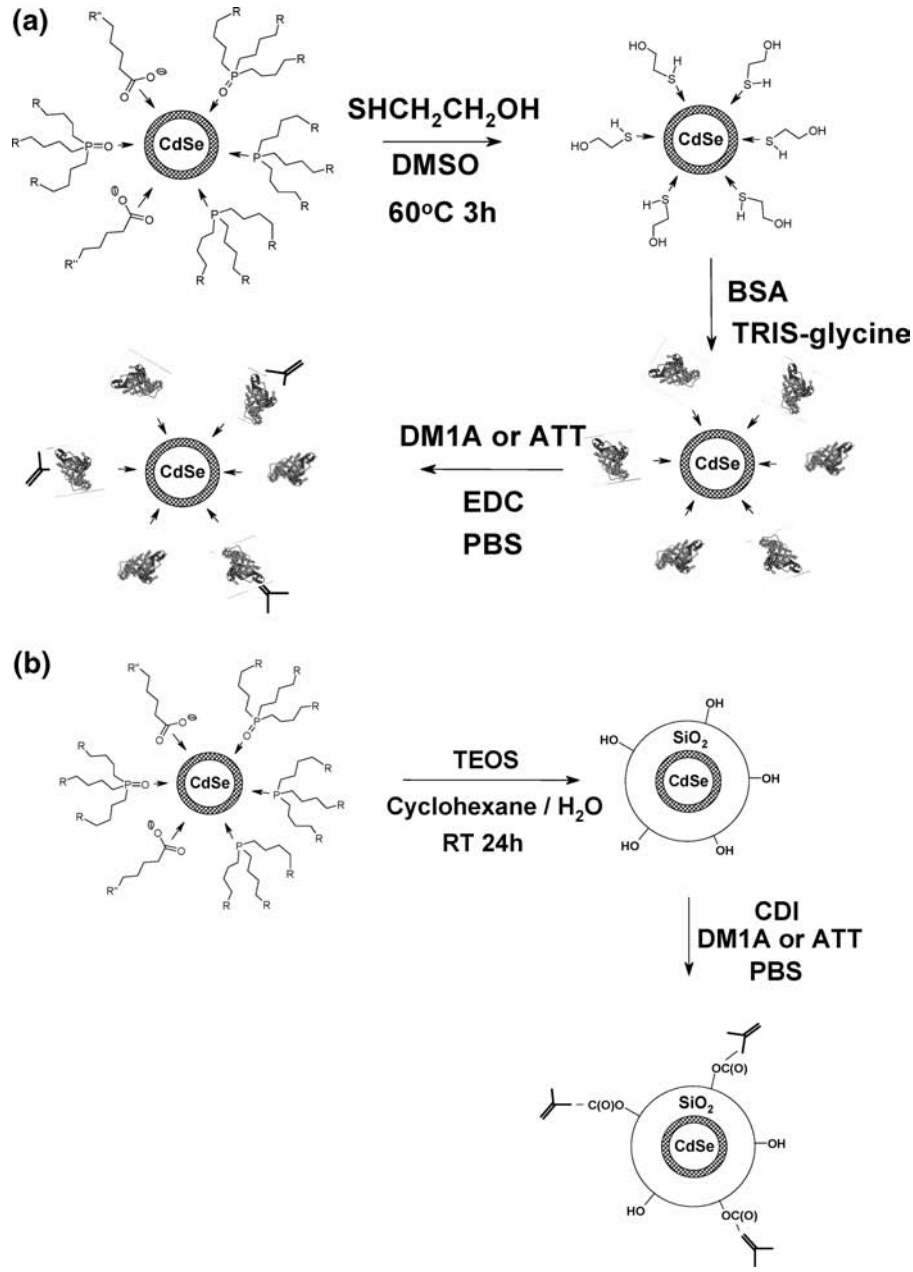

Figure 1. Strategies to conjugate fluorescent CdSe semiconductor nanocrystals to monoclonal antibodies: (a) coupling through coating with bovine serum albumine; (b) coupling through coating with a silica shell with surface functionalities. The black layer around the CdSe core crystal stands for the ZnS shell.

characterize the conjugates by electron microscopy or any other method, such as gel electrophoresis, dynamic light scattering, or size exclusion chromatography. To assess the success of the bioconjugation, we therefore tested the biological functionality (i.e., the immunofluorescence in the target cells) as indicator.

Tubulin Antibodies Conjugated to BSA-Coated Nanocrystals Decorate Microtubules. As the first approach, antibodies conjugated to biofunctionalized, BSA-shelled nanocrystals were used for direct immunofluorescence of microtubules in the tobacco cell line BY-2 (Figure 4). These cells divide readily in suspension culture and are endowed with a clear axis and polarity, which allows very clear identification of the various microtubular arrays that form during the cell cycle.

In premitotic interphase cells, the antitubulin–NC conjugates visualize punctate signals in the cell periphery that are aligned perpendicular to the main axis of the cell file (Figure 4A). This specific orientation, the general appearance, and the localization in the cortical cytoplasm show that these structures correspond to the cortical microtubules typical for this stage of the cell cycle. When confocal sections are recorded from the cell center (parts B1 and B2 of Figure 4), the nanocrystal signal is observed

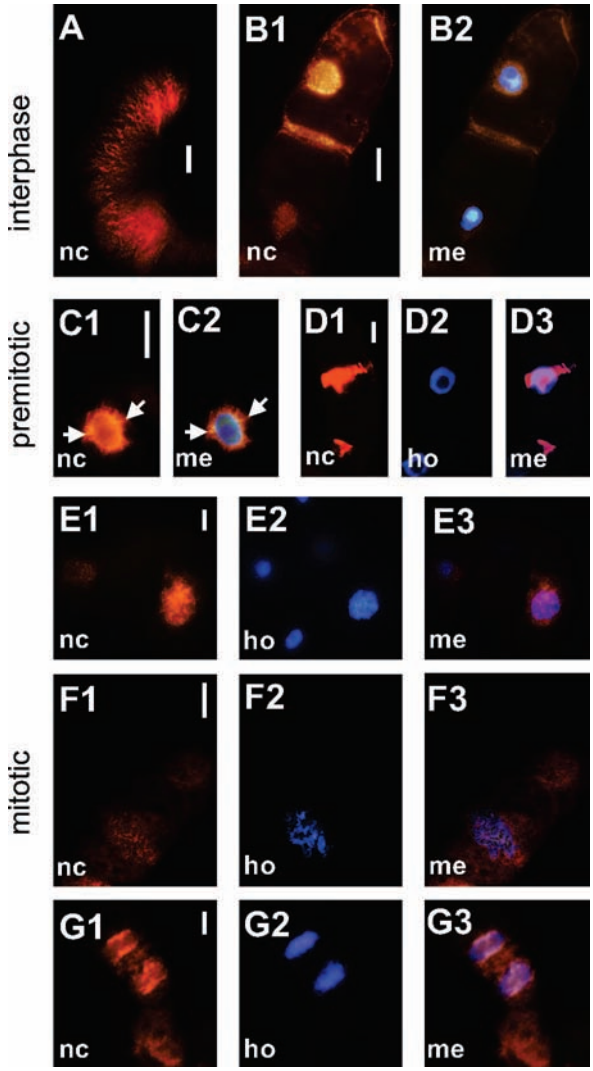

Figure 4. Direct immunofluorescence of tubulin with monoclonal mouse antitubulin antibodies conjugated to BSA-coated QDs followed through different stages of division in tobacco BY-2 cells: (nc) optical setup for the detection of nanocrystals; (ho) optical setup for the detection of DNA (through Hoechst 33258); (me) merge of the two channels to show the QD signal in relation to the DNA. Size of bar is 10 μm.

at the nuclear envelope that ensheaths the DNA. The nuclear envelope is the major microtubule-organizing center in the acentriolar cells of higher plants, and therefore, this nanocrystal signal corresponds to the microtubule-organizing centers that decorate the nuclear surface of plant cells.

Cell division is heralded by a movement of the nucleus into the cell center to the prospective division site and the formation of a microtubular preprophase band from the nuclear envelope that predicts position and orientation of the future cross wall. Both the nuclear envelope (parts C1 and C2 of Figure 4) and the preprophase band that progressively emerges from the nuclear envelope (white arrows in parts C1 and C2 of Figure 4) until a massive band of microtubules is produced (parts D1–D3 of Figure 4) are decorated by the nanocrystal signal.

During the mitotic prophase, when the DNA is condensed into chromosomes (part E2 of Figure 4), the nuclear envelope collapses and the nanocrystals are found to surround the forming spindle (parts E1 and E3 of Figure 4). In the following metaphase, the nanocrystal signal will then attach to the chromosomes spread in the equatorial cell plane (parts F1–F3 of Figure 4) and redistribute to the newly reestablished nuclear envelopes of the daughter nuclei and at the newly forming cross wall in the final telophase (parts G1–G3 of Figure 4).

Thus, the distribution of the nanocrystal–antibody conjugates mirrors exactly the behavior of the microtubular cytoskeleton during the cell cycle. However, the signal obtained by this approach was never contiguous but remained punctate.

As to testing whether the punctate nanocrystal signal was in fact colocalizing with microtubules or whether it was produced by disintegration of microtubules, we counterstained the samples with a FITC-conjugated secondary antibody raised against the primary antitubulin antibody. By dual-channel visualization of the nanocrystal and the FITC signal, it was thus possible to see the context of the nanocrystals with microtubules (Figure 5). To check for a potential filter leakage of the FITC signal upon the nanocrystal signal, we viewed cells, where microtubules had been visualized by a primary antibody that was not conjugated to nanocrystals, as a negative control. When these cells were incubated with the FITC-conjugated secondary antibody (part A1 of Figure 5) and then viewed with the filter used to record the nanocrystal signal, the result was clearly negative (part A1 of Figure 5), demonstrating that the optical setup was tight enough to separate the FITC signal and the nanocrystal signal in dual-channel configurations.

We therefore followed the cell cycle of tobacco cells using triple staining (nanocrystal–antitubulin antibodies, FITC, and Hoechst 33258 for the visualization of DNA). In interphase cells (parts B1–B4 of Figure 5), the cortical microtubules visualized by the secondary antibody (part B2 of Figure 5) were found to

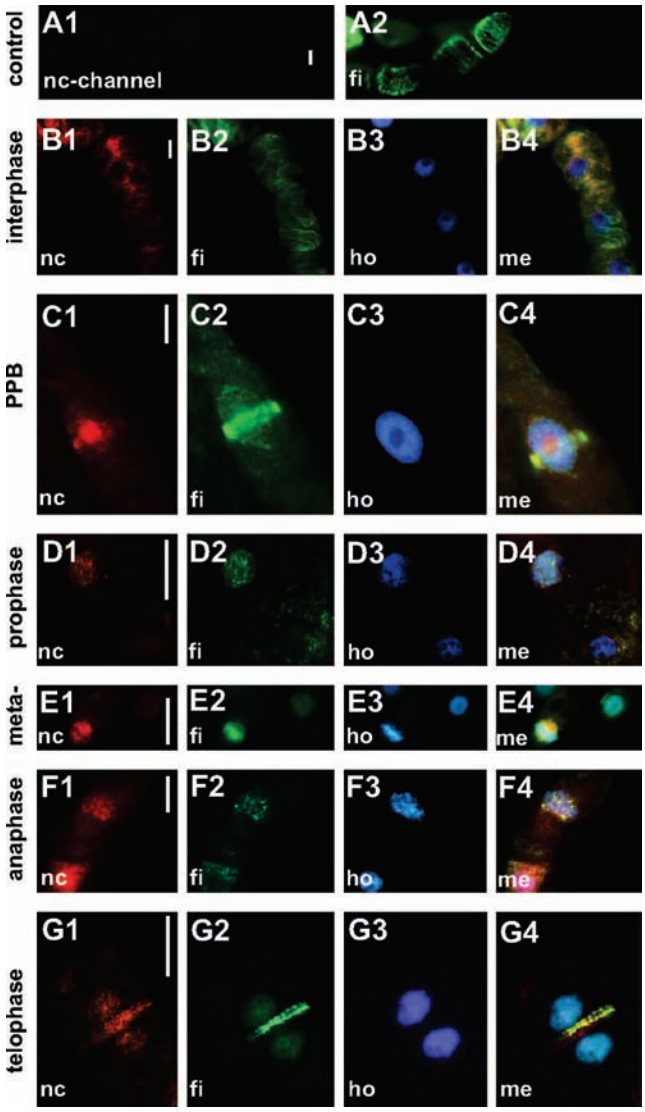

Figure 5. Direct immunofluorescence of tubulin with monoclonal mouse antitubulin antibodies conjugated to BSA-coated QDs and after-staining with FITC-conjugated antimouse IgG followed through different stages of division in tobacco BY-2 cells: (nc) optical setup for the detection of nanocrystals; (fi) optical setup for the detection of the FITC after stain; (ho) optical setup for the detection of DNA (through Hoechst 33258); (me) merge of the three channels to show the QD signal in relation to microtubules and DNA. Size of bar is 10 μm. Parts A1 and A2 show the negative control using unconjugated primary antibody and after stain with FITC-conjugating antimouse IgG (i.e., omitting the QD-conjugated antibodies) to test for potential optical cross-contamination of the nc optical setup through the FITC signal. The negative results show that the optical setup is tight against filter leakage.

be decorated with the nanocrystal signal (part B1 of Figure 5). The merged image exhibited numerous yellow microtubules indicating the high congruence of both signals (part B4 of Figure 5). This congruence was maintained when the cells were prepared for mitosis and generated a preprophase band (parts C1–C4 of Figure 5). Also, the various microtubular arrays characteristic for mitosis such as the nuclear cap in the late prophase (parts D1–D4 of Figure 5), the division spindle in metaphase (parts E1–E4 of Figure 5), and the exploratory microtubules formed at anaphase (parts F1–F4 of Figure 5) were correctly depicted by the two signals. When the microtubular phragmoplast in the late telophase is formed (parts G1–G4 of Figure 5), the nanocrystals decorate the complete region where FITC-labeled microtubules are seen. In addition, the nanocrystal conjugates can be detected in the adjacent cytoplasm and already

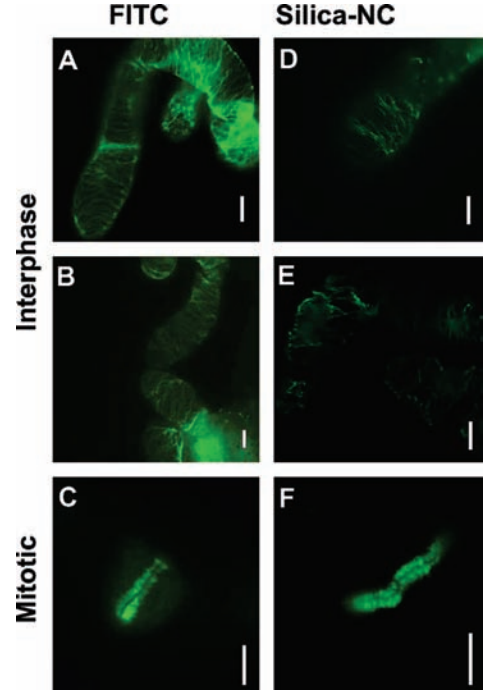

Figure 6. Direct immunofluorescence of tubulin with monoclonal antitubulin antibodies conjugated to silica-coated QDs (D–F) in comparison to the signal obtained by conventional indirect immunofluorescence using secondary antibodies conjugated to FITC (A–C) followed through different stages of division in tobacco BY-2 cells. Size of bar is 10 μm. The two labels are equivalent in terms of specificity, signal-to-noise ratio, intensity, and structural preservation.

very clearly at the nuclear surface of the daughter nuclei (part G1 of Figure 5), where the FITC signal is much weaker (part G2 of Figure 5).

Thus, upon counterstaining with a FITC-conjugated secondary antibody and dual visualization of both signals, the entire dynamics of microtubule arrays characteristic for the plant-cell cycle can be reliably followed. The punctate staining seen for the nanocrystal–antibody conjugates (Figure 4) is therefore not due to microtubules that had been disrupted by the incubation with the nanocrystal–antibody conjugates. Microtubules have remained intact during the labeling procedure and can be contiguously stained by a FITC-conjugated secondary antibody. This indicates that the affinity of the nanocrystal–antibody conjugate for tubulin has been preserved as well as the specificity of binding. However, either a significant proportion of the antitubulin antibody is not conjugated with the nanocrystals or the fluorescence has been lost during the conjugation. These unlabeled primary mouse antibodies are still functional and bind to their cellular target but will not display the fluorescent signal. They can be rendered visible, however, by addition of an antimouse IgG secondary antibody coupled to FITC.

Tubulin Antibodies Conjugated to Silica-Shelled Nanocrystals Label Microtubules. To obtain a contiguous microtubule signal, we therefore tested an alternative approach for the conjugation of the nanocrystals to antitubulin antibodies. The nanocrystals were surrounded by a silica shell that was coated with functional groups that could be used for coupling (*20*). These silica-shelled nanocrystals were then conjugated with antitubulin antibodies and used for direct immunofluorescence in both interphase and mitotic cells of tobacco BY-2 (Figure 6). Conventional labeling of microtubules by indirect immunofluorescence using FITC (parts A–C of Figure 6) was performed in comparison, and both the cortical microtubules (parts A and

B of Figure 6) and mitotic arrays such as the phragmoplasts that organize the new cell plate after completed segregation of the daughter nuclei (part C of Figure 6) were visualized. The silica-shelled nanocrystals (parts D–F of Figure 6) produced a contiguous microtubule signal by direct immunofluorescence that was equivalent, in both the signal amplitude and morphology, to the signal of the conventional label. This signal was now contiguous for both the cortical microtubules (parts D and E of Figure 6) and the phragmoplast (part F of Figure 6) at a simultaneously very low background signal. Thus, the result obtained for the silica-shelled nanocrystals was equivalent to the conventional indirect immunofluorescence.

To summarize our results, we state that both approaches were successful in visualizing the specific epitopes of the antitubulin antibodies through QD-based direct immunofluorescence. However, the conjugation in the BSA-coating approach seemed to be only partial, whereas the SiO_2-coat approach produced a more complete conjugation. This difference might be due to the considerably larger surface of the silica-coated particles at the same concentration of the core CdSe/ZnS Qds. The functionality of the tubulin antibody was maintained in both cases; this is also seen in the FITC-afterstain experiment (Figure 5), where the unconjugated tubulin antibodies were stained by the FITC-labeled secondary antibody and found to be perfectly aligned with microtubules. The signal strengths obtained with direct immunofluorescence using the QDs were absolutely comparable to those resulting from conventional indirect immunofluorescence (Figure 6). Given the fact that up to 50 secondary antibodies bind to one primary antibody in the conventional indirect immunofluorescence, one has to conclude that the fluorescence intensity produced by an individual QD-conjugated antibody is very high.

OUTLOOK

Functional genomics is increasingly extending into the analysis of differentially modified subpopulations of a given protein in order to understand the spatiotemporal dynamics and cell biological function of these modifications (*26*). Double visualization of such subpopulations using highly specific monoclonal antibodies is so far impaired by the fact that these antibodies are almost exclusively available from one animal species (mouse). It is extremely difficult to safeguard against illegitimate cross-reaction of the secondary fluorescent antisera. Direct immunofluorescence would be a good alternative but is limited by low signal strength because the signal amplification due to the labeled secondary antibody is lacking. We could demonstrate in our study that this limitation can be overcome by direct coupling of fluorescent QDs to highly specific antisera while preserving functionality and specificity of the antibody. This should now allow, for instance, visualization of different modifications on the tubulin on the same microtubule. By use of QDs with specific optical properties (such as delayed photostimulated luminescence), it should be possible to obtain higher levels of specificity and better spatiotemporal resolution in confocal applications because a higher number of individual scans can be averaged to increase signal/noise ratios and input amplifications (possible reduced noise/signal ratios). We have demonstrated for the first time that QDs can be successfully utilized in intact, unsectioned plant cells despite the presence of a massive cellulosic cell wall. In the next step we want to extend the use of QDs to the in vivo situation by mild and transient permeabilization of the plasma membrane without infringing viability. In this context it is mainly size that matters such that the BSA-coated particles with their considerably smaller size might become crucial. By use of nanoparticles that are magnetic, it should become possible not only to visualize but also to manipulate specific cellular targets in living plant cells.

ACKNOWLEDGMENT

This work was supported by the Research Priority Programme of the State of Baden-Württemberg (Project LuNaCell) to T.N. and P.N. and by the Center for Functional Nanoscience of the University of Karlsruhe (Project E1.5) to P.N. The authors thank Dr. Jürgen Riegler and Dr. Ralf Thomann for preparation of the CdSe/ZnS nanoparticles and for TEM measurements, respectively. Sabine Purper is ackowledged for the technical assistance in the culture of tobacco cells.

Here, we present the synthesis of a library of end-modified poly(*β*-amino ester)s and assess their utility as gene delivery vehicles. Polymers were synthesized using a rapid, two-step approach that involves initial preparation of an acrylate-terminated polymer followed by a postpolymerization amine-capping step to generate end-functionalized polymers. Using a highly efficient poly(*β*-amino ester), C32, we show that the terminal amine can greatly affect and improve polymer properties relevant to gene delivery. Specifically, the *in vitro* transfection levels can be increased by 30% and the optimal polymer:DNA ratio lowered 5-fold by conjugation of the appropriate end group. The most effective modifications were made by grafting primary diamine molecules to the chain termini. The added charge and hydrophobicity of some derivatives enhanced DNA binding and resulted in the formation of polymer–DNA complexes less than 100 nm in diameter. In addition, cellular uptake was improved 5-fold over unmodified C32. The end-modified poly(*β*-amino ester)s presented here are some of the most effective gene-delivery polycations, superior to polyethylenimine and previously reported poly(*β*-amino ester)s. These results show that the end-modification of poly(*β*-amino ester)s is a general strategy to alter functionality and improve the delivery performance of these materials.

INTRODUCTION

Incorporation of new genetic information into cells is a promising strategy for the treatment of many inherited and acquired genetic disorders. In order for gene-based therapeutics to be clinically applicable, a safe and efficient delivery system for DNA needs to be developed. Modified viruses are the most heavily researched agents but continue to be limited by their toxicity, immunogenicity, and low carrying capacity (*1*). As a result, various cationic polymers have been developed as alternative delivery vectors (*2*–*4*).

The most common polycations used for gene delivery are poly(L-lysine) (PLL) and polyethylenimine (PEI) (*3, 5*). High molecular weight derivatives of both polymers have been shown to self-assemble with plasmid DNA to form nanoparticles capable of transfecting a variety of cell types. Furthermore, functionalization of these polymers with PEG chains and targeting ligands has allowed for cell-specific delivery, which is particularly important for cancer gene therapies (*6*–*8*). Despite their widespread use, both PLL and PEI have significant disadvantages that may ultimately limit their clinical utility. In particular, both polymers are known to be very cytotoxic and have relatively low transfection efficiencies compared to viruses, especially in nondividing cells (*9*–*11*).

Poly(*β*-amino ester)s are an alternative class of cationic polymers that have been recently developed and explored as gene delivery vectors (*12*). These polymers are degradable by hydrolysis of backbone ester bonds and contain tertiary amines to facilitate DNA binding (*12*). They are synthesized by Michael addition of bifunctional amines to diacrylates, and can be prepared without solvents, catalysts, or complex protecting-group strategies (*12, 13*). The polymer molecular weight and chain end groups can be easily controlled by adjusting the amine/diacrylate monomer ratio (*14, 15*). Ease of synthesis, along with the commercial availability of many amine and diacrylate monomers, has allowed for the generation of large, structurally diverse libraries of poly(*β*-amino ester)s (*15, 16*). High-throughput transfection screens have identified many polymers that are capable of transfecting cells with much higher efficiencies than PEI, while also demonstrating less toxicity both *in vitro* and *in vivo* (*15, 17*). The polymer libraries have also been useful to elucidate structure–function relationships. These studies have shown that high molecular weight, amine-terminated poly(*β*-amino ester)s with hydroxyl-functionalized side chains are highly efficient polymers for gene delivery (*15*). The most effective polymer discovered, C32, has also been used *in vivo* for the gene-based treatment of prostate cancer (*17*).

The continued development of poly(*β*-amino ester)s for gene therapy and other biomedical applications requires an effective method to chemically modify these materials. As with other polycations, it is necessary to incorporate additional levels of functionality such as serum stability and cell targeting to improve the gene delivery properties of these polymers. The ideal approach to poly(*β*-amino ester) modification would involve a chemistry that is simple, versatile, and adaptable to a high-throughput format. It is important to generate many polymeric derivatives, since any modification has a nontrivial affect on gene delivery. Previous studies have shown that even single carbon or functional group differences between polymer repeat units can drastically affect their transfection efficiencies (*15, 16*).

We have recently shown that end-modification of poly(β-amino ester)s is a useful approach to improve both the *in vitro* and *in vivo* polymer transfection efficiency (*18*). In this study, we present a rapid, parallel approach to synthesize end-modified poly(β-amino ester)s and explore the effects of end-group structure on polymer gene delivery properties. End-modified polymers were synthesized following a two-step procedure in which an acrylate-terminated base polymer is first prepared by polymerization using excess diacrylate over amine monomer. In a second stage, the base polymer was reacted with various amine reagents to generate amine-capped polymer chains. Following this approach, we have generated a library of end-modified C32 polymers and demonstrate that the terminal amine has a large effect on C32 transfection. Similar to polymer repeat units, end segments differing in a single additional carbon or functional group can drastically affect the polymer delivery properties. In addition, the terminal amine structure has a large influence on cytotoxicity, physical properties, and cellular uptake of polymer–DNA complexes. These results indicate that end-modification is a useful strategy to functionalize poly(β-amino ester)s and improve their gene delivery performance.

EXPERIMENTAL SECTION

Materials. Polyethylenimine (water-free, M_w ~25 kDa, M_n ~10 kDa) was purchased from Sigma-Aldrich (St. Louis, MO). A 25 mM sodium acetate buffer solution pH 5.2 (NaAc buffer) was prepared by diluting a 3 M stock (Sigma-Aldrich). 1,4-Butanediol diacrylate (99%) and 5-amino-1-pentanol (97%) were from Alfa Aesar (Ward Hill, MA). Amine capping reagents were purchased from Sigma-Aldrich, Alfa Aesar, Acros Organics/Fisher Scientific (Pittsburgh, PA), TCI America (Portland, OR), Molecular Biosciences (Boulder, CO), and Toronto Research Chemicals (Ontario, Canada). All chemicals were used as received without any further purification. PicoGreen and Rediplate 96 PicoGreen dsDNA Quantification Kit were purchased from Molecular Probes (Eugene, OR). pCMV-Luc plasmid DNA stock solution (1 mg/mL in water) was obtained from Elim Biopharmaceuticals (Hayward, CA). gWIZ-β-gal plasmid DNA stock solution (5 mg/mL) was obtained from Aldevron (Fargo, ND). The MTT Cell Proliferation Assay and Bright Glo Luciferase Assay Kits were purchased from Promega Corporation (Madison, WI). White and black polystyrene tissue culture treated 96-well plates and half-area polystyrene 96-well plates were obtained from Corning Costar. Clear polystyrene tissue culture treated 96-well plates were obtained from Becton Dickinson (Bedford, MA). Polypropylene 96-well deep-well plates were purchased from Sigma-Aldrich.

Cell Culture. COS-7 cells were obtained from ATCC (Manassas, VA) and maintained in phenol red free DMEM supplemented with 10% fetal bovine serum and 100 units/mL of penicillin/streptomycin. All cell culture reagents were purchased from Invitrogen Corporation (Carlsbad, CA) unless otherwise noted. COS-7 were grown at 37 °C in a 5% CO_2 atmosphere.

Methods. ^{1}H NMR was conducted on a Varian Inova 500 MHz Spectrometer.

Synthesis of Acrylate-Terminated C32 Poly(β-amino ester). Acrylate-terminated C32 polymer was prepared by mixing 793 mg of 1,4-butanediol diacrylate (4 mmol) with 344 mg of 5-amino-1-pentanol (3.3 mmol). Polymerization was performed in a Teflon-lined screw-cap vial under magnetic stirring at 90 °C for 24 h. ^{1}H NMR (d_6-DMSO): δ (ppm) 1.2–1.4 (m, -$NCH_2(CH_2)_3CH_2OH$), 1.6 (bs, -$N(CH_2)_2COOCH_2CH_2$- and $CH_2CHCOOCH_2CH_2$-), 2.3–2.4 (m, -$COOCH_2CH_2N$- and -$NCH_2(CH_2)_4OH$), 2.6–2.7 (m, -$COOCH_2CH_2N$-), 3.4 (bs, -$N(CH_2)_4CH_2OH$), 4.0 (bs, -$N(CH_2)_2COOCH_2CH_2$-), 4.1 (m, $CH_2CHCOOCH_2CH_2$-), 4.4 (bs, -$N(CH_2)_5OH$), 5.9 (m, $CH_2CHCOOCH_2CH_2$-), 6.1–6.2 (m, $CH_2CHCOOCH_2CH_2$-), 6.3–6.4 (m, $CH_2CHCOOCH_2CH_2$-).

Synthesis of Amine-Capped C32 Poly(β-amino ester)s. Acrylate-terminated C32 polymer was dissolved in DMSO at 31.13 wt %/wt. Amine capping reagents were dissolved in DMSO at 0.25 M. End-chain capping reactions were performed by mixing 321 mg of polymer/DMSO solution with 800 μL of amine solution. Reactions were performed in Eppendorf tubes with constant agitation for 24 h. Polymers were stored at −20 °C until use for each experiment. ^{1}H NMR of C32-Ac capped with 5-amino-1-pentanol (i.e., C32–32) (d_6-DMSO): δ (ppm) 1.2–1.4 (m, -$NCH_2(CH_2)_3CH_2OH$), 1.6 (bs, -$N(CH_2)_2COOCH_2CH_2$-), 2.2–2.4 (m, -$COOCH_2CH_2N$- and -$NCH_2(CH_2)_4OH$), 2.4–2.7 (m, -$COOCH_2CH_2N$-), 3.3 (t, J = 6.6 Hz, -$N(CH_2)_4CH_2OH$), 4.0 (bs, -$N(CH_2)_2COOCH_2CH_2$-).

Polymer Transfections. COS-7 cells (15 000 cells/well) were plated in opaque 96-well plates and allowed to adhere overnight. Polymers at 100 mg/mL in DMSO were diluted accordingly into NaAc buffer to concentrations that yield the different polymer:DNA weight ratios. One hundred microliters of diluted polymer solution was mixed vigorously with 100 μL of DNA (60 μg/mL in NaAc buffer) in a 96-well polystyrene plate. The solutions were left undisturbed for 5 min, after which time 120 μL of each was added to 800 μL of cell culture media in a deep-welled polypropylene plate. The media over the cells was then removed with a 12-channel aspirator wand followed by the addition of 150 μL/well of polymer–DNA complex solution. Complexes were incubated over the cells for 1 h after which time they were aspirated off and replaced with 105 μL/well of fresh cell culture media. Cells were allowed to grow for three days at 37 °C, 5% CO_2, and then analyzed for luciferase protein expression.

Luciferase expression was analyzed using Bright-Glo assays kits. Briefly, 100 μL/well of Bright-Glo solution was added to the cell plates. The plates were gently agitated to promote mixing for 2 min Luminescence was then measured on a Perkin Elmer Victor 3 plate luminometer using a 1% neutral density filter and 1 s/well counting time.

Measurements of Polymer Cytotoxicity. Cytotoxicity measurements of polymer–DNA complexes were performed essentially as described for the transfection experiments except that cellular metabolic activity was measured instead of Luciferase protein expression. One day after the transfection, MTT reagent was added to the cell plates at 10 μL/well. The plates were incubated at 37 °C for 2 h. Detergent reagent was then added at 100 μL/well, and the cell plates were left in the dark at room temperature for 4 h. Optical absorbance was measured at 570 nm using a Molecular Devices SPECTRAmax PLUS384 absorbance plate reader and converted to % cell viability relative to untreated cells.

Polymer–DNA Binding Assay with PicoGreen. Polymer solutions at 100 mg/mL in DMSO were diluted into NaAc buffer to a final concentration of 6 mg/mL. In a half-area 96-well plate, 50 μL/well of diluted polymer was added to 50 μL/well of DNA (60 μg/mL in NaAc buffer). The solutions were mixed vigorously and allowed to sit undisturbed for 5 min to allow for polymer–DNA complexation. After this time, 100 μL/well of PicoGreen solution was added. PicoGreen working solution was prepared by diluting 80 μL of the purchased stock into 15.2 mL NaAc buffer. After 5 min, 30 μL/well of polymer–DNA–PicoGreen solution was added to 200 μL/well of DMEM media in black 96-well polystyrene plates. The plate fluorescence was then measured on a Perkin Elmer Victor 3 plate reader using an FITC filter set (excitation 485 nm, emission 535 nm). The relative fluorescence (RF) was calculated using the following relationship

$$\mathrm{RF} = (F_{\mathrm{sample}} - F_{\mathrm{blank}})/(F_{\mathrm{DNA}} - F_{\mathrm{blank}})$$

where F_{sample} is the fluorescence of the polymer–DNA–PicoGreen sample, F_{blank} is the fluorescence of a sample with no

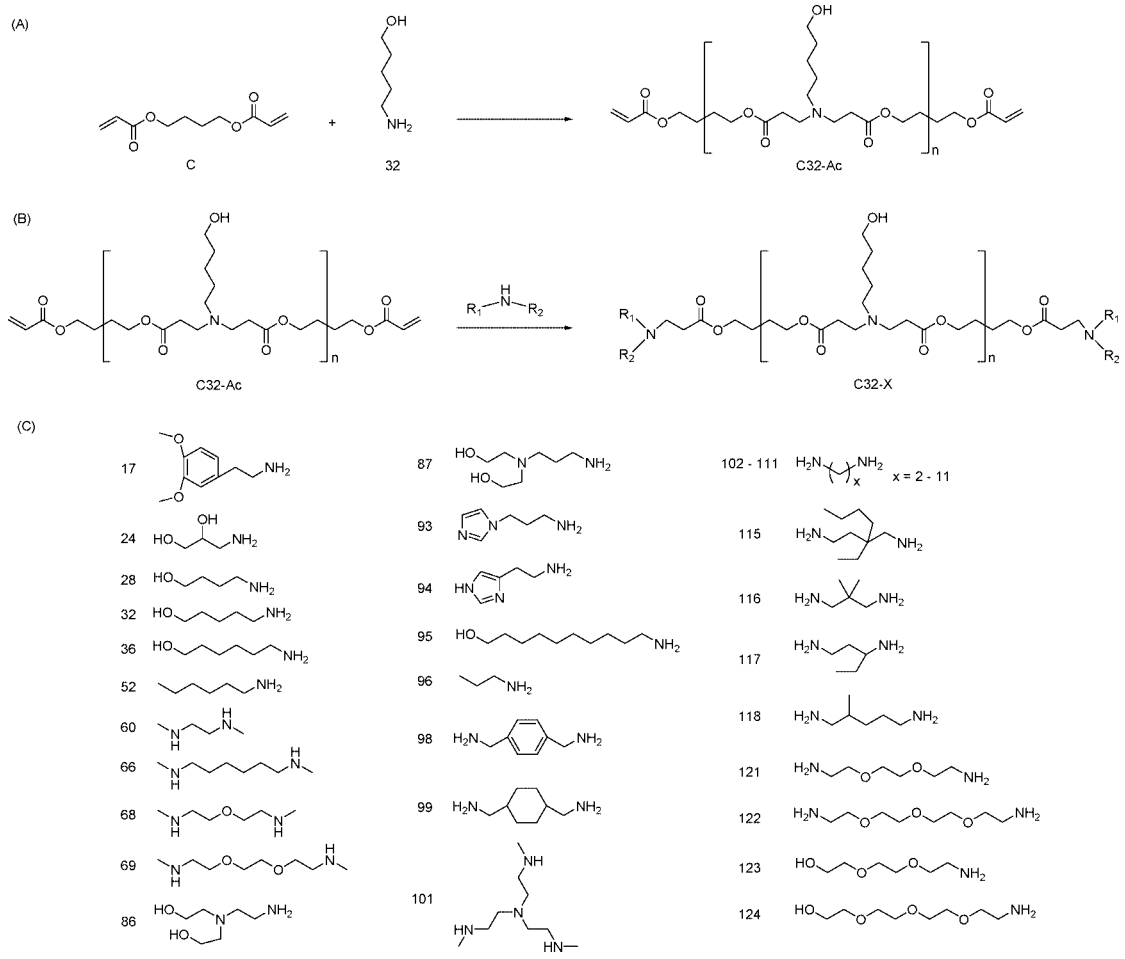

Figure 1. (A) Synthesis of acrylate-terminated C32 polymer (C32-Ac). (B) Synthesis of end-modified C32 polymers (C32-X). (C) Amine capping molecules.

polymer or DNA (only PicoGreen), and F_{DNA} is the fluorescence of DNA–PicoGreen (no polymer).

Polymer–DNA Complex Size. Polymer solutions at 100 mg/mL in DMSO were diluted into NaAc buffer at the appropriate concentration. Concentrations were adjusted for each polymer so that the final polymer:DNA ratio was the same as the ratio that produced the highest transfection. To prepare polymer:DNA complexes, 100 μL of diluted polymer was added to 100 μL of DNA (60 μg/mL in NaAc) and pipetted vigorously. Complexation was allowed to proceed undisturbed for 5 min, after which time 150 μL of the sample was diluted into 1.8 mL of DMEM media. Polymer:DNA complex size was measured on a Zeta-PALS dynamic light scattering detector (Brookhaven Instruments Corporation, Holtsville, NY; 15 mW laser; 676 nm incident beam, 90° scattering angle). Effective particle diameters were calculated from the autocorrelation function using the MAS option of the BIC particle-sizing software assuming a log normal distribution. The solution viscosity and refractive index were assumed equal to those of pure water at 25 °C.

Cellular Uptake Assay. Uptake measurements of polymer–DNA complexes were performed essentially as described for the transfection experiments but using the β-galactosidase (β-gal) plasmid. Instead of quantifying protein expression levels after three days, total cellular DNA was isolated 4 h post-transfection using a DNeasy 96 Tissue Kit (Qiagen; Valencia, CA). DNA isolation was performed according to the supplied instructions and included two PBS washes of the cells before lysis to ensure that surface-bound complexes were removed (*19*). Total DNA was quantified using a Redi-Plate 96 PicoGreen dsDNA Quantification Kit following the supplied instructions. The amount of β-gal DNA delivered was quantified using RT-PCR with a custom Taqman primer and probe set specific for the β-gal plasmid (Applied Biosystems; Foster City, CA). The primers and probe spanned an 80 bp sequence in the β-gal coding region of the plasmid and had the following sequences: forward primer 5′-TTA CAG GGC GGC TTC GTC T-3′, reverse primer 5′-TAA GCC GAC CAC GGG TTG-3′, and the Taqman probe 5′-6FAM-CTG GGT GGA TCA GTC GCT GAT TAA ATA TGA TG-TAMRA-3′. The primers and probes were used at concentrations of 400 nM and 25 nM, respectively. After activating the Taq enzyme at 95 °C for 10 min, 40 cycles of amplification were performed, with each cycle consisting of 95 °C for 15 s, 60 °C for 1 min, followed by a fluorescent plate read using a Chromo4 Continuous Fluorescence Detector (MJ Research; Waltham, MA). Plasmid copy numbers were determined by comparing the RT-PCR cycle threshold values to a plasmid standard curve and analyzed using the *Opticon Monitor 3* sofware package (MJ Research).

RESULTS AND DISCUSSION

Polymer Synthesis. We developed a two-step approach to synthesize end-modified C32 poly(β-amino ester)s, as illustrated in Figure 1A,B (*18*). In the first step, acrylate-terminated C32 polymer was prepared by mixing the corresponding diacrylate and amine monomers in a 1.2:1 molar ratio, as shown previously (Figure 1A) (*14*). This ratio was selected since C32 and many other top-performing, amine-terminated polymers are made at an inverse ratio of 1:1.2 acrylate/amine (*15*). We hypothesized then that the exact opposite ratio may be optimal so that the

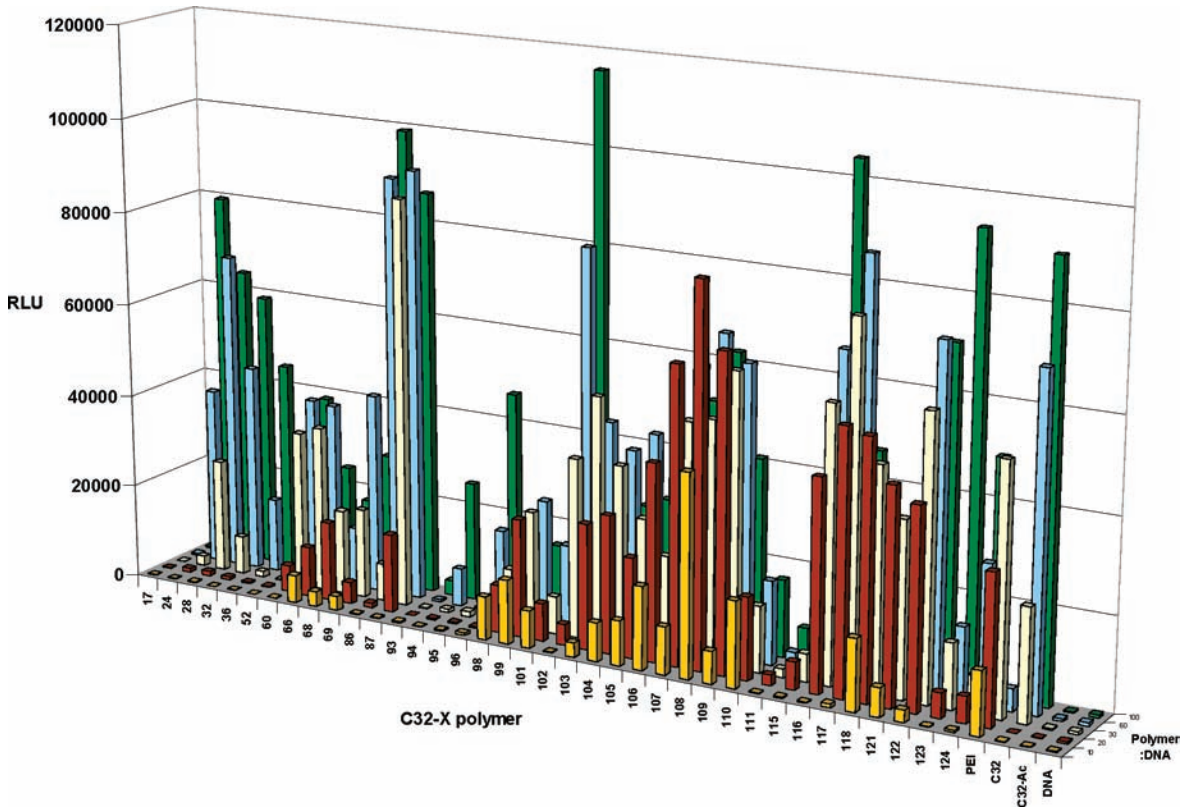

Figure 2. Transfection of COS-7 cells. The relative light units (RLU) from luciferase reporter protein expression are shown for each end-modified C32 polymer (C32-X) at five polymer:DNA weight ratios (10, 20, 30, 60, and 100:1).

relative number of interior to terminal units is approximately preserved, with the end-capping step causing a relatively small change to this balance. Therefore, the diacrylate/amine ratio selected directly controls the final molecular weight. For many poly(β-amino ester)s, molecular weights greater than 10 kDa are usually most effective and can be achieved using a 1.2:1 molar monomer ratio (*15*). For the C32-acrylate polymer (C32-Ac), the weight-average molecular weight is approximately 8800 Da, relative to polystyrene standards, with a 1.9 polydispersity index.

In the second step, acrylate-terminated C32 polymer is reacted with various amine molecules to generate amine-capped polymer chains (Figure 1B). In this way, the chain ends contain amine functionalities different than those present in the interior of the polymer. Most chain-capping reactions are performed using a primary amine molecule, which results in an amine-capped polymer containing secondary amines at the chain end points. Secondary amine molecules are also used but result in tertiary amine groups at the polymer ends. The 37 different amine molecules used for this secondary capping step are shown in Figure 1C. These compounds were selected on the basis of their DMSO solubility, biocompatibility, and ability to assess structure–function relationships. In addition, many of these molecules have proven useful in the synthesis of poly(β-amino ester)s with high transfection efficiencies (*15*).

The end-capping reaction occurs via an amine-acrylate Michael addition, identical to that used in the polymerization. Since acrylates have no detectable reactivity toward hydroxyls, ethers, tertiary amines, amides, aromatics, and some types of heterocycles, all of these functionalities can be incorporated at the chain ends using the appropriate amine reagents (*16*). The reaction is carried out by mixing a concentrated polymer solution with an excess of amine in DMSO at room temperature. The conditions have been optimized with excess amine to fully end-cap all chains without causing any detectable cross-linking or aminolysis of backbone ester bonds, as determined by ^{1}H NMR and GPC analysis (data not shown). Presumably, aminolysis is avoided due to the higher reactivity of acrylates compared to esters and the mild end-capping reaction conditions used. The resulting end-modified polymers can be directly tested for transfection efficiency without prior purification, since the DMSO and excess amine were determined to be nontoxic (data not shown). Therefore, this chemistry permits many polymers with structurally diverse end functionalities to be synthesized and screened in parallel. We show here that such a synthetic method is useful to assess end amine structure–function relationships and improve the gene delivery properties of poly(β-amino ester)s.

For the analysis presented here, we use C32 as a base polymer to examine the effects of the end amine structure on polymer transfection and also explore structure–function relationships. This polymer was identified from previous studies to be the most efficient poly(β-amino ester) for gene delivery (*15*). In principle, other base polymers, diacrylate/amine ratios, and amine-capping agents may be used and could generate more effective polymers for gene delivery.

Cellular Transfections. The DNA delivery efficiency of end-modified poly(β-amino ester)s was evaluated using a high-throughput assay (*20*). Concentrated polymer solutions in DMSO were diluted in sodium acetate buffer and complexed with plasmid DNA to form polymer–DNA nanoparticles. A range of polymer:DNA weight ratios was tested for each polymer, since this parameter is known to have a critical effect on polycation-mediated transfection (*15*). Nanoparticles were then diluted into cell culture media and incubated on COS-7 cells. The diluting media contained 10% serum to account for the effect of serum proteins on polymer transfection.

The transfection efficiencies of amine-terminated C32 polymers are shown in Figure 2. The average luciferase expression levels, measured in relative light units (RLUs), are given for

each polymer at five different polymer:DNA ratios. We have previously shown the transfection data for each end-modified polymer at its optimal ratio and present here the complete data set containing all polymer:DNA ratios (*18*). Also included are the transfection data for 25 kDa branched PEI, one of the most efficient commercially available polycations, and C32, one of the best performing poly(β-amino ester)s synthesized to date. The unmodified, acrylate-terminated C32 polymer is also shown on the far right and demonstrates weak activity that is similar to other acrylate-terminated poly(β-amino ester)s (*14*). While amine-capping reactions of this polymer were verified by ^{1}H NMR analysis, the data in Figure 2 provide functional confirmation by the large increase in transfection between acrylate- and amine-terminated polymers. An overall inspection of the data reveals that the structure of the terminal amine has a dramatic effect on the C32 transfection efficiency. In general, polymers capped with hydrophilic amine end groups containing hydroxyls or additional amines proved most effective. In contrast, chain termination with more hydrophobic amines containing alkyl chains or aromatic rings led to much lower transfection activity.

Perhaps the most important result is that very subtle structural differences in just the terminal amine can have a large effect on polymer transfection efficiency. This is most evident by comparing the C32–36 and C32–52 polymers. The C32–52 polymer, which contains a six-carbon alkyl chain extending from the terminal secondary amine, has a maximum transfection only twice that of naked DNA. In contrast, the C32–36 polymer is 34-fold more effective than C32–52, but only differs in a single hydroxyl group on carbon-6 at the chain end. In fact, the C32–36 polymer is half as effective as C32, demonstrating that a single functional group, in this case a terminal hydroxyl, can significantly alter the polymer delivery properties. A similar effect can be seen between the C32–95 and C32–110 polymers, which consist of terminal decylamines containing either a hydroxyl group or primary amine on carbon-10, respectively. In this case, substituting the terminal hydroxyl for an amine improves the transfection performance by over 1 order of magnitude. This same substitution pattern also changes the optimal polymer:DNA ratio. Comparing two highly efficient polymers, C32–122 and C32–124, the former displays very high RLU output at a 20:1 ratio, whereas the latter requires 5-fold more polymer (i.e., a 100:1 ratio) to achieve the same effect. A similar trend is also seen between the C32–36 and C32–106 polymers. Therefore, amine-capping molecules with hydroxyls and primary amines are most effective, with the latter being optimal at 5-fold lower polymer:DNA ratios in general.

Polymers terminated with primary diamine molecules had the highest transfection efficiency, as determined by both RLU output and lowest optimal polymer:DNA ratio. Specifically, the C32–102 polymer had a very similar transfection profile to that of C32, with a maximum occurring at the highest polymer:DNA ratio of 100:1, but had an overall 30% higher RLU output. This demonstrates that modification at the chain ends can significantly improve the delivery performance. Primary diamine capping also lowered the optimal polymer:DNA ratio substantially in many cases. Seven primary amine-terminated polymers had optimal polymer:DNA ratios of 20:1, while one polymer, C32–110, had a maximum RLU at a 10:1 ratio. The transfection profile at the 20:1 ratio for diamine-capped polymers, C32–102 through C32–111, appears to be a skewed bell-shaped curve with a maximum occurring at the C32–108 polymer. This indicates that larger alkyl chains bridging the diamine functionalities are generally more effective than their short-chain counterparts, with an optimum of eight carbons. The C32–108 polymer had an optimal transfection at a 20:1 ratio that is almost as high as that for C32, which requires a 100:1 ratio. Such a significant reduction in the amount of polymer needed to mediate high levels of transfection has important implications for *in vivo* delivery, where the amount of polymer injected needs to be limited to minimize toxic side effects (*18*).

Cytotoxicity. Many polycations have been shown to elicit considerable cell toxicity that may limit their utility as gene delivery vectors (*10, 11*). The biocompatibility of cationic polymers is determined by a number of factors that include molecular weight, charge density, type of amines, polymer structure (linear, branched, dentritic), and chain flexibility (*21–27*). In general, high molecular weight polymers with a high density of primary and/or secondary amines usually result in substantial cytotoxicity (*28*).

The cytotoxicity of end-modified poly(β-amino ester)s was evaluated using the MTT assay. This colorimetric test is based on the ability of mitochondrial reductase enzymes in viable cells to reduce 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide to a purple formazan. Toxicity of end-modified polymers was assessed by performing the same transfection experiment, but assaying for metabolic activity instead of luciferase expression. All polymers were tested at the highest 100:1 polymer:DNA weight ratio, which corresponds to an approximate 400 ug/mL concentration of polymer on the cells. Toxicity analysis at such a high polymer concentration may explain the differences in polymer transfection at high polymer:DNA ratios and simultaneously assess polymer biocompatibility under very aggressive conditions that may be important for their future use and development.

The cytotoxicity levels of end-modified C32 polymers are shown in Figure 3. The percentage of viable cells is displayed as a function of the amine-terminated polymer. Positive and negative control conditions are shown to the far right for PEI and naked DNA. At such high polymer concentrations, PEI is very cytotoxic, as reflected by the low 3% cell viability. In contrast, both C32 and the acrylate-terminated C32 polymer (C32-Ac) show no significant affects on the growth and metabolism of COS-7 cells.

The majority of end-modified C32 polymers show good biocompatibility. This is especially true of all polymers capped with primary monoamine reagents, regardless of the functional groups extending from the amine. Aromatic, alkyl, hydroxyl, secondary and tertiary amines, and imidazole functionalities at the chain end points do not appear to induce any significant adverse effects. Therefore, elevated cytotoxic effects do not sufficiently explain the low transfection ability of polymers terminated with the more hydrophobic amines. In contrast to the polymers capped with monoamines, polymers terminated with primary diamine molecules compromise cell viability to varying extents. While the increased charge is a determining factor, the overall toxicity is also strongly dependent on the hydrophobicity of the end group. In general, increasing the size of the alkyl chain bridging the amine groups increases the toxicity, as is evident by comparing the C32–102 through C32–109 polymers. Furthermore, C32–121, a polymer containing a terminal poly(ethylene glycol amine) with an eight-atom spacer between amine groups, is much less toxic than the corresponding alkyl derivative, C32–108. This indicates that both the spacing between amines and the degree of hydrophobicity in the terminal amine spacer are important determinants of end-amine toxicity.

These significant cytotoxic effects, in large part, explain the decreasing transfection ability of most primary diamine-capped polymers at the higher polymer:DNA ratios. The additional charge, in conjunction with increased hydrophobicity, may be particularly damaging to the cell membranes, since both properties are known to disrupt lipid bilayers (*26*).

DNA Binding. An important requirement for cationic transfection agents is the ability to bind and condense plasmid DNA

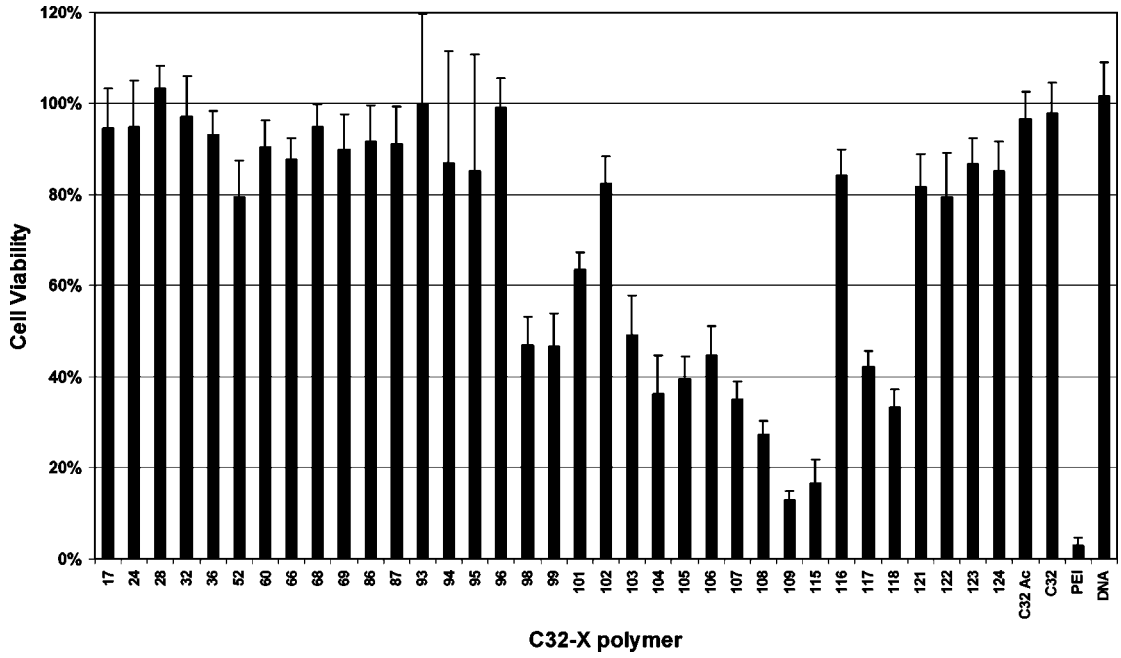

Figure 3. Cytotoxicity levels of end-modified C32 polymers (C32-X) measured using the MTT assay. PEI, C32, C32-Ac, and free DNA toxicity are shown on the far right.

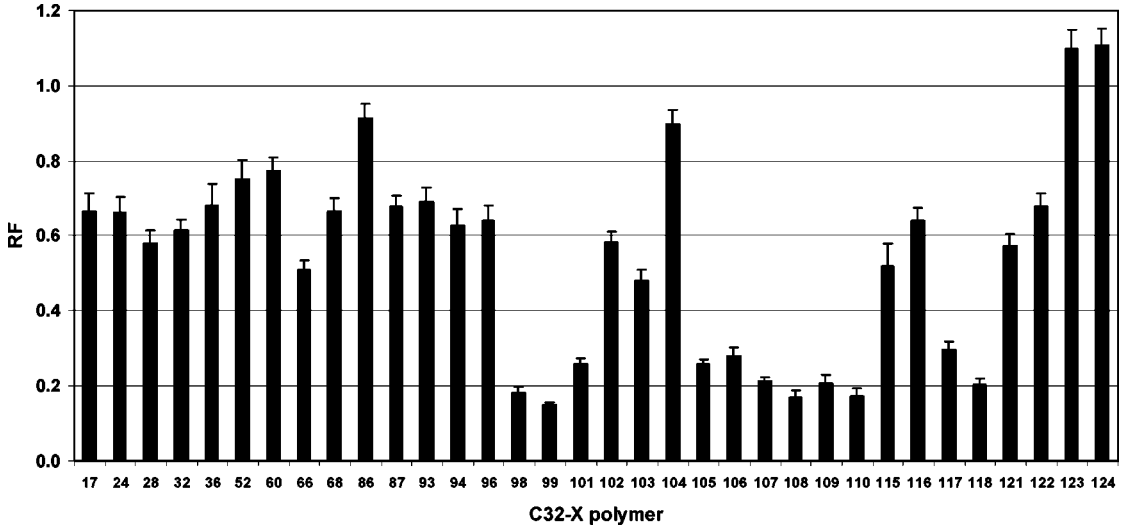

Figure 4. Polymer–DNA binding measured using a PicoGreen assay. Fluorescence reductions relative to free DNA (RF) are shown for each end-modified C32-polymer (C32-X) at the optimal transfecting polymer:DNA ratio for each polymer.

for cell entry (*29*). In general, higher molecular weight polymers with increased cationic charge density display stronger DNA binding at low polymer:DNA ratios (*21, 30, 31*). While strong electrostatic interactions are important to effectively condense and deliver the DNA, the polymer must possess a mechanism to unbind from the DNA once inside the nucleus (*32*). For this reason, the poly(β-amino ester)s may be particularly advantageous, since they undergo hydrolysis with short half-lives (*12*), which may aid in DNA unpackaging.

The binding and condensation of DNA by polycations is often monitored using an agarose gel electrophoresis assay (*33*). This assay can be used to adequately determine the minimum polymer:DNA ratio required for plasmid condensation but does not provide any information on the strength of this interaction. In contrast, dye-binding assays provide a quantitative measure of the polymer–DNA binding event at all polymer:DNA ratios (*34–36*). As a result, we utilized a PicoGreen dye penetration assay to determine the degree of plasmid condensation by the end-modified poly(β-amino ester)s. In this assay, polymer–DNA complexes are formed in a manner similar to their preparation for transfection experiments. The complexes are then mixed with a PicoGreen dye solution, diluted into cell culture media, and the solution fluorescence is measured. The dye exhibits fluorescence only when it intercalates between the DNA base pairs. High fluorescence is typically seen with free plasmid, but significant reductions can occur for polymer–DNA complexes in which the DNA is partially shielded from dye penetration. The magnitude of this fluorescence reduction relative to free DNA correlates to the strength of the polymer–DNA interaction (*14, 37*).

The DNA binding levels for each end-modified polymer are shown in Figure 4. Fluorescence measurements relative to free DNA are given at the optimal transfecting polymer:DNA ratio for each polymer. With the exception of monoamine PEG-terminated polymers, all end-modified materials displayed some level of DNA binding. In general, increased cationic charge at the end groups increased the polymer–DNA binding affinity. This effect is most noticeable by comparing the results of the

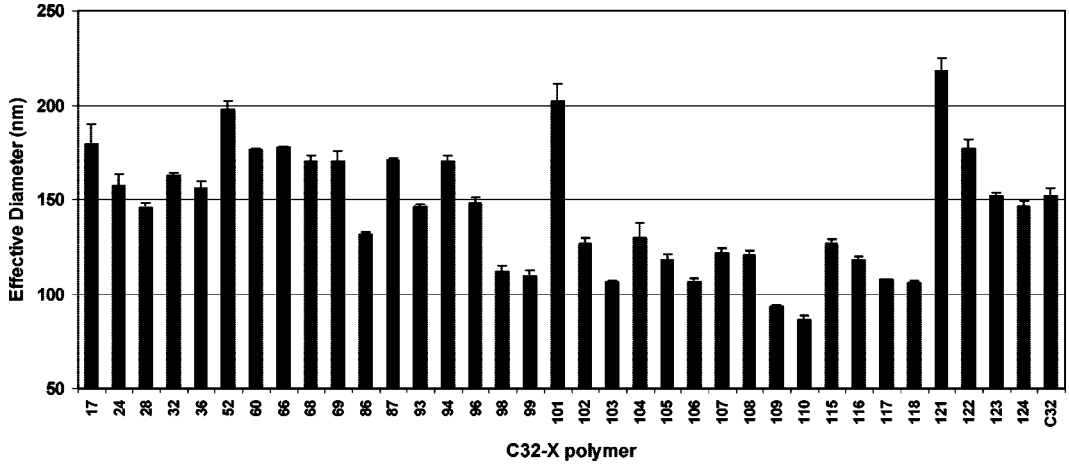

Figure 5. Polymer–DNA complex size measured by dynamic light scattering. The effective diameters of complexes are shown for each end-modified C32 polymer (C32-X) at the optimal transfecting polymer:DNA ratio for each polymer.

PEG amine-capped polymers. The monoamine-capped polymers, C32–123 and C32–124, displayed no measurable binding. However, the substitution of a single primary amine for a hydroxyl at the chain ends (C32–121 and C32–122) leads to increased polymer–DNA binding and less dye penetration. This result indicates that a single functional group only at the very end point of the polymer can bring about large changes in polymer function. Similar conclusions were reached when assessing the overall transfection ability of the polymer but now are seen at just one part of the delivery process.

Perhaps the most noticeable trend in the data is that polymers terminated with primary diamine molecules are most effective at condensing and binding DNA. Additional secondary or tertiary amines at the chain ends were not as effective at increasing the DNA binding ability of the polymer, possibly due to pK_a differences or a more sterically crowded environment that may prevent their electrostatic interaction with DNA (*38, 39*). Similar to the cytotoxicity data, more effect is seen with increased terminal hydrophobicity in addition to the added positive charge. In general, smaller relative fluorescence is seen as the alkyl chain length is increased between terminal amine groups, as is evident by comparing polymers C32–102 through C32–110. These results are supported by lower DNA binding affinity of polymers terminated with the more hydrophilic primary ethylene glycol amine polymers (C32–121 and C32–122).

Polyplex Sizing. Simple electrostatic interactions between the polycation and the negatively charged DNA can often lead to their spontaneous self-assembly into cationic polymer–DNA nanoparticles (*40, 41*). The physical properties of these complexes are particularly important for their subsequent uptake into cells. Complexes with a positive surface charge and a diameter less than 200 nm are usually sufficient for cellular endocytosis (*42*). These properties are dependent upon a number of polymer characteristics and the polymer-DNA mixing technique (*43–47*). Since the terminal amine has demonstrated significant effects on the DNA binding ability of polymers, it should also affect the physical properties of the polymer–DNA complexes.

The effective diameter of complexes formed between end-modified poly(β-amino ester)s and plasmid DNA were measured using dynamic light scattering. Polymer–DNA complexes were formed at the optimal transfecting polymer:DNA ratio for each polycation and then diluted into cell culture media prior to each measurement. Concentrations, solution compositions, and polymer–DNA complexing procedures in each step were identical to those used in the transfection assay. In this way, the nanoparticle physical properties measured in this experiment reflect the actual particle properties in the transfection screen.

Average diameters of the polymer–DNA complexes are presented in Figure 5 for each end-modified C32 polymer. The average diameter varied between 85 to 220 nm, demonstrating the crucial effects of terminal amine structure on the physical properties of polymer–DNA complexes. Also shown on the far right is the average diameter of C32 complexes, which is determined to be 152 nm. In a previous study, C32 complexes were diluted into HEPES buffer and subsequently measured to be 79 nm in diameter (*15*). This difference in particle size illustrates the large effect of serum proteins to disrupt or interact with cationic polymer–DNA complexes. Increases in polymer–DNA complex size in the presence of serum have been seen in our previous studies and with other polycations such as PEI, and have a well-known effect on polymer–DNA properties (*48, 49*). Importantly, the C32 complex diameter is still below the threshold for endocytosis and maintains high transfection levels.

All end-modified polymers formed complexes with effective diameters in a suitable range for cellular uptake. Only two polymers, C32–101 and C32–121, formed complexes with diameters slightly above 200 nm. The former material consists of highly charged chain end groups, whereas the latter contains a short PEG diamine at the chain end points. In general, the PEG-terminated polymers (C32–121 to C32–124) formed larger complexes with diameters between 150 and 220 nm. Despite the large size and weak DNA binding of these polycations, they can still deliver DNA with relatively high efficiencies. This effect is also true of most polymers terminated with monoprimary amine molecules. These polymers, shown on the left side of Figure 5, mostly result in complexes with diameters greater than 150 nm and lower DNA binding ability than primary diamine-capped polymers. Although a general conclusion cannot be made, it is interesting to note that some polymers with very low transfection efficiencies (e.g., C32–117, −52, −101) also form relatively large complexes, suggesting that their physical properties may not be conducive to uptake.

Similar to the DNA binding data, particle sizing appears to be more favorable for polymers capped with primary diamine molecules. For almost all of these polymers, their complexes with DNA have diameters between 85 and 130 nm. The more hydrophilic PEG diamines, C32–121 and C32–122, are the exception, illustrating the importance of a hydrophobic alkyl chain space between amines at the terminus. Although the trend is not as pronounced as that for the DNA binding, it appears that the sizing is somewhat improved by increasing the alkyl chain length. This is especially true at the long chain lengths where C32–109 and C32–110 form the smallest complexes that have diameters less than 100 nm. These polymers assemble into smaller complexes with DNA compared to those terminated with

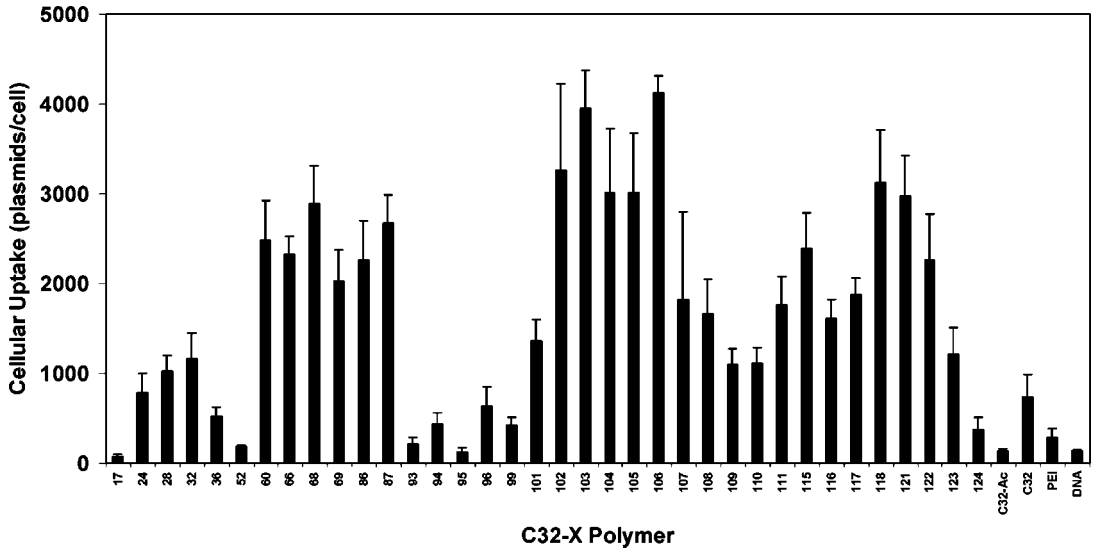

Figure 6. Polymer–DNA uptake into COS-7 cells. DNA uptake levels are shown in the number of plasmids per cell for each end-modified C32 polymer (C32-X).

additional secondary and/or tertiary amines, again illustrating the benefits of primary amines at the chain ends over these other amine functionalities. Consequently, it appears that polymers terminated with alkyl primary diamine molecules have the highest DNA binding affinity and assemble into the smallest polymer–DNA complexes.

DNA Uptake. Differences in the physical properties of polymer–DNA complexes can lead to differences in the rates and levels at which they are endocytosed into cells. Previous studies with poly(β-amino ester)s have shown that smaller complexes with high cationic surface charge are more favorable for cellular uptake (*42*). In addition, amine termination has been shown to promote higher cellular internalization over the corresponding acrylate-terminated polymer (*14*). In light of these findings and the terminal amine affects on polymer–DNA properties, we measured the uptake levels of end-modified C32 polymers. Although previous studies with poly(β-amino ester)s used a novel fluorescence-based technique (*19*), we choose to use a DNA extraction and real-time PCR (RT-PCR) amplification protocol to quantify the amount of endocytosed DNA (*9*). This method provides (1) high sensitivity due to the PCR amplification, (2) linearity over several orders-of-magnitude, (3) the ability to quantify DNA uptake without prelabeling the plasmid, and (4) a high-throughput, 96-well plate format to simultaneously and rapidly analyze all polymers. For this experiment, transfections were performed following the standard protocol using a β-galactosidase (β-gal) plasmid. This DNA was isolated from the cells after a 4 h incubation period, then amplified and quantified using RT-PCR. The total number of β-gal DNA plasmids harvested for each sample was calculated using a standard curve and normalized to the number of COS-7 cells.

The DNA uptake levels for each end-modified polymer are shown in Figure 6. The results are expressed as the number of plasmids endocytosed per cell for each polymer at its optimal transfecting polymer:DNA ratio. Also shown is the low uptake level of free plasmid DNA, which is most likely due to its large size and high anionic charge density that repels the cell surface. Positive control polymers C32 and PEI are also shown to the far right, both of which increase DNA uptake by approximately 5-fold over the free plasmid. In addition to increasing endocytosis, these polycations lead to higher cellular DNA levels by protecting the plasmid from intracellular nucleases. Unlike C32 and PEI, plasmid condensation with the C32-Ac polymer did not improve uptake to any measurable level, which explains the inability of this polymer to mediate transfection. The large difference between C32 and C32-Ac, in terms of both uptake and transfection, highlight the importance of amine termination to improve the C32 polymer delivery properties.

The results in Figure 6 demonstrate that the type of amine at the chain ends has a considerable effect on the endocytosis of C32 polymer–DNA complexes. The uptake levels varied over 2 orders of magnitude among the end-modified polymers, with polymer C32–106 mediating the highest plasmid internalization that is 30-fold greater than free DNA. The most obvious trend in the data is the improved uptake that occurs for polymers with additional terminal amines. This is evident for polymers containing extra secondary and tertiary end amines (C32–60 through C32–87) and mostly for those with an additional primary end amine (C32–102 through C32–122). These results suggest that conjugation of targeting ligands to the chain ends may be a promising strategy to achieve cell-specific delivery.

The differences in uptake between each polymer also explain some important differences in their transfection efficiencies. First, many polymers that are poor transfection agents also displayed very low uptake (e.g., C32–17, −52, −93, −95). This indicates that the extra charge alone at the chain end points (compared to C32-Ac) is not sufficient to promote C32-DNA endocytosis. Specific functional groups at the chain ends, such as hydroxyls and amines, have an enhanced capacity to interact with cell surfaces and increase uptake as compared to more hydrophobic terminal segments. For example, the transfection differences between C32–36 and C32–52 are largely related to their differences in uptake. This comparison demonstrates that a single functional group in the polymer chain, in this case, a terminal hydroxyl, can have a large effect on cell interactions and endocytosis. Extending the comparison further, C32–106 differs from these two materials by a terminal primary amine. The results show that this single substitution at the terminal amine carbon-6 can increase uptake by over 20-fold. This effect is even more surprising considering that the polymer:DNA ratio used for C32–106 is 20:1, 5-fold less than that used for C32–36 and C32–52. In general, the increased uptake by the polymers capped with primary diamines largely explains their increased effectiveness at reduced polymer:DNA ratios. The overall transfection levels may not be substantially improved over C32 and other nonprimary amine polymers because the terminal

functionalities may have important effects on other downstream gene delivery barriers such as endosomal escape, cytosolic trafficking, or nuclear import.

CONCLUSIONS

In this work, we present a fast and simple method to generate end-modified polymer derivatives. Variations in the terminal amine structure are shown to affect many properties that are important for effective polymeric gene delivery. Surprisingly, single carbon and functional group differences only at the chain ends have large effects on the physical properties of polymer–DNA complexes, their cellular uptake, and subsequent transfection. The best results occurred with primary diamine end cappings, which improved transfection of the C32 poly(β-amino ester) and lowered the optimal polymer:DNA ratio by 5-fold. These modifications effectively decreased the polymer–DNA nanocomplex size and increased cellular uptake. This suggests that ligand attachments to the polymer ends may be a promising strategy to achieve cell-specific targeting and improve the *in vivo* biodistribution of polymer–DNA complexes. To our knowledge, the modified poly(β-amino ester)s presented here are some of the most effective and efficient degradable polycations to date, superior to PEI and previously optimized poly(β-amino ester)s. We are currently evaluating the *in vivo* transfection potential of these polymers for the systemic treatment of cancer.

Determination of the Optimized Conditions for Coupling Oligonucleotides with 16-Mercaptohexadecanoic Acid Chemically Adsorbed upon Au

Yi-Te Wu,[†] Jiunn-Der Liao,*[,†,‡] Je-Inn Lin,[†] and Cheng-Chan Lu[§]

Department of Materials Science and Engineering, Center for Micro/Nano Science and Technology, and Department of Pathology, National Cheng Kung University, No. 1, University Road, Tainan 70101, Taiwan. Received June 18, 2007; Revised Manuscript Received September 17, 2007

A specific 5′-modified amino group oligonucleotide (Primer 1), 15-mers in length, is selectively coupled with the carboxyl terminated 16-mercaptohexadecanoic acid (MHDA) chemically adsorbed on Au and subsequently hybridized with Antisense Primer. The amide-coupling process is of significance to create an intermediate structure for the purpose of adding Primer 1, while the hybridization reaction is relevant to various diagnostic purposes to determine the presence in nucleic acids for a target sequence. In this work, the coupling setting was particularly emphasized by varying commonly used temperatures and pH values with a definite concentration of coupling agents (i.e., 10 mM). The recombination with analogous hybridization treatment was investigated using high resolution X-ray photoelectron spectroscopy and a 75° grazing angle Fourier transform infrared spectrometer. On the basis of the spectroscopic studies, the optimized conditions for the coupling process that is also correlated with the molecular density of subsequent hybridization process on MHDA/Au have been proposed at 37 °C and a pH value of 4.5. Therefore, it is pertinent to intensify the joining of short-chain DNA strands by complementary base pairing in diagnostic applications such as the identification of single nucleotide polymorphisms.

1. INTRODUCTION

Single nucleotide polymorphisms (SNPs) are common DNA sequence variations that cause phenotypic differences among individuals. Most SNPs do not lead to physical changes in humans; however, a small part of them may predispose individuals to disease and even influence their complex response to medical treatments or drug regimens (*1–3*). A considerable effort to decode the human genome or to further the understanding of human genetics has been promoted to identify SNPs, for example, SNPs related to drug-metabolizing enzymes (*4*), secretion disorder (*5*), allele-specific extensions (*6*). In particular, only a small percentage of a person's DNA sequence code is necessary for the production of proteins or those involved in transcription regulation (*7*). SNPs found within a coding sequence are therefore of special interest when they are highly associated with the structural and functional properties of proteins. Recent advances in biotechnology have significantly enhanced the process of disease or protein detection (*4–10*) and the practice of preventative and curative medicine. In particular, association study (*11, 12*) can detect and indicate which pattern is most likely associated with the disease-causing genes or complex human disorders. In a recent verification process (*13*), SNP finding is automatically achieved using a combined approach between sequence-specific pattern matching of flanking sequence and a quality assessment of inconsistencies on the average once every kilo-base pair in the human genome.

The use of specific oligonucleotides as therapeutic agents or biomarkers (*14*), for example, lies upon their ability to interfere with the molecular machinery of protein synthesis either by binding to the mRNAs transcribed from a gene or by binding directly to a target gene. In recent years, oligonucleotide hybridization has become relevant to various diagnostic purposes to determine the presence in nucleic acids for a target sequence that is complementary to the oligonucleotide probe (*15–17*). Hybridization on a solid support involves the immobilization of one of the interacting nucleic acids on the surface, while the other is free in solution. For the former, high-density DNA microarrays with the immobilization of aptamers (short, known single-stranded DNA or RNA sequences) are a well-established method capable of measuring gene expression levels (*8, 16*). The chip-based optical detection of the molecular interactions occurring on the immobilized and labeled DNA sequence or functional protein as a probe has been promptly developed (*18–20*). This process combined with a recent technique on microelectronics and rich SNP profiles meets the demands for rapid screening with reduced sample amounts. For the latter, the use of colloidal Au as a color label as bridged between the attached DNA and the oligonucleotides with sequences complementary to either ends of the target DNA is successfully delivered for the detection of DNA hybridization in solution (*21*). However, specific DNA probes attached on magnetic particles are also used for the detection of viable bacteria (*22*).

A perceptive detection of specific molecular binding that is based on optical visualization of the labeled molecules on a microstructured chip surface is still improving. One of the major problems relies on the stability of molecular interactions in varying conditions such as the variation of ionic strengths (*23, 24*), pH values (*23*), and temperatures (*25*). In this study, self-assembled monolayers (SAMs) chemically adsorbed on Au substrates have been introduced for the construction of molecular additions. SAMs are well-ordered and densely packed two-dimensional ensembles of long-chain molecules, which have attracted tremendous attention because of the potential applications in various fields, such as DNA chips, microelectronics, sensors, and nanopatterned SAMs (*26–28*). The SAMs treatment is also one of the proposed methods for extending lithography down to the nanometer scale by applying electron-beam patterning for a new kind of lithography resist (*29, 30*). Much

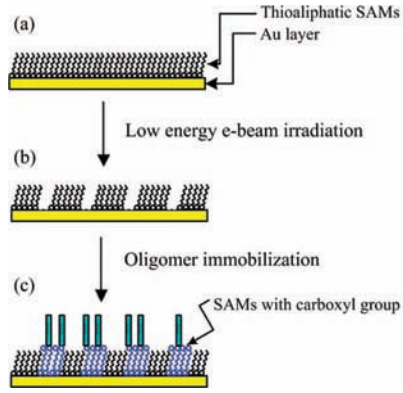

Figure 1. For a practical SAM application, a tailored surface containing $-CH_3$ and carboxyl tail groups can be patterned for the subsequent addition of short-chained oligonucleotides.

attention is devoted to aliphatic SAMs and, above all, to films of *n*-alkanethiol on noble metal substrates. In this study, alkanethiolate monolyers with the carboxyl tail group are chemically adsorbed on Au. A synthesized oligonucleotide with 5′-modified $-NH_2$ or 3′-modified $-OH$ ends on the respective sequences, in association with an allelic polymorphism within the human tumor necrosis factor alpha (TNF-α) promoter region (*31–34*), is subsequently immobilized on SAMs/Au. Optimized conditions for DNA hybridization based on the combination of temperatures, pH values, and the concentration of coupling agents are particularly investigated. As compared with previous measurements using 2D electrospray ionization tandem mass spectroscopy (*35*), this study utilizes surface-sensitive measurements for the identification of chemical bindings in the respective reactions and possibly for subsequent SNPs diagnostic applications.

2. EXPERIMENTAL PROCEDURES

2.1. Preparation of SAMs/Au with Carboxyl Tail Groups. The substrates for thiol-derived SAM fabrication were prepared by thermal evaporation of ≈50 nm of Au onto the polished single crystal silicon (100) wafers (Silicon Sense) primed with a ≈5 nm titanium adhesion layer. The octadecanethiol (ODT, HS-$(CH_2)_{17}$-CH_3) SAMs were formed by standard immersion procedure (*36*), resulting in the homogeneous ODT SAMs on Au (Figure 1a). For the practical applications, a particular part of the ODT SAMs can be easily removed by low-energy electron beam irradiation (Figure 1b), followed by immersion into an ethanolic 1 mM solution of 16-mercaptohexadecanoic acid (MHDA, HS-$(CH_2)_{15}$-COOH, Aldrich) for 1–2 h. A tailored surface with mixed $-CH_3$ and carboxyl tail groups is produced for subsequent treatments (Figure 1c). To investigate the succeeding reactions on the surfaces, a uniform MHDA/Au representing the MHDA-modified part was employed, followed by coupling and hybridizing with the respective oligonucleotides.

2.2. Preparation of the Oligonucleotides. Four types of the oligonucleotides, 15-mers in length, were employed for the experiments.

A digested probe, 5′-GGGCATGGGGACGGG (MDBio Inc., type-1) as an aptamer, with a concentration of 5 μM was synthesized by means of polymerase-mediated single-base primer extension. It was first verified by Dot Hybridization method using Digoxigenin (DIG)-labeled Sequence Specific Oligonucleotide Probe (SSOP, 5′-CCCGTCCCCATGCCC, type-2) with a concentration of 100 μM, followed by dilutions to different concentrations.

The modified amino group at the 5′-end, H_2N-$(CH_2)_6$-5′-GGGCATGGGGACGGG-3′ (MDBio Inc., type-3) as Primer 1, was expected to be amide-bonded on MHDA/Au by adding the coupling agents, 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC, Sigma) and *N*-hydroxysuccinimide (NHS, Sigma), in PBS or MES buffer solution with various concentrations (1, 10, or 100 mM) and various pH values (4.5, 5.5, 6.5, or 7.4). The Primer 1/MHDA/Au was annealed at 42 °C and thereafter hybridized with the 5′-CCCGTCCCCATGCCC-3′ (MDBio Inc., type-4) as Antisense Probe. The concentration of Primer 1 or Antisense Probe was ≈5 μM, which was first dissolved in deionized water and preserved at −20 °C.

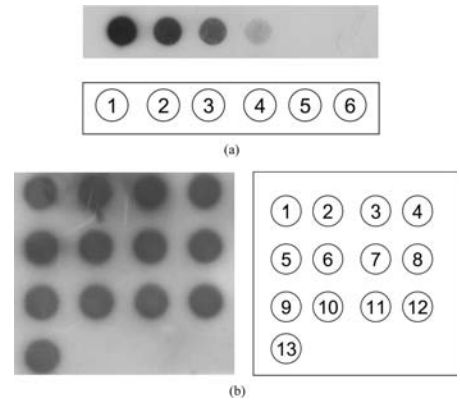

Figure 2. (a) Oligonucleotides were verified by 100 μM SSOP diluted to five different concentrations (i.e., 100, 10, 1.0, 0.1, 0.01, and 0.001 μM, for marks 1–6). (b) Oligonucleotides were assessed in different pH values and reaction times. The pH values of marks 1–4 were 4.5, 5.5, 6.5, and 7.4, respectively (buffered for 6 h). Those of marks 5–8 were analogous in pH values but buffered for 4 h. Those of marks 9–12 were also analogous in pH values but buffered for 2 h. Mark 13 was a control for reference.

2.3. Surface Characterization. Water contact angles were measured immediately after preparing MHDA/Au substrates. The measurements were performed under an argon atmosphere at 22 ± 1 °C. The sessile drop method was used, and a JVC-TK1200 microscope with processing software took the droplet image. A droplet of ≈5 μL was used. For each sample, 10 measurements with a standard deviation below 1° were carried out, and an average value was calculated. Water contact angles of the pristine Au and a uniform MHDA/Au were ≈83.4° and ≈23.2°, respectively. The decrease of contact angle is expected in the presence of the hydrophilic group.

Fourier-transform infrared (FTIR, Bomem DA8.3) with 75° grazing incident angle reflectance (Harrick) was utilized for identifying chemical species in the specific range of 1000–2000 cm^{-1} with 0.5 cm^{-1} resolution and precision of a wavenumber no less than 0.01 cm^{-1}. In this range, positions of the band frequencies were assigned to major IR-active groups in the as-prepared oligonucleotides (*37*).

Synchrotron-based high-resolution X-ray photoelectron spectroscopy (HRXPS) was utilized to characterize the chemical structures of MHDA on Au, amide bonds with Primer 1, and subsequent hybridization with Antisense Probe. HRXPS measurements were carried out at the U5 Undulatory Beam Line of the National Synchrotron Radiation Research Center in Hsinchu, Taiwan. The time for the acquisition of the entire set of the HRXPS spectra for an individual sample was selected as a compromise between spectral quality and the damage induced by X-rays. Details about HRXPS measurements can be found elsewhere (*36*, *38*).

To determine the elemental compositions at the respective surface, the C 1s, S 2p, O 1s, N 1s, and P 2p core level spectra were measured and calculated from HRXPS peak area with correction algorithms and atomic sensitivity factors. The spectra were fitted using Voigt peak profiles and a Shirley background (*38*). The stability of Au–S bonds subsequent to the treatments

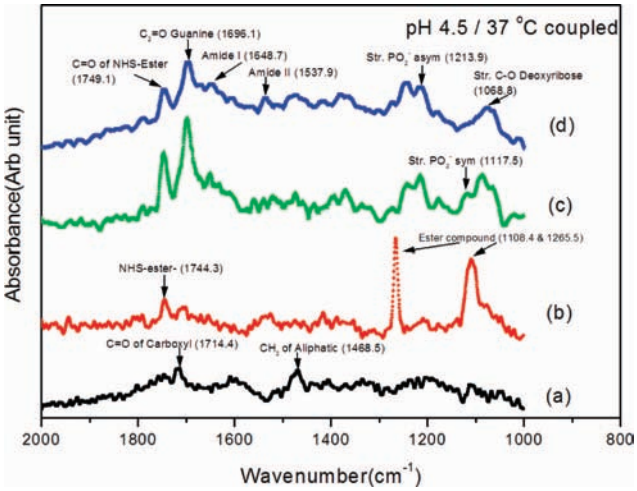

Figure 3. IR absorption spectra of Primer 1/MHDA/Au prepared in different concentrations of EDC and NHS at a pH value of 4.5 at 37 °C. The as-measured surfaces were (a) MHDA/Au and (a) with the concentrations of EDC and NHS at (b) 1 mM, (c) 10 mM, and (d) 100 mM.

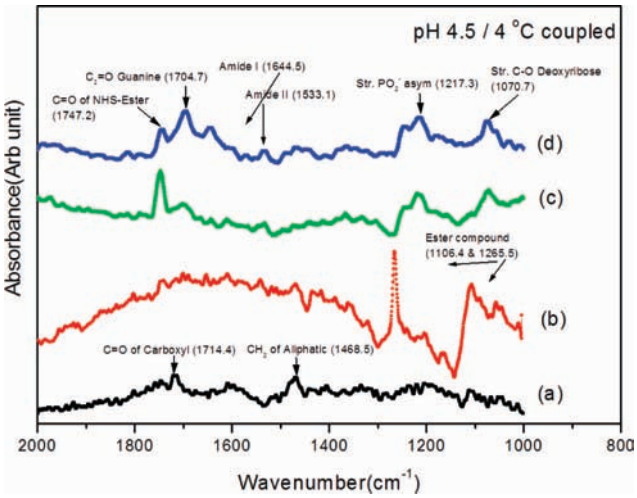

Figure 4. IR absorption spectra of Primer 1/MHDA/Au prepared in different concentrations of EDC and NHS at a pH value of 4.5 at 4 °C. The as-measured surfaces were (a) MHDA/Au and (a) with the concentrations of EDC and NHS at (b) 1 mM, (c) 10 mM, and (d) 100 mM.

was correlated with the S 2p doublet with a binding energy (BE) of ≈162.0 eV. The decrease of the intermediate amide bonds due to the addition of the oligonucleotides was calculated by comparing the intensity of the amide group with that of -N*= from the oligonucleotides (*39*).

3. RESULTS AND DISCUSSION

3.1. Preliminary Tests on the Oligonucleotides Using SSOP Method. The oligonucleotides, Primer 1 and Antisense Probe, with a concentration of 5 μM were first verified by 100 μM SSOP diluted to five different concentrations (Figure 2a). The indications revealed a good relationship with the diluted concentrations. The SSOP diluted to 0.1 μM was still distinguishable (mark 4 in Figure 2a). In Figure 2b, the quality of the oligonucleotides was assessed in different buffer solutions, that is, with MES at pH 4.5, 5.5, and 6.5 or PBS at pH 7.4, with a reaction time of 2, 4, or 6 h. The variations of the buffer solution and the reaction time did not cause structural damage or hydrolysis in the oligonucleotides.

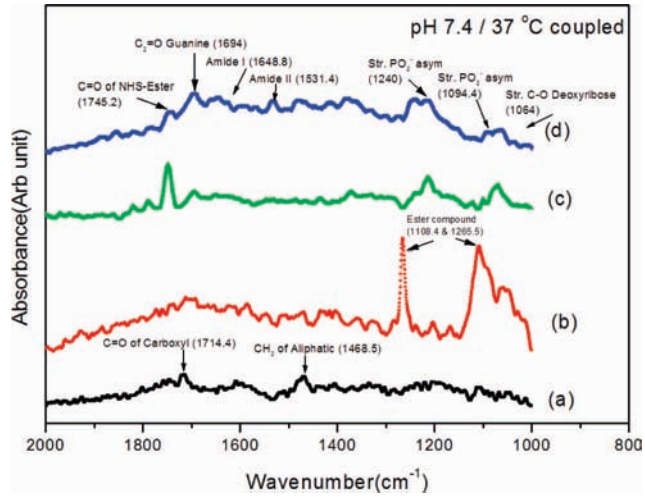

Figure 5. IR absorption spectra of Primer 1/MHDA/Au prepared in different concentrations of EDC and NHS at a pH value of 7.4 at 37 °C. The as-measured surfaces were (a) MHDA/Au and (a) with the concentrations of EDC and NHS at (b) 1 mM, (c) 10 mM, and (d) 100 mM.

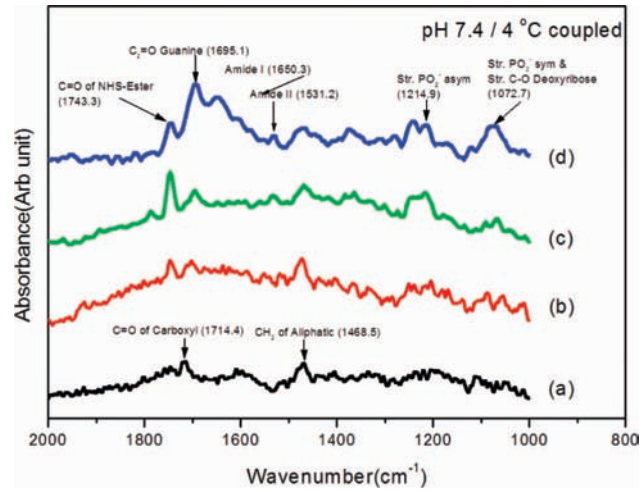

Figure 6. IR absorption spectra of Primer 1/MHDA/Au prepared in different concentrations of EDC and NHS at a pH value of 4.5 at 4 °C. The as-measured surfaces were (a) MHDA/Au and (a) with the concentrations of EDC and NHS at (b) 1 mM, (c) 10 mM, and (d) 100 mM.

3.2. Chemical Structures Examined by FTIR with 75° Grazing Incident Angle Reflectance. An analogous FTIR curve of the pristine surface was taken as the reference and is shown in the bottom curves of Figures 3–6. The characteristic IR peaks for MHDA/Au at 1714.4 cm^{-1} (i.e., C=O in the carboxyl acid) and 1468.5 cm^{-1} (i.e., CH_2 in aliphatic chains) were identified.

The carboxyl tail group of MHDA was anticipated to create an amide bond with the NH_2-modified Primer 1 using EDC and NHS as the coupling agents (*35*, *40*). In the case of the acidic environment at pH 4.5 and 37 °C (Figure 3), the addition of 1 mM EDC and NHS buffered in MES solution (Figure 3b) mainly created ester compounds (1265.5 cm^{-1} and 1108.4 cm^{-1}). The NHS-ester (1744.3 cm^{-1}) was formed transitionally, whereas the coupling of the NH_2-modified Primer 1 was not found. As the buffered concentration of EDC and NHS was increased to 10 mM (Figure 3c), IR absorptions of C-O in deoxyribose of nucleoside (1068.8 cm^{-1}), phosphodiester bond (1117.5 and 1213.9 cm^{-1}), C=O in NHS-ester (1749.1 cm^{-1}), and C=O in Guanine of Purine (1696.1 cm^{-1}), in association with Primer 1, were detected (*40*). Nevertheless, IR absorptions in the range of 1500–1650 cm^{-1}, correlating with the presence

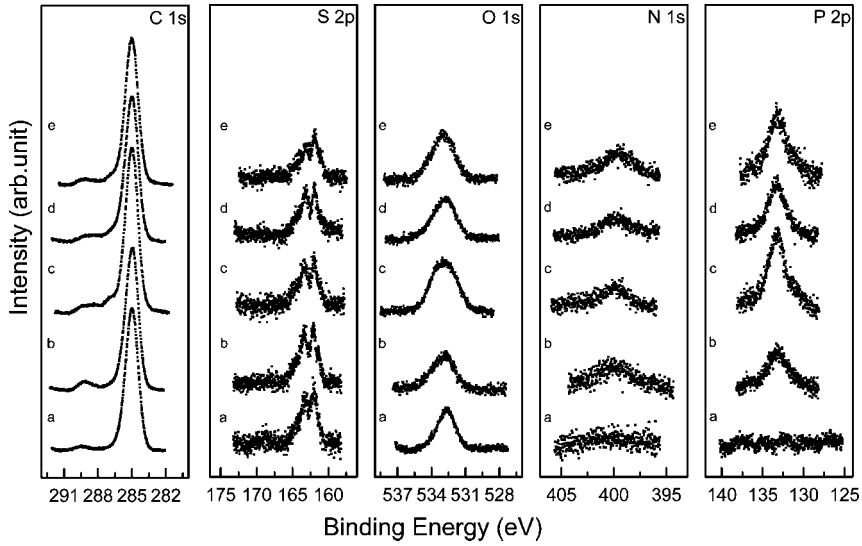

Figure 7. HRXPS spectra of Primer 1/MHDA/Au prepared in 10 mM EDC and NHS at 37 °C. The as-measured surfaces were (a) MHDA/Au, (b) Primer 1 coupled with MHDA/Au at pH 4.5, (c) Primer 1 from (b)/MHDA/Au hybridized with Antisense Probe, (d) Primer 1 coupled with MHDA/Au at pH 7.4, and (e) Primer 1 (from d)/ MHDA/Au hybridized with Antisense Probe. The changes of the intensities of the elements are illustrated in Figure 10.

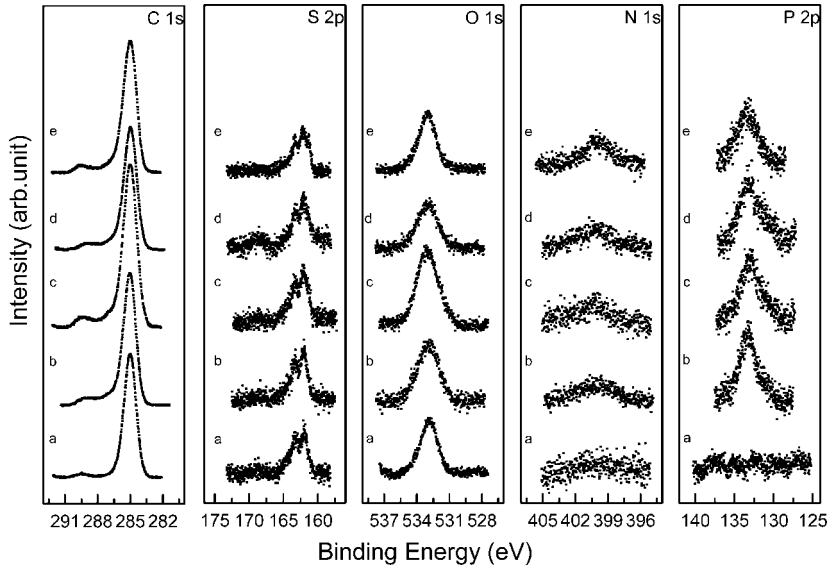

Figure 8. HRXPS spectra of Primer 1/MHDA/Au prepared in 10 mM EDC and NHS at 4 °C. The as-measured surfaces were (a) MHDA/Au, (b) Primer 1 coupled with MHDA/Au at pH 4.5, (c) Primer 1 from (b)/MHDA/Au hybridized with Antisense Probe, (d) Primer 1 coupled with MHDA/Au at pH 7.4, and (e) Primer 1 (from d)/MHDA/Au hybridized with Antisense Probe. The changes of the intensities of the elements are illustrated in Figure 11.

of amide bonds, were considerably weak. It is likely that the sensitivity of the measurement is insufficient to interpret a minor quantity of the intermediate amide bonds. Furthermore, with the addition of 100 mM EDC and NHS in the buffered solution (Figure 3d), the characteristic amide group at 1648.7 (amide I) and 1537.9 cm^{-1} (amide II) and most of the analogous species associated with Primer 1 were simultaneously found.

Analogous results were obtained in the case of the acidic environment at pH 4.5 and 4 °C (Figure 4) and the alkaline environment at 37 °C (Figure 5) and 4 °C (Figure 6). By comparison, the NH_2-modified Primer 1 was well coupled with MHDA/Au in the case of 100 mM EDC and NHS buffered in MES solution at pH 4.5 and 37 °C, while IR intensity of the characteristic amide group and most of the analogous species associated with Primer 1 were clearly found.

From the above measurements, as the coupling agents were buffered to a concentration of 10 mM, the covalently bonded Primer 1 could be identified, whereas the IR intensity correlated with the amide group, the intermediate structure, was relatively insignificant.

3.3. Chemical Bonds Examined by HRXPS. For the pristine MHDA/Au, the characteristic structures of MHDA were determined by HRXPS and presented in the bottom curves of Figures 7 and 8. After carrying out the decompositions of the C 1s, O 1s, and N 1s spectra illustrated in Figure 9, the C 1s spectrum exhibited a major emission peak at a BE of ≈284.8 eV (i.e., C*-C or C*-H) with a fwhms of ≈0.9 eV and chemical shifts at BEs of 285.9 eV (C*-O) and ≈289.2 eV (i.e., O=C*-OH). The S 2p spectrum exhibited a single S 2p doublet with a BE of ≈162.0 eV for the S $2p_{3/2}$ component. This doublet is commonly related to the thiolate species bonded to Au surface (*36, 38, 41, 42*). The O 1s spectrum exhibited the emission peaks at BEs of 532.1 eV (C-O) and 533.4 eV (C=O), resulting from the presence of MHDA. No traces of nitrogen or phosphorus were found.

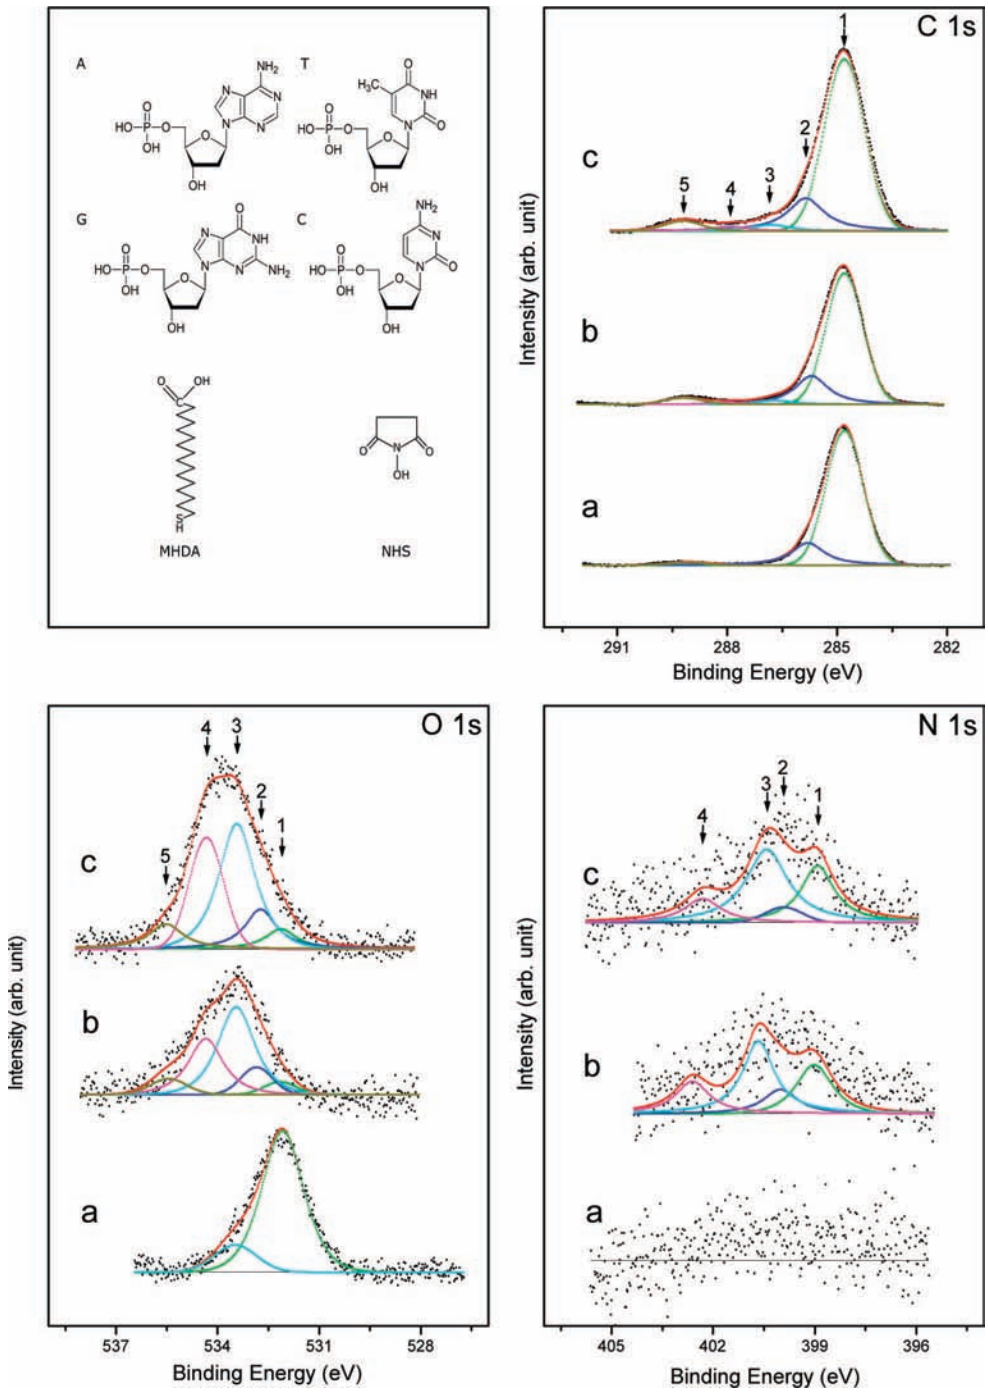

Figure 9. Curve-fitted HRXPS spectra for Primer 1/MHDA/Au prepared in 10 mM of EDC and NHS at 37 °C. The as-measured surfaces were (a) MHDA/Au, (b) Primer 1 coupled with MHDA/Au at pH 4.5, and (c) Primer 1 from (b)/MHDA/Au hybridized with Antisense Probe at 42 °C. The decomposition of the respective C 1s, O 1s, and N 1s spectra is described in section 3.4.

Interfacing of surface characterization with analytical data is not well-developed. Particularly, chemical species of covalent attachment presenting in the multiple linkages are difficult to be defined by configurations. In this section, the respective samples with the coupling agents of 10 mM are purposely studied using HRXPS to gain information of the aptamers upon MHDA/Au under different pH values and coupling or annealing temperatures.

The HRXPS spectra for Primer 1/MHDA/Au, prepared at different pH values or temperatures, are shown in Figures 7b and d and 8b and d, which exhibit analogous BEs. Followed by hybridization with Antisense Probe, their C and O intensities and BEs exhibited variable data (shown in Figures 7c and 7e and 8c and e). Among them, the HRXPS spectra for Primer 1/MHDA/Au prepared in 10 mM EDC and NHS at 37 °C were curve-fitted and studied. In Figure 9, the decompositions of the C 1s spectra were assigned: (1) 284.8 eV, C*-C, (2) 285.9 eV, C*-O, (3) 286.7 eV, amide group or NHS-ester, (4) 287.9 eV, from the oligonucleotide G or C, and (5) 289.1 eV, O=C*-OH or from the oligonucleotide C. The decompositions of the O 1s spectra were assigned: (1) 532.1 eV, C-O*-C from the oligonucleotide G or C, (2) 532.8 eV, amide group or $(N)_2C=O^*$ from the oligonucleotide G, (3) 533.4 eV, C=O* from the oligonucleotide, (4) 534.4 eV, O*=C-OH or C-O-P from the oligonucleotide and (5) 535.6 eV, NHS-ester. The decompositions of the N 1s spectra were assigned: (1) 399.0 eV, -N*= from the oligonucleotide G or C, (2) 400.0 eV, O=C-N*-H from the amide group, (3) 400.5 eV, -N*-, -N*H-, $-N^*H_2$ from the

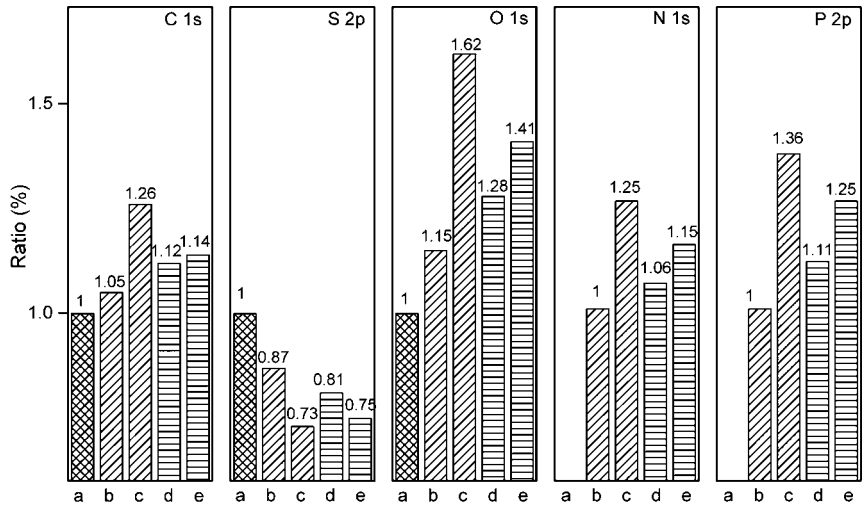

Figure 10. Variations of the content of the elements on Primer 1/MHDA/Au prepared in 10 mM EDC and NHS at 37 °C. The as-measured surfaces were (a) MHDA/Au, (b) Primer 1 coupled with MHDA/Au at pH 4.5, (c) Primer 1 from (b)/MHDA/Au hybridized with Antisense Probe, (d) Primer 1 coupled with MHDA/Au at pH 7.4, and (e) Primer 1 (from d)/ MHDA/Au hybridized with Antisense Probe.

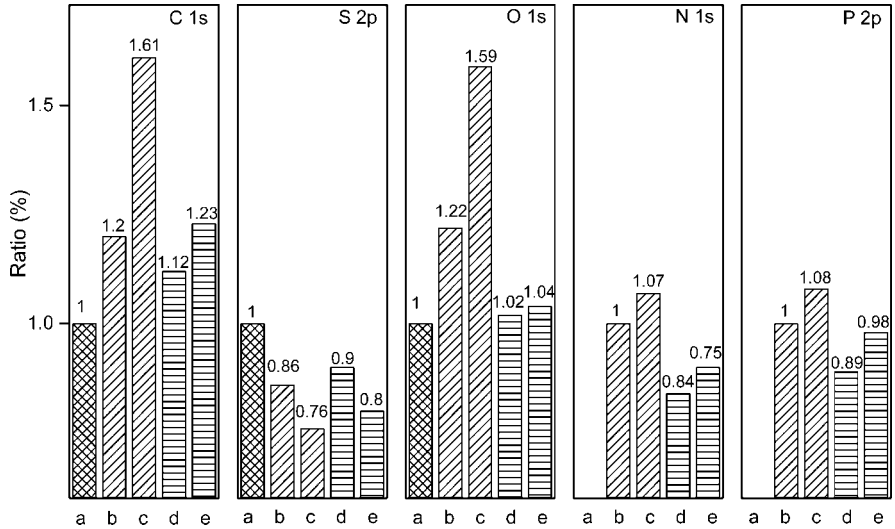

Figure 11. Variations of the content of the elements on Primer 1/MHDA/Au prepared in 10 mM of EDC and NHS at 4 °C. The as-measured surfaces were (a) MHDA/Au, (b) Primer 1 coupled with MHDA/Au at pH 4.5, (c) Primer 1 from (b)/MHDA/Au hybridized with Antisense Probe, (d) Primer 1 coupled with MHDA/Au at pH 7.4, and (e) Primer 1 (from d)/ MHDA/Au hybridized with Antisense Probe.

oligonucleotide G or C, and (4) 402.5 eV, -N*-O from NHS-ester. For the P 2p spectra shown in Figures 7 and 8, the emission peak at a BE of 133.2 eV was associated with the presence of oligonucleotides.

In Figure 9, the ratio of peak 1 over peak 3 at *b* of N1s spectra was close to 2/3, which is identical to the presence of Primer 1 (i.e., mainly from oligonucleotide G), while that at *c* of N 1s spectra was close to 3/5 (*39*), which is approximately the product of Primer 1 in hybridization with Antisense Probe. On the basis of these qualitative measurements, the hybridization between Primer 1 and Antisense Probe noticeably occurred as a result of the particular treatments.

3.4. Semiquantitative Measurements for S–Au and Amide-Coupled Bonds. The addition of Antisense Probe in hybridization with Primer 1 also resulted in decreasing the HRXPS intensity of the amide group, which was associated with the assignments of peak 3 of C 1s, peak 2 of O 1s, and peak 2 of N 1s (Figure 9). In the case of *b* of Primer 1 coupled on MHDA/Au at pH 4.5 and *c* of surface *b* in hybridization with Antisense Probe, the relative intensities of peak 2 over peak 1 in *b* and in *c* were calculated as ≈0.57 for *b* and ≈0.22 for *c*. The spectroscopic result estimated that the intermediate amide bonds significantly decreased from an intensity ratio of ≈0.57 to that of ≈0.22 (or −61.4%) due to the hybridization with Antisense Probe that increased the packing density of the oligonucleotide molecules on Primer 1/ MHDA/Au.

The average thickness of MHDA uultrathin film on Au is ≈19.4 Å, in comparison with ≈18.9 Å for the CH_3 terminated thiols with analogous chain length on Au, whereas a relatively disordered carboxyl terminated SAM on Au is anticipated (*43*). In our previous calculations, the intermolecular spacing of the headgroup S–S for MHDA/Au is presumably larger than that for CH_3 terminated thiols on Au (≈4.97 Å) (*44*) due to the functions and/or the interactions of hydrogen bonds between the tail groups (*43*). As a result, the headgroup (i.e., S adsorbed on Au) of MHDA/Au is not as closely packed as that of CH_3-terminated thiols on Au. As illustrated in Figures 7 and 8, the S–Au bonds kept nearly intact during the coupling and subsequent hybridization processes. It implied that the MHDA uultrathin film on Au was suitable as a molecular support. For a stable coupling process, the bond angle for O=C*−O (≈120°) and that for O=C*−N (≈109°) is changed, which will alter the molecular arrangement as well as the packing density of the oligonucleotide on MHDA/Au. With these calculations, the

photoelectron intensity of the intermediate amide bonds continuously decreases because of the completion of hybridization naturally increases the packing density of the oligonucleotides on MHDA/Au.

The element's ratios calculated from Figures 7 and 8 with respect to the pristine MHDA/Au surface are shown in Figures 10 and 11, respectively. Note that an equal concentration (i.e., 10 mM) of the coupling agent was used. The intensity ratios of the C 1s, O 1s, N 1s, and P 2p spectra increased with the addition of Primer 1 and subsequent to the hybridization of Antisense Probe. Those of the S 2p spectra decreased with the addition of the oligonucleotides because of the increase of molecular density on MHDA/Au. No significant traces of other sulfur-derived species (*45, 46*) were found during the processes. The coupling process in the acid environment (i.e., pH 4.5) either at 37 or 4 °C steadily decreased the S 2p intensities, that is, *c* or *e* with respect to *b* or *d* of S 2p spectra in Figures 10 and 11. In combination with the calculation of molecular density on MHDA/Au, an optimized coupling condition was first suggested at pH 7.4 and 37 °C. However, the increased packing density of the oligonucleotides on MHDA/Au resulted in increasing the elements' ratios of *c* or *e* with respect to *b* or *d* in C 1s, O 1s, N 1s, and P 2p spectra. In combination with the elements' ratio of the oligonucleotide G, C, A, or T, an optimized coupling condition was suggested at pH 4.5 and 37 °C.

Comparing the case of the coupling temperature at 37 °C with that at 4 °C, the former exhibited proficiency in increasing the quantity of the oligonucleotides on MHDA/Au, particularly on the basis of the increased intensity ratios of N 1s and P 2p spectra and the decreased intensity ratios of S 2p spectra. However, comparing the pH value for amide coupling at 4.5 with that at 7.4, the former exhibited values in correlation with the elements' ratio of the oligonucleotide. From these measurements, the optimized coupling conditions in this study were presumably placed at pH 4.5 and 37 °C.

CONCLUSIONS

The use of tailored SAMs chemically adsorbed upon Au is increasingly important for recent techniques in microelectronics. In combination with specific short-chain oligonucleotides along with rich SNP profiles on the microelectronic device, the invention meets the demands for rapid screening with reduced sample amounts. The coupling of the carboxyl tailed MHDA ($\approx$2 nm) with a 5′-modified amino group oligonucleotide 15-mers in length forms an ultra-thin layer. Such a coupled oligonucleotide is relevant to determine the presence of nucleic acids and to act as a diagnostic probe for a target sequence. A perceptive detection for the specific molecular binding on a microstructured chip surface has been highly improved. Therefore, this study particularly emphasizes the stability of molecular interactions under treatment conditions such as pH values and temperatures for the coupling or annealing process. On the basis of the high-resolution spectroscopic studies and the definite concentration of coupling agents (i.e., 10 mM), the optimized conditions for the coupling process have been proposed at pH 4.5 and 37 °C. At the same time, the S–Au bonds and the intermediate amide-coupled structure are considerably resistant to subsequent treatments. Thus, this work provides a method to intensify the joining of short-chain DNA strands with the tailored SAMs/Au prior to completing a hybridization process. It is also promising in creating nanopatterned SAMs/Au for advanced DNA chips, in particular for the detection of SNPs.

ACKNOWLEDGMENT

This work has been supported by the National Science Council of R.O.C under grant No. 95–2621-Z-006–002. The authors would like to thank the Center for Micro/Nano Science and Technology and the Sustainable Environment Research Center, National Cheng Kung University, and National Synchrotron Radiation Research Center, Hsinchu, Taiwan for access to equipment, technical support, and partial financial support.

Antisense targeting of tumor with fluorescent conjugated DNA oligomers has the potential of improving tumor/normal tissue ratios over that achievable by nuclear antisense imaging. When administered as a linear duplex of two fluorophore-conjugated oligomers arranged in a manner that inhibits fluorescence as the duplex and designed to dissociate only in the presence of the target mRNA, the fluorescence signal should in principle be inhibited everywhere except in the target cell. Optical imaging by fluorescence quenching using linear fluorophore-conjugated oligomers has not been extensively investigated and may not have been previously considered for antisense targeting. We evaluated in cell culture and in KB-G2 tumor bearing nude mice a 25-mer phosphorothioate (PS) anti-*mdr1* antisense DNA conjugated with the Cy5.5 emitter on its 3′ equivalent end and hybridized as a linear duplex with a shorter 18-mer phosphodiester (PO) complementary DNA (cDNA) with the Black Hole inhibitor BHQ3 on its 5′ end. In serum environments, 90% of the DNA25-Cy5.5 fluorescence was inhibited immediately following addition of the cDNA18-BHQ3 and showed only slight loss of inhibition over 24 h at 37 °C. As evidence of antisense specific binding, when incubated with the DNA25-Cy5.5/cDNA18-BHQ3 duplex, the fluorescence was lower in KB-31 (Pgp +/−) cells compared to KB-G2 (Pgp++) cells, but when incubated with the control cDNA18-Cy5.5/DNA25-BHQ3 duplex in which the fluorophores were reversed, the fluorescence of both cell types was low. As further evidence of specific binding, the fluorescent intensity of total RNA from KB-G2 cells incubated with the study duplex showed evidence of dissociation and hybridization with the target mRNA. Furthermore, the fluorescence microscopy images of KB-G2 cells incubated with DNA25-Cy5.5 as the singlet or study duplex show that migration in both cases is to the nucleus. The animal studies were performed in mice bearing KB-G2 tumor in one thigh and receiving iv the study or control duplexes. The tumor/normal thigh fluorescence ratio was clearly positive as early as 30 min postinjection in the study mice and reached a maximum at 5 h. By contrast, much lower fluorescence was observed in mice receiving the control duplex at the same dosage. Fluorescence microscope imaging showed that the Cy5.5 fluorescence was much higher in tumor sections from the animal that had received the study rather than control duplex. Thus combining a fluorophore-conjugated antisense DNA with an inhibitor-conjugated shorter complementary cDNA inhibited fluorescence both in cell culture and in tumored animals except in the presence of the target mRNA. This proof of concept investigation of optical antisense targeting therefore suggests that further studies including optimization of this approach are appropriate.

INTRODUCTION

Our laboratories now have extensive experience in antisense targeting of a variety of mRNAs with radiolabeled DNAs and other oligomers (*1, 2*). However, our experience and that of other laboratories suggest that achieving adequate tumor/normal radioactivity ratios are often problematic (*3–5*). In the course of our investigations, it became apparent that the hybridization properties of oligomers may have applications in optical imaging as an alternative to nuclear imaging. While nuclear imaging offers many advantages over other imaging modalities including high sensitivity of detection, quantitation accuracy, and the availability of numerous contrast agents (*6*), one disadvantage is the physics of nuclear decay that does not permit manipulation of the γ ray emissions. A property of optical imaging unique among most molecular imaging modalities is the potential to modulate the detectable signal in the target. When two fluorophores are brought into proximity, it is possible to shift the emission fluorescence to a lower energy or higher frequency by fluorescence resonance energy transfer (FRET) or to quench the fluorescence entirely (*7*). Molecular beacons consisting of DNAs in the form of hairpins with fluorophores on each end are already in use in this manner for in vitro assays and for vivo studies as well (*8–12*).

Thus, optical antisense targeting of tumor with fluorescent conjugated DNA oligomers may have the potential of improving tumor/normal tissue ratios. When administered as a linear duplex designed to inhibit fluorescence and to dissociate only in the presence of the target mRNA, the fluorescence signal in principle should be inhibited everywhere except in the target cell. Optical imaging by fluorescence quenching using linear fluorophore-conjugated oligomers has not been extensively investigated and may not have been previously considered for antisense targeting. In this proof of concept study, the target was again the *mdr1* mRNA. We have demonstrated that *mdr1* antisense DNA accumulates in the KB-G2 Pgp++ cells and to a lesser extent in the KB-31 Pgp+/− cells by an antisense mechanism (*13, 14*).

For optical antisense targeting, the properties of the duplex are exacting; the duplex must be sufficiently stable to remain intact in circulation and in normal tissues but yet sufficiently unstable to dissociate in the presence of the target mRNA. Fortunately, we have been able to confirm another essential property of the duplex, namely, that it crosses cell membranes without entrapment (*15*). In this investigation we evaluate a

strategy of delivering a 25-mer phosphorothioate (PS) *mdr1* antisense DNA25 conjugated as a linear duplex with the Cy5.5 emitter on its 3′ equivalent end and complexed with a complementary shorter 18-mer phosphodiester (PO) *mdr1* sense DNA18 with the BHQ3 inhibitor on its 5′ end. The DNA25 emitter and cDNA18 inhibitor are so arranged that fluorescence is effectively inhibited with the DNAs in their duplex form. Once in the vicinity of its mRNA target, a new and stable antisense DNA25-Cy5.5/target mRNA duplex forms spontaneously with the release of the shorter DNA along with its inhibitor. This proof of concept study was conducted in cell culture and in KB-G2 tumor bearing mice.

MATERIALS AND METHODS

The duplex consisted of an *mdr1* uniform PS antisense DNA25 (5′- AAG-ATC-CAT-CCC-GAC-CTC-GCG-CTC-C) and a uniform PO complementary sense cDNA18 (5′-GGA-GCG-CGA-GGT-CGG-GAT). The antisense DNA sequence was elongated from the antisense 20-mer DNA used in these laboratories previously (underlined) (*13*). All DNAs were purchased HPLC purified. The antisense DNAs were obtained with Cy5.5 (Sigma-Proligo, Woodlands, TX) or Black Hole Quencher 3 (BHQ3, Biosearch Technologies, Novato, CA) on the 3′ end (designated herein as DNA25-Cy5.5 and DNA25-BHQ3), and the complementary sense cDNAs were obtained with Cy5.5 or BHQ3 on the 5′ end (designated herein as cDNA18-Cy5.5 and cDNA18-BHQ3). Regardless of whether the DNA was native (i.e., without fluorophore) or whether the attached fluorophore was the Cy5.5 or BHQ3 and regardless of whether the DNA was used as the singlet or duplex, the antisense DNA was always the 25-mer and the sense complementary DNA was always the 18 mer. The KB-G2 (Pgp++) and KB-31 (Pgp+/−) human epidermoid carcinoma cell lines were a gift from Isamu Sugawara (Research Institute of Tuberculosis, Tokyo, Japan) and were cultured in Dulbecco's modified Eagle's medium (DMEM) (Gibco BRL Products, Gaithersburg, MD) containing 10% fetal bovine serum (FBS) for 18–24 h at 37 °C, 5% CO_2. Cells were cultured until about 60–70% confluence was reached. The cells were incubated with DNAs in serum-free DMEM in the cell studies of this investigation.

Duplex Preparation and Stability. Both the study DNA25-Cy5.5/cDNA18-BHQ3 duplex and the control cDNA18-Cy5.5/DNA25-BHQ3 duplexes were prepared by mixing the antisense DNA25 and complementary cDNA18 at a 1:1 molar ratio in 150 mM phosphate buffered saline (PBS). The duplex mixtures were vortexed for 10 s, heated in a boiling water bath for 10 min to dissociate any intrastrand duplexes and allowed to cool to room temperature (25 °C).

To measure stability, the duplexes were added in triplicate at 100 μL per well to a 96-well plate to a final concentration of 0.1 nM in 10% FBS/DMEM and 70% normal mouse serum (Jackson ImmunoResearch Laboratories, Inc., West Grove, PA) and incubated at 37 °C for different times up to 24 h. The control was the singlet free DNA25-Cy5.5 added at the identical molar concentration in the identical manner. The fluorescence intensity (excitation 681 nm/emission 700 nm) was read at each time point on a SpectraMax M5/M5^e Microplate fluorescence plate reader (Molecular Devices Corporation, Sunnyvale, CA).

Cell Studies. Rhodamine 123 (Sigma, St. Louis, MO) was used to confirm that the difference in multidrug resistance (i.e., Pgp expression) between the KB-G2 and KB-31 cells was preserved. Both cells were treated with the study duplex to a final concentration of 0.3 μM, and after 3 h, the cells were trypsinized and suspended in 1% FBS/DMEM. The cells were washed twice and resuspended in the same medium at 37 °C before adding rhodamine 123 at 1 μg/ml. After 1 h at 37 °C, the cells were washed twice and resuspended in ice-cold PBS buffer with 1% BSA. Viable cells were analyzed for rhodamine fluorescence on a Becton Dickinson flow cytometer (BD Biosciences, Franklin Lakes, NJ) using CellQuest software (BD Biosciences).

Two duplex accumulation studies were performed in KB-G2 and KB-31 cells in triplicate in 96-well plates seeded at 5000 cells per well and incubated with 10% FBS/DMEM culture medium overnight. In one study, the DNA25-Cy5.5/cDNA18-BHQ3 duplex and singlet DNA25-Cy5.5 were incubated with KB-G2 cells in serum-free DMEM at dosages of 0.02, 0.1, and 0.3 nmol for 3 h at 37 °C. In the other study, the DNA25-Cy5.5/cDNA18-BHQ3 duplex and the control cDNA18-Cy5.5/DNA25-BHQ3 duplex were incubated with both KB-G2 and KB-31 cells in serum-free DMEM at the same dosage of 0.1 nmol for 3 h at 37 °C. The cells were then washed twice with 10% FBS/DMEM and incubated for 1 h in 10% FBS/DMEM before being washed twice with PBS. The lysis buffer (10 mM Tris-HCl, pH 8.0, 150 mM NaCl, 1% Triton X-100) was then added at 100 μL per well, and the cells were incubated for 1 h at 37 °C. The fluorescence intensity of each lysis solution was measured on the fluorescence plate reader. The data were normalized to the total protein content of each well as determined by the Bradford protein assay (Pierce, Rockford, IL).

To measure total RNA binding, KB-G2 cells were seeded in triplicate in six-well plates at 10 000 cells per well and incubated with 10% FBS/DMEM culture medium overnight. Duplex DNA was added into each well with serum-free DMEM at dosages of 0.9 nmol/well, and the cells were incubated for 3 h at 37 °C. Total RNA was extracted using the RNeasy Mini extraction kit (Qiagen, Valencia, CA). Each sample was then added to the 96-well plate, and fluorescence intensity was measured as above.

The intracellular distribution of fluorescence was measured in KB-G2 cells seeded onto glass bottom culture dishes and incubated in 10% FBS/DMEM overnight. The study duplex DNA was added into each well in serum-free DMEM at a final concentration of 0.3 μM for 3 h at 37 °C. The cells were then washed twice with 10% FBS/DMEM and incubated for 1 h in 10% FBS/DMEM before being washed twice with PBS. For living cell imaging, the cells were directly observed on a Nikon Eclipse TE 2000-S microscope (Nikon Instruments Inc., Melville NY) equipped with a Cy5.5 filter and CCD camera and the images processed using IPLab software (BD Biosciences). For nucleus colocalization analysis, the cells were further incubated with 1 μM Sytox Green (Molecular Probes, Eugene, OR) in 95% ethanol for 15 min to fix and stain the nuclei before being washed twice with PBS and examined under the microscope equipped with a filter (excitation 480 nm/emission 535 nm). In the microscopic images, Cy5.5 and Sytox Green were pseudo-colored red and green, respectively.

Animal Studies. All animal studies were performed with the approval of the UMMS Institutional Animal Care and Use Committee. Male nude mice (NIH Swiss, Taconic Farms, Germantown, NY, 30–40 g) at 7 weeks of age were each injected subcutaneously in the right thigh with a 0.1 mL suspension containing 10^6 KB-G2 cells with greater than 95% viability. Mice were used for imaging studies 14 days later when the tumors reached 0.4–0.6 cm in diameter and were placed on a chlorophyll-free diet (AIN-93G Purified Diet, Harlan Teklad, Madison, WI) for 5 days prior to imaging.

Mice bearing KB-G2 tumor were administered 3 nmol of the control duplex, while additional animals received the study duplex at 1, 3, or 5 nmol in 100 μL of PBS per mouse via a tail vein. Mice were then anesthetized ip with ketamine (8 mg/kg) and xylazine (2 mg/kg). In vivo fluorescence imaging was performed on an IVIS 100 small-animal imaging system

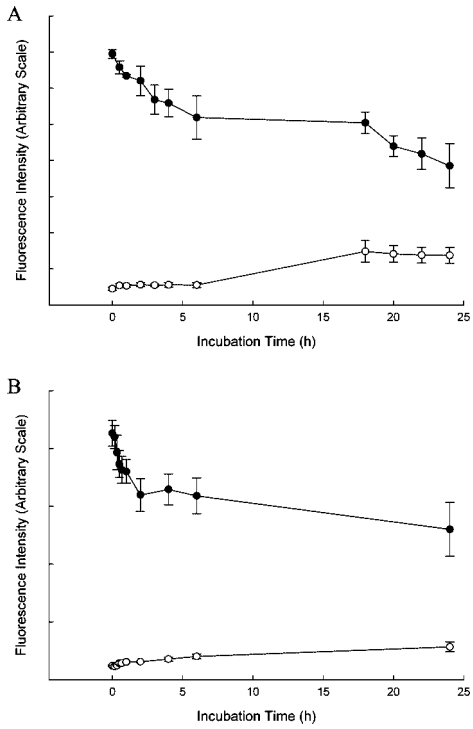

Figure 1. Relative fluorescence intensities of the control singlet PS DNA25-Cy5.5 (closed circles) and the study PS DNA25-Cy5.5/PO cDNA18-BHQ3 duplex (open circles) at 37 °C 10% FBS/DMEM (A) and 70% normal mouse serum (B) over 24 h. Error bars represent 1 sd of the mean ($N = 3$).

(Xenogen, Alameda, CA) using a Cy5.5 filter set. Identical illumination settings (lamp voltage, filters, *f*/stop, field of view, binning) were used for all images, and fluorescence emission was normalized to photons per second per centimeter squared per steradian (p s^{-1} cm^{-2} sr^{-1}). Fluorescence images were acquired at 0.5, 3, 5, and 24 h after injection using 1 s exposure time (*f*/stop 4). Images and measurements of fluorescence signals were acquired and analyzed with Living Image 2.5 software (Xenogen). Regions of interest (ROI) of equal size were centered about the target sites and nontarget sites (i.e., control tumor, contralateral control thigh).

The tumors from mice administered either 3 nmol of the study duplex or the same dosage of control duplex were removed at 24 h, dissected, and treated for fluorescence microscopy imaging. The tumors were placed in tissue holders that were then filled with Tissue-Tek Optimal Cutting Temperature Compound (Sakura Finetek USA, Torrance, CA) and immediately frozen in dry ice. The distribution of the fluoresence within tumor slices of 10 μm thickness was examined, and images were obtained in the GFP channel to locate the cells and in the Cy5.5 channel to show targeting cells. The two images were merged.

Statistical Analysis. Data are presented as the mean ± sd of at least $N = 3$, and statistical analysis was performed using Student's *t* test. A *p* value of less than 0.05 was considered statistically significant.

RESULTS

Duplex Stability. The stability of the DNA25-Cy5.5/cDNA18-BHQ3 duplex was evaluated at 37 °C in 10% FBS/DMEM (Figure 1A) and 70% normal mouse serum (Figure 1B) at 0.1 nM over 24 h and compared to the singlet DNA25-Cy5.5. The fluorescence intensities presented in Figure 1 demonstrate that the duplex is sufficiently stable at least over 24 h in these media. Compared to the fluorescence of the singlet, over 90% of the duplex fluorescence was quenched initially and largely remained

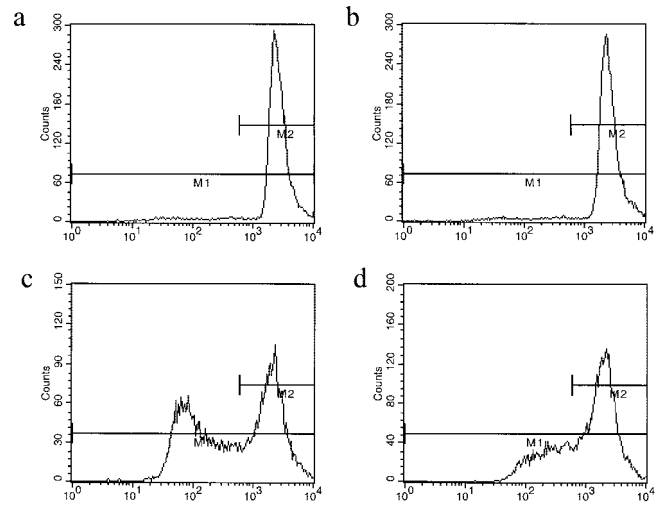

Figure 2. Flow cytometry of KB-31 cells before (a) and after (b) incubation with the study duplex and of KB-G2 cells before (c) and after (d) incubation with the study duplex.

so for about 6 h. Thereafter, the intensity increased but only slowly. The fluorescence intensities of the singlet decreased over this period presumably because of fluorescence decay (*16*).

Cell Studies. *Rhodamine 123 Accumulation.* One major form of multidrug resistance to cancer therapeutic agents is mediated by overexpression of P glycoprotein (Pgp), a membrane protein ATPase that serves as a drug efflux pump (*17, 18*). Rhodamine 123 is a substrate for the Pgp efflux pump and is often used as a surrogate for drug accumulations (*18*). The accumulation of rhodamine 123 by KB-G2 (Pgp++) and KB-31 (Pgp+/−) cells were measured by flow cytometry after incubation with the study duplex at 0.3 μM. Fluorescence intensity was detected in the FL1-H channel. To obtain a histogram from the FACS analysis, the gate M1 was placed to count all cells while gate M2 was placed to count only those cells with high rhodamine 123 fluorescence. Acquisition was set to 20 000 events, and results depict the viable/intact cell population as routinely gated in the forward and side scatter plot. As shown in Figure 2 before incubation with the study duplex, 93% of KB-31 cells showed high accumulations of rhodamine 123 fluorescence (Figure 2a) compared to only 53% of KB-G2 cells (Figure 2c), no doubt because rhodamine 123 was less effectively excreted from KB-31 cells because of a low Pgp expression level in these cells. Thus, these results show that the KB-31 cells used in this investigation were low-level expressors of Pgp compared to KB-G2. As also shown, incubation of KB-G2 cells with the duplex led to a dramatic 35% increase in rhodamine 123 accumulation and therefore a strong inhibition of Pgp expression (Figure 2d compared to Figure 2c). By contrast, incubating KB-31 cells with the duplex had no effect (Figure 2b compared to Figure 2a). Thus, these results also indicate that the duplex is capable of inhibiting Pgp expression by what is almost certainly an antisense effect.

Cellular Accumulation. The KB-G2 cells were incubated with DNA25-Cy5.5 as the singlet and as the study DNA25-Cy5.5/cDNA18-BHQ3 duplex at 0.02, 0.1, or 0.3 nmol for 3 h, and the fluorescence was measured. The histograms of Figure 3A show that the fluorescence intensity of the cells is in all cases significantly higher when incubated with the DNA25-Cy5.5 as the singlet compared to the duplex. The lower fluorescence of cells incubated with the duplex at the same molarity is therefore evidence that the DNA25-Cy5.5/cDNA18-BHQ3 duplex is still largely intact at 3 h, especially given that duplex DNAs appear to accumulate in cells more efficiently than singlet DNAs (*15*).

Both the KB-G2 and KB-31 cells were incubated with both the study DNA25-Cy5.5/cDNA18-BHQ3 and the control

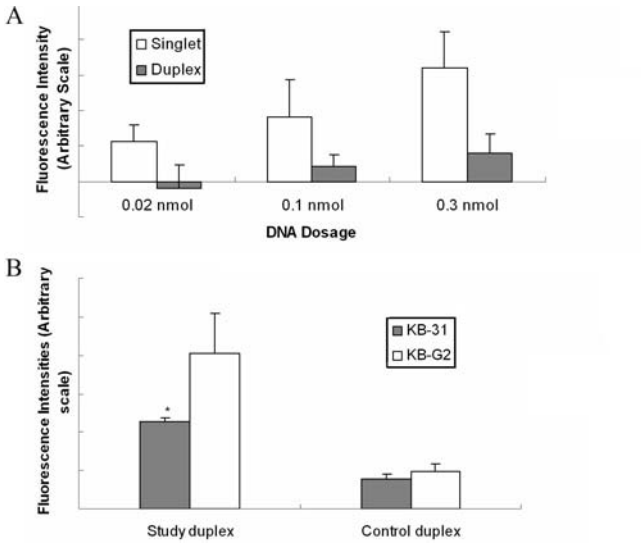

Figure 3. Relative cellular fluorescence intensity at 3 h in KB-G2 cells after incubation with the DNA25-Cy5.5 singlet or the study DNA25-Cy5.5/cDNA18-BHQ3 duplex at three dosages (A) and the relative cellular fluorescence intensity at 3 h in KB-31 and KB-G2 cells after incubation with 0.1 nmol of the study or control duplex (B). Error bars represent 1 sd of the mean ($N = 3$). The higher fluorescence of KB-G2 cells when incubated with the study duplex and the identical fluorescence when incubated with the control duplex are both evidence of antisense binding.

cDNA18-Cy5.5/DNA25-BHQ3 duplex. As shown in Figure 3B, when incubated with the study duplex, the fluorescence was statistically lower ($p = 0.042$) in the KB-31 cells compared to the KB-G2 cells, as expected since the number of mRNA targets in KB-31 cells is limited. However, as also shown in the figure, the fluorescence intensities of the two cell types were statistically identical ($p = 0.211$) when incubated with the control duplex, also as expected since in this case the Cy5.5 fluorophore has been placed on the sense DNA and therefore without affinity for the target mRNA. Both these results provide evidence of antisense binding.

RNA Binding. The KB-G2 cells were incubated with the DNA25-Cy5.5 as the singlet or study duplex at the same molar concentration for 3 h. Total RNA was then extracted and the fluorescence measured. The relative fluorescence intensities in total RNA for cells exposed to the duplex DNA was 189 ± 61 ($N = 3$) and therefore lower than in cells exposed to the singlet DNA at 544 ± 289 ($N = 3$). Under the reasonable assumption that the fluorescence of total RNA is due to specific binding of the DNA25-Cy5.5 to the target mRNA, the higher fluorescence intensity of total RNA incubated with the singlet DNA25-Cy5.5 is not surprising because the duplex requires dissociation before binding. That the RNA binding of the duplex was still about 35% of that of the singlet is therefore promising. The fluorescence intensities of the mRNA themselves were too low to provide a meaningful result.

Intracellular Distribution. The fluorescence images of live and fixed KB-G2 cells are shown in Figure 4 after incubation with the DNA25-Cy5.5 as the singlet or duplex. Live cells (Figure 4A) show similar fluorescence when incubated with the duplex compared to singlet, and in both cases accumulations appear in the nucleus. That the intracellular distributions in fixed cells (Figure 4B) are identical for cells previously incubated with the singlet or duplex and that the accumulations are primarily in the nucleus are obvious by comparison of the Cy5.5 images with that of the nucleus staining Sytox Green. These results suggest that both forms of DNA25-Cy5.5 have the same cellular target and that the target is the nucleus.

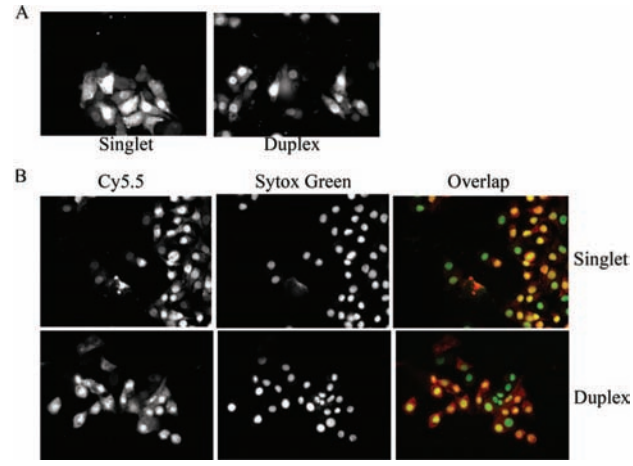

Figure 4. Fluorescence images in live KB-G2 cells incubated with the DNA25-Cy5.5 as the singlet (left) and duplex (right) (A) and the fluorescence images of fixed KB-G2 cells previously incubated with the DNA25-Cy5.5 as the singlet (top row) or duplex (bottom row) (B). The cells were incubated with the DNAs at 0.3 μM for 3 h at 37 °C. Nuclei were labeled with Sytox Green. Fluorescence signal from Cy5.5 was pseudocolored red. Magnification is $\times 400$.

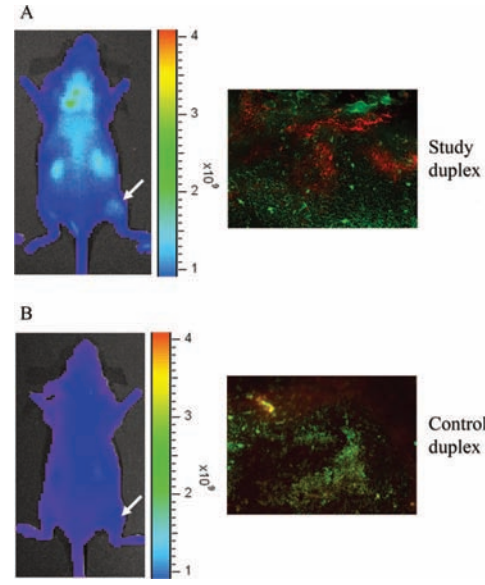

Figure 5. Whole-body fluorescence images of KB-G2 tumor bearing mice in the dorsal view at 5 h following administration of 3 nmol of the study DNA25-Cy5.5/cDNA18-BHQ3 duplex (A) or control cDNA18-Cy5.5/DNA25-BHQ3 duplex (B). The arrow indicates the tumor location. Also presented are microscopic analysis of tissue sections of tumor obtained at 24 h after injection of both study and control duplexes. Magnification is $\times 100$.

Animal Studies. Figure 5 presents whole-body fluorescence images at 5 h in the dorsal view of mice with KB-G2 tumors and images of the sectioned excised tumors in animals receiving the study duplex (Figure 5A) or the control duplex (Figure 5B) at 3 nmol. The whole-body image of the animal receiving the control duplex shows little or no Cy5.5 fluorescence. By contrast, images obtained simultaneously of the animal receiving the study duplex show pronounced whole-body fluorescence and an obvious accumulation in the tumored thigh. The fluorescence in the tumored thigh of mice increased with increasing dosage of study duplex (data not presented); however, the background fluorescence also increased in proportion possibly because of instability of the study duplex toward dissociation in background tissues.

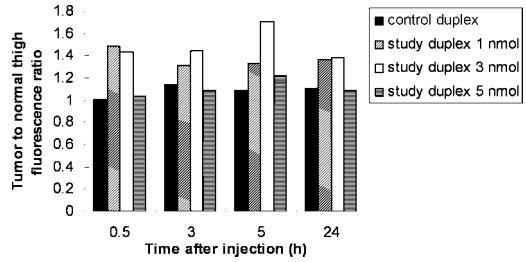

Figure 6. Tumor-to-normal thigh fluorescent ratios at 0.5, 3, 5, and 24 h postadministration in one animal receiving the control duplex and in one study animal receiving 1, 3, or 5 nmol of study duplex. The figure shows higher fluorescence in the tumored thigh in the study animals compared to the control animal.

Further evidence for the preferential targeting of tumor by the study duplex is shown in the ex vivo images of tumor tissue slices from both the study and control animals. In this figure, the green color is due to autofluorescence originating in tumor and muscle tissues and is much weaker than the red Cy5.5 fluorescence due to duplex dissociation. Accordingly, the yellow color that would be expected to show overlap is obscured by the intense red color. Nevertheless, the figure clearly shows the higher Cy5.5 fluorescence in the study tumor compared to the control tumor, in agreement with the animal images.

Regions of interest of equal area were placed over each animal's tumor and contralateral thigh and the fluorescent intensities ratios calculated for all four measurements over the 24 h imaging period. As shown in the histograms of Figure 6, a positive tumor/normal thigh ratio was achieved as early as 30 min postinjection. At all time points, the tumor/normal ratio was never less than about 1.2–1.6 times higher in the animal receiving the study duplex compared to the animal receiving the control duplex.

DISCUSSION

Optical imaging has emerged as an attractive modality capable of investigating biological/molecular events in both cell culture and small living subjects. The modality is noninvasive, highly sensitive, and affordable. Furthermore, the use of fluorescent contrast agents, unlike radiolabeled contrast agents, provides the potential of modulating the detectable signal in the target (*4, 19, 20*). A disadvantage to optical imaging is the much greater influence of tissue absorption and scatter on a fluorescent signal compared to a nuclear signal. Nevertheless, the use of fluorophores emitting in the near-infrared (700–900 nm) range minimizes tissue absorption and also minimizes autofluorescence from nontarget tissues (*21*). Many studies have now demonstrated that optical imaging is practical in small animals (*4, 19, 22*).

These laboratories are investigating antisense DNAs and other oligomers and lately are investigating the use of double-stranded duplexes to improve cellular delivery (*15*). We and others have compared single-stranded and double-stranded DNAs or siRNAs and have shown that double-stranded oligomers (*15, 23, 24*) are stable both in cell culture and in animal (*25*) and appear to show greater accumulates in cells compared to singlet oligomers (*15*). However, a duplex under consideration for antisense targeting must be sufficiently stable to remain intact in circulation and throughout its passage across the cell membrane but not so stable as to interfere with its dissociation and the subsequent binding of the labeled antisense DNA to its mRNA target.

While use of a radiolabeled duplex has now been shown to improve delivery of radiolabeled antisense oligomers, the free duplex in surrounding tissues provide an unwanted background radioactivity level. However, if a fluorescent label were used in place of the radioactivity label and if the complementary oligomer were to contain an inhibiting fluorophore, in principle free duplex would not fluoresce, resulting in an improved target/nontarget ratio. This approach is similar to that already in practice in connection with stem–loop hairpin oligomers (*8, 26*). However, to our knowledge, this report describes the first attempt to use linear duplexes for fluorescent quenching in connection with antisense targeting.

These laboratories and others have observed that the stability of the PS DNA/PO DNA heteroduplex was higher than the stability of an equivalent PS DNA/PS DNA homoduplex (*15, 27, 28*) and that duplexes consisting of two 25-mer phosphorodiamidate morpholino (MORF) oligomers show less evidence of instability in vitro and in vivo compared to duplexes with one or two 15-mer MORF oligomers (*29*). For these reasons a 25-mer PS DNA25/18-mer PO cDNA18 duplex was selected for this study.

The identical antisense DNA sequence used previously in these laboratories (but elongated to 25-mer) and the *mdr1* target mRNA were again used in this investigation. When radiolabeled, successful tumor targeting of this antisense PS DNA by an antisense mechanism was achieved in cell culture (*13*) and in tumored mice (*3*). Furthermore, when the *mdr1* mRNA is targeted, the cells showing high level (KB-G2) and low level (KB-31) *mdr1* mRNA and therefore different Pgp expression may again be used as a study/control pair. Since the *mdr1* mRNA expression of the control Pgp+/– KB-31 cells can be variable and the cells can be inadverently modified to express *mdr1* mRNA and Pgp at levels approaching that of the study Pgp++ KB-G2 cells (*13*), rhodamine 123 was used to confirm that the difference in multidrug resistance (i.e., Pgp expression) between the KB-31 and KB-G2 cells was preserved, as shown in Figure 2.

The Cy5.5 emitter was selected because of its emission in the near-infrared, and BHQ3 was selected as a nonfluorescent quencher both because of its lack of self fluorescence and because it provides spectral overlap over the entire range of Cy5.5 fluorescence. Thus, when the 3′-Cy5.5 conjugated antisense DNA is hybridized with the 5′-BHQ3 complementary DNA, about 90% of the Cy5.5 fluorescence is quenched as shown in Figure 1. As also shown in the figure, the duplex is stable in normal cell media and in 70% serum over 24 h. Furthermore, as shown in Figure 3A, when incubated with KB-G2 cells, the fluorescence intensity of DNA25-Cy5.5 was much lower as the duplex compared to singlet at all dosages as evidence of duplex intracellular stability. To address the question of whether the fluorescence of the duplex is specific and the result of antisense targeting, the identical studies were performed with the Cy5.5 on the complementary sense strand and the BHQ3 on the antisense strand (i.e., cDNA18-Cy5.5/DNA25-BHQ3 duplex) and the results compared with the study duplex (i.e., DNA25-Cy5.5/cDNA18-BHQ3) after incubation in the KB-G2 cells with the high *mdr1* mRNA level and KB-31 cells with a lower *mdr1* mRNA level. As shown in Figure 3B, the cellular accumulations of the control duplex was statistically identical in both cells while the accumulation of the study duplex was statistically higher in the KB-G2 cells as evidence of specific antisense binding.

Further evidence for specific antisense binding of the duplex was obtained in the fluorescent images of KB-G2 cells shown in Figure 4. Evidence from this laboratory (*14*) and other laboratories (*17, 23, 30*) shows that antisense DNAs migrate to the nucleus of target cells. The images in the figure for both the live and fixed KB-G2 cells show similar migration of DNA25-Cy5.5 to the nucleus when incubated as the singlet or duplex. Finally, that incubation of KB-G2 cells with the study duplex increased the accumulation of rhodamine 123 as shown in Figure 2 may also be taken as evidence of specific antisense

targeting because the duplex in this case was apparently interfering with Pgp efflux pump expression and therefore *mdr1* mRNA translation.

The whole-body fluorescent images of KB-G2 tumor bearing mice presented in Figure 5A provide further evidence in support of the hypothesis that the duplex dissociates as expected in the presence of its target mRNA and provides evidence that it does so in vivo at the tumor site. The figure presents images at 5 h of two identical tumored mice receiving either the study or control duplex and at the same 3 nmol dosage and imaged simultaneously. The increased fluorescence in the tumored thigh in the animal receiving the study duplex is apparent in these images as well as in the images obtained following administration of the 1 and 5 nmol dosage of study duplex (data not presented). Regions of interest of equal area were set around both thighs in all animals to generate the ratio of fluorescence in the study thigh compared to normal thigh. As shown in Figure 6, this ratio was never less than 1.2–1.6. Also presented in Figure 5 are fluorescent microscopy images of tumor slices taken from animals receiving either the study or control duplexes. By comparison of the images with that obtained by imaging in the GFP channel, it is apparent that the Cy5.5 fluorescence is emanating from the tumor cells as evidence of tumor targeting.

An interesting observation within Figure 5A is the background fluorescence in animals receiving the study but not the control duplex. Since more than 90% of the Cy5.5 fluorescence may be quenched in the duplex (Figure 1), much lower backgrounds were expected. We hypothesize that the study duplex (PS DNA25-Cy5.5/PO cDNA18-BHQ3) used in this investigation is unstable to dissociation in circulation and/or in normal organs within the 3 h period between administration and imaging. Thus, once the PO DNA-BHQ3 in its singlet form is released, it is expected to rapidly degrade in vivo as any singlet PO DNA (*31*). By contrast, the free PS DNA-Cy5.5 will be stable to enzymatic degradation along with its fluorescence. However, when the control duplex dissociates, the PO DNA-Cy5.5 will be released to be degraded within minutes such that the Cy5.5 may clear the cell and the whole body along with its fluorescence. To investigate this possibility, two tumored animals were imaged immediately following administration of a PO DNA-Cy5.5 or a PS DNA-Cy5.5. At 12 min, the mouse receiving the PO DNA-Cy5.5 showed minimal fluorescence in blood and, in this case, high florescence in kidneys and bladder. By contrast, the mouse receiving the PS DNA-Cy5.5 showed whole-body fluorescence similar to that of Figure 5A (data not presented).

CONCLUSION

In conclusion, our results provide a proof of concept that fluorophore-conjugated linear DNA duplexes may be used to provide a fluorescent image of tumor in mice by an antisense mechanism. We have shown that our selection of Cy5.5 and BHQ3 conjugated DNAs provides efficient fluorescent quenching when hybridized and produces florescence in tumor cells in culture and tumors in vivo when dissociated in the presence of the mRNA target. However, it will be apparent from these results that the selection of a 25-mer antisense PS DNA and an 18-mer complementary sense PO DNA may not be ideal for this application. Additional studies will be needed to investigate the influence of chain length and backbone modifications on future duplexes.

ACKNOWLEDGMENT

We thank Dr. Isamu Sugawara (Research Institute of Tuberculosis, Tokyo, Japan) for providing the KB-G2 and KB-31 cell lines for this investigation. We thank Dr. Alexei Bogdanov, Jr., for assistance with the in vitro fluorescence measurements. Novel Method for *in Vitro* O-Glycosylation of Proteins: Application for Bioconjugation

Boopathy Ramakrishnan,[†,‡] Elizabeth Boeggeman,[†,‡] and Pradman K. Qasba*[,†]

Structural Glycobiology Section, and Basic Research Program, SAIC-Frederick, Inc., Center for Cancer Research Nanobiology Program, Center for Cancer Research, NCI-Frederick, Frederick, Maryland 21702. Received June 23, 2007; Revised Manuscript Received August 27, 2007

Here, we describe a new method for the bioconjugation of a nonglycoprotein with biomolecules. Using polypeptide-α-*N*-acetylgalactosaminyltransferase II (ppGalNAc-T2), we transfer a C2-modified galactose that has a chemical handle, such as ketone or azide, from its respective UDP-sugars to the Ser/Thr residue(s) of an acceptor polypeptide fused to the nonglycoprotein. The protein with the modified galactose is then coupled to a biomolecule that carries an orthogonal reactive group. As a model system for the nonglycoprotein, we engineered glutathione-*S*-transferase (GST) protein with a 17-amino-acid-long fusion peptide at the C-terminal end that was expressed as a soluble protein in *E. coli*. The ppGalNAc-T2 protein, the catalytic domain with the C-terminal lectin domain, was expressed as inclusion bodies in *E. coli*, and an *in vitro* folding method was developed to produce milligram quantities of the active enzyme from a liter of bacterial culture. This ppGalNAc-T2 enzyme transfers from the UDP-sugars not only GalNAc but also C2-modified galactose with a chemical handle to the Ser/Thr residue(s) in the fusion peptide. The chemical handle at the C2 of galactose is used for conjugation and assembly of bionanoparticles and preparation of immuno-liposomes for a targeted drug delivery system. This novel method enables one to glycosylate, using ppGalNAc-T2, the important biological nonglycoproteins, such as single-chain antibodies, growth factors, or bacterial toxins, with an engineered 17-residue peptide sequence at the C-terminus of the molecule, for conjugation and coupling.

Conjugation of monoclonal antibodies with toxins, drugs, and radioisotopes is becoming a new strategy in the diagnosis and treatment of cancer (*1*). A number of such immuno-conjugates are being used to treat cancer (*2–4*). Various methods are being used with mixed success in conjugating antibodies with the cargo molecule. Often, the primary amine groups present on the surface of the protein molecule are used for conjugation; however, since every lysine residue present on the protein molecule would be reactive, this method results in undesirable heterogeneous conjugation and even loss of antibody activity (*5, 6*). Alternatively, the free Cys residue, either naturally present or engineered in the protein molecule, is widely used for conjugation. Since the freely exposed Cys residue is highly reactive in basic pH, these protein molecules require special handling (*7–9*). It has long been demonstrated that the sugar moieties present on the glycoproteins, such as IgG, can be used as a chemical handle for such conjugation (*10–14*). However, the heterogeneous nature of the glycan moiety on the recombinant glycoprotein causes poor coupling. We have recently developed a unique conjugation method that utilizes the *N*-acetylglucosamine residue, (GlcNAc), which is present at the nonreducing end of the glycans of glycoproteins (*15–17*). In this scheme, using the β1,4-galactosyltransferase mutant enzyme, Y298L-Gal-T1, we enzymatically transfer the 2-acetonyl-2-deoxy-galactose (2-keto-Gal) sugar, which has a unique chemical handle, to the GlcNAc residue of the glycoprotein. After the transfer of the sugar residue, this chemical handle can be used for selective conjugation with biologically important molecules (*15, 16*). Using this method, we have shown that even the *N*-glycan moiety of the IgG molecule can be used as the substrate for the transfer of the 2-keto-Gal sugar by the mutant Y298L-Gal-T1 (*17*). However, this method requires the presence of a free GlcNAc moiety on the nonreducing end of the glycan chain of the glycoprotein and cannot be used for nonglycoproteins, such as single-chain antibodies or bacterial toxins expressed in *E. coli*.

Herein we describe a method that takes advantage of the polypeptide-α-*N*-acetylgalactosaminyltransferase enzyme (ppGalNAc-T), which transfers the *N*-acetylgalactosamine sugar (GalNAc) from UDP-GalNAc to Thr/Ser residues on an acceptor polypeptide that is at least 11 amino acids long (*18*). We have engineered an acceptor polypeptide substrate as a fusion peptide at the C-terminus of a nonglycoprotein of interest and used this fusion peptide moiety as an acceptor substrate for the ppGalNAc-T in the transfer of GalNAc residue, thus converting the nonglycoprotein to a glycoprotein. Interestingly, previous *in vivo* studies have shown that ppGalNAc-T can also transfer GalNAc analogue sugars with a unique chemical handle, such as GalNAz, to the acceptor polypeptide (*19*). We show here that the ppGalNAc-T enzyme can also transfer 2-keto-Gal from its UDP-derivative to the acceptor polypeptide. Therefore, it is possible to glycosylate a nonglycoprotein using ppGalNAc-T with a modified sugar carrying a unique chemical handle that can be used for conjugation. Furthermore, in the present study, we have expressed the soluble form of ppGalNAc-T2 in *E. coli* as inclusion bodies and developed an *in vitro* folding method to make large quantities of active ppGalNAc-T2. We have used glutathione-*S*-transferase (GST) protein as a model system for engineering, at its C-terminus, the fusion peptide sequence with a single Thr residue, which is the acceptor substrate for ppGalNAc-T2. We show that ppGalNAc-T2 transfers not only GalNAc or GalNAz, but also 2-keto-Gal, to the single Thr

residue present in the peptide tag of the GST-tag fusion protein, demonstrating that this method can be used for glycosylating nonglycoproteins, such as single-chain antibodies (scFv), bacterial toxins, and so forth.

EXPERIMENTAL PROCEDURES

Polypeptide-α-*N*-acetylgalactosaminyltransferase-2 Gene Construction and Expression in *E. coli.* The human polypeptide-α-*N*-acetylgalactosaminyltransferase-2 (ppGalNAc-T2) clone (BC041120) was obtained from Open Biosystems. The C-terminal His tag carrying the catalytic and lectin domains of ppGalNAc-T2, coding residues 60 to 583 of the protein, were PCR amplified using the following primers with *Bam*HI and *Eco*RI restriction enzyme sites (shown in italics) at their 5′ terminal: (1) CGC*GGATCC*CGCG GCACAAAGCATGGAGAC-CCTCCCTCCAGGGAAA and (2) GCGCGC C*GAATTC*G-GTCCCTGCTGCAGGTTGAGCGTGAACTTTCCA CTGCTG.

The PCR-amplified product was digested with *Bam*HI and *Eco*RI restriction enzymes and ligated with the pET23a vector digested with the same enzymes. The ligated vector was transfected into XL2 supercompetent cells. The ampicillin-resistant clones were screened for the presence of the ppGalNAc-T2 gene in their plasmid DNA between their *Bam*HI and *Eco*RI restriction sites. The positive clones were sequenced and transfected into Rosetta (DE3) LysS competence cells for the expression of the protein.

In Vitro* Folding of Inclusion Bodies of the ppGalNAc-T2 Protein Produced in *E. coli. The Rosetta (DE3) LysS cells containing the ppGalNAc-T2 cDNA sequence in the pET23a vector were grown to an optical density of 0.7–0.8 and then induced with IPTG. The inclusion bodies were purified from the bacterial pellet as described earlier (*20*). From 1 L of bacterial culture, 60–70 mg of protein were obtained as inclusion bodies. The *in vitro* folding of ppGalNAc-T2 was carried out in a way similar to that of β4Gal-T1 (*20*), with a few modifications. Typically, 100 mg of sulfonated protein were folded for 48 h in 1 L of folding solution that contained oxido-shuffling agents, 500 mM arginine, 10% glycerol, and 10 mM lactose. The presence of glycerol and lactose in the folding solution enhances the folding efficiency of ppGalNAc-T2. After refolding the protein, the folding solution was extensively dialyzed against water. During dialysis, the misfolded protein precipitated out, while the folded protein remained soluble. The soluble protein was concentrated on an Amicon stirred cell using a YM-10 membrane, and further purified on a Ni-column. There was no significant loss of protein observed during concentration and Ni-column purification steps, as estimated by measuring the protein concentration using the Bradford method (BioRad). Nearly 2 mg of folded ppGalNAc-T2 protein wais obtained from 1 L of folding solution. Using the method described previously (*21*), the purified protein was tested for its catalytic activity using a 13-amino-acid peptide, PTTDSTTPAPTTK, as an acceptor. The specific activity of the refolded ppGalNAc-T2 was 20 pmol/min/ng protein.

Construction and Expression of GST Protein with the C-terminal 17-Amino-Acid Glycosylation Tag. The GST gene from the pGEX-2T vector (General Electric (GE)) was amplified first with the 5′-primer and 3′-primer-1, and purified on a low-melt agarose gel. The purified GST gene was further amplified with the 5′-primer and 3′-primer-2, which coded for a 17-amino-acid peptide, GAGGPIMAAATPAPAAK, as a C-terminal extension of GST following a thrombin cleavage site.

5′-Primer: CGC*GGATCC*GCGTCCCCTATACTAGGT-TATTGGAAAATTAAGGGCCTTGTG.

3′-Primer-1: CGCCGGCGTAGCAGCGGCCATGATGGGTC-CGCCGGCTCCACGCGGAACCAGATCCGA.

3′-Primer-2: CCG*GAATTC*CGGCTACTTCGCCGCCG-GCGCCGGCGTAGCAGCGGCCATGATGGG.

The final PCR-amplified DNA fragment was digested with *Bam*HI and *Eco*RI enzymes and ligated with digested pET23a vector with the same enzymes. The ligated vector was transfected into XL2 competent cells. The ampicillin-resistant clones were screened for the presence of the full GST gene between the *Bam*HI and *Eco*RI sites in their plasmid DNA. The positive plasmid DNA was transfected into Rosetta (DE3) LysS cells. The GST-tag protein was expressed as a soluble protein in *E. coli* and purified on a glutathione affinity column (GE). Fifty to sixty milligrams of purified protein were obtained from 1 L of bacterial culture. The C-terminal glycosylation peptide tag was released from a 5 μg protein by thrombin cleavage and analyzed by mass spectrometry. The other GST-tag fusion proteins containing the multiple glycosylation sites were also made using a method similar to that described above. All of the oligonucleotides were synthesized by the Molecular Technology Branch, NCI-Frederick, Frederick, MD.

Glycosylation of the GST-Tag with the *in Vitro* Folded ppGalNAc-T2. Five micrograms of GST-tag protein was incubated overnight at 37 °C with 50 ng of ppGalNAc-T2 in the presence of 25 mM Tris-HCl (pH 8.0), 10 mM $MnCl_2$, and 0.5 mM UDP-sugar (UDP-GalNAc, UDP-2-keto-Gal, or UDP-GalNAz) in a total volume of 25 μL. To remove all of the reaction buffer, the glycosylated GST-tag protein was centrifuged on a centricon filter (10 K molecular weight cutoff) and washed twice with deionized water. The salt-free glycosylated GST-tag was recovered in 20 μL of water, and an aliquot (4 μL) was cut with human thrombin and analyzed by mass spectrometry (MALDI-TOF).

Biotinylation of the Glycosylated GST-Tag and Gel Electrophoresis. The desalted glycosylated GST-tag protein with 2-keto-Gal was biotinylated in 60 μL volume containing 75 mM sodium acetate buffer (pH 5.0) and 3 mM *N*-aminoxymethylcarbonylhydrazino-D-biotin (ARP, Dojindo Laboratories). The reaction was carried out overnight at room temperature. The biotinylated sample was desalted using a centricon filter (10 K molecular weight cutoff) and recovered in 20 μL of water. An aliquot of the sample was cut with thrombin and analyzed using mass spectrometry. The biotinylated proteins uncut and cut with thrombin were analyzed by Western blotting, and they were detected by chemiluminescence using streptavidin–horseradish peroxidase (HRP), as described previously (*17*).

Equal amounts of thrombin-cleaved and -uncleaved GalNAz glycosylated GST-tags were biotinylated using Click-iT Biotin Glycoprotein Detection Kit from Invitrogen, following the manufacturer's instructions. The reaction was carried out for 1 h at room temperature. Since biotinylation was carried out using the unknown components supplied by the manufacturer, it was not possible to simply desalt the protein using centricon filters. Therefore, the mass spectrometry analysis could not be carried out. However, because the Click-iT reaction buffer did not interfere with the protein gel electrophoresis, Western blotting was carried out, and the biotinylated protein was detected by chemiluminescence using HRP, as described earlier (*17*). All of the mass spectroscopic analyses were carried out in the Protein Chemistry Laboratory, NCI-Frederick, Frederick, MD.

RESULTS AND DISCUSSION

The glycoconjugation of a nonglycoprotein was afforded by engineering a C-terminal fusion peptide sequence containing a Thr/Ser residue in the nonglycoprotein (Figure 1a). The fusion peptide can then be glycosylated with ppGalNAc-T, which transfers GalNAc from UDP-α-GalNAc to the Thr/Ser residue

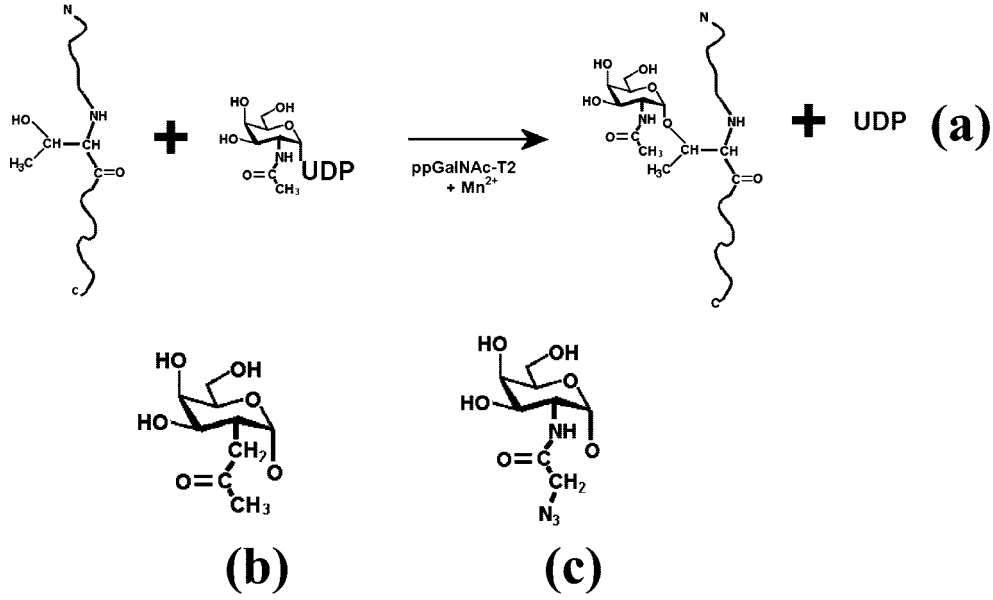

Figure 1. Catalytic reaction of polypeptide-α-*N*-acetylgalactosaminyltransferase (ppGalNAc-T). (a) In the presence of Mn^{2+}, the enzyme transfers GalNAc sugar from its UDP-α-GalNAc donor substrate to the side chain hydroxyl group of the Thr/Ser residue present in a polypeptide acceptor substrate. Here, we show that in addition to transferring GalNAc, the enzyme can transfer (b) 2-keto-Gal and (c) GalNAz from the respective UDP-sugars.

in the fusion peptide. Furthermore, ppGalNAc-T is known to transfer GalNAc analogues with a unique chemical handle (Figure 1b and c) such as the 2-azido-acetyl group. The glycosylated glycoprotein with the modified sugar can then be conjugated through this unique chemical handle to a bioactive molecule, such as immunoglobulin, toxins, and so forth. Although there are 17 homologues in the ppGalNAc-T enzyme family in humans, any one of them, with its preferred acceptor substrate, may be used. Here, we have used ppGalNAc-T2 since its three-dimensional crystal structure and enzymology are well known from previous studies (*21*). We have used GST as a model for a nonglycoprotein because it has been used for the expression of a number of fusion recombinant proteins at its C-terminal end. Here, we have expressed GST-tag protein with a 17-amino-acid fusion peptide with one or many Thr residues at the C-terminal end. These peptides were designed on the basis of a 13-amino-acid peptide, PTTDSTTPAPTTK, known as EA2, which was used for enzymology and crystallographic studies with ppGalNAc-T2 (*21*) and ppGalNAc-T10 (*22*). In the crystal structure of the complex of ppGalNAc-T2 with EA2 acceptor peptide (*21*), only the nanopeptide, STTPAPTTK, was clearly observed, while the N-terminal tetra-peptide, PTTD, was considered to be disordered (*21*). The Thr residue found in the TPAP peptide sequence was found in the ppGalNAc-T2 acceptor binding site, while the remaining N- and C-terminal peptide residues were bound in the extended peptide binding site (*21*). On the basis of these observations, we engineered the peptide tag, SGGPIMDSTTPAPTTK, following the thrombin protease binding sequence found at the C-terminal end of the GST protein (Figure 1a). The hexa-peptide, SGGPIM, was used as a spacer between the protease site and the ppGalNAc-T2 binding peptide, DSTTPAPTTK (Figure 1c). When designing a tag with a single Thr residue, we kept the Thr residue that was found in the acceptor binding site of the ppGalNAc-T2, while the remaining residues were mutated to alanine, thus resulting in a deca-peptide, AAATPAPAAK.

ppGalNAc-T2 Expression in *E. coli* and the *in Vitro* Folding of the Inclusion Bodies. Although the ppGalNAc-T2 enzyme, with a stem region followed by the catalytic domain (CD) and lectin domain (LD), has been expressed previously in various expression systems producing an active soluble protein (*21*), the expression in *E. coli* has produced inactive inclusion bodies. The ppGalNAc-T2 expressed in yeast showed no *N*-glycosylation in the crystal structure and was considered a perfect candidate for expression in *E. coli*, which could be folded from inclusion bodies. Therefore, an *in vitro* folding method was developed to generate active protein. Previously in our laboratory, we have used the S-sulfonation method to produce large quantities of β-1,4-galactosyltransferase (β4Gal-T1) from inclusion bodies (*20*). An active ppGalNAc-T2 can be obtained using this method, albeit at low efficiencies. However, we found that including 10% glycerol and 10 mM lactose during *in vitro* folding increases the folding efficiency of ppGalNAc-T2 to nearly 2 mg of purified protein from 1 L of folding solution containing 100 mg of sulfonated protein obtained from 1.5 L of bacterial culture (Figure 2a and b). The specific activity of the *in vitro*-folded enzyme (20 pmol/min/ng) is comparable to that of the same protein expressed in other systems (*21*). The *in vitro*-folded ppGalNAc-T2 has been used in the experiments described in this article.

Recently, ppGalNAc-T1 has been used for the glycosylation of the nonglycoform of muc1 protein expressed in *E. coli* (*23*). Similarly, ppGalNAc-T2 has been used to construct the *O*-mucin structure on the nonglycoform of the interferon-alpha2b (IFN-alpha2b) expressed in *E. coli* (*24*). Thus, *in vitro* glycosylation of the nonglycoform of glycoproteins is becoming increasingly important. The *in vitro* folding method for ppGalNAc-T2 from inclusion bodies described here shows that large quantities of these glycosyltransferases can be generated from *E. coli* and can be used for such applications as well.

Glycosylation of GST-Tag Protein. GST protein with a 17-amino-acid tag at the C-terminus, following a thrombin cleavage site, has been successfully expressed as a soluble protein from *E. coli* and purified on a glutathione column. First, we expressed the tag with an oligopeptide sequence, SGGPIMDSTTPAPTTK, similar to the one used in the enzyme kinetic studies of ppGalNAc-T2 (*21*). After completion of the enzyme reaction, the 17-amino-acid tag was released by thrombin digestion and analyzed by mass spectrometry (MALDI-TOF) (Figure 3a). The MS analysis of the glycosylated peptide tag showed that it exists as a mixture of three to four glycosylated peptides, suggesting that the four Thr residues present in the peptide tag have been

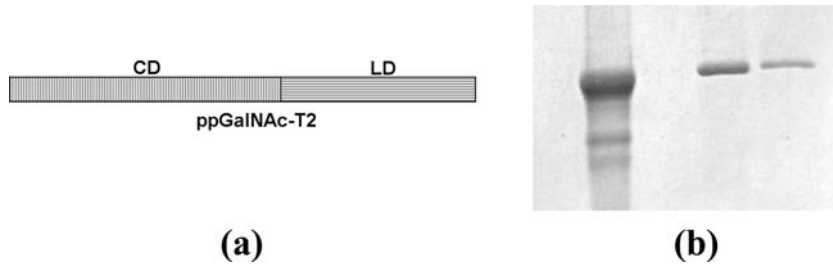

Figure 2. SDS–gel analysis of the inclusion bodies and *in vitro*-folded protein of ppGalNAc-T2. (a) The soluble domain of ppGalNAc-T2, which contains a stem region, catalytic domain (CD), and the lectin domain (LD), is expressed in *E. coli* as inclusion bodies. We have used an *in vitro* folding method to generate active protein. (b) SDS–gel analysis of the inclusion bodies (left lane) and the purified *in vitro* folded active proteins; 1 μg and 0.5 μg, middle and right lanes, respectively.

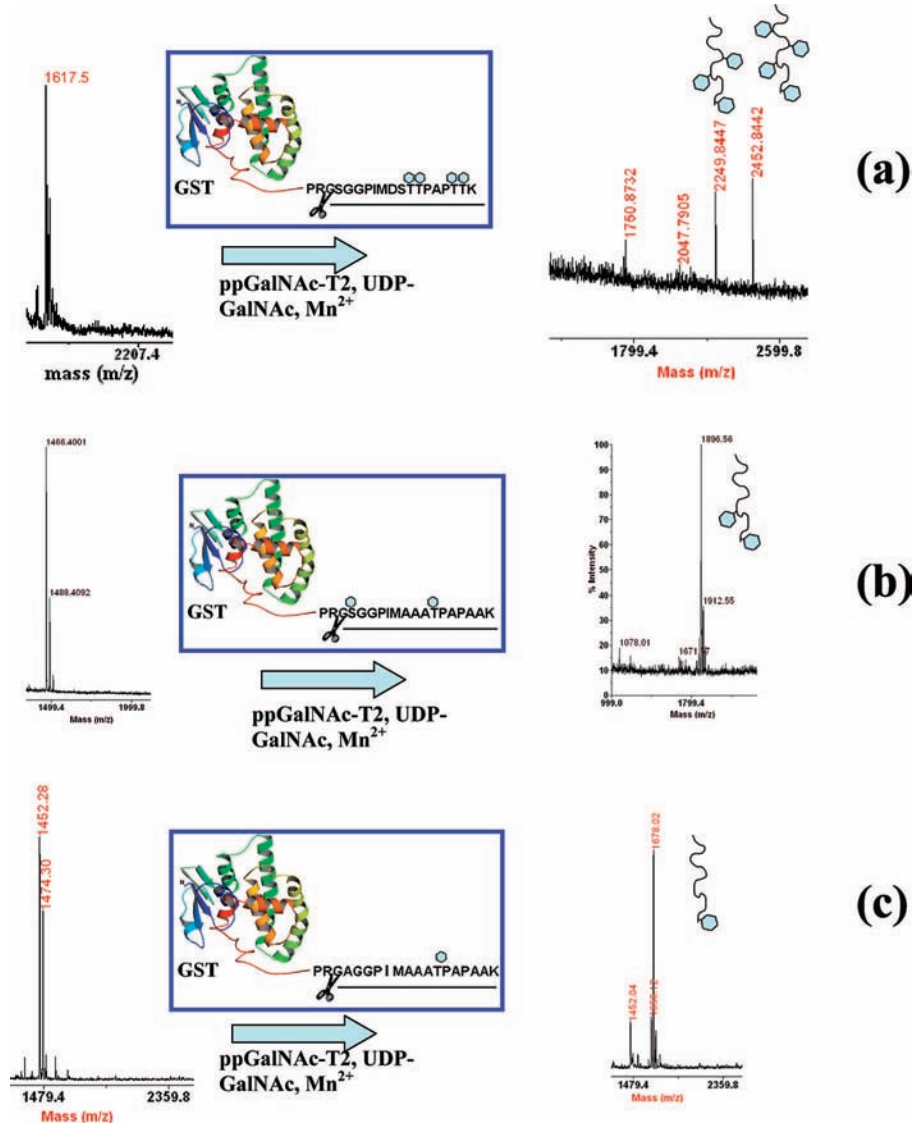

Figure 3. GalNAc transfer by the *in vitro*-folded ppGalNAc-T2 enzyme to GST-tag protein. The glutathione-*S*-transferase protein (shown in the cartoon diagram insert) is expressed with 17 amino acids (in single-letter code) as a fusion peptide at its C-terminus following the thrombin site (RG), shown as cutting scissors. The blue hexagons indicate the potential O-glycosylation residues. The fusion peptides are designed on the basis of the acceptor substrates of ppGalNAc-T2 (*21*). The mass spectrum (MALDI-TOF) of the thrombin-cleaved, nonglycosylated, and glycosylated peptides (panels (a), (b), and (c)) are shown in the left and right side of the arrow, respectively. (a) Although the fusion-peptide tag contains four Thr residues and two Ser residues, the overnight incubation of the GST-tag protein with the ppGalNAc-T2 seems to glycosylate a maximum of four glycosylation sites. (b) When one Thr and one Ser residue are present, they both have been found to be glycosylated. (c) The presence of one Thr residue results in a single glycosylation of the peptide tag; thus, this tag is used for further studies.

glycosylated. Since ppGalNAc-T2 prefers to transfer GalNAc to a Thr residue rather than to a Ser residue, it is expected that all the possible Thr residues present in an acceptor peptide would be glycosylated first, prior to any Ser residues. On the contrary, the redesigned peptide tag, SGGPIMAAATPAPAAK, with one Thr and one Ser residue, was found to have glycosylated with two sugars, suggesting that, in addition to the glycosylation of the single Thr residue, the less-preferred Ser residue is also

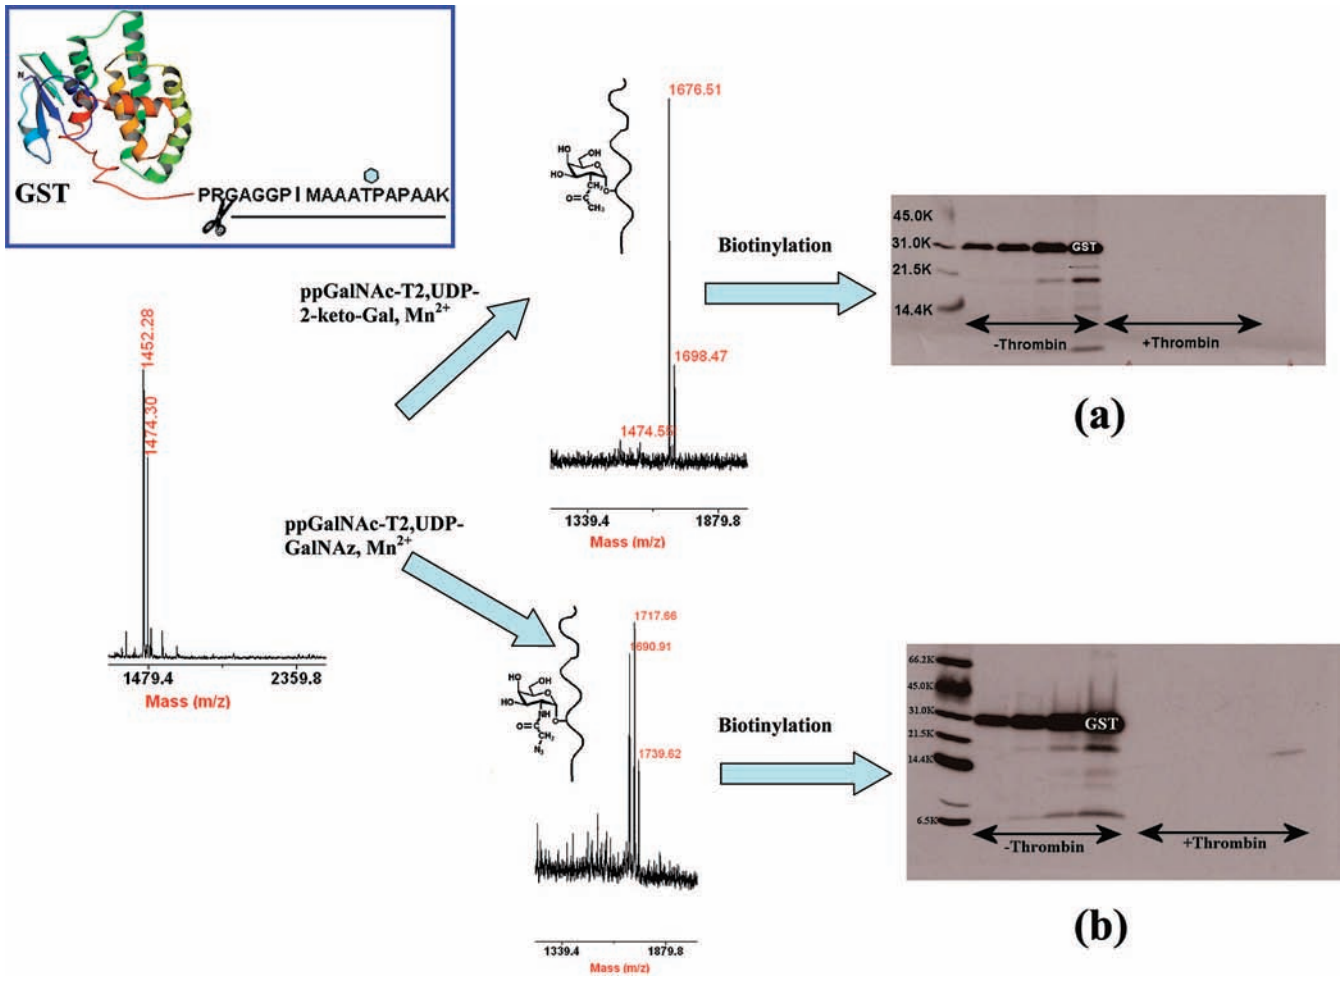

Figure 4. 2-Keto-Gal and GalNAz transfer by the *in vitro*-folded ppGalNAc-T2 enzyme to GST-tag protein. The GST-tag protein with a single Thr residue in its fusion peptide has been used for the transfer of (a) 2-keto-Gal and (b) GalNAz sugars from their respective UDP-derivatives. The mass spectrum (MALDI-TOF) of the nonglycopeptide and glyco-peptide released by thrombin digestion are shown on the left and right sides of the arrows, respectively. The glycosylated protein is biotinylated using the biotin-carrying, appropriate orthogonal reactive group to react with the ketone or azide moiety of the modified sugars. The proteins in the Western blotting were visualized using the streptavidin-HRP chemiluminescence technique. A strong luminescence is observed only for the biotinylated proteins with the fusion peptide (− thrombin), while in the proteins without the fusion peptide (+ thrombin), no trace of chemiluminescence has been observed. This observation indicates that the biotinylation takes place only at the sugar moiety present in the fusion peptide tag.

glycosylated (Figure 3b). The glycosylation of the Ser residue in the second tag, but not in the first tag, could be due to the experimental condition used for glycosylation. Under this condition, the glycosylation of more than three Thr residues in the first tag has been observed (Figure 3a); since the second tag has only one Thr residue, it is not surprising to find that in addition to this single Thr residue, the remaining single Ser residue, though less preferred, is also glycosylated. Mutating the Ser residue to Ala in the peptide tag produced the tagged peptide sequence AGGPIMAATPAPAAK with only one Thr residue, which underwent glycosylation at only one site (Figure 3c). When this Thr was mutated to the Leu residue (AGGPI-MAALPAPAAK), no glycosylation was observed, confirming that the glycosylation takes place at the unique Thr residue (not shown). Although a number of peptides have been previously tested as the acceptor substrates for the ppGalNAc-T2, none of them are presented as a fusion peptide. Thus, these glycosylation studies confirm that the fusion peptide tag can be glycosylated at one or more sites with a Thr, or even Ser, residue present in the fusion peptide tag.

It has been previously shown that ppGalNAc-T enzymes in the live cell can incorporate GalNAz, a modified sugar resembling GalNAc, to the glycan chains (*19*). The incorporation of such unnatural monosaccharides such as azides, which bear a uniquely reactive chemical handle, has enabled the selective labeling of glycoconjugates with a variety of reagents (*19*). Since these studies were carried out *in vivo*, it was not possible to identify the specific ppGalNAc-T that is responsible for the transfer of GalNAz among the 17 family members of ppGalNAc-Ts present in humans. We used ppGalNAc-T2 to transfer a modified galactose that resembles GalNAc, such as 2-keto-galactose or GalNAz, to the fusion peptide in the GST-tag protein. In the present study, we have used the GST-tag protein with only one Thr residue present in its fusion peptide tag.

The catalytic reaction using UDP-α-2-keto-Gal or UDP-α-GalNAz as donor substrates was carried out under the same conditions as the those used for UDP-GalNAc. After catalysis, the thrombin digestion released the glycopeptide that showed the presence of one sugar moiety in the fusion peptide, as indicated by mass spectrometry (Figure 3a). This result suggested that the Thr residue is glycosylated by the ppGalNAc-T2 with modified sugars. To detect the presence of the unique chemical handle, such as the ketone or the azide in the galactose of the peptide tag of GST-tag protein, the samples were biotinylated by appropriate chemical reactions. The biotinylated samples with and without the peptide tag were then subjected to Western blotting, and the proteins were detected by the chemiluminescence technique (*16*, *17*) (Figure 4). The chemi-

luminescence observed only from the protein with the attached peptide tag clearly indicated that the biotinylation was done on the modified sugars of the peptide tag and not on the GST protein, whereas the thrombin-cleaved protein afforded no observable chemiluminescence. Thus, these studies show that ppGalNAc-T2 can efficiently transfer the modified galactose from its UDP derivatives to the fusion peptide and that the chemical handle present in the glycan moiety is readily available for further modification such as biotinylation.

Applications in Glycoconjugation. We have previously shown that the mutant β4Gal-T1 enzyme, Y289L-Gal-T1, can transfer GalNAc from UDP-GalNAc as efficiently as galactose (Gal) from UDP-Gal to the GlcNAc residue present at the nonreducing end (*15*). In addition, we have found that it can also transfer modified sugars, such as 2-keto-galactose, from their UDP-derivative, and this catalytic activity was successfully applied in detecting *O*-GlcNAc modification in the proteins (*16*). The same technique was expanded to other glycoproteins, such as ovalbumin and immunoglobulin IgG, with free GlcNAc at the nonreducing end of their *N*-glycans (*17*). On the basis of the results of these techniques, it was proposed that two glycoproteins with modified sugars with a unique chemical handle such as 2-keto-Gal may be conjugated with chemical cross-linkers, thus enabling the design of novel immunotoxins and MRI contrast agents (*25*). In the present study, we have shown that nonglycoproteins can be glycosylated by engineering a peptide sequence in the protein that can be glycosylated with the modified sugar so that they can also be cross-linked to the other glycoproteins such as IgG with similar modified sugars. Thus, the present study extends our previous technique by showing that an engineered nonglycoprotein with a peptide tag at its C-terminal end can be glycosylated with a modified sugar and coupled to a biomolecule that carries an orthogonal reactive group, making the method very useful in many nanobiological applications. For example, single-chain antibodies (scFv), which are easily expressed in large amounts in *E. coli* as soluble proteins, are increasingly used for immunotherapy compared to their full-length IgG counterparts (*26*). A fusion peptide attached at the C-terminal end of the scFv molecule that can be glycosylated with a modified sugar at a unique site, by the method described here, can be conjugated next with a biomolecule having a corresponding reactive group, such as aminooxy or alkynes, for the assembly of immunoliposome (*27*) or for applications in immunotherapy and targeted drug delivery (*25, 26*).

Although the glycosylation of a surface Thr/Ser residue on the protein by the ppGalNAc-T is possible, the crystal structure of the ppGalNAc-T2 suggests that such a Thr/Ser residue not only has to be present in at least 11-amino-acid-long peptides in the extended conformation but also has to be well exposed to the solvent region. Since cytoplasmic proteins, in contrast to cell-surface proteins, do not get *O*-GalNAc modification, such peptide sequences may not be present on these proteins. However, proteins with a long flexible region that has an accessible Thr/Ser residue may be the candidate acceptors for such undesired glycosylation. In such cases, the O-glycosylation site itself-can be used for glyco-conjugation using modified GalNAc, such as 2-keto-Gal or GalNAz. Although immunogenicity due to the C-terminal tag or the presence of modified sugar is a concern, it may not be well exposed to the environment because of the presence of the bulky conjugating chemical moiety, which may reduce the immunogenic effect. However, such general concerns are associated with most conjugation techniques.

Other recent methods include site-directed introduction and chemoselective ligation of cysteine residues to convert a nonglycoprotein to a glycoprotein (*28*) and site-directed introduction of azido/alkynyl-tagged methionine analogues into proteins (*29*). However, the former method needs special handling of the protein to prevent its free Cys residue from undergoing undesired oxidation, while in the latter method, all the of methionine residues present in the protein are modified. Recently, Carrica et al. (*30*) have described a method for introducing genetically encoded aldehydes at either one of the terminal ends of proteins, which then can be used for conjugation. The present technique demonstrates the fusion of a peptide tag with a single O-glycosylation site, which can be glycosylated with a stable modified sugar moiety with a chemical handle that can be used for linking various biomolecules. These biomolecules, in turn, may be used to design novel nanoparticles for the development of a targeted drug delivery system.

ACKNOWLEDGMENT

We thank Dr. John T. Simpson, Protein Chemistry Laboratory, NCI-Frederick for the mass spectroscopic analysis of the samples. We thank Dr. Linda Hsieh-Wilson, CalTech, for UDP-2-keto galactose; Drs. Tomomi Kubota and Hisashi Narimatsu for providing their ppGalNAc-T2 sample for comparison, and Drs. Maria Manzoni and Marta Pasek for discussions and comments on the manuscript. The rational design of surfaces for immobilization of proteins is essential to a variety of biological and medical applications ranging from molecular diagnostics to advanced platforms for fundamental studies of molecular and cell biology. We have developed an advanced electrochemically based approach for site-selective and reaction-controlled immobilization of proteins on surfaces. When a molecular monolayer of 4-nitrothiophenol on gold electrode surfaces is reduced electrochemically in a selective fashion at its nitro groups, to afford amino groups by potentiometric scans, the amine can be employed to orchestrate the immobilization of proteins to the surface. This protein immobilization strategy could allow one to fabricate intricate protein structures on surfaces for addressing fundamental and applied problems in biology and medicine.

INTRODUCTION

The controlled immobilization of proteins on surfaces is of paramount importance for a wide variety of applications, ranging from the development of model substrates for mechanistic studies of cell behavior to high-throughput protein assays for drug discovery, clinical diagnostics, and proteomics (*1–7*). In particular, stimulated by the success of DNA arrays in genomics (*1*), substantial scientific and commercial interest has been generated in the use of protein arrays as tools for proteomics (*1, 2*). However, proteins are much more chemically and structurally diverse than nucleic acids, making them intrinsically more complicated to be immobilized on surfaces (*1, 2*). Other difficulties result from the intrinsic fragility of proteins, which have modest conformational stability and can be damaged upon surface immobilization (*1, 2*). Moreover, proteins can adhere and adsorb to most surfaces through a variety of mechanisms (electrostatic interaction, hydrogen bonding, hydrophobic interactions, and/or a combination of these), resulting in nonspecific protein binding (*8*).

Therefore, a primary enabling technology is the ability of controlling the immobilization of proteins on surfaces while avoiding nonspecific protein binding and retaining protein native biological features and properties (*1–3, 5–7*). Molecular surface science has greatly contributed to the advancement of this technology by providing ideal platforms for bioengineering surfaces on a molecular level (*9–15*). For instance, self-assembled monolayers (SAMs), which form spontaneously by the adsorption of an active surfactant onto a solid surface, possess important properties of self-organization and adaptability to a number of technologically relevant surface substrates. The properties of a SAM (thickness, structure, surface energy, stability) can be easily controlled, and specific functionalities can also be introduced into the building blocks. For instance, SAMs of thiols on gold and triethoxysilanes on silicon dioxide (SiO_2) have been exploited (*6, 8, 16–18*) to provide the surfaces not only with active groups that interact with specific moieties of the protein to be immobilized, but also with protein-resistant groups such as poly(ethylene glycol) (PEG).

Proteins have been immobilized onto these surfaces by either adsorption of the proteins (*8*), molecular recognition between the proteins and immobilized ligands (*19*), or covalent coupling to the SAM surface (*16, 17*). The most common conjugation methods rely on the covalent attachment of proteins to "static" (*20*) surfaces chemically modified with different protein-reactive groups, including activated esters (*16*), aldehydes (*21*), or maleimides (*22–24*). On the other hand, strategies for "turning-on" protein reactive groups at SAM surfaces by an "on demand" surface reaction using an external stimulus have great potential as versatile platforms for protein immobilization. Similar strategies have been employed to immobilize urease onto a polymer film (*25*), as well as other biomolecules, such as DNA (*26*) and peptides (*27, 28*) on SAM surfaces, yet protein immobilization onto a SAM using this "on demand" surface reaction approach has not been previously demonstrated.

Here, we report an approach to control protein immobilization on surfaces based on SAMs that can switch from bio-inert to bioactive states in response to an applied electrical potential. The approach we have developed is based on an electrochemical reaction in which aromatic nitro (NO_2) groups, self-assembled on gold surfaces, can be chemically modified by a redox process to amino (NH_2) groups, which can then be used to orchestrate the immobilization of the proteins. Our strategy involves (Figure 1) five steps: (1) functionalization of the electrically addressable gold surfaces with NO_2-terminated SAMs; (2) spatially selective electrochemical reduction (*26, 29–31*) of the NO_2 groups

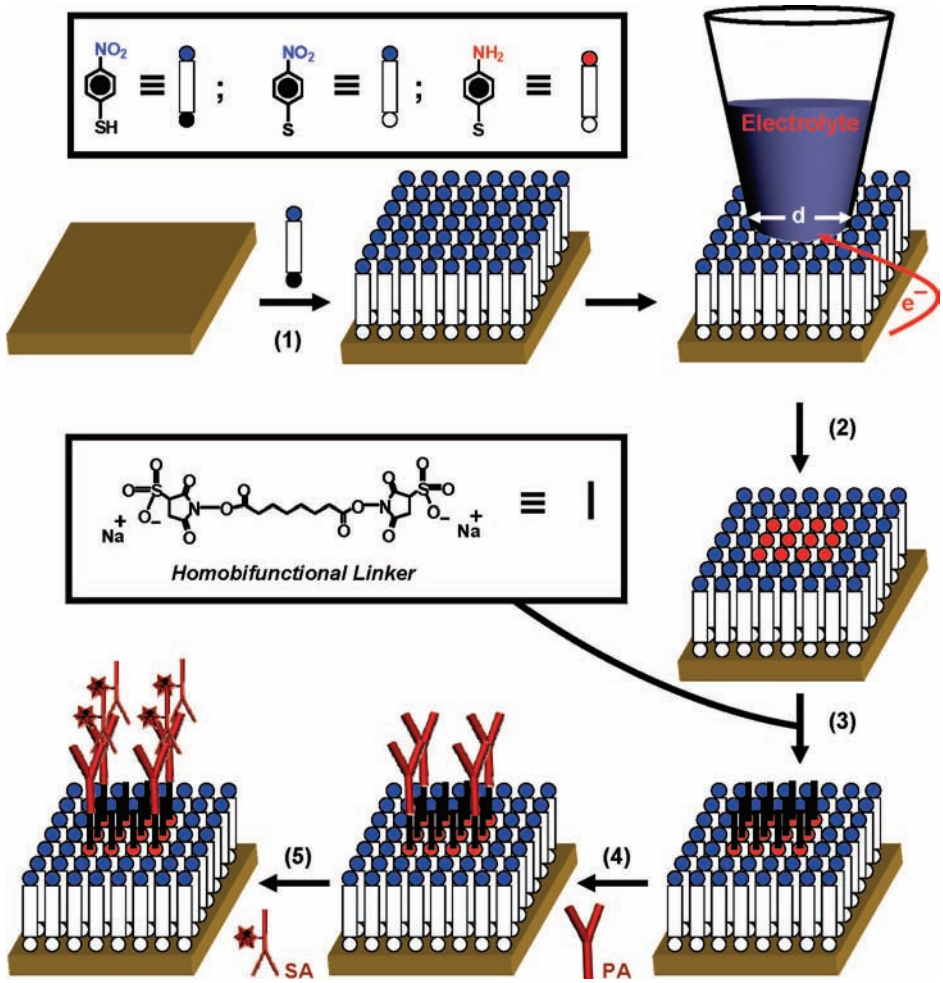

Figure 1. Schematic illustration of the electrochemical conversion from a NO_2 group in the SAMs of 4-nitrothiophenol on an Au electrode to an NH_2 group, which is capable of subsequently inducing the immobilization of primary antibodies, PA (red). Bound primary antibodies are detected using fluorescently labeled secondary antibodies, SA (red). The electrochemical reduction is conducted selectively on the Au electrode area exposed to the electrolyte (diameter (d) = 8 mm).

to primary NH_2 groups; (3) selective reaction of the resulting NH_2-terminated monolayers with a homobifunctional linker; (4) covalent immobilization of primary antibodies; (5) visualization of these bound primary antibodies using fluorescently labeled secondary antibodies. Fluorescence microscopy and surface plasmon resonance (SPR) spectroscopy were employed to characterize the immobilization of antibodies and their selective assembly to the modified areas of the SAM.

EXPERIMENTAL PROCEDURES

SAM Preparation. Substrates with 30 nm thick Au employing a 10 nm thick Ti adhesion layer on an n-type Si wafer were fabricated by electron-beam evaporation. The Au substrates were cleaned with piranha solution (3:1, H_2SO_4/30% H_2O_2), rinsed with ultra high purity (UHP) H_2O (resistivity = 18 MΩ cm) and then HPLC-grade EtOH thoroughly for 1 min. (*Caution: Piranha solution reacts violently with all organic compounds and should be handled with care*). Subsequently, the substrates were immersed in a 0.1 mM ethanolic solution of 4-nitrothiophenol (Sigma-Aldrich) for 12 h to form the SAMs on the Au surfaces. The substrates were rinsed with EtOH and UHP H_2O.

Electrochemical Conversion. The cyclic voltammograms (CVs) of the NO_2-terminated SAMs and their conversion on the Au electrodes were performed using a Princeton Applied Research VMP multichannel potentiostat with a custom-designed Teflon cell, equipped with the functionalized Au substrate as the working electrode, a Pt wire as the counter electrode, and the standard calomel electrode (SCE) as the reference electrode. The planar gold working electrode exposes a circular geometric area of 50 mm^2 to the electrolyte solution. Cyclic voltammetry was carried out at a scan rate of 200 mV/s.

Protein Immobilization. The pristine 4-nitrothiophenol and converted 4-nitrothiophenol SAMs were incubated with a 5 mg/mL solution of bis(sulfosuccinimidyl)suberate (BS^3; Pierce) in phosphate buffered saline pH 7.4 (PBS) for 20 min at room temperature. Samples were rinsed with PBS (~1 min) and incubated with a primary mouse anti-human vascular endothelial growth factor (VEGF) antibody (Biosource) with a concentration of 25 μg/mL in PBS containing 0.1% Triton X-100 (PBS–Triton) for 20 min. The samples were rinsed in PBS buffer solution for 10 min and incubated in the dark for 20 min in a 20 μg/mL PBS–Triton solution of Alexa Fluor 568 goat anti-mouse IgG antibody (Molecular Probes). The substrates were rinsed with PBS for 10 min and mounted for fluorescence microscopy. For the control samples, the pristine 4-nitrothiophenol and converted 4-nitrothiophenol SAMs were stained as described above, without first immobilizing the BS^3 homobifunctional linker.

X-ray Photoelectron Spectroscopy (XPS). XPS experiments were performed in an Omicron XPS/UPS system using a monochromatic Al K_α X-ray source (1486.6 eV) with a pass energy of 50 eV. Fitting of XPS peaks was performed using the *Avantage v2.2* processing software. All spectra were fitted using 30% Lorentzian/70% Gaussian peaks.

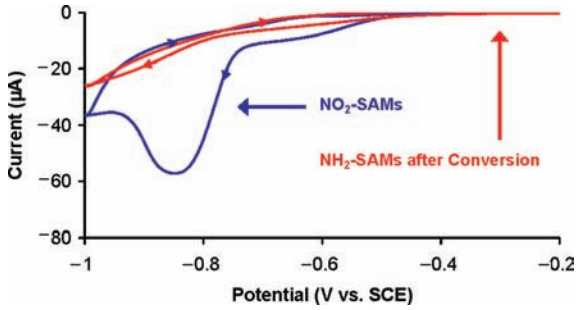

Figure 2. CV (blue curve) of a SAM of 4-nitrothiophenol—the reduction of NO_2 to NH_2 groups appears as a pronounced peak at around −0.85 V. CV (red curve) of the SAM of 4-nitrothiophenol after the reductive scan.

Fluorescence Microscopy. Fluorescence images were collected on a Zeiss Axiovert 200 fluorescent microscope, equipped with an AxioCam MRm monochrome camera. Pictures were acquired using AxioVision LE 4.1 with identical exposure parameters and analyzed using *Image J 1.33u* (NIH). No postexposure image processing was performed.

Surface Plasmon Resonance. SPR spectroscopy experiments were performed with a Biacore X at 25 °C at a flow rate of 2 μL/min. Two different monolayers—pristine 4-nitrothiophenol and converted 4-nitrothiophenol—were prepared on Biacore gold sensor chips. Prior to protein binding studies, 40 μL of a 5 mg/mL solution of the BS^3 homobifunctional linker in PBS, was injected into the gold sensor, followed by a PBS–Triton washing for 10 min. The functionalized gold surfaces (either pristine or converted) were subsequently exposed to a primary antibody by injection of 40 μL of anti-streptavidin produced in rabbit (Sigma) at a concentration of 1.4 mg/mL in PBS–Triton. The protein solution was replaced with the PBS–Triton solution for 25 min to remove any unbound primary antibody. Subsequently, a 40 μL sample of the secondary antibody, Alexa Fluor 488 goat anti-rabbit IgG (Molecular Probes), with a concentration of 20 μg/mL in PBS–Triton was injected, followed by a 10 min PBS–Triton washing.

RESULTS

Cyclic voltammetry (CV) was used to investigate the characteristics of the SAMs and for the chemical conversion ($NO_2 \rightarrow NH_2$) on the gold surfaces. The CV study of the NO_2-terminated SAMs was carried out in three subsequent CV scans. A 0.1 M KCl solution (9:1, EtOH/UHP H_2O) (*26*) was employed as the electrolyte to check the characteristic CV peak that the NO_2 group exhibits (blue curve in Figure 2) (*29*). Next, a second scan was carried out in a 0.1 M KCl aqueous solution to ensure (*29*) an adequate supply of H^+ ions for the complete electrochemical reduction of the NO_2 to NH_2 groups. Finally, the disappearance of the NO_2 group-related peak was observed by running a third scan (red curve in Figure 2) in a 0.1 M KCl solution (9:1, EtOH/UHP H_2O). The potential was swept from 0 to −1.0 V with respect to the SCE. The reductive peak of the NO_2 group was observed at −0.85 V (blue curve in Figure 2). By integrating the area under the reductive peak, the SAMs density was found to be 2.6×10^{14} molecule/cm^2. After the reduction of the NO_2 groups during the second scan, no redox activity was observed (red curve in Figure 2), implying complete conversion of the NO_2-terminated SAMs.

High-resolution XPS spectra were acquired on the gold electrodes before and after surface electrochemical modification. XPS measurements confirmed the conversion of the NO_2 groups (N(1s) binding energy = 405.6 eV; blue curve in Figure 3) to the NH_2 counterparts (N(1s) binding energy = 399.6 eV; red curve in Figure 3). XPS of the pristine 4-nitrothiophenol surfaces also indicated the presence of primary amines. This behavior can be attributed (*32*, *33*) to the gradual reduction of the NO_2 groups to NH_2 groups (Figure 3; blue curve) during X-ray irradiation initiated by the photoelectrons and secondary electrons emitted from the surface. However, in the electrochemically converted NO_2-terminated SAM, the XPS of the N(1s) binding energy region indicated only the presence of the NH_2 group with a strong peak at 399.6 eV.

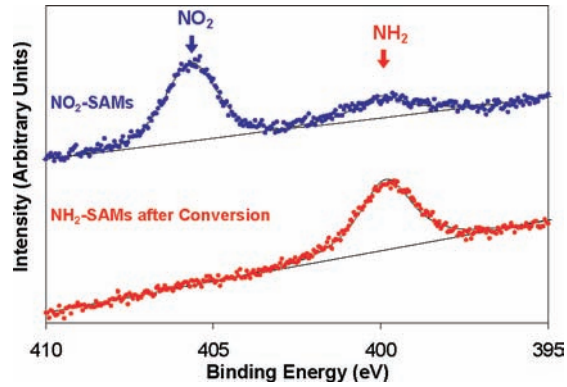

Figure 3. XPS spectra of the N(1s) peak region of a SAM of 4-nitrothiophenol before (blue curve) and after (red curve) the reductive scan. The binding energy of the N (1s) has been shifted by 6 eV, which is consistent with a reduction of NO_2 to NH_2 groups.

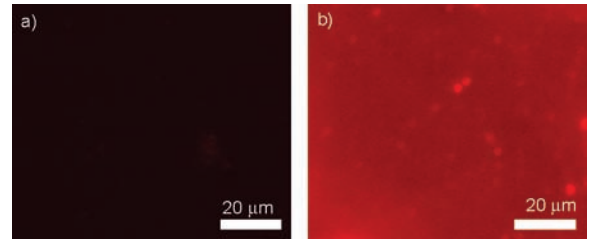

Figure 4. Fluorescence microscope images of a (a) nonconverted and (b) converted NO_2-terminated monolayer region after being sequentially exposed to BS^3, a primary antibody, and a red fluorescent Alexa Fluor 568 conjugated secondary antibody.

Following the XPS confirmation of the efficient electrochemical reduction, the viability of this strategy for the site-selective assembly of proteins on gold surfaces was demonstrated first by fluorescence microscopy. After performing electrochemical conversion on large-scale electrodes (converted area: 50 mm^2 on a 1 cm^2 gold surface area), the electrochemically generated NH_2 groups were activated with the BS^3 homobifunctional linkers to expose amine-reactive *N*-hydroxysulfosuccinimide (Sulfo-NHS) groups. Subsequently, the primary mouse anti-human VEGF antibody was allowed to react with the modified gold surface, followed by incubation with a red fluorescent secondary antibody. Detection of the binding of the primary antibodies to the electrochemically modified surfaces was evaluated by fluorescence microscopy. Figure 4a,4b illustrates the fluorescence microscope images collected from the NO_2- and NH_2-terminated regions of the surface, respectively. The fluorescence images of the regions terminated by the amino groups (Figure 4b) clearly revealed high fluorescence intensity, while the unmodified areas (NO_2 groups) showed minimal fluorescence. The signal-to-noise ratio (specific binding on NH_2-terminated regions/nonspecific binding on NO_2-terminated regions) was determined to be 26, a ratio which demonstrates the high degree of biological specificity to the NH_2 surface over the NO_2 surface.

Control experiments were also established to verify that the selective immobilization of proteins on the NH_2-terminated regions relied on the formation of amide bonds first between

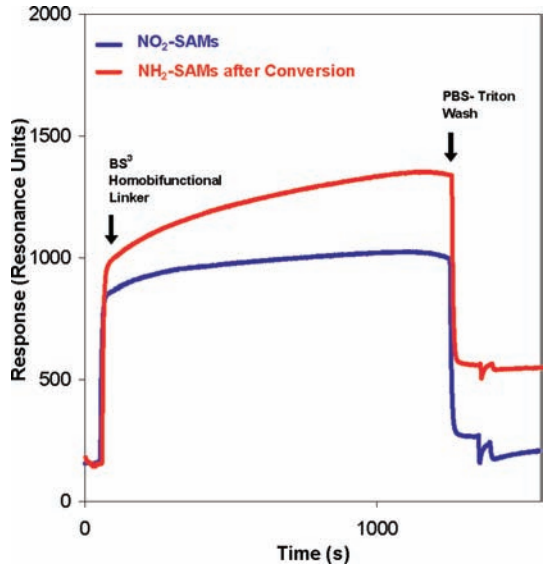

Figure 5. SPR sensorgram traces for the immobilization of BS^3 homobifunctional linker on a SAM of 4-nitrothiophenol (blue curve) and 4-nitrothiophenol after the reductive scan (red curve). SPR spectroscopy data show the selective immobilization of BS^3 to the converted NO_2-terminated monolayers.

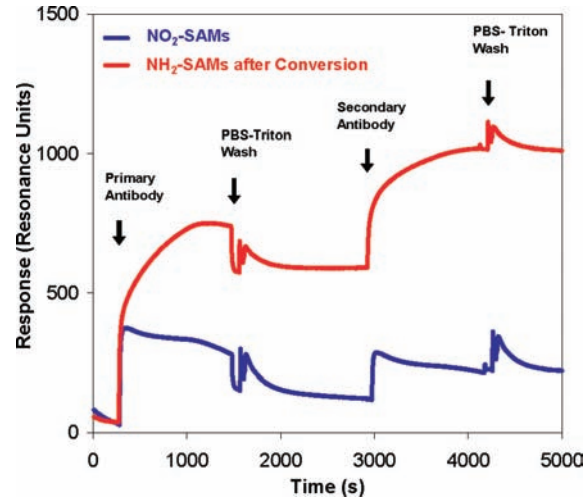

Figure 6. SPR sensorgram traces for the sequential immobilization of a primary antibody followed by a secondary antibody on a SAM of 4-nitrothiophenol (blue curve) and 4-nitrothiophenol after the reductive scan (red curve). The surfaces were washed with PBS–Triton after each protein injection. The antibodies show high binding affinity for converted NO_2-terminated monolayers, whereas negligible antibody adsorption is noted on nonconverted NO_2-terminated monolayers.

the BS^3 homobifunctional linker and the amino groups on the surface, and subsequently between the BS^3 homobifunctional linker and the primary amine groups in the primary antibody. For instance, in the absence of immobilization of the BS^3 homobifunctional linker on the nonconverted and converted NO_2-terminated monolayers, no protein immobilization occurred and no fluorescence was observed. Further evidence of the covalent immobilization of BS^3 on the NH_2 monolayers was obtained by surface plasmon resonance spectroscopy. Nonconverted and converted NO_2-terminated monolayers were exposed to a BS^3 linker solution and their immobilization monitored by SPR (Figure 5). BS^3 was shown to bind irreversibly to the converted NO_2-terminated monolayers, whereas no immobilization was observed for the NO_2-terminated monolayers.

A large SPR response was also observed upon introducing the primary rabbit anti-streptavidin antibody to the NH_2 monolayers activated with succinimidyl esters (Figure 6). When PBS buffer was passed through the system for approximately 30 min, essentially no protein desorbed from the converted monolayer surface. These data establish that the proteins are not nonspecifically adsorbed on the gold surface and thus are likely covalently attached to the surface via the BS^3 linker. These results contrasted with the negligible nonspecific protein binding on pristine NO_2-terminated monolayers, particularly after washing with PBS. Indeed, the protein surface coverage was determined (*34*) to be 56 ng/cm^2 for the NH_2 monolayer regions compared to 8 ng/cm^2 on the pristine NO_2 monolayer regions. The primary antibody immobilized on the NH_2 monolayers was subsequently recognized by the secondary antibody, leading to another sharp increase in the SPR response. After injection of the secondary antibody, the irreversible nature of the protein binding was confirmed by the steady SPR response, following PBS–Triton washing for 10 min. SPR spectroscopy showed that the irreversible immobilization of protein was specific for NH_2 monolayers, and that the pristine NO_2 monolayers effectively prevented unwanted nonspecific binding. This feature is particularly important for binding multiple proteins to a single substrate via the electrochemical activation described herein.

CONCLUDING REMARKS

The NO_2-terminated groups in the SAMs of 4-nitrothiophenol on gold surfaces can be reduced electrochemically and selectively to NH_2 groups by applying a negative voltage between the addressed electrode and its counter electrode in the presence of an electrolyte. By employing the homobifunctional activated ester linker, proteins can then be attached specifically to the NH_2 monolayer region. We have demonstrated that immobilized antibodies exhibit high affinity and selectivity for these NH_2 regions, after activation, as monitored by fluorescence microscopy and surface plasmon resonance spectroscopy. This strategy can potentially be extended to immobilize sequentially a series of different proteins onto selected gold nanoelectrodes by carrying out repeated cycles with the entirely aqueous solution-based, and hence biocompatible, electrochemical and protein immobilization processes. Efforts in this direction are underway.

Received June 25, 2007; Revised Manuscript Received August 25, 2007

In a search for an infarct avid tracer agent with improved properties, we have observed that bis-DTPA derivatives of pamoic acid have a high avidity for necrotic tissue. Here, we report the synthesis, radiolabeling, and preliminary evaluation in normal mice and rats with hepatic infarction of the ^{99m}Tc-tricarbonyl complexes of *N*,*N*′-bis(diethylenetriaminopentaacetato)-4,4′-methylene bis(2-hydroxy-3-naphthoic hydrazide) ($^{99m}Tc(CO)_3$-bis-DTPA-pamoate) and [*N*-(5-aminopentyl)pyridin-2-yl-methylamino]methylacetato-4,4′-methylene-2-hydroxy-3-napthalenecarboxamide-(2′-hydroxy-3′-naphthoic acid methyl ester) ($^{99m}Tc(CO)_3$-**12**). Radiolabeling with $^{99m}Tc(CO)_3^+$ was achieved with a radiochemical yield of over 95% for both tracer agents. In normal mice, the polar $^{99m}Tc(CO)_3$-bis-DTPA-pamoate was cleared from plasma via both the liver and the kidneys, while the more lipophilic $^{99m}Tc(CO)_3$-**12** was rapidly cleared via the liver. Blood clearance in mice was faster for $^{99m}Tc(CO)_3$-**12** (0.1% injected dose per gram at 4 h postinjection) than for $^{99m}Tc(CO)_3$-bis-DTPA-pamoate (9.3% injected dose per gram at 4 h postinjection). Affinity and specificity of the tracers for necrotic tissue was studied in rats with hepatic infarction and ethanol-induced necrosis of the liver or muscles. Activity ratios of infarct to viable liver tissue of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate quantified by autoradiography of tissue slices ranged from 4 to 18, depending on the necrosis model and time postinjection of the tracer. Infarcts were also visualized *in vivo* by $^{99m}Tc(CO)_3$-bis-DTPA-pamoate planar gamma imaging. After injection of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate, *in vivo* and *ex vivo* images correlated well with histochemical staining with triphenyltetrazolium chloride and hematoxylin and eosin. $^{99m}Tc(CO)_3$-**12** on the other hand showed no uptake in necrotic tissue. Stability of the tracers was determined *in vitro* after storage at room temperature and by histidine challenge experiments, and *in vivo* in mouse plasma and in urine (for $^{99m}Tc(CO)_3$-bis-DTPA-pamoate). $^{99m}Tc(CO)_3$-bis-DTPA-pamoate was unstable *in vitro* to histidine challenge, while $^{99m}Tc(CO)_3$-**12** was 98% stable *in vitro* in the same conditions. Both tracers showed good *in vivo* stability. $^{99m}Tc(CO)_3$-bis-DTPA-pamoate shows high specificity for necrotic tissue and merits further evaluation as a necrosis avid imaging agent. $^{99m}Tc(CO)_3$-**12** is not useful for visualization of necrotic tissue.

INTRODUCTION

Cell death occurs by two distinct mechanisms: a disorganized nonphysiologic mechanism called necrosis and a well-orchestrated physiologic mechanism termed apoptosis (*1*–*3*). Both forms of cell death have been implicated in many diseases, notably, acute myocardial infarction (AMI), even though it is not very certain which form of death is predominant in the case of AMI (*4, 5*). Therapies aimed at restoring reperfusion to the infarcted organ most often aggravate the injury by shifting the cell towards death by apoptosis (*4, 6, 7*).

Imaging of apoptosis has become a reality with the discovery that annexin-V binds specifically and with nanomolar affinity (K_d = 7 nM) to externalized phosphatidylserine (PS) (*8*–*11*). Targeting of necrosis in AMI has been challenging, given the fact that a multitude of compounds are suddenly released by the dying cells following disintegration of the sarcolemma. A few necrosis avid tracer agents have been in use in nuclear medicine with none having ideal imaging characteristics (*12*). Among these tracers, ^{99m}Tc-glucarate looks the most promising but presents two limitations to its potential clinical applications for imaging AMI (*13*): (1) it is rapidly washed out from the infarcted myocardium and (2) its localization is limited to the early hours of the acute event, thus limiting its potential usefulness to the acute phase of AMI.

In preliminary experiments, we have found that bis-gadolinium *N*,*N*′-bis(diethylenetriaminopentaacetato)-4,4′-methylene bis(2-hydroxy-3-naphthoic hydrazide (bisGd bis-DTPA-pamoate) specifically localizes in necrotic tissue in different animal models of necrosis (*14, 15*). Radiolabeled derivatives of this class of compounds could find more clinical applications in nuclear medicine, e.g., when radiolabeled with technetium-99m, which has almost ideal physical properties for planar and single photon emission computed tomography (SPECT). Classical labeling of diethylene triamine pentaacetate (DTPA) derivatized biomolecules with technetium-99m (^{99m}Tc), i.e., addition of ^{99m}Tc-pertechnetate in the presence of stannous ions, requires a rather large amount of DTPA (5–10 mg) and often results in compounds with rather low stability due to reoxidation of technetium to pertechnetate. Technetium-99m tricarbonyl labeling of biomolecules has the advantage of ease of preparation, efficient complex formation, and inertness of the complex due to the d^6 metal core (*16, 17*). Therefore, we have studied the synthesis and labeling of bis-DTPA pamoate with a $^{99m}Tc(CO)_3^+$ core (Figure 1A) and report here a preliminary evaluation of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate in rats with rep-

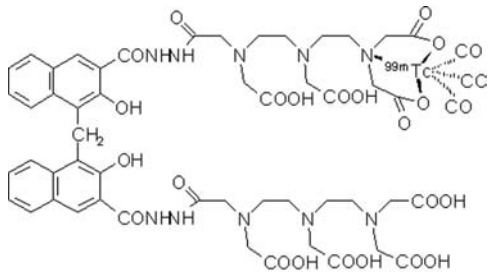

Figure 1. Proposed structures of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate (A) and $^{99m}Tc(CO)_3$-[*N*-(5-aminopentyl)pyridin-2-yl-methylamino]methyl-acetato-4,4′-methylene-2-hydroxy-3-napthalenecarboxamide-(2′-hydroxy-3′-naphthoic acid methyl ester) ($^{99m}Tc(CO)_3$-**12)** (B).

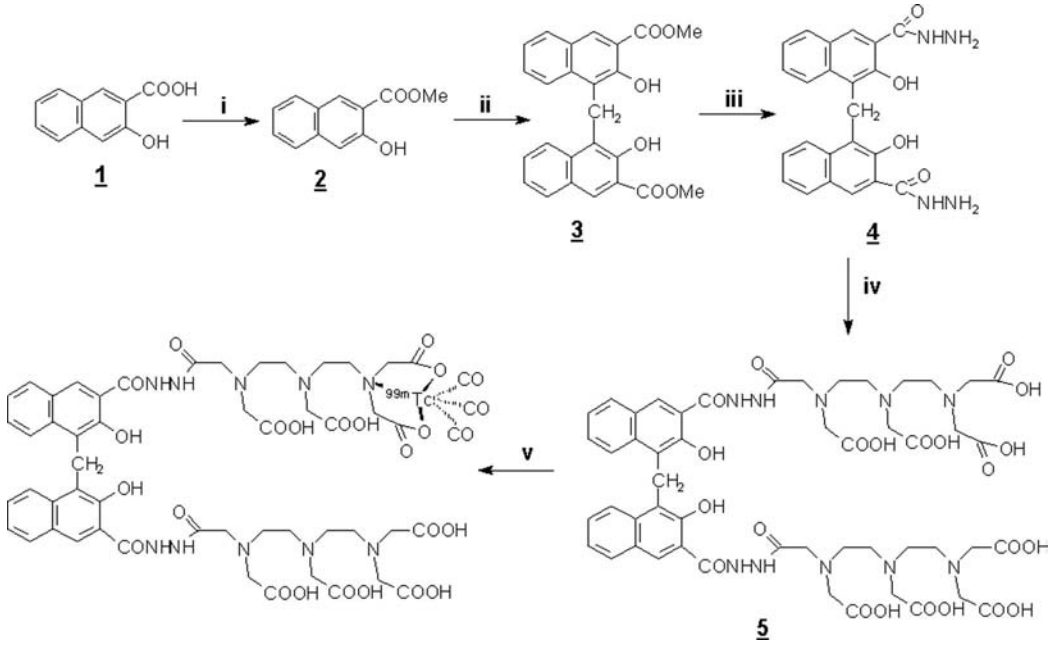
erfused hepatic infarction and ethanol-induced hepatic or muscular necrosis. Necrosis specificity was assessed *in vivo* by planar gamma scintigraphy and *ex vivo* by gamma counting and autoradiography and was compared to TTC and H&E staining techniques at different time points postinjection (p.i.). However, DTPA is not an ideal bifunctional chelating agent for labeling a bioactive compound with a ^{99m}Tc-tricarbonyl core. For this reason, we have derivatized pamoic acid also via a hydrazine spacer with [*N*-(5-aminopentyl)pyridyl-2-yl-amino] methyl acetate (*18*), which is considered an ideal bifunctional chelator for labeling biomolecules with $^{99m}Tc(CO)_3^+$ because of the relatively fast complexation and very high thermodynamic and kinetic stability of a $Tc(CO)_3$ complex with this tridentate system (*17*, *18*). The stability and biological characteristics of the resulting $^{99m}Tc(CO)_3^+$ complex named $^{99m}Tc(CO)_3$-**12** (Figure 1B) have been compared with those of $^{99m}Tc(CO)_3$-bis-DTPA pamoate.

EXPERIMENTAL PROCEDURE

Reagents. 2-Hydroxy-3-naphthoic acid, *N*-ethyldiisopropylamine, *N*,*N*′-dicyclohexylcarbodiimde, *N*-hydroxysuccinimide, N-Boc-1,5-diaminopentane, pyridine, and hydrazine monohydrate were obtained from Sigma Aldrich (Steinheim, Germany); paraformaldehyde and all solvents were obtained from Acros Organics (Geel, Belgium) and were used as purchased. Generator eluate containing $Na^{99m}TcO_4$ was obtained from an Ultratechnekow generator (Tyco Healthcare, Petten, The Netherlands). The Isolink kit used for preparing $^{99m}Tc(CO)_3^+$ was a generous gift from Tyco Healthcare.

Instruments and Methods. ^{1}H NMR spectra were acquired with a Gemini 300 MHz spectrometer (Varian, Palo Alto, CA, USA). Chemical shifts are reported in parts per million (ppm) relative to TMS ($\delta = 0$). Coupling constants are reported in hertz (Hz). Normal-phase column chromatography was performed using silica gel (silica 63–200, 60 Å, MP Biomedicals, Eschwege, Germany). Thin layer chromatography (TLC) was performed on normal-phase 0.2-mm-thick silica gel 60 plates with UV fluorescence (Macherey-Nagel, Düren, Germany), and spots were visualized with UV light (Spectroline, Westbury, NY). TLC plates were developed using one of the following mobile-phase systems: system A, EtOAc/MeOH 70/30 v/v; system B, CH_2Cl_2/hexane 50/50 v/v; system C, $CHCl_3$/hexane 5/95 v/v. High-pressure liquid chromatography (HPLC) analysis was performed on a LaChrom Elite HPLC system (Hitachi, Darmstadt, Germany) using an XTerra RPC_{18} column (5 μm, 4.6 mm $\times$ 250 mm; Waters, Milford, USA). The compounds were eluted from the column using mixtures of 0.05 M ammonium acetate buffer pH 6.8 (solvent A) and acetonitrile (solvent B): 0–8 min, linear gradient from 100% A to 60% A; 8–15 min, 60% A; 15–25 min, linear gradient to 100% B, at a flow rate of 1 mL/min over 30 min. The column effluent was monitored using a UV detector set at 254 nm, and the output signal was acquired on a Laura Lite system (Lablogic, Sheffield, UK). For analysis of radiolabeled compounds, the HPLC eluate was led over a 3 in NaI(Tl) scintillation detector connected to a single-channel analyzer. Radioactivity counting for biodistribution studies was done using an automated system with a gamma counter (3 in NaI(Tl) well crystal) coupled to a multichannel analyzer in a sample changer (Wallac, 1480 Wizard 3", Turku, Finland). The results were corrected for background radiation and physical decay during counting. Accurate mass measurement was performed by coinfusion with a 10 μg/mL solution of a reference as an internal calibration standard on a time-of-flight mass spectrometer (LCT, Micromass, Manchester, UK) equipped with an electrospray ionization (ESI) interface, operated in positive (ES+) or negative (ES−) mode. Samples were infused in acetonitrile/water using a Harvard 22 syringe pump (Harvard instruments, Massachusetts). Acquisition and processing of data was done using *Masslynx* software (Micromass, version 3.5).



All animal experiments were conducted with the approval of the institutional ethical committee for conduct of experiments on animals.

CHEMISTRY

2-Hydroxy-3-methylnaphthoate (2). To a solution of 2-hydroxy-3-naphthoic acid (19.2 g, 0.094 mol) in acetone (250 mL) was added K_2CO_3 (13 g, 0.1 mol), water (25 mL), and then with stirring over a period of 3.5 h a solution of dimethyl sulfate (11.1 mL, 0.12 mol). The solution was further stirred at room temperature (RT) until all starting material was esterified as judged by TLC (system C, ester (**2**) $R_f = 0.9$). Undissolved K_2CO_3 was filtered off and washed with acetone. The combined filtrates were evaporated *in vacuo* and the residue was dissolved in CH_2Cl_2 and dried over sodium sulfate. The filtrate was concentrated, methanol was added to the warm solution, and the precipitate was filtered off. The resulting yellow powder was purified using column chromatography on silica gel eluted with CH_2Cl_2. Yield 17.8 g (87%). Accurate mass $[C_{12}H_9O_3\text{-}H]^-$: theoretical 201.0557 Da, found 201.0559 Da. ^{1}H NMR ($CDCl_3$, 300 Hz) δ 8.46 (s, 1H, 11-CH), 7.78 (d, 1H, $^3J = 8.3$ Hz, 6-CH), 7.67 (d, 1H, $^3J = 8.4$ Hz, 9-CH), 7.48 (t, 1H, $^3J = 7.4$ Hz, 7-CH), 7.29 (t, 1H, $^3J = 9.1$ Hz, 8-CH), 4.0 (s, 3H, CH_3).

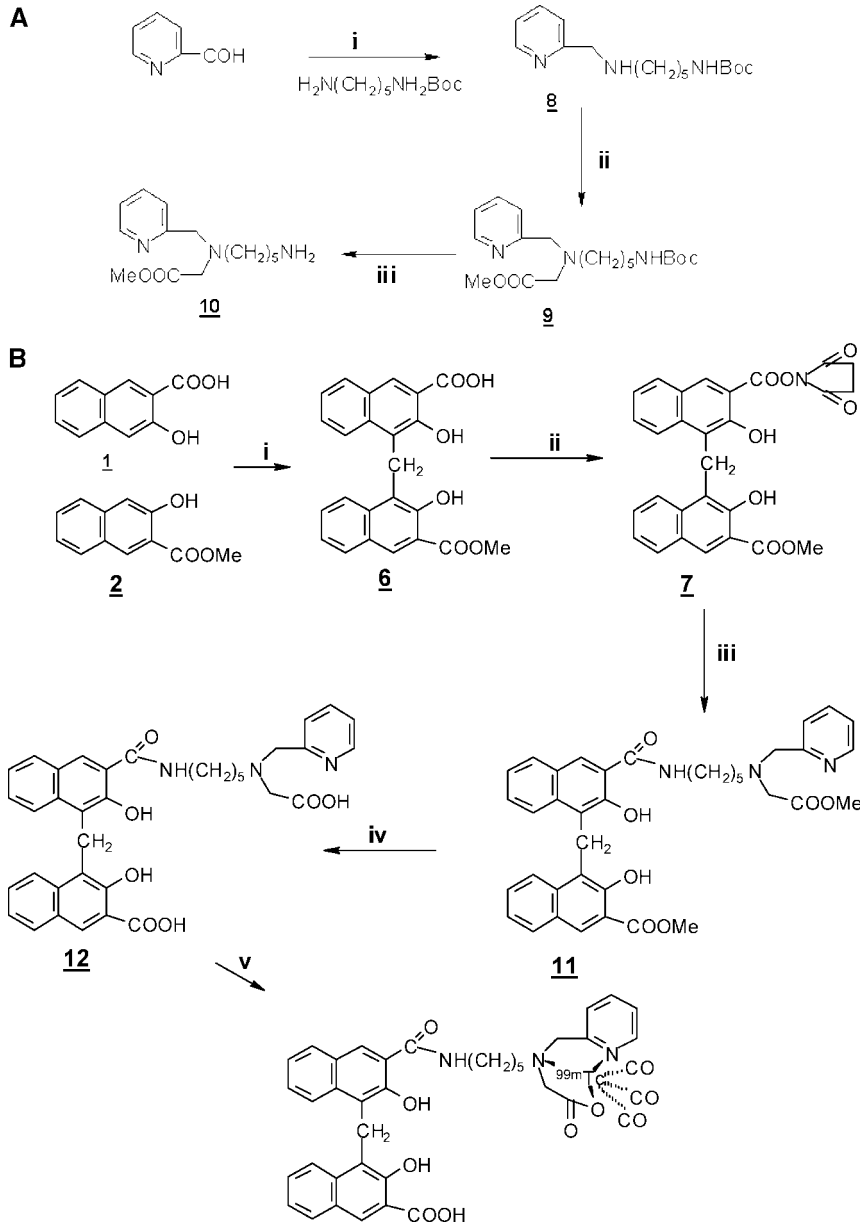
4,4′-Methylene-bis(2-hydroxy-3-methylnaphthoate) (Pamoic Acid Bis-Methyl Ester) (3). To a solution of compound **2** (10.1 g, 46 mmol) in a mixture of acetic acid (80 mL) and sulfuric acid (0.5 mL), paraformaldehyde (2 g, 66.6 mmol) was added, and the mixture was stirred overnight at RT. The yellow precipitate was collected and filtered off, washed with acetic acid and water, and dried. TLC: $R_f = 0.95$ (system C). Yield 9.46 g (97%). Accurate mass $[C_{25}H_{19}O_6\text{-}H]^-$: theoretical 415.1187 Da, found 415.1208 Da. ^{1}H NMR ($CDCl_3$, 300 Hz) δ 8.38.(s, 2H, 11,11′-CH), 8.23 (d, 2H, $^3J = 8.7$ Hz, 9,9′-CH), 7.67 (d, 2H, $^3J = 8.1$ Hz, 6,6′-CH), 7.35 (t, 2H, $^3J = 7.5$ Hz, 7,7′-CH), 7.18 (t, 2H, $^3J = 7.1$ Hz, 8,8′-CH), 4.95 (s, 2H, 4,4′-CH_2), 4.0 (s, 6H, 2 $\times$ CH_3).

Scheme 1[a]

[a] (i) $(CH_3)_2SO_4$, K_2CO_3, RT overnight; (ii) paraformaldehyde, CH_3COOH, H_2SO_4, RT; (iii) NH_2NH_2, reflux (80 °C), 2 h; (iv) DTPA monoanhydride monoethyl ester, DIEA, followed by hydrolysis (NaOH); (v) $^{99m}Tc(CO)_3^+$, pH 11, 70 °C, 20 min.

4,4′-Methylene-bis(2-hydroxy-3-naphthoic hydrazide) (4). A mixture of compound **3** (5.25 g, 12.6 mmol), pyridine (100 mL), methanol (50 mL), and hydrazine monohydrate (16 mL, 1.24 mol) was refluxed for 2 h. Solvents and excess hydrazine were removed azeotropically under reduced pressure with water. The suspension of the residue in methanol was stirred overnight. The hydrazide was collected by filtration and washed with methanol followed by drying over P_2O_5. Yield 5.05 g (97%). TLC: $R_f = 0$ (system B), $R_f = 0.6$ (system A). Accurate mass $[C_{23}H_{19}N_4O_4\text{-}H]^-$: theoretical 415.1412 Da, found 415.1451 Da. ^{1}H NMR (DMSO-d_6, 300 Hz) δ 10.62 (s, 2H, 2 × CONH), 8.38 (s, 2H, 11,11′-CH), 8.14 (d, 2H, $^3J = 8.6$ Hz, 9,9′-CH), 7.68 (d, 2H, $^3J = 8.0$ Hz, 6,6′-CH), 7.31 (t, 2H, $^3J = 7.4$ Hz, 7,7′-CH), 7.19 (t, 2H, $^3J = 7.1$ Hz, 8,8′-CH), 4.99 (s, 4H, NH_2), 4.78 (s, 2H, 4,4′-CH_2).

***N,N′*-Bis(diethylenetriamino pentaacetato)-4,4′-methylene Bis(2-hydroxy-3-naphthoic hydrazide) Sodium Salt (Bis-DTPA-Pamoate) (5).** To a stirred suspension of diethylenetriamine pentaacetic acid monoethyl ester monoanhydride (*15*) (3.4 g, 8.45 mmol) in dry DMF (50 mL), *N*,*N*-diisopropylethylamine (3.7 mL, 21 mmol) and compound **4** (1.5 g, 3.6 mmol) were added and the mixture was stirred at RT for 5 h. Solvents were evaporated under reduced pressure, the oily residue was dissolved in water, and the pH was adjusted to >12 using concentrated NaOH solution. After hydrolysis of the ethyl esters (as judged by HPLC), the volume was reduced at reduced pressure at 60 °C and the pH adjusted to 7.4 with 1 M HCl. The reaction product was purified by reversed-phase adsorption chromatography on silica C-18 stationary phase using a water–acetonitrile gradient. Fractions containing compound **5** were pooled, and the solvents were removed in vacuo. Methanol was added to induce precipitation of compound **5**, and the precipitate was collected by filtration and dried over P_2O_5. Accurate mass $[C_{51}H_{60}N_{10}O_{22}\text{-}2H]^{2-}/2$: theoretical 582.1947 Da, found 582.1916 Da. ^{1}H NMR (DMSO-d_6) δ 8.3 (d, 2H, Ar-H), 8.0 (d, 2H, Ar-H), 7.5 (m, 6H, Ar-H), 4.6 (s, 2H, methylene-H), 4.0 (t, 4H, 2 × CH_2), 2.9–3.4 (m, 36H, methylene of DTPA).



4,4′-Methylene-bis(2-hydroxy-3-naphthalene carboxylic acid) Monomethyl Ester (Pamoic Acid Monomethyl Ester) (6). To a solution of compound **1** (2-hydroxy-3-naphthoic acid, 2 g, 9.8 mmol) and **2** (2-hydroxy-3-methylnaphthoate, 2 g, 9.2 mmol) in a mixture of acetic acid (30 mL) and sulfuric acid (0.2 mL), paraformaldehyde (0.42 g, 14 mmol) was added and stirring was continued for 9 h at RT. The yellow precipitate was collected by filtration, washed successively with acetic acid and water, and dried. The precipitate was then dissolved in $CHCl_3$/hexane (1/3 v/v) and purified by column chromatography on silica gel eluted with a gradient from 100% hexane to 100% $CHCl_3$. The first fraction consisted of pamoic acid bis-methyl ester. Pamoic acid monomethyl ester (purity >80%) was eluted together with pamoic acid using $CHCl_3$/MeOH 95/5 v/v. Pure pamoic acid monomethyl ester was obtained by a second purification on silica gel eluted with $CHCl_3$/MeOH 95/5 v/v. The fractions containing pure pamoic acid monomethyl ester (>95%) were evaporated to give 1.55 g (41%) of a yellow powder. TLC: $R_f = 0.6$ (system A). Accurate mass $[C_{24}H_{17}O_6\text{-}H]^-$: theoretical 401.1031 Da, found 401.1058 Da. ^{1}H NMR (DMSO-d_6, 300 Hz), δ 11.23 (s, 1H, -COOH), 8.49 (s, 2H, 11,11′-CH), 8.12 (t, 2H, $^3J = 9.5$ Hz, 7,7′-CH), 7.9 (d, 2H, $^3J = 7.9$ Hz, 6,6′-CH), 7.43–7.36 (m, 2H, 9.9′-CH), 7.28–7.21 (m, 2H, 8,8′-CH), 4.9 (s, 2H, 4,4′-CH_2), 4.0 (s, 3H, CH_3).

Succinimidyl Pamoic Acid Monomethyl Ester (7). To a solution of compound **6** (0.5 g, 1.24 mmol) and *N*-hydroxysuccinimide (0.143 g, 1.25 mmol) in tetrahydrofuran (THF) (50 mL), dicyclohexylcarbodiimide (DCC, 0.25 g, 1.25 mmol, in 10 mL THF) was added dropwise at 0 °C. The reaction mixture was further stirred at RT overnight, after which it was filtered and washed with THF. The filtrate was evaporated to yield a yellow powder. Yield 85%. TLC: $R_f = 0.85$ (system A). Accurate mass $[C_{28}H_{20}NO_8\text{-}H]^-$: theoretical 498.1194 Da, found 498.1254 Da.

The bifunctional chelator (BFC) [*N*-(5-aminopentyl)pyridin-2-yl-methylamino]methyl acetate (**10**) was synthesized in three steps (**8**, **9**, **10**; Scheme 2A) as previously reported (*18*).

[*N*-(5-Aminopentyl)pyridin-2-yl-methylamino]methylacetato-4,4′-methylene-2-hydroxy-3-napthalenecarboxamide-(2′-hydroxy-3′-naphthoic acid methyl ester) (11). *N*,*N*′ Diisopropylethylamine (171 μL, 1 mmol) was added to a solution of compound **7** (0.32 g, 0.64 mmol) in a mixture dry THF-DMF (1/1 v/v, 20 mL), followed by the dropwise addition of a solution of compound **10** (0.2 g, 0.8 mmol) in dry THF-DMF (1/1 v/v)

Scheme 2[a]

[a] A. (i) (1) 0 °C; (2) $NaBH_4$, RT; (ii) bromomethyl acetate, TEA, RT; (iii) TFA. B. (i) Paraformaldehyde, CH_3COOH, H_2SO_4, RT; (ii) *N*-hydroxysuccinimide, DCC, RT; (iii) bifunctional chelator (**10**), DIEA, RT; (iv) 1 M NaOH; (v) $^{99m}Tc(CO)_3^+$, pH 7.4, 70 °C, 15 min.

under stirring at RT, and stirring was continued for 15 h. The solvents were evaporated and the crude product was purified by column chromatography on silica gel. Lipophilic impurities were washed off with ethyl acetate, and pure compound **11** was eluted with ethyl acetate–methanol (85/15 v/v). The solvents were evaporated to obtain the title compound as a viscous yellow oil (0.25 g, 60%). Its purity was verified by RP-HPLC on an XTerra C_{18} column (5 μm, 4.6 mm × 250 mm) using isocratic elution with acetonitrile–0.05 M NH_4OAc buffer (pH 6.8) (60/40 v/v) at a flow rate of 1 mL/min. The purity was >98%. TLC: $R_f = 0.8$ (system A). Accurate mass $[C_{38}H_{38}N_3O_7\text{-}H]^-$: theoretical 648.2715 Da, found 648.2661 Da. ^1H NMR ($CDCl_3$) δ 8.45 (1H, d, $^3J = 4.8$, 24-CH), 8.40 (s, 1H, 11′-CH), 8.3 (d, 1H, $^3J = 8.7$, 9′-CH), 8.2 (d, 1H, $^3J = 8.7$, 9-CH), 8.0 (s, 1H, 11-CH), 7.7 (d, 1H, $^3J = 8.1$, 6′-CH), 7.5 (d, 1H, $^3J = 8.2$, 6-CH), 7.4 (d, 2H, 21,23-CH), 7.38–7.28 (m, 2H, 7,7′-CH), 7.2–7.1 (m, 2H, 8,8′-CH), 4.9 (s, 2H, 4,4′-CH_2), 4.0 (s, 3H, -CH_3), 3.9 (s, 2H, 19-CH_2), 3.7 (s, 3H, -CH_3), 3.5 (m, 2H, 12-CH), 3.4 (s, 2H, 18-CH_2), 2.7 (t, 2H, 16-CH_2), 1.3 (m, 6H, 13,14,15-CH_2).

[*N*-(5-Aminopentyl)pyridin-2-yl-methylamino]acetato-4,4′-methylene-2-hydroxy-3-napthalenecarboxamide-(2′-hydroxy-3′-naphthoic acid) (12). To a solution of compound **11** (0.1 g, 0.15 mmol) in acetonitrile (10 mL) 1 M NaOH (10 mL) was added. The mixture was stirred at RT for 1 h after which the solution was neutralized with 1 M HCl. The solvents were evaporated, and the crude product was purified using column chromatography on silica gel eluted with ethyl acetate–methanol (70/30 v/v). TLC: $R_f = 0.1$ (system A). Accurate mass $[C_{36}H_{34}N_3O_7\text{-}H]^-$: theoretical 620.2402 Da, found 620.2393 Da.

RADIOCHEMISTRY

$^{99m}Tc(CO)_3(H_2O)_3^+$ Precursor. The technetium-99m tricarbonyl precursor was prepared using an Isolink kit (*19*) by adding 1.1–2.5 GBq of $Na^{99m}TcO_4$ in 1 mL saline to the kit followed by heating at 100 °C for 20 min. After cooling, the pH was adjusted as desired with 1 M HCl. Alternatively, homemade $^{99m}Tc(CO)_3(H_2O)_3^+$ was prepared by bubbling CO gas through a 10 mL sealed vial containing Na_2CO_3 (4.5 mg), Na/K tartrate

(20 mg), and $NaBH_4$ (25 mg) and adding 1.1–2.5 GBq of $Na^{99m}TcO_4$ in 1 mL saline followed by heating at 100 °C for 20 min. The vial was cooled to RT followed by neutralization with 1 M HCl. The precursor solution was then adjusted to the desired pH with 1 M NaOH before use. The yield of the precursor was 99% using the Isolink kit and 90% using the homemade method.

^{99m}Tc(CO)$_3$-bis-DTPA-pamoate. To a 10 mL labeling vial was added 1 mg of bis-DTPA pamoate (**5**) dissolved in 0.2 mL of 0.5 M phosphate buffer pH 11. The vial was purged with nitrogen, and 0.2–1.1 GBq of $^{99m}Tc(CO)_3(H_2O)_3^+$ precursor (0.2–0.5 mL, pH 11) was added. The final pH of the labeling mixture was 11. The mixture was heated at 70 °C for 20 min followed by cooling to RT. The crude labeling reaction mixture was analyzed and purified by RP-HPLC as described above. As the radiolabeled compound was not separated from the ligand bis-DTPA pamoate (**5**) by the HPLC purification, the specific activity of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate was rather low (1 GBq/μmol) if the nonradioactive precursor was taken into account.

^{99m}Tc(CO)$_3$-12. To a 10 mL labeling vial containing 0.5 mg of compound **11** dissolved in 0.5 M phosphate buffer pH 7.4 under nitrogen was added 0.2–1.1 GBq $^{99m}Tc(CO)_3(H_2O)_3^+$ (0.2–0.5 mL, pH 7). The mixture was heated at 70 °C for 15 min followed by cooling and HPLC purification. In this case, the radiolabeled compound was well-separated from the ligand **12** by the HPLC purification; so the specific activity of $^{99m}Tc(CO)_3$-**12** was identical to that of the ^{99m}Tc-pertechnetate eluate, i.e., about 19 350 GBq/μmol.

Octanol/Buffer Partition Coefficient Determination. To 50 μL (74 kBq) of a solution of HPLC-purified radiolabeled compound in a test vial was added 2 mL of 1-octanol and 2 mL of 0.025 M phosphate buffer pH 7.4. The vial was vortexed at room temperature for 2 min and then centrifuged (Centrifuge 4226, Analis, Gent, Belgium) at 1700 g for 10 min. Approximately 50 μL of the 1-octanol phase and 500 μL of the phosphate buffer phase were pipetted and weighed into separate tared test tubes with adequate care to avoid cross contamination between the phases. The volume of fluid pipetted was calculated by dividing the net weight of the fluid by its density. The radioactivity of the test tubes was counted using a 3 in NaI(Tl) scintillation detector mounted in a sample changer. Corrections were made for background radiation and physical decay during counting. The octanol/buffer partition coefficient P was calculated as $P =$ cpm/mL in octanol / cpm/mL in buffer where cpm = counts per min.

***In Vitro* and *in Vivo* Stability of Tracers.** *In vitro* stability of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate and $^{99m}Tc(CO)_3$-**12** at RT was studied by HPLC analysis of the HPLC-purified tracers over a 24 h period and by histidine challenge experiments. 200 μL aliquots (90 MBq) of solutions of the HPLC-purified ^{99m}Tc complexes were incubated with 0.5 mL of a 0.02 M solution of histidine at 37 °C, and the mixtures were analyzed over a 24 h period by RP-HPLC.

In vivo stability of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate was studied in normal mice by determination of the relative amounts of the parent tracer and metabolites in mouse plasma and urine, while *in vivo* stability of $^{99m}Tc(CO)_3$-**12** was only evaluated in mouse plasma since renal excretion was minimal. After tail vein injection of 2.6 MBq of the tracer into mice, the animals were sacrificed by decapitation at 30 min, 4 h, or 24 h postinjection (one mouse per time point). For urine analysis, urine samples were directly injected onto an Oasis HLB column (hydrophilic–lipophilic balanced; 4.6 mm × 20 mm, Waters) in series with a RP-HPLC column (XTerra RPC_{18}, 5 μm, 4.6 mm × 250 mm; Waters, Milford, USA). Blood was collected into a BD vacutainer (containing 7.2 mg K_2EDTA; Beckton Dickinson, Franklin Lakes, USA) and subsequently transferred to a 1.5 mL Eppendorf tube. The blood samples were then centrifuged at 3000 rpm (1837 g) for 5 min to separate plasma. The supernatant plasma sample was injected onto an Oasis column that was preconditioned by successive washings with acetonitrile and water. The proteins of the biological matrix were washed from the Oasis column with 6 mL of water, which was collected in 6 1-mL fractions. The outlet of the Oasis column was then connected to an analytical RP-HPLC column, and both columns in series were then eluted using slightly modified HPLC conditions as compared to the analysis of the intact tracers [0.05 M ammonium acetate buffer (pH 6.8) (solvent A) and acetonitrile (solvent B): 0–8 min, linear gradient from 100% A to 50% A; 8–15 min, 50% A; 15–25 min, linear gradient to 100% B, at a flow rate of 1 mL/min over 30 min]. The HPLC eluate was collected in 35 1-mL fractions, and their radioactivity was measured using a gamma counter.

Biodistribution in Normal Mice. Mice were anesthetized with isoflurane (2%) in oxygen at a flow rate of 1 L/min and then injected via a tail vein with 74 kBq of either $^{99m}Tc(CO)_3$-bis-DTPA-pamoate in 0.1 mL of saline or $^{99m}Tc(CO)_3$-**12** in 0.1 mL of water/poly(ethylene glycol) 400 (PEG 400) 80/20 v/v. They were sacrificed by decapitation under anesthesia at 30 min, 4 h, or 24 h p.i. ($n = 4$ mice per time point). The organs were dissected and weighed in tared tubes, and radioactivity in all organs was counted in a gamma counter. Corrections were made for background radiation and physical decay during counting. Activity in the organs was expressed as % injected dose (I.D.)/organ and % I.D./g of organ. Activity in blood was calculated on the assumption that blood constitutes 7% of total body weight.

Rat Model of Reperfused Hepatic Infarction. Six adult Wistar rats weighing 350–450 g were anesthetized with i.p. injection of pentobarbital at a dose of 40 mg/kg. Under laparotomy, reperfused hepatic infarction was induced by clamping of the hilum of the right liver lobe for 3 h. After reperfusion by declamping hepatic inflow, the abdominal cavity was closed with two layered sutures, and the animals were allowed to recover for at least 8 h (*20*). A solution containing 18.5–74 MBq of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate in 0.5 mL saline was injected via a tail vein, and the rats were sacrificed under anesthesia at 4 h ($n = 3$) or 24 h ($n = 3$) postinjection, followed by *ex vivo* studies.

Rat model of ethanol induced liver or muscular necrosis. Eight adult Wistar rats (body weight 350–450 g) were anesthetized as described above. Under laparotomy necrosis of the liver was induced by slow infusion of 0.2 mL ethanol into the left liver lobe (*21*). The abdominal cavity was closed and the animals were allowed to recover for 8–12 h. A solution containing 18.5–74 MBq of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate or $^{99m}Tc(CO)_3$-**12** in 0.5 mL water/PEG 400 80/20 V/V was injected via a tail vein and the rats were sacrificed under anesthesia at 4 h postinjection ($n = 4$ per tracer) followed by *ex vivo* studies.

Under anesthesia, muscular necrosis was induced in four adult Wistar rats by gradual infusion of 0.2 mL ethanol into the right hind limb. The left hind limb was injected with saline and served as control. The animals were injected via a tail vein with 18.5–74 MBq of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate in 0.5 mL saline and then sacrificed under anesthesia at 5.5 h p.i.. The muscles from the treated and control limbs were then subjected to *ex vivo* studies.

***Ex Vivo* Evaluation of Tracer Uptake.** For *ex vivo* studies, the necrotic tissues (liver and muscle) and healthy control tissues were thoroughly washed with saline (4 °C) to remove blood pool activity. The tissues were then stained separately in TTC solution (1% solution in normal saline) at 37 °C for

Table 1. Biodistribution in Normal Mice ($n \geq 3$ per time point) and in Rats with Reperfused Hepatic Infarction ($n = 3$ per time point) of $^{99m}Tc(CO_3)$-bis-DTPA-Pamoate[a]

15 min. Guided by TTC, the necrotic and viable tissue areas were identified, separated, and weighed; and radioactivity in the tissues was immediately counted in a 3 in NaI(Tl) scintillation detector mounted in a sample changer (Wallac Wizard). Corrections were made for background radiation and physical decay during counting, and activity was expressed as % I.D./g tissue. Digital photographs were taken prior to and after staining. The tissues were then quickly frozen in isopentane–liquid nitrogen and cut with a cryotome (Microm HM 550, Walldorf, Germany) into 5–50-μm-thick serial sections mounted on slides. Autoradiograms were obtained from these sections by exposing the slides for 2 days to a high-performance phosphor screen (super resolution screen; Canberra-Packard, Meriden, CT). The images were analyzed with *Optiquant* software (Canberra-Packard), and the radioactivity concentration in the autoradiograms was expressed in digital light units (DLU)/mm^2. Relative tracer concentrations in the necrotic and viable sections of the tissues were estimated by regions of interest (ROIs) analysis of the necrotic and the viable regions of 30 and 50-μm-thick sections of the autoradiograms of all the slices. After exposure for autoradiography, the samples were stained with H&E using a conventional procedure. The stained slices were digitally photographed and contrast enhanced with *Image J* software (NIH, Bethesda, MD). The H&E stained slices were used to examine microscopic evidence of tissue necrosis.

***In Vivo* Detection of Hepatic Infarction by $^{99m}Tc(CO)_3$-bis-DTPA-pamoate Planar Scintigraphy.** Three additional rats with reperfused hepatic infarction and two control rats were used to explore the feasibility of *in vivo* detection of necrosis by $^{99m}Tc(CO)_3$-bis-DTPA-pamoate planar gamma scintigraphy. Rats with reperfused hepatic infarction and a control rat were injected with 53 or 85 MBq of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate followed by 20 min planar imaging at 7 or 23 h p.i. using a parallel hole collimator of a dual-head gamma camera (E-Cam, Siemens Medical Systems, Hoffman Estates, IL) equipped with a pinhole and a parallel hole collimator. Planar imaging was immediately followed by a computed tomography scan (CT, Biograph16, Siemens, Knoxville, TN) for anatomical delineation of the liver.

RESULTS AND DISCUSSION

Chemistry. Bis-DTPA-pamoate (**5**) was synthesized as shown in Scheme 1. Compound **2** was synthesized using dimethyl sulfate in high yield. Coupling of DTPA through one of the terminal carboxylates to pamoic acid bis-hydrazide was realized in good yield using DTPA monoanhydride monoethyl ester (yield 75%). All compounds were characterized by ^{1}H NMR (recorded at 300 Hz).

[*N*-(5-Aminopentyl)pyridin-2-yl-methylamino]acetato-4,4′-methylene-2-hydroxy-3-napthalenecarboxamide-(2′-hydroxy-3′-naphthoic acid) (**12**) was synthesized as shown in Scheme 2B. Synthesis of compound **11** started from pamoic acid monomethyl ester followed by activation of the second carboxylic acid using *N*-hydroxysuccinimide in the presence of DCC as an *in situ* dehydration reagent with a yield of 60%. Ester hydrolysis of compound **11** with 1 M NaOH provided compound **12** with a yield of 85% (HPLC analysis). Labeling of crude **12** or HPLC-purified **12** resulted in similar labeling yields. In all cases, intermediate and final products were purified on normal-phase or reversed-phase silica gel and the purity verified by RP-HPLC to be >95%.

Radiochemistry. Labeling of bis-DTPA-pamoate with a $^{99m}Tc(CO)_3$ core at pH 11 resulted in a main peak (retention time $t_R = 13.5$ min, 1 GBq/μmol) and a slightly more polar peak. The low specific activity of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate resulted from a partial coelution of the unlabeled precursor (bis-DTPA-pamoate) with the labeled compound. However, experience from experiments with Gd-labeled pamoate derivatives for MRI, where milligram amounts are used, and from experiments with derivatives of hypericin, both with low and high specific activity, has shown that specific activity

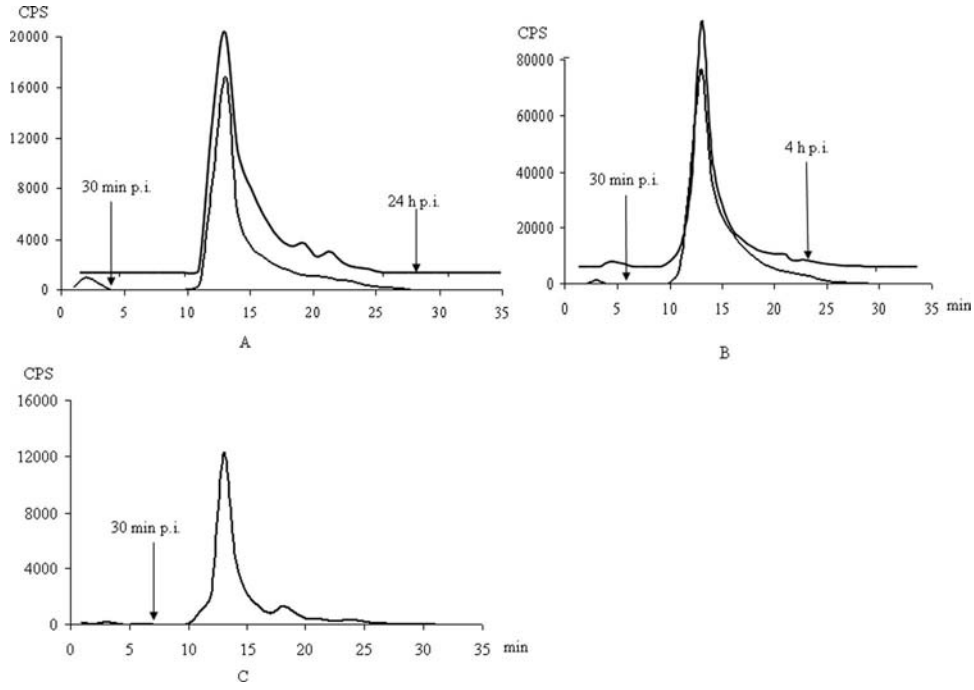

Figure 2. RP-HPLC analysis of mouse plasma (A) and urine (B) after intravenous injection of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate at 30 min p.i. and 24 h p.i. (C) RP-HPLC analysis of mouse plasma after intravenous injection of $^{99m}Tc(CO)_3$-**12** (B) at 30 min p.i.

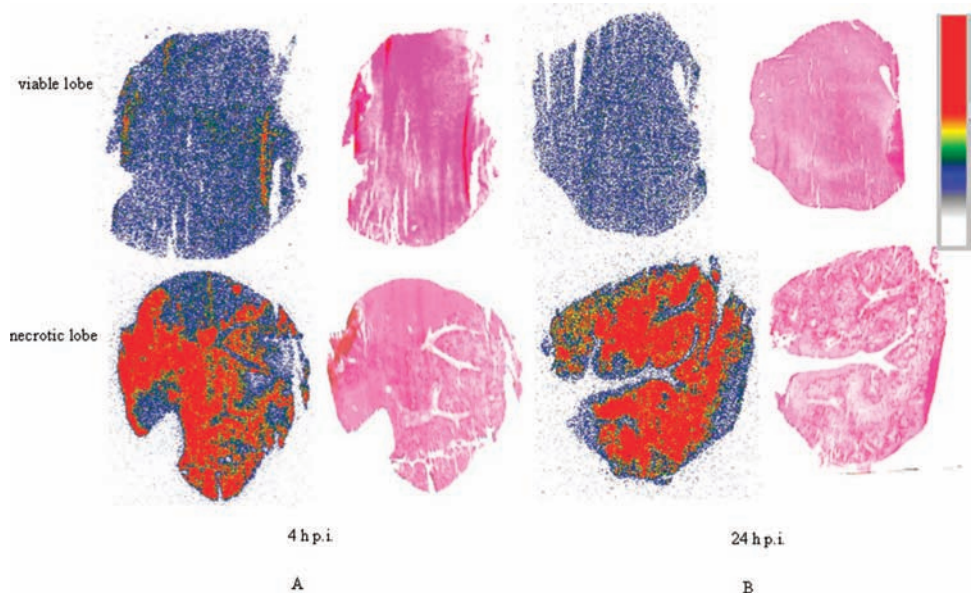

Figure 3. (A) Representative autoradiograms (first and third columns) and corresponding H&E stained sections (second and fourth columns) of 30 μm slices of rat liver with reperfused hepatic infarction. Viable liver lobe (upper row) and necrotic liver lobe (bottom row) at 4 h postinjection of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate and (B) at 24 h postinjection.

is not important with respect to the ability of these agents to localize to a high and sufficient degree in necrotic tissue. A number of isomers could arise from $^{99m}Tc(CO)_3$ labeling of such a bis-DTPA-derivatized compound, including binding of the $^{99m}Tc(CO)_3$ core between the two DTPA ligands or coordination via two amino nitrogens and a carboxylic oxygen, or via three amino nitrogen atoms besides binding in the way suggested in Figure 1A. The main peak containing 95% of the activity was used for the biological evaluation and is thought to consist of a $^{99m}Tc(CO)_3$ core bonded to two carboxylic oxygens and one amino nitrogen of one of the DTPA chains (Figure 1) analogous to the binding of a $^{99m}Tc(CO)_3$ core to iminodiacetic acid (*22*). The structure for the $^{99m}Tc(CO)_3$-DTPA moiety as presented in Figure 1 has also been proposed by a number of other authors (*23*, *24*).

Labeling of compound **12** with technetium-99m tricarbonyl was achieved in very good yield (97%) by heating a buffered solution (pH 7.4) of the precursor and the ^{99m}Tc-tricarbonyl precursor at 70 °C for 15 min. After efficient HPLC purification, a specific activity of about 19 350 GBq/μmol was obtained. Facile labeling of compound **12** is the result of stabilization by π-electrons of the aromatic nitrogen and d^6 electrons of the Tc-metal core (*18*). We also labeled the BFC (**10**) as a reference (HPLC t_R = 12.6 min vs 23.5 min for $^{99m}Tc(CO)_3$-**12**).

Octanol/Phosphate Buffer Partition Coefficient. The log *P* values (±SD) were found to be −1.93 (±0.03) and 2.85

(±0.13) for $^{99m}Tc(CO)_3$-bis-DTPA-pamoate and $^{99m}Tc(CO)_3$-**12,** respectively. Carboxylic acid functions not participating in complex formation account for the hydrophilic nature of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate, but the hydrophilic character may be different in an *in vivo* situation, where there is a possibility of complexation with Ca^{2+} ions in blood, leading to increased lipophilicity and potential retention.

Biodistribution and Stability (*in Vitro* and *in Vivo*) of Tracers. Biodistribution results for $^{99m}Tc(CO)_3$-bis-DTPA-pamoate in normal NMRI mice and in rats with reperfused liver infarction are shown in Table 1 with the results expressed as % injected dose (% I.D.)/g tissue (±SD), except for urine and intestines, where the radioactivity is expressed as % I.D./tissue in view of the variable amount of urine produced and food intake. In normal mice, the tracer was cleared mainly via the kidneys resulting in urine activity of 15.9%, 18.4%, and 34.6% I.D. at 30 min, 4 h, and 24 h p.i., respectively. There was also a significant clearance via the hepatobiliary system resulting in high activity in intestines and feces. Plasma clearance was slow with 6.4% I.D. remaining in blood at 24 h p.i.. Radioactivity in mice carcass was 28.6% and 17.1% I.D. at 30 min p.i. and 24 h p.i., respectively. The reason for the slightly higher carcass activity can be attributed to the slow blood clearance and retention of tracer in muscles. As expected, there was negligible brain uptake of the tracer.

Guided by TTC staining, the necrotic lobes of rats with reperfused liver infarction (TTC negative) were separated from the viable lobes (TTC positive). $^{99m}Tc(CO)_3$-bis-DTPA-pamoate showed higher uptake in liver with reperfused infarction than in normal liver at 4 h and 24 h p.i. At 4 h p.i., the radioactivity concentration was 1.7 times higher in necrotic liver tissue than in normal liver, and this ratio increased to 3.5 at 24 h p.i. Apart from this, biodistribution in rats was similar to that in mice. In rats with ethanol-induced liver necrosis, radioactivity per gram tissue at 4 h p.i. was 1.3 times higher in necrotic liver tissue as compared to normal liver (biodistribution data not shown). The actual ratio was higher, as it appeared impossible to dissect purely necrotic tissue, which always was mixed with some healthy tissue. Therefore, uptake in different areas was more accurately quantified by autoradiography.

Biodistribution results of $^{99m}Tc(CO)_3$-**12** in normal mice are shown in Table 2. The tracer agent showed more rapid clearance from the blood circulation than the more polar $^{99m}Tc(CO)_3$-bis-DTPA-pamoate. Activity of $^{99m}Tc(CO)_3$-**12** in blood was 0.6% and 0.2% I.D at 30 min and 4 h p.i., respectively. The tracer was cleared mainly via the hepatobiliary pathway, resulting in high radioactivity in intestines and feces. Uptake in carcass was negligible at 30 min and 4 h p.i.. Surprisingly, $^{99m}Tc(CO)_3$-**12** did not show any preferential uptake in the necrotic cells in rat studies, both by activity counting (necrotic to viable tissue radioactivity ratio was 0.9 at 4 h p.i.) and by autoradiography (results not shown).

The very high lipophilicity of $^{99m}Tc(CO)_3$-**12** is without doubt the reason for its prominent and fast clearance via liver and intestines and can explain why it is cleared more rapidly from plasma than $^{99m}Tc(CO)_3$-bis-DTPA-pamoate. At this moment, however, no further conclusions can be drawn with respect to a potential relationship between the observed lipophilicity of the complexes and the uptake in necrotic tissue. Both hydrophilic agents (e.g., ^{99m}Tc-glucarate (*25*) and $^{99m}Tc(CO)_3$-bis-DTPA-pamoate) and very lipophilic agents (derivatives of hypericin) (*20, 21*) have shown high avidity for necrotic tissue, so necrosis avidity does not seem to be primarily associated with the lipophilicity of a compound). It is unclear why $^{99m}Tc(CO)_3$-bis-DTPA-pamoate has a higher uptake in necrotic tissue as compared to ^{99m}Tc-**12**. One of the possibilities is that the rapid blood clearance of $^{99m}Tc(CO)_3$-**12** does not allow for time needed for efficient tracer perfusion into the necrotic lesions. On the other hand, the structural differences and the different overall charge and lipophilicity of both tracer agents may contribute to the clearly different biological properties and uptake in necrotic tissue.

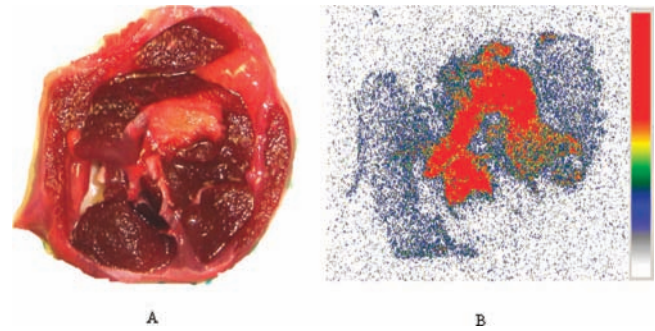

Figure 4. (A) TTC stained muscle after ethanol injection (pale stained, TTC negative area) and adjacent viable muscle tissue (deep red). (B) Autoradiogram of necrotic muscle shows high uptake of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate (5.5 h postinjection) in necrotic area with a necrotic to viable tissue ratio of 18.

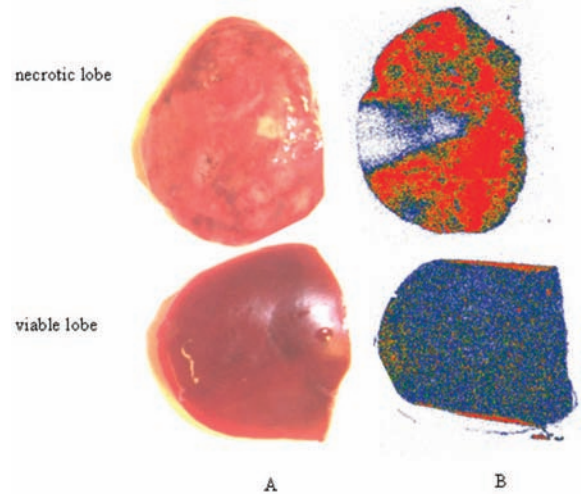

Figure 5. (A) TTC stained liver lobes of rat with ethanol-induced liver necrosis and (B) corresponding autoradiogram of 50 μm slice of the necrotic and viable liver lobes after intravenous injection of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate.

For both tracers, more than 98% of intact tracer was recovered after incubation of the radiolabeled compound for 24 h at room temperature. In challenge experiments with histidine, known to be one of the most potent tridentate chelators for binding of a $^{99m}Tc(CO)_3$ core and often used in tricarbonyl organometallic chemistry to investigate the *in vitro* stability of $^{99m}Tc(CO)_3$ complexes (*18*), $^{99m}Tc(CO)_3$-bis-DTPA-pamoate was less than 50% stable after 24 h in the presence of 0.01 M histidine (>20-fold excess of histidine) at 37 °C, while $^{99m}Tc(CO)_3$-**12** was 98% stable under the same conditions. Results of HPLC analysis of mouse plasma and urine after intravenous injection of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate are shown in Figure 2A,B, respectively. $^{99m}Tc(CO)_3$-bis-DTPA-pamoate showed good stability in plasma and in urine: 98% and 90% of intact tracer were recovered from plasma at 30 min and 24 h p.i., respectively (Figure 2A), while 98% of intact tracer was recovered in urine at 30 min and 4 h p.i. (Figure 2B). This indicates that the *in vivo* stability is sufficient for its use *in vivo* despite its relative instability in histidine-challenging experiments. Less than 10% of lipophilic metabolites were found at 24 h p.i. Such metabolites could result from *in vivo* transchelation of the radiometal to more stable and more lipophilic complexes with plasma proteins.

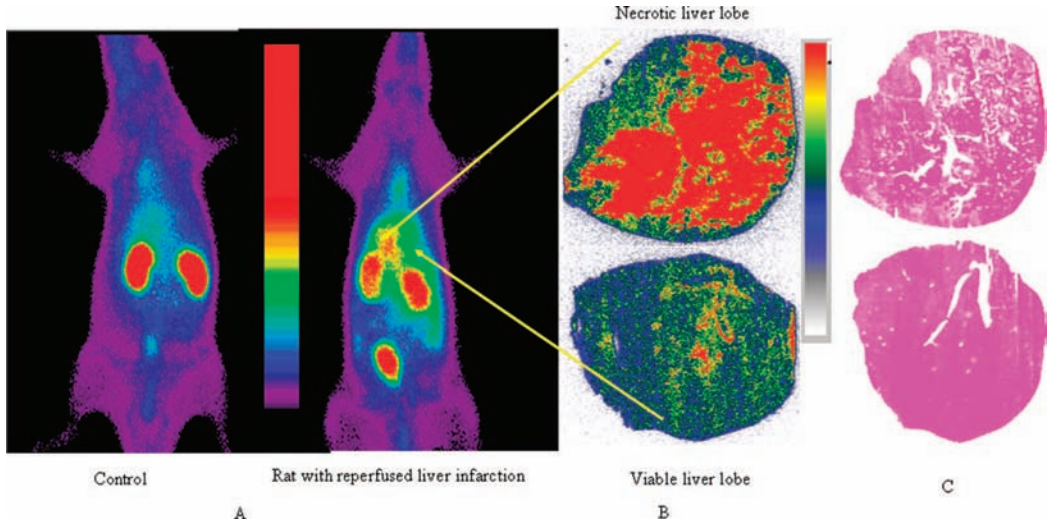

Figure 6. (A) *In vivo* planar image of a control rat and a rat with reperfused hepatic infarction at 7 h postinjection of ^{99m}Tc(CO)$_3$-bis-DTPA-pamoate. (B,C) Autoradiograms of 30 μm liver slices of the same rat after sacrifice (B, top row = necrotic liver and bottom row = viable liver) and scanned photographs of the same slices after H&E staining (C) staining show good correlation with the *in vivo* planar image.

^{99m}Tc(CO)$_3$-**12** was stable in histidine challenge experiments, as 98% of the intact tracer was recovered after 24 h incubation in the presence of excess histidine at 37 °C. The tracer was also stable *in vivo* in mice. At 30 min, there was 97% of intact tracer in plasma (Figure 2C). Plasma stability was not evaluated at later time points, since activity in blood was negligible. For both tracers, however, there was minimal reoxidation to TcO_4^- at all time points examined.

***Ex Vivo* and *in Vivo* Specificity for Necrotic Tissue.** In all rat models, TTC staining confirmed the presence of necrosis. TTC is an avid dye for mitochondrial dehydrogenase activity, and its absence results in pale staining of necrotic tissues by TTC (TTC negative), whereas viable tissues with enzymatic activity would reduce TTC into deep red insoluble formazan (TTC positive) (*26*). Autoradiograms and photographs of the corresponding H&E stained slices of liver of rats with reperfused liver infarction and sacrificed at 4 h or 24 h p.i are shown in Figure 3A,B, respectively. Necrotic to viable tissue activity ratios of ^{99m}Tc(CO)$_3$-bis-DTPA-pamoate in rats with reperfused liver infarction were 7 and 9 at 4 h and 24 h p.i., respectively, as determined by quantitative autoradiography. The contrast ratios at 4 h and 24 h did not differ much because of the rather slow clearance of ^{99m}Tc(CO)$_3$-bis-DTPA-pamoate from liver. Since the tracer is also excreted via the liver, the specificity was further explored in rats with ethanol-induced muscular necrosis (Figure 4). Following infusion of 0.2 mL ethanol (right hind limb) or 0.2 mL saline (left hind limb, control), ^{99m}Tc(CO)$_3$-bis-DTPA-pamoate was administered via i.v.. injection to the rats ($n = 4$) which were sacrificed at 5.5 h p.i.. A TTC negative area was visible in the treated limb (Figure 4A) but not in the control limb (data not shown). Necrotic to viable tissue activity ratios were 15–18 on autoradiography (Figure 4B). The lower necrotic to viable tissue ratio (4:1) observed in the case of ethanol-induced liver necrosis (Figure 5B) could be due to a complete collapse of vasculature following ethanol infusion leading to severe perfusion defects and consequently restricted accessibility of the tracer to necrotic tissue.

In vivo planar imaging was performed in rats with reperfused hepatic infarction at 7 h and 23 h p.i. of ^{99m}Tc(CO)$_3$-bis-DTPA-pamoate. Figure 6A shows representative *in vivo* planar images obtained at 7 h p.i. from a control rat and a rat with hepatic infarction, respectively. Corresponding autoradiograms of 30 μm liver slices of the same rat after sacrifice are shown in Figure 6B (top row = necrotic liver and bottom row = viable liver) and scanned photographs of the same slices after H&E staining in Figure 6C. As can be seen from these images, there was a good match between *in vivo* and *ex vivo* images with high tracer uptake in necrotic liver lobe (hot spots on planar images and autoradiograms). This high uptake was confirmed by gamma counting of dissected liver tissue. For an infarct avid agent to be clinically useful, it should show rapid localization in the infarcted tissue, high avidity and high specificity for necrotic tissue, and a reasonable duration of scan positivity. In the case of AMI, it is important that an infarct avid agent localizes early enough within the time window for thrombolytic therapy (usually <6 h) of the acute event, because delineation and sizing of the infarct is important to determine prognosis and decision making for further therapeutic interventions. A number of infarct avid imaging agents have been used in nuclear medicine for infarct delineation and sizing after AMI with none having all the afore-mentioned optimal imaging characteristics. These include ^{111}In-labeled antimyosin monoclonal antibody (*27*), ^{99m}Tc-pyrophosphate (*28*) and more recently ^{99m}Tc-glucarate (*25*). In the present preliminary evaluation, ^{99m}Tc(CO)$_3$-bis-DTPA-pamoate was localized and retained in the necrotic tissue both early (4 h p.i.) and late (24 h p.i.) in rat liver with reperfused infarction. Late retention in necrotic liver tissue was confirmed by *in vivo* planar imaging, a result which was confirmed by gamma counting and autoradiography (results not shown).

Figure 7 shows a representative photomicrograph of an H&E stained slice of rat liver after reperfused hepatic infarction. Severe tissue thinning and the absence of intact nuclei and cytoplasm are evident in the necrotic regions, while adjacent viable tissue shows intact structures and corresponding low tracer uptake. These necrotic regions are the areas that show high uptake of ^{99m}Tc(CO)$_3$-bis-DTPA-pamoate.

Although the mechanism of uptake of ^{99m}Tc(CO)$_3$-bis-DTPA-pamoate still has to be fully elucidated, one speculative hypothesis is that the tracer binds to Ca^{2+} stores (for which DTPA has a high complexation constant) released during necrotic death, a strong characteristic signal of necrotic cell death (*29*). In addition, ^{99m}Tc-pyrophosphate has been shown to bind to sequestered Ca^{2+} stores that are released during necrotic cell death in the case of AMI (*30*). Ca^{2+} sequestration, however, is

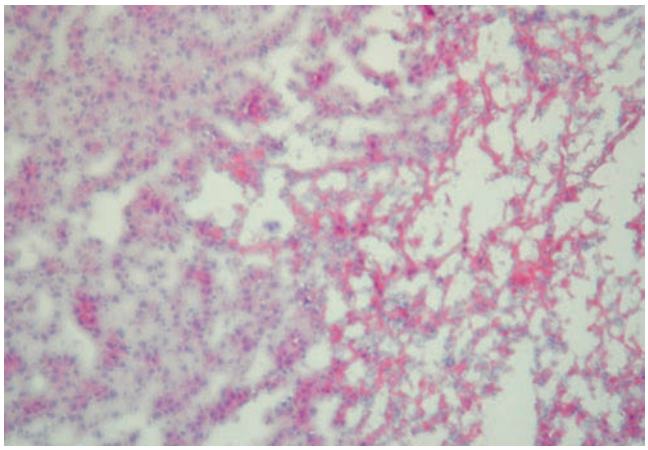

Figure 7. Photomicrograph of rat liver after reperfused hepatic infarction. Disintegrated nuclei and lack of cytoplasm are characteristic evidence of necrosis.

a fairly late but persistent event that occurs during necrotic cell death. This hypothesis remains to be tested.

CONCLUSION

In this study, we have shown that $^{99m}Tc(CO)_3$-bis-DTPA-pamoate is avid for necrotic tissue in three animal models of necrosis, with necrotic to viable tissue activity ratios as high as 18, as determined by quantitative autoradiography. The multiple negative charges of the unbound DTPA chelator at physiological pH could be essential for the *in vivo* binding to necrotic tissue, given the fact that $^{99m}Tc(CO)_3$-**12** did not show avidity for necrotic tissue. To verify this hypothesis, it is our intention to couple different bifunctional chelators (with different charges) to pamoic acid and to evaluate their avidity for necrotic tissue. On the other hand, In^{3+} and Ga^{3+} form more stable complexes with DTPA than technetium-99m. Labeling of $^{99m}Tc(CO)_3$-bis-DTPA-pamoate with $^{111}In^{3+}$ or $^{67/68}Ga^{3+}$could result in radiotracers with versatile imaging properties, a study that is ongoing.

ACKNOWLEDGMENT

The authors would like to thank Peter Vermaelen and Sofie Celen for their contributions to the study. Financial support for the project was obtained from grants awarded by Geconcerteerde Onderzoeksactie (GOA) of the Flemish Government, FWO-Vlaanderen grant G. 0257.05, and in part by the EC - FP6-project DiMI, LSHB-CT-2005-512146.

A Multipurpose Receptor Composed of Promiscuous Proteins. Analyte Detection through Pattern Recognition

Johan Viljanen,[†] Jenny Larsson,[†] Andréas Larsson,[†] and Kerstin S. Broo*[,‡]

IFM, Linköping University, S-581 83 Linköping, Sweden, and Department of Chemistry, Göteborg University, S-412 96 Göteborg, Sweden. Received July 5, 2007; Revised Manuscript Received August 17, 2007

A multipurpose receptor akin to the "electronic nose" was composed of coumarin-labeled mutants of human glutathione transferase A1. We have previously constructed a kit for site-specific modification of a lysine residue (A216K) using a thiol ester of glutathione (GSC-Cou_{bio}) as a modifying reagent. In the present investigation, we scrambled the hydrophobic binding site (H-site) of the protein scaffold through mutations at position M208 via random mutagenesis and isolated a representative library of 11 A216K/M208X mutants. All of the double mutants could be site-specifically labeled to form the $K216_{Cou}$ conjugates. The labeled proteins responded to the addition of different analytes with signature changes in their fluorescence spectra resulting in a matrix of 96 data points per analyte. Ligands as diverse as *n*-valeric acid, fumaric acid monoethyl ester, lithocholic acid, 1-chloro-2,4-dinitrobenzene (CDNB), glutathione (GSH), *S*-methyl-GSH, *S*-hexyl-GSH, and GS-DNB all gave rise to signals that potentially can be interpreted through pattern recognition. The measured K_d values range from low micromolar to low millimolar. The cysteine residue C112 was used to anchor the coumarin-labeled protein to a PEG-based hydrogel chip in order to develop surface-based biosensing systems. We have thus initiated the development of a multipurpose, artificial receptor composed of an array of promiscuous proteins where detection of the analyte occurs through pattern recognition of fluorescence signals. In this system, many relatively poor binders each contribute to detailed readout in a truly egalitarian fashion.

INTRODUCTION

The human olfactory system has inspired researchers to develop an electronic nose based on relatively nonspecific sensor electrodes (*1, 2*). The identification of a particular compound is then based on a mathematical interpretation of the signals from the array of electrodes (*3, 4*). Colorimetric sensor arrays for molecular recognition are also common in biosensing applications (*5–8*). We realized that this approach could be extended to utilize proteins as receptors and that the scaffolds we use in our protein reengineering efforts, the glutathione transferases (GSTs,[1] E.C. 2.5.1.18) (*41*) are in fact exceptionally well suited for this type of experiment.

Our previous studies have led us to focus on human glutathione transferase (hGST) A1-1 (Figure 1), a protein that is easy to express and purify, displays a high stability, and is tolerant to mutations (*9–11*). The crystal structure has been solved both with and without ligands (*12, 13*). The GSTs are dimeric detoxication enzymes (phase II) that catalyze the nucleophilic addition of the thiol of glutathione (GSH) to a wide range of hydrophobic electrophilic molecules (*14*). Since they have evolved to function as detoxication enzymes, GSTs have a promiscuous H-site that accepts a large variety of hydrophobic electrophiles (*15–18*), but the glutathione-binding site (G-site) is quite specific (*13, 16*). The modular features of the GSTs are ideal from a protein reengineering aspect with specific binding of GSH in the G-site combined with an adjacent, promiscuous H-site.

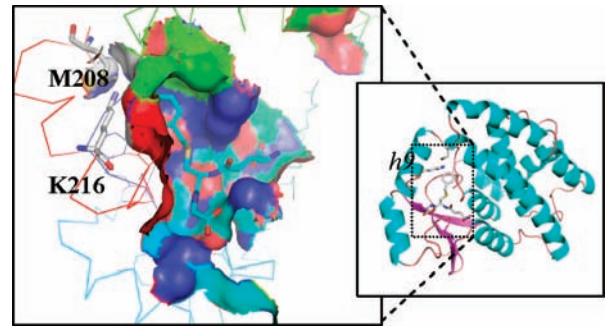

Figure 1. Close-up of the crystal structure (1GUH) of wt hGST A1-1 (A216 replaced with K216) in a complex with *S*-benzyl-GSH. Positions 216 and 208 are shown in "stick" representation, and the flexible helix 9 (h9) is also indicated in the figure. The protein is dimeric but shown here as a monomer for reasons of clarity of presentation. The figure was done with the help of the PyMol (DeLano Scientific LLC) software.

In our previous studies we have extended the repertoire of the protein scaffolds by chemical modifications (*19, 20*). Some of the introduced moieties have fluorescent properties, and we recently developed a method for clean labeling through surface-assisted delivery of fluorescent acyl groups to a specific lysine (K216) introduced through mutation of hGST A1 (*21*) (Scheme 1). The introduced K216 is located in the H-site of the folded

Scheme 1

protein scaffold (Figure 1), and we hypothesized that K216$_{Cou}$ could report changes if the protein scaffold binds a molecule in its vicinity. In analogy to the electronic nose where the electrodes display broad and overlapping binding capacities to a number of substances (*4*), we needed to scramble the binding of different molecules by A216K. However, the overall fold of the protein and thus labeling of K216 by a thiol ester of glutathione (GSC-Cou$_{bio}$) need to be retained. We decided to make a focused library of K216/M208X mutants because position 208 is located in the H-site (Figure 1) and it has previously been shown to be of importance in the binding of the electrophilic substrate (*22*).

MATERIALS AND METHODS

All chemicals and reagents used were of the highest purity available. The tripeptides were synthesized using solid-phase Fmoc chemistry, and protected amino acids were purchased from Novabiochem (Darmstadt, Germany) or Bachem Holding AG (Weil am Rhein, Germany). The fluorescent acyl groups were purchased from Sigma-Aldrich, Inc. (St. Louis, MO) or Molecular Probes, Inc. (Eugene, OR). EZ-Link PEO-iodoacetyl biotin and immobilized NeutrAvidin (NA) gel were purchased from Pierce Biotechnology, Inc. (Rockford, Il). All solid-phase syntheses were carried out in a VacMaster (International Sorbent Technology). The synthesis of GSC-Cou$_{bio}$ has been described elsewhere (*21*). The HPLC experiments were carried out using a Kromasil C_8 column (4.6 mm × 250 mm, Supelco, Inc.) or a Grace Vydac EVEREST C_{18} column (4.6 mm × 150 mm) attached to a Varian system with a ProStar 230 delivery system and a ProStar 330 photodiode array detector, controlled by the Varian LC Software. All mass spectra were recorded using a MALDI-TOF MS (Voyager System 4212, Applied Biosystems) with detection in the positive mode. The UV measurements were performed using a Varian Cay 100 Scan UV–visible spectrophotometer and the results analyzed with the CaryWin UV software. The fluorescence measurements were carried out on a Safire^2 (Tecan), a SpectraMax M2 (Molecular Devices), or a Hitachi F-4500 fluorescence spectrophotometer. The degree of immobilization of labeled A216K on the hydrogel chip was examined with an epifluorescence microscope (Zeiss Axiovert inverted microscope A200 Mot) equipped with a charge coupled device camera (Axiocam HRc, three chips).

Site-Directed Mutagenesis, Protein Expression, and Purification. The vector pET 21 a (+) containing the hGST A1-1 mutant A216K gene was used as a template for replacement of M208 by site-directed mutagenesis using the Quik-Change site directed mutagenesis kit (Stratagene). Oligonucleotide, M208NNN forward (5′-GCCCAAGGAAGCCTCCCNNNGATGAGAAA-TCTTTAGAAG-3′), and its complement (M208NNN reverse) were designed in order to replace codon ATG (M208) with random nucleotide bases to create codons coding for different amino acids. The mutations were checked by DNA sequencing (GATC Biotech, Germany).

From glycerol stocks of the different mutants, an amount of 200 μL of each was plated out on agar plates containing 100 μg/mL ampicillin and incubated at 37 °C over night. The next day the bacteria on the plates were resuspended in a few milliliters of 2YT-medium (16 g/L peptone, 10 g/L yeast extract, 5 g/L NaCl) and approximately half of the bacteria were pored into 1 L of 2YT medium containing 100 μg/mL ampicillin and incubated, shaking at 37 °C until the OD_{600} was about 0.6–0.7. The bacteria were induced to start producing the recombinant protein by adding isopropyl-β-D-thiogalactopyranoside (IPTG) to a final concentration of 1 mM and incubating the mixture at 37 °C with shaking for 3.5 h. The cells were harvested by centrifugation (3000*g*, 30 min, 4 °C), and the pellets were resuspended in a protease inhibitor cocktail (Complete Mini EDTA-free, Roche) containing 20 mM NaP_I, 0.02 % NaN_3, pH 7, with one tablet per 10 mL of buffer. For lysing of the cells, freezing at −80 °C and thawing at 37 °C were performed four times. After the final thawing the lysates were centrifuged at 11000*g* for 30 min at 4 °C.

The supernatants from the different cell lysates were desalted using PD-10 desalting columns (Amersham Biosciences). Purification of the different mutants was performed on a 3 × 5 mL HiTrap SP HP cation exchange column (Amersham Biosciences) attached to an ÄKTA purifier system (Amersham Biosciences). The column was equilibrated with 4 column

volumes of buffer A (20 mM NaP_i, 0.02% NaN_3, pH 7). The eluates from the PD-10 columns were loaded onto the cation exchange column with a flow of 3 mL/min, and thereafter, the column was washed with another 3 column volumes of buffer A. The different recombinant hGST A1-1 mutants were eluted from the column in a linear 13 column volumes gradient at a flow rate of 2 mL/min expanding from 100% buffer A to 100% buffer B (buffer A with 1 M NaCl). From the gradient, 2 mL fractions of the eluted proteins were collected. The peak fractions were pooled and concentrated using Amicon Ultra-15 centrifugal filter units, 10000 MWCO (Millipore). Purity was confirmed by SDS–PAGE, and protein concentrations were determined spectrophotometrically using $\varepsilon_{280} = 24\,700\ M^{-1}\cdot cm^{-1}$ (*23*).

The activities of the GSTs were measured with a standard assay with 1 mM each of 1-chloro-2,4-dinitrobenzene (CDNB) and GSH (pH 6.5 in 0.1 M NaP_i at 30 °C). The proteins were stored in NaP_i buffered solutions containing NaCl and 10% glycerol at −80 or −20 °C until use in the experiments.

Fluorescence measurements were performed on a Hitachi F-4500 fluorescence spectrophotometer, with excitation at 280 nm and emission scanning between 310 and 380 nm. Prior to the measurements, the proteins were diluted to 1 μM in 100 mM NaP_i, pH 7.0, and the fluorescence spectra of A216K and wt hGST A1-1 were also collected for comparison purposes (Supporting Information).

Preparative Labeling of A216K/M208X Mutants. The labeling reactions were performed in 200 μL mixtures of 20 μM protein, 0.1 M NaP_i, pH 7, with 300 μM GSC-Cou_{bio}. The reaction was allowed to proceed at 25 °C for 5 h. For protease treatment, 2 μL of modification reaction mixture was diluted with 17 μL of 75 mM NH_4OAc, pH 4, and the cleavage was started by adding1 μL of *Staphylococcus aureus* protease V-8 (1 μg/μL stock solution in 75 mM NH_4OAc, pH 4). The mixture was then incubated at 25 °C and stopped by adding an equal amount of 0.2% TFA (e.g., 20 μL reaction mixture) after 2 h.

Following incubation, 0.5 μL of the reaction mixture was mixed with 0.5 μL of saturated α-cyano-4-hydroxycinnamic acid matrix, and 0.5 μL of citrate (10 mg/mL) was also added to quench salts from the buffers. The samples were then analyzed by MALDI-MS with detection in the positive mode. Proteolytic digestion with this protease results in K216-containing fragments K_{216}RKIFRF and EK_{216}RKIFRF, corresponding to one missed cleavage.

After modification was complete, 1.1 equiv of NA beads (binding capacity of ≥80 nmol of biotin/mL of gel) was added to the reaction mixture. The gel had been pre-equilibrated in 0.1 M NaP_i, pH 7.1, containing 75 mM NaCl in VacMaster (International Sorbent Technology) tubes. After incubation with the gel (45 min), the labeled protein was eluted by a brief spin in a tabletop centrifuge (Scheme 1).

Array Experiments with Addition of *n*-Valeric Acid, Fumaric Acid Monoethyl Ester, and Lithocholic Acid. A typical array experiment was performed in the following way: 300 μL mixtures of 1 μM labeled protein and 200 μM analyte (0.1 M NaP_i, pH 7) were transferred to a 96-well black microplate (Nunc). A sample of each protein without analyte was also included. Each well was analyzed with respect to direct excitation of the coumarin residue at 355 nm and of the tryptophan residue at 280 nm. The emission was monitored from 370 to 500 nm. The fluorescence intensity at 408 nm was noted and plotted as a function of total analyte concentration. The equivalent parameters were also collected following addition of 200 μM GSH (20 mM stock solution) to each well containing the analytes.

Affinity Determination Using Fluorescence Spectroscopy. Samples of coumarin-labeled mutants (1 μM in 0.1 M NaP_i, pH 7.0) were set up in a 96-well half-area black microplate with a clear bottom (Corning, Inc.). The analytes (GSH, CDNB, GS-DNB, or S-hexyl-GSH) were then added to the wells: GSH, CDNB, and GS-DNB in the range 10 μM to 1.5 mM and *S*-hexyl-GSH in the range 1 nM to 1.5 mM ($V_{tot} = 75\ \mu$L). The optical density (340–500 nm) was recorded for each well. In cases where the optical density exceeded 0.05 at the wavelength of excitation and emission, the fluorescence intensities were corrected according to the following equation (*24*):

$$F_{corr} = F_{obs}\,\mathrm{antilog}\left(\frac{OD_{ex} + OD_{em}}{2}\right) \quad (1)$$

where F_{obs} and F_{corr} are experimental values and corrected fluorescence intensities, respectively, and OD_{ex} and OD_{em} are the optical densities of the sample at the wavelengths of excitation and emission, respectively. The dissociation constant K_d was determined by fitting the following equation to the experimental results under the assumption of a 1:1 binding model:

$$F_{obs} = \frac{F_{bound}[A] + F_{free}K_d}{[A] + K_d} \quad (2)$$

where F_{obs} is the observed fluorescence intensity, F_{bound} is the fluorescence of the protein bound to the analyte, F_{free} is the fluorescence of free protein, and [A] is the concentration of free analyte. The numerical value of [A] can be derived from the following:

$$[A] = \frac{[P]_{tot} + K_d - [A]_{tot}}{2} + \sqrt{\left(\frac{[P]_{tot} + K_d - [A]_{tot}}{2}\right)^2 + K_d[A]_{tot}} \quad (3)$$

where $[P]_{tot}$ is the total concentration of protein and $[A]_{tot}$ is the total concentration of analyte. The fitting of the equations to the experimental values was done with the IGOR Pro 5.0 software (WaveMetrics, Inc.).

Reproducibility of GSH Addition. The reproducibility was checked by splitting a sample of A216K/M208T (1 μM in 0.1 M NaP_i, pH 7.0) in three different wells. As a control, GSH (200 μM) was added and the resulting coumarin fluorescence was recorded. The values differed by less than 5%.

Immobilization of A216Kcou on a PEG-Based Biosensor Chip and Fluorescence Microscopy. A thiol self-assembled monolayer (SAM) was formed by incubating gold-coated silica substrates with 100 μM $HS(CH_2)_{11}CONH(C_2H_4O)_{11}CH_3$ (Polypure AS, Norway) in 99.5% ethanol for at least 24 h at room temperature. The thiol SAM was used as a platform for UV grafted polymerization of a polyethylene glycol (PEG) based matrix, using a process described in detail elsewhere (*25, 26*). By use of masks, arrays of matrix spots were prepared by irradiating the samples with a Philips TUV PL-L 18 W Hg lamp in the presence of a PEG methacrylate monomer (∼10 EG units) (PEG_{10}MA) and 2-hydroxyethyl methacrylate (HEMA). Two different arrays of (i) 200 μm and (ii) 300 μm spots, both with a spacing of 50 μm, were irradiated for 6 and 4 min, respectively. The matrix spots were then carboxylated using bromoacetic acid (*27*). Both samples were activated for 20 min with an aqueous mixture of *N*-ethyl-*N*′-[3-(dimethylamino)propyl]carbodiimide (Biacore AB, Uppsala, Sweden) and *N*-hydroxysuccinimide (Sigma-Aldrich Sweden AB) at 0.2 and 0.05 M, respectively. A216K_{cou} was then immobilized on the hydrogel chip (i) via nucleophilic amino acid residues on the protein and (ii) via Cys112 subsequent to 30 min of incubation in 80 mM 2-(2-pyridinyldithio)ethaneamine in Milli-Q water. The concentration of A216K_{cou} was 0.5–1.0 μM in 10 mM sodium acetate buffer, pH 4.5, and the immobilization time was 60 and 40 min for steps i and ii,, respectively. In addition, sample i was deactivated with 1 M ethanolamine in Milli-Q

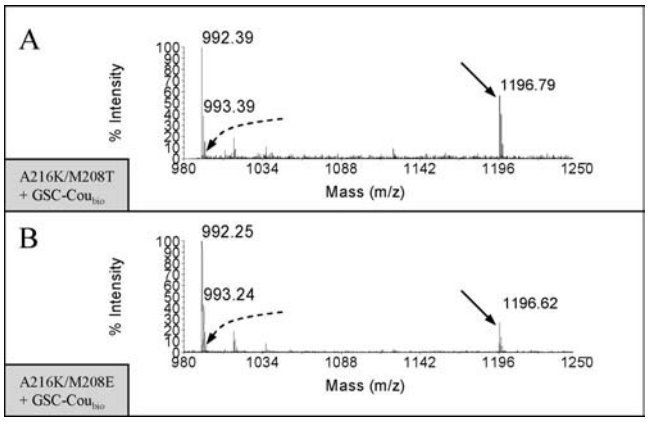

Figure 2. MALDI-MS spectra of proteolytic (*S. aureus* V-8) peptide fragments from (A) A216K/M208T (10 μM) incubated with GSC-Cou$_{bio}$ (100 μM) for 5 h and (B) A216K/M208E (10 μM) incubated with GSC-Cou$_{bio}$ (100 μM) for 5 h. The reaction has gone to completion, but the parent fragments would have an *m*/*z* of 994 g/mol as indicated by a dotted arrow. Modified fragments are highlighted with arrows. The peak at 992 g/mol corresponds to the sodium adduct of GSC-Cou$_{bio}$.

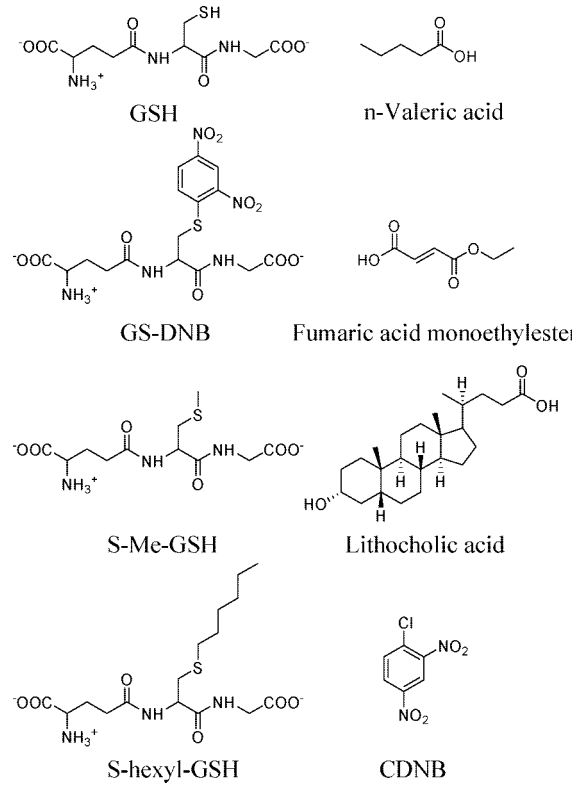
water for 30 min. The arrays were then examined with an epifluorescence microscope (Zeiss Axiovert inverted microscope A200 Mot) equipped with a charge coupled device camera (Axiocam HRc, three chips). A 10× magnification objective was used along with a 365/15 nm band-pass excitation filter and a 397 nm low-pass emission filter. The exposure time was 1.25 s, and the obtained images were enhanced with respect to color and contrast.

RESULTS



Preparation of the A216K/M208X Library and Pilot Labeling of the Purified A216K/M208X Mutants. Eleven double mutants (A216K/M208L, F, S, Y, A, E, R, T, G, K, and C) were isolated and purified as described elsewhere (*28*). The purities were confirmed by SDS–PAGE, their specific activities toward the standard substrates CDNB and GSH were measured, and their fluorescence spectra resulting from excitation at W21 were recorded and compared to those of wt hGST A1-1 and A216K, respectively (Supporting Information).

Pilot labeling experiments were performed in 20 μL aliquots with GSC-Cou$_{bio}$ (100 μM) and purified protein (10 μM) in buffer (0.1 M NaP$_i$, pH 7.0). The reactions were analyzed by MALDI-MS following proteolytic digestion. To simplify subsequent analyses, we used *S. aureus* V-8 protease because it cleaves after acidic residues and is thus unaffected by lysine modification. For control purposes, the proteins were also digested after incubation in buffer without addition of any reagent. The single mutant A216K was included in all experiments leading to a total of 12 proteins in the receptor family. All mutants became acylated by GSC-Cou$_{bio}$ at residue K216 (Figure 2).

Preparative Labeling of the Receptor Family. The 12 proteins were labeled on a preparative scale in solutions containing 20 μM protein and 300 μM GSC-Cou$_{bio}$ in 0.1 M NaP$_i$, pH 7.0, buffer. On the basis of the results from the pilot experiments, the reactions were allowed to proceed at 25 °C for 5 h. In all subsequent experiments, the labelling reactions were monitored by subjecting 2 μL of the reaction mixtures to proteolytic digestion with subsequent analysis by MALDI-MS.

In order to remove used and excess reagent, an amount of 1.1 equiv of NA beads (binding capacity of ≥80 nmol of biotin/mL of gel) was added to each reaction mixture after 5 h as described previously (*21*) (Scheme 1). After incubation with the gel for 45 min, the labeled protein was eluted by a brief spin in a tabletop centrifuge. We have previously demonstrated that this treatment quantitatively removes residual reagent. After treatment with the NA beads, the fluorescence spectra of the protein eluates displayed the typical coumarin emission (Supporting Information).

Scheme 2

Addition of *n*-Valeric Acid, Fumaric Acid Monoethyl Ester, and Lithocholic Acid to the Receptor Family. In order to explore the signaling potential of the receptor family and find out what kind of information that could be extracted, a screening experiment was set up with 3 analytes (*n*-valeric acid, fumaric acid monoethyl ester, and lithocholic acid) (Scheme 2) and all 12 proteins (the double mutants and A216K) in a microplate format. The chosen analytes do not display any significant absorbance at the measured wavelengths and concentrations (data not shown). The fluorescence spectra of 12 proteins by 3 analytes plus those of the proteins without analytes, the analytes without proteins, and the buffer alone were thus collected (Figure 3). Each well was analyzed with respect to direct excitation of the coumaryl residue at 355 nm and also through excitation at 280 nm (W21) with concomitant FRET to the coumaryl residue. Excitation of GSC-Cou$_{bio}$ at 280 nm did not result in any emission from the coumaryl moiety. In these experiments, both the changes in fluorescence intensities (ΔF_{Cou}) and the positions of the emission maxima ($\Delta\lambda_{em,max}$) were documented. The equivalent parameters were also collected following addition of 200 μM GSH to each sample, resulting in a matrix of eight data points for each analyte and protein combination or 96 data points per analyte (Table 1).

Affinity Studies. In order to investigate the capacity of binding, the K_d values were determined for a subset of analytes. In this experiment, labeled protein was titrated with analytes (all in 0.1 M NaP$_i$ buffer, pH 7.0) (Figures 5 and 6). The fluorescence spectra were recorded using $\lambda_{exc} = 295$ nm (W21) and $\lambda_{exc} = 355$ nm (K216$_{Cou}$). In the case of GSH and *S*-hexyl-GSH, the spectra could be analyzed directly. However, both CDNB and GS-DNB absorb light at the wavelengths used for both excitation and emission. Before the results could be

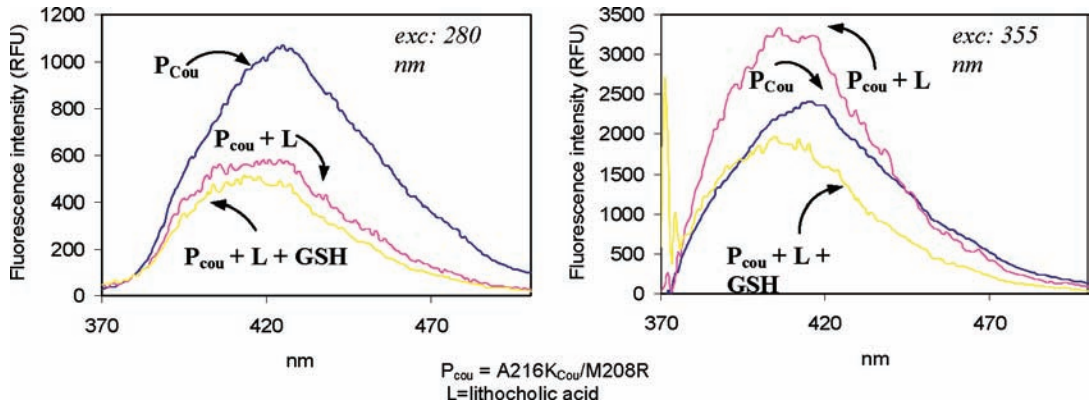


Figure 3. Example of the screening experiment showing changes in fluorescence after addition of first lithocholic acid (200 μM) to wells containing 1 μM labeled A216K$_{Cou}$/M208R followed by GSH (200 μM). For each protein and analyte combination, excitation at 280 nm (W21) with concomitant FRET to the coumaryl residue was followed by direct excitation of the coumaryl residue at 355 nm.

interpreted, the emission intensities were corrected using the approximate correction equation (*24*):

$$F_{corr} = \frac{F_{obs}\,\text{antilog}(OD_{exc} + OD_{em})}{2} \quad (4)$$

We found that the proteins bound GSH, *S*-hexyl-GSH, CDNB, and GS-DNB with K_d values spanning more than 3 orders of magnitude (from 2.5 μM to 6.9 mM) (Table 3).

Immobilization of A216K$_{Cou}$ on a Hydrogel Chip. The cysteine residue C112 (Figure 8) was utilized to couple A216K$_{Cou}$ site specifically to a microarray hydrogel surface (Figure 9). Labeled protein (0.5–1.0 μM) was incubated together with the PDEA activated surface in 10 mM NaOAc buffer, pH 4.5, for 40 min. A216K$_{Cou}$ was also immobilized on a NHS-activated surface via nucleophilic amino acids on the protein. The attachment of protein was verified by MALDI-MS, following direct proteolytic digestion (*S. aureus* V-8) on the array surface (Supporting Information). The arrays were then examined with an epifluorescence microscope equipped with a charge coupled device, and the obtained images were enhanced with respect to color and contrast (Figure 9).

DISCUSSION

This investigation was performed because we wanted to emulate the ideas of the "electronic nose" (*1, 2, 4, 29, 30*) using proteins instead of electrodes, thus getting access to the complex and vast amount of interactions between proteins and small molecules. The idea of having an array of mediocre binders that combine to form a module that can report the presence of a given molecule with a much higher degree of specificity is highly appealing from a scientific point of view, and it can conceivably be of some commercial interest in the future. The inherently relaxed substrate requirements, a hallmark of GST catalysis and a prerequisite for detoxication, together with our newly developed kit for user-friendly protein labeling (*21*) are the perfect combination for building a multipurpose, protein-based sensor of this type.

The task was to deform the binding site (the H-site) of A216K to an appropriate degree, not too much and not too little. Too

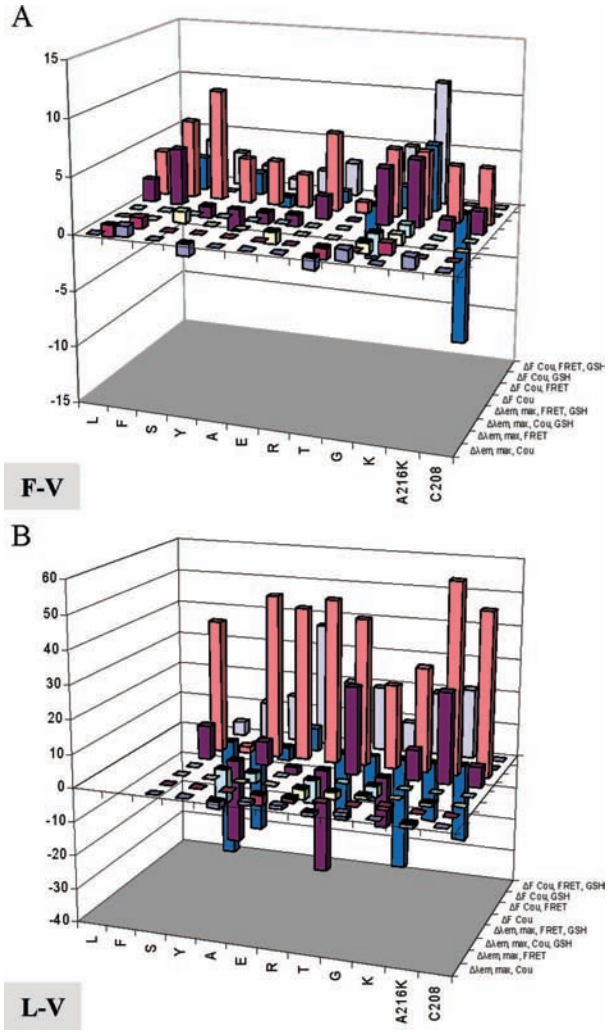

Figure 4. Graphic representation of the changes in fluorescence described in Table 2. Each protein to analyte combination gives rise to eight parameters. In order to simplify the interpretation, the diagrams show the differences in changes between (A) fumaric acid monoethyl ester and *n*-valeric acid and (B) lithocholic acid and *n*-valeric acid. Valeric acid has thus been used as a sort of standard or normalizing substance. The mutants A216K/M208F and L were omitted in the investigation with lithocholic acid.

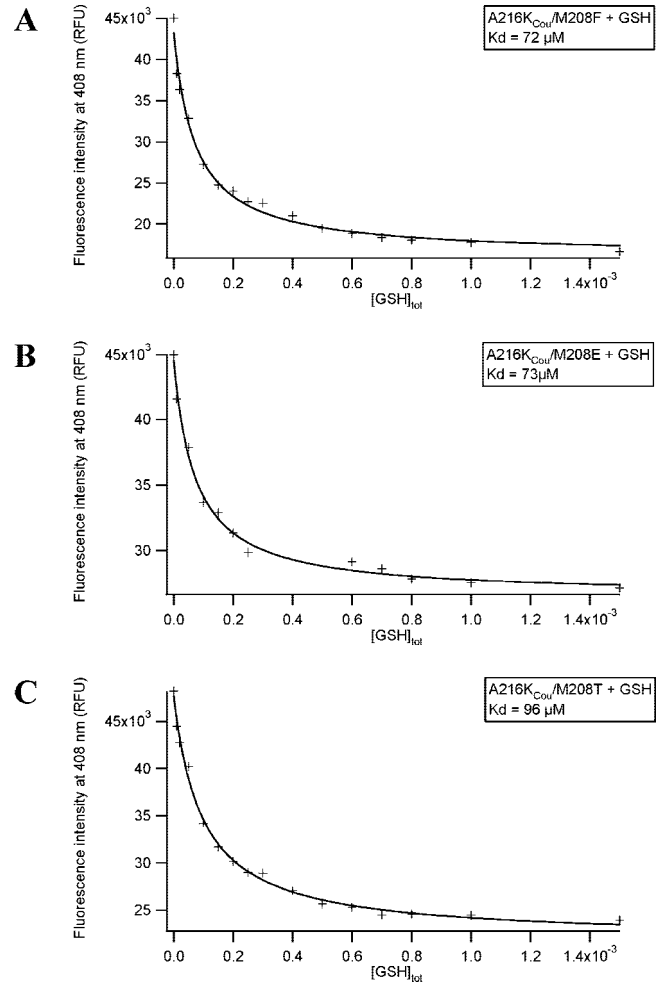

Figure 5. Addition of increasing amounts of GSH to (A) 1 μM A216K$_{Cou}$/M208F, (B) 1 μM A216K$_{Cou}$/M208E, and (C) 1 μM A216K$_{Cou}$/M208T. An equation that describes the dissociation of a bimolecular complex was fitted to the experimental data and gave K_d values of 72, 73, and 96 μM, respectively. Solid lines represent the best fits to the experimental results. The *x*-axis corresponds to the total amount of added GSH ([GSH]$_{tot}$). At the concentrations shown here, [GSH]$_{tot}$ $\approx$ [GSH]$_{free}$.

much would perhaps result in nonexistent binding in the H-site and thus no analyte recognition or spoilage of the G-site with no labeling as a potential outcome. Too little would result in a protein array without binding diversity, somewhat like having an array with just one protein attached to the surface. The mutations also have to be relatively close (in the folded state) to position 216 so that K216$_{Cou}$ can sense and report changes upon binding. In addition, the new mutations also need to be located in or near the H-site where the ligands/analytes are supposed to bind. Previous studies concerning hGST A1-1 have reported that M208 can be mutated with altered substrate preferences as a result (*22, 31*). The side chain of M208 points into the H-site and is located in a region that presumably can undergo changes upon binding of electrophiles because helix9 changes its conformation upon binding of substrates (Figure 1). We wanted a varied panel with mutations ranging from negatively to positively charged, from small to large, from hydrophilic to hydrophobic, and with and without functional groups such as –OH or –SH. We therefore created a A216K/M208X library using a randomized primer and sequenced, expressed, and purified enough clones to obtain 11 double mutants with a wide spread of properties. One of the clones, A216K/M208K, has an additional lysine residue in the H-site, and we therefore studied if that could also become acylated by GSC-Cou$_{bio}$ or if the protein would only become singly labeled.

The double mutants A216K/M208X can react with GSC-Cou$_{bio}$ to form K216$_{Cou}$ conjugates. We have previously shown that A216K can be treated with GSC-Cou$_{bio}$ to form an A216K$_{Cou}$ conjugate and that any used up or excess reagent can be quantitatively removed using NA beads relying on the biotin–streptavidin interaction (*21*) (Supporting Information). Fortunately, the double mutants retained this crucial capacity, enabling us to quick and easy labeling of the receptor family. The speed of the reaction varied, but incubation over 5 h resulted in >85% labeling for all but two mutants (Supporting Information), which we deemed high enough for our needs. We thus have a system where we can start with pure proteins (SDS–PAGE gels, Supporting Information) that can be labeled to more than 85% (Figure 2 and Supporting Information) and where there is no residual fluorescent labeling reagent left in solution after treatment with NA beads (HPLC chromatograms in Supporting Information).

Similar analytes (*n*-valeric acid and fumaric acid monoethyl ester) result in different patterns. In order for this system to work, the receptor must be able to report "signature changes" for different molecules even if they appear similar from the

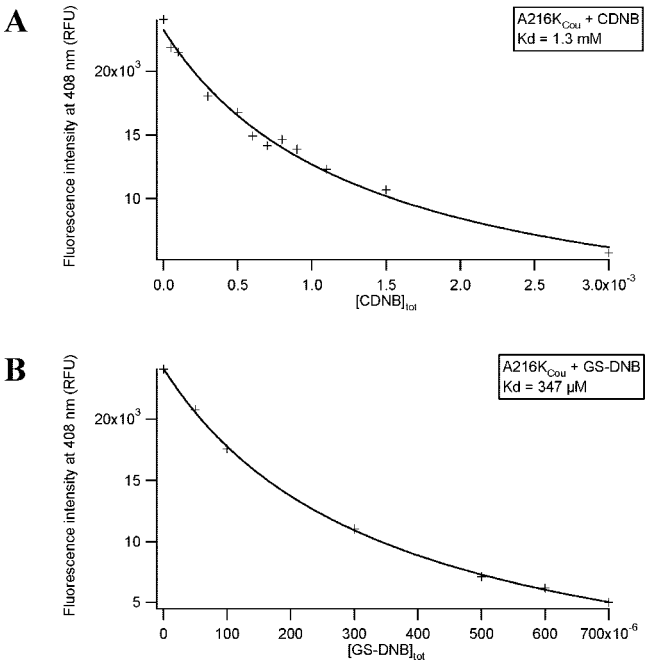

Figure 6. Addition of increasing amounts of (A) CDNB and (B) GS-DNB to the parent protein A216K$_{cou}$ (1 μM). The resulting K_d values were determined by fitting an equation that describes the dissociation of a bimolecular complex, to 1.3 mM and 347 μM, respectively. Solid lines represent the best fits to the experimental results. At the concentrations shown here, [analyte]$_{tot}$ $\approx$ [analyte]$_{free}$.

viewpoint of a promiscuous GST. It is also an advantage if a totally dissimilar molecule (with respect to size, hydrophobicity, charge, etc.) gives a completely dissimilar response. In order to test this and also to obtain information about what parameters are exploitable and how substantial the changes in fluorescence would be, we set up a pilot experiment using all 12 proteins (A216K and the 11 A216K/M208X mutants) and 3 different analytes: *n*-valeric acid, fumaric acid monoethyl ester, and lithocholic acid (Scheme 2). These molecules are all soluble in buffer, and they do not have complicating absorbance spectra at the concentrations used in the experiments. The first two are quite small and have fairly similar structures, and the last one is a large, bulky steroid that is a naturally occurring bile acid known to be a liver-toxic metabolite (*32, 33*) and to probably bind in the groove between the subunits (*34, 35*).

We also wanted to investigate whether W21 that is used to study folding of hGST A1-1 (*11, 36*) could report binding and whether the coumarin that is located in or near the H-site could report binding through direct excitation. The results from the FRET experiments showed competing mechanisms between energy transfer from W21 to the coumarin fluorophore and coumarin quenching. Since the values differ between ΔF_{Cou} and $\Delta F_{Cou,FRET}$ following blank reduction and upon analyte addition (Table 1) and also since the emission intensity influence for the coumarin is much more significant than the emission intensity influence for W21, we concluded that the parameter $\Delta F_{Cou,FRET}$ includes both information contributed from coumarin quenching and distance changes between W21 and coumarin.

Addition of GSH to GSTs can affect the binding of a second substrate in the H-site, and we therefore added GSH to each well after collecting the data in the analyte plus protein experiment. We are of course aware of the fact that GSH alone can cause changes in the fluorescence of the coumarin moiety (*21*) and that the overall signal we observe upon addition of GSH is a combination of both effects. On a cautionary note, GSH can also form adducts with some electrophilic substances, so it should be used with discretion. One final parameter that we were interested in was the change in position of $\lambda_{em,max}$. In the literature, coumarin derivatives are reported to change their emission maxima up to 14 nm going from $CHCl_3$ to MeOH as a solvent (*24*).

In all, this set of parameters ($\Delta\lambda_{em,max,Cou}$, $\Delta\lambda_{em,max,FRET}$, $\Delta\lambda_{em,max,GSH}$, $\Delta\lambda_{em,max,FRET,GSH}$, ΔF_{Cou}, $\Delta F_{Cou,FRET}$, $\Delta F_{Cou,GSH}$, $\Delta F_{Cou,FRET,GSH}$) resulted in a matrix of 12 proteins by 8 data points, or a total of 96 measured parameters for each analyte (Table 1, Figure 4). In an effort to aid visualization, the data from fumaric acid monoethyl ester and lithocholic acid were compared to the changes obtained when *n*-valeric acid was added. This choice was simply based on the fact that *n*-valeric acid is the analyte with the least amount of functional groups in the test set.

We were pleased to observe that the biosensor panel could differentiate between *n*-valeric acid and fumaric acid monoethyl ester (Table 1). The numbers were relatively small, but that is perhaps to be expected when the analytes differ so little. These changes reported by a single protein or just a few proteins in an array would not amount to anything useful, but the combined effect from all 12 proteins is quite promising.

On the other hand, adding lithocholic acid to the panel of proteins resulted in large changes in fluorescence. This molecule definitely affects both W21 and K216$_{Cou}$ in a completely different way than either of the two smaller ligands. Interestingly, we observed wavelength shifts of 10 nm for A216K/M208Y, suggesting a quite substantial change in the hydrophobicity of the microenvironment of the coumarin moiety upon binding of lithocholic acid.

It appears that the most common result when a ligand is added to the panel of labeled proteins is quenching of the fluorescence of coumarin. The most likely cause for this is static quenching; i.e., upon addition of the analyte a nonfluorescent complex is formed between the coumarin and the quencher that serves to limit the absorption by reducing the population of active, excitable molecules. There is a small variation in the degree of quenching of the coumaryl residue between the A216K/M208X mutants, probably resulting from differing microenvironments in the binding site leading to different orientations of K216$_{Cou}$ and analyte. Interestingly, when *S*-hexyl-GSH is added to A216K$_{cou}$, the fluorescence intensity actually increases (Figure 7) but no wavelength shift is observed.

The wavelength shifts upon analyte addition are probably due to solvent or polarity effects. Control experiments demonstrated that GSC-Cou$_{bio}$ in buffer has a significantly lower emission intensity and a $\lambda_{em,\ max}$ that is red-shifted with 17 nm compared to A216K$_{cou}$ (data not shown). This strengthens the notion that the coumaryl group is positioned in a hydrophobic environment in a relatively static manner when attached to K216, since no shift or small wavelength shifts are observed upon analyte addition (Table 1). The small shifts that we do observe in some cases are probably caused by a reorganization of the C-terminal helix upon analyte addition with concomitant alteration of the position of K216$_{Cou}$ from a hydrophobic environment (H-site) to a hydrophilic one (water outside H-site) or vise versa.

No Apparent Correlation between Mutations and Signal Changes. The mutations in position 208 represent a wide range of functionalities. Despite this, there are no striking and consistent trends. In fact, the most striking result seems to be that there are no predictable trends regarding changes in fluorescence. The mutants do not seem to follow any rules, for example adding lithocholic acid to A216K/M208S, T, and Y results in ΔF_{Cou} values of 9, 25, and –26, respectively (Table 1). Another noteworthy example of this is that the ΔF_{Cou} changes recorded for E, R, and K208 are 0, −34, and 1,

[a] Not determined.

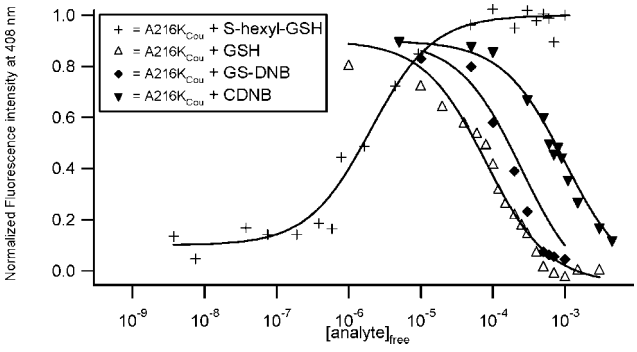

Figure 7. Normalized fluorescence intensity at 408 nm was plotted against the concentration of free analyte, $[analyte]_{free}$. The concentrations were calculated from K_d values. An equation that describes the dissociation of a bimolecular complex was fitted to the experimental data to obtain K_d values: *S*-hexyl-GSH (+, K_d = 2.5 μM), GSH (△, K_d = 108 μM), GS-DNB (◆, K_d = 347 μM), CDNB (▼, K_d = 1.3 mM). The solid lines represent the best fits to the experimental results.

respectively. Here, the negatively charged E208 and the positively charged K yield similar values, whereas R208 is an outsider.

Is one of the proteins more sensitive than the others? Is one of the parameters more sensitive than the others? Upon inspection of Figure 4 (staple F-V and L-V) and Table 2, it is quite clear that the magnitude of changes reported from a protein depends on the ligand it encounters. For example, adding lithocholic acid to A216K/M208T gives rise to large changes in almost all parameters. On the other hand, this particular mutant does not signal any large differences between valeric

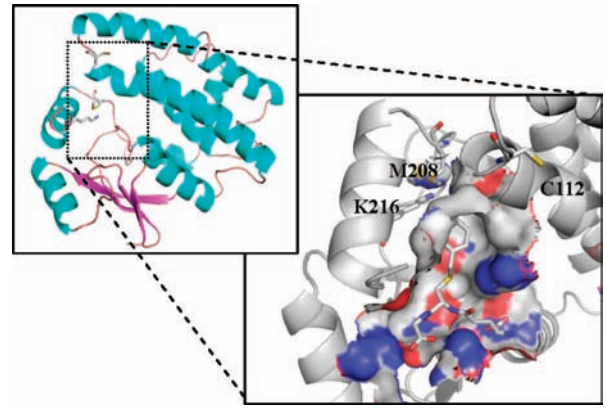

Figure 8. Close-up of the crystal structure (1GUH) of wt hGST A1-1 (A216 replaced with K216) in a complex with *S*-benzyl-GSH. Positions 216, 208, and 112 are shown in "stick" representation. The protein is dimeric but shown here as a monomer for reasons of clarity of presentation. The figure was done with the help of the PyMol (DeLano Scientific LLC) software.

acid and fumaric acid monoethyl ester. One of the weakest candidates is of course A216K/M208C because it is prone to oxidation at the introduced C208 and the stability of this mutant is correspondingly less than that of the others (data not shown). However, from a practical point of view it is the total signature from the panel of proteins that is important, not the behavior of an individual protein.

The related question is of course whether one of the parameters is more sensitive than the others. Again, judging from Figure 4 (staple F-V and L-V) and Table 2, it would appear that perhaps FRET data ($\Delta F_{Cou,FRET}$ and $\Delta F_{Cou,FRET,GSH}$) give rise to relatively large differences. But again, in this case less is not more, since a larger matrix allows for a higher degree of certainty.

The ligands bind in a specific manner to the proteins. In a more quantitative part of the study, we performed titration studies with several molecules: GSH, CDNB, GS-DNB, and *S*-hexyl-GSH. We used a subset of double mutants and included the parent protein A216K as well. The experiments supplied us with information regarding the binding of the ligands (K_d values) and presented an opportunity to work with compounds that have absorbance spectra that interfere with the excitation and emission wavelengths of the probes. Even if it is not ideal,

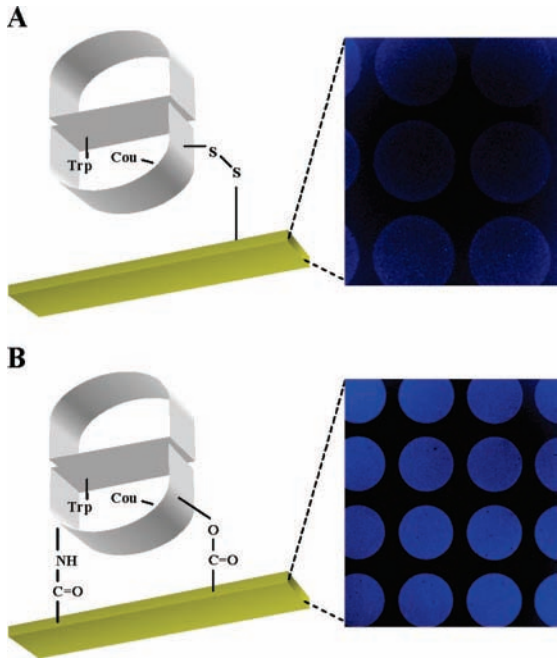

Figure 9. Pictures from epifluorescence microscopy following immobilization of $A216K_{Cou}$ to a PEG-based (hydrogel) surface: (A) site-specific immobilization on a PDEA-activated hydrogel surface through C112 and (B) immobilization on an NHS-activated hydrogel surface through NHS-reactive residues on $A216K_{Cou}$.

the optical density problem can be dealt with using an equation that corrects the fluorescence intensity for inner filter effects (*24*).

The titrations were performed in a black microplate with a clear bottom. Thus, we obtained information regarding the optical density, fluorescence intensity, and wavelength shift in the same experimental setup. The protein concentrations were 1 μM throughout the titrations, since we were expecting affinities in the low micromolar to low millimolar range, based on the K_d for GSH (190 $\pm$ 50 μM) of wild type hGST A1-1 (*37*). The results (Table 3) showed that the affinity for GSH for seven tested mutants varied over quite a narrow range (73–179 μM), in line with our expectations because GSH is known to bind in the G-site. The affinities for CDNB varied between 601 μM for A216K/M208E to 6.8 mM for A216K/M208A. The larger variation for CDNB binding between the mutants was not surprising because position 208 is located in the H-site, where CDNB is known to bind. The nucleophilic aromatic substitution reaction between GSH and CDNB to form GS-DNB is catalyzed by wt hGST A1-1, and the proteins showed affinities for GS-DNB between those for GSH and CDNB, respectively. Also included in the affinity array was *S*-hexyl-GSH, which is a well-known inhibitor of the α class GSTs. This ligand showed the highest affinity, 2.5 μM for A216K. The light-up effect was a positive surprise, enhancing the strength of the biosensor module (Figure 7).

The coumarin-labeled protein scaffold can be anchored to a hydrogel microarray chip using C112 or nucleophilic residues. We used the by now well-studied protein $A216K_{cou}$ to initiate the development of a surface-based biosensing system. The results from IR spectroscopy measurements (data not shown), MALDI-MS measurements following direct proteolytic digestion on the surface (Supporting Information), and fluorescence microscopy studies (Figure 9A), showed that $A216K_{cou}$ could indeed be site-specifically introduced on the hydrogel surface through C112. We also found that $A216K_{cou}$ could be attached to a NHS-activated hydrogel surface (Figure 9B), resulting in an even higher intensity of the emitted light, indicating a higher concentration of $A216K_{cou}$ in the spots. This is not surprising because the protein surface contains many potential NHS-reactive groups. We concluded that an optimization is needed before further development of the surface-based biosensor.

Is this enough? This work constitutes "proof of principle" demonstrating that the ideas of the electronic nose and tongue can be transferred into the protein world. We have no illusions that this array of GST mutants could be used in real life to solve real life problems. Before the step from basic science to a real life application is taken, further diversification of the proteins is necessary as well as screening with real life analytes. However, it is very promising that ligands as diverse as *n*-valeric acid, fumaric acid monoethyl ester, lithocholic acid, CDNB, GSH, *S*-hexyl-GSH, and GS-DNB give rise to different signals that in more mature systems potentially can be distinguished and interpreted through pattern recognition. It is noteworthy that the K_d values we have measured (Table 3) span a range from low micromolar to low millimolar.

The proposed use of our affinity array would in an initial stage be in a relatively controlled environment with a low noise from contributing compounds. This has so far also been true for the electronic nose sensor (*38*), which has for example been employed for quality measurements for commercial cardboard papers (*39*). However, the beauty of the GSTs lies in their promiscuity; it is easy to envision a selection where the scaffold is fine-tuned toward various types of analytes. Indeed, Mannervik et al. (*40*) have already performed a phage-display selection based on hGST A1-1. One can also envision a coupled system wherein GST(s), naturally existent, or mutant(s) attaches GSH to an analyte in situ to hitch a ride with the glutathione backbone and thus lower K_d values. This latter approach is of course only amenable if the analyte is an electrophile. Here also, if there is no GST that can catalyze the desired reaction, one can again think of a selection system to obtain the needed catalyst.

The current system employs probes that are excited at relatively low wavelengths. This causes problems because many substances absorb light in this region and many biologically related solutions absorb or scatter light in this part of the spectrum. This obstacle can also almost certainly be overcome through some sort of selection or screening procedure to obtain mutants that can be labeled at K216 with a fluorescent acyl group that is excited at a higher wavelength.

All of these things are made possible because, amazingly, hGST A1-1 seems to be an almost indestructible parent scaffold. It tolerates double mutations, rt handling over several days, and attachment to a surface without losing its structural integrity or ability to bind its natural substrates.

CONCLUSIONS

We have constructed a multipurpose affinity array composed of a designed family of promiscuous proteins carrying introduced fluorescent residues. It is the pattern of changes generated by binding a specific ligand, i.e., its "signature" that constitutes the readout. This is an approach that turns the aspect of what constitutes a good biosensor upside-down. Here, the strength lies in the numbers; many relatively poor binders each contribute to the overall result.

ACKNOWLEDGMENT

The authors express their sincere gratitude toward Professor Bengt-Harald Jonsson for his kind support. This work was financially supported by The Wenner-Gren Foundation, The Carl-Trygger Foundation, the Knut and Alice Wallenberg Foundation, and the Swedish Research Council.

Polyspermine-ribonuclease A (PS-RNase A) and polyspermine-dimeric ribonuclease A (PS-dimeric RNase A) were prepared by cross-linking ribonuclease A or its covalently linked dimer to polyspermine (PS) using dimethyl suberimidate. The two RNase A derivatives were tested for a possible antitumor action. The *in vitro* and *in vivo* cytotoxic activity of PS-RNase A, although strong, is not higher than that known for free polyspermine. PS-dimeric RNase A, which was characterized by mass spectroscopy, titration of free amine groups, and enzymatic assays, proved instead to be a definitely more efficient antitumor agent, both *in vitro* and *in vivo*. This result could tentatively be explained in view of the importance of positive charges for ribonuclease activity, considering the higher basicity of PS-dimeric RNase A compared to that of PS-(monomeric)RNase A. It must be also taken into account that the dimeric RNase A moiety of PS-dimeric RNase A could evade the cytoplasmic ribonuclease inhibitor, which instead could trap the monomeric RNase A moiety of the other derivative. The two RNase A derivatives degrade poly(A)·poly(U) under conditions where native RNase A is inactive. The results of this work demonstrate once again the importance of positive charges for the functions of mammalian pancreatic type ribonucleases in general, in particular for RNase A derivatives, and the potential therapeutic use of the ribonuclease A derivatives.

INTRODUCTION

Wang and Moore described the preparation of bovine ribonuclease A (RNase A[1]) covalently linked to polyspermine and called the product polyspermine-ribonuclease (*1*). Polyspermine consisted of a chain of spermine residues linked one to another by the bifunctional reagent dimethyl suberimidate. The polyspermine chain, which in the authors' best preparation consisted of eight spermine residues (*1*), was in turn linked, again through dimethyl suberimidate, to a lysine residue of an RNase A molecule (see Figure 1 for the structures of these molecules). The aim of Wang and Moore's work was to obtain ribonuclease A molecules endowed with a definitely higher basicity and higher affinity to nucleic acid molecules than native RNase A within the hypothesis advanced some years before (*2–5*) that pancreatic type ribonucleases are able to degrade not only single-stranded RNA but also double-stranded RNA as well as poly(A) or the RNA moiety of DNA/RNA hybrids (*2*) if they are more basic than bovine RNase A. Although the derivative obtained by Wang and Moore could have been heterogeneous in terms of which amine group on the protein was modified, it was found to maintain the activity on ssRNA but also acquire a very remarkable activity against double-helical polyribonucleotides as substrates (*1*). While the ability of mammalian RNases more basic than RNase A to attack dsRNA is between 10 and 40 times higher than that of RNase A (*2*), except for the special case of human pancreatic RNase, whose activity is very high (*2, 5*), polyspermine-ribonuclease was 115, 176, and 382 times more efficient than RNase A at degrading poly(A)·poly(U), poly(I)·poly(C), and the hybrid molecule poly(rU)·poly(dA), respectively (*1*). Recently, dimers, trimers, tetramers, and higher order oligomers of RNase A, formed by 3D domain swapping of the N-terminus and/or C-terminus of the protein (*6–8*), were shown to be able to remarkably degrade double-stranded polyribonucleotides and poly(A). DsRNA degradation increases as a function of the size of the oligomers, i.e., of the number or density of positive charges available on the oligomers' surface (*6*). Dimers, trimers, and tetramers of RNase A also display interesting biological actions (*9*), such as significant antitumor activity, demonstrated both *in vitro* and *in vivo*, and aspermatogenic action, under conditions where monomeric RNase A is inactive. A possible reason for these activities of the RNase A oligomers is that they could escape, different from native RNase A, interaction with the cytoplasmic ribonuclease inhibitor ((*10*), and references therein). It is worth pointing out that a parallelism exists between the enzymatic activity of the oligomers of RNase A toward dsRNA and its antitumor action. Indeed, both activities increase as a function of the size of the oligomers, and the interpretation of this finding is that both effects might be dependent on the number or density of positive charges present on the protein surface and on their increase (*11*). The high

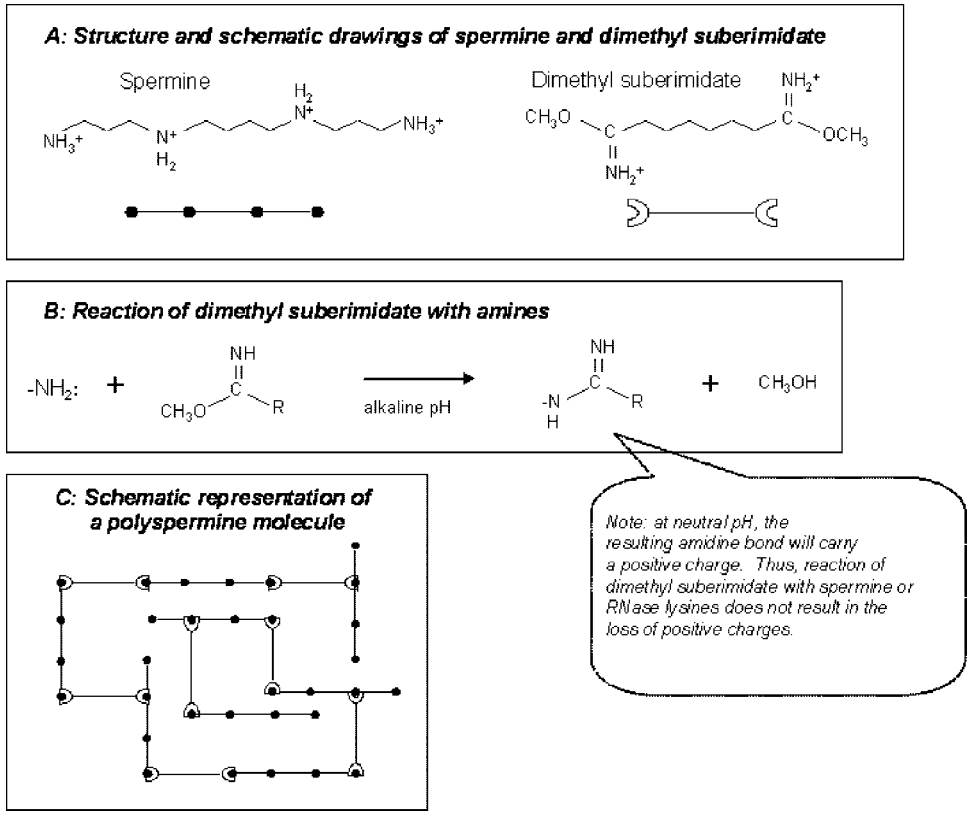

Figure 1. Structure and formation of polyspermine.

number or density of positive charges of an RNase A oligomer would favor the cleavage of dsRNA thanks to, as proposed for basic ribonucleases (*2*), a previous destabilization (*12*) of its secondary structure, thus making available, within the double-helix, single-stranded RNA segments to the action of the RNase. Moreover, the high basicity of an RNase A oligomer could favor its absorbance to and permeation of the cell membrane and enhance, once the oligomer is inside the cell, its enzymatic action toward all RNA secondary structures present in the cell. Besides the double-helical regions of rRNA, mRNA, and tRNA (*9, 11*), transient but important DNA/RNA hybrid structures, such as those occurring during the priming of DNA synthesis by RNA or during the synthesis of mRNA, as well as the polyadenylate tail of mRNA, could become good targets of the catalytic action of oligomeric RNase A (*11*).

In line with these facts, our idea now is to see if the binding of monomeric RNase A or cross-linked RNase A dimers (as the simplest example of oligomeric RNase A) to polyspermine, with the consequent increase of the basicity of the two enzyme species, could evoke a cytotoxicity of the two polyspermine-RNase A complexes higher than the cytotoxicity exerted by free polyspermine or spermine, which is already known (*13, 14*). The cross-linked RNase A dimer, notwithstanding a lower activity towards dsRNA compared to that of aggregated dimers (*15*), has the advantage of being stable, whereas all aggregated oligomers are meta-stable (*11, 16*). Moreover, it should also be able to evade the cRI (*17*). The present investigation, whose results support the ideas advanced (*2–5, 9, 11*) and reported above, is also in line with past work by some of us in searching for ribonuclease derivatives active as antitumor agents (*9, 18–23*).

EXPERIMENTAL PROCEDURES

Preparation of Cross-Linked Dimers of RNase A. To prepare the covalently linked dimer, we followed the procedure outlined by Wilson, Wang, and Moore (*24*). Forty milligrams of RNase A (Type XII-A, purchased from Sigma Chem. Co.) were dissolved in 0.64 mL of 0.2 M sodium phosphate buffer at pH 8.0. One milligram of solid dimethyl suberimidate (Sigma-Aldrich) was added in small aliquots to this solution with stirring. The pH of the solution was adjusted and maintained at 8.0 with 1 M NaOH. The reaction was carried out with stirring for 10 min at room temperature and stopped by adding 0.64 mL of 0.2 M ammonium acetate. The product was then purified and isolated by gel filtration through a Superdex 75 GL 10/300 column in an FPLC system (GE-Healthcare), equilibrated with 0.2 M sodium phosphate buffer at pH 6.7. The flow rate was 0.10 to 0.15 mL/min. The material was concentrated with Millipore Centricon YM-3 and 3000 MW cut-off, the solvent was exchanged to remove dissolved salts, and the sample was finally lyophilized.

Preparation of Polyspermine. One hundred twenty micromoles of spermine (41.78 mg; Sigma-Aldrich) were dissolved in 2 mL of 0.2 M triethanolamine at pH 9.7. To this solution, under stirring, small aliquots of solid dimethyl suberimidate (124 μmol, 33.88 mg) were added, controlling and adjusting the pH to 9.7 with 1 M NaOH. The reaction time was 1 min at room temperature (*1*).

Preparation of (Cross-Linked) Polyspermine-RNase A and Polyspermine-Dimeric RNase A. We cross-linked polyspermine to monomeric RNase A or its dimer following the method described by Wang and Moore (*1*). After the two steps of the previous preparation were completed, 1.1 μmol of monomeric or dimeric RNase A, dissolved in 2 mL of 0.1 M sodium phosphate buffer, pH 9.0, were added to the solution containing 120 μmol of polyspermine + 124 μmol of dimethyl suberimidate (see above). The reaction was carried out, with stirring, for five minutes and stopped by adding 1.5 mL of 2 M ammonium acetate. The products of the mixture were then purified and isolated by gel filtration through a Superdex 75 GL 10/300 column in an FPLC system (GE-Healthcare), equilibrated with

0.2 M sodium phosphate buffer at pH 6.7. The flow rate was 0.1 mL/min. The sample was then concentrated and lyophilized as described above.

Bovine Seminal Ribonuclease (BS-RNase). BS-RNase was isolated from bull seminal plasma obtained from healthy bulls bred in Litohor Insemination Station (Czech Republic). One volume of seminal plasma was diluted with 2.5 volumes of 2% acetic acid. The precipitate was removed by centrifugation and solid ammonium sulfate added to the supernatant up to a concentration of 3 M. After a second centrifugation, the supernatant was dialyzed using the Vivaflow 50 linked module flow system (Vivascience Ltd., Sonehouse, UK) and freeze-dried. For complete purification, chromatographies with CM Sephadex C-50 and Sephadex C-100 columns were used (*25*).

Determination of Free NH_2 Groups on RNase A, Dimeric RNase A, and PS-Dimeric RNase A. One hundred fifty micrograms of protein were dissolved in 1 mL of 0.15 M sodium tetraborate ($Na_2B_4O_7$) at pH 9.5. To this solution, 0.2 mL of 0.015 M trinitrobenzensulfonic acid (Fluka) was added in the dark with stirring. The incubation of this mixture was carried out, without stirring, for 45 min at 37 °C. The reaction was stopped by adding 2 mL of 85–90% formic acid. Finally, the absorbance at 340 nm of the samples and controls of unmodified RNase A was determined. The number of free lysine residues remaining was ascertained using the extinction coefficient of $\varepsilon_{340\ nm} = 12{,}000\ cm^{-1}\ M^{-1}$ per trinitrobenzenyl-lysine. The precision of this assay is ±10% or about one lysine group per RNase A molecule. Unmodified RNase A contains a total of 11 amine groups (10 Lys and one N-terminal amine).

Mass Spectrometry Analyses of the Cross-Linked RNase A Dimer Alone or Conjugated with Polyspermine. Matrix-assisted laser desorption–ionization time-of-flight (MALDI-TOF) mass spectra were recorded with an applied Biosystems Voyager System 6214 mass spectrometer using sinapinic acid in the matrix. The data were analyzed using the software supplied by Applied Biosystems.

Assays of Enzymatic Activity. Enzymatic activity on single-stranded RNA (purified yeast RNA) as substrate was performed according to Kunitz (*26*). The activity toward double-helical polyribonucleotide poly(A)·poly(U) was measured spectrophotometrically according to Libonati and Floridi (*1, 4*).

Assay of Antiproliferative Effect *in Vitro.* (a) ML-2 and K-562 cell lines derived from human leukemias were used for testing the antiproliferative activity of free spermine or polyspermine and the RNase A derivatives, polyspermine-ribonuclease A and polyspermine-dimeric RNase A, side-by-side with bovine seminal ribonuclease, as described previously (*9*). Briefly, ML-2 or K-562 cells (2×10^4) in 0.2 mL of RPMI 1640 medium supplemented with fetal calf serum (10% v/v) were established in microtiter plates (NUNC, FB type) and cultivated in humidified atmosphere, containing 5% CO_2 for 48 h. Four hours before ending cultivation, samples were pulsed with 24 kBq of 6-^{3}H-thymidine (specific activity 980 GBq/mmol, Institute for Research, Development and Application of Radioisotopes, Prague, Czech Republic). Cells were then collected with the Scatron harvester, and the incorporated radioactivity was measured with a Beckman scintillation counter. The mean value of three cultures containing one of the compounds to be tested was compared with the mean value of untreated control cells and the percentage of inhibited proliferation calculated. (b) In addition, human pancreas adenocarcinoma cell lines PaCa44 and PSN1 were used to test the action of the RNase A derivatives or other substances. The cells were grown in RPMI 1640 supplemented with 20 mM glutamine, 10% FBS, and 50 μg/mL gentamicin sulfate (BioWhittaker, Italy). Normal primary fibroblasts (Promocell, PBI Milan) were grown in DMEM supplemented with 10% FBS and 50 μg/mL gentamicin sulfate (BioWhittaker, Italy). All cell lines were incubated at 37 °C with 5% CO_2. Cells were plated in 96-well cell culture plates (4×10^3 cells/well) and treated with the substances to be tested at the concentrations indicated. Treated cells were maintained at 37 °C in the 5% CO_2 atmosphere for 24 h, then stained with Crystal Violet (Sigma). The dye was dissolved with 1% SDS in PBS and measured spectrophotometrically (A_{595}) to determine cell viability. Three independent experiments were performed for each assay condition.

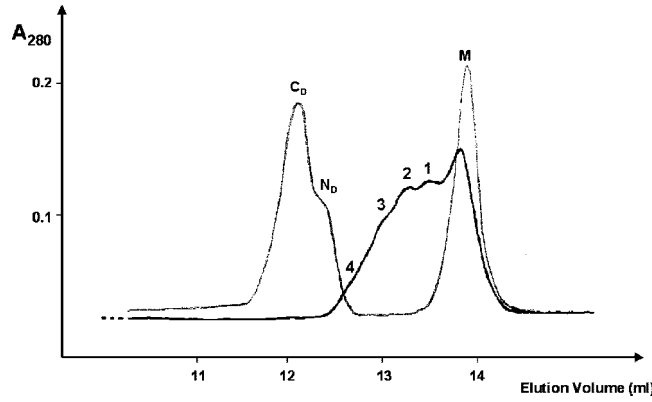

Figure 2. Size exclusion chromatography of polyspermine-ribonuclease A. One-half milligrams of the cross-linking PS-RNase A reaction mixture was applied onto a Superdex 75 GL 10/300 column equilibrated with 0.2 M sodium phosphate buffer, pH 6.7, in a FPLC system (GE-Healthcare). Flow rate was 0.1 mL/min at room temperature. C_D, C-terminal swapped dimeric conformer of RNase A; N_D, N-terminal swapped dimeric conformer of RNase A (*6, 8, 9, 11*). M, monomeric RNase A. 1, 2, 3, and 4, the four detectable PS-RNase A fractions (see text).

Assay of Immunosuppressive Activity on Mixed Lymphocyte Culture (MLC). Immunosuppressive activity of the various compounds was assessed on human lymphocytes stimulated in mixed lymphocyte culture (MLC), as described previously (*18*). Lymphocytes from two unrelated donors were mixed and cultivated in a humidified atmosphere containing CO_2 (5% v/v), at 37 °C, in RPMI 1640 medium supplemented with mixed human AB serum (10% v/v). RNase A derivatives or other substances were added at the beginning of the experiment, and cell mixtures were incubated for six days. Pulsation with (6-^{3}H)-thymidine and calculation of the inhibitory effect were carried out as described above.

Evaluation of the Action of RNase A Derivatives in Nude Mice. The antitumor activity of polyspermine-dimeric RNase A, RNase A cross-linked dimer, or free polyspermine was studied in athymic female nude CD-1 mice (Anlab-Charles River) weighing 18–20 g. Groups of six mice were housed under aseptic conditions (*20*). Human melanoma (tumor line C-32) was obtained from a European tumor bank, ECACC (European Collection of the Cell Cultures, CAMR, Salisbary, Wiltshire SP4 0JG, U.K.). This tumor line was amplified in a tissue culture and was administered subcutaneously to nude mice, on the right flank, with 1×10^7 tumor cells together with 0.1 mL of Matrigel. Intratumoral (i.t.) or intravenuous (i.v.) treatment was initiated when the area of the tumor transplanted in mice reached 5 × 5 mm. The RNase A derivative and other substances were injected (doses specified in Figure legends) three times a week over a period of 18 days. Tumor size was measured twice a week using a slide caliper (length × width × depth) (*9*).

RESULTS

Purification of Polyspermine-Ribonuclease A and Polyspermine-Dimeric Ribonuclease A. PS-RNase A was partly purified by gel filtration (Figure 2). The gel filtration pattern consists of

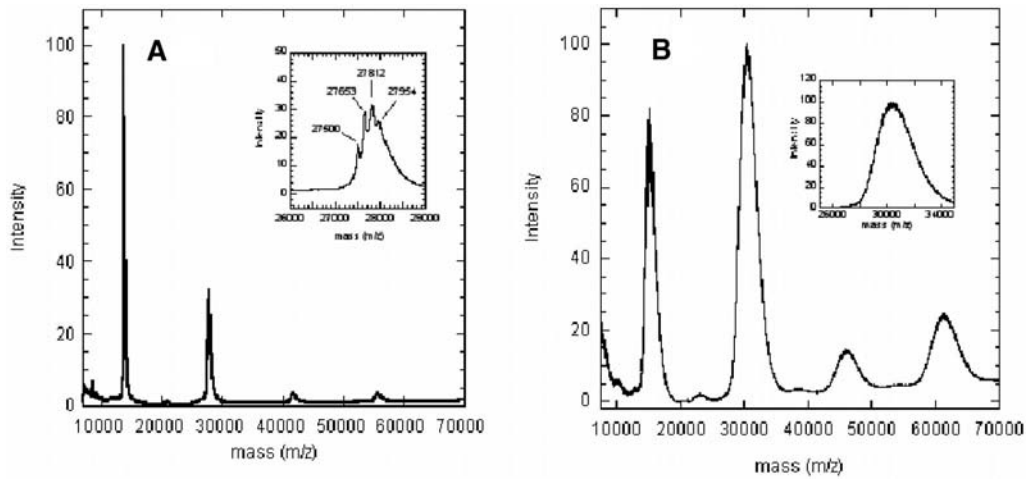

Figure 3. MALDI-TOF mass spectra of (A) cross-linked dimer of RNase A and (B) PS-dimeric RNase A. The fine structure of the dimer peaks is shown in the insets. See Experimental Procedures for details.

a large heterogeneous peak that includes various fractions of monomeric RNase A that reacted with polyspermine. The largest portion of this peak, eluting before the peak corresponding to native, un-reacted RNase A (M in Figure 2), consists of four almost unresolved fractions (indicated as 1, 2, 3, and 4 in Figure 2). Although quite scarcely resolved, fractions 1 and 2 show sufficiently clear apexes (less clear are those of fractions 3 and 4). These apexes were used to calculate the elution volumes, and hence the molecular weight, of the four fractions. The profile of the large peak clearly shows that none of the fractions 1, 2, 3, and 4 elutes in positions similar to or overlapping those of the 3D domain-swapped dimeric RNase A conformers (N_D and C_D) (*11*) used as standards. This is a further indication that the fractions are indeed monomeric variants of RNase A. We assume that the differences in weight between fractions 1, 2, 3, and 4 and native RNase A are due to different amounts of polyspermine bound to the protein, i.e., to the different number of spermine and dimethyl suberimidate residues, whose ratio is always about 1:1, linked to the RNase A molecule. The calculated molecular weight values of the four fractions indicated that sample 1 should contain 2 spermine residues, sample 2 between 2 and 5, sample 3 between 5 and 8, and sample 4 between 9 and 14 spermine residues. An attempt to further purify polyspermine-ribonuclease A by cation exchange chromatography was unsuccessful (data not shown), revealing great heterogeneity, which was already observed by Wang and Moore (*1*) and was also detected in the dimeric RNase A and polyspermine-dimeric ribonuclease A patterns by mass spectra, as described in the next section. This heterogeneity led us to distinguish the eluted fractions of the monomeric RNase A derivative in four final groups that correspond to the four peaks identified in the gel filtration pattern (Figure 2). Fractions that showed, on the basis of the cation exchange chromatography results (not shown), a relatively similar degree of basicity were combined. It must be taken into account that in addition to the number of spermine molecules within the polyspermine moiety, the location of the lysine residues reacting with polyspermine could also influence the elution position. These four PS-RNase A groups have been dialyzed, concentrated, and tested for their enzymatic and biological actions. A similar procedure was followed to isolate PS-dimeric RNase A. A gel filtration analysis, methodologically identical to that used for PS-RNase A, revealed a peak slightly larger than a second, distinct peak of un-reacted dimeric RNase A. The calculation of the molecular weight of the main symmetric peak indicated the presence of about 20–25% of polyspermine and 75–80% of protein, values that are sufficiently close to those calculated by mass spectroscopy (see later). The analysis of PS-dimeric RNase A with cation exchange chromatography did not give a clearer pattern than that obtained with PS-RNase A. We therefore used the total PS-dimeric RNase A peak as such to determine both the enzymatic and antiproliferative activities of PS-dimeric RNase A.

Further Characterization of Polyspermine-Dimeric Ribonuclease A. *(a) Titration of Lysine Groups.* The cross-linked (with dimethyl suberimidate) dimers of RNase A and PS-dimeric RNase A were characterized, side-by-side with native RNase A, by titration of the free amine groups according to Wang and Moore (*1*) (see Experimental Procedures). The number of unmodified amines groups was found to be 9 ± 1 in native RNase A, 8 ± 1 in cross-linked dimeric RNase A, and 6 ± 1 in the PS-dimeric RNase A.

(b) Analysis of Polyspermine-Dimeric Ribonuclease A by Mass Spectroscopy. The mass spectra of the cross-linked RNase A dimers revealed strong peaks with mass/charge ratios corresponding to monomeric and dimeric species and much weaker ones corresponding to trimeric and tetrameric species (Figure 3A). It is important to note that the absolute amount of dimer may actually be as high as that of the monomer since mass spectroscopy tends to exaggerate the intensity of lighter species, which fly better. Both the monomeric and dimeric peaks contain fine peaks with mass/charge values of 13682, 13839, and 14002 (monomer) and 27500, 27653, 27812, and 27954 (dimer) (Figure 3A inset). The lightest monomer has a mass corresponding to native RNase A, and the mass of the lightest dimer is that expected for the dimethyl suberimidate cross-linked dimer of RNase A. The mass/charge increment between the fine peaks observed for both the monomer and dimer is about 153–163 mass units, which corresponds reasonably well to the mass of a molecule of dimethyl suberimidate that has reacted with only one lysine residue (expected mass increase = 170). This increment corresponds even better to the mass of a molecule of dimethyl suberimidate that has reacted with a lysine residue at one end and with a water molecule at the other end to lose a molecule of methanol (expected mass increase = 156). The mass spectrum of PS-dimeric RNase A is shown in Figure 3B. A series of broad peaks can be observed, with masses corresponding approximately to monomer, dimer, trimer, and tetramer. The dimer appears to be the most populated species. The dimer peak is broad; its mass ranges from 28,000 Da (the unmodified dimer) up to 34,000 Da (Figure 3B, inset). This indicates that the number of attached spermine groups present in the dimer varies significantly. The number of spermine groups attached per dimer can be calculated considering that one molecule of dimethyl suberimidate (mass = 138 Da when fully reacted) is required

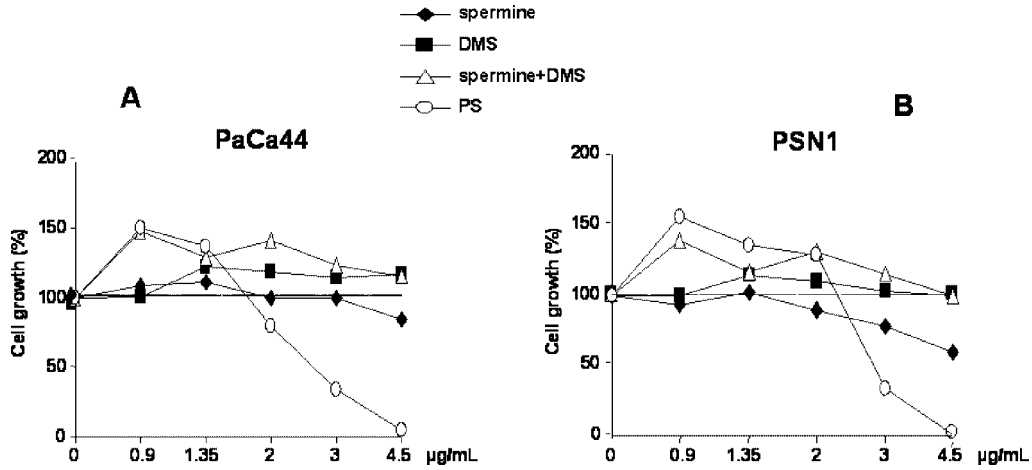

Figure 4. Dose-dependent effects of polyspermine, spermine, and dimethyl suberimidate, alone or mixed together, on two pancreatic adenocarcinoma cell lines. Cells were seeded in 96-well plates and incubated overnight; they were further incubated in the presence of the various substances for 24 h. The concentrations indicated are relative to the concentrations of free polyspermine used. Since the ratio of the amounts of spermine and DMS in polyspermine was about 1:1, the concentrations used of single spermine or DMS were 50% of those indicated on the abscissa. Cell proliferation was determined with the crystal violet colorimetric assay (see Experimental Procedures). The values reported are the means of triplicate wells from three independent experiments. DMS, dimethyl suberimidate. PS, polyspermine.

to couple each spermine molecule (mass = 203 Da). Since the range of dimer peak mass is about 34,000–28,000 Da = 6000 Da, the maximum number of spermine groups attached is about 6000 Da/(138 + 203 Da) = 18.

Taken together, these data suggest (i) that the cross-linked RNase A dimers contain some monomeric species, some of which have half-reacted with additional molecules of dimethyl suberimidate and (ii) that the preparation of PS-dimeric RNase A contains a rich diversity of species bearing from 1 to 18 spermine moieties.

Tests for Possible Biological Actions Displayed by the Single Components of the Polyspermine-RNase A Derivatives. In preliminary *in vitro* experiments, free polyspermine, spermine, the bifunctional reagent dimethyl suberimidate (DMS), and DMS mixed with spermine were tested on two human pancreas adenocarcinoma cell lines, PaCa44 and PSN1, in order to see possible effects that single components of the PS-RNase A complex could evoke in transformed cells. Figure 4A shows that while spermine, DMS, or spermine plus DMS did not show any effect on the two cell lines, and spermine just a small one on PSN1 cells (Figure 4B), the action of polyspermine on both lines was strong, starting at a polyamine concentration between 1 (Figure 4A) and 2 (Figure 4B) μg/mL of culture medium.

Antiproliferative Action *in Vitro* of Polyspermine-Ribonuclease A. The four distinct PS-RNase A fractions eluted in the gel filtration (Figure 2) and grouped on the basis of their basic charge characters (cation exchange chromatography) were tested for their ability to inhibit the proliferation of ML-2 and HT 1197 cell lines side-by-side with spermine, polyspermine, and bovine seminal RNase. Briefly (data not shown), while spermine was only slightly active, the four PS-RNase A fractions, free polyspermine and bovine seminal RNase were found to be efficient antiproliferative agents but without significant differences between PS-RNase A and free polyspermine. Similar results were obtained by testing the immunosuppressive activity of the same substances on mixed lymphocyte cultures (data not shown). Moreover, the PS-RNase A fraction n. 3 (see Figure 2), as one endowed with high basicity and the one showing maximal dsRNase activity (as described later; see Table 1), was also tested on the PaCa44 and SPN1 cell lines, side-by-side with spermine and polyspermine (Figure 5A and B). While free spermine was inactive on PaCa44 cells and just very slightly active on SPN1 cells (in agreement with that shown in Figure 4B), a higher antiproliferative action exerted by free polyspermine relative to that of the PS-RNase A fraction 3 could be observed on PaCa44 cells (Figure 5A). The two agents instead showed similar antiproliferative actions on PSN1 cells (Figure 5B).

Table 1. Enzymatic Activity of the Various Ribonuclease A Species on Single-Stranded RNA and Double-Stranded Poly(A)·Poly(U)[a]

monomeric or dimeric RNase A species	(A) specific activity yeast RNA as substrate	(B) specific activity poly(A)·poly(U) as substrate
native, monomeric RNase A	84.55 ± 6.30	1.55 ± 0.21
DMS-treated monomeric RNase A	49.33 ± 3.06	1.14 ± 0.12
PS-RNase A-1	n.d.	40.25 ± 19.90
PS-RNase A-2	n.d.	76.30 ± 21.70
PS-RNase A-3	n.d.	116.16 ± 39.91
PS-RNase A-4	n.d.	96.73 ± 22.72
domain swapped RNase A C-Dimer	53.46 ± 4.04	12.15 ± 3.04
cross-linked (DMS) RNase A Dimer	12.67 ± 3.02	2.22 ± 0.36
PS-dimeric RNase A	13.33 ± 1.15	25.21 ± 3.88

[a] Incubation mixtures: 0.4 mL of SSC (0.15 M sodium chloride/0.015 M sodium citrate, pH 7.0), containing poly(A)·poly(U), 40 μg, and 1–6 μg of the various RNase A species. Monomeric RNase A, 12 μg. The mixtures were normalized in their sodium phosphate content. (A) Kunitz units. (B) Enzyme units: increase in absorbance at 260 nm/min/total measurable change (*2*). Temperature, 25 °C. PS-RNase A 1, 2, 3, and 4 are the polyspermine-(monomeric) RNase A groups obtained by combining fractions with similar degree of basicity (see text). DMS-treated monomeric RNase A is the ribonuclease A recovered after the cross-linking reaction.

In summary, from this set of experiments, we can conclude that any activity of the polyspermine-ribonuclease A complex should actually be ascribed to the action of polyspermine or, rather, to the polyspermine moiety of the complex.

Antiproliferative Action *in Vitro* of Polyspermine-Dimeric Ribonuclease A. A preliminary experiment was performed by comparing side-by-side the action of the cross-linked RNase A dimers, PS-dimeric RNase A, and free polyspermine on normal primary fibroblast cells (Figure 6A). The RNase A dimers do not show any activity, and the action of free polyspermine is very modest and slightly higher that of PS-dimeric RNase A.

The same substances were then tested for their action on PSN1 cells. As shown in Figure 6B, dimeric RNase A does not show any significant action, while free polyspermine and PS-

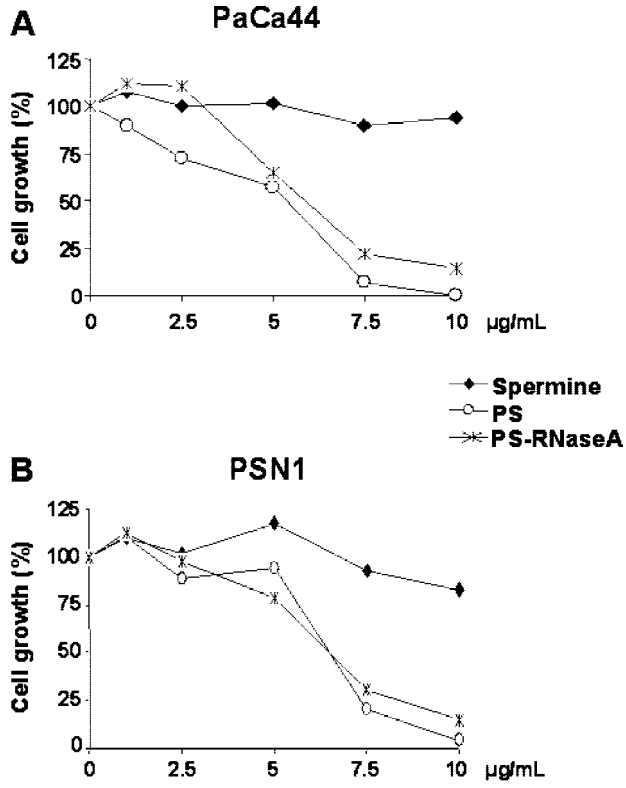

Figure 5. Dose-dependent effects of spermine, polyspermine, or PS-RNase A (group of fractions n. 3) on the two pancreatic adenocarcinoma cell lines, PaCa44 and PSN1. Cells were seeded in 96-well plates and incubated overnight. Cells were further incubated in the presence of the various molecules for 24 h. The concentrations indicated are relative to PS-RNase A. In line with the relative amount of polyspermine present in the RNase A derivative (group n. 3 of eluted fractions) as determined by mass spectroscopy (and gel filtration), the concentrations of single spermine and polyspermine used were 22% and 44%, respectively, of the concentrations of PS-RNase A used. Cell proliferation was determined with the crystal violet colorimetric assay, as described in the Experimental Procedures section. The values are the means of triplicate wells from three independent experiments. PS, polyspermine; PS-RNase A, polyspermine-ribonuclease A (group of fractions n. 3).

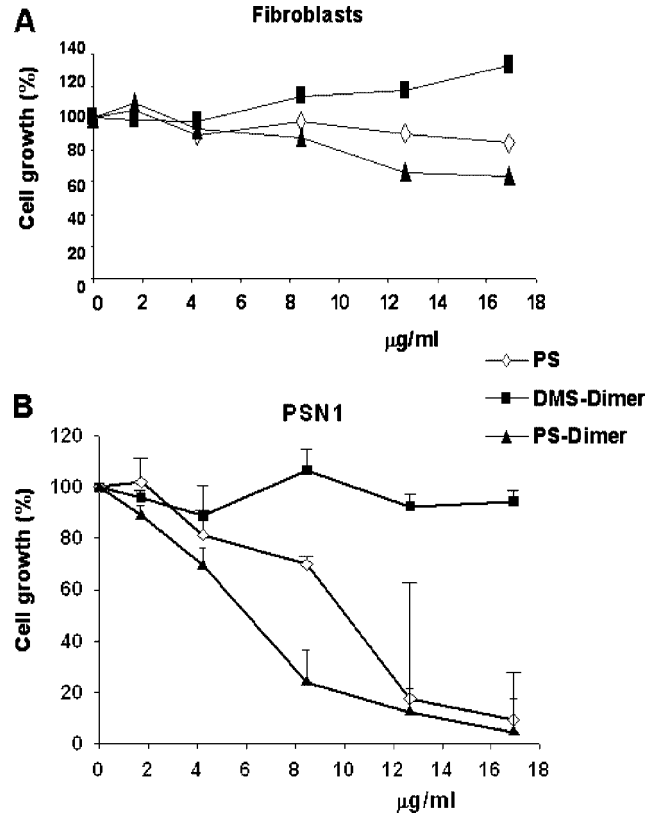

Figure 6. Dose-dependent effects of polyspermine, the cross-linked RNase A dimer, and PS-dimeric RNase A on the growth of (A) normal human fibroblasts and (B) the human pancreatic adenocarcinoma cell line PSN1. Cells were seeded in 96-well plates and incubated overnight. Cells were further incubated in the presence of the various substances for 24 h. The concentrations reported are referred to PS-dimeric RNase A. Considering that this RNase A derivative resulted by mass spectroscopy analyses to be formed by about 20% polyspermine and 80% dimeric RNase A in weight, while calculations by gel filtration were slightly higher, free polyspermine was used in some excess (25%) compared to the calculated concentrations. Cell proliferation was determined using the crystal violet colorimetric assay, as described in the Experimental Procedures section. The values are the means of triplicate wells from three independent experiments. PS, polyspermine; DMS-Dimer, cross-linked dimers of RNase A; PS-Dimer, polyspermine-dimeric ribonuclease A.

dimeric RNase A display a definite antiproliferative activity within almost the entire range of concentrations used, the RNase A derivative appearing to be more efficient than polyspermine alone.

Free polyspermine and PS-dimeric RNase A were also tested side-by-side with bovine seminal RNase on the two tumor cell lines ML-2 and K-562. Quite interestingly (see Figure 7A and B), the antiproliferative effect of free polyspermine on both cell lines is definitely higher than that of bovine seminal RNase, but PS-dimeric RNase A undoubtedly had the strongest antiproliferative action on ML-2 and K 562 cells. Similar results were obtained by assaying polyspermine and PS-dimeric RNase A side-by-side with bovine seminal RNase on the proliferation of a mixed lymphocyte culture (MLC; Figure 7C). Here too, the antiproliferative effect of bovine seminal RNase is remarkably lower than that exerted by the two other agents, and PS-dimeric RNase A is, again, definitely more efficient than polyspermine alone.

Antiproliferative Activity *in Vivo* of Polyspermine-Dimeric RNase A. PS-dimeric RNase A was tested, side-by-side with the cross-linked RNase A dimers and free polyspermine on the growth of a human melanoma (tumor line C-32) transplanted in nude mice. PS-dimeric RNase A was administered either intravenously or intratumorally. The results are shown in Figure 8. When injected intravenously, the inhibiting effect of PS-dimeric RNase A appears to be similar or slightly lower than that of both cross-linked RNase A dimers and free polyspermine. When administered directly into the tumor, although both dimeric RNase A and free polyspermine appear to be quite efficient and similar to each other at inhibiting tumor growth, PS-dimeric RNase A is definitely the most efficient antitumor agent.

Enzymatic Activity of Polyspermine-Ribonuclease A and Polyspermine-Dimeric Ribonuclease A. The ribonuclease activity of the RNase A species of interest was determined on single-stranded RNA according to the method of Kunitz (*26*) and on double-stranded poly(A)·poly(U) using a spectrophotometric assay (*2, 4, 5*). Table 1 (A) shows the activity, expressed in terms of Kunitz specific activity values, of native RNase A, the monomeric RNase A recovered from the cross-linking reaction, the aggregated RNase A C-dimer (formed by the swapping of the C-terminal β-strand of each monomer) (*8, 11*), the cross-linked RNase A dimer, and PS-dimeric RNase A. Both RNase A dimers show less activity against ssRNA compared to that of native, monomeric RNase A. This result, whose interpretation is not straightforward (*2, 11*), agrees with data repeatedly and consistently obtained in a number of assays performed in the past. Indeed, aggregated dimers or oligomers of RNase A, cross-linked oligomers, and even monomeric

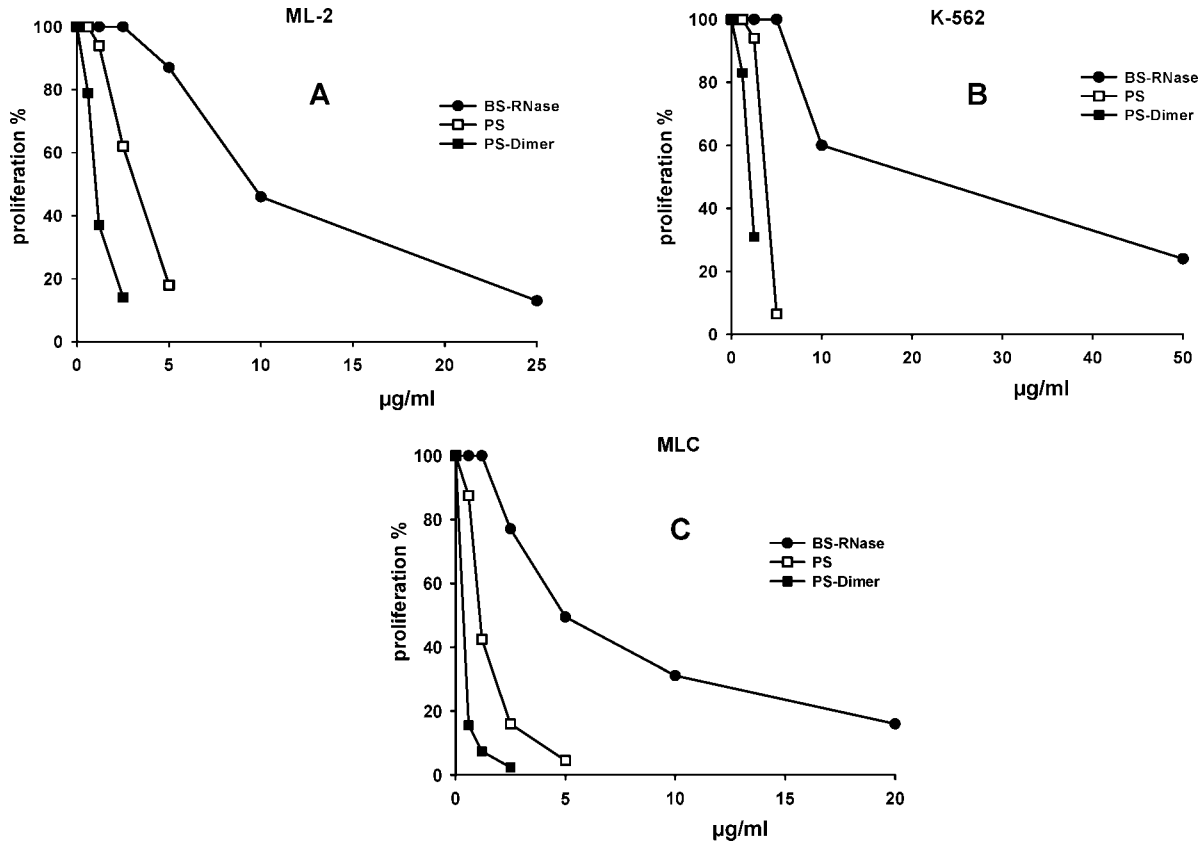

Figure 7. Dose-dependent effects of polyspermine, PS-dimeric RNase A, and bovine seminal RNase on the proliferation of human leukemic cell lines ML-2 (A), K-562 (B), and human lymphocytes stimulated in mixed lymphocytes culture, MLC (C). (A and B) Proliferation was evaluated after two days of incubation by the incorporation of ^{3}H-thymidine into cellular DNA. Each value is the mean of triplicate wells from two experiments and is reported in percent values compared to the value of untreated control samples. (C) Cell proliferation was determined by the incorporation of ^{3}H-thymidine into cellular DNA after six days of incubation. Each value is the mean of three cultures from two experiments and is reported in percent values compared to the value of untreated control cells. As mentioned in the legends to previous Figures, the doses of PS-dimeric RNase A and free polyspermine were calculated by taking into account the actual amount of polyspermine present in the RNase A derivative. BS-RNase, bovine seminal RNase; PS, polyspermine; PS-Dimer, polyspermine-dimeric ribonuclease A.

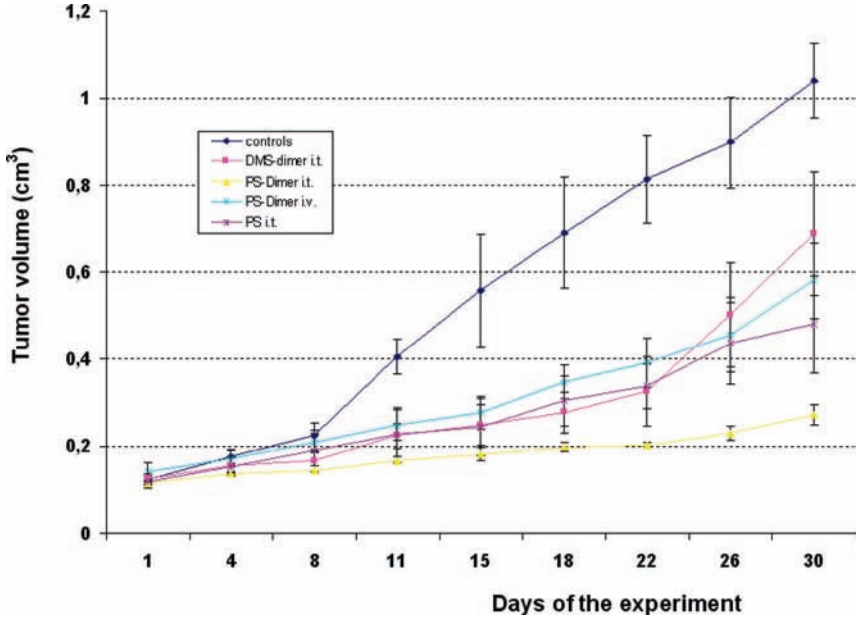

Figure 8. Effects of PS-dimeric RNase A, cross-linked dimers of RNase A, and free polyspermine on the growth of a human melanoma (tumor line C-32) transplanted in nude mice. PS-dimeric RNase A (100 μg/20 g), the cross-linked RNase A dimer (100 μg/20 g), and free polyspermine (25 μg/20 g) were administered intratumorally (i.t.). PS-dimeric RNase A was also administered intravenuously (i.v.) three times a week (total, nine doses). DMS-dimer, cross-linked RNase A dimer; PS-Dimer, PS-dimeric ribonuclease A; PS, free polyspermine.

mammalian ribonucleases endowed with a higher basicity than that of bovine pancreatic RNase A show lower Kunitz specific activity values relative to that of native, monomeric RNase A (*2*, *5*, *11*, *27*, *28*). A remarkably different rank order is

observed for the efficiency of the various RNase A species at cleaving poly(A)·poly(U) (Table 1 (B)). While for native RNase A we obtained a specific activity value that is consistent with values obtained in past experiments (*4, 5, 11, 28*), monomeric RNase A recovered from the cross-linking reaction shows, as already observed (*15*), a slightly lower activity than expected. On the contrary, the four polyspermine-ribonuclease groups, combining fractions endowed with similar degrees of basicity, displayed substantially stronger activity, which for at least three out of the four groups tested appears to be related or dependent on their increased basicity. As for the dimeric RNase A species, the cross-linked dimer shows a significantly lower activity than the C-terminal domain-swapped dimer does, while the action displayed by PS-dimeric RNase A is remarkably higher.

DISCUSSION

The principal aim of this work was to verify whether derivatives of bovine RNase A formed by monomeric or dimeric ribonuclease A cross-linked to polyspermine could display significant *in vitro* and *in vivo* cytotoxic action. Two well-established results provide a basis for expecting PS-RNase A to have strong antitumor activity. The first is that while native, monomeric RNase A is inactive at degrading dsRNA (*2, 29, 30*) and devoid, at least within a reasonable range of concentrations, of any antitumor action, its oligomers formed by simple aggregation (*9*), or dimers and trimers obtained by cross-linkage with dimethyl suberimidate (*15*) show an increased capacity of degrading double-stranded RNA (*11*) as well as remarkable *in vitro* and *in vivo* antitumor activity, which is accompanied by some other biological actions (*9, 11, 15*). The second, well-established finding is that polyspermine-ribonuclease (the product obtained by Wang and Moore (*1*) by cross-linking RNase A to polyspermine) acquires, when compared with that of native RNase A, a very remarkable ability to degrade double-stranded polyribonucleotides (*1*). Wang and Moore also studied the action of spermine or polyspermine added separately to a solution of PS-RNase A and poly(A)·poly(U) as substrate and saw that at concentrations between 1 μM to 0.2 mM the two polyamines increased the catalytic action of the RNase A derivative by less than 10%, while at higher concentrations (0.72 to 2.87 mM), spermine inhibited the enzyme (*1*). The ability to degrade double-helical RNA or DNA/RNA hybrids could be explained, both for RNase A oligomers and PS-RNase A, by the hypothesis ((*2*), and references therein) that the higher basicity of the enzyme molecule (due to its oligomerization, on one side, or to the presence of polyspermine, on the other) could induce, by interacting with dsRNA, a destabilization of the double-helix, with the exposure of single-stranded RNA segments sensitive to ribonucleolytic attack. Also, the biological activity of the RNase A oligomers might be explained with their increased basicity, which could favor their interaction with the cell membrane, their entrance in the cells, and hence their ability to degrade double-helical polyribonucleotide structures vital for the cells (*9, 11*). Moreover, a possible additional reason for the activity of RNase A oligomers is their size, which could ensure their partial or total escape from interaction with the cRI (*8, 11*), which completely inhibits monomeric RNase A.

The results obtained in this work appear to support, at least partly, the original idea. While PS-RNase A does not show an antitumor activity significantly higher than that of polyspermine alone, PS-dimeric RNase A displays both *in vitro* and *in vivo* cytotoxic action definitely higher than that exerted by polyspermine alone. Moreover, it should be taken into account that the activity of polyspermine-dimeric RNase A *in vitro* on several transformed cell lines and *in vivo* against a human melanoma transplanted in nude mice might appear to be lower than it really is because, as indicated by mass spectrometry analyses, some PS-RNase A could be present in the preparation. It is also worth pointing out here that the different effects of the two RNase A derivatives could be partly explained on the basis of a successful interaction of the cRI with the monomeric protein moiety of PS-RNase A. This interaction has been proved to occur also between cRI and the two domain swapped dimers of RNase A (*17*), although, at the same time, these oligomers were found to be biologically active (*9*). In our present case, the cRI could have been unable to interact or able to interact less efficiently with the dimeric protein moiety of PS-dimeric RNase A because of an increased steric hindrance caused by the polyspermine chain(s) linked to the protein. The results presented are also evidence of the already well known antitumor or, more generally, cytotoxic actions of polyamines due to their reaction products, H_2O_2 and aldehyde(s), formed by the oxidative deamination of biogenic amines or polyamines by cellular amine oxidases (*13*). This intrinsic toxicity of spermine and polyspermine may also totally or partially mask the antitumor action of the ribonuclease moiety of the two RNase A derivatives considered here, PS-RNase A and PS-dimeric RNase A. As mentioned above, no antitumor activity significantly higher than that displayed by polyspermine alone could be detected for the former derivative. This might be due not only to the successful intracellular interaction of the monomeric RNase moiety of PS-RNase A with the cytosolic inhibitor but also to the strong cytotoxic action of its polyspermine moiety. Actually, these uncertain results led us to construct the second RNase A derivative. PS-dimeric RNase A in fact shows a definitely higher cytotoxic action than that of polyspermine alone. The divergence in the biological activities of the two polyspermine derivatives of RNase A, partly ascribable to the cytotoxicity intrinsic to the polyspermine moiety, contradicts the fact that the other property, i.e., the ability to degrade *in vitro* double-stranded polyribonucleotides, is shared by both derivatives. This points out, once again, the role of the cRI. As discovered by Wang and Moore (*1*), PS-RNase A is remarkably efficient at degrading double-helical polyribonucleotides. The same is true for PS-dimeric RNase A, although its action on double-stranded poly(A)·poly(U) is lower than expected. This and in general the lower enzymatic activities toward dsRNA shown by cross-linked derivatives of pancreatic ribonuclease A (*15*) compared to that of aggregated dimers is difficult to explain. Indeed, the reaction with dimethyl suberimidate should not change the net charge of the protein since the resulting amidine bond carries a positive charge. However, the loss of enzymatic activity against dsRNA when many lysine-NH_3^+ groups of RNase A were modified was also observed and not explained by Wang, Wilson, and Moore (*24*). A lower activity of the positive charge at the amidine bond as well as the possibility that Lys-41 of some RNase A molecules of the population of reacting ribonuclease A molecules might be modified, or the variable and unspecific location of the dimethyl suberimidate chains on the RNase A surface could be responsible for the reduced enzymatic activity of the RNase A derivatives. The importance of a specific location of positive charges on RNase A for its catalytic activity has been stated, among others (*12, 31*), by McPherson et al. (*32*), who suggested that nine basic amino acid residues can constitute a cationic linear array complementary to the phosphate groups of a polyribonucleotide chain and was also pointed out by some of us for the activity against double-stranded polyribonucleotides shown by mammalian ribonucleases endowed with a higher basicity than bovine RNase A (*2, 5, 11*). In this regard, it is worth mentioning that cationic ribonucleases, such as EDN and ECP, whose positive charges are mainly located far from their active site regions, are inactive on dsRNA (*5, 33*). The same reasons mentioned above could also make polyspermine-monomeric or polyspermine-dimeric ribonuclease A less

efficient in their biological actions. In this regard, the more appropriate dimeric species of RNase A for cross-linking to polyspermine could possibly be the RNase A tandem variants constructed by Leich et al. (*34*) by gene duplication with insertion of the sequence of a peptide linking the C-terminus of an RNase A molecule and the N-terminus of a second RNase A molecule, as well as the new form of RNase A dimer recently described by Simons et al. (*35*). This dimer is stabilized by a single amide bond between the side chain NH_3^+ of Lys-66 and the side chain COO^- group of Glu-9, with no change of the protein net charge.

In conclusion, the results obtained and discussed here support on one side the importance, often pointed out (*1, 2, 11, 24, 27, 36–39*), of the positive charges present on a ribonuclease molecule for its functions and on the other side the potential therapeutic use of ribonucleases and RNase A derivatives (*37, 39–45*).

Received July 13, 2007; Revised Manuscript Received September 10, 2007

Detection of HER2-overexpression in tumors and metastases is important for the selection of patients who will benefit from trastuzumab treatment. Earlier investigations showed successful imaging of HER2-positive tumors in patients using indium- or gallium-labeled Affibody molecules. The goal of this study was to evaluate the use of ^{99m}Tc-labeled Affibody molecules for the detection of HER2 expression. The Affibody molecule $Z_{HER2:342}$ with the chelator sequences mercaptoacetyl-Gly-Glu-Gly (maGEG) and mercaptoacetyl-Glu-Glu-Glu (maEEE) was synthesized by peptide synthesis and labeled with technetium-99m. Binding specificity, cellular retention, and *in vitro* stability were investigated. The biodistribution of ^{99m}Tc-maGEG-$Z_{HER2:342}$ and ^{99m}Tc-maEEE-$Z_{HER2:342}$ was compared with ^{99m}Tc-maGGG-$Z_{HER2:342}$ in normal mice, and the tumor targeting properties of ^{99m}Tc-maEEE-$Z_{HER2:342}$ were determined in SKOV-3 xenografted nude mice. The results showed that the Affibody molecules were efficiently labeled with technetium-99m. The labeled conjugates were highly stable *in vitro* with preserved HER2-binding capacity. The use of glutamic acid in the chelator sequences for ^{99m}Tc-labeling of $Z_{HER2:342}$ reduced the hepatobiliary excretion 3-fold with a single Gly-to-Glu substitution and 10-fold with three Gly-to-Glu substitutions. ^{99m}Tc-maEEE-$Z_{HER2:342}$ showed a receptor-specific tumor uptake of 7.9 ± 1.0 %IA/g and a tumor-to-blood ratio of 38 at 4 h pi. Gamma-camera imaging with ^{99m}Tc-maEEE-$Z_{HER2:342}$ could detect HER2-expressing tumors in xenografts already at 1 h pi. It was concluded that peptide synthesis for the coupling of chelator sequences to Affibody molecules for ^{99m}Tc labeling is an efficient way to modify the *in vivo* kinetics. Increased hydrophilicity, combined with improved stability of the mercaptoacetyl-triglutamyl chelator, resulted in favorable biodistribution, making ^{99m}Tc-maEEE-$Z_{HER2:342}$ a promising tracer for clinical imaging of HER2 overexpression in tumors.

INTRODUCTION

Malignant transformation of cells may cause altered expression of distinctive molecular features relative to the surrounding tissues. Overexpression of a certain protein is often correlated with tumor progression and/or with tumor response to a certain treatment. Molecular imaging of such protein targets provide important diagnostic information that can influence patient management (*1*). One such target that has been extensively studied is the HER2/*neu* receptor (also known as *erb*B-2), a member of the receptor tyrosine kinase superfamily. HER2 is overexpressed in 20–30% of all breast cancers and in a variety of other tumors of epithelial origin (*2, 3*). Treatment with the humanized antibody trastuzumab (Herceptin, Genentech) improves the survival of patients with HER2-positive breast cancers, likely by the prevention of receptor dimerization and disruption of signaling pathways (*4*). Other anti-HER2 therapeutic agents are under clinical evaluation, including the monoclonal antibody pertuzumab (Omnitarg) (*5*), the heat-shock protein 90 inhibitor 17-AAG (*6*), and the tyrosine kinase inhibitor lapatinib (*7*).

An accurate determination of HER2 status is required in order to select breast cancer patients for Herceptin therapy. Currently, both the American Association of Clinical Oncology (*8*) and the European Group on Tumor Markers (*9*), recommend that HER2 expression should be evaluated on every primary breast cancer in order to identify patients who may benefit from Herceptin treatment. The most widely used methods for the detection of HER2 are immunohistochemical staining (IHC) and fluorescence *in situ* hybridization (FISH) of biopsy samples (*10*). However, these tests have some limitations (*8*), including inability to detect expression heterogeneity within a tumor lesion (*11, 12*) and discordance in HER2 expression between the primary tumor and the metastases (*13*). There is also subjectivity in evaluating the staining score (*11*). In contrast, radionuclide imaging may be applied to visualize HER2 expression in both whole primary tumors and metastatic lesions.

HER2 has no natural ligands (*14*), and monoclonal antibodies have been evaluated as targeting agents for radionuclide imaging (*15*). The general issues associated with the large size of intact IgG (Mw ~150 kDa) are slow blood clearance and slow tumor penetration, leading to low contrast of images (*16*). Reduction of the size of targeting proteins is considered a promising approach to improve the image contrast (*17*) and has generated a number of anti-HER2 antibody fragments such as $F(ab')_2$ (*18*), Fab (*19*), single chain Fv (25–55k Da) (*20*), and diabody (*21*).

Our approach to improve the radionuclide imaging contrast is to create a relatively small HER2-targeting protein by using

Affibody technology, on the basis of the 58 amino acid B-domain of staphylococcal protein A. Randomization of 13 solvent-exposed residues has generated an Affibody library (3×10^9 variants), which has been used for the selection of affinity ligands to a variety of proteins (*22*). Affibody molecules are low molecular weight (7 kDa) and cysteine-free three-helix bundle proteins. The anti-HER2 Affibody molecule $Z_{HER2:342}$ binds to the extracellular domain of HER2 with an affinity of 22 pM (*23*).

Recombinant $Z_{HER2:342}$, labeled with ^{125}I and ^{111}In, demonstrated clear visualization of HER2-expressing SKOV-3 xenografts in mice (*23, 24*). However, the use of peptide synthesis for the production of targeting agents offers the advantage of site-specific incorporation of chelators. $Z_{HER2:342}$ has been produced by peptide synthesis with concomitant coupling of a DOTA chelator to the N-terminus of the protein (*25*). The labeling of this protein with ^{111}In and ^{68}Ga also provided high quality imaging of HER2-expressing tumors in patients (*26*).

One of the most commonly used radionuclides for diagnostics is ^{99m}Tc, as it has favorable photon energy (140 keV), is relatively inexpensive, and readily available. Its physical half-life ($t_{1/2} = 6$ h) is compatible with the rapid kinetics of Affibody molecules. Previously, the synthetic Affibody molecule $Z_{HER2:342}$ has been produced with the chelator maGGG (mercaptoacetyltriglycyl) site-specifically introduced at the N-terminus for the attachment of technetium-99m (*27*). The ^{99m}Tc-maGGG-$Z_{HER2:342}$ specifically targets HER2-expressing tumors in mice, resulting in high tumor-to-nontumor ratios for imaging (*27*). However, this conjugate had predominant hepatobiliary clearance that caused a high radioactivity accumulation in the intestine (intestine plus content contained 30% of the injected activity at 4 h pi). This would restrict its use for the detection of HER2 tumors and metastases in the abdominal area on the day of injection (*27*).

The excretion pathway can be shifted from hepatobiliary to renal if the lipophilicity of the radiolabeled conjugates is reduced (*28, 29*). For example, the use of the aspartic acid-containing chelators MADG and MAD2, for chelation of ^{99m}Tc has clearly increased the renal and decreased the hepatobiliary excretion of ^{99m}Tc-labeled chemotactic peptide conjugates (*30*). Glutamic acid (E) is a polar, negatively charged, and very hydrophilic amino acid (*31*). Moreover, glutamic acid is more suitable for peptide synthesis than aspartic acid since a commonly occurring side reaction under synthetic conditions is the formation of aspartimide by cyclization of aspartyl residues (*32*). We hypothesized that the use of glutamic acid instead of glycine in the chelating sequence of $Z_{HER2:342}$ would decrease the lipophilicity of Affibody molecules enough to suppress hepatobiliary excretion. The goal of this study was to investigate whether the use of mercaptoacetyl-triglutamyl chelator would provide better biodistribution properties of Affibody molecules, resulting in a tracer suitable for imaging on the day of injection. Here, we compare the biodistribution of ^{99m}Tc-labeled mercaptoacetyl-Gly-Gly-Gly-$Z_{HER2:342}$ (^{99m}Tc-maGGG-$Z_{HER2:342}$), mercaptoacetyl-Gly-Glu-Gly-$Z_{HER2:342}$ (^{99m}Tc-maGEG-$Z_{HER2:342}$), and mercaptoacetyl-Glu-Glu-Glu-$Z_{HER2:342}$ (^{99m}Tc-maEEE-$Z_{HER2:342}$) and describe the *in vivo* tumor targeting properties of the best conjugate, ^{99m}Tc-maEEE-$Z_{HER2:342}$.

MATERIALS AND METHODS

Peptide Synthesis. The $Z_{HER2:342}$-sequence was assembled using Fmoc/*t*Bu solid phase peptide synthesis on an Fmoc-amide resin with a substitution of 0.67 mmol/g (Applied Biosystems) as previously described (*27*). 1-Hydroxybenzotriazole (HOBt) and 2-(1*H* -benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) (Advanced ChemTech, Louisville, KY) were used to activate equal molar equivalents of Fmoc-protected amino acid.

The Tc-chelating sequences were introduced by step-wise manual synthesis on the N-terminus of the $Z_{HER2:342}$-sequence. Twenty percent piperidine-*N*-methylpyrrolidone (NMP, from VWR) was used for Fmoc deprotection. Acylations were performed with 5 molar equivs of amino acid, HBTU, and HOBt and 10 equivs of *N*-ethyldiisopropylamine (DIEA, from Lancaster Synthesis, Morecambe, England). *S*-trityl-mercaptoacetic acid was from AnaSpec Inc. (San Jose, CA).

Peptides were released from the solid support and permanent protection groups by incubation in trifluoroacetic acid (TFA, Merck international)/H_2O/ethanedithiol (EDT, Aldrich chemical company Inc.)/triisopropylsilane (TIS, Merck International) (94:2.5:2.5:1) for 2 h. The proteins were extracted in *tert*-butyl methyl ether/H_2O (50:50).

Analytical RP-HPLC was run on the crude synthetic product using a 4.5×150 mm polystyrene/divinylbenzene matrix column with 5 μm particles (Amersham Biosciences, Sweden) and a 20 min elution gradient from 20 to 60% B (B, 0.1% TFA-CH_3CN; A, 0.1% TFA-H_2O). The molecular weights of the modified Affibody molecules were confirmed by mass spectrometry, and the proteins were purified on the same column in a 20 min gradient from 25 to 45% B.

Biosensor Analysis. EDC/NHS chemistry was used to immobilize the extracellular domain of HER2 (Fox Chase Cancer Center, Philadelphia, PA) and Human Serum Albumin, HSA, (KabiVitrum, Sweden) on a CM5 sensor chip (Biacore AB, Sweden). HER2 and HSA were diluted to 20 μg/mL in 20 mM NaOAc at pH 4.5, and the immobilization levels reached 500 and 900 response units (RU), respectively. The different Affibody conjugates were diluted to concentrations varying from 0.5 to 10 nM in HBS (10 mM HEPES, 150 mM NaCl, 3.4 mM EDTA, and 0.005% surfactant P20 at pH 7.4), and the binding kinetics were studied in a 5 min association phase and a 10 min dissociation phase, followed by regeneration with 20 mM HCl in HBS.

^{99m}Tc Labeling. For labeling, 20 μL of maGEG-$Z_{HER2:342}$ or maEEE-$Z_{HER2:342}$ (1 mg/mL in deionized degassed water) was mixed with 20 μL of 0.15 M NaOH to obtain a final pH of about 11. A solution of 10 μL of $SnCl_2 \cdot 2\ H_2O$ in 0.01 M HCl (1 mg/mL) was added to the mixture, followed by 100–200 μL of freshly eluted pertechnetate solution. The mixture was slightly vortexed and incubated at room temperature for 60 min. After labeling, ^{99m}Tc-maGEG-$Z_{HER2:342}$ and ^{99m}Tc-maEEE-$Z_{HER2:342}$ were isolated from unreacted technetium and other low-molecular-weight components using size-exclusion chromatography on disposable NAP-5 columns (Amersham Pharmacia Biotech AB, Uppsala, Sweden) pre-equilibrated with PBS. The purity was assessed by analysis with ITLC SG (Gelman Sciences Inc., Ann Arbor), eluted in PBS. Validation experiments demonstrated that in this system, pertechnetate and cysteine complexes of ^{99m}Tc migrate with the eluent front, while labeled Affibody molecules under these conditions remain at the origin. The labeling yield and the stability were determined using ITLC strips, eluted with PBS, and analyzed with Cyclone Storage Phosphor System. To determine the presence of reduced hydrolyzed technetium, ITLC was eluted with pyridine/acetic acid/water (5:3:1.5). In this eluent, the technetium colloids remained at the origin, while the radiolabeled Affibody molecules, pertechnetate and other complexes of ^{99m}Tc, migrated with the solvent front.

Stability Studies. *Cysteine Challenge.* The stability of labeled Affibody conjugates was tested in 300 molar excess of cysteine. A fresh solution of cysteine was prepared (1 mg/mL in PBS at pH 7.0). The radiolabeled conjugates were added to a final molar ratio of cysteine to peptide of 300:1. The test tubes were incubated for 2 h at 37 °C, and the radiochemical purity was analyzed using ITLC.

Plasma Stability Test. Serum samples were prepared as described in ref *27*. Shortly, a serum sample (240 μL) was mixed with freshly labeled ^{99m}Tc-maEEE-$Z_{HER2:342}$ (10 μL) to obtain an Affibody molecule concentration similar to the concentration in blood at the moment of injection. The sample was incubated for 1 h at 37 °C. After incubation, the sample was analyzed on NuPAGE 4–12% Bis-Tris Gel (Invitrogen) in MES buffer (200 V constant). A sample of pertechnetate, not treated in blood serum, was used as reference and run in parallel with the test sample on the same gel. After electrophoresis, the radioactivity distribution along the gel was evaluated using a Cyclone Storage Phosphor System.

***In Vitro* Cell Studies.** The HER2-expressing ovarian carcinoma cell line SKOV-3, displaying approximately 1.2×10^6 HER2 receptors per cell (*33*), was used in this study. The cell line was cultured in McCoy's medium (Flow Irvine, UK). The medium was supplemented with 10% fetal calf serum (Sigma, USA), 2 mM L-glutamine and PEST (penicillin 100 IU/mL and 100 μg/mL streptomycin), all from Biokrom Kg, Germany. The cells were cultured at 37 °C in a humidified incubator with 5% CO_2 and trypsinized using trypsin–EDTA solution (0.25% trypsin and 0.02% EDTA) from Biokrom Kg, Germany. SKOV-3 cells were cultivated on Petri dishes with a diameter of 3.5 cm to a cell density of 2–5 $\times 10^5$ cells per dish.

Binding Specificity Study. To test the binding specificity of the labeled conjugates, one set of SKOV-3 cells was presaturated with a 100-fold excess of nonlabeled Affibody molecules 10 min before the labeled conjugate was added and measured according to Engfeldt et al. (*27*).

Cellular Retention Study. Labeled conjugate (0.8 ng/10^5 cells) was added in 1 mL complete medium to SKOV-3 cells and incubated for 2 h at 37 °C. The incubation medium was removed, and the cells were washed six times with ice-cold serum-free medium, and after the addition of 1 mL of complete medium, the cell dishes were incubated at 37 °C and 5% CO_2 at predetermined time points. The incubation medium was removed, and the dishes were washed six times with 1 mL serum-free medium. The cells were detached with 0.5 mL of trypsin–EDTA for 10 min in 37 °C and resuspended with 0.5 mL of complete medium. The media were collected, and the radioactivity was measured on an automated gamma counter.

Antigen Binding Capacity Study. An assessment of the antigen binding capacity of ^{99m}Tc-labeled conjugates was performed using SKOV-3 cells according to Engfeldt et al. (*27*).

***In Vivo* Animal Studies.** The animal study was approved by the Local Ethics Committee for Animal Research. In comparative biodistribution studies, nontumor-bearing NMRI mice were used. In tumor-targeting and imaging experiments with ^{99m}Tc-maEEE-$Z_{HER2:342}$, female BALB/c *nu/nu* nude mice were used. The animals were acclimatized for one week at the Rudbeck laboratory animal facility before tumor implantation. The tumors were grafted by subcutaneous injection of $\sim 10^7$ SKOV-3 cells in the right hind leg. Xenografts were allowed to develop during 6 weeks. In all biodistribution studies, the mice were euthanized at predetermined time points with an intraperitoneal injection of Ketalar-Rompun solution (20 μL of solution per gram of body weight: Ketalar [ketamine], 10 mg/mL; Rompun [xylazin], 1 mg/mL). The mice were heart-punctured with a 1 mL syringe rinsed with diluted heparin (5,000 IE/mL, Leo Pharma, Copenhagen, Denmark). Blood and organ samples were taken, weighed, and their radioactivity measured using an automatic gamma counter. The organ uptake values were calculated as percent injected activity per gram tissue (% IA/g).

Biodistribution in NMRI Mice. Eight mice were randomly divided into two groups with four animals each. The two groups were subcutaneously injected with ^{99m}Tc-maGEG-$Z_{HER2:342}$ and ^{99m}Tc-maEEE-$Z_{HER2:342}$ (1μg Affibody ligand, $\sim$100 kBq in 100 μL of PBS). The mice were euthanized at 4 h pi; organ samples were collected and measured.

Table 1. Peptide Synthesis and Characterization Data

Biodistribution in Mice with SKOV-3 Xenografts. The tumor-targeting properties of ^{99m}Tc-maEEE-$Z_{HER2:342}$ were evaluated in female BALB/c *nu/nu* nude mice bearing SKOV-3 xenografts. The mice were subcutaneously co-injected with ^{99m}Tc-maEEE-$Z_{HER2:342}$ and ^{125}I-PIB-$Z_{HER2:342}$ (total of 1 μg Affibody ligand and $\sim$100 kBq in 100 μL of PBS). In previous studies, we have validated that the biodistribution of radiolabeled Affibody molecules 4 h pi is the same for both i.v. and s.c. injection and is independent of the label (*34*, *35*). However, subcutaneous injections are generally more reproducible (smaller errors), which is important for comparative biodistribution studies. After 1, 4, and 6 h pi, the mice were euthanized as described earlier. In the binding specificity study, one group of mice was preinjected with 1,000-fold molar excess of nonlabeled Affibody molecules prior to injection of ^{99m}Tc-maEEE-$Z_{HER2:342}$. At 4 h pi, the mice were sacrificed, and organ samples were collected and measured.

Gamma Camera Imaging with ^{99m}Tc-maEEE-$Z_{HER2:342}$. One group of mice was preinjected through the tail vein with 1000-fold excess of nonlabeled Affibody molecules in order to block the receptors and was imaged after 5 h pi. The other three groups were intravenously injected through the tail vein with 3 MBq of ^{99m}Tc-maEEE-$Z_{HER2:342}$ (10 μg in 100 μL of PBS) and imaged at 1, 2, and 5 h pi. Imaging was performed using a Siemens gamma camera equipped with a LEHR collimator at the Department of Nuclear Medicine of Uppsala University Hospital. Static images were collected for 10 min, and evaluation of the images was performed with a Hermes system (Hermes Medical Solutions).

RESULTS

Peptide Synthesis. The Fmoc solid-phase synthesis of $Z_{HER2:342}$ resulted in a yield of 21% of the full-length peptide, as determined by analytical RP-HPLC. The ^{99m}Tc-chelating sequences of maGEG or maEEE were introduced N-terminally by manual synthesis, resulting in total synthetic yields of 17% and 13%, respectively (Table 1). Following purification by RP-HPLC, the purity was higher than 90%. The molecular weights of the different conjugates were determined by mass spectrometry and correlated well with the theoretically calculated masses, as shown in Table 1.

Biosensor Analysis. The binding kinetics of the different Tc-chelating peptides were compared in a biospecific interaction analysis on a Biacore 2000 instrument. As indicated in Table

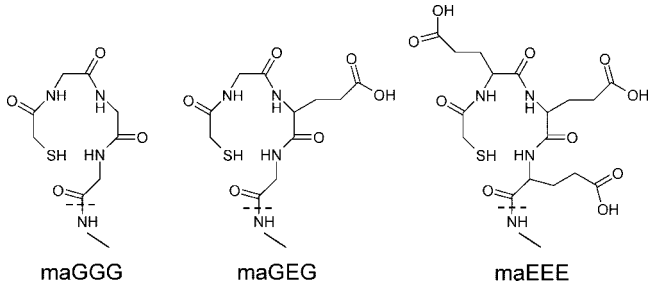

Figure 1. Chelator structures.

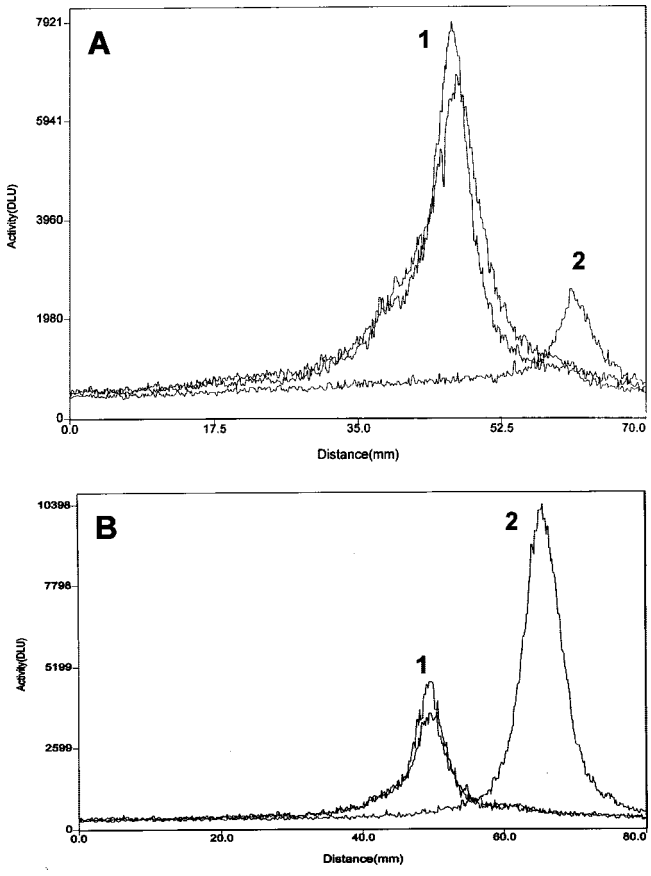

Figure 2. Stability of (A) ^{99m}Tc-maGEG-$Z_{HER2:342}$ and (B) ^{99m}Tc-maEEE-$Z_{HER2:342}$ in mouse serum at 1 h and 37 °C was analyzed using SDS–PAGE. The left peaks (1) represent intact ^{99m}Tc-labeled $Z_{HER2:342}$ (two samples were analyzed). The right peak (2) indicates the reference sample of free pertechnetate.

1, both conjugates showed similar subnanomolar affinities to surface-immobilized HER2 receptors: the dissociation constants (K_D) were 410 pM and 360 pM for maEEE-$Z_{HER2:342}$ and maGEG-$Z_{HER2:342}$, respectively.

^{99m}Tc Labeling. The radiolabeling efficiencies were over 90% for both ^{99m}Tc-maEEE-$Z_{HER2:342}$ and ^{99m}Tc-maGEG-$Z_{HER2:342}$, as shown in Table 2. The isolated yield from size-exclusion chromatography using NAP-5 columns was about 76%, and the radiochemical purity of purified products was typically over 95% for both conjugates. The presence of reduced hydrolyzed technetium was less than 2% in all experiments.

Stability Studies. The *in vitro* stability of the labeled conjugates was evaluated in a cysteine challenge test.

Incubation of the labeled Affibody molecules for 2 h in the presence of a 300-fold molar excess of cysteine demonstrated high stability, with 93% radioactivity still attached to the conjugate (Table 2). The *in vitro* stability of ^{99m}Tc-maGEG-$Z_{HER2:342}$ and ^{99m}Tc-maEEE-$Z_{HER2:342}$ in mouse serum is shown

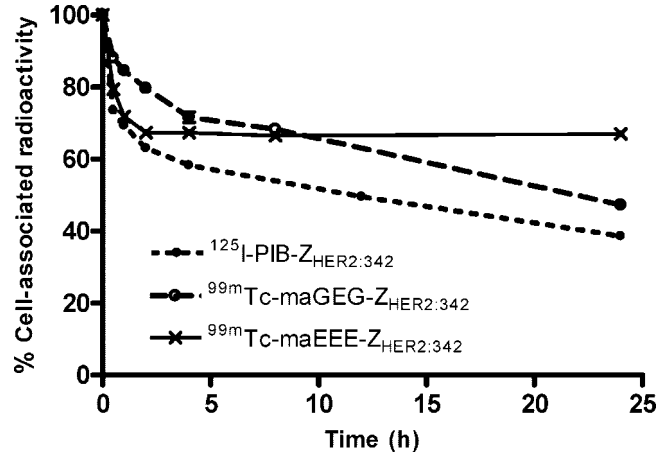

Figure 3. Cellular retention of labeled conjugates in HER2-expressing ovarian carcinoma cells, SKOV-3 cells. ^{125}I-PIB-$Z_{HER2:342}$ (*23*) was included for a comparison.

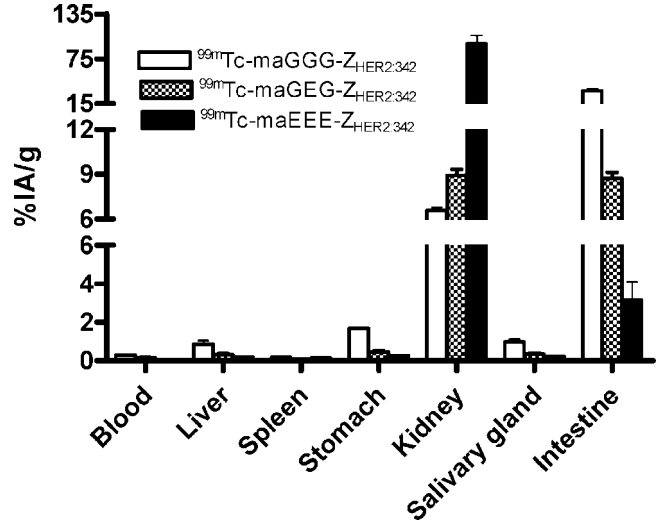

Figure 4. Biodistribution of labeled conjugates in NMRI normal mice at 4 h pi. Data are presented as an average from four animals ± SEM. Uptake in thyroid and muscle were less than 0.08%IA per whole sample and 0.09%IA/g, respectively.

in Figure 2. The radioactivity in the gel showed a single peak of the ^{99m}Tc-labeled $Z_{HER2:342}$ (two samples were analyzed on the same gel), indicating that no detectable transchelation to serum proteins or release of pertechnetate occurred. This experiment also confirmed that Affibody molecules were stable against degradation by blood plasma proteases since no fragments with lower molecular weights were detected.

***In Vitro* Cell Studies.** *Binding Specificity and Antigen Binding Capacity.* The binding specificity of ^{99m}Tc-maEEE-$Z_{HER2:342}$ and ^{99m}Tc-maGEG-$Z_{HER2:342}$ was evaluated in the HER2-expressing ovarian cancer cell line SKOV-3. The binding was specific since it could be blocked with receptor saturation by a 100-fold excess of unlabeled $Z_{HER2:342}$. The antigen binding capacity was estimated to be around 60% for the ^{99m}Tc-maEEE-$Z_{HER2:342}$, indicating that the labeling procedure had a minor effect on the conjugates.

Cellular Retention. The cellular retention of ^{99m}Tc-labeled $Z_{HER2:342}$ and a radioiodinated Affibody molecule, ^{125}I-PIB-$Z_{HER2:342}$, is illustrated in Figure 3. The radioiodinated Affibody molecule was described in earlier studies (*23*) and included here for comparison. ^{99m}Tc-maEEE-$Z_{HER2:342}$ and the radioiodinated conjugate displayed a similar pattern in the beginning, but after 4 h, the iodine label continued to decrease, while the technetium

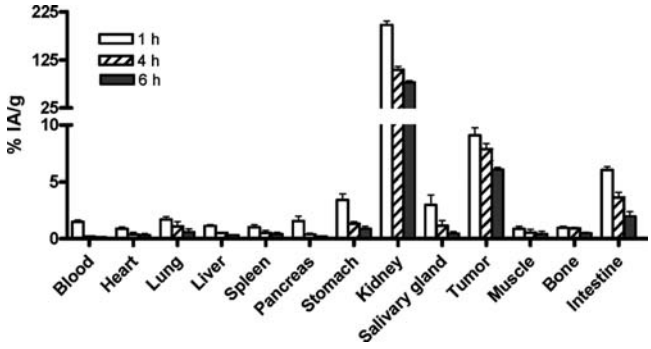

Figure 5. Biodistribution of ^{99m}Tc-maEEE-$Z_{HER2:342}$ in BALB/c *nu/nu* mice with HER2-expressing SKOV-3 xenografts at 1, 4, and 6 h pi. Data are presented as an average from four animals ± SEM. The uptake in thyroid was less than 0.09%IA per whole sample.

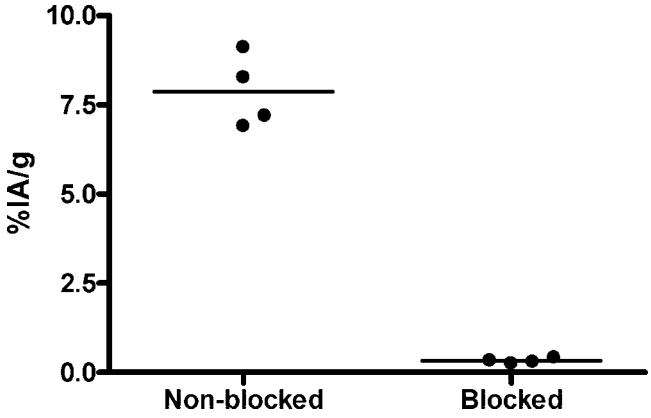

Figure 6. Dot plot of tumor uptake (%IA/g) in BALB/c *nu/nu* mice with SKOV-3 xenografts. Blocked mice received an excess of nonlabeled Affibody molecule prior to the injection of ^{99m}Tc-maEEE-$Z_{HER2:342}$. Student's *t*-test gave $p < 0.0001$.

label showed a discrete slow increase in radioactivity over time. After 24 h, the cell-associated radioactivity retained in the SKOV-3 cells was about 70% for ^{99m}Tc-maEEE-$Z_{HER2:342}$ and 40% for the counterpart, ^{125}I-PIB-$Z_{HER2:342}$ ($p < 0.001$). ^{99m}Tc-maGEG-$Z_{HER2:342}$ possessed higher cell-associated radioactivity retention than ^{99m}Tc-maEEE-$Z_{HER2:342}$ in the first hours but decreased in the same way as that of ^{125}I-PIB-$Z_{HER2:342}$, with 50% of the cell-associated radioactivity retained after 24 h.

***In Vivo* Animal Studies.** *Biodistribution in Normal Mice.* Figure 4 presents the comparative biodistribution of ^{99m}Tc-maGEG- and ^{99m}Tc-maEEE-$Z_{HER2:342}$ in normal NMRI mice at 4 h pi compared to that of ^{99m}Tc-maGGG-$Z_{HER2:342}$. It was shown that the radioactivity uptake was low in all organs, except in the kidneys and intestines. The high uptake in the kidneys is explained by the renal clearance and tubular reabsorption of the small-sized Affibody molecules. A significant difference between the conjugates was observed in the kidneys and intestines. ^{99m}Tc-maEEE-$Z_{HER2:342}$ had 3 times lower radioactivity in the intestines compared to that of ^{99m}Tc-maGEG-$Z_{HER2:342}$ (3.1 ± 1.9%IA/g vs 8.7 ± 0.8%IA/g; $p < 0.001$), while the kidney uptake was 10 times higher (95 ± 23 vs 8.9 ± 0.8 %IA/g; $p < 0.001$). The uptake in the liver, stomach, and salivary glands of ^{99m}Tc-maEEE-$Z_{HER2:342}$ was significantly lower ($p < 0.05$) compared with that of ^{99m}Tc-maGEG-$Z_{HER2:342}$ and ^{99m}Tc-maGGG-$Z_{HER2:342}$ (Figure 4).

Biodistribution in Mice with SKOV-3 Xenografts. The *in vivo* tumor-targeting properties of ^{99m}Tc-maEEE-$Z_{HER2:342}$ were evaluated in BALB/c *nu/nu* mice bearing HER2-expressing SKOV-3 xenografts (Figure 5). The results showed that the radioactivity was cleared rapidly from blood circulation, reaching 0.15 ± 0.05 %IA/g at 6 h pi. The radioactivity clearance from other organs followed the same pattern. Tumor uptake was 9.1 ± 1.4 %IA/g at 1 h pi, 7.9 ± 1.0 %IA/g at 4 h pi, and 6.1 ± 0.4 %IA/g at 6 h pi, indicating a decrease over time.

In the receptor specificity study, one group of mice was preinjected with 1,000-fold molar excess of nonlabeled $Z_{HER2:342}$ in order to saturate the receptors before the administration of ^{99m}Tc-maEEE-$Z_{HER2:342}$. The tumor uptake (Figure 6) in the blocked group was 0.3 ± 0.07 %IA/g and 7.9 ± 1.0 %IA/g in the nonblocked group ($p < 0.0001$), demonstrating that tumor uptake was HER2-specific.

The radioiodinated Affibody molecule ^{125}I-PIB-$Z_{HER2:342}$ (*23*) visualizes HER2-expressing xenografts with high contrast and was therefore co-injected with ^{99m}Tc-maEEE-$Z_{HER2:342}$ as an internal reference for comparison. The tumor-to-organ ratios are listed in Table 3, showing that there was a significant ($p < 0.05$) difference in most organs between the two labels. Especially, the blood radioactivity concentration was much lower for the ^{99m}Tc-label than for the ^{125}I-label at all time points ($p < 0.001$), while the uptake in liver and stomach was lower for the ^{125}I-label. In general, the use of the technetium label provided better tumor-to-organ ratios than the iodine label.

Gamma Camera Imaging with ^{99m}Tc-maEEE-$Z_{HER2:342}$. The tumor-targeting capacity of ^{99m}Tc-maEEE-$Z_{HER2:342}$ was evaluated in BALB/c *nu/nu* mice bearing SKOV-3 tumors. The gamma camera images were acquired 1, 2, and 5 h after the administration of ^{99m}Tc-maEEE-$Z_{HER2:342}$. The tumors could be detected as early as 1 h pi, and the image contrast became better with time (Figure 7A and B). Tumor-to-nontumor ratios for the contralateral thigh were (average ± maximum error) 8.3 ± 0.3, 19 ± 2.1, and 35 ± 0.6 at 1, 2, and 5 h pi, respectively. Two mice were preinjected with nonlabeled Affibody molecules in order to block the receptors, and it was shown clearly that the binding of ^{99m}Tc-maEEE-$Z_{HER2:342}$ was receptor-specific *in vivo* because the tumors were not seen, while the tumors in the nonblocked mice were clearly visualized (Figure 7B). Some radioactivity accumulation is seen in the salivary glands at 1 h pi, which might indicate some release of free pertechnetate. No uptake in any other organs was seen, except in the kidneys, which corresponded well with the biodistribution data. Tumor-to-nontumor ratios for the contralateral thigh were 35 ± 0.6 for the nonblocked mice and 3.6 ± 1.4 for the blocked mice.

DISCUSSION

Affibody molecules are a new class of small targeting proteins displaying optimal biodistribution properties for imaging purposes (*24, 27*). Pilot patient investigations with ^{68}Ga- and ^{111}In-labeled Affibody molecules have demonstrated their utility for the imaging of HER2 expression in metastatic breast cancer (*26*). However, for SPECT imaging, technetium-99m might be the most ideal radioisotope for the labeling of Affibody molecules because of convenient logistics, dosimetric properties, and particularly because the physical half-life ($t_{1/2} \sim 6$ h) matches the quick blood clearance of Affibody molecules.

Earlier studies on a ^{99m}Tc-labeled Affibody molecule, containing a mercaptoacetyltriglycyl chelator (*27*), showed favorable tumor-targeting properties (high tumor-to-blood ratios and excellent binding specificity) of the conjugate. However, this conjugate exhibited high hepatobiliary clearance, making scintigraphic detection of tumors in the abdominal area difficult. It has previously been reported that it is possible to shift the excretion pathway from hepatobiliary to renal by substituting the chelating amino acids with more hydrophilic characters. For this reason, substitution with more hydrophilic chelating residues in the mercaptoacetyl-containing Affibody molecule $Z_{HER2:342}$ was investigated as a strategy for the reduction of abdominal

Table 3. Tumor-to-Organ Ratios of ^{99m}Tc-maEEE-$Z_{HER2:342}$ and ^{125}I-PIB-$Z_{HER2:342}$ in BALB/c *nu/nu* Mice Bearing SKOV-3 Xenografts

accumulation. We have found that in the case of the ^{99m}Tc-labeled Affibody molecule $Z_{HER2:342}$, a substitution of the maGGG-chelator with maSSS (mercaptoacetyl-triseryl chelator) caused a clear shift from hepatobiliary to renal excretion (*36*). Still, this conjugate was not optimal for detecting tumors in the abdomen area on the day of injection, thus additional improvement was necessary. One way to further increase the hydrophilicity is to use amino acids with charged side chains such as glutamic acids.

The results from the Biacore experiments showed that the $Z_{HER2:342}$ with the N-terminally incorporated maGEG or maEEE by peptide synthesis bound with high affinity to HER2. Both maGEG-$Z_{HER2:342}$ and maEEE-$Z_{HER2:342}$ were successfully ^{99m}Tc-labeled with a labeling yield of over 90% and a radiochemical purity of more than 95%. Both ^{99m}Tc-maGEG- and ^{99m}Tc-maEEE-$Z_{HER2:342}$ were stable *in vitro* during incubation in 300-fold molar excess of cysteine for 2 h at 37 °C. Furthermore, no evidence of the release of radioactivity from both conjugates or technetium transchelation to blood plasma proteins could be detected after incubation in mouse serum for 1 h, signifying its suitability for *in vivo* use. The labeled conjugates also preserved specific binding to HER2 receptors in SKOV-3 ovarian carcinoma cells *in vitro*. The cellular retention of ^{99m}Tc-maGEG-$Z_{HER2:342}$ in SKOV-3 cells was higher compared with the radioiodinated counterpart, ^{125}I-PIB-$Z_{HER2:342}$. The cell-associated radioactivity of ^{99m}Tc-maEEE-$Z_{HER2:342}$ decreased rapidly in the first 4 h after interrupted incubation and had an appearance similar to that of the radioiodinated one. Surprisingly, the cell-associated radioactivity increased slowly at later time points, indicating some residualizing properties of this conjugate. One possible explanation is that the dissociated conjugate was reabsorbed and internalized, causing the slow increase in the curve. The same phenomenon has been observed earlier with ^{111}In-labelled Affibody molecules (*24*). A possible method to discriminate between the internalized and membrane-bound fractions would be very helpful for a more reliable interpretation of the results of the cellular retention experiment. However, as we have reported earlier (*24*), common methods of internalization assays are inefficient with $Z_{HER2:342}$ because of strong binding to cells, even in an acidic environment.

The substitution of a single glycine with glutamic acid (maGGG vs maGEG) in the chelator showed a clear effect on the excretion pattern in normal mice, with a significant 3-fold reduction of the radioactivity accumulation in the intestines (hepatobiliary excretion). The hepatobiliary clearance was even more reduced when all three glycines in the chelator were replaced by glutamic acids (maGGG to maEEE), resulting in a 10-fold decrease in intestine accumulation. The reduced hepatobiliary excretion, accompanied by the increased kidney uptake, which was especially pronounced in the case of a triple substitution, verified that a clear shift from hepatobiliary to renal excretion occurred. Interestingly, reduction of the radioactivity level in the intestines was not directly translated into an increase of renal accumulation, and the use of the maEEE moiety as chelator caused a higher reabsorption of radioactivity in the kidneys. This effect could be considered as negative per se, but the overall effect on the changed excretion pattern is positive

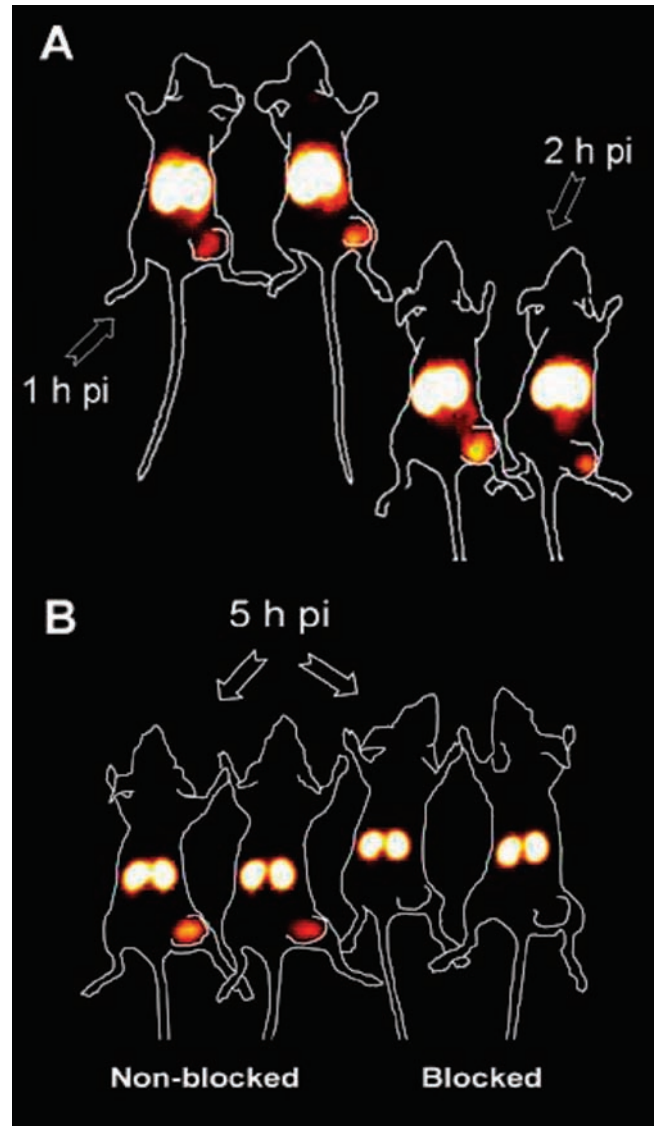

Figure 7. Gamma-camera imaging with ^{99m}Tc-maEEE-$Z_{HER2:342}$ in BALB/c *nu/nu* mice bearing SKOV-3 xenografts. (A) Tumors were well visualized on the right hind legs already at 1 and 2 h pi. (B) The image contrast was better at 5 h pi, and the tumors were blocked with a preinjection of excess of nonlabeled Affibody molecules.

since the position of the kidneys is well-defined, and the use of SPECT/CT makes it possible to distinguish the high radioactivity accumulation in the kidneys from other organs. In contrast, radioactivity in the gastrointestinal tract is more problematic, both by elevated background level and by the occasional formation of hot spots. One concern is the high renal radioactivity accumulation of ^{99m}Tc-maEEE-$Z_{HER2:342}$. This high kidney accumulation could potentially be dose-limiting when using radiolabeled proteins for therapy. In the case of diagnostic applications, the conjugates are labeled with gamma-emitting nuclides, which generate low local doses. The only particulate

intestine[b]	32 ± 4	12.6 ± 0.7	12.0 ± 0.6	17 ± 2	11 ± 2	8.7 ± 0.8	3 ± 2

[a] Data on the chelators maGGG, CGG (cysteinyl-diglycyl), CGGG (cysteinyl-triglycyl) maGSG (mercaptoacetyl-glycyl-seryl-glycyl) and maSSS (mercaptoacetyl-triseryl) are historical controls, taken from refs *34 and 35*. [b] Uptake is presented as %IA/g organ, except for the intestine, where the uptake is for the whole sample.

radiations of such nuclides (^{99m}Tc or ^{111}In) are the Auger and conversion electrons, which are inefficient in causing renal damage. For example, the use of ^{111}In-labeled Octreoscan for therapy demonstrated that renal doses as high as 45 Gy did not cause negative side effects (*37*). Apparently, renal doses in the case of diagnostic application will be much lower.

Another interesting observation is that uptake in the liver, stomach, and salivary glands was significantly lower for ^{99m}Tc-maEEE-$Z_{HER2:342}$ compared with that for ^{99m}Tc-maGEG-$Z_{HER2:342}$ and ^{99m}Tc-maGGG-$Z_{HER2:342}$ (Figure 4). This indicates that the glycine-to-glutamic acid substitution improves the overall *in vivo* stability of the chelates to reoxidation, as these organs are well known to accumulate free pertechnetate. This stabilizing effect on the conjugate is probably contributed from the side chains of the glutamic acid residues in the chelator.

Earlier, the maGGG chelator has been compared with the cysteine-based chelators, cysteine-diglycyl (CGG) and cysteine-triglycyl (CGGG) (*34*). As summarized in Table 4, a comparison with historical data showed a 3-fold reduction of hepatobiliary excretion and a 2-fold increase of renal excretion in the case of the maEEE chelator in comparison with those of cysteine-based chelators. This shift indicates the higher hydrophilicity of the maEEE compared to that of the cysteine-based chelator. A comparison with our previous data (*36*) shows also that the incorporation of glutamic acid in meracaptoacetyl-based chelators shifts the excretion pathway more efficiently to renal than does the incorporation of serine.

^{99m}Tc-maEEE-$Z_{HER2:342}$ was the obvious choice for further evaluation in SKOV-3 xenografted mice because this conjugate showed the best pharmacokinetics properties in normal mice (a low degree of hepatobiliary excretion and the lowest uptake in liver, salivary glands, and stomach). Tumor targeting was efficient, with the highest value of 9.1 ± 1.4 %IA/g reaching 1 h pi. Tumor uptake was HER2-specific since the administration of an excess amount of nonlabeled Affibody molecules could saturate HER2-receptors in the tumors and significantly reduce the uptake of ^{99m}Tc-maEEE-$Z_{HER2:342}$ *in vivo*. The receptor saturation led to a 24-fold decrease in tumor uptake at 4 h pi, from 7.9 ± 1.0 %IA/g to 0.33 ± 0.07 %IA/g ($p < 0.0001$). The accumulated radioactivity in the tumor uptake decreased slowly over time. At the same time, radioactivity in the kidneys and other organs also declined rapidly, resulting in a tumor-to-blood (T/B) ratio of 38 at 4 h pi and 43 at 6 h pi, respectively. It is worthwhile to mention that ^{99m}Tc-maEEE-$Z_{HER2:342}$ seems to be superior in comparison with antibody-based HER2 imaging agents that are under preclinical investigation. For example, the T/B ratio was 3 at 24 h pi for ^{99m}Tc-HYNIC-trastuzumab (*19*), 1.6 at 24 h pi for ^{111}In-DTPA-trastuzumab (*38*), 2.3 at 6 h pi for ^{111}In-T84.66 minibody (*39*), 0.7 at 6 h pi for the ^{111}In-DOTA 10H8 hinge-minibody (*40*), 2.6 at 4 h pi for the ^{125}I-labeled sFv (*21*), and 1.3 at 4 h pi for the ^{125}I-labeled $(sFv')_2$ (*41*).

Gamma camera imaging showed that ^{99m}Tc-maEEE-$Z_{HER2:342}$ accumulated specifically in SKOV-3 tumors since the tumors were blocked with a preinjection of nonlabeled Affibody molecules (right group, Figure 7B). Most interestingly, the tumors were clearly visualized at 1 h pi, and the contrast in the image at 2 h pi did not differ significantly, enabling early detection of HER2-tumors.

The clinical potential of an imaging agent relies on a number of parameters, such as high affinity and selectivity, low nonspecific uptake, and high specific tumor accumulation. Early detection is preferable in patient management, and high tumor-to-organ ratios are crucial. This can be achieved by rapid blood clearance and favorable excretion kinetics (renal clearance being preferred) (*42*). The current study presents an imaging agent that fulfilled these requirements, suggesting a very high potential of ^{99m}Tc-maEEE-$Z_{HER2:342}$ for the detection of HER2 expression. To our knowledge, this is the first time mercaptoacetyl-triglutamyl is being characterized as a chelator for ^{99m}Tc. The results have demonstrated that this chelator decreases the hepatobiliary excretion of peptides and provides a more stable technetium attachment than the mercaptoacetyl-triglycyl chelator.

CONCLUSIONS

The use of peptide synthesis for the coupling of chelator sequences to Affibody molecules for ^{99m}Tc-labeling is an efficient way to modify *in vivo* kinetics of Affibody molecules. Increased hydrophilicity, combined with improved stability of the mercaptoacetyl-triglutamyl chelates, resulted in minimal abdominal accumulation, enabling the rapid detection of HER2-positive tumors and their metastases in the abdominal area. Thus, ^{99m}Tc-maEEE-$Z_{HER2:342}$ appears as a promising tracer for clinical imaging of HER2-overexpression in tumors and metastases.

A Novel G418 Conjugate Results In Targeted Selection of Genetically Protected Hepatocytes without Bystander Toxicity†

Martina Volarevic, Catherine H. Wu, Robert Smolic, John H. Andorfer, and George Y. Wu*

Division of Gastroenterology-Hepatology, Department of Medicine, University of Connecticut Health Center, Farmington, Connecticut. Received July 23, 2007; Revised Manuscript Received September 13, 2007

G418, an aminoglycoside neomycin analogue, is an antimicrobial agent that interferes with protein synthesis and has been used extensively for selection of mammalian cell lines that possess neomycin resistance (NR). It is potent and nonspecific in its effects that occur through tight binding to ribosomal elements. Because of the potent intracellular effect, we wondered whether G418 could be used to select a specific cell type based on receptor-mediated endocytosis. The objective of this study was to target G418 specifically to liver cells via asialoglycoprotein receptors (AsGR) which are known to be highly selective for these cells. A novel G418 conjugate was synthesized chemically by coupling G418 to a galactose-terminating carrier protein, asialoorosomucoid (AsOR), in a molar ratio of 5:1. AsOR–G418 conjugates inhibited viability of AsGR (+) cells by 84.3%, while inhibition in AsGR (–) cells was only by 19%. In AsGR (+) cells, stably transfected with a NR gene, the conjugate decreased viability by less than 9%. Furthermore, incubation of conjugate in cocultures of AsGR (+), and AsGR (–) cells did not result in the loss of viability of neighboring AsGR (–) cells. Our data demonstrate for the first time that G418 can be covalently bound to AsOR to form a conjugate for hepatocyte-specific targeting and toxicity. AsOR–G418 conjugates may be useful tools for genetic manipulation of human liver cells in the presence of nonhepatic cells.

INTRODUCTION

Gentamicin G or G418, a 4,6-disubstituted geneticin, is commonly used to select eukaryotic cells transfected with a neomycin resistance gene (NR) encoding aminoglycoside-modifying enzymes. These enzymes catalyze the covalent modification of specific amino or hydroxyl functional groups leading to inactive drug which binds poorly to ribosomes (*1–4*). G418 inhibitors include a class of aminoglycoside-modifying enzymes, the *O*-phosphotransferases (APH), which use ATP as a donor and modify hydroxyl groups (*5*).

It has been shown previously that high-affinity asialoglycoprotein receptors (AsGR) are predominantly expressed on the sinusoidal surface of mammalian liver cells and represent a useful system for targeting biologically active molecules specifically to the liver (*6, 7*). AsGR allows for efficient uptake of galactose-terminal (asialo)-glycoproteins by receptor-mediated endocytosis. Binding of ligands by the AsGR results in ligand internalization into an endosomal compartment and ultimately to degradation in lysosomes (*8*). This targeting strategy was used for liver-specific delivery of conjugates of antiviral agents (*9, 10*), antimalarial drugs (*11*), foreign genes *in vitro* (*12*), as well as *in vivo* (*13*); in animal models of human diseases (*14, 15*); and recently to systematically induce apoptosis in malignant hepatocytes *in vivo* (*16*). We and others have shown previously that targeted delivery of small molecules can be achieved by direct chemical linkage to an asialoglycoprotein carrier, and those molecules could retain their biological activity (*17, 18*). We wondered whether the potent nonspecific toxicity of G418 could be used to produce specific cell toxicity by taking advantage of receptor-mediated endocytosis, and ultimately to use AsOR–G418 conjugate as a tool for increasing the proportion of human liver cells in the HCV infection rat model recently developed in our laboratory (*19*).

EXPERIMENTAL PROCEDURES

Conjugation of G418 to Asialoorosomucoid. Asialoorosomucoid (AsOR) was produced, as described previously (*20*), by acid hydrolysis of orosomucoid isolated from pooled human serum (American Red Cross) (*21*). Purified AsOR was covalently linked to geneticin (Gibco, Invitrogen Corp.) using 1-ethyl-3 (3-dimethylaminopropyl) carbodiimide (EDC) (Pierce, Rockford, IL) (*22*). Twenty milligrams of AsOR was dissolved in 4 mL of 0.1 M 2-(*N*-morpholino) ethanesulfonic acid (MES), pH 6.0, and filtered through a 0.45 μ syringe-tip filter (Acrodisc, Gelman Sciences, Ann Arbor, MI). Thirty milligrams of geneticin (G418) was dissolved in 1 mL of 0.1 M MES, pH 6.0, and added to AsOR. To this mixture was added 18 mg of EDC, and the solution was incubated with stirring at 25 °C for 4 h followed by dialysis of the reaction mixture through membranes with 12–14 kDa exclusion limits (Spectra/Por, Spectrum Medical Industries, Houston, TX) against 40 L of water at 4 °C for 72 h. The dialyzate was desalted using PD-10 columns (GE Healthcare, Chalf-ont St. Giles, UK). Samples of 2.5 mL were applied on the column and eluted with 3.5 mL water, and samples of 0.5 mL each were collected and absorption at 280 nm monitored. For mass spectrometry analyses, samples were lyophilized and redissolved in water to a concentration of 2 mg/mL, filtered through a 0.45 μm syringe tip, and applied on a Waters RP-HPLC system (Waters, Milford, MA) using semipreparative C-18 polymeric reverse-phase column (Polymer Laboratories Inc., Amherst, MA). Proteins (100 μg) were injected onto the C-18 column, equilibrated with 95% buffer A (0.1% trifluoroacetic acid (TFA)) in H_2O and 5% buffer B (0.085% TFA in acetonitrile), eluted with linear gradients of buffer B at a flow rate of 0.5 mL/min in two phases (5%/min, 0–7 min; 2%/min, 7–27 min). 0.5 mL effluent fractions were collected, and UV absorption was monitored at 280 nm. Fractions with significant 280 nm absorption were analyzed by

12% SDS PAGE and submitted for identification by matrix assisted laser desorption–ionization (MALDI) mass spectrometer (LCQ-Finnigan Corp., San Jose, CA) (performed at the Albert Einstein College of Medicine, Bronx, NY) to determine the molecular weight and ratios of components present.

As a control for possible nonspecific effects of conjugates in general, a G418 conjugate was prepared with orosomucoid (OR), which does not have exposed terminal galactose residues required for AsGR recognition and uptake. This conjugate was prepared in a manner identical to that for AsOR. To control for possible nonspecific effects of chemical linkage and modification of AsOR, a conjugate was prepared using glycine (Gly) instead of G418 in the same molar ratio. Each was purified and submitted for mass spectrometry analysis.

Cell Lines and Cell Culture. Huh7 [AsGR (+), NR (–)], a well-differentiated human hepatoma cell line that can produce liver-specific enzymes and plasma proteins (*23*), and has asialoglycoprotein receptor activity (*24*) but lacks neomycin resistance (NR), was maintained in Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% fetal bovine serum (FBS) and antibiotic/antimycotic solution (Invitrogen Corp., Carlsbad, CA). Cells were passaged every 3–4 days to maintain 75% confluent conditions.

GFP-Huh7 [AsGR (+), NR (+)], a hepatocyte-derived cell line that contains both asialoglycoprotein receptors (AsGR) and neomycin resistance (NR) was prepared by stable transfection of Huh7 [AsGR (+)] cells with a green fluorescent protein (GFP) gene and a neomycin resistance gene (NR) in a murine retroviral vector, MG-1 (a generous gift from Dr. David I. Dorsky, University of Connecticut Health Center, Farmington, CT). Viral particles, 3×10^4, in medium were mixed with polybrene (at 8 μg/mL final concentration) and placed in the medium of Huh7 cells at 25% confluency at 37 °C for 2 h. The inoculation medium was exchanged with fresh medium, and after 24 h of viral exposure, cells were trypsinized and replated onto a new dish containing medium with 200 μg/mL G418. Fluorescent cells resistant to G418 toxicity were harvested after 3 weeks.

For additional control experiments, NIH 3T3 [AsGR (–), NR (–)], a mouse fibroblast cell line, was obtained from ATCC and cultured in DMEM supplemented with 10% FBS and 1× antibiotic/antimycotic solution. Cells were grown at 37 °C in a humidified atmosphere of 5% CO_2 (v/v) in air. Cells were passaged every 3–4 days to maintain 75% confluent conditions.

Western Blot Analyses. To determine whether incorporation of GFP and neomycin resistance genes into Huh7 cells had an effect on AsGR expression in GFP-Huh7 cells, total protein extracts of cell lysates were evaluated by Western blot analyses. Cells were harvested in RIPA buffer (50 mM Tris–HCl, pH 7.4, 1% NP-40, 0.25% Na-deoxycholate, 150 mM NaCl, 1 mM EDTA) supplemented with a protease inhibitor cocktail (Roche Applied Science, Indianapolis, IN). Cell debris was removed by centrifugation. Protein concentration was determined with Bio-Rad protein assay. Forty micrograms of protein was resolved by SDS-PAGE and transferred to Hybond nitrocellulose membranes (Amersham Pharmacia, Piscataway, NJ). Membranes were sequentially blocked with 5% nonfat milk in PBS, incubated with a 1:1000 dilution of the polyclonal rabbit AsGR antibody (a gift of Dr. Richard Stockert, Liver Research Center, Albert Einstein College of Medicine, Bronx, NY), washed 3 times with PBS/0.05% Tween 20, incubated with horseradish peroxidase-conjugated goat antirabbit antibody (Pierce, Rockford, IL) at 1:20 000 dilution, and washed again. Bound antibody complexes were detected with SuperSignal chemiluminescent substrate (Pierce, Rockford, IL). To ensure a comparable loading of the samples, blots were incubated with a 1:1000 dilution of a polyclonal rabbit α-tubulin antibody (Abcam Inc., Cambridge, MA) and horseradish peroxidase conjugated goat antirabbit secondary antibody using the same procedures as described above.

Cell-Associated [^{125}I]-AsOR in Huh7 Cells and GFP-Huh7 Cells. To determine whether incorporation of GFP and neomycin resistance genes into Huh7 cells had any effect on AsGR activity, a specific cell-associated ligand was evaluated by assays as described previously (*25*). AsOR (a ligand specific for AsGR) was radiolabeled with carrier-free Na [^{125}I] (Amersham Biosciences) using Iodobeads (Pierce Biotechnologies, Rockford, IL) according to the manufacturer's instructions. [^{125}I]-AsOR at a specific activity of 2×10^6 cpm/μg protein was administered to Huh7 or GFP-Huh7 cells in serum-free DMEM containing 3 mM $CaCl_2$ at 37 °C. The nonspecific uptake was determined by adding unlabeled AsOR in 100-fold molar excess together with [^{125}I]-AsOR. At varying times, radioactive media were removed, cell surfaces washed 5× with ice–cold PBS, and cells solubilized with 0.01 M NaOH. Cell-associated radioactivity was determined in triplicate at varying time points as measured by gamma counting and reported as means ± SD in units of micrograms of AsOR per million cells per hour.

Cell-Associated [^{125}I]-AsOR–G418 in Huh7 Cells. To determine whether covalent binding of G418 to AsOR affected conjugate recognition by the receptor, cell-associated [^{125}I]-AsOR-G418 was compared to that of [^{125}I]-AsOR alone. AsOR–G418 was radiolabeled with carrier-free Na [^{125}I] (Amersham Biosciences) using the method described above. [^{125}I]-AsOR or [^{125}I]-AsOR–G418 at specific activity of 2×10^6 cpm/μg protein was administered to Huh7 cells in serum-free DMEM containing 3 mM $CaCl_2$ at 37 °C. Nonspecific uptake was determined by adding unlabeled AsOR in 100-fold molar excess together with [^{125}I]-AsOR or [^{125}I]-AsOR–G418. At varying times, radioactive medium was removed, cell surfaces washed 5× with ice–cold PBS, and cells solubilized with 0.01 M NaOH. Cell-associated radioactivity was determined by gamma counting and reported as means ± SD in units of nanograms AsOR or [^{125}I]-AsOR–G418 per hour per million cells.

G418 Toxicity Assays. The cytotoxicity of AsOR–G418 conjugate and free G418 against Huh7 [AsGR (+), NR (-)], GFP-Huh7 [AsGR (+), NR (+)], and NIH 3T3 [AsGR (–), NR (–)] cells were determined using TACS-MTT Assay (R&D Systems, Minneapolis, MN) according to the manufacturer's instructions. Cells were plated at a density of 2×10^4 cells/well in flat-bottom 96-well plates as mono- or cocultures. The cells were grown for 24 h and then treated in quadruplicate with 400 μg/mL G418 or AsOR–G418 containing the equivalent number of moles of G418. Cells were continuously incubated at 37 °C under 5% CO_2 for 6 days with the test substances. Following incubation, the media were removed, fresh media containing MTT reagent (0.5 mg/mL) added to the wells, and the incubations continued for 4 h to allow living cells to metabolize MTT to a dark formazan dye. Cell culture media were removed by aspiration, and 100 μL of acidic alcohol (0.04 M HCl–isopropyl alcohol) was added to solubilize the dye. The suspensions were gently mixed for 5 min, and the plates read in a model 680 series microplate reader at 570 nm (BioRad Laboratories, Hercules, CA). The absorbance values provided a direct measure of the number of live cells post-treatment (*26*). Responses were reported as the means ± SD of the numbers of live cells compared to untreated controls (*27*) reported in units of percent.

Coculture Assays for G418 Bystander Toxicity. Equal numbers of GFP- Huh7 [AsGR (+), NR (+)] were cocultured with Huh7 [AsGR (+), NR (–)] or NIH 3T3 [AsGR (–), NR (–)] to provide total cell densities of 2×10^4/mL in 96-well flat-bottom plates and treated as described in G418 toxicity assays. Bystander toxicity was determined using a combination

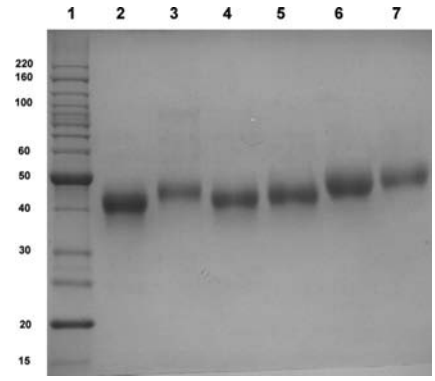

Figure 1. 12.5% SDS–PAGE of purified AsOR-G418 conjugate and controls prepared as described in the Experimental Procedures section. Lane 1, MW marker; lanes 2 and 4, AsOR alone; lane 3, AsOR–G418 conjugate; lane 5, AsOR–Gly conjugate; lane 6, OR; lane 7, OR–G418 conjugate.

Table 1. Mass Spectrometry Analyses of Parent Proteins and Their Conjugates as Determined by MALDI

protein	average most abundant mass peak (kDa)	change in mass from parent protein (kDa)	calculated number of modifications
AsOR	32.371		
AsOR–G418	34.917	2.546	5.20
AsOR–Gly	33.375	0.633	8.46

OR–G418	37.260	3.152	6.43

of light and fluorescent microscopy using an Image-iT LIVE Plasma Membrane and Nuclear Labeling Kit (I34406) (Molecular Probes, Invitrogen Corp., Carlsbad, CA) according to the manufacturer's instructions. Briefly, Alexa Fluor 594 WGA and Hoechst 33342 stains provided in the kit were diluted to a concentration of 5 μg/mL with Hanks' Balanced Salt Solution (HBSS) (Invitrogen Corp., Carlsbad, CA). Labeling solution, 100 μL, was applied onto cells and incubated for 10 min at 37 °C. After labeling was complete, the labeling solution was removed, and cells were washed and mounted in HBSS for imaging. Cells were analyzed using an inverted fluorescence microscope with 509 nm filter (Nikon, Avon, MA). Cell images were obtained by using a 10× dry immersion objective without postacquisition enhancement of images.

Statistical Analyses. Statistical analyses were performed using Student's *t* test; *P* values of <0.05 were considered statistically significant.

RESULTS

Elution of AsOR–G418 conjugates during purification by HPLC showed a single peak having absorbance at 280 nm. The AsOR–G418 conjugate migrated slightly slower on 12.5% SDS–PAGE gel compared to AsOR (Figure 1, lanes 3 and 2, respectively), consistent with a molecular weight of 46 000 Da.

From mass spectrometry analyses, the most abundant peak for AsOR had a mass of 32.371 kDa (range 30.473–34.282 kDa), whereas the abundant peak for the AsOR–G418 conjugate had a considerably higher mass of 34.917 kDa (range 34.286–37.461 kDa). From this difference, the G418 to AsOR molar ratio was calculated to be 5:1. For a control conjugate prepared with glycine instead of G418 (AsOR-Gly), the most abundant peak had a mass of 33.375 kDa (range 32.886–33.413 kDa), from which a molar ratio of Gly to AsOR was calculated to be 8:1. For a second control conjugate prepared with OR, OR–G418, the most abundant peak had a mass of 37.260 kDa (range 37.028–37.547 kDa), whereas the mass of the most abundant peak for OR was 34.109 kDa (range 33.848–34.339 kDa) permitting calculation of the molar ratio of G418 to OR to be 6:1. (Table 1).

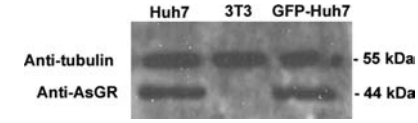

Figure 2. Western blot analysis of AsGR expression in Huh7, GFP-Huh7, and 3T3 cell lines. Cell lysates (40 μg of protein/lane) were resolved by 10% SDS–PAGE and transferred to nitrocellulose. As described in the Experimental Procedures section, prior to probing with anti-AsGR antibody, membranes were probed with antitubulin antibody to assess protein loading. Antibody deposition was detected by chemiluminescence and visualized on XAR film.

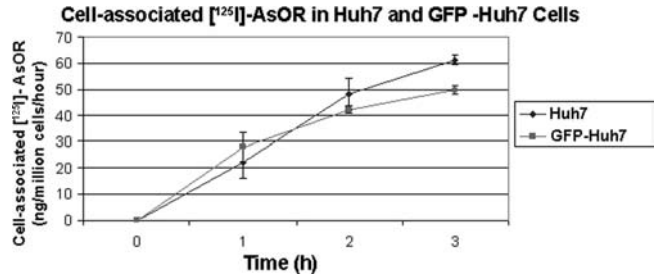

Figure 3. Kinetics of cell-associated [^{125}I]-AsOR in Huh and GFP–Huh7 cells. Confluent dishes of Huh7 cells and GFP–Huh7 cells were incubated with [^{125}I]-AsOR at 37 °C as described in the Experimental Procedures section, in the presence of 3 mM $CaCl_2$ for 1, 2, and 3 h. Nonspecific cell association was determined by the addition of 100-fold molar excess of unlabeled AsOR to medium containing [^{125}I]-AsOR. Cell-associated radioactivity was determined by gamma counting and reported as means ± SD in units of nanograms [^{125}I]-AsOR per hour per million cells.

Western blot analyses of asialoglycoprotein receptor protein from total protein extracts of cell lysates were carried out as described in the Experimental Procedures section. Figure 2 shows that the intensity of the band that migrated as expected for AsGR for a protein of 44.000 kDa, from native Huh7 [AsGR (+)] cells, in lane 1 was not significantly different from that of GFP-Huh 7 [AsGR (+), NR (+)] cells in lane 3. Also, as shown in lane 2, as expected, 3T3 cells, which are nonhepatocellular, lacked the band altogether. The intensities of the tubulin bands were similar in all lanes, indicating that there were no significant differences in the amount of samples loaded.

Figure 3, shows that [^{125}I]-AsOR associated with both Huh7 and GFP–Huh7 cells. The cell-association rate was linear up to 2 h with values of 28.5 ± 5 and 25 ± 2 ng/million cells/h for Huh7 and GFP-Huh7, respectively. The lack of significant difference in AsGR function in this assay suggests that incorporation of GFP and neomycin-resistant genes did not significantly alter the activity of AsGR in GFP–Huh7 cells compared to the original Huh7 cells.

To determine whether conjugation of G418 to AsOR changed asialoglycoprotein recognition by AsGR on liver cells, cell-association studies of labeled AsOR and AsOR–G418 were performed. Figure 4 shows that conjugation of G418 to AsOR did not significantly affect AsOR association by AsG receptors on Huh7 cells. In 1 h, 28.8 ± 5 ng of AsOR–G418 was found to be associated with 1 million Huh7 cells compared to 26.2 ± 6 ng of AsOR. Cell-associated [^{125}I]-AsOR–G418 was competed down to approximately 7% by addition of 100-fold excess of unlabeled AsOR in the medium indicating that internalization of conjugate was mediated by AsGR.

Free G418, AsOR–G418 conjugate, OR–G418 control, and AsOR–Gly control were assessed for their growth inhibitory effects on Huh7 [AsGR (+), NR (–)], GFP–Huh7 [AsGR (+), NR (+)], and NIH 3T3 [AsGR (–), NR (–)] cells. Figure 5

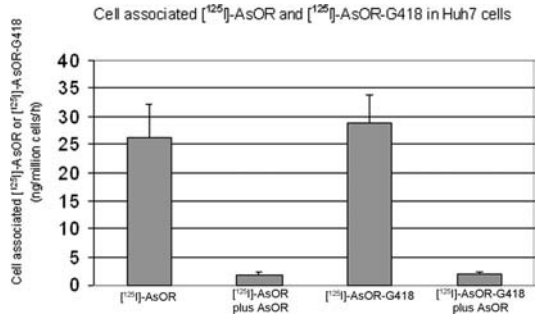

Figure 4. Comparison of cell-associated [^{125}I]-AsOR and [^{125}I]-AsOR–G418 conjugate by Huh7 cells. Confluent dishes of Huh7 cells were incubated with [^{125}I]-AsOR or [^{125}I]-AsOR–G418 at similar specific activity. Nonspecific interaction was determined by addition of 100× molar excess of unlabeled AsOR to the medium. Cell-associated radioactivity was determined by gamma counting and reported as means ± SD in units of nanograms [^{125}I]-AsOR or [^{125}I]-AsOR–G418 per hour per million cells.

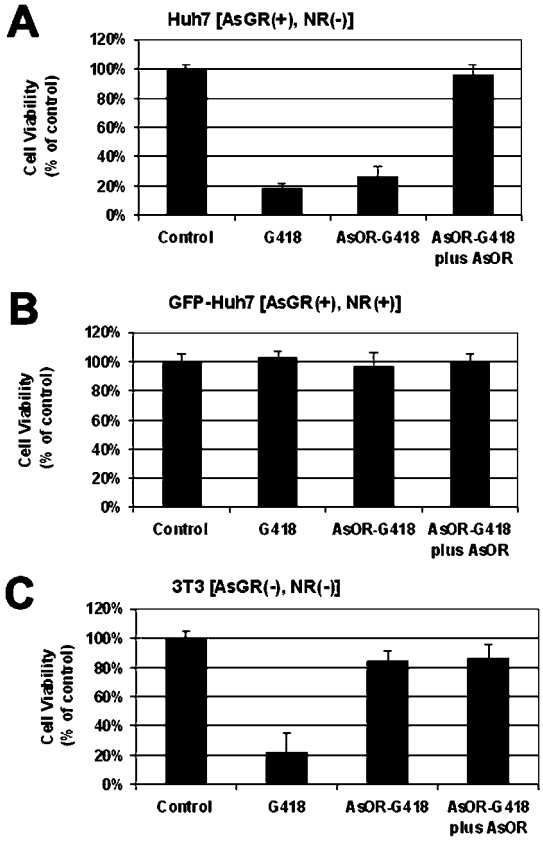

Figure 5. Toxicity of conjugate. Huh7 [AsGR (+), NR (–)], GFP–Huh7 [AsGR (+), NR (+)], and NIH 3T3 [AsGR (–), NR (–)] cells were incubated separately with media alone, AsOR–G418 conjugate, free G418, or AsOR–G418 conjugate in the presence of a 100-fold excess of AsOR as described in the Experimental Procedures section. Cell viability was determined by MTT assay. Panel A, Huh7 [AsGR (+), NR (–)]; Panel B, GFP–Huh7 [AsGR (+), NR (+)]; Panel C, NIH 3T3 [AsGR (–), NR (–)] cell lines. The results represent means ± SD of three independent experiments relative to controls. *$P > 0.05$.

illustrates that after 6 days of AsOR-G418 treatment, Huh7 [AsGR (+), NR (–)] proliferation was inhibited by 84.3% compared to 92% inhibition by G418 alone using molar equivalents of G418 in the media. AsOR–G418 toxicity in Huh7 cells was blocked by excess free AsOR (cell viability was not significantly different from control) in the medium, indicating that the observed toxicity of conjugate was mediated via AsG receptors, and not due to free G418. In contrast, incubation of

Medium alone, panels 1A,B, and 4A,B; medium with AsOR–G418 conjugate, panels 2A,B and 5A,B; or medium with G418 alone, panels 3A,B and 6A,B; 6 days after treatment as described in the Experimental Procedures section. For each pair of photomicrographs, the A panels shows phase contrast results, while the B panels shows fluorescence photomicrographs of the exact same cells. Panels 1A–3B, cocultures of Huh7 [AsGR (+), NR (–)] and GFP–Huh7 [AsGR (+), NR (+)] cells; panels 4A–6B, cocultures of NIH 3T3 [AsGR (–), NR (–)] and GFP–Huh7 [AsGR (+), NR (+)] cells.

3T3 [AsGR (–), NR (–)] cells with free G418 resulted in toxicity, while AsOR–G418 had no effect on 3T3 cell proliferation. GFP–Huh7 cells [AsGR (+) and NR (+)] were not susceptible either to free or conjugated G418, which supports the conclusion that the presence of a neomycin resistance gene in the cells protected them from G418 toxicity. OR–G418 and AsOR–Gly controls did not show significant toxicity to either cell type, indicating that toxicity involved AsGR recognition, was receptor-specific, and required the presence of G418.

To detect possible bystander effects, two pairs of cell lines, Huh7 [AsGR (+), NR (–)] and GFP–Huh7 [AsGR (+), NR (+)] cells; and 3T3 [AsGR (–)] and GFP–Huh7 [AsGR (+), NR (+)] cells were cocultured. The mixed cultures were treated with free G418, AsOR–G418 conjugate, or control media for 6 days. An essential precondition for these experiments was that the cell types could be clearly distinguished from each other by either cell morphology or by an intracellular marker. Because GFP–Huh7 [AsGR (+), NR (+)] express GFP, they can be identified by fluorescence microscopy. Under appropriate UV exposure, GFP-Huh7 cells will emit green fluorescence, while Huh7 and 3T3 do not. 3T3 cells can be distinguished as spindle-shaped cells in contrast to the round Huh7 cells when observed under phase contrast microscopy as described in the Experimental Procedures section. Figure 6 demonstrates the results of cocultures of Huh7 [AsGR (+), NR (–)] and GFP–Huh7 [AsGR (+), NR (+)] cells 6 days after exposure to media alone (panels 1A and 1B). The combined cells reached 100% confluence, and many cells were seen in panel 1A that were not fluorescent, NR (–), in panel 1B. However, after exposure to media containing AsOR–G418 conjugate for 6 days, there were few viable Huh7 [AsGR (+), NR (–)] cells, seen in phase contrast (2A) that were not also fluorescent (panel 2B). The total number of cells were clearly decreased compared to control untreated cells 1A and 1B. In contrast, the morphology of GFP–Huh7 [AsGR (+), NR (+)] cells exposed to conjugated G418 remained normal, and the number of cells attached to the plates visible by phase contrast (panel 2A) were similar compared to the number fluorescent cells (panel 2B). The data support the conclusion that AsGR (+) cells that possessed the NR gene had a selective advantage in the presence of conjugated G418. Cells that had AsGR but lacked an NR gene demonstrated G148-mediated toxicity. The results of exposure of cocultures to free G418 are shown in panels 3A and 3B. As seen before in panels 2A and 2B, the numbers of G418-treated Huh7 cells

lacking NR (nonfluorescent cells in panel 3B) decreased substantially compared to untreated controls, seen by phase contrast (panel 3A) and by fluorescence (panel 3B). Panels 4A and 4B show that cocultures of 3T3 [AsGR(+), NR(–)] and GFP–Huh7 [AsGR (+), NR (+)] cells 6 days after exposure to media alone reached confluency with almost equal representation of nonfluorescent spindle-shaped 3T3 cells and fluorescent GFP–Huh7cells. Panels 5A and 5B show that conjugated G418 had no significant effect on GFP–Huh7 [AsGR (+), NR (+)], (fluorescent) cells, or 3T3 (nonfluorescent spindle-shaped) cells compared to untreated controls (panels 4A and 4B). Because 3T3 cells lack AsG receptors, it was expected that they would not have been affected adversely by the conjugate alone. However, if conjugated G418 taken up by GFP–Huh7 [AsGR (+), NR (+)] had resulted in the release of free G418 into the medium, toxicity to 3T3 cells could have ensued. Panel 5B shows that, although GFP–Huh7 [AsGR (+), NR (+)] cells can take up conjugated G418, they were not only resistant to conjugated G418, but also demonstrated no observable toxicity to neighboring nonfluorescent 3T3 cells (panel 5A). In contrast, free G418-treated 3T3 cells resulted in few viable nonfluorescent cells under identical conditions (panel 6A), demonstrating that those cells were susceptible to free G418. Therefore, the observed survival of those cells following exposure to G418 conjugate suggests that release of free G418 from GFP–Huh7 [AsGR (+), NR (+)] cells, if it occurred, was insufficient to result in bystander toxicity.

DISCUSSION

Our results demonstrate that AsOR–G418 conjugates retain AsGR activity by hepatocyte-derived cells indicating that chemical linkage of G418 to the carrier did not interfere significantly with this biological interaction. Appropriate numbers of exposed terminal galactose residues in close proximity to each other are known to be required for this receptor recognition (*28*). Our results also suggest that five (on average) residues of G418 coupled per AsOR molecule did not significantly affect the interaction of the carbohydrate residues with the membrane-bound cell receptor.

It is well-known that different cell types have differences in sensitivities to G418 (*29*). It could be hypothesized that the differences in AsOR–G418 induced toxicity in different cell lines presented here merely reflected different sensitivities to G418 in each cell line (*29*). However, a G418 dose–response curve was done for each cell line used (data not shown), and 400 μg/mL of free G418 was shown to be the optimal concentration to kill over 90% cells after 6 days of exposure in all cell lines used in our experiments. Furthermore, nearly identical molar ratios of G418 in free and conjugated forms were administered. Therefore, differences in sensitivities or amounts of G418 administered cannot account for the observed differences in toxicity. Lastly, Huh7 cells that lacked the NR gene were highly susceptible to AsOR–G418 conjugates, indicating that the lack of toxicity seen in GFP–Huh7 cells was not due to a lack of activity of the G418 in conjugate form.

Aminoglycosides act by impairing bacterial protein synthesis (*30*) through binding to different regions of the 30 S ribosomal particle based on their chemical structure (*31*). The 4-substituted, 4,5-, and 4,6-disubstituted aminoglycosides are ligands of the eubacterial ribosome decoding aminoacyl-tRNA site (A site) (*32–34*). Among them, the 4,6-disubstituted geneticin, G418, contains three rings that are functionalized by hydroxyl, ammonium, and methyl groups, and has been shown to be toxic to eukaryotic organisms (*35–38*), yeast (*1*), and mammals (*2*) by binding to the 80 S ribosome (*39*). Crystallographic structures of various ribosomal particle complexes revealed the mechanism of action of G418 at the ribosomal level with atomic detail. The two sugar rings constituting the nonamine component common to most of the aminoglycosides bind to the A site. The essential hydrogen bonds involving ring I (to A1408) and ring II (to the phosphate oxygen atoms of a bulge of adenine bases 1492 and 1493, and to G1494) are conserved, and additional contacts are observed from ring III (to phosphate oxygen atoms of G1405 and U1406) (*40*). G418 locks the A site in the open conformation, and by doing so disrupts ribosomal proofreading capability, leading to pretermination or mistranslation (*41*). It is still controversial, however, how G418 reaches its target in the cytosol in sufficient amounts (*42*), because it is too polar to cross mammalian cell membranes by diffusion and is mainly stored in lysosomes of mammalian cells (*43*). However, with some limitations due to its kidney and ear toxicity (*4445*) , geneticin has been used clinically as an antiparasitic agent (*46*). Moreover, administration of geneticin (*47*) has proven helpful in the treatment of patients suffering from some genetic disorders (*48*).

The mechanism by which AsOR–G418 conjugates cause toxicity in target cells has not been elucidated. However, from crystallographic studies of various ribosomal particle complexes which revealed the mechanism of action of G418, it appears clear that toxicity of targeted conjugate depends on retention of G418 structure required for interaction with ribosomes (*40, 41*). Conjugation to a large protein might be expected to interfere with that interaction. However, it has been well-established that the AsGR pathway results in proteolytic degradation of the majority of material taken up by AsGR receptors. Thus, it is possible that G418 is released in the free form following degradation of the protein carrier in lysosomes. The extent to which G418 itself is susceptible to degradation in lysosomes is not known. However, it is known that G418 in the free form after cellular uptake is mostly stored in lysosomes and remains active after this storage (*43*).

Targeting of hepatocytes by the asialoglycoprotein receptors was selected for liver cell targeting based on our previous studies which demonstrated that targeted delivery of small molecules could be achieved by chemical linkage to asialoglycoprotein carriers. As observed in the current study, those small molecules retained their biological activities (*18, 19*).

Collateral toxicity to surrounding tissues, the bystander effect, is a complex phenomenon and appears to be based on different mechanisms, the most important of which is transfer of the toxic metabolite from cells that possess the toxin to their neighbors. This can occur via gap junctions (*49, 50*) consisting of connections that permit the passage of hydrophilic molecules smaller than 1 kDa from one cell to another (*51*). Although genetic resistance to neomycin is known to be due to phosphorylation-mediated inactivation of G418 in surviving cells, it has not been shown previously whether such inactivation is complete or whether free G418-exposed cells could release the toxin to neighboring cells resulting in a bystander effect. The coculture experiments in the current study provide a clear demonstration that, when conjugated G418 is administered to genetically resistant cells, if free G418 is released, the quantities are insufficient to cause toxicity to neighboring cells.

We conclude that chemical coupling of G418 to an asialoglycoprotein results in the targeted delivery of active toxin to cells possessing the appropriate receptor. In the presence of NR, there was no detectable bystander effect. This represents the first description of the use of G418 for targeted selection *in vivo*. While the studies here have focused on liver cells, because many other receptor–ligand combinations are known, the technique may be extended to manipulation of populations of various other non-hepatocellular cell types in cocultures and explants. Indeed, it is possible that such a targeted selection strategy may be applied to animal models to increase the

predominance of one cell type over another. For example, an AsOR–G418 conjugate is being developed to increase the proportion of genetically protected human liver cells at the expense of host rat hepatocytes in an immunocompetent rat model possessing a chimeric human liver (*19*). Such models may be useful in the evaluation of drug toxicity or metabolism in human hepatocytes in animals.

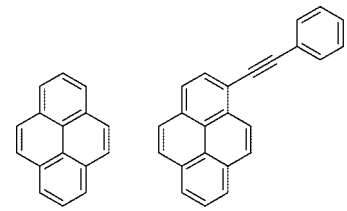
1-Phenylethynylpyrene (1-PEPy) as Refined Excimer Forming Alternative to Pyrene: Case of DNA Major Groove Excimer

Irina V. Astakhova,[†] Andrei D. Malakhov,[†] Irina A. Stepanova,[†] Alexey V. Ustinov,[†] Stanislav L. Bondarev,[‡] Alexander S. Paramonov,[†] and Vladimir A. Korshun*[,†]

Shemyakin-Ovchinnikov Institute of Bioorganic Chemistry, Miklukho-Maklaya 16/10, 117997 Moscow, Russia, and Institute of Molecular and Atomic Physics, Nezavisimosti av. 70, 220072 Minsk, Belarus. Received July 24, 2007

1-Phenylethynylpyrene fluorochrome was studied as *meta*- and *para*-derivatives of *arabino*-uridine-2′-carbamates in ss and dsDNA. 1-PEPy showed red-shifted emission and increased fluorescence quantum yield compared to pyrene. Although 1-PEPy has very short excited lifetime (<2.5 ns), it is able to form inter- and intrastrand excimers on DNA, probably resulting from spatial preorganization of two dye molecules.



INTRODUCTION

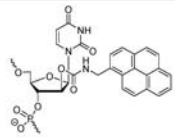
Pyrene (Chart 1) excimer fluorescence (*1, 2*) is a useful tool for structural studies in biochemistry and molecular biology as "a probe of proximity" (*3*). The broad long-wavelength maximum of pyrene excimer emission (typically around 450–500 nm) clearly differs from the structured emission of a single pyrene molecule (370–400 nm). The emission of the pyrene excimer appears as a result of three successive processes: (a) photoexcitation of the pyrene molecule; (b) its reaction with ground-state pyrene and formation of a stacked excited dimer (excimer); (c) emission of a photon with synchronous dissociation of the dimer. The prominent excimer-forming ability of pyrene (among other flat fluorochrome molecules) is determined by its long excited lifetimes (up to hundreds of nanoseconds in several solvents). Thus, an excited pyrene molecule has enough time to meet a spatially reachable ground-state pyrene molecule. Pyrenes in an excimer are coplanar (to a greater or lesser extent) and less than 4 Å apart. Hence, in the case of two pyrenes covalently bound to biomolecule(s), the broad band of excimer emission is unambiguous evidence that the residues are *able* to come into close proximity. The more intense the excimer emission is, the closer the pyrenes are located.

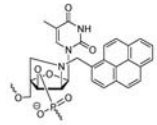
Pyrene excimer on nucleic acids (NA) has been widely studied. It has been applied for the detection of point mutations using tandem hybridization of 5′- and 3′-pyrene-labeled oligonucleotides on complementary targets (*4–9*). Various excimer-forming pyrene bichromophores were used to monitor hybridization (*10–17*). Two or more pyrene residues attached to one (*8, 18–31*) or several different oligonucleotides (*18, 32–43*) were used in studies of NA hybridization, including parallel duplexes (*32, 34*), triplexes (*30, 33, 40, 41, 43*), and quadruplexes (*28*).

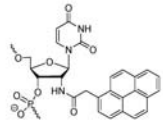
However, fluorochromes with excited lifetime of a few nanoseconds are much less prone to forming excimers. For example, perylene displayed a very weak excimer upon tandem hybridization on DNA (*44*). Nevertheless, *preorganized* ethynylpyrene and even ethynylperylene fluorochromes showed explicit excimer fluorescence (*45*).

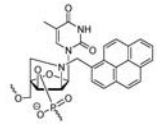
Chart 1. Structures of Pyrene and 1-PEPy Fluorochromes

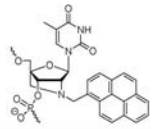
Recently, we (*46–50*) and others (*51–53*) introduced 1-PEPy fluorochrome as a label for nucleic acids. It is well-known that introduction of a phenylethynyl group in a fluorescent molecule leads to an increase in absorption together with a bathochromic shift in absorption and emission, a decrease in Stoke's shift and excited lifetime, and an increase in emission quantum yield (fluorescence intensity) (*48* and refererces cited therein). These changes are also the case for pyrene. The parent dye, 1-PEPy (Chart 1), is able to form excimers in THF solution (*47*); the concentration required ($>10^{-2}$ M) is, however, 2–3 orders of magnitude higher compared to pyrene. This correlates with its short excited lifetime (7.72 ns for 1-PEPy in EtOH (*52*)). The absorbance and fluorescence of 1-PEPy derivatives on DNA are approximately 50 nm and 30 nm red-shifted, respectively, in comparison with pyrene derivatives; the first fluorescence maximum of 1-PEPy in oligonucleotides is within 400–405 nm (*48–52*). These spectral features reduce 100-fold the 1-PEPy detection limit with respect to that of pyrene (*52*). 1-PEPy is able to form strong (*48, 50, 51*) or weak (*49, 52*) excimers on DNA.











With a short excited lifetime taken into account, the pronounced PEPy excimer should be evidence not only for mutual attainability, but rather preassociation of two PEPy molecules. Thus, an excimer-forming 1-PEPy fluorochrome could become a label of choice for some structural studies of biomolecules. However, photophysical properties of 1-PEPy on nucleic acids have not been reported. Our aim was to explore further 1-PEPy on DNA and to elucidate its potential as an excimer-forming fluorescent probe.

Pyrene attached to the sugar part of a nucleoside in dsDNA can form interstrand excimers located in +2 zipper (*24, 27, 35*), +1 zipper (*27*), or −1 zipper (*8*) mode (Table 1). We have

Table 1. Reported Examples of Interstrand Pyrene Excimers on DNA from Sugar-Modified Nucleosides

Zipper	Schematic structure	Modified nuleoside	Reference
+2			(*24*)
			(*27*)[a]
			(*35*)
+1			(*27*)
−1			(*8*)

[a]Weak excimer.

chosen the case of the +2 zipper major groove excimer formed by 1-pyrenemethyl *ara*-uridine-2′-carbamate (*24*), replaced pyrene with 1-PEPy, and studied the structural requirements for the 1-PEPy excimer.

EXPERIMENTAL PROCEDURES

General. Reagents obtained from commercial suppliers were used as received; 2′-*O*-(imidazol-1-ylcarbonyl)-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)uracil-1-*β*-D-arabinofuranoside (*24*), $Pd(PPh_3)_4$ (*54*), 1-ethynylpyrene (*47*), bis(*N*,*N*-diisopropylamino)-2-cyanoethoxyphosphine (*55*), and diisopropylammonium tetrazolide (*56*) were synthesized as described. HPLC-grade DMF was distilled under reduced pressure and stored over 4 Å molecular sieves under nitrogen. DCM was always used freshly distilled over CaH_2. Other solvents were used as received.

500 MHz ^{1}H, 125.7 MHz ^{13}C, and 202.4 MHz ^{31}P NMR spectra were recorded on a Bruker DRX-500 spectrometer at 303 K and referenced to DMSO-d_6 (2.50 ppm for ^{1}H and 39.5 ppm for ^{13}C), MeCN-d_3 (1.96 ppm for ^{1}H) (*57*), and 85% aq H_3PO_4 (0.00 ppm for ^{31}P). ^{1}H–^{13}C gradient-selected HMQC and HMBC spectra were obtained by using 2048 (t_2) × 256 (t_1) complex point data sets, zero-filled to 2048 (F_2) × 1024 (F_1) points. The spectral widths were 13 ppm and 200 ppm for ^{1}H and ^{13}C dimensions, respectively. HMBC spectra were measured with 50 ms delay for evolution of long-range couplings. ^{1}H NMR coupling constants are reported in hertz (Hz) and refer to apparent multiplicities. High-resolution mass spectra were recorded in positive ion mode using IonSpec Fourier Transform ISR mass spectrometer (MALDI) or PE SCIEX QSTAR pulsar mass spectrometer (ESI). Melting points were determined using a Boetius heating table and are uncorrected. Analytical thin-layer chromatography was performed on Kieselgel 60 F_{254} precoated aluminium plates (Merck). Silica gel column chromatography was performed using Merck Kieselgel 60 0.040–0.063 mm. The oligonucleotide synthesis was carried out on a BiosSet ASM-800 instrument in a 200 nmol scale using standard manufacturer's protocols. The coupling step time for modified phosphoramidites was extended to 5 min. Oligonucleotides were isolated using 20% denaturing (7 M urea) PAGE in Tris-borate buffer, pH 8.3, and desalted by gel filtration on a Sephadex G-25 column eluting with saltless buffer. MALDI-TOF mass spectra of oligonucleotides were recorded on Bruker Ultraflex mass spectrometer in positive ion mode; a mixture (1:1 v/v) of 2,6-dihydroxyacetophenone (40 mg/mL in MeOH) and diammonium hydrogen citrate (80 mg/mL in water) was used as a matrix. Theoretical masses of oligonucleotide conjugates were calculated using the monoisotopic element masses. UV spectra were recorded using Beckman DU520 general purpose UV/vis spectrometer. Thermal denaturation experiments were performed on a Perkin Elmer Lambda 40 UV/vis spectrometer with PTP 6 (Peltier temperature programmer) in the medium salt hybridization buffer containing 100 mM NaCl, 10 mM Na_3PO_4, 0.1 mM EDTA, pH 7.0 (concentration of duplex 1.0×10^{-6} M). Fluorescence spectra were obtained in same buffer using a Varian Cary Eclipse fluorescence spectrophotometer (λ_{ex} 360 nm, excitation and emission slits 5 nm, concentrations of each oligonucleotide or duplex 1.0×10^{-7} M). Photophysical studies in the same buffer were performed using a large-aperture apparatus described earlier (*58*). The fluorescence quantum yields Φ_f were measured by the relative method using standards of quinine sulfate in 1 N H_2SO_4 (Φ_f 0.55 (*59*)). The measurements were performed at an angle of 90° to the exciting light beam. The optical density of the solutions in 1-cm quartz cuvettes at the excitation wavelength did not exceed 0.1. The values of Φ_f were corrected with the refractive index of the solvent; the measured refractive indexes of 1 N H_2SO_4 and phosphate buffer were 1.338 and 1.334 at 20 °C, respectively. Fluorescence lifetimes were determined by the method of time-correlated single-photon counting using a PRA model 3000 ns lifetime fluorometer. The parameters of the fluorescence decays were analyzed using T900 software (Edinburgh Instruments). The samples used in quantum yield and lifetime fluorescence measurements were not degassed; concentrations were 3.0×10^{-6} M.

General Procedure for the Preparation of 2′-*O*-(3(4)-Iodobenzylaminocarbonyl)-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)uracil-1-*β*-D-arabinofuranosides (2a,b). To a solution of 2′-*O*-(imidazol-1-ylcarbonyl)-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)uracil-1-*β*-D-arabinofuranoside **1** (2.90 g, 5.0 mmol) in THF–MeCN, 1:1 (v/v) (60 mL) 3- or 4-iodobenzylamine (1.63 g, 7.0 mmol) was added, and the mixture was refluxed for 40 h. After conversion of the starting compound **1** is complete (monitoring by TLC, EtOAc–$CHCl_3$, 2:3 v/v), the mixture was diluted with $CHCl_3$ (150 mL), washed with water (100 mL), 5% citric acid (100 mL), and water (100 mL), then dried over Na_2SO_4 and evaporated to dryness. The residue was purified by chromatography on a silica gel column (100 g) with a step gradient of EtOAc (0→5%) in $CHCl_3$ (v/v) as the mobile phase to give carbamates **2a**,**b** as white amorphous foams.

2′-*O*-(3-Iodobenzylaminocarbonyl)-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)uracil-1-*β*-D-arabinofuranoside (2a). Yield 3.50 g (94%), white foam, R_f 0.52 (EtOAc–$CHCl_3$, 2:3 v/v). MALDI-TOF HRMS: m/z = 768.1642 $[M + Na]^+$, calcd for $[C_{29}H_{44}N_3O_8Si_2 + Na]^+$ 768.1604. ^{1}H NMR (DMSO-d_6, δ): 11.33 (s, 1H, H-3), 7.88 (t, 1H, J = 6.0 Hz, OCON*H*), 7.58 (m, 2H, H-2″, 4″), 7.45 (d, 1H, $J_{5,6}$ = 8.1 Hz, H-6), 7.16–7.05 (m, 2H, H-5″, 6″), 6.12 (m, 1H, H-1′), 5.57 (d, 1H, $J_{5,6}$ = 8.1 Hz, H-5), 5.42 (m, 1H, H-2′), 4.38 (m, 1H, H-3′), 4.17–3.90 (m, 4H, H-5′, NCH_2), 3.86 (m, 1H, H-4′), 1.10–0.92 (m, 28H, Pr^i). ^{13}C NMR (DMSO-d_6, δ): 163.0 (C4), 154.8 (O*C*O), 150.0 (C2), 142.1 (C1″), 140.6 (C6), 135.5 (2C, C2″,4″), 130.5 (C5″), 126.2 (C6″), 101.3 (C5), 94.7 (C3″), 81.0 (C1′), 79.0 (C4′), 76.1 (C2′), 72.6 (C3′), 60.6 (C5′), 43.1 (N*C*H$_2$), 17.3, 17.2 (3C), 16.9, 16.8 (2C), 16.7 (*C*H$_3$), 12.8, 12.4, 12.2, 11.9 (Si*C*).

2′-*O*-(4-Iodobenzylaminocarbonyl)-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)uracil-1-β-D-arabinofuranoside (2b). Yield 3.14 g (84%), white foam, R_f 0.50 (EtOAc–$CHCl_3$, 2:3 v/v). MALDI-TOF HRMS: m/z= 768.1631 $[M + Na]^+$, calcd for $[C_{29}H_{44}N_3O_8Si_2 + Na]^+$ 768.1604. ^{1}H NMR (DMSO-d_6, δ): 11.38 (s, 1H, H-3), 7.86 (m, 1H, OCON*H*), 7.64 (d, 2H, J = 8.2 Hz, H-3″,5″), 7.45 (d, 1H, $J_{5,6}$ = 8.1 Hz, H-6), 6.94 (d, 2H, J = 8.2 Hz, H-2″,6″), 6.14 (m, 1H, H-1′), 5.59 (d, 1H, $J_{5,6}$ = 8.1 Hz, H-5), 5.38 (m, 1H, H-2′), 4.39 (m, 1H, H-3′), 4.14 (m, 1H, ^2J = 15.9 Hz, J_{NHCH} = 6.4 Hz, NC*H*H), 4.08 (m, 1H, $^2J_{5′a,5′b}$ = 13.0 Hz, $J_{4′,5′a}$ = 3.3 Hz, H-5′a), 4.02 (m, 1H, ^2J = 15.9 Hz, J_{NHCH} = 5.5 Hz, NCH*H*), 3.94 (m, 1H, $^2J_{5′a,5′b}$ = 13.0 Hz, $J_{4′,5′b}$ = 2.7 Hz, H-5′b), 3.86 (m, 1H, H-4′), 1.10–0.93 (m, 28H, Pr^i). ^{13}C NMR (DMSO-d_6, δ): 163.0 (C4), 154.9 (O*C*O), 150.0 (C2), 140.9 (C6), 139.3 (C1″), 137.0 (2C, C3″,5″), 129.0 (2C, C2″,6″), 101.3 (C5), 92.4 (C4″), 81.2 (C1′), 78.8 (C4′), 76.1 (C2′), 72.7 (C3′), 60.7 (C5′), 43.2 (N*C*H$_2$), 17.3, 17.2, 17.1 (2C), 16.9, 16.8 (2C), 16.7 (*C*H$_3$), 12.8, 12.4, 12.2, 11.9 (Si*C*).

General Procedure for the Preparation of 2′-*O*-[3(4)-(Pyren-1-ylethynyl)phenylmethylaminocarbonyl]-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)uracil-1-β-D-arabinofuranosides (3a,b). To a solution of 2′-*O*-(3(4)-iodobenzylaminocarbonyl)-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)uracil-1-β-D-arabinofuranoside **2a**(**2b**) (1.49 g, 2.0 mmol), 1-ethynylpyrene (588 mg, 2.4 mmol) and triethylamine (560 μL, 4.0 mmol) in DMF (40 mL) $Pd(PPh_3)_4$ (116 mg, 0.10 mmol) and CuI (38 mg, 0.20 mmol) were subsequently added, and the mixture was stirred under argon for 16 h. After completion of conversion of the starting nucleoside **2** (monitoring by TLC in EtOAc), the mixture was poured into $CHCl_3$ (150 mL). The resulting solution was washed with 3% EDTA-Na_2 (4 × 100 mL) and water (4 × 100 mL), dried over Na_2SO_4, and evaporated to dryness. The residue was purified by chromatography on a silica gel column (150 g) with a step gradient of MeOH (0→3%) in $CHCl_3$ (v/v) as the mobile phase to give 1-PEPy derivatives **3a**,**b** as yellow amorphous foams. Compounds were dissolved in DCM (5 mL), and the solution was added dropwise to hexane (50 mL), the solid precipitated was filtered off, washed with hexane, and dried *in vacuo*.

2′-*O*-[3-(Pyren-1-ylethynyl)phenylmethylaminocarbonyl]-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)uracil-1-β-D-arabinofuranoside (3a). Yield 1.60 g (95%), yellow amorphous solid, R_f 0.46 (EtOAc–toluene, 1:1 v/v). MALDI-TOF HRMS: m/z = 866.3266 $[M + Na]^+$, calcd for $[C_{47}H_{53}N_3O_8Si_2 + Na]^+$ 866.3263. ^{1}H NMR (DMSO-d_6, δ): 11.37 (s, 1H, H-3), 8.61 (d, 1H, $J_{9‴,10‴}$ = 9.1 Hz, H-10‴), 8.37 (m, 3H, H-6‴,8‴,9‴), 8.33 (m, 1H, $J_{2‴,3‴}$ = 8.0 Hz, H-3‴), 8.26 (m, 2H, H-2‴,5‴), 8.23 (m, 1H, $J_{4‴,5‴}$ = 8.9 Hz, H-4‴), 8.14 (apparent t, 1H, $J_{6‴,7‴}$ = $J_{7‴,8‴}$ = 7.6 Hz, H-7‴), 7.97 (m, 1H, OCON*H*), 7.64 (d, 1H, J = 7.6 Hz), 7.61 (s, 1H), 7.49 (d, 1H, J = 8.0 Hz) (H-6, H-2″, H-4″), 7.44 (apparent t, 1H, J = 7.6 Hz, H-5″), 7.23 (d, 1H, J = 7.6 Hz, H-6″), 6.15 (br.s, 1H, H-1′), 5.60 (d, 1H, $J_{5,6}$ = 8.2 Hz, H-5), 5.46 (m, 1H, H-2′), 4.38 (m, 1H, H-3′), 4.28 (m, 1H, ^2J = 15.9 Hz, J_{NHCH} = 6.4 Hz, NC*H*H), 4.17 (m, 1H, ^2J = 15.9 Hz, J_{NHCH} = 5.8 Hz, NCH*H*), 4.07 (m, 1H, $^2J_{5′a,5′b}$ = 12.8 Hz, $J_{4′,5′a}$ = 3.0 Hz, H-5′a), 3.92 (m, 1H, $^2J_{5′a,5′b}$ = 12.8 Hz, $J_{4′,5′b}$ = 2.4 Hz, H-5′b), 3.86 (m, 1H, H-4′), 1.07–0.87 (m, 28H, Pr^i). ^{13}C NMR (DMSO-d_6, δ): 163.0 (C4), 154.9 (O*C*O), 150.1 (C2), 140.3 (C1″), 140.2 (C6), 131.2 (C10a‴), 131.1 (C3a‴), 130.9 (C5a‴), 130.6 (C8a‴), 130.0 (2C, C2″, C4″), 129.6 (C2‴), 128.9 (2C, C9‴, C5″), 128.5 (C4‴), 127.4 (C5‴), 127.3 (C6″), 126.8 (C7‴), 126.0 (2C, C6‴, C8‴), 125.0 (C3‴), 124.8 (C10′′), 123.7 (C10b‴), 123.5 (C10c‴), 122.4 (C3″), 116.8 (C1‴), 101.4 (C5), 95.2 (Cb), 88.2 (Ca), 80.4 (C1′), 78.7 (C4′), 75.9 (C2′), 72.5 (C3′), 60.6 (C5′), 43.5 (N*C*H$_2$), 17.3, 17.2, 17.1 (2C), 16.8 (3C), 16.7 (*C*H$_3$), 12.8, 12.4, 12.2, 11.8 (Si*C*).

2′-*O*-[4-(Pyren-1-ylethynyl)phenylmethylaminocarbonyl]-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)uracil-1-β-D-arabinofuranoside (3b). Yield 1.58 g (93%), yellow amorphous solid, R_f = 0.43 (EtOAc–toluene, 1:1 v/v). MALDI-TOF HRMS: m/z= 866.3223 $[M + Na]^+$, calcd for $[C_{47}H_{53}N_3O_8Si_2 + Na]^+$ 866.3263. ^{1}H NMR (DMSO-d_6, δ): 11.44 (s, 1H, H-3), 8.63 (d, 1H, $J_{9‴,10‴}$ = 9.1 Hz, H-10‴), 8.44–8.20 (m, 7H, H-2‴–6‴,8‴,9‴), 8.14 (apparent t, 1H, $J_{6‴,7‴}$ = $J_{7‴,8‴}$ = 7.6 Hz, H-7‴), 7.96 (m, 1H, OCON*H*), 7.71 (d, 2H, $J_{2″,3″}$= $J_{5″,6″}$= 8.1 Hz, H-3″, H-5″), 7.48 (d, 1H, $J_{5,6}$ = 8.0 Hz, H-6), 7.27 (d, 2H, $J_{2″,3″}$ = $J_{5″,6″}$ = 8.1 Hz, H-2″, H-6″), 6.17 (m, 1H, H-1′), 5.64 (d, 1H, $J_{5,6}$ = 8.0 Hz, H-5), 5.42 (m, 1H, H-2′), 4.43 (m, 1H, H-3′), 4.29 (m, 1H, ^2J = 15.9 Hz, J_{NHCH} = 6.4 Hz, NC*H*H), 4.16 (m, 1H, ^2J = 15.9 Hz, J_{NHCH} = 5.5 Hz, NCH*H*), 4.10 (m, 1H, $^2J_{5′a,5′b}$ = 13.1 Hz, $J_{4′,5′a}$ = 3.4 Hz, H-5′a), 3.95 (m, 1H, $^2J_{5′a,5′b}$ = 13.1 Hz, $J_{4′,5′b}$ = 2.7 Hz, H-5′b), 3.88 (m, 1H, H-4′), 1.12–0.92 (m, 28H, Pr^i). ^{13}C NMR (DMSO-d_6, δ): 163.1 (C4), 155.0 (O*C*O), 150.1 (C2), 140.4 (C1″), 140.3 (C6), 131.6 (2C, C3″, C5″), 131.1 (C10a‴), 131.0 (C3a‴), 130.9 (C5a‴), 130.6 (C8a‴), 129.6 (C2‴), 128.9 (C9‴), 128.4 (C4‴), 127.3 (C5‴), 127.0 (2C, C2″, C6″), 126.8 (C7‴), 126.0 (2C, C6‴, C8‴), 125.0 (C3‴), 124.9 (C10′′), 123.8 (C10b‴), 123.5 (C10c‴), 120.8 (C4″), 116.9 (C1‴), 101.4 (C5), 95.4 (Cb), 88.0 (Ca), 81.0 (C1′), 78.6 (C4′), 75.9 (C2′), 72.6 (C3′), 60.6 (C5′), 43.6 (N*C*H$_2$), 17.3, 17.2 (3C), 16.9 (3C), 16.7 (*C*H$_3$), 12.9, 12.4, 12.2, 11.9 (Si*C*).

General Procedure for the Preparation of 2′-*O*-[3(4)-(Pyren-1-ylethynyl)phenylmethylaminocarbonyl]uracil-1-β-D-arabinofuranosides (4a,b). To a solution of 2′-*O*-[3(4)-(pyren-1-ylethynyl)phenylmethylaminocarbonyl]-3′,5′-*O*-(tetraisopropyldisiloxan-1,3-diyl)uracil-1-β-D-arabinofuranoside **3a**(**3b**) (1.69 g, 2 mmol) in THF (5 mL), Et_3N·3HF (0.814 mL, 5 mmol) was added, and the mixture was kept at room temperature overnight. The mixture was diluted with $CHCl_3$ (20 mL), and the title compound was precipitated by addition of Et_2O (20 mL). The solid was filtered off, washed with $CHCl_3$ (15 mL) and Et_2O (2 × 20 mL), and dried *in vacuo* to afford the pure nucleoside **4a**(**4b**).

2′-*O*-[3-(Pyren-1-ylethynyl)phenylmethylaminocarbonyl]-uracil-1-β-D-arabinofuranoside (4a). Yield 1.14 g (95%), yellow crystals, R_f 0.32 (MeOH–toluene, 1:9 v/v), mp 118–121 °C (96% aq ethanol). MALDI-TOF HRMS: m/z = 624.1757 $[M + Na]^+$, calcd for $[C_{35}H_{27}N_3O_7 + Na]^+$ 624.1741. ^{1}H NMR (DMSO-d_6, δ): 11.31 (s, 1H, H-3), 8.63 (d, 1H, $J_{9‴,10‴}$ = 9.1 Hz, H-10‴), 8.39 (m, 3H, H-6‴,8‴,9‴), 8.33 (m, 1H, $J_{2‴,3‴}$ = 8.2 Hz, H-3‴), 8.29 (m, 1H, H-2‴), 8.27 (m, 1H, H-5‴), 8.23 (m, 1H, $J_{4‴,5‴}$ = 8.9 Hz, H-4‴), 8.15 (apparent t, 1H, $J_{6‴,7‴}$ = $J_{7‴,8‴}$ = 7.6 Hz, H-7‴), 7.94 (m, 1H, OCON*H*), 7.65 (m, 3H, H-6, H-2″, H-4″), 7.46 (apparent t, 1H, J = 7.6 Hz, H-5″), 7.25 (d, 1H, J = 7.6 Hz, H-6″), 6.18 (d, 1H, J = 4.9 Hz, H-1′), 5.75 (d, 1H, $J_{3′,OH}$ = 4.9 Hz, 3′-O*H*), 5.62 (d, 1H, $J_{5,6}$ = 8.0 Hz, H-5), 5.09 (m, 1H, H-2′), 5.01 (t, 1H, $J_{5′,OH}$ = 5.5 Hz, 5′-O*H*), 4.23 (m, 2H, NHCH_2), 4.14 (m, 1H, H-3′), 3.80 (m, 1H, H-4′), 3.73–3.59 (m, 2H, H-5′). ^{13}C NMR (DMSO-d_6, δ): 163.1 (C4), 154.9 (O*C*O), 150.1 (C2), 141.6 (C6), 140.1 (C1″), 131.2 (C10a‴), 131.1 (C3a‴), 130.8 (C5a‴), 130.6 (C8a‴), 130.1 (2C, C2″, C4″), 129.7 (C2‴), 129.0 (2C, C5″, C9‴), 128.5 (C4‴), 127.5 (C5‴), 127.3 (C6″), 126.9 (C7‴), 126.1 (3C, C6‴, C8‴), 125.0 (C3‴), 124.9 (C10′′), 123.7 (C10b‴), 123.5 (C10c‴), 122.4 (C3″), 116.8 (C1‴), 100.9 (C5), 95.2 (Cb), 88.3 (Ca), 83.9 (C4′), 82.9 (C1′), 77.2 (C2′), 73.0 (C3′), 60.2 (C5′), 43.6 (N*C*H$_2$).

2′-*O*-[4-(Pyren-1-ylethynyl)phenylmethylaminocarbonyl]-uracil-1-β-D-arabinofuranoside (4b). Yield 1.12 g (93%), yellow crystals, R_f 0.30 (MeOH–toluene, 1:9 v/v), mp 114–115 °C (96% aq ethanol). MALDI-TOF HRMS: m/z = 624.1722 $[M + Na]^+$, calcd for $[C_{35}H_{27}N_3O_7 + Na]^+$ 624.1741. ^{1}H NMR

RESULTS AND DISCUSSION

The synthesis of reagents for placement of 1-PEPy in a major groove is shown on Scheme 1. The starting imidazolide **1** (*24*) was reacted with 3- or 4-iodobenzylamine to give 3′,5′-Markiewicz-protected iodobenzyl *ara*-uridine-2′-carbamates **2a**,**b**. 1-PEPy fluorochrome was assembled using Sonogashira coupling of iodobenzyl compounds with 1-ethynylpyrene (*47*). Nucleosides **3** contain 1-PEPy unit connected to the sugar part of nucleoside through meta (series **a**) and para (series **b**) positions of a phenyl ring. Silyl protection was removed with triethylamine trihydrofluoride to yield fluorescent nuclesides **4a**,**b** as crystalline solids. These were converted into phosphoramidite reagents using standard methods of nucleoside chemistry—5′-*O*-dimethoxytritylation and 3′-*O*-phosphitylation.

Suddenly, signals from C1′–C5′ and C6 carbons were missing in ^{13}C NMR spectra of 3′,5′-silyl Markiewicz-protected compounds **2a**,**b** and **3a**,**b**. In contrast, nucleosides **4a**,**b** gave normal C1′–C5′ and C6 signals in ^{13}C NMR. Therefore, we repeated

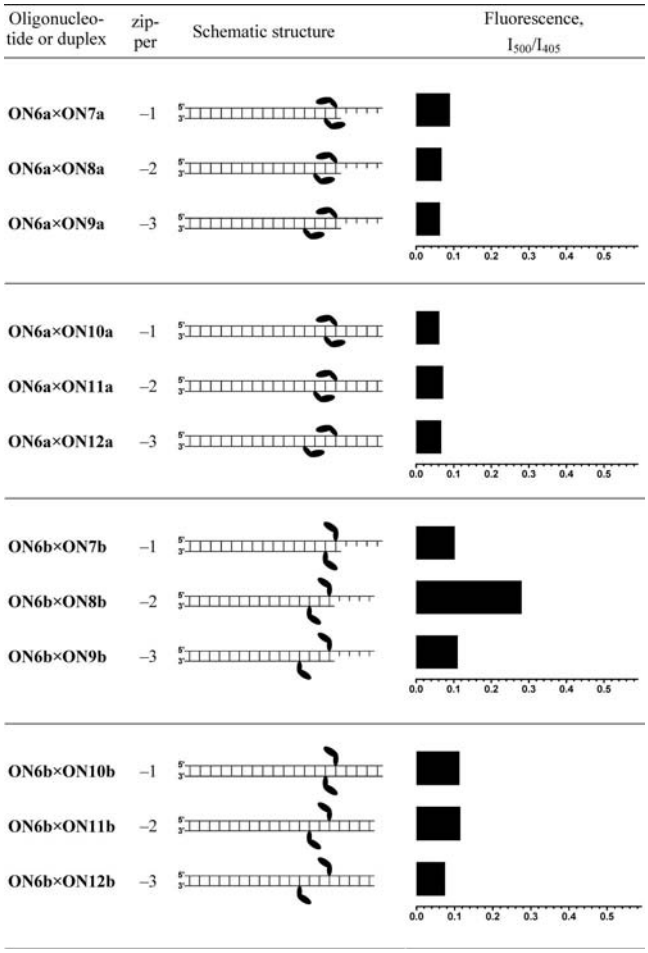
Table 5. Fluorescent Properties of *meta*- and *para*-1-PEPy Pairs Located in −1, −2, and −3 Zipper Modes



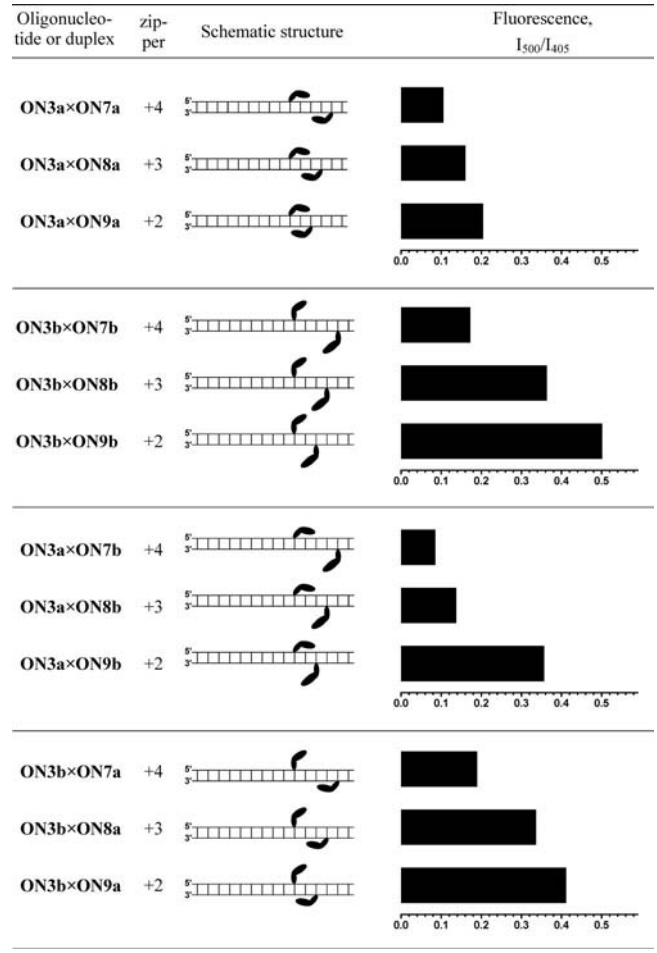


Table 6. Fluorescent Properties of *meta*- and *para*-1-PEPy Pairs Located in +2, +3, and +4 Zipper Modes

^{13}C NMR experiments for compounds **2a**,**b** and **3a**,**b** using 4096 scans. Indeed, broad (up to 200 Hz) signals appeared in expected regions (50–100 ppm for sugar carbons and 140 ppm for C6). Typical sugar carbon signals are shown on Figure 1. The signals gave normal cross-peaks in HMQC spectra and can be easily assigned. The nature of the observed effect is not clear. Evidently, two prerequisites—silyl Markiewicz group and aryl carbamate modification—contribute cooperatively in the unusual shielding of six carbon atoms in compounds **2a**,**b** and **3a**,**b**.

Phosphoramidites **6a**,**b** were used in automated oligonucleotide synthesis to prepare a series of modified oligonucleotides (Table 2) similar to those described for studies of pyrene excimer in DNA major groove (*24*).

It is known that 2′-carbamate modification destabilize dsDNA, but pyrene modification can relieve the negative carbamate influence (*20*, *24*), and *para*-1-PEPy-*ribo*-carbamate even displayed some stabilization of the DNA duplex (*49*). Thermal denaturation studies (Table 3) show that *meta*-1-PEPy-*arabino*-carbamate (series **a**) is similar to pyrene (*24*) in its ability to neutralize the negative carbamate effect. In contrast, PEPy in *para*-1-PEPy-*arabino*-carbamate (series **b**) has no influence on duplex stability: the resulting destabilization is similar to that from aliphatic carbamate (*24*). We speculate that, in the case

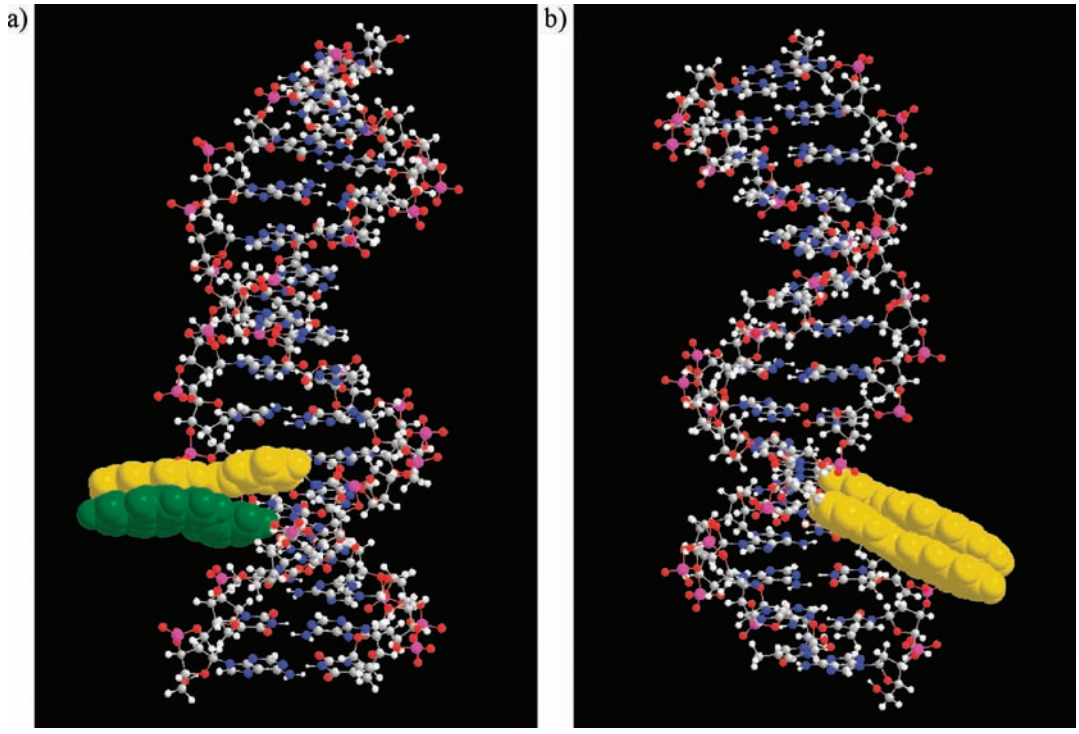

Figure 2. Molecular models of duplexes **ON3b**×**ON9a** (a) and **ON3b**×**ON9b** (b). 1-PEPy residues are shown in space-filling mode and marked in green (meta) and yellow (para attachment). Models constructed in HyperChem 7.5 and GaussView 3.0 with use of standard B-DNA parameters.

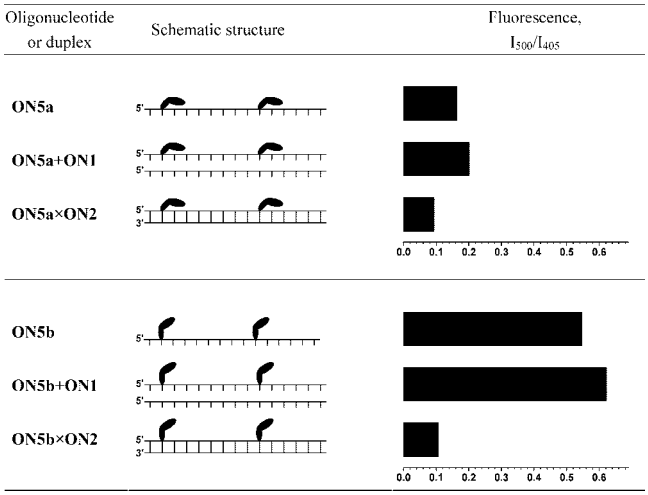
of *meta*-1-PEPy-*arabino*-carbamate modification, the aromatic residue fits the major groove of duplex, and in the case of *para*-modification, it is exposed in the environment. There are also no direct data for or against intercalation of PEPy residues into the DNA duplex. The intercalation of PEPy in fully matched duplexes is, however, highly unlikely because of excimer formation in +2 and +3 zipper modes (see below). On the other hand, in mismatched sequences, pyrene can probably replace a nonpairing nucleobase (*20*), and further studies would be useful for 1-PEPy.

Next, we determined spectral and photophysical properties of the *meta*- and *para*-1-PEPy labels as *arabino*-2′-carbamates (Table 4). There are minor variations in absorbances between single-stranded oligonucleotides and their duplexes. Hybridization causes a 4 nm bathochromic shift of fluorescence maximum in the **a** series and a 5 nm shift in the **b** series. The data show that 1-PEPy fluorescence kinetics in ss and dsDNA always fit to two exponential components with different lifetimes, and the average fluorescence lifetime is between 0.84 and 2.40 ns. This is approximately 2 orders of magnitude less than for pyrene derivatives. Not surpisingly, fluorescence quantum yields (9–32%) are much higher than typical quantum yields of pyrene fluorescence on DNA, except for pyrenoyl on amino-LNA (*60*). Hybridization causes a 2–3-fold decrease in average excited lifetime and emission quantum yield for conjugates **ON3a**, **ON4a**, and **ON4b**. In contast, Φ_f and $\langle\tau_f\rangle$ of 1-PEPy fluorochrome in **ON3b** slightly increased in the course of duplex formation.

Further, we studied the possibilities of PEPy interstrand excimer formation in DNA duplexes. In cases of excimer formation, the dye showed a broad emission band around 500 nm. We used the excimer-to-monomer fluorescence intensity ratio, I_{500}/I_{405}, as an excimer formation criterion. In the absence of excimer emission, I_{500}/I_{405} is approximately 0.1. First, we studied a "negative zipper" mode (Table 5). There was no detectable excimer fluorescence in continuous duplexes (**ON6**×**ON10**, **ON6**×**ON11**, **ON6**×**ON12**). In the case of truncated duplexes, an excimer was observed once, for −2 zipper mode in series **b** (**ON6b**×**ON8b**), probably resulting from duplex distortion. Interestingly, pyrene gave −1 zipper excimer in a similar case (*24*).



Then, we checked +2, +3, and +4 zippers for *meta*- and *para*- series of 1-PEPy pairs (Table 6). The intensity of excimer fluorescence always increased within the sequence +4 zipper < +3 zipper < +2 zipper. The weakest +2 excimer forms from two *meta*-PEPys, and the strongest from two *para*-compounds. All cases of combinations of **a** and **b** series were studied. The configuration **b** × **a** is always preferable for excimer formation than **a** × **b**. In cotrast to pyrene data (*24*), not only +2, but +3 and even weak +4 zipper excimers were observed in some cases. This can be easily explained by taking into account that the 1-PEPy molecule is approximately 1 nm longer than the pyrene one.

To confirm that the PEPy excimer can be formed in a major groove of a normal B-DNA duplex, molecular models were built (Figure 2). They showed, however, that stacked structures from two spatially accessible PEPy residues are not only located in a major groove, but considerably exposed in a solvent.

In addition, fluorescence data revealed that a doubly labeled oligonucleotide can form a metastable hairpin in aq solutions (Table 7). In the hairpin, two *para*-PEPys are located in close proximity and showed considerable excimer emission. The addition of the same nonlabeled sequence does not decrease the excimer fluorescence. Expectedly, the excimer completely disappears after hybridization with a complementary strand. Thus, the PEPy fluorochrome can be used for preparation of a "molecular beacon"-like excimer-forming probe.

To conclude, we report synthesis of meta and para derivatives of 1-phenylethynylpyrene (1-PEPy) *arabino*-uridine-2′-carbamates, their incorporation into oligonucleotides, spectral and photophysical properties in ss and dsDNA, and stuctural preferences for 1-PEPy major groove excimer. Although the excited lifetime of 1-PEPy derivatives on DNA is ca. 100-fold shorter compared to that of pyrene, PEPy molecules, being

Table 7. Fluorescent Properties of Oligonucleotides Doubly Labeled with *meta*- or *para*-1-PEPy Fluorochromes

located in +2, +3, and even in +4 zipper modes, are able to form a major groove or environmentally exposed interstrand excimer on the DNA duplex. The 1-PEPy excimer, more fastidious about the proximity of fluorochromes, could become a useful tool in structural studies of biomolecules.

ACKNOWLEDGMENT

We thank Maksim Kvach and Youri Habrus for oligonucleotide synthesis, Dmitry Alexeev for mass spectra, Larisa Grusintseva for technical assistance, and Zakhar Shenkarev for helpful advice with NMR spectra. This work was supported by the Russian Foundation for Basic Research (grant no. 06-03-32426).

Paclitaxel (Taxol), an effective anticancer agent, is known to bind to tubulin and induce tubulin polymerization. Several other binding proteins of paclitaxel, such as Bcl-2, heat shock proteins, and NSC-1, have also been reported. Here, we describe a T7 phage-based display to screen for paclitaxel-binding molecules from a random peptide library using paclitaxel-photoimmobilized TentaGel resin. Specific phage particles that bind the paclitaxel-immobilized resin were obtained. Among them, two phage clones included the same consensus amino acid sequence (KACGRTRVTS). Analysis of the protein database using BLAST revealed that a portion of this sequence is conserved in the zinc finger domain of human NFX1. Binding affinity of paclitaxel against the partial recombinant protein of NFX1 (424aa–876aa) was confirmed by pull-down assays and surface plasmon resonance analyses.

INTRODUCTION

Paclitaxel is a highly effective antineoplastic agent used in the treatment of a wide variety of tumors (Figure 1) (*1*).

There are numerous reports in the literature describing the candidate binding proteins of paclitaxel. Paclitaxel promotes tubulin polymerization by binding and stabilizing microtubules (*2–7*). Heat shock proteins 70 and 90 were identified to be paclitaxel-binding proteins from a macrophage cell lysate using biotinylated paclitaxel (*8*). An antiapoptotic protein, Bcl-2, and a neuronal calcium sensor protein, NSC-1, were also recognized as paclitaxel-binding proteins by phage display technology (*9–11*). Bcl-2 was identified from a library of random phage-displayed peptides by an analysis of affinity-selected peptides (*9, 10*). NCS-1 was also found to be a paclitaxel-binding protein using a similar selection procedure from a human brain cDNA phage library (*11*) .

Phage display is one of the best methods for the identification of drug-binding proteins (*12*). Indeed, this method has been successfully applied to the determination of drug-binding proteins for FK506 (*13*), doxorubicin (*14*), HBC (*15*) and paclitaxel (*9–11*). Moreover, phage display technology can be used to efficiently identify the specific drug-binding site within the identified protein (*9, 10*). The combination of screening a library of phage-displayed peptides and the analysis of affinity-selected peptides is anticipated to become a powerful tool for identifying drug-binding sites (*16–21*).

Screening phage display libraries generally entails immobilizing the drug onto a solid surface (*22*). Immobilization of the drug onto an affinity matrix is usually achieved by the formation of a biotinylated derivative, which can then be applied to a streptavidin-coated matrix. Conventional immobilization requires the presence of desirable functional groups within the drug molecule as well as a multistep process to prepare the biotinylated derivatives. However, photoimmobilization makes it possible to covalently immobilize drugs onto the solid surface without the need for derivatization. Kanoh and ourselves have reported the affinity purification of proteins using affinity matrices, in which small molecules were photoimmobilized by photoreaction (*23–25*). Because the photoreaction proceeds in a functional group-independent manner, the molecules are immobilized onto the solid surface in a nonoriented fashion. Thus, photoimmobilization can be a useful tool for the comprehensive analysis of drug-binding proteins.

In this study, paclitaxel-binding molecules were identified from a library of random peptides displayed on T7 phage particles using paclitaxel-photoimmobilized TentaGel.

EXPERIMENTAL PROCEDURES

Materials. Paclitaxel was purchased from Hoechst Marion Roussel (now known as Aventis Pharmaceuticals Inc., Paris, France). Photoaffinity beads were prepared as described previously, and paclitaxel was immobilized on the beads according to the literature (*24*). A 10.2 mg quantity of paclitaxel was used for immobilization onto 30 mg of photoaffinity beads. Photoaffinity beads, which were treated after UV irradiation in the absence of paclitaxel, were used for the control resin. The T7 phage library displaying a random 12 amino acid peptide was prepared as described in our previous paper (*21*). A sensor chip of CM5 and an Amine Coupling Kit were obtained from Biacore AB (now known as GE Healthcare, Amersham, UK). A mouse IgG-κ monoclonal antibody for anti-6His was purchased from Sigma-Aldrich (St Louis, MO). An alkaline phosphatase conjugated with a goat IgG antibody was obtained from Santa Cruz Biotechnology (Santa Cruz, CA).

Panning the Phage Library. A modified version of the biopanning technique given in the manufacturer's instructions (Novagen, Madison, WI) was used in this study (*21*). One milliliter of a random 12 amino acid T7 display library (approximately 9×10^{10} pfu) was added to 100 μg of pretreated

resin in TBS (50 mM Tris-HCl at pH 8.0 and 150 mM NaCl) for 12 h at room temperature. After incubation at 4 °C for 12 h, the resin was precipitated and the phage solution removed. The resin was then washed 25 times with 1 mL of TBST buffer (50 mM Tris-HCl at pH 8.0, 150 mM NaCl, and 0.1% Tween 20). Adsorbed phage particles were subsequently removed from the resin by 15 min of incubation in 1% SDS solution. The eluted phage particles were amplified after infection into *Escherichia coli* strain BLT5615 as host cells. The amplified phage was applied to the resin, and subsequent rounds of panning were carried out. The titer was monitored at each panning step. The eluted phage solution at each step was used for the immediate infection of 3 mL of host cells. Incubation with shaking at 37 °C was continued until lysis was observed. Amplified phage titers of each round were estimated to be 1–6 $\times$ 10^{10} pfu. After each round, the eluted phage titers were compared to those of the previous round.

Validation of Interaction between Monoclonal T7 Phage and Ligand. The T7 phage mixture from the final round of panning was incubated at low density on an LB plate containing 50 μg/mL of carbenicillin. Individual plaques were randomly picked and diluted into 50 μL of phage extraction buffer (20 mM Tris-HCl at pH 8.0, 100 mM NaCl, and 6 mM $MgSO_4$). To validate the affinity between monoclonal phage and paclitaxel-immobilized resin, the isolated phage particles were amplified with *E. coli* BLT5615. Binding, washing, and elution procedures were carried out as described in the screening procedure. Blank resin, without immobilized paclitaxel, was prepared, and the eluted phage titers were compared to those of the binding phage.

PCR Amplification and Sequencing. For PCR amplification of DNA fragments and sequencing, 5 μL of T7 phage solution was used as the template. T7 UP new (5′-TGCTAACTTC-CAAGCGGACC-3′) and T7 DOWN (5′-AACCCCTCAAGAC-CCGTTA-3′) primers, corresponding to the sequences in the phage vector that flanks the insert, were used to amplify inserted DNA sequences. PCR was performed in a 20 μL of reaction mixture with gene Taq polymerase (Nippon gene, Tokyo, Japan). Amplified fragments were analyzed by agarose gel (1.5%) electrophoresis. After purification of the amplified fragments by ethanol-precipitation, and DNA fragments were sequenced using PRISM BigDye terminator ready reaction kit (version 3.1) (PE-ABI, Foster City, CA) and applied to an ABI3100 sequencer (Applied Biosystems, Foster City, CA). The BLAST program was used for comparing the obtained sequences with sequences in the protein database (*27*).

Protein Expression and Purification. DNA encoding a fragment of the NFX1-type zinc finger domain of NFX1 (424aa–876aa) was amplified from a human leukocyte cDNA library using the forward primer (5′-GGGAATTCTGTGGT-GAGGTTTGTAGAAAG-3′) and the reverse primer (5′-CCCTCGAGACATTCACACTGTAGCTCTACC-3′). The amplified DNA was then cloned into a derivative of pET22b, constructed by insertion of the *E. coli* DsbC chaperone/disulfide isomerase gene. A truncated form of NFX1 (424–876) containing an N-terminal His-tag was coexpressed with DsbC after induction with 0.4 mM IPTG at 16 °C. The harvested cells were lysed by sonication, and cell debris was removed by centrifugation at 12000*g* for 10 min. The crude extract was then loaded onto a Ni-NTA column, and the bound proteins were eluted with a solution of 200 mM imidazole (pH 7.4). The eluted proteins were then dialyzed against PBST buffer.

Table 1. Results of Biopanning with Paclitaxel Immobilized on Photoaffinity Beads

round (th)	input[a] ($\times$ 10^{10})	output[a] ($\times$ 10^{5})	recovery[b] ($\times$ 10^{-6})	enrichment (per round)	enrichment (total)

3	1.70	1.20	7.06	3.31	3.53

[a] Plaque forming unit. [b] Output/input.

Pull down Assay and Western Blotting. Small molecule pull-down assays were carried out as described previously (*24*). NFX1 adsorbed on the resin was detected using the Bradford assay and Western blot analysis. Western blotting was performed with a mouse IgG monoclonal antibody for anti-6His (used at 1:1000 dilution). A goat antimouse IgG conjugated with alkaline phosphatase was used as the secondary antibody at a dilution of 1:1000. Immunoreacted signals were detected with nitro blue tetrazolium and 5-bromo-4-chloro-3-indolyl phosphate.

Surface Plasmon Resonance (SPR) Analysis. SPR analysis was performed on a BIAcore X (Biacore AB, Sweden, now known as GE Healthcare). The truncated form of NFX1 (424aa–876aa) with an N-terminal His-tag was covalently immobilized to a hydrophilic carboxymethylated dextran matrix on a CM5 sensor chip using a standard amine coupling reaction in 10 mM CH_3CO_2Na (pH 4.0) at a level of approximately 7500 resonance units (RU). Binding analysis was carried out in PBST buffer (20 mM, 150 mM NaCl, 10 μM $ZnCl_2$, and 0.001% Tween 40) containing 8% DMSO at a flow late 20 μL/min. Appropriate concentrations of paclitaxel were injected over the flow cell. The bulk effects of DMSO were subtracted by using reference surfaces. To derive binding constants, data was analyzed by means of global fitting by using the BIA evaluation software (version 3.1).

RESULTS

Selection of T7 Phage Associated with Paclitaxel. A library of random peptides displayed on phage particles was screened for the ability to specifically bind paclitaxel-immobilized resin. Phage particles having affinity for paclitaxel-immobilized resin were efficiently enriched (Table 1). The ratio of eluted phage titer increased in each successive round of screening. We anticipated that the eluted phage particles from the third round would display high affinity for paclitaxel. Thus, 32 phage clones were randomly selected from plates and then sequenced. To estimate the binding specificities of the peptides displayed on phage particles, each single phage clone was amplified, and the resultant phage clones were used for a binding assay (Table 2). The affinity titers of eight selected phage clones (numbers 13, 15, 18, 20, 21, 26, 27, and 29) from paclitaxel-immobilized resins were more than 6.7 times higher than those of the background phage from the control resin. Phage clones 18, 20, and 21 displayed a series of peptides of more than 12 amino acids and had specific affinity for paclitaxel immobilized on the resin. The sequence of clones 20 and 21 were identical for the C-terminal 10 amino acid residues (KACGRTRVTS).

Recombinant Protein Interacts with Paclitaxel. A homology search using the BLAST program demonstrated that the amino acid sequence of the consensus peptide (KACGRTRVTS)

[a] Estimation of binding specificities for selected phage clones by affinity titers. The titers of the input phages were adjusted to 1.0×10^{10} cfu/mL. Binding assays were performed on paclitaxel-immobilized resins (paclitaxel +) or control resins (paclitaxel –). [b] The relative enrichment ratio is determined as the output phages from paclitaxel-beads divided by the output phages from control beads.

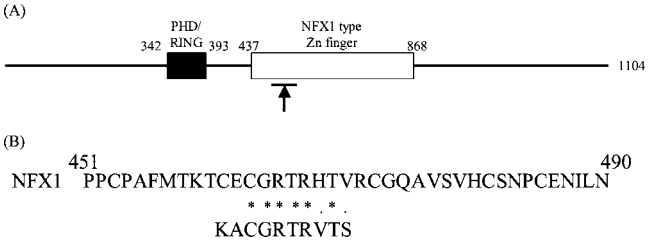

Figure 2. Alignment between obtained amino acid sequence and human NFX1. (A) The similarity site (marked by upward arrow/underline) is contained in the NFX1-type zinc finger domain of NFX1. This region affects the DNA binding of NFX1. (B) The obtained amino acid sequence indicated similarity to C463-T469 of human NFX1. The numbers show amino acid positions in NFX1. The asterisk indicates identical amino acids.

is similar to a part of the zinc finger domain of human NFX1 (Figure 2) (*20, 21, 26*). This region affects the DNA binding of NFX1 (*28*).

A truncated recombinant NFX1 (424aa–876aa) was overexpressed and purified for the binding assays (*28*). The recombinant NFX1 (424aa–876aa) contains an amino acid sequence similar to that of the consensus sequence selected by phage screening.

The amount of truncated NFX1 (424aa–876aa) bound to the paclitaxel-immobilized resin (10 mg) or control resin (10 mg) was determined using the Bradford assay by monitoring absorbance at 595 nm (Figure 3). Approximately 30% of the applied recombinant NFX1 (424aa–876aa) was recovered from the palitaxel-immobilized resin. The recovered NFX1 (424aa–876aa) from the palitaxel-immobilized resin was detected by Western blotting using an anti-6His monoclonal antibody (Figure 3). By contrast, only a small amount of NFX1 bound to the control resin.

Binding analysis between paclitaxel and the truncated form of NFX1 (424aa–876aa) was performed by surface plasmon resonance. The recombinant NFX1 (424aa–876aa) was fixed on a CM5 sensor chip using an amine coupling reaction. The dissociation constant of paclitaxel with NFX1 (424aa–876aa) was determined to be 8×10^{-7} M, using BIA evaluation 3.1 software (Figure 4A). Specificity of binding was confirmed by analyzing the interaction of NFX1 (424aa–876aa) with doxorubicin and ampicillin, whose structures are different from that of paclitaxel. Unlike paclitaxel, neither doxorubicin nor ampicillin showed significant interaction with immobilized NFX1 (424aa–876aa) (Figure 4B).

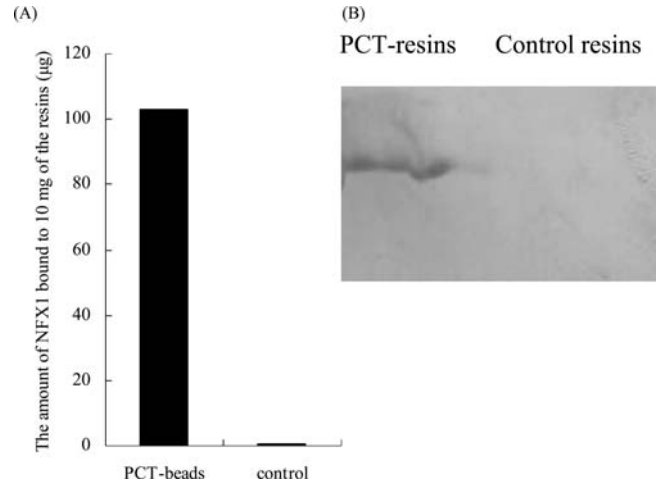

Figure 3. Binding analysis of the recombinant NFX1 (424aa–876aa) with the paclitaxel-immobilized resins (PCT-resins) and control resins (Control resins). (A) Quantitative analysis of proteins bound to 10 mg of resin using the Bradford assay. Note that 348 μg of the recombinant NFX1 (424aa–876aa) was applied to the binding assay. (B) Western blot analysis of the His-tagged zinc finger domain of NFX1 bound to the resin.

DISCUSSION

Identification of binding partners to biologically active small molecules is an important step in elucidating the corresponding mechanism of action. Phage display is a versatile method for the detection of small molecule-binding proteins. One advantage of phage display is that the technique can also be used to identify binding sites within the target protein itself. Indeed, several binding sites for bioactive compounds have been elucidated by screening with phage display.

In the conventional method of phage display, small molecules are usually converted into the biotinylated derivatives and immobilized on a streptavidin-coated matrix. Preparation of biotinylated derivatives can be a laborious and time-consuming process. Furthermore, biotinylation of a small molecule might interfere with binding to the cognate binding partner(s). By contrast, immobilization of small molecules on a solid support using UV irradiation can be readily achieved without the need for derivatization. Using this procedure, the molecules will be immobilized in a nonoriented manner. Therefore, photoimmobilization can eliminate serious problems associated with biotinylation, which could potentially abolish the functional groups required for protein binding.

In the present study, we isolated phage clones that show affinity for paclitaxel-photoimmobilized TentaGel resin. Two of the selected clones have the consensus amino acid sequence KACGRTRVTS. A comparison of this short peptide sequence with the protein database revealed similarity to residues 463–469 of human NFX1. NFX1 is known to be a transcriptional regulator of the human major histocompatibility complex (MHC) class II gene, although it is also expressed in MHC class II-negative cells (*28*). Analysis of NFX1 shows that it possesses a central DNA-binding domain that is subdivided into repeated Cys-rich motifs (437–868 amino acids of NFX1). The motif is similar to, but distinct from, LIM and RING finger domains. NFX1 binds to the conserved X-box motif of MHC class II genes via a repeated zinc finger domain and represses their expression to regulate the duration of an inflammatory response (*28*). The RING-type zinc finger domain also interacts with a ubiquitin-conjugating enzyme (E2) and facilitates ubiquitination (*29*).

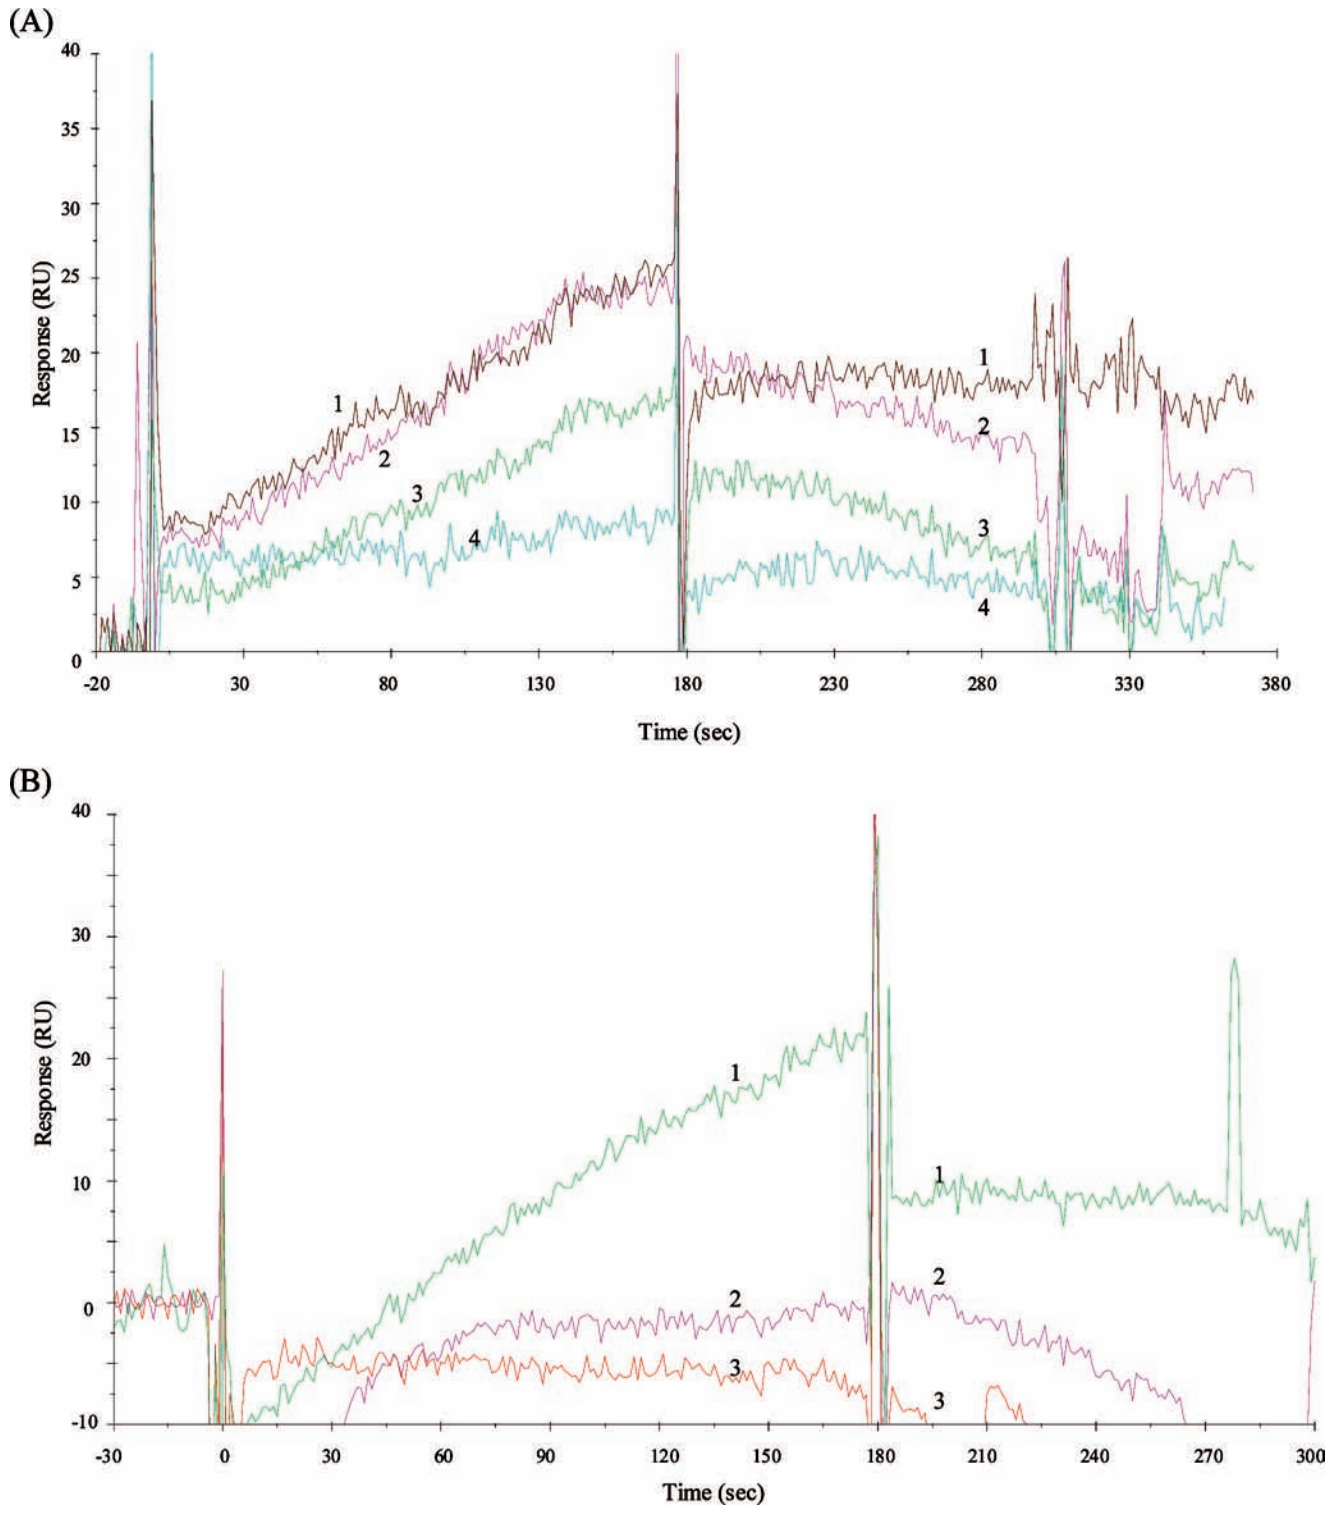

Figure 4. SPR analysis of the binding between paclitaxel and partial recombinant NFX1 (424aa–876aa). Analytes in PBST buffer (containing 8% DMSO) were injected over flow cells on the immobilized NFX1 (424aa–876aa). The background resulting from an injection of running buffer was subtracted from the data before plotting. Response units (RU) were generated by subtraction of the background signal generated simultaneously on the control flow cell. (A) Binding of paclitaxel on immobilized NFX (424aa–876aa) at various concentrations (1, 7.5 μM; 2, 5 μM; 3, 2.5 μM; 4, 1.25 μM). Kinetic studies were performed with BIA evaluation software. (B) Estimation of binding specificity. A 5 μM solution of paclitaxel (1), doxorubicin (2), or ampicillin (3) was loaded.

Interaction between paclitaxel and the partial recombinant NFX1 (424aa–876aa) was confirmed by pull-down assays and surface plasmon resonance analyses. Recombinant NFX1 (424aa–876aa) selectively binds the pactitaxel-photoimmobilized resin by the pull-down assay. Paclitaxel bound the immobilized recombinant NFX1 (424aa–876aa) with a dissociation constant (K_d) of 8×10^{-7} M. By contrast, doxorubicin and ampicillin did not show significant interaction with the immobilized NFX1 (424aa–876aa). Sengupta et al. measured the binding of *N*-dibenzoyl-*N*-[3-(dimethylamino)benzoyl]-paclitaxel, a fluorescent derivative of paclitaxel, to tubulin. Data from these experiments gave an equilibrium dissociation constant of 4.9×10^{-5} M for the binding of paclitaxel to unpolymerized tubulin (*30*). Rodi et al. reported that paclitaxel binds to Bcl-2 with a dissociation

constant of 4×10^{-7} M (*9*). Although we have not examined whether paclitaxel influences the activities of NFX1 and its resultant effects, these results verify that NFX1 is one of the binding proteins of paclitaxel. Interestingly, our experiments established that paclitaxel binds to the zinc finger domain of NFX1, which requires NFX1–DNA interaction. Considering that NFX1 functions as a repressor, paclitaxel might inhibit the repressive effect of NFX1 for MHC class II gene expression, suggesting that paclitaxel activates MHC class II gene expression. Indeed, this hypothesis is consistent with a previous report, which demonstrated that paclitaxel induced MHC class II genes in dendritic cells (*31*).

A homology search of our selected consensus peptide by BLAST gives other candidate binding proteins of paclitaxel. For example, tropoelastin has an amino acid sequence (^{779}KACGRKR^{785}) similar to that of the consensus sequence in the C-terminal region (*32*). Furthermore, placenta-specific 1-like protein precursor contains a segment of sequence (^{76}CGIRTRVVS^{84}) that displays similarity to the selected peptide sequence (*33*). Surprisingly, none of our isolated clones showed similarity to known paclitaxel-binding proteins such as tubulin, heat shock proteins, Bcl-2, or NCS-1. One possible explanation for these results is that our original phage library was not sufficiently diverse. The titer of the primary clones in the library used in this study was 4×10^6 pfu/mL (*21*). The use of a high diversity library would provide a greater amount of information on paclitaxel-binding peptides. Alternatively, interaction of paclitaxel with proteins such as tubulin may involve multiple binding motifs, which despite being far apart in the primary amino acid sequence are spatially close together in the three-dimensional structure. Indeed, paclitaxel binds to a pocket in the second globular domain of β-tubulin facing the microtubule. The use of a highly diverse library would also contribute to more comprehensive information on the binding peptides.

In summary, we have used a T7 phage display screening method to identify paclitaxel-binding molecules from a random peptide library using paclitaxel-photoimmobilized resin. Two of the selected clones have the consensus peptide KACGRTRVTS, which displays similarity to a part of the zinc finger domain of human NFX1. Binding between paclitaxel and recombinant NFX1 was confirmed by pull-down and SPR analyses. Our results demonstrate that this methodology can be used to identify novel binding proteins of small molecules. Studies on the biological effect of paclitaxel on human NFX1 as well as further application and optimization of this methodology are currently underway.

Click Chemistry for ^{18}F-Labeling of RGD Peptides and microPET Imaging of Tumor Integrin $\alpha_v\beta_3$ Expression

Zi-Bo Li,[†] Zhanhong Wu,[†,‡] Kai Chen,[†] Frederick T. Chin,[†] and Xiaoyuan Chen*[,†]

The Molecular Imaging Program at Stanford (MIPS), Department of Radiology and Bio-X Program, Stanford University School of Medicine, Stanford, California, and Department of Nuclear Medicine, Peking Union Medical College Hospital, Beijing, P.R. China. Received June 20, 2007; Revised Manuscript Received August 3, 2007

The cell adhesion molecule integrin $\alpha_v\beta_3$ plays a key role in tumor angiogenesis and metastasis. A series of ^{18}F-labeled RGD peptides have been developed for PET of integrin expression based on primary amine reactive prosthetic groups. In this study, we report the use of the Cu(I)-catalyzed Huisgen cycloaddition, also known as a click reaction, to label RGD peptides with ^{18}F by forming 1,2,3-triazoles. Nucleophilic fluorination of a toluenesulfonic alkyne provided ^{18}F-alkyne in high yield (nondecay-corrected yield: 65.0 ± 1.9%, starting from the azeotropically dried ^{18}F-fluoride), which was then reacted with an RGD azide (nondecay-corrected yield: 52.0 ± 8.3% within 45 min including HPLC purification). The ^{18}F-labeled peptide was subjected to microPET studies in murine xenograft models. Murine microPET experiments showed good tumor uptake (2.1 ± 0.4%ID/g at 1 h postinjection (p.i.)) with rapid renal and hepatic clearance of ^{18}F-fluoro-PEG-triazoles-RGD$_2$ (^{18}F-FPTA-RGD2) in a subcutaneous U87MG glioblastoma xenograft model (kidney 2.7 ± 0.8%ID/g; liver 1.9 ± 0.4%ID/g at 1 h p.i.). Metabolic stability of the newly synthesized tracer was also analyzed (intact tracer ranging from 75% to 99% at 1 h p.i.). In brief, the new tracer ^{18}F-FPTA-RGD2 was synthesized with high radiochemical yield and high specific activity. This tracer exhibited good tumor-targeting efficacy and relatively good metabolic stability, as well as favorable in vivo pharmacokinetics. This new ^{18}F labeling method based on click reaction may also be useful for radiolabeling of other biomolecules with azide groups in high yield.

INTRODUCTION

The vitronectin receptor integrin $\alpha_v\beta_3$ has been the focus of intensive research because of its major role in several distinct processes, particularly osteoclast-mediated bone resorption (*1*), angiogenesis and pathological neovascularization (*2*), and tumor metastasis (*3*). Integrin $\alpha_v\beta_3$ has distinct functional properties that are mediated through interactions with a variety of extracellular matrix (ECM) proteins (*4, 5*) and a number of important intracellular signaling molecules (including paxillin, focal adhesion kinase caspase-8, and others) (*6–8*). These interactions play a part in regulating intracellular signaling, cell migration, cell proliferation, and cell survival.

Since integrin $\alpha_v\beta_3$ plays a key role in multiple physiological and pathological processes, a method to noninvasively visualize and quantify $\alpha_v\beta_3$ integrin expression levels will provide a means to document integrin levels, wisely choose patients for anti-integrin treatment, and monitor treatment efficacy in integrin-positive patients. Multimodality approaches have been applied to image integrin expression in vivo, including magnetic resonance (MR) (*9, 10*), ultrasound (*11, 12*), near-infrared fluorescence (NIRF) (*13, 14*), single photon emission computed tomography (SPECT), and positron emission tomography (PET) (*15–17*). Due to the high sensitivity and reasonably good spatial/temporal resolution, PET probe development for targeting integrin expression continues to be an area of great interest.

Because ^{18}F is readily available from most small medical cyclotrons and has almost 100% positron efficiency, the physical half-life of ^{18}F (109.7 min) is well-suited for routine clinical use and is well-matched to the biological half-life (blood clearance) of peptides (usually minutes to less than a few hours), ^{18}F-labeled target-specific peptides are becoming widely used as in vivo imaging agents, a few of which have entered early-phase clinical trials (*15*). Different from small organic molecules, direct labeling of peptides via either SN_1 or SN_2 nucleophilic substitution is usually not an option, as peptides will not tolerate the harsh reaction conditions associated with these procedures. Radiofluorination of peptides thus generally uses ^{18}F-prosthetic groups (synthons) that will form stable chemical bonds on the peptides. ^{18}F labeling could be accomplished through the amino group at the N terminus or the lysine side chain using *N*-succinimidyl-4-^{18}F-fluorobenzoate (^{18}F-SFB) (*18, 19*), 4-^{18}F-fluorobenzaldehyde (^{18}F-FBA, via oxime formation and reductive amination) (*20, 21*), 3-^{18}F-fluoro-5-nitrobenzimidate (^{18}F-FNB, via imidation reaction) (*22*), 4-azidophenacyl ^{18}F-fluoride (^{18}F-APF, via photochemical conjugation) (*23*), and 4-^{18}F-fluorophenacyl bromide (^{18}F-FPB, via alkylation reactions) (*22*). ^{18}F labeling of peptide or protein via the carboxylic acid group at the C terminus or glutamic/aspartic acid side chain is less common, and only a few reports exist (*24*). We have previously reported the Michael addition reaction for labeling thiolated RGD peptides (*25*). However, most of these procedures suffer from lengthy and tedious multistep synthetic procedures. As a result, these long, difficult processes make them a challenge to automate and adversely decrease the overall radiolabeling yield.

The recent discovery that Cu(I) catalyzes the Huisgen 1,3-dipolar cycloaddition of organo azides with terminal alkynes to form 1,2,3-triazoles (*26, 27*), often referred to as click chemistry (*28*), has led wide-ranging applications in combinatorial chemistry (*29–31*). This reaction could be carried out in high yields under mild conditions, and the 1,2,3-triazole formed has similar polarity and size with an amide bond (*32*). Due to these favorable aspects with click chemistry, the use of this reaction for making ^{18}F-labeled model peptides have been recently reported (*33, 34*). However, no in vivo PET study has

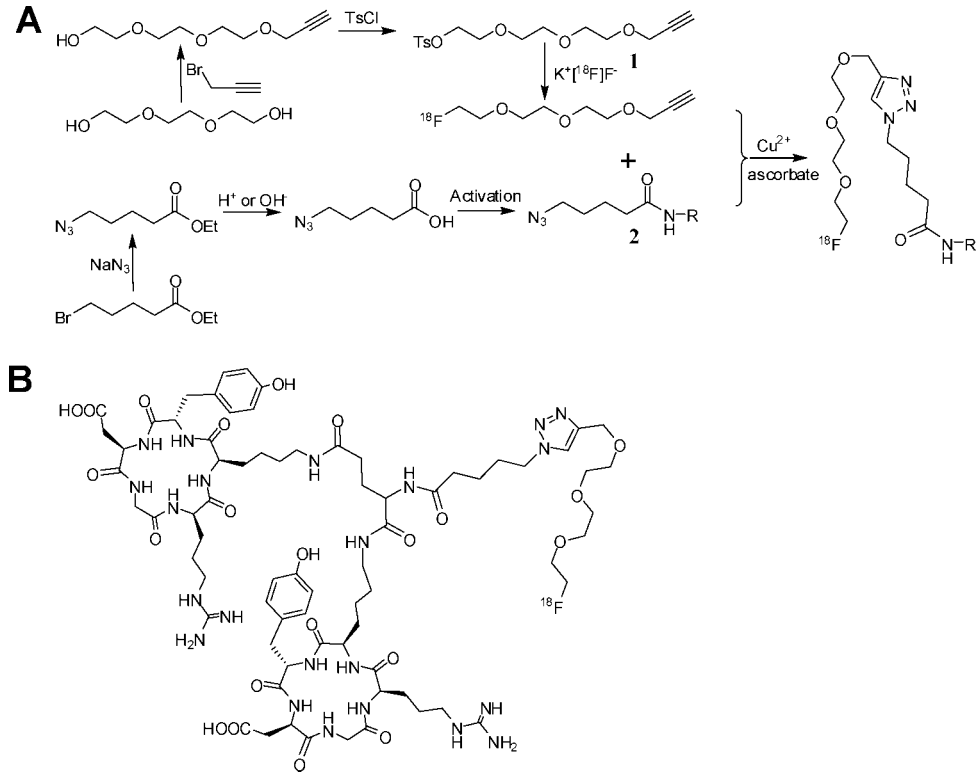

Figure 1. (A) Radiosynthesis of ^{18}F-fluoro-PEG-alkyne intermediate and 1.3-dipolar cycloaddition with terminal azide. R = targeting biomolecule (peptides, proteins, antibodies, etc.). (B) Structure of ^{18}F-fluoro-PEG-alkyne labeled E[c(RGDyK)]$_2$: ^{18}F-fluoro-PEG-triazole-E(RGDyK)$_2$ (^{18}F-FPTA-RGD2).

been reported on ^{18}F-labeled tracers synthesized by click chemistry. Moreover, distillation was required for some of the reported methods (*34*), which is unfortunately difficult to automate. In this study, we labeled dimeric-RGD peptide with our newly developed ^{18}F synthon based on click chemistry and studied the tumor targeting efficacy, in vivo kinetics, and metabolic stability of this tracer in tumor-bearing mice.

MATERIALS AND METHODS

All chemicals obtained commercially were of analytical grade and used without further purification. No-carrier-added ^{18}F–F$^-$ was obtained from a PETtrace cyclotron (GE Healthcare). Reversed-phase extraction C-18 Sep-Pak cartridges were obtained from Waters and were pretreated with ethanol and water before use. The syringe filter and polyethersulfone membranes (pore size, 0.22 μm; diameter, 13 mm) were obtained from Nalge Nunc International. ^{125}I-Echistatin, labeled by the lactoperoxidasemethod to a specific activity of 74 000 GBq/mmol (2000 Ci/mmol), was purchased from GE Healthcare. Analytical as well as semipreparative reversed-phase high-performance liquid chromatography (RP-HPLC) was performed on a Dionex 680 chromatography system with a UVD 170U absorbance detector and model 105S single-channel radiation detector (Carroll & Ramsey Associates). The recorded data were processed using *Chromeleon* v 6.50 software. Isolation of peptides and ^{18}F-labeled peptides was performed using a Vydac protein and peptide column (218TP510; 5 μm, 250 × 10 mm). The flow rate was set at 5 mL/min, with the mobile phase starting from 95% solvent A (0.1% trifluoroacetic acid [TFA] in water) and 5% solvent B (0.1% TFA in acetonitrile [ACN]) (0–2 min) to 35% solvent A and 65% solvent B at 32 min The analytical HPLC was performed using the same gradient system, but with a Vydac column (218TP54, 5 μm, 250 × 4.6 mm) and a flow rate of 1 mL/min. The UV absorbance was monitored at 218 nm, and the identification of the peptides was confirmed by separate standard injection.

Preparation of Alkyne Tosylate (1). The alkyne tosylate (**1**) (Figure 1) was prepared by using the modified method reported by Burgess (*35*). In brief, sodium hydride (1 g, 25 mmol, 60%) was slowly added to the THF solution of triethylene glycol (5.8 g, 38 mmol) at 0 °C. The mixture was stirred for 30 min and propargyl bromide (2.1 mL, 19 mmol) was then added dropwise. The mixture was stirred at room temperature for 18 h, and the triethylene glycol alkyne was obtained as a light yellow oil after purification by chromatography (2.5 g, 70%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 4.13 (d, J = 2.5 Hz, 2H), 3.61–58 (m, 10H), 3.52–3.50 (m, 2H), 2.75 (br, 1H), 2.38 (t, J = 2.5 Hz, 1H). After the triethylene glycol alkyne (1 g, 5.4 mmol) was reconstituted in ACN (15 mL) and triethylamine (2 mL, 14 mmol), *p*-toluenesulfonyl chloride (2.1 g, 11 mmol) was added slowly, and the mixture was stirred at room temperature for 16 h. After the reaction was quenched followed by general workup, the crude product was purified by flash chromatography to afford the alkyne tosylate (**1**) (1.5 g, 81%) as a colorless oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.75 (d, J = 8.4 Hz, 2H), 7.30 (d, J = 8.4 Hz, 2H), 4.14–4.06 (m, 4H), 3.65–3.58 (m, 6H), 3.55–3.52 (m, 4H), 2.38 (s, 3H), 2.37 (t, J = 2.5 Hz, 1H).

Preparation of Azido-RGD2. The 5-azidopentanoic acid was obtained as colorless oil according to the procedure published by Carrié (*36*). ^{1}H NMR (400 MHz, $CDCl_3$) δ 3.25 (t, J = 6.5 Hz, 2H), 2.34 (t, J = 7.1 Hz, 2H), 1.68–1.59 (m, 4H). The azido-RGD2 was prepared from cyclic RGD dimer E[c(RGDyK)]$_2$ (denoted as RGD2). To a solution of 5-azidopentanoic acid (18.6 mg, 0.13 mmol) and 20 μL DIPEA in ACN (0.5 mL), *O*-(*N*-succinimidyl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TSTU, 27 mg, 0.09 mmol) was added. The reaction mixture was stirred at room temperature for 0.5 h and then added to E[c(RGDyK)]$_2$ (20 mg, 14.8 μmol) in *N*,*N*′-dimethylformamide (DMF). The

Table 1. Radiolabeling Yields (decay-corrected) of ^{18}F-Fluoro-PEG-Alkyne Intermediate at Various Conditions ($n = 3$)

entry	solvent	temperature and time	yield (%)
1	ACN	90 °C for 15 min	61.2 ± 2.5
2	ACN	110 °C for 15 min	71.4 ± 3.0
3	ACN/DMSO	110 °C for 15 min	75.0 ± 1.8
4	**DMSO**	**110 °C for 15 min**	**78.5 ± 2.3**
5	DMSO	110 °C for 30 min	84.3 ± 2.1

reaction was stirred at room temperature for another 2 h, and the desired product azido-RGD2 was isolated by preparative HPLC. The collected fractions were combined and lyophilized to give a white fluffy powder (12 mg, 57% yield) with a retention time of 14.8 min on analytical HPLC. MALDI-TOF-MS: *m*/*z* 1475.87 for $[MH]^+$ ($C_{64}H_{95}N_{22}O_{19}$, calculated molecular weight [MW] 1475.71).

Preparation of Fluoro-PEG-Triazole-E(RGDyK)$_2$ (FPTA-RGD2). To a solution of alkyne tosylate (**1**) (6.8 mg, 0.02 mmol) in ACN, powdered potassium fluoride (6 mg, 0.10 mmol), potassium carbonate (3 mg), and Kryptofix 222 (15 mg) were added, and the mixture was heated at 90 °C for 40 min The reaction mixture was evaporated to dryness, and the residue was redissolved in 0.4 mL water and 0.4 mL THF. Azido-RGD2 (1 mg, 0.7 μmol) was then added, followed by $CuSO_4$ (100 μL, 0.1 N) and sodium L-ascorbate (100 μL, 0.3 N) solution. The resulting mixture was stirred at room temperature for 24 h, and the reaction was then quenched and purified by semi-preparative HPLC. The final product fluoro-PEG-triazole-E(RGDyK)$_2$ (FPTA-RGD2) was obtained in 81% yield (0.91 mg) with a retention time of 13.4 min on analytical HPLC. MALDI-TOF-MS: *m*/*z* 1665.82 for $[MH]^+$ ($C_{73}H_{110}FN_{22}O_{22}$, calculated [MW] 1665.81).

Radiochemistry. [^{18}F] Fluoride was prepared by the ^{18}O(p,n)^{18}F nuclear reaction, and it was then adsorbed onto an anion exchange resin cartridge. Kryptofix 222/K_2CO_3 solution (1 mL 9:1 ACN/water, 15 mg Kryptofix 222, 3 mg K_2CO_3) was used to elute the cartridge, and the resulting mixture was dried in a glass reactor. A solution of alkyne tosylate (**1**) (4 mg in 1 mL ACN/DMSO) was then added, and the resulting mixture was heated at the desired temperature (Table 1). After cooling, the reaction was quenched, and the mixture was injected onto a semipreparative HPLC for purification. The collected radioactive peak was diluted in water (10 mL) and passed through a C18 cartridge. The trapped activity was then eluted off the cartridge with 1 mL THF and used for the next reaction. To the reactor vial with azido-RGD2 (1 mg), 37 MBq activity, $CuSO_4$ (100 μL, 0.1 N), and sodium L-ascorbate (100 μL, 0.3 N) were added sequentially. The resulting mixture was heated at 40 °C for 20 min, and the reaction was then quenched and purified by semipreparative HPLC. The final product ^{18}F-FPTA-RGD2 (R_t 13.4 min; decay-corrected yield 69 ± 11%; radiochemical purity >97%) was concentrated and formulated in saline (0.9%, 500 μL) for in vivo studies.

Octanol–Water Partition Coefficient. Approximately 111 kBq of ^{18}F-FPTA-RGD2 in 500 μL of PBS (pH 7.4) were added to 500 μL of octanol in an Eppendorf microcentrifuge tube (model 5415R, Brinkman). The mixture was vigorously vortexed for 1 min at room temperature and centrifuged at 12 500 rpm for 5 min. After centrifugation, 200 μL aliquots of both layers were measured using a γ-counter (Packard Instruments). The experiment was carried out in triplicate.

Cell Line and Animal Models. U87MG human glioblastoma cells were grown in Dulbecco's medium (Gibco) supplemented with 10% fetal bovine serum (FBS), 100 IU/mL penicillin, and 100 μg/mL streptomycin (Invitrogen Co.). Animal procedures were performed according to a protocol approved by the Stanford University Institutional Animal Care and Use Committee. A U87MG xenograft model was generated by subcutaneous (s.c.) injection of 1×10^7 U87MG cells (integrin $\alpha_v\beta_3$-positive) into the front flank of female athymic nude mice. Three to four weeks after inoculation (tumor volume: 100–400 mm^3), the mice (about 9–10 weeks old with 20–25 g body weight) were used for microPET studies.

Cell Integrin Receptor-Binding Assay. In vitro integrin-binding affinity and specificity of E[c(RGDyK)]$_2$ and FPTA-RGD2 were assessed via competitive cell binding assays using ^{125}I-echistatin as the integrin $\alpha_v\beta_3$-specific radioligand (*17*). The best-fit 50% inhibitory concentration (IC_{50}) values for U87MG cells were calculated by fitting the data with nonlinear regression using *GraphPad Prism* (GraphPad Software, Inc.). Experiments were performed with triplicate samples.

In Vivo Metabolic Stability Studies. The metabolic stability of ^{18}F-FPTA-RGD2 was evaluated in an athymic nude mouse bearing a U87MG tumor. 60 min after intravenous injection of 2 MBq of ^{18}F-FPTA-RGD2, the mouse was sacrificed, and relevant organs were harvested. The blood was collected and immediately centrifuged for 5 min at 13 200 rpm. Liver, kidneys, and tumor were homogenized and then centrifuged for 5 min at 13 200 rpm. After removal of the supernatants, the pellets were washed with 1 mL PBS. For each sample, supernatants of both centrifugation steps of blood, liver, and kidneys were combined and passed through C18 Sep-Pak cartridges. The urine sample was directly diluted with 1 mL of PBS and passed through a C18 Sep-Pak cartridge. The cartridges were each washed with 2 mL of water and eluted with 2 mL of ACN containing 0.1% TFA. After evaporation of the solvent, the residues were redissolved in 1 mL PBS and were injected onto the analytical HPLC. The eluent was collected with a fraction collector (0.5 min/fraction), and the radioactivity of each fraction was measured with the γ-counter.

microPET Studies. PET scans and image analysis were performed using a microPET R4 rodent model scanner (Siemens Medical Solutions) as previously reported (*17, 19*). About 2 MBq of ^{18}F-FPTA-RGD2 was intravenously injected into each mouse ($n = 3$) under isoflurane anesthesia (1–3%) and then subjected to a 30-min dynamic scan (1×1 min, 1×1.5 min, 1×3.5 min, 3×5 min, 1×6 min, total of 7 frames) starting from 1 min p.i. 5 min static PET images were also acquired at 1 and 2 h p.i. For each microPET scan, regions of interest (ROIs) were drawn over the tumor, normal tissue, and major organs on decay-corrected whole-body coronal images. The radioactivity concentration (accumulation) within a tumor was obtained from the mean value within the multiple ROIs and then converted to %ID/g (*17*). For a receptor-blocking experiment, mice bearing U87MG tumors on the front left flank were scanned (5 min static) after coinjection with ^{18}F-FPTA-RGD2 (2 MBq) and c(RGDyK) (10 mg/kg).

Statistical Analysis. Quantitative data were expressed as mean ± SD. Means were compared using one-way ANOVA and Student's *t* test. *P* values of <0.05 were considered statistically significant.

RESULTS

Chemistry and Radiochemistry. Both alkyne tosylate (**1**) and azido-RGD2 were obtained in high yields (Figure 1). The alkyne fluoride was prepared in situ and could be used directly for the reaction with azido-RGD2 to make the cold standard, which was purified by HPLC and confirmed by MALDI-TOF mass spectrometry. ^{18}F-alkyne was also obtained in high yield at various conditions (Table 1). The presence of acetonitrile may lower the labeling yield to some extent (Table 1, entries 1–3). Although entry 5 gave the highest decay-corrected yield (84.3 ± 2.1%), the non-decay-corrected yield was 69.8%, which is actually slightly lower than the non-decay-corrected yield from entry 4 (71.4%). Thus, the condition from entry 4 was used for

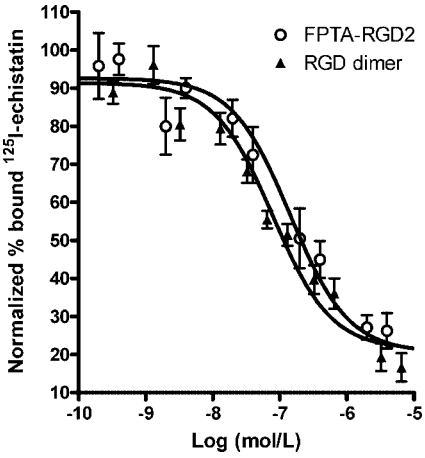

Figure 2. Cell binding assay of E[c(RGDyK)]$_2$ and FPTA-RGD2 using U87MG cells with competitive displacement studies using ^{125}I-echistatin. The IC_{50} values for E[c(RGDyK)]$_2$ and FPTA-RGD2 were 79.2 ± 4.2 and 144 ± 6.5 nM, respectively (n = 3).

the subsequent studies. We also noted that the ^{18}F-alkyne intermediate had to be purified before the conjugation with azido-RGD2 to guarantee high labeling yield (this might due to the removal of a large excess amount of unreacted alkyne). The radiochemical purity of the ^{18}F-labeled peptide ^{18}F-FPTA-RGD2 was higher than 97% according to analytical HPLC. The specific radioactivity of ^{18}F-FPTA-RGD2 was determined to be about 100–200 TBq/mmol based on the labeling agent ^{18}F-SFB, as the unlabeled azido-RGD2 was efficiently separated from the product.

The octanol/water partition coefficient (log P) for ^{18}F-FPTA-RGD2 was −2.71 ± 0.006, indicating that the tracer is slightly more hydrophilic than ^{18}F-FB-RGD2 (^{18}F-FRGD2, −2.103 ± 0.030) and ^{18}F-FB-PEG3-RGD2 (^{18}F-FPRGD2, −2.280 ± 0.054) (*18*).

In Vitro Cell Integrin Receptor-Binding Assay. The receptor-binding affinity of RGD2 and FPTA-RGD2 was determined by performing competitive displacement studies with ^{125}I-echistatin. All peptides inhibited the binding of ^{125}I-echistatin (integrin $\alpha_v\beta_3$-specific) to U87MG cells in a concentration-dependent manner. The IC_{50} values for RGD2 and FPTA-RGD2 were 79.2 ± 4.2 and 144 ± 6.5 nM, respectively (n = 3) (Figure 2). In a parallel experiment, the IC_{50} value for FPRGD2 was 97 ± 4.8 nM. The comparable IC_{50} values of these compounds suggest that the introduction of miniPEG linker and triazole group had little effect on the receptor-binding affinity.

microPET Imaging of U87MG Tumor-Bearing Mice. Dynamic microPET scans were performed on U87MG xenograft model and selected coronal images at different time points after injecting ^{18}F-FPTA-RGD2 were shown in Figure 3A. Good tumor-to-contralateral background contrast was observed as early as 10 min after injection (5.4 ± 0.7%ID/g). The U87MG tumor uptake was 3.1 ± 0.6, 2.1 ± 0.4, and 1.3 ± 0.4%ID/g at 0.5, 1, and 2 h p.i., respectively (n = 3). Most activity in the nontargeted tissues and organs was cleared by 1 h p.i. For example, the uptake values in the kidney, liver, and muscle were as low as 2.7 ± 0.8, 1.9 ± 0.4, and 1.0 ± 0.3%ID/g, respectively, at 1 h p.i. The averaged time–activity curves (TACs) for the U87MG tumor, liver, kidney, and muscle were shown in Figure 4. ^{18}F-FPTA-RGD2 was cleared mainly through the kidneys. Some hepatic clearance was also observed. The integrin $\alpha_v\beta_3$ specificity of ^{18}F-FPTA-RGD2 in vivo was confirmed by a blocking experiment where the tracer was coinjected with c(RGDyK) (10 mg/kg). As can be seen from Figure 3B, the U87MG tumor uptake in the presence of

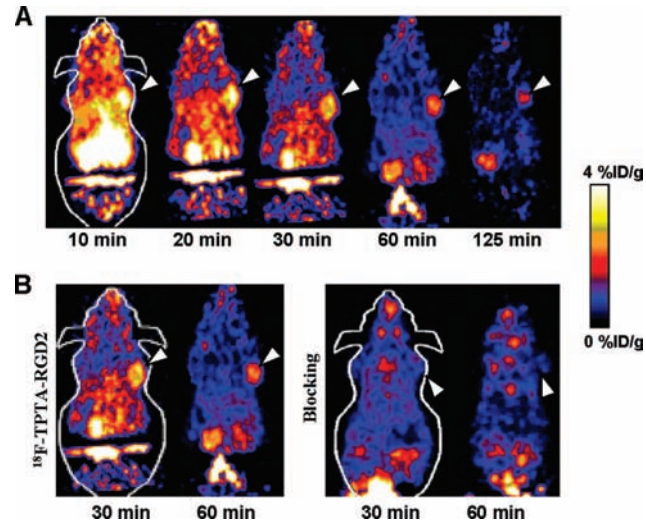

Figure 3. (A) Decay-corrected whole-body coronal microPET images of athymic female nude mice bearing U87MG tumor at 10, 20, 30, 60, and 125 min postinjection (p.i.) of about 2 MBq of ^{18}F-FPTA-RGD2. (B) Coronal microPET images of U87MG tumor-bearing mice at 30 and 60 min p.i. of ^{18}F-FPTA-RGD2 with (denoted as "blocking") and without coinjection of 10 mg/kg mouse body weight of c(RGDyK). Tumors are indicated by arrows.

nonradiolabeled RGD peptide (0.9 ± 0.3%ID/g) is significantly lower than that without RGD blocking (2.1 ± 0.4%ID/g) (P < 0.05) at 1 h p.i.

The comparison of tumor and various organ uptake of ^{18}F-FPTA-RGD2 with ^{18}F-FPRGD2 and ^{18}F-FRGD2 was shown in Figure 5. The uptake in the U87MG tumor was slightly lower for ^{18}F-FPTA-RGD2, which might be caused by integrin $\alpha_v\beta_3$ binding affinity difference (Figure 5A). The kidney uptake for these three tracers was comparable (Figure 5B), and the clearance rate was highest for ^{18}F-FPTA-RGD2. ^{18}F-FPTA-RGD2 had lowest liver uptake, which was consistent with the hydrophilic sequence of these three compounds (Figure 5C). The nonspecific uptake in the muscle was at a very low level for all three compounds (Figure 5D).

In Vivo Metabolic Stability Studies. The metabolic stability of ^{18}F-FPTA-RGD2 was determined in mouse blood and urine and in the liver, kidney, and tumor homogenates at 1 h after intravenous injection of radiotracer into a U87MG tumor-bearing mouse. The extraction efficiency of all organs was between 86% and 99% (Table 2). The lowest extraction efficiency was found for the kidney. 1% to 41% of the total activity could not be trapped on the C-18 cartridges, which can be related to very hydrophilic metabolites and protein-bound activity. After ACN elution, the radioactivity of each sample was injected onto an analytical HPLC, and the HPLC chromatograms are shown in Figure 6. The fraction of intact tracer was between 75% and 99% (Table 2). Although we did not identify the metabolites, we found that all metabolites eluted earlier from the HPLC column rather than the parent compound (Figure 6), which behaved similarly to ^{18}F-FRGD2 (*19*) and ^{18}F-FPRGD2 (*18*).

DISCUSSION

^{18}F-labeling of cyclic RGD peptide was first reported by Haubner et al. (*37*). A monomeric glycopeptide based on c(RGDfK) was ^{18}F-radiolabeled via ^{18}F-2-fluoropropionate prosthetic group and the resulting ^{18}F-galacto-RGD exhibited integrin $\alpha_v\beta_3$ specific tumor uptake in integrin-positive xenograft models. Initial clinical trials in a limited number of cancer patients revealed that this tracer can be safely given to patients and is able to delineate certain lesions that are integrin-positive (*15*). We have ^{18}F-radiolabeled both monomeric and dimeric

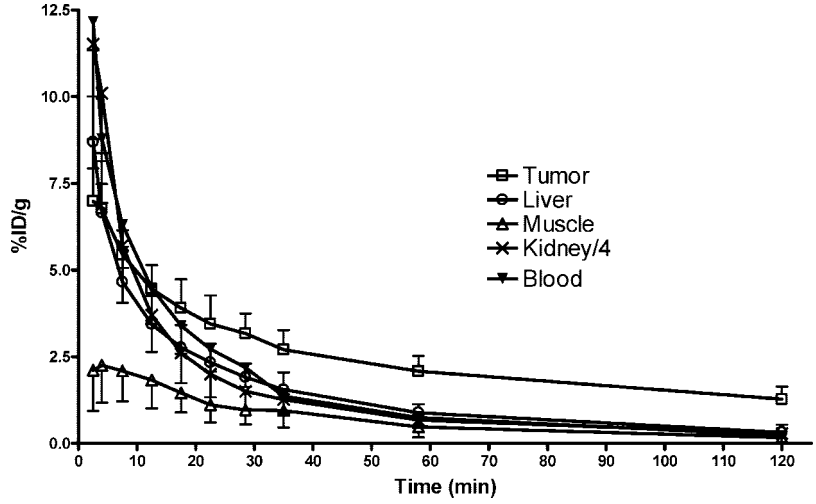

Figure 4. Time–activity curves of the U87MG tumor, liver, kidney, blood, and muscle after intravenous injection of ^{18}F-FPTA-RGD2. Data were derived from multiple time-point microPET study. ROIs are shown as the %ID/g ± SD ($n = 3$). Note that the kidney uptake in the figure is 1/4 of the actual value.

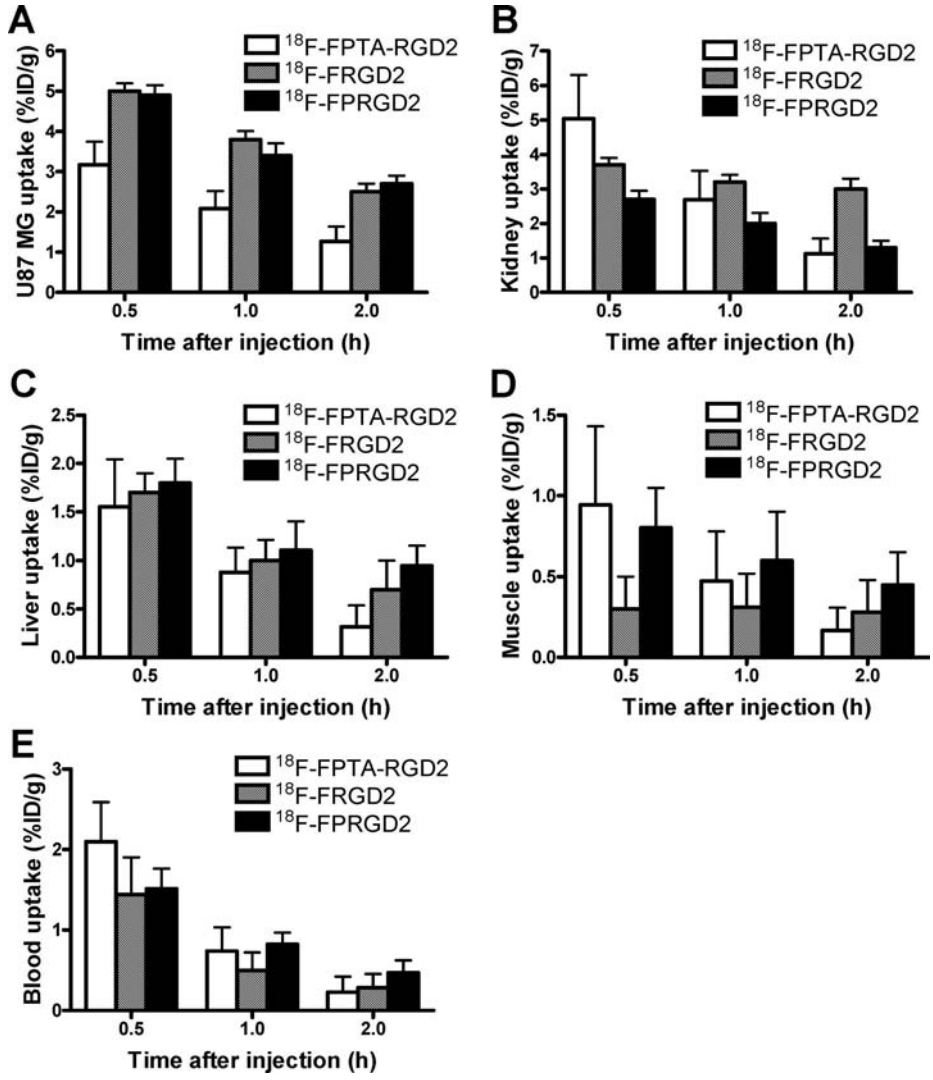

Figure 5. Comparison of ^{18}F-FPTA-RGD2, ^{18}F-FB-RGD2 (^{18}F-FRGD2), and ^{18}F-FB-PEG3-RGD2 (^{18}F-FPRGD2) in U87MG tumor, kidney, liver, muscle, and blood over time.

RGD peptides using an ^{18}F-4-fluorobenzoyl (^{18}F-FB) prosthetic group (*16*, *19*). The dimeric RGD peptide tracer, ^{18}F-FB-E[c(RGDyK)]$_2$ (denoted ^{18}F-FRGD2), exhibited excellent integrin $\alpha_v\beta_3$-specific tumor imaging with favorable in vivo pharmacokinetics (*19*, *38*). The binding potential extrapolated from Logan plot graphical analysis of the PET data correlated well with the receptor density measured by SDS-PAGE/autoradiography in various xenograft models. The tumor-to-

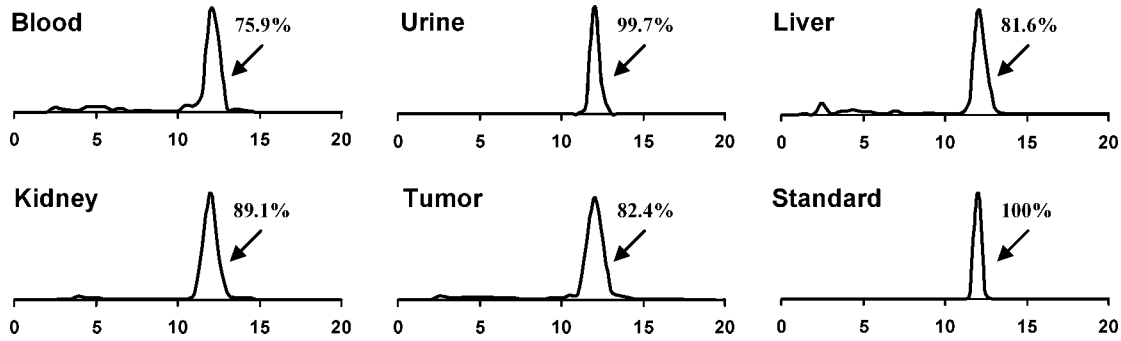

Figure 6. Metabolic stability of ^{18}F-FPTA-RGD2 in mouse blood and urine samples and in liver, kidney, and U87MG tumor homogenates at 1 h after injection. The HPLC profile of pure ^{18}F-FPTA-RGD2 (Standard) is also shown.

background ratio at 1 h after injection of ^{18}F-FRGD2 also gave a good linear relationship with the tumor tissue integrin $\alpha_v\beta_3$ expression level (*19*). We have also reported a thiol-reactive synthon, *N*-[2-(4-^{18}F-fluorobenzamido)ethyl]maleimide (^{18}F-FBEM), for labeling monomeric and dimeric sulfhydryl-RGD peptides (*25*). To extend our efforts of ^{18}F-radiolabeling strategies, we explored and reported the possibility of labeling dimeric RGD peptide E[c(RGDyK)]$_2$ using Hsuigen 1,3-dipolar cycloaddition reaction (one of the click chemistry reactions) and evaluated the ability of the new PET tracer for integrin $\alpha_v\beta_3$ targeting in vitro and in vivo.

Alkyne tosylate (**1**) was designed as the labeling precursor that allowed nucleophilic fluorination and displacement of the tosyl group to occur in high yield under mild conditions (15 min, 78.5 ± 2.3% yield). A triethylene glycol linker was employed in the structure to reduce volatility and obtain water solubility. The azido group was introduced to RGD dimer RGD2 by reacting the glutamate amine group with the azido-NHS ester. A robust catalytic system, Cu^{2+}/ascorbate, was used for the labeling reaction (*27*). In comparison with the SFB labeling procedure (starting from ^{18}F–F$^-$, the total synthesis time of ^{18}F-FPRGD2 was about 180 min with an overall non-decay-corrected yield of 12.9% (decay-corrected yield 40%)) (*18*), click-labeled ^{18}F-FPTA-RGD2 could be obtained in 110 min with 26.9% non-decay-corrected yield (decay-corrected yield 53.8%). The reduced reaction time and increased labeling yield make click chemistry a valuable method for labeling RGD peptide with ^{18}F.

We also studied the application of ^{18}F-FPTA-RGD2 for in vivo imaging. We found that this tracer had good tumor-to-muscle ratio and predominant renal excretion. Compared with ^{18}F-FPRGD2 and ^{18}F-FRGD2, the tumor-targeting efficacy of ^{18}F-FPTA-RGD2 was decreased to some extent, which might be caused by the slightly decreased integrin binding affinity based on cell binding assay. The unspecific blood pool activity could be another factor. However, no significant difference was observed for these compounds ($P > 0.5$) (Figure 5E). ^{18}F-FPTA-RGD2 also had a faster clearance rate and lower liver uptake which might due to the increased hydrophilicity of this tracer ($\log P = -2.710 \pm 0.006$), after the replacement of the benzoic group with a short PEG linker. A metabolic stability study revealed that the triazoles unit, formed by click chemistry in ^{18}F-FPTA-RGD2, has comparable in vivo stability compared with the amide bound made from SFB in the case of ^{18}F-FRGD2 and ^{18}F-FPRGD2 (*18, 19*).

This study demonstrated that RGD peptide can be labeled efficiently through click chemistry. The major advantage of ^{18}F-FPTA-RGD2 would be shortened reaction time, increased labeling yield, and comparable in vivo stability. The tumor-targeting efficacy of this tracer was comparable with SFB-labeled RGD peptides and can be further improved. First, the relatively long linker (triethylene glycol plus four methylene groups) in ^{18}F-FPTA-RGD2 might account for the decreased intergin binding affinity. Our future work will focus on the development of various linkers suitable for this new labeling method and study the in vivo pharmacokinetics of the resulting tracers. Second, high $\alpha_v\beta_3$ binding affinity is needed to afford high tumor uptake and retention. Based on polyvalency effect, tetrameric RGD peptide (*17*), labeled with the synthon described here, would have more effective binding to integrin $\alpha_v\beta_3$ and better tumor targeting efficacy. Third, the click labeling method developed here could also be applied to label a variety of other peptides, proteins, antibodies, or oligonucleotides after the introduction of the azido group. Due to the mild labeling conditions, ^{18}F might be easily engineered to incorporate the organo azide residue without compromising the biological activity.

CONCLUSIONS

The new tracer ^{18}F-FPTA-RGD2 was synthesized with high specific activity based on click chemistry. This tracer exhibited good tumor-targeting efficacy, relatively good metabolic stability, as well as favorable in vivo pharmacokinetics. The new

^{18}F labeling method developed in this study could also have general application in labeling azido-containing bioactive molecules in high radiochemical yield and high specific activity for successful PET applications.

ACKNOWLEDGMENT

This work was supported in part by the National Cancer Institute (NCI) (R21 CA102123, ICMIC P50 CA114747, CCNE U54 CA119367, and SARIP R24 CA93862), Department of Defense (DOD) (W81XWH-04-1-0697, W81XWH-06-1-0665, W81XWH-06-1-0042, DAMD17-03-1-0143, and BC061781), and a Dean's Fellowship (to ZL) from the Stanford University. We thank Dr. David W. Dick from the cyclotron facility for ^{18}F–F$^-$ production.

Reductively Aminated D-Xylose–Albumin Conjugate as the Immunogen for Generation of IgG and IgE Antibodies Specific to D-Xylitol, a Haptenic Allergen

Kundimi Sreenath and Yeldur P. Venkatesh*

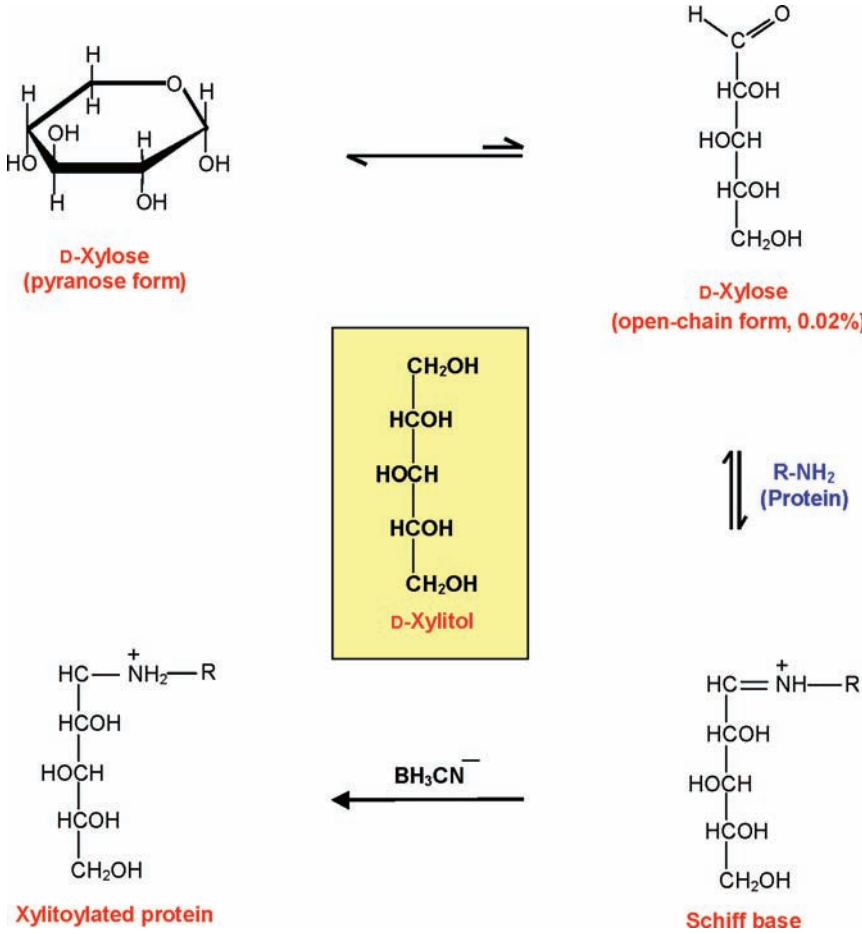
Department of Biochemistry and Nutrition, Central Food Technological Research Institute (CFTRI), Mysore-570020, Karnataka State, India. Received May 16, 2007; Revised Manuscript Received August 1, 2007

Sugar alcohols are widely used as food additives and drug excipients. Xylitol, a five-carbon sugar alcohol, and a low-calorie alternative sweetener to sucrose (approx 40% fewer calories), has enjoyed an enviable record of safety, and allergic reactions to xylitol are very rare. A case of oral erosive eczema to xylitol has been reported recently [Hanakawa, Y., Hanakawa, Y., Tohyama, M., Yamasaki, K., Hashimoto, K. (2005) Xylitol as a causative agent of oral erosive eczema. *Brit. J. Dermatol. 152*, 821–822]. Xylitol does not contain any reactive groups; hence, it is nonimmunogenic. In order to explain the immunogenicity of xylitol, polyclonal antibodies to xylitol have been raised using the reductive aminated product of D-xylose conjugated to bovine serum albumin (BSA) as the immunogen. Rabbits immunized with xylitol–BSA conjugate (52 haptens/molecule) gave a good antibody response. Purification of antixylitol antibodies was carried out using hapten-affinity chromatography on xylitol–keyhole limpet hemocyanin–Sepharose CL-6B; the yield was ~40 μg/mL of rabbit immune serum. Purified xylitol-specific antibodies appeared to be homogeneous by native PAGE with a pI of ~7.2 by isoelectric focusing. Although the purified antibodies are specific for the xylitoyl moiety of xylitol–protein conjugates, they reacted equally well with the Schiff base conjugate of xylosyl–protein conjugates (68% cross-reactivity) indicating that carbons 2 to 5 of xylitol act as an epitope. Xylitol antibodies showed excellent specificity towards xylitol and <4.4% cross-reactivity with D-xylose and various sugar alcohols except ribitol and galactitol, which showed ~11% and 8% cross-reactivity, respectively. D-Xylitol–BSA conjugate was used to raise IgE antibodies in BALB/c mice by repeated intradermal administration. Passive cutaneous anaphylaxis using the immune sera confirmed the haptenic nature of xylitol.

INTRODUCTION

Sugar alcohols (also known as polyhydric alcohols or polyols) are low-calorie bulk sweeteners. They are being used as food additives and drug excipients, as they are chemically inert, nontoxic, nonhygroscopic, and sweet in taste. Sugar alcohols commonly used as food additives are sorbitol (international numbering system: INS[1] 420), mannitol (INS 421), xylitol (INS 967), and erythritol (INS 968); maltitol (INS 965) and lactitol are used to a lesser extent. Xylitol, a pentitol, has been widely used in foods since its approval by the U.S. Food and Drug Administration (FDA) in 1960, because of its slow absorption, partial utilization, and reduced calories (2.4 calories/g) (*1*). Besides its uses as food additive and sweetener, xylitol has many medical uses such as prevention of dental caries (*2*), middle ear infections (*3*), and experimental osteoporosis (*4*). Xylitol occurs naturally in many fruits and vegetables at concentrations as high as 935 mg (yellow plum) and as low as 14 mg (chestnut) per 100 g dry substance (*5*). Xylitol is a popular sweetener for the diabetic diet in some countries, as it is metabolized independently of insulin and is extremely safe. Xylitol is used in unlimited quantity for foods with special dietary purposes. Sugar-free chewing gums and candies made with xylitol as the principal sweetener have received official endorsements from six national dental associations.

Mannitol, a hexitol, occurs naturally in many plant foods including mushrooms (*6*). The use of mannitol in foods is broadly permitted by the food additive regulations of FDA. In addition, intravenous infusion of 20% (w/v) mannitol (equivalent to 1100 mM) has been used as a therapeutic agent in many clinical situations due to its osmotically active property. Hypersensitivity reactions to 20% mannitol infusion have been reported in a small number of susceptible patients. Recently, mannitol was identified as an allergen for a sensitized subject (*7*, *8*), and mannitol-specific IgE was demonstrated for the first time in the serum of the subject sensitized to mannitol (*9*). Allergic reactions caused by erythritol as a sweetener in processed foods have been reported in three cases (*10*, *11*). On the basis of the inert nature of mannitol and erythritol, a hypothesis has been proposed to explain the mechanism of sensitization and hypersensitivity to these sugar alcohols (*12*). In this hypothesis, the sugar acts as a *prosensitizer*, its Schiff base adduct with proteins acts as a *sensitizer*, and the sugar alcohol acts as a *nonsensitizing elicitor*.



Allergic reactions to xylitol are also rare, similar to the case of mannitol and erythritol. However, one case of oral erosive

Scheme 1. Reaction of D-xylose with carrier protein by reductive amination to obtain xylitoyl epitopes. The structure of D-xylitol is shown in the box (carbons C1 to C5 should be viewed from top to bottom. The percentage of open-chain form of D-xylose is based on the circular dichroism study (*22*).

eczema to foods containing xylitol has been reported recently (*13*). Although the skin patch test was positive, the presence of xylitol-specific IgE has not been demonstrated in that study. Therefore, it is likely that the mechanism of formation of IgE antibodies to xylitol (Scheme 1) could follow the general scheme described for mannitol and other sugar alcohols (*12*).

Anticarbohydrate antibodies with specificity towards various monosaccharides, disaccharides, and oligosaccharides have been studied extensively (*14–19*). These are generally specific to *cyclic* pyranose or furanose structures of sugars. Only certain disaccharides have been conjugated to proteins by reductive amination with the aim of obtaining antibodies specific for a terminal nonreducing monosaccharide (cyclic) determinant (*14–16*); however, the acyclic monosaccharide arm formed by the reducing sugar unit was also involved in the antigenic determinant. Unlike saccharides, sugar alcohols possess *acyclic* straight chain structure; they are inert and do not have any reactive aldehyde or ketone groups. Hence, they cannot form conjugates with proteins to mount an immune response. This necessitates an indirect method to obtain sugar alcohol groups on a carrier protein for immunogenicity. Such a strategy was applied for the generation of polyclonal antibodies to erythritol and D-mannitol (*20*, *21*). With this background, it appeared interesting to demonstrate the formation of IgG antibodies to xylitol in rabbits using a xylitol–protein conjugate as the immunogen and characterize the affinity-purified antibodies in terms of specificity and cross-reactivity. The allergenic nature of xylitol was investigated by repeated intradermal administration of xylitol–BSA conjugate in BALB/c mice followed by homologous passive cutaneous anaphylaxis (PCA) assay for the demonstration of xylitol-specific IgE.

EXPERIMENTAL PROCEDURES

Reagents and Chemicals. D-Xylose, Sepharose CL-6B (6% beaded agarose, wet bead diameter: 40–165 μm), bovine serum albumin (BSA), keyhole limpet hemocyanin (KLH), sodium cyanoborohydride, periodic acid, and borane–pyridine complex solution ($C_5H_5N.BH_3$; BH_3 concentration ~8M; excess pyridine ~20%) were obtained from Sigma-Aldrich Chemical Co., St. Louis, MO. Trinitrobenzenesulfonic (TNBS) acid was a product of HiMedia Laboratories, Mumbai, India. Schiff reagent (1-fluoro-2,4-dinitrobenzene) was procured from Sisco Research Laboratories, Mumbai, India. Maxisorp ELISA microtiter plates (flat-bottom) were a product of Nunc A/S, Roskilde, Denmark. Goat antirabbit IgG–alkaline phosphatase conjugate, 5-bromo-4-chloro-3-indolyl phosphate (BCIP)/nitro blue tetrazolium (NBT), Freund's complete adjuvant (FCA), and Freund's incomplete adjuvant (FIA) were products of Bangalore Genei, Bangalore, India. Ampholines (pH 5–8) were procured from Pharmacia, Uppsala, Sweden. All other chemicals were of analytical grade.

Animals. New Zealand white male rabbits (7 months old) and Swiss albino mice (6–8 weeks old) were obtained from the animal house facility of our institute. BALB/c mice aged 6–8 weeks were procured from Central Animal Facility (CAF), Indian Institute of Science, Bangalore, India. Each experimental group consisted of 6 mice.

Preparation of Hapten–Protein Conjugates Containing Xylitol Epitopes. D-Xylose was conjugated to a carrier protein, bovine serum albumin (BSA), or keyhole limpet hemocyanin (KLH), by reductive amination (also termed as reductive alkylation) in the presence of a mild reducing agent, sodium cyanoborohydride, as described earlier for *meso*-erythritol and D-mannitol conjugates (*20, 21*) to obtain stable xylitol epitopes on the conjugated carrier protein.

In a separate experiment, D-xylose (100 mg) was incubated with BSA (68 mg) in the absence of sodium cyanoborohydride to obtain a Schiff base conjugate of D-xylosyl–BSA. The degree of substitution was determined by the decrease in amino groups as quantified by trinitrobenzenesulfonic acid (TNBS) assay. Protein estimation of conjugates was carried out as per the procedure of Bradford (*23*) using BSA as a standard.

Trinitrobenzenesulfonic Acid Assay for Amino Groups. The number of ε-amino groups remaining in conjugated BSA samples was determined using TNBS reagent (*24*). To 1 mL of D-xylitol–BSA conjugate/D-xylosyl–BSA Schiff base conjugate (100 μg protein) solution, 1 mL of 4% $NaHCO_3$ (pH 8.5) and 1 mL of 0.01% freshly prepared aqueous TNBS solutions were added. The reaction was carried out at 42 ± 2 °C for 2 h, followed by the addition of 1 mL of 10% SDS and 0.5 mL of 1 N HCl. The absorbance of the solution was monitored at 335 nm in a spectrophotometer, and a standard curve was obtained with unconjugated BSA (50–200 μg range) after appropriate blank corrections. The percent conjugation for a conjugate at a specified time was calculated from the decrease in absorbance, when compared with that of an identical concentration of standard BSA in the TNBS assay. Percent conjugation was converted to degree of substitution in terms of moles of xylosyl Schiff base or xylitol per mole of carrier, assuming that BSA has 61 TNBS-reactive amino groups (*24, 25*).

Periodic Acid Schiff (PAS) Staining for Glycoconjugates. This was performed to confirm the glycated nature (*26*) of xylitol–BSA conjugate following the reductive amination. Following SDS-PAGE (*27*), the gel was immersed in 12.5% trichloroacetic acid solution for 30 min, transferred to 1% periodic acid solution, and kept in the dark for 50 min. Then, the gel was washed thoroughly with distilled water to remove the periodic acid, followed by the addition of Schiff reagent and incubation at 4 °C for 1 h. After the color development, the reaction was arrested by adding 7% glacial acetic acid.

Immunization and Collection of Antiserum. Three New Zealand white male rabbits (*Oryctolagus cuniculus*), 7 months old, housed in the animal house facility of this institute, were used for the immunization according to standard protocols (*28, 29*), after obtaining approval from the institutional animal ethics committee (IAEC).

Initially, the immunogen, D-xylitol–BSA conjugate (52 mol D-xylitol/mol BSA; 0.5 mL, 1 mg protein) microemulsified with 0.5 mL of 3× concentrated Freund's complete adjuvant, was administered subcutaneously at 8–10 sites on the back of the animal. After 4 weeks, booster doses containing 0.5 mg of the antigen microemulsified with Freund's incomplete adjuvant were administered intramuscularly at 15 day intervals. The animal was bled by marginal ear vein puncture 1 week before the first injection (to obtain preimmune serum) and 1 week after each booster dose (to obtain immune serum). The pooled serum was stored in aliquots below −20 °C.

Titration of Antiserum. To check for the formation of hapten-specific antibodies, the antiserum was analyzed initially by dot-immunoblot assay (*30*) and later by noncompetitive ELISA using the coated antigen format (*31*). The titer of the antiserum was determined by measuring the binding of serial dilutions of the antiserum to coated D-xylitol–KLH (conjugate in which 50% of the amino groups of KLH have been modified with xylitol). Flat-bottom polystyrene microtiter wells were coated with D-xylitol–KLH conjugate at 1000, 100, 50, and 10 ng per well (100 μL volume) in 0.1 M carbonate–bicarbonate buffer, pH 9.6, by incubating at 4 °C overnight. The wells were washed thrice between steps using PBS containing 0.05% Tween-20 (PBS-T). Blocking was done using 0.5% gelatin in PBS-T at 37 °C for 30 min. Antiserum diluted in blocking buffer (1:10 to 1:400 000) was added (100 μL/well) and incubated at 37 °C for 2 h. Goat antirabbit IgG-alkaline phosphatase secondary antibody (1:5000 dilution in blocking buffer; 100 μL/well) was added and incubated at 37 °C for 1 h. Color development was done using *p*-nitrophenyl phosphate (1 mg/mL; 100 μL/well) in 1% diethanolamine buffer, pH 9.8, at 37 °C for 30 min. The reaction was stopped by adding 3 M NaOH (40 μL/well), and the absorbance was read at 405 nm in an ELISA microplate reader.

A positive value in ELISA is defined as the absorbance value obtained with immune serum samples (as measured by absorbance value at 405 nm) 2-fold greater than that obtained in the case of preimmune serum. Antibody titer is defined as the reciprocal of the highest dilution that gave a positive value in ELISA.

Purification of Antixylitol Antibodies. *(a) Preparation of D-Xylitol–Keyhole Limpet Hemocyanin (D-xylitol–KLH)–Sepharose CL-6B Affinity Matrix.* D-Xylitol–KLH conjugate with 50% modification of amino groups was used for immobilization onto Sepharose CL-6B (*32*). Sepharose CL-6B gel was first washed thoroughly with water to remove preservative, and then suspended in water to obtain 0.2 g moist gel/mL (total 10 mL). The washed gel was then oxidized by adding solid sodium periodate ($NaIO_4$) to a final concentration of 25 mM. The mixture was swirled at 25 °C for 30 min; unreacted $NaIO_4$ was inactivated by the addition of an equimolar amount of ethylene glycol. After 15 min, the gel was thoroughly washed with water followed by 0.2 M phosphate buffer, pH 7.0. The moist gel (0.2 g/mL suspension) in phosphate buffer was mixed with D-xylitol–KLH conjugate (2 mg) followed by direct addition of borane–pyridine complex to a final concentration of 25 mM. The reaction mixture was mildly agitated, first at 25 °C for 3 h, and then at 4 °C for 10 h. Next, gel beads were washed extensively with water to remove unreacted borane–pyridine and the ligand. The gel was finally packed into a glass column (2 mL bed volume), and equilibrated with 20 mM phosphate buffer, pH 7.4, containing 140 mM NaCl, and stored at 4 °C in the same buffer with 0.01% merthiolate as a preservative.

(b) Hapten Affinity Chromatography for Purification of Antixylitol Antibodies. Antixylitol–BSA antiserum (6 mL) obtained from the immunized rabbit was diluted 1:1 in PBS (pH 7.4), and passed through the D-xylitol–KLH–Sepharose CL-6B column (0.8 cm id × 4 cm; 2 mL bed volume) that had been pre-equilibrated with PBS at 4 °C. The flowthrough was recycled twice through the column. After washing with 50 mL PBS, the bound antibodies were eluted with 0.1 M glycine–HCl buffer, pH 2.9; the eluate was neutralized immediately using 0.5 M Tris base. The eluate was aliquoted in 200 μL portions and stored below −20 °C. The concentration of specific antibody was calculated on the basis of the reference value of $A^{0.1\%,\ 1\ cm}$ at 280 nm of 1.4 for rabbit IgG (*33*). The affinity-purified antixylitol antibodies were subjected to native-PAGE (basic) using Tris-glycine buffer system, and isoelectric focusing (*29*).

Titration of Hapten Affinity Purified Antibodies and Determination of Cross-Reactivity. The affinity-purified antibodies were tested for their ability to bind to Schiff base conjugate of D-xylosyl–BSA and its reductive aminated product, namely, D-xylitol–BSA conjugate. Therefore, the Schiff base conjugate of D-xylosyl–BSA, or its reduced product (D-xylitol–BSA conjugate) having approximately similar modification of

amino groups was used as the coating antigen; in the case of D-xylosyl–BSA, 20 amino groups had been substituted as compared to 19 amino groups in D-xylitol–BSA. The linear regression analysis was performed using *SigmaStat 3.1* software (Systat Software Asia Pacific Ltd., Bangalore, India).

The affinity-purified antixylitol antibodies were used for noncompetitive ELISA experiments to obtain the binding curves using D-xylitol–KLH (50 ng/well) conjugate as the coating antigen. Specificity and cross-reactivity of the affinity-purified antibodies were studied by inhibition–ELISA experiments. Here, purified antibodies were preincubated with various concentrations (0.01–1000 mM) of test compounds (competitors like D-xylitol, D-mannitol, sorbitol, D-ribitol, L-arabinitol, glycerol, ethylene glycol, D-xylose) and L-lysine at 37 °C for 1 h before adding to coated (D-xylitol–KLH, 50 ng/well) microtiter wells. Other steps were as described in the Titration of Antiserum section. The percent cross-reactivity for various inhibitors was calculated using the formula (IC_{50} for xylitol ÷ IC_{50} for test compound) × 100 where IC_{50} is the concentration required for 50% inhibition in ELISA.

Calculation of Affinity Constant of the Purified Antixylitol Antibodies. The affinity constants of the purified antixylitol antibodies were calculated using a computer program described by Raghava and Agrewala (*34*). This is a simple and reliable method based upon the law of mass action for calculating the affinity constant of a monoclonal antibody directed against the haptenic 2,4,6-trinitrophenyl group using the data obtained from noncompetitive ELISA.

D-Xylitol–KLH conjugate (10 μg/mL) was prepared in 0.1 M carbonate–bicarbonate buffer. A series of 4 doubling dilutions were made so that the final concentration was 1/8 of the starting one. In a 96-well microtiter plate, rows A, B, C, and D were coated with 100 μL D-xylitol–KLH containing 1000, 500, 250, and 125 ng, respectively. KLH (1000 ng in 100 μL) was added in row E that worked as control. After overnight incubation at 4 °C, the plate was washed thrice with PBS-T. The concentration of the affinity-purified antibodies used was 4 ng in 100 μL. All the other steps were followed as described in the Titration of Hapten-Purified Antibodies section.

The menu-driven computer program (Ab_affi program) for calculating the affinity constant of hapten-specific antibody from noncompetitive ELISA data written in GW-BASIC is available from the internet (http://www.imtech.res.in/bic/achsw.html#serv3). Absorbance data obtained from the microtiter plate can be fed to the computer either directly by interfacing or by using the keyboard. Before starting the calculation, a "dilution template" should be defined and the information about the serial dilutions of antibody added to the wells, and antigen coated on the plate must also be supplied.

Induction of Hypersensitivity in BALB/c Mice. BALB/c mice ($n = 6$ in each group) were immunized with 60 μL of saline (negative control), 1 mg/mL ovalbumin (positive control), D-xylitol (1 mg/mL), D-xylitol–BSA conjugates (2 mg/mL), and 2 mg/mL BSA (carrier protein control) by intradermal injection. The use of an adjuvant was avoided in order to assess the inherent allergenicity of the xylitol–BSA conjugate. On days 5, 12, 19, 26, and 33, booster doses were given with 30 μL of each of the antigens mentioned above (*35*). Blood was collected from the retro-orbital vein on days 8 and 22, and finally on day 36, and processed to obtain serum (1.8 mL per collection per group). Serum samples are pooled on a treatment group basis; equal volumes of serum from 3 collections contribute to the pool. Samples were stored at −70 °C until analysis.

Measurement of Serum Antixylitol IgE Antibody by PCA. The antixylitol IgE titer of BALB/c mouse immune serum was measured by the homologous passive cutaneous anaphylaxis (PCA) assay (*36*) performed in Swiss albino mice. For this experiment, 100 μL of 1:1 diluted pooled serum (with saline) obtained from each of the treatment groups (BALB/c mice that were administered separately with different antigens, viz., saline, ovalbumin, D-xylitol–BSA conjugates, BSA, D-xylitol) were injected intradermally on the shaved back of male Swiss albino mice ($n = 5$ for each group). After 24 h, 30 μL of D-xylitol–BSA conjugates having different hapten densities or other antigens (saline, ovalbumin, BSA, D-xylitol) with 0.25% Evans blue were injected intravenously into the respective group ($n = 5$) of animals. The animals were sacrificed 30 min after the i.v. injection, and infiltration of the dye into the skin around the injection sites was observed. A serum sample (representative of a particular antigen) is identified as an IgE responder if the challenge resulted in a blue lesion in the skin with a mean diameter of 3 mm or greater (*37*).

RESULTS

Preparation and Characterization of Xylitol–Protein Conjugates by Reductive Amination. D-Xylose was coupled to BSA by reductive amination (Scheme 1) as described in the Experimental Procedures section. The time course of reductive amination reaction for D-xylose is shown in Figure 1 (panel a). The reaction is faster initially (up to 25 h), and slowly reaches a plateau thereafter. At 20 h of reaction, approximately 32 mol of xylitol have been conjugated per mole of BSA.

The xylitol–BSA conjugate was analyzed by SDS-PAGE (Figure 1, panel b), wherein an increase in molecular mass was apparent for the conjugate as compared to control BSA. The R_f values of the mol wt markers, control (BSA), and D-xylitol–BSA conjugate were calculated (data not shown). The increase in the relative molecular mass (M_r) of xylitol–BSA conjugate when compared to control BSA was ~8 kDa, which translates to 52 mol of xylitol coupled per mole BSA. Since BSA is devoid of glycans, the glycation of D-xylitol–BSA conjugates was detected by PAS staining. The PAS staining (Figure 1, panel c) clearly confirms the addition of glycans by way of xylitoyl groups on the carrier protein, BSA.

D-Xylose was incubated with BSA (without sodium cyanoborohydride) to form Schiff base conjugates. The time course of the reaction is shown in Figure 1, panel d. It is observed that the reaction of D-xylose with BSA is faster initially (up to 3 h) with the availability of almost all the accessible amino groups. As the reaction time progresses, the modification of the amino groups of BSA decreases due to the unstable nature of the Schiff base conjugate and the reversibility of the reaction. TNBS assay showed modification of 20 amino groups at the end of 3 h incubation, and as the time progresses, the rate of conjugation decreases. In the case of the reductive amination reaction (shown for comparison in Figure 1, panel d), the conjugation of D-xylose with BSA gradually increases with time. Approximately 19 and 32 amino groups have been modified in the reductive amination reaction at 3 and 6 h, respectively.

Immunochemical Analyses of Rabbit D-Xylitol–BSA Antiserum. The immunoreactivity of antiserum with D-xylitol–KLH can be detected easily at 1 in 2×10^4 dilution, in the dot-immunoblot analysis, which is shown in Figure 2 (panel A, strip a). The antiserum was positive for D-xylitol–BSA conjugate (Xyt-BSA), D-xylitol–KLH conjugate (Xyt-KLH), and BSA, but was negative for KLH. The highest dilution of antiserum for perceptible detection of dots was found to be 1 in 5×10^4 (strip b). The sensitivity of antixylitol–BSA antiserum was determined by checkerboard analysis of the immune serum where the concentrations of both the antigen and antiserum are varied (Figure 2, panel B). The antiserum titration curves show that the sensitivity of antibodies is seen at 1 in 1×10^4 dilution using 1000 ng per well of coating antigen, D-xylitol–KLH. An optimal titer of 1:100 antiserum dilution was evident at a coating antigen (D-xylitol–KLH) concentration of 100 ng/well.

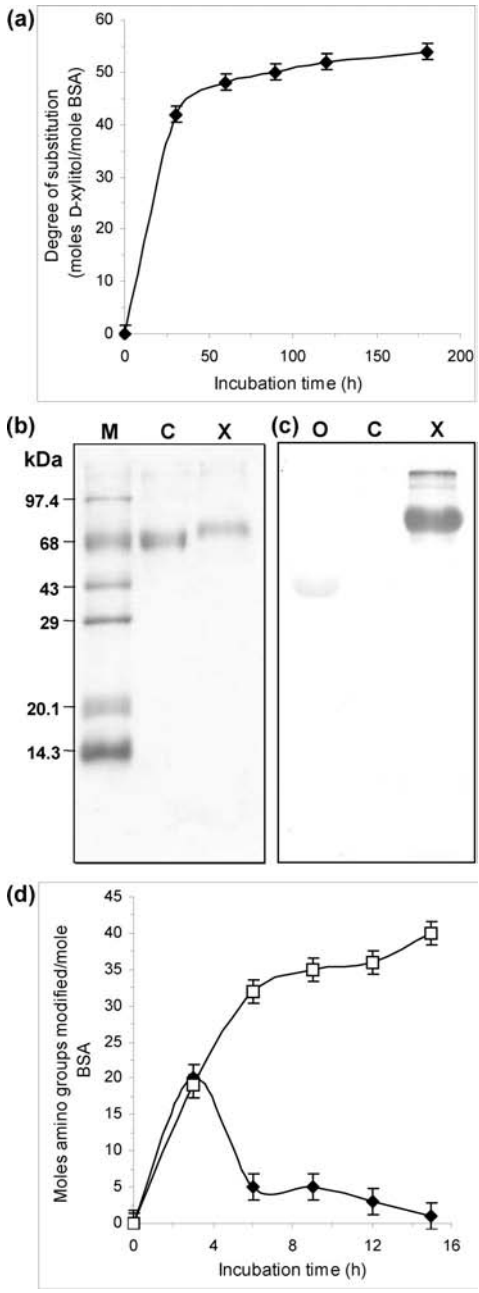

Figure 1. Preparation of D-xylitol–bovine serum albumin (BSA) conjugate by reductive amination at pH 8 and 37 °C. Panel a: Time course of reaction for the formation of D-xylitol–BSA. Panel b: SDS-PAGE (15%; reducing) analysis of D-xylitol–BSA sample from the 180 h reductive amination reaction. Staining: Coomassie blue. Lane M, molecular weight markers in kDa; lane C, control BSA (10 μg); lane X, D-xylitol–BSA conjugate (10 μg). Panel c: Periodic acid–Schiff (PAS) staining of D-xylitol–BSA conjugate analyzed by SDS-PAGE (15%; reducing). Lane O, ovalbumin, a glycoprotein (positive control); lane C, BSA, a nonglycoprotein (negative control); lane X, D-xylitol–BSA conjugate. Protein load: 15 μg in all cases. Panel d: Time course of reaction for the formation of Schiff base conjugate of D-xylose with BSA (♦) or D-xylitol–BSA conjugate by reductive amination (□).

Hapten Affinity Purification of Antixylitol Antibodies. The xylitol-specific antibodies were purified from the antiserum by hapten affinity chromatography on D-xylitol–KLH–Sepharose CL-6B. The elution of bound antibody, after loading the sample and washing, is presented in Figure 3. The antibodies were found to elute in the first 3–4 fractions. The yield of xylitol-specific antibodies was found to be in the range of 36–42 μg per milliliter of rabbit antiserum, based on six chromatographic analyses.

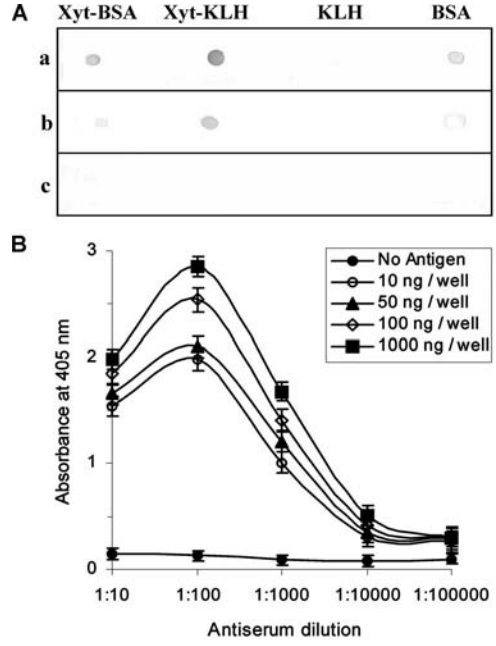

Figure 2. Immunochemical analyses of rabbit antiserum to xylitol–BSA conjugate. Panel A: Dot-immunoblot analysis on nitrocellulose strips. Antigens: 5 μg each of D-xylitol–BSA (Xyt-BSA); D-xylitol–KLH (Xyt-KLH); KLH; BSA. Antixylitol–BSA antiserum dilutions: a, 1:20 000; b, 1:50 000; c, preimmune serum as control (1:2000 dilution). Secondary antibody: goat antirabbit IgG-alkaline phosphatase (1:4000 dilution). Panel B: Checkerboard analysis by ELISA at different coated antigen concentrations and antiserum dilutions. Coating antigen: D-Xylitol–KLH conjugate (concentrations shown as inset). Secondary antibody: goat antirabbit IgG-alkaline phosphatase (1:4000 dilution). The absorbance values are the means of triplicate analysis.

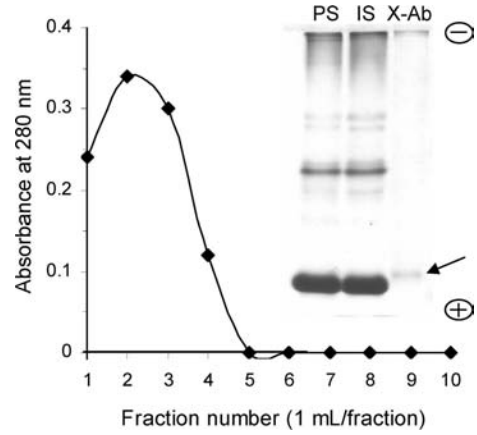

Figure 3. Elution profile of antixylitol antibodies from D-xylitol–KLH–Sepharose CL-6B affinity column (0.8 cm id × 4 cm; 2 mL bed volume). Sample load, 6 mL rabbit antixylitol–BSA antiserum; elution buffer, 0.1 M glycine–HCl, pH 2.9. Inset: Native PAGE (7.5%, basic) analysis of affinity-purified xylitol-specific antibodies. Staining: Coomassie blue. PS, preimmune serum (10 μg); IS, immune serum (10 μg); X-Ab, affinity-purified xylitol-specific antibodies (5 μg); arrow indicates the position.

Affinity-purified antixylitol antibodies were analyzed by native-PAGE (basic), which showed a single band on the gel indicating the homogeneity of the antibodies (Figure 3, inset). Isoelectric focusing (IEF) analysis of affinity-purified antixylitol antibodies showed only a single band at approximately pI 7.2, suggesting a single specific clone and isotype (data not shown).

Characterization of Antixylitol Antibodies. The affinity constant of antixylitol antibodies was calculated using noncom-

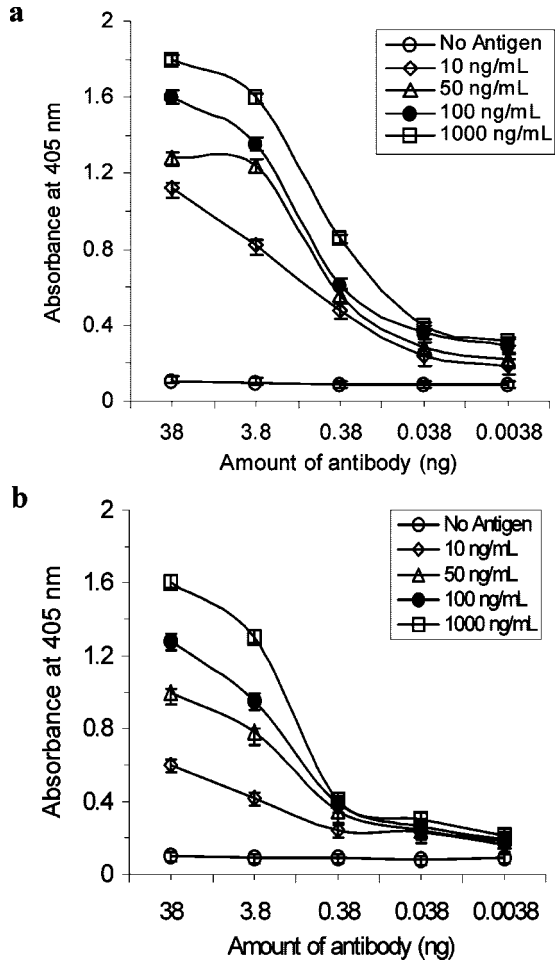

Figure 4. Comparison of binding curves for affinity-purified xylitol antibodies with xylitol–BSA/xylosyl–BSA conjugates. The absorbances at 405 nm for all the antigen concentrations at three different antibody concentrations (38, 3.8, and 0.38 ng) were analyzed between the two data sets by linear regression analysis. The *R* values were found to be 0.979 (at 38 ng), 0.991 (at 3.8 ng), and 0.699 (at 0.38 ng). Panel a: Binding curves obtained with xylitol-specific antibodies as a function of protein concentration and varying coated antigen, D-xylitol–BSA conjugate concentrations. Hapten density: 19 mol/mol BSA. Other details are as given in Figure 2, panel B. Panel b: Binding curves obtained with xylitol-specific antibodies as a function of protein concentration and varying coated antigen, D-xylosyl–BSA (Schiff base conjugate) concentrations. Hapten density: 20 mol/mol BSA.

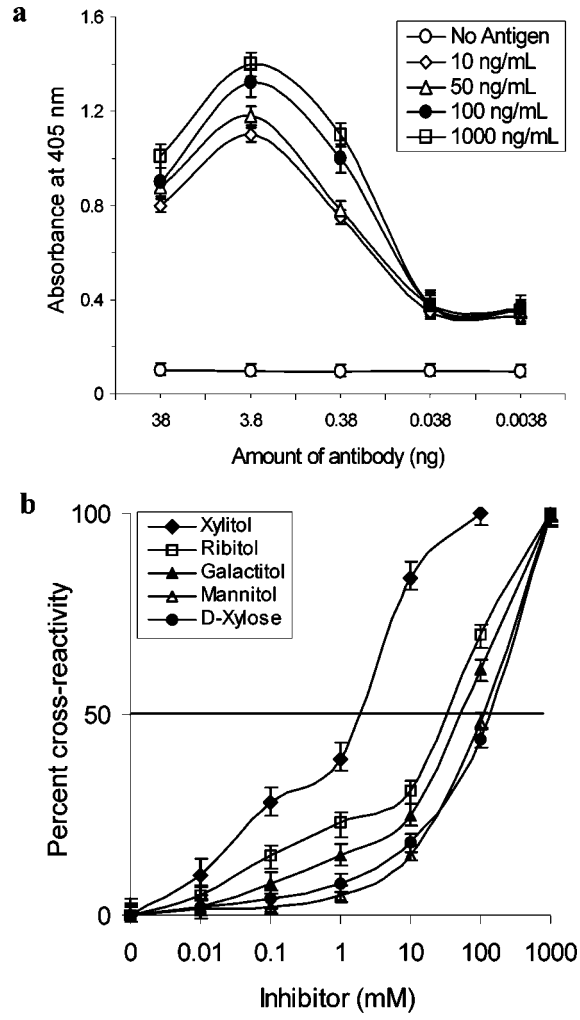

Figure 5. Immunochemical analyses of affinity-purified xylitol antibodies. Panel a: Binding curves of xylitol-specific antibodies as a function of protein concentration and varying coated antigen, D-xylitol–KLH (reductively aminated product) concentrations. Other details are as given in Figure 2, panel B. Panel b: Specificity of purified xylitol antibodies as determined by inhibition ELISA. Coating antigen: D-xylitol–KLH conjugate, 100 ng/well. Purified antixylitol antibodies (~4 ng in 100 μL volume) were preincubated with various concentrations of D-xylitol, ribitol, galactitol, and so forth, at 37 °C for 1 h and then transferred to ELISA wells. Other details are as given in Figure 2, panel B.

petitive ELISA by the method of Raghava and Agrewala (*34*) and was found to be 3.86×10^9.

In order to find out whether the xylitol-specific antibodies can recognize the Schiff base conjugate of xylosyl–BSA, the binding curves with both xylitol–BSA conjugate and xylosyl–BSA conjugate (Schiff base) were examined. The binding curves are shown in Figure 4. It is seen that the affinity-purified antibodies recognize the Schiff base conjugate of xylosyl–BSA (panel b) to a slightly lesser extent—approximately two-thirds the reactivity of xylitol–BSA conjugate (panel a).

Cross-Reactivity of Antixylitol Antibodies. The binding curves obtained with purified xylitol antibodies (Figure 5, panel a) shows that the sensitivity of antibodies can be observed even at ~200 pg (data not shown) for a coating antigen (D-xylitol–KLH) concentration of 100 ng/well. Optimal concentrations of ~4 ng of affinity-purified xylitol antibodies and 100 ng/well of D-xylitol–KLH coating antigen were selected from this checkerboard analysis for the inhibition ELISA studies with various sugars, sugar alcohols, and other small molecules.

Table 1. Specificity and Cross-Reactivity of Affinity-Purified Antixylitol Antibodies

test compound	IC_{50} (mM)	% cross-reactivity
D-xylitol	4.0	100.0
D-ribitol	35.0	11.4
D-galactitol	50.0	8.0
D-mannitol	90.0	4.4
D-xylose	102.5	3.9
L-arabinitol	108.0	3.8
meso-erythritol	108.1	3.8
D-sorbitol	135.1	3.7
D-threitol	350.0	3.0
glycerol	380.0	1.1
ethylene glycol	400.0	1.0
L-lysine	500.0	0.8

Inhibition ELISA was performed to check the cross-reactivity of the purified antixylitol antibodies (Figure 5, panel b). The panel of compounds tested (competitive inhibitors) included sugars like D-xylose and various sugar alcohols (*meso*-erythritol, D-xylitol, L-arabinitol, D-ribitol, D-mannitol, sorbitol, D-galactitol), ethylene glycol, glycerol, and L-lysine. The percent cross-

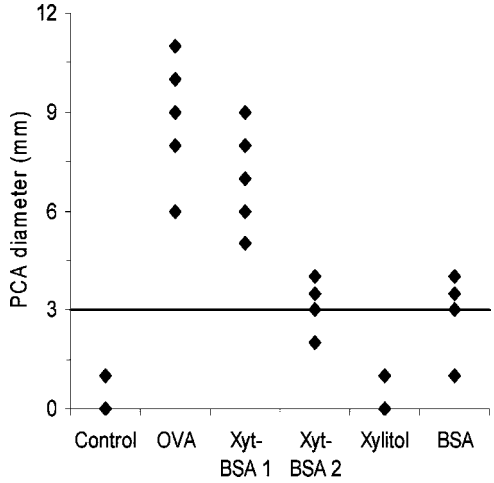

Figure 6. Passive cutaneous anaphylaxis (PCA) assay performed in Swiss albino mice ($n = 5$ per group) of different sera obtained on days 8, 22, and 36 from BALB/c mice ($n = 6$ per treatment group) that received repeated intradermal administration of antigens. The amount of different antigens used for immunization is 60 μg. Xyt–BSA 1, D-xylitol–BSA conjugate with 52 haptens; Xyt–BSA 2, D-xylitol–BSA conjugate with 32 haptens; OVA, ovalbumin; BSA, bovine serum albumin; control, saline. Horizontal line denotes cutoff for positivity at 3 mm. The PCA response from each animal is represented as a data point. Note the overlaps in the data points of control, xylitol, Xyt–BSA 2, and BSA groups.

reactivity for D-xylose and sugar alcohols is summarized in Table 1. Among the sugar alcohols tested, only D-ribitol showed 11.4% and galactitol showed 8% cross-reactivity, whereas for D-xylose and other sugar alcohols, the cross-reactivity ranged from 3.0% to 4.4%. The cross-reactivity was found to be 2–4% in the case of some monosaccharides such as D-glucose, D-mannose, and D-ribose (data not shown). The cross-reactivity was ~1% in the case of ethylene glycol, glycerol, and lysine.

Measurement of Antixylitol–IgE Antibody by Passive Cutaneous Anaphylaxis (PCA). BALB/c mice were immunized with various antigens, saline (negative control), ovalbumin (positive control), D-xylitol–BSA conjugates (Xyt-BSA 1, 52 haptens/mole; Xyt-BSA 2, 32 haptens/mole), D-xylitol, and BSA to evaluate the inherent potential of these antigens to produce IgE response. BALB/c mice immunized with high hapten density D-xylitol–BSA conjugate (Xyt-BSA 1, 60 μg) showed a positive reaction (5–9 mm range) in passive cutaneous anaphylaxis (PCA) when compared to 2–4 mm range seen in mice immunized with moderate hapten density D-xylitol–BSA conjugate (Xyt-BSA 2, 60 μg). Ovalbumin showed a strong positive reaction (6–11 mm range), whereas D-xylitol, BSA, and saline showed a negative reaction (Figure 6).

DISCUSSION

The hypothesis proposed for the mechanism of sensitization as well as IgE-mediated type I (immediate) hypersensitivity to mannitol (*12*) appears to be applicable to xylitol also (Scheme 1). Nearly 52 out of 61 amino groups of BSA can be reductively alkylated with D-xylose. The xylitoylation of BSA was confirmed by an increase in the relative molecular mass as well as positive PAS staining.

D-Xylitol–BSA conjugate as the immunogen produced good antibody response in rabbits, as evidenced by the sensitivity and specificity in dot immunoblots. Xylitol-specific antibodies were purified by affinity chromatography for characterization studies. In order to remove antibodies to BSA from D-xylitol–BSA antiserum, an affinity matrix was prepared by conjugating D-xylose to KLH, a carrier protein other than the one used for immunization, and then covalently coupling this conjugate (D-xylitol–KLH) to Sepharose CL-6B. Another advantage of using KLH for the affinity matrix is its high molecular weight possessing a large number of amino groups (*38*), which are absolutely essential for the coupling of D-xylitol to Sepharose CL-6B, through KLH. The affinity matrix, xylitol–KLH–Sepharose CL-6B, should be of value in purifying xylitol-specific IgE from the serum of allergic subjects sensitized to xylitol. The affinity constant of antixylitol antibodies was 3.86×10^9, which appears to be in the range of affinity constants reported for many monoclonal antibodies raised against haptens.

Interestingly, the affinity-purified antibodies also reacted with the Schiff base conjugate of D-xylosyl–BSA, indicating that antixylitol IgE can react with the Schiff base conjugates of D-xylose with serum proteins which may be formed in vivo by nonenzymic glycation of proteins by xylose. However, the reactivity of purified antibodies with the Schiff base conjugate of D-xylosyl–BSA was roughly two-thirds compared to xylitol–BSA conjugate (Figure 4, panel b).

On the basis of the checkerboard analysis of purified antibodies, the optimal conditions for inhibition ELISA were found to be 100 ng/well coating antigen D-xylitol–KLH, and 4 ng affinity-purified xylitol antibodies in a volume of 100 μL. It is clear from the inhibition ELISA experiments that the antibodies showed the least cross-reactivity with most monosaccharides including D-xylose and sugar alcohols. D-Xylitol showed maximum (100%) cross-reactivity, and among other sugars/sugar alcohols tested, only ribitol and galactitol showed 11.4% and 8% cross-reactivity, respectively. In the reductive amination reaction, the epsilon amino groups of L-lysyl residues of BSA react with the aldehyde group of the sugar D-xylose. Therefore, L-lysine was tested in the cross-reactivity studies to check whether the antibody also recognizes a portion of lysyl residue as an epitope. The results from Table 1 show that the cross-reactivity of L-lysine is only 0.8%, which clearly indicates that the xylitol-specific antibody is not recognizing the lysyl residue. On the basis of the low cross-reactivity of 2-carbon alcohol (ethylene glycol), 3-carbon alcohol (glycerol), and 4-carbon alcohol (*meso*-erythritol), it appears that the portion of xylitol molecule representing carbon atoms 2 to 5 most likely represents a single epitope.

Immunization study using D-xylitol–BSA conjugate in BALB/c mice (without the use of an adjuvant) demonstrated that the conjugate with high hapten density (52 haptens/mole) has the potential to induce IgE response, which is evidenced by the positive reaction in the passive cutaneous anaphylaxis. However, D-xylitol–BSA conjugate with moderate hapten density (32 haptens/mole), D-xylitol, and BSA showed a negative reaction, indicating that they cannot induce IgE response under identical conditions. Thus, the xylitol moiety as a hapten appears to possess allergenicity.

Only a single case of oral erosive eczema to xylitol has been reported so far, based on case history and skin patch test for IgE-mediated hypersensitivity (*13*). However, the presence of xylitol-specific IgE in the serum of the xylitol-sensitized subject has not been demonstrated. Xylitol is currently being used as a low-calorie alternative sweetener, and is listed as a GRAS (generally recognized as safe) substance under food additives. Xylitol and its parent monosaccharide D-xylose are considered safe even at high concentrations as evidenced by several studies (*1–3*, *39–41*). However, the incidence of allergic reactions could slightly increase in the future due to the increased consumption of a variety of processed foods containing D-xylose and/or covalently bound xylitol. Additionally, xylitol may undergo oxidation to xylose in vivo, which can then follow the reactions outlined in Scheme 1. On the basis of the results of our study, it should be possible to demonstrate by ELISA the presence of xylitol-specific IgE in serum using D-xylitol–protein

as the coating antigen. In fact, the presence of mannitol-specific IgE in the serum of the allergic subject sensitized to mannitol has been demonstrated earlier (*9*).

Xylitol conjugate of human serum albumin (HSA) or other endogenous proteins may be formed in vivo, which can give rise to an IgE immune response in humans who are susceptible to sensitization to xylitol. Alternatively, xylitol conjugates or corresponding Schiff bases formed under certain food processing conditions may also act as sensitizing agents. Although not tested, it is possible that the Schiff base conjugate of xylosyl–protein may act as an immunogen to produce antibodies which can recognize both the Schiff base as well as free xylitol, albeit not to a similar extent. In the rare case of oral erosive eczema caused by xylitol as a contact allergen described by Hanakawa et al. (*13*), wherein the presence of xylitol-specific IgE has not been shown, it is highly probable that the afore-mentioned possibilities are operating. On the basis of our earlier hypothesis enunciated for mannitol sensitization and hypersensitivity (*12*), it appears very likely that D-xylose acts as a noneliciting prosensitizer and free D-xylitol acts as a nonsensitizing elicitor. This means that, although xylitol cannot act as a sensitizing agent, it will elicit an allergic reaction in persons sensitized to xylosyl–protein (Schiff base) conjugates. The question of how Schiff base conjugates get reduced in vivo is yet to be investigated.

IgG antibodies specific to xylitol described here should prove useful in developing immunoassays for D-xylitol or D-xylitol epitopes on modified proteins in biological samples, natural and processed foods (*42*), and pharmaceuticals. It is interesting to note in this context that xylosyl–lysyl linkages (aldimine) and xylosyl–seryl linkages are present on core proteins of dermatan sulfate of connective tissues (*43*), and reducible lysine–carbohydrate condensation products have been identified in collagen as a result of age-related changes (*44*).

CONCLUSIONS

The results from this study demonstrate that xylitoyl epitopes can be easily formed on a suitable carrier protein by reductive amination. D-Xylitol–BSA conjugate thus formed (with 52 xylitoyl groups) has been used as an immunogen in rabbits to generate antixylitol antibodies, which have been purified from D-xylitol–BSA antiserum on a hapten-affinity column (D-xylitol–KLH–Sepharose CL-6B) for characterization. The purified antibodies show excellent specificity for xylitol; only ribitol was found to give significant cross-reactivity. Schiff base conjugates of xylosyl–protein are also recognized although to a slightly lesser extent. Immunization study in BALB/c mice has clearly shown that D-xylitol–BSA conjugate with high hapten density induces an IgE response as confirmed by homologous PCA.

ACKNOWLEDGMENT

We wish to thank Dr. V. Prakash, Director, CFTRI, Mysore for his support, keen interest, and constant encouragement in this work. The research work was supported by Council of Scientific and Industrial Research (CSIR), New Delhi (institutional project MLP-1407 to Y.P.V.), and senior research fellowship to K.S. The skillful assistance rendered by Dr. S. P. Muthukumar in animal experiments with BALB/c mice is gratefully acknowledged. We also thank Mr. R. Ravi, Department of Sensory Science, CFTRI, for his valuable assistance in linear regression analysis.

Received July 10, 2007; Revised Manuscript Received September 3, 2007

Cysteine sulfenic acid formation in proteins results from the oxidative modification of susceptible cysteine residues by hydrogen peroxide, alkyl hydroperoxides, and peroxynitrite. This species represents a biologically significant modification occurring during oxidant signaling or oxidative stress, and it can modulate protein function. Most methods to identify such oxidatively modified proteins rely on monitoring the loss of one or more thiol group(s) or on selective labeling of nascent thiol groups following reduction of oxidized proteins. Our previous work reported the direct labeling of these chemically distinct modifications with a dimedone analogue, 1,3-cyclohexadione, to which a linker and functional group (an alcohol) had been added; further addition of a fluorescent isatoic acid or methoxycoumarin reporter allowed detection of the incorporated tag by fluorescence techniques (Poole, L. B., Zeng, B. B., Knaggs, S. A., Yakubu, M., and King, S. B. (2005) Synthesis of chemical probes to map sulfenic acid modifications on proteins. *Bioconjugate Chem. 16*, 1624–1628). We have now expanded our arsenal of tagging reagents to include two fluorescein-, two rhodamine-, and three biotin-conjugated probes based on the original approach. The new tools provide readily detectable fluorescent and affinity probes to identify sulfenic acid modifications in proteins and have been used in subsequent mass spectrometric analyses to confirm covalent attachment of the conjugates and directly determine the site of modification.

INTRODUCTION

Given the significant role played by formation of cysteine sulfenic acid (*S*-hydroxycysteine, R–SOH) in the redox regulation of enzymes and transcription regulators (*1*–*3*) and its general instability toward protein analytical methods (*4*), there is a critical need for better reagents to trap and identify these modifications in proteins. On the basis of a known alkylator of R–SOH, dimedone (5,5-dimethyl-1,3-cyclohexanedione), we previously designed, synthesized, and validated the use of two fluorescent reagents linked to the reactive core of dimedone, 1,3-cyclohexadione, as detectable markers of R–SOH formation in proteins (*5*). These reagents were shown to specifically trap only the R–SOH modification in a test protein, AhpC (a cysteine-based peroxidase from bacteria), leaving underivatized the other protein functional groups (including amines), as well as the thiol, disulfide, or hyperoxidized forms of AhpC. Other oxidized, sulfur-containing functional groups such as *S*-nitrosothiols and sulfoxides were similarly unreactive toward these reagents and dimedone. A limitation of the fluorophores chosen for these initial studies, isatoic acid and 7-methoxycoumarin, is their poor detectability in polyacrylamide gels; they are also not useful as affinity reagents for the isolation of R–SOH forming proteins.

To provide an expanded array of chemical tools to identify and isolate proteins that undergo oxidative modification to form R–SOH, we have implemented a strategy similar to that previously used to incorporate isatoic acid and methoxycoumarin into our dimedone-like reagent. Here, we describe the generation of seven new reagents through the attachment of fluorescein, rhodamine, or biotin moieties to an alcohol functional group on a linker attached to 1,3-cyclohexadione. In related work, generation of a biotinylated, dimedone-like reagent was also very recently reported by another group (*6*); this latter reagent was used to detect and isolate sulfenic acid-modified proteins from cells treated with hydrogen peroxide. Our new compounds are all useful for detecting labeled proteins in polyacrylamide gels; with the fluorescent reagents, a major advantage is that the labeled proteins are directly observable both in solution and after gel electrophoresis. Our data also demonstrate that all of our reagents are compatible with mass spectrometric approaches to confirm covalent attachment and identify the specific site of modification. Three of the reagents with biotin reporter groups offer advantages not only of being detectable through Western blotting type approaches but also of enabling affinity techniques for isolating such modified proteins.

EXPERIMENTAL PROCEDURES

General Synthetic Methods. Glassware was oven-dried before use and cooled to room temperature under N_2. All reagents and solvents were obtained from a commercial source and used without further purification unless noted otherwise. Analytical thin layer chromatography was performed on 250 μm silica gel 60 plates (DC-Fertigplatten Krieselgel 60 F254). Visualization was accomplished with UV light, ethanolic phosphomolybdic acid solution, ethanolic ninhydrin solution,

or aqueous potassium permanganate solution followed by heating. Purification of the reaction products was carried out by flash column chromatography using silica gel 60 (32–63 μm). NMR spectra were recorded on a Bruker DPX 300 spectrometer, operating at 300 MHz (^{1}H NMR) and 75 MHz (^{13}C NMR), with chemical shifts referenced to the residual solvent peak. ^{1}H NMR data are reported as follows: chemical shift, integration, multiplicity (s = singlet, bs = broad singlet, d = doublet, t = triplet, q = quartet, m = multiplet), and coupling constants (Hz). Melting points were determined on a Thomas Hoover Uni-melt capillary melting point apparatus and are uncorrected. Mass spectra of synthesized compounds were obtained as a service by HT Laboratories (San Diego, CA) and are reported as *m/z*. Elemental combustion analysis was performed as a service by Atlantic Microlab Inc. (Atlanta, GA). For log *P* analyses, UV–vis spectra were recorded on a Cary 100 Bio UV–visible spectrophotometer.

Fluoresceinamine 5′-*N*-(*p*-Nitrophenyl)carbamate (2). To a solution of fluoresceinamine isomer I (**1**) (1.0 g, 2.88 mmol) in acetone (40 mL) was added *p*-nitrophenyl chloroformate (638 mg, 3.17 mmol) (Scheme 1). The resultant mixture was refluxed for 4 h and then stirred at room temperature for 24 h. The crude product was filtered from the reaction mixture and washed with dichloromethane (DCM)[1]/acetone (3/1 v/v, 40 mL) to yield a yellow-orange solid (1.42 g, 96.3%). TLC analysis and NMR indicated adequate purity for use in the next step: mp 186–189 °C (dec); R_f = 0.30 (hexanes/EtOAc/MeOH, 5/4/1); ^{1}H NMR (300 MHz, DMSO-d_6, δ) 11.05 (1H, bs), 8.34 (2H, d, J = 9.3 Hz), 8.18 (1H, s), 7.87 (1H, dd, J = 1.5, 8.1 Hz), 7.60 (2H, d, J = 9.0 Hz), 7.29 (1H, d, J = 8.4 Hz), 6.77 (2H, d, J = 1.5 Hz), 6.67–6.60 (4H, m); ^{13}C NMR (75 MHz, DMSO-d_6, δ) 168.7, 160.7, 155.7, 152.7, 151.2, 145.1, 140.4, 129.6, 127.9, 126.2, 125.7, 125.5, 123.3, 113.9, 113.5, 110.4, 102.6; ESI MS *m/z* 513 $(M + H)^+$.

Fluoresceinamine 5′-*N*-[3-(4-Ethoxy-2-oxocyclohex-3-enyl)-propyl)]carbamate (4). To a suspension of fluoresceinamine-5′-*N*-(*p*-nitrophenyl)carbamate (**2**) (500 mg, 0.91 mmol) in THF (10 mL) was added NEt_3 (130 μL, 0.91 mmol) and a solution of 3-ethoxy-6-(3-hydroxypropyl)-cyclohex-2-enone (**3**) (343 mg, 1.73 mmol) in THF (2 mL) (Scheme 1). Alcohol **3** was prepared by previously reported methods (*5*). The resultant mixture was stirred at reflux for 48 h. When the mixture was cooled, MeOH (10 mL) was added. The mixture was filtered, and the filtrate was reduced to dryness to yield an orange oil that was purified by flash column chromatography (hexanes/EtOAc/MeOH, 4/2/1). The pure product (**4**) was obtained as an orange solid (350 mg, 68.4%): mp 172–174 °C (dec); R_f = 0.28 (hexanes/EtOAc/MeOH, 4/2/1); ^{1}H NMR (300 MHz, MeOH-d_4, δ) 7.96 (1H, s), 7.52 (1H, dd, J = 2.9, 8.5 Hz), 6.90 (1H, d, J = 8.4 Hz), 6.46–6.41 (4H, m), 6.32 (2H, dd, J = 2.3, 8.7 Hz), 5.13 (1H, s), 4.40 (2H, t, J = 6.3 Hz), 3.75 (2H, q, J = 6.3 Hz), 2.29 (2H, t, J = 5.7 Hz), 2.23–2.04 (1H, m), 1.96–1.87 (1H, dq, J =

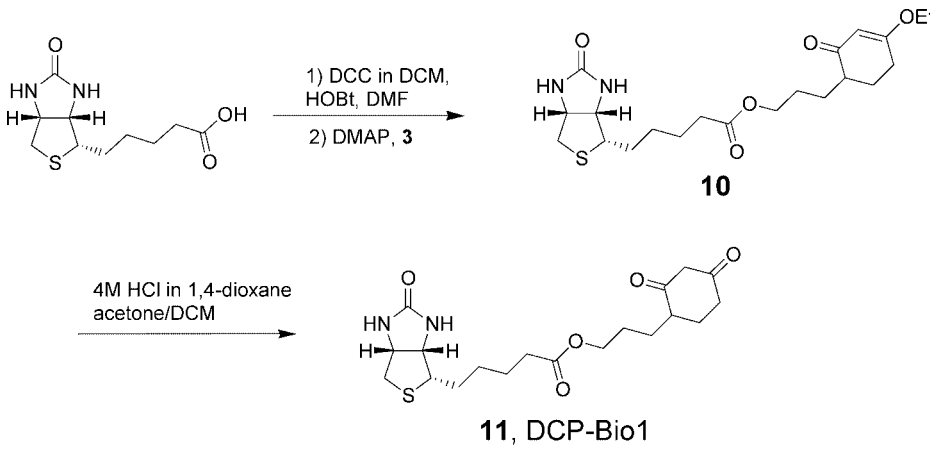
Anal. Calcd for $C_{32}H_{29}NO_9 \cdot H_2O$: C, 65.19; H, 5.30; N, 2.38. Found: C, 65.08; H, 5.30; N, 2.40.

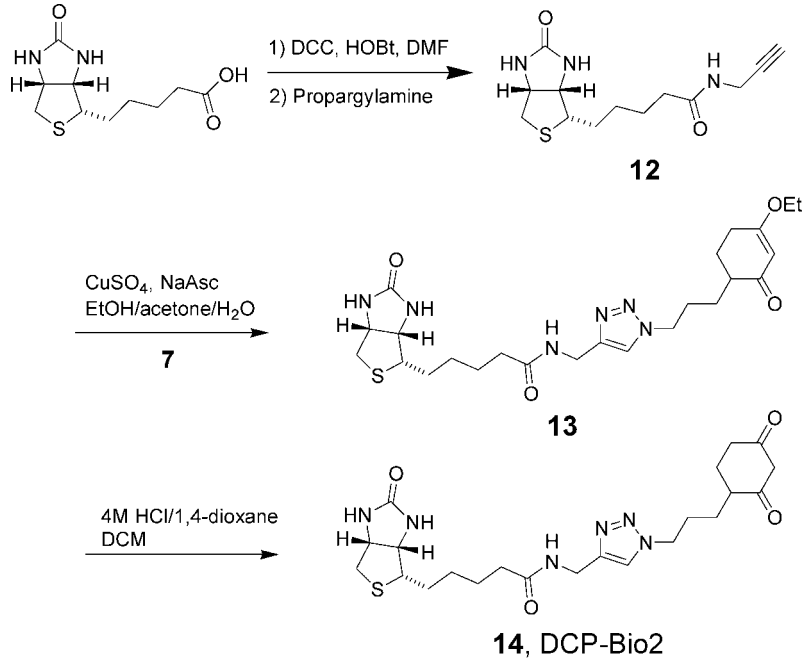
Fluoresceinamine 5′-*N*-[3-(2,4-Dioxocyclohexyl)propyl)]-carbamate (5, DCP-FL1). Fluoresceinamine 5′-*N*-[3-(4-ethoxy-2-oxocyclohex-3-enyl)propyl)]carbamate (**4**) (60 mg, 0.1 mmol) was stirred in a mixture of acetone (10 mL) and 3 N HCl (200 μL) (Scheme 1) until TLC analysis showed complete conversion. The reaction mixture was carefully neutralized (with either 10% NaOH solution or solid Na_2CO_3 followed by filtration) and reduced to dryness. The crude product (**5**) was purified by flash column chromatography (DCM/Et_2O/^{i}PrOH, 8/8/1) to yield the pure product as a yellow solid (54 mg, 94.7%): mp 239 °C (dec); $R_f = 0.19$ (hexanes/EtOAc/MeOH, 4/2/1); log *P* (octan-1-ol/phosphate buffer, pH 7.2) $= -0.89 \pm 0.20$; ^{1}H NMR (300 MHz, MeOH-d_4, δ) 8.23 (1H, s), 7.75 (1H, dd, $J = 1.9$, 8.4 Hz), 7.14 (1H, d, $J = 8.3$ Hz), 6.73–6.69 (4H, m), 6.58 (2H, dd, $J = 2.3$, 8.7 Hz), 4.27 (2H, t, $J = 6.2$ Hz), 2.45 (2H, q, $J = 6.1$ Hz), 2.41–2.34 (1H, m), 2.20–2.10 (1H, m), 2.00–1.75 (3H, m), 1.67–1.57 (1H, m); ^{13}C NMR (75 MHz, acetone-d_6, δ) 202.7, 169.8, 160.6, 155.1, 153.8, 148.1, 142.5, 130.6, 129.3, 126.6, 126.5, 125.7, 113.6, 112.4, 105.1, 103.7, 84.0, 66.3, 66.2, 50.0, 40.7, 27.8, 27.6, 26.1, 24.7; ESI MS *m/z* 544 $(M + H)^+$. Anal. Calcd for $C_{30}H_{25}NO_9 \cdot i$PrOH: C, 65.66; H, 5.51; N, 2.32. Found: C, 64.84; H, 5.38; N, 2.34.

Fluoresceinamine-5′-*N*-(3-propargyl)urea Triethylamine Salt (6). To a suspension of fluoresceinamine 5′-*N*-(*p*-nitrophenyl)carbamate (**2**) (160 mg, 0.31 mmol) in acetone/THF (2/1 v/v, 8 mL) was added propargylamine (21 μL, 0.34 mmol) and NEt_3 (44 μL, 0.31 mmol) (Scheme 2). The resultant solution was stirred at room temperature for 3 h during which the product (**6**) precipitated from the reaction mixture. This was filtered off and washed with DCM/acetone (2/1 v/v, 30 mL) to yield **6** as an orange solid (132 mg, 80.0%). TLC analysis and NMR indicated adequate purity for use in the next step: mp 187–189 °C (dec); $R_f = 0.56$ (EtOAc/hexanes/MeOH, 6/3/1); ^{1}H NMR (300 MHz, MeOH-d_4, δ) 7.96 (1H, d, $J = 2.0$ Hz), 7.79 (1H, dd, $J = 2.1$, 8.3 Hz), 7.13 (1H, d, $J = 8.3$ Hz), 7.06 (2H, d, $J = 8.9$ Hz), 6.64 (2H, dd, $J = 2.2$, 5.4 Hz), 6.61 (2H, d, $J = 2.2$ Hz), 4.03 (2H, q, $J = 2.4$ Hz), 3.07 (6H, q, $J = 7.3$ Hz), 2.62 (1H, t, $J = 2.4$ Hz), 1.22 (9H, t, $J = 7.3$ Hz); ^{13}C NMR (75 MHz, MeOH-d_4, δ) 173.0, 157.9, 157.4, 142.4, 132.1, 129.6, 122.6, 119.8, 118.9, 114.5, 103.9, 81.6, 72.0, 47.6, 30.2; ESI MS *m/z* 429 $(M + H)^+$.

3-Ethoxy-6-(3-azidopropyl)cyclohex-2-enone (7). To a cooled solution of 3-ethoxy-6-(3-hydroxylpropyl)cyclohex-2-enone (**3**) (2.0 g, 10.0 mmol) in THF (40 mL) at 0 °C was added triphenylphosphine (2.91 g, 11.0 mmol), diisopropyl azodicarboxylate (DIAD, 2.15 mL, 11.0 mmol), and diphenylphosphorylazide (DPPA, 2.4 mL, 11.0 mmol) sequentially (Scheme 2). The resultant mixture was stirred at 0 °C and then at room temperature for 16 h before being partitioned between DCM (100 mL) and water (50 mL). The aqueous phase was extracted with DCM (100 mL), and the organic phases were combined, washed with brine (50 mL), dried over anhydrous Na_2SO_4, filtered, and reduced to dryness. The resultant oil was purified by flash column chromatography (2×, hexanes/EtOAc, 2/1, and hexanes/EtOAc/MeOH, 12/2/1) to yield the pure product (**7**) as a pale-yellow liquid (1.6 g, 71.3%). $R_f = 0.31$ (EtOAc/hexanes/MeOH 12/2/1); ^{1}H NMR (300 MHz, $CDCl_3$, δ) 5.31 (1H, s), 3.89 (2H, q, $J = 6.9$ Hz), 3.30 (2H, dt, $J = 1.6$, 6.8 Hz), 2.44 (2H, t, $J = 5.9$ Hz), 2.25–2.16 (1H, dpentet, $J = 1.8$, 5.2 Hz), 2.12–2.03 (1H, dq, $J = 5.0$, 13.2 Hz), 1.95–1.80 (1H, m), 1.78–1.59 (3H, m), 1.53–1.41 (1H, m), 1.36 (3H, t, $J = 7.0$ Hz); ^{13}C NMR (75 MHz, $CDCl_3$, δ) 201.2, 117.2, 102.5, 64.6, 51.9, 45.1, 28.5, 27.2, 26.9, 14.5.



Scheme 2



Fluoresceinamine-5′-*N*-[3-((1-(3-(4-ethoxy-2-oxocyclohex-3-enyl)propyl)-1*H*-1,2,3-triazol-4-yl)methyl]urea (8). Fluoresceinamine-5′-*N*-(3-propargyl)urea triethylamine salt (**6**) (132 mg, 0.25 mmol) and 3-ethoxy-6-(3-azidopropyl)cyclohex-2-enone (**7**) (139 mg, 0.62 mmol) were solubilized in a mixture of acetone/EtOH/H_2O (1/2/1 v/v, 4 mL). Sodium ascorbate (12 mg, 0.062 mmol) and $CuSO_4 \cdot 5H_2O$ (156 μL of a 0.1 M solution in H_2O, 0.0156 mmol) were added, and the resultant solution stirred at room temperature for 16 h (Scheme 2). The solvent was removed under reduced pressure and the resultant orange oil purified by flash column chromatography (gradient elution with EtOAc/hexanes/MeOH, 6/3/1, to EtOAc/MeOH, 7/1) to yield the pure product (**8**) as a bright-yellow foam (151 mg, 71.4 %): mp 157 °C (dec); $R_f = 0.14$ (EtOAc/hexanes/MeOH 6/3/1); ^{1}H NMR (300 MHz, MeOH-d_4, δ) 8.10 (1H, s), 7.85 (1H, s), 7.56 (1H, d, $J = 8.3$ Hz), 6.96 (1H, d, $J = 8.3$ Hz), 6.59 (2H, d, $J = 2.0$ Hz), 6.53 (2H, d, $J = 8.7$ Hz), 6.44 (2H, dd, $J = 2.0$, 8.7 Hz), 5.19 (1H, s), 4.43 (2H, s), 4.28 (2H, t, $J = 6.7$ Hz), 3.80 (2H, q, $J = 7.1$ Hz), 2.38–2.21 (2H, m), 2.16–2.08 (1H, m), 1.97–1.78 (3H, m), 1.72–1.61 (1H, m), 1.59–1.48 (1H, m), 1.22 (3H, t, $J = 7.0$ Hz); ^{13}C NMR (75 MHz, acetone-d_6) δ 200.8, 177.9, 170.5, 160.6, 156.5 (x2), 156.4, 153.8, 147.0, 143.6 (x2), 130.6, 129.1, 126.5, 126.4, 125.4, 123.7, 113.6, 112.4, 103.7, 102.9, 84.1, 65.4, 51.2, 45.6, 36.6 (×2), 29.1, 27.7, 14.9; ESI MS *m/z* 652 $(M + H)^+$, 674 $(M + Na)^+$. propyl)-1*H*-1,2,3-triazol-4-yl)methyl]urea (**8**) (70 mg, 0.11 mmol) was stirred in a mixture of THF/acetone/H_2O (4/4/1 v/v/v, 9 mL) and treated with 3 N HCl (500 μL) (Scheme 2). The solution was stirred until TLC analysis indicated near complete conversion of **8** to **9** (3 h to 3 days). The reaction mixture was neutralized and then reduced to dryness. The resulting solids were washed with MeOH and filtered, and the filtrate was concentrated. The crude product was purified by flash column chromatography (gradient elution with DCM/MeOH, 8/2 to 6/4) to yield the pure product (**9**) as a yellow solid (64 mg, 95.5%): mp 224 °C (dec); $R_f = 0.31$ (DCM/MeOH 8/2); log *P* (octan-1-ol/phosphate buffer, pH 7.2) = -1.61 ± 0.24; ^{1}H NMR (300 MHz, MeOH-d_4, δ) 8.10 (1H, d, $J = 1.7$ Hz), 7.86 (1H, s), 7.55 (1H, dd, $J = 2.0$, 8.4 Hz), 6.95 (1H, d, $J = 8.3$ Hz), 6.57 (4H, d, $J = 2.2$ Hz), 6.45 (2H, dd, $J = 2.2$, 8.7 Hz), 4.40 (2H, s), 4.30 (2H, t, $J = 6.9$ Hz), 2.26 (2H, t,$J = 7.0$ Hz), 2.21–2.13 (1H, m), 2.05–1.80 (3H, m), 1.69–1.55 (2H, m), 1.37–1.28 (1H, m), 1.27–1.17 (2H, m); ^{13}C NMR (75 MHz, MeOH-d_4, δ) 204.4, 181.6, 173.0, 172.2, 170.9, 168.5, 167.3, 161.2, 160.8, 144.6, 144.5, 134.7, 134.5, 133.2, 132.4, 131.9, 127.5, 123.6, 122.0, 121.6, 118.9, 118.6, 103.7, 52.5, 52.2, 36.3, 29.2, 29.0, 27.9, 27.7, 27.2; ESI MS *m/z* 624 $(M + H)^+$, 646 $(M + Na)^+$.

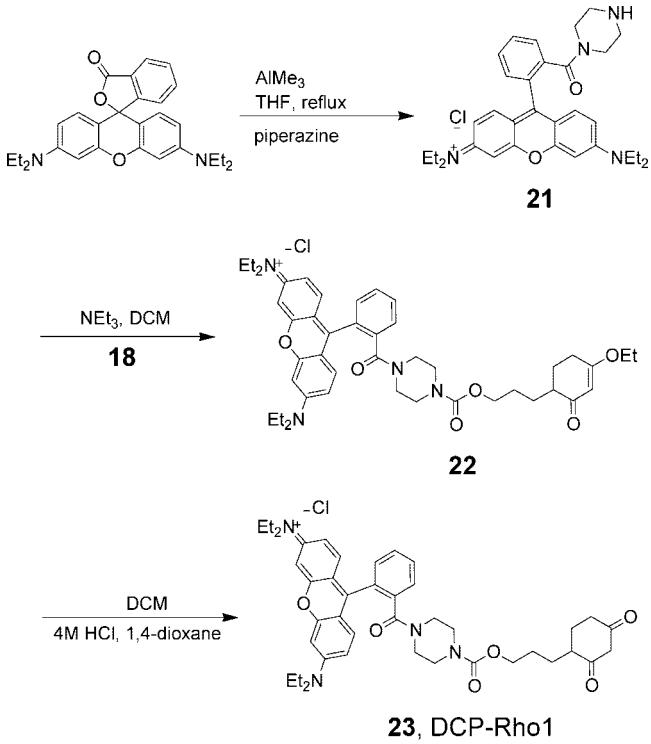
3-(4-Ethoxy-2-oxocyclohex-3-enyl)propyl 5-((3a*R*,6*S*,6a*S*)-Hexahydro-2-oxo-1*H*-thieno[3,4-*d*]imidazol-6-yl)pentanoate (10). D-(+)-Biotin (600 mg, 2.46 mmol) and hydroxybenzotriazole (HOBt, 66 mg, 0.49 mmol) were suspended in anhydrous DMF (20 mL) with 4 Å molecular sieves and heated until a clear solution was obtained. When the mixture was cooled, a solution of dicyclohexylcarbodiimide (DCC) in DCM (2.7 mL of a 1.0 M solution in DCM, 2.70 mmol) was added dropwise and the mixture stirred at room temperature for 3 h (solution goes cloudy). 3-Ethoxy-6-(3-hydroxypropyl)cyclohex-2-enone (584 mg, 2.95 mmol) and *N*,*N*-dimethylaminopyridine (DMAP, 30 mg, 0.025 mmol) were added, and the mixture was stirred at 60 °C for 4 h and then at room temperature for 24 h. The mixture was filtered and washed with DCM/MeOH (1/1 v/v, 20 mL), and the filtrate was reduced to dryness and purified by column chromatography (2×, DCM/MeOH, 92/8, then DCM/MeOH, 95/5). The pure product was obtained as white foam (805 mg, 77.2%): mp 164–166 °C; $R_f = 0.43$ (DCM/MeOH 9/1); ^{1}H NMR (300 MHz, $CDCl_3$, δ) 6.14 (1H, s), 5.70 (1H, s), 5.29 (1H, s), 4.49–4.45 (1H, m), 4.27 (1H, dd, $J = 4.7$, 7.2 Hz), 4.04 (2H, t, $J = 6.5$ Hz), 3.85 (2H, q, $J = 7.0$ Hz), 3.12 (1H, q, $J = 4.6$, 7.2 Hz), 2.87 (1H, dd, $J = 4.9$, 12.8 Hz), 2.71

Scheme 5



(1H, d, J = 12.7 Hz), 2.40 (2H, t, J = 5.8 Hz), 2.29 (2H, t, J = 7.4 Hz), 2.23–2.12 (1H, m), 2.09–2.00 (1H, dq, J = 5.0, 13.1 Hz), 1.93–1.81 (1H, m), 1.76–1.57 (6H, m), 1.46–1.36 (4H, m), 1.32 (3H, t, J = 7.1 Hz); ^{13}C NMR (75 MHz, $CDCl_3$, δ) 201.5, 177.3, 174.2, 164.3, 102.6, 64.7 (×2), 62.3, 60.5, 55.9, 50.4, 45.1, 34.4, 28.7, 28.6, 28.5, 26.8, 26.6 (×2), 26.4, 25.2, 14.5; ESI MS m/z 425 $(M + H)^+$.

3-(2,4-Dioxocyclohexyl)propyl 5-((3a*R*,6*S*,6a*S*)-Hexahydro-2-oxo-1*H*-thieno[3,4-*d*]imidazol-6-yl)pentanoate (DCP-Bio1, 11). 3-(4-Ethoxy-2-oxocyclohex-3-enyl)propyl 5-((3a*R*,6*S*,6a*S*)-hexahydro-2-oxo-1*H*-thieno[3,4-*d*]imidazol-6-yl)pentanoate (**10**) (600 mg, 1.41 mmol) was solubilized in acetone/DCM (3/1 v/v, 24 mL) and treated with 4 M HCl in 1,4-dioxane (2 mL) (Scheme 3). The mixture was stirred at room temperature for 5 h and then carefully neutralized by the addition of solid Na_2CO_3. The inorganic solids were filtered off and washed with 10% MeOH in DCM, and the combined filtrates were reduced to dryness. The crude yellow oil was purified by flash column chromatography (gradient elution, DCM/MeOH, 90/10 to 89/11) to yield the pure product (**11**) as a glassy solid (390 mg, 69.6% [83.5% based on recovery of **3**]): mp 90–91 °C; R_f = 0.25 (DCM/MeOH 9/1); ^{1}H NMR (300 MHz, MeOH-d_4, δ) 4.74 (1H, dd, J = 5.0, 7.4 Hz), 4.55 (1H, dd, J = 4.4, 7.6 Hz), 4.35 (2H, t, J = 6.1 Hz), 3.46 (1H, m), 3.18 (1H, dd, J = 4.9, 12.8 Hz), 2.96 (1H, d, J = 12.7 Hz), 2.69–2.52 (5H, m), 2.44–2.29 (1H, m), 2.16–1.68 (12H, m); ^{13}C NMR (75 MHz, $CDCl_3$, δ) 204.8, 204.2, 174.1, 164.4 (163.9), 104.6, 64.6 (64.5), 62.5 (62.4), 60.7 (60.6), 58.7, 55.8 (×2), 53.8, 51.2, 49.3, 40.9, 40.1, 34.5 (34.3), 33.5, 30.1 (29.7), 28.7, 27.1, 26.7, 26.6, 26.4, 26.0, 25.3 (25.1); ESI MS m/z 419 $(M + Na)^+$. Anal. Calcd for $C_{19}H_{28}N_2O_5S \cdot 0.5$MeOH: C, 56.77; H, 7.33; N, 6.79. Found: C, 56.91; H, 7.27; N, 6.78.

5-((3a*R*,6*S*,6a*S*)-Hexahydro-2-oxo-1*H*-thieno[3,4-*d*]imidazol-6-yl)-*N*-(prop-2-ynyl)pentanamide (12). When D-(+)-biotin (400 mg, 1.64 mmol), HOBt (44 mg, 0.33 mmol), DCC (1.8 mL of a 1.0 M solution in DCM), and propargyamine (170 μL, 2.46 mmol) were used, the pure product (**12**, Scheme 4) was obtained after flash column chromatography (gradient elution, DCM/MeOH, 92/8 to 90/10) as a white solid (395 mg, 85.7%): mp 169–170 °C; R_f = 0.24 (DCM/MeOH, 9/1); ^{1}H NMR (300 MHz, MeOH-d_4, δ) 4.28 (1H, dd, J = 4.9, 7.9 Hz), 4.10 (1H, dd, J = 4.4, 7.9 Hz), 3.04–2.97 (1H, m), 2.73 (1H, dd, J = 4.9, 12.7 Hz), 2.50 (1H, d, J = 12.7 Hz), 2.38 (2H, t, J = 2.5 Hz), 2.02 (2H, t, J = 7.4 Hz), 1.60–1.31 (4H, m), 1.25 (2H, q, J =

The filtrate was reduced to dryness to yield a yellow oil that was purified by column chromatography (DCM/MeOH, 85/15). The pure product (**19**) was obtained as a white solid (200 mg, 48.8%): mp 191–192 °C; R_f = 0.13 (DCM/MeOH, 9/1); ^{1}H NMR (300 MHz, $CDCl_3$/MeOH-d_4, δ) 5.05 (1H, s), 4.05 (1H, dd, J = 4.5, 7.8 Hz), 3.78 (2H, t, J = 6.3 Hz), 3.69 (2H, q, J = 7.1 Hz), 2.96–2.91 (3H, m), 2.87 (2H, t, J = 6.8 Hz), 2.67 (1H, dd, J = 4.9, 12.9 Hz), 2.47 (1H, d, J = 12.9 Hz), 2.21 (2H, t, J = 5.8 Hz), 2.00–1.98 (1H, m), 1.94 (2H, t, J = 7.2 Hz), 1.89–1.81 (1H, m), 1.66–1.52 (1H, m), 1.50–1.33 (6H, m), 1.30–1.18 (6H, m), 1.12 (3H, t, J = 7.0 Hz); ^{13}C NMR (75 MHz, $CDCl_3$/MeOH-d_4, δ) 207.2, 205.5, 182.8, 178.7, 168.6, 162.0, 105.9, 105.6, 68.8, 66.3, 64.5, 61.7, 59.9, 48.9, 44.5, 43.2, 40.0, 32.7, 32.4, 32.2, 31.4, 30.8, 30.7, 30.4, 30.2, 29.8, 21.9, 18.1, 12.8; ESI MS *m/z* 561 $(M + Na)^+$.

3-(2,4-Dioxocyclohexyl)propyl 4-(5-((3a*R*,6*S*,6a*S*)-Hexahydro-2-oxo-1 *H*-thieno[3,4-*d*]imidazol-6-yl)pentanamido)butylcarbamate (DCP-Bio3, 20). 3-(4-Ethoxy-2-oxocyclohex-3-enyl)propyl 4-(5-((3a*R*,6*S*,6a*S*)-hexahydro-2-oxo-1*H*-thieno[3,4-*d*]imidazol-6-yl)pentanamido)butylcarbamate (**19**) (110 mg, 0.20 mmol) was solubilized in DCM/MeCN/acetone (2/1/1 v/v/v, 12 mL) and treated with a 4 M solution of HCl in 1,4-dioxane (0.5 mL) (Scheme 5). The mixture was stirred at room temperature for 4 h and then neutralized by the addition of solid sodium carbonate. The mixture was then filtered and washed with DCM/MeOH (3/1 v/v, 20 mL). The filtrate was reduced to dryness and purified by flash column chromatography (gradient elution with DCM/MeOH, 90/10 to 80/20) to yield the pure product (**20**) as a tan foamy solid (82 mg, 78.8%): mp 155 °C (dec); R_f = 0.42 (DCM/MeOH, 80/20); ^{1}H NMR (300 MHz, MeOH-d_4, δ) 4.60 (1H, dd, J = 4.8, 7.4 Hz), 4.40 (1H, dd, J = 4.4, 7.8 Hz), 4.13 (2H, t, J = 5.8 Hz), 3.28 (2H, bd, J = 3.7 Hz), 3.20 (2H, m), 3.02 (1H, dd, J = 4.9, 12.7 Hz), 2.80 (1H, d, J = 12.7 Hz), 2.50 (2H, m), 2.42–2.39 (1H, m), 2.30 (2H, t, J = 7.2 Hz), 2.25–2.15 (1H, m), 1.96–1.50 (16H, m); ^{13}C NMR (75 MHz, MeOH-d_4, δ) 176.5, 166.4, 159.7, 66.2, 63.8, 62.1, 57.4, 53.0, 43.6, 41.8, 41.5, 40.4, 37.3, 34.3, 31.1, 30.2, 29.9, 28.7, 28.3, 28.1, 27.7, 27.3, 26.7, 26.6; ESI MS *m/z* 533 $(M + Na)^+$.

Rhodamine B Piperazine Amide (21). To a solution of piperazine (4.67 g, 54 mmol) in anhydrous DCM (50 mL) was added trimethylaluminum (13.6 mL of a 2 M solution in toluene) dropwise. The resulting mixture was stirred at room temperature for 1 h, and then a solution of rhodamine B base (6.0 g) in DCM (15 mL) was added dropwise (Scheme 6). The reaction mixture was refluxed for 72 h. Upon cooling, the mixture was carefully neutralized by the dropwise addition of a 0.1 M HCl aqueous solution. The heterogeneous mixture was filtered, and the inorganics salts were washed sequentially with DCM (100

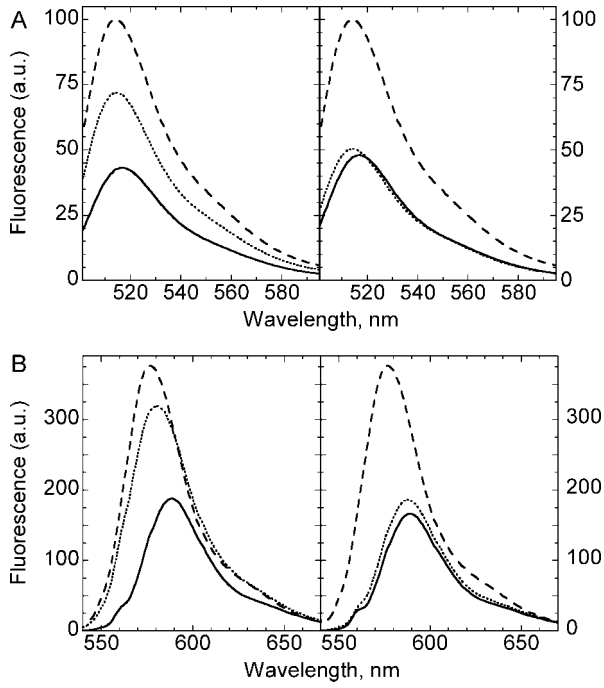

Figure 1. Fluorescence spectra of fluorescein- (A) and rhodamine-linked (B) reagents before (dotted) and after (solid) reaction with cysteine sulfenic acid-containing AhpC. Free fluorescein (A) and rhodamine B (B) are shown as the dashed spectra for comparison. Labeled C165S AhpC was prepared as described in the Experimental Procedures with the cysteine sulfenic acid form of the protein incubated anaerobically with 5 mM **5** (DCP-FL1), **9** (DCP-FL2), **23** (DCP-Rho1), or **26** (DCP-Rho2) for 60 min and then washed free of the unreacted reagent and buffer components into a final buffer of 50 mM Tris-HCl at pH 8 (fluorescein) or 50 mM potassium phosphate buffer at pH 7 (rhodamine) using an Apollo concentrator. Samples in panel A at ~0.5 absorbance (491 nm excitation) were analyzed on a Tecan Safire 2 monochromator-based microplate reader with a gain of 68. Samples in panel B at an absorbance of 0.14 (560 nm excitation) were analyzed on a Varian Cary Eclipse fluorescence spectrophotometer at medium sensitivity, with 5 nm bandwiths for both excitation and emission wavelengths in both instruments.

mL) and DCM/MeOH (4/1 v/v, 150 mL). The filtrate was reduced to partial dryness and partitioned between EtOAc (3 × 200 mL) and saturated $NaHCO_3$ solution (300 mL). The aqueous phase was saturated with NaCl, acidified with 1 M HCl, and extracted with *i*PrOH/DCM (2/1 v/v, 5 × 150 mL). The organic phase was dried over $MgSO_4$, filtered, and reduced to dryness to yield a purple oil. This was solubilized in a minimal amount of MeOH and added dropwise to Et_2O (500 mL), and the crude product (**21**) was filtered off and obtained as a purple-gold solid (5.88 g, 79.3%). ^{1}H NMR (300 MHz, $CDCl_3$, δ) 7.59–7.53 (2H, m), 7.46–7.41 (1H, m), 7.25–7.17 (1H, m), 7.10 (1H, d, J = 9.5 Hz), 7.02 (1H, d, J = 9.5 Hz), 6.84–6.79 (2H, m), 6.64 (2H, dd, J = 2.3, 6.2 Hz), 3.78 (2H, bd, J = 14.1 Hz), 3.63–3.40 (8H, m), 3.32–3.18 (4H, bs), 3.25 (4H, m), 2.98 (2H, bd, J = 20.4 Hz), 2.42 (1H, bs), 1.20 (12H, t, J = 7.0 Hz); ^{13}C NMR (75 MHz, $CDCl_3$, δ) 167.5, 158.0, 156.0, 155.9, 155.8, 134.6, 132.4, 131.7, 131.4, 131.0, 130.7, 130.6, 130.4, 130.3, 127.9, 114.7, 114.4, 96.7, 58.1, 50.4, 46.6, 46.5, 18.7, 13.0; ESI MS *m/z* 511 $(M + H)^+$.

Rhodamine B [4-[3-(4-Ethoxy-2-oxocyclohex-3-enyl)propyl]carbamate]piperazine Amide (22). To a solution of rhodamine B piperazine amide (**21**) (434 mg, 0.79 mmol) in anhydrous DCM (10 mL) was added NEt_3 (180 μL, 1.32 mmol) and 3-(4-ethoxy-2-oxocyclohex-3-enyl)propyl 4-nitrophenylcarbonate (**18**) (240 mg, 0.66 mmol) (Scheme 6). The reaction mixture was stirred at reflux for 6 h and then at room temperature for 16 h, reduced to dryness, and purified by flash column chromatography (2×, DCM/MeOH, 90/10 and then 91/9) to yield the pure product (**22**) as a purple foam (300 mg, 58.8%). R_f = 0.25 (DCM/MeOH 9/1); ^{1}H NMR (300 MHz, $CDCl_3$, δ) 7.64 (2H, m), 7.48 (1H, dd, J = 2.8, 6.8 Hz), 7.30 (1H, dd, J = 2.6, 5.9 Hz), 7.16 (2H, q, J = 9.5 Hz), 6.89 (2H, d, J = 7.6 Hz), 6.74 (2H, bs), 5.24 (1H, s), 3.99 (2H, t, J = 6.5 Hz), 3.80 (2H, q, J = 7.0 Hz), 3.59 (8H, q, J = 7.1 Hz), 3.32 (4H, bs), 3.25 (4H, bs), 2.34 (2H, d, J = 5.3 Hz), 2.15–2.06 (1H, m), 2.04–196 (1H, m), 1.84–1.75 (1H, m), 1.69–1.49 (3H, m), 1.38–1.18 (16H, m); ^{13}C NMR (75 MHz, $CDCl_3$, δ) 201.4, 201.3, 177.4, 168.0, 158.0, 156.0, 155.9, 155.5, 135.3, 132.3, 131.0, 130.8, 130.6, 127.9, 114.5, 114.0, 102.4, 96.8, 66.1, 64.6, 53.9, 46.5, 45.0, 28.5, 26.8, 26.7, 26.2, 14.5, 13.0.

Rhodamine B [4-[3-(2,4-Dioxocyclohexyl)propyl]carbamate]piperazine Amide (DCP-Rho1, 23). Rhodamine B [4-[3-(4-ethoxy-2-oxocyclohex-3-enyl)propyl]carbamate]piperazine amide (**22**) (280 mg, 0.36 mmol) was solubilized in DCM (16 mL) and treated with 4 M HCl in 1,4-dioxane (1 mL) (Scheme 6). The mixture was stirred at room temperature for 16 h, then carefully neutralized by the addition of solid Na_2CO_3. The inorganic solids were filtered off and washed with 10% MeOH in DCM, and the combined filtrates were reduced to dryness. The crude purple oil was purified by flash column chromatography (gradient elution, DCM/MeOH, 92/8 to 90/10) to yield the pure product (**23**) as a purple solid (215 mg, 79.6%): log *P* (octan-1-ol/phosphate buffer, pH 7.2) = 1.026 ± 0.113; ^{1}H NMR (300 MHz, $CDCl_3$, δ) 7.62 (2H, d, J = 3.3 Hz), 7.48 (1H, d, J = 3.0 Hz), 7.29 (1H, d, J = 3.0 Hz), 7.17 (2H, d, J = 9.0 Hz), 6.90 (2H, bs), 6.75 (2H, bs), 5.24 (1H, bs), 3.99 (2H, t, J = 6.0 Hz), 3.82 (8H, t, J = 7.8 Hz), 3.32 (4H, bs), 3.26 (4H, bs), 2.35 (2H, d, J = 5.4 Hz), 2.14–2.08 (1H, m), 2.03–1.98 (1H, m), 1.79–1.75 (1H, m), 1.74–1.62 (3H, m), 1.61–1.44 (1H, m), 1.26 (12H, t, J = 6.6 Hz); ^{13}C NMR (75 MHz, $CDCl_3$, δ) 201.3, 178.2, 168.1, 158.1, 156.1, 155.6, 135.4, 132.4, 131.1, 130.8, 130.6, 128.0, 114.6, 114.1, 102.4, 96.9, 66.2, 66.0, 56.1, 46.6, 45.1, 28.4, 27.7, 27.1, 26.8, 26.7, 26.4, 26.2, 13.1; ESI MS *m/z* 708 $(M + H)^+$.

Rhodamine B *tert*-Butyl 4-oxo-4-(piperazin-1-yl)butylcarbamate (24). *N*-Boc GABA-OH (149 mg, 0.73 mmol) in anhydrous DCM/THF/acetone (1/1/3 v/v/v, 10 mL) was treated with DCC (0.8 mL of 1.0 M solution in DCM). After the mixture was stirred at room temperature for 2 h, rhodamine B piperazine amide (**21**) (400 mg, 0.73 mmol) was added. The mixture was stirred at room temperature for 16 h and reduced to dryness. The residue was purified by flash column chromatography (DCM/MeOH, 90/10) to yield the pure product (**24**) as a purple foam (351 mg, 65.6%). ^{1}H NMR (300 MHz, $CDCl_3$, δ) 7.76 (2H, bs), 7.63 (1H, bs), 7.41–7.01 (5H, m), 6.98 (1H, bs), 6.78 (1H, bs), 3.82–3.57 (10H, m), 3.51–3.36 (5H, m), 3.25–3.18 (3H, m), 2.62–2.57 (1H, m), 1.92–1.88 (4H, m), 1.51 (9H, d, J = 5.0 Hz), 1.42 (12H, t, J = 7.0Hz); ^{13}C NMR (75 MHz, $CDCl_3$, δ) 172.6, 168.0, 158.1, 156.7, 156.6, 156.1, 135.6, 132.5, 131.4, 131.3, 130.6, 130.5, 128.0, 115.3, 114.2, 96.9, 96.4, 79.2, 78.9, 53.9, 48.5, 46.5 (46.3, 42.1, 41.3, 40.5, 32.6, 31.5, 30.7), 28.8, 25.8, 13.0.

Rhodamine B 3-(4-Ethoxy-2-oxocyclohex-3-enyl)propyl 4-Oxo-4-(piperazin-1-yl)butylcarbamate (25). Rhodamine B *tert*-butyl 4-oxo-4-(piperazin-1-yl)butylcarbamate (**24**) (350 mg, 0.48 mmol) in DCM (6 mL) was treated with 4 M HCl in 1,4-dioxane (0.5 mL). The mixture was stirred at room temperature until TLC showed no starting material remaining (5 h), and the mixture was reduced to dryness to yield the crude product as a purple solid (320 mg, 100%). This was directly used in the next step without purification, resolubilized in DCM (10 mL), and treated with NEt_3 (133 μL, 0.96 mmol) and 3-(4-ethoxy-2-oxocyclohex-3-enyl)propyl 4-nitrophenylcarbonate (**18**) (174 mg, 0.48 mmol). The mixture was stirred at room temperature

Table 1. Mass and Spectral Information for Sulfenic Acid-Directed Reagents and Their Adducts with AhpC

reagent	empirical formula	monoisotopic molecular mass	average molecular weight (g/mol)	characteristic ion mass ($[M + H]^+$, Da)[a]	mass of AhpC protein adduct (Da)[b]	$\lambda_{max,ex}$ and $\lambda_{max,em}$ of free reagent (nm)	λ_{max} and $\lambda_{max,em}$ of protein adduct (nm)

[a] *m/z* value of ion released during MS–MS analysis of the labeled peptide from AhpC, as described in the text. [b] Mass of adduct by electrospray ionization mass spectrometry in a triple quadrupole mass spectrometer. For comparison, the underivatized sulfenic acid form of the C165S mutant of AhpC analyzed under these conditions gave a major peak at 20648.7 Da, accounting for the addition of three oxygen atoms to the protein (presumably the sulfonic acid form at the active site cysteine). The errors listed reflect the hardware accuracy of ±0.01%. Where the MaxEnt error was greater than the instrument error, this number was used instead. [c] NF = nonfluorescent. [d] $[M^+]$, positively charged without the addition of H^+.

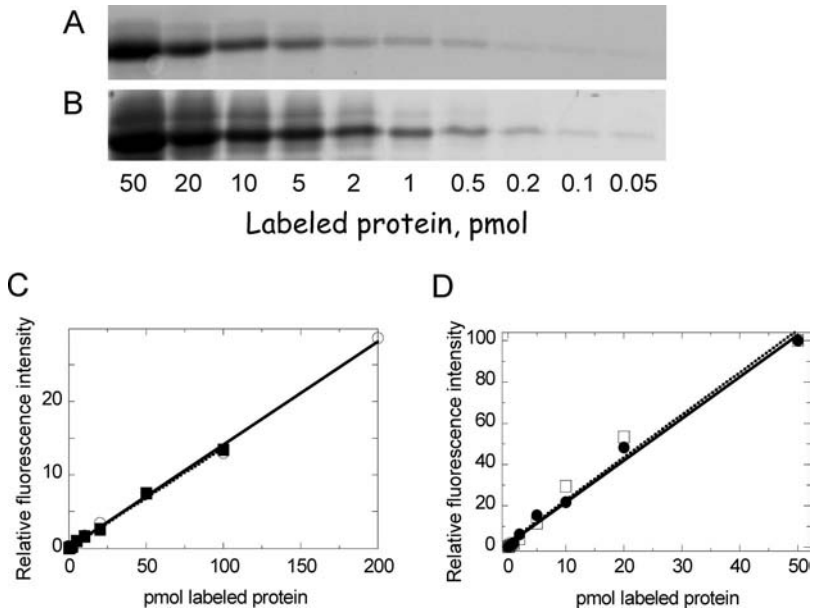

Figure 2. Visualization of labeled AhpC proteins after 1D gel electrophoresis. Varying amounts of AhpC C165S labeled with DCP-FL1 (A) or DCP-Rho1 (B) were loaded onto SDS–polyacylamide gels and resolved by electrophoresis. Gels were washed in deionized water for 30 min and then imaged on an Amersham Storm 840 for fluorescein reagents (using a 450 nm LED at normal sensitivity) or on a Typhoon 8600 fluorescence imager for rhodamine reagents (with a 633 nm red laser and Tamara 580 BP 30 filter at normal sensitivity). Relative fluorescence intensity was determined using ImageQuant software and plotted vs pmol of labeled protein for (C) DCP-FL1 (■) and DCP-FL2 (○) or for (D) DCP-Rho1 (●) and DCP-Rho2 (□).

for 16 h, reduced to dryness, and purified by flash column chromatography (gradient elution, DCM/MeOH, 93/7 to 90/10) to yield the pure product (**25**) as a purple foam (229 mg, 55.9%). R_f = 0.35 (DCM/MeOH 9/1); ^{1}H NMR (300 MHz, $CDCl_3$, δ) 7.61 (2H, bs), 7.48 (1H, bs), 7.27–7.16 (4H, m), 6.85–6.37 (3H, m), 5.20 (1H, s), 3.93 (2H, bs), 3.79 (2H, q, J = 7.0 Hz), 3.57–3.50 (10H, m), 3.34–3.23 (6H, m), 3.13 (2H, bs), 2.68 (2H, bs), 2.48 (1H, bs), 2.35 (2H, t, J = 5.7 Hz), 2.10–1.97 (2H, m), 1.75–1.57 (5H, m), 1.30–1.23 (12H, m); ^{13}C NMR (75 MHz, $CDCl_3$, δ) 201.7, 177.3, 172.7, 168.0, 158.0, 157.5, 156.3, 156.0, 135.6, 132.5, 131.4, 130.5, 130.4, 130.3, 128.0, 115.2, 114.4, 114.1, 102.4, 96.8, 96.4, 64.8, 64.5, 48.5, 46.5, 46.3, 45.1, (42.1, 41.3, 40.9, 31.6, 31.3, 30.0), 28.4, 27.0, 26.6, 26.2, 25.7, 14.5, 13.0; ESI MS *m/z* 821 $(M + H)^+$.

Rhodamine B 3-(2,4-Dioxocyclohexyl)propyl 4-Oxo-4-(piperazin-1-yl)butylcarbamate (DCP-Rho2, 26). Rhodamine B 3-(4-ethoxy-2-oxocyclohex-3-enyl)propyl 4-oxo-4-(piperazin-1-yl)butylcarbamate (**25**) (200 mg, 0.23 mmol) was solubilized in DCM (10 mL) and treated with 4 M HCl in 1,4-dioxane (1 mL). The mixture was stirred at room temperature for 6 h and then carefully neutralized by the addition of solid Na_2CO_3. The inorganic solids were filtered off and washed with 10% MeOH in DCM, and the combined filtrates were reduced to dryness. The residue was purified by flash column chromatography (2×, DCM/MeOH, 86/14 and then 88/12) to yield the product (**26**) as a purple foam (99 mg, 51.3%). ^{1}H NMR (300 MHz, $CDCl_3$, δ) 7.64 (2H, m), 7.48 (1H, dd, J = 2.8, 6.8 Hz), 7.30 (1H, dd, J = 2.6, 5.9 Hz), 7.16 (2H, q, J = 9.5 Hz), 6.89 (2H, d, J = 7.6 Hz), 6.74 (2H, bs), 5.24 (1H, s), 3.99 (2H, t, J = 6.5 Hz), 3.80 (2H, q, J = 7.0 Hz), 3.59 (8H, q, J = 7.1 Hz), 3.32 (4H, bs), 3.25 (4H, bs), 2.34 (2H, d, J = 5.3 Hz), 2.15–2.06 (1H, m), 2.04–196 (1H, m), 1.84–1.75 (1H, m), 1.69–1.49 (3H, m), 1.38–1.18 (16H, m); ^{13}C NMR (75 MHz, $CDCl_3$, δ) 201.7, 177.3, 172.7, 168.0, 158.0, 157.5, 156.3, 156.0, 135.6, 132.5, 131.4, 130.5, 130.4, 130.3, 128.0, 115.2, 114.4, 114.1, 102.4, 96.8, 96.4, 64.8, 64.5, 48.5, 46.5, 46.3, 45.1, (42.1, 41.3, 40.9, 31.6, 31.3, 30.0), 28.4, 27.0, 26.6, 26.2, 25.7, 14.5, 13.0; ESI MS *m/z* 793 $(M + H)^+$.

Generation and Labeling of Sulfenic Acid-Containing C165S AhpC and Papain for Spectral and Mass Spectrometric Analysis. The C165S mutant of AhpC, stored in 5 mM 1,4-dithiothreitol (DTT) but washed free of DTT prior to use, was purified essentially as described previously (*7*). Papain was purchased from Sigma-Aldrich and subjected to concentration and redilution in Apollo concentrators (Orbital Biosciences, Topsfield, MA; 20 kDa cutoff) before use to remove low

molecular weight contaminants. Generation of the sulfenic acid form of AhpC followed earlier procedures (*5*). The corresponding oxidized form of papain was generated by addition of 2 equiv of hydrogen peroxide under anaerobic conditions (in a 10 mL pear-shaped flask subjected to a gentle vacuum and flushed with argon multiple times).

Labeling procedures for generating the alkylated forms of AhpC and papain for subsequent mass spectrometric (MS) analysis were performed with approximately 6 nmol of the sulfenic acid-containing protein under anaerobic conditions. Reactions in either an anaerobic flask or argon-flushed Eppendorf tubes were started with the addition of 5 mM (final concentration) of the reagent of choice in a final volume of 50–100 μL. Reagents were added from a 250 mM stock predissolved in dimethyl sulfoxide (DMSO). Following incubation at room temperature for 60 min or overnight, samples were concentrated and rediluted (at least 3 times, 6 times or more for sticky fluorescein and rhodamine-based reagents) into the buffer of choice using 20 kDa cutoff Apollo ultrafiltration devices. Samples were stored at −20 °C until further use.

Spectral and Gel Analysis of Reagents and Labeled Proteins. UV–visible absorbance spectra were acquired with either an Agilent HP8452A UV–vis diode array spectrophotometer or a Beckman DU-7500 diode array spectrophotometer. Fluorescence measurements were made with either a Varian Cary Eclipse fluorescence spectrophotometer or a Tecan Safire 2 monochromator-based microplate reader. Approximate 100 or 250 mM stock solutions of DCP-FL1 or DCP-FL2 (**5** or **9**, respectively) in DMSO were in some cases standardized using the published extinction coefficient of ∼75 000 M^{-1} cm^{-1} for free fluorescein in pH 9 buffer at 491 nm (*8*). By use of this value and by comparison of the free reagents in pH 9 ammonium bicarbonate and pH 7 phosphate buffers, these reagents and presumably their protein-bound counterparts exhibited average extinction coefficients of ∼67 000 M^{-1} cm^{-1} for both fluorescein reagents. For the rhodamine-linked reagents DCP-Rho1 and DCP-Rho2 (**23** and **26**, respectively), the extinction coefficient for free rhodamine B in methanol (90 000 M^{-1} cm^{-1} at 554 nm) was used (Sigma-Aldrich data sheet); in neutral pH phosphate buffer, this extinction coefficient decreases to about 80 000 M^{-1} cm^{-1} for rhodamine B. Again, assuming the same extinction coefficient for both rhodamine reagents as for rhodamine B in methanol, DCP-Rho1 and DCP-Rho2 exhibited extinction coefficients of approximately 70 000 and 61 000 M^{-1} cm^{-1} in neutral pH phosphate buffer, respectively.

One-dimensional 12% SDS–polyacrylamide gels were electrophoresed using a BioRad Mini-PROTEAN 3 system and standard procedures. Two-dimensional gels used the Bio-Rad Protean IEF cell and Criterion gel systems from Bio-Rad, including 11 cm, pH 3–10 NL IPG strips and 8–16% gradient gels, and methods recommended by the manufacturer. Various amounts of DCP-FL1 labeled C165S AhpC were loaded onto separate strips and focused for ∼5½ h. After focusing, each strip was trimmed to within about 2 cm of the protein band (as estimated from one control strip that was stained with Coomassie blue) and then three different strips were loaded onto the top of each Criterion gel to run the second dimension. All gels were soaked in water for 30 min and then imaged for fluorescence on either an Amersham Storm 840 or a Typhoon 8600 fluorescence imager. Data were analyzed either with ImageQuant software (for 1D gels) or by direct analysis of the images with MATLAB (for 2D gels). Amounts of labeled protein loaded onto each gel were determined using the absorbance of the chromaphores attached to the protein (at 491 and 570 nm for fluorescein- and rhodamine-labeled samples, respectively) and the approximate extinction coefficients, given above. A completely independent calculation was conducted in each case using the known amount of protein and the percent modified based on mass spectral analysis of the intact protein (and an assumed recovery of 100% from the Apollo concentrators) and gave a difference in amounts of ∼10% or less.

Mass Spectrometric Analysis of Labeled Proteins and Peptides. To confirm the size and covalent attachment of each adduct, 1–2 nmol of labeled or unlabeled protein (∼60 μL) in 10 mM ammonium bicarbonate was submitted to the Analytical Chemistry Core Laboratory at Wake Forest University School of Medicine for infusion analysis on a Micromass Quattro II triple quadrupole mass spectrometer equipped with a Z-spray source. Just prior to analysis, samples were diluted 1:1 with acetonitrile and 1% formic acid was added. The data were processed and analyzed using MassLynx, version 3.5.

For MS–MS analysis of alkylated peptides, 0.5 nmol of labeled AhpC proteins was digested in 25 mM ammonium bicarbonate with 50 ng of AspN for ∼16 h at 37 °C. Peptide mixtures were analyzed with a Waters/Micromass Q-TOF API US tandem mass spectrometer equipped with a nanospray source interfaced to a Waters CapLC to detect labeled peptides and reagent-specific ions released by fragmentation. AhpC labeled with DCP-Bio1 and digested as above was also analyzed on a Thermo LTQ ion-trap mass spectrometer coupled with an Ultimate 3000 nano-HPLC system. A typical gradient was run for 60 min from 0% to 100% solvent B (80% acetonitrile, 20% H_2O, and 0.1% formic acid). Solvent A consists of 5% acetonitrile, 95% H_2O, and 0.1% formic acid. The flow rate was set at 200 nL/min on a 75 μm × 10 cm fused silica capillary column (New Objectives) in-house-packed with Michrom Magic C18AQ (200 Å, 5 μm). The analysis was performed in SIM mode where the DCP-Bio1-labeled peptide (*m*/*z* 811.77, +2 charge) was isolated for further fragmentation. Peptide identification was performed using the SEQUEST module in Bioworks suite 3.1 software.

Kinetic Studies of Reagents Reacting with Sulfenic Acid-Containing Proteins. To 5 nmol of papain in 25 mM potassium phosphate buffer at pH 7.0, with 1 mM EDTA, was added DCP-Bio1 (from a 250 mM stock solution in DMSO) at final concentrations of 0.5–5 mM and a total volume of 50 μL. The reaction was initiated with the addition of 2 equiv of hydrogen peroxide. At the appropriate incubation time, each sample was applied to a Bio-Gel P6 spin column to remove small molecules and exchange the buffer into 50 mM ammonium bicarbonate, and then the mass spectra were obtained after rapid addition of acetonitrile and formic acid and injection into an Agilent electrospray ionization (ESI)-TOF mass spectrometer. Fits of the data were carried out using KinTekSim using the model A → B → C, where A is the R–SH form, B the R–SOH form, and C the biotinylated form of papain. The pseudo-first-order rate of A → B was considered unchanging at all concentrations of DCP-Bio1 used, and the rate of B → C varied with the amount of reagent added.

RESULTS AND DISCUSSION

Synthesis of Two Fluorescein Derivatives, DCP-FL1 and DCP-FL2. Initial synthetic approaches involving the synthesis of 5(6)carboxyfluorescein did not yield separable derivatives, which prompted us to explore a different synthetic strategy utilizing commercially available fluoresceinamine isomer I (**1**). Treatment of **1** with *p*-nitrophenyl chloroformate in refluxing acetone gave carbamate derivative (**2**) in near-quantitative yield (Scheme 1). The product could be filtered from the reaction mixture and separated from unreacted starting material. TLC and NMR analyses indicated that this material could be used without additional purification. Reaction with our protected alcohol derivative of 1,3-cyclohexadione (**3**) yielded the protected fluorescein–carbamate conjugate (**4**) in moderate

yield (Scheme 1). Deprotection of the enol ether proceeded cleanly using 4 M HCl in 1,4-dioxane without concomitant carbamate cleavage to give the desired fluorescein derivative (DCP-FL1, **5**; note that the use of this abbreviation is carried over from the nomenclature previously introduced (*5*)).

Synthesis of a more stable urea derivative (DCP-FL2, **9**) involved the introduction of a urea "linker", which began with the reaction of the *p*-nitrophenyl carbamate of fluoresceinamine (**2**) with propargylamine (Scheme 2). Careful addition of 1 equiv of triethylamine induced salt formation, and the product (**6**) could be simply filtered from the reaction mixture, thus obviating the need for purification by column chromatography. Utilization of "click" chemistry (*9*) enabled us to couple the propargylurea (**6**) with the azide derivative (**7**) of our alcohol (synthesized using Mitsunobu conditions; Scheme 2) to form triazole (**8**, Scheme 2). Acid deprotection yielded the urea-linked fluorescein conjugate (DCP-FL2, **9**) in near-quantitative yield.

Synthesis of Three Biotin Derivatives: DCP-Bio1, DCP-Bio2, and DCP-Bio3. To generate the first biotinylated derivative, D-(+)-biotin was coupled with alcohol (**3**) under standard dicyclohexylcarbodiimide (DCC) coupling conditions to yield ester **10** in good yield (Scheme 3). Acid deprotection using anhydrous HCl followed by silica gel column chromatography reproducibly gave the deprotected biotin probe (DCP-Bio1, **11**) in >60% yield (Scheme 3).

Other synthetic strategies were tried to link D-(+)-biotin to our sulfenic acid-reactive compound, as the lability of the ester linkage in **11** was expected to preclude its use in cellular assays because of nonspecific esterase cleavage. On the basis of the "click" chemistry utilized in the synthesis of the fluorescein triazole conjugate (**9**), we applied this strategy to the synthesis of a biotin amide derivative (DCP-Bio2, **14**, Scheme 4). Finally, a further biotin derivative incorporating a longer linker was synthesized as depicted in Scheme 5. Mono *N*-Boc protection of 1,4-diaminobutane was carried out as previously described (*10*), followed by DCC coupling to D-(+)-biotin and Boc deprotection to give the amine hydrochloride salt (**17**, Scheme 5). Coupling of the free amine of **17** with the *p*-nitrophenyl carbonate derivative (**18**) of alcohol **3** gave the protected version of this biotin derivative (**19**, Scheme 5). Similar deprotection methods yielded the extended biotin derivative as before (DCP-Bio3, **20**, Scheme 5).

Synthesis of Two Rhodamine Derivatives: DCP-Rho1 and DCP-Rho2. The utility of cell-permeable fluorophores with spectral profiles different from that of fluorescein may permit future multiplex, differential labeling of protein sulfenic acids. The synthesis of rhodamine B derivatives was explored because rhodamine B is known to be cell-permeable (*11*), absorbs and emits at a longer wavelength than fluorescein, and has a large extinction coefficient.

The synthesis and spectral properties of rhodamine B piperazine amide (**21**) have previously been described (*12*), and this was used as a starting point in our syntheses of rhodamine B probes. Rhodamine B piperazine amide was synthesized as described and isolated as a crude iridescent purple-gold solid in 57–79% yield (**21**, Scheme 6). Coupling of compound **18** and deprotection proceeded smoothly to give the rhodamine derivative (DCP-Rho1, **23**, Scheme 6). The synthesis of a second rhodamine B derivative was undertaken as outlined in Scheme 7. The piperazine amide (**21**) was coupled, using DCC, to *N*-Boc GABA to give the extended protected derivative (**24**, Scheme 7). Deprotection of the *N*-Boc group and further coupling to the carbonate derivative (**18**) followed by enol ether deprotection yielded the second rhodamine probe (DCP-Rho2, **26**, Scheme 7).

Reactivity of Cyclohexadione-Linked Reagents toward Cysteine Sulfenic Acid. Spectroscopic Properties of Free Reagents and Protein Adducts. As described previously, the C165S mutant of AhpC, a cysteine-based peroxidase enzyme (peroxiredoxin) from *Salmonella typhimurium*, is a good test protein because of its rapid formation of the sulfenic acid intermediate at the active site (Cys46) upon oxidation by peroxides and the relative stability of this species under anaerobic condtions when the resolving cysteine (Cys165) is not present to generate the disulfide bond (*4*, *13*). By use of AhpC, all seven conjugates linked to the alcohol functional group of **3** were shown to possess approximately the same reactivity and specificity toward the cysteine sulfenic acid form of C165S AhpC as dimedone and the two conjugates previously synthesized (*5*). Papain (a cysteine-based protease) has also been used as a test protein in the studies described below because of its known propensity to form sulfenic acid at the active site cysteine (*14*, *15*).

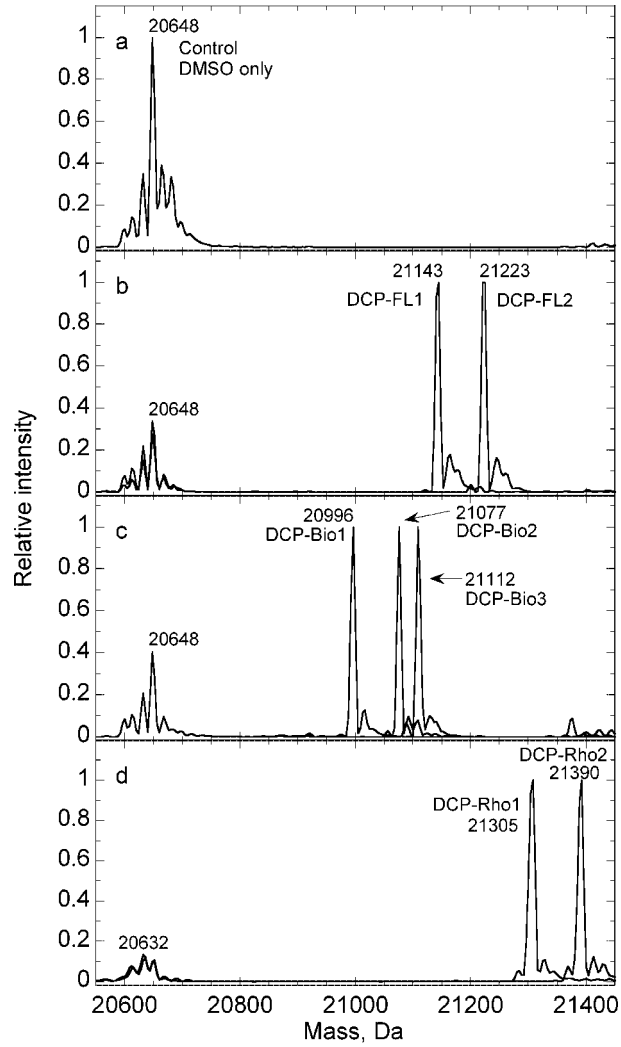

Figure 3. Electrospray ionization mass spectrometry analysis of adducts with the sulfenic acid form of C165S AhpC. The mutant of the bacterial peroxidase AhpC (C165S) containing only the peroxidatic cysteine (Cys46) but not the resolving cysteine (Cys165) that participates in disulfide bond formation was treated with hydrogen peroxide to yield the relatively stabilized sulfenic acid form of the protein under anaerobic conditions, then incubated with DMSO (a) or DMSO containing DCP-FL1 or DCP-FL2 (b), DCP-Bio1, DCP-Bio2, or DCP-Bio3 (c), or DCP-Rho1 or DCP-Rho2 (d) to yield the covalent protein adduct. The treated protein samples were washed, diluted with acetonitrile and formic acid, and analyzed by electrospray ionization mass spectrometry. Shown are the transformed data that represent the relative abundance of the prominent species of C165S AhpC. The peaks observed at 20 632 and 20 648 amu represent the protein with the active site Cys46 in the sulfinic and sulfonic acid states, respectively. Exact masses of the covalent adducts are listed in Table 1.

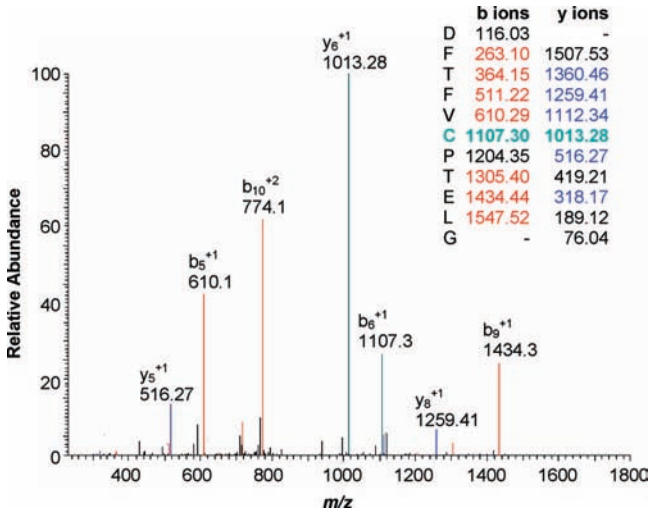

Figure 4. Nano-LC–MS/MS spectrum of the DCP-Bio1-labeled peptide of C165S AhpC containing an adduct at Cys46. The covalent adduct with DCP-Bio1 was prepared from the R–SOH form of the AhpC mutant and digested with AspN in order to generate an 11-residue peptide. The AspN digest was separated by nano-HPLC coupled to a Thermo LTQ ion trap mass spectrometer. The analysis was performed in SIM mode where the DCP-Bio1-labeled peptide (*m/z* 811.77, +2 charge) was isolated for further fragmentation. Cleavage of the amide bond results in N-terminal fragments designated as "b" and C-terminal fragments designated as "y". The masses of both sets of ions are consistent with DCP-Bio1 linked covalently to Cys46 (b6 – b5 = y6 – y5 = 497.1 *m/z*).

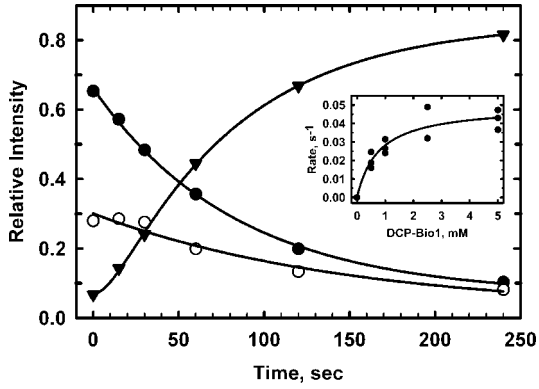

Figure 5. Kinetic studies of modification rates of sulfenic acid-containing papain with DCP-Bio1. Papain in 25 mM potassium phosphate buffer, pH 7, with 1 mM EDTA was incubated with DCP-Bio1 and 2 equiv of hydrogen peroxide, with the time of reaction taken after addition of the oxidant. At each time point a 50 μL sample containing 5 nmol of papain was applied to a Bio-Gel P6 spin column to remove small molecules and exchange the buffer into 10 mM ammonium bicarbonate. Then the mass spectra were obtained after rapid addition of acetonitrile and formic acid and injection into an an Agilent LC/MSD TOF mass spectrometer. Data plotted from one reaction with 5 mM DCP-Bio1 show the loss of the thiol form of papain (closed circles), the appearance of the covalent adduct with DCP-Bio1 (inverted triangles), and the putative sulfenic acid form (open circles) over time. Data from multiple concentrations of reagent and three independent experiments were fit to a A → B → C kinetic model as described in the text, giving a single first-order rate in this experiment of 0.024 ± 0.007 s^{-1} for formation of the sulfenic acid form of papain, and a second, saturable step with a maximal rate of 0.050 ± 0.005 s^{-1} and apparent K_m = 0.77 ± 0.24 mM for reaction of DCP-Bio1 with the sulfenic acid of papain.

The fluorescein- and rhodamine-linked reagents possess highly fluorescent chromophores that are incorporated into the target protein upon modification. Compared with free fluorescein, the DCP-FL1 and DCP-FL2 (**5** and **9**, respectively) reagents in 50 mM Tris-HCl buffer, pH 8, are partially quenched in their emission (Figure 1A) but are not shifted in their absorbance maxima (Table 1). Upon covalent attachment to protein, DCP-FL1 yields a conjugate that is further quenched in emission intensity at the peak by about 40% relative to the free reagent; under these same conditions, DCP-FL2 is not further quenched upon attachment to protein (Figure 1A). Reaction of DCP-FL1 with papain leads to even greater quenching of the fluorophore (by about 75% compared with free DCP-FL1, data not shown). For rhodamine compounds compared with rhodamine B, DCP-Rho1 (**23**) is slightly quenched in its free form but significantly quenched when covalently attached to AhpC (Figure 1B, left panel) and papain (data not shown). DCP-Rho2 (**26**) fluorescence is already significantly quenched (by about 50%) for the free reagent and largely unchanged upon attachment to either AhpC or papain proteins (Figure 1B, right panel and not shown). The quenching of fluorescence in bound DCP-Rho1 and in free and bound DCP-Rho2 is accompanied by a shift in the λ_{max} of both the excitation and emission to longer wavelengths (Table 1).

To evaluate the limit of detection and the linearity of response for the fluorophore-labeled AhpC protein, various amounts of C165S AhpC protein labeled with the different fluorescein- and rhodamine-linked reagents were analyzed in 1D and 2D polyacrylamide gels. For fluorescein, amounts as low as 0.1–0.2 pmol of protein were still detectable using a Storm 840 imager with a 450 nm LED for excitation (Figure 2A) (no improvement in sensitivity was observed using the Typhoon 8600 imager with a 532 nm laser for excitation). Furthermore, quantitation of the signal indicated linearity over at least 4 orders of magnitude (Figure 2C), even though the protein on the gel was significantly overloaded at 100 and 200 pmol (~2 and 4 μg). For comparison, 0.5 pmol was readily detected in a two-dimensional gel spot with good linearity up to at least 5 pmol (see Supporting Information, Figure S1). Gels with rhodamine-labeled AhpC showed similar, but perhaps slightly enhanced, sensitivity of detection (with a Typhoon 8600 imager and a 633 nm laser for excitation) and a reasonable degree of linearity of the signal with the amount of labeled protein loaded (parts B and D of Figure 2).

Because the biotin reagents cannot be directly observed, biotinylated protein was visualized by a Western blotting-like technique that involved transfer of the labeled proteins in the gel to nitrocellulose, addition of a 1:20000 dilution of HRP-conjugated streptavidin, and detection of HRP using the Pico chemiluminescence kit from Pierce. The limit and range of linearity for detection are thus highly dependent on the efficiency of transfer, the chemiluminescence substrate added, and the amount of time the blot is exposed to film. As with Western blots, linearity of signal with the applied biotinylated protein is over a limited range for any one exposure to a chemiluminescent reporter substrate but might be extended by obtaining multiple different exposures of a single gel. In our studies, an approximate lower limit of 0.2–0.5 pmol is typically achievable (e.g., with the Supersignal West Dura HRP detection kit from Pierce), but linearity of response must be established each time (data not shown).

Mass Spectrometry Analysis of Labeled Protein Conjugates, Intact and Proteolytically Digested. Collision-Induced Fragmentation of Label to Trigger MS–MS Sequencing. Covalent adducts of each of the probes were observed only with the sulfenic acid form of AhpC and were not generated with sulfhydryl or disulfide-containing forms of the protein; the covalent modification of AhpC with each probe was confirmed using ESI-MS analysis of the intact, labeled proteins (Figure 3 and Table 1). In each case, the higher molecular weight adduct gave a mass within 1–2 Da of the calculated masses of reduced protein (20 600 Da) plus reagent minus 2 H atoms (as expected

when the covalent bond forms) (Table 1). As shown previously, if not trapped with one of these reagents, the sulfenic acid form of AhpC undergoes further oxidation to sulfinic and sulfonic acids, presumably during incubation of the sample in acetonitrile and formic acid before MS analysis or during the analytical procedure itself (*5, 13*).

To confirm the site of AhpC modification with different probes, AspN digestion of the labeled AhpC was also carried out to generate an 11-residue peptide containing the expected cysteine site susceptible to oxidation. The peptide mixtures were analyzed using liquid chromatography and either a Q-TOF or an LTQ MS. As shown in Figure 4 and in Figure S2 of the Supporting Information, MS–MS analysis of the parent peptides gives high-quality spectra that accurately sequence the labeled peptide and confirm the presence of the covalent adduct on Cys46 of this AhpC peptide. Furthermore, for each of the fluorescein-, biotin- and rhodamine-linked adducts, a characteristic ion is detected of a mass that suggests fragmentation during collision-induced decay between the sulfur and β-carbon of the adducted cysteinyl residue (Table 1). For appropriately equipped mass spectrometers, this specific ion can be used to trigger MS–MS analysis, as was carried out for the DCP-FL1-modified peptide analyzed in the Q-TOF (Supporting Information, Figure S2). Alternatively, several analyses can be conducted with different collision energies, first to identify those peptides giving rise to the characteristic ion of interest and then in a second pass to carry out MS–MS analysis of that set of peptides.

MS-Linked Kinetic Studies of the Reactivity of DCP-Bio1 with Sulfenic Acid-Containing Proteins. To determine the rate of reaction of our reagents with the sulfenic acid forms of AhpC or papain, we used an Agilent ESI-TOF spectrometer to monitor the appearance of sulfenic acid and alkylated protein after the addition of DCP-Bio1 (or dimedone) and hydrogen peroxide. Our initial studies of C165S AhpC indicated a surprisingly slow reaction of the sulfenic acid-containing protein with dimedone; in the presence of 5 mM dimedone, the alkylated protein was generated at an initial rate of about 0.1 min^{-1}, slowing to about 0.009 min^{-1} in a second phase. During this extended incubation, the aerobic sample was also generating the further oxidized sulfinic and sulfonic acid-containing protein, complicating the kinetic analysis. On the basis of what is already known about the active site cysteine group of AhpC, the reactivity of the R–SOH group may be restricted in its "fully folded" form where the active site pocket acts as a shield against modification (*16, 17*).

We then used the same approaches to monitor the reaction of commercially available papain with hydrogen peroxide and DCP-Bio1 and discovered the alkylation reaction to be far faster than that observed between dimedone and AhpC (Figure 5). The reaction in this case is essentially complete within 5 min in the presence of 5 mM DCP-Bio1 and a 2-fold excess of hydrogen peroxide. While additional oxidized species are formed to a limited extent, these species are present at levels of less than 10% at the start of the reaction and at less than 20% at the final time point for concentrations of DCP-Bio1 down to 0.5 mM. The kinetic fits of the data are not significantly affected by ignoring these additional species; from these, the rate constant for formation of the sulfenic acid was determined to be 0.024 $\pm$ 0.007 s^{-1} in 200 μM hydrogen peroxide and potassium phosphate buffer at neutral pH and room temperature (from three independent experiments). This value (translating to a second-order rate constant of 7.2×10^3 M^{-1} min^{-1}) is in very good agreement with a previous determination, where activity loss of papain in the presence of hydrogen peroxide at pH $\sim$6 and 23 °C was found to occur with a second-order rate constant of 3.7×10^3 M^{-1} min^{-1} (*15*). As shown in Figure 5 (inset), the rate constant for modification of the sulfenic acid of papain by DCP-Bio1 increased with reagent concentration to a maximal value of $\sim$0.05 s^{-1} at 5 mM reagent. These data, from multiple reagent concentrations and three independent experiments, fit a Michaelis–Menten type of saturation curve, as is sometimes observed with irreversible inhibitors, with an apparent K_m of 0.77 ± 0.24 mM for DCP-Bio1 and a maximal rate of 0.050 ± 0.005 s^{-1} (Figure 5, inset). This implies a reversible binding step prior to irreversible modification of papain. If this represents pre-equilibrium binding followed by a slow chemical step, 0.77 mM is the K_i of the inhibitor. We had anticipated a simple bimolecular process of sulfenic acid alkylation but instead saw saturation kinetics; whether or not saturable kinetics are typically observed or are unique to papain and/or other cysteine-based proteases remains to be determined. Regarding the differences we observed between AhpC and papain reactivity, it is not surprising to find different rates of reaction in different proteins because the accessibility and stability of the sulfenic acid will vary greatly depending on its microenvironment; this species in papain appears to be far more accessible and/or reactive than that in C165S AhpC.

CONCLUSIONS

Seven new reagents bearing fluorescein, biotin, or rhodamine as detectable tags have now been generated for detection and isolation of proteins or peptides that form sulfenic acids at susceptible cysteinyl residues. These labeled species can be detected at high sensitivity upon gel analysis or can be shown by mass spectrometric analyses to incorporate the covalent label in each case. A further feature of these conjugates is their ability to release specific, detectable fragments upon fragmentation during mass spectrometric analyses that can be used to trigger MS–MS analysis for sequence determination of labeled peptides. Modification of sulfenic acids in the presence of 5 mM reagents can occur within as little as 5 min, as shown in this study for papain. These sulfenic acid-reactive reagents provide a diverse set of new tools with which we can greatly enhance our understanding of the contributions of sulfenic acid formation to protein function and cellular processes like redox signaling.

ACKNOWLEDGMENT

The authors thank Laura Soito for technical assistance and Mike Samuel for mass spectrometry analyses and acknowledge financial support from the American Heart Association Established Investigatorship program (to both L.B.P., Grant 0140175N, and S.B.K., Grant 0140020N), from the Cross Campus Collaborative Research Program at Wake Forest University (to S.B.K. and L.B.P.), and from the National Institutes of Health to L.B.P., with S.B.K., L.W.D., and J.S.F. as coinvestigators (Grant R21 CA112145). Support from the NSF-NIGMS Program in Mathematical Biology through a grant to J.S.F., with L.B.P. and L.W.D. as coinvestigators (Grant RO1 GM075304), is also acknowledged. The Quattro II tandem mass spectrometer was purchased and updated with funds from National Science Foundation (Grant BIR-9414018), the North Carolina Biotechnology Center (Grant 9903IDG-1002), and the Winston-Salem Foundation. The Waters Q-TOF mass spectrometer was purchased with funds from the National Institutes Health (Grant 1S10RR017846). The maintenance of these instruments was supported in part by the Comprehensive Cancer Center of Wake Forest University. A donation from the Dorothy Rhyne and Willard Duke Kimbrell family supported the purchase of the mass spectrometers in the CMF laboratory. The NMR spectrometers used in this work were purchased with partial support from NSF (Grant CHE-9708077) and the North Carolina Biotechnology Center (Grant 9703-IDG-1007).

Supporting Information Available: Experimental details for 2D gel analyses of DCP-FL1 modified AhpC, MS–MS analysis of the labeled peptide from that protein, and log *P* analyses for the compounds synthesized. This material is available free of charge via the Internet at http://pubs.acs.org.

A Novel Functional Translocator Protein Ligand for Cancer Imaging

Mingfeng Bai,[†] Malena B. Rone,[‡] Vassilios Papadopoulos,[‡] and Darryl J. Bornhop*[,†]

Department of Chemistry, Vanderbilt University, VU Station B 351822, Nashville, Tennessee 37235-1822, and Department of Biochemistry and Molecular and Cellular Biology, Georgetown University Medical Center, BSB Rm 315 3900 Reservoir Rd NW, Washington, D.C. 20057. Received July 6, 2007; Revised Manuscript Received September 20, 2007

The translocator protein (TSPO) is an attractive target for tumor imaging due to its up-regulation in numerous cancer cell types. Here, we report a series of functional TSPO ligands, n-TSPOmbb732, which can be conjugated to a variety of signaling moieties and are widely applicable in TSPO-targeted molecular imaging. Two fluorescent dye-labeled 6-TSPOmbb732 displayed nanomolar binding affinities to TSPO and were successfully imaged in vitro.

INTRODUCTION

The 18 kDa translocator protein (TSPO)[1] , previously known as the peripheral-type benzodiazepine receptor (PBR), has become an attractive target for cancer imaging (*1*). Overexpression of TSPO has been observed in a variety of cancers, including brain, breast, colorectal, prostate, and ovarian cancers, astrocytomas, and hepatocellular and endometrial carcinomas (*2*). TSPO is associated with a number of biological processes, such as cell proliferation, apoptosis, steroidogenesis, and immunomodulation; however, its exact physiological role still is not clear.

Several TSPO-selective ligands have been developed, including the diazepam derivative (Ro5–4864), the isoquinoline derivative (PK11195), the 2-acryl-3-indoleacetamide derivative (FGIN-1), and the phenoxyphenyl–acetamide derivative (DAA-1106) (*3, 4*). DAA1106 has become an attractive TSPO ligand, because it has higher binding affinity for TSPO than PK11195, Ro5–4864, and FGIN1. DAA1106 has been shown to displace TSPO-complexed PK11195 and Ro5–4864 at a very low concentration (10^{-15}–10^{-12} M), however, 0.1–1 μM amounts of PK11195, Ro5–4864, or FGIN1 were necessary to displace DAA1106 (*5*). Although promising, TSPO studies using DAA1106 have been limited because the molecule is not easily functionalized.

A conjugable analogue of DAA1106, which can be coupled to a variety of signaling moieties, would be a valuable tool for studying TSPO function. Even though DAA1106 labeled with ^{11}C, ^{3}H, and ^{18}F have been used to study TSPO activity, these labels are limited by their short half-lives and low surface resolution during imaging (*6–8*). Furthermore, biological studies using tritium are cumbersome, expensive, time-consuming, and create radioactive waste. Conjugable analogues of PK11195 and Ro5–4864 were developed previously and labeled with a fluorescent dye (*9–11*). Unfortunately, the binding affinities of the imaging agents were rather low (1 μM for PK11195 analogue and 2.6 μM for Ro5–4864 analogue).

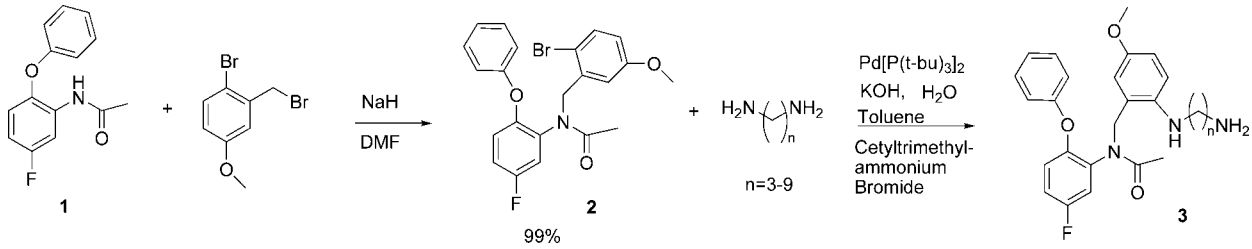
Table 1. *n*-TSPOmbb732 Reactions Summary

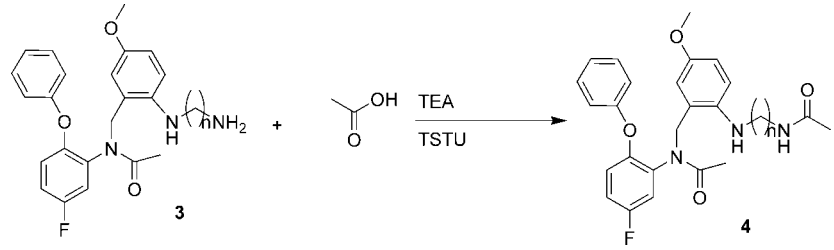
n-TSPOmbb732	reaction time (h)	yield (%)
3-TSPOmbb732	3	12.7
4-TSPOmbb732	2	7.9
5-TSPOmbb732	2	10
6-TSPOmbb732	6	33
7-TSPOmbb732	2.5	12
8-TSPOmbb732	2.5	5.8
9-TSPOmbb732	2.5	11

In the current study, a conjugable analogue of DAA1106, *n*-TSPOmbb732 (*n* is the number of carbons on the linker) was synthesized and characterized. The analogue has a terminal amino group that facilitates coupling reactions. Two fluorescent dyes, IRDye 800CW NHS ester (LI-COR Biosciences, ε =300 000 L/mol cm in methanol) and Lissamine rhodamine B sulfonyl chloride (Invitrogen, ε =88 000 L/mol cm in methanol) were selected as signaling moieties for conjugation to *n*-TSPOmbb732. As presented here, the resulting molecules have nanomolar binding affinities to TSPO and target TSPO in vitro.



EXPERIMENTAL PROCEDURES

Synthesis. *N-(2-Bromo-5-methoxybenzyl)-N-(5-fluro-2-phenoxphenyl)acetamide (***2***).* To a dry round-bottom flask was added anhydrous DMF (10 mL) and sodium hydride (100 mg), followed by *N*-(5-fluoro-2-phenoxyphenyl)acetamide **1** (1.08 g, 4.4 mmol). After the solution was stirred for 15 min, 2-bromo-5-methoxybenzyl bromide (1.4 g, 5.0 mmol) was added. After another 30 min, the reaction was added to stirring water chilled to 0 °C (60 mL). The mixture was extracted with dichloromethane three times. The organic solutions were combined, dried over sodium sulfate, and evaporated to dryness. The residue was chromatographed (silica gel) using 1:3 ethyl acetate/hexanes as the eluent to yield compound **2** as a yellow oil (1.94 g, 99%). ^{1}H NMR 300 MHz ($CDCl_3$) δ 7.29–7.33 (m, 3H), 7.12 (t, J = 7.6 Hz, 1H), 7.02 (d, J = 3.2 Hz, 1H), 6.80–6.96 (m, 5H), 6.62 (dd, J = 8.4, 2.8 Hz, 1H), 4.96 (AX, J = 15.2 Hz, $\Delta\nu$ = 178 Hz, 2H), 3.66 (s, 3H), 2.00 (s, 3H). MS $(ESI)^+$ $[M + H]^+$ calcd 444.1, found 444.3.



*General Method for n-TSPOmbb732 (***3***) Synthesis.* Pd[P(t-Bu)$_3$]$_2$ (102 mg, 0.2 mmol), cetyltrimethylammonium bromide (36 mg, 0.1 mmol), potassium hydroxide (842 mg, 15 mmol), and diamine (30 mmol) were mixed in toluene (4 mL) under argon. **2** (4.44 g, 10 mmol) in toluene (6 mL) and water (270

μL, 15 mmol) were added to the mixture by syringe. The flask was sealed with a septum, and the reaction mixture was stirred vigorously at 90 °C for 2–6 h, depending on the length of linker. The reaction then was concentrated by vacuum and purified by column chromatography using 9:1:0.1 methylene chloride/methanol/ammonium hydroxide on silica gel to yield *n*-TSPOmbb732 as a colorless oil. The optimal reaction time and yields of each *n*-TSPOmbb732 are listed in Table 1.

3-TSPOmbb732 (Y = 8.7%). NMR data are not shown because diastereomers could not be separated. MS (ESI)$^+$ [M + H]$^+$ calcd 438.2, found 438.2.

4-TSPOmbb732 (Y = 7.9%). NMR data are not shown because diastereomers could not be separated. MS (ESI)$^+$ [M + H]$^+$ calcd 452.2, found 452.3.

*General Method for n-TSPOmbb732 Amide (**4**) Synthesis.* A mixture of acetic acid (1.6 μL, 27.5 μmol), triethylamine (TEA) (50 μL) and 2-succinimido-1,1,3,3,-tetramethyluronium tetrafluoroborate (TSTU) (8.3 mg, 27.5 μmol) in anhydrous methylene chloride (1 mL) was stirred at room temperature under argon for 3 h. A solution of **3** (25 μmol) in anhydrous methylene chloride (1 mL) was added to the mixture, and the mixture was stirred for another 2.5 h. The reaction solution was then concentrated by vacuum rotary evaporation, and the product was purified via silica gel column chromatography using 3% methanol in methylene chloride as eluent. *n*-TSPOmbb732 amide was collected as a colorless oil.

3-TSPOmbb732 Amide. ^{1}H NMR 300 MHz ($CDCl_3$) δ 7.27 (t, J = 7.5 Hz, 2H), 7.10 (t, J = 7.2 Hz, 1H), 6.71–6.84 (m, 3H), 6.63 (d, J = 7.5 Hz, 2H), 6.40 (d, J = 8.7 Hz, 1H), 6.19 (d, J = 2.7 Hz, 1H), 6.04 (br s, 1H), 5.12 (br s, 1H), 4.77 (AX, J = 14.4 Hz, $\Delta\nu$ = 36.9 Hz, 2H), 3.61 (s, 3H), 3.29 (q, J = 6.3 Hz, 2H), 2. 94–3.13 (m, 2H), 1.97 (br s, 6H), 1.75–1.79 (m, 2H), 1.67 (br s, 1H). IRDye 800CW-6-TSPOmbb732 (NIR6T). IRDye 800CW NHS ester (3 mg, 2.6 μmol) and 6-TSPOmbb732 (3 mg, 6.3 μmol) were mixed in DMSO (7 mL) in a round-bottom flask and stirred under argon flow for 1 h. HPLC analysis was performed on a Varian Polaris C-18 column (250 × 4.6 mm) at a flow rate of 0.8 mL/min. Flow A was 0.1% TEA in water and flow B was 0.1% TEA in acetonitrile. The elution method for analytical HPLC started with a linear gradient from 100% to 70% A over 20 min, continued to 50% A over 5 min, arrived at 20% A in another 10 min, held at 20% A for 3 min, and finally returned to 100% A over 1 min. The elution profile was monitored by UV absorbance at 254 and 780 nm. The product was purified by preparative HPLC using a Varian Polaris C-18 column (250 × 21.2 mm) at 12 mL/min. The collected solution was concentrated by vacuum rotary evaporation, frozen to −78 °C, and dried using a freeze–dry system. NIR6T was collected as a dark green solid (1.2 mg, 31%). ^{1}H NMR 500 MHz (MeOD) δ 7.99–7.91 (m, 3H), 7.86–7.78 (m, 6H), 7.34 (d, J = 8.0 Hz,

Lissamine-6-TSPOmbb732 (Liss6T). A mixture of Lissamine rhodamine B sulfonyl chloride (10 mg, 17 μmol), 6-TSPOmbb732 (10 mg, 20 μmol), and triethylamine (15 μL) in dichloromethane (1.6 mL) was stirred under argon at room temperature for 1 h. The reaction solution was concentrated by vacuum rotary evaporation, and the crude product was purified through column chromatography (silica gel) using a 19:1 dichloromethane/methanol solution to yield Liss6T as a pink solid (isomer I, 5.7 mg, 32%; isomer II, 4.7 mg, 27%). ^{1}H NMR 400 MHz ($CDCl_3$) isomer I: δ 8.84 (s, 1H), 7.98 (d, J = 7.6 Hz, 1H), 7.30–7.24 (m, 3H), 7.19 (d, J = 7.6 Hz, 1H), 7.08 (t, J = 7.2 Hz, 1H), 6.93–6.90 (m, 2H), 6.78 (t, J = 8.8 Hz, 3H), 6.70 (dd, J = 8.4,

Isomer II: δ 8.72 (s, 1H), 8.36 (d, J = 7.2 Hz, 1H), 7.27–7.18 (m, 5H), 7.08 (t, J = 7.6 Hz, 1H), 6.95–6.89 (m, 2H), 6.87–6.85 (m, 3H), 6.79–6.76 (m, 1H), 6.71 (d, J = 2.4 Hz, 2H), 6.65 (d, J = 8.0 Hz, 2H), 6.20 (d, J = 2.8 Hz, 1H), 6.05–6.00 (m, 1H), 4.77 (s, 2H), 3.62–3.56 (m, 11H), 3.32–3.27 (m, 1H), 3.02–2.96 (m, 1H), 2.96–2.91 (m, 3H), 2.85–2.79 (m, 2H), 1.95 (s, 3H), 1.52–1.42 (m, 4H), 1.32 (t, J = 7.2 Hz, 12H), 1.15–1.11 (m, 3H). MS (ESI)$^+$ $[M + H]^+$ calcd 1020.4, found1020.4. R_f 0.39 (isomer I), 0.32 (isomer II) (6% methanol in dichloromethane).

Spectroscopic Characterization. Upon preparing NIR6T and Liss6T, absorption and emission spectra were obtained at room temperature with a Shimadzu 1700 UV–vis spectrophotometer and ISS PTI spectrofluorometer, respectively. NIR6T was found to have an absorption maximum at 778 nm and fluorescence maximum at 800 nm in methanol. The two isomers of Liss6T have similar absorption maxima (isomer I at 561nm and isomer II at 563nm) and that same fluorescence maximum at 583 nm.

Binding Studies. C6 glioma cells were cultured in Dulbecco's modified Eagle medium (DMEM)-F12 medium (Gibco/Invitrogen) supplemented with 0.5% FBS and 2.5% horse serum (HS) at 3.7% CO_2. Cells were scraped from 150 mm culture dishes into 5 mL phosphate buffered saline (PBS), dispersed by trituration, and centrifuged at 500× g for 15 min. Cell pellets were resuspended in PBS and assayed for protein concentration. [^{3}H]PK 11195 binding studies on 30 μg of protein from cell suspensions were performed as previously described (*15*). Displacement studies using increasing concentrations of synthesized TSPO ligands were performed in the presence of 15 nM [^{3}H]PK11195. Data were analyzed using *PRISM* software (v 4.0, GraphPad, Inc., San Diego, CA).

Cell Imaging. MDA-MB-231 mammary adenocarcinoma breast cancer cells or C6 rat glioma cells in MaTek dishes were incubated with 1 μM NIR6T and 1 μM Liss6T in culture media for 30 min. 1 nM MitoTracker Green was then added to the plate and incubated for another 10 min. Cells were rinsed and reincubated with saline before imaging using a Nikon epifluorescence microscope equipped with a Hamamatsu C4742–98 camera, Nikon Plan Apo 60×/1.40 oil objective, a mercury lamp, an ICG filter set (excitation 750–800 nm; emission 815–875 nm), a Texas Red filter set (emission 600–660 nm), and a FITC filter set (emission 513–548 nm). Cell uptake of NIR6T and Liss6T was observed in fluorescence images of both cell lines (Figures 5 and 6), while the controls exhibited no significant fluorescence (Supporting Information Figures S1 and S2).

In Vitro Competition. C6 glioma cells were plated in MaTek dishes. The growth media was removed and replaced with media containing the contrast agent. Unchallenged C6 cells were dosed with 1 μM NIR6T or Liss6T. Challenged cells were dosed with 1 μM NIR6T/Liss6T and 10 μM DAA1106. DAA1106 was synthesized in our laboratory as reported (*12*). All cells were incubated for 30 min at 37 °C under 5% CO_2. At the end of the incubation time, cells were rinsed with cell media three times and imaged under a Nikon Eclipse TE2000-U microscope (Lewisville, TX).

RESULTS AND DISCUSSION

The *n*-TSPOmbb732 synthetic pathway is shown in Scheme 1 Compound **1** was synthesized as previously reported (*12*). The alkylation reaction of **1** with 2-bromo-5-methoxybenzyl bromide was straightforward and produced compound **2** at 99% yield. The following aromatic substitution of a diamine (with a 3–9 carbon linker) resulted in relatively low yield (6–33%). This was due to several byproducts and decomposition of the desired product prior to reaction completion. The optimal reaction time for the *n*-TSPOmbb732 reaction is listed in Table 1.

The effect of spacer length on the binding affinity of the *n*-TSPOmbb732 was also investigated. More specifically, *n*-TSPOmbb732 with 3–9 carbon spacers was synthesized, characterized, and used in a competitive binding assay. The amino group was capped by an acetyl group to reduce nonspecific binding (Scheme 2). The binding affinity data are shown in Table 2. *n*-TSPOmbb732 with a three-carbon linker (3-TSPOmbb732) (IC_{50} = 0.39 μM) and 7-TSPOmbb732 (IC_{50} = 0.40 μM) have higher binding affinities than 4-TSPOmbb732 (IC_{50} = 0.80 μM) and 5-TSPOmbb732 (IC_{50} = 0.84 μM), but relatively low binding affinities compared to 6-TSPOmbb732 (IC_{50} = 0.29 μM), 8-TSPOmbb732 (IC_{50} = 0.24 μM) and 9-TSPOmbb732 (IC_{50} = 0.29 μM). Even though these binding affinities are much lower than DAA1106 (IC_{50} = 0.28 nM) and [^{11}C]DAA1106 (IC_{50} = 0.91 nM), the nanomolar binding affinities (K_i = 43–149 nM) appeared rather promising (*12, 13*). A six-carbon linker seemed to be the most optimal due to its relatively high binding affinity and yield (33%) of 6-TSPOmbb732.

NIR probes capable of targeting specific receptors are attractive noninvasive imaging tools for preclinical diagnosis (*14*); therefore, we conjugated our relatively high binding affinity TSPO-targeted ligand, 6-TSPOmbb732, to IRDye 800CW NHS ester. The reaction was straightforward, but the dye conjugation reaction yield was relatively low (31%), mainly due the impurities in the dye sample and side reactions.

HPLC was used to monitor the production of IRDye 800CW-6-TSPOmbb732 (NIR6T). The chromatographs for both the NIR dye and NIR6T at 780 nm are shown in Figure 2 (left). Figure 2 (right) shows the excitation and emission spectra. The excitation of NIR6T at 778 nm and its subsequent NIR emission at 800 nm allow deep tissue penetration with reduced absorption and scattering for in vivo imaging.

Lissamine rhodamine B sulfonyl chloride also was used to conjugate 6-TSPOmbb732 (Liss6T). Lissamine is optimized for the commonly used Texas Red filter set and is well-known for providing high-quality images. Since the commercially available Lissamine dye has two isomers, the conjugation reaction yielded two isomers as well. The spectroscopy curves are shown in Figure 3. Isomer I, which has a higher molar extinction coefficient (ε = 124 000 L/mol cm in methanol) than isomer II (ε = 80 000 L/mol cm in methanol), was selected for imaging.

Both NIR6T ($K_i = 42$ nM) and Liss6T ($K_i = 0.91$ nM) have nanomolar binding affinities to TSPO (Table 2). Conjugation of NIR dye to 6-TSPOmbb732 did not seem to affect the binding affinity significantly; however, Liss6T has significantly higher binding affinity than both NIR6T and 6-TSPOmbb732 amide. This is probably because lissamine dye contributed in the binding mode of Liss6T to TSPO whereas NIR dye did not.

Two cell lines we chose for in vitro imaging are MDA-MB-231 (human metastatic mammary adenocarcinoma) and C6 (rat glioma) cells. Both types of cells overexpress TSPO. Glioma is a type of primary central nervous system (CNS) tumor that arises from glial cells. Currently, surgery is the most effective treatment for glioma. However, unlike most other types of tumors, glioma is infiltrated, which makes it extremely challenging to determine the diseased area. Glioma cell targeted molecular imaging agent that can specifically label glioma cells would be important to guide surgery. Breast cancer is the second most commonly diagnosed cancer among women. Early detection of breast cancer is very important for survival. Currently, breast cancer is usually screened by X-ray. In this process, the breast has to be compressed very hard. In addition, the breast will be exposed to high radiation. Breast cancer targeted optical probe would make optical mammography possible, which does not require breast compression and involves no radiation.

Fluorescence microscopy imaging studies were then performed to investigate the cellular uptake of NIR6T and Liss6T in MDA-MB-231and C6 cells. Accumulation of both agents in these cells was observed (Figures 4 and 5). To demonstrate mitochondrial binding of the dyes, cultures were coincubated with MitoTracker Green, a mitochondrial marker, and our two molecules. Overlaid pictures demonstrate colocalization of all three molecules, which suggested that the optical probes preferentially bind to mitochondria, the primary site of TSPO expression. Furthermore, cells incubated with free dyes (IRDye 800CW acid or Lissamine rhodamine B sulfonyl chloride) did not show significant fluorescence (data shown in Supporting Information). The nanomolar binding affinities of NIR6T and Liss6T provided further evidence for the selective binding.

The specificity of NIR6T and Liss6T to TSPO is further verified by in vitro competition study. In this experiment, C6 glioma cells were treated with 1 μM NIR6T/Liss6T and 10 μM DAA1106 as competitor. Challenged cells showed reduced fluorescence signal compared to unchallenged cells (Figure 6 and 7). Taken together, these data suggest that NIR6T and Liss6T are promising TSPO targeted MI agents.

CONCLUSION

In conclusion, we have synthesized a functional TSPO ligand, *n*-TSPOmbb732, which can be conjugated to a variety of signaling moieties and widely applied for TSPO targeted cancer imaging. In addition, this DAA1106 analogue has been labeled with two fluorescent dyes, and the resulting imaging probes, NIR6T and Liss6T, display nanomolar binding affinities to TSPO and have been successfully imaged in vitro.

ACKNOWLEDGMENT

Magnetic Relaxation Switch Detection of Human Chorionic Gonadotrophin

Grace Y. Kim,[†,△] Lee Josephson,[‡] Robert Langer,[§] and Michael J. Cima*[,△]

Harvard–MIT Division of Health Sciences and Technology, Cambridge, Massachusetts, Center for Molecular Imaging Research, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, Department of Chemical Engineering and Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts. Received April 2, 2007; Revised Manuscript Received June 14, 2007

Functionalized nanoparticle contrast agents, also known as magnetic relaxation switches (MRS), were prepared to detect protein A and the β subunit of human chorionic gonadotrophin (hCG-β). Antibodies were attached to cross-linked iron oxide (CLIO) nanoparticles using standard peptide chemistry. Protein A was used as a simple model analyte, as it is naturally multivalent and can bind multiple CLIO-IgG simultaneously. The addition of PA to CLIO-IgG resulted in transverse relaxation time (T_2) shortening compared to a blank control as seen by NMR relaxometry measurements. Analyte-induced aggregation was confirmed by light scattering particle size analysis. A two-particle system was designed to measure hCG-β, as it is not multivalent and requires conjugation of a matched pair of monoclonal antibodies to CLIO (referred to as C95 and C97). Measurement of hCG-β is important, as elevated serum levels are associated with malignancies including testicular and ovarian cancers. The addition of hCG-β to C95 and C97 resulted in T_2 shortening with a linear dynamic concentration range of 0.1 to 1 molecules of analyte per nanoparticle. Similar data were obtained for the hCG dimer. Observations with higher stoichiometric ratios of analyte to nanoparticle and increased nanoparticle valency were also made. This method can potentially be adapted to detect other biomarkers in solution.

INTRODUCTION

Magnetic resonance imaging (MRI) has an important clinical role in the detection and monitoring of cancerous masses. Molecular imaging contrast agents have enhanced these abilities beyond imaging shrinking and growing tumor borders to reporting on the presence and state of additional targets of interest (*1*). Recently, a modification of paramagnetic nanoparticle contrast agents has been used for diagnostic measurements of specific targets, including DNA (*2*), viruses (*3*), cells (*4*), and ions (*5*). The sensitivity of detection varies from 10^{-21} M for DNA to 10^{-6} M for Ca^{2+} depending on a variety of factors, including binding affinity, particle concentration, and sensor format. These particles are called magnetic relaxation switches (MRS) because they "switch" from dispersed to aggregated in the presence of a target molecule or analyte. The aggregation is accomplished by the presence of functional groups on the particle surface that have an affinity for the analyte. The change of state from dispersed to aggregated affects the transverse relaxation time (T_2) of the aqueous medium that surrounds the particles. Thus, aggregation can be detected by magnetic means, enabling measurements in turbid and opaque solutions as well as real-time measurements in patients. Magnetic detection, therefore, has a distinct advantage over optical or electrochemical assays (*6, 7*).

Here, we report the detection of protein A (PA) and human chorionic gonadotrophin (hCG) by functionalized magnetic cross-linked iron oxide nanoparticles (CLIO). PA is a stable cell surface receptor that is naturally multivalent and serves as a simple model system for aggregation. One PA molecule can bind to the Fc portion of least two molecules of IgG at the same time, and thus forms a simple aggregating system. Other proteins, however, may not naturally be multivalent and require a matched pair of antibodies to form a "sandwich"with the analyte in the middle, similar to an ELISA. Detection of hCG requires such a strategy to form networked aggregates, since hCG is not multivalent (Figure 1a). hCG is a heterodimer, consisting of an α and β subunit. Many other hormones share a similar structure to hCG-α, whereas the hCG-β serum level is elevated in testicular and ovarian cancers and locally elevated in cystic fluid and ascites often to concentrations greater than in serum (*8, 9*). It is one of the more well-characterized soluble cancer biomarkers, as it is also a pregnancy marker.

Aggregation of multivalent systems is actively being studied (*10–12*). Functional group balance is important in the formation of aggregates (*12*). An optimum ratio of particle to analyte exists where the analytes form interparticle bridges between two nanoparticles. A network or branched aggregate can be created if the nanoparticle has more than one receptor (Figure 1c). In the low analyte regime, there is insufficient analyte to cause aggregation and very few bridges are created (Figure 1b). High concentrations of analyte will, however, saturate the receptors and prevent cross-linking of nanoparticles (Figure 1d). This phenomenon is known as the prozone effect or high-dose hook effect and is a limitation of all agglutination assays.

MATERIALS AND METHODS

Nanoparticle Conjugation. Magnetic iron oxide nanoparticles with amine-terminated dextran shell (CLIO-NH_2) were produced as described previously (*13*). CLIO-NH_2 was treated with sulfo-succinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (Sulfo-SMCC, Pierce, Rockford, IL) to create a maleimide functional group. Antibodies (Mouse IgG, Sigma;

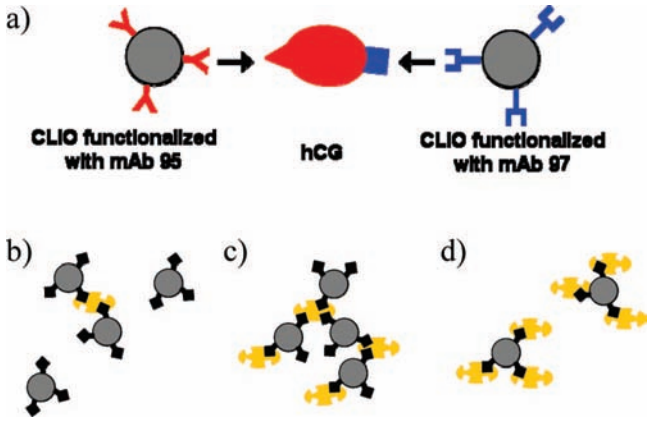

Figure 1. (a) Schematic of hCG aggregation. C95 and C97 recognize a separate epitope on hCG. Aggregation also occurs with hCG-β subunit. (b−d) Schematics of the effect of increasing analyte to particle ratio. Adapted from Costanzo (*12*). (b) Low analyte to particle ratio causes insufficient aggregation for detection. (c) The range of aggregate formation relies on a stoichiometric balance of analyte to particle. (d) The prozone effect is seen at high analyte to particle ratio, where analytes have saturated the particles such that cross-linking of particles is impaired.

anti-HCG-β, Scripps Laboratories, San Diego, CA) were activated with *N*-succinimidyl-*S*-acetylthioacetate (SATA, Pierce) to generate a blocked sulfanyl group which was deprotected with hydroxylamine. The CLIO-SMCC was incubated with the prepared antibody solutions for 4 to 8 h at 4 °C. The reaction was quenched with 2-sulfanylethanol and purified with a Sephacryl 300 column (Sigma). Iron concentrations were determined by absorbance at 410 nm after 1 h incubation in 6 N HCl and H_2O_2 to dissolve CLIO. Protein concentrations were determined by bicinchoninic acid assay (Pierce). The protein concentration was divided by the iron concentration to estimate the number of antibody conjugated to each nanoparticle, assuming 8000 iron molecules per CLIO (*14*). Anti-hCG-β monoclonal antibody-conjugated CLIO are referred to by a shortened form of their product numbers, C95 and C97. The antibodies for C95 and C97 are a matched pair to separate, nonoverlapping epitopes on hCG-β, with K_d values of 10^{-10} M and 5×10^{-9} M, respectively. A second batch of each conjugate, C95–2 and C97–2, was produced by starting with a 3-fold volumetric scaleup of reactants.

Determination of Proton Relaxation Times. Proton relaxation time measurements were performed at 0.47 T and 40 °C (Bruker NMR Minispec, Billerica, MA). Samples were incubated at 40 °C for 1 h for thermal equilibration before measurements were taken. Relaxivities were determined as the slope of a plot of $1/T_2$ or $1/T_1$ (s^{-1}) as a function of the iron concentration (mM).

Aggregation experiments were performed by mixing equal volumes of nanoparticle solutions and analyte solutions. The mixture was incubated at 40 °C for 1 h for thermal equilibration before measurements were taken. CLIO-IgG nanoparticles were mixed with various PA concentrations. An equal mixture of C95 and C97 (C95/C97) or C95–2 and C97–2 (C95–2/C97–2) solutions were used for hCG-β and hCG detection. Analyte dilutions of PA (Sigma, 45 kDa), hCG-β (Scripps Laboratories, 28 kDa), or hCG (Sigma, 37.9 kDa) were prepared in phosphate buffered saline pH 7.4 with 1% penicillin−streptomycin and 0.1% or 1% bovine serum albumin (PBS) to reduce nonspecific adsorptive loss of analyte. Reported concentrations are the final analyte concentrations obtained after mixing. Stability measurements were obtained by measuring relaxation times after incubation at room temperature. Data were plotted as average relaxation time ± standard deviation.

Table 1. Characterization of CLIO Conjugates

sample	analyte	R_2 relaxivity $(mM \cdot s)^{-1}$	R_1 relaxivity $(mM \cdot s)^{-1}$	valency (# Ab per CLIO)
CLIO	n/a[a]	54.2	21.53	n/a
CLIO-IgG	Protein A	47.0	n/m[b]	3.6
CLIO-95 (C95)	hCG-β, hCG	44.1	n/m	2.2
CLIO-97 (C97)	hCG-β, hCG	44.9	n/m	3.1
CLIO-95–2 (C95–2)	hCG-β, hCG	67.9	17.8	4.1
CLIO-97–2 (C97–2)	hCG-β, hCG	76.4	20	4.5

[a] n/a - not applicable. [b] n/m - not measured.

Dynamic Light Scattering. Particle sizes were determined using a 90 Plus Particle Size Analyzer (Brookhaven Instrument Corporation, Holtsville, NY). Samples were measured at 37 °C in PBS, $\lambda = 658$ nm, 90° fixed angle. The log-normal intensity-weighted effective diameter was reported. Population distribution was determined by peak integration of the volume-weighted scattering intensity.

RESULTS

CLIO Conjugation and Characterization. Five batches of CLIO-NH_2 were conjugated with antibodies. The relaxivity and valency of the unconjugated CLIO-NH_2 and conjugated CLIO are reported in Table 1. The relaxivities of conjugated CLIO are similar to those of unconjugated CLIO-NH_2. The same initial concentration of antibody was used in all conjugations. No specific attempt was made to increase the degree of conjugation; however, C95–2 and C97–2 resulted in higher valencies than C95 and C97, yielding approximately 1 to 2 more antibodies per nanoparticle.

CLIO-IgG + Protein A Aggregation. CLIO-IgG was used as a simple model system to assess the conjugation scheme and aggregate formation without the need for a matched pair of antibodies to two nonoverlapping epitopes on the analyte. CLIO-IgG were mixed with PA solutions. The T_2 relaxation time of a CLIO-IgG + PBS control was 101 ± 7 ms. Lower T_2 values were observed when CLIO-IgG was mixed with PA solutions varying from 0.1 to 8 μg/mL. T_2 decreased with PA concentration, and the largest change was seen at 2 μg/mL PA (27%) (Figure 2a). Concentrations between 0.1 and 2 μg/mL correlate with the dynamic concentration range of CLIO-IgG for the given CLIO concentration (Figure 1c). The response flattens at the higher concentrations tested. CLIO-IgG of a higher nanoparticle concentration resulted in the same trend with T_2 decreases up to 40% (data not shown).

The change in T_2 upon addition of PA was attributed to PA-induced aggregation of CLIO-IgG. The formation of aggregates was confirmed by measurements of the particle size (Table 2). The mean particle size of the CLIO-IgG was 52.3 nm. PA solution alone showed no detectable particles by light scattering. Two peaks were observed 2 min after mixing CLIO-IgG and PA to a final PA concentration of 2 μg/mL. The major particle population with a size of 76.1 nm comprised 90% of the volume-weighted scattering efficiency, and the remainder of the population was a size of 620 nm. The initial bimodal distribution formed indicates that some particles react extensively to create large aggregates while the smaller 76.1 nm population may comprise single CLIO-IgG nanoparticles or CLIO-IgG:PA complexes. The time for temperature equilibration required for accuracy precludes rapid T_2 measurements with the current benchtop NMR relaxometer setup; however, uncalibrated measurements of room-temperature samples suggest that T_2 is sensitive to the formation of small populations of aggregates as quickly as it can be measured. This further implies that the small aggregates formed in the initial minutes to hours contribute to the majority of the T_2 changes. The aggregates grow such that nearly half of the particles were in an aggregate at 24 h. These aggregates remain stable up to 5 days at room temperature

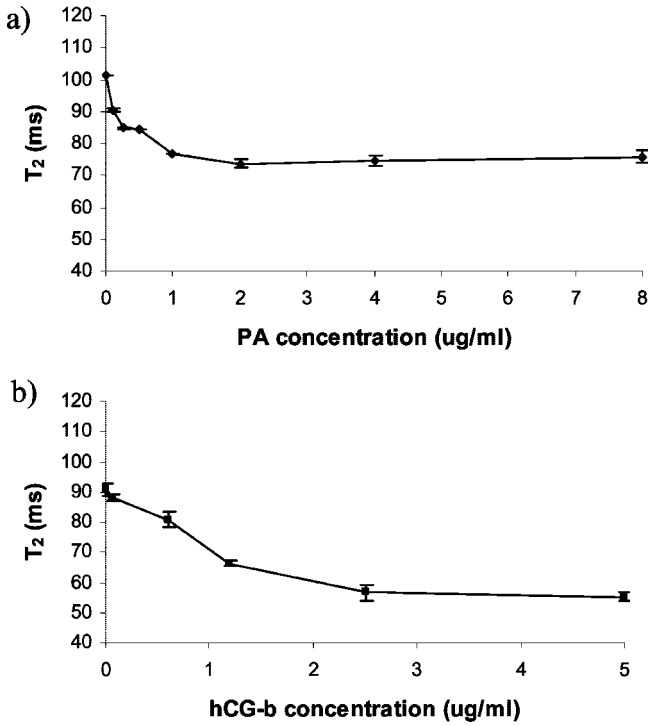

Figure 2. (a) CLIO-IgG's were incubated with various concentrations of protein A. Aggregation of CLIO-IgG is indicated by the decrease in T_2. (b) C95/C97 were incubated with various concentrations of hCG-β. T_2 decreased with increasing concentrations of hCG-β. The data are plotted as averages ± standard deviation ($n = 4$). All concentrations refer to final concentrations after incubation.

Table 2. Particle Size Measurements of CLIO-IgG + Protein A[a]

time	population 1		population 2	
	size (nm)	percent of sample	size (nm)	percent of sample
no analyte	52.3	100	–	–
2 min	76.1	89.7	619.8	10.3
1 day	97.9	58.7	375.5	41.3
5 days	63.4	55.1	551.9	44.9

[a] Particle size analysis of CLIO-IgG upon addition of protein A (final concentration 2 μg/mL). Population distribution was determined by peak integration of the volume-weighted scattering intensity. No particles were detected in PA solution alone.

as confirmed by particle size measurements and NMR relaxometry. T_2 values varied by 6% for 2 μg/mL PA concentration examined by particle sizing (Table 2) over this time period. A variation in T_2 of 6–12% was observed for all other PA samples.

SATA, a nonsite-specific coupling agent, has the potential to interfere with some antibody functionality, but the formation of PA-induced aggregates confirms that sufficient antibody functionality is retained with this conjugation reaction. Higher antibody functionality may be achieved with site-specific coupling such as mercaptoethylamine, which directs modification away from the antibody binding region.

CLIO-95/CLIO-97 Aggregation. CLIO-95/CLIO-97 blends were mixed with various hCG-β concentrations. The T_2 relaxation time of C95/C97 + PBS control was 91 ± 2 ms (Figure 2b). T_2 varied inversely with the amount of hCG-β, with the largest decrease observed at a concentration of 5 μg/mL ($T_2 = 55 \pm 2$ ms, 40% decrease). The change in T_2 was attributed to hCG-β induced aggregation with an apparent dynamic concentration range of 1 order of magnitude. These aggregates were stable over 6 days at room temperature (data not shown). A change in T_2 was found with the addition of hCG-β or hCG. Furthermore, hCG added to C95 alone or C97

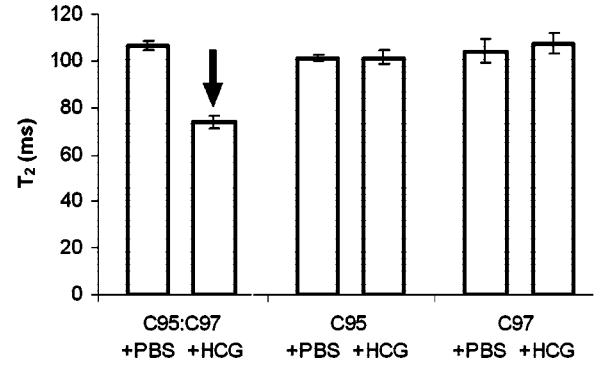

Figure 3. C95/C97 solutions were incubated with PBS or hCG. T_2 shortening is observed with the addition of hCG to C95/C97. Both C95 and C97 are required for hCG induced T_2 changes. Similar results are observed with hCG-β.

alone did not cause a change in T_2 from the respective PBS control (Figure 3), supporting the hypothesis that both antibody-conjugated nanoparticles are required to form an aggregate (Figure 1a). Control solutions contained dispersed nanoparticles as confirmed by DLS. The addition of analyte to CLIO conjugated to a monoclonal antibody can produce analyte:antibody−CLIO complexes, but this is not sufficient to induce a measurable T_2 change. MRS assays require agglomeration of at least two CLIO for "switching" of this sensor.

A larger concentration range was studied to estimate the dynamic range. Responses to the hCG-β subunit and hCG dimer were evaluated. Analyte concentrations were converted to molecular equivalents per CLIO nanoparticle using the theoretical molecular weight and the CLIO concentration. This conversion facilitates the comparison between hCG and hCG-β and interpretation of the stoichiometric nature of this sensor. The C95/C97 mixture was sensitive to both the hCG heterodimer and the hCG-β subunit with a linear dynamic concentration range of 1 order of magnitude (Figure 4a). The decrease in T_2 was much more significant in response to equivalent numbers of hCG molecules as compared with hCG-β. This may be due to stronger avidity and cooperative binding of the antibodies to the hCG molecule over hCG-β alone.

Aggregation behavior with the second, higher-valency CLIO mixture (C95–2/C97–2) was compared to the initial lot of lower-valency C95/C97 (Figure 4b). Similar trends were observed in both lots. The linear dynamic concentration range was the same, with the largest T_2 changes for both C95–2/C97–2 and C95/C97 lots observed at 2.5 molecules of hCG-β per CLIO and 1 molecule of hCG per CLIO. The magnitude of changes in T_2 was larger with hCG over that observed for hCG-β. A decrease in T_2 was, however, not observed at the higher hCG analyte concentrations (2.5, 5, and 10 analyte molecules per CLIO) with C95–2/C97–2. Repeated measurements of these samples yielded a T_2 that was rapidly changing, and in certain cases, a precipitate could be seen to settle overnight. These data are in agreement with a recent study that found the largest stable T_2 change at approximately 1.2 equiv of avidin per biotin-functionalized nanoparticle (*15*). Coefficients of variation above 2% were seen when larger equivalents of avidin were added. Thus, it seems that solution stable CLIO agglutination is subject to an upper limit of approximately 1 equiv of analyte per nanoparticle and that lower valency particles are preferred.

The limit of detection was 0.1 molecules of analyte per CLIO (3.57 nM hCG-β and 3.57 nM hCG) as defined by the concentration where the standard deviation does not overlap with the standard deviation of the PBS control. The limit of detection is an order of magnitude greater than the K_d of the antibody (0.1 nM). Thus, the sensitivity of this stoichiometric sensor at

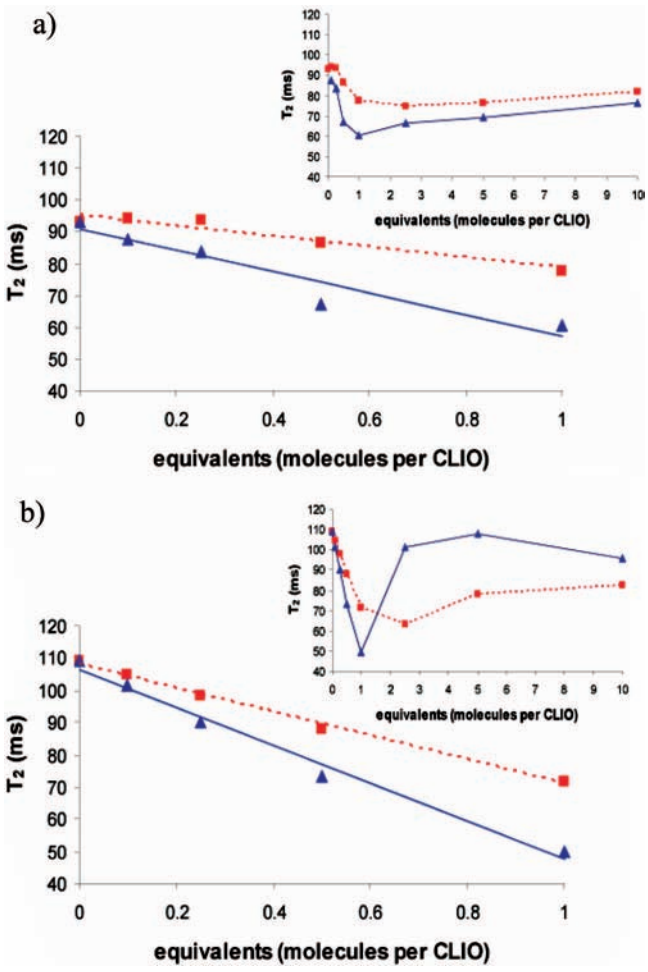

Figure 4. CLIO were incubated with hCG-β (■) and hCG dimer (▲). T_2 varies linearly with analyte concentration between 0.1 and 1 molecules of analyte per CLIO nanoparticle; inset shows the wider concentration range for (a) lower valency C95/C97 mixture and (b) higher valency C95–2/C97–2. Both show enhanced T_2 shortening with hCG compared to hCG-β. The higher valency C95–2/C97–2 particles show larger differences in T_2 and instabilities at the higher analyte regime, which becomes more pronounced with additional incubation time. Error bars are of similar size as the symbols.

the given CLIO concentrations is not limited by the dissociation constant of the antibody. Sensitivity can be enhanced by using a lower CLIO concentration, as fewer total analyte molecules are needed to induce a T_2 change.

Kinetics of Aggregation. The kinetics of aggregation were examined by particle size analysis (Figure 5). It has been suggested that the aggregates are of a fractal nature (*10*), whereas dynamic light scattering assumes a hard-sphere hydrodynamic model. Nevertheless, the effective diameter produces a convenient, single value which represents relative changes in the entire particle population. The effective diameter was approximately 140 nm for the unaggregated C95–2/C97–2 particles and increased with the addition of hCG. The initial rates of increase were 17 ± 1 nm/hr and 21 ± 1 nm/hr for 0.5 and 2.5 μg/mL hCG, respectively. The effective diameter of the aggregates reached 1 μm in hours. Particle size measurements at that size are imprecise due to the heterogeneous population of aggregates formed and the settling of precipitates. Indeed, precipitates can be observed at the bottom of some cuvettes after incubation overnight. Measurements of these settled solutions show that the autocorrelation function has difficulty establishing a baseline and no particles are detected. Micrometer-sized particles are observed upon resuspension of the particles by mixing. Samples

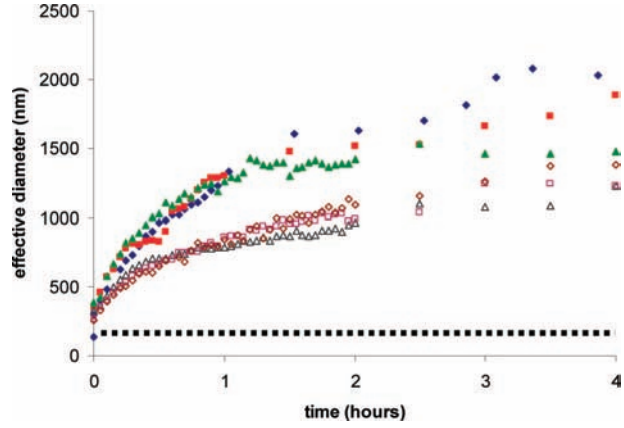

Figure 5. Particle aggregation kinetics as measured by dynamic light scattering. Effective diameter of the C95–2/C97–2 aggregates forming in 2.5 μg/mL hCG (solid symbols, ♦ ■ ▲) and 0.5 μg/mL hCG (open symbols, ◇ □ △). Unaggregated particles show no change in size (dotted line).

were not available for aggregation kinetics with the C95/C97 mixture, but measurements of similar lower-valency conjugate lots show the effective diameter increases to a lower plateau value of less than 200 um in size for all hCG concentrations tested. Particle sizing supports the stable T_2 measurements that were made with CLIO-IgG and C95/C97 days later and the rapidly changing measurements made with C95–2/C97–2.

Agglutination-based assays are subject to the prozone effect when analyte excess results in the formation of analyte/antibody−CLIO complexes without cross-linking (Figure 1d). It is of particular concern for false-negative assay results in syphilis and HIV/AIDS testing (*16, 17*). Measurements are typically repeated with a one-tenth dilution when a false negative is suspected to obtain values in the dynamic range of the assay.

Solution-based magnetic aggregation measurements have an additional limitation due to precipitation. Higher-valency particles produced more pronounced changes in T_2 and have been predicted to aggregate faster (*10*). Higher valency may also be a disadvantage, especially in the higher analyte regime, wherein a greater degree of aggregation may form much larger networks that are prone to insolublity and precipitation. It is interesting that the addition of approximately one antibody more per CLIO has a dramatic effect on aggregation kinetics under these experimental conditions. Thus, both the prozone and insolubility effects may be occurring above the one analyte per nanoparticle ratio to various extents depending on the nanoparticle (size, density, and valency), extent of analyte excess, K_d, and kinetics of aggregate growth. Stabilization of nanoparticle aggregates and control of aggregate growth in favor of nucleation of smaller aggregates will be important to the further development of these types of assays.

The sequential sample analysis format of the benchtop relaxometer and the need for thermal equilibration of samples impede measurements of large sample numbers and relaxation time kinetics. Custom instruments, such as one featuring a microfabricated coil (*18*), a portable sensor (*19*), or the ex situ NMR plate reader being developed in our laboratory, allow these dilute nanoparticle solutions to be measured with more compact instrumentation in small volumes for higher throughput screening and research purposes than is possible with conventional methods. This one-pot sensor system has the advantages of being able to work with an opaque sample with a single mixing step at the expense of the sensitivity that can be obtained by ELISA. This may be useful in instances where fast or sequential measurements are required. Additional applications may exploit the reversible nature of antibody/analyte binding by removal

of analyte, such as through dialysis (*20*). Thus, the same nanoparticle solution can be used for continuous measurements if a fixed volume container is used to achieve a constant nanoparticle concentration.

CONCLUSION

Monoclonal antibodies against hCG-β were attached to each nanoparticle using standard peptide chemistry. The addition of hCG-β or hCG to the MRS resulted in T_2 shortening compared to a blank control value as seen by NMR relaxometry. The size of the particles increased with the addition of hCG, independently confirming that aggregation was occurring. Particle size measurements also suggest that control of aggregate size will be important in enhancing the dynamic range and stability of this type of assay. This method can potentially be adapted to detect other biomarkers in solution.

Dexamethasone, a glucocorticoid steroid, can dilate the nuclear pore complexes and translocate into the nucleus when it is bound to its glucocorticoid receptor, suggesting that the transport of DNA into the nucleus may be facilitated by the reagent. In this research, dexamethasone was conjugated to low molecular weight polyethylenimine (2kDa) for efficient translocation of the polymer/DNA complex into the nucleus. Polyethylenimine (PEI)–dexamethasone (PEI–Dexa) was synthesized by one-step reaction using the Traut's reagent. In gel retardation assay, the PEI–Dexa/DNA complex was completely retarded at or above 0.3/1 weight ratio (polymer/DNA). The average size distributions and ζ-potential values of the complexes were measured at various weight ratios. In vitro transfection assay showed that the PEI–Dexa/DNA complex had higher gene delivery efficiency compared to PEI 2kDa/DNA complex. The localization of PEI–Dexa/plasmid DNA complexes in the nucleus was confirmed by using total internal reflection fluorescence and Nomarski differential interference contrast microscope as well as confocal microscope. Therefore, with efficient nuclear translocation and low cytotoxicity, PEI–Dexa may be useful for nonviral gene therapy.

INTRODUCTION

Gene therapy is an interdisciplinary field, including basic sciences, engineering, pharmacology, and medicines. For more than two decades, it has been gaining interests and prospects as one of the most promising custom-made platform therapeutic technologies in the post-genomic era. The vehicle for encapsulation and delivery of therapeutic genes is either viral vectors or nonviral synthetic vectors, such as cationic liposomes and cationic polymers or the combination of both vectors (*1*). In the view of targeting and transfection efficiency, viral vectors are better than nonviral vectors, but their inevitable problems, such as immune response and possible tumorigenesis, are still difficult barriers to overcome. As an alternative, nonviral synthetic vectors have been actively studied and developed over the past decade, and some recent studies showed promising results for future clinical applications with DNA and RNA delivery (*2, 3*). For the synthetic vectors, the liposome system is one of the most promising carriers for delivering therapeutic genes as well as biologically active molecules into mammalian cells (*4*). The application of such synthetic nonviral vectors is dependent on several factors, such as the solubility in water, the size and surface charge of the complexes, and the lipid composition of liposomes. Therefore, it is necessary to control such conditions and to check every preparation step to get optimal transfection efficiency in vitro and/or in vivo.

Glucocorticoid receptor is an intracellular receptor, which regulates gene expression in the presence of specific ligands. In the presence of glucocorticoid, the receptor binds to the ligand and the receptor–ligand complex is translocated into the nucleus (*5*). It is also reported that the nuclear pore complexes were dilated by the glucocorticoid receptor in the presence of dexamethasone, a potent glucocorticoid (*6, 7*). This dilation effect is considered to be helpful for nonviral gene delivery, which is favorable for translocation of polymer/DNA complex into the nucleus. Also, it was suggested that the transport of the polymer/DNA complex into the nucleus may be facilitated by the ligand–receptor-mediated transport when glucocorticoid is conjugated to the polymer. It was successfully verified in some reports using dexamethasone-mediated gene delivery (*8–10*), and we recently reported that the conjugation of dexamethasone to polyamidoamine dendrimer (PAMAM) increased the transfection efficiency of the polymer (*11*).

The goal of this study is to synthesize and characterize a lipopolymer composed of nontoxic small molecular weight polyethylenimine (PEI) (2kDa) and dexamethasone. We synthesized dexamethasone conjugated PEI with a Traut's coupling reagent. PEI–Dexa might have improved transfection efficiency due to efficient translocation of PEI–Dexa/DNA complex into the nucleus. To prove the hypothesis, we characterized physicochemical properties, cytotoxicity, and in vitro transfection efficiency of PEI–Dexa. Also, the localization of the PEI–Dexa/DNA complex in the nucleus was verified by confocal, total internal reflection fluorescence (TIRF), and Nomarski differential interference contrast (DIC) microscopy.

EXPERIMENTAL METHODS

Materials. Polyethylenimine (branched, 2kDa, and 25kDa), polyamidoamine dendrimer (PAMAM, generation 4), ethidium

bromide, and 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma-Aldrich Korea. Dexamethasone-21-mesylate was purchased from Steraloids Inc. Luciferase 1000 assay kit and reporter lysis buffer were purchased from Promega (Madison, WI). The luciferase expression plasmid (pCN-Luci) was prepared as reported previously (*12*). HepG2 and 293 cell lines were obtained from Korean Cell Line Bank. PicoGreen reagent and Alexa Fluor 488 protein labeling kit were purchased from Invitrogen. Fetal bovine serum (FBS), Dulbecco's modified Eagle's medium (DMEM), and 100× antibiotic-antimycotic reagent were purchased from GIBCO (Gaithersburg, MD). Micro BCA protein assay kit and 2-iminothiolane (Traut's reagent) were purchased from Pierce (Rockford, IL).

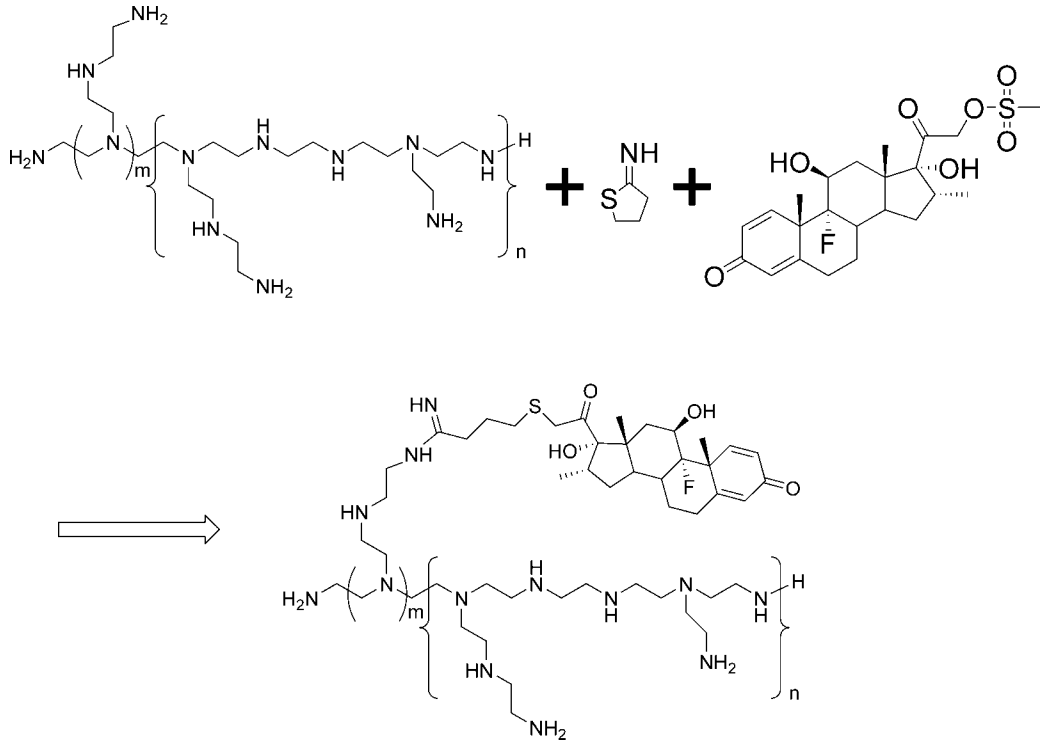
Synthesis of PEI–Dexa. The conjugation reaction was performed as reported previously with some modification (*8, 11*). Low molecular weight PEI (2 kDa) was dissolved in 1.8 mL of anhydrous dimethyl sulfoxide (DMSO) with 2-fold molar excess of Traut's reagent and dexamethasone-21-mesylate. To minimize the crosslinking side reaction, we used anhydrous DMSO and tried to keep away humidity during the reaction. The reaction was allowed to proceed for 4 h at room temperature and was quenched by the addition of an excess amount of cold ethyl acetate. The precipitated product was solubilized in water and dialyzed for 1 day against pure water using dialysis membrane (MWCO 1000). It was further freeze-dried and a white product was obtained (60% yield). The product was solubilized in DMSO-d_6/D_2O for ^1H NMR analysis (300 MHz, Korea Basic Science Institute).

Gel Retardation Assay and PicoGreen Assay. Polymer/plasmid complexes were prepared at various weight ratios ranging from 0.1 to 0.5 in Hepes-buffered saline (20 mM Hepes, 150 mM NaCl, pH 7.4). After 30 min incubation at room temperature for complex formation, the samples were subject to electrophoresis on a 0.7% (w/v) agarose gel containing ethidium bromide (0.5 μg/mL of the gel). After electrophoresis, the gel was analyzed on a UV illuminator to show the location of the DNA. PicoGreen assay for complex formation was also performed as reported previously (*12*).

Dynamic Light Scattering and ζ-Potential Measurements. The hydrodynamic diameters and ζ-potential values of polyplexes at various weight ratios were determined by the Zetasizer Nano ZS system (Malvern Instruments, UK) (*12*). After 30 min incubation, the complex solution was diluted to a final volume of 2 mL prior to measurements. The complex size was measured using Dispersion Technology Software 4.30, and data analysis was performed in automatic mode. The refractive index (n = 1.33) and the viscosity (0.89) of ultrapure water were used at 25 °C for measurements. The measured value is presented as the average size plus or minus a standard deviation of three runs.

Cell Culture and in vitro Transfection. Human embryonic kidney 293 cells and human liver carcinoma HepG2 cells were grown in DMEM with 10% FBS. The cells were routinely maintained on plastic tissue culture dishes at 37 °C in an incubator with a humidified atmosphere containing 5% CO_2/95% air. All media routinely contained antibiotic–antimycotic agent. For the transfection studies, cells were seeded at a density of 2×10^5 cells/well in 24 well flat-bottomed microassay plates 24 h before transfection. Polyplexes were prepared at various weight ratios and added to the cells. For competition assay, dexamethasone stock solution prepared in ethanol was added to each well (final ethanol concentration was 1.6%, v/v) and incubated for 30 min before polyplexes were added. The dexamethasone and polyplexes were incubated for 24 h in the presence of 10% FBS before assay. The amount of plasmid DNA was fixed at 1 μg/well. The cells were then incubated for 1 day at 37 °C in a 5% CO_2 incubator before assay.

Luciferase Assay. After transfection, the cells were washed with phosphate-buffered saline (PBS), and 150 μL of reporter lysis buffer (Promega, Madison, WI) was added to each well. After 15 min of incubation at room temperature, the cells were harvested and transferred to microcentrifuge tubes. After 15 s of vortexing, the cells were centrifuged at 12 000 rpm for 3 min. The protein concentrations of the extracts were determined by using protein assay kit. Luciferase activity was measured in terms of relative light units (RLU) using a luminometer. The final values of luciferase were reported in terms of RLU/μg total protein.



Cytotoxicity Assay. Evaluation of cytotoxicity was performed by the MTT assay (*13*). Cells were seeded at a density of 2×10^4 cells/well in 96 well microassay plates and were incubated for 1 day before adding the polymers. After the addition of each polymer, cells were further incubated for 24 h at 37 °C. After the incubation, 24 μL of 2 mg/mL MTT solution in DPBS was added. The cells were incubated for 4 h at 37 °C and then MTT-containing medium was removed, and 150 μL of DMSO was added to dissolve the formazan crystal formed by live cells. Absorbance was measured at 570 nm using a microplate reader (VersaMax, Molecular Devices).

Fluorescence Labeling of PEI and PEI–Dexa and Complex Formation with Plasmid DNA. PEI and PEI–Dexa (2 mg/mL) were prepared in 0.1 M sodium bicarbonate and mixed with the reactive Alexa Fluor 488 dye followed by stirring for 1 h at room temperature. Each reaction mixture was dialyzed (MWCO 1000) against pure water and freeze-dried yielding a fluorescent product. The Alexa488-labeled PEI or PEI–Dexa and 1.0 μg of plasmid DNA were mixed in 200 μL of FBS-free DMEM (GIBCO, Gaithersburg, MD) to form complexes at a charge ratio of 4. The mixture was incubated for 30 min at room temperature. DNA-linked dendrimer solution was then added to the cells and incubated for the indicated time prior to imaging. The complexes were added to the cells and incubated for 24 h before imaging experiments.

Cell Culture Preparation for Microscopy. 293 cells were grown in a cell culture dish (T25, Falcon), in a DMEM medium supplemented with antibiotic–antimycotic agent (GIBCO) and 10% FBS (GIBCO). The cells were maintained in an incubator with a humidified atmosphere containing 5% CO_2/95% air. Approximately 2×10^4 cells per well were seeded in bare cover glass (22 mm sq, No. 1 Dow Corning, Corning, NY) the day before the experiment, and the cells were maintained with serum-free DMEM. The luciferase expression plasmid (pCN-Luci) was used to prove that the dynamics and localization of polyethyleneimine (PEI) dendrimer and PEI–dexamethasone (PEI–Dexa) conjugated fluorescent dye Alexa 488. HEK 293 cells were examined by adding the DNA-linked functional dendrimer in cover glass before 24 h. Before initiating an experiment, the medium was then removed, and the adherent cells were rinsed twice with DPBS to remove the unbound complexes. A cover glass was placed on the all-side polished dove prism (BK7, 15 mm × 63 mm × 15 mm, n = 1.522, Korea Electro-Optics Co., Ltd., Korea). Surface and interior localization of the polymer/DNA complexes were detected using the epifluorescence and TIRF microscope. Nomarski DIC imaging was used to examine the details of the living cell structure.

Confocal Microscopy Experiments. 293 cells were seeded at a density of 2×10^5 cells/well on a cover glass (18 mm sq) that was spread in each well of a 6 well plate (Falcon) and incubated at 37 °C for a day. Alexa Fluor 488-labeled PEI–Dexa/plasmid DNA complexes were prepared at a 4/1 weight ratio (polymer/plasmid DNA). The amount of plasmid DNA was

Scheme 1. Synthesis Scheme of Polyethylenimine-Dexamethasone (PEI-Dexa)

fixed at 2 μg per well. The polymer/plasmid DNA complex was added to the cells and incubated for 24 h in 10% FBS-containing media. For nucleus labeling, cells were washed with PBS and further incubated for 30 min with 1.8 mL (4 μM) Hoechst 33342 dye (Molecular Probes, U.S.A.). The cells were then finally washed with PBS, and the cells were observed using confocal laser-scanning microscopy (Radiance 200 MP, Bio-Rad, U.K.).

Combined System of Nomarski DIC and TIRFM. We used a combined system of DIC and TIRF microscope for the real-time detection of polymer/DNA complexes localization in living 293 cells. The combined microscope system was similar to the system reported recently (*14*). A 100× (Olympus UPLFL 100×/1.3 N.A., W.D. 0.1) oil immersion objective lens was used for the image acquisition. A charge-coupled device (CCD) camera (Cascade 512B, Photometrics, Tucson, AZ) was mounted on the top of the microscope. The CCD exposure time was 100 ms. The combined system, which we integrated, consists of an upright Olympus BX51 microscope (Olympus Optical Co., LTD, Shinjuku-ku, Tokyo, Japan) equipped with a DIC slider (U-DICT, Olympus) and a Hg lamp for epifluorescence illumination. DIC imaging was used to examine the image and the details of the living cell structure, and epifluorescence imaging was used to detect the distribution of the polymer/DNA complexes in the bulk. The epifluorescence filter cube consisted of U-MWB2 (excitation filter, 460–490 nm; barrier filter, 520 nm; dichromatic mirror, 500 nm, Olympus Optical Co., Ltd., Shinjuku-ku, Tokyo, Japan). The TIRFM imaging was used to detect complexes within the HEK 293 cells. An argon ion laser at 488 nm with a 30 mW output (model 532-LAP-431–220, Melles Griot, Irvin, CA) was used as the excitation source for TIRF. The bare cover glass (No.1 Corning, 22 mm square) incubating the cells was placed on the all-side polished dove prism (BK7, 15 mm × 63 mm × 15 mm, n =1.522, Korea Electro-Optics Co., Ltd., Korea). The cover glass and the prism were index-matched with a drop of immersion oil (Immersol 518F, Zeiss, n =1.518). The laser beam was directed through the prism toward the cover glass/media interface. The angle of incidence, θ_i, was slightly greater than 72°. The laser beams were transmitted through an optical pinhole to eliminate extraneous light and plasma lines and to reduce the laser diameter. A Uniblitz mechanical shutter (model LS3Z2, Vincent Associates, Rochester, NY) was used to reduce photobleaching. The shutter was controlled by a model VMM-D1 shutter driver. All the experiments were performed on the all-side polished dove prism without moving the sample. MetaMorph 6.3 software (Universal Imaging Co., Downingtown, PA) was used to collect the image of the individual single molecules and to process the data.

RESULTS

Synthesis and Properties of PEI–Dexa. In this report, we conjugated low molecular weight PEI with the nucleus-targeting glucocorticoid dexamethasone and applied it to nonviral gene delivery experiments. PEI–dexamethasone, referred to as PEI–Dexa in this study, is one kind of functional water-soluble lipopolymers with nucleus receptor targeting characteristics. As described in Scheme 1, dexamethasone was efficiently conjugated by using the method recently reported (*8*, *11*). In addition to the pH sensitiveness of the linkage, the benefit of this approach was that there was no cationic charge sacrifice effect. The ^{1}H NMR data of the product is presented and each proton peak is identified (Figure 1). The peak intensity ratio was calculated between the ethyl protons of PEI backbone and the two methyl protons at 13′ and 16′ position of the five-numbered ring of dexamethasone (δ = 0.7–0.9 ppm). From the ^{1}H NMR calculations, it was observed that one mole of dexamethasone was conjugated per 1.3 mol of PEI.

Analysis of Complex Formation by Agarose Gel Electrophoresis and PicoGreen Reagent Assay. The complex formation of PEI–Dexa with plasmid DNA was investigated by agarose gel electrophoresis and PicoGreen reagent assay. Polymer/DNA complexes were prepared at various weight ratios ranging from 0.1 to 0.5. As shown in Figure 2A,B, PEI–Dexa was more effective in retardation of complexes at each weight ratio, and it was further approved by PicoGreen reagent assay. We have already reported the same approach for polyplexes

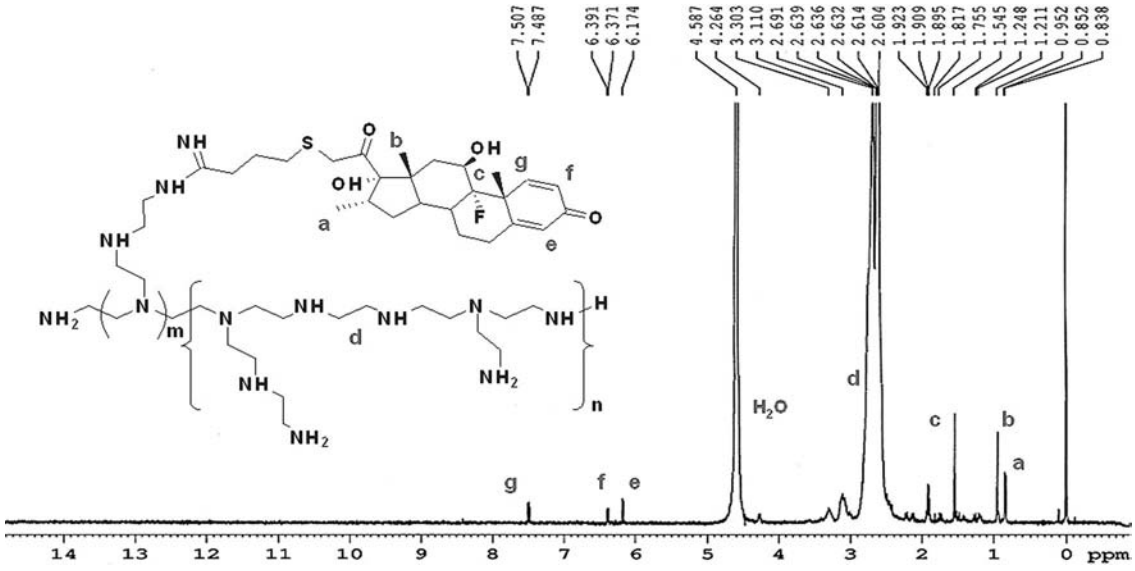


Figure 1. [1]H NMR of PEI–Dexa.

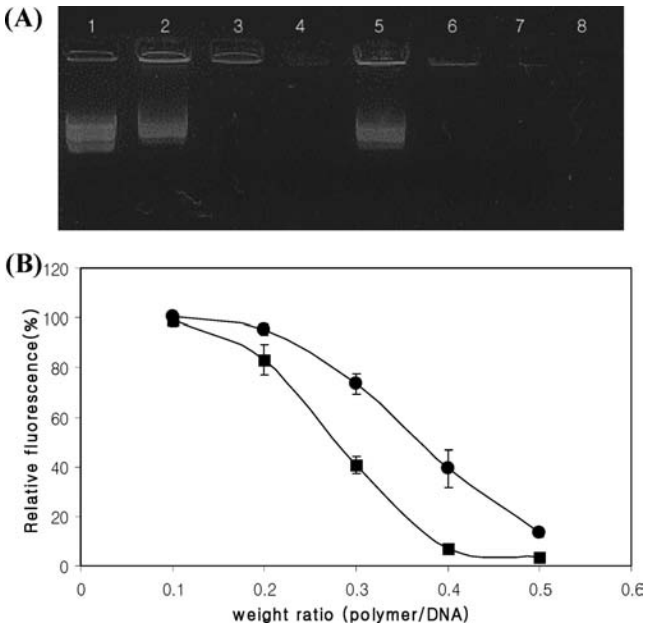

Figure 2. The DNA complexation assay. (A) Agarose gel retardation assay. Plasmid DNA only (lane 1, 5), polymer/DNA weight ratio 0.1 (lane 2, 6), 0.3 (lane 3, 7), 0.5 (lane 4, 8). and proved that this application is much more effective and sensitive than using EtBr for the characterization of polyplexes (*12*). For PEI–Dexa, the fluorescence intensity decreased more rapidly compared to that of PEI 2kDa, which means that PEI–Dexa can construct more mature complexes inhibiting the PicoGreen reagent from binding the uncomplexed DNA. We think that there is another important factor governing the effective complex formation between PEI–Dexa and DNA compared to PEI. Even though the charge density of PEI–Dexa is lower at the same weight ratio than PEI, the conjugated dexamethasones will function as hydrophobic cores that may facilitate the complex formation in addition to the process of charge neutralization. So it is considered that the presence of hydrophobic dexamethasones may contribute to the complex formation and collapse into complexed particles more effectively with plasmid DNA than PEI.

Size Measurements of the PEI-Dexa/Plasmid DNA Complex. PEI/DNA and PEI–Dexa/DNA complexes were prepared at various weight ratios (polymer/DNA) and the mean particle sizes and the ζ-potential values of polyplexes were measured using the Zetasizer Nano ZS system. As presented in Figure 3, there was no remarkable difference in the mean diameter between PEI/DNA and PEI–Dexa/DNA complexes at the weight ratios tested. In addition, for ζ-potential experiments, PEI–Dexa/DNA complexes showed lower values compared to PEI/DNA complexes. Because the particle sizes of PEI–Dexa/DNA complexes are very similar to those of PEI/DNA complexes and the ζ-potentials of PEI–Dexa/DNA show a few lower values at the same conditions, it is likely that other factors may contribute to the enhanced transfection efficiency of PEI–Dexa compared to PEI.

Transfection Experiments. Low molecular weight PEI (2kDa) or PEI–Dexa was mixed with plasmid DNA at various weight ratios and each complex was evaluated in terms of the transfection efficiency in 293 and HepG2 cells in the presence of 10% FBS (Figure 4A,B). PEI 25kDa and PAMAM polymer was used as positive control reagents. After 24 h of transfection, cells were harvested for assaying the expressed luciferase activity. As in the previous report (*15*), the transfection efficiency of low molecular weight PEI was not remarkable at low weight ratios. In comparison, PEI–Dexa showed a greater increased level of gene expression compared to native PEI 2kDa at all weight ratios tested. As compared with the transfection efficiency of native PEI, the gene expression level of PEI–Dexa increased by 1 order of magnitude for HepG2 and at least 2 orders for 293 cells. Even though the transgene expression level was lower than PEI 25kDa for both cell lines, PEI–Dexa showed comparable transfection efficiency for 293 cells and one order of increased efficiency for HepG2 at weight ratio 8 (polymer/DNA) in comparison with PAMAM. We also studied the effect of dexamethasone incubation on transfection efficiency at different concentration ranges from 10 to 50 nM. As shown in Figure 4C, we observed that the transfection efficiency of PEI–Dexa/DNA constructed at weight ratio 2 apparently decreased to 15%, whereas no competition effects were detected for PEI/DNA.

Cytotoxicity Assay Results. The cytotoxicity of PEI–Dexa was examined and compared with PEI and PAMAM at various concentration ranges for 293 and HepG2 cells. As shown in Figure 5, PEI–Dexa showed no toxicity at the concentration ranges tested in this experiment, whereas PEI 25kDa displayed

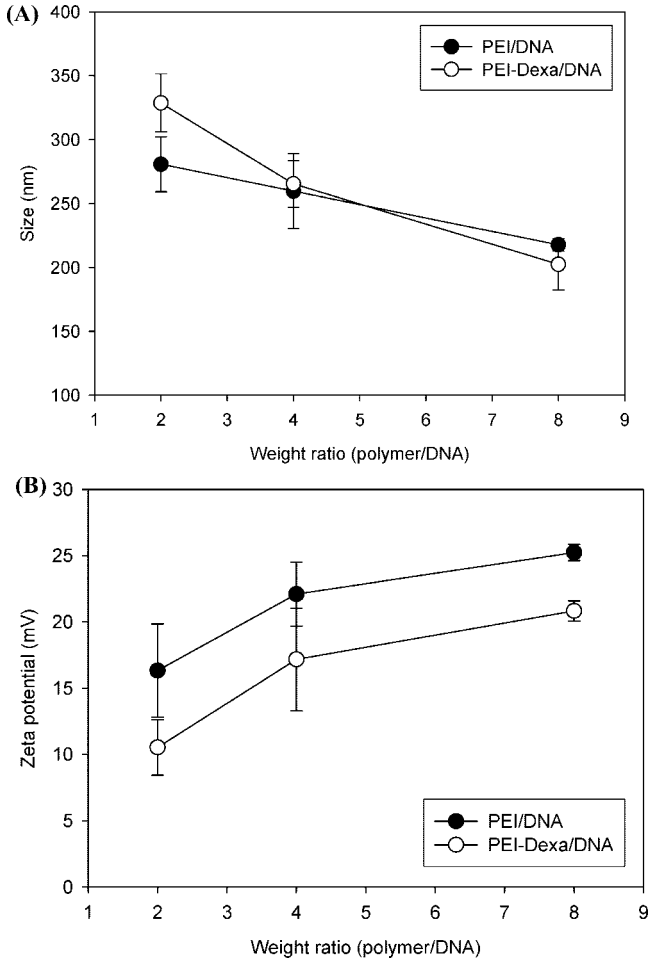

Figure 3. The average size data (A), and ζ-potential values (B) of PEI/DNA and PEI–Dexa/DNA complexes at various weight ratios. Each value is the average plus or minus the standard deviation of three different experiments.

cytotoxicity with increasing concentration levels. This result indicates that dexamethasone conjugated to low molecular weight PEI did not cause any harmful effects at the concentration ranges for the cell lines tested in these experiments.

Confocal Microscopy and TIRFM/DIC Microscopy Experiments. To identify the localization of polyplexes inside cells, confocal microscopy and TIRFM/DIC microscopy experiments were performed in parallel and compared. Each complex constructed at weight ratio 4 (polymer/DNA) was incubated with 293 cells and the difference in cell-associated fluorescence was monitored. Alexa 488 was used to label PEI and PEI–Dexa for complex-mediated fluorescence monitoring. The amount of labeled Alexa 488 for each polymer was calculated using the molar extinction coefficient of the dye at 494 nm (71 000 cm^{-1} M^{-1}), and each value was 2.3×10^{-4} and 4.5×10^{-5} moles of dye per 4.0 μg of PEI and PEI–Dexa, respectively. The labeling efficiency for native PEI was about five times higher than PEI–Dexa.

As shown in Figure 6, many fluorescent complexes were found inside the nucleus in the confocal microscopy image of Alexa 488-labeled PEI–Dexa/plasmid DNA complexes on 293 cells. In addition, in the TIRF/DIC microscopy images, more PEI–Dexa/DNA complexes were found in the nucleus region compared to PEI 2kD/DNA complexes (Figure 7). These results clearly indicate that PEI–Dexa/DNA complexes were more effectively translocated into the nucleus than native PEI 2kDa. This efficient translocation into the nucleus may contribute to the higher transfection efficiency of PEI–Dexa at a lower polymer concentration.

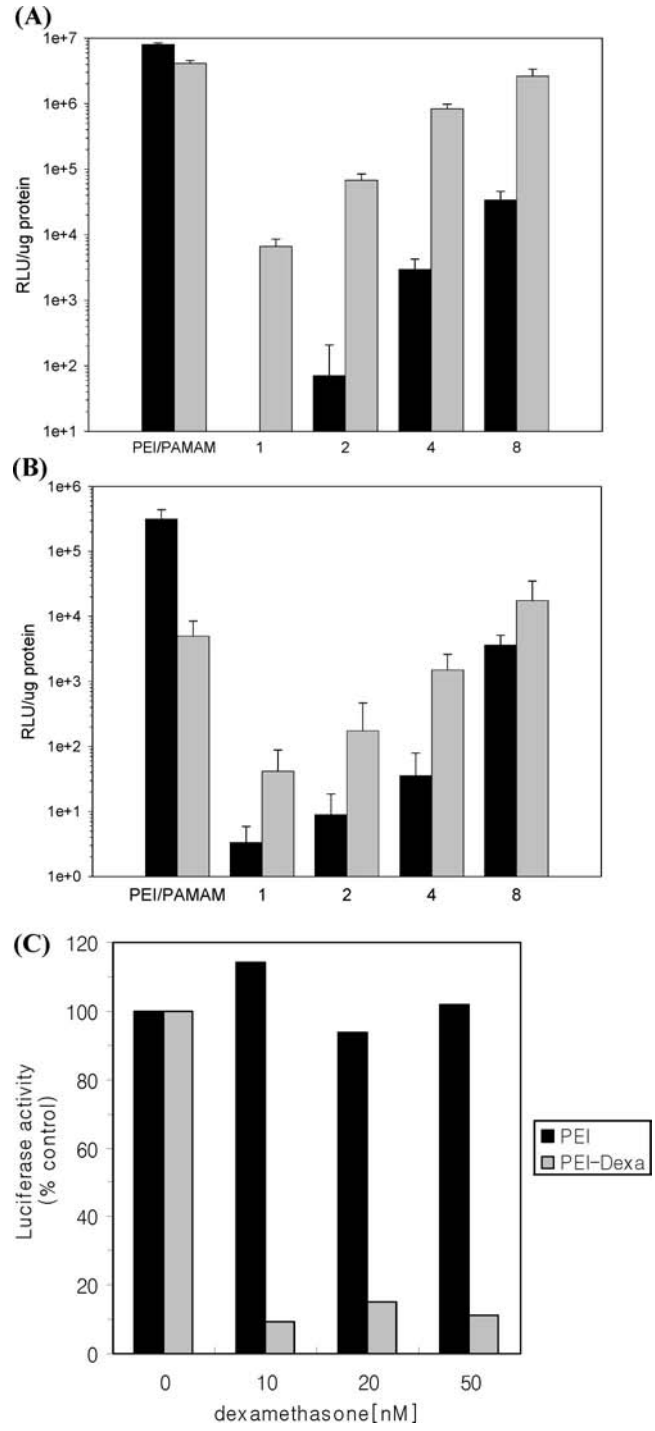

Figure 4. Transfection efficiency of PEI–Dexa for 293 cells (A) and HepG2 cells (B). PEI/PAMAM indicates the control data for PEI 25kDa (black) and PAMAM (gray). The numbers in the *x*-axis are the weight ratios of polymer/DNA complexes for PEI 2kDa (black bars) and PEI–Dexa (gray bars). The competition effects of dexamethasone incubation with each polyplex on transfection efficiency for HepG2 at different nanomolar concentrations (C). Each polyplex was constructed at the weight ratio of 2 and was introduced to cells with dexamethasone. The data are presented as average percent control values of three results of the expressed luciferase activity compared to the nontreated one.

DISCUSSION

The effective cell-specific targeting, endosomal escape, and nuclear localization are key factors for nonviral vectors to

improve transfection efficiency (*16–18*). Nuclear localization signal peptides have been employed to increase efficiency for nondividing cells as well as dividing cells (*19, 20*).

PEI 25kDa showed the highest gene transfection efficiency among the polymer vectors that have been reported so far. However, the cytotoxicity of the high molecular weight PEI is a major obstacle in application of the polymer to clinical gene therapy approach. So, low molecular weight PEI 2kDa has been investigated as a gene carrier, because it is relatively nontoxic compared to the higher molecular weight PEI derivatives and it showed remarkable level of transfection efficiency at high polymer/DNA ratios (*15, 21–24*). Many studies have been conducted to modify low molecular weight PEI for enhanced functionality and targeting activity using the polymer as a starting material. In some reports, it was attempted to construct hyperbranched PEI derivatives with high molecular weight using low molecular weight PEI as a building block and to introduce various biodegradable linkages in the backbone (*25–27*). In

The arrows indicate the polymer/DNA complexes.

another study, cholesterol was conjugated to low molecular weight PEI as a hydrophobic moiety to increase membrane perturbation effect leading to enhanced gene delivery, and they named the system as "water-soluble lipopolymer" (*28*).

We reported that the preincubation of free dexamethasone could increase the polyplex-mediated gene transfection efficiency and that it could be attributed to the nuclear pore dilation effect of the drug (*29*). However, due to the reduced solubility of dexamethasone in water, the emulsification step is generally needed using organic solvents and/or other surfactants, which may cause negative effects to cell viability. So it is needed to prepare water-soluble dexamethasone derivatives to make other emulsifying additives unnecessary. The recent development of a novel functional liposomal system known as spermine–dexamethasone provided some valuable characteristics as a nonviral vector system (*8*). The liposome is composed of a cationic spermine headgroup and a nuclear-targeting hydrophobic ligand, dexamethasone, which showed remarkable gene transfection efficiency. Our group also recently reported the synthesis of dexamethasone-conjugated PAMAM, and that the water-soluble conjugate polymer showed higher transfection efficiency than PEI 25kDa in a specific cell line in vitro (*11*).

In line with the previous reports, we attempted to prepare novel functional water-soluble lipopolymeric gene carriers by conjugating nontoxic low molecular weight PEI and dexamethasone. Therefore, PEI–Dexa may be a nuclear-targeting carrier with the functions of carrying the cargo attached to it into the nucleus and dilating nuclear pore complexes. These properties may contribute synergistically to the enhanced transfection efficiency of PEI–Dexa. Indeed, PEI–Dexa showed the enhanced gene transfection efficiency at lower polymer concentrations compared to native PEI, and the transfection efficiency of PEI–Dexa was greatly affected in the presence of dexamethasone for such conditions as presented in Figure 4C.

So, it is presumed that there may be two possible explanations for the enhanced gene transfection efficiency. First, PEI–Dexa is one of the hydrophobic group-containing lipopolymers, which might have membrane perturbation effect like many other cationic liposomes including the water-soluble lipopolymer, PEI–cholesterol. Second, based upon the previous microscope observations that more PEI–Dexa/plasmid DNA complexes were found in the nucleus region compared to PEI 2kDa/DNA complexes, it is possible to propose that PEI-conjugated dexamethasone might have contributed to the enhanced nucleus-localization activity of the complexes causing greater increased transfection efficiency.

Taken together, the results suggest that the conjugation of a glucocorticoid to a polymeric gene carrier may have two favorable effects. First, because dexamethasone is prescribed as a drug for the treatment of inflammation and autoimmune diseases, PEI–Dexa may be a water-soluble lipopolymeric prodrug that enhances the solubility of dexamethasone. Therefore, PEI–Dexa may have dual functions as a water-soluble steroid drug and a gene carrier for combinational approaches of drug/gene therapy. Second, in addition to the nuclear pore complex dilation effect, PEI–Dexa could act as a ligand for intracellular glucocorticoid receptors that are present in mammalian cells. So it is expected that PEI–Dexa may function as a potent nucleus-targeting signal following the ligand–receptor interaction, and the receptor may facilitate the translocation of dexamethasone-decorated complexes into the nucleus and also may function as a reagent that makes the nuclear membrane more vulnerable to the nanoparticles by enlarging the nuclear pores at the same time.

Received February 11, 2007; Revised Manuscript Received July 29, 2007

Novel 4-branched diblock copolymers consisting of cationic chains as an inner domain and nonionic chains as an outer domain were prepared by iniferter-based living radial polymerization and evaluated as a polymeric transfectant. The cationic polymerization of 3-(*N*,*N*-dimethylamino)propyl acrylamide (DMAPAAm) using 1,2,4,5-tetrakis(*N*,*N*-diethyldithiocarbamylmethyl)benzene as a 4-functional iniferter followed by the nonionic block polymerization of *N*,*N*-dimethylacrylamide (DMAAm) afforded 4-branched diblock copolymers with controlled compositions. By changing the solution or irradiation conditions, 4-branched PDMAPAAms with molecular weights of 10 000, 20 000, and 50 000 were synthesized. In addition, by graft polymerization, PDMAPAAm–PDMAAm blocked copolymers with copolymer composition (unit ratio of DMAAm/DMAPAAm) ranging from 0.18 to 1.0 for each cationic polymer were synthesized. All polymers were shown to interact with and condense plasmid DNA to yield polymer/DNA complexes (polyplexes). A transfection study on COS-1 cells showed that the polyplexes from block copolymers with cationic chain length of approximately 50 000 and a nonionic chain length of 30 000, which were approximately 200 nm in diameter and very stable in aqueous media, had the most efficient luciferase activity with minimal cellular cytotoxicity under a charge ratio of 20 (vector/pDNA). The PDMAPAAm–PDMAAm-blocked, star-shaped polymers are an attractive novel class of nonviral gene delivery systems.

INTRODUCTION

Cationic polymers such as poly(ethylenimine) (PEI) (*1–4*) and poly(*N*,*N*-dimethylaminopropyl acrylamide) (PDMAPAAm) (*5, 6*), which can generate nanoparticles by the formation of polyion complexes, i.e., "polyplexes" with DNA, are highly expected as one of the major carriers in nonviral gene delivery systems due to the many advantages they offer over viral systems (*7–11*). These advantages include blocking of specific immune responses, no restrictions in the size of DNA, and ease of large-scale production. However, the primary obstacle toward implementing an effective gene therapy using cationic polymers remains their relatively inefficient gene transfection *in vivo* when compared to virus vectors.

Recently, to improve gene transfection efficiency using cationic polymers, we designed a series of branched cationic polymers, linear and 3-, 4-, or 6-branched PDMAPAAm as a novel high-performance gene carrier called star vector (*5*), prepared to have the same molecular weights (Mn 18 000) by iniferter (initiator–transfer agent–terminator)-based photoliving radical polymerization (*12, 13*) from the respective multidithiocarbamate-derivatized benzenes (multifunctional iniferters) and DMAPAAm as a cationic monomer. This experiment revealed that the relative gene expression efficiency increased in the degree of branching that may affect the cationic charge density, and that the compaction of DNA polyplexes was stabilized on an increase in the branch number (*5*). However, the *in vivo* transfection efficiency was not satisfactory because of the high interaction between DNA polyplexes, which was caused by the low colloidal stability of the polyplex particles.

On the other hand, the conjugation of cationic polymers with a hydrophilic and biocompatible polymer such as poly(ethylene glycol) (PEG) (*14–18*) has been reported as a major vector modification strategy to improve transfection efficiency (*19–22*). Surface modification of the cationic polymers with PEG was effective in increasing the long circulation time for DNA delivery system, and PEGylation effect for PEI was studied in detail by Kissel and co-workers (*23, 24*). Kim et al. reported that triblocking by PEG of PEI caused the lack of serum inhibition of transfection activity with low cytotoxicity (*19*).

Therefore, it is highly expected that, by linking the nonionic hydrophilic chains with PDMAPAAm-branched polymers, DNA condensation and gene transfection efficiency will be improved by shielding the particles from unspecific interactions and conferring them stability in a similar fashion as PEGylation of polyplexes. To this end, in this study, we report novel structurally well-defined PDMAPAAm-branched polymers blocked with poly(*N*,*N*-dimethyl acrylamide) (PDMAAm), which is a biocompatible nonionic polymer, as a nonionic chain for *in vitro* gene delivery. The blocked, branched copolymers were synthesized by photoliving radical polymerization of DMAPAAm using benzene derivatized from four dithiocarbamate groups as a 4-functional iniferter followed by block copolymerization of DMAAm. Their DNA-binding properties were studied using dynamic light scattering (DLS). The *in vitro* transfection activity

as well as the cytotoxicity of the block copolymer-based polyplexes was evaluated using COS-1 cells.

EXPERIMENTAL PROCEDURES

Materials. 1,2,4,5-Tetrakis(bromomethyl)benzene was obtained from Sigma-Aldrich (Milwaukee, WI). Sodium *N*,*N*-diethyldithiocarbamate and *N*,*N*-dimethylacrylamide (DMAAm) were purchased from Wako Pure Chemical Ind., Ltd. (Osaka, Japan), and 3-(*N*,*N*-dimethylamino)propyl acrylamide (DMAPAAm) was from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan). Other chemical reagents were commercially obtained from Wako Pure Chemical Ind., Ltd. DMAAm and DMAPAAm were distilled under reduced pressure before use to remove the stabilizer, and other reagents were purified before use according to the requirements.

The luciferase reporter vector plasmid pGL3 control (3.5 MDa, 5256 bp) was purchased from Promega Inc. (Tokyo, Japan) and was amplified with a competent *E. coli* strain DH5α (Promega) and purified using Maxiprep according to a protocol from QIAGEN (Tokyo, Japan). The purity of the plasmid was checked by electrophoresis on a 1% agarose gel, and the concentration was determined by measuring UV absorbance at 260 and 280 nm. Exgen 500 (liner 22 kDa PEI) was obtained from COSMO BIO Co., Ltd. (Tokyo, Japan).

Polymer Synthesis. PDMAPAAm–PDMAAm 4-branched block copolymers were synthesized by iniferter-based photoliving radical polymerization (*12*, *13*) from 1,2,4,5-tetrakis(*N*,*N*-diethyldithiocarbamylmethyl)benzene as a 4-functional iniferter with DMAPAAm and DMAAm as cationic and nonionic monomers, respectively.

*Synthesis of 4-Functional Iniferter (***2***).* We dissolved 1,2,4,5-tetrakis(bromomethyl)benzene (**1**, 5 g) in ethanol (250 mL) and added sodium *N*,*N*-diethyldithiocarbamate (4.8 equiv for **1**) at 0 °C, followed by stirring at room temperature for 24 h. After filtering out the resulting sodium chloride, the filtrate was concentrated, dissolved in water (200 mL), and the extraction was repeated with ether (50 mL × 3). The organic layer was dried using $MgSO_4$ and condensed to yield iniferter **2**. ^{1}H NMR (in D_2O): δ 1.30–1.26 (t, 24H, -CH_2-CH_3), 3.77–3.69 (q, 8H, -N-CH_2-), 4.07–3.99 (q, 8H, -N-CH_2-), 4.57 (s, 8H, Ar-CH_2S), 7.49 (s, 2H, Ar-H).

Synthesis of PDAPAAm 4-Branched Polymer. The iniferter-based photoliving radical reaction of **2** with DMAPAAm was carried out as follows. A methanol solution (20 mL) of **2** (72 mg, 0.1 mmol) and DMAPAAm (3.43 g, 220 equiv) was placed into a 50 mL quartz crystal tube; subsequently, dry N_2 gas was bubbled into the tube to preclude the air gas from solution for 5 min. The mixture solution was then irradiated for 30 min with a 200 W high-pressure mercury lamp (SPOT CURE, USHIO, Tokyo, Japan) under N_2 atmosphere at room temperature, and the light intensity was set to 1 mW/cm^2 at a wavelength of 250 nm (UVR-1; TOPCON, Tokyo, Japan). The reaction mixture was concentrated and adjusted to an appropriate concentration to purify it by precipitation in a large amount of ether. Reprecipitation was carried out in a methanol–ether system. The last precipitate was dried under vacuum to yield PDMAPAAm 4-branched polymer (conv. 40%). The molecular weight was determined by gel permeation chromatography (GPC) analysis: Mn 50 000. ^{1}H NMR: δ 1.7–1.5 (br, 3H, -C<u>H</u>$_2$-CH- and -CH_2-C<u>H</u>$_2$-CH_2-), 2.0–1.8 (br, 1H, -C<u>H</u>-CO), 2.2–2.1 (br, 6H, -N-C<u>H</u>$_3$), 2.4–2.2 (br, 2H, -C<u>H</u>$_2$-N(CH_3)$_2$), 3.2–3.0 (br, 2H, -NH-C<u>H</u>$_2$-), 7.8–7.4 (br, 1H, -NH). Other branched polymers with different number average molecular weights were also synthesized using a similar procedure by changing the monomer concentration (see Table 1).

Synthesis of PDMAPAAm-PDMAAm 4-Branched Copolymer. The general procedure of the synthesis of PDMAPAAm–PDMAAm 4-branched copolymer is described below. A methanol solution (20 mL) of PDMAPAAm 4-branched polymer (Mn 50 000, 125 mg, 2.5 μmol) and DMAAm (2.97 g, 1200 equiv) was placed into a 50 mL quartz crystal tube and deoxygenated by bubbling with dry N_2 gas for 5 min. The mixture solution was then irradiated for 30 min under the above-mentioned conditions. The reaction mixture was concentrated and precipitated in 500 mL of ether. Reprecipitation was carried out in a methanol–ether system. The last precipitate was dried under

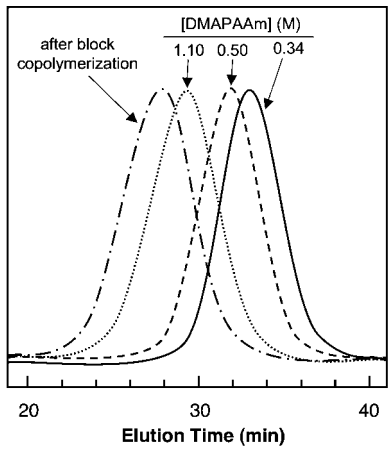

Figure 2. GPC elution curves after polymerization of DMAPAAm from 4-functional iniferter (**2**) as a function of monomer concentration (polymerization conditions were summarized in Table 1) and PDMAPAAm–PDMAAm 4-branched block copolymer (Mn 83 000) obtained after block copolymerization from PDMAPAAm 4-branched polymer (Mn 50 000) under polymerization conditions in Table 2.

vacuum to yield the PDMAPAAm–PDMAAm 4-branched block copolymer (conv. 19%). The total molecular weight was estimated from the integral value of ^{1}H NMR spectra between PDMAPAAm and PDMAAm (see Figure 2): Mn 83 000. ^{1}H NMR (in D_2O): δ 1.0–1.7 (br, 1922H, -C$\underline{H}_2$CH- and -CH$_2$C$\underline{H}_2$CH$_2$-), 1.9 (br, 315H, -CH$_2$C$\underline{H}$- of PDMAPAAm), 2.1 (s, 1890H, -N(C$\underline{H}_3$)$_2$ of PDMAPAAm), 2.3 (br, 630H, -C$\underline{H}_2$N(CH$_3$)$_2$), 2.4–2.7 (br, 331H, -CH$_2$C$\underline{H}$- of PDMAAm), 2.8–2.9 (br, 1986H, -N(C$\underline{H}_3$)$_2$ of PDMAAm), 3.0 (br, 630H, -CONHC$\underline{H}_2$-). Other 4-branched block copolymers with different compositions were also synthesized using a similar procedure by changing the concentrations of PDMAPAAm 4-branched polymer and DMAAm or reaction times (see Table 2).

General Methods. ^{1}H NMR spectra were recorded in D_2O with a 300 MHz NMR spectrometer (Gemini-300; Varian, Palo Alto, CA) at room temperature. GPC analyses in *N*,*N*-dimethylformamide were carried out with a HPLC-8020 instrument (Tosoh, Tokyo, Japan) (column: Tosoh TSKgel α-3000 and α-5000). The columns were calibrated with narrow weight distribution PEG standards (Tosoh). UV–vis spectra in H_2O were recorded with a UV–vis spectrophotometer (UV-1700, Shimadzu Co., Kyoto, Japan).

Preparation of Polymer/Plasmid Complexes. The PDMAPAAm–PDMAAm 4-branched copolymer was dissolved in a saline solution. Aliquots of these solutions (60 μL) were added to the plasmid dissolved in 90 μL of Tris-HCl buffer (pH7.4) to obtain polymer/DNA ratios of 1–20, which correspond to cation/anion (C/A) ratios. The solutions (total volume, 150 μL; plasmid concentration, 20 μg/mL) were mixed using a pipette. After 10 min of complex formation, 25 μL of the complex solutions were added into each well of 24-multiwell dishes for transfection (the amount of DNA added to a well, 0.5 μg/well).

Biophysical Characterization of Polymer/Plasmid Complexes. The ζ-potentials and mean diameters of the polymer/plasmid complexes in a saline solution having the same concentration that was used for transfection at a C/A ratio of 5 were obtained by employing dynamic light scattering (DLS) on an ELS-8000 system (Otuska Co., Osaka, Japan) equipped with a 10 mW He–Ne laser. The mean diameters were determined by cumurant analysis in multimodal setting.

The colloidal stability of polymer/plasmid complexes was studied using DLS at 37 °C and pH 7.4 and 2.0, which was adjusted by 0.1 N HCl solution. The polyplexes were prepared as described above with a C/A ratio of 5. The ionic strength of the suspension was adjusted to 150 mM NaCl.

***In Vitro* Transfection and Cell Viability Assays.** COS-1 cells (approximately 3×10^4 cells per well) were seeded prior to treatment in 24-well plates and grown for 24 h in DMEM (Gibco, Invitrogen Corp., Carlsbad, CA) containing 10% fetal calf serum (Hyclone Laboratories Inc., Logan, UT), penicillin (200 units/mL; ICN Biomedicals Inc., Aurora, OH), and streptomycin (200 mg/mL; ICN) in an atmosphere of 5% CO_2 at 37 °C. Transfections were performed with 0.5 μg of plasmid DNA (pGL3-control) in 24-multiwell dishes in 0.2 mL of OPTI-MEM I (Gibco). After 3 h of incubation, the cells were washed once with PBS(–) and cultured in 1 mL of DMEM containing 10% fetal calf serum for an additional 48 h. The medium was removed and the cells were washed twice with PBS(–). The cells were lysed with 0.2 mL of cell lysis buffer (Promega, Madison, WI) and mixed by vortexing. The lysate was centrifuged at 15 000 rpm for 1 min at 4 °C, and 5 μL of the supernatant was analyzed for luciferase activity using a Luminous CT-9000D (Dia-Iatron, Tokyo, Japan) luminometer. The relative light unit/s (RLU) were converted into the amount of luciferase (pg) using a luciferase standard curve, which was obtained by diluting recombinant luciferase (Promega) in lysis buffer. The protein concentrations of cell lysates were measured by performing a Bio-Rad protein assay (BIO-RAD, Hercules, CA) using bovine serum albumin as a standard. The expressed luciferase represented the amount (mole quantity), which is standardized for the total protein content of the cell lysate. The data are presented as means $\pm$ SD ($n = 5$).

Cytotoxicity was assessed by performing a cell viability assay using the WST-8 method (Dojindo, Kumamoto, Japan). COS-1 cells were seeded 24 h prior to treatment in 96-well plates at 5000 cells per well. Cells were treated under the same conditions used for luciferase assay with 6.2 μL of the transfection mixture including 0.124 μg of pDNA added to each well. They were treated under appropriate conditions for 3 h, washed once with PBS, and cultured in 50 μL of DMEM (Gibco) containing 10% fetal calf serum for an additional 24 h. To each well, 10 μL of WST-8 reagent (5 mmol/L) was added. After 2 h of incubation at 37 °C, absorbance at 450 nm was read in a BIO-RAD microplate reader (model 680). The data are presented as means $\pm$ SD ($n = 5$).

RESULTS AND DISCUSSION

Synthesis and Characterization of the Block Copolymers. The reaction scheme for the preparation of PDMAPAAm–PDMAAm 4-branched block copolymers is depicted in Figure 1. In this reaction, iniferter-based photoliving radical polymerization (*12, 13*), in which chain length can be easily controlled by changing irradiation conditions such as time or

[a] Solvent: methanol. [b] Determined by GPC (PEO standard). [c] Irradiation intensity: 1 mW/cm^2. [d] Polymerization ratios were determined by ^{1}H NMR.

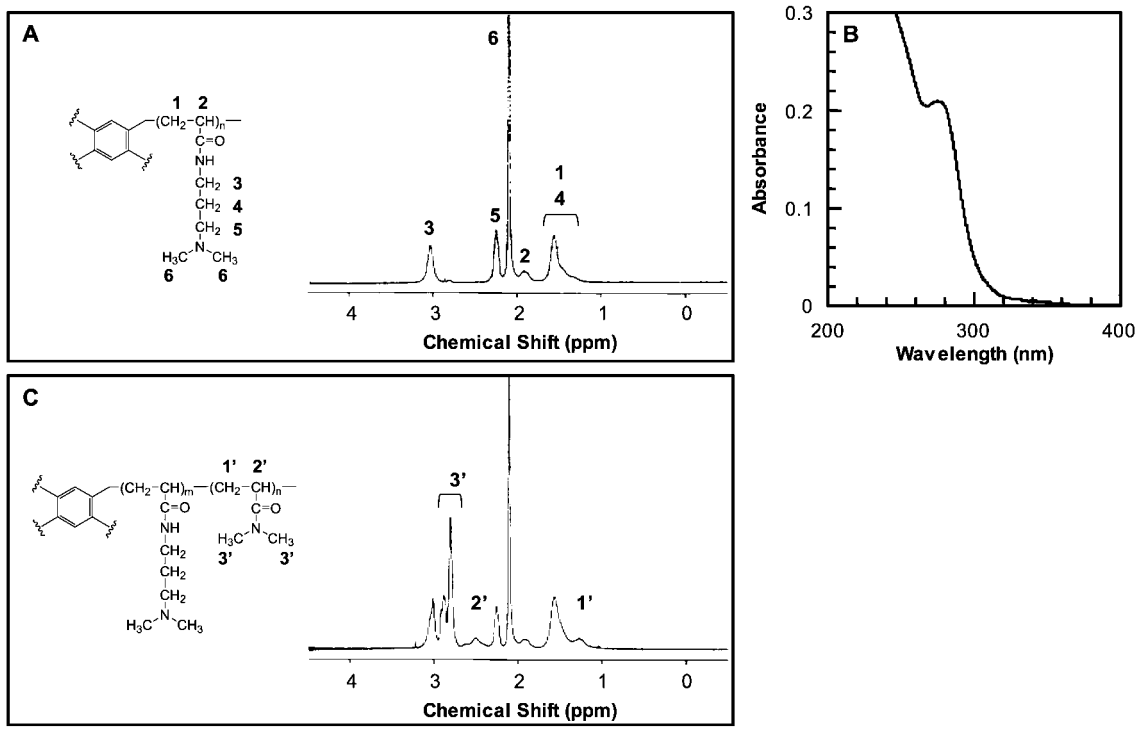

Figure 3. ^{1}H NMR spectra (300 MHz) in D_2O of (A) PDMAPAAm 4-branched polymer and (C) PDMAPAAm–PDMAAm 4-branched block copolymer. (B) Absorption spectrum of PDMAPAAm 4-branched polymer in H_2O. PDMAPAAm 4-branched polymer was prepared by iniferter-based living radical polymerization of 3-(*N*,*N*-dimethylamino)propyl acrylamide initiated from 1,2,4,5-tetrakis(*N*,*N*-diethyldithiocarbamylmethyl)-benzene as a 4-functional iniferter. PDMAPAAm–PDMAAm 4-branched block copolymer was obtained by similar living radical polymerization of *N*,*N*-dimethylacrylamide from PDMAPAAm 4-branched polymer.

light intensity, and solution conditions such as the concentration of iniferter or monomer, was repeated for two different monomers of DMAPAAm and DMAAm. The iniferter-based photoliving radical polymerization was a powerful tool for precise structural design in macromolecules (*5*, *18*, *25*). In a previous paper, we reported that coating materials and surface modification for the improvement of biocompatibility in medical devices were precisely developed (*26*, *27*).

At first, the polymerization of a cationic monomer (DMAPAAm) from 4-functional iniferter (**2**), which was synthesized by the dithiocarbamylation of 1,2,4,5-tetrakis(bromomethyl)benzene (**1**), was performed using a different monomer concentration to obtain PDMAPAAm 4-branched polymers. The preparation conditions are listed in Table 1. Upon 30 min of UV light irradiation at a DMAPAAm concentration of 0.34 M, the initial GPC trace of the iniferter (**2**) with an Mn of 720 g mol^{-1} was completely absent (Figure 2). An increase in the DMAPAAm concentration at a fixed irradiation condition resulted in an increase in the molecular weight with complete shift of the GPC curves toward a high-molecular-weight region, with a narrow polydispersity at 1.3–1.4.

On the other hand, a ^{1}H NMR spectrum showed that no nonreactive monomer and iniferter were detected completely in the all polymers obtained (Figure 3A). In addition, the broad peaks of N-methyl protons originating from the cationic chains were observed at approximately 2.1 ppm. However, the peak of ethyl protons corresponding to the dithiocarbamate group was not detected in the spectrum due to an extremely low existence ratio of the dithiocarbamate group against cationic chains, whereas a UV spectrum showed the remaining dithiocarbamate group (Figure 3B). The number of dithiocarbamate groups in one 4-branched PDMAPAAm molecule ranged from 3.6 to 4.2, which was close to the theoretical value of 4, irrespective of the molecular weigh of PDMAPAAm (Table 1). These results, combined with the afore-mentioned GPC data, indicated that the polymerization of DMAPAAm occurred from iniferter (**2**) via a living radical polymerization mechanism, resulting in the preparation of PDMAPAAm 4-branched cationic polymers. In this reaction, each branch was end-capped almost completely with the dithiocarbamate group, with molecular weights of approximately 10 000, 20 000, and 50 000.

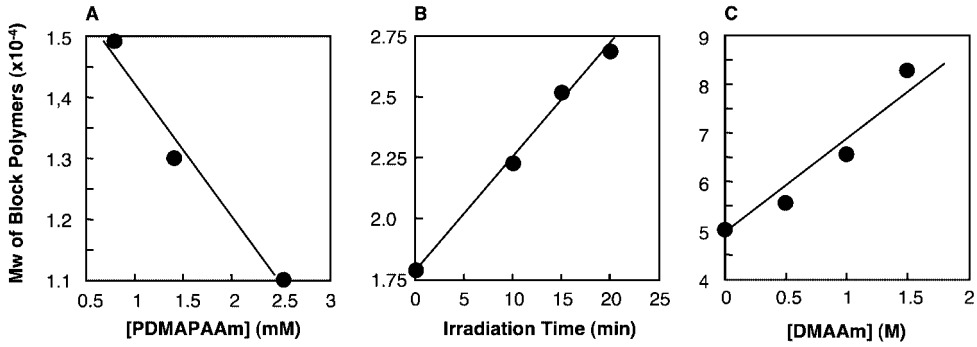

Figure 4. Changes in number average molecular weight (Mn) by changing (A) concentration of macroiniferter (PDMAPAAm 4-branched polymer), (B) irradiation time, and (C) concentration of monomer (*N,N*-dimethylacrylamide). Polymerization conditions were summarized in Table 2.

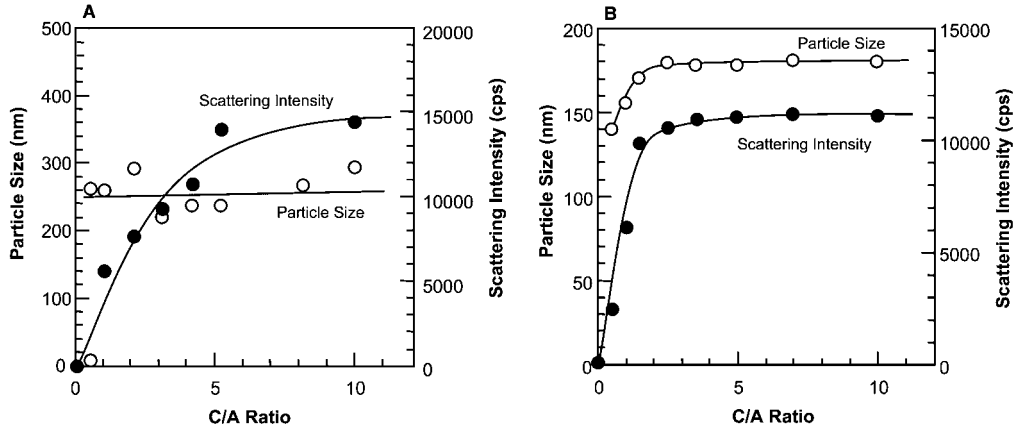

Figure 5. Scattering intensity and cumulant diameter of aqueous solutions of polyplexes prepared by mixing DNA (pGL3-control plasmid, 3 μg) and (A) PDMAPAAm 4-branched polymer with molecular weight of approximately 50 000 or (B) PDMAPAAm–PDMAAm 4-branched block copolymer with molecular weight of approximately 83 000 in different charge ratios.

Second, the photopolymerization of the nonionic monomer, DMAAm, from the obtained PDMAPAAm 4-branched polymers was conducted under a similar UV irradiation condition. Upon UV irradiation, the GPC curves of the polymers were completely shifted to a high-molecular-weight region as shown in Figure 2, indicating that block copolymerization occurred from dithiocarbamated groups located at the terminals of each branch in PDMAPAAm. Narrow polydispersity around 1.4 remained after block copolymerization. Table 2 summarizes the preparation conditions, molecular weight defined by ^{1}H NMR spectra, and the composition of PDMAPAAm–PDMAAm block copolymers. Because the polymerization reactivity of the macroiniferters was very low, it was necessary to raise monomer concentration. Therefore, monomer conversion was controlled at a very low level under 20%. The ^{1}H NMR spectrum of the obtained polymers showed that the peaks of N-methyl protons at approximately 2.8 ppm, carbonyl methyl protons at approximately 2.5 ppm, and methylene protons at approximately 1.3 ppm, all of which originated from the nonionic monomer, were newly detected in the obtained polymers. This indicates that the PDMAPAAm 4-branched polymers could function as a macroiniferter, and the block polymerization of DMAAm occurred from the terminals of each chain of the PDMAPAAm (Fig. 3C).

The dependency of molecular weight on the concentration of the macroiniferters, i.e., PDMAPAAm 4-branched polymers, at a fixed monomer concentration and irradiation time is shown in Figure 4A. The molecular weight of PDMAPAAm–PDMAAm block copolymers that were obtained tended to decrease with an increase in the concentration of the macroiniferter. The molecular weight also increased with irradiation time at a fixed concentration of the macroiniferter and monomer (Figure 4B), and with the concentration of the monomer at a fixed irradiation time and concentration of macroiniferter (Figure 4C). Thus, it can be said that the molecular weight of the PDMAPAAm–PDMAAm block copolymers was precisely controlled by changing the irradiation time and the concentration of the macroiniferter, i.e., PDMAPAAm, and monomer, i.e., DMAAm.

Formation of Polymer/Plasmid Complexes and Their Stability. When a Tris–HCl-buffered solution of pDNA (pGL3-control plasmid) was mixed with a saline solution of the cationic polymers, namely, PDMAPAAm 4-branched polymers, the scattering intensity in DLS measurements was immediately observed regardless of the molecular weight of the cationic polymers, indicating that polymer/plasmid complexes (polyplexes) were formed. Figure 5A shows the typical behavior of the scattering intensity obtained from the cationic polymer with a molecular weight of 50 000, by changing the charge ratio (polymer/pDNA). The intensity increased with the charge ratio and reached a plateau over the ratio of 5, indicating that, for sufficient complex formation, a minimum charge ratio of 5 was required. It was considered that the formation was due to nonspecific electrostatic interaction between the cationic polymers and anionic DNA as previously described in reports (*28, 29*).

The effective diameters of the polyplexes prepared from the cationic polymer (Mn = 50 000), measured by DLS, were approximately 250 nm irrespective of the charge ratio (Figure 5A). The surface charge as revealed by ζ-potential measurements was approximately +30 mV, which was similar to the value observed for the PEI with an Mn of approximately 25 000 (*19*). The size of the formed polyplexes increased upon reduction of the molecular weight of the cationic polymers as shown in Figure 6A. With molecular weight of 10 000, the complex size was approximately 900 nm at a charge ratio of 5. It was

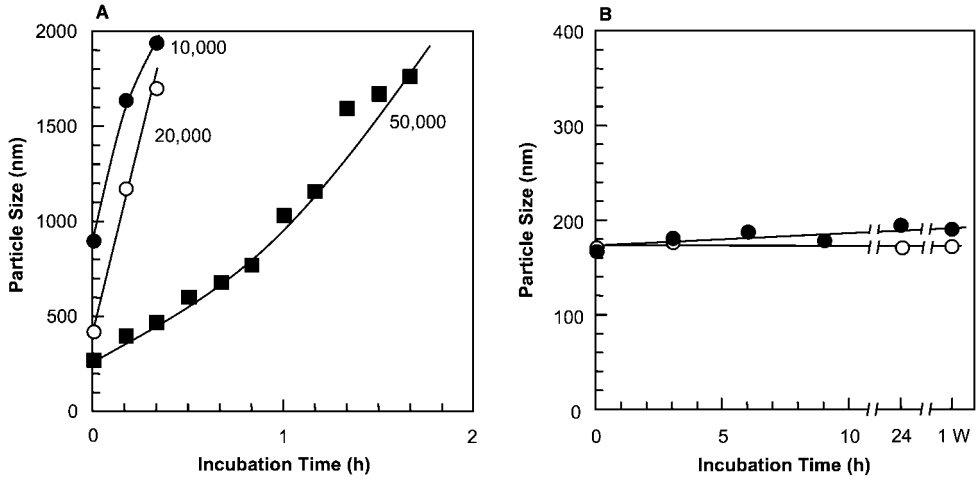

Figure 6. Incubation time dependent cumulant diameter changes in aqueous solutions of polyplexes prepared by mixing DNA (pGL3-control, 3 μg) and (A) PDMAPAAm 4-branched polymer with molecular weights of approximately 10 000, 20 000, and 50 000 at a charge ratio of 5 at pH 7.4 or (B) PDMAPAAm–PDMAAm 4-branched block copolymer with molecular weight of approximately 83 000 at a charge ratio of 5 at pH 7.4 (●) and 2.0 (○).

considered that, in polymers with higher molecular weights, a higher compaction of the polyplexes might occur. In addition, the polyplexes were gradually aggregated with increasing incubation time; that is, the size of the polyplexes formed from cationic polymers with the lowest molecular weight increased to approximately 2000 nm until 20 min after mixing. On the other hand, in the polymer with the highest molecular weight, the increase in the polyplex size was more or less prevented. The stability was higher in the polyplexes formed from polymers with higher molecular weight. Since in those studies the charge ratio was fixed at 5, the outermost surface of the complexes must be completely covered with the cationic polymers. The higher the molecular weigh is, the higher the charge density is. Therefore, it was considered that the electrostatic repulsion power rises with molecular weight, by which the aggregation of the polyplexes might be suppressed in the polymer with highest molecular weight.

On the other hand, in PDMAPAAm–PDMAAm 4-branched block copolymer a similar increase in the scattering intensity was observed immediately after mixing the polymer and DNA. A stable intensity was obtained for charge ratios greater than 2. The formed polyplexes were smaller in size (approximately 180 nm) than the nonblocked polymer. Interestingly, the size remained small even 1 month after complex formation (Figure 6B). The polyplexes were very stable under acidic conditions (Figure 6B) with moderate ζ-potentials of approximately +10 mV, which remained constant over a broad range of charge ratios between 2 and 20. This value was significantly lower than that observed for the cationic homopolymers (~30 mV). This reduced ζ-potential can be ascribed to shielding of the positive surface charge of the polyplexes by the nonionic PDMAAm chains. In addition, there was little change in the size of polyplexes after dilution to 1/20 with saline solution (Figure 7), which may be a great advantage when used for animal application. Obviously, the presence of PDMAAm leads to good colloidal stability of the PDMAPAAm–PDMAAm 4-branched block copolymers.

***In Vitro* Transfection Efficiency.** The transfection efficiency of the two types of cationic polymers—PDMAPAAm 4-branched polymer and PDMAPAAm–PDMAAm 4-branched block copolymer—at the charge ratio of 5 was tested on the model cell line of COS-1 monkey kidney cells. In our previous study, the transfection efficiency was higher in a branching polymer than a linear one (*5*). Therefore, in this study, optimization in 4-branched polymers was performed.

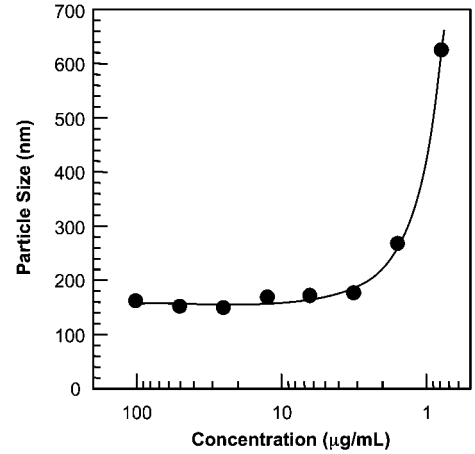

Figure 7. Dilution-dependent cumulant diameter changes in aqueous solutions of polyplexes prepared by mixing DNA (pGL3-control, 3 μg) and PDMAPAAm–PDMAAm 4-branched block copolymer with molecular weight of approximately 83 000 at a charge ratio of 5.

The cells transfected with the luciferase-encoding plasmid (pGL3), in the absence of any polymer, exhibited negligible luciferase expression. On the other hand, in cationic homopolymers the luciferase expression increased with the molecular weight of the polymers (Figure 8). The highest luciferase expression consistently occurred at the highest molecular weight, which may be due to the stability of the polyplexes as shown in Figure 6A.

Figure 9 shows the dependency of the molecular weight of the blocked polymers, which had the same core cationic polymer chain with molecular weight of approximately 50 000 but a nonionic polymer chain with different molecular weights ranging from 0 to approximately 33 000. Blocking resulted in an increase in luciferase activity with the peak transfection activity observed at a total molecular weight of approximately 83 000. The highest activity was approximately 3 times higher than that in PEI (ExGen 500) (*30*), which is a major commercially available typical polymeric vector used as a positive control. It is considered that the DNA expression using the polyplex was observed by the following 5 sequential steps: (1) attachment of the polyplex onto the cell surface, (2) internalization of the polyplex into the cell, (3) endosomal escape of the polyplex, (4) DNA release from the polyplex, and (5) internalization of DNA into the nucleus. Almost all of the cationic homopolymers

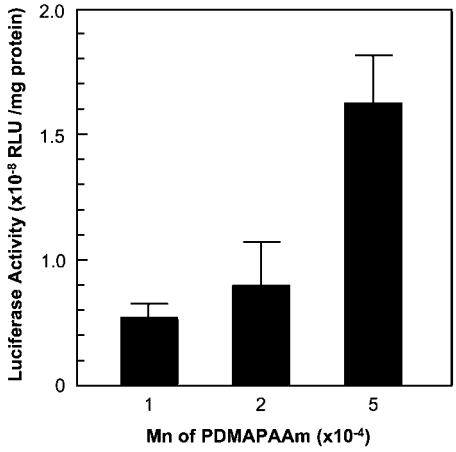

Figure 8. Transfection efficiency of polyplexes prepared by mixing DNA (pGL3-control, 3 μg) and PDMAPAAm 4-branched polymers at a charge ratio of 5.

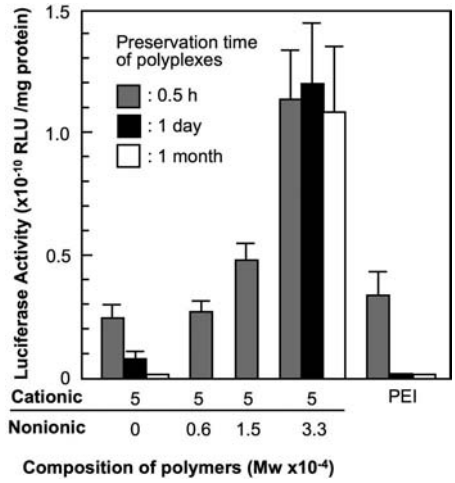

Figure 9. Transfection efficiency of polyplexes prepared by mixing DNA (pGL3-control, 3 μg) and PDMAPAAm–PDMAAm 4-branched block copolymers at a charge ratio of 5 at different preservation times of polyplexes after preparation. For comparison, transfection efficiency data of polyplexes of linear PEI (ExGen 500) at the charge ratio of 5 is also given.

including PEI can conjugate with DNA to prepare nanosized polyplexes immediately after mixing by electrostatic affinity. However, the polyplexes are gradually aggregated with an increase in incubation time to grow to micrometer size by similar electrostatic affinity as demonstrated in Figure 6A. In general, it was reported that transfection efficiency was low in large particles due to difficulty internalizing polyplexes into the cells, which is the afore-mentioned second step. In addition, polyplexes formed from DNA and cationic polymer were relatively rigid compared to those from DNA and block copolymer with a combination of cationic and nonionic chains, because a nonionic chain in the block copolymer can function as a buffer layer to weaken the electrostatic affinity between DNA and polymer. Therefore, it is considered that the only cationic polymer based polyplexes may be not dissociated easily. That is, this may prevent DNA release from the polyplex, which is the afore-mentioned fourth step. For these two reasons it is considered that the 4-branched block copolymer had higher transfection efficiency than linear PEI.

Interestingly, the high activity using the block copolymer was maintained at least 1 month after polyplex formation though the activity markedly decreased with time in nonblocked cationic polymers where approximately 60% of the activity was lost after 1 day (Figure 9). In PEI, little activity remained even 1 day after polyplex formation. In addition, the block copolymer could work as a gene delivery vector in the presence of serum. When serum was present, the transfection activity decreased to approximately 60% at serum concentration of 10%, and approximately 50% at 20%. Even at the serum concentration of 50%, approximately 30% of the initial activity remained.

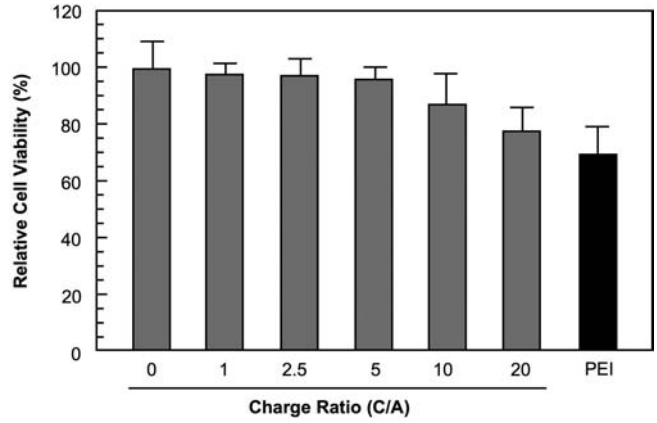

Figure 10. Cytotoxicity of polyplexes prepared by mixing DNA (pGL3-control, 3 μg) and PDMAPAAm–PDMAAm 4-branched block copolymers in different charge ratios. Cell viability was determined by the WST assay.

The *in vitro* cytotoxicity of polyplexes based on the block copolymers was studied as a function of the charge ratio by using the WST assay. The block copolymer with a cationic chain of 50 000 and nonionic chain of 30 000 had little nontoxicity at charge ratios up to 20 (Figure 9B). At high charge ratios of 10 and 20, permissible viability, which was higher than that in PEI at a charge ratio of 6, was observed.

In conclusion, we have demonstrated that nonionic polymer blocked, 4-branched cationic copolymers are a novel class of efficient polymeric carriers for DNA delivery *in vitro*. Excellent colloidal stability with low cytotoxicity of polyplexes based on PDMAPAAm–PDMAAm block copolymer with a cationic chain length of approximately 50 000 and nonionic chain length of approximately 33 000 makes it very promising for *in vivo* gene transfer. The most important advantage of the 4-branched block copolymer is high stability in the formed polyplexes, in which, however, DNA and the polymer were moderately binded. That is, excellent balance between polymer formation and dissociation may be realized in the branched blocked copolymer. In addition, the branched blocked copolymer was applied to an animal model (*31*). Even though the study was limited to only preliminary stages, mice injected with the polyplexes showed a high level of gene expression in liver, kidney, or spleen without any tissue damage. Therefore, in the near future, our research will be directed at verifying the macromolecular structure and molecular weights and the balance of the ratio in the cationic block and the nonionic block with detailed molecular characterization, including mass spectroscopy for several types of cells, for detailed study in *in vitro* and *in vivo* gene delivery.

Received February 12, 2007; Revised Manuscript Received June 11, 2007

4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) is one of the most abundant and potent procarcinogens in tobacco smoke. In order to induce a strong and substained antibody response against NNK, we developed a functionalized derivative that closely mimicked its structural features, in particular, the pyridyloxobutyl moiety, the adjacent ketone, and the N-nitrosamino group. This hapten was conjugated via a C_2 linker to the highly immunogenic diphteria toxoid licensed as a vaccine in humans to induce polyclonal and monoclonal antibodies. Two monoclonal antibodies were obtained with K_d values of 45.8 nM (P9D5) and 37.6 nM (P7H3), respectively, for NNK-C_2. Both the monoclonal (P9D5 and P7H3) and polyclonal antibodies reacted strongly with NNK (IC_{50} = 80 μM or 160 μM) and NNAL (IC_{50} = 29 μM or 93 μM) and to a lesser extent with some of the metabolites of NNK. Interestingly, the mAbs did not react with the metabolites of the detoxification pathways such as NNK-N-Oxide and NNAL-N-Oxide (IC_{50} > 512 μM). Therefore, such antibodies detect NNK and NNAL and may have the potential to modulate their redistribution in vivo, perhaps reducing some detrimental effects of smoking.

INTRODUCTION

4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK)[1] is one of the most abundant and potent procarcinogens in tobacco and tobacco smoke. It results from the nitrosation of nicotine and exhibits lung-selective toxicity in several species (*1*). In vivo, NNK is metabolized, either to detoxified species or to activated metabolites responsible for its carcinogenic effect (*2*). The metabolic pathways are similar in rodents and humans although with some quantitative differences (*3, 4*).

NNK is first converted by carbonyl reduction to 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL). NNK and NNAL are then further metabolized by α-hydroxylation of both carbons adjacent to the N-nitroso group by cytochrome P450 enzymes (*5*). During this activation process, several reactive electrophilic intermediates are generated that methylate and pyridyloxobutylate DNA (*6*). These DNA adducts may, for instance, inactivate the *p*53 tumor-suppressor gene (*7, 8*) or activate the *k-ras* protooncogene (*9–11*) both responsible for NNK carcinogenesis. Two other main metabolic pathways include pyridine N-oxidation to NNK-N-oxide and NNAL-N-oxide, both of which are significantly less tumorigenic than their parent compounds and are therefore regarded as detoxification products (*1, 2*). Glucuronidation of NNAL generates species that can be excreted via bile and urine; it is the main pathway for NNK detoxification in humans (*12*).

The risk for cancers related to NNK depends on the dose, the individual activation and detoxification capacity, and the extent of DNA adduct formation. Many agents have been tested for their ability to inhibit carcinogenesis by chemoprevention (*13, 14*), and some, such as phenethyl isothiocyanate (PEITC), showed some benefit in preliminary studies (*15*). Vaccination against nicotine has spurred renewed interest in prophylactic strategies against low molecular weight compounds, and several vaccines are currently under development (*16–20*). The aim of such prophylactic vaccines is to interrupt the drug-induced dependency of nicotine by preventing the molecule from reaching the central nervous system (*21–24*). Similarly, antibodies against NNK may affect the redistribution of the NNK and its metabolites and reduce their carcinogenicity, but an immunoprophylactic approach against NNK has never been explored.

In order to induce sustained and specific antibodies, a functionalized derivative of NNK must be conjugated to a carrier protein providing the T cell epitopes to activate T helper cells. Here, we show that a conjugate vaccine based on a hapten closely mimicking the structure of NNK and coupled to a protein carrier induces polyclonal and monoclonal antibodies reacting with NNK and NNAL, two major procarcinogens in cigarette smoke.

MATERIALS AND METHODS

Synthesis of NNK Haptens. *Synthesis of the Common Intermediate* **4.** *Preparation of 4-Oxo-4-pyridin-3-yl-butyronitrile (***2***).* A suspension of finely ground sodium cyanide (490 mg, 10 mmol) in 50 mL dry *N*,*N*-dimethylformamide was vigorously stirred at 35 °C for 15 min before undiluted 3-pyridinecarboxaldehyde (**1**, 98%, 10.93 g, 100 mmol) was added dropwise over a period of 30 min. The dark brown

solution was stirred for another 30 min, after which acrylonitrile (5.31 g, 100 mmol, 1 equiv) was added over 1 h. The red–orange, viscous solution was mixed for 3 h before glacial acetic acid (629 μl, 11 mmol) was added. After stirring the solution for 5 more minutes, the solvent was partially removed under vacuum and the residue quenched with sat aq NH_4Cl soln. The aq phase was extracted 4 times with $CHCl_3$, then twice with EtOAc, and then mixed with CH_2Cl_2 overnight. The pooled organic extracts were dried ($MgSO_4$), the solvents evaporated *in vacuo*, and the residual oil purified by column chromatography (CC) on SiO_2 (EtOAc/PET 4:1 → 6:1 → 1:0). Recrystallization of the obtained orange-colored solid from 2-propanol yielded product **2** as yellow crystals (11.0 g, 69%). R_f 0.47 (EtOAc); ^{1}H NMR (250 MHz, $CDCl_3$) δ 9.16 (1H, d, J = 2.0 Hz), 8.82 (1H, dd, J = 2.0 Hz), 8.24 (1H, dt, J = 2.0, 7.3 Hz), 7.49 (1H, dd, J = 4.4, 7.3 Hz), 3.40 (2H, t, J = 6.6 Hz, CH_2CH$_2$CN), 2.84 (2H, t, J = 6.6 Hz, CH$_2$CH_2CN) ppm; ^{13}C NMR (63 MHz, $CDCl_3$) δ 198.3, 154.2, 149.4, 135.4, 131.8, 124.0, 118.8, 34.5, 11.6 ppm; *m/z* (ES$^+$) 161.1 ([M + H]$^+$, 100%).

*Preparation of 3-(2-Pyridin-3-yl-[1,3]dioxolan-2-yl)-propionitrile (**3**).* A mixture of 4-oxo-4-pyridin-3-yl-butyronitrile (**2**, 16 g, 0.1 mol), ethylene glycol (100 mL), and *p*-toluenesulfonic acid (20.9 g, 0.11 mol, 1.1 equiv) in 150 mL dry toluene was refluxed for 2 days using a Dean–Stark apparatus. The oily reaction mixture was subsequently evaporated to dryness, and the residue taken up in $CHCl_3$ and washed with sat aq K_2CO_3 soln and ddH_2O. Purification of the crude product by CC (DCM/MeOH 50:1) yielded **3** as a yellow oil (10.6 g, 52%). R_f 0.25 (92:8 DCM/MeOH); ^{1}H NMR (250 MHz, $CDCl_3$) δ 8.7 (1H, s), 8.6 (1H, d, J = 4.7 Hz), 7.7 (1H, dd, J = 7.8, 1.8 Hz), 7.3 (1H, dd, J = 8.1, 5.1 Hz), 4.1 (2H, m), 3.8 (2H, m), 2.5 (2H, t, J = 7.5 Hz), 2.25 (2H, t, J = 7.5 Hz) ppm; ^{13}C NMR (63 MHz, $CDCl_3$) δ 149.9, 147.4, 136.7, 133.4, 123.3, 119.3, 107.3, 64.9, 35.6, 11.4 ppm; *m/z* (ES$^+$) 205.1 ([M + H]$^+$, 100%), 227.1 ([M + Na]$^+$, 15%), 243.0 ([M + K]$^+$, 20%).

*Preparation of 3-(2-Pyridin-3-yl-[1,3]dioxolan-2-yl)-propylamine (**4**).* Nitrile **3** (4.1 g, 20.0 mmol, 1 equiv) was dissolved in 40 mL methanolic ammonia (MeOH sat with gaz NH_3) and hydrogenated with H_2 in the presence of Raney-Ni (ca. 410 mg, 10 wt %) at 10 bar and 40 °C for 3 days in a Parr hydrogenation apparatus. The catalyst was then removed by filtration on Celite and the filter cake extensively washed with MeOH to release the product trapped on the catalyst surface. The filtrate was evaporated *in vacuo* and the residue purified by CC on SiO_2 (DCM/MeOH/25% aq NH_3 soln 90:10:2) to yield amine **20** as a yellow oil (3.3 g, 79%). R_f 0.31 (90/10/2 DCM/MeOH/NH_4OH); ^{1}H NMR (250 MHz, $CDCl_3$) δ 8.7 (1H, s), 8.6 (1H, d, J = 5.5 Hz), 8.0 (1H, d, J = 7.9 Hz), 7.5 (1H, dd, J = 7.8, 5.7 Hz), 4.1 (2H, m), 3.75 (2H, m), 3.6 (2H, t, J = 6 Hz), 2.3 (2H, m), 2.0 (2H, t, J = 7.5 Hz), 1.60 (2H, q, J = 6.5 Hz) ppm; ^{13}C NMR (63 MHz, $CDCl_3$) δ 149.3, 147.7, 137.9, 133.6, 123.0, 109.2, 64.7, 42.1, 37.8, 27.7 ppm; *m/z* (ES$^+$) 209.1 ([M + H]$^+$, 100%).

Synthesis of Linker Molecules **10.** *Preparation of tert-Butyl (3-Hydroxyethyl)carbamate (**9**).* A soln of aminoalcohol **8** in dry DCM was treated with Et_3N (1.1 equiv) at rt for 30 min before a solution of Boc_2O (1.1 equiv) in DCM was slowly added. The mixture was stirred at room temperature overnight and quenched with sat aq NH_4Cl soln. The aq phase was extracted twice with DCM and the combined organic extracts washed with brine, dried ($MgSO_4$), and concentrated *in vacuo* to give crude product **9** as a colorless oil (91–99 %). ^{1}H NMR of the raw (*N*-Boc)-protected product showed that it was generally pure enough to be used in the next step without further purification. R_f 0.68 (20/1 DCM/MeOH); ^{1}H NMR (250 MHz, $CDCl_3$) δ 4.96 (1H, br), 3.70 (2H, dt, J = 11.6, 5.8 Hz), 3.29 (2H, dt, J = 12.45, 6.2 Hz), 2.52 (br, OH), 1.44 (9H, s) ppm; ^{13}C NMR (63 MHz, $CDCl_3$): δ 159.0, 80.0, 62.6, 43.2, 28.3 ppm.

*Preparation of tert-Butyl (2-Iodoethyl)carbamate (**10**).* Iodine (1.2 equiv) was added portionwise to a soln of imidazole (1.2 equiv) and PPh_3 (1.2 equiv) in DCM (50 mL) at 0 °C. The resulting, deeply yellow colored suspension was warmed to rt before a soln of **9** (1 equiv) in DCM was added. The reaction mixture was stirred at rt for 24 h, filtered over Celite, and washed twice with 5% aq $Na_2S_2O_3$ soln. The aq washing phases were extracted with DCM and the organic phases dried ($MgSO_4$) and evaporated *in vacuo*. The residual yellow-colored oil was subjected to purification by CC (ether/EtOAc 1:1) and yielded desired iodide **10** as a pale yellow oil (81%). R_f 0.51 (5/1 PET/EtOAc); ^{1}H NMR (250 MHz, $CDCl_3$) δ 4.95 (1H, br), 3.50 (2H, m), 3.20 (2H, m), 1.47 (9H, s) ppm. ^{13}C NMR (63 MHz, $CDCl_3$) δ 155.8, 79.3, 43.0, 28.3, 5.9 ppm.

N-Alkylation of **4** *with Linkers* **10.** *Preparation of {3-[3-(2-Pyridin-3-yl-[1,3]dioxolan-2-yl)propylamino]ethyl}-carbamic Acid tert-Butyl Ester (**5**).* A soln of amine **4** (1 equiv) in dry DMF (10 mL/mmol) was treated with Cs_2CO_3 (1.2 equiv, dried *in vacuo* prior to use) at rt for 30 min before a soln of **10** (0.99–1.0 equiv) in DMF (2 mL/mmol) was added dropwise. The pale yellow suspension was heated to 60 °C, vigorously stirred overnight, and the solvent evaporated under vacuum. The crude product was redissolved in DCM and washed with sat aq NH_4Cl soln and H_2O. The combined aq phases were extracted with DCM (3×) and EtOAc (1×) and the collected organic layers washed with 5% aq $Na_2S_2O_3$ soln, dried ($MgSO_4$), and evaporated *in vacuo*. The residual oil was subjected to CC (DCM/MeOH 98:2 → 95:5 → 92:8 → 90:10) to separate the monoalkylation product **5** (40%) from the overalkylated material. R_f 0.29 (92/8 DCM/MeOH); ^{1}H NMR (300 MHz, $CDCl_3$) δ 8.66 (1H, s), 8.53 (1H, d, J = 4.3 Hz), 7.73 (1H, d, J = 7.8 Hz), 7.27 (1H, t, J = 7.8 Hz), 6.26 (1H, br), 4.07 (2H, t, J = 6.8 Hz), 3.73 (2H, t, J = 6.8 Hz), 3.54 (2H, m), 3.09 (2H, m), 3.03 (2H, m), 1.99 (4H, m), 1.41 (9H, s) ppm; ^{13}C NMR (75 MHz, $CDCl_3$) δ 157.5, 150.4, 148.3, 138.4, 134.5, 124.0, 109.2, 80.5, 65.2, 48.7, 48.4, 43.5, 37.1, 28.5, 20.3 ppm; *m/z* (ES$^+$) 252.1 ([M + H]$^+$, 100%).

Acid-Catalyzed Nitrosation of **5.** *Preparation of {3-[3-(2-Pyridin-3-yl-[1,3]dioxolan-2-yl)propyl(nitrosamino)]ethyl}-carbamic Acid tert-Butyl Ester (**6**).* Compound **5** (1 equiv) was suspended in ddH_2O (2.5 mL/mmol), the oily droplets dissolved through addition of 1 N aq HCl soln, and the pH of the resulting homogenous layer adjusted to 5–6 with 25% aq NaOH soln. After cooling the solution to 0 °C, an aq soln of $NaNO_2$ (2 equiv) was added dropwise over 20 min. The reaction was allowed to proceed at rt overnight, then diluted with DCM and alkalinized with sat aq $NaHCO_3$. The basic aq layer was extracted with DCM (3×) and EtOAc (1×), the combined organic layers dried ($MgSO_4$), evaporated, and purified by CC on SiO_2 (DCM/MeOH 98:2 → 95:5). Product **6** was obtained as a yellow oil (53–75%). R_f 0.47 (95/5 DCM/MeOH); ^{1}H NMR (250 MHz, $CDCl_3$) δ 8.70 (1H, s), 8.59 (1H, d, J = 4.5 Hz), 7.79 (1H, d, J = 7.8 Hz), 7.32 (1H, t, J = 5.1 Hz), 4.79 (1H, br), 4.12 (2H, m), 4.06 (2H, m), 3.78 (2H, m), 3.36 (2H, m), 3.19 (2H, m), 1.92 (2H, t, J = 7.8 Hz), 1.59 (2H, m), 1.44 (9H, s) ppm; ^{13}C NMR (63 MHz, $CDCl_3$) δ 155.8, 149.5, 147.5, 137.7, 133.5, 123.3, 108.7, 82.4, 64.7, 52.1, 51.8, 43.8, 37.2, 27.7, 22.4 ppm; *m/z* (ES$^+$) 381.0 ([M + H]$^+$, 100%).

*Cleavage of Protection Groups. Preparation of 4-[2-Aminoethyl(nitrosamino)]-1-pyridin-3-yl-butan-1-one (**7**).* Nitrosation product **6** (1 equiv) was dissolved in EtOAc (1 mL/mmol) and treated with a 5-fold excess of conc aq HCl (10 N, 5 equiv) at reflux overnight. The cloudy reaction mixture was then cautiously alkalinized to pH 14 with 25% aq NaOH soln,

and the aq phase vigorously extracted with DCM (3×) and EtOAc (2×). The combined organic phases were washed with brine, dried ($MgSO_4$), and evaporated *in vacuo*. The residual oil was purified by CC (DCM/MeOH/25% aq NH_3 soln 90:10:3) to give the free amine **7** as a yellow oil (40–45%), which was stored at −20 °C under argon. The free amine **7** was then converted into a stable hydrochloride salt by HCl/MeOH-treatment for 2 h at rt and subsequent drying under vacuum. R_f 0.27 (90/10/3 DCM/MeOH/NH_4OH); ^{1}H NMR (200 MHz, D_2O) δ 9.22 (1H, s), 8.97 (1H, d, $J = 6.8$ Hz), 8.88 (1H, d, $J = 4.5$ Hz), 8.10 (1H, dd, $J = 6.8, 4.5$ Hz), 3.34 (1H, q, $J = 2.6$ Hz), 3.26 (2H, t, $J = 5$ Hz), 3.14 (2H, q, $J = 5$ Hz), 3.03 (2H, t, $J = 6.2$ Hz), 2.1 (2H, q, $J = 5$ Hz) ppm; ^{13}C NMR (50 MHz, D_2O) δ 197.0, 145.2, 144.9, 142.06, 134.6, 127.7, 48.9, 47.2, 38.7, 35.6, 20.6 ppm.

Conjugation of Hapten 7 to Proteins. A two-step zero-length cross-linking procedure using active esters was adopted for conjugating amine **7** to ovalbumin (OVA, MW 45 000 g/mol), and diphtheria toxoid (DT, 63 000 g/mol), a kind of gift from the Serum Institute of India (Hadapsar, India). OVA (10 mg mL^{-1}) was dissolved in 100 mM TrisHCl buffer pH 7.5. Crude DT was purified by buffer exchange using a 10K Da cutoff amicon (Millipore, Marlborough, USA) in 100 mM TrisHCl buffer pH 7.5 and the solution adjusted to 10 mg mL^{-1} concentration. 1 mL aliquots of both protein solutions were then reduced by treatment with 1 mL of DTT (2 mg mL^{-1}) in 100 mM TrisHCl buffer pH 7.5 and 7 mL of ddH_2O at 50 °C for 15 min. The reduced proteins were subsequently alkylated without further purification by addition of 1 mL of iodoacetamide (5 mg mL^{-1}) in 100 mM TrisHCl buffer pH 7.5 After stirring the mixture for 15 min at rt, the reduced and alkylated protein solutions were purified by buffer exchange in 100 mM MES buffer pH 6 using a 10K Da cutoff amicon cell. The solution titer were determined by standard protein quantification assays kit (BC-Uptima, Amersham Biosciences, San Francisco, CA). and the concentration adjusted to 10 mg mL^{-1} by dilution.

In a second step, 100 μL of the reduced and alkylated proteins solutions (10 mg mL^{-1}) were activated for 15 min at rt with a mixture of 200 μL of sulfo-NHS (8 mg mL^{-1}, Pierce Rockford, USA; in 100 mM MES buffer pH 6), 200 μL of EDC (2.75 mg mL^{-1} in 100 mM MES buffer pH 6) and 400 μL of ddH_2O. After activation, the excess reagents were quenched at rt for 10 min with 100 μL of β-mercaptoethanol (20 mg mL^{-1} in 100 mM MES buffer pH 6). Finally, 1 mL of NNK hapten **7** (20 mg mL^{-1}) in PBS (0.1 M sodium phosphate, 0.15 M NaCl at pH 7.5) was added to the activated protein solutions and the mixtures left to react overnight in the dark.

The bioconjugate solutions were purified by buffer exchange with 50 mM ammonium bicarbonate buffer pH 7.8 using a 10K Da cutoff amicon cell and quantified through standard protein quantification kit (BC-Uptima, Amersham Biosciences, San Francisco, CA).

Mass Spectroscopy. Positive ion MALDI-TOF mass spectrometry was performed on the [NNK-C_2] conjugates using a Bruker Daltonics ULTRAFLEX TOF/TOF equipped with a 337 nm, 50 Hz N_2 laser of 100 μJ. The crystal matrix, 3,5-dimethoxy-4-hydroxycinnamic acid (sinapinic acid) from Bruker Daltonics (Leipzig, Germany), was prepared at a concentration of 10 mg mL^{-1} in TFA 0.2%/acetonitrile 75:25. Protein samples were 1 mg mL^{-1} in 50 mM ammonium bicarbonnate buffer pH 7.8. 0.5 μL sample and 1 μL matrix solutions were mixed directly on the stainless steel probe and allowed to dry (10 min) at rt. Spectra were recorded in the linear mode, and the resulting data were analyzed using the software supplied by Bruker Daltonics. The instrument was calibrated using a 10 mg mL^{-1} BSA solution in ddH_2O.

Monoclonal antibody production. *Immunization.* Groups of five 8–10-week-old pathogen-free BALB/c mice were primed intraperitoneally (i.p.) with 25 μg of [NNK-C_2]-DT using complete Freund's adjuvant (v/v) (Sigma). Mice were boosted by gastric intubation on day 14, 16, 28, 30, 42, and 44 with the same dose of antigen in the presence of 5 μg cholera toxin (Sigma). Sera were drawn on day 0, 14, 28, 42, 55, and 84 and the anti-NNK-C_2 antibody titer was measured by direct ELISA. Three days prior to the hybridoma fusion, a final boost was performed i.p. with incomplete Freund's adjuvant (v/v) (Sigma) to two mice with the highest NNK-C_2 specific antibody titers.

Hybridoma Production. Hybridomas were produced using ClonaCell-HY complete kit (StemCell Technologies). Briefly, from immunized mice spleen, 10^8 splenocytes were washed and incubated in PEG-containing medium with 2.10^7 parental myeloma cells, SP2/0 for 5 min at 37 °C. After a 24 h expansion, cells were mixed with a methylcellulose-based HAT (hypoxanthine, aminopterin, and thymine) selective medium for hybridomas, and the mixture was plated on dishes and incubated at 37 °C, allowing fused cells to grow for 14 days. Hybridoma colonies were picked and transferred into 96-well plates with growth medium. After 4 days of growth at 37 °C, each supernatant was tested for the presence of specific [NNK-C_2]-antibodies by direct ELISA. Positive clones were further adapted to RPMI-1640 supplemented with HyClone HyQ PF-Mab (Perbio Sciences), a protein-free nutrient supplement for mAb production.

Enzyme-Linked Immunoassays (ELISA). *Indirect ELISA.* 384-well microtiter plates (Microlon, Greiner) were coated overnight with 20 μL of 0.125 μM [NNK-C_2]-OVA in 0.1 M bicarbonate buffer (pH 9.6). After washing, free binding sites were saturated with 1% BSA in Tris-buffered (15 mM) saline (TBS, pH 7.4). 20 μL of diluted mouse serum in TBS containing 0.1% Tween-20 or nondiluted supernatants was incubated for 90 min at rt. Alkaline phosphatase-conjugated goat antimouse mAb (1:750; Southern Biotechnology Associates) and a substrate solution of 0.05% *p*-nitrophenyl phosphate in 1 mM 2-amino-2-methyl-1-propanol (Sigma) and 0.1 mM $MgCl_2$ (pH 10.2) were used to detect antibody binding. Optical density (O.D.) was measured after 60 min at 405 nm. Net OD was calculated by subtraction of the relevant background as described in each figure.

Competition ELISA. In all competition experiments, optimal antigen coating conditions and serum dilutions were determined by direct ELISA. 384-well plates were coated with the minimal amount of antigen required for maximal signal. Sera or mAb supernatants were diluted to obtain 70% binding and a signal of 1.0 to 1.5 O.D. at 0% competition (highest signal). The competitors (NNK metabolites or derivatives, from Toronto Research Chemicals Inc., Canada, and Acros Organics, Geel, Belgium) were resuspended in 100% DMSO, and stock solutions of 100 μM were frozen at −80 °C. Competitors were mixed 1:1 with sera or mAb supernatants to final concentrations of 0 to 512 μM for mAbs or 0 to 1024 μM for serum. Zero (highest signal) and 100% competition (background signal) were determined using no or NNK-C_2 as competitor. The difference between these two values corresponds to the dynamic range of the assay. For each competitor concentration, 50% of the inhibitory concentration, IC_{50}, was calculated. Experiments were independently repeated three times, and data were analyzed used *SigmaStat* software. Net OD was calculated by subtraction of the relevant background as described in each figure.

Affinity Measurements by Surface Plasmon Resonance. BIACORE 3000 instrument, CM5 sensor chip, HBS-EP buffer [10 mmol/L HEPES, 0.15 mol/L NaCl, 3 mmol/L EDTA, and 0.005% surfactant P20 (pH 7.4)], amine coupling kit (*N*-hydroxysuccinimide; *N*-ethyl-*N*′-dimethylaminopropylcarbodi-

imide), and ethanolamine were all obtained from GE Healthcare (Diegem, Belgium). [NNK-C2]-DT and DT were immobilized on CM5 sensor chips according to standard amino coupling procedure. Briefly, the carboxymethylated dextran-coated surface was activated by a 7 min injection of a solution containing 200 mmol/L EDC and 50 mmol/L NHS; then, [NNK-C2]-DT or DT (10μg/mL in 10 mmol/L sodium acetate pH 4.5) was injected. A continuous flow of HBS-EP at 5 μL/min was maintained, and capping of unreacted sites was achieved by injecting 1 mol/L ethanolamine–HCl (pH 8.5). Final immobilization responses of 500 resonance units were achieved. Sensorgrams for kinetic measurements were generated by injection of mAbs at concentrations ranging from 0 to 100 nM in HBS-EP at a flow rate of 30 μL/min. The association and dissociation times were 120 and 900 s, respectively. The chip was regenerated by injection of consecutive pulses of 10 mM glycine pH 1.5 for 30 s and 10 mM glycine pH 2 for 60 s until the difference between the baselines before and after injection was <10 resonance units. Biosensor data were prepared, modeled, and fitted by means of the *BIAevaluation 4.1* software. Data from the reference surface were subtracted to remove the effects of unspecific binding in order to calculate the specific binding. The presence of mass transfer phenomena were excluded by performing the control assays as recommended by BIACORE. Evaluation of the data was done using a bivalent-analyte model with simultaneous determination of association and dissociation constants. The quality of the fitted data was evaluated by comparing the calculated and experimental curves (residual values) and by the $\chi 2$ parameter.

RESULTS

Synthesis of the Hapten. Retrosynthetic analysis of the pyridyl–oxobutyl structure of NNK guided our synthetic effort towards the nitrile route (Figure 1A). This approach took advantage of the commercially available nicotine aldehyde, which already contains the carbonyl function of the hapten. Condensing nicotine aldehyde **1** with acrylonitrile according to Stetter's procedure (*25*) gave the nitrile intermediate **2**, whose carbonyl function was subsequently protected by a 1,3-dioxolane group through treatment with ethylene glycol in boiling toluene. Once the carbonyl was safely masked, the nitrile was catalytically reduced with H_2/Raney-nickel as described by Soyka et al. (*26*). An aliphatic linker chain was then attached on the free amine terminus of **4** using a classical nucleophilic substitution with electrophilic partner **10**. The electrophilic linker chain was constructed by *N*-Boc protection of a commercial aminoalcohol followed by iodination (Figure 1B). The coupling product **5** was obtained with moderate yields and subsequently nitrosated with $NaNO_2$ and cat HCl under biphasic conditions to give compound **6**, which shows all the required structural similarities with NNK, except for the protective groups.

Simultaneous cleavage of the Boc-group and the 1,3-dioxolane was not possible under standard Boc-deprotection conditions (15 equiv CF_3COOH in boiling $CHCl_3$), and compound **6** was dissolved in boiling EtOAc and stirred with conc

aq HCl overnight. The deprotected compound **7** was extracted in low yields from the aq layer at pH 14. After purification, the substance was redissolved in 1 N aq HCl; the water was eliminated with MeOH as dragging agent and by drying under high vacuum. The resulting hydrochloride salt of compound **7** was deep-frozen until used for bioconjugation.

Conjugation of Hapten To Carrier Proteins. The small synthetic hapten NNK-C_2 **7** was coupled to the large carrier proteins OVA and DT using a standard active ester procedure (*27*) as described in Materials and Methods (Figure 1C). Before conjugation, the native proteins were reduced and alkylated with iodoacetic acid. In all cases, a minimum of a 120-fold molar excess of hapten over the protein carboxylic reactive groups was used. After the coupling reactions, the protein conjugates were purified by dialysis.

MWs of protein conjugates were determined by MALDI-TOF MS, and the average unit of hapten per carrier estimated by mass difference. The typical mass difference between free (61 350 Da) and conjugated DT ([NNK-C_2]-DT, 62 650 Da) of 1.3 KDa (Figure 2) corresponds to an average number of approximately 5.5 NNK-C_2 molecules (235.1 Da) per molecule of carrier. Analysis of OVA conjugate gave very similar estimated numbers of hapten per protein (data not shown).

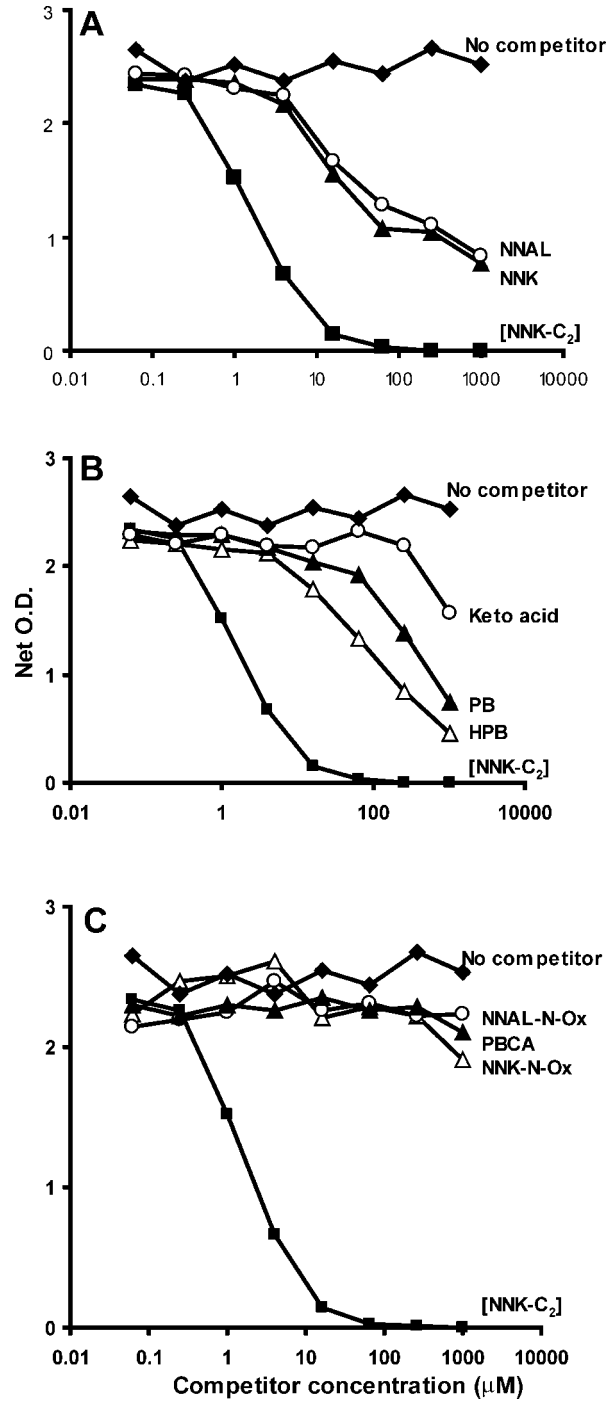

Figure 4. Binding inhibition of mouse anti-[NNK-C_2]-DT sera (1/2500) to coated [NNK-C_2]-OVA by increasing concentration of competitors. (A) NNK, NNAL, NNK-C_2. (B) PB, HPB, keto acid. (C) NNK-N-Ox, NNAL-N-Ox, PBCA. No competitor and NNK-C_2 are shown for comparison in each panel. Reactivity of serum tested after subtraction of background (0.077) corresponding to maximal competition with the highest NNK-C_2 concentration (1024 μM).

Induction of NNK-Specific Antibodies. Specific antibodies were monitored after each injection of [NNK-C_2]-DT (Figure 3). Antibodies against the homologous conjugate appeared within two weeks after the first injection. Significant levels of NNK-C_2 specific antibodies were detected with [NNK-C_2]-OVA after the second injection and increased with each boost (Figure 3). No specific IgA antibodies were detected despite the partially oral route (data not shown). NNK-specific antibodies were monitored by competition ELISA by adding increasing concentrations of NNK as competitors (0–256 μM) (Figure 4) to

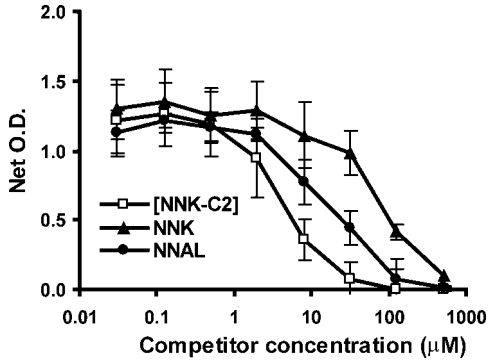

Figure 5. Inhibition of binding of P9D5 to coated [NNK-C_2]-OVA by increasing concentration of NNK, NNAL, and NNK-C_2. Mean ± SD of triplicates is shown. The background corresponding to maximal competition with NNK-C_2 at the highest concentration (512 μM) is 0.079 ± 0.007.

measure their capacity to inhibit the binding of serum antibodies to coated [NNK-C_2]-OVA. The IC_{50} of NNK and NNAL was 26 and 80 μM, respectively, while the IC_{50} of the hapten NNK-C_2 was 16–50-fold lower (Figure 4A). Also, HPB (80 μM) and PB (230 μM) were recognized by mouse sera, while essentially no specific reactivity was detected against NNK-N-Ox, NNAL-N-Ox, PBCA, and keto acid (Figure 4B,C).

Characterization of Monoclonal Antibodies. The spleen of a mouse with high levels of specific antibodies to NNK-C_2 and NNK was used for the production of mAbs. We described here two IgG1 mAbs (P9D5; Figure 5 and P7H3) that reacted strongly with [NNK-C2]-OVA.

The affinity of P9D5 and P7H3 toward the hapten [NNK-C2] was estimated by surface plasmon resonance (BiaCore) following the bivalent analyte model evaluation (Figure 6). K_d of P9D5 was 45.8 nM ($k_{a1} = 1.11 \times 10^5 \pm 202$; $k_{d1} = 5.09 \times 10^{-3} \pm 4.25 \times 10^{-5}$; $\chi^2 = 7.07$); K_d of P7H3 was 37.6 nM ($k_{a1} = 1.99 \times 10^5 \pm 334$; $k_{d1} = 7.49 \times 10^{-3} \pm 8.38 \times 10^{-5}$; $\chi^2 = 5.68$).

The reactivity of P9D5 and P7H3 was also assessed by competition ELISA using NNK metabolites and other derivatives as competitors. Binding was inhibited by NNK-C_2 (range of IC_{50}: 4.4–12 μM), NNAL (range of IC_{50}: 29–93 μM), and NNK (range of IC_{50}: 80–160 μM) (Table 1). Furthermore, the binding of P9D5 was strongly inhibited by HPB ($IC_{50} = 50$ μM), PB ($IC_{50} = 72$ μM), and ENAT ($IC_{50} = 49$ μM). A moderate inhibition of P9D5 binding was observed with keto acid and with PBCA. Weak or no competition was measured with the other metabolites and derivatives. P7H3 showed a similar reactivity: its binding was strongly inhibited by ENAT ($IC_{50} = 80$ μM); moderately inhibited by HPB, PB, keto acid, and PBCA; and weakly or not inhibited by the other metabolites and derivatives.

DISCUSSION

To induce specific antibodies against tobacco smoke associated nitrosamines, we developed a hapten, which closely mimics the common structural features of NNK and NNAL. Both parent molecules share the pyridyl–oxobutyl structure and the N-nitroso functional group responsible for the formation of DNA adducts. Our synthetic route was designed to include the 3-pyridyl group common to all activated NNK metabolites, as well as the possibility of nitrosation of the secondary amine later during the synthesis, while N-oxide groups characteristic of detoxified metabolites were avoided. As a result of our choice of 3-pyridinecarboxaldehyde as the starting material, the ketone differentiating NNK from NNAL was preserved and the N-nitroso functional group was added. In order to elicit a sustained immune response, T cell epitopes were added to the final immunogen by coupling the hapten to carrier proteins, and the tertiary amine was chosen to mediate this conjugation via a C_2 linker. Diphtheria toxoid was selected as a carrier protein, because it is highly immunogenic and is licensed in humans as a vaccine. It has also been extensively used as a carrier in a number of highly successful human conjugate vaccines, e.g., against *Haemophilus influenza* (*28, 29*), *Streptococcus pneumoniae* (*30, 31*), and meningococcal infections (*32, 33*). OVA was used as a control protein carrier to produce the antigen used in the immunoassays.

Thus, our synthetic approach and the final conjugate vaccine differ considerably from that of Talbot et al. (*34*), who used the 4-(carbethoxynitrosamino)-1-(3-pyridyl)-1-butanone, lacking in particular the tertiary amine with its nitroso group and bovine serum albumin as a protein carrier.

The resulting conjugate was successfully used to generate specific polyclonal and monoclonal antibodies. The small size of the hapten molecule, the limited number of specific structural features, and the need for a generic linker directly affected the specificity and the affinity of the antibodies obtained. After immunization with [NNK-C_2]-DT, the antibodies were selected against the heterologous antigen [NNK-C_2]-OVA.

Both conjugates share the NNK-C_2 motif, which was preferentially recognized by both polyclonal and monoclonal antibodies with K_d of 37–46 nM. Because of the 300-fold mass difference, direct binding of NNK to mAbs was not measurable by surface plasmon resonance; therefore, the relative specificity of some structurally and metabolically related molecules were ranked by competition ELISA. In contrast to the antibodies induced against the pyridyl–oxobutyl moiety by Talbot et al. (*34*), our antibodies recognized NNK and, even better, NNAL. The competition capacity of the pyridyl ring ($IC_{50} = 400$ μM

Table 1. IC50 of Each Competitor (NNK Metabolites and Derivates) for the Binding of P7H3 and P9D5 to the Coated Antigen [NNK-C_2]-OVA

Chemicals Name	Abbreviation	Formula	IC50 (μM) P7H3	IC50 (μM) P9D5
4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone	NNK		160	80
4-[2-Amino-ethyl(nitrosamino)]-1-pyridin-3-yl-butan-1-one	NNK-C_2		12	4.4
NNK metabolites				
4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol	NNAL		93	29
4-(methylnitrosamino)-1-(3-pyridyl-N-oxide)-1-butanone	NNK-N-Ox		>512	>512
4-(methylnitrosamino)-1-(3-pyridyl-N-oxide)-1-butanone	NNAL-N-Ox		>512	>512
4-Hydroxy-1-(3-pyridyl)-1-butanone	HPB		210	50
1-(3-pyridyl)-1-butanediol	PB		500	72
1-(3-pyridyl)-1-butanone-4 carboxylic acid	Keto Acid		270	210
1-(3-pyridyl)-1-butanol-4 carboxylic acid	PBCA		500	190
NNK derivatives				
Ethyl nicotinate	ENAT		80	49
Nicotinamide	NAD		>512	>512
Nicotinic acid	NIA		>512	>512
3-acetyl pyridine	AcP		500	>512
3-picoline	PC		400	320
Nicotinamide-N-oxide	NAD-N-Ox		>512	>512
Nicotinic acid-N-oxide	NIA-N-Ox		>512	>512

or 320 μM for 3-picoline) corresponded to 25–40% of the competition capacity of NNK (IC_{50} = 80 μM or 160 μM) for P9D5 or P7H3 calculated from the OD using the dynamic range of the assay. The N-oxidation of the pyridyl ring (e.g., NAD-N-Ox, NIA-N-Ox, NNK-N-Ox and NNAL-N-Ox) totally oblitterated antibody binding. This shows that the pyridyl ring is an important part of the epitope but the antibody paratope cannot accommodate the bulkier charged groups of the N-Ox species. The side chain in position 3 of the pyridine ring improved the recognition as exemplified by the efficient binding of ethyl nicotinate (IC_{50} = 49–80 μM); however, both mAbs showed some differential sensitivity to functional groups on the side chain. P7H3 required the nitroso group absent in HPB, PB, the ketoacid, and PBCA. In contrast, P9D5 was less sensitive to modification at the nitroso end, with the IC_{50} of HPB and PB being similar to that of NNK, but this mAb was sensitive to the acid moiety in the keto acid and PBCA with a significant increase of the IC_{50}. Surprisingly, the carbonyl reduction of

NNK to NNAL improved the binding by 2–3-fold, although this was not the case for their acid endpoint metabolites. Furthermore, the polyclonal antibodies generated in the serum after vaccination exhibited a very similar recognition pattern with a preferential reactivity toward NNK and NNAL, a low reactivity toward the end point metabolites (HPB, PB, PBCA, and the keto acid) and no reactivity with the detoxified species (NNK-N-Ox, NNAL-N-Ox).

Both the polyclonal and monoclonal antibodies induced by our conjugate vaccine showed an excellent selectivity for NNK and the activated metabolite NNAL but did not recognize the detoxified N-oxide derivatives. It is also reasonable to assume that they will not recognize the NNAL-glucuronidate (generated by the main detoxification pathway in humans) because of steric hindrance of the bulky glucuronic acid moiety adjacent to the pyridyl ring. Also, as a result of the low reactivity of the endpoint metabolites (HPB, PB, PBCA, and the keto acid), these would not compete effectively for the antibodies against activated NNK metabolites. Finally, in contrast to the antibodies induced by the pyridyl–oxobutyl hapten of Talbot et al. (*34*), our antibodies would not only bind to NNK but also to NNAL, the two most carcinogenic species of the metabolic cascade.

In summary, we describe the chemical synthesis of a novel functionalized NNK derivative, which was conjugated to diphtheria toxoid, a highly immunogenic antigen in humans to induce sustained and specific polyclonal and monoclonal antibodies against activated NNK and NNAL nitrosamines but not against their detoxified metabolites. Our results show that these antibodies can be used to detect these two main activated metabolites. Similarly, the concept of a conjugate vaccine against benzo[a]pyrene has previously been discussed (*35*–*37*).

Further in vitro and in vivo studies will be necessary to estimate whether a conjugate vaccine against cigarette smoke associated nitrosamines could potentially alleviate some of the detrimental effects of smoking and ultimately reduce the risk of chemical carcinogenesis in self-exposing individuals. However, the use of such a vaccine would have to be critically assessed to avoid misleading consumers about the many other health risks associated with cigarette smoking.

Surface Acetylation of Polyamidoamine (PAMAM) Dendrimers Decreases Cytotoxicity while Maintaining Membrane Permeability

Rohit B. Kolhatkar, Kelly M. Kitchens, Peter W. Swaan, and Hamidreza Ghandehari*

Center for Nanomedicine and Cellular Delivery, Department of Pharmaceutical Sciences, University of Maryland, Baltimore, Baltimore, Maryland. Received December 18, 2006; Revised Manuscript Received September 13, 2007

Improving the oral bioavailability of therapeutic compounds remains a challenging area of research. Polyamidoamine (PAMAM) dendrimers are promising candidates for oral drug delivery due to their well-defined compact structure, versatility of surface functionalities, low polydispersity, and ability to enhance transepithelial transport. However, potential cytotoxicity has hampered the development of PAMAM dendrimers for in vivo applications. In this article, we have systematically modified the surface groups of amine-terminated PAMAM dendrimers with acetyl groups. The effect of this modification on cytotoxicity, permeability, and cellular uptake was investigated on Caco-2 cell monolayers. Cytotoxicity was reduced by more than 10-fold as the number of surface acetyl groups increased while maintaining permeability across the cell monolayers. Furthermore, a decrease in nonspecific binding was evident for surface-modified dendrimers compared to their unmodified counterparts. These studies point to novel strategies for minimizing PAMAM dendrimer toxicity while maximizing their transepithelial permeability.

INTRODUCTION

Polymeric drug delivery systems generally entail improved efficacy while concomitantly decreasing the dose limiting toxicity of therapeutically active compounds (*1, 2*). Due to ease of administration and patient compliance, oral delivery remains the preferred route of drug intake; however, the macromolecular nature of polymers oftentimes necessitates their administration by intravenous injection. Polyamidoamine (PAMAM) dendrimers, owing to their unique characteristics such as nanoscopic size range, high drug-loading capacity, low polydispersity, and predictable size and surface charge, have shown promise in drug delivery (*1, 3–5*). Depending on their surface properties and size, PAMAM dendrimers are transported across epithelial barriers to a higher extent than some of the conventional linear water-soluble polymers (*6*). Our recent data suggest that cationic PAMAM dendrimers may permeate across Caco-2 cells to a higher extent than their neutral and anionic counterparts (*7*). However, an important element limiting the clinical application of cationic dendrimers is their cytotoxicity, which is dependent on concentration, generation, and exposure time to the cellular barriers (*8–12*). Studies using epithelial cell lines have shown that the cytotoxicity of cationic dendrimers can be reduced by functionalizing their surface amine groups (*13, 14*). In this article, a small acetyl group was used for neutralization of surface amines to avoid the influence of molecular weight on the properties of the polymer. Other factors that prompted the use of acetyl groups for surface functionalization were as follows: (1) an increasing interest in surface-modified dendrimers for drug delivery; (2) ease of controlling the degree of acetylation by controlling stoichiometry; (3) mild reaction conditions required for acetylation; and (4) increased solubility of acetylated dendrimers. Two different generations of PAMAM dendrimers, namely, G2 and G4, were acetylated and the effect of surface modification on cytotoxicity, permeability, and uptake on Caco-2 epithelial cells was studied.

EXPERIMENTAL PROCEDURES

Materials. PAMAM-G2NH_2 (molecular weight = 3214, 16 amine end groups), PAMAM-G4NH_2 (molecular weight = 14215, 64 amine end groups), Acetic anhydride, [^{14}C]-mannitol (specific activity 50 mCi/mmol), D_2O, and Triton X-100 were purchased from Sigma-Aldrich Co. (St. Louis, MO). ^{3}H-Acetic anhydride was purchased from American Radiolabeled Chemicals Incorporation. Superose 12 HR 16/50 column was purchased from Amersham Pharmacia Biotech (Piscataway, NJ). Caco-2 cells were purchased from American Type Cell Culture (ATCC, Rockville, MD). WST-1 cell proliferation reagent was purchased from Roche Applied Science (Indianapolis, IN). Precast 4–20% gradient express gels for PAGE were obtained from ISC Bioexpress (Kaysville, UT). Tris-glycine-SDS (TGS) buffer (pH = 8.3) was purchased from Invitrogen (Carlsbad, CA). ^{1}H NMR and ^{13}C NMR spectra were obtained using Varian 500 MHz FT NMR. The NMR solvent used was D_2O unless otherwise indicated. All other chemicals used were analytical grade.

Surface Acetylation of PAMAM Dendrimers. Conjugates are designated as G*x*A*y* where *x* represents the PAMAM dendrimer generation and *y* represents the number of acetamide groups on the surface (number of amine groups functionalized). PAMAM dendrimers were reacted with different molar ratios of acetic anhydride in the presence of excess triethylamine to quench acetic acid which was formed as a side product during the reaction (Figure 1) (*15*). A typical procedure for the synthesis of acetylated PAMAM dendrimers (G2A16) was as follows. G2-PAMAM dendrimer (0.100 g, 0.03 mmol) was dissolved in dry methanol (10 mL) followed by addition of acetic anhydride (0.062 g, 0.61 mmol) and triethylamine (0.12 g, 1.2 mmol). The solution was stirred for 12 h at room temperature, and methanol was then evaporated to obtain crude acetylated PAMAM dendrimers. The crude product was redissolved in water and purified by extensive dialysis against distilled water using dialysis membrane of 500 MWCO (Spectrum Laboratories, Inc., Rancho Dominguez, CA). Purified acetylated PAMAM

dendrimer was then freeze-dried, and solid product was stored in a refrigerator. G2A7, G4A32, and G4A60 were synthesized following a similar procedure with different molar equivalents of acetic anhydride.

Characterization of Acetylated PAMAM Dendrimers. Acetylated PAMAM dendrimers were characterized by size exclusion chromatography (SEC) on a Superpose 12 column (Amersham Biosciences, Piscataway, NJ) using a fast protein liquid chromatography (FPLC) system with phosphate buffer (pH 7.4) as the mobile phase. Eluting molecules were detected using UV detector at 280 nm. The number of surface amine groups modified was determined from ^{1}H NMR by calculating the ratios of integral values of the signal for upfield CH_3 protons (1.8 ppm) and integral values of the signal for -CH_2- protons from PAMAM dendrimer (2.2–4 ppm) (*15*). Figure 2A shows a typical NMR spectrum for acetylated PAMAM dendrimer. ^{1}H-NMR (D_2O, 500 MHz) values for the surface-modified polymers were as follows:

G2A16. δ = 1.89 (48H, s, $COCH_3$), 2.30–2.40 (56H, m, C-C$\underline{H_2}$-CONH), 2.53–2.58 (28H, m, N-C$\underline{H_2}$-CH_2NH), 2.70–2.78 (56H, m, N-CH_2-C$\underline{H_2}$-CO), 3.18–3.25 (88H, CONH-C$\underline{H_2}$).

G2A7. δ = 1.88 (21H, s, $COCH_3$), 2.28–2.42 (56 H, m, C-C$\underline{H_2}$CONH), 2.50–2.60 (28H, m, N-C$\underline{H_2}$-CH_2NH), 2.68–2.80 (56H, m, N-CH_2-C$\underline{H_2}$-CO), 2.96–3.06 (18H, C$\underline{H_2}$$NH_2$), 3.18–3.38 (70H, CONH-C$\underline{H_2}$).

G4A60. δ = 1.89 (180H, s, $COCH_3$), 2.30–2.42 (248H, m, C-C$\underline{H_2}$-CONH), 2.56–2.68 (124H, m, N-C$\underline{H_2}$-CH_2NH), 2.74–2.88 (248H, m, N-CH_2-C$\underline{H_2}$-CO), 3.18–3.30 (376H, CONH-C$\underline{H_2}$).

G4A32. δ = 1.88 (96H, s, $COCH_3$), 2.30–2.42 (248 H, m, C-C$\underline{H_2}$CONH), 2.50–2.60 (124H, m, N-C$\underline{H_2}$-CH_2NH), 2.68–2.80 (248H, m, N-CH_2-C$\underline{H_2}$-CO), 2.96–3.06 (64H, C$\underline{H_2}$$NH_2$), 3.18–3.38 (312H, CONH-C$\underline{H_2}$).

The dendrimers were further characterized using matrix assisted laser desorption–ionization-time of flight mass spectrometry (MALDI-TOF MS) on a Bruker Omniflex (Bruker Daltonics, Billerica, MA) to determine their molecular weights. A stock solution of the dendrimer was prepared by dissolving 1 mg of the sample in methanol. A 1 μL aliquot of the stock solution was mixed with 9 μL of matrix solution. The matrix solution used for characterizing G2 analogues consisted of saturated solution of α-hydroxycinnamic acid, and the matrix solution used for G4 analogues consisted of 10 mg/mL 2,5-dihydroxybenzoic acid in 20:80 acetonitrile/ water containing 0.1% trifluoroacetic acid. The dendrimer matrix mixture was spotted on the target plate (1 μL per spot), and the solvent was allowed to evaporate under ambient conditions. Analysis was performed in the linear mode.

The variations in charge ratio of the dendrimers were analyzed by native polyacrylamide gel electrophoresis (PAGE) and SDS PAGE on a BioRad vertical electrophoresis system (Power Pac 200, BioRad, CA, USA). For SDS PAGE analysis, TGS buffer (10×, pH = 8.3) was diluted with water by a factor of 10 to prepare the running buffer. Each well was loaded with 2.0 μL sample solution comprising 1.0 μL of 1.0 mg/mL PAMAM dendrimer and 1.0 μL sample buffer Laemmli (Sigma, MO). Developed gels were stained with Bio-Safe Coomassie Blue and destained with water. Native PAGE analysis was performed following similar procedures but with reverse polarity, Tris–glycine buffer (pH = 8.3) and methylene blue sucrose dye solution (50% sucrose, 1% methylene blue) were used as the loading buffer.

The surface density of amine groups, SD_a (i.e., the number of amine groups/nm^2 of the surface), was calculated by dividing the number of amine groups on each dendrimer by its surface area. Surface area was calculated by assuming a spherical shape for the dendrimer and the R_G (radius of gyration) values obtained from molecular modeling calculations for different-generation dendrimers (*16*).

Synthesis and Characterization of Radiolabeled PAMAM Dendrimers. The surface modified G4 analogues (G4A32, G4A60) as well as unmodified $G4NH_2$ PAMAM dendrimers were reacted with [^{3}H]-labeled acetic anhydride (5 mCi/mmol of the polymer) as described above to obtain [^{3}H]-labeled G4A32 and G4A60 PAMAM dendrimers. The crude product was purified by dialysis against distilled water for 48 h using dialysis membranes of 1000 MWCO (Spectrum Laboratories, Inc., Rancho Dominguez, CA). The polymers did not show any small molecular weight impurities as examined by size exclusion chromatography using a PD-10 column while measuring the radioactivity of the fractions collected. The specific activity for each radiolabeled polymer was in the range 2–3 mCi/mmol.

Cell Culture. Caco-2 cells (passages 30–60) were grown at 37 °C in an atmosphere of 5% CO_2 and 95% relative humidity. Cells were maintained in T-75 flasks using Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum, 1% nonessential amino acids, 10 000 units/mL penicillin, 10 000 μg/mL streptomycin, and 25 μg/mL amphotericin. Medium was changed every other day, and cells were passaged at 70–90% confluency using 0.25% trypsin/ethylenediamine tetraacetic acid (EDTA) solution. Incubation buffer consisted of Hank's balanced salt solution (HBSS) supplemented with 10 mM *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid) hemisodium salt (HEPES) buffer (pH 7.4).

Cytotoxicity Assay. Caco-2 cells were seeded (50 000 cells/well) in 96-well cell culture plates (Corning, Inc., Corning, NY) and maintained for 48 h. The cells were washed twice with HBSS and incubated with 100 μL of unmodified and modified PAMAM dendrimer solutions in HBSS. After 3 h, the cells were washed with HBSS to remove the dendrimers and replaced with 100 μL HBSS. Thereafter, 10 μL of cell proliferation reagent WST-1 was added to each well, followed by an incubation period of 4 h. Absorbance was measured at 440 nm using a SpectraMax 384 Plus plate reader (Molecular Devices, Sunnyvale, CA). HBSS was used as a negative control. The experiment was repeated 3 times in triplicate for each concentration of the PAMAM dendrimer.

Cellular Uptake of PAMAM Dendrimers. To determine cellular uptake of radiolabeled PAMAM dendrimer, Caco-2 cells were seeded with a cell density of 80 000 cells per well on cell culture-treated 12-well plates (Becton Dickinson). After 48 h, cells were washed with HBSS and incubated with 0.01 mM radiolabeled PAMAM dendrimers for 30, 60, and 120 min, respectively. At the end of the incubation period, 20 μL of the sample of donor dendrimer solution was collected for measuring radioactivity, and the cells were washed twice with ice–cold HBSS buffer to stop the uptake process. The cells were then lysed with 1 N NaOH solution which was then neutralized with HCl. The cell-associated radioactivity was determined using liquid scintillation counting (Beckman Coulter, Fullerton, CA). The uptake data was normalized to total protein content determined using BCA protein assay kit (Pierce, Evanston, IL).

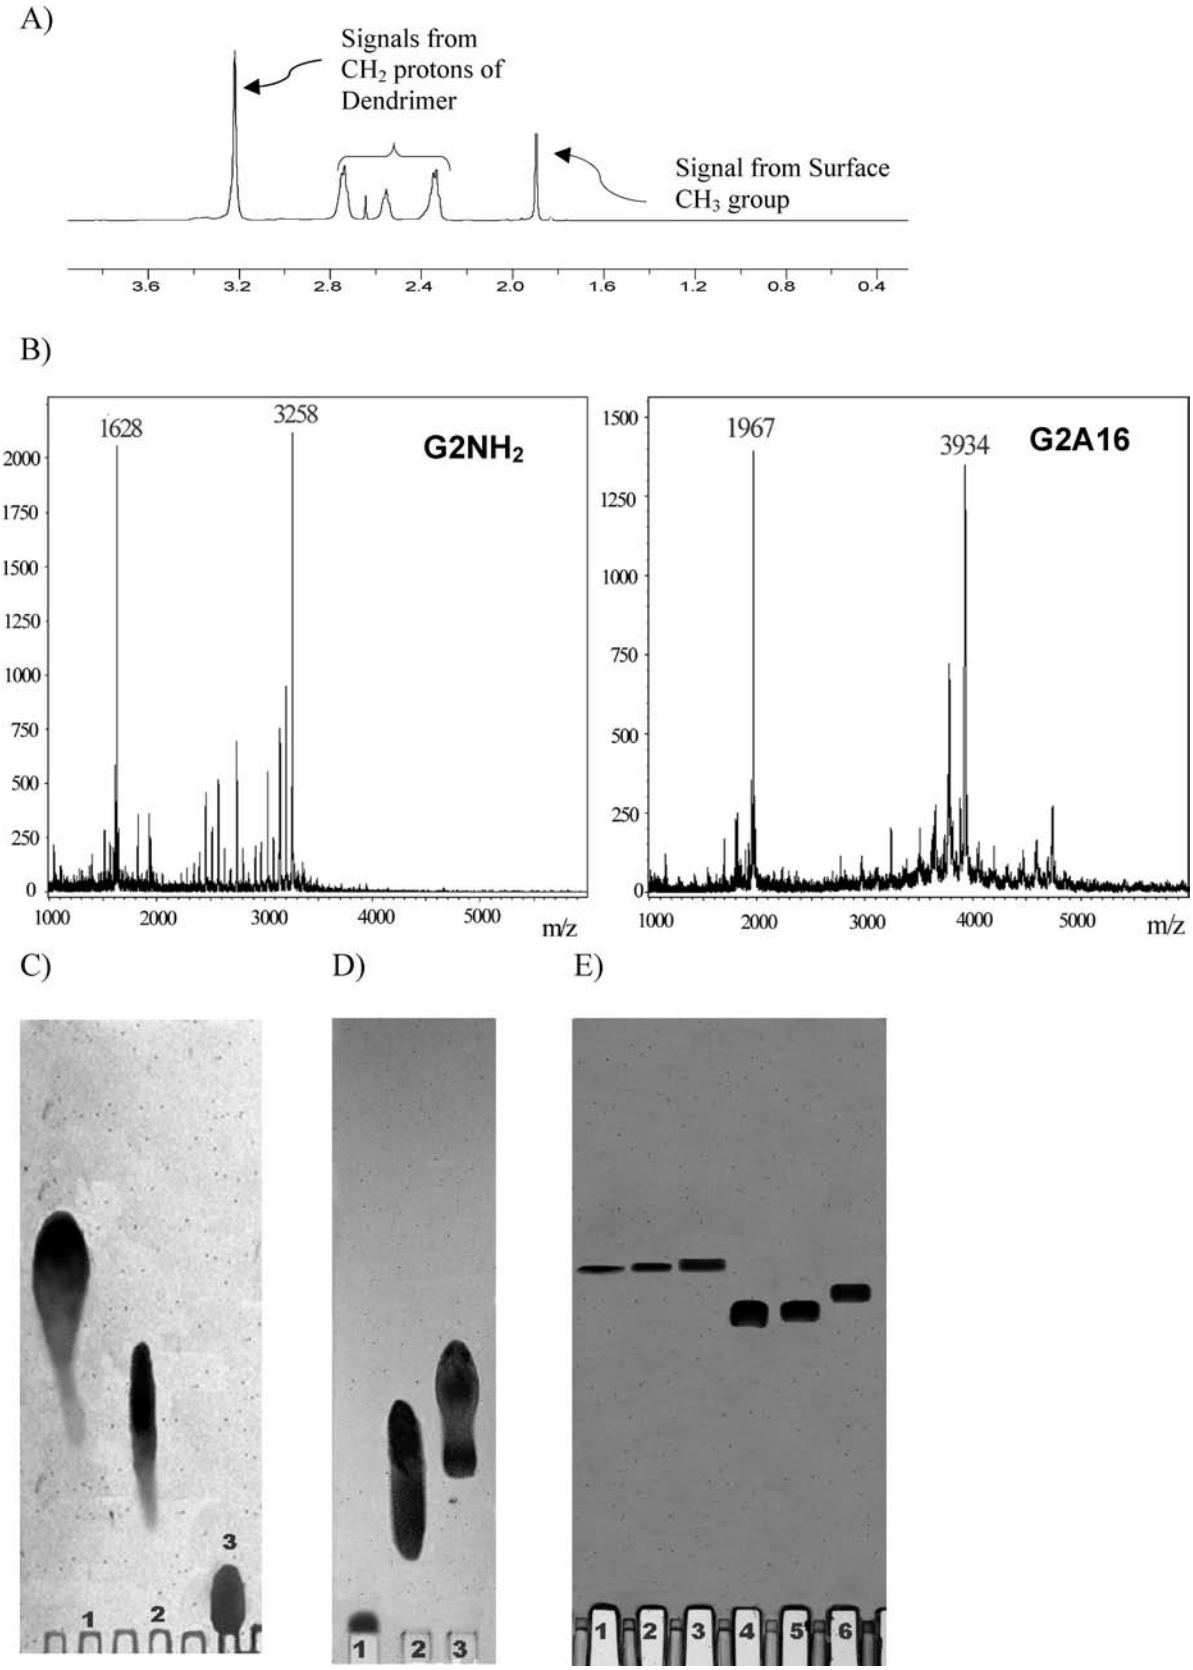

Figure 2. (A) ^{1}H NMR of G2A16. (B) MALDI TOF MS spectra for unmodified G2 (left) and G2A16 (right). (C) Native PAGE analysis of G2, G2A7, and G2A16 in lanes 1, 2, and 3, respectively. (D) Native PAGE analysis of G4A60, G4A32, and G4 in lanes 1, 2, and 3, respectively. (E) SDS PAGE analysis of G2, G2A7, G2A16, G4, G4A32, and G4A60 in lanes 1, 2, 3, 4, 5, and 6, respectively.

Transepithelial Transport Studies. Caco-2 cell monolayers were seeded (80 000 cells/well) on 12-well Transwell cell culture inserts (3 μM pore size). After the cells reach confluency (21–28 days in culture), the transport of PAMAM dendrimers from the apical to the basolateral direction was investigated at donor concentrations of 0.01 mM for G4, 0.01 mM and 0.1 mM for G4A32, and 0.01 mM, 0.1 mM, and 1 mM for G4A60. Prior to experiments, the cells were washed with HBSS buffer, and then

500 μL of the [^{3}H]-labeled polymer was added to the apical side of each insert while 1500 μL of the HBSS buffer was added on the basolateral side. Samples were collected at 0, 30, 60, 90, and 120 min from the basolateral compartment and analyzed for accumulated radiolabel using a liquid scintillation counter (Beckman Coulter, Fullerton, CA). The activity of the apical donor solution was also measured at $t = 0$ and 120 to assess mass balance and determine accurate donor concentrations. The apparent permeability (P_{app}) coefficients for PAMAM dendrimers were calculated as follows:

$$P_{app} = \frac{dM}{C_0 \cdot S \cdot dt} \quad (1)$$

where dM represents the change in dendrimer accumulation on the basolateral side, C_0 the concentration on the apical side of the membrane, S the surface area of the insert (1.12 cm^2), and dt the change in time. Monolayers were considered to be confluent when P_{app} for mannitol was less than $2 \cdot 10 \cdot 10^{-6}$ cm/s.

Additionally, cell monolayer integrity was monitored during transport studies by using an epithelial voltohmmeter (EVOM) (World Precision Instruments, Inc., Sarasota, FL) to measure the transepithelial electrical resistance (TEER) at time points coinciding with sample collection. TEER values (Ω cm^2) were corrected for background (obtained from inserts without cells) and normalized to untreated inserts (% control). After 120 min, the dosing solution was removed, and cells were washed with HBSS. Subsequently, cells were incubated in DMEM and placed at 37 °C overnight. After 24 h, TEER was measured to assess reversibility of tight junctional perturbance.

In a different set of experiments using a similar procedure, the relative integrity of the paracellular (tight junctional) pathway was assessed by evaluating [^{14}C]-mannitol (2.0 μM) permeability in the presence of PAMAM dendrimer.

Statistical Analysis. Statistical analysis was carried out using Student's t-test with a probability value $p < 0.05$ considered statistically significant.

RESULTS AND DISCUSSION

Synthesis and Characterization of Acetylated PAMAM Dendrimers. This study is a logical extension of our previous investigation in which we demonstrated that the permeability of amine-terminated PAMAM dendrimers across Caco-2 cell monolayers is controlled by size, molecular weight, and concentration (*4, 11*). Subsequent studies indicated that cationic PAMAM dendrimers modulate tight junctions of Caco-2 cells, thereby enhancing the transepithelial transport of mannitol (*7*). However, the surface amine groups also render cationic PAMAM dendrimers cytotoxic, limiting their utility as safe and effective drug delivery systems (*7, 12*). With the hypothesis that surface modification can reduce cytotoxicity while maintaining optimal cellular uptake as well as transepithelial permeability, in this study 47% and 100% of the surface amine groups of G2 were functionalized to acetamide to yield G2A7 and G2A16, respectively. Likewise, 50% and 94% of the surface amine groups of G4 were functionalized to acetamide to yield G4A32 and G4A60, respectively. A typical ^{1}H NMR spectrum obtained for completely modified G2A16 dendrimer is shown in Figure 2A. In the ^{1}H NMR spectra, a downfield shift of the signal for CH_2-NH$_2$ and the appearance of a new signal for CH$_3$ protons at 1.89 ppm, as well as the appearance of a new peak at 21.94 ppm corresponding to CO$\underline{C}$H$_3$ in ^{13}C NMR spectra (data not shown) indicate the formation of a covalent bond between surface amine and carbonyl carbon from acetic anhydride. MALDI-TOF MS analysis (Figure 2B) demonstrated an increase in the molecular weight of the polymer as the number of surface acetyl groups increased, suggesting the formation of a covalent bond rather than a complex. Similar MALDI-TOF spectra were obtained for all other unmodified and surface-modified PAMAM dendrimers. The estimated molecular weights (Table 1) were in good agreement with the NMR data obtained.

Table 1. Characteristics of PAMAM Dendrimers Studied

PAMAM dendrimer	no. of surface NH$_2$/acetyl groups[a]	Mw calcd	Mw (MALDI)	elution volume (FPLC) ml	surface density of amine groups[b]
G2NH$_2$	16/0	3250	3258	14.85	0.60
G2A7	9/7	3550	3563	14.77	0.34
G2A16	0/16	3928	3934	14.74	0
G4NH$_2$	64/0	14215	13337	13.10	0.71
G4A32	32/32	15559	14782	12.94	0.35
G4A60	4/60	16735	15887	12.76	0.04

[a] Determined from NMR data. [b] Calculated by dividing number of surface amine groups by surface area (nm^2).

Size exclusion analysis of the polymers showed the absence of small molecular weight impurities. A decrease in the elution volume of the polymers was observed as the number of surface acetyl groups increased (Table 1). Native PAGE analysis with reverse polarity showed that gel migration slowed as the positive charge on the polymer reduced (Figure 2C,D), whereas SDS-PAGE analysis revealed that fully acetylated dendrimers migrated farther as compared to unmodified and partially acetylated dendrimers (Figure 2E). No differences were observed in bands of unmodified and partially acetylated dendrimers (Figure 2E). The bands in native page analysis were broad when compared to the narrow bands obtained from SDS-PAGE. The reason for this is that the native page separated compounds on the basis of charge and molecular weight whereas in SDS-PAGE separation is achieved on the basis of molecular weight only. Thus, in both native PAGE and SDS-PAGE analyses lower-generation smaller dendrimers (G2) migrated farther than higher-generation dendrimers (G4). Interestingly, in a subset of one generation subjected to native PAGE analysis, dendrimers with more positive charge showed farther migration as compared to dendrimers with a lower number of positively charged amine groups. As expected, fully acetylated dendrimers remained at the base due to lack of surface charge.

Acetylation of PAMAM Dendrimers Reduces Cytotoxicity. An evaluation of the effect of dendrimer concentration and the relative degree of surface amine group acetylation on cell viability (Figure 3A) revealed a complete absence of cytotoxicity at the lowest concentration of all PAMAM dendrimers tested (0.01 mM). Increasing the concentration to 0.1 mM significantly decreased cell viability for unmodified dendrimers; however, cell incubation with either partially or fully acetylated PAMAM dendrimers resulted in greater than 90% cell viability. These data suggest that even partial surface modification at this concentration reduces cytotoxicity. Another 10-fold increase in dendrimer concentration (1 mM) demonstrated a concomitant drop in cell viability for unmodified dendrimers. Interestingly, cytotoxicity was absent in cells incubated with PAMAM dendrimers exhibiting the highest degree of acetylation, suggesting a linear relationship between the number of amine groups and cellular cytotoxicity. In fact, a simple plot of cell viability vs the number of surface amine groups (Figure 3B) suggests that cytotoxicity is dependent on the dendrimer generation, probably due to the intrinsic toxicity associated with higher generation dendrimers. However, when cell viability was plotted as a function of surface density (SD_a), a linear correlation was observed irrespective of dendrimer generation (Figure 3C). Overall, G4 dendrimers showed lower cell viability (27%) as compared to G2 (56%) because of an increase in the surface density of amine groups, whereas G2A7 and G4A32 showed similar cell viability (73% vs 70%) due to

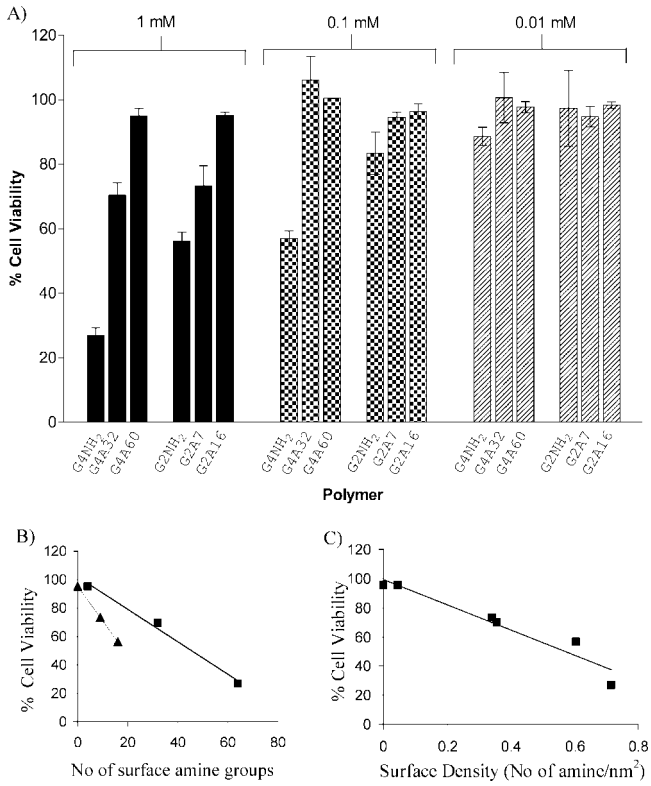

Figure 3. (A) Viability of Caco-2 cells after incubation for 3 h with dendrimers at 1 mM, 0.1 mM, and 0.01 mM. Results are expressed as mean ± SEM ($n = 9$). (B) Relationship between cell viability and number of surface amine groups for (■) G4 ($R^2 = 0.99$) and (▲) G2 analogues ($R^2 = 1$). (C) Relationship between cell viability and surface density ($R^2 = 0.93$).

similar surface density (0.34 vs 0.35) of amine groups. Previously, various investigators (*17–19*) found that cytotoxicity of water-soluble cationic polymers is governed by molecular weight, charge density, and the type of amine functionality (primary vs tertiary). Ryser (*18*) suggested a three-point attachment for eliciting a biological response on the cell membrane and speculated that the cytotoxicity of a polymer will decrease when the space between reactive amine groups is increased. In the current report, we have tried to quantify these observations with PAMAM dendrimers. A multiregressional analysis ($F < 0.001$; $R^2 = 0.7$) using cell viability, %CV, as a dependent variable with surface density, SD_a, and concentration, *C*, as independent variables revealed the following relationship:

$$\%CV = -15.5 \log C - 50.9SD_a + 87.6 \qquad (2)$$

Equation 2 suggests that cell viability in the presence of amine-terminated PAMAM dendrimers is influenced by concentration, size, and number of surface amine groups. This mathematical expression can be useful in predicting the appropriate surface modification required to minimize toxicity of PAMAM dendrimers in the size range studied.

Acetylated PAMAM Dendrimers Retain Cellular Permeability Comparable to Unmodified Dendrimers. The permeability of native and surface-modified G4 analogues was evaluated across Caco-2 cell monolayers (Figure 4A). At previously determined nontoxic concentrations (0.01 and 0.1 mM; Figure 3A), we observed a significant increase in [^{14}C]-mannitol permeability (Figure 4B) and a reduction in TEER values (Figure 4C). Since mannitol is a compound that exclusively traverses the cell monolayer via the paracellular pathway, these data indicate that PAMAM dendrimer incubation led to modulation of the epithelial tight junctions. As further evidence that incubation with acetylated PAMAM dendrimers

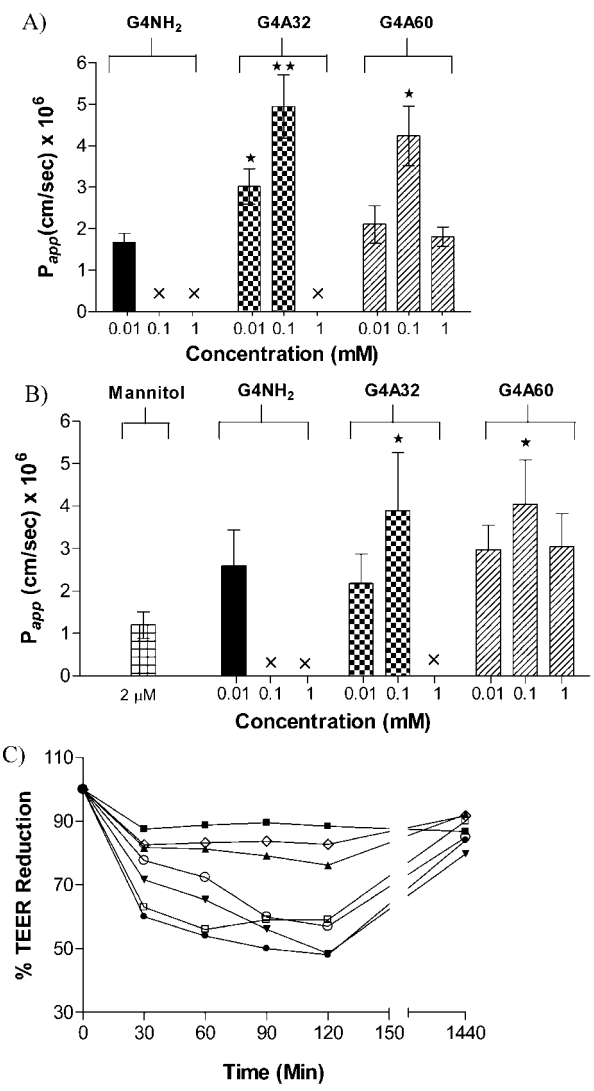

Figure 4. (A) Permeability of $G4NH_2$, G4A32, and G4A60 across Caco-2 cell monolayers after 120 min. Results are reported as mean ± SEM ($n = 6$). (*) ($p < 0.05$) and (**) ($p < 0.01$) denote a significant difference in permeability when compared to permeability of unmodified PAMAM dendrimer at 0.01 mM. (×) Permeability is not evaluated due to cytotoxicity. (B) Permeability of [^{14}C]-mannitol across Caco-2 cell monolayer in the absence and presence of $G4NH_2$, G4A32, and G4A60 dendrimers. Results expressed as mean ± SEM ($n = 6$). (×) Permeability is not evaluated due to cytotoxicity. (C) Effect of unmodified and surface-modified PAMAM dendrimers on transepithelial electrical resistance (TEER): (■) control, (▼), $G4NH_2$ (0.01 mM), (▲) G4A32 (0.01 mM), (○) G4A32 (0.1 mM), (◊) G4A60 (0.01 mM), (□) G4A60 (0.1 mM), (•) G4A60 (1 mM). Results expressed as mean ± SEM ($n = 6$). For clarity, error bars are not shown in the figure.

does not lead to permanent cell damage, we observed the full reversal of tight junctional modulation, as demonstrated by cellular TEER values, after a 24 h equilibration period (Figure 4C).

Permeability enhancement was a function of both dendrimer surface acetylation and donor concentration. At 0.01 mM, a significant increase in the permeability ($p < 0.05$) of G4A32 was observed when compared to unmodified G4 dendrimer. However, an additional increase in acetylation levels (e.g., G4A60) did not further enhance permeability. Although unmodified G4 is toxic at 0.1 mM, 1.5- and 2-fold enhancements of cellular permeability can be achieved by increasing the G4A32 and G4A60 concentration from 0.01 to 0.1 mM, respectively (Figure 4B). Paradoxically, permeability at 1 mM G4A60 led to a significant decrease in its permeability, which

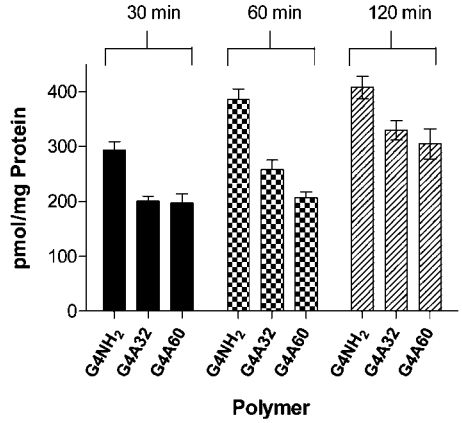

Figure 5. Cellular uptake (pmol of dendrimer/mg of protein) of 0.01 mM G4, G4A32, and G4A60 at 30, 60, and 120 min.

cannot be ascribed to intrinsic cytotoxicity and needs to be further addressed. Overall, the highest level of permeation enhancement was achieved at 0.1 mM with partially acetylated G4. It is interesting to note that the permeation enhancement of acetylated dendrimer is strongly correlated with [^{14}C]-mannitol permeability, but not to concomitant linear changes in TEER values. This would suggest that surface-modified PAMAM dendrimers do not enhance their permeability via the tight junctional route alone, but their enhanced cellular translocation may entail a combined effect on paracellular as well as transcellular permeation pathways.

Previous observations have shown that positively charged dendrimers exert higher permeability when compared to neutral and negatively charged dendrimers. Contrary to expectations, however, surface-modified dendrimers retained their permeability relative to unmodified dendrimers. Whereas this observation is unexpected, it should be noted that the effect of charge on permeability of dendrimer generation is generally more pronounced for lower-generation dendrimers (G2) (*7*). Alternatively, sustained permeability of surface-modified PAMAM dendrimers could be the result of a decrease in hydrophilicity of the polymers and/or conformational changes. Modification of the amine groups to amides renders the dendrimer surface neutral, thereby reducing the repulsive forces between amine groups and potentially leading to a more compact structural assembly. Another possible explanation for the increase in the permeability of G4A32 could be a reduction in nonspecific binding. Quintana and co-workers (*20*) reported that acetylation can be used to reduce nonspecific binding associated with amine-terminated nanoparticles. A decrease in the number of positively charged surface groups may reduce the nonspecific interaction of acetylated PAMAM dendrimers with the negatively charged cell membrane. This, in turn, may result in a relatively higher concentration of free dendrimer at the apical side of the membrane contributing to increased permeability through the paracellular route. These data are in good agreement with studies by Wiwattanapattapee and colleagues (*6*), who observed higher tissue uptake and lower serosal transfer rate for cationic dendrimers compared to anionic dendrimers. In addition, higher-generation dendrimers (G4) used in the current study will still carry a large number of internal tertiary amine groups, which can potentially interact with negatively charged cell membranes, enhancing permeability.

To further investigate their cellular entry mechanism, the uptake into Caco-2 cells of G4 surface-modified dendrimers was determined at nontoxic concentrations (0.01 mM). Assuming steady-state conditions after 30 min of equilibration, we found linear cellular accumulation of dendrimer with increasing incubation time (Figure 5), with a P_{app} (cm/s) of $1.7 \cdot \times 10^{-6}$, $3.0 \cdot \times 10^{-6}$, and $2.1 \cdot \times 10^{-6}$ for $G4NH_2$, G4A32, and G4A60, respectively. Although a significant decrease ($p < 0.05$) in initial uptake for acetylated G4 dendrimer was observed when compared to native dendrimer, there was no apparent decrease in permeability for G4A32 and G4A60, respectively. These data indicate that surface modification of cationic PAMAM dendrimers leads to only modest decreases in cellular uptake compared to native dendrimer, but results in a significant decrease in dendrimer-associated cytotoxicity.

Therapeutic agents are often conjugated to PAMAM dendrimers to gain an overall improvement of their bioavailability. Such surface modification can change cellular permeability characteristics and contribute to changes in the transepithelial transport of PAMAM dendrimers across intestinal cell lines. The remaining surface amine groups available on partially acetylated dendrimers can be used for drug loading and conjugation of targeting moieties to the PAMAM dendrimers while effectively reducing their cytotoxicity in parallel. Thus, the observations from the current study indicate that surface modification of PAMAM dendrimers is a strategy that can be utilized for oral drug delivery.

CONCLUSIONS

In this study, we differentially surface modified a series of cationic amine-terminated PAMAM dendrimers with acetyl groups. Although cationic dendrimers display concentration-dependent cytotoxicity, we observed a significant reduction of cellular toxicity with an increase in surface modification. Cell viability was strongly correlated with surface density of amine groups regardless of dendrimer generation. Surface-modified PAMAM dendrimers displayed permeability and uptake profiles similar to those of unmodified (native) dendrimer. Thus, acetylated PAMAM dendrimers feature reduced cytotoxicity while maintaining appreciable permeability. Taken together, these results suggest that it is possible to tailor-make surface-modified PAMAM dendrimers for specific oral drug delivery needs.

ACKNOWLEDGMENT

Authors appreciate the efforts of Dr. Julie A. Ray for assisting with MALDI-TOF MS experiments. Received March 6, 2007; Revised Manuscript Received July 30, 2007

Targeted α-particle emitters hold great promise as therapeutics for micrometastatic disease. Because of their high energy deposition and short range, tumor targeted α-particles can result in high cancer-cell killing with minimal normal-tissue irradiation. Actinium-225 is a potential generator for α-particle therapy: it decays with a 10-day half-life and generates three α-particle-emitting daughters. Retention of ^{225}Ac daughters at the target increases efficacy; escape and distribution throughout the body increases toxicity. During circulation, molecular carriers conjugated to ^{225}Ac cannot retain any of the daughters. We previously proposed liposomal encapsulation of ^{225}Ac to retain the daughters, whose retention was shown to be liposome-size dependent. However, daughter retention was lower than expected: 22% of theoretical maximum decreasing to 14%, partially due to the binding of ^{225}Ac to the phospholipid membrane. In this study, Multivesicular liposomes (MUVELs) composed of different phospholipids were developed to increase daughter retention. MUVELs are large liposomes with entrapped smaller lipid-vesicles containing ^{225}Ac. PEGylated MUVELs stably retained over time 98% of encapsulated ^{225}Ac. Retention of ^{213}Bi, the last daughter, was 31% of the theoretical maximum retention of ^{213}Bi for the liposome sizes studied. MUVELs were conjugated to an anti-HER2/neu antibody (immunolabeled MUVELs) and were evaluated *in vitro* with SKOV3-NMP2 ovarian cancer cells, exhibiting significant cellular internalization (83%). This work demonstrates that immunolabeled MUVELs might be able to deliver higher fractions of generated α-particles per targeted ^{225}Ac compared to the relative fractions of α-particles delivered by ^{225}Ac-labeled molecular carriers.

INTRODUCTION

Targeted α-particle emitters hold great promise as therapeutic agents for micrometastases (*1*). Alpha-particles are highly potent cytotoxic agents, potentially capable of killing tumor cells without limiting morbidity. The increased effectiveness of α-particles is due to the amount of energy deposited per unit distance traveled (high LET), which is of the order of approximately 80 keV/μm. Cell survival studies have shown that α-particle-induced killing is independent of oxygenation state or cell-cycle during irradiation and that as few as 1–3 tracks across the nucleus may result in cell death (*2–4*). In addition, the 50- to 100-μm range of α-particles is consistent with the dimensions of micrometastatic disseminated disease, allowing for localized irradiation of target cells with minimal normal-cell irradiation. Actinium-225 (^{225}Ac) is an α-particle emitter with increased cell killing efficacy (*5–7*) because each actinium-225 decay ($t_{1/2}$ = 10 d) generates three α-particle-emitting daughters (^{221}Fr ($t_{1/2}$ = 4.9 min), ^{217}At ($t_{1/2}$ = 32.3 ms), and ^{213}Bi ($t_{1/2}$ = 45.59 min)) and a total of 4 α -particles per decay. Thus, ^{225}Ac is an attractive candidate for α-particle therapy.

However, the optimal increase in the cell killing efficacy of ^{225}Ac will occur only if all (or most of the) α-emissions occur at the tumor site; otherwise, toxicity may be potentially increased. This is a fundamental difficulty if antibodies or other molecules with attached chelating ligands are to be used as the cell targeting vehicle since the coordination bonds from the chelate to the ^{225}Ac atom will not be retained after the decay of ^{225}Ac. This will leave the first daughter in the decay-chain free to distribute throughout the body where it and the resulting daughters will decay and increase toxicity. Thus, confinement of the intermediate radioactive daughters within the delivery carrier (during circulation) and at the tumor (after targeting) is desirable.

Liposomes have been previously considered for diagnostic and therapeutic delivery of radionuclides (*8–10*). We have previously investigated the encapsulation of ^{225}Ac in liposomes as a means of retaining the α-particle-emitting daughters within liposomes during delivery (*11*). Because of their high kinetic energy, α-particle emissions will escape the liposomal phospholipid membrane to irradiate the targeted cells. Similarly, daughter atoms, during their recoil trajectory (80 to 90 nm), can also penetrate the phospholipid membranes. Because the newly produced daughter atoms are charged, after losing their recoil energy, they cannot diffuse freely across the hydrophobic compartment of the phospholipid bilayer. Consequently, if the end point of a radioactive daughter's recoil trajectory is located within a liposome, the lipid membrane will inhibit free diffusion of the radioactive daughters, thereby retaining them at the site of liposome delivery. The probability of daughter retention is greater for larger liposomes, assuming homogeneous distribution of the parent radionuclides within the liposomal aqueous core.

Our theoretical calculations (*11*) predicted negligible, <0.001 %, (last) daughter retention for 100 nm diameter liposomes and more than 50% retention (of the last daughter) for liposomes larger then 650 nm (in diameter). For giant liposomes with 1 μm diameter, the maximum calculated retention of the last

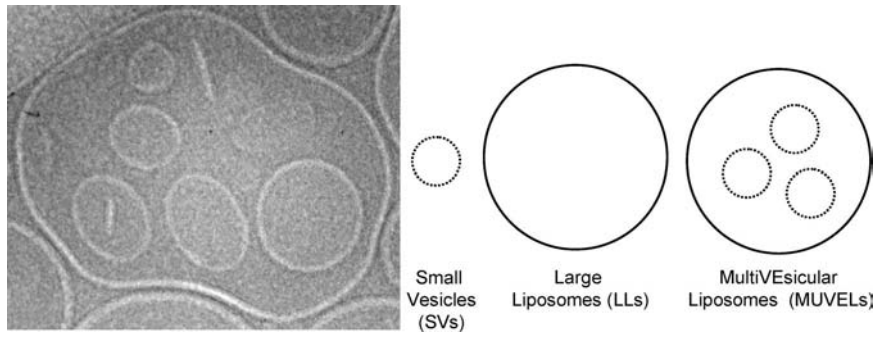

Figure 1. Cryo-TEM image of multivesicular liposomes (horizontal edge is approximately 400 nm), and schematic representation of Multivesicular liposomes (MUVELs) and their components.

daughter does not exceed 65%. However, the measured last daughter retention (11 % decreasing to 7% after 10 days) of 650 nm diameter liposomes was not consistent with the theoretical prediction (50%), and this was shown to be caused, in part, by the binding of ^{225}Ac to the phospholipid membrane. Actinium-225 localization at the liposomal membrane increases daughter loss after nuclear recoil, compared to daughter loss from uniformly distributed ^{225}Ac atoms within the liposomal aqueous core. In this work, we describe and characterize a construct designed to overcome this problem.

To increase daughter retention during circulation, ^{225}Ac was passively entrapped in multivesicular liposomes (MUVELs) (Figure 1). MUVELs are large liposomes (LLs) with entrapped small vesicles (SVs). Actinium-225 was only contained in the small vesicles. This strategy provides (1) confinement of entrapped ^{225}Ac within the aqueous compartment of the large liposomes (LLs) where the small vesicles are contained and thus away from the membrane of large liposomes, and (2) decreased radionuclide partition to the external membrane (large liposome membrane), due to increased internal membrane because of the encapsulated small vesicles. Retention of ^{225}Ac and its last radioactive daughter ^{213}Bi by MUVEL was evaluated over time. In these studies, MUVELs were PEGylated to assure long blood circulation times (*12*). MUVELs were then labeled with the monoclonal anti-HER2/neu antibody Trastuzumab (immunolabeled MUVELs) and were evaluated *in vitro* for targeted delivery of ^{225}Ac to ovarian carcinoma cells (SKOV3-NMP2).

EXPERIMENTAL PROCEDURES

Reagents. The lipids 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC), 1,2-diheneicosanoyl-*sn*-glycero-3-phosphocholine (21:0 PC), 1,2-dipalmitoyl-sn-glycero-3-phosphoethanolamine-*N*-[methoxy(polyethyleneglycol)-2000] (ammonium salt) (PEG-labeled lipid), L-α-phosphatidylethanolamine-*N*-(lissamine rhodamine B sulfonyl) (egg) (rhodamine-PE), and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[maleimide (polyethylene glycol) 2000] (ammonium salt) (maleimide-PE) (purity >99%) were purchased from Avanti Polar Lipids (Alabaster, Al). Cholesterol, phosphate buffered saline (PBS), fluorexon (calcein), Sephadex G-50, diethylenetriaminepentaacetic acid (DTPA), ascorbic acid, and Triton X-100 were purchased from Sigma-Aldrich (St. Louis, MO). *p*-Isothiocyanatobenzyl-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) was purchased from Macrocyclics (Dallas, TX). Traut's reagent (2-Iminothiolane-HCl) was purchased from Pierce (Rockford, IL). Actinium-225 nitrate was purchased from the Department of Energy, Oak Ridge National Laboratories (Oak Ridge, TN).

Liposome Preparation. The protocol to prepare MUVELs involves passive entrapment of small vesicles (SVs) into large liposomes (LLs). The phospholipid-cholesterol combinations chosen for the encapsulated small vesicles (SVs) and the large liposomes (LLs) were those that resulted in (1) the lowest release of contents by SVs after annealing at 40 °C (40 °C annealing is required for the hydration of the membranes of the LLs that contain encapsulated SVs), (2) the greatest passive entrapment efficacy by the LLs, and (3) the minimum fraction of fusion between lipids of SVs and LLs.

To make small vesicles, mixtures of phosphatidyl choline (21:0 PC), cholesterol (1:1 molar ratio), and PEG-labeled lipids (5.3 mol % of total lipid) in $CHCl_3$ were dried in a rotary evaporator. For ^{225}Ac passive entrapment, the lipids (30 mM final concentration) were resuspended in PBS (1 mM EDTA, pH 7.4) containing the chelated actinium complex (^{225}Ac-DOTA, 3.7–37.0 MBq, depending on radionuclide availability) and DTPA (1 mM). DTPA was used to potentially chelate free ^{225}Ac and ^{213}Bi. The protocol for ^{225}Ac-DOTA chelation is published elsewhere (*5*). The lipid suspension was then annealed to 55 °C for 2 h. Small vesicles were prepared by brief sonication (1–2 min) of the lipid suspension in a bath sonicator (Branson, Danbury, CT) at 75–80 °C until the appearance of a clear solution. The vesicle suspension was then incubated at room temperature for 15 min with 0.050 mL of externally added 10 mM DTPA to complex any free metals before purification during size-exclusion chromatography (SEC) in a Sephadex G-50 (Aldrich, St. Louis, MO) packed 1 × 10 cm column, eluted with sucrose isotonic PBS.

Then to prepare MUVELs, small vesicles were passively encapsulated into large liposomes (LLs). For LLs, mixtures of phosphatidyl choline (DMPC), cholesterol (2:1 molar ratio), maleimide-PEG-labeled lipids (1 mol % of total lipid) and PEG-labeled lipids (4.3 mol % of total lipid) in $CHCl_3$ were dried in a rotary evaporator. For passive entrapment of small vesicles, the dry lipids (60 mM final lipid concentration) were resuspended in the isosmolar sucrose–PBS suspension containing small vesicles (described above). The lipid suspension was then annealed to 40 °C for 2 h. MUVELs were prepared by the extrusion method. The lipid suspension was taken through 21 cycles of extrusion (LiposoFast, Avestin, Ontario, Canada) through two stacked polycarbonate filters (800 nm filter pore diameter) and then diluted in sucrose-free isosmotic PBS solution. Unentrapped small vesicles were removed by centrifugation, and the majority of MUVELs (90% as calculated by the fluorescent intensity of rhodamine-labeled lipids in parallel measurements) were collected in the pellet.

Plain large liposomes (LLs) were prepared as described above, without encapsulating small vesicles.

In all preparations, ascorbic acid (8 mmol/L) was coentrapped to minimize lipid oxidation due to gamma- (*13*) and beta-radiation (*14*), and possibly due to alpha-emissions (*15, 16*).

Liposome Size Distribution Determination. For dynamic light scattering (DLS), an N4 Plus autocorrelator (Beckman-Coulter) was used, equipped with a 632.8 nm He-Ne laser light source. The measurement protocol is published elsewhere (*11*).

Cryo-TEM. MUVELs were imaged using a FEI Tecnai 20 cryo-TEM. Measurements were performed by the staff of the Analytical Imaging Facility at the Albert Einstein College of Medicine, Yeshiva University. Samples were frozen, and thin frozen sections were imaged without staining.

Retention of Entrapped Contents by Liposomes. The protocol to measure the retention of ^{225}Ac and its last radioactive daughter ^{213}Bi by liposomes is described in detail elsewhere (*11*). Briefly, the γ-emissions (radioactivity increase over time and equilibrium values) of ^{213}Bi were measured in liposome fractions, which were separated, at different times, from the parent liposome population and the free radionuclides by SEC (Sephadex G-50). The samples were counted using a Cobra γ-counter (Packard Instrument Co., Inc.). For monitoring ^{213}Bi, the energy window 360–480 keV was used, and for ^{225}Ac, the window 150–600 keV was used, which includes the chief ^{221}Fr and ^{213}Bi photopeaks. Repeated measurements were performed on three different preparations of each liposome structure.

Liposome Immunolabeling. The protocol to immunolabel liposomes is described elsewhere (*17*). Briefly, Trastuzumab purified from Herceptin (Genentech, South San Francisco, CA) or Rituximab (used as isotype-matched control mAb to Trastuzumab in the flow cytometry studies) was activated with Traut's reagent, and was reacted with maleimide-lipids contained in liposomes (1 mol % of total lipid). In purified immunoliposome suspensions (after SEC in 4B Sepharose, 1 × 10 cm), a protein assay was used to quantify the concentration of antibodies, and lipid concentration was determined by the fluorescence intensity of rhodamine-lipids contained in liposomes (0.5–1 mol % of total lipid). Using the measured values of conjugated antibodies per lipid, the average number of antibodies per liposome was calculated (*17*) using for input values the mean size of liposomes (as measured by DLS) and the head group surface area per lipid (70 Å^2) (*18*).

Trastuzumab was also directly radiolabeled with ^{225}Ac. This preparation protocol is published elsewhere (*5, 19*). Conventional labeling of a DOTA-IgG construct does not yield stable product in high yield under any conditions (*19, 20*), which led to the development of the 2-step labeling method. Briefly, the antibody was radiolabeled in 2-steps: the first step entails ^{225}Ac + DOTA-NCS, which proceeded to >95% completion in 30 min; the second step involves the conjugation of the reactive isothiocyanate moiety on the ^{225}Ac -DOTA-NCS product with lysines on the Trastuzumab. This synthetic path was used as the ^{225}Ac + DOTA chelation only goes to completion at elevated temperatures, 55–60 °C, a temperature that will denature the IgG.

Immunoreactivity. Cells were washed twice with ice-cold PBS and blocked by incubation on ice with 2% BSA. Then, ^{225}Ac-labeled antibody (2.6 ng) in 1% HSA, small vesicles, and liposomes (LLs and MUVELs) at 1.0–1.9 μg and 100–190 μg total lipid were added to 10^7 cells and incubated on ice for 30 min. Cells were then washed twice with ice-cold PBS and centrifuged. Twenty-four hours later, supernatants and pellets were counted by scintigraphy (Beckman-Coulter, Fullerton, CA).

Cell Line. The metastatic ovarian carcinoma cell line, SKOV3-NMP2, was derived from serial passage of the parental SKOV3 cell line in nude mice (*21*) and used. Stock T-flask cultures (*20*) were propagated at 37 °C, in 5% CO_2 in RPMI 1640 media supplemented with 10% fetal calf serum (Sigma-Aldrich), 100 units/mL penicillin, and 100 μg/mL streptomycin. Cell concentration was determined by counting trypsinized cells with a hemocytometer.

Cell Binding and Internalization of Liposomes and Radiolabeled Antibody. Harvested SKOV3-NMP2 cells were washed twice with ice-cold media (RPMI 1640/10% FBS/2% BSA) and then resuspended in ice-cold media at a density of 10^6 cells/mL. Radiolabeled liposomes (0.1–1.8 μM lipid, final concentration) or antibody (25 ng) were added to 3.5 mL of cell suspension, and two 200 μL samples were immediately taken and processed as described below. The cells were then placed in a humidified 37 °C incubator with 5% CO_2, where they were periodically swirled and sampled at 0.5, 1, 2, 4, and 24 h. The cells were washed three times with 2 mL of ice-cold PBS, and then 1 mL of an acidic striping buffer (50 mM glycine and150 mM NaCl, pH 2.8) was added for 10 min at room temperature to eliminate the charge-specific binding of membrane-bound conjugates and to remove the surface-bound immunoliposomes or antibodies. After centrifugation, supernatants and pellets were allowed to reach equilibrium before counting (20h).

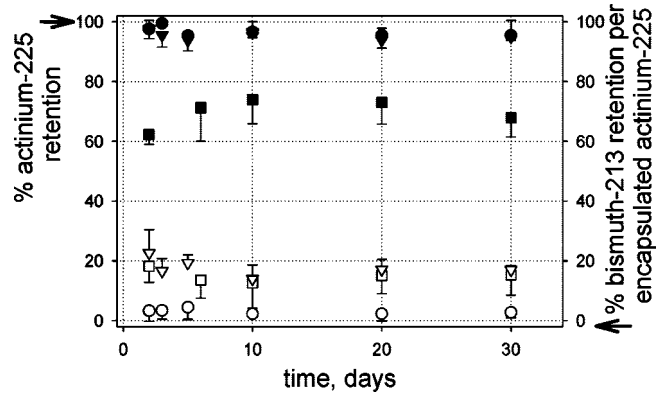

Figure 2. Fraction of ^{225}Ac retention (upper left, closed symbols) and ^{213}Bi retention per encapsulated ^{225}Ac (lower right, open symbols) by multivesicular liposomes (MUVELs) (triangles), large liposomes (LLs) (squares), and small vesicles (SVs) (circles) during 30 days. The error bars correspond to standard deviations of measurements performed on three different preparations of each liposome structure.

Flow Cytometry. Liposomal membranes were labeled with the fluorescent lipid rhodamine-PE (excitation, 550 nm; emission, 590 nm). Harvested cells (ovarian cancer SKOV3-NMP2 cells and fibroblast AL67 cells) were washed three times with ice-cold buffer (PBS/0.5% BSA/0.02% NaN_3) and then resuspended at a density of 5.6 × 10^6 cells/mL. Then 10^6 cells were incubated on ice with liposomes for 25 min (3.3 mM final lipid concentration), washed three times, and finally resuspended at a density of 2.5 × 10^6 cells/mL. To determine the extent of specific binding of immunoliposomes to the HER2/neu antigen receptor, cells were also preincubated with Trastuzumab at 5 μg of antibody per one million cells for 25 min on ice. Cells were then washed twice with ice-cold buffer and incubated with liposomes as above. Fluorescence counting of cell suspensions (50,000 events) was measured using a Beckman-Coulter Cytonics FC500 flow cytometer (Fullerton, CA), and analyzed with the software FlowJo (Tree Star, Inc., Ashland, OR).

RESULTS

Retention of ^{225}Ac by Liposomal Structures. In multivesicular liposomes (MUVELs), ^{225}Ac was encapsulated only into small vesicles (SVs). For 30 days (Figure 2, upper part), more than 95% of the encapsulated ^{225}Ac activity was retained by MUVELs (black triangles) and SVs (black circles). In large liposomes (LLs), only 70% of ^{225}Ac was retained stably over time (black squares).

The retention of ^{225}Ac by liposomes depends on the permeability of the liposomal membrane to the ^{225}Ac–DOTA complex and is not dependent on the radioactive character of ^{225}Ac, which after its recoil may eject the next daughter out of the physical boundaries of liposomes (as is the case for ^{213}Bi). The results on ^{225}Ac retention are identical for both MUVELs and the small

vesicles (SVs) (Figure 2). In both of these cases, ^{225}Ac is encapsulated into the same rigid membranes composed of diheneicosanoyl phosphocholine (21:0 PC, $T_g = 72$ °C) and cholesterol. Small vesicles (SVs) comprised this lipid composition. In MUVELs, the encapsulated small vesicles (SVs) that contain ^{225}Ac also comprise exactly this lipid composition. However, large liposomes (LLs) are made up of more fluid lipids (dimyristoyl phosphocholine (16:0, $T_g = 23$ °C) and cholesterol) that appear to have more permeable membranes to ^{225}Ac–DOTA complexes.

Retention of ^{213}Bi by Liposomal Structures. MUVELs (white triangles) and LLs (white squares) retained over a period of 30 days (Figure 2, lower part), 17 ± 3% and 15 ± 7% of ^{213}Bi, respectively (approximately one-third of the theoretical maximum) (*11*). Both MUVELs and LLs exhibited almost identical ^{213}Bi retention profiles per encapsulated ^{225}Ac nucleus, suggesting that the particular composition of the (external) liposomal membrane does not promote radionuclide localization as opposed to the lipid composition chosen in our first studies (*11*). However, as shown above (Figure 2, upper part), LLs failed to adequately retain the parent ^{225}Ac. Therefore, MUVELs increase the fraction of overall delivered daughters. For example, on day 20, the retention of ^{213}Bi by MUVELs is 17% and by LLs is 15% of the total ^{213}Bi per encapsulated ^{225}Ac. The retention of ^{225}Ac by MUVELs is 94% and by LLs is 73% of the initially encapsulated radioactivity. Therefore, in terms of the initially encapsulated ^{225}Ac radioactivity, $0.17 \times 0.94 = 16\%$ and $0.15 \times 0.73 = 11\%$ of ^{213}Bi is delivered at the site of MUVELs and LLs, respectively.

Also, the insignificant retention of ^{213}Bi (white circles) by small vesicles with sizes comparable to the recoil range of the α-emitting daughters is consistent with our previous theoretical predictions (*22*).

Liposome and Antibody Radiolabeling and Quality Control. More than 95% of ^{225}Ac was chelated to DOTA. The maximum encapsulation efficiency of ^{225}Ac by the liposomal structures using passive entrapment did not exceed 10% of the total initial activity.

The efficiency of radioconjugation to antibody was low with a radiochemical yield of 3% (of the total activity applied) and resulted in radiolabeled antibodies with low specific activity, 1.406 KBq/μg. The radiosynthesis of the ^{225}Ac–DOTA-IgG constructs has been described (*19*), and while the products were radiochemically pure and biologically reactive, the yields were low (<10%). The antibody was radiolabeled in 2-steps, and the specifications and yields of the ^{225}Ac–DOTA-Trastuzumab construct were similar (*20, 23*) to those of the other constructs tested (*19*). The low yield in the second step results from the competing hydrolysis reaction of the isothiocyanate moiety. The mass amounts of DOTA and IgG as well as the activity amount of ^{225}Ac were optimized (*19*), and adding more or less of any of these components will not significantly improve the overall yield. The reported specific activity 1.406 kBq/μg (0.038 Ci/g) was on the same order as the specific activities used clinically with the ^{225}Ac–DOTA-HuM195 therapeutic drug (*24*), and these small doses have demonstrated antileukemic effects.

The conjugation reaction resulted in 937 ± 110 antibodies per liposome. Leakage of entrapped radioactive or fluorescent (calcein) content due to conjugation was not detected (data not shown). The measured average large liposome size for MUVELs was 758 ± 287 nm.

The Her2/neu cell-surface density of $1–3 \times 10^5$ per cell was used (*25*), and approximately one Trastuzumab molecule per 100–300 cell receptors were mixed. The immunoreactivity of radiolabeled Trastuzumab was 65.74 ± 7.51%. For liposomes, two ratios were tested: (a) 100 liposomes per cell (or one liposome-conjugated antibody per 1–3 receptors) and (b) one liposome per cell (or one liposome-conjugated antibody per 100–300 receptors). The antigen binding activity of liposomes was similar for both ratios tested: 4.40 ± 0.89% of immunolabeled MUVELs and 1.83 ± 0.52% of immunolabeled LLs were bound to cells at both lipid-to-cell ratios. Small vesicles (SVs) that were not immunolabeled bound nonspecifically at a low extent (0.75 ± 0.02%).

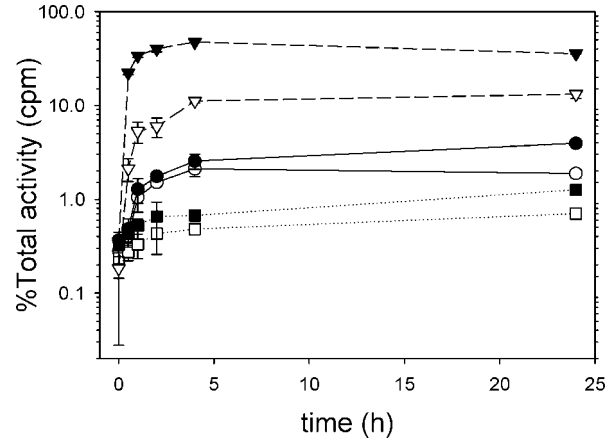

Figure 3. Cell binding and internalization of immunolabeled lipid-structures with encapsulated ^{225}Ac, and ^{225}Ac-conjugated antibody. Closed symbols: fraction of the total initial-activity that became cell-associated. Open symbols: fraction of cell-internalized activity. Triangles, radiolabeled antibody; circles, immunolabeled MUVELs; squares, immunolabeled LLs. The error bars correspond to standard deviations of measurements performed in duplicate.

Cell Binding and Internalization. After 4 h of incubation, the relative total cell-associated radioactivities (Figure 3, closed symbols), compared to $t = 0$, were 2-, 7-, and 135-fold higher for LLs (closed squares), MUVELs (closed circles), and the radiolabeled antibody (closed triangles), respectively. Both types of immunoliposomes (MUVELs and LLs) internalized to a greater extent than the antibody: 83% of the activity of bound immunolabeled MUVELs and 70% of the activity of bound immunolabeled LLs were internalized (4 h incubation) as opposed to only 23% of bound antibody. Also, the fraction of total cell-associated activity (^{225}Ac) delivered by immunolabeled MUVELs (2.5 ± 0.5%) was 3.8 times greater than the fraction of total associated radioactivity delivered by immunolabeled LLs (0.7 ± 0.1%), probably due to the less stable retention of the parent nuclide by LLs (Figure 2, upper part). For the same incubation time, the fraction of total cell-associated activity for nonimmunolabeled MUVELS, LLs, and SVs was 0.47%, 0.61%, and 0.16% of the total added radioactivity, respectively (data not shown). Cell uptake kinetics was significantly slower for all liposome structures compared to that of the radiolabeled antibody.

Using flow cytometry, a significant shift in fluorescence counts (one log unit) was detected only when anti-HER2/neu-immunoliposomes were incubated with SKOV3-NMP2 cells with unblocked HER2/neu receptors (Figure 4A, thick line). Neither specific nor nonspecific binding of liposomes to AL67 (fibroblast cells not expressing the HER2/neu receptor) was detected. The specificity of binding of Trastuzumab-conjugated liposomes to SKOV3-NMP2 cells was also compared to the binding of liposomes conjugated to Rituximab, an anti-CD20 antibody that was used as the isotype-matched control to Trastuzumab. Trastuzumab-labeled liposomes resulted in a shift of fluorescence counts of SKOV3-NMP2 cells that was more

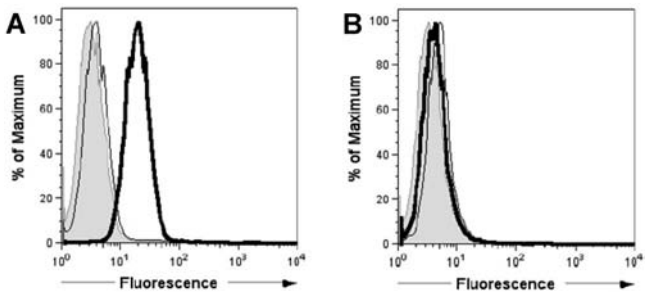

Figure 4. Binding of rhodamine-lipid-containing Trastuzumab-labeled liposomes to SKOV3-NMP2 (A) and AL67 cells (B). Area shaded gray, cells; thin line, cell fluorescence due to immunoliposomes bound to cells that have been preincubated with Trastuzumab; thick line, cell fluorescence due to immunoliposomes bound to cells with unblocked receptors.

than one log unit greater than the shift measured for Rituximab-labeled liposomes. (flow data shown in Supporting Information).

DISCUSSION

Multivesicular liposomes (MUVELs) result in minimal leakage of ^{225}Ac and in significant retention of the α-emitting daughters. MUVELs with encapsulated ^{225}Ac deliver 2.8 out of 4 α-particles emitted per ^{225}Ac decay. This ratio is calculated on the basis of the assumption that the last two radioactive daughters have the same probability x to be retained within liposomes after decay. Assuming probability one for the first daughter ^{221}Fr since ^{225}Ac should be confined close to the core of the large liposomes with a radius larger than the daughter's recoil distance, for the four decays (^{225}Ac to ^{221}Fr, ^{221}Fr to ^{217}At, ^{217}At to ^{213}Bi, and ^{213}Bi to stable ^{209}Pb) the probability of daughter retention (and thus targeted delivery of the subsequently emitted alphas) is x^2. From Figure 2, $1 \times x^2$ is approximately 0.18, x should be equal to 0.42, and the total alphas retained should equal to $1 + 1 + 0.42 \times 2 = 2.8$.

We have previously calculated that for liposomes as large as 750 nm in diameter (similar to the sizes of MUVELs and LLs) not more than 55% of generated ^{213}Bi from the total ^{213}Bi generated by the encapsulated ^{225}Ac is retained by liposomes and can therefore be expected to decay at the cite of the liposome carriers (*11*). These calculations were based on the average recoil trajectory of each daughter (80–90 nm) that is comparable to the size of the liposomal carriers. For this geometry, the probability that a generated daughter would be retained within a liposome decreases as the previous radioactive daughter's location approaches the liposome membrane at the time point of radionuclide decay. In addition, for every subsequent radioactive daughter, the probability of remaining within the physical limits of the liposomal carrier is decreasing compared to the probability corresponding to the previous radioactive daughter. MUVELs exhibit retention of ^{213}Bi that is 17–18% of the total ^{213}Bi generated by the encapsulated ^{225}Ac. In other words, these values correspond to 31–33 % of the theoretical maximum retention for this size of delivery carriers.

In vitro, immunolabeled MUVELs demonstrated greater specific binding to human ovarian carcinoma cells (SKOV3-NMP2) compared to nontargeted liposomes but showed lower immunoreactivity compared to that of the radiolabeled antibody. This result could be due to the relatively large size of liposomes that may interfere with the extracellular matrix by obstructing free diffusion towards the cell surface. The targeting antibodies were conjugated on the free ends of surface-grafted PEG chains of the same length (*26*) to exclude steric hindrance to targeting from neighboring grafted PEG chains. Also, cell uptake kinetics was slower for immunoliposomes compared to that of the free antibody, which could be justified by the different diffusibilities of each structure studied. Measured diffusion coefficients of free IgGs are of the order of 10^{-7} cm^2/s in water at 20 °C (*27*). At the same conditions, the calculated values for liposomes (using the Stokes–Einstein equation for spherical objects) are two orders of magnitude lower (10^{-9} cm^2/s).

In ^{225}Ac-radioimmunotherapy, renal toxicity can become a major dose constraint because of the localization of escaped ^{213}Bi in the kidneys (*28, 29*). MUVELs are proposed for retaining the radioactive daughters at the site of the carrier for the interval between the administration of the carriers and before the carriers are internalized by the targeted cancer cells. Such radioimmunoliposomes would reduce the fraction of escaped radioactive daughters and could potentially be used for the therapy of disseminated micrometastatic tumors in the peritoneal cavity using direct intraperitoneal administration. This approach could combine the following beneficial features: (a) targeting efficacy and specificity due to surface-conjugated tumor-specific antibodies (*17, 30*); (b) long retention times in the peritoneal cavity (*31, 32*) due to large liposome sizes; (c) direct tumor access (*20, 33, 34*) combined with a radiation dose range tailored to micrometastases that do not have developed vasculature (*35*) and cannot be differently accessed; and (d) minimal irradiation of the surrounding healthy tissues because of the α-particles' comparatively short range.

The stable retention of ^{225}Ac by MUVELs will probably be challenged in the presence of serum proteins *in vivo* since proteins are known to interact with the lipid membrane of these carriers in a variety of ways (*36*). Preliminary *in vivo* biodistributions of ^{225}Ac-loaded immunolabeled-liposomes (MUVELs and LLs) that were administered intraperitoneally in BALB/c nude mice bearing intraperitoneally disseminated SKOV3-NMP2 tumors resembling micrometastatic disease (*37*) suggest that *in vivo* MUVELs retain ^{225}Ac to a larger extent than LLs and therefore deliver higher activities of ^{213}Bi to the tumor sites. In addition, both types of immunoliposome compositions exhibit significant hepatic and splenic uptake that is characteristic of this size of drug carriers and could determine the maximum tolerated dose. The short range of α-particles emitted at the sites of normal organs could, however, result in relatively low toxicities at these organs because of the short range of α-particles.

Finally, immunolabeled MUVELs may be particularly useful in delivering lethal radiation doses to cancer cells with low expression levels of molecular targets (*38*). Actinium-225 labeled antibodies generally have low specific activity (1.406 MBq/mg in this study) that corresponds to one conjugated ^{225}Ac atom per 2,300 antibodies. For MUVELs, two passive entrapment steps are required (each with a maximum of 10% encapsulation efficiency). Thus, for 370 MBq (10 mCi) ^{225}Ac initial activity and 1% actinium overall entrapment efficacy, we can encapsulate one actinium nuclide per MUVEL and two actinium nuclides in every 8 MUVELs (for 4×10^{12} liposomes with a mean diameter of 750 nm). Our current work is focused on increasing the encapsulated ^{225}Ac activity within small vesicles using active (ionophore-driven) loading (*39*). Additional structural optimization of MUVELs is also required to further increase ^{213}Bi retention at the liposome sites.

Intraperitoneal micrometastatic disease constitutes a treatment challenge and is common among patients with advanced gynecological and gastrointestinal cancers. In this work, the ovarian carcinoma cells SKOV3-NMP2 were selected to prove the feasibility of targeted delivery *in vitro* of the α-particle nanogenerator ^{225}Ac and its radioactive daughters using immunolabeled MUVELs that can potentially be used against disseminated intraperitoneal micrometastases following locoregional administration. Our findings show that immunolabeled MUVELs retain a third of the theoretical maximum of the

radioactive daughters and that the cell-bound structures become considerably more internalized by ovarian cancer cells than the radiolabeled antibody. These results suggest that the effective numbers of α-particles emitted at the target per delivered ^{225}Ac using MUVELs could be significant, thus providing a promising therapeutic modality for disseminated micrometastatic disease. Additional optimization of MUVELs is necessary to increase the encapsulated radioactivity of ^{225}Ac in order to enable the evaluation of the potential of these liposomes for therapeutic use. Additional increase in daughter retention could be achieved by further increasing the size of the delivery carrier (to 1 μm diameter), but given the limitations of stable intact liposomes of such large diameters, different materials could probably be evaluated to form the outer large shell encapsulating Small Vesicles (SVs) with entrapped ^{225}Ac.

Conjugation of Polyamidoamine Dendrimers on Biodegradable Microparticles for Nonviral Gene Delivery

Xue-Qing Zhang, Janjira Intra, and Aliasger K. Salem*

Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, Iowa 52242. Received April 5, 2007; Revised Manuscript Received May 30, 2007

We report on the preparation and characterization of poly(D,L-lactide-*co*-glycolide) (PLGA) microparticles with surface-conjugated polyamidoamine (PAMAM) dendrimers of varying generations. The buffering capacity and zeta-potential of the PLGA PAMAM microparticles increased with increasing generation level of the PAMAM dendrimer conjugated. Conjugation of the PAMAM dendrimer to the surface of the PLGA microparticle removed generation-dependent cytotoxicity in HEK293 and COS7 cell lines. PLGA PAMAM pDNA microparticles displayed similar cytotoxicity profiles to unmodified PLGA pDNA microparticles in COS7 cells. A generation three PAMAM dendrimer conjugated to PLGA microparticles significantly increased transfection efficiencies in comparison to unmodified PLGA microparticles.

1. INTRODUCTION

Delivery of plasmid DNA (pDNA) using biodegradable microparticles has shown significant potential for improving the efficacy of transgene expression (*1*). These microparticles are commonly prepared from poly (D,L-lactide-*co*-glycolide) (PLGA), a polymer that is biodegradable and biocompatible and has FDA approval for use in the clinic (*1–8*). Delivery of pDNA using PLGA microparticles can be achieved using two approaches. In the first approach, pDNA is entrapped into the matrix of the microparticle, allowing for sustained release. Drawbacks to this approach include inactivation of the pDNA during the harsh manufacturing conditions of the microparticles. These conditions include exposure to organic solvents and shear forces associated with the homogenization and sonication steps (*3, 5, 8*). Several approaches have sought to overcome these limitations. These approaches include incorporating cationic excipients that condense and protect the pDNA during entrapment or minimizing shear stress during homogenization by using a cryopreparation modification of the double emulsion method (*9*). In the second approach, pDNA is adsorbed onto the surface of the microparticles after they have been prepared (*3, 10–13*). This method prevents pDNA damage due to microparticle preparation techniques. This approach has found the most promise in genetic vaccination applications (*11, 13, 14*). In addition, microparticles can be loaded with drugs or proteins that complement or enhance the efficacy of the surface-bound pDNA. To bind the pDNA to the surface of the microparticles, a cationic agent is typically incorporated into the formulation method to prepare microparticles that have a net positive charge (*3, 10–13*). This facilitates binding of the negatively charged pDNA to the surface of the microparticles by electrostatic interactions. Approaches to date for preparing cationic microparticles have included the use of cationic surfactants such as cetyltrimethylammoniumbromide (CTAB) (*15*) or cationic polymers such as polyethyleneimine (PEI) that are adsorbed, blended, or covalently attached to the microparticles (*3, 10, 13, 16, 17*). In this study, we prepare PLGA microparticles that have cationic polyamidoamine (PAMAM) dendrimers covalently attached to the surface of the PLGA microparticles. PAMAM dendrimers have several advantages over linear cationic polymers (*18, 19*). Similar to polymers such as PEI, PAMAM dendrimers have both primary and secondary amines that generate significant buffering capacity (*18, 19*). This imparts the carriers with the ability to release from the endosomes into the cytoplasm via the proton sponge mechanism (*19,20*). In comparison to PEI, however, dendrimers are nanoscale, spherical, monodisperse polymers that display lower cytotoxicity and reduced structural density in the intramolecular core (*19*). As the generation of the PAMAM dendrimer increases, the transfection efficiency increases (*21, 22*). A drawback to PAMAM dendrimers, however, is their generation-dependent cytotoxicity (*21–23*). As the generation of the PAMAM molecule increases, its cytotoxicity increases proportionally. In this study, we show, for the first time, that conjugation of PAMAM dendrimers onto the surface of PLGA microparticles imparts the microparticles with generation-dependent buffering capacity and net positive charge while removing generation-dependent cytotoxicity. PLGA microparticles with PAMAM conjugated to the surface produce significantly higher transgene expression than unmodified PLGA microparticles. These results will have considerable potential for a wide variety of applications in microparticle-based nonviral DNA, RNA, and oligonucleotide delivery.

2. MATERIALS AND METHODS

2.1. Materials. D,L-Lactide/glycolide copolymer (PLGA, molar ratio with acid terminal group 50:50, inherent viscosity 0.54 dL/g) was purchased from Absorbable Polymers International (Pelham, AL). PAMAM dendrimers from generations 3–6 (G3, G4, G5, and G6, ethylenediamine core), PEI (25 kDa), and poly(vinyl alcohol) (PVA, MW 30–70 kDa) were purchased from Sigma-Aldrich (St. Louis, MO). 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC), *N*-hydroxysulfosuccinimide (Sulfo-NHS), and bicinchoninic acid (BCA) protein assay kit were purchased from Pierce Biotechnology Inc. (Rockford, IL). Dulbecco's Modified Eagle's Medium (DMEM) was obtained from Gibco BRL (Grand Island, NY). The luciferase assay system was purchased from Promega (Madison, WI). For cellular uptake studies, FITC (fluorescein isothiocyanate, Sigma-Aldrich)-labeled dendrimers G3–G6 were prepared by reaction of FITC and PAMAM dendrimers in 0.1

M sodium carbonate buffer (pH 9) at 4 °C in darkness overnight. FITC-conjugated dendrimers were purified by dialysis (MWCO 7000, Pierce Biotechnology Inc., Rockford, IL) and then lyophilized (Labconco FreeZone 4.5, Kansas City, MO). The level of fluorescein in the dendrimers was determined by measuring their absorbance at 498 nm using standard curves for FITC. Spectrofluorometric analysis (Spectramax M5 Microplate reader, Molecular Device) revealed that approximately 3% of the dendrimer amino groups were attached with FITC.

2.2. Cell Culture. Human embryonic kidney cells (HEK293) and monkey African green kidney fibroblast-like cell line (COS7) were obtained from the American Type Culture Collection (ATCC, Rockville, MD). The cells were maintained in DMEM supplemented with 10% FBS, streptomycin at 100 μg/mL, penicillin at 100 U/mL, and 4 mM L-glutamine at 37 °C in a humidified 5% CO_2-containing atmosphere.

2.3. Amplification and Purification of Plasmid DNA. VR1255 plasmid is a 6.4-kb cDNA encoding firefly luciferase driven by the cytomegalovirus (CMV) promoter/enhancer. The plasmid was transformed in *Escherichia coli* DH5α and amplified in Terrific Broth media at 37 °C overnight with a shaking speed of 300 rpm. The plasmid was purified by an endotoxin-free QIAGEN Giga plasmid purification kit (QIAGEN, Valencia, CA) according to the manufacturer's protocol. Purified pDNA was dissolved in saline, and its purity and concentration were determined by UV absorbance at 260 and 280 nm.

2.4. Preparation of PLGA pDNA and PLGA PAMAM pDNA Microparticles. *2.4.1. PLGA pDNA Microparticles.* PLGA microparticles were prepared using a water in oil in water (w/o/w) double emulsion, solvent evaporation technique. Briefly, 100 mg of 50:50 PLGA was dissolved in 5 mL of dichloromethane (DCM). VR1255 pDNA in 0.5% (w/v) PVA solution was prepared at a concentration of 4mg/mL. Using a microtip probe sonicator set at level 2 (Sonic Dismembrator model 100, Fisher Scientific, Pittsburgh, PA), 500 μL of the PVA solution containing 2 mg of VR1255 pDNA was mixed with the PLGA/DCM solution for 20 s to form the first emulsion. This emulsion was then rapidly added to 50 mL of 0.5% (w/v) PVA solution with stirring at 13,500 rpm for 30 s using an IKA Ultra-Turrax T25 basic homogenizer (IKA, Wilmington, NC). The second emulsion was stirred overnight during which time the DCM solvent was evaporated. The microparticles were then washed 3 times with deionized water and then lyophilized (Labconco FreeZone 4.5, Kansas City, Missouri). The supernatant was collected and analyzed spectrophotometrically at 260 nm using a SpectraMax Plus^{384} microplate spectrophotometer (Molecular Device) for pDNA content. Plasmid DNA entrapped in the PLGA microparticles was calculated by subtracting the pDNA content in the supernatant from the initial concentration of pDNA added. Microparticles were stored at −20 °C until use. For *in vitro* microparticle uptake studies, PLGA microparticles loaded with Rhodamine 123 were prepared using a single emulsion evaporation methodology. Briefly, 100 mg of 50:50 PLGA and 2 mg of Rhodamine 123 (Sigma-Aldrich, St. Louis, MO) were dissolved in 5 mL of DCM. This was then rapidly added to 50 mL of 0.5% (w/v) PVA in deionized water with stirring at 13,500 rpm for 30 s. After evaporation overnight, the rhodamine-labeled microparticles were washed and collected as described above.

2.4.2. PLGA PAMAM pDNA Microparticles. A modified EDC/NHS chemistry was used to conjugate PAMAM dendrimers to the surface of PLGA microparticles to obtain cationic microparticles. Blank PLGA microparticles were prepared with 500 μL of the 0.5% (w/v) PVA solution and 5 mL of DCM containing 200 mg of 50:50 PLGA–COOH using a w/o/w double emulsion, solvent evaporation technique as described above. 100 mg of the PLGA–COOH microparticles were then suspended in 10 mL of 0.1 M MES (2-(*N*-morpholino)ethanesulfonic acid) buffer, pH 5.1. 1 mL of EDC solution (60 mM) in 0.1 M MES buffer and 1 mL of Sulfo-NHS solution (60 mM) in 0.1 M MES buffer were added dropwise to the PLGA microparticle suspension. EDC activation was carried out for 2 h at room temperature. A 10 molar excess of dendrimers G3, G4, G5, G6 or 25 kDa branched PEI was dissolved in 5 mL of 0.1 M MES buffer, respectively. Activated PLGA microparticles were added dropwise to the G3, G4, G5, G6 dendrimer or 25 kDa branched PEI solutions with magnetic stirring and incubated for another 4 h at room temperature. Dendrimer-conjugated PLGA microparticles were washed twice in 1 M NaCl to remove physically adsorbed polymer and twice with deionized water. The resulting microparticles, which were thereafter named PG3, PG4, PG5, PG6, and P-PEI were lyophilized and stored at −20 °C until use. Fluorescamine (4-phenylspiro[furan-2(3H),1′-phthalan]-3,3′-dione) has been used for colorimetric quantification of primary amines and to quantify dendrimers associated with microparticles (*24*). Microparticles PG3, PG4, PG5, PG6, or P-PEI were hydrolyzed in 0.1 N NaOH overnight, and the dendrimer content was measured using spectrofluorometric analysis (Spectramax M5 microplate reader, Molecular Device). Fluorescamine reacts with primary amines in dendrimers to form pyrrolinones, which are excited at 390 nm and have peak emission at 475–490 nm. Quantification of dendrimer conjugated to the PLGA microparticles (w/w) was estimated using standard curves of dendrimer with corresponding generation.

2.5. Microparticle Size and Surface Morphology Analysis. Microparticle size and zeta potential measurements were conducted using the Zetasizer Nano ZS (Malvern, Southborough, MA). Briefly, the microparticles were suspended in deionized water at a concentration of 1 mg/mL. The size measurements were performed at 25 °C at a 173° scattering angle. The mean hydrodynamic diameter was determined by cumulative analysis. The zeta potential determinations were based on electrophoretic mobility of the microparticles in the aqueous medium, which was performed using folded capillary cells in automatic mode. Microparticle morphology was assessed by scanning electron microscopy (SEM, Hitachi S-4000). Briefly, air-dried microparticles were placed on adhesive carbon tabs mounted on SEM specimen stubs. The specimen stubs were coated with approximately 5 nm of gold by ion beam evaporation before examination in the SEM operated at 5 kV accelerating voltage.

2.6. Buffering Capacity of PLGA pDNA and PLGA PAMAM pDNA Microparticles. The ability of PLGA PAMAM microparticles (PG3 to PG6) to resist acidification was tested using the acid titration assay as described by Tang et al. (*24*) Briefly, 10 mg/mL PG3, PG4, PG5, or PG6 microparticles were suspended in 150 mM NaCl, respectively. The pH was first adjusted to ∼9.0 and then titrated in small increments with 0.1 N HCl until a pH of 3.0 was reached. The slope of the pH versus HCl added graph provides an indication of the intrinsic buffering capacity of the delivery vehicles.

2.7. Plasmid DNA Loading on Dendrimer-Conjugated Cationic Microparticles. VR1255 pDNA was loaded on the surface of cationic microparticles PG3, PG4, PG5, or PG6 as described by Singh et al. (*11*) Plasmid DNA was incubated with PG3, PG4, PG5, or PG6 suspensions in PBS (pH adjusted to 6.5) at a concentration of 20 μg pDNA/mg microparticles at 4 °C for 6 h, respectively. The resulting microparticles were centrifuged at 13,200 rpm for 5 min on a microcentrifuge and washed twice with the loading buffer to obtain PG3 pDNA, PG4 pDNA, PG5 pDNA, or PG6 pDNA microparticles. The supernatant was collected and analyzed spectrophotometrically at 260 nm using a SpectraMax Plus^{384} microplate spectrophotometer (Molecular Device) for pDNA content. Plasmid DNA

loading on the cationic microparticles was calculated by subtracting the pDNA content in the supernatant from the initial concentration of pDNA added.

2.8. Cytotoxicity Evaluation using the MTT Assay. The cytotoxicity of the PLGA pDNA, PLGA PAMAM pDNA microparticles, PLGA PEI pDNA microparticles, and PEI pDNA was evaluated using the MTT (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide) assay (*25*). COS7 and HEK293 cells were seeded in a 96-well plate at a density of 1×10^4 cells/well. Twenty-four hours later, cells were incubated with 200 μL of complete DMEM containing PLGA pDNA or PLGA PAMAM pDNA microparticles at various concentrations. After 4 h of incubation, the medium in each well was replaced with 100 μL of fresh complete medium. Twenty-five microliters of 5 mg/mL MTT solution in PBS was added to each well and incubated with cells for additional 2 h. Cells were lysed with 100 μL of the extraction buffer (20% SDS in 50% DMF, pH 4.7) overnight. The optical density of the lysate was measured at 550 nm using a Spectramax Plus^{384} microplate spectrophotometer (Molecular Device). Values were expressed as a percentage of the control to which no microparticles were added.

2.9. Cellular Uptake of PLGA pDNA and PLGA PAMAM pDNA Microparticles. Dendrimer-conjugated PLGA microparticles PG3, PG4, PG5, and PG6 were prepared using FITC-labeled dendrimers. HEK293 cells were seeded into 12-well plates at a density of 1×10^6/well 24 h before transfection. After 24 h incubation, the medium was replaced with fresh DMEM containing 10% FBS. 0.5 mg/well PLGA/Rhodamine 123, FITC-labeled PG3, PG4, PG5, or PG6 microparticles with and without loaded pDNA were incubated with HEK293 cells for 16 h. Then, the cells were vigorously washed with PBS three times to remove free fluorescent-labeled microparticles and the microparticles adsorbed on the cells surface. Samples were then assessed using flow cytometry (Becton Dickinson). Dot plots were gated on FSC/SSC properties of HEK293 cells to exclude free fluorescent-labeled microparticles. Data was analyzed using *Cell-Quest^{Pro}* software. All samples were tested in triplicate. To confirm that fluorescence would be detectable in the acidic environment of the endosomes, FITC was dissolved into a 150 mM NaCl aqueous solution. When the solution was adjusted to pH 4–5 using 0.1 N HCl, fluorescence could still be clearly detected in comparison to FITC at pH 7.4. To confirm that FITC-labeled particles had been internalized, cells were viewed under a confocal microscope (Bio-Rad Radience 2100MP). Orthogonal sections from stacked images confirmed that particles were predominantly located inside the cell and not just on the surface (data not shown).

2.10. Evaluation of Luciferase Expression in COS7 and HEK293 Cells. COS7 and HEK293 cells were seeded into 24-well plates at a density of 8×10^4/well 24 h before transfection. 0.2 mg/well PLGA pDNA and PLGA PAMAM pDNA microparticles were added to the cells in transfection medium (serum-free) and incubated for 4 h at 37 °C, followed by further incubation in serum-containing medium for 44 h. The concentration of the microparticles was selected on the basis of a target pDNA loading of 5 μg/mg microparticles and an equivalent pDNA dose of 1 μg/well. After the incubation, cells were treated with 200 μL of lysis buffer (Promega). The lysate was subjected to two cycles of freezing and thawing, then transferred into tubes and centrifuged at 13,200 rpm for 5 min. Twenty microliters of supernatant was added to 100 μL of luciferase assay reagent (Promega), and samples were measured on a luminometer for 10 s (Lumat LB 9507, EG&G Berthold, Bad Wildbad, Germany). The relative light units (RLU) were normalized against protein concentration in the cell extracts, measured by a micro BCA protein assay kit (Pierce). Luciferase activity was expressed as relative light units (RLU/mg protein in the cell lysate). The data were reported as mean ± standard deviation for triplicate samples. Every transfection experiment was repeated at least twice.

2.11. Statistical Analysis. Group data were reported as mean ± SD. Differences between groups were analyzed by one-way analysis of variance with a Tukey post-test analysis. Levels of significance were accepted at the $P < 0.05$ level. Statistical analyses were performed using *Prism 3.02* software (Graphpad Software, Inc., San Diego, CA.)

3. RESULTS

3.1. PAMAM Dendrimers Can Be Conjugated To the Surface of PLGA Microparticles Using EDC/NHS Chemistry. Figure 1 schematically shows our approach for preparing unmodified PLGA pDNA microparticles and dendrimer-conjugated PLGA microparticles. PLGA pDNA microparticles were prepared using a w/o/w double emulsion, solvent evaporation technique. 0.5% (w/v) PVA solution was chosen to prepare PLGA microparticles based on results of a previous optimization study on microparticle fabrication processes. Rhodamine 123 is soluble in DCM. Therefore, PLGA microparticles loaded with Rhodamine 123 were prepared using a single emulsion technique that used identical stirring and PVA concentration conditions to the PLGA pDNA microparticles.

For dendrimer-conjugated PLGA microparticles, PAMAM dendrimers from generations 3–6 were covalently attached to the surface of PLGA microparticles using EDC/NHS chemistry. Each of the PAMAM dendrimers from G3 to G6 was conjugated to PLGA microparticles prepared from the same batch. The conjugation of dendrimers was quantified using a fluorescamine assay, which indicated that the amounts of G3, G4, G5, and G6 present on the microparticle surfaces were 5.0, 5.5, 4.6, and 5.4 μg per milligram of microparticles, respectively (Table 1).

3.2. Microparticles Size, Zeta Potential, and Morphology of Microparticles. Figure 2a shows the microparticle size of the PLGA and PLGA PAMAM microparticles. Unmodified PLGA microparticles had an average size of 2.2 μm. After conjugation of PAMAM dendrimers onto the PLGA microparticles surface, the average PLGA microparticle size ranged from 2.3 to 3.2 μm. Figure 2b shows the zeta potential of these PLGA microparticles before and after loading with pDNA. Blank PLGA microparticles with carboxyl groups displayed a net negative surface charge of approximately −50 mV. After the conjugation of PAMAM dendrimers, the surface charge of PLGA microparticles turned positive with values ranging from +20 to +40 mV. After pDNA was electrostatically bound to the PAMAM-conjugated microparticle surface, the zeta potential was reduced to values ranging from +0.5 to +13.5 mV. Furthermore, both before and after pDNA binding, the surface charge of the dendrimer-conjugated PLGA microparticles increased in the order PG6 > PG5 > PG4 > PG3. SEM images (figure 2c) demonstrated that all the PLGA microparticles had a smooth morphology and spherical shape.

3.3. Increases in Buffering Capacity of PLGA PAMAM Microparticles Are Dependent on the Generation of the Conjugated PAMAM Dendrimer. Covalent attachment of PAMAM to PLGA microparticles is expected to provide the microparticles with tertiary and secondary amines that impart endolysosomal pH buffering capacity. This could lead to increased phagoendosomal escape of the carrier microparticles (proton sponge mechanism) (*21*). The buffering capacity of the dendrimer-conjugated PLGA microparticles was assessed by measuring the change in pH of a microparticle suspension (10 mg/mL) upon addition of increasing amounts of 0.1 N HCL. As shown in figure 3, buffering capacity of PAMAM PLGA microparticles is directly correlated with the generation level. The higher the generation level of the PAMAM

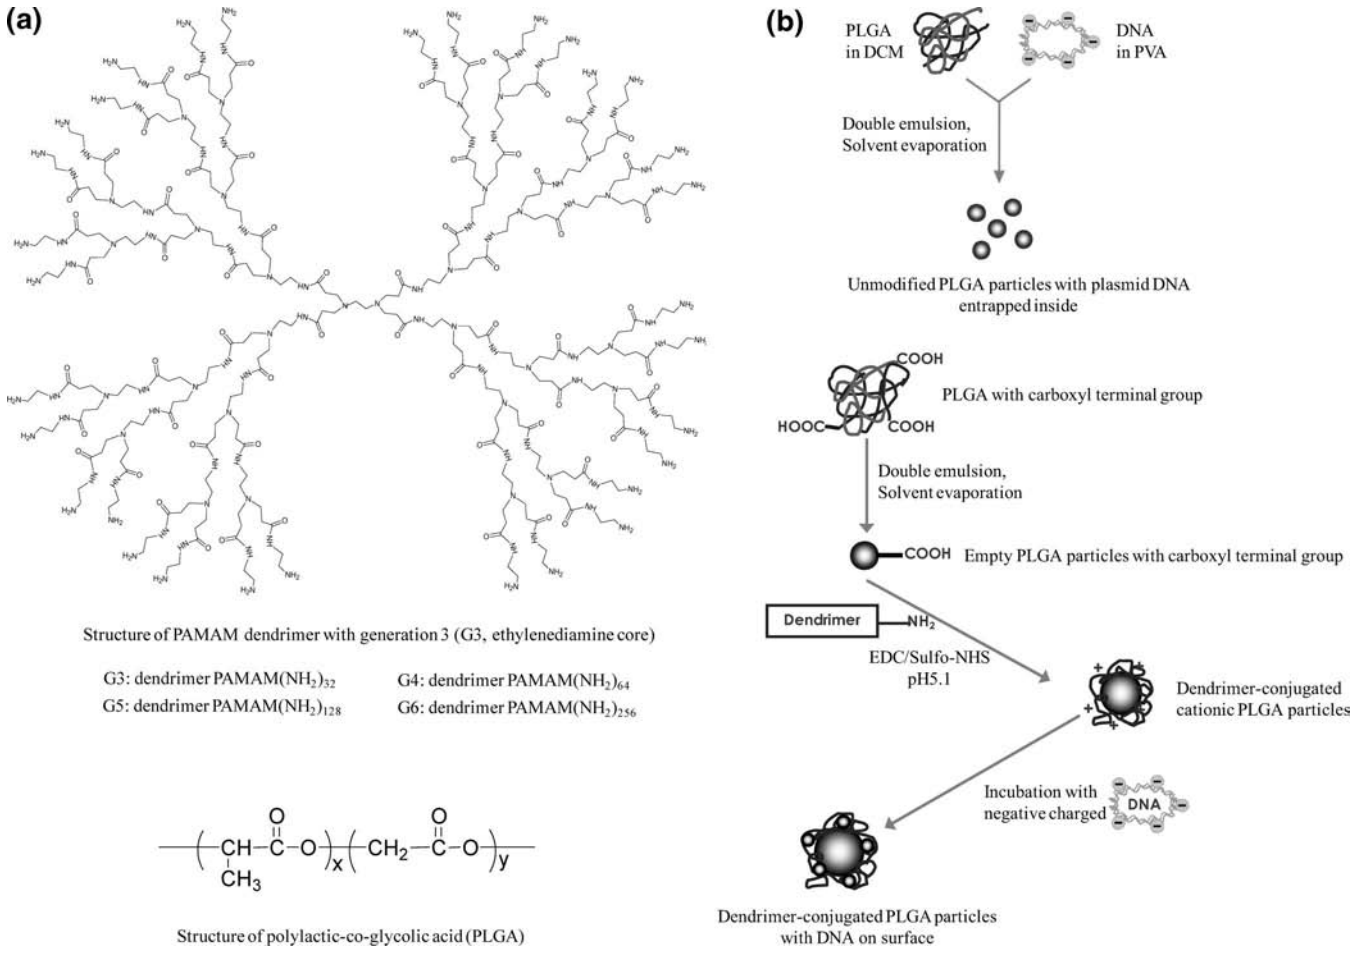

Figure 1. (a) Structure of poly(lactic-*co*-glycolic acid) (PLGA) and PAMAM dendrimers with ethylenediamine core. (b) Schematic of preparation of dendrimer-conjugated PLGA microparticles and unmodified PLGA microparticles.

Table 1. PAMAM Dendrimer Conjugation Efficiency and pDNA Loading Efficiency of PLGA and PAMAM-Conjugated PLGA Microparticles[a]

	dendrimer-conjugation efficiency (μg dendrimer/mg particles)	DNA-loading efficiency (μg pDNA/mg particles)
PLGA/pDNA		3.5 ± 0.1
PG3	5.0	4.0 ± 0.1
PG4	5.5	4.2 ± 0.5
PG5	4.6	4.1 ± 0.1
PG6	5.4	4.8 ± 0.2

[a] Averages representative of 3 measurements $\pm$ standard deviation.

dendrimer conjugated to the PLGA microparticle, the more effective it is at buffering against pH changes. This is indicated by the shift and decrease in the slope of the titration curves.

3.4. PAMAM Conjugation to PLGA Microparticles Significantly Increases pDNA Loading. Covalent attachment of cationic PAMAM dendrimers to the surface of PLGA microparticles significantly increases the efficacy of pDNA binding in comparison to PLGA microparticles entrapping pDNA using a double emulsion, solvent evaporation technique. Plasmid DNA loading on the surface of PG3 microparticles was 15% higher than pDNA entrapment in unmodified PLGA microparticles. Increasing the generation of the PAMAM dendrimer conjugated to the PLGA microparticle from 3 to 6 increased pDNA loading from 4.0 μg to 4.8 μg pDNA/mg particles, respectively. This was 37% higher than the pDNA loading in PLGA microparticles using the double emulsion, solvent evaporation technique and 540% higher than pDNA adsorbed onto the surface of unmodified PLGA microparticles ($\sim$1 μg pDNA/mg particles).

3.5. PAMAM Conjugation to PLGA Microparticles Removes Generation-Dependent Toxicity. *In vitro* cytotoxicity was evaluated in COS7 and HEK293 cells with increasing doses of PLGA pDNA and PLGA PAMAM pDNA microparticle concentrations (from 7.8 to 250 μg of microparticles per milliliter of DMEM). As shown in figure 4, PLGA PAMAM pDNA microparticles had similar cytotoxicity profiles to unmodified PLGA pDNA microparticles in COS7 cells. Cytotoxicity of PLGA PAMAM dendrimers was moderately higher than unmodified PLGA pDNA microparticles in HEK293 cells. No significant difference in the toxicity of PLGA PAMAM pDNA microparticles was observed in either cell line for increasing generation levels of the PAMAM dendrimer conjugated. No significant difference was observed in cytotoxicity between PLGA PAMAM pDNA microparticles and PLGA PEI pDNA microparticles. PLGA PAMAM microparticles were significantly less toxic than PEI alone.

3.6. PAMAM Dendrimer-Conjugated PLGA Microparticles Could Be Efficiently Taken Up by HEK293 Cells. Figure 5 shows cellular uptake data of fluorescence-labeled microparticles incubated with HEK293 cells. PLGA PAMAM pDNA microparticles displayed 6–7-fold higher uptake in cells than unmodified PLGA microparticles. No significant difference in the cell uptake of PLGA PAMAM pDNA microparticles was observed for increasing generation levels of the conjugated PAMAM dendrimer.

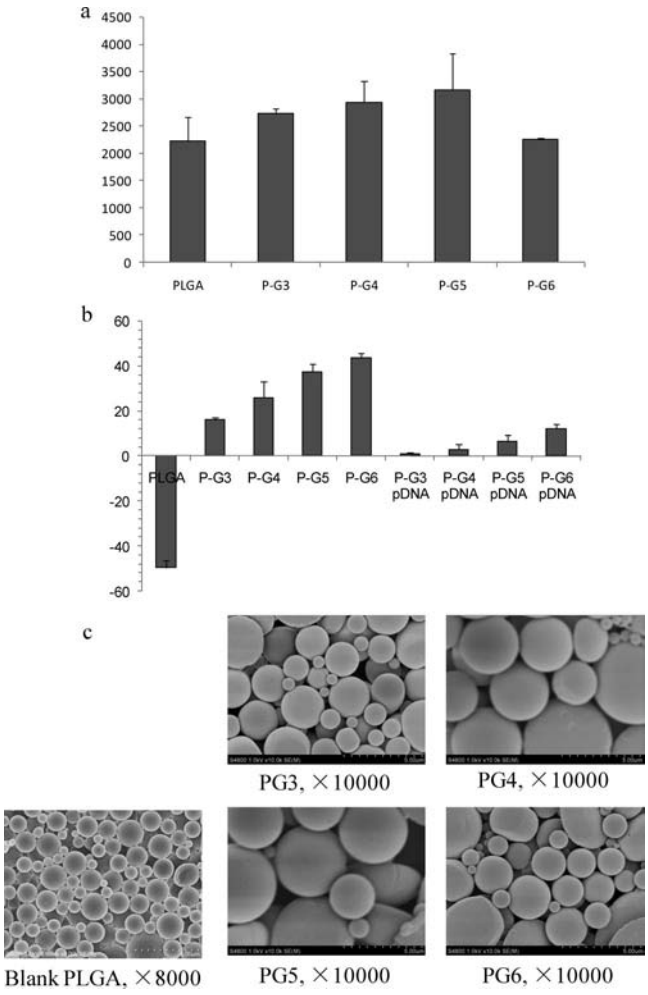

Figure 2. Size (a) and zeta potential (b) of PLGA PAMAM microparticles before and after pDNA binding. Data are represented as the mean ± standard deviation ($n = 3$). SEM images (c) show that the morphology of all the PLGA particles is smooth and spherical in appearance.

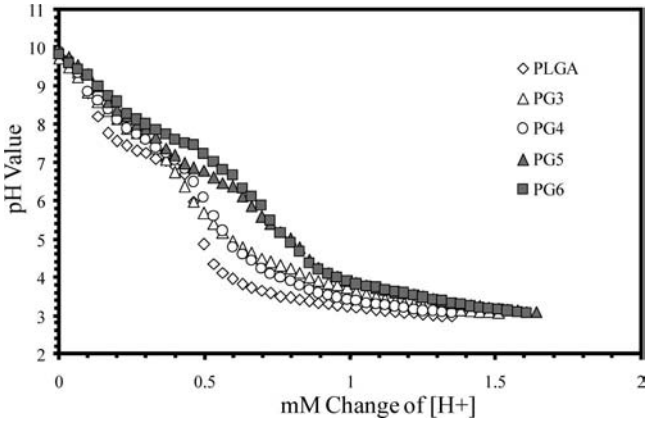

Figure 3. Acid titration experiments with 0.1 N HCL demonstrate the buffering capacity of PAMAM-conjugated and unmodified PLGA microparticles. The data show significantly increased buffering by PAMAM-conjugated PLGA microparticles in comparison to unmodified PLGA microparticles.

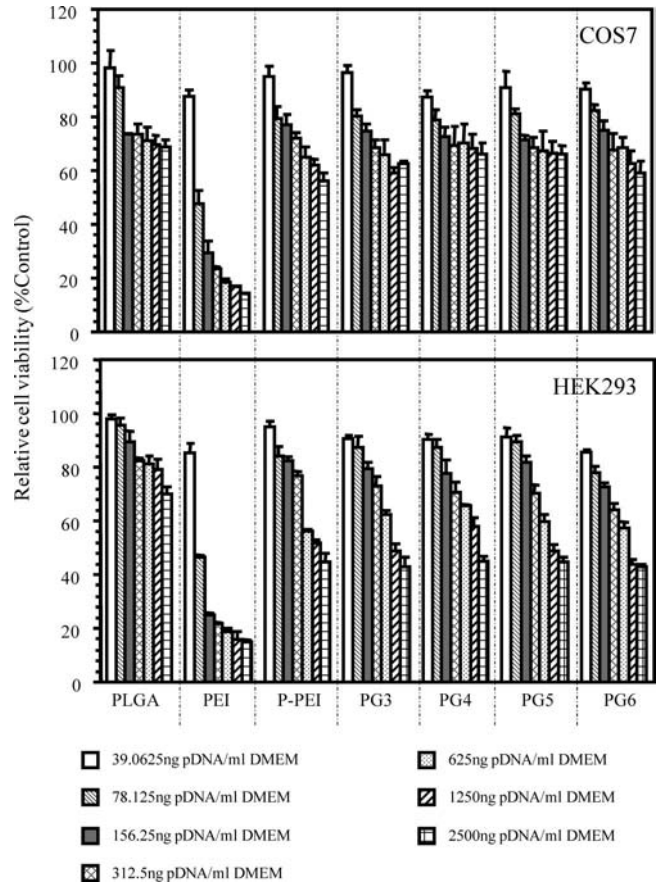

Figure 4. Cytotoxicity of dendrimer-conjugated PLGA pDNA microparticles in COS7 and HEK293 cells in comparison with PEI-conjugated PLGA pDNA microparticles, unmodified PLGA pDNA microparticles, and PEI alone. PEI amounts were selected on the basis of an estimated pDNA dose using an N/P ratio of 10:1. Cell viabilities were evaluated by MTT assay as described in the Materials and Methods section. Data is represented as the mean ± standard deviation ($n = 6$).

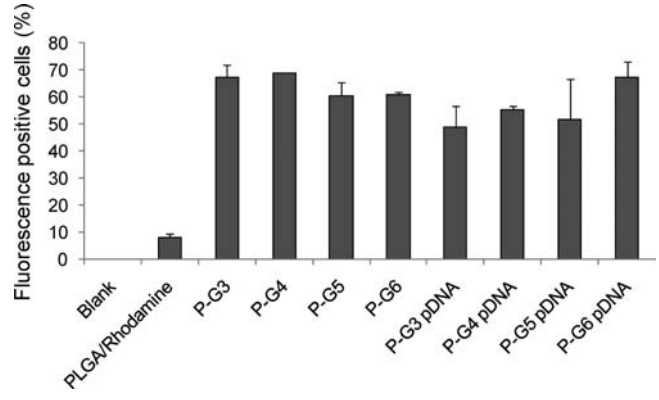

Figure 5. Flow cytometry data of fluorescence-labeled PLGA microparticles that have been incubated with HEK293 cells. The cellular uptake of the PLGA formulations is presented as a percentage of fluorescence-labeled cells ($n = 3$ per group). PLGA microparticle formulations were added at doses of 0.5 mg/well in HEK293 cells. The concentrations of PLGA particles were chosen from an estimated pDNA loading of 5 μg/mg particles and a target pDNA dose of 2.5 μg/well.

3.7. Dendrimer Conjugation Enhanced the Gene Transfection Mediated by PLGA Microparticles in COS7 and HEK293 Cells. Gene transfection mediated by PLGA pDNA and PLGA PAMAM pDNA microparticle formulations was evaluated in COS7 and HEK293 cells (Figure 6). All PLGA PAMAM microparticles showed significantly higher transgene expression than unmodified PLGA microparticles. In contrast with zeta potential and buffering capacity measurements, transfection efficiencies with PLGA PAMAM pDNA microparticles were not dependent on the generation of conjugated

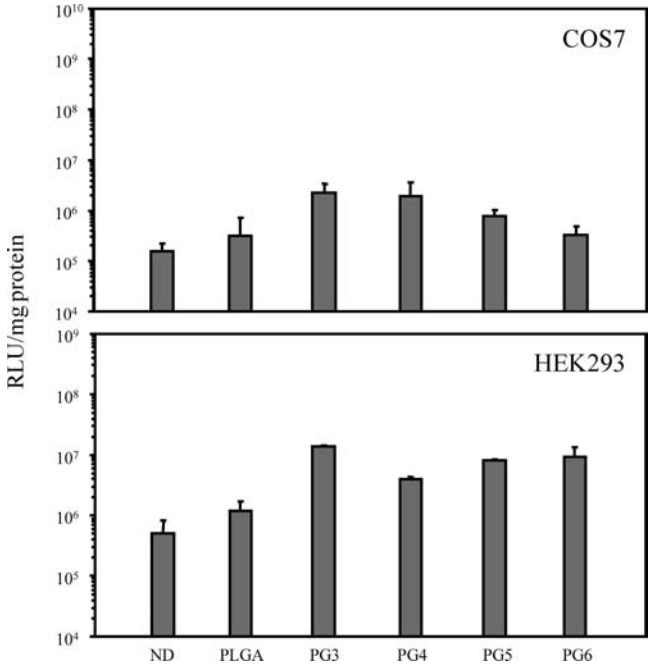

Figure 6. PLGA pDNA and PLGA PAMAM pDNA microparticle mediated gene transfection in COS7 and HEK293 cells. Microparticles were incubated with cells at a concentration of 0.2 mg/well with a target pDNA dose of 1 μg/well. Cell harvesting and luciferase assays were performed 48 h after transfection as described in the Materials and Methods section. Data are represented as mean ± standard deviation ($n = 3$). All the dendrimer-conjugated PLGA microparticles exhibited efficient gene delivery.

PAMAM. PG3 pDNA microparticles mediated the highest luciferase expression in both cell lines, which was 11-fold or 7-fold higher than unmodified PLGA pDNA microparticles in HEK293 or COS7 cells, respectively.

4. DISCUSSION

Delivery of pDNA from PLGA microparticles has shown significant potential in nonviral gene delivery. Entrapping pDNA in PLGA microparticles exposes the pDNA to potentially inactivating solvents and shear forces. (*3, 5, 8*). In addition, the local acidic microenvironment of PLGA microparticles has been reported to nick and subsequently inactivate pDNA (*5, 8*). Loading pDNA onto microparticles after they have been prepared overcomes several of these barriers for efficient pDNA delivery. However, PLGA microparticles are typically prepared using poly(vinyl alcohol) (PVA) surfactants. PVA surfactants impart a negative surface charge on the microparticles because of physical entrapment in the surface of the microparticles (*11,12,26,27*). As a result, pDNA, which has a net negative charge, does not bind efficiently to the PLGA microparticle surface. Several investigators have sought to overcome this limitation by preparing cationic microparticles that bind pDNA electrostatically. Methodologies that have been developed for preparing cationic PLGA microparticles include the use of cationic agents such as cetyltrimethylammoniumbromide (CTAB) (*15*), cetyldimethylethylammonium bromide (CDAB), dimethyldioctadecylammonium bromide (DDA) (*28*), 1,2-dioleoyl-1,3-trimethylammoniopropane (DOTAP), cationic DDAB (*28*), poly(L-lysine) (PLL), (*29–32*) chitosan (*33*) and polyethyleneimine (PEI) (*10, 34*). Preparation of the cationic microparticles has included blending, surface coating, and covalent attachment of these agents (*3, 10, 13, 16, 17*). Each method has its attributes and drawbacks. However, covalent attachment of cationic agents to the surface of microparticles is particularly advantageous because it minimizes toxicity associated with noncovalently attached cationic polymers or surfactants. This method also provides a method for more reliable loading levels—a prerequisite for the pharmaceutical industry (*10*). A significant advantage of these systems is the ability to instantaneously deliver DNA/RNA-based material followed by sequential delivery of complementary agents such as antigens, chemokines, or cytokines entrapped in the PLGA microparticle matrix (*10, 11*). In this study, we evaluated the impact of conjugating PAMAM dendrimers onto the surface of PLGA microparticles for enhanced pDNA delivery. SEM analysis showed that covalent attachment of PAMAM dendrimers to the surface of PLGA microparticles resulted in a smooth and spherical appearance at all generation levels of the PAMAM dendrimer. No statistical difference was observed in particle size after PAMAM conjugation ($P > 0.05$). Covalent attachment of G3 PAMAM dendrimers onto PLGA microparticles (PG3) increased the zeta potential from −50 mV to +20 mV ($P < 0.001$). The zeta potential of the PAMAM dendrimer-conjugated microparticle significantly decreased to values ranging from +0.5 mV to 13.5 mV after pDNA binding. This is most likely because pDNA has a net negative charge that neutralizes the positive charges associated with PAMAM dendrimer when binding electrostatically. Increasing the generation of the PAMAM dendrimer conjugated to the PLGA microparticle surface increased the zeta potential proportionally both before and after plasmid binding. For example, PG6 microparticles displayed zeta potentials of approximately +40 mV before pDNA binding and +12.2 mV after pDNA binding. This presumably relates to the fact that dendrimers at higher generations have more surface amine groups and a higher positive charge density. This change from negative to positive zeta potential increased the ability of pDNA to bind to the surface of the microparticles. PLGA microparticles with PAMAM conjugated to the surface displayed on average 5-fold higher pDNA loading levels in comparison to unmodified PLGA microparticles ($P < 0.001$). PG6 microparticles had significantly higher pDNA loadings than PG3, PG4, and PG5 microparticles ($P < 0.05$). No significant difference in pDNA loading was observed among PG3, PG4, and PG5 ($P > 0.05$). The presence of secondary and tertiary amines on the PAMAM dendrimer structures enabled the PAMAM-modified PLGA microparticles to resist acidification in acid titration experiments ($P < 0.001$ in comparison to unmodified PLGA microparticles). This ability to buffer against pH changes is believed to contribute to endophagosomal escape into the cytoplasm as described by the proton sponge hypothesis (*20, 24*). Increases in the generation level of the PAMAM conjugated to the PLGA microparticles correlated to increases in buffering capacity. The buffering capacity of PLGA PAMAM microparticles also correlated to zeta potential values. Dose-dependent toxicity measurements were made using the MTT assay (*21*). PLGA PAMAM microparticles could be incubated at concentrations as high as 500 μg of particles per milliliter of DMEM with more than 50% of the cells still viable. Several investigators have reported that PAMAM dendrimers alone display generation-dependent toxicity. For example, Duncan and colleagues reported that PAMAM dendrimers display concentration- and generation-dependent cytotoxicity and hemolysis as observed by changes in red cell morphology (*22*). The mechanism by which PAMAM dendrimers induce cytotoxicity is apoptosis involving a caspase-dependent pathway (*35*). Of notable interest in this study is that no significant differences in cytotoxicity were observed for PG3 pDNA, PG4 pDNA, PG5 pDNA, and PG6 pDNA microparticles. PLGA PAMAM microparticles retained the low cytotoxicity properties of unmodified PLGA microparticles in COS7 cells ($P > 0.05$). In the HEK293 cell line, cytotoxicity of PLGA PAMAM microparticles was mod-

erately higher than unmodified PLGA microparticles. This result suggests that cytotoxicity is cell-type dependent, and for certain applications that target specific tissues or cells, PAMAM conjugation to PLGA microparticles could completely remove the undesirable toxicity associated with PAMAM dendrimers alone. These results are consistent with the reduced cytotoxicity that is observed when PEI (25 kDa) is attached to PLGA microparticles in comparison to PEI alone (Figure 4) (*10*). Flow cytometry studies showed that conjugation of PAMAM to the PLGA microparticles significantly enhanced cell uptake by 6–7-fold in comparison to unmodified PLGA microparticles ($P < 0.001$). Changes in particle size were not significant between each group ($P > 0.05$) and were therefore not responsible for this increase in cell uptake. The zeta potential of PLGA PAMAM microparticles was significantly higher than unmodified PLGA microparticles even after pDNA binding. Cationic microparticles demonstrate an enhanced interaction with the negatively charged cellular membranes that is most likely responsible for the enhanced cell uptake. However, increasing the generation of the PAMAM dendrimer conjugated to the PLGA microparticles had no impact on increasing cell uptake further.

Gene transfection experiments were carried out on two model cell lines commonly used to evaluate transfection efficiency. Conjugation of PAMAM dendrimers to PLGA microparticles significantly enhanced luciferase expression in comparison to unmodified PLGA microparticles in both COS7 and HEK293 cell lines. G3 dendrimers covalently attached to PLGA microparticles generated the highest transgene luciferase expression. In contrast to dendrimers alone, however, increasing the generation of the dendrimer conjugated to the PLGA microparticle did not increase luciferase transgene expression. This result was consistent in both HEK293 and COS7 cell lines. This observation is important with respect to the manufacture of the PLGA PAMAM microparticles because G3 PAMAM dendrimers are easier to synthesize (*23*) and four times cheaper than G6 PAMAM dendrimers when purchased commercially (Dendritech). In addition, lower generation number PAMAM dendrimers have longer circulation times (*22*). Lower-generation PAMAM dendrimers that would eventually become free from the microparticle are also substantially less cytotoxic than higher-generation PAMAM dendrimers (*21–23, 35, 36*). Lin and colleagues have shown that G2 dendrimer conjugated to mesoporous silica nanoparticles can generate transfection efficiencies that are significantly higher than commercial transfection reagents because of a sedimentation effect previously described by Luo et al. *(37)* Given that we have observed generation-dependent increases in the buffering capacity and zeta potential for PLGA PAMAM microparticles, we would have expected corresponding transfection efficiency increases. However, in our studies, increases in zeta potential and buffering capacity do not correlate to further increases in transfection efficiency. This is consistent with a number of studies that have shown that zeta potential of dendrimers and transfection efficiency do not necessarily correlate (*38, 39*). The increase in transfection efficiency of PLGA PAMAM pDNA microparticles in comparison to PLGA pDNA microparticles is therefore related to the increased pDNA loading and increased interaction of microparticles with the cell surface. The existence of some buffering capacity may enhance transfection, but this study suggests that further promotion of the proton sponge effect does not further enhance transfection efficiency with this delivery system.

Conjugating PAMAM dendrimers to the surface of PLGA microparticles reveals a number of options for further exploration. The PAMAM dendrimers impart the PLGA microparticles with a much greater proportion of reactive surface functional groups. These could be used for efficient pegylation (*40, 41*), conjugation of cell targeting ligands to the microparticle surface (*42*), or a combination of both (*43*). Loading of the PLGA microparticles with radioisotopes or fluorescent dyes also provides the potential for combined imaging and delivery of biomolecules (*23*).

5. CONCLUSION

We have prepared PLGA microparticles with PAMAM dendrimers conjugated to the surface. The buffering capacity and zeta potential of the microparticles increases with increasing generation level of the conjugated PAMAM dendrimer. Conjugation of the PAMAM dendrimer to the surface of the PLGA microparticle removes generation-dependent toxicity. PLGA PAMAM microparticles displayed similar cytotoxicity profiles to unmodified PLGA microparticles. A G3 PAMAM dendrimer conjugated to PLGA microparticles significantly increased transfection efficiencies in comparison to unmodified PLGA microparticles. Further increases in the generation level of the PAMAM did not increase transfection efficiency. Plasmid DNA entrapped in PLGA microparticles has shown *in vivo* efficacy in animal models and phase II clinical trials (*44–47*). Therefore, the development of PLGA polymers with optimized cationic surfaces should have significant potential for enhancing the response of these systems further.

Degradable-Brushed pHEMA–pDMAEMA Synthesized via ATRP and Click Chemistry for Gene Delivery

Xulin Jiang,[†,‡] Martin C. Lok,[†] and Wim E. Hennink*[,†]

Department of Pharmaceutics, Utrecht Institute for Pharmaceutical Sciences (UIPS) Utrecht University, P.O. Box 80 082, 3508 TB Utrecht, The Netherlands, and Key Laboratory of Biomedical Polymers of Ministry of Education and Department of Chemistry, Wuhan University, Wuhan 430072, P.R. China. Received April 7, 2007; Revised Manuscript Received August 20, 2007

Brushed polymers composed of a backbone of poly(hydroxyethyl methacrylate) (pHEMA) onto which poly(2-(dimethylamino)ethyl methacrylate)s (pDMAEMAs) was grafted via a hydrolyzable linker were synthesized and evaluated as nonviral gene delivery vectors. Both pDMAEMA and pHEMA polymers with controlled molecular weights and narrow distributions were synthesized by controlled atom transfer radical polymerization (ATRP). The azide initiator was used to ensure complete and monoazide functionalization of the pDMAEMA polymer chains. Click reaction between pHEMA with alkyne side groups and the azide end group in the pDMAEMA resulted in a high-molecular-weight polymer composed of low-molecular-weight constituents via an easily degradable carbonate ester linker. The length of the pDMAEMA grafts as well as the number of grafts of the brushed pHEMA–pDMAEMA can be easily varied. At physiological conditions (pH 7.4 and 37 °C), the brushed polymer degraded by hydrolysis of the carbonate ester with a half-life of 96 h. The molecular weights of the formed degradation products was very close to that of the starting pDMAEMA, which is likely below the renal excretion limit (<30 kDa). It was shown that the degradable brushed pHEMA–pDMAEMAs were able to condense plasmid DNA into positively charged nanosized particles. The resulting polyplexes were able to transfect cells efficiently in the presence of the endosomal membrane disrupting INF-7 peptide, and all these degradable polymers showed lower cellular toxicity compared to a high-molecular-weight pDMAEMA reference. On the other hand, the low-molecular-weight pDMAEMA used for the grafting to pHEMA was neither able to condense the structure of DNA nor able to transfect cells. This study demonstrates that grafting a low-molecular-weight cationic polymer via a hydrolyzable linker to a neutral hydrophilic polymer is an effective approach to modulate the transfection activity and toxicity profile of gene delivery polymers.

INTRODUCTION

Gene therapy is considered to be a very promising approach to tackle genetic diseases, slow the progression of tumors, fight viral infections, and stop neurodegeneration (*1–3*). The major challenge in gene therapy is to design vector systems that are able to deliver therapeutic genes efficiently and specifically to the target site (*4*). The gene delivery strategies currently used include viral and nonviral systems. Although viral vectors, such as retroviruses, adenoviruses, and adeno-associated viruses, show efficient delivery and expression of genes, they possess some serious disadvantages, such as the possible introduction of immunogenic and inflammatory response, random DNA insertion, size limitations of the DNA, and problems with pharmaceutical-grade productions (*5–8*). Over the past decades, cationic polymers have been receiving much attention as nonviral gene delivery vectors, because they offer good biosafety and biocompatibility, a high flexibility regarding the size of the DNA that they can deliver, and can be produced relatively easily (*3*). For effective gene delivery, polymer carriers have to meet a series of requirements for the extracellular and intracellular transport of the DNA vector. First of all, the polymers have to be able to bind to and compact the DNA into small particles, called polyplexes. Therefore, the polymers have to be positively charged under physiological conditions. Second, the polyplexes have to be able to target specific cells, facilitating endosomal escape and localizing in the nucleus as well as vector unpacking (*3*, *9*). Third, the polymers should be nontoxic, nonimmunogenic, and preferably biodegradable in a controlled way to yield low-molecular-weight compounds that can be further metabolized or degradation products with molecular weight lower than 30 kDa, which can be excreted by the kidneys (*10*). However, none of the well-known polymers as nonviral carriers that have been evaluated so far, such as poly(L-lysine) (PLL) (*11*), poly(ethylene imine) (PEI) (*5*), chitosan and its derivatives (*12*, *13*), and poly(2-(dimethylamino)ethyl methacrylate) (pDMAEMA) and other cationic polymethacrylates (*14–16*), fulfills all the above functions. The major drawbacks of the generation of cationic gene delivery polymers are their relatively low transfection efficiency and significant cytotoxicity (*17–20*). In order to reduce the cytotoxicity and enhance vector unpacking into the cytosol and/or nucleus, degradable polymeric vectors have been recently investigated for gene delivery. These encompass polymers which degrade via chemical hydrolysis such as poly(4-hydroxy-L-proline ester) (*21*), poly[α-(4-aminobutyl)-L-glycolic acid] (*22*), poly(amino ester)s (*23*, *24*), polyphosphazenes (*9*), and degradable PLL (*25*) and PEI derivatives (*10*, *26*). In recent years, cationic polymers that contain disulfide bridges in the main chain (*27–29*) or in their cross-links (*30–32*) have been investigated for gene delivery. These bonds are reduced in the cytosol by which the polyplex destabilizes and DNA is released.

The transfection efficiency and cytotoxicity of cationic polymers complexed with plasmid DNA are strongly dependent

Scheme 1. (a) ATRP of 2-(Dimethylamino)ethyl Methacrylate (DMAEMA) Using N_3-Functionalized Initiator in Dichlorobenzene (DCB); (b) pHEMA with Side Chain of Alkynes; (c) Click Chemistry To Form Degradable Brushed pHEMA–pDMAEMA

on their molecular weights. Generally speaking, both the transfection efficiency and the cytotoxicity increase with increasing molecular weight of the cationic polymer, as reported for pDMAEMA (*33*, *34*), PLL (*35*), and PEI (*36*, *37*). In the present study, we therefore designed a high-molecular-weight polymer composed of a low-molecular-weight cationic polymer (pDMAEMA) that is grafted via a degradable linker to a hydrophilic, uncharged polymer (pHEMA). It is expected that these polymers show transfection efficiency comparable to that of high-molecular-weight polymers and degrade to low-molecular-weight cationic polymers, which are less cytotoxic than their high-molecular-weight counterparts.

The synthetic strategy we followed is depicted in Scheme 1. Degradable-brushed pHEMA–pDMAEMA polymers were synthesized via atom transfer radical polymerization (ATRP) (*38*, *39*) of HEMA and DMAEMA and click chemistry between azide-telechelic pDMAEMA and pHEMA with alkyne side groups (*40*–*42*). A carbonate ester, whose hydrolysis rate is higher than that of a "normal" ester (*43*, *44*), was selected as a degradable linker to couple pDMAEMA to the pHEMA backbone. This paper describes the synthesis and degradation of the brushed pHEMA–pDMAEMA polymers and the gene transfection activities of the corresponding polyplexes.

EXPERIMENTAL PROCEDURES

Materials. All chemicals were purchased from Sigma-Aldrich at the highest available purity and used as received, unless stated otherwise. 2-(Dimethylamino)ethyl methacrylate (DMAEMA) and hydroxyethyl methacrylate (HEMA) were obtained from Fluka (Buchs Switzerland). These monomers were distilled over calcium hydride prior to polymerization. Water purified by reverse osmosis was used throughout the study. The plasmid pCMVLacZ, containing a bacterial LacZ gene preceded by a nuclear localization signal under control of a CMV promoter, was purchased from Sanvertech (Heerhugowaard, The Netherlands). An ethidium bromide (EtBr) stock solution was obtained from Sigma (Zwijndrecht, The Netherlands). INF-7, a 24 amino acid containing peptide with fusogenic activity derived from the influenza virus, was synthesized via standard Fmoc solid-phase synthesis (*45*, *46*). The reference poly((dimethylamino)-ethyl methacrylate) (pDMAEMA, $M_n = 200$ kDa, $M_w = 1300$ kDa,) was synthesized via radical polymerization (*33*), and linear PEI (22 kDa, ExGen 500) was purchased from Fermentas (Burlington, Ontario, Canada).

Synthesis of 2-Bromo-Isobutyric Acid 3-Azidopropylester (BiBAP). BiBAP was synthesized from azidopropanol and 2-bromoisobutyryl bromide essentially reported as previously with some slight modifications (*39*). Azidopropanol (*47*) was synthesized as follows. 3-Bromo-1-propanol (3.58 g, 25.8 mmol) and sodium azide (6.71 g, 103.2 mmol) were dissolved in a mixture of 24 mL ethanol and 24 mL water. The solution was stirred at 70 °C in an oil bath for 24 h. Ethanol was then removed by evaporation under reduced pressure, and the product was extracted with dichloromethane (DCM, 3 × 20 mL). The organic layer was dried over Na_2SO_4, filtered, and evaporated to obtain a colorless oil (yield: 1.55 g, 60%). ^{1}H NMR (Gemini 300-MHz spectrometer, Varian, Palo Alto, CA, USA, $CDCl_3$, 298 K), $\delta = 3.76$ (t, $J = 6.0$ Hz, 2H, CH_2O), 3.45 (t, $J = 6.0$ Hz, 2H, CH_2N$_3$), and 1.83 (app. quint, $J = 6.1$ Hz, 2H, CCH_2C). No unreacted 3-bromo-1-propanol was detected by NMR. IR spectrum (neat): 3351 (broad, $\nu_{O\text{-}H}$), 2948, 2882, and 2099 cm^{-1} (ν_{N3}).

A solution of azidopropanol (1.28 g, 12.7 mmol) and triethylamine (3.9 mL, 28 mmol) in Et_2O (40 mL) was cooled to 0 °C in an ice bath, and 2-bromoisobutyryl bromide (3.12 mL, 25.3 mmol) was added dropwise. After stirring the mixture for 1 h at 0 °C, it was stirred for another 17 h at room temperature. Next, the resulting white suspension was filtered, and the filtrate was washed 3 times with 50 mL of a saturated $NaHCO_3$ aqueous solution. The organic layer was dried over

Na_2SO_4, filtered, and evaporated to obtain a yellow oily crude residue, in which no unreacted azidopropanol was detected by ^{1}H NMR. The resulting oil was purified by versa flash chromatography (silica column, petroleum ether/Et_2O 20:1) to obtain a colorless oil (yield: 1.98 g, 63%). ^{1}H NMR (300.10 MHz, $CDCl_3$, 298 K), $\delta = 4.28$ (t, $J = 6.1$ Hz, 2H, C*H*$_2$OCO), 3.45 (t, $J = 6.6$ Hz, 2H, C*H*$_2$N$_3$), 1.97 (app. quint, $J = 6.5$ Hz, 2H, CC*H*$_2$C), and 1.94 (s, 6H, C*H*$_3$). IR spectrum (neat): 3005, 2978, 2933, and 2101 cm^{-1} (ν_{N3}).

ATRP of DMAEMA. Following the literature (*38*), ligand 1,1,4,7,10,10-hexamethyltriethylenetetramine (HMTETA), DMAEMA, CuBr, dichlorobenzene (DCB), and initiator BiBAP were introduced in a reaction flask and subjected to five vacuum-N_2 cycles. Polymerizations with 1 g of monomer dissolved in 2 mL DCB were done using different ratios of monomer to initiator (Table 1). The monomer conversion was determined on the basis of the ratio of the polymer protons at 4.25 ppm (2*H*) to the corresponding monomer protons at 4.03 ppm (2*H*) by ^{1}H NMR (300.10 MHz, $CDCl_3$, 298 K). The polymerization was done at room temperature or 50 °C while stirring. After different times, hexane (~20 mL) was added to stop the polymerization and precipitate the polymers. The precipitated polymers were washed with hexane and dried at room temperature. Next, the polymers were dissolved in 10 mL water, extensively dialyzed against water (dialysis tube MWCO 1 kDa), and collected by lyophilization. The ^{1}H NMR spectra of the obtained pDMAEMAs with an azide functional group on the α-terminus and Br atom at the ω-terminus (pDMAEMA-N_3, **1**, Scheme 1) were recorded, and their number-average molecular weight (M_n) was calculated on the basis of the ratio of the polymer protons at 4.03 ppm (2*H*) to the initiator protons at 3.37 ppm (2 *H*, next to azide group). IR spectrum of the polymer: 2947, 2820, 2770, 2099 (ν_{N3}), 1729, 1459, 1269, 1151 cm^{-1}. The molecular weight and the distribution of the pDMAEMA were determined using the SEC method reported previously (*48*).

Synthesis of Propargyl Ester of Carbonyl Imidazole (PPA-CI, 2, Scheme 1). 1,1′-Carbonyldiimidazole (CDI, 29.19 g, 0.18 mol) and 200 mL dichloromethane (DCM) were loaded into a dry round-bottom flask. Then, propargyl alcohol (PPA, 5.82 mL, 0.1 mol) was added dropwise. The obtained clear solution was stirred at room temperature for 1 h, washed with water (3 × 70 mL), dried over sodium sulfate, and evaporated to obtain a white solid (yield: 13.0 g, 87%). ^{1}H NMR (300.10 MHz, $CDCl_3$, 298 K), $\delta = 8.19$ (s, 1H, NC*H*N), 7.45 (s, 1H, NC*H*CHN), 7.10 (s, 1H, NCHC*H*N), 5.0 (s, 2H, OC*H*$_2$C), and 2.63 (s, 1H, CC*H*).

ATRP of HEMA. Following the literature (*49*), 3 mL HEMA (3.21 g, 24.7 mmol), the initiator ethyl 2-bromoisobutyrate (79 or 158 mg, 0.405 or 0.81 mmol), 2,2′-dipyridyl (63 or 126 mg, 1.21 or 2.42 mmol), and CuBr (58 or 166 mg, 0.405 or 0.81 mmol) were dissolved into 3 mL of a mixture of acetone and 1-propanol (2:1, v/v). Then, the reaction mixture was cooled in an ice bath, and oxygen was removed by three vacuum nitrogen cycles. The polymerizations were conducted at 50 °C while stirring for 3 h. The solutions were diluted with about 30 mL methanol and passed over an alumina column to remove the copper. The polymers were precipitated using an excess of diethylether, washed with the same solvent, and dried at room temperature. The obtained colorless polymers were subjected to SEC analysis (2 PLgel Mixed-D columns, mobile phase DMF with 0.02 M LiCl) to obtain their molecular weights and distributions using PEG standards.

Table 2. HEMA–PPA Content of the Copolymers p(HEMA-*co*-HEMA-PPA)

name	pHEMA used	aimed HEMA–PPA content, %	HEMA–PPA content, %
p(HEMA-*co*-HEMA-PPA) **1**	pHEMA-2	50	52
p(HEMA-*co*-HEMA-PPA) **2**	pHEMA-1	50	45
p(HEMA-*co*-HEMA-PPA) **3**	pHEMA-1	25	23

Synthesis of p(HEMA-*co*-HEMA-PPA) (3, Scheme 1). pHEMA (1.0 g; 7.7 mmol OH groups) and PPA-CI (575 mg, 3.8 mmol, OH/CI ratio 2:1; or 285 mg, 1.9 mmol, OH/CI ratio 4:1; see Table 2) were dissolved in 16 g DMSO and stirred overnight at 50 °C under a nitrogen atmosphere. Next, the DMSO solution was dropped into 300 mL diethyl ether to precipitate the polymer, which was dissoved in chloroform after filtration and precipitated twice to yield a white solid (yields about 90%) after drying at room temperature. No peaks above 5 ppm were observed in the ^{1}H NMR spectrum of the resulting polymers (300 MHz, DMSO-d_6, 298 K), which shows that PPA-CI was not present in the isolated polymers. The HEMA–PPA content of the polymer was determined using ^{1}H NMR analysis (ratio of integral between 4.0 and 4.5 ppm (the -COO-C$\underline{H}_2$C$\underline{H}_2$-OCOO- protons of the carbonate ester group) to that of 3.4–4.0 ppm (the -COO-C$\underline{H}_2$C$\underline{H}_2$-OH protons of the hydroxy ethyl group)).

Synthesis of Brushed pHEMA–pDMAEMA by Conjugation of pDMAEMA-N_3 to Polyalkynes via Click Chemistry. Azide-functional pDMAEMA **1** and polyalkynes, p(HEMA-*co*-HEMA-PPA) **3**, were dissolved in DMF and reacted in the presence of a copper(I) catalyst under a nitrogen atmosphere (Scheme 1c). The general procedures involved pDMAEMA-N_3 (1 equiv of N_3), p(HEMA-*co*-HEMA-PPA) (0.8–8 equiv of alkyne), and CuBr (1 equiv) being dissolved in DMF, and the resulting solution (200 mg pDMAEMA in 4 mL DMF) was subjected to five vacuum N_2 cycles. Then, the reaction mixtures were stirred at different temperatures (room temperature up to 80 °C). At regular time intervals, aliquots (10 μL containing about 1 mg of polymer) were withdrawn with a syringe, and added to 1 mL aqueous solution of 0.3 M NaAc (pH 4.4) for SEC molecular weight analysis (*48*). In some reactions, after 4 h, an extra amount of p(HEMA-*co*-HEMA-PPA) was added to consume remaining nonreacted pDMAEMA. If SEC analysis showed the absence of unreacted pDMAEMA, the solutions were extensively dialyzed (dialysis tube MWCO 12–14 kDa) against an NH_4Ac buffer pH 5.0 (10 mM, last step 5 mM). Water was removed by evaporation until about 10 mL remained, and the solutions with the brushed polymers were frozen and stored at −25 °C. The concentration of the brushed polymers was measured by SEC analysis with RI detection (*48*).

Hydrolysis of the Brushed pHEMA–pDMAEMAs. The brushed pHEMA–pDMAEMA polymers were dissolved in 10 mL buffer solutions at a concentration of 2 mg/mL. Buffers used were 0.1 M HEPES (pH 7.4) and 0.2 M NaAc (pH 5.0). These solutions were incubated at 37 °C, and at regular time intervals, 100 μL samples were withdrawn and added to 100 μL of aqueous solution of 0.3 M NaAc (pH 4.4), and stored at

−25 °C. After thawing, the samples were analyzed by SEC as described previously (*48*).

Particle Size and Zeta Potential of Polyplexes. The *Z*-average diameter and polydispersity of the polymer/DNA complexes were measured by dynamic light scattering (DLS) using a Malvern ALV CGS-3 system equipped with an argon-ion laser (488 nm, 10.4 mW) (Uniphase). The ALV correlator software in combination with DTS (Nano) and *ALVFilereader* software was used. Viscosity and refractive index of water at 25 °C were used. The instrument was calibrated with 100 nm polystyrene particles dispersed in water. In a typical experiment, 800 μL of buffer (5 mM HEPES, pH 7.4, or 20 mM HEPES, pH 7.4, adjusted to 150 mM with NaCl (HBS)) with various amounts of polymer was added to 200 μL of the same buffer containing 10 μg of plasmid DNA. The resulting solution was vortexed for 5 s, and after 30 min of incubation time at room temperature, the size of the polyplexes was determined using DLS at 25 °C.

The zeta potential of the polyplexes was measured at 25 °C using a Zetasizer 2000 unit (Malvern) equipped with a DTS5001 cell. The instrument was calibrated using a polystyrene dispersion with a known zeta potential. In a typical experiment, 800 μL of HEPES buffer (5.0 mM, pH 7.4) with various amounts of polymer was added to 200 μL of the same buffer containing 10 μg of plasmid DNA. The resulting solution was vortexed for 5 s, and after 30 min of incubation time at room temperature, the zeta potentials of the polyplexes were determined.

DNA Binding. The binding of the cationic polymers to DNA was examined by the fluorescence-quenching assay of ethidium bromide (EtBr), at a DNA concentration of 10 μg/mL in 20 mM HBS buffer (*9*). EtBr was added at a 1:10 molar ratio to DNA phosphates in 20 mM HBS buffer. Then, the polymer in 20 mM HBS was added to the DNA/EtBr solution to form the polyplexes at different polymer/DNA ratios, followed by vortexing and incubation at room temperature for 30 min. The fluorescence was measured using a Fluorstar Optima plate reader (BMG Laboratory Tech, Germany) at excitation/emission wavelengths of 500 and 600 nm, respectively. The relative fluorescence (F_r) values were calculated as follows:

$$F_r = (F_{obs} - F_e)/(F_0 - F_e)$$

where F_{obs} is the measured fluorescence, F_e is the fluorescence of EtBr in the absence of DNA, and F_0 is the initial fluorescence of DNA/EtBr in the absence of a cationic polymer.

In Vitro Transfection and Toxicity. Transfection and toxicity studies were done in COS-7 cells as described previously using plasmid pCMVLacZ as reporter gene (*33*). Two parallel experimental series, one for the determination of reporter gene expression and the other for the evaluation of number of viable cells using an XTT colorimetric assay, were carried out in separate 96-well plates with cells at a density of 3×10^4 cm^{-2}. Polyplexes were prepared as follows: 150 μL of polymer solution (various concentrations) in HBS was added to 50 μL of 50 μg/mL plasmid solution in HBS buffer. After shaking and incubation for 30 min at room temperature, 50 μL solution of the endosomal membrane disrupting INF-7 peptide (150 μg/mL) was added, and the polyplexes were incubated for another 15 min before addition to the cells. After the cells were rinsed with HBS, 100 μL of the polyplex dispersion and 100 μL of serum-free culture medium were incubated with the cells for 1 h. After removal of the polyplex dispersion, fresh culture medium was added, and the cells were incubated for another 48 h. The transfection efficiency was determined by the activity of β-galactosidase using an ONPG colorimetric assay, of which the value was normalized to that of reference pDMAEME polyplexes (polymer/DNA ratio of 3/1) in the absence of serum. For comparison, the transfection activity of polyplexes of linear PEI (22 kDa, ExGen 500) in the absence of serum was also measured. The cell toxicity was measured using the XTT assay. The XTT value for the untreated cells (without polymer and DNA) was taken as 100% cell viability. All the transfection and toxicity assays were carried out in triplicate.

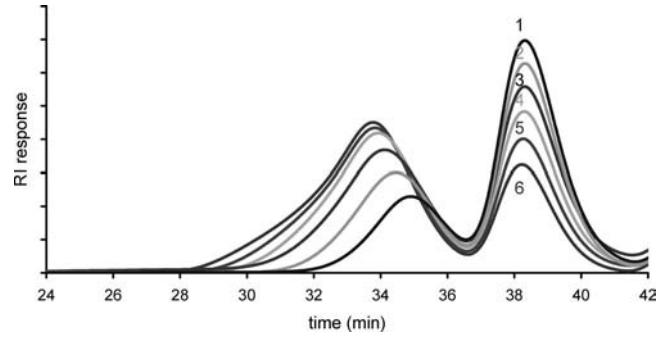

Figure 1. Kinetics of the click reaction of pDMAEMA-N_3 and p(HEMA-*co*-HEMA-PPA) in DMF at a molar ratio of alkyne to azide 1:0.8 at room temperature as followed by SEC. Trace 1 (SEC method as described previously (*48*)), 10 min; 2, 25 min; 3, 50 min; 4, 90 min; 5, 150 min; 6, 240 min. Remark: p(HEMA-*co*-HEMA-PPA) is not detected because it is not soluble in the SEC mobile phase; pDMAEMA-1 and pHEMA-1 were used.

RESULTS AND DISCUSSION

Synthesis of N_3-Telechelic pDMAEMA Using ATRP. Using the azide-initiator (2-bromo-isobutyric acid 3-azidopropylester, BiBAP), ATRP of DMAEMA gave a monoazido-functionalized polymer (Scheme 1). The polymerization kinetics (data not shown) indicated negligible termination and controlled/"living" characteristics of the DMAEMA polymerization under the selected conditions. Further, ^{1}H NMR analysis of the obtained polymer showed the presence of the protons (2*H*, 3.37 ppm) originating from the used initiator, whereas IR analysis showed an absorption peak at 2099 cm^{-1} corresponding to the asymmetric stretching vibration of the azide group. The number-average molecular weights (M_n) of the pDMAEMAs as determined by NMR (e.g., $M_{n(NMR)} = 8.7$ kDa for pDMAEMA-2) are in excellent agreement with those obtained by SEC (for the same polymer, $M_{n(SEC)} = 8.6$ kDa). SEC analysis also showed that the polydispersities are low (PDI = 1.15–1.18), as expected for polymers prepared with ATRP. From these analyses, it is concluded that N_3-telechelic pDMAEMAs have been obtained.

Synthesis of pHEMA with Alkyne Side Groups. pHEMAs with alkyne side groups were synthesized in two steps. First, pHEMAs were synthesized by ATRP (pHEMA-1, insoluble in water; pHEMA-2, water-soluble). The SEC results are shown in Table 1. Second, propargyl alcohol activated with 1,1′-carbonyldiimidazole (PPA-CI) was reacted with pHEMA. The HEMA-PPA contents of the polymers as measured by ^{1}H NMR are shown in Table 2. It can be seen from this table that the HEMA-PPA contents were close to the desired values.

Brushed pHEMA–pDMAEMA Synthesized by Click Reaction. At room temperature, N_3-telechelic pDMAEMA (pDMAEMA-N_3) was coupled to p(HEMA-*co*-HEMA-PPA) in DMF with CuBr as catalyst. A slight molar excess of alkyne to azide groups (1/0.8 mol/mol) was used. The coupling progress was monitored by SEC analysis (Figure 1). This figure shows that the (pDMAEMA-N_3) fraction (retention time ~36.5–41 min) decreased, whereas a high-molecular-weight fraction (retention time ~28–36 min), consisting of brushed pHEMA–pDMAEMA, was formed in time. When no copper catalyst was used, no high-molecular-weight fraction was observed within the investigated time (15 h). This demonstrates that the high-molecular-weight fraction as observed in Figure 2 consisted of brushed pHEMA–pDMAEMA "clicked" via a triazole group

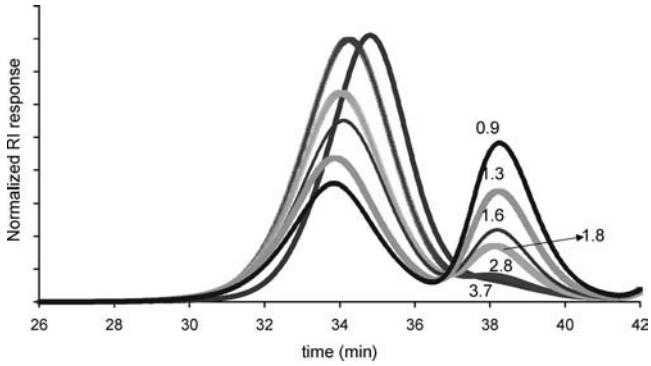

Figure 2. SEC profiles of various brushed pHEMA–pDMAEMA polymers synthesized at different alkyne/azide ratios in DMF at 50 °C for 3 h (SEC method as described previously (*48*)); molar ratios of azide to alkyne are indicated, pDMAEMA-1 and pHEMA-1 were used.

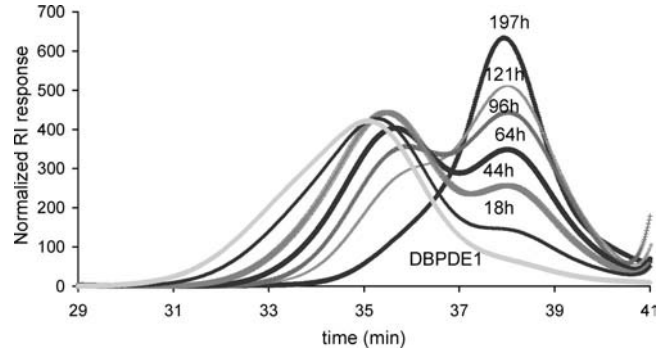

Figure 3. SEC profiles of pHEMA–pDMAEMA-1 incubated for various times at pH 7.4 and 37 °C.

that was formed by the Cu(I)-catalyzed reaction of the terminal azide group of pDMAEMA and the alkyne side groups of p(HEMA-*co*-HEMA-PPA). Figure 1 also shows that after 90 min reaction time almost half of the pDMAEMA-N_3 was coupled to p(HEMA-*co*-HEMA-PPA). However, the click reaction slowed down at the later stages, likely because the grafted pDMAEMA hindered the coupling of pDMAEMA-N_3 to unreacted propagyl groups. After 4 h, prolongation of the reaction time did not decrease the fraction of nonreacted (pDMAEMA-N_3). To optimize the click reaction conditions, different brushed pHEMA–pDMAEMA polymers were synthesized at different alkyne/azide ratios at 50 °C. As seen in Figure 2, the fraction of nonreacted pDMAEMA-N_3 decreased with an increasing alkyne/azide ratio. At the highest alkyne/azide ratio (3.7/1 mol/mol) investigated, hardly any unreacted pDMAEMA-N_3 was detected with SEC after 3 h reaction time at 50 °C. Figure 2 also shows that the molecular weight of the synthesized brushed pHEMA–pDMAEMA decreased with increasing alkyne/azide ratio. This is expected, since with an increasing alkyne/azide ratio the grafting density of the brushed pHEMA–pDMAEMA decreases. The SEC results of the synthesized brushed pHEMA–pDMAEMAs are summarized in Table 3.

Hydrolytic Degradation of Brushed pHEMA–pDMAEMA. The pDMAEMA chains are coupled via a carbonate ester and a "normal" ester to pHEMA (Scheme 1). In previous studies, it has been shown that, in particular, carbonate esters are sensitive towards hydrolysis under physiological conditions (*43, 45*). SEC was used to monitor the hydrolytic degradation of brushed pHEMA–pDMAEMA. As an example, Figure 3 shows the SEC profiles of the brushed pHEMA–pDMAEMA-1 incubated at 37 °C and pH 7.4. This figure clearly demonstrates that the high-molecular-weight brushed pHEMA–pDMAEMA decreases in time with a concomitant increase of a low-molecular-weight fraction (retention time ~36.5–41 min). The molecular weight of the formed polymers after a degradation time of 197 h is very close to that of the starting pDMAEMA, which was coupled to p(HEMA-*co*-HEMA-PPA) via the click reaction. The half-life time (*50*) of the degradable brushed pHEMA–pDMAEMA-1 polymer is about 96 h under the tested conditions. Once pHEMA–pDMAEMA-1 had been incubated for 10 days at pH 5.0 and 37 °C, no degradation was seen with SEC. At this pH, esters have the highest resistance toward chemical hydrolysis. Taken together, the data demonstrate that brushed pHEMA–pDMAEMA most likely degrades by chemical hydrolysis of the carbonate ester bonds via which the pDMAEMA are grafted to p(HEMA-*co*-HEMA-PPA), yielding pDMAEMA and pHEMA as degradation products with a molecular weight allowing excretion via the kidneys.

DNA Condensation and Polyplex Stability. The DNA binding and condensation properties of the starting pDMAEMA and the degradable brushed pHEMA–pDMAEMAs were investigated by dynamic light scattering (DLS) and zeta potential measurement. Once pDMAEMA (pDMAEMA-1, M_w 11.1 kDa) was added to a solution of DNA, only large polymer/DNA polyplex particles (size above 1000 nm) were formed, of which the size did not decrease with increasing polymer concentration, although a positive zeta potential of 28 mV was obtained. However, all the synthesized brushed pHEMA–pDMAEMA polymers (M_w >75 kDa) were able to condense DNA into small particles (90–190 nm, at a polymer to plasmid mass ratio ≥6). This is in agreement with a previous report in which it was demonstrated that only high-molecular-weight pDMAEMA is able to condense the structure of plasmid DNA effectively (*33*). As can be seen in Figure 4, the size of the pHEMA–pDMAEMA-1 based polyplexes is smaller than that of the pHEMA–pDMAEMA-3-based polyplexes when the polymer/DNA mass ratio is >3, although the weight-average molecular weight of pHEMA–pDMAEMA-1 is lower than that of pHEMA–pDMAEMA-3. This implies that the size of the polyplexes does not increase with the molecular weight of the polymer anymore when the molecular weight is high enough (M_w above 75 kDa). The zeta potentials of the brushed pHEMA–pDMAEMA-based polyplexes were independent of the molecular weight of pHEMA–pDMAEMA. The binding of polymers to plasmid DNA was also studied by ethidium bromide fluorescence measurement in HBS buffer (Table 4). This table shows that all tested polymers quenched the plasmid DNA/ethidium bromide fluorescence. The brushed pHEMA–pDMAEMAs showed more quenching than the starting pDMAEMA, indicating a weaker binding of this low-molecular-weight polymer to the plasmid DNA. However, the brushed pHEMA–pDMAEMAs

Table 3. SEC Results of Brushed pHEMA–pDMAEMA Copolymers (Alkyne/Azide Molar Ratio 4:1)[a]

name	p(HEMA-*co*-HEMA-PPA) used	M_n, kDa	M_w, kDa	PDI

[a] SEC method as described previously (*48*).

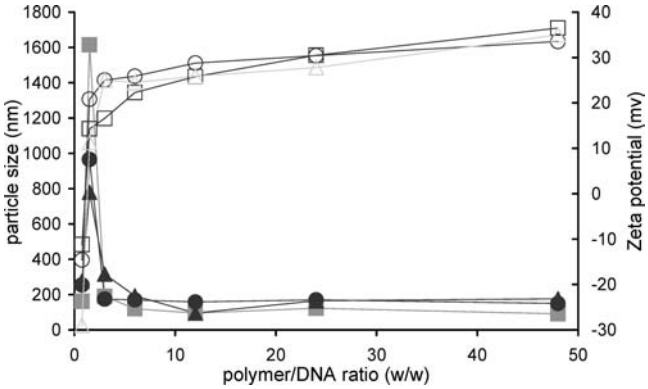

Figure 4. Particle size and zeta potential of brushed pHEMA–pDMAEMA-based polyplexes as a function of polymer/DNA ratio. Square, size of pHEMA–pDMAEMA-1-based polyplexes; circle, size of pHEMA–pDMAEMA-2-based polyplexes; triangle, size of pHEMA–pDMAEMA-3-based polyplexes; open square, zeta potential of pHEMA–pDMAEMA-1-based polyplexes; open circle, zeta potential of pHEMA–pDMAEMA-2-based polyplexes; open triangle, zeta potential of pHEMA–pDMAEMA-3-based polyplexes.

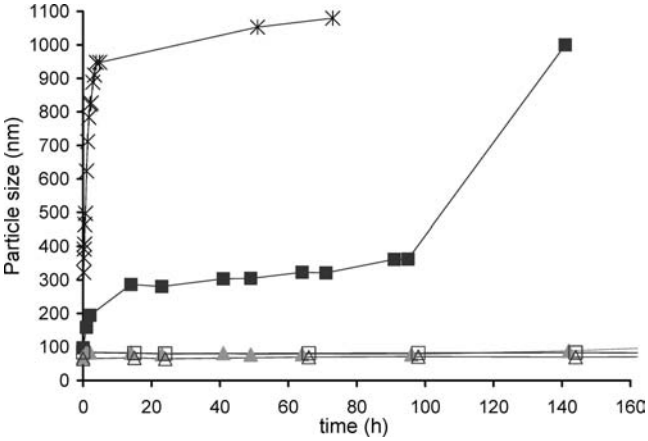

Figure 5. Polyplex (polymer/DNA mass ratio 3:1) destabilization studied by DLS. Square, pHEMA–pDMAEMA-1-based polyplexes at pH 7.4 and 5 mM HEPES; triangle, pHEMA–pDMAEMA-3-based polyplexes at pH 7.4 and 5 mM HEPES; open square, pHEMA–pDMAEMA-1-based polyplexes at pH 5 and 10 mM NaAc; open triangle, pHEMA–pDMAEMA-3-based polyplexes at pH 5 and 10 mM NaAc; star, pHEMA–pDMAEMA-1-based polyplexes at pH 7.4 and HBS.

showed similar quenching as high-molecular-weight pDMAEMA. This is in agreement with the DLS results.

The destabilization of pHEMA–pDMAEMA polyplexes was investigated by DLS. Figure 5 shows the particle size of pHEMA–pDMAEMA-1 and pHEMA–pDMAEMA-3 polyplexes (with the polymer to DNA mass ratio of 3) as a function of time at 37 °C and at pHs 5.0 and 7.4. The size of the polyplexes was constant at pH 5.0 in 10 mM NaAC over the investigated time period (7 days), while the size of the pHEMA–pDMAEMA-1-based polyplexes incubated at pH 7.4 increased substantially over time (Figure 5). The size of pHEMA–pDMAEMA-3 (relatively higher molecular weight) based polyplexes in 10 mM HEPES at pH 7.4 increased very

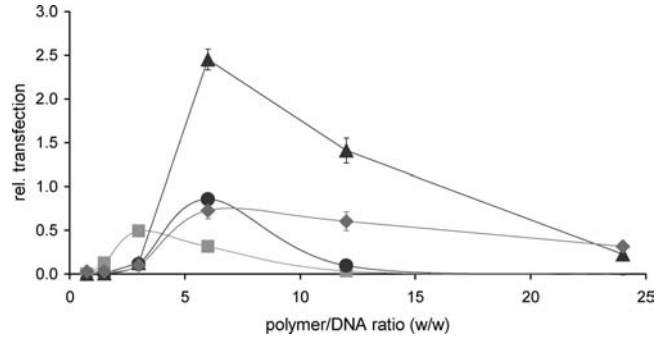

Figure 6. β-Galactosidase expression after incubation of COS-7 cells with polyplexes based on the degradable brushed pHEMA–pDMAEMA polymers and the reference polymer linear PEI in the presence of INF-7 peptide. Square, pHEMA–pDMAEMA-1; circle, pHEMA–pDMAEMA-2; triangle, pHEMA–pDMAEMA-3; diamond, linear PEI.

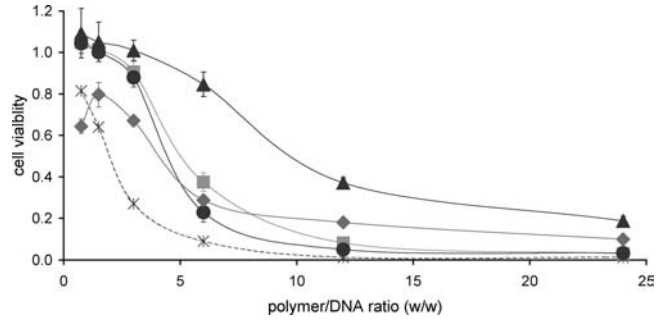

Figure 7. Relative cell viability of polyplexes based on the degradable brushed pHEMA–pDMAEMA polymers and the reference polymers pDMAEMA and linear PEI in the presence of INF-7 peptide in COS-7 cells. slowly, and the size of the polyplexes based on high-molecular-weight pDMAEMA was very stable under the same conditions (data not shown). Likely, the higher-molecular-weight brushed pHEMA–pDMAEMA needs more time to degrade completely than the lower-molecular-weight ones. The observation that polyplexes based on high-molecular-weight pDMAEMA are stable over time after incubation at physiological conditions is in agreement with previous data that this polymer is very stable at pH 7.4 and 37 °C (*51*). The time period in which aggregation of the polyplexes occurred is on the same order of magnitude as pHEMA–pDMAEMA-1 polymer hydrolysis (compare Figure 5 (95 h) with Figure 3 (96 h)), which indicates that the degradation of brushed pHEMA–pDMAEMA polymers is hardly influenced by the complexation with DNA (*45*). The polyplexes in HBS buffer aggregated much more quickly than those in 5 mM HEPES buffer, especially for low polymer/DNA ratio or for polymers with low molecular weight (Figure 5). Obviously, chemical degradation results in a decrease in the colloidal stability of the polyplexes in HEPES-buffered saline.

In Vitro Transfection Efficiency and Cytotoxicity Studies. The transfection activity and toxicity of the different polyplexes was studied in vitro in COS-7 cells (Figures 6 and 7). Figure 6 shows the expression levels of β-galactosidase after incubation of COS-7 cells for 1 h with polyplexes based on the

three degradable brushed pHEMA–pDMAEMA polymers and the reference polymer, linear PEI, as a function of the polymer to DNA ratio in the presence of INF-7 peptide. The transfection efficiency of the polyplexes based on high-molecular-weight pDMAEMA at a polymer/DNA ratio of 3/1 (w/w) was set at 1.0 (*33*). The highest transfection was observed for the polyplexes based on the highest-molecular-weight pHEMA–pDMAEMA-3 at a polymer/DNA mass ratio of 6/1, with a tranfection efficiency about 2.5 times higher than that of the polyplexes based on the reference pDMAEMA and about 3.1 times higher than that of the polyplexes based on linear PEI (Exgen 500). The polyplexes based on lower-molecular-weight brushed pHEMA–pDMAEMA showed lower transfection, which is in agreement with the results reported previously (*33*). The transfection of the pDMAEMA-2-based polyplexes was negligible (data not shown). We also studied the transfection activity of the polyplexes without addition of the INF peptide. In line with previous data (*52*), the transfection was lower (3–4 times), but the observed trends were the same as those observed for the polyplexes with INF.

Importantly, the brushed pHEMA–pDMAEMAs showed lower cellular toxicity as compared to reference pDMAEMA (Figure 7). Of the investigated brushed polymers, pHEMA–pDMAEMA-3-based polyplexes showed the highest transfection efficiency and the lowest toxicity, making this polymer an interesting candidate for future studies.

CONCLUSION

A new degradable brushed pHEMA–pDMAEMA was synthesized via ATRP and click chemistry for gene delivery. The click reaction and the degradation process were monitored clearly by aqueous SEC. The molecular weight of the final main degradation product pDMAEMA was very close to that of the starting pDMAEMA, which was coupled to p(HEMA-*co*-HEMA-PPA) via the click reaction and is likely below the renal excretion range (<30 kDa). It was shown that all the degradable brushed pHEMA–pDMAEMA polymers were able to condense DNA into small particles (90–190 nm) and were able to quench the plasmid DNA/ethidium bromide fluorescence. The resulting polyplexes were able to transfect cells efficiently in the presence of INF-7 peptide and showed lower toxicity compared to high-molecular-weight pDMAEMA. Future work will be focused on the coupling of PEG to prevent nonspecific interactions and of targeting moieties to introduce cell specificity into the systems.

Synthesis of *p*-(Di-*tert*-butyl[^{18}F]fluorosilyl)benzaldehyde ([^{18}F]SiFA-A) with High Specific Activity by Isotopic Exchange: A Convenient Labeling Synthon for the ^{18}F-Labeling of N-amino-oxy Derivatized Peptides

Esther Schirrmacher,*[,∇,†] Björn Wängler,[∇,‡,§] Marek Cypryk,[||] Gerrit Bradtmöller,[⊥] Martin Schäfer,[‡] Michael Eisenhut,[‡] Klaus Jurkschat,[⊥] and Ralf Schirrmacher*[,#]

Received May 30, 2007; Revised Manuscript Received August 14, 2007

The syntheses of different ^{18}F-labeled peptides using the highly effective labeling synthon *p*-(di-*tert*-butylfluorosilyl) benzaldehyde ([^{18}F]SiFA-A) for the development of ^{18}F-radiopharmaceuticals for oncological positron emission tomography (PET) is reported. The novel and mild labeling technique for the radiosynthesis of [^{18}F]SiFA-A, based on an unexpectedly efficient isotopic ^{19}F–^{18}F exchange, yielded the ^{18}F-synthon [^{18}F]SiFA-A in almost quantitative yields in high specific activities between 225 and 680 GBq/μmol (6081–18 378 Ci/mmol) without applying HPLC purification. The [^{18}F]SiFA-A was finally used to label the N-terminal amino-oxy (N-AO) derivatized peptides AO-Tyr^3-octreotate (AO-TATE), *cyclo*(fK(AO-N)RGD and N-AO-PEG$_2$-[D-Tyr-Gln-Trp-Ala-Val-βAla-His-Thi-Nle-NH$_2$] (AO-BZH3, a bombesin derivative) in high radiochemical yields. Density functional theory (DFT) calculations confirmed high efficiency of the isotopic exchange, which is predicted to proceed via a pentacoordinate siliconate intermediate dissociating immediately to form the radiolabeled [^{18}F]SiFA-A.

INTRODUCTION

Due to the high dissemination of positron emission tomography (PET) (*1*), an imaging modality investigating the distribution of radioactively labeled biomarkers *in vivo*, the synthesis of radiolabeled peptides with the radiohalide fluorine-18 for the detection of cancer of various origins has gained widespread interest in nuclear medicine oncology (*2*). The labeling methods for peptides so far are characterized by multistep synthetic pathways using secondary labeling precursors (prostetic groups) which have to be prepared prior to final bioconjugation to the peptide of interest (*3, 4*). Even novel methods such as chemoselective bioconjugation of aldehydes (*5–7*), solid-phase ^{18}F-fluoropropionylation (*8*), thiol-reactive ^{18}F-labeling agents (*9–12*), and the most recently introduced "click-chemistry" approach for the ^{18}F-labeling of peptides (*13, 14*), although great improvements, still suffer from drawbacks. The need to use HPLC or distillation for purification of the ^{18}F-synthon for final peptide coupling or time-consuming workup often reduce the final preparative yields and are cumbersome for automation. As a completely new labeling method and in addition to other recently published Si-^{18}F chemistry (*15*), our group has introduced an organosilicon-containing fluoride acceptor (Silicon Fluoride Acceptor, SiFA) conjugated to the peptide Tyr^3-octreotate (TATE) as the first practical example applying an ^{18}F-labeling chemistry based on isotopic ^{19}F for ^{18}F-exchange at a silicon atom (*16*). Although the final radiolabeling of SiFA-TATE is easy, the specific activities (SA) so far obtained (3–5 GBq/μmol) are unsatisfying and encouraged us to establish a complementary labeling approach where the *p*-(di-*tert*-butylfluorosilyl) benzaldehyde, hereafter referred to as SiFA-A (**1**), is ^{18}F-labeled in high SAs prior to solution-phase chemoselective conjugation to amino-oxy (AO) derivatized peptides (Figure 1). The fluorosilane [^{18}F]fluorodi-*t*-butylphenylsilane has previously been proven to be stable in human serum at 37 °C as well as under *in vivo* conditions in healthy rats and is therefore suited to be conjugated to peptides (*16*). We applied this two-step ^{18}F-labeling approach to N-terminal AO-derivatized peptides such as AO-Tyr^3-octreotate, AO-poly(ethylene glycol) (PEG)-conjugated bombesin (BN6-14) analogue (BZH3), and a small cyclic peptide containing the Arg-Gly-Asp (RGD) sequence *cyclo*(fK(AO-N)RGD) to cover a wide range of biologically interesting peptides for tumor imaging. Additional DFT calculations on the isotopic ^{19}F–^{18}F isotopic exchange reaction of three different model fluorosilicon compounds gave further insight into this new and exciting radiochemistry. We could demonstrate for the first time that highest SAs of ^{18}F-labeled compounds can be achieved by a simple isotopic exchange using a minimum amount of precursor in the lower nanomolar range.

EXPERIMENTAL SECTION

Materials. Amino acids and resins for Fmoc SPPS were purchased from Novabiochem (Germany). The Rink amide resin and solid-phase C18 cartridges were obtained from Merck (Germany). All other chemicals were obtained from Sigma-Aldrich. HPLC columns: the Chromolith SemiPrep (RP-18e 100–10mm) was purchased from Merck (Germany) and the PerfectSil column (120 C4 5μm, 100 × 4.0 mm) was obtained from MZ-ANALYTICAL (Germany).

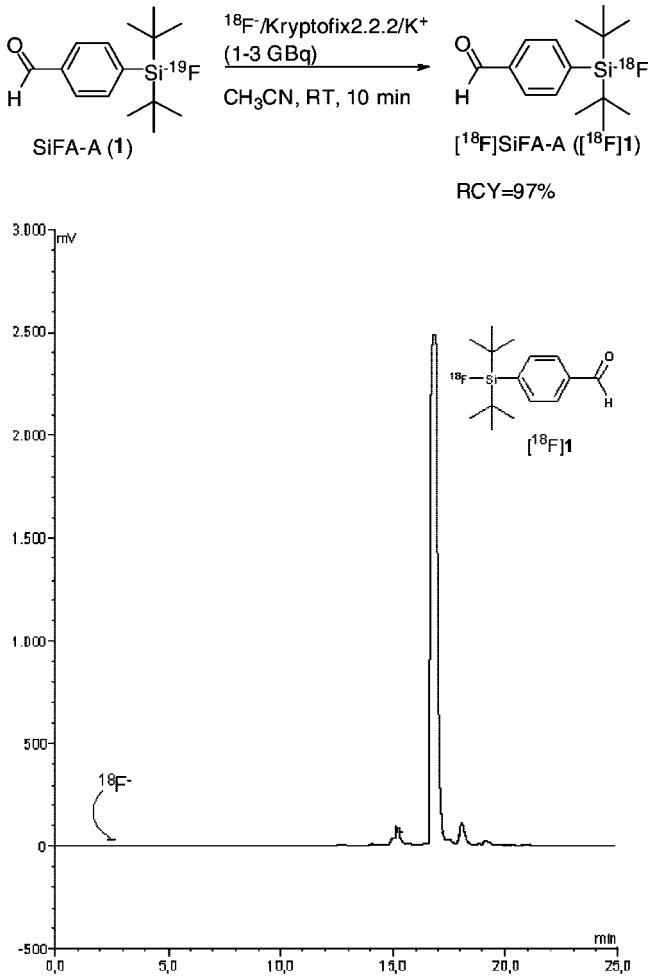

Figure 1. (top) Highly efficient isotopic exchange ^{18}F-radiofluorination of SiFA-A (**1**) (1 μg, 3.75 nmol) with $^{18}F^-$/Kryptofix 2.2.2./K^+ complex (1–3 GBq) in acetonitrile (200 μL) at room temperature yielding [^{18}F]SiFA-A (**1**) with high specific activity (~225–680 GBq/μmol). (bottom) Radio-HPLC chromatogram (HPLC system 1) of the crude reaction mixture.

Instruments. MALDI-TOF molecular weight determination of all peptide conjugates were carried out using a Kratos Kompact MALDI-III apparatus. For AO-derivatized peptide purification, an Agilent 1100 series liquid chromatograph with UV detection (Agilent 1100 multiple wavelength detector G1365B) was used. For radioactivity detection, an HPLC system (Dionex P680 HPLC) with UV detection (Dionex UVD 170U/340U) and radioactivity detector (Raytest, chromatography software *Gabi Star*) was used for the determination of radiochemical yields.

Synthesis of Amino-Oxy(AO)-Derivatized Peptides. The peptide synthesis was conducted using manual Fmoc solid-phase techniques. As for the chain elongation of peptides, N^{α}-(9-fluorenylmethyloxycarbonyl) (Fmoc)-protected aminoacids were used. Amino-oxy derivatized Tyr^3-octreotate (AO-TATE) was synthesized as previously described (*16*).

cyclo(fK(AO-N)RGD). The peptide (0.1 mmol) was synthesized according to a published procedure (*17*). Briefly, the peptide was derivatized on resin with bis-boc-amino-oxyacetic acid (123.7 mg, 0.4 mmol) on the deprotected lysine side chain according to standard Fmoc SPPS coupling procedures (0.98 equiv HBTU/1.0 equiv DIPEA) and subsequently cleaved from the resin (TFA/TIS/H_2O 95/2.5/2.5). For purification, reversed-phase semipreparative HPLC separations were carried out on an Agilent 1100 series liquid chromatograph with UV detection (Agilent 1100 multiple wavelength detector G1365B). HPLC runs were performed using a linear AB gradient (0% A to 100% B in 12 min) where solvent A was 0.1% aq TFA and solvent B was 0.1% TFA in acetonitrile using a Chromolith SemiPrep RP-18e 100-10 mm column at a flow rate of 8 mL/min. The preparative yield after purification and freeze-drying was 10%. MALDI-TOF-MS: *m/z* 676.33 M^+.

Table 1. Retention Times of [^{18}F]SiFA-A ([^{18}F]1) and ^{18}F-Labeled Peptides

compound	retention time [min] HPLC system 1 for preparative HPLC purification	retention time [min] HPLC system 2
[^{18}F]SiFA-A ([^{18}F]**1**)	16.8	31.5
[^{18}F]SiFA-TATE	14.1	28.4
[^{18}F]SiFA-BZH3	13.9	27.8
cyclo(fK([^{18}F]SiFA-AO-N)RGD)	13.9	27.7

N-AO-PEG$_2$-[D-Tyr-Gln-Trp-Ala-Val-βAla-His-Thi-Nle-NH$_2$] (AO-BZH3, a bombesin derivative). The bombesin derivative was synthesized by standard Fmoc solid-phase peptide synthesis (SPPS) using a Rink amide AM resin (200–400 mesh, Merck, 0.15 mmol). Bis-Boc-amino-oxyacetic acid (4.0 equiv, 185.6 mg, 0.6 mmol) was coupled to the N-terminal end of the peptide on resin after N-terminal derivatization with 8-(Fmoc-amino)-3,6-dioxaoctanoic acid using standard Fmoc-SPPS procedures. After cleavage from the resin, the peptide was purified analogously to the procedure described above for *cyclo*(fK(AO-N)RGD) to give a preparative yield of 25% after freeze-drying. MALDI-TOF-MS: *m/z* 1356.63 M^+.

SiFA–Peptide Conjugates. The corresponding SiFA-derivatized peptides *cyclo*(fK(SiFA-AO-N)RGD), MALDI-TOF-MS *m/z* 938.5 M^+; SiFA-BZH3 (N-SiFA-AO-PEG$_2$-[D-Tyr-Gln-Trp-Ala-Val-βAla-His-Thi-Nle-NH$_2$]), MALDI-TOF-MS *m/z* 1618.8 M^+; SiFA-TATE, MALDI-TOF-MS *m/z* 1369.9 M^+ as ^{19}F-standard compounds for HPLC evaluation of the conjugation of [^{18}F]**1** and AO-derivatized peptides were synthesized following a general procedure (*16*).

Radiosynthesis of [^{18}F]SiFA-A ([^{18}F]1) with [^{18}F]F$^-$/Kryptofix 2.2.2./K$^+$-Complex in Acetonitrile. To SiFA-A (**1**) (1 μg, 3.75 nmol; from stock solution in acetonitrile) the [^{18}F]F$^-$/Kryptofix 2.2.2./K^+ complex (~1.5–3.5 GBq, cf. Supporting Information) in acetonitrile (0.2 mL) was added and reacted for 10 min at rt without stirring. Two milliliters of water were added, and the resulting mixture was loaded onto a small solid-phase C18 cartridge (C18, Merck). The trapped [^{18}F]SiFA-A ([^{18}F]**1**) was washed with water (5 mL) and then eluted with hot (60 °C) acetonitrile (1 mL, elution efficiency >98%) to obtain a stock solution (~1–3 GBq, [^{18}F]**1**) for further peptide labeling.

Coupling of ([^{18}F]1) to Amino-oxy (AO)-derivatized peptides. To AO-derivatized peptide (20–100 μg, 0.014–0.147 μmol) dissolved in a minimum amount of water with trifluoroacetic acid at pH4 was added [^{18}F]SiFA-A (170–500 MBq; from stock solution in acetonitrile) and the appropriate amount of water (pH 4, TFA) to obtain a 90/10 acetonitrile/water solution (~150–200 μL). The solution was kept at room temperature for 10 min and injected into an HPLC system (column: PerfectSil 120 C4 5μm, 100 × 4.0 mm, MZ-ANALYTICAL, Germany. HPLC system 1: linear gradient, 30/70 CH_3CN/H_2O over 20 min to 100% CH_3CN; flow, 1 mL/min; Table 1). The peaks corresponding to the peptides (Table 1) were collected, water (10 mL) was added, and the mixture was loaded onto a solid-phase cartridge (C18, Merck). After washing the column with water (10 mL), the purified peptide was eluted with ethanol (0.5 mL, elution efficiency 85%) and diluted with physiological saline (5 mL) to obtain an injectable solution. The overall radiochemical yields (RCY) of the procedure were 50–55 % (referring to the starting activity of

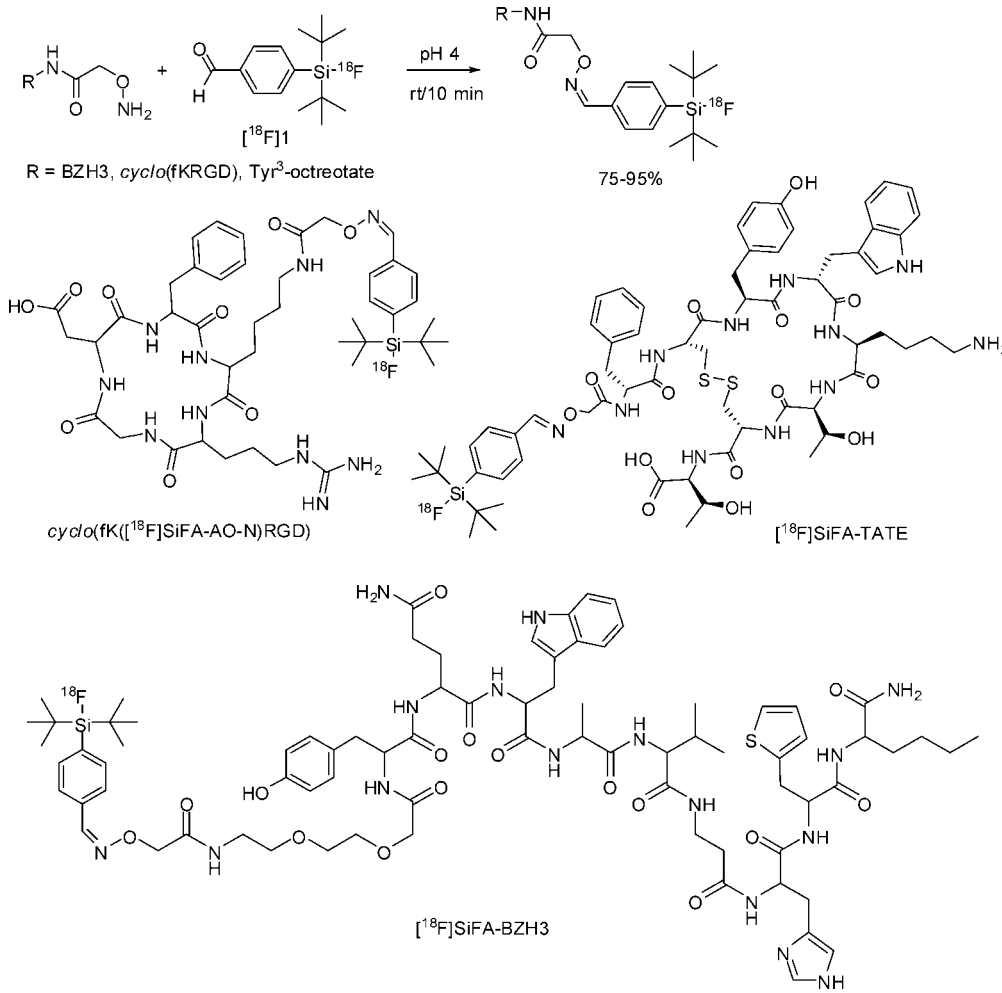

Figure 2. Chemoselective conjugation of [^{18}F]SiFA-A ([^{18}F]**1**) to three AO derivatized peptides (20–100 μg, 14–147 mol) at rt and pH 4 within 10 min in 150–200 μL acetonitrile/H_2O–TFA solution (90:10) and structures of *cyclo*(fK([^{18}F]SiFA-AO-N)RGD), [^{18}F]SiFA-TATE, and [^{18}F]SiFA-BZH3.

[^{18}F]F^-/Kryptofix 2.2.2./K^+ complex) after a total synthesis time of ~40 min (including azeotropic drying of $^{18}F^-$ and synthesis of [^{18}F]**1**). Isolated yields of all [^{18}F]SiFA derivatized peptides were between 110 and 400 MBq. A second HPLC system (HPLC system 2: linear gradient, 100% H_2O over 30 min to 100% CH_3CN; flow, 0.7 mL/min) was used to confirm the experimental outcome obtained with HPLC system 1 for preparative purification (Table 1).

RESULTS AND DISCUSSION

For the synthesis of [^{18}F]**1** by isotopic exchange (Figure 1), the precursor amount of **1** for the reaction with "dried" $^{18}F^-$/Kryptofix 2.2.2./K^+ complex (1.5–3.5 GBq) in acetonitrile (200 μL) to obtain radiochemical yields (RCY) up to 97% of [^{18}F]**1** within 10 min could be downscaled to 1 μg (3.75 nM). This is about 20 times less than the previously published amount of SiFA–peptide conjugate (SiFA-TATE) (*16*) resulting in extraordinarily high SAs. When 1.5–3.5 GBq of the ^{18}F-complex were used, the SAs obtained were between 225–680 GBq/μmol (6,081–18,378 Ci/mmol) which is unexpectedly high for an isotopic exchange reaction. Taking into account that the theoretical SA for cyclotron produced $^{18}F^-$ from the irradiated [^{18}O]water target is 63,270 GBq/μmol (1.71×10^6 Ci/mmol), the loss in SA during synthesis of [^{18}F]**1** is relatively low. The theoretical value of the SA can not be reached in practice. The obtained SA for ^{18}F is always lower due to dilution with the stable element and the SA of applied ^{18}F-labeled PET tracers normally varies between 100–10,000 Ci/mmol. For purification of [^{18}F]**1**, no HPLC is needed because the $^{19}F^-$ for $^{18}F^-$ exchange is highly selective and proceeds without formation of any by-products at room temperature. Solid phase cartridge extraction was performed by diluting with water (5 mL) to dispose of the un-reacted $^{18}F^-$ as well as the Kryptofix 2.2.2. and potassium ions followed by elution with acetonitrile (1 mL) of the purified [^{18}F]**1**. Thus, a stock solution of [^{18}F]**1** for labeling (c[^{18}F]**1**: 1–3 GBq/mL) was obtained for further experiments. The procedure including azeotropic drying of aqueous $^{18}F^-$ took 15 min only. This is in contrast to other one-step labeling synthons for peptides such as 4-[^{18}F]fluorobenzaldehyde ([^{18}F]FB-CHO) (*6*) and N-succinimidyl 4-([^{18}F]fluoromethyl)-benzoate, (*18*) the syntheses of which require more than 30 min and, in addition, still need HPLC purification. To use [^{18}F]SiFA-A ([^{18}F]**1**) as a labeling synthon for chemoselective oxime formation, three different N-terminal modified peptides, namely the AO-derivatized bombesin analog BZH3 (N-AO-PEG_2-[D-Tyr-Gln-Trp-Ala-Val-βAla-His-Thi-Nle-NH_2; PEG_2 is ethyleneglycol (2-aminoethyl)carboxymethyl ether), *cyclo*(fK(AO-N)RGD) (*17*) and AO-Tyr^3-octreotate (N-AO-D-Phe-Cys-Tyr-D-Trp-Lys-Thr-Cys-Thr) (*16*) for the potential use as imaging agents in nuclear medicine oncology were synthesized by means of Fmoc-solid phase peptide synthesis (SPPS). These peptides, radio-labeled mostly with indium-111 (for Single Photon Emission Tomo-

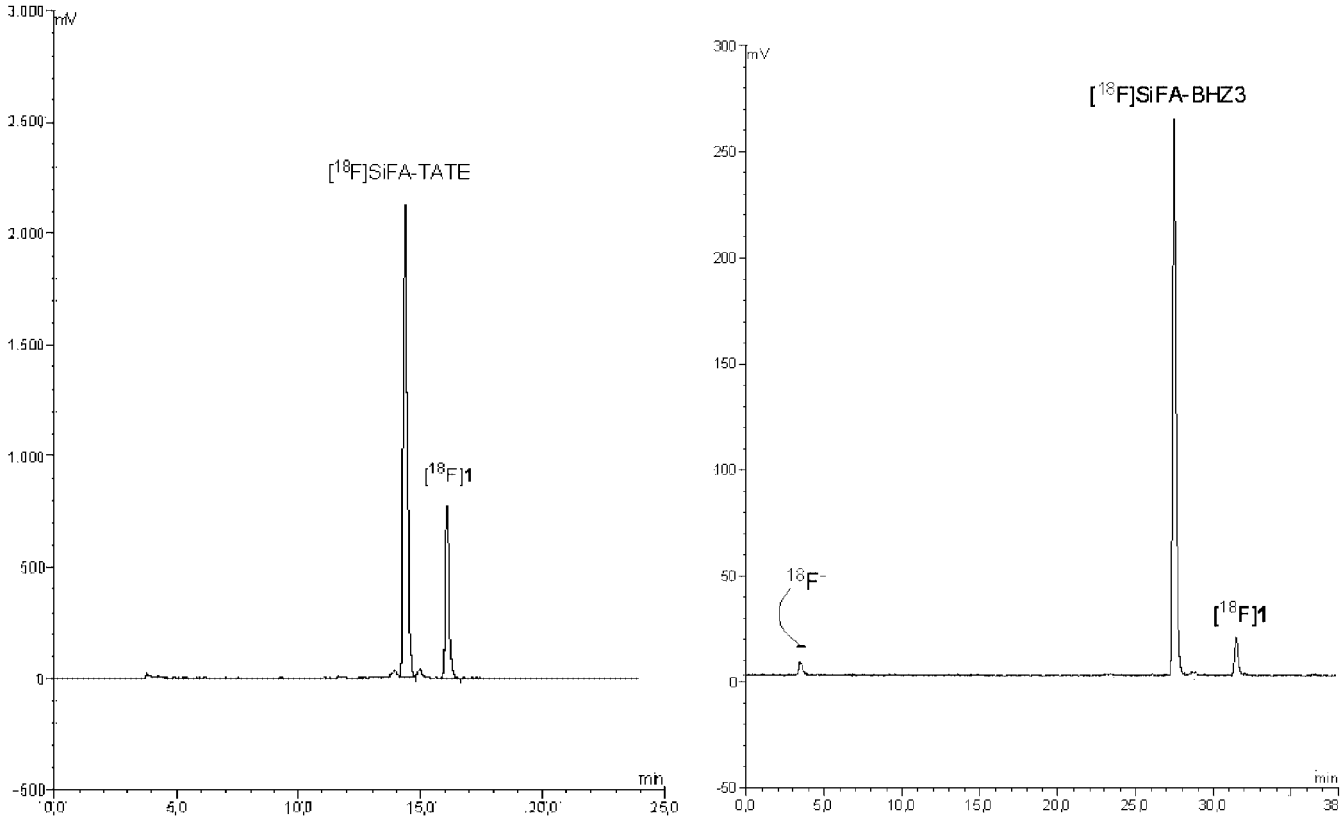

Figure 3. Two exemplary radio-HPLC chromatograms of the reaction of [^{18}F]**1** with AO-Tyr^3-octreotate (AO-TATE) (rt, acetonitrile/water 90/10, pH 4, HPLC system 1 for preparative HPLC conditions, RCY 75%) and the bombesin derivative AO-BZH3 (rt, acetonitrile/water 90/10, pH4, HPLC system 2, RCY 95%) showing the radiolabeled peptides, unreacted [^{18}F]**1**, and, in the case of AO-BZH3 labeling, trace amounts of $^{18}F^-$ (<1%) which could not be separated from [^{18}F]**1** during solid-phase extraction.

graphy (SPECT), gallium-68 (for PET) and therapeutic radionuclides (*19*, *20*) are gaining more and more importance in nuclear medicine and belong now to the more frequently applied imaging agents. Due to the physical properties of ^{18}F (lowest available positron energy of 635 keV), which result in images of higher resolution, the usefulness of these peptides labeled with ^{18}F would increase considerably. [^{18}F]**1** can be coupled to the N-terminal AO-moiety by selective oxime formation, a method described by Thumshirn et al. (*5*) This coupling method has been successfully employed for the syntheses of radiolabeled bioconjugates. Poethko et al. reported the labeling of cyclic RGD peptides as well as octreotide analogs with [^{18}F]FB-CHO in methanolic solution at 60 °C (*6*). We found that the conjugation step applying [^{18}F]**1** and the above mentioned AO-derivatized peptides (20–100 μg, 0.014–0.147 μmol) in acetonitrile/H_2O-TFA solution at pH 4 (total volume of 150–200 μL) proceeds even at room temperature within 10 min thus providing an even milder labeling approach. The yields of the coupling reaction were generally between 75–95% (Figure 3), and the final ^{18}F-labeled peptide conjugates could easily be separated by fast gradient HPLC giving an overall RCY of 50–55% after a total synthesis time of 40 min. In some rare cases, unreacted $^{18}F^-$ from the first reaction step could not be completely removed (<1%) by solid-phase extraction and appears in the final HPLC chromatogram (Figure 3). Although the use of HPLC for final purification is an inevitable shortcoming, one advantage is that the precursor peptide (AO-derivatized peptide), the ^{18}F-labeled conjugate, and the labeling synthon [^{18}F]**1** display very different retention times on the HPLC, making purification extremely simple and fast. Only one HPLC purification is necessary to obtain the ^{18}F-labeled

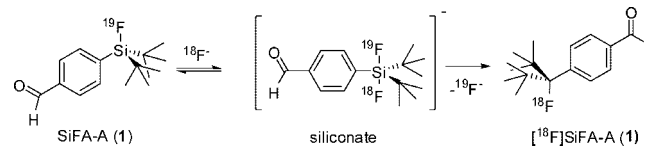

Figure 4. Formation of a pentacoordinate silicon intermediate and further elimination of either $^{19}F^-$ or $^{18}F^-$. As result of the calculated positive Gibbs energy in acetonitrile, the equilibrium concentration of the siliconate is predicted to be low, perhaps undetectable.

peptides, whereas most current methods require at least two HPLC purifications (one for the labeling synthon and one for the labeled peptide). Moreover, this efficient one-column separation gives rise to extraordinarily high SAs of the labeled peptide conjugates, which are in the same range as the SA of [^{18}F]**1** used as a labeling synthon. The question of why the isotopic ^{19}F–^{18}F exchange reaction proceeds so efficiently was further elucidated by conducting DFT calculations on three model fluorosilanes ($R'_nR''_{3-n}SiF$, R′=Ph, R″=*tert*-Bu; n = 1–3) reacting with $^{18}F^-$. According to our calculations, the fluorine exchange reaction in the gas phase should result in a thermodynamically stable pentacoordinated silicon intermediate, in accordance with the known mechanism of nucleophilic substitution at Si (Figure 4) (*21*, *22*). Similar siliconates have been isolated and characterized (*23*). Gibbs free energies of their formation in the gas phase are in the range of −50 to −40 kcal/mol. In acetonitrile, however, the formation of organosiliconates is much less favored. The enthalpies range from −5 to 2 kcal/mol and Gibbs free energies from 5 to 10 kcal/mol. The difference between the thermodynamics in the gas phase and in solution is mainly the result of a dramatically reduced basicity of the fluoride

anion. The energy of $R_3SiF_2^-$ formation increases in the series Ph_3SiF < Ph_2t-$BuSiF$ < Pht-Bu_2SiF, being in line with decreasing Lewis acidity of the silicon atoms and increasing steric hindrance of the organic substituents. Assuming that the changes in solvent effects upon fluoride exchange are similar for all organofluorosilanes, it is reasonable to suppose that the energy barriers are rather low, and in the series of organofluorosilanes studied, they are proportional to the relative energies of the intermediate organosiliconates. These data are in agreement with the high rate of fluorine exchange observed in acetonitrile, meaning that the equilibrium is reached very rapidly (Figure 4). The only detectable ^{18}F-labeled compounds by HPLC were unreacted $^{18}F^-$ (<5%) and [^{18}F]**1**, suggesting that the ^{18}F-siliconate is formed very quickly and eliminates fluoride ($^{18}F^-$ or $^{19}F^-$) immediately. Furthermore, as a result of the very low concentration of both $^{19}F^-$ and [^{18}F]**1** (the compound in excess is nonradioactive SiFA-A (**1**)), there is only a minor probability that the liberated $^{19}F^-$ will collide again with a formed [^{18}F]**1**, making this isotopic exchange statistically virtually irreversible.

In conclusion, the outlined ^{18}F-labeling procedure was shown to be applicable to the syntheses of various AO-derivatized peptides, which in turn are currently used as tumor imaging agents in nuclear medicine. The concept can be further expanded to all sorts of AO-derivatized peptides. The synthesis of [^{18}F]**1** provides the first example of an isotopic exchange reaction leading to SAs which even surpass SAs in conventional nca ^{18}F-radiochemistry. The usefulness of the ^{18}F-labeled peptides as tumor imaging agents is currently under investigation. Due to the demand for easy ^{18}F-labeling techniques in PET radiochemistry, we furthermore anticipate that the SiFA labeling approach will become a useful method in ^{18}F-radiochemistry.

Oligonucleotide-Coated Metallic Nanoparticles as a Flexible Platform for Molecular Imaging Agents

Nitin Nitin, David J. Javier, and Rebecca Richards-Kortum*

Department of Bioengineering, Rice University. Received April 13, 2007; Revised Manuscript Received August 14, 2007

Targeted metallic nanoparticles have shown promise as contrast agents for molecular imaging. To obtain molecular specificity, the nanoparticle surface must be appropriately functionalized with probe molecules that will bind to biomarkers of interest. The aim of this study was to develop and characterize a flexible approach to generate molecular imaging agents based on gold nanoparticles conjugated to a diverse range of probe molecules. We present two complementary oligonucleotide-based approaches to develop gold nanoparticle contrast agents which can be functionalized with a variety of biomolecules ranging from small molecules, to peptides, to antibodies. The size, biocompatibility, and protein concentration per nanoparticle are characterized for the two oligonucleotide-based approaches; the results are compared to contrast agents prepared using adsorption of proteins on gold nanoparticles by electrostatic interaction. Contrast agents prepared from oligonucleotide-functionalized nanoparticles are significantly smaller in size and more stable than contrast agents prepared by adsorption of proteins on gold nanoparticles. We demonstrate the flexibility of the oligonucleotide-based approach by preparing contrast agents conjugated to folate, EGF peptide, and anti-EGFR antibodies. Reflectance images of cancer cell lines labeled with functionalized contrast agents show significantly increased image contrast which is specific for the target biomarker. To demonstrate the modularity of this new bioconjugation approach, we use it to conjugate both fluorophore and anti-EGFR antibodies to metal nanoparticles, yielding a contrast agent which can be probed with multiple imaging modalities. This novel bioconjugation approach can be used to prepare contrast agents targeted with biomolecules that span a diverse range of sizes; at the same time, the bioconjugation method can be adapted to develop multimodal contrast agents for molecular imaging without changing the coating design or material.

1. INTRODUCTION

The aim of this study is to develop and characterize a bioconjugation approach which combines the flexibility and specificity of oligonucleotide hybridization with the excellent optical contrast properties of gold nanoparticles to develop biocompatible molecular imaging agents. Gold nanoparticles provide strong contrast when imaged in reflectance mode based on their unique optical absorption and scattering properties (*1–5*). In current clinical practice, reflectance imaging is used to aid in the diagnosis of various cancers and precancers based on differences in the native optical properties of neoplastic and normal epithelial tissue (*6–8*). The development of molecular-specific contrast agents which can be imaged in reflectance mode has the potential to improve the sensitivity and specificity of detection of early-stage precancers and cancers by providing the ability to noninvasively image the molecular changes associated with early neoplastic transformation.

Studies by Sokolov et al. (*4*) and El-Sayed et al. (*3*) have shown the potential of using gold nanoparticles to image receptor overexpression in various tumor model systems. Gold nanoparticle-based contrast agents have distinct advantages due to their biocompatibility, photostability, and ease of coating with proteins and polymers. In these studies, gold nanoparticles were linked to antibodies by direct absorption of protein on the surface of the nanoparticle. It has been established that electrostatically adsorbed gold–protein conjugates are stable only in the presence of excess protein in solution (*9*). This result suggests that there is a dynamic exchange between coated protein molecules and excess proteins in solution. This exchange is not desired for biological applications, as targeting proteins may be displaced by the high concentration of native proteins in biological samples. In addition, electrostatic protein adsorption offers very little control over the orientation of bound molecules; inappropriate orientation and conformational changes in antibodies during adsorption can reduce their binding affinities (*10*). Further, this approach cannot be easily extended to other potential probe biomolecules of interest including peptides and small molecules; small biomolecules cannot provide enough surface coverage to prevent the aggregation of gold nanoparticles in physiological buffers.

As an alternative to direct protein adsorption, other polymeric coatings including dextran, chitosan (*1, 11*), and self assembled monolayers (SAM) have been developed for surface modifications of nanoparticles. In the case of dextran- and chitosan-based coatings, typically large molecular weight polymers (>50 000 MW) are required to coat nanoparticles. This limitation is due to small numbers of reactive groups present on polymer chains with lower molecular weight. The use of large MW polymers leads to coated nanoparticles with a large effective size. In the case of SAM-based coatings, the solubility of the resulting nanoparticle in an aqueous environment is limited by the hydrophobic nature of the coating polymer, leading to aggregation in high-salt solutions.

In addition, various other chemical functionalization techniques have been developed for coating gold nanoparticles in aqueous settings, but in many cases, this has led to aggregation (*12*). This limitation has been overcome by adding various polymeric stabilizers which nonspecifically interact with the particle surface, but these stabilizers can potentially limit the biological applications as well as interfere with surface conjugations (*13*). Further disulfide-modified polymer (e.g., OPSS-PEG) coatings may also absorb nonspecifically on the surface of gold nanoparticles, as the affinities for some of these polymer

backbones are only slightly less than the specific gold–disulfide interactions (*12*). Thus, the functional groups in these coatings will have very limited accessibility for further surface bioconjugation to probe biomolecules. In some cases, polymer molecules with bifunctional ends have been linked to antibodies or other biomolecules before coating the gold nanoparticles. In this case, it is expected that nonspecific adsorption will play a significant role as compared to the single thiol interaction with the gold nanoparticle.

To overcome these limitations, we have developed a bioconjugation approach which combines the stability of thiol-modified oligonucleotide coatings for gold nanoparticles with the ease of bioconjugation using bifunctionally modified oligonucleotides to develop gold-based reflectance contrast agents. This coating approach has been optimized for various analytical assays (*14*) (*15*) and is stable at high salt conditions as well as in the presence of other proteins and biomolecules. The approach provides flexibility to conjugate a variety of biomolecules, to control the orientation of conjugated biomolecules, and to control the size of the functionalized particles. Further, the sequence specificity of oligonucleotides can be exploited to develop flexible approaches for assembly of contrast agents and the development of multifunctional contrast agents, with either multiple targeting moieties or multiple reporting agents.

2. EXPERIMENTAL PROCEDURES

2.1. Materials. Gold nanoparticles (~25 nm) were synthesized using gold chloride ($HAUCl_4$, >99.999% purity, Sigma) and sodium citrate (Sigma). The gold nanoparticles were coated with 19-mer oligonucleotides (MWG, 5′-thiol-AAAAAAAAAA**ATCCTTTAC**-amine) functionalized with a thiol group on the 5′ end and an amino group at the 3′ end. The oligonucleotide was first reduced with TCEP·HCl (Tris(2-carboxyethyl) phosphine hydrochloride, Pierce) before adding it to the gold nanoparticles. Its complementary sequence was also used (MWG, 3′-**TAGGAAATG**TTATAA-amine) for the conjugation of targeting molecules. Targeting molecules were chosen to represent a wide range of molecular weight molecules which include a 165 kD EGFR antibody (epidermal growth factor receptor antibody, Baylor College of Medicine antibody facility), a short 5.5 kD peptide EGF (epidermal growth factor peptide, US Biological), and a small 0.5 kD molecule (folate, Sigma). The following reagents and cross-linkers were used for bioconjugation of the targeting molecules to the oligonucleotide-coated gold nanoparticles: C6-SANH (C6-SANH (C6-succinimidyl 4-hydrazinonicotinate acetone hydrazone, Pierce), C6-SFB (C6-succinimidyl 4-formylbenzoate, Pierce), DMSO (Sigma), 2-mercaptoethanol (Sigma), EDAC (1-ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride, Pierce), and sulfo-NHS (Pierce). For characterization, sodium cyanide (Sigma) was used to dissolve the gold nanoparticles. Purification columns that were used include a Zeba desalting column (Pierce), a YM-3 Microcon spin column (Millipore), and an S-400 spin column (GE Healthcare). For cellular targeting, various cancer cell lines obtained from ATCC were cultured using DMEM (Dulbecco's minimum essential media) or MEM with 5% FBS (fetal bovine serum) with antibiotics as recommended by ATCC. The cell lines include 1483 cells and SiHa cells for EGFR targeting with antibodies and EGF peptides, and Kb cells for targeting folate receptors. A Cy5 dye modified complementary oligonucleotide (MWG) was used to demonstrate the flexibility of the coating and conjugation approach to develop multimodal/multifunctional contrast agents.

2.2. Methods. *2.2.1. Synthesis and Coating of Gold Nanoparticles.* Gold nanospheres (~25 nm) were synthesized using the sodium citrate reduction of gold ions developed by Frens et al. (*16*). The size of the nanospheres was controlled by adjusting the ratio of Au ions ($HAuCl_4$) and sodium citrate. The procedure for coating gold nanoparticles with oligonucleotides was adapted from Mirkin et al. (*14*). This protocol is based on the Au–S interaction between the gold lattice and thiol-functionalized oligonucleotides. The colloidal gold nanoparticles were first stabilized and coated using chemisorption of thiol-modified oligonucleotides (*14*). These oligonucleotides were also modified with NH_2 reactive group at the 3′-terminus. Briefly, 100 μL of 30 μM oligonucleotide was reduced with ~1 mM TCEP for 15 min. The reduced oligonucleotide containing free thiol was then added to 900 μL of gold nanoparticles (~0.1 nM concentration) and aged for 24–48 h with increasing salt concentration (until 1× PBS concentration is reached). The resulting oligonucleotide-coated nanoparticles were concentrated 10-fold by centrifugation at 6000 rpm for 30 min. To illustrate the flexibility of the approach, oligonucleotide-coated nanoparticles were then functionalized with several types of probe molecules, including anti-EGFR antibodies, EGF peptide, and folate.

2.2.2. Bioconjugation of Oligonucleotides and Targeting Molecules To Gold Nanoparticles. a. Direct Approach. In this method, the targeting molecules were directly incorporated onto the oligonucleotide-coated Au nanoparticles. After first coating the gold nanoparticles with oligonucleotides, complementary oligonucleotides (~3 uM) were hybridized to increase the number of amino functional sites. Anti-EGFR (1 mg/mL) or EGF (200 ug/mL) proteins were conjugated to oligonucleotide-coated Au (~1 nM) using heterobifunctional cross-linkers, SANH and SFB. The amino groups present on proteins were functionalized with SFB (20× molar excess), while amino groups present on the oligonucleotide–Au were functionalized with SANH (20× molar excess) for 1–2 h. Excess SANH and SFB were removed by passage on a Zeba desalting column twice. The SFB-modified protein and SANH-modified oligonucleotide Au were then mixed overnight (pH 7.0) at room temperature. The unreacted anti-EGFR or EGF proteins were removed by spinning the gold nanoparticles at 6000 rpm for 30 min. For folate-functionalized nanoparticles, the direct conjugation of folate to oligonucleotide–Au was accomplished using EDAC chemistry. The COOH group present on folate (1 mg/mL, 1 mL) was reacted with EDAC (0.6 mg) and sulfo-NHS (1.1 mg) for 15 min. After quenching the reaction with mercaptoethanol, an aliquot of the highly reactive NHS–folate (~20 uM) was added to oligonucleotide–Au for 2–3 h. Excess NHS–folate was also removed by centrifuging the gold nanoparticles at 6000 rpm for 30 min.

b. Indirect Approach. In this method, complementary oligonucleotides and the targeting molecules were conjugated first before hybridizing them to the oligonucleotide-coated gold nanoparticles. Similar to the direct approach, anti-EGFR or EGF proteins were reacted with SFB, while complementary oligonucleotides (~3 uM) were reacted with SANH. The resulting oligonucleotide–protein was purified using an S-400 spin column and then hybridized to its corresponding oligonucleotide-coated Au nanoparticles overnight at room temperature. For folate conjugation, folate was first added to EDAC/sulfo-NHS, before mixing with complementary oligonucleotides. The oligonucleotide folate conjugate was purified using a YM-3 column and hybridized to its corresponding oligonucleotide–Au. The excess oligonucleotide–protein and oligonucleotide–folate were removed by spinning the gold nanoparticles at 6000 rpm for 30 min.

c. Adsorption of Antibodies on Gold Nanoparticle Surface. For the development of antibody-coated gold nanoparticle-based contrast agents using adsorption of biomolecules on the surface, we followed the procedure developed by Slot and Geuze (1985) (*17*) and adapted by Sokolov et al. (*4*) and

El-Sayed et al. (*3*). Briefly, in this procedure the anti-EGFR antibody was incubated with gold nanoparticles for ~30 min in a salt-free environment. After incubation, the gold nanoparticles were centrifuged to remove excess antibodies in the presence of 1% PEG (10 000 MW). After centrifugation and decantation of solution, the pellet of gold nanoparticles was dispersed in 1× PBS (phosphate buffered saline) and tested for colloidal stability using the conventional salt test. In this test, the gold nanoparticle solution was tested using 10% NaCl solution, and stability was determined by visual assessment of color change. In the case of antibody-coated particles, we did not observe any color change, indicating colloidal stability based on this salt test procedure.

2.2.3. Characterization. Various qualitative and quantitative approaches were used to characterize the gold nanoparticle conjugates.

a. Size Characterization. Dynamic light scattering (DLS, Brookhaven) was used to measure the size of the oligonucleotide-coated nanoparticles, with and without the targeting molecules, and also gold nanoparticles with physically adsorbed antibodies. To evaluate the colloidal stability of gold nanoparticle conjugates, the size measurements were repeated 24 h postsynthesis of contrast agents.

b. Biocompatibility. The biocompatibility of oligonucleotide-coated nanoparticles was determined using the MTT assay following the procedure recommended by ATCC. Briefly, cells were cultured in 90-well plates for 24 h prior to incubation with oligonucleotide-conjugated gold nanoparticles. In each experiment, three wells were incubated with oligonucleotide-coated gold nanoparticles along with triplicate control wells. The experiment was carried out using SiHa and 1483 cell lines. Coated gold nanoparticles were incubated at twice the concentration levels used for cell labeling experiments. After 24 h of incubation, the plates were assayed using reagents provided with the MTT kit. The results were analyzed using absorbance measurements at 570 nm. The background level was determined using cells without any treatment and MTT reagents.

c. Concentration Estimation for Conjugated Antibodies and Peptides on Oligonucleotide-Coated Gold Nanoparticles. To determine the estimated concentration of antibodies and peptides conjugated to oligonucleotide coated gold nanoparticles, we used a protein quantification assay kit based on Coomassie staining. Prior to staining with Coomassie dye, the gold nanoparticles were dissolved using 100 mM potassium cyanide (KCN). This step was essential to remove the contribution from the gold nanoparticle plasmon band during the absorbance assay. Coomassie staining was carried out using the procedure recommended by the Pierce Protein Quantification kit. In addition, we used known concentrations of antibodies and peptides respectively as standards to establish the linear range for the assay and to calculate the concentration of conjugated proteins/peptides on gold nanoparticles.

2.2.4. Reflectance Imaging Using Oligonucleotide-Coated Nanoparticles. Oligonucleotide-coated nanoparticles functionalized with the targeting molecules were incubated with different cancer cell lines (1483 and SiHa for EGFR and EGF targeting, and Kb for folate targeting) at 37 °C for 30 min. 1483 and SiHa are oral and cervical cancer cell lines, respectively, which overexpress the EGF receptor (*18*). Kb cell is an oral cancer cell line which overexpresses the folate receptor (*19*). The cells were washed three times and centrifuged to remove unbound conjugate. Confocal reflectance images were obtained from the resulting cell pellet using a Zeiss LSM 510 microscope in reflectance mode. All images were acquired under the same imaging conditions. Postacquisition, the image contrast was adjusted in images of the folate-targeted cells to facilitate comparison with images acquired from cells labeled with EGF- and EGFR-targeted contrast agents.

2.2.5. Bimodal Contrast Agents and Imaging. To demonstrate the flexibility of the coating approach to develop multifunctional contrast agents, we used the indirect method to develop a contrast agent which combines both reflectance and fluorescence imaging capabilities in a single contrast agent. To develop this bimodal contrast agent, gold nanoparticles coated with oligonucleotides were hybridized overnight with complementary oligonucleotides modified with Cy5 dyes and complementary oligonucleotides conjugated with EGFR antibody. To provide efficient hybridization for antibody-conjugated complementary oligonucleotides, an excess of antibody-conjugated oligonucleotide (5:1 ratio) was used as compared with dye-labeled oligonucleotide. The use of a near-IR dye can be potentially useful for *in vivo* imaging as well as reduce the quenching effects due to gold nanoparticles. After the hybridization step and removal of excess complementary oligonucleotide, the purified product was used to label 1483 cancer cells. Labeled cells were imaged using both fluorescence and reflectance confocal microscopy.

3. RESULTS AND DISCUSSION

Figure 1 shows a schematic representation of the two complementary oligonucleotide-based bioconjugation approaches to develop gold nanoparticle based molecular contrast agents. In the direct approach, a complementary oligonucleotide was hybridized with the oligonucleotide coating on the surface of the gold nanoparticles (Figure 1). This stabilized and extended double-stranded DNA was then further conjugated with target protein or biomolecules of interest using bifunctional cross-linkers. In the indirect approach, a complementary oligonucleotide was first conjugated to targeting molecules (Figure 1). These modified oligonucleotides were then hybridized with the coated oligonucleotides on the surface of gold nanoparticles to generate a molecular contrast agent. These bioconjugation approaches have different advantages for developing molecular contrast agents. In the direct approach, the significant advantage is the ease of separation of small molecules and peptides after a conjugation reaction. In this case, a series of simple centrifugation steps can remove excess unbound targeting molecules from gold-conjugated molecules. In the indirect approach, the significant advantage is the ease with which multifunctional contrast agents can be developed. Using this approach, we can place multiple targeting moieties or multiple reporting moieties on the surface of gold nanoparticles by ratiometric mixing of oligonucleotides conjugated to different moieties. To further enhance the specificity of this process and provide ratiometric control over conjugation processes, different sequences of oligonucleotides can be coated on the surface of gold nanoparticles. These sequences can be hybridized with their respective complementary sequences modified with multiple reporting or targeting agents. In this study, we evaluated contrast agents produced with both the direct and indirect approaches as outlined above.

After developing gold nanoparticle conjugates, our next step was to characterize the bioconjugates and compare their size and stability with conjugates made using absorption of antibodies. We used dynamic light scattering (DLS) to analyze the diameter of the conjugated gold nanoparticles with anti-EGFR, EGF peptide, and folate-based targeting. Results for conjugates prepared using the direct approach are shown in Figure 2a; similar results were obtained using indirect conjugates. The size of the contrast agent increased as the size of the conjugated probe molecule was increased from a small molecule (folate) to a peptide (EGF) to an antibody (anti-EGFR). For example, antibody-conjugated gold nanoparticles prepared using oligo-

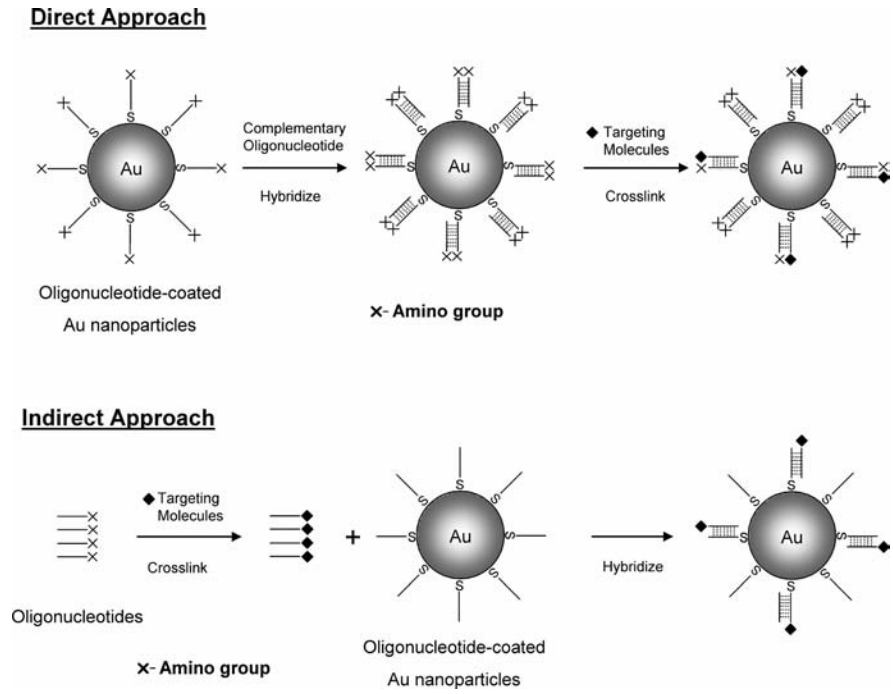

Figure 1. Schematic outline of conjugation of biomolecules to the oligonucleotide-functionalized gold nanoparticles. In the direct approach, the complementary oligonucleotides are first hybridized to the surface of the oligonucleotide-coated gold nanoparticles followed by conjugation of targeting molecules using hetero-bifunctional cross-linkers. In the indirect approach, the targeting biomolecules are first conjugated to the complementary oligonucleotides, which are then hybridized to oligonucleotides coated on the surface of gold nanoparticles. The conjugation approaches offer flexibility in processing and developing a molecular-specific contrast agent.

nucleotide coatings show an increase of approximately ~15–20 nm in diameter as compared with bare gold nanoparticles; this is consistent with an approximate antibody size of 15 nm. In contrast, antibody-targeted contrast agents prepared using adsorption are significantly larger (~80 nm) and show a wide distribution in size as compared to oligonucleotide-conjugated antibodies (~40 nm). These results suggest that the adsorption process leads to larger conjugates either as a result of multiple protein layers per nanoparticle or due to aggregation of nanoparticles.

To characterize and compare the stability of gold nanoparticle conjugates prepared using the adsorption and oligonucleotide procedure, we measured the change in size of anti-EGFR conjugates at 24 h postsynthesis. Results for conjugates prepared using direct oligonucleotide conjugation are shown in Figure 2b; again, similar results were obtained for those prepared using the indirect method. While the sizes of the oligonucleotide-coated, antibody-targeted contrast agents were stable over this time period, we observed a significant increase in the size of the adsorbed conjugates, suggesting that aggregation occurs over time. These results demonstrate the greater stability and smaller size of antibody-targeted, oligonucleotide-coated gold nanoparticles.

To establish biocompatibility of these agents, we carried out the standard MTT-based cytotoxicity assay. Figure 3 shows results of the assay for oligonucleotide-coated gold nanoparticles prepared using the direct method; similar results were obtained for conjugates prepared using the indirect method. No significant change was observed in cell viability even after 24–48 h incubation of these agents with cells, establishing the biocompatibility of oligonucleotide-coated gold nanoparticles in cell culture models. Future studies are warranted to study similar processes in animal models before clinical translation of these contrast agents.

We next estimated the concentration of the proteins or peptides conjugated on the surface of gold nanoparticles using the direct and indirect approaches. The results of this quantification assay are shown in Table 1. Both the direct and indirect methods yield similar concentrations of biomolecules conjugated to the surface of oligonucleotide-coated gold nanoparticles. This indicates that both approaches have similar efficiency for loading probe biomolecules on the surface of gold nanoparticles.

In a next step, we labeled cells in culture with targeted contrast agents; images of labeled cells were obtained using confocal reflectance microscopy. To demonstrate that gold nanoparticles can be conjugated to a wide size range of biomolecules (from antibodies to small molecules), we conjugated gold nanoparticles with anti-EGFR (150 kDa), EGF (6 kDa), and folate (~0.3 Da) using both direct and indirect approaches. To demonstrate the specificity of the resulting contrast agents, we prepared IgG gold nanoparticle conjugates and oligonucleotide-coated particles without any targeting biomolecules as controls. In this study, we used 1483 and SiHa oral and cervical cancer lines to evaluate EGFR-specific contrast and KB cancer cells for folate-specific imaging. Representative confocal reflectance images obtained from cells labeled with direct and indirect conjugates are shown in Figure 4a,b, respectively. Results show strong reflectance signal from the cell membrane of SiHa cells labeled with both anti-EGFR-targeted gold nanoparticles and EGF peptide-based targeting. Images obtained from cells targeted with both direct and indirect conjugates are similar, indicating that effective contrast agents can be generated with either conjugation approach. With targeting of folate overexpression using folate-conjugated gold nanoparticles, we also obtained similar results with both direct and indirect conjugates. The specificity in this case was evaluated using oligonucleotide-modified gold nanoparticles without any targeting molecules.

Based on these results, we have demonstrated that gold nanoparticles can be modified with variety of biomolecules including antibodies, peptides, and small molecules to develop effective reflectance contrast agents for molecular imaging applications. Thus, with this bioconjugation platform, molecular imaging applications with gold nanoparticles are no longer

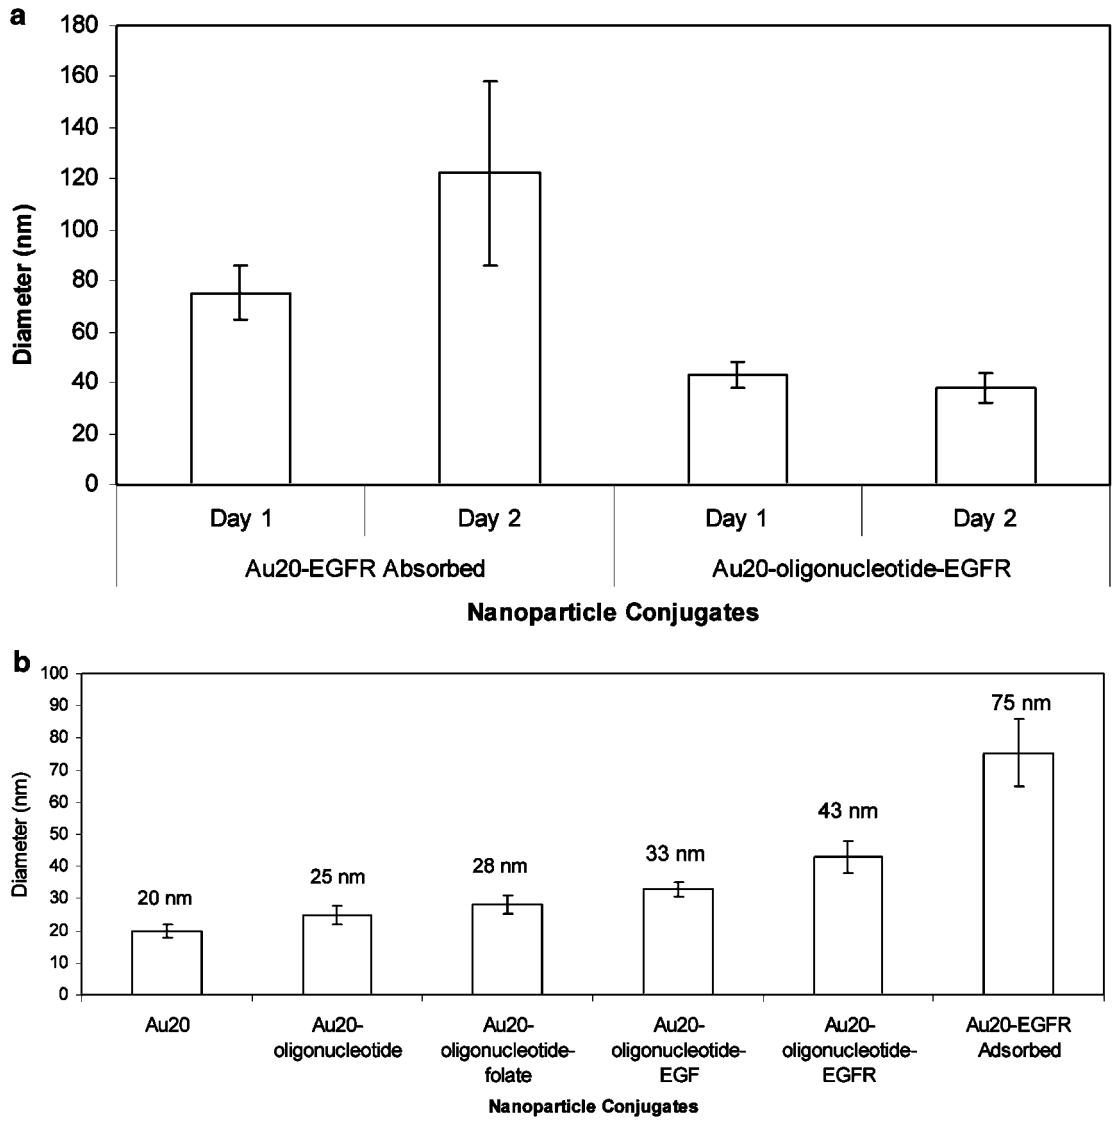

Figure 2. (a) Size measurements of oligonucleotide-coated gold nanoparticles and their conjugates using dynamic light scattering (DLS). The conjugates were prepared using the direct approach. Similar sizes were observed for conjugates prepared using the indirect approach (data not shown). Conjugation using the oligonucleotide approach was compared with methods of directly adsorbing large biomolecules on the surface of gold nanoparticles. (2) Size stability of gold nanoparticle conjugates measured using dynamic light scattering (DLS). Over a period of 24 h, results show an increase in size of gold conjugates with adsorbed antibodies as compared to antibodies chemically conjugated to the surface of gold nanoparticles using the direct approach. Conjugates prepared using the indirect approach showed similar size stability (data not shown).

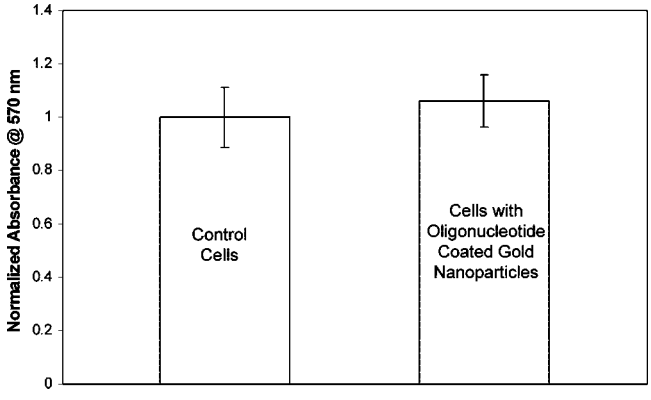

Figure 3. Biocompatibility studies of oligonucleotide-coated gold nanoparticles using standard MTT assay. Cells were incubated for 48 h with gold nanoparticles coated with oligonucleotides and analyzed by measuring absorbance at 570 nm using a standard plate reader.

limited to antibody-based approaches for targeting, and these designs can be easily extended to a variety of biomolecules.

Table 1. Estimated Concentration of Conjugated EGFR Antibodies and EGF Peptide on Surface of Gold Nanoparticles[a]

[protein]	direct μg/mL	indirect μg/mL
anti-EGFR	3.6	4.6
EGF	3.3	4.3

[a] Protein concentration was measured using Coomassie stain after dissolution of protein-conjugated gold nanoparticles in KCN.

To demonstrate the flexibility of this platform to develop bimodality contrast agents, we used the indirect approach to develop a single contrast agent capable of simultaneous reporting in both fluorescence and reflectance modes. The development of multimodality reporting is of significant interest in the area of molecular imaging, as multiple reporters can extend the range of sensitivity, penetration depth, and resolution for reporting molecular events. Figure 5a illustrates the approach to develop a dual-reporting contrast agent directed by the hybridization of complementary oligonucleotides. The cellular assay of this contrast agent was carried under similar conditions as for the direct and indirect conjugates in Figure 4. After

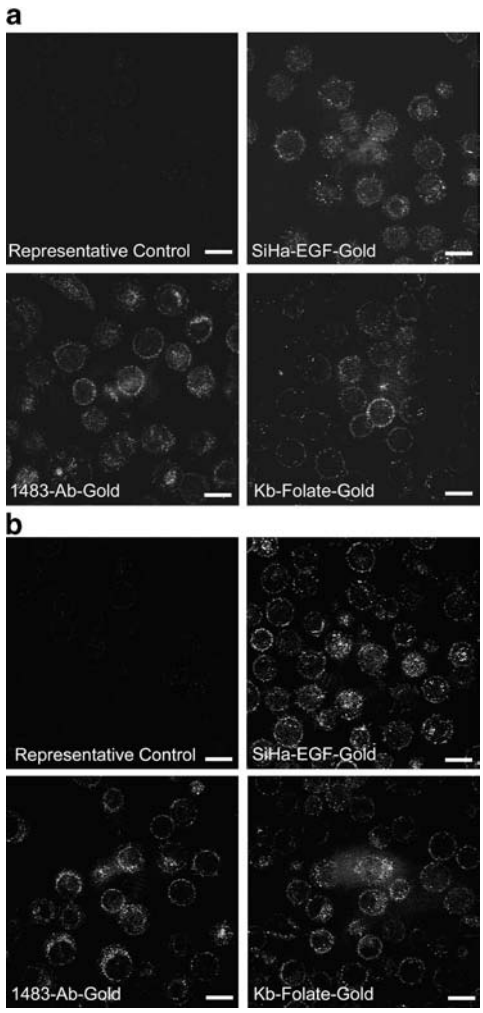

Figure 4. (a) Evaluation of molecular specific targeting of direct conjugates using confocal reflectance imaging. The contrast agents were prepared by conjugating different size-targeting molecules (antibody, peptides, and small molecules) to oligonucleotide-coated gold nanoparticles in various cancer cell lines. IgG-conjugated gold nanoparticles were used as controls in these cell lines (representative control image is shown). The scale bar represents 15 μm. (b) Evaluation of molecular-specific targeting of indirect conjugates using confocal reflectance imaging. The contrast agents were prepared by conjugating different size targeting molecules (antibody, peptides, and small molecules) to oligonucleotide-coated gold nanoparticles in various cancer cell lines. IgG-conjugated gold nanoparticles were used as controls in these cell lines (representative control image is shown). The scale bar represents 15 μm.

incubation with the contrast agent, cells were imaged using both reflectance and fluorescence confocal microscopy. Since the reflectance signal is significantly stronger than the fluorescence signal, the pinhole size and laser power used in reflectance imaging were significantly smaller than that used for fluorescence imaging. Results are shown in Figure 5b and show a similar distribution of reflectance and fluorescence signal on the surface of the cells. The reflectance image collected with a smaller confocal pinhole shows a significantly sharper image than the fluorescence image. This study demonstrates the concept for dual modality imaging, which can be extended to a variety of reporting schemes including MR contrast agents such as Gd^{3+} or PET contrast agents based on modification of oligonucleotides with chelating groups.

4. SUMMARY AND CONCLUSIONS

In this study, we have developed and characterized a bioconjugation approach which combines the flexibility and specificity of oligonucleotide hybridization with the excellent optical contrast properties of gold nanoparticles. The approach yields biocompatible molecular imaging agents which can be targeted with a wide variety of probe molecules to yield high-contrast molecular images in cell model systems. The stability and size distribution of the contrast agents produced using this approach are superior to those of contrast agents based on protein absorbed gold nanoparticles, which have been previously been used to produce targeted gold nanoparticles for use as molecular contrast agents. To demonstrate the flexibility of the conjugation approach, we illustrate the development of multimodal contrast agents which can be imaged in both reflectance and fluorescence modes. The results highlight the potential of oligonucleotide coatings for development of multifunctional molecular contrast agents.

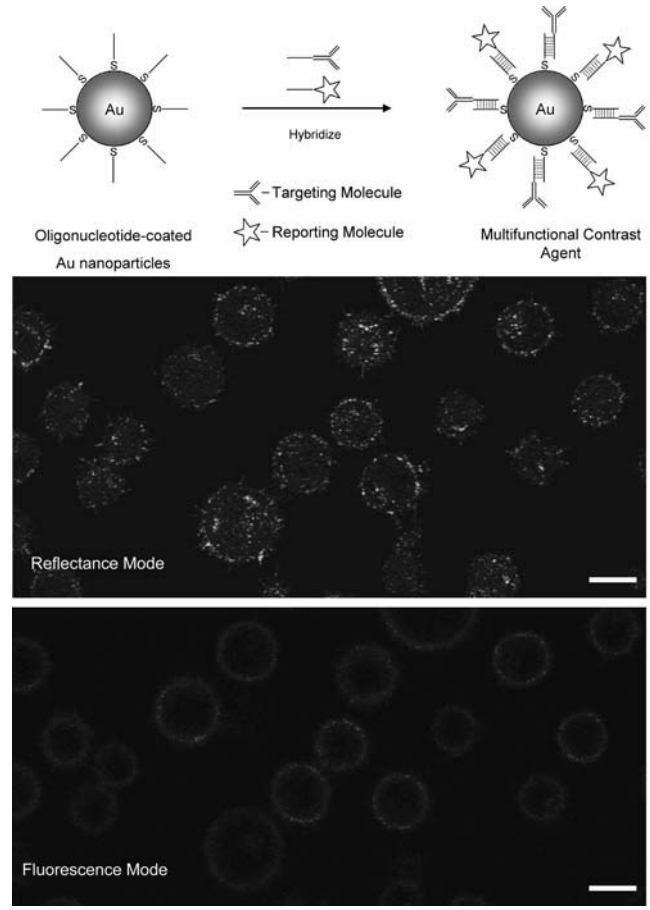

Figure 5. (a) A conceptual approach of using oligonucleotide-coated gold nanoparticles to develop multifunctional contrast agents for targeting, reporting, and delivery. In this example, the ratio of targeting and reporting molecules on the surface of gold nanoparticles can be controlled by controlling the ratio of modified oligonucleotides during the hybridization step. (b) Proof of concept study to illustrate development of bimodal reporting molecular contrast agents. Fluorescence and reflectance confocal images of SiHa cells labeled with bimodal contrast agent targeting the EGF receptor. The scale bar represents 15 μm.

Synthesis, Analysis, in Vitro Characterization, and in Vivo Disposition of a Lamivudine–Dextran Conjugate for Selective Antiviral Delivery to the Liver

Krishna C. Chimalakonda,[†] Hitesh K. Agarwal,[‡] Anil Kumar,[‡] Keykavous Parang,*[,‡] and Reza Mehvar*[,†]

Department of Pharmaceutical Sciences, School of Pharmacy, Texas Tech University Health Sciences Center, 1300 Coulter, Amarillo, Texas 79106, and Department of Biomedical and Pharmaceutical Sciences, College of Pharmacy, University of Rhode Island, Kingston, Rhode Island 02881. Received May 29, 2007; Revised Manuscript Received August 18, 2007

A liver-selective prodrug (3TCSD) of the antiviral drug lamivudine (3TC) was developed and characterized. 3TC was coupled to dextran (~25 kDa) using a succinate linker, and the in vitro and in vivo behavior of the conjugate was studied using newly developed size-exclusion and reversed-phase analytical methods. Synthesized 3TCSD had a purity of >99% with a degree of substitution of 6.5 mg of 3TC per 100 mg of the conjugate. Furthermore, the developed assays were precise and accurate in the concentration ranges of 0.125–20, 0.36–18, and 1–50 μg/mL for 3TC, 3TC succinate (3TCS), and 3TCSD, respectively. In vitro, the conjugate slowly released 3TC in the presence of rat liver lysosomes, whereas it was stable in the corresponding buffer. In vivo in rats, conjugation of 3TC to dextran resulted in 40- and 7-fold decreases in the clearance and volume of distribution of the drug, respectively. However, the accumulation of the conjugated 3TC in the liver was 50-fold higher than that of the parent drug. The high accumulation of the conjugate in the liver was associated with a gradual and sustained release of 3TC in the liver. These studies indicate the feasibility of the synthesis of 3TCS–dextran and its potential use for the selective delivery of 3TC to the liver.

INTRODUCTION

Lamivudine (β-L-2′,3′-dideoxy-3′-thiacytidine, 3TC) is a deoxycytidine nucleoside analogue that inhibits hepatitis B virus (HBV) replication and is used in the treatment of chronic hepatitis B infection (*1*). In addition to the efficacy of antiviral drugs against HBV, treatment of HBV infection is significantly dependent on the pharmacokinetics of these drugs, in particular their distribution and accumulation in the liver. To be effective, 3TC needs to enter liver cells and be phosphorylated to its active form 3TC 5′-triphosphate intracellularly before incorporation into DNA of HBV by DNA polymerase (*2, 3*). Therefore, strategies that direct the drug to its site of action (liver) may increase the effectiveness of the drug and decrease its potential side effects in other nontarget organs. Indeed, several studies (*4–10*) have attempted to target antiviral drugs to the liver for the treatment of HBV infection.

Dextrans are glucose polymers, which are under investigation as macromolecular carriers for delivery of drugs and other therapeutic agents, such as proteins, after the systemic administration of the dextran–drug conjugates (*11–14*). Additionally, conjugates of dextrans with nonsteroidal (*15, 16*) and steroidal (*17, 18*) anti-inflammatory drugs have been studied for local delivery of these drugs to the colon. In a series of studies (*19–21*), we previously showed that the plasma kinetics and tissue distribution of dextran carriers are dependent on the M_w of the polymer. Therefore, dextrans of different M_w may be useful for the delivery of drugs to different tissues after the systemic administration of the conjugate. For example, dextrans with M_w values of 20–70 kDa showed a high degree of selectivity for the liver when the liver/plasma area under the concentration–time curve (AUC) ratio was considered (*21*). The liver selectivity of these dextrans was attributed to their sizes, which restrict their passage through most vascular bed pores while allowing unrestricted passage through the substantially larger pore sizes of the liver sinusoids (*21, 22*).

In addition to the molecular weight, both the electric charge (*23, 24*) and chemical modification (*25, 26*) of dextrans may affect their organ and cellular distribution. For example, it has been reported that positively charged dextrans are taken up by the liver more rapidly and extensively than neutral or negatively charged dextrans (*23, 24*). Additionally, whereas unmodified dextrans distribute to both parenchymal and nonparenchymal cells of the liver (*27*), galactosylation or mannosylation of dextrans results in selective delivery of the macromolecule to the parenchymal and nonparenchymal cells, respectively (*25, 26*). Because electrical or chemical modifications of dextrans may alter their safety profiles (*28*), we have recently used unmodified neutral dextrans for delivery of methylprednisolone to the liver for local immunosuppression (*29–32*). These studies showed that after systemic administration, the conjugate selectively accumulates in the liver, where it gradually releases the active drug, resulting in more intense and sustained pharmacologic effects. Collectively, the above studies suggest that both unmodified and glycosylated dextrans may be suitable for systemic delivery of therapeutic agents to the liver.

The aim of the present study was to synthesize and characterize a conjugate of 3TC with dextran, ~25 kDa, intended for selective delivery of the anti-HBV drug to the liver. The conjugation of 3TC to dextran was achieved through a succinate linker, resulting in a macromolecular prodrug, potentially releasing 3TC and 3TC succinate (3TCS). Therefore, analytical methods were also developed for quantitation of the intact prodrug and simultaneous quantitation of its potential release products (3TC and 3TCS) in biological samples. In addition to in vitro characterization, the plasma pharmacokinetics and tissue disposition of the prodrug and parent drug were also studied in

rats, a species that has recently been used as a model for human HBV infection (*33–35*). To the best of our knowledge, this is the first report of designing a macromolecular prodrug of anti-HBV drug lamivudine for targeted delivery to the liver.

EXPERIMENTAL PROCEDURES

Chemicals. Dextran with an average M_w of ~25 kDa (actual M_w = 23 500 Da) was purchased from Dextran Products (Scarborough, Ontario, Canada). Lamivudine (3TC) was purchased from Kemprotec (Middlesbrough, U.K.). Stavudine and kits for liver lysosomal isolation and acid phosphatase were purchased from Sigma Chemical (St. Louis, MO). For chromatography, HPLC grade acetonitrile (Mallinckrodt Chromar HPLC) was obtained from VWR Scientific (Minneapolis, MN). All other reagents were analytical grade and obtained through commercial sources.

Animals. Adult male Sprague-Dawley rats were used in this study for in vitro blood and liver lysosome and in vivo disposition studies as outlined in the subsequent sections. All the procedures involving animals in this study were consistent with the "Principles of Laboratory Animal Care" (NIH Publication Vol. 25, No. 28, revised 1996) and approved by the Texas Tech University Health Sciences Center Institutional Animal Care and Use Committee.

Synthesis of 3TCS–Dextran (3TCSD) Conjugate. The complete procedure for the synthesis of 3TCSD conjugate is depicted in Schemes 1 and 2 and described in detail below. The chemical structures of the intermediates and the final

product were determined by nuclear magnetic resonance spectroscopy (^{1}H NMR) on a Bruker NMR spectrometer (400 MHz) and/or a high-resolution PE Biosystems Mariner API time-of-flight electrospray mass spectrometer.

*1. (–)-5′-O-(tert-Butyldimethylsilyloxy)-2′,3′-dideoxy-3′-thiacytidine (***2***).* *tert*-Butyldimethylsilyl chloride (TBDMSCl) (2.0 g, 13.27 mmol) and imidazole (360 mg, 5.29 mmol) were added to a solution of 3TC (**1**, 1.0 g, 4.36 mmol) in dry *N*,*N*-dimethylformamide (DMF) (50.0 mL). The reaction mixture was stirred at room temperature for 18 h. After completion of the reaction, the solvent was removed under reduced pressure, and the crude compound was purified by column chromatography over silica gel using hexane/dichloromethane as the eluents to afford **2** (1.47 g, 98%). ^{1}H NMR (400 MHz, CD_3OD, δ ppm): 8.21 (d, $J = 7.7$ Hz, 1H, H-6), 6.32 (dd, $J = 5.8$, 2.8 Hz, 1H, H-1′), 6.02 (d, $J = 7.7$ Hz, 1H, H-5), 5.26 (t, $J = 3.0$ Hz, 1H, H-4′), 4.18 (dd, $J = 11.8$, 3.0 Hz, 1H, H-5′), 3.96 (dd, $J = 11.8$, 3.0 Hz, 1H, H-5″), 3.54 (dd, $J = 12.5$, 5.8 Hz, 1H, H-2′), 3.19 (dd, $J = 12.5$, 2.8 Hz, 1H, H-2″), 0.95 (s, 9H, $C(CH_3)_3$), 0.15 (s, 6H, CH_3-Si). HR-MS (ESI-TOF) (*m/z*): $C_{14}H_{25}N_3O_3SSi$ calcd, 343.1386; found 344.3933 [M + H$^+$], 686.4590 [2M$^+$].

*2. (–)-4-N-(4,4′-Dimethoxytrityl)-5′-O-(tert-butyldimethylsilyloxy)-2′,3′-dideoxy-3′-thiacytidine (***3***).* Compound **2** (1.0 g, 2.91 mmol) and 4,4′-dimethoxytrityl chloride (DMTrCl, 1.08 g, 3.19 mmol) were dissolved in dry pyridine (80 mL) and stirred for 4 h at 0 °C and then for an additional 16 h at room temperature. The solution was then neutralized with aqueous sodium bicarbonate (5.0%) and extracted with dichloromethane (3 × 100 mL). The organic layer was dried with anhydrous sodium sulfate, and the solvent was removed under reduced pressure. The crude compound was purified by column chromatography over silica gel using hexane/dicloromethane containing 1.0% triethylamine as the eluents to yield **3** (1.79 g, 95%). ^{1}H NMR (400 MHz, $CDCl_3$, δ ppm): 7.81 (d, $J = 7.7$ Hz, 1H, H-6), 7.74 (dd, $J = 5.7$, 3.3 Hz, 1H, aromatic hydrogen, DMTr), 7.55 (dd, $J = 5.7$, 3.2 Hz, 1H, aromatic hydrogen, DMTr), 7.12–7.33 (m, 7H, aromatic hydrogens, DMTr), 6.82–6.88 (m, 4H, aromatic hydrogens, DMTr), 6.33 (dd, $J = 5.2$, 3.1 Hz, 1H, H-1′), 5.19 (t, $J = 3.1$ Hz, 1H, H-4′), 5.03 (d, $J = 7.7$ Hz, 1H, H-5), 4.30–4.45 (m, 1H, H-5′), 4.00–4.20 (m, 1H, H-5″), 3.81 (s, 6H, DMTr-OCH_3), 3.52 (dd, $J = 12.2$, 5.2 Hz, 1H, H-2′), 3.17 (dd, $J = 12.2$, 3.1 Hz, 1H, H-2″), 0.80 (s, 9H, $C(CH_3)_3$), 0.06 (s, 6H, CH_3–Si). HR-MS (ESI-TOF) (*m/z*): $C_{35}H_{43}N_3O_5SSi$ calcd, 645.2693; found 686.4634 [M + K + 2H]$^+$, 1289.3676 [2M – 1]$^+$.

*3. (–)-4-N-(4,4′-Dimethoxytrityl)-2′,3′-dideoxy-3′-thiacytidine (***4***).* Compound **3** (1.10 g, 1.70 mmol) was stirred with 1 M solution of *tert*-butylammonium fluoride (TBAF) in THF (5.0 mL) in the presence of molecular sieves (4 Å) at room temperature for 12 h. The reaction mixture was concentrated under reduced pressure and dried under vacuum. The crude compound was purified by column chromatography over silica gel using hexane/dichloromethane containing 1.0% triethylamine as the eluents to yield **4** (0.89 g, 98%). ^{1}H NMR (CD_3OD, δ ppm): 8.53 (d, $J = 7.8$ Hz, 1H, H-6), 7.32–7.34 (m, 2H, aromatic hydrogens, DMTr), 7.17–7.23 (m, 6H, aromatic hydrogens, DMTr), 7.11–7.13 (m, 1H, aromatic hydrogen, DMTr), 6.75–7.78 (m, 4H, aromatic hydrogens, DMTr), 6.22 (dd, $J = 5.3$, 2.5 Hz, 1H, H-1′), 6.01 (d, $J = 7.8$ Hz, 1H, H-5), 5.25 (t, $J = 3.1$ Hz, 1H, H-4′), 3.99 (dd, $J = 12.8$, 3.1 Hz, 1H, H-5′), 3.84 (dd, $J = 12.8$, 3.1 Hz, 1H, H-5″), 3.69 (s, 6H, DMTr-OCH_3), 3.51 (dd, $J = 12.6$, 5.3 Hz, 1H, H-2′), 3.27 (dd, $J = 12.6$, 2.5 Hz, 1H, H-2″). HR-MS (ESI-TOF) (*m/z*): $C_{29}H_{29}N_3O_5S$ calcd, 531.1828; found 531.9215 [M + H]$^+$, 632.6915 [M + TEA]$^+$.

*4. (–)-4-N-(4,4′-Dimethoxytrityl)-5′-O-(succinate)-2′,3′-dideoxy-3′-thiacytidine (***5***).* 4-Dimethylaminopyridine (DMAP, 100 mg, 0.82 mmol) and succinic anhydride (290 mg, 2.90 mmol) were added to a solution of compound **4** (770 mg, 1.45 mmol) in dry pyridine (15.0 mL). The reaction mixture was stirred at room temperature overnight. After completion of the reaction, the solvent was evaporated under reduced pressure and the crude compound was purified by column chromatography over silica gel using dichloromethane/methanol containing 1% triethylamine as the eluent to yield **5** (0.82 g, 90%). ^{1}H NMR (400 MHz, DMSO-d_6, δ ppm): 8.56 (br s, 1H, NH), 7.60–7.70 (d, $J = 7.8$ Hz, 1H, H-6), 7.14–7.24 (m, 9H, aromatic hydrogens, DMTr), 6.72–6.84 (m, 4H, aromatic hydrogens, DMTr), 6.30–6.38 (m, 1H, H-1′), 6.10 (d, $J = 7.8$ Hz, 1H, H-5), 5.25–5.35 (m, 1H, H-4′), 4.22–4.34 (m, 2H, H-5′ and H-5″), 3.71 (s, 6H, DMTr-OCH_3), 3.58–3.63 (m, 2H, H-2′ and H-2″), 3.00–3.10 (m, 4H, CH_2CH_2). HR-MS (ESI-TOF) (*m/z*): $C_{33}H_{33}N_3O_8S$ calcd, 631.1988; found 632.1715 [M + H]$^+$, 654.1472 [M + Na]$^+$.

5. (–)-5′-O-(Succinate)-2′,3′-dideoxy-3′-thiacytidine (3TCS, **6***).* Acetic acid (AcOH, 10 mL, 80%) was added to compound **5** (100 mg, 0.16 mmol). The reaction mixture was heated at 80 °C for 30 min. The solvent was removed under reduced pressure and the crude compound was purified by HPLC (acetonitrile/water gradient) to yield **6** (47 mg, 90%). ^{1}H NMR (400 MHz, DMSO-d_6, δ ppm): 12.29 (s, 1H, COOH), 9.50–9.80 (br s, 2H, NH_2), 7.60–7.70 (m, 1H, H-6), 6.20–6.32 (m, 1H, H-1′), 5.81–5.93 (m, 1H, H-5), 5.30–5.36 (m, 1H, H-4′), 4.30–4.40 (m, 2H, H-5′ and H-5″), 3.71–3.80 (m, 2H, H-2′), 3.00–3.200 (m, 5H, H-2″, and CH_2CH_2). HR-MS (ESI-TOF) (*m/z*): $C_{12}H_{15}N_3O_6S$ calcd, 329.0682; found 330.3316 [M + H]$^+$, 658.3471 [2M]$^+$.

6. (–)-Dextran-5′-O-(succinate)-2′,3′-dideoxy-3′-thiacytidine (3TCS–Dextran Conjugate, 3TCSD, **8***).* DMAP (70.0 mg, 0.57 mmol), *N*,*N*′-diisopropylethylamine (DIPEA, 100 μL, 0.61 mmol), and *N*,*N*′-diisopropylcarbodiimide (DIC) (50 μL, 0.32 mmol) were added to a solution of compound **5** (275.0 mg, 0.44 mmol) and dextran (20 kDa, 130 mg) in dry dimethyl sulfoxide (DMSO, 3.0 mL) under nitrogen atmosphere. The reaction mixture was stirred at 40 °C for 48 h. After the completion of the reaction, the reaction mixture was cooled to room temperature and cold diethyl ether/ethanol (45 mL, 50:50 v/v) was added. The mixture was washed twice with cold ethanol/diethyl ether (50:50, v/v) and finally with cold ethanol/acetonitrile (70:30, v/v) and centrifuged. The precipitate was dried under vacuum to give (−)-dextran-4-*N*-(4,4′-dimethoxy trityl)-5′-*O*-(succinate)-2′,3′-dideoxy-3′-thiacytidin [4-*N*-(4′-dimethoxytrityl)lamivudine succinate–dextran conjugate, **7**].

Acetic acid (AcOH, 10 mL, 80%) was added to compound **6**. The reaction mixture was stirred at room temperature for 3 h and then heated at 80 °C for 30 min. The solvent was removed under reduced pressure, and the residue was washed three times with cold diethyl ether/ethanol (45 mL, 50:50 v/v) and centrifuged to give 3TCS–dextran conjugate (3TCSD, **8**). ^{1}H NMR (400 MHz, D_2O, δ ppm): 7.88–8.04 (br s, 1H, H-6), 6.25–6.35 (m, 1H, H-1′), 6.05–6.15 (br s, 1H, H-5), 5.41–5.50 (m, 1H, H-4′), 4.85–5.05 (m, anomeric hydrogen of dextran, H-1), 4.28–4.58 (m, 2H, H-5′ and H-5″), 3.40–4.10 (m, H-2′ and H-2″ of 3TC, H-2, H-3, H-4, H-5, and H6 of dextran), 3.30–3.38 (m, 4H, CH_2CH_2 of succinate).

Further Characterization of 3TCS–Dextran Conjugate (3TCSD, 8). The purity of the powder was determined using both the size-exclusion (SEC) and reversed-phase (RPC) chromatographic methods. The degree of substitution of 3TC in 3TCSD was determined by hydrolysis of the conjugate under basic conditions. To 1 mg of the conjugate were added 1 mL of 0.1 N NaOH and 0.6 mL of methanol. After the mixture was left at room temperature for 5 min, 30 min, and 24 h, 100 μL of the sample was micropipetted into a microcentrifuge tube containing 100 μL of 0.1 M HCl. An aliquot (50 μL) was then

injected into an HPLC instrument. The concentration of the released 3TC was determined using a reversed-phase method based on 3TC standard solutions as described below.

High Performance Liquid Chromatography. Size-exclusion and reversed-phase chromatographic methods were developed and validated for quantitation of the conjugate (3TCSD) and its potential hydrolysis products (3TC and 3TCS), respectively, in buffers or biological samples.

1. Size-Exclusion Liquid Chromatography (SEC). Lamivudine succinate–dextran conjugate (3TCSD) was analyzed in nonbiological and biological (plasma and tissue) samples at ambient temperature using a 30 cm × 7.8 mm analytical gel chromatography column (PolySep-GFC 3000; Phenomenex, Torrance, CA). The mobile phase consisted of water/acetonitrile/acetic acid (75:25:0.2, v/v/v) and was pumped at a flow rate of 1.0 mL/min.

2. Reversed-Phase Liquid Chromatography (RPC). A reversed-phase chromatographic method was developed to quantitate the concentrations of 3TC and 3TCS in aqueous and biological samples. The separation of 3TC, 3TCS, and internal standard (stavudine, IS) was achieved on a 250 mm × 4.6 mm C_{18} column (Microsorb-MV, Varian, Lake Forest, CA) preceded by a 5 cm guard column. The mobile phase consisted of KH_2PO_4 (50 mM)/methanol/triethylamine (90:10:0.1, v/v, pH 7.0), which was pumped at a flow rate of 1.0 mL/min.

3. HPLC System. The HPLC instrument consisted of a 510 pump (Waters; Milford, MA), a 717 plus autosampler (Waters; Milford, MA), and a 486 UV detector (Waters) set at a wavelength of 276 nm. The chromatographic data were managed using Empower, version 2, software. Calibration curves were constructed by plotting the peak areas of 3TCSD or peak area ratios of 3TC or 3TCS over IS against the concentration in the sample using a weight of 1 per concentration.

4. Sample Preparation. For the size exclusion chromatography, to 100 μL of plasma in microcentrifuge tubes were added 20 μL of methanol and 20 μL of 20% (w/v) trichloroacetic acid. After being vortex-mixed for 5 s, the samples were centrifuged in a microcentrifuge at 16 000 rpm for 5 min. A 100 μL aliquot of the supernatant was mixed with 50 μL of 0.5 M phosphate buffer (pH 6.0), and a 75 μL aliquot was injected into the HPLC.

To determine the concentrations of 3TCSD in the tissues by the SEC method, tissues were homogenized in three volumes of water using a homogenizer at a rate of 10 000 rpm. To 100 μL of the whole homogenate in siliconized microcentrifuge tubes were added 50 μL of 0.5 M phosphate buffer (pH 7.0) and 50 μL of cold methanol. Samples were then briefly vortex-mixed, and 40 μL of trichloroacetic acid (40%) was added to precipitate proteins. After being vortex-mixed for 5 s, the samples were centrifuged in a microcentrifuge at 10 000 rpm for 3 min A 100 μL aliquot of the supernatant was mixed with 50 μL of 1 M sodium acetate, and a 75 μL aliquot was injected into the HPLC.

The preparation of plasma samples for reversed-phase chromatography was similar to that for the SEC method with one exception; for the reversed-phase system, 50 μL of 50 μg/mL stavudine was added as an internal standard to the plasma sample before protein precipitation. Similarly, the tissue samples for reversed-phase chromatography were prepared as described above for the SEC method but without the addition of 0.5 M phosphate buffer.

5. Validation of Assays. The inter-run precision (% CV) and accuracy (% error) of the assays were determined from the analysis of quality control samples ($n = 5$) based on reported guidelines (*36*). The concentrations of quality control samples were 1.0, 10, or 50 μg/mL for 3TCSD (SEC method), 0.125, 5.0, and 20 μg/mL for 3TC (RPC method), and 0.36, 5.4, and 18 μg/mL for 3TCS (RPC method). Calibration curves for SEC of 3TCSD contained 0, 1, 2, 5, 10, 15, 25, or 50 μg/mL of the prodrug (3TC equivalent). For RPC, calibration curves consisted of 0, 0.125, 0.25, 0.5, 1.0, 2.0, 5.0, 10, or 20 μg/mL 3TC and 0, 0.36, 0.72, 1.80, 3.6, 5.4, 9.0, or 18 μg/mL 3TCS as 3TC equivalents.

To determine the recovery of 3TCSD, 3TC, and 3TCS from plasma after protein precipitation, plasma samples ($n = 5$) containing 5 or 100 μg/mL 3TCSD, 5 or 50 μg/mL 3TC, or 1.8 or 18 μg/mL 3TCS were subjected to the above assays and the peak areas were determined. The peak areas of these samples were then compared with those containing an equal concentration of each analyte in distilled water, injected directly into the HPLC. Similarly, the recoveries of 3TCSD and 3TC from the liver samples ($n = 5$) containing 5 μg/mL 3TCSD or 0.5 μg/mL of 3TC were determined.

In Vitro Release Characterization. *1. Release Characteristics in Buffers.* The prodrug (3TCSD), at a concentration equivalent to 100 μg/mL 3TC, was dissolved in 10 mM KH_2PO_4 (pH 4.4) or phosphate buffer (pH 7.4). The solutions were then incubated at 37 °C ($n = 3$). Samples (100 μL) were taken at 0, 3, 6, 12, and 24 h and subjected to the above HPLC methods for the quantitation of intact 3TCSD (SEC method) and released 3TC or 3TCS (RPC method).

2. Release Characteristics in Rat Blood. Blood was obtained from rats by cardiac puncture. Approximately 4 IU of heparin was added to each mL of blood to prevent coagulation. Immediately after the collection of blood, 3TCSD conjugate (in 10 mM isotonic phosphate buffer at pH 7.4) was added to produce a blood concentration of 100 μg/mL (3TC equivalent) ($n = 3$). The solution was then incubated at 37 °C. Blood samples (1 mL) were collected at 0, 3, 6, and 12 h in heparinized microcentrifuge tubes. After centrifugation of the blood, the plasma samples (100 μL) were subjected to the assays described above for the determination of 3TC, 3TCS, and/or intact 3TCSD.

3. Release Characteristics in Rat Liver Lysosomes. Crude lysosomal fractions were prepared from the liver of untreated rats according to the procedure described in the lysosome isolation kit (Sigma). Briefly, the rat livers were perfused with ice-cold PBS before removal of the livers. The livers were then homogenized in four volumes of the extraction buffer, followed by differential centrifugation for isolating the lysosomal fraction. The protein concentrations in lysosomal preparations were determined by Bio-Rad protein assay (Bio-Rad, Herecules, CA). The activity of acid phosphatase, a lysosomal marker, in the preparation was tested using a commercial kit (Sigma). The specific enzyme activity in the lysosomal fraction was >9-fold that in the liver homogenate.

For lysosomal hydrolysis studies, 3TCSD (100 μg/mL, 3TC equivalent) was incubated at 37 °C in 50 mM acetate buffer (pH 4.0) in the presence of 5 mM reduced glutathione and 5 mg/mL lysosomal protein ($n = 3$). Samples (100 μL) were then taken at 0, 3, 6, 9, 12, and 24 h and treated as described above for size-exclusion and reversed-phase HPLC analysis.

In Vivo Disposition. A total of 42 adult male Sprague-Dawley rats were divided equally into two groups of 21 rats each, treated with 3TCSD or 3TC. The mean ± SD of the body weights of rats were 241 ± 8 and 240 ± 6 g for the 3TCSD- and 3TC-injected groups, respectively. The animals had free access to drinking water and rat chow before and during the course of experiments.

Single iv bolus doses (5 mg/kg, 3TC equivalent) of 3TCSD or the parent drug 3TC were injected into the penile vein of the animals under isoflurane anesthesia. Different groups of rats ($n = 3$/group per time point) were euthanized at 0 (before drug administration), 5, 15, 60, 120, or 180 min following drug administration, and tissues (liver, spleen, kidneys, heart, lungs, and brain) and blood (cardiac puncture) were collected. Ad-

ditionally, total urine output was collected from zero to 180 min or to 24 h for the 3TC- or 3TCSD-injected group (n = 3/group).

Immediately after excision, the tissues were rinsed in ice-cold saline solution to remove excess blood. Afterward, the tissues were blotted dry and kept frozen until analysis. After centrifugation of the blood in a prechilled and heparin-coated microcentrifuge tube, the plasma was collected. To prevent in vitro hydrolysis of 3TCSD during storage, plasma (500 μL) was mixed with a 10% acetic acid solution (100 μL). Plasma, tissue, and urine samples were kept frozen at −80 °C until analysis.

Pharmacokinetic Analysis. Noncompartmental analysis was performed by using WinNonlin5.0.1 computer program (Pharsight Co.; Mountain View, CA). Terminal elimination rate constant (λ_z) was estimated from the log-linear portion of the plasma or tissue concentration–time courses. Area under the plasma or tissue concentration–time curve (AUC) was estimated from the average plasma or tissue concentrations at different time points using a linear trapezoidal rule with extrapolation to infinity only for the plasma profiles. For tissues, AUCs were not extrapolated beyond the quantifiable samples because of uncertainty about the terminal half-lives. Other estimated pharmacokinetic parameters included apparent total body clearance (CL), renal clearance (CL_R), volume of distribution at steady state (V_{ss}), terminal volume of distribution (V_z), fraction of the drug excreted unchanged in urine (f_e), mean residence time (MRT), and maximum observed drug concentration (C_{max}). The maximum concentrations of 3TCSD or 3TC in plasma (C_0) after the injection of the conjugate or parent drug were estimated by the program. The concentrations of drugs in the tissues were corrected (*21*) for the residual blood using the blood volume fraction of different tissues.

Statistical Analysis. Because of the destructive sampling procedure used for the collection of blood and tissues from different animals at each time point, the composite kinetic parameter AUC could not be obtained for individual rats (*21*). Therefore, the variance of AUC was estimated by a reported (*37*, *38*) procedure based on the standard error of mean and number of samples at each time point. The pairwise comparison of AUCs was then carried out at an α level of 0.05 and a Bonferroni adjusted α of 0.05 or 0.0167 for pairwise comparison of two (one comparison) or three (three comparisons) mean values, respectively. The critical values of Z (Z_{crit}) for the two-sided test using the Bonferroni adjusted α of 0.05 and 0.0167 were 1.96 and 2.39, respectively, and the observed Z (Z_{obs}) was calculated as reported before (*37*, *38*). A Z_{obs} value greater than Z_{crit} was used as an indication of a significant difference between the AUCs.

The differences between groups in their kinetic parameters that could be estimated for individual rats (e.g., C_{max} and CL_R) were determined using a two-tailed unpaired t test at a significance level (α) of 0.05. When possible, data are presented as the mean ± SD.

RESULTS

Synthesis and Characterization of 3TCSD. Lamivudine (3TC) was conjugated to dextran using a succinate linker in two major steps by synthesis of 5′-*O*-succinate ester of the drug (Scheme 1), followed by the reaction of the ester conjugate with dextran (Scheme 2). Lamivudine was initially reacted with TBDMSCl in the presence of imidazole to yield 5′-*O*-TBDMS-lamivudine **2**. The protection of the *N*4-amino group of 5′-*O*-protected lamivudine was carried out in the presence of DMTr-Cl and pyridine to give *N*4-DMTr-5′-*O*-TBDMS-lamivudine **3**. The deprotection of 5′-*O*-TBDMS in the presence of tetrabutylammonium fluoride afforded the *N*4-DMTr derivative of lamivudine **4**, which was used in the reaction with succinic anhydride to generate the *N*4-DMTr-5′-*O*-succinate ester conjugate of lamivudine **5** (Scheme 1). Compound **5** was reacted with dextran in the presence of DIC and DMAP to afford the *N*4-(DMTr)lamivudine succinate–dextran conjugate **7** that was deprotected in the presence of acetic acid to afford the lamivudine succinate–dextran conjugate (3TCSD, **8**) (Scheme 2).

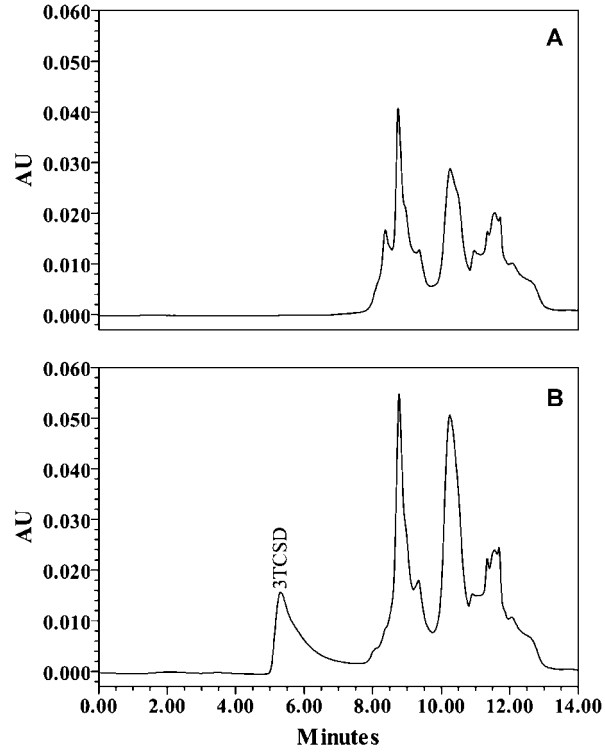

Figure 1. Chromatograms of plasma samples taken from a rat before (A) and 180 min after (B) the administration of a single 5 mg/kg dose (3TC equivalent) of 3TCSD, subjected to the size-exclusion chromatographic method. The 180 min sample contained 9.70 μg/mL 3TCSD.

The purity of the conjugate was >99% as determined by the reversed-phase analysis of a 100 μg/mL solution of the conjugate (n = 3), which contained only 0.296 ± 0.041 μg/mL 3TC without any measurable peak of 3TCS. The degree of substitution of the final product, which was obtained by the base hydrolysis of 3TCSD to 3TC followed by reversed-phase quantitation of the released 3TC, was 6.5 mg of lamivudine in 100 mg of 3TCSD powder. The complete hydrolysis of 3TCSD was confirmed by a complete disappearance of the 3TCSD peak in the SEC method. Additionally, the area of the unhydrolyzed 3TCSD peak in the SEC method was the same as the area of the released 3TC peak in the reversed-phase method after appropriate volume correction, indicating that the degree of substitution may be determined directly from the area of 3TCSD peak without hydrolysis. In terms of size, the peak of 3TCSD in the SEC chromatogram was slightly shifted to the left compared with the peak of the unconjugated dextran carrier, suggesting an increase in the size upon conjugation of dextran with 3TC.

Size-Exclusion Chromatographic Method. Chromatograms of plasma samples taken from a rat before (blank) and 180 min after the administration of a single 5 mg/kg dose (3TC equivalent) of 3TCSD are demonstrated in Figure 1. Dextran–lamivudine succinate eluted at ~5.3 min and was well separated from the endogenous peaks in plasma, which eluted after the conjugate peak (Figure 1). Additionally, the relationship between the peak area of 3TCSD and the detector response was linear ($r^2 \geq 0.998$) over the studied range 1–50 μg/mL.

Table 1. Inter-Run Accuracy and Precision for Quantitation of 3TCSD Using the SEC Assay ($n = 5$)

added concn (μg/mL)	calcd concn (μg/mL)	CV (%)	error (%)
1	0.992	12.8	−0.84
10	10.1	2.34	0.70
50	49.6	1.60	−0.80

The results of the assay validation in plasma are presented in Table 1. Excellent accuracy of the assay is demonstrated by error values of <1% for all the concentrations (even at the lowest concentration of 1 μg/mL). The assay is also deemed precise because the CV values are <13% for the inter-run data (Table 1). On the basis of the data presented in Table 1, the limit of quantitation of the assay is at least equal to 1 μg/mL.

The recovery of 3TCSD from plasma was 88.0 ± 4.2% and 94.1 ± 4.6% at concentrations of 5 and 50 μg/mL, respectively. The recovery of 3TCSD from liver was 94.2 ± 9.5% at a concentration of 5 μg/mL.

Reversed-Phase Chromatographic Method. Figure 2 depicts the chromatograms of plasma samples at zero (blank) and 15 min after the administration of a single 5 mg/kg dose of 3TC to rats and at 3 h after the in vitro incubation of 3TCSD in blood. Lamivudine, internal standard (stavudine), and 3TCS eluted at ∼11, 17, and 26 min, respectively, and were well separated from the endogenous peaks in plasma (Figure 2). Additionally, the relationship between the peak area ratios of 3TC and 3TCS and the sample concentrations was linear ($r^2 \geq$ 0.998) over the studied concentration ranges of 0.125–20 μg/mL for 3TC and 0.36–18 μg/mL (3TC equivalent) for 3TCS.

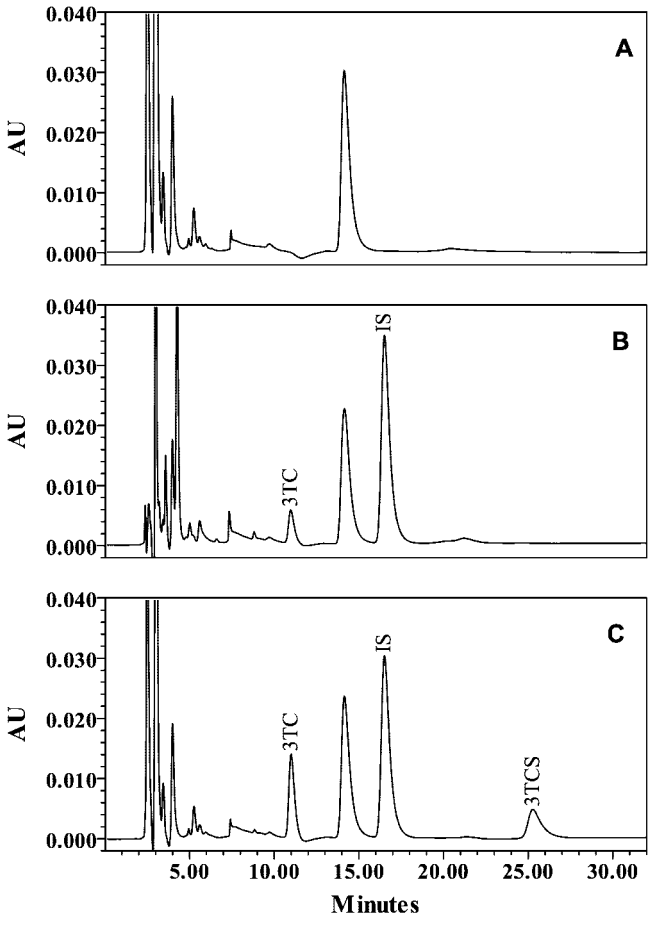

Figure 2. Chromatograms of plasma samples taken from a rat before (A) and 15 min after (B) the administration of a single 5 mg/kg dose of 3TC to rats and at 3 h after in vitro incubation of 3TCSD with rat blood (C), subjected to the reversed-phase chromatographic method. Sample B contained 1.84 μg/mL 3TC, and sample C contained 3.97 and 5.12 μg/mL 3TC and 3TCS, respectively.

Table 2. Inter-Run Accuracy and Precision for Quantitation of 3TC and 3TCS in Plasma Using the Reversed-Phase Assay ($n = 5$)

analyte	added concn (μg/ml)	calcd concn (μg/ml)	CV (%)	error (%)
3TC	0.125	0.138	16.8	10.9
3TC	5.0	4.75	3.15	−5.04
3TC	20	20.8	5.83	4.00
3TCS	0.36	0.378	8.33	5.14
3TCS	5.4	5.18	4.18	−3.73
3TCS	18	18.8	3.93	4.32

Validation results for the reversed-phase assay of 3TC and 3TCS in plasma are presented in Table 2. Excellent accuracy of the assay is demonstrated by error values of <11% for all the concentrations. The assay is also deemed precise because the CV values are <9% for all the concentrations except for the lowest concentration of 3TC, which showed an acceptable CV of 16.8% (Table 2). On the basis of the data presented in Table 2, the limit of quantitation of the assay is 0.125 and 0.36 μg/mL for 3TC and 3TCS, respectively.

For 3TC, the degrees of recovery from plasma were 101 ± 1.8% and 104 ± 1.8% at concentrations of 5 and 50 μg/mL, respectively. For 3TCS, the values were 89.7 ± 8.5% and 85.7 ± 2.6% at concentrations of 1.8 and 18 μg/mL, respectively. The recovery of 3TC from the liver samples at a concentration of 0.5 μg/mL was 95.7 ± 5.25%.

Release Characteristics in Buffers. The SEC and reversed-phase HPLC assays described above were used to investigate the stability of 3TCSD and formation of 3TC and 3TCS at 37 °C at pH 4.4 (Figure 3) or 7.4 (Figure 4). The conjugate was very stable at pH 4.4 as demonstrated by both SEC (Figure 3, top) and reversed-phase (Figure 3, bottom) assays. The concentrations of 3TCSD did not significantly change over 24 h of incubation at 37 °C at pH 4.4 (Figure 3, top). Additionally, reversed-phase analysis showed minor concentrations (<1% of

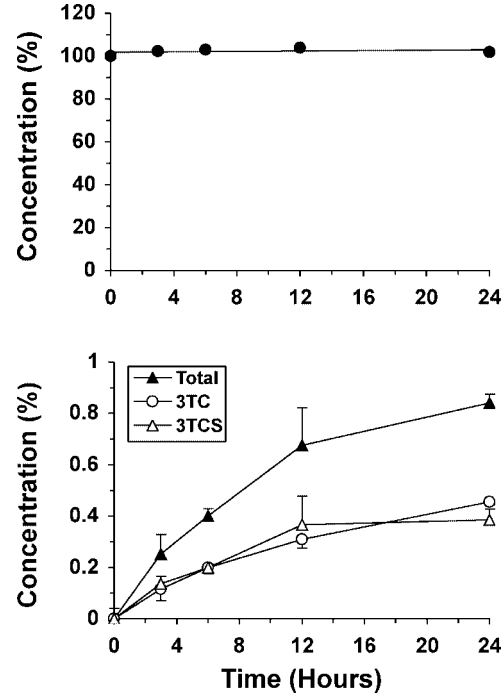

Figure 3. Average concentration–time courses of the intact 3TCSD (top) and released 3TC, 3TCS, and total 3TC (3TC plus 3TCS) (bottom) after incubation of the conjugate at pH 4.4 (37 °C). Error bars represent SD values ($n = 3$). Error bars for 3TCSD are too small to be observable.

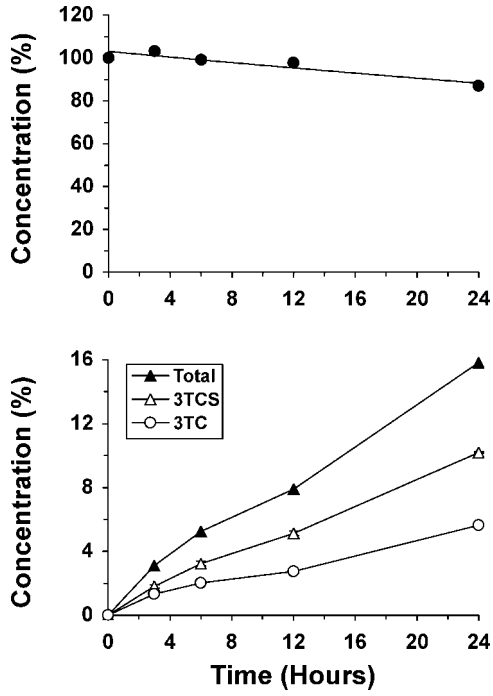

Figure 4. Average concentration–time courses of the intact 3TCSD (top) and released 3TC, 3TCS, and total 3TC (3TC plus 3TCS) (bottom) after incubation of the conjugate at pH 7.4 (37 °C). Error bars represent SD values ($n = 3$). In most cases, error bars are too small to be observable.

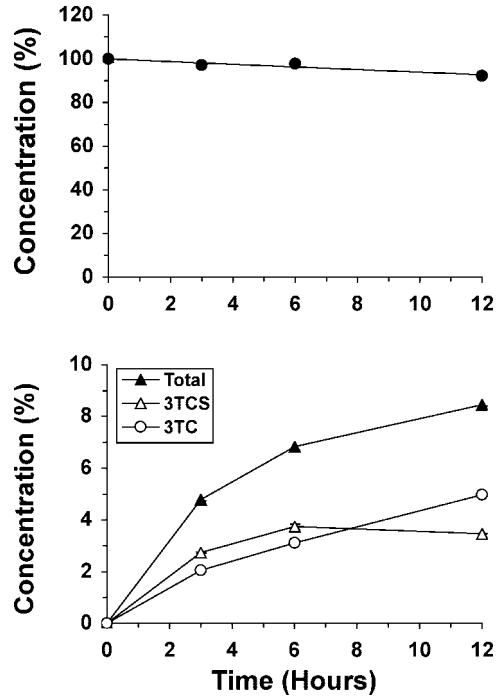

Figure 5. Average concentration–time courses of the intact 3TCSD (top) and released 3TC, 3TCS, and total 3TC (3TC plus 3TCS) (bottom) after incubation of the conjugate in rat blood (37 °C). Error bars represent SD values ($n = 3$). In most cases, error bars are too small to be observable.

the initial concentration of 3TCSD) of 3TC and 3TCS released over the incubation time of 24 h (Figure 3, bottom). On the other hand, measurable hydrolysis of 3TCSD occurred at pH 7.4 (Figure 4). In the SEC method, the concentrations of 3TCSD declined ~16% during 24 h of incubation at pH 7.4 and 37 °C, with an apparent first-order half-life of 108 h (Figure 4, top). The decline in the concentration of 3TCSD (Figure 4, top) was associated with an almost identical increase in the concentrations of free 3TC and 3TCS in the sample analyzed by the reversed-phase method (Figure 4, bottom).

Release Characteristics in Rat Blood. Figure 5 shows the decline in the 3TCSD concentration (top) and associated increases in the concentrations of 3TC and 3TCS (bottom) after incubation of the conjugate in rat blood at 37 °C. The total 3TC (3TC plus 3TC succinate) released during 12 h of incubation in blood was 8.45 ± 0.04% (Figure 5, bottom), in agreement with an equivalent decline (7.75 ± 0.80%) in the concentration of the prodrug in the SEC assay (Figure 5, top). The first-order half-life of the decline in the 3TCSD concentration in plasma was 110 h.

Release Characteristics in Rat Liver Lysosomes. The concentration–time courses of 3TC release following incubation of 3TCSD in the presence and absence of rat liver lysosomes are depicted in Figure 6. The presence of lysosomes in the medium induced a slow release of 3TC (7.36 ± 0.30 μg/mL after 24 h) without any detectable 3TCS. In contrast, the release of 3TC or 3TCS in the same medium in the absence of lysosomes was negligible (Figure 6).

In Vivo Disposition. Plasma concentration–time courses of 3TCSD and 3TC after the injection of single 5 mg/kg (3TC equivalent) doses of the prodrug or the parent drug are depicted in Figure 7. After the injection of unconjugated 3TC, the drug was eliminated relatively rapidly and could not be detected at the last sampling time of 3 h (Figure 7). In contrast, the concentrations of 3TCSD were several-fold higher than those of 3TC and remained high even at the last sampling time after the injection of the conjugate. The plasma concentrations of

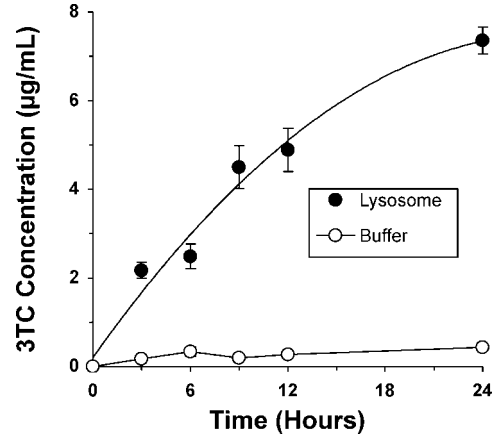

Figure 6. Average concentration–time courses of released 3TC after incubation of the conjugate in rat liver lysosomes or buffer (37 °C). Error bars represent SD values ($n = 3$). In most cases, error bars are too small to be observable.

both 3TC and 3TCSD declined multiexponentially (Figure 7). Additionally, no quantifiable concentrations of 3TC or 3TCS were detected in plasma of 3TCSD-injected rats.

The plasma pharmacokinetic parameters of 3TC and 3TCSD after the injection of the parent drug or the prodrug are listed in Table 3. Conjugation of 3TC to dextran resulted in an almost 40-fold decrease in the total CL of the drug and a similar degree of increase in its plasma AUC. The decrease in total CL was associated with an 80-fold decrease in the CL_R of the drug when conjugated to dextran. Consequently, the fraction of the drug excreted unchanged into urine decreased from 65% for the parent drug to 31% for the conjugate (Table 3). Additionally, dextran conjugation decreased the extent of distribution of the drug as reflected in V_{ss} and V_z values (Table 3), although to a lesser degree than that seen with the CL values (7- to 12-fold versus 40- to 80-fold, respectively). The declines in both the

parameter	3TC-injected rats, 3TC	3TCSD-injected rats, 3TCSD[a]
C_{max}, μg mL^{-1}	4.94 ± 0.93[c]	52.5 ± 6.5
AUC, μg min mL^{-1}	153 ± 7[c]	5930 ± 153
CL, mL min^{-1} kg^{-1}	32.6[b]	0.844[b]
CL_R, mL min^{-1} kg^{-1}	21.3 ± 2.1[c]	0.263 ± 0.089
f_e, %	65.3 ± 6.5[c]	31.2 ± 10.6
V_z, mL kg^{-1}	1786[b]	152[b]
V_{ss}, mL kg^{-1}	930[b]	135[b]
λ_z, min^{-1}	0.0183[b]	0.00554[b]
$t_{1/2}(\lambda_z)$, min	37.9[b]	125[b]
MRT, min	28.5[b]	160[b]

[a] No quantifiable concentrations of 3TC or 3TCS were detected in plasma after 3TCSD injection. [b] Standard deviations could not be determined because of destructive sampling method. [c] Significantly different ($P < 0.05$) from the corresponding value for the 3TCSD-injected rats.

clearance and volume of distribution upon conjugation resulted in longer terminal half-lives and MRT values for the conjugate, compared with the parent drug (Table 3).

The hepatic concentration–time courses (top) and AUC values (bottom) of the conjugate and regenerated 3TC after the administration of the conjugate and those of 3TC after the injection of the parent drug itself are depicted in Figure 8. After the injection of 3TC, the hepatic concentrations of the drug were measurable only in the first two samples; no detectable 3TC levels were found in the liver beyond 15 min following the administration of the parent drug (Figure 8, top). However, relatively high concentrations of 3TCSD were detected until the last sampling point. This resulted in >50-fold higher ($P < 0.0001$) AUCs for the conjugated 3TC, compared with the parent drug (Figure 8, bottom). Additionally, the conjugated 3TC slowly released 3TC in the liver (Figure 8, top) with an AUC that was approximately 2.5-fold larger ($P < 0.0001$) than that of the parent drug during the sampling time (Figure 8, bottom). No measurable concentrations of 3TCS were found in the liver.

The kidney concentration–time courses (top) and AUC values (bottom) of the conjugate and regenerated 3TC after the administration of the conjugate and those of 3TC after the injection of the parent drug itself are depicted in Figure 9. In addition to the liver (Figure 8), the kidney was the only other organ where high concentrations of the conjugated and regenerated 3TC were found (Figure 9). In contrast to the liver (Figure 8), however, relatively high and persistent concentrations of 3TC

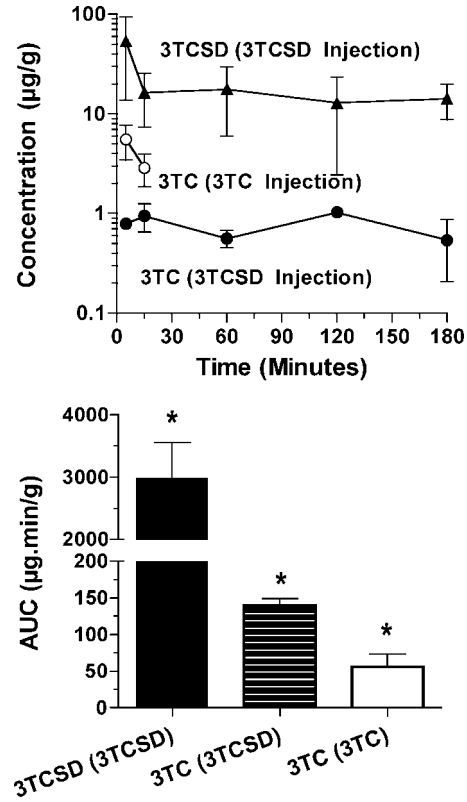

Figure 8. Liver concentration–time courses (top) and AUC values (bottom) of parent (3TC) and/or conjugated (3TCSD) lamivudine after iv administration of single 5 mg/kg doses (3TC equivalent) of 3TC or 3TCSD to rats. Standard deviation values are shown as error bars ($n = 3$ rats for each time point). Asterisks indicate significant differences from the other two groups.

were found in the kidney even after the injection of the parent drug (Figure 9). Therefore, conjugation of 3TC with dextran did not increase the availability of free 3TC in the kidneys, as the AUCs of the regenerated and parent 3TC were not significantly different (Figure 9).

In contrast to the liver (Figure 8) and kidneys (Figure 9), the concentrations of the conjugate and/or regenerated 3TC were very low or undetectable in the lungs, spleen, heart, and brain after 3TCSD injection (data not shown). Additionally, no released 3TC could be detected in these tissues. The concentrations of 3TC after 3TC injection in organs other than kidney were also low or below the limit of detection in most of the samples.

DISCUSSION

Targeted delivery of anti-HBV drugs to the liver, for the treatment of viral hepatic diseases, has attracted the attention of scientists for several years. In one of the first publications on this subject, Balboni et al. (*39*) showed that conjugation of cytosine arabinoside and 5-fluorodeoxyuridine to albumin resulted in accumulation of these antiviral drugs in the mouse liver cells, increasing the effectiveness of the drugs in comparison with the free drugs. Further work by Fiume and colleagues (*6*) modified this strategy by the use of lactosaminated albumin as the carrier, selectively targeting the asialoglycoprotein receptors on the hepatocytes with the galactose moiety of lactose. Additionally, conjugates of antiviral drugs with galactosylated poly-L-lysine, instead of albumin, have been synthesized and tested by the same group (*40, 41*). Others have used arabinogalactan (*42*) or glycosylated lipoproteins (*4, 7*), as liver-accumulating carriers, or prodrugs that release the active drug based on metabolism by hepatic cytochrome P450 (*9, 10*) for

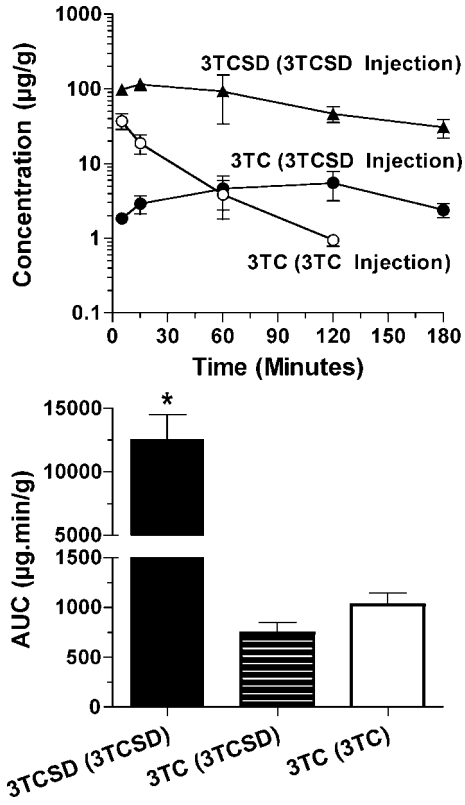

Figure 9. Kidney concentration–time courses (top) and AUC values (bottom) of parent (3TC) and/or conjugated (3TCSD) lamivudine after iv administration of single 5 mg/kg doses (3TC equivalent) of 3TC or 3TCSD to rats. Standard deviation values are shown as error bars (n = 3 rats for each time point). Asterisk indicates significant differences from the other two groups.

targeted delivery of antiviral drugs to the liver. These studies support the general concept that targeted delivery of antiviral drugs to the liver potentially increases the efficacy of these drugs in the treatment of viral liver infections while, at the same time, decreasing their toxic effects in other tissues. However, the choice of carrier and targeting moieties needs optimization to reduce carrier-related side effects, such as increased alkaline phosphatase levels seen with lactosylated human serum albumin (*6*), or to mitigate drawbacks associated with variability in density and affinity seen with the asialoglycoprotein receptors (*5*).

In the present study, we used dextran with a M_w of ~25 kDa as an alternative to the currently studied carriers for the selective delivery of 3TC to the liver in HBV treatment. The synthesis of the conjugate was challenging because of the presence of the free *N*4-amino group in the structure of 3TC, which had to be protected before the reaction of 3TC with succinic anhydride for the synthesis of 3TCS (Scheme 1). Therefore, additional protection/deprotection steps were used by the synthesis of intermediates **2**–**4** to selectively protect the *N*4-amino group before the 5′-O-esterification reaction to afford *N*4-protected 3TCS (Scheme 1). Furthermore, one additional step was used in the deprotection of the *N*4-amino group in the synthesis of the final conjugate 3TCSD (Scheme 2). These extra steps are not needed for the synthesis of the dextran conjugates of other nucleosides such as zidovudine and alovudine, which do not possess a free amino group (*43*). Nevertheless, the synthetic strategy (Schemes 1 and 2) described here afforded a conjugate with a reasonable degree of 3TC substitution (6.5%, w/w).

In addition to our study, we are aware of only one other study that used dextran as a macromolecular prodrug of antiviral agents (*8*). In that study, acyclovir was conjugated to dextran with a M_w of 40 kDa. However, to synthesize the conjugate, dextran was first oxidized to dextran aldehyde before direct reaction of the aldehyde groups of dextran with the amine group of acyclovir to produce a Schiff's base, without any spacer between acyclovir and dextran. Modification of dextrans, including their oxidation, may alter the degradation and safety profiles of native dextrans, which have been used clinically for almost 6 decades as plasma volume expanders (*44*). Therefore, we designed a strategy for conjugation of 3TC to dextran to minimize changes of the structure of native dextran molecule. Consequently, 3TC was coupled to dextran through a succinate linker (Scheme 2), thus avoiding the need for oxidation of dextran as previously reported (*8*).

Lamivudine succinate–dextran (3TCSD) has two ester bonds in its structure (Scheme 2), whose hydrolysis potentially releases 3TC or 3TCS. Therefore, to completely determine the fate of the conjugate and its potential release products in both in vitro and in vivo experiments, analytical methods capable of measurement of all three moieties are needed. To quantitate 3TCSD in both aqueous and biological samples, a SEC assay was developed. The method is capable of separating the conjugate peak from the endogenous peaks (Figure 1) and of accurately and precisely quantitating the conjugate (Table 2).

Several HPLC assays are currently available for the determination of 3TC in plasma and/or tissues (*45–50*). These assays use either solid-phase extraction (*46, 47, 49*) or protein precipitation (*45, 48, 50*) for sample preparation. Additionally, all of them use reversed-phase chromatography with C_{18} (*45, 46, 49*), C_8 (*50*), or phenyl (*47, 48*) columns for separation of 3TC from the endogenous peaks. To quantitate both 3TC and 3TCS simultaneously in our samples, we had to modify these assays. We found that a protein precipitation method with a combination of methanol and trichloroacetic acid resulted in the highest recovery (≥86%) for both 3TC and 3TCS from biological samples. Additionally, our chromatographic conditions resulted in complete separation of 3TC, 3TCS, and IS from the endogenous peaks (Figure 2) and in accurate and precise quantitation of 3TC and 3TCS (Table 2).

The results of our in vitro studies in buffers with different pH (Figures 3 and 4) and rat blood (Figure 5) suggest that the conjugate is relatively stable in buffers and blood. The conjugate was almost completely stable at a pH of 4.4, which was used to simulate any chemical hydrolysis at a pH similar to that of lysosomes, where the conjugate is expected to end up. Also, a comparison of 24 h degradation data at pH 7.4 (Figure 4) with 12 h degradation data in blood (Figure 5) suggests that the degradation of 3TCSD in blood is only due to a slow chemical hydrolysis of the conjugate. This is because the degradation half-lives of 3TCSD in buffer at pH 7.4 and in blood are almost identical (108 and 110 h, respectively), indicating lack of enzymatic hydrolysis of the conjugate in blood. These data are consistent with our previous report on a dextran conjugate of methylprednisolone succinate, which similarly showed little, if any, enzymatic hydrolysis in blood (*51*). Nevertheless, the relatively long half-life of 3TCSD in blood in vitro (110 h) indicates that the conjugate is stable in blood long enough for the uptake by the liver.

Previous studies (*16, 52*) on other ester conjugates of dextrans have proposed that the intact conjugates are resistant to the effects of esterases because of steric hindrance of dextrans. However, after exposure of the conjugate to dextranases, which depolymerize dextrans, esterases can hydrolyze the ester bonds in the conjugate. It has been reported (*11*) that dextranases are present in lysosomes, predominantly in the liver. Additionally, dextrans enter cells via endocytosis, which results in their accumulation in the lysosomal compartments (*53, 54*). Therefore, lysosomal exposure of dextran conjugates to dextranases

may facilitate their further enzymatic hydrolysis. Indeed, our previous work with dextran carriers showed that the M_w of the macromolecule found in the liver slowly decreased over a period of 96 h after its in vivo administration to rats (*20*). Because of our short sampling time of 3 h, we could not detect a significant change in the M_w (retention time in SEC assay) of the 3TCSD conjugate in the liver samples in our current study. However, our in vitro data showing significant amounts of 3TC released at pH 4.0 only in the presence of rat liver lysosomes (Figure 6) are in agreement with these reports.

The literature information about the pharmacokinetics of 3TC in rats is limited. We are aware of only one study reporting the plasma concentration–time course and AUC of the drug after a 230 mg kg^{-1} iv dose (*10*). However, no other pharmacokinetic parameters were reported in that study. We estimated a CL value of 27.1 mL min^{-1} kg^{-1} from the AUC and dose values reported in that study. This value is very close to our value of 32.6 mL min^{-1} kg^{-1} after a much smaller dose of 5 mg kg^{-1} (Table 3), suggesting linear pharmacokinetics of 3TC in the dosage range of 5–230 mg kg^{-1}.

In our study, conjugation of 3TC to dextran substantially decreased both the CL and volume of distribution of 3TC (Table 3) while at the same time increasing the accumulation of the drug in the liver (Figure 8). A similar disposition pattern was also observed for a dextran prodrug of methylprednisolone with a succinate linker (*30*). The simultaneous decrease in volume of distribution and increase in liver accumulation upon dextran conjugation is due to the relatively large pore sizes of the liver sinusoids in comparison with those in the vascular beds of most other organs, allowing unrestricted access of the conjugate to the space of Disse and internalization of the conjugate (*21*).

Because of the limited number of liver samples with quantifiable 3TC concentrations after 3TC injection and slow apparent declines in the liver concentrations of the conjugate and regenerated 3TC after conjugate injection (Figure 8, top), terminal half-lives were not estimated for the liver. Consequently, liver AUC values depicted in Figure 8 (bottom panel) are related to the sampling period without extrapolation to infinity. However, the significant differences between the liver AUCs after 3TC and 3TCSD injections would be expected to be even larger if extrapolated AUCs were used. This is because the apparent decline in the 3TCSD or regenerated 3TC concentrations was substantially slower than that in the liver concentrations of the parent drug (Figure 8, top).

The slow decline in the 3TCSD concentrations in the liver (Figure 8, top) is in agreement with previous ex vivo studies using isolated perfused rat livers (*19*) showing that, once in the liver, the rate of exocytosis of dextrans from the liver cells is negligible. Therefore, the main reason for the decline in the liver concentrations of the conjugate is its elimination by the liver, which is relatively slow based on the in vitro studies in lysosomes (Figure 6). Nevertheless, in contrast to undetectable concentrations of 3TC in the liver beyond 15 min after the parent drug injection, high concentrations of the conjugate in the liver were associated with a gradual and sustained generation of the parent drug in this tissue (Figure 8).

Other than the liver, the conjugate accumulated to a substantial degree and released 3TC only in the kidneys (Figure 9). The substantial accumulation of the conjugate in the kidneys is consistent with the M_w dependency of the renal excretion of the carrier dextrans in rats (*22*). Whereas a significant portion of the dose of dextrans with M_w values of 4 and 20 kDa was excreted into urine, renal excretion of dextrans with M_w values of 70 and 150 kDa was negligible. Interestingly, kidneys have been suggested as an extrahepatic site for virus replication in different models of HBV infection (*55, 56*). Therefore, accumulation of the conjugate and release of 3TC in this organ, in addition to that in the liver, may be of potential therapeutic benefit in chronic HBV infection.

The tissue exposure to 3TC after the administrations of the equivalent doses of the conjugate and the parent drug is the most relevant parameter in terms of targeting index. The ratios of 3TC AUCs after the conjugate and parent drug administration were 2.41 for the liver and 0.721 for the kidneys (see Results). These data clearly show that the conjugation of 3TC to dextran only increased the targeting of the drug to the liver. The significantly higher accumulation of 3TC in the liver is in conformity with the hypothesis of the study; i.e., conjugation of 3TC with dextran allows preferential accumulation of the drug in the liver.

Although our conjugate released both 3TC and 3TCS in vitro in buffers (Figures 3 and 4) and rat blood (Figure 5), only 3TC was observed in biological samples after in vivo administration of the conjugate (Figures 8 and 9). This suggests rapid conversion of any released 3TCS to 3TC in vivo. Our previous work on a methylprednisolone succinate–dextran conjugate (*30*) also showed similar results in that no measurable concentrations of methylprednisolone succinate were found in biological samples after the administration of the conjugate to rats. The rapid conversion of 3TCS to 3TC in vivo is advantageous because 3TCS is not expected to have any biological effects by itself. This is due to the fact that to be effective, 3TC should undergo stepwise phosphorylation at the 5′-position to monophosphate, diphosphate, and triphosphate forms before 5′-triphosphate 3TC is incorporated into the viral DNA (*57*). Therefore, 3TCS, which has a succinate moiety at the 5′-position (Scheme 1, **6**), cannot be converted to the active 5′-triphosphate 3TC without first being converted to 3TC.

In conclusion, a method is presented for the synthesis of a conjugate of native dextran with the antiviral drug 3TC using a succinate linker. Additionally, validated size-exclusion and reversed-phase assays are developed for the determination of purity, in vitro release characteristics, and in vivo disposition of 3TCSD. By use of these methods, the parent conjugate and its degradation products, 3TC and 3TCS, may be quantitated in nonbiological and biological samples. In vitro studies indicate evidence of lysosomal degradation and relative stability of the conjugate in buffers and blood. Additionally, in vivo studies after the administration of the conjugate or the parent drug to rats suggest that the conjugation increases the delivery of the drug to the liver, resulting in higher exposure of the liver to the regenerated antiviral drug.

Received June 6, 2007; Revised Manuscript Received July 19, 2007

The equilibrium binding constants and stoichiometries between PEGylated biotins and avidin have been studied for a range of PEGylated biotin molecular weights. These studies show that as the molecular weight of PEG (polyethylene glycol) increases over the range 588, 3400, and 5000 g/mol, the equilibrium dissociation constants of PEGylated biotins with avidin increase to $\sim 10^{-8}$ M compared with 10^{-15} M for the biotin–avidin complex. The stoichiometries of PEGylated biotins with avidin are 4:1 for 588 and 3400 g/mol PEG and 1:1 for 5000 g/mol PEG. The data demonstrate that the equilibrium binding constant and the stoichiometry of the avidin–biotin–PEG complex system can be adjusted by the length of PEG chains. This approach may be used with PEGylated biotin analogues for pretargeting in drug delivery, such as a biotin-PEGylated enzyme for converting an inactive prodrug into a cytotoxin. When a PEG chain is chosen as an appropriate spacer, the length of the PEG chain must be considered because PEG can block the binding sites on avidin.

INTRODUCTION

We have attempted to modify therapeutic proteins with PEG (polyethylene glycol) and deliver the PEGylated proteins to tumor tissues through the enhanced permeability and retention (EPR) effect (*1*). The EPR effect results in the selective sequestration of the therapeutic proteins in tumors. After administration of prodrugs, the therapeutic proteins can convert the prodrugs into toxic forms that kill tumor cells. The efficacy of this process depends on optimizing the delivery of the therapeutic proteins to the tumor while eliminating the proteins from the plasma before administration of the prodrug. The enhancement of the plasma half-life of a PEGylated protein is an important prerequisite for EPR targeting tumor tissues and the size of a PEGylated protein is a crucial factor to keep the PEGylated protein circulating in the plasma. It is generally recommended that the size of a therapeutic protein should be larger than the glomerular filtration threshold in order to avoid being cleared too quickly by the renal system (*2*). We believe that an ideal avidin–biotin–PEG–enzyme complex has a molecular weight higher than the glomerular filtration threshold and can increase the EPR tumor targeting. At the same time, this complex must dissociate into avidin and biotin–PEG–CPA (CPA, carboxypeptidase A) in the circulation system so that it can be cleared by the renal system before administration of the prodrug. Once the glomerular filtration threshold is reached, the half-life of the avidin–biotin–PEG–CPA complex in the plasma is primarily dependent on the dissociation kinetics of the complex that allows it to be removed by the renal system. The half-life of the avidin–biotin–PEG–CPA complex must be sufficiently long for significant tumor accumulation but short enough to allow the prodrug administration.

The avidin–biotin technology has been an essential tool in modern bioscience (*3*). The unusually strong interaction of avidin and biotin is often the basis for pretargeting strategies in cancer treatments. For example, avidin or streptavidin has been employed as a bridge between a biotinylated target protein and a biotinyl anticancer reagent (*4–7*). However, the binding between avidin and biotin is so strong that the unmodified avidin–biotin system has a dissociation half-life of ~200 days, a period that is too long to have any potential for our enzyme delivering strategy. The avidin–biotin system has to be modified to reduce the affinity. For this goal we chose biotinylated PEGs, which not only form a complex with avidin with a reduced affinity but also protects the enzyme during delivery (*8*, *9*). Before the synthesis and characterization of the complete avidin–biotin–PEG–enzyme complex, this study examines the intermolecular interaction between avidin and PEGylated biotin as a function of the PEG molecular weight. The work focuses on three areas. (1) One area is affinity. How does the length of PEG chain affect the affinity of biotinylated PEG for avidin? (2) Another area is stoichiometry. Avidin has four binding sites for biotin with a stoichiometry of 1:4 of avidin/biotin. It was reported that PEGylated biotin has a lower affinity for avidin than biotin (*10*), but it is important to learn whether a PEG chain blocks the biotin terminus from binding with avidin/streptavidin and reduces the effective stoichiometry of the complex. (3) Does a long PEG chain envelop avidin in the complex or is the PEGylated biotin preferentially excluded from the avidin?

EXPERIMENTAL PROCEDURES

Materials. The reagents used in this study were commercially available analytical or higher grade materials except for PEGylated biotins, which have a purity ranging from 80% to 98%. 2-Iminobiotin and D-biotin were obtained from Sigma (St. Louis, MO). Avidin and Immuno Pure 2-(4′-hydroxyazobenzene)benzoic acid (HABA) were purchased from Pierce (Rockford, IL). Biotin–PEG(3400) and biotin–PEG(5000) were obtained from Nektar (Huntsville, AL). Biotin–PEG(588) was purchased from Quanta BioDesign (Powell, OH). 2,6-Anilinonaphthalene sulfonate (2,6-ANS) was obtained from Molecular Probes (Carlsbad, CA).

Buffer. The PBS buffer was prepared with 8.00 g of NaCl, 0.20 g of KCl, 2.68 g of $Na_2HPO_4 \cdot 7H_2O$ and 0.24 g of KH_2PO_4, diluted to 1 L with Millipore water, pH 7.4. If necessary, the pH was adjusted using NaOH or HCl. The stability of the

avidin–biotin complex is insensitive to the ionic strength unless a very low ionic strength solution (<20 mM) is used (*11*). The ionic strengths of the solutions in the present study were kept higher than 100 mM.

Quantitative Fluorometric Assay for Binding Sites of Avidin with PEGylated Biotin. The stoichiometry of the binding between a PEGylated biotin and avidin was determined by a dye displacement assay, using 2,6-anilinonaphthalene sulfonate (2,6-ANS) as a fluorescent probe (*12*). Without biotin or biotinylated derivatives, the pseudoligand 2,6-ANS weakly binds to all four functional biotin binding sites on avidin, resulting in the strongly fluorescent 2,6-ANS–avidin complex. Introducing D-biotin or a PEGylated biotin displaces the bound 2,6-ANS from avidin, and the fluorescence decreases to the background fluorescence intensity at the equivalence point. The equivalence point defines the stoichiometry of D-biotin or PEGylated biotin per functional avidin tetramer. It provides a more definitive measure of the stoichiometry than measurements that rely on the magnitude of the fluorescence. D-Biotin solution was used as the primary standard to titrate the avidin solution. The avidin solution was then used as the secondary standard to titrate the unknown PEGylated biotin solution. During the titration, the standard D-biotin solution or the PEGylated biotin solution was added in increments into the 2 mL PBS buffer containing 0.5 nmol of avidin and 50 nmol of 2,6-ANS. After each addition, the fluorescence intensity was measured at 408 nm (slit, 10 nm) with excitation at 328 nm (slit, 10 nm) using a Shimadzu RF-1501 spectrofluorophotometer (Shimadzu, Tokyo 101-8448, Japan). A typical systematic titration took ~1.5 h. The PEGylated biotins in this work had molecular weights of 588, 3400, and 5000 g/mol.

Quantitative Absorbance Assay for Equilibrium Binding Constant of PEGylated Biotin with Avidin. The equilibrium association constant of a PEGylated biotin with avidin, K_a, was also determined by a dye displacement assay, using 2-(4′-hydroxyazobenzene)benzoic acid (HABA). HABA has a large association constant ($K_a' = 1.7 \times 10^5\ M^{-1}$) and competes effectively with PEGylated biotin for avidin (*13, 14*). Introduction of a PEGylated biotin to an avidin–HABA complex solution displaces HABA from avidin, and the absorbance at 500 nm (A_{500}) decreases because of the loss of the avidin–HABA complex. The avidin–complex is the only species that absorbs at 500 nm. Uncomplexed HABA has negligible absorption at 500 nm compared with that of the HABA–avidin complex, and its absorbance was removed by using the same concentration of HABA in PBS buffer as the reference during absorbance measurements.

We assumed that the four biotin-binding sites on avidin are equivalent and do not interact (*15*), so the equilibrium association constant K_a represents the binding of an avidin binding site with a PEGylated biotin. The relationship between A_{500} and the concentrations of PEGylated biotin (S), avidin binding site (P), HABA (I), and their complexes (SP and IP) is defined by the following equilibria and mass balance relationships:

$$S + P \leftrightarrow SP \qquad K_a$$

$$I + P \leftrightarrow IP \qquad K_a'$$

We make the following definitions: S_t, total concentration of PEGylated biotin; [*SP*], concentration of avidin (one binding site) PEGylated biotin complex; [*S*], concentration of the uncomplexed PEGylated biotin; I_t, total concentration of HABA; [*IP*], concentration of avidin (one binding site) HABA complex; [*I*], concentration of the uncomplexed HABA; P_t, total concentration of avidin binding site; [*P*], concentration of the uncomplexed avidin binding site.

At thermodynamic equilibrium,

$$K_a = \frac{[SP]}{[S][P]} \tag{1}$$

$$K_a' = \frac{[IP]}{[I][P]} \tag{2}$$

If S_t, P_t, and I_t represent the total concentrations, the mass balances relations are

$$S_t = [SP] + [S] \tag{3}$$

$$P_t = [P] + [SP] + [IP] \tag{4}$$

$$I_t = [IP] + (I) \tag{5}$$

When eqs 1–5 are combined, the following is obtained:

$$P_t = [P] + \frac{K_a[P]S_t}{1 + K_a[P]} + \frac{K_a'[P](I_t)}{1 + K_a'[P]} \tag{6}$$

The indicator ratio Q is defined as

$$Q = \frac{[I]}{[IP]} \tag{7}$$

where I_P is directly proportional to A_{500}. When eqs 6 and 7 are combined, the following equation results:

$$P_t = \frac{1}{QK_a'} + \frac{K_aS_t}{QK_a' + K_a} + \frac{I_t}{1 + Q} \tag{8}$$

We define the R factor as

$$R = P_t - \frac{1}{QK_a'} - \frac{I_t}{1 + Q} \tag{9}$$

Combining eqs 8 and 9, we obtain the following relationship:

$$\frac{S_t}{R} = \frac{K_a'}{K_a}Q + 1$$

In our experiments, the HABA–avidin solution was prepared by adding HABA and avidin into the PBS buffer. It was followed by the introduction of different amounts of PEGylated biotins (or iminobiotin). The concentrations of avidin and PEGylated biotin solutions were determined by the D-biotin standard titration 2,6-ANS method described above using the stoichiometries defined by the fluorescence assay. The HABA was weighed and quantitatively diluted to a known concentration. After the solution was allowed to reach equilibrium over 5 days, A_{500} was monitored for both the HABA–avidin solution and the HABA–avidin–biotin–PEG solutions. The solution with the same concentration of HABA in PBS buffer was used as the reference to subtract the absorbance from HABA in the sample. All values of A_{500} in the present paper are the absorbance average from at least 10 measurements using an Ultrospec 4000 UV/visible Spectro (Amersham Pharmacia Biotech, Piscataway, NJ) instrument.

Surface Plasmon Resonance (SPR) Measurements of the PEGylated Biotin Binding Constant with Streptavidin. SPR measurements were taken using a Biacore 2000 and the Biacore SA gold film sensor chip where streptavidin is immobilized on the gold surface (Biacore, NJ). Avidin sensor chips were not available. The analysis was performed by injecting the analyte solution so that it flowed over the modified surface of a gold film sensor chip from the instrument (*16*). Prior to use, the biosensor SA chips were preconditioned by applying three consecutive 1 min injections of 1.0 M NaCl in 50 mM NaOH with running PBS buffer at 20 μL/min. The flow rate was then adjusted to 10 μL/min, and 10 μL of ~10^{-6} M PEGylated biotin in PBS buffer was injected. SPR measurements were made using standard procedures (*16*).

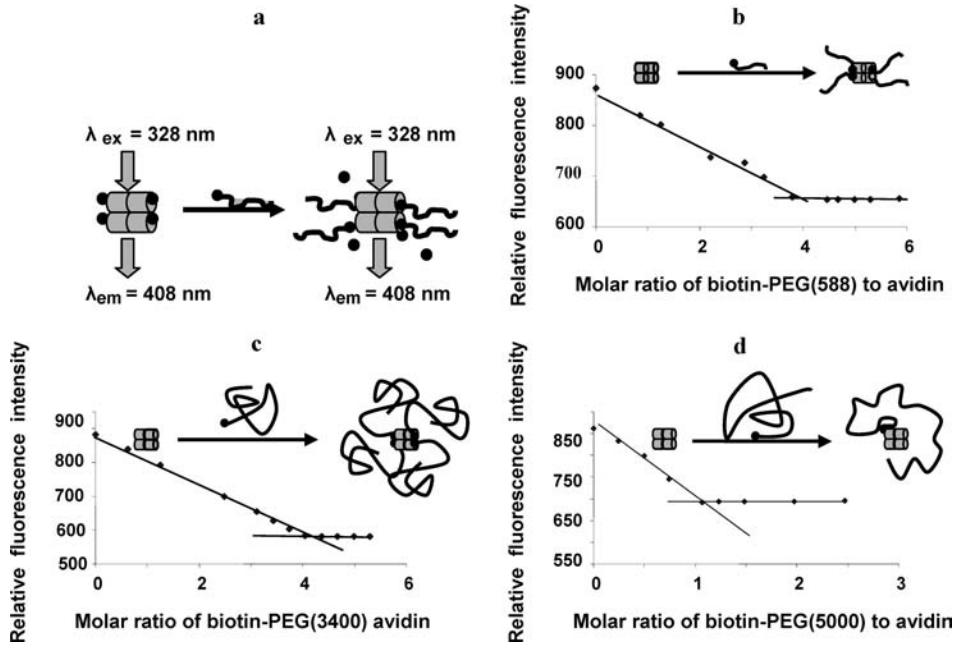

Figure 1. (a) 2,6-ANS fluorometric assay for measuring the avidin–biotin–PEG stoichiometry. The titration curves correspond to (b) biotin–PEG(588), (c) biotin–PEG(3400), and (d) biotin–PEG(5000) with avidin/2,6-ANS in PBS buffer (pH 7.4).

Previous research shows that the binding between avidin and a polymer with a biotin terminus is temperature-dependent (*17*). All the data in the present study were collected at 24 °C.

RESULTS

Stoichiometry of Avidin–Biotin–PEG Complex. Avidin has four binding sites for biotin, two each located at opposite sides of the tetrameric structure of avidin (*18, 19*). Figure 1 shows the 2,6-ANS fluorescence assay that defines the stoichiometry of PEGylated biotin with avidin. If we assume that the PEGylated biotin purity is 100%, the measured stoichiometries of biotin–PEG(588) and biotin–PEG(3400) with avidin are 4.09:1 and 4.56:1, respectively. However, the PEGylated biotin solutions have purities ranging from 80% to 98%. If we assume that the stoichiometry of the PEGylated biotin–avidin complexes is 4:1, the purity of biotin–PEG(588) and biotin–PEG(3400) is 98% and 88%. Similarly, the measured stoichiometry of biotin–PEG(5000) with avidin is 1.11:1, indicating that the stoichiometry is 1:1 and the biotin–PEG(5000) purity is 90%. These results demonstrate that PEGylated biotins of 588 and 3400 g/mol access all four sites on avidin. In contrast, PEGylated biotin of 5000 g/mol accesses only one site on avidin, presumably because of steric hindrance. It appears that at 5000 g/mol, PEGylated biotin bound on avidin sterically hinders the binding to both adjacent and oppositely located biotin binding sites on avidin.

Test Competitive Binding Method Using Small-Molecule Iminobiotin–Avidin System. To test our competitive binding method, we first applied it to the iminobiotin–avidin complex, a small molecule system where the binding between iminobiotin and avidin and its pH dependence has been systematically studied (*20*). PBS buffers with pH 9.0, pH 7.4, and pH 5.4 were chosen for this investigation, and the results are shown in Figure 2. The plot of S_t/R versus Q is linear as our method predicts. The determined K_d values are similar to those obtained by Green using a conventional radiation titration method (*20*).

Equilibrium Binding Constant of Avidin–Biotin–PEG Complex. This competitive binding method was then applied to the systems of avidin with three PEGylated biotins with molecular weights of 588, 3400, and 5000 g/mol, respectively. The analytical measurements of the avidin–biotin–PEG(3400) complex is shown in Table 1, and the determined binding constants are shown in Figure 3. For all three PEGylated biotins, a plot of S_t/R versus Q is linear, and K_a is $\sim 10^8$ M^{-1}, decreasing slightly with molecular weight (Table 2). The K_a of PEGylated biotin with avidin is similar to that of antibody–antigen interactions but much less than the value of biotin. However, the strength of interaction of PEGylated biotin with avidin is sufficient to consider use in pretargeting work.

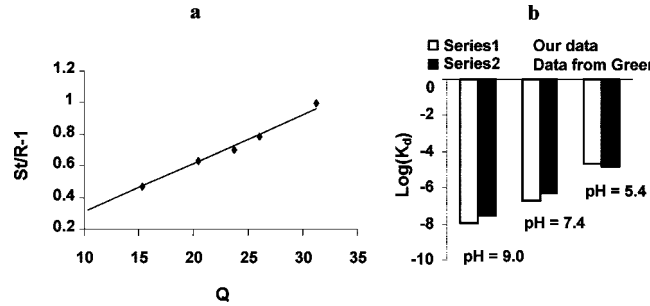

Figure 2. (a) Equilibrium association constant assay for iminobiotin with avidin in a PBS buffer (pH 7.4) and (b) comparison between values thus determined with those obtained by Green using a conventional titration method.

Equilibrium binding constants for the PEGylated biotins with streptavidin were calculated from SPR analysis using an SA sensor chip, and these results are shown in Table 2.

DISCUSSION

Concentration of HABA. To get a measurable change in the absorbance at 500 nm, it is necessary to control the concentration of HABA in order to make the binding of HABA and the binding of biotin–PEG (or iminobiotin) compatible. We controlled the binding ability of two ligands to lie within the range 10^{-2}–10^2 by adjusting the ratio of the concentrations of the two ligands. For example, the concentration of HABA in the biotin–PEG–avidin–HABA system was as high as 1.32×10^{-3} M in order to make HABA binding similar to the binding of biotin–PEG. In contrast, it was 1×10^{-5} M in the iminobiotin–avidin–HABA system with pH 5.42. In both cases, the avidin concentrations were $\sim 10^{-6}$ M.

	Flory radius R_F (Å)	stoichiometry with avidin	K_a (competitive binding) (M^{-1})	K_a (SPR) (M^{-1})
biotin–PEG(588)	17	4:1	1.7×10^{8}	3.0×10^{8}
biotin–PEG(3400)	48	4:1	1.3×10^{8}	2.6×10^{8}
biotin–PEG(5000)	60	1:1	1.1×10^{8}	1.8×10^{8}

[a] R_F, Flory radius, obtained by using $R_F = aN^{0.6}$, with a (the persistence length of PEG) = 3.5 Å and N = number of ethylene glycol monomer unit in polymer (*37*).

Competitive Binding for Avidin and PEGylated Biotin Complex. The method we presented here relies on the changes of the absorption of the avidin–HABA complex when the protein undergoes competitive binding with biotin–PEG. The advantages of this solution-based method are (1) eliminating the complexity and instability from the attached label groups, (2) rapidly screening the binding ability of the biotinylated derivatives with avidin without requiring expensive instrumentation, and (3) approximating real physiological conditions (*21–23*). To accurately estimate the binding equivalency of a competing PEGylated biotin, it is important that equilibrium is achieved for both competing ligands. The time required to achieve equilibrium binding is a function of the dissociation rate constant of the slower dissociating ligand. Since PEGylated biotin has a higher affinity for avidin than HABA, we assumed that an equilibration time equal to 5 times the half-life of its dissociation is adequate. Gruber reported that the half-life time of 1:3 complex is 10 h for avidin–biotin–PEG(800 and 1900) conjugate complexes (*10*). In our case, full binding of avidin with either HABA or biotin–PEG only resulted in the 1:4 complex, which dissociates more quickly than the 1:3 complex. Considering the stability of avidin (*24*) and the weaker steric blocking effects of HABA compared with PEG, we chose a 5 day equilibration period. This result is reinforced because the same results were observed for a 3 day equilibration period, so it is clear that equilibrium was reached.

Avidin has four binding sites for biotin. We assumed that the four biotin-binding sites on an avidin are almost equivalent or do not interact for the avidin–biotin–PEG(3400) or biotin–PEG(588) complexes (*10*). This assumption is based on the values of $(S_t/R - 1)/Q$ in Table 1, which is constant around 1.35×10^{-3} against the molar ratio of biotin–PEG(3400)/avidin-binding-site of 0.076–1.22 (*25*). Simulations show that differences in the binding constants for the 1:1, 1:2, 1:3, and 1:4 avidin–biotin–PEG complexes change the shape of the curve in Figure 3 and the $(S_t/R - 1)/Q$ values are no longer constant. For the avidin–biotin–PEG(5000) complex, the stoichiometry is defined and there is only a single equilibrium binding constant corresponding to its 1:1 avidin complex.

The Biacore surface plasmon resonance (SPR) based biosensor is used extensively to measure the binding constants for macromolecular interactions (*26, 27*). To check our solution-based competitive binding measurements, we attempted to obtain the equilibrium binding constants of the avidin–biotin–PEG complexes on a Biacore 2000. Since avidin chips were not available through Biacore, we used the SA sensor chip, where streptavidin (SA) is immobilized on the surface. Like avidin, streptavidin also has a high affinity with biotin ($K_d = 10^{-14}$ M) that makes it difficult to regenerate the SA chip surface (*3*). Therefore, our chips were used once, and we have only a single SPR value for K_a. The binding constants determined from the SPR Biacore are similar to those determined by the solution-based competitive binding method (see Table 2). Except for the variation between avidin and streptavidin, this difference also reflects a variety of potential artifacts in surface-based measurements that may create differences between SPR bio-

sensor-based and solution-based measurements (*28, 29*). The data from our solution-based method have been used for further study.

Effects of PEG on Binding Sites of Avidin. The use of PEG as a spacer has been reported to create a high affinity of biotin derivatives with avidin because PEG reduces the steric interaction of all interconnected elements and relieves any nonspecific binding of attached functional groups. More importantly, it is hypothesized that any PEG can be used and the longer PEG chains are advantageous if steric hindrance is not reduced by 7–27 atom spacers (*30–33*). Beyond these broad considerations, it is still not clear whether using the PEG chain as a spacer would block the biotin terminus from binding to avidin/streptavidin. The decreased affinity of PEGylated biotin with avidin in the present study is ascribed to steric hindrance because the bound PEG chain prevents a close approach of biotin to the binding sites of avidin. Nevertheless, the $\sim 10^8$ M^{-1} affinity is still strong enough for a PEG to function as an effective spacer or linker. However, for applications where two binding sites are required, the 1:1 stoichiometry of the avidin–biotin–PEG(5000) complex shows that the PEG(5000) chain is not an effective spacer, since the PEG(5000) chain can block the biotin binding sites on avidin. This blocking may occur because the secondary biotin–PEG(5000) cannot bind an avidin molecule firmly enough to displace 2,6-ANS during the titration. However, biotin–PEG(3400) binds all four sites on avidin and indicates that the subsequent equilibrium association constant of PEGylated biotin is much higher than that of 2,6-ANS (about 10^3 M^{-1}) (*34*). Although PEG–PEG repulsion could allow the exploitation of only one site per pair at opposite sides of the tetrameric structure of avidin, the result from the 1:1 stoichiometry of the avidin–biotin–PEG(5000) complex demonstrates that at 5000 g/mol, PEGylated biotin hinders the binding to not only adjacent but also oppositely located biotin binding sites on avidin. It seems appropriate to speculate that a bound and heavily hydrated PEG chain can surround the avidin and effectively block all other binding sites. If so, the lengths of PEG chains play an important role in such blocking (*35, 36*). The Flory radius of PEG in the bulk solution indicates that 588, 3400, and 5000 Da PEGs occupy spheres with radius of 17, 48, and 60 Å, respectively (*37*), while avidin has dimensions of approximately 56 Å × 50 Å × 40 Å (*38*). Our study shows that biotin–PEG(3400) and biotin–PEG(588) bind to avidin with the same 4:1 ratio as D-biotin. Biotin–NH–PEG1900–$NH_3^+Cl^-$ and biotin–PEG1900–PDP also bind avidin with a 4:1 stoichiometry (*19*). However, in the case of biotin–PEG(5000), even with the preferential exclusion between PEG and avidin (*39*), biotin–PEG(5000) can quickly envelop the avidin after first binding by the biotin terminus and can block further binding of biotin–PEG(5000) by PEG–PEG steric repulsion. Further study on the stoichiometry of avidin and PEGylated biotin with molecular weights varying from 3400 to 5000 Da may lead to a PEG chain that allows the formation of 1:2 avidin–biotin–PEG complex as well.

CONCLUSIONS

The solution-based competitive binding method was successfully applied to the HABA–avidin–biotin–PEG system and used to measure the equilibrium binding constant of PEGylated biotin with avidin. The equilibrium association constants of PEGylated biotin (588, 3400, and 5000 g/mol) are on the order of 10^8 M^{-1} and vary slightly with molecular weight of PEG. The stoichiometries of PEGylated biotins with avidin are 4:1 for 588 and 3400 g/mol PEG and 1:1 for 5000 g/mol PEG. The results demonstrate that the equilibrium binding constant and the stoichiometry of the avidin–biotin–PEG complex system can be adjusted by varying the lengths of PEG chains. Another essential point in the present study is that a long PEG chain could block further binding of biotin-PEGylated derivatives with avidin. On the basis of the binding constant and stoichiometry, the avidin–biotin–PEG complex and their analogues have potential as carriers for pretargeting drug delivery. For example, ref 4 describes how biotin or biotin derivatives can be conjugated with many possible therapeutic molecules, including small molecules, DNA, and larger proteins. We have conjugated bovine carboxypeptidase A (CPA) with biotin–PEG–NHS and obtained a novel and reversible avidin–biotin–PEG–CPA complex system with potential as a therapeutic protein delivery system for solid tumor prodrug targeting (*40*).

ACKNOWLEDGMENT

We thank Dr. McClain for his assistance in the fluorometric assay for the stoichiometry quantitative evaluation and helpful discussion of the paper.

Conjugation to Increase Treatment Volume during Local Therapy: A Case Study with PEGylated Camptothecin

Kraig Haverstick,[†] Alison Fleming,[‡] and W. Mark Saltzman*[,‡]

Department of Chemical and Biomolecular Engineering, Cornell University, and Department of Biomedical Engineering, Yale University. Received June 16, 2007

Controlled release of chemotherapy drugs from polymer implants placed directly at the tumor site is a proven method for treatment of cancers of the brain. Although this method provides high doses of drug at the tumor site, the drug does not penetrate far enough into the brain for optimum treatment in most cases. Rapid drug elimination leads to more than a 10-fold drop in concentration within 2 mm of the implant. Conjugation to water-soluble polymers, such as poly(ethylene glycol) (PEG) or dextran, has the potential to increase drug distribution in the brain. We have recently PEGylated the chemotherapy drug camptothecin and found a large increase in the extent of distribution of camptothecin in the rat brain, but most of the drug in tissue was in the less-active conjugated form. Stability of the conjugation bond, activity of the drug–polymer conjugate, solubility of the conjugate relative to the drug, and molecular weight of the polymer must all be considered in the design of a conjugate to maximize drug distribution. Therefore, to optimize the PEGylated system, we have developed a pharmacokinetic model to determine the relative importance of parameters involved in the distribution of drug–polymer conjugates after release from a polymer implant. Our modeling shows that PEGylation has the potential to increase treatment distances to more than a centimeter, which may be sufficient to prevent the recurrence of human brain tumors.

INTRODUCTION

Drug–polymer conjugation is a promising approach for improving systemic and targeted drug delivery. Systemic delivery of camptothecin, an antitumor, topoisomerase I inhibiting drug, has been enhanced by conjugation to dextran (*1*), poly(2-hydroxypropyl) methacrylamide (*2*, *3*), and poly(ethylene glycol) (*4*). Conjugation extends circulation time in the bloodstream, and additional attachment of protease-specific sequences can target release of the free drug. Recently, we have shown that conjugation of camptothecin to PEG can dramatically improve solubility and penetration through tissue (*5*).

Drug delivery to the brain faces challenges not present for delivery to other parts of the body. The blood–brain barrier limits systemic delivery of most drugs (*6*). Local administration by direct injection or controlled-release implantation overcomes this obstacle, but since diffusion becomes the primary means of distribution in the brain, the drug moves slowly from the initial injection or implantation site (*7*). The treatment volume is limited by rapid drug elimination, primarily through capillaries for small, hydrophobic molecules, relative to the rate of diffusion.

The pharmacokinetics of a number of therapeutic drugs in the brain has been studied with the general result being that rapid elimination quickly produces a steady-state profile, where drug concentration decreases sharply with distance from the implant site: the extent of penetration—or the characteristic distance for the drop in concentration—depends on the rate of diffusion of drug in the brain and the rate of elimination (for a review of this literature, see (*8*)). Diffusion and elimination properties in brain tissue have previously been reported for a variety of compounds, including our recent measurements for camptothecin (*5*). These drugs have low molecular weights (below 500, except for paclitaxel), and are fairly hydrophobic (except sucrose), making them susceptible to rapid elimination through capillaries. The dimensionless coefficient, ϕ, analogous to the Thiele modulus in reaction catalysis (*9*), has been previously defined as

$$\varphi = a\sqrt{\frac{k}{D}} \tag{1}$$

where a is the radius of porous catalyst particles, k is the first-order reaction rate, and D is the rate of diffusion of reactant in the catalyst pores. For low values of ϕ, reactant penetrates throughout the catalyst, and reaction efficiency is high; for high values of ϕ, reactant does not penetrate, and the reaction efficiency is low.

This same coefficient can be used to predict the extent of penetration in the brain; in this case, a is the characteristic implant length, k is the first-order rate of elimination in the brain, and D is the effective diffusion coefficient in the brain (*7*). For most drugs, the value for ϕ is greater than 1 (see (*8*)).

Previous modeling results, which assume the presence of only diffusion and first-order elimination, predict that ϕ values in this range lead to a distribution where the drug does not penetrate very far from the surface of a spherical implant. Figure 1 illustrates the steady-state concentration profile of drug around a spherical implant. As ϕ decreases, drug distribution improves, but for ϕ greater than 1, drug concentrations decrease by an order of magnitude within 2 mm of the implant. To improve the distribution of a particular drug, its ϕ value in the brain must be reduced. Since the rate of diffusion cannot be increased, it is necessary to find a way to slow the rate of drug elimination. This can be accomplished by attachment of a polymer. Another factor working against many drugs is their low solubility in water; conjugation to a water-soluble polymer has an additional advantage, since it can significantly increase the maximum achievable concentration of a poorly soluble drug in the brain.

Although elimination is not solely driven by molecular size, larger molecules tend to be retained in the brain for longer

periods of time. While most drugs have half-lives in the ranges of minutes, larger polymers such as dextran are retained with half-lives of 15 h or more (*10*). Since poly(ethylene glycol) is known for its biocompatibility and its ability to solubilize hydrophobic molecules in water, we believe that PEG–drug conjugates show great potential for improving the brain distribution of drug released from controlled-release polymers.

Since the ultimate goal in improving the distribution of chemotherapy drug is to increase the volume of tissue treated, the potency of the drug must also be considered. The form of the drug is often critical to its potency. When paclitaxel, methotrexate, and doxorubicin were permanently modified with PEG, the toxicity of the conjugates was found to be lower than the toxicity of the free drugs by a factor of 50 to 1000 (*11*). Therefore, as drug–polymer conjugates are evaluated, the toxicity of the conjugate in comparison to the free drug must also be considered in order to determine the relative value of conjugation.

Finally, the time of exposure can be just as important as the level of exposure in the treatment of tumors. A low dose of drug over a long period of time can be more effective than a high dose for a short period for certain kinds of agents. Use of a controlled release implant can provide low levels of chemotherapy drug for periods of weeks or longer. Since conjugation of drug to a polymer will reduce the rate of elimination, residence time in the brain will increase, and dosing with conjugates over a longer time course may be possible.

We have investigated three different types of model drug–polymer systems to compare to a free drug system (Figure 2). In the first case, we looked at release of drug alone as a basis for comparison with conjugates. In the second case, the drug is attached permanently to the diffusable polymer, but the potency of the drug is reduced in conjugated form. In the third case, the drug is coupled by an ester bond, which hydrolyzes under physiological conditions with a half-life of 1 to 3 days. While the drug is attached to the polymer, it is not active. After

hydrolysis, the free drug is released and biologically active. Therefore, we initially implant an inactive species, which travels away from the implant site, becomes hydrolyzed in water, and releases the free drug in its active form. In the final case, the drug–polymer conjugate is active but at a lower level than the free drug, and the bond can be hydrolyzed to release the free drug. Each of these systems has the potential to improve distribution of active drug in the brain; our goal in this present study was to determine essential characteristics of PEGylated camptothecin and to model each of these cases to determine which system would be more effective.

EXPERIMENTAL SECTION

Materials. Carboxymethyl poly(ethylene glycol), molecular weight 3400, was purchased from Shearwater Polymers. 10-hydroxycamptothecin was purchased from NetQem. All other reagents and solvents were acquired from Aldrich Chemical Company.

Methods. *Synthesis of Poly(ethylene glycol)–Camptothecin Conjugates.* These procedures were modified from previously published protocols (*12*), as described completely earlier (*5*). The structures of these conjugates appear in Figure 3, and their physical properties are listed in Table 1.

Determination of Solubility. For CPT, excess CPT was added to a PBS solution (pH 7.4). The container was sealed and placed at 37 °C overnight. The UV absorbance of the solution at 369 nm was measured and compared to a calibration curve for CPT to determine the saturated concentration. A Hitachi U-2001 spectrophotometer was used for all UV measurements. For conjugates, approximately 10 mg of conjugate was weighed in a vial. PBS was added in 10 μL increments until all conjugate was dissolved.

Determination of Hydrolysis Rate. Conjugate was weighed and dissolved at a concentration of 9 mg/L in phosphate-buffered saline at 37 °C. The solution was capped and stored in a 37 °C shaker. At increasing intervals of 1 h to a half-day, a 1 mL sample was taken for HPLC analysis. A Waters 2690 Separation module with photodiode array detector was used with a Zorbax 300SB-CN column. A 10 μL volume was injected into a solvent gradient of 80:0:20 to 40:40:20 (water/acetonitrile/0.5% TFA in water) over 20 min to elute the free camptothecin in 12.9 min. The areas under the absorbance curve at 254 nm, 354 nm, and 369 nm were compared to a calibration curve from injected known concentrations of camptothecin to determine the concentration of free camptothecin in the sample. Concentrations

were plotted versus time and fitted to a first-order curve to determine the hydrolysis rate and initial loading of CPT.

Determination of IC_{50} Values. IC_{50} values were determined for free CPT, PEG3400-Sar-CPT, and PEG3400-Gly CPT using rat 9L glioma cells. Values were based on different exposure times in culture. Experiments were repeated four times for each condition. Conjugates showed activity that was time-delayed by the hydrolysis required to produce active free drug.

Determination of Elimination Rate. Elimination rate was assumed to be first-order. For camptothecin, the elimination rate was determined in rat brains by measuring the total amount of CPT released from a biodegradable polymer implant and remaining in the brain at various time points after implantation. Elimination of PEG4000 and PEG900 has been previously studied in the rat brain (*13*). We have estimated the conjugate elimination rate in a human brain based on these rat data. The overall rate of 1.5×10^{-5} s^{-1} includes 0.2×10^{-5} s^{-1} across the blood–brain barrier and 1.3×10^{-5} s^{-1} from elimination at structural boundaries. Since the length scale of the human brain is ten times that of the rat brain, we estimated conservatively a boundary rate 1/5 the rate in the rat. This gives a total human elimination rate of $(0.2 + 0.26) \times 10^{-5}$ s^{-1} or 0.017 h^{-1}, which we have used in our modeling.

Determination of Effective Diffusion Coefficient. Diffusion coefficients in the brain were calculated empirically using the Wilke–Chang equation (*14*) and multiplying by 0.4 to account for tortuosity in the brain (*7*).Brain diffusion coefficients were also determined experimentally in a previous report (*5*). For CPT, this experimentally determined diffusion coefficient (0.282 mm^2/h) was significantly lower than what we empirically calculated (0.825 mm^2/h) both from Wilke–Chang and from molecules of comparable molecular weights (*15*). Lower-than-expected experimental diffusion coefficients have been reported for other small molecules such as paclitaxel (*16*) and fluorescein (*10*). Experimental PEG3400 conjugate diffusion coefficients (0.14 mm^2/h) in rat brains, assuming an elimination rate of 1.5×10^{-5} s^{-1}, were also found to be lower than expected for PEG based on Wilke–Chang and aqueous experimental values (*17*) (0.18 mm^2/h) for equivalent PEG molecular weight. We have chosen to use the more conservative experimentally determined values.

Model. To predict the effect of different conjugate parameters on distribution of drug in the brain, we have modified a previously established model (*7*) to estimate the treatment volume surrounding a conjugate-loaded polymer implant. This model assumes that drug moves only by simple diffusion and is removed by first-order elimination. Treatment distance and volume will be defined as the brain space, which receives an IC_{50} concentration of chemotherapy drug for 72 h. Treatment distance is measured from the surface of the implant, which is assumed to be stationary and to maintain a constant conjugate concentration. Since drug–polymer conjugates in cases 3 and 4 can be hydrolyzed to release free drug, the model is designed to monitor the distribution of both conjugate and free drug.

For the conjugate, the governing equation in spherical coordinates for distribution after release from a sphere is

$$\frac{\partial C_c}{\partial t} = D_c\left(\frac{\partial^2 C_c}{\partial r^2} + \frac{2}{r}\frac{\partial C_c}{\partial r}\right) - (k_{e,c} + k_h)C_c \qquad (2)$$

and for the free drug, when it is generated only by hydrolysis of the conjugate

$$\frac{\partial C_d}{\partial t} = D_d\left(\frac{\partial^2 C_d}{\partial r^2} + \frac{2}{r}\frac{\partial C_d}{\partial r}\right) + k_h C_c - k_{e,d}C_d \qquad (3)$$

where C_c = concentration of the conjugate; C_d = concentration of the free drug; D_c = effective diffusion coefficient of the conjugate; D_d = effective diffusion coefficient of the drug; $k_{e,c}$ = elimination rate of the conjugate; $k_{e,d}$ = elimination rate of the drug; k_h = hydrolysis rate of the conjugate; t = time; r = radial distance from the center of the implant.

These equations were implemented with the following initial and boundary conditions: When $t = 0$, $C = 0$ for all $r > a$. When $t > 0$, $C \rightarrow 0$ as $r \rightarrow \infty$.

For the conjugate: When $t > 0$, $C = C_0$ at $r = \infty$.

For the free drug: When $t > 0$, $\partial C / \partial r = 0$ at $r = a$ where a is the radius of the implant.

When we are simply releasing free drug or stable drug-polymer conjugate from a polymer, the governing equation is

$$\frac{\partial C_d}{\partial t} = D_d\left(\frac{\partial^2 C_d}{\partial r^2} + \frac{2}{r}\frac{\partial C_d}{\partial r}\right) - k_{e,d}C_d \qquad (4)$$

where the same boundary conditions are applied as for eq 2 for the hydrolyzing conjugate.

The transient solution to eqs 2 and 4 has been obtained and published previously

$$\frac{C}{C_0} = \frac{a}{2r}\left\{\exp\left[-(r-a)\sqrt{\frac{k}{D}}\right]\left[1 - \mathrm{erf}\left(\frac{r-a}{2\sqrt{Dt}} - \sqrt{kt}\right)\right] + \exp\left[(r-a)\sqrt{\frac{k}{D}}\right]\left[1 - \mathrm{erf}\left(\frac{r-a}{2\sqrt{Dt}} + \sqrt{kt}\right)\right]\right\} \qquad (5)$$

where $k = k_{e,c} + k_h$ for the released conjugate and $k = k_{e,d}$ for the released drug (*18*). Therefore, in both of these cases we can easily calculate the distribution of the released material at a given time.

Since eq 3 is coupled to eq 2 by a conjugate concentration term, hydrolyzed drug distribution cannot be determined explicitly. We have used two different approximations to calculate the distribution of drug that has been hydrolyzed from the conjugate. For one approximation, the drug does not diffuse after hydrolysis and goes to steady state. Therefore, eq 3 reduces to

$$\frac{\partial C_d}{\partial t} = k_h C_c - k_{e,d}C_d = 0 \qquad (3a)$$

A second way to simplify eq (3 is to assume that the drug does diffuse and goes rapidly to steady state, or

$$0 = D_d\left(\frac{\partial^2 C_d}{\partial r^2} + \frac{2}{r}\frac{\partial C_d}{\partial r}\right) + k_h C_c - k_{e,d}C_d \qquad (3b)$$

Both approximations simplify calculation of the profile of hydrolyzed drug concentration. Equation 3a greatly overestimates drug concentration close to the implant but slightly underestimates drug concentration far from the site. Equation 3b slightly overestimates drug concentration far from the site. The true transient concentration at the treatment distance should

Table 2. Modeling Values for Determination of Treatment Distances

fall between the treatment distances estimated by eqs 3a and 3b. In practice, we found a minimal difference between calculated treatment distances from eqs 3a and 3b for the model parameters used for CPT and PEG-CPT, and therefore eq 3a was used to give the results presented.

RESULTS

Three PEG-camptothecin conjugates were synthesized as described in the Experimental Section. They differed in the stability of the linkage between the polymer and the 20-hydroxyl group of camptothecin. In a previous report, we provided analysis by MALDI-TOF to confirm the chemical modifications (*5*); those results were verified for all of the preparations used here. Table 1 lists the relevant physical properties in the brain for these three compounds in comparison to camptothecin. Solubilities were measured in phosphate-buffered saline at 37 °C, and the CPT solubility is consistent with a previously reported value of 25 mg/L (*18*). An additional benefit of CPT conjugation is stabilization of the active lactone form to higher pH values (*19*). Conjugate concentrations in Table 1 and future discussions refer to the free drug equivalent concentration of the conjugate. For example, 1 mg/L of conjugate has 1 mg/L of CPT attached to PEG. Diffusion coefficients were determined experimentally for CPT and conjugates and are slightly lower than empirically expected. Hydrolysis rates, elimination rates, and IC_{50} values were determined as described in the Experimental Section.

Modeling incorporated simple diffusion, first-order hydrolysis and elimination, and several constraints on the physical system. A spherical polymer implant 3 mm in diameter was assumed. This is the average size of the implants used in typical experiments. PEGs of molecular weights 2000 and 3400 were modeled with the assumption that PEG 2000 will have the same rate of elimination and solubility as PEG 3400. Our model assumes that release from the implant occurs with a constant concentration maintained at the implant surface. Since a homogenous environment was assumed, the concentration of drug varied only with radial distance from the center of the implant. The treatment area, therefore, was a sphere surrounding the implant site.

Four different systems were modeled. Relevant parameters and variables for modeling of these systems are listed in Table 2. In the first case, unconjugated drug is released. A permanent conjugate with reduced cytotoxicity of the conjugate relative to the drug itself is released in case 2. In case 3, the conjugate is assumed to have no toxicity, and the hydrolysis-released drug has the same properties as the drug itself. Case 4 is identical to case 3, except that the conjugate form has cytotoxicity in the range 50–500 times less than the free drug. Variables for the different cases consisted of the C_0 value, hydrolysis rate (0.05–0.035 h^{-1}), conjugate diffusion coefficient (PEG2000 or PEG3400), and IC_{50} value of the conjugate.

The drug and conjugate profiles at 96 h, with a $C_{0,CPT}$ of 25 and a $C_{0,conj}$ of 500 mg/L, appear in Figure 4. These profiles assume a conjugate diffusion coefficient of 0.14 mm^2/h (PEG3400) and, for case 3 (lines 3a and 3b), a hydrolysis rate of 0.018 h^{-1}. The slope of the CPT (line 1) in the semilog plot is very steep, as the drug is eliminated quickly. Released CPT in Figure 4 (line 3b) was calculated using a numerical solution to eq (3b. Although the concentration of CPT released from conjugate (line 3b) is clearly lower at the implant surface than what can be achieved with CPT alone, drug concentration has a much smaller slope in the semilog plot. With no hydrolysis (line 2), the conjugate can reach higher concentrations farther from the implant, but this is offset by the lower cytotoxicity of the conjugate relative to the free drug. Optimization of treatment becomes a balance of these effects.

For all cases, concentration profiles were computed at 96 h after implantation. At this time, concentration profiles were close to steady-state values, and enough drug was present to maintain C_0 values for at least 72 more hours. "Treatment distances" were determined as the farthest distances from the implant surface at which the concentration at 96 h was above the IC_{50} value. For unconjugated drug, this IC_{50} value was 0.0129 mg/L. For conjugated drug, it was A multiplied by 0.0129 mg/L, where A is the toxicity reduction factor for the conjugated form. When both unconjugated and conjugated forms of the drug were present and active (case 4), they were assumed to have an additive effect toward achieving an IC_{50} concentration.

Samples of treatment distance results for cases 2, 3, and 4 appear in Figures 5, 6, and 7, where C_0 = 500 mg/L for all curves in Figure 7. Treatment distances for case 1 were 0.235, 0.264, 0.281, 0.293, and 0.303 cm for C_0 values of 5, 10, 15, 20, and 25 mg/L, respectively. Concentration profiles, and hence treatment distances, for the first two cases were determined exactly using eq 5. Figure 5 shows that increasing the toxicity

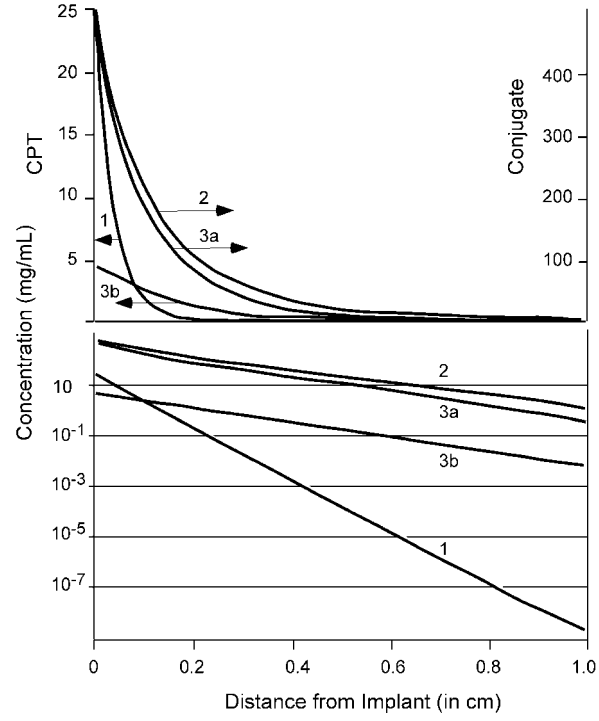

Figure 4. Concentration profiles at 96 h. 1 = CPT (case 1, C_0 = 25 mg/L); 2 = PEG3400═CPT (case 2, C_0 = 500 mg/L); 3a = PEG3400—CPT (case 3/4, C_0 = 500 mg/L); and 3b = CPT released (case 3/4, from PEG3400—CPT). (A) Direct plot. (B) Semilog plot.

of the conjugate, the C_0 concentration, and the effective diffusion coefficient all lead to larger treatment distances for a case 2 conjugate. For cases 3 and 4, concentration profiles of conjugate were determined exactly with eq 5. Equation 3a was used to get drug concentrations for treatment distance calculations for cases 3 and 4. The results of these calculations appear in Figures 6 and 7. Figure 6 illustrates that, as C_0 decreases for a case 3 conjugate, the optimal hydrolysis rate increases from about 0.018 h^{-1} for $C_0 = 500$ to about 0.035 h^{-1} for $C_0 = 50$ mg/L. Finally, in Figure 7, if A is 100 or less, a nearly permanent conjugate gives the largest treatment distance. The optimal hydrolysis rate increases as A increases to 200 and higher.

DISCUSSION

PEG–CPT conjugates were synthesized and characterized as drug–polymer conjugates to determine appropriate parameters for modeling of drug distribution in the human brain. Our goal was to determine the potential advantage of a drug–polymer conjugate over drug alone in terms of distribution from a controlled-release polymer and tumor treatment. This would allow rational design of future conjugates with optimal physical properties for treatment of a cancer site. Although these equations can be applied to other drug conjugate systems, our results are specific for PEG–camptothecin conjugates.

Case 1 serves as a baseline for comparison to conjugate systems. The C_0 value for camptothecin is severely limited by low water solubility, and camptothecin is rapidly eliminated from the brain. If a saturated concentration can be maintained at the implant surface, a treatment distance of 0.3 cm is achieved. Experimentally, C_0 values as high as 20 mg/L have been maintained in a rat brain for several days after implantation. (*5*) Although the IC_{50} value may not be the critical concentration necessary for effective tumor site treatment, we believe it to be a more appropriate choice than the $C_0/10$ value often used, since it does account for the toxicity of the drug. As a result of the high diffusion and elimination rates, free drug approaches a steady-state profile within a matter of minutes.

The two major advantages of the PEG conjugates are a much greater solubility in water than the drug itself and a much slower rate of elimination. Obviously, increasing the C_0 value increases the treatment distance. Additionally, since we assume PEG2000 differs from PEG3400 only in having a larger diffusion coefficient, a PEG2000 system will give a larger treatment distance than an otherwise equivalent PEG3400 system. Finally, a decrease in A, the toxicity reduction factor, always leads to an increase in treatment distance. The most interesting of the variables is the hydrolysis rate of the conjugate, which will show an internal optimum for treatment distance under most of our conditions.

While a conjugate system allows for considerably more design freedom than a drug alone, we still face physical limitations. We assume that PEG2000 stands at the low molecular weight end for conjugate, or else we risk lower conjugate solubility. Although PEG as low as 900 has been shown to have the same elimination rate as PEG4000, (*13*) we expect the solubilizing power, and hence potential C_0, to be reduced. Therefore, diffusivity of the conjugate has an upward bound of $\sim$0.18 mm^2/h. Depending on the drug, some flexibility in the A factor of the conjugate is possible by using different linkages, such as a 10-hydroxy linkage for CPT, but it is unlikely that a factor less than 50 will be achieved. Additionally, variation of the linkage can be used to produce a range of hydrolysis rates. Within the parameter space we investigated, the largest treatment distance was 1.343 cm for a case 2 PEG2000 conjugate with $A = 50$ and $C_0 = 1000$ mg/L. We have found it difficult to determine A experimentally for our conjugates, because the experimental error is greater than the difference we would predict in the cytotoxicity assays between $A = \infty$ and $A = 50$.

The modeling results can be applied to the CPT conjugates that we synthesized, assuming $C_0 = 500$ mg/L and $1/A = 0$. These cases led to treatment distances of 0.817 cm for the sarcosine conjugate, 0.842 cm for the glycine conjugate, and 0.855 cm for the ester conjugate. The ester conjugate had the optimal hydrolysis rate for these conditions. Although these conjugates already show a significant improvement over the 0.3 cm treatment distance of camptothecin alone, we discuss approaches that might increase treatment distances further in the next few paragraphs.

Decreasing the surface concentration, C_0, decreases the treatment distance. The treatment distance relative to that for $C_0 = 1000$ seems to be fairly independent of the other variables, and doubling C_0 from 500 to 1000 increases the treatment distance an average of 14% for case 2 and 12% for cases 3 and 4. We set 500 mg/L as a practical C_0 limit, which should be achievable *in vivo*. Advantages for further increases are tempered with a very high conjugate loading requirement and concentrations that may be difficult to sustain.

Although drug conjugates have a greatly reduced cytotoxicity relative to the native drug, they have been found to be active at concentrations 50 to 1000 times greater than their parent drug. We assumed an initial $1/A$ value of zero, meaning that the conjugate is completely inert. Increasing conjugate activity in our models with A values of 500, 200, 100, and 50 will lead to an increase in treatment distance and will also decrease the optimum hydrolysis rate. We have found that increases in treatment distance with decreasing A are approximately independent of C_0. As the hydrolysis rate increases, the benefit of increasing $1/A$ to 0.02 decreases from 0.31 to 0.075 cm for PEG3400 and from 0.35 to 0.085 cm for PEG2000.

Increasing the rate of diffusion will also increase the treatment distance. This can only be done by decreasing the molecular weight of PEG, which may have implications for the solubility and elimination rate. Decreasing PEG from 3400 to 2000 increases the conjugate diffusion coefficient from 0.14 to 0.18 mm^2/h. This leads to an average increase of 10.9% in the treatment distance for cases 3 and 4 and an average increase of 9.5% for case 2.

Finally, we can control the hydrolysis rate through the conjugation linkage, so that this variable can be adjusted to maximize treatment distance for a given set of conditions. The optimal hydrolysis rate balances the properties of the conjugate with the properties of the released drug. Increasing the cytotoxicity of the conjugate shifts the optimum hydrolysis rate to lower values, as does increasing the implant surface concentration. Optimizing over the range 0–0.035 h^{-1} can increase treatment distance by as much as 0.287 cm. As conjugate toxicity decreases, increasing the C_0 value leads to an improvement in the treatment distance.

On the basis of our modeling results, the PEG3400–CPT conjugate version gives the greatest treatment distance of the conjugates we have synthesized. On the assumption that it is a case 3 conjugate with no cytotoxicity in the conjugated form and a C_0 value of 500 mg/L, this version gives a treatment distance of 0.855 cm. This value is significantly greater than the 0.3 cm that we calculate for release of unconjugated drug. Released conjugate should treat a volume of 4.24 cm^3, which is 11 times the 0.37 cm^3 treated by unconjugated drug. Reducing to PEG2000–CPT improves the treatment distance to 0.950 cm.

Producing an implant that can sustain a C_0 value as high as 500 mg/L requires some special consideration. As an estimate of total conjugate required, a steady-state profile of PEG3400–CPT with $C_0 = 500$ mg/L contains 0.44 mg of conjugate (with 15 wt % CPT/conjugate). Therefore, the rate of loss of conjugate is 0.44 mg $\times$ 0.035 h^{-1}, or 0.0154 mg/h, for 168 h requires 2.59 mg of conjugate. Placing this mass into a 0.15 cm radius pellet at a density of 1.5 g/cm^3 requires a loading of 12.2%. Several controlled-release polymers have been used for implants of this kind including nonbiodegradable EVAc (polyethylene-*co*-vinyl acetate) (*20, 21*) and biodegradable p(CPP:SA) (poly(1,3-bis(p-carboxyphenoxy)propane/sebacic acid)). (*16, 22*) On the basis of our experience, both EVAc and p(CPP:SA) could be loaded at 15% (or more) and could be designed to maintain such a high C_0. Since PEG–CPT conjugate could be thought of as a "controlled release" device on its own, another possibility would be to create an implant of pure conjugate. A final consideration would be to include free CPT along with conjugate in the loaded implant. This free CPT should be more soluble in the presence of conjugate and may slow hydrolysis when present in high concentrations near the implant.

These calculations help in the interpretation of our previous experimental results with conjugate penetration in the brain (*5*) and also point toward approaches that might improve conjugate design for this application. We note that this study has limitations: in particular, we have made assumptions about the rate of elimination of PEG from the brain and about the relationship between conjugate diffusion and PEG diffusion that need to be verified. In addition, we note that it is difficult to estimate actual values for the parameter A.

CONCLUSIONS

Low solubility and rapid elimination in the brain prevent most drugs from diffusing more than a few millimeters away from an implant site. Poly(ethylene glycol)–drug conjugates have much longer residence times and higher solubilities than their free drug counterparts. For the chemotherapy drug camptothecin, these improvements allow greater distribution of the drug in the brain. This translates into a greater volume of tissue receiving a therapeutic dose of drug and, therefore, a greater likelihood of prevention of tumor recurrence. Specifically, if a therapeutic dose is defined as the IC_{50} concentration of 0.0129 mg/L for 72 h, we predict a 3 mm diameter PEG3400–CPT implant to treat 4.24 cm^3, more than 11 times the volume treated by a CPT implant of the same diameter. This increase in treatment volume may be sufficient to improve the clinical effectiveness of controlled-release implants on human brain tumors.

A Radioiodinated MIBG–Octreotate Conjugate Exhibiting Enhanced Uptake and Retention in SSTR2-Expressing Tumor Cells

Ganesan Vaidyanathan,*[,†] Donna J. Affleck,[†] Joseph Norman,[†] Susan O'Dorisio,[‡] and Michael R. Zalutsky[†]

Department of Radiology, Duke University Medical Center, Durham, North Carolina, and Division of Pediatric Hematology/Oncology, University of Iowa, Iowa City, Iowa. Received June 28, 2007; Revised Manuscript Received September 11, 2007

Several neuroendocrine tumors are known to express both the somatostatin receptor subtype 2 (SSTR2) and the norepinephrine transporter (NET), and radiopharmaceuticals directed toward both these targets such as MIBG and octreotide derivatives are routinely used in the clinic. To investigate the possibility of targeting both NET and SSTR2 conjointly, a conjugate of radioiodinated MIBG and octreotate was synthesized. Attempts to synthesize the radioiodinated target compound (MIBG-octreotate; [^{131}I]**12a**) from a tin precursor were futile; however, it could be accomplished from a bromo precursor by exchange radioiodination in 3–36% ($n = 10$) radiochemical yields. The total uptake of [^{131}I]**12a** in SK-N-SH human neuroblastoma cells transfected to express SSTR2 (SK-N-SHsst2) was similar to that for [^{125}I]MIBG at all time points (34.9 ± 2.4% vs 43.8 ± 1.2% at 4 h; $p < 0.05$), while it was substantially lower (5.4 ± 0.3% vs 35.9 ± 1.2%) in the SH-SY5Y cell line, a subclone of SK-N-SH line that is known to express SSTR2. The NET blocker desipramine reduced the uptake of [^{131}I]**12a** only to a small extent, further suggesting a limited role of NET in its binding and accumulation. Uptake of [^{131}I]**12a** in SK-N-SHsst2 cells was 8–10-fold higher ($p < 0.05$) than that of [^{125}I]I-Gluc-TOCA, an octreotide analogue, at all time points over a 4 h period and was reduced to about 20% by 10 μM octreotide demonstrating that the uptake of [^{131}I]**12a** in this cell line is predominantly mediated by SSTR2. The intracellularly trapped radioactivity in SK-N-SHsst2 cells was substantially higher for [^{131}I]**12a** compared to that for [^{125}I]OIBG-octreotate, an isomeric congener of **12a**. Because MIBG has more specific NET-mediated uptake than OIBG, this suggests at least a partial role for NET-mediated uptake of [^{131}I]**12a** in this cell line. While further refinement in the structure of the conjugate—probably interposition of a flexible and/or cleavable linker between the MIBG and octreotate moieties—may be necessary to make it a substrate/ligand for both NET and SSTR2, this conjugate is demonstrated to be much superior than I-Gluc-TOCA with respect to the uptake in SSTR2-expressing cells.

INTRODUCTION

Neuroblastoma (NB) and other neuroendocrine tumors accumulate *meta*-iodobenzylguanidine (MIBG), an analogue of the neurotransmitter norepinephrine, via the norepinephrine transporter (NET), which is also known as the uptake-1 pump (*1, 2*). MIBG, labeled with the β-particle-emitter ^{131}I, has been used extensively in the treatment of NB (*3*). However, responses were not of long duration even when targeted [^{131}I]MIBG therapy was combined with other modalities (*4*). Many neuroblastomas and other neuroendocrine tumors express somatostatin receptors as well (*5–7*), and a number of radiolabeled derivatives of octreotide, an octapeptide ligand for somatostatin receptor subtype 2, have been developed for diagnosis and targeted therapy of these tumors (*8–11*). The complementary role of [*I]MIBG and ^{111}In-pentetreotide in the imaging of neuroendocrine tumors has been demonstrated (*12–14*). For imaging, while tumor foci of certain cancers have been visualized by both labeled radiopharmaceuticals, there are cases in which one of these radiopharmaceuticals and not the other is sequestered in the tumors. In general, ^{111}In-labeled octreotide was found to be more sensitive; however, it was also less selective (*15–20*). For therapy, the combined use of [^{131}I]MIBG and ^{90}Y-labeled octreotide derivatives has been recommended (*12, 21, 22*).

We hypothesized that a radiopharmaceutical derived by combining the structural elements of MIBG and octreotide may have an additive, if not synergistic, effect with respect to uptake and retention in a neuroendocrine tumor that expressed both somatostatin receptor and NET; in addition, it could limit false negative lesion detection because the hybrid radiopharmaceutical might be taken up by tumors via either mechanism. Another impetus for developing such a reagent is that it could overcome the fast washout of labeled MIBG from tumors, presumably also mediated by NET, that likely contributes to the mismatch between [^{131}I]MIBG tumor pharmacokinetics and the 8.1-day half-life of ^{131}I. Our working hypothesis was that a chimeric molecule containing both SSTR2 and NET binding elements could have higher tumor retention. Octreotide derivatives undergo endocytosis after receptor binding, translocating the receptor–ligand complex to lysosomes wherein they undergo extensive catabolism (*23*) with polar and charged catabolites generally being retained in lysosomes. Attempts have been made to exploit this property of octreotide derivatives in order to increase the tumor specificity and intracellular bioavailability of various pharmaceuticals by conjugating them with octreotide analogues. For example, oligonucleotides (*24*), peptide nucleic acids (*25*), as well as the chemotherapeutic agents doxorubicin (*26*) and paclitaxel (*27*) have been conjugated to somatostatin analogues for such a purpose. Recently, hybrid molecules derived by covalent conjugation of an octreotate (Thr-ol at the C-terminus in octreotide replaced with Thr; Chart 1) derivative and the $\alpha_v\beta_3$-targeting RGD peptide also have been described (*28, 29*). In addition, simultaneous targeting of multiple receptors has become an emerging paradigm in drug discovery (*30–35*).

Chart 1. Chemical Structures of Octreotate, Iodo-Gluc-TOCA, MIBG-Octreotate, MBBG-Octreotate, and OIBG-Octreotate

Herein, we describe the synthesis of a conjugate of [^{131}I]MIBG and octreotate and its evaluation in human tumor cell lines expressing both SSTR2 and NET. This chimeric conjugate demonstrated superior targeting to SSTR2 receptors compared to one of the best-known SSTR2 targeting peptides; however, unexpectedly, NET-mediated binding of the conjugate was only moderate.

EXPERIMENTAL PROCEDURES

General. All chemicals were purchased from Sigma-Aldrich unless otherwise noted. Sodium [^{125}I]iodide and sodium [^{131}I]iodide with specific activities of 2200 Ci/mmol and 1200 Ci/mmol, respectively, were obtained from Perkin Elmer Life and Analytical Sciences (Boston, MA). N^{ϵ}-Dde-Lys^5-octreotate (**9**), *N*-(4-guanidinomethyl-3-[^{125}I]iodobenzoyl)-D-Phe^1-octreotate ([^{131}I]OIBG-octreotate), and [*I]Iodo-Gluc-TOCA were synthesized as reported earlier (*36*). No-carrier-added [*I]MIBG was synthesized from a silicon precursor (*37*).

Aluminum-backed sheets (Silica gel 60 F254) were used for analytical TLC, and normal-phase column chromatography was performed using silica gel 60, both obtained from EM Science (Gibbstown, NJ). Preparative thick-layer chromatography was performed using 20 × 20 cm, 1000 μm plates (Whatman, Clifton, NJ). Before applying the sample, the plates were run in ethyl acetate to remove any adsorbed impurities. Radio-TLC was initially analyzed using a System 200 Imaging Scanner (BioScan, Washington, DC); sheets were then cut into strips and counted using an automated gamma counter (LKB 1282, Wallac, Finland). High-pressure liquid chromatography was performed using a Beckman System Gold HPLC equipped with a model 126 programmable solvent module, a model 168 diode array detector, a model 170 radioisotope detector, and a model 406 analogue interface module. Reversed-phase chromatography utilized a Waters XTerra C18 column (4.6 × 250 mm, 5 μ) and a Waters XTerra C18 column (19 × 50 mm) for analytical and semipreparative runs, respectively. Proton NMR spectra were obtained on a Varian Mercury 300 spectrometer. Chemical shifts are reported in δ units; solvent peaks are referenced appropriately. Mass spectra were obtained on a JEOL SX-102 high-resolution mass spectrometer (FAB, EI, and GC-MS), an Applied Biosystems Voyager DE Pro (MALDI), or an Agilent 1100 LC/MSD Trap SL (electrospray). High-resolution mass spectra were obtained using a JEOL SX-102 high-resolution mass spectrometer.

Cells and Culture Conditions. SH-SY5Y (*38*), a thrice-cloned subline of the NET-expressing human neuroblastoma cells SK-N-SH (*39*), was obtained from American type Culture Collection (Manassas, VA). Evidence for the presence of somatostatin receptors in the SH-SY5Y cell line has been reported (*40–42*). The incubation medium for these cells was made by mixing 500 mL of RPMI 1640 (GIBCO), 55 mL of fetal calf serum, and 2.7 mL of penicillin-G/streptomycin (10 000 U of penicillin and 10 000 μg of streptomycin in 1 mL of 0.85% saline). SK-N-SH cells stably transfected with SSTR2 (SK-N-SHsst2) were derived as described previously (*5*). The mRNA level in these cells, relative to that in parent SK-N-SH line, was 28.3 ± 5.8 as determined by quantitative RT-PCR (*5*). A medium consisting of 500 mL MEM, 15% FBS, 12 mL penicillin/streptomycin (200 U/mL penicillin and 200 μg/mL streptomycin), 6 mL nonessential amino acids, 6 mL L-glutamine, and 300 mg G418 was used for the culturing these cells. The cells were grown at 37 °C in a humidified incubator containing 5% CO_2. Cell viability was evaluated prior to each experiment by trypan blue dye exclusion (*43*), and was 95–98% for all studies.

2-Iodo-4-methylbenzoic Acid (1a). A solution of sodium nitrite (747 mg; 10.8 mmol) in 6 mL of water was added to a suspension of 2-amino-3-methylbenzoic acid [(Ryan Scientific, Isle of Palms, SC, or Maybridge Building Blocks, Cornwall, UK) 1.51 g; 10 mmol] in cold dilute sulfuric acid (2 mL conc H_2SO_4, 12 g ice, and 18 mL water) at 2–3 °C over a period of 10 min. The mixture was stirred for 2 h at 2–3 °C, and a solution of KI (2.28 g; 10.8 mmol) in 5 mL of water was then added over a period of 15 min while maintaining the temperature at 2–3 °C. The mixture was subsequently heated in an oil bath maintained at 60 °C for 1 h. The reaction mixture was partitioned between ethyl acetate and water, and the aqueous layer was washed twice with ethyl acetate. The combined ethyl acetate layer was washed twice with saturated sodium thiosulfate solution and once with brine. The dried ethyl acetate layer was

evaporated, and the crude product was chromatographed on silica gel using 70:30:0.1 ethyl acetate/hexanes/acetic acid to yield 1.5 g solid (57%). It was further purified by precipitation from an ethyl acetate solution by hexanes: mp 134–136 °C [lit. (*44*) mp 128–130 °C]. The melting point was similar to that of a commercial sample (Maybridge Building Blocks, Cornwall, UK)—individually and mixed.

2-(Trimethylsilyl)ethyl 2-iodo-4-methylbenzoate (2a). Polymer-bound DCC [(Argonaut Technologies, Inc., San Carlos, CA, now a division of Biotage, Uppsala, Sweden), 5.0 g; 5 mmol] was added to a stirred solution of **1a** (930 mg, 3.6 mmol), DMAP (45 mg; 0.4 mmol), and trimethylsilylethanol (570 mg; 4.8 mmol) in 35 mL of dry ethyl acetate. The heterogeneous mixture was stirred at 20 °C under argon atmosphere for 3–4 h. The polymer was filtered and washed with ethyl acetate, which was evaporated from the combined filtrate using a rotary evaporator under aspirator vacuum. The residual oil was chromatographed using a gradient of 0–5% ethyl acetate/hexanes to yield 1.0 g (77%) of **2a** as an oil: ^{1}H NMR ($CDCl_3$) 0.07 (s, 9H), 1.15 (m, 2H), 2.33 (s, 3H), 4.41 (m, 2H), 7.18 (ddd, 1H), 7.72 (dd, 1H), 7.83 (dd, 1H). MS (EI^+), *m*/*z*: 362 (M^+), 245. HRMS (EI^+) Calcd for $C_{13}H_{19}IO_2Si$ (M^+): 362.0199. Found: 362.0197 ± 0.0004 ($n = 2$).

2-(Trimethylsilyl)ethyl 2-bromo-4-methylbenzoate (2b). The title compound was synthesized from 2-bromo-4-methylbenzoic acid similar to **2a** above but using DCC (not polymer-supported). Starting from 2.15 g (10 mmol) of 2-bromo-4-methylbenzoic acid, 2.5 g (80%) of **2b** was obtained as an oil: ^{1}H NMR ($CDCl_3$) 0.07 (s, 9H), 1.15 (m, 2H), 2.36 (s, 3H), 4.42 (m, 2H), 7.15 (ddd, 1H), 7.49 (m, 1H), 7.71 (dd, 1H). MS (GC-EI^+), *m*/*z*: 313 and 315 (M^+), 299 and 301 $(M - CH_3)^+$, 271 and 273 (100%), 227 and 229, 197 and 199 ($M - OCH_2CH_2SiMe_3$).

2-(Trimethylsilyl)ethyl 4-Bromomethyl-2-iodobenzoate (3a). A mixture of **2a** (1.02 g; 2.82 mmol), *N*-bromosuccinimide (473 mg; 2.66 mmol), 1,1′-azo-biscyclohexanenitrile, and 1,2-dichloroethane (DCE; 25 mL) was heated at reflux under an incandescent lamp for 3 h. DCE was evaporated from the cooled mixture, and the residue was partitioned between ethyl acetate and water. The aqueous layer was extracted twice with ethyl acetate, and the pooled ethyl acetate solution was washed with sodium thiosulfate solution and dried. The ethyl acetate was evaporated, and the residual oil was chromatographed on silica gel using a gradient of 0–3% ethyl acetate in hexanes to yield 541 mg (44%) of an oil: ^{1}H NMR ($CDCl_3$) 0.08 (s, 9H), 1.15 (m, 2H), 4.39 (s, 2H), 4.43 (m, 2H), 7.42 (ddd, 1H), 7.76 (dd, 1H), 8.00 (ddd, 1H). MS (EI^+), *m*/*z*: 440 and 442 (M^+), 412 and 414, 397 and 399 (100%), 361, 334. HRMS (EI^+) Calcd for $C_{13}H_{17}BrIO_2Si$ $(M - H)^+$: 438.9226. Found: 438.9231. This compound was contaminated with less than 10% of the dibromo derivative (based on NMR data) and was used as such for the synthesis of **4a**.

2-(Trimethylsilyl)ethyl 2-Bromo-4-bromomethylbenzoate (3b). This compound was synthesized from **2b** following the procedure described for the preparation of **3a**. Starting from 670 mg (2.13 mmol) of **2b**, 526 mg (63%) of **3b** was obtained as an oil: ^{1}H NMR ($CDCl_3$) 0.08 (s, 9H), 1.15 (m, 2H), 4.42 (s, 2H), 4.43 (m, 2H), 7.37 (ddd, 1H), 7.68 (ddd, 1H), 7.74 (dd, 1H).

2-(Trimethylsilyl)ethyl 4-[N^1,N^2-Bis-(*tert*-butyloxycarbonyl)guanidinomethyl]-2-iodobenzoate (4a). N^1,N^2-bis-(*tert*-butyloxycarbonyl)guanidine (412 mg; 1.6 mmol) was added to a stirred suspension of sodium hydride (60% dispersion in mineral oil) (62.5 mg; 1.6 mmol) in 6 mL of dry DMF under argon and the mixture stirred at room temperature for 5 min, whereby a homogenous solution was obtained. A solution of **3a** (504 mg; 1.14 mmol actual) in 2.3 mL of DMF was added to the above solution of the guanidine derivative and the reaction mixture stirred at room temperature for 10–15 min The reaction mixture was partitioned between water and ethyl acetate and the aqueous layer extracted a couple of times with ethyl acetate. The pooled ethyl acetate solution was washed once with brine, dried, and evaporated. The crude mixture was chromatographed on silica gel with a gradient of 5–20% ethyl acetate in hexanes to yield 591 mg (83%) of a white solid: m.p. 103–105 °C. ^{1}H NMR ($CDCl_3$) 0.08 (s, 9H), 1.15 (m, 2H), 1.38 (s, 9H), 1.48 (s, 9H), 4.43 (m, 2H), 5.17 (s, 2H), 7.32 (dd, 1H), 7.75 (dd, 1H), 7.91 (dd, 1H). MS (FAB^+), *m*/*z*: 620 $(M + H)^+$, 564, 508, 436, and 392. HRMS (FAB^+) Calcd for $C_{24}H_{39}IN_3O_6Si$ $(M + H)^+$: 620.1653. Found: 620.1654 ± 0.0016 ($n = 2$).

2-(Trimethylsilyl)ethyl 2-Bromo-4-[N^1,N^2-bis-(*tert*-butyloxycarbonyl)guanidinomethyl]benzoate (4b). This compound was prepared following a procedure similar to that used for the synthesis of **4a**. Starting with 820 mg (2.1 mmol) of **3b**, 551 mg (46%) of a white solid was obtained. ^{1}H NMR ($CDCl_3$) 0.06 (s, 9H), 1.12 (m, 2H), 1.35 (s, 9H), 1.47 (s, 9H), 4.41 (m, 2H), 5.13 (s, 2H), 7.24 (dd, 1H), 7.55 (d, 1H), 7.73 (dd, 1H). MS (FAB^+), *m*/*z*: 572 and 574 $(M + H)^+$, 516 and 518, 460 and 462, 388 and 390, and 344 and 346. HRMS (FAB^+) Calcd for $C_{24}H_{39}{}^{79}BrN_3O_6Si$ $(M + H)^+$: 572.1792. Found: 572.1786 ± 0.0021 ($n = 2$).

4-[N^1,N^2-Bis-(*tert*-butyloxycarbonyl)guanidinomethyl]-2-iodobenzoic Acid (5a). Tetrabutyl ammonium fluoride (0.18 mL of 1 M solution in THF; 0.18 mmol) was added dropwise to a solution of **4a** (40 mg; 0.06 mmol), and the mixture was stirred at 20 °C for 3–4 h. THF was evaporated, and the residue was partitioned between ethyl acetate and 1 N HCl. The aqueous layer was extracted twice with ethyl acetate, and the pooled ethyl acetate solution was washed with brine and dried. Evaporation of ethyl acetate yielded 30 mg (89%) of an oil: ^{1}H NMR ($CDCl_3$) 1.35 (s, 9H), 1.49 (s, 9H), 5.15 (s, 2H), 7.29 (dd, 1H), 7.87 (d, 1H), 7.92 (d, 1H), 9.28 (br d; 2H). MS (FAB^+), *m*/*z*: 520 $(M + H)^+$, 408. HRMS (FAB^+) Calcd for $C_{19}H_{27}IN_3O_6$ $(M + H)^+$: 520.0945. Found: 520.0931 ± 0.0000 ($n = 2$). This compound was carried to the next step without further purification.

4-[N^1,N^2-Bis-(*tert*-butyloxycarbonyl)guanidinomethyl]-2-bromobenzoic Acid (5b). This compound was prepared from **4b** (30 mg; 0.05 mmol) in a fashion similar to the preparation of **5b** in an almost quantitative yield and was used for the next step without further purification. ^{1}H NMR ($CDCl_3$) 1.36 (s, 9H), 1.49 (s, 9H), 5.18 (s, 2H), 7.25 (dd, 1H), 7.58 (d, 1H), 7.88 (dd, 1H), 9.4 (br d; 2H).

***N*-Succinimidyl 4-[N^1,N^2-Bis-(*tert*-butyloxycarbonyl)guanidinomethyl]-2-iodobenzoate (6a).** Polymer-bound DCC (400 mg; 0.4 mmol) and *N*,*N*-dimethylaminopyridine (3 mg) in that order were added to a solution of **5a** (147 mg; 0.28 mmol) in 3 mL of dry ethyl acetate. The mixture was stirred at 20 °C under a positive pressure of argon for a few minutes after which *N*-hydroxysuccinimide (72 mg; 0.6 mmol) was added and then further stirred for 1 h at 20 °C. The resin was filtered off, washed with ethyl acetate, and the filtrate concentrated. Silica gel chromatography using a gradient of 25–40% ethyl acetate in hexanes yielded 50.8 mg (41%) of a foamy solid: m.p. 79–80 °C. ^{1}H NMR ($CDCl_3$) 1.40 (s, 9H), 1.50 (s, 9H), 2.90 (s, 4H), 5.18 (s, 2H), 7.40 (dd, 1H), 8.02 (d, 1H), 8.08 (d, 1H), 9.36 (br d; 2H). MS (FAB^+), *m*/*z*: 617 $(M + H)^+$, 561, 505, 460. HRMS (FAB^+) Calcd for $C_{23}H_{30}IN_4O_8$ $(M + H)^+$: 617.1108. Found: 617.1104 ± 0.0010 ($n = 2$).

***N*-Succinimidyl 4-[N^1,N^2-Bis-(*tert*-butyloxycarbonyl)guanidinomethyl]-2-bromobenzoate (6b).** This compound was prepared from **5b** (30 mg) in 49% yield following the procedure for the preparation of **6a**. ^{1}H NMR ($(CD_3)_2SO$) 1.32 (s, 9H),

1.39 (s, 9H), 2.90 (s, 4H), 5.10 (s, 2H), 7.45 (dd, 1H), 7.78 (dd, 1H), 8.05 (dd, 1H).

2-(Trimethylsilyl)ethyl 4-[N^1,N^2-Bis-(*tert*-butyloxycarbonyl)guanidinomethyl]-2-trimethylstannylbenzoate (7). The title compound was synthesized from either **3a** or **3b** using similar procedures (procedure using **3a** is given below). A mixture of **3a** (128 mg; 0.21 mmol), hexamethylditin (652 mg; 2 mmol), $(Ph_3)_2PdCl_2$ (100 mg; 0.14 mmol) in 4 mL of dioxane was heated at reflux under argon for 1 h. The mixture was cooled to room temperature and passed over a bed of Celite, which was then washed with ethyl acetate. The solvents from the combined filtrate were evaporated, and the residual oil was loaded onto a silica bed. The nonpolar byproducts were washed out with a large excess of hexanes, and the product and polar byproducts were eluted with ethyl acetate. The ethyl acetate was evaporated from latter fractions and the residue chromatographed on silica gel using 5% ethyl acetate in hexanes to yield 107 mg (79%) of an oil: ^{1}H NMR ($CDCl_3$) 0.07 (s, 9H), 0.24 (s, 9H [^{119}Sn-H, d]), 1.13 (m, 2H), 1.31 (s, 9H), 1.48 (s, 9H), 4.38 (m, 2H), 5.22 (s, 2H), 7.24 (dd, 1H), 7.56 (d, 1H), 8.03 (dd, 1H), 9.40 (br d; 2H). MS (FAB^+), *m/z*: cluster peaks at 658 $(M + H)^+$, 642, 602, 546, 514, 414, 356. HRMS (FAB^+) Calcd for $C_{27}H_{48}N_3O_6Si^{120}Sn$ $(M + H)^+$: 658.2334. Found: 658.2328 ± 0.0000 ($n = 2$).

***N*-Succinimidyl 4-[N^1,N^2-Bis-(*tert*-butyloxycarbonyl)guanidinomethyl]-2-(trimethylstannyl)benzoate (8).** A solution of tetrabutylammonium fluoride (317 μL of 1 M in THF; 0.32 mmol) was added to a solution of **7** (76.1 mg; 0.12 mmol) in 1.73 mL of dry THF, and the mixture was stirred at 20 °C for 1–2 h. THF was evaporated and the residue partitioned between water and ethyl acetate. The aqueous layer was extracted twice with ethyl acetate, and the combined ethyl acetate fractions were washed with brine and dried. Ethyl acetate was evaporated and the crude product dried. Polymer-bound DCC 163 mg (0.16 mmol) and 1.4 mg of DMAP were added to a solution of the above acid in 1.3 mL of dry ethyl acetate. Five minutes later, *N*-hydroxysuccinimide (31 mg; 0.27 mmol) was added and the mixture stirred at 20 °C under argon for 2–3 h. The resin was filtered and washed with ethyl acetate. Ethyl acetate was evaporated from the filtrate, and the residue was purified by thick-layer chromatography using 25% ethyl acetate in hexanes to yield 36.2 (46%) mg of an oil: ^{1}H NMR ($CDCl_3$) 0.25 (s, 9H [^{119}Sn-H, d]), 1.35 (s, 9H), 1.48 (s, 9H), 2.90 (br s, 4H), 5.22 (s, 2H), 7.30 (dd, 1H), 7.63 (d, 1H), 8.21 (dd, 1H), 9.40 (br d; 2H). MS (FAB^+), *m/z*: cluster peaks at 655.2 $(M + H)^+$, 543. HRMS (FAB^+) Calcd for $C_{26}H_{39}N_4O_8{}^{120}Sn$ $(M + H)^+$: 655.1784. Found: 655.1907 ± 0.0026 ($n = 4$).

***N*-(4-Guanidinomethyl-2-iodobenzoyl)-D-Phe^1-octreotate (12a).** Compound **6a** (3.4 mg; 5.5 μmol) was added to a solution of **9** (6.2 mg; 5.2 μmol) in 0.1 mL of 0.1 M DIEA in NMP. The homogeneous mixture was heated at 45 °C for 30 h. The progression of the reaction was periodically checked by HPLC. For this, the reversed-phase analytical column was eluted with a gradient consisting of 0.1% HOAc (w/v) in each water (solvent A) and acetonitrile (solvent B) at a flow rate of 1 mL/min. The percentage of solvent B was increased from 30% to 60% over 15 min and to 100% in the next 15 min and then held at 100% for 5 min. Under these conditions, the retention times for peptide **9**, compound **6a**, and the product **10a** were 11.3, 25.5, and 29.0 min, respectively. Several analytical HPLC runs of the reaction mixture were performed to yield 3 mg of **10a**. MS *m/z*: Calcd for $C_{78}H_{100}IN_{13}O_{18}S_2$ 1698.7419. Found (LCMS-ESI) 1699.6 (MH^+), 849.7 (MH^{2+}). Ethanolamine (0.98 mL) was added to a solution of **10a** in 0.98 mL of ethanol and left at 20 °C. The removal of the Dde group was complete in 30 min as judged by HPLC. The HPLC was conducted using the same solvents as above at a flow rate of 1 mL/min; the percentage of B was increased from 10% to 40% over a period of 30 min and to 100% in the next 10 min and then held at 100% for 5 min The retention times of **10a** and **11a** under these conditions were 45.5 and 38.6 min, respectively. Several analytical HPLC runs were performed to obtain 2.5 mg of **11a**. MS *m/z*: Calcd for $C_{68}H_{88}IN_{13}O_{16}S_2$: 1534.5408. Found (MALDI): 1356.4 $(M + Na - 2Boc)^+$, 1334.8 $(MH - 2Boc)^+$. A 95:2.5:2.5 (v/v/v) mixture of TFA/water/triisopropylsilane (0.2 mL) was added to the above peptide (**11a**; 2.5 mg), and the mixture left at 20 °C for 30 min. HPLC (conditions as above for the deprotection of **10a**) indicated complete disappearance of **11a** ($t_R = 38.6$ min) and appearance of a peak at 24.8 min. The solvents were evaporated with a stream of argon and the residue redissolved in 0.5 mL of ethanol, and the ethanol evaporated. The process of coevaporation with ethanol was repeated once, and finally the residue was triturated with ether to obtain 1.9 mg of **12a**. MS *m/z*: Calcd for $C_{58}H_{72}IN_{13}O_{12}S_2$: 1334.3092. Found (MALDI): 1356.26 $(M + Na)^+$, 1334.27 $(MH)^+$.

***N*-(2-Bromo-4-(guanidinomethyl)benzoyl)-D-Phe^1-octreotate (12b).** A solution of **9** (3.2 mg; 2.7: mol) and **6b** (4.8 mg; 8.4: mol) in 0.1 mL of 0.1 M DIEA in NMP was incubated at 20 °C for 20 h whereupon HPLC (same conditions as for the synthesis of **10a**; $t_R = 25.0$ and 27.9 min for **6b** and **10b**, respectively) indicated the complete consumption of **9**. Semipreparative HPLC (same conditions as for analytical with a flow rate of 10 mL/min) of the reaction mixture yielded 1–2 mg of **10b** ($t_R = 22.0$ and 24.0 min for **6b** and **10b**, respectively). MS *m/z*: Calcd for $C_{78}H_{100}BrN_{13}O_{18}S_2$ 1651.7414. Found (FAB^+) 1652.5 and 1650.5 $(M)^+$, 1552.5 and 1550.5 $(M - Boc)^+$, 1452.4 and 1450.4 $(M - 2Boc)^+$. Ethanolamine (0.25 mL) was added to a solution of the above peptide (**10b**) in 0.25 mL ethanol, and the deprotection reaction was allowed to proceed at 20 °C. HPLC (same conditions as for the deprotection of **10a**) at 60 min indicated the complete disappearance of **10b** ($t_R = 44.3$ min) and the appearance of a peak at 38.5 min. Semipreparative HPLC of the reaction mixture (same conditions as analytical except for a flow rate of 10 mL/min; $t_R = 35.3$ min) yielded 1.2 mg of **11b**. MS *m/z*: Calcd for $C_{68}H_{88}BrN_{13}O_{16}S_2$ 1487.5403. Found (FAB^+) 1488.5 and 1486.5 $(M)^+$, 1288.5 and 1286.5 $(M - 2Boc)^+$. A 95:2.5:2.5 mixture of TFA/water/triisopropylsilane (0.2 mL) was added to the above peptide and the mixture incubated at 20 °C for 30 min. HPLC (same conditions as used for the conversion of **10b** to **11b**) indicated complete removal of Boc groups (t_R for **12b** = 22 min). MS *m/z*: Calcd for $C_{58}H_{72}BrN_{13}O_{12}S_2$ 1287.3087. Found (MALDI) 1310.5 and 1308.5 $(M + Na)^+$, 1288.5 and 1286.5 $(MH)^+$.

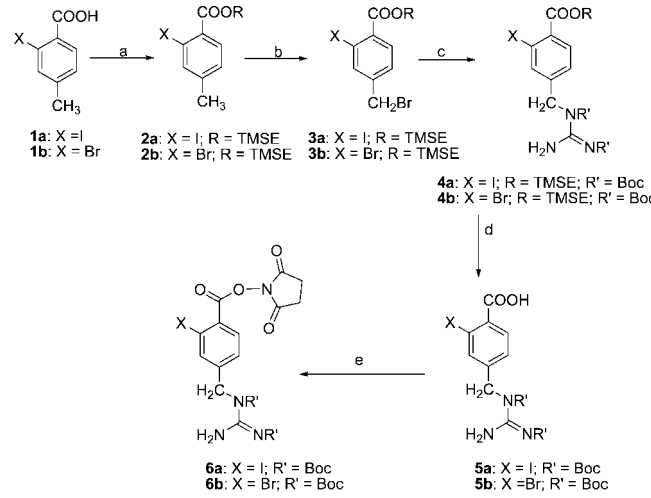
***N*-[4-(N',N''-Bis-*tert*-butyloxycarbonyl)guanidinomethyl-2-(trimethylstannyl)benzoyl]-D-Phe^1-octreotate (11c).** A solution of **8** (13.8 mg; 21.1 μmol) and **9** (9.4 mg; 7.9 μmol) in 0.15 mL of 0.1 M DIEA in NMP was incubated at 20 °C for 7 d. The reaction progress was monitored by the same reversed-phase HPLC conditions that were used for the synthesis of **10a** and **10b**. The retention times of **8** and **10c** were 29.0 and 32.1 min, respectively. The reaction mixture was subjected to semipreparative HPLC using the conditions used for the isolation of **10b** to yield 5.5 mg of **10c**. MS *m/z*: Calcd for $C_{81}H_{109}N_{13}O_{18}S_2Sn$ 1735.6510. Found (MALDI) cluster peaks around 1537.5 $(M - 2Boc)^+$. Ethanolamine (0.25 mL) was added to a solution of the above peptide in ethanol (0.25 mL) and the mixture left at 20 °C. HPLC (same conditions as for the synthesis of **11a** and **11b**) indicated that the removal of the Dde group was complete in about an hour ($t_R = 47.1$ and 39.1 min for **10c** and **11c**, respectively). The reaction mixture was subjected to semipreparative HPLC (same conditions as for **11b**; $t_R = 36.5$ min) to isolate 2.8 mg of **11c**. MS *m/z*: Calcd for $C_{71}H_{97}N_{13}O_{16}S_2Sn$ 1571.4499. Found (MALDI) cluster peaks around 1375.2 $(M - 2Boc)^+$; (FAB) cluster peaks around 1572.0 $(MH)^+$, 1474.1, 1372, 1354.9.

***N*-(4-Guanidinomethyl-2-[^{131}I]iodobenzoyl)-D-Phe^1-octreotate ([^{131}I]12a).** A mixture of **12b** (50 μg), ^{131}I (0.2–4.0 mCi) and 25 μL of glacial acetic acid in a closed ½-dram vial was heated at 100 °C for 20 min The entire reaction mixture was injected into the analytical reversed-phase HPLC column and eluted with the gradient conditions used for the synthesis of **12a**. The HPLC fractions containing [^{131}I]**12a** were isolated and the radioactivity concentrated using a C18 solid-phase cartridge as reported for the isomeric compound (*36*).

Paired-Label Uptake of [^{125}I]MIBG and [^{131}I]12a by SH-SY5Y and SK-N-SH-sst2 cells as a Function of Time. Cells (5×10^5 per well in 2 mL) in 6-well plates in the respective medium was incubated for 24 h. The medium was removed, and the medium containing 100 nCi of each tracer (in 2 mL) was added to the wells. The cells were incubated at 37 °C for 15, 30, 60, 120, and 240 min, and then the medium was aspirated and the cells were washed with the medium and solubilized in 1 N NaOH. Cell-associated radioactivity was determined by counting for both ^{125}I and ^{131}I in an automated gamma counter. For each time point, the assay was performed in triplicate. To determine whether the uptake was NET-mediated, a parallel assay was performed in the presence of 1.5 μM DMI. The results are expressed as the percentage of total activity that was associated with the cells.

Time-Dependent Paired-Label uptake of [^{131}I]12a and [^{125}I]-I-Gluc-TOCA by SK-N-SH-sst2 Cells. This assay was performed essentially like the above except that a different tracer pair was employed and the assay was done using only the transfected cell line. To determine the extent of SSTR-mediated uptake, a parallel assay was performed in the presence of 10 μM octreotide.

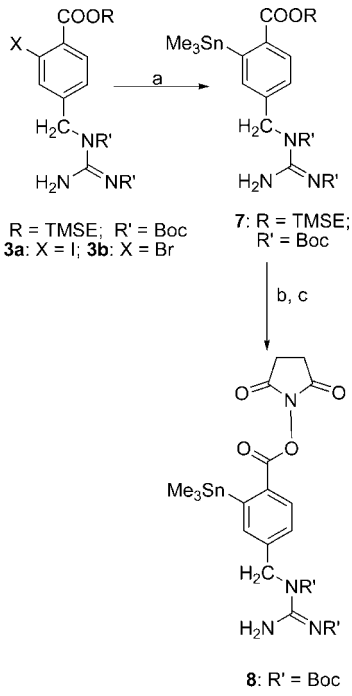
Internalization of [^{131}I]12a versus That of [^{125}I]I-Gluc-TOCA and [^{125}I]OIBG-Octreotate by SK-N-SH-sst2 Cells. These assays were performed in a paired-label format following a procedure reported for octreotate derivatives in another cell line (*36*). Briefly, about 200 000 CPM of each tracer was incubated with 5×10^5 cells at 37 °C for 30 min, 1, 2, 3, and 4 h in the presence or absence of 1 μM octreotide. The cell culture supernatants were removed, and the cells were incubated with an acidic (pH 5) buffer to remove surface-bound radioactivity. Cells were finally lysed with 1 N NaOH and counted for radioactivity. The percentage of input radioactivity that was present in the intracellular compartment was determined. Specific internalized radioactivity, defined as the difference in internalized radioactivity in the presence and absence of 1 μM octreotide, was plotted as a function of time.



Paired-Label Washout of [^{125}I]MIBG and [^{131}I]12a from SK-N-SH-sst2 Cells. The cells were allowed to take up the tracers for 4 h as in the uptake experiment described above. The medium containing unbound tracers was removed, and the cells were supplemented with fresh medium. Subsequently, the cell-associated radioactivity was determined as above at 0, 4, 8, 16, 24, and 48 h. A paired-label Student's *t* test was used to determine the statistical significance of the difference in the measured values for ^{125}I and ^{131}I.

RESULTS AND DISCUSSION

Radioiodinated MIBG has been widely used for the diagnosis of a number of neuroendocrine tumors as well as imaging the pathophysiology of the heart. MIBG labeled with the β-emitter ^{131}I has been used in the targeted radiotherapy of the above neoplasms. With the hope that a conjugate of [*I]MIBG and an octreotate derivative may deliver a higher cumulative radiation dose to the tumor, we have developed such a fusion molecule and subjected it to preliminary in vitro evaluation of SSTR2- and NET-mediated accumulation in human cancer cells.



It was envisaged that the easiest way to append an MIBG moiety to a peptide would be to introduce a carboxylic acid function on the MIBG molecule and conjugate it to the N-terminus of the peptide to form an amide bond. We chose to modify MIBG at its 4-position because we showed earlier that the introduction of functional groups at this position did not interfere appreciably with NET-related biological properties of MIBG (*45*). To avoid the potential interference of the carboxyl function present in the peptide in the direct coupling of MIBG derivative with a COOH group, we set forward to synthesize its active ester. Thus, our target was compound **6a** (Scheme 1) wherein the guanidine function of the active ester of an MIBG derivative with an added carboxyl group was protected with Boc groups. Both **6a** and the corresponding trimethylstannyl derivative **8** were prepared as shown in Schemes 1 and 2. The starting material for the iodo derivative, 2-iodo-4-methyl benzoic acid (**1a**), was synthesized from 2-amino-4-methylbenzoic acid. A standard of the final MIBG–octreotate conjugate (**12a**) and the tin precursor (**11c**) were synthesized following protocols reported earlier (*36*) for the isomeric peptide derivatives (Scheme 3). Several sets of different conditions were utilized for the radioiodination of **11c** but less than 1% radiochemical yields of [*I]**11a**, which can be converted to the final target [*I]**12a**, were obtained. Although difficulty in radioiodinating compounds with a carbonyl moiety ortho to the trialkyltin group has been reported, utilizing very harsh conditions has resulted in decent radiochemical yields (*46*). Attempts to radioiodinate **7** to [*I]**4a** under a variety of conditions including those reported by the above authors for their target compound also were futile, and it was not possible to convert the free acid of **7** (R = H) to unlabeled **5a**. Modest radiochemical yields (15–20%) were obtained, however, for the iododestannylation of **8** under relatively mild conditions. It was possible to obtain radioiodinated 4-guanidinomethyl-2-iodobenzoic acid by the nucleophilic iododebromination of the corresponding bromo precursor in 85–90% radiochemical yields (experimental details of the above reactions are not provided). Therefore, a bromo derivative of the peptide conjugate (**12b)** was synthesized (Schemes 1 and 3). Heating a mixture of this peptide and radioiodine in acetic acid yielded the target compound [*I]**12a** (Scheme 4) albeit in modest radiochemical yields (3–36%; $n = 10$). Higher yields might have been obtained with higher amounts of the starting bromo peptide; however, the difference in HPLC retention times between **12a** and **12b** was only 2–3 min, which precluded the use of larger amounts of **12b** for this reaction.

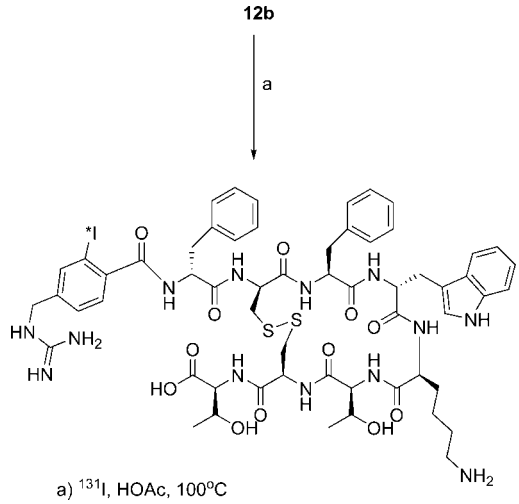
The accumulation and retention properties of the MIBG-octreotate ([^{131}I]**12a**) conjugate were evaluated in two cell lines that express both SSTR2 and NET. First, the uptake of [^{125}I]MIBG and [^{131}I]**12a** as a function of time was determined in a paired-label format using SH-SY5Y (*38, 40*) and SK-N-SH-sst2 (*5*) cell lines. Both cell lines demonstrated significant uptake of [^{125}I]MIBG, which appeared to plateau at 4 h (Figure 1). As seen with the wild-type SK-N-SH cells (*2, 47, 48*), the uptake was NET-mediated as shown by its abrogation by DMI treatment. The level of [^{125}I]MIBG uptake in these cell lines was similar to that seen typically in the parental line SK-N-SH (*49*). While specific uptake of radioiodinated MIBG in the SH-SY5Y line has been shown to be similar to the SK-N-SH cell line (*50*), this is the first time the specific uptake of MIBG has been demonstrated in the SSTR2-cloned line. Unlike the case with [^{125}I]MIBG, the uptake of [^{131}I]**12a** did not reach a plateau in either cell line. The total uptake of [^{131}I]**12a** in SK-N-SHsst2 cells was similar to that for [^{125}I]MIBG at all time points (34.9 $\pm$ 2.4% vs 43.8 $\pm$ 1.2% at 4 h; $p < 0.05$), while it was substantially lower in the SH-SY5Y line (5.4 $\pm$ 0.3% vs 35.9 $\pm$ 1.2%). However, DMI did not decrease the uptake of [^{131}I]**12a** in either cell line to the same degree as was seen for [^{125}I]MIBG. This suggests that, while there may be an NET-mediated component to its cell accumulation, the uptake of [^{131}I]**12a** in these cell lines, especially in the SK-N-SH-sst2 cells, might be predominantly related to SSTR2 binding. Although SSTR2 expression in SH-SY5Y cells has been demonstrated (*41*), to our knowledge, its expression level relative to that in SK-N-SH cells has not been reported. On the other hand, quantitative RT-PCR showed that the transfected cells express about a 28-fold higher amount of SSTR2 mRNA than that by the SK-N-SH line.

To investigate the extent of SSTR2 involvement in the uptake of [^{131}I]**12a** by SK-N-SH-sst2 cells, another paired-label assay was performed in which the time-dependent uptake [^{131}I]**12a** was compared to that of [^{125}I]I-Gluc-TOCA. Among various labeled octreotide derivatives, [^{125}I]I-Gluc-TOCA and other sugar-conjugated congeners have demonstrated high accumulation in



Scheme 3. Synthesis of Octreotate Conjugates 12a, 12b, 12c, 13a, and 13b

a) **6a**, **6b**, or **8**, DIEA/NMP; b) Ethanolamine; c) TFA cocktail

SSTR2-expressing tumor cells and xenografts (*51, 52*). Surprisingly, the uptake of [^{131}I]**12a** was 8–10-fold higher ($p < 0.05$) than that for [^{125}I]I-Gluc-TOCA at all time points (Figure 2). Importantly, the uptake was reduced to about 20% when the cells were coincubated with 10 μM octreotide, demonstrating again that the uptake of [^{131}I]**12a** in this cell line is predominantly mediated by SSTR2. The absolute magnitude of total cellular uptake of [^{131}I]**12a** was lower than that seen in the previous experiment (see Figure 1) and of the intracellularly trapped radioactivity from another experiment (see below; Figure 3). We speculate that this might be due to the use of different passages of cells in different experiments. However, the assays were performed in a paired-label format, and therefore, any changes in receptor and/or transporter expression affected the uptake of both tracers used to the same level, making the comparison meaningful. An exciting observation from these results is that [^{131}I]**12a** exhibits considerably higher SSTR2-mediated cell uptake compared with [^{125}I]I-Gluc-

Scheme 4. Synthesis of Radioiodinated MIBG–Octreotate (12a)

TOCA, which perhaps is one of the best agents for targeting SSTR2-positive tumors.

One of the motivations for development of a hybrid molecule derived from MIBG and octreotate is the feasibility of augmenting the retention of radioactivity in the tumor caused by the possible translocation of the peptide–receptor conjugate to lysosomes after internalization. If the radioactivity were trapped in the lysosomes and, in this manner, NET-mediated egress from the cell was avoided, this could lead to the enhanced residence time in tumor cells, a feature of obvious advantage with such a long-lived radionuclide as ^{131}I. We first determined the extent of internalization of [^{131}I]**12a** by SK-N-SHsst2 cells and compared it to that of [^{125}I]I-Gluc-TOCA and [^{125}I]OIBG-octreotate (*36*)—a position isomer of [^{131}I]**12a**—in two separate paired-label experiments. As depicted in Figure 3, the intracellularly trapped radioactivity from [^{131}I]**12a** steadily increased with time. In concert with the results from the uptake assay, the specific (total minus that in presence of 1 μM octreotide) internalized radioactivity from [^{131}I]**12a** was substantially higher (3–4-fold; $p < 0.05$) than that from [^{125}I]I-Gluc-TOCA. Interestingly, the internalized radioactivity of [^{131}I]**12a** was also higher than that for [^{125}I]OIBG-octreotate. OIBG-octreotate and **12a** differ only in the position of iodine on the aromatic ring (Chart 1). In their seminal work, Wieland and colleagues have shown that, among the three iodobenzylguanidine derivatives, 2-iodobenzylguanidine (OIBG) is the weakest norepinephrine analogue (*53*, *54*). Thus, the above results tempt us to speculate that the enhanced residence time of [^{131}I]**12a** in SK-N-SHsst2 cells is mediated partly by NET.

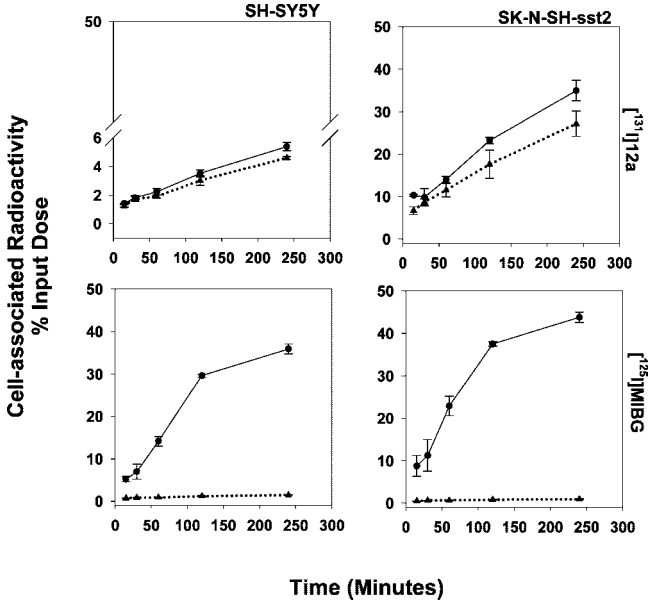


Figure 1. Paired-label time-dependent uptake of [^{125}I]MIBG (bottom panel) and [^{131}I]**12a** (top panel) by SH-SY5Y cells (left panel) and SK-N-SH-sst2 (right panel) in the presence (triangle) and absence (circle) of DMI. Cells (5×10^5 per well) were allowed to take up both tracers in the presence or absence of DMI over various time points, and the cell-associated radioactivity was determined.

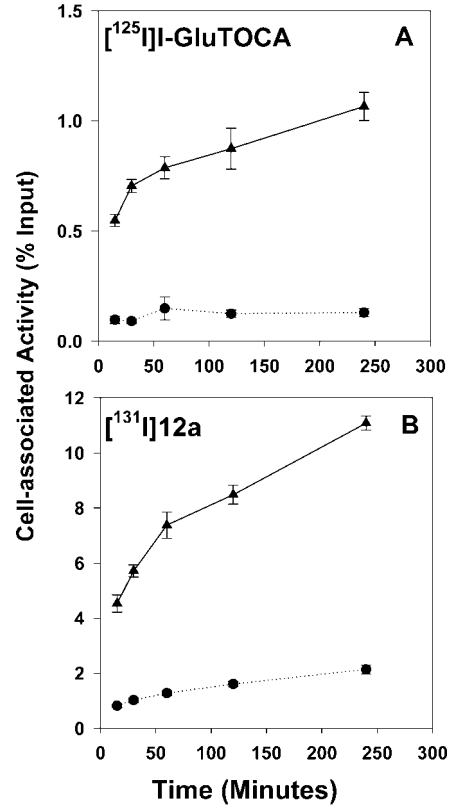

Figure 2. Paired-label uptake of (A) [^{125}I]I-Gluc-TOCA and (B) [^{131}I]**12a** by SK-N-SH-sst2 cells as a function of time in the presence (circle) and absence (triangle) of 1 μM octreotide. The cells were incubated with both tracers for various periods of time in the presence or absence of unlabeled octreotide, and the cell-associated radioactivity was determined. Note that the *Y*-axis scales are not the same for the two plots.

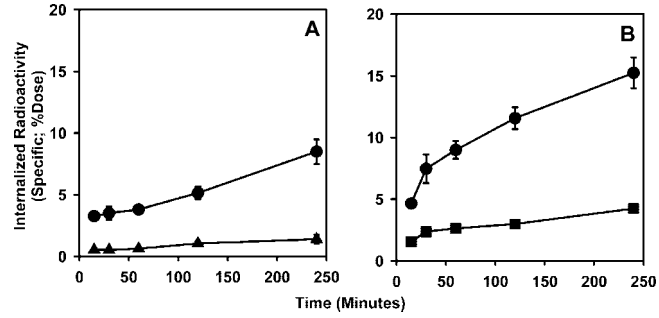

Figure 3. Paired-label specific internalized radioactivity (total minus that in presence of 1 μM octreotide) over a period of 4 h in SK-N-SH-sst2 cells: (A) [^{131}I]**12a** (circle) vs [^{125}I]OIBG-octreotate (triangle) and (B) [^{131}I]**12a** (circle) vs [^{125}I]I-Gluc-TOCA (square). See text for details.

Finally, an assay was performed to determine the extent of egress of [^{131}I]**12a**, in comparison to that of [^{125}I]MIBG, from SK-N-SHsst2 cells. The results from this paired-label study are shown in Figure 4. Up to 24 h, the radioactivity from [^{131}I]**12a** was retained by these cells to a higher extent than from

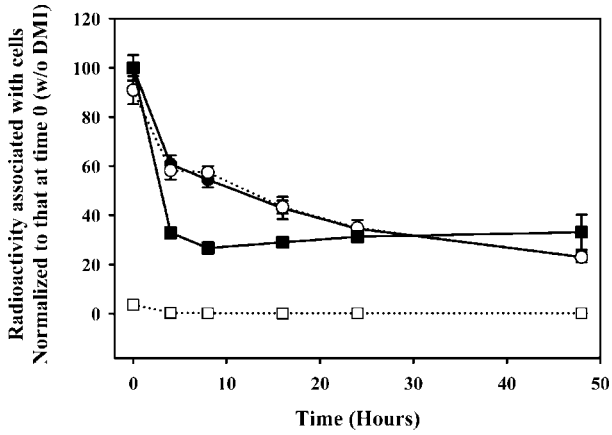

Figure 4. Paired-label washout of [^{125}I]MIBG (square) and [^{131}I]**12a** (circle) from SK-N-SH-sst2 cells in the presence (open) and absence (closed) of 1.5 μM DMI. Cells were allowed to take the two tracers for a period of 4 h; the free radioactivity-containing medium was removed and supplemented with fresh medium with or without DMI. The cell-associated radioactivity was determined periodically afterwards.

[^{125}I]MIBG possibly due to the hypothesized lysosomal trapping. As observed before (*45*), DMI obliterated the retention of [^{125}I]MIBG; on the other hand, it did not have any effect on the retention of [^{131}I]**12a**. Because DMI blocks the NET-mediated uptake, this again demonstrates that NET plays only a minimal role in the uptake of [^{131}I]**12a**.

CONCLUSIONS

In summary, we have developed a method for the synthesis of a conjugate of radioiodinated MIBG and octreotate. While it demonstrated considerable uptake in a tumor cell line expressing both NET and SSTR2, it appears that the predominant pathway for its uptake is via the somatostatin receptor. This might be due to the fact that **12a**, compared to MIBG, lost its affinity to NET due to the presence of the large peptide moiety. MIBG with a COOH function at its 4-position had an uptake 8% that of MIBG in SK-N-SH cells (unpublished results). A conjugate with a long, flexible, and/or cleavable linker may have to be interposed between MIBG and octreotate moieties. On the other hand, the MIBG–octreotate conjugate exhibited excellent retention in these cells that express both NET and SSTR2.

Received July 4, 2007; Revised Manuscript Received September 13, 2007

We prepared thermosensitive poly(*N*-(2-hydroxypropyl)methacrylamide mono/dilactate) (pHPMA mono/dilactate) polymer and studied temperature-triggered contents release from polymer-coated liposomes. HPMA mono/dilactate polymer was synthesized with a cholesterol anchor suitable for incorporation in the liposomal bilayers and with a cloud point (CP) temperature of the polymer slightly above normal body temperature (42 °C). Dynamic light scattering (DLS) measurements showed that whereas the size of noncoated liposomes remained stable upon raising the temperature from 25 to 46 °C, polymer-coated liposomes aggregated around 43 °C. Also, noncoated liposomes loaded with calcein showed hardly any leakage of the fluorescent marker when heated to 46 °C. However, polymer-coated liposomes showed a high degree of temperature-triggered calcein release above the CP of the polymer. Likely, liposome aggregation and bilayer destabilization are triggered because of the precipitation of the thermosensitive polymer above its CP onto the liposomal bilayers, followed by permeabilization of the liposomal membrane. This study demonstrates that liposomes surface-modified with HPMA mono/dilactate copolymer are attractive systems for achieving temperature-triggered contents release.

INTRODUCTION

Liposomes have been widely studied as nanosized carriers in drug delivery. They are biocompatible, nontoxic, and nonimmunogenic, and they can be used for the delivery of both hydrophilic and hydrophobic drug molecules (*1, 2*). A major challenge in liposomal drug delivery is the triggered release of the drug only at the site of action, resulting in exposure of the target cells to a high concentration of the drug. Several approaches for triggered drug release from liposomes have been investigated. These involve enzyme-activated (*3, 4*), pH-sensitive (*5*), light-sensitive (*6*), ultrasound-triggered (*7*), and temperature-sensitive liposomes (*8, 9*).

Temperature-sensitive liposomes can be prepared from phospholipids that have a sharp gel-to-liquid crystalline transition, but they can be also prepared by functionalizing liposomes with polymers that exhibit a lower critical solution temperature (LCST) (*10*). These polymers are water-soluble below their cloud point (CP) temperature, but they become hydrophobic and subsequently precipitate when the temperature is raised above the CP. Because of the polymer precipitation on the liposome surface, the polymer interacts with the liposomal bilayer resulting in bilayer destabilization, and this feature could be applied for temperature-triggered contents release from the liposomes. Such temperature-sensitive liposomes remain intact at 37 °C and avoid drug leakage in the blood circulation. Heating at the target site (e.g., tumor, skin, back of the eye) subsequently triggers the release of the drug from the liposomes locally, which improves the efficacy of the treatment and reduces side effects. The release temperature should be adjusted to 41–42 °C so that heating does not cause damage to healthy tissues.

Poly(*N*-isopropylacrylamide) [p(NIPAM)] exhibits the CP at 32 °C, and it has been studied as a thermosensitive coating for liposomes by Kono and co-workers (*11–14*). They showed that p(NIPAM) can induce temperature-triggered contents release from liposomes. Hayashi et al. reported that the CP of p(NIPAM) can be increased by copolymerization NIPAM with acrylamide (*12*). This is important because in clinical use the polymer precipitation and drug release from liposomes should occur at a few degrees above normal body temperature. Han and co-workers studied the temperature-triggered release of doxorubicin from liposomes that were coated with p(NIPAM-*co*-acrylamide) and polyethyleneglycol (PEG) (*15*). The major drawback of p(NIPAM) is that it is not biodegradable, and therefore, there is a risk for side effects related to polymer accumulation in the body.

Poly(*N*-(2-hydroxypropyl)methacrylamide) (HPMA) polymers have been widely studied as biodegradable macromolecular carriers for anticancer drugs (*16*). Recently, HPMA-based copolymers with tuneable thermosensitivity were synthesized by free radical polymerization of HPMA monolactate and HPMA dilactate (*17*). It was shown that the CP of HPMA mono/dilactate copolymers can be tailored between 13 and 65 °C by varying the monolactate/dilactate ratio in the copolymer. Importantly, it was also shown that the polymers were biodegradable.

Because of their adjustable thermosensitivity and biodegradability, HPMA mono/dilactate copolymers are a promising tool for temperature-triggered contents release from liposomes. In this study, we synthesized thermosensitive HPMA mono/dilactate copolymers with a cholesterol anchor suitable for incorporation in liposomal bilayers. Liposomes were successfully coated with the polymer, and the temperature-triggered

Scheme 1. Synthesis of Poly(HPMA mono/dilactate)–Cholesterol

liposome aggregation and the release of encapsulated fluorescent marker were determined.

EXPERIMENTAL SECTION

Materials. Thiocholesterol, Ellman's reagent [5,5′-dithiobis(2-nitrobenzoic acid)], cysteine, cholesterol, and calcein were purchased from Sigma-Aldrich Chemie BV, Zwijndrecht, The Netherlands. *N*,*N*′-azobisisobutyronitrile (AIBN) and 1,4-dioxane were purchased from Fluka Chemie AG, Buchs, Switzerland. Egg phosphocholine (EPC), 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC), and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) were purchased from Lipoid GmbH, Ludwigshafen, Germany.

Synthesis of HPMA Mono/Dilactate Copolymers with Cholesterol Anchor. The synthetic route to poly(HPMA mono/dilactate) with a cholesterol anchor is illustrated in Scheme 1. HPMAm monolactate and HPMAm dilactate monomers were synthesized as reported earlier (*18*), and copolymers were prepared by radical polymerization using thiocholesterol as a chain transfer agent (CTA). Thiol compounds act as CTA in radical polymerization (*19*). The molar ratios between HPMAm monolactate and HPMAm dilactate used in polymerization ranged from 70/30 to 85/15. Monomers were dissolved in freshly distilled 1,4-dioxane at the concentration of 100 mg/mL. *N*,*N*′-azobisisobutyronitrile was used as radical initiator at a molar ratio of 500/1 (monomers/AIBN), and thiocholesterol as chain transfer agent was used at a molar ratio of 50/1 (monomers/thiocholesterol). Desired amounts of monomers, AIBN, and thiocholesterol were transferred into sealable glass vial, followed by five freeze–thaw cycles under a nitrogen atmosphere in order to remove oxygen. Polymerization was carried out at 70 °C for 24 h. The obtained polymers were precipitated dropwise into an excess of diethyl ether under vigorous stirring. After centrifugation, the supernatants were discarded and traces of diethyl ether were removed in vacuo. The prepared polymers were dissolved in water, freeze-dried, and stored in a freezer.

Characterization of the Polymers. Traces of unreacted thiocholesterol in the crude polymers were determined by Ellman's assay (*20*). A calibration curve was obtained with cysteine standards (0.25–1.5 mM) by measuring UV absorbance at 412 nm (Perkin Elmer Lambda 2 UV/vis spectrometer, Überlingen, Germany). The molecular weights and their distributions were determined by gel permeation chromatography (GPC). Analysis was performed with a Waters GPC system (Waters Associates Inc., Milford, MA) at 40 °C in Plgel 3 μm MIXED-D column (Polymer Laboratories), using poly(ethylene glycol) standards. The eluent was DMF containing 10 mM LiCl, and the elution rate was 0.7 mL/min.

The polymers were characterized by ^{1}H NMR (Gemini 300 MHz spectrometer, Varian Associates Inc., NMR Instruments, Palo Alto, CA) using $CDCL_3$ as a solvent. The ratios of monolactate to dilactate side chains in the polymers were determined from the peaks at 5.0 and 4.3 ppm as described earlier (*17*), and the cholesterol peak was observed at 0.7 ppm.

The cloud point (CP) temperature of the polymers was measured by static light scattering (SLS) using a temperature gradient (approximately 1 °C/min). The polymers were dissolved in 120 mM ammonium acetate buffer (pH 5) at a concentration of 1, 2, or 5 mg/mL, and the scattering was measured with a fluorometer (Fluorolog Horiba, Edison, NJ) in a quartz cuvette at 650 nm. The samples were under constant stirring during the experiment. The onset of transition from a scattering intensity–temperature curve was considered as the CP temperature.

Preparation of Polymer-Coated Liposomes. Two different liposome formulations were coated with 5 mol % poly(HPMA mono/dilactate)–cholesterol. With this method, polymer chains are expected to be located both on the outer and on the inner surface of the liposomes. One formulation was prepared from DPPC, cholesterol, and the polymer with a molar ratio of 100:42.5:7.5 (DPPC/cholesterol/polymer). The polymers used for coating were 49/51 (monolactate/dilactate) and 71/29, respectively. Another liposome formulation was prepared from DOPE, EPC, and the polymer (71/29) with a molar ratio of 70:25:5 (DOPE/EPC/polymer). Lipids and polymer were dissolved in chloroform in a 50 mL round bottom flask, and the solvent was evaporated in a rotating vacuum evaporator at 35 °C. The resulting lipid–polymer film was further dried under a nitrogen stream and then hydrated with 3 mL of isotonic 20 mM HEPES buffer (pH 7.4) to obtain a final lipid concentration of 30 μmol/mL. For calcein-loaded liposome preparation, the lipid–polymer film was hydrated with 3 mL of calcein solution (60 mM, 280 mOsm). This solution was prepared by dissolving 374 mg of calcein and 17 mg of NaCl in 10 mL of water, and the pH was adjusted to 7.4 with NaOH. The DPPC/cholesterol liposomes were sized by multiple extrusions through two stacked polycarbonate filters with a pore size of 100 nm, and the DOPE/EPC liposomes were extruded through filters with pore sizes of 100 and 50 nm. In the case of calcein-loaded liposomes, free calcein was removed by column filtration using a Sephadex G-50 (Pharmacia Fine Chemicals AB, Uppsala, Sweden) column; samples (500 μL liposomes) were eluted with 20 mM HEPES buffer. The same protocol was used to prepare control liposomes (DPPC/cholesterol (molar ratio 2:1) and DOPE/EPC (molar ratio 7:3)) without polymer coating.

Characterization of Polymer-Coated Liposomes. The amount of incorporated polymer on the DPPC/cholesterol liposome surface was estimated with ^{1}H NMR using a method described earlier (*21*). Briefly, part of the polymer-coated liposome dispersion was subjected to ultracentrifugation (Optima LE-80K, Beckman Instruments, Inc.) at 200000*g* for 1 h to separate liposomes from nongrafted polymer molecules. The supernatant was removed, and the liposome pellet was dispersed in 20 mM HEPES buffer. Subsequently, liposomes were freeze-dried and the cake was dissolved in $CDCl_3$ and analyzed with ^{1}H NMR. The amount of polymer associated with the liposomes

Table 1. Poly(HPMA mono/dilactate)–Cholesterol Copolymer Characteristics

copolymer feed ratio (monolactate/dilactate)	C	yield (%)	M_n (Da)	PDI (M_w/M_n)	CP (°C)
70/30	49/51	60	6200	1.44	36
75/25	55/45	61	5850	1.47	37.5
80/20	71/29	56	5800	1.46	42
85/15	79/21	59	5600	1.42	44

was estimated by comparing the polymer peak (5.0 ppm)/DPPC peak (5.2 ppm) ratio between liposomes before and after ultracentrifugation.

The mean particle size of the liposomes was evaluated by dynamic light scattering (DLS). Liposome samples were diluted with 20 mM HEPES buffer (30 μL of liposomes + 1 mL of buffer) and measured with a Malvern ALV/CGS-3 goniometer (Malvern, U.K.). Also, the polydispersity index (PDI), a value indicating the size distribution of the liposomes, was determined. Measurements were done at different temperatures between 25 and 46 °C in order to investigate the temperature-dependent behavior of the liposomes.

Temperature-Triggered Calcein Release. The release of calcein from liposomes was studied fluorometrically. Calcein does not show fluorescence emission when entrapped at high concentration (60 mM) inside the liposomes but gives strong fluorescence when it is released from the liposomes and diluted in the surrounding buffer. Different calcein concentrations were measured to determine the linear part of the fluorescence signal, and all the subsequent sample measurements were performed in the range 0.01–2 μM. Excitation and emission wavelengths were 490 and 520 nm, respectively. DPPC/cholesterol/polymer liposomes containing calcein were diluted 1:40 in 20 mM HEPES buffer, and the calcein fluorescence was monitored with Fluorolog Horiba by heating the samples from 25 to 50 °C with a heating rate of approximately 1 °C/min. The calcein-loaded DOPE/EPC/polymer liposomes were diluted 1:400 in 20 mM HEPES buffer, and the fluorescence was determined with Fluostar Optima fluorometer (BMG Labtech, Offenburg, Germany) after incubation of the samples in different temperatures. The percent release was then calculated as follows:

$$\% \text{ calcein release} = \frac{F - F_I}{F_T - F_I} \times 100$$

where F is the sample fluorescence at certain temperature, F_I is the initial fluorescence, and F_T is the fluorescence of calcein after solubilization of liposomes by addition of 50 μL of 10% Triton X-100 (Sigma-Aldrich).

RESULTS AND DISCUSSION

Polymer Synthesis and Characterization. Poly(HPMA mono/dilactate)–cholesterol copolymers were synthesized by free radical polymerization using thiocholesterol as a CTA. Ellman's assay showed less than 1% free thiol goups of the original amount in the crude reaction mixture. This suggests that thiocholesterol was built in the polymer. The characteristics of the cholesterol-containing copolymers are summarized in Table 1. The yield of all copolymers was around 60%. Figure 1 shows a ^{1}H NMR spectrum of poly(HPMA mono/dilactate)–cholesterol with a monomer ratio of 71/29 (monolactate/dilactate). The copolymer composition (C) was determined from ^{1}H NMR analysis, and it was observed that the amounts of HPMA monolactate in the products were slightly lower when compared to the feed ratios, suggesting that HPMA dilactate is more reactive than HPMA monolactate under the used polymerization conditions. The peak at 0.7 ppm (Figure 1) indicates the presence of the cholesterol in the copolymer, but because of peak overlap, quantitative analysis of the cholesterol amount could not be performed. GPC results showed that the number average molecular weight (M_n) of the copolymers ranged from 5600 to 6300 Da, depending on the monomer ratio. The polydispersity index (M_w/M_n) of all the copolymers was below 1.5, which indicates a relatively narrow size distribution (Table 1).

Static light scattering measurements showed that the aggregation onset of all the copolymers was sharp; aggregation did not occur below the CP. The CP of the different copolymers in 1 mg/mL solution could be adjusted between 36 and 44 °C by changing the monolactate/dilactate ratio (Table 1). In agreement with previous data (*17*), the CP of the polymer decreased when the concentration of the polymer solution was increased to 2 and 5 mg/mL (Figure 2). The CP of the copolymers increased with higher monolactate content in the copolymer. The increase of the CP is due to the higher hydrophilicity of the monolactate side group. The CPs of the cholesterol anchor containing 71/29 polymer and 79/21 polymer (Table 1) were approximately 4 °C lower than those without anchor (*17*). This can be explained in that the hydrophobicity of the polymers is increased because of the cholesterol anchor. The CPs of cholesterol containing 49/51 polymer and 55/45 polymer were close to the CP of polymer without cholesterol. In these polymers the hydrophobicity of cholesterol is probably masked under hydrophobic dilactate side groups and does not decrease the CP.

Polymer-Coated Liposomes. ^{1}H NMR analysis showed that approximately 60% of the copolymer (copolymer composition of 71/29, Table 1) that was added at the start of the liposome preparation became associated with the liposomes. Probably not all polymer chains contain a cholesterol anchor and therefore were not grafted onto the liposomal bilayers. It is also possible that the longer polymer chains containing the anchor may have been extracted out of the liposomes during extrusion and/or ultracentrifugation.

Dynamic light scattering measurements showed that the mean size and the polydispersity index (PDI) of noncoated liposomes were stable upon heating of the liposome dispersion from 25 to 46 °C (Figure 3). However, both the mean size and the PDI of the DPPC/cholesterol/polymer liposomes were strongly increased at 43 °C (Figure 3A), which corresponds with the CP of the 71/29 polymer (42 °C). Also, when polymers with different CPs were used for coating, DPPC/cholesterol liposomes showed aggregation at the polymer CP (data not shown). When the coating polymer chains become hydrophobic and precipitate above the CP, they interact with the liposomal bilayers and cause liposome aggregation. It was also observed that liposome aggregation was reversible. When the temperature was set back to 25 °C, the mean diameter of the liposomes decreased to 200 nm.

Noncoated DOPE/EPC liposomes were stable between 25 and 46 °C. The mean size and the PDI of DOPE/EPC/polymer liposomes did not increase upon heating to 43 °C, but aggregation was observed at 46 °C (Figure 3B). The size increase was not as pronounced as with DPPC/cholesterol/polymer liposomes, but substantial increase in the PDI indicated liposome aggregation. These findings are likely related to the properties of the lipids. DOPE alone does not form liposomes because it has a tendency to take a hexagonal II phase at 3 °C (*22*). However, liposomes can be prepared by mixing DOPE with stabilizing components, such as cholesterol or phosphocholines. EPC is a natural mixture of saturated and unsaturated phosphocholines with gel-to-liquid crystalline transition temperatures ranging from −70 to 55 °C.

Temperature-Triggered Calcein Release. Uncoated DPPC/cholesterol liposomes remained intact and did not release calcein when the dispersion was heated from 25 to 50 °C. Temperature-triggered calcein release was observed when poly(HPMA mono/dilactate)–cholesterol (monolactate/dilactate ratio of 49/51) was

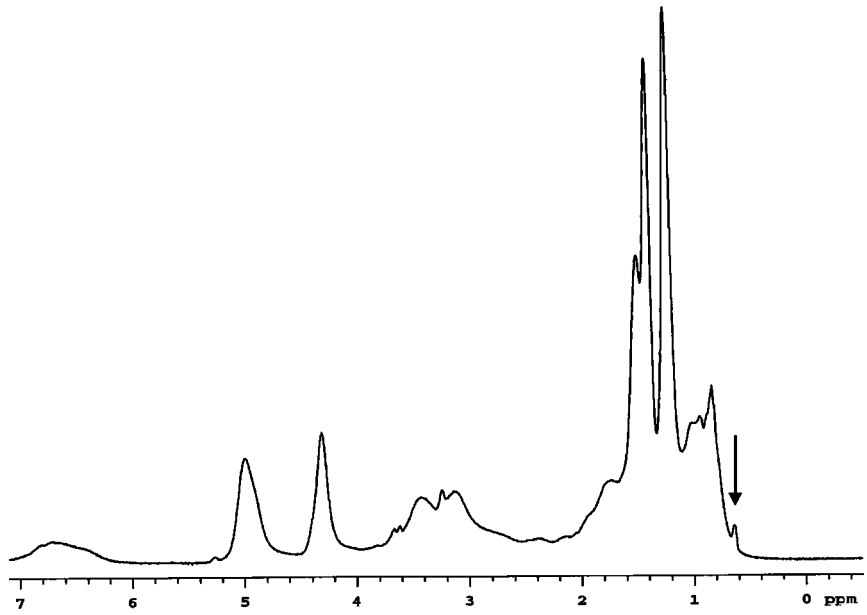

Figure 1. NMR spectrum of poly(HPMA mono/dilactate)–cholesterol (monolactate/dilactate side chain ratio of 71/29). The copolymer composition was calculated from the peak integrals at 5.0 and 4.3 ppm as described earlier (*17*). The arrow indicates the peak at 0.7 ppm that can be ascribed to the cholesterol anchor. This peak is present in cholesterol-containing polymers and absent in a control polymer synthesized without thiocholesterol.

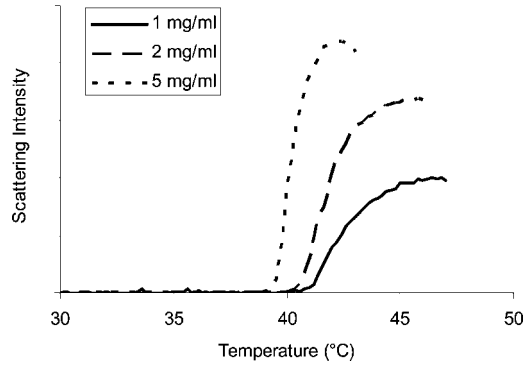

Figure 2. Temperature-dependent precipitation of poly(HPMA mono/dilactate)–cholesterol (71/29) at different polymer concentrations.

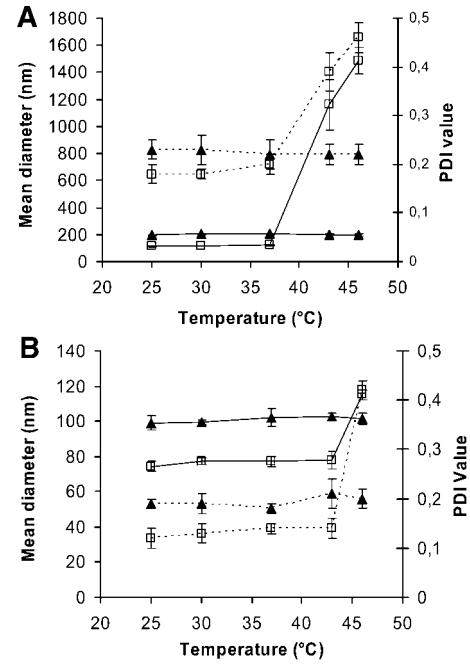

Figure 3. Mean size (solid line) and polydispersity (dashed line) of (A) poly(HPMA mono/dilactate)–cholesterol (71/29) coated DPPC/cholesterol liposomes (open square) and uncoated DPPC/cholesterol liposomes (triangle) and (B) poly(HPMA mono/dilactate)–cholesterol (71/29) coated DOPE/EPC liposomes (open square) and uncoated DOPE/EPC liposomes (triangle). Each data point represents the average ± SE, $n = 4$.

used as coating polymer (Figure 4A). The calcein release onset temperature corresponds with the CP of the coating polymer (36 °C). As mentioned, once the CP is passed, the polymer molecules become hydrophobic, precipitate, and interact with the liposome surface. As a consequence, they destabilize the bilayer and facilitate the release of calcein by disturbing the ordered structure of the lipid bilayer. Aggregation of the liposomes was reversible, which suggests that liposomal bilayers are not decomposed when the polymer precipitates. However, when the 71/29 polymer with a CP of 42 °C was used as coating polymer, no temperature-triggered contents release was observed even when the temperature was increased to 50 °C. It is well-known that DPPC has a transition temperature from the gel to the liquid crystalline phase at 41.5 °C. Probably the interaction between the polymer and the lipid bilayer above the transition temperature of DPPC is not effective enough to induce calcein release because of the higher fluidity of the lipid bilayer.

For many clinical applications it is desirable to prepare drug-containing liposomes that remain intact at 37 °C but will release their contents within the target site when the temperature is locally increased by a few degrees. Kono et al. reported that incorporation of DOPE into the liposome composition increased the temperature-triggered contents release from poly(NIPAM) coated liposomes (*14*). The enhancement of the temperature sensitivity is thought to result from the hydrogen bonding between DOPE and the coating polymer. We determined the temperature-triggered calcein release from poly(HPMA mono/dilactate)–cholesterol (71/29) coated DOPE/EPC liposomes. The CP of the coating polymer was 42 °C, and calcein release was observed above this temperature (Figure 4B). After the polymer-coated liposomes were incubated at 46 °C, almost 90% of the calcein was released, while temperature-triggered release enhancement from uncoated liposomes was not observed. It is

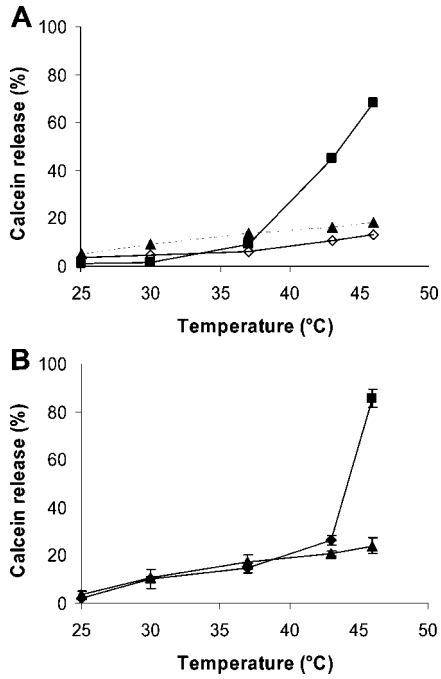

Figure 4. (A) Calcein release from DPPC/cholesterol liposomes coated with 49/51 polymer (square) and 71/29 polymer (open diamond) and from uncoated liposomes (triangle). (B) Calcein release from DOPE/EPC liposomes coated with 71/29 polymer (square) and from uncoated liposomes (triangle) at temperatures between 25 and 46 °C.

likely that the interaction between precipitated polymer and DOPE/EPC liposomes is effective enough to induce calcein release because of the hydrogen bonding. The release temperature (46 °C) is likely too high for clinical applications and should be decreased to ~42 °C. This can be done by using a polymer with lower CP but also by modifying the liposome composition to be more responsive to the phase transition of the polymer.

In conclusion, this study introduces a temperature-sensitive HPMA based copolymer with a cholesterol anchor suitable for incorporation in liposomal bilayers, which is able to mediate temperature-triggered liposome aggregation and contents release. Biodegradability and adjustable release temperature make this system attractive for numerous medical applications in the future, e.g., for targeted anticancer therapy to enhance the efficacy. Such temperature-sensitive liposomes can be prepared to remain intact at 37 °C to avoid drug leakage in the blood circulation and to accumulate in tumor tissue by virtue of the enhanced permeation and retention (EPR) effect. Pegylation or other similar protective coating is probably needed to shield the liposomes against plasma proteins and to extend the liposome half-life in bloodstream. Local heating of the tumor with external heating device can subsequently trigger the drug release because of the aggregation of the thermosensitive polymer, followed by permeabilization of the liposomal membrane.

ACKNOWLEDGMENT

The authors thank Dr. Tina Vermonden and Mr. Najim el Morabit for providing the monomers. In an attempt to develop collagen-growth factor composites for use in tissue engineering, chimeric proteins consisting of epidermal growth factor and collagen binding domains derived from von Willebrand factor or fibronectin were synthesized by means of recombinant technology. These chimeric proteins were bound to type I collagen fibrils, and the ultrastructures of composites were analyzed by transmission electron microscopy combined with the gold nanoparticle labeling technique. The results of the ultrastructural study revealed that chimeric proteins were densely assembled on collagen fibrils through the specific recognition of binding sites, producing the ordered array of chimeric proteins.

INTRODUCTION

Collagen is the most abundant and ubiquitous extracellular matrix in mammals and has been utilized as biomaterials in a variety of medical applications (*1, 2*). More recently, collagen-based hydrogels and porous materials have been used as scaffolds for tissue regeneration (*3*). In these tissue engineering approaches, signaling molecules such as growth factors have been frequently incorporated into collagen-based scaffolds for optimizing cellular responses (*4*). However, growth factors physically entrapped in scaffolds are rapidly released in an uncontrollable manner, reducing the efficacy of growth factors. To overcome this limitation, several attempts have been made to develop collagen binding growth factors by combining growth factors with polypeptide domains or short peptide sequences having an affinity for collagen α chains (*5–8*).

Collagen-binding chimeric proteins have been rationally designed by means of recombinant technology. Using a bacterial expression system, Tuan et al. (*5*) synthesized biologically active transforming growth factor-β1 fused with a collagen-binding peptide. The research group extended this technology to prepare various growth factors having an affinity for collagen (*6*). Nishi et al. (*7*) and Ishikawa et al. (*8*) developed epidermal growth factor (EGF) that was fused with collagen binding domains (CBDs) derived from *Clostridium histolyticum* collagenase and human fibronectin, respectively. It was shown that these fusion proteins have potential for use in the controlled delivery of growth factors (*7, 8*), especially for accelerating wound-healing processes (*8*).

Collagen also provides attractive materials for neural progenitor cell (NPC) transplantation that aims at the structural and functional restoration of the central nervous system suffering from degenerative diseases and traumatic injuries. In an attempt to provide favorable microenvironments for the survival and the controlled differentiation of NPCs, several groups utilized collagen hydrogels as scaffolds (*9–12*). However, current technologies have limited effects of scaffolding, probably due to the low availability of external signals for adhesion, proliferation, and differentiation. To address this limitation, we are currently involved in the development of collagen binding growth factors that improve their availability for NPCs enclosed in collagen-based materials.

Our previous studies (*13, 14*) revealed that neural stem cells recognized histidine-tagged EGF anchored to the surfaces of culture substrates through coordination of the histidine tag with surface-immobilized metal ions. We found that the density of specifically anchored EGF was one of the most important factors for the attachment of neural stem cells mediated by EGF–EGF receptor interactions. This finding led us to suppose that the density of growth factors on collagen-based materials and their binding specificity play an important role in the successive signal transduction into cells. Therefore, the present study is undertaken to explore the spatial distribution of collagen binding EGF on the surface of type I collagen fibrils. We prepared EGF fused with CBD and labeled the chimeric proteins with gold nanoparticles (GNPs) to study the ultrastructure of the composites consisting of chimeric proteins and collagen fibrils by transmission electron microscopy (TEM).

EXPERIMENTAL PROCEDURES

Construction of Recombinant Plasmids. A bacterial expression system was used to prepare two chimeric proteins consisting of human EGF, CBD derived from either the human von Willebrand factor (vWFCBD; 189 aa, residues 922−1110, A3 domain) (*15*) or human fibronectin (FNCBD; 340 aa, residues 260−599) (*16*), and the hexahistidine tag (6 × His). Control protein lacking CBD (EGF having 6 × His) was prepared as before (*13*). The structures of these proteins are shown in Figure 1.

For the preparation of chimeric genes, the overlap extension method was employed (*17–19*). Primers used in polymerase chain reaction (PCR) are shown in Table 1. Forward primers for EGF (**P1** and **P3**; identical to each other) contained an Nde I restriction site in the 5′ region, while reverse primers for vWFCBD (**P6**) and FNCBD (**P8**) contained, respectively, Xho I and Not I sites in the 5′ region. For subsequent overlap extension, reverse primers for EGF (**P2** and **P4**) contained sequences complementary to the 5′-region of vWFCBD and FNCBD (21 bases in **P2** and 19 bases in **P4**), whereas forward primers for vWFCBD (**P5**) and FNCBD (**P7**) contained sequences complementary to the 3′-region of EGF (21 bases in **P5** and 19 bases in **P7**). Thus, **P2** and **P4** were exactly complementary to **P5** and **P7**, respectively. In addition, six bases

were inserted between EGF and CBD to add Gly-Gly as a linker in between (GGTGGT in **P5** and **P7**; ACCACC in **P2** and **P4**).

The cDNA of EGF and CBD were separately amplified from human cDNA libraries of the pancreas (for EGF and vWFCBD) and placenta (for FNCBD) (both from Takara Bio, Inc., Otsu, Japan), using **P1** and **P2** for EGF to be fused with vWFCBD, using **P3** and **P4** for EGF to be fused with FNCBD, using **P5** and **P6** for vWFCBD, and using **P7** and **P8** for FNCBD. An amount of 100 ng of DNA was used as templates in a 100 μL reaction volume that contained 2.5 units of DNA polymerase (Ex Taq, Takara), 0.2 mM dNTP mixture, and 0.4 μM primers. PCR was performed using a thermal cycler (Gene Amp PCR 9700G, Applied Biosystems) under the following cycling conditions: for EGF and vWFCBD, 30 cycles, denaturation at 94 °C for 30 s, annealing at 60 °C for 30 s, extension at 72 °C for 60 s; for FNCBD, 35 cycles, denaturation at 94 °C for 30 s, annealing at 55 °C for 30 s, extension at 72 °C for 90 s. DNA fragments thus obtained were separated by 2% agarose gel electrophoresis and purified using a gel extraction kit (Qiagen).

An amount of 100 ng of each DNA obtained by PCR was mixed (EGF + vWFCBD or EGF + FNCBD) in a solution (100 μL) containing 2.5 units of DNA polymerase (Takara Ex Taq) and 0.2 mM dNTP mixture. These overlapping fragments were denatured, annealed to generate heteroduplexes, and extended to obtain full-length DNA. For the fill-in reaction, the following thermal cycling conditions were employed: seven cycles, denaturation at 94 °C for 1 min, and annealing and extension at 63 °C for 4 min. In the second PCR, 50 μL of reaction products from the above fill-in reaction was used to amplify full-length DNA by priming with **P1** and **P6** for EGF–vWFCBD and with **P3** and **P8** for EGF–FNCBD under the following cycling conditions: for EGF–vWFCBD, 30 cycles, denaturation at 94 °C for 30 s, annealing at 55 °C for 30 s, extension at 72 °C for 120 s; for EGF–FNCBD, 30 cycles, denaturation at 94 °C for 30 s, annealing at 60 °C for 30 s, extension at 72 °C for 90 s.

Chimeric genes thus obtained were purified by gel electrophoresis and subjected to digestion with restriction enzymes, Nde I and Xho I for EGF–vWFCBD and Nde I and Not I for EGF–FNCBD, followed by gel purification to obtain inserts with cohesive ends. These inserts were ligated using T4 ligase (Ligation High, Toyobo, Osaka, Japan) to the upstream of the 6 × His tag in pET-22b(+) plasmid (Novagen) previously linearized by digestion with the same restriction enzymes and transformed to *Escherichia coli* (*E. coli*) strain DH5α (Toyobo). Colonies were randomly picked up, and the presence of the plasmid was verified by colony PCR. Plasmid-containing colonies were then amplified in Luria–Bertani (LB) medium containing 100 μg/mL ampicillin, and plasmids were isolated by the QIAprep Spin Miniprep kit (Qiagen) and ethanol precipitation. After sequence verification, the plasmids obtained were transformed into the *E. coli* host strain BL21(DE3)pLysS (Novagen), and one of the colonies containing plasmids, checked by colony PCR, was amplified in LB medium containing 100 μg/mL ampicillin to obtain glycerol stocks.

Protein Expression and Purification. The expression, purification, and refolding of chimeric proteins were carried out as before (*13*). In brief, the *E. coli* strain BL21(DE3)pLysS harboring recombinant plasmids were grown in 100 mL of LB medium containing 100 μg/mL ampicillin for 1 h. Then, 1 mM isopropyl β-D-thiogalactoside (IPTG) was added to the culture to induce gene expression. After 4 h of additional culture, cells were collected by centrifugation and chilled at –80 °C for 24 h. The cells were thawed and lysed in BugBuster protein extraction reagent (Novagen) containing 25 unit/mL Benzonase nuclease (Novagen). The inclusion bodies containing expressed proteins were purified according to the manufacture's instructions and were solubilized in 20 mM PBS (pH 7.4) containing 8 M urea, 20 mM imidazole, and 5 mM 2-mercaptoethanol. After removal of insoluble particles by centrifugation and filtration, affinity purification was performed using His Trap HP column (Amersham). Trapped proteins were eluted with 20 mM PBS (pH 7.4) containing 8 M urea and 500 mM imidazole. Purified proteins were analyzed by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) using 16% polyacrylamide gel with Tris/tricine/SDS buffer and visualized by staining with Coomassie brilliant blue. The refolding of proteins was performed by the stepwise dialysis method using dialysis membranes with a molecular weight cutoff of 3.5 kDa. Dialysis was performed sequentially against the following buffers: (i) 20 mM Tris-HCl, 0.2 mM dithiothreitol (pH 8.5), (ii) 20 mM Tris-HCl (pH 8.5), (iii) 20 mM Tris-HCl, 0.2 mM oxidized glutathione, 2 mM reduced glutathione (pH 8.0), and (iv) PBS (pH 7.4). Finally, PBS solutions of the refolded proteins were aliquoted and stored at –80 °C until use.

Affinity Precipitation Assay. After being washed with pure water, Speharose CL-6B microbeads (Pharmacia) were suspended in 0.6 M epichlorohydrin in a 1:1 mixture of 0.4 M NaOH and bis(2-methoxyethyl) ether and kept at room temperature for 1 h to introduce epoxides to the beads (*20*). After being washed with water, the beads were transferred to 1 mM 11-mercapto-1-undecanoic acid in a 1:1 mixture of ethanol and PBS and kept overnight at room temperature to allow the reaction of epoxide with nucleophilic thiol (*21*). The resulting

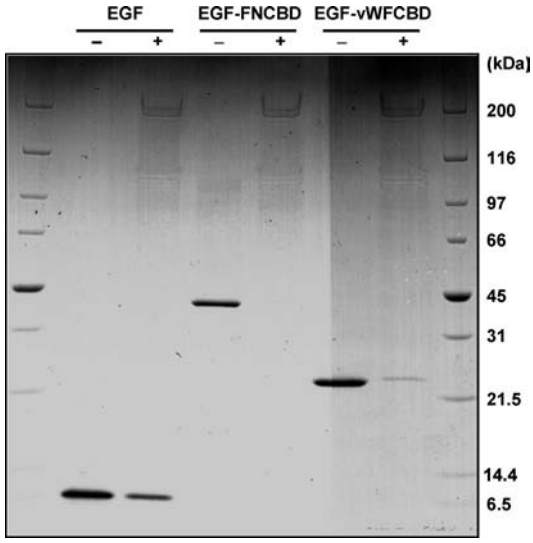

Figure 3. SDS–PAGE analysis results of chimeric and control proteins before (−) and after (+) contact with collagen-adsorbed gel beads.

beads presenting carboxylic acid were washed with water and suspended in 1 mg/mL type I collagen solution (Collagen I-PC, Koken, Tokyo, Japan) in 1×10^{-2} M HCl and kept at room temperature for 3 h to physically adsorb collagen to the beads. Then the beads were washed extensively with 1×10^{-2} M HCl to remove weakly adsorbed collagen. The adsorption of collagen was confirmed by micro-BCA protein assays (Pierce). The suspension of collagen-adsorbed beads (total volume of 100 μL with a bed volume of ~70 μL) was mixed with an equal volume of PBS containing 0.2 mg/mL chimeric proteins or native EGF and kept at 37 °C for 20 min. Then the microbeads were separated from protein solutions by centrifugation. Supernatants and original protein solutions were analyzed by SDS–PAGE to assess concentration depletion due to adsorption to collagen-modified beads.

Enzyme-Linked Immunosorbent Assay (ELISA). An amount of 100 μL microliter of 0.1 mg/mL type I collagen solution (I-PC, Koken) was added to each well of a 96-well polystyrene plate and incubated for 1 h at room temperature to allow the adsorption of collagen. Then the solution was aspirated, and the plate was washed with PBS. After blocking with Blocking One (Nacalai Tesque, Kyoto, Japan), 50 μL of PBS containing chimeric protein or CBD-deficient EGF at 0–50 μg/mL was

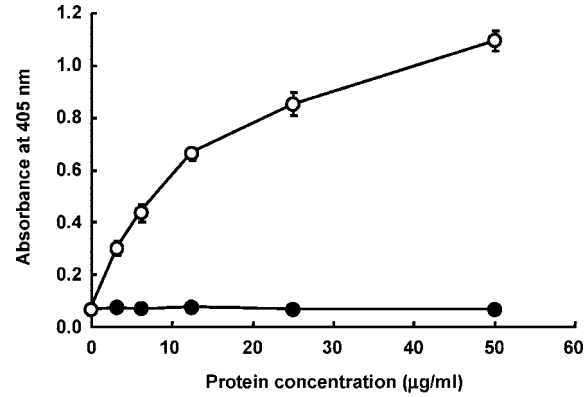

Figure 4. Enzyme-linked immunosorbent assays for the binding of (open circle) EGF–vWFCBD and (closed circle) wild-type EGF onto collagen-coated surfaces. Data are expressed as the mean ± standard deviation for $n = 4$.

added to each well in quadruplicate and incubated at room temperature for 30 min to allow the binding of these proteins to preadsorbed collagen. The solution was aspirated, and the plate was extensively washed with PBS containing 0.05% Tween-20 (PBS-Tween20) followed by binding of goat anti-EGF antibody [1:100, EGF (C20) sc-1341, Santa Cruz] and subsequently rabbit antigoat IgG (1:500, Molecular Probes). The plate was washed with PBS-Tween20. Then a solution of alkaline phosphatase-conjugated antirabbit IgG (Sigma) was added to the plate to allow binding of the antibody at room temperature for 30 min. After the plate was washed with PBS-Tween20, 100 μL of *p*-nitrophenyl phosphate solution (pNPP, Sigma) was added to the wells. The coloring reaction was allowed to proceed at 37 °C for 15 min and was stopped by adding NaOH solution. Finally, the optical density of the solution was recorded at 405 nm with a plate reader.

GNP Labeling. GNPs were prepared according to the reported methods in which $HAuCl_4$ was reduced by sodium citrate (*22*) or sodium borohydride (*23*). The average diameter of GNPs was 15 nm by citrate reduction and 5 nm by $NaBH_4$ reduction when determined by TEM. The suspension of GNPs was centrifuged at 17000*g* for 1 h, and the pellet obtained was washed with water. This procedure was repeated two times, and then GNPs were suspended in H_2O of $^1/_5$ volume relative to the volume of the original suspension. To the suspension, a solution of EGF–vWFCBD, EGF–FNCBD, or EGF was added to a final concentration of 20 μg/mL, and the mixture was incubated at room temperature to physically adsorb these proteins to GNPs. After 2 h of incubation, the suspension was centrifuged at 17000*g* for 15 min and the pellet obtained was suspended in H_2O. EGF–vWFCBD, EGF–FNCBD, and EGF possess intramolecular disulfide bonds and no free cysteine in their folded state. We consider that these proteins are adsorbed to GNPs primarily through nonspecific interactions, as in the case of bovine serum albumin (*24*). Although we have no experimental data that show the efficiency of the interactions for each protein, most of the GNPs are expected to adsorb nonspecifically these proteins from solutions at relatively high concentration.

Binding to Collagen Fibrils. The tail tendon obtained from Fisher344 rats of 12 weeks old was cut into pieces with a length of approximately 1 mm, unraveled using fine forceps, and deposited onto a Cu grid that had been laminated with a polyvinylformal membrane, reinforced with a thin carbon layer, and treated with oxygen plasma. It is reported that the rat tail tendon mostly consists of type I collagen (*25*). To the grid, a drop of 2% Pluronic F-127 (Sigma) solution in water was pipetted and kept at room temperature for 6 h to block the

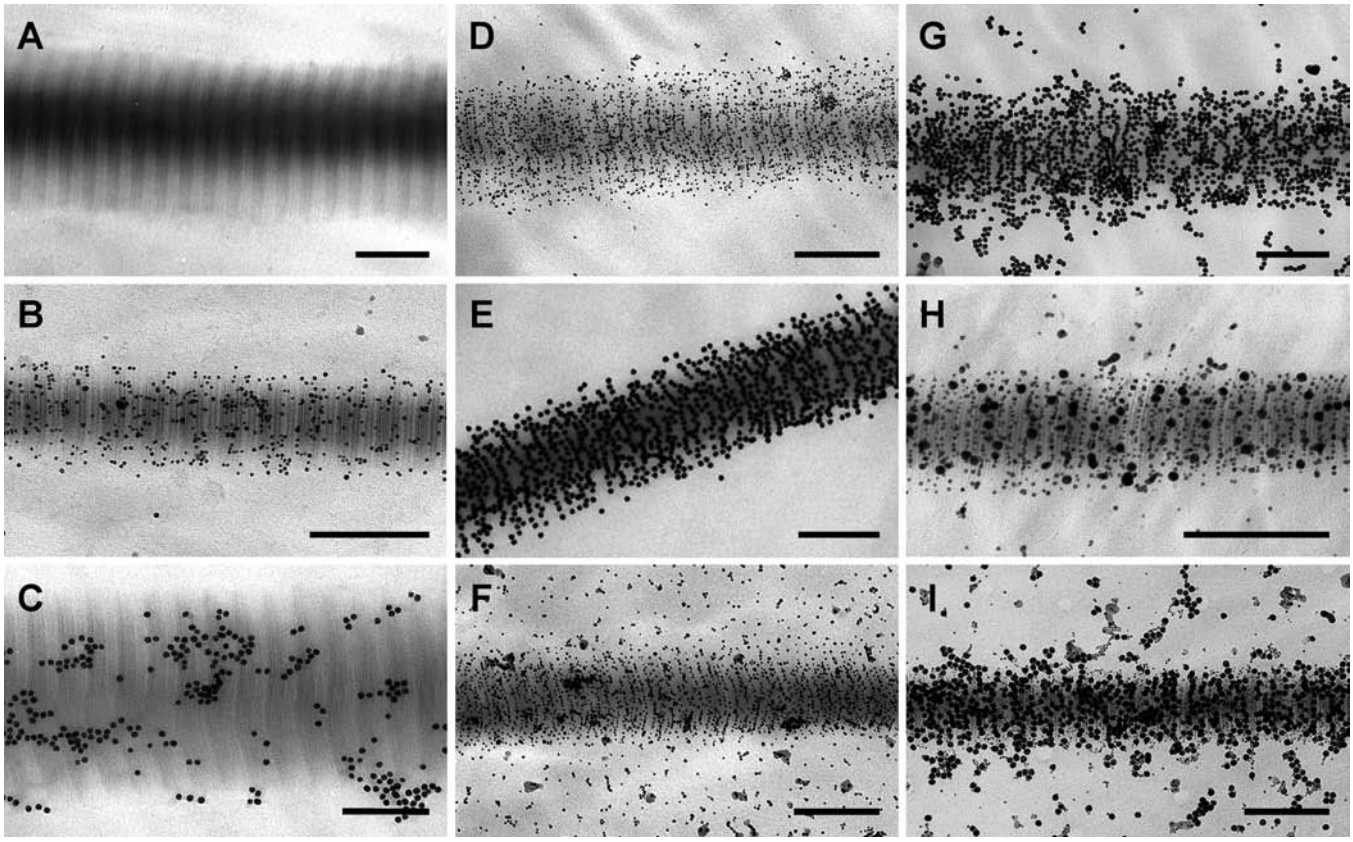

Figure 5. TEM images of (A) a negatively stained collagen fibril and (B–I) a collagen fibril bound with GNP-labeled chimeric proteins. A single chimeric protein was used in parts B–G, whereas two different chimeras were (H) simultaneously or (I) sequentially bound to the fibrils. Parts B and C show the result of control experiments in which (B) nontreated GNPs and (C) GNPs with CBD-deficient EGF (control EGF) were adsorbed. Protein and diameter of GNPs in nm are as follows: (B) no protein, 5; (C) EGF (control), 15; (D) EGF–vWFCBD, 5; (E) EGF–vWFCBD, 15; (F) EGF–FNCBD, 5; (G) EGF–FNCBD, 15; (H, I) EGF–FNCBD, 5, and EGF–vWFCBD, 15. Scale bar is 200 nm.

nonspecific adsorption of GNPs. Then Pluronic solution was removed by absorbing with lint-free paper, and an aliquot of GNP-labeled protein solutions was pipetted to the grid to allow the binding of chimeric proteins to collagen fibrils at 4 °C overnight. When the assembly of two different proteins was studied, chimeric proteins (EGF–vWFCBD or EGF–FNCBD) labeled with different diameters of GNPs (5 or 15 nm) were applied in a mixture or in a sequential manner. The grid was washed with PBS–Tween20 and then fixed with 4% glutaraldehyde solution in PBS. Finally the grid was washed with water and air-dried.

TEM. The grid with collagen fibrils and GNP-labeled chimeric protein was immersed in a 1:1 mixture of ethanol and water, saturated with uranyl acetate, and kept at room temperature for 30 min for negatively staining collagen fibrils. Then the grid was extensively washed with water and finally air-dried. TEM observation was carried out using Hitachi H-7000 operating at an accelerate energy of 75 kV and a typical magnification of 30000× to 60000×.

Two-Dimensional Fast Fourier Transform. Digitized TEM images were rotated using Adobe Photoshop 5.0 to align a fibril of interest with the *y*-axis for the simplicity of later analyses and further transformed to binary images for avoiding interference by the banding patterns of negatively stained collagen fibrils. In addition, surrounding areas around fibrils were masked to eliminate noise originating from nonspecific GNPs. The images were trimmed into 1 μm × 1 μm and adjusted to 512 pixels × 512 pixels. The modified images thus obtained were analyzed by two-dimensional fast Fourier transform (2D-FFT) using the Scion Image software (Scion Corp., MD).

RESULTS

Chimeric Proteins. Figure 2 shows the result of SDS–PAGE analysis for proteins synthesized in this study. As can been seen, three proteins were separated as single bands. Estimated molecular weights are 7 kDa for EGF–His, 28 kDa for EGF–vWFCBD, and 44 kDa for EGF–FNCBD, and they are in accordance with those expected from the number of amino acids contained.

Affinity for Collagen. The results of precipitation assays are shown in Figure 3. The bands of EGF–vWFCBD and EGF–FNCBD were significantly weakened after the compounds made contact with collagen-adsorbed gel beads, while the band of CBD-deficient control EGF remained almost unchanged. These results suggest that CBD-containing chimeric proteins have an affinity for type I collagen. The slight reduction in band intensity observed with control EGF is probably due to its nonspecific adsorption to the beads. To verify further an affinity for collagen, chimeric proteins were subjected to ELISA. As shown in Figure 4, EGF–vWFCBD was bound to the collagen-coated surface. This is in marked contrast to CBD-deficient EGF that exhibited no sign of collagen binding. The results of precipitation assays and ELISA demonstrate that the chimeric proteins, EGF–vWFCBD and EGF–FNCBD, bind to collagen through collagen–CBD interactions.

TEM Observation. The TEM image of negatively stained collagen fibrils (Figure 5A) exhibited a clear banding pattern along the fibril axis with a period of 67 nm, representing the

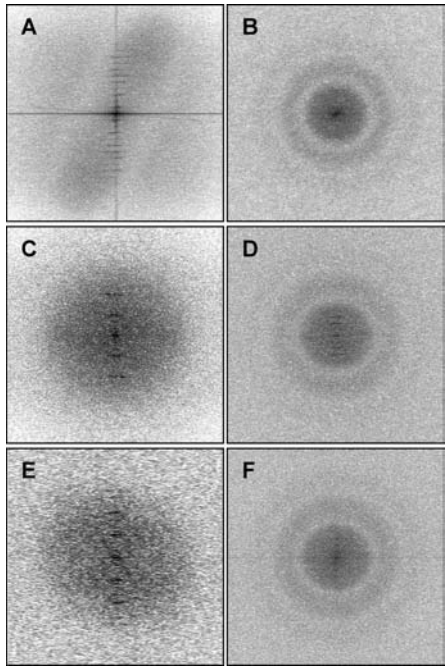

Figure 6. Power spectra obtained by 2D-FFT of TEM images: (A) a negatively stained collagen fibril; (B–F) collagen fibrils with GNP-labeled chimeric or control proteins. Protein and diameter of GNP (nm) are as follows: (B) EGF, 15; (C) EGF–vWFCBD, 5; (D) EGF–vWFCBD, 15; (E) EGF–FNCBD, 5; (f) EGF–FNCBD, 15.

ordered assembly of collagen molecules according to the D-staggered model (*26*).

As shown in Figure 5D–G, GNPs with CBD-containing chimeric proteins are observed selectively and tightly on collagen fibrils. In both cases with EGF–vWFCBD and EGF–FNCBD, it is frequently seen that the strings of GNPs are aligned perpendicular to the fibril axis. We could not observe clear difference between vWFCBD- and FNCBD-chimeras regarding the alignment of GNPs. The difference in the diameter of GNPs had small effects on the formation of strings, exhibiting a similar center-to-center distance between neighboring strings. In contrast, nontreated GNPs (Figure 5B) and GNPs with control EGF (Figure 5C) are seen sparsely on the fibril surface without noticeable ordered structure, suggesting no specific interactions operated between GNPs and collagen. Adsorption of GNPs occasionally took place at the surrounding regions around fibrils. The aggregation of GNPs was also observed especially for GNPs with EGF–FNCBD. These results are likely due to the strong propensity of GNPs for aggregation and adsorption.

Attempts were further made to assemble two types of chimeric proteins carrying different CBDs on the same collagen fibril. vWFCBD and FNCBD are expected to recognize different binding sites on the collagen fibrils (*27*). It is seen that the ordered assembly is clear for smaller GNPs. On the other hand, a smaller number of larger GNPs is seen on the collagen fibrils, with much disordered arrangements compared to the case with smaller GNPs (Figure 5H). This is probably due to steric hindrance because similar results were obtained when EGF–FNCBD and EGF–vWFCBD were labeled with smaller and larger GNPs, respectively. Sequential binding of larger GNPs with EGF–vWFCBD and smaller GNPs with EGF–FNCBD resulted in the improved order of GNP arrangements (Figure 5I).

2D-FFT. To assess the periodical appearance of the strings, 2D-FFT was performed on the TEM images modified as described in the Experimental Procedures. The power spectra are shown in Figure 6. The meridional profiles (corresponding to the fibril axis) were obtained from the power spectra to extract

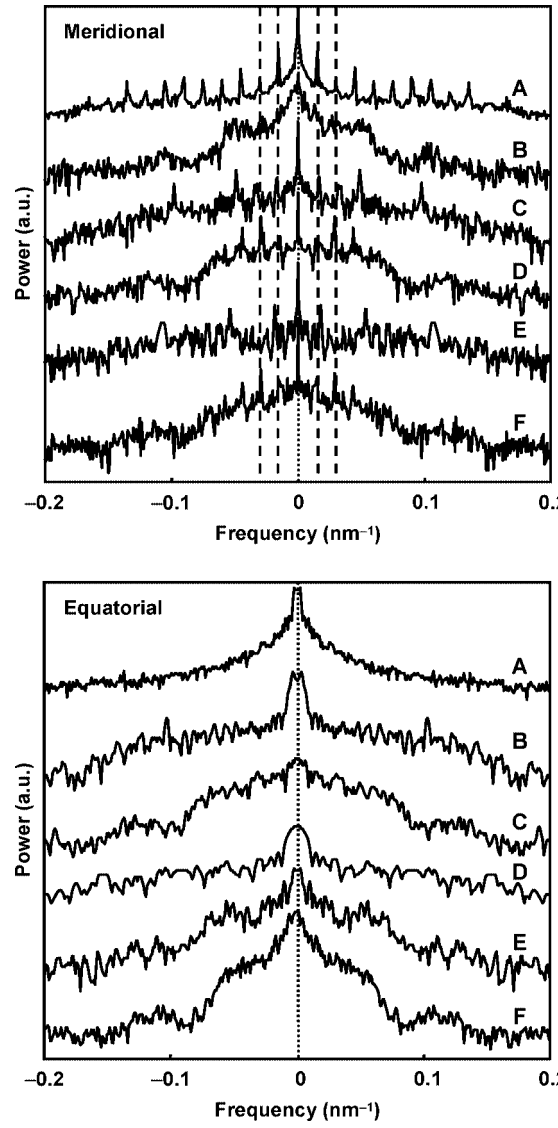

Figure 7. Meridional and equatorial profiles of the power spectra obtained by 2D-FFT of TEM images: (A) a negatively stained collagen fibril; (B–F) collagen fibrils with GNP-labeled chimeric or control proteins. The dashed lines in the meridional profiles indicate the position of lower-order diffraction peaks. Protein and diameter of GNP (nm) are as follows: (B) EGF, 15; (C) EGF–vWFCBD, 5; (D) EGF–vWFCBD, 15; (E) EGF–FNCBD, 5; (F) EGF–FNCBD, 15.

information about periodicity of the strings (Figure 7). Sharp peaks appearing in the meridional profile for a collagen fibril represent the periodic appearance of banding patterns with a frequency of 0.015 nm^{-1} [period = 67 nm, identical to the D-period (*26*)], while no peaks were observed in the equatorial profile (corresponding to the transversal direction of collagen fibrils). In the case of collagen with EGF–vWFCBD, line profiles exhibited characteristic peaks representing the periodic appearance of strings along the longitudinal fibril axis with a frequency of 0.015 nm^{-1} (period = 67 nm). Similar results were obtained for the case with EGF–FNCBD. In contrast, the profile for CBD-deficient EGF had no evident peaks. Alternatively, equatorial profiles exhibited no noticeable peaks in all the GNP–chimeric protein combinations.

DISCUSSION

Collagen-based materials loaded with growth factors are expected to provide artificial microenvironments that mimic a natural extracellular matrix. In the present study, we utilized

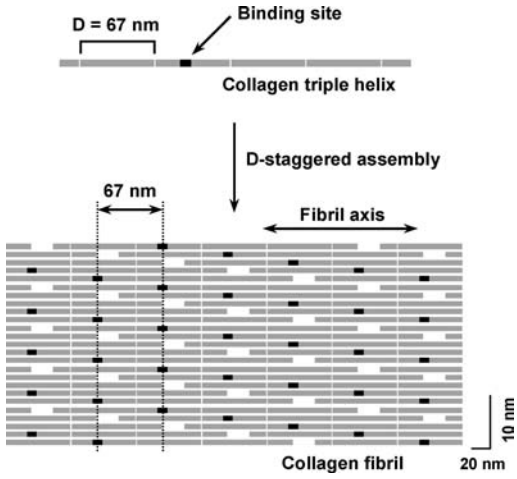

Figure 8. Illustration of the expected distribution of binding sites on the surface of a collagen fibril. When a binding site for CBD (marked in black) is located at a certain region in a collagen triple helix, the D-staggered assembly of collagen monomers produces an array of binding sites on the fibril surface. CBD contained in the EGF chimera recognizes these binding sites to present densely EGF on the fibril surface with nanometer-scale periodicity.

CBDs for the efficient loading of EGF to fibrillar collagen. Because the nanometer scale spatial distribution of surface-immobilized EGF is anticipated to have an influence on its recognition by cell surface receptors (*13*, *14*), we studied here the ultrastructure of composites consisting of collagen fibrils and CBD-containing EGF.

It is known that a collagen fibril is formed by the D-staggered arrangement of collagen molecules (*26*). According to the previous studies on 3D molecular packing by computational modeling (*28*, *29*) and on surface microstructure by scanning electron microscopy (*25*) and atomic force microscopy (*30*), it seems that the D-staggered arrangement also explains in essence the assembled structure at the fibril surface. Because the extended form of a collagen triple helices laterally aligns with D-staggered arrangements, generating a fibril in which individual helices are aligned in the same or slightly declined (*25*) direction as the longitudinal fibril axis, any peptide segments in the collagen α chains are expected to appear periodically with an interval of 67 nm along the longitudinal fibril axis (*26*). This interval is identical to the observed periods of GNP strings, suggesting that the chimeric proteins recognized specific binding sites for CBD involved in the collagen α chains (Figure 8).

However, it is further observed in the TEM images (Figure 5D–G) that the apparent interval of strings is smaller than 67 nm, with at least one more intermitting string. We speculate that this finding accounts for the existence of multiple binding sites on a single α chain for both vWFCBD (*31*, *32*) and FNCBD (*33*) (Figure 8). It is also predicted that the binding sites are periodically distributed in the transversal direction on the fibril surface. However, there is not enough evidence to show the periodical distribution of chimeric proteins along the transversal axis. This is probably because of the small interhelix distance (1.5 nm) (*26*) compared to the size of GNPs (5 or 15 nm in diameter), which might hamper the binding of the GNP-labeled proteins to the neighboring sites by steric hindrance.

In summary, EGF genetically engineered to carry CBDs recognizes their specific binding sites distributed on collagen fibrils. This produces a nanometer-scale molecular assembly, although the minor disorder of assembly was observed occasionally even in single-component systems. The utilization of different CBD-binding sites has potential for loading multiple growth factors in a single matrix. Further study is currently underway to design collagen-growth factor composites that optimize proliferation and differentiation of neural stem/progenitor cells.

Received May 18, 2007; Revised Manuscript Received August 27, 2007

Design, syntheses, and gene delivery efficacies of fifteen novel gemini (dimeric) and three monomeric cationic lipids anchored on an aromatic backbone have been described. Each new lipid has been used for liposome formation, and optimal formulations were used to determine the structure–activity correlation of the gene transfection efficacies of these lipids in HeLa and HT1080 cells. The results of the present investigation bring out the effect of hydrocarbon chain lengths and the length of the spacer between the headgroups on gene transfection efficiencies of the cationic gemini lipids based on aromatic backbone. The lipids bearing *n*-$C_{14}H_{29}$ hydrocarbon chain lengths have been found to be the best transfecting agents compared to their counterparts with *n*-$C_{16}H_{33}$ and *n*-$C_{12}H_{25}$ chains in HeLa cells. On the other hand, in HT1080 cells, the lipids based on *n*-$C_{12}H_{25}$ and *n*-$C_{14}H_{29}$ chains were found to be more potent transfecting agents than lipids possessing *n*-$C_{16}H_{33}$ chains. Transmission electron microscopy examination revealed the existence of spherical lipid–DNA complexes.

INTRODUCTION

Over the years, the definition of a "drug molecule" has changed considerably. Drugs have emerged from active components of certain natural products, or via the design of specific enzyme inhibitors. The recent realization of using the genetic material, DNA as a potential drug has led to the development of gene therapy (*1*). Gene therapy can be envisaged as an attempt to cure a disease by supplementing the aberrant gene with a functional one or by the delivery of a suicide gene (*2*) or by transfer of a gene for the production of a therapeutic protein (*3, 4*).

In recent years, many cationic lipid based formulations have been developed to aid the delivery of DNA, *m*RNA, *si*RNA, antisense oligonucleotide, proteins and even drugs into eukaryotic cells. Because of low levels of toxicity and very low immunogenicity, their ability to deliver large pieces of DNA, and ease of preparation, cationic lipids are increasingly used as the nonviral transfection vectors as compared to viral vectors, which have several limitations (*5–13*). In addition, viral vectors add complications during gene transfer by generating adverse immunogenic responses through recombination events with the host genome (*14*).

Cationic lipid and polymeric suspensions readily form complexes with the negatively charged DNA (gene) under ambient conditions (*15*). The molecular structure of cationic lipids is an important parameter that controls their DNA complexation and gene transfection activity (*16*). Accordingly, we have investigated the role of various molecular-level modifications in different synthetic lipids on their membrane-forming properties (*17, 18*) and further influence on gene delivery events (*19–22*). For instance, the functional group that links the polar headgroup and the hydrocarbon chains of such lipid molecules plays a crucial role in their utilization in gene transfer events. Thus, *N*-[1-(2,3-dioleyloxy)propyl)]-*N*,*N*,*N*-trimethylammonium chloride (DOTMA), which contains an ether linkage between the headgroup and the long oleyl chains shows greater *in vivo* transfection efficiency than the corresponding ester analogue *N*-[1-(2,3-dioleoyloxy)propyl)]-*N*,*N*,*N*-trimethylammonium chloride (DOTAP) (*23*). Similarly, cholesterol-based lipids (*24*) and lipopolymers (*25, 26*) are also known as potent transfection agents. Here also, the role of functional group that connects cationic headgroup with a cholesteryl backbone assumes importance (*19*).

Gemini surfactants, i.e. amphiphiles molecules containing two head groups and two aliphatic chains, linked by a rigid or flexible spacer, show more interesting surfactant properties in solution compared to their monomeric counterparts. Recently, a number of reports appeared in the literature which describe the aggregation and transfection properties of gemini surfactants (*27–30*). We reported, for the first time, the synthesis and aggregation behavior of gemini pseudoglyceryl lipids (*31, 32*). It was shown that the aggregation properties of the gemini lipids could be modulated by the length of the spacer (*33*). Recently, the role of the oxyethylene-type spacer between the cationic headgroups on membrane aggregation and hydration properties was also investigated (*34*). Ahmad and co-workers showed the transfection properties of the cardiolipin-based cationic lipids (*35*). Cholesterol-based gemini lipids have been shown to deliver the DNA into the mammalian cells very efficiently and even in the presence of serum (*36, 37*). The gene delivery efficiencies strongly depend on the length of the spacer between the headgroups.

Although there is no systematic study on the use of gemini lipids for gene transfer that are based on aromatic units, there are a few reports in the literature that describe the transfection activities of cationic liposomes based on aromatic headgroups or backbones. Hoekstra et al. showed the gene delivery properties of certain pyridinium surfactants (*38*). Balaban and co-workers reported the transfection properties of various pyridinium based cationic Monomeric, gemini, and oligomeric

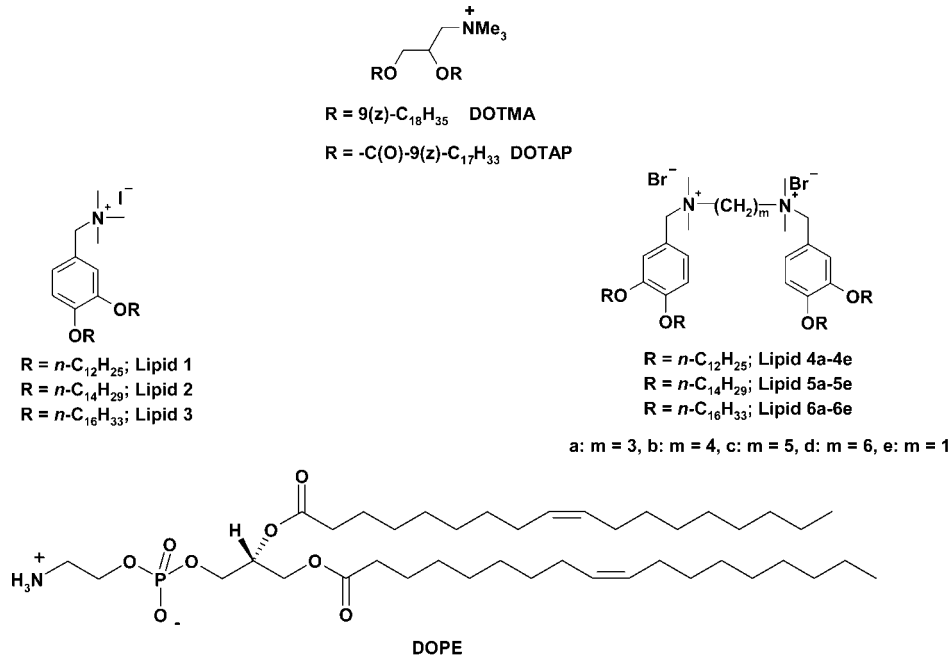

Figure 1. Molecular structures of the monomeric lipids **1**–**3**, gemini lipids **4**–**6** synthesized and studied in this work, and structures of DOTMA, DOTAP, and DOPE.

surfactants having structural variations at the level of hydrophobic segment, linker, and counter ions (*39*). Safinya and co-workers have shown that multivalent cationic lipids with an aromatic backbone hold promise for superior gene transfection (*40*). Aromatic cationic lipids (TRX) possessing amidine headgroup have been developed by Sakurai and co-workers (*41*). Recently, Phanstial and co-workers reported the transfection properties of aromatic lipophilic polyamines (*42*). However, there is no systematic study that examines the transfection activities of a series of gemini lipids based on an aromatic backbone. In addition, none of above reports addressed the important issue of serum compatibility of the liposomal formulations.

We previously reported the aromatic backbone based gemini lipids (*43*). Subsequently, we described the synthesis of aromatic lipids bearing *n*-$C_{16}H_{33}$ hydrocarbon chains that differ from each other in the length of the polymethylene spacer (*44*). Herein, we present the synthesis of two analogous series of gemini lipids based on aromatic backbone bearing *n*-$C_{12}H_{25}$ and *n*-$C_{14}H_{29}$ hydrocarbon chains (Figure 1). We also report the transfection properties of these new gemini and three monomeric cationic lipids based on an aromatic backbone that differ in the hydrocarbon chain lengths and the length of the spacer between the headgroups. We investigated their transfection properties in detail in HeLa and HT1080 cells in the absence and presence of serum conditions. Gemini lipids showed enhanced transfection as compared to Lipofectin, which is a monomeric lipid, structurally related to the present set of gemini lipids, and commercially available reagent based on a 1:1 (w/w) ratio of DOTMA/DOPE[1] formulation. The gemini lipids bearing *n*-$C_{14}H_{29}$ chain lengths have been found to be more effective transfecting agents than their analogues with *n*-$C_{16}H_{33}$ and *n*-$C_{12}H_{25}$ chains in HeLa cells, whereas in HT1080 cells, we observed that the lipids based on *n*-$C_{12}H_{25}$ and *n*-$C_{14}H_{29}$ chains were more effective than lipids bearing *n*-$C_{16}H_{33}$ chains.

EXPERIMENTAL DETAILS

Materials and Methods. All reagents, solvents, and chemicals used in this study were of the highest purity available. The solvents were dried prior to use. Column chromatography was performed using 60–120 mesh silica gel. NMR spectra were recorded using a Jeol JNM λ-300 (300 MHz for ^{1}H) spectrometer. The chemical shifts (δ) are reported in ppm downfield from the internal standard, TMS, for ^{1}H NMR. Mass spectra were recorded on a Kratos PCKompact SEQ V1.2.2 MALDI-TOF spectrometer or on a MicroMass ESI-TOF spectrometer or Shimadzu tabletop GC-MS or ESI-MS (HP1100LC-MSD). Infrared (IR) spectra were recorded on a Jasco FT-IR 410 spectrometer using KBr pellets or neat. Lipids were synthesized as described below and were characterized fully by their ^{1}H NMR, mass spectra, and elemental analysis.

Synthesis. *Methyl-3,4-dihydroxybenzoate (***8***) (45).* To a solution of 2 g (12.98 mol) of 3,4-dihydroxy benzoic acid (**7**) in dry MeOH (8 mL) was added conc HCl dropwise in ice–cold conditions with constant stirring. The resultant mixture was then refluxed at 70 °C for 12 h. After that, the solution was concentrated and extracted using EtOAc, and the pure product was isolated as a brown solid in 90% yield upon rotary evaporation. IR (neat, cm^{-1}): 3351, 1696, 1603, 1532, 1435. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 3.87 (s, 3H, -O-*CH*$_3$), 5.52 (s, 1H, -*OH*), 5.77 (s, 1H, -*OH*), 6.89–6.92 (d, 1H, J = 9.0 Hz, ArH), 7.57–7.59 (m, 2H, ArH).

*Methyl-3,4-dialkyloxybenzoate (***9a**–**9c***).* A mixture of 1.84 g (11.2 mmol) of **8**, 28 mmol of appropriate alkyl bromide, and 33.6 mmol of K_2CO_3 in acetone was refluxed at 70 °C for 3 days. After that, the solution was concentrated, and the reaction mixture was taken in EtOAc. The organic layer was washed with water, brine, and then dried over anhydrous Na_2SO_4. The resulting solution was concentrated, and the residue was purified by chromatography over silica gel column using *n*-hexane/EtOAc as eluent. The pure product was isolated as a white solid in 70–75% yield.

*Methyl-3,4-didodecyloxybenzoate (***9a***) (46).* IR (neat, cm^{-1}): 2910, 2848, 1712, 1590, 1517, 1467. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.86–0.90 (t, 6H, J = 6Hz, 2× -CH_3), 1.26–1.46 (br m, 36H, 2× -$(CH_2)_9$), 1.78–1.86 (m, 4H, 2× -O-CH_2-CH_2), 3.88 (s, 3H, -O-CH_3), 4.01–4.06 (m, 4H, 2× -O-CH_2), 6.84–6.87 (d, 1H, J = 9.0 Hz, ArH), 7.53 (s, 1H, ArH), 7.61–7.65 (m, 1H, ArH). LRMS: 505 ($M + H^+$). HRMS: Calcd 505.4257 ($M + H^+$); found 505.4253.

*Methyl-3,4-ditetradecyloxybenzoate (***9b***) (46).* IR (neat, cm^{-1}): 2917, 2850, 1712, 1598, 1517, 1467. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.86–0.90 (t, 6H, J = 6Hz, 2× -CH_3), 1.26–1.46 (br m, 44H, 2× -$(CH_2)_{11}$), 1.82 (m, 4H, 2× -O-CH_2-CH_2), 3.88 (s, 3H, -O-CH_3), 4.04 (m, 4H, 2× -O-CH_2), 6.84–6.88 (d, 1H, J = 9.0 Hz, ArH), 7.54 (s, 1H, ArH), 7.64 (m, 1H, ArH). LRMS: 561 ($M + H^+$). HRMS: Calcd 561.4883 ($M + H^+$); found 561.4871.

*Methyl-3,4-dihexadecyloxybenzoate (***9c***) (46).* IR (neat, cm^{-1}): 2910, 2848, 1712, 1590, 1517, 1467. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.86–0.90 (t, 6H, J = 6Hz, 2× -CH_3), 1.26–1.46 (br m, 52H, 2× -$(CH_2)_{13}$), 1.78–1.86 (m, 4H, 2× -O-CH_2-CH_2), 3.88 (s, 3H, -O-CH_3), 4.01–4.06 (m, 4H, 2× -O-CH_2), 6.84–6.87 (d, 1H, J = 9.0 Hz, ArH), 7.53 (s, 1H, ArH), 7.61–7.65 (1H, m, ArH), LRMS: 656 ($M + K^+$).

*3,4-Dialkyloxybenzyl aAlcohol (***10a**–**10c***).* To a suspension 0.6 g (5 mmol) of $LiAlH_4$ in dry THF (5 mL) was added a solution of 3.24 mmol of **9a**–**9c** dropwise in ice–cold conditions with constant stirring under a nitrogen atmosphere. The ice bath was removed, and the resultant was refluxed at 70 °C overnight. Then, moist EtOAc (20 mL) was added slowly and stirred for 10 min at room temperature. The solvent was removed under vacuum, and then the reaction mixture was taken in $CHCl_3$ and washed with saturated Na, K-tartrate solution (50 mL). The aqueous layer was extracted twice with $CHCl_3$. All organic layers were collected together and dried over anhydrous Na_2SO_4, and the solvent was evaporated to leave a solid, which was purified by column chromatography using *n*-hexane/EtOAc as eluent. The pure product was isolated as a white solid in 90–95% yield.

*3,4-Didodecyloxybenzyl Alcohol (***10a***).* IR (neat, cm^{-1}): 3332, 2956, 2917, 2850, 1590, 1517, 1467. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.86–0.90 (t, 6H, J = 6Hz, 2× -CH_3), 1.26–1.46 (br m, 36H, 2× -$(CH_2)_9$) 1.79 (m, 4H, 2× -O-CH_2-CH_2), 3.96–4.02 (m, 4H, 2× -O-CH_2), 4.60 (s, 2H, -CH_2-Ar), 6.85 (s, 2H, ArH), 6.92 (s, 1H, ArH). LRMS: 499 ($M + Na^+$). HRMS: Calcd 499.4127 ($M + Na^+$); found 499.4231.

*3,4-Ditetradecyloxybenzyl Alcohol (***10b***).* IR (neat, cm^{-1}): 3342, 2917, 2850, 1590, 1517, 1467. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.86–0.90 (6H, t, J = 6Hz, 2× -CH_3), 1.26–1.46 (br m, 44H, 2× -$(CH_2)_{11}$), 1.79 (m, 4H, 2× -O-CH_2-CH_2), 3.96–4.02 (m, 4H, 2× -O-CH_2), 4.60 (s, 2H, -CH_2-Ar), 6.85 (s, 2H, ArH), 6.92 (s, 1H, ArH). LRMS: 555 ($M + Na^+$). HRMS: Calcd 555.4753 ($M + Na^+$); found 555.4743.

*3,4-Dihexadecyloxybenzyl Alcohol (***10c***).* IR (neat, cm^{-1}): 3348, 2954, 2916, 2849, 1518, 1466. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.86–0.90 (t, 6H, J = 6Hz, 2× -CH_3), 1.26–1.46 (br m, 52H, 2× -$(CH_2)_{13}$), 1.80 (m, 4H, 2× -O-CH_2-CH_2), 3.96–4.02 (m, 4H, 2× -O-CH_2), 4.6 (s, 2H, -CH_2-Ar), 6.86 (s, 2H, ArH), 6.92 (s, 1H, ArH). LRMS: 612 ($M + Na^+$). HRMS: Calcd 611.5379 ($M + Na^+$); found 611.5370.

*1-(3,4-Dialkanoyloxyphenylmethyl) Dimethylamine (***11a**–**11c***).* To a stirring solution of 0.76 mmol of the benzyl alcohol (**10a**–**10c**), 0.620 g (3 mmol) of PBr_3 in dry DCM was added dropwise in ice–cold conditions. Slowly, the resultant was allowed to rise to room temperature, and the mixture continued to stir for 24 h. Since the bromo compound was unstable, no isolation was attempted. The subsequent step was done *in situ* by adding excess Me_2NH in MeOH and again kept for 12 h. The mixture was concentrated, and the residue was dissolved in $CHCl_3$. The organic mixture was washed with 1 N HCl (2 × 50 mL) followed by water, saturated $NaHCO_3$, and brine, and then dried over anhydrous Na_2SO_4. The organic solvent was removed and then subjected to column chromatography over silica gel using MeOH/$CHCl_3$as an eluent. The pure compound was isolated as a white solid in 80–85% yield.

*1-(3,4-Didodecyloxyphenylmethyl) Dimethylamine (***11a***).* IR (neat, cm^{-1}): 2921, 2852, 1589, 1513, 1467. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.86–0.90 (t, J = 6Hz, 6H, 2× -CH_3), 1.26–1.46 (br m, 36H, 2× -$(CH_2)_9$), 1.79–1.82 (m, 4H, 2× -O-CH_2-CH_2), 2.23 (s, 6H, 2× -N-CH_3), 3.78 (s, 2H, -CH_2-Ar), 3.95–4.01 (m, 4H, 2× -O-CH_2), 6.78–6.87 (m, 3H, ArH). LRMS: 504 ($M + H^+$). HRMS: Calcd 504.4780 ($M + H^+$); found 504.47.

*1-(3,4-Ditetradecyloxyphenylmethyl) Dimethylamine (***11b***).* IR (neat, cm^{-1}): 2923, 2854, 1590, 1511, 1467. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.86–0.90 (t, 6H, J = 6Hz, 2× -CH_3), 1.26–1.46 (br m, 44H, 2× -$(CH_2)_{11}$), 1.80 (m, 4H, 2× -O-CH_2-CH_2), 2.21 (s, 6H, 2× -N-CH_3), 3.33 (s, 2H, -CH_2-Ar), 3.97 (m, 4H, 2× -O-CH_2), 6.79 (m, 3H, ArH). LRMS: 561 ($M + H^+$). HRMS: Calcd 560.5406 ($M + H^+$); found 560.5416.

*1-(3,4-Dihexadecyloxyphenylmethyl) Dimethylamine (***11c***).* IR (neat, cm^{-1}): 2917, 2850, 1590, 1517, 1467. ^1H NMR ($CDCl_3$, 300 MHz): δ 0.86–0.90 (t, 6H, J = 6Hz, 2× -CH_3), 1.26–1.46 (br m, 52H, 2× -$(CH_2)_{13}$), 1.79 (m, 4H, 2× -O-CH_2-CH_2), 2.56 (s, 6H, 2× -N-CH_3), 3.78 (s, 2H, -CH_2-Ar), 3.92–3.98 (m, 4H, 2× -O-CH_2), 6.80 (s, 2H, ArH), 6.93 (s, 1H, ArH). LRMS: 617 ($M + H^+$). HRMS: Calcd 616.6032 ($M + H^+$); found 616.5940.

*1-(3,4-Dialkyloxyphenylmethyl)- N,N,N-trimethyl Ammonium Iodide (***1**, **2**, **3***).* To a solution of **11a–c** (0.11 mmol) in dry EtOH, MeI (excess) was added in a screw-top pressure tube. The resulting mixture was heated to reflux at 80 °C for 24 h. The removal of solvent and subsequent washing with EtOAc–MeOH (9:1) produced a yellowish–white compound. The compound was isolated in quantitative yield.

Lipid **1.** ^1H NMR (300 MHz, $CDCl_3$): δ 0.86–0.90 (t, 6H, J = 6.0 Hz, 2× -CH_3), 1.26–1.46 (m, 36H, 2× -$(CH_2)_9$), 1.75–1.87 (m, 4H, 2× -O-CH_2-CH_2-), 3.35 (s, 9H, 3× -N^+-CH_3), 3.98–4.06 (m, 4H, 2× -O-CH_2-CH_2-), 4.87 (s, 2H, -N^+-CH_2-Ar), 6.88 (d, 1H, J = 9.0 Hz, ArH), 7.11 (d, 1H, J = 9.0 Hz, ArH), 7.20 (s, 1H, ArH). ESI-MS: 519.2 (M^+). Anal. ($C_{34}H_{64}NO_2I \cdot 2H_2O$) C, H, N.

Lipid **2.** ^1H NMR (300 MHz, $CDCl_3$): δ 0.86–0.90 (t, 6H, J = 6.0 Hz, 2× -CH_3), 1.26–1.46 (m, 44H, 2× -$(CH_2)_{11}$), 1.80 (m, 4H, 2× -O-CH_2-CH_2-), 3.36 (s, 9H, 3× -N^+-CH_3), 3.98–4.06 (m, 4H, 2× -O-CH_2-CH_2-), 4.92 (s, 2H, -N^+-CH_2-Ar), 6.86–6.89 (d, 1H, J = 9.0 Hz, ArH), 7.10–7.13 (d, 1H, J = 9.0 Hz, ArH), 7.23 (m, 1H, ArH). ESI-MS: 574.5 (M^+). Anal. ($C_{38}H_{72}NO_2I$) C, H, N.

Lipid **3.** ^1H NMR (300 MHz, $CDCl_3$): δ 0.85 (t, 6H, J = 7.0 Hz, 2× -CH_3), 1.25–1.46 (m, 52H, 2× -$(CH_2)_{13}$), 1.78–1.80 (m, 4H, 2× -O-CH_2-CH_2-), 3.35 (s, 9H, 3× -N^+-CH_3), 3.97–4.05 (m, 4H, -O-CH_2-CH_2-), 4.91 (s, 2H, -N^+-CH_2-Ar), 6.87 (d, 1H, J = 8.1 Hz, ArH), 7.11 (d, 1H, J = 8.1 Hz, ArH), 7.21 (s, 1H, ArH). ESI-MS: 631 (M^+). Anal. ($C_{42}H_{80}NO_2I \cdot 2H_2O$) C, H, N.

*General Method for the Synthesis of Gemini Lipids (***4**, **5**, **6***).* A solution of **11a–c** (0.24 mmol) and appropriate α,ω-dibromoalkane (0.080 mmol) in dry MeOH/EtOAc mixture was refluxed over a period of 48–96 h. It was cooled, and solvent was evaporated to produce a crude solid. It was repeatedly washed with dry EtOAc to remove unreacted starting material and finally subjected to repeated crystallization from a mixture of EtOAc and MeOH (9:1), which gives white solid. Yield 40–50%.

Lipid **4a.** ^1H NMR (300 MHz, $CDCl_3$): δ 0.86–0.90 (t, J = 6.0 Hz, 12H, 4× -CH_3), 1.26–1.46 (m, 72H, 4× -$(CH_2)_9$), 1.80

(m, 8H, 4× -O-CH_2-CH_2), 3.07 (br m, 2H, -N^+-CH_2-CH_2-), 3.22 (s, 12H, 4× -N^+-CH_3), 3.98–4.01 (m, 12H, 4× -O-CH_2-CH_2- and 2× -N^+-CH_2-CH_2), 4.71 (s, 4H, 2× -N^+-CH_2-Ar), 6.86 (d, J = 9.0 Hz, 2H, ArH), 7.08 (m, 4H, ArH). ESI-MS: 459.4 (($C_{12}H_{25}O)_2C_6H_3CH_2^+$), 589.5 (($C_{12}H_{25}O)_2C_6H_3CH_2N^+(CH_3)_2(CH_2)_3N(CH_3)_2$). Anal. ($C_{69}H_{128}N_2O_4Br_2 \cdot 2H_2O$) C, H, N.

Lipid **4b.** ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.86–0.90 (t, J = 6.0 Hz, 12H, 4× -CH_3), 1.25–1.46 (m, 72H, 4× -$(CH_2)_9$), 1.77 (m, 12H, 4× -O-CH_2-CH_2- and 2× -N^+-CH_2-CH_2-), 3.12 (s, 12H, 4× -N^+-CH_3), 3.96–4.02 (m, 12H, 4× -O-CH_2-CH_2- and -N^+-CH_2-CH_2), 4.67 (s, 4H, 2× -N^+-CH_2-Ar), 6.88 (d, J = 9.0 Hz, 2H, ArH), 7.11 (m, 4H, ArH). ESI-MS: 459.4 (($C_{12}H_{25}O)_2C_6H_3CH_2^+$), 603.5 (($C_{12}H_{25}O)_2C_6H_3CH_2N^+(CH_3)_2(CH_2)_4N(CH_3)_2$). Anal. ($C_{70}H_{130}N_2O_4Br_2 \cdot 3H_2O$) C, H, N.

Lipid **4c.** ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.86–0.90 (t, J = 6.0 Hz, 12H, 4× -CH_3), 1.25–1.47 (m, 74H, 4× -$(CH_2)_9$ and -N^+-CH_2-CH_2-CH_2-), 1.80 (m, 8H, 4× -O-CH_2-CH_2), 2.23 (m, 4H, 2× -N^+-CH_2-CH_2-), 3.18 (s, 12H, 4× -N^+-CH_3), 3.99 (m, 12H, 4× -O-CH_2-CH_2- and 2× -N^+-CH_2-CH_2), 4.75 (s, 4H, 2× -N^+-CH_2-Ar), 6.89 (d, 2H, J = 9.0 Hz, ArH), 7.13 (m, 4H, ArH). ESI-MS: 459.4 (($C_{12}H_{25}O)_2C_6H_3CH_2^+$), 617.6 (($C_{12}H_{25}O)_2C_6H_3CH_2N^+(CH_3)_2(CH_2)_5N(CH_3)_2$). Anal. C, H, N, ($C_{71}H_{132}N_2O_4Br_2$).

Lipid **4d.** ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.86–0.90 (t, J = 6.0 Hz, 12H, 4× -CH_3), 1.26–1.46 (m, 76H, 4× -$(CH_2)_9$ and 2× -N^+-CH_2-CH_2-CH_2-), 1.79 (m, 12H, 4× -O-CH_2-CH_2- and 2× -N^+-CH_2-CH_2-CH_2-), 3.23 (s, 12H, 4× -N^+-CH_3), 3.82 (m, 4H, -N^+-CH_2-CH_2), 3.96–4.03 (m, 8 H, 4× -O-CH_2-CH_2-), 4.78 (s, 4H, 2× -N^+-CH_2-Ar), 6.85–6.88 (d, J = 9.0 Hz, 2H, ArH), 7.12–7.16 (m, 4H, ArH). ESI-MS: 547.5 (M^{+2}/2). Anal. ($C_{72}H_{134}N_2O_4Br_2$) C, H, N.

Lipid **4e.** ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.86 (t, J = 6.0 Hz, 12H, 4× -CH_3), 1.26 (m, 92H, 4× -$(CH_2)_9$ and 2× -N^+-CH_2-CH_2-CH_2-CH_2-CH_2-), 1.79 (m, 8H, 4× -O-CH_2-CH_2-), 3.05 (s, 12H, 4× -N^+-CH_3), 3.73 (m, 4H, 2× -N^+-CH_2-CH_2), 3.98 (m, 8H, 4× -O-CH_2-CH_2-), 4.82 (s, 4H, 2× -N^+-CH_2-Ar), 6.84–6.87 (d, J = 9.0 Hz, 2H, ArH), 7.14–7.18 (m, 4H, ArH). ESI-MS: 588 (M^{+2}/2). Anal. ($C_{78}H_{146}N_2O_4Br_2$) C, H, N.

Lipid **5a.** ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.86–0.90 (t, 12H, J = 6.0 Hz, 4× -CH_3), 1.25–1.47 (m, 88H, 4× -$(CH_2)_{11}$), 1.83 (m, 8H, 4× -O-CH_2-CH_2-), 3.05 (m, 2H, -N^+-CH_2-CH_2-), 3.22 (s, 12H, 4× -N^+-CH_3), 4.00 (m, 12H, 4× -O-CH_2-CH_2- and 2× -N^+-CH_2-CH_2), 4.68 (s, 4H, 2× -N^+-CH_2-Ar), 6.88–6.91 (d, 2H, J = 9.0 Hz, ArH),7.06 (m, 4H, ArH). Lipid **6d.** ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.88 (t, 12H, J = 7.0 Hz, 4× -CH_3), 1.25–1.46 (m, 108H, 4× -$(CH_2)_{13}$ and 2× -N^+-CH_2-CH_2-CH_2-), 1.78–1.82 (m, 8H, 4× -O-CH_2-CH_2-), 2.24–2.40 (m, 4H, 2× -N^+-CH_2-CH_2-), 3.21 (s, 12H, 4× -N^+-CH_3), 3.84–3.95 (m, 4H, 2× -N^+-CH_2-CH_2), 3.97–4.03 (m, 8H, 4× -O-CH_2-CH_2-), 4.62 (s, 4H, -N^+-CH_2-Ar), 6.87 (d, 2H, J = 8.1 Hz, ArH), 7.13–7.19 (m, 4H, ArH). ESI-MS: 657 (M^{2+}/2). Anal. ($C_{88}H_{166}N_2O_4Br_2$) C, H, N.

Lipid **6e.** ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.86 (t, 12H, J = 7.0 Hz, 4× -CH_3), 1.16–1.40 (m, 124H, 4× -$(CH_2)_{13}$ and 2× -N^+-CH_2-CH_2-CH_2-CH_2-CH_2-CH_2-), 1.76–1.78 (m, 8H, 4× -O-CH_2-CH_2-), 3.17 (s, 12H, 4× -N^+-CH_3), 3.62–3.70 (m, 4H, 2× -N^+-CH_2-CH_2), 3.94–3.99 (m, 8H, 4× -O-CH_2-CH_2-), 4.79 (s, 4H, 2× -N^+-CH_2-Ar), 6.82 (d, 2H, J = 8.1 Hz, ArH), 7.09 (d, 2H, J = 8.1 Hz, ArH), 7.15–7.21 (m, 2H, ArH). ESI-MS: 700 (M^{2+}/2). Anal. ($C_{94}H_{178}N_2O_4Br_2$) C, H, N.

Liposome Preparation. Individual lipid or its mixture with DOPE in the desired mole ratio was dissolved in chloroform in autoclaved Wheaton glass vials. Thin films were made by evaporation of the organic solvent under a steady stream of dry nitrogen. Last traces of organic solvent were removed by keeping these films under vacuum overnight. Freshly autoclaved water (Milli-Q) was added to individual film such that the final concentration of the cationic lipid was 0.5 mM. The mixtures were kept for hydration at 4 °C for 10–12 h and subjected to repeated freeze–thaw cycles (ice–cold water to 70 °C) with intermittent vortexing to ensure hydration. Sonication of these

suspensions for 15 min in a bath sonicator at 70 °C afforded closed cationic liposomes as evidenced from transmission electron microscopy. Liposomes were prepared and kept under sterile conditions. Formulations were stable and, if stored frozen, possessed long shelf life.

Transmission Electron Microscopy. Freshly prepared aqueous suspensions of lipoplexes were examined under transmission electron microscopy by negative staining using 1% uranyl acetate. A 10 μL sample of the suspension was loaded onto Formvar-coated, 400 mesh copper grids and allowed to remain for 1 min. Excess fluid was wicked off the grids by touching their edges to filter paper, and 10 μL of 1% uranyl acetate was applied on the same grid, after which the excess stain was similarly wicked off. The grid was air-dried for 30 min, and the specimens were observed under TEM (JEOL 200-CX) operating at an acceleration voltage of 120 keV. Micrographs were recorded at a magnification of 5000–20 000×.

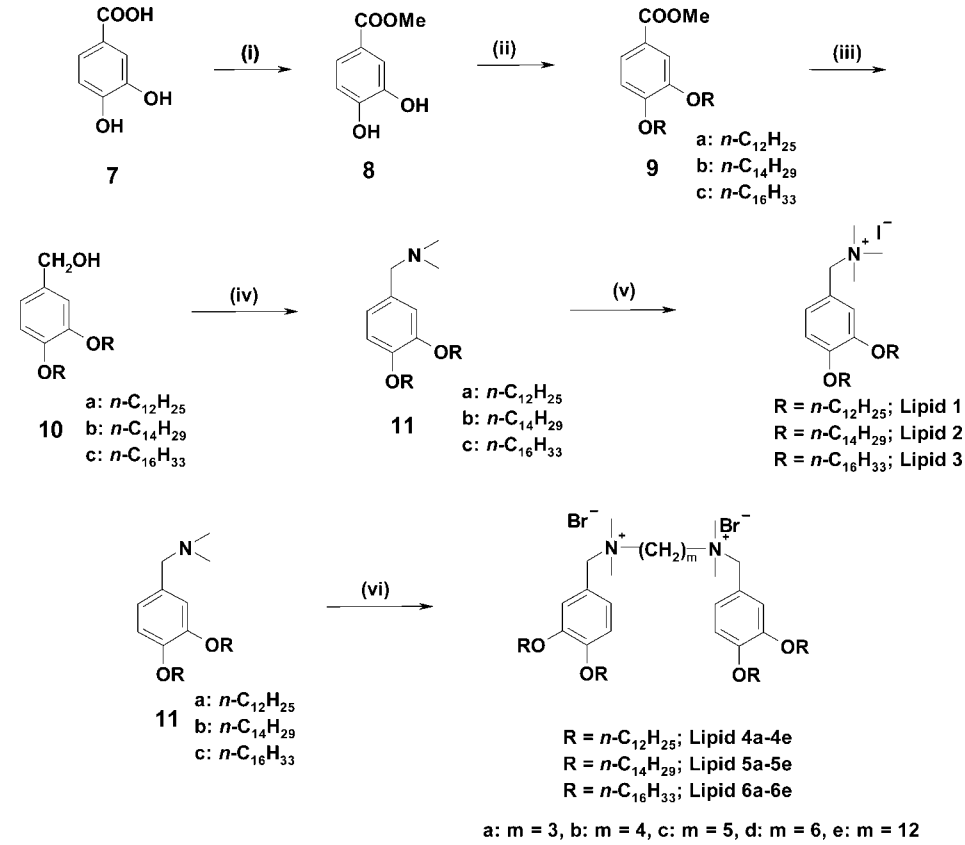
Plasmid DNA. pEGFP-c3 (Clontech, USA), which encodes for an enhanced green fluorescence protein (GFP) under a CMV promoter, was amplified in *Escherichia coli* (DH5α) and purified using Qiagen Midi Prep Plasmid Purification protocol (Qiagen, Germany). Purity of the plasmid was checked by electrophoresis on 1.0% agarose gel. Concentration of the DNA was estimated spectroscopically by measuring the absorption at 260 nm and confirmed by gel electrophoresis. The plasmid preparations showing a value of $OD_{260}/OD_{280} > 1.8$ were used.

Cell Culture. Cells (HeLa or HT1080) were cultured in Dulbecco's Modified Eagle's Medium (DMEM; Sigma) supplemented with 10% fetal bovine serum (FBS) in T25 culture flasks (Nunc, Denmark) and were incubated at 37 °C in a humidified atmosphere containing 5% CO_2. Cells were regularly passaged by trypsinization with 0.1% trypsin (EDTA 0.02%, dextrose 0.05%, and trypsin 0.1%) in PBS (pH 7.2).

Cytotoxicity. Toxicity of each cationic lipid formulation towards HeLa cells was determined using 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide reduction assay following the literature procedures (*47*). MTT is converted to an insoluble blue dye, formazan, in actively respiring cells. The assay estimates the concentration of the formazan formed, which in turn gives a measure of the population of cells that are metabolically active.

Cytotoxicity of the lipid formulations optimal for transfection experiments were found out under conditions exactly similar for transfection conditions. Nearly 12 000 cells/well were plated in a 96 well plate. After 24 h, optimized lipid/DOPE formulations were complexed with 0.2 μg of the DNA at an N/P ratio of 0.75 for 30 min. DNA–lipid complexes were added to the cells in the absence of serum. After 4 h of incubation, lipoplexes were removed and 200 μL of media with 10% FBS was added. After 42 h, 20 μL of MTT solution was added and the cells were incubated further for 4 h. Blue formazan crystals were seen as well when checked under the microscope. Media was removed and 200 μL of DMSO was added per well. The absorbance was measured using a microtiter plate reader. The % viability was then calculated as $[\{A_{590}(\text{treated cells}) - \text{background}]/[A_{590}(\text{untreated cells}) - \text{background}\}] \times 100$.

Transfection Procedure. All transfection experiments were carried out in HeLa or HT1080 cells in antibiotic-free media unless specified otherwise. In a typical experiment, 24 well plates were seeded with 45 000 cells/well in antibiotic-free media 24 h before transfection such that they were at least ~70% confluent at the time of transfection. For transfection, to have the required working stocks lipid formulation and DNA were serially diluted separately in DMEM containing no serum. DNA was used at a concentration of 0.8 μg/well unless specified otherwise. The lipid and DNA were complexed in a volume of 200 μL by incubating the desired amount of lipid formulation and DNA together at room temperature for about 30 min. The lipid concentrations were varied so as to obtain the required lipid/DNA (N/P) charge ratios. Charge ratios here represent the ratio of charge on cationic lipid (in mol) to nucleotide base molarity and were calculated by considering the average nucleotide mass of 330. After 30 min of complexation, 200 μL of media were added to the complexes (final DNA concentration = 12.12 μM). Old medium was removed from the wells, cells were washed with DMEM, and lipid–DNA complexes in 200 μL media were added to the cells. The plates were then incubated for 4 h at 37 °C in a humidified atmosphere containing 5% CO_2. At the end of incubation period, medium was removed and cells were washed with DMEM, 500 μL of DMEM containing 10% FBS was added per well. Plates were further incubated for a period of 44 h before checking the reporter gene expression. GFP expression was examined by fluorescence microscopy and was quantified by flow cytometry analysis. Control transfections were performed in each case using a commercially available transfection reagent Lipofectin based on the standard conditions specified by the manufacturer. All the experiments were done in duplicates, and results presented are the average of at least two such independent experiments done on two different days.



For transfections in the presence of serum, lipid and DNA were separately diluted in serum-free media as already mentioned, and the complexation was done in serum-free media (200 μL) for 30 min. The complex was then diluted to 400 μL with DMEM containing 20% FBS so as to achieve a final serum concentration of 10%. The cells were then incubated with these complexes for 4 h. At the end of the incubation period, medium was removed and cells were washed with DMEM; 500 μL of DMEM containing 10 % FBS was added per well. For transfections at 30% and 50% of serum concentrations, complexes were diluted with DMEM containing 60% FBS or with neat FBS, respectively.

Gel Electrophoresis. To examine the complexation of DNA with cationic lipid suspensions at different lipid–DNA ratios, we prepared lipid–DNA complexes at different lipid–DNA charge ratios in an identical manner as was done with the transfection experiments. After 30 min of incubation, these complexes were electrophoretically run on a 1.0% agarose gel. The uncomplexed DNA moved out of well, but the DNA that was complexed with lipid remained inside the well (*7*).

Flow Cytometry. The reporter gene expression was examined by fluorescence microscopy at regular intervals and was quantified 48 h post-transfection by flow cytometry. The percentage of transfected cells was obtained by determining the statistics of cells fluorescing above the control level wherein nontransfected cells were used as the control. Approximately 10 000 cells were analyzed to achieve the statistical data, which have been presented as the average of at least two such independent measurements. For flow cytometry analysis, ~48 h post-transfection, old medium was removed from the wells; cells were washed with PBS and trypsinized by adding 100 μL of 0.1% trypsin. To each well, 200 μL of PBS containing 20% FBS was added. Duplicate cultures were pooled and analyzed by flow cytometry immediately using a Becton and Dickinson flow cytometer equipped with a fixed laser source at 488 nm.

FACS Analysis. FACS data were analyzed by public domain *WinMDI* software to eliminate data from cell debris (particles smaller than cells), dead cells, and clumps of two or more cells. Subcellular debris and clumps can be distinguished from single cells by size (estimated by the intensity of low angle forward scatter). Dead cells have lower forward-scatter and higher side-scatter than living cells. The FACS scans had been configured to display the fluorescence signals only from those particles with a specified set of scatter properties, namely, living single cells.

Scheme 1[a]

[a] Reagents, conditions, and yields: (i) HCl, MeOH, 80 °C, 12 h, 90%; (ii) RBr, K_2CO_3, dry acetone, 70 °C, 72–86 h, 70–75%; (iii) $LiAlH_4$, dry THF, 70 °C, 12 h, 90–95%; (iv) (a) PBr_3, CH_2Cl_2, rt, 24 h; (b) Me_2NH (excess), MeOH, rt, 12 h (overall yield = 80–85% for steps (a) and (b)); (v) MeI, EtOH, 80 °C, 24 h, screw-top pressure tube, quantitative yields; (vi) $Br(CH_2)_mBr$, MeOH–EtOAc (2:1), 80 °C, screw-top pressure tube, 2–4 days, 40–50%.

This is called a scatter-gated fluorescence analysis. Therefore, the data from dead cells had been eliminated by gating out brightly fluorescent cells.

RESULTS AND DISCUSSION

Chemistry. Fifteen new gemini cationic lipids (**4**–**6**) of different hydrocarbon chain lengths have been synthesized. For comparison of their transfection properties with those of their monomeric counterparts, lipids **1**–**3** were also synthesized (Figure 1). Each of these lipids possesses an aromatic backbone which anchors the linkage between the hydrocarbon chains and the charged headgroup. Two cationic ammonium headgroups are joined through flexible polymethylene spacers.

For the synthesis, first the 3,4-dihydroxy benzoic acid (**7**) was esterified in the presence of conc HCl and dry MeOH under reflux conditions to protect the -COOH moiety (Scheme 1). The corresponding ester (**8**) was obtained in 90% yield. The ester (**8**) was then subjected to alkylation with appropriate *n*-alkyl bromide under reflux conditions in dry acetone in the presence of K_2CO_3 to furnish the dialkylated products (**9a**–**9c**) in 70–75% yields. The ester group of the product (**9a**–**9c**) was then reduced with $LiAlH_4$ in dry THF, under reflux conditions over a period of 12 h, to afford **10a**–**10c** in 90–95% isolated yields. Next, the conversion of **10a**–**10c** to corresponding benzylic bromide was attempted. However, under Appel conditions (CBr_4/PPh_3 in CH_2Cl_2), although TLC indicated satisfactory conversion, during the isolation, a significant part of the product decomposed. The conversion of the alcohol to the corresponding bromide by PBr_3 in CH_2Cl_2 appeared to be complete by TLC. However, again it was not possible to isolate the corresponding bromide presumably because of its high instability. Therefore, upon confirming the formation of the bromide after reaction with PBr_3 in CH_2Cl_2 for 24 h by TLC, a methanolic solution of dimethylamine was introduced directly into the reaction mixture, and the mixture was stirred at room temperature for 12 h. After the usual workup, compounds **11a**–**11c** were obtained in 80–85% yields. Lipids **1**–**3** were prepared upon refluxing the tertiary amines **11a**–**11c** with an excess of MeI in EtOH in quantitative yields (Scheme 1). The gemini cationic lipids with polymethylene spacers, **4**–**6**, were synthesized by heating **11a**–**11c** with the appropriate α,ω-dibromoalkanes to 80 °C in a mixture of MeOH–EtOAc (1:1) for 48–96 h in a screw-top pressure tube (Scheme 1). After repeated crystallizations from a mixture of MeOH-EtOAc, the isolated yields of the gemini lipids ranged from 40% to 50%. All the gemini lipids were adequately characterized by ^{1}H NMR, mass spectra, and elemental analysis.

Aggregate Formation from Cationic Gemini Lipids. Upon hydration, all the cationic lipids were dispersed in water at ~70 °C. The suspensions formed from lipids were found to be translucent. Lipids bearing *n*-$C_{14}H_{29}$ and *n*-$C_{16}H_{33}$ chains were found to be dispersed with difficulty even at ~80 °C. Therefore, we also did not observe their thermal phase transition temperature, whereas lipids bearing *n*-$C_{12}H_{25}$ chains were found to form suspensions easily at ~70 °C and they afforded detectable phase transition temperatures. TEM examination of air-dried, aqueous suspensions of each lipid revealed the existence of vesicular aggregate structures (not shown).

Mixed Liposome Formation with 1,2-dioleoyl-L-α-glycero-3-phosphatidyl Ethanolamine (DOPE). Liposomes could be conveniently prepared from each lipid with naturally occurring lipid (1,2-dioleoyl-L-α-glycero-3-phosphatidyl ethanolamine

Table 1. Optimized Lipid/DOPE Mole Ratios for Cationic Lipids for Transfection Studies

lipid	lipid/DOPE	lipid	lipid/DOPE	lipid	lipid/DOPE
1	1:1	**2**	1:2	**3**	1:2
4a	1:2	**5a**	1:8	**6a**	1:4
4b	1:2	**5b**	1:6	**6b**	1:4
4c	1:2	**5c**	1:2	**6c**	1:4
4d	1:2	**5d**	1:2	**6d**	1:8
4e	1:2	**5e**	1:2	**6e**	1:8

(DOPE)) by first subjecting the films of lipid mixtures to hydration, repeated freeze–thaw cycles, followed by sonication at 70 °C for 15 min. All the DOPE doped lipids formed optically transparent suspensions. The vesicular suspensions were sufficiently stable and no precipitation was observed within three months if stored at 4 °C.

TRANSFECTION BIOLOGY

Optimization of the Lipid/DOPE Ratio. Incorporation of the helper lipid DOPE is known to enhance the transfection efficiencies of many of the cationic lipid-based formulations (*48*). Therefore, we first decided to investigate the optimized lipid/DOPE mole ratio for our newly developed cationic lipids in HeLa cells, as their neat lipid suspensions were found to show very low transfection efficacies (not shown). To find out the optimized transfection efficiency, both the number of transfected cells and mean fluorescence intensity were considered. The mean fluorescence intensities (MFI) defined for GFP-positive cells reveal that the level of GFP expression with a higher MFI value correlate positively with a high GFP expression (*49*). These data were obtained from the flow cytometric analysis. In order to determine the most effective formulations, transfections were performed with identical amounts of the DNA (0.8 μg) and lipid (2.5 μg) upon variation of the mole ratios of cationic lipids in DOPE. Optimized lipid/DOPE ratios were found to vary with different cationic lipids depending upon the hydrocarbon chain lengths and the spacer segment between the cationic headgroups. The optimized lipid/DOPE ratios for all cationic lipids are given in Table 1. Monomeric lipids **2** and **3** showed the maximum transfection at optimized lipid/DOPE ratio of 1:2, whereas monomeric lipid **1** showed the optimum activity at a lipid/DOPE ratio of 1:1. Gemini lipids (**4a**–**4d**) bearing *n*-$C_{12}H_{25}$ hydrocarbon chains showed the maximum transfection efficiency at lipid/DOPE ratio of 1:2. In the case of the other gemini lipids, optimized lipid/DOPE ratios differed depending on both the length of the spacer and the hydrocarbon chain lengths. Lipids **5a**, **6d**, and **6e** showed transfections at the highest optimized lipid/DOPE ratios of 1:8, whereas lipids **5c** and **5d** showed the best activity at lipid/DOPE ratio of 1:2. These differences in the optimized lipid/DOPE ratios could be attributed to their different interaction behavior with DNA and the cell membranes, depending upon the lipid chain lengths and spacers between the headgroups.

Optimization of Lipid/DNA Charge Ratio. After the optimization of the lipid/DOPE ratios for lipids, we performed transfection studies in HeLa cells at different lipid/DNA charge ratios using optimized lipid/DOPE ratios. Monomeric lipid **1** formulation showed 30–40 % GFP cells with MFI of ∼40 by FACS analysis. With the introduction of the spacer between the two monomeric lipid **1** molecules, transfection efficiency increased especially in the number of cells getting transfected (Figure 2). Gemini lipid formulations based on **4a**–**4e** were able to transfect 60–80% of the cells, but the MFI values observed in all the formulations were very low. This suggests that these gemini lipid (**4a**–**4e**) formulations were able to transfect a large number of cells, but the amount of the DNA delivered was low. All these gemini lipid formulations (**4a**–**4e**) were found to be better than the monomeric lipid **1** formulation in terms of their ability to gene transfer. These gemini lipid formulations showed maximum transfection at an N/P ratio of 0.75–1.0 and followed a bell-shaped graph (Figure 2).

The formulation based on monomeric lipid **2** was able to transfect nearly 40% of cells with MFI of ∼75 as compared to the monomeric lipid **1** formulation, which transfected 40% of cells with MFI of ∼40 (Figure 3). This shows that the tetradecyl chain based monomeric lipid **2** is nearly two times better than the monomeric lipid **1** with dodecyl chains especially in terms of the MFI. On dimerization of lipid **2** with -$(CH_2)_3$- propanediyl spacer (lipid **5a**), the transfection efficiency decreased in terms of the number of transfected cells, while the MFI remained nearly the same. This indicates that propanediyl spacer based lipid (**5a**) aggregates were able to transfer nearly the same amount of the DNA but the efficiency reduced to nearly 30%. With an increase in the spacer length to -$(CH_2)_5$- pentanediyl, the transfection efficacy increased dramatically. Lipid **5c** was able to transfect ∼60% of the cells with high MFI of ∼100 at an N/P ratio of 1.0 as compared to its monomeric lipid counterpart **2**, which transfected only 40% of cells with MFI of ∼75. In the case of lipid **5d** and **5e** formulations, the transfection efficacies, however, decreased. The lipid **5d** formulation transfected nearly 40% of the cells with an MFI of ∼75, and lipid **5e** was able to transfect only 30% of the cells with MFI of ∼70. Therefore, among the *n*-$C_{14}H_{29}$ chain-based gemini lipids, lipid **5c** bearing -$(CH_2)_5$- showed maximum transfection efficiency.

Gemini lipid formulations based on hexadecyl chains were found to show the lowest transfection efficiency, in terms of both the number of transfected cells and the MFI. The monomeric lipid **3** formulation was able to transfect nearly 30% of the cells with an MFI of ∼40 (Figure 4). The maximum transfection was observed with the lipid **6d** formulation, transfecting nearly 20% of the cells with an MFI of ∼60, whereas the lipid **6e** formulation transfected ∼20% of the cells with a high MFI of ∼80.

The overall analysis of the data clearly shows that cationic lipids based on *n*-$C_{12}H_{25}$ and *n*-$C_{14}H_{29}$ hydrocarbon chains are better transfecting agents than the lipids possessing *n*-$C_{16}H_{33}$ chains in HeLa cells (Figure 5). Lipids possessing *n*-$C_{12}H_{25}$ chains (**1**, **4a**–**4e**) were able to transfect the highest number of cells with a low MFI, whereas *n*-$C_{14}H_{29}$ chain based lipids (**2**, **5a**–**5e**) transfected cells with a high MFI. This indicates that lipids **2** and **5a**–**5e** were able to deliver a larger amount of the DNA as indicated from MFI as compared to that delivered by lipid **1** and **4a**–**4e** based formulations. Gemini lipids possessing *n*-$C_{16}H_{33}$ chains were found to be the least effective. Formulations based on lipid **5c** possessing the *n*-$C_{14}H_{29}$ chain and the pentamethylene -$(CH_2)_5$- spacer were found to be the best recipe, which transfected nearly 60% of the cells with an MFI of ∼100, which was nearly three times more than a commercially available Lipofectin in terms of the number of cells and four times more efficient in terms of the MFI.

Transfection Studies in HT 1080 Cells. To assess the general utility of these new lipid formulations, transfection studies with optimized lipid formulations were performed in HT1080 cells as well. Nearly 70% of the cells were transfected with the monomeric lipid **1** formulation with an MFI of ∼45 at an N/P ratio of 1.5 as observed by FACS analysis (Supporting Information Figure S-1). Gemini lipid formulations based on **4a** and **4d** were able to transfect 60–80% of the cells with MFI values of ∼40 and 50, respectively, whereas lipid **4b**, **4c,** and **4d** formulations showed ∼40–50% transfection activity.

Monomeric lipid **2** based formulations were able to transfect nearly 50% of cells with MFI ∼35 (Supporting Information Figure S-2). Lipid **5a** and **5b** formulations bearing -$(CH_2)_3$- and

Concentration of the DNA = 0.8 μg/well. Data are expressed as number of transfected cells and MFI as obtained from flow cytometry analysis.

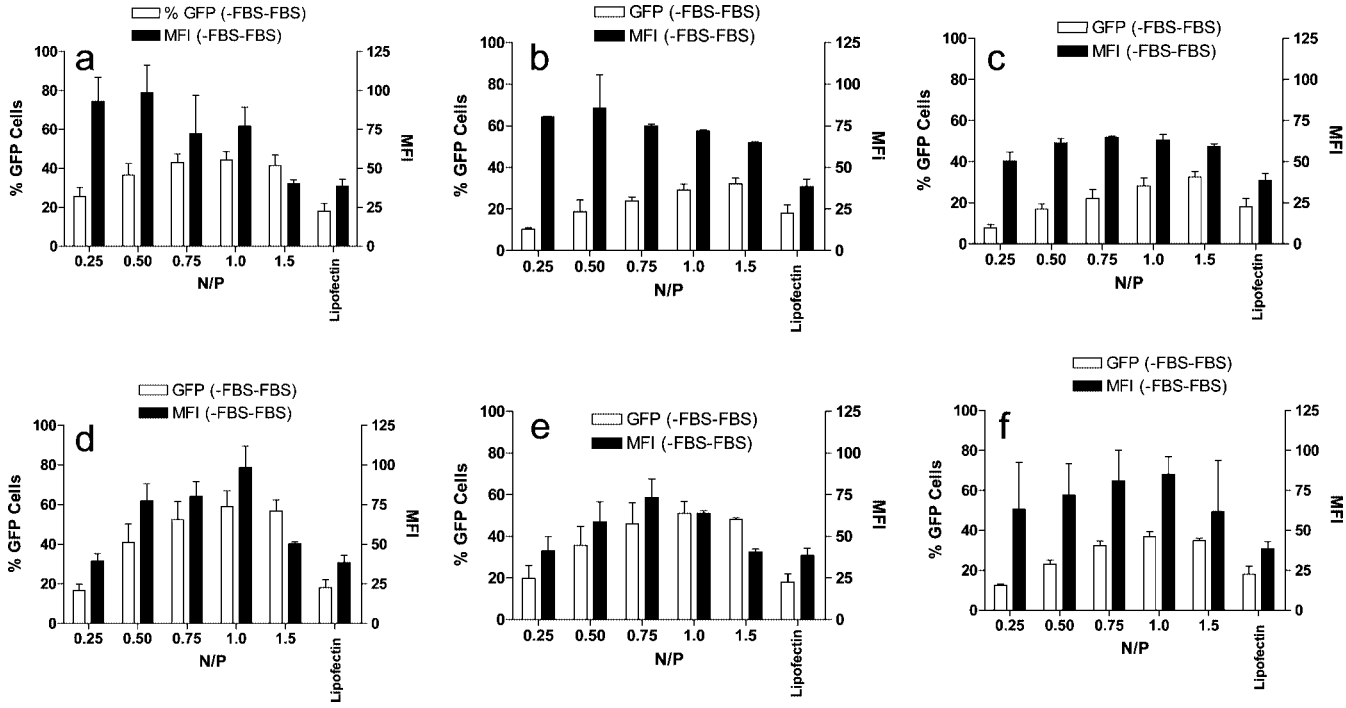


Figure 3. Transfection efficiencies of cationic lipids using optimized lipid/DOPE formulations at various N/P ratios in the absence of serum (−FBS−FBS) in HeLa cells: (a) lipid **2**; (b) lipid **5a**; (c) lipid **5b**; (d) lipid **5c**; (e) lipid **5d**; (f) lipid **5e**. Concentration of the DNA = 0.8 μg/well. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis.

-$(CH_2)_4$- spacers are not very effective, transfecting ∼20% cells with MFI of ∼20, whereas the lipid **5c** formulation with a -$(CH_2)_5$- spacer showed ∼50% transfection efficacy with MFI of ∼35. Nearly 40% of the cells with an MFI of ∼20 were transfected with lipid **5d** formulations. The lipid **5e** formulation was found to be highly effective with more than 80% transfection efficiency with an MFI of ∼40. Gemini lipid formulations based on *n*-$C_{16}H_{33}$ chains were found to show the least transfection activity, in terms of both the number of transfected cells and MFI even in HT1080 cells, as was seen with HeLa cells (Supporting Information Figure S-3).

Figure 6 presents the comparative transfection efficacies of all lipid formulations at N/P ratio of 0.75 in HT1080 cells. Lipid formulations **1**, **4a**, **4c**, **4d**, and **5c** were found to be the best transfecting agents among all lipid formulations. Formulations of lipids possessing *n*-$C_{16}H_{33}$ chains were not found to be effective at all. Comparing the transfection efficacies of lipid formulations in HeLa and HT1080 cell lines showed interesting features. Overall, the MFI observed in HT1080 cell lines was lower compared to HeLa cells, which indicates that the release of the DNA from lipoplexes in HT1080 is not as easy as in HeLa cells where high MFI was observed.

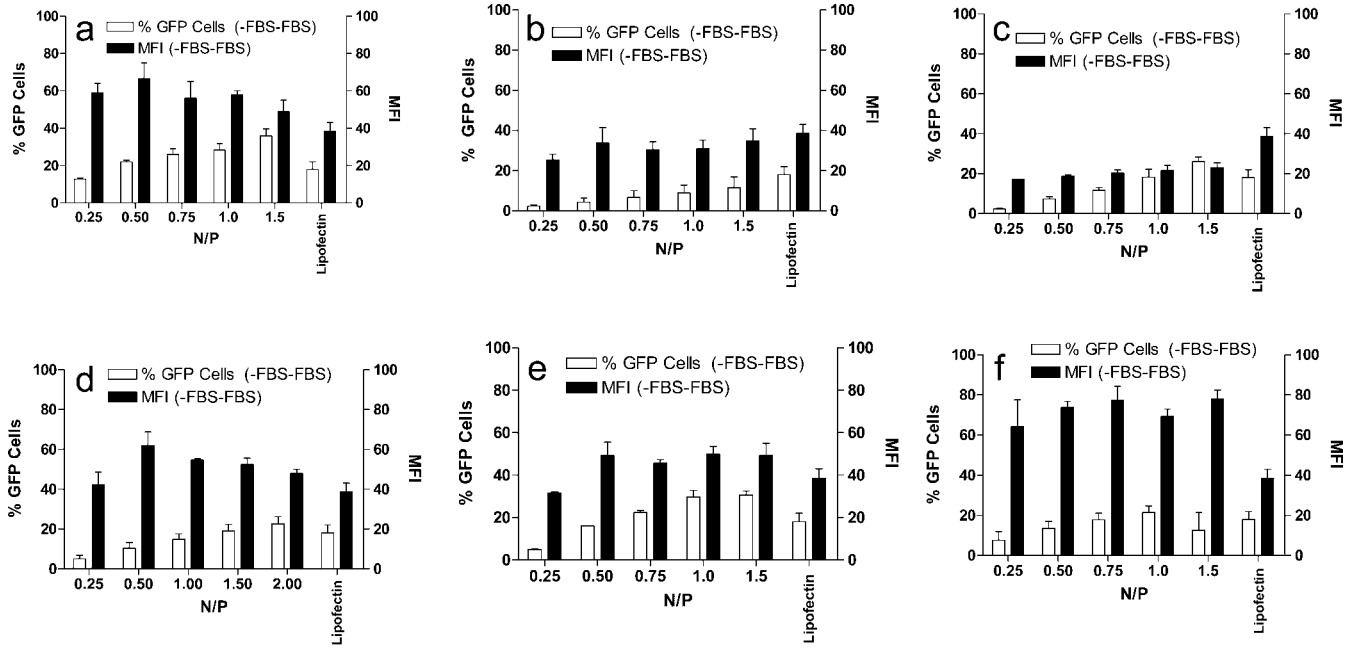

Figure 4. Transfection efficiencies of cationic lipids using optimized lipid/DOPE formulations at various N/P ratios in the absence of serum (−FBS−FBS) in HeLa cells: (a) lipid **3**; (b) lipid **6a**; (c) lipid **6b**; (d) lipid **6c**; (e) lipid **6d**; (f) lipid **6e**. Concentration of the DNA = 0.8 μg/well. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis.

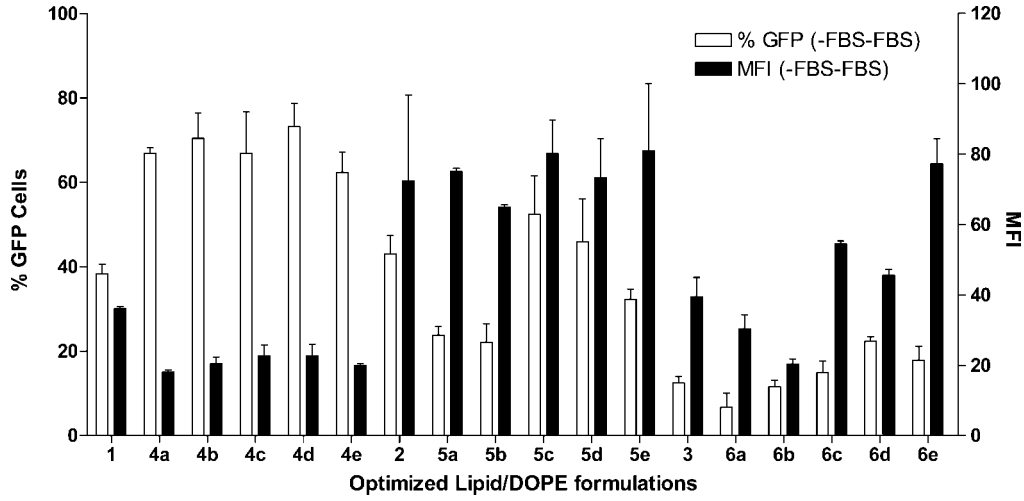

Figure 5. A comparative study showing the effect of the spacer length and hydrocarbon chain lengths on gene transfection efficiencies of gemini lipids based on aromatic backbone in the absence of serum (−FBS−FBS) at an N/P ratio of 0.75 in HeLa cells.

Effect of the Serum. One of the serious limitations of the cationic lipid-mediated gene delivery, especially involving *in vivo* trials, is that the transfection is inefficient particularly in the presence of serum proteins. Transfections in the absence of serum even for *in vitro* experiments are also cumbersome due to the increased toxicity of cationic lipid formulations. To have better potential especially in gene therapy, it is important to develop lipids that are capable of delivering and expressing an external gene inside a cell in the presence of serum (*13, 21, 50*). To have a clear understanding of the effect of the serum in the present set of cationic lipid mediated gene delivery, we performed transfections with our optimized lipid formulations in the presence of serum in HeLa and HT1080 cells.

Monomeric lipid **1/DOPE** was able to transfect nearly 30% of the cells with a low MFI of ∼30 in the presence of 10% serum (Figure 7). With the introduction of the spacer, the transfection efficiency increased in the presence of serum especially in the number of cells. Lipid **4b**–**4d** formulations were able to transfect nearly 60% of the cells in the presence of 10% serum with low MFI, whereas the lipid **4e/DOPE** formulation transfected only 20% of cells. A closer examination of these results suggests that lipid dimerization increases the transfection efficiency in the presence of 10% serum conditions, and this efficiency depends on the length of the spacer. The maximum transfection efficiency was achieved at N/P ratio of 0.75–1.5. The transfection efficiency observed in the presence of serum is comparable to that observed in the absence of serum, which clearly shows that serum does not inhibit the transfection efficacy of these formulations.

The monomeric lipid **2/DOPE** formulation in the presence of 10% serum was able to transfect nearly 40% of cells at N/P ratio of 1.0–1.5 (Figure 8). The lipid **5a/DOPE** formulation was able to transfect nearly 30% of the cells with an MFI of ∼80 at N/P ratio of 1.5. Lipid **5c** and **5d** formulations in the presence of DOPE showed maximum transfection efficiency in the presence of serum, transfecting nearly 60% of cells with MFI which was nearly two times more than that observed in the case of **4b**–**4d/DOPE** formulations. This indicates that the *n*-$C_{14}H_{29}$

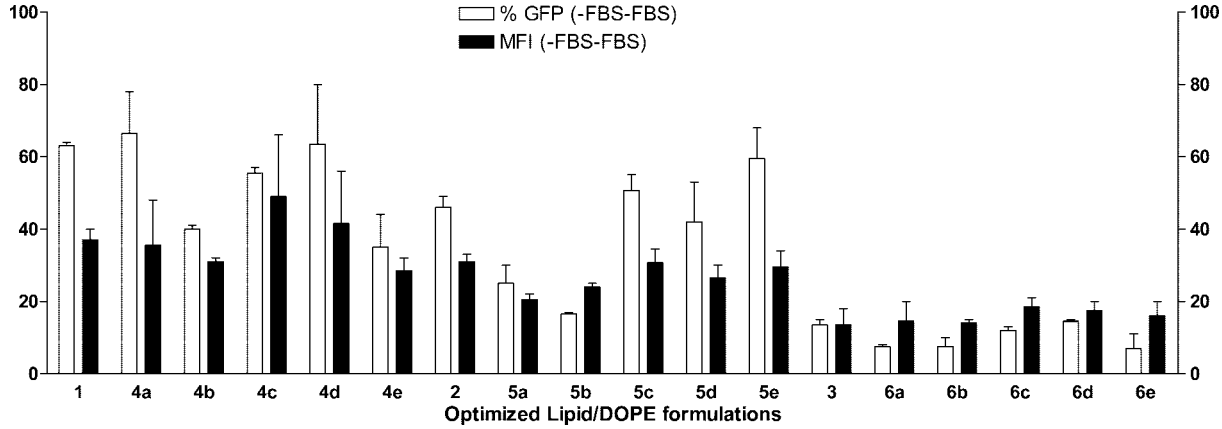

Figure 6. A comparative study showing the effect of the spacer length and hydrocarbon chain lengths on gene transfection efficiencies of gemini lipids based on aromatic backbone in the absence of serum (−FBS−FBS) at N/P ratio of 0.75 in HT 1080 cells.

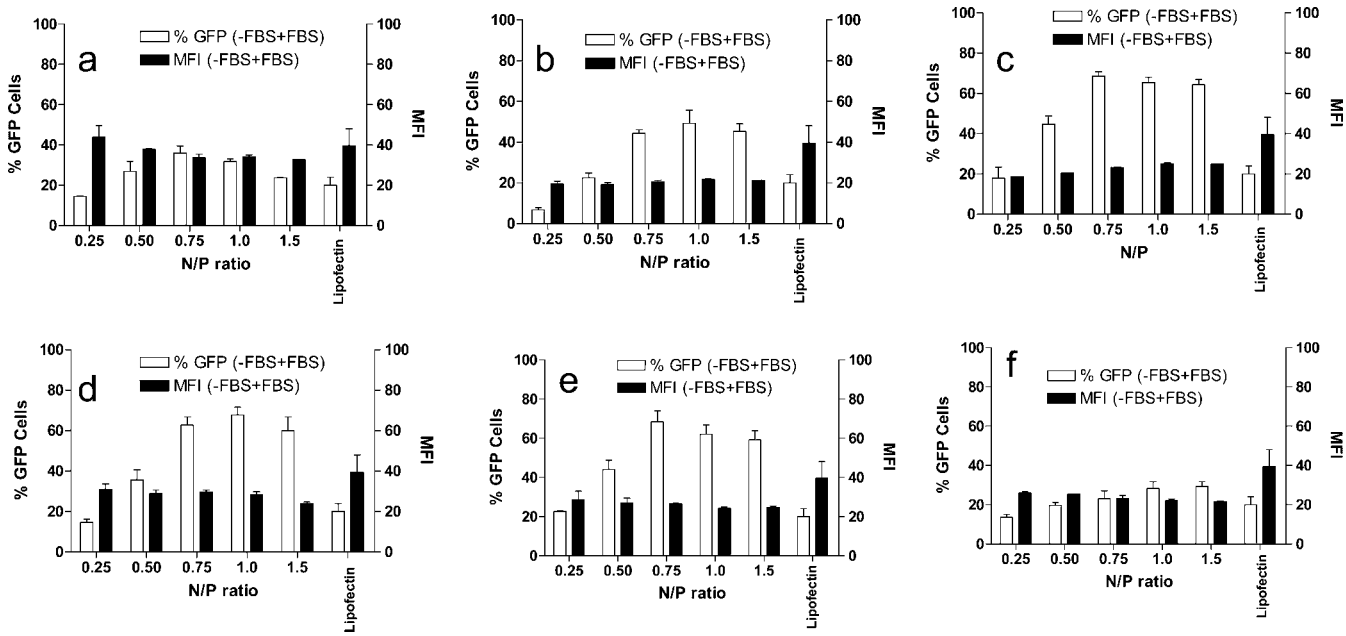

Figure 7. Transfection efficiencies of cationic lipids using optimized lipid/DOPE formulations at various N/P ratios in the presence of serum (−FBS + FBS) in HeLa cells: (a) lipid **1**; (b) lipid **4a**; (c) lipid **4b**; (d) lipid **4c**; (e) lipid **4d**; (f) lipid **4e**. Concentration of the DNA = 0.8 μg/well. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis.

chain based lipid **5c** and **5d** formulations are two times better in transfection activity as compared to *n*-$C_{12}H_{25}$ chain based lipid **4c** and **4d** formulations in terms of MFI. This means that lipid **5c** and **5d** formulations are able to transfect a greater amount of the DNA into the cells in the presence of serum as well. As observed in the absence of serum conditions, *n*-$C_{16}H_{33}$ chain based lipids (**3**, **6a**–**6e**) were again less efficient in the presence of serum as compared to other lipids (Figure 9).

Effect of Serum on the Transfection in HT1080 Cells. We also performed transfection studies in the presence of 10% serum conditions in HT1080 cells. In the presence of serum, as expected, there is little decrease in the transfection activities of all the lipid formulations in terms of both the number of transfected cells and the MFI. Among the dodecyl chain based lipid formulations, monomeric lipid **1** and gemini lipid **4d** formulations showed maximum activities transfecting ∼60% cells with MFI of ∼40 (Supporting Information Figure S-4). The gemini lipid **5e** formulation was found to be the best among all the formulations in HT1080 cells (Supporting Information Figure S-5). Lipids (**3**, **6a-6e**) with *n*-$C_{16}H_{33}$ were found to be the least efficient even in the presence of serum as compared to other analogues in HT1080 cells. (Supporting Information Figure S-6).

Effect of High Percentage of Serum. To approach the realistic *in vivo* conditions, we performed transfections in the presence of high percentages of serum using the lipid **5c** formulation at different N/P ratios in HeLa cells. We performed transfection in the presence of 10%, 30%, and 50% serum conditions using the optimized lipid/DOPE formulation of **5c**. The transfection profiles are shown in Figure 10. In the presence of 10% serum, nearly 60% of the cells were found to get transfected at an N/P ratio of 4.5 with MFI of 40. The decrease in MFI in the presence of serum is because of the delivery of a low amount of the plasmid DNA. In the presence of serum, negatively charged serum proteins start competing with cationic lipids for negatively charged plasmid DNA, which leads to the delivery of less amount of the DNA inside the cells, because of which the MFI decreased.

In the presence of 30% serum, the lipid **5c** formulation was able to transfect nearly 50% of the cells with MFI of 40. To

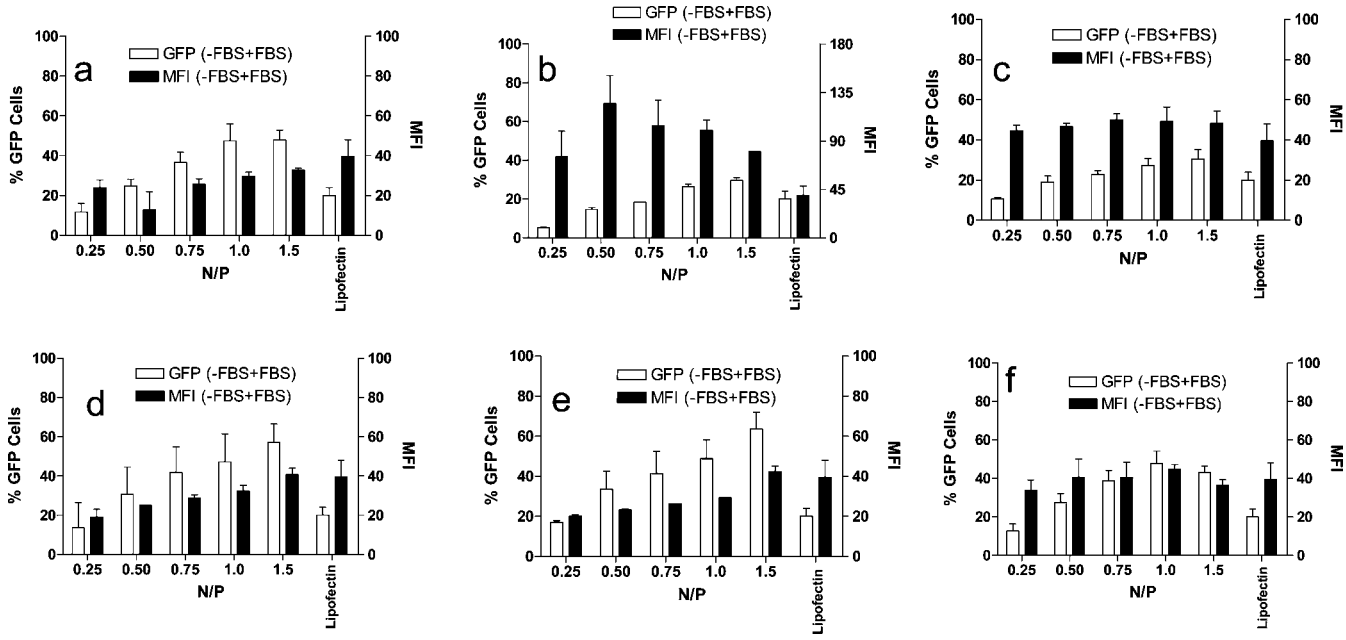

Figure 8. Transfection efficiencies of cationic lipids using optimized lipid/DOPE formulations at various N/P ratios in the presence of serum (−FBS + FBS) in HeLa cells: (a) lipid **2**; (b) lipid **5a**; (c) lipid **5b**; (d) lipid **5c**; (e) lipid **5d**; (f) lipid **5e**. Concentration of the DNA = 0.8 μg/well. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis.

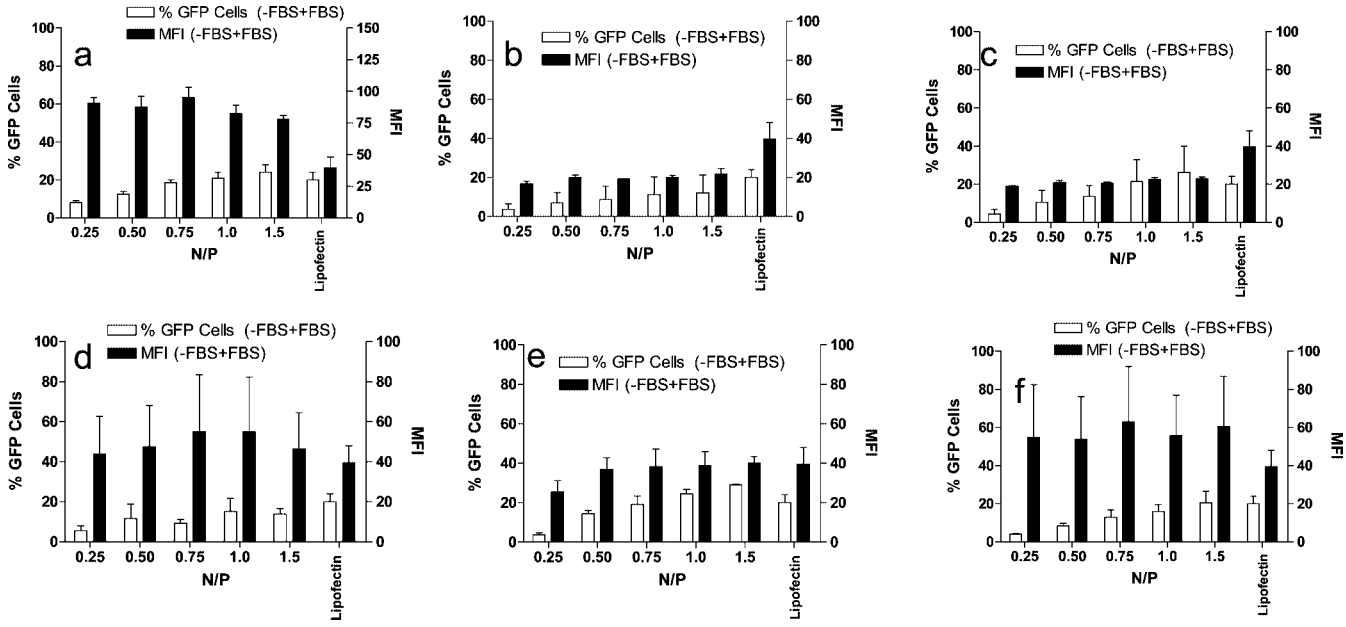

Figure 9. Transfection efficiencies of cationic lipids using optimized lipid/DOPE formulations at various N/P ratios in the presence of serum (−FBS + FBS) in HeLa cells: (a) lipid **3**; (b) lipid **6a**; (c) lipid **6b**; (d) lipid **6c**; (e) lipid **6d**; (f) lipid **6e**. Concentration of the DNA = 0.8 μg/well. Data are expressed as number of transfected cells and MFI as obtained from flow cytometry analysis.

our pleasant surprise, nearly 40% of the cells have been found to be GFP positive in the presence of 50% serum conditions, with very little decrease in MFI. These results showed the unusual behavior of the lipid **5c** formulation, transfecting as many as 40 % of the cells in the presence of 50% serum conditions, where the commercially available formulation Lipofectin failed to transfect.

Cytotoxicity. We performed the MTT-based cell viability assays for all the lipid–DNA complexes in HeLa cells. The cell viability results shown in Figure 11 clearly demonstrate that all the formulations showed more than 80% cell viability except the **4d**, **5d**, and **6d** lipid (based on -$(CH_2)_6$- hexanediyl spacer between the headgroups) based lipid–DNA complexes. The best lipid formulation **5c** showed more than 90% cell viability.

CHARACTERIZATION OF LIPID–DNA COMPLEXES

Gel Electrophoresis. Electrostatic interactions between the plasmid DNA and cationic liposomes as a function of lipid/DNA charge (N/P) ratios were determined by electrophoretic gel retardation assay. Gel electrophoretic patterns for all lipid formulations have been shown in Figures 12 and 13. All lipid formulations showed more than 90% DNA retardation at an N/P ratio of 1.0. Nearly 50% retardation was observed at an N/P ratio of 0.75. The best lipid **5c** formulation showed DNA

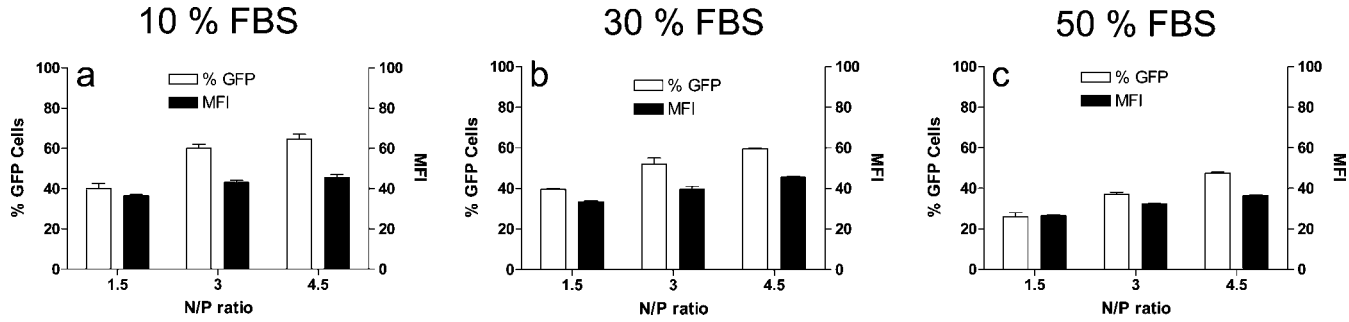

Figure 10. Transfection efficiencies using the optimized lipid **5c**/DOPE formulation at various N/P ratios in the 10%, 30 %, and 50% serum conditions (−FBS + FBS) in HeLa cells: (**a**) 10% FBS; (**b**) 30% FBS; (**c**) 50% FBS. Concentration of the DNA = 0.8 μg/well. Data are expressed as the number of transfected cells and MFI as obtained from flow cytometry analysis.

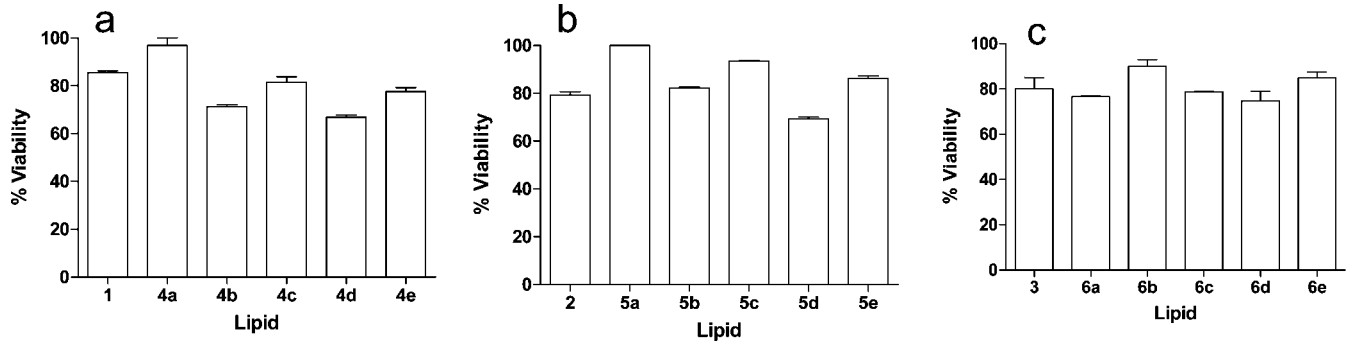

Figure 11. MTT-assay based cellular cytotoxicities of cationic lipid/DNA complexes at their optimized lipid/DNA ratios in HeLa cells: (a) lipids **1**, **4a**–**4e**; (b) lipids **2**, **5a**–**5e**; (c) lipids **3**, **6a**–**6e**.

retardation at an N/P ratio of 1.0, and more than 50% DNA was retarded at an N/P ratio of 0.75. At an N/P ratio of 1.0, maximum transfection had been achieved with this formulation.

Electron Microscopy. To get further insights into the lipid–DNA complexes, we performed electron microscopy of the lipid–DNA complexes using the optimized lipid/DOPE formulations. (*51–56*) Representive electron micrographs of lipid–DNA complexes have been shown in Figure 14. Most of the lipid formulations formed spherical lipid–DNA complexes. Lipid–DNA complexes from lipid **3a** formulations were very uniform and small in size with diameters of ∼150 nm, whereas other lipid–DNA complexes (**4b**, **4c**, **4d**, **4e**) in this series were considerably larger in size ranging from 200 to 400 nm. Lipid **5a** and **5c** formulations showed irregular morphologies, whereas the **5d** formulation showed spherical lipid–DNA complexes. The lipid **5e** formulation formed thread-like lipid–DNA complexes.

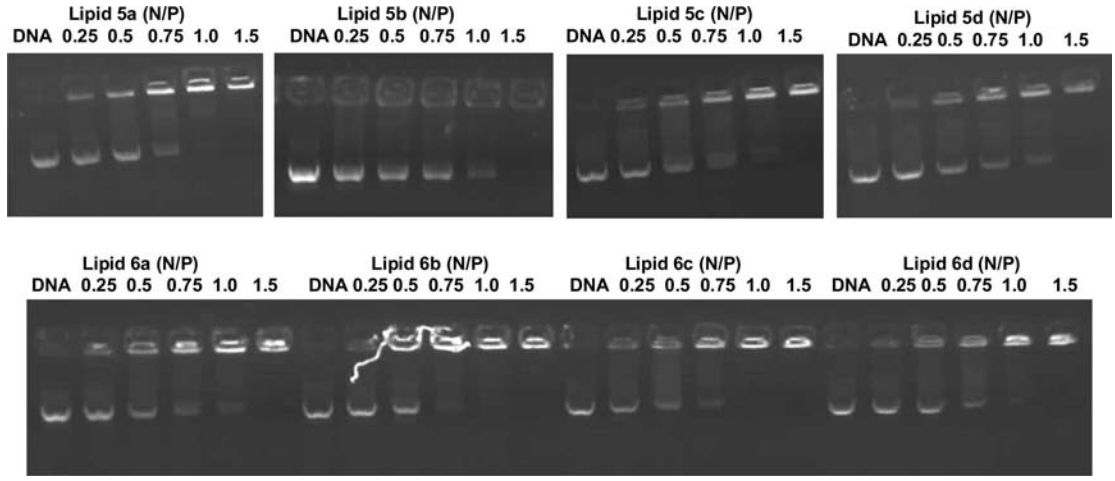

Figure 13. Electrophoretic gel patterns for lipoplex-associated DNA in gel retardation for cationic lipid formulations. The N/P ratios are indicated at the top of each lane.

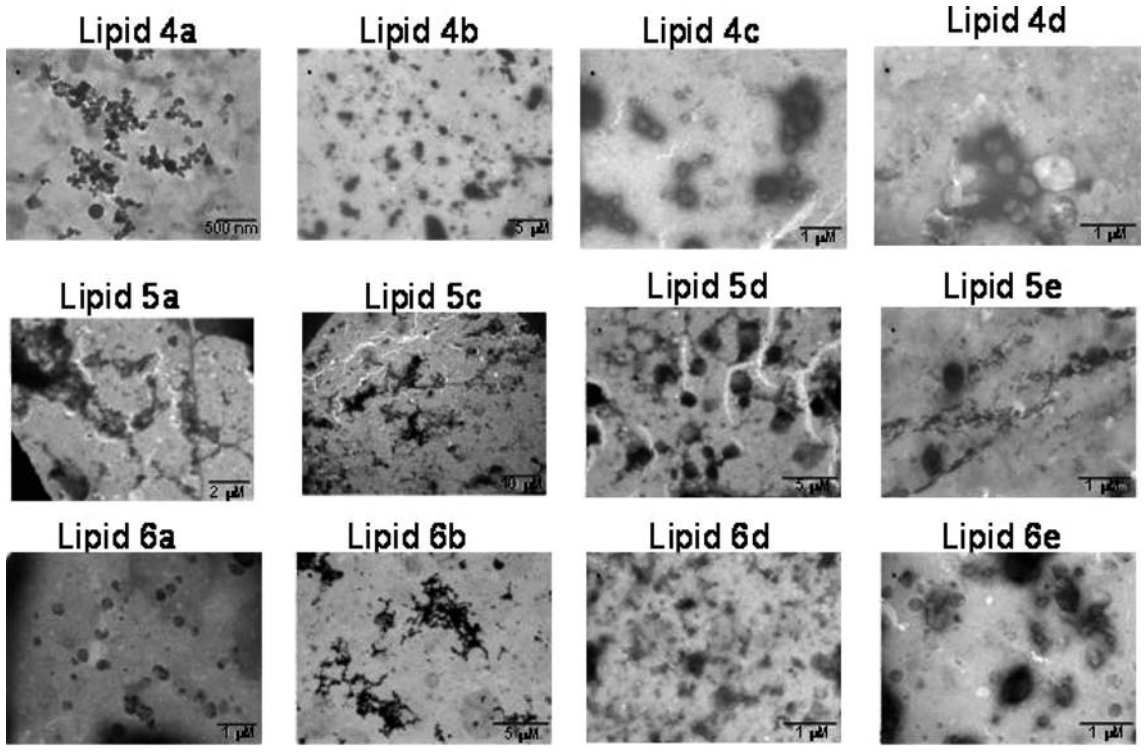

Figure 14. Transmission electron micrographs for the lipoplexes prepared from most effective gemini lipid/DOPE liposome/DNA complexes at the optimized N/P ratio.

Similar observation were also noted by Mahato and co-workers. (*57*) Among *n*-$C_{16}H_{33}$ chain based lipid formulations, lipids **6a** and **6e** formed spherical structures, whereas lipid **6b** formed condensed DNA structures and lipid **6d** afforded small rodlike structures in their electron micrographs.

CONCLUSIONS

Although diverse kinds of cationic lipids have been designed and tested as gene delivery vehicles, there remains a need for continuous improvement in the design of lipids for gene transfer. Keeping these targets in mind, we designed and synthesized a new kind of gemini lipid molecule based on aromatic backbone. Three series of gemini lipids differing in the length of the hydrocarbon chains have been synthesized. Polymethylene spacers of varying length were incorporated between the headgroups. In HeLa cells, gemini lipids bearing *n*-$C_{12}H_{25}$ chains were found to transfect a greater number of cells with low MFI intensity, whereas *n*-$C_{14}H_{29}$ chain based lipids showed transfection with high MFI, and lipids based on *n*-$C_{16}H_{33}$chains were found to be the least effective. Lipid formulation **5c**, possessing tetradecyl chains and pentamethylene spacers, showed the highest gene transfection efficacy in this series. A major characteristic feature of the lipid **5c** formulation is its high serum compatibility, which is one of the major challenges in the lipid-mediated gene delivery. In HT1080 cells, lipid formulations **1**, **4a**, **4c**, **4d**, and **5c** were found to be the best transfecting agents among all lipid formulations. MFI observed in HT1080 cell lines was lower compared to that in HeLa cells, which indicates that the release of the DNA from lipoplexes in HT1080 is more difficult than in HeLa cells where a high MFI was observed. Transmission electron microscopy revealed spherical lipid–DNA complexes for most of the formulations. Regardless of the actual

mechanism (*58–62*) for transfection mediated by this class of gemini lipid formulations, the interesting and meaningful results obtained with these novel aromatic gemini lipids should be of interest to researchers working in the field of gene therapy using nonviral vectors.

Received June 22, 2007; Revised Manuscript Received September 5, 2007

Water soluble, metallo-pthalocyanine (MPc) near-IR fluorophores were designed, synthesized, and evaluated as highly stable and sensitive reporters for fluorescence assays. Their conjugation to oligonucleotides was achieved via succinimidyl ester-amino coupling chemistry with the conditions for conjugation extensively examined and optimized. In addition, various conjugate purification and isolation techniques were evaluated as well. Results showed that under proper conditions and following purification using reverse-phase ion-pair chromatography, labeling efficiencies near 80% could be achieved using ZnPc (Zn phthalocyanine) as the labeling fluorophore. Absorption and fluorescence spectra accumulated for the conjugates indicated that the intrinsic fluorescence properties of the MPc's were not significantly altered by covalent attachment to oligonucleotides. As an example of the utility of MPc reporters, we used the MPc–oligonucleotide conjugates as primers for PCR (polymerase chain reaction) amplifications with the products sorted via electrophoresis and detected using near-IR fluorescence ($\lambda_{ex} = 680$ nm). The MPc dyes were found to be more chemically stable under typical thermal cycling conditions used for PCR compared to the carbocyanine-based near-IR reporter systems typically used and produced single and narrow bands in the electrophoretic traces, indicative of producing a single PCR product during amplification.

INTRODUCTION

Because of a number of compelling advantages associated with near-IR fluorescence ($\lambda > 650$ nm), such as low scattering cross sections, reduced autofluorescence, lower radiation energy, and readily available diode lasers as excitation sources, it can provide better overall detection sensitivity compared to the visible and/or UV regions of the electromagnetic spectrum using rather simple instrumentation, especially when analyzing complex biological systems (*1*–*3*). Applications where the viability of near-IR fluorescence has been demonstrated include DNA sequencing (*4*–*6*), detecting DNA restriction fragments (*7*) and adducts (*8*), analysis of PCR products (*9*), DNA microarrays (*10*), mutation detection (*11*), enzymatic substrate monitoring (*12*), and various fluorescence resonance energy transfer (FRET)-based assays (*11, 13*).

Unfortunately, hurdles still exist, hampering the widespread utilization of near-IR fluorescence. The primary challenge is the limited set of fluorophores available for deep-red excitation that possess favorable chemical and photophysical properties for applications requiring covalent or noncovalent labeling of targets. Despite the growing number of fluorophores that show absorbing properties in the near-IR (*14, 15*), the demands of modern multiplexed, ultrasensitive analyses require the development of new bright fluors with the following properties: (a) a diverse range of photophysical and spectral characteristics that can be easily tuned; (b) good chemical, thermal, and light stability; (c) availability of a wide range of functional groups for covalent conjugation to a variety of targets; and (d) narrow emission envelopes to minimize spectral leakage into various detection channels required for spectral multiplexing.

Phthalocyanines (Pc's) and metallo-phthalocyanines (MPc's) are well-known near-IR absorbing/fluorescing dyes (*16*). Various MPc's have been extensively studied, and many display photophysical properties that are comparable or even superior to those of the most commonly used near-IR reporter systems. These properties include high extinction coefficients ($>10^5$ M^{-1} cm^{-1}) (*17, 18*), favorable fluorescence quantum yields (>0.6) (*19*–*21*), excellent photostability with photobleaching quantum yields as low as 10^{-7} (*17, 22, 23*), and good chemical and thermal stabilities. Another appealing feature of MPc's is that their photophysical properties can be tuned by simply varying peripheral substitution patterns around the macrocycle (*17, 22, 24*) and/or altering the identity of the metal center (*25, 26*).

Covalent attachment of MPc's with various biomolecules that have been reported include those with nucleobases (*27*), oligonucleotides (*28*–*31*), proteins (*23, 32*–*35*), peptides (*36*), or monoclonal antibodies (*35, 37*–*39*) as targets. However, in spite of the impressive photophysical and spectral properties associated with these near-IR dye systems, the analytical utility of MPc's when covalently attached to biomolecular targets have not been extensively reported.

The first commercially available MPc-based reporters were SiPc's (La Jolla Blue), which contained axial polyethylene glycol ligands used to prevent self-aggregation and improve water solubility. Oligonucleotides conjugated to La Jolla Blue were utilized for homogeneous hybridization assays of DNA and RNA targets with the hybridions monitored via transient-state polarized fluorescence with a detection limit reported to be 1 fmol (*28, 29*). Peng and co-workers (*35*) developed another SiPc dye with highly charged axial ligands,

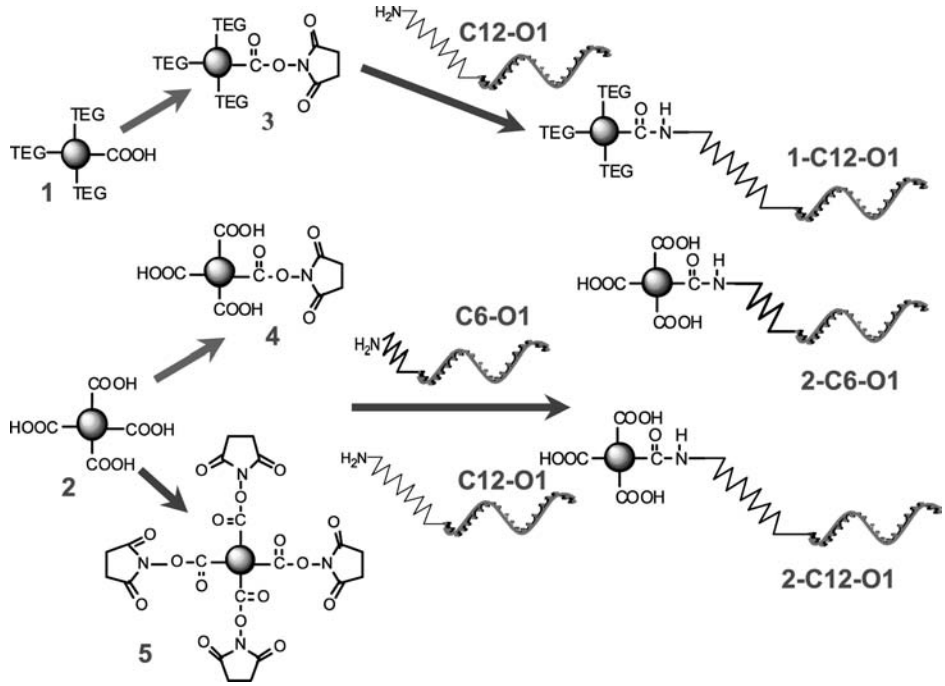
[a] These primers were modified with an amino-group attached to its 5′ end and were labeled with either ZnPc **1** (**1-C12-O1**, using a $C_{12}H_{24}$ linker) or **2** (**2-C12-O1** or **2-C6-O1**, using a $C_{12}H_{24}$ or C_6H_{12} linker, respectively). [b] This primer was modified with an amino-group attached to its 5′ end via a C_6H_{12} linker and was labeled with ZnPc **2**. [c] The underlined sequence is complementary to **O1**.

IRD700DX, and demonstrated its applicability as a bright and photostable near-IR fluorescent label (fluorescence quantum yield of 0.14 in PBS and photobleaching quantum yield of 1.6×10^{-7}) for antibody conjugation.

Duan et al. (*37*) reported on the conjugation of ZnPc, which lacks axial ligands to the metal center, to monoclonal antibodies used to bind to cells bearing the relevant antigenic species. We have previously reported the design, synthesis, and conjugation of MPc's and naphthalocyanines to proteins and oligonucleotides in which two water-soluble asymmetric ZnPc- and naphthalocyanine-based near-IR labeling dyes with isothiocyanate functional groups were conjugated to primary amine-containing targets (*30*). Conjugates of a water soluble ZnPc (**2**, Scheme 1) to streptavidin were prepared and the properties of the conjugates studied (*23*).

The limited use of *Pc*-based labeling fluors have resulted from the lack of (a) appropriately designed molecules that are soluble, possess favorable photophysical properties in aqueous media, and bear functional groups for conjugation; (b) documented labeling conditions that result in the facile and high yield conjugation to biomolecules; and (c) simple and efficient purification protocols for isolating the conjugate.

Herein we report on two water-soluble MPc's, asymmetrical and symmetrical ZnPc's with no axial ligands (**1** and **2**, respectively, see Scheme 1), for conjugation to targets containing primary amine groups. To demonstrate the utility of these labeling fluorophores, the conditions for highly efficient labeling of oligonucleotide targets and robust approaches for the effective isolation and purification of the conjugates are provided as well as the spectral and photophysical properties of the conjugates. Finally, we evaluate the use of these ZnPc-oligonucleotide conjugates as primers for PCR amplifications as analyzed by the gel electrophoretic sorting of the generated amplicons with near-IR fluorescence detection.



EXPERIMENTAL PROCEDURES

Materials. All materials were of reagent grade and were purchased from commercial suppliers, such as Sigma-Aldrich, EMD or Fisher, and used as received unless otherwise noted. Anhydrous DMF (*N*,*N*-dimethylformamide) and ether were dried before use by passing through columns with molecular sieves and activated alumina. Milli Q water (18 mΩ) produced in-house was used for all solution preparations. Oligonucleotide sequences modified with an amino group at their 5′-end via aliphatic (C_6H_{12} or $C_{12}H_{24}$) linkers or unmodified were obtained from IDT (Coralville, IA). Their sequences and melting temperatures (T_m) for fully matched duplexes are listed in Table 1. Precast agarose gel plates (3%) were purchased from BioRad (Hercules, CA). dNTPs (deoxynucleotides triphosphates) and PCR buffers were purchased from Applied Biosystems (Foster City, CA).

Synthesis of ZnPc's 1, 2, and Succinimidyl Ester 5 (Scheme 2). The preparation of these compounds has been reported elsewhere (*23, 40*).

Synthesis of Succinimidyl Ester 3. The synthesis of this compound was adapted from published procedures with slight modifications (*41*). A mixture of DCC (6 mg, 0.029 mM) and NHS (4 mg, 0.035 mM) was added to ZnPc **1** (12.6 mg, 0.010 mM) dissolved in anhydrous DMF (2 mL). The reaction was

Scheme 2. Conjugation Chemistries of ZnPc 1 and 2 and Their Corresponding Succinimidyl Esters to Oligonucleotide Targets

stirred for 18 h at room temperature in an argon atmosphere while protecting it from light. After the reaction, diethyl ether (approximately 20 mL) was added to the reaction mixture. The sample was centrifuged and the supernatant discarded. The residue was dissolved in acetone, filtered through a 0.2 μm Teflon filter, and evaporated, which afforded 8 mg (59% yield) of succinimidyl ester **3** as a dark-blue powder. MS *m/z* ($M + H^+$) 1296.481, calculated for $C_{64}H_{66}N_9O_{17}Zn$ 1296.387.

Synthesis of Succinimidyl Ester 4. The synthesis of this compound was adapted from published procedures with slight modifications (*41*). A solution of ZnPc **2** (42 mg, 0.037 mmol), NHS (*N*-hydroxysuccinimide) (4.7 mg, 0.041 mmol), and DCC (*N*,*N*′-dicyclohexylcarbodiimide) (8.4 mg, 0.041 mmol) in anhydrous DMF (1.5 mL) was stirred at room temperature in an argon atmosphere for 60 h. The reaction mixture was filtered, the precipitate washed with DMF (5 mL), and the clear filtrate diluted with ether (70 mL) inducing precipitation of the product, which was then centrifuged and the supernatant discarded. The crude product was redissolved in DMF (3 mL) and reprecipitated with ether. After centrifugation, the product was dried *in vacuo*, which afforded 25 mg (56% yield) of succinimidyl ester **4** as a dark-blue powder. ^{1}H NMR (400 MHz, DMSO-d_6) δ 9.10–8.80 (br. s, 4H), 8.75–8.40 (m, 4H), 8.37–8.18 (m, 2H), 8.20–8.00 (m, 6H), 7.90–7.74 (m, 4H), 7.70–7.35 (m, 8H), 2.92 (br. s, 4H). MS *m/z* 1217.09, calcd for $C_{64}H_{35}N_9O_{14}Zn$, 1217.16.

Oligonucleotide–ZnPc Conjugation Reactions. The labeling procedure used was adapted from Molecular Probe's (Carlsbad, CA) standard protocol for amino-reactive Alexa Fluor succinimidyl esters. Stock solutions of **3**–**5** (5–10 mM) were prepared in DMSO (dimethyl sulfoxide). Labeling buffers were prepared in-house by dissolving the appropriate amount of the corresponding salts in water and adjusting the pH using HCl and/or NaOH. The amino-modified oligonucleotide was purified by ethanol precipitation before the conjugation reaction to remove any amino-containing impurities. The purified oligonucleotide was redissolved in water to yield a solution with a concentration of ~25 μg/mL (5 mM).

Unless otherwise noted, the reaction mixture included (in order of addition) succinimidyl ester **3**, **4**, or **5** (200 nmol), water (7 μL), labeling buffer (75 μL), and oligonucleotide (20 nmol). The reaction was incubated at room temperature for 15–18 h. Labeled oligonucleotides were purified by ethanol precipitation (to partially remove excess unreacted dye) using 250 μL of cold absolute ethanol and 10 μL of 3 M NaCl added to the reaction mixture. The solutions were mixed and kept at −20 °C for 30–60 min and centrifuged at 12,000 rpm with the supernatant discarded. The precipitate was dried on air and reconstituted in 100 μL of 0.1 M TEAA (triethylammonium acetate) for chromatographic analysis and purification. The isolated fractions were combined and concentrated in a rotary evaporator. The excess TEAA was removed by drying in high vacuum (<0.01 mmHg) at room temperature.

High Performance Liquid Chromatography (HPLC). The HPLC separations were performed using a JASCO (Easton, MD) 2000-series HPLC equipped with a quaternary gradient pump, autosampler, and fluorescence and diode-array detectors. The analytical column (Zorbax C18, 5 μm, 4.6 mm × 150 mm) was purchased from Agilent Technologies (Santa Clara, CA). The following gradient was used (flow rate = 1.0 mL/min): initial hold at 95% 0.1 M TEAA/5% MeOH for 5 min; ramp up to 5% 0.1 M TEAA/95% MeOH in 30 min; hold for 5 min; and wash for 15 min with 100% MeOH at 1.5 mL/min. The column was allowed to equilibrate at the initial mobile phase conditions for 20 min before the next injection. Typically, two wavelengths were monitored using the diode-array detector: 260 and 680 nm. The fluorescence detector was set to an excitation wavelength of 677 nm, and the emission wavelength was set to 687 nm, the corresponding maxima for ZnPc **2** absorption and emission (*23*).

Determination of Conjugate Concentrations. The concentrations of the ZnPc-labeled oligonucleotides were determined by HPLC against a calibration curve obtained using solutions of the corresponding ZnPc at various concentrations (0.5&–100 μM) when monitoring absorption at 680 nm, where the oligonucleotide offered little if any absorption.

Absorption and Fluorescence Measurements. All absorption spectra were acquired using an Ultrospec 4000 spectrophotometer (Pharmacia Amersham Biosciences, Piscataway, NJ) or Cary 50 UV&–vis (Varian, Palo Alto, CA) with 10 mm path length quartz cuvettes. Emission spectra were acquired using a FLUOROLOG-3 spectrofluorometer (Horiba Jobin Yvon, Edison, NJ) equipped with a 450 W xenon lamp and a cooled

Hamamatsu R928 photomultiplier operated at 900 V in the photon-counting mode. All spectral measurements were performed under ambient conditions within 3 h of solution preparation.

DNA Hybridization. The hybridization of conjugate **2-C6-O1** (here and elsewhere, **1** or **2** represents ZnPc label (Scheme 1, **1** or **2**); **C6** or **C12**, aliphatic linker containing 6 or 12 carbon atoms, respectively; **O1** or **O2**, oligonucleotide sequence (see Table 1)) with complement **O2** was performed by incubating 1 μM solutions of both the labeled oligonucleotide (**2-C6-O1**) and its complement **O2** at equal molar concentrations in a buffer containing 10 mM Tris-HCl, 4 mM $MgCl_2$, and 15 mM KCl at pH 8.5 for 2 h at 30 °C.

Polymerase Chain Reactions (PCRs). PCRs were performed on M13mp18 DNA (USB, Cleveland, OH) or human placental DNA (Sigma-Aldrich, St. Louis, MO) targets. PCR primers (see Table 1 for sequences) were designed to amplify 185 bp, 272 bp, and 381 bp regions of the M13mp18 DNA target and a 98 bp region of human placental DNA. PCRs were performed using a GeneAmp reagent kit with AmpliTaq DNA polymerase (Applied Biosystems, Foster City, CA). PCR cocktails consisted of 1 μL of each of the primers ($\sim$1 μM whenever known), 2 μL of dNTPs (0.2 mM), 10 μL of 10$\times$ PCR buffer, 1 μL of Taq DNA Polymerase (0.5 unit/μL), 1 μL of DNA template (2 ng/μL), and 84 μL of PCR qualified water. PCR was carried out using a commercial thermal cycling instrument (Eppendorf, Hamburg, Germany or Techne, Burlington, NJ). M13mp18 amplifications consisted of the following (30 cycles): 94 °C for 30 s; 57 °C for 40 s; 72 °C for 60 s; and a final extension at 72 °C followed by a cooling step at 4 °C. Thermal cycling of the human placental DNA was designed to amplify the CFTR (cystic fibrosis transmembrane conductance regulator) gene and consisted of an initial denaturation step at 94 °C for 5 min followed by (30 cycles) 94 °C for 40 s; 62 °C for 40 s; 72 °C for 60 s; and a final extension at 72 °C followed by a cooling step to 4 °C. PCRs were also conducted using unlabeled primers of the same sequence as those of the labeled primers to evaluate PCR performance in the presence of the MPc dye reporter.

Gel Electrophoresis. PCR products were electrophoresed either in a 3% precast agarose gel (Bio-Rad Laboratories, Hercules, CA) or a 5.5% (w/v) cross-linked polyacrylamide gel (Li-COR Biosciences, Lincoln, Nebraska). For the agarose gel, separation was performed at 140 mV in 1 $\times$ TAE buffer (Bio-Rad Laboratories, Hercules, CA). Amplicons were indexed against a DNA sizing ladder (50–1000 bp, Promega, Madison, WI). After separation, the gels were stained with ethidium bromide ($\sim$0.3 μL/mL), and images were collected using a Logic Gel imaging system (Eastman Kodak Company, Rochester, NY).

The polyacrylamide gel was polymerized between two borofloat glass plates (21 cm $\times$ 25 cm) and placed in the Global IR^2DNA analysis system (Li-COR Biosciences, Lincoln, NE). The electrophoresis was typically run at 1,500 V for 2.5 h. Amplicons were indexed against a 50–350 bp IRD700-labeled size standard (Li-COR Biosciences, Lincoln, NE). The fluorescence detector contained in this instrument consisted of a scanning laser (λ = 680 nm), an avalanche photodiode detector, and a bandpass filter (preset center wavelength = 720 nm; pass band $\sim$20 nm) situated in front of this detector to isolate the monitored fluorescence.

RESULTS AND DISCUSSION

ZnPc's **1** and **2** (asymmetrical and symmetrical, respectively; see Scheme 1) possess photophysical properties that are comparable or superior to those of commercially available near-IR dyes (e.g., ZnPc **2**: extinction coefficient = 2.9×10^5, fluorescence quantum yield = 0.41, and photobleaching quantum yield = 5.0×10^{-7}; commercially available near-IR dye IRD700: fluorescence quantum yield = 0.70; photobleaching quantum yield = 4.6×10^{-6} (*23*)), are chemically, thermally, and light stable, and are fairly water-soluble, which was achieved by decorating the macrocycle periphery with polar solubilizing groups (triethylene glycols (TEG) or carboxylates). These ZnPc's have narrower absorption and emission envelopes compared to those of the carbocyanine-based near-IR dyes (see Figure 1), making them particularly attractive for spectral multiplexing applications. Additionally, these dyes contained at least one carboxylic group, a convenient and common functionality that can be used for robust labeling of amino-modified biomolecules such as oligonucleotides via succinimidyl ester chemistry (*43*).

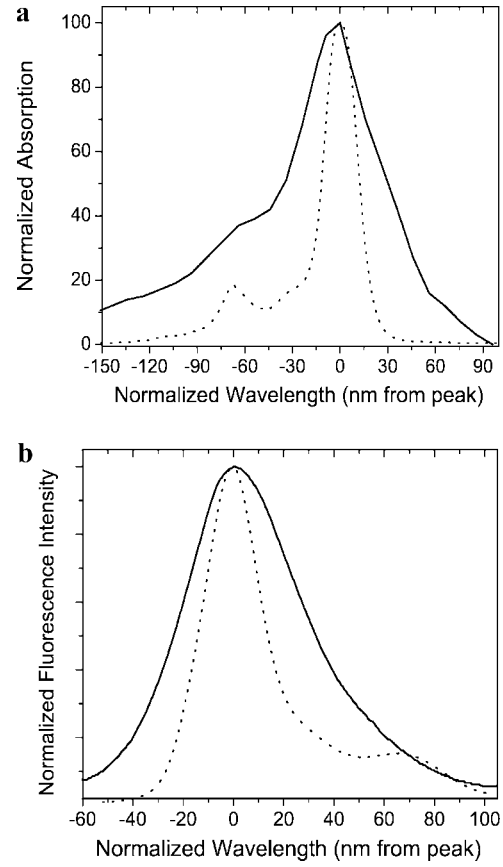


Figure 1. Electronic absorption (a) and emission (b) spectra of a cyanine dye, Cy7 (—), and ZnPc **2** (---). All spectra were acquired using the dyes at a concentration of approximately 1 μM and placed in a DMSO solvent. The spectra were normalized to the absorption or emission maxima.

Two types of MPc's were evaluated in this study: an asymmetric ZnPc **1** containing three triethylene glycol groups to provide solubility in aqueous media and a functional carboxylic group that could be used for labeling reactions, and a symmetric ZnPc **2**, which contained four carboxylic groups that provided both solubilization of the dye in aqueous media and a functional handle to covalently attach the fluorophore to a target.

Conjugation Reactions. The use of succinimidyl esters and their reaction with primary amines has been reported for several MPc's (*28, 29, 31*). We applied this coupling approach to amino-modified oligonucleotides, and ZnPc's **1** and **2** converted into succinimidyl esters **3**–**5** (see Scheme 2). The conjugates, **1-C12-O1**, **2-C12-O1**, and **1-C6-O1**, were isolated using ion-pair reverse-phase chromatography. The chromatographic separation was achieved using a 0.1 M TEAA/CH_3OH gradient (see Figure 2a and Figure S1 in Supporting Information). Using similar

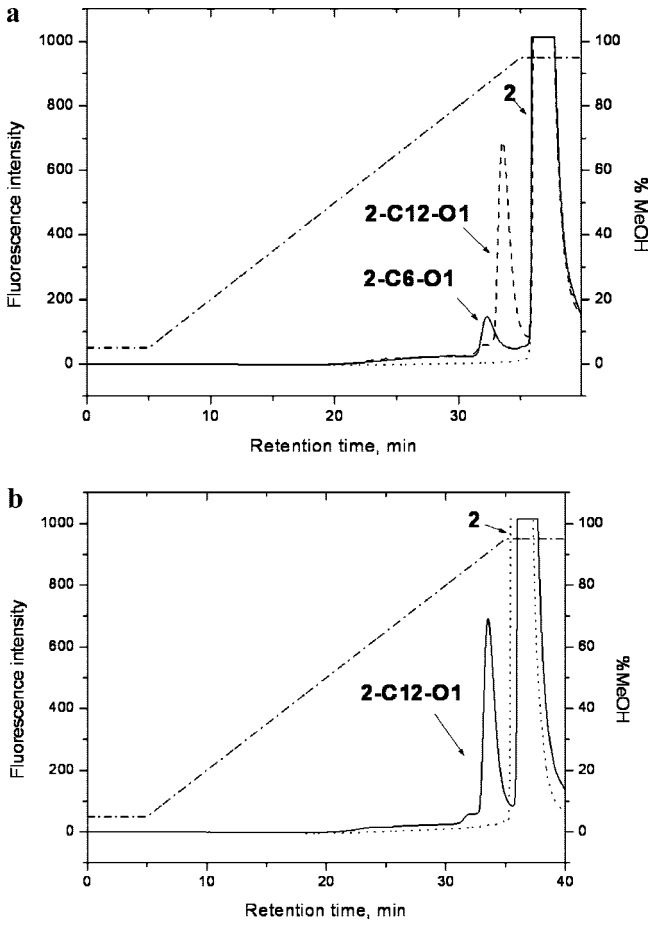

Figure 2. Ion pair, reverse-phase chromatograms of reaction mixtures consisting of a ZnPc succinimidyl ester and an oligonucleotide along with control reactions consisting of the native ZnPc dye and an oligonucleotide. (a) Reactions with succinimidyl ester **4** (—, reaction with **C6-O1**; ---, **C12-O1**; ···, ZnPc **2**; •—•—•, gradient composition). (b) Reaction with succinimidyl ester **4** and a control reaction with the native ZnPc **2** dye (—, reaction with succinimidyl ester **4**; ···, reaction with ZnPc **2**; •—•—•, gradient composition).

gradients with CH_3CN rather than CH_3OH did not result in complete separation of the labeled conjugates from excesses of the corresponding MPc's.

As a control, it was necessary to demonstrate that conjugations were not simply noncovalent associations between the MPc dye and the oligonucleotide. To verify this, a reaction involving a nonreactive MPc (carboxylic acid **2** instead of succinimidyl ester **4** or **5**) and the amino-modified oligonucleotide **O1** was conducted. Inspection of the control chromatograms (Figure 2b) showed no evidence of the MPc's nonspecifically associating with the oligonucleotides; no peak for an association complex was detected in the chromatographic trace. Similar data was also obtained for PEG-modified ZnPc **1** (data not shown).

Experiments were then conducted to optimize the extent of the conjugation reaction by altering reaction conditions, such as pH, buffer composition, and the dye-to-oligonucleotide molar ratio. The labeling efficiencies were evaluated by monitoring the decrease in the original oligonucleotide content observed from the chromatographic traces (details are included in the Supporting Information; see Figure S2). The labeling efficiencies were estimated for various conditions, the results of which are summarized in Tables 2 and 3.

For molecules containing more than one carboxylic group (e.g., ZnPc **2**), several types of succinimidyl esters with different numbers of carboxylic groups converted to succinimidyl esters were possible. Two activated esters of ZnPc **2** were obtained

[a] The conjugation reactions used a C_6H_{12} linker, ZnPc **2**, succinimidyl ester **4**, and an MPc/oligonucleotide molar ratio of 9:1.

and used for the labeling evaluation: the tetra-succinimidyl ester **5** (all four carboxylic groups are converted to the succinimidyl esters) and the monosuccinimidyl ester **4** (only one carboxylic group is converted to the succinimidyl ester). As seen in Table 2, tetra-succinimidyl ester **5** resulted in better labeling efficiencies (78%) compared to that of the monosuccinimidyl ester **4** (53%) when using an MPc/oligonucleotide molar ratio of 11:1. This may have resulted from a higher effective concentration of the succinimidyl ester groups associated with the tetra-succinimidyl ester **5** compared to that of the monosuccinimidyl ester **4**. However, multiple targets may become attached to the same fluorophore when using labeling fluors that have several functional groups, as in the case of tetra-ester **5** compared to the monoester **4**, which can complicate the purification step. Indeed, multiple products were observed in the chromatogram when the succinimidyl ester **5** was used. At least two products were observed in the chromatogram when an 11-fold molar excess of the ester was used (see Figure S3 in Supporting Information), one which could be ascribed to the 1:1 MPc/oligonucleotide conjugate and another to a conjugate in which two oligonucleotides were linked to the same dye. The use of molar excesses below 11:1 (MPc/oligonucleotide) when using succinimidyl ester **5** yielded appreciable levels of the tri- and tetra-substituted products (data not shown).

It was generally observed that the labeling efficiency improved with increases in the MPc-to-oligonucleotide molar concentration ratio up to 11:1 (see Table 2), irrespective of the identity of the dye or succinimidyl ester used. The use of an excess of succinimidyl ester was necessary to overcome competing hydrolysis reactions of these functional groups. However, increasing the MPc/oligonucleotide molar ratio beyond approximately 11:1 reduced the extent of labeling (see Table 2). For example, succinimidyl ester **5** showed decreases in the reaction yield from 78% to 39% when the MPc/oligonucleotide molar ratio changed from 11:1 to 38:1, respec-

tively. At higher dye concentrations, aggregation effects between MPc dyes began to dominate (*44*), which reduced the number of monomeric molecules available for the conjugation reaction. Thus, an MPc/oligo molar concentration ratio of approximately 10:1 was found to be optimal for these conjugation reactions.

We also investigated the effect of different aliphatic linker lengths used to tether the functional group (i.e., primary amine) to the oligonucleotide on the MPc-oligonucleotide labeling efficiency. As noted for ZnPc **2** and the monosuccinimidyl ester **4** (see Table 2), better overall labeling efficiencies were observed for oligonucleotides containing a $C_{12}H_{24}$ linker compared to those with C_6H_{12} linkers. The improved labeling efficiency for the $C_{12}H_{24}$ linker may be explained by reductions in electrostatic interactions between the anionic MPc and oligonucleotides when compared to that in the C_6H_{12} linker.

Various buffer compositions and pH values were also investigated as to their effects on the extent of labeling oligonucleotides with these ZnPc dyes. Inspection of Table 3 shows that for the labeling conditions tested (C_6H_{12} linker, ZnPc **2**, succinimidyl ester **4**, and MPc/oligonucleotide molar ratio of 9:1), better labeling was achieved at pH 7.5 when using the carbonate buffer (67%), while for the borate buffer, higher labeling efficiencies were obtained at a pH value of 8.5 (38%). It was also observed that at all pH values, carbonate buffers yielded higher labeling efficiencies. The effects of pH on labeling efficiency most likely resulted from the necessary balance between three factors: succinimidyl ester group hydrolyzis rate, amine group reactivity, and solubility of **1** and **2** in aqueous media. All of these parameters are known to increase with increasing pH (*43*). The enhancement of the labeling efficiency when carbonate buffer was used compared to that with borate (59% vs 38% at pH 8.5; see Table 3) agreed with similar observations reported in the literature using succinimidyl chemistry (*45*).

Conjugate Purification and Isolation. The standard protocols used to purify oligonucleotides from low molecular weight components, SEC filtration, ethanol precipitation, and HPLC, were evaluated for the isolation of MPc–oligonucleotide conjugates. Sephadex G25 size-exclusion columns were found to retain not only ZnPc **2** but also conjugate **2-C6-O1** (see HPLC traces in Figure S4 in Supporting Information), indicating that the separation was not exclusively based on size but also partially on interactions of the dye with the solid support. Ethanol precipitation, an approach based on the limited solubility of oligonucleotides in cold ethanol, also did not provide adequate purification of the conjugates to allow it to be used exclusively. ZnPc's **1** and **2** have limited solubility in EtOH, which results in only ~40% of the unreacted dye being removed in the ethanol supernatant (see HPLC traces in Figure S5 in Supporting Information). A combination of ethanol precipitation followed by reverse-phase ion pair chromatography was found to give the most efficient isolation/purification approach for the MPc–oligonucleotide conjugates. It allowed for pure conjugates to be isolated, even when 10-fold molar excesses of the dye were used; no residual MPc's and/or unlabeled oligonucleotide were observed in chromatograms of the isolated conjugates when subjected to a precleanup with cold ethanol followed by reverse-phase chromatography (data now shown).

Spectral Properties of the MPc–Oligonucleotide Conjugates. Electronic absorption spectra of the conjugate **2-C12-O1** (Figure 3a) contained features characteristic of both domains, MPc and the oligonucleotide, including absorption bands at ~360 and 680 nm associated with the ZnPc and strong absorption between 250 and 260 nm indicating the presence of the oligonucleotide. Also, strong fluorescence was observed around 690 nm from the ZnPc moiety. The fluorescence emission profiles of the isolated conjugates and the corresponding MPc's were similar with no spectral feature changes observed in the conjugates compared to the corresponding ZnPc dyes (see Figure 3b).

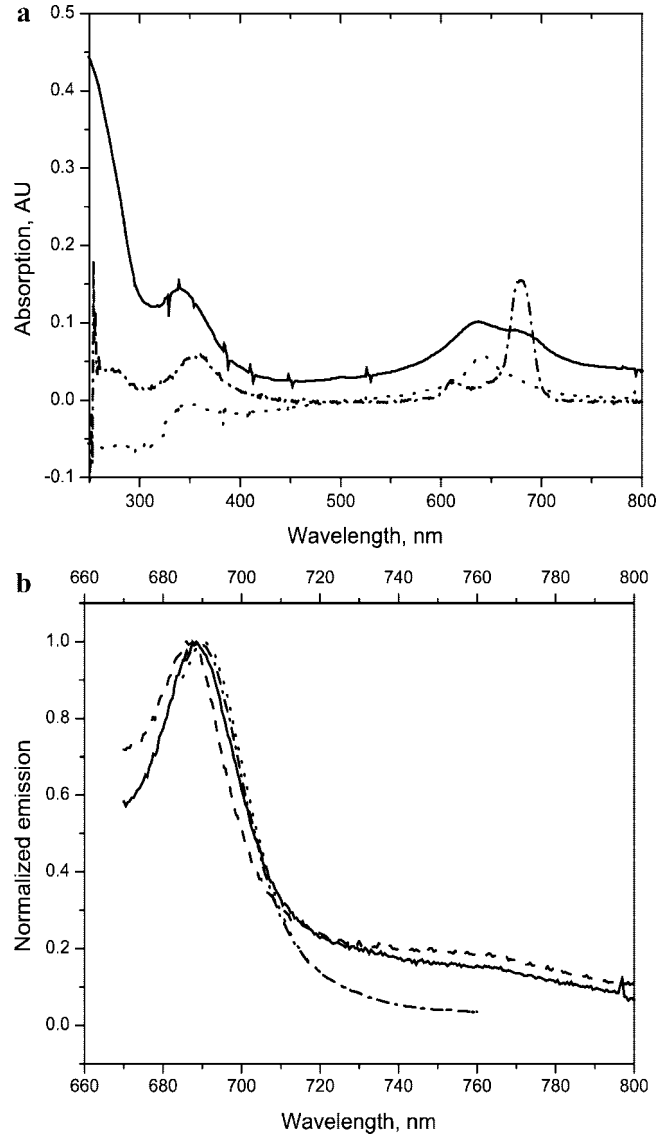

Figure 3. Absorption and emission spectra of purified conjugates and the native MPc dyes. (a) Electronic absorption spectra of **2** (2 μM) in NH_4OH (pH 11) (•••), **2-C12-O1** (concentration unknown) in NH_4OH (pH 11) (—), and **2** (2 μM) in DMSO (•−•−•); (b) Fluorescence emission spectra (λ_{ex} = 650 nm) of **1** (100 nM) in NH_4OH at pH9/MeOH (50/50) (•−•−•), conjugate **1-C12-O1** (concentration unknown) in NH_4OH at pH9/MeOH (50/50) (•••), **2** (100 nM) in carbonate buffer at pH11/MeOH (50:50) (---) and **2-C12-O1** (concentration unknown) in carbonate buffer at pH11/MeOH (50:50) (—).

One of the important intrinsic properties of *Pc*'s and MPc's is their high propensity to aggregate in aqueous solutions (*21*, *26*) with dimerization constants as high as 10^{-9} M^{-1} (*46*). With very few exceptions, neither MPc dimers nor higher order cofacial aggregates fluoresce (*47–49*). Electronic adsorption spectra of MPc's can provide insight into ground-state aggregation processes (*50*); a split and blue-shifted Q-band typically indicates cofacial ground-state aggregation of *Pc* rings (*19*, *44*, *46*, *51*, *52*). Both the free ZnPc **2** and its conjugate **2-C12-O1** showed various degrees of ground-state aggregation in aqueous media as noted from blue-shifts in the absorption maximum, generating a broadband as compared to the molecule in DMSO, where aggregation is expected to be minimal (see Figure 3a).

The absorption spectra of **2-C6-O1** and **2-C6-O1** hybridized to a 42-bp complement oligonucleotide **O2** (see Table 1) were

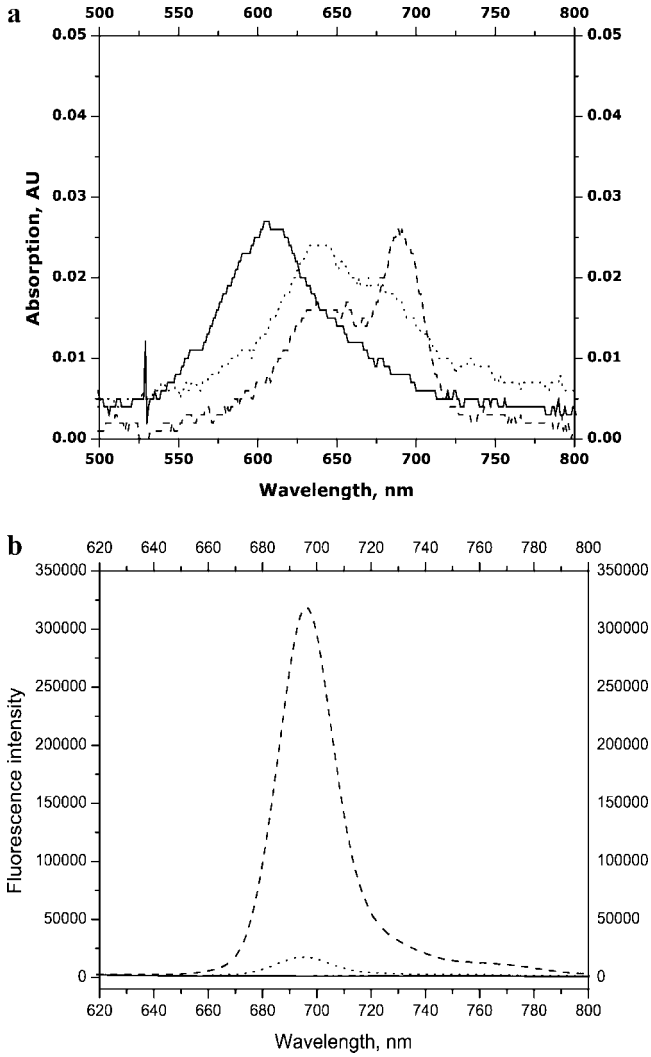

Figure 4. Absorption (a) and emission (b) spectra of solutions of ZnPc **2** (—), conjugate **2-C6-O1** (···), and the hybrid of **2-C6-O1** and **O2** (---). The spectra were measured in a buffer containing 10 mM Tris-HCl, 4 mM $MgCl_2$, and 15 mM KCl at pH 8.5.

also interrogated. The electronic absorption spectra (Figure 4a) indicated almost complete aggregation of ZnPc **2**, partial aggregation of conjugate **2-C6-O1**, and significant reductions in aggregation for the hybrid of **2-C6-O1** with **O2**. The fluorescence results correlated well with the adsorption spectra (see Figure 4b); no detectable fluorescence was observed for ZnPc **2** with a 13-fold increase in fluorescence for the **2-C6-O1**/**O2** hybrid compared to that for **2-C6-O1** alone. These results indicate that MPc aggregation can be substantially diminished when the MPc reporter is part of relatively large oligonucleotide constructs. Similar phenomena have been observed for MPc aggregation upon conjugation to monoclonal antibodies (*37*). However, for the tricarbocyanine near-IR dyes, complete deaggregation effects were observed when this dye was attached to a single nucleotide base (*53*) consistent with the fact that the carbocyanines have low aggregation propensities compared to those of the MPc-based dye systems.

PCR-Based Applications. The ZnPc–oligonucleotide conjugates were next evaluated as potential reagents/reporters for PCR by amplifying different sized regions of an M13mp18 DNA template and a 98 bp region of the exon-10 CFTR gene containing the δF508 mutation, which can provide a high diagnostic value for cystic fibrosis (*54*). The amplicons were sorted by gel electrophoresis using either an agarose gel with

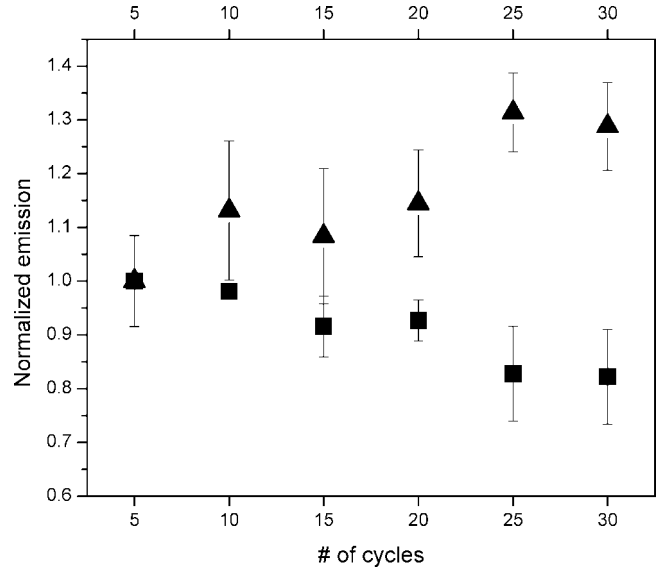

Figure 5. Fluorescence emission intensity of near-IR dye-labeled oligonucleotides (■, IRD700; ▲, ZnPc **2**) as a function of thermal cycle number. The reactions did not contain a target DNA or DNA polymerase. Thermal cycling conditions: 94 °C for 1 min; 55 °C for 40 s; 72 °C for 1 min. Emission wavelengths used were 700 nm for IRD700 and 690 nm for ZnPc **2**. Emission intensities were normalized to the intensity secured after 5 thermal cycles.

UV detection after staining with ethidium bromide or a polyacrylamide gel with near-IR fluorescence detection at ~700 nm.

A comparison of the chemical/thermal stability of ZnPc- and carbocyanine-based near-IR fluorophores was first investigated using PCR, which contained all reagents except the amplification target and polymerase, and was carried through typical thermal cycling conditions. The results of this investigation are shown in Figure 5. (The fluorescence measurements were performed at room temperature following thermal cycling.) As can be seen in the results in Figure 5, the emission intensities for the carbocyanine-labeled oligonucleotide showed incremental decreases with increasing thermal cycle number, while the ZnPc **2** reporter showed modest increases in its fluorescence intensity with increasing thermal cycle number. The loss in fluorescence intensity for the carbocyanine is indicative of chemical changes in the chromophore induced by thermally activated reactions, which result in decreases in the fluorescence of this molecule. In the case of ZnPc **2**, no such reactions were found to occur at the conditions used herein. We also note that the slight increases in the fluorescence observed for the ZnPc **2** chromophore as a function of cycle number could have resulted from deaggregation of the ZnPc-oligonucleotide conjugate (see results in Figures 3 and 4).

We next performed PCR amplification of an M13mp18 or human genomic DNA target using the ZnPc **1** (asymmetrical) and **2** (symmetrical) reporter dyes. The size of the PCR amplicons obtained using both *Pc*-based dye/oligonucleotide conjugates correlated well with their expected sizes based on the known sequences of the test templates and the primer sequences when referenced against standard DNA ladders (see Figure 6). Another important conclusion is that no erroneous bands were detected in either of the PCRs, indicating that the ZnPc-based fluorophores did not perturb the PCR process. The results in Figure 6a show agarose gel electropherograms of PCR amplicons (381 bp) generated using **1**- and **2**-labeled primers or an unlabeled DNA primer. Qualitatively, the correct amplicons were generated for PCRs using the MPC-labeled primers when compared to the same PCRs using the unlabeled primers based on product size.

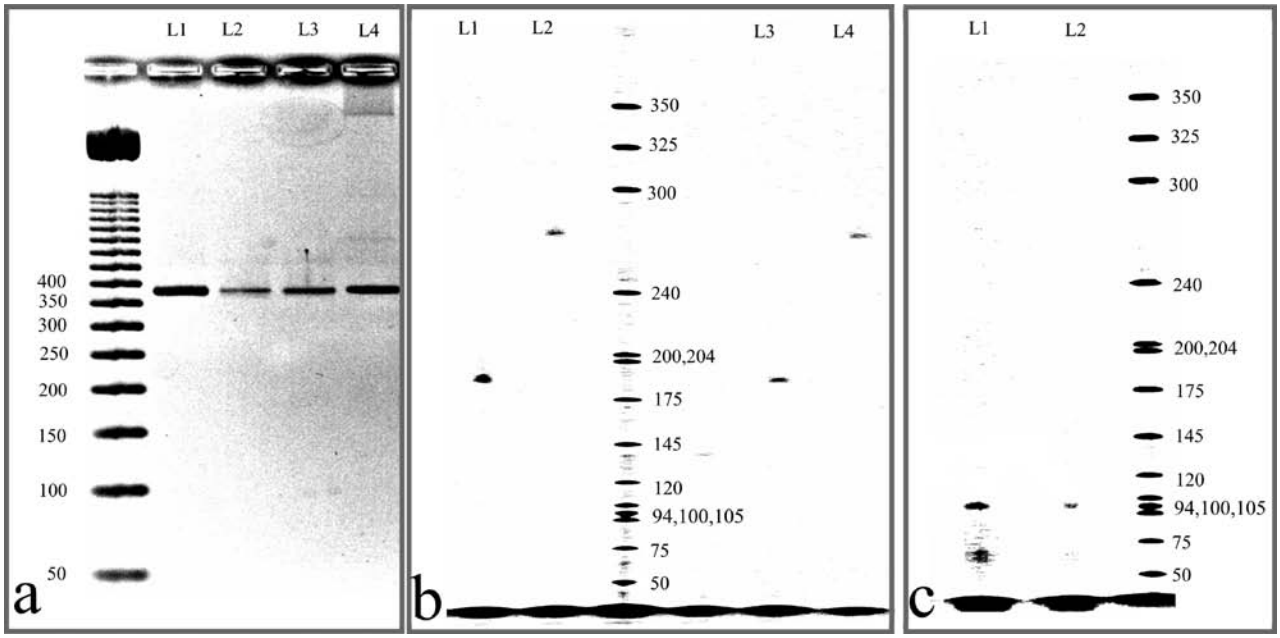

Figure 6. Images of agarose (a) and polyacrylamide (b and c) gels after electrophoresis of PCR products. Detection was accomplished using UV absorption at 254 nm after staining the gel with ethidium bromide (a) or near-IR fluorescence at 700 nm (b and c). (a) 381 bp regions of M13mp18 amplified using primers **1-C12-O1** (L2), **2-C12-O1** (L3), **2-C6-O1** (L4), and unlabeled primer (L1). (b) 185 bp (L1, L3) and 272 bp (L2, L4) amplicons of a M13mp18 template amplified via PCR using primers **2-C6-O1** (L1, L2) or **1-C12-O1** (L3, L4). (c) (L1 and L2), 98 bp region of CFTR gene amplified via PCR using primer labeled with ZnPc **2**.

From the polyacrylamide gel electropherogram shown in Figure 6b, single bands were observed irrespective of amplicon size (185 or 272 bp) with similar amplicon yields using either **1** or **2** as the fluorescent label. The lack of smearing in the electrophoretic bands or the presence of phantom bands indicated that the dye–oligonucleotide constructs did not interact due to dye/dye-induced aggregation to either the amplicons or unconsumed primers following PCR.

As a demonstration of the ability to use these labels for the analysis of PCR products with diagnostic value, human genomic DNA was amplified using primers specific for exon-10 of the CFTR gene, which contains a mutation that provides molecular diagnostic information for cystic fibrosis. As can be seen from the image displayed in Figure 6c, 98 bp amplicons were clearly visible. It should be noted that the fluorescence detector used in this electrophoresis unit was not optimized for the MPc dye systems; the filter system installed in the instrument was designed for dicarbocyanine dyes, which have comparatively larger Stoke's shifts and broader excitation/emission envelopes compared to those of the ZnPc dyes (see Figure 1).

CONCLUSIONS

ZnPc's **1** and **2** (asymmetrical and symmetrical, respectively) were designed to provide water solubility and carboxylic groups that could be used for labeling biomolecules through succinimide-based chemistry. The ZnPc's afforded labeling efficiencies of 80% of target oligonucleotides using optimized conditions, including proper pH (7.5), buffer composition (carbonate), linker structure ($C_{12}H_{24}$), and stoichiometry between the MPc and oligonucleotide (~10:1, respectively). In addition, facile purification strategies were reported on the basis of ion-pair reverse-phase chromatography preceded by cold ethanol precipitation.

Spectroscopic investigations indicated that the conjugation of ZnPc's **1** and **2** to oligonucleotides did not alter their intrinsic fluorescence emission properties but affected the aggregation properties of the MPc's when placed in aqueous media. Partial deaggregation of ZnPc **2** was observed when this dye was attached to a 17mer oligonucleotide as revealed from its ground-state spectrum with slight fluorescence noted for the conjugate compared to that for the native dye in aqueous buffer. When the conjugate was hybridized to its complement, creating a double-stranded 42mer, a 13-fold increase in the fluorescence was observed compared to that in the dye/17mer construct. Because most molecular biology applications, such as PCR and cycle sequencing, create constructs that are larger than the starting primer and the primers are used in large molar excesses, this property could potentially reduce interferences from unextended primers when fluorescence is used for readout.

Another attractive feature of the MPc dyes compared to other near-IR dyes is their superior thermal/chemical stability. These features along with their outstanding photostability (photobleaching quantum yield of 5×10^{-7} (*23*)), narrow absorption/emission envelopes (see Figure 1), and near-IR excitation/emission properties will make *Pc* dyes very attractive candidates for a variety of highly sensitive and multiplexed biomolecular applications (*55*).

Novel Polymerizable Surfactants with pH-Sensitive Amphiphilicity and Cell Membrane Disruption for Efficient siRNA Delivery

Xu-Li Wang, Sergej Ramusovic, Thanh Nguyen, and Zheng-Rong Lu*

Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, Utah 84108. Received July 27, 2007; Revised Manuscript Received September 4, 2007

Small interfering RNA (siRNA) is a promising new therapeutic modality that can specifically silence disease-related genes. The main challenge for successful clinical development of therapeutic siRNA is the lack of efficient delivery systems. In this study, we have designed and synthesized a small library of novel multifunctional siRNA carriers, polymerizable surfactants with pH-sensitive amphiphilicity based on the hypothesis that pH-sensitive amphiphilicity and environmentally sensitive siRNA release can result in efficient siRNA delivery. The polymerizable surfactants comprise a protonatable amino head group, two cysteine residues, and two lipophilic tails. The surfactants demonstrated pH-sensitive amphiphilic hemolytic activity or cell membrane disruption with rat red blood cells. Most of the surfactants resulted in low hemolysis at pH 7.4 and high hemolysis at reduced pH (6.5 and 5.4). The pH-sensitive cell membrane disruption can facilitate endosomal–lysosomal escape of siRNA delivery systems at the endosomal–lysosomal pH. The surfactants formed compact nanoparticles (160–260 nm) with siRNA at N/P ratios of 8 and 10 via charge complexation with the amino head group, lipophilic condensation, and autoxidative polymerization of dithiols. The siRNA complexes with the surfactants demonstrated low cytotoxicity. The cellular siRNA delivery efficiency and RNAi activity of the surfactants correlated well with their pH-sensitive amphiphilic cell membrane disruption. The surfactants mediated 40–88% silencing of luciferase expression with 100 nM siRNA and 35–75% with 20 nM siRNA in U87-luc cells. Some of the surfactants resulted in similar or higher gene silencing efficiency than TransFast. EHCO with no hemolytic activity at pH 7.4 and 6.5 and high hemolytic activity at pH 5.4 resulted in the best siRNA delivery efficiency. The polymerizable surfactants with pH-sensitive amphiphilicity are promising for efficient siRNA delivery.

INTRODUCTION

RNA interference (RNAi) is a natural biological process involving gene silencing or regulation with small interfering RNA (siRNA) (*1, 2*). siRNA is a double-stranded RNA molecule (dsRNA) with approximately 20 to 25 nucleotides. The function of siRNA involves specific incorporation into the RNA-induced silencing complex (RISC) and guiding the RNAi machinery to destroy a target mRNA containing complementary sequences (*3*). It has been demonstrated that siRNA is effective to silence specific genes in mammalian cells and nonhuman primates. It is believed that siRNA can target every gene in the human genome and has unlimited potential to treat human disease with RNAi (*4–9*). However, the challenge for successful clinical applications of RNAi remains the *in vivo* delivery of therapeutic siRNAs into target cells with high efficiency.

Systemic *in vivo* siRNA delivery is a complicated process, which involves protecting siRNA from enzymatic degradation, preventing rapid elimination from the body, and facilitating specific tissue and cell uptake, endosomal–lysosomal escape, and siRNA release in cytoplasm. Although various systems have been reported for siRNA delivery, most of these delivery systems are developed based on the concept for the delivery of plasmid DNA, using cationic lipids (*10, 11*) or polymers (*12–14*). These cationic materials form stable nanoparticles with anionic siRNA via charge complexation and protect siRNA from degradation. These siRNA delivery systems are either toxic or inefficient for specific siRNA delivery (*15*). Innovative approaches are needed to design and develop safe and efficient siRNA delivery systems. New siRNA delivery systems should be safe and have a comprehensive multifunctionality to address the complexity of *in vivo* delivery of therapeutic siRNA.

One of the challenges for efficient siRNA delivery is the escape of siRNA delivery systems from the endosomal–lysosomal compartments and siRNA release in cytoplasm after the systems are internalized through endocytosis. We hypothesize that the incorporation of pH-sensitive amphiphilicity and environmentally sensitive siRNA release will result in efficient siRNA delivery systems that facilitate endosomal–lysosomal escape and cytoplasmic siRNA release. Numerous amphiphilic materials present in nature are able to disrupt cell membranes (*16–18*). The pH-sensitive amphiphilicity of an siRNA carrier will allow the carrier to change its amphiphilic structure at endosomal–lysosomal pH (5.0–6.0), resulting in disruption of endosomal–lysosomal membranes and escape of siRNA delivery systems. It has been shown that the incorporation of degradable disulfide bonds into cationic polymeric delivery systems promotes the release of nucleic acids in the reductive environment of cytosol (*19–21*). According to the hypothesis, we have designed polymerizable surfactants containing dithiol groups, protonatable amines with different pK_a's and lipophilic units as novel multifunctional carriers for siRNA delivery. The surfactants can readily form compact nanoparticles with siRNA via charge–charge complexation and hydrophobic interaction. The dithiol groups in the surfactants in the nanoparticles can be polymerized by forming disulfide bonds via autoxidation to further stabilize siRNA nanoparticles. The pH-sensitive amphiphilicity of the carriers can be tuned by modifying the structures of the protonatable amines and lipophilic groups to allow the nanoparticles escaping from endosomal–lysosomal compartments via amphiphilic membrane disruption. The disulfide bonds will be

reduced in the cytoplasm to facilitate the dissociation of nanoparticles and the release of siRNA.

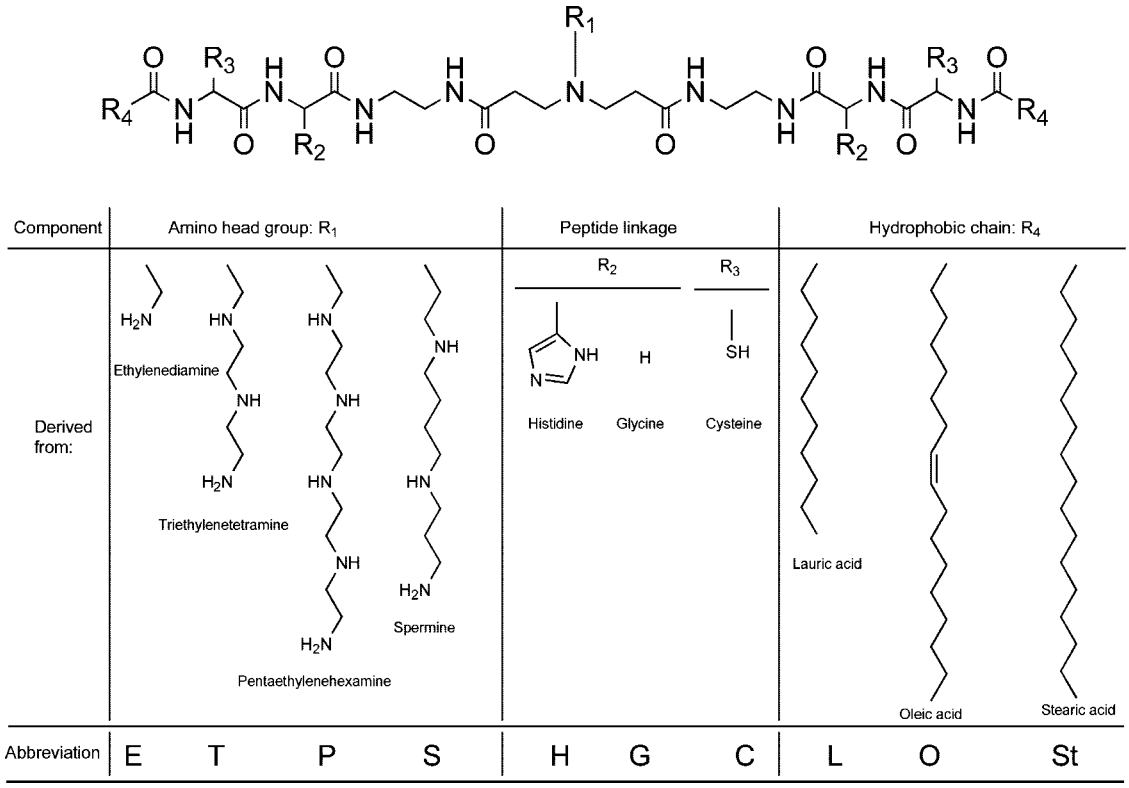
We report here the synthesis and evaluation of a small library of polymerizable surfactants with pH-sensitive amphiphilicity for efficient siRNA delivery. The surfactants were synthesized using combinatorial solid-phase chemistry. The pH-sensitive amphiphilic cell membrane disruption of the surfactants was investigated using hemolysis assay of rat red blood cells at different pH values. The cellular siRNA delivery efficiency of the novel surfactants was evaluated with an antiluciferase siRNA in U87-luc cells with constitutive firefly luciferase expression.

EXPERIMENTAL SECTION

Materials. 2-Chlorotrityl chloride resin, *N*-fluorenylmethoxycarbonyl-*N*-im-trityl-L-histidine, *N*-fluorenylmethoxycarbonyl-*S*-trityl-L-cysteine, 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU), *N*-hydroxybenzotriazole (HOBt), and 2-acetyldimedone (Dde-OH) were purchased from EMD Biosciences (San Diego, CA). Ethylenediamine, pentaethylenehexamine, spermine, triethylenetetraamine, *N*,*N*-diisopropylethylamine (DIPEA), methyl acrylate, hydrazine, 4-dithiothreitol (DTT), piperidine, trifluoroacetic acid (TFA), hyperbranched PEI (Mw = 25 KDa), *N*-(2,3-dioleoyloxy-1-propyl)trimethylammonium methyl sulfate (DOTAP), bovine serum albumin (BSA), and 2,5-diphenyl-3-(4,5-dimethyl-2-thiazolyl)tetrazolium bromide (MTT) were purchased from Sigma-Aldrich (St. Louis, MO). Anhydrous dimethyl sulfoxide (DMSO), *N*,*N*-dimethylformamide (DMF) and dichloromethane (DCM) were purchased from Acros (Pittsburgh, PA). ISOLUTE column reservoirs (Charlottesville, VA) were used for the solid-phase synthesis. The amines were purified by distillation under reduced pressure before they were used for synthesis. All other materials and solvents were used without additional purification. 5,5′-Dithiobis-(2-nitrobenzoic acid) (DTNB) was purchased from Pierce Inc. (Rockford, IL). TransFast that is formulated with *N*,*N*-[bis-(2-hydroxyethyl)-*N*-methyl-*N*-[2,3-di(tetradecanoyloxy)propyl] ammonium iodide and dioleoyl phosphatidylethanolamine (DOPE) was purchased from Promega. siRNA targeting firefly luciferase was purchased from Dharmacon (Chicago, IL). The sequence of antisense is 5′-UCGAAGUACUCAGCGUAAGdTdT-3′ and that of sense is 3′-dTdTAGCUUCAUGAGUCGCAUUC-5′.

Synthesis of Polymerizable Surfactants. The polymerizable surfactants were synthesized by solid-phase chemistry. The synthetic procedure of (1-aminoethyl)imino-bis[*N*-(oleicyl-cysteinyl-histinyl-1-aminoethyl)propionamide] (EHCO) is described as the representative procedure for the synthesis of the library.

2-Chlorotrityl chloride resin (300 mg) was extensively washed with anhydrous DCM. A mixture of ethylenediamine (1.0 mL, excess) and DIPEA (64 mg) in DCM was added to the resin, and the suspension was shaken for 2 h. The solvent was drained, and the resin was washed with DCM and MeOH. The resin was further shaken with 10 mL DCM/MeOH/DIPEA (17/2/1, v/v/v) for 20 min. The resin was then mixed with methyl acrylate (50 mL, excess) in 10 mL DMF to introduce methyl carboxylate via Michael addition. The reaction was carried out in a rotary evaporator at 50 °C with continuous rotating. A solution of 1,2-ethylenediamine (50 mL, excess) in 10 mL DMF was then mixed with the resin methyl carboxylate. The mixture was rotated in a rotary evaporator at 50 °C for 5 days. The resin containing primary amines was transferred into an ISOLUTE column, mixed with a solution of activated N-α-Fmoc-N-im-trityl-L-histidine (2.0 g, excess) with TBTU/HOBt/DIPEA (excess) in DMF and shaken for 2 h. The resin was subjected to a washing cycle, and the Fmoc protecting group was removed with 20% piperidine in DMF (20 min × 3) to give a resin containing histidine residues. Cysteine residues were similarly incorporated by reacting the resin with N-α-Fmoc-S-trityl-L-cysteine (2.0 g, excess) and TBTU/HOBt/DIPEA (excess) in DMF, followed by removal of Fmoc protecting groups. Finally, oleicyl groups were incorporated by reacting the resin with oleic acid (2 g) in the presence of TBTU/HOBt/DIPEA in DMF for 2 h. The quality of each coupling reaction involving primary amino groups was monitored with the Kaiser test. The resin in each reaction cycle was extensively washed with DMF, MeOH, and DCM and dried under reduced pressure before proceeding to the next reaction. The final resin was then suspended in a solution of TFA/H_2O/EDT/TIBS (94/2.5/2.5/1) and shaken for 3 h at room temperature. The solution was collected and concentrated under reduced pressure. The residue was washed with cold diethyl ether (40 mL × 5) and dried. The final product EHCO was purified by preparative HPLC equipped with a ZORBAX PrepHT C-18 column using an Agilent 1100 series purification system. Product fractions were collected and lyophilized. The purity of the final product was verified by analytic HPLC. The structure of the compound was analyzed by ^{1}H NMR spectroscopy using a Varian Mercury 400 (Palo Alto, CA) and matrix-assisted laser desorption–ionization (MALDI) time-of-flight (TOF) mass spectrometry.



Hemolysis Assay. The surfactants (16.7 μM), DOTAP (16.7 μM), and Triton X-100 (1%, w/v) were dissolved in phosphate buffered saline (PBS) with pH adjusted to 7.4, 6.5, or 5.4 as stock solutions. Rat erythrocytes (RBC) were suspended in prechilled PBS at a concentration of 2 % (w/v) RBC at appropriate pH values and then seeded (100 μL) into a 96-well plate. The sample solutions (100 μL) were added to each well of the RBC suspensions and incubated for 1 h at 37 °C. The absorbance of the supernatant from each sample was measured at 550 nm using a microplate reader to determine the released hemoglobin. The relative hemolysis efficiency was calculated as the percentage of released hemoglobin by the surfactants or DOTAP to that by Triton X-100.

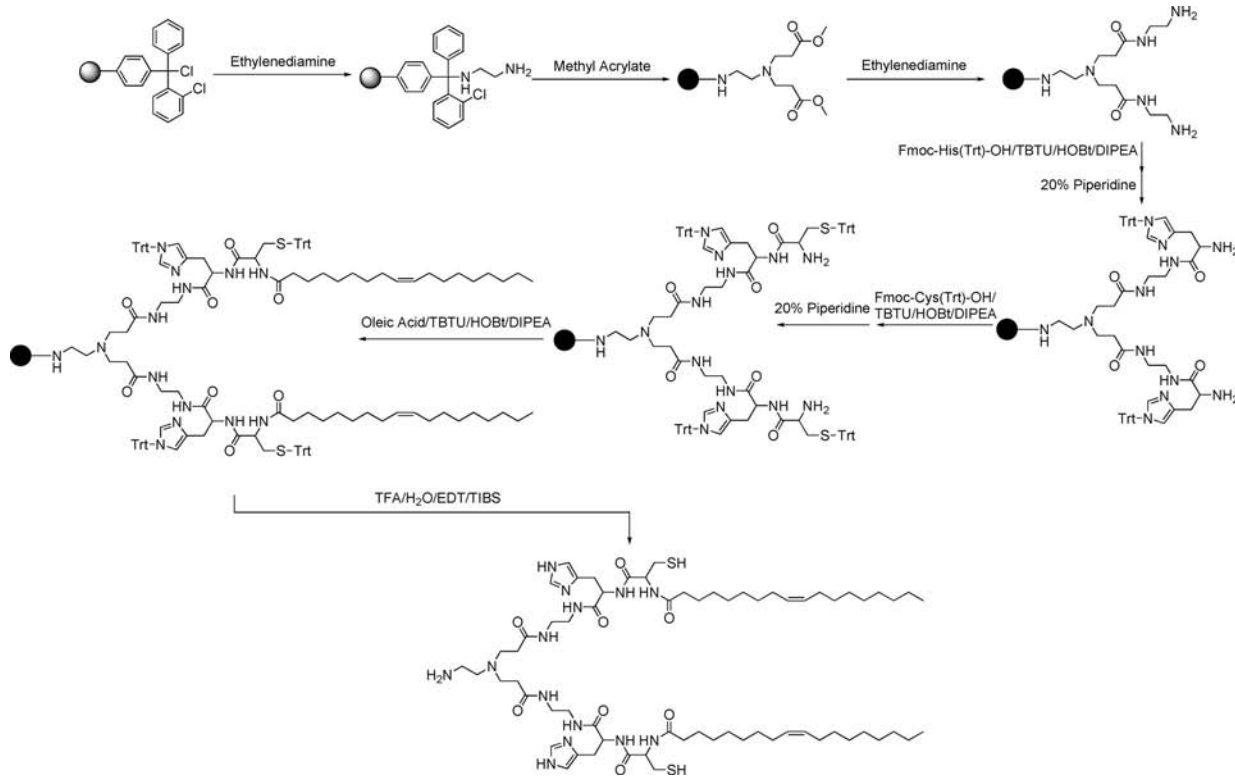
Formation and Size Measurement of Surfactant/siRNA Nanoparticles. Surfactant/siRNA nanoparticulate complexes were prepared by mixing siRNA solution with an equal volume of surfactant solutions at predetermined N/P ratios, followed by 30 min incubation. The size of the nanoparticles was analyzed using a Brookhaven Instruments BI-200SM system equipped with a 5 mW helium neon laser with a wavelength output of 633 nm. The effective diameter and population distribution were computed from the diffusion coefficient. Measurements were made at 25 °C at an angle of 90°, and each sample was analyzed in triplicate.

Autoxidation of the Polymerizable Surfactants. The polymerizable surfactants were diluted from stock solutions (N_2-protected, 2 mg/mL) to an initial thiol concentration of 150 μM in Tris buffer (10 mM pH 8.0). The autoxidation of the dithiols in the surfactants was performed with the working solutions (400 μL) in the absence or presence of 10 μg siRNA (N/P = 10). For each predetermined time point, an aliquot was taken and mixed with an equal volume of Ellman's solution (2 mM DTNB in 50 mM NaOAc solution), and the free thiol concentration was determined by Ellman assay using UV–vis spectrophotometry (Cary-300 Bio).

Polymerizable Surfactant Mediated *in Vitro* Gene Silence with siRNA. U87-luc cells with constitutive expression of firefly luciferase were maintained in minimal essential medium (ATCC) containing 10% FBS, G418 (300 μg/mL), streptomycin (100 μg/mL), and penicillin (100 units/mL). U87-Luc cells were seeded 24 h prior to transfection into a 96-well plate at a density of 5000 cells/well. At the time of siRNA transfection, the medium in each well was replaced with fresh serum-free medium. Antiluciferase siRNA was complexed with the polymerizable surfactants, TransFast, or DOTAP and in-

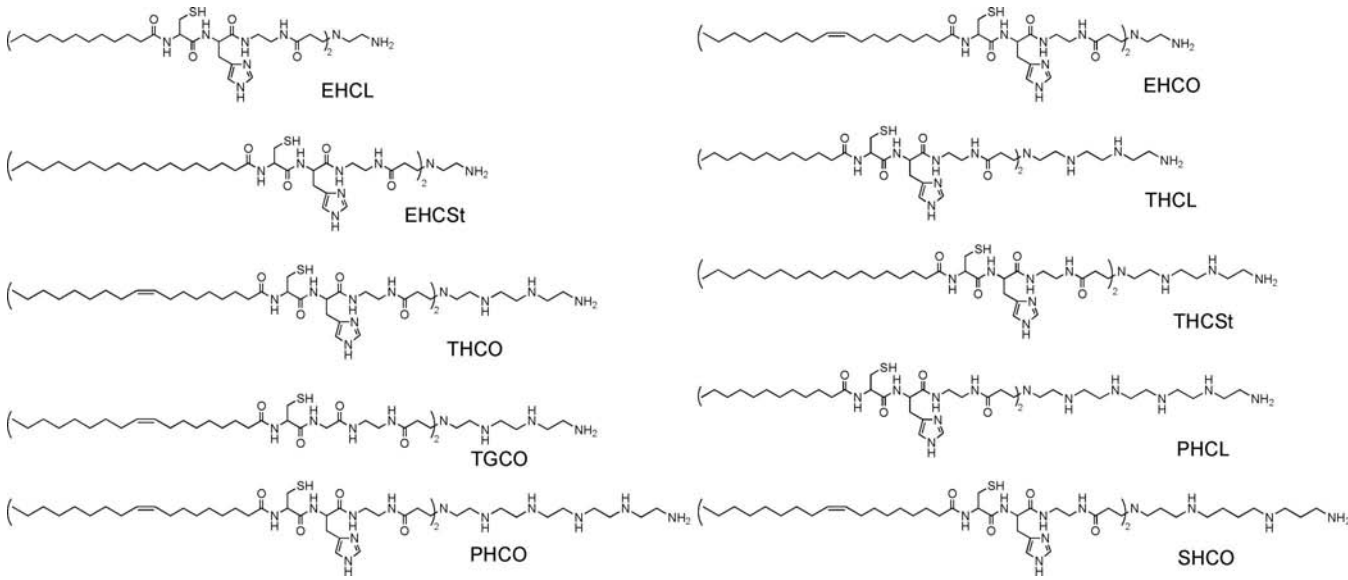
Scheme 1. General Structure of Polymerizable Surfactants

cubated for 30 min before use. Complexes were incubated with the cells for 4 h at 37 °C. The medium was then replaced with 100 μL of fresh complete medium, and cells were incubated for an additional 44 h. The cells were then washed with prewarmed PBS, treated with 200 μL cell lysis buffer, and subjected to a freeze–thaw cycle. Cellular debris was removed by centrifugation at 14 000 g for 5 min. The luciferase activity in the cell lysate (20 μL) was measured using a luciferase assay kit (100 μL luciferase assay buffer) on a luminometer for 10 s (Lumat 9605, EG&G Wallac). The gene silencing efficiency was normalized against the luciferase expression of untreated cells.



Cytotoxicity of Surfactant/siRNA Complexes. U87-luc cells were incubated with siRNA complexes of different carriers according to the protocol described above. MTT in PBS (5 mg/mL, 25 μL) was added to each well after incubation, and cells were incubated for another 2 h. After cell culture medium was removed, 200 μL DMSO was added to each well, and cells were incubated at 37 °C for 5 min. The optical absorption was measured at 570 nm using a microplate reader (model 550, Bio-Rad Laboratory. Hercules, CA). The relative cell viability was calculated with the equation $([Abs]_{sample} - [Abs]_{blank})/([Abs]_{control} - [Abs]_{blank}) \times 100\%$.

RESULTS AND DISCUSSION



Design and Synthesis of Polymerizable and pH-Sensitive Amphiphilic Surfactants. The polymerizable surfactants with pH-sensitive amphiphilicity are designed based on the hypothesis that pH-sensitive amphiphilicity can facilitate the escape of siRNA delivery systems from endosomal–lysosomal compartments and environmentally sensitive disulfide cross-linking can stabilize the siRNA delivery system in the plasma and facilitate the release of siRNA in cytoplasm for efficient siRNA delivery and effective RNAi. The general structure of the designed polymerizable surfactants is shown in Scheme 1. Each surfactant is composed of three key components in its structure, including a protonatable amino head group, dual cysteine residues, and lipophilic tails. The protonatable amino head group comprises primary, secondary, tertiary, and aromatic amino groups of various pK_a's, which is designed to complex with siRNA and alter the pH-sensitive amphiphilicity of the surfactants. Lipophilic tails are designed to introduce lipophilicity in the surfactants and to condense the nanoparticulate siRNA complexes though hydrophobic interactions. Cysteine residues are designed to further stabilize nanoparticles through polymerization of the surfactants by forming disulfide bonds via autoxidation of thiols. The disulfide bonds are relatively stable in the plasma during the delivery process and can be reduced in the reductive cytosolic environment to facilitate siRNA release. The pH-sensitive amphiphilicity of the surfactants can be tuned by varying the composition of amino groups of different pK_a's and structures of the lipophilic groups.

Different polyamines, including ethylenediamine, triethylenetetraamine, pentaethylenehexamine, and spermine, and histidine have been chosen to build the protonatable head groups. Fatty acids of different chain lengths and structures, including lauric acid, stearic acid, and unsaturated oleic acid, have been used as the hydrophobic units. The small library of surfactants with different combinations of protonatable head groups and lipophilic tails were synthesized using resin-supported solid-phase chemistry. Scheme 2 shows the synthetic procedure of EHCO. The structures of the polymerizable surfactants and their abbreviated names, according to their head group, peptide linkage, and tail chains (Scheme 1), are shown in Scheme 3. For triethylenetetraamine, pentaethylenehexamine, and spermine, their primary and secondary amines were selectively protected by 2-acetyldimedone (Dde-OH) and *tert*-butyloxycarbonyl (Boc) groups, respectively, as described in our previous publication . The polymerizable surfactants with high purity were obtained after purification with preparative HPLC and characterized by ^{1}H NMR and mass spectrometry. The ^{1}H NMR spectrum of EHCO is shown in Figure 1 as a representative example. The

calculated mass and measured mass of the polymerizable surfactants are summarized in Table 1. No evidence of oligomers or cyclic byproducts was observed in the mass spectra of the compounds. Over 98% of thiol groups remained in a reduced state as determined by Ellman's assay. TGCO with glycine replacing histidine was prepared to study the impact of imidazole groups on the pH-sensitive amphiphilicity and cell membrane disruption of the surfactants.

pH-Sensitive Hemolysis. Amphiphilic cell membrane disruption is a common phenomenon in nature. Numerous amphiphilic materials have been found to have a fusogenic property of mediating material transport across cell membranes (*22–24*). Amphiphilic peptide sequences are used by viruses, the highly efficient gene delivery systems, in their membrane surface protein to facilitate cell entry or endosomal–lysosomal escape (*25–27*). Several amphiphilic lipids, e.g., DOPE, have been used to enhance the fusion of nucleic acid lipoplexes with cellular membrane for gene delivery (*28, 29*). However, these lipids may not have the ability of selective amphiphilic membrane disruption at the endosomal–lysosomal pH. It is critical for siRNA delivery if siRNA delivery systems have low amphiphilicity at the physiological pH and high amphiphilicity at the endosomal–lysosomal pH, which will only cause selective endosomal–lysosomal membrane disruption. The polymerizable surfactants may not have strong amphiphilicity before the amino head groups are completely protonated at neutral pH. The amphiphilicity of the surfactants may increase with increasing protonation degrees of the head groups at reduced pH.

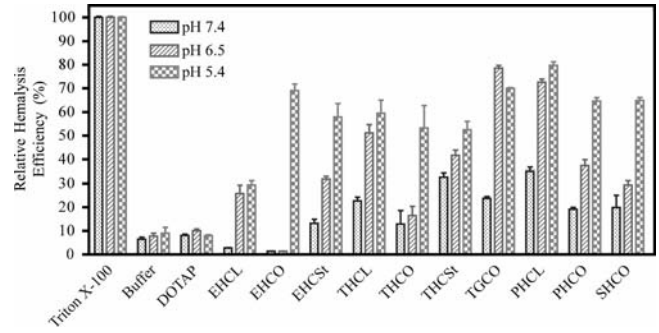

Figure 2. Hemolytic activity of polymerizable surfactants (8.3 μM) and DOTAP (8.3 μM) at pHs of 7.4, 6.5, and 5.4, respectively. Triton X-100 (1%, w/v) and PBS were used as controls.

The pH-sensitive amphiphilic cell membrane disruption of the polymerizable surfactants was evaluated by hemolysis assay with rat red blood cells at different pHs. Figure 2 shows the hemolytic activity of the compounds at pHs 7.4, 6.5, and 5.4 in PBS buffer. The positive control Triton X-100 (1%, w/v) resulted in complete hemolysis. Little hemolysis was shown with the buffer and DOTAP in all cases. The polymerizable surfactants showed various pH-dependent hemolytic activities. Generally, all surfactants had lower hemolytic activity at pH 7.4 than at pHs 6.5 and 5.4. At pH 7.4, EHCL and EHCO resulted in negligible hemolysis, while the rest of the surfactants showed moderate hemolytic activities with 10–35% hemolysis. At pH 6.5, hemolytic activity of the surfactants increased except for EHCO, which still showed negligible hemolysis. At pH 5.4, all surfactants exhibited high hemolysis, and the surfactants except EHCL resulted in 50–80% hemolysis.

The pH-sensitive hemolysis of the surfactants is clearly governed by their structural characteristics. For the surfactants containing histidine residues and the same lipophilic tails, the hemolytic activity increased with increasing number of protonatable amino groups in the head group at pHs 7.4 and 6.5. More protonatable amino groups could result in more charges in the head groups and higher amphiphilicity for the surfactants at neutral pH. For the EHC and THC series, the unsaturated oleicyl group resulted in less hemolysis than the saturated lipophilic tails in the same series at pHs 7.4 and 6.5 except for EHTL at pH 7.4. The comparison between THCO and TGCO suggests that the histidine residues are critical for pH-sensitive amphiphilicity of the surfactants. Overall, the pH-sensitive hemolysis, disruption of membrane of red blood cells, is caused by the pH-sensitive amphiphilicity of the surfactants derived from the combination of protonatable amino head groups and lipophilic tails. When more amino groups are protonated, the surfactants become more amphiphilic and result in more significant hemolysis. The protonation and pH-sensitive amphiphilicity may be governed by the overall pK_a of the head groups of the surfactants. As we have shown here, they can be tuned by using amino groups with different pK_a's.

The pH-sensitive amphiphilicity of the surfactants is critical for efficient cellular siRNA delivery. It is known that pH in the late endosomal compartment is in the range 5.0–6.0 and pH in the lysosomal compartment is 5.0–5.5. Therefore, the pH-responsive amphiphilicity and membrane disruption of the polymerizable surfactants is an ideal feature to trigger endosomal–lysosomal membrane destabilization. Low amphiphilicity of the surfactants at physiological pH will minimize nonspecific cell membrane disruption and nonspecific tissue uptake of siRNA delivery systems. To this end, EHCO with no hemolytic activity at pHs 7.4 and 6.5 and high membrane disruption activity at pH 5.4 could be a suitable carrier for siRNA delivery.

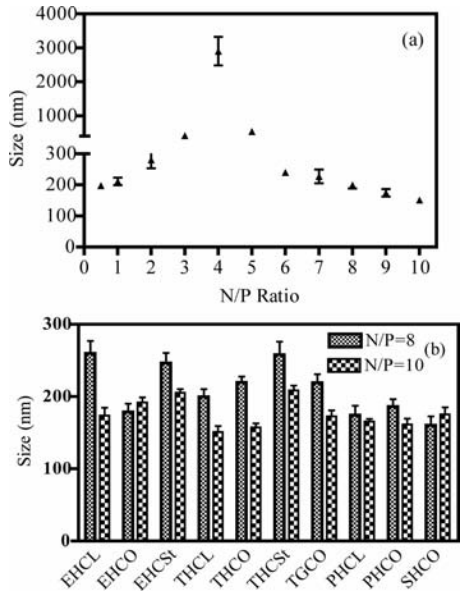

Figure 3. Particle size of the siRNA complexes with the polymerizable surfactants: (a) size of EHCO/siRNA complexes at different N/P ratios; (b) sizes of siRNA complexes with the polymerizable surfactants at N/P ratios of 8 and 10.

Formation of Nanoparticles of the Polymerizable Surfactants with siRNA. The complexation of the polymerizable surfactants with siRNA and formation of nanoparticles of the complexes were investigated by dynamic light scattering. EHCO was first used to study the complexation with siRNA and the impact of N/P ratios on the complexation and formation of nanoparticles. No nanoparticulate formation was detected in either EHCO or siRNA solutions. When EHCO was mixed with siRNA and incubated for 30 min, the formation of nanoparticulate complexes was observed with an N/P ratio as low as 0.5. The particle size changed with N/P ratios of the complexes (Figure 3a). The initial size was approximately 200 nm in diameter at an N/P ratio of 0.5, and the size then increased with increasing N/P ratio up to an N/P ratio of 4. The particle size was as large as about 3 μm at the N/P ratio of 4, possibly due to aggregation of relatively neutral complex particles. The particle size decreased to approximately 240, 200, and 151 nm at the N/P ratios of 6, 8, and 10, respectively. The particle size of siRNA complexes with other polymerizable surfactants was measured at the N/P ratios of 8 and 10 based on the observation with EHCO. As shown in Figure 3b, the average particle sizes of the complexes were in the ranges of 160–260 nm at N/P ratio of 8 and 160–210 nm at N/P ratio of 10. The sizes of most complexes were under the reported cutoff size of 250 nm for efficient cellular uptake (*30*).

The polymerizable surfactants formed relatively compact and small nanoparticles as compared to other reported siRNA delivery systems (*21*). It is speculated that complexes were formed by charge interaction between the carriers and siRNA. Hydrophobic interaction of lipophilic tails and polymerization of dithiols facilitated the formation of stable compact nanoparticles. The polymerization of the surfactants via oxidation was confirmed by the disappearance of thiols after they were mixed with siRNA, as determined by Ellman's assay (Figure 4). The autoxidation rate of thiols was faster in the presence of siRNA than that in the absence of siRNA, possibly because the complexation with siRNA facilitated autoxidation. These disulfide linkages could further stabilize the nanopaticulate complexes. Due to the significant difference of thiol/disulfide redox potential between the extracellular space and the intracellular environment, the disulfide bonds would be stable in the extracellular space during the delivery process and then reduced in cytosol, facilitating the disassociation of nanoparticles and the release of siRNA. A number of recent reports have shown that incorporation of disulfide cross-linking in the siRNA/cationic polymers can stabilize the siRNA nanoparticles and facilitate siRNA release into the reductive cytoplasm, resulting in high transfection efficiency (*19–21*).

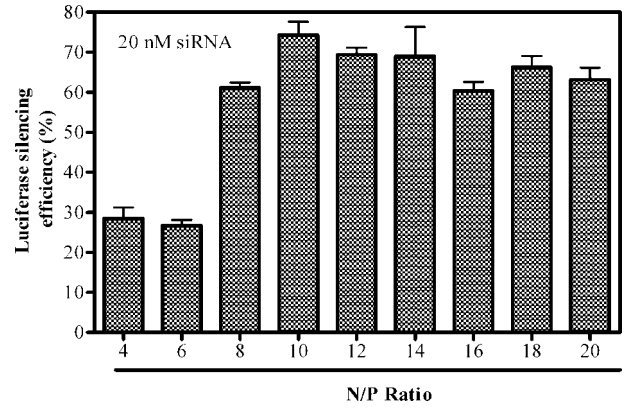

Figure 5. EHCO-mediated luciferase gene silencing efficiency in U87-luc cells at different N/P ratios.

Cellular siRNA Delivery. The efficacy of the polymerizable surfactants for cellular siRNA delivery was evaluated using an antiluciferase siRNA in U87-luc cell line with stable expression of firefly luciferase. Commercial transfection agents TransFast and DOTAP were used as controls. The silencing efficiency of luciferase expression mediated by the surfactants was first evaluated with EHCO at different N/P ratios to obtain the best N/P ratios for effective siRNA delivery. High luciferase expression knockdown efficiency was observed with N/P ratios ranging from 8 to 20 for EHCO (Figure 5). The peak silencing efficiency was observed at the N/P ratio of 10 for the surfactants. The silencing efficiency of luciferase expression mediated by the polymerizable surfactants was evaluated at the fixed N/P ratio of 10. Viability of cells incubated with the siRNA complexes was also investigated at the same time by MTT assay to assess the cytotoxicity of the surfactants. As shown in Figure 6a, TransFast resulted in an 89.6 $\pm$ 5.6% knockdown of luciferase expression as compared to untreated cells with 100 nM siRNA, but significant cellular cytotoxicity was observed with a cell viability of only 57.6 $\pm$ 2.2%. The relatively high gene silencing efficiency of TransFast with 100 nM siRNA could also be the result of low cell viability. DOTAP/siRNA complexes at the same siRNA concentration had higher viability (85.8 $\pm$ 1.6%), but resulted in significantly lower luciferase knockdown efficiency (56.7 $\pm$ 3.1%). The cells incubated with the siRNA complexes of the polymerizable surfactants had a relatively high viability ranging from 78.6 $\pm$ 5.7% to 88.2 $\pm$ 1.3%. The luciferase expression knockdown efficiencies varied from 47.8 $\pm$ 4.2% to 88.4 $\pm$ 3.1%. EHCO resulted in the highest

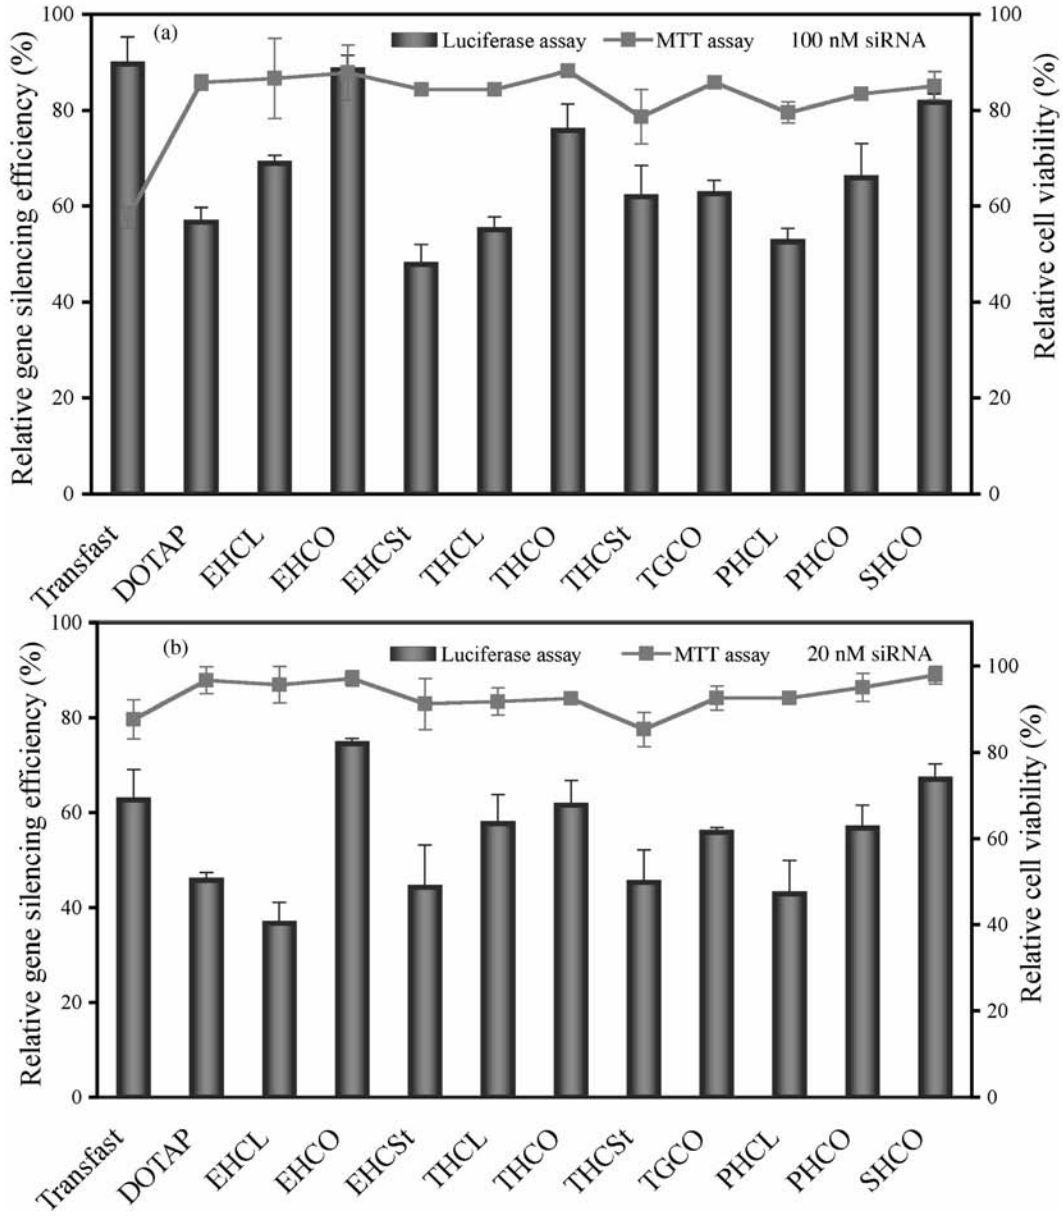

Figure 6. The polymerizable surfactants mediated luciferase gene silencing efficiency and the viability of cells incubated with MFC/siRNA complexes in U87-Luc cells. Transfast and DOTAP were used as controls. Transfection experiments were performed at siRNA concentration of 100 nM (a) or 20 nM (b).

gene silencing efficiency (88.4 ± 3.1%) with high cell viability (86.7 ± 8.3%) among the polymerizable surfactants.

All of the siRNA complexes demonstrated low cytotoxicity at a low siRNA concentration (20 nM), (Figure 6b). Cell viability was high in all cases including Transfast (87.6 ± 4.6%). Under this condition, the polymerizable surfactants except EHCL resulted in higher luciferase silencing efficiency than DOTAP. THCL, THCO, TGCO, PHCO, and SHCO resulted in comparable transfection efficiency to that of TransFast (62.6 ± 6.4%). EHCO (74.5 ± 1.0%) resulted in significantly higher transfection efficiency than TransFast. The cellular siRNA delivery efficiency correlated well to the pH-sensitive hemolytic activity and amphiphilicity of the polymerizable surfactants. EHCO exhibited the highest gene silencing efficiency at both siRNA concentrations. THCO and SHCO with relatively low hemolysis at pHs 7.4 and 6.5 also showed relatively high gene silencing efficiency among the surfactants.

Although the polymerizable surfactants have similar gemini lipid tails to other commercial lipid transfection agents, e.g., DOTAP, no helper molecule like DOPE or cholesterol is needed to achieve high siRNA delivery efficiency. This is an advantageous feature for the polymerizable surfactants as ready-to-use carriers compared to the commercially available liposome or lipid-based transfection agents. To the best of our knowledge, this is the first example of lipid-containing siRNA carriers achieving high siRNA delivery efficiency without a helper lipid. However, helper molecules are required for commercially available lipid-based siRNA carriers, including TransIT-siQUEST and X-tremeGENE, to enhance delivery efficiency (*15*). Some of helper molecules may introduce cytotoxicity in formulations. It is reported that DOTAP was nontoxic as a siRNA carrier, but the formulation of DOTAP with DOPE resulted in significant toxicity (*31*).

It is speculated that the polymerizable surfactants form compact nanoparticles with siRNA through charge–charge complexation, lipophilic condensation, and oxidative polymerization. The lipophilic chains may facilitate lipophilic condensation rather than forming lipid bilayers, because they are further

apart in the polymerizable surfactants as compared to the gemini lipophilic chains in commercial lipids. The cellular siRNA delivery efficiency clearly correlates to pH-sensitive amphiphilicity and pH-sensitive cell membrane disruption of the surfactants. EHCO with no hemolytic activity at pHs 7.4 and 6.5 and high hemolytic activity at the endosomal–lysosomal pH (5.4) has shown the highest cellular siRNA delivery efficiency among the tested polymerizable surfactants. The polymerizable surfactants may have another advantage in that the surface of their siRNA nanoparticles can be readily modified by reacting the unreacted thiols at the surface for various purposes, including pegylation and incorporation of targeting agents. Further study is ongoing to expand the library of the polymerizable surfactants, to develop targeted siRNA delivery systems with the surfactants and to study the factors, including formation of disulfide bonds and polymerization degree of the surfactants, on siRNA delivery efficiency and the mechanism of cellular uptake and intracellular siRNA release with the novel carriers.

CONCLUSION

We have designed and synthesized a small library of novel polymerizable surfactants as multifunctional siRNA carriers based on the hypothesis that pH-sensitive amphiphilicity and environmentally sensitive siRNA release of siRNA delivery systems will result in efficient siRNA delivery and effective RNAi. The polymerizable surfactants showed pH-sensitive amphiphilic hemolysis or cell membrane disruption of rat red blood cells. They formed compact nanoparticles with siRNA. The siRNA delivery and gene silencing efficiency of the surfactants correlated well to their pH-sensitive amphiphilicity. EHCO with low hemolytic activity at the physiological pH and high hemolytic activity at pH 5.4 showed the best gene silencing efficiency in U87-luc cells. The polymerizable surfactants with pH-sensitive amphiphilicity are promising multifunctional carriers for siRNA delivery.

ACKNOWLEDGMENT

We thank Mr. Shawn Owen for his technical support in the synthesis of some of the compounds and Dr. Randy Jensen for providing the U87-luc cells.

TECHNICAL NOTES

Synthesis and Properties of Phosphonic Acid Containing Cyanine and Squaraine Dyes for Use as Fluorescent Labels

Mark V. Reddington[†]

Biosearch Technologies, Inc., 81 Digital Drive, Novato, California 94949. Received March 14, 2007; Revised Manuscript Received August 24, 2007

Cyanine and squaraine dyes that contain one or two phosphonate groups attached directly to the aromatic residues of the dyes were synthesized. Absorption and fluorescence properties of the dyes were determined. Succinimidyl active esters were prepared from the dyes and were used to label proteins and oligonucleotides. Some of the dyes permit the preparation of brighter conjugates than do commercially available analogues such as Cy3 and Cy5.

INTRODUCTION

Fluorescent reporters are widely used as labels in biology and medicine (*1*, *2*). As researchers seek to interrogate smaller sample volumes and fewer molecules of analyte, the requirements for the reporter become more demanding. In the case of fluorescent dyes, certain properties have been found to be advantageous. These include (1) high extinction coefficients, (2) high fluorescence quantum yields, (3) low nonspecific binding, (4) high photostability, and (5) ease of chemical modification to permit the ready incorporation of different reactive functionalities and the tuning of absorption and emission wavelengths. For many applications, good water solubility and resistance to the formation of dimers and higher aggregates are essential to prevent adverse effects upon substrate solubility and to prevent quenching of fluorescence through dye–dye ground-state interactions (*1*–*5*). Generally, these latter properties are achieved by attaching charged or neutral water-solubilizing residues to the dye. Subtle differences in the position, the hydrophilicity, and the charge of the water-solubilizing group often result in vastly different performance of a dye as a label (*1*). The sulfonate group is one of the most commonly used water solubilizing groups for commercial fluorescent labels (e.g., Alexa and Cy dyes) in applications where high labeling densities are required because electronic repulsion of the negatively charged dyes inhibits dye–dye contact and quenching interactions (*3*–*6*). To a lesser degree, quaternary ammonium groups (*7*), carbohydrates (*8*), oligonucleotides (*9*), polyethylene glycol residues (*10*), and phosphonate monoesters (*11*) have also been considered for this purpose but have yet to find wide-scale commercial acceptance. Except in the cases of porphyrins (*12*) and cyanines (*13*), where aliphatic phosphonates were used, the phosphonic acid group has remained largely ignored as a means to provide water solubility, resistance to aggregation, and other useful properties for fluorescent labels. Since the phosphonate group may carry two negative charges at some biologically relevant pH values, compared to one charge for the sulfonate group, it offers the possibility of water-soluble labels with enhanced resistance to aggregation and fluorescence quenching and therefore to more brightly labeled substrates. Herein, the synthesis, the photophysical properties, and the protein and oligonucleotide labeling capabilities of some representative examples of phosphonic acid containing cyanine and squarane dyes are presented and discussed. These new dyes have phosphonic acid groups attached directly to the aromatic residues of the dyes rather than through aliphatic linkers because this approach was proven to be more advantageous in the case of analogous sulfonated cyanine dyes (*4*, *5*).

EXPERIMENTAL PROCEDURES

General Methods. All reagents and solvents were either ACS reagent grade or HPLC/spectroscopy grade and were obtained from Sigma-Aldrich, Acros, TCI, or Burdick & Jackson unless otherwise noted. Cy3 monofunctional and Cy5 monofunctional active esters were obtained from Amersham Pharmacia Biotech. Quasar 570 amidite and Quasar 670 amidite were obtained from Biosearch Technologies, Inc. Analytical TLC was performed on EM Biosciences 5534-3 aluminum-backed silica-254 plates or Analtech RPS-F hydrocarbon impregnated silica gel plates. Column chromatography was performed on either Merck silica gel 60 or Analtech bonded C18 reversed-phase (RP) silica gel. For RP column chromatography compressed air was applied to the top of the column to achieve convenient flow rates. For RP column chromatography of dyes, movement of dyes through the column was monitored qualitatively by eye. Deionized (DI) water was used in the preparation of all solvent mixtures used for RP and ion exchange chromatography. Preparative HPLC was run on a Waters HPLC system with a 600E controller, a 600 pump, and a 490E detector using either a Dionex DNAPac (9 × 250 mm) PA-100 column or a Hamilton PRP-1 column. Analytical HPLC was performed on a Waters 2795 system with a 996 photodiode array detector using either a Dionex DNAPac (4 × 250 mm) PA-100 column or a Higgins Haisil HL C18 column. Buffers used for preparative and analytical HPLC were AXA (15% acetonitrile, 0.038 M Tris), AXB (15% acetonitrile, 0.038 M Tris, 1.0 M sodium bromide), RPA (5% acetonitrile, 0.05 M triethylammonium acetate), and RPB (acetonitrile). MALDI mass spectrometry was performed on a Bruker Biflex III MALDI-TOF instrument. Electrospray mass spectrometry was performed on a Finnigan LC Q, and LC–MS was

performed on a Micromass LCT ESI mass spectrometer coupled with a Waters 2790 HPLC and a 996 PDA detector. NMR analysis (^{1}H, 400 Mz; ^{13}C, 100 Mz) was performed by Acorn NMR (Livermore, CA). ^{13}C NMR spectra were acquired with broadband proton–carbon decoupling. Coupling constants reported for ^{13}C NMR spectra are for phosphorus–carbon coupling. Elemental analysis was performed by Desert Analytics (Tucson, AZ). UV–vis spectra were recorded on a Hewlett-Packard 8453 spectrophotometer. Fluorescence spectra were recorded on a PTI spectrofluorometer and were corrected for instrument response characteristics. DNA synthesis was performed on a Biosearch 8700 DNA synthesizer using fast-deprotecting phosphoramidites from Pierce (Milwaukee, WI). Phosphate buffered saline (PBS), pH 7.3 (137 mM NaCl, 2.7 mM KCl, 4.3 mM $Na_2HPO_4 \cdot 7H_2O$, 1.4 mM KH_2PO_4), borate buffered saline (BBS), pH 8.1 (12.5 mM $Na_2B_4O_7 \cdot 10H_2O$, 0.25 mM $HCl_{(aq)}$), carbonate–bicarbonate buffer, pH 9.3 (0.1 M Na_2CO_3, 0.1 M $NaHCO_3$), and PCR buffer (50 mM KCl, 10 mM Tris-HCl, 1.5 mM $MgCl_2$) were prepared according to standard methods.

***p*-Bromophenylhydrazine Hydrochloride (3).** To a 1 L flask were added finely powdered *p*-bromoaniline (69 g, 0.4 mol), water (200 mL), and concentrated hydrochloric acid (100 mL, 1.2 mol). The mixture was cooled in an ice bath to less than 5 °C. A solution of sodium nitrite (30 g, 0.43 mol) in water (90 mL) was added dropwise to the aniline suspension over approximately 1 h while maintaining the temperature at less than 5 °C. The mixture was stirred for a further 0.5 h and then was gravity-filtered through a no. 1 paper into a chilled flask. The solution was added in small portions to a solution of 92% ammonium sulfite (118 g, 0.8 mol) in water (250 mL), which had been chilled to 0 °C, at a rate such that the temperature remained at less than 5 °C (approximately 1 h). During the addition, a yellow solid formed in the mixture. After the addition was completed, stirring was continued for 1 h at 0 °C and then the mixture was allowed to warm to room temperature. The solid was filtered off, and the filtrate was treated with concentrated hydrochloric acid (120 mL). The solution was heated to reflux, during which time a solid formed and then mostly dissolved. The hot solution was filtered and then allowed to cool to room temperature before being chilled in a refrigerator overnight. The crystals that formed were filtered off, washed with 1.0 M hydrochloric acid (60 mL), and dried under vacuum to afford **3** (54.3 g, 60%).

5-Bromo-2,3,3-trimethyl-3*H*-indole (4). To a 500 mL flask were added **3** (40.0 g, 0.179 mol), glacial acetic acid (250 mL), and 3-methylbutanone (50 mL, 0.36 mol). The mixture was heated at reflux for 3 h and then was cooled to room temperature. The volatile components were removed under vacuum, and the residue was partitioned between ether (350 mL) and water (100 mL). The aqueous phase was washed again with petroleum ether (2 × 100 mL), and then the combined organic solutions were dried ($MgSO_4$), filtered, and evaporated under vacuum to afford **4** (35 g, 82%). The bulk of the material was used without further purification. A sample of the oil was distilled on a Kugelrohr to yield a colorless oil: bp, 75 °C at 0.20 mmHg; R_f = 0.62 (SiO_2, dichloromethane (DCM)/methanol, 19:1); ^{1}H NMR ($CDCl_3$) δ 1.29 (s, 6H), 2.26 (s, 3H), and 7.36–7.44 (m, 3H); ^{13}C NMR δ 15.5, 23.0, 54.2, 118.9, 121.4, 124.9, 130.7, 147.9, 152.7, 188.5; ESI-MS obsd (+) 238.0 $(M + H)^+$, calcd 237.02 ($M = C_{11}H_{12}NBr$).

5-Bromo-1-ethyl-2,3,3-trimethyl-3*H*-indolium Iodide (5). To a 250 mL flask were added **4** (12 g, 50.4 mmol), acetonitrile (25 mL), and ethyl iodide (20 mL). The mixture was heated at reflux under argon for 40 h, and then most of the volatile components were removed by distillation. The residue was triturated with ether (100 mL) to give a powder. The solid was filtered off, washed with ether (2 × 150 mL), and dried under high vacuum to afford **5** as a solid (17.3 g, 87%): R_f = 0.70 (SiO_2, DCM/methanol, 9:1); ^{1}H NMR (DMSO-d_6) δ 1.42 (t, J = 7.3 Hz, 3H), 1.55 (s, 6H), 2.84 (s, 3H), 4.48 (quartet, J = 7.3 Hz, 2H), 7.84 (dd, J = 1.9 Hz and J = 8.6 Hz, 1H), 7.96 (d, J = 8.6 Hz, 1H) and 8.19 (d, J = 1.9 Hz, 1H); ^{13}C NMR δ 12.8, 14.3, 21.8, 43.5, 54.6, 117.5, 122.9, 127.1, 132.0, 140.2, 144.4, 196.8; ESI-MS obsd (+) 266.1 $(M - I)^+$, calcd 392.96 ($M = C_{13}H_{17}NBrI$). Anal. Calcd for $C_{13}H_{17}NBrI$: C, 39.62; H, 4.35; N, 3.55. Found: C, 39.56; H, 4.28; N, 3.57.

5-Bromo-1-(5-carboxypentyl)-2,3,3-trimethyl-3*H*-indolium iodide (6). To a 250 mL flask were added **4** (5.8 g, 24 mmol), acetonitrile (25 mL), and 6-iodohexanoic acid (5.1 g, 21 mmol). The mixture was heated at reflux under argon for 40 h. Most of the volatile components were removed by distillation, and then the mixture was heated at 140 °C for 2 h. The mixture was cooled and was triturated with DCM (100 mL) to give a powder. The solid was filtered off, washed with DCM (2 × 50 mL), and dried under high vacuum to afford **6** (8.7 g, 87 %): R_f = 0.38 (SiO_2, DCM/methanol, 9:1); ^{1}H NMR (DMSO-d_6) δ 1.43–1.48 (m, 2H), 1.50–1.55 (m, 8H), 1.82 (quintet, J = 7.5 Hz, 2H), 2.22 (t, J = 7.1 Hz, 2H), 2.83 (s, 3H), 4.44 (t, J = 7.6 Hz, 2H), 7.82–7.85 (m, 1H), 7.95 (d, J = 8.5 Hz, 1H) and 8.19 (d, J = 1.7 Hz, 1H); ^{13}C NMR δ 14.4, 22.0, 24.2, 25.6, 27.1, 33.5, 47.8, 54.6, 117.7, 123.0, 127.1, 132.0, 140.6, 144.3, 174.5, 197.62; ESI-MS obsd (+) 352.2 $(M - I)^+$, calcd 479.00 ($M = C_{17}H_{23}NO_2BrI$). Anal. Calcd for $C_{19}H_{27}NO_2BrI$: C, 42.52; H, 4.83; N, 2.92. Found: C, 42.34; H, 4.78; N, 2.94.

5-Bromo-1-(5-ethoxycarbonylpentyl)-2,3,3-trimethyl-3*H*-indolium iodide (7). To a 250 mL flask were added **6** (2.00 g, 4.17 mmol), ethanol (60 mL), and concentrated sulfuric acid (0.2 mL). The mixture was heated at reflux for 2 h and then was cooled to room temperature. The ethanol was removed under vacuum, and the residue was partitioned between water (40 mL) and DCM (80 mL). The organic layer was washed with 1 M HCl (40 mL), water (40 mL), and a saturated solution of sodium iodide (40 mL). It was dried ($MgSO_4$) and was evaporated under vacuum to afford **7** as a brown solid (1.74 g, 82 %): R_f = 0.79 (SiO_2, DCM/methanol, 9:1); ^{1}H NMR (DMSO-d_6) δ 1.15 (t, J = 7.1 Hz, 3H), 1.43–1.48 (m, 2H), 1.53–1.60 (m, 8H), 1.82 (quintet, J = 7.5 Hz, 2H), 2.29 (t, J = 7.3 Hz, 2H), 2.84 (s, 3H), 4.02 (quartet, J = 7.1 Hz, 2H), 4.44 (t, J = 7.5 Hz, 2H), 7.83–7.86 (m, 1H), 7.95 (d, J = 8.6 Hz, 1H), and 8.19 (d, J = 1.7 Hz, 1H); ^{13}C NMR δ 14.3, 14.4, 22.0, 24.2, 25.4, 27.0, 33.4, 47.8, 54.6, 59.9, 117.6, 123.0, 127.1, 132.0, 140.6, 144.3, 172.9, 197.2; ESI-MS obsd (+) 380.3 $(M - I)^+$, calcd 507.03 ($M = C_{19}H_{27}NO_2BrI$).

(1-Ethyl-3,3-dimethyl-2-methylene-2,3-dihydro-1*H*-indol-5-yl)-phosphonic Acid Diethyl Ester (8). To a dry three-neck 500 mL flask were added **5** (9.6 g, 20 mmol) and nickel chloride (0.52 g, 4.0 mmol). The flask was fitted with a dropping funnel and a condenser and then was lowered into an oil bath. The mixture was heated to 175 °C. At approximately 165 °C triethyl phosphite (15 mL, 86 mmol) was added dropwise over 0.5 h. The mixture fizzed and became dark at first before turning a dark straw color. After the mixture was heated at 175 °C for 0.5 h, a second portion of nickel chloride (0.52 g, 4.0 mmol) was added. The mixture fizzed vigorously, gave off much vapor, and became dark gray-green in color. Heating was continued for 0.5 h, and then the mixture was cooled to room temperature. The mixture was treated with methanol (100 mL) and was filtered through a bed of Celite. The methanol was evaporated under vacuum to leave an oil that was distilled on a Kugelrohr to afford **8** as a colorless liquid that was stored under argon (4.0 g, 62%): bp 155–165 °C at 0.4 mmHg; R_f = 0.67 (SiO_2,

DCM/methanol, 9:1); ESI-MS obsd (+) 324.2 $(M + H)^+$, calcd 323.17 ($M = C_{17}H_{26}NO_3P$).

(1-(5-Ethoxycarbonylpentyl)-3,3-dimethyl-2-methylene-2,3-dihydro-1*H*-indol-5-yl)phosphonic Acid Diethyl Ester (9). To a dry three-neck 500 mL flask were added **7** (11.2 g, 22.1 mmol) and nickel chloride (0.72 g, 5.6 mmol). The flask was fitted with a dropping funnel and a condenser. The mixture was heated to 170 °C, and then triethyl phosphite (30 mL, 173 mmol) was added dropwise over 0.5 h. The temperature was raised to 180 °C, and then a second portion of nickel chloride (0.72 g, 5.6 mmol) was added. After about 20 s, rapid fizzing occurred and the mixture turned grey-green in color. After heating for a further 0.5 h, the mixture was cooled to room temperature and was treated with DCM (200 mL). The mixture was filtered through a fiberglass filter pad, and then the DCM was removed under vacuum. The excess triethyl phosphite and volatile components were removed using a Kugelrohr (110 °C at 0.4 mmHg), and the residue was subjected to column chromatography on silica gel (6 cm × 14 cm) using 2.5–10 % (v/v) methanol in DCM as an eluent. Fractions containing the required compound had a tendency to turn pink upon exposure to air. Evaporation of the fractions afforded **9** as a pink oil that was stored under argon (8.0 g, 86 %): $R_f = 0.68$ (SiO_2, DCM/methanol, 9:1); ESI-MS obsd (+) 438.2 $(M + H)^+$, calcd 437.23 ($M = C_{23}H_{36}NO_5P$).

1-Ethyl-2,3,3-trimethyl-5-phosphono-3*H*-indolium (1). To a 250 mL flask were added **8** (4.8 g, 14.8 mmol) and 6 M hydrochloric acid (60 mL). The mixture was stirred at room temperature until the oil dissolved and then was heated at reflux overnight. After cooling, the mixture was filtered and was evaporated to dryness under vacuum. The residue was treated with water (100 mL) and, after the mixture was stirred for 30 min, was filtered. The aqueous solution was washed with DCM (2 × 60 mL), filtered, and concentrated under vacuum to approximately 4–6 mL. The solution was loaded onto a column of RP silica gel (7 cm × 15 cm) in water, and then the column was eluted with water. Pure fractions (by RP HPLC) were evaporated under vacuum to afford **1** as an off-white solid that was dried over phosphorous pentoxide and stored under argon (3.67 g, 80%): $R_f = 0.50$ (C18-SiO_2, water/methanol, 3:1); ^{1}H NMR (D_2O) δ 1.54 (t, $J = 7.4$ Hz, 3H), 1.60 (s, 6H), 4.52 (quartet, $J = 7.4$ Hz, 2H), 7.86–7.90 (m, 1H), 7.94–8.01 (m, 1H), and 8.03–8.08 (m, 1H). ^{13}C NMR δ 15.1, 15.9, 24.4, 46.5, 57.6, 118.1 (d, $J = 15$ Hz), 128.2 (d, $J = 12$ Hz), 134.4 (d, $J = 11$ Hz), 138.5 (d, $J = 178$ Hz), 144.9 (d, $J = 15$ Hz), 145.6 (d, $J = 3$ Hz), 200.6; ESI-MS obsd (+) 268.2 $(M + H)^+$, 534.7 $(2M + H)^+$, (–) 532.9 $(2M - H)^-$, 799.5 $(3M - H)^-$ 266.1 $(M - H)^-$, calcd 267.10 ($M = C_{13}H_{18}NO_3P$).

1-(5-Carboxypentyl)-2,3,3-trimethyl-5-phosphono-3*H*-indolium (2). Procedure is as for **1** using **9** (8.0 g, 18.3 mmol) and 6 M hydrochloric acid (280 mL) to afford **2** (5.3 g, 76%): $R_f = 0.54$ (C18-SiO_2, water/methanol, 3:1); ^{1}H NMR (D_2O) δ 1.42–1.51 (m, 2H), 1.58–1.72 (m, 8H), 2.04 (quintet, $J = 7.8$ Hz, 2H), 2.38 (t, $J = 7.2$ Hz, 2H), 4.52 (t, $J = 7.4$ Hz, 2H), 7.83–7.87 (m, 2H), 7.93–7.98 (m, 1H), and 8.02–8.06 (m, 1H); ^{13}C NMR δ 15.9, 24.6, 26.7, 28.2, 29.8, 36.4, 50.9, 57.6, 118.1 (d, $J = 15$ Hz), 128.1 (d, $J = 11$Hz), 134.2 (d, $J = 12$ Hz), 140.3 (d, $J = 176$ Hz), 144.7 (d, $J = 15$ Hz), 145.4 (d, $J = 4$ Hz), 181.6, 200.7; ESI-MS obsd (+) 354.3 $(M + H)^+$, 706.9 $(2M + H)^+$, (–) 705.0 $(2M - H)^-$, 352.2 $(M - H)^-$, calcd 353.14 ($M = C_{17}H_{24}NO_5P$).

1-Ethyl-5-formylaminomethyl-2,3,3-trimethyl-3*H*-indolium iodide (13). 4-Aminomethylindole (*18*) (21.4 g, 0.114 mol) was dissolved in methyl formate (60 mL), and the mixture was heated at reflux for 2 days. The volatile components were evaporated under vacuum to leave the formamide as a pale-yellow oil. The bulk of the material was used without further purification. A sample of the oil was distilled on a Kugelrohr to afford the formamide as a colorless oil: bp 182 °C at 0.15 mmHg: $R_f = 0.28$ (SiO_2, DCM/methanol, 19:1); IR (film, ν_{max} cm^{-1}) 1668, 3256; ^{1}H (DMSO-d_6) 1.20 (s, 6H), 2.18 (s, 3H), 4.37 and 4.42 (2 × d, $J = 6$ Hz, 2H), 6.81 and 6.48 (2 × s, 1H), 7.11–7.16 (m, 2H), 7.32–7.40 (m, 1H), and 8.18 (s, 1H); ^{13}C NMR δ 15.4, 23.1, 42.1, 53.7, 119.8, 121.1, 127.3, 134.7, 146.4, 153.1, 161.3, 188.7; ESI-MS obsd (+) 217.1 $(M + H)^+$, calcd 216.13 ($M = C_{13}H_{16}N_2O$). The amide (10.8 g, 50 mmol) was dissolved in acetonitrile (25 mL), and ethyl iodide (25 mL) was added. The mixture was heated at reflux for 40 h, and then the volatile components were removed under vacuum. The residue was dissolved in methanol (20 mL), and this solution was added dropwise to stirred ether (700 mL). After the mixture was stirred for 1.5 h, the solid was filtered off and was washed with ether to afford **13** as a pale-pink solid (17.8 g, 96%): $R_f = 0.25$ (SiO_2, DCM/methanol, 9:1); ^{1}H (DMSO-d_6) δ 1.43 (t, $J = 7.3$ Hz, 3H), 1.52 (s, 6H), 2.84 (s, 3H), 4.42 (d, $J = 6.1$ Hz, 2H), 4.48 (quartet, $J = 7.0$ Hz, 2H), 7.48–7.51 (m, 1H), 7.72 (d, $J = 1.1$ Hz, 1H), 7.94 (d, $J = 8.4$ Hz, 1H), 8.17 (m, 1H), and 8.62 (t, $J = 5.3$ Hz, 1H); ^{13}C NMR δ 12.9, 14.1 22.3, 40.3, 43.7, 54.2, 115.8, 122.5, 127.9, 139.8, 141.1, 142.4, 161.4, 195.8; ESI-MS obsd (+) 245.2 $(M - I)^+$, calcd 372.07 ($M = C_{15}H_{21}N_2OI$). Anal. Calcd for $C_{15}H_{21}N_2OI$: C, 48.4; H, 5.69; N, 7.53. Found: C, 48.35; H, 5.39; N, 7.29.

Dye 14. To a 100 mL flask were added **2** (0.37 g, 1.04 mmol), diphenylformamidine (0.10 g, 0.5 mmol), sodium acetate (0.13 g, 1.6 mmol), and acetic anhydride (5 mL). The mixture was heated at 110 °C for 4.5 h and then was cooled to room temperature. The volatile components were removed under vacuum to leave a tar that was dissolved in concentrated hydrochloric acid (20 mL). The solution was stirred for 3 h and then was diluted by addition to water (500 mL). The mixture was loaded onto a column of RP silica gel (3 cm × 12 cm) in water. The column was washed with water (approximately 1 L) to load all of the compound onto the column and to remove the excess acid. Gradient elution from 0% to 40% (v/v) methanol in water (the methanol was increased in steps of 5%, and volumes from 300 mL to 1 L of eluent were used for each step) eluted the dye. Fractions were evaporated under vacuum to leave a red residue that was treated with the minimum 20% (v/v) water in methanol to dissolve the dye. The solution was filtered through a medium frit and then was evaporated under vacuum. The residue was dried under vacuum to afford **14** (0.080 g, 22%): $R_f = 0.56$ (C18-SiO_2, water/methanol, 3:1), 0.22 (C18-SiO_2, RPA/methanol, 3:1); ^{1}H NMR (D_2O + 2% (v/v) of 30% NaOD) δ 1.42–1.50 (m, 4H), 1.64 (quintet, $J = 7.5$ Hz, 4H), 1.78 (s, 12H), 1.88 (quintet, $J = 7.5$ Hz, 4H), 2.20 (t, $J = 7.4$ Hz, 4H), 4.12 (t, $J = 7.3$ Hz, 4H), 6.33 (d, $J = 13.7$ Hz, 2H), 7.30 (dd, $J = 1.6$ and 8.3 Hz, 2H), 7.72–7.78 (m, 2H), 7.81 (d, $J = 11$ Hz, 2H) and 8.56 (t, $J = 13.6$ Hz, 2H); ^{13}C NMR δ 28.6, 29.0, 29.5, 30.1, 40.3, 46.9, 42.1, 105.1, 113.2 (d, $J = 14$ Hz), 127.0 (d, $J = 9$ Hz), 133.5 (d, $J = 10$ Hz), 140.8 (d, $J = 168$ Hz), 143.3 (d, $J = 13$ Hz), 145.3 (d, $J = 3$ Hz), 153.7, 178.0, 186.6; ESI-MS obsd (+) 717.3 $(M + H)^+$, (–) 715.1 $(M - H)^-$, calcd 716.26 ($M = C_{35}H_{46}N_2O_{10}P_2$). Anal. Calcd for $C_{35}H_{46}N_2O_{10}P_2 \cdot H_2O$: C, 57.22; H, 6.59; N, 3.81; P, 8.43. Found: C, 57.18; H, 6.38; N, 4.08; P, 7.90.

Dye 15. To a 100 mL flask were added **2** (0.37 g, 1.04 mmol), pyridine (25 mL), and triethyl orthoformate (0.28 mL). The mixture was heated at 110 °C for 1.5 h. Triethyl orthoformate (0.25 mL) was added, and heating was continued for 2.5 h. After the mixture was cooled to room temperature, the volatile components were removed under vacuum to leave a tar. The tar was worked up as described for compound **14** (concentrated hydrochloric acid (20 mL), RP column chromatography (3 cm × 12 cm), 0–40% (v/v) methanol in water) to afford **15** as a red solid (0.195 g, 24 %): $R_f = 0.56$ (C18-SiO_2, water/methanol,

3:1), 0.55 (C18-SiO_2, RPA/methanol, 3:1); ^{1}H NMR (D_2O + 2% (v/v) of 30% NaOD) δ 1.21 (t, J = 7.2 Hz, 6H), 1.41–1.49 (m, 4H), 1.64 (quintet, J = 7.4 Hz, 4H), 1.75 (s, 12H), 1.86 (quintet, J = 7.3 Hz, 4H), 2.20 (t, J = 7.5 Hz, 4H), 3.85 (quintet, J = 7.2 Hz, 4H), 4.11 (t, J = 7.2 Hz, 4H), 6.38 (d, J = 13.4 Hz, 2H), 7.40 (dd, J = 1.3 and 8.1 Hz, 2H), 7.74–7.82 (m, 4H) and 8.55 (t, J = 13.4 Hz, 1H); ^{13}C NMR δ 18.6, 28.5, 28.9, 29.5, 30.0, 40.2, 47.0, 52.0, 64.0, 105.9, 114.0 (d, J = 15 Hz), 127.5 (d, J = 11 Hz), 132.6 (d, J = 181 Hz), 134.7 (d, J = 12 Hz), 143.9 (d, J = 15 Hz), 147.0 (d, J = 3 Hz), 154.4, 178.3, 186.4; ESI-MS obsd (+) 773.4 $(M + H)^+$, (–) 771.3 $(M - H)^-$, calcd 772.33 ($M = C_{39}H_{54}N_2O_{10}P_2$).

Dye 16. To a 50 mL flask were added **1** (0.31 g, 1.16 mmol), diphenylformamidine (0.30 g, 1.53 mmol), acetic acid (2 mL), and acetic anhydride (2 mL). The mixture was heated at 120 °C for 1.5 h and then was cooled to room temperature. The volatile components were removed under vacuum to leave a tar that was washed with ether (2 × 30 mL). The residue was dissolved in acetic acid (2 mL), and then pyridine (4 mL) and **10** (0.40 g, 1.14 mmol) were added. The mixture was heated at 120 °C for 0.75 h and then was cooled to room temperature. The volatile components were removed under vacuum, and the residue was dissolved in concentrated hydrochloric acid (30 mL). After being stirred for 3 h, the mixture was diluted by addition to water (200 mL) and then was basified, first by addition of 4 M sodium hydroxide solution until the pH was approximately 4 and then with saturated sodium bicarbonate solution. Initially dye was precipitated from the mixture, but then it redissolved. The aqueous solution was filtered and was loaded onto a column of RP silica gel (4 cm × 15 cm) in water. The column was washed with water (200 mL), 1 M hydrochloric acid (100 mL), and water until the pH of the effluent was neutral. Gradient elution from 0% to 50% (v/v) methanol in water (the methanol was increased in steps of 5% and volumes from 300 mL to 1 L of eluent were used for each step) eluted the symmetrical diphosphonate dye first and then the unsymmetrical dye. The fractions were evaporated under vacuum to leave a red residue that was taken up in methanol. The solution was filtered through a medium frit, and the methanol was removed under vacuum. The residue was washed with acetonitrile and was dried under vacuum to give dye **16** as a red solid (0.32 g, 51%): R_f = 0.26 (C18-SiO_2, water/methanol, 3:1), 0.17 (C18-SiO_2, RPA/methanol, 3:1); ^{1}H NMR (CD_3OD) δ 1.42 (t, J = 7.3 Hz, 3H), 1.51–1.58 (m, 2H), 1.71 (quintet, J = 7.3 Hz, 2H), 1.78 (s, 14H), 1.88 (quintet, J = 7.4 Hz, 2H), 2.33 (t, J = 7.4 Hz, 2H), 4.18–4.24 (m, 4H), 6.48–6.56 (m, 2H), 7.32–7.50 (m, 4H), 7.58 (d, J = 7.0 Hz, 1H), 7.86–7.93 (m, 2H), and 8.57 (t, J = 13.4 Hz, 1H). ^{13}C NMR δ 12.5, 25.7, 27.3, 28.2, 28.3, 34.6, 40.3, 45.3, 50.4, 50.9, 103.5, 104.6, 111.5 (d, J = 16 Hz), 112.8, 123.6, 125.9 (d, J = 12 Hz), 127.2, 130.1, 132.8 (d, J = 194 Hz), 133.2 (d, J = 11 Hz), 141.8 (d, J = 16 Hz), 142.4, 143.2, 145.0 (d, J = 3 Hz), 152.5, 175.4, 176.8, 177.2; ESI-MS obsd (+) 551.4 $(M + H)^+$, (–) 549.3 $(M - H)^-$, calcd 550.26 ($M = C_{31}H_{39}N_2O_5P$). Anal. Calcd for $C_{31}H_{39}N_2O_5P$: C, 67.62; H, 7.14; N, 5.09; P, 5.63. Found: C, 67.25; H, 6.87; N, 5.01; P, 5.6.

Dye 17. To a 100 mL flask were added **1** (0.29 g, 1.08 mmol), diphenylformamidine (0.40 g, 2.0 mmol), acetic acid (5 mL), and acetic anhydride (5 mL). The mixture was heated at 125 °C for 3 h and then was cooled to room temperature. The volatile components were removed under vacuum to leave a tar that was washed with ether (2 × 30 mL) and ethyl acetate (2 × 50 mL). The residue was dissolved in acetic acid (5 mL), and then pyridine (8 mL) and **11** (0.370 g, 1.0 mmol) were added. The mixture was heated at 125 °C for 3 h. The volatile components were removed under vacuum to leave a tar. The tar was worked up as described for compound **16** (concentrated hydrochloric acid (30 mL), RP column chromatography (3 cm × 15 cm), 0–55% (v/v) methanol in water) to afford **17** as a red solid (0.072 g, 14%): R_f = 0.19 (C18-SiO_2, water/methanol, 3:1), 0.24 (C18-SiO_2, RPA/methanol, 3:1); ^{1}H NMR (CD_3OD) δ 1.40–1.46 (m, 6H), 1.78 (s, 6H), 1.79 (s, 6H), 3.73 (s, 2H), 4.18–4.30 (m, 4H), 6.48 (d, J = 13.2 Hz, 1H), 6.58 (d, J = 13.6 Hz, 1H), 7.38–7.44 (m, 3H), 7.53 (s, 1H), 7.85–7.91 (m, 2H), and 8.57 (t, J = 13.4 Hz, 1H); ^{13}C NMR δ 12.5, 12.8, 28.1, 28.3, 40.2, 40.8, 41.5, 50.2, 51.1, 103.3, 104.9, 111.6 (d, J = 15 Hz), 112.7, 124.9, 125.9 (d, J = 12 Hz), 129.2 (d, J = 190 Hz), 131.3, 133.4 (d, J = 11 Hz), 134.8, 141.7, 142.0 (d, J = 15 Hz), 142.9, 145.9 (d, J = 3 Hz), 152.5, 174.9, 175.1, 176.9; ESI-MS obsd (+) 523.3 $(M + H)^+$, 545.3 $(M + Na)^+$, calcd 522.3 ($M = C_{29}H_{35}N_2O_5P$).

Dye 18. To a 250 mL flask were added **12** (0.60 g, 2.04 mmol), diphenylformamidine (0.50 g, 2.6 mmol), acetic acid (21 mL), and acetic anhydride (15 mL). The mixture was heated at 115 °C for 3 h and then was cooled to room temperature. The volatile components were removed under vacuum, and the residue was washed with ethyl acetate (3 × 100 mL) to give a powder. To the powder were added **2** (0.70 g, 2.0 mmol) and acetic acid (25 mL). The mixture was warmed until the solids dissolved, and then pyridine (35 mL) was added. The mixture was heated to 115 °C for 0.5 h and then acetic anhydride (15 mL) was added. The mixture was heated for a further 2 h during which time the mixture became deep-red. The mixture was cooled to room temperature, and then the volatile components were removed under vacuum. The residue was treated with saturated aqueous sodium bicarbonate solution (250 mL) to dissolve the dye. The solution was filtered and was loaded onto a column of RP silica gel (4 cm × 20 cm) in water. The column was washed with water (approximately 200 mL) and 0.5 M hydrochloric acid (approximately 500 mL), RPA buffer (500 mL) and then was eluted with a gradient from 0 to 30% (v/v) methanol in RPA buffer (the methanol was increased in steps of 5%, and volumes from 500 mL to 1 L of eluent were used for each step). The fractions were evaporated under vacuum to leave a red residue that was dissolved in 1 M hydrochloric acid (approximately 100 mL). The solution was loaded onto a column of RP silica gel (3 cm × 10 cm) in water. The column was washed with 1.0 M hydrochloric acid (200 mL) and then with water until the pH of the effluent was neutral. The column was eluted with a sharp gradient from 0 to 50% (v/v) methanol in water. The dye-containing fractions were evaporated under vacuum to afford **18** as a red solid (0.45 g, 34%): R_f = 0.62 (C18-SiO_2, water/methanol, 3:1), 0.55 (C18-SiO_2, RPA/methanol, 3:1); ^{1}H NMR (D_2O) δ 1.38–1.47 (m, 2H), 1.59–1.72 (m, 14H), 1.78–1.94 (m, 6H), 2.20 (t, J = 7.4 Hz, 2H), 2.95 (t, J = 7.5 Hz, 2H), 4.03–4.09 (m, 4H), 6.27–6.32 (m, 2H), 7.24–7.38 (m, 4H), 7.50 (d, J = 7.0 Hz, 1H), 7.75–7.80 (m, 2H), and 8.43 (t, J = 13.5 Hz, 1H); ^{13}C NMR δ 24.4, 28.4, 28.9, 29.4, 29.9, 30.0, 40.1, 40.2, 46.3, 46.9, 51.8, 52.0, 53.2, 105.3, 113.6 (d, J = 15 Hz), 114.0, 125.1, 126.9 (d, J = 11 Hz), 128.3, 131.5, 133.8 (d, J = 11 Hz), 136.3 (d, J = 175 Hz), 143.4 (d, J = 14 Hz), 143.7, 144.5, 146.2, 153.8, 177.7, 177.8, 186.2; ESI-MS obsd (+) 681.3 $(M + Na)^+$, (–) 657.2 $(M - H)^-$, calcd 658.25 ($M = C_{33}H_{43}N_2O_8PS$). Anal. Calcd for $C_{33}H_{43}N_2O_8PS \cdot H_2O$: C, 58.57; H, 6.70; N, 4.14; P, 4.58. Found: C, 58.78; H, 6.83; N, 4.41; P, 4.80.

Dye 18 Disodium Salt. Dye **18** (0.40 g) was dissolved in a mixture of deionized (DI) water (200 mL) and methanol (50 mL). The solution was passed through a column (2.5 cm × 10 cm) of Dowex 50-8X anion exchange resin, sodium form. After the remaining dye was washed off the column with DI water, the solution was concentrated to approximately 20 mL, filtered through a medium frit, and then evaporated under vacuum to afford the disodium salt of **18** as a red solid (0.41 g, 97%). Anal. Calcd for $C_{33}H_{41}N_2O_8PSNa_2 \cdot H_2O$: C, 54.99; H, 6.01; N,

3.89; P, 4.30; Na, 6.38. Found: C, 54.15; H, 6.03; N, 4.03; P, 3.90; Na, 6.30.

Dye 19. To a 100 mL flask were added **2** (0.41 g, 1.15 mmol), malonaldehyde dianilide hydrochloride (0.142.g, 0.55 mmol), acetic anhydride (5 mL), and sodium acetate (0.13 g). The mixture was heated at 110 °C for 4.5 h and then was cooled to room temperature. The volatile components were removed under vacuum to leave a tar. The tar was worked up as described for compound **14** (concentrated hydrochloric acid (30 mL), RP column chromatography (4 cm × 15 cm), 0–40% (v/v) methanol in water) to afford **19** as a blue solid (0.23 g, 51%): $R_f = 0.$ 36 (C18-SiO_2, water/methanol, 3:1), 0.17 (C18-SiO_2, RPA/methanol, 3:1); ^{1}H NMR (D_2O + 2% (v/v) of 30% NaOD) δ 1.41–1.47 (m, 4H), 1.59–1.66 (m, 16H), 1.83 (quintet, $J = 7.3$ Hz, 4H), 2.20 (t, $J = 7.5$ Hz, 4H), 4.07 (t, $J = 7.4$ Hz, 4H), 6.28 (d, $J = 13.6$ Hz, 2H), 6.57 (t, $J = 12.5$ Hz, 1H), 7.26 (dd, $J = 1.9$ and 8.3 Hz, 2H), 7.64–7.67 (m, 2H), 7.75 (d, $J = 11.5$ Hz, 2H), and 7.99 (t, $J = 13.1$ Hz, 2H); ^{13}C NMR δ 28.6, 29.0, 29.5, 29.7, 40.2, 46.7, 51.8, 106.3, 113.2 (d, $J = 15$ Hz), 126.9 (d, $J = 11$ Hz), 127.6, 133.5 (d, $J = 11$ Hz), 136.9 (d, $J = 175$ Hz), 143.8 (d, $J = 15$ Hz), 146.2 (d, $J = 3$ Hz), 156.3, 176.3, 186.5; ESI-MS obsd (+) 743.3 $(M + H)^+$, (–) 741.3 $(M - H)^-$, calcd 742.28 ($M = C_{37}H_{48}N_2O_{10}P_2$). Anal. Calcd for $C_{37}H_{48}N_2O_{10}P_2 \cdot (H_2O)_2$: C, 57.06; H, 6.73; N, 3.60; P, 7.95. Found: C, 56.70; H, 6.62; N, 3.67; P, 7.4.

Dye 20. To a 50 mL flask were added **1** (0.36 g, 1.34 mmol), malonaldehyde dianilide hydrochloride (0.36 g, 1.40 mmol), acetic acid (4 mL), and acetic anhydride (4 mL). The mixture was heated at 110 °C for 1.5 h and then was cooled to room temperature. The volatile components were removed under vacuum to leave a tar. The tar was dissolved in acetic acid (4 mL), and then pyridine (5 mL) and compound **2** (0.46 g, 1.30 mmol) were added. The mixture was heated at 110 °C for 3 h and then was cooled to room temperature. The volatile components were removed under vacuum to leave a dark-blue tar. The tar was worked up as described for **14** (concentrated hydrochloric acid (30 mL), RP column chromatography (4 cm × 15 cm), 0–45% (v/v) methanol in water) to afford **20** as a blue solid (0.205 g, 24%): $R_f = 0.46$ (C18-SiO_2, water/methanol, 3:1), 0.31 (C18-SiO_2, RPA/methanol, 3:1); ^{1}H NMR (CD_3OD) δ 1.43 (t, $J = 7.2$ Hz, 3H), 1.51–1.57 (m, 2H), 1.69–1.89 (m, 16H), 2.35 (t, $J = 7.1$ Hz, 2H), 4.14–4.23 (m, 4H), 6.27–6.37 (m, 2H), 6.68 (t, $J = 12.4$ Hz, 1H), 7.31–7.34 (m, 2H), 7.87–7.95 (m, 4H) and 8.24–8.36 (m, 2H); ESI-MS obsd (+) 657.3 $(M + H)^+$, (–) 655.3 $(M - H)^-$, calcd 656.24 ($M = C_{33}H_{42}N_2O_8P_2$).

Dye 21. To a 100 mL flask were added **1** (1.87 g, 7.0 mmol), malonaldehyde dianilide hydrochloride (2.0 g, 7.73 mmol), acetic acid (20 mL), and acetic anhydride (20 mL). The mixture was heated at 110 °C for 2.5 h and then was cooled to room temperature. The volatile components were removed under vacuum to leave a tar that was washed with ether (2 × 60 mL). The tar was dissolved in acetic acid (30 mL), and then pyridine (40 mL) and **10** (2.5 g, 7.1 mmol) were added. The mixture was heated at 110 °C for 1 h and then was cooled to room temperature. The volatile components were removed under vacuum to leave a tar. The tar was worked up as described for compound **16** (concentrated hydrochloric acid (70 mL), RP column chromatography (4 cm × 20 cm), 0–50% (v/v) methanol in water) to afford a **21** as a blue solid (1.54 g, 38%): $R_f =$ 0.09 (C18-SiO_2, water/methanol, 3:1), 0.10 (C18-SiO_2, RPA/methanol, 3:1); ^{1}H NMR (CD_3OD) δ 1.37 (t, $J = 7.4$ Hz, 3H), 1.46–1.55 (m, 2H), 1.64–1.75 (m, 14H), 1.84 (quintet, $J = 7.4$ Hz, 2H), 2.32 (t, $J = 7.3$ Hz, 2H), 4.11–4.17 (m, 4H), 6.26–6.34 (m, 2H), 6.64 (t, $J = 12.4$ Hz, 1H), 7.25–7.33 (m, 3H), 7.39–7.44 (m, 1H), 7.50 (d, $J = 7.2$, 1H), 7.84–7.90 (m, 2H), and 8.22–8.31 (m, 2H); ^{13}C NMR δ 12.5, 25.7, 27.4, 27.9, 28.2, 34.7, 39.9, 44.9, 50.4, 50.7, 104.0, 104.8, 110.8 (d, $J = 15$ Hz), 112.2, 123.5, 125.9 (d, $J = 10$ Hz), 126.5, 126.8, 129.8, 132.8 (d, $J = 9$ Hz), 135.7 (d, $J = 181$ Hz), 141.9 (d, $J = 15$ Hz), 142.8, 143.5, 144.2 (d, $J = 3$ Hz), 155.5, 155.8, 174.2, 175.2, 177.4; ESI-MS obsd (+) 577.4 $(M + H)^+$, (–) 575.4 $(M - H)^-$, calcd 576.28 ($M = C_{33}H_{41}N_2O_5P$). Dye 23 Disodium Salt. Dye **23** (0.50 g, 0.73 mmol) was dissolved in a mixture of DI water (200 mL) and methanol (50 mL). The solution was passed through a column (2.5 cm × 10 cm) of Dowex 50-8X anion exchange resin, sodium form. After the remaining dye was washed off the column with DI water, the aqueous solution was concentrated to approximately 20 mL. The solution was filtered through a medium frit and was evaporated under vacuum to afford the sodium salt of dye **23** as a blue solid (0.49 g, 92%). Anal. Calcd for $C_{35}H_{43}N_2O_8PSNa_2 \cdot (H_2O)_2$: C, 54.97; H, 6.19; N, 3.66; P, 4.05; Na, 6.01. Found: C, 54.66; H, 5.97; N, 3.66; P, 3.90; Na, 6.30.

Dye 24. To a 100 mL flask were added **1** (0.50 g, 1.87 mmol), malonaldehyde dianilide hydrochloride (0.50 g, 1.93mmol), acetic acid (6 mL), and acetic anhydride (6 mL). The mixture was heated at 110 °C for 2.5 h and then was cooled to room temperature. The volatile components were removed under vacuum to leave a tar that was washed with ether (2 × 40 mL). The tar was dissolved in acetic acid (4 mL), and then pyridine (5 mL) and **13** (0.75 g, 2.0 mmol) were added. The mixture was heated at 110 °C for 1 h and then was cooled to room temperature. The volatile components were removed under vacuum to leave a dark-blue tar. The tar was worked up as described for compound **16** (concentrated hydrochloric acid (30 mL), RP column chromatography (4 cm × 15 cm), 0–55% (v/v) methanol in water) to afford **24** as a blue solid (0.47 g, 46%): R_f = 0.26 (C18-SiO_2, water/methanol, 1:1), 0.18 (C18-SiO_2, RPA/methanol, 3:1); ^{1}H NMR (CD_3OD) δ 1.36–1.40 (m, 6H), 1.73 (s, 12H), 4.12–4.18 (m, 4H), 4.47 (s, 2H), 6.27–6.32 (m, 2H), 6.62 (t, J = 12.4 Hz, 1H), 7.25–7.29 (m, 2H), 7.36–7.39 (m, 1H), 7.46 (d, J = 1.2 Hz, 1H), 7.83–7.90 (m, 2H), 7.18 (s, 1H) and 8.22–8.30 (m, 2H); ^{13}C NMR δ 12.5, 12.6, 27.7, 27.9, 39.9, 40.2, 42.6, 50.4, 50.7, 104.0, 104.4, 110.8 (d, J = 14 Hz), 111.9, 123.0, 125.9 (d, J = 10 Hz), 126.8, 129.3, 132.8 (d, J = 12 Hz), 135.7 (d, J = 192 Hz), 137.2, 141.9 (d, J = 15 Hz), 142.4, 143.3, 144.2 (d, J = 3 Hz), 155.5, 155.9, 163.8, 174.2, 174.7; ESI-MS obsd (+) 548.4 $(M + H)^+$, (–) 546.4 $(M - H)^-$, calcd 547.26 ($M = C_{31}H_{38}N_3O_4P$).

Dye 25. To a 500 mL flask were added dye **24** (0.39 g, 0.713 mmol), methanol (100 mL), and concentrated HCl (10 mL). The mixture was stirred at room temperature for 40 h. The mixture was diluted with water (200 mL) and then was basified by addition of saturated sodium bicarbonate solution. The aqueous solution was filtered and was loaded onto a column of RP silica gel (3 cm × 10 cm) in water. The column was washed with water to remove the salts and excess base, 1.0 M HCl (50 mL) and finally with water (500 mL) to remove the excess acid. Gradient elution from 0% to 80 % (v/v) methanol in water (the methanol was increased in steps of 10% and volumes from 500 mL to 1 L of eluent were used for each step) first eluted residual starting material and then **25**. The fractions were evaporated under vacuum to leave a blue residue that was taken up in methanol (10 mL). The solution was filtered through a medium frit, and the methanol was removed under vacuum to afford **25** as a blue solid (0.266 g, 72%): R_f = 0.12 (C18-SiO_2, water/methanol, 1:1), 0.12 (C18-SiO_2, RPA/methanol, 3:1); ^{1}H NMR (CD_3OD) δ 1.23–1.33 (m, 6H), 1.63 (s, 12H), 4.00–4.12 (m, 6H), 6.20 (d, J = 13.8 Hz, 1H), 6.28 (d, J = 13.8 Hz, 1H), 6.56 (t, J = 12.3 Hz, 1H), 7.19–7.25 (m, 2H), 7.41–7.43 (m, 1H), 7.53 (s, 1H), 7.72–7.84 (m, 2H), and 8.12–8.22 (m, 2H); ^{13}C NMR δ 12.5, 12.6, 27.8, 27.9, 40.0, 40.2, 42.3, 50.4, 50.7, 104.0, 104.9, 111.2 (d, J = 14 Hz), 111.9, 124.4, 126.0 (d, J = 11 Hz), 127.1, 130.8, 132.3, 132.8 (d, J = 10 Hz), 136.7 (d, J = 177 Hz), 142.1 (d, J = 15 Hz), 143.4, 143.7, 144.0 (d, J = 3 Hz), 155.5, 156.2, 173.9, 175.3; ESI-MS obsd (+) 520.3 $(M + H)^+$, 542.3 $(M + Na)^+$, calcd 519.27 ($M = C_{30}H_{38}N_3O_3P$).

Dye 26. To a 100 mL flask were added **2** (0.41 g, 1.15 mmol), squaric acid (0.063 g, 0.54 mmol), *n*-butanol (50 mL), and toluene (30 mL). The flask was fitted with a Dean–Stark trap, and then the mixture was heated at reflux overnight. After the mixture was cooled to room temperature, the solid was filtered off, washed with DCM (3 × 30 mL), and dried. The solid was dissolved in 0.2 M potassium carbonate solution (150 mL), and the solution was stirred for 6 days. Hydrochloric acid (1.0 M) was added to lower the pH to approximately 1–2. A suspension formed that was stirred for a further 1 h. The solid was filtered off and was washed with water (2 × 3 mL). The solid was dried under vacuum to afford dye **26** as a blue solid (0.32 g, 72%): R_f = 0.11 (C18-SiO_2, water/methanol, 3:1), 0.16 (C18-SiO_2, RPA/methanol, 3:1); ^{1}H NMR (DMSO-d_6) δ 1.35–1.42 (4H, m), 1.56 (quintet, J = 7.3 Hz, 4H), 1.65–1.75 (m, 16H), 2.21 (t, J = 7.2 Hz, 4H), 4.07–4.14 (m, 4H), 5.85 (s, 2H), 7.39–7.42 (m, 2H), 7.63–7.69 (m, 2H), 7.73 (d, J = 11.8 Hz, 2H); ^{13}C NMR δ 24.4, 26.0, 26.5, 26.7, 33.7, 43.2, 48.8, 87.1, 110.2 (d, J = 16 Hz), 124.4 (d, J = 12 Hz), 129.1 (d, J = 184 Hz), 131.3 (d, J = 11 Hz), 141.2 (d, J = 16 Hz), 144.5 (d, J = 3 Hz), 169.5, 174.5, 179.9, 180.8; ESI-MS obsd (–) 783.2 $(M - H)^-$, 805.3 $(M + Na - 2H)^-$, calcd 784.26 ($M = C_{38}H_{46}N_2O_{12}P_2$). Anal. Calcd for $C_{38}H_{46}N_2O_{12}P_2$: C, 58.16; H, 5.91; N, 3.27; P,7.89. Found: C, 57.84; H, 6.13; N, 3.60; P, 7.70.

Dye 14-(NHS Ester)$_2$. To a 25 mL flask were added **14** (44.8 mg, 0.059 mmol), water (0.3 mL), DMF (3 mL), and diisopropylethylamine (DIEA) (0.2 mL). The mixture was stirred until the solid dissolved, and then succinimidotetramethyluronium tetrafluoroborate (TSTU) (35.8 mg, 0.119 mmol) was added. Stirring was continued for 1 h, and then the volatile components were removed under high vacuum without heating. The residue was washed with ethyl acetate (2 × 20 mL), THF (2 × 20 mL), and acetonitrile (2 × 20 mL). The residue was dried under high vacuum overnight with phosphorus pentoxide to afford **14**-(NHS ester)$_2$ as a dark-red solid (48.1 mg). Dye content by RP HPLC was 71% **14**-(NHS ester)$_2$, 24% **14**-NHS ester, and 5% **14**. ESI-MS obsd (–) 909.2 $(M - H)^-$, calcd 910.3 ($M = C_{43}H_{52}N_4O_{14}P_2$).

Dye 16-NHS Ester. To a 25 mL flask were added **16** (89.5 mg, 0.161 mmol), water (0.7 mL), and DMF (1.4 mL). The mixture was stirred until the solid dissolved, and then DIEA (0.24 mL) and DMF (4.8 mL) were added. After the mixture was stirred for 10 min, TSTU (50.3 mg, 0.167 mmol) was added. Stirring was continued for 1 h, and then the volatile components were removed under high vacuum without heating. The residue was dissolved in DCM, and the solution was filtered through a medium frit. The DCM was evaporated under vacuum without heating, and the residue was dried under high vacuum overnight with phosphorus pentoxide to afford **16**-NHS ester as a dark-red solid (147 mg). Dye content by RP HPLC was 96% **16**-NHS ester and 4% **16**. ESI-MS obsd (–) 646.2 $(M - H)^-$, calcd 647.3 ($M = C_{35}H_{42}N_3O_7P$).

Dye 18-NHS Ester. To a 50 mL flask were added **18** (102.5 mg, 0.150 mmol), water (0.8 mL), and DMF (1.8 mL). The mixture was stirred until the solid dissolved, and then DIEA (0.16 mL) and DMF (3.6 mL) were added. After the mixture was stirred for 10 min, TSTU (70 mg, 0.23 mmol) was added. Stirring was continued for 1 h, and then the volatile components were removed under high vacuum without heating. The residue was washed with DCM (3 × 30 mL) to afford a solid. The solid was filtered off, washed with acetonitrile (3 × 20 mL), and dried under high vacuum overnight with phosphorus pentoxide to afford **18**-NHS ester as a dark-red solid (109 mg). Dye content by RP HPLC was 92% **18**-NHS ester and 8% **18**. ESI-MS obsd (–) 754.1 (M – H), calcd 755.3 ($M = C_{37}H_{46}N_3O_{10}PS$).

Dye 20-NHS Ester. To a 25 mL flask were added **20** (42 mg, 0.064 mmol), water (0.3 mL), DMF (3 mL), and DIEA

(0.2 mL). The mixture was stirred until the solid dissolved, and then TSTU (19 mg, 0.119 mmol) was added. Stirring was continued for 1 h, and then the volatile components were removed under high vacuum without heating. The residue was washed with ethyl acetate (2 × 20 mL), THF (2 × 20 mL), and acetonitrile (2 × 20 mL). The residue was dried under high vacuum overnight with phosphorus pentoxide to afford **20**-NHS ester as a dark-blue solid (37.2 mg). Dye content by RP HPLC was 82% **20**-NHS ester and 18% **20**. ESI-MS obsd (–) 752.1 $(M - H)^-$, calcd 753.3 ($M = C_{37}H_{45}N_3O_{10}P_2$).

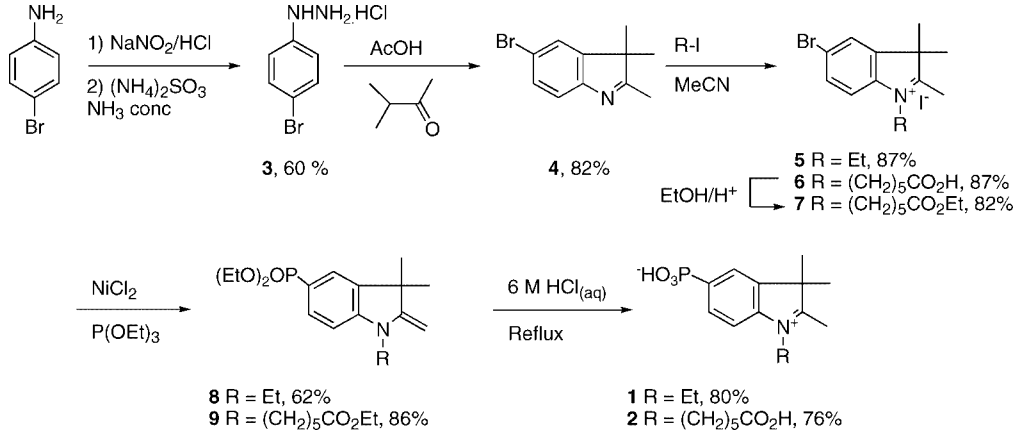
Dye 21-NHS Ester. Procedure as for compound **16**-NHS ester with **21** (93 mg, 0.163 mmol), water (0.7 mL), DMF (1.4 mL), DIEA (0.20 mL), DMF (4.9 mL), and TSTU (50 mg, 0.166 mmol) gave **21**-NHS ester as a blue solid (137 mg). Dye content by RP HPLC was 90% **21**-NHS ester and 10% **21**. ESI-MS obsd (–) 672.2, calcd 673.3 ($M = C_{37}H_{44}N_3O_7P$).

Dye 23-NHS Ester. Procedure as for compound **18**-NHS ester with **23** (95 mg, 0.161 mmol), water (0.7 mL), DMF (1.4 mL), DIEA (0.14 mL), DMF (2.8 mL), and TSTU (60 mg, 0.20 mmol) gave **23**-NHS ester as a dark-blue solid (101 mg). Dye content by RP HPLC was 94% **23**-NHS ester and 6% **23**. ESI-MS obsd (–) 780.1 (M – H), calcd 781.28 ($M = C_{39}H_{48}N_3O_{10}PS$)

Dye 26-(NHS ester)$_2$. To a 50 mL flask were added **26** (49.7 mg, 0.061 mmol), water (0.3 mL), and DMF (3.0 mL). The mixture was stirred until the solid dissolved, and then DIEA (0.3 mL) was added. After the mixture was stirred for 20 min, TSTU (36.7 mg, 0.121 mmol) was added. Stirring was continued for 1 h, and then the mixture was filtered. The volatile components were removed under high vacuum without heating, and the residue was washed with ethyl acetate (3 × 30 mL), THF (30 mL), and acetonitrile (2 × 30 mL). The solid was dried under high vacuum overnight with phosphorus pentoxide to afford **26**-(NHS ester)$_2$ as a dark-blue solid (109 mg). Dye content by RP HPLC was 83% **26**-(NHS ester)$_2$ and 17% **26**-NHS ester. ESI-MS obsd (–) 977.2 (M – H), calcd 978.3 ($M = C_{46}H_{52}N_4O_{16}P_2$).

Protein Labeling with Dye Succinimidyl Esters. A stock solution of the sheep γ globulin (S-IgG) (Sigma-G9887) was prepared at a concentration of 2 mg/mL (approximately 1.33×10^{-5} M) in carbonate–bicarbonate buffer, pH 9.3. One milliliter aliquots of the stock were dispensed into vials. Stock solutions of the active esters of dyes **16**, **18**, **21**, **23**, and **26** were prepared at a concentration of 0.01 M in DMSO. Saturated solutions of the active esters of dyes **14** and **20** were prepared by adding sufficient material to produce a 0.01 M solution to the appropriate volume of DMSO and shaking the mixture for 2 h at room temperature. Aliquots of the active ester stock solutions were added to the protein solutions to provide a range of starting dye to protein ratios from 0.7:1 to 50:1. The solutions were mixed well and left to stand at room temperature overnight. The samples were divided into two or three equal portions and were purified by size exclusion chromatography on Sephadex G50 (0.7 cm × 12 cm) using either carbonate–bicarbonate buffer, pH 9.3, BBS, pH 8.1, or PBS, pH 7.3, as effluent. The labeled proteins, which eluted from the column prior to the hydrolyzed active esters, were stored at 4 °C. Solutions were warmed to room temperature and were filtered before absorption and fluorescence spectra were recorded. Conjugates of Cy3 and of Cy5 were prepared by following the methods supplied with the products.

Extinction Coefficients and Fluorescence Quantum Yields. Stock solutions of dyes were prepared from weighed samples of dried material and then were serially diluted to provide five solutions with absorbance values in the range 0.2–1. Extinction coefficients (ε) were determined from plots of the absorbance values vs concentration according to Beer's law. Measurements were repeated with fresh solutions, and average values were calculated. Solutions used for absorbance measurements were diluted 20× prior to use in fluorescence measurements. Quantum yields (QYs) were determined relative to standards (rhodamine 6G (QY = 0.86 in ethanol (*14*)) for dyes with absorption maxima in the range 540–560 nm; Cy5.18 (QY = 0.27 in PBS pH 7.3 (*4*)) for dyes with absorption maxima in the range 630–680 nm) and are intended to indicate trends rather than absolute values. For dyes used in labeling experiments, QYs are an average of at least three measurements. Variation between measurements used to calculate extinction coefficients and quantum yields fell within 15% of each other. Values for quantum yields were rounded to two decimal places.



Determination of Dye to Protein Ratios and Conjugate Brightness. Dye to protein (*D*/*P*) ratios were determined as outlined in ref *5*. In cases where absorbance spectra recorded in aqueous solution indicated significant dye aggregation, the solutions were diluted (1:2) with formamide and absorbance spectra recorded again. For each conjugate solution the concentration of dye was estimated using the absorbance of the dye at the peak maximum and the extinction coefficient of free dye according to Beer's law. The absorbance of the conjugated dye at 280 nm was calculated using the ratio of the extinction coefficients of the free dye at 280 nm to that at the peak maximum. (For squarane dye **26**, $\varepsilon_{280nm}/\varepsilon_{peak\ max} = 0.041$. For trimethine cyanine dyes **14**, **16**, and **18**, $\varepsilon_{280nm}/\varepsilon_{peak\ max} = 0.083$. For pentamethine cyanine dyes **20**, **21**, and **23**, $\varepsilon_{280nm}/\varepsilon_{peak\ max} = 0.026$.) The concentration of the protein (MW = 155 000, $\varepsilon_{280nm} = 165\,000$ L mol^{-1} cm^{-1}) was determined from the absorbance value of the solution at 280 nm after correction for the absorbance of the conjugated dye at 280 nm. Conjugate brightness is defined as the product of the extinction coefficient, the quantum yield, and the number of dyes per protein molecule ($(\varepsilon)(QY)(D/P)$). Quantum yields of conjugates were determined in wholly aqueous solutions.

Oligonucleotide Labeling with Dye Succinimidyl Esters. A T_{10} DNA oligonucleotide was prepared using standard automated synthesis regimes on a Biosearch 8700 oligonucleotide synthesizer. For Quasar 570 and Quasar 670, amidites of the dyes were coupled to the DNA fragment on the controlled pore size glass (CPG) solid support. For the other dyes, a monomethoxytrityl (MMT) protected amino C6 functionalized amidite (Biosearch Technologies, Inc.) was manually coupled to the DNA fragment and then the protecting group was removed to afford the amino-modified oligonucleotides still attached to CPG. For cyanine monophosphonates **16**, **18**, **21**, and **23**, the CPG (10 mg) was shaken overnight in a DMSO solution (0.30 mL) of the active ester (3 mg) and *N*-methylmorpholine (0.020 mL). For Cy3 and Cy5, the CPG (10 mg), DMSO (0.3 mL), and *N*-methylmorpholine (0.020 mL) were added to the vial of reactive dye supplied by the manufacturer and the mixtures were shaken overnight. The DNA was cleaved from the CPG using concentrated aqueous ammonia at room temperature for 1 h. The solutions were frozen, and the volatile components were removed using a speed vac. The crude oligonucleotides were purified by a combination of AX and RP HPLC to afford the labeled oligonucleotides that were characterized by electrospray MS. RESULTS AND DISCUSSION

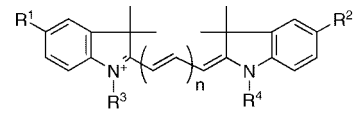
1. Synthesis of Dyes. Key intermediates for the syntheses of the cyanine and squarane dyes are the indolium phosphonates **1** and **2** (Scheme 1). *p*-Bromoaniline was converted into the hydrazine hydrochloride **3**, which was then subjected to Fischer indole condensation with methylbutanone to afford bromoindole

Scheme 1. Synthetic Route To Indolium Phosphonates



4 (*15*). Preliminary investigation of the nickel-catalyzed substitution reaction of the bromine for phosphonate (*16*) demonstrated that bromoindole **4** could be phosphonated in high yield, but partial ethylation of the indole nitrogen also occurred resulting in a mixture of products. It should be noted that this reaction is extremely vigorous once it begins because of the generation of ethyl bromide in the reaction mixture at temperatures of 160–180 °C. Further study indicated that bromoindolium salts **5** and **6** could be phosphonated with this method. To avoid the possibility of partial ethylation of the carboxylic acid of **6** and a mixture of reaction products, **6** was converted to the ethyl ester **7**. The phosphonation reaction of salts **5** and **7** generated the charge neutral compounds **8** and **9**, which proved to be difficult to isolate in analytically pure form. Hydrolysis of **8** and **9** using refluxing in 6 M hydrochloric acid gave indolium phosphonates **1** and **2** and also small quantities of byproducts in which the phosphonic acid residue was removed from the indolium residue. Compounds **8** and **9** turned pink-red upon exposure to air in a matter of hours, whereas **1** and **2** became colored over a few days. All of these compounds can be stored indefinitely in a desiccator under argon.

Indolium salts **10**–**12** were prepared by literature methods (*17*). Formyl protected aminomethyl indolium salt **13** was prepared from the corresponding aminomethylindole (*18*) by sequential treatment with methyl formate and with ethyl iodide.

Symmetrical and unsymmetrical cyanine dyes and squarane dyes **14**–**25** (Chart 1) were prepared from salts **1** and **2**, and the nonphosphonate indolium salts **10**–**13** were prepared using literature methods with some minor changes as noted below. Attempts to prepare the symmetrical trimethine cyanine dye **14** with the commonly used reaction mixture of triethyl orthoformate in pyridine generated dye **15** in which monophosphonate ethyl esters were formed. Treatment of **15** with refluxing in 6 M hydrochloric acid to hydrolyze these esters resulted in stepwise cleavage of the phosphonate groups from the dye in

addition to phosphonate ester cleavage. Symmetrical trimethine and pentamethine cyanine dyes were prepared in acetic anhydride with sodium acetate as base catalyst using either diphenylformamidine or malonaldehyde dianilide, respectively. Unsymmetrical trimethine and pentamethine cyanine dyes were prepared by first reacting one salt with either diphenylformamidine or malonaldehyde dianilide, respectively, in a mixture of acetic anhydride and pyridine and then treating the resulting intermediate with the second salt in a mixture of pyridine and acetic acid. Analysis of the crude reaction mixtures by RP HPLC indicated that in addition to the desired dyes, significant quantities of byproducts with absorption spectra resembling those of cyanine dye dimers were present. Treatment of the crude reaction mixtures with 1.0 M hydrochloric acid or with 1.0 M sodium carbonate solution for 16 h altered the HPLC trace profile by reducing the products with dimerlike absorption spectra and enhancing those with monomer like spectra. Treatment with concentrated hydrochloric acid for 3 h eliminated these byproducts completely. It seems likely that under the conditions of the condensation reactions dimeric and oligomeric species in which the dyes are connected through the phosphonate groups are formed. These byproducts were more prevalent the longer the phosphonic acid containing salts were heated with acetic anhydride. In the case of some of the unsymmetrical dyes the byproducts were avoided by using the indolium phosphonate in the second step of synthesis rather than the first. In the case of the formyl protected dye **24** partial cleavage of the formyl group was observed during the acid treatment. The formyl group was removed from purified dye **24** using methanolic hydrochloric acid. All of the dyes were isolated by RP column chromatography using gradient elution of methanol in either water or RPA buffer. Elemental analysis indicated that cyanine monophosphonates and diphosphonates were isolated as the zwitterionic forms.

Squaraine diphosphonate **26** was prepared by condensation of indolium salt **2** with squaric acid in a boiling mixture of butanol and toluene (*19, 20*), followed by cleavage of any butyl esters that formed with aqueous potassium carbonate, and was isolated in 72% yield as the zwitterion without the need for chromatography.

26 R = PO_3H_2
Sq 635-b R=SO_3H (*20*)

2. Properties of Dyes. All of the dyes are soluble in water to a greater or lesser degree. The cyanine diphosphonates **14**, **19**, and **20** are readily soluble in aqueous media over a wide range of pH (2–12). In contrast, the zwitterionic cyanine monophosphonates such as **16**, **17**, **21**, and **22** have limited solubility in water and in buffers below pH 7. Sodium salts of cyanine monophosphonates **16** and **21** are highly soluble in water. Cyanine monophosphonates **18**, **23**, and **25**, which have additional water solubilizing groups, maintained good solubility at lower pH (2–7). Cyanine monophosphonates and diphosphonates and squarane diphosphonate **26** may be precipitated from aqueous solution by lowering the pH to 1–2 with hydrochloric acid. After the precipitates were washed with water, the dyes were isolated in their zwitterionic forms.

The cyanine and squaraine phosphonates have similar absorption maxima, emission maxima, and extinction coefficients as their sulfonated analogues (Table 1). In the case of the pentamethine cyanine dyes **19–25**, the pH sensitivity of absorption maxima, emission maxima, and fluorescence quantum yields (QYs) were investigated to determine the effect of the protonation state of the phosphonic acid group on photophysical properties of the dyes. On the basis of the p*K* values for phenylphosphonic acid, 1.83 and 7.07 (*21*), it was assumed that at pH 9.3 the phosphonate group will carry two negative charges; at pH 4 it will have one charge, and at pH 1 it would be neutral. For the pentamethine dyes **19–25** the absorption and emission maxima shift 4–10 nm to the blue when the pH is lowered from 9.3 to 1. The QYs of cyanine diphosphonates **19** and **20** increase slightly as the pH is lowered, whereas those of the cyanine monophosphonates **21–23** decrease dramatically when the pH is lowered from 4 to 1. Comparison of the absorption spectra of **21** at the different pH values shows that at pH 1 the shorter-wavelength shoulder (approximately 605 nm) is significantly higher with respect to the peak maximum than at pH 4. This suggests that aggregation, which usually causes fluorescence quenching, is occurring (Figure 1 in Supporting Information). No such absorption spectrum changes were seen with cyanine diphosphonate **19**. Cyanine monophosphonate **23**, which has the pendent sulfonate group, shows intermediate behavior. The QY of amine containing monophosphonate **25** increases as the pH is lowered presumably because the protonated amine assists

[a] pH 1, 1.0 M hydrochloric acid; pH 4, 1.0 M NaH_2PO_4; pH 7.3, PBS; pH 9.3, carbonate–bicarbonate buffer. [b] Errors are estimated to be ±10%.

in preventing aggregation. For biological applications, measurements are typically made in the pH range 6–8 within which likely falls the second p*K* of the phosphonic acid group of the dyes. Consequently, the phosphonic acid group should not be considered completely in either the deprotonated or the monoprotonated forms within this pH range.

The cyanine diphosphonates **19** and **20** have lower QYs than do their respective sulfonate analogues Cy5.18 and Cy5.29. Cyanine diphosphonate **14** was found to have similar QY as Cy3.18, although the current study was unable to reproduce the reported QY of 0.04 for Cy3.18 (*4*). Squarane diphosphonate **26** has a higher extinction coefficient but lower QY than its sulfonated analogue Sq635-b (*20*).

3. Synthesis of Succinimidyl Esters. Succinimidyl esters are one of the most commonly used reactive forms of dyes for labeling of amine containing substrates such as proteins and were thought to be a suitable form for the testing of the new dyes. Treatment of the cyanine monophosphonates, such as **16** and **21**, with commonly used activating reagents such as disuccinimidyl carbonate/pyridine, dicyclohexylcarbodiimide/*N*-hydroxysuccinimide, or succinimidotetramethyluronium tetrafluoroborate (TSTU)/diispropylethylamine (DIEA) under anhydrous conditions resulted in mixtures of products some of which exhibited cyanine dimerlike absorption maxima. LC–MS confirmed the presence of dye dimers. Treatment of these mixtures with carbonate-bicarbonate buffer, pH 9.3, for several days did not convert the mixtures back to the starting material, but rather the dimer impurities persisted indicating that the dyes had been linked to each other through the phosphonate groups. The reactivity of phosphonate groups to these activating agents under anhydrous conditions is serious enough to prevent selective activation of carboxylic acid of the dye. Treatment of the cyanine monophosphonates with TSTU/DIEA under partially aqueous (10–15% water) conditions suppressed the formation of the dimer byproducts. It is important to avoid excess TSTU and to ensure that the dye is completely dissolved before the TSTU is added. Active esters of cyanine monophosphonates **16**, **18**, **21**, and **23** were prepared with approximately 90% yield, but separation of the nondye byproducts of the reaction proved to be difficult, and therefore, the crude mixtures were used in labeling experiments without purification. To permit accurate estimation of stoichiometry for labeling experiments, effective molecular weights were calculated on the basis of the mass of starting dye, the mass of final product, and the amount of the dye in the active ester form as determined by RP HPLC at the absorption maximum of the dye. When the disodium salts of dyes **18** and **23** were used, then the active esters were easily separated from the nondye byproducts of the activation reaction. HPLC analysis of the cyanine monophosphonate active esters indicated little decomposition or hydrolysis during storage in a freezer at −8 °C at for at least 3 months.

Application of the partially aqueous activating conditions to the squaraine diphosphonate **26** generated the disuccinimidyl ester in good yield, but activation of cyanine diphosphonates **14**, **19**, and **20** under similar conditions was problematic. After removal of the volatile components from the reaction mixtures and washing, the residues exhibited poor solubility in solvents such as DMSO and DMF. The active esters of **14** and **20** are highly soluble in aqueous media, and solid samples that were added to carbonate–bicarbonate buffer dissolved immediately. RP HPLC analysis of these solutions indicated that the active esters were hydrolyzed back to the starting acids in a few hours. Saturated solutions of the active esters of **14** and **20** in DMSO were used for labeling studies.

4. Protein Labeling Studies. Sheep IgG was labeled in carbonate-bicarbonate buffer at pH 9.3 using the active esters of diphosphonate dyes **14**, **20**, and **26** and of monophosphonate dyes **16**, **18**, **21**, and **23** to produce conjugates with a range of dye to protein (*D*/*P*) ratios. Samples were divided and were purified by G50 size exclusion chromatography using PBS, pH 7.3, BBS, pH 8.1, or carbonate-bicarbonate buffer, pH 9.3. All conjugates remained soluble during labeling at pH 9.3 and during purification in the three buffer systems, but solutions of conjugates of cyanine monophosphonates **16** and **21** with high (>5) *D*/*P* ratios developed precipitates when stored for several days at 4 °C in PBS at pH 7.3. Some of the precipitates dissolved when the solutions were warmed to room temperature. Conjugates of the other dyes did not form precipitates in any of the buffer media. Sheep IgG that was mixed with the parent dyes under conditions identical to those used for labeling separated completely from the dyes when subjected to size exclusion chromatography, indicating that nonspecific binding of the dyes to the protein does not occur. Sheep IgG was also labeled with Cy3.29 and Cy5.29 (known commercially as Cy3 monofunctional and Cy5 monofunctional, respectively) using methods supplied by the manufacturer. Previous studies have determined that labeling of proteins with disuccinimidyl active esters of cyanine and squaraine dyes under conditions similar to those used here does not cause a noticeable amount of protein cross-linking (*17*, *20*). Conjugation of the cyanine dyes and the squaraine dye to the protein resulted in a red shift to the absorption maximum of the dyes by 2–3 and 6 nm, respectively.

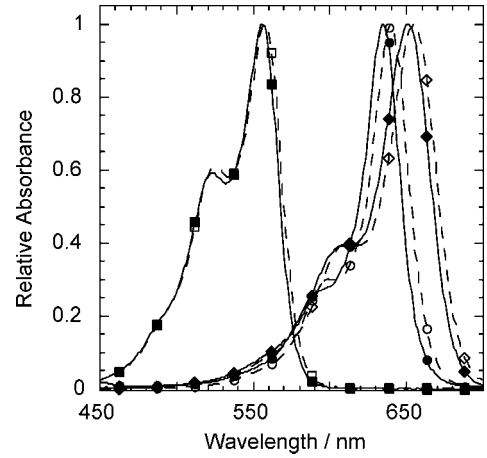

Figure 1. Absorption spectra of dyes (solid lines) and conjugates (dashed lines): **14** (solid squares) and conjugate IgG–(**14**)$_6$ (transparent squares) in BBS, pH 8.1; **20** (solid diamonds) and conjugate IgG–(**20**)$_5$ (transparent diamonds) in BBS, pH 8.1; **26** (solid circles) and conjugate IgG–(**26**)$_3$ (transparent circles) in PBS, pH 7.3.

Typical absorption spectra of the dyes **14**, **20**, and **26** and of their conjugates are shown in Figure 1. Most noticeable is that the absorption spectra of conjugates are almost identical to those of the parent dyes despite the relatively high labeling densities. Usually, in aqueous media, organic dyes held in proximity to each other on the surface of a substrate clump together to form dimers and higher aggregates. Electronic ground-state coupling between the dyes in these aggregates results in different absorption and emission properties than those of the free dye. While some exceptions exist (*5*), it is most common for aggregates of cyanine dyes to show peak maxima that are blue-shifted relative to the free dye. The absorption spectrum of the labeled substrate is the sum of the spectra of the aggregates and of the dye that is still independent. Consequently, aggregation manifests itself in the absorption spectrum as a shoulder on the shorter-wavelength side of the peak maximum of the independent dye, and in extreme cases this shoulder becomes the peak maximum. Thus, the relative height of the shoulder to the peak maximum is an indication of whether aggregation is occurring. Additionally, such aggregates have significantly lower

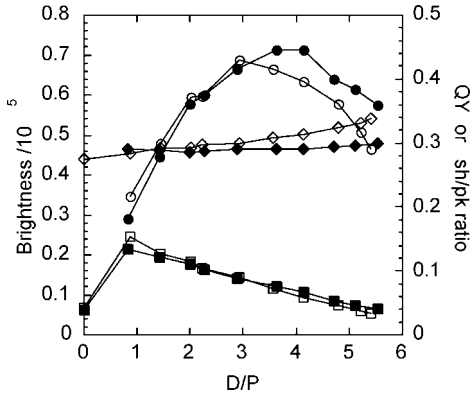

Figure 2. Plots of conjugate brightness (circles), quantum yields (QYs) (squares), and shoulder to peak maximum height (sh/pk) ratio (diamonds) as a function of dye to protein ratio for IgG–**26** conjugates at pH 9.3 (solid symbols) and pH 7.3 (transparent symbols).

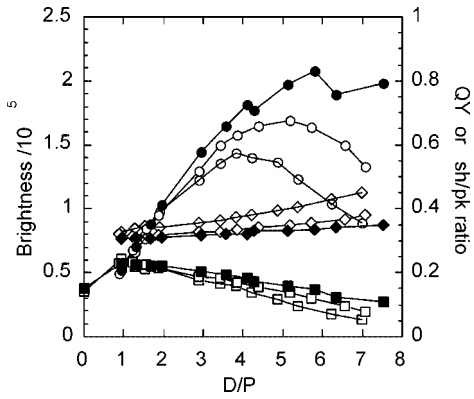

Figure 3. Plots of conjugate brightness (circles), quantum yields (QY) (squares), and shoulder to peak maximum height (sh/pk) ratio (diamonds) as a function of dye to protein ratio for IgG–**20** conjugates at pH 9.3 (solid symbols), pH 8.1 (empty symbols), and pH 7.3 (transparent symbols).

QYs of fluorescence than the free fluorophore and so reduce the QY and the brightness of the labeled substrate (*5, 17, 22*).

At pH 7.3, absorption spectra of the IgG–**26** conjugates show a slight increase in the ratio of the short wavelength shoulder to the peak maximum height (sh/pk ratio) as the *D*/*P* ratio increases, whereas in pH 9.3 buffer there is little change (Figure 2, diamonds). The QY of squaraine **26** increases 4-fold when attached to the protein but then decreases as the dye *D*/*P* ratio increases (Figure 2, squares). The QY is slightly less sensitive to the *D*/*P* ratio at pH 9.3 than at pH 7.3. These differences in the observed absorption and fluorescence properties at the two pH values most likely result from increased ionization of the phosphonic acid residues at the higher pH, with concomitant increases in repulsive dye–dye interactions. The brightness of the conjugates ((ε)(QY)(*D*/*P*)) reaches a maximum with a *D*/*P* ratio of 3 at pH 7.3 and with a *D*/*P* ratio of 4 at pH 9.3 (Figure 2, circles). For comparison, the sulfonate analogue of dye **26**, Sq635-b, was reported to show an increase in QY from 0.15 to 0.68 upon conjugation to bovine serum albumin, but no *D*/*P* ratio for such conjugates was presented (*20*).

The absorption and fluorescence properties of conjugates of cyanine diphosphonate **20** exhibit similar trends as those of squarane diphosphonate **26** (Figure 3). In all three buffers there is a slight increase in the sh/pk ratio and a decrease in QY as the *D*/*P* ratio increases, but at lower pH the changes are more pronounced. The optimal labeling density is pH-dependent with values of 3.5*D*/*P* at pH 7.3, 5*D*/*P* at pH 8.1, and 6*D*/*P* at pH 9.3. For comparison, optimal labeling of IgG with Cy5.29 is

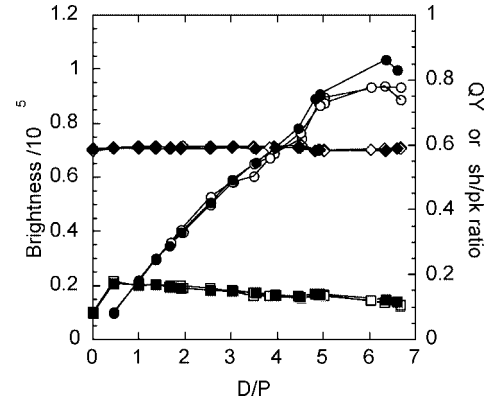

Figure 4. Plots of conjugate brightness (circles), quantum yields (QY) (squares), and shoulder to peak maximum height (sh/pk) ratio (diamonds) as a function of dye to protein ratio for IgG–**14** conjugates at pH 9.3 (solid symbols), pH 8.1 (empty symbols), and pH 7.3 (transparent symbols).

achieved with only 2–3*D*/*P* at which the QY is 0.2 and the conjugate brightness is approximately 1×10^5 (derived from data in ref *22*). Thus, at pH 7.3 the cyanine diphosphonate **20** generates a brighter conjugate than Cy5. If experimental conditions permit the use of media of higher pH, then considerably greater advantage may be gained by use of dye **20**.

Absorption spectra of conjugates of cyanine diphosphonate **14** are relatively insensitive to the *D*/*P* ratio and to pH (Figure 4). The sh/pk ratio remained constant throughout the *D*/*P* range investigated. QY of the dye doubles upon attachment to the protein and then decreases as the *D*/*P* ratio increases. The optimal labeling density with dye **14** is greater than 6*D*/*P* compared 5–6*D*/*P* for Cy3, with the latter having a conjugate brightness of approximately 0.9×10^5 (derived from data in ref *22*). Cyanine diphosphonate **14** offers at least equivalent performance as Cy3.

Cyanine monophosphonates **16**, **18**, **21**, and **23** are more prone to aggregate when attached to sheep IgG than are the cyanine diphosphonates **14** and **20**, as evidenced by the increase of the sh/pk ratio (Figure 2 of Supporting Information). Absorption spectra of dyes **18** and **21**, Cy3 and Cy5, and their conjugates are shown in Figure 5. It is common practice to estimate the concentration of dye in solutions of labeled conjugates through application of Beer's law using the absorbance value at the peak maximum and the extinction coefficient of the free dye. This approach underestimates the *D*/*P* ratio when dye–dye aggregation is significant. Conjugates of the cyanine monophosphonates dyes were diluted with formamide (1:2) to break up the aggregates and permit more accurate estimations of the *D*/*P* ratio. Following the manufacturer's recommended procedures for labeling with Cy3 and Cy5 generated conjugates with 5*D*/*P* and 7*D*/*P*, respectively. In the latter case this *D*/*P* ratio is far from the optimal of 2–3*D*/*P* (*22*).

The absorption and fluorescence properties of conjugates of dyes **16**, **18**, **21**, and **23** followed the same trends as those observed for the conjugates of the cyanine diphosphonates **14** and **20** except that the QY of dye **23** did not increase when the dye was attached to the protein but instead decreased (Figure 6). Optimal labeling densities for the conjugates were determined to be 4*D*/*P* for IgG–**16**, 5*D*/*P* for IgG–**18**, 2–3*D*/*P* for IgG–**21**, and 4*D*/*P* for IgG–**23** (Figure 6). These are lower than for the cyanine diphosphonates **14** and **20** because of increased aggregation and fluorescence quenching of less highly charged dyes. Surprisingly, at optimal labeling densities, dye **21** gives significantly brighter conjugates with 2*D*/*P* than does the sulfonate containing dye **23** with 4*D*/*P*. In all cases, at higher labeling densities the conjugates are brighter at pH 9.3 than at

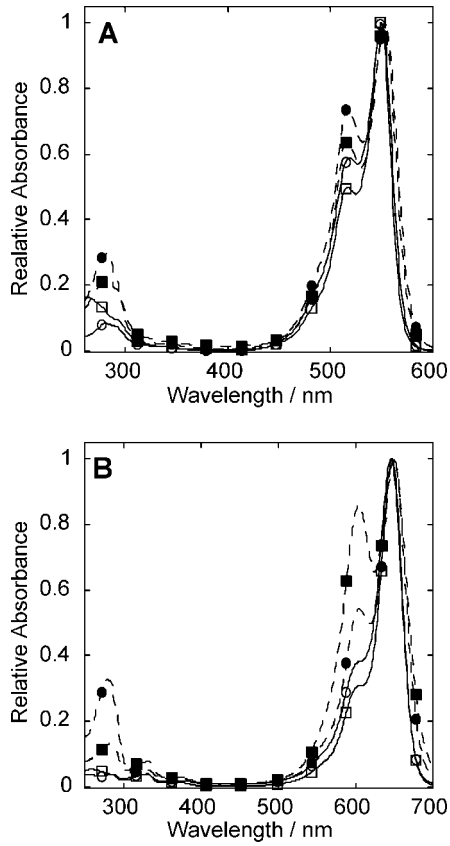

Figure 5. Absorption spectra of dyes (solid lines) and conjugates (dashed lines) in PBS, pH 7.3: (A) **18** (transparent circles), IgG–(**18**)$_4$ (solid circles), Cy3 (transparent squares), IgG–(Cy3) (solid squares); (B) **21** (transparent circles), IgG–(**21**)$_2$ (solid circles), Cy5 (transparent squares), IgG–Cy5 (solid squares).

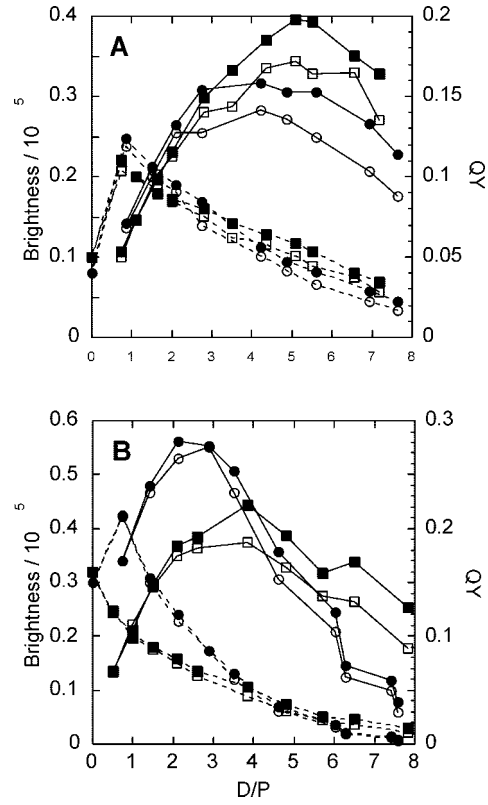

Figure 6. Plots of conjugate brightness (solid lines) and quantum yields (dashed lines) at pH 9.3 (solid symbols) and at pH 7.3 (transparent symbols): (A) IgG–**16** (circles) and IgG–**18** (squares); (B) IgG–**21** (circles) and IgG–**23** (squares).

pH 7.3 whereas at lower labeling densities little difference is seen, again indicating that increased ionization of the phosphonic acid reduces quenching interactions.

The absorption spectra and fluorescence properties of IgG conjugates with cyanine dyes such as Cy3 and Cy5 have been studied at length (*4–6*, *8*, *17, 22*). The initial increase in QY that is seen on conjugation to IgG of the trimethine cyanine dyes such as Cy3, **14**, **16**, and **18** is attributed to a rigidifying effect on the dye caused by association of the dye with the surface of the protein (*4, 22*). In contrast, QYs of pentamethine cyanine dyes, such as Cy5, are less dependent on the environment of the dye, and QYs of conjugates of Cy5 with *D*/*P* ratios less than 1 are similar to those of the free dye (*22*). Labeling of IgG with Cy5 was proposed to proceed in a nonrandom manner with binding of one Cy5 to the protein predisposing the region around the dye to further labeling (*22*), thereby accentuating the likelihood of dye dimer formation on the surface and leading to greater fluorescence quenching than would be seen with random labeling. If this is indeed the case, then labeling with the phosphonated cyanines at pH 9.3, where the phosphonate groups are expected to carry two negative charges, should result in more random labeling and in conjugates that are not so quenched. For cyanine diphosphonate **20**, which is structurally similar to Cy5, the differences between the sh/pk ratios and the large differences in brightness of identical conjugates at pH 9.3 compared to those at pH 7.3 strongly suggest that electronic repulsion between the attached dyes is greater at pH 9.3. Reasons for the differences between the labeling properties of dyes **21** and **23** are not so obvious. The additional sulfonate group of dye **23** has the expected effect of increasing the optimal *D*/*P* ratio, presumably through assisting in solubilizing the dye and offering some inhibition to aggregation. The decrease in QY of dye **23** that is seen when the first dye is attached to the protein is in contrast to all of the other cyanine phosphonates studied here but is commonly seen with cyanine dyes that do not have charges appended to the aromatic residues (*17*). Whatever the mechanisms of labeling and quenching may be, it is clear that the cyanine diphosphonates can produce conjugates that are as bright or brighter than those of commercial Cy3 and Cy5. Conjugates of the monophosphonate cyanines dyes are not as bright as those of Cy3 and Cy5 because of the inherently lower QYs of the parent dyes and because they have a greater tendency to aggregate when attached to the protein.

5. Oligonucleotide Labeling Studies. 5′-Labeled oligodeoxyribonucleotides (ODNs) were prepared by conjugation of the active esters of dyes **16**, **18**, **21**, **23**, Cy3.29, and Cy5.29 to an amino functionalized T_{10}-ODN or by coupling of the amidites of Quasar 570 (Q570) and Quasar 670 (Q670) to a T_{10}-ODN. The pentamethine cyanine dyes **21**, **23**, Q670, and Cy5 in particular decomposed somewhat during the ammonia workup process.

On conjugation to the ODNs, the absorbance maxima of the cyanine monophosphonates are shifted 4 nm to the red and their QYs increase (Table 2), which is consistent with previous observations for cyanine dyes with and without anionic substituents (*9*). ODNs T_{10}-**16** and T_{10}-**18** have similar QYs as ODN T_{10}-Cy3.29, which is lower than that of ODN T_{10}-Q570. ODNs T_{10}-**21** and T_{10}-**23** have lower quantum yields than ODNs T_{10}-Cy5.29 and T_{10}-Q670, which have similar values. The cyanine monophosphonates, and other cyanines that carry anionic charges, such as Cy3 and Cy5, offer no advantage in QY over cyanines that do not carry anionic charges as 5′-fluorescent labels for ODNs, although they may be advantageous when multiple labeling of ODNs or DNA is required.

In conclusion, synthetic methods for the preparation of phosphonic acid containing cyanine and squarane dyes were

Table 2. Photophysical Data for T_{10}-Dye Oligonucleotide Conjugates in PCR Buffer

5′-labeled oligonucleotide	absorption max, nm	emission max, nm	QY
T_{10}-**16**	552	568	0.10
T_{10}-**18**	553	567	0.11
T_{10}-Cy3.29	551	563	0.11
T_{10}-Q570	549	564	0.14
T_{10}-**21**	650	668	0.21
T_{10}-**23**	651	669	0.23
T_{10}-Cy5.29	649	666	0.32

developed. The new dyes have similar spectral properties to existing sulfonic acid containing analogues and can be used to generate brightly labeled dye–protein conjugates. As protein labels, trimethine cyanine diphosphonates, such as dye **14**, are more or less equivalent to the commercial sulfonate analogue Cy3, whereas pentamethine cyanine diphosphonates, such as dye **20**, are superior to the commercial sulfonate analogue Cy5, particularly when used in higher pH environments.

ACKNOWLEDGMENT

The author thanks Alex Herrault for assistance in acquiring LC–MS spectra.

A Facile Synthesis of Azido-Terminated Heterobifunctional Poly(ethylene glycol)s for "Click" Conjugation

Shigehiro Hiki[†] and Kazunori Kataoka*[,†,‡,§]

Department of Materials Engineering, Graduate School of Engineering, and Center for NanoBio Integration, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan, Core Research Program for Evolutional Science and Technology (CREST), Japan Science and Technology Agency (JST), Tokyo, Japan, and Center for Disease Biology and Integrative Medicine, Graduate School of Medicine, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-0033, Japan. Received April 27, 2007; Revised Manuscript Received July 26, 2007

New azido-terminated heterobifunctional poly(ethylene glycol) (PEG) derivatives having primary amine and carboxyl end groups, (Azide-PEG-NH_2 and Azide-PEG-COOH, respectively) were synthesized with high efficiency. An α-allyl-ω-hydroxyl PEG was prepared as the first step to Azide-PEG-X (X = NH_2 and COOH) through the ring-opening polymerization of ethylene oxide (EO) with allyl alcohol as an initiator, followed by two-step modification of the hydroxyl end to an azido group. To introduce primary amino or carboxyl functional groups, amination and carboxylation reactions of the allyl terminal ends was then conducted by a radical addition of thiol compounds. Molecular functionalities of both ends of the PEG derivatives thus prepared were characterized by ^1H, ^{13}C NMR, and MALDI-TOF MS spectra, validating that the reaction proceeded quantitatively. The terminal azido functionality is available to conjugate various ligands with an alkyne group through the 1,3-dipolar cycloaddition reaction condition ("click chemistry").

INTRODUCTION

Poly(ethylene glycol) (PEG) conjugation chemistry, termed "PEGylation", has widely been used for the modification of biomolecules such as peptides, proteins, and enzymes (*1–3*), as well as of nanocarriers for drug delivery systems (DDS) such as liposomes and nanoparticles (*4, 5*). The advantages of PEGylation include the improvement of pharmaceutical and pharmacological properties, e.g., increased water solubility and circulatory half-life in vivo, the reduced antigenicity and immunogenicity, and the tolerance of biomolecules against degradation (*1–3*). Actually, several PEG-conjugated proteins have already been available as clinical therapeutics (*6*). Methoxy-terminated monofunctionalized PEG derivatives have mainly been used in these systems. Of further interest from the viewpoint of constructing multifunctionalized biopharmaceutics with PEGylation is the introduction of reactive groups at the α-chain end of PEG to prepare α,ω-heterobifunctional derivatives (heterobifunctional PEG). Heterobifunctional PEG may be useful to install ligands and probes at the distal end of PEGylated liposomes (*7*), polymeric micelles (*8*), synthetic polymers (*9*), and metallic colloids (*10*). So far, several types of heterobifunctional PEG derivatives with reactive groups, such as aldehyde, primary amine, mercapto, and maleimide, have been developed to install a variety of ligands (*8, 11–17*). Nevertheless, to expand the heterobioconjugation through PEG linker into a various combination of ligands and substrates, further improvement in the design of heterobifunctional PEG, particularly from the viewpoint of versatility, is crucial.

Generally, several features such as high yields, chemoselectivity, and the mild reaction condition in aqueous media are indispensable for the bioconjugation. In this regard, the 1,3-dipolar cycloaddition reaction between alkyne and organic azides, yielding the corresponding 1,2,3-triazoles in the mild aqueous condition, has recently received considerable attention in wide areas of chemistry (*18–20*) and has been recognized as particularly useful in the field of bioconjugate chemistry (*21–24*). This Cu(I)-catalyzed 1,3-dipolar cycloaddition reaction (termed "click chemistry") is highly chemoselective and can be performed under mild conditions in aqueous buffers with wide range of pH values. Therefore, the combination of heterobifunctional PEGs with "click chemistry" is a promising approach for bioconjugation (*25*). Indeed, the introduction of biological ligands by "click chemistry" onto the liposomal surface (*26*) and the Au nanoparticle surface (*27*) through the heterobifunctional oligo(ethylene glycol) spacers was recently reported, indicating the high utility of "click"-based bioconjugation.

Nevertheless, little attention has been placed on the novel and versatile method to prepare the azido-terminated heterobifunctional PEGs with a wide range of molecular weight useful for "click"-based bioconjugation. Although, azido-containing oligo(ethylene glycol) derivatives (e.g., N_3-$(CH_2CH_2O)_2$-$CH_2CH_2NH_2$) have been commercialized (*28*), the azido-terminated heterobifunctional PEGs having high molecular weight useful in the bioconjugate chemistry field are not yet available.

Here, we wish to communicate the new synthetic route of azido-terminated heterobifunctional PEGs possessing primary amino and carboxyl groups (Azide-PEG-NH_2 and Azide-PEG-COOH, respectively) with controlled molecular weight through the ring-opening polymerization of ethylene oxide from allyl alcohol as an initiator followed by a quantitative modification of α- and ω-end groups (Scheme 1).

EXPERIMENTAL PROCEDURES

Materials. Ethylene oxide (EO; Sumitomo Seika Chemical, Japan) was dried over calcium hydride and distilled under an argon atmosphere. Allyl alcohol, tetrahydrofuran (THF), *N,N*-

Scheme 1. Synthetic Route to α-Amino-ω-azido-PEG (3) and α-Carboxy-ω-azide-PEG (4)

dimethylformamide (DMF), triethylamine, 2,2′-azobisisobutyronitrile (AIBN), and methanesulfonyl chloride were purchased from Wako Pure Chemical Industries, Ltd., (Osaka, Japan) and purified by conventional methods. Potassium naphthalene was prepared as a THF solution according to a previous paper (*29*), whose concentration was determined by titration. 2-Aminoethanethiol hydrochloride, mercaptopropionic acid, sodium azide, and other reagents were used as received.

Synthesis of α-Allyl-ω-hydroxyl PEG (1). Allyl alcohol (2.3 mmol, 135 μL) and potassium naphthalene (2 mmol) in 6.6 mL of THF were added to dry THF (75 mL) in a 200 mL flask equipped with a three-way stopcock under argon atmosphere to form potassium allyl alcoholate as an initiator. After stirring for 10 min, liquid EO (302 mmol, 13.3 g) was added to the solution via a cooled syringe. The mixture was allowed to react for 2 days at 25 °C followed by pouring into diethyl ether to precipitate the polymer. The recovered polymer was dried in vacuo and then freeze-dried from benzene. The yield of obtained polymer after purification was 91% (12.1 g). GPC: Number-average molecular weight (M_n) = 5500, M_w/M_n = 1.03. ^{1}H NMR (300 MHz, $CDC1_3$, δ in ppm): 3.63 (m, O-(C$\underline{H}_2$)$_2$-O), 4.02 (d, C$\underline{H}_2$ of allyl group), 5.17–5.30 (dd, C$\underline{H}_2$ of allyl group), 5.87–5.96 (m, C$\underline{H}$ of allyl group).

Synthesis of α-Allyl-ω-azide PEG (2). The azide end group was introduced by the mesylation of the hydroxyl terminus and subsequent substitution with sodium azide, referring to the literature methods (*30*).

Freeze-dried polymer **1** (Allyl-PEG-OH) (2.20 g, 0.40 mmol) from benzene was dissolved in anhydrous THF (15 mL) followed by triethylamine (162 mg, 1.60 mmol) addition. The mixture was then added to a solution of methanesulfonyl chloride (160 mg, 1.40 mmol) in THF (8 mL) under Ar stream, and stirred overnight at room temperature. After the reaction, THF was partially evaporated under reduced pressure. The residue was redissolved in water (40 mL) and extracted with dichloromethane (5 × 100 mL). The organic layers were combined and dried over Na_2SO_4. After filtration and concentration, the polymer was recovered by precipitation into ether and dried in vacuo, yielding a white solid.

This mesylated polymer (620 mg, 0.113 mmol) was dissolved in DMF (12 mL), followed by sodium azide (521 mg, 8.01 mmol) addition, and was stirred for 2 days at 30 °C. Dichloromethane (100 mL) was then added, and the reaction mixture was washed five times with water and brine. The organic layer was dried over Na_2SO_4, filtered, concentrated, and then reprecipitated into ether. The recovered polymer was freeze-dried from benzene (508 mg, 82%). ^{1}H NMR (300 MHz, $CDC1_3$, δ in ppm): 3.46 (t, CH_2-C$\underline{H}_2$-N_3), 3.63 (s, O-(C$\underline{H}_2$)$_2$-O), 4.02 (d, C$\underline{H}_2$ of allyl group), 5.17–5.30 (dd, C$\underline{H}_2$ of allyl group), 5.87–5.96 (m, C$\underline{H}$ of allyl group).

Synthesis of α-Amino-ω-azide PEG (3). Amination of the allyl terminus of polymer **2** was conducted by the radical addition reaction of 2-aminoethanethiol hydrochloride (*31*). Polymer **2** (Allyl-PEG-azide, 502 mg, 0.091 mmol) was freeze-dried from benzene and mixed with the solution in DMF (5 mL) containing 213 mg of 2-aminoethanethiol hydrochloride (1.87 mmol, 20 equiv) and 15 mg of AIBN (0.091 mmol, 1 equiv). The reaction mixture was stirred at 65 °C for 24 h under argon atmosphere. The polymer was precipitated twice in a large excess of ether. The resulting white product was dissolved into methanol, and 5.1 mg (1 equiv) of potassium hydroxide dissolved in water was added. The mixture was stirred for approximately 4 h. Then, methanol was partially evaporated and diluted with water (30 mL), and extracted by dichloromethane (5 × 80 mL). The combined organic layer was dried over Na_2SO_4, filtered, and concentrated to 1/100 of the initial volume. The polymer was reprecipitated from an excess volume of ether and freeze-dried from benzene to lead to a white powder (397 mg, yield = 79%).

Synthesis of α-Carboxy-ω-azide PEG (4). The carboxylation reaction of allyl terminus of polymer **2** was performed in the same manner as described above for the preparation of polymer **3**. Typically, 409 mg of Allyl-PEG-azide, in 4 mL of DMF, was reacted with 159 mg of 3-mercaptopropionic acid (1.50 mmol, 20 equiv) in the presence of 12.2 mg of AIBN (1 equiv). After the reaction, the solution was precipitated into ether twice, and polymer **4** was obtained as a white powder (317 mg, yield = 77%).

Polymer Analysis. ^{1}H and ^{13}C NMR spectra were recorded on a JEOL JNM-AL 300 spectrometer (JEOL, Tokyo, Japan) at 300 and 75.45 MHz, respectively. Chemical shifts are reported in parts per million (ppm) downfield from tetramethylsilane. Number-average molecular weight (M_n) and molecular weight distribution (M_w/M_n) were determined using a GPC (TOSOH HLC-8220) system equipped with two TSK gel columns (G4000HHR and G3000HHR) and an internal refractive index (RI) detector. Columns were eluted with DMF containing lithium chloride (10 mM) at a flow rate of 0.8 mL/min and temperature of 40 °C. Molecular weights were calibrated with poly(ethylene glycol) standards (Polymer Laboratories, Ltd., UK). MALDI-TOF-MS spectra were recorded using Bruker

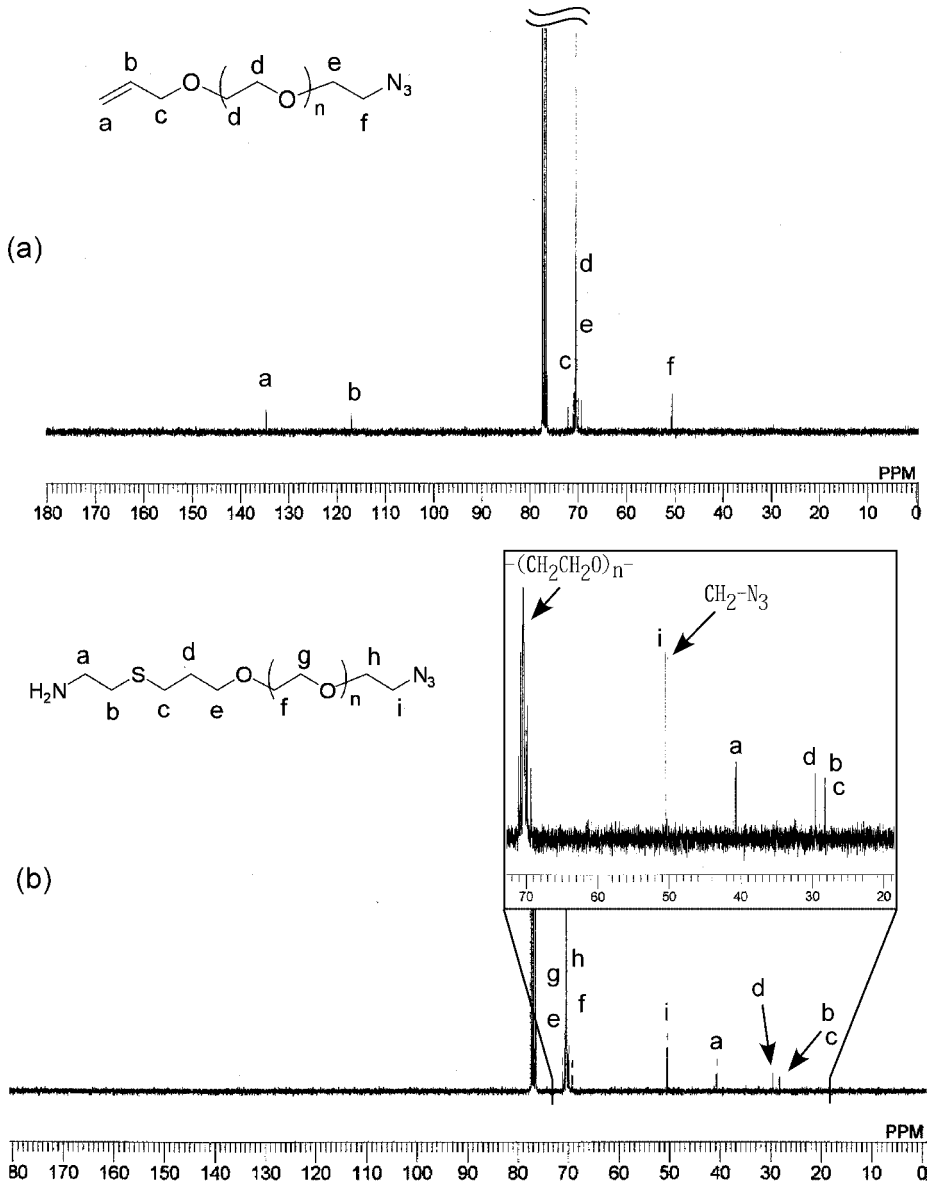

Figure 1. (a) ^{13}C NMR spectrum of Allyl-PEG-Azide ($CDCl_3$ at 20 °C). (b) ^{13}C NMR spectrum of Azide-PEG-NH_2 ($CDCl_3$ at 20 °C).

REFLEX III. α-Cyano-4-hydroxycinnamic acid (CHCA) was used as the matrix for the ionization operated in the reflection mode.

RESULTS AND DISCUSSION

There are several reports on the preparation of oligo(ethylene glycol)s having azido and amino groups from homotelechelic oligo(ethylene glycol)s as the starting materials (*32, 33*). Nevertheless, the synthetic methods involve several complicated reactions as well as separation steps such as chromatographic isolation due to the difficulty of selective monoprotection of the hydroxyl termini. Thus, the application of these synthetic approaches of end-group modification is not expedient for a large-scale synthesis of heterobifunctional PEGs having high molecular weight, giving an impetus to develop a novel synthetic route to the azide-functionalized heterobifunctional PEG with quantitative yields and high specificity under mild reaction conditions.

In this study, allyl alcoholate was selected as an initiator for anionic polymerization of EO, because the allyl end group of the PEG chain allows several kinds of chemical modifications such as addition reactions. To prepare α-allyl-ω-hydroxyl PEG (**1**), the anionic polymerization of EO initiated with potassium allyl alcoholate was carried out in THF solution for 48 h. After precipitation into ether, the product was obtained as white powder. The MW of the polymer **1** (Allyl-PEG-OH) determined from GPC [M_n(GPC) 5500] was close to that from the initial monomer/initiator ratio [M_n(calcd) 5780], indicating an effective initiation efficiency of potassium allyl alcoholate without detrimental side reactions.

α-Allyl-ω-azide PEG (**2**) was obtained through the two-step modification, the mesylation and the subsequent substitution by sodium azide, of hydroxyl function as described in the Experimental Procedures. In the ^{13}C NMR spectrum (Figure 1a), the signals of the carbons of the allyl group are detected at δ 134.7 ppm (a), 117.0 ppm (b), and 72.1 ppm (c), respectively. In addition to these signals, the methylene unit adjacent to the azido group ($CH_2\underline{C}H_2N_3$) was observed at 50.5 ppm (f). Moreover, no signal of the methylene carbon adjacent to the hydroxyl terminus ($CH_2\underline{C}H_2OH$ δ = 61.5 ppm) (*34*) was detected.

Figure 2a shows the MALDI-TOF MS spectra of α-allyl-ω-azide PEG (**2**). In this analysis, although the major peaks of the polymer were detected as the species derived from loss of N_2 from azido group which ascribed to fragmentation due to

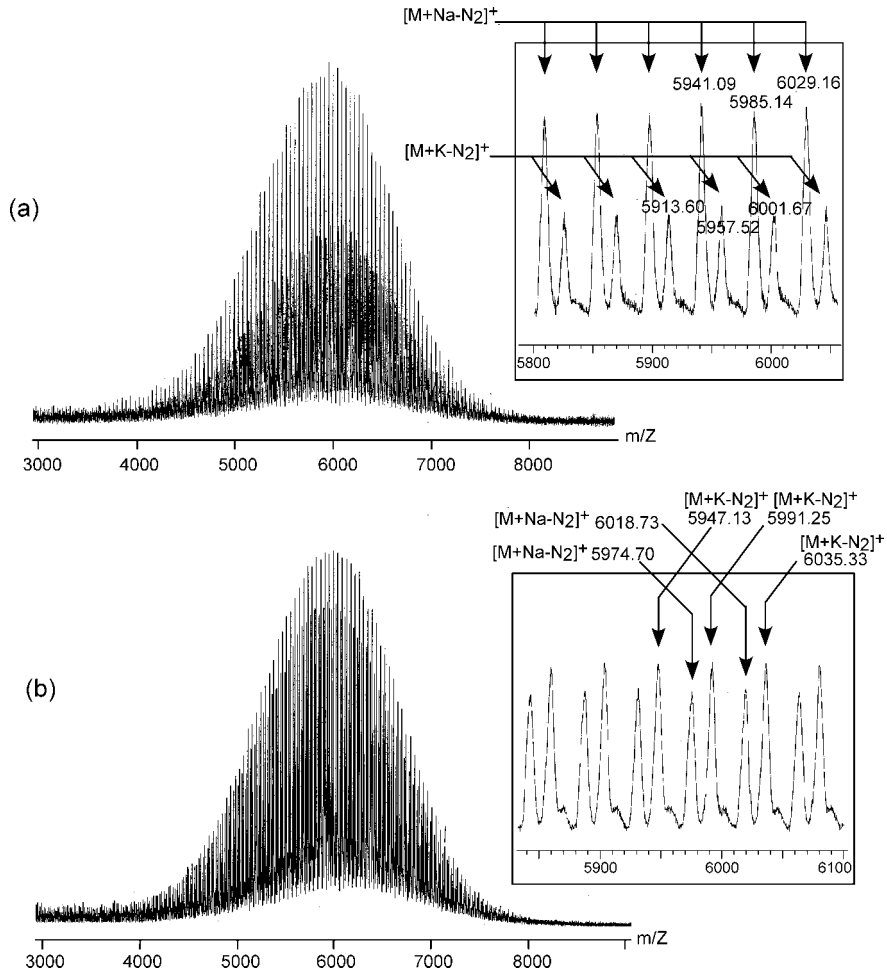

Figure 2. MALDI-TOF Mass Spectrum of Allyl-PEG-Azide (a) and Azide-PEG-NH_2 (b).

the higher laser power during MALDI experiment (*35*), only parent ions of each polymer molecule as planned are observed, without the signal of the side reaction product. From the expanded view of the spectrum in Figure 2a, the mass of the products appears to be around 5900 (M_n = 5670; M_w/M_n = 1.03), which is in a good accordance with the GPC results (M_n = 5500). These data demonstrated that α-allyl-ω-hydroxyl PEG (**1**) was successfully transformed to α-allyl-ω-azide PEG (**2**). Note that there was a report on the chain degradation of tosylate-activated PEG derivatives (*36*). Nevertheless, no sign of degradation was found in the present case of mesylate-activated PEG samples by MALDI-TOF MS spectroscopy, indicating that essentially no degradation of PEG occurred in the activation route via mesylation.

To prepare α-amino-ω-azide PEG, the radical addition reaction of 2-aminoethanethiol hydrochloride to an allyl end group of polymer (**2**) was examined according to the previous method with a slight modification (*31*). The reaction was carried out under the varying ratios of [allyl-PEG-azide]$_0$/[$HSCH_2CH_2NH_3^+Cl^-$]$_0$/[AIBN]$_0$ (=1/5/1, 1/7.5/1, 1/10/1, and 1/20/1 mol equiv) in DMF at 65 °C. The resulting polymer was precipitated twice in ether in order to remove excess of reagents. After the subsequent aqueous workup with potassium hydroxide, the amino-terminated PEG sample was obtained (Scheme 1). The ^{1}H NMR spectrum of the polymer obtained at the conditions of [allyl-PEG-azide]$_0$/[$HSCH_2CH_2NH_3^+Cl^-$]$_0$/[AIBN]$_0$ = 1/10/1 and 1/20/1 revealed the complete disappearance of the signals assigned to the allyl protons at 4.02 (CH_2═$CHC\underline{H_2}$), 5.17–5.30 ($C\underline{H_2}$═$CHCH_2$), and 5.87–5.96 ppm (CH_2═$C\underline{H}CH_2$). Concomitantly, the new signals were clearly observed at 1.82 ($CH_2C\underline{H_2}CH_2S$), 2.60 ($SC\underline{H_2}CH_2NH_2$), 2.62 ($C\underline{H_2}SCH_2CH_2NH_2$), and 2.86 ppm ($CH_2SCH_2C\underline{H_2}NH_2$) corresponding to the resulting structure via the radical addition of 2-aminoethanethiol to allyl group. A decreased ratio of thiol compound in the initial reaction mixture to less than 10 equiv ([allyl-PEG-azide]$_0$/[$HSCH_2CH_2NH_3^+Cl^-$]$_0$/[AIBN]$_0$ = 1/5/1 and 1/7.5/1) resulted in the incomplete amination judged from the observation of the remaining ally protons in the ^{1}H NMR spectra of the obtained polymer samples, suggesting that 10 mol excess equiv of thiol group may be required for the complete amination of allyl group settled at the PEG chin end. No prohibitive effect was observed even at 20 equiv of thiol to allyl groups. In the ^{13}C NMR spectra of the sample obtained at [allyl-PEG-azide]$_0$/[$HSCH_2CH_2NH_3^+Cl^-$]$_0$/[AIBN]$_0$ = 1/20/1 (Figure 1b), no carbon signal corresponding to allyl function remained. The signals detected around δ 40.7 (a), 29.6 (d), and 28.4 ppm (c,d) can be assigned to the $\underline{C}H_2NH_2$, $CH_2\underline{C}H_2CH_2S$, and $CH_2CH_2\underline{C}H_2S\underline{C}H_2$ of the end groups, respectively. Note that no side reaction of the azido group such as a radical scavenging and a subsequent decomposition with denitrogenation occurred, because the signal corresponding to the azido group was detected as intact.

The quantitative conversion of the end allyl group to the primary amino group was also monitored by the MALDI-TOF MS analysis. Figure 2b shows the MALDI-TOF MS spectrum of the reaction product after the radical addition reaction of 2-aminoethanethiol hydrochloride ([allyl-PEG-azide]$_0$/[$HSCH_2CH_2NH_3^+Cl^-$]$_0$/[AIBN]$_0$ = 1/20/1). As mentioned above, the mass distribution of the obtained polymer after the radical addition was the same as that before the reaction, indicating the occurrence of no side reaction. The major series of the molecular masses of the product is expressed in the following equation.

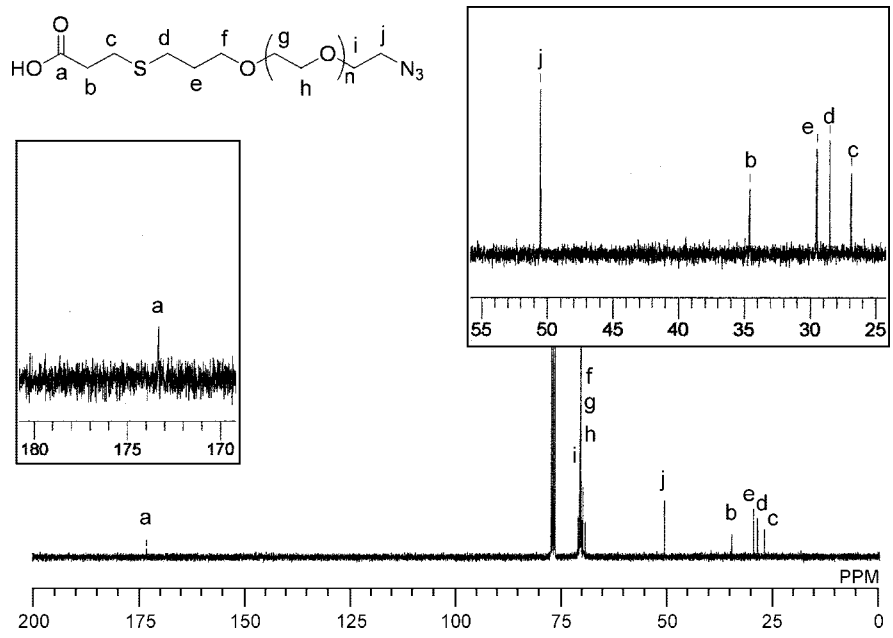

Figure 3. ^{13}C NMR spectrum of Azide-PEG-COOH ($CDCl_3$ at 23 °C).

MW_{MS} = 44.053n (EO) + 70.07 (Azide) + 134.22 ($OCH_2CH_2CH_2SCH_2CH_2NH_2$) + 22.99 (sodium).

These results strongly supported the statement that the novel heterobifunctional PEG possessing an azido group at one end and a primary amino group at the other end was quantitatively prepared.

To demonstrate the versatility of this synthetic route with azido-containing PEG, the carboxylation of α-allyl-ω-azide PEG (**2**) was examined under the same conditions as the amination reaction ([allyl-PEG-azide]$_0$/[$HSCH_2CH_2COOH$]$_0$/[AIBN]$_0$ = 1/20/1). From the ^1H NMR analysis of the resultant polymer, the signals assigned to the allyl group completely disappeared after the reaction, while the methylene protons of the 3-mercaptoacetic acid unit were clearly observed at 1.84 ($CH_2C\underline{H_2}CH_2S$), 2.60 ($SC\underline{H_2}CH_2COOH$), 2.62 ($C\underline{H_2}SCH_2CH_2COOH$), and 2.79 ppm ($CH_2SCH_2C\underline{H_2}COOH$), respectively. In addition, the structure of the resulting polymer after the carboxylation reaction was confirmed by ^{13}C NMR. The corresponding carbon signals of the terminal groups appeared at δ 173.0 ((a) $CH_2\underline{C}OOH$), 50.4; ((j) $\underline{C}H_2N_3$), 34.5; ((b) $\underline{C}H_2COOH$), 29.6; ((e) $CH_2\underline{C}H_2CH_2S$), 28.5; ((d) $CH_2CH_2\underline{C}H_2S$), and 26.9; ((c) $S\underline{C}H_2CH_2COOH$) ppm, respectively, and no signal corresponding to allyl group was detected (Figure 3). These results indicate the successful preparation of heterobifunctional PEG possessing azido and carboxyl groups at the chain ends.

In conclusion, the facile and quantitative synthesis of azido-containing heterobifunctional PEGs via EO polymerization was demonstrated in this study. These azido-containing PEGs can be used to Cu(I)-catalyzed 1,3-dipolar cycloaddition reaction (click chemistry) to introduce versatile biofunctional ligands into the azido terminus, and are thus relevant to a wide range of applications in the field of bioconjugate chemistry. We focused here on the PEG with MW of 5000 because of its versatility in bioconjugate applications, including liposome modification, polymeric micelle formation, and protein conjugation. Basically, chemistry developed here may be applicable to PEG with even higher MW, because the reaction scheme may not be directly influenced by the MW. Nevertheless, the quantitative conversion is still in an issue for the higher MW PEG due to the limited availability of the chain end possibly buried in the coil of PEG strands. We feel that this issue may be better addressed in a future study directly focusing on the reactivity of the allyl group located at the chain end of PEG with different molecular weights.

Effective surface immobilization is a prerequisite for numerous carbohydrate-related studies including carbohydrate–biomolecule interactions. In the present work, we report a simple and rapid modification technique for diverse carbohydrate types in which direct oriented immobilization onto a gold surface is accomplished by coupling the amine group of a thiol group-bearing aminophenyl disulfide as a new coupling reagent with an aldehyde group of the terminal reducing sugar in the carbohydrate. To demonstrate the generality of this proposed reductive amination method, we examined its use for three types of carbohydrates: glucose (monosaccharide), lactose (disaccharide), and GM1 pentasaccharide. Through successful mass identifications of the modified carbohydrates, direct binding assays on gold surface using surface plasmon resonance and electrochemical methods, and a terminal galactose-binding lectin assay using atomic force microscopy, we confirmed several advantages including direct and rapid one-step immobilization onto a gold surface and exposure of functional carbohydrate moieties through oriented modification of the terminal reducing sugar. Therefore, this facile modification and immobilization method can be successfully used for diverse biomimetic studies of carbohydrates, including carbohydrate–biomolecule interactions and carbohydrate sensor or array development for diagnosis and screening.

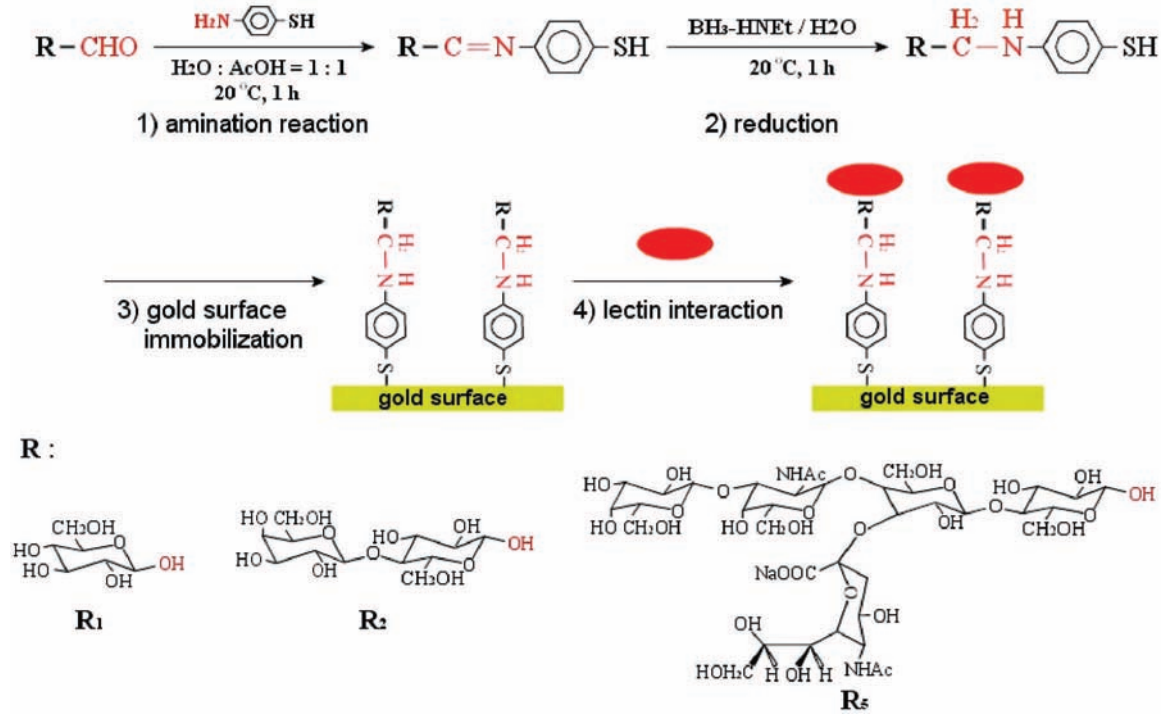
INTRODUCTION

Carbohydrates encode information for specific molecular recognition, help determine protein folding, stability, and pharmacokinetics, play critical roles in determining biological functions, and affect diverse physiological processes (*1–4*). In addition, carbohydrate–protein interactions have been used to elucidate fundamental biochemical processes and identify new pharmaceutical substances in living cell systems (*1–4*). In order to fully study specific carbohydrate interactions with biomolecules such as proteins, DNA, and other carbohydrates in the cell, researchers need effective methods for carbohydrate immobilization (*5–8*).

To date, modification for carbohydrate immobilization has been attempted using several techniques, including copolymerization, coupling with divinyl sulphone, coupling to CNBr-activated substrates, and reductive amination (*9, 10*). However, although these modification methods have demonstrated promising results, general usefulness for diverse carbohydrate types has not been proven (*11, 12*). Previous studies have mainly focused on mono and/or disaccharides, with a few attempts made to immobilize oligo or polysaccharides, because of their structural complexity and problems with severe structural deformity during modification (*13–15*). Therefore, more advanced methods including alternative surface modification have been developed for diverse carbohydrate types (*6, 16–20*). However, these strategies also have tended to be multistep protocols aimed at indirect immobilization. Especially, for biosensor applications, it is desirable to directly and rapidly immobilize various carbohydrates on surfaces by one-step protocols.

Successful surface immobilization of carbohydrates has been further complicated by the need to retain the original structure and expose the functional sites so that the immobilized molecule can mimic the specific biomolecular interactions occurring on the cell surface. Because carbohydrates do not have functional groups for orientation, it has proven technically challenging to immobilize carbohydrates (especially oligo and polysaccharides) in an oriented fashion while retaining their inherent structures and functionalities (*11,12*). Therefore, we sought to develop a method for orienting and immobilizing various carbohydrate types directly and rapidly onto a gold surface that will allow specific carbohydrate–biomolecule recognition. Immobilization of carbohydrates on gold surface can be easily applicable for gold-based biosensors, such as electrochemical (EC) sensors, surface plasmon resonance (SPR), and quartz crystal microbalances (QCM).

We herein report a simple and rapid reductive amination technique by using aminophenyl disulfide as a new coupling reagent for diverse carbohydrate types in which orientation is accomplished by coupling a thiol (-SH) group to the terminal reducing sugar of the carbohydrate, and the oriented carbohydrate is directly immobilized onto a bare gold surface (Scheme 1). To show the generality of our proposed modification/immobilization method, we examined its use for three types of carbohydrates having terminal reducing sugar moieties, namely, glucose (monosaccharide), lactose (disaccharide), and GM1 pentasaccharide. We also demonstrated the interaction of a representative protein with carbohydrates surface-immobilized using our method (Scheme 1).



EXPERIMENTAL PROCEDURES

Carbohydrate Modification. Glucose (Sigma), lactose (Sigma), and GM1 pentasaccharide (Alexis Biochemicals) at 100 mM each were separately dissolved in water, and 50 mM aminophenyl disulfide (Aldrich) was dissolved in acetic acid.

Scheme 1. Strategy for the Modification and Direct Immobilization of Various Carbohydrate Types[a]

[a] Modified SH-saccharides can be directly immobilized on gold and interact specifically with lectin. R_1, glucose (monosaccharide); R_2, lactose (disaccharide); R_5, GM1 pentasaccharide.

The carbohydrate and aminophenyl disulfide solutions were mixed well and incubated in sealed tubes for 1 h at 20 °C (glucose and lactose) or 30 °C (GM1 pentasaccharide) for the amination reaction step. Then, freshly prepared reducing reagent, 100 mM dimethylamine borane (Fluka), was added to each reaction, and the tubes were incubated unsealed for 1 h at 20 °C for the reduction step. The tubes were then resealed and heated for 1 h at 50 °C under nitrogen gas steaming for the condensation step. All modified carbohydrates were dissolved in 5% acetic acid solution and preserved at −20 °C under light-blocking conditions. Without further purification steps, modified samples were used for MALDI-TOF MS analysis and immobilization.

Mass Identification Using MALDI-TOF MS. To improve the ionization efficiency of MALDI-TOF MS, the samples were desalted using Zip-tip C18 (Millipore) and then eluted onto MALDI target plates using matrix solution (10 mg/mL; α-cyano-4-hydroxycinnamic acid dissolved in a solution consisting of 50% acetonitrile and 0.5% trifluoroacetic acid). All mass spectra were acquired in reflection mode using a 4700 Proteomic Analyzer (Applied Biosystems) at Korea Basic Science Institute. Spectra were obtained in the mass range between 100 to 2000 Da with ~200 laser shots. Internal calibration was performed with 4700 Cal Mix (Applied Biosystems).

SPR-Based Immobilization Analysis. All SPR experiments were performed using a Biacore 2000 instrument (Biacore AB) with a flow system that loaded the solutions as discrete channels. The SIA Kit Au (Biacore AB) was used as the bare gold surface for the direct immobilization of modified SH-containing carbohydrates. The flow rate for binding onto the gold surface was 5 μL/min, and a noninjected channel was used as the baseline. Immobilization was performed by injecting 60 μL of each sample onto the gold surface, and immobilized carbohydrate amounts were measured as RU. All measurements were performed in HEPES-EP buffer (Biacore AB; 10 mM HEPES at pH 7.4, 150 mM NaCl, 3 mM EDTA, and 0.005% surfactant F20).

EC-Based Immobilization Analysis. EC experiments were performed using a BAS 100 B/W potentiostat (Bioanalytical System) at room temperature. The biosensor consisted of an 8-multielectode chip comprising an array of 200-nm diameter gold electrodes on glass (*21–23*). Modified GM1 pentasaccharide (1 μL at 5 mM in HEPES-buffered saline) was directly immobilized onto the multigold electrodes for 1 h at room temperature, and unmodified GM1 pentasaccharide (1 μL at 5 mM) was loaded as a negative control. Electrode pretreatment was carried out for 3 min at 1.8 V in 10 mM H_2SO_4. All CV measurements were performed in solutions containing 5 mM $K_3Fe(CN)_6$ at a scan rate of 100 mV/s. A solid bar of Ag/AgCl in 100 mM KCl and a 5-mm diameter platinum wire were used as the reference and the counter electrode, respectively. The SWV curves were recorded at a 10 mV/s scan rate with a pulse height of 25 mV and a step time of 0.2 s.

Lectin Interaction Analysis Using AFM. We deposited a layer of 99.5% pure Au(111) on a cleaved mica surface using a high speed vacuum (base pressure, 5×10^{-7} Pa) at 450 °C. After the immobilization of SH-GM1 pentasaccharide onto the gold surface, we added 20 mg/mL of galectin (Biovision) and incubated the samples for 1 h. Topology was imaged using Multimode DI AFM (Veeco Instruments).

RESULTS AND DISCUSSION

For the efficient immobilization of diverse carbohydrate types onto a bare gold surface, we used an amination reaction to couple the aldehyde (-CHO) group of the carbohydrate's terminal reducing sugar with the amine ($-NH_2$) group of a thiol-bearing aminophenyl disulfide (Scheme 1). A reductive amination reaction, namely, coupling the aldehyde group of a carbohydrate's terminal reducing sugar with the amine group of 2-aminopyridine, is commonly used for pyridylamination tagging of glycans with 2-aminopyridine in order to facilitate their purification and molecular weight analysis (*13, 14, 24, 25*).

In the present work, we found that mono and disaccharides could be modified at 20 °C reaction temperature, whereas modification of GM1 pentasaccharide was successful at 30 °C. This may suggest that a comparatively higher reaction temper-

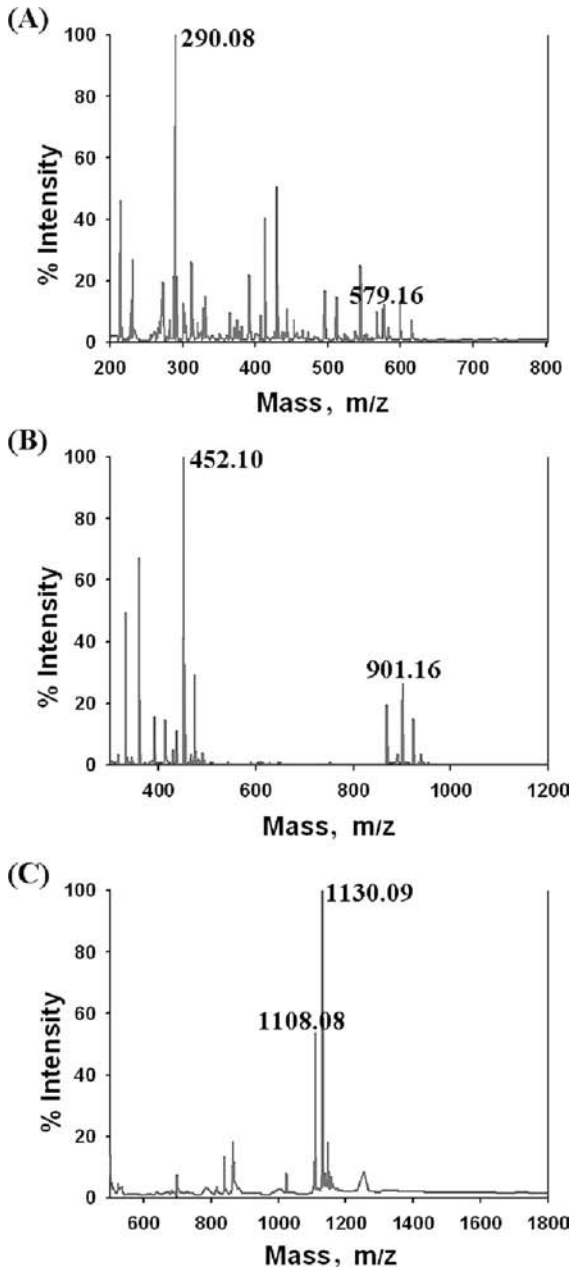

Figure 1. MALDI-TOF MS analysis of SH-modified monosaccharide glucose (A), disaccharide lactose (B), and GM1 pentasaccharide (C).

ature is required to give a higher ratio of an acyclic form of the terminal reducing sugar of complex carbohydrates. We further found that the modification efficiency depended on the concentration of reactants, with experiments containing 100 mM GM1 pentasaccharide showing a higher efficiency than those containing 10 mM of the same carbohydrate at the same concentration (50 mM) of aminophenyl disulfide (data not shown).

To check the feasibility of the modification of target carbohydrates using the proposed reductive amination reaction, we first performed nuclear magnetic resonance spectroscopy (NMR). The NMR spectrum contained features consistent with a -CH_2-NH- moiety (for glucose, ^{1}H NMR [600 MHz, D_2O] δ 3.42–3.48 [3H, m], 3.58–3.62 [5H, m], 6.48 [2H, d, J=8.0 Hz], 7.09 [2H, d, J=8.0 Hz]). We then used matrix-assisted laser desorption–ionization mass spectrometry with time-of-flight (MALDI-TOF MS) analysis to investigate the molecular weights of the modified carbohydrates (Figures 1A–C). Although we used aminophenyl disulfide as the coupling reagent, the modification primarily occurred through the aminophenyl sulfide

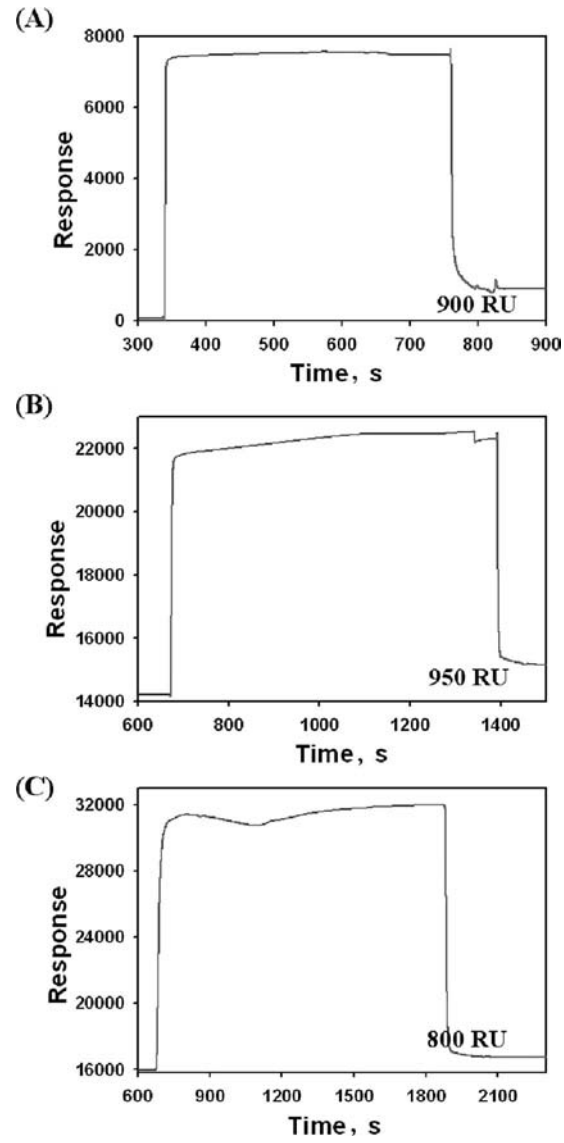

Figure 2. SPR binding assays of SH-modified monosaccharide glucose (A), disaccharide lactose (B), and GM1 pentasaccharide (C).

that might be formed from disulfide bond breakage under acidic (pH 2–3) conditions or reduction of its bond by dimethylamine borane. Therefore, the molecular weights of the modified glucose, lactose, and GM1 pentasaccharide were 290, 452, and 1108 (1130: +Na), respectively. Interestingly, all of the examined samples yielded a double mass value, representing a small peak of modified carbohydrates that had reacted directly with the aminophenyl disulfide. In addition, we also performed the modification of four other types of carbohydrates and confirmed their modifications using mass analyses (data not shown). Overall, these mass analyses confirmed that all of the target carbohydrates were successfully modified.

Without further purification, we then directly immobilized the SH-modified carbohydrates onto a gold surface. All of the SH-modified carbohydrates showed successful binding on the gold surface, as assessed by SPR binding assays (Figure 2A–C). Since the mass of lactose is somewhat higher than that of glucose at the same mole concentration, the resonance unit (RU) value of SH-lactose (950 RUs) was slightly higher than that of SH-glucose (900 RUs). In the case of GM1 pentasaccharide, although we used a carbohydrate concentration of 100 mM for the modification step, we diluted the SH-GM1 pentasaccharide 10-times for immobilization because of its limited available amount. Although GM1 pentasaccharide has a much higher

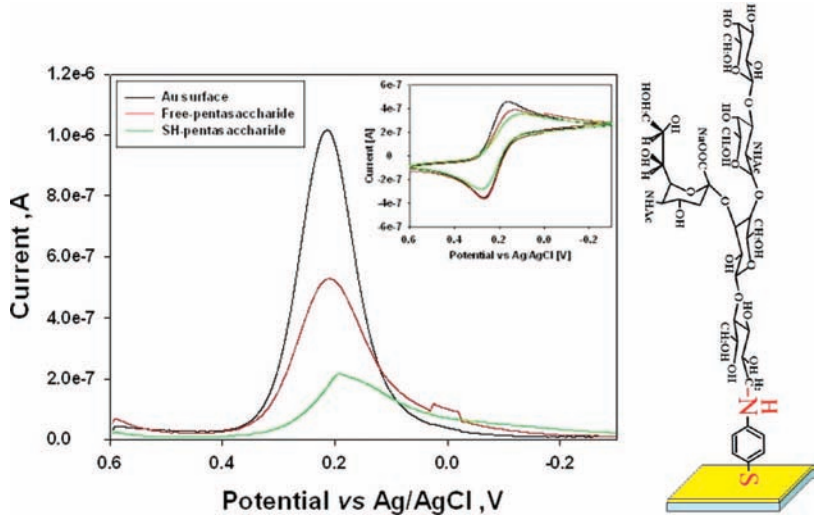

Figure 3. EC response of gold electrodes bound with unmodified GM1 pentasaccharide (red line) and modified SH-GM1 pentasaccharide (green line) compared to that of the bare gold electrode (black line). Inset, CV; main figure, SWV. The schematic illustration represents immobilization of modified SH-GM1 pentasaccharide on the gold surface.

molecular weight than glucose or lactose, the RU value was lower (800 RUs) because the utilized concentration was one-tenth that used in the other experiments. Collectively, these findings indicate that all of the SH-modified carbohydrates were successfully immobilized onto the gold surface without requiring additional treatment steps.

To further evaluate the direct immobilization of SH-modified carbohydrates onto the gold surface, we used EC analysis, which has the advantages of easy detection and high sensitivity at low concentrations (*19–21*) and which might be a useful tool for practical application as a carbohydrate sensor that needs high sensitivity due to very low portion of carbohydrates in the cellular materials. EC analysis was used to obtain the cyclic voltammetry (CV) and square wave voltammetry (SWV) curves from SH-modified and unmodified GM1 pentasaccharide exposed to 200-μm diameter gold electrodes (Figure 3). The CV measurements showed that the EC responses were significantly enhanced for immobilized SH-GM1 pentasaccharide (Figure 3, inset). The peaks and dips in the redox current of the CV signal showed the typical oxidation and reduction responses in the electrolyte of $K_3Fe(CN)_6$. The SWV curves (Figure 3, main figure) revealed that the limiting redox current decreased from 1.05 on the bare gold electrode to 0.2 μA in the presence of immobilized SH-GM1 pentasaccharide. The change ratios of the redox currents of bare gold electrodes in the presence or absence of unmodified or SH-modified GM1 pentasaccharide were ~45% and ~80%, respectively. This clearly showed that the EC signal ratio changed in response to carbohydrate immobilization, indicating that EC could have potential carbohydrate sensor applications. The reduced redox current is due to the decrease in reactive surface area exposed to the electrolyte. Notably, while the current ratio decreased to some extent in the presence of unmodified GM1 pentasaccharide, likely due to physical adsorption from the relatively small carbohydrate size, the redox current was almost completely blocked by the binding of SH-GM1 pentasaccharide to the gold electrode. Future systematic studies may be warranted to examine additional levels of control that may be exerted over this physical adhesion. Therefore, these results collectively indicate that our proposed method is a highly efficient strategy for immobilizing carbohydrates to the tested substrate.

Although the structure of the terminal reducing sugar is changed to the acyclic form by coupling of the aldehyde and amine groups (see Scheme 1), this should not be a problem in long chain carbohydrates such as GM1 pentasaccharide because the generation of the acyclic form only occurred at the surface-linked terminal sugar. A previous study showed that galactose and sialic acid, two terminal sugars of the branched GM1 pentasaccharide, exhibited substantial specific binding interactions (~39% from galactose and ~43% from sialic acid), with a smaller contribution (~17%) arising from the *N*-acetyl galactosamine residue (*26*). However, the central galactose and terminal reducing glucose residues do not appear to make direct interactions with the receptor protein (*26*), indicating that the terminal reducing and central sugars are more likely to act as bridges or linkers. Accordingly, we examined the binding of GM1 pentasaccharide to its terminal galactose-binding lectin, galectin, by topology analysis using atomic force microscopy (AFM) (Figure 4). Our results revealed that galectin did not bind in the case of unmodified, nonimmobilized GM1 pentasaccharide (Figure 4A), whereas galectin was clearly detected as a white spot on SH-GM1 pentasaccharide-immobilized gold

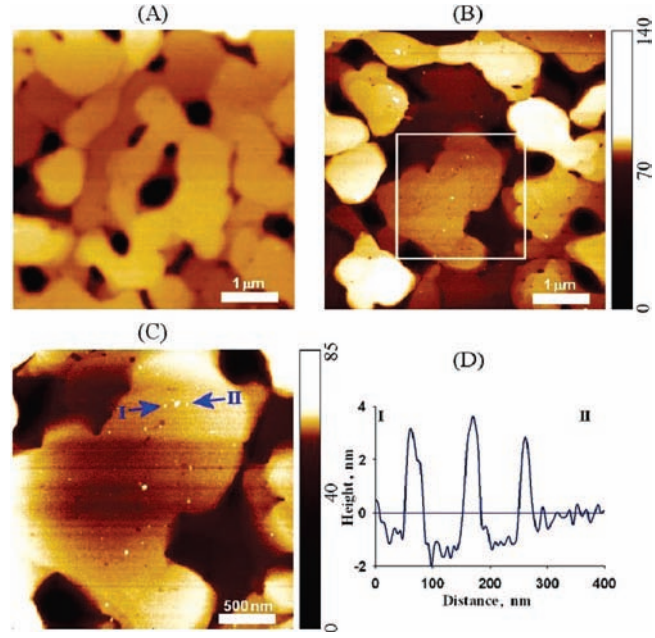

Figure 4. AFM analysis of the GM1 pentasaccharide–galectin interaction on Au(111). (A) Unmodified pentasaccharide, (B) modified SH-pentasaccharide, (C) magnified image of box in B, and (D) line profile of the SH-modified GM1 pentasaccharide–galectin interaction.

(Figure 4B and C). Line profile analysis revealed that the protein spots were 3–4 nm in size (Figure 4D). Importantly, since galectin should interact with only the terminal galactose, these findings confirmed that the modified carbohydrate had been successfully immobilized with the proper orientation.

In the present work, we kept our method simple by using aminophenyl disulfide as both the coupling reagent and the linker. In the future, the use of a longer coupling reagent might help increase the flexibility and receptor binding of the target carbohydrate. However, since increasing the length of the alkyl chain group can change the hydrophobicity of the molecule, the use of an overly long chain could inhibit carbohydrate modification. One of the advantages of our immobilization method is that only the terminal reducing sugar is specifically coupled with the linker reagent, so that the functional sites (e.g., biomolecule recognition or binding sites) of the carbohydrate can be preserved.

In summary, we herein demonstrated that the amine group of thiol-bearing aminophenyl disulfide was successfully coupled with the aldehyde group of the terminal reducing sugar in three types of carbohydrates, namely, glucose (monosaccharide), lactose (disaccharide), and GM1 pentasaccharide. The proposed modification method has several advantages over previously reported methods, including direct and rapid one-step immobilization onto a gold surface without surface pretreatment(s) by thiol group coupling in a mild reaction environment and exposure of functional carbohydrate moieties through oriented immobilization of the terminal reducing sugar. This modification and immobilization method should prove useful for diverse biomimetic studies in carbohydrates, including carbohydrate–biomolecule interaction and carbohydrate sensor or array development for diagnosis and screening.
