Fluorescence Visualization/Histological Processing. Poly(ethylene glycol)−amino conjugated 705 nm emitting quantum dots (QDs) were sonicated for 10 min prior to injection. Superficial CAM veins were injected with 20−25 μL QDs using an aspirator tube assembly (Sigma) and borosilicate capillaries (Sutter Instruments, Novato, CA) that were pulled into microneedles using a model P-87 micropipette puller (Sutter Instruments, Novato, CA).

After QD injection, the fibrin construct and surrounding CAM were excised and fixed in 1% glutaraldehyde and 3% paraformaldehyde (Electron Microscopy Sciences, Hatfield, PA) in PBS for 3 h at room temperature followed by three 5 min washes in PBS. Samples were sectioned in the perpendicular plane in relation to their original orientation on the CAM at 300 μm thicknesses using a vibratome VT 1000S (Leica, Wetzlar, Germany). Each resulting section is a cross section containing the fibrin construct and underlying CAM. Sections were mounted on glass microslides including a coverslip and imaged for QD fluorescence using a Zeiss Axioplan 2 (Thornwood, NY) epifluorescence microscope with a 2.5× objective (0.12NA), Zeiss AxioCam MRm CCD camera, and Zeiss *AxioVision* acquisition software v 4.3. Cy3 and 705 nm QDs were imaged using Ex:Em 540/25:620/60 and 460spuv:705/40 filter sets (Chroma, Rockingham, VT), respectively.

Vibratomed sections of interest were prepared for transmission electron microscopy (TEM) analysis. The section was washed with three changes of PBS followed by fixation with 1% OsO_4 buffered with PBS for 30 min at room temperature. After osmium fixation, sections were washed with three changes of dH_2O and dehydrated with an ascending series of ethanol (50%, 70%, 80%, 90%, and 100%). Propylene oxide was used as a transitional solvent, and the specimens infiltrated with LR White (London Resin Company, Reading, Berkshire, England). The LR White was polymerized at 60 °C for 48 h. Thin (100 nm) sections were cut using a diamond knife on a Reichert-Jung Ultracut E ulatramicrotome (Leica, Wetzlar, Germany), picked up using copper grids, and stained with uranyl acetate and lead citrate. The grids were viewed on a Hitachi H-7100 transmission electron microscope (Pleasanton, CA) operating at 50 kV. Digital images were obtained using an AMT Advantage 10 CCD Camera System (Advanced Microscopy Techniques Corporation, Danvers, MA) and NIH *Image* software.

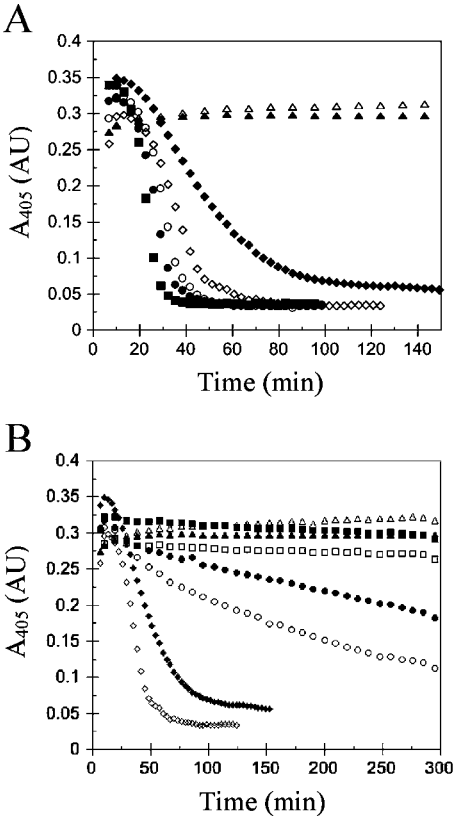

Figure 2. Plasmin degradation of fibrin gels. Fibrin gels containing indicated levels of aprotinin and plasmin in 96 well plates were followed over time by absorbance at 405 nm. The experiment was performed in triplicate. A representative data set was split into two panels for clarity. A: Fibrin gels (1 mg/mL) subjected to 100 nM plasmin containing 5 (circles) and 10 (diamonds) nM soluble (● and ◆) or fibrinogen-conjugated (○ and ◇) aprotinin. Fibrin (▲) and aprotinin-conjugated (30 nM) fibrin (△) controls were not subjected to plasmin, and the plasmin control (■) contained no aprotinin. B: Data from the same experiment as in panel A showing fibrin gels subjected to 100 nM plasmin containing 10 (diamonds), 30 (circles), and 50 (squares) nM soluble (◆, ●, and ■) or fibrinogen-conjugated (◇, ○, and □) aprotinin. The same fibrin controls from A are also shown.

Scanning Electron Microscopy. Gels were made in the same manner as for the ex ovo CAM assay: 17 mg/mL fibrinogen, 10 ng/mL FGF-2, and 61.7 nM thrombin containing 0, 5, 10, 30, 50, and 150 nM of either soluble aprotinin or aprotinin conjugated to fibrinogen. Gels were fixed overnight in 1% glutaraldehyde and 3% paraformaldehyde in PBS followed by three 5 min washes in PBS. Samples were then fixed in 1% OsO_4 buffered with PBS. The OsO_4 was removed with three 5 min washes with dH_2O, followed by dehydration in an ascending series of ethanol (50%, 70%, 80%, 90%, and three changes of 100%). The samples were held in each ethanol wash for 10 min and then held in 100% ethanol overnight. Samples were dried in a Pelco CPD2 critical point dryer (Clovis, CA) and using CO_2 at 1200 psi and 42 °C. Dried samples were attached to SEM stubs using double-sided tape and coated with gold using a Pelco SC-6 sputter coater. Specimens were examined using a Hitachi 2460N scanning electron microscope (Pleasanton, CA). Digital images were obtained using *Quartz PCI* software (Vancouver, BC, Canada).

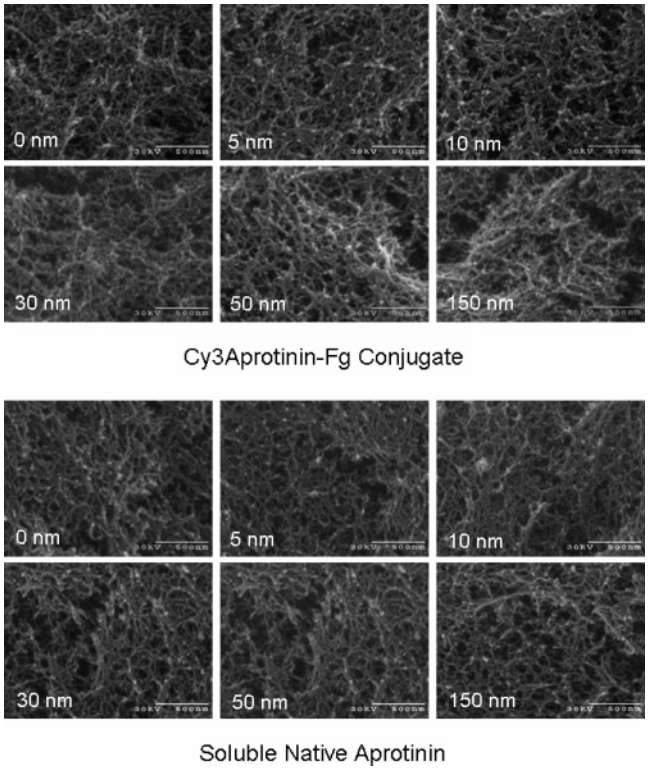

Figure 3. Aprotinin does not affect fibrin structure. 17 mg/mL fibrin gels containing 0, 5, 10, 30, 50, and 150 nM of either fibrinogen-conjugated aprotinin (top panel) or soluble aprotinin (bottom panel) were analyzed by SEM. No significant differences were seen within a sample group or between the soluble aprotinin-containing gels and the conjugated aprotinin-containing gels.

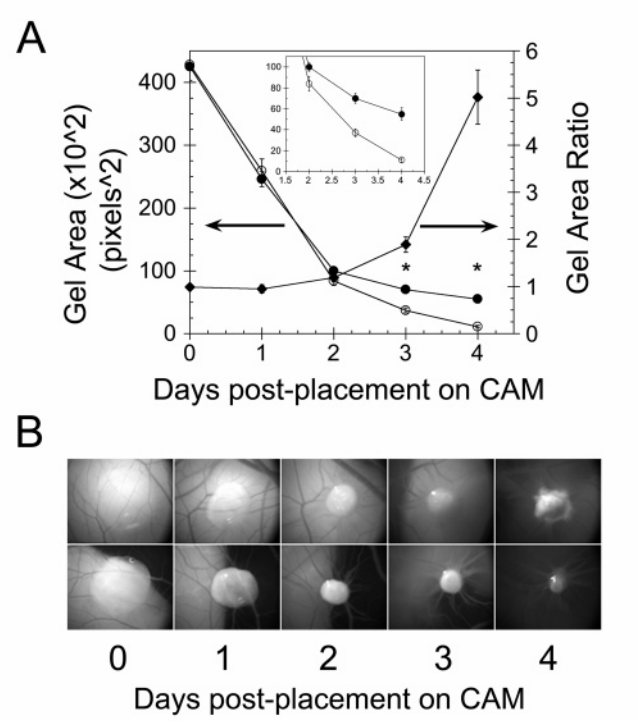

Figure 4. Degradation of conjugated and nonconjugated aprotinin fibrin in the chick CAM assay. A: Fibrin gels containing 10 ng/mL FGF-2 and either 1 μg/mL conjugated or nonconjugated aprotinin were placed on the CAM of 10 day old embryos. Images of the gels were obtained over 4 days using bright field microscopy, and gel areas were calculated using *Image J* software. Data represent the average area over time ± SEM ($n = 12$ each, aprotinin-conjugated and nonconjugated gels). B: A representative image set of the data shown in panel A. Images in the top and bottom rows are of gels containing conjugated and nonconjugated aprotinin, respectively. Asterisks indicate statistical significance ($P \leq 0.05$).

RESULTS

Fibrin concentrations used in these experiments were on the same order as those used in clinical fibrin glues (*22*, *24*). These constructs, however, typically degraded within 5 days post-placement on the CAM. We hypothesized that blood vessels did not invade the fibrin because it was degraded too quickly. Aprotinin was added to our constructs to slow degradation but due to its small size quickly diffused out of the construct and no longer conferred protection. In fact, constructs containing no aprotinin demonstrated the same residence time on the CAM as constructs containing 1 μg/mL of aprotinin, a typical concentration used in clinical settings (data not shown). In an effort to retain plasmin inhibition, and thus inhibit fibrin degradation, we chemically conjugated aprotinin to fibrinogen (Figure 1).

Aprotinin was conjugated to fibrinogen using a cysteine-based trifunctional cross-linker (Figure 1). Cy3 was co-conjugated as a reporter of construct localization as well as a tool for quantitating conjugated aprotinin levels. To minimize possible interference with aprotinin activity, the Cy3 was not linked directly to the aprotinin. Similarly, aprotinin's N-terminus was chosen as the cysteine conjugation site due to its location opposite the plasmin binding site. The conjugate molecule was linked to fibrinogen's glycosylation sites for two reasons: (*1*) these sites serve to limit the number of linkages that can occur and (*2*) the antenna-like structure of the sugar moieties may possibly serve to better display the aprotinin to "intercept" plasmin. At this point, the construct has been successfully synthesized three out of five times. For this work, the construct aprotinin/fibrinogen molar ratio was approximately 5:1.

The aprotinin-conjugated fibrinogen was first tested in an in vitro microplate absorbance assay. Absorbance-based assays have been extensively used to study fibrin structure, gelation, and fibrinolysis (*23*, *25*, *26*). Fibrin gels containing plasmin were made with varying levels of soluble aprotinin and compared to gels containing conjugated aprotinin to theoretically equal levels. Variable aprotinin addition, both soluble and conjugated, was able to tune fibrin degradation times from just a few minutes to many hours (Figure 2A,B). The data also show that at equal concentrations the immobilized aprotinin has a lower (approximately 2-fold) but comparable activity to its soluble-form counterpart. As controls, cysteine, Cy3, and the MPBH cross-linker were assayed at concentrations equivalent to the 30 nM conjugated aprotinin test case. None were found to significantly inhibit degradation over the plasmin-only control (data not shown).

The effect of soluble vs conjugated aprotinin on fibrin structure was further examined by scanning electron microscopy (Figure 3). 17 mg/mL gels containing the indicated aprotinin levels were examined, and aprotinin levels were not shown to significantly alter fibrin structure. More importantly, there was no difference seen between soluble and conjugated aprotinin-containing samples. Therefore, these results would indicate that the effects of the conjugated aprotinin were due to aprotinin's anti-proteolytic activity rather than an indirect effect due to fibrin structural changes.

We next tested the aprotinin-conjugated fibrinogen in an in vivo setting—the chick CAM assay. Fibrin gels containing either soluble or conjugated aprotinin at 1 μg/mL (154 nM), a concentration typically used in clinical application, were placed on the CAMs of ten day old embryos. FGF-2 was added to induce an angiogenic response and along with it fibrin degradation. Images of the gels were acquired every 24 h for 4 days

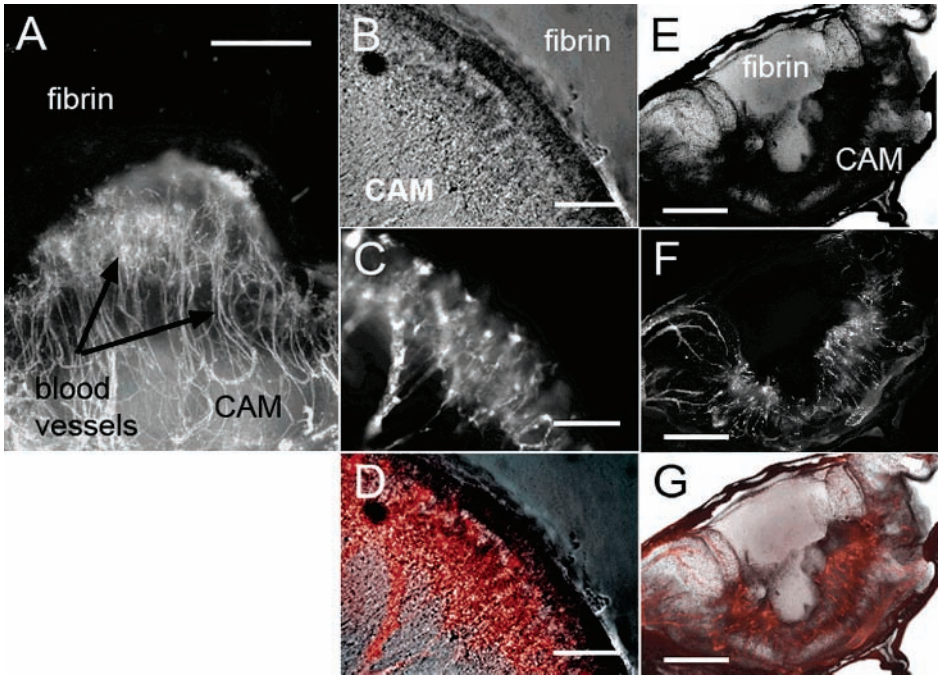

Figure 5. Blood vessel response to fibrin containing soluble aprotinin. Fibrin gels containing 10 ng/mL FGF-2 and 154 nM aprotinin were placed on the CAM of 10-day old embryos. Three (A−D) or four (E−G) days post-placement 705 nm emitting quantum dots were intravitally injected. Fibrin and connected CAM were excised, fixed in 3% paraformaldehyde in PBS, vibratomed to 300 μm thickness, and imaged on a Zeiss Axioplan 2 epifluorescence microscope. A: Fibrin and underlying CAM showing blood vessel fluorescence. B−D: Interfacial area between CAM and fibrin construct. B,C: Bright field (E) and QD-labeled blood vessel fluorescence (F) images. G: Overlay of images in E and F with QD fluorescence artificially colored red. Overlay shows blood vessels follow invasion front. E−G: Bright field (D) and QD-labeled blood vessel fluorescence (E). F: Overlay of images in D and E with QD fluorescence artificially colored red. Overlay shows blood vessels do not invade the construct. Scale bars are 200 μm in A−D and 50 μm in E−G.

using a stereomicroscope. Because we could not determine fibrin volumes from these images, we estimated fibrin size from measured fibrin areas (Figure 4).

Two distinct modes of area loss are seen. Gel area is greatly reduced during the first 48 h where CAM adhesion and CAM-mediated fibrin gel contraction take place. Both sets of fibrin gels were affected equally. After the initial 48 h, degradation becomes the driving force. At this point, the immobilized aprotinin gels degraded more slowly than the soluble aprotinin gels, and after 4 days were approximately 5 times larger than fibrin-containing soluble aprotinin. Unlike fibrin-containing immobilized aprotinin, by day 5 soluble aprotinin gels were completely degraded.

Finally, we examined the blood vessel response to fibrin gels containing either soluble or conjugated aprotinin. As in the time course, in vivo experiment fibrin gels (17 mg/mL) containing FGF-2 and either soluble or conjugated aprotinin were placed on the CAMs of ten day old chick embryos. Three or four days later, 705 nm emission quantum dots were intravitally injected, and the fibrin and connected CAM were excised, fixed, and vibratomed as described in the Materials and Methods. Fibrin gels containing soluble aprotinin demonstrated no direct blood vessel invasion into the construct (Figure 5). At three days post-placement on the CAM, blood vessels can be seen moving vertically toward the fibrin and then becoming a dense network of vessels at the fibrin interface (Figure 5A). This is most likely due to the effect of FGF-2 being released from the fibrin/CAM interface as the fibrin is degraded. A closeup of the interfacial region in Figure 5A shows that a non-vascularized cellularized zone precedes vascular invasion into the fibrin construct (Figure 5B−D). Additionally, examination of gels at four days post-placement, a time when the gels are almost completely degraded, shows a lack of vessel invasion (Figure 5E−G).

Fibrin gels containing 1 μg/mL conjugated aprotinin were also examined in the same manner. In these experiments, we have the added benefit of a fluorescent fibrin marker, Cy3, to visualize its localization. Samples examined four days post-placement on the CAM showed large-scale vessel invasion into the fibrin construct as visualized by the overlap of blood vessel and fibrin label fluorescence (Figure 6A−C, D−F). Although these samples still maintain substantial amounts of fibrin (Figure 4B), the more slowly degrading fibrin allowed for fibrin degradation and remodeling without complete destruction of the original construct. Interestingly, the rate of fibrin degradation may be important for blood vessel invasion, since areas of low fibrinolysis demonstrated poorer vascularization (Figure 6D,E arrows).

Closer examination of these samples by TEM shows the fibrin degradation and replacement by newly forming CAM-derived tissue. Blood vessels were confirmed by TEM analysis (Figure 6G); however, most of the vessels examined failed to have recruited pericytes or smooth muscle cells, an indication of their immaturity. Additionally, we observed multiple cell types as well as the production of new collagen fibers (Figure 6H,I).

DISCUSSION

In this work, we created a novel synthesis strategy for protein conjugation. This method is somewhat complex and not without its difficulties. The initial linkage of cysteine to Cy3 is quite straightforward (Figure 1, species I). On the other hand, the reaction to create species II (Figure 1) was a slow process and suffered from lower yields. Also, monitoring of the reaction by SDS-PAGE was difficult due to the small molecular weight differences between the reaction products. Most importantly, the synthesis was troubled by a lack of confirmation of aprotinin conjugation with MPBH. The two reported synthesis failures were due to this problem. Current work is focusing on improving synthesis speed and efficiency with positive results.

In the in vitro assay, the conjugated aprotinin had comparable activity to the soluble form (Figure 2). Due to the high aprotinin

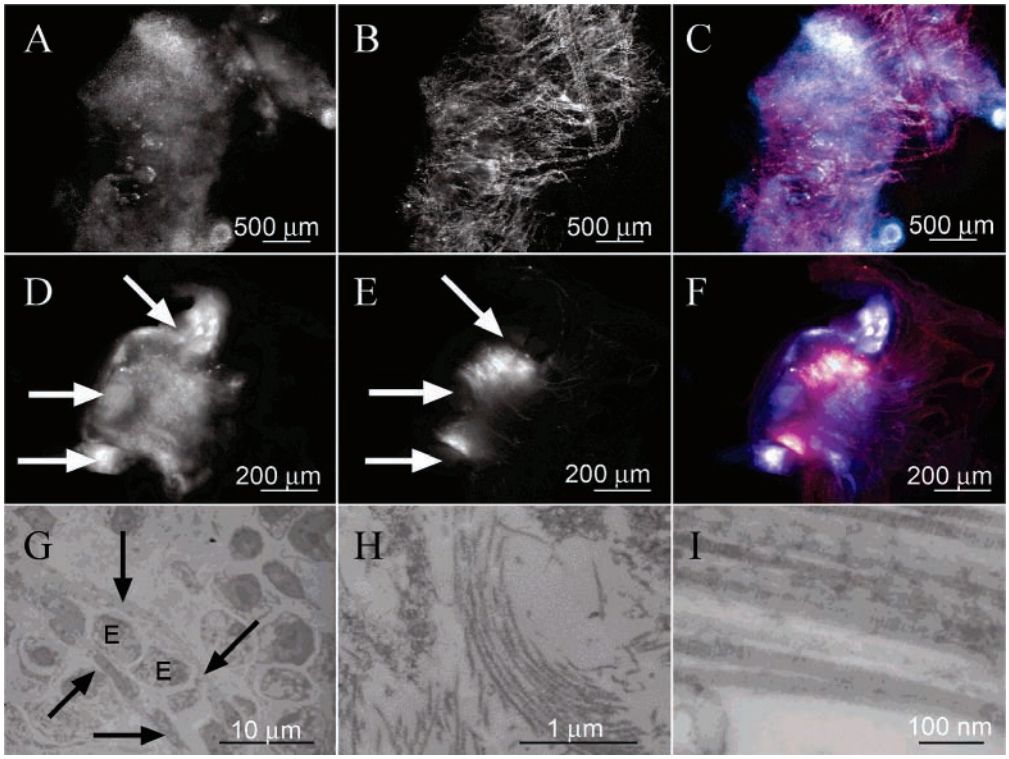

Figure 6. Blood vessel response to fibrin containing conjugated aprotinin. Fibrin gels containing 10 ng/mL FGF-2 and 154 nM conjugated aprotinin were placed on the CAM of 10 day old embryos. Four days post-placement, 705 nm emitting quantum dots were intravitally injected. Fibrin and connected CAM were excised, fixed in 3% paraformaldehyde in PBS, vibratomed to 300 μm thickness, and imaged on the Zeiss Axioplan 2. Cy3 fibrin label (A,C,D,F) and QD blood vessel label (B,C,E,F) fluorescence images of two sections from individual fibrin constructs (A−C and D−F). Fluorescence overlays (C,F) show the blood vessels (red) have invaded the fibrin construct (blue). Sections shown are derived from the central region of each sample. Arrows in D,E indicate higher-density fibrin areas. The sample shown in D−F was processed for TEM analysis revealing immature blood vessels (G) and collagen fiber production (H,I). G: Arrows indicate capillary endothelial cells. Erythrocytes (E) are seen within the vessel. H: Collagen fiber production and remodeling. I: The banding pattern distinctive of collagen fibers is clearly seen.

labeling ratio, there was only one aprotinin-conjugated fibrinogen for every 50 or 150 unconjugated fibrinogen for the 10 nM and 30 nM aprotinin gels, respectively. It is quite interesting that highly localized and immobilized aprotinin inhibited plasmin with similar efficiency as freely diffusing aprotinin. The small difference in conjugated and soluble aprotinin activity could be due to a number of factors including steric hindrance (i.e., burial of the immobilized aprotinin within fibrin fibrils), inactivation during synthesis, or the inability of the immobilized aprotinins to uniformly protect the fibrin. We are currently examining methods to address the contributions of these factors to conjugated aprotinin activity.

Experiments performed in vitro indicate that not only can varying levels of aprotinin-conjugated fibrinogen control degradation rate but also the conjugated aprotinin does not significantly alter the properties of the gel. Microplate assays demonstrate that gelation and gel absorbance (a measure of fibrin structure) is not significantly impacted by the presence of conjugated aprotinin over soluble aprotinin (Figure 2). Also, SEM analysis shows that, indeed, the fibrillar architecture of gels containing soluble or conjugated aprotinin was not significantly different (Figure 3). SEM-analyzed samples were those of identical composition to the in vivo assay. Lower concentrations, such as those tested in the in vitro microplate assay, were not able to be tested due to the fragile nature of those gels and their collapse upon dehydration during SEM sample preparation.

The ratio of aprotinin to fibrinogen molecules is expected to impact cell mediated fibrin degradation. At 1 μg/mL aprotinin with a 4.8:1 aprotinin/fibrinogen labeling ratio, there was only 1 conjugated fibrinogen molecule per 1600 native fibrinogens. These small regions of protease protection within the larger gel space resulted in non-homogeneous globular degradation fragments of fibrin. This can be seen to some degree with the large and small globular patterns of Cy3-fibrin fluorescence in the images in Figures 4 and 6. Lower aprotinin labeling ratios would be expected to create a more homogeneous degradation pattern whose affect on the CAM response has yet to be determined. Thus, varying the inhibitor level or its distribution may represent a method for modulating regenerative responses within tissue engineering applications.

There are differences in the degradation times seen in Figures 2 and 4. Low fibrin concentrations (1 mg/mL) were utilized for the in vitro experiments due to the need to keep low gel absorbances. High concentrations (17 mg/mL) were used for the ex ovo CAM experiments in order to obtain sufficient residence times. The in vitro tests were purely to demonstrate proof of concept and were not meant to be directly translatable into the CAM experiment. Besides, the presence of cells, additional proteases, and other factors make prediction of degradation time a priori impossible. Higher aprotinin concentrations were used in the ex ovo experiments to be comparable to aprotinin levels used in clinical fibrin applications. However, these results do show that the conjugated aprotinin works over a range of fibrin concentrations.

The conjugated aprotinin has at least two potential applications. Because tissue regeneration occurs over different time frames for different tissues, the conjugated aprotinin could be used to optimally tune fibrin degradation over a particular time frame. Additionally, complex constructs could be created with solid free-form fabrication (SFF) (*27*) techniques to specifically control degradation within the construct. This may possibly allow for architectural control of the regenerating tissue, all with the use of fibrin.

The conjugated aprotinin might also be used for temporal growth factor delivery. For example, Richardson et al. (*28*) showed that delivery of vascular endothelial growth factor (VEGF) followed by platelet-derived growth factor (PDGF-BB) from synthetic constructs improved angiogenesis when compared to delivering either growth factor alone or simultaneously. If aprotinin-conjugated fibrin can be patterned (by SFF techniques for example) to degrade more slowly than neighboring, unaltered fibrin, then it is possible that growth factors bound to the aprotinin-conjugated fibrin would be seen by cells after growth factors within nonconjugated fibrin. We tended to see immature vessels within the fibrin construct when using only FGF-2 (Figure 6G); therefore, temporal delivery of PDGF-BB may lead to improved vessel maturity, similar to that seen by Richardson et al. (*28*).

We have presented an approach to engineer fibrin degradation within fibrin constructs, which allows us to better tune degradation rates independent of simply increasing fibrin density, as this may be undesireable or impossible for the particular application. Control remains critical as the presence of too much aprotinin may have deleterious effects in fibrin-glue applications (*29*). The ability to control fibrin degradation, the possibility of temporal growth factor delivery, and/or the manipulation of structural features within a constant fibrin density construct (*27*) is quite intriguing and worth further examination.

ACKNOWLEDGMENT

Albumin-Binding Prodrugs of Camptothecin and Doxorubicin with an Ala-Leu-Ala-Leu-Linker That Are Cleaved by Cathepsin B: Synthesis and Antitumor Efficacy

Björn Schmid,[†,§] Da-Eun Chung,[†,§] André Warnecke,[†] Iduna Fichtner,[‡] and Felix Kratz*[,†]

Tumor Biology Center, Breisacher Strasse 117, 79106 Freiburg, Germany, and Max-Delbrück Centrum, Robert-Rössle-Strasse 10, 13122 Berlin, Germany. Received September 5, 2006; Revised Manuscript Received November 20, 2006

We have recently validated a macromolecular prodrug strategy for improved cancer chemotherapy based on two features: (a) rapid and selective binding of thiol-reactive prodrugs to the cysteine-34 position of endogenous albumin and (b) acid-sensitive promoted or enzymatic release of the drug at the tumor site [Kratz, F., Warnecke, A., Scheuemann, K., Stockmar, C., Schwab, J., Lazar, P., Druckes, P., Esser, N., Drevs, J., Rognan, D., Bissantz, C., Hinderling, C., Folkers, G., Fichtner, I., and Unger, C. (2002) *J. Med. Chem. 45*, 5523−33]. In the present work, we developed water-soluble camptothecin (CPT) and doxorubicin (DOXO) prodrugs that incorporate the peptide linker Ala-Leu-Ala-Leu that serves as a substrate for the tumor-associated protease, cathepsin B, which is overexpressed in several solid tumors. Consequently, two albumin-binding prodrugs were synthesized [EMC-Arg-Arg-Ala-Leu-Ala-Leu-Ala-CPT (**1**) and EMC-Arg-Arg-Ala-Leu-Ala-Leu-DOXO (**2**) (EMC = 6-maleimidocaproic acid)]. Both prodrugs exhibited excellent water-solubility and bound rapidly and selectively to the cysteine-34 position of endogenous albumin. Further in vitro studies showed that the albumin-bound form of the prodrugs was cleaved specifically by cathepsin B as well as in human tumor homogenates. Major cleavage products were CPT−peptide derivatives and CPT for the CPT prodrug and H-Leu-Ala-Leu-DOXO, H-Leu-DOXO, and DOXO for the doxorubicin prodrug. In vivo, **1** was superior to free camptothecin in an HT-29 human colon xenograft model; the antitumor efficacy of prodrug **2** was comparable to that of free doxorubicin in the M-3366 mamma carcinoma xenograft model at equimolar doses.

INTRODUCTION

Both anticancer agents camptothecin (CPT) and doxorubicin (DOXO) are DNA-damaging drugs, which act by inhibiting the progression of the enzymes topoisomerase I (CPT) and II (DOXO), which unwind DNA for transcription. Doxorubicin is one of the most active antineoplastic agents developed to date and shows a broad spectrum of antitumor efficacy against hematological and solid cancers (*1*). Camptothecin gained clinical importance with the development of water-soluble topotecan and irinotecan that have meanwhile been approved for the therapy of colorectal, ovarian, and lung cancer (*2*, *3*).

Even though both agents show significant antitumor activity, their clinical potential is limited by severe side effects, such as myelosuppression, nausea, vomiting, and especially cardiotoxicity with DOXO and gastrointestinal disorders and stomatitis with topotecan and irinotecan. In order to circumvent these limitations and to improve the therapeutic potential of anticancer drugs, several synthetic polymers and proteins have been investigated as drug carriers (*4*−*6*).

We have recently described maleimide-bearing prodrugs of CPT and DOXO that bind in situ to the cysteine-34 position of circulating albumin after intravenous administration and release the drug at the tumor site (*7*, *8*). Albumin is a promising drug carrier because of its passive accumulation in solid tumors due to their high metabolic turnover, angiogenesis, hypervasculature, defective vascular architecture, and impaired lymphatic drainage (*9*). An acid-sensitive prodrug of doxorubicin, i.e., the 6-maleimidocaproyl hydrazone derivative (DOXO-EMCH), demonstrated superior antitumor efficacy compared to the parent compound doxorubicin in several preclinical models. In a recently completed clinical phase I study, DOXO-EMCH exhibited a good safety profile and antitumor efficacy (*10*, *11*).

In our present work, we set out to develop albumin-binding prodrugs of CPT and DOXO that incorporate the cathepsin-sensitive peptide linker Ala-Leu-Ala-Leu. This peptide sequence has been used as an inactivating moiety in several low-molecular-weight DOXO prodrugs, in particular, (CPI-0004Na) by Trouet et al. (*12*) releasing the derivative *N*-(L-leucyl)-doxorubicin that diffuses inside cells where it is cleaved to DOXO as the final product. In addition, Trouet et al. (*13*) have shown that an Ala-Leu-Ala-Leu-linker is cleaved by lysosomal enzymes in vitro. This linker has been integrated in several other conjugates, i.e., in MTX immunoconjugates by Umemoto et al. (*14*) and in human serum albumin (HSA) conjugates of MTX by Fitzpatrick et al. (*15*) to liberate the anticancer agent at the tumor site by unspecific lysosomal enzymes.

Furthermore, Struder et al. (*16*) used this linker to prepare an antibody conjugate with benzyl-EDTA that was efficiently cleaved by cathepsin B and to a lesser degree by cathepsin D. In the work by Michejda et al. (*17*), a pentapeptide Ala-Leu-Ala-Leu-Ala linker was used in a receptor-targeted drug derivative of ellipticine (an ellipticine-peptide conjugate). This linker was cleaved by the aspartate protease cathepsin D between the Ala-Leu bonds releasing Ala- and Ala-Leu-Ala derivatives of ellipticine. Both cathepsins B and D are localized in lysosomes (*18*, *19*), and overexpression in various malignant tumors has been shown, especially in breast cancer (*19*−*21*),

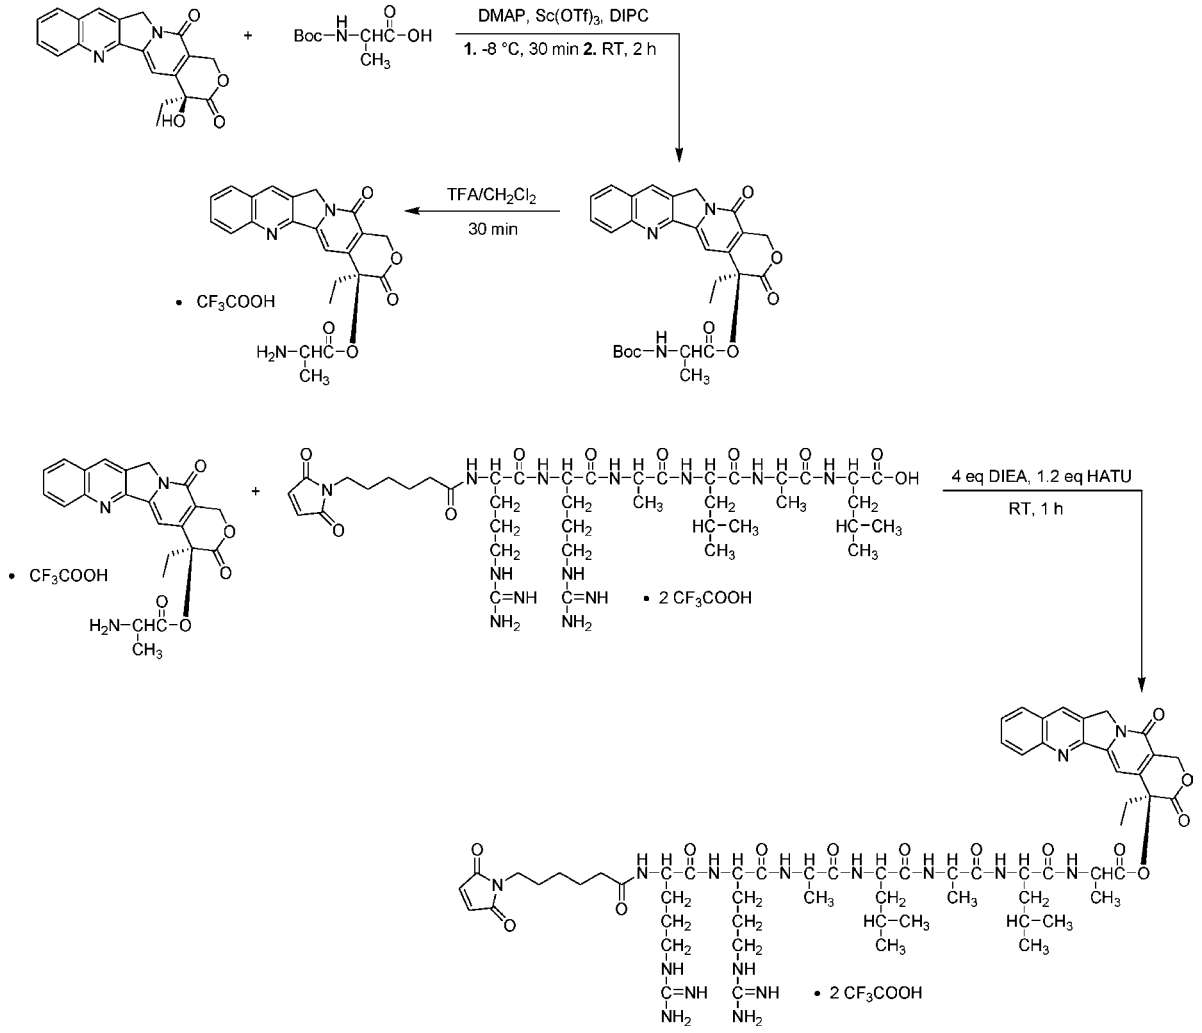
and for cathepsin B also in melanoma (*22*), lung (*23*, *24*), and colon (*25*) carcinoma.

Inspired by this work, we developed albumin-binding prodrugs with DOXO and CPT of the general formula EMC-Arg-Arg-Ala-Leu-Ala-Leu-Ala-CPT and EMC-Arg-Arg-Ala-Leu-Ala-Leu-DOXO [EMC = 6-maleimidocaproic acid] (see Figure 1). Two arginine residues were introduced in the prodrugs to render water solubility, an important prerequisite for intravenous application and in situ coupling to endogenous albumin.

The aim of this work was to assess in detail the pH-dependent cleavage profile of the prodrugs in the presence of cathepsins B and D, as well as in biological fluids, i.e., blood plasma and tumor homogenates, and to evaluate the antitumor efficacy in vivo in comparison to free CPT and DOXO, respectively. Our cleavage studies with the Ala-Leu-Ala-Leu prodrugs showed that they exhibited a distinct cleavage pattern for cathepsin B but not for cathepsin D.

EXPERIMENTAL PROCEDURES

General. Chemicals and solvents were purchased from Sigma-Aldrich, Fluka, Merck, KMF, LGC Promochem, and Roth and were used without further purification. Camptothecin was purchased from Hande Tech Development, Inc. (U.S.A.). Doxorubicin hydrochloride was purchased from Yick-Vic Chemicals & Pharmaceuticals (HK), China. EMC-Arg-Arg-Ala-Leu-Ala-Leu-OH was custom-made by JPT Peptide Technologies GmbH (FRG). Human serum albumin (5% solution) was purchased from Octapharma GmbH. The protein contained approximately 60% free thiol groups as assessed with the Ellmann's test. The buffers used were vacuum-filtered through a 0.2 μm membrane (Sartorius, FRG) and thoroughly degassed with ultrasound prior to use. Enzymatically active cathepsins B and D were purchased from Calbiochem (Bad Soden, FRG). Xenograft tumors were gratefully received from Dr. I. Fichtner (Experimental Pharmacology and Oncology GmbH, Berlin). Lyophilization was performed with a lyophilizator Alpha 2-4 (Christ, FRG).



Spectral Analyses. Mass spectra were obtained on a Thermo Electron LCQ Advantage with associated MAT SS 200 data system using electron spray ionization. UV/vis spectrophotometry was carried out with a double-beam spectrophotometer U-2000 from Hitachi. LC-MS-ESI spectrometry was carried out on a Finnigan LCQ Advantage mass spectrometer (capillary temperature, 300 °C; source-induced dissociation voltage, 25 V; Thermo Electron, Dreieich, FRG) coupled to a Finnigan Surveyor HPLC system (Thermo Electron, Dreieich, FRG) with a Jupiter C_4 column (300-5, 150 × 2 mm, Phenomenex, Aschaffenburg, FRG). Chromatographic conditions: flow, 300 μL/min; mobile phase A, 1% MeCN, 99% H_2O demin, 0.06% TFA; mobile phase B, 100% MeCN, 0.06% TFA; gradient, 15−20 min increase from 10% mobile phase B to 50% mobile phase B; injection volume, 15 μL.

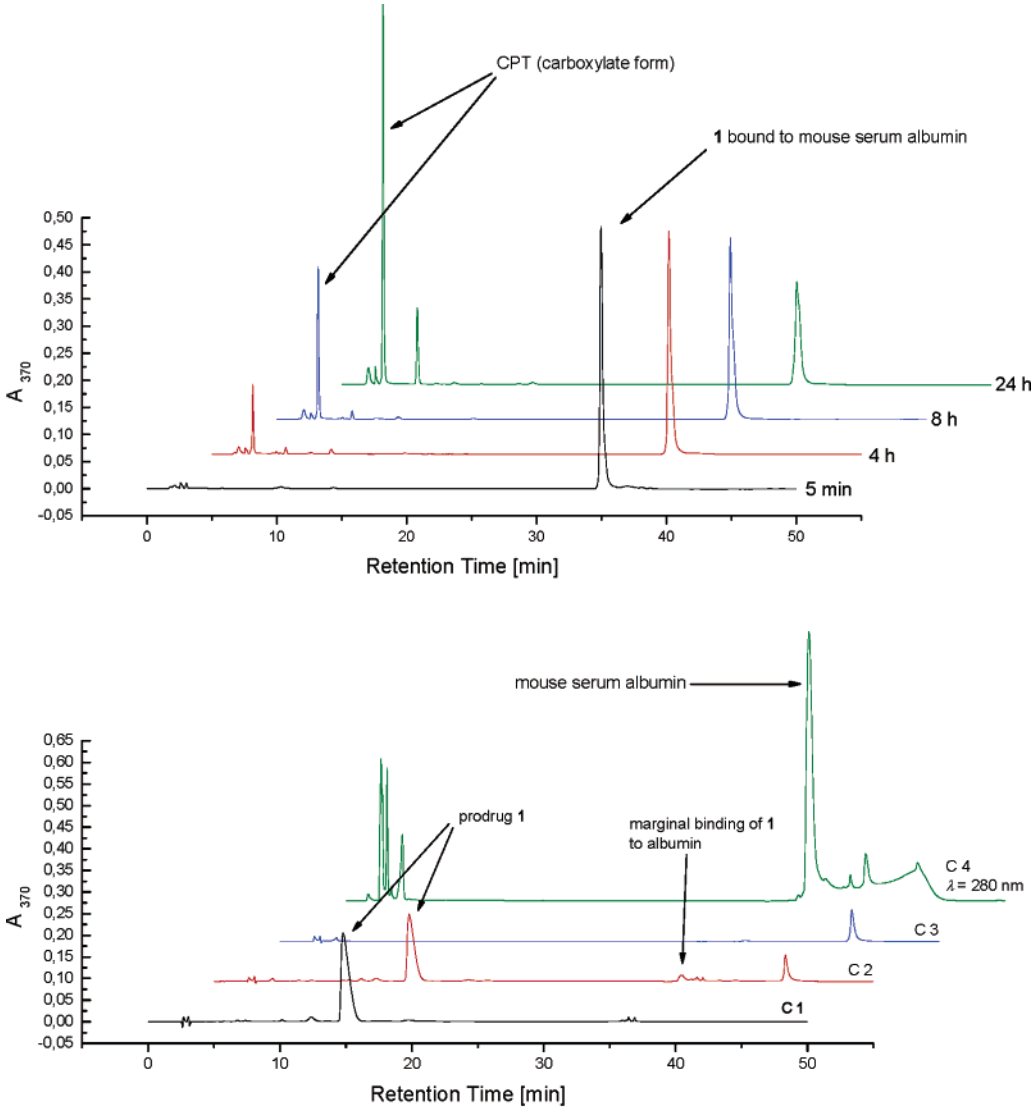
Chromatography. Details of the chromatographic conditions are available as Supporting Information.

Synthesis of Camptothecin-20-*O*-(L-alaninate) × TFA. The compound was synthesized according to a published procedure (*26*) and subsequent BOC cleavage with TFA/CH_2Cl_2.

Synthesis of EMC-Arg-Arg-Ala-Leu-Ala-Leu-Ala-CPT × 2 TFA (1). To a solution of camptothecin-20-*O*-(L-alaninate) trifluoroacetate (32.5 mg, 0.061 mmol), EMC-Arg-Arg-Ala-Leu-Ala-Leu-OH × 2 TFA (75 mg, 0.067 mmol), and *N*-ethyldiisopropylamine (DIEA) (42 μL, 0.240 mmol) in 1 mL *N*,*N*-dimethylformamide (DMF) was added *O*-(azabenzotriazol-1-yl)-*N*,*N*,*N*',*N*'-tetramethyluronium hexafluorophosphate (HATU)

Scheme 1. Synthesis of the Albumin-Binding CPT Prodrug 1

(25.5 mg, 0.067 mmol) under a nitrogen atmosphere. The solution was stirred for 1 h at room temperature. Subsequently, the product was precipitated with diethyl ether, and the crude product was purified by preparative chromatography on a Nucleosil C18 column (100-7, 250 × 21 mm) with precolumn (100-7, 50 × 21 mm) from Macherey-Nagel. Chromatographic conditions: flow, 10.0 mL/min; mobile phase A, 30% MeCN, 70% demin H_2O, 0.1% TFA; mobile phase B, 50% MeCN, 50% demin H_2O, 0.1% TFA; gradient, 1−43 min 0% to 100% mobile phase B; 43−53 min 100% mobile phase B isocrat; 53−63 min 0% to 100% mobile phase A; injection volume, 500−1000 μL. After lyophilization, 34 mg (36%) of **1** was obtained as a bright yellow solid.



ESI-MS dir-pos (4.0 kV, 30% MeCN, 0.2% triethylammonium acetate (TEAA)): *m/z* (%) 1293.4 ($[M]^+$, 100), 1294.5 ($[M + H]^+$, 66). HPLC purity (λ = 370 nm): >95%.

Synthesis and Characterization of EMC-Arg-Arg-Ala-Leu-Ala-Leu-Doxo × 2 TFA (2). Doxorubicin hydrochloride (10.6 mg, 0.017 mmol), EMC-Arg-Arg-Ala-Leu-Ala-Leu-OH × 2 TFA (21.6 mg, 0.019 mmol), and DIEA (10 μL, 0.060 mmol) were dissolved in 5 mL of anhydrous DMF. After stirring at room temperature for 15 min, HATU (6.5 mg, 0.017 mmol) was added, and the mixture was stirred at room temperature for 2 h. The product was precipitated with anhydrous diethyl ether, washed three times, and the solvent removed by centrifugation. The crude product was then purified by flash chromatography using reverse-phase Lichroprep RP-C18 from Merck with a particle size of 0.040−0.063 mm and acetonitrile/water 30:70 to afford 20 mg (83%) of product as a red powder after lyophilization. Mass (ESI-MS 5.0 kV, MeCN, 0.05% TFA): *m/z* (%) 1417.7 ($[M]^+$, 100), 1418.7 ($[M + H]^+$, 68). HPLC purity (495 nm): >95%.

Synthesis and Characterization of H-Leu-DOXO. Doxorubicin hydrochloride (696 mg, 1.20 mmol), Fmoc-Leu-OH (424 mg, 1.20 mmol), 1-hydroxybenzotriazole hydrate (162 mg, 1.20 mmol), and 4-methylmorpholine (264 μL, 2.40 mmol) were suspended in 20 mL of DMF. After stirring for 2 h, the solution became clear, and *N,N′*-diisopropylcarbodiimide (DIPC) (223 μL, 1.44 mmol) was added. After stirring at +5 °C for 4 days, DMF was removed in high vacuum. The doxorubicin amino acid derivative Fmoc-Leu-DOXO was purified through chromatography on silica gel using chloroform/methanol 10:1, affording 650 mg (62%) product as a red powder.

The protecting group was removed by dissolving Fmoc-Leu-DOXO (400 mg, 0.45 mmol) in 16 mL tetrahydrofuran and subsequent addition of 1,8-diazabicyclo[5.4.0]-undec-7-ene (98%) [(DBU, 400 μL)]. The blue mixture was stirred for 5 min and the product precipitated with diethyl ether. The crude solid was dried in high vacuum and then purified through chromatography on silica gel using chloroform/methanol 5:1 to afford 69 mg (23%) of H-Leu-DOXO as a red powder. Mass (ESI-MS, 4.0 kV, MeOH): *m/z* 657.1 $[M]^+$. HPLC purity (495 nm): >95%.

Synthesis of the Albumin Conjugates of 1 and 2 (HSA-1 and HSA-2). *For 1:* 1.5 mg of **1** were dissolved in 2 mL of human serum albumin (HSA) and were incubated under stirring at 37 °C for 1 h, after which no free **1** was detectable. The

C 1	**1** in glucose-phosphate buffer pH 5.8

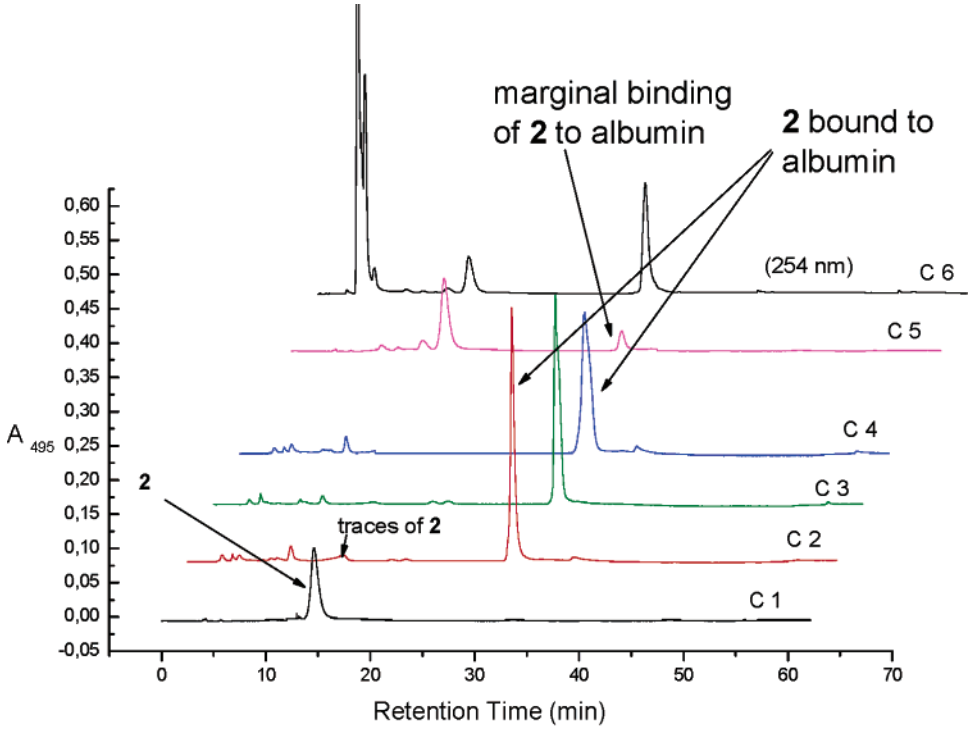
Figure 2. Chromatograms of incubation studies of mouse plasma after 5 min, 4 h, 8 h, and 24 h with **1** at 37 °C and chromatograms of incubation studies of mouse plasma preincubated with an excess of 6-maleimidocaproic acid (EMC) for 2 h and subsequent incubation with **1** after 10 min at 37 °C. Chromatographic conditions: see Experimental Section. The peak in the blocking study with EMC at ~ 43 min results from a compound in the mouse plasma absorbing at 370 nm.



concentration was adjusted to 500 μM. The sample was kept frozen at −20 °C and thawed prior to use.

*For **2**:* 1.7 mg of **2** was dissolved in 2 mL HSA, and the solution was incubated at room temperature for 2 h. The albumin conjugate was obtained after subsequent size-exclusion chromatography (sephacryl S-100; Tris buffer: 50 mM Tris-HCl pH 7.4 or 50 mM sodium acetate buffer pH 5.0). The content of anthracycline in the sample was determined using the ϵ-value for doxorubicin [ϵ_{495} (pH 7.4) = 10 650 M^{-1} cm^{-1}]. The concentration of **2** in the conjugate was adjusted to 600 ± 50 μM by concentrating the sample with CENTRIPREP-10 concentrators (Amicon, FRG) (4 °C and 4500 rpm). Samples were kept frozen at −20 °C and thawed prior to use.

Incubation Studies of 1 and 2 with Mouse Blood Plasma. 0.75 mg of **1** or **2** was dissolved in 100 μL of sterile-filtered glucose-phosphate buffer (10 mM sodium phosphate/5% D-glucose buffer, pH 5.8). 30 μL aliquots of these solutions were added immediately to 570 μL of mouse plasma (gratefully received from Dr. N. Esser, Tumor Biology Center, Freiburg, FRG) and incubated at 37 °C. Samples were collected after 5 min, 4 h, 8 h, and 24 h and analyzed by HPLC. The decrease in the peak area of the conjugate at 370 nm for **1** and at 495 nm for **2** with time was used to determine the half-lives.

Incubation Studies of HSA-1 and HSA-2 with Cathepsin B. *For **1**:* 300 μL of the **HSA-1** stock solution (500 μM) were mixed with 290 μL of TEAA buffer (20 mM, pH 7.4 and pH 5.0) containing L-cysteine (8 mM) and 10 μL of a cathepsin B solution (71.7 μg/mL, 110 mU). The samples were incubated at 37 °C for 5 min, 2 h, and 24 h, and were analyzed by HPLC. Each 150 μL aliquot of the 2 and 24 h samples was kept frozen at −20 °C for subsequent analysis by LC-MS spectrometry.

*For **2**:* 150 μL of the **HSA-2** stock solution (600 μM) was mixed with 6 μL cathepsin B (71.7 μg/mL, 110 mU) and 204 μL of buffer (Tris buffer pH 7.4 and sodium acetate buffer pH

C 5/C 6	**2** + mouse plasma blocked with EMC after 10 min, **C 6**: λ = 254 nm

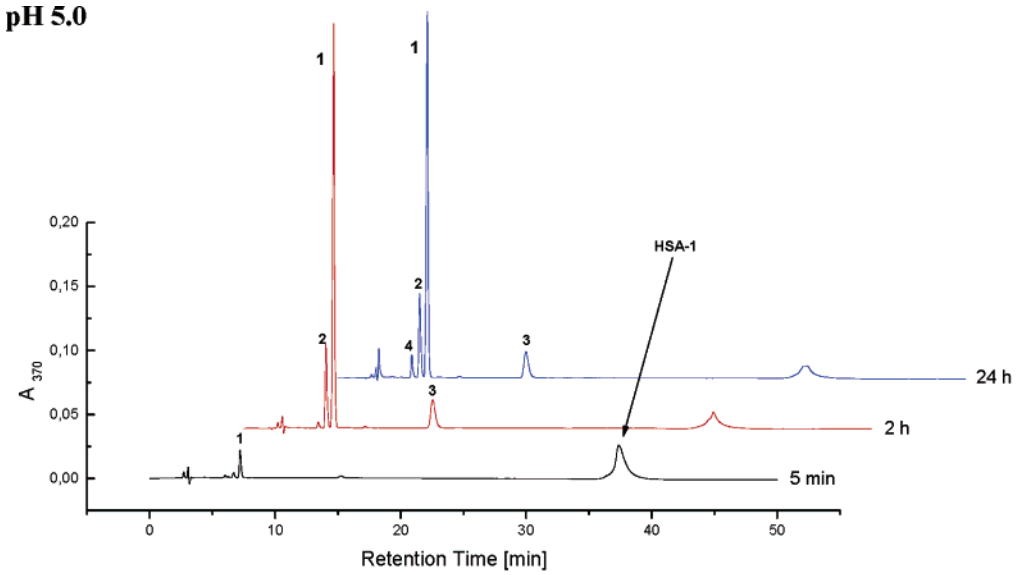
Figure 3. Chromatograms of incubation studies of mouse plasma after 5 min, 4 h, 8 h, and 24 h with **2** at 37 °C and chromatograms of incubation studies of mouse plasma preincubated with an excess of 6-maleimidocaproic acid (EMC) for 2 h and subsequent incubation with **2** after 10 min at 37 °C. Chromatographic conditions: see Experimental Section.

5.0) containing cysteine (8 mM). The samples at each pH (7.4 and 5.0) were incubated at 37 °C and were collected after 5 min, 1.5 h, 3 h, and 24 h. 60 μL of each sample was diluted with 40 μL of buffer to a final concentration of 150 μM and analyzed by HPLC with fluorescence detection.

Incubation Studies of HSA-1 and HSA-2 with Cathepsin D. *For **1**:* 150 μL of the **HSA-2** stock solution (500 μM) was mixed with 100 μL of cathepsin D (110.3 μg/mL, 15 U) and 50 μL of TEAA buffer pH 5 or pH 7.4. The samples were incubated at 37 °C for 5 min, 2 h, and 24 h and were analyzed by HPLC.

*For **2**:* 150 μL of the **HSA-2** stock solution (600 μM) was mixed with 150 μL cathepsin D (110.3 μg/mL, 15 U) and 150 μL of buffer (sodium acetate buffer pH 5.0) containing cysteine (8 mM). The samples were incubated at 37 °C for 5 min, 1.5 h, 3 h, and 24 h and were analyzed by HPLC.

Incubation Studies of HSA-1 and HSA-2 with Tumor Tissue Homogenates. For preparing the tumor homogenates, two protocols were used, the first at pH 5.0 that primarily liberates intracellular proteases (*27*) and the second at pH 7.4 that is used for extracting extracellular proteases (*28*). All following steps were carried out on ice. Tissues of colon HT-29 and mamma 3366 (M-3366) xenografts were cut into small pieces, and 200 mg samples were transferred into a 2 mL Eppendorf tube to which was added 800 μL of buffer (50 mM Tris−HCl buffer, pH 7.4, containing 1 mM monothioglycerol; or 50 mM sodium acetate buffer, pH 5.0, containing 100 mM sodium chloride, 4 mM EDTA Na_2, and 0.1% Brij 35). Homogenization was carried out with a micro-dissmemberator at 3000 rpm for 3 min with the aid of glass balls. Afterward, the samples were centrifuged at 5000 rpm for 10 min at 4 °C. The supernatant was aliquoted and kept frozen at −78 °C prior to use.



*For **1**:* 300 μL of the **HSA-1** stock solution (500 μM) was mixed with 150 μL of TEAA buffer (20 mM, pH 7.4 and pH 5.0) and 150 μL of HT-29 colon tumor tissue homogenate (pH 7.4 and pH 5.0). The samples were incubated at 37 °C for 5 min, 4 h, 8 h, and 24 h and were analyzed by HPLC. 150 μL of the 4 and 24 h samples were kept frozen at −20 °C and thawed prior to analysis by LC-MS spectrometry.

*For **2**:* 100 μL of the **HSA-2** stock solution (600 μM) was incubated with 100 μL of M-3366 tumor tissue homogenate (pH 7.4 and pH 5.0) at 37 °C for 5 min, 2 h, 5 h, and 24 h. At the mentioned times, 50 μL of each sample was diluted 1:1 to a final concentration of 150 μM and analyzed by HPLC.

Additionally, the HT-29 and M-3366 tumor homogenates were preincubated for 30 min with a 100 μM solution of the cathepsin B inhibitor CA074 (*29*) at a ratio of 10:1 (v/v), and cleavage properties were evaluated as described above.

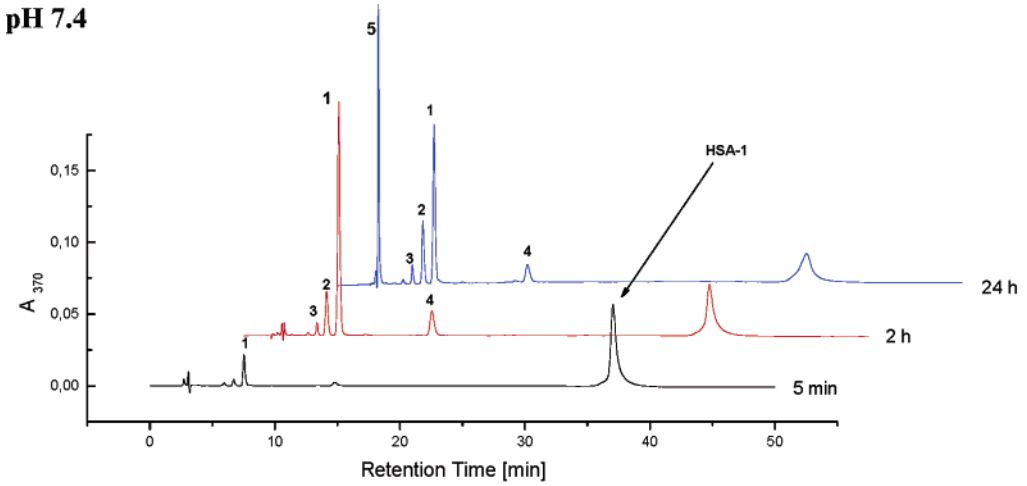
In Vivo Efficacy of 1 and 2. For the in vivo testing of **1** and **2** in comparison with their parent compounds, female NMRI: nu/nu mice (in-house breeding) were used. The mice were held in individually ventilaged cages under sterile and standardized environmental conditions (25 ± 2 °C room temperature, 50 ± 10% relative humidity, 12 h light-dark rhythm). They received autoclaved food and bedding (ssniff, Soest, Germany) and acidified (pH 4.0) drinking water ad libitum. All animal experiments were performed under the auspices of the German Animal Protection Law.

Ten million cells of HT-29 and fragments of M-3366 tumor

Peak number	Retention time [min]	Observed fragment ions [*m/z*]	Peak assignment
1	7.20	555.1 $[M + Na]^+$	H-Leu-Ala-CPT
2	6.54	626.0 $[M + Na]^+$	H-Ala-Leu-Ala-CPT
3	15.04	739.1 $[M + Na]^+$, 717.0 $[M + 2H]^+$	H-Leu-Ala-Leu-Ala-CPT
4	5.88	349.1 $[M + H]^+$	CPT lactone

Figure 4. Chromatograms of incubation studies with **HSA-1** in the presence of cathepsin B (71.7 μg/mL, 110 mU) at pH 5.0 at 37 °C after 5 min, 2 h, and 24 h.

tissue were transplanted subcutaneously (s.c.) into the left flank region of anesthetized (40 mg/kg i.p. Radenarkon, Asta Medica, Frankfurt, Germany) mice on day zero. Mice were randomly distributed to the experimental groups (six mice per group). When the tumors were grown to a palpable size (90−130 mm^3), treatment was initiated. HT-29 xenografted mice were treated intravenously at days 6, 13, and 20 with 10 mM sodium phosphate/5% D-glucose buffer pH 5.8, camptothecin, or **1** (compound was administered as a solution in 10 mM sodium phosphate/5% D-glucose buffer pH 5.8); for doses, see corresponding tables and figures. The volume of administration was 0.23 mL/25 g body weight. M-3366 xenografted mice were treated intravenously at days 19 and 26 with 10 mM sodium phosphate/5% D-glucose buffer pH 7.0, doxorubicin, or **2** (compound was administered as a solution in 10 mM sodium phosphate/5% D-glucose buffer pH 7.0). The volume of administration was 0.2 mL/20 g body weight.



Tumor size was measured twice weekly with a caliper-like instrument in two dimensions. Individual tumor volumes (V) were calculated by the formula $V = (\text{length} + [\text{width}]^2)/2$ and related to the values on the first day of treatment (relative tumor volume, RTV). At each measurement day, treated/control values (T/C) were calculated as a percentage for each experimental group; the optimum (lowest) values obtained within four weeks after treatment were used for evaluating the efficacy of the compounds, and optimum T/C values are presented in the respective tables. Statistical analysis was performed with the U-test (Mann and Whitney) with $p < 0.05$. The body weights of mice were determined every 3 to 4 days.

RESULTS AND DISCUSSION

Chemistry. For the synthesis of the albumin-binding prodrug **1**, EMC-Arg-Arg-Ala-Leu-Ala-Leu-OH was reacted with H-Ala-CPT × TFA, prepared according to a two-step procedure in which the first step is a stereoselective acylation of 20-(*S*)-camptothecin (*26*). Treatment of H-Ala-CPT × TFA with EMC-Arg-Arg-Ala-Leu-Ala-Leu-OH × 2 TFA in the presence of HATU and DIEA afforded a quantitative reaction in a short time (Scheme 1). Purification of the crude product was achieved by preparative HPLC with a considerable loss in yield. The bright yellow solid was characterized by mass spectrometry, and purity was determined by HPLC (see Experimental Section). The incorporation of two arginines into the peptide linker of the prodrug **1** resulted in superior water solubility in buffer solution (>7 mg/mL) compared to the almost insoluble CPT (2.5 μg/mL).

For the synthesis of the albumin-binding prodrug **2**, EMC-Arg-Arg-Ala-Leu-Ala-Leu-OH × 2TFA was coupled to the 3′-NH_2 position of doxorubicin in anhydrous DMF in the presence of HATU and DIEA as a one-step procedure. The crude product was purified through chromatography on a reverse-phase RP-C18 column. Prodrug **2** showed excellent water solubility with up to 10 mg/mL being dissolved in buffer solution in the pH range of 6.0 to 7.0.

Albumin-Binding Properties and Stability of 1 and 2. In order to show that prodrugs **1** and **2** bind rapidly and selectively to the cysteine-34 group of endogenous serum albumin, HPLC studies were performed in which mouse plasma was incubated with the prodrugs. Figures 2 and 3 show the chromatographic profiles of **1** and **2** incubated with mouse blood plasma after 5 min (λ = 370 nm for CPT derivatives, and λ = 495 nm for DOXO derivatives). While the free prodrugs elute at ∼15 min (**1**) and ∼14 min (**2**), the signals disappeared almost completely after incubation with mouse plasma, and a single peak eluting

Peak number	Retention time [min]	Observed fragment ions [*m/z*]	Peak assignment
1	7.54	555.1 $[M + Na]^+$	H-Leu-Ala-CPT
2	6.87	626.0 $[M + Na]^+$	H-Ala-Leu-Ala-CPT
3	5.88	349.1 $[M + H]^+$	CPT lactone
4	15.04	739.1 $[M + Na]^+$, 717.0 $[M + 2H]^+$	H-Leu-Ala-Leu-Ala-CPT
5	3.37	349.1 $[M + H]^+$, 305.2 $[M + H - CO_2]^+$	CPT carboxylate

Figure 5. Chromatograms of incubation studies with **HSA-1** in the presence of cathepsin B (71.7 μg/mL, 110 mU) at pH 7.4 at 37 °C after 5 min, 2 h, and 24 h.

at the retention time of mouse serum albumin (MSA) (33−37 min) was observed.

In order to prove the fast binding results from a Michael addition of the sulfhydryl group of MSA with the maleimide group of the prodrugs, analogous HPLC experiments were carried out in which the cysteine-34 position of MSA was blocked with an excess of EMC prior to incubation with **1** and **2** (see Figures 2 and 3). In this case, marginal binding (**1**, ∼8%; **2**, <10%) to MSA was observed after incubating plasma with **1** and **2** for 10 min.

In order to determine the plasma stability of **1,** the respective albumin conjugate was generated by incubation of the CPT derivative with mouse blood plasma at 37 °C and subsequently analyzing samples after 3 min, 4 h, 8 h, 24 h, and 28 h through HPLC. From the decrease of the peak areas, the half-life of the conjugate of **1** was calculated as $t_{1/2} = 32$ h. Additionally, buffer stability of the albumin conjugate of **1** at pH 7.4 and pH 5.0 over 24 h was tested with the following results: degradation at pH 7.4, ∼15%; degradation at pH 5.0, <5% (chromatograms available as Supporting Information).

The stability of albumin-bound **2** in mouse blood plasma was assessed after **2** had been incubated at 37 °C with plasma for 4 and 24 h. HPLC showed that the albumin conjugate is highly stable over 24 h (∼5% degradation) (see Figure 3).

Cleavage Profiles of the Albumin Conjugate of 1. The ratio of the carboxylate form and the lactone form of released CPT is essential for the antitumor activity of the prodrug. It is known that the carboxylate form of CPT is inactive and even toxic, whereas the lactone form of CPT is the active agent. At more acidic pH, the equilibrium between the carboxylate and lactone forms generally shifts to the lactone form of CPT.

The cleavage properties of compound **1** were evaluated using enzymatically active cathepsin B, cathepsin D, and HT-29 colon tumor tissue homogenates at both pH 7.4 and pH 5.0. After incubation with cathepsin D, no cleavage of **HSA-1** could be detected (data not shown). In contrast, incubation with cathepsin B and HT-29 colon tissue homogenate resulted in a fast and almost complete cleavage over a period of 24 h, especially at pH 5.0 (see Figures 4, 5, 7, and 8). The different cleavage products were identified by LC-MS and by the use of CPT and H-Ala-CPT standards. Unfortunately, the HPLC method used for incubation studies could not be transferred one-to-one to the LC-MS investigations. Therefore, the cleavage products could not be assigned by retention times but by their peak areas and by the use of the reference substances (mass spectra of the individual peaks are available as Supporting Information). For cleavage with cathepsin B (see Figures 4 and 5), the following products were identified: H-Leu-Ala-Leu-Ala-CPT, H-Ala-Leu-Ala-CPT, H-Leu-Ala-CPT as the major product, CPT (lactone form), and additionally at pH 7.4, CPT in the carboxylate form. Cleavage in HT-29 colon tumor homogenate (see Figures 7 and 8) at pH 5.0 resulted in a more pronounced degradation of the albumin conjugate over 24 h than that observed at pH 7.4. Interestingly, the cleavage profile with tumor homogenate additionally showed the formation of H-Ala-CPT, which could not be observed after cleavage with cathepsin B. The identified cleavage products at pH 5.0 were H-Ala-Leu-Ala-CPT, H-Leu-Ala-CPT, H-Ala-CPT, and CPT (lactone form). After 4 h of incubation, the main products were H-Leu-Ala-CPT and H-Ala-CPT, changing after 24 h of incubation to H-Ala-CPT and CPT in the carboxylate form. At pH 7.4, H-Leu-Ala-CPT, H-Ala-CPT, CPT (lactone form), and CPT in the carboxylate form were found. Cleavage at pH 7.4 to CPT in the carboxylate form is also attributed to unspecific hydrolysis, although cleavage in pH 7.4 buffer solution after 24 h was not as

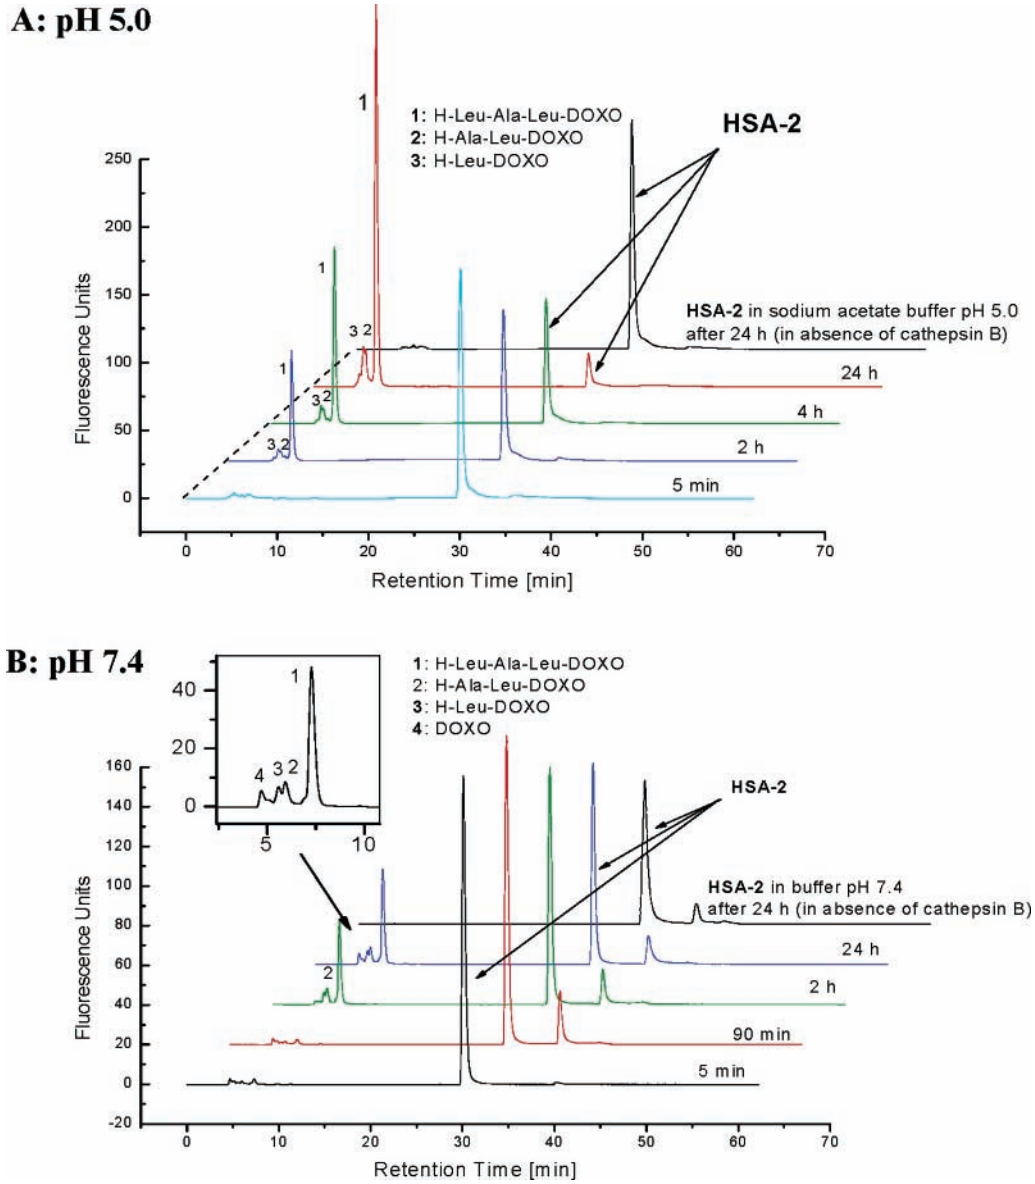


Figure 6. Chromatograms of incubation studies with **HSA-2** in the presence of cathepsin B (71.7 μg/mL, 110 mU) at pH 5.0 (A) and pH 7.4 (B) at 37 °C after 5 min, 2 h, 24 h and 5 min, 90 min, 2 h, 24 h respectively.

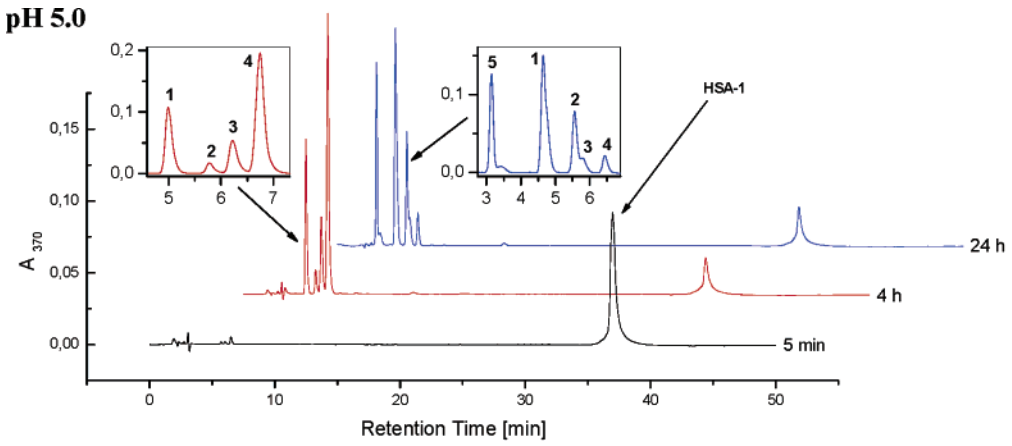
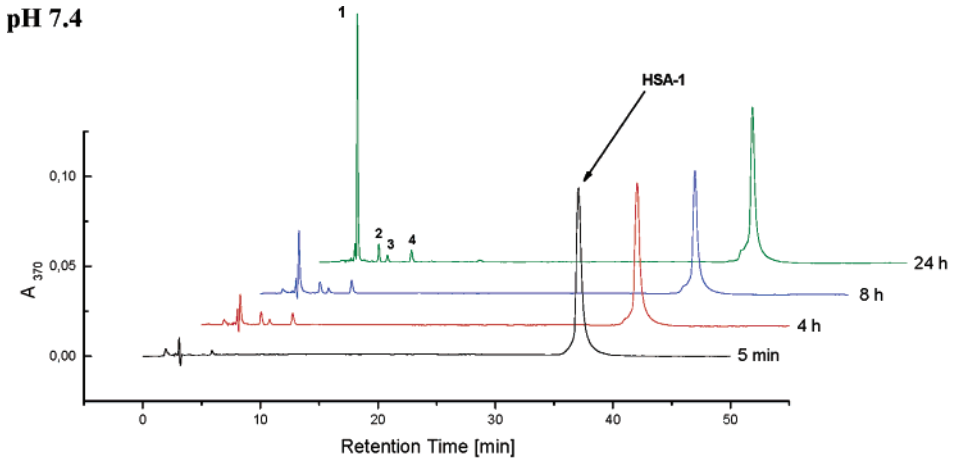


pronounced as with tumor tissue homogenate or cathepsin B. Additionally, the cleavage properties of the HT-29 tumor homogenate preincubated with the cathepsin B inhibitor CA074 (*29*) at pH 5.0 were investigated to determine if cathepsin B is the major protease responsible for the cleavage of the peptide sequence. The corresponding chromatograms (see Figure 9) recorded after 5 min, 4 h, and 24 h show that the cleavage of prodrug **1** was notably inhibited with respect to the cleavage products H-Leu-Ala-CPT, H-Ala-Leu-Ala-CPT, and CPT (carboxylate form).

The appearance of the carboxylate form of CPT at pH 7.4 in several studies, especially in the mouse plasma stability study (Figure 2) and the study with tumor homogenate (Figure 8), might be related to the fact that proteins, primarily albumin, switch the equilibrium to the carboxylate form due to interaction with the binding domain IIA (*30*−*35*).

The incubation study at pH 5 with **HSA-1** in the presence of cathepsin B (Figure 4) showed no generation of CPT in the carboxylate form, in contrast to the incubation study with HT-29 tumor homogenate at the same pH value (Figure 7). Two reasons could explain this difference: (a) preferential binding of the carboxylate form to proteins in the tumor tissue homogenate, and (b) in the presence of cathepsin B, no H-Ala-CPT was generated, which readily releases free CPT; di-, tri-, and tetrapeptide derivatives of CPT are reported to be more stable than amino acid derivatives of CPT (*36*).



Cleavage Profiles of the Albumin Conjugate of 2. In order to investigate whether and how fast **HSA-2** is cleaved by cathepsin B at pH 5.0 and pH 7.4 as well as by cathepsin D at pH 5.0, **HSA-2** was incubated with the enzymes and chromatograms recorded with fluorescence spectrophotometer using reverse-phase HPLC.

Rapid cleavage to a main product eluting at 6.3 min (see Figure 6A) was observed after incubating **HSA-2** with cathepsin B at pH 5.0. After 24 h of incubation, cleavage was almost complete. In order to characterize this cleavage product, 1000 μL [1100 μM] **HSA-2** and 300 μL of cathepsin B were incubated, and the cleavage product was isolated through size exclusion chromatography (sephadex G-25) using demineralized water. Mass spectrometry of the lyophilized sample showed a distinct mass peak at 840.8 $[M]^+$ and its Na^+ adduct at 863.1 $[M + Na]^+$ corresponding to [H-Leu-Ala-Leu-DOXO] (mass spectrum available as Supporting Information). Small amounts

Peak number	Retention time [min]	Observed fragment ions [*m/z*]	Peak assignment
1	5.05	331.2 [– alanine]$^+$, 303.2 [– alanine – CO]$^+$	H-Ala-CPT
2	5.71	349.1 [M + H]$^+$	CPT lactone
3	6.21	626.1 [M + Na]$^+$	H-Ala-Leu-Ala-CPT
4	6.75	555.0 [M + Na]$^+$	H-Leu-Ala-CPT
5	3.20	349.1 [M + H]$^+$, 305.2 [M + H – CO_2]$^+$	CPT carboxylate

Figure 7. Chromatograms of incubation studies with **HSA-1** and HT-29 tissue homogenate after 5 min, 4 h, (8 h), and 24 h at pH 5.0 at 37 °C.

Peak number	Retention time [min]	Observed fragment ions [*m/z*]	Peak assignment
1	3.22	349.1 [M + H]$^+$, 305.2 [M + H – CO_2]$^+$	CPT carboxylate
2	5.05	331.2 [– alanine]$^+$, 303.2 [– alanine – CO]$^+$	H-Ala-CPT
3	5.88	349.1 [M + H]$^+$	CPT lactone
4	7.88	555.0 [M + Na]$^+$	H-Leu-Ala-CPT

Figure 8. Chromatograms of incubation studies with **HSA-1** and HT-29 tissue homogenate after 5 min, 4 h, (8 h), and 24 h at pH 7.4 at 37 °C.

of the cleavage products H-Leu-DOXO and H-Ala-Leu-DOXO were also observed, which were identified by an additional LC-MS experiment (mass spectra available as Supporting Information).

The cleavage of **HSA-2** by cathepsin B at pH 7.4 showed the same cleavage products, especially [H-Leu-Ala-Leu-DOXO] at pH 5.0, but cleavage at pH 7.4 proved to be less effective and much slower; therefore, the cathepsin B concentration for the incubation study at pH 7.4 was increased (see Figure 6B). Incubation studies at pH 7.4 with **HSA-2** also show a sparse degradation to an unidentified product eluting at ~37 min only visible with fluorescence detection.

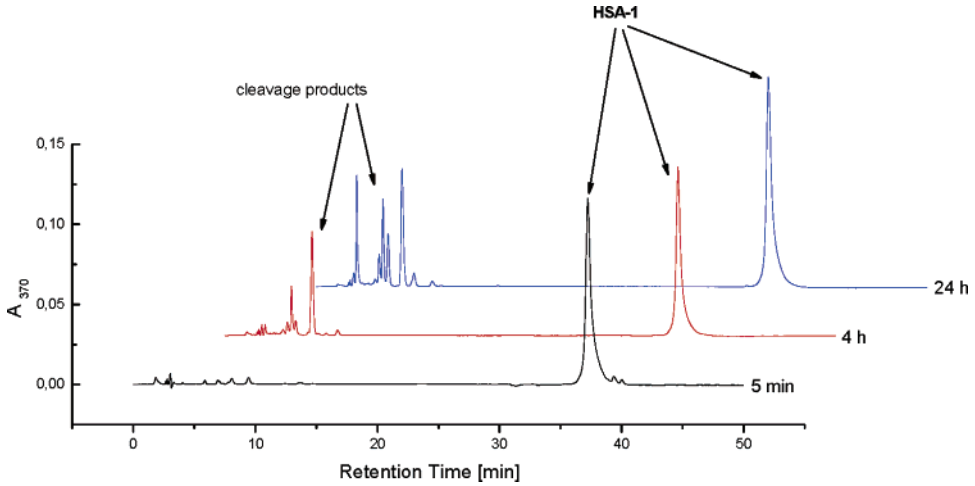


Figure 9. Chromatograms of incubation studies with **HSA-1** and HT-29 tissue homogenate preincubated with the cathepsin B inhibitor CA-074 after 5 min, 4 h, and 24 h at pH 5.0 and 37 °C. Chromatographic conditions: see Experimental Section.

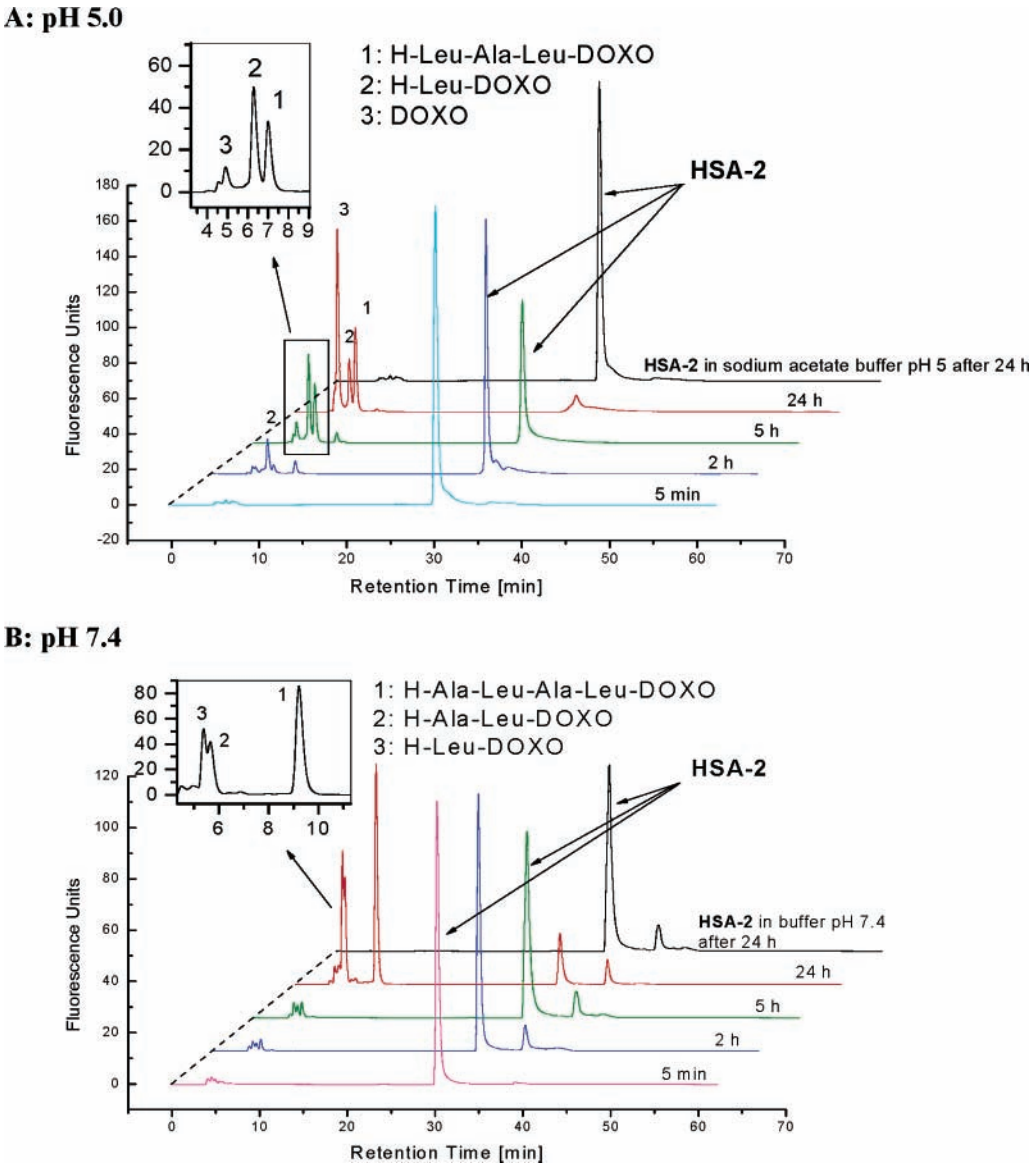

Figure 10. Chromatograms of incubation studies with **HSA-2** and M-3366 tissue homogenate after 5 min, 2 h, and 5 h at pH 5.0 (A) and pH 7.4 (B) at 37 °C.

Incubation studies with **HSA-2** and cathepsin D showed only marginal cleavage (data not shown).

In order to obtain a picture of the cleavage profile in biological samples, we incubated both **HSA-2** and the cleaved

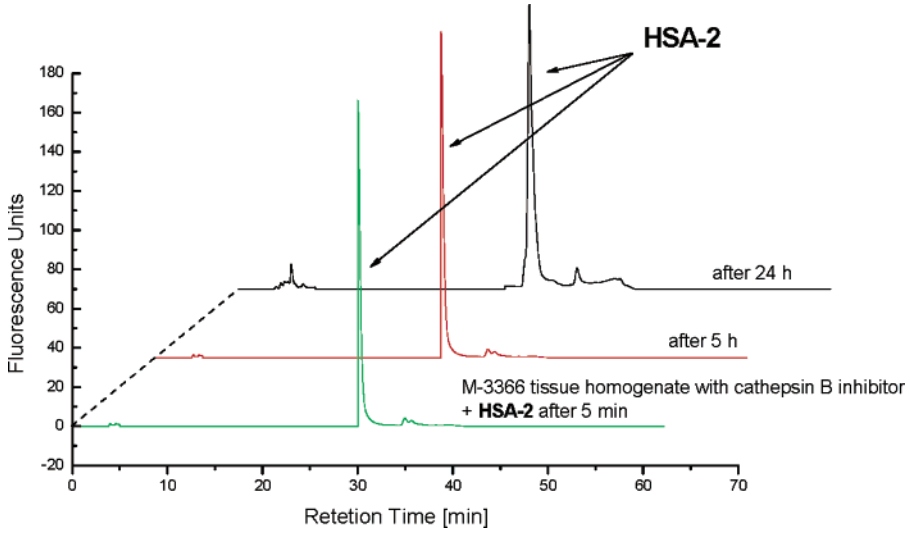

Figure 11. Chromatograms of incubation studies with **HSA-2** and M-3366 tissue homogenate preincubated with the cathepsin B inhibitor CA-074 after 5 min, 5 h, and 24 h at pH 5.0 and 37 °C.

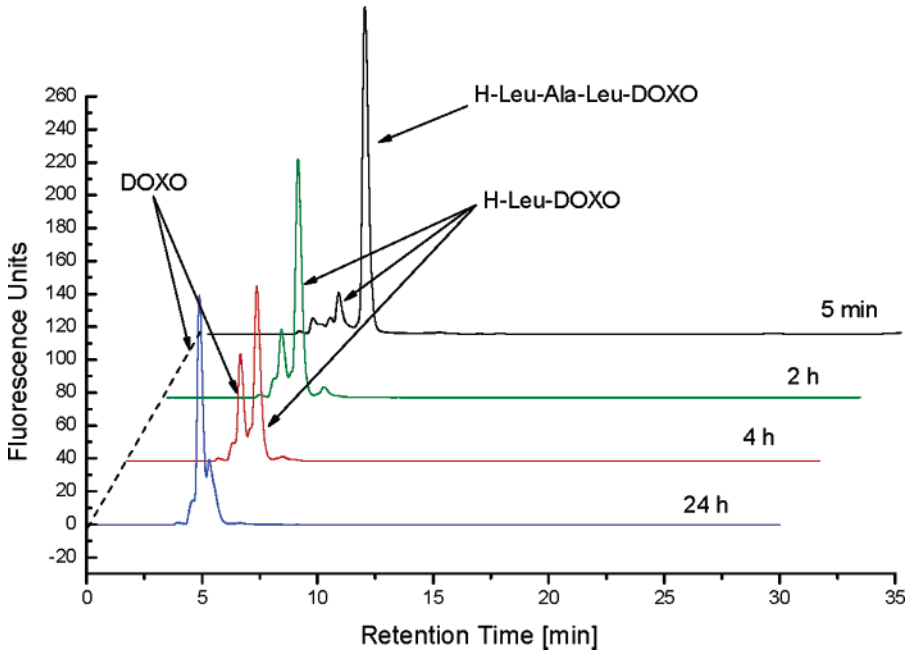

Figure 12. Chromatograms of incubation studies with the cleavage product [H-Leu-Ala-Leu-DOXO] and M-3366 tissue homogenate after 5 min, 2 h, 4 h, and 24 h at 37 °C. Concentration of [H-Leu-Ala-Leu-DOXO] was 125 μM. Chromatographic conditions: see Experimental Section.

Table 1. Antitumor Activity of CPT Prodrug 1 against Human Colorectal Xenografts (HT-29) in Vivo

compound	dose[a] [mg/kg]	total mortality	body weight change [%] (day 6−9)	*T/C* [%] maximal
CPT	3 × 12.5	0/6	−2	40[b] (day 22)
1	3 × 12.5	1/6 (on day 20)	−1	17[b,c] (day 29)

[a] Dose refers to CPT equivalents. [b] Significant to buffer solution. [c] Significant to camptothecin.

doxorubicin tripeptide [H-Leu-Ala-Leu-DOXO] with M-3366 tissue homogenates and analyzed the cleavage products over 24 h (see Figures 10and 12). The cleavage products were identified by "peak spiking" with H-Leu-DOXO, H-Leu-Ala-Leu-DOXO, and DOXO references, which were added to the incubated samples. An increase of the peak area at the corresponding retention time confirmed the identification of the respective cleavage product.

Incubation with **HSA-2** at pH 5.0 showed two cleavage products, H-Leu-Ala-Leu-DOXO and H-Leu-DOXO after 2 h. After 5 h, the main cleavage product was H-Leu-DOXO and small amounts of DOXO were observed, which increased over 24 h (see Figure 10A). Incubation with **HSA-2** at pH 7.4 showed a different cleavage profile than at pH 5.0. Only after 24 h were the cleavage products H-Leu-DOXO, H-Ala-Leu-DOXO, and the tetrapeptide derivative H-Ala-Leu-Ala-Leu-DOXO eluting at 9 min observed that were obviously produced by enzymes in M-3366 tissue homogenate other than cathepsin B (see Figure 10B). Identification of these cleavage products was performed by LC-MS (mass spectra of the individual peaks are available as Supporting Information).

In a further experiment, we preincubated the M-3366 tissue homogenate with the cathepsin B inhibitor CA-074 at pH 5.0 in order to elucidate whether cathepsin B is responsible for cleaving the peptide sequence to the cleavage products H-Leu-Ala-Leu-DOXO and H-Leu-DOXO. As shown in Figure 11, no cleavage was observed after 5 and 24 h, confirming that

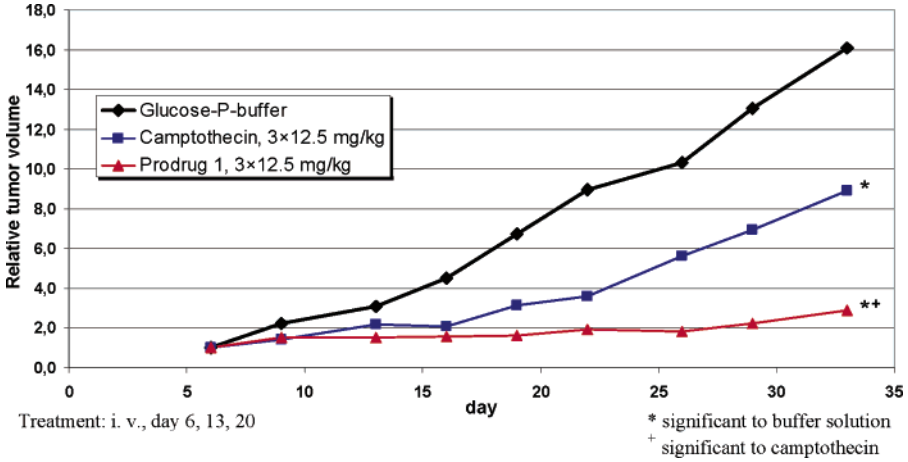

Figure 13. Curves depicting tumor growth inhibition of subcutaneously HT-29 xenografts under therapy with CPT and prodrug **1**.

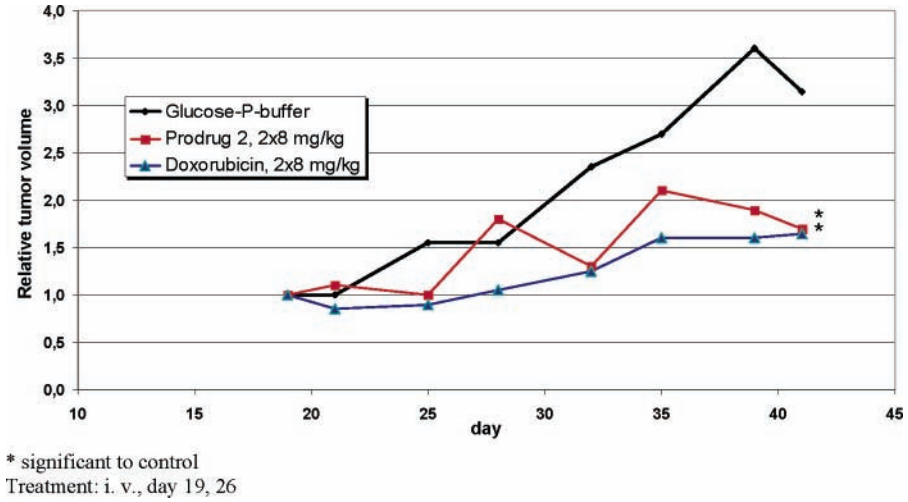

Figure 14. Curves depicting tumor growth inhibition of subcutaneous M-3366 xenografts under therapy with doxorubicin and prodrug **2**.

cathepsin B is the major enzyme responsible for the cleavage in M-3366 tissue homogenate at pH 5.0.

H-Leu-Ala-Leu-DOXO was cleaved primarily to H-Leu-DOXO in M-3366 tissue homogenate after 2 h, and almost complete degradation to DOXO over 24 h was observed (see Figure 12).

H-Leu-DOXO is known to have activity against several human tumor cell lines, e.g., MCF-7 (breast carcinoma) (*37*, *38*), HT-1080 (fibrosarcoma) (*39*), and LNCaP (prostate carcinoma) (*40*−*46*); it was also shown to have less cardiac toxicity than DOXO in animal models (*40*, *41*).

In Vivo Activity of 1 and 2 Compared to the Free Drug. The in vivo efficacy of **1** and CPT was assessed in xenografted nude mice using a human HT-29 colorectal cell line. CPT was evaluated at a dose of 3 × 12.5 mg/kg (i.v.), which was reported to be the maximum tolerated dose (MTD) for camptothecin in nude mice (*47*). Prodrug **1** was tested at the same dose of 3 × 12.5 mg/kg (i.v.) CPT equivalents. Table 1 and Figure 13 show the results of this experiment. In general, although one animal died, therapy with **1** produced no significant body weight loss (see Table 1 and curves depicting body weight change, available as Supporting Information). Whereas CPT (3 × 12.5 mg/kg) was moderately active (*T*/*C* max: 40%), **1** exhibited superior antitumor activity at the same dose, and mice treated with **1** showed a good antitumor response (*T*/*C* max: 17%).

The antitumor efficacy of **2** was evaluated in nude mice using a breast carcinoma 3366 (M-3366) xenograft in a strict comparison to free doxorubicin. A preliminary toxicity study in two healthy mice showed that the MTD of **2** was 1 × 24 mg/kg doxorubicin equivalents and thus ∼3-fold higher than for free doxorubicin. Consequently, **2** was compared with doxorubicin at the following doses: doxorubicin at a dose of 2 × 8 mg/kg corresponding to the MTD of doxorubicin in nude mice and **2** at doses of 2 × 8 mg/kg doxorubicin equivalents and 1 × 24 mg/kg doxorubicin equivalents. The results of these in vivo experiments are shown in Table 2 and Figure 14.

Table 2. Antitumor Activity of DOXO Prodrug 2 Against Human Mamma Carcinoma Xenografts (M-3366) in Vivo

compound	dose[a] [mg/kg]	total mortality	body weight change [%] (day 6−9)	*T*/*C* [%] maximal
DOXO	2 × 8	0/6	−9	44[b] (day 39)
2	2 × 8	1/6 (on day 20)	0	53[b] (day 39)
2	1 × 24	5/6 (on day 20)	−14	n.e.[c]

[a] Dose refers to DOXO equivalents. [b] Significant to buffer solution [c] n.e.: not evaluatable.

Table 2 and Figure 14.

Doxorubicin at its optimal dose of 2 × 8 mg/kg produced a moderate inhibition in tumor growth with a body weight loss of up to −9% with a slow recovery thereafter. The efficacy of **2** at 2 × 8 mg/kg was comparable with the therapeutic results of doxorubicin at 2 × 8 mg/kg, but no body weight loss was observed (see curves depicting body weight change, available as Supporting Information). After the first application of **2** at the dose of 2 × 8 mg/kg, one animal died due to an acute reaction. After application, all mice showed a mild ataxia and red flushing prolonging for 20 min. The in vivo testing of **2** at the dose of 1 × 24 mg/kg was aborted after the first application

due to acute toxicity (5 of 6 mice died), an observation that was not made in preliminary toxicity studies in healthy nude mice.

CONCLUSIONS

In the past 30 years, cysteine proteases have been known to be involved in a number of steps in tumor progression, such as tumor growth, invasion, migration, and the formation of metastasis (*48*). Especially, the cysteine proteases of the papain family such as cathepsins B, L, H, and S have been investigated intensively in the past. Cathepsins are known to digest and cleave a number of tissues such as collagen and proteoglycane (*49*). The cysteine protease cathepsin B is mostly localized in lysosomes (*18*), and overexpression of cathepsin B has been found in various malignant tumors, especially in melanoma (*22*), breast (*20*), lung (*23*, *24*), and colon (*25*) carcinoma. The overexpressed levels of cathepsin B in tumors as well as in some extracellular fluids are associated with tumor progression and with disease-free and overall survival and may therefore serve as a prognostic factor for cancer patients.

Thus, we developed two albumin-binding prodrugs incorporating a peptide sequence which can be specifically cleaved by cathepsin B, releasing an amino acid derivative of doxorubicin or camptothecin, which subsequently is cleaved to free doxorubicin and camptothecin as the final product.

In the past few years, several low- and high-molecular-weight prodrugs of doxorubicin have been developed that were designed to be activated by cathepsin B. The HPMA copolymer-Gly-Phe-Leu-Gly-doxorubicin conjugate PK1 incorporating a cathepsin B cleavable linker has been evaluated clinically (*50*). Furthermore, two immunoconjugates of doxorubicin, in which DOXO is linked to the chimeric BR96 antibody through lysosomally cleavable dipeptides Phe-Lys or Val-Cit (BR96-Phe-Lys-PABC-DOXO and BR96-Val-Cit-PABC-DOXO; PABC = *para*-aminobenzyloxycarbonyl) (*51*) have been developed. Both conjugates showed rapid and nearly quantitative drug release with cathepsin B.

To date, three polymeric derivatives of camptothecin have entered clinical trials: two HPMA copolymer-bound camptothecin drugs (*47*, *52*) and Prothecan, a PEG-based CPT-Ala prodrug (*53*). In all cases, binding CPT to polymers leads to highly water-soluble formulations which release the drug in a controlled fashion due to the incorporation of a hydrolyzable or enzymatically degradable amino acid spacer. Especially, cleavage by cathepsin B was described for the following CPT prodrugs: a camptothecin analogue-carboxymethyl dextran conjugate bearing a Gly-Gly-Gly linker (*54*), an immunoconjugate of CPT containing a Phe-Lys linker (*55*), a poly(ethylene glycol) conjugate of 10-amino-7-ethylcamptothecin (*56*), and recently a folate receptor-targeted PEG-peptide conjugate of CPT (*57*).

In the present work, we could show that cathepsin B cleaves the Ala-Leu-Ala-Leu linker in the albumin-bound form of the CPT prodrug **1** and the DOXO prodrug **2** in all of the peptide bonds adjacent to the EMC-Arg-Arg-Ala residue. Cleavage was more efficient at pH 5.0 than at pH 7.4. In tumor homogenates, the cleavage pattern was similar, but a pronounced cleavage to CPT (and the CPT carboxylate form) and to DOXO was observed. Although the extent of cleavage for both prodrugs was similar in the HT-29 and M-3366 tumor xenografts, **1** was significantly more active than CPT in contrast to **2**, which was as effective as doxorubicin. A possible explanation for this difference could be differences in the EPR (enhanced permeation and retention) effect for these tumors.

In summary, we have prepared albumin-binding prodrugs with the anticancer drug camptothecin and doxorubicin that are water-soluble, bind rapidly and selectively to the cysteine-34 position of endogenous serum albumin, and are cleaved specifically by cathepsin B. Further studies of **1** in a larger panel of human tumor xenografts should reveal the potential of this CPT prodrug.

ACKNOWLEDGMENT

The support of the Dr. Mildred-Scheel Stiftung der Deutschen Krebshilfe is gratefully acknowledged. We thank Christoph Warth for carrying out the LC-MS experiments.

Supporting Information Available: Chromatography; curves depicting body weight change; chromatograms of the albumin conjugate of prodrug **1** (250 μM) depicting the buffer stability; mass spectra of the cleavage products of **1** and mass spectra of the cleavage products of **2**. Biotinylated Photocleavable Polyethylenimine: Capture and Triggered Release of Nucleic Acids from Solid Supports

Rachel G. Handwerger[†] and Scott L. Diamond[†,‡,*]

Institute for Medicine and Engineering, 1024 Vagelos Laboratories, University of Pennsylvania, Philadelphia, Pennsylvania 19104. Received September 8, 2006; Revised Manuscript Received January 2, 2007

A *b*iotinylated *p*hotoc*l*eavable *p*oly*e*thylen*i*mine (B-PC-PEI) was designed and synthesized for the capture and controlled release of nucleic acids from solid supports. B-PC-PEI was synthesized via a three-step reaction process and verified by ^{1}H NMR and mass spectrometry. In aqueous solution, the *o*-nitrobenzyl group within B-PC-PEI was efficiently cleaved by 5 min of 365 nm light exposure from a distance of 20 cm (9 mW/cm^2). When coupled to streptavidin-coated beads, the PEI domain of Cy5-labeled B-PC-PEI was released by 365 nm light exposure. In contrast, a Cy5-labeled biotinylated PEI (B-PEI) was used as a control and negligible fluorescence loss was observed. Cy5-labeled siRNA was electrostatically captured to streptavidin-coated beads preabsorbed with B-PC-PEI or B-PEI, and flow cytometry demonstrated significant loss of fluorescence from the bead surface after 5 min of light exposure only for B-PC-PEI, demonstrating controlled release of siRNA from the bead surface. Finally, the release of the Cy5-labeled siRNA into the supernatant was quantified. The release of Cy5-siRNA into the supernatant was significantly greater after 5 min of light exposure for B-PC-PEI/streptavidin beads compared to 0 min exposure and remained unchanged for B-PEI/streptavidin beads. B-PC-PEI facilitates capture and triggered release of surface-tethered nucleic acids with light exposure and is fully compatible with streptavidin-based applications.

INTRODUCTION

Photolabile protecting groups function by rendering a molecule of interest inert until photolysis and have been used extensively since their introduction in 1962 (*1*) for controlled release and kinetic studies (*2*−*13*). For biological systems, this approach allows control of concentration, location, and timing of the compound's release into a system. Furthermore, this technology, when applied to biomedical release applications, may mitigate problems such as off-target effects of a therapeutic agent. The potential to use photolytic release for gene delivery was first described by Monroe et al., who synthesized a 1-(4,5-dimethoxy-2-nitrophenyl)diazoethane caged plasmid DNA (pDNA) for light-activated gene delivery. However, the caging group limited transcription of pDNA because of direct modification of the pDNA backbone, and photolysis caused pDNA nicking. Also the caged pDNA had to be formulated with liposomes or precipitated onto gold beads for transfection (*8*).

Spatially controlled delivery of nucleic acids often involves substrate-mediated delivery or encapsulation within a polymeric scaffold. For substrate-mediated delivery of DNA, biotinylated polymers such as polyethylenimine (PEI)[1] and polylysine (PLL) have been attached to avidin-coated supports and provided for increased and positionally controlled transfection compared to polymer/DNA polyplexes absorbed nonspecifically onto the surface (*14*, *15*) or delivered via standard transfection methods (*14*). The increased function of surface-tethered polyplexes could be due to inhibition of aggregation and consequent intracellular sequestration (*15*) or to elevated local concentration of nucleic acids at the cell surface, which can increase transfection efficiency (*16*). Nucleic acids have also been immobilized in degradable scaffolds for localized delivery. There are many examples of both biological and synthetic scaffolds in the literature (as reviewed by Pannier and Shea (*17*)). The delivery of pDNA to cells from polymer scaffolds is controlled by the polymer degradation rate, a property that can be engineered (*18*).

2-Nitrobenzyl groups for photolability have been commonly used for biomedical applications. While the exact mechanisms and chemical intermediates leading to photolability are not fully resolved, light exposure does cause an intramolecular H-atom transfer which leads to an *aci*-nitro tautomer followed by nitroso group formation. This process is discussed in detail in McCray and Trentham (*7*), Pillai (*19*), Il'ichev et al. (*20*), and Schwörer and Wirz (*21*). In particular, α-substituted 2-nitrobenzyl esters exhibit highly efficient cleavage and are stable in biological systems (*4*, *6*, *22*, *23*) and under synthetic conditions for biomolecules such as peptide synthesis (*19*). Moreover, the near-UV light used to activate the photolysis is not harmful to many biomolecules and biological systems (*24*).

Photocleavable biotin molecules (B-PC) have been previously developed to combine both photolability and high affinity capture (*25*). The biotin−avidin association is essentially irreversible ($K_a = 10^{15}$ M^{-1}) and commonly used. Subsequent release of the biomolecule after isolation remains a challenge, as the association is relatively unaffected by pH, temperature, and 8 M guanidine-HCl at neutral pH. Typically, harsh conditions (e.g., detergents in combination with high temperature) succeed in dissociating the biotin−avidin interaction. B-PCs eliminate this shortcoming because exposure to light at specific wavelengths can cleave the biomolecule from the biotin. B-PCs have been used for several applications, including isolation and release of small peptides (*25*) and nucleotides for DNA extension products (*22*), and phosphorylation and purification of oligonucleotides (*26*).

In this report, we present a new approach that combines photolability and surface-tethering technology for the capture and controlled release of nucleic acids without covalent modification of the nucleic acids. PEI was covalently modified with a photolabile biotin group. This new compound was attached to the surface of streptavidin-coated beads and then mixed with siRNA to form tethered polyplexes. Exposure at 365 nm to the functionalized beads caused the release of PEI/siRNA complexes from the surface of the bead into the supernatant. Spatially and temporally controlled release of metered doses of nucleic acids from a solid surface can be potentially useful for biomedical applications, determination of rate-limiting factors for gene delivery, and for screening studies where temporally and spatially controlled release could offer insight into cellular processes.

EXPERIMENTAL PROCEDURES

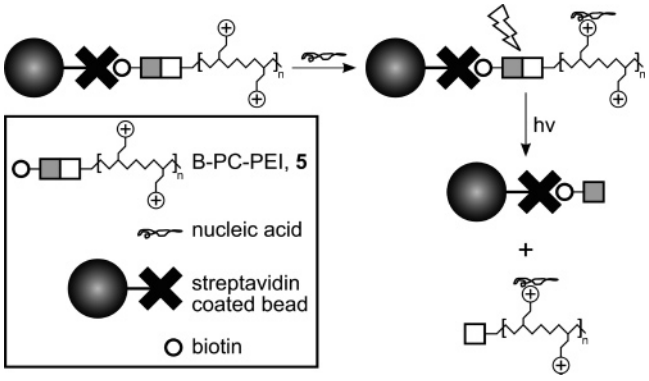
Synthesis of Biotin−PC-PEI. All chemicals were purchased from Sigma-Aldrich (St. Louis, MO) unless otherwise specified. All experiments were performed under dimmed light conditions and with foil coverings.

Biotin−PC-Linker **3** was synthesized as previously described in Bai et al. (*22*). Briefly, 1-[5-(aminomethyl)-2-nitro]phenylethanol **1** (0.045 g, 0.23 mmol), a generous gift from Dr. Jingyue Ju of Columbia University, was dissolved in 1.5 mL of DMF. A volume of 0.325 mL of 1 M $NaHCO_3$ was added to the solution and stirred. To the mixture, biotin-NHS ester **2** (0.045 g, 0.10 mmol, Invitrogen, Carlsbad, CA) in 1.5 mL of DMF was slowly added while stirring. The reaction solution was stirred for 5 h (RT). The final product, **3** (0.048 g, 0.090 mmol, 90% yield), was purified using a silica gel column (80% CH_2Cl_2:20% MeOH (v:v)). ^{1}H NMR (300 MHz, MeOH-*d*) δ 7.89 (d, 1H), 7.80 (s, 1H), 7.34 (d, 1H), 5.35 (q, 1H), 4.52−4.48 (m, 3H), 4.33−4.29 (m, 1H), 3.23−3.18 (m, 3H), 2.95 (d, 1H), 2.70 (d, 1H), 2.30 (t, 2H), 2.20 (t, 2H), 1.78−1.47 (m, 16H).

Biotin−PC-NHS ester **4** was synthesized as previously described in Bai et al. (*22*). Briefly, **3** (0.011 g, 0.021 mmol) and *N*,*N*′-disuccinimidyl carbonate (0.0092 g, 0.036 mmol) were dissolved in 0.3 mL of anhydrous DMF. Triethylamine (0.008 mL, 0.057 mmol) was added, and the reaction mixture was stirred under Ar for 6 h (RT). The solvent was evaporated and the product dissolved in 1 mL of 1 M $NaHCO_3$. The solution was extracted 3× with EtOAc and concentrated in vacuo. The product mixture was dissolved in DMF and purified by preparative TLC (85% CH_2Cl_2:15% MeOH (v:v)). The product band was isolated from the TLC plate and soaked in DMF for 4.5 h (RT), after which it was centrifuged to separate the product from the silica. The solvent was removed in vacuo to yield **4** (0.0022 mg, 0.0032 mmol, 16% yield). ^{1}H NMR (300 MHz, DMSO-d_6) δ 8.74 (s, 1H), 8.02 (d, 1H), 7.75 (t, 1H), 7.66 (s, 1H), 7,47 (s, 1H), 6.42 (s, 1H), 6.36 (s, 1H), 6.28 (q, 1H), 4.40 (d, 2H), 4.35−4.28 (m, 1H), 4.12 (m, 1H), 3.09−3.01 (m, 1H), 2.99 (s, 2H), 2.89−2.78 (m, 6H), 2.56 (s, 1H), 2.16 (t, 2H). 2.03 (t, 3H), 1.72 (d, 2H), 1.50−1.24 (m, 12H).

Biotin−PC-PEI (B-PC-PEI) **5**. Polyethylenimine (PEI, 800 Da, 0.0006 g, 0.00075 mmol) was dissolved in 0.3 mL of H_2O, to which 0.07 mL of 1 M $NaHCO_3$ was added dropwise. The reaction mixture was allowed to equilibrate and **4** (0.0011 g, 0.0016 mmol) in 0.3 mL of DMSO was slowly added. The reaction was stirred for 5 h and then concentrated in vacuo to yield **5**.

Synthesis of Biotin−PEI. PEI (800 Da, 0.0083 g, 0.010 mmol) was dissolved in 0.2 M $NaHCO_3$ (1 mL) and stirred to equilibrate. To the mixture was slowly added biotin-NHS ester **2** (0.010 g, 0.022 mmol) in anhydrous DMSO (1 mL). The reaction was stirred for 5.5 h and concentrated in vacuo to yield Biotin−PEI (B-PEI).



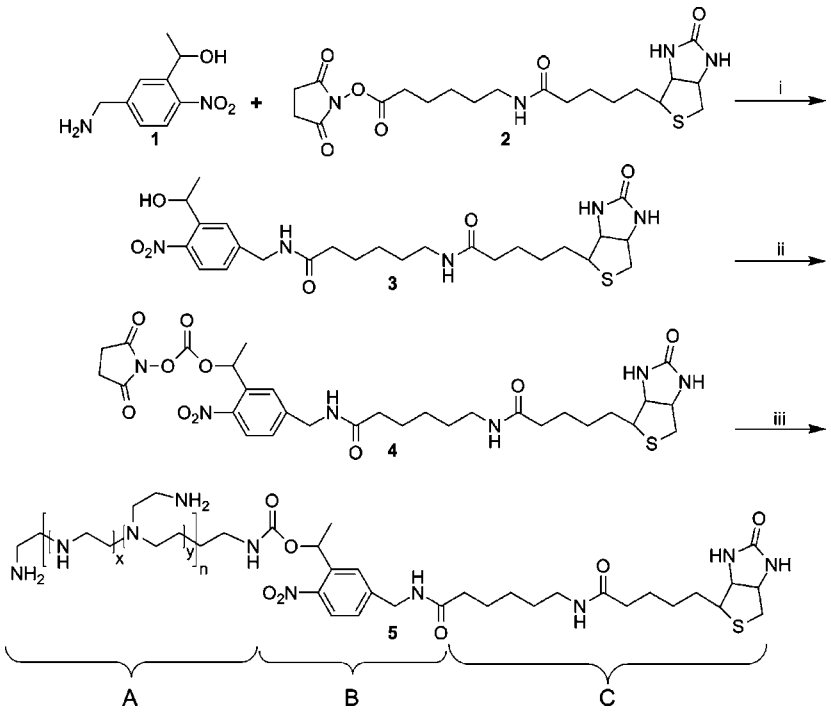


Figure 1. Schematic of B-PC-PEI bead formulation with nucleic acids and release with light exposure.

Testing for Photocleavability. UV irradiation was performed with a Model B-100A Hi Intensity UV Lamp (UVP Inc., Upland, CA) at a distance of 20 cm (emission peak at 365 nm, 9 mW/cm^2). B-PC-PEI, B-PEI, and PEI (0.01 mM) in H_2O receiving either 0, 5, or 10 min of 365 nm light exposure were analyzed by mass spectrometry on a 4700 Proteomics Analyzer with TOF/TOF optics (Applied Biosystems, Foster City, CA) at the University of Pennsylvania's Proteomics Core Facility.

Measuring Release of PEI from Streptavidin Microbeads. UV irradiation was performed, as described previously. For tracer studies, B-PC-PEI and B-PEI were covalently labeled with Cy5 NHS ester (Amersham Biosciences, Piscataway, NJ) according to the manufacturer's protocol using the ratio 1 mol Cy5 per 1 mol PEI primary amine. Streptavidin-coated magnetic beads (600 000 beads, Dynabeads M-280 streptavidin beads, Invitrogen) in 0.92 μL of phosphate-buffered saline (PBS, pH 7.4, Invitrogen) were added to 0.92 μL of 4.96 pmol/μL Cy5-labeled B-PEI or B-PC-PEI. A volume of 1.86 μL PBS was added, and the beads were allowed to incubate for 2 h (RT). The volume was brought to 300 μL, and 100 μL aliquots received either 0, 5, or 10 min of 365 nm light exposure. The samples were analyzed in a total volume of 400 μL of PBS on a BD FACSCalibur system (BD Biosciences, Franklin Lakes, NJ) at the University of Pennsylvania's Flow Cytometry and Cell Sorting Facility; 10 000 events were recorded per sample. The machine was calibrated to a negative control of unmodified streptavidin beads and a positive control of streptavidin beads directly labeled with Cy5 NHS ester. Flow cytometry data was analyzed with a custom Matlab (Mathworks Inc., Natick, MA) script designed to calculate the *x*-distance of the weighted maximum peak height for each sample. The fluorescence remaining on the bead after light exposure was calculated as a ratio comparing the *x*-distance of the maximum peak height at the specified time of 365 nm exposure to the *x*-distance of the maximum peak height for 0 min of 365 nm exposure.

Measuring Release of siRNA/PEI Polyplexes from Streptavidin Microbeads. Small interfering RNAs (siRNA) for lysosomal DNase II (siRNA ID = 121319, Ambion, Austin, TX) were labeled with Cy5 using a Label IT Nucleic Acid Labeling Kit (Mirus Bio Corporation, Madison, WI) according to the manufacturer's protocol and purified by ethanol precipitation. B-PC-PEI and B-PEI (unlabeled) were incubated with the streptavidin beads, as above, except for 1.5 h. The coated beads were diluted 10× with HEPES-buffered saline (HBS, 15 mM HEPES, 150 mM NaCl, pH 7.2) and added to the Cy5-labeled siRNA in HBS at varying N/P ratios. The polyplexes were allowed to form for 15 min (RT), and then the volume was adjusted to 300 μL with HBS. Aliquots (100 μL) were exposed to either 0, 5, or 10 min of 365 nm light (Figure 1). The samples

Scheme 1. Three-Step Synthesis of B-PC-PEI 5[a]

[a] Reagents and conditions: (i) $NaHCO_3$, DMF for 5 h; (ii) *N*,*N*′-disuccinimidyl carbonate, anhydrous DMF, Et_3N for 6 h; (iii) polyethylenimine, $NaHCO_3$, DMSO for 5 h.

were analyzed in a total volume of 400 μL of HBS on a BD FACSCalibur.

Quantifying the Amount of siRNA Released into the Supernatant. Streptavidin beads were prepared as above for siRNA/PEI polyplexes except after incubation with the Cy5-labeled siRNA the volume was brought to 100 μL with HBS. The samples were then placed on a Dynal MPC magnet (Invitrogen), and the supernatant was removed to remove any unbound siRNA/PEI polyplexes. The beads were then dissolved in 200 μL of HBS, and 100 μL aliquots received either 0, 5, or 10 min of 365 nm exposure. After exposure, the samples were placed on the magnet, the supernatant was separated from the beads, and the fluorescence of each was measured in 100 μL of HBS. The measurements were taken in a black 96-well plate (Nunc, Rochester, NY) on an EnVision Multilabel Plate Reader (Perkin-Elmer, Wellesley, MA). The fluorescence intensity (FI) data was used to calculate percent release [$100 \times FI_{supernatant}/(FI_{supernatant} + FI_{beads})$].

siRNA Stability. Negative control siRNA (0.4 μg, #4611G, Ambion) was tested alone, complexed with B-PC-PEI (N/P = 0.4), and complexed with B-PC-PEI attached to streptavidin beads (as described above). Each of these conditions received either 0 or 5 min of 365 nm light exposure, after which 2 μL of 6x loading dye (Promega, Madison, WI) was added. The samples (10 μL) were loaded into the wells of a 1% agarose gel in 1x TAE with SYBR Safe gel stain (Molecular Probes, Carlsbad, CA). The gel was run at 100 V for 30 min. Positive and negative controls were naked siRNA and B-PC-PEI, respectively.

RESULTS

Design, Synthesis, and Validation of Biotin−PC-PEI. Biotin−PC-PEI (B-PC-PEI) was designed to consist of three functional domains: (1) a cationic polymer domain (A in Scheme 1), in this case PEI, to electrostatically interact with and condense nucleic acids; (2) a photolabile domain (B in Scheme 1) to selectively release the polyplexes; (3) a biotin domain (C in Scheme 1) used to tether the compound to a streptavidin-coated surface or interact with free streptavidin. B-PC-PEI was synthesized via a three-step reaction process (Scheme 1) and was verified by ^{1}H NMR (Figure 2) and mass spectrometry (Figure 3A). By comparing mass spectrometry data from B-PC-PEI (Figure 3A) and unmodified PEI (not shown), it is estimated that the majority of the PEI received, on average, one photolabile-biotin arm (domains B and C, peaks centered around m/z = 966.62) and a smaller percentage received two photolabile-biotin arms (peaks centered around m/z = 1527.86).

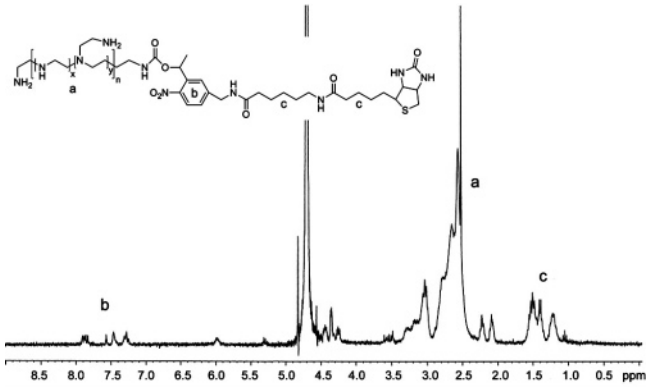

Figure 2. ^{1}H NMR of B-PC-PEI.

After validation of its formation, B-PC-PEI was analyzed for the ability to breakdown after exposure to 365 nm light. B-PC-PEI was analyzed by mass spectrometry before and after 5 min of 365 nm light exposure (Figures 3A and 3B, respectively). After 5 min of light exposure, the peaks centered around m/z = 1527.86 completely disappeared and the peaks centered around m/z = 966.62 shifted to a lower m/z value, indicating that the photolabile biotin arms were cleaved from the PEI. Increasing the duration of light exposure to 10 min did not further increase the breakdown of B-PC-PEI (not shown). As a control, Biotin−PEI (B-PEI) was synthesized to have

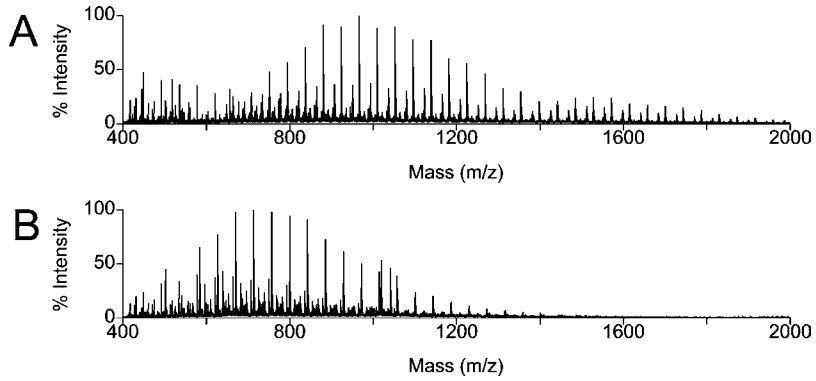

Figure 3. Mass spectrometry for B-PC-PEI without light exposure (A) and with 5 min of 365 nm light exposure (B).

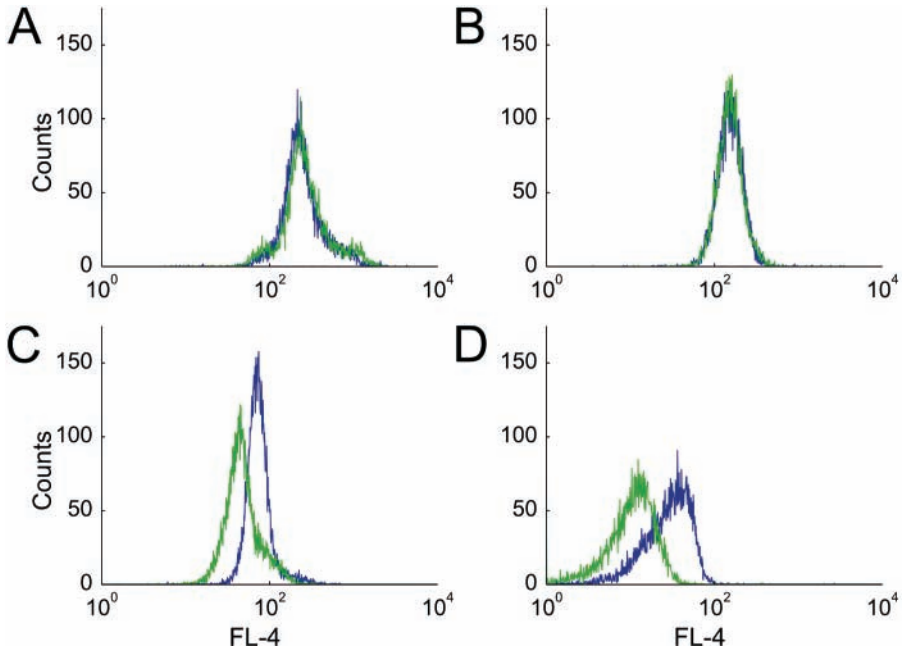

Figure 4. Flow cytometry data showing the fluorescence shifts of B-PEI/streptavidin beads without (A) or with (B) siRNA, and of B-PC-PEI/streptavidin beads without (C) or with (D) siRNA due to light exposure (green line, 10 min (A and C) or 5 min (B and D) of 365 nm exposure; blue line, 0 min exposure).

domains A and C of B-PC-PEI (i.e., no photolabile domain B, see Scheme 1 for designations). Mass spectrometry validated the formation of this compound and showed no change in the spectra with exposure to 5 or 10 min of 365 nm light (not shown).

Release of PEI from Streptavidin Beads. B-PC-PEI was immobilized to the surface of streptavidin-coated beads as depicted in Figure 1. To determine release of the PEI domain from the streptavidin beads, the PEI primary amines of B-PC-PEI were labeled with Cy5 NHS ester prior to immobilization. The streptavidin beads bound with Cy5-labeled B-PC-PEI were then exposed to 0, 5, or 10 min of 365 nm light and analyzed by flow cytometry for fluorescence loss. As a control, B-PEI, labeled with Cy5, was subjected to the same procedure to differentiate between fluorescence loss due to photobleaching from the 365 nm light exposure and fluorescence loss due to actual release of the Cy5-labeled PEI domain from the surface of the bead.

As can be seen in Figure 4A and 4C, after 10 min of 365 nm exposure, there was a negligible loss of fluorescence due to photobleaching (Figure 4A, B-PEI) and a much larger shift (fluorescence loss) due to actual cleavage of the Cy5-labeled PEI domain from the surface of the bead (Figure 4C, B-PC-PEI). This data when looked at numerically as the fraction of remaining fluorescence associated with the bead (see Experimental Procedures for details of the calculations) translates to values of 0.78 ± 0.15 and 0.90 ± 0.09 ($n = 6$, $p < 0.07$) for B-PC-PEI and B-PEI, respectively, after 5 min of light exposure, and 0.51 ± 0.12 and 0.97 ± 0.23 ($n = 6$, $p < 0.0008$) for B-PC-PEI and B-PEI, respectively, after 10 min of light exposure.

Release of siRNA from Streptavidin Beads. To quantify the release of nucleic acids from streptavidin beads, unlabeled B-PC-PEI was immobilized to streptavidin beads, as described above, and added to Cy5-labeled siRNA at an N/P ratio = 0.16 (Figure 1). The immobilized siRNA/B-PC-PEI polyplexes received either 0, 5, or 10 min of 365 light exposure and were analyzed by flow cytometry for fluorescence loss. As with the experiments measuring the loss of PEI from the surface of the streptavidin beads, B-PEI in place of B-PC-PEI was used as a control. As seen in Figure 4B and 4D, after 5 min of 365 nm light exposure, there was negligible fluorescence loss due to photobleaching (Figure 4B, B-PEI/siRNA), and significant fluorescence loss due to release of siRNA from the surface of the bead (Figure 4D, B-PC-PEI/siRNA). Quantitatively, the fraction of remaining fluorescence was 0.52 ± 0.14 and 0.94 ± 0.10 ($n = 3$, $p < 0.007$) for B-PC-PEI/siRNA and B-PEI/siRNA polyplexes, respectively. Increasing the light exposure to 10 min further increased the release of the B-PC-PEI/siRNA polyplexes with the fraction remaining reduced to 0.27 ± 0.13

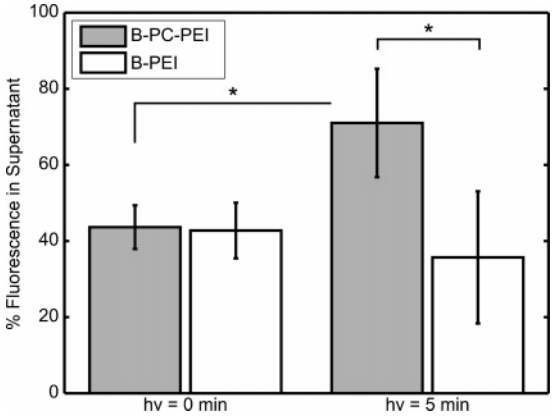

Figure 5. Release of surface bound siRNA/PEI complexes into the supernatant (* = $p < 0.03$).

($p < 0.05$ comparing B-PC-PEI/siRNA at 5 and 10 min light exposure). This data was consistent at N/P ratios of 1.6 and 4.8 for B-PC-PEI, but N/P = 0.16 showed optimal fluorescence readings for flow cytometry.

As an additional test, siRNA was immobilized to the streptavidin beads as above, but the fluorescence in both the supernatant and on the bead were measured. Fluorescence was measured as relative fluorescence units on a plate reader and converted into percent fluorescence in the supernatant (as described in the Experimental Procedures). After 0 min of 365 nm light exposure, both B-PC-PEI and B-PEI immobilized polyplexes (N/P = 0.4) released a similar amount of fluorescence in the supernatant (Figure 5). With 5 min of 365 nm light exposure, the amount of fluorescence in the supernatant was significantly higher for B-PC-PEI than for B-PEI immobilized polyplexes ($p < 0.03$, Figure 5). Increasing light exposure to 10 min did not enhance release of siRNA from B-PC-PEI polyplexes (71.03 ± 14.24% and 78.34 ± 7.59% at 5 and 10 min of light exposure, respectively ($p > 0.05$)). Using these measurements, it is estimated that about 7 μg siRNA/mg bead is immobilized.

Finally, agarose gel electrophoresis was used to assess the integrity of the siRNA after exposure to the light-activated release conditions. The gels showed no difference in mobility between naked siRNA before or after light exposure, B-PC-PEI/siRNA polyplexes before or after light exposure, and B-PC-PEI/siRNA polyplexes released from streptavidin beads before or after light exposure (not shown).

DISCUSSION

Spatially and temporally controlled release of nucleic acids has many potential applications, including disease treatment and discovery of molecular processes involved in gene delivery. For nonviral gene therapy applications, spatial targeting has been attempted though inclusion of receptor targeting ligands to facilitate vector uptake into specific cells populations (*27*−*30*) and through the use of biotinylated cationic polymers for substrate-mediated delivery (*14*, *15*).

We developed a novel compound, B-PC-PEI, that combines surface-mediated delivery with photolabile technology for capture and light-activated controlled release of nucleic acids from solid supports. B-PC-PEI consists of three functional domains designed to tether the compound to a surface, interact with nucleic acids, and release the nucleic acids from the surface through exposure to 365 nm light. This represents the first time this type of compound has been used for the controlled release of noncovalently modified nucleic acids from streptavidin-coated solid supports.

The use of biotinylated PEI for substrate-mediated delivery of pDNA can result in positive transfection (*15*). The retention of nucleic acids within a PEI polyplex depends on the molecular weight of the polymer used (*31*), the characteristics of the polymer (e.g., linear versus branched (*32*)), and the N/P ratio (*33*). Additionally, the extent of biotinylation will also affect the electrostatic interactions between PEI and nucleic acids because each biotin added should remove one free primary amine. The amount of release for a biotinylated PEI should be tunable by adjusting each of these properties, and therefore it should be easy to design the system to have negligible nucleic acid release from the polymer unless the whole polyplex is released from the substrate with light, as with B-PC-PEI. Further validating this point, the use of biotinylated PLL did not show enhanced transfection unless the majority of the polyplex was formed with a non-biotinylated PLL (*15*).

For B-PC-PEI, photolysis of the PEI domain from the remaining molecule occurred within 5 min when in free solution (Figure 3) and 10 min when attached to streptavidin beads (Figure 4C). It is possible that increased light exposure was necessary to release the Cy5-labeled PEI domain from the streptavidin beads because the beads or the Cy5 attenuated some of the light. Also, PEI has been thought to form nonspecific interactions with streptavidin (*15*) so it is possible that for this experiment, those forces needed to be overcome as well. Comparing the fluorescence loss from the Cy5-labeled B-PC-PEI (Figure 4C) and B-PEI (Figure 4A) beads upon light exposure shows clearly that the loss is due to actual cleavage of the PEI domain from the bead and not photobleaching.

In addition to the two causes of fluorescence loss described previously, for the siRNA there could also be loss due to release of weakly associated siRNA from the bead. Similar to the results with the Cy5-labeled biotin-compounds, there was negligible fluorescence loss due to photobleaching or diffusion after 5 min of 365 nm light exposure (B-PEI polyplexes, Figure 4B). For polyplexes made with B-PC-PEI there was a significant loss of bead-associated fluorescence after only 5 min of light exposure (Figure 4D). As with the PEI domain, increasing the duration of light exposure further increased polyplex loss; however, the majority of siRNA was released in the first 5 min. This differs from the PEI results possibly because PEI is less able to nonspecifically interact with the streptavidin when it is electrostatically condensing the siRNA.

The loss of siRNA fluorescence from the bead was further validated by a gain in fluorescence in the supernatant (Figure 5). At 0 min of 365 nm light exposure both B-PC-PEI and B-PEI polyplexes have a similar percent fluorescence in the supernatant (presumably due to diffusion), but by 5 min of light exposure the B-PC-PEI/siRNA polyplexes had released 71.03 ± 14.24% of the polyplexes into the supernatant while the B-PEI polyplexes remained unchanged from the 0 min time point. Additionally, increasing the duration of light to 10 min did not significantly enhance the release of the B-PC-PEI polyplexes. It is important to note that release of siRNA at 0 min for both B-PC-PEI and B-PEI polyplexes is most likely due to the low N/P ratio. Increasing the N/P ratio would cause greater retention of the siRNA within the polyplex; however, N/P = 0.4 gave optimal fluorescence readings. Additionally, since it is the PEI and not the siRNA that is directly coupled to the beads and the light-activated mechanism, any released siRNA should be released as polyplexes with the PEI.

Finally, the integrity of the siRNA was tested with agarose gel electrophoresis, and under all conditions tested, light exposure did not change the mobility or noticeably degrade the siRNA. This result is expected, as experiments conducted by Quick and Anseth showed negligible change in pDNA integrity after 365 nm light exposure (*34*). Additionally, Quick and

Anseth showed retained pDNA activity after light exposure at 365 nm (*34*).

While polymers have been previously engineered for the controlled release of nucleic acids (*35*−*39*), the release has largely relied on cellular process. In this report, we have demonstrated the synthesis and functionality of a compound, B-PC-PEI, that is able to selectively release nucleic acids from a solid support after light application and which has many potential applications ranging from biological studies to therapeutic applications.

ACKNOWLEDGMENT

Drs. Xiaopeng Bai and Jingyue Ju of Columbia University for their help with chemical synthesis. This research was funded by NIH grants HL64388 and HL66565 (S.L.D.).

Received September 8, 2006; Revised Manuscript Received February 5, 2007

Bombesin is a tetradecapeptide neurohormone that binds to gastrin-releasing peptide receptors (GRPR). GRPRs have been found in a variety of cancers including invasive breast and prostate tumors. The peptide MP2346 (DOTA−(Pro^1,Tyr^4)-bombesin(1−14)) was designed to bind to these GRP receptors. This study was undertaken to evaluate radiolabeled MP2346 as a positron emission tomography (PET) imaging agent. MP2346 was radiolabeled, in high radiochemical purity, with the positron-emitting nuclides ^{64}Cu ($t_{1/2}$ = 12.7 h, β^+ = 19.3%, E_{avg} = 278 keV) and ^{86}Y ($t_{1/2}$ = 14.7 h, β^+ = 33%, E_{avg} = 664 keV). ^{64}Cu-MP2346 and ^{86}Y-MP2346 were studied *in vitro* for cellular internalization by GRPR-expressing PC-3 (human prostate adenocarcinoma) cells. Both ^{64}Cu- and ^{86}Y-MP2346 were studied *in vivo* for tissue distribution in nude mice with PC-3 tumors. Biodistribution in PC3 tumor-bearing mice demonstrated higher tumor uptake, but lower liver retention, in animals injected with ^{86}Y-MP2346 compared to ^{64}Cu-MP2346. Receptor-mediated uptake was confirmed by a significant reduction in uptake in the PC-3 tumor and other receptor-rich tissues by coinjection of a blockade. Small animal PET/CT imaging was carried out in mice bearing PC-3 tumors and rats bearing AR42J tumors. It was possible to delineate PC-3 tumors *in vivo* with ^{64}Cu-MP2346, but superior ^{86}Y-MP2346-PET images were obtained due to lower uptake in clearance organs and lower background activity. The ^{86}Y analogue demonstrated excellent PET image quality in models of prostate cancer for the delineation of the GRPR-rich tumors and warrants further investigation.

INTRODUCTION

Gastrin-releasing peptide (GRP), a 27-amino acid mammalian peptide, is responsible for the release of gastrin from stomach cells. The receptor for GRP (GRPR) has been found in a variety of cancers including ovarian, lung, gastrointestinal, and colon (*1*−*6*). GRPRs have also been shown to be present on invasive breast and prostate tumors (*7*, *8*). Bombesin (BN) is a 14-amino acid neuropeptide that was originally isolated from the skin of the Bombina frog and binds with high affinity to GRPR (*9*). A noninvasive method of detecting (by imaging) and treating GRPR-positive tumors has been achieved by the radiolabeling of BN analogues with diagnostic and therapeutic radionuclides (*10*−*12*).

Indium-111- and ^{99m}Tc-labeled BN analogues have been studied as potential single-photon emission computed tomography (SPECT) radiopharmaceuticals (*13*−*20*). BN analogues radiolabeled with ^{131}I, ^{188}Re, and ^{177}Lu (*21*−*23*) have been evaluated for potential radiotherapy applications. Positron emission tomography (PET) is a more quantitative imaging method compared to SPECT with better spatial resolution and image contrast. Animal studies have been carried out using ^{68}Ga-, ^{18}F-, and ^{64}Cu-labeled BN analogues utilizing PET and have shown good tumor localization and visualization (*24*−*28*).

Copper-64 ($t_{1/2}$ = 12.7 h, β^+ = 19.3%, E_{avg} = 278 keV) and ^{86}Y ($t_{1/2}$ = 14.7 h, β^+ = 33%, E_{avg} = 664 keV) can both be prepared on small cyclotrons utilizing the ^{64}Ni(p,n)^{64}Cu and ^{86}Sr(p,n)^{86}Y reactions, respectively (*29*, *30*). Because of the decay scheme of ^{64}Cu (17.4% β^+, 41% EC, 40% β^-), it has the potential to be used both for diagnostic and therapeutic applications (*31*). Yttrium-86 is a PET-emitting nuclide and can act as an imaging surrogate for ^{90}Y, which has been used extensively in nuclear medicine as a therapeutic nuclide. DOTA−(Pro^1, Tyr^4)-bombesin(1−14) (MP2346), where DOTA = 1,4,7,10-tetraazacyclododecan-*N*,*N*′,*N*″,*N*‴ tetraacetic acid (Figure 1) was previously synthesized and demonstrated promise for scintigraphic imaging of GRPR-expressing tumors after radiolabeling with ^{111}In (*13*). The goal of this study was to evaluate both ^{64}Cu- and ^{86}Y-radiolabeled MP2346 as candidates for the noninvasive detection of GRPR-positive tumors using PET.

EXPERIMENTAL PROCEDURES

General Methods and Materials. All chemicals unless otherwise stated were purchased from the Sigma-Aldrich Chemical Co. (St. Louis, MO). Water was distilled and then deionized (18 MΩ/cm^2) by passing through a milli-Q water filtration system (Millipore Corp., Milford, MA). Copper-64 and ^{86}Y were produced on a CS-15 biomedical cyclotron at Washington University School of Medicine, using published methods (*29*, *30*). PC-3 (human prostate adenocarcinoma) cells were obtained from American Type Culture Collection (ATCC) (Manassas, VA) and maintained in our laboratories by serial cell culture. Radioactivity was counted with a Beckman Gamma

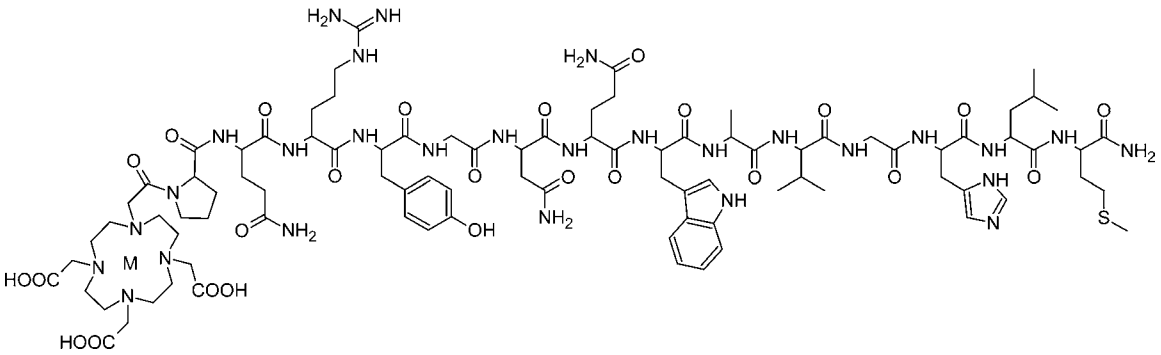

Figure 1. Structure of MP2346 (DOTA−Pro-Gln-Arg-Tyr-Gly-Asn-Gln-Trp-Ala-Val-Gly-His-Leu-Met-NH_2) with M corresponding to the chelated ^{64}Cu or ^{86}Y metal.

8000 counter containing a NaI crystal (Beckman Instruments, Inc., Irvine, CA).

Radiolabeling of MP2346. The GRPR binding peptide MP2346 (CAS 593287-40-2) was synthesized by a solid-phase method as described, and its purity was confirmed with HPLC and mass spectrometry (*14*). Labeling of MP2346 (10 μg) with $^{64}CuCl_2$ (11.15 mCi) took place in a 100 μL aliquot of 0.5 M NH_4OAc (pH 5.5) incubated at 80 °C for 30 min. Quality control of the product was performed using radio thin-layer chromatography on $MKC_{18}F$ silica gel plates using NH_4OAc/methanol (30:70) as the mobile phase ($^{64}CuCl_2$ $R_f = 0$; ^{64}Cu-MP2346 $R_f = 0.7$). The reaction between MP2346 (1.8 μg) with $^{86}YCl_3$ (2.1 mCi) took place in 0.5M NH_4OAc (pH 6.5) incubated at 80 °C for 30 min. Quality control was performed using the same TLC conditions as with the ^{64}Cu analogue ($^{86}YCl_3$ $R_f = 0$; ^{86}Y-MP2346 $R_f = 0.5$). Reaction progress and purity were also monitored by analytical reversed-phase HPLC, which was performed on an Waters Alliance 2695 Separations Module (Milford, MA) with a Waters 996 photodiode array detector (PDA) and an Carroll & Ramsey 105-S1 radioactivity detector (Berkeley, CA) with a Waters XTerra MS C_{18} 3.5 μm (2.1 × 50 mm) column. The mobile phase was H_2O (0.1% formic acid) and CH_3CN (solvent B). The gradient consisted of 15% B to 85% A in 60 min (0.5 mL/min flow rate) (^{64}Cu-MP2346, $t_R =$ 5.8 min; ^{86}Y-MP2346, $t_R = 6.9$ min; unreacted ^{64}Cu or ^{86}Y were eluted in the void volume, $t_R < 1.0$ min; uncomplexed MP2346, $t_R = 16.4$ min).

Internalization Studies. PC-3 cells were harvested and seeded into six-well plates at 5×10^5 cells per well. On the following day, the cells were washed with Hanks balanced salt solution (HBSS), and 1 mL of internalization media (DMEM plus 30 mM HEPES, 2 mM L-glutamine, 1 mM sodium pyruvate, and 1% BSA) was added to each well. The ^{64}Cu-MP2346 or ^{86}Y-MP2346 was then added such that the final concentration of peptide was approximately 1 nM. To three of the six wells per plate was added an excess (10 μg) of [Tyr^4]-bombesin (Sigma Chemical Co., St. Louis, MO) to act as an inhibitor. The plates (one per time point) were then incubated at 37 °C for 15, 30, 60, 120, 240, or 1200 min. At each time point, the corresponding plate was removed, the radioactive media was aspirated, and the cells were washed with cold HBSS. This was followed by an acid wash (HBSS plus 20 mM sodium acetate, pH 4.0), which was collected for the determination of surface-bound radioactivity. Immediately after collection of the acid wash, 1 mL of 10 mM sodium borate/1.0% SDS was added to the wells and allowed to incubate for 2−3 min at room temperature to facilitate cell lysis. The lysates were collected and, along with the surface fractions, were counted on a gamma counter. Protein amounts were determined using the Pierce BCA Protein Assay Kit (Rockford, IL) in a separate set of plates in which all of the steps were followed, but no radioactivity was added. The data are presented as fmol of internalized radioactivity normalized to protein amount. Maximum internalizations were determined from nonlinear curve fitting using Prism software and the one site binding hyperbola equation provided.

Biodistribution Studies. All animal experiments were conducted in compliance with the Guidelines for the Care and Use of Research Animals established by Washington University's Animal Studies Committee. Biodistribution studies were carried out on male athymic nude mice (Charles River Laboratories, Wilmington, MA) that had been implanted with 3×10^6 PC-3 cells into either the upper-right or lower-left flank of the animal. Tumors were allowed to grow for 36 days after implantation, at which time the animals received either 8−10 μCi of ^{64}Cu-MP2346 or ^{86}Y-MP2346 (7−10 ng) in 50 μL of saline via lateral tail vein injection. Animals were then euthanized at desired time points (1, 4, and 24 h, $n = 5$ per group). Two additional groups of mice (1 h time point only) were preinjected with unlabeled peptide to act as a receptor-blockade (100 μg of [Tyr^4]-bombesin) immediately prior to administering ^{64}Cu-MP2346 or ^{86}Y-MP2346. This constitutes a 10 000- or 15 000-fold increase over the mass of peptide injected with ^{64}Cu-MP2346 or ^{86}Y-MP2346, respectively. Following sacrifice, selected tissues and organs of interest were then removed and weighed and radioactivity measured in a gamma counter. The percent dose per gram (%ID/g) was then calculated.

Imaging Studies. Small animal PET images were obtained on a microPET-FOCUS 220 (Siemens Medical Solutions USA, Inc.) (*32*) and were coregistered with CT images from a MicroCAT II System (ImTek Inc., Knoxville, TN). Mice were anesthetized with 1−2% isoflurane prior to scanning, positioned supine, and immobilized in a custom prepared cradle. To reduce scattering caused by the prompt gammas of ^{86}Y, the energy window of the small animal PET (typically 250−750 keV) was narrowed to 470−580 keV and the data obtained normalized to a ^{86}Y cylinder phantom. The image registration between microCT and PET images was accomplished by using a landmark registration technique with AMIRA image display software (AMIRA, TGS Inc, San Diego, CA.). The registration method proceeds by rigid transformation of the microCT images from landmarks provided by fiducial markers directly attached to the animal bed. Images were obtained of male athymic nude mice (Charles River Laboratories, Wilmington, MA) that had been implanted with 3×10^6 PC-3 cells into the right flank. Images of male Lewis rats (Charles River Laboratories, Wilmington, MA) that had been implanted with AR42J tumor pieces in the left flank of the rat 10 days before the study were also obtained. In these studies, the mice received either ^{64}Cu-MP2346 ($n = 3$, 125 μCi, 125 ng) or ^{86}Y-MP2346 ($n = 3$, 200 μCi, 200 ng). These mice were imaged side by side with mice ($n = 3$ per group) that had been coadministered with 100 μg of [Tyr^4]-bombesin along with the radiolabeled peptide. The Lewis rats in the ^{86}Y-MP2346 PET study were imaged individually. One group ($n = 3$) was given ^{86}Y-MP2346 (200 μCi, 200 ng) and

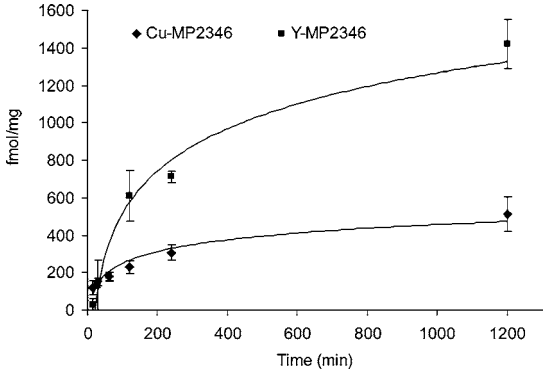

Figure 2. Internalization of ^{64}Cu-MP2346 and ^{86}Y-MP2346 into PC-3 cells. ^{64}Cu-MP2346 or ^{86}Y-MP2346 was added to the cells and incubated at 37 °C. At various time points, the media was removed and the cells were acid-washed to remove surface-bound radioactivity and harvested. The cell pellets (internalized) and acid wash (surface-bound) were counted. The data are presented as fmol of internalized radioactivity normalized to protein amount against time. The data are shown as the mean of three experiments ± SD with each experiment being performed in triplicate.

another group ($n = 3$) was coadministered 100 μg of [Tyr^4]-bombesin. For imaging studies tumor, kidney, and liver standard uptake values (SUV, defined as the ratio of activity in tissue per milliliter to the activity in the injected dose per subject body weight; (nCi/mL) × [weigh (g)/injected dose (nCi)]) of ^{64}Cu- or ^{86}Y-activity were generated by measuring regions of interest that encompassed the entire organ from the small animal PET images.

Statistical Methods. All of the data are presented as mean ± SD. For statistical classification, a Student's t test was performed using GraphPad PRISM (San Diego, CA). Differences at the 95% confidence level ($p < 0.05$) were considered significant.

RESULTS

Radiolabeling of MP2346. Radiolabeling of MP2346 with ^{64}Cu and ^{86}Y was performed over a range of temperatures, incubation times, and buffer pHs. The optimal conditions for labeling MP2346 with $^{64}CuCl_2$ in 0.5M NH_4OAc (pH 5.5) were found to be 80 °C for 30 min. Radiochemical yields >99% at a specific activity of 0.99 mCi/μg (1958 mCi/μmol) were achieved. The ^{86}Y analog was labeled with $^{86}YCl_3$ in 0.5 M NH_4OAc (pH 6.5) at 80 °C over 30 min. Radiochemical yields >94% (1.0 mCi/μg; 2000 mCi/μmol) were obtained by this method.

Internalization Studies. The internalization of ^{64}Cu-MP2346 and ^{86}Y-MP2346 into PC-3 (human prostate adenocarcinoma) cells is shown in Figure 2. The internalization of ^{64}Cu-MP2346 and ^{86}Y-MP2346 were monitored over a 20 h period. The amount of specifically internalized peptide normalized to the protein content of the cells was 121.83 ± 33.74 fmol/mg for ^{64}Cu-MP2346 and 28.09 ± 30.76 fmol/mg for ^{86}Y-MP2346 after 15 min incubation. Internalization increased steadily for both compounds and after 20 h of incubation, 512.04 ± 83.41 fmol/mg of ^{64}Cu-MP2346 and 1420.419 ± 129.94 fmol/mg of ^{86}Y-MP2346 were internalized into the PC-3 cells. The amount of surface-bound radioactivity was <100 fmol/mg for all time points (data not shown). Nonlinear curve fitting showed that the maximum internalization was 535 fmol/mg for ^{64}Cu-MP2346 and 1945 fmol/mg for ^{86}Y-MP2346.

Biodistribution Studies. Biodistribution studies were carried out on male athymic nude mice that had been implanted with PC-3 tumors into the right flank of the animals. Tumors were allowed to grow for 36 days, at which time the animals either received 8−10 μCi (~8−10 ng) of ^{64}Cu-MP2346 or 8−10 μCi (~8−10 ng) of ^{86}Y-MP2346 via tail vein injection. The mass of the injected peptide was the same for the two radiocompounds, and therefore differences between the biodistribution profiles are not due to the mass of the peptide administered. Table 1 shows the summary of the biodistribution data of ^{64}Cu-MP2346 and ^{86}Y-MP2346 in male nude mice bearing PC-3 tumors at 1, 4 and 24 h. Table 2 gives selected tumor/organ ratios for ^{64}Cu-MP2346 and ^{86}Y-MP2346.

Table 1. Biodistribution of ^{64}Cu-MP2346 and ^{86}Y-MP2346 in Male Nude Mice Bearing Day-36 PC-3 Tumors (%ID/g ± Standard Deviation, $n = 5$) at 1, 4, and 24 h[a]

[a] Two additional groups were preadministered blockade (100 μg of [Tyr^4]-bombesin) immediately prior to administering ^{64}Cu-MP2346 or ^{86}Y-MP2346. Similar trends were also observed for the other receptor-rich tissues, the stomach and intestines, where uptake of the two radiocompounds was significantly reduced by administration of blockade.

Table 2. Selected Tumor/Organ Ratios for ^{64}Cu- and ^{86}Y-MP2346 in Male Nude Mice Bearing Day-36 PC-3 Tumors (%ID/g ± Standard Deviation, $n = 5$) at 1, 4, and 24 h

	^{64}Cu (1 h)	^{86}Y (1 h)	^{64}Cu (4 h)	^{86}Y (4 h)	^{64}Cu (24 h)	^{86}Y (24 h)
tumor/blood	6.192	12.074	5.511	134.3	4.487	1680

tumor/liver	0.597	15.60	0.298	8.590	0.284	9.223
tumor/kidney	0.129	0.318	0.085	0.141	0.253	0.536

Both ^{64}Cu-MP2346 and ^{86}Y-MP2346 demonstrated rapid clearance of radioactivity from the blood over the 24 h period. Although blood levels of ^{86}Y-MP2346 were initially higher at 1 h compared to the ^{64}Cu analog (0.219 ± 0.098 vs 0.128 ± 0.015 %ID/g, $p < 0.005$), by 24 h there was a significant reduction in the blood levels of ^{86}Y-MP2346 compared to ^{64}Cu-MP2346 (0.001 ± 0.001 vs 0.069 ± 0.007 %ID/g, $p < 0.0001$). This combined with the increased uptake of ^{86}Y-MP2346 in the tumor resulted in over a 300-fold increase in the tumor/blood ratio for ^{86}Y-MP2346 compared to ^{64}Cu-MP2346 at 24 h.

The liver activity of ^{64}Cu-MP2346 is consistently higher at all time points (1 h, 1.329 ± 0.304 %ID/g; 4 h, 1.412 ± 0.345 %ID/g; 24 h, 1.089 ± 0.429 %ID/g) compared to ^{86}Y-MP2346 (1 h, 0.170 ± 0.027 %ID/g; 4 h, 0.145 ± 0.048 %ID/g; 24 h, 0.152 ± 0.069 %ID/g). These data result in superior tumor/liver ratios for the ^{86}Y-MP2346 (Table 2). It is also important

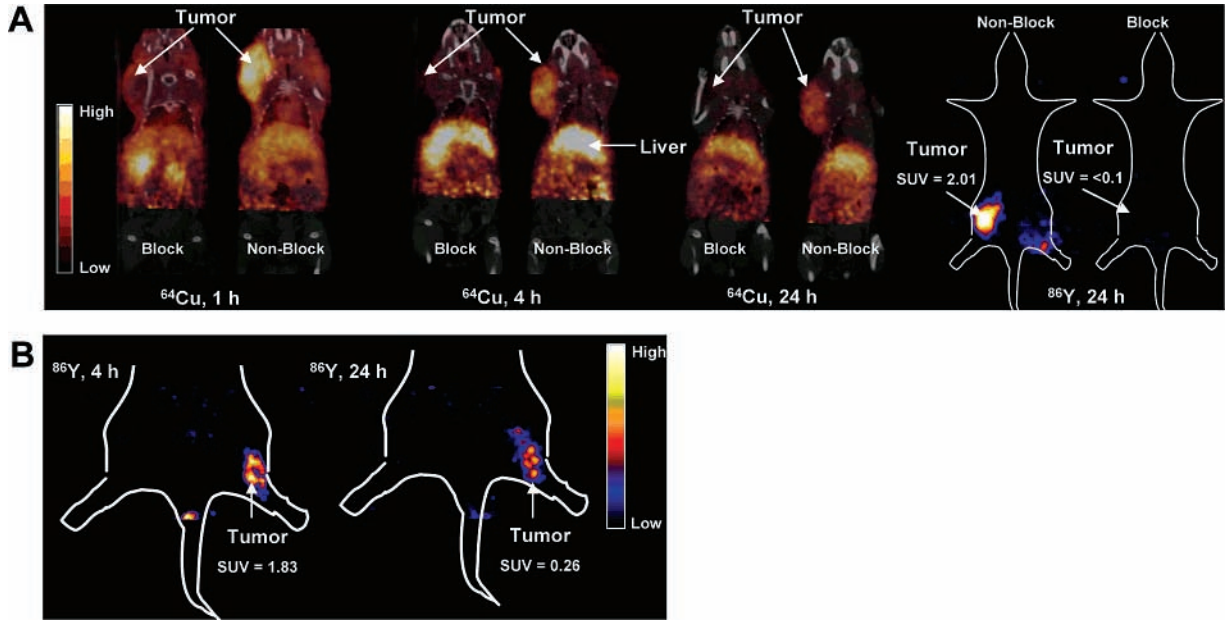

Figure 3. (A) ^{64}Cu-MP2346 PET with coregistered CT at 1, 4, and 24 h in nude mice with PC-3 tumors in the right neck (SUV values not shown on figure). At each time point, a mouse that received blockade (left) was coimaged with a mouse that did not receive blockade (right). Also shown is ^{86}Y-MP2346 PET (without CT coregistration) in nude mice with PC-3 tumors in right flank At each time point, a mouse that received blockade (right) was coimaged with a mouse that did not receive blockade (left). The PET images also show that the administration of a blockade dose substantially reduces tumor uptake of both agents by such an extent that the tumor cannot be delineated for either compound at any time point. (B) ^{86}Y-MP2346 PET at 4 and 24 h postinjection in male Lewis Rats with AR42J tumors in left leg. In both the mice and rats PET imaging it is evident from the ^{86}Y images that background accumulation is very low (i.e., low nontarget tissue uptake) and that in the nonblockade mouse very little tumor tracer accumulation is noted.

to note that for both agents, there is very little liver clearance of activity over 24 h. Kidney uptake of ^{64}Cu-MP2346 was initially high but reduced ~5-fold by 24 h (1 h, 6.148 ± 1.067 %ID/g; 4 h, 4.936 ± 0.810 %ID/g; 24 h, 1.222 ± 0.296 %ID/g). In contrast ^{86}Y-MP2346 showed slightly higher kidney retention at 1 h (8.309 ± 2.412 %ID/g), which remained constant over 4 h (8.789 ± 2.106 %ID/g) and then only showed a 3-fold decrease by 24 h (2.623 ± 0.391 %ID/g).

The GRPR-rich pancreas demonstrated uptake of ^{64}Cu-MP2346 (1 h, 4.387 ± 1.090 %ID/g; 4 h, 3.339 ± 0.463 %ID/g; 24 h, 1.155 ± 0.327 %ID/g) which was significantly lower ($p < 0.001$) than values obtained for ^{86}Y-MP2346 at all time points (1 h, 14.456 ± 5.719 %ID/g; 4 h, 13.358 ± 2.954 %ID/g; 24 h, 12.965 ± 2.229 %ID/g). To demonstrate receptor-mediated targeting of the agents two additional groups were preadministered blockade (100 μg of [Tyr^4]-bombesin) immediately prior to administering ^{64}Cu-MP2346 or ^{86}Y-MP2346 and were sacrificed at 1 h postinjection. In these animals, the pancreas demonstrated receptor-mediated blocking with a significant decease in tissue retention of the tracers in the receptor-rich pancreas compared to the nonblocked animals (^{64}Cu-MP2346, 0.464 ± 0.259 vs 4.387 ± 1.090 %ID/g, $p < 0.0005$; ^{86}Y-MP2346, 0.304 ± 0.018 vs 14.456 ± 5.719 %ID/g, $p < 0.0005$). Similar trends were also observed for the other receptor-rich tissues, the stomach and the intestines, where uptake of the tracers was significantly reduced by administration of blockade (data not shown).

Uptake of ^{86}Y-MP2346 into the GRPR-rich PC-3 tumor was significantly higher at all time points compared to ^{64}Cu-MP2346 (1 h, 2.646 ± 1.228 vs 0.793 ± 0.181 %ID/g, $p < 0.0005$; 4 h, 1.243 ± 0.658 vs 0.421 ± 0.214 %ID/g, $p < 0.0005$; 24 h, 1.405 ± 0.222 vs 0.309 ± 0.199 %ID/g, $p < 0.0005$), resulting in superior tumor/blood, tumor/muscle and tumor/liver ratios for ^{86}Y-MP2346 compared to ^{64}Cu-MP2346 (Table 2). Administration of blockade (100 μg of [Tyr^4]-bombesin) immediately prior to administering ^{64}Cu-MP2346 or ^{86}Y-MP2346 resulted in significant reduction in PC-3 tumor accumulation for both agents (^{64}Cu-MP2346, 0.099 ± 0.134 vs 0.793 ± 0.181 %ID/g, $p < 0.0005$; ^{86}Y-MP2346, 0.667 ± 0.179 vs 2.646 ± 1.228 %ID/g, $p < 0.0005$) confirming receptor-mediated accumulation of the compounds into the tumor.

Imaging Studies. Small animal PET/CT images of ^{64}Cu-MP2346 and ^{86}Y-MP2346 in PC-3 tumor-bearing mice and ^{86}Y-MP2346 in AR42J-bearing rats are shown in Figure 3A and 3B. SUV data for ^{64}Cu-MP2346 over 24 h is shown in Figure 4. Small animal PET/CT images of ^{64}Cu-MP2346 in the PC-3 model allows for clear delineation of the PC-3 tumor in the upper-right flank of the animal after 1 h and as far out as 24 h postinjection (Figure 3A). Also noted in these images is the accumulated activity in the liver of the mice consistent with the data obtained from the acute biodistribution data (Table 1). In the ^{86}Y-MP2346 images, low background accumulation is observed (i.e., low nontarget tissue accumulation), and this is consistent with the biodistribution data and the tumor/tissue ratios reported (Tables 1 and 2). In all cases the ^{86}Y-MP2346 images in the PC-3-bearing mice are superior to the ^{64}Cu-MP2346 images because of the high tumor/tissues ratios reported from the biodistribution data (Table 2). Because of the excellent image quality obtained with ^{86}Y-MP2346 in the PC-3-bearing mice, we wanted to confirm this in a second rodent model and therefore undertook imaging in Lewis rats bearing AR42J tumors. The low tumor/background ratio associated with ^{86}Y-MP2346 also allows for excellent tumor visualization in the AR42J rats (Figure 3B), where the tumor is easily delineated in the lower-left flank of the rat at 4 and 24 h postinjection.

In Figure 3A the significant reduction in tumor accumulation in the blocked animals confirmed specific uptake of the ^{64}Cu-MP2346 and ^{86}Y-MP2346 in the receptor-rich tumor tissue. SUV data were calculated for the tumors in both blocked and nonblocked animals (Figure 3 and Figure 4). This analysis showed that there were statistical differences ($p < 0.001$) between tumor concentration of mice that did and did not receive a coinjection of blockade at all time points examined and that

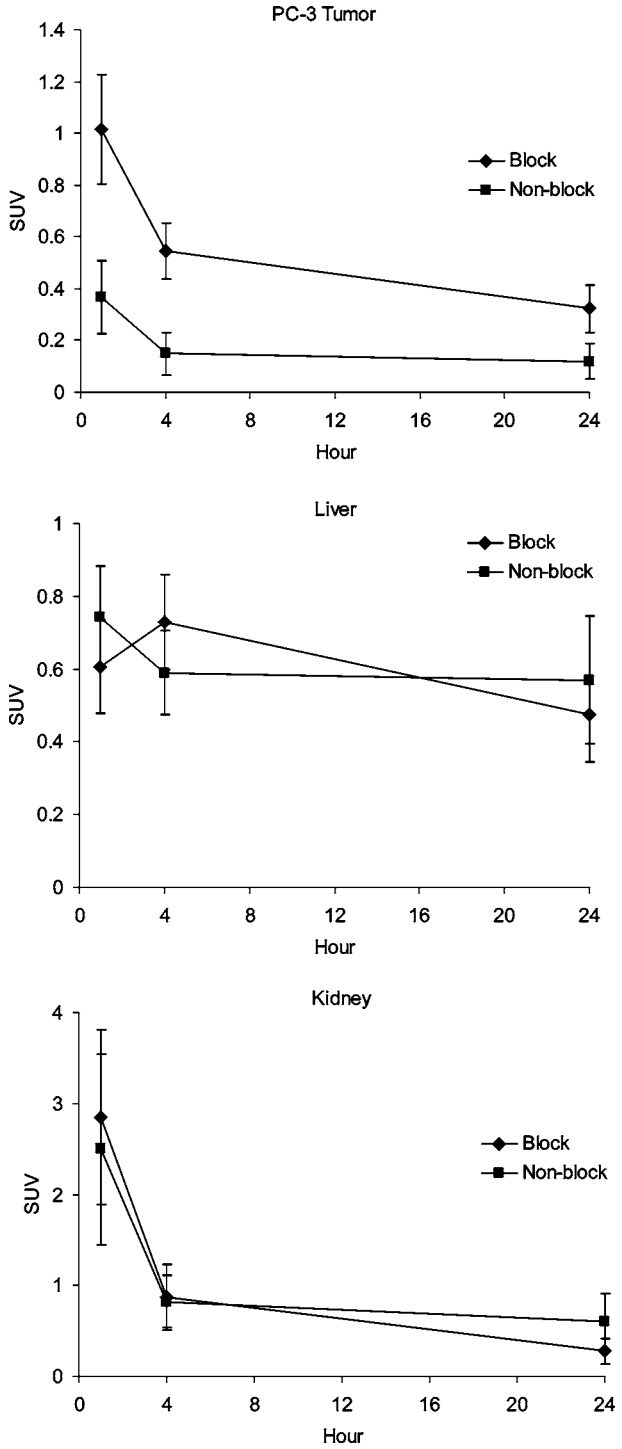

Figure 4. SUV data obtained for PET analysis of ^{64}Cu-MP2346 in mice implanted with PC-3 tumors. In these studies, the mice received ^{64}Cu-MP2346 ($n = 3$, 125 μCi, 125 ng). These mice were imaged side by side with mice ($n = 3$ per group) that had been coadministered with 100 μg of [Tyr^4]-bombesin along with the radiolabeled peptide.

the PET data were consistent with the trends and relationships observed with the acute biodistribution data.

DISCUSSION

Peptide-based agents targeting the GRPRs on tumors have been developed and studied in animals and humans for diagnostic and therapeutic applications (*10*−*26*). The breadth of work undertaken on GRPR-targeting radiopharmaceuticals has been comprehensively reviewed by Smith et al. in 2003 and 2005 (*11*, *12*). Multiple BN analogs have been explored and compared (*11*, *12*) and have demonstrated the potential of these systems for use in humans. In this current report we evaluated both ^{64}Cu- and ^{86}Y-radiolabeled MP2346 [DOTA−(Pro^1, Tyr^4)-bombesin(1−14)] as candidates for the noninvasive detection of GRPR-positive tumors using PET. DOTA is able to chelate a variety of β-, β+, or α-particle-emitting radiometals, remaining stable under a variety of physiologic conditions.

Both agents were radiolabeled in high specific activity by the addition of the radionuclides of choice to the peptide in ammonium acetate buffer. The specific activities obtained (∼1 mCi/μg) are high, but higher values are achievable, especially if the HPLC conditions used are utilized for an additional purification step, removing unlabeled peptide from labeled peptide. Figure 2 shows that the ^{64}Cu-peptide, ^{64}Cu-MP2346, internalized into PC-3 cells with ∼34% of the maximum internalized reached by 1 h. This is similar to the 1 h internalization of ^{111}In-MP2346 into CA20948 and AR42J cells (*13*). ^{86}Y-MP2346 internalized into PC-3 cells with only ∼13% of the maximum internalized reached by 1 h. However, after 20 h of incubation, nearly a 3-fold higher level of internalization is noted for the ^{86}Y-MP2346 analogue compared with ^{64}Cu-MP2346. It has been reported that the level of peptide internalization is crucial for *in vivo* targeting with radiolabeled peptides (*33*, *34*). For example, in the well-defined model of somatostatin receptor targeting, a significant correlation exists between the level of somatostatin peptide internalization into receptor positive tissues and the *in vivo* uptake (*35*). It is reasonable to assume that the bombesin receptor-targeting peptides discussed in this current work will follow similar patterns to those reported for somatostatin peptides, and therefore the higher level of internalization of the ^{86}Y analogue explains in part the superior *in vivo* properties of ^{86}Y-MP2346 compared to ^{64}Cu-MP2346.

The biodistribution data presented in Table 1 for ^{64}Cu-MP2346 and ^{86}Y-MP2346 show distinct differences in the kinetics of the two compounds in both receptor-rich and nontarget organs. This can be attributed to inherent differences in the physical and chemical properties of the individual agents (e.g., overall charge, pK_a) due to the different metals incorporated into MP2346, and not the mass of the peptide administered since this was identical in the comparative experiments. As discussed above, it is likely that cellular internalization is the most influential factor in the uptake and retention of the agents in the tumor and other receptor-positive tissues. In other nontarget tissues, the ^{86}Y analogue in general showed a more favorable biodistribution compared with ^{64}Cu-MP2346. This was most notable in the higher tumor uptake and lower nontarget tissue (in particular the liver) accumulation resulting in superior tumor/tissue ratios (Table 2). The reasons for these differences are not due to cellular internalization but are consequences of the different chemical and physical properties of ^{86}Y-MP2346 and ^{64}Cu-MP2346.

The kidney uptake of ^{86}Y-MP2346 is not optimal and is higher than ^{64}Cu-MP2346 and could be a problem in the translation of this agent to the clinic due to high absorbed doses. Although these kidney values are lower than those found for the ^{18}F-labeled peptides, ^{18}F-FB[Lys^3]BBN (1 h, ∼16 %ID/g) and ^{18}F-FB-Aca-BBN(7−14) (1 h, ∼8 %ID/g) (*27*), they are comparable to those found with other ^{64}Cu-BN systems (*24*−*26*). The uptake of ^{86}Y-MP2346 and subsequent retention, compared to the uptake and washout noted with the ^{64}Cu analogue could be attributed to the net charge of the compound. It has been reported that the renal retention of ^{64}Cu- and ^{111}In-labeled chelates was higher for positively charged peptides and lower for neutral and negatively charged ones (*36*−*38*). Given the expected charge of ^{86}Y-MP2346 is +1 and ^{64}Cu-MP2346 is neutral (at slightly acid pH), this could account for the difference in renal uptake and clearance. Subtle alteration

of ^{86}Y-MP2346 to present an overall neutral or negative charge could reduce renal uptake and improve clearance. If this strategy does not work tracer accumulation could possibly be tempered by the use of D-lysine or a similar agent to decrease this retention (*39*).

The liver burden associated with ^{64}Cu-MP2346 (1 h, 1.329 %ID/g), although significantly lower than that found with other ^{64}Cu-BN peptide systems, (^{64}Cu-DOTA−[Lys^3]BBN, ∼4.5 %ID/g (*26*); ^{64}Cu-DOTA−Aca-BBN(7−14), ∼13 %ID/g (*25*); ^{64}Cu-DOTA−Aoc-BN(7−14), ∼13 %ID/g (*24*)) could still hinder the delineation of GRPR-positive tumors in anatomical regions in close proximity to the liver and could also lead to high radiation-absorbed doses. Although DOTA is a promiscuous chelator for many 2+ and 3+ charged metals, ^{64}Cu has been shown to dissociate *in vivo* from DOTA and DOTA conjugates (*40*). Copper-64 then undergoes metabolism and transchelation to superoxide dismutase and other proteins causing increased blood and liver accumulation (*41*, *42*). The cross-bridged cyclam chelator, CBTE2A, has demonstrated improved *in vivo* stability and consequently a reduction in transchelation (*40*−*43*). CBTE2A has been conjugated to the somatostatin peptide analogue Tyr^3-octreotate (Y3-TATE) and ^{64}Cu-CBTE2A−Y3-TATE showed improved nontarget organ clearance and higher tumor ratios compared with ^{64}Cu-TETA anolog (*42*). By incorporation of the CBTE2A moiety (replacing DOTA) onto the peptide system used in this study, an improved biodistribution would be anticipated.

The tumor uptake of ^{86}Y-MP2346 at all time points is superior to that found with ^{64}Cu-MP2346 (Table 1) and can be attributed to the superior cellular internalization of this agent (Figure 2). These values compare well with those found for other analogs in the same tumor model; for example, La Bella et al. showed with two ^{99m}Tc-labeled BN analogues showed 0.3−0.6 %ID/g at 24 h postinjection in the PC-3 tumor (*17*, *20*). These values are similar to that found with ^{64}Cu-MP2346 but ∼2−6-fold lower than those for ^{86}Y-MP2346. The PET agents ^{18}F-FB[Lys^3]-BBN and ^{18}F-FB-Aca-BBN(7−14) showed PC-3 uptake values at 1 h of 5.94 ± 0.78 %ID/g and 0.43 ± 0.18 %ID/g, respectively (*27*). ^{177}Lu-DOTA−Aoc-BN(7−14) was reported to have 4.2 %ID/g in the PC-3 tumor with a tumor/blood ratio of 11.1 at 1 h, an uptake value slightly higher than that found with ^{86}Y-MP2346 but resulting in a similar tumor/blood ratio (Table 2) (*23*). The ^{64}Cu analogue of DOTA−Aoc-BN(7−14) was shown to have 5.5 %ID/g at 2 h in the PC-3 tumor, a value much higher than that found with ^{64}Cu-MP2346, but only ∼2-fold higher than that determined with ^{86}Y-MP2346. However, on comparison of the tumor/blood ratios, ^{64}Cu-DOTA−Aoc-BN(7−14) had a tumor/blood ratio of 4.2, a value lower than that for ^{64}Cu-MP2346 (6.192 at 1 h, Table 2) and 3-fold lower than that for ^{86}Y-MP2346 (12.074 at 1 h, Table 2). ^{64}Cu-DOTA−[Lys^3]BBN demonstrated 3.97 ± 0.15 %ID/g in the PC-3 tumor (*26*) with the truncated analog showing ∼3.0 %ID/g (*25*). These values are comparable to those found for ^{86}Y-MP2346 but higher than those for ^{64}Cu-MP2346, but as discussed above, the liver burden, with the other analogs, is significantly higher. In all of these studies nontarget tissue accumulation differed again presumably because of peptide affinity, overall charge, and metal−chelate stability. Overall differences in tumor accumulation could also be attributed to the amount of peptide mass administered to the animals, the tumor volume and the status of the PC-3 cells maintained within each laboratory so care must be taken in the comparison of the current studies with those previously reported.

The PET imaging confirms the data obtained in the biodistribution studies. The less than optimal biodistribution of ^{64}Cu-MP2346 results in high background and liver accumulation. ^{86}Y-MP2346 produces high quality PET images (Figure 2 and 3) in PC-3-bearing mice and this excellent image quality was confirmed in AR42J-bearing rats where tumor activity is high even after 1 h against very low background activity. The liver shows very low accumulation of the ^{86}Y-labeled peptide, suggesting that the Y-DOTA chelate is more stable that the Cu analog and is not susceptible to transchelation *in vivo*. It is important to note that these images have been produced following the administration of larger amounts of peptide due to the higher dose (∼20 fold) than that given in the biodistribution studies. Nevertheless, the observed tissue distribution in the rat images is consistent with the biodistribution found in sampled tissues in mice. Additionally, in both studies, animals that were preinjected with a large quantity of [Tyr^4]-bombesin had significantly reduced uptake of the agents in the receptor positive tumors with little change in uptake in receptor negative tissue. This further confirms the receptor-mediated uptake of the agents *in vivo*.

CONCLUSION

In conclusion, ^{64}Cu-MP2346 and ^{86}Y-MP2346 were evaluated as agents for the PET imaging of the GRP receptor. In particular ^{86}Y-MP2346 due to its good tumor concentration and low nontarget tissue accumulation allows for the excellent delineation of the GRPR-positive PC-3 tumor and warrants further evaluation for diagnostic purposes as a GRPR PET imaging agent.

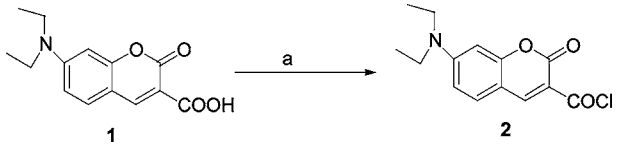
N,N-Dimethylsphingosine−Coumarin: Synthesis, Chemical Characterization, and Biological Evaluation

Sukhen C. Ghosh,[†] Edmond Auzenne,[‡] David Farquhar,[†] and Jim Klostergaard*[,‡]

Departments of Experimental Therapeutics and Molecular and Cellular Oncology, The University of Texas M. D. Anderson Cancer Center, 1515 Holcombe Boulevard, Houston, Texas 77030. Received September 11, 2006; Revised Manuscript Received February 1, 2007

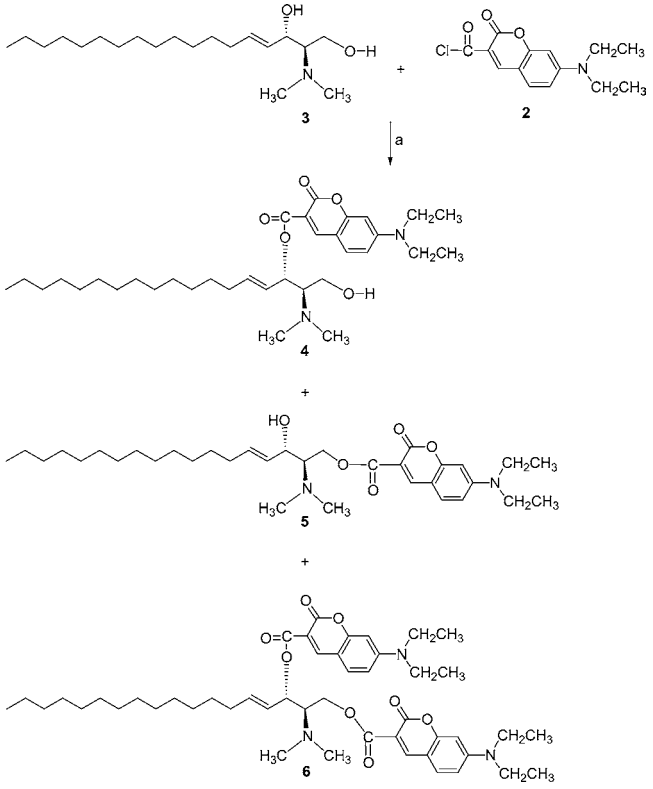
Coumarin derivatives of *N,N*-dimethylsphingosine (DMSP) were prepared and chemically characterized. They were apparently biologically equivalent to DMSP in terms of tumor cell cytotoxicity and were used to establish the rapid mitochondrial localization of this sphingolipid in tumor cells, followed closely by its marked reduction of mitochondrial membrane potential.



INTRODUCTION

Sphingolipids (SLs) and their metabolic pathways are increasingly recognized as promising targets for cancer therapy. Of particular focus in these pathways is the conversion of pro-apoptotic sphingosine (Sp) to anti-apoptotic sphingosine-1-phosphate (Sp-1-P) by the enzyme sphingosine kinase (SpK) (*1*). Since Sp is derived by deacylation of ceramide (Cer), a SL or Cer/Sp-1-P rheostat has been hypothesized to determine cellular fate; the relative cellular concentrations of Cer and Sp vs Sp-1-P determine whether a cell proliferates or undergoes apoptosis (*2*). SpK is itself oncogenic (*3*), governed by growth factors (*4*) and protein kinases (*5*).

Dimethylsphingosine (DMSP) is a competitive inhibitor of SpK (*6*) and is a useful tool to elucidate the role of Sp-1-P as an intracellular second messenger. DMSP is also a promising compound for the chemotherapeutic management of various types of malignancies (*7*). Aside from inhibition of SpK, some evidence indicates that mitochondria are a target of Sp, the parent compound (*8*). Since DMSP lacks a significant spectroscopic signature and in order to facilitate mechanistic studies of this SL, we incorporated a fluorescent probe into it and conducted chemical and biological characterization of the fluorescenated DMSP.

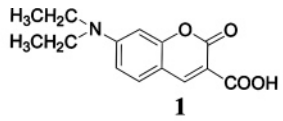


7-(Diethylamino)coumarin-3-carboxylic acid, **1**, was converted to the corresponding acid chloride, **2**, by reaction with oxalyl chloride in dichloromethane (Scheme 1). Compound **2** was then reacted with DMSP, **3**, to give a mixture of the isomeric esters, **4** and **5**, together with a trace amount of the diester **6** (Scheme 2). These products were separated by column chromatography on silica gel. No differences in cytotoxic activity against three tumor cell lines were observed among compounds **4**, **5**, and DMSP, indicating that these substitutions were without significant effect on the biological activity of DMSP. Time-lapse fluorescence microscopy studies with **4** and **5** indicated that they were rapidly accumulated intracellularly and localized in mitochondria. This localization was associated with a rapid and marked reduction in mitochondrial membrane potential.

Scheme 1 [a]

[a] Reagents and conditions: (a) oxalyl chloride, CH_2Cl_2, catalytic amount of DMF, rt for 12 h.

Scheme 2 [a]



[a] Reagents and conditions: (a) 2,4,6-collidine, CH_2Cl_2, −40 °C for 4 h, then 25 °C for 12 h.

EXPERIMENTAL PROCEDURES

Chemistry. All chemicals and reagents were purchased either from Sigma-Aldrich Company (St. Louis, MO) or from Molecular Probes, Inc. (Carlsbad, CA). Nuclear magnetic resonance spectra (^{1}H NMR and ^{13}C NMR) were recorded at ambient temperature on Bruker Advance model 300 or 500 MHz spectrometers. Samples were dissolved in an appropriate deuterated solvent ($CDCl_3$ or D_2O). The ^{1}H chemical shifts are

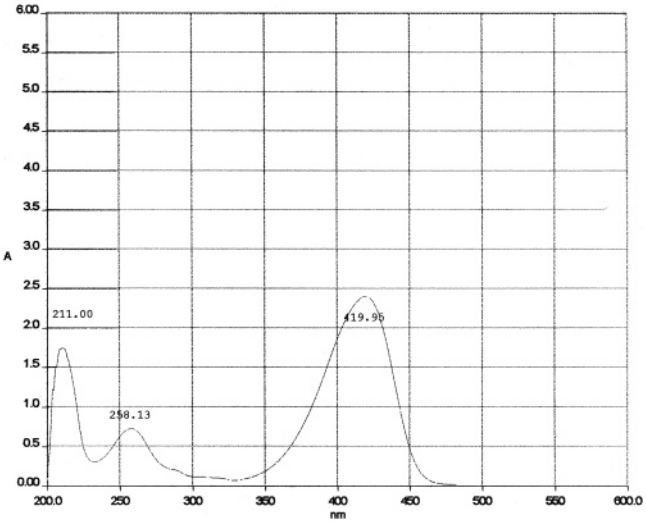

Figure 2. Absorption spectrum of compound **5** in methanol solution (UV cutoff 205 nm).

reported as parts per million (δ ppm) relative to tetramethylsilane (Me_4Si, $\delta = 0.00$) as an internal standard. Chemical shifts for ^{13}C are reported as δ relative to deuterated chloroform ($CDCl_3$, central peak $\delta = 77.0$ ppm) as an internal standard. Column chromatography was performed on silica gel (Merck, 230−400 mesh). UV spectra were obtained on a Perkin-Elmer spectrophotometer. Mass spectra analyses were performed by the analytical services section of the Department of Experimental Therapeutics, M. D. Anderson Cancer Center, Houston, TX. All reactions were carried out in dry glassware and protected from atmospheric moisture. Solvents were dried over freshly activated (300 °C, 1 h) molecular sieves (type 4A). Evaporations were carried out on a rotary evaporator under aspirator vacuum at a bath temperature of 30−40 °C.

Synthesis of 7-(Diethylamino)-2-oxo-2*H*-chromene-3-carboxylic Acid Chloride (2). Oxalyl chloride (150 μL, 240 mg, 1.9 mmol) was added, under a dry argon atmosphere, to a solution of 7-(diethylamino)coumarin-3-carboxylic acid, **1** (100 mg, 0.38 mmol), in anhydrous CH_2Cl_2 (20 mL), followed by DMF (20 μL) as a catalyst. Gas evolution ensued for about 5 min during which time the solution darkened. After 12 h at room temperature, the solvent was evaporated under vacuum to give a red solid. ^1H NMR ($CDCl_3$): δ 8.68 (s, 1H), 7.45 (d, 1H, $J = 9.0$ Hz), 6.69 (dd, 1H, $J_1 = 9.0$ Hz and $J_2 = 3.9$ Hz), 6.48 (d, 1H, $J = 3.0$ Hz), 3.50 (q, 4H), 1.35 (t, 6H, $J = 6.0$ Hz). The UV spectrum of the starting compound **1** is shown in Figure 1.

Syntheses of 2-*N*,*N*-Dimethylamino-3-[7-(diethylamino)-2-oxo-2*H*-chromone-3-carboxyl]-octadec-4-ene-1-ol (4), 2-*N*,*N*-Dimethylamino-1-[7-(diethylamino)-2-oxo-2*H*-chromone-3-carboxyl]-octadec-4-ene-3-ol (5), and 2-*N*,*N*-Dimethylamino-1,3-bis[7-(diethylamino)-2-oxo-2*H*-chromone-3-carboxyl]-octadec-4-ene (6). *N*,*N*-Dimethylsphingosine (**3**, 100 mg, 0.30 mmol) was added under a dry argon atmosphere to a solution of **2** (80 mg, 0.30 mmol) in anhydrous CH_2Cl_2 maintained at −40 °C. 2,4,6-Collidine (75 mg, 0.60 mmol) was added, and the reaction mixture was maintained at −40 °C for 4 h and then at 25 °C for a further 12 h. It was washed several times with an equal volume of saturated sodium bicarbonate solution, dried, and evaporated. The crude reaction product was separated into its individual components, **4**, **5**, and **6**, by column chromatography on silica gel using CH_2Cl_2 and CH_3OH (9:1) as eluent.

*Compound **4***. Yield 18%. $R_f = 0.5$ (CH_2Cl_2/MeOH, 9:1). ^1H NMR ($CDCl_3$): δ 8.42 (s, 1H), 7.36 (d, 1H, $J = 8.7$ Hz), 6.61 (dd,1H, $J_1 = 9.0$ Hz and $J_2 = 2.4$ Hz), 6.45(d,1H, J= 2.4 Hz), 5.86−5.76 (m,1H), 5.71 (t, 1H, $J = 6.6$ Hz), 5.53 (dd, 1H, $J_1 = 15.3$ Hz and $J_2 = 6.9$ Hz), 3.81 (m, 2H), 3.48 (q, 4H), 2.80 (m, 1H), 2.41 (s, 6H), 2.02 (q, 2H), 1.26 (m, 28H), 0.9(t, 3H, $J = 6.0$ Hz). ^{13} C NMR ($CDCl_3$): δ 163.44, 158.59, 158.49, 153.06,149.77, 135.57, 131.20, 126.98, 109.64, 108.46, 107.79, 96.67, 72.87, 68.19, 58.22, 45.13, 41.44, 32.28, 31.93, 29.68, 29.66, 29.61, 29.45, 29.36, 29.21, 28.80, 22.69, 14.13, 12.43.

*Compound **5***. Yield 50%. $R_f = 0.4$ (CH_2Cl_2/MeOH, 9:1). ^1H NMR ($CDCl_3$): δ 8.44 (s, 1H), 7.37 (d, 1H, $J = 8.7$ Hz), 6.62 (dd, 1H, $J_1 = 9.0$ Hz and $J_2 = 2.4$ Hz), 6.45 (d, 1H, $J = 2.1$ Hz), 5.79 (m, 1H), 5.54 (dd, 1H, $J_1 = 15.45$ Hz and $J_2 = 6.0$ Hz), 4.51 (m, 2H), 4.38 (t, 1H, $J = 5.4$ Hz), 3.66 (d, 1H, $J = 5.7$ Hz), 3.47 (q, 4H), 2.88 (q, 1H), 2.50 (s, 6H), 2.03 (q, 2H), 1.26 (m, 28 H), 0.9 (t, 3H, $J = 6.3$ Hz). ^{13} C NMR ($CDCl_3$): δ 164.40, 158.61, 158.36, 153.06, 149.71, 132.59, 131.21, 129.78, 109.63, 108.28, 107.76, 96.70, 70.76, 66.26, 62.06, 45.13, 43.05, 32.37, 31.93, 29.69, 29.66, 29.64, 29.52, 29.36, 29.25, 29.22, 22.69, 14.13, 12.43.

The UV spectrum and the MALDI-TOF mass spectrogram of compound **5** are shown in Figures 2 and 3, respectively.

*Compound **6***. Yield 2% ($R_f = 0.7$, CH_2Cl_2/MeOH, 9:1). ^{1} H NMR ($CDCl_3$): δ 8.42 (s, 1H), 8.41 (s, 1H), 7.38 (d, 1H, $J = 4.2$ Hz), 7.36 (d, 1H, $J = 4.2$ Hz), 6.60 (t, 1H, $J = 2.4$ Hz), 6.57 (t, 1H, $J = 2.4$ Hz), 6.41 (t, 2H, $J = 3.0$ Hz), 5.8 (m, 2H), 5.64 (dd, 1H, $J_1 = 4.2$ Hz and $J_2 = 8.7$ Hz), 4.64 (m, 2H), 3.45 (q, 8H), 3.20 (q, 1H), 2.43 (s, 3H), 2.07 (q, 2H), 1.61 (s, 3H), 1.23 (m, 28 H), 0.88 (t, 3H, $J = 6.0$ Hz). ^{13} C NMR: δ 164.02, 163.12, 158.86, 158.81, 158.60, 158.44, 153.28, 149.68, 149.52, 135.88, 131.69, 126.97, 109.86, 109.04, 108.07, 97.01, 73.34, 65.80, 61.79, 45.46, 42.28, 32.75, 32.31, 30.08, 30.05, 29.85, 29.74, 29.61, 29.27, 23.07, 14.51, 12.82.

Cytotoxicity Assays. Human PC-3 prostatic carcinoma cells were cultured in DMEM/F-12 medium (GIBCO, Grand Island,

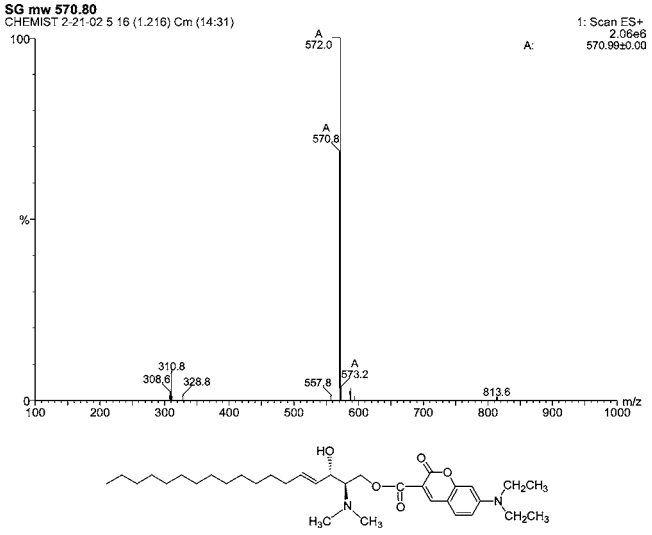

Figure 3. ESI mass spectrogram of compound **5**.

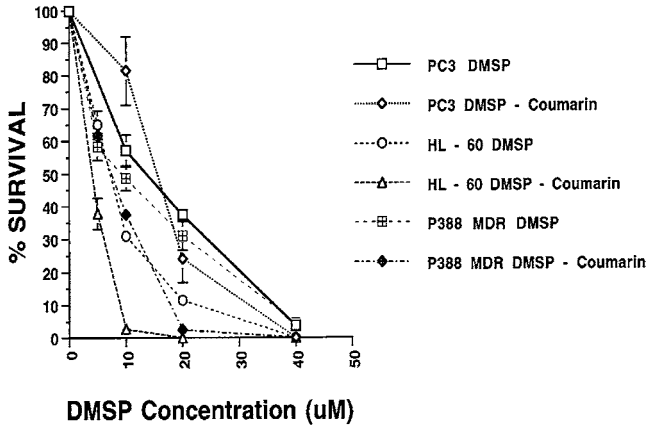

Figure 4. Dose–response effects of DMSP and DMSP–coumarin on viability (24 h MTT assay) of human PC-3 prostatic carcinoma, human HL60 acute myelogenous leukemia, and mouse P388 multidrug-resistant lymphocyte leumemia cell lines.

NY) supplemented with 5% fetal calf serum (GIBCO) at 37 °C in an incubator supplied with 5% CO_2/95% air, as previously described (*9*). The murine P388 acute myelogenous leukemia (AML) MDR-expressing subline P388MDR, and HL60, a human promyelocytic-like AML line, were cultured similarly. The P388MDR line had been selected from the parental cells by growth in the presence of increasing concentrations of doxorubicin (Dox) and displayed a stable resistance phenotype in the absence of further selection pressure. To ensure that the leukemia cells were in the logarithmic phase of growth for the cytotoxicity assays, they were allowed to grow to a density of 10^6 cells/mL before experimental manipulation.

Tumor cells were plated at (1.5−2.0) × 10^4 cells in 100 μL of medium per triplicate cell in flat-bottom 96-well microwell plates (Corning Glass Works, Corning, NY). Thereafter, they were incubated with known concentrations of DMSP or coumarin-tagged DMSP for 24 h. Since preliminary studies had revealed that the cytotoxic activity of compounds **4** and **5** were indistinguishable, their admixture was used in these cytotoxicity assays, as well as in the time-lapse fluorescence studies (see below). Remaining viable cells were stained with MTT. Resolubilized dye (MTT−formazan) was quantified by measurement of optical density at 570 nm in a microplate reader. The viability of treated cells was determined as a percentage of the optical density of dye in control cultures.

Time-Lapse Fluorescence Microscopy. Digital time lapse acquisition of PC-3 cells was performed using the Cell Observer function of a Zeiss Axiovert 200M motorized inverted microscope. Cells growing in a 12-well tissue culture plate were placed in a chamber on a temperature-controlled stage and maintained in a heated, humidified, 5% CO_2 atmosphere. The Axiovision Software was used to program the motorized stage to move sequentially from well-to-well and to acquire phase contrast as well as fluorescent color images at preselected time points. Phase images and fluorescent images, using appropriate excitation and emission settings for DMSP−coumarin (490/515 nm), were acquired.

Mitochondrial Membrane Potential (MMP) Plate-Based Fluorescence Assay. PC-3 cells were plated in triplicate in flat-bottom 96-well microwell plates (CoStar), essentially as described above for the cytotoxicity assays. After overnight incubation, DMSP (20 μM), DMSP−coumarin (20 μM), or control media was added and incubation was continued for 2 h. Thereafter, the protocol of the vendor (Cell Technology, Mountain View, CA) was followed for the addition of the fluorescent cationic dye to detect MMP. MMP-linked fluorescence in untreated control and treated (DMSP or DMSP−coumarin) cells was detected by excitation at 530 nm and emission at 590 nm. Background fluorescence was determined in untreated control cells that did not have the cationic dye added.

The percentage of MMP in treated cells was compared with that in untreated control cells by the expression Percentage of control MMP = (fluorescence in treated cells − background fluorescence) ÷ (fluorescence in untreated control cells − background fluorescence).

RESULTS AND DISCUSSION

Cytotoxicity Assays. The results are shown in Figure 4. PC-3 cells were essentially all killed by the highest concentration (40 μM) of either DMSP or DMSP−coumarin, whereas the IC_{50} was reached between 10 and 20 μM of either agent, indicating that substitution with coumarin did not cause significant effects on DMSP functions associated with induction of cell death. Similar results were obtained with these reagents on HL-60 cells, although both of the IC_{50}'s were lower: ∼5−10 μM for DMSP and 5 μM slightly exceeded 50% killing of HL60 cells for DMSP−coumarin. With the P388MDR targets, again there was minimal distinction between DMSP and DMSP−coumarin, and the IC_{50}'s were ∼10 μM for DMSP and ∼5−10 μM for DMSP−coumarin. Overall, based on the cytotoxicity assays in the prostatic as well as the leukemia models, substitution of DMSP with coumarin was well-tolerated.

Time-Lapse Fluorescence Microscopy. The results in Figure 5 demonstrate the uptake of DMSP−coumarin in PC-3 cells, tracking its green fluorescence. PC-3 cells viewed prior to or immediately after introduction of DMSP−coumarin (20 μM) were clearly evident by phase contrast but not by fluorescence microscopy (data not shown). However, already after 60 min of further incubation (panel A), initial intracellular accumulation and localization to perinuclear mitochondria was apparent. This localization became increasingly pronounced and more clearly punctate after 2 h (panel B) and 4 h (panel C). (In related studies, we have shown that this accumulation is closely linked with loss of inner mitochondrial membrane potential, release of cytochrome *c*, and caspase activation).

Effects of DMSP−Coumarin on MMP. PC-3 cells were treated with DMSP or DMSP−coumarin (20 μM) for 2 h prior to assaying mitochondrial membrane potential in control and treated cells. The results are shown in Table 1. DMSP rapidly and dramatically reduced the MMP of PC-3 cells to only background levels; similarly, the effect of DMSP−coumarin was

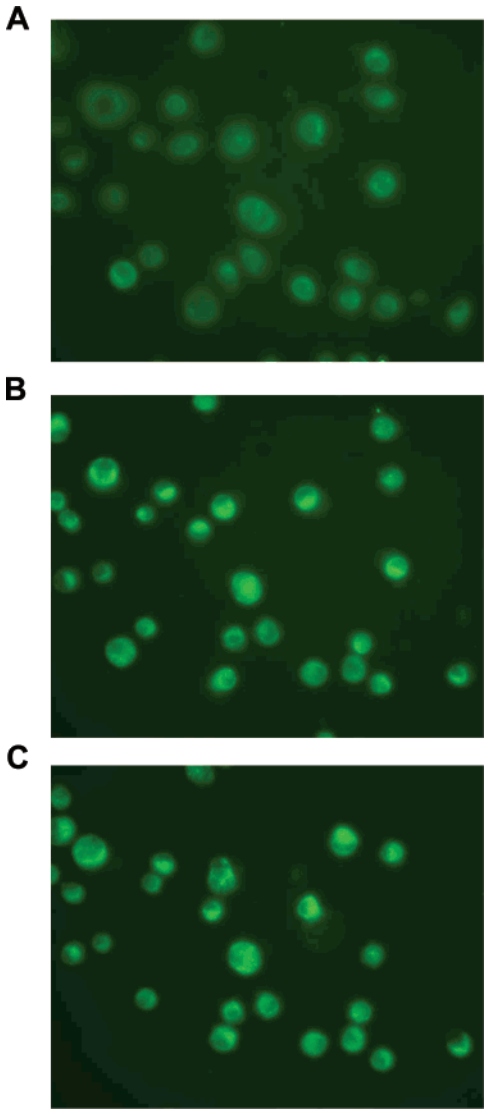

Figure 5. Time-lapse fluorescence microscopy of uptake of DMSP−coumarin in PC-3 cells. Green fluorescence is evident after 60 min of incubation (A) as intracellular accumulation and localization to perinuclear mitochondria; localization became increasingly pronounced after 2 h (B) and 4 h (C).

Table 1. Effect of DMSP and DMSP−coumarin on MMP in PC-3 Cells[a]

treatment	% MMP[b,c]
DMSP	−3.0 ± 8.8
DMSP−coumarin	7.1 ± 6.4

[a] PC-3 cells were treated with DMSP or DMSP−coumarin (both at 20 μM) for 2 h prior to addition of fluorescent cationic dye to detect MMP. MMP-linked fluorescence was detected by excitation at 530 nm and emission at 590 nm. [b] Percentage of MMP in DMSP- or DMSP−coumarin-treated cells compared with that in untreated control PC-3 cells. Calculated as (fluorescence in treated cells − background fluorescence) ÷ (fluorescence in untreated control cells − background fluorescence). [c] Mean ± SEM from six determinations.

also pronounced, causing reduction to 7.1% ± 6.4% of control MMP. Thus, when considered together, the kinetics of localization and subsequent loss of MMP indicate that a very rapid depolarization is induced by DMSP in PC-3 targets once it reaches the mitochondria.

Recent studies have revealed pharmacological tools with which to perturb the SL rheostat, *in vitro* and *in vivo*. For example, chemical library screening has defined inhibitors of SpK that are reportedly more specific and potent than DMSP, for example, SKI II (*10*, *11*). In our hands, SKI II causes a much more protracted effect against human prostatic cancer and leukemic target cell lines than does DMSP and, particularly, lacks the rapid effect on MMP observed with DMSP (Klostergaard et al., in preparation). The fungal metabolite FTY720 has been shown to down-regulate G-protein-coupled receptors through which extracellular Sp-1-P exerts its effects; further, FTY720 is endowed with a modified sphingoid backbone and also displays rapid homing to mitochondria and the ability to disrupt MMP (*12*, *13*), suggesting that the latter property might be inherent in this backbone structure. The identification of mitochondrial domains with which the sphingoid backbone interacts might be illuminating with regard to its mechanism of induction of the intrinsic apoptotic pathway: for example, by conducting experiments using fluorescenated sphingosine(s) and mitochondria prelabeled with suitable fluorescent dyes appropriate for a donor−acceptor interaction for fluorescence resonance energy transfer (*14*).

In summary, the availability of a fluorescent, biologically equivalent DMSP will advance studies both *in vitro* and *in vivo*, such as of its subcellular localization, mechanism of action, biodistribution, and pharmacology.

ACKNOWLEDGMENT

We thank Mr. William Spohn for assistance with the time-lapse fluorescence microscopy studies and Dr. Jaw-Ching Liu for assistance with manuscript preparation.

Synthesis and in Vitro Characterization of an ABC Triblock Copolymer for siRNA Delivery

Tatiana Segura[†,‡] and Jeffrey A. Hubbell*[,†]

Ecole Polytechnique Fédérale de Lausanne (EPFL), Institute of Bioengineering and Institute of Chemical Sciences and Engineering, CH-1015, Lausanne, Switzerland, and University of California, Los Angeles, Chemical and Biomolecular Engineering Department, Los Angeles, California. Received September 11, 2006; Revised Manuscript Received December 18, 2006

The ability to specifically down-regulate gene expression using the RNAi pathway in mammalian cells has tremendous potential in therapy and in basic science. However, delivery systems capable of efficient and biocompatible delivery of siRNA to target cells are not yet satisfactory. Here, we report the synthesis and in vitro characterization of ABC triblock copolymers that self-assemble with siRNA based on electrostatics and with each other by hydrophobic interactions. The ABC triblock copolymer is based on poly(ethylene glycol) (PEG), poly(propylene sulfide) (PPS), and a positively charged peptide (PEG−PPS−peptide). The diblock copolymer PEG_{45}−$PPS_{5,10}$ was synthesized using anionic polymerization of propylene sulfide upon a PEG macroinitiator, and the peptide domain was coupled to the PPS terminus using a disulfide exchange reaction with an N-terminal cysteine residue on the peptide. The peptides were designed to interact electrostatically with siRNA, selecting the TAT peptide domain of HIV (RKKRRQRRR) and an oligolysine (Lys_9). The resulting triblock copolymers were able to self-assemble with siRNA as demonstrated by dynamic light scattering and gel electrophoresis. Complex size was found to be dependent on the amount of polymer used (charge ratio) and the length of the hydrophobic PPS block, achieving sizes ranging from 171 nm to 601 nm. Cell internalization and gene expression down-regulation studies showed that the triblock copolymers are able to transport siRNA inside the cell and mediate gene expression down-regulation, with the amount of internalization and gene transfer affected by charge ratio, PPS length, and the presence of serum. The proposed triblock was able to mediate gene expression down-regulation of GAPDH, achieving up to 90.5% ± 0.02% down-regulation.

INTRODUCTION

In 2001, Elhashir and co-workers (*1*) demonstrated that incorporation of double-stranded, 21-nucleotide-long pieces of RNA results in activation of the RNA interference (RNAi) pathway and the specific down-regulation of genes with sequences that are homologous to the double-stranded RNA. This RNAi pathway activation did not result in the activation of the interferon response, which was seen with longer double-stranded RNAs (*1*, *2*). They called the double-stranded RNA small interfering RNA or siRNA. Since this finding, the idea of using siRNAs as a genetic therapeutic and as a basic science tool has been investigated by many groups (*3*). In the area of basic science, decreasing the expression level of a gene within a cell has the power to reveal or confirm the roles of specific components of signaling pathways and can lead to a mechanistic understanding of cell behavior, disease pathogenesis, and drug action (*4*, *5*). Therapeutic strategies using siRNA are also under development and have recently shown promise to reduce of tumor growth (*6*, *7*), reduce neovascularization in the eye (*8*), reduce viral infection (*9*), and reduce postoperative adhesions (*10*). However, the lack of an efficient delivery system that can efficiently target and deliver the siRNA to the desired cell population is limiting the full therapeutic potential of this approach.

Nonviral siRNA delivery suffers from many of the same limitations as other gene delivery approaches, including packaging efficiency, colloidal stability, targeted internalization, endosomal escape, and vector decomplexation, for which a delivery system has yet to be found that is as efficient as viral vectors. Nevertheless, current strategies for siRNA delivery employ the same delivery vectors as used for nonviral gene delivery such as cationic polymers (*7*, *11*, *12*), lipids (*13*, *14*), and peptides (*15*), which self-assemble with siRNA electrostatically.

In the field of drug delivery, there is extensive interest in amphiphilic block copolymers that can self-assemble in aqueous environments into stable supermolecular structures. A variety of such structures can be generated, such as micellar and vesicular assemblies, both of which can be important for pharmacological applications. Extensive investigation has been conducted in poly(ethylene glycol) (PEG)-containing block copolymers, such as copolymers with poly(propylene glycol) (*16*−*18*), and poly(ethylene) (*19*). In our laboratory, a novel class of amphiphilic triblock copolymers (ABA) composed of hydrophilic PEG (A) and hydrophobic poly(propylene sulfide) (PPS) (B) polymer domains has been synthesized using mild polymerization conditions that do not require extremely anhydrous conditions and allow for incorporation of biological molecules such as peptides (*20*). When these triblock copolymers contain a substantial hydrophobic portion (as determined by PPS block length), they have been found to self-assemble into vesicular polymersomes of ca. 100 nm size that have a watery core, which could be used for encapsulating drugs (*21*). Other supermolecular structures, such as spherical and cylindrical micelles, have also been observed, being obtained by

modifying the length of the hydrophobic and hydrophilic polymer domains (*22*). The presence of PEG in the surface of these supermolecular structures also makes them ideal for biological applications, given that their surface would be relatively protein-resistant.

Here, we report the synthesis and in vitro characterization of ABC triblock copolymers that self-assembles with siRNA based on electrostatics and with each other by hydrophobic interactions. The ABC triblock copolymer is based on PEG (A), PPS (B), and a peptide (C). The peptide was designed to interact electrostatically with siRNA: two peptide sequences were investigated, namely, the HIV-1 TAT sequence (CGGWRK-KRRQRRR, the terminal C being used for block conjugation, the W for detection at 280 nm, and the intervening GG being used as a linker) or a Lys_9 sequence (K_9, CGGWKKKKKKKKK, likewise, the C, W, and GG residues being used for block conjugation, detection, and linking). The proposed triblock copolymer was able to form condensed structures with siRNA and mediate gene down-regulation of GAPDH, achieving up to 90.5% ± 0.02% down-regulation.

MATERIALS AND METHODS

Materials. Peptides were purchased from NeoMPS (Strasburg, France) at >95% purity by HPLC. All synthesis reagents were purchased from Fluka (Buchs, Switzerland). siGlo (siL-amin A/C-Cy3) was purchased from Perbio (Lausanne, Switzerland). KDarlet GAPDH enzymatic activity assay, siRNA GAPDH, siRNA NEG were purchased from Ambion (Austin, TX). All other reagents were purchased from VWR (Dietikon, Switzerland) unless otherwise noted.

PEG−Allyl Ether Synthesis. PEG_{45} monomethyl ether (PEG_{45}) was modified with allyl bromide as previously described (*20*) with modifications. In short, PEG_{45} (20 g, 10 mmol) was dissolved in tetrahydrofuran (THF, 300 mL) under inert atmosphere and heated to reflux for 3 to 4 h in a Soxhlet apparatus filled with molecular sieves. The solution was allowed to cool to the touch, and 2.5 equiv of NaH (0.6 g, 25 mmol) was added. The solution was stirred and allowed to react for 15 min before 1.4 mL (3.46 g, 40 mmol) of allyl bromide was added to the solution under stirring and allowed to react for 24 h. The reaction mixture was passed through a filter to remove the NaBr salt formed during the reaction. The volume of the solution was reduced to about 20 mL by evaporation and precipitated two times in diethyl ether. A white solid polymer was obtained (16.68 g, 83.4% yield, conversion 100%). ^{1}H NMR ($CDCl_3$): δ 3.56−3.7 (broad, PEG polymer protons), 3.41 (s, 3H, $-OC\mathbf{H}_3$), 4.01−4.04 (dd, 2H, $-CH_2OC\mathbf{H}_2CH{=}CH_2$), 5.15−5.30 (m, 2H, $-CH_2OCH_2CH{=}C\mathbf{H}_2$), 5.85−5.98 (m, 1H, $-CH_2OCH_2C\mathbf{H}{=}CH_2$).

PEG−Thioacetate Synthesis. PEG−allyl ether was modified with thioacetic acid to form PEG−thioacetate as previously described (*20*) with modifications. PEG−allyl ether (8 g, 4 mmol) was introduced to a Schlenck tube in toluene (64 mL). The toluene was degassed with sonication for 20 min and bubbling with argon gas for 30 min. The PEG/toluene solution was further degassed with pump evacuation and filling the Sclenck tube with argon. This procedure was repeated five times. The reaction mixture was then warmed to 60 °C, and the first of five AIBN aliquots were added (1.3 g × 5, 0.8 mmol × 5), followed by the first of five thioacetic acid aliquots (0.456 mL × 5, 6.4 mmol × 5). The five aliquots were added over an 8−10 h period. The reaction was allowed to continue for 18 h at 60 °C and an additional 24 h at room temperature. The reaction mixture was mixed with activated DOWEX 1/8−100 (Cl) resin and incubated for 1 h. After filtration, the volume of the solution was reduced to about 20 mL by evaporation and then precipitated three times with diethyl ether. Dichloromethane was used to redissolve the precipitate. A slightly pale yellow solid was obtained (5.26 g, 65.7% yield, conversion 90%). ^{1}H NMR ($CDCl_3$): δ 1.81−1.90 (q, 2H, $-OCH_2C\mathbf{H}_2CH_2S-$), 2.35 (s, 3H, $-SCOC\mathbf{H}_3$), 2.92−2.97 (t, 2H, $-OCH_2CH_2C\mathbf{H}_2S-$), 3.39−3.89 (broad, PEG chain protons), 3.41 (s, 3H, $-OC\mathbf{H}_3$).

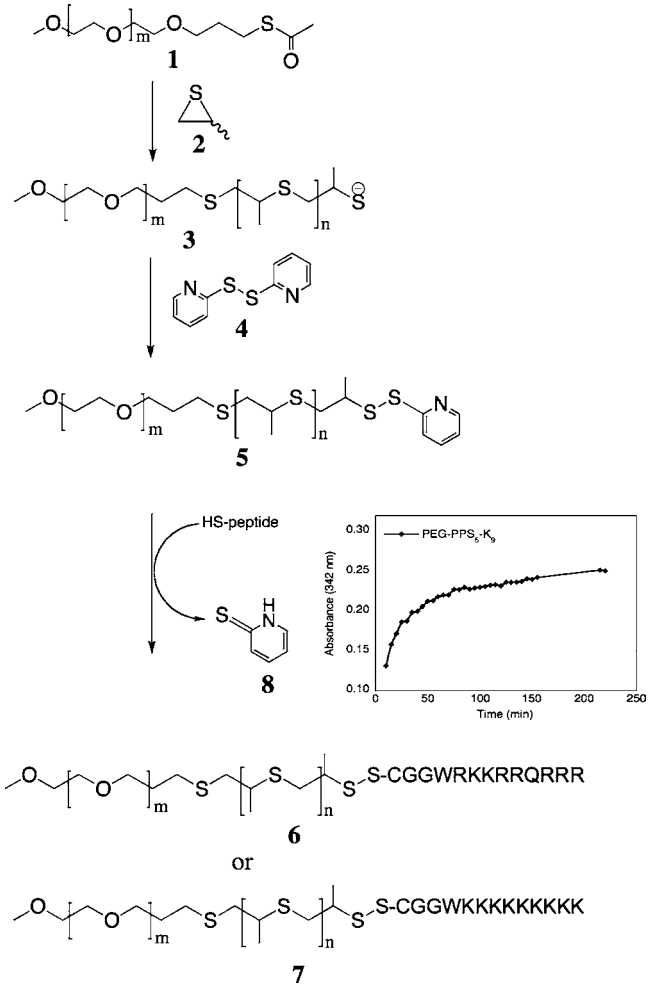

Figure 1. Synthetic scheme of poly(ethylene glycol)−poly(propylene sulfide)−peptide (PEG−PPS−peptide). PEG−thioacetate **1** is activated by sodium methoxylate to form a sulfide that can initiate the anionic polymerization of propylene sulfide **2** to form the AB block copolymer PEG−PPS **3**. 2,2-Dipyridine dithione **4** was used as the end-capping agent to generate the AB diblock copolymer terminated with a mixed disulfide **5**. The peptides TAT (CGWRKKRRQRRR) and K_9 (CGG-WKKKKKKKKK) reacted with **5** via a disulfide exchange reaction to generate the ABC triblock copolymers shown, **6** and **7**. The formation of the triblock copolymer was monitored by recording the absorbance at 342 nm, which corresponded to the release of pyridine thione, **8** (graphical insert).

PEG−PPS Diblock Copolymer Synthesis. The polymer $PEG_{45}-PPS_x$−pyridyldithione was synthesized using anionic polymerization of propylene sulfide (PS) with 2,2-dipyridine dithione as the end-capping agent to form PEG−PPS−pyridyldithione (Figure 1). PEG−thioacetic acid (1 g, 0.5 mmol) was dissolved in dry THF (23 mL). Sodium methoxylate (NaMeOH, 1.1 mL, 0.55 mmol) was added to the solution and allowed to react for 30 min. Propylene sulfide (0.394 mL, 5 mmol or 0.196 mL, 2.5 mmol) was added via syringe and allowed to react for 1.5 h. Dipyridine dithione (0.44 mg, 2 mmol) was dissolved in THF and added to the reaction mixture via syringe. The progress of the reaction can be easily followed by the appearance of an intense yellow color. After filtration and solvent evaporation, the product was precipitated in diethyl ether. A pale yellow solid was obtained (336.2 mg, 33.6% yield for $n = 5$; and 284 mg, 28.41% yield for $n = 10$). ^{1}H NMR

($CDCl_3$): δ 1.35−1.45 (d, C**H**$_3$ in PPS chain), 1.81−1.90 (broad q, 2H, −OC**H**$_2$CH$_2$CH$_2$S), 3.6−3.7 (broad PEG chain protons), 7.8−7.83 (m, 1H pyridine group). The degree of polymerization of the PPS block was determined by taking the ratio of PEG protons to PPS protons, resulting in polymers with $n = 5.06$ and $n = 10.71$. The polydispersity index (PDI) of the polymers was determined by GPC with PDI = 1.15 and PDI = 1.26, respectively.

PEG−PPS−Peptide Triblock Polymer Synthesis. The peptides Ac-CGGWRKKRRQRRR-NH_2 (TAT) and Ac-CGG-WKKKKKKKKK-NH_2 (K_9) were bound to the PEG_{45}−PPS−pyridyldithione polymers using a disulfide exchange reaction between the disulfide end-capping PEG−PPS and the cysteine group of the peptide. The course of the reaction was monitored following the release of 2-pyridinethione at 342 nm (see inset in Figure 1). Upon dilution in D_2O at 12 mg/mL, the solution turned cloudy, indicating the formation of aggregates. Furthermore, upon dilution in $CDCl_3$ at 12 mg/mL, the solution again turned cloudy with a green color indicating the formation of aggregates and the strong amphiphilic nature of the molecule. ^{1}H NMR in water: δ 1.35−1.45 (broad d, C**H**$_3$ in PPS chain), 1.81−1.90 (broad peak no q visible and signal integration reduced, 2H, −OC**H**$_2$CH$_2$CH$_2$S), 3.6−3.7 (broad PEG chain protons unchanged). Protons from the peptide were not observed. ^{1}H NMR in $CDCl_3$: δ 1.35−1.45 (broad no d visible, C**H**$_3$ in PPS chain), 1.81−1.90 (q, 2H, −OC**H**$_2$CH$_2$CH$_2$S), 3.6−3.7 (broad PEG chain protons), 7.08−7.13 and 7.2−7.24 (t, tryptophan amino acid residue), and 7.5−7.54 and 7.6−7.64 (d, tryptophan amino acid residue).

Fluorescence Reduction Assay. The ability of PEG−PPS−peptide to form complexes with siRNA was tested using an ethidium bromide (EtBr) fluorescence reduction assay. siRNA (15 pmol, 100 μL) was mixed with EtBr, and the resulting fluorescence emission was measured using a fluorescence microplate reader (Tecan, Männedorf, Switzerland). The reduction of fluorescence emission was measured as triblock copolymer was added to generate the indicated charge ratio.

Dynamic Light Scattering Analysis. The ability of PEG−PPS−peptide alone or in solution with siRNA to form nanosized aggregates was studied using dynamic light scattering (DLS) in a nanozetasizer (Malvern, U.K.). Size measurements of triblock copolymers alone were measured dissolving the individual polymers in Tris-buffer saline (TBS) at a 10 mg/mL and using the standard settings in the instrument. For PEG−PPS−peptide/siRNA size measurements, complexes were formed by adding the triblock copolymer solution (150 μL) to an siRNA solution (150 pmol, in 150 μL TBS) at different charge ratios. 100 μL of the solution was used to measure size, and the other was dissolved in MiliQ water to 1000 μL and used to measure ζ-potential of the complexes.

Cellular Internalization in Vitro. Cell internalization studies were assessed via fluorescence microscopy (Zeiss, Feldbach, Switzerland) and fluorescence-activated cell sorting (FACS). HeLa cells (40 000 cells/well, 24-well plate) were seeded the day before adding complexes with siRNA labeled with Cy3 (microscopy) or Cy5 (FACS). The day of transfection, siRNA/polymer complexes (25 pmol siRNA) were formed at charge ratios of ±6 for the microscopy studies and ±3 or ±6 for the FACS studies, were added to the cells, and were incubated with the cells for either 24 or 4 h for the microscopy experiments and FACS experiments, respectively. After incubation, the cells were washed three times with PBS and either visualized using a fluorescence microscope or trypsinized, centrifuged, and resuspended in 1% FBS in PBS and analyzed via FACS. The cells were not fixed. Untreated cells were used to determine the native background of the cells and to adjust the gates. The live cell gate was adjusted so that 10 000 events were read. The positive cell gate was defined as having less than 0.5% positive cells for untreated cells (a 95% confidence interval).

Cell Proliferation Assay. The toxicity of the triblock copolymer/siRNA complexes was assessed using the MTT assay (Promega Corp, Madison, Wisconsin). HeLa cells (7000 cells/well) were plated on a 96-well plate the day before they were exposed to the triblock copolymers/siRNA complexes. To determine the effect of complex concentration on toxicity, different siRNA concentrations were delivered with complexes at a charge ratio of ±6. Complexes were incubated with the cells for 24 h, then removed, and new media added. The MTT solution (20 μL) was added to each well and incubated for 2 h. Absorbance readings were measured at 490 nm. Untreated cells were used as the 100% cell proliferation control and siRNA complexed with Lipofectamine 2000 (LF2000, Invitrogen, Basel, Switzerland) was used as a comparative control using a 20 pmol siRNA/μL LF2000.

GAPDH Gene Expression Down-Regulation. The efficacy of the delivery strategy was studies using a GAPDH enzyme activity assay (Ambion, Austin, Texas). HeLa cells (7000 cells/well) were plated in 96-well plates the day before transfection and transfected with 10 pmol siRNA at a charge ratio of ±6. The transfections were done both in the presence and absence of FBS (0% or 10%) and in the presence and absence of chloroquine (Sigma, Lyon, France, 100 μM). Before transfection, the cell culture medium was replaced with transfection medium. For complexation, siRNA (30 pmol, 60 μL Optim-Mem) was mixed with the triblock copolymer or unmodified peptide (60 μL, TBS) and mixed by vortexing for 10 s. The complex was allowed to form undisturbed for 10 min. The extent of gene expression down-regulation was assessed 48 h post-transfection. LF2000 complexes were formed using a 1 μL of LF2000 to 20 pmol of siRNA. To determine if the transfection procedure affected GAPDH expression, a nontargeting sequence of siRNA was used (siNEG). GAPDH activity was only significantly reduced when LF2000 was used as the delivery vector for siNEG. The remaining GAPDH activity was measured as described by the manufacturer using the kinetic fluorescence increase method over 5 min and was calculated according to the following equation: % remaining expression = $\Delta_{\text{fluorescence,GAPDH}}/\Delta_{\text{fluorescence,siNEG}}$, where $\Delta_{\text{fluorescence}} = \text{fluorescence}_{1\text{min}} - \text{fluorescence}_{5\text{min}}$ for either transfected (GAPDH), mock transfected (siNEG), or untransfected cells. Untransfected cells are cells that are exposed to serum or serum-free media for the 4 h of transfection and then replaced with cMEM. For LF2000, the control is a mock transfection using siNEG to determine the level of down-regulation that occurs due to the transfection procedure.

Statistics. All statistical analyses were performed using the computer program *Prism* (GraphPad, San Diego, CA). Experiments were statistically analyzed using a one-way analysis of variance using the Tukey test, which compares all pairs of columns, using a 95% confidence interval. When only two groups were compared, the Student *t* test was used as indicated in the figure legends.

RESULTS

Polymer Synthesis and Characterization. The ABC triblock copolymer PEG−PPS−peptide was synthesized using anionic polymerization of propylene sulfide upon the terminus of an activated PEG−thiol under an inert atmosphere, followed by peptide grafting using a disulfide exchange reaction (see Figure 1 and Material and Methods). The peptide coupling reaction was monitored using the release of 2-pyridine dithione at 342 nm, which demonstrated that the reaction reached a plateau after 2 h (see inset in Figure 1). After each step of the synthesis and purification, the intermediate product was characterized with

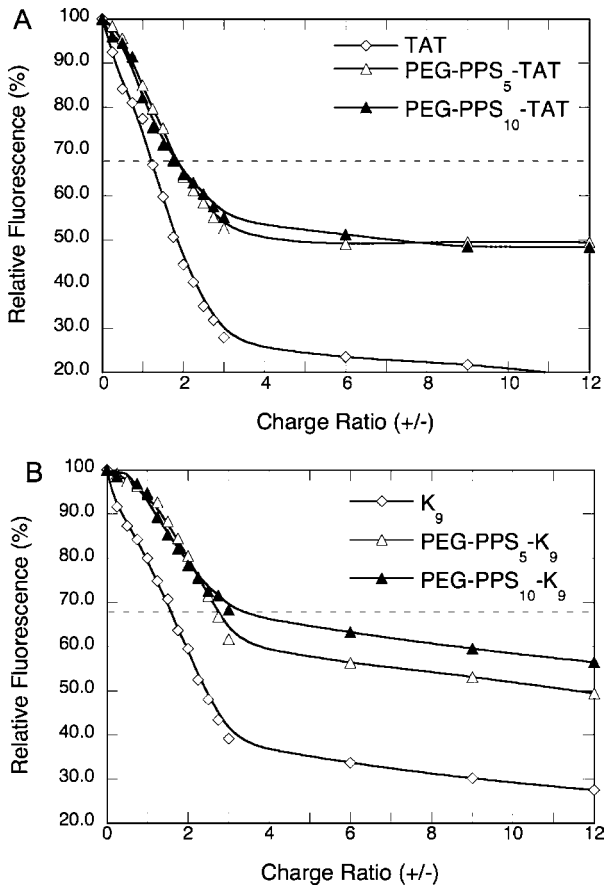

Figure 2. Relative fluorescence intensity of siRNA−EtBr complexes with PEG−PPS_n−TAT (A) and PEG−PPS_n−K_9 (B) at different charge ratios. The florescence intensity decreases as more polymer is added until a plateau is reached, indicating that particles have formed. The dotted line indicates the charge ratio at which complex migration in agarose gel electrophoresis is stopped.

^{1}H NMR to confirm that the correct product was achieved and that there were not remaining impurities. At the concentrations required for ^{1}H NMR analysis, however, the triblock copolymer formed aggregates, presumably micelles, both in an aqueous environment (D_2O) or in deuterated chloroform, due to its strong amphiphilic nature. ^{1}H NMR of the triblock thus contained broad peaks that were difficult to integrate. On the basis of the characterization performed, the polymers PEG_{45}−PPS_5−peptide and PEG_{45}−PPS_{10}−peptide were obtained, where the subscripted numbers indicate the degree of polymerization of the respective blocks.

EtBr Exclusion Assay. The ability of the triblock polymer to form condensed structures with siRNA was studied using an EtBr dye exclusion assay (Figure 2). All polymers were able to exclude EtBr from the siRNA as more polymer was added (higher charge ratios), indicating that condensed particles were forming. Both the TAT and K_9 peptides when used alone resulted in the highest condensation, reaching up to an 80% decrease in fluorescence intensity. Triblock copolymers based on TAT (Figure 2A) showed little dependence on the PPS degree of polymerization in their ability to form condensed particles with siRNA, with the maximum fluorescence decrease being reached at a charge ratio of 3, showing a 50% decrease. Triblock copolymers based on K_9 (Figure 2B), on the other hand, showed more of an effect of PPS length, with PPS_5 resulting in more condensed structures than PPS_{10}. The maximum fluorescence decrease was also 50%.

Size and ζ-Potential Characterization. In the absence of siRNA, the triblock polymers PEG−PPS_5−TAT, PEG−PPS_{10}−TAT, PEG−PPS_5−K_9, and PEG−PPS_{10}−K_9 each formed aggregates in solution at a concentration of 10 mg/mL, with sizes of 11.3 ± 0.4, 16.0 ± 0.3, 13.1 ± 0.1, and 16.0 ± 0.6 nm, respectively (Figure 3A,D). These measurements are consistent with a nanostructure morphology of spherical micelles. There was a statistical significance between the sizes of PEG−PPS_5−peptide and PEG−PPS_{10}−peptide aggregates for both TAT and K_9 peptides ($p < 0.001$), indicating that the degree of polymerization of the PPS domain affects the overall size of the particles formed. Furthermore, for triblock copolymers with PPS degree of polymerization of 5, there was a statistical difference of the size of aggregates formed between TAT and K_9 peptides ($p < 0.01$), indicating that the character of the peptide also affects the size of the resulting micellar aggregates.

Size and surface charge of the aggregates formed between siRNA and PEG−PPS_5−TAT, PEG−PPS_{10}−TAT, PEG−PPS_5−K_9, and PEG−PPS_{10}−K_9, as well as the TAT and K_9 peptides not associated to the block copolymer, were measured using DLS and ζ-potential (Figure 3). Complex size was found to be dependent on the amount of polymer used (charge ratio) and the length of the hydrophobic domain (PPS degree of polymerization). For PEG−PPS_5−TAT triblock polymers, the size of the particles formed decreased as the amount of polymer increased, with sizes ranging from 199.0 ± 79.3 to 160.2 ± 1.5 nm (Figure 3B, open triangles). However, for the triblock polymers where the PPS unit was longer (PPS_{10}), the trend was reversed, such that increasing the amount of polymer from a charge ratio of ±3 to ±24 increased the size of the particles, with particle size ranging from 222.2 ± 0.8 to 601.2 ± 72.8 nm and 182.4 ± 6.5 to 312.3 ± 42.7 nm for PEG−PPS_{10}−TAT (Figure 3B, closed triangles) and PEG−PPS_{10}−K_9 (Figure 3E, closed triangles), respectively. ζ-Potential measurement for particles formed with TAT-containing polymers increased from ∼−20 mV to ∼0 mV (Figure 3C) and for K_9-containing polymers from ∼0 mV and to ∼+10 mV (Figure 3F) as charge ratio was increased from ±3 to ±24.

PEG−PPS−Peptide/siRNA Internalization Studies. HeLa cell internalization of PEG−PPS−peptide complexes with siRNA was assessed by FACS and confirmed with fluorescence microscopy. FACS data were analyzed by determining the number of cells in the positive gate and the total mean fluorescence intensity (MFI) of the cell population (Figures 4 and 5). Cellular internalization of PEG−PPS−peptide complexes was greatly affected by the presence of serum as well as the length of the PPS domain and the charge ratio of the complex. For the TAT-containing polymers, maximal internalization in the presence of serum was only 38.2 ± 0.1%, whereas in the absence of serum, 99.9 ± 0.1% of the cells had internalized the polymer complex with siRNA (Figure 4A compared to C). Polymers formed with the K_9 peptide were also sensitive to the presence of serum (Figure 5A compared to C); however, polymer structure could somehow overcome this difference. For example, 93.3 ± 1.6% of the cells treated with PEG−PPS_{10}−K_9 at a charge ratio ±6 were positive for internalization in the presence of serum, compared with 99.0 ± 0.3% in the absence of serum. For these polymers, charge ratio was important: the PEG−PPS_{10}−K_9 polymer at a charge ratio of ±3 were internalized by only 63.4 ± 3.1% and 94.7 ± 0.6% of the cells in the presence and absence of serum, respectively, compared to the above-mentioned 93.3% and 99.00% for ±6 ($p < 0.001$). In contrast, internalization by TAT-containing polymers was not affected by the charge ratio used.

The mean fluorescence intensity (MFI) of the cells was also affected by the presence of serum, the length of the PPS domain, and the charge ratio of the complexes (Figures 4 and 5, panels B,D). In general, longer PPS domains and higher charge ratio achieved more particle internalization (higher MFI) than shorter

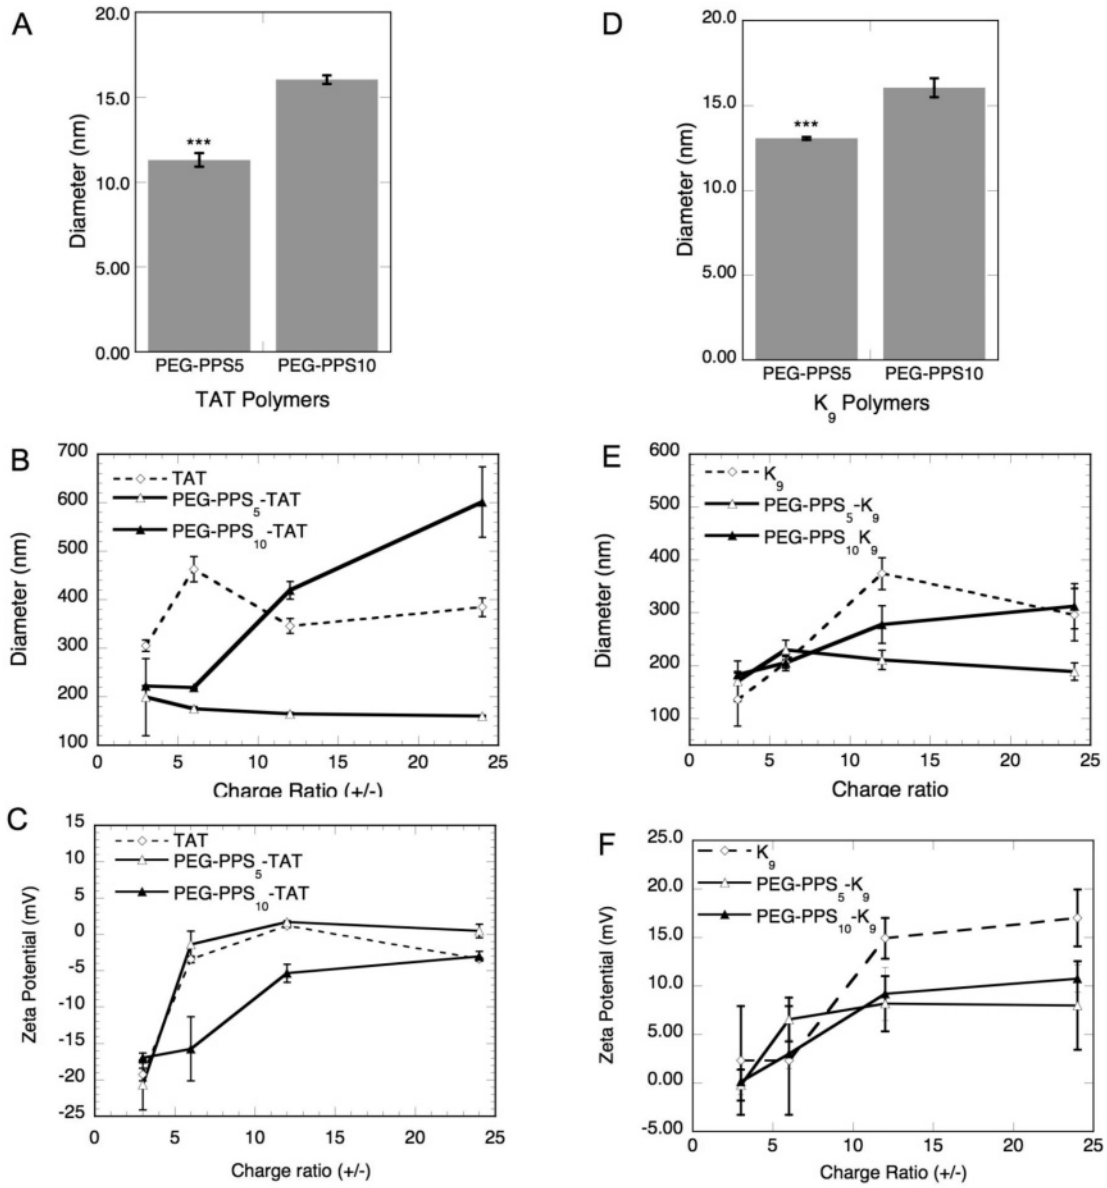

Figure 3. Mean diameter of micelles forming in 1% w/v solutions of PEG−PPS_n−TAT (A) and PEG−PPS_n−K_9 (D) in the absence of siRNA. Size and ζ-potential measurements as a function of charge ratio for TAT peptide-based polymers (B,C) and K_9-based polymers (E,F). The siRNA complexes with copolymers are much larger than the copolymer micelles that form without siRNA. Statistical analyses were done using the Student *t* test. The symbol *** indicates statistical significance at a level of $p < 0.001$.

PPS domains or lower charge ratio. Interestingly, the MFI was also affected by the type of peptide used, with the polymers formed with the K_9 peptide (Figure 5B,D) being less adversely affected by serum than the polymers formed with the TAT peptide (Figure 4B,D). In the presence of serum, the maximum MFI observed with PEG−PPS_{10}−K_9 was 12.4 ± 0.1 (at a charge ratio of ±6), compared to 22.4 ± 1.6 in the absence of serum (Figure 5, B vs D). The effect for the polymers formed with the TAT peptide was stronger: in the presence of serum, the maximum MFI observed with PEG−PPS_{10}−K_9 was 4.7 ± 0.01 (at a charge ratio of ±6), compared to 263.3 ± 63.8 in the absence of serum (Figure 4, B vs D). Fluorescence microscopy of complexes formed with Cy3-labeled siRNA corroborate the data found in FACS analysis. Figures 4E and 5E show fluorescence images for internalization of PEG−PPS_5−TAT and PEG−PPS_5−K_9 complexes, respectively, which show substantially more internalization than those complexes formed with TAT or K_9 (Figures 4F and 5F).

Comparisons with LF2000 were also made, and in all cases evaluated at the same siRNA dose (as in Figures 4 and 5), complex uptake was less with the polymer vectors than with the cationic lipid vector.

Toxicity of PEG−PPS−Peptide/siRNA Complexes. A cellular proliferation assay was used as an indirect measure of the toxicity caused by exposure to the triblock copolymer/siRNA complexes (Figure 6). None of the concentrations used for the different triblock copolymer/siRNA transfections resulted in a statistically significant reduction of cell proliferation, indicating that no toxicity occurred as a result of treatment with the complexes. In contrast, LF2000/siRNA complexes resulted in significant toxicity at concentrations of more than 10 pmol/well.

Gene Expression Down-Regulation. The ability of PEG−PPS−peptide/siRNA complexes to mediate gene expression down-regulation of GAPDH enzyme in vitro in the presence and absence of serum was investigated at 20 pmol/well siRNA (Figure 7). In the presence of serum, significant down-regulation was observed with PEG−PPS_{10}−K_9 ($p < 0.01$), but not with any other triblock polymer. In the absence of serum, however, significant down-regulation was observed for all triblock

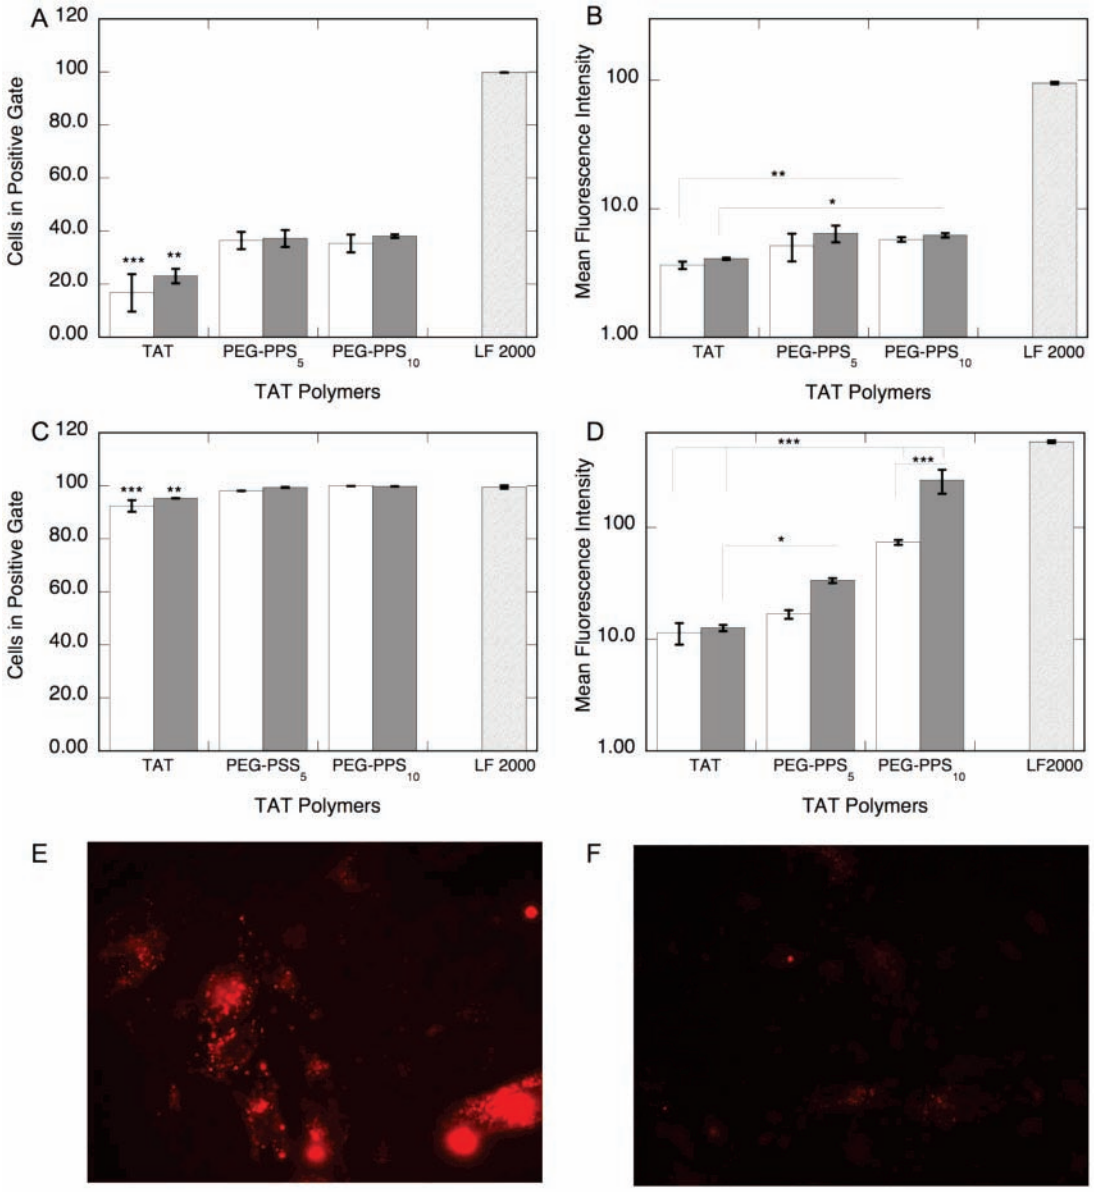

Figure 4. HeLa cell internalization of siRNA−Cy5 complexes with TAT peptide-based polymers over a 4 h period in the presence of 10% serum (A,B) and 0% serum (C,D). The bars in A and C represent the percent of cells in the positive gate, and B and D represent the mean fluorescent intensity of the cells. Open bars represent cells treated at a charge ratio of ±3, and filled bars at ±6. Fluorescence micrographs of complexes with PEG−PPS_5−TAT (E) and TAT peptide (F) are shown. Statistical analyses were done using multiple comparisons and the Tukey analysis of variance. The symbols *, **, and *** indicate statistical significance at levels of $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively, for the comparison indicated. Symbols placed directly on top of the bar indicate a significant difference between the TAT peptide and the all-TAT peptide-based polymers.

polymers, with PEG−PPS_5−TAT and PEG−PPS_{10}−TAT achieving 53 ± 0.01 and 56 ± 0.1 GAPDH gene expression down-regulation, respectively. PEG−PPS_5−TAT and PEG−PPS_{10}−TAT were statistically more able to mediate gene expression down-regulation than the TAT peptide alone ($p < 0.01$), achieving more than 50% down-regulation with the triblock copolymers compared to only 30% with the TAT peptide alone. Interestingly, the K_9 peptide-containing polymers in general were not as able to mediate gene expression down-regulation as the TAT polymers, achieving at most a 34 ± 0.1% GAPDH gene expression down-regulation for PEG−PPS_5−K_9 at a dose of 20 pmol/well.

To determine the effect of siRNA complex concentration on transfection efficiency, transfections were done using 10, 20, or 100 pmol/well of siRNA at a charge ratio of ±6 in the absence of serum (Figure 8). It was found that an increase in complex concentration from 10 to 20 pmol/affected GAPDH down-regulation of all complexes tested, including those with LF2000 ($p < 0.05$). However, an increase from 20 to 100 pmol/well only resulted in enhanced GAPDH down-regulation for the K_9 peptide-containing polymers (at least $p < 0.01$). Results for transfection with the PEG−PPS_5−K_9 polymer were particularly satisfactory, the level of gene expression down-regulation reaching 90.5%, statistically higher than that achieved with LF2000 at its highest acceptable concentration, 20 pmol/well ($p < 0.01$). Transfection at 100 pmol/well with LF2000 was not possible, due to the toxicity of the vector.

DISCUSSION

Efficient and safe siRNA-mediated gene silencing could benefit both basic science and therapeutic applications. Working toward these ends, we have developed a novel self-assembling triblock copolymer for siRNA delivery based on a triblock copolymer architecture. We sought to use short cationic peptides to reversibly bind siRNA, here using the HIV-1 TAT peptide

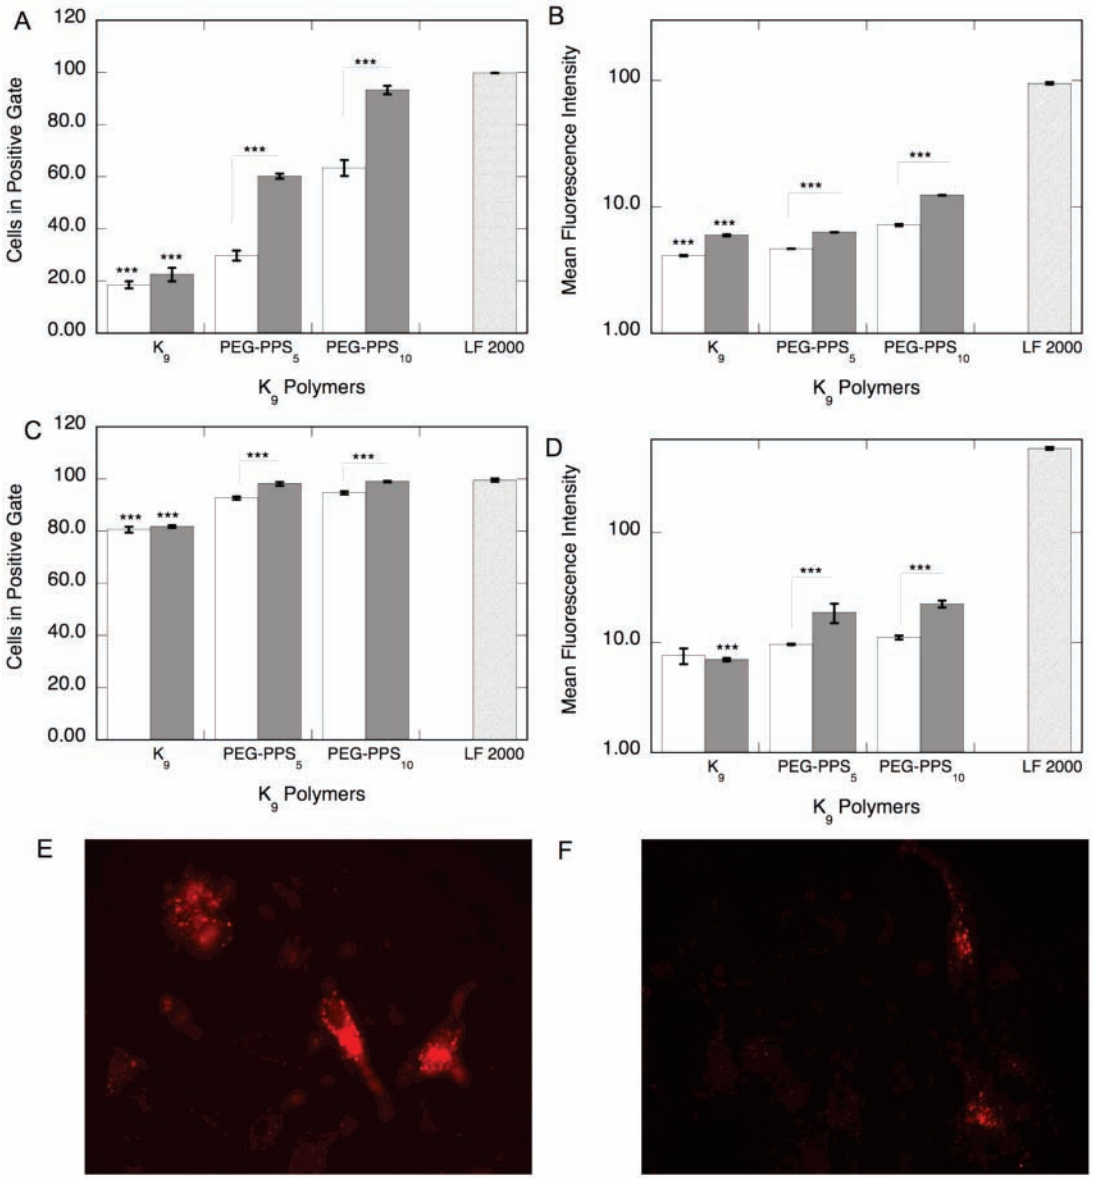

Figure 5. HeLa cell internalization of siRNA−Cy5 complexes with K_9 peptide-based polymers over a 4 h period in the presence of 10% serum (A,B) and 0% serum (C,D). The bars in A and C represent the percent of cells in the positive gate, and B and D represent the mean fluorescent intensity of the cells. Open bars represent cells treated at a charge ratio of ±3, and filled bars at ±6. Fluorescence micrographs of complexes with PEG−PPS_5−K_9 (E) and K_9 peptide (F) are shown. Statistical analyses were done using multiple comparisons and the Tukey analysis of variance. The symbol *** indicates statistical significance at a level of $p < 0.001$ for the comparison indicated. Symbols placed directly on top of the bar indicate significant difference between the K_9 peptide and the all-K_9 peptide-based polymers.

sequence and a synthetic lysine 9-mer, K_9. In order to enhance the formation of nanoparticles from these short peptides, we conjugated them to a hydrophobic polymer of controllable length, based on PPS with a degree of polymerization of either 5 or 10. Since a dimer of PPS with the peptide might have had limited solubility, the third block, a hydrophilic polymer also of controllable length, namely, a PEG of degree of polymerization of 45, was utilized. Our group has previously investigated PEG−PPS block copolymers (*20*, *22*) and has determined that this architecture is within a range that will form micelles, as was also demonstrated by measurements of particle size using DLS in this study as well. This concept for nanoparticle design, forming nanoparticles based on assembly of the hydrophobic PPS domains controlled by the attached hydrophilic PEG domains, and binding siRNA based on electrostatic interactions with the cationic peptides TAT and K_9 was explored for siRNA delivery. The TAT peptide was investigated as a means to enhance endosomal escape and K_9 as a control peptide to allow conclusions regarding endosomal escape enhancements. As mentioned in the Results section, however, the triblock copolymers made with the TAT peptide did not seem to have any added benefit as to endosomal escape compared to K_9-containing polymers; both polymers achieved enhanced gene transfer when choloquine was added to the media.

The triblock copolymers, PEG−PPS_5−TAT, PEG−PPS_{10}−TAT, PEG−PPS_5−K_9, and PEG−PPS_{10}−K_9 were able to self-assemble with siRNA into nanoparticles and mediate siRNA internalization with an efficiency (fraction of cells taking up the siRNA/copolymer complex) of up to 93% in the presence of serum and 100% in the absence of serum. Furthermore, the relative number of complexes internalized (mean fluorescence intensity) was 45% of that of a reference transfection agent, cationic liposomes (LF2000). Given that the copolymers demonstrated no measurable cytotoxicity, whereas the LF2000 demonstrated substantial cytotoxicity, much higher doses of siRNA/copolymer complexes could be applied, which resulted in up to 90.5 ± 0.02% GAPDH expression down-regulation

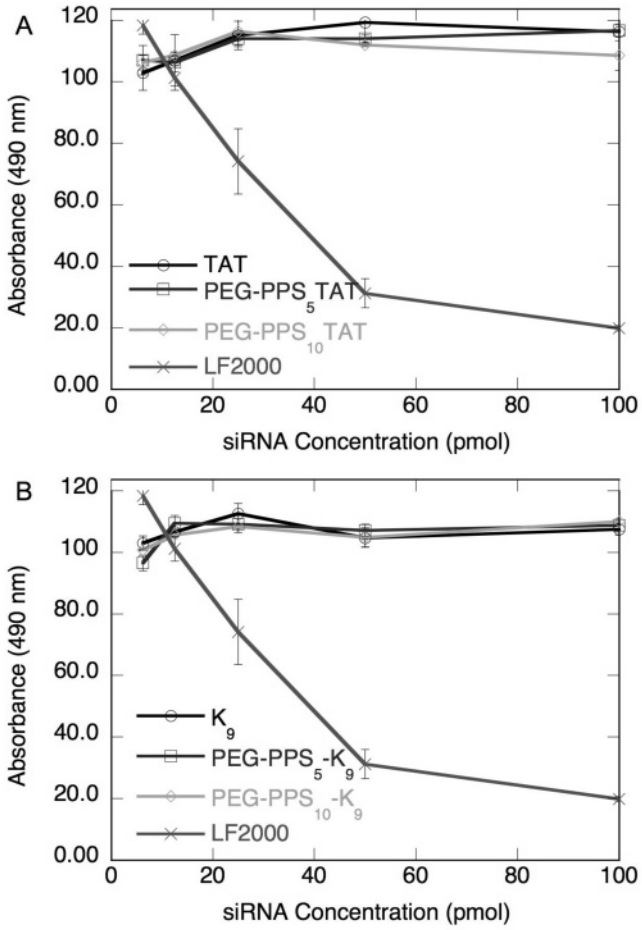

Figure 6. MTS toxicity assay (using cell proliferation) of (A) TAT peptide-based polymers and (B) K_9 peptide-based polymers, using lipofectamine 2000 (LF2000) as a positive control and untreated cells as a negative control.

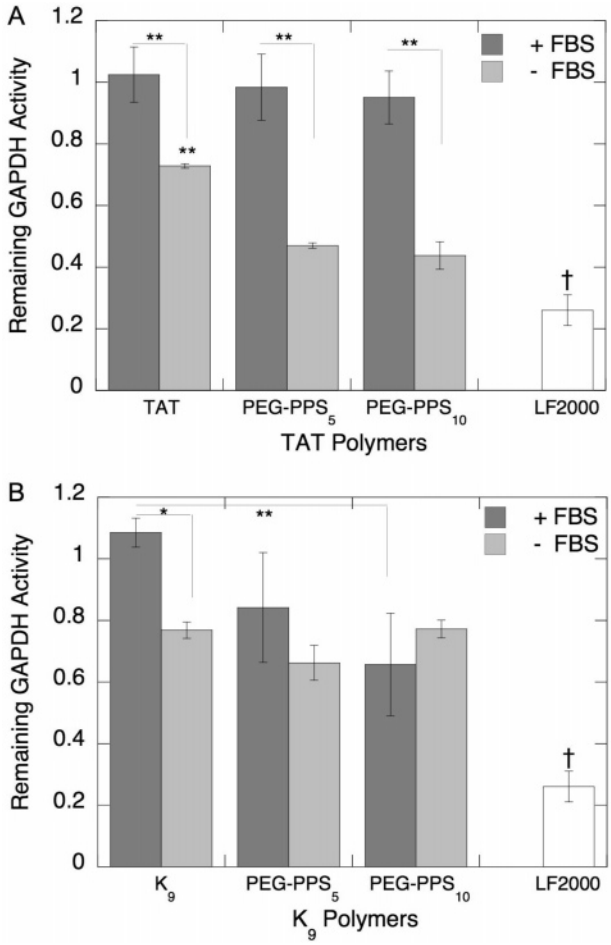

Figure 7. siRNA GAPDH down-regulation assay. HeLa cells were transfected with siRNAs at 20 pmol/well encoding for GAPDH enzyme using complexes with TAT peptide-based polymers (A) or K_9 peptide-based polymers (B) in the presence of 10% FBS (dark bars) or 0% FBS (medium bars). LF2000 was used as a comparison (white bar). Statistical analyses were done using multiple comparisons and the Tukey analysis of variance. The symbols *, **, and *** indicate statistical significance at levels of $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively, for the comparison indicated. Symbols placed directly on top of the bar indicate a significant difference between the peptide and the all-peptide-based polymers for the same charge ratio. The symbol † indicates a statistical significance at a level of $p < 0.001$ for all comparisons with LF2000.

when PEG−PPS_5−K_9 was used as the delivery vehicle in the absence of serum.

For some formulations, the hydrophobic character of the nanoparticles appeared to affect the internalization of PEG−PPS−peptide/siRNA complexes. The length of the hydrophobic domain in PEG−PPS−K_9 triblocks affected the amount of PEG−PPS−K_9/siRNA nanoparticle internalization, resulting in complexes with longer PPS domains achieving higher rates of internalization. This finding is not likely to be a result of the charge of the particles or their size, given that they were the same for both PEG−PPS_5−K_9 and PEG−PPS_{10}−K_9, suggesting that the hydrophobic domain directly affects internalization (Figure 5A). Limited hydrophobicity has been used in the design of other vectors as well: our results are consistent with findings exploring a dextran−spermine (D−SPM) delivery strategy for DNA, which found that the addition of hydrophobic domains, N-oleyl moieties (ODS), to D−SPM (D−SPM−ODS) enhanced transfection in the presence of serum (*23*). Taken together, these results suggest that optimizing the hydrophobic nature of the complexes may be another strategy to improve transfection efficiency. An influence of PPS block length was less apparent with the TAT peptide-based copolymer vectors.

With PEG−PPS_5−K_9 and PEG−PPS_{10}−K_9 formulations, the charge ratio of the PEG−PPS−peptide/siRNA nanoparticles also affected their internalization, with higher charge ratios (±6) resulting in statistically higher internalization than at lower charge ratios (±3) ($p < 0.001$ for all comparisons). Differing charge ratios may have resulted in differing levels of condensation of the siRNA within the nanoparticles; increasing copolymer content in the complexes resulted in more condensed particles (Figure 2), suggesting that, if the particles are more compact, they can be internalized at a higher rate. More compact DNA/polyethyleneimine and DNA/polylysine complexes have been found to internalize at higher rates and achieve higher transfection efficiencies (*24*, *25*).

The nature of the cationic peptide used in the copolymer also affected internalization of siRNA and gene expression down-regulation. Internalization by PEG−PPS_5−K_9/siRNA complexes at charge ratios of ±3 and ±6 was statistically higher than internalization mediated by PEG−PPS_5−TAT, with $p < 0.05$ and $p < 0.001$, respectively. Likewise, internalization of PEG−PPS_{10}−K_9/siRNA complexes resulted in statistically more internalization than with PEG−PPS_{10}−TAT, with $p < 0.001$ for both charge ratios tested. Moreover, PEG−PPS_5−TAT and PEG−PPS_{10}−TAT were more affected by serum and less affected by charge ratio than PEG−PPS_5−K_9 and PEG−PPS_{10}−K_9. Differences in internalization could be hypothesized to be due to differences in the biological activity of the peptides or differences in surface charge of the complexes. HIV-1 TAT has been reported to be able to translocate across cell membranes independently of receptors and temperature (*26*). More recently,

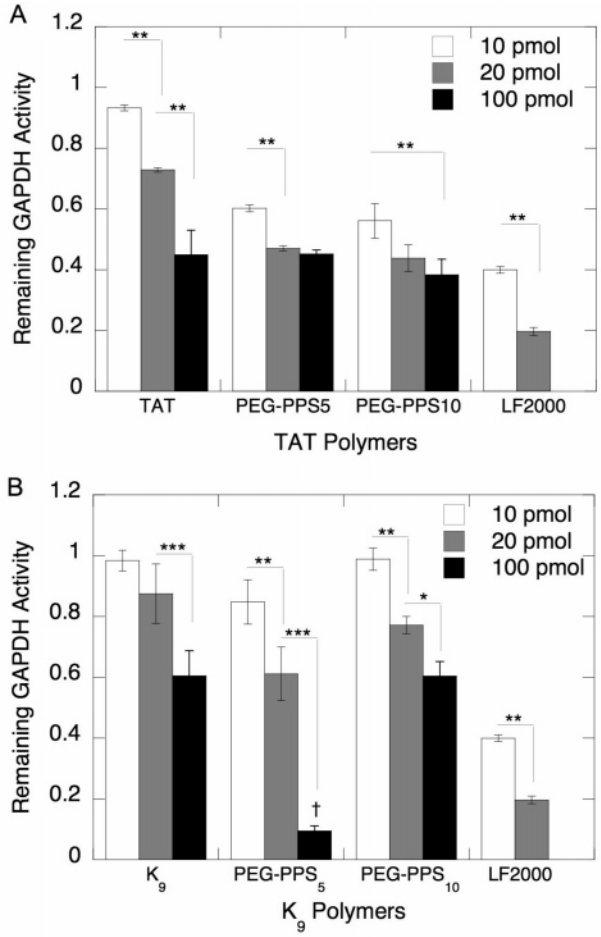

Figure 8. siRNA GAPDH down-regulation assay. HeLa cells were transfected with siRNAs encoding for GAPDH enzyme using increasing concentrations of siRNA (10, 20, and 100 pmol/well) using complexes with TAT peptide-based polymers (A) and K_9 peptide-based polymers (B). Measurement of GAPDH activity at 100 pmol/well for LF2000 was not possible due to extreme toxicity. Statistical analyses were done using multiple comparisons and the Tukey analysis of variance. The symbols *, **, and *** indicate statistical significance at levels of $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively, for the comparison indicated. Symbols placed directly on top of the bar indicate a significant difference between the peptide and the all-peptide-based polymers for the same charge ratio. The symbol † indicates a statistical significance at a level of at least $p < 0.05$ for PEG−PPS_5−K_9 with all other conditions.

however, these findings have been disputed, and the mechanism of TAT-mediated internalization has been associated with adsorptive endocytosis (*27*, *28*) and fluid-phase macropinocytosis (*29*, *30*). No specific biological activity has been associated with short polylysine oligomers. Complexes with the K_9 peptide are positively charged, whereas complexes with TAT are not. Positively charged complexes have been previously demonstrated to affect internalization of cationic polymer/DNA complexes, with positively charged complexes achieving higher internalization rates and transgene expression (*31*, *32*).

In comparison to the TAT or K_9 peptides alone, the ABC triblock copolymers were able to achieve more siRNA particle internalization (Figures 4 and 5) and higher gene expression down-regulation levels in the presence and absence of serum (Figures 7 and 8), indicating that the architecture of the triblock positively affects siRNA uptake and trafficking. In terms of comparison with reference materials such as cationic liposomes, the triblock copolymers demonstrated enhanced biocompatibility compared to the commercially available delivery vehicle LF2000. This, in turn, allowed use of higher siRNA doses with the triblock PEG−PPS−peptide copolymers, which achieved similar levels of gene expression down-regulation as with LF2000. The polymer PEG_{45}−PPS_5−K_9 was particularly interesting in this regard, achieving 90% gene expression down-regulation. Although we were able to achieve significant levels of down-regulation with higher doses of siRNA, it is more desirable to achieve significant levels using lower doses of siRNA. This could be accomplished by more efficient intracellular trafficking of the siRNAs such as by adding fusogenic peptides.

ACKNOWLEDGMENT

We would like to acknowledge the Simona Cerritelli for training on the PEG−PPS polymer synthesis and general discussions, and Andre Van der Vlies, Yun Suk Jo, and Conlin O'Neil for assistance with the NMR analysis of the polymer and helpful comments. This project was supported in part by grant F32GM72428 (TS).

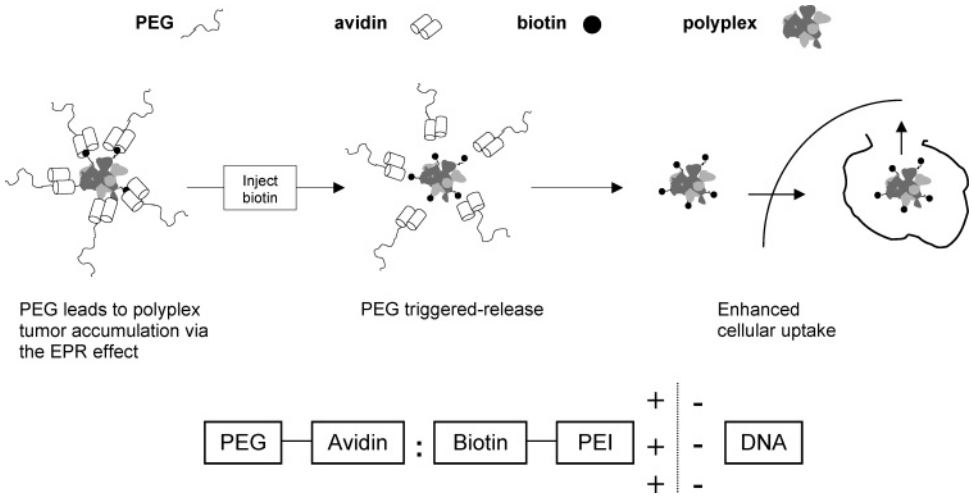
Covalently poly(ethylene glycol) (PEG)-ylated polyethylenimine (PEI)/pDNA complexes display prolonged blood circulation profiles compared with PEI/pDNA complexes, but such PEGylated particles may not be suitable for tumor targeting due to low interaction with cell membranes, low internalization, and low gene expression. Noncovalent PEGylation of cationic particles via PEG−avidin/biotin−PEI is an attempt to bridge the gap between the positive attributes of PEG (prolonged particle circulation) and the positive attributes of nontoxic cationic polymers (enhanced cell interactions) for greater gene expression. Our polymer, 2PEG−avidin/biotin−PEI8, forms salt-stable particles (∼100 nm) under physiologic conditions with a minimum of two 2PEG−avidin molecules bound per polymer chain (biotin−PEI8, 8 biotins/PEI). Following 10 days of incubation with 3000-fold excess biotin, 2PEG−avidin completely dissociated from biotin−PEI8, and gene expression was increased 2.1−32-fold in various cell lines when the desirable transfection feature of the cationic polymer was retained. This new PEGylation approach has implications for generally improving the clinical aspect of gene delivery via a two-step therapeutic strategy: (1) intravenous injection of noncovalent PEG−avidin/biotin−polycation nanoparticles for prolonged circulation, followed by (2) temporal release of PEG−avidin from biotin−polycation through either endogenous biotin or intravenous injection of biotin.

INTRODUCTION

In gene delivery, it has been shown that nanoparticles formed with cationic polymers readily lead to gene transfections *in vitro*; however, the *in vivo* toxicity and undesirable uptake of these complexes by reticuloendothial system (RES) organs (liver, spleen) limit their use for systemic delivery in solid tumor therapy. To date, most attempts to achieve therapeutic gene expression levels have focused on either new polymeric delivery systems or intracellular strategies for increasing pDNA escape from endosomes. Branched polyethylenimine (25 000 g/mol, PEI) remains one of the most efficient cationic polymers in nonviral gene transfer. It is a readily available polycation composed of approximately 25% primary, 50% secondary, and 25% tertiary amines (*1*). This off-the-shelf polymer is not optimized for safe gene delivery due to its high toxicity on cells, and cationic PEI analogues have been synthesized to minimize side effects (*2, 3*). Other groups have investigated the important role of pDNA unpackaging from cationic polymers (*4*), as well as the cellular mechanisms for cationic polymer-mediated pDNA transport to the nucleus (*5, 6*), including endosomal escape. Before any of these rate-limiting obstacles are encountered in cells, nonviral vectors must first and foremost not only successfully localize at the target site but also ensure transport of their cargo across the cell membrane (*7*). The focus of this study is to tackle the first barrier to gene translation: tumor localization for *in vivo* gene delivery through a proof-of-concept system, by using commercially available PEI as the model polycation.



Nonspecific accumulation of cationic particles into RES organs has been attributed to their aggregation behavior (*8, 9*). This issue is often tackled by conjugating poly(ethylene glycol) (PEG) onto the cationic particles. The presence of PEG can reduce particle aggregation under salt conditions (*10*), thereby decreasing nonspecific particle uptake, and minimize interactions with serum proteins for prolonged circulation of nanoparticles and tumor accumulation through the enhanced permeability and retention (EPR) effect (*11, 12*). However, covalently linked PEG−PEI particles are not suitable for enhanced gene transfection (*13*). Godbey and co-workers have demonstrated that PEI/DNA complexes adhere to cell surfaces before endocytosis (*14*); therefore in the absence of ligands or sufficient charge, this interaction with the cell membrane may be diminished in the presence of PEG and the transfection efficiency decreased. For example, Mishra et al. have shown that in the case of cationic PEI, polyplex aggregation leads to greater interactions with cells and might be a mechanism for high gene expression in cultured cells compared with PEGylated-PEI particles that did not exhibit aggregation behavior (*15*). Other groups have also reported lower transfections when PEG was covalently grafted onto PEI (*16, 17*). The clinical significance for solid tumor gene therapy is that the stealth properties of covalently linked PEG particles may minimize cell interactions, endosomal escape, and hence gene expression.

To address this challenging issue, we propose to enhance cellular interactions of PEG−PEI particles through the introduction of a noncovalent avidin−biotin bridge, which is used to link PEG to PEI, forming PEG−avidin/biotin−PEI particles that can potentially be more suitable for gene delivery (Scheme 1). We show that gene expression is increased when the desirable features of cationic PEI (high transfection efficiency) are retained near cells. Using a similar avidin/biotin bridge approach, Segura et al. have reported enhanced *in vitro* pDNA delivery through biotin-complex immobilization on neutravidin-coated substrates (*18*). Wild-type avidin and biotin form strong noncovalent interactions with $K_d = 10^{-15}$ M at pH 7.0 (*19*), but it has been shown that attaching a bulky polymer to biotin can substantially decrease its binding affinity to avidin (*20*). Likewise in our system, conjugation of biotin groups to PEI decreases PEG−avidin binding affinity to biotin−PEI. Here, we introduce a novel PEGylation approach, noncovalent PEG−

Scheme 1. Model of PEG−Avidin/Biotin−PEI Polyplex[a]

[a] Injection of excess biotin triggers the release of PEG−avidin, revealing the cationic polyplex. Enhanced cell interaction leads to more particle uptake and greater gene expression. PEG−avidin/biotin−PEI: Positive amines of PEI can complex with negative phosphate groups of DNA via electrostatic interactions; presence of PEG forms salt-stable nanoparticles; avidin/biotin bridge permits temporal release of PEG−avidin from the cationic polymer in the presence of excess biotin.

avidin/biotin−PEI, that combines desirable features of PEG (stealth properties) followed by its temporal biotin-triggered release from biotin−PEI to enhance gene delivery.

EXPERIMENTAL PROCEDURES

Materials. *Cell Culture Media.* Dulbecco's modified Eagle's medium (DMEM), phosphate-buffered saline, fetal bovine serum (FBS), trypsin−EDTA (0.25% trypsin, 2.21 mM EDTA in Hank's buffered salt solution (HBSS)) and penicillin−streptomycin were purchased from Cellgro (Mediatech, Herndon, VA).

Plasmids. The 5.3 kb pDNA encoding firefly luciferase (pGL3) was obtained from Promega Corporation (Madison, WI). The pGL3 plasmid was transformed into electrocompetent DH5α cells, propagated in 1 L of Luria−Bertani (LB) broth supplemented with 100 μg/mL ampicillin and purified with a plasmid maxiprep kit (BioRad, Hercules, CA). The 4.7 kb plasmid encoding enhanced green fluorescent protein (pEGFP-N1) was obtained from David M. Lynn (University of Wisconsin), propagated in 1 L of LB broth supplemented with 50 μg/mL kanamycin and purified as previously described. All pDNA had purity levels of 1.8 or greater when measured with a UV spectrophotometer (A_{260}/A_{280}).

Cell Lines. COS-7 cells (African green monkey kidney) were obtained from David M. Lynn (University of Wisconsin). MDA-MB-231 (human breast cancer), C2C12 (murine myoblasts), and SKBR-3 (human breast cancer) cells were purchased from ATCC. All cell lines were cultured according to ATCC protocols.

Transfections and Toxicity. The luciferase assay system was purchased from Promega Corporation (Madison, WI). Luminescence was measured with a microplate Tropix luminometer (Applied Biosystems). Protein content was obtained using the DC protein assay kit from BioRad (Hercules, CA), absorbance was measured with the Spectramax 190 microplate reader (Molecular Devices, Sunnyvale, CA), and results were fitted to a known protein calibration curve. Cytotoxicity was assessed following manufacturer's instructions with the cell proliferation XTT kit from Roche (Indianapolis, IN). One-way analysis of variance (ANOVA) was used to statistically compare transfection data, and two-way ANOVA was used for the toxicity data. A value of $p < 0.05$ was considered statistically significant.

Chemicals. NHS-LC-biotin was purchased from Pierce (Rockford, IL). Branched 25-kD polyethylenimine (PEI) and chloroquine (CQ) were purchased from Sigma-Aldrich (Milwaukee, WI). Monomethoxypoly(ethylene glycol) succinimidyl propanoate (5000 g/mol, PEG5k-SPA) was purchased from Shearwater Corporation (Huntsville, AL). Chicken avidin was purchased from Invitrogen (Carlsbad, CA). All materials were used without further purification.

Instruments. Fluorescence measurements were obtained with a Fluoromax 3 fluorometer ($\lambda_{exc/emis} = 328/408$ nm, Horiba Jobin Yvon, Edison, NJ). Dynamic light scattering experiments were conducted using a 100 mW 532 nm laser (Coherent Compass 315M-100) filled with a refractive-index-matching fluid (decahydronaphthalene). Autocorrelation functions were obtained using a BI-9000AT digital autocorrelator (Brookhaven Instruments Corporation, Holtsville, NY), and diameters are reported as intensity-averaged diameters. Fluorescence images were captured with a digital camera (63× magnification) mounted on a Zeiss Axioplan 2 imaging system (Thornwood, NY). Image processing was limited to false coloring and automatic contrast enhancements using the free image analysis program, ImageJ, from NIH. Flow cytometry was performed with a FACSCalibur cytometer (BD Biosciences, Franklin Lakes, NJ) equipped with 488-nm (530/30-nm bandpass emission filter) and 633-nm lasers (661/16-nm bandpass emission filter). Live cells were gated using forward and side scatter based on operator experience. Flow data were analyzed with FlowJo software, and means were determined based on live cells ($n = 10\,000$).

Synthesis of Biotinylated PEI. NHS-LC-biotin (25 mg) was dissolved in 1 mL of DMSO. Then 10, 7.5, 5, or 2.5 mg from the 25 mg/mL stock NHS-LC-biotin solution was added to 25 mg of PEI in 20 mM phosphate-buffered saline (PBS); total volume of each reaction was 5 mL. Reaction mixtures were stirred at 4 °C for 2 h, dialyzed against water overnight (MWCO 1000, SpectraPor, Gardena, CA), lyophilized, and redissolved in 2 mL of PBS. Biotin−PEI polymers were purified through a monomeric avidin column (Pierce, Rockford, IL), dialyzed against water (MWCO 1000), and lyophilized to yield the final product. Biotin to PEI ratio was calculated based on integrations with respect to one of the biotin bridgehead protons and are shown in Table 1 (Varian 400 MHz, D_2O, δ 4.6, 4.4 ppm (m, bridgehead CH of biotin), 2.5−3.7 ppm (br. m, CH_2 of PEI, CH_x of biotin), 2.3 ppm (m, CH_2CO of biotin), 1.2−1.9 ppm (br. m, CH_2 of biotin)).

Transfection and Cytotoxicity of Biotinylated PEI. pGL3 and biotin−PEI polymers were mixed in PBS by addition of an equal volume of polymer to an equal volume of pGL3 and

Table 1. Biotinylation Levels for Biotin−PEI Series Based on ^{1}H NMR Integrations

polymer	biotin/PEI	% of 1° amines[a] modified
biotin−PEI18	18	9.8
biotin−PEI11	11	6.0
biotin−PEI8	8	4.3
biotin−PEI4	4	2.2

[a] 32.3% total primary (1°) amines in PEI based on ^{13}C NMR.

allowed to incubate at RT for 15 min. Samples were loaded onto a 0.75% agarose gel and stained with ethidium bromide. Experimental isoelectric points (equivalent nitrogen to phosphate ratio N/P = 1 for polymer to pGL3, defined as the minimum amount of polymer it took to completely retard pGL3 on the gel) were obtained based on w/w. MDA-MB-231 (human breast cancer) cells were seeded at 300 000 cells/well and cultured in six-well plates for 24 h. The next day, wells were aspirated and washed with 1 mL of PBS (×2), and medium was replaced with serum-free DMEM (1% penicillin/streptomycin). Complexes (2 μg of pGL3/well) formed at N/P = 10 were added to wells and incubated for 4 h, and the media was replaced with regular DMEM (10% FBS, 1% penicillin/streptomycin). After 24 h, plates were assayed with the Promega luciferase assay system. Relative light units (RLUs) of luciferase were converted to concentrations by using known luciferase concentration standards. Results were normalized to total protein content of the sample with the DC protein assay kit from BioRad.

Cytotoxicity of the free polymer was assessed as a decrease in metabolic rate through the cell proliferation XTT kit from Roche. Briefly, 96-well plates were seeded at 50 000 cells/well and incubated for 24 h. Media containing free polymer at increasing concentrations from 0 to 50 μg/mL was added to wells, incubated in serum-free DMEM for 4 h, and replaced with regular DMEM. After 24 h, XTT reagent was added to each well and incubated for 4 h before reading absorbance ($A = \lambda_{492} - \lambda_{690}$ nm). Cell viability for the polymers is reported as relative metabolic rates with respect to controls without polymers.

Synthesis of PEG−Avidin. A mole ratio of 3.2:1 PEG5k-SPA to chicken avidin was used to attach one to two PEG chains to lysine ϵ-amines of the protein under aqueous conditions. PEG5k-SPA (15 mg) was dissolved in 1 mL of reaction buffer (20 mM PBS, pH 7.2) and added dropwise to reaction buffer containing avidin (63 mg, 10 mg/mL). The reaction was allowed to proceed for 2 h at 4 °C. Fast protein liquid chromatography (FPLC; 0.5 mL/min, 20 mM PBS, pH 7.2) with a Superose 12 10/300 GL size-exclusion column (GE Healthcare, Piscataway, NJ) was used to separate and collect different conjugates. Pooled fractions for two PEG chains on avidin (2P−avidin) and one PEG chain on avidin (1P−avidin) were characterized through matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) and denaturing protein gels (*21*). In addition, work by others has shown that conjugation at mole ratios of 10:1 have no more than four PEG5k chains attached to avidin (*22*).

Characterization of PEG−Avidin/Biotin−PEI Binding Interactions. *Fluorometric Studies.* Into 2 mL of 2.0 μM 2P− or 1P−avidin (0.2 M *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES), 2 M NaCl, pH 7.0) was added 25 μL of 100 μM 2-anilinonaphthalene-6-sulfonic acid (2,6-ANS, Invitrogen, Carlsbad, CA) (*23*). Next 5−10 μL of biotin−PEI18, biotin−PEI11, biotin−PEI8, or biotin−PEI4 (1 mg/mL) was titrated into the cuvette with mixing, and 2,6-ANS fluorescence was measured after each addition. The minimum average avidin bound per biotin−PEI polymer was extrapolated from the decrease in fluorescence at the equivalence point.

Size-Exclusion Chromatography (SEC) Studies. 2P−avidin or 1P−avidin (3.17 mg) was incubated with equivalent amounts of biotin−PEI18 and biotin−PEI8 in 3 mL of aqueous buffer (0.2 M HEPES, 2 M NaCl, pH 7.0) for 2 days. Reactions were filtered through a 0.45 μm syringe and analyzed with SEC (0.5 mL/min, 20 mM PBS, pH 7.2) by monitoring avidin absorbance at 280 nm. The fraction corresponding to 2P−avidin/biotin−PEI8 (highest yield) was pooled and incubated with 3000-fold excess biotin in a final volume of 5 mL (20 mM PBS, pH 7.2, 37 °C). A 1 mL injection into the FPLC was made on days 3, 5, 7, and 10 to monitor 2P−avidin release from the polymer.

Characterization of PEG−Avidin/Biotin−PEI Particles. *Pre-PEGylation and Salt Stability Studies.* 2P−avidin (190 μg, 6.34 mg/mL) and 1P−avidin (190 μg, 13.4 mg/mL) were mixed with either PEI, biotin−PEI18, or biotin−PEI8 at N/P = 10 and incubated at RT for 1 h. Polymer solutions were mixed with pGL3 (1 μg) and incubated for at least 10 min to form polyplexes. Salt (1 mL, 20 mM PBS, pH 7.2) was added, and aggregate formation was monitored for 30 min with dynamic light scattering.

Cell Transfection Studies. 2P−avidin was incubated with biotin−PEI8 as described earlier. After 2 days, the reaction was split into two vials, each containing 2.66 mg of 2P−avidin/biotin−PEI8. A stock concentration of biotin with maximum solubility of 6.4 mg/mL (0.2 M HEPES, 2 M NaCl, pH 7.0) was prepared and filtered before use. A 3000-fold excess biotin to avidin was added to one vial of 2P−avidin/biotin−PEI8, abbreviated 2PABP(+), and an equivalent amount of buffer volume without biotin was added to the parent control vial, abbreviated 2PABP(−). Vials were covered with parafilm and incubated at 37 °C for 10 days. Resulting polymers were dialyzed against 20 mM PBS (MWCO 3500), lyophilized to yield a white powder, and reconstituted in 5 mL of MilliQ water to a final concentration of 532 μg/mL. The experimental p*I* was obtained as described before through agarose gels. COS-7, MDA-MB-231, C2C12, and SKBR-3 cells were seeded in 12-well plates at 200 000 cells/well. Transfection efficiency of the polymers (N/P = 20, 2 μg of pGL3/well) in serum-containing media was evaluated as described earlier under both 2PABP(−) and 2PABP(+) conditions.

Comparison of Cell Toxicity. Glass cover slips were cleaned in NaOH/EtOH, coated with poly(D-lysine) (MW 70 000−150 000 g/mol, Sigma-Aldrich), dried in a vacuum oven (45 °C) and inserted into six-well plates. COS-7 and SKBR-3 cells were seeded at 300 000 cells/well and incubated overnight. Particles were formed with pEGFP-N1 (N/P = 20, 6 μg of pDNA/well) and incubated in wells for 4 h before replacing the media, and the next day live fluorescence images of cells were captured from the glass cover slips. Dead cells and the presence of cytoplasmic green fluorescent protein (GFP) released in the media are indicative of PEI and biotin−PEI8 toxicity.

Polymer Uptake Studies. AlexaFluor 633 (1 mg, Invitrogen, Carlsbad, CA) was dissolved in 1 mL of DMSO. Next 250 ng of AlexaFluor 633 was reacted with 2.13 mg of 2PABP(−) and 2PABP(+) separately in 4 mL of PBS. Because 2P−avidin (MW 78 kDa) that was competitively displaced from biotin−PEI8 was not removed by dialysis (MWCO 3500), the labeling for both 2PABP(−) and 2PABP(+) is equivalent. The reaction vials were wrapped in aluminum foil, stirred for 1 h at RT and dialyzed (MWCO 3500) against 50 mM PBS overnight (while covered in aluminum foil). Labeled polymers were lyophilized and redissolved with water to a final concentration of 532 μg/mL.

COS-7 and SKBR-3 cells were seeded in six-well plates and transfected using the fluorescently tagged polymers (formed under similar conditions described with pEGFP-N1). At harvest, the growth medium was gently aspirated, and the cells were

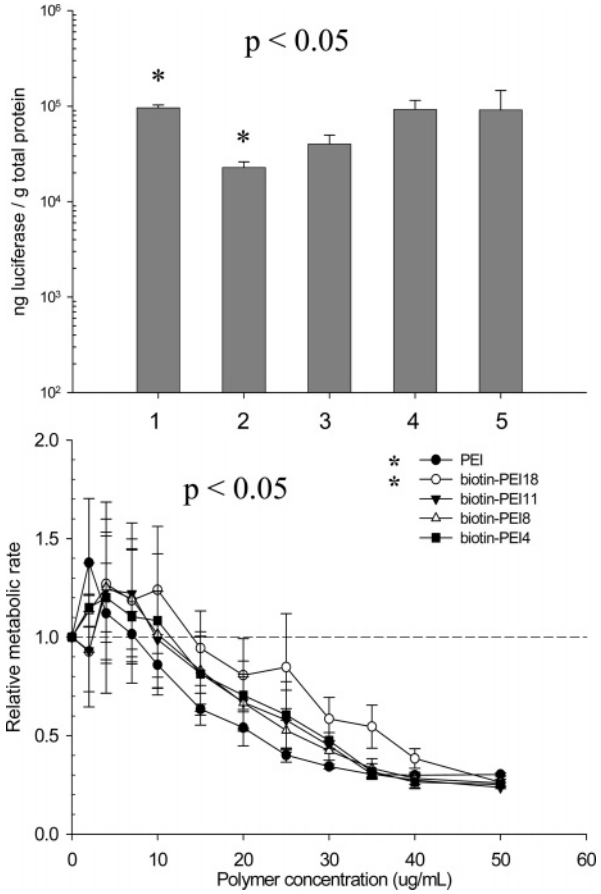

Figure 1. Effect of varying biotinylation levels in MDA-MB-231 cells on transfection efficiency (N/P = 10, pGL3, $n = 3$) and free polymer toxicity in serum-free DMEM. Increasing biotinylation levels (biotin−PEI18) statistically decreases transfection efficiency compared with PEI. Polymer 1 = PEI; polymer 2 = biotin−PEI18; polymer 3 = biotin−PEI11; polymer 4 = biotin−PEI8; polymer 5 = biotin−PEI4. One-way and two-way ANOVA were used; $p < 0.05$ was considered statistically significant.

washed in PBS containing 0.001% SDS (×1) to remove uninternalized polyplexes from cell surfaces. Cells were washed with regular PBS (×2), detached with 700 μL of trypsin and quenched by addition of 150 μL of serum-containing media. Contents were transferred to Eppendorf tubes and stored on ice until analysis.

RESULTS

Synthesis and Characterization of Biotinylated PEI. The primary amines of PEI were conjugated to biotin groups with 2.2−9.8% biotin conjugations based on ^{1}H NMR integrations (Table 1). The total percentage of primary amines in this particular batch of commercial PEI was 32.3% and was obtained through an inverse gated decoupled ^{13}C NMR experiment as described by von Harpe et al. (*24*), assuming an average molecular weight of 43 g/mol for each PEI repeating unit, CH_2-CH_2NH_x (Varian 500 MHz, D_2O, delay 30 s, pw 90, temp 30 °C). This still leaves, respectively, between 30.1% and 22.5% primary amines remaining on PEI.

Increasing the conjugation level of biotin decreases the transgene expression of PEI (Figure 1). Indeed, the conjugation of 11 or 18 biotins (biotin−PEI11, biotin−PEI18) reduced luciferase expression 2- and 4-fold, respectively ($p < 0.05$). Attaching four or eight biotins to PEI (biotin−PEI4, biotin−PEI8) did not lower luciferase expression ($p > 0.05$), with levels remaining comparable to PEI. On the other hand, the 50% cell death (IC_{50}) based on polymer concentration increased with more biotin conjugation, suggesting less toxicity to cells with decreasing primary amine content (e.g., the IC_{50} for biotin−PEI18 is statistically lower than that for PEI based on two-way ANOVA, $p < 0.05$).

Table 2. Fluorescence Studies with 2,6-ANS to Calculate the Minimum Average 2P− and 1P−Avidin Molecules Bound to Each Biotin−PEI Chain[a]

		2P−avidin, 4.1×10^{-9} mol		**1**P−avidin, 4.1×10^{-9} mol	
	new MW	biotin−PEI (mol)	no. of 2P−avidin per biotin−PEI	biotin−PEI (mol)	no. of 1P−avidin per biotin−PEI
biotin−PEI18	31 600	1.3×10^{-9}	3.3	1.3×10^{-9}	3.3
biotin−PEI11	28 400	1.5×10^{-9}	2.7	1.3×10^{-9}	3.2

biotin−PEI4	26 300	4.3×10^{-9}	1.0	4.2×10^{-9}	1.0

[a] PB polymer (1 mg/mL) was titrated into the protein at 5−10 μL increments.

Synthesis and Characterization of PEG−Avidin. One and two PEG chains were randomly conjugated to avidin (Figure 1, Supporting Information). Avidin can condense pDNA in a highly specific manner into nanoparticles (*25*), and light scattering shows that these particles tend to aggregate with increasing N/P (Figure 2, Supporting Information). However, in the presence of PEG conjugated to avidin, 2P− and 1P−avidin did not exhibit aggregation behavior under salt conditions. We found that despite forming nanoparticles suitable for transfecting cells, lack of buffering and membrane disruptions prevented particles from mediating high gene expression in the absence of PEI and chloroquine (CQ) (Figure 3, Supporting Information).

Characterization of PEG−Avidin/Biotin−PEI Interactions. Avidin, 2P−avidin, and 1P−avidin were determined to have 3.7, 3.2, and 3.1 biotin-binding sites, respectively (data not shown). The minimum average number of 2P− and 1P−avidin molecules bound to the biotin−PEI series was surprisingly low based on fluorescence experiments (Table 2). This discrepancy is due to the large number of unoccupied sites on avidin in the cuvette and low biotin levels presented during early biotin−PEI titrations, thereby driving the interaction toward avidin−polymer cross-linkages and further limiting accessibility to remaining sites during later stages of biotin−PEI addition. All the biotin−PEI polymers interacted with 1P− and 2P−avidin (Figure 2).

Focusing on 2P−avidin/biotin−PEI8, biotin (10×, 50×, 500×, 1000×, and 3000×) was incubated with the polymer. With respect to measured avidin concentration on the polymer, a 3000-fold excess biotin and 10 days of incubation was required to observe complete release of the protein (Figure 3). The typical half-life of a biotin-bound avidin is approximately 200 days (*19*); therefore, this corresponds to a substantial decrease in the half-life of avidin/biotin−PEI8.

Characterization of PEG−Avidin/Biotin−PEI Complex. We investigated the salt stability conferred by 2P− and 1P−avidin to biotin−PEI18 and biotin−PEI8 using dynamic light scattering (Figure 4). When 2P− or 1P−avidin was mixed with PEI and then formulated with pGL3, no interaction occurred and resulting nanoparticles slowly aggregated over time. In comparison, premixing 2P− and 1P−avidin with biotin−PEI18 and biotin−PEI8 before particle formulation resulted in a decrease in aggregation behavior, suggesting that only polymers with biotin moieties could interact with 2P− and 1P−avidin to form salt-stable particles in solution.

The transfection efficiencies of 2P−avidin/biotin−PEI8 particles were compared at N/P = 20 in four different cell lines: COS-7, SKBR-3, MDA-MB-231, and C2C12 (Figure 5). We chose to test at N/P = 20 since this ratio gave us the highest

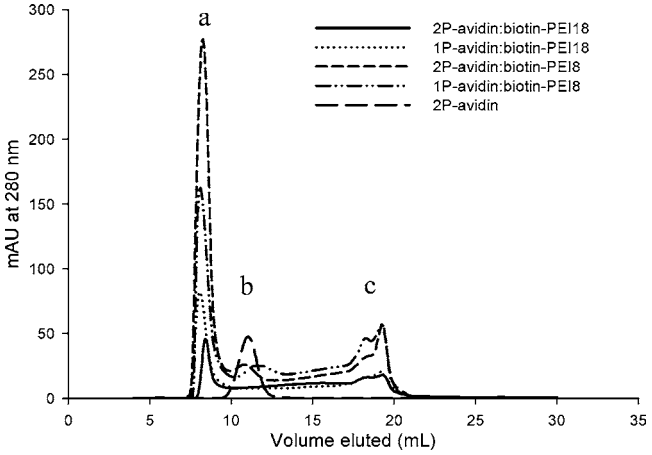

Figure 2. SEC yields for 2P− and 1P−avidin binding interactions with biotin−PEI. 2P− and 1P−avidin were incubated with biotin−PEI polymers at RT in a high salt buffer (0.2 M HEPES, 2 M NaCl, pH 7.0) for 2 days. The reactions were filtered through a 0.45 μm filter before injection into the FPLC (0.5 mL/min, eluent 20 mM PBS, pH 7.2). The highest yield of product, as detected by absorbance at 280 nm, occurred with 2P−avidin/biotin−PEI8. Peak a = PEG−avidin/biotin−PEI polymers; peak b = 2P−avidin for reference; peak c = biotin−PEI polymers.

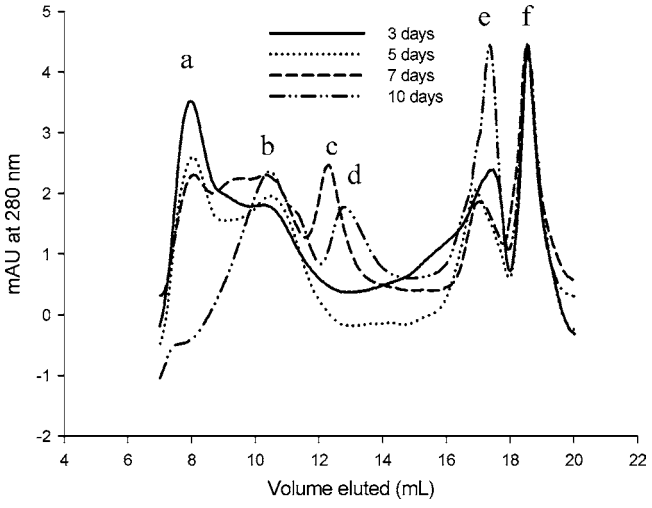

Figure 3. Monitoring 2P−avidin release from biotin−PEI8 in the presence of exogenous biotin. A 3000-fold excess of biotin with respect to measured avidin concentration was incubated with 2P−avidin/biotin−PEI8 at 37 °C in PBS. After 10 days of incubation, 2P−avidin completely dissociated from biotin−PEI8 (0.5 mL/min, 20 mM PBS, pH 7.2). Peak a = 2P−avidin/biotin−PEI8; peak b = 2P−avidin; peak c = peak d = subunit dissociations; peak e = biotin−PEI8; peak f = biotin.

transfection efficiency for PEI (tested at N/P = 10, 20, 30, and 40; data not shown). The transfection efficiency for 2PABP-(+) particles was higher compared with that for 2PABP(−), except in COS-7 cells. These cells did not discriminate between particles because they had similar luciferase values ($p > 0.05$). However in SKBR-3 cells, 2PABP(+) particles transfected cells 32-fold better than 2PABP(−) particles ($p < 0.05$). In MDA-MB-231 cells, the transfection was enhanced 2.7-fold ($p < 0.05$), and in C2C12, we saw a 2.1-fold enhancement in transfection ($p < 0.05$).

Cytoplasmic release of GFP into the surrounding medium is an additional cytotoxic marker for PEI. In COS-7 and SKBR-3 cells, the 2PABP(−) polymer shows no cytoplasmic release of GFP into the surrounding area (Figure 6). On the other hand, there is a substantial increase in GFP leakage (toxicity) after transfecting the cells with 2PABP(+). White arrows point to GFP presence in the surrounding medium. Overall, there was

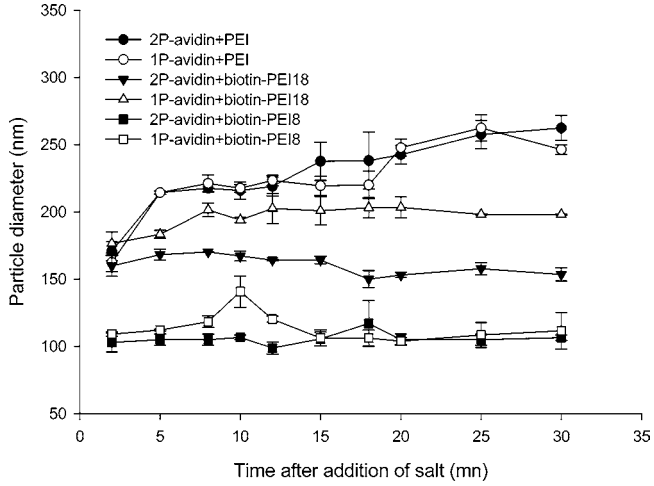

Figure 4. Salt-stability trends for 2P− and 1P−avidin premixed with PEI, biotin−PEI18, or biotin−PEI8. Resulting polymers were mixed with 1 μg of pGL3 at N/P = 10 in water and incubated for 10 min at RT. Light scattering intensity-weighted diameters for each ($n = 3$) were monitored for 30 min following addition of 1 mL of salt (20 mM PBS, pH 7.2).

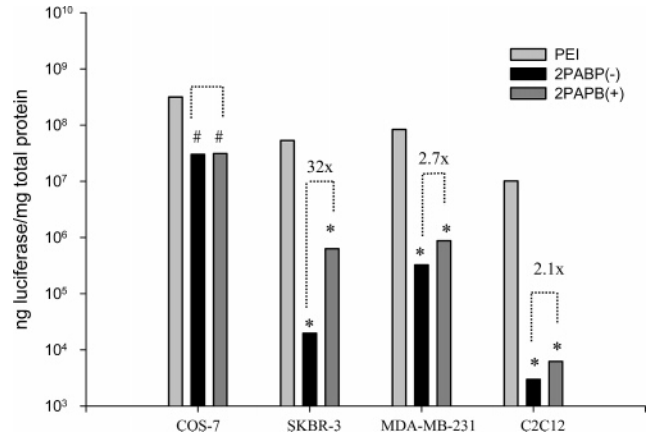

Figure 5. Comparison of luciferase expression in four cell lines transfected with 2PABP(−) and 2PABP(+). Particles were formed at 2 μg of pGL3/well (N/P = 20). COS-7 cells had the same transfection efficiency, while SKBR-3 had a 32-fold, MDA-MB-231 a 2.7-fold, and C2C12 a 2.1-fold enhancement in luciferase expression; $n = 4$, error bars are minimal: # denotes $p > 0.05$ and ∗ denotes $p < 0.05$ using one-way ANOVA.

more evidence of cell death throughout the area compared with cells that had been transfected with 2PABP(−) particles. Because biotin−PEI8 toxicity is similar to PEI toxicity (Figure 1), these data indicate that we indeed were able to competitively displace 2P−avidin from biotin−PEI8 (2PABP(+)) and that the transfection and toxic properties of PEI were retained by the biotin−PEI8 polymer following release of 2P−avidin. In order to investigate the different levels of polymer uptake in SKBR-3 and COS-7 cells, we fluorescently labeled 2PABP(−) and 2PABP(+) with AlexaFluor 633. Flow cytometry reveals that in SKBR-3 cells, 2PABP(+) polymer is taken up 2-fold more than 2PABP(−). Similar to the transfection data (Figure 5), COS-7 kidney cells did not demonstrate a preference for uptake of either one or the other polymer (Figure 7) with luciferase expression being equivalent ($p > 0.05$).

DISCUSSION

Covalently linked PEG−PEI can minimize particle aggregation and serum protein interactions in the body, resulting in higher localization of particles near the solid tumor via the

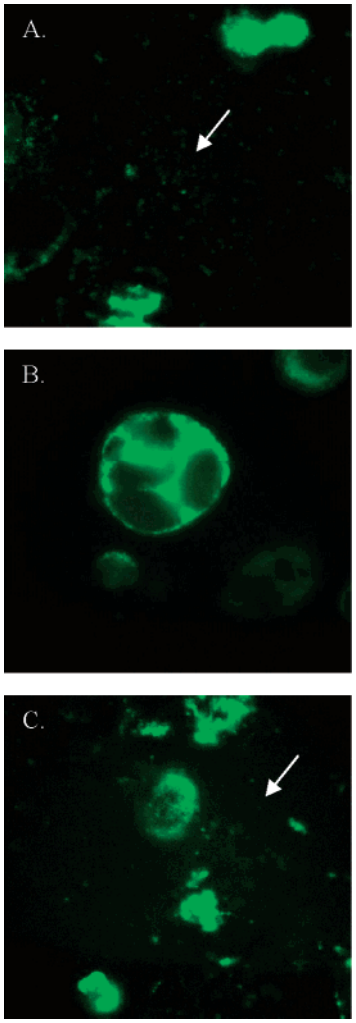

Figure 6. Comparison of GFP cytoplasmic release (toxicity) in SKBR-3 cells (6 μg of pEGFP-N1/well): incubation with PEI (A) and 2PABP(+) polymer (C) reveals shrunken cells and GFP release; incubation with 2PABP(−) (B) shows less toxicity. White arrows point to evidence of GFP presence in the surrounding medium due to toxicity from PEI- and PEG-released cationic biotin−PEI8, 2PABP(+). Images were taken at 63× magnification.

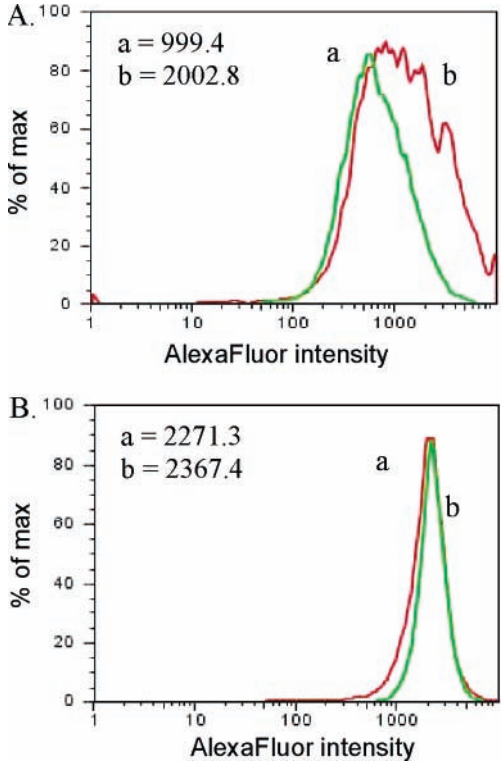

Figure 7. Polymer uptake studies for 2PABP(−) and 2PABP(+) in SKBR-3 and COS-7 cells. Gated AlexaFluor 633 intensity of mean scattering and forward scattering for fluorescently labeled polymers in (A) SKBR-3 and (B) COS-7 cells, where line a is mean intensity for 2PABP(−) and line b is mean intensity for 2PABP(+). SKBR-3 cells take up 2PABP(+) polymer 2-fold better than 2PABP(−), whereas in COS-7 cells the uptake is similar.

enhanced permeability and retention (EPR) effect (*12*). However, lower interactions with blood components can also indicate decreased interactions with cancer cells in the absence of targeting ligands and result in lower gene expression. We propose a new sheddable form of PEGylation for PEI. The model (Scheme 1) is based on the noncovalent interaction between avidin and biotin, which is exploited to temporarily provide stealth properties to cationic PEI particles. Although chicken avidin is a foreign protein, which may induce the generation of an immune response, it has been shown that conjugation of PEG chains can mask immunogenicity and prolong blood circulation (*26*, *27*).

Various groups reported enhancements in transfection efficiency and decreases in toxicity upon modification of PEI (*10*, *28*, *29*). However, conjugation of biotin groups to PEI did not favorably increase polymer hydrophobicity (*28*) or pDNA unpackaging (*4*), and we saw a decrease in transfection with increasing biotin content (Figure 1) and a decrease in the buffering capacity (data not shown). We opted to continue further studies with biotin−PEI18, showing decreased transfection and toxicity, and biotin−PEI8, showing equivalent transfection and toxicity, compared with PEI. With these polymers, we investigated post- and pre-PEGylation strategies for the biotinylated particles. For the post-PEGylation strategy, PEG−avidin (pI = 10.5) was mixed with preformed biotinylated particles, but we saw no evidence of interactions between PEG−avidin and the particles (data not shown). Similar results were obtained using deglycosylated PEG−neutravidin (pI = 6.3) conjugates (data not shown).

Our preferred method of PEGylation (pre-PEGylation) was to incubate PEG−avidin conjugates with biotin−PEI before mixing with pDNA to form PEG−avidin/biotin−PEI particles. As expected, 2P− and 1P−avidin can bind to biotin−PEI8 and biotin−PEI18, leading to salt stability due to PEG presence (Figure 2). This trend was not observed when PEI was incubated with PEG−avidin for 10 min or when biotin−PEI particles were incubated under similar salt conditions (~200 nm, data not shown). The smallest and most stable particles were formed with 2P−avidin and biotin−PEI8. Even though it is not possible to determine the exact number of PEG−avidin per biotin−PEI polymer due to inter- and intra-PEG-avidin/biotin−PEI cross-linkages, we can estimate a minimum average of two 2P−avidins per biotin−PEI8 chain (Table 2). Although typically ζ potentials are used to characterize the distinct surface properties of colloidal particles, in this system 2P−avidin can also condense pDNA to form nanoparticles, which we show can transfect cells but cannot mediate gene expression (see Supporting Information). Therefore, it is difficult to distinguish between surface charge of 2P−avidin/biotin−PEI8 particles and 2P−avidin nanoparticles in solution. Hence to show that PEG is present on the polyplexes, we monitored the change in particle size under salt conditions, a technique previously demonstrated to prove the PEGylation concept (*10*), knowing that biotin−PEI particles aggregate in the absence of PEG−avidin.

The *in vitro* kinetics for complete particle de-PEGylation in PBS took 10 days in the presence of 3000-fold excess biotin.

Such biotin concentrations are unlikely to be reached *in vivo*; however de-PEGylation is not a passive process as in our closed assay system and presence of blood components during circulation may further precipitate de-PEGylation (since avidin/biotin interactions are characterized by on/off associations). In humans, the endogenous level of plasma biotin varies among individuals and values in normal subjects can range from 0.82 to 1.64 nmol/L (*30*) with an estimated 81% of the endogenous biotin being freely available in the blood (unbound to proteins) (*31*). Depending on the release kinetics of de-PEGylation in the blood, additional biotin can be either orally or intravenously administered to temporarily increase plasma concentration of biotin, an advantage since the risk of toxicity in humans to high intake of biotin appears to be low, most likely due to its renal clearance capability (*32*). It is also interesting to note the appearance of two unknown peaks on days 7 and 10 during the incubation with excess biotin (Figure 3), which may correspond to dissociated avidin or PEG−avidin subunits. Green et al. have extensively studied avidin/biotin interactions and dissociations under extreme conditions (*19*, *33*−*35*), and this dissociation may be favorable for enhanced PEG−avidin clearance from the blood.

Due to the complexity of the system, there are obvious limitations *in vitro* for comparing the transfection efficiencies following 2P−avidin release from biotin−PEI8. The release assay had to be done in a vial instead of cultured cells due to the 10 day incubation. Released 2P−avidin could not be purified from biotin−PEI8 without 2P−avidin absence affecting transfection results (since avidin can also interact with pGL3) and relative fluorescent polymer labeling (since AlexaFluor could have been conjugated to either PEI amines or avidin amines). Therefore, to show *in vitro* proof-of-concept, we compared the polymers before and after biotin incubation and compared the effect of 2P−avidin presence and release on gene expression along with polymer uptake. Because 2P−avidin is present in the vial after release, it may interact with pGL3 during particle formulation. However, we have shown that the presence of avidin in solution plays no role in mediating gene delivery in the absence of both PEI and chloroquine (CQ) (Figure 3, Supporting Information). Therefore the expectation for the assay is that the transfection efficiency of 2PABP(+) should be higher than that of 2PABP(−), regardless of transfection magnitude.

We found that the transfection efficiencies were diverse in the cell lines studied but overall followed similar trends (Figure 5). The COS-7 kidney cells expressed the same levels of luciferase for 2PABP(−) and 2PABP(+) particles ($p > 0.05$). These cells are not very sensitive to charge and size, since they have been reported to take up particles as large as 3000 nm (*36*). On the other hand, luciferase expression was 32-fold higher in SKBR-3, 2.7-fold higher in MDA-MB-231, and 2.1-fold higher in C2C12 cells when transfected with just 2 μg of pGL3/well. Currently, there is no clear correlation between polymer charge and extracellular (membrane disruption) toxicity since cationic PEI analogues that are degradable under low pH conditions are less toxic to cells than nondegradable commercial PEI (*2*). Despite the high toxicity of PEI, the greater gene expression of cationic polymers may be explained by greater cell membrane interactions and the ability to use the cell's trafficking machinery to transport pDNA from the cytoplasm to the nucleus (*6*). Our flow cytometry analysis concurs with the transfection data and reveals that in SKBR-3 cells, 2PABP(+) polymer is taken up 2-fold better than 2PABP(−) with a 32-fold increase in gene expression, whereas in COS-7 cells, the uptake was indiscriminate (similar gene expression levels). Although 2PABP(−) uptake and gene expression was lower than its cationic counterpart, the polymer was favorably less toxic to cells (Figure 6) and could still mediate gene expression. Similar studies with covalently grafted PEG−PEI show less toxicity with a high degree of PEG shielding but also less transfection when the level and length of PEG grafting began to impede with pDNA complexation, and PEG−PEI complexes with high positive surface charge and less degree of grafting proved to be the most efficient for *in vitro* gene transfer (*16*). Nevertheless, there is still some contradiction in the literature when it comes to the transfection properties of PEG. Kataoka et al. reported less toxicity and higher transfections with PEGylated complexes (*37*, *38*) compared with their un-PEGylated counterparts, but their results might be cell line dependent and affected by amounts of pDNA used and ultimately polymer properties.

In conclusion, we have shown that the interaction between avidin and biotin can be exploited in gene delivery to noncovalently link PEG to PEI. 2P−avidin/biotin−PEI8 (2PABP(−)) internalization might lower gene expression due to decreased interactions with cell components, but this property may also explain the favorable decrease in intracellular toxicity observed with the polymer. Therefore, it does appear that greater cellular interactions may lead to enhanced gene expression but that polycations less toxic than PEI will probably make the most use of this new noncovalent PEGylation approach in gene delivery applications. This new PEGylation concept via avidin/biotin interactions has potential implications for improving clinical gene delivery via a two-step therapeutic approach: (1) injection of noncovalent PEG−avidin/biotin−polycation nanoparticles for prolonged systemic circulation, followed by (2) endogenous biotin-based competition (or supplemental biotin injection) for PEG−avidin release from nanoparticles to enhance tumor localization and gene expression.

Evaluation of Chemical, Physical, and Biologic Properties of Tumor-Targeting Radioiodinated Quinazolinone Derivative

Ketai Wang, Agop M. Kirichian, Ayman F. Al Aowad, S. James Adelstein, and Amin I. Kassis*

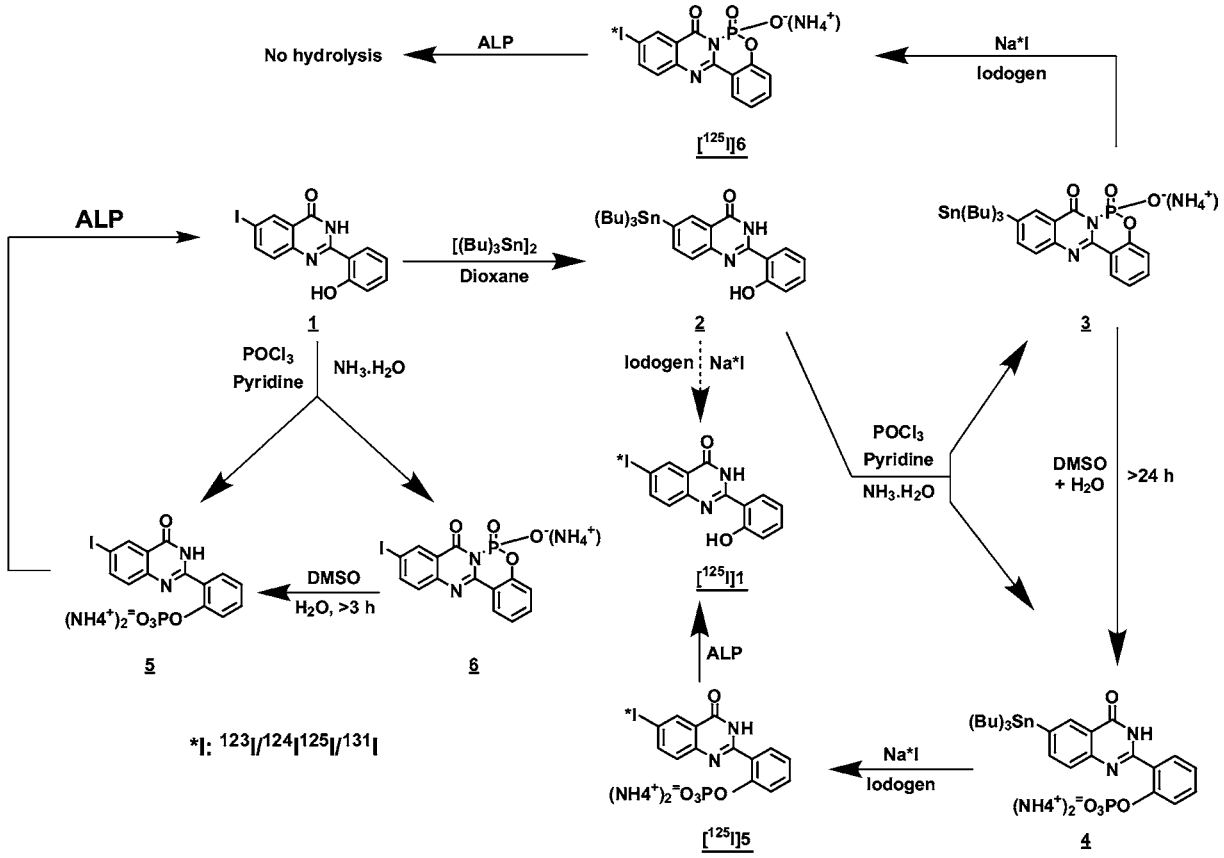
Harvard Medical School, Department of Radiology, 200 Longwood Avenue, Boston, Massachusetts 02115. Received September 18, 2006; Revised Manuscript Received November 28, 2006

Our group is developing a novel technology, enzyme-mediated cancer imaging and therapy (EMCIT), that aims to entrap radioiodinated compounds within solid tumors for noninvasive tumor detection and therapy. In this approach, a water-soluble, radioiodinated prodrug is hydrolyzed in vivo to a highly water-insoluble compound by an enzyme overexpressed extracellularly by tumor cells. We have synthesized and characterized the water-soluble prodrug, 2-(2′-phosphoryloxyphenyl)-6-[^{125}I]iodo-4-(3*H*)-quinazolinone **[^{125}I]5**, which is readily hydrolyzed by alkaline phosphatase, an enzyme expressed by many tumor cell lines, to a water-insoluble drug, 2-(2′-hydroxyphenyl)-6-[^{125}I]iodo-4-(3*H*)-quinazolinone **[^{125}I]1**. In the course of our study, we discovered that ammonium 2-(2′-phosphoryloxyphenyl)-6-tributylstannyl-4-(3*H*)-quinazolinone, an intermediate in the radioiodination of the prodrug, exists as two isomers (**3** and **4**) whose radioiodination leads, respectively, to **[^{125}I]6** and **[^{125}I]5**. These prodrugs have different in vitro and in vivo biologic activities. Compound **6** is not hydrolyzed by alkaline phosphatase (ALP), whereas **5** is highly soluble (mg/mL) in aqueous solution and is rapidly dephosphorylated in the presence of ALP to **1**, a water-insoluble molecule (ng/mL). Mouse biodistribution studies indicate that **[^{125}I]6** has high uptake in kidney and liver and **[^{125}I]5** has very low uptake in all normal organs. Compounds **3** and **6** are converted, respectively, to **4** and **5** after incubation in DMSO. The stability of **5** in human serum is high. The minimum ALP concentration needed to hydrolyze **5** is much greater than the ALP level in the blood of patients with cancer, and the latter should not affect the pharmacokinetics of the compound. Incubation of **5** with viable human and mouse tumor-cell lines—but not with normal human cells and mouse tissues—leads to its hydrolysis and the formation of large crystals of **1**. We expect that **5** will also be hydrolyzed in vivo by tumor cells that express phosphatase activity extracellularly and anticipate the specific precipitation of radioiodinated **1** within tumor cell clusters. This should lead to high tumor-to-normal-tissue ratios and enable imaging (SPECT/PET) and radionuclide therapy of solid tumors.

INTRODUCTION

We are developing a novel strategy called enzyme-mediated cancer imaging and therapy (EMCIT), which is a method for enzyme-dependent, site-specific, in vivo precipitation of a water-soluble radioactive molecule (prodrug) within the extracellular space of solid tumors (*1*). The radiolabeled prodrug is hydrolyzed to its water-insoluble form by a hydrolase overexpressed on the extracellular surface of tumor cells, and the resulting water-insoluble drug is expected to be trapped within the extracellular spaces of the targeted solid tumor. Following tumor targeting and clearance from normal tissues and organs, the entrapped radioactive compound should lead to high tumor-to-normal-tissue ratios and enable the imaging (SPECT/PET) and radiotherapy of solid tumors.

Alkaline phosphatase (ALP) was investigated to ascertain the validity of the proposed approach, since this hydrolase (i) is known to be minimally expressed on the plasma membrane of normal cells and overexpressed on the membrane of many human tumor cells (*2*−*9*), (ii) is post-translationally modified with two *N*-glycosylation sites and a glycosylphosphatidylinositol (GPI) anchor by which it is tethered to the cell membrane, (iii) has a reasonably high second-order rate constant ($k_{cat}/K_m = 5 \times 10^7\ M^{-1}\ s^{-1}$), and (iv) has already been used to hydrolyze several chemotherapeutic prodrugs in vitro and in tumor-bearing animals in vivo (*10*−*14*). Additionally, (i) a high-resolution structure of the human placental isoform (PLAP) has been determined at 1.8 Å resolution and is available from the Protein Data Bank (code 1EW2) for analysis (*15*), and (ii) ALP-expressing tumors in cancer patients and tumor-bearing mice have been successfully imaged with radiolabeled antiALP antibodies (*16*−*20*). Consequently, we have been carrying out in silico molecular modeling to systematically investigate the structure−activity relationships of phosphorylated quinazolinone derivatives with PLAP.



In 2002, we reported the synthesis and characterization of ammonium 2-(2′-phosphoryloxyphenyl)-6-iodo-4-(3*H*)-quinazolinone (**5**) and 2-(2′-hydroxyphenyl)-6-iodo-4-(3*H*)-quinazolinone (**1**) (*1*). In these studies, we demonstrated that nonfluorescent and water-soluble **5** is hydrolyzed by alkaline phosphatase to water-insoluble and highly fluorescent **1**. We also synthesized ammonium 2-(2′-phosphoryloxyphenyl)-6-tributylstannyl-4-(3*H*)-quinazolinone (**4**) (Scheme 1), a precursor for the synthesis of **5**, and found that the intravenous injection of **[^{125}I]5** in normal mice leads to high activity (∼5%−7% ID/g) in normal liver and kidneys (*1*).

Having observed that the pharmacokinetics of **[^{125}I]5** in mice are very different when the prodrug is radioiodinated using **4** that has been dissolved in DMSO, we have been reevaluating the findings and interpretation of some of our earlier studies. It has become evident that the tin precursor of **5** is a mixture of two compounds—**3** (MW 590) and **4** (MW 608)—whose radioiodination results in the formation of a mixture of **[^{125}I]6** (MW 426) and **[^{125}I]5** (MW 444). We describe herein the

Scheme 1. Pathway for Synthesis of Tributyltin and $^{125}I/^{127}I$ Quinazolinone Derivatives

syntheses of the derivatives and their chemical and biologic characterization.

EXPERIMENTAL PROCEDURES

General Remarks. Alkaline phosphatase (bovine intestinal mucosa, calf intestinal mucosa, human placental type XXIV, porcine kidney) and all other chemicals were obtained from Sigma-Aldrich Incorporated. Carrier-free sodium [^{125}I]iodide was purchased from Amersham Corporation. HPLC separations (Waters) were performed on a reversed-phase Zorbax SB-C_{18} column, 9.4 × 250 mm (Agilent Technology), with UV absorption (Waters 486 detector) and γ-ray detection (gamma-ram, IN/US Systems) used to analyze the eluates.

Syntheses (Scheme 1) and Chemical and Biophysical Characterization. *Ammonium 2-(2′-Phosphoryloxyphenyl)-6-tributylstannyl-4-(3H)-quinazolinone (**3** and **4**).* 2-(2′-Hydroxyphenyl)-6-iodo-4-(3*H*)-quinazolinone (**1**) and 2-(2′-hydroxyphenyl)-6-tributylstannyl-4-(3*H*)-quinazolinone (**2**) were synthesized as previously reported (*1*). To phosphorylate the tin derivative, phosphorus oxychloride (5 μL, 53.6 μmol) in dry pyridine (0.5 mL) was added dropwise to a stirred solution of **2** (25 mg, 47.5 μmol) in dry pyridine (0.4 mL) cooled to 0 °C. The solution turned yellow. The reaction mixture was stirred for 1 h at 0 °C and then was neutralized by adding ammonium hydroxide (0.5 mL diluted from 15 μL 28% ammonium hydroxide solution). The solvent was evaporated under reduced pressure (rotary evaporator), and a light-yellow solid was produced. HPLC and ^{31}P NMR showed two peaks, **3** and **4** (Figure 1A,C). When a mixture of **3** and **4** (0.5 mg) was dissolved in DMSO (100 μL) and left overnight, a solution containing only **4** was obtained (Figure 1B,D). ESI-HRMS: calcd for **3** $[M - H]^-$ 589.1296, found 589.1296; calcd for **4** $[M + H]^+$ 609.1540, found 609.1539. ^{31}P NMR for **3** and **4**: −16.922 ppm and −2.958 ppm, respectively.

Ammonium 2-(2′-Phosphoryloxyphenyl)-6-[^{125}I]iodo-4-(3H)-quinazolinone ([^{125}I]5 and [^{125}I]6). Ammonium 2-(2′-phosphoryloxyphenyl)-6-tributylstannyl-4-(3*H*)-quinazolinone (mixture of **3** and **4**, 0.5 mg) was dissolved in DMSO (100 μL) for 1 min, 3 h, or overnight; and 1 μL (5 μg/μL DMSO solution) was added to a reaction vial coated with 1,3,4,6-tetrachloro-3α,6α-diphenylglycouril (Iodogen, 10 μg), along with phosphate buffer (12 μL, 0.1 M, pH 7.4) and the desired quantity of Na^{125}I (0.2−2.0 mCi, 400 μCi/μL). After vortex mixing at ambient temperature for 5 min, the solution was analyzed by HPLC (linear gradient from 10% disodium hydrogen phosphate, 0.05 M, pH 2.5, to 100% methanol for 6 min; flow rate of 3 mL/min) for the presence of **[^{125}I]5** and **[^{125}I]6**.

2-(2′-Hydroxyphenyl)-6-[^{125}I]iodo-4-(3H)-quinazolinone ([^{125}I]1). Compound **[^{125}I]5** (5 μL, 200 μCi) was incubated with ALP (10 U/2 μL) at 37 °C for 5 min. The product **[^{125}I]1** was identified by HPLC against a 2-(2′-hydroxyphenyl)-6-[^{125}I]iodo-4-(3*H*)-quinazolinone standard. In addition, **2**, incubated for 5 min in DMSO, was radioiodinated using Iodogen and Na^{125}I as described above, and the solution was analyzed by C_{18} HPLC.

*Ammonium 2-(2′-Phosphoryloxyphenyl)-6-iodo-4-(3H)-quinazolinone (**5** and **6**).* Compound **1** (25 mg, 47.4 μmol) was added to dried pyridine (0.5 mL) at 0 °C, followed by phosphorus oxychloride (5 μL, 53 μmol) dissolved in dried pyridine (0.5 mL) under argon gas. The reaction was complete within 1 h, as indicated by silica gel TLC. The solution was cleared and neutralized to pH 7 by adding ammonium hydroxide (0.5 mL diluted from 15 μL 28% ammonium hydroxide solution). At the end of neutralization, the solution turned light yellow. The solvent was evaporated, and a mixture of yellow solids including **5** and **6** was obtained. After an overnight incubation of the mixture in DMSO, **6** was converted to **5**, as indicated by HPLC and ^{31}P NMR with one peak present at −2.897. ESI-HRMS: calcd for **5** $[M + H]^+$ 444.9451, found

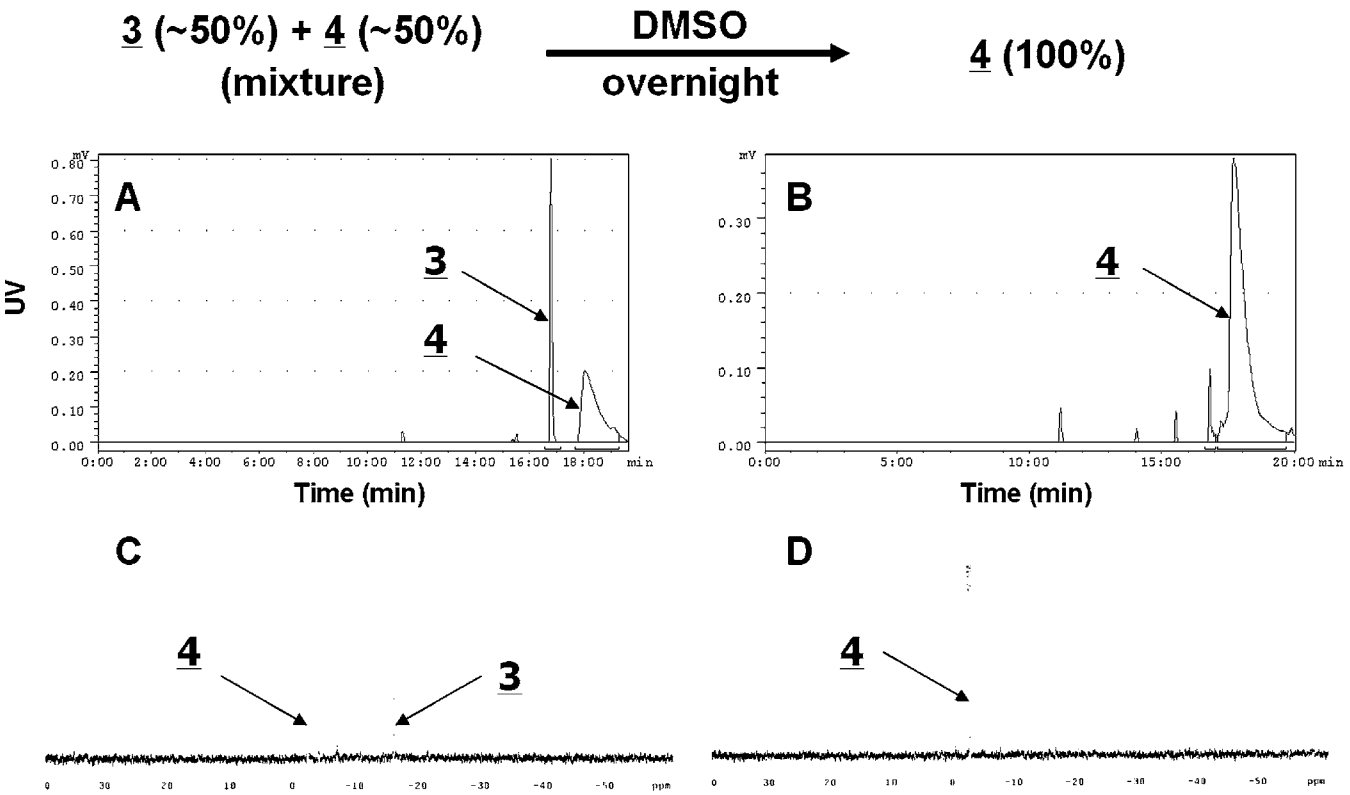

Figure 1. HPLC (A and B) and ^{31}P NMR (C and D) of stannylated intermediates **3** and **4**, demonstrating conversion of **3** to **4** upon incubation in DMSO.

444.9443; calcd for **6** $[M - H]^-$ 424.9175, found 424.9188. ^{31}P NMR for **5** and **6**: −2.897 ppm and −16.568 ppm, respectively.

*Water Solubility of 2-(2′-Hydroxyphenyl)-6-[^{125}I]iodo-4-(3H)-quinazolinone ([**^{125}I**]**1**) and 2-(2′-Phosphoryloxyphenyl)-6-[^{125}I]-iodo-4-(3H)-quinazolinone ([**^{125}I**]**5**).* Since **1** is highly water-insoluble, a novel radiotracer method was developed to determine its solubility (*21*). In this approach, various volumes of a saturated solution of ^{127}I-labeled **1**, spiked with ^{125}I-labeled **1**, in DMSO are placed in centrifuge tubes, and sufficient deionized water is added to make the final volumes equivalent. After vortex mixing, the tubes are centrifuged. Since (i) the ^{127}I- and ^{125}I-labeled compounds have the same solubilities and are, therefore, equally distributed in the DMSO−water solution, and (ii) the amount of nonradioactive compound (added in the DMSO solution) is known, the concentration of the compound in solution can be calculated and plotted as a function of the DMSO-to-water ratio. The water solubility of the compound is then determined by extrapolation of the linear fit of the data points to zero DMSO, i.e., the *y*-axis intercept when $x = 0$ (*Origin 7.0*, OriginLab Corporation, Northampton, MA). The water solubility of prodrug **5** was assessed by the conventional UV spectrophotometry method.

*Kinetics of 2-(2′-Phosphoryloxyphenyl)-6-[^{125}I]iodo-4-(3H)-quinazolinone ([**^{125}I**]**5**) Hydrolysis by Alkaline Phosphatase.* Compound **5** (4 μg) was incubated with bovine ALP (10 U/mL) at 37 °C for 8 min. The kinetics of hydrolysis of nonfluorescent, water-soluble **5** to fluorescent, water-insoluble **1** were followed with a luminescence spectrometer (Perkin-Elmer S50B, excitation at 340 nm, emission at 504 nm). To assess the kinetics of the hydrolysis, the Michaelis−Menten constant of the enzyme (K_m) and the maximum velocity of the reaction (V_{max}) were determined by a Lineweaver-Burke straight-line plot with a slope equal to K_m/V_{max}, where the *y*-intercept of the line is $1/V_{max}$ and the *x*-intercept is $-1/K_m$.

To determine the minimum concentration of ALP required to hydrolyze **[^{125}I]5** to **[^{125}I]1**, **[^{125}I]5** was incubated with various concentrations of human, bovine, porcine, and calf ALP (between 0.0001 and 1 U/μL PBS) for 5 min, and the formation of **[^{125}I]1** was assessed by HPLC. After integrating the peak area of **[^{125}I]1**, the percentage conversions of **[^{125}I]5** to **[^{125}I]1** were determined. The mean (±sem) values of **[^{125}I]1** (at the same ALP concentration for all four phosphatases) were calculated and plotted versus each ALP concentration. A fit of the data points furnished a sigmoidal line from which the IC_{50} value as well as the minimum concentration of ALP needed for hydrolysis was calculated.

Compound **[^{125}I]5** (2 μL, 0.1 mCi/μL) was also incubated at 37 °C with various human ALP concentrations (0.000 01, 0.0001, 0.001, 0.01, and 0.1 U/μL PBS) for 5 min, 1 h, 12 h, 24 h, and 48 h. At each of these incubation times, the concentration of ALP needed to convert 50% **[^{125}I]5** to **[^{125}I]1** was determined (IC_{50}) and plotted against time.

*Stability of Radiolabeled Prodrug ([**^{125}I**]**5**) in Serum.* Compound **[^{125}I]5** (2 μL, 0.2 mCi/μL) was incubated at 37 °C with human and other animal sera (18 μL) for 48 h. The percentage of **[^{125}I]5** remaining in the serum solution was measured at multiple times by HPLC, and the breakdown products of the prodrug were analyzed by HPLC. Alkaline phosphatase (10 U/20 μL) was also added to human serum−**[^{125}I]5** mixtures, and the ability of the hydrolase to dephosphorylate the quinazolinone was determined 5 min later.

Biologic Studies. *Mammalian-Cell-Mediated Hydrolysis of 2-(2′-Phosphoryloxyphenyl)-6-[^{125}I/^{127}I]iodo-4-(3H)-quinazolinone ([**^{125}I**]**5**/5) to 2-(2′-Hydroxyphenyl)-6-[^{125}I/^{127}I]iodo-4-(3H)-quinazolinone ([**^{125}I**]**1**/1).* The cell-mediated hydrolysis of the nonfluorescent, water-soluble prodrug (**5**) to the fluorescent, water-insoluble drug (**1**) was assessed in the presence of human and mouse tumor cells, including human breast cell lines (BT-474 and MCF7), human ovarian carcinoma (SKOV-3, OVCAR-

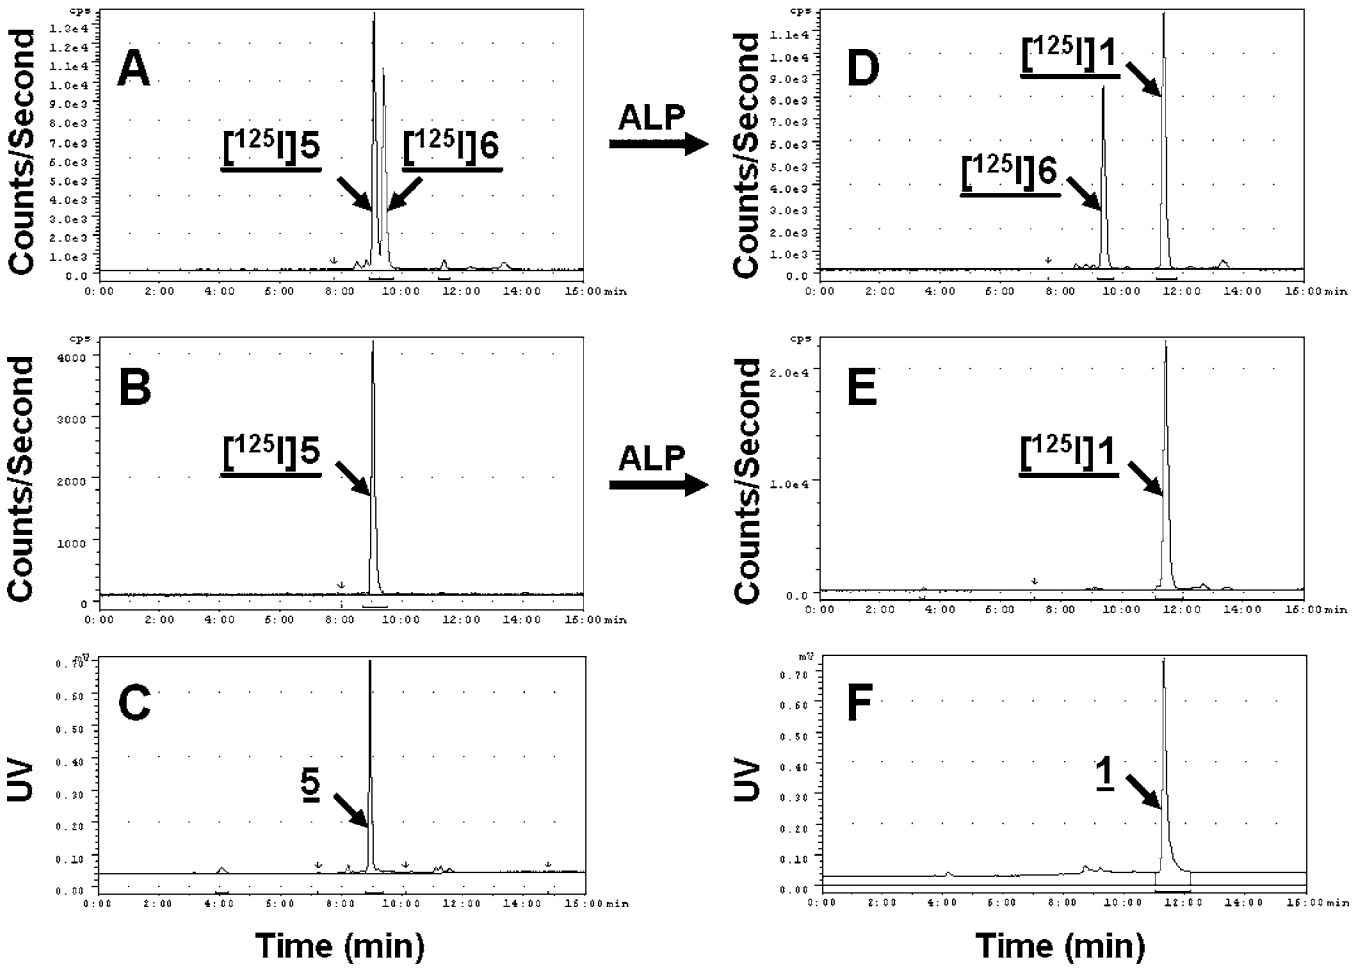

Figure 2. HPLC profiles of **[^{125}I]1**, **1**, **[^{125}I]5**, **5**, and **[^{125}I]6**, demonstrating (i) time-dependent conversion of **3** to **4** upon preincubation of mixture in DMSO for <1 min (A) and 24 h (B); (ii) selective hydrolysis of **[^{125}I]5** to **[^{125}I]1** following 5 min incubation in ALP (A and D) (note absence of hydrolysis of **[^{125}I]6**); and (iii) hydrolysis of **[^{125}I]5** to **[^{125}I]1** following 5 min incubation in ALP (B and E). HPLC profiles of authentic **5** (C) and **1** (F).

3), human small-cell lung carcinoma (HTB-173), mouse Lewis lung carcinoma (LLC1), and human mammary endothelial cells (HMEC), and mouse kidney, liver, and spleen tissues. For cultured cells, logarithmically growing cells were trypsinized and suspended in medium, and 5×10^4 cells (in 0.2 mL DMEM, pH 7.4) were seeded onto slides (Lab-Tek II Chamber Slide, Nalge Nunc International Company) and allowed to adhere by an overnight incubation at 37 °C. They were then washed with medium, and **5** (1 mg/mL medium, pH 7.4) was added. The slides were incubated an additional 24 h, washed with PBS, and fixed in ice-cold ethanol, and the cell nuclei were stained with DAPI. The slides were observed under a light/fluorescence microscope. Similarly, normal mouse tissues (liver, kidney, and spleen) were dissected and incubated for 24 h in **5** (1 mg/mL medium, pH 7.4), washed in PBS, and cut into ~1 mm^3 fragments that were then pressed between two glass slides and observed under the fluorescence microscope.

To ascertain that the cell-mediated hydrolysis occurs through ALP, OVCAR-3 cells were incubated with **5** (24 h, 37 °C, pH 7.4) in the presence or absence of levamisole (10 mM), a specific inhibitor of alkaline phosphatase (*22*, *23*). The cells were then observed and photographed under a fluorescence microscope (before and after being washed with PBS).

Logarithmically growing viable human squamous-cell lung carcinoma cells (HTB-182) were also seeded onto Lab-Tek chamber slides. After an overnight incubation at 37 °C, the medium was removed, **[^{125}I]5** (~20 μCi, 0.2 mL DMEM, pH 7.4) was added, and the cells were reincubated for 24 h. The slides were then washed in PBS (0.01 M, pH 7.4), and the cells were fixed in ice-cold ethanol (−20 °C) for 10 min. After the slides were dried, they were dipped vertically into Kodak NTB-2 emulsion, melted at 45 °C, withdrawn, and left to drain and gel. They were stored at 4 °C in a black box containing Drierite (anhydrous $CaSO_4$). After exposure (3 days to 1 week), the emulsion-coated slides were dipped at room temperature in Kodak developer D-19 for 5 min, washed in distilled water, immersed in Kodak Fixer for 5 min, and rinsed again in distilled water. Finally, the nuclei were stained with Vecta-Shield Mounting Medium with DAPI (Vector Laboratories), and the slides were viewed under a light (ARG grains)/fluorescence (DAPI-stained nuclei) microscope.

*Ex Vivo Conversion of 2-(2′-Phosphoryloxyphenyl)-6-iodo-4-(3H)-quinazolinone (**5**) to 2-(2′-Hydroxyphenyl)-6-iodo-4-(3H)-quinazolinone (**1**) by Solid Tumors Grown in Vivo.* The ability of tumor cells grown as solid tumors in vivo to hydrolyze **5** to **1** in vitro was examined. Balb/c nude female mice were injected intraperitoneally (i.p.) with 2×10^6 SKOV-3 cells. When the tumors became palpable, the animals were killed and the tumors were dissected and incubated with **5** (1 mg/mL) for 3 h. The tumors were then washed, pressed between two glass slides, and observed under the light/fluorescence microscope. Similarly, C57BL/6 mice were injected i.p. with 2×10^6 mouse metastatic B16F10 melanoma cells and were killed when the abdomen became distended. The tumor-laden spleens were dissected and incubated with **5** for 3 h before being washed and observed under the fluorescence microscope.

*Biodistribution of 2-(2′-Phosphoryloxyphenyl)-6-[^{125}I]iodo-4-(3H)-quinazolinone (**[^{125}I]5**) and **[^{125}I]6** in Mice.* C57BL/6

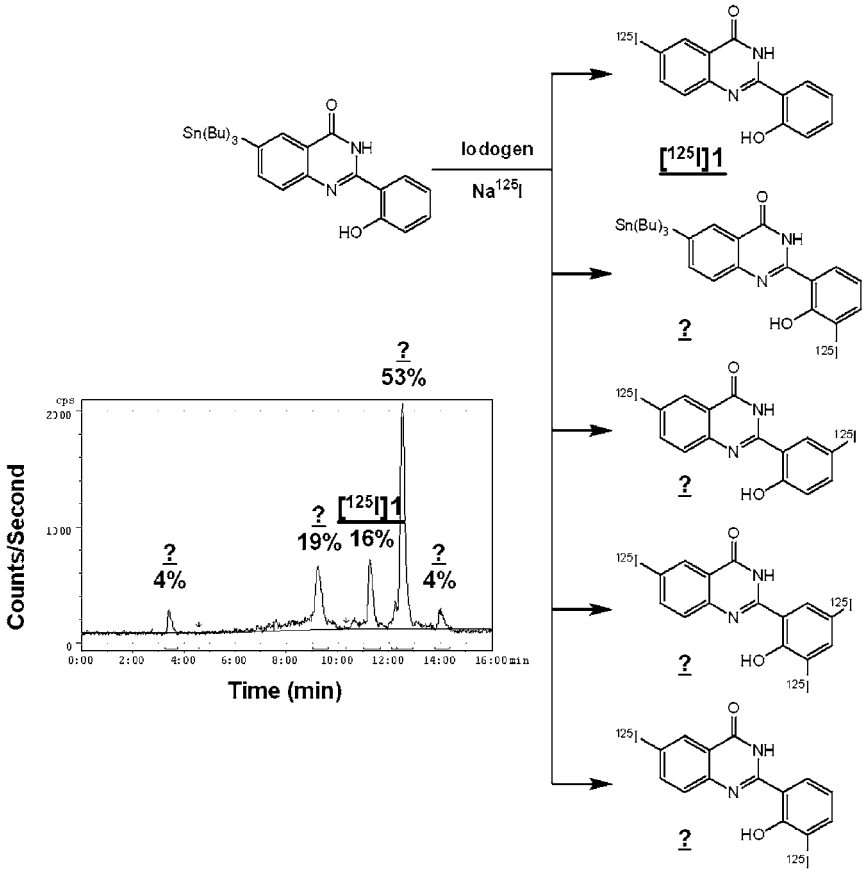

Figure 3. HPLC profile after radioiodination of **2**, demonstrating multiproduct formation including **[^{125}I]1** in low yield. Other possible derivatives (?) are shown.

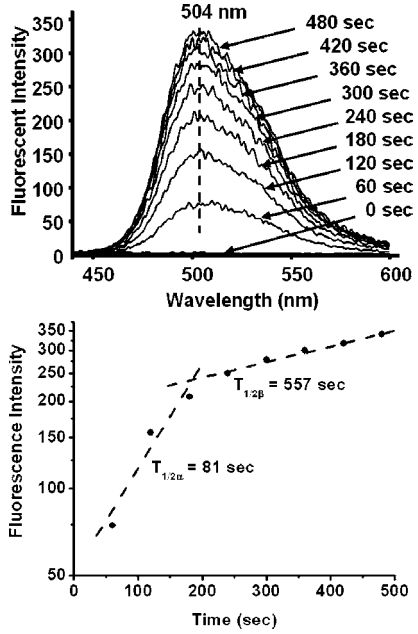

Figure 4. Kinetics of ALP-mediated hydrolysis of **5** to **1** at 37 °C (excitation at 340 nm, emission at 504 nm). Top: change in UV fluorescence spectra of **1** after incubation of **5** (4 μg) with ALP (10 U/mL water) as function of time. Bottom: change in fluorescence intensity of **1** at 504 nm as function of time.

mice ($n = 5$) were injected i.v. with **[^{125}I]5** or a mixture of **[^{125}I]5** and **[^{125}I]6** (5−10 μCi/0.1 mL) synthesized either following a 24 h incubation in DMSO or in the absence of DMSO. The animals were killed 1 and 24 h later, and radioactivity present in various tissues was assayed in a γ counter. On the basis of the injected activity and the weight of these organs, the percentage injected dose per gram (% ID/g) was calculated. Blood clearance was also followed over a 24 h period by counting 10 μL aliquots of blood, obtained from five mice each injected intravenously with **[^{125}I]5** (100 μCi /0.1 mL), in a γ counter. Whole-body clearance was also determined in these mice using a Capintec counter.

RESULTS

Syntheses (Scheme 1) and Chemical and Biophysical Characterization. *Syntheses and Radioiodination.* The key precursor for synthesizing radioiodinated prodrug **5** is ammonium 2-(2′-phosphoryloxyphenyl)-6-tributylstannyl-4-(3*H*)-quinazolinone (**4**) (*1*). In the current studies, we show that this stannylated derivative exists as two isomers, **3** and **4** (Scheme 1, Figure 1), that are readily radioiodinated to **6** and **5**, respectively. The data also demonstrate that, in the presence of DMSO, **3** is converted to **4** over time, and this process can be followed with HPLC and ^{31}P NMR (Figure 1). Consequently, when the tin precursor mixture of **3** and **4** is kept in DMSO for less than 1 min before radioiodination, the HPLC profile shows two peaks that correspond to **6** (∼44%) and **5** (∼55%) (Figure 2A) even though the radioiodination yield of both compounds is >99%. After the mixture of **3** and **4** is incubated at room temperature in DMSO overnight and then radioiodinated, the radiolabeled yield is ∼100% **5** (Figure 2B). Similarly, the incubation of a mixture of **6** and **5** in DMSO for 1 h also results in the complete conversion of **6** to **5**. Why the conversion of **6** to **5** occurs faster (within 2 h) than that of **3** to **4** (within 24 h) is unclear.

Unlike the quantitative yield that occurs when **4** is radioiodinated (Figure 2B), the treatment of **2** with Iodogen and Na^{125}I leads to the formation of a complex mixture of radioiodinated products that includes **[^{125}I]1** (∼16% yield) and several yet-to-

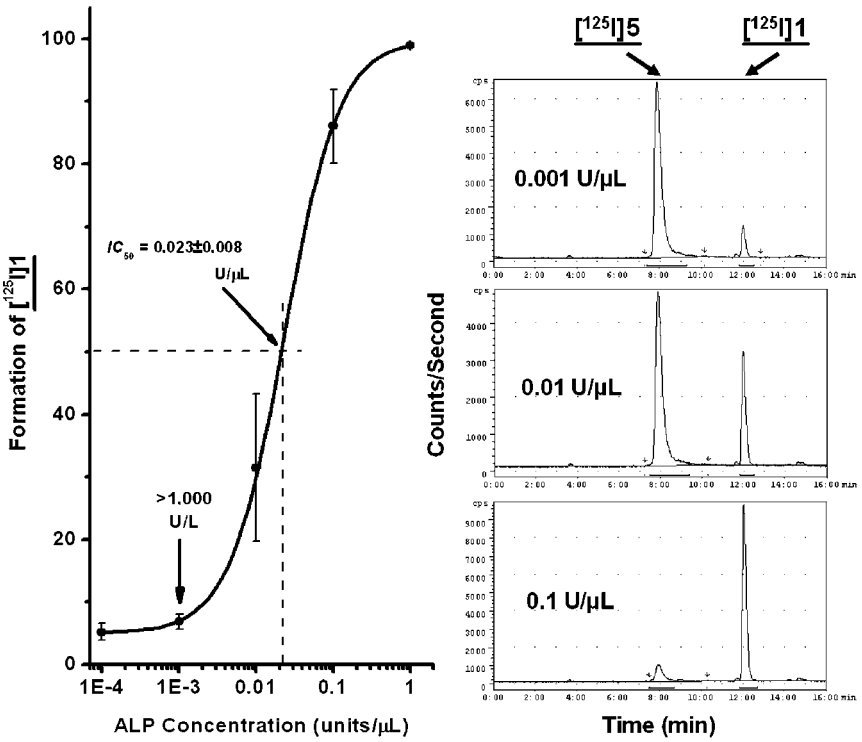

Figure 5. Kinetics of hydrolysis (HPLC quantitative analysis) of **[125I]5** to **[125I]1** determined after 5 min incubation in various concentrations of human, bovine, porcine, and calf ALP (PBS, pH 7.4), demonstrating that >1000 U/L is necessary to initiate hydrolysis. Sample HPLC profiles (with human ALP) are shown on right.

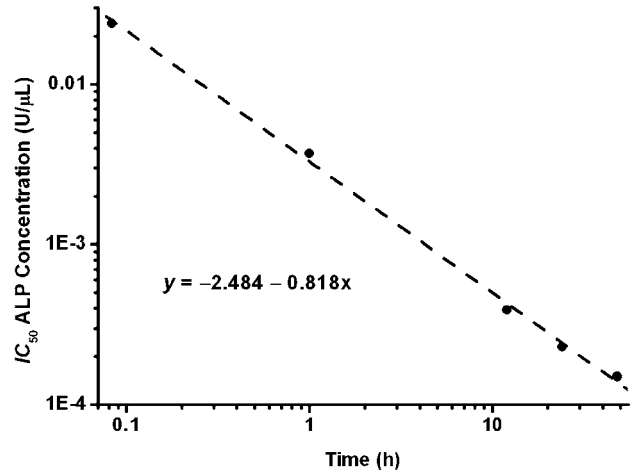

Figure 6. IC_{50} of ALP (bovine intestinal mucosa)-mediated hydrolysis of **[125I]5** as function of time (0.1 M PBS, 37 °C, pH 7.4).

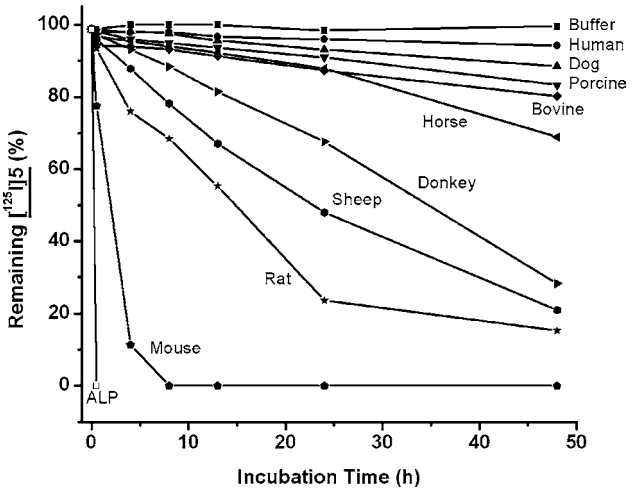

Figure 7. Stability of **[125I]5** in various types of mammalian serum (at 37 °C). $T_{1/2\alpha}$ in mouse serum = 2.0 h; $T_{1/2\alpha}$ in rat serum = 15.6 h; $T_{1/2\alpha}$ in human serum = several months. Complete hydrolysis of **[125I]-5** is seen upon 5 min incubation in ALP (□).

be identified ^{125}I-labeled products (Figure 3). Our current approach for the synthesis of pure **[125I]1** is via the ALP-mediated dephosphorylation of **[125I]5**.

*Water Solubility of 2-(2′-Hydroxyphenyl)-6-iodo-4-(3H)-quinazolinone (**1**) and 2-(2′-Phosphoryloxyphenyl)-6-iodo-4-(3H)-quinazolinone (**5**).* The solubility of **1**, as measured by the radiotracer method (*21*), is 1.9 ng/mL. The solubility of **5**, determined by spectrophotometry, is 7.8 mg/mL. Therefore, **5** is 4.18×10^6 times more soluble than **1**.

*Kinetics of 2-(2′-Phosphoryloxyphenyl)-6-iodo-4-(3H)-quinazolinone (**5**) Hydrolysis by Alkaline Phosphatase.* The ALP conversion of water-soluble, nonfluorescent prodrug **5** to water-insoluble, fluorescent drug **1** was determined spectroscopically. The fluorescence intensity at 504 nm increases with time (Figure 4). Further analysis of the data indicates that the enzyme-dependent appearance of **1** is biphasic with $T_{1/2\alpha}$ of 81 s and $T_{1/2\beta}$ of 557 s.

HPLC analysis has been utilized to determine the minimum concentration of ALP necessary for the hydrolysis of **[125I]5**. In these studies, **[125I]5** was incubated (room temperature, 5 min) with various concentrations (U/μL) of ALP (human, bovine, porcine, and calf), and the appearance of dephosphorylated **[125I]-1** was quantified. The HPLC peak corresponding to that of substrate **[125I]5** ($t_R \approx 8$ min) disappears as a function of increasing ALP concentration (Figure 5). Simultaneously, a new peak appears at $t_R \approx 12$ min that matches the retention-time value of nonradiolabeled **1**. Complete conversion of **[125I]5** to **[125I]1** occurs when the ALP concentration is $>10^6$ U/L. A plot of formation of **[125I]1** versus ALP concentration furnishes a sigmoidal curve (IC_{50} = 23 000 U/L) indicating that the minimum ALP concentration needed to hydrolyze **[125I]5** is ≥1000 U/L (Figure 5).

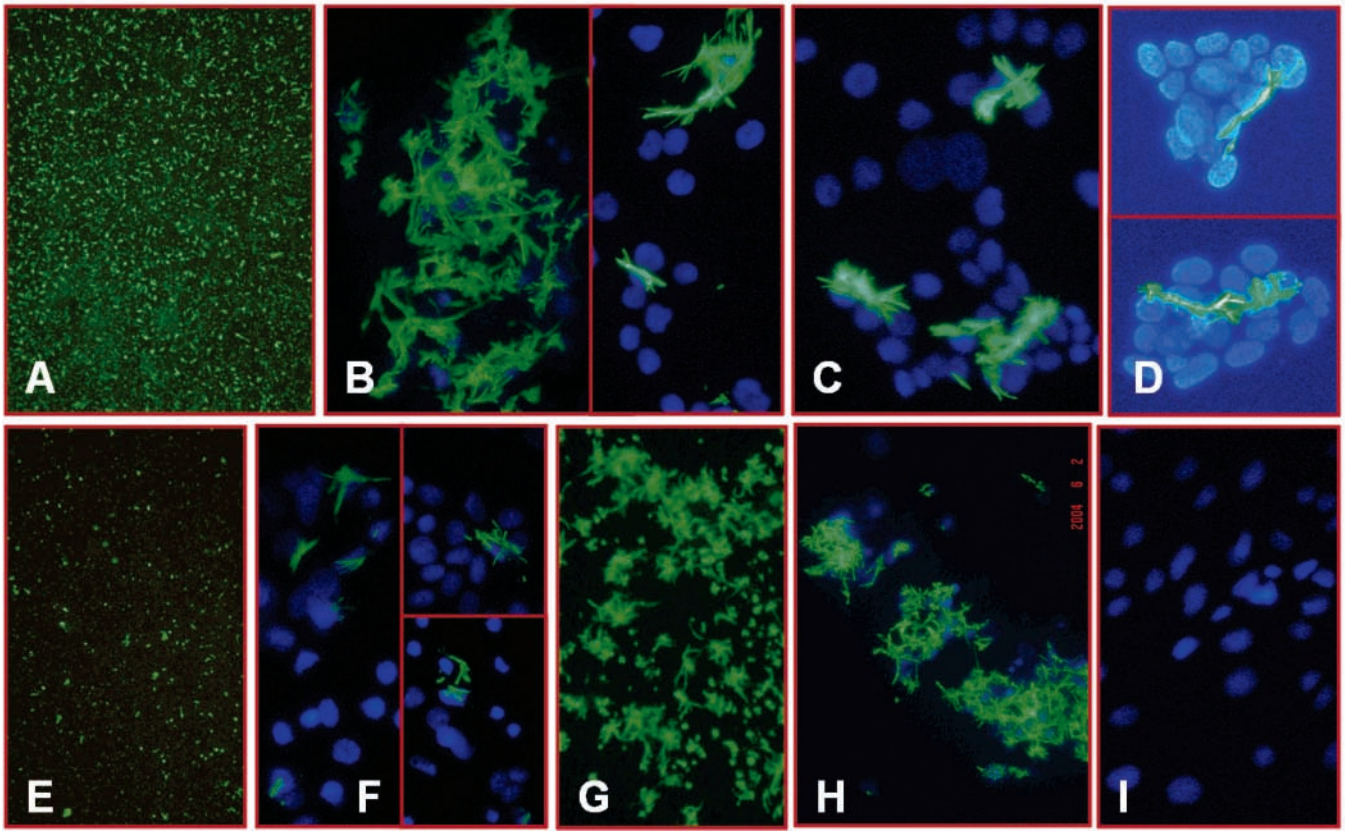

Figure 8. Fluorescence microscopy of viable human (A−G) and mouse (H) tumor cell lines incubated in vitro for 24 h with **5** showing its hydrolysis and crystallization of **1** (green). OVCAR-3 (A,B) and SKOV-3 (C) ovarian carcinoma cells; BT-474 (D) and MCF7 (E,F) breast cancer cells; HTB-173 small-cell lung carcinoma cells (G); and LLC1 Lewis lung carcinoma cells (H). Incubation of **5** with viable normal human mammary epithelial cells (HMEC) does not induce any observable hydrolysis (I). A and E: cells not washed, low power; B−D and F−I: cells washed, and counterstained with DAPI (blue nuclei), high power.

When **[^{125}I]5** is incubated with ALP (≥1 U/μL) for 5 min at room temperature, the compound is rapidly hydrolyzed, and a new peak appears on HPLC whose retention time is identical to that of **[^{125}I]1** (Figure 2B,E). However, when a mixture of **[^{125}I]5** and **[^{125}I]6** is incubated with ALP, only **[^{125}I]5** is converted to **[^{125}I]1** (55% of mixture) (Figure 2A,D).

HPLC has also been used to determine the IC_{50} when the incubation time of **[^{125}I]5** in varying ALP concentrations is changed. When the log IC_{50} is plotted as a function of log time, a linear relationship is obtained (Figure 6).

*Stability of Radiolabeled 2-(2′-Phosphoryloxyphenyl)-6-[^{125}I]-iodo-4-(3H)-quinazolinone (**[^{125}I]5**) in Animal and Human Serum.* Pure **[^{125}I]5** (20 mCi/mL) kept in buffer for a week is still 100% radiochemically unadulterated. However, this compound has very different stabilities in animal and human serum (Figure 7). In mouse serum, its half-life is 2.0 h, whereas in human serum, even after 48 h, 94% of **[^{125}I]5** is unchanged radiochemically. HPLC analysis indicates that the product of decomposition is the same in various types of serum and has the same retention-time peak as **[^{125}I]1**. That the observed stability of **[^{125}I]5** in human serum is not due to the presence of alkaline phosphatase inhibitors is demonstrated by the quantitative and rapid hydrolysis of **[^{125}I]5** to **[^{125}I]-1** upon the addition of alkaline phosphatase to the serum samples.

Biologic Studies. *Mammalian-Cell-Mediated Hydrolysis of 2-(2′-Phosphoryloxyphenyl)-6-iodo-4-(3H)-quinazolinone (**5**) to 2-(2′-Hydroxyphenyl)-6-iodo-4-(3H)-quinazolinone (**1**).* We determined the ability of human ovarian carcinoma cells (OVCAR-3 and SKOV-3), human breast cancer cells (BT-474 and MCF7), human small-cell lung carcinoma cells (HTB-173), and mouse Lewis lung carcinoma (LLC1) to hydrolyze water-soluble **5** to fluorescent, water-insoluble **1**. The in vitro incubation (37 °C, pH 7.4) of all these tumor cell lines with **5** leads to the formation of very large (≤20 μm) fluorescent crystals (Figure 8A−H), many of which are irreversibly bound to the cells (Figure 8B−D and 8F−H). Furthermore, autoradiography of viable human squamous-cell lung carcinoma cells (HTB-182) incubated with **[^{125}I]5** shows the presence of intense grains (Figure 9), consistent with the dephosphorylation of this radioiodinated analog and the formation of water-insoluble **[^{125}I]1**.

To ascertain that the hydrolysis of **5** by tumor cells is ALP-mediated, human tumor cells (OVCAR-3) cells were incubated with the quinazolinone derivative in the presence and absence of levamisole. The presence of this specific inhibitor of alkaline phosphatase (*22*, *23*) completely inhibits **5** dephosphorylation, as exemplified by the absence of any fluorescent crystal formation (Figure 10B). As expected, **1** is formed in the absence of levamisole (Figure 10A).

We also assessed the ability of normal human cells and mouse tissues to hydrolyze **5**. No hydrolysis (no fluorescent **1** crystal formation) is observed when human mammary epithelial cells (HMEC) are incubated with **5** (Figure 8I) or when this derivative is incubated in medium (in the absence of cells). Similar results (minimal fluorescence or its absence) have also been obtained following a 24 h incubation of normal mouse tissues (kidneys, liver, and spleen) with **5** (Figure 11A−C).

Finally, the incubation of mammalian cells up to 48 h with **5** (1 mg/mL) does not lead to any microscopic alterations in their appearance and in their attachment to the incubation flasks.

*Ex Vivo Conversion of 2-(2′-Phosphoryloxyphenyl)-6-iodo-4-(3H)-quinazolinone (**5**) to 2-(2′-Hydroxyphenyl)-6-iodo-4-(3H)-quinazolinone (**1**) by Solid Tumors Grown in Vivo.* Human ovarian SKOV-3 tumors grown in the peritoneal cavity of nude

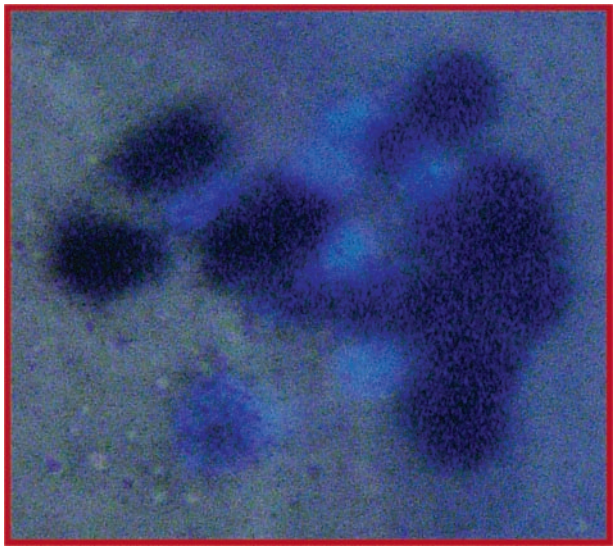

Figure 9. Autoradiography of viable human squamous-cell lung carcinoma cells (HTB-182) after 24 h, in vitro incubation (37 °C, pH 7.4) with **[^{125}I]5**, demonstrating its hydrolysis and formation of intense black grains where **[^{125}I]1** is formed. Cells counterstained with DAPI (blue nuclei).

mice and mouse B16F10 melanoma tumor metastases present within the spleen of mice were dissected and incubated ex vivo with **5**. Under both circumstances, fluorescence microscopy indicates the presence of fluorescent crystals (**1**) that are associated with the SKOV-3 solid tumors (Figure 11D) and within the B16F10 melanoma-infiltrated spleens (Figure 11E).

Biodistribution of 2-(2′-Phosphoryloxyphenyl)-6-iodo-4-(3H)-quinazolinone [^{125}I]5 and [^{125}I]6 in Mice. Table 1 contains the biodistribution data obtained 1 and 24 h after the i.v. injection of **[^{125}I]5** and **[^{125}I]6** into mice. Compound **[^{125}I]5** has minimal uptake in all normal organs and tissues with less than 0.2% ID/g remaining by 24 h. On the other hand, the i.v. injection of **[^{125}I]6** (mixed with [^{125}I]**5**, ∼50:50) demonstrates substantially higher uptake in the kidneys, liver, lungs, and blood (∼2%−12% ID/g). Since the % ID/g values for **[^{125}I]5** are all very low, the values obtained for the mixture of **[^{125}I]5** and **[^{125}I]6**, in fact, reflect those of **[^{125}I]6**. The blood clearance of **[^{125}I]5** is triphasic with $T_{1/2\alpha}$ of 13 min, $T_{1/2\beta}$ of 1.3 h, and $T_{1/2\gamma}$ of 18.1 h, whereas the whole body clearance has a $T_{1/2}$ of 5.3 h (Figure 12).

DISCUSSION

Ideally, radiolabeled agents for cancer imaging and therapy must (i) be stable in blood following their administration in an animal, (ii) be taken up rapidly by tumors ($T_{1/2}$ in circulation much shorter than physical $T_{1/2}$ of the radionuclide), (iii) be retained for long periods of time within tumors ($T_{1/2}$ in tumor much longer than physical $T_{1/2}$ of the radionuclide), (iv) be concentrated efficiently by tumors (i.e., high % ID/g), (v) be taken up minimally by normal tissue cells, (vi) have a short residence in normal tissues, (vii) achieve high tumor-to-normal-tissue uptake ratios, and (viii) be labeled with an emitter whose decay characteristics are suitable for imaging (SPECT or PET) or therapy. We believe that the EMCIT strategy meets many of these requirements. First, being molecules of low molecular weight (MW <500), the administered phosphorylated quinazolinone derivatives (e.g., **5**/**[^{125}I]5**) have very short residence times within the blood and are rapidly cleared from the circulation and the body (Figure 12). Additionally, **[^{125}I]5** is not taken up or retained by normal tissues (Table 1), i.e., the compound has minimal affinity for normal cells and is not significantly hydrolyzed by them. Second, the high stability of **5** in human serum is very promising (Figure 7). However, the unexpected variable (and lower) stability of such quinazolinone derivatives in the sera from other animal species may, from a practical point

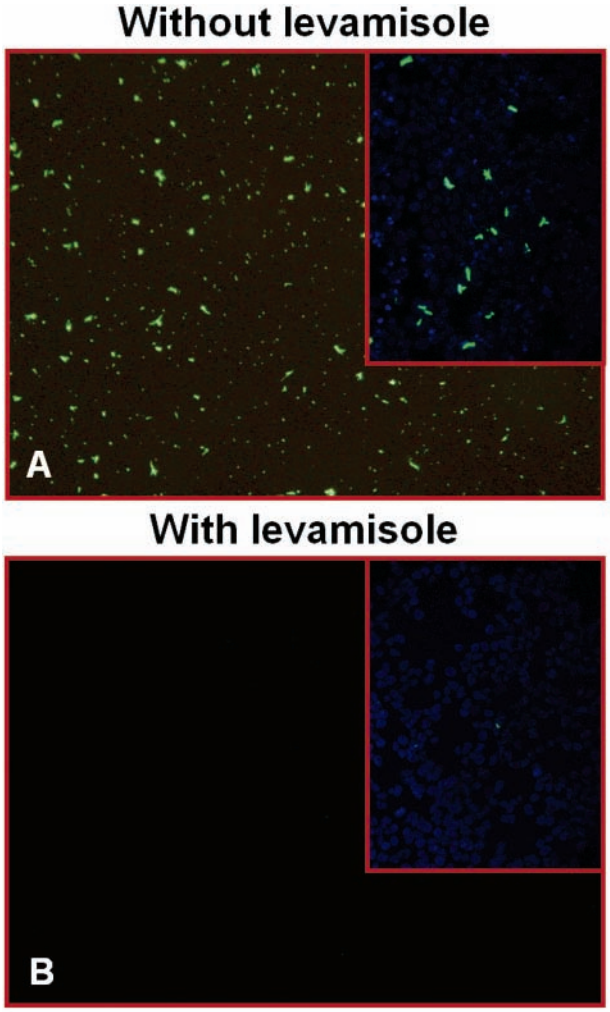

Figure 10. Fluorescence microscopy of human OVCAR-3 ovarian carcinoma cells after 24 h, in vitro incubation (37 °C, pH 7.4) with **5** ±10 mM levamisole, showing absence of hydrolysis and lack of crystallization to **1** (green) in presence of ALP-specific inhibitor levamisole. Inserts: cells washed and counterstained with DAPI, high power.

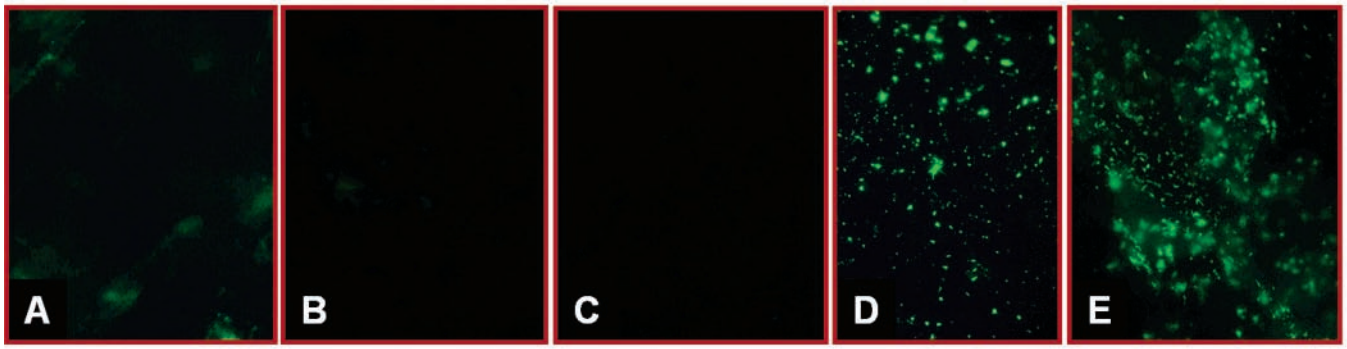

Figure 11. Fluorescence microscopy of (i) three normal mouse tissues (A, kidneys; B, liver; and C, spleen) after 24 h, in vitro incubation with **5**, showing absence of **5** hydrolysis (lack of green crystals); (ii) spleen tissue from mouse injected (i.p.) earlier with B16F10 melanoma cells (D) after 3 h, in vitro incubation with **5** (nonfluorescent), demonstrating its hydrolysis to **1** (fluorescent) by tumor cell metastases present within spleen; (iii) SKOV-3 tumor mass grown i.p. in nude mouse (E) after 20 h, in vitro incubation with **5** (nonfluorescent), demonstrating its hydrolysis to **1** (fluorescent).

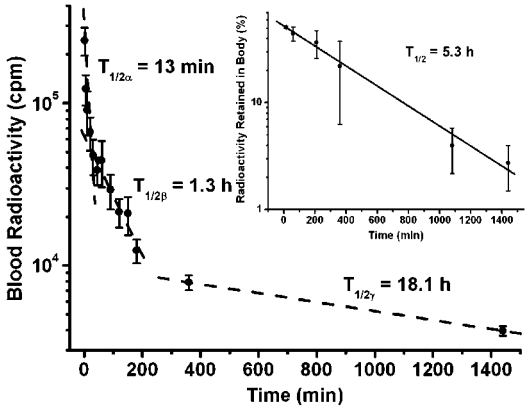

Figure 12. Blood clearance of radioactivity in mice after i.v. injection of **[^{125}I]5**. Insert: whole-body clearance of radioactivity in mice after i.v. injection of **[^{125}I]5**.

of view, create a problem in assessing the full potential of the EMCIT technology in small-animal (e.g., mouse) tumor models. Third, the molecule is an excellent enzyme substrate, hydrolyzed very efficiently and specifically to **1** by those tumor cells overexpressing ALP extracellularly and not by normal cells (Figures 8−11). Fourth, the EMCIT approach provides a repetitive hydrolysis machine, i.e., the enzyme enables the continuous hydrolysis of its water-soluble substrate (e.g., **[^{123}I]-5**, **[^{124}I]5**, **[^{131}I]5**), an event that leads to the formation and concentration of radioimaging (e.g., **[^{123}I]1** or **[^{124}I]1**) or radiotherapeutic (e.g., **[^{131}I]1**) precipitates within targeted tumors and metastases. Moreover, previous experimental in vivo data had shown that (i) the intravenous injection of **[^{125}I]5** into mice preinjected subcutaneously with ALP leads to the efficient uptake of radioactivity (i.e., **[^{125}I]1**) within the ALP-rich regions (*1*), and (ii) once formed, the water-insoluble radiolabeled **[^{125}I]-1** molecules (>6-fold less soluble than **5**) do not transit through the tissues and are therefore indefinitely entrapped (*1*).

Our current results indicate the direct radioiodination of the stannylated quinazolinone derivative **2** produces a mixture of products (Figure 3) and the yield of **[^{125}I]1** among these products is only 16%. This mixture of radioiodinated products may be a consequence of the presence of the hydroxyl group on the benzene ring, an activating group that permits introduction at its neighboring 3-position of a second group by electrophilic substitution. When the hydroxyl group within stannylated **2** is phosphorylated to stannylated prodrugs **3** and **4** and this mixture is left in DMSO for >24 h, all of **3** converts to **4** (Figure 1). Since the reactivity of the various positions on the phosphorylated benzene ring to halogenation is now lost, the radioiodination of **4** leads to the production of a single radioiodinated quinazolinone derivative **5** in greater than 99% yield (Figure 2B). The hydrolase ALP is then used to quantitatively and rapidly (<5 min) dephosphorylate the intermediate **5** to **1** (Figure 2E).

In an earlier publication (*1*), we had reported the synthesis and in vitro and in vivo characterization of what we believed to be pure **[^{125}I]5**. We have since come to realize that the tributyltin quinazolinone precursor used to synthesize the radioiodinated product exists as two isomers, **3** (MW 590) and **4** (MW 608) (Scheme 1 and Figure 1), and that, in the presence of DMSO, **3** is completely converted to **4** over a 24 h period (Figure 1A,B). The ^{31}P NMR spectrum indicates that the conversion process occurs at the phosphorus atoms (Figure 1C,D). This characteristic of the ^{31}P NMR spectrum is observed with similar compounds reported in the literature (*24*). Mass spectrum analysis shows that the molecular weights of 590 for **3** and 608 for **4** have an 18 unit difference—a value that equals a water molecule. This is consistent with the structures of **3** and **4** in Scheme 1. Consequently, the radioiodination of this mixture led to the synthesis of what is now known to be a mixture of **[^{125}I]5** and **[^{125}I]6**, two isomers of the same phosphorylated iodoquinazolinone derivative that differ substantially. Specifically, the retention times of the two derivatives on C_{18} HPLC separation are different (Figure 2A). In addition, while **5** is an excellent substrate for ALP (Figure 2B,E), as well as for prostatic acid phosphatase (*25*), **[^{125}I]6** is not hydrolyzed by either enzyme (Figure 2A,D). In another set of studies (*26*), the structural differences of the two iodoquinazolinone isoforms were examined using in silico molecular modeling techniques and docking methods to model the interaction/binding between the isoforms and ALP. The docking results demonstrate that **5** fits the active binding site of ALP favorably and interacts with the catalytic amino acid Ser92, which plays an important role in the hydrolysis process, whereas **6** does not. Finally, the uptake and retention of the two isomers by various normal tissues following their intravenous injection into mice is different (Table 1). The observations that **[^{125}I]5** are (i) minimally hydrolyzed by normal tissues (Figure 11A−C), (ii) not taken up or retained by any normal tissue (Table 1), (iii) an excellent substrate for ALP (Figure 2B,E), (iv) specifically hydrolyzed by ALP-expressing tumor cells (Figures 8−10 and 11D,E), and (v) not toxic to cells emphasize the suitability of this compound for the EMCIT approach.

Phosphatases, such as ALP, are often elevated in the sera of patients with various cancers and certain other diseases (*27*−*41*). To ascertain that these phosphatases will not lead to significant hydrolysis of the radioiodinated quinazolinone derivatives during the transit/sojourn of the latter through the blood and normal tissues of an animal, i.e., prior to their specific hydrolysis by the ALP-overexpressing tumor cells, HPLC was used to determine the minimum ALP concentration necessary

to initiate the hydrolysis of **5** to **1**. The data show that (i) complete conversion of **5** to **1** occurs when the ALP concentration is $>10^6$ U/L, and (ii) the minimum ALP concentration needed to hydrolyze **[^{125}I]5** is ≥1000 U/L, a value that is 2-fold higher than the 500 U/L found in the blood of cancer patients (*29*, *42*−*48*). Consequently, such radioiodinated quinazolinone analogues are not expected to be hydrolyzed en route following their intravenous injection into cancer patients.

CONCLUSIONS

The prodrug ammonium 2-(2′-phosphoryloxyphenyl)-6-iodo-4-(3*H*)-quinazolinone exists in two forms, **5** (MW 444) and **6** (MW 426). Compound **6** is not hydrolyzed by alkaline phosphatase and has a high uptake in key nontargeted organs; its presence needs to be avoided during preparation of the radiopharmaceutical, and this can be accomplished by leaving the mixture of **3** and **4** in DMSO for at least 24 h. Compound **6** is also readily converted to **5** in the presence of DMSO. Compound **5** is stable in human serum and is completely (>99%) and rapidly (<5 min) hydrolyzed by alkaline phosphatase (1 U/μL). The concentration of ALP present in the sera of patients with cancer and/or other disease is insufficient to hydrolyze **5**. The very low uptake of **[^{125}I]5** in almost all normal organs (<0.2% ID/g) and the efficient hydrolysis by various human and mouse tumor cells indicate that the tumor-to-normal-tissue uptake ratios will be favorable. Compound **5** is highly soluble in water (7.8 mg/mL), and its hydrolysis product **1** is very insoluble in water (1.9 ng/mL), which is advantageous for trapping the precipitated drug within the interstitial spaces of solid tumors. On the basis of these in vitro cell and ex vivo tumor studies, we anticipate that radiolabeled **5** will be hydrolyzed by tumor cells and water-insoluble **1** will be retained indefinitely within solid tumors in vivo. We believe that these quinazolinone-based radiopharmaceuticals will eventually lead to the development of a novel noninvasive approach for imaging (^{123}I—SPECT; ^{124}I—PET) and treating (^{131}I) solid tumors and their metastases.

^{64}Cu-Labeled Alpha-Melanocyte-Stimulating Hormone Analog for MicroPET Imaging of Melanocortin 1 Receptor Expression

Zhen Cheng,*,† Zhengming Xiong,†,‡ Murugesan Subbarayan,† Xiaoyuan Chen,† and Sanjiv Sam Gambhir†

Molecular Imaging Program at Stanford (MIPS), Departments of Radiology and Bioengineering, Bio-X Program, Stanford University, Stanford, California 94305-5344 and Department of Pediatrics, Tongji Medical College, Huazhong University of Science and Technology & Tongji Hospital, Wuhan, China 430030. Received October 3, 2006; Revised Manuscript Received January 3, 2007

The alpha-melanocyte-stimulating hormone (α-MSH) receptor (melanocortin type 1 receptor, or MC1R) plays an important role in the development and growth of melanoma cells. It was found that MC1R was overexpressed on most murine and human melanoma, making it a promising molecular target for melanoma imaging and therapy. Radiolabeled α-MSH peptide and its analogs that can specifically bind with MC1R have been extensively explored for developing novel agents for melanoma detection and radionuclide therapy. The goal of this study was to evaluate a ^{64}Cu-labeled α-MSH analog, Ac-Nle-Asp-His-D-Phe-Arg-Trp-Gly-Lys(DOTA)-NH_2 (DOTA−NAPamide), as a potential molecular probe for microPET imaging of melanoma and MC1R expression in melanoma xenografted mouse models. 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) conjugated NAPamide was synthesized and radiolabeled with ^{64}Cu ($t_{1/2}$=12 h) in NH_4OAc (0.1 M; pH 5.5) buffered solution for 60 min at 50 °C. Cell culture studies reveal rapid and high uptake and internalization of ^{64}Cu−DOTA−NAPamide in B16F10 cells. Over 90% of receptor-bound tracer is internalized at 3 h incubation. A cellular retention study demonstrates that the receptor-bound ^{64}Cu−DOTA−NAPamide is slowly released from the B16F10 cells into the medium; 66% of the radioactivity is still associated with the cells even after 3 h incubation. The biodistribution of ^{64}Cu−DOTA−NAPamide was then investigated in C57BL/6 mice bearing subcutaneous murine B16F10 melanoma tumors with high capacity of MC1R and Fox Chase Scid mice bearing human A375M melanoma with a relatively low number of MC1R receptors. Tumor uptake values of ^{64}Cu−DOTA−NAPamide are found to be 4.63 ± 0.45% and 2.49 ± 0.31% ID/g in B16F10 and A375M xenografted melanoma at 2 h postinjection (pi), respectively. The B16F10 tumor uptake at 2 h pi is further inhibited to 2.29 ± 0.24% ID/g, while A375M tumor uptake at 2 h pi remains 2.20 ± 0.41% ID/g with a coinjection of excess α-MSH peptide. MicroPET imaging of ^{64}Cu−DOTA−NAPamide in B16F10 tumor mice clearly shows good tumor localization. However, low A375M tumor uptake and poor tumor to normal tissue contrast were observed. This study demonstrates that ^{64}Cu−DOTA−NAPamide is a promising molecular probe for α-MSH receptor positive melanoma PET imaging as well as MC1R expression imaging in living mice.

INTRODUCTION

Malignant melanoma has emerged as a significant public health problem in western countries (*1*). Currently, effective therapies are not available for treatment of metastatic melanoma. Extensive efforts have been spent to develop novel strategies for melanoma systemic treatment. For example, immunotherapy, chemotherapy, and biological therapy have been investigated intensively; however, little success has been achieved. The most important approach responsible for the improvement of survival rate of melanoma still remains early diagnosis (*2*).

Recently, peptide receptor-targeted radionuclide therapy (PRRT) has been shown to be an attractive approach for treatment of receptor-expressing tumors in preclinical and clinical settings (*3*, *4*). It was shown that the somatostatin analog, [tetraazacyclododecane-tetraacetic acid (DOTA[1]), Tyr^3] octreotide radiolabeled with ^{90}Y could effectively inhibit tumor growth in a rat subcutaneous tumor model (*5*). Complete or partial remissions were also achieved in a study using ^{177}Lu-labeled [DOTA,Tyr^3] octreotate for treating patients with gastroenteropancreatic neuroendocrine tumors (*6*). The success of using radiolabeled somatostatin analogs for tumor radiotherapy has inspired researchers to develop other radiolabeled peptides for treatment of different tumors.

It has been reported that most murine and human melanoma metastases bear up-regulated alpha-melanocyte-stimulating hormone (α-MSH) receptors (melanocortin type 1 receptor, or MC1R) (*7*, *8*). This suggests that α-MSH peptides may serve as vehicles for delivering radionuclides, fluorescent molecules, or chemotherapeutic drugs for targeting melanoma. Novel radiolabeled α-MSH analogs for melanoma imaging or therapy have been investigated, and significant progress has been achieved in this field. For example, a library of α-MSH analogs radiolabeled with ^{99m}Tc (*9*, *10*), ^{111}In (*11*−*14*, *26*, *27*), ^{125}I (*15*), ^{67}Ga (*16*), ^{86}Y (*17*), and ^{64}Cu (*17*, *18*) exhibited excellent tumor-targeting abilities and pharmacokinetic properties in xenografted or metastastic melanoma models, suggesting the potential application of these radiometals or radiohalogens labeled α-MSH peptides for melanoma detection. Most importantly, it was reported that an α-MSH peptide ReCCMSH(Arg^{11}) radiolabeled with therapeutic radionuclide, either ^{188}Re or ^{212}Pb, showed promising therapeutic effects in mice bearing either

B16F1 murine or TXM13 human xenografted melanoma (*19*, *20*). These results highlight the possibility of using α-MSH peptide tagged with therapeutic radionuclides for metastatic melanoma therapy.

However, it was found that on different human and murine melanoma cell lines the receptor number of MC1R ranged from as low as undetectable to around 10 000 (*7*). Considering the density of MC1R is one of the major factors that ultimately determine the uptake of the MC1R ligand in melanoma, to develop a noninvasive imaging tool with an ability to visualize the MC1R expression in living subjects will be very useful. This type of molecular probe may eventually render us the power to not only diagnose melanoma early but also screen patients suitable for PRRT strategy. To this end, an α-MSH analog, Ac-Nle-Asp-His-D-Phe-Arg-Trp-Gly-Lys(DOTA)-NH_2 (DOTA−NAPamide, *16*), was radiolabeled with a positron emitter ^{64}Cu ($t_{1/2}$ = 12.7 h, $E_{\beta^+\text{max}}$ = 656 keV, 19%) (Figure 1). The ability of ^{64}Cu−DOTA−NAPamide to image the MC1R expression using micropositron emission tomography (microPET) was further evaluated on two melanoma mice models with different MC1R densities.

MATERIALS AND METHODS

General. DOTA was obtained from Macrocyclics Inc. (Richardson, TX). NAPamide was synthesized with over 95% purity by the Stanford Protein and Nucleic Acid Biotechnology Facility using standard 9-fluorenylmethyloxycarbonyl (Fmoc)/*O*-benzotriazolyl-tetramethyluronium hexafluorophosphate (HBTU) chemistry on rink amide MBHA resin. All other chemicals were obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO). ^{64}Cu was provided by the Washington University School of Medicine (St. Louis, MO). A CRC-15R PET dose calibrator (Capintec Inc., Ramsey, NJ) was used for all radioactivity measurements. Reverse-phase high-performance liquid chromatography (RP-HPLC) was performed on a Dionex Summit HPLC system (Dionex Corp., Sunnyvale, CA) equipped with a 170U 4-Channel UV−vis absorbance detector and radioactive detector (Carroll & Ramsey Associates, model 105S, Berkeley, CA). UV detection wavelengths were 218, 254, and 280 nm for all experiments. Both semipreparative (Zorbax SB-C18, 9.4 mm × 250 mm) and analytical (Dionex Acclaim120 C18, 4.6 mm × 250 mm) RP-HPLC columns were used. The mobile phase was solvent A, 0.1% trifluoroacetic acid (TFA)/H_2O, and solvent B, 0.1% TFA/acetonitrile. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) was performed on a Perseptive Voyager-DE RP Biospectrometry instrument (Framingham, MA) by the Stanford Protein and Nucleic Acid Biotechnology Facility. Alpha-cyano-4-hydroxy-cinnamic acid (α-CHCA, prepared as 10 g/L in 33.3% CH_3CN:33.3% EtOH:33.3% H_2O:0.1% TFA) was used as solid matrix. A375M cell line was a generous gift from Dr. M. Kolodny; University of California, Los Angeles, CA, and B16/F10 murine melanoma cells were obtained from the American Type Tissue Culture Collection. C57BL/6 and Fox chase scid mice were purchased from Charles River Laboratories (Boston, MA).

Chemistry and Radiochemistry. DOTA was conjugated with NAPamide in a manner similar to that described before (*21*). Briefly, DOTA, 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide (EDC), and *N*-hydroxysulfonosuccinimide (SNHS) at a molar ratio of 1:1:0.8 were mixed and incubated at 4 °C for 30 min (pH = 5.5). NAPamide was then added to the in-situ-prepared sulfosuccinimidyl ester of DOTA (DOTA−OSSu) in a theoretical stoichiometry of 5:1. The reaction solution was mixed and reacted at 4 °C overnight (pH 8.5−9.0). The resulting DOTA−NAPamide conjugate was then purified by HPLC on a semipreparative C-18 column. The flow rate was 3 mL/min, with the mobile phase starting from 95% solvent A and 5% solvent B (0−3 min) to 35% solvent A and 65% solvent B at 33 min, then going to 85% solvent B and 15% solvent A (33−36 min), maintaining this solvent composition for another 3 min (36−39 min), and returning to initial solvent composition by 42 min. Fractions were collected and lyophilized. The target product was characterized by MALDI-TOF-MS and ready for use in the radiolabeling reactions. Analytic HPLC was performed on the same HPLC system using a C-18 analytical column and flow rate of 1 mL/min.

The DOTA−NAPamide was radiolabeled with ^{64}Cu by addition of 185 MBq (5 mCi) $^{64}CuCl_2$ (2 μg of peptide per 37 MBq ^{64}Cu) in 0.1 N NaOAc (pH 5.5) buffer followed by a 1 h incubation at 50 °C. The reaction was then terminated by adding 5 μL of TFA, and radiolabeled complex was purified by analytical radio-HPLC. The flow rate was 1 mL/min, with the mobile phase starting from 80% solvent A and 20% solvent B (0−3 min) to 70% solvent A and 30% solvent B at 33 min, then going to 85% solvent B and 15% solvent A (33−36 min), maintaining this solvent composition for another 3 min (36−39 min), and returning to initial solvent composition by 42 min. Purified radiolabeled peptide was dried by a rotary evaporator. The radiolabeled compound was reconstituted in phosphate-buffered saline (PBS) and passed through a 0.22 μm Millipore filter into a sterile vial for in vitro and animal experiments.

The nonradioactive ^{nat}Cu−DOTA−NAPamide was also synthesized by mixing DOTA−NAPamide (400 μg, 0.269 μmol) with high-purity natural copper chloride ($CuCl_2$, 55 μg, 0.409 μmol) in 0.1 N NaOAc (pH 5.5) buffer followed by 2 h incubation at 70 °C. The product was purified by HPLC and confirmed by MALDI-TOF−MS.

Octanol/Water Partition Coefficient. To determine the lipophilicity of ^{64}Cu−DOTA−NAPamide, approximately 370

kBq of ^{64}Cu-labeled complex in 500 μL of PBS (pH 7.4) was added to 500 μL of octanol in an Eppendorf microcentrifuge tube. The resulting biphasic system was mixed vigorously for 10 min and left at room temperature for another 60 min. The two phases were then separated by centrifugation at 2000 *g* for 5 min (model 5415R Eppendorf microcentrifuge; Brinkman, Westbury, NY). From each layer an aliquot of 100 μL was removed and counted in a γ-counter (Packard Instruments). The partition coefficient (log *P*) was then calculated as a ratio of counts in the octanol fraction to the counts in the water fraction. The experiment was repeated 3 times.

In Vitro Cell Assays. B16F10 murine and A375M human melanoma cells were cultured in Dulbecco's Modified Eagle Medium (DMEM) high glucose medium, which was supplemented with 10% heat-inactivated fetal bovine serum (FBS), 2 mM L-glutamine, and 48 mg of gentamicin. The cells were expanded in 75-cm^2 tissue culture flasks and kept in a humidified atmosphere of 5% CO_2 at 37 °C, with the medium changed every other day. A confluent monolayer was detached with trypsin and dissociated into a single-cell suspension for further cell culture.

The in vitro cell binding assays were performed with the murine melanoma cell line B16F10 as previously described (*7*−*9*). Briefly, cells were seeded at a density of 0.2 million/well in 24-well tissue culture plates and allowed to attach overnight. Following a wash with the binding medium [Modified Eagle's Media with 25 mM HEPES, 0.2% bovine serum albumin (BSA), and 0.3 mM 1,10-phenanthroline], the cells were incubated at 25 °C for 2 h with either DOTA−NAPamide or ^{nat}Cu−DOTA−NAPamide (peptide concentration varying from 10^{-12} to 10^{-6} M) and approximately 50 000 counts per minute (cpm) of ^{125}I-(Tyr^2)- [Nle,^{4}D-Phe^7]-α-MSH [^{125}I-(Tyr^2)-NDP] in 0.5 mL of binding media. The cells were rinsed twice with 0.01 M PBS (pH 7.4)/0.2% BSA and lysed in 0.5 mL of 1.0 M NaOH for 5 min, and the radioactivity of the cells was measured. The data was analyzed using the ORIGIN6.0 computer program (Northampton, MA), and the IC_{50} values, the concentration of competitor required to inhibit 50% of radioligand binding, of the DOTA−NAPamide and ^{nat}Cu−DOTA−NAPamide were calculated.

A typical saturation binding experiment was performed to determine the MC1R densities on the A375M and B16F10 melanoma cells. The cells (1×10^6) were incubated in 0.15 mL of binding medium in the presence of ^{125}I-(Tyr^2)-NDP ranging from approximately 2×10^3 to 2×10^6 cpm per tube with and without 10^{-6} M NDP for 2 h at 37 °C. The radioactivity of bound and free radioligand was counted. The data were analyzed by ORIGIN6.0, and the binding capacities of the B16F10 and A375M were calculated.

Cell uptake, internalization, and cellular retention of the ^{64}Cu−DOTA−NAPamide were examined in B16F10 cells using the method described previously (*15*). Briefly, in 24-well tissue plates prepared as described above, approximately 170 000 dpm of ^{64}Cu-labeled peptide (76.5 nCi, 0.283 ng, 0.38 nM) in 0.5 mL of binding media were added to each well containing cells and incubated at 37 °C for 5 min to 3 h. The nonspecific binding was determined by coincubation with nonradiolabeled NDP at a final concentration of 10 μM. Internalization of the radiolabeled peptide was determined by washing the cells with acidic buffer [40 mM sodium acetate (pH 4.5) containing 0.9% NaCl and 0.2% BSA] to remove the membrane-bound radiocomplex and then measuring the remaining internalized radioactivity. The cellular retention properties of the membrane-bound and internalized ^{64}Cu-labeled peptides were determined by incubating B16F10 cells in binding media at 37 °C with the radiolabeled complexes for 3 h. The binding media were then removed, the cells were washed twice with cold 0.01 M PBS (pH 7.4)/0.2% BSA, 0.5 mL of culture media was added, and radioactivity released into the media was monitored at various time points over a 3-h incubation period.

Animal Biodistribution Studies. All animal studies were carried out in compliance with Federal and local institutional rules for the conduct of animal experimentation. C57 BL/6 female mice, 7−8 weeks old, were inoculated subcutaneously in the right shoulder with 1×10^6 cultured B16/F10 murine melanoma cells. Nine to ten days postinoculation, the tumors grew to a weight of ∼500 mg and the tumor-bearing mice were subject to in vivo biodistribution and imaging studies, while 6 week old Fox chase ICR Scid mice were inoculated with 4×10^6 A375M human melanoma cells. Three to four weeks postinoculation, the mice bearing A375M tumors were ready for further studies.

For biodistribution studies the C57 BL/6 mice bearing B16F10 mouse melanoma and Fox chase mice bearing A375M human melanoma ($n = 4$ for each group) were injected with 703−777 KBq (19−21 μCi, 70−78 ng) of ^{64}Cu−DOTA−NAPamide with (blocking group, $n = 3$) or without coinjection of 200 μg of NDP through the tail vein and sacrificed at different time points from 30 min to 24 h postinjection (pi). Tumor and normal tissues of interest were removed and weighed, and their radioactivity was measured in a gamma counter. The radioactivity uptake in the tumor and normal tissues was expressed as a percent of the injected radioactive dose per gram of tissue (% ID/g).

MicroPET Imaging. PET imaging of tumor-bearing mice was performed on a microPET R4 rodent model scanner (Concorde Microsystems Inc., Knoxville, TN). The mice bearing B16F10 and A375M melanoma were injected with about 4.44 MBq (120 μCi) of ^{64}Cu−DOTA−NAPamide via the tail vein. At 120 min postinjection, the mice were anesthetized with 2% isoflurane and placed in the prone position and near the center of the field of view of microPET. The 10-min static scans were obtained, and the images were reconstructed by a two-dimensional ordered subsets expectation maximum (OSEM) algorithm. Regions of interest (ROIs) were then drawn over the tumor on decay-corrected whole-body coronal images. The counts per pixel per minute were obtained from the ROI and converted to counts per milliliter per minute using a calibration constant. By assuming a tissue density of 1 g/mL, the ROIs were converted to counts/g/min. An image ROI-derived % ID/g of tissue was then determined by dividing counts per gram per minute with injected dose (ID).

Statistical Method. Statistical analysis was performed using the Student's *t*-test for unpaired data. A 95% confidence level was chosen to determine the significance between groups, with $P < 0.05$ being significantly different.

RESULTS

Chemistry and Radiochemistry. Synthesis of DOTA−NAPamide conjugate (Figure 1) was achieved through coupling of in-situ-prepared DOTA−OSSu ester with the ϵ-amino group of the lysine residue in the NAPamide. The desired product was purified by semipreparative HPLC, and the purity of the target compound was generally obtained in 70% yield with over 95% purity. The retention time on analytical HPLC for DOTA−NAPamide was found to be 19.1 min. The purified DOTA−NAPamide was characterized by MALDI-TOF-MS. The measured molecular weight (MW) was consistent with the expected MW: $m/z = 1485.97$ for $[M + H]^+$ ($C_{68}H_{101}N_{20}O_{18}$, calcd MW = 1485.75). For ^{nat}Cu−DOTA−NAPamide, MW was measured as 1546.36 for $[M + H]^+$ ($C_{68}H_{99}CuN_{20}O_{18}$, calcd MW = 1546.67).

DOTA−NAPamide conjugate was then successfully labeled with ^{64}Cu at 50 °C for 1 h incubation. The purification of radiolabeling solution using RP-HPLC afforded ^{64}Cu−DOTA−

NAPamide with >95% radiochemical purity. Under several of HPLC conditions tested in this study, separation of ^{64}Cu−DOTA−NAPamide and unlabeled DOTA−NAPamide was not achieved. A modest specific activity of 0.4 Ci/μmol (14.8 MBq/nmol, 270 μCi/μg) ^{64}Cu−DOTA−NAPamide was obtained as determined by analytic HPLC (decay corrected). The specific activity of the tracer prepared in this research is very close to that of another ^{64}Cu-labeled α-MSH analog, ^{64}Cu−DOTA−ReCCMSH(Arg^{11}) (300 μCi/μg) which was reported recently (*17*). From the octanol−water partition coefficient measurements the log *P* value of tracer was determined to be −1.15 ± 0.01, indicating intermediate hydrophilicity of this compound.

In Vitro Receptor-Binding Assay and Biological Activity. A typical saturation binding experiment was performed to determine the MC1R densities on A375M and B16F10 melanoma cells. The cells (1×10^6) were incubated in 0.15 mL of binding medium in the presence of ^{125}I-(Tyr^2)-NDP ranging from approximately 2×10^3 to 2×10^6 cpm per tube with and without 10^{-6} M NDP for 2 h at 37 °C. The radioactivity of bound and free radioligand was counted. The data were analyzed by ORIGIN6.0, and the binding capacity of B16F10 and A375M were calculated to be 21 687 ± 4171 and 400 ± 93 (sites/cell ± SD), respectively.

The receptor-binding affinity study of peptides for MC1R was performed using B16F10 cells. The IC_{50} values of DOTA−NAPamide and ^{nat}Cu−DOTA−NAPamide were determined to be 2.67 ± 0.23 and 3.66 ± 0.29 nM, respectively, from the competitive receptor binding assay (Figure 2A). The IC_{50} value of DOTA−NAPamide is very close to what is reported in the literature (1.19 ± 0.19 nM, determined by using B16F1 cells) (*14*). Furthermore, the binding affinity of DOTA−NAPamide is only slightly reduced by chelation with Cu. Figure 2B shows the cell binding and internalization of ^{64}Cu−DOTA−NAPamide in B16F10 cells at 37 °C over a 3 h incubation period. The cell binding observed for the radiolabeled peptide steadily increased over the 3-h incubation time, and it reached a plateau 4.7% at 3 h. The ^{64}Cu−DOTA−NAPamide showed rapid internalization with approximately 73% internalization of the receptor-bound radiolabeled complexes within 5 min of incubation, while around 94% of receptor-bound tracer was internalized at 3-h incubation. Cellular retention of the radiolabeled complex as a function of time is shown in Figure 2C. The receptor-bound ^{64}Cu−DOTA−NAPamide slowly released from the cells into the medium, with 66% of the radioactivity still associated with the cells even after 3 h incubation.

Biodistribution Studies. The in vivo biodistribution of ^{64}Cu−DOTA−NAPamide was examined with both the B16F10 mouse melanoma and the A375M human melanoma tumor-bearing mouse model. Biodistribution of the radiolabeled peptide at 1, 2, 4, and 24 h was obtained in the B16F10 mouse model (Figure 3A), while 2 and 24 h biodistribution data was obtained in the A375M melanoma model (Figure 3B). In both tumor models the radiolabeled complex displayed rapid blood clearance; 0.97 ± 0.47% and 1.33 ± 0.34% ID/g blood uptake was observed at 2 h pi for B16F10 and A375M tumor bearing mice, respectively. Rapid and moderate activity accumulation in the high MC1R expressing B16F10 tumors was observed at early time points (3.69 ± 0.28% ID/g at 1 h pi). Tumor uptake slowly increased to 4.63 ± 0.45% ID/g at 2 h pi and 4.43 ± 0.94% ID/g at 4 h pi, then the activity was slowly washed out from the tumor, and uptake dropped to 1.67 ± 0.58% ID/g over 24 h (Figure 3A). While for the A375M tumor with low MC1R expression, tumor uptake was 2.49 ± 0.31% ID/g at 2 h pi (Figure 3B), which was significantly lower than the uptake of ^{64}Cu−DOTA−NAPamide in the B16F10 tumor model ($P < 0.05$). Furthermore, the in vivo specificity of ^{64}Cu−DOTA−NAPamide tumor uptake was investigated by coinjection of 200 μg of nonradiolabeled NDP with the radiolabeled peptide complex to the A375M melanoma-bearing Fox Chase ICR Scid mice and B16F10 melanoma-bearing C57 mice at 2 h. In the B16F10 tumor model, coinjection of NDP specifically reduced the tumor uptake of ^{64}Cu−DOTA−NAPamide from 4.63 ± 0.45 to 2.29 ± 0.24 (% ID/g; $P < 0.05$) without changing the distribution of ^{64}Cu−DOTA−NAPamide in most of the normal tissues studied (Figure 4). However, coinjection of NDP with radiolabeled peptide did not reduce uptake of ^{64}Cu−DOTA−NAPamide in the A375M tumor (2.49 ± 0.31% ID/g for nonblocking versus 2.20 ± 0.41% ID/g for blocking) at 2 h pi.

For both tumor models ^{64}Cu−DOTA−NAPamide displayed high accumulation and retention in the liver. It was observed that 12.17 ± 2.00% and 4.53 ± 1.19% ID/g remaining was still in the liver at 24 h pi for A375M and B16F10 tumor mice model, respectively. High renal activity accumulation was also observed at all times in both tumor models (Figure 3A and B).

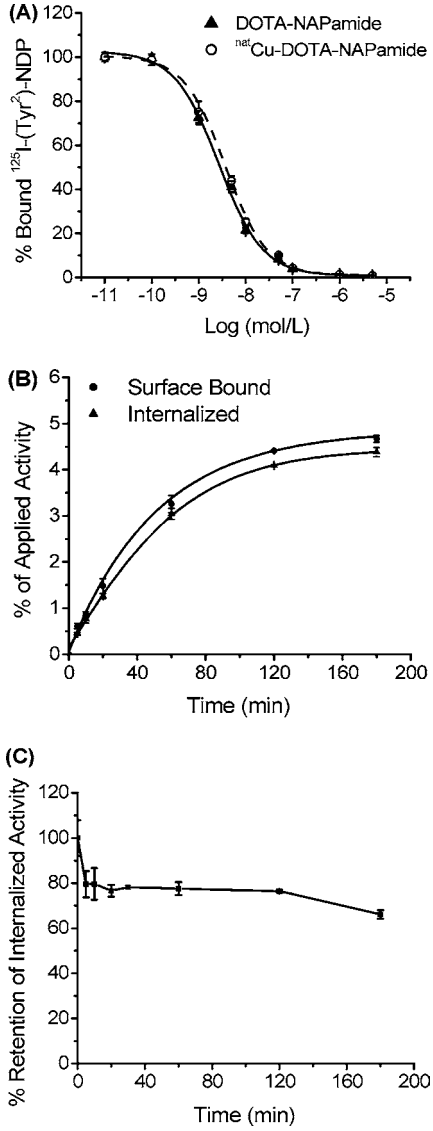

Figure 2. (A) In vitro inhibition of ^{125}I-(Tyr^2)-NDP binding to MC1R on murine B16F10 melanoma cell line by DOTA−NAPamide (IC_{50} = 2.67 ± 0.23 nmol/L) and ^{nat}Cu−DOTA−NAPamide (IC_{50} = 3.66 ± 0.29 nmol/L). Results expressed as percent of binding are mean of triplicate measurement ± standard deviation. (B) Cell binding and internalization over time for ^{64}Cu−DOTA−NAPamide with B16/F10 cells at 37 °C. Surface-bound radioactivity and internalized activity are expressed as a percent of total applied activity. (C) Percent retention of internalized ^{64}Cu−DOTA−NAPamide radioactivity in B16/F10 cells over time at 37 °C.

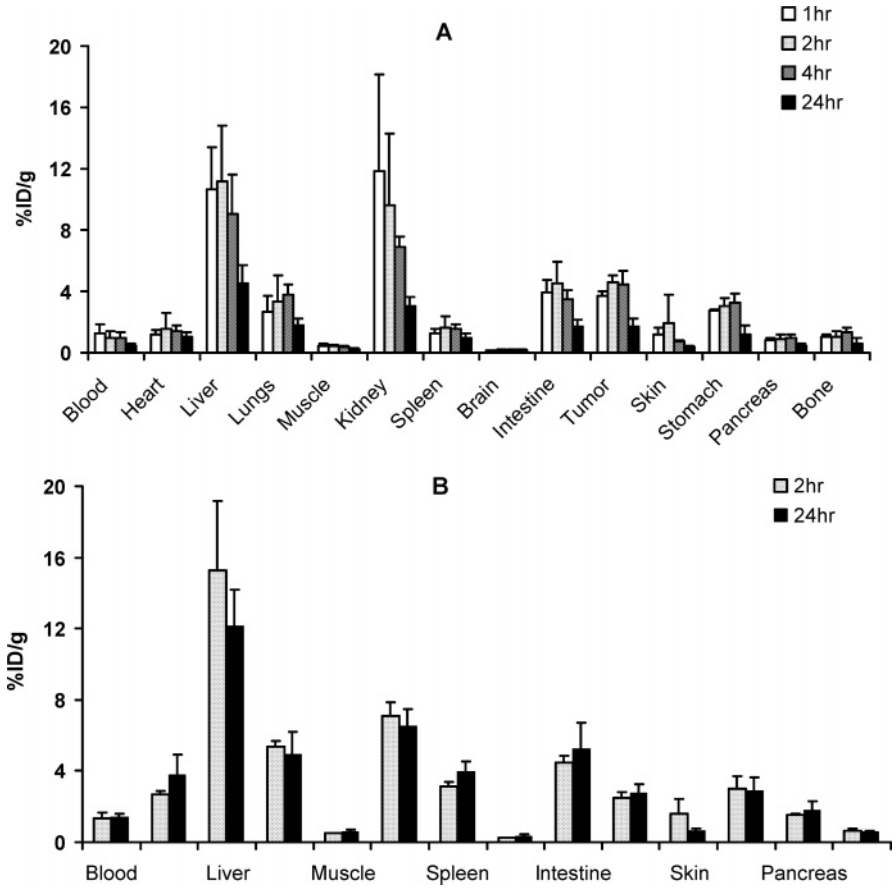

Figure 3. (A) Biodistribution data for ^{64}Cu−DOTA−NAPamide in C57 mice bearing subcutaneously xenotransplanted B16F10 murine melanoma (A) and Fox Chase ICR Scid mice bearing A375M human melanoma (B). Data are expressed as the percent administered activity (injected dose) per gram of tissue (% ID/g) ($n = 4$). ^{64}Cu−DOTA−NAPamide exhibited significantly higher uptake in B16F10 at 2 h postinjection than in A375M ($P < 0.05$).

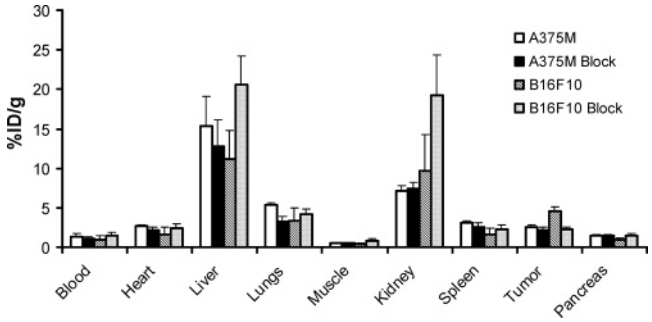

Figure 4. Receptor-blocking study: biodistributions of ^{64}Cu−DOTA−NAPamide in A375M melanoma-bearing Fox Chase ICR Scid mice and B16F10 melanoma-bearing C57 mice at 2 h with and without coinjection of 200 μg of NDP as a blocking agent. Significant inhibition of uptake in B16F10 melanoma ($P < 0.0015$), while not in A375M melanoma ($P > 0.05$), was observed. Data are expressed as normalized accumulation of activity in % ID/g ± SD ($n = 3$ for each group).

MicroPET Imaging. Decay-corrected coronal (top) and transaxial (bottom) microPET images of mouse bearing A375M tumor on the right shoulder and mouse bearing B16F10 tumor at 1, 2, and 4 h after tail veil injection of 4.44 MBq (120 μCi) ^{64}Cu−DOTA−NAPamide are shown in the Figure 5A and C, respectively. Although the radioactivity accumulation in the liver and kidney are quite high, the B16F10 tumor is still clearly visualized with good tumor to contralateral background contrast at 1−4 h pi. However, lower uptake in A375M tumor was observed, resulting in poor tumor to normal tissue contrast. Quantification of activity accumulation in the A375M and B16F10 melanoma and major organs (Figure 5B and D) agreed well with the biodistribution results.

DISCUSSION

Molecular imaging of cancer is a fast-growing research field (*22*). Molecular imaging technologies have demonstrated great benefits for better understanding cancer biology as well as facilitating cancer drug development and cancer early detection (*22, 23*). Development of novel imaging methods and molecularly targeted probes will allow us to not only locate a tumor but also visualize the expression and activity of specific molecular targets and biological processes in a tumor. Currently, 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) is widely used in malignant melanoma diagnosis and staging in clinic. The molecular targets for [^{18}F]FDG are glucose transporters (e.g., GLUT1), and hexokinase. [^{18}F]FDG only provides the glucose metabolic activity of a tumor (*24*). MC1R plays an important role in the proliferation and differentiation of melanocytes as well as in the development and growth of melanoma cells. It is also considered as a genetic linker to skin cancer (*25*). Overexpression of MC1R in melanoma cells makes it a promising molecular target for melanoma imaging and therapy. Thus, it is important to develop a PET molecular probe for imaging MC1R expression in living subjects.

Several α-MSH analogs which can recognize the MC1R have been labeled with different radionuclides for melanoma detection and radiotherapy (*9*−*20*, *26*−*28*). The most promising melanoma-targeting peptides are linear peptide NAPamide (*16*) and rhenium-cyclized CCMSH peptides (*9*, *11*, *15*). NAPamide is a short peptide with only eight amino acid residues. It can be easily synthesized in high yield and purity using the conventional solid-phase peptide synthesis and Fmoc/HBTU chemistry. Conjugating the peptide with metal chelate, DOTA, can also be easily achieved through reaction between the Lys^8 ϵ-amino

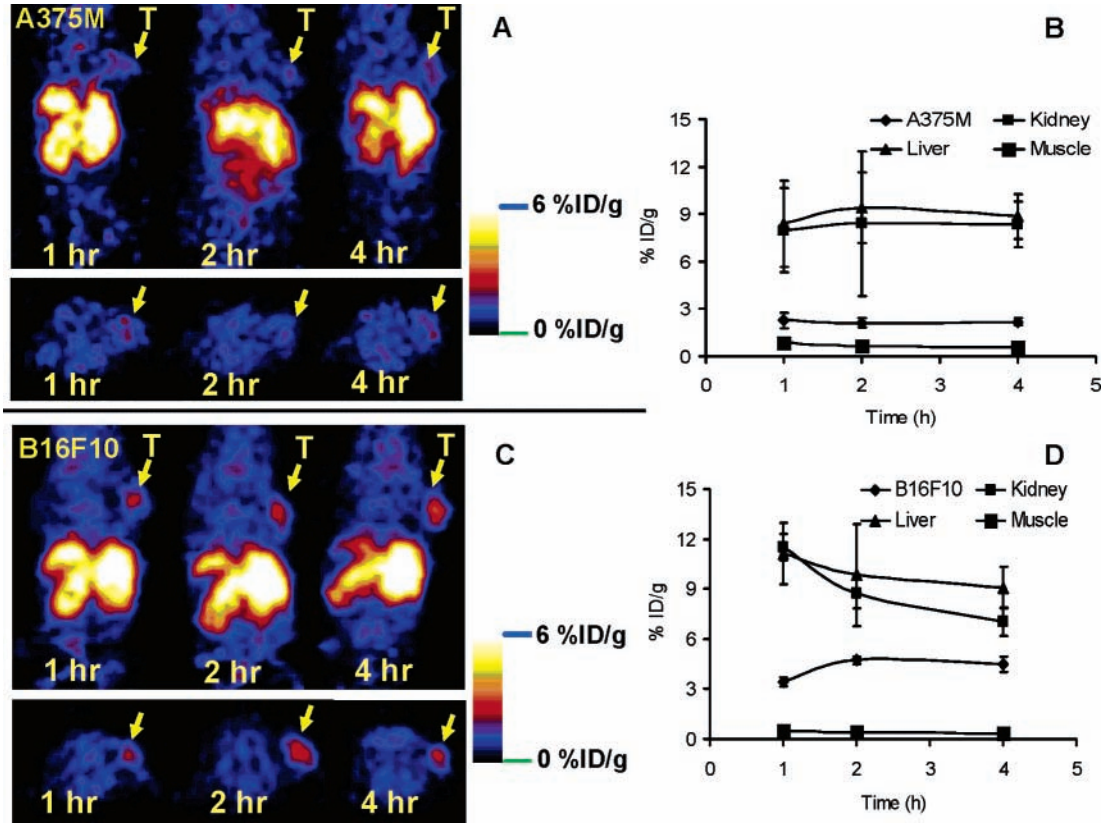

Figure 5. Decay-corrected coronal (top) and transaxial (bottom) microPET images of Fox Chase ICR Scid mouse bearing A375M tumor on the right shoulder (A) and C57 mouse bearing B16F10 tumor (C) at 1, 2, and 4 h after tail veil injection of (4.44 MBq, 120 μCi) ^{64}Cu−DOTA−NAPamide. Arrows indicate location of tumors (T). Time activity curves derived from the multitime point microPET imaging of mice bearing A375M (B) and B16F10 (D) melanoma. The regions of interest (ROIs) are shown as mean % ID/g ± SD ($n = 3$).

group in the NAPamide and in-situ-activated DOTA in buffered solution. The resulting DOTA−NAPamide conjugate as well as Cu-coordinated ligand (^{nat}Cu−DOTA−NAPamide) displays high binding affinity to MC1R (Figure 2A). ^{111}In- and ^{67}Ga-labeled DOTA−NAPamide exhibit high tumor, moderate kidney, and low blood uptake at 4 h pi (*16*). ^{64}Cu is a positron emitter that can be readily produced using a medical cyclotron. Its intermediate half-life makes it suitable for small peptide radiolabeling (*29*−*33*). Considering all of these advantages, we hypothesized that radiolabeling DOTA−NAPamide with ^{64}Cu would generate a novel molecular probe for routine PET imaging of melanoma and MC1R expression.

Subsequently, ^{64}Cu−DOTA−NAPamide was prepared and its MC1R targeting ability evaluated in cell culture and in vivo. Murine melanoma cell line B16F10 and human melanoma cell line A375M were then used in biological studies because they express different levels of MC1R ($B_{max} = 2.2 \times 10^4$ and 400 receptors/cell for B16F10 and A375M, respectively). In vitro B16F10 cell studies show that ^{64}Cu−DOTA−NAPamide specifically binds to MC1R and reaches a plateau at 3 h incubation. The majority of receptor-bound radiolabeled complexes are rapidly internalized from 5 min to 3 h incubation (Figure 2B). A cellular retention study demonstrates that the receptor-bound ^{64}Cu−DOTA−NAPamide is slowly washed out from cells, with 66% of the radioactivity still associated with the cells even after 3 h incubation. These results are quite similar to the results of cell uptake, internalization, and retention of ^{99m}Tc−CCMSH reported previously (*9*). The high MC1R binding and internalization property of ^{64}Cu−DOTA−NAPamide in cell culture justifies its further evaluation in animal models.

In vivo biodistribution studies show that ^{64}Cu−DOTA−NAPamide possesses reasonable uptake in high MC1R expression B16F10 melanoma at 1−24 h pi (Figure 3A) and that the maximum uptake of 4.63 ± 0.45% ID/g is achieved at 2 h pi. When coinjected with a large amount of NDP peptide, accumulation of the tracer at 2 h pi is reduced by 50% (Figure 4), demonstrating the specific accumulation of the tracer. More interestingly, the tracer uptake in low MC1R expression A375M tumor at 2 h pi is around 50% uptake of B16F10 tumor. Coinjection of NDP cannot inhibit tracer uptake in A375M tumor. These data indicate that the 2.49% ID/g uptake of A375M at 2 h pi is likely nonspecific accumulation. We also observe increased liver and kidney uptake values in the B16F10 blocked mice group compared to B16F10 group in this research. It is possible that the large amount of NDP peptide used in this study (200 vs 20 μg used in ref *17*) may play a role in altering the biodistribution of the tracer in the kidney and liver. Further studies are needed to confirm and elucidate this phenomenon.

High accumulation and retention of ^{64}Cu−DOTA−NAPamide in the liver is observed in both B16F10 and A375M tumor models (Figure 3A and B). This can be explained by the release of uncoordinated ^{64}Cu from radiolabeled peptide by decomposition in the blood or transchelation in the liver. Better chelation systems for ^{64}Cu such as TETA (1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid) or cross-bridged cyclam ligands may improve the metal−chelate stability and subsequently improving the biodistribution (*34*−*35*). Similar to other radiometal-labeled peptides (*9*, *11*, *17*, *21*, *30*), high renal activity accumulation and retention of ^{64}Cu−DOTA−NAPamide is also observed in both tumor models (Figure 3A and B). This could possibly be decreased by the use of L- or D-lysine without affecting tumor attention (*9*, *15*) in order to achieve a better kidney to normal tissue ratio and reduce radiation dose to the tested subject.

The biodistribution of ^{111}In- and ^{67}Ga-labeled DOTA−NAPamide was evaluated in the study using B6D2F1 mice

bearing B16F1 melanoma (*16*). Both ^{111}In- and ^{67}Ga-labeled DOTA−NAPamide exhibit high tumor uptake and rapid clearance from normal tissue. For example, ^{111}In- and ^{67}Ga-labeled DOTA−NAPamide display 7.56 ± 0.51 and 9.43 ± 1.06% ID/g tumor uptake at 4 h pi, respectively. The uptake values for normal tissues such as liver, lung, spleen, and muscle are all below 0.45% ID/g at 4 h pi (*16*). In contrast, ^{64}Cu-labeled DOTA−NAPamide shows lower B16F10 tumor uptake (for example, 4.43 ± 0.94% ID/g at 4 h pi) but higher uptake and retention in normal tissues when used in C57 BL/6 mice bearing B16F10 murine melanoma. The observation that the α-MSH peptide labeled with different radiometals can change their in vivo properties has been reported before (*17*). It is generally believed that the charge of the radiopeptide and the in vivo stability of the metal−chelate are responsible for their different in vivo behaviors. Our results reported here further highlight the importance of selecting the appropriate radiometal for peptide labeling so that the best tracer can be developed for molecular target imaging.

MicroPET imaging and quantification analysis of ^{64}Cu−DOTA−NAPamide in mice bearing A375M or B16F10 tumor 1, 2, and 4 h after tail veil injection reveal moderate B16F10 tumor-to-background, while the A375M tumor-to-background ratio is low (Figure 5). These results are consistent with the finding obtained from the biodistribution studies. Therefore, in addition to early detection of α-MSH receptor positive melanoma, it is also possible to differentiate melanoma with different MC1R densities in living subjects using the molecular probe ^{64}Cu−DOTA−NAPamide in conjunction with quantitative PET imaging technology. Future research is needed to further evaluate whether this tracer can help in selection of patients for anti-MC1R treatment.

In conclusion, ^{64}Cu−DOTA−NAPamide demonstrates high cell uptake, internalization, and retention in MC1R high expression melanoma. Biodistribution and microPET imaging studies show moderate specific uptake in a B16F10 melanoma model with high MC1R density while a low uptake in A375M melanoma with low MC1R capacity. ^{64}Cu−DOTA−NAPamide is a promising molecular probe for PET imaging MC1R expression in living subjects.

Recombinant immunotoxins exhibit targeting and cytotoxic functions needed for cell-specific destruction. However, antitumor efficacy, safety, and pharmacokinetics of these therapeutics might be improved by further macromolecular engineering. SS1P is a recombinant anti-mesothelin immunotoxin in clinical trials in patients with mesothelin-expressing tumors. We have modified this immunotoxin using several PEGylation strategies employing releasable linkages between the protein and the PEG polymers, and observed superior performance of these bioconjugates when compared to similar PEG derivatives bearing permanent linkages to the polymers. PEGylated derivatives displayed markedly diminished cytotoxicity on cultured mesothelin-overexpressing A431-K5 cells; however, the releasable PEGylated immunotoxins exhibited increased antitumor activity in A431-K5 xenografts in mice, with a diminished animal toxicity. Most significantly, complete tumor regressions were achievable with single dose administration of the bioconjugates but not the native immunotoxin. Pharmacokinetic analysis of the releasable PEGylated derivatives in mice demonstrated an over 80-fold expansion of the area under the curve exposure of bioactive protein when compared to native immunotoxin. A correlation in degree of derivatization, release kinetics, and polymer size with potency was observed in vivo, whereas in vitro cytotoxicity was not predictive of efficacy in animal models. The potent antitumor efficacy of the releasable PEGylated mesothelin-targeted immunotoxins was not exhibited by similar untargeted PEG immunotoxins in this model. Since the bioconjugates can also exhibit the attributes of passive targeting via enhanced permeability and retention, this is the first demonstration of a pivotal role of active targeting for immunotoxin bioconjugate efficacy.

INTRODUCTION

Mesothelin is an attractive target for tumor-specific therapy due to its high expression on several cancers and limited expression on normal tissues. The 40 kDa glycosylphosphatidyl inositol-linked cell surface glycoprotein is overexpressed in pancreatic carcinoma, ovarian cancer, and malignant mesotheliomas, whereas normal pleura, pericardium, and peritoneum exhibit detectable mesothelin expression in the surrounding mesothelial cells (*1*−*15*). The biological function of mesothelin is not established; although it is not essential for normal mouse development (*16*−*21*), recent studies suggest that mesothelin binds to the mucin glycoprotein CA125 and that this interaction mediates cell adhesion (*22*).

An anti-mesothelin mAb[1] was generated by immunizing mice with a mesothelin expression plasmid and library screening of splenic RNA variable domains using scFv phage display technology. Affinity maturation was conducted using site-selected mutagenesis and screening (*6*, *12*−*15*, *23*). The isolated SS1 Fv exhibited high affinity for mesothelin (K_d = 0.7 nM) and was stabilized by a disulfide bond between the light and heavy variable domains of the Fv (*24*−*26*). The SS1 Fv was employed in the construction of an immunotoxin SS1P via genetic fusion to a truncated *Pseudomonas* exotoxin A (PE) (*27*−*30*). SS1P is highly cytotoxic to mesothelin-expressing cells in culture and demonstrates antitumor effects against the human epidermoid carcinoma cell line, A-431, that is stably transfected with a mesothelin cDNA expression vector (A431-K5) and subcutaneously implanted in mouse xenografts. SS1P [SS1-(dsFv)PE38] has recently been investigated in clinical trials (*1*, *7*, *9*).

Several recombinant immunotoxins composed of an antibody Fv targeting moiety and a PE cytotoxic moiety have been evaluated in animal models and clinical studies (*31*, *32*). These immunotoxins have produced potent antitumor responses in human cancer xenografts in nude mice (*33*, *34*), and major clinical responses to recombinant immunotoxins were observed in hematologic malignancies (*35*, *36*). However, these chimeric proteins also exhibit side effects that limit the dose and frequency of administration. The PE domain of the immunotoxin may exhibit nonspecific binding to normal tissues, while

neutralizing human anti-PE antibodies, and less frequently, anti-mouse Fv antibodies, are formed in patients treated with these therapeutics, resulting in either dose-limiting toxicity or diminished therapeutic potency. In addition, recombinant immunotoxins (~63 kDa) do not exhibit prolonged blood residency, in contrast to mAbs, leading to increased distribution in both tumors and normal tissues, including kidneys and liver. Although a prolonged blood residency might be achieved via continuous infusion, it would be desirable to construct an immunotoxin with intrinsically improved pharmacokinetics, reduced toxicity, and diminished antigenicity/immunogenicity.

PEGylation is a well-developed technology that has shown the capacity to address each of the above concerns. Bioconjugation of proteins with PEG via permanent linkages is employed in at least six marketed protein therapeutics (*37*). We previously reported an improvement in serum half-life, a reduction in immunogenicity and toxicity, and enhanced antitumor efficacy in a PEGylated chimeric toxin composed of transforming growth factor-α and PE (*28*). However, these positive attributes came at the expense of a marked loss of specific cytotoxic activity. Site-specific PEGylation of anti-Tac(Fv)-PE immunotoxin LMB-2 also improved antitumor activity and diminished toxicity and immunogenicity (*29, 38*). In this case, the engineered protein design of the bioconjugate employed a free thiol in the connector peptide of the immunotoxin. In practice, this approach may be limited by the inefficiency of protein refolding due to incorrectly disulfide-linked, misfolded protein impurities, and also by the inefficiency of conjugation and purification of the conjugates. It would be desirable to develop a bioconjugate strategy wherein no special polypeptide alterations are required and whereby nearly quantitative yields of bioconjugate from native protein are achieved. Designing the optimal immunotoxin through the combination of protein engineering and bioconjugation approaches is a challenging undertaking. Recombinant immunotoxins, such as SS1P, are multifunctional proteins that exhibit biological activity only after intracellular processing. Chemical modification strategies must consider the preservation of antigen-binding, translocation, and ADP-ribosylation functions, while enhancing composite pharmacological properties, including avoidance of rapid clearance from renal filtration, antibody or cellular clearance, or physical degradation.

Although conventional PEGylation utilizes stable linkages between the polymers and the protein, recent research has investigated the potential of releasable PEGylation (rPEGylation), wherein the designed covalent linkages of the PEG strands are chemically unstable within a physiological environment and the attached polymers are detached via a controlled release mechanism (*30, 39*−*44*). This unconventional prodrug-based PEGylation approach might have an appropriate application in immunotoxin engineering. Immunotoxins are themselves biological prodrugs that are activated by a designed intracellular release mechanism. Further engineering of the immunotoxin as a double prodrug bioconjugate offers several hypothetical advantages. rPEGylation could provide multiple PEG attachments over the protein surface and allow optimized pharmacokinetics and biodistribution, with diminished immunogenicity and antigenicity. Although the rPEGylated immunotoxin may have severely compromised cytotoxic activity in its prodrug form, a designed incremental release in vivo of the unmodified immunotoxin protein from the attached polymers may provide a superior distribution of fully active protein at the target sites. Underlying this hypothesis is a requirement for a beneficial shift in the balance between the counteracting forces of clearance of the released protein and retention of the PEG modified protein. Furthermore, rPEGylated immunotoxins might accrue additional tumor targeting benefits from the enhanced permeability and retention (EPR) phenomenon (*45, 46*). In the first investigations to examine the in vitro and in vivo performance of immunotoxins modified with rPEGylation, we have studied several rPEGylated bioconjugates composed of SS1P and designed rPEG polymers of varying release kinetics, polymer size, and degree of modification.

EXPERIMENTAL PROCEDURES

Materials. PEG_2-40 kDa-NHS was obtained from Nektar Therapeutics (Huntsville, AL). All other activated PEG polymers were supplied by Enzon Pharmaceuticals, Inc. (Piscataway, NJ). Hiload Superdex 75 or 200, Q Sepharose Fast Flow, and HiTrap Q-XL were supplied by GE Healthcare (Piscataway, NJ).

Production of Recombinant SS1P. The subunits of SS1P were expressed in *Escherichia coli* BL21(λDE3) and purified as previously described for other immunotoxins (*23*, *25*, *31*). Active monomeric protein was purified from the refolding solution by ion exchange and size exclusion chromatography. LC-MS analysis confirmed the predicted 62 591 mass of SS1P.

Linker Synthesis. The Bicin3, DGA2, and RNL-8a linkers were synthesized as previously described (*39*−*41, 44*).

Preparation of Releasable PEG−SS1P Conjugates. In PEGylation reactions employing releasable linkers such as DGA2, RNL-8a, and Bicin3, SS1P at 1.5−2.5 mg/mL was PEGylated in 0.05−0.1 M sodium phosphate, pH 7.6, 25 °C, and purified by reported procedures (*40, 44*). With fast stirring without creating foam, the PEG powder at 10:1 to 50:1 reaction molar ratio of PEG to SS1P was added to the SS1P solution at 1 g/min. The reaction was continued at 25 °C for 1 h and quenched by adding glycine. Immediately after quenching, the solution pH was lowered to 6.5 with monobasic sodium phosphate and the conjugate was purified on a size exclusion column (Superdex 200 or 75 Hiload) equilibrated in 20 mM sodium phosphate, pH 6.5, 140 mM NaCl. Alternatively, the conjugate was purified on an anion exchange column (Q Sepharose Fast Flow) using either 10 mM sodium phosphate, pH 7.4, as the equilibration buffer, with 0.3 M NaCl in 10 mM sodium phosphate, pH 7.4, as the gradient elution buffer, or 10 mM Tris−HCl, pH 7.6, as the equilibration buffer, and 0.3 M NaCl in 10 mM Tris−HCl, pH 7.6, as the gradient elution buffer. The column fractions containing the peak were combined and dialyzed against PBS, pH 6.5. The sample was concentrated to about 1 mg/mL using Centriplus 30k (Millipore, MA) and passed through a sterile filter (Acrodisc Syringe Filter, 0.2 μm HT Tuffyn membrane, Pall, MI). The number of PEG polymers per SS1P molecule was initially estimated by SDS-PAGE prior to further analysis. The release of SS1P from releasable PEG−SS1P was conducted by incubation in a PBS pH 8.5 buffer, at 37 °C or 25 °C. The purity of the product was analyzed on a TSK gel filtration column equilibrated in 50 mM sodium phosphate, pH 6.5, 150 mM NaCl (G4000SWXL, 7.8 × 30 cm, 8 μm, Tosoh Biosciences). The peak area was calculated at 220 nm. Since the conventional TNBS and fluorescamine assay methods for measurement of percent PEG modification require a basic pH which is not suitable for rPEG−SS1P, we used the ammonium ferrothiocyanate colorimetric method to analyze free and protein-coupled PEG (*47*).

Preparation of Permanent PEG−SS1P Conjugates. For PEGylation reactions that employed permanent linkers such as SC and NHS, SS1P at 1.5−2.5 mg/mL was PEGylated in 0.05 M sodium phosphate, pH 6.0−9.0, at 25 °C and purified as previously described (*29, 30, 37*−*41*). With fast stirring without creating foam, the PEG powder at 3:1 to 15:1 reaction molar ratio of PEG to SS1P was added to SS1P solution at 1 g/min. The reaction was continued at 25 °C for 1−2 h for the pH 7.4−9.0 reactions and 4 h for pH 6.0−7.0 reactions. The reaction was quenched by adding glycine. The conjugate was purified by an anion exchange column (Q Fast Flow Sepharose) where

the equilibration buffer was 10 mM Tris−HCl, pH 7.6, and the gradient elution buffer contained 0.3 M NaCl in 10 mM Tris−HCl, pH 7.6. Alternatively, a size exclusion column (Superdex 200 or 75 Hiload) was used for purification with a pH 7.4 PBS equilibration buffer. The sample was concentrated to about 1 mg/mL using Centriplus 30k and passed through an Acrodisc sterile filter.

Preparation of ALD−PEG−SS1P. For N-terminal selective PEGylation, SS1P at 2 mg/mL was incubated with aldehyde-PEG-20k (ALD-PEG-20k) at a 10:1 reaction molar ratio (PEG/SS1P) in 100 mM sodium phosphate, pH 6.5, 25 °C, for 3 h. The reduction of Schiff base was completed in 15 mM sodium cyanoborohydride at 25 °C, 16 h. Mono-PEGylated and di-PEGylated conjugates were isolated on HiTrap Q-XL at pH 7.5. SDS-PAGE analysis showed that the PEG attachment in mono PEG-SS1P was selectively located on the heavy chain (V_H-PE) and the PEG in di-PEG-SS1P was found on both the heavy and light chains (V_L) of SS1P.

Cell Lines and Cytotoxicity Assay. A431-K5, a cell line established by transfection of an expressible cDNA encoding mesothelin into human epidermoid cancer A431 cells (American Type Culture Collection, Manassas, VA), was used in cytotoxicity assays in vitro and in vivo. A431-K5 has a stable and uniform expression of mesothelin (33 000 mesothelin sites per cell; Raffit Hassan, NCI, unpublished data), which is similar to that observed with tumor specimens obtained from patients (*9, 10, 17, 18, 20*). The specific cytotoxicity of SS1P and PEGylated SS1P compounds was assessed by protein synthesis inhibition assays in 96-well plates, by a modified nonradioactive assay (*10, 34*).

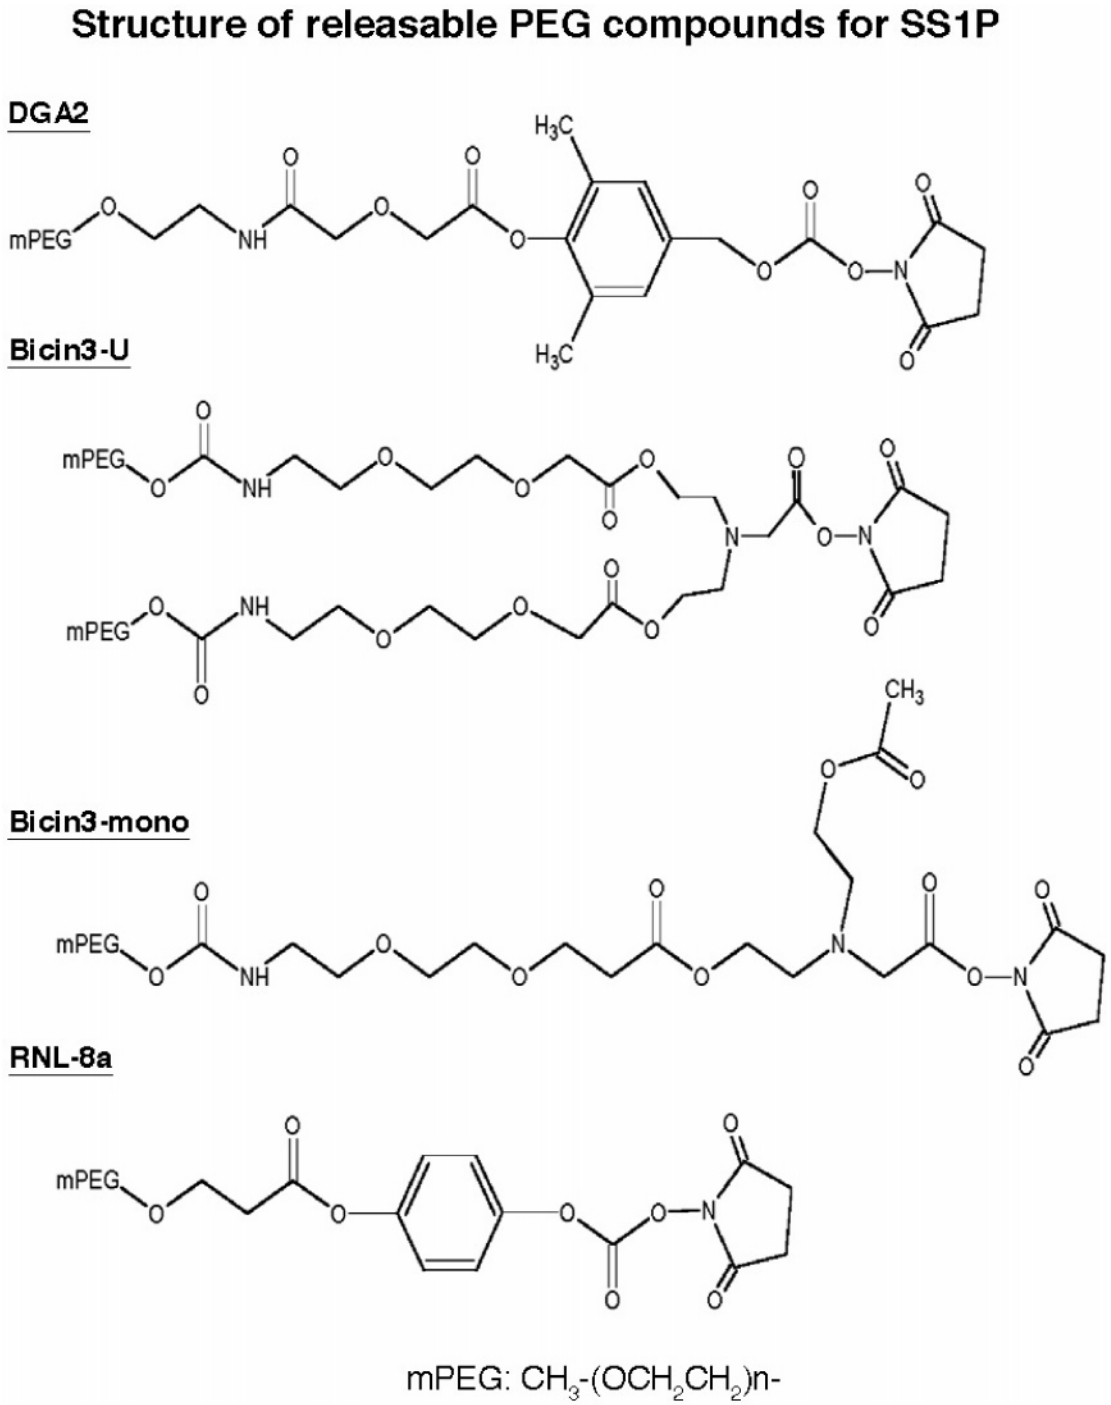
Antitumor Activity of SS1P and PEGylated SS1P. The antitumor activity of SS1P and PEG−SS1P compounds was determined in nude mice bearing A431-K5 human cancer cells that express mesothelin. Starting on day 7, animals were treated with i.v. injections of each of the immunotoxin compounds diluted in 0.2 mL of phosphate buffered saline (PBS)/0.2% mouse serum albumin (MSA).

Pharmacokinetics. BALB/c mice (6−8 week old females) were supplied by Sprague Dawley Harlan (Madison, WI). Mice (3/group) were injected i.v. with 100 μL per mouse of SS1P (0.125 or 0.4 mg/kg) or its PEGylated conjugates (0.5 or 1.5 mg/kg). Mice were terminally bled by cardiac puncture at 0.17, 0.5, 1, 3, 6, 24, 48, and 120 h. The concentrations of the compounds were analyzed by in vitro cytotoxicity with A431-K5 cells, and data were modeled using *WinNonlin* software to determine pharmacokinetic parameters.

Flow Cytometry. Flow cytometry studies with A431-K5 cells were used to analyze SS1P and PEG−SS1P compounds binding to mesothelin cell receptors. Cells were resuspended (10^6 cells/mL) in D-MEM, 5% FBS. SS1P compounds (0.1, 1, 10, or 100 ng) in 100 μL of FACS medium were added to each tube and incubated for 30 min on ice, and 100 μL of mouse anti-PE-40 mAb (1 μg/mL) was added and incubated 30 min on ice. Phycoerythrin-conjugated goat anti-mouse polyclonal antibody (10 μg/mL; 100 μL) was added, and analysis was conducted on FACS Calibur (BD Biosciences, San Jose, CA).

Surface Plasmon Resonance Analysis. Surface plasmon resonance techniques were performed using a Biacore X instrument (Biacore, Inc., Piscataway, NJ). Recombinant mesothelin-maltose binding protein (MBP) was prepared using the pMAL protein fusion and purification system (New England BioLabs, Beverly, MA). Anti-MBP mAb was immobilized on a CM5 chip and subjected to ligand stability analysis for six cycles with 500 nM mesothelin-MBP. For each kinetic experiment, equal amounts of mesothelin-MBP were allowed to be captured by the surface-immobilized anti-MBP mAb. The SS1P or PEG−SS1P proteins served as analytes. Over the stable mAb-MBP-mesothelin surface, different concentrations of SS1P or PEG−SS1P were examined. The data were analyzed using Biacore *BiaEvaluation* software (version 3.0).

Analysis of Anti-SS1P Antibodies in Human Sera by Competition ELISA. Microtiter wells were coated with 1 μg SS1P/50μL in 20 mM Tris−HCl, pH 8.0. Diluted human antisera, combined with serial dilutions of either SS1P or PEG−SS1P, were added (100 μL total volume) and incubated at 25 °C for 1.5 h. The wells were washed and HRP conjugated rabbit anti-human Ig (1:40 000 dilution), 50 μL/well, was added and incubated at 25 °C for 45 min. Following washing, 100 μL of TMB-E substrate was added, and the plates were read at 450 nm.



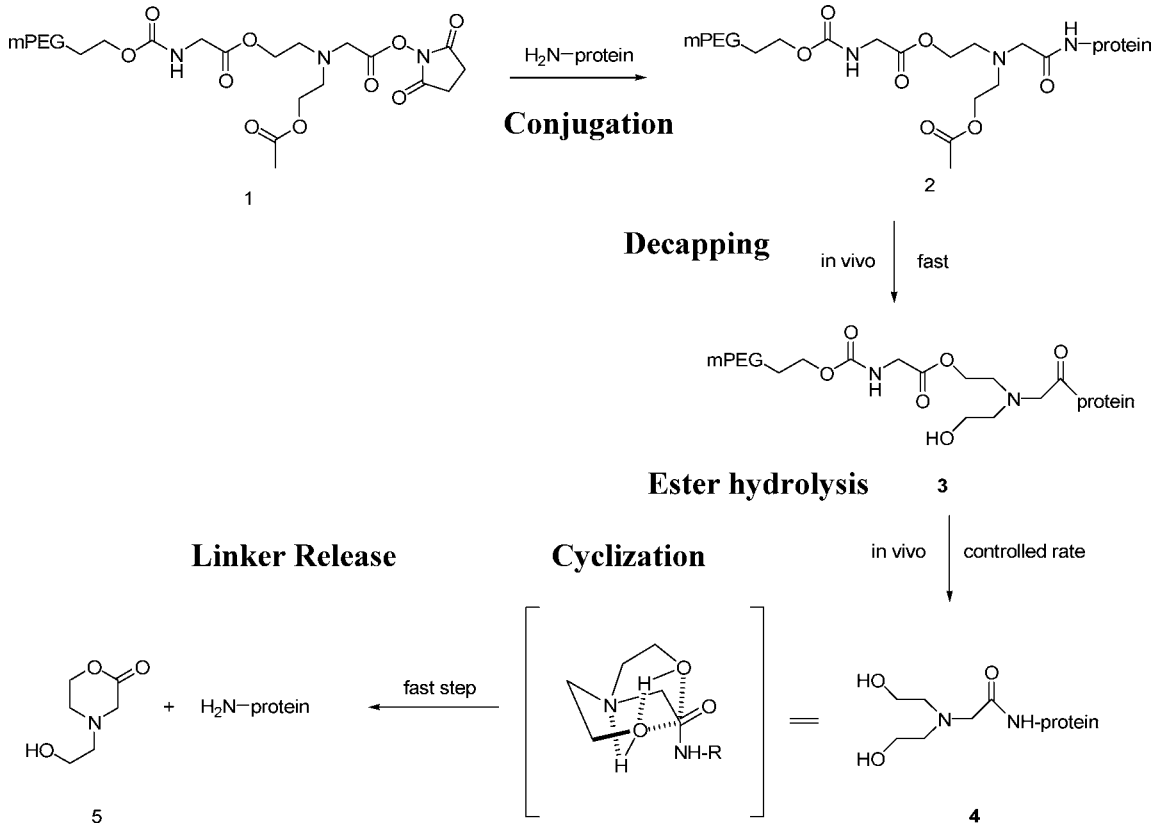
RESULTS

Preparation and Characterization of PEG−SS1P Compounds. Seven amine-reactive, NHS-activated PEG polymers were employed in the construction of PEGylated bioconjugates of the immunotoxin SS1P. As shown in Chart 1, four unconventional releasable linker designs were evaluated. The bis-*N*-2-hydroxyethylglycine (Bicin3), diglycolic acid (DGA2), and reversible nitrogen linker (RNL-8a) linker chemistries have been recently described with regard to their mechanism of controlled release from PEGylated proteins (*39−41*, *44*). The DGA2 (fast release) and RNL-8a (slow release) linkers are both aromatic designs wherein an initial ester cleavage triggers a classical 1,6-benzyl elimination reaction which releases the original amine and results in linker degradation. In contrast, the Bicin3 linker employs a wholly aliphatic design. Following the hydrolysis of the exposed ester group of the linker, a cyclization event promotes linker self-immolation and release of the original amine (lysine) group. The Bicin3 linker was employed as a release linkage to either mono (linear) PEG or to branched (U) PEG in our studies such that examination of the influence of PEG geometry could also be included in our investigations. Release kinetics for either type of linker may be tailored by the inclusion of side chain groups strategically designed in the linker to provide either steric interference (for slower release) or anchimeric assistance (for faster release) to the degradation pathway, and we chose representative linkers from the two structural types that include a range of release kinetics.

For example, Scheme 1 depicts the linkage chemistry of the Bicin3-mono version and its proposed mechanism of release. The NHS-activated PEG (**1**) is conjugated to SS1P protein to form the bioconjugate (**2**). Decapping is very rapid in vivo to produce **3**, and the ester hydrolysis reaction proceeds at a rate determined by the molecular design of the linker side chains to produce **4**. Cyclization occurs via participation of both hydroxyethyl side chains, and linker detachment releases the original lysine(s) of SS1P plus the morpholinolactone (**5**). DGA2 and RNL-8a linker characteristics and release mechanisms have also been described (*40, 41*).

Protein bioconjugates with these rPEG polymers bonded to lysine residues are stable at pH <7 and release the original unmodified protein with release kinetics in the therapeutically useful range of hours to days, depending on linker design, polymer size, total number of PEG attachment sites, and pH of release medium. Figure 1 and Table 1 show the effects of pH on release kinetics. Following conjugation reactions, unmodified SS1P protein and free PEG polymers are removed from the PEGylated SS1P compounds by ion exchange chromatography and size exclusion chromatography. Both aromatic and aliphatic linker designs allow recovery of multi-PEGylated bioconjugates in >90% yields and provide the option of tailoring the number of PEG attachments through adjustments of reaction stoichiometry and purification protocols. Since both types of linkers have been successfully employed in reversible protein conjuga-

Chart 1. Structure of Activated PEG Polymers Composed Of Poly(ethylene glycol) Polymer, Releasable Linker, and *N*-Hydroxysuccinimide (NHS) Leaving Group[a]



[a] Amide or carbamate linkages to primary amines in conjugates of SS1P are formed at the linker carbonyl group proximal to the NHS ester. The mechanisms of controlled release of authentic native protein from the linker and PEG have been described for both the aromatic-based DGA2 and RNL-8a linkers (*40*, *41*) and the aliphatic Bicin3 linker (*39*, *44*).

tion, further comparative studies in animal models may be instructive to evaluate these individual chemistries.

We chose to focus our investigations on SS1P with an intermediate degree of rPEGylation, such that the number of PEG attachments and total PEG mass of most of the test compounds were comparable. In the design of the PEG−SS1P conjugates, a molecular mass mainly in the 40−60 kDa range was selected, since this strategy provided a practical compromise between optimizing the compound's pharmacokinetics and ensuring release of the SS1P before systemic clearance of the intact bioconjugate. Bioconjugates of this size will not exhibit rapid renal clearance, due to their sufficient total polymer mass. Therefore, the total numbers of PEG attachments were fewer for the large (40 kDa) PEG polymers than for smaller (12 kDa) PEG polymers. In addition, the use of branched linkers for PEG attachments allowed fewer total attachment sites for 12 kDa or 20 kDa linear PEGs, since the branched 40 kDa design tethers two 20 kDa linear PEGs to a common linker; similarly, the branched 24 kDa design contains two linear 12 kDa PEGs per linker. Multiple analytical methods were employed to characterize the composition of the multi-PEGylated SS1P compounds and confirmed batch consistency, as summarized in Table 1, using capillary electrophoresis, size-exclusion chromatography, chemical analysis of PEG, and SDS-PAGE. SS1P bioconjugates

Scheme 1. Example of the Chemistry of Conjugation and the Linker Decomposition in Vivo for the Bicin3-Mono Linker[a]

[a] Reaction of an activated PEG of the bicin linker type (**1**) with a protein amine forms the bioconjugate (**2**). In vivo, the acetyl group is rapidly lost, while the elimination reaction to release the PEG segment from (**3**) occurs at a controllable rate to produce (**4**). The final release of the original protein and morpholinolactone (**5**) is predicted to occur via a cyclization intermediate.

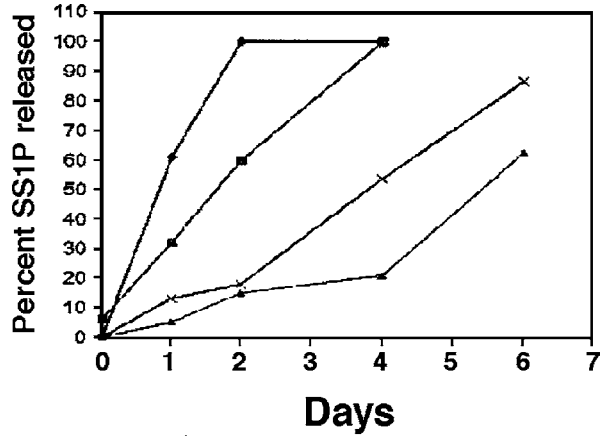


Figure 1. Comparison of release kinetics of four rPEG−SS1P compounds in PBS at pH 8.5, 25 °C: DGA2-12 kDa-PEG-SS1P (◆), Bicin3-U-24 kDa-PEG-SS1P (■), Bicin3-mono-30 kDa-PEG-SS1P (▲), and RNL-8a-12 kDa-PEG-SS1P (×). Release was monitored at 220 nm on SE chromatography on a TSK-gel, G4000SWXL column with a mobile phase of 50 mM sodium phosphate, pH 6.5, 140 mM NaCl, 0.5 mL/min. See Table 1 for release rates at pH 7.4.

with conventional permanent PEG polymers (SC-12k, ALD-20k, PEG_2-40k) (*48*) were further analyzed by MALDI-TOF, LC-MS, and reversed-phase chromatography.

Cytotoxic Activity of PEG−SS1P. A modified nonradioactive cytotoxicity assay was used for the SS1P immunotoxin and its PEGylated counterparts. The specific cytotoxicity (IC_{50}) of the immunotoxins was determined on A431-K5 cells, which highly express the target mesothelin surface protein (*4*, *23*). As shown in Table 1, the in vitro potency of the SS1P immunotoxin was markedly compromised by the random PEGylation strategies used in this study. SS1P conjugates bearing three or more permanent PEG attachments exhibited marginal or no activity in this bioassay. With conjugates derived from the site-selective PEG−aldehyde linkage, a single PEG attachment at one of the N-termini of the Fv subunits virtually eliminates in vitro bioactivity. Although releasable compounds such as DGA2-12 kDa-PEG-SS1P and Bicin3-24 kDa-PEG-SS1P, which also contain about 3−6 PEGs, retained some cytotoxic activity, this is attributed to the partial release of PEG during the incubation in cell culture. However, it is not uncommon for highly effective PEGylated protein therapeutics to exhibit fractional activity in vitro (*37*, *41*, *48*).

Pharmacokinetics of PEG−SS1P. BALB/c mice were injected i.v. at 100 μL per mouse with SS1P (0.125 or 0.4 mg/kg) or its PEGylated conjugates (0.5 or 1.5 mg/kg). Plasma concentration profiles of unmodified SS1P exhibited a rapid elimination with a half-life of about 26 min. In contrast, the plasma concentration profiles of DGA2-12 kDa-PEG and Bicin3-U-24 kDa-PEG bioconjugates demonstrated more complex elimination kinetics, as expected for these rPEG−SS1P compounds. As shown in Table 2, the plasma half-life, maximal concentration, and mean retention time of these two PEG−SS1P proteins were extended over 10-fold, while the time of maximal concentration was delayed from 30 min for SS1P to 2 h for the bioconjugates. Most significantly, the area under the plasma concentration curve (AUC) exposure of both rPEG−SS1P derivatives was increased about 80-fold compared to native SS1P. The PEG_2-40 kDa-PEG-SS1P compound contained a permanent amide linkage of only one PEG per SS1P. In comparison to native SS1P, prolonged blood residency was achieved, although not to the extent exhibited by the first three rPEG−SS1P derivatives (Table 2).

Animal Toxicity Studies. The nonspecific toxicity of the PEGylated immunotoxins in mice was examined by i.v.

Table 1. Features and Analysis of PEGylated SS1P and αCD22 Bioconjugates

compound	linker[a]	PEG mass on linker (kDa)	PEG # (AFTC/TNBS)[b]	PEG # (SEC/CE)	PEG # (PAGE)	SS1P release in vitro $t_{1/2}$[c](h)	IC_{50} (ng/mL)	flow cyt[d] (% of SS1P)

administration of 2.0, 3.0, 4.0, or 6.0 mg/kg. Almost all deaths occurred within 4 days of treatment. The enormous increase in drug exposure provided by the rPEGylated derivatives did not, however, correspond to an increase in animal toxicity. The LD_{50} of native SS1P was found to be about 1.0 mg/kg; in contrast, the PEG−SS1P compounds were much better tolerated. The LD_{50} values (mg SS1P protein/kg) for DGA2-12kDa-SS1P, Bicin3-U-24kDa-SS1P, and RNL-8a-12kDa-SS1P were 3.0, 3.0, and 4.0 mg/kg, respectively. For the antitumor studies, we employed one or two dose levels below the dose that produced sickness or death.

Antitumor Activity of Permanent or rPEG−SS1P. Antitumor activity of SS1P and PEG−SS1P compounds was determined in nude mice bearing A431-K5 human cancer cells that express mesothelin. Cells (3×10^6) were injected s.c. into nude mice on day 0. Tumors of ~140 mm^3 in size developed in animals by day 7 after tumor implantation, after which animals were treated with i.v. injections of each of the immunotoxin compounds. In most experiments, therapy with native SS1P or with the PEG−SS1P compounds was given only once on day 7. In some experiments, animals received PEG−SS1P twice on days 7 and 11 or SS1P three times on days 7, 9, and 11. The control groups received vehicle only. It was previously determined that SS1P inhibited tumor growth in a dose-dependent manner and that at least three doses of SS1P (0.5 mg/kg) were required to achieve regression in this mouse xenograft model (*4*, *23*). Usually three independent studies were conducted with each of the PEGylated compounds using two different preparations of the SS1P conjugates.

As shown in Figure 2A, DGA2-12 kDa-PEG-SS1P (D−SS1P) was extremely active. A single dose of 2.0 mg/kg produced 90% tumor shrinkage on day 14 and 3/6 mice showed complete tumor regression. Mice receiving two doses of D-SS1P also showed a profound antitumor response with 4/8 mice showing complete response and an average tumor size regression of 90% (Table 3).

As shown in Figure 2B, Bicin3-U-24 kDa-PEG-SS1P (B−SS1P) was also very active. Complete regression was achieved in 1/4 mice receiving 2.0 mg/kg and 3/4 mice receiving 3.0 mg/kg. In mice receiving two doses of 2.0 mg/kg, 4/8 mice showed complete regression of the tumors.

Figure 2C shows the antitumor effects of the Bicin3-mono-30 kDa-PEG-SS1P; it appeared to be somewhat less active than the first two compounds tested. At 3 mg/kg, a single dose caused a maximal decrease in tumor size of 68%, whereas two doses of 2.0 mg/kg caused an average decrease in size of 92% with 1/5 complete remission.

The other compound with a slowly reversible linkage that showed significant antitumor activity in a small pilot study is RNL-8a-12 kDa-PEG-SS1P. However, as shown in Table 3, it is less active than the other compounds.

Further antitumor investigations were carried out with permanent PEG derivatives, multi-PEGylated SC-12 kDa-PEG-SS1P and mono-PEGylated PEG_2-40 kDa-PEG-SS1P. Only the latter compound produced sustained regression with 1/4 of the mice showing complete regression at a dose of 3.0 mg/kg (Figure 3 and Table 3).

PEGylated proteins have also been reported to accumulate in tumor xenografts via passive targeting by the EPR effect due to the leaky vasculature and deficient lymphatic drainage exhibited by tumors (*45*, *46*). To investigate the capability of nontargeted rPEGylated immunotoxins to demonstrate antitumor effects, we generated analogous rPEGylated immunotoxins targeting CD22, which is not present on A431-K5 cells. These compounds showed no antitumor activity, confirming that the antitumor activities of the PEG−SS1P derivatives are specific.

Immunogenicity and Immunoreactivity of PEG−SS1P. Since the immune response of patients to immunotoxins may limit their duration of efficacy, we assessed the immunoreactivity of PEG−SS1P compounds relative to unmodified SS1P. Figure 4A shows the results of sandwich ELISA analysis of SS1P and several PEG−SS1P derivatives, in which plates coated with a mAb reacting with PE38 were exposed to increasing amounts of each conjugate and the amount of immunotoxin bound was detected with a rabbit polyclonal antibody to PE38. Cross-reactivity of the PEG−SS1P compounds to the rabbit anti-PE antibodies is diminished compared to native SS1P. Two independent preparations of SS1P exhibited equivalent strong immunoreactivity, while the two independent preparations of heavily PEGylated Bicin3-mono-30 kDa-PEG-SS1P demonstrated the weakest cross-reactivity. The N-terminally mono-PEGylated ALD-20 kDa-PEG-SS1P was strongly reactive with the anti-PE antibodies as expected due to PEG attachment on the Fv portion of the Fv-PE toxin. Other rPEGylated derivatives were intermediate in signal. This suggests a possible strategy for evading the rapid drug clearance in patients due to existing neutralizing antibodies.

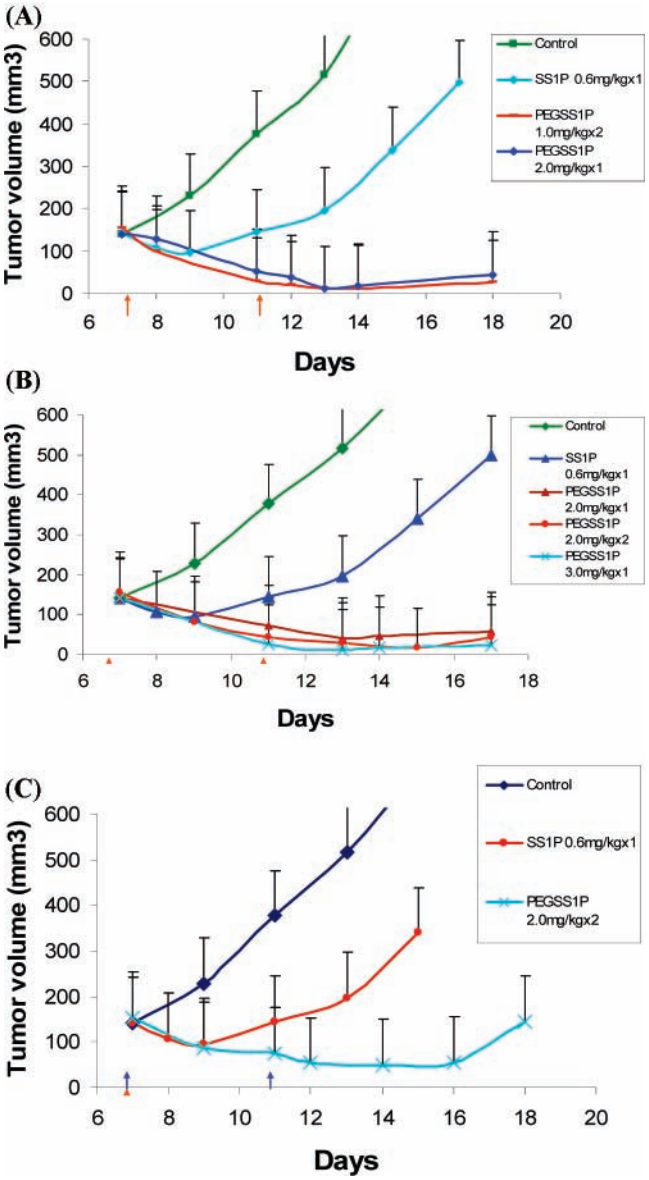

Figure 2. Antitumor effects of rPEG−SS1P and SS1P on A431-K5 solid tumors. Cells (3×10^6) were injected s.c. into nude mice on day 0. Starting on day 7 (tumor volume = ~140 mm^3), animals were treated with i.v. injections of each of the immunotoxin compounds at the indicated doses. Therapy with native SS1P or PEG−SS1P was given once on day 7. In an additional group, therapy with the PEG−SS1P compounds was given on days 7 and 11 (arrows). Control mice received vehicle only. All PEG−SS1P compounds are compared to SS1P (0.6 mg/kg × 1) administration and tumor volumes (mm^3) are shown (mean ± SD). (A) DGA2-12 kDa-PEG-SS1P (1.0 mg/kg × 2, or 2.0 mg/kg × 1). (B) Bicin3-U-24 kDa-PEG-SS1P (2.0 mg/kg × 1, 2.0 mg/kg × 2, or 3.0 mg/kg × 1). (C) Bicin3-mono-30 kDa-PEG-SS1P (2.0 mg/kg × 2).

To assess the immunogenicity of the PEG−SS1P compounds, BALB/c mice were immunized i.v. once per week with SS1P (2.5 μg/mouse) or PEG−SS1P (10 μg/mouse) for four weeks. Higher doses of unmodified SS1P could not be administered due to toxicity of the native toxin. Blood samples were collected every 7 days before subsequent immunization. The specific IgG and IgM levels were determined by capture ELISA. At day 28, IgM antibody levels were similar for SS1P and two rPEGylated derivatives; IgG antibody levels were also similar at day 28 for these compounds (data not shown). The mouse antisera were also investigated in cytotoxicity assays, and both the anti-SS1P and anti-PEG−SS1P antisera were determined to contain neutralizing antibodies. Although immunogenicity in mice does not predict human immunogenicity, these data do suggest that an immune response is not precluded in the current rPEG−SS1P compounds. The great increase in blood residency time of the PEG−SS1P compounds in mice might provide an increased opportunity for development of an immune response.

Table 3. Antitumor Effects of PEGylated SS1P Bioconjugates

compound	dose	day of best response	% decrease in size	CR	mice/ group
DGA2-12k-SS1P	1.0 mg/kg × 2	13	92%	4/8	8
DGA2-12k-SS1P	2.0 mg/kg × 1	13	92%	3/6	6
Bicin3-U-24k-SS1P	2.0 mg/kg × 1	13	78%	1/4	4
Bicin3-U-24k-SS1P	2.0 mg/kg × 2	13	92%	4/8	8
Bicin3-U-24k-SS1P	3.0 mg/kg × 1	11	92%	3/4	4
Bicin3-mono-30k-SS1P	2.0 mg/kg × 2	13	68%	1/5	5
Bicin3-mono-30k-SS1P	3.0 mg/kg × 1	13	68%	0/2	2
RNL-8a-12k-SS1P	2.0 mg/kg × 1	14	73%	0/2	2
RNL-8a-12k-SS1P	4.0 mg/kg × 1	14	89%	1/2	2
SC-12k-SS1P	1.0 mg/kg × 1	4	51%	0/2	2
SC-12k-SS1P	2.0 mg/kg × 1	5	38%	0/2	2
PEG_2-40k-SS1P	2.0 mg/kg × 1	12	64%	0/4	4
PEG_2-40k-SS1P	3.0 mg/kg × 1	14	86%	1/4	4
positive control: SS1P	0.6 mg/kg × 1	9	32%	0/5	5
negative control: no SS1P	none	none	none	0/20	20

To assess the cross-reactivity of PEG-SS1P and native SS1P to human antibodies versus SS1P, antisera were collected from two patients undergoing SS1P therapy and analyzed in competition ELISA as shown in Figure 4B. Human antisera were mixed with dilutions of either SS1P or PEG−SS1P and then added to SS1P coated plates. The detection reagent was rabbit anti-human IgG (HRP conjugate). The permanent or rPEG−SS1P compounds demonstrated cross-reactivity to the anti-SS1P human antibodies, although the PEG−SS1P compounds exhibited a one- to two-log reduced binding efficiency in this competition immunoassay when compared to native SS1P. These data support the hypothesis that PEG−SS1P may be less prone to rapid clearance in patients with existing antibodies to the SS1P protein.

Target Binding and Uptake of PEG−SS1P. To assess the bioactivity of the PEG−SS1P derivatives in (1) mesothelin binding, (2) cell surface mesothelin binding, and (3) cell uptake and processing, we performed several studies. For the DGA2-12 kDa-PEG-SS1P (D−SS1P) and Bicin3-U-24 kDa-PEG-SS1P (B−SS1P), a determination of K_D, k_{on}, and k_{off} were performed

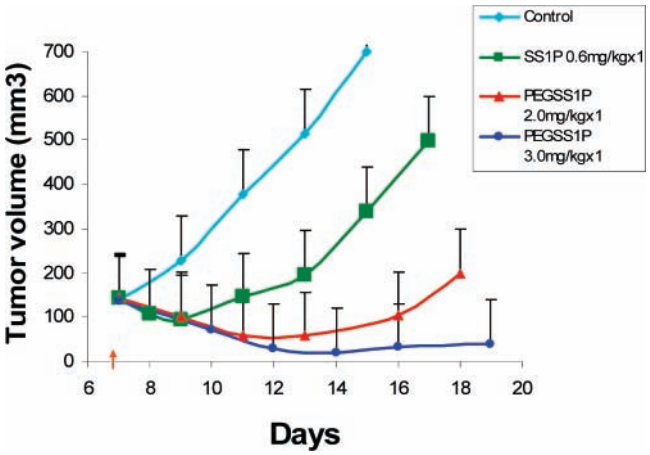

Figure 3. Antitumor effects of PEGylated SS1P with a nonreleasable linker on A431-K5 solid tumors. Cells (3×10^6) were injected s.c. into nude mice on day 0. Starting on day 7, animals were treated with i.v. injections of the immunotoxin compounds (arrow). Therapy with native SS1P (0.6 mg/kg × 1) was given once on day 7; therapy with the PEG_2-40 kDa-PEG-SS1P compound was given once at day 7 (2.0 mg/kg or 3.0 mg/kg). Control mice received vehicle only. Tumor volumes (mm^3) are shown (mean ± SD).

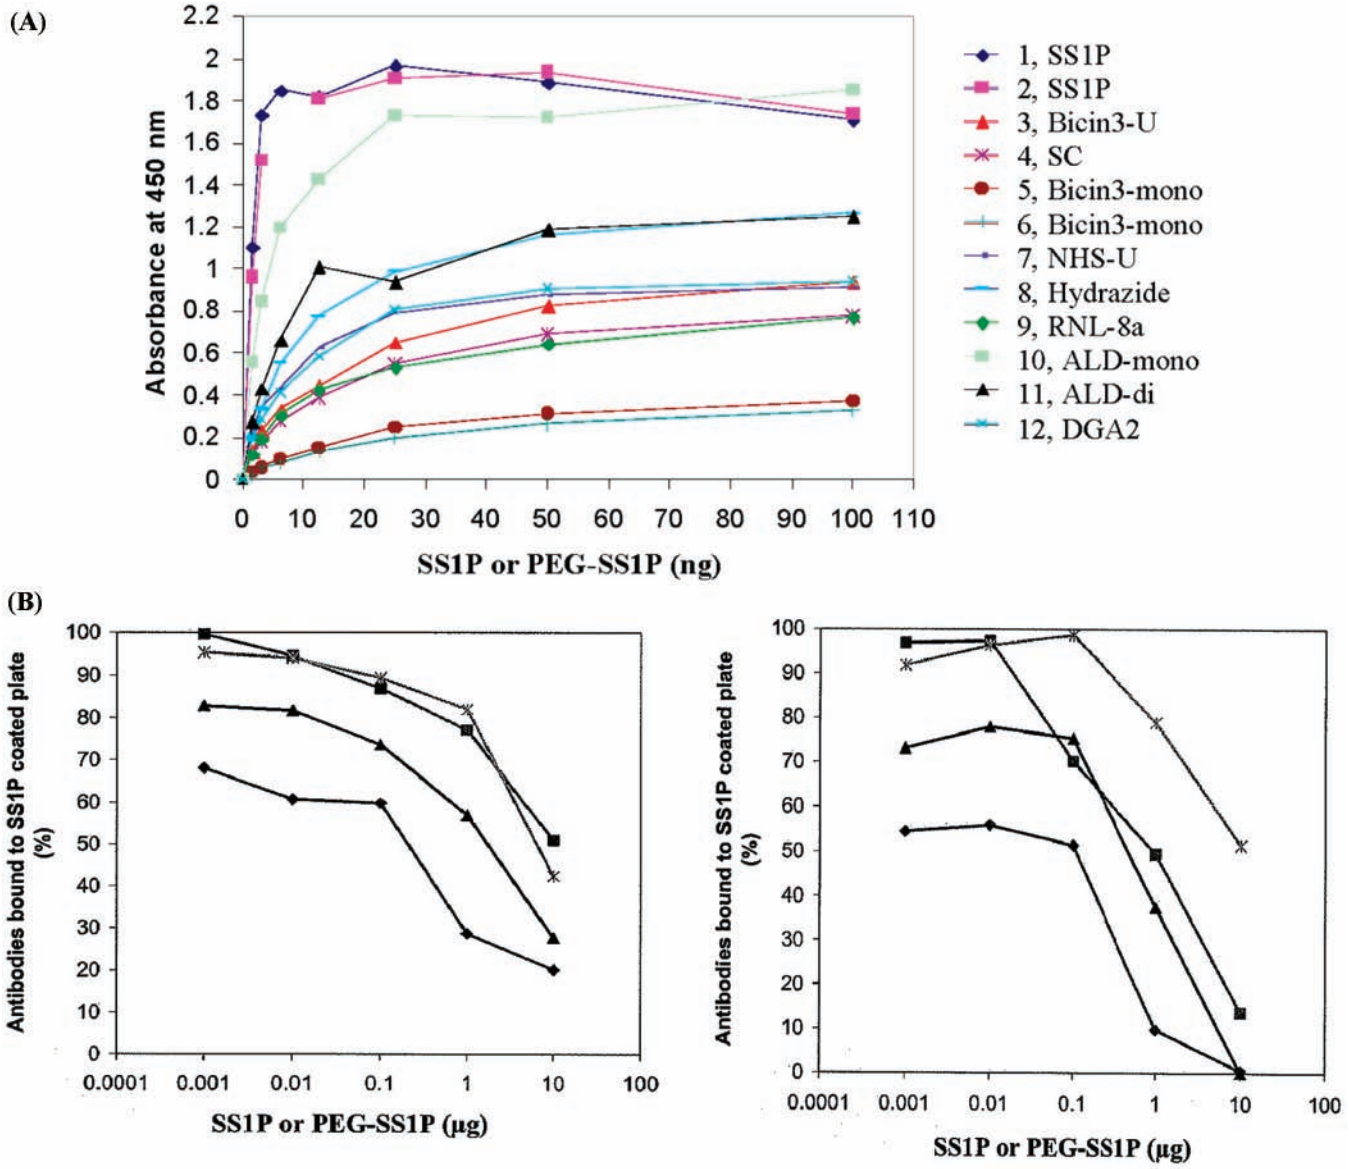

Figure 4. Immunoreactivity of PEG−SS1P. (A) Antigenicity of PEG−SS1P compounds was evaluated by sandwich ELISA. The ELISA plate was coated with mouse monoclonal anti-PE antibody. Different concentrations of SS1P or PEG−SS1P conjugate were added, and rabbit polyclonal anti-PE antiserum (1:40 000 dilution) was added as the primary antibody reagent, while HRP conjugated goat anti-rabbit IgG (1:5000 dilution) and TMB were the secondary reagents. Absorbance was read at 450 nm. The 12 compounds are numbered: (1) native SS1P, lot #1; (2) native SS1P, lot #2; (3) Bicin3-24 kDa-PEG-SS1P; (4) SC-12 kDa-PEG-SS1P; (5) Bicin3-mono-30 kDa-PEG-SS1P, lot #1; (6) Bicin3-mono-30 kDa-PEG-SS1P, lot #2; (7) PEG_2-40 kDa-PEG-SS1P; (8) hydrazide-12 kDa-PEG-SS1P; (9) RNL-8a-12 kDa-PEG-SS1P; (10) ALD-mono-20 kDa-PEG-SS1P; (11) ALD-di-20 kDa-PEG-SS1P; and (12) DGA2-12 kDa-PEG-SS1P. (B) (left) Cross-reactivity of human anti-SS1P serum to PEG−SS1P (patient #1). Plates were coated with 1 μg SS1P/50 μL per well. Human antiserum (1:40 000 dilution) versus SS1P was mixed with serial dilutions of SS1P or PEG−SS1P compounds (based on μg protein) and added to the wells (25 °C, 1.5 h). Following incubation and washing, HRP conjugated rabbit anti-human Ig was added to each well. Following incubation and washing, 100 μL TMB-E substrate were added, and the plates were read immediately at 450 nm. Native SS1P (◆), DGA2-12 kDa-PEG-SS1P (■), PEG_2-40 kDa-PEG-SS1P (▲), and SC-12 kDa-PEG-SS1P (∗) were included in the analysis. (right) Cross-reactivity of human anti-SS1P serum to PEG-SS1P (patient #2, 1:4000 dilution).

by Biacore analysis. The high-affinity SS1P (K_d = 0.7 nM) demonstrated diminished affinity in the D−SS1P (K_d = 39.5 nM) and B−SS1P (K_d = 8.1 nM) derivatives. In agreement with prior studies on PEGylated Fv compounds (*49*, *50*), this was largely the consequence of a reduction in association rate. For SS1P, $k_{on} = 1.1 \times 10^6$ M^{-1} s^{-1}, while the D−SS1P and B−SS1P derivatives have k_{on} rates of 6.3×10^3 M^{-1} s^{-1} and 6.4×10^4 M^{-1} s^{-1}, respectively. Dissociation rates (k_{off}) were relatively conserved among the compounds, SS1P (8.3×10^{-4} s^{-1}), D−SS1P (2.5×10^{-4} s^{-1}), and B−SS1P (5.1×10^{-4} s^{-1}). It is noteworthy that on-rates of a binding molecule are concentration-dependent, whereas off-rates are not. Hence, the attached PEG strands may in effect diminish the dynamic concentration of binding competent molecules available for association with their target.

Flow cytometry investigations were conducted with the PEG−SS1P compounds to evaluate their cell surface binding to A431-K5 cells. SS1P and PEG−SS1P compounds at equimolarity were incubated with the cells, and mouse anti-PE mAb was added, followed by phycoerythrin-conjugated goat anti-mouse polyclonal antibody. A shift toward low fluorescence intensity indicates reduced binding of PEG−SS1P to the cells. These flow cytometry results (Figure 5) correlate with the determined IC_{50} values from the cytotoxicity analysis (see Table 1). For example, SS1P demonstrated maximal cell binding and maximal cytotoxicity (IC_{50} = 0.7 ng/mL) in these analyses,

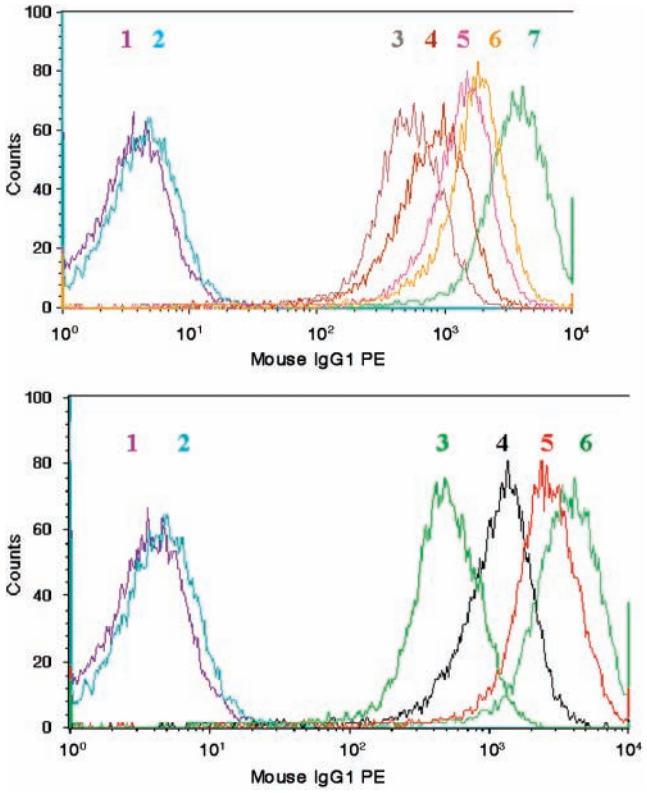

Figure 5. Flow cytometry analysis following PEG−SS1P binding to A431-K5 cells. In flow cytometry studies, A431-K5 cells were incubated with PEG−SS1P compounds prior to addition of mouse anti-PE mAb and phycoerythrin-conjugated goat anti-mouse polyclonal antibody for analysis on FACS Calibur. A shift toward low fluorescence intensity indicates reduced binding of PEG−SS1P to the cells. Cell populations are shown (upper graph): (1) cells without anti-mouse Ab fluorescence labeling, (2) without SS1P, with labeled anti-mouse Ab, (3) with di-PEGylated ALD-20 kDa-PEG-SS1P, (4) with mono-PEGylated ALD-20 kDa-PEG-SS1P, (5) with mono-PEGylated NHS-40 kDa-PEG-SS1P, (6) with mono-PEGylated SC-20 kDa-PEG-SS1P, and (7) with native SS1P; or (lower graph): (1) as above, (2) as above, (3) with DGA2-12 kDa-PEG-SS1P, after 16 h in vitro PEG release, (4) with DGA2-12 kDa-PEG-SS1P, before PEG release, (5) with DGA2-12 kDa-PEG-SS1P, after 4 h in vitro PEG release, and (6) with native SS1P.

whereas the mono-PEGylated ALD−PEG−SS1P (IC_{50} = 39 ng/mL) and di-PEGylated ALD−PEG−SS1P (IC_{50} = 310 ng/mL) demonstrated decreasing cell binding with PEG attachments. Two independent preparations of PEG_2-40 kDa-SS1P compounds were intermediate in IC_{50} and in cell binding in this comparison. As shown in Figure 5 (lower graph), SS1P exhibited maximal binding, while DGA2-12 kDa-PEG-SS1P (IC_{50} = 2.1 ng/mL) showed reduced cell binding. Upon 4 h of in vitro pH 8.5 hydrolysis of the PEG linkage and release of native SS1P, both the cytotoxicity (IC_{50} = 0.93 ng/mL) and the degree of cell binding increase together. However, following prolonged hydrolysis at pH 8.5, the immunotoxin partially denatures as revealed by both a decrease in cytotoxicity (IC_{50} = 30.2) and diminished cell binding by flow cytometry.

Overall activity is a function of the efficiency of intracellular processing of the PEG−SS1P compounds as well. To investigate the immunotoxin processing of PEG−SS1P from binding through subcellular localization, we used a fluorescein-linked 5 kDa NHS−PEG, which forms a permanent amide linkage in conjugation with SS1P. Mono-PEGylated conjugates were purified and characterized. Although the fluorescein−PEG conjugated SS1P exhibited stronger cell binding by flow cytometry than any of the rPEG−SS1P compounds (data not shown), it demonstrated essentially no in vitro cytotoxicity (IC_{50} >1000 ng/mL). We used fluorescence microscopy (Figure 6) and differential interference contrast (DIC) microscopy (data not shown) to investigate the subcellular localization of this fluorescein-labeled PEG−SS1P compound after incubation with A431-K5 cells in vitro. Figure 6 shows phase contrast, fluorescence, and merged microscopic analysis of cellular uptake and subcellular localization. The images revealed an efficient uptake of the compound by A431-K5 cells and localization mainly in the endosomal/lysosomal compartment in the perinuclear area of the cytoplasm, probably as a consequence of the interference of the dye moiety in correct protein processing and trafficking. Control cells (A431), which do not exhibit cell surface expression of mesothelin, demonstrated no cellular uptake of the fluorescein-labeled PEG−SS1P compound. Therefore, as expected, SS1P bioconjugates must maintain at least two general biological functions for efficacy, both cell binding and intracellular processing.

DISCUSSION

We describe macromolecular engineering of recombinant immunotoxin SS1P through employment of rPEGylation. Four rPEGylated designs were investigated wherein three to five large PEG polymers were linked to SS1P via releasable linkers. The rPEG−SS1P compounds exhibited prolonged blood residency time and greatly expanded AUC therapeutic exposure while reducing the nonspecific toxicity of the immunotoxin. A major achievement of this program was a substantial improvement in antitumor efficacy demonstrated by the rPEG−SS1P compounds. For the first time, complete remissions of established mesothelin-expressing tumor xenografts were observed in mice with single-dose administration of rPEG−SS1P conjugates. The significant increase in a therapeutic window for rPEG−SS1P may offer clinical advantages for the use of immunotoxins in cancer patients.

Bioconjugation of proteins with PEG via permanent linkages is a well-developed technology employed in marketed PEGylated protein therapeutics and numerous experimental compounds (*37*, *48*). PEG attachments to proteins have significant benefits in prolonging the in vivo activity of proteins by impeding the rapid clearance of proteins from renal filtration, antibody or cellular recognition, or physical degradation. Although an extensive surface modification of proteins, especially foreign proteins, by multiple PEG strands is often preferred in development of PEGylated protein drugs, this strategy can be limited by the reduction or elimination of biological activity of the PEG protein. Recent methods in PEGylation technology have focused on designing a composite bioconjugate using both protein engineering and improved chemical linkages (*13*, *36*, *42*). Site-specific attachments of PEG polymer strands may afford better retention of bioactivity, while minimizing the heterogeneity of the conjugates. However, some unwanted polymer-derived effects may still be encountered either in formulation or in pharmacological outcomes. Therefore, our recent research has examined the potential development of rPEGylation, wherein covalent attachments of strands of PEG polymers are shed via a controlled release mechanism derived from a degradable linkage at the attachment site on the protein surface (*39*, *40*, *44*).

The immunotoxin SS1P must maintain target binding, protein translocation/processing, and enzymatic ADP-ribosylating activities to be an effective therapeutic. These requirements challenge conventional PEGylation approaches. First, random permanent attachment of one large polymer (or a few small polymers) to the protein will likely compromise one or more of these functions while providing suboptimal surface shielding from antibodies. Second, permanent site-specific attachments of PEG will also reduce biological activity and may drastically reduce yields during manufacturing. In contrast, employment

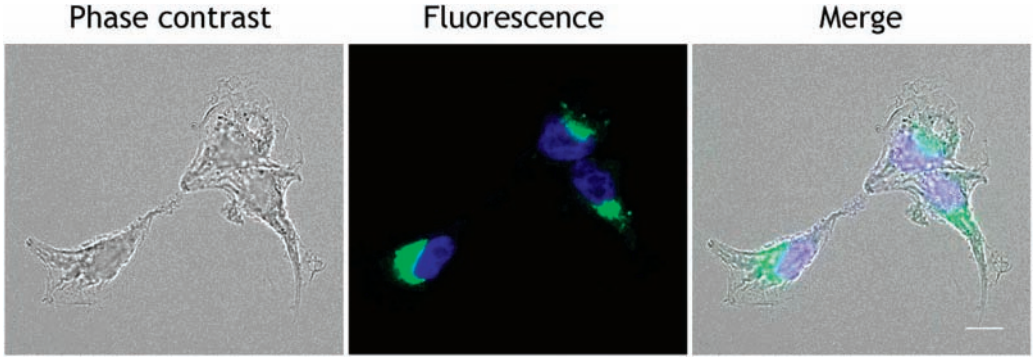

Figure 6. A431-K5 cellular internalization studies with 20 nM fluorescein labeled 5 kDa-PEG-SS1P in vitro (16 h). Phase contrast, fluorescence, and merged microscopic images are shown with 10 μm scale bar (lower right) with fluorescein in green and the nucleus stained blue with DAPI.

of rPEGylation may allow widespread modification of the protein while actually simplifying purification, since the heavily PEGylated proteins are readily purified from native protein. While such formulations of SS1P are heterogeneous, the end product is homogeneous and corresponds to the original unmodified SS1P, which is regenerated in vivo. Although this strategy does add complexity to the analysis of in vivo biodistribution, pharmacokinetics, and pharmacodynamics, the overall benefits in increased antitumor efficacy and diminished toxicity, suggested by our present work, support rPEGylation as an important new platform technology for immunotoxins and related therapeutics. Further studies on the biodistribution of the PEG−SS1P compounds may provide insight into the differential deposition of the immunotoxin in tumors and major organs. However, the design of these labeled conjugates may be more complex than the recently reported biodistribution study of ^{111}In-labeled SS1P, which also used a conjugation method for the radioisotope complex (*51*).

Immunogenicity is a central concern in the development and drug monitoring of protein therapeutics, including PEGylated proteins. Binding antibodies and neutralizing antibodies are commonly encountered. Clinical experience with SS1P has revealed the eventual development of neutralizing antibodies in most patients. It is uncertain whether our current rPEG−SS1P can completely overcome this problem. Immunized mice did develop neutralizing antibodies against SS1P following prolonged administration of rPEG−SS1P compounds. While these animal results are not predictive of outcomes in patients, it may be challenging to completely abolish the immune response to the SS1P conjugates in humans. In this context, however, two PEGylated nonhuman protein drugs, ADAGEN and ONCASPAR, have been administered to patients successfully over multiple cycles, despite the occurrence of antibody responses in several of these patients. Either animal or human antisera against SS1P bind much less efficiently to the PEG−SS1P compounds, suggesting that PEG−SS1P compounds will have a lower in vivo clearance in patients as a result of binding or neutralizing antibodies.

We also utilized multiple physical and functional assays to evaluate the composition, stability, and activities of the rPEG−SS1P conjugates. From flow cytometry and cytotoxicity investigations, we established a correlation between the efficiency of target binding by the SS1P derivatives and their in vitro IC_{50} values. However, using fluorescence and DIC microscopy, we also demonstrated that uptake alone of a fluorescein labeled PEG−SS1P conjugate does not guarantee correct intracellular processing. In this instance, it is proposed that the PEG−dye moiety, while permitting internalization, interferes with the biological release mechanism of the toxin. We further observed that in vitro binding or activity assays are inadequate to predict efficacy in vivo of the rPEG−SS1P, since the controlled release of the active drug is not fully revealed in vitro. rPEG−SS1P may acquire full bioactivity in vivo following programmed release.

An intrinsic feature of recombinant immunotoxins is target-specific delivery. In juxtaposition to active targeting, the phenomenon of passive targeting of drugs via the EPR effect has been shown to offer significant drug accumulation in tumors (*45*, *46*). PEG modification is one common approach to exploiting the EPR effect (*45*). Therefore, we wished to determine the extent to which an analogous nontargeted immunotoxin would produce antitumor responses in the mesothelin-expressing xenografts. An rPEGylated dsFv-PE immunotoxin, which binds CD22, was prepared with equivalent linkers and PEG attachments and investigated in the A431-K5 xenograft model. No antitumor effects were observed. These results suggest a pivotal role of active targeting via mesothelin binding and internalization for the antitumor effects of the PEG−SS1P bioconjugates.

In summary, rPEGylation of mesothelin-targeted immunotoxin SS1P greatly improves antitumor efficacy while decreasing nonspecific toxicity. The further co-development of protein engineering and bioconjugate technologies may provide superior immunotoxins with tailored pharmacological properties.

ACKNOWLEDGMENT

This research was supported in part by the Intramural Research Program of the NIH, National Cancer Institute, Center for Cancer Research. We thank Steve Youngster, Diane Chang, Qing Dong, and Michelle Boro for performance of SE-HPLC, RP-HPLC, and endotoxin analysis. We are grateful to Mary Mehlig and Virna Borowski for performance of mouse PK and immunogenicity studies. We are also grateful to Jack Lipman and Ivan Horak for critical review of the manuscript.

Received October 9, 2006; Revised Manuscript Received February 1, 2007

Identification of a tumor angiogenesis specific ligand would allow targeting of tumor vasculature. Lipidic vehicles can be used to deliver therapeutic agents for treatment of disease or contrast agents for molecular imaging. A targeting ligand would allow specific delivery of such formulations to angiogenic sites, thereby reducing side effects and gaining efficiency. Anginex, a synthetic 33-mer angiostatic peptide, has been described to home angiogenically activated endothelium, suggesting an ideal candidate as targeting ligand. To investigate this application of anginex, fluorescently labeled paramagnetic liposomes were conjugated with anginex. Using phase contrast and fluorescence microscopy as well as magnetic resonance imaging (MRI), we demonstrate that anginex-conjugated liposomes bind specifically to activated endothelial cells, suggesting application as an angiogenesis targeting agent for molecular targeting and molecular imaging of angiogenesis-dependent disease.

INTRODUCTION

Lipid-based vesicles, such as liposomes, can be used as therapeutic vehicles for transport, e.g., drugs, DNA, proteins/peptides, and antibodies (*1*, *2*), or for diagnostic purposes such as the delivery of MRI contrast agents (*3*). However, liposomes have a relatively short circulation time because they are taken up by the mononuclear phagocyte system (MPS) (*4*−*6*). In order to increase their circulation time, hydrophilic carbohydrates or polymers (e.g., PEG) can be included in the lipidic formulation which prevents rapid clearance and uptake by MPS (*7*). Moreover, the use of pegylated lipids with distal functional moieties such as maleimide allows the conjugation of targeting ligands to the liposomes. Targeted liposomes enhance the specificity and efficiency of treatment which may result in a higher therapeutic success rate and in reduction of undesirable side effects (*8*). An important requirement for successful targeted delivery is the specificity of the ligand/receptor pair for the site of interest. For example, we have previously demonstrated that a RGD−peptide functions as a targeting ligand for integrin $\alpha v\beta 3$ which can be used to target liposomes specifically to angiogenically activated endothelial cells (*9*).

Angiogenesis, i.e., the outgrowth of new vessels from pre-existing vasculature, is a prerequisite for tumor growth and metastasis (*10*, *11*). The tumors' dependence on this process, together with the observation that the endothelial cells that mediate the vessel growth change the expression of specific cell surface-related molecules (*12*), makes tumor angiogenesis receptive for targeted treatment strategies. We have previously described the (33-mer) synthetic angiostatic peptide anginex that inhibits migration and proliferation of activated EC *in vitro* (*13*, *14*) and exerts a strong antitumor response *in vivo* without affecting physiological angiogenesis (*15*). It has been demonstrated that fluorescently labeled anginex specifically homes to tumor vasculature (*15*, *16*). Recently, we identified galectin-1 as the main receptor of anginex on activated endothelial cells (*17*).

In the clinical oncology field there is a need for targeting ligands that allow more specific therapy and can be used for noninvasive imaging techniques (*18*). Using tumor angiogenesis markers for targeting, noninvasive imaging would allow more accurate diagnosis and monitoring of angiogenic development and the effect of angiostatic treatment (*19*, *20*). On the basis of our observations, we hypothesized that anginex is an excellent ligand for targeting of therapeutic or diagnostic liposomes to activated endothelial cells in the tumor vasculature. To test this hypothesis, we conjugated anginex to fluorescently labeled and paramagnetic liposomes. The endothelial cell specificity of the anginex−liposome conjugates was confirmed on human umbilical vein endothelial cells (HUVEC) and an immortalized endothelial cell line (EVL-C2). In addition, we were able to demonstrate, by microscopic analysis and by MR imaging, that anginex-conjugated liposomes specifically bind to and are taken up by activated endothelial cells, making them attractive vehicles for targeted delivery or diagnostic use in the treatment of disease.

MATERIALS AND METHODS

Materials. 1,2-Distearoyl-*sn*-glycero-3-phosphocholine (DSPC), cholesterol (Chol), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(polyethylene glycol)-2000] (PEG2000−DSPE), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[maleimide(polyethylene glycol)2000] (Mal-PEG2000−DSPE), and 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (rhodamine-PE) were obtained from Avanti Polar Lipids (Albaster, AL). Gd-DTPA−bis(stearylamide) (Gd-DTPA−BSA) was purchased from Gateway Chemical Technology (St.Louis, MO). HEPES was obtained from Merck (Darmstadt, Germany). All other chemicals were of analytic grade or the best grade available. Polycarbonate filters for liposome extrusion were from Costar (Cambridge, MA).

Peptide Synthesis. Anginex with an additional cysteine at the N-terminal site was synthesized using a Milligen/Biosearch 9600 peptide solid-phase synthesizer using Fmoc chemistry. Lyophilized peptides were purified by preparative reversed-phase HPLC on a C18 column with an elution gradient of 0−60% (v/v) acetonitrile with 0.1% (v/v) trifluoroacetic acid in water. Purity and composition of the peptides were verified by HPLC (Beckman Model 6300) analysis of amino acid composition of hydrolysates prepared by treating the peptides under argon in 6 N HCl for 24 h at 110 °C. The amino acid sequences of peptides were confirmed by N-terminal sequencing and mass spectometry. As described before, the cyclic 5-mer RGD peptide (c(RGDf(-S-acetylthioacetyl)K)) was synthesized at a purity of 95% by Ansynth Service BV (*9*).

Liposome Preparation. Liposomes were prepared by lipid film hydration. A mixture of the appropriate amounts of lipids (typically 100−200 μmol of total lipid) was dissolved in chloroform/methanol 1:1 (v/v) and evaporated to dryness by rotary evaporation at 40 °C. For the paramagnetic PEG liposomes that were used to couple RGD or anginex peptides covalently to the distal end of the PEG chains, Gd-BSA, DSPC, cholesterol, PEG2000−DSPE, and Mal-PEG2000−DSPE were mixed at a molar ratio of 0.75/1.10/1/0.075/0.075. For fluorescence microscopy, 0.1 mol % of rhodamine−PE was added. The lipid film was subsequently hydrated in 3 mL of HEPES-buffered saline (HBS), containing 20 mM HEPES and 135 mM NaCl (pH 6.5). The resulting lipid dispersion was extruded sequentially six times through polycarbonate membrane filters with a pore diameter of 400 nm and subsequently 10 times through filters with a pore diameter of 200 nm using a Lipofast Extruder (Avestin, Canada). The temperature during extrusion was 65 °C.

Peptide Coupling to Liposomes. The cyclic 5mer RGD (c(RGDf(-S-acetylthioacetyl)K)) and anginex were conjugated to the liposomes by sulfhydryl-maleimide coupling maleimide-PEG−DSPE. Acetyl-protected RGD−peptide was deacetylated in 0.05 M HEPES/0.05 M hydroxylamine-HCl/0.03 mM ethylenediamine tetraacetic acid (pH 7.0) for 1 h at room temperature (*21*). The activated peptide was added to the Mal-PEG2000−DSPE-containing liposomes in a 3 μg peptide/μmol lipid ratio. Anginex, synthesized with a C-terminal cysteine, was dissolved in water and added to the liposomal solution (10 μg peptide/1 μmol lipid). Coupling of both peptides was allowed overnight at 4 °C, and uncoupled peptide was separated from the liposomes by centrifugating at 200 000*g* with a Beckman OptimaTM LE-80K ultracentrifuge and a Ti70 fixed angle rotor for 60 min. The liposomes were respectively conjugated with ~700 cyclic RGD moieties and ~125 anginex moieties per particle. The supernatant was removed, and an appropriate amount of buffer, typically 1.5 mL, was added to the pellet to obtain a lipid suspension with a lipid concentration of ~40 mM (10 mM gadolinium). The final liposomal suspension was stored at 4 °C under N_2.

Cell Culture. HUVECs were isolated as described before (*22*). Isolated cells were cultured in gelatin-coated culture flasks (Costar) with RPMI1640 (Gibco) supplemented with 20% human serum, 2 mM L-glutamine (Gibco) and 50 U/mL penicillin/streptomycin (Life sciences). Immortalized endothelial cell line EVL-*C2* (*23*) was cultured under the same culture conditions as HUVEC. Cultures were incubated at 37 °C in the presence of 5% CO_2.

***In Vitro* Targeting of Endothelial Cells.** For all tested applications the initial steps were similar. Endothelial cells were cultured in gelatin-coated flasks to approximately 75% confluency (appoximately 1.5×10^6 cells) using standard culture conditions. Flasks were washed once with PBS before 4 mL of fresh culture medium was added. Anginex-conjugated, RGD-conjugated, and nonconjugated liposomes (150 μL of liposomes; total amount anginex 60 μg) were added to the cells and incubated in the CO_2 incubator at 37 °C for 3 h. Subsequently, liposome-containing medium was removed, the cells were washed with 14 mL of PBS, and fresh medium was added. The final wash step was skipped for the control cells. Finally, the association of the targeted and nontargeted liposomes with endothelial cells was assessed under a phase contrast fluorescence microscope (Leica), at 20× and 40× magnification. Experiments were carried out in triplicate. Competition experiments were performed with free anginex. To that end, anginex (3 mg/mL in MQ) was added to the medium to a final concentration of respectively 10 or 30 μg/mL (total anginex concentration respectively 60 and 180 μg) immediately before addition of the liposome solution.

Magnetic Resonance Imaging of Cell Pellets. For MRI imaging, cells were harvested using trypsine digestion and centrifuged for 5 min at 400*g*. The obtained cell pellet was washed with approximately 5 mL of culture medium. After a second centrifugation step, the cell pellet was fixed with 1% paraformaldehyde and put in small 200 μL tubes. MRI experiments were performed on fixed cell pellets using a 6.3 T horizontal bore magnet (Oxford Instruments Superconductivity, Eynsham, Oxon, England) interfaced to a Varian (Varian, Palo Alto, CA) VXR-S MRI console. A 3 cm quadrature-driven birdcage coil was used. The cups containing cell pellets were placed in a custom-made sample holder, capable of carrying four Eppendorf cups. Quantification of $T1$ was done with an inversion recovery spin−echo sequence with 13 different inversion times, ranging from 10 to 3100 ms in an exponential fashion. The MRI data analysis was performed using Mathematica 5.0 (Wolfram Research, Inc., Champaign, IL). $T1$ maps of HUVEC pellets were calculated in one slice through the pellet on a pixel-by-pixel basis. The $T1$ is reported as mean ± SD of the pixels in a circular region of interest (ROI) defined by the contour of the pellet. In Student's t tests, $P < 0.05$ was considered statistically significant.

RESULTS

We set out to test the applicability of anginex as a ligand to target liposomes to activated endothelial cells. To that end, fluorescent paramagnetic liposomes were prepared to allow parallel detection of the liposomes with optical methods as well as with MR imaging. Targeting specificity was introduced by covalently linking anginex containing a free cysteine via the thiol group to the maleimide group of the lipid Mal-PEG−DSPE (*24*). As a control, cyclic RGD was coupled as described previously (*9*). A schematic presentation of the ligand-conjugated liposomes is given in Figure 1.

To demonstrate specific binding to endothelial cells, cultured human umbilical vein endothelial cells (HUVEC) were incubated for 3 h with either anginex-conjugated liposomes or with bare liposomes. After liposome incubation and extensive washing, phase contrast microscopy revealed that only anginex-conjugated liposomes efficiently bound to the cell surface (data not shown). RGD-conjugated liposomes, used as a positive control, also bound the endothelial monolayer. Using fluorescence microscopy, the liposomes were visualized and were found to bind throughout the endothelial surface (Figure 2a, left and middle panel). Cells incubated with bare liposomes did marginally or did not show fluorescence signal (Figure 2a, right panel). Although small differences in morphology were visible between the three independent experiments due to different passage numbers, the binding or presence of the liposomes did not induce obvious changes in EC morphology or signs of apoptosis. At higher magnification, internalization of part of the conjugated liposomes was visible in vesicles (Figure 2b,

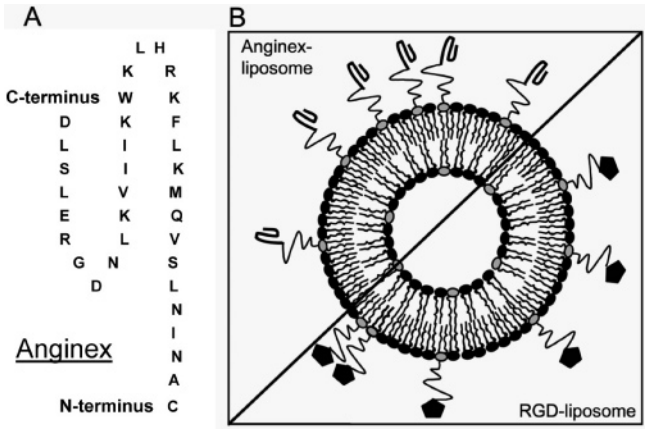

Figure 1. Schematic representation of (A) anginex and (B) paramagnetic liposomes conjugated to the peptides anginex and cyclic-RGD respectively. The black lipids represent Gd-DTPA-BSA and the gray lipids PEG−DSPE. Peptides are covalently conjugated to the maleimide group of Mal-PEG−DSPE.

middle panel). Addition of the nuclear stain 4,6-diamidino-2-phenylindole (DAPI) demonstrated that the liposomes did not enter the nucleus. Similar results were obtained with the RGD−liposome conjugates (data not shown)

To demonstrate that the interaction of the anginex−liposome conjugates with the HUVEC was mediated through anginex, a competition assay with free anginex was performed by adding anginex prior to incubation with the anginex−liposome conjugates. There was a clear concentration dependent inhibition of anginex−liposome binding following addition of free anginex (Figure 2c). At a concentration of 10 μg/mL, reduced fluorescence signal from the anginex−liposome conjugates was observed as compared to the situation in which no free anginex was added to HUVEC (Figure 2c, middle panel). In the case where cells were preincubated with 30 μg/mL anginex, almost no association of anginex−liposome conjugates with HUVEC was observed (Figure 2c, right panel). Comparable results were obtained with the endothelial cell line EVL-c2 (data not shown).

To test the applicability of anginex-targeted contrast agents, magnetic resonance imaging was applied to HUVEC incubated with paramagnetic conjugated liposomes. After 3 h of incubation with either anginex, RGD, or bare liposomes, HUVEC were washed twice and pelleted in small cups. As control nontreated cells were used. Visible inspection of the pelleted cells revealed an intense pink color in only anginex− and RGD−liposome-treated cells. Before imaging, all cells were fixed with 1% paraformaldehyde. MR imaging was performed on approximately 1.5×10^6 cells (Figure 3a). A quantitative *T*1-map, in which cells with a high concentration of contrast liposomes have a lower *T*1 than cells with a low concentration of contrast liposomes, was made of the various cell pellets. The *T*1-values of cell pellets that were incubated with anginex− and RGD−liposome conjugates had comparable values, which were significantly lower than the controls (Figure 3b). The *T*1 of the anginex pellet was 862 ± 41 ms and for RGD 1287 ± 33 ms, whereas control HUVEC and nonligand liposomes were respectively 2363 ± 88 ms and 1766 ± 30 ms. These data show that the level of association of the anginex−liposome conjugates, like that of the control RGD−liposome conjugates, is sufficient to be detected by MRI.

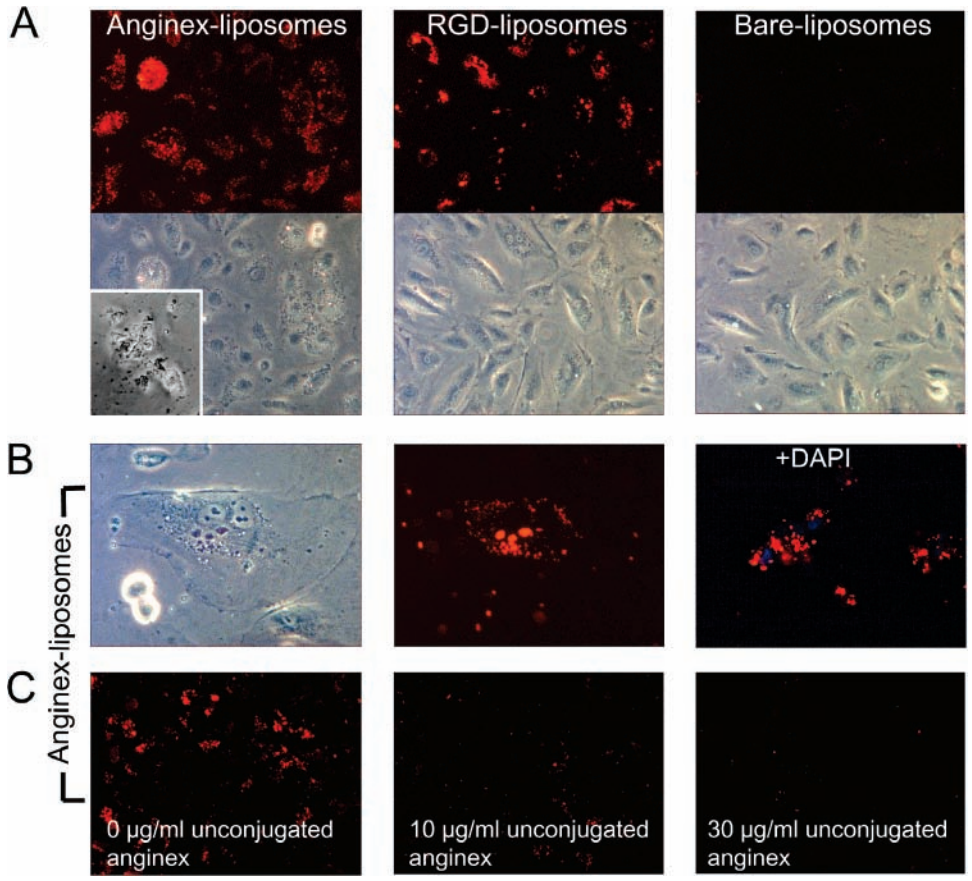
DISCUSSION

We hypothesized that anginex is an excellent ligand for targeted delivery of lipidic vehicles with therapeutic and/or contrast agents to activated endothelial cells in the tumor vasculature. In this study, we demonstrate that anginex can be conjugated to liposomes, and these conjugated liposomes indeed target to activated endothelial cells. Furthermore, we show that anginex-targeted paramagnetic liposomes can be used for MR imaging of activated endothelial cells *in vitro*.

To develop improved and new antitumor therapies, specific targets are needed to deliver drugs or contrast agents for imaging to the tumor without introducing toxic side effects or background signals. Tumor angiogenesis is a very suitable process for targeting because tumor growth and metastasis are dependent on angiogenesis. Furthermore, activated endothelial cell, which are the key players in this process, have a unique expression profile, are easily accessible, and are less prone to develop resistance against treatment. We previously described anginex, a *de novo*-designed small 33 amino acid angiostatic peptide, which is capable of inhibition of angiogenic endothelial cell migration and proliferation, subsequently leading to apoptosis. Additionally, anginex was shown to home specifically to tumor vasculature in a mouse model. To confirm the targeting qualities of anginex, we coupled the peptide covalently to maleimide moieties exposed at the distal end of PEG chains of liposomes. The applicability of these contrast-enhancing paramagnetic liposomes has already been demonstrated for the use of molecular MR imaging of endothelial cells *in vitro* using an E-selectin specific antibody and *in vivo* by using cyclic RGD−peptide as targeting unit (*9*, *24*). Similar to that for RGD, we observed binding of anginex−liposome conjugates to activated endothelial cells *in vitro*. Conjugated liposomes seemed to bind to all available endothelial cells, whereas using unconjugated liposomes hardly any binding was observed. This indicates a specific binding of the liposomes due to conjugation of the ligand, supporting the hypothesis of the applicability of anginex as a potent targeting ligand. Apparently, adding an additional cysteine to the N-terminus of anginex and linking it to a lipidic vehicle does not affect the binding of anginex to its receptor. This was expected since recombinant anginex, which has an extra N-terminal methionine is also fully active and retains the required β-sheet structure (*25*). Furthermore, addition of human serum albumin also has no influence on the *in vitro* activity of anginex (*26*). This is most likely due to the fact that the N-terminus is flexible and that the N-terminal amino acids are not required for the function of anginex (*14*, *27*).

An important prerequisite for targeting is the presence of a site-specific interaction molecule for the targeting ligand. For the RGD−liposome conjugates, this is the $\alpha v\beta 3$-integrin receptor (*28*). We recently identified galectin-1 as the main tumor endothelial cell-specific receptor for anginex (*17*). Galectin-1 expression is rapidly upregulated upon endothelial cell activation, and expression levels have been shown to be increased in the vasculature of different human tumors (*17*, *29*, *30*). This renders anginex/galectin-1 an excellent pair for targeting of liposomes to tumor vessels, which makes it an attractive target that can be used for diagnostic purposes in imaging.

Fluorescence microscopy revealed that a substantial part of the anginex-conjugated liposomes is internalized into the cell in perinuclear vesicles. This is consistent with galectin-1-mediated uptake of free anginex (*17*). This was confirmed in our competition experiment where increasing amounts of free anginex were able to inhibit binding and internalization of anginex−liposome conjugates , indicating an anginex-dependent binding of the anginex−liposome conjugates to HUVEC. The concentrations of free anginex in the competition experiments were based on the concentration needed to reach maximum therapeutic effect (40 μg/mL) (*13*). Considering that not all anginex molecules conjugated to the liposomes will be available for binding to the cell, we expected that the used concentrations



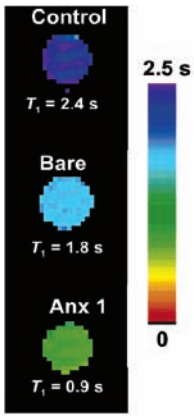


Figure 2. Fluorescence microscopy of HUVEC incubated with fluorescently labeled paramagnetic liposomes. Pictures are representative for all experiments. (A) HUVEC were incubated for 3 h with respectively anginex, RGD, and nontargeted liposomes. Insert: HUVEC undergoing apoptosis as a result of anginex treatment. (B) Perinuclear localization of anginex−liposome conjugates in one HUVEC cell shown by phase contrast and fluorescence image. Anginex−liposome conjugates do not enter the nucleus as shown by blue DAPI counter staining. (C) Competition of anginex−liposome conjugates with respectively 0, 10, 30 μg/mL free anginex.

HUVEC incubated with (n=2)	T_1(ms)
Control	2363 ± 88
Bare liposomes	1766 ± 30
RGD-liposomes	1287 ± 33
Anginex-liposomes	862 ± 41

Figure 3. *T*-1 weighted image of cells incubated with anginex, bare liposomes, or without liposomes. The *T*1 relaxation times of the different cell pellets are presented on the right.

would be sufficient to attain partial or complete blocking of anginex−liposome binding. Ultimate proof for receptor-mediated uptake of the anginex−liposome conjugates would be obtained in galectin-1 knockout endothelial cells. Indeed, tumors in galectin-1 knockout mice no longer respond to anginex treatment, suggesting that the binding of the anginex−liposome conjugates to HUVEC is anginex- and galectin-1-dependent.

To evaluate if anginex is also suitable as targeting ligand for MRI contrast agents, a quantitative *T*1-measurement was made of HUVEC pellets incubated with anginex-conjugated paramagnetic liposomes. As a positive control, RGD−liposome conjugates were used (*9*), and as negative control, bare paramagnetic liposomes or no liposomes were applied. Both conjugated paramagnetic liposomes were shown to bind specifically to endothelial cells. Furthermore, a clear difference in contrast was seen between ligand-conjugated liposomes and the controls leading to a significant difference in *T*1 values. The fact that the conjugated liposomes were internalized might also be a benefit for imaging. By internalizing the contrast agent, the concentration per cell can be elevated, revealing a brighter signal (*31*).

Besides diagnostic applications, anginex-targeted liposomes might be used as drug carrier. Therefore, water soluble drugs (e.g., doxorubicin) or even DNA constructs for gene therapy can be put inside the liposomal lumen (*32*, *33*). Thus, anginex-mediated targeting to tumor vasculature might be used to combine diagnosis and local therapy of cancer. However, for imaging, stabilization of liposomes is useful with drug delivery because the stability causes a slow release of the drugs. Another problem is the measurement of the amount of drugs released in the tissue. This can be solved by combining the drug and the contrast agent instead of loading drugs into liposomes with contrast-enhancing components in their bilayer (*34*, *35*). Nevertheless, preliminary data with contrast-enhancing liposomes loaded with doxorubicin show promising results *in vivo* (unpublished data).

Anginex is a potent angiostatic agent, and one of the main angiostatic characteristics of anginex is induction of apoptosis in activated EC. Although this might interfere with targeting, we have demonstrated that the induction of apoptosis by anginex occurs more than 48 h after administration (*13*). This is far beyond the time frame of targeting, suggesting that the induction

of apoptosis will not affect targeting. This is supported by the fact that other vascular targeting ligands, such as RGD−peptides, also induce endothelial cell apoptosis (*36*−*38*) without affecting their applicability as a targeting ligand (*39*, *40*).

Similar to that for apoptosis, the time frame of the experiments in this study did not allow us to investigate the effects of conjugated anginex on migration and proliferation (*41*). However, for imaging purposes, a possible effect will not influence the targeting ability and its function as a contrast agent.

In conclusion, we have demonstrated that the angiostatic peptide anginex is a potent ligand for the targeting of liposomes to activated endothelial cells. In addition, the *in vitro* results show a high specificity of the anginex-conjugated paramagnetic liposomes for endothelial cells that was confirmed by MRI. Therefore, anginex might serve as a targeting ligand for drug and gene therapy applications and for imaging of tumor vasculature in order to diagnose, treat, and monitor cancer.

Dendrimer conjugation with low molecular weight drugs has been of increasing interest recently for improving pharmacokinetics, targeting drugs to specific sites, and facilitating cellular uptake. Opportunities for increasing the performance of relatively large therapeutic proteins such as streptokinase (SK) using dendrimers are being explored in this study. Using the active ester method, a series of streptokinase−poly(amido amine) (PAMAM) G3.5 conjugates were synthesized with varying amounts of dendrimer-to-protein molar ratios. Characterization of these conjugates by GPC, IEC, and native-PAGE suggested that the conjugation reaction was successful, resulting in relatively pure SK−dendrimer conjugates. The conjugate made with an equimolar ratio of dendrimer to streptokinase (1:1) exhibited the highest enzymatic activity retention (∼80% retained) that has been reported so far for conjugated streptokinase with macromolecules such as PEG or dextran. SK conjugates with higher streptokinase-to-dendrimer molar ratios (1:10 and 1:20) exhibited lower initial enzymatic activities. However, these conjugates showed sustained thrombolytic activity in plasma, perhaps due to the release of SK from the conjugate. All of the SK conjugates displayed significantly improved stability in phosphate buffer solution, compared to free SK. The high coupling reaction efficiencies and the resulting high enzymatic activity retention achieved in this study could enable a desirable way for modifying many bioactive macromolecules with dendrimers.

INTRODUCTION

Acute thromboembolic events such as stroke, myocardial ischemia, pulmonary embolism, and deep vein thrombosis are major causes of increased morbidity. Of these, coronary artery disease and stroke account for 40% of all annual deaths in the U.S.A. Timely therapy is crucial for achieving adequate reperfusion to salvage the affected organ. Local or systemic infusion of thrombolytic agents is the most common treatment for clot dissolution. A number of clinical trials have demonstrated the benefits of thrombolytic treatment, especially in myocardial ischemia and stroke. Streptokinase (SK), a 47 kDa single-chain protein, was one of the first clinically used intravenous thrombolytic agents. The initial studies comparing streptokinase to a placebo in the 1980s were extremely influential in proving the benefits of the use of thrombolytic agents in myocardial ischemia. Streptokinase interacts with the circulating or clot-bound plasminogen to form a noncovalent, 1:1 stoichiometric complex capable of converting another plasminogen molecule to active plasmin (*1*−*4*). The latter degrades fibrin, the main component and skeleton of a clot network, leading to rapid lysis of intravascular clots. Though SK is a relatively inexpensive and effective thrombolytic agent, its clinical use is limited by its short *in vivo* half-life, immunogenicity, and high incidence of systemic bleeding, undermining its therapeutic efficacy (*5*). Due to the short plasma half-life of SK (30 min) (*6*), higher doses and continuous infusion of SK are often required for clinical treatment; this in turn increases the risk of bleeding and immune reactions. Over the past decade, a number of studies have concentrated on improving the efficacy, potency, ease of administration, and duration of action of thrombolytic agents, while trying to decrease the side effects. Development of new or modified thrombolytic agents with higher clot specificity, longer circulation time, and lower antigenicity still remains a challenge.

Strategies that have been attempted to improve the therapeutic efficacy of thrombolytic agents include attachment of polymers such as poly(ethylene glycol) (PEG) or polysaccharides (dextran) (*7*−*9*) and encapsulation in liposomes or microsomes (*10*). Attachment of SK to PEG appeared to decrease SK's antigenicity, thereby increasing its circulation time, but resulted in a 67% loss in its enzymatic activity. Conjugation of SK with dextran (MW 35−50 kDa) increased its circulation time to over 3 days, with a reduction in the hemorrhagic complications and allergic reactions associated with SK use (*8*, *11*, *12*). This conjugate had a 50% loss in enzymatic activity (*8*) and was less efficient than free SK in achieving fibrinolysis (*13*). Liposomal entrapment suffered from drawbacks such as poor stability, low entrapment efficiency (30% to small liposomes and up to 60% to large liposomes) (*14*, *15*), and a great loss in protein activity (5−15% activity retained), thus limiting its further application.

Recently, there has been a significant thrust to explore dendrimers as potential drug delivery vehicles. Dendrimers are monodisperse, branched polymers with highly reactive end functionalities (Figure 1) that can be used for covalent conjugation of drugs, ligands, and/or antibodies for targeted delivery of the drug to the site of action (*16*−*27*). Dendrimers have predominantly been conjugated to small molecules, rather than biological macromolecules. The few previous attempts to conjugate dendrimers with proteins have mostly focused on antibodies (*28*−*36*) using an amine-terminated dendrimer and relatively lengthy coupling procedures to introduce sulfhydryl

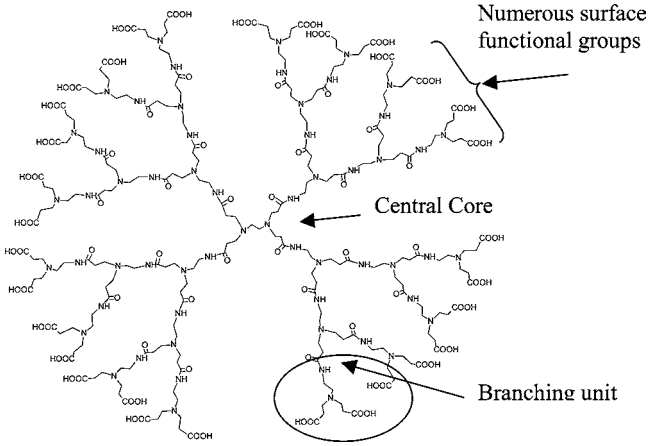

Figure 1. Dendritic structure with the core and branching units.

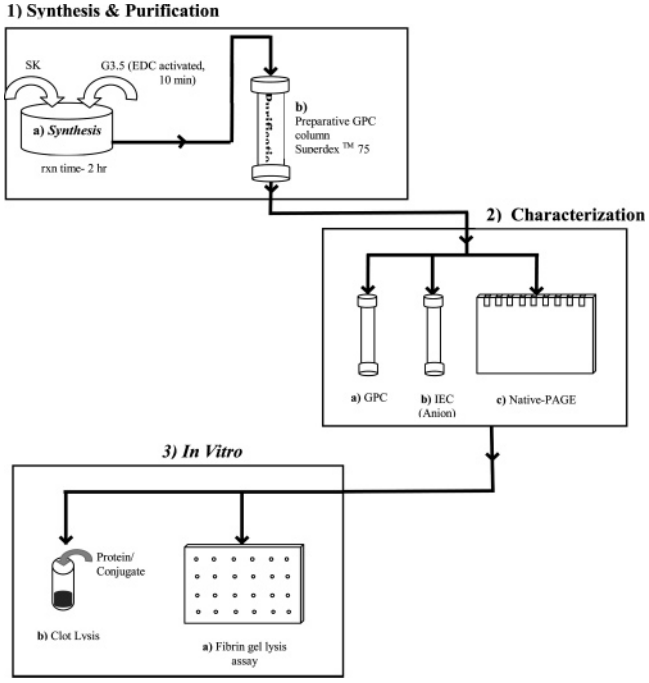
groups onto the dendrimer/protein. Nearly all of the conjugates maintained, to varying degrees, the binding specificity of the original antibody (*28*).



Unlike linear polymers such as PEG, we hypothesize that dendrimers, with their compact structure, may not wrap around proteins to mask the enzyme's active sites but might still increase the protein stability by occupying the antigen recognition sites. Therefore, conjugating SK with dendrimer may not only retain the enzymatic activity of the drug but also improve its stability by increasing its circulation time. Anionic dendrimers have been shown to have lower toxicity with a longer clearance time from the blood than cationic dendrimers (*37*−*40*). Hence, the commercially available starburst poly(amidoamine) (PAMAM) dendrimer of generation G3.5 (Figure 1) with an ethylenediamine core and peripheral carboxyl groups was used to attach SK (30). Our long-term goal is to utilize this novel dendritic nanodevice to achieve effective clot lysis while minimizing immunogenicity and the risk of bleeding. As a first step toward this goal, dendrimer−SK conjugates with varying SK−dendrimer molar ratios were prepared and characterized to determine coupling efficiency, and *in vitro* enzymatic activity was tested and compared against free streptokinase.

EXPERIMENTAL PROCEDURES

Materials. 1-[3-(Dimethylamino)propyl]-3-ethylcarbodiimide methiodide (EDC-methiodide), *N*-hydroxysulfosuccinimide sodium salt (sulfo-NHS), tris (hydroxymethyl)aminomethane hydrochloride, and agarose (for routine use, gelling temperature 36 ± 1.5 °C) were purchased from Sigma. Generation 3.5 PAMAM COOH dendrimer was purchased from Dendritech, Inc., MI, and dialysis membranes (MWCO 3500 Da) from Spectra Pore, CA. Recombinant streptokinase and SK activity assay kit were purchased from Shanghai SIIC−SMU Biotech Com, Ltd. (Shanghai, PR China). ^{125}I-fibrinogen was obtained from Amersham Corp. (Arlington Heights, IL). Ultracel YM-3, YM-10, and YM-30 Centricon centrifugal filters (regenerated cellulose 3000 Da MWCO, 10 000 Da MWCO, and 30 000 Da MWCO) were purchased from Millipore Corporation (Bedford, MA). Superdex 75 prep grade (34 μm), Superdex G-25 PD-10 Column, and Mono QTM 4.6/100 PE column were purchased from Amersham Bioscience AB (SE-751 84 Uppsala Sweden). 4−20% Tris−glycine gradient precast polyacrylamide minigels were purchased from ISC BioExpress (Kaysville, UT). All other reagents were of analytical grade or HPLC grade.

Purification of PAMAM G3.5 Dendrimer. A BioSuite 250 HR SEC column (5 μm, 7.8 × 300 mm) connected to a Waters HPLC system was used for PAMAM dendrimer purification. The column was eluted with orthophosphate buffer (0.1 M, pH 7.00) at a flow rate of 0.5 mL/min. UV absorbance of the eluent was detected at both 280 and 210 nm. Fractions containing pure G3.5 peak were collected, concentrated by Ultracel YM-3 Centricon centrifugal filter (MWCO 3000 Da), dialyzed against water for 24 h (dialysis membrane MWCO 3500 Da, under perfect sink conditions), and lyophilized to obtain solid purified G3.5 (50−60% in yield).

Scheme 1. Schematic Representation of the Experimental Protocol[a]

[a] Three major steps: 1. Synthesis (1a) of the protein−dendrimer conjugates (EDC as coupling agent) and purification using a Superdex 75 preparative column (1b). 2. Characterization of the conjugates using GPC (2a), Anion exchange column (2b), and native-PAGE (2c). 3. *In vitro* performance of the conjugates using a fibrin gel (3a) and clot (3b) lysis assays.

SK−G 3.5 Conjugation. SK (13.5 mg, lyophilized powder) containing mannitol as the stabilizing agent was reconstituted with deionized water. A PD-10 column was used to remove mannitol from the reconstituted SK by eluting with borate buffer (0.1 M, pH 8.50). The carboxyl groups of PAMAM G3.5 dendrimer were activated in aqueous solution (pH 2.0) at ambient temperature for 10 min using EDC-methiodide and s-NHS as the coupling reagents (G3.5/EDC/sulfo-NHS = 1:64:64 molar ratio). The activated dendrimer solution was added to SK solution (in borate buffer, 0.1 M, pH 8.50) at different SK/G3.5 molar ratios (1:1, 1:5, 1:10, and 1:20) and gently stirred at ambient temperature for 2 h (Scheme 1).

Purification of SK−G3.5 Conjugates. The experimental protocol followed in this study is depicted in Scheme 1. The reaction solution was initially purified by gel permeation chromatography (GPC) using a Superdex 75 column (40 × 1.6 cm i.d.; 50 mL Superdex 75, preparative grade, 34 μm) connected to a Waters HPLC system. The column was eluted with orthophosphate buffer (0.1 M, pH 7.00) as the mobile phase (flow rate 0.6 mL/min), and UV absorbance was measured at 210 and 280 nm. Fractions containing SK conjugate and possibly free SK were collected and concentrated by Ultracel YM-30 Centricon centrifugal filter (MWCO 30 000 Da). The concentrated fractions were further purified by ion exchange chromatography (IEC) to remove free protein from the conjugate.

Chromatographic Characterization of SK−G3.5 Conjugates by GPC and IEC. Analytical gel permeation chromatography (GPC) was used to analyze the obtained SK−G3.5 conjugates using a BioSuite 250 HR SEC column and ortho-

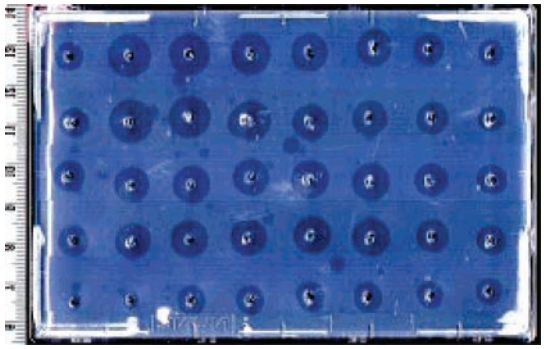


Figure 2. Agar gel plate and the fibrin lysis cycles, scanned against black background.

phosphate buffer (0.1 M, pH 7.00) as eluent at 0.6 mL/min. The progress of the coupling reaction was monitored by analyzing the diluted reaction solution using GPC. For IEC examination, a prepacked Mono Q 4.6/100 PE column was pre-equilibrated with Tris−HCl buffer (20 mM, pH 6.50) containing 0.15 M sodium chloride. After sample injection, the column was eluted at 0.9 mL/min with a gradient pattern: 0−4 min, Tris−HCl buffer (20 mM, pH 6.50) containing 0.15 M NaCl; 4−16 min, Tris−HCl buffer with NaCl concentration (from 0.15 to 1 M). UV absorbance was measured at 210 and 280 nm.

Native PAGE. Native PAGE conditions used for the analysis of SK−dendrimer conjugates were similar to those described previously for dendrimers (*41*, *42*). The free protein, free dendrimer, and protein−dendrimer conjugates (1:1, 1:5, 1:10, and 1:20; SK/G3.5 molar ratio) were analyzed using 4−20% Tris−glycine gradient express gel under native conditions. The running buffer used was Tris−glycine native buffer (2.5 mM Tris, 19.2 mM glycine, pH 8.3). A sample buffer containing 50% sucrose and 1% methylene blue was mixed with an equal volume of salt-free sample solution, and 10 μL of the mixture was loaded into each well. The gel was run at low voltage on a Bio-Rad Mini PROTEAN III vertical gel electrophoresis system at 4 °C and then stained overnight with 2.5% Coomassie Blue−R250 solution (in 10% acetic acid and 50% methanol). The destaining solution used was a 10% acetic acid solution with 50% methanol. Both staining and destaining were performed at 4 °C.

Activity Assay Based on Fibrin Gel Lysis. A modified fibrinolytic activity assay method based on that described by Li (*43*) was used to determine the *in vitro* biological activity of SK. 250 mg of agarose was dissolved in 20 mL normal saline at 60 °C and mixed with human fibrinogen (100 mg, in 10 mL normal saline), thrombin (0.1 mL, 10 U/mL), and plasminogen (120 μg, 1.2 μg/mL). This mixture was then quickly poured into a 12.5 × 8 × 0.5 cm^3 plastic plate to form an even, solidified, fibrin gel. Wells of 2 mm in diameter were made in the solidified fibrin gel, and 10 μL of free SK or conjugates (400 IU/mL of SK calculated from the amount used for the conjugation reaction) were loaded in each well in triplicate. The plate was then sealed and incubated at 37 °C. Streptokinase loaded into the wells converted plasminogen in the gel to plasmin, which lyses the fibrin, leading to a transparent ring around the well. After 8 h, the plate was scanned to record the size of the lytic ring (Figure 2). The area and the diameter of the lytic rings in the gel were measured using *Image J* software. The regression of the average diameter of the lytic rings against the logarithm of the activity was calculated to get a calibration curve from standard SK. The activities of the test samples were determined from this calibration curve based on the average diameter of the corresponding rings.

Lysis of ^{125}I-Fibrinogen Clots in Plasma. ^{125}I-labeled clots were prepared from human plasma as previously described (*44*, *45*). ^{125}I-fibrinogen containing plasma (0.68 μCi/mL) was quickly mixed with $CaCl_2$ (20 mM) and thrombin (1 U/mL). The mixture was aliquoted (100 μL each) into 1.5 mL Eppendorf tubes to form clots and then incubated at 37 °C for 2 h. The obtained clots were washed four times with PBS to remove free ^{125}I or unconverted ^{125}I-fibrinogen. The clots were then suspended in 1 mL of plasma containing free SK or SK−G3.5 conjugates (400 U/mL) and incubated at 37 °C. The negative control sample contained clot suspended in plasma without SK. At different time intervals, 25 μL of supernatant was collected with a corresponding amount of plasma supplementation. The radioactivity was measured using Packard Cobra II Auto Gamma Counters (Canberra Packard, Meriden, CT 06450, U.S.A.). The overall radioactivity in the supernatant was calculated and divided by the original radioactivity of the clot after accounting for time decay in radioactivity to obtain the percent clot lysis.

RESULTS AND DISCUSSION

Purification of PAMAM G3.5 Dendrimer and SK. The GPC analysis of commercially available PAMAM G3.5 displayed a single peak at 210 nm and three to four peaks at 280 nm, indicating some impurities (Figure 3). After purification, the dendrimer displayed a single peak at both 210 and 280 nm (Figure 3). BSA, glutamine, glycine, and mannitol are the widely used stabilizing agents for SK to maintain its enzymatic activity during lyophilization and storage (*46*, *47*). However, the functional groups (amine and hydroxyl groups) on these additives can compete with SK for reacting with the carboxyl groups of PAMAM G3.5 dendrimer, leading to reduced coupling efficiency, heterogeneous conjugates, or conjugation failure. Therefore, SK needs to be purified before reaction. The mannitol in the received SK product was removed using a PD-10 column.

Preparation of SK−G3.5 Conjugates. Water-soluble EDC−methiodide and sulfo-NHS were used to activate the carboxyl groups of PAMAM G3.5 dendrimer in aqueous solution. The activated ester of the dendrimer would be expected to react with the amine groups of SK to form an amide bond. We found that the activation step played a key role in the bioconjugation. Since active ester is unstable and can be easily hydrolyzed by water, the activated dendrimer should be reacted immediately with SK. However, if the activation time is too short, the active coupling reagents may cause SK cross-linking. Activation times of 10, 30, and 60 min were tried, and a 10 min activation time was found to be optimal, resulting in high coupling efficiency. Also, no obvious protein cross-linking was suggested by chromatographic analysis (data not shown). Therefore, a 10 min activation time was used for all the conjugates. Since carboxyl groups are easily activated in neutral to slightly acidic conditions, the purified G3.5 dendrimer was dissolved in water (pH 2) to reach a final pH of 4.0 activation (*48*). After activation, SK in borate buffer (0.1 M, pH 8.5) was immediately added, and the final pH of the reaction solution ranged between 8.2 and 8.5, at which SK is stable.

Several reaction times (2, 4, and 6 h) and SK/G3.5 molar ratios (1:1, 1:5, 1:10, and 1:20) were investigated. The conjugates synthesized with reaction times of 4−6 h displayed nearly identical chromatographic profiles to those synthesized in 2 h (Figure 4). Since shorter reaction times are desirable to preserve the stability of protein, we used a 2 h reaction time for all the conjugates. We have shown here that relatively mild conjugation conditions involving dendrimer activation at a pH of 4.0 for 10 min, followed by a 2 h reaction with SK in borate buffer, were effective in achieving PAMAM G3.5−SK conjugates.

Purification and Characterization of SK−G3.5 Conjugates. Purification of protein−dendrimer conjugates is challenging because attaching a polymer usually widens the protein peak, thus reducing the separation resolution (*49*). For this

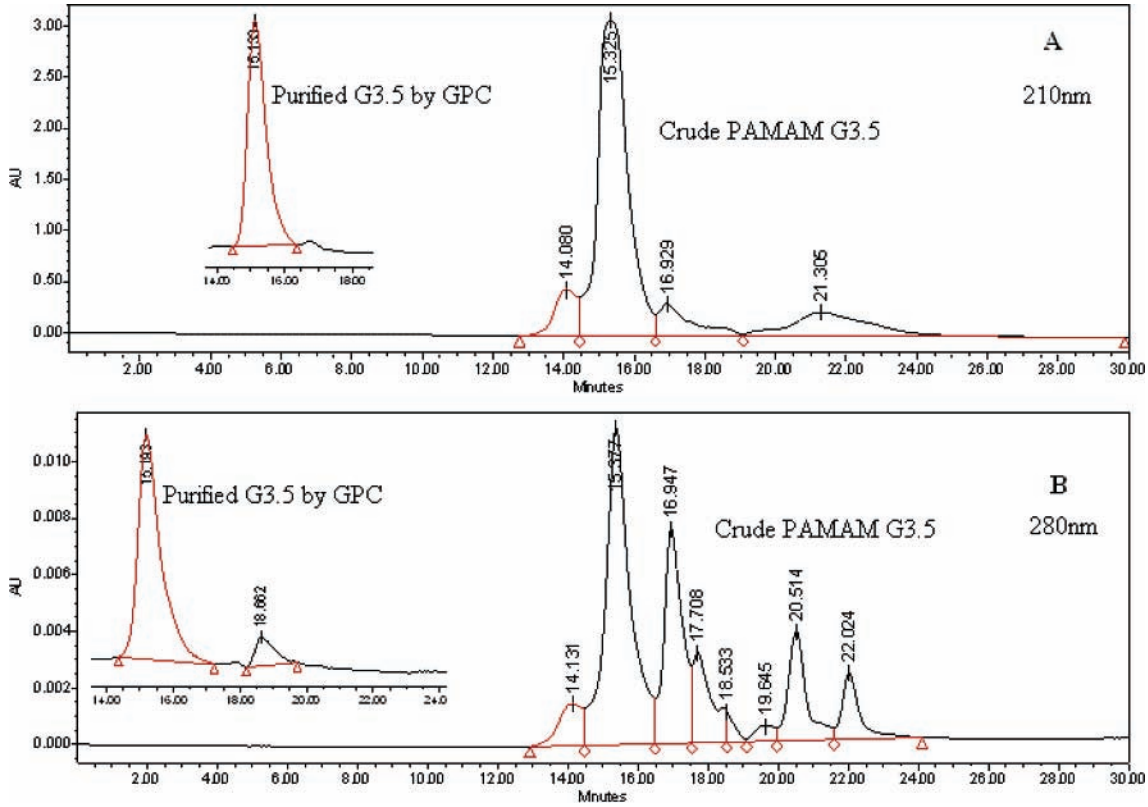

Figure 3. Comparison of GPC profiles of crude PAMAM G3.5 dendrimer and purified PAMAM G3.5 dendrimers (A, 210 nm; B, 280 nm). After purification by GPC, the PAMAM dendrimer displayed as single peaks at both 210 nm and 280 nm.

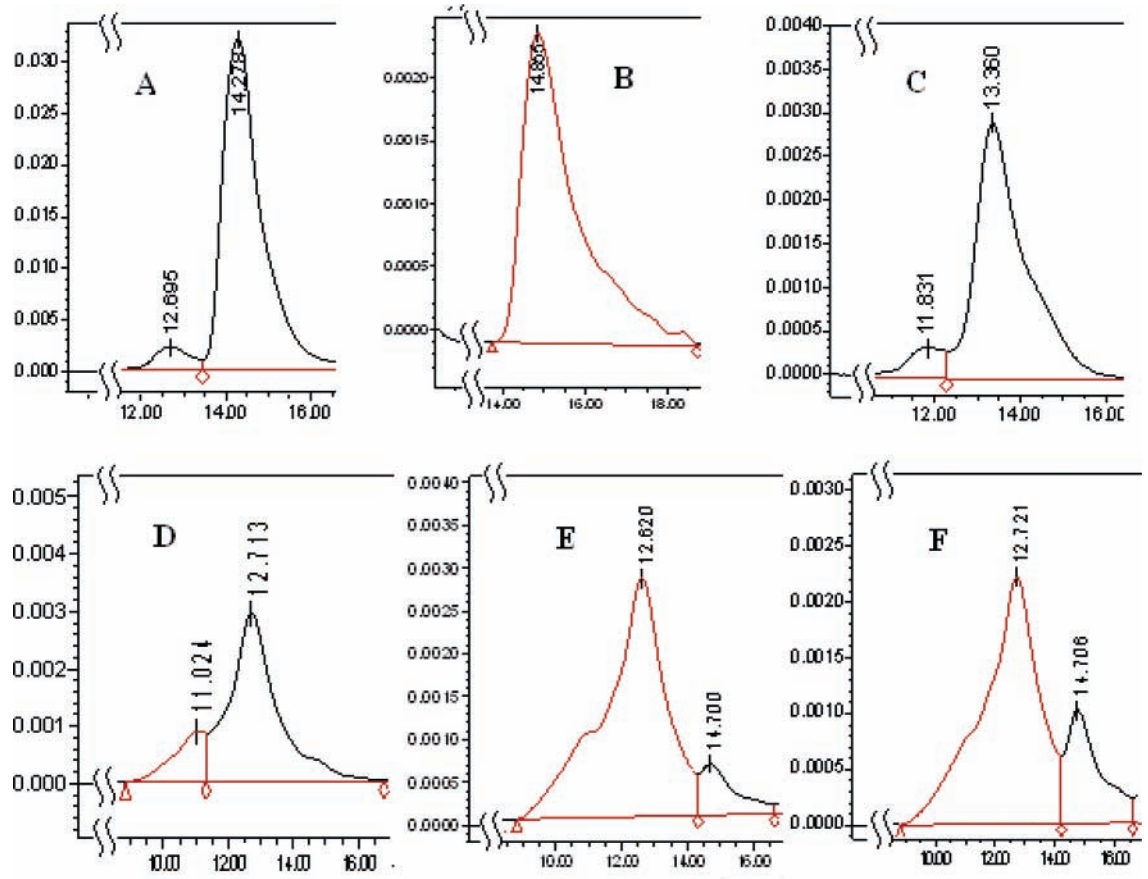

Figure 4. GPC comparisons of SK−G3.5 conjugation solutions of different starting SK−G3.5 molecular ratios (reaction solution, 2 h, at 280 nm): A for free SK, B for free PAMAM, C for SK−G3.5 (1:1), D for SK−G3.5 (1:5), E for SK−G3.5 (1:10), F for SK−G3.5 (1:20).

purpose, a preparative GPC column was used with Superdex 75 (34 μm) as packing material. This column has a M_r fractionation range of 3×10^3 to 7×10^4 Da, suitable for separating SK−G3.5 conjugates (theoretical MW > 6×10^4

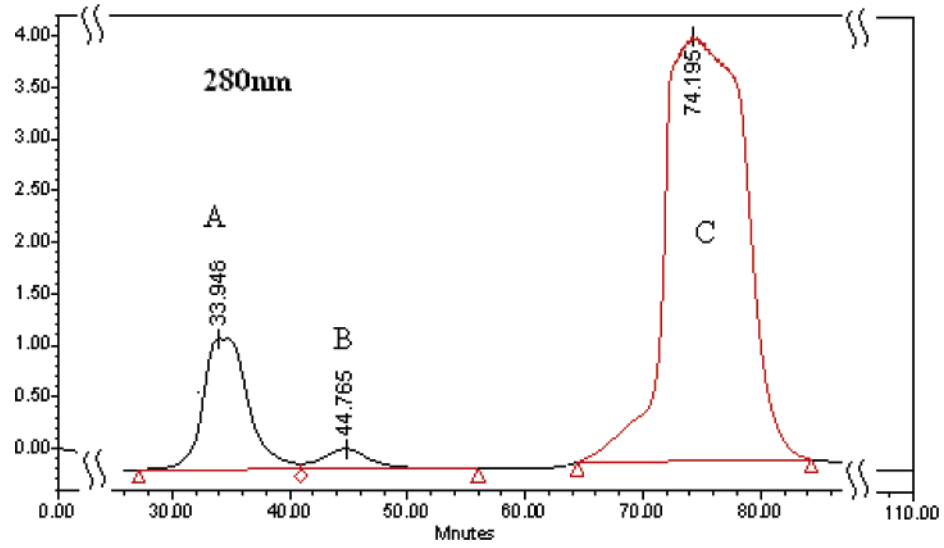

Figure 5. Chromatographic profile of separation of SK−G3.5 (1:5) conjugate using Superdex 75 column. Peak A: conjugate (plus free SK if there was some left in the reaction solution). Peak B: unreacted PAMAM G3.5 dendrimer. Peak C: coupling reagents.

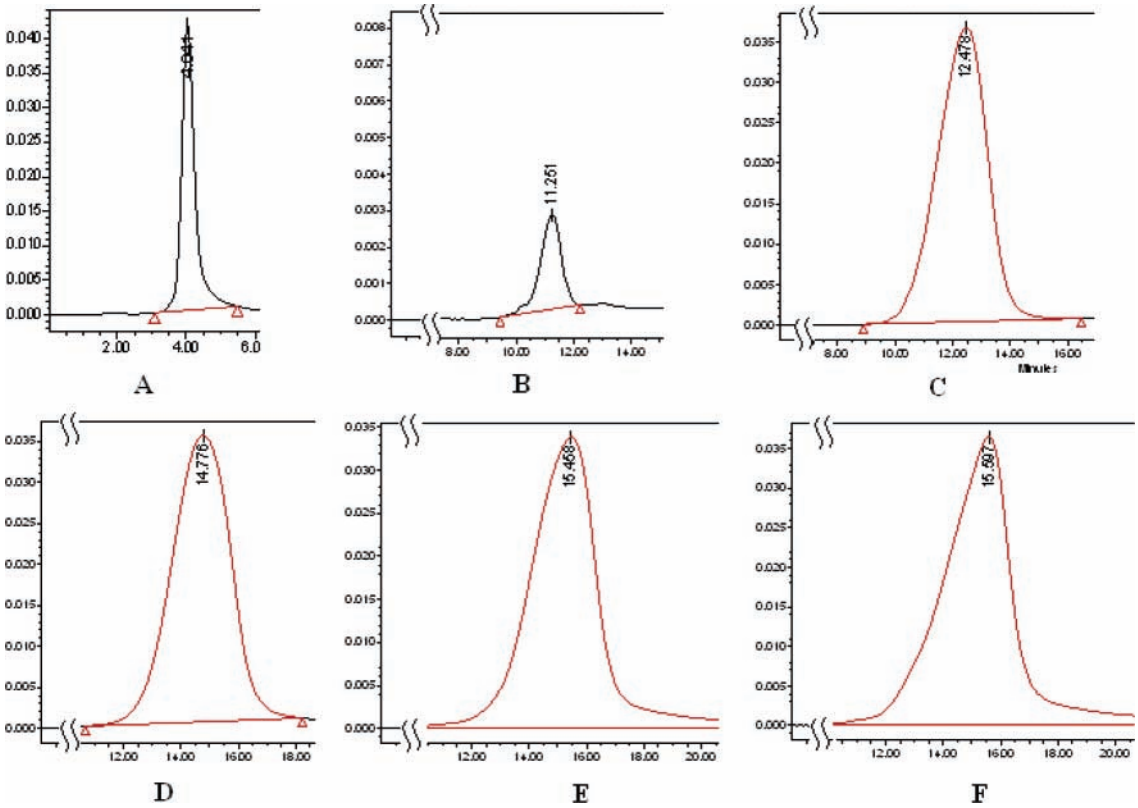

Figure 6. IEC comparison (280 nm) of SK−G3.5 (1:1, 1:5, 1:10, 1:20, molar ratio) conjugates with free SK and free dendrimer: A for free SK (RT = 4.041 min), B forfree PAMAM G3.5 dendrimer (RT = 11.323 min), C for SK−G3.5 (1:1), D for SK−G3.5 (1:5), E for SK−G3.5 (1:10), and F for SK−G3.5 (1:20). (Only the sections of the original IEC chromatograms containing the SK−G3.5 conjugate peak are shown here; however, the complete IEC profiles were similar to those presented in Figure 7, with no free SK or free dendrimer observed.)

Da) from unreacted PAMAM G3.5 dendrimer (MW 12 931 Da) and coupling reagents (EDC−methiodide and sulfo-NHS, MW < 400). Figure 5 depicts the chromatographic profile of SK−G3.5 conjugate solution, where the dendrimer−SK conjugate along with possibly free SK was separated from unreacted dendrimer and coupling agents (retention times around 34, 45, and 74 min, respectively). Fractions containing SK conjugate and possibly some free SK (peak at 34 min in Figure 5) were collected.

Free SK in the reaction solution cannot be clearly separated from the conjugate by GPC. However, using IEC, a separation technique based on surface charge density of molecules, a clear separation of free SK (RT = 4.0 min) and free dendrimer (RT = 11.3 min) from SK conjugates (RT = 12.5 to 15.6 min) was achieved (Figure 6 and Table 1). PAMAM G3.5 is a highly branched polymer with 64 carboxyl groups on the surface carrying a high density of negative charge. When conjugated to SK, the high negative charge of the dendrimer will lead to a significant change in the surface charge density of SK. We expect that attaching more dendrimer molecules leads to a greater negative charge and hence longer IEC retention time for the conjugates. Thus, desirable separation was achieved using anion IEC. We observed no free SK peak in IEC analysis of the SK conjugates (Figure 7), suggesting that the conjugation

Table 1. Comparison of IEC Retention Time of SK−G3.5 Conjugates with That of Free PAMAM G3.5 Dendrimer (280 nm)

	RT (min)	ΔRT[a] (min)
free SK	4.041	
purified G3.5	11.340	
SK−G3.5 (1:1)-2 h	12.478	1.138
SK−G3.5 (1:5)-2 h	14.776	3.436
SK−G3.5 (1:10)-2 h	15.458	4.118
SK−G3.5 (1:20)-2 h	15.597	4.257

[a] ΔRT was the retention time shift using free dendrimer as reference.

reaction was effective. We would expect the retention time of the conjugate to increase with an increase in the molar ratios of dendrimer used (1:1 < 1:5 < 1:10 < 1:20), as the charge of the conjugate becomes more negative when more dendrimer molecules are attached to SK (Figure 6 and Table 1). However, it was observed that the increase in retention time of the 1:20 conjugate was not appreciably different from that of the 1:10 conjugate. This may be ascribed to the steric hindrance of the attached dendrimer that prevents more dendrimer molecules from approaching the amine groups of the SK molecule, leading to saturation in the number of dendrimer molecules that could be attached to SK.

After purification by GPC, the product displayed a single peak for the SK conjugate. There was no peak observed at retention times less than 5 min, indicating the absence of unreacted or cross-linked SK in the final product (Figures 6 and 7). This also suggests that our coupling efficiency was high. These purified conjugates were then used for the *in vitro* studies. The possibility of formation of the SK−G3.5 complex was excluded on the basis of the observation that a physical mixture of PAMAM G3.5 and SK (at similar molar ratios in borate buffer) demonstrated only individual peaks for dendrimer and SK, by both GPC and IEC.

The conjugates were also characterized by native PAGE, where the SK conjugates migrated differently from that of free SK (Figure 9). The migration distance in native PAGE is dependent upon the charge and molecular weight of the protein. The attachment of a negatively charged dendrimer to SK results in a conjugate that is more negatively charged than free SK and thus has a longer migration distance (Figure 9). The purified conjugates did not demonstrate any bands in the regions corresponding to either free SK or free dendrimer.

The dendrimer−protein conjugations that have been previously attempted used high amounts of NH_2-terminated dendrimer with expensive heterobifunctional cross-linking agents and lengthy procedures of introducing sulfhydryl groups on the dendrimer or protein before conjugation, leading to reduced overall yield and loss of protein activity (*33*−*35*, *40*). This is the first study reporting conjugation of a therapeutic protein with dendrimer with high coupling efficiency. The inherent properties of this negatively charged PAMAM dendrimer, such as low cytotoxicity and longer blood circulation times, together with mild reaction conditions and high coupling efficiency as demonstrated here, makes it suitable for conjugating dendrimer to various biologically active proteins and polypeptides.

Previous attempts at conjugating polymers such as PEG to SK have involved long reaction times and use of large amounts of polymer, resulting in low yield of conjugates (*9*, *50*). However, in this study, even at a molar ratio of 1:1 (SK/G3.5), most of the SK was attached to PAMAM G3.5 dendrimer within 2 h. This may be because of the remarkably higher reactivity of the dendrimer functional groups (*36*, *51*). This unusual

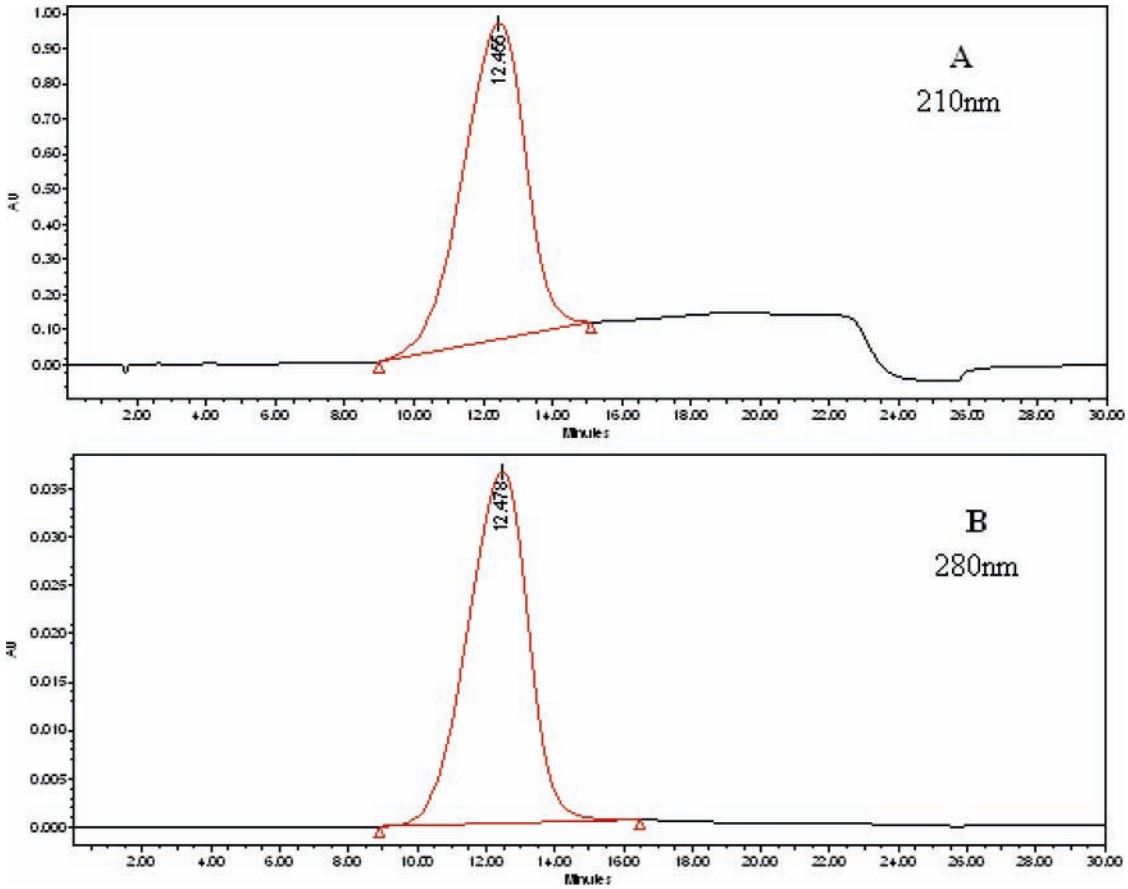

Figure 7. IEC examination of the purity of the SK−G3.5 (1:1)-2 h conjugate (A, 210 nm; B, 280 nm) fraction collected from GPC. Free SK was usually eluted out at about 4 min under the same condition, and free dendrimer around 11.2 min. IEC chromatograms of other conjugates were similar, with no peak observed between 0 and 10 min (also see Figure 6).

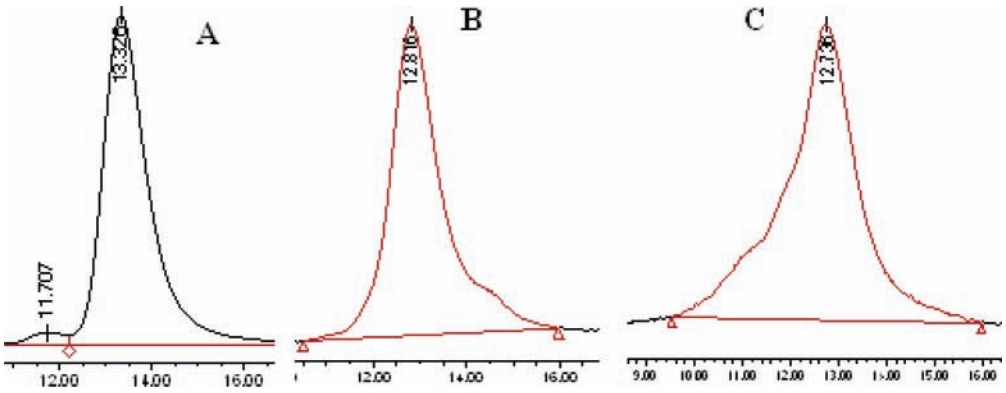

Figure 8. GPC of purified SK−G3.5 conjugates (A for SK−G3.5 (1:1), B for SK−G3.5 (1:10), C for SK−G3.5 (1:20).

Table 2. SK Activity Measured for Different Conjugates (mean ± SD) ($n = 3$)[a]

SK−G3.5 conjugate	average activity (U/mL)	% activity retention
1:1-2 h	319.40 ± 2.73	79.8 ± 0.7
1:5-2 h	94.52 ± 2.38	23.6 ± 0.6
1:10-2 h	62.66 ± 0.75	15.7 ± 0.2
1:20-2 h	40.55 ± 1.63	10.14 ± 0.4

[a] Theoretical activity of all the SK conjugates was 400 IU/mL based on calculation.

reactivity appears to allow coupling reactions under mild reaction conditions and with high efficiency.

Fibrin Gel Lysis. The activity of the SK−dendrimer conjugates, as measured by fibrin gel lysis, decreased as the molar ratio of dendrimer used for conjugation increased (Table 2). The 1:1 conjugate (molar ratio, SK/dendrimer) retained almost 80% of the original activity, while the 1:5, 1:10, and 1:20 conjugates retained only 24%, 16%, and 10% respectively. Similar results have also been recently reported for SK−polyglycerol conjugates (*52*).

The problem of significant loss (sometimes even 95%) in biological activity during conjugation is one of the major concerns with protein modification (*53*). Attaching a polymer conveys many advantages to proteins, e.g., increased blood circulation, improved stability, and reduced immunogenicity. However, the same mechanism that prevents the approach of proteolytic enzymes or antibodies to modified protein can also hinder a substrate from approaching the active site of the protein,

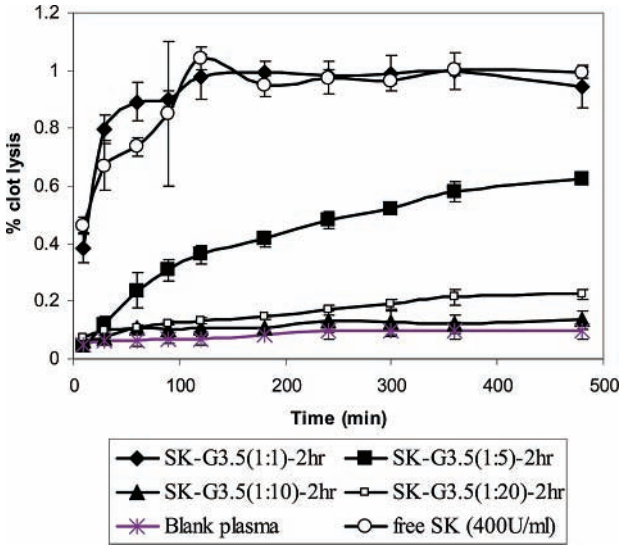

Figure 10. Radiation clot lysis of SK conjugates of different SK−G3.5 molar ratios in comparison with free SK (within 8 h).

especially when the substrate has high molecular weight. It is also possible that any nonspecific attachment of polymer to SK may directly occupy or shield SK's active sites, especially when a large amount of polymer is used. Hence, less modification would lead to higher activity in the SK conjugates. However, for SK conjugates with a higher degree of modification, the activity may be recovered once the dendrimers are detached, which could result in sustained release of SK and a longer duration of action. This is further detailed in the *in vitro* clot lysis assay.

Lysis of ^{125}I-Fibrinogen Clots. The thrombolytic activity of the conjugates compared to that of free SK over 8 h is depicted in Figure 10. The activities of free SK and SK−G3.5 (1:1) conjugate were similar to each other with 100% clot lysis within 3 h, whereas SK−G3.5 (1:5), SK−G3.5 (1:10), and SK−G3.5 (1:20) conjugates showed much less activity (62%, 22%, and 13% clot lysis, respectively) even at 8 h. However, when thrombolytic activities of the conjugates were compared over a prolonged period of time (Figure 11, up to nearly 48 h), a rapid increase in the rate of clot lysis was noted for SK−G3.5 (1:10) and SK−G3.5 (1:20) conjugates after the initial slow phase of thrombolysis. This variation in the thrombolytic profiles of the conjugates with greater protein modification may be due to a difference in the release of SK or active SK fragments from the conjugates over time. Although amide bonds between SK and dendrimer are generally considered to be stable in plasma (*12*), it is possible that proteolytic enzymes in plasma may cause degradation of the SK conjugate with prolonged incubation, leading to a release of free SK and/or of active SK fragments. Since SK has to bind to plasminogen to form the activator

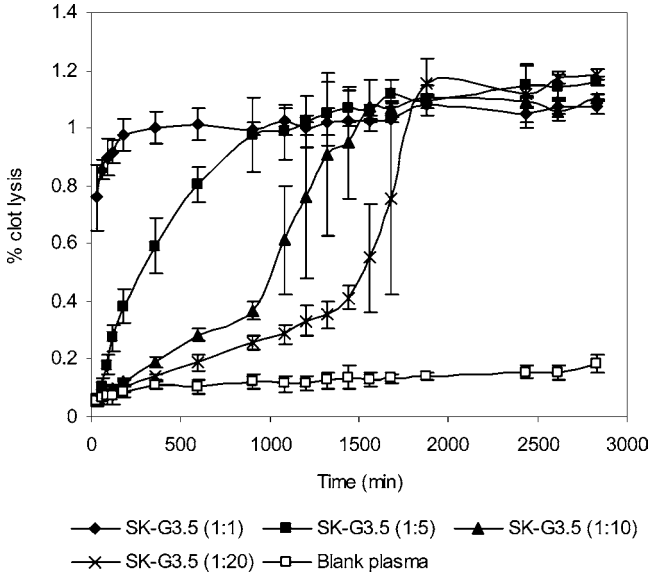

Figure 11. Radiation clot lysis of SK conjugates of different SK−G3.5 molar ratios over 48 h and the possible activity release.

complex, it is possible that the plasminogen binding sites are not readily accessible in the SK conjugates containing more dendrimer molecules. As the dendrimer gets released over time, the SK molecule may become more accessible. Once plasminogen binds with SK to form the activator complex, the thrombolytic activity rapidly increases leading to 100% clot lysis.

In order to assess the release of SK and SK fragments from the conjugates, the stability of these conjugates was studied in PBS at 37 °C. While free SK was completely degraded at 34 h, the SK−G3.5 conjugates degraded slowly, with only 4% of the 1:1 conjugate, 11% of the 1:5, 15% of the 1:10, and 34% of the 1:20 conjugate remaining intact even at 94 h. This indicates that attaching dendrimer greatly improved SK stability, and this improvement was dependent on the degree of modification of SK conjugates, with higher modification leading to higher stability.

The thrombolytic action regained from the SK−G3.5 (1:10) and SK−G3.5 (1:20) conjugates demonstrated that their initial reduced activity was not completely due to the real activity loss during conjugation but at least partly due to temporary coverage of the SK active sites by dendrimers. Through careful tailoring of the linkage between SK and dendrimer (for example, ester bond, Schiff base bond, or stimuli-sensitive spacer), the highly modified SK conjugates could offer a prodrug model to provide a sustained release or long-term effectiveness for a large number of bioactive proteins.

CONCLUSIONS

Dendrimers are being used for drug targeting, imaging, and many other biomedical applications. This paper describes a useful method for effective attachment of dendrimer to various proteins, peptides, and other amine-containing hydrophilic molecules. Through a simple active ester reaction, carboxyl groups of the PAMAM G3.5 dendrimer were reacted with the amino groups of SK under mild aqueous conditions. A series of conjugates with increasing amounts of dendrimer to protein molar ratios have been synthesized. Optimal activation conditions (pH and activation time) led to rapid conjugation (2 h) with high coupling efficiency, as verified by GPC, IEC, and PAGE. The SK−dendrimer molar ratio had a major effect on the activity retention of SK conjugates. With an increase in the number of dendrimer molecules attached to SK, the activity (at shorter time points) decreases for the conjugate. This is possibly due to the masking of active sites of SK by dendrimer. The SK−G3.5 (1:1) conjugate retained up to 80% of protein activity and exhibited quick *in vitro* clot lysis (comparable to that of free SK). The *in vitro* stability study indicates that attachment of dendrimer improved SK stability. Along with the increasing dendrimer/SK ratio, the stability increased. Hence, it could be expected that all of the SK conjugates would have much better stability and longer circulation times than free SK *in vivo*. SK−G3.5 (1:1) conjugate could also be further conjugated to thrombus-specific antibodies or ligands to realize thrombus-targeted SK delivery and targeted thrombolysis.

Single Cell Fluorescence Imaging Using Metal Plasmon-Coupled Probe

Jian Zhang, Yi Fu, and Joseph R. Lakowicz*

Center for Fluorescence Spectroscopy, University of Maryland School of Medicine, Department of Biochemistry and Molecular Biology, 725 West Lombard Street, Baltimore, Maryland 21201. Received October 27, 2006; Revised Manuscript Received February 5, 2007

This work constitutes the first fluorescent imaging of cells using metal plasmon-coupled probes (PCPs) at single cell resolution. *N*-(2-Mercapto-propionyl)glycine-coated silver nanoparticles were synthesized by reduction of silver nitrate using sodium borohyride and then succinimidylated via ligand exchange. Alexa Fluor 647-labeled concanavalin A (con A) was chemically bound to the silver particles to make the fluorescent metal plasmon-coupled probes. The fluorescence images were collected using a scanning confocal microscopy. The fluorescence intensity was observed to enhance 7-fold when binding the labeled con A on a single silver particle. PCPs were conjugated on HEK 293 A cells. Imaging results demonstrate that cells labeled by PCPs were 20-fold brighter than those by free labeled con A.

INTRODUCTION

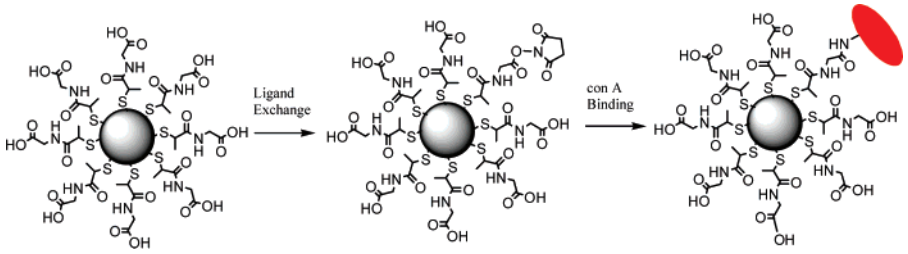
Molecular fluorescence imaging techniques play critical roles in the early detection, diagnosis, and treatment of disease, as well as aid in the studies of biological and biochemical mechanisms, immunology, and neuroscience on single cells (*1*−*4*). Generally, an imaging agent consists of an organic fluorophore moiety and a targeting functionality, such as an antibody, peptide, DNA, or a special ligand (*5*−*7*). However, most imaging agents have several limitations: complicated preparation, strong signal background, fast photobleaching, and single color.

Recently, the use of fluorescently labeled metal particles has become attractive due to near-field interaction of the fluorophore with metal particles (*8*−*17*). The metal particle with the subwavelength size usually displays an energy resonance arising from the collective oscillation of migrated electrons on its surfaces (*18*, *19*), which is defined as plasmon resonance. The wavelength of plasmon resonance is closely relevant to the metal core including metal species, core size, and core shape as well as the dielectric properties of coating layer (*19*−*21*). The fluorophore can be described as an oscillating dipole to radiate energy during fluorescence occurrence (*22*). When it is localized near the metal particle, the radiating energy is dramatically altered through coupling with the metal plasmon resonance to cause a change of the emission properties, which is defined as radiative decay engineering (RDE) (*23*−*25*). Generally, RDE can lead to an enhancement of intensity to be 10^1 to 10^3 times depending upon both the fluorophore and metal core factors as well as the distance between them. Besides the intensity enhancement, the near field interaction of fluorophore with the metal particle can also result in its shorter lifetime (*26*), which leads to less time for the photochemistry while in the excited-state and thus more excitation−emission cycles prior to photobleaching. Hence, the fluorophore usually displays a better photostability near the metal particle (*27*).

The metal particle is known to have large surface area, good chemical stability, and homogeneous dispersion in solution (*28*−*30*). The development of surface chemistry can enable versatile decoration of fluorophores as well as provide targeting functionalities on the metal particle (*31*, *32*). Hence, we can use the dye-labeled metal particle as a novel fluorescence imaging agent to satisfy our specific requirements in the measurements. Because the optical properties of dye-labeled metal particles can be controlled well by the metal plasmon resonance as discussed above, we define it as metal plasmon-coupled probe (PCP). PCP is suggested to be able to offer easier preparation, higher brightness, better photostability, and multiple colors as a new generation of fluorescence imaging agent (*22*, *23*). In this paper, we are concerned with developing a method to make PCPs and label cells using these PCPs. The fluorescence images by PCPs were collected using scanning confocal microscopy at the single cell level and compared with those by unmodified fluorophores.

Dye-labeled concanavalin A (abbreviated as con A) can bind to sugars residing on the cell membrane (*33*−*35*), so it is commonly used in cell labeling in culture (*36*, *37*). In this study, the dye-labeled con A was chemically bound to the silver particle to generate PCP (Scheme 1). The silver particle was synthesized in a typical protocol by reduction of silver salt (*28*). In order to bind con A, the metal particle was functionalized by succinimidyl ester at a terminal position via ligand exchange (*30*, *38*). The con A was bound to the succinimidylated particle by condensation between the succinimidyl ester on the metal particle and the lysine residual on the protein molecule. Alexa Fluor 647-labeled con A was used in the study because of its efficient enhancement as a near-infrared fluorophore near the metal substrate (*39*). HEK 293 A cell line, which is originally derived from human embryonic kidney and utilized frequently in *in vivo* imaging (*40*, *41*), was conjugated by PCPs, and the fluorescence imaging was monitored using confocal microscopy.

EXPERIMENTAL PROCEDURES



All reagents and spectroscopic grade solvents were used as received from Fisher or Aldrich. Alexa Fluor 647-labeled concanavalin A (con A) was commercially available from Molecule Probes. HEK293 A cell line was from Invitrogen. RC dialysis membrane (MWCO 50 000) was purchased from Spectrum Laboratories, Inc. Nanopure water (>18.0 MΩ cm) purified using Millipore Milli-Q gradient system was used in all experiments.

Preparation of Tiopronin-Coated Silver Nanoparticles. *N*-(2-Mercaptopropionyl)glycine (abbreviated as tiopronin)-

Scheme 1. Tiopronin-Coated Silver Particles Were Succinimidylated via Ligand Exchange and Then Chemically Bound by Alexa Fluor 647-Labeled Con A via Condensation

coated silver nanoparticles were prepared using a modified Brust reaction with a mole ratio of tiopronin/silver nitrate = 1/6 in methanol using an excess amount of sodium borohydride as reducing agent (*42*−*44*). Removal of the solution by filtration, the residual precipitated solid was washed with methanol and acetone, respectively, to obtain the metal particles. The particles (1 mg/mL) and tiopronin (10 mM) were codissolved in water, and the solution was stirred for 24 h to anneal the particles (*45*, *46*). The water was removed under vacuum and the residue was washed thoroughly with methanol and acetone. The solid tiopronin-coated particles were further purified through dialysis against water (MWCO 50 000).

Functionalization of Silver Particles. (2-Mercapto-propionylamino)acetic acid 2,5-dioxo-pyrrolidin-1-yl ester was synthesized as previously reported (*47*). A 4×10^{-8} mol amount of this compound was codissolved with a 4×10^{-8} mol amount of tiopronin-coated silver particles in water and stirred for 72 h at room temperature for ligand exchange. Some tiopronin molecules were expected to be displaced by the succinimidyl ester molecules on the metal cores in a mole ratio of 1/1 (*38*). Unbound compounds were removed by dialysis against water (MWCO 50 000), and the resultant metal particles were obtained under vacuum.

Binding con A onto Silver Particles. Alexa Fluor 647-labeled concanavalin A (con A) was chemically bound on the succinimidylated metal particle by condensation between the terminal succinimidyl ester on the metal particle and the lysine residue on the con A (*35*, *36*). The metal particles (2×10^{-8} M) and dye-labeled con A (2×10^{-8} M) were codissolved in molar ratio of 1/1 in water and stirred for 2 h at room temperature. One drop of ammonia was added to the solution to block the nonreacting succinimidyl ester on the metal particle. The solution was centrifuged at 5000 rpm/s to remove the aggregates in the reaction and then dialyzed against 10 mM glucose−BAS buffer solution to remove the impurities.

Conjugating Dye-Labeled con A and PCPs on Cell Lines. HEK293 A cell lines were suspended in 500 μL aliquots of 250 g/mL con A solutions made in 0.01 M PBS buffer (pH = 7.2) and agitated for 1 h at room temperature (*37*). PCPs were incubated with the cells at the same fluorophore concentration and for the same incubation time as the unmodified dye-labeled con A. All cell samples were washed three times with PBS buffer solution before using imaging measurements.

Spectra and Imaging Measurements. Absorption spectra were monitored with a Hewlett-Packard 8453 spectrophotometer. Ensemble fluorescence spectra were recorded with a Cary Eclipse Fluorescence Spectrophotometer. Transmission electron micrographs (TEM) were taken with side-entry Philips electron microscopy at 120 keV. Samples were cast from water solutions onto standard carbon-coated (200−300 Å) Formvar films on copper grids (200 mesh) by placing a droplet of a 10-fold diluted aqueous sample solution on the grids. The size distribution of the metal core was analyzed with Scion Image Beta Release 2 counting at least 200 particles. For fluorescence imaging measurements, the diluted samples were dispersed on a pre-cleaned glass coverslip. The coverslips (18×18 μm, Corning) were first soaked in a 10:1 (v:v) mixture of concentrated H_2SO_4 and 30% H_2O_2 overnight, thoroughly rinsed with water, sonicated in absolute ethanol, and dried with an air stream. All the single-molecule measurements were performed using time-resolved confocal microscopy (MicroTime 200, PicoQuant). Briefly, it consists of an inverted confocal microscope coupled to a high-sensitivity detection setup. A single mode pulsed laser diode (635 nm, 100 ps, 40 MHz) (PDL800, PicoQuant) was used as the excitation light. An oil immersion objective (Olympus, 100×, 1.3NA) was used both for focusing laser light onto the sample and collecting fluorescence emission from the sample. The fluorescence that passed a dichroic mirror (Q655LP, Chroma) was focused onto a 75 μm pinhole for spatial filtering to reject out-of-focus signals. The emission signals were discretely focused onto single photon avalanche diodes (SPAD) (SPCM-AQR-14, Perkin-Elmer Inc). The data collected using the TimeHarp 200 board was stored in the time-tagged time-resolved mode (TTTR), recording every detected photon with its individual timing, which is the basis for the following single-molecule analysis.

RESULTS AND DISCUSSION

The tiopronin-coated silver particles displayed a typical silver plasmon absorbance at 405 nm in water (Figure 1) (*43*). The average diameter of the metal cores was 20 nm as measured from 200 transmission electron micrographs images (TEM, Figure 2a), and their *average* chemical compositions were estimated to be ca. $(Ag)_{2.5\times105}(Tio)_{5.0\times103}$. The silver particles were succinimidylated via ligand exchange using (2-mercapto-propionylamino)acetic acid 2,5-dioxo-pyrrolidin-1-yl ester. Typically, such ligand exchange occurs in a molar ratio of 1/1 on the surface of metal particles according to Murray et al. (*38*), so we suggest that there exists average one succinimidyl ligand on each metal particle even though the ligand exchange is completely accomplished. The reason for one succinimidyl ester ligand/per particle is to compare the cell imaging by PCPs and unmodified con A at the same quantity of fluorophore. In future work, we can conjugate more dye-labeled con A molecules to

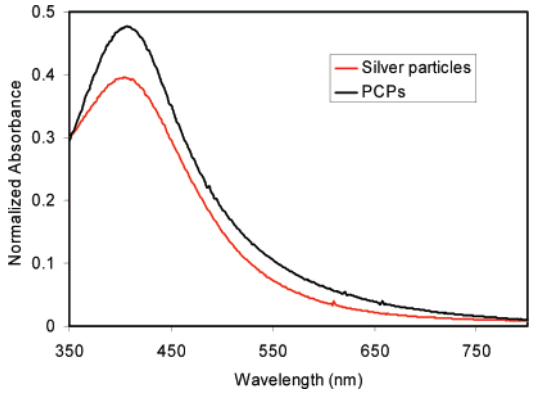

Figure 1. Normalized absorbance spectra of tiopronin-coated silver particle and con A-bound silver particles in water.

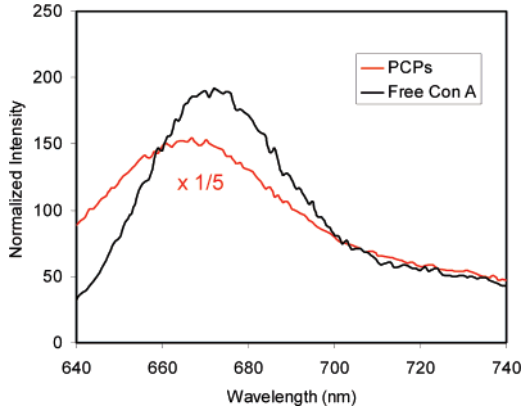

Figure 3. Ensemble fluorescence spectra of Alexa 647-labeled con A and con A-bound silver particle in water.

get PCPs with higher brightness and more capability to capture on the membranes of cells.

Alexa Fluor 647-labeled con A was chemically bound to the silver particle via condensation reaction (Scheme 1). Because only one succinimidyl ester was expected to bind per metal particle, each metal particle was bound maximally by one con A molecule. No significant cross-linking was observed from TEM images (Figure 2b). Even if cross-linking had occurred in the con A binding, the aggregate was removed by the centrifugation. The con A-bound silver particles, so-called PCPs, displayed a blue-shifting of fluorescence wavelength from 672 to 667 nm with the binding, accompanied by simultaneous band broadening (Figure 3). However, the binding did not alter the metal plasmon absorbance (Figure 1), which was principally due to the limitation of the con A amount on each metal particle. This result is consistent with what we require for PCPs in this case.

In order to obtain the exact amount of con A on each metal particle, the metal cores of PCPs (1×10^{-6} M) were removed by adding dropwise sodium cyanide (*32*). The concentration of con A in the residual solution was measured to be 8×10^{-7} M according to the fluorescence intensity. Hence, the molar ratio of bound con A/metal particle was estimated to be 0.8, showing that one metal particle was bound by less than one con A. TEM images of PCPs (Figure 2b) displayed an insignificant change from the tiopronin-coated particles (Figure 2a), indicating that the above surface reactions did not obviously influence the metal core. Furthermore, TEM results also confirmed that there was not significant cross-linking between the metal particles and con A molecules as described earlier.

Fluorescence images were collected by scanning confocal microscopy. Tiopronin-coated silver particles displayed light-scattering images with typical photoblinking behavior, which take on 'streaky" appearances and the spots no longer appear as full and round shapes (Figure 4a). The streaks are not noise, having intensity levels significantly greater than the background. The strong blinking behavior may arise from temporal variations in the emission rate during illumination, most likely from strong "nondestructive" silver blinking as confirmed by our previous result (*48*). Contrarily, full and round spots were observed from the unmodified con A with an average intensity at 50 kHz (Figure 4b). A representative time trace was given as gradual intensity decay (Figure 5), indicating that each con A molecule consists of multiple dye molecules. After binding con A to the silver particle, the fluorescence of PCPs became more intense (Figure 4c), about 7 fold brighter than that of unmodified con A. This enhancement efficiency is in good agreement with the value obtained from the ensemble spectra in solution (6 fold). Most of the unmodified con A molecules were bleached away within 15 s (Figure 5), while at least half of the PCPs were monitored indefinitely without photobleaching, implying that the fluorophores on the metal particles became more photostable. Enhanced brightness and lengthened photostability are typical properties of metal-enhanced fluorescence as in our previous description (*24*, *25*).

HEK293 A cell lines were conjugated with either unmodified con A or PCPs. The imaging was monitored with confocal microscopy at the single cell level (Figure 6). At least 50 images were collected for each sample. Although the cells were measured under dry conditions, the averaged size of the HEK293 A cells was in the range of 5−10 μm, close to those of living cells on a glass substrate, reported by Zeng, et al. (*49*). It was difficult to distinguish the individual bright spots on the cells, implying that the probes were packed densely on the cell membranes in both situations. The brightness was analyzed on the basis of the average value of the cell images. It is shown that the image brightness of cells by unmodified con A (Figure 6d,e) is identical to that of free unmodified con A (Figure 4b), implying that the conjugation cannot significantly alter the brightness of the probe on the cell. However, the image brightness of cells labeled by PCPs (Figure 6a−c) is 20-fold greater than that of free unmodified con A. Theses images by PCPs are even 4-fold brighter than those by unconjugated PCPs, which is most likely attributed to the coupling effect of PCPs on the cell membrane (*42*).

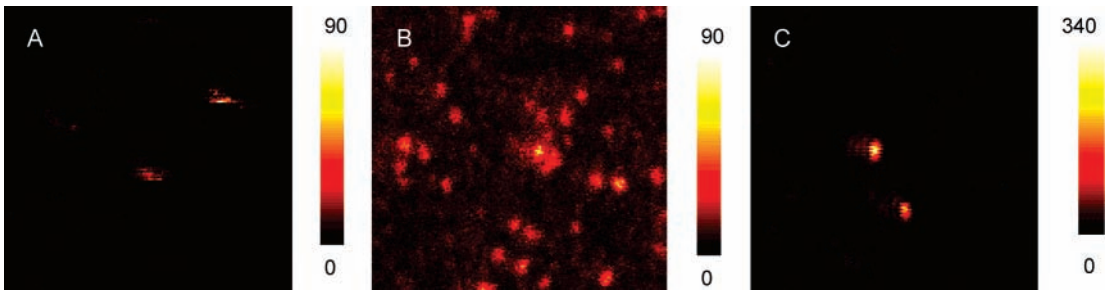

Figure 4. Scattering/fluorescence images (a) tiopronin-coated silver particles, (b)Alexa Fluor 647 labeled con A, and (c) con A-bound silver particles.

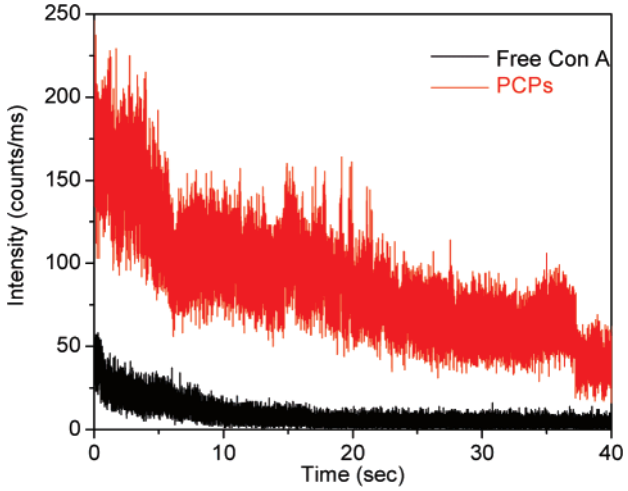

Figure 5. Respective time traces of unmodified con A and bound silver particles.

In order to understand the possible interactions between the metal particles and cells, we utilized the tiopronin-coated metal particles instead of PCPs in the incubation experiment. The metal particles were hardly observed near the cells after washing, implying that PCPs were conjugated on thee cultured cell basically through the interaction of bound con A instead of the silver particles. However, bulky PCPs may meet stronger steric hindrance when being proximate to and conjugating to the cells. The quantity of PCP on the cell surface must be less than that of unmodified con A. Because there is only one con A on each PCP, the quantity of fluorophore by PCP is proposed to be less than that by unmodified con A on the cell membrane. Therefore, the intensity enhancement of fluorescence on the cell images by PCPs is most probably attributed to the coupling effect among PCPs (*24*). In fact, when the metal particles are in close proximity to each other, the electric fields have been estimated to become more intensive due to overlapping from the individual fields (*50*), and the fluorophore localized in these overlapped fields is enhanced more efficiently (*43*). This result reveals that the signal intensity on the cell membrane can be enhanced not only as individually but more efficiently as coupled when PCPs are conjugated.

The coupling effect of PCPs also displays a better photostability on the cell membrane. Real-time intensity traces illustrate that almost half of the unmodified con A molecules on cells were bleached out in 5 s, while intensities of PCPs decay more gradually (Figure 7). If the fluorophores are supposed to be bleached proportionally with time as shown in the decay curves, we can propose that the photostability of PCPs on the cell membrane is at least 10 times longer than that of unmodified con A.

The coupling mechanism of fluorophore with metal particles can be discussed by lifetimes. It is known that the interaction between the fluorophore and metal particles can result in a dramatic change of radiating energy that is expressed as an apparent increase of intrinsic decay rate (*25*). Such an increase of intrinsic decay rate can be monitored by the lifetime of a fluorophore. In this study, the lifetime data were collected from the time traces using single molecule time-corrected single photon counting (TCSPC). The lifetime of unmodified con A was estimated to be 2.5 ns and furthermore shortened to be 1.2 ns when bound to the metal particles, affirming the existence of interaction between fluorophores and metal particles. When the fluorophore was associated on the cells as an unmodified state or PCP, the intensity was observed to decay differently in which the decay by PCP was more rapid than that by unmodified con A (Figure 8), and the lifetimes were estimated to be 1.1 ns (PCPs) and 2.4 ns (unmodified con A), respectively. It is uncertain why the lifetime did not further shorten when associating PCPs on the cells membrane. Many factors including the distance between the PCPs and environmental changes for the fluorophore, etc., may be partially responsible.

The tiopronin-coated metal particles with an average diameter of 20 nm were decorated quantitatively by Alexa Fluor 647-labeled con A in a molar ratio of 1:1 to generate metal plasmon-coupled probes (PCPs) as fluorescence imaging agents. HEK293 A cells were conjugated by PCPs and unmodified dye-labeled con A, respectively, and fluorescently imaged using scanning

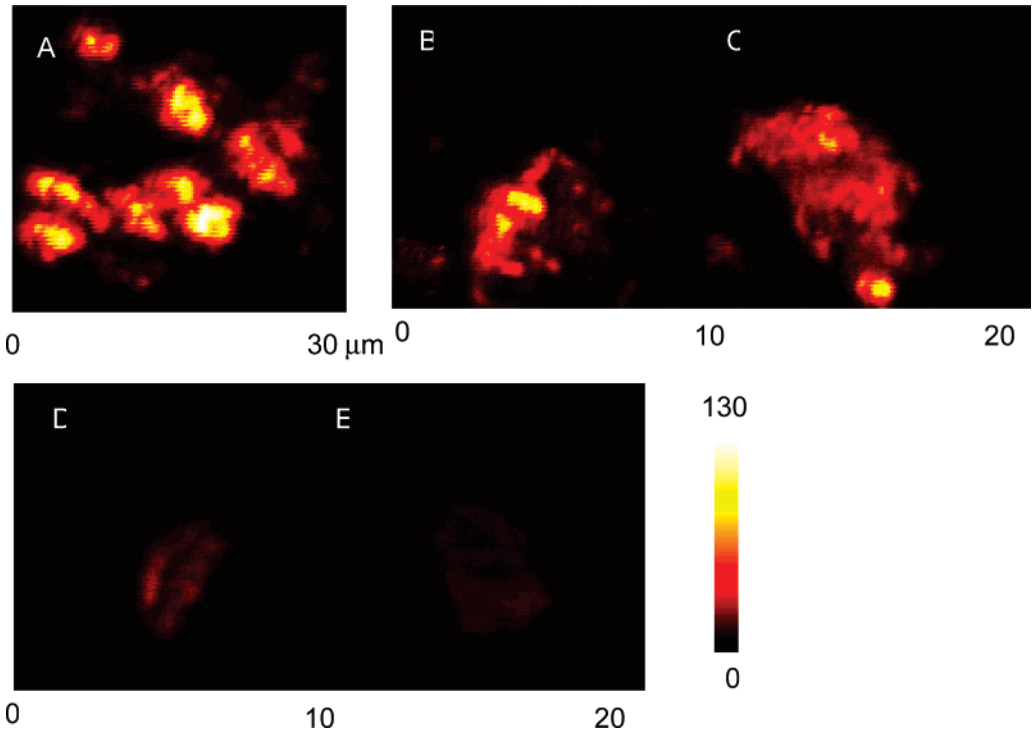

Figure 6. Representative fluorescent images of HEK 293 A cell lines (a−c) labeled by PCPs, and (d and e) labeled by unmodified con A.

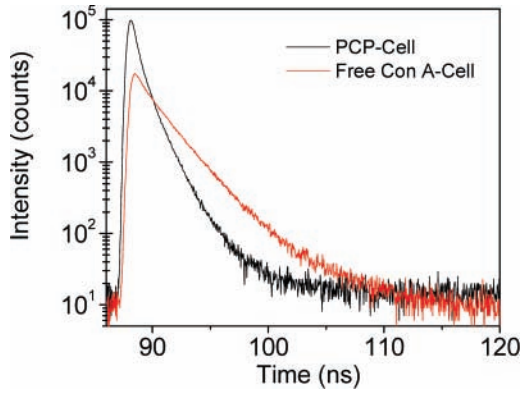

Figure 8. Respective TCSPC curves from fluorescent images labeled by unmodified con A and PCPs on the cell membrane.

confocal microscopy at the single cell level. The fluorescence images of cell lines by PCPs were 20 times brighter than those by unmodified con A, and the photostability was 10 times longer. These results reveal that the PCPs can work efficiently as brighter and more photostable imaging agents. In this case, the dye-labeled con A is only bound to the silver particles in a molar ratio of 1:1 for research convenience. Actually, with increasing the binding number of con A on each metal particle to an optimal value, PCP is supposed to be brighter up to hundreds of times than unmodified con A. The high number of con A on PCP can increase its capability to catch the target on the cell membrane. One metal particle can also be decorated readily by more than one kind of fluorophore, so multicolor PCP will be investigated in further work. In addition, PCP displays a longer photostability, so it can be utilized in long-range diagnosis and treatment of disease.

ACKNOWLEDGMENT

This research was supported by a grant from NIH, EB-00682, HG-02655, and NCRR, RR-08119. We greatly appreciate the discussion with Dr. Hali Hartmann in Medical Biotechnology Center and the University of Maryland Biotechnology Institute.

The mutant β1,4-galactosyltransferase (β4Gal-T1), β4Gal-T1-Y289L, in contrast to wild-type β4Gal-T1, can transfer GalNAc from the sugar donor UDP-GalNAc to the acceptor, GlcNAc, with efficiency as good as that of galactose from UDP-Gal. Furthermore, the mutant can also transfer a modified sugar, C2 keto galactose, from its UDP derivative to *O*-GlcNAc modification on proteins that provided a functional handle for developing a highly sensitive chemoenzymatic method for detecting *O*-GlcNAc post-translational modification on proteins. We report herein that the modified sugar, C2 keto galactose, can be transferred to free GlcNAc residues on N-linked glycoproteins, such as ovalbumin or asialo-agalacto IgG1. The transfer is strictly dependent on the presence of both the mutant enzyme and the ketone derivative of the galactose. Moreover, the PNGase F treatment of the glycoproteins, which cleaves the N-linked oligosaccharide chain, shows that the modified sugar has been transferred to the N-glycan chains of the glycoproteins and not to the protein portion. The application of the mutant galactosyltransferase, β4Gal-T1-Y289L, to produce glycoconjugates carrying sugar moieties with reactive groups, is demonstrated. We envision a broad potential for this technology such as the possibilities to link cargo molecules to glycoproteins, such as monoclonal antibodies, via glycan chains, thereby assisting in the glycotargeting of drugs to the site of action or used as biological probes.

INTRODUCTION

In recent years, it has become evident that a number of biological processes, such as cell adhesion (*1*, *2*), cell−cell recognition (*3*), formation of glycosynapses (*4*, *5*), immune defense (*6*), targeting, and signaling, appear to be modulated by the glycan moieties of glycoproteins and glycolipids, where they serve as ligands in the specific protein−carbohydrate (*7*), lipid−carbohydrate, and carbohydrate−carbohydrate interactions (*5*, *8*). They also serve as recognition targets for their complementary binding proteins, the lectins (*7*). Because of the molecular diversity of glycans, and being specific recognition ligands in various biological processes, they are also used to design drugs that target various diseases (*9*).

Glycans can be classified as linear or branched sugars. The linear sugars are the glycosaminoglycans comprising polymers of sulfated disaccharide repeat units that are O-linked to a core protein, forming a proteoglycan aggregate (*10*). The branched glycans are found as N-linked and O-linked sugars on glycoproteins or on glycolipids (*11*). These carbohydrate moieties of the linear and branched glycans are synthesized by a super family of enzymes, the glycosyltransferases, which transfer a sugar moiety from a sugar donor to an acceptor molecule.

X-ray crystal structures of the catalytic domain of many glycosyltransferases have been determined in recent years. These studies show that the specificity of the sugar donor is determined by a few residues in the sugar−nucleotide binding pocket of glycosyltransferases, which are conserved among family members from different species (*12*). This structural information has made it possible to reengineer the existing glycosyltransferases. For example, the β1,4-galactosyltranferase family in vertebrates (β4Gal-T1 to T7) is responsible for the transfer of galactose from the donor UDP-galactose (UDP-Gal) to various glycans in a β1−4 linkage (*13*, *14*). The residue Tyr289 (or Phe) in the catalytic pocket of β4Gal-T1, determines the sugar donor substrate specificity of the enzyme toward UDP-Gal (*12*, *15*). Mutation of Tyr289 to Leu or Ile enlarges the binding pocket such that the mutant enzyme, β4Gal-T1-Y289L, has β1,4-*N*-acetylgalactosaminyltransferase (β4GalNAc-T) activity, which is as efficient as its β1,4-galactosyltransferase (β4Gal-T) activity (*15*, *16*). Similarly, in blood group A GalNAc-transferase, the residues Leu266 and Gly268, and in blood group B Gal-transferase, the residues Met266 and Ala268 determine the specificities toward their respective sugar donors, UDP-GalNAc and UDP-Gal (*17*). Mutation of Met266 to Leu266 in blood group B Gal-transferase changes the enzyme sugar donor specificity toward UDP−GalNAc. Furthermore, in β1,3-glucuronyltransferase-1 (GlcA-T1), His 308 (His 311 in GlcAT-P) (*18*, *19*) determines the enzyme specificity toward the sugar donor UDP−GlcUA. Mutation of His308 to Arg308 changes the specificity of the sugar donor to UDP−Glc, UDP−Man, or UDP−GlcNAc.

The *O*-GlcNAc modification on proteins is the dynamic posttranslational modification in which the β-*N*-acetylglucosamine is covalently attached to serine or threonine residues in proteins. Several methods have been reported for the identification of *O*-GlcNAc modification on proteins. One of the detection methods involves the enzymatic labeling by β4Gal-

[a] Galactosyltransferase assays with GalNAc were performed as described in the Materials and Methods section. The mutant β4Gal-T1-Y289L was assayed at a final concentration of 24 μg/mL. Assays were done at 30 °C with overnight incubations using 1.5 mM of UDP-GalNAc and 1 mM of acceptors. [b] The pentasaccharide substrate, GlcNAcβ1,2-Manα1,6(GlcNAcβ1,2-Manα1,3)Man, and the heptasaccharide tetrapeptide substrate, Arg-[GlcNAcβ1,2-Manα1,6-(GlcNAcβ1,2-Manα1,3)-Manβ1,4-GlcNAcβ1,4-GlcNAcβ]-Asn-Glu-Gly, are branched structures which have 2 mol of GlcNAc per mole of substrate available for the transfer reaction. [c] GalNAc is transferred to only 50% of the available GlcNAc residues in the branched substrate structures. [d] Ovalbumin also has a branched N-linked glycan. The amount of GlcNAc available for transfer is variable. [e] Percentage of the acceptor converted to product has been calculated on the basis of the amount of ovalbumin used in the assay.

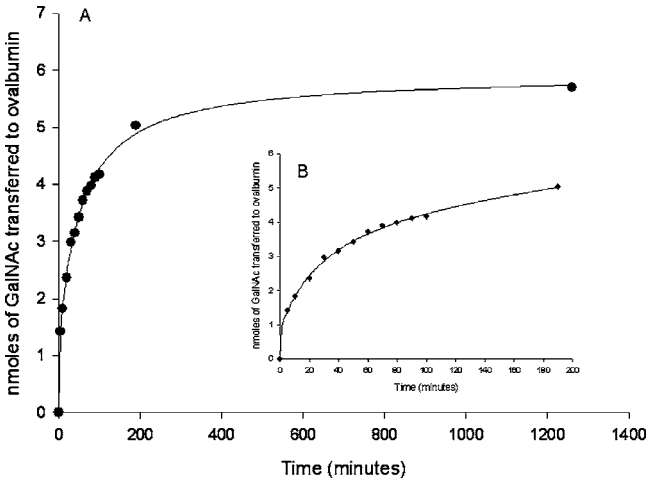

Figure 1. (A) Enzyme kinetics activity of the mutant enzyme, β4Gal-T1-Y289L, with UDP−GalNAc as a donor substrate and ovalbumin as a glycoprotein acceptor substrate. GalNAc-T activity was measured using 500 μM UDP−GalNAc and 0.5 mg of ovalbumin in 100 μL incubation mix containing Mn^{2+} and Tris pH 8.0 (Material and Methods section). The mutant enzyme was used at a final concentration of 40 μg/mL, and activity was measured at the indicated times. For MS analysis, the reaction was carried out for a period of 20 h at 30 °C. (B) The insert shows the results of the kinetic analysis between zero and 200 min of incubation time.

T1 of *O*-GlcNAc using UDP-^{3}H galactose (*20*). However, this method is time-consuming and expensive. The engineered β4Gal-T1-Y289L was shown to transfer from a UDP derivative, a galactose moiety that has a ketone substitution at the C2 position of the galactose ring (*21*). The introduced ketone was then used as a functional handle that allowed the development of a highly sensitive and rapid chemoenzymatic method to detect *O*-GlcNAc modification on proteins (*21*).

Here, we show that the C2 keto galactose moiety can also be transferred from its UDP derivative to only free GlcNAc residues on the N-linked glycan chains of ovalbumin or on asialo-agalacto IgG1 molecules. That the modified galactose is transferred only to the GlcNAc residues on the N-glycan chains was confirmed by the PNGase F treatment of the glycoprotein that cleaves the N-linked glycan chains. As previously described (*21*), the transfer was followed by coupling the C2 keto galactose moiety on the glycan chain to an aminooxy biotin which was then detected by a sensitive chemiluminescence assay. Using this strategy, one can couple two glycoproteins that have modified glycan chains, with each having reactive functional groups with heterobifunctional linkers (*22*). The advantage of this methodology is that the modification occurs in a site-directed manner, only where the carbohydrate is attached to the glycoprotein. This specificity permits the use of site-directed immunotherapy without affecting the antigen binding affinity of the immunoglobulin. The advantages and potential use of this approach in developing a drug delivery system or a biological probe are discussed.

EXPERIMENTAL PROCEDURES

Preparation and Purification of Wild-Type β4Gal-T1 and Mutant β4Gal-T1-Y289L. The β4Gal-T1 that has a Cys342 mutated to Thr342 was used as wild-type β4Gal-T1. This mutation does not affect the enzymatic properties of β4Gal-T1, and it makes the protein stable at room temperature (*15*). This wild-type β4Gal-T1 and the mutant β4Gal-T1-Y289L, derived from the wild type, were constructed in the pET23a vector (Novagen, Inc.) as described previously (*15*, *23*, *24*). The *E. coli* strain BL21(DE3)pLysS, containing these plasmids, was used for the expression of these proteins (Novagen, Inc). The recombinant proteins were expressed in the inclusion body fraction and purified according to the published method (*25*). From a liter of induced bacterial culture, the yield of purified inclusion bodies is generally 80−100 mg. However, the presence of PEG-400 and L-arginine during folding of the inclusion bodies increases the yields of the native protein, resulting in an overall folding efficiency of ∼60% (*25*).

Supply of Reagents. The oligosaccharide acceptors, *N*-acetylglucosamine (GlcNAc), chitobiose (GlcNAcβ1,4-GlcNAc), and chitotriose (GlcNAcβ1,4-GlcNAcβ1,4-GlcNAc) were obtained from Sigma Chemicals, U.S.A.; chitotetrose (GlcNAcβ1,4-GlcNAcβ1,4-GlcNAcβ1,4-GlcNAc) and the pentasaccharide GlcNAcβ1,2-Mana1,6-(GlcNAcβ1,2-Mana1,3)-Man were purchased from Dextra-labs, U.K. The heptasaccharide tetrapeptide, Arg-[GlcNAcβ1,2-Manα1,6-(GlcNAcβ1,2-Mana1,3)-Manβ1,4-GlcNAcβ1,4-GlcNAcβ]-Asn-Glu-Gly, which carries both 1,2−1,6-arm and 1,2−1,3-arm linked to core mannose, was purchased from Calbiochem, U.S.A. The UDP derivative of C2 keto galactose was synthesized as described earlier (*21*). The *N*′-aminooxymethylcarbonylhydrazino-D-biotin (ARP) was purchased from Dojindo Laboratories. Peptide *N*-glycosidase F (PNGase F) was obtained from New England Labs. Albumin from chicken egg white grade VI was purchased from Sigma, and IgG1 was provided by Drs. Mei-Yun Zhang and Yang Feng from Dr. Dimiter S. Dimitrov's laboratory at the Nanobiology program, CCR, NCI.

GalNAc-T Enzyme Assays. The protein concentrations were measured using the Bio-Rad Protein Assay kit on the basis of the method of Bradford and further verified by SDS-PAGE electrophoresis. An enzymatic assay procedure for β4Gal-T1 has been reported previously (*26*). The enzyme activities of the β4Gal-T1-Y289L mutant were measured using UDP−GalNAc as the sugar nucleotide donor, and at various concentrations of the acceptors, GlcNAc, chitobiose, chitotriose, chitotetrose, the mono, di-, tri-, tetrasaccharides, respectively, and the N-linked branched oligosaccharide structures. For the specific activity measurements, a 100 μL incubation mixture containing 10 mM $MnCl_2$, 25 mM Tris−HCl, pH 8.0, 500 μM of UDP−GalNAc, 20 ng of the mutant β4Gal-T1-Y289L, and 0.5 μCi ^{3}H-UDP−GalNAc was used for the GalNAc-T reaction. The reaction was terminated by adding 200 μL of cold water, and the mixture

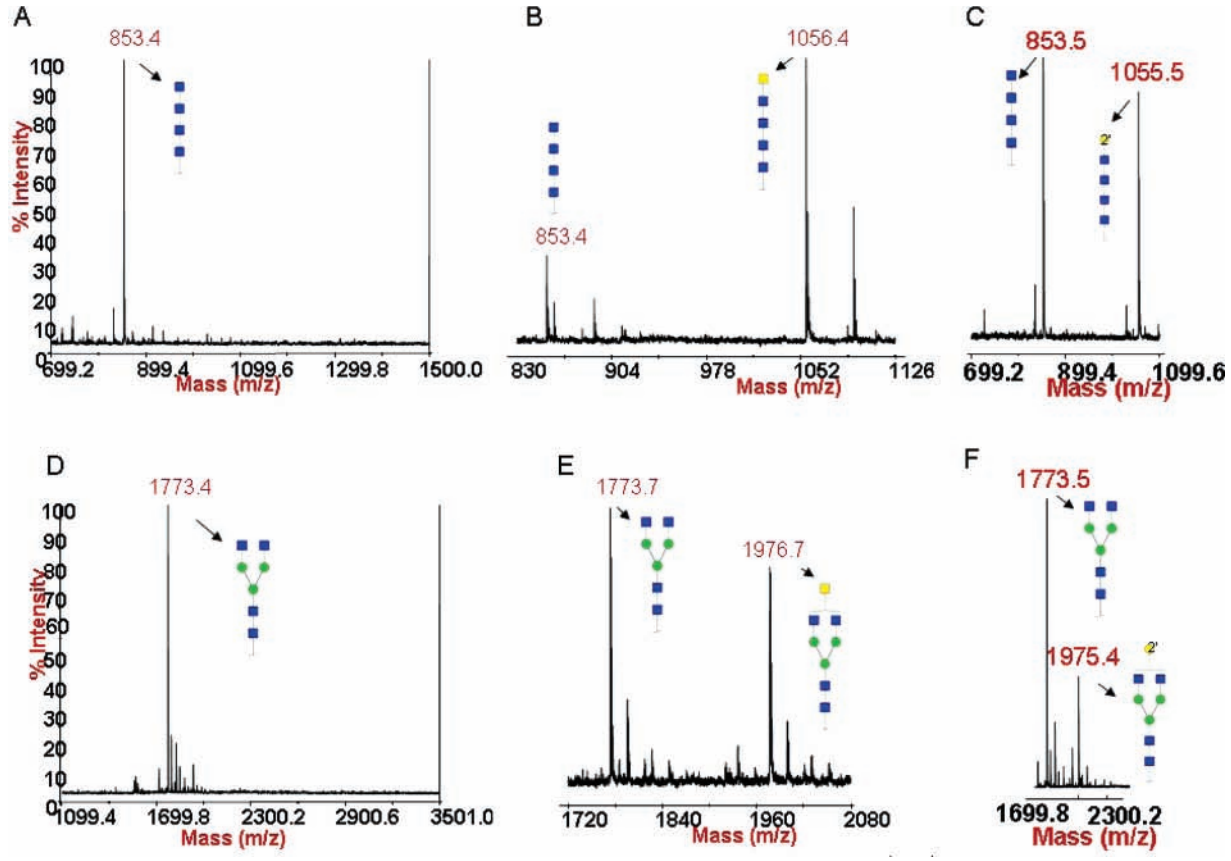

Figure 2. MALDI mass spectra of glycans after the transfer of GalNAc to the sugar acceptors chitotetrose GlcNAcβ1,4-GlcNAcβ1,4-GlcNAcβ1,4-GlcNAcβ (A,B,C) and a heptasaccharide tetrapeptide Arg-[GlcNAcβ1,2-Manα1,6-(GlcNAcβ1,2-Manα1,3)-Manβ1,4-GlcNAcβ1,4-GlcNAcβ]-Asn-Glu-Gly (D,E,F). Major peaks are annotated with the carbohydrate structure shown in the symbols for monosaccharides, according to the nomenclature adopted by the consortium for functional glycomics, http://www.functionalglycomics.org/static/consortium/. GlcNAc (blue squares), mannose (green spheres), GalNac (yellow squares), and C2 keto galactose (yellow sphere). The symbols were drawn using the GlycoWorkbench program found in the eurocarb database http://www.eurocarbdb.org/. The transferred C2 keto galactose moiety in panels C and F is shown. Panel A shows a peak at 853.4 *m*/*z* corresponding to the linear glycan structure chitotetrose. Panel B shows a shift in the molecular mass from the starting ion at 853.4 *m*/*z* to a peak of 1056.4 *m*/*z* after addition of a GalNAc moiety (Material and Methods section). Panel C shows chitotetrose with the transferred C2 keto galactose moiety to the terminal GlcNAc residue. Panel D shows a peak at 1773.4 *m*/*z* corresponding to the starting branched heptasaccharide peptide structure, Arg-[GlcNAcβ1,2-Manα1,6-(GlcNAcβ1,2-Manα1,3)-Manβ1,4-GlcNAcβ1,4-GlcNAcβ]-Asn-Glu-Gly. Panel E shows a peak at 1976.7 *m*/*z* that corresponds to a heptasaccharide peptide having one added GalNAc moiety. Panel F shows the peak at 1975.4 *m*/*z* that corresponds to a heptasaccharide to which one C2-keto galactose moiety has been transferred to one of the available terminal GlcNAc moieties.

was passed through a 0.5 mL bed volume column of AG 1-X8 cation resin (Bio-Rad) to remove any unreacted ^{3}H-UDP−GalNAc. The column was washed successively with 300, 400, and 500 μL of water, and the column flowthrough was diluted to 20 mL with Biosafe scintillation fluid; radioactivity was measured with a Beckman counter LS-3801. A reaction without the acceptor sugar was used as a control.

Transfer of C2 Keto Galactose from its UDP Derivative to Free GlcNAc Residues on Glycoacceptors Using the Mutant of β4Gal-T1-Y289L. Albumin from chicken egg white grade VI (40 μg) and recombinant IgG1 (2−5 μg) were incubated with 1 mM UDP-C2 keto galactose and 500 ng of the mutant β4Gal-T1-Y289L or 488 ng of wild-type β4Gal-T1 in a 10 μL final incubation mixture containing 10 mM $MnCl_2$ and 25 mM Tris−HCl (pH 8.0). Reactions were incubated at 30 °C for 3 h.

Biotinylation of Ovalbumin and IgG1. The ketone-labeled proteins were subsequently diluted to 30 μL in a mixture containing 50 mM NaOAc (pH 3.9) and *N*-aminooxymethylcarbonylhydrazino-D-biotin (ARP). The biotinylation reactions were incubated with gentle shaking for 12−16 h at 25 °C. The reactions were stopped by boiling in Tris-glycine-SDS sample buffer containing β-mercaptoethanol and analyzed as described (*21*).

Western Blotting of Ovalbumin and Asialo-Agalacto-IgG1. Proteins were resolved in 14% Tris−glycine gel (Invitrogen) and then transferred by electrophoresis to nitrocellulose (0.45 μm pore size) for 2 h at 25 V, and biotinylated protein bands identified as described previously (*21*). Briefly, the nitrocellulose blots were blocked for 1 h at room temperature with shaking in a solution containing 5% dry milk in 0.02% Tween-20. Blots were rinsed thoroughly with water and probed with streptavidin conjugated with horseradish peroxidase (HRP) (Amersham Biosciences) (1:4000) in 1× PBS pH 7.4, 0.02% Tween-20 containing 3% BSA for 1 h at 25 °C. After probing with the conjugated streptavidin, the nitrocellulose membranes were washed 4× for 10 min in 5% dry milk containing 0.02% Tween-20. The streptavidin−HRP signal was visualized by chemiluminescence after 2 min exposure to ECL detection reagents (Amersham) and exposure to Kodak Biomax XAR film.

Peptide: *N*-Glycosidase F Treatment. Ovalbumin and asialo-agalacto-IgG1 samples, approximately 3 μg each, were boiled for 10 min in 1% SDS and 1% β-mercaptoethanol. Samples were then incubated in the presence or absence of PNGase F (2500 units) for 16 h at 37 °C in a buffer containing 5 mM sodium phosphate and 1% NP-40. Samples were then

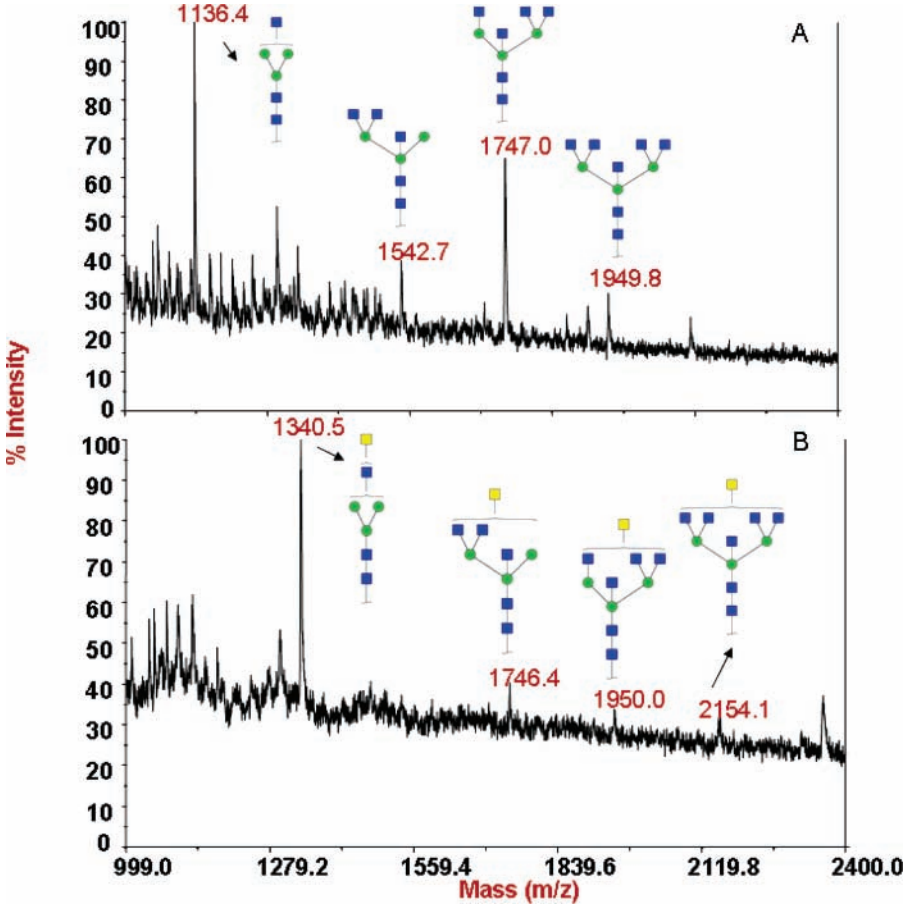

Figure 3. MALDI mass spectra of the glycans released from chicken ovalbumin. After PNGase F treatment of chicken ovalbumin, the released oligosaccharides were passed through the microcon YM-10 columns and analyzed by MALDI mass spectrometry. Only the peaks of interest are annotated, showing their molecular mass and possible structures. Carbohydrate structures are shown in symbol form, as described in the Figure 2 legend. (A) Glycans released from the commercial sample (Sigma) of chicken ovalbumin before GalNAc transfer. Ions at 1136.4, 1542.7, 1747.0, and 1949.8 *m*/*z* are assigned to ovalbumin structures reported (*29*). (B) Glycan structures released from chicken ovalbumin after the transfer of GalNAc from UDP−GalNAc with the mutant enzyme β4Gal-T1-Y289L. Ions at 1340.5, 1746.4, 1950.0, and 2154.1 *m*/*z* are assigned to structures in the ovalbumin preparation onto which GalNAc moieties have been transferred.

boiled in SDS-PAGE loading buffer and then resolved by SDS-PAGE.

MALDI Mass Spectrometric Analyses of Oligosaccharides. An Applied Biosystems Voyager-DE Pro time-of-flight mass spectrometer was utilized for analyses. The accelerating voltage was 20 kV, guide wire 0.05%, and grid voltage 94%. The instrument was operated in linear mode under positive ion conditions. A nitrogen laser was used at 337 nm with 150 laser shots averaged per spectrum. 2,5-Dihydroxybenzoic acid (Aldrich Chemicals, St. Louis, MO) was used as the matrix for all experiments. The matrix concentration was 20 mg/mL in water. Sample preparation was a modified "dried droplet" procedure, whereby 0.3 μL of sample was spotted onto the MALDI target, followed by 0.3 μL of matrix. The mixture was then allowed to air-dry prior to analysis. Calibration was performed using instrument default settings, and data analysis was carried out using Data Explorer software residing on the Voyager mass spectrometer.

MALDI Mass Spectrometric Analyses of the N-Glycans of Ovalbumin. Albumin from chicken egg white (grade VI), 1 mg in 100 μL deionized water, was washed in a microcon YM-10 centrifugal filter device with 1.5 mL of deionized water to remove free oligosaccharide chains. The washed sample was concentrated and incubated at 30 °C for 18 h in a 100 μL final incubation mixture containing 0.5 mM UDP−GalNAc, 2 μg of the mutant β4Gal-T1-Y289L, 10 mM $MnCl_2$, and 25 mM Tris−HCl (pH 8.0). The samples were then digested for 18 h at 37 °C with 2500 units of PNGase F (NEB) in 50 mM sodium phosphate buffer. The digested samples were applied onto a Microcon YM-10 filter device, and the filtrate containing the released N-glycans was analyzed by mass spectrometry as described above.

RESULTS

Sugar Donor Specificity of β4Gal-T1. Our laboratory previously showed that the sugar donor specificity of β4Gal-T1 toward UDP−Gal is determined by a single amino acid, Tyr, at position 289 (*15*). When Tyr289 is mutated to Leu, the sugar donor specificity of β4Gal-T1 is broadened in a way that, in contrast to the wild-type enzyme which lacks GalNAc-T activity, the mutant β4Gal-T1-Y289L exhibits both β4Gal-T and β4GalNAc-T activities (*15*). The Tyr289 mutant can also transfer from the UDP derivatives the galactose moiety that has, at the C2 position, substitutions other than the 2-N-acetyl group (−NH−CO−CH_3 in GalNAc) (*21*). Here, we first investigated the transfer of GalNAc to N-glycans of glycoproteins by the mutant enzyme, β4Gal-T1-Y289L.

Transfer Preferences of β4Gal-T1-Y289L to oligosaccharide acceptors. In a previous study from our laboratory, we had shown by double substrate kinetics that the true K_m for both chitobiose and chitotriose was nearly the same (*27*), suggesting that the presence of an additional GlcNAc residue in chitotriose, not present in chitobiose, did not affect the ground-state binding of these acceptor substrates to the enzyme. Moreover, the apparent K_m values for chitobiose and chitotriose were similar

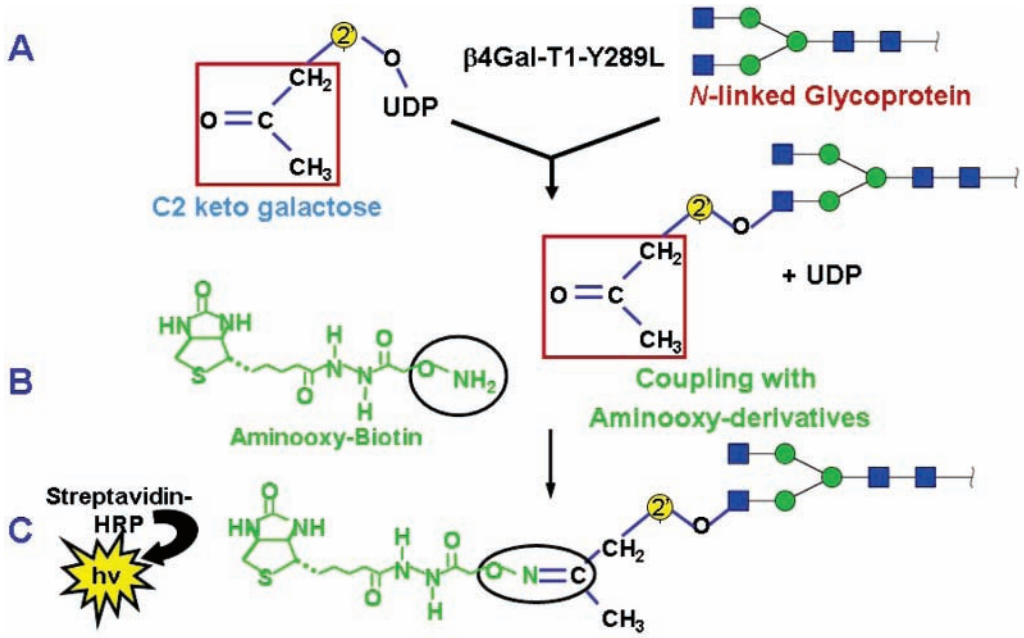

Figure 4. Detection of GlcNAc glycosylated proteins by β4Gal-T1-Y289L. Strategy for the detection of a terminal GlcNAc residue in the N-linked glycoprotein by the mutant β4Gal-T1-Y289L. (A) In contrast to the wild-type β4Gal-T1, the mutant enzyme β4Gal-T1-Y289L transfers to the GlcNAc residues of the N-linked glycoprotein a Gal moiety, from the UDP derivative, that has modifications located at the C2 position of galactose, such as the N-acetyl moiety (GalNAc) (*15*) or a ketone moiety (*21*). (B) The C2 ketone moiety of the substituting group in galactose can then be coupled with aminooxy derivatives under mild conditions (*21*). (C) When aminooxy biotin (*N*-(aminooxyacetyl)-*N*′-(D-biotinoyl) hydrazine) is used as the coupling agent, the product can be labeled by streptavidin conjugated to horseradish peroxidase (HRP) and detected by a sensitive chemiluminescence method.

to the true K_m values obtained by double substrate kinetics. In this study, we tested the amount of acceptor converted to product for various linear and branched structures (Table 1). In the linear structures, 25 nmol of the acceptor GlcNAc was available in the reaction, and in the branched structures with two terminal GlcNAc residues, 50 nmol of the acceptor GlcNAc was available in the reaction mixture. The linear acceptors, mono-, di-, tri- and tetrasaccharides, all showed 97% to 100% conversion of the acceptor to product (Table 1). Both chitobiose and chitotriose showed 99% conversion. In the pentasaccharide, GlcNAcβ1,2-Manα1,6-(GlcNAcβ1,2-Manα1,3)-Man, and the heptasaccharide tetrapeptide, Arg-[GlcNAcβ1,2-Manα1,6-(GlcNAcβ1,2-Mana1,3)-Manβ1,4-GlcNAcβ1,4-GlcNAcβ]-Asn-Glu-Gly (which carries GlcNAc on both the 1,2−1,6-arm and the 1,2−1,3-arm linked to core mannose), GalNAc is only transferred to 50% of the available GlcNAc residues on these acceptor substrates (Table 1).

Transfer of GalNAc Residue to N-Linked Glycoproteins. Over 20 years ago, it was shown β4Gal-T1 could transfer galactose from UDP−Gal to ovalbumin in the absence of α-lactalbumin (*28*). Only recently, the permissive mutant β4Gal-T1-Y289L was shown to transfer GalNAc from UDP−GalNAc to GlcNAc residues (*15*). Galactosyltransferase and *N*-acetylgalactosaminyltransferase assays with the β4Gal-T1-Y289L mutant, using ovalbumin as the acceptor, were performed by a radiochemical assay as described previously (*15*, *25*). The kinetics of transfer of GalNAc to ovalbumin was analyzed over a period of 20 h as described in the Materials and Methods section (Figure 1). Due to the heterogeneity observed with commercial ovalbumin preparations (*29*), the amount of available acceptor substrate is variable, and we show that, after overnight incubation, only 37% of acceptor is converted into product (Table 1).

MALDI Mass Spectra Determination of Glycans before and after Treatment with UDP−GalNAc and UDP-C2 Keto-Modified Galactose. The transfer of GalNAc and C2 keto-modified galactose from their respective UDP derivatives was followed by MALDI mass profiling (Figure 2). In the MALDI profile, in the range between *m*/*z* 700 and 1500, a unique peak at *m*/*z* 853.4 corresponds to the chitotetrose, prior to the transfer of the donor sugar (Figure 2A). Transfers of GalNAc (Figure 2B) and C2 keto-modified galactose (Figure 2C) are observed as peaks at *m*/*z* 1056.4 and 1055.5, respectively. The MALDI profile in a range between *m*/*z* 1099.4 and 3501.0 (Figure 2D) shows a major peak at *m*/*z* 1773.4 corresponding to the heptasaccharide tetrapeptide, Arg-[GlcNAcβ1,2-Manα1,6-(GlcNAcβ1,2-Manα1,3)-Manβ1,4-GlcNAcβ1,4-GlcNAcβ]-Asn-Glu-Gly. The addition of GalNAc (Figure 2E) and C2-keto galactose (Figure 2F) to either antenna of the heptasaccharide is observed as peaks at *m*/*z* 1976.7 and 1975.4, respectively. Under the conditions used in this experiment (Materials and Methods section), the transfer of GalNAc to the GlcNAc residue on one of the antenna of the biantennary structure was observed.

MALDI Mass Spectra Determination of N-Linked Carbohydrates from Ovalbumin. To determine the nature of the N-glycans attached to ovalbumin, glycans were released with PNGase F, purified on amicon filters, and analyzed by MALDI. In the MALDI profile, obtained from the released N-glycan chains of ovalbumin, peaks in the range between *m*/*z* 999.0 and 2400.0 were observed. Four major peaks were found at *m*/*z* 1136.4, 1542.7, 1747.0, and 1949.8 (Figure 3A). These are mainly bi- to penta-antennary structures which lack the terminal sialic acid and galactose present on N-glycans of mammalian proteins. Upon transfer of GalNAc to one antenna of the penta-antennary structures, the peaks observed at *m*/*z* 1340.5, 1746.4, 1950.0, and 2154.1 correspond to structures with one additional monosaccharide unit, the GalNAc residue that has been transferred from UDP−GalNAc by the mutant enzyme β4Gal-T1-Y289L (Figure 3B).

Detection of GlcNAc Residue on Glycosylated Proteins by β4Gal-T1-Y289L. Figure 4 shows the schematics of the transfer of C2 keto galactose to the N-glycan moiety of a glycoprotein. The ketone moiety at the C2 position of galactose

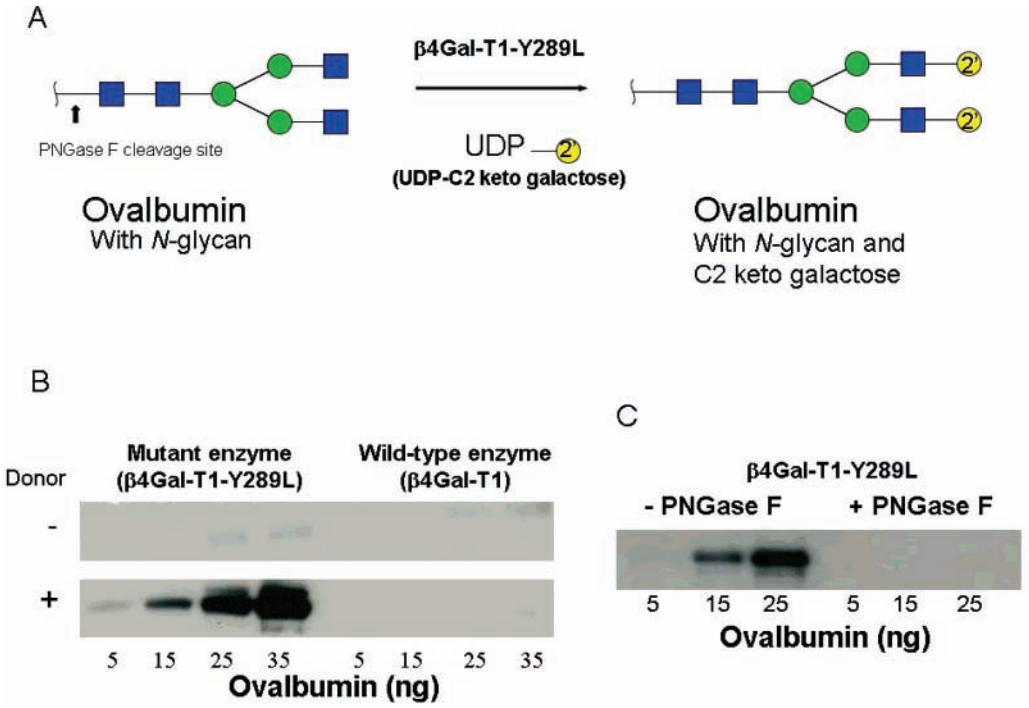

Figure 5. Transfer of the C2 keto derivative of galactose to free GlcNAc residues on the N-glycan chains of ovalbumin by the mutant enzyme β4Gal-T1-Y289L and the chemoenzymatic detection of the transferred C2 keto derivative. (A) N-Glycan chain, attached to ovalbumin, has been shown using the symbols for monosaccharides as described in Figure 2. The C2 keto galactose (yellow spheres) is transferred to the GlcNAc residues (blue squares) at the nonreducing end of the glycan chain, by the mutant enzyme β4Gal-T1-Y289L. The mannose residues in ovalbumin are shown as the green spheres. An arrow shows the cleavage site for PNGase F. (B) Detection of the transferred C2 keto galactose is accomplished by linking with the aminooxy biotin, followed by the chemiluminescence technique. After the transfer of the sugar moiety by the transferase enzyme and subsequent linking to the aminooxy biotin, the mixtures were resolved by SDS-PAGE, transferred by Western blot to nitrocellulose membranes, and probed with streptavidin−HRP. In the absence of the sugar donor substrate (−), little signal was detected using either the wild-type enzyme β4Gal-T1 or the mutant enzyme β4Gal-T1-Y289L. The chemiluminescence was detected only in the samples that contained UDP-C2 keto galactose, mutant enzyme (+), and at least 5 ng of ovalbumin. The wild-type enzyme, β4Gal-T1, having Tyr at position 289, cannot transfer the modified C2 keto galactose. (C) PNGase F treatment of the biotinylated ovalbumin. Ovalbumin samples, after the transfer of the modified C2 keto galactose, were treated with PNGase F (Materials and Methods section), which removes the N-glycan chains from the protein. In contrast to untreated samples (−), in the PNGase F-treated samples (+) no chemiluminescence was detected, showing that the transfer of the modified C2 keto galactose is selective for the glycan portion of ovalbumin.

is a flexible chemical handle, which under mild conditions can be coupled to aminooxy-containing ligands (Figure 4B). When a biotinylated derivative of the aminooxy-containing ligand (*N*-(aminooxyacetyl)-*N*′-(D-biotinoyl) hydrazine) was used as a coupling agent, the transfer and coupling reaction could be followed by detecting the biotinylated product by chemiluminescence with streptavidin conjugated to horseradish peroxidase (HRP) (Figure 4C).

Transfer of C2 Keto Galactose from its UDP Derivative to GlcNAc Residues on the Glycan Chains of Ovalbumin and Asialo-Agalacto-IgG1 by the Mutant Enzyme *β*4Gal-T1-Y289L and Coupling of Aminooxy biotin to the Modified Sugar. The mutant enzyme, β4Gal-T1-Y289L, can transfer the C2 keto galactose from its UDP derivative to the GlcNAc residue on the N-glycan chain of ovalbumin (Figure 5A) or to an asialo-agalacto-IgG1 molecule (Figure 6A). The transfer of the modified sugar by the mutant enzyme is carried out at 30 °C for 3 h. Reactions were also performed in the absence of UDP donor (Figure 5B). The transfer has been followed by coupling to the ketone group at the C2 position of galactose, the biotinylated aminooxy ligand, followed by resolving proteins by SDS-PAGE analysis, transfer of proteins to nitrocellulose filters by Western blotting, and probing by streptavidin−HRP techniques. The transfer is strictly dependent on the presence of the donor and the mutant enzyme, as observed by the strong chemiluminescence of the transferred material (Figure 5B). The wild-type enzyme cannot utilize the C2 ketone derivative of the galactose (Figure 5B).

Peptide: *N*-Glycosidase F (PNGase F) Treatment Removes N-Glycan Chains with Modified Sugar on Glycoproteins. The biotinylated aminooxy ligand is linked only to the N-glycan chain of ovalbumin or IgG1, as shown by PNGase F treatment, which removes N-glycan chains from the protein. No chemiluminescence was detected at ovalbumin or IgG1 protein bands in the Western blot analysis, suggesting that the transferred C2 keto-modified galactose was linked only to the released carbohydrate moiety (Figures 5C and 6B).

DISCUSSION

This study has shown that it is possible to modify free GlcNAc residues on two N-linked glycoproteins, ovalbumin and immunoglobulin, by enzymatic methods. These modifications have only been possible due to the availability of the structural information of glycosyltransferases which helped to design mutant enzymes that can transfer unnatural sugar donors (*15*, *21*, *30*). Here, we show that the transfer is strictly dependent on the presence of both the mutant enzyme β4Gal-T1-Y289L and the ketone derivative of the galactose, while the wild-type enzyme cannot transfer the galactose with the C2 ketone moiety. We also show that the modifications occur only at the N-glycan chains of the glycoproteins, as indicated by PNGase F treatment.

The results of the transfer of ^{3}H-labeled GalNAc by β4Gal-T1-Y289L to several linear and N-linked branched oligosaccharides concur with the results obtained by the MALDI mass spectral analysis. Also, the results obtained by the chemoenzymatic method are consistent with the MALDI mass spectral analysis. The efficiency of transfer of GalNAc to various linear

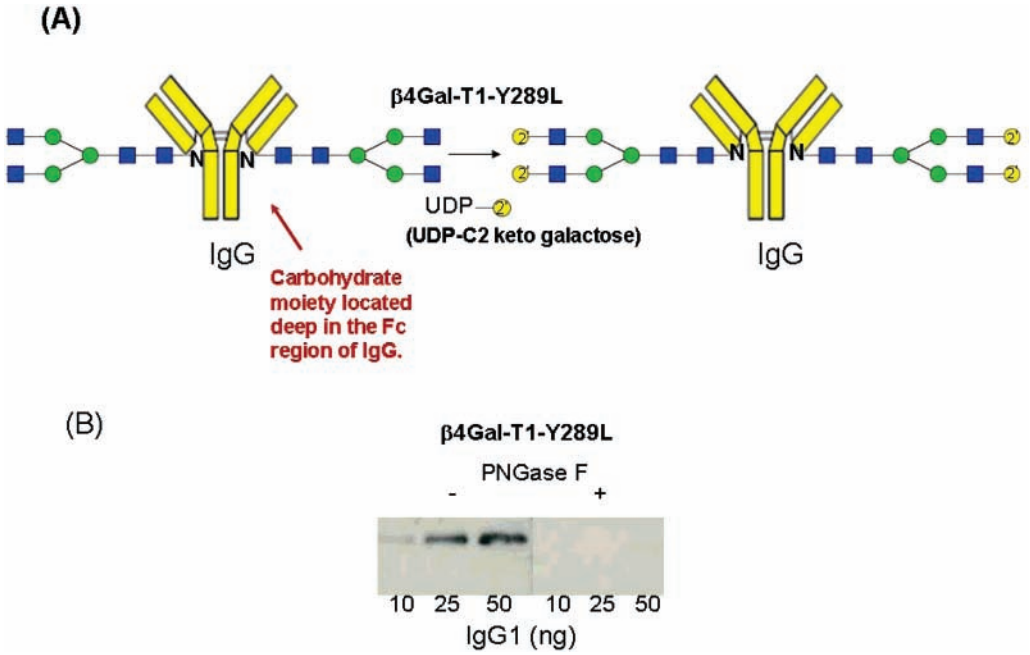

Figure 6. Coupling to IgG via N-glycan chains. Selective labeling of the asialo- IgG1 molecule confirmed by PNGase F treatment. (A) Schematic diagram of an IgG molecule with the N-glycan structures attached at the Fc region. (B) The C2 keto galactose moiety was transferred to the carbohydrate in the Fc region of IgG1, using the mutant enzyme β4Gal-T1-Y289L. Mixtures were either treated without PNGase F (−) or with PNGase F (+) containing NP-40, prior to the coupling to aminooxy biotin. The mixtures were resolved by SDS-PAGE, transferred by Western blot to nitrocellulose membranes, and probed with streptavidin−HRP. No chemiluminescence was detected in PNGase F treated sample (+), showing that the transfer of the modified C2 keto galactose moiety is selective for the glycan portion of IgG1 and glycosylation has occurred in the heavy chain of IgG1 at the free GlcNAc residues (10, 25, and 50 ng).

oligosaccharide acceptors was nearly 100%. The length of the oligosaccharide acceptor did not affect the transfer efficiency of GalNAc. However, when branched oligosaccharide acceptors are used in the enzymatic assay, the efficiency of transfer of GalNAc is reduced. Comparison of the MALDI profiles before and after addition of GalNAc and C2 keto galactose indicated that only one molecule of GalNAc is transferred to one of the two GlcNAc residues available for the transfer on the pentasaccharide, GlcNAcβ1,2-Manα1,6-(GlcNAcβ1,2-Manα1,3)-Man and the heptasaccharide tetrapeptide, Arg-[GlcNAcβ1,2-Manα1,6-(GlcNAcβ1,2-Manα1,3)-Manβ1,4-GlcNAcβ1,4-GlcNAcβ]-Asn-Glu-Gly. Both enzymatic and MALDI analysis showed that GalNAc is transferred to only 50% of the available GlcNAc residues in the branched structures. This may be explained by the results of a previous work from our laboratory using kinetic and crystallographic analysis, which showed that, at lower concentrations, the 1,2−1,6-arm of a biantennary N-glycan is a preferred antenna for galactosylation by β4Gal-T1 (*27*). In contrast, at higher concentrations, the 1,2−1,3-arm of a biantennary N-glycan is a preferred antenna for galactosylation (unpublished results).

When the acceptor is ovalbumin, the transfer efficiency is reduced to 37%. This can be explained by the known structural variability of N-glycans on ovalbumin preparations as has been previously observed (*29*). The largest ovalbumin structure found by MALDI mass spectral analysis was a galactosylated hybrid glycan of composition $(Man)_3(GlcNAc)_7(GalNAc)_1$ (2154.1 *m*/*z*; see Figure 3B).

Having demonstrated the labeling of ovalbumin by enzymatic and MALDI mass analysis, we explored the sensitivity of the chemoenzymatic approach for the detection of N-linked modifications on ovalbumin. This chemoenzymatic method enabled the detection of N-linked modifications within minutes using as little as 5 ng of ovalbumin and 10 ng of IgG1. This study also shows the possibility of modifying the single N-linked glycosylation site at Asn297 on the Fc domain of IgG1. Although some glycosylation may occur outside the Fc domain, this is usually a rare event (*31*). The glycans that are linked to Asn297 of IgG1 have been characterized on the basis of the number of terminal galactoses into three groups, IgG1-G2, IgG1-G1, and IgG1-G0 (*32*). In the IgG1-G0, the glycans do not have terminal galactose residues, but instead have terminal GlcNAc residues, as in the heptasaccharide tetrapeptide used in this study. Only 5% to 14% of the total serum IgG1 is fully sialylated (*32*, *33*), and generally, IgG1-G2, IgG1-G1, and IgG1-G0 fractions are present in 16%, 35%, and 35% of the total IgG glycan pool, respectively (*32*). Here, we show that the C2 keto galactose moiety can be transferred from its UDP derivative to the free GlcNAc residues on the N-linked glycan chains of the IgG1 molecules. The transfer was followed by coupling the ketone handle to an aminooxy biotin, which was then detected by a sensitive chemiluminescence assay (*21*).

The method of coupling a target agent to a carrier protein via glycan chains, as described here using ovalbumin and IgG1 as model systems, offers an advantage over other cross-linking methods. Here, the target agent is linked in a site-directed manner, only where the carbohydrate is attached to the glycoprotein, as in the IgG1 molecule at the Fc domain, away from the antigen binding site. The problem common to previous approaches using monoclonal antibodies for immunotherapy is the lack of specificity of the reactions, resulting in heterologous labeling and a decrease in the antibody affinity for the antigen.

The currently described method also represents a sensitive and effective approach to monitor the glycosylation of therapeutic glycoproteins and monoclonal antibodies. The potential of glycosyltransferase mutants to produce glycoconjugates carrying sugar moieties with reactive groups may be a benefit to the glycotargeting of drugs to their site of action. The role of glycotargeting in the internalization of drugs has been established by numerous studies (*34*, *35*) since the discovery of the asialoglycoprotein receptor (*36*); however, much of its potential remains unexplored. Although a great number of pharmaceutical agents are discovered each year, the clinical

application of these is many times hindered because of failure to reach the site of action. Our approach using mutant glycosyltransferases to transfer chemically reactive sugar residues for linking of other molecules via specific glycan chains has the potential for development of an efficient drug delivery system. A word of caution is that there is still the challenge to up-scale the production of chimeric proteins needed in pharmaceutical settings.

ACKNOWLEDGMENT

We thank Drs. Dimiter S. Dimitrov, Mei-Yun Zhang, and Yang Feng from the Nanobiology program, CCR, NCI, for providing IgG1samples, and Dr. Maria Manzoni from the Structural Glycobiology Section, CCR, NCI, for the critical reading of the manuscript. Received November 2, 2006; Revised Manuscript Received January 24, 2007

We have demonstrated synthesis and application of a water-soluble, folate-substituted poly(*p*-phenyleneethynylene) (PPE) as a fluorescent contrast agent to image cancer cells. This fluorescent polymer targets and images KB cancer cells *in vitro* with high selectivity. To deliver PPE to the cells, folate ligands have been attached to an amine-functionalized PPE via an amide coupling agent. The hydrolysis of the ester groups gave a water-soluble PPE, **5**. The PPE **5** is minimally cytotoxic at concentrations of 1−10 μg/mL, which is sufficient to stain KB cancer cells efficiently. PPE **6**, devoid of folate ligands, did not stain KB cells. As a low folic acid (−) receptor control group, NIH 3T3 fibroblast cells were incubated with **5** and did not show fluorescent labeling. The folate receptor-mediated endocytosis of KB cells was evidenced by laser scanning confocal microscopy and fluorescence microscopy. The photochemical stability and ability to sustain multivalency provide advantages of PPEs over other fluorescent contrast agents. Their minimal cytotoxicity makes the PPE superior to the cytotoxic CdSe quantum dots.

INTRODUCTION

Molecular imaging with small fluorescent molecules or with inorganic II−VI semiconductor quantum dots (CdS, CdSe, CdTe) is pervasive in biomedical applications, including in the detection of cancer cells (*1*−*3*). Although organic dyes have a long history in biological applications, their limitations are their susceptibility to often rapid photobleaching and their general inability to sustain multivalent interactions (*4*). Inorganic semiconductor nanoparticles (quantum dots) have been intensively studied in *in vitro* and *in vivo* to image cancer cells, as they overcome the limitations of conventional dyes, i.e., attachment of multiple binding elements combined with often low fluorescence quantum yield in water (*5*−*7*). However, the popular CdSe-core quantum dots are composed of individually cytotoxic ions. Due to residual leaching such nanoparticles are cytotoxic (*8*, *9*).

Poly(*p*-phenyleneethynylene)s are fluorescent, photostable, and easily functionalized and can be made in water soluble form for bioanalytical applications (*10*−*12*). They have been used in the detection of heavy metal ions, lectins, proteases, and bacteria, playing out the intrinsic strengths of polymeric, i.e., multivalent, yet fluorescent scaffolds (*13*−*17*). We expected that grafting of folic acid onto a PPE could selectively deliver the polymer to folate-receptor-overexpressing KB cells because of the high binding affinity ($K_d \sim 100$ pM) of folic acid for the folate-receptor proteins. Folic acid and its conjugate enter into the intracellular cytoplasm via endocytosis and are widely used for the targeted delivery of anticancer drugs to folate-receptor-positive cancer cells such as ovarian, prostate, and breast cancers, where the folate receptors are overexpressed while having limited expression in normal cells (*18*−*22*). Despite several promising results in cancer cell targeting, the design of folate-mediated delivery systems remains challenging due to several constraints of commonly used materials such as cytotoxicity, complexity of conjugation processes, immunogenicity, and limited endocytotic permeability. For the fluorescent staining of FR-overexpressing cancer cells, it would be beneficial to use the fluorescent water-soluble polymers, acting as not only the delivery vehicles but also the fluorescent imaging agents. Here, we report synthesis of a folate−PPE conjugate **5** and its selective uptake by and imaging of cancer cells with minimal cytotoxicity to normal cells.

EXPERIMENTAL PROCEDURES

Synthesis of Monomers (1−3). Synthesis of **1**, **2**, and **3** were described in our previous reports (*10*, *12*).

Synthesis of Polymer (4). Monomer **1** (222 mg, 0.300 mmol), **2** (160 mg, 0.300 mmol), and **3** (218 mg, 0.660 mmol) were dissolved in a mixture of triethylamine (1 mL) and DMF (5 mL) in a Schlenk flask (25 mL) under a flow of nitrogen with magnetic stirring. $(Ph_3P)_2PdCl_2$ (2.0 mg, 2.8 μmol) CuI (0.5 mg, 2.8 μmol) were added to the flask. The reaction mixture was stirred at room temperature for 24 h. The solution was slowly added to ether (200 mL). The precipitate was washed with ether and water. A yellow solid was obtained in 99% yield (421 mg). PPE **4** shows an absorption maximum at 436 nm and an emission maximum at 470 nm in chloroform, typical for a dialkoxy-PPE. ^{1}H NMR (DMSO-d_6): δ 7.14, 4.92, 4.19, 3.56, 3.49, 3.09, 1.21.

Synthesis of Polymer (5). Polymer **4** (100 mg, 0.0715 mmol) was dissolved in DMF (10 mL) in a flask (50 mL) under a flow of nitrogen under magnetic stirring. Folic acid (74 mg, 0.17 mmol), 2,4,6-Trimethylpyridine (20 mg, 0.17 mmol), and EDC·HCl (33 mg, 0.17 mmol) were added to the flask in an ice bath. The reaction mixture was stirred at the room temperature for 24 h. The solvent was evaporated under a reduced pressure.

Scheme 1. Synthesis and Structures of PPEs Used in This Work

Methanol (20 mL) and NaOH (400 mg, 10.0 mmol) were added to the reaction mixture, and the temperature was increased to 40 °C. The mixture was stirred for 24 h. The precipitate was collected in a glass funnel and washed with methanol and acetone. An orange solid (94 mg, 74% yield) was obtained. ^{1}H NMR (D_2O): δ 7.40, 6.97, 6.88, 6.50, 4.44, 3.78, 3.29, 2.10.

Cell Culture. A frozen vial of KB cells (passage number: 17) in MEM-EBSS media (Hyclone, UT) containing 10% FBS and 1% penicillin−streptomycin (pen/strep) was thawed, immediately resuspended with RPMI 1640 folate-free media with 10% FBS (Hyclone, UT) and 1% pen/strep (herein referred to folate-free RPMI 1640), and inoculated onto a cell culture treated Petri dish (100 mm in diameter). The cells were cultured for 10 days before use at 37 °C, 95% relative humidity, and 5% CO_2 with repetitive change of the media every 3 days. NIH 3T3 fibroblasts were obtained from ATCC (American Type Culture Collection, Manassas, VA) and maintained in Delbecco's Modified Eagles Media (DMEM) supplemented with 10% FBS and 1% pen/strep.

Cytotoxicity and Proliferation Assay. The cytotoxicity of **5** was examined as previously described (*23*). Briefly, 24 h prior to the cytotoxicity test, KB cells cultured on the Petri dish were enzymatically lifted by using a trypsin−EDTA solution (0.5%), resuspended with folate-free RPMI 1640 media, and replated on 96-well plates at 500 000 cells/mL media. The cells were allowed to attach to the plate overnight. On the day of the assay, the yellowish colored powder of **5** was dissolved in phosphate-buffered saline (PBS, pH 7.4) (Invitrogen) solution. The conditioned media was prepared by mixing the solution of **5** with folate-free RPMI 1640 media. The concentration of **5** in the conditioned media varied from 1 μg/mL media to 100 μg/mL. The media of KB cells cultured for 24 h were evaporated, replenished with the conditioned media containing **5**, and cultured for additional 4 and 24 h. On the specified time point, the media was aspirated and the plates were washed three times with serum-free, folate-free RPMI 1640 media. The LIVE/DEAD viability cytotoxicity assay reagents were prepared (combination of 4 μM ethidium homodimer-1 and 2 μM calcein AM), added to the 96-well samples, wrapped with aluminum foil, and incubated for 30 min. The positive control was KB cells only, without **5**, and the negative control was to expose KB cells to 70% (v/v) methanol for 30 min. Following the incubation for 30 min, the fluorescence intensity of each sample was measured using a microplate reader and then was normalized by the value for the positive control (cell viability). The live/dead cell population following the treatment with LIVE/DEAD reagents was visualized by fluorescence microscopy to corroborate the quantitative results. We also investigated the effect of **5** on the metabolic activity of KB cells. At each time point of cell culture (4 and 24 h) following exposure to **5**, the number of cells was measured using a PicoGreen DNA kit (Molecular Probes, Eugene, OR). PicoGreen binds to double stranded DNA in cells and the fluorescence intensity of each sample was obtained using a microplate reader.

Folate-Receptor-Mediated Targeting. The intercellular uptake of **5** was investigated with KB cells and NIH 3T3 fibroblasts. On the day before the experiment, KB cells were lifted from the plate and resuspended with folate-free RPMI 1640 media. Approximately 100 000 cells/mL were seeded on Lab-Tek chamber slides (Nalge Nunc, Naperville, IL) and incubated overnight; **6** and **5** were dissolved in folate-free RPMI 1640 media to prepare a series of concentrations ranging from 0.001 mg/mL to 0.1 mg/mL. KB cells cultured for 24 h on the chamber slides were rinsed with serum-free, folate-free RPMI 1640 media and a solution of either **5** or **6** was then added to the chamber slides. The slides were incubated for 4 and 24 h at

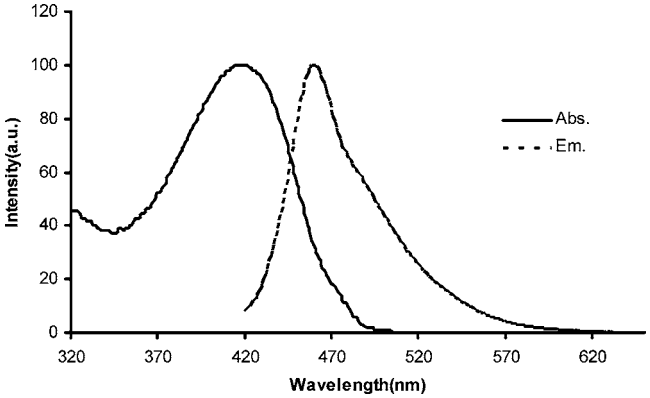

Figure 1. Normalized absorption and emission spectra of PPE **5** in water. $\lambda_{max\ abs} = 421$ nm, $\lambda_{max\ emiss} = 460$ nm. The emission spectrum of **5** is typical for a dialkoxy PPE. The shoulder near 490 nm is of vibronic origin.

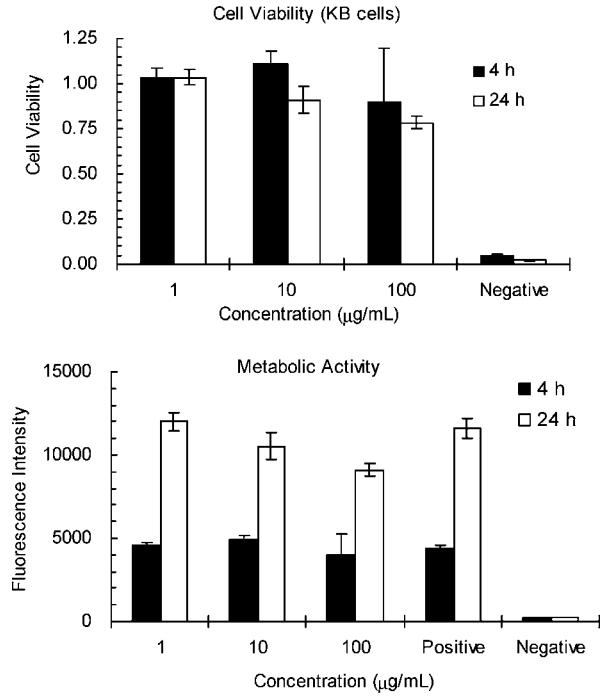

Figure 2. KB cell viability upon different concentrations of PPE **5** after 4 and 24 h incubation (viability = 1 means that 100% of cells in the condition were viable). The negative control was the group in which cells were treated with 70% methanol for 30 min before treatment with each dye (LIVE/DEAD reagent or PicoGreen), and the positive control was the cells cultured without exposure to PPE **5**. The concentration of PPE **5** in the media was varied from 1 to 100 μg/mL. At 4 and 24 h after incubation with PPE **5**, LIVE/DEAD reagents were added to each sample, and the fluorescence intensity was measured. Cell viability was calculated by normalization of the fluorescence intensity from each sample with that of the control that was under no treatment. The metabolic assay measures change in DNA content produced by cells, which is indicative of proliferation capability. The metabolic assay, combined with the cell viability assay, supports that KB cells exposed to PPE **5** are not only viable but also are capable of proliferating under the concentrations tested in this study.

37 °C. At each time point, the media were aspirated completely and the cells were rinsed with folate-free RPMI 1640 media and PBS three times, fixed with 3.7% formaldehyde for 10 min, rinsed with PBS twice, and blocked in 5% FBS for 1 h. For microscopic analysis, a coverslip was mounted on the slide with a drop of VECTRASHIELD mounting media (Vector Laboratories, Inc., CA). The samples were cured overnight, preventing exposure to light sources. The intercellular distribution of the conjugated polymers **5** and **6** was visualized by normal

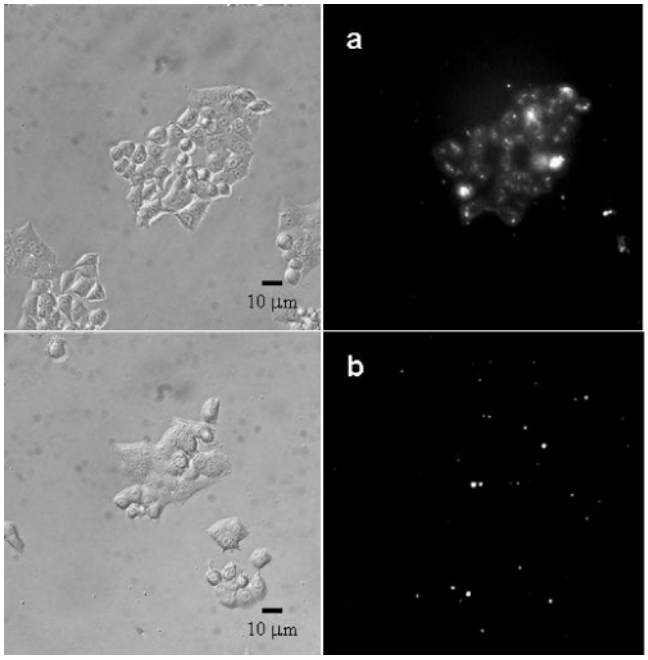

Figure 3. Fluorescence microscopy images (10×) of KB cells after incubated with (a) PPE **5**, and (b) PPE **6** for 24 h. Transmittance images (left) and fluorescence images (right). Punctuate staining has appeared (b) after KB cells were incubated with **6** and washed with PBS buffer several times, indicating some nonspecific interactions between KB cells and **6**. The normal fluorescence microscopy allows visualization of localized PPE **5** on KB cells; however, it does not provide the information whether the dye was permeablized through the cellular membrane and placed within the cytoplasm. This figure shows that **5** was colocalized on KB cells while PPE **6** only had little nonspecific binding to KB cells or the tissue culture plate.

fluorescence microscopy and two-photon confocal microscopy at excitation and emission wavelength of approximately 480 and 540 nm, respectively. The same procedure was applied to NIH 3T3 fibroblasts except using normal DMEM supplemented with 10% FBS.

RESULTS AND DISCUSSION

Synthesis of **5** is accomplished by the postfunctionalization of the random copolymer, PPE **4** (Scheme 1), which was synthesized from **1**−**3** in the presence of $(Ph_3P)_2PdCl_2$/CuI and a triethylamine/DMF mixture as solvent. This approach allows controlling the molar ratio of amine monomer **1** and diester monomers **2** and **3** to 1:1:2. The PPE **4** is well soluble in THF, CH_2Cl_2, and DMF. The number average molecular weight (M_n) of **4** is 8.3×10^3 with a polydispersity index of 1.70 (GPC, polystyrene standard). The coupling reaction of folic acid with **4** was carried out in the presence of the carbodiimide EDC (1-ethyl-3-(3′-(dimethylamino)propyl)carbodiimide) (*24*) in anhydrous DMF. PPE **5** was obtained after hydrolysis of the ester groups by NaOH in methanol. Based on the molecular weight of PPE **4**, the length of one extended PPE chain of **4** (and therefore **5**) is 12 nm. It is well soluble in water and shows an absorption maximum at 420 nm and an emission maximum at 460 nm (*25*−*27*). Even though the peak fluorescence of **5** in water is in the blue, which can interfere with autofluorescence of tissues and proteins, **5** has a broad emission that tails into the green (Figure 1). Using a green fluorescence filter, the KB cells are easily visualized after staining with **5**.

The fluorescence quantum yield of dialkoxy PPEs in organic solvents is high, up to 0.86; the quantum yields of PPEs **5** and **6**, however, were only 0.02 and 0.08 in water, respectively. The decrease in the quantum yield of PPE **5** compared to that of PPE **6** is probably due to the presence of the electron-accepting

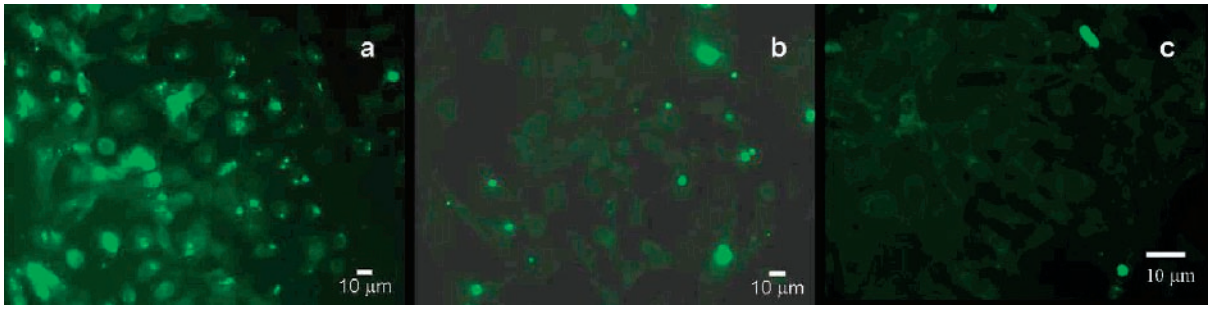

Figure 4. Fluorescence microscopy images (40×) of (a) KB cells after incubation with PPE **5**, (b) KB cells after incubation with PPE **6**. The KB cells are slightly stained by **6** due to nonspecific interactions, (c) NIH 3T3 fibroblast cells after incubation with PPE **5** for 4 h. The fluorescence microscopy images were obtained from KB cells incubated for 4 h.

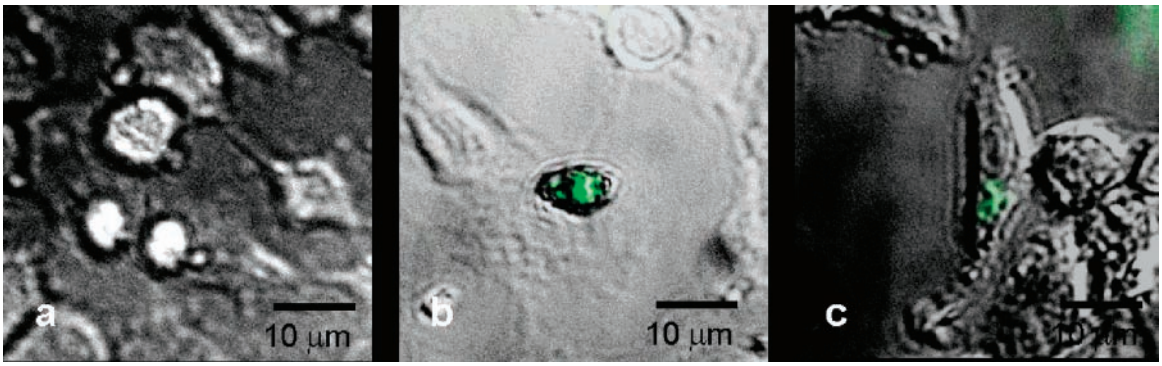

Figure 5. Confocal microscopy images (63×) of KB cells after incubation with (a) PPE **6** for 4 h, (b and c) PPE **5** for 4 h. The features highlighted in green show the fluorescence. Confocal microscopy allowed us to obtain figures at the interface where the KB cells had contact with the tissue culture plate. When we analyzed the image according to layer-by-layer z scanning, no fluorescence from PPE **5** was observed at the membrane while the fluorescence intensity was increased as we focused down to the cell-culture plate interface, confirming that PPE **5** was internalized and emitted measurable amounts of fluorescence within KB cells.

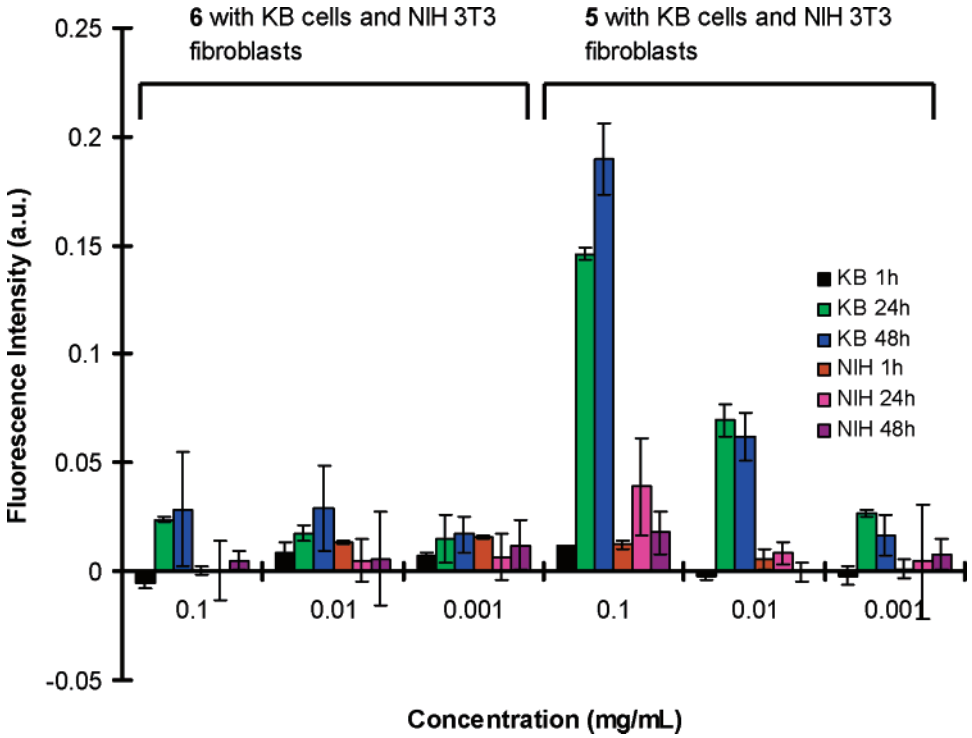

Figure 6. Fluorescence intensity of KB cells and NIH 3T3 fibroblasts after incubation with PPE **5** and PPE **6** for 1, 24, and 48 h.

folate substituent that will act as an intrinsic energy transfer fluorescence quencher. We were concerned about the low quantum yield, but we expected that a more hydrophobic environment would increase the quantum yield. In the presence of bovine serum albumin (5 μM), the most abundant protein in serum, the quantum yield of **5** increased from 0.02 to 0.15 due to the significant decrease in polarity of the formed complex of BSA and **5** (*11*), suggesting that **5** would function well as fluorescent beacon in a hydrophobic environment.

The cytotoxic effects of PPE **5** and PPE **6** on KB cells were investigated (Figure 2) (*28*). Cell viability decreased slightly at a concentration of >10 μg/mL of **5**. KB cells incubated with

PPE **5** showed no enhanced rate of cell death relative to PPE **6** or to a control without added PPE. A functional assay was conducted to evaluate the cytotoxic effects of PPE **5** on KB cells in more detail. The total number of metabolically active (active mitochondrial dehydrogenase enzyme) cells increased approximately 2-fold after the exposure of the cell culture to **5**. At a concentration of >1 μg/mL, PPE **5** exhibits sufficient fluorescent intensity to be detected inside the intracellular domain, yet at this concentration the cytotoxic effects of **5** are minimal, suggesting that the endocytosis of **5** by KB cells is facile and that there is probably fluorescence enhancement of **5** in the cells. We attribute the fluorescence enhancement to a decrease in polarity and/or the complexation of the folate ligand, leading to its spatial separation from the main chain.

To visualize the receptor-mediated uptake, separate samples of KB cells were incubated for 4 h with both PPE **5** and PPE **6**. Spatial distribution of the PPEs was examined by fluorescence microscopy (Figure 3). KB cells treated with **5** displayed cellular localization of the fluorescence, while **6** showed negligible fluorescent labeling of KB cells but some punctuate staining, due to nonspecific interactions between the KB cells and **6**. The magnified image suggests that endocytosed PPE **5** is primarily localized in the cytoplasm, not in the cell nucleus (Figure 5), and although the nucleus was not counterstained, it was easily recognizable after uptake of **5**. A concentration of 10 μg/mL **5** is sufficient to image targeted KB cells *in vitro*. Interestingly enough, the microscopy experiments were not disturbed by the blue autofluorescence of the cells. As a low folic acid (−) receptor control group, NIH 3T3 fibroblast cells were incubated with both PPE **5** and PPE **6** for 4 h. Compared to KB cells incubated with **5**, we observed no fluorescent labeling of the NIH 3T3 cells (Figure 4). Although there is some nonspecific binding of PPE **6** to KB cells, only PPE **5** was internalized by the folate receptor-mediated endocytosis pathway. The quantification of endocytosis-mediated PPE inside the cells was done by fluorescence microreader, showing that only **5** was significantly incorporated inside KB cells (Figure 6). A time-dependent increase of fluorescence intensity was only observed in KB cells incubated with **5**, but not in any of the controls (**6** and NIH 3T3 fibroblasts). The cell culture under low temperature (4 °C) showed significantly decreased uptake of **5** by KB cells, suggesting that ATP-consuming endocytosis is the mechanism for the PPE uptake.

In conclusion, **5** is of low cytotoxicity, making it promising as an imaging agent for biological applications at concentrations <10 μg/mL. The photochemical stability of PPE allowed imaging the cells after 48 h without any loss in fluorescence intensity. The folate−PPE conjugate **5** shows specific targeting and imaging of KB cancer cells *in vitro* by folate receptor-mediated endocytosis. The endocytosed PPE is localized in the cytoplasm. The combination of photochemical stability and low cytotoxicity suggests **5** as a potentially useful *in vivo* imaging agent for folate-receptor overexpressing cancer cells. Multivalency (*29*) and chemical versatility of PPEs are their advantages over conventional organic dyes. We will construct multitasking PPEs containing targeting agents and small molecule therapeutics.

Use of Antibody as Carrier of Oligomers of Peptidomimetic $\alpha_v\beta_3$ Antagonist to Target Tumor-Induced Neovasculature

In Soo Shin,[†] Beom-Su Jang,[†] S. Narasimhan Danthi,[‡] Jianwu Xie,[‡] Sarah Yu,[†] Nhat Le,[†] Jin-Soo Maeng,[†] In Sook Hwang,[†] King C. P. Li,[‡,§] Jorge A. Carrasquillo,[†,||] and Chang H. Paik*[,†]

Department of Nuclear Medicine and Department of Radiology, Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda, Maryland 20892. Received November 7, 2006; Revised Manuscript Received January 19, 2007

Sulfhydryl selective reactions were explored to conjugate oligomers of a peptidomimetic integrin $\alpha_v\beta_3$ antagonist, 4-[2-(3,4,5,6-tetrahydropyrimidine-2-ylamino)ethyloxy]benzoyl-2-(*S*)-aminoethylsulfonylamino-β-alanine (IA) to monoclonal antibody (MoAb) to increase integrin $\alpha_v\beta_3$ receptor-binding avidity. To generate sulfhydryl groups, *N*-succinimidyl-*S*-acetylthioacetate (SATA) was conjugated to both MoAb and IA. Sulfhydryl groups were then generated upon the deacetylation of the protecting acetyl group from the *S*-acetylthioacetato (ATA) moiety of MoAb−$(ATA)_n$ or IA−ATA with 0.02 M hydroxylamine in the presence of 1 mM EDTA at pH 7.2. The major focus was on optimizing the reaction concentrations, molar ratios, and reaction pH to conjugate high levels of IA−(A-SH) to MoAb−$(A\text{-}SH)_n$ without causing the inter- and intramolecular cross-linking of MoAb. Stepwise reactions of MoAb−$(A\text{-}SH)_n$ (15 μM MoAb) with a homobifunctional cross-linker, 1,8-bis(maleimido)diethylene glycol (BM$[PEO]_2$) at a >50× molar excess to the −SH, followed by the reaction of the purified product MoAb−$(A\text{-}S\text{-succinimidomaleimido-}[PEO]_2)_n$ with IA−(A-SH) at pH 7.2 afforded monomeric MoAb−(A-*S*-succinimido-$[PEO]_2$-succinimido-*S*-A-IA)$_n$ with <10% high molecular weight oligomeric MoAb. Monomeric MoAb−(A-*S*-S-$[PEO]_2$-S-*S*-A-IA)$_{10}$ (MoAb−IA_{10}) radiolabeled with ^{111}In using 2-(*p*-isothiocyanatobenzyl)cyclohexyl−DTPA and with ^{125}I using the Iodogen method showed >70% bindability to 0.4 μM $\alpha_v\beta_3$. When injected iv to nude mice with the receptor-positive M21 tumor, MoAb−IA_{10} radiolabeled with both ^{111}In and ^{125}I accumulated rapidly and was retained in the tumor for a 44 h period while the radioactivity cleared rapidly from the blood, thereby resulting in increasing tumor-to-blood ratios over time. The tumor uptake was similar between the ^{125}I label and the ^{111}In label for a 44 h period. In contrast, the blood radioactivity was lower, but liver and other organ uptakes were much higher for the ^{111}In label than for the ^{125}I. The ^{111}In label produced higher tumor-to-blood ratios but much lower tumor-to-organ ratios than the ^{125}I. The rapid blood clearance, a short peak tumor uptake time, and a low peak tumor uptake value with prolonged tumor retention of this macromolecule appear to support a hypothesis that MoAb−IA_{10} primarily binds to $\alpha_v\beta_3$ receptors on angiogenic vessels, but not on the tumor. This hypothesis was substantiated by the fluorescence microscopic analysis of FITC−MoAb−IA_{10}, which showed that FITC−MoAb−IA_{10} outlined neovasculatures but not tumor cells at 4 and 21 h ex vivo. Additional proof was observed when blood vessels outlined with rhodamine−lectin, which specifically binds to blood vessels, were superimposable on neovasculatures outlined with FITC−MoAb−IA_{10}.

1. INTRODUCTION

Angiogenesis is the physiological process in which new blood vessels are formed from pre-existing blood vessels. This process is essential for a tumor to receive nutrients and oxygen for survival (*1*). Since tumor angiogenesis precedes the anatomical change of tumor size and the newly formed vessels are readily accessible, the detection of tumor angiogenesis should be a sensitive means of assessing the status of tumors. Antiangiogenesis therapy using cytotoxic α- and β-emitters may be an effective approach, because damaged endothelial cells and adjacent tumor cells can block blood flow to tumors, thereby killing a wide variety of solid tumors.

Integrins are a family of heterodimeric endothelial transmembrane glycoproteins composed of α and β subunits (*2*). Integrins expressed on activated endothelial cells regulate cell migration, differentiation, and proliferation during angiogenesis (*3*). One of these integrins, integrin $\alpha_v\beta_3$, is overexpressed in tumor-induced angiogenic vessels, various malignant human tumors, and diseases such as osteoporosis, rheumatoid arthritis, and macular degeneration, whereas it is not expressed in blood vessels of normal mature tissues (*4*, *5*). Integrin $\alpha_v\beta_3$ is a receptor for extracellular proteins including vitronectin, fibronectin, and fibrinogen, which contain an arginine-glycine-aspartic acid (RGD) sequence (*6*). Recently, RGD peptides and peptidomimetic antagonists (IA) specific for the integrin receptors have been synthesized and labeled with various γ and positron emitters (*7*−*13*) for scintigraphic detection, and γ- and β-emitters for radiotherapy of tumors (*10*, *14*−*24*). Steady progress has been reported in optimizing the radiolabeling methods of RGD peptides to improve the receptor-binding and tumor-targeting pharmacokinetics (*18*, *25*, *26*). Recently, RGD peptides were conjugated to antibodies to increase the receptor-binding affinity (*27*). It was also reported that RGD-conjugated Fc fragments (*26*) and RGD-conjugated anti-CD3 antibodies (*28*) inhibited angiogenesis in the tumor and redirected the cytolytic property of cytotoxic T lymphocytes to $\alpha_v\beta_3$-expressing endothelial cells, respectively.

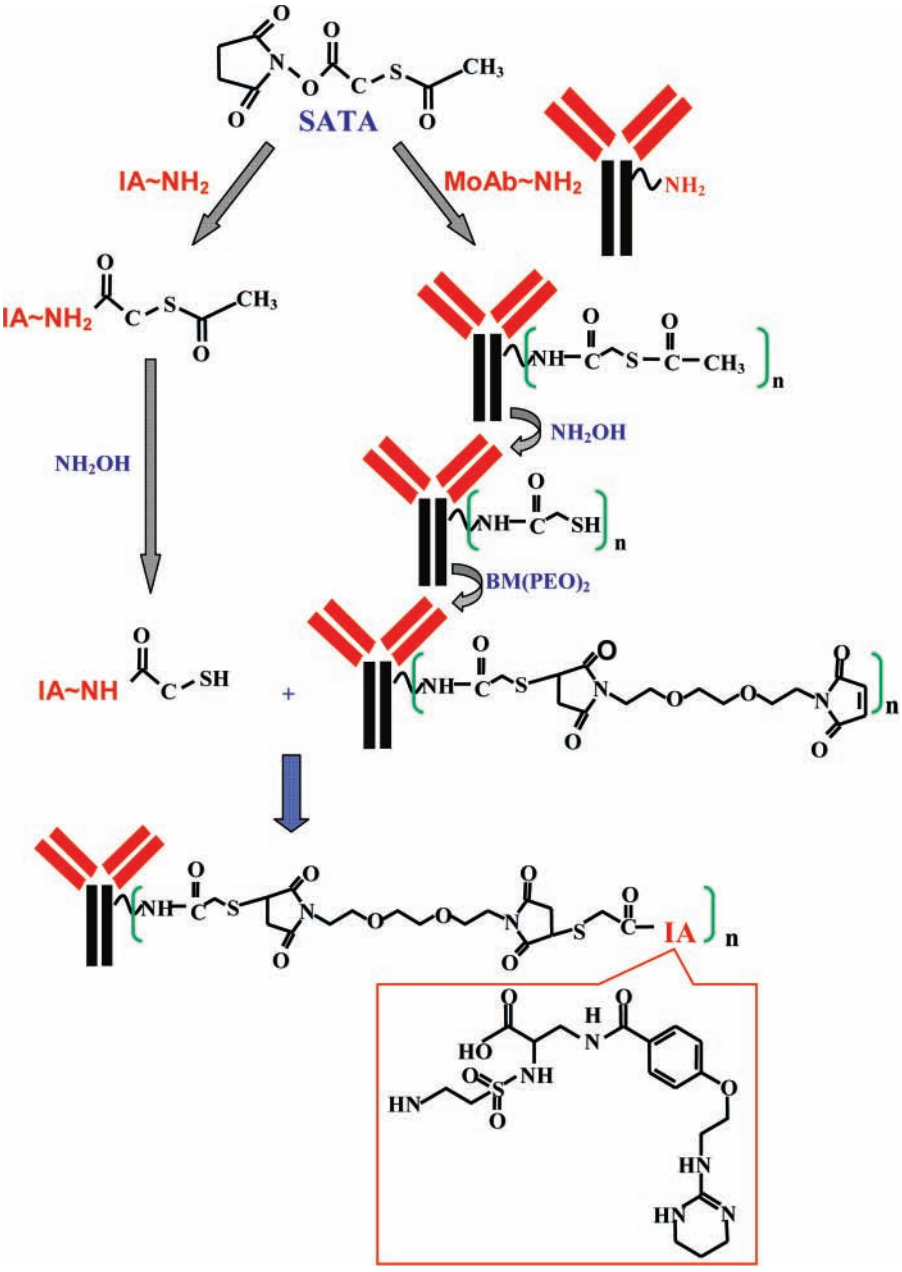
To increase the affinity, Burnett et al. (*29*) modified the ethylamine terminus of IA to a series of the corresponding carbamate derivatives and reported that the hydrophobic carbamate-linked appendages improved the $\alpha_v\beta_3$ receptor-binding affinity of the parent compound IA by 2 to 20 times. The affinity of IA was also improved by coupling to a cationic polymerized lipid-based nanoparticle that was successfully used to deliver a gene (*30*) or ^{90}Y (*20*) to neovasculature for tumor regression.

We have undertaken the conjugation of high levels of IA molecules to monoclonal antibody T101 to improve the affinity of IA and to test a possibility of targeting $\alpha_v\beta_3$ receptors on neovasculature. T101 (MoAb) is a murine anti-CD5 monoclonal antibody of IgG_{2a} isotype and is nonspecific to $\alpha_v\beta_3$ receptor. We used whole IgG as a carrier because this IgG has a large number (>60) of lysine residues, each of which contains a reactive ϵ-amino group. Thus, intact MoAb can be conjugated at the lysine residues with a large number of antagonists to increase receptor-binding avidity, and sequentially conjugated with other molecules such as pendant groups to radiolabel with γ or positron emitters for scintigraphic imaging or β-emitters for cancer therapy and fluorescein for optical imaging. We also used intact MoAb instead of antibody fragments, because we were interested in assessing the status of tumor-induced angiogenesis and because IgG does not readily cross the endothelial tight junctions due to its large molecular size (150 kDa), thus more suitable for specific imaging of tumor-induced neovasculature than antibody fragments. Another advantage of using antibody as a carrier is that it would also provide an opportunity to diversify into a pretargeting approach using an antibody specific for radiometal chelates as a carrier described initially by Meares et al. (*31*−*36*) or a three-step pretargeting approach involving injection of three components: MoAb conjugated with both IA and biotin, avidin, and radiolabeled biotin (*37*−*42*). These pretargeting approaches could potentially amplify tumor-to-nontumor background ratios. This paper describes the conjugation of IA molecules to MoAb; the labeling of IA-conjugated MoAb with FITC, ^{125}I, and ^{111}In; in vitro binding study with $\alpha_v\beta_3$ receptor; and biodistribution and histochemistry studies using nude mice with the receptor-positive M21 tumor to demonstrate the accumulation of the IA-conjugated MoAb on tumor-induced neovasculature.

2. EXPERIMENTAL PROCEDURES

2.1. Conjugation of SATA to MoAb. A heterofunctional cross-linker, *N*-succinimidyl-*S*-acetylthioacetate (SATA; Pierce, Rockford, IL) at a concentration ranging from 0.135 to 13 mM was reacted with MoAb (27 μM) in 0.1 M phosphate buffer, pH 7.2, at room temperature for 1 h. MoAb conjugated with several different levels of *S*-acetylthioacetyl moieties (ATA) was purified with size exclusion Zeba Desalt Spin Columns (Pierce, Rockford, IL). To determine the level of the *S*-acetylthioacetato moiety per MoAb, the S-acetyl protecting group was deacetylated with hydroxylamine (0.02 M) at room temperature in the presence of 1 mM EDTA to generate the mercaptoacetyl (A-SH) group. The concentration of the sulfhydryl group was then titrated with Ellman's reagent (Pierce, Rockford, IL) following manufacturer's instructions. The MoAb concentration was determined by measuring the absorbance at 280 nm (ϵ = 1.4 mL/mg) or by Bradford assay with Coomassie plus protein assay reagent (Pierce, Rockford, IL) according to manufacturer's instructions (*43*).



***2.2.* Preparation of *S*-Acetylthioaceto−IA.** The synthesis of IA was previously reported (*29*). The amino terminus of IA (0.02 M) was reacted with SATA (0.2 M) in 0.1 M sodium phosphate buffer, pH 7.2, at room temperature for 1 h to modify IA with a moiety containing an ATA. The product mixture was loaded on a Sep-Pak C18 cartridge (Pierce, Rockford, IL) and eluted with a stepwise gradient of acetonitrile solution from 0% to 50% acetonitrile in water. The product IA−ATA was collected with 50% acetonitrile. The chemical purity of IA−ATA was confirmed by HPLC (Gilson, Middleton, WI) equipped with a reverse-phase ACE 5C-18 column (4.6 × 100 mm, 5 μm, MAC-MOD Analytical Inc., Chadds Ford, PA) and a UV monitor. The HPLC system was operated under the following gradient elution conditions: eluent A, 50 mM triethylammonium phosphate in water; eluent B, 100% acetonitrile; gradient, 0−2 min with 100% eluent A, 2−5 min with 100%−80% eluent A, 5−12 min with 80%−65% eluent A, and 12−20 min with 65%−0% eluent A; flow rate, 1.0 mL/min. The concentration of IA−SATA was determined by the Ellman's reagent as described above.

2.3. Conjugation of IA−ATA to MoAb−$(ATA)_n$. IA−ATA was conjugated to MoAb−$(ATA)_n$ using a homobifunctional cross-linker, 1,8-bis(maleimido)diethylene glycol ($BM[PEO]_2$). MoAb−$(ATA)_n$ (20 μM) was reacted with $BM[PEO]_2$ at a molar excess in the presence of hydroxylamine (0.02 M) and 1 mM EDTA in 0.1 M sodium phosphate, pH 7.2, at room temperature for 30 min. To ensure MoAb−$(ATA)_n$ (n = 5 and 10) conjugation to only one maleimido group of the homobifunctional $BM[PEO]_2$ and prevent the inter- and intramolecular cross-linking of MoAb caused by $BM[PEO]_2$, MoAb−$(A\text{-}SH)_n$ (n = 5 and 10) was reacted with $BM[PEO]_2$ at ≥50× molar excess to the concentration of A-SH. The resulting product, MoAb−(acetyl-*S*-succinimidomaleimido$[PEO]_2)_n$, was purified using a size exclusion Zeba Desalt Spin Columns (Pierce, Rockford, IL). The purified product was immediately reacted with IA-A-SH at a 4× molar excess to the concentration of the maleimido$[PEO]_2$. The level of IA-(A-SH) conjugated per MoAb was determined by titrating the concentration of IA-(A-SH) before and after the conjugation reaction with the Ellman's reagent as describe above. The product MoAb−(acetyl-*S*-succinimido-$[PEO]_2$-succinimido-*S*-acetyl-$IA)_n$ (MoAb−(A-*S*-$S[PEO]_2$S-*S*-A-$IA)_n$) was purified with a size exclusion Zeba Desalt. The protein concentration was determined as described above.

2.4. Radiolabeling. The final products MoAb−(A-*S*-$S[PEO]_2$S-*S*-A-$IA)_n$ with n = 5 and 10 were conjugated with 2-(*p*-isothiocyanatobenzyl)cyclohexyl−DTPA (CHX-A″; Macrocyclic, Dallas, TX) and labeled with $^{111}InCl_3$ (Perkin-Elmer, Boston, MA) as described previously (*44*, *45*). The product was purified with a size exclusion Zeba Desalt Spin column (Pierce, Rockford, IL) or a microcon filter with a 30 kDa cutoff (Millipore, Bedford, MA). The purified product was labeled with ^{111}In chloride in 0.2 M sodium acetate, pH 4.5, at room temperature for 1 h. DTPA (0.2 mM) was then added to the reaction solution to bind possible free ^{111}In ion. The labeled product was purified with a size exclusion PD-10 column (GE Healthcare Bio-Sciences AB, Uppsala, Sweden). The radiochemical purity was assessed by HPLC (Gilson, Middleton, WI) equipped with a size exclusion TSK gel $G3000SW_{XL}$ column (7.8 × 300 mm, 5 μm, TOSOH Bioscience, Japan; 0.067 M sodium phosphate/0.15 M sodium chloride, pH 6.8; 1.0 mL/min), a UV monitor, and an on-line flow radioactivity detector (Bioscan Inc., Washington, DD).

2.5. Fluorescein Labeling. MoAb−(A-*S*-$S[PEO]_2$S-*S*-A-$IA)_{10}$ (12 μM) was reacted with FITC (0.18−1.6 mM) in 0.1 M sodium bicarbonate buffer, pH 8.4, for 18 h at room temperature. The labeled product with four fluorescein molecules per MoAb (10 μM) was purified with a size exclusion Zeba Desalt Spin column (Pierce, Rockford, IL) or by HPLC equipped with a size exclusion TSK $G3000SW_{XL}$ column, and the fluorescein-labeled product with a molecular weight similar to monomeric MoAb was collected.

Scheme 1. Synthesis of IA-Conjugated MoAb

2.6. SDS-PAGE Analysis. To estimate the extent of the inter- and intramolecular cross-linking caused by the conjugation reaction with $BM(PEO)_2$, electrophoresis was performed with 14% Tris−glycine gel (Invitrogen, Carlsbad, CA) in a running buffer containing 25 mM Tris, 192 mM glycine, pH 8.3, and 0.1% (w/v) SDS (Bio-Rad, Hercules, CA). The MoAb conjugates from the reactions of MoAb−$(acetylthiol)_{10}$ with $BM(PEO)_2$ at a molar ratio of $BM(PEO)_2$ to thiol ranging from 50 to 200 were treated with 5% β-mercaptoethanol (ICN Biomedicals Inc., Aurora, OH) at 90 °C for 5 min to reduce the interchain disulfide bonds. The samples were loaded on the gel together with a mixture of molecular weight standards (SeeBluePlus2, Invitrogen, Carlsbad, CA; the standards include myosin, phosphorylase B, BSA, glutamic dehydrogenase, alcohol dehydrogenase, carbonic anhydrase, myoglobin lysozyme, aprotinin, and insulin B chain). The runned gel was stained for proteins with colloidal Coomassie blue (Invitrogen, Carlsbad, CA).

2.7. Receptor-Binding Assay. To assess the receptor-binding ability of the ^{111}In labeled MoAb−$(A\text{-}S\text{-}S[PEO]_2S\text{-}S\text{-}A\text{-}IA)_n$, ^{111}In-labeled MoAb with $n = 10$ (2.2×10^6 cpm, 0.04 μM) was incubated with human integrin $\alpha_v\beta_3$ (M_w 237 000; Chemicon, Temecula, CA) at a concentration ranging from 0.1 to 0.4 μM in 32 μL PBS at 37 °C for 3 h. To assess the percentage of nonspecific binding, the binding assay was performed in the presence of a 20× molar excess of cold MoAb−$(A\text{-}S\text{-}S[PEO]_2S\text{-}S\text{-}A\text{-}IA)_{10}$ to integrin $\alpha_v\beta_3$. In a separate experiment, ^{111}In-labeled MoAb−$(A\text{-}S\text{-}S[PEO]_2S\text{-}S\text{-}A\text{-}IA)_n$ with $n = 5$ and 10 (2.2×10^6 cpm, 0.04 μM MoAb) were incubated with 0.4 μM $\alpha_v\beta_3$ to determine the effect of the level of IA conjugation on the receptor binding. The percent binding to the integrin $\alpha_v\beta_3$ was analyzed by size exclusion HPLC. The binding of the ^{111}In-labeled MoAb to $\alpha_v\beta_3$ shifted the HPLC peak (9.5 min) for the ^{111}In-labeled MoAb to a higher molecular weight peak (6.8 min). The addition of the molar excess of MoAb−$(A\text{-}S\text{-}S[PEO]_2S\text{-}S\text{-}A\text{-}IA)_{10}$ completely blocked the formation of the higher molecular weight complex.

2.8. Tumor Model. A human M21 melanoma cell line that expresses $\alpha_v\beta_3$ was used to make an in vivo tumor model. Human M21 melanoma cells initially received from Dr. David Cheresh (Scripps Research Institutes, La Jolla, CA) were

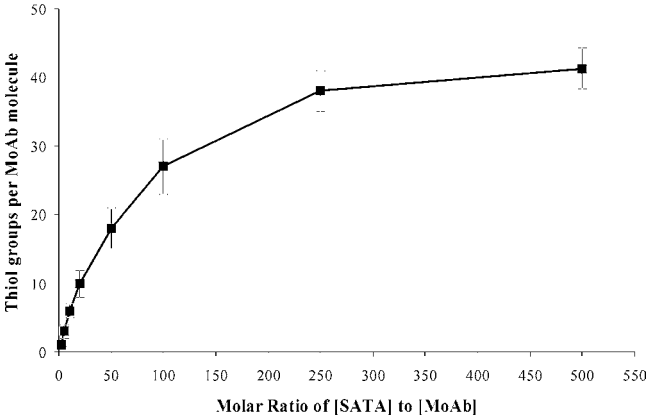


Figure 1. Relationship between level of SATA conjugation to MoAb and SATA to MoAb reaction molar ratios. [MoAb] = 27 μM. The number of SATA conjugated per MoAb increased up to 40 as the reaction concentration of SATA was increased. The values represent means and standard deviations. $N = 5$.

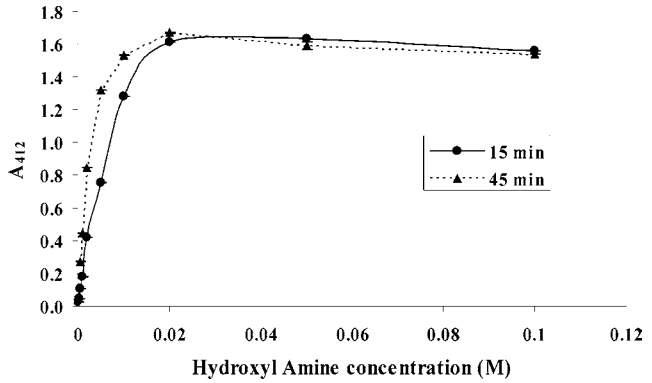

Figure 2. Relationship between hydroxylamine concentration and deacylation level of the S-acetyl protecting group of MoAb−(SATA). [SATA] in MoAb−$(SATA)_n$ = 0.21 mM. The concentration of hydroxylamine ranged from 0.5 to 100 mM. The reaction was performed at pH 7.2 at room temperature for 15 or 45 min. The optimal concentration of hydroxylamine was determined to be 0.02 M for these reaction times. [−SH] was titrated with Ellman's reagent. The absorbance at 412 nm was plotted vs hydroxylamine concentration. The values represent means and standard deviations. $N = 3$.

cultured in RPMI 1640 supplemented with 10% FBS and 1% penicillin−streptomycin under a humidified atmosphere with 5% CO_2. The cell culture medium was then exchanged with PBS. Tumor xenografts were established by inoculation of 3×10^6 cells subcutaneously into the right flank of athymic mice (NCI−DCT, Frederick, MD).

2.9. Biodistribution Studies. Animal experiments were performed under a protocol approved by the NIH Animal Care and Use Committee. Biodistribution was performed when the tumor size reached approximately 0.5 cm^3. Groups of five mice with M21 tumor were injected iv with the ^{111}In-labeled MoAb−(A-*S*-S[PEO]$_2$S-*S*-A-IA)$_{10}$ (MoAb−IA_{10}) (2 μCi/0.2 μg) with or without coinjection of 240 μg IA in 0.2 mL PBS containing 1% BSA. Similarly, nude mice with tumor were injected with the ^{125}I-labeled MoAb−IA_{10} (2 μCi/0.5 μg). The ^{111}In product and the ^{125}I product with >70% binding ability to $\alpha_v\beta_3$ at 0.4 μM were used for the biodistribution studies. The animals were euthanized at 4, 21, and 44 h by CO_2 inhalation and exsanguinated by cardiac puncture before dissection. Blood and various organs were removed and weighed, and their decay-corrected radioactivity counts were measured with a γ-counter (Wallac, Inc., Perkin-Elmer, Inc., Boston, MA). The percentage of injected dose per gram (% ID/g) of the blood or each organ was calculated and was normalized to a 20 g mouse. The whole-body (WB) radioactivity count was obtained by adding the

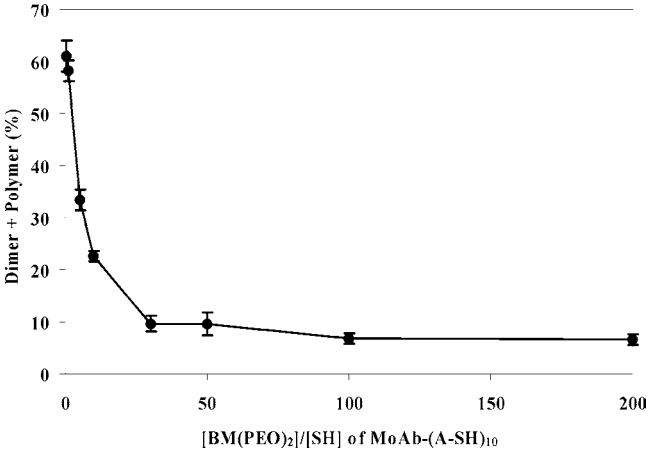

Figure 3. Relationship between formation of MoAb dimer plus polymer and $BM(PEO)_2$ to MoAb−$(A\text{-}SH)_{10}$ reaction molar ratios. MoAb−$(A\text{-}SH)_{10}$ at 15 μM MoAb was reacted with $BM(PEO)_2$ in sodium phosphate buffer, pH 7.2, at room temperature for 0.5 h. The products were analyzed by size exclusion HPLC. The formation of higher molecular weight MoAb due to the intermolecular cross-linking decreased as the concentration of the homobifunctional cross-linker $BM(PEO)_2$ was increased. The formation of the higher molecular weight MoAb became <10% when a 50× molar excess of $BM(PEO)_2$ to the A-SH concentration was reacted with MoAb−$(A\text{-}SH)_{10}$. The values are means and standard deviations. $N = 3$.

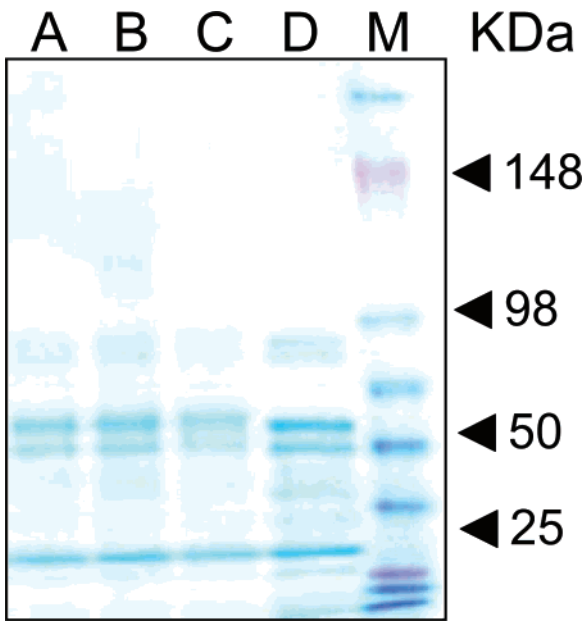

Figure 4. SDS PAGE analysis of MoAb−$(COCH_2\text{-}S\text{-}SM[PEO]_2)_{10}$. MoAb−$(COCH_2SH)_{10}$ (15 μM MoAb) was reacted with $BM(PEO)_2$ in sodium phosphate buffer, pH 7.2, at room temperature for 30 min. The products were treated with 2-mercaptoethanol before the SDS PAGE analysis to reduce the interchain disulfide bridges. Lanes: (A) [BM-$(PEO)_2$]/[-SH] = 50; (B) [$BM(PEO)_2$]/[-SH] = 100; (C) [$BM(PEO)_2$]/[-SH] = 200; (D) MoAb; (M) molecular weight markers. All three samples showed bands corresponding to 25 and 50 kDa fragments indicating that the homobifunctional cross-linker $BM(PEO)_2$ reacted at a [$BM(PEO)_2$]/[-SH] ratio higher than 50 did not cause the inter- and intramolecular cross-linking of MoAb.

radioactivity of all organs and that of the carcass measured by the γ-counter, and the whole-body radioactivity was expressed as the percentage of the injected dose (% ID).

2.10. Ex Vivo Fluorescence Microscopy. Mice with M21 tumor were injected iv with the fluorescein-labeled MoAb−IA_{10} (200 μg) in 0.2 mL PBS, pH 7.2, containing 1% BSA. The animals were euthanized at 4 and 21 h by CO_2 inhalation and exsanguinated by cardiac puncture before dissection. The animals were injected iv with rhodamine−lectin (1 mg) in 0.2

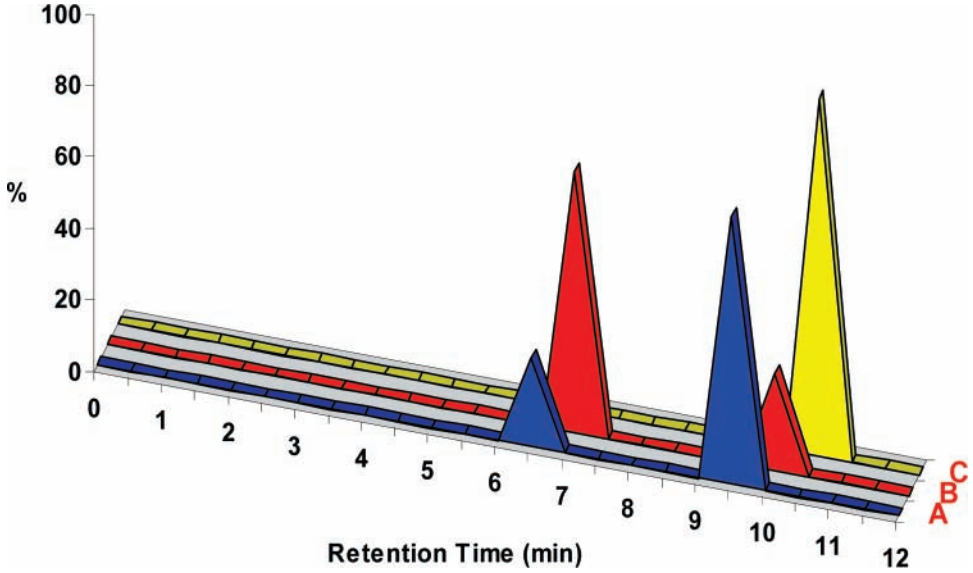

Figure 5. Size exclusion HPLC profile for binding of ^{111}In-labeled MoAb−IA$_n$ to integrin $\alpha_v\beta_3$. (A) 25% of the total ^{111}In-labeled MoAb−IA$_5$ was bound to the receptor at 0.4 μM, whereas (B) 73% of the total ^{111}In-labeled MoAb−IA$_{10}$ was bound. (C) The receptor binding was completely blocked when ^{111}In-labeled MoAb−IA$_n$ was incubated with 0.4 μM $\alpha_v\beta_3$ in the presence of 8 μM cold MoAb−IA$_{10}$.

mL PBS 5 min before the animals were euthanized to delineate vessels during observation with fluorescence microscopy (Olympus, Melville, NY). Tumors were dissected, mounted, and counterstained with 4,6-diamidino-2-phenylindole (DAPI).

2.11. Statistical Analysis. Statistical analysis was performed using ANOVA for comparing multiple groups, and the Student's *t* test was performed for unpaired data between two groups. All tests were two-sided, and a probability value (*P*) of less than 0.05 was considered significant.

3. RESULTS AND DISCUSSION

3.1. Chemistry. This research was undertaken to explore the use of antibody as a carrier of peptidomimetic antagonists specific for integrin $\alpha_v\beta_3$ receptor to improve its receptor-binding affinity and to target $\alpha_v\beta_3$ receptor on neovasculature. To achieve this goal, T101, an irrelevant MoAb to $\alpha_v\beta_3$ receptor, was used as a carrier of a peptidomimetic integrin $\alpha_v\beta_3$ antagonist, 4-[2-(3,4,5,6-tetrahydropyrimidine-2-ylamino)ethyloxy]benzoyl-2-(*S*)-aminoethylsulfonylamino-β-alanine (IA). Sulfhydryl selective reactions were used to conjugate IA to MoAb, because the sulfhydryl group could be readily quantified with Ellman's reagent. High levels of IA molecules were conjugated to MoAb in three steps (Scheme 1). In the first step, a large number of *S*-acetylthioacetato (ATA) moieties were conjugated to MoAb upon the reaction with *N*-succinimidyl-*S*-acetylthioacetate (SATA) at a molar excess. The number of ATA molecules conjugated per MoAb increased proportionally to the concentration of SATA, and the conjugation was then leveled off at approximately 40 ATA molecules conjugated per MoAb (Figure 1). The products MoAb−(ATA)$_n$ with $n = 5$ and 10 were used for the further reactions. In a separate reaction, the *S*-acetylthioaceto moiety was conjugated to IA. The concentration of the *S*-acetylthioaceto moiety was estimated by titrating the sulfhydryl group by the Ellman's reagent following removal of the protecting acetyl group from the *S*-acetylthioaceto moiety. Hydroxylamine was used for this deacetylation reaction. The optimum concentration of hydroxylamine to complete the deacetylation was determined to be 0.02 M (Figure 2). Hydroxylamine at 0.02 M in phosphate buffer, pH 7.2, completed the deacetylation within 15 min at room temperature without interfering with the addition of the mercaptoacetyl (A-SH) of MoAb−(A-SH)$_n$ with $n = 5$ or 10 to the maleimido group of BM[PEO]$_2$. Then, the MoAb−(A-SH)$_n$ and IA−(A-SH) were coupled via stepwise reactions with a homobifunctional reagent, BM[PEO]$_2$. We used BM[PEO]$_2$ with an eight-atom water-soluble polyether spacer arm to minimize the insolubility of the products and keep IA molecules away from MoAb to achieve more effective binding of IA to the $\alpha_v\beta_3$ receptor.

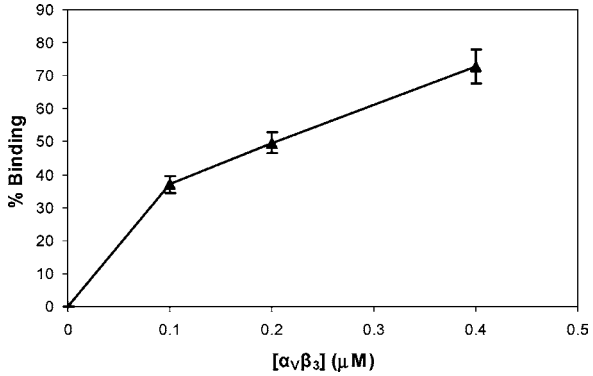

Figure 6. Percent binding of ^{111}In-labeled MoAb−IA$_{10}$ to $\alpha_v\beta_3$. ^{111}In-labeled MoAb−IA$_{10}$ (<0.04 μM MoAb) was incubated with $\alpha_v\beta_3$ integrin (M_w 237 KDa) at 0.1, 0.2, and 0.4 μM at 37 °C for 3 h and analyzed with size exclusion HPLC. The percent binding increased proportionally to the concentration of $\alpha_v\beta_3$. The percent binding increased to 73% when $\alpha_v\beta_3$ concentration was 0.4 μM.

The major focus was on optimizing the reaction concentrations, molar ratios, and the reaction pH to conjugate high levels of IA to MoAb without causing the inter- and intramolecular cross-linking of MoAb. First, an SH group was generated in the presence of 1 mM EDTA at pH <7.2 when the acetyl-protecting group of ATA of MoAb−(ATA)$_n$ was deacetylated by hydroxylamine. Second, we used MoAb−(A-SH)$_n$ with the MoAb concentration of <15 μM when conjugated with (BM-[PEO]$_2$). Finally, we used a molar excess of a homobifunctional cross-linker, BM[PEO]$_2$, to the sulfhyryl group of MoAb−(A-SH)$_n$ to minimize the inter- and intramolecular cross-linking of MoAb. Consequently, we synthesized the final product MoAb−(A-*S*-S[PEO]$_2$S-*S*-A-IA)$_n$ with $n = 5$ and 10. The results of size exclusion HPLC analysis (Figure 3) and SDS PAGE electrophoresis profile (Figure 4) indicated that the formation of dimeric and polymeric forms of MoAb was less than 9.6% of the total when MoAb−(A-SH)$_n$ was reacted with ≥50× molar excess of BM−[PEO]$_2$ to the sulfhydryl and the resulting MoAb−(COCH$_2$-*S*-SM[PEO]$_2$)$_n$ was reacted with a 4× molar

excess of IA−(A-SH). To investigate the receptor binding activity, the products MoAb−(A-*S*-S[PEO]$_2$S-*S*-A-IA)$_n$ with $n = 5$ and 10 IA molecules were conjugated with 2-(*p*-isothiocyanatobenzyl)cyclohexyl−DTPA, labeled with ^{111}In, and purified by size exclusion HPLC to obtain monomeric MoAb products. Comparing ^{111}In-labeled MoAb−(A-*S*-S[PEO]$_2$S-*S*-A-IA)$_n$ with $n = 5$ and 10, the product with $n = 10$ showed a higher percent binding (72.9%) to 0.4 μM $\alpha_v\beta_3$ than that (25.0%) with $n = 5$ (Figure 5). The percent binding also increased proportionally to the concentration of $\alpha_v\beta_3$ up to 0.4 μM, which was the highest concentration available (Figure 6). The binding was blocked by adding a 20× molar excess of cold MoAb−(A-*S*-S[PEO]$_2$S-*S*-A-IA)$_{10}$ to $\alpha_v\beta_3$ (Figure 5). Since MoAb−(A-*S*-S[PEO]$_2$S-*S*-A-IA)$_n$ with $n = 10$ showed higher affinity to $\alpha_v\beta_3$ than that with $n = 5$, MoAb−(A-*S*-S[PEO]$_2$S-*S*-A-IA)$_{10}$ (MoAb−IA$_{10}$) was radiolabeled with ^{111}In and ^{125}I for biodistribution studies.

3.2. Animal Studies. We performed comparative biodistribution studies between the ^{125}I-labeled MoAb−IA$_{10}$ and the ^{111}In-labeled MoAb−IA$_{10}$, because these two radiolabels often show large differences in organ retention due to the differences in their metabolism and the structure of the catabolites. Thus, comparative biodistribution studies between these two radiolabels would provide useful information in developing radiopharmaceuticals for tumor detection. The comparative biodistribution studies showed similar tumor uptake between the ^{125}I-labeled MoAb−IA$_{10}$ and the ^{111}In-labeled MoAb−IA$_{10}$ for a 44 h period. A slightly higher concentration of the ^{125}I-labeled MoAb−IA$_{10}$ in tumor could be accounted for by the contribution from the higher blood ^{125}I concentration, assuming that about 10% of radioactivity in the tumor is contributed from the radioactivity in blood (Table 1). In contrast to the similarity shown in tumor uptake, there were large differences in blood and organ concentrations between the ^{125}I-labeled MoAb−IA$_{10}$ and the ^{111}In-labeled MoAb−IA$_{10}$ for a 44 h period. The ^{111}In label resulted in lower radioactivity in the blood but much higher radioactivity in most organs including the liver, spleen, kidney, and bone than the ^{125}I label. The ^{125}I concentration was especially low in the liver, but high in the thyroid and the stomach, indicating that the ^{125}I label was rapidly catabolized in the liver and the ^{125}I catabolite re-entered the circulation. The ^{125}I catabolite in the circulation was either taken up by the thyroid and the stomach or excreted through the renal system as shown by low whole-body retention (12% ID at 44 h) of the ^{125}I label (Table 1). The ^{111}In label was taken up primarily by the liver, spleen, and kidney. However, only a little ^{111}In activity was cleared from those organs during a 44 h period (Table 1), indicating that the ^{111}In product is catabolized more slowly or the ^{111}In catabolites are eliminated more slowly from those organs. This slow organ clearance was reflected in high whole-body retention of the ^{111}In label with 64% ID retained at 44 h. The ^{111}In-labeled MoAb−IA$_{10}$ also showed much higher liver uptake but lower blood retention than ^{111}In-labeled MoAb without IA conjugation that we previously reported (*44*). The coinjection of the ^{111}In label with cold IA (240 μg) drastically decreased the liver uptake at 21 h ($P < 0.01$), whereas it substantially increased the ^{111}In in the blood ($P < 0.01$), tumor, and all organs except spleen and bone compared to the ^{111}In without the IA coinjection (Table 2). The mechanism of liver uptake of the radioabeled MoAb−IA$_{10}$ was not investigated, but it may be that the modified MoAb was taken up in large part by reticuloendothelial cells and in some portions by receptor-mediated uptake. High liver uptake is the major drawback for the use of MoAb−IA$_{10}$ as a carrier of the γ-emitter ^{111}In for scintigraphic imaging of tumor-induced neovasulature. Nevertheless, the rapid blood clearance, short peak tumor uptake time, and low peak tumor uptake value with prolonged tumor retention of this macromolecule appear to indicate that it was localized on angiogenic vessels mediated by binding to $\alpha_v\beta_3$ receptors. To substantiate a hypothesis that MoAb−IA$_{10}$ accumulated on angiogenic vessels but not on the tumor, the receptor-positive M21 tumors excised from the tumor-bearing nude mice 4 and 21 h after receiving FITC-labeled MoAb−IA$_{10}$ were analyzed by a fluorescence microscope. The fluorescence microscopic analysis showed that FITC−MoAb−IA$_{10}$ outlined neovasculatures but not tumor cells at 4 and 21 h (Figure 7). The neovasculatures outlined with FITC−MoAb−IA$_{10}$ were superimposed with blood vessels outlined with rhodamine−lectin. This fluorescence microscopic analysis supports the hypothesis that the ^{111}In-labeled MoAb−IA$_{10}$ accumulated on the neovasculatures via binding to $\alpha_v\beta_3$ receptors. In conclusion, MoAb−IA$_{10}$, which clears rapidly from the circulation and accumulates in tumor-induced blood vessels without accumulating in $\alpha_v\beta_3$-expressing tumors, was synthesized. High retention in the liver and kidney was shown to be a drawback for the use of the ^{111}In-labeled MoAb−IA$_{10}$ in scintigraphic detection of tumors near the abdomen, although

Table 2. Biodistribution of ^{111}In-Labeled MoAb−IA$_{10}$ with and without 240 μg IA Coinjection in M21 Tumor-Bearing Mice at 21 h (% ID/g, mean ± S.D, $N = 5$)

organ	without IA coinjection	with 240 μg IA coinjection

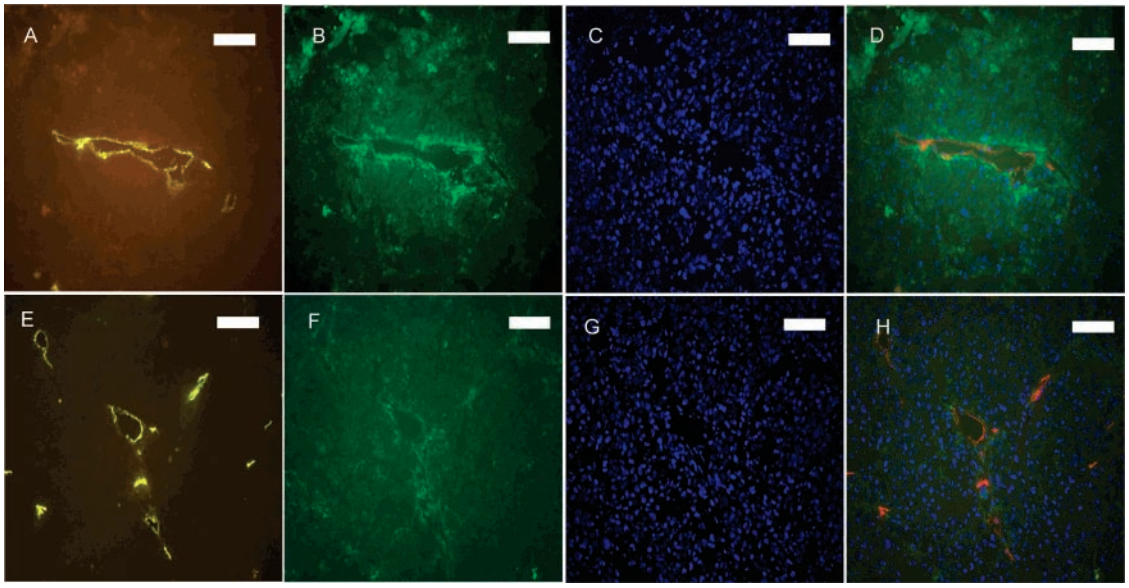

Figure 7. Fluorescence microscopy of $\alpha_v\beta_3$-expressing M21 tumors. Mice with M21 tumor were injected iv with the fluorescein-labeled MoAb−IA_{10} (200 μg) in 0.2 mL PBS, pH 7.2, containing with 1% BSA. The animals were euthanized at 4 h (A−D) and 21 h (E−H) by CO_2 inhalation and exsanguinated by cardiac puncture before dissection. The animals were injected iv with rhodamine−lectin (1 mg) in 0.2 mL PBS 5 min before they were euthanized to delineate vessels during observation with fluorescence microscope. (A,E) rhodamine−lectin; (B,F) FITC-labeled MoAb−IA_{10}; (C,G) DAPI; (D,H) merge. Bar represents 100 μm.

the tumor-to-blood ratio reached 3.9 at 43 h postinjection. In contrast, the tumor-to-liver and tumor-to-kidney ratios became ≥1 at 43 h for the ^{125}I-labeled MoAb−IA_{10}, but slow clearance from blood was the drawback for the ^{125}I-labeled MoAb−IA_{10} because this slow blood clearance would delay imaging time substantially (Table 1). Further optimization of tumor targeting methods is needed to improve angiogenesis detection agents. We are currently investigating a pretargeting approach using an avidin−biotin system to amplify tumor-to-background ratios to image tumor-induced neovasculature.

Quantum dots (QDs) have been used extensively as fluorescent markers in several studies on living cells. Here, we report the synthesis of conjugates based on glutathione (GSH) and QDs (GSH−QDs) and we prove how these functionalized fluorescent probes can be used for staining a freshwater invertebrate called *Hydra vulgaris*. GSH is known to promote *Hydra* feeding response by inducing mouth opening. We demonstrate that GSH−QDs as well are able to elicit biological activity in such an animal, which results in the fluorescent staining of *Hydra*. GSH−QDs, once they reach the gastric region, are internalized by endodermal cells. The efficiency of GSH−QD internalization increases significantly when nanoparticles are coadministrated with free GSH. We also compared the behavior of bare QDs to that of GSH−QDs both in the presence and in the absence of free GSH. The conclusions from these series of experiments point to the presence of GSH binding proteins in the endodermal cell layer and uncover a novel role played by glutathione in this organism.

INTRODUCTION

Colloidal semiconductor nanocrystals, also known as quantum dots (QDs), are emerging as a new class of inorganic fluorophores for imaging living and fixed cells in fluorescence microscopy (*1*). The QD probes have unique photophysical properties, such as size-tunable emission spectrum, narrow emission peak, broad absorption profile, and high brightness. In addition, QDs are much more stable to the permanent loss of fluorescence than conventional organic fluorophores (*2*, *3*). Therefore, they offer several advantages over standard organic dyes for multicolor, long-term, and high-sensitivity fluorescence imaging.

Recently, several strategies have been developed to deliver stable, water-soluble quantum dots (*4*). These procedures allow also to introduce on the outmost shell of the QDs specific anchoring points by which biomolecules can be conjugated to the nanoparticles. In the latest years, it has been demonstrated that these new bioconjugates are useful for applications in many of the classical immunocytochemistry protocols, as well as for *in vivo* staining of living cells on higher vertebrates (*5*). On the other hand, no studies of cell tracking, migration, or physiological response using QD functionalized with bioactive molecules have been reported on less-evolved organisms.

The tripeptide glutathione (γ-L-glutamyl-L-cysteinylglycine, GSH) has been well-known to biochemists for generations. Both the reduced form (GSH) and its oxidized dimer (GSSG) have been implicated in a variety of molecular reactions throughout the animal kingdom. Although it is best known for its role as a free radical scavenger, GSH also performs a number of other functions in cell survival and metabolism, including amino acid transport, detoxification of xenobiotics, maintenance of protein redox state, neuromodulation, and neurotransmission (*6*). Almost 50 years ago, Loomis and Lenhoff (*7*) suggested a role of GSH in signal transduction in the coelenterate *Hydra*. Hydra, together with coral, sea anemones, and jellyfish, are members of the primitive phylum Cnidaria. It is shaped as a "two-ply hollow tube", made up of both outer (ectodermal) and inner (endodermal) epithelial layers. The mesoglea, an extracellular matrix, separates the two epithelia. At the posterior end of the tube, there is a basal disk with which the *Hydra* usually attaches to a surface, whereas at the anterior end, there is a mouth surrounded by a ring of tentacles (Figure SI1, Supporting Information). The tentacles are armed with many nematocytes, which contain nematocysts (stinging capsules). The latter start the feeding process by reverting a coiled tube, which pierces and wounds the prey. In the absence of prey, GSH is the physiological stimulator of the feeding behavior (*8*), by inducing tentacle contraction and mouth opening. Grosvenor et al. (*9*) and Bellis et al. (*10*) described a class of binding sites for GSH in *Hydra* that provides the basis for the behavioral response.

Hydra is a model organism that offers several potential advantages as an investigation target by means of QDs, such as (i) the simplicity of the body structure, which allows easy detection of fluorescent probes; (ii) the dynamics of the two epithelia, as *Hydra* cells, which continuously divide, migrate and are eliminated at the apical and basal ends of the polyp, allow cell migration and tracking studies; and (iii) the regenerating capability, involving extensive remodeling and plasticity phenomena, whose temporal dynamics can be best approached by using photostable fluorescent probes. Finally, and most importantly, *Hydra* allows us to validate by a reliable assay the biological activity of GSH-conjugated QDs.

In this report, we describe the synthesis and the characterization of core−shell CdSe/ZnS QDs conjugated to glutathione for the staining of *Hydra*. The biological activity evoked by GSH−QDs in living *Hydra* animals was also studied. We found that cells lining the gastric cavity were able to internalize the bare QDs in the presence of reduced GSH in the media bath, as intense fluorescence was present in this cell type. Interestingly, in the same conditions, the efficacy of the internalization

doubled in the presence of GSH-coated QDs. These results demonstrate the involvement and the activation of GSH-specific endodermal cell uptake mechanisms in *Hydra*, such as those mediated by carriers, specific receptors, or membrane metabolic enzymes into any type of living cells. GSH-functionalized nanoparticles represent the first example of fluorescent and bioactive GSH adduct suitable for specific staining of one type of tissue on *Hydra*.

MATERIALS AND METHODS

Chemicals. (1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride) (EDC), γ-L-glutamyl-L-cysteinylglycine (GSH), 5,5′-dithiobis(2-nitrobenzoic acid) (Ellman's reagent), and 4′,6-diamidino-2-phenylindole dihydrochloride (DAPI) were purchased from Aldrich. *O*,*O*′-Bis(2-aminoethyl)octadecaethylene glycol, diamino-PEG-897) was purchased from Fluka. DL-Dithiothreitol (DTT) was purchased from Biochemika. *N*-Hydroxysuccinimide (NHS) was purchased from Pierce. Agarose gel EEO was purchased from Eppendorf. All solvents that we used had purity of analytical grade.

Synthesis of Water-Soluble Quantum Dots. TOP/TOPO-capped CdSe/ZnS core/shell QDs were prepared by following standard colloidal synthesis procedures (*11*, *12*). For fluorescence imaging, given the *Hydra* autofluorescence, we found it more convenient to work with QD samples with an emission band peaked at wavelengths longer than 590 nm. As-synthesized QDs are hydrophobic, and therefore, they were transferred into water by means of a standard procedure based on wrapping them within an amphiphilic polymer shell, which had been developed in a previous work by our group (*13*). The resulting polymer-coated particles (PC-QDs) were purified twice by high-performance liquid chromatography HPLC (Agilent1100 on a Sephacryl S-300 HR column, using 150 mM NaCl in 50 mM phosphate buffer at pH 7.0 as mobile phase). These purified PC-QDs have carboxyl groups dangling at the outer surface of the polymer layer. The concentration of the quantum dots was determined by measuring their optical absorption spectra, as their molar extinction coefficient is know from the literature (*14*). As an example, the extinction coefficient of a quantum dot sample with the first exciton peak centered at 590 nm was estimated as 258 050 cm^{-1} M^{-1} by extrapolation from the published curve (*14*).

Functionalization of Quantum Dots with Diamino-PEG 897 ($NH_2-PEG-NH_2$). The buffer of the HPLC-purified, PC-QDs was exchanged with 50 mM sodium borate buffer (pH 9.0) by using a centrifuge tube (MWCO 30 000). The same buffer was used to dissolve diamino-PEG ($NH_2-PEG-NH_2$) with molecular weight equal to 897.10. For the coupling experiments, one of the two amine groups of the diamino-PEG molecules was linked to one of the carboxyl groups present on the PC-QDs. This was achieved by using EDC as cross-linker, which induced amide bond formation (*15*). Interparticle cross-linking, due to the bridging of one or more diamino-PEG molecules between two PC-QDs via both terminal amine groups, was negligible at ratios of diamino-PEG molecules to PC-QDs equal to 500:1 or lower. Therefore, a 500:1 ratio was used in all experiments.

In a typical procedure, a buffer solution of 6 μM PC-QDs and a solution of 3 mM diamino-PEG were mixed together, after which a solution of 600 mM EDC was added to reach an excess molar ratio of EDC to PC-QDs equal to 10^5:1. The resulting solution was incubated for 3 h under vigorous stirring. To remove the excess of unreacted diamino-PEG, the solution was filtered several times through centrifuge tubes (MWCO 30 000). Diamino-PEG-functionalized QDs (PEG−QDs) were resuspended in water at a 6 μM final concentration.

Conjugation of GSH to Quantum Dots. GSH has two free carboxyl groups and a free thiol group. The COOH groups can be exploited to link the GSH to the PEG−QDs via formation of an amide bond with the free amino groups of the diamino-PEG molecules bound to the polymer shell that encases the PC-QDs. In detail, to a 6 μM solution of PEG−QDs dissolved in sodium borate buffer (pH 9.0), a 10 mM GSH solution dissolved in the same buffer was added, to reach a molar excess of GSH per PEG−QD equal to 1700:1. Borate buffer solutions containing EDC 100 mM and NHS 75 mM, respectively, were then added. The resulting solution was incubated at room temperature for 3 h under vigorous stirring. To remove the unreacted GSH, the sample was washed five times on 20 mL centrifuge filters (30 000 MWCO). In general, for the experiments carried out on *Hydra*, the sample was then reconcentrated on the filter to reach a final concentration equal to 6 μM.

Characterization by Gel Electrophoresis. Prior to gel electrophoresis, to each sample a solution containing Orange G and 30% glycerol in gel-loading buffer corresponding to 20% of the sample volume was added. 2% agarose gels were prepared in 0.5× TBE buffer. The electrophoretic run was carried out for 60 min at 100 V. After the run, the gel was observed under UV light.

Ellman's Test and DTT Treatment. To assess the amount of GSH bound to the PEG−QDs, Ellman's assays were carried out (*16*). This procedure allowed us to quantify the SH groups of the glutathione. The Ellman's reagent, namely, 5,5′-dithiobis(2-nitrobenzoic acid), reacts with free thiol groups (SH) and releases a chromogenic compound (5-thio-2-nitrobenzoic acid) that can be detected easily by means of its optical absorption band peaked at 412 nm. The absorbance at this wavelength is therefore directly proportional to the concentration of −SH groups in solution. Due to the broad optical absorption spectrum of the QDs, the absorption region of the 5-thio-2-nitrobenzoic acid is covered and the absorbance of this chromogen could not be read directly in the presence of GSH−QD. In order to overcome this inconvenience, after the Ellman's reaction the sample solution was centrifuged in cutoff filters in order to separate the yellow chromogen (which passed easily through the membrane) from the GSH−QD conjugates (which did not pass through the pore membrane).

The concentration of thiol groups in solutions of GSH−QDs was determined by extrapolation from a calibration curve that was built by carrying out the Ellman's test on free GSH solutions at known concentrations. Ellman's tests were actually carried out both on solutions of GSH−QDs conjugates and on the same solutions after they had been treated with a 10 mM solution of dithiothreitol (DTT). DTT is able to cleave the disulfide bonds to form free −SH groups (*17*). The DTT treatment was applied routinely to both PEG−QDs and GSH−QDs samples immediately prior to the *in vivo* experiments. In a typical procedure, a solution of 10 mM DTT was added to a 6 μM solution of GSH−QDs. The resulting mixture was left under stirring for 3 h, after which the sample was centrifuged in 30 000 MWCO centrifuge filters in order to remove the excess of free DTT. At least five washes were carried out before redissolving the sample in *Hydra* physiological solution (Hy Sol: $CaCl_2$, 1 mM; and $NaHCO_3$, 0.1 mM).

Growth and Maintenance of *Hydra*. *Hydra vulgaris* (strain Zurich, originally obtained by P. Tardent) were asexually cultured in physiological solution by the method of Loomis and Lenhoff (*7*) with minor modifications. The animals were kept at 18 ± 1 °C and fed three times per week with freshly hatched *Artemia salina nauplii*. All animals were starved 24 h prior to the experiments.

***In Vivo* Experiments.** Groups of 20 animals were collected in plastic multiwells, allowed to equilibrate at room temperature in physiological solution (Hy Sol) buffered with 1 mM Tris−HCl (pH 7.4). The test was initiated by adding 300 μL of Hy

Sol containing either PEG−QDs or GSH−QDs at different concentrations (ranging from 3 to 300 nanomolar) to each well containing 20 polyps. One hour after incubation, the final volume was brought to 1 mL and the animals were kept at 18 °C for 24 h. For each QD concentration tested, a parallel trial was performed by adding GSH 10 μM. 24 h after incubation, the samples were rinsed in Hy solution several times before observation by fluorescence microscopy.

Fluorescence Microscopy. *In vivo* experiments were monitored for the first hour under a fluorescence stereomicroscope (Olympus ZSX-RFL2) equipped with a GFP filter set (BP460−490/DM505/LP510). In vivo fluorescence imaging of the whole animals and dissociated cells, along with imaging of fixed tissue sections, was accomplished by using an inverted microscope (Axiovert 100, Zeiss) equipped with a digital color camera (Olympus, DP70) and fluorescence filter sets (BP450−490/FT510/LP515). For imaging acquisition and analysis, the software system *Cell F* (Olympus) was used.

***Hydra* Tissue Dissociation and Cryosectioning.** *Hydra* polyps were dissociated according to Flick and Bode (*18*) with minor modifications. This procedure allows dissociation of *Hydra* tissue into a suspension of viable cells. Briefly, test animals were rinsed with Hy Sol and soaked in the dissociation solution for 60 min at 0 °C. Following a mechanic dissociation by a narrow glass pipet, the suspensions containing dissociated cells were transferred on microscope slides for fluorescence microscopy.

For tissue sectioning, test animals were fixed in 4% paraformaldeyde, pH = 7.4, at 4 °C, rinsed three times in phosphate saline buffer (PBS: 8 g/L NaCl; 0.2 g/L KCl; 1.44 g/L $Na_2HPO_4 \bullet 7H_20$; 0.24 g/L KH_2PO_4), soaked overnight in 30% saccharose in PBS and then embedded in the frozen section medium Neg-50 (Richard-Allan Scientific). Cryosections of 10 μm thickness were obtained by a cryostat (Leitz, digital 1760), collected on gelatin-coated slides (Superfrost microscope slides, Menzel), and mounted with Aquatex mounting medium (Merk) before imaging. For cell nuclei detection, sections were stained with 4′,6-diamidino-2-phenylindole dihydrochloride (DAPI) 1 mg/L before mounting.

RESULTS

Synthesis of Glutathione−Quantum Dots Conjugates. In Figure 1A, a sketch of the GSH−QDs conjugates is shown. We transfer hydrophobic TOP/TOPO capped CdSe−ZnS nanocrystals into water by wrapping the QDs in an amphiphilic polymer (poly(maleic anhydride-*alt*-1-tetradecene)) and then by cross-linking this polymer shell using bis(6-aminohexyl)amine (*13*). The resulting water-soluble polymer-coated quantum dots have a negatively charged surface, due to the hydrolyzed carboxyl groups present at the surface of the polymer shell. Therefore, these nanoparticles migrate from the negative pole toward the positive pole in the gel electrophoresis run (Figure 1B, lane 1). The carboxyl groups are then used to link diamino-PEG molecules through amide bond formations via the cross-linker EDC. The diamino-PEG molecules are introduced because they stabilize more effectively the nanoparticles in the *Hydra* solution and also because they introduce amino groups at the surface of the QDs. These amino groups in turn are used to link the tripeptide glutathione (GSH) through an additional amide bond formation. In a previous study, it was demonstrated by some of us that it is possible to tune the number of PEG molecules attached per nanoparticle by varying the length of the PEG molecule and the ratio of EDC added per molecule (*19*). In the present case, to achieve a dense surface of glutathione molecules attached per QDs, we have chosen PEG molecules of molecular weight equal to 897. At this length, it is possible to pack the surface of the quantum dots with a saturated number of PEG molecules (*19*). This prevents the nanoparticles from precipitating (as they become highly stable), and in addition, it ensures a saturated number of amino groups attached per PC-QDs. To verify the linkage of the PEG molecules to the QDs, we used gel electrophoresis. The PEG−QDs still move toward to the positive pole, although they are visibly retarded with respect to the original polymer-coated QDs (Figure 1B, lane 2). Once the glutathione is attached to the PEG−QDs, these dots have almost the same mobility on the gel as the starting PEG−QDs, although the front edge of the band is slightly retarded with respect to the latter (Figure 1B, lane 3), a behavior that can be attributed to the attachment of the small gluthatione tripeptide to the PEG−QDs.

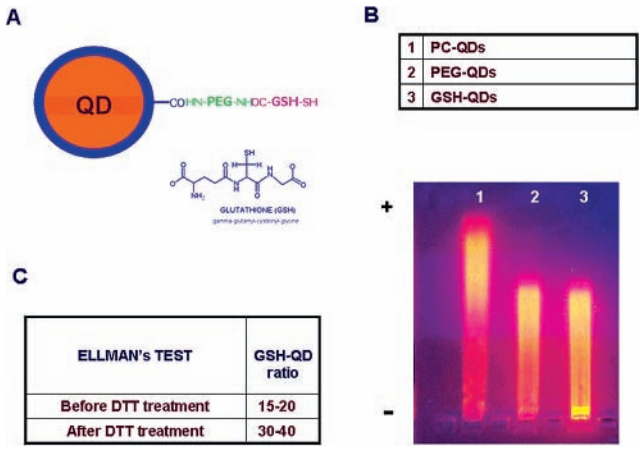

Figure 1. (A) Schematic representation of a GSH−QD conjugate. Polymer-coated quantum dots were first conjugated to diamino-modified PEG molecules and then to GSH through amide bond formation. (B) Characterization of the GSH−QD conjugates by means of gel electrophoresis. The samples loaded on the bottom part of the gel move through the gel from the negative to the positive pole. Lane 1 represents the migration of the polymer-coated quantum dot (PC-QD). Lane 2 corresponds to the migration of polymer-coated quantum dot functionalized with diamino PEG molecules having a molecular weight of 897 (PEG−QD). Lane 3 corresponds to the migration of PEG-coated quantum dots bound to GSH molecules (GSH−QD). (C) Evaluation of the number of GSH attached per nanoparticle. Ellman's test allows one to detect the number of thiol groups and therefore the cysteine groups attached per quantum dot. The measure was repeated on GSH−QD samples before and after DTT addition.

Furthermore, the GSH−QD band also shows a partial precipitation in the loading well. This behavior is very likely due to the formation of interparticle S−S bridges that could form among some GSH−QDs. This hypothesis is supported by the Ellman's test performed on GSH−QD samples before and after treatment with a reducing agent such as DTT. Statistically, the number of free thiol groups and therefore of reduced GSH molecules attached per QD doubles after treatment with DTT (Figure 1C).

We have also characterized the various steps of the conjugation reaction by FT−IR measurements. By checking the absorption spectra of the polymer-coated QDs, the PEG−QDs, and the GSH−QDs, respectively, a significant change of the corresponding profiles was observed. In the spectra corresponding to the GSH−QDs, a new peak appeared at 1776 cm^{-1}. While the assignment of this new peak is not obvious, we believe that it can be ascribed to the formation of a new amide bond between the carboxy group of the GSH and the amino group of a PEG molecule present on the surface of the PC-QDs (see Supporting Information, Figure SI2).

One critical aspect of the linking reaction is that it must ensure that the thiol groups of the cysteine are still present in the reduced form after the attachment to the dots. Lenhoff and Bovaird (*20*) showed in fact that *Hydra* recognizes the specific

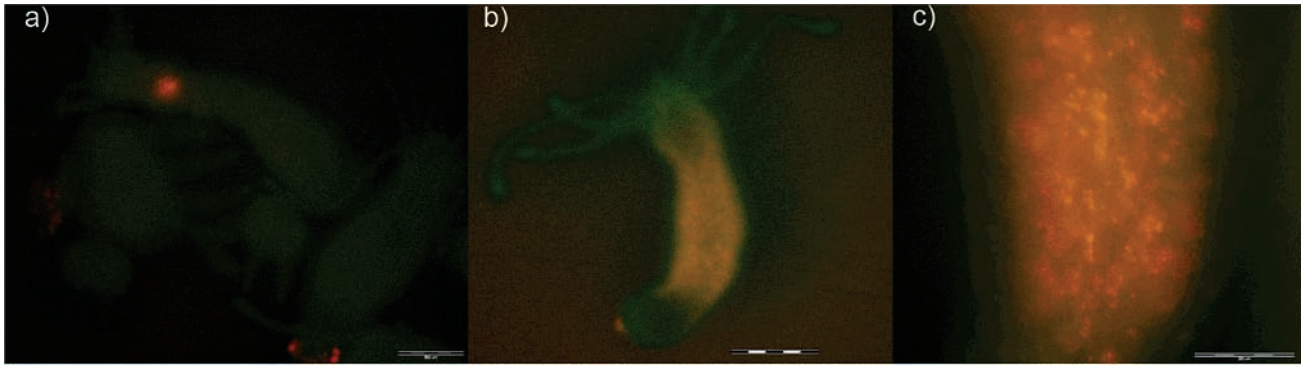

Figure 2. *In vivo* fluorescence imaging of *Hydra* polyps treated with 300 nM GSH−QDs (emission max: 610 nm). (a) Image taken 1 h after treatment. A fluorescent stain is located inside the body and can move along it. (b) 24 h after treatment, an intense fluorescence is distributed all along the gastric region. (c) Enlargement of the body column showing clearly the signal inside the body of the animal. The plane of focus lies close to the outer body surface. Scale bars: 500 μm (a,b) and 200 μm (c). The same results where observed when the feeding activator GSH (10 μM) was added to the bathing solution, stimulating mouth opening and allowing the nanoparticles to reach the gastrovascular cavity.

structure of the intact tripeptide backbone of glutathione, while tripeptide analogues with large and charged substituents at the sulfydryl group of glutathione competitively inhibit glutathione action. It is worth noting that the conversion of the oxidized form of gluthatione (GSSG) to its reduced form is crucial not only to ensure the activation of the feeding response but also because GSSG is actually known to act as an inhibitor of the feeding response (*20*). Therefore, before studying the interaction of GSH−QDs with *Hydra*, we always carried out a treatment of the GSH−QD sample with a reducing agent, in this specific case, DTT.

Activity of GSH−QDs on Living *Hydra*. The biological activity exerted by GSH−QDs and the putative cell targets were assayed in living *Hydra* by incubation of groups of animals separately with either polymer-coated QDs (PC-QDs) or PEG−QDs or with GSH−QDs. In a first series of experiments, the hydra bath was exposed only to quantum dot samples (either PEG−QDs or GSH−QDs), while in a second series of experiments, 10 μM GSH was also added together with the nanoparticles. At this concentration, the feeding response (i.e., tentacle writhing and mouth opening) was induced, allowing the medium that bathes the polyps to enter the body cavity. This assay, modified from Lenhoff (*21*) by Pierobon (*22*), and used as a reliable and quantifiable assay for study of aminoacid neurotransmitters in *Hydra*, allowed us to investigate the putative effect of the functionalized nanoparticles on the endodermal cells.

When the *Hydra* bath contained GSH−QDs, after incubation for 1 h at room temperature, fluorescence was detected in a small number of animals inside the body, as shown in Figure 2a. After 24 h of incubation at 18 °C, this fluorescent signal was spread inside the whole animal body (Figure 2b). By zooming in on the *Hydra* body, as shown in Figure 2c, the fluorescent regions always appeared out of focus, indicating that the fluorescent material was located inside the body cavity. At this stage, it was not possible to determine whether internalization of the nanoparticles from endodermal cells had occurred or whether the fluorescent material had simply filled the body cavity. The percentage of animals showing this phenotype was equal to 15% when using GSH−QDs, while no animals showed a similar phenotype when using differently coated QDs (PC-QDs and PEG−QDs) (see below). The percentage of *Hydras* able to stably internalize the nanoparticles increased up to 71% when in a parallel experiment 10 μM GSH was added together with the GSH−QDs to the *Hydra* bathing solution (Figure 2). In both cases, in fact, the fluorescence pattern and intensity lasted unaltered until the animals were fed again, after which the signal started to face slowly and was diluted throughout the emerging buds. To investigate the possible uptake mechanisms of QDs from endodermal cells, the same experiment was repeated at the same conditions, but the incubation was carried out at 4 °C, when endocytosis mechanisms, among all, are inhibited. After a 24 h incubation time, no spreading of the fluorescence inside the *Hydra* body was observed and the quantum dots remained localized in large aggregation spots inside the animal body (data not shown). To establish whether there was any concentration dependence in the uptake, GSH−QD conjugates were tested at different concentrations, ranging from 3 to 400 nM. Higher concentrations (up to 0.8−1 μM) were shown to affect animal vitality, as they induced irreversible death. It was observed that the optimal concentration of GSH−QDs required to stain the highest percentage of *Hydra* was 300 nM. When 10 μM GSH was also added to the bath, the concentration of GSH−QDs was kept constant at 300 nM.

Selective Uptake of GSH−QDs. In order to study more in detail the cellular localization of the nanoparticles that had entered into the body cavity, two types of experiments were performed. A first type of experiment is based on the fluorescence microscopy analysis of *Hydra* tissue slices obtained by standard cryosectioning of whole, stained animals. Figure 3a shows an optical image of the Hydra transverse section. In the image a thin cell spacer, called mesoglea (forming a line in the middle of the section) clearly separates two types of tissues: the endodermal cell layer (in Figure 3a is the region above the mesoglea, on the upper left region of the figure) and the ectodermal layer (on the right edge of the same figure). In Figure 3b, DAPI staining defines the position of the nuclei of the same cross sections, while in Figure 3c, the corresponding fluorescence derived from the QDs is shown. Figure 3d, obtained by merging Figure 3b with Figure 3c, shows the locations of both the nuclei and the QDs and confirms that the fluorescence from the QDs is located in the endodermal cells, probably in the cytoplasm. A subcellular location of QDs was not possible with this procedure. A second proof of the cell internalization of the GSH−QDs was provided by fluorescence imaging of the stained polyps after tissue dissociation. By applying the procedure of Flick and Bode (*18*) (see Materials and Methods section), stained *Hydra* were dissociated into single cells or clusters of cells and immediately observed under a fluorescence microscope. This procedure, although it does not allow us to define the cell type, confirmed the location of the QDs fluorescence inside the cells, as shown in Figure 4.

PC-QDs and PEG−QDs are not active on Living *Hydra*. As control experiments, bare PC-QDs and PEG−QDs were tested on living *Hydra* as described above. No animals showed a fluorescence phenotype similar to that observed with GSH−QDs. Instead, a more localized fluorescence was detected on the basal disk confined on the foot of the animal, as shown in

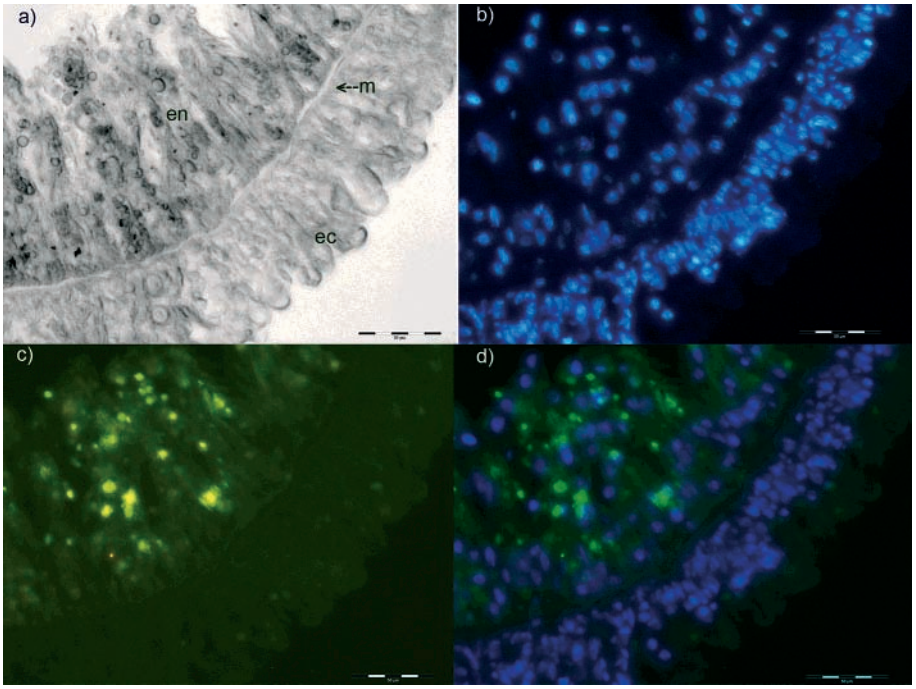

Figure 3. Cellular localization of QDs in *Hydra* cross sections. The whole *Hydra* was treated with 300 nM GSH−QDs for 24 h, fixed in 4% paraformaldehyde, and included for cryosectioning as described in the Materials and Methods section. Images were collected using an inverted microscope (Axiovert, 100, Zeiss) equipped with fluorescence filter sets. (a) Nomarski-DIC picture of 10 mM transversal section. Endodermal cells (en) are separated from ectodermal cells (ec) by an extracellular matrix, the mesoglea (m), indicated by the arrow. (b) DAPI staining of the same section to aim at the localization of the cell nuclei (blue color). (c) Fluorescence imaging under BP450−490/FT510/LP515 filter sets. Nanoparticles are located into endodermal cells. (d) Picture merged from parts b and c showing both DAPI (blue color) and nanoparticle (green color) fluorescence. QDs did not colocalize with nuclei.

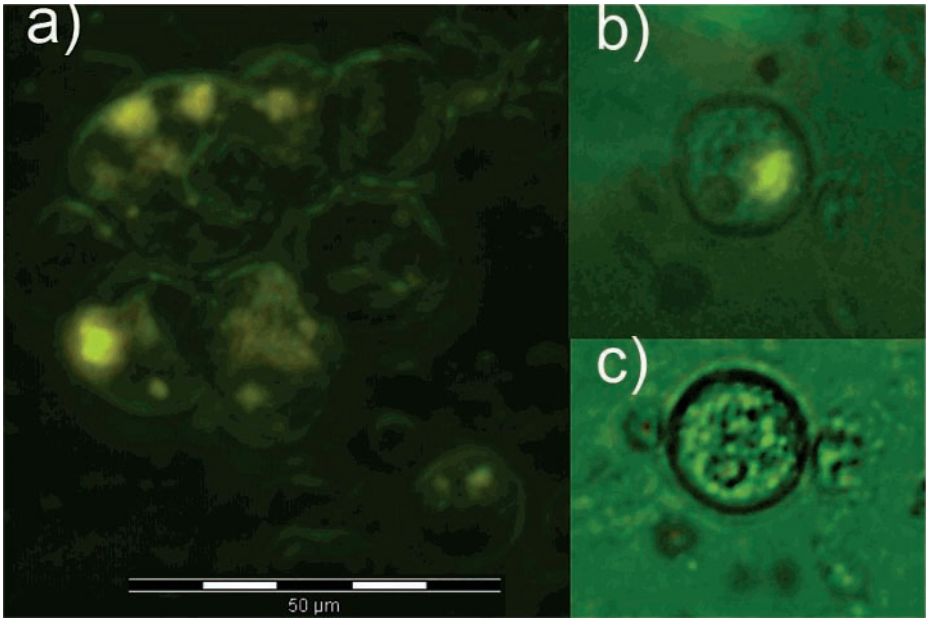

Figure 4. Dissociated cells from whole *Hydra* polyps treated with 300 nM GSH−QDs for 24 h. Single and clustered cells show nanoparticle fluorescence (yellow) inside the cytoplasm. The picture is merged from Nomarski-DIC and fluorescence images. Scale bar = 50 μm.

Figure 5a, 5b. These figures report bright-field and fluorescence images of a *Hydra* treated with PC-QDs. The same phenotype was still observed on *Hydra* treated with PEG−QDs, as shown in Figure 5c. QDs binding to the basal disk might depend on the sticky properties of the mucous secreted in this region, which serves to anchor the animal to a substrate. A further control experiment was carried out in parallel to evaluate the effect of PC-QDs and PEG−QDs on the endodermal cells. 10 μM GSH was added to the *Hydra* bathing medium together with the QDs in order to induce mouth opening and to allow QDs to enter the body cavity. No internalization was observed in the case of PC−QDs, while an effect similar to that observed with GSH−QDs was found with PEG−QDs. In fact, after 1 h of incubation, fluorescent material was detected in the body lumen, and it spread inside the animal body over the following 24 h. However, the fluorescence lasted only 48 h, after which it became weaker until it almost faded completely. In this set of experiments, only 27% of the *Hydra* showed fluorescence signal. Table 1 reports a summary of the different trials that were performed.

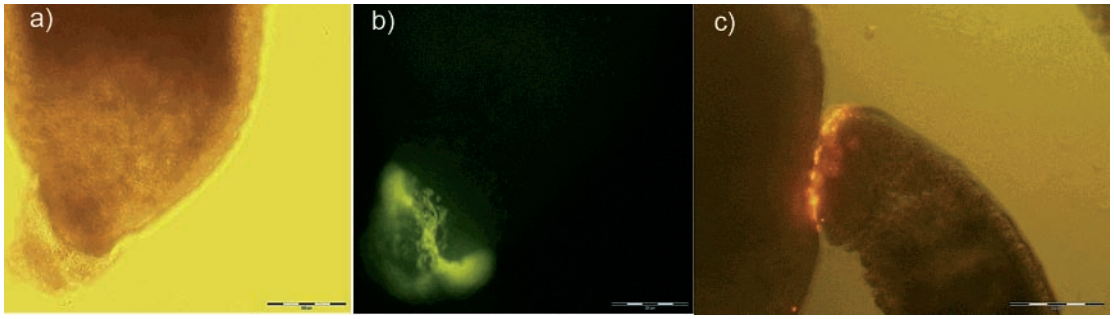

Figure 5. *In vivo* fluorescent imaging of *Hydra* polyps treated with different QDs (a) bright-field image of the *Hydra* peduncle and basal disc. (b) Fluorescence microscopy of the same region as in part a. Polyps were treated with PC-QDs (max emission = 510 nm). Fluorescence is present in the basal disk. (c) Image merge from bright-field and fluorescence images of *Hydra* treated with PEG−QDs (max emission = 610 nm). Fluorescence is present at the basal disk of a budding *Hydra.* Scale bar = 200 mm.

Table 1. Number of animals, expressed as a percentage of 20 treated animals, showing endodermal fluorescent signal after 24 h incubation with the indicated type of QDs, with or without addition of 10 μM GSH[a]

	free GSH added	no free GSH added
PEG−QDs	27%	0%
GSH−QDs	71%	15%

[a] The data shown are averaged over three independent experiments.

DISCUSSION

Overall, the results reported here suggest several interesting conclusions about the behavior of the *Hydra* when exposed to quantum dots. In the case of GSH−QDs, a fluorescent signal inside the body of the animal was observed. Because no ectodermal cells but only endodermal cells were stained by using GSH−QDs, a delivery of QDs inside the animal body must have occurred. This means that a response that culminated in mouth opening was promoted by GSH−QDs. The activity induced by GSH−QDs appeared different from the feeding behavior evoked by unbound GSH, as in fact tentacle writhing and wide mouth opening were not observed. However, such activity appears specific for GSH−QDs, as it was not induced in any of the observed cases by bare polymer-coated QDs (PC-QDs) or by diamino-PEG-functionalized quantum dots (PEG−QDs). Both PC-QDs and PEG−QDs were adsorbed to the mucous-producing ectodermal cells in the basal disk of living animals, but were unable to induce any behavioral response. This foot fluorescence was rapidly lost, due to the continuous cell displacement at the animal basal end. These data show that GSH−QDs alone can stimulate a response, although in a small percentage (15%) of the treated animals. Possible reasons for this low percentage could be a low concentration of the GSH molecules conjugated to the QD surface or the modified stereochemical conformation of the bound GSH molecules, which does not allow for correct interaction with the protein target. From Lenhoff's studies (*20*) of the kinetics of the *Hydra* GSH-activated feeding response, it was shown that the duration of the feeding response increased with increasing GSH concentration, in a range from 1 to 10 μM. In the present work, under the experimental condition at which biological activity was observed, the concentration of GSH molecules bound to the nanoparticles was estimated to be around 5 μM, thus falling into the "active" GSH concentration range. Therefore, the low level of evoked activity of the GSH−QDs might be due to the fact that, once GSH is bound to the QDs, its active site either is not accessible or is not properly oriented to bind to the protein target effectively. In addition, it must be noted that, when a GSH−QD binds to the protein target via a GSH molecule, all the remaining GSH molecules located on that specific QD will no longer be available to other protein targets. Therefore, this should also account for the low level of activity observed for GSH−QDs.

Upon addition of unbound GSH to the treated animals, which allowed the nanoparticles to reach the gastric cavity, the functionalized QDs were unexpectedly taken up by the endodermal cells.

An important consideration raised by this internalization concerns the specificity of this process. Is there a specific uptake or is there a GSH-receptor-mediated process occurring in the gastric cavity? One way to address this point is by considering that, once the QDs are driven into the gastric cavity, there is a substantial difference regarding whether they carry GSH bound to their surface or not. The first difference concerns the percentage of the stained animals, which is 71% for GSH−QDs and only 27% in the case of PEG−QDs. The second important difference concerns the fate of the nanoparticles taken up by the endodermal cells. Bare PEG−QDs driven into the *Hydra* body by free GSH are taken up by endodermal cells within 24 h. However, 48 h later the fluorescence is weaker, and it becomes hard to detect a few days later. This suggests the presence of a nonspecific uptake process, probably due to endocytosis operated by endodermal cells. On the other hand, GSH−QDs, no matter how they are driven into the gastric cavity (with or without addition of free GSH), once they are taken up by the endodermal cells, show no signs of weakening over time, as they last up to a new animal feeding. These results suggest that GSH−QDs might follow a different path as compared to that followed by PEG−QDs. Furthermore, it appears likely that the GSH-mediated pathway preserves the QDs from photodegradation, as opposed to the fate of PEG−QDs, whose fluorescence is rapidly degraded.

Apart from previous studies on radioligand binding of GSH to its putative receptors in a crude membrane preparation, including membranes coming from whole *Hydra vulgaris* homogenates (*10*, *23*), no studies of *in vivo* imaging of the GSH binding sites had been reported so far. Recently, Shaw et al. (*24*), while attempting to synthesize a fluorescent probe to study GSH receptor localization, produced a ligand that binds and antagonizes the NMDA receptor in cultured mammalian neuronal cells. To the best of our knowledge, the present study is the first one which allows localization *in vivo* of a GSH binding site, and we are confident that future investigations might shed light on the nature of this molecule as GSH-carrier, -receptor, or -membrane bound metabolic enzyme. Considering the multiple roles played by glutathione in metabolic functions, and in particular in the nervous system of higher vertebrates, GSH-functionalized nanocrystals prepared and tested in this work represent promising tools for a wide variety of investigations, such as the elucidation of the role played by GSH in neurotransmission and the identification of its putative receptor. Finally,

considering the more conventional and best-known antioxidant and free radical scavenging action of glutathione, GSH−QDs represent potentially useful redox-sensitive probes which could be used to label living cells or subcellular components according to their redox state.

CONCLUSIONS

In conclusion, we have designed and prepared GSH-functionalized quantum dot conjugates which allowed us to study the behavior of a small freshwater invertebrate called *Hydra*. We have tested and shown the biological activity of GSH molecules linked to fluorescent quantum dots by assaying the behavior of *Hydra vulgaris*.

Furthermore, by comparing the behavior of PEG−QDs in presence of free GSH to that of GSH−QDs both in the case of free GSH addition and in the absence of free GSH, we could suggest the presence of at least two mechanisms of internalization of particles of endodermal and not ectodermal cells, one relying upon particle size, charge, and surface composition, and the other, GSH-mediated, highly specific, which indicates the presence of GSH binding proteins in the endodermal cell layer. Considering the plasticity of *Hydra* tissues and the extensive remodeling that underlies the regeneration mechanism in this model organism, we can conclude that these photostable fluorophores represent suitable probes for this type of investigation.

ACKNOWLEDGMENT

We thank Vittorio Guglielmotti and Luigia Cristino for help with the cryostat sections and for discussion on fluorescent patterns, and Luigi Carbone, Angela Fiore, and Riccardo Di Corato for supplying QD samples. We thank also Giuseppe Ciccarella and Andrea Ragusa for helpful discussion on the characterization of samples. The authors are especially grateful to P. Pierobon for many inspiring discussions. This work was partially supported by the Italian Ministry of Research (FIRB grants RBN01KJHT-007 and RBIN048TSE, RBLA03ER38) and by the European STREP project SA-NANO (contract number 013698).

Folic Acid-Conjugated Protein Cages of a Plant Virus: A Novel Delivery Platform for Doxorubicin

Yupeng Ren,[†] Sek Man Wong,[‡,§] and Lee-Yong Lim[†,||,*]

Department of Pharmacy and Department of Biological Sciences, National University of Singapore, Science Drive 4, Singapore 117543, Temasek Life Sciences Laboratory, 1 Research Link, Singapore, 117604, and Pharmacy, School of Biomedical, Biomolecular and Chemical Sciences, University of Western Australia, Crawley, WA 6009, Australia. Received November 20, 2006; Revised Manuscript Received January 22, 2007

The protein cage of a plant virus may provide a template for monodispersed nanosized systems for drug delivery. Using the Hibiscus chlorotic ringspot virus (HCRSV) as a model plant virus, we have prepared nanosized protein cages (30 nm) capable of encapsulating the anticancer drug, doxorubicin. The technique utilized the simultaneous encapsulation of a polyprotic acid of mw 200 kDa to produce an encapsulation efficiency for doxorubicin of about 7.5%. Folic acid was conjugated onto the capsids to impart cancer-targeting capability. The resultant nanosized systems improved the uptake and cytotoxicity of doxorubicin in the ovarian cancer cells, OVCAR-3, with statistical significance. Plant virus capsids may therefore provide viable templates for targeted drug delivery in cancer chemotherapy.

INTRODUCTION

Plant viruses which have genomic materials encapsidated within protein cages may provide viable delivery platforms for drugs (*1*). Unlike viruses isolated from animal origins, plant viruses are less pathogenic (*2*, *3*) and may avoid the immunogenicity response in animals (*4*). The protein cages, or capsids, offer versatility for drug loading. Compounds can either be physically encapsulated within the capsids following the removal of native RNA, or chemically conjugated onto the capsid. As the capsids are assembled from identical coat protein units, they are exact in molecular weight (mw), uniform in size, and precise in structure (*5*). This homogeneity in size and shape is an advantage over most nanoscale drug delivery systems prepared from random aggregation of macromolecules such as lipids or polymers (*6*).

Plant viral capsids provide other advantages for drug delivery. Amino acids in the coat protein are potential chemical conjugation sites for ligand attachment to develop stealth and/or targeting drug delivery platforms. Both macromolecules, such as polyethylene glycol or entire proteins (*4*, *7*), and small inorganic atoms, such as gold (*8*), have been conjugated onto the surface of viral protein cages to yield novel properties. The insertion of foreign peptides by recombinant DNA technology can further entitle the capsids to specific bioactivity (*9*, *10*).

Of the wide variety of plant viruses known to man, the icosahedral plant viruses are to date the most researched as vessels for foreign material loading. By adjusting the environmental pH and ion content, the capsids of these viruses can be transformed from assembled to swollen to disassembled states (*11*). This permits the removal of native viral RNA from the coat proteins, which are then purified and reassembled into protein cages for cargo loading. Proof of concept was first demonstrated with the Cowpea chlorotic mottle virus (CCMV)[1] (*12*, *13*). The protein cages of CCMV could host foreign ions as well as polyacids (*12*), the capacity to host different ions being made possible by modulating the inner surface charges of the protein cage through gene mutation (*13*). More recently, gold nanoparticles of appropriate size were also encapsidated within the CCMV-derived protein cages (*14*, *15*). Success in these experiments has prompted an interest in using the plant viral protein cages as platforms for drug delivery. Loading of cargo has been achieved through chemical conjugation of the molecules with specific amino acid groups presenting on the interior surface of the viral protein cages (*16*, *17*). In another development, the anticancer drug, doxorubicin, was covalently attached to the interior surface of small heat-shocked viral protein cages (*18*).

To date, there is no report on the loading of small chemotherapeutic drugs into plant viral protein cages by physical encapsulation, although this method has proven effective for the loading of crystals (*12*, *13*), polymers (*12*), and gold nanoparticles (*14*, *15*). Our previous research on another plant virus, the HCRSV, has established two prerequisites for the successful loading and retention of exogenous material in the viral protein cages (*19*). First, the material should possess a negative charge so that it will bind with the coat protein and initiate the reassembly of the icosahedral capsid structure. Second, the material should have an adequately high mw to

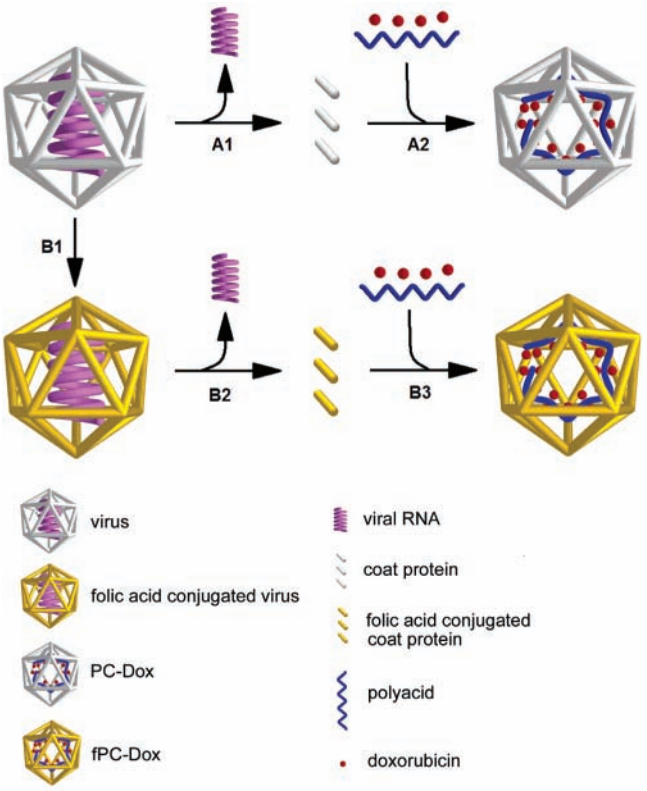

Figure 1. Schematic illustration of the preparation of doxorubicin-loaded viral protein cage without (PC−Dox) and with folic acid conjugation (fPC−Dox). Steps A1 and B2 are indicative of the removal of viral RNA from the plant virus and purification of coat proteins. Steps A2 and B3 involve the encapsulation of polyacid and doxorubicin during the reassembly of protein cage. Step B1 refers to the conjugation of folic acid onto the viral protein coat.

avoid excessive leaching of encapsidated material through the cavities present on the capsid surface upon dilution.

Doxorubicin, like many other anticancer drugs, is a small molecule (mw = 545 Da), and it is positively charged (pK_a = 8.4) in physiological fluids as well as under the conditions for reassembling of plant virus capsids (*20*). These properties made it difficult to load and retain doxorubicin within the plant virus capsid by simple encapsulation during the reassembly of the protein cage.

To impart the requisite size and charge to the anticancer agent, we employed the aid of a polyacid. This method, which we termed "polyacid association", involved the simultaneous loading of doxorubicin with polystyrenesulfonic acid (PSA) of mw 200 kDa into the capsid of the HCRSV. The 3:1 (PSA:drug) w/w ratio of mixing ensures the attraction of doxorubicin molecules to the polyacid by electrostatic forces, and a net negative charge for the resultant complex. The complex thus provided the nucleus for binding with, and initiation of, the final reassembly of coat proteins into the viral capsids (Figure 1). The resultant system was denoted as PC−Dox.

We also prepared folic acid-conjugated equivalents, denoted as fPC−Dox, where the HCRSV viruses were conjugated with folic acid before they were disassembled for doxorubicin−PSA encapsulation. Folic acid has been widely studied as a small molecule−ligand for targeting drug delivery systems to cancer cells. The principle of this application is based on the differential expression of folic acid receptor (FR) on normal and cancer cells. FR expression is elevated in malignant cancer cells, e.g., cancer cells of ovary, uterus, and mesothelium (*21, 22*), while most normal cells express low levels of FR. Proof of concept of the folic acid-mediated targeting systems have been shown with the delivery of drugs and liposomes to a variety of cancer cells (*22, 23*). In this study, folic acid was conjugated on the protein cages to promote the cellular uptake of drug by cancer cells.

EXPERIMENTAL PROCEDURES

Materials. HCRSV was purified from infected kenaf leaves (*24*). RPMI 1640 medium and folic acid-deficient RPMI 1640 medium were purchased from Sigma Chemical Co. (Steinheim, Germany) and supplemented with 10% fetal bovine serum (Gibco BRL Life Technologies, Grand Island, NY). OVCAR-3 cell line (Passage 22 to 32) was obtained from ATCC (Manassas, VA) and maintained in folic acid-deficient RPMI 1640 medium for 2 months before use (*25*). CCL-186 cell line (Passage 15 to 25) was obtained from ATCC and cultured in RPMI 1640 medium. Polystyrenesulfonic acid and folic acid were from Sigma (St. Louis, MO). Doxorubicin was purchased from Pharmacia (Bentley, WA, Australia).

Preparation of Doxorubicin-Loaded Capsids (PC−Dox). The coat protein of HCRSV was purified by dialysis against 1000 mL of pH 8.0 Tris buffer (50 mM Tris/base, 5 mM EDTA, 2 mM DTT, 0.2 mM PMSF, pH 8.0) for 12 h followed by centrifugation to remove viral RNA as described previously (*19*). After further dialysis against 1000 mL of pH 7.0 Tris buffer (50 mM Tris/base, 5 mM EDTA, 2 mM DTT, 0.2 mM PMSF, 1 M NaCl, pH 7.0) for 4 h, 1 mL of the coat protein solution (1 mg/mL) was incubated with 0.5 mL of doxorubicin−PSA solution (0.2 mg/mL of doxorubicin, 0.6 mg/mL of PSA (mw = 200 kDa) in pH 7.0 Tris buffer) for 8 h at 4 °C. The solution was adjusted to pH 5 with sodium acetate buffer (1 M sodium acetate, pH 5.0), and $CaCl_2$ was added to a final concentration of 5 mM to reassemble the protein cages. The solution was centrifuged under 15 000*g* for 10 min, and the supernatant was put on a 15% sucrose cushion and ultracentrifuged at 100 000*g* (SW41 rotor) for 1 h to sediment the protein cages. The pelleted PC−Dox was suspended in 0.1 mL of resuspension buffer (50 mM sodium acetate, 20 mM NaCl, 5 mM EDTA, 20 mM $CaCl_2$, pH 5.0) and stored at 4 °C until use.

Preparation of Folic Acid-Conjugated, Doxorubicin-Loaded Capsids (fPC−Dox). The carbodiimide coupling method was used to conjugate folic acid onto the capsids (*26−30*). Five milligrams of folic acid, 50 mg of 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride (EDAC), and 50 mg of *N*-hydroxysuccinimide (NHS) were dissolved in 50 mL of bicarbonate buffer (50 mM $NaHCO_3$, pH 6) at ambient temperature. Five milligrams of HCRSV was then incubated with the reaction mix at 4 °C for 8 h**.** The solution was concentrated to about 0.5 mL by ultrafiltration and washed thrice with 10 mL of resuspension buffer to remove the unreacted materials. Dialysis against Tris buffers as described above was employed to remove the viral RNA and purify the coat protein. To determine the conjugation efficiency of a sample, the conjugated folic acid was quantified based on OD_{360nm} using an extinction coefficient of 5312 mol^{-1} cm^{-1} (Beckman Du 640B spectrometer, CA) (*28−32*), while the protein content was determined by the bis-cinchoninic acid assay (TECAN SpectraFluor, MA) (*33*). Reassembly of the purified folic acid-conjugated coat protein into protein cages, with simultaneous loading of doxorubicin and polystyrenesulfonic acid, were also conducted using methods similar to those described for the unconjugated protein coats.

Characterization of PC−Dox and fPC−Dox. The morphology of HCRSV, PC−Dox, and fPC−Dox were observed under a transmission electron microscope (TEM) (CM10, Philips Electronic Instruments Co, NJ) after staining with 1% of phosphotungstic acid. Sucrose gradient centrifugation was performed to confirm the existence of the drug-loaded protein cages. About 0.5 mL of PC−Dox and fPC−Dox in resuspension

buffer was centrifuged on 10−40% sucrose gradient at 100 000*g* for 3 h. Fractions of the sucrose gradient were collected for OD_{485nm} measurement to detect for doxorubicin. Control samples, including free doxorubicin, doxorubicin complexed with PSA at a weight ratio of 3:1 (Dox−PSA), doxorubicin incubated with empty viral capsids under reassembly conditions (Dox-CP), and doxorubicin incubated with preformed PSA-loaded capsids (PSA-PC) (*19*), were also subjected to the sucrose gradient centrifugation.

Native electrophoresis of PC−Dox and fPC−Dox was performed on 1% agarose gel under 5 V/cm for 1 h (Bio-Rad Sub-Cell electrophoresis system). Bands of coat protein were visualized by Coomassie blue staining, while the doxorubicin bands were visualized under ultraviolet light. Loading efficiency (LE), encapsulation efficiency (EE), reassembly efficiency (RE), and the number of doxorubicin molecules encapsidated within each capsid (*N*) were calculated using eqs 1−4. The amount of doxorubicin was calculated by comparing the $OD_{485\ nm}$ of sample and standard solutions, both of which were diluted with resuspension buffer (pH 5). The amount of reassembled coat protein (protein cage) was quantified by the BCA assay after the encapsidated doxorubicin was removed via a 6-day dialysis against PBS (pH 7.4). Drug release experiments were performed by the dialysis method (*34*). Fifty microliters of PC−Dox and fPC−Dox suspensions, with an equivalent doxorubicin concentration of 100 μg/mL, were placed in separate dialysis tubes (mw cutoff 12 400, Sigma-Aldrich) and dialyzed against 25 mL of PBS (pH 7.4) at 37 °C. At specified time points, 0.2 mL of the dialysis buffer was sampled for fluorescence measurements (Ex 480 nm, Em 535 nm) to quantify the released doxorubicin.

$$\text{LE}\ (\%) = \text{weight}_{\text{doxorubicin loaded}}/\text{weight}_{\text{protein cage}} \times 100\% \quad (1)$$

$$\text{EE} = \text{weight}_{\text{doxorubicin loaded}}/\text{weight}_{\text{total doxorubicin used}} \times 100\% \quad (2)$$

$$\text{RE} = \text{weight}_{\text{protein cage}}/\text{weight}_{\text{total coat protein used}} \times 100\% \quad (3)$$

$$N = \text{LE}/\text{mw}_{\text{doxorubicin}} \times (\text{mw}_{\text{coat protein}} \times 180) \quad (4)$$

The $mw_{doxorubicin}$ and $mw_{coat\ protein}$ values were 545 and 37 000, respectively.

Cellular Uptake of Doxorubicin. OVCAR-3 and CCL-186 cells were subcultured in six-well plates at concentrations of 100 000 cells/well. After 24 h, the cells were incubated with doxorubicin, PC−Dox, and fPC−Dox at equivalent doxorubicin concentration of 5 μg/mL. In the case of fPC−Dox, the incubation was also conducted in the presence of 1 mM of folic acid (fPC−Dox + f). The cells were washed thrice in ice-cold PBS to remove the samples, then lyzed with 0.5 mL of lysis buffer (50 mM Tris, 0.8% Triton, 0.2% SDS, pH 7.4). Cell-associated doxorubicin was determined by measuring the fluorescence of the lysate using a microplate reader (TECAN SpectraFluor, MA, Ex 485 nm and Em 535 nm) (*35*).

Confocal Microscopy. Cells were cultured in Lab-Tek chambered glass system and incubated for 1 h with samples of doxorubicin, PC−Dox, fPC−Dox and fPC−Dox + f, at a doxorubicin concentration of 5 μg/mL. The cells were washed thrice with PBS and the intracellular doxorubicin was visualized under a confocal microscope (CSLM, Zeiss Axiovert 200M, Oberkochen, Germany, Ex_{480nm} and Em_{540nm}) (*36*).

MTT Assay. PC−Dox, fPC−Dox and fPC−Dox + f samples were diluted with folic acid-deficient RPMI 1640 medium to give doxorubicin concentration in the range of 0.005 to 30 μg/mL. OVCAR-3 and CCL-186 cells were subcultured in 96-well plates at a density of 20 000 and 5000 cells/well, respectively. After 24 h, the culture medium was aspirated, and the cells were incubated with 0.1 mL of doxorubicin, PC−Dox, fPC−Dox, or fPC−Dox + f samples for 2 h. The cells were then washed thrice in ice-cold PBS and incubated with 0.2 mL of fresh cell culture medium for 3 days. Cell viability was determined by the MTT assay, and IC_{50} values were calculated using the nonlinear regression sigmoidal dose−response equation (Prism Version 3.00) (*25, 37−39*).

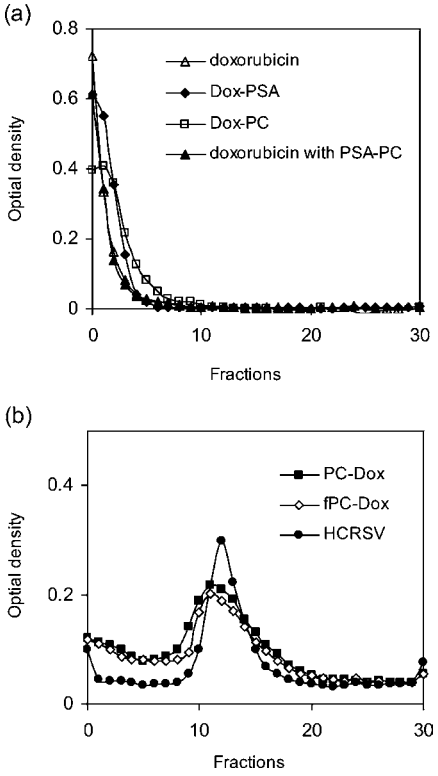

Figure 2. Optical density of fractions obtained from sucrose gradients. HCRSV was detected at 260 nm while other samples were detected at 485 nm. (a) Doxorubicin in control samples stayed at the top of the sucrose gradient after centrifugation. (b) Doxorubicin in PC−Dox and fPC−Dox showed greater propensity to sediment after centrifugation.

RESULTS AND DISCUSSION

Fractions isolated from the sucrose gradient centrifugation and subjected to optical density (OD) measurements indicated that the free doxorubicin, Dox−PSA, Dox-CP, and doxorubicin incubated with preformed PSA-PC were retained at the top (Figure 2, a), while native HCRSV were retained in fraction 13 of the sucrose gradient. In contrast, sucrose gradient centrifugation analysis of PC−Dox and fPC−Dox showed high doxorubicin content in fractions 11−15, with peak doxorubicin content noted in fraction 12 (Figure 2, b). The sedimentation rate of doxorubicin in these samples is higher than that of free doxorubicin, indicating that the drug had been loaded into the viral capsids. Interestingly, the sedimentation rates of PC−Dox and fPC−Dox were comparable with that of native HCRSV, suggesting similar cargo loads in the viral capsids of these samples. It may therefore be concluded that successful drug encapsulation was achieved in the PC−Dox and fPC−Dox samples but not in the Dox-CP and preformed PSA-PC samples. The failure to load doxorubicin into the preformed PSA-PC suggests that the drug could only be encapsulated during protein cage reassembly. The implication is that doxorubicin loaded in the PC−Dox and fPC−Dox samples was not likely to result from physical or chemical binding onto the surface of the protein cages but was contained within the HCRSV capsids.

Native agarose gel electrophoresis was applied to analyze the electrostatic properties of the samples. As shown in Figure 3 a,

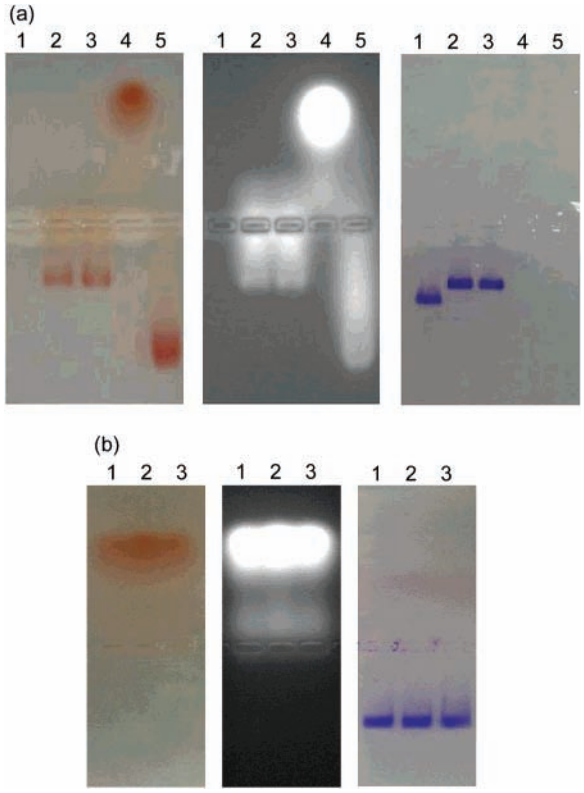

Figure 3. Native agarose gel electrophoresis. (a) Lanes 1−5 contain HCRSV, fPC−Dox, PC−Dox, doxorubicin, and doxorubicin−PSA complex. (b) Lanes 1−3 contain doxorubicin incubated with HCRSV, preformed PSA-PC, and PSA-fPC. The photos were taken by a digital camera, under ultraviolet light and after staining with coomassie blue, respectively.

free doxorubicin had migrated to the cathode, while PC−Dox, fPC−Dox, and the doxorubicin−PSA complex had moved in the opposite direction toward the anode. The relative positions of the bands indicate the opposing polarity of the samples and confirmed that the PSA−doxorubicin complex possessed a strong net negative charge. A comparison of the gels following coomassie blue staining showed that the doxorubicin band colocalized with the protein bands in the PC−Dox and fPC−Dox samples, once more underscoring the successful encapsulation of the drug in the viral capsids. Compared with the native HCRSV, the PC−Dox and fPC−Dox possessed a slightly lower charge density. In our previous study, HCRSV capsids loaded with PSA alone were determined to have the same negative charge density as the native HCRSV (*19*). Therefore, the lower charge density of PC−Dox and fPC−Dox could be attributed to the loaded doxorubicin. Samples in which doxorubicin was incubated with the preformed polyacid-loaded protein cages showed an absence of drug-loaded capsids (Figure 3, b). This negative control, together with that the results obtained from the sucrose gradient analysis, further confirms the encapsulation of doxorubicin during the process of capsid reassembly.

Both PC−Dox and fPC−Dox appeared as spherical particles with a diameter of about 30 nm and were indistinguishable from the native HCRSV when viewed under the TEM (Figure 4). The "polyacid association" method was found to be efficient for capsid reassembly and drug loading. As shown in Table 1, doxorubicin loaded into PC−Dox and fPC−Dox amounted to 59 and 49%, respectively, of the initial doxorubicin load used to prepare the samples, while more than 60% of the coat protein was found to have reassembled into capsids in these two samples. Measured against the coat protein content, the drug loading efficiency (LE) was 7.5%, amounting to about 900 doxorubicin molecules encapsulated in each protein cage. The encapsulated doxorubicin concentration would be in the vicinity of 300 mM, given that the inner diameter of the HCRSV protein cage was about 110 Å (*40*).

Folic acid conjugation efficiency ($\text{weight}_{\text{folic acid}}/\text{weight}_{\text{coat protein}}$) for fPC−Dox was 1.9% (SD = 0.1%, $n = 3$), which translated to about two folic acid molecules conjugated to each coat protein. The folic acid is postulated to bind with the Lys amino acids on the exposed protruding domain of the coat proteins. Since the icosahedral HCRSV capsid is made up of 180 coat protein units (*24*, *40*), the implication is that each fPC−Dox particle would have 360 conjugated folic acid molecules.

The release of doxorubicin from PC−Dox and fPC−Dox following dilution was evident during sucrose gradient centrifugation and agarose gel electrophoresis. Fractions obtained from the sucrose gradient showed increasing doxorubicin concentration from fractions 0 to 10. Since the viral capsids were retained in fraction 12, this suggests that doxorubicin was released from the capsids as they sediment along the centrifugation path. Observation of the agarose gel also showed a strong trail of doxorubicin associated with the bands for PC−Dox and fPC−Dox (Figure 3, a). As the protein bands of PC−Dox and fPC−Dox (Figure 3, a) did not exhibit degradation trails, the protein cages were probably stable under the experimental conditions. The orange color trails and fluorescence trails might therefore be attributed to the doxorubicin which had been released from the capsids and had migrated toward the cathode.

In vitro drug release experiments were conducted under simulated physiological conditions (pH 7.4, 37 °C) (*34*). Sustained release was evident when the drug release profiles of PC−Dox and fPC−Dox were compared with that of free doxorubicin (Figure 5). More than 80% of the drug load was released from the free doxorubicin into the receptor chamber after 5 h, whereas the drug-loaded capsids yielded the same amount of doxorubicin only after 24 h. Drug release from the PC−Dox and fPC−Dox did not, however, occur at a constant rate. There was a fairly rapid release of doxorubicin in the initial phase, where 40% of the drug load was released in 4 h, followed by a slower pace of release of the remaining drug load from the capsids. The mechanisms that effect drug release upon dilution were probably similar to those that allowed doxorubicin to be loaded into the viral capsids in the first place, i.e., reversible electrostatic attraction with the polyacid and physical entrapment by the viral protein cage. The sustained-release profile, coupled with the almost complete release of the entire drug load, rendered the HCRSV protein cages as attractive platforms for controlled release drug delivery. However, to reduce drug release during storage, the samples should be stored in small volumes of resuspension buffer at low temperature (4 °C).

In vitro cellular uptake and cytotoxicity experiments were conducted on the ovarian epithelial adenocarcinoma OVCAR-3 cell line, and the CCL-186 cells, a human diploid fibroblast. The OVCAR-3 cells have been used to evaluate folic acid-targeting drug delivery systems because of the presence of overexpressed folic acid receptors in these cells (*41*−*43*). The CCL-186, on the other hand, served as a representative human normal cell and was used as a control to evaluate the capacity of the delivery systems to selectively deliver doxorubicin to cancer cells.

Cellular uptake of doxorubicin was visualized by confocal microscopy and quantified by fluorimetry. Quantitative data showed a 2-fold higher cellular uptake of doxorubicin from fPC−Dox than from PC−Dox by the OVCAR-3 cells (Figure 6). Uptake of doxorubicin from PC−Dox was in fact no different from that of free doxorubicin, suggesting that the encapsulation of doxorubicin within the HCRSV capsids could not by itself aid in the intracellular accumulation of the drug in the

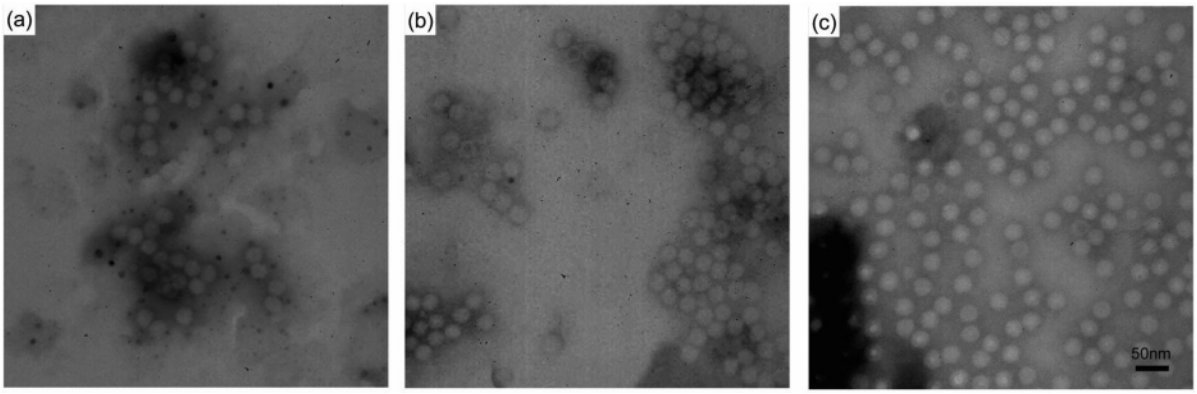

Figure 4. TEM micrographs of (a) PC−Dox, (b) fPC−Dox, and (c) native HCRSV without modifications. The two drug-loaded viral protein cage particles were comparable in morphology and size with the native HCRSV.

Table 1. PC−Dox and fPC−Dox Samples: Efficiency of Doxorubicin Loading and Reassembly of Coat Proteins into Capsids. Data Represent Mean ± SD, $n = 3$.

samples	EE (%)[a]	RE (%)[b]	LE (%)[c]	N^d
PC−Dox	59.3 ± 13.7	74.7 ± 12.1	7.8 ± 0.5	953
fPC−Dox	48.7 ± 4.7	63.8 ± 5.1	7.5 ± 0.3	916

[a] $\text{weight}_{\text{doxorubicin}}/\text{weight}_{\text{coat protein}}$ expressed as a percentage. [b] $\text{weight}_{\text{doxorubicin loaded}}/\text{weight}_{\text{doxorubicin used for preparation}}$ expressed as a percentage. [c] $\text{weight}_{\text{capsids}}/\text{weight}_{\text{coat protein used for preparation}}$ expressed as a percentage. [d] Number of doxorubicin molecules encapsidated within each capsid.

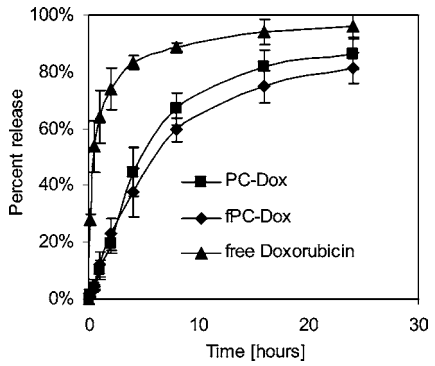

Figure 5. Doxorubicin release profile of PC−Dox, fPC−Dox, and free doxorubicin. More than 80% of free doxorubicin was released into the receptor chamber after 5 h whereas the drug-loaded capsids yielded the same amount of doxorubicin after 24 h.

OVCAR-3 cells. Coincubation of fPC−Dox with folic acid negated the higher cellular uptake of doxorubicin from this sample, implicating a folic acid-mediated uptake mechanism in the OVCAR-3 cells. Enhanced uptake of doxorubicin from fPC−Dox was not observed in the CCL-186 cells, which showed comparable drug uptake from the free doxorubicin, PC−Dox, and fPC−Dox samples.

Confocal micrographs provided supporting evidence for the folic acid-mediated preferential uptake of fPC−Dox by the OVCAR-3 cells (Figure 7). OVCAR-3 cells incubated with fPC−Dox showed more intense fluorescence compared to cells incubated with free doxorubicin or PC−Dox. Upon the addition of folic acid to the fPC−Dox sample, however, the fluorescence exhibited by the cells was reduced to a level similar to those observed in cells incubated with PC−Dox or free doxorubicin. Doxorubicin typically accumulates in the nuclei of cells. However, for the fPC−Dox, which increased the intracellular fluorescence of doxorubicin, the fluorescence was not concentrated in the nuclei but in many bright small spots in the cytoplasm (Figure 7, c). The phenomenon was consistent with a FR-mediated uptake, whereby the drug-loaded capsids following endocytosis would be directed to the endosomes (*44*).

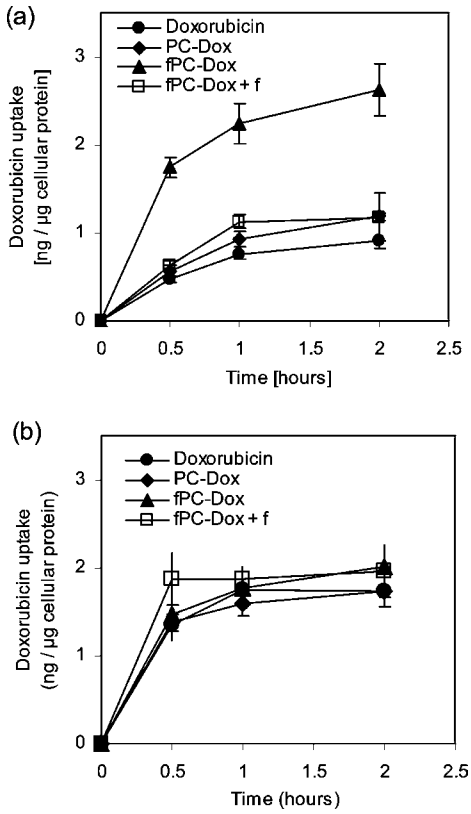

Figure 6. Cellular uptake of doxorubicin by (a) OVCAR-3 and (b) CCL-186 cells incubated with free doxorubicin, PC−Dox, and fPC−Dox. Uptake of fPC−Dox was also undertaken in the presence of folic acid (fPC−Dox + f). Data represent mean ± SD ($n = 3$).

For the CCL-186 cells, slightly stronger fluorescence was observed in cells incubated with free doxorubicin than in cells incubated with PC−Dox or fPC−Dox. These observations are therefore in good agreement with the quantitative uptake data.

Cytotoxicity of the various doxorubicin formulations against the OVCAR-3 and CCL-186 cells was assessed via the MTT assay after 2 h of exposure. The log *C* vs viability curves of OVCAR-3 cells showed that the fPC−Dox had higher cytotoxicity against this cell line compared with the other formulations (Figure 8). The PC−Dox formulation did not decrease the $IC_{50\text{doxorubicin}}$, again affirming that the encapsulation of the drug alone did not confer additional benefits to its delivery to cancer cells. The $IC_{50\text{doxorubicin}}$ of fPC−Dox formulation (0.11 μg/mL) was observed to decrease 4-fold compared with the $IC_{50\text{doxorubicin}}$ of free doxorubicin (0.48 μg/mL). This enhancement of kill was again mediated by the folic acid conjugation on the capsid surface, for the addition of free folic acid

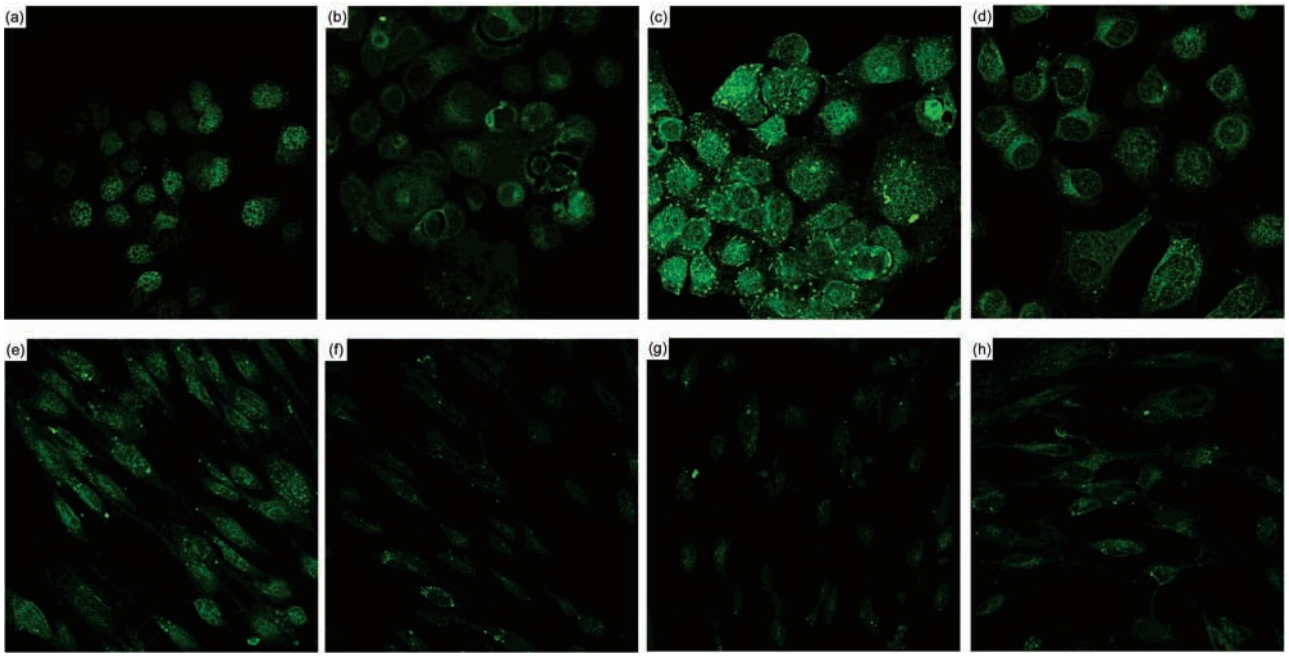

Figure 7. Confocal micrographs of OVCAR-3 cells incubated for 1 h with free doxorubicin (a), PC−Dox (b), fPC−Dox (c), and fPC−Dox in the presence of folic acid (d), and of CCL-186 cells incubated for 1 h with free doxorubicin (e), PC−Dox (f), fPC−Dox (g), and fPC−Dox in the presence of folic acid (h).

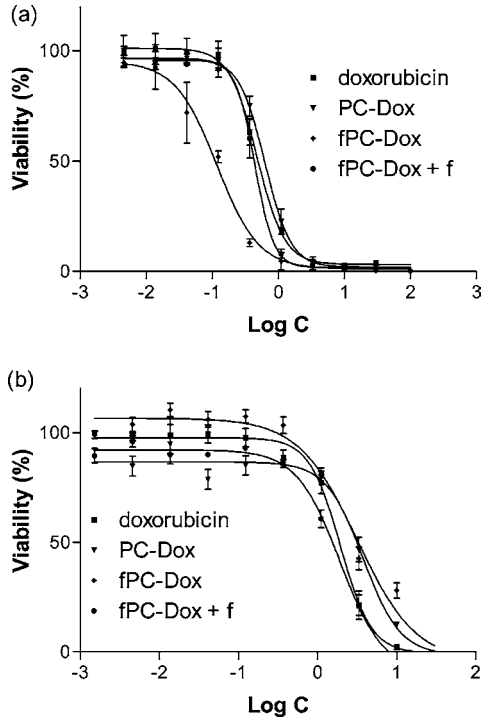

Figure 8. Viability of cells after treated by different formulations. (a) Cell viability of OVCAR-3. (b) Cell viability of CCL-186. The fPC−Dox was more efficient in inhibiting the growth of OVCAR-3 cells than other formulations while there was no such difference between the formulations in CCL-186 cells.

effectively abolished the added effect. A comparison of the $IC_{50doxorubicin}$ across cell types indicates that the CCL-186 cells, with the $IC_{50doxorubicin}$ of 1.95 μg/mL, were about 4-fold more resistant to the cytotoxicity of the drug than the OVCAR-3 cells. Interestingly, the encapsulation of doxorubicin in either the PC−Dox or fPC−Dox led to increased $IC_{50doxorubicin}$ of 3.4 μg/mL and 3.2 μg/mL against the CCL-186 cells, alluding to a conferred protection of the cells against the drug.

The selective higher uptake rate and cytotoxicity of fPC−Dox in cancer cells relative to normal cells may be explained by the up-regulation of folic acid receptors, in some cases approaching 2 orders of magnitude, in many cancer cell types (*22*, *45*). To confirm a folic acid-mediated mechanism, the uptake and cytotoxicity experiments for fPC−Dox were conducted in the presence of high concentration of free folic acid, which was found to negate the benefits of fPC−Dox. This suggested the uptake of fPC−Dox by folic acid-mediated endocytosis in the OVCAR-3 cells. The preferential uptake of fPC−Dox led to its stronger cytotoxic effect, as denoted by the lower $IC_{50doxorubicin}$ value, in cancer cells.

On the other hand, the uptake and cytotoxicity data suggest that the PC−Dox was not an efficient delivery system for cancer chemotherapy. This is reasonable considering the current lack of evidence to support cytoinvasive and cytotoxicity properties of plant viruses in animal cells. PC−Dox could, however, be useful in clinical applications where sustained drug release and/or protection against cytotoxic drugs are desired.

To conclude, a new "polyacid association" method was established to physically encapsulate the anticancer drug, doxorubicin, inside the protein cage of HCRSV at high loading efficiency. The conjugation of folic acid allows the viral capsids to selectively increase the uptake and cytotoxicity of doxorubicin in the ovarian cancer cells OVCAR-3. This indicates that the folic acid-conjugated, doxorubicin-loaded HCRSV capsid has potential for the targeted delivery of cancer chemotherapeutics. However, much work remains to be done to develop the protein cages of plant viruses into feasible drug delivery systems. For the fPC−Dox, further work on the immune response and *in vivo* efficacy of the formulation will be required to assess its potential for clinical applications.

Received November 21, 2006; Revised Manuscript Received January 30, 2007

We report herein the molecular engineering of an efficient two-photon absorbing (TPA) chromophore based on a donor−donor bis-stilbenyl entity to allow conjugation with biologically relevant molecules. The dye has been functionalized using an isothiocyanate moiety to conjugate it with the amine functions of poly(ethylenimine) (PEI), which is a cationic polymer commonly used for nonviral gene delivery. Upon conjugation, the basic architecture and photophysical properties of the active TPA chromophore remain unchanged. At the usual N/P ratio (ratio of the PEI positive charges to the DNA negative charges) of 10 used for transfection, the transfection efficiency and cytotoxicity of the labeled PEI/DNA complexes were found to be comparable to those of the unlabeled PEI/DNA complexes. Moreover, when used in combination with unlabeled PEI (at a ratio of 1 labeled PEI to 3 unlabeled PEI), the labeled PEI does not affect the size of the complexes with DNA. The labeled PEI was successfully used in two-photon fluorescence correlation spectroscopy measurements, showing that at N/P = 10 most PEI molecules are free and the diffusion coefficient of the complexes is consistent with the 360 nm size measured by quasielastic light scattering. Finally, two-photon images of the labeled PEI/DNA complexes confirmed that the complexes enter into the cytoplasm of HeLa cells by endocytosis and hardly escape from the endosomes. As a consequence, the functionalized TPA chromophore appears to be an adequate tool to label the numerous polyamines used in nonviral gene delivery and characterize their complexes with DNA in two-photon applications.

INTRODUCTION

During the past decade, two-photon fluorescence imaging has evolved as a powerful technique for three-dimensional scanning microscopy in biological research (*1*, *2*). This technique offers many advantages over conventional confocal microscopy. First of all, the two-photon absorption only occurs at the laser focus where the laser light intensity is maximum, so that dye bleaching and fluorescence above and below the focused spot are avoided. Furthermore, the excitation source is generally an IR laser, which takes advantage of the transparency window of biological tissues. In addition, the IR light is more penetrating and less damaging to cells than the more energetic UV−vis light, enabling observation of thicker samples and during more extended periods without degradation (*3*). Furthermore, two-photon excitation was found to be ideally suited for fluorescence correlation spectroscopy (FCS), allowing the determination of the local concentrations and diffusion coefficients of fluorescently labeled molecules in cells (*4*, *5*). However, the use of two-photon microscopy and FCS is still hampered by the availability of appropriate two-photon dyes. Indeed, classical one-photon dyes, well-known in epifluorescence or confocal microscopy, are still largely used in two-photon applications, though they exhibit only low two-photon cross sections. Consequently, the development of new water-soluble dyes, specifically engineered for their multiphoton absorption and fluorescence, is strongly required. Recently, we reported the synthesis of water-soluble efficient blue TPA fluorophores (*6*). These compounds present a D-π-rigid core-π-D symmetric architecture, where D = donor group(s), π = conjugated spacer, and rigid core = biaryl system (Figure 1a). By introducing oligo(ethylene glycol) moieties, we obtained good water solubility (up to 100 g.L^{-1} for the fluorophore shown in Figure 1b), which enables the use of these dyes for cellular imaging (*7*). To go one step further in the validation and application of these water-soluble dyes, our aim in this work was to prepare functionalized TPA fluorophores in order to label biologically relevant molecules and monitor them in cells by two-photon microscopy and FCS. For this purpose, we selected poly(ethylenimine)s (PEIs) that are among the most efficient nonviral gene delivery agents (*8*, *9*). PEIs are rich in amino groups and positively charged at neutral pH. Due to their high cationic charge density, PEIs are proficient condensing agents for DNA that lead to the formation of small particles (<100 nm) at high nitrogen-to-phosphate ratios (N/P > 5) (*10*). These DNA/PEI complexes exhibit good transfection efficiency in vitro and in various in vivo applications (*11*). To conjugate the amine functions of PEI, we synthesized the isothiocyanate-functionalized TPA chromophore **1** (Figure 2). This dye was conjugated to PEI at a ratio of 1 dye per 40 amine functions. The corresponding conjugate PEI derivative was shown to substitute nonconjugated PEIs in their complexes with DNA and can be used to monitor the intracellular pathway of the complexes in cells by two-photon microscopy.

EXPERIMENTAL PROCEDURES

Materials. Branched PEI (25 kDa) was purchased from Aldrich. Lysis reagent was from Promega. All other chemicals and reagents were purchased from Aldrich or Acros Organics and were used as received unless specified otherwise. THF was distilled over sodium under argon atmosphere prior to use. Compounds **3**, **4**, and **7** were prepared as previously described (*6*).

Synthesis. ^{1}H and ^{13}C NMR spectra were recorded with a 300 MHz Brucker Advance 300 instrument in $CDCl_3$ (Aldrich) with $CHCl_3$ as an internal standard (7.24 ppm for ^{1}H and 77 ppm, middle of the three peaks, for ^{13}C spectra). High-resolution ESI mass spectra were recorded with a Microtof instrument at Service de spectrométrie de masse de l'Institut de chimie LC3-ULP- Strasbourg. TLC was run on Merck precoated aluminum plates (Si 60 F254). Column chromatographies were run on Merck silica gel (60−120 mesh) or neutral alumina (Merck) 70−230 mesh.

*4-(t-Butyldimethylsilanyloxy)-3,5-dimethoxybenzaldehyde (**5**).* Under argon, in a 250 mL two-necked flask, 4.6 g of *t*-butyldimethylsilylchloride (30 mmol) and 2.1 g of imidazole (30 mmol) were dissolved in 120 mL of a dimethylformamide/dichloromethane mixture (1/1 v/v). When the solution became homogeneous, 5 g of syringaldehyde (27 mmol) was added and the mixture was heated at 80 °C overnight. Then, the solvents were evaporated under vacuum. The yellow solid was dissolved in 200 mL of CH_2Cl_2, washed with water (150 mL), dried on $MgSO_4$, and evaporated under reduced pressure to give a yellow oil. The oil was solubilized in ethanol (40 mL) and cooled down in the freezer overnight. The white precipitate was filtered and dried to give 4.96 g of the desired protected product **5** in 62% yield. ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm): 9.82 (s, 1H), 7.10 (s, 2H), 3.87 (s, 6H), 1.01 (s, 9H), 0.16 (s, 6H). ^{13}C NMR (75.75 MHz, $CDCl_3$, δ ppm): 191.98, 151.92, 140.98, 129.3, 106.66, 55.75, 25.62, 18.73, 4.58. HRMS calculated *m*/*z* for $C_{15}H_{24}O_4SiLi$, 303.1604; found, 303.1599.

*4-{2-[4-(t-Butyldimethylsilanyloxy)-3,5-dimethoxy]styryl}-4′-(diethoxyphosphinylmethyl)-9,9′-di-n-propylfluorene (**6**).* To a solution of 4,4′-bis(diethoxyphosphinylmethyl)-9,9′-dipropylfluorene **4** (3.34 g, 6.08 mmol, 1 equiv) in 50 mL of anhydrous THF was added 0.73 g of NaH (30.4 mmol, 5 equiv, 60% in mineral oil). After the effervescence ceased, the suspension was stirred for 1 h at room temperature under an argon atmosphere. After cooling at 0 °C, a solution of 1.80 g of **5** (6.08 mmol, 1 equiv) in anhydrous THF (50 mL) was added slowly. The mixture was stirred for 24 h and neutralized by ethanol (10 mL). The solvents were evaporated under vacuum giving an oil, which was dissolved in CH_2Cl_2 and washed with brine (50 mL) and water (50 mL). The crude product was purified by column chromatography on silica gel with dichloromethane/methanol as eluant (97/3 in vol). The desired product **6** was obtained as a yellow oil (m = 1.47 g, 35% yield). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm): 7.65−7.60 (m, 2H), 7.48−7.45 (m, 2H), 7.29−7.26 (m, 2H), 7.07 (s, 2H), 6.76 (s, 2H), 4.09−3.98 (m, 4H), 3.87 (s, 6H), 3.24 (d, 2H, J = 21.49 Hz), 2.20−1.97 (m, 4H), 1.23 (t, 6H, J = 7.02 Hz), 1.03 (s, 9H), 0.67 (s, 10H), 0.16 (s, 6H). ^{13}C NMR (75.75 MHz, $CDCl_3$, δ ppm): 151.27, 151.27, 151.22, 151.11, 140.23, 104.20, 139.69, 139.64, 136.41, 136.39, 134.42, 130.29, 130.25, 130.17, 128.55, 128.46, 128.27, 127.50, 125.37, 124.28, 124.19, 120.45, 119.75, 119.61, 119.56, 103.61, 62.13, 62.04, 55.74, 55.10, 42.78, 35.00, 33.18, 25.76, 18.76, 17.12, 16.38, 16.30, 14.37, −4.66. HRMS calculated *m*/*z* for $C_{40}H_{57}O_6PSi$, 692.3662; found, 692.3664.

*4-{2-[4-(t-Butyldimethylsilanyloxy)-3,5-dimethoxy]styryl}-4′-{2-[3,4,5-tris(1,4,7,10,13-pentaoxotetradecyl)]styryl}-9,9′-di-n-propylfluorene (**2**).* This product was prepared as described for **6** using 500 mg of **6** (0.72 mmol, 1 equiv), 144 mg of NaH (3.6 mmol, 5 equiv), and 523 mg of aldehyde **7** (0.72 mmol, 1 equiv). Product **2** was obtained as a yellow oil (m = 909.80 mg, 85% yield). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm): 7.64 (d, 2H J = 8.33 Hz), 7.48−7.46 (m, 4H), 7.08 (s, 2H), 7.05 (d, J = 1.32 Hz), 6.80 (s, 2H), 6.76 (s, 2H), 4.25−4.16 (m, 6H), 3.89 (t, 4H, J = 5.26 Hz), 3.87 (s, 6H), 3.81 (t, 2H, J = 5.26 Hz), 3.77−3.61 (m, 24H), 3.57−3.53 (m, 6H), 3.38 (s, 3H), 3.37 (s, 6H), 2.02−1.97 (m, 4H), 1.03 (s, 9H), 0.70 (s, 10H), 0.16 (s, 6H). ^{13}C NMR (75.75 MHz, $CDCl_3$, δ ppm): 152.74, 151.72, 151.45, 140.58, 140.23, 138.26, 136.46, 136.04, 134.42, 133.10, 130.26, 128.72, 128.31, 127.64, 127.50, 125.59, 125.44, 120.60, 120.46, 119.81, 119.77, 106.13, 103.62, 71.88, 70.79, 70.65, 70.62, 70.57, 70.54, 70.47, 69.73, 68.81, 58.97, 55.73, 55.10, 53.39, 42.86, 25.76, 18.71, 17.15, 14.45, −4.65.

*4-{2-[4-(2,6-Dimethoxy-4-vinylphenoxy)butyl]isoindolin-1,3-dione-4′-[3,4,5-tris-(1,4,7,10,13-pentaoxotetradecyl)]styryl}-9,9′-di-n-propylfluorene (**9**).* (a) Deprotection of the phenol moiety: In a 100 mL two-necked flask, under an argon atmosphere, 550 mg of **2** (0.43 mmol, 1 equiv) was dissolved in 50 mL anhydrous THF. A solution of TBAF (0.19 g, 0.65 mmol, 1.5 equiv) in THF (1 mL) was introduced dropwise into the flask. The mixture was stirred at room temperature for 2 h and put in 100 mL of 1 M phosphoric acid. The aqueous phase was extracted with diethyl ether, washed with water, and dried on magnesium sulfate. The solvent was removed under reduced pressure, and the crude product was purified by column chromatography on silica gel (ethyl acetate/hexane mixture as eluant 50/50 in vol). The phenolic product was obtained as a yellow oil (m = 1.02 g, 90% yield). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm): 7.64 (d, 2H J = 8.33 Hz), 7.48−7.46 (m, 4H), 7.08 (d, 2H, J = 2.20 Hz), 7.05 (d, 2H, J = 1.09 Hz), 6.809 (s, 2H), 6.801 (s, 2H), 5.58 (s, 1H), 4.23 (t, 4H, J = 4.83 Hz), 4.18 (t, 2H, J = 4.83 Hz), 3.97 (s, 6H), 3.89 (t, 4H, J = 5.26 Hz), 3.81 (t, 2H, J = 5.26 Hz), 3.77−3.61 (m, 24H), 3.57−3.53 (m, 6H), 3.38 (s, 3H), 3.37 (s, 6H), 2.02−1.97 (m, 4H), 0.70 (s, 10H). ^{13}C NMR (75.75 MHz, $CDCl_3$, δ ppm): 152.72, 151.51, 151.45, 147.19, 140.55, 140.31, 138.30, 136.34, 136.09, 134.68, 133.08, 129.14, 128.71, 128.09, 127.67, 127.40, 125.59, 125.43, 120.61, 120.44, 119.83, 106.15, 103.21, 77.16, 72.38, 71.90, 70.81,

70.65, 70.57, 70.54, 70.51, 70.49, 69.73, 68.83, 59.10, 58.99, 56.27, 55.11, 42.86, 29.66, 24.20, 19.76, 17.15, 14.45, 13.65.

(b) Product **9**. In a 100 mL three-necked flask were introduced DMF (50 mL), 340 mg of the previous deprotected phenolic compound (0.29 mmol, 1 equiv), 204 mg of K_2CO_3 (1.48 mol, 5 equiv), and 100.15 mg of *N*-(4-bromobutyl)phthalimide (0.35 mmol, 1.20 equiv). The mixture was then heated at 80 °C for 4 days under an argon atmosphere. The solvent was removed under vacuum, and the residue dissolved in dichloromethane, washed with water, and dried over magnesium sulfate. After evaporation of the dichloromethane, the crude product was purified by column chromatography on silica gel, with dichloromethane as eluant to give the desired product **9** as a yellow oil (m = 333 mg, 85% yield). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm): 7.86−7.83 (m, 2H), 7.72−7.69 (m, 2H), 7.65 (d, 2H J = 8.33 Hz), 7.50−7.46 (m, 4H), 7.09 (s, 2H), 7.05 (d, 2H, J = 0.87 Hz), 6.80 (s, 2H), 6.76 (s, 2H), 4.23 (t, 4H, J = 4.83 Hz), 4.18 (t, 2H, J = 4.83 Hz), 4.03 (t, 2H, J = 6.35 Hz), 3.91 (s, 6H), 3.89 (t, 4H, J = 5.26 Hz), 3.81 (t, 2H, J = 5.26 Hz), 3.77−3.61 (m, 24H), 3.57−3.53 (m, 6H), 3.38 (s, 3H), 3.37 (s, 6H), 2.02−1.76 (m, 8H), 0.70 (s, 10H). ^{13}C NMR (75.75 MHz, $CDCl_3$, δ ppm): 168.40, 153.59, 152.74, 151.51, 140.49, 140.31, 138.29, 136.83, 136.18, 136.14, 133.78, 133.11, 133.08, 132.15, 128.70, 128.57, 127.98, 127.70, 125.57, 123.09, 120.61, 120.44, 119.84, 106.16, 103.49, 77.17, 72.55, 72.38, 71.89, 70.79, 70.65, 70.62, 70.58, 70.57, 70.54, 70.52, 70.48, 69.74, 68.82, 58.98, 56.07, 55.13, 42.86, 37.78, 27.44, 25.22, 17.15, 14.45. HRMS m/z calculated for $C_{76}H_{103}NO_{20}Na$, 1372.6971; found, 1372.7004.

*4-{2-[4-(4-Aminobutyloxy)-3,5-dimethoxy]styryl}-4′-{2-[3,4,5-tris(1,4,7,10,13-pentaoxotetradecyl)]styryl}-9,9′-di-n-propylfluorene (**10**).* In a 250 mL two-necked flask, 240 mg of **9** (0.2 mmol, 1 equiv) was dissolved in absolute ethanol (30 mL) under argon atmosphere. Hydrazine hydrate (0.2 mL, 0.802 mmol) was then added. The mixture was refluxed for 5 h, then cooled to room temperature, after which aqueous 1 M HCl (5 mL) was added slowly. Then, the reaction mixture was neutralized with dilute sodium carbonate solution to pH = 7. The aqueous phase was extracted with dichloromethane, the organic phase was dried on $MgSO_4$, and the solvent was removed under vacuum. The crude product was purified by column chromatography on silica gel with methanol/dichloromethane mixture (5/95 in vol) as eluant to give 163 mg of the free amine **10** as a yellow oil (75% yield). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm): 7.65 (d, 2H J = 8.33 Hz), 7.50−7.46 (m, 4H), 7.10 (s, 2H), 7.05 (s, 2H), 6.80 (s, 2H), 6.78 (s, 2H), 4.23 (t, 4H, J = 4.83 Hz), 4.18 (t, 2H, J = 4.83 Hz), 4.02 (t, 2H, J = 6.35 Hz), 3.92 (s. 6H), 3.89 (t, 4H, J = 5.26 Hz), 3.81 (t, 2H, J = 5.26 Hz), 3.77−3.61 (m, 22H), 3.57−3.53 (m, 6H), 3.38 (s, 3H), 3.37 (s, 6H), 2.80 (t, 2H, J = 7.01 Hz), 2.02−1.65 (m, 8H), 0.70 (s, 10H). ^{13}C NMR (75.75 MHz, $CDCl_3$) δ (ppm): 153.54, 153.13, 152.73, 152.35, 151.49, 151.23, 140.52, 138.26, 137.00, 136.15, 133.09, 128.65, 127.92, 127.71, 125.57, 122.80, 120.62, 119.84, 119.55, 111.27, 108.05, 106.13, 105.47, 103.57, 77.17, 73.23, 73.08, 72.38, 71.88, 70.78, 70.73, 70.63, 70.61, 70.56, 70.46, 69.73, 68.81, 68.70, 58.97, 56.11, 55.98, 55.13, 55.02, 42.85, 41.87, 38.19, 29.97, 27.45, 17.16, 14.45. HRMS calculated m/z for $C_{68}H_{102}NO_{18}$, 1220.7096; found, 1220.7090.

*4-{2-[4-(4-Isothiocyanatobutyloxy)-3,5-dimethoxy]styryl}-4′-{2-[3,4,5-tris(1,4,7,10,13-pentaoxotetradecyl)]styryl}-9,9′-di-n-propylfluorene (**1**).* In a 100 mL two-necked flask, 350 mg of the amine derivative **10** (0.28 mmol, 1 equiv) was dissolved in 5 mL of anhydrous dichloromethane under argon atmosphere. The resulting solution was cooled at −20 °C. Then, 169 mg of 4-*N*,*N*-dimethylaminopyridine (1.29 mmol, 4.50 equiv) and 0.13 mL of thiophosgene (0.46 mmol, 1.60 equiv) were added. The reaction progress was monitored by TLC (silica, CH_2Cl_2/MeOH 85/15 in vol as eluant). After the disappearance of the starting materials, the solvent was removed under vacuum, and the crude product was chromatographed on silica gel, with CH_2Cl_2/MeOH 90/10 in vol as eluant. The desired amine-reactive chromophore **1** was obtained as a yellow oil (m = 346 mg, 99% yield). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm): 7.65 (d, 2H, J = 8.33 Hz), 7.53−7.44 (m, 4H), 7.11 (s, 2H), 7.05 (s, 2H), 6.80 (s, 2H), 6.78 (s, 2H), 4.23 (t, 4H, J = 4.83 Hz), 4.18 (t, 2H, J = 4.83 Hz), 4.02 (t, 2H, J = 6.35 Hz), 3.92 (s, 6H), 3.89 (t, 4H, J = 5.26 Hz), 3.81 (t, 2H, J = 5.26 Hz), 3.77−3.61 (m, 24H), 3.57−3.53 (m, 6H), 3.38 (s, 3H), 3.37 (s, 6H), 2.03−1.85 (m, 8H), 0.70 (s, 10H). ^{13}C NMR (75.75 MHz, $CDCl_3$, δ ppm): 153.50, 152.74, 151.52, 140.58, 140.47, 136.68, 136.18, 136.10, 133.34, 133.08, 128.79, 128.69, 127.86, 127.73, 125.60, 120.63, 119.85, 106.15, 103.43, 77.17, 72.38, 72.07, 71.89, 70.79,70.74, 70.65, 70.62, 70.57, 70.48, 69.73, 68.81, 58.98, 56.06, 55.93, 55.13, 44.79, 42.85, 26.99, 26.84, 17.15, 14.45. HRMS calculated m/z for $C_{69}H_{99}NO_{18}S$, 1262.5853; found, 1262.5827.

Two-Photon Absorption Properties. The TPA cross section spectra were obtained by up-conversion fluorescence using a Nd:YAG pumped optical parametric oscillator that produces 2.6 ns [full width at half-maximum (fwhm)] pulses in the 450−650 nm spectral range and using a Ti:sapphire femtosecond laser in the range 700−900 nm. This setup does not allow TPA measurements between 650 and 700 nm. The excitation beam is collimated over the cell length (10 mm). The fluorescence, collected at 90° of the excitation beam, was focused into an optical fiber connected to a spectrometer. The incident beam intensity was adjusted to ensure an intensity-squared dependence of the fluorescence over the whole spectral range. Calibration of the spectra was performed by comparison with *p*-bis(*o*-methylstyryl)benzene, for which σ_2 = 70 GM (Göppert-Mayer) at 570 nm (1 GM = 10^{-50} cm^4.s.photon^{-1}) and with the published 700−900 nm Rhodamine B two-photon absorption spectrum (*12*).

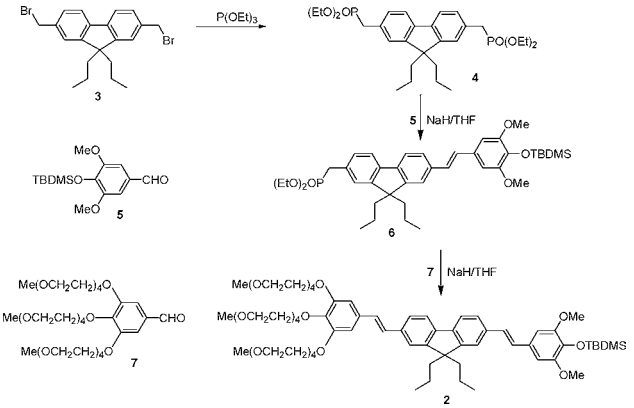
PEI−Dye Conjugation. In all experiments, we used a fresh stock solution of branched PEI (Mw = 25 kDa) with 100 mmol/L of primary amino groups (determination by the TNBS method, using spermine for the calibration curve (*13*)). Conjugation was achieved in microcentrifuge tubes by adding 50 μL of a solution of dye **1** in water (5 mg/mL) and 450 μL of borate buffer (pH = 9.4) to 500 μL of the PEI solution. PEI was incubated with dye **1** for 1 h with continuous stirring at room temperature. The mixture was allowed to stand overnight, and the unreacted dye was removed by gel chromatography (Sephadex G-25, Pharmacia, Freiburg Germany). The dye concentration of the PEI−**1** conjugate was then determined by absorption spectroscopy, using an extinction coefficient of 3.8 × 10^4 M^{-1} cm^{-1} at 354 nm.

Preparation of PEI/DNA Complexes. Complexes of DNA with PEI or PEI−**1** were prepared as described previously (*8*). Briefly, the indicated amounts of plasmid DNA (expressed in phosphate groups) and PEI−**1** (expressed in amine groups) prepared in 250 μL HEPES 20 mM, pH 7.4, were briefly mixed and incubated at room temperature. PEI/DNA complexes were formed at molar ratios of PEI nitrogen to DNA phosphate (N/P) ranging from 0.5 to 10.

Spectroscopic Measurements and Particle Size Measurements. One-photon absorption and fluorescence spectra were recorded on a Cary 400 spectrophotometer and a Fluorolog (Jobin-Yvon) spectrofluorimeter, respectively. The condensation of DNA by PEI−**1** was monitored by using the fluorescence of the DNA bis-intercalator YOYO-1. Plasmid DNA−YOYO-1 complexes were obtained by mixing equal volumes of solutions of DNA and YOYO-1 in 20 mM HEPES, 150 mM NaCl, pH 7.4. To ensure a uniform distribution of YOYO-1, the solution was incubated overnight at 4 °C under continuous stirring. The sizes of the PEI−**1**/DNA complexes were determined using a

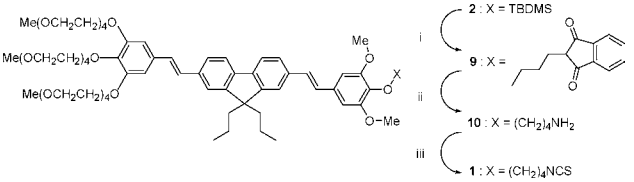
Zetamaster 3000 (Malvern Instruments, Paris, France) with the following specifications: sampling time, 30 s; medium viscosity, 1.054 cP; refractive index (RI) medium, 1.34; RI particle, 1.45; scattering angle, 90°; temperature, 25 °C. Data were analyzed using the multimodal number distribution software of the instrument.

Two-Photon Imaging and FCS Measurements. Two-photon FCS and microscopy were performed on a home-built setup. Two-photon excitation (TPE) is provided by a Tsunami Ti:sapphire laser pumped with a Millennia V solid-state laser (Spectra-Physics, Mountain View, CA). Pulses of ~100 fs are produced with a 80 MHz frequency at 760 nm. After a beam expander, the infrared light is focused into the sample by a water-immersion Olympus objective (60×, NA = 1.2) mounted on an Olympus IX70 inverted microscope. The back aperture of the objective is slightly overfilled, creating a diffraction-limited focal spot. Samples were placed in eight wells of a Lab-Tek chambered cover glass (Nalge Nunc International, Rochester, NY) positioned in the *X* and *Y* directions by a motorized stage (Märzhäuser, Germany). The fluorescence from the samples was collected through the same objective and directed by a COWL750 dichroic mirror (Coherent, Orsay, France) toward a 50 μm diameter optical fiber coupled to an avalanche photodiode (SPCM 200 FC, EG&G, Canada). The residual infrared light was rejected by a BG39 Filter (Coherent). For FCS measurements, the normalized autocorrelation function (ACF), $G(\tau)$, of the fluorescence intensity fluctuations was calculated online by an ALV5000E digital correlator card (ALV, Langen, Germany). Calibration of the system was performed with a 50 nM tetramethylrhodamine (TMR) solution. Assuming a diffusion constant of 2.8×10^{-10} m^2 s^{-1} (*14*), the equatorial (r_0) and axial (z_0) radii of the focal volume were, respectively, 0.29 and 1.3 μm, giving an effective volume of 0.2 fL. Assuming a three-dimensional Gaussian distributed excitation intensity, the ACF curves were fitted with eqs 1 and 2 of Clamme et al. (*15*).



The imaging system on the same setup is based on the use of two galvo mirrors (model 6210, Cambridge Technology), in the so-called descanned detection mode. The two mirrors are used to deflect the beam along the *X*-axis and *Y*-axis, respectively. Each axis is driven by a closed-loop power amplifier, and the position of the mirrors is controlled through two ADC electronic boards (PCI6711, National Instruments). The photons were counted using a counter/timer board (PCI6602, National Instruments), synchronized with the scan of the galvo-mirrors. Nominally, one picture is 512 × 512 in size, and the dwelling time for each pixel is 4 μs (about 1 s per scan).

PEI−**1**/DNA complexes for two-photon imaging were prepared in 20 mM HEPES, 150 mM NaCl, pH 7.4, buffer. Equal volumes of 5 mM PEI−**1** (expressed in amine groups) and 1.4 mM DNA (expressed in phosphate groups) were mixed to reach a 60 μM final concentration of DNA and a N/P ratio of 10. Solutions were briefly vortexed and left for equilibration for 20 min before cell transfection. Prior to transfection, cells were seeded for 24 h in two wells of a Lab-Tek chambered coverglass at 10^5 cells per well in order to reach 70% confluence. After 24 h, the cells were rinsed and supplemented with 1.5 mL 10% FBS DMEM and 200 μL of complexes in order to deliver 4 μg of plasmid to the cells. After 2 h incubation, the cells were rinsed three times and covered with Hank's balanced salt solution (HBSS) for two-photon imaging.



Cell Transfection and Cytotoxicity. HeLa cells were incubated in serum-free Opti-MEM with pCMVLuc plasmid (2 μg/well) complexed with PEI−**1** at N/P ratios ranging from 0.5 to 10. After 3 h 30 min, the transfection medium was replaced with fresh complete medium, and cells were cultured for an additional 24 h. Then, cells were lysed for luciferase activity quantization. Luciferase expression was recorded over 10 s using a Lumat LB9501/16 instrument (Berthold, Bad Wildbad, Germany) from an aliquot of the supernatant (5−10 μL) and expressed as RLU/mg of protein (luciferase activity per mg of protein in cell lysates).

Cytotoxicity of the PEI−**1**/DNA complexes was evaluated by quantification of the cellular content in proteins. The cells were transfected with PEI−**1**/DNA complexes in serum-free Opti-MEM. Twenty-four hours after the addition of the transfection solution, the cells were washed three times in PBS and lysed by the addition of 100 μL of cell culture lysis reagent (Promega). The cellular proteins were measured using the bicinchoninic acid assay (Interchim, Montlucon, France) following an incubation time of 30 min at 60 °C. The absorbance was read at 562 nm (*16*).

RESULTS AND DISCUSSION

Synthesis and Characterization of the Isothiocyanate-Functionalized Two-Photon Fluorophore. The reactive group chosen in this study is an isothiocyanate moiety for its versatility in bioconjugation with amines. The basic architecture of the target isothiocyanate fluorophore is identical to our previously described active two-photon excited fluorescent (TPEF) chromophores (*6*). On one side of this fluorophore, three identical oligo(ethylene glycol) chains are used to provide good water solubility. On the opposite side, we opted for a syringaldehyde derivative (three ether functions, two as methyl ether, one as linker for further conjugation) in order to keep three O-alkyl groups (Figure 2). To prepare the chromophore **1**, the key intermediate is the protected phenol **2**. To get this intermediate, we prepared first the TBDMS-protected syringaldehyde derivative **5** and followed then the synthetic pathway shown in Scheme 1. The bisphosphonate **4** was reacted with 1 equiv of TBDMS-protected syringaldehyde **5** in basic conditions at 0 °C, and the pure dissymmetric compound **6** was isolated in 35% yield from the reaction mixture containing the monophosphonate compound **6**, the unreacted bis-phosphonate **4**, and the bis-coupled symmetric molecule. Compound **6** was then reacted at room

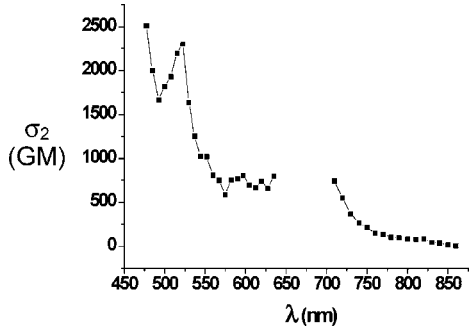

Figure 3. TPA spectra of **1** in water.

Table 1. Spectroscopic Properties of the Isothiocyanate-Functionalized Fluorophore 1

solvent	λ_{max}abs (nm)	ϵ ($M^{-1}\,cm^{-1}$)	λ_{max}ex (nm)	λ_{max}em (nm)	Φ (%)
CH_2Cl_2	365	6.9×10^4	365	435	83
H_2O	354	3.8×10^4	354	450	15

temperature with 1 equiv of aldehyde **7** to give the protected phenol derivative **2** in 44% yield. Chromophore **1** was finally obtained following the synthetic way described in Scheme 2. Fluoride deprotection of the TBDMS group affords the reactive phenolic moiety, which is etherified in situ with the commercially available *N*-(4-bromobutyl)phtalimide **8** according to Williamson conditions, to give the protected amine **9**. The amino group is then deprotected by hydrazine in ethanol to yield the free amine **10**. The isothiocyanate reactive group was finally obtained by reaction of the primary amine in **10** with thiophosgene. The targeted functionalized dye **1** was obtained in 95% yield. Structures of all new compounds have been confirmed by ^1H and ^{13}C NMR, and high-resolution mass spectrometry. Dye **1** has been designed to exhibit good water solubility to allow efficient conjugation in buffered aqueous media. Its solubility is over 10 $g.L^{-1}$ in saline physiological solution (turbidimetric method). The linear photophysical properties of this novel functionalized dye are similar to those of the parent symmetrical chromophore previously described (*6*), since the basic photoactive structure remains unchanged. The absorption and emission characteristics of **1** in dichloromethane and water solutions are described in Table 1. This fluorophore presents an intense absorption band in the 365 nm region in dichloromethane and 354 nm in water. This dye also exhibits an intense blue fluorescence in both methylene chloride (435 nm) and water (450 nm).

The nonlinear photophysical properties of **1** have been determined in water and methylene chloride from 480 to 650 nm in the visible, and from 700 to 900 nm in the IR (Figure 3). This chromophore exhibits a large TPA absorption in the red-IR region over 250 GM at 700 nm and a good resistance to photobleaching. Both the one- and two-photon properties of this blue fluorescent dye are promising for two-photon applications in biology.

PEI Conjugation and Spectroscopic Characterization of the Conjugated PEI. To show the potency of the isothiocyanate-functionalized chromophore to be used for two-photon microscopy applications, we conjugated PEI with derivative **1** (Figure 4). Conjugation was performed in borate buffer, pH 9.4, and unreacted dye was removed by gel chromatography. A conjugation of 2.6% of the primary amines of the PEI molecule, corresponding to an average number of 15 fluorophores per PEI molecule, was achieved. The absorption properties of the free chromophore **1** and PEI−**1** are compared in Figure 5. Conjugation to PEI slightly affects the vibronic structure of the absorption spectrum of **1**. In fact, the most pronounced change is the slight blue shift and relative increase of the vibronic peak

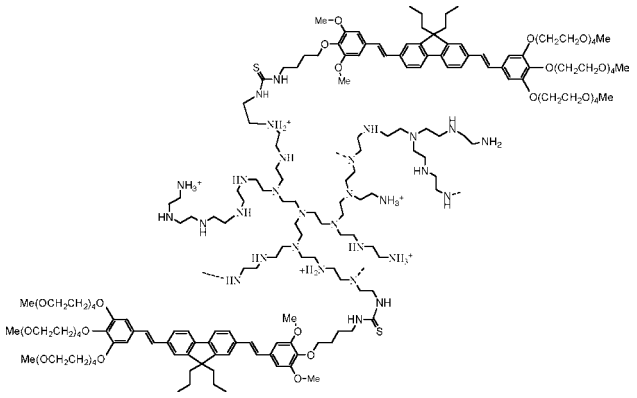

Figure 4. Schematic structure of the conjugate PEI−**1**.

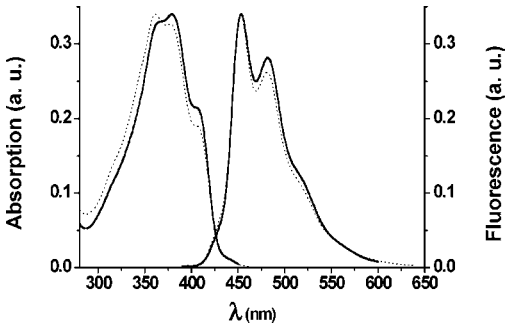

Figure 5. Absorption and fluorescence emission spectra of **1** and PEI−**1**. Both compounds are in 20 mM HEPES and 150 mM NaCl buffer, pH 7.4. $\lambda_{ex} = 354$ nm.

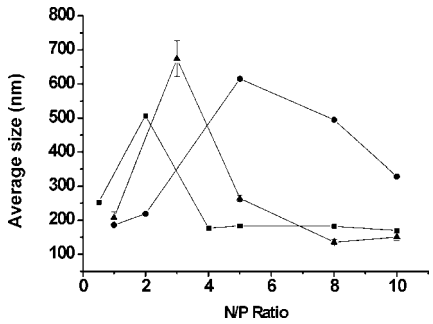

Figure 6. Average size of the PEI−**1**/DNA binary complexes as a function of the N/P ratio. The complexes are in 20 mM HEPES and 150 mM NaCl buffer, pH 7.4. PEI/DNA (■); PEI−**1**/DNA (●); DNA complexes with a mixture of labeled and unlabeled PEI added at a 1:3 ratio (▲).

at 361 nm, which becomes the strongest absorption peak of **1** in the conjugate. In the emission spectrum, no shift of the maximum emission accompanies the coupling of **1** to PEI, but only a slight relative increase of the emission shoulder at 480 nm. The quantum yield of fluorescence is not significantly affected by the conjugation of chromophore **1** with PEI (12% for PEI−**1** compared to 15% for free dye). It thus appears that conjugation of **1** to PEI only marginally modifies the electronic properties of **1**.

Size of the PEI−1/DNA Complexes and Condensation of DNA in These Complexes. The size of the complexes of calf thymus DNA with PEI−**1** at various N/P ratios was measured by light scattering and compared with the corresponding complexes obtained with nonlabeled PEI (Figure 6). In the case of nonlabeled PEI/DNA complexes, the size of the complexes increases with N/P, reaches a maximum at N/P = 2, and then decreases at higher N/P ratio. At N/P = 2, the complexes are neutral and thus have a strong tendency to aggregate, explaining the large size at this N/P ratio (*17*). In contrast, the smallest sizes are obtained at N/P ≥ 5 when the complexes are strongly

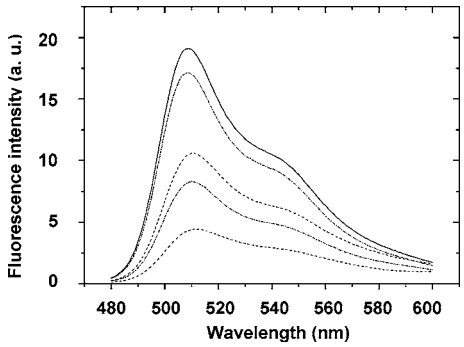

Figure 7. Fluorescence spectra of YOYO-1-labeled DNA complexed with PEI and PEI−**1**. The concentrations of DNA (phosphate) and YOYO-1 were 60 and 1.2 μM, respectively, to ensure a ratio of 1 YOYO-1 molecule per 50 bases. Spectra were recorded in the absence (solid line) or presence of PEI (dashed line) or PEI−**1** (dash−dotted line) at N/P ratios of 2 (top spectra) and 5 (bottom spectra). Samples were prepared as described in Figure 4. Excitation was at 470 nm.

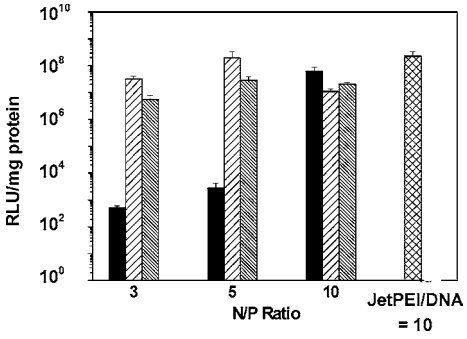

Figure 8. Transfection efficiency of PEI−**1**/DNA complexes. HeLa cells were incubated with pCMVLuc plasmid (2 μg/well) complexed to PEI−**1** (left), unlabeled PEI (center), or a mixture of PEI−**1** and unlabeled PEI (at a 1:3 ratio, right) in serum-free Opti-MEM. After 3 h 30 min, the transfection medium was replaced with fresh complete medium, and cells were cultured for an additional 24 h, before lysis. Gene expression was determined by the luciferase assay and expressed as RLU/mg of protein (luciferase activity per mg of protein in cell lysates). JetPEI was used as a control.

positively charged (*8*) and have thus no tendency to aggregate, due to electrostatic repulsions. A similar qualitative dependence of the size of the complexes as a function of N/P is obtained when PEI is substituted by PEI−**1**. However, two major differences are immediately apparent. The first one is the significant shift of the N/P ratio (from 2 to 5) at which the complexes are probably neutral and exhibit a size maximum. The second difference is the larger size of the complexes obtained with PEI−**1**, not only at the size maximum (650 nm vs 500 nm) but also at higher N/P ratios. Indeed, even at N/P = 10, the DNA/PEI−**1** complexes are about 350 nm and, thus, more than two times bigger than the complexes with unlabeled PEI. Both differences may be partly attributed to the decrease of the amine content of PEI−**1** due to labeling. This decreases the charge density of PEI and, thus, its ability to condense DNA, since condensation is strongly dependent on the extent of charge neutralization (*18*). The second and probably most important reason for the differences between labeled and unlabeled complexes may be related to the large size of dye **1** that may sterically hinder the proper neutralization of DNA charges by the labeled PEI and, consequently, the optimal compaction of the bound DNA. These drawbacks could be partially avoided if the complexes are obtained by adding labeled PEI together with unlabeled PEI at a ratio of 1:3 to the DNA. In these conditions, the complexes at N/P $\geq$ 8 are the same size as the complexes with unlabeled PEI, and the size maximum is shifted to N/P = 3. Importantly, both the larger maximum size of the latter complexes and the systematic shift of their sizes at N/P < 8 with respect to the unlabeled complexes suggest that both labeled and unlabeled PEI molecules are bound in the complexes with DNA. It may thus be inferred that, in these complexes, unlabeled PEI largely compensates for the defects of DNA compaction induced by the labeled PEI. To further investigate the condensation level of DNA in its complexes with PEI and PEI−**1**, we used the fluorescent DNA bis-intercalator YOYO-1 (*19*). This compound is characterized by a very high affinity for DNA (*20*) and remains bound to DNA during condensation by PEI (*19*). Moreover, the fluorescence intensity of free YOYO-1 is 3200 times lower than that of the bound form and could thus be neglected. When the level of DNA-bound YOYO-1 is sufficiently large (1 YOYO-1 for 50 bases), condensation by PEI was shown to induce a dramatic fluorescence decrease due to electronic interaction among YOYO-1 molecules bound on the same DNA molecule (*19*). Fluorescence spectra of YOYO-1 bound to DNA complexed with PEI and PEI−**1** at different N/P ratios are given in Figure 7. In excellent agreement with our conclusions above, the fluorescence of YOYO-1 in complexes with PEI−**1** was significantly higher than in complexes with unlabeled PEI at N/P ratios of 2 and 5, indicating that PEI−**1** less efficiently condenses DNA than unlabeled PEI.

Transfection Efficiency and Cytotoxicity of DNA/PEI−1 Complexes. PEI−**1**/DNA complexes were assessed for their in vitro transfection efficiency by monitoring the transient expression of the luciferase reporter gene in Hela cells. At N/P $\leq$ 5, the complexes gave luciferase signals (10^3 RLU/mg protein, Figure 8) that were 3 to 4 orders of magnitude lower than those obtained with unlabeled PEI but comparable to that of naked DNA (data not shown). This indicates that complexes with PEI−**1** are unable to transfect cells at these ratios. In sharp contrast, PEI−**1**/DNA complexes and PEI/DNA complexes show comparable transfection efficiencies at N/P > 5. Moreover, complexes obtained by mixing DNA with PEI−**1** and PEI at a 1:3 ratio were found to be as active as PEI/DNA complexes at all N/P ratios. These data show that by analogy to a large variety of compounds (poly(ethylene glycol), sugars, peptides, etc.; for a review, see Godbey et al. (*9*, *21*, *22*)), the conjugation of **1** does not compromise the transfection properties of PEI. In fact, the poor transfection observed with PEI−**1**/DNA complexes at N/P $\leq$ 5 may be rationalized by the size measurements, which suggest that the complexes may be negatively charged or neutral at these ratios and thus cannot efficiently interact with the cell membrane and be internalized by the cells (*8*, *23*). Finally, cell viability experiments using the bicinchoninic acid assay showed that only 10% of dead cells were observed after transfection with PEI−**1**/DNA or PEI/DNA complexes at N/P = 10 (data not shown), indicating that conjugation with **1** does not increase the cytotoxicity of PEI.

Two-Photon FCS and Microscopy of PEI−1/DNA Complexes. To demonstrate the validity of PEI−**1** in two-photon applications, we first performed two-photon FCS measurements of PEI−**1** either in its free form or bound to DNA. Two-photon excitation of the dye was provided by a tunable Ti:sapphire laser. Due to the optical specifications of our setup, it was not possible to excite the sample at wavelengths lower than 760 nm. Unfortunately, the TPA cross section of **1** at 760 nm is far from its maximum (below 700 nm, Figure 3). As a consequence, the brightness per molecule did no exceed 0.5 kHz/molecule and the signal-to-noise ratio was fair in the FCS measurements. Nevertheless, the fit of the FCS curves of free PEI−**1** (Figure 9) provided an observed diffusion constant of 1.6×10^{-10} $m^2.s^{-1}$ that is consistent with the previously reported diffusion constant of Rhodamine-labeled PEI (*15*). Moreover, in further agreement with the Rhodamine-labeled PEI data, a population with a slower diffusion constant ($(3.8 \pm 0.3) \times 10^{-11}$ $m^2.s^{-1}$) was detected

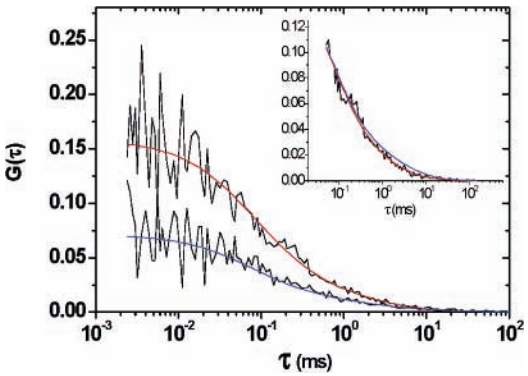

Figure 9. Autocorrelation curves of free PEI−**1** and PEI−**1**/DNA complexes. The concentration of PEI−**1** was 600 μM for both curves. The complexes were obtained at N/P = 10. The red and blue lines correspond to the best fits of the autocorrelation curves of PEI−**1** and PEI−**1**/DNA complexes, according to eq 2 of Clamme et al. (2003) with the diffusion coefficients given in the text. In the inset, the fitted curves were normalized and their bottom part was highlighted to show their differences.

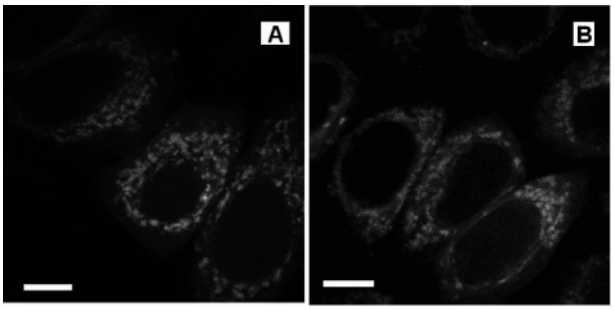

Figure 10. Two-photon microscopy of free PEI−**1** (A) and PEI−**1**/DNA complexes (B) in HeLa cells. Free PEI−**1** (600 μM) and PEI−**1**/DNA complexes (60 μM DNA, N/P = 10) were incubated for 2 h with HeLa cells, as described in Materials and Methods. Images were taken 30 min, post-transfection. Each bar represents 10 μm.

in some autocorrelation curves. However, since this diffusion constant is significantly different from that associated with the complexes and since its contribution to the autocorrelation curve is limited, this population corresponds to a minor species that cannot interfere with PEI−**1**/DNA measurements. Next, the FCS curve of the PEI−**1**/DNA complexes at N/P = 10 was recorded. In full agreement with our previous data using rhodamine-labeled PEI (*15*), the autocorrelation curves of PEI−**1**/DNA complexes were similar to the curves obtained with free PEI−**1** and, thus, were largely dominated by the contribution of free PEI. This confirms that a large proportion of PEI remains free when PEI is mixed with DNA. In fact, the only difference with free PEI is the presence of a small shoulder at long times in the autocorrelation curve of the complexes. The autocorrelation curves could be adequately fitted with a two-population model. If the correlation times of the two populations were allowed to float, the short correlation time was typical of that of free PEI. According to its small contribution, the correlation time (which is inversely related to the diffusion constant) of the complexes fluctuates in a larger range than that of free PEI. Nevertheless, if we assume that complexes are spherical, we obtained from their diffusion constant ($(1.2 \pm 0.6) \times 10^{-12}$ m^2.s^{-1}) a diameter of 360 nm that is in excellent agreement with that determined by light scattering (Figure 6).

In a next step, two-photon imaging of HeLa cells incubated with free PEI−**1** or transfected with PEI−**1** complexes at N/P = 10 was performed with the same setup as for FCS. In excellent agreement with previous studies (*15*, *24*), both free PEI−**1** and PEI−**1**/DNA complexes were found in discrete fluorescence patches that accumulate around the nucleus (Figure 10). This shows that conjugation of PEI by the chromophore does not compromise the efficient internalization of free and bound PEI by the cells and their accumulation in perinuclear compartments, identified as endosomes.

CONCLUSION

We described herein the synthesis and characterization of a functionalized two-photon absorbing chromophore with blue emission. This chromophore was successfully conjugated to PEI and was found to substitute unlabeled PEI, without compromising the transfection properties of PEI. In spite of a nonoptimized excitation wavelength, the labeled PEI was successfully used in two-photon FCS and imaging. The obtained results were close to those previously reported for Rhodamine-labeled PEI. However, due to its rather large size, the dye decreases to some extent the condensing properties of PEI, affecting the size of the PEI/DNA complexes. Thus, it is recommended to use them in a mixture with unlabeled PEI, since complexes obtained with a 3:1 ratio of unlabeled to labeled PEI were found to be highly similar to the unlabeled PEI/DNA complexes.

Turnip Yellow Mosaic Virus as a Chemoaddressable Bionanoparticle

Hannah N. Barnhill,[†] Rachel Reuther,[†] P. Lee Ferguson,[†] Theo Dreher,[‡] and Qian Wang*,[†]

Department of Chemistry and Biochemistry and Nanocenter, University of South Carolina, 631 Sumter Street, Columbia, South Carolina 29208, and Department of Microbiology, Oregon State University, Corvallis, Oregon 97331. Received December 18, 2006; Revised Manuscript Received February 2, 2007

Viruses and virus-like particles (VLPs) have been demonstrated to be robust scaffolds for the construction of nanomaterials. In order to develop new nanoprobes for time-resolved fluoroimmuno assays as well as to investigate the two-dimensional self-assembly of viruses and VLPs, the icosahedral turnip yellow mosaic virus (TYMV) was investigated as a potential building block in our study. TYMV is an icosahedral plant virus with an average diameter of 28 nm that can be isolated inexpensively in gram quantities from turnips or Chinese cabbage. There are 180 coat protein subunits per TYMV capsid. The conventional *N*-hydroxysuccinimide-mediated amidation reaction was employed for the chemical modification of the viral capsid. Tryptic digestion with sequential MALDI-TOF MS analysis identified that the amino groups of K32 of the flexible N-terminus made the major contribution for the reactivity of TYMV toward *N*-hydroxysuccinimide ester (NHS) reagents. The reactivity was also monitored with UV−vis absorbance and fluorescence, which revealed that approximately 60 lysines per particle could be addressed. We hypothesized that the flexible A chain contains the reactive lysine because the crystal structure of TYMV has shown that chain A is much more flexible compared to B and C, especially at the N-terminal region where the Lys-32 located. In addition, about 90 to 120 carboxyl groups, located in the most exposed sequence, could be modified with amines catalyzed with 1-(3-dimethylaminopropyl-3-ethylcarbodiimide) hydrochloride (EDC) and sulfo-NHS. TYMV was stable to a wide range of reaction conditions and maintained its integrity after the chemical conjugations. Therefore, it can potentially be employed as a reactive scaffold for the display of a variety of materials for applications in many areas of nanoscience.

INTRODUCTION

Viruses and virus-like particles (VLPs), also known as bionanoparticles, have recently emerged as promising building blocks for nanomaterials (*1*−*7*). For example, it has already been shown that semiconductive or conductive nanowires can be prepared with rod-like tobacco mosaic virus (TMV) as the template (*2*, *7*−*14*). Spherical nanoparticles were produced using the hollow protein shell of icosahedral cowpea chlorotic mottle virus (CCMV) as a nanoreactor (*4*, *15*). With genetically modified filamentous bacteriophage M13 as a template, inorganic, organic, and biological nanosized materials have been aligned into nanowires (*16*, *17*), nanorings (*18*), nanofibers (*19*), films (*20*, *21*), and other nanostructures (*22*−*24*).

Because of increasing interest in using bionanoparticles for drug delivery and other biomedical applications (*1*, *25*−*27*), it is of particular demand to develop methods to anchor functional groups on viral particles. Cowpea mosaic virus (CPMV) was the first virus to be demonstrated as a robust platform for the conjugation with a variety of molecules, ranging from small molecules such as fluorescent dyes (*5*, *28*−*31*) to larger particles such as quantum dots (*32*). In addition, polymers (*33*, *34*), stilbene derivatives (*30*), biotin (*28*, *29*), DNA (*35*), peptides and proteins (*36*−*38*), and carbohydrates (*34*, *39*) have been successfully conjugated to CPMV in an ordered and predictable manner. Following CPMV, the chemical reactivities of many other viruses have been studied, including CCMV (*40*), *Nudaurelia capensis omega* virus (*41*), TMV (*42*, *43*), and bacteriophage MS2 (*44*). Moreover, it is possible to engineer multiple orthogonal reactive sites on the viral capsid using conventional bioconjugation techniques or newly developed chemistries (*5*, *42*, *44*).

In order to develop new nanoprobes for time-resolved fluoroimmuno assays as well as to investigate the two-dimensional self-assembly of bionanoparticles (*6*, *45*, *46*), the icosahedral turnip yellow mosaic virus (TYMV) was explored as a potential building block in our study. As a member of the tymovirus group, TYMV is a plant virus with an average diameter of 28 nm and made of a single-stranded RNA of 1.9 $\times$ 10^6 Da and 180 chemically identical protein subunits of 20 133 Da. The subunits arrange into 60 trimeric asymmetric units loosely assembled in a $T = 3$ icosahedral symmetry as shown in Figure 1 (*47*−*49*). The structure of TYMV has been exhaustively studied by X-ray crystallographic analysis (*47*, *48*) and electron microscopy using negative staining (*50*). It can be isolated from the infected leaves of either the turnip or Chinese cabbage in gram quantities. Comparing with other plant viruses, TYMV has some unique advantages in chemistry, biomedical applications, and materials development. First, empty capsids can be isolated naturally from the host plant or generated artificially by treating under pressure (*51*), basic environment (*52*), or repeated freeze−thaw process (*53*). Second, some of these methods result in a hole in the otherwise intact capsid, which may provide a route for the introduction of useful materials, such as quantum dots or drugs, and opens the possibility of interior modification of the capsid. Third, TYMV is stable from 4 °C to RT for months and 60 °C for several hours. It can withstand, for a wide pH range (4−10), up to 50% organic solvent and a variety of reaction conditions. Finally, the capsid of TYMV represents a very rigid spherical assembly; therefore, we can predict the conformation of the coat proteins and attached molecules based on the X-ray structural data (*48*). In this paper, we will report the chemoselective modification of native TYMV at the lysine residues and carboxyl groups.

Scheme 1

EXPERIMENTAL PROCEDURES

General. Most bioreagents were purchased from Bio-Rad or Fisher and used without further purification. Anti-TYMV antibody was raised in rabbits. Reactive dyes were purchased from Molecular Probes and used without further purification. Unless otherwise indicated, "buffer" refers to 10 mM potassium phosphate at pH 7.8. Size exclusion columns for purification of virus-containing reaction mixtures were prepared by pre-swelling 23 g of Bio-Gel P-100 (Bio-Rad) in 400 mL of buffer and loading the gel into Bio-Spin disposable chromatography columns (Bio-Rad). The columns were allowed to drain upon standing and were then further dried by centrifugation (3 min at 800 *g*). For 80 μL of virus solution (1 mg/mL), approximately 1 mL of prepared gel is required. Ultracentrifugation was performed at the indicated rpm values using a Beckman Optima L-90K Ultracentrifuge equipped with either SW41 or 50.2 Ti rotors. TEM analyses were carried out by depositing 20 μL aliquots of each sample at a concentration of 0.1 to 0.3 mg/mL onto 100-mesh carbon-coated copper grids for 2 min. The grids were then stained with 20 μL of 2% uranyl acetate and viewed with a Hitachi H-8000 TEM electron microscope. FPLC analyses were performed on an AKTA Explorer (GE Biotech) using a Superose-6 size-exclusion column. Potassium phosphate buffer (0.05 M, pH 7.0) with 0.15 M NaCl was used as eluent, and the intact virions show retention volume of approximately 10 mL at an elution rate of 0.4 mL/min, whereas broken particles and individual subunit proteins elute after more than 20 mL. Western Blot analysis was carried out using a Bio-Rad Mini Trans-Blot Electrophoretic Transfer Cell with a 15% polyacrylamide gel.

Purification of TYMV. Chinese cabbage was grown for 3 weeks after which it was inoculated with TYMV. After one week leaves began showing symptoms. After an additional 2 weeks, the leaves were picked and subjected to purification. Infected leaves were blended with 3× volume of buffer and 0.1% β-mercaptoethanol. The mixture was filtered and the filtrate subjected to centrifugation to remove bulk plant material. The supernatant was collected and clarified by adding an equal volume of $CHCl_3$/1-butanol (v/v = 1:1). The aqueous layer was collected, and the virus was precipitated with 8%

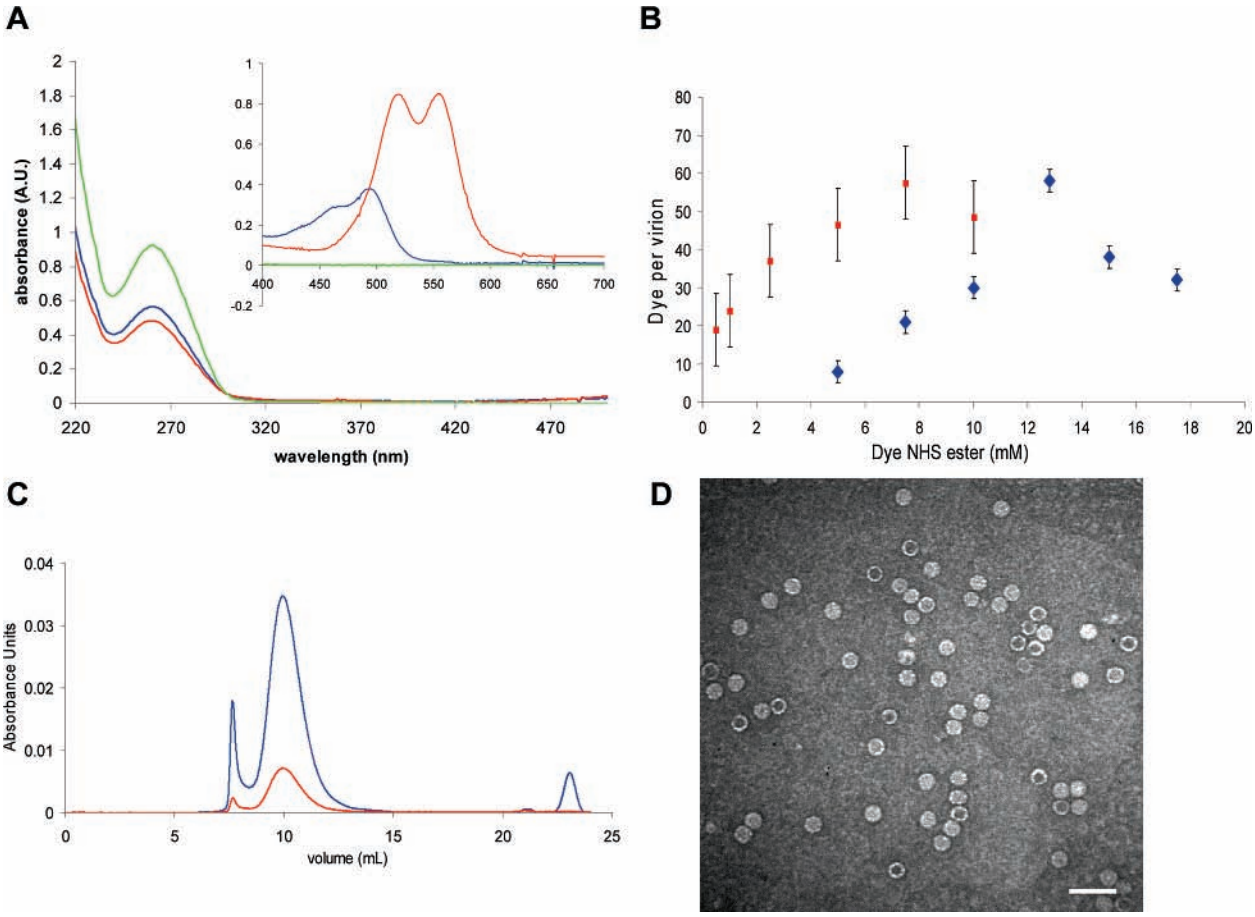

Figure 2. (A) UV−vis spectra show virus absorbance of WT−TYMV (green line) and TYMV after modification with **1** (blue line) and **2** (red line) after purification and a 20-fold dilution. UV−vis absorbances of the dyes on TYMV directly after purification with no dilution are shown in the inset. (B) Loading of **1** (blue) and **2** (red) on TYMV related to concentration of reagents in the reaction mixture. (C) Size exclusion FPLC analysis of **2**-modified TYMV: intact particles elute at 10 mL, denatured protein at 23.5 mL, and aggregated TYMV at 8 mL. Blue line is absorbance at 260 nm and red line is absorbance at 555 nm, indicating that **2** is attached to the intact particles. (D) TEM image of **1**-modified TYMV, the scale bar = 100 nm.

PEG 8K and 0.2 M NaCl. The pellet was centrifuged, resuspended in buffer, and purified by centrifuging over a sucrose gradient which showed two bands, one for the filled particle and one for the empty particle. In general, the virus was stored in buffer at a concentration of 10 mg/mL at 4 °C and stable for months.

SDS-PAGE Analysis. Polyacrylamide gel electrophoresis was carried out in Bio-Rad MiniPROTEAN 3 gel electrophoresis cell. For analysis by coomassie blue staining, 1 μg of TYMV was denatured by heating at 95 °C for 5 min with Tris-HCl buffer containing β-mercaptoethanol, bromophenol blue, and glycerol. The proteins were then resolved on a 15% polyacrylamide gel at 200V for 1 h and stained with Bio-Rad Biosafe Coomassie Blue stain for 1 h and destained with distilled water. Fluorescently labeled TYMV was visualized with a UVP Epi Chemi II imager before staining.

MALDI-TOF MS of TYMV Subunit. A solution of TYMV (1 mg/mL, 26 μL) was treated with guanidinium-HCl (6.0 M, 4 μL) for 5 min at RT. The denatured protein was spotted onto a MALDI plate using Millipore ZipTip $_{\mu-C18}$ tips to remove the salts. The samples were analyzed using a Bruker Ultra-Flex I TOF/TOF mass spectrometer with MS grade sinapinic acid in 70% acetonitrile and 0.1% TFA as the matrix.

Trypsin in-Gel Digestion and MALDI Study. Pure viral protein (1 mg) was resuspended in Tris−HCl buffer (pH 7.4, 100 mM, 26 μL). Urea (6.0 M, 100 μL) and DTT (200 mM, 5 μL) were added, and the solution was incubated for 1 h at RT. Then the solution was diluted ten times and incubated with sequencing-grade modified trypsin (protein:enzyme = 50:1) for 18 h at 37 °C. The pH was then adjusted to slightly below 6 to quench the reaction. Tryptic digests were then analyzed by MALDI-TOF MS and MALDI-TOF-TOF MS-MS using a Bruker Ultra-Flex I TOF/TOF mass spectrometer and mass spectroscopy grade trypsin in 70% acetonitrile and 0.1% TFA as the matrix.

Reactivity Screening of TYMV. The reactivity of the lysine residues of TYMV was screened by incubating with varying concentrations of fluorescein *N*-hydroxysuccinimidyl (NHS) ester **1** or *N*,*N*,*N*′,*N*′-tetramethylrhodamine NHS ester **2** at a virus concentration of 1.0 mg/mL in a mixed solution of buffer and DMSO (v/v = 80:20). Reactions were purified by size-exclusion chromatography using Bio-Gel P-100 (Bio-Rad) in Bio-Spin disposable chromatography columns as described above. The carboxylic acid residues of TYMV were screened for reactivity by incubating with varying concentrations of fluoresceinamine **3**, EDC (10 mM), and sulf-NHS (5.0 mM) in buffer and purified by size exclusion chromatography. The loading of dyes per virion was determined by UV−visible spectroscopy. Virus concentrations were determined by measuring the absorbance at 260 nm; virus at 1.0 mg/mL gives a standard absorbance of 8.3. The average molecular weight of the TYMV capsid is 3.6 $\times$ 10^6. Dye concentrations were obtained by measurement of absorbance at λ_{max} (495 nm for **1** and 555 nm for **2**), with molar absorbtivity calibrated for each use by mixing known quantities of dye with TYMV (1.0 mg/mL). The integrity of the modified TYMV was determined by TEM, FPLC, and SDS-PAGE. Reactive residues were identified using tryptic digestion of

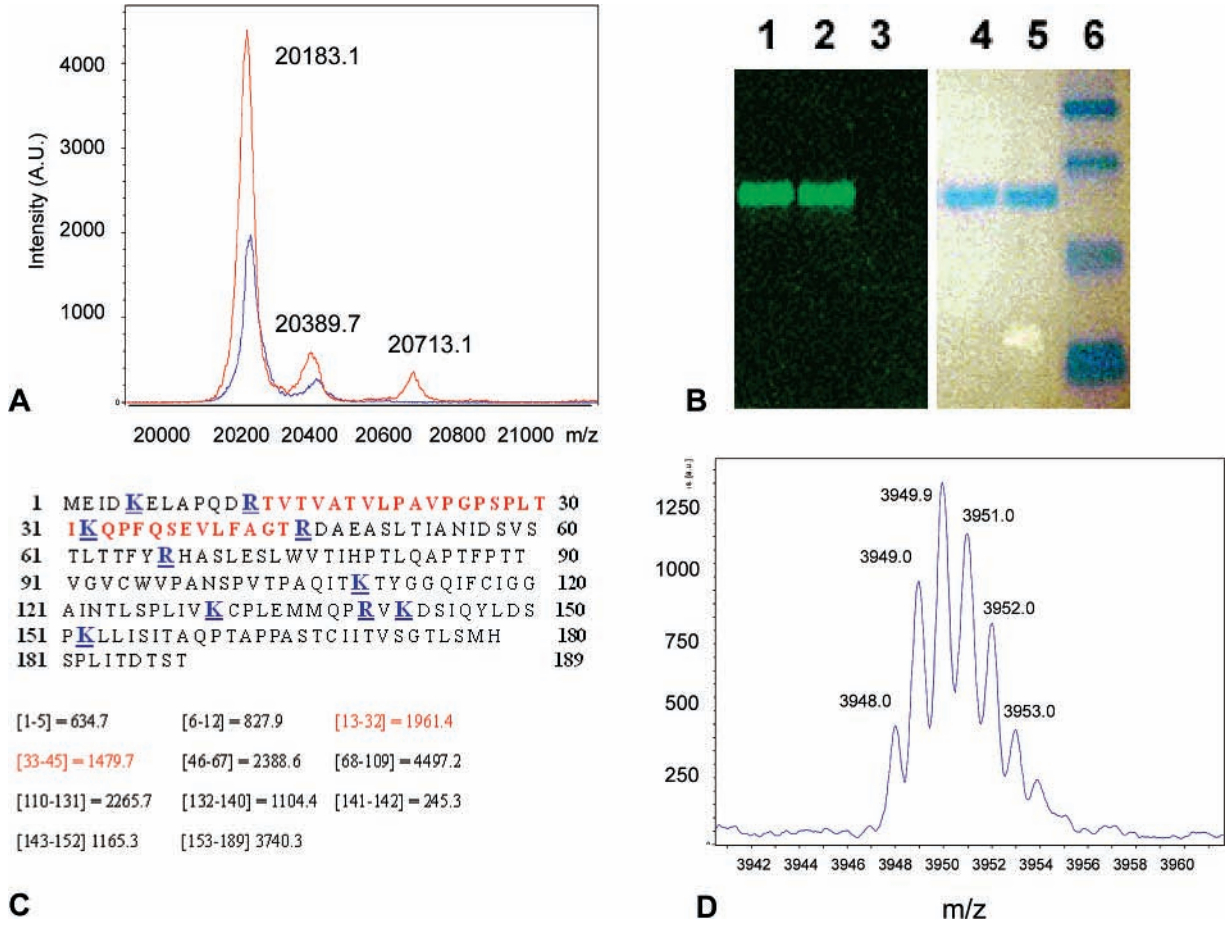

Figure 3. (A) MALDI-TOF MS of whole subunit of WT−TYMV (blue line) and TYMV after modification with **2** (red line). WT peak = 20 183 *m/z*, modified peak = 20 713 *m/z* (the mass of modification with **2** = 527 Da). Peak at 20 389 *m/z* is a matrix adduct. (B) SDS-PAGE of fluorescein-modified TYMV visualized under UV irradiation (left) or upon Coomassie Blue staining (right). (C) Tryptic digestion map of the coat protein of TYMV with the tryptic residues (K and R) highlighted in blue and the peptide sequence including reactive Lys-32 highlighted in red. (D) MALDI-TOF MS spectrum of tryptic digest, highlighting the peak corresponding to **2**-modified peptide containing residues T13−R45. Theoretical *m/z* = 3950.1, measured *m/z* = 3949.9 indicating Lys-32 as the reactive residue on the basis that the dye adduct suppresses tryptic cleavage at K32.

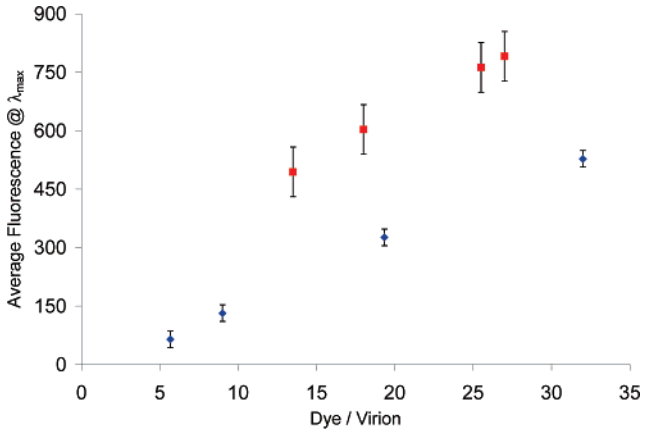

Figure 4. Fluorescence vs dye loading for **1** modified (blue) and **2** modified (red) TYMV.

modified particles and MALDI-TOF mass spectrometry as described above.

RESULTS AND DISCUSSION

TYMV was able to be purified in high yield from Chinese cabbage, i.e., about 0.5 mg of pure virus per gram of wet leaves. Purification yields from turnips were slightly lower, i.e., 0.2 mg of virus per gram of wet leaves. The integrity of virus through the purification was confirmed by FPLC, TEM, SDS-PAGE, and Western-blot analysis. Fluorescein (FL) *N*-hydroxysuccinimidyl (NHS) ester **1** and *N*,*N*,*N*′,*N*′-tetramethylrhodamine (TMR) NHS ester **2**, which are selective for reactions with amino groups of proteins, were utilized to screen the reactivity of TYMV at pH 7.8 to give TYMV−FL and TYMV−TMR (Scheme 1).

The reactions were purified over size exclusion chromatography and analyzed by UV−vis absorbance. As shown in Figure 2A, the absorbance of the virus, taken after a 20-fold dilution, gives the absorbance of viral genome and capsid proteins at 260 and 280 nm together with the absorbance of the dyes on TYMV. The UV−vis measurements were used to calculate the dye/virion ratios based on the molar absorbtivity of the dye and of the virus. When different concentrations of reagent **1** were used, up to 60 fluorescein molecules were attached on TYMV (see Figure 2B) although a loading of 40 dye molecules per virion was more typical. A consistent loading of 60 TMR were anchored on TYMV using dye **2** (Figure 2B). The different reactivities are likely due to the accessibility of the dyes to the reactive sites. Dye **2** has an additional five-carbon spacer between the bulky dye moiety and the NHS group, which makes it easier to access the reactive sites. The TYMV particles were stable to the reactions and remained intact as shown by FPLC and TEM (Figure 2C and 2D).

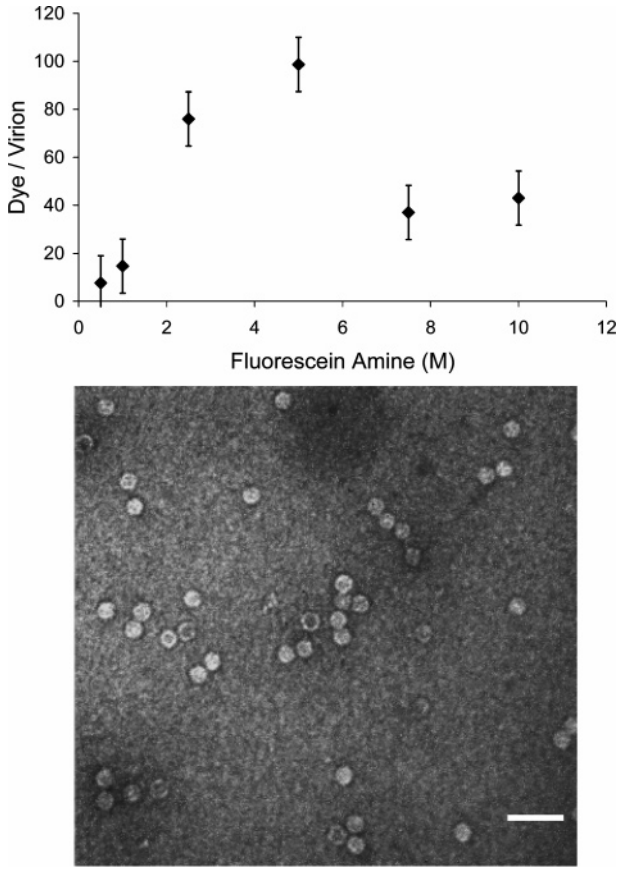

Figure 5. (Top) Reactivity of the carboxylic acid residues of TYMV with **3** activated with EDC and sulfo-NHS. (Bottom) TEM analysis of **3**-modified TYMV (scale bar = 100 nm).

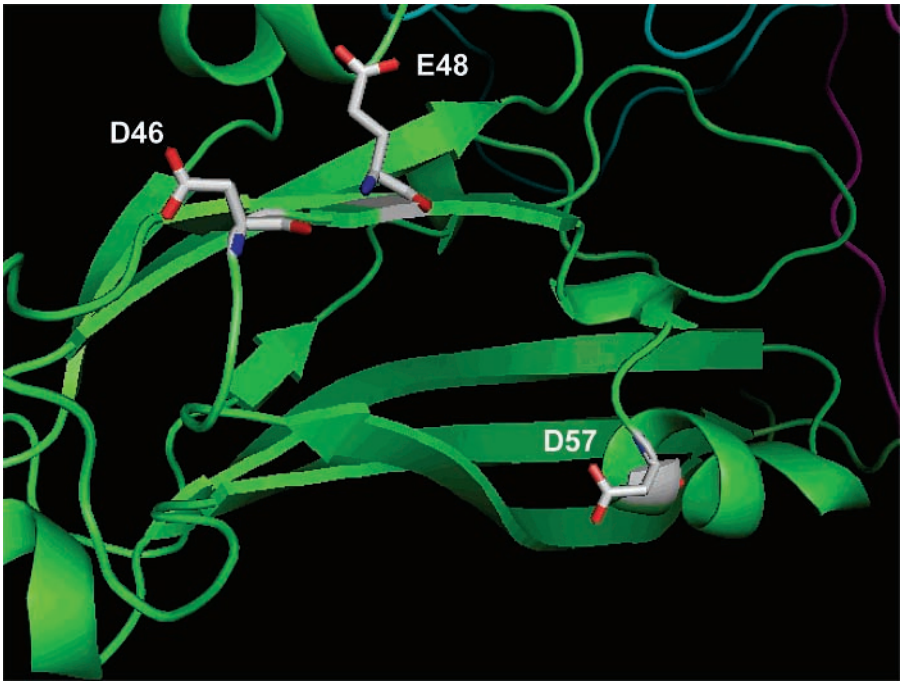
MALDI-TOF MS analysis of the subunit of TYMV (before and after the modification) confirmed a partial single modification (Figure 3A). The addition of dye motifs will alter the ionization efficiency of the protein in MALDI due to capping of basic residues; however, the presence of the peak at m/z = 20713.1 corresponds to the addition of one TMR unit on the TYMV coat protein and is only present in the mass spectrum of the modified TYMV [The peak at m/z = 20389.7 corresponds to a matrix adduct commonly seen in MALDI-TOF mass spectra of proteins and is present in both the WT−TYMV and the modified TYMV (*54*)]. Therefore, the absolute signal intensity could not precisely reflect the relative ratio of modified vs unmodified protein. SDS-PAGE of the fluorescein-modified particles also showed the covalent attachment of dyes to the TYMV subunit (Figure 3B). Figure 3C shows tryptic map of the TYMV coat protein, with the reactive peptide highlighted in red and K32 underlined. Upon in-solution digestion of the protein bands with trypsin, the digested fragments were analyzed by MALDI-TOF MS and confirmed that K32 is the reactive residue as shown by appearance of the peak m/z = 3949.9, indicating K32 as the reactive residue. This mass was calculated based on the attachment of the dye and on the fact that the dye adduct suppresses tryptic cleavage at K32 (Figure 3D). Using trypsin alone, we were able to achieve 88.8% to 93.7% sequence coverage for the WT protein; however, using V8 protease digestion in addition to trypsin gave us between 95.2% and 100% sequence coverage.

Within each asymmetric unit of TYMV capsid, there are three different subunits chains termed A, B, and C as shown in Figure 1. Although they are chemically identical proteins, each subunit is located in a different microenvironment and adapts a slightly different configuration. While chains B and C make up hexameric structures on the virus, chain A makes up the pentameric units. Studies on the crystal structure of TYMV have shown that chain A is much more flexible compared to B and C, especially at the *N*-terminal region where the K32 located (*55*, *56*). It is possible that the flexibility of A chain allows the access of NHS reagents; therefore, only about one-third of the K32 residues are chemically addressable. Other than trace amount of modification at K142, forced reaction conditions (longer reaction time or more concentrated starting reagents) could not accomplish quantitative modification of K32, as demonstrated by the existence of the unmodified peptide peak containing K32 at m/z = 1961.4 in the tryptic digestion of modified TYMV.



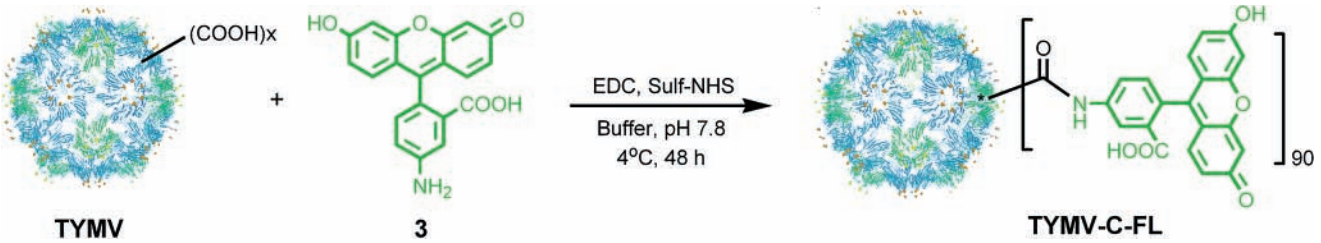


Figure 6. TYMV coat protein highlighting reactive peptide sequence (D46 to R67). Aspartate and glutamate residues (D46, E48, and D57) are highlighted as wire models. The figure is generated with PyMol software.

Scheme 2

Since the fluorescent dyes were covalently linked to the viral capsid at the defined position, they were isolated by the protein scaffold which prohibited the possible concentration quenching. As shown in Figure 4, for both **1** and **2**, the fluorescence signals increased linearly over a wide range of dye-per-virus ratios, suggesting negligible quenching in the virus conjugates even at dye loadings up to ca. 40 dye/virion (a local concentration of dye equal to 4.6 mM considering TYMV occupies a space of 1.4×10^{-23} m^3). This result is very similar to the recent report from Ratna, Soto, and co-workers (*31*), that fluorescent dyes can be anchored on CPMV with controlled distance which prevented the formation of nonfluorescent dimers and subsequent quenching and afforded highly fluorescent viral nanoparticles (*31*). Such kind of engineered viral particles can potentially be used as probes in microarray-based genotyping assays and sandwich immunoassays with improved sensitivities (*31*, *38*).

Many studies have shown that the carboxyl residues of various viral capsids are amenable to reaction with primary amines under activation (*40*, *42*, *57*). Besides the C-terminus of the protein, there are 13 carboxylic acid residues per TYMV subunit which belong to Asp and Glu side chains. As shown in Scheme 2, upon treating with fluorescein amine **3** under activation with 1-(3-dimethylaminopropyl-3-ethylcarbodiimide) hydrochloride (EDC) and sulf-NHS, about 90 carboxyl groups were derivatized after 24 h incubation. Under forcing conditions, i.e., longer reaction time, up to 120 units of **3** could be attached to TYMV without affecting the integrity of the capsid (Figure 5). The reactivity drops sharply at higher concentrations of **3** as the dye precipitates out of solution. In general, the reactivity of carboxyl groups greatly depends on their accessibility to solvent, and the modification often takes place at the most exposed residues or the most flexible loops. Proteomic studies have shown that the most exposed loop containing residues D46 through R67 is the reactive peptide. Shown in Figure 6 is the loop highlighting all the aspartate and glutamate residues. Work is ongoing to determine the exact position of the carboxylic acid modification, although fluorescent resonance energy transfer studies suggested the energy transfer takes place in a single environment, indicating a single reactive site (*58*).

CONCLUSION

The bionanoparticle TYMV was purified in high yield from infected plant tissue and was shown to be stable to a variety of reaction conditions. On the basis of orthogonal chemical reactions, specific sites on the virion surface can be labeled selectively. Amine-targeted chemistry afforded functionalization at the Lys-32 lysine residue, as confirmed by the proteomic analysis. The use of dyes showed no self-quenching of fluorescence even at high labeling values. Targeting the chemical reaction toward carboxylate residues pointed to three possible reactive sites, Asp-46, Glu-48, and Asp-57. This could lead to dual-modified particles with multiple functionalities for the application of TYMV as a fluorescent biological probe (*58*). Studies are underway toward the genetic manipulation of the TYMV scaffold, as well as the application of dual-modified TYMV nanoparticles in the development of new functional materials.

ACKNOWLEDGMENT

This work was supported by USA NSF-NER program, DOD-DURIP, and the W. M. Keck Foundation. We are grateful to Alex McPherson for the TYMV inocula, Lisa Alexander and Venkata S. Kotakadi for the assistance of TYMV production, Mike Walla for the assistance of the proteomics study, and Loic Charbonnière for helpful discussions about the manuscript.

An Enzyme-Labeled Protein Polymer Bearing Pendent Haptens

Jo Tominaga,[†] Noriho Kamiya,[†,‡,*] and Masahiro Goto[†,‡]

Department of Applied Chemistry, Graduate School of Engineering, and Center for Future Chemistry, Kyushu University, 744 Motooka, Fukuoka 819-0395, Japan. Received June 9, 2006; Revised Manuscript Received December 1, 2006

A new methodology for the preparation of enzyme-labeled protein polymers bearing pendent haptens was developed through the combination of chemical modification and posttranslational protein modification catalyzed by microbial transglutaminase (MTG). As a model hapten, trinitrobenzene (TNB) was chosen and chemically conjugated with the accessible Lys residues of β-casein. The resultant trinitrophenylated β-casein was further modified with formaldehyde to render the residual Lys residues inert toward self-cross-linking by MTG. *Escherichia coli* alkaline phosphatase (AP), comprising a specific peptide tag carrying a MTG-reactive Lys residue, was then conjugated to the Gln residues in β-casein−TNB conjugates. The resultant AP-labeled β-casein-bearing pendent TNB moieties (AP-βCT) showed comparable specific activity with native AP. It was found that only the AP-βCT with a sufficient number of pendent TNBs are capable of binding to a surface adsorbed with anti-TNP and anti-TNT antibodies, indicating the presence of polyvalent interactions. The utility of AP-βCT was demonstrated by competitive immunoassays for trinitrophenol (TNP) and trinitrotoluene (TNT), with detection limits of 0.99 μg/L and 0.18 μg/L, respectively. The present study demonstrates the potential of dual labeling of protein scaffolds by chemical and enzymatic protein manipulation to create a new proteinaceous architecture.

1. INTRODUCTION

Enzyme−antigen conjugates hold great promise as versatile molecular tools for biotechnological applications. These conjugates have found notable usage in the oriented immobilization of enzymes via the specific interaction between antigen and antibody (*1*−*3*), and in enzyme-linked immunosolvent assays (ELISAs) for the detection and quantitative analysis of target substances (*4*−*8*). In general, the chemical conjugation of antigens to enzymes is conducted using cross-linking reagents such as glutaraldehyde and bifunctional protein cross-linkers (*9*). However, depending on the number of reactive amino groups available on the enzyme molecules, the conjugates often represent heterogeneous molecular species due to the uncontrollable and unpredictable chemical attachment of labeling molecules, which could lead to partial or complete inactivation of the target functionality. Site-specific conjugation between enzymes and antigens can alleviate such obstacles.

Recent advances in recombinant DNA technology have facilitated genetic approaches to conduct the site-specific labeling of an enzyme with an antigen. For instance, the affinity peptide tag, Asp-Try-Lys-Asp-Asp-Asp-Asp-Lys (FLAG), was genetically fused to an enzyme, and the FLAG-labeled recombinant enzyme was subsequently immobilized on a support displaying anti-FLAG antibodies (*1*−*3*). With respect to ELISA applications, the C-terminal fusion of horseradish peroxidase (HRP) with a human heart fatty acid binding protein (hFABP) was prepared, and the HRP-hFABP fusion protein was applied to competitive ELISA for the detection of hFABP (*10*). However, it should be noted that by genetic manipulation, site-specific enzyme−antigen conjugation was basically limited to the N- or C-terminus of the target enzymes. Moreover, the site-specific labeling of low-molecular-weight antigens (i.e., haptens) with enzymes is difficult to perform through genetic approaches. Here, we report on a new methodology for linking enzymes with multiple antigens while retaining perfect orientation for optimal enzymatic activity.

To avoid inactivation of the enzymes through modification, we turned our focus to site-specific protein modification using enzymes that perform posttranslational modifications on proteins. Microbial transglutaminase (MTG) from *Streptomyces mobaraensis* is a unique enzyme that catalyzes the acyl transfer reaction between a primary amine and the γ-carboxyamide group of Gln residues in peptides and proteins (*11*). When the ϵ-amino groups of certain Lys residues act as acyl-acceptors, proteins are site-specifically conjugated through the formation of covalent ϵ-(γ-Gln)Lys bonds (*12*−*14*). Toward a variety of applications, the *direct* incorporation of primary amine-derivatized organic molecules into proteins through the use of MTG has been investigated so far. For instance, polyethylene glycol−protein conjugates (*15*), hapten−protein conjugates (*16*), biotin−antibody conjugates (*17*), and trypsin−cyclodextrin conjugates (*18*) were successfully obtained using MTG as a protein modifier. In the present study, we explored the *indirect* introduction of small organic molecules into enzymes using a template protein polymer.

β-Casein is a major component of milk proteins and is basically a flexible, nonglobular protein whose precise secondary structure has still yet to be assigned (*19*). Since our previous research (*20*−*22*), which showed that β-casein is an excellent proteinaceous substrate possessing reactive Gln and Lys residues toward MTG, we are now looking to employ β-casein as a template protein polymer. Our concept is thus based on the targeted modification of either Lys or Gln residues in β-casein, in which chemical and enzymatic modifications are combined. To demonstrate this idea, the stepwise labeling of haptens and enzymes to β-casein was conducted in order to create an enzyme-labeled polymer-bearing pendent haptens. We selected trinitrophenol (TNP) and trinitrotoluene (TNT) as targets, because the ϵ-amino groups of proteins are known to be easily trinitrophenylated by the chemical protein modifier, trinitrobenzene sulfonic acid (TNBS) (*23*). Since TNT serves as an indicator for environmental contamination with nitroaromatic

Scheme 1

compounds, a number of immunological detection methods for TNP/TNT were developed (*24*−*28*). Here, *Escherichia coli* alkaline phosphatase (AP), a widely used enzyme in ELISA (*29*, *30*), was employed a model enzyme. A recombinant AP tagged with a specific peptide linker bearing a MTG-reactive Lys residue was prepared. The MTG-mediated labeling of the recombinant AP with multi-trinitrophenylated β-casein and its immobilization and potential in competitive ELISA for TNP/TNT detection were discussed.

2. EXPERIMENTAL PROCEDURES

2.1. Materials. MTG was provided by Ajinomoto Co. Inc. (Japan), and its activity was measured using the colorimetric hydroxamate procedure with N-carbobenzyloxy-glutaminyl-glycine (Sigma), as previously described (*31*). One unit (U) of activity was defined as the amount of enzyme that catalyzes the formation of 1 μmol of the hydroxamate per minute using L-glutamic acid γ-monohydroxamate (Sigma) as standard. Bovine β-casein was purchased from Sigma and used without further purification. A fluorescent substrate of AP, ECF substrate, was purchased from Amersham Biosciences. Prior to use, the ECF substrates were dissolved in ECF detection buffer provided by the manufacturer and then 10-fold diluted by deionized water prior to use. TNP was purchased from Kishida Chemical Co. (Japan). A dilute solution of TNT was purchased from Chugokukayaku Co. (Hiroshima, Japan). Anti-TNP goat polyclonal IgG antibodies were purchased from Biomeda (Foster City, CA). Anti-TNT mouse monoclonal IgG antibody was purchased from Strategic Diagnostics Inc. (Newark, DE). All other reagents were of analytical grade and commercially available.

2.2. Preparation of Recombinant AP Tagged with Specific Peptide Linker for MTG. A specific peptide consisting of six amino acids (MKHKGS) was genetically attached to the N-terminus of AP. The resultant recombinant AP was abbreviated as NK6-AP. The plasmid vector construction, protein expression in *E. coli* strain BL21(DE3) (Novagen), and purification procedures of NK6-AP were described in our previous report in detail (*20*).

2.3. Measurement of AP Activity. The catalytic activity of AP was measured with *p*-nitrophenylphosphate (*p*-NPP) as a substrate. The hydrolysis of *p*-NPP (1 mM) was initiated by the addition of each AP formulation to 1 mL of 1 M Tris-HCl buffer (pH 8.0) at 25 °C under vigorous stirring. The initial activity was determined by detecting the increase in the absorbance at 410 nm (derived from *p*-nitrophenol (*p*-NP)). The molar extinction coefficient of *p*-NP under experimental conditions was determined to be 1.69×10^4 using UV−vis spectrophotometry (Jasco V-570, Japan). One unit (U) of AP activity was defined as the amount of enzyme that catalyzes the formation of 1 μmol of *p*-NP per minute.

2.4. Preparation of a β-Casein−TNB Conjugate. β-Casein (5 mg/mL) was dissolved in 100 mM borate buffer at pH 9.2. Preparation of the β-casein−TNB conjugate (abbreviated as βCT) was initiated by the addition of TNBS (dissolved in the same buffer to a final concentration of 0.2 mM or 10 mM), and the reaction mixture was stirred overnight at 25 °C (Scheme 1a). The remaining TNBS was removed by repeated dialysis against deionized water (three times) and more thoroughly by gel chromatography on a PD-10 column (Amersham Biosciences) using deionized water as eluent. N,N-Dimethylation of the remaining Lys residues (Scheme 1b) was conducted as follows. The reaction was initiated by the addition of $NaBH_4$ (2 mg), followed by the five-times addition of formaldehyde (2 μL) to the βCT solutions (4 mL) at 5-min intervals. The remaining formaldehyde was removed from the reaction mixture by repeated dialysis against deionized water (three times), and more thoroughly by gel chromatography on a PD-10 column using deionized water as eluent. The overall procedure for N,N-dimethylation was conducted twice. Trinitrophenylated amino groups in β-casein was calculated by the absorbance at 344 nm ($\epsilon_{344} = 1.1 \times 10^4\ M^{-1}\ cm^{-1}$) derived from trinitrophenylamino groups (*23*). The susceptibly of βCT to MTG-mediated cross-linking was analyzed by SDS-PAGE after incubating MTG (1.1 U) and βCT (0.8 mg/mL) for 3 h.

2.5. Site-Specific Conjugation of NK6-AP to βCT by MTG. As preliminary experiments to test the reactivity of NK6-AP to βCT, the conjugation of NK6-AP (0.17 mg/mL) and βCT (0.8 mg/mL) was investigated in the presence of MTG (1.1 U/mL) in 100 mM Tris-HCl buffer (pH 8.0). After incubation overnight at 25 °C, SDS-PAGE analysis of the reaction products was conducted. When preparing the final construct (Scheme

1c), an excess amount of NK6-AP (0.75 mg/mL) compared to βCTs (0.04 mg/mL) was reacted with MTG (1.1 U/mL) for 24 h to modify as much MTG-reactive Gln residues as possible. The resultant NK6-AP-βCT conjugate (abbreviated as AP-βCT) was purified by gel filtration chromatography using a HiLoad 16/60 Superdex 200 pg column (Amersham Biosciences) with 100 mM Tris-HCl buffer (pH 8.0) as eluent, at a flow rate of 1 mL/min. The fractions of AP-βCT were collected by measuring the AP activity of each fraction. The molecular weight distribution of AP-βCT was estimated using a Gel Filtration LMW Calibration Kit and a Gel Filtration HMW Calibration Kit (Amersham Biosciences).

2.6. Competitive Immunoassay of TNP and TNT with AP-βCT. ELISA experiments were carried out with Nunc Maxi Sorp microtiter plates (Nalge Nunc, Germany) with the aid of an ELISA washer, Model 1575 (Bio-Rad, Hercules, CA) and a microplate reader, LS-55KG (Perkin-Elmer, Wellesley, MA). The washing buffer solution (TBST) employed was prepared from TBS (Tris buffered saline, comprising 25 mM Tris, 137 mM sodium chloride, 2.68 mM potassium chloride, pH 7.4) by adding 0.05% (v/v) polyoxyethylene sorbitan monolaurate (Tween 20). Commercial stock solutions of the anti-TNP and anti-TNT antibodies were diluted to 2 μg/mL in 50 mM carbonate buffer, pH 9.6, and incubated at room temperature for 1 h (100 μL/ well). After the microtiter plate was washed three times with TBST, each well was blocked with 200 μL of TBS containing 0.5% BSA for 1 h and washed again. A mixture of AP-βCT and TNP or TNT (0−1 mg/L) in TBS (100 μL/ well) was incubated for 1 h at room temperature, and the plate was washed again three times. Finally, 150 μL of the ECF substrate solution was added to each well and left to incubate for 30 min. The fluorescence intensity of each well was measured using a microplate reader (excitation: 430 nm, emission: 560 nm). The data obtained were fitted to the following four-parameter logistic plot:

$$y = (a - d)/[1 + (x/c)^b] + d$$

where y represents the fluorescence intensity, x is the concentration of analyte, a and d are the upper and lower asymptotes, b is the slope, and c is the midpoint of the liner portion of the curve. The detection limit was defined as the concentration of analyte yielding 15% inhibition of the maximum.

3. RESULTS AND DISCUSSION

3.1. Lys-Specific Labeling of β-Casein with TNB: Preparation of βCT. TNBS, a well-known amine modification reagent, was used to label the Lys residues in β-casein, thus leaving the remaining Gln residues for the subsequent MTG-mediated conjugation with NK6-AP. In the present study, we prepared two types of enzyme-labeled protein polymers, of which a different number of haptens are formed to establish the preparation procedures, as well as to investigate the basic characteristics of the resultant conjugates. The two types of βCTs possessing different numbers of TNB moieties were prepared by changing the molar ratio of TNBS to β-casein in the preparation of βCTs. From the spectroscopic measurement of βCTs, it was found that about 1 or 12 Lys residues of β-casein were trinitrophenylated. Since β-casein has twelve amine groups (eleven ε-amino groups of Lys residues and one N-terminal α-amine (*32*)), it was suggested that all the amino groups were substantially labeled with TNBs in the latter construct. Since the residual Lys residues are capable of participating in the self-cross-linking of βCTs in the presence of MTG, they were further modified with formaldehyde. The resultant β-caseins bearing either 1 or 12 TNB moieties are abbreviated as βCT1 and βCT12, respectively. To confirm whether all of the MTG-reactive Lys residues were modified with TNBS or formaldehyde, two types of βCTs were treated with MTG. SDS-PAGE analyses showed that the self-cross-linking of βCT1 and βCT12 by MTG was virtually suppressed (data not shown), suggesting that both βCTs were suitable for the subsequent MTG-mediated conjugation with NK6-AP.

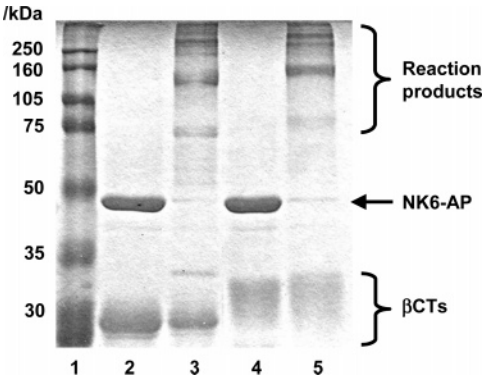

Figure 1. SDS-PAGE analysis of MTG-mediated conjugation of NK6-AP to βCTs (lane 1, molecular weight markers; lane 2, NK6-AP and βCT1; lane 3, NK6-AP and βCT1 treated with MTG; lane 4, NK6-AP and βCT12; lane 5, NK6-AP and βCT12 treated with MTG;). The protein band observed around 50 kDa was of NK6-AP (lanes 2 and 4). The concentrations of NK6-AP and βCTs were 0.17 mg/mL and 0.8 mg/mL, respectively.

3.2. Gln-Specific Conjugation of NK6-AP with βCT by MTG. We first tested if MTG-mediated labeling of NK6-AP directing to MTG-reactive Gln residues in βCTs is possible. Figure 1 shows the SDS-PAGE analysis of the cross-linking reaction in the presence of an excess amount of βCTs compared to NK6-AP. Under the experimental conditions, the protein bands of NK6-AP had almost disappeared in both cases, while new bands were evident in the high-molecular-weight range (lanes 3 and 5 in Figure 1). This suggests that the Gln residues in β-casein could also be recognized by MTG even after modification of the Lys residues. Note that the catalytic activity of NK6-AP was perfectly retained after the treatment of both βCTs with MTG (data not shown), which can be explained by the fact that the active site of AP is located at the opposite side of its N-terminus (*33*).

Next, AP-βCTs were prepared in the presence of an excess amount of NK6-AP as compared to βCTs, in order to modify as much MTG-reactive Gln residues as possible. Figure 2 shows the gel filtration chromatograms of NK6-AP and AP-βCTs. With respect to the conjugation of NK6-AP with βCT1, the major fraction of reaction products was distributed to the molecular weight markers ranging from 232 to 440 kDa, which corresponds to about 4−8 NK6-AP molecules (i.e., 2−4 NK6-AP dimers) per βCT1. On the other hand, the apparent molecular weight of the conjugate prepared with NK-AP and βCT12 was estimated to be about 440−669 kDa, which corresponds to about 8−12 NK6-AP molecules (i.e., 4−6 NK6-AP dimers) per βCT12. The results imply that βCT12 is more reactive toward MTG than βCT1. Since MTG-reactive Gln residues are often located close to the bulky and hydrophobic amino acids, such as Val and Phe residues (*34*), increasing the hydrophobicity of β-casein by trinitrophenylation and N,N-dimethylation may increase the reactivity of the Gln residues in MTG-mediated protein conjugation. The resultant NK6-AP-βCT1 and NK6-AP-βCT12 conjugates (abbreviated as AP-βCT1 and AP-βCT12, respectively) corresponding to the major fraction of reaction products were employed in the subsequent experiments.

3.3. Immobilization of AP-βCTs on a Surface via Antigen−Antibody Interaction. Figure 3 shows the result of immobilization of both AP-βCTs on a microtiter plate via antigen−antibody interactions. Here, the concentrations of AP-βCTs applied to

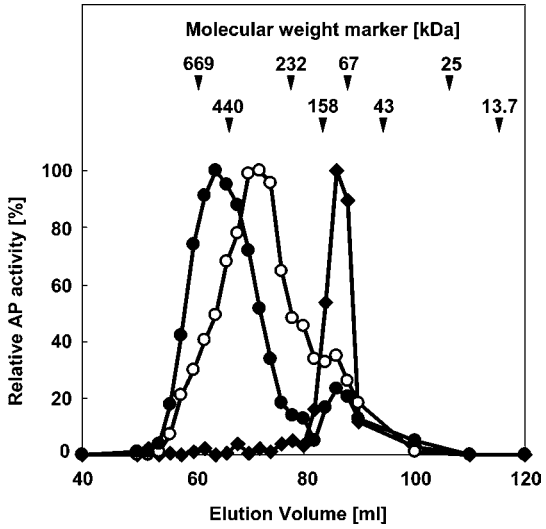

Figure 2. Gel filtration chromatograms of free NK6-AP (closed diamonds), NK6-AP after MTG conjugation with βCT1 (open circles), and NK6-AP after MTG conjugation with βCT12 (closed circles). The concentrations of NK6-AP and βCTs in the cross-linking reaction were 0.75 mg/mL and 0.04 mg/mL, respectively.

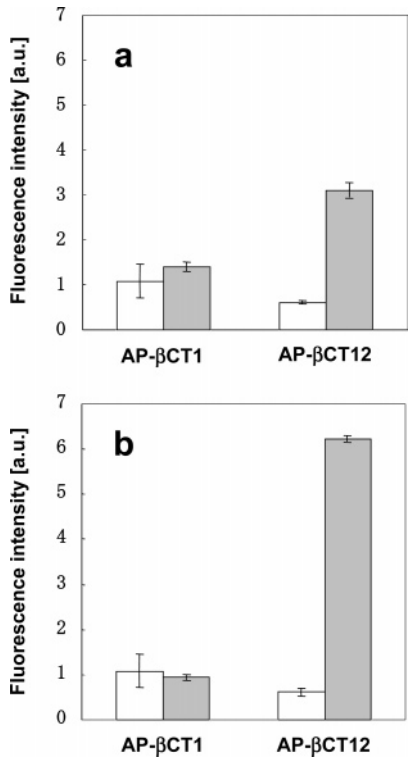

Figure 3. Comparison of the immobilization efficacy of AP-βCTs to (a) anti-TNP antibody- and (b) anti-TNT antibody-immobilized surfaces evaluated by the fluorescence intensity of AP-catalyzed reaction products at 560 nm. Nonspecific adsorption to a surface without antibodies (open bars) and adsorption to a surface displaying antibodies (dark bars) are shown. The mean values and standard deviations (error bars) are depicted in the figure.

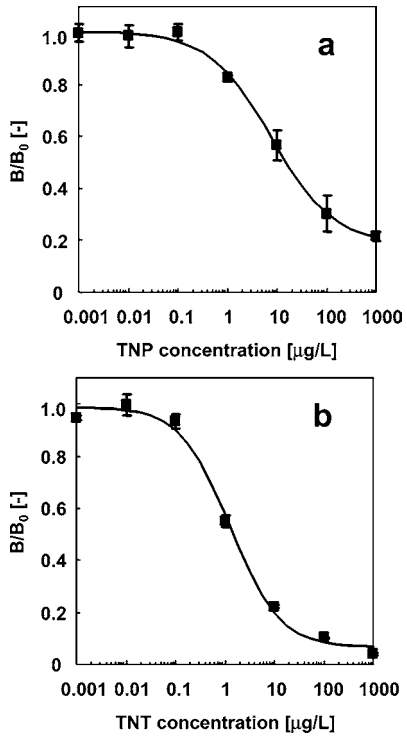
the wells were adjusted by the TNB basis, which means that approximately 10-fold higher amount of AP-βCT1 (1.8 mU/mL) than AP-βCT12 (0.18 mU/mL) was applied to the wells. The difference in the applied concentration may be attributed to the higher background signal of AP-βCT1 compared to AP-βCT12 (white bars in Figure 3a and 3b) due to the increase in nonspecific adsorption of AP-βCT1. Interestingly, only AP-βCT12 was efficiently immobilized on a surface displaying anti-TNP antibodies (Figure 3a) and anti-TNT antibodies (Figure



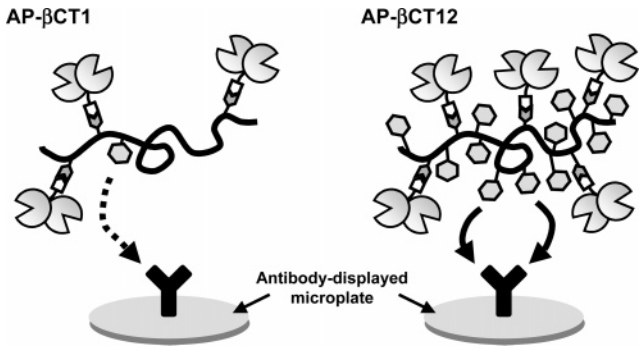


Figure 4. Calibration curves of the competitive ELISA for (a) TNP and (b) TNT detection obtained with AP-βCT12. The results are expressed in terms of B/B_0, where B and B_0 represent the fluorescent intensity in the presence and absence of TNT, respectively. The mean values and standard deviations (error bars) are depicted in the figure.

Scheme 2

3b), whereas limited immobilization was observed with AP-βCT1 in both cases. The results suggest that the accessibility of TNB moieties in AP-βCT1 was lower than that in AP-βCT12, which leads to the inhibition of hapten-antibody interactions on the microplate surface, possibly due to steric hindrance. On the other hand, AP-βCT12 with a sufficient number of TNB moieties is likely to facilitate interactions with the surface-bound antibodies. Moreover, the distinct immobilization behaviors of the AP-βCTs could also be explained by the higher apparent affinity (i.e., avidity) of AP-βCT12 due to divalent binding to the antibodies (Scheme 2). Therefore, it was suggested that the multiple labeling of a template protein polymer with antigens is particularly helpful for the stable capture of recombinant proteins on the same template via antigen−antibody interactions.

3.4. Competitive ELISA for TNP and TNT Detection by AP-βCT12. To explore the potential of an enzyme-labeled protein polymer bearing pendent haptens, TNP and TNT detection by competitive ELISA was conducted with AP-βCT12 showing a capability for binding to the immobilized antibodies. The calibration curves obtained with AP-βCT12 are shown in Figure 4. The fluorescence intensity detected in each well decreased in response to the concentration of TNP (Figure 4a)

and TNT (Figure 4b), and concentrations over 0.99 μg/L and 0.18 μg/L were detected for TNP and TNT, respectively. With respect to TNP detection, relatively lower signal-to-noise ratio observed in AP-βCT12 immobilization against anti-TNP antibodies compared with anti-TNT antibodies (Figure 3) is likely to increase the background signal in the presence of 1000 μg/L TNP (Figure 4a). In terms of TNT, the detection limit is slightly higher than the reported value using the same antibody (0.06 μg/L), in which the competitive ELISA was conducted with HRP directly labeled with TNB (*35*). This suggests that a nonglobular protein polymer labeled with multiple TNBs exhibits a higher affinity for the anti-TNT antibody, compared to its globular counterpart labeled with the same hapten, possibly due to the presence of polyvalent interactions.

In closing, we have demonstrated the dual labeling of a protein polymer by targeting the different side chains of amino acids through a combination of chemical, genetic, and enzymatic approaches. We found that multiple labeling of a protein polymer with haptens can add polyvalency that could be useful for increasing the affinity to a target receptor (*36*). Since β-casein can be replaced by native (*37*) and synthetic (*38*) protein polymers, the MTG-mediated site-specific and multiple labeling of recombinant proteins on a protein polymer can expand the possibility of designing a novel proteinaceous architecture.

ACKNOWLEDGMENT

We thank Prof. Yoshihiko Imato and Mr. Masahiro Sato of Kyushu University for helpful discussions on designing competitive ELISA. We are grateful to Ajinomoto Co., Inc. (Japan) for providing MTG samples. The present work was supported by the 21st Century COE Program, "Functional Innovation of Molecular Informatics" from the MEXT of Japan (to M.G.) and Industrial Technology Research Grant Program in '06 from New Energy and Industrial Technology Development Organization (NEDO) of Japan (to N.K.). J.T. was supported by Research Fellowships of the Japan Society for the Promotion of Science (JSPS) for Young Scientists.

Synthesis of Amphiphilic Derivatives of Rose Bengal and Their Tumor Accumulation

Nami Sugita,*,† Ken-ichi Kawabata,† Kazuaki Sasaki,† Isao Sakata,‡ and Shin-ichiro Umemura§

Central Research Laboratory, Hitachi, Ltd., 1-280 Higashi-koigakubo, Kokubunji-shi, Tokyo 185-8601, Japan, Photochemical Co., Ltd., Okayama 701-1221, Japan, and School of Health Sciences, Faculty of Medicine, Kyoto University, Kyoto 606-8507, Japan. Received June 30, 2006; Revised Manuscript Received January 18, 2007

It is known that the combination of laser light and its sensitizer is effective for noninvasive tumor treatment, referred to as photodynamic therapy. Using the combination of ultrasound and its sensitizer has also been suggested for a similar kind of tumor treatment, referred to as sonodynamic therapy. The purpose of this paper is to obtain such sensitizers accumulating selectively in tumors. Amphiphilic derivatives of rose bengal (RB) were synthesized to add a tumor-accumulating property to RB. One type of the synthesized RB derivatives (RBD3), having an alkyl chain with a branching carboxyl group, was found to be superior in amphiphilicity to the other types. Tumor tissue distribution of the synthesized derivatives in mice bearing colon 26 carcinoma was evaluated. It was found that RBD3s with carbon chain lengths of 12, 14, and 16 had higher concentrations in the tumor tissue than RB by more than 1 order of magnitude, several hours after administration. The concentrations correlated well with their water/1-octanol partition coefficients. Since RB is known to induce *in vitro* cell damage in combination with either laser light or ultrasound, the newly synthesized amphiphilic RB derivatives may be potentially useful as a tumor-selective sensitizer for both light and ultrasound.

INTRODUCTION

Photodynamic therapy (PDT) is known as a non- or less-invasive tumor treatment (*1*, *2*). The key components of PDT are a photosensitizer and laser light. The light activates a photosensitizer to react with oxygen, forming singlet oxygen that kills tumor cells. PDT may have some advantages: it can target the tissue to be treated very precisely, and can be repeated multiple times targeting the same tissue. However, it can treat only superficial regions because of the poor penetration of light into tissue.

Similar to laser light, ultrasound can enhance the bioeffect of some chemicals (*3*, *4*) and can even activate its sensitizers through the collapses of cavitation bubbles (*5*). Furthermore, it has a unique feature of penetrating deeply into tissue. The thermal bioeffect of ultrasound alone has already been used clinically for tumor treatment, known as high-intensity focused ultrasound (HIFU) treatment (*6*−*8*). It was found that some photosensitizers such as hematoporphyrin, protoporphyrin, a gallium-deutroporphyrin complex, ATX-70, and a chlorine derivative, ATX-S10, also showed an ultrasonically induced antitumor effect on tumor cells (*9*−*13*), based on which sonodynamic therapy (SDT) was proposed. From the effect of active oxygen scavengers on the ultrasonically induced *in vitro* cell damage, it was hypothesized that active oxygen generated by ultrasonically activated porphyrins was the most important mediator for the porphyrin-enhanced ultrasonically induced cell damage (*10*, *11*, *13*). *In vivo* animal experiments strongly suggested the potential effectiveness of SDT with such porphyrins (*13*−*15*).

Some xanthene photosensitizers have been found not only to be ultrasonically activated (*16*) but also to reduce both *in vitro* and *in vivo* cavitation thresholds, the acoustic intensity needed to induce cavitation, by more than 1 order of magnitude (*17*−*19*). Therefore, their potential as a sonosensitizer for SDT can be even higher than porphyrins. Rose bengal (3′,4′,5′,6′-tetrachloro-2′-(2,4,5,7-tetraiodo-6-hydroxy-3-oxo-3*H*-xanthen-9-yl)benzoic acid, bis(sodium salt), RB (**1**), Scheme 1) is one such xanthene photosensitizer, known to produce singlet oxygen with a quantum yield of nearly 100% on illumination (*19*). RB is reported to induce plasma membrane damage on illumination at 514 nm (*21*) and may have potential as a sensitizer for PDT. RB is also reported to induce *in vitro* cell damage when activated with ultrasound (*20*). The reason why both sensitizing effects of RB were shown in only *in vitro* experiments and not *in vivo* experiments with solid tumors is because RB cannot accumulate in tumor tissue. When RB is introduced into a living body, it is excreted immediately after accumulation in the liver (*22*). Although RB has high potential to be a sensitizer for both PDT and SDT, it cannot be used to treat solid tumors as is. To obtain a RB derivative (RBD) useful for PDT and SDT of solid tumors, its tumor-accumulative derivatives were newly synthesized and the process is described in this paper.

As a guide to adding a tumor-accumulative property to the xanthene dye, we referred to the cases where porphyrin dyes were used. Dougherty et al. reported that amphiphilicity was an important factor in tumor accumulation of porphyrin dyes (*23*). Since RB dissolves well in water but not well in nonpolar solvents, a lipophilic property needed to be added to obtain its amphiphilic derivatives. An alkyl group was used to add the lipophilic property, while a carboxyl group was used as the hydrophilic group to obtain the hydrophilic−lipophilic balance as an amphiphilic compound. To examine the amphiphilicity of the newly synthesized derivatives, their solubility in both polar and nonpolar solvents and their partition coefficients between polar and nonpolar phases were measured. Furthermore, their accumulation in murine tumor tissue was studied. It was quantified by measuring fluorescence from the compound in a slice of excised tissue (*24*).

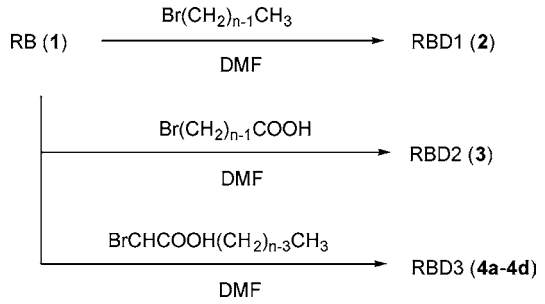
Scheme 1. Structure of Rose Bengal and Derivatives



EXPERIMENTAL PROCEDURES

Chemicals. RB (**1**), 90% dye content, was purchased from Sigma Chemical Co. (St. Louis, MO), and ATX-70 was supplied by Photochemical Co. (Okayama, Japan). All bromides used in the esterification reactions can be obtained from Kanto Chemical Co. (Tokyo, Japan), Wako Pure Chemical Industries (Osaka, Japan), Aldrich (Milwaukee, WI), or Lancaster Synthesis UK (Lancashire, UK). Phosphate-buffered saline (PBS) solution (pH = 7.4) was prepared in water using powder purchased from Sigma Chemical Co. (St. Louis, MO). Tetraborate pH standard solution (pH = 9.18) was purchased from Wako Pure Chemical Industries (Osaka, Japan). All products were used without prior purification. Deionized and distilled water was used throughout the experiments.

General Procedures. ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were measured on a Bruker AMX-500 spectrometer in dimethyl sulfoxide (DMSO)-d_6, and tetramethylsilane was used as external standard. Chemical shifts were reported in δ (ppm) and J values in hertz. Infrared (IR) spectra were obtained using a Hitachi I-3000 spectrophotometer, visible absorption spectra were obtained on a Hitachi U-3400 spectrophotometer, and fluorescence spectra were measured with a Hitachi F-4500 spectrofluorometer. High-resolution mass spectrometry (HRMS) was performed by Toray Research Central, Inc.

Synthetic Procedures. Three types of derivatives were synthesized (Scheme 1). RBD1 (**2**, RB, C-2′ alkyl ester, C-6 sodium salt) was synthesized with a method described by Lamberts et al. for the preparation of the C-2′ benzyl ester, C-6 sodium salt (*25*, *26*). Syntheses of RBD2 (**3**, RB, C-2′ ω-carboxyalkyl ester, C-6 molecular form) and RBD3 (**4**, RB, C-2′ α-carboxyalkyl ester, C-6 molecular form) consisted of the same basic procedure as the synthesis of RBD1, except ω-carboxyalkyl bromide was used in RBD2 and α-carboxyalkyl bromide was used in RBD3 in place of the alkyl bromide. The synthetic route to RBDs is shown in Scheme 2.

Scheme 2. Synthesis of Rose Bengal Derivatives

*Synthesis of Rose Bengal Octyl Ester, Monosodium Salt (**2**).* RB (**1**) (1.0 g; 1.0 mmol) was dissolved in *N*,*N*-dimethylformamide (DMF, 10 mL), and 1-bromooctane (0.5 g; 2.7 mmol) was added. This solution was magnetically stirred and heated for 6 h at 80 °C. The excess 1-bromooctane and DMF were distilled off *in vacuo*, and the residue was stirred with diethyl ether overnight. After filtration and thorough diethyl ether washing, in order to remove excess **1** and inorganic species, the residue was stirred with water overnight and was filtered to afford a deep purple powder which had no distinct mp. The isolated yield of **2** was 1.0 g (95%). IR (KBr) 1736 cm^{-1} (ester C═O). ^{1}H NMR (DMSO-d_6) δ (ppm): 0.84 (t, CH_3, 3H, J = 7.3 Hz), 0.88 (m, CH_2, 2H, J = 7.7 Hz), 1.01 (m, CH_2, 2H, J = 7.3 Hz), 1.09 (m, CH_2, 4H, J = 7.0 Hz), 1.16 (m, CH_2, 2H, J = 7.1 Hz), 1.24 (m, CH_2, 2H, J = 7.1 Hz), 3.93 (t, OCH_2, 2H, J = 6.8 Hz) 7.47 (s, ArH, 2H). ^{13}C NMR (DMSO-d_6) δ (ppm): 14.1(CH_3), 22.1, 25.0, 27.7, 28.4, 28.5, 31.3 (CH_2), 66.2 (OCH_2), 76.0 (C-2,7), 97.2 (C-4,5), 110.4 (C-8a,8b), 128.8, 129.9, 131.9, 133.8, 134.4, 134.9, 139.3, (C-1′, 2′, 3′, 4′, 5′, 6′, 9) 136.1 (C-1,8), 157.0 (C-4a,4b), 163.2 (C═O), 171.8 (C-3,5). HRMS Calculated for $C_{28}H_{21}O_5Cl_4I_4$: $(M + H)^+$, *m*/*z* 1084.6322 Found: *m*/*z* 1084.6309.

*Synthesis of Rose Bengal ω-Carboxyheptyl Ester, Molecular Form (**3**).* RB (**1**) (1.0 g; 1.0 mmol) was dissolved in DMF (10 mL), and 8-bromooctanoic acid (0.68 g; 3.1 mmol) was added. This solution was magnetically stirred and heated for 7 h at 80 °C. DMF was distilled off *in vacuo* and the residue was stirred with diethyl ether overnight. After filtration and thorough diethyl ether washing the residue was stirred with water overnight, in order to remove excess **1** and inorganic species. After filtration, it was recrystallized from ethanol, yielding 0.54 g (49%) of reddish purple powder, which had no distinct mp. Measurement of Solubility. In these experiments, 1-octanol was used as the nonpolar solvent, and PBS solution (pH7.4) and tetraborate pH standard solution (pH = 9.18) were used as the polar solvents. One milliliter of an appropriate solvent was added to excess dye in a centrifuge tube. The tube was covered and sonicated for 15 min. After that, it was heated for 2 h in a hot water bath (80−90 °C). Then it was sonicated for another 15 min. After allowing the mixtures to stand overnight at 25 °C, they were centrifuged. Then the supernatant was centrifuged again. The dye contents of each solvent were determined by UV−vis absorbance. Each measurement was performed at least three times.

Measurement of Partition Coefficient. The partition coefficient (P) values of RB and RBDs were measured using 1-octanol and tetraborate pH standard solution (pH = 9.18). Dyes were dissolved at a final concentration of 50 μM in 1.5 mL of 1-octanol and 1.5 mL of tetraborate solution (pH = 9.18). The phases were mixed for 10 min (200 rpm). Samples were centrifuged at 1077g for 10 min, and the dye contents of the organic and aqueous phases were determined by UV−vis absorbance. Each measurement was performed at least three times.

Tumor Cells and Animals. Colon 26 adenocarcinoma used in our research was supplied by the Cancer Institute (Tokyo, Japan). The cell lines were passed weekly through male BALB/c mice (five weeks old). Transplanted tumors were initiated with a subcutaneous trocar injection of approximately 1 mm^3 pieces of fresh tumor into the left dorsal scapula region of male five-week-old CDF_1 mice. When the tumor grew to a diameter of about 10 mm approximately 14 days after implantation, the drug-accumulation study was started.

Preparation of Injections. RB and ATX-70 were dissolved in PBS solution. RBD2 was dissolved in 0.1 N sodium hydroxide aqueous solution. After that, pH of the solution was adjusted to about 7.5 by adding hydrochloric acid, and then it was added to the PBS solution. RBD1 was dissolved in DMSO, which had a volume of about 40% of the solution and then was handled in the same way as described for RBD2. RBD3s were dissolved in DMSO, which accounted for about 20% of the total volume of the solution and then was handled in the same way as described for RBD2 and RBD1. The dye concentration was 2 mg/mL.

Preparation of Tissue Sample. The injections described in the previous section were administered to tumor-bearing CDF_1 mice at doses of 10 mg/kg, by intravenous injections into the caudal vein. The tumor and liver were immediately taken from the animals after sacrificing them at arranged times after injection. The tissue were softly washed with saline and divided into several pieces about 1 mm in thickness.

Measurement of Fluorescence Index. Accumulation of dyes in tissue was quantified referring to a method described by Nakajima et al. (*24*), in which they directly measured the fluorescence spectra of porphyrin dyes in solid tissue samples. It is known that both tissues and porphyrin dyes emit fluorescence when excited at around 350 nm. They excited the tissue samples at 337 nm and observed the fluorescence emissions at around 470 nm as well as 650 nm. The former arose solely from the biological tissue itself (autofluorescence), and the latter mainly from the porphyrin dye. The fluorescence index of the dye was obtained by subtracting the autofluorescence from the peak intensity of the latter and dividing it by the peak intensity of the former. They confirmed that the fluorescence indices of the porphyrin dyes in the tissue samples were proportional to the administered doses.

RB and its derivatives emit fluorescence when excited at 530 nm while tissues alone do not, and tissues emit fluorescence when excited at 337 nm while neither RB nor its derivatives do. Therefore we modified Nakajima's method using two excitation wavelengths: one to excite the dye and the other to excite the tissue itself. The experimental setup is shown in Figure 1. To avoid direct interference of the excitation light with the photon detector, a tissue sample was placed at an angle of 45° to the light path. It was affixed to the inner wall of a 1-cm quartz cell and placed in a solid specimen holder (Hitachi 650-0161).

The autofluorescence intensity was obtained as the peak fluorescence intensity observed at around 460 nm when the tissue taken from a mouse was excited at 337 nm. The dye fluorescence intensity was obtained as the peak fluorescence intensity observed at around 580 nm when the tissue was excited

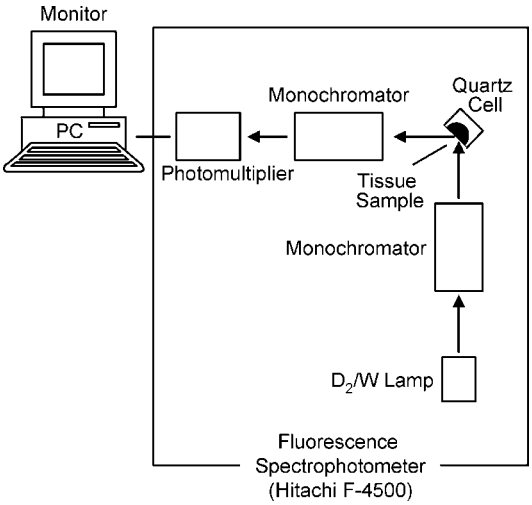

Figure 1. Experimental setup for quantification of tissue accumulation of dyes.

at 530 nm. Dividing the dye fluorescence intensity by the autofluorescence intensity obtained the fluorescence index of the dye.

ATX-70 emits fluorescence when excited at 410 nm while tissues alone do not, and it does not emit fluorescence at around 460 nm when excited at 337 nm. The fluorescence intensity of ATX 70 was therefore obtained as the peak fluorescence intensity observed at around 580 nm when the tissue was excited at 410 nm. The autofluorescence intensity was obtained, and the fluorescence index of the dye was calculated in the same way as for RB and RBDs.

RESULTS

Pursuit of Reaction to Rose Bengal Derivatives. RB was completely consumed in the synthesis of RBD1 and RBD2 at 80 °C. No existence of RB in reaction solvent was checked by thin layer chromatography. However, the conversion rate of RB to RBD3s did not improve sufficiently at 80 °C even when the reaction time was extended.

We followed the reactions of RB to RBD3s by ^{1}H NMR. At more than 35 °C, before the peak of RB at 7.3 ppm disappeared, a peak of side product appeared at around 2.5 ppm. On the other hand, at not more than 30 °C, although the reaction time was greatly extended from several hours to several days, RB was completely converted to RBD3s. The peak of RB completely disappeared and the peak of side product was not observed.

Identification. The structures of the synthesized RBDs were confirmed by IR, NMR, and HRMS. IR and NMR experiments showed the presence of an ester bond in RBDs. The results of the IR analysis of RBDs indicated the band at around 1720−1760 nm^{-1}, typical of C═O stretching of an ester carbonyl group. This was not found in the parent RB spectrum. The ^{13}C NMR spectra showed the peak attributed to a carbonyl carbon in RB that shifted to higher magnetic field from 164.8 ppm in RB to around 162.5−163.2 ppm in RBDs.

The NMR experiments showed the presence of an alkyl chain in RBDs. The results of the ^{1}H NMR analysis of RBDs indicated peaks at around 0.8−1.5 ppm, typical of methylene groups, and the results of the ^{13}C NMR analysis indicated peaks at around 22−31 ppm, also typical of methylene groups. The NMR analysis of RB, which was the starting material, indicated peaks only in low magnetic field, typical of aromatic groups. The results of the ^{1}H NMR analysis of RBD1 and RBD2 indicated a triplet peak at 3.93 ppm, a typical situation where CH_2 is next to the ester carbonyl group. In contrast, the results for RBD3s indicated the double doublet peak at around 4.7 ppm, which is typical of a CH found next to an ester carbonyl group. The results of the ^{1}H NMR analysis of RBD1 and RBD3s indicated a triplet peak at around 0.85 ppm, which is typical of a terminal CH_3 of an alkyl chain. For RBD2 no such peak was indicated at this position. In the ^{1}H NMR spectra of RBD2 and RBD3s, peaks attributed to the hydrogen of a carboxyl group around 13 ppm and a hydroxyl group around 8.3 ppm were observed.

The HRMS experiments showed chemical formulas and molecular weights that supported the estimated structures of RBDs. The results of the HRMS analysis of RBD1 and RBD2 indicated a Na adduct ion $(M + 23)^+$.

Table 1. Solubility and Partition Coefficient for Rose Bengal and Derivatives

	solubility (mM) (25 °C)			
		water		
compound code	1-octanol	pH 7.4	pH 9.18	1-octanol/water (pH 9.18) partition coefficient
RB	3.64	197	313	1.5
RBD1 ($n = 8$)	8.9	<0.013	<0.009	-
RBD2 ($n = 8$)	0.23	0.7	2.1	155
RBD3 ($n = 8$)	0.53	1.0	4.43	48.7
RBD3 ($n = 12$)	7	0.019	0.6	30.1
RBD3 ($n = 14$)	7	0.011	1.6	17.3
RBD3 ($n = 16$)	6.9	0.034	1.4	45.4

Solubility. The solubility of RB and RBDs in nonpolar and polar solvents was measured, and the results are listed in Table 1. In these measurements, 1-octanol was used as the nonpolar solvent, and PBS solution (pH = 7.4) and tetraborate solution (pH = 9.18) were used as the polar solvents. Regarding polar solvents, the solubility of RB and RBDs at pH 9.18 was higher than those at pH 7.4.

RB dissolved greatly in polar solvents, but the solubility in 1-octanol was 2 orders of magnitude lower than that in the polar solvents. The solubility of RBD1 with a carbon chain length of eight in 1-octanol was about twice as high as that of RB. In contrast, RBD1 hardly dissolved at all in polar solvents. RBD2 and RBD3 with a carbon chain length of eight both dissolved slightly in polar solvents, but their solubility in 1-octanol was lower than that of RB. The solubility of RBD3 was twice as high as that of RBD2. Therefore, we chose RBD3 for a more detailed investigation, and synthesized RBD3s with several carbon chain lengths. The solubility of RBD3s with carbon chain lengths of 12, 14, and 16 in 1-octanol was almost the same. It was a little lower than that of RBD1 with a carbon chain length of eight, but about twice as high as that of RB. The solubility of RBD3s with carbon chain lengths of 12, 14 and 16 in polar solvents varied a little. It was 2 orders of magnitude lower than that of RBD3 with a carbon chain length of eight at pH 7.4, but the difference was reduced to less than an order of magnitude at pH 9.18.

Partition Coefficient. *P* of RB and RBDs between polar and nonpolar phases was measured, and the results are also listed in Table 1. Here, 1-octanol and tetraborate solution (pH = 9.18) were used as the partition solvent. *P* of RB was the lowest. *P* of RBD1 could not be calculated because the tetraborate solution phase was too dilute to find UV−vis absorbance. If *P* of RBD1 had been calculated, it would have been the highest. Among the results of finite numbers, *P* of RBD2 was the highest and it was 2 orders of magnitude higher than that of RB. Among the RBD3s, there was no simple relation between the carbon chain lengths and the values of *P*.

Accumulation in Tissues. Figures 2 and 3 plot the fluorescence indices of RBDs with a carbon chain length of eight after administration in the murine liver tissue and in the tumor tissue, respectively. Those of the starting material, RB, and a tumor-selective porphyrin dye, ATX-70, are also shown for compari-

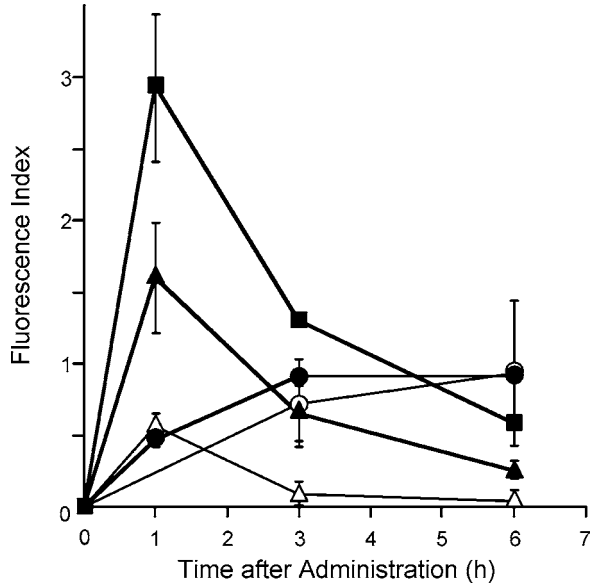

Figure 2. Fluorescence index of various RBDs ($n = 8$) in liver tissue. Solid circles are RBD1, solid triangles are RBD2, and solid squares are RBD3. For reference, the data of RB (open triangles) and ATX-70 (open circles) are also shown. These are the mean values ± SD of three mice.

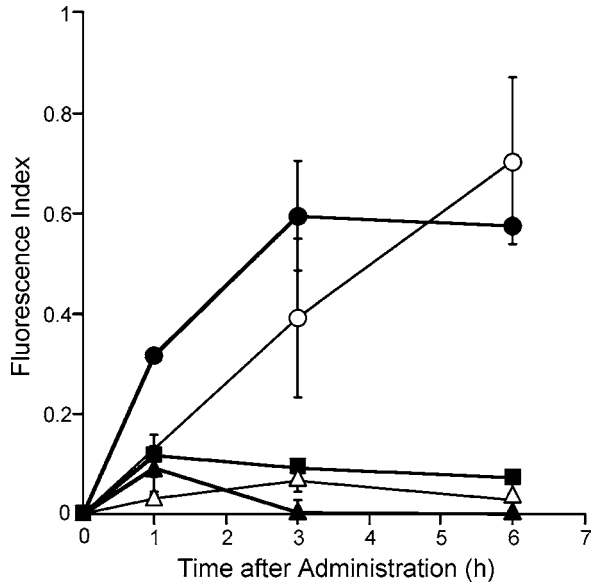

Figure 3. Fluorescence index of various RBDs ($n = 8$) in tumor tissue. Solid circles are RBD1, solid triangles are RBD2, and solid squares are RBD3. For reference, the data of RB (open triangles) and ATX-70 (open circles) are also shown. These are the mean values ± SD of three mice.

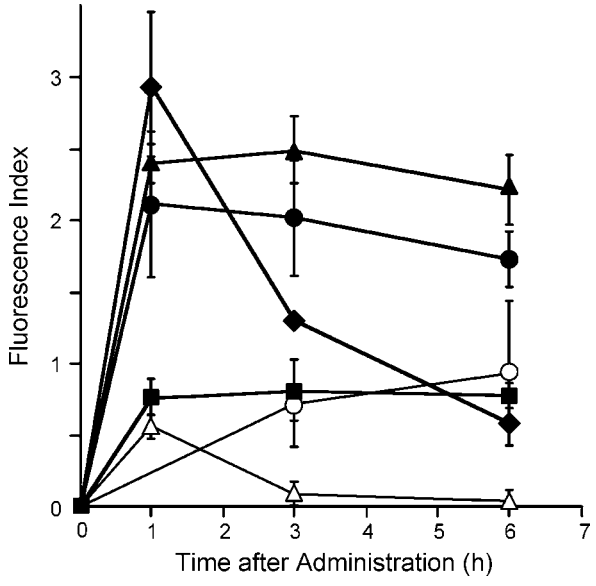

Figure 4. Fluorescence index of RBD3 with various carbon chain lengths in liver tissue. Solid diamonds are $n = 8$, solid triangles are $n = 12$, solid circles are $n = 14$, and solid squares are $n = 16$. For reference, the data of RB (open triangles) and ATX-70 (open circles) are also shown. These are the mean values ± SD of three mice.

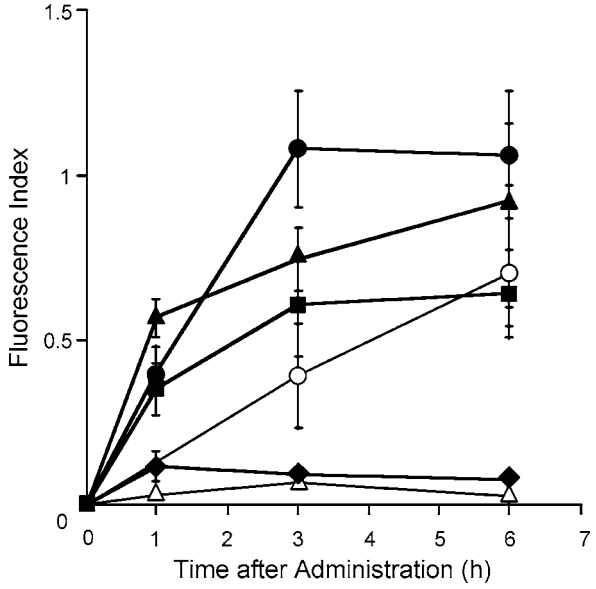

Figure 5. Fluorescence index of RBD3 with various carbon chain lengths in tumor tissue. Solid diamond are $n = 8$, solid triangles are $n = 12$, solid circles are $n = 14$, and solid squares are $n = 16$. For reference, the data of RB (open triangles) and ATX-70 (open circles) are also shown. These are the mean values ± SD of three mice.

son. RB suddenly accumulated in liver tissue after administration and then was excreted. In contrast, ATX-70 accumulated in both liver and tumor tissues, and both fluorescence indices increased as time proceeded. RBD1 behaved similarly to ATX-70 in both liver and tumor tissues. However, RBD2 and RBD3 showed the same tendency as RB.

Figures 4 and 5 plot the fluorescence indices of RBD3s with different carbon chain lengths after administration in the murine liver tissue and in the tumor tissue, respectively. The behavior of the RBD3 fluorescence indices in liver tissue changed from being similar to RB to being similar to ATX-70 as the chain length increased. In tumor tissue, the fluorescence indices of RBD3 with a chain length of eight were as low as those of RB. However, with longer chain lengths, a remarkable accumulation in tumor tissue was observed. It reached a level similar to or even higher than that of ATX-70. The optimum carbon chain length was found to be 14. The fluorescence index of RBD3 with a carbon chain length of 14 in the murine tumor tissue 6 h after administration was not only approximately 40 times higher than that of RB but also about 1.5 times higher than that of ATX-70.

Relationship between Amphiphilicity and Accumulation in Tumor Tissue. Figure 6 shows the relationship between the solubility in 1-octanol of RBDs and their fluorescence index in the tumor 6 h after administration. The dyes are divided into two groups. One group (solid circles), with relatively high solubility in 1-octanol, higher than 6 mM, showed relatively high accumulation in tumor tissue. The other group (open circles), with relatively low solubility in the nonpolar solvent, showed very low accumulation in tumor tissue.

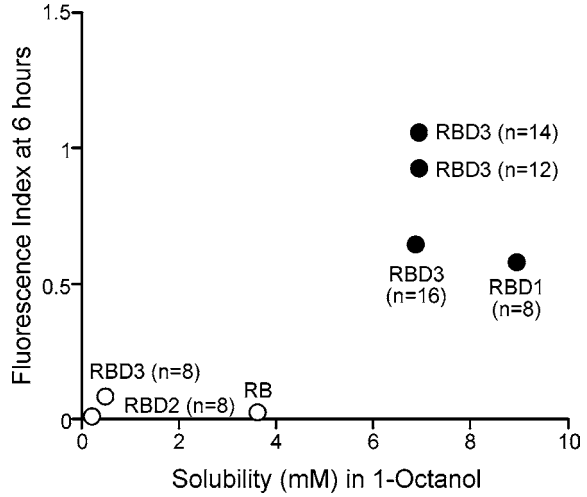

Figure 6. Relationship between lipophilicity (solubility in 1-octanol) of RBDs and their 6-h fluorescence index in tumor tissue. For reference, RB data are also shown.

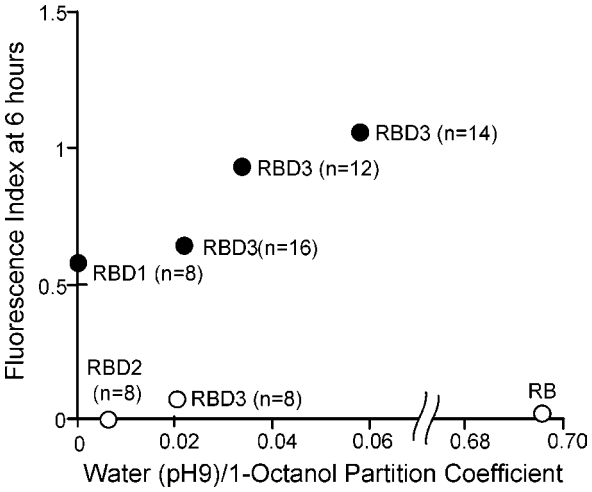

Figure 7. Relationship between amphiphilicity (partition coefficient) of RBDs and their 6-h fluorescence index in tumor tissue.

Figure 7 shows the relationship between the water (pH 9.18)/1-octanol partition coefficient, *P*wo, of RBDs and their fluorescence index in the tumor 6 h after administration. Here, we chose to use P_{wo} instead of P_{ow}, the 1-octanol partition coefficient/water, as an indicator of amphiphilic property. For the group of solid circles, a good correlation between P_{wo} and the fluorescence index in tumor tissue, with a correlation coefficient of 0.95, is observed.

DISCUSSION

As the method to synthesize RBDs, esterification of a carboxylate anion and an alkyl bromide was chosen. RB has two nucleophiles. One is the carboxylate anion at the C-2′ position and the other is the phenolate anion at the C-6 position. However, because of the sterically imposing iodines ortho to the phenoxide at the C-6 position, a nucleophilic substitution occurs selectively at the C-2′ position (*27*). Lamberts et al. synthesized various RBDs with various substituents at the C-2′ position (*25*−*27*).

From the spectroscopic results, it was confirmed that the couplings of RB and the three types of bromide were accomplished (Scheme 2). Regarding the C-6 position, it was found that the sodium salt was retained in RBD1, but the sodium was substituted by the hydrogen in RBD2 and RBD3s. We think this difference between RBD1 and the other derivatives is due to the difference in the reaction condition. The bromide used in the syntheses of RBD2 and RBD3s had a carboxyl group in them, so the reaction environment may have become acidic. Lamberts et al. used DMF as a reaction solvent to synthesize sodium salt-type derivatives of RB, on the other hand they used water and acetone to synthesize its molecular form derivatives (*25*, *26*).

Two kinds of reaction should have competed with each other in the syntheses of RBD2 and RBD3s. One is the desired esterification of the carboxylate anion in RB and the carbocation in the bromide. The other is an unexpected coupling of the bromides, between the carboxyl group and the carbocation both in the bromides. In the bromides used in the syntheses of RBD3s, a carboxyl group is bonded to the carbon next to the bromine. In the syntheses of RBD3s, the reaction point of desirable esterification between RB and the bromide is crowded. We think this is the reason why the reaction was difficult to run in the syntheses of RBD3s especially.

The yield of RBD2 and RBD3s was considerably low in comparison with that of RBD1 though RB was mostly converted to RBD2 and RBD3s. The purification of RBD2 and RBD3s was difficult because of their amphiphilicity. We think this is the reason for their low yield. A better method of purification should be developed in the future.

We modified Nakajima's method (*24*) and used it to evaluate the accumulation of dyes in tissues. Since the fluorescence indices of dyes in tissues, obtained by their method, were confirmed to be proportional to the doses, they should be proportional to the concentrations of the dyes in tissues.

In what follows, we discuss the relationship between the amphiphilicity of the synthesized derivatives and their accumulation in tumor tissue. From Figures 6 and 7, the balance between lipophilicity and hydrophilicity of a compound is confirmed to be an important factor for its tumor accumulation. Furthermore, the regiochemical arrangement of lipophilic and hydrophilic substituents in the compound's structure is speculated to have contributed to its amphiphilicity.

It is known that RB is excreted rapidly into the bile by carrier-mediated hepatobiliary transport (*22*, *28*). Our results for RB in Figures 2 and 3 are consistent with this knowledge. RB was quickly excreted from the body before it could be accumulated in tumor tissue. Among the RBDs with a carbon chain length of eight, RBD1 showed the most drastic improvement from RB in tumor accumulation, while RBD2 and RBD3 showed much less improvement. The solubility of RBD1 in 1-octanol was about twice as high as that of RB (Table 1). This increment in the lipophilicity seems to have been sufficiently effective for RBD1 not to bind to the carriers and be excreted by the transport mediated by them. The level and the time course of concentration of RBD1 in both liver and tumor tissues were similar to those of ATX-70, an amphiphilic porphyrin dye known to accumulate well in tumor tissue (*14*).

However, the water solubility of RBD1 may be too low to be delivered intravenously as a stable aqueous solution in a practical case. The hydrophilicity that RB originally had was lost because a part of the carboxylate anion, one of the two hydrophilic groups in RB, was converted to the ester when the alkyl chain was added to RB. To solve this problem, not only a lipophilic group but also a hydrophilic group was introduced in the synthesis of RBD2 and RBD3 (Scheme 1). Of these two, RBD3 accumulated in the tumor tissue significantly better than both RBD2 and RB (Figure 3), although its solubility in 1-octanol was reduced to less than that of RB (Table 1). Therefore, we chose RBD3 and synthesized RBD3s with longer carbon chains in order to improve its lipophilicity.

As shown in Figure 5, RBD3s with carbon chain lengths of 12, 14, and 16 accumulated in the tumor tissue at a concentration

level similar to or even higher than ATX-70. The improvement in the tumor accumulation from RBD3 with a carbon chain length of eight and RB was dramatic. RBD3s with longer carbon chain lengths also accumulated in liver tissue in a similar way to ATX-70, and very differently from RBD3 with a carbon chain length of eight and RB (Figure 4).

A distinct relationship between the lipophilicity and the tumor accumulation of RBDs was seen in Figure 6. This is consistent with reports on photosensitizing agents for PDT stating that the agents with lipophilicity tend to localize in tumor tissue because they are bound to lipoproteins and are transported (*23*). The tumor accumulation of RB itself was too low to correlate well with the other RBDs because of its carrier-mediated rapid excretion from the body.

Amphiphilicity is also known to be a key factor for tumor-targeting agents as reported for porphyrin dyes (*29*, *30*). Zhang et al. reported that a homologous series of 2-nitroimidazoles with similar lipophilicity showed significantly different *in vivo* tumor uptake depending on their amphiphilicity, and that the octanol-to-water partition coefficient, P_{ow}, of 1 was optimal to achieve their renal excretion and high target-to-background distribution ratios (*31*).

It is interesting that a good correlation between the tumor accumulation and the water-to-octanol partition coefficient, P_{wo}, rather than P_{ow}, is seen for the group of solid circles in Figure 7. Since their P_{wo} are much less than 1, this result is consistent with the report by Zhang et al. in spite of the significant difference in the structure (*31*).

It is even more interesting that the hydrophilicity to lipophilicity ratio, P_{wo}, of RBD3s increased as the length of their alkyl chain increased from 8 to 14. It started decreasing only after the chain length exceeded 14. In other words, both hydrophilicity and lipophilicity increased at the same time when the chain length increased from 8 to 14. In RBD3s, the hydrophilic carboxyl group and lipophilic alkyl chain branch locate right next to each other. We would speculate that the alkyl chain may change its three-dimensional conformation in relation to the carboxyl group according to the hydrophilicity and lipophilicity of the environment, and that the advantage in the degree of freedom of a long chain may overcome the potential increase in hydrophobicity up to a certain chain length. Kim et al. also mentioned that the regiochemical arrangement of lipophilic and hydrophilic substituents in the structure is needed for amphiphilicity (*30*).

In measuring of the partition coefficient, we used tetraborate pH standard solution of pH 9.18 rather than PBS of pH 7.4, which is normally used, because of its closeness to plasma in pH. It was much easier to perform reproducible measurements at pH 9.18 than pH 7.4. The dissociation of RBD2 and RBD3s may not be stable at pH 7.4, which is close to their pK_a.

In this study, the importance of amphiphilicity with a balance between lipophilicity and hydrophilicity to obtain tumor-accumulative agents was shown. Among the RBDs we synthesized, RBD3, which has an alkyl chain and a branching carboxyl group located next to each other, showed the highest potential as such an agent. By optimizing the length of the alkyl chain, we were able to obtain RBDs, that accumulated in tumor tissue at a concentration level similar to or even better than the known tumor-accumulative porphyrin dye. The poor tumor accumulation of RB has been its greatest drawback as a potential agent for tumor treatment. This paper would eliminate this drawback by proposing the tumor-accumulative RBDs. Further *in vitro* and *in vivo* experiments are currently underway to confirm whether the obtained RBDs maintain the excellent photo- and sono-sensitizing abilities of RB.

ACKNOWLEDGMENT

The authors thank Dr. N. Yumita for his advice on the animal experiments and Dr. B. Choi for his advice on the synthetic procedures. Part of this work was supported by the New Energy and Industrial Technology Development Organization (NEDO), Japan.

Hydrogels derived from synthetic polymers have been previously engineered to degrade under the activity of matrix metalloproteinases (MMPs). It is believed that these systems can act as extracellular-matrix (ECM) equivalents mimicking the degradation and remodeling of the ECM through the activity of cell-secreted enzymes. In this study, MMP-sensitive hydrogels derived from dextran were developed. In order to avoid the incorporation of hydrolyzable esters often introduced in dextran modification strategies, the polysaccharide was modified with *p*-maleimidophenyl isocyanate (PMPI) thereby introducing maleimide functionalities in the backbone and resulting in dextran derivatized with *p*-maleimidophenyl isocyanate (Dex-PMPI). This strategy was favored to separate out the effects of random hydrolysis and enzymatic digestion in the degradation of the dextran hydrogels. A peptide cross-linker, derived from collagen and susceptible to gelatinase A (MMP-2) digestion, was synthesized with bifunctional cysteine termini and used to cross-link the Dex-PMPI. These hydrogels were found to be hydrolytically stable for more than 200 days yet degraded either within 30 h when exposed to bacterial collagenase or within 16 days when exposed to human MMP-2, demonstrating enzymatic-mediated digestion of the peptide cross-links. Further modification of the cross-linked hydrogels with laminin-derived peptides enhanced cell adhesion and survival, demonstrating the potential of these materials for use in tissue engineering applications.

INTRODUCTION

One aspect of tissue engineering is the development of multicomponent scaffolds that can elicit specific biological functions. Ideally, these scaffolds would act as extracellular-matrix (ECM) equivalents, mimicking the cellular environment as closely as possible. The natural ECM is not only a physical support for the cells but also plays a key role in signal transduction by presenting adhesion molecules and serving as a reservoir for other molecules, such as cytokines, that influence growth and cell function. The dynamic interactions between cell and ECM have been mimicked in scaffold design where both physical and chemical stimuli have been incorporated to guide tissue regeneration both spatially and temporally (*1*−*4*); however, these scaffolds have not been optimized for nerve repair strategies.

Most biodegradable synthetic polymers studied for tissue-engineering applications, such as polycaprolactone, polylactide, polyglycolide, and poly(lactide-*co*-glycolide), rely on random ester hydrolysis of the backbone chain instead of tailoring the degradation to specific cellular activity. Over the years, advances in molecular biology have provided a better understanding of the cellular environment which has been used to design scaffolds that mimic the degradation and the remodeling of the ECM. In this environment, growth, repair, and development are controlled by cell-secreted and cell-activated enzymes, such as matrix metalloproteinases (MMPs) and plasmin. These processes are regulated through enzymatic degradation and *de novo* synthesis of ECM components, making the degradation of this natural support dynamic. Due to their involvement in tissue remodeling, the activity of these enzymes is highly localized in the cellular periphery and is tightly regulated.

MMPs, which are calcium-requiring and zinc-dependent endopeptidases, constitute one of the major families of proteinases playing key roles in the responses of cells to their environment (*5*). They have the ability to hydrolyze one or several components of the ECM, as well as nonmatrix proteins thereby influencing cell migration, proliferation, differentiation, and death by both modifying the cellular microenvironment and regulating the activity of biological molecules. MMPs are secreted as inactive zymogens, and their activity is highly regulated at the transcriptional and posttranscriptional level. Expressed during development (*6*, *7*), most MMPs have been found to be produced at very low or undetectable levels in the adult central nervous system (CNS); however, they are up-regulated following spinal cord injury (*8*, *9*) and may play a beneficial role in CNS repair strategies (*5*, *9*). MMPs are expressed in the growth cones of numerous vertebrate neurons (*10*−*12*) and may regulate axonal guidance (*13*−*15*). Muir and co-workers previously reported that MMP-2 activity facilitated neurite extension of dorsal root ganglia (DRG) neurons within a reconstituted ECM (*11*) and promoted axonal growth by degrading inhibitory chondroitin sulfate proteoglycans (*15*). MMP-2 is therefore highly relevant to the enzymatic degradation of ECM analogues designed for neuronal applications.

Hubbell and West introduced the concept of mimicking the dynamic remodeling of the ECM through the development of telechelic peptide-poly(ethylene glycol) (PEG)-peptide block copolymers which were degraded either by plasmin or bacterial collagenase (*16*). Different hydrogels sensitive to proteases such as MMPs (*3*, *4*, *17*) and plasmins (*17*, *18*) have been developed for various tissue engineering applications, mimicking some fundamental aspects of cell−ECM interactions by taking advantage of the time- and location-dependent ECM degradation activity exhibited during cellular outgrowth.

Dextran is a natural polysaccharide which consists mainly of linear chains of α-1,6 linked D-glucopyranose residues. It has been widely used in biotechnology applications (*19*−*22*), studied as a drug delivery vehicle (*23*−*26*), and more recently has been investigated as a biomaterial (*27*−*30*). Dextran hydrogels are particularly compelling as scaffolds for soft tissue-engineering applications because dextran is resistant to both protein adsorption (*31*, *32*) and cell adhesion (*27*, *33*, *34*), allowing specific cellular behavior, such as adhesion (*34*, *35*), to be dialed into the hydrogel design. Unlike PEG, which has modifiable groups only at the termini, dextran has three hydroxyl groups on each glucopyranose repeat unit that are available for chemical modification with either cross-linking agents for hydrogel formation (*36*, *37*) or bioactive molecules (*38*−*41*).

In previous studies, we have reported methods to create macroporous, interconnected dextran scaffolds for tissue-engineering applications using glycidyl-methacrylate derivatized dextran (Dex-MA) (*36*) and to render these hydrogels cell-adhesive by covalently immobilizing ECM-derived peptides (*42*). To create biodegradable hydrogels, we cross-linked the dextran with MMP-2-labile oligopeptides and characterized it for degradation and cytocompatibility *in vitro*. Specifically, dextran was first modified with *p*-maleimidophenyl isocyanate (PMPI), a sulfhydryl- and hydroxyl-reactive heterobifunctional cross-linker. The isocyanate terminus of PMPI reacts with the dextran hydroxyl functional group forming a hydrolytically stable carbamate linkage and provides a maleimide moiety on the other terminus, which reacts by Michael-type addition with a sulfhydryl functionalized cross-linker to form a thioether cross-linked hydrogel. The peptide cross-linker was specifically designed to be susceptible to MMP-2 degradation and to have a cysteine residue at each terminus, allowing conjugate addition to dextran derivatized with *p*-maleimidophenyl isocyanate (Dex-PMPI). To gain greater insight into the specificity of the protease activity, dicysteine peptides with high and low MMP-2-sensitive peptide sequences, GCRD**GPQGIASQ**DRCG and GCRD**GPQGPAGQ**DRCG, were used to create the cross-linked gels and compared in terms of enzymatic degradation. Moreover, to explore these materials for tissue engineering applications, these dextran cross-linked hydrogels were modified with cell-adhesive peptides, CGDPG*YIGSR* and CQAAS*IKVAV*, and compared in terms of neural cell adhesion.

EXPERIMENTAL PROCEDURES

Materials and Methods. All chemicals were purchased from Sigma-Aldrich Canada Ltd. (Oakville, ON) and used as received, unless otherwise noted. Water was distilled and deionized using Millipore Milli-RO 10 Plus at 18 MΩ resistance.

Synthesis of Functionalized Dextran. *Synthesis of Dex-PMPI.* Dextran 40 kDa (*Leuconostoc mesenteroides*) was dried under vacuum and dissolved under nitrogen in 12 mL of anhydrous dimethyl sulfoxide (DMSO) at predetermined reaction temperatures (25 °C or 45 °C), after which dibutylin dilaurate (DBTDL) was added. A range of catalyst concentrations from 0 to 5.4 mM was examined. PMPI (50 mg; Pierce Chemical Co., Rockford, IL) was dissolved in 3 mL of DMSO and then added to the dextran solution. The amount of dextran used varied from a molar ratio of 0.1 to 0.4 of PMPI to dextran glucopyranose residue. The reaction was conducted in the dark for 4 and 24 h. The solution was precipitated in 70 mL of cold ethanol, washed several times with ethanol to remove any residual traces of DMSO and catalyst, dried at room temperature under nitrogen, and stored as a yellow powder at −20 °C. Proton nuclear magnetic resonance (^{1}H NMR) spectra were collected on a Gemini 300 MHz spectrometer (Varian Associates, Inc. NMR Instruments, Palo Alto, CA) using HOD (4.8 ppm) as the reference. ^{1}H NMR (D_2O): δ 7.6 ppm (d, 2H, Ar−H ortho to maleimide), 7.4 ppm (d, 2H, Ar−H ortho to carbamate), 7.0 ppm (s, 2H, maleimide vinyl), 5.0 ppm (s, 1H, anomeric proton), 5.3 ppm (s, 1H, α-1,3 linkage) 3.3−4.2 ppm (br m, 6H, glucopyranosyl ring). The degree of modification (DS) was determined according to eq 1

$$DS = \frac{I_B}{I_A} \times 100 \quad (1)$$

where I_B is the integrated region of PMPI around δ 7.0−7.6 ppm (6H) and I_A is the integrated area of the glucopyranosyl ring of dextran at δ 3.3−4.2 ppm (6H).

Fourier transform infrared spectroscopy (FTIR) spectra were obtained on a Nicolet Avatar E.S.P. spectrometer (Thermo Electron Co., Waltham, MA). Samples of dextran and Dex-PMPI were ground separately with KBr powder (10-fold excess relative to sample mass) and pressed into pellets for FTIR examination. OMNIC software (Thermo Electron Co., Waltham, MA) was used for data acquisition and analysis. FTIR (KBr, in cm^{-1}): dextran 3398 (s, ν_{O-H}), 2915 (s, $\nu_{C-H/C-H2}$), 1013 (s, ν_{C-OH}); PMPI 3120 (s, $\nu_{sym\ maleimide\ C-H}$), 3088 (s, $\nu_{asym\ maleimide\ C-H}$), 3073 (s, $\nu_{aromatic\ C-H}$), 2275 (s, $\nu_{asym\ N=C=O}$), 1776 (w, $\nu_{sym\ maleimide\ C=O}$), 1719 (s, $\nu_{asym\ maleimide\ C=O}$), 1583 (w, $\nu_{maleimide\ C=C}$), 1529 (s, $\nu_{sym\ aromatic\ C-C}$), 1447 (w, $\nu_{asym\ aromatic\ C-C}$), 1386 (s, $\nu_{sym\ maleimide\ C-N-C}$), 1145 (s, $\nu_{asym\ maleimide\ C-N-C}$), Dex-PMPI 1714 (s, $\nu_{carbamate\ C=O}$), 1519 (s, ν_{N-H}), 1232 (s, $\nu_{carbamate\ =C-O-C-}$).

Typical Synthesis of Dex-PMPI DS 10. Dextran 40 kDa (378 mg) was dissolved under nitrogen in 12 mL of anhydrous DMSO at 45 °C after which 45 μL of DBTDL was added. PMPI (50 mg) was dissolved in DMSO (17 mg/mL) and then added to the dextran solution in order to obtain a DS of 10. The reaction mixture was stirred overnight under nitrogen and in the dark. Dex-PMPI was purified as reported previously and stored at −20 °C (recovery yield: 87%, DS: 10; based on ^{1}H NMR).

Peptide Synthesis. Two collagen-derived peptides containing octapeptide sequences cleavable by MMP (in **bold** and \ indicates the cleavage point) and capped by a tetrapeptide containing a cysteine residue at opposite ends were used as peptide cross-linkers: Ac-Gly-Cys-Arg-Asp-**Gly-Pro-Gln-Gly-Ile-Ala-Ser-Gln**-Asp-Arg-Cys-Gly-COOH (GCRD**GPQG\IASQ**-DRCG) and Ac-Gly-Cys-Arg-Asp-**Gly-Pro-Gln-Gly\Pro-Ala-Gly-Gln**-Asp-Arg-Cys-Gly-COOH (GCRD**GPQG\PAGQ**DRCG). **GPQGIASQ** was selected as a highly MMP-2 sensitive sequence while **GPQGPAGQ** was chosen for its very low sensitivity to MMP-2 (*43*, *44*). The GCRD sequence capping the peptides was used to improve peptide solubility and to introduce thiols as previously described by Lutolf et al. (*3*).

For the studies of hydrogel degradation, three peptides with fluororescent labels were synthesized. Two mono-cysteine collagen-derived peptides with sequences similar to the peptide cross-linkers but containing a fluorescent 5-carboxyfluorescein (5-FAM)-L-lysine residue were synthesized: Ac-Gly-Cys-Arg-Asp-**Gly-Pro-Gln-Gly\Ile-Ala-Ser-Gln**-Asp-Arg-Gly-Lys(5-FA M)-$CONH_2$ (GCRD-**GPQG\IASQ**DRGK-FAM) and Ac-Gly-Cys-Arg-Asp-**Gly-Pro-Gln-Gly\Pro-Ala-Gly-Gln**-Asp-Arg-Gly-Lys(5-FAM)-$CONH_2$ (GCRD**GPQG\PAGQ**DRGK-FAM). A nonfunctional monothiol peptide terminated by a fluorescent 7-methoxycoumarin (Mca)-L-lysine residue, Cys-Gly-Lys(Mca) (CGK-Mca), was also synthesized.

Finally, two laminin-derived peptides containing respectively the Tyr-Ile-Gly-Ser-Arg and Ile-Lys-Val-Ala-Val motifs (in italic) were synthesized to promote cellular adhesion and neurite outgrowth: H_2N-Cys-Asp-Pro-Gly-*Tyr-Ile-Gly-Ser-Arg*-COOH (CDPG*YIGSR*) and H_2N-Cys-Gln-Ala-Ala-Ser-*Ile-Lys-Val-Ala-*

Val-COOH (CQAAS*IKVAV*), where the spacer group results in a more biomimetic conformation (*45*).

All peptides were synthesized by solid-phase synthesis using a Pioneer Peptide Synthesis System (Applied Biosystems, Foster City, CA) with standard Fmoc/ HATU chemistry. Amino acids including Fmoc-Lys(Mca)-OH were purchased from Novabiochem (EMD Biosciences, Inc., La Jolla, CA). Fmoc-Lys(5-FAM)-OH was from AnaSpec, Inc. (San Jose, CA). Activators and resins were purchased from Applied Biosystems and *N*,*N*-dimethylformamide (DMF) was from Caledon Laboratories Ltd. (Georgetown, ON). Laminin-derived peptides and fluorophore-labeled peptides were cleaved and deprotected from the resin for 2 h, and the peptide cross-linkers were treated for 4 h as previously described (*42*). The sulfhydryl content of peptide cross-linkers was determined photometrically using Ellman's reagent (5,5′-dithio-bis(2-nitrobenzoic acid). Peptide cross-linkers with free thiol content higher or equal to 80% were used for the experiments.

Degradation of Soluble Peptide Cross-Linkers. The substrate specificity of MMP-2 toward the cross-linkers was determined using a previously published fluorometric assay (*46*). Briefly, peptides were prepared as 540 mM stock solution in degradation buffer (50 mM Tricine, pH 7.5, 200 mM NaCl, 10 mM $CaCl_2$, 0.05% Brij-35). Digestion assays were carried out in degradation buffer by incubating a range of substrate concentrations (40, 80, 125, 160, 250, and 340 μM) with 40 nM MMP-2 at 30 °C. At predetermined time points, 20-μL aliquots of the degradation assay solution were withdrawn and added to 30 μL of *o*-phenanthroline (20 mM) to quench the enzymatic reaction. Rates of hydrolysis were monitored through the formation of free amines resulting from the peptide cleavage by active human MMP-2 (recombinant MMP-2; Calbiochem, San Diego, CA). Fluorescamine solution (200 μL, 5 mM in degradation buffer solution minus Brij-35) was added to the aliquots. The formation of fluorophores by the reaction of fluorescamine with the free amino groups was quantifed by fluorimetric measurement ($\lambda_{excitation} = 387$ nm, $\lambda_{emission} = 480$ nm) using a Gemini EM microplate spectrofluorometer (Molecular Devices Corp., Sunnyvale, Ca). The kinetic parameters of the peptides were determined by Michaelis−Menten analysis as reported in Supporting Information.

Hydrogel Formation. Hydrogels were formed by the conjugate addition of the sulfhydryl groups on PEG-dithiol or peptide cross-linkers to the maleimides of derivatized dextran. Dex-PMPI was dissolved in 100 mM phosphate buffered saline (PBS) pH 6.5 to give a final desired concentration (2.5, 5, 10, or 20 wt %). For example, 2.5 mg of Dex-PMPI was dissolved in 12.5 μL PBS buffer and mixed with 1.6 mg of peptide cross-linker dissolved in 12.5 μL of PBS buffer to make 10 wt % dextran hydrogel. The reaction solution was quickly vortexed, transferred into a mold, and placed in an incubator at 37 °C overnight.

Hydrolytic Stability of Hydrogels. *Dextran Hydrogels Cross-Linked with PEG-Dithiol.* Hydrogel samples (100 μL) of 2.5% dextran cross-linked with PEG-dithiol were immersed in 100 mM PBS solution (pH 7.4, 0.02% sodium azide) and incubated at 37 °C with buffer exchange every 2 days. The hydrolytic stability was determined by measuring the hydrogel water content (WC) according to eq 2. The hydrogels were weighed daily to determine the hydrated mass (W_h). The dry mass (W_d) was obtained for each hydrogel by freeze-drying the hydrogels and subsequently measuring the mass.

$$\mathrm{WC} = \frac{W_h - W_d}{W_h} \times 100\% \qquad (2)$$

Dex-Peptide Hydrogels. Hydrogel samples (50 μL) of 20% Dex-PMPI cross-linked with GCRD**GPQGIASQ**DRCG were immersed in 100 mM PBS solution (pH 7.4, 0.02% sodium azide), incubated at 37 °C with weekly buffer exchanges. Dex-MA (*36*) was also cross-linked with the peptide cross-linker through Michael-type reaction to form a 20% hydrogel and was used as comparison for stability. The hydrogels were weighed periodically to determine the normalized hydrogel weight (NW_h; eq 3) in the buffer.

$$\mathrm{NW}_h = \frac{W_t}{W_o} \qquad (3)$$

where W_t is the hydrated mass at time t and W_o the initial mass of the hydrogel after gelation.

Enzymatic Degradation. *Collagenase Degradation.* Hydrogel samples (50 μL) of 20% Dex-PMPI cross-linked with GCRD**GPQGIASQ**DRCG were placed in PBS, pH 7.4, 100 mM with 0.2 mg/mL of sodium azide and 1 mM $CaCl_2$ at 37 °C for 24 h at which time their hydrated mass was measured. Methacrylated dextran hydrogels obtained by redox polymerization of Dex-MA were prepared as previously described (*36*) and were used as controls. Each sample was then immersed into 1 mL of PBS solution with 0.2 mg/mL of sodium azide and either without enzyme or with 2 ng/mL of bacterial collagenase (from *Clostridium histolyticum*) and incubated at 37 °C. At predetermined time points, the hydrogels were removed from the medium and their NW_h was determined.

MMP-2 Degradation. The degradation of hydrogels was followed with both bacterial collagenase (as described above) and with MMP-2. With bacterial collagenase, degradation was followed by measuring hydrogel wet mass, which is suitable when the enzyme concentration is maintained by the use of a large volume of degradation media. For practical reasons, with MMP-2, degradation was monitored by measuring the release of fluorescent peptides in the media, which is suitable for maintaining the enzyme concentration when small degradation-media volumes are required. To study the degradation of the hydrogel through the activity of MMP-2, two mono-cysteine fluorescent peptides, CGK-Mca and either GCRD**GPQGIASQ**DRGK-FAM or GCRD**GPQGPAGQ**DRGK-FAM, were covalently immobilized to Dex-PMPI followed by its cross-linking using either GCRD**GPQGIASQ**DRCG or GCRD**GPQGPAGQ**DRCG peptides, respectively. Dex-PMPI (2.5 mg) was dissolved in 25 μL of a solution of fluorescent peptides (0.4 mM/peptide). After 10 min, 25 μL of peptide cross-linker (27 mg/mL) was added. The solution was vortexed and transferred to a mold and incubated overnight. Hydrogels were washed for 1 week in degradation buffer to remove any unreacted fluorescent peptides. They were then placed in 1 mL of degradation buffer containing 40 nM of MMP-2. The enzymatic activity was correlated to the release of the dextran-CGK-Mca ($\lambda_{excitation} = 340$ nm, $\lambda_{emission} = 405$ nm) and the fluorescein-labeled peptide fragment ($\lambda_{excitation} = 494$ nm, $\lambda_{emission} = 521$ nm), **IASQ**DRGK-FAM or **PAGQ**DRGK-FAM, into the degradation buffer solution. At predetermined time points, the release of the fluorophore was quantified by transferring 100-μL aliquots of supernatant to a 96-multiwell opaque plate and measuring the sample fluorescence. The aliquots were returned back to the degradation buffer solution. The degradation solution was refreshed daily until complete degradation of the hydrogel.

Cytotoxicity Assay. *Macromer Cytotoxicity.* The cytotoxity of Dex-PMPI was investigated. Cells were incubated in presence of soluble dextran or Dex-PMPI in the medium solution. NIH-3T3 fibroblast cells were cultured at 37 °C in culture medium (Dulbecco's Modified Eagle Medium (DMEM) supplemented with 2 mM L-glutamine, 10% fetal bovine serum (FBS), 50 units/mL penicillin/50 mg/mL streptomycin; all from Invitrogen Corp., Grand Island, NY).

Dextran and Dex-PMPI DS 10 with Mw of 6 kDa and 40 kDa were added to medium at the following concentrations: 10, 1, 0.1, 0.01, 0,001, and 0 mg/mL dextran and 10, 1, 0.1, 0.01, 0,001, 0.0001, and 0 mg/mL Dex-PMPI. Cells were plated on collagen-coated 96-multiwell black-wall clear-bottom Costar plate (Corning Inc. Acton, MA) and cultured for 2 days. Samples were prepared in sextuplicate. To test for cell viability, a luminescent cell proliferation assay using CellTiter-Glo (Promega Corp., Madison, WI) was used. The CellTiter-Glo assay quantif the amount of ATP present, indicating presence of metabolically active cells. The amount of ATP is directly proportional to the number of cells present in culture (*47*).

Hydrogel Cytotoxicity. The toxicity was also investigated on hydrogel extracts. Dex-PMPI hydrogels cross-linked with GCRD**GPQGIASQ**DRCG only or also containing CDPG*YIGSR* and CQAAS*IKVAV* were prepared. Similar hydrogels with grafted laminin-derived peptides were used in the next section to briefly investigate cell adhesion on the dextran-peptide hydrogels. Dex-PMPI (1.25 mg) was dissolved in 25 μL of a solution of laminin-derived peptides (0.8 mM/peptide). After 10 min, the solution was sterilized via centrifugation filtration using an Ultrafree MC sterile centrifugal filter (0.22 μm; Millipore, Billerica, MA) and 25 μL of filter-sterilized peptide cross-linker (27 mg/mL) was added. The solution was vortexed, transferred to a mold and incubated overnight at 37 °C.

Hydrogels were washed for 1 week with daily changes with DMEM supplemented with 10% FBS, 2 mM L-glutamine, and 50 units/mL penicillin/50 mg/mL streptomycin at 37 °C to remove any unreacted laminin-derived peptides or any leachables. The medium collected daily was pooled together and store at 4 °C. The collected medium was mixed with fresh culture medium (DMEM supplemented with 10% FBS, 2 mM L-glutamine, and 50 units/mL penicillin/50 mg/mL streptomycin) in order to have sufficient volume for cell culture (25% diluted in DMEM).

Embryonic day (E)15 dissociated rat DRG neurons were isolated from embryonic day 15 (E15) rats as reported in Supporting Information. NIH-3T3 fibroblast cells and DRGs were exposed to the tested gel extracts at 37 °C (50 ng/ mL nerve growth factor (NGF; Invitrogen Corp.) was added for DRGs), plated on collagen-coated 96-multiwell black-wall clear-bottom plate, and cultured up to 3 days (1 plate/day) at 37 °C. Cells were also cultured into medium without extract as control. Samples were prepared in dodecaplicate. Once a day, cell culture was terminated and cell viability was assessed using the CellTiter-Glo assay.

Cell Adhesion. On the basis of previous results (*42*), cell adhesion was briefly investigated using laminin-derived peptides, CDPG*YIGSR* and CQAAS*IKVAV*. The cell-adhesive peptides were introduced into the hydrogel to promote cellular adhesion. Dex-PMPI (0.88 mg) was dissolved in 17.5 μL of a solution of cell-adhesive peptides (0.8 mM/ peptide). The solution was vortexed for 10 min and sterilized via centrifugation filtration, and 17.5 μL of filter-sterilized peptide cross-linker (27 mg/mL) was added. The solution was vortexed and transferred to the bottom of well of a 96-multiwell half-area plate and incubated overnight. Hydrogels were washed for 1 week with culture medium (DMEM supplemented with 10% FBS, 2 mM L-glutamine, and 50 units/mL penicillin/50 mg/mL streptomycin) at 37 °C to remove any unreacted laminin-derived peptides.

NIH-3T3 fibroblast cells and DRGs were cultured separately at 37 °C in culture medium. NGF (50 ng/mL) was added to the culture medium used for DRGs. Cells were plated onto the gels at a cell density of 3200 cells/gel. Cells were incubated at 37 °C for 2 days and then fixed in 3.7% formaldehyde for 20 min, rinsed with HBSS, and incubated in 0.1% Triton X-100 for 90 s. Finally, each well was rinsed with HBSS and incubated for 20 min in Alexa Fluor 488 phalloidin (Molecular Probes, Burlington, ON) solution (5 μL in 200 μL of HBSS). The phalloidin solution was replaced with HBSS, and the samples were stored at 4 °C until viewed under fluorescent microscopy. Samples were visualized with a Ziess Axiovert 100 inverted microscope (Carl Zeiss Canada Ltd., Toronto, ON), and images were captured using a digital camera.

Statistics. The statistics were performed with commercially available software program SigmaStat 3.11 (Systat Software Inc., Richmond, CA). All experimental results are reported as mean ± 95% confidence interval. For multiple comparisons, one-way ANOVA was performed using Bonferroni *t*-test as posthoc test. Student's *t*-test was used to make pairwise comparisons. In all tests a *p*-value of <0.05 was regarded as significant.

RESULTS

Synthesis of PMPI-Derivatized Dextran. The heterobifunctional linker PMPI, introduced by Annunziato et al. (*48*), has been used to modify biomolecules (*48*) and PEG (*49*−*51*). In this project, it was used to derivatize natural polymers such as dextran for the purpose of forming hydrogels. Here, dextran reacts with PMPI in DMSO in the presence of the DBTDL as catalyst (Figure 1A). The successful conjugation of PMPI to dextran was confirmed by the FTIR spectrum of the Dex-PMPI adduct, which indicated the formation of carbamate linkages (1714, 1519, and 1232 cm^{-1}) and the disappearance of the isocyanate peak (2275 cm^{-1}). The ^1H NMR spectrum for Dex-PMPI showed distinctive peaks: the anomeric proton of the dextran glucopyranosyl ring at δ 5.0 ppm (singlet), the PMPI group at 7.0 ppm (singlet) for the maleimide carbon−carbon double bond, and at 7.4 ppm (doublet) and 7.6 ppm (doublet) for the aromatic protons. The DS of PMPI coupled to dextran was quantitatively determined using the integrated areas of the relevant chemical shifts, according to eq 1.

The coupling reaction between dextran and PMPI was studied in the presence of different amounts of DBTDL at either 25 °C or 45 °C for 4 h or 24 h. As shown in Table 1, successful coupling required the DBDTL catalyst, without which no or little product formation was observed. Under identical reaction conditions at 4 h and 25 °C, the coupling yield of 0% without DBTDL increased to 15% with 30 μL of DBTDL. The importance of DBTDL was further confirmed when the reaction was repeated at 45 °C; the yield increased from 14% to 58% in the presence of 15 μL of DBTDL. At a temperature of 25 °C and in presence of 30 μL of DBTDL, the coupling yield increased from 15% to 33% when the reaction time was extended from 4 to 24 h. The optimum coupling yield was obtained after reaction for 24 h at 45 °C in the presence of a minimum of 30 μL of DBTDL, which yielded DEX-PMPI with a DS of 10 or 20 depending on the initial amount of PMPI used. These reaction conditions were used to synthesize DEX-PMPI DS10 (hereafter referred as Dex-PMPI), which was used for the remaining studies.

Hydrogel Formation and Hydrolytic Stability. Dextran hydrogels were first formed by cross-linking Dex-PMPI with PEG-dithiol via Michael-type addition. The PEG-dithiol was a useful model system to test the cross-linking system and the hydrolytic stability of the resulting hydrogels. The concentration of polymeric precursors was found to affect the rate of gelation: 20% Dex-PMPI gelled within seconds, whereas 2.5% Dex-PMPI only gelled after several minutes. The hydrogels were allowed to swell in PBS, and their WC was followed over 15 days (according to eq 2) during which time the WC was found to be constant at 94.9 ± 0.2%. No excessive swelling was observed, suggesting that the cross-linked gels were hydrolytically stable.

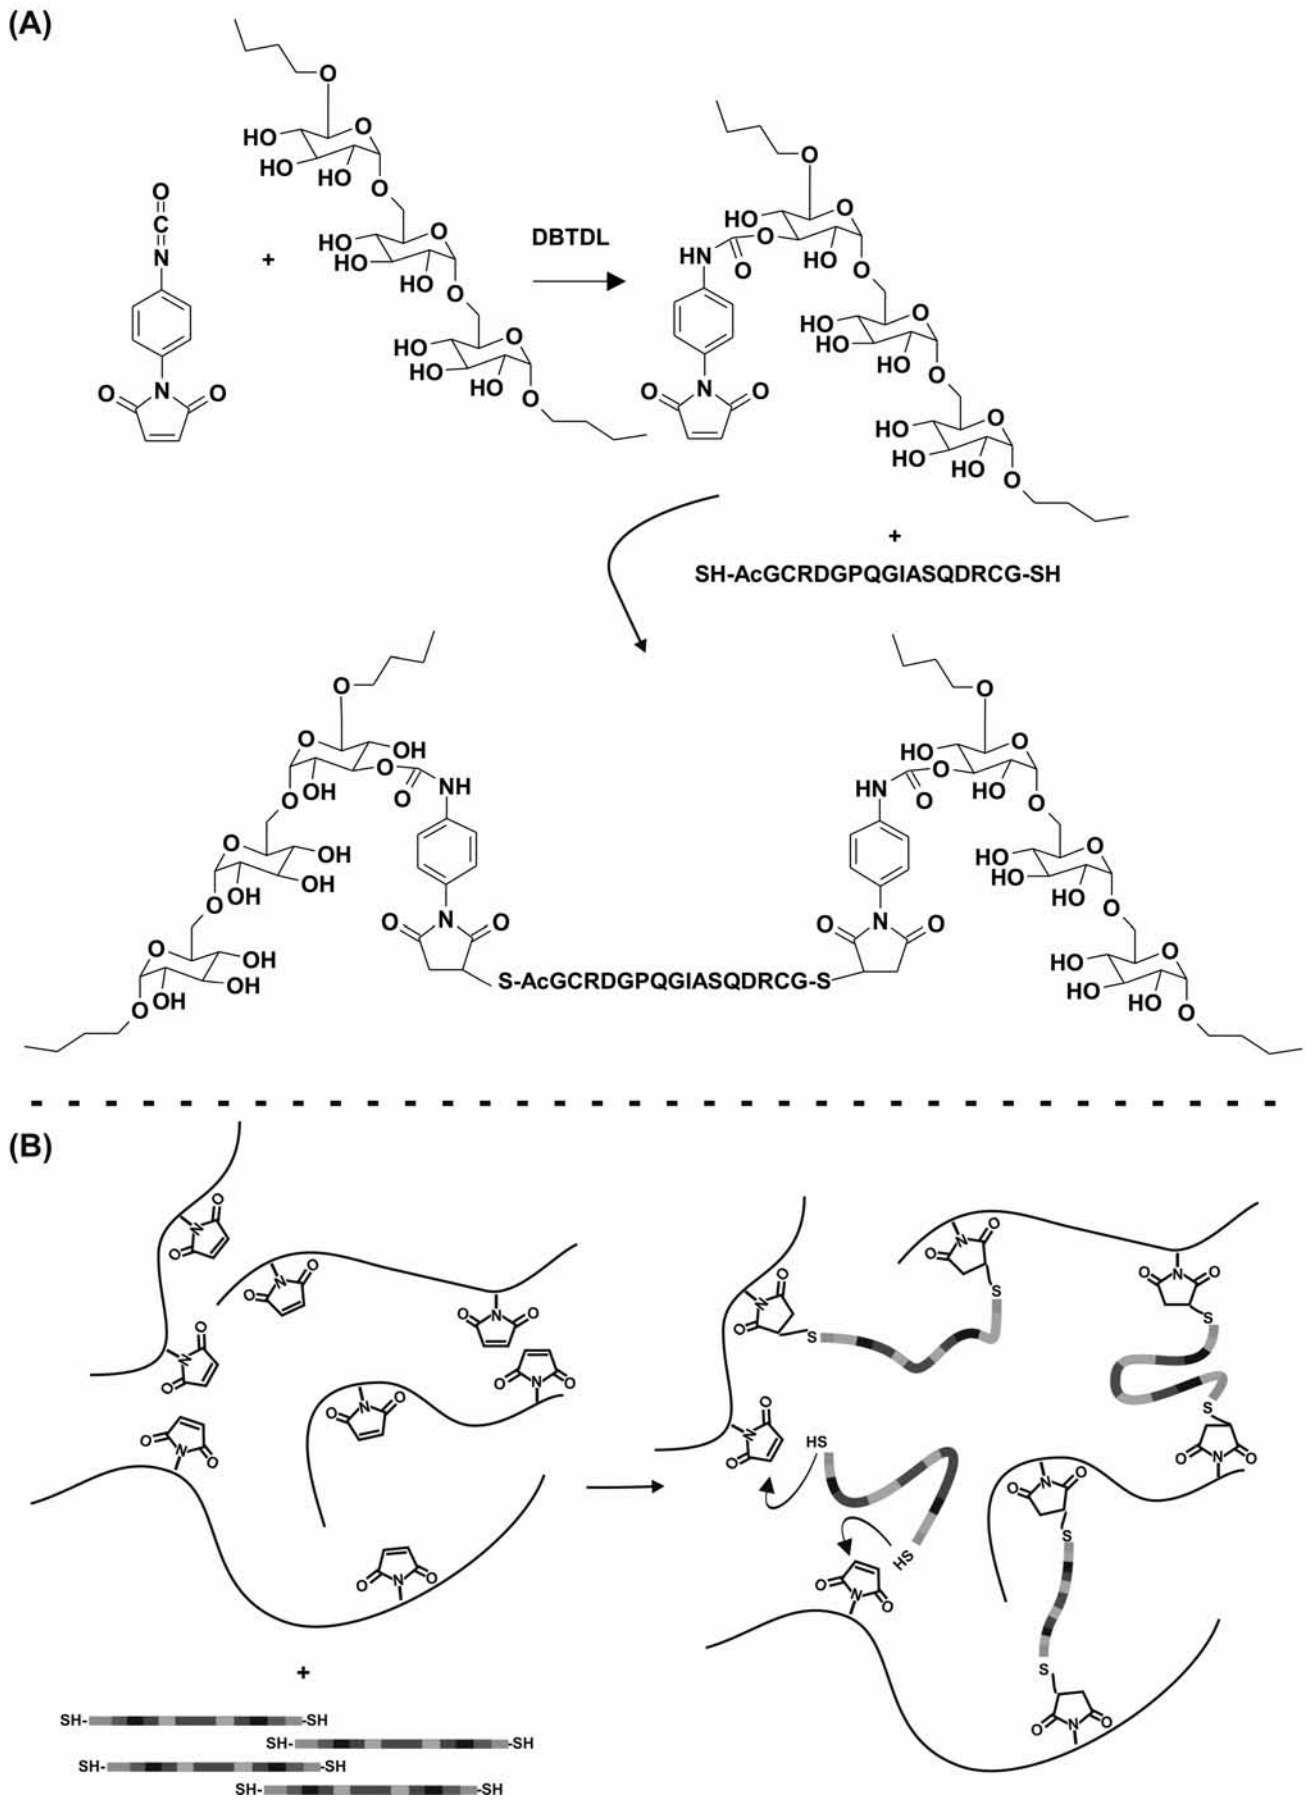

Figure 1. (A) Reaction of dextran with *p*-maleimidophenyl isocynate (PMPI) and (B) preparation of dextran-peptide hydrogel through the Michael-type reaction of peptide cross-linker to Dex-PMPI.

Table 1. Reaction Conditions for the Coupling of PMPI to Dextran

theoretical DS (%)	exptl DS (%)	DBTDL (mL)	time (h)	*T*, °C	coupling yield (%)

Table 2. Degradation Kinetics of Soluble Peptides by MMP-2

peptide	k_{cat}/K_M, $M^{-1}\,S^{-1}$	k_{cat}, S^{-1}	K_M, μM
GPQGIASQ	583[a]	2[a]	3400[a]
GPQGPAGQ	<9[a]	ND[b]	ND[b]
GCRD**GPQGIASQ**DRCG	2591 ± 570[c]	0.47 ± 0.21[c]	189 ± 106[c]
GCRD**GPQGPAGQ**DRCG	20 ± 13[c]	ND[c]	ND[c]

[a] ND, not determined. [b] Netzel-Arnett, S., Sang, Q.-X., Moore, W., et al. (1993) *Biochemistry 32*, 6427−6432. [c] ±95% confidence interval (n = 3).

The hydrolytic stability of the dextran hydrogel cross-linked with dithiol peptides was similarly analyzed by evaluating the NW_h of 20% Dex-MA or Dex-PMPI hydrogels cross-linked with the peptide GCRD**GPQGIASQ**DRCG over a 200-day period (Figure 2). The Dex-PMPI-peptide hydrogel swelled to 2.25 times its original mass within the first 20 days and then did not change appreciably for the remaining 200 days, demonstrating the hydrolytic stability of these hydrogels. Both the thioether obtained by the conjugate addition of the thiol to the maleimide and the carbamate formed by coupling PMPI to dextran were resistant to hydrolysis. In contrast, Dex-MA-peptide hydrogel swelled to 3.25 times of their original mass within the first 8 days and then completely dissolved on day 9 due to the hydrolysis of glycidyl-methacrylate esters in Dex-MA.

Degradation of Soluble Peptide Cross-Links. As reported by Netzel-Arnett et al. (*43*), the **GPQGIASQ** sequence, derived from the calf and chick α1 (I) collagen chain, is highly sensitive to hydrolysis by MMP-2, whereas **GPQGPAGQ**, with Ile and Ser substituted by Pro and Gly, respectively, has low sensitivity (Table 2). Both peptides were extended on each terminus with the tetrapeptide sequence GCRD to improve solubility and to introduce the thiol groups required for cross-linking (*3*). The kinetic parameters for MMP-2 degradation of the peptides with and without GCRD were determined by Michaelis−Menten analysis. Substrate degradation was followed by measuring the fluorescence of fluorescamine adduct fragments of the peptide cleavage reaction ($\lambda_{excitation}$ = 387 nm, $\lambda_{emission}$ = 480 nm) and the kinetic parameters k_{cat}, K_m and k_{cat}/K_M were obtained using Lineweaver−Burk plots (eq 2S, Supporting Information) and by plotting the initial rate versus the product between the enzyme and substrate concentrations (eq 3S, Supporting Information). As it was previously reported (*3*), elongating the peptide sequence up to the P8 position changed the kinetic parameters and improved both the catalytic efficiency (i.e., higher k_{cat}/K_M) and the substrate affinity (i.e., lower K_M). As shown in Table 2, elongation of the peptide sequences with GCRD fragments led to a greater than fourfold increase in k_{cat}/K_M for GCRD**GPQGIASQ**DRCG and more than doubled the k_{cat}/K_M for GCRD**GPQGPAGQ**DRCG. Despite the increase in k_{cat}/K_M values, the higher MMP-2 cleavage efficiency for **GPQGIASQ** relative to **GPQGPAGQ** was maintained, with GCRD**GPQGIASQ**DRCG having a k_{cat}/K_M 2 orders of magnitude larger than that for GCRD**GPQGPAGQ**DRCG.

Enzymatic Degradation. *Collagenase Degradation.* Collagenase-mediated degradation of 20% Dex-PMPI-GCRDGPQGIASQDRCG cross-linked hydrogels was followed by monitoring the hydrated mass of the hydrogel over time and compared to two controls: (1) identical hydrogels without collagenase and (2) a redox-polymerized poly(Dex-MA) hydrogel exposed to the same amount (2 ng/mL) of bacterial collagenase. As shown in Figure 3, dextran-peptide hydrogels degraded completely after 30 h of incubation with collagenase whereas without collagenase, the mass increased to a NW_h of 1.2, demonstrating swelling but no degradation. These data demonstrate that the dextran-peptide hydrogels degraded only by an enzymatic process. Moreover, poly(Dex-MA) hydrogels obtained by redox polymerization did not degrade when exposed to collagenase, demonstrating that dextran-peptide hydrogels degrade by collagenase cleavage of the peptide cross-link and not the dextran backbone.

MMP-2 Degradation. MMP2-mediated degradation of the dextran-peptide hydrogels was assessed using a fluorimetric assay. Hydrogels were synthesized with 5% Dex-PMPI cross-

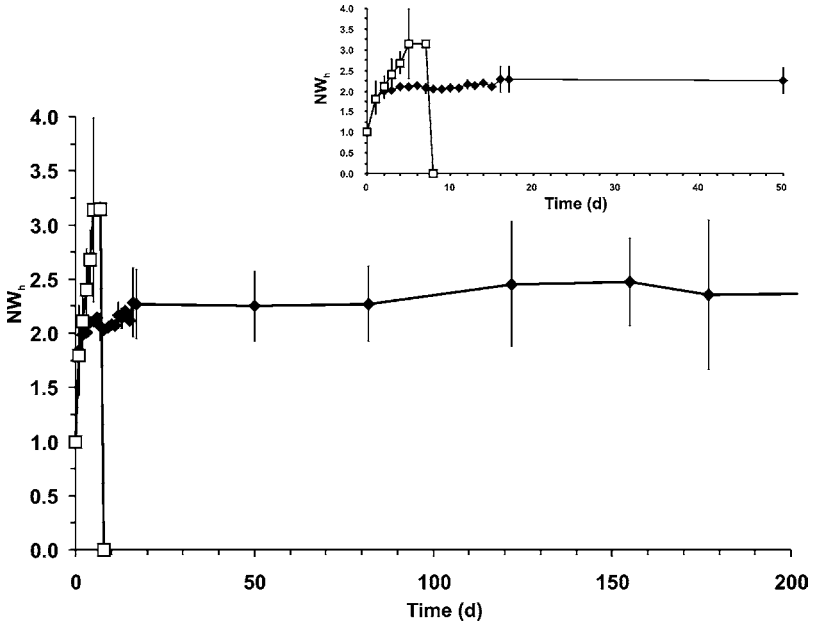

Figure 2. Hydrolytic stability of water dextran-peptide hydrogels; normalized hydrogel weight (NW_h) of 20% dextran-peptide hydrogels cross-linked through conjugate addition **GPQGIASQ** peptides to (□) Dex-MA and (◆) Dex-PMPI (n = 3, mean ± 95% confidence interval).

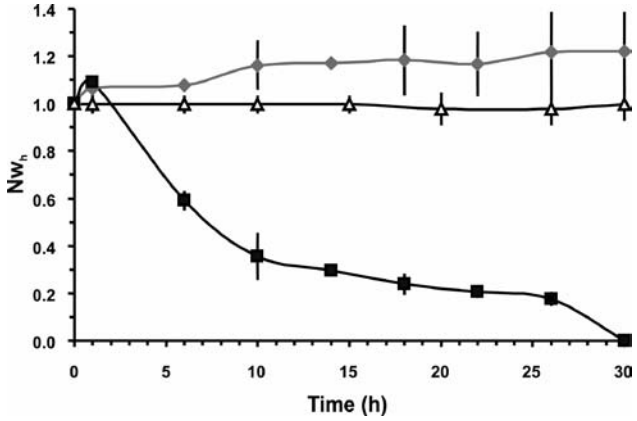

Figure 3. Bacterial collagenase degradation of dextran-peptide hydrogels; normalized hydrogel weight (NW_h) of (grey diamond) 20% dextran-peptide, no collagenase, (■) 20% dextran-peptide, 2 ng/mL collagenase, (△) 20% poly(Dex-MA) by redox polymerization, 2 ng/mL collagenase (peptide = GCRD**GPQGIASQ**DRCG, $n = 3$, mean ± 95% confidence interval).

linked with GCRD**GPQGIASQ**DRCG. During hydrogel preparation, CGK-Mca and GCRD**GPQGIASQ**DRGK-FAM peptides were added in order to follow hydrogel degradation/dissolution by Mca fluorescence ($\lambda_{excitation} = 340$ nm, $\lambda_{emission} = 405$ nm) independently of cross-link cleavage (measured by FAM fluorescence; $\lambda_{excitation} = 494$ nm, $\lambda_{emission} = 521$ nm) in the supernatant, assuming that the cross-link peptides and FAM-modified peptides degrade at similar rates. Hydrogels were incubated with 40 nM MMP-2, and the fluorescence of the supernatant was followed overtime. As shown in Figure 4, there was 100% release of both fluorophores and complete dissolution of the hydrogels after 16 days of incubation, which corresponds to the plateau observed in Figure 4. There was a near-linear increase in the release of the fluorescent **IASQ**DRGK-FAM fragment into the degradation medium from dextran-peptide hydrogels due to MMP-2 digestion. Fluorescent dextran-CGK-Mca was released at a slower rate until close to the end of the incubation period, indicating that a substantial amount of cross-links must be digested prior to dextran dissolution. The dextran-peptide hydrogels appeared to decrease in size during degradation, suggesting a surface erosion process. The same experiment was repeated with dextran hydrogels cross-linked with GCRD**GPQGPAGQ**DRCG, the peptide with low sensitivity to MMP-2, and modified with GCRD**GPQGPAGQ**DRGK-FAM to examine MMP-2 susceptibility (Figure 5). The degradation experiment with GCRD**GPQGPAGQ**DRCG was pursued for 7 days due to the low enzyme sensitivity of the cross-links. As shown in Figure 6, the release of the fluorescent **PAGQ**DRGK-FAM fragment was significantly slower than that of **IASQ**DRGK-FAM, confirming the higher sensitivity to cleavage by MMP-2 for GCRD**GPQGIASQ**DRCG compared to GCRD**GPQGPAGQ**DRCG in the cross-linked hydrogel. Moreover, this demonstrates that the rate of peptide-cross-linked dextran hydrogel degradation can be controlled by the choice of peptide cross-link and enzyme affinity.

Cytotoxicity Assay. The cytotoxicity of dextran and Dex-PMPI DS 10 with Mw of 6 kDa and 40 kDa was investigated by incubating cells in presence of soluble polysaccharides in the medium solution. Dextran and Dex-PMPI solutions were incubated with fibroblast cultures for 2 days at concentrations up to 10 mg/mL (Figure 7). The cytotoxicity was assessed by determining the presence of metabolically active cells by quantifying the amounts of ATP present. It was previously reported that the amount of ATP is directly proportional to the number of cells present in culture (*47*). As shown in Figure 7A, the presence of dextran 6 kDa and 40 kDa in the medium did not significantly impede the metabolic activity of the cultured fibroblasts. These results suggest that the polysaccharide, under its natural form, is not cytotoxic for the molecular weights and concentrations investigated. By contrast, as shown in Figure 7B, increasing the concentration of Dex-PMPI 6 kDa or 40 kDa in the culture medium to 1 mg/mL and 10 mg/mL resulted in a significant decrease in the production of ATP ($p < 0.001$ and $p = 0.049$ for 1 mg/mL and $p < 0.001$ for 10 mg/mL). This indicates that, above a Dex-PMPI concentration

of 1 mg/ mL, the maleimide functionalities covalently immobilized to the dextran backbone can affect the cellular activity and even lead to some cytoxicity.

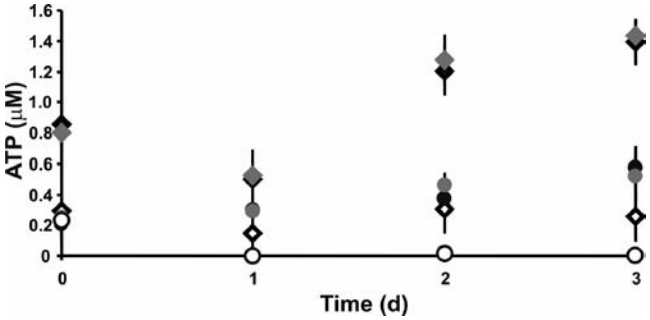

Figure 8. Cell viability of 3T3 cells and DRG neurons exposed to hydrogel extracts; control: ◆ 3T3, ● DRG, extracts from Dex-PMPI cross-linked with GCRD**GPQGIASQ**DRCG: (tilted gray square) 3T3, (gray circle), extracts from Dex-PMPI cross-linked with GCRD**GPQGIASQ**DRCG and immobilized CDPG*YIGSR* and CQAAS*IKVAV*: (grey square) 3T3, (grey circle) DRG (cell viability is expressed in ATP production) ($n = 12$, mean ± 95% confidence interval).

The cytotoxicity of polysaccharide-based hydrogels was studied by exposing fibroblasts and DRGs respectively to culture medium containing extracts of Dex-PMPI hydrogels cross-linked with GCRD**GPQGIASQ**DRCG. Two sets of hydrogels were used for the extraction assay; in one set, the hydrogels were simply Dex-PMPI cross-linked with GCRD**GPQGIASQ**DRCG, and in the second set, the hydrogels were cross-linked with the same peptide but also contained CDPG*YIGSR* and CQAAS*IKVAV* as cell-adhesive peptides. Both sets of hydrogels were extracted in cell culture medium for 7 days at 37 °C, and the extracts were incubated with fibroblast and DRG cultures for 3 days. Again the cytotoxicity was assessed by quantifying the amounts of ATP present. As seen in Figure 8, when compared to the controls, no cytotoxicity was detected from Dex-PMPI hydrogel extract, indicating that an insufficient amount of unreacted Dex-PMPI or peptide cross-linkers diffused from the hydrogels to cause any significant cytotoxicity to the fibroblasts or DRGs. The metabolic activity of 3T3 cells and DRG neurons significantly decreased when exposed to extracts obtained from hydrogels containing laminin-derived peptides. These results indicate that the cytotoxicity was probably caused by unreacted laminin-derived peptides binding and saturating the cell-surface receptors, thus interfering with the cell adhesion mechanism required for survival of these anchorage-dependent cells. These results are important because they underline the importance of thoroughly washing the hydrogels prior to cell culture.

Cell Culture. Cell adhesion of NIH-3T3 fibroblast cells and primary chick DRG neurons was investigated on MMP-degradable dextran hydrogels. Dex-PMPI hydrogels were modified with laminin-derived peptides CDPG*YIGSR* and CQAAS*IKVAV* to provide a cell-adhesive substrate to the cells and cross-linked with GCRD**GPQGIASQ**DRCG. As shown in Figure 9, both fibroblasts and DRGs adhered, respectively, to dextran-peptide hydrogels containing the laminin-derived peptides but did not adhere to hydrogels lacking cell-adhesive peptides. This was not surprising given the high water content of dextran hydrogels, which are known to be non-cell adhesives (*27*, *33*, *34*) and based on the results previously (*42*). Imaging was difficult due to the uneven surface of the hydrogels.

DISCUSSION

Since the first MMP-sensitive telechelic peptide-PEG-peptide block copolymers were developed by West and Hubbell (*16*), polymers such as PEG and poly-*N*-isopropylacrylamide have been used to develop other MMP-degradable hydrogels (*3*, *4*, *17*). In the present study, a MMP-degradable dextran was synthesized and characterized. Dextran is the first naturally derived polymer to be tested for this type of application and is particularly compelling because it is inherently nonadhesive to

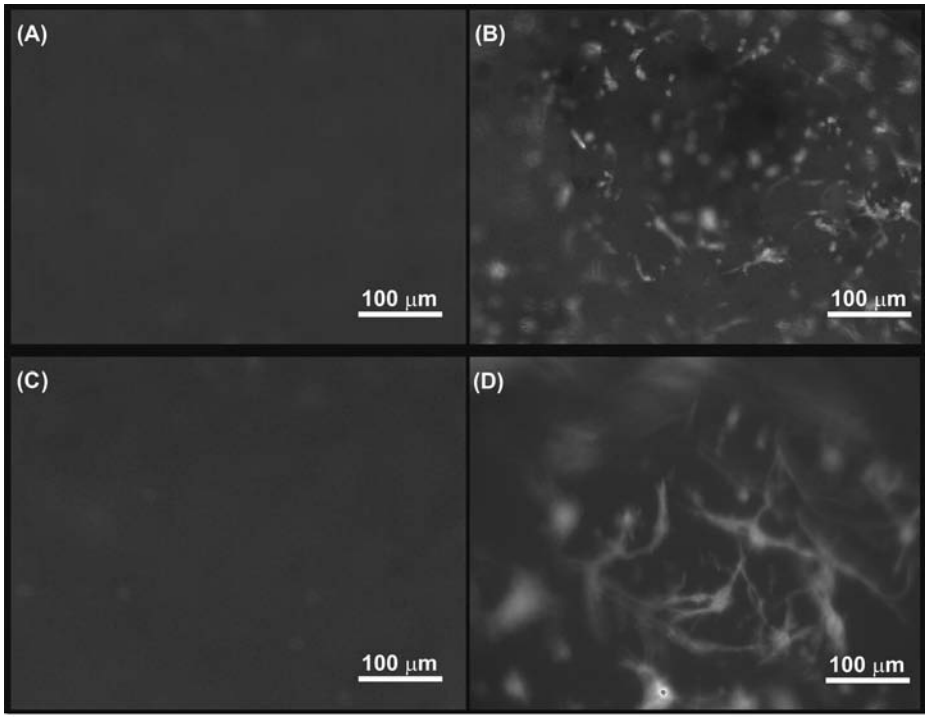

Figure 9. Cellular adhesion of NIH-3T3 fibroblast cells and DRG neurons to dextran-peptide hydrogels. Representative images of (A) NIH 3T3 fibroblasts cultured on unmodified dextran-peptide hydrogel demonstrates no visible adherent cells, (B) NIH 3T3 fibroblasts cultured on dextran-peptide hydrogel containing laminin-derived peptides after 2 days in vitro (2×10^5 cells/cm^2 were plated), (C) DRGs plated on unmodified dextran-peptide hydrogel demonstrate no visible adherent cells, and (D) DRGs cultured on dextran-peptide hydrogels containing laminin-derived peptides after 2 days of culture (2×10^5 cells/cm^2 were plated).

proteins (*31*, *32*) and cells (*27*, *33*, *34*), allowing cell adhesion to be "dialed-in" with peptide modification. In addition, dextran has multiple functional hydroxyl groups available for derivatization and conjugation. For example, there are significantly more reactive functional groups on dextran than on a multiarm PEG. Dextran 40 kDa derivatized to a DS of 10 has approximately 25 modified hydroxyls per polysaccharide molecule, whereas commercially available modified four-arm PEG has 4 reactive hydroxyls per molecule. These multiple sites allow efficient covalent modification with ECM-derived peptides to promote cellular adhesion or to immobilize bioactive molecules, such as growth factors, without having a significant impact on the degree of cross-linking required for gelation.

There have been several studies on dextran bioconjugation. However, most of these methods are either two-step conjugation procedures, such as carboxymethylation followed by carbodiimide conjugation (*52*) or periodate oxidation followed by Schiff base reaction (*53*, *54*), or introduce hydrolyzable esters, such as meth(acrylates) (*55*−*57*). The dextran derivatization method described here with PMPI is a one-step reaction which introduces a stable carbamate bond and a maleimide group for Michael-type addition.

Prior to this work, PMPI had been primarily used to modify bioactive molecules (*48*) and PEG (*49*−*51*) or to immobilize biomolecules such as proteins (*48*), DNA (*58*), or oligonucleotides (*51*) on surfaces. In unpublished work, we have also extended the utility of this cross-linking agent to other polymers, including four-armed PEG-PMPI and PMPI-derivatized methylcellulose, demonstrating broad applicability as a heterobifunctional agent for hydrogel applications through Michael-type addition. Moreover, by using the DBTDL catalyst common in the polyurethane literature (*59*, *60*), we were able to achieve high yield for PMPI modification of dextran (Table 1). The Dex-PMPI cross-linked hydrogels were shown to be hydrolytically stable, demonstrating that the peptide dictates the degradation rate.

GPQGIASQ, an eight-amino-acid sequence derived from the α1 (I) collagen chain of calf and chick, was selected as the MMP substrate (*43*, *44*). Many MMPs, such as MMP-1, MMP-2, MMP-3, MMP-7 MMP-8, and MMP-9, can cleave this peptide at the Gly-Ile bond; however, MMP-2 has the greatest digestive efficiency (*43*, *44*). **GPQGPAGQ** was selected as a control because it has been reported to have little degradation sensitivity to most MMPs (*43*, *44*). Nagase et al., in studying the human MMP specificity using collagen-derived synthetic peptides, have assembled a database of more than 45 peptide sequences that have different degrees of sensitivity to MMP digestion (*44*). They reported that the efficiency of peptide hydrolysis varied for different MMPs, giving sequences that were more or less susceptible to cleavage by collagenases, gelatinases, matrilysins, or stromelysins. The kinetic characteristics of the 16-amino-acid GCRD-capped sequence used in this study follow the trend of their respective 8-amino-acid sequences (Table 2). On the basis of these data and on the synthetic peptide database built by Nagase et al., MMP-sensitive hydrogels can be designed to have higher affinity for one or more specific MMPs and this can be used, in turn, to control hydrogel degradation.

MMPs are highly involved in ECM remodeling processes such as tissue morphogenesis and wound healing. They are expressed following spinal cord injury and recent data suggest a beneficial role for MMP activity following SCI (*5*, *9*). Enzyme-degradable hydrogels susceptible to MMP digestion have been previously investigated for bone, cartilage, and vascular applications where they are postulated to provide greater control over tissue regeneration. The MMP-sensitive hydrogels described in this report were designed for neural tissue-engineering applications and may be useful for investigating the mechanisms of cell migration and/or axonal outgrowth.

The Dex-PMPI-peptide hydrogel was found to degrade under the actions of both bacterial collagenase and MMP-2, as shown through the wet mass variation and the release of fluorophores

into solution, respectively. Although hydrogels were exposed to lower concentration of bacterial collagenase than MMP-2, they degraded significantly more rapidly. This faster rate of degradation when exposed to bacterial collagenase likely reflects the fact that bacterial collagenases, unlike mammalian collagenases, are more active and less specific in cleaving collagen (*61*). As reported previously by Hennink and co-workers, the swelling behavior of dextran hydrogels degrading through bulk degradation is characterized by hydrogel swelling followed by rapid dissolution (*62*). It is believed that during bulk degradation, the cross-links are cleaved throughout the hydrogel to a point where the dextran chains only bear about two cross-links per chain, and further degradation of the cross-links results in the rapid disintegration of the hydrogel to soluble products. Similar observations were reported with MMP-degradable PEG hydrogels (*3*). In this study, hydrogels degraded by bacterial collagenase were characterized by an absence of significant swelling and a progressive mass loss (Figure 3). In addition, as shown in Figure 4, hydrogel degradation mediated by the activity of MMP-2 is accompanied by a continuous and progressive release of soluble dextran. These observations suggest proteolytic degradation of dextran-peptide hydrogels by a predominantly surface-erosion mechanism rather than by bulk degradation, which has been reported for MMP-degradable PEG hydrogels.

Interestingly, the activity of MMP-2 toward the **GPQGIASQ** sequence is 2 orders of magnitude greater than toward the **GPQGPAGQ** sequence for soluble peptides (Table 2). The difference in rates of hydrogel degradation by MMP-2 appear to be much closer for the respective dextran-peptide hydrogels (Figure 6). Under their soluble form, the peptides are very mobile and can adopt a conformation that will facilitate binding and cleavage by MMP-2. Once immobilized within the hydrogel, they likely lose some of this mobility. Moreover, the hydrogel degradation seems to be predominantly driven by surface erosion, thus limiting the access of MMP-2 to the surface of the hydrogel.

This study focused on preparing a new type of MMP-sensitive dextran-based hydrogel which could be used in neural tissue engineering. Although, many MMPs have been reported to be present following spinal cord injury and are believed to have a beneficial role in the healing process, MMP-2 was selected as a model enzyme. Along with previous observations reported by other groups (*3*, *4*, *63*−*65*) and our results, the degradation rate of the hydrogel can be tailored by enzyme specificity to the peptide sequence.

As reported, the gelation of Dex-PMPI hydrogels through Michael-type reaction is very fast, which may be advantageous for *in situ* gelation. Dex-PMPI was found to be non-cytotoxic as monomers at concentrations lower than 1 mg/mL. In addition, following gelation, the amount of un-cross-linked Dex-PMPI leaching out of the hydrogel was insufficient to cause any cytotoxicity. As shown in Figure 8, unreacted peptides leaching out of the Dex-PMPI hydrogel impeded cell viability. To pursue the *in situ* gelation use, peptide purification techniques have to be refined in order to improve the purity of peptides containing reactive thiols and optimized peptide immobilization.

Given that neural cells produce MMP-2 after injury and that MMP-2 degrades the dextran-peptide scaffolds, we were interested in cellular activity on the hydrogels and specifically cell adhesion. MMP-degradable hydrogels require the presence of cell-adhesive peptides for cell adhesion, survival, and ultimately invasion into the network (*17*, *65*, *66*). These data, coupled with previous reports, prompted us to explore modification of dextran-cross-linked hydrogels with laminin-derived peptides. Results reported previously showed that dextran hydrogels modified with CQAAS*IKVAV* and CDPG*YIGSR* promote greater adhesion of DRG neurons than those hydrogels modified with CG*RGD*S (*42*). Interestingly, both NIH-3T3 and DRG cells adhered and survived when plated on dextran-peptide hydrogels modified with these laminin-derived peptides. Just as the cross-link density influenced the cell invasion (*3*), the ECM-peptide modification for cell adhesion must be optimized for cell migration (*3*, *17*) and neurite outgrowth (*67*, *68*). Interestingly, ECM peptides may also be manipulated to promote the expression of the MMPs (*69*).

CONCLUSIONS

MMP-sensitive dextran hydrogel systems were synthesized using peptide cross-linkers to control the rate of MMP-2 degradation and susceptibility to proteolytic remodeling. We have reported a new method to conjugate dextran through the use of the heterobifunctional PMPI molecule. Dextran-peptide hydrogels synthesized with Dex-PMPI degraded when incubated in the presence of bacterial collagenase or MMP-2 through enzymatic digestion of the peptide cross-links. Laminin-derived peptide-modified dextran hydrogels promoted cell adhesion and survival, allowing questions of cell-mediated expression of MMP for cell-based degradation to be pursued.

ACKNOWLEDGMENT

We are grateful to Ying Fang Chen for the cell culture experiments, to Dr. Nam-Chiang Wang for his advice on peptide synthesis (Advanced Protein Technology Centre, The Hospital for Sick Children, Toronto), and to Dr. Ying Yang and Dr. Ling Xu for the mass spectrometer analyses (Proteomics and Mass Spectrometry Centre, Medical Sciences Building, University of Toronto, Toronto, ON). We thank the Natural Sciences and Engineering Research Council of Canada (MSS), the Advanced Regenerative Tissue Engineering Center (an ORDCF-funded center), Matregen Corp., and the Fonds québécois de la recherche sur la nature et les technologies (SGL) for financial support.

New Triphosphate Conjugates Bearing Reporter Groups: Labeling of DNA Fragments for Microarray Analysis

Ludmila A. Alexandrova, Maxim V. Jasko, Elena E. Belobritskaya, Alexander V. Chudinov, Olga N. Mityaeva, Tatyana V. Nasedkina, Alexander S. Zasedatelev, and Marina K. Kukhanova*

Engelhardt Institute of Molecular Biology, Russian Academy of Sciences, 32 Vavilov Street, Moscow 119991, Russian Federation. Received July 14, 2006; Revised Manuscript Received January 17, 2007

A simple and convenient method for incorporation of fluorescent or ligand groups into 3′-termini of DNA fragments is proposed. A set of triphosphoric acid monoesters bearing fluorescent groups or biotin attached to the triphosphate fragment through linkers of different lengths and structures was synthesized. All the compounds were substrates for calf thymus terminal deoxynucleotidyltransferase and were used for incorporation of marker groups into 3′-termini of DNA fragments. The compounds were successfully applied for DNA labeling during post-PCR target preparation for microarray analysis.

INTRODUCTION

Non-radioactive labeled DNA and deoxyoligomers bearing different marker groups such as fluorescent dyes, biotin, or photo-cross-linking reagents are widely applied in molecular biology, biotechnology, and medicine. They are used as hybridization probes in medical diagnostics of hereditary diseases, detection of infectious agents, identification of individuals in forensic testing, and for high throughput genetic analysis. DNA fragments joined to marker groups can be synthesized by either enzymatic or chemical methods (*1*−*7*). Chemical methods yield as a rule oligomers with functional groups easily modified with markers, but they can neither guarantee regiospecificity nor high efficacy. Efficient and base-specific DNA labeling can be ensured by using dNTP analogues bearing marker groups in the reactions catalyzed by either template-dependent DNA polymerases or template-independent calf thymus TdT[1] [EC 2.7.7.31] (*1*, *2*). However, a set of labeled and biologically active dNTP analogues that display substrate properties for these enzymes is very limited. Recently it was shown that monoesters of triphosphoric acid bearing bulky substituents were substrates for both template-independent calf thymus TdT (*8*−*10*) and template-instructed DNA polymerses (*11*). The efficacy of incorporation of such triphosphates into the oligomer 3′-ends depends on the nature of substituents and the length of linker between the triphosphate residue and the marker group.

Herein, we developed a simple and convenient method for the introduction of fluorescent groups or biotin into DNA fragments during post-PCR target preparation for microarray analysis. We synthesized triphosphates bearing different marker groups attached to the triphosphate moiety through different linkers and showed that they are effective substrates for TdT and could be used for DNA labeling.

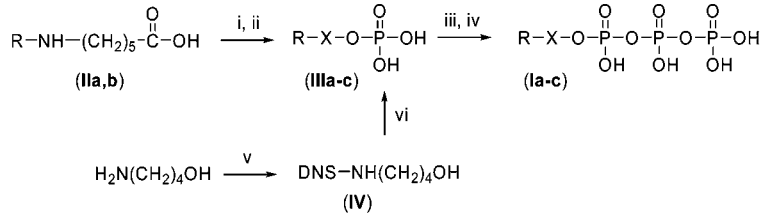
[1] Abbreviations: Bio, biotinyl; Bio-dUTP, 5-(3-*N*-biotinylaminopropen-1-yl)-2′-deoxyuridine 5′-triphosphate; CDI, 1,1′-carbonyldiimidazole; Cy5-dUTP, 5-aminopropargyl-2′-deoxyuridine 5′-triphosphate coupled to Cy5 fluorescent dye; DBI, 3-(4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-*s*-indacene-2-yl)propionyl; DNP, 2,4-dinitrophenyl; DNS, 5-*N*,*N*-dimethylamino-1-naphthalenesulfonyl (dansyl); DSC, *N*,*N*′-disuccinimidyl carbonate; Fmoc, 9-fluorenylmethoxycarbonyl; Flu, fluoresceinyl; RdB, rhodaminyl; TdT, terminal deoxynucleotidyltransferase; PAAG, polyacrylamide gel.

EXPERIMENTAL PROCEDURES

Chemicals. 2-Aminoethyl dihydrogen phosphate, dansyl chloride, 2,4-dinitrofluorobenzene, fluorescein isothiocyanate (isomer I), rhodamine B isothiocyanate (mixture of isomers), and *N*-(9-fluorenylmethoxycarbonyloxy)succinimide were purchased from Aldrich; 4-amino-1-butanol, $POCl_3$, CDI, and Dowex 50 Wx8 were obtained from Fluka; LiChroprep RP-18 (23−40 μm) and LiChroprep RP-8 (40−63 μm) were obtained from Merck; DEAE-cellulose DE 32 was from Whatman, Cy5-dUTP and streptavidin conjugated with Cy5 were purchased from Amersham Biosciences. 5-(3-*N*-Biotinylaminopropen-1-yl)-2′-deoxyuridine 5′-triphosphate (Bio-dUTP) was prepared according to the reported procedure (*12*). *N*-(9-Fluorenylmethoxycarbonyl)-8-amino-3,6-dioxaoctanoic and 4-amino-1-butylic esters of triphosphoric acid were obtained similarly to (*8*, *9*). 6-*N*-(5-*N*,*N*-Dimethylamino-1-naphthalenesulfonyl)aminohexanoic acid and 6-*N*-(2,4-dinitrophenyl)aminohexanoic acid were prepared according to the reported procedures (*13*, *14*), respectively.



[γ-^{32}P]ATP (6000 Ci/mmol) was from "Isotop" (Russia); T4 polynucleotide kinase and TdT were purchased from Fermentas (Lithuania). The 18-mer oligonucleotide primer CCGTCAATTCCTGTAGTC was from "Litech" (Russia). The primer was labeled at the 5′-end with T4 polynucleotide kinase using [γ-^{32}P]-ATP (*15*), purified on a Sephadex-G50 spin-column (Amersham Biosciences) and used for elongation reactions. All solvents were purchased from Fluka.

Spectroscopic Analysis. UV spectra were measured in water at pH 7.0 on a UV-vis-2401 P (Shimadzu, Japan) spectrophotometer. ^{1}H NMR spectra were recorded on an AMX III-400 (Bruker) SY spectrometer (Billerica, MA, USA) at 400 MHz with Me_4Si and sodium 3-(trimethylsilyl)propane-1-sulfonate as internal standards for $CDCl_3$ and D_2O solutions, respectively. ^{31}P NMR spectra were recorded at 162 MHz with ^{1}H-decoupling in D_2O if not stated otherwise and 85% H_3PO_4 as an external standard. Chemical shifts (δ) are in ppm and coupling constants (J) are in hertz. MALDI-TOF MS (matrix-assisted laser desorption ionization−time-of-flight mass spectra) were measured using Kompact MALDI 4 (Kratos Analytical, Manchester, U.K.). The fluorescence spectra were registered by a Photon

Technology International spectrofluorimeter (PTI, Canada). Melting points were determined on a Koffler bloc (Dresden, Germany) and uncorrected.

The compounds (Table 1) were synthesized by the methods similar to described previously (*8*−*10*) (Scheme 1, 2).

Synthesis. 2-*N*-[6-*N*-(5-*N*,*N*-Dimethylamino-1-naphthalenesulfonyl)aminohexanoyl]aminoethyl Phosphoric Acid IIIa and 2-*N*-[6-*N*-(2,4-Dinitrophenyl)aminohexanoyl]aminoethyl Phosphoric Acid IIIb. CDI (48 mg, 0.3 mmol) was added to solutions of 6-*N*-(5-*N*,*N*-dimethylamino-1-naphthalenesulfonyl)-aminohexanoic acid **IIa** (55 mg, 0.15 mmol) or 6-*N*-(2,4-dinitrophenyl)aminohexanoic acid **IIb** (44 mg, 0.15 mmol) in dry DMF (3 mL). The reaction mixture was stirred for 1 h at 20 °C and added to a solution of 2-aminoethyl dihydrogen phosphate (28 mg, 0.2 mmol) in water (3 mL) containing Et_3N (20 μL), and the mixture was stirred at 20 °C for 18 h. After dilution with water (50 mL), the mixture was loaded on a DEAE-cellulose (HCO_3^-) column (2 × 9 cm). The column was washed with 20% aqueous MeOH (100 mL) and eluted in a linear gradient of NH_4HCO_3 (0 → 0.3 M) in 20% aqueous MeOH (pH 7.5, total volume 0.6 L). The target fractions were collected, evaporated, and coevaporated with water, and the residues were dissolved in water (1 mL) and purified on a LiChroprep RP-8 column (1.5 × 20 cm) in a linear gradient of

Scheme 2[a]

[a] (i) CH_2═$CHCOOCH_3$, K_2CO_3; (ii) 1. $CH_3C(O)CH_2COOEt$ (**IX**), $NaNO_2$, CH_3COOH, 2. Zn; (iii) NaOH; (iv) $POCl_3$, DMF; (v) HBr, CH_3COOH; (vi) BF_3·OEt_2, iPr_2EtN, THF; (vii) DSC, Py, CH_3CN.

MeOH (0 → 20%, total volume 0.6 L) in 0.01 M NH_4HCO_3 under UV control. The target fractions were freeze-dried to give **IIIa** (28 mg, 53%) or **IIIb** (30 mg, 67%).

2-*N*-[6-*N*-(5-*N*,*N*-Dimethylamino-1-naphthalenesulfonyl)-aminohexanoyl]aminoethyl phosphoric acid IIIa: UV−vis (H_2O, pH 7.0): λ_{max} 333 nm (ϵ = 2500 M^{-1} cm^{-1}), 245 nm (ϵ = 8670 M^{-1} cm^{-1}), λ_{max} 216 nm (ϵ = 21700 M^{-1} cm^{-1}). ^1H NMR (D_2O): δ 8.47 (d, 1H, J = 8.72 Hz, H-2 (DNS)), 8.24 (d, 1H, J = 8.72 Hz, H-4 (DNS)), 8.22 (d, 1 H, J = 6.54, H-8 (DNS)), 7.66 (m, 2H, H-3 + H-7 (DNS)), 7.39 (d, 1H, J = 7.79 Hz, H-6 (DNS)), 3.51 (m, 2H, CH_2O), 3.20 (t, 2H J = 7.17 Hz, CH_2NHCO), 2.89 (t, 2H, J = 6.53 Hz, CH_2NH(DNS)), 2.84 (s, 6H, $(H_3)_2$), 1.80 (t, 2H, J = 7.5 Hz, CH_2CO), 1.08 (m, 6H, $(CH_2)_3$-central). ^{31}P NMR (D_2O): δ 4.50 s.

2-*N*-[6-*N*-(2,4-Dinitrophenyl)aminohexanoyl]aminoethyl phosphoric acid IIIb: UV−vis (H_2O, pH 7.0): λ_{max} 363 nm (ϵ = 17500 M^{-1} cm^{-1}), 265 nm (ϵ = 8340). ^1H NMR (D_2O): δ 8.70 (d, 1H, J = 2.18 Hz, H-3 (DNP)), 7.97 (dd, 1H, J = 2.18 Hz, J = 9.65, H-5 (DNP)), 6.85 (d, 1H, J = 9.65 Hz, H-6 (DNP)), 3.72 (m, 2H, CH_2O), 3.25 (m, 4H, 2 NCH_2), 2.13 (m, 2H, t, J = 7.16 Hz, CH_2CO), 1.51 (m, 4H, $(CH_2)_2$), 1.26 (m, 2H, CH_2-central). ^{31}P NMR (D_2O): δ 2.12 s.

4-*N*-(5-*N*,*N*-Dimethylamino-1-naphthalenesulfonyl)amino-1-butanol IV. A mixture of 4-amino-1-butanol (178 mg, 2 mmol) and dansyl chloride (135 mg, 0.5 mmol) in 1,4-dioxane (3 mL) was kept overnight at 20 °C. The solution was evaporated, and the residue was dissolved in $CHCl_3$ (1 mL) and loaded on a silica gel column (2 × 17 cm). The column was washed with $CHCl_3$ (50 mL), and the product was eluted with 4% MeOH in $CHCl_3$. The target fractions were combined and evaporated to yield **IV** (67 mg, 41%) as light-yellow solid residue. UV−vis (MeOH): λ_{max} 337 nm (ϵ = 2500 M^{-1} cm^{-1}), 250 nm (ϵ = 8670 M^{-1} cm^{-1}), λ_{max} 219 nm (ϵ = 21700 M^{-1} cm^{-1}). ^1H NMR ($CDCl_3$): δ 8.29 (d, 1H, J = 8.4 Hz, H-2), 8.23 (d, 1H, J = 8.41 Hz, H-4 (DNS)), 8.21 (d, 1H, J = 7.16 Hz, H-8 (DNS)), 7.53 (m, 2H, H-3 + H-7), 7.17 (d, 1H, J = 7.48 Hz, H-6 (DNS)), 5.21 (t, 1H, J = 5.9 Hz, NH), 3.50 (t, 2H, J = 5.9 Hz, CH_2O), 2.91 (m, 8H, CH_2N+$(CH_3)_2$), 1.40 (m, 4H, $(CH_2)_2$-central).

4-*N*-(5-*N*,*N*-Dimethylamino-1-naphthalenesulfonyl)aminobutyl Phosphoric Acid IIIc. Phosphorus oxychloride (16 μL, 0.17 mmol) was added dropwise to a precooled (0 °C) solution of 4-*N*-(5-*N*,*N*-dimethylamino-1-naphthalenesulfonyl)amino-1-butanol **IV** (18 mg, 0.057 mmol) in triethyl phosphate (1 mL), and the reaction mixture was kept at 0 °C for 20 h and diluted with water (50 mL). The target product was purified as described above for **IIIa**,**b** to give 12 mg (50%) of **IIIc** as ammonium salt. UV−vis (H_2O, pH 7.0): λ_{max} 333 nm (ϵ = 2500 M^{-1} cm^{-1}), 245 nm (ϵ = 8670 M^{-1} cm^{-1}), λ_{max} 216 nm (ϵ = 21700 M^{-1} cm^{-1}). ^1H NMR (D_2O): δ 8.34 (d, 1H, J = 8.4 Hz, H-2 (DNS)), 8.29 (d, 1H, J = 8.41 Hz, H-4 (DNS)), 8.14 (d, 1H, J = 7.16 Hz, H-8 (DNS)), 7.58 (m, 2H, H-3 + H-7 (DNS)), 7.43 (d, 1H, J = 7.78 Hz, H-6 (DNS)), 3.50 (m, 2H, CH_2O), 3.03 (m, 6H, $(CH_3)_2$), 2.87 (m, 2H, CH_2N), 1.14 (m, 4H, $(CH_2)_2$-central). ^{31}P NMR (D_2O): δ 2.10 s.

Synthesis of Triphosphoric Acid Monoesters Ia−c (Scheme 1A). 1,1′-Carbonyldiimidazole (32 mg, 0.2 mmol) was added to a solution of tri-*n*-butylammonium salt of phosphate ester (**IIIa**, **IIIb**, or **IIIc**, 50 μM) in dry DMF (3 mL), and the reaction mixture was stirred for 1 h at 20 °C. Anhydrous MeOH (0.33 mL, 8 mmol) was added, the solvents were evaporated after 40-min stirring, and the residue was dissolved in dry DMF (5 mL) followed by the addition of bis(tri-*n*-butylammonium) pyrophosphate (0.5 mL, 0.15 mmol). The mixture was stirred at 20 °C overnight. After dilution with water (50 mL), the mixture was loaded on a DEAE-cellulose (HCO_3^-) column (2 × 9 cm). The column was washed with 20% aqueous MeOH (100 mL), and the products were eluted in a linear gradient of NH_4HCO_3 (0 → 0.4 M) in 20% aqueous MeOH (pH 7.5, total volume 0.6 L). The target fractions were collected, evaporated, and coevaporated with water, and the residues were dissolved in water (1 mL). The product was purified on a LiChroprep RP-8 column (1.5 × 20 cm). The target fractions were eluted in a linear gradient of MeOH (0 → 20%, total volume 0.6 L) in 0.01 M NH_4HCO_3 under the UV control, and freeze-dried to give 4.7 mg (27%) of **Ia**, 5.5 mg (35%) of **Ib**, and 5.9 mg (37%) of **Ic** as ammonium salts.

2-*N*-[6-*N*-(5-*N*,*N*-Dimethylamino-1-naphthalenesulfonyl)-aminohexanoyl]aminoethyl triphosphoric acid Ia: UV−vis (H_2O, pH 7.0): λ_{max} 333 nm (ϵ = 2500 M^{-1} cm^{-1}), 245 nm (ϵ = 8670 M^{-1} cm^{-1}), λ_{max} 216 nm (ϵ = 21700 M^{-1} cm^{-1}). ^1H NMR (D_2O): δ 8.47 (d, 1H, J = 8.72 Hz, H-2 (DNS)), 8.24 (d, 1H, J = 8.72 Hz, H-4 (DNS)), 8.22 (d, 1H, J = 6.54 Hz, H-8 (DNS)), 7.66 (m, 2H, H-3 + H-7 (DNS)), 7.39 (d, 1H, J = 7.79 Hz, H-6 (DNS)), 3.85 (m, 2H, CH_2O), 3.24 (t, 2H, J = 4.78 Hz, CH_2NHCO), 2.87−2.71 (m, 8H, CH_2NH(DNS) + $(CH_3)_2$), 1.70 (t, 2H, J = 7.5, CH_2CO) 1.08 (m, 6H, $(CH_2)_3$-central). ^{31}P NMR (D_2O): δ −8.42 (d, 1P, J = 21.3 Hz, P_γ), −10.35 (d, 1P, J = 19.3 Hz, P_α), −21.80 (dd, 1P, P_β).

2-*N*-[6-*N*-(2,4-Dinitrophenyl)aminohexanoyl]aminoethyl triphosphoric acid Ib: UV−vis (H_2O, pH 7.0): λ_{max} 363 nm (ϵ = 17500 M^{-1} cm^{-1}), 265 nm (ϵ = 8340 M^{-1} cm^{-1}). ^1H NMR (D_2O): δ 8.93 (d, 1H, H-3 (DNP)), 8.10 (dd, 1H, J = 2.8 Hz, H-5 (DNP)), 6.97 (d, 1H, J = 9.65 Hz, H-6 (DNP)), 3.88 (m, 2H, CH_2OP), 3.34 (t, 1H, J = 7.16 Hz, CH_2NH (DNP)), 3.27 (t, 1H, J = 4.98 Hz, CH_2NHCO), 2.13 (t, 2H, J = 7.47 Hz, CH_2CO), 1.55 (q, 2H, J = 6.48 Hz, CH_2), 1.46 (q, 2H, J = 6.48 Hz, CH_2), 1.28 (m, 2H, CH_2-central). ^{31}P NMR (D_2O): δ −7.88 (d, 1P, J = 21.4 Hz, P_γ), −10.32 (d, 1P, J = 19.3 Hz, P_α), −21.77 (dd, 1P, P_β).

4-*N*-(5-*N*,*N*-Dimethylamino-1-naphthalenesulfonyl)aminobutyl triphosphoric acid Ic: UV−vis (H_2O, pH 7.0): λ_{max}

333 nm ($\epsilon = 2500\ M^{-1}\ cm^{-1}$), 245 nm ($\epsilon = 8670\ M^{-1}\ cm^{-1}$), λ_{max} 216 nm ($\epsilon = 21700\ M^{-1}\ cm^{-1}$). ^{1}H NMR ($D_2O$): δ 8.37 (d, 1H, $J = 8.4$ Hz, H-2), 8.33 (d,1H, $J = 8.41$ Hz, H-4), 8.12 (d, 1H, $J = 7.16$ Hz, H-8), 7.56 (m, 2H, H-3 + H-7), 7.29 (d, 1H, $J = 7.78$ Hz, H-6), 3.59 (m, 2H, CH_2O), 2.81 (m, 2H, CH_2N), 2.74 (s, 6H, $(CH_3)_2$), 1.27 (m, 4H, $(CH_2)_2$-central). ^{31}P NMR (D_2O): δ −8.74 (d, 1P, $J = 19.5$ Hz, P_γ), −10.6 (d, 1P, $J = 20.3$ Hz, P_α), −22.2 (dd, 1P, P_β).

Synthesis of Triphosphoric Acid Monoesters Id−f (Scheme 1B). 9-Fluorenylmethoxycarbonyl)aminobutyl triphosphoric acid **Va** (44 mg, 0.08 mmol) was dissolved in 25% aqueous ammonia (2 mL) and kept for 16 h at 5 °C. The reaction mixture was filtered, the filtrate was evaporated and coevaporated with water, and the residue was dissolved in water (1 mL) and purified on a LiChroprep RP-18 column (2 × 16 cm) in 0.01 M NH_4HCO_3 as an eluent. The target fractions were collected, evaporated, coevaporated with water, and freeze-dried to give **VIa** (24 mg, 97%). To the solution of **VIa** (12 mg, 0.04 mmol) in a mixture of H_2O (1 mL) and DMF (5 mL) was added Et_3N (0.5 mL), and the solvents were evaporated to a volume of approximately 2 mL. Rhodamine B isothiocyanate (21.4 mg, 0.04 mmol), BDI *N*-hydroxysuccinimide ester (16.7 mg, 0.04 mmol), or biotin *N*-hydroxysuccinimide ester (13.6 mg, 0.04 mmol), Et_3N (0.08 mL), and *N*-methylimidazole (0.04 mL) were added, and the mixture was stirred at 20 °C overnight. The reaction mixture was evaporated, and the residue was dissolved in water (10 mL) and extracted with CCl_4 (3 mL) and *n*-butanol (2 × 3 mL). The aqueous solution was diluted with water (50 mL). The target products were purified as described above for **Ia−c** to give **Id** (25 mg, 75%), **Ie** (4.4 mg, 12%), or **If** (2.3 mg, 11%) as ammonium salts.

Aminobutyl triphosphoric acid VIa: ^{1}H NMR (D_2O): δ 3.8 (m, 2H, CH_2O), 2.89 (m, 2H, CH_2N), 1.53 (m, 4H, $(CH_2)_2$). ^{31}P NMR (D_2O): δ −8.92 (d, 1P, $J = 18.3$ Hz, P_γ), −10.41 (d, 1P, $J = 19.4$ Hz, P_α), −22.07 (dd, 1P, P_β).

4-*N*-(Rhodaminylaminothiocarbonyl)aminobutyl triphosphoric acid Id: UV−vis (H_2O, pH 7.0): λ_{max} 556 nm ($\epsilon = 59000\ M^{-1}\ cm^{-1}$), 355 nm ($\epsilon = 4700\ M^{-1}\ cm^{-1}$), 284 nm ($\epsilon = 13100\ M^{-1}\ cm^{-1}$), 258 nm ($\epsilon = 18100$). ^{1}H NMR ($D_2O$): δ 7.75 m, 6.87 m, 6.54 m, 6.38 m, 6.25 m (9H, aryl), 3.87 (m, 2H, CH_2O), 3.21 (m, 10H, CH_2N and $(CH_2CH_3)_4$), 1.63 (m, 4H, $(CH_2)_2$), 0.91 (m, 12H, $(CH_2CH_3)_4$). ^{31}P NMR (D_2O): δ −10.07 (d, 1P, $J = 18.3$ Hz, P_γ), −10.34 (d, 1P, $J = 19.3$ Hz, P_α), −21.94 (dd, 1P, P_β).

4-*N*-[3-(4,4-Difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-*s*-indacene-2-yl)propionyl]aminobutyl triphosphoric acid Ie: UV−vis (H_2O, pH 7.0): λ_{max} 517 nm ($\epsilon = 72000\ M^{-1}\ cm^{-1}$). ^{1}H NMR ($D_2O$): δ 7.35 (s, 1H, H-8), 6.14 (s, 1H, H-6), 3.85 (m, 2H, CH_2O), 2.89 (m, 2H, CH_2N), 2.72 (t, 2H, $J = 8.0$ Hz, CH_2CH_2CO), 2.49 (t, 2H, CH_2CH_2CO), 2.45 and 2.44 (2 × s, 6H, 3-CH_3 and 5-CH_3), 2.23 and 2.25 (2 × s, 6H, 1-CH_3 and 7-CH_3), 1.63 (m, 4H, $(CH_2)_2$). ^{31}P NMR (D_2O): δ −10.05 (d, 1P, $J = 18.3$ Hz, P_γ), −10.38 (d, 1P, $J = 19.5$ Hz, P_α), −22.21 (dd, 1P, P_β).

4-*N*-(Biotinyl)aminobutyl triphosphoric acid If: UV (H_2O, pH 7.0): λ_{max} 195 nm (ϵ 2220 $M^{-1}\ cm^{-1}$). ^{1}H NMR (D_2O): δ 4.25 and 4.05 (2 m, 2H, 2 CHN (Bio)), 3.85 (m, 2H, CH_2O), 3.15 (m, 1H, CHS (Bio)), 3.02 (t, 2H, $J = 6.3$ Hz, CH_2N), 2.83 (dd, 1H, $J = 13.5$ Hz, CH_aS), 2.61 (d, 1H, CH_bS), 2.23 (t, 2H, $J = 7$ Hz, CH_2CO), 1.62 and 1.41 (m, 10H, 5 × CH_2). ^{31}P NMR (D_2O): δ −9.72 (d, 1P, $J = 19.1$ Hz, P_γ), −10.42 (d, 1P, $J = 20.1$ Hz, P_α), −21.9 (dd, 1P, P_β).

***N*-(Fluoresceinylaminothiocarbonyl)-8-amino-3,6-dioxaoctanoic Triphosphoric Acid Ig.** *N*-(9-Fluorenylmethoxycarbonyl)-8-amino-3,6-dioxaoctanoic triphosphoric acid **Vb** (20 mg, 0.03 mmol) was dissolved in 25% aqueous ammonia (2 mL), and the reaction mixture was kept for 16 h at 5 °C and filtered. The filtrate was evaporated to a volume of approximately 1 mL, and DMF (1 mL), Et_3N (0.02 mL), and fluorescein isothiocyanate (20 mg, 0.05 mmol) were added. The mixture was stirred at 20 °C overnight, evaporated, and coevaporated with water (3 × 10 mL), and the residue was dissolved in 1 mL of water. The products were purified on a LiChroprep RP-8 column (2 × 18 cm) in 0.05 M NH_4HCO_3 as an eluent. The target fractions were collected, evaporated, coevaporated with water, and freeze-dried to give **Ig** (1 mg, 5%) as the ammonium salt.

Ig: UV−vis (H_2O, pH 9.0): λ_{max} 492 nm ($\epsilon = 65000\ M^{-1}\ cm^{-1}$), 320 nm ($\epsilon = 7000\ M^{-1}\ cm^{-1}$), 293 nm ($\epsilon = 42100\ M^{-1}\ cm^{-1}$), 207 nm ($\epsilon = 36000\ M^{-1}\ cm^{-1}$). ^{1}H NMR ($D_2O$): 6.94 m, 7.50 m, 7.76 m, 7.92s (9H, Flu), 4.25 (m, 2H, CH_2-OP), 3.89 (m, 10H, $(CH_2)_5$). ^{31}P NMR (D_2O): δ −9.84 (d, 1P, $J = 18.3$ Hz, P_γ), −10.49 (d, 1P, $J = 19.3$ Hz, P_α), −22.59 (dd, 1P, P_β).

Methyl 4-acetyl-5-oxo-hexanoate VIII. Methyl acrylate (86.1 g, 1.0 mol) was added dropwise during 30 min to a mixture of acetylacetone **VII** (110.1 g, 1.1 mol) and potassium carbonate (7.0 g, 50.6 mmol) under stirring at 100 °C. The mixture was stirred for 3 h at 100 °C and filtered, and the residue was washed with acetone (10 mL). The combined filtrates were concentrated in vacuum to give a viscous oil (117 g, 63%). ^{1}H NMR ($CDCl_3$): δ 3.68 (t, 1H, $J = 7.1$ Hz, CH), 3.61 (s, 3H, $COOCH_3$), 2.52 (t, 2H, $J = 7.1$ Hz, $CH_2CH_2COOCH_3$), 2.14 (s, 6H, 2 $C(O)CH_3$), 2.07 (m, 2H, $CH_2CH_2COOCH_3$). Bp 140−143 °C/12 mm.

4-(2′-Methoxycarbonylethyl)-2-ethoxycarbonyl-3,5-dimethylpyrrole X. A solution of ethyl acetoacetate **IX** (61.2 g; 0.47 mol) in acetic acid (180 mL) was treated with sodium nitrite (37.4 g; 0.23 mol) in water (61 mL) under stirring at 4−7 °C. The mixture was stirred for 1 h at 5−7 °C and 24 h at ambient temperature. Methyl 4-acetyl-5-oxo-hexanoate **VIII** (98.5 g; 0.53 mol), acetic acid (100 mL), and then zinc dust (68.5 g; 1.05 mol) were gradually added under stirring. The mixture was heated at 80 °C for 1 h and refluxed for additional 2 h. The hot solution was poured onto ice (800 g) and filtered off, zinc powder was washed with the hot acetic acid, and the filtrates were combined. The oil layer was separated, and product was allowed to crystallize under storage. The product was filtered off, washed with water, and recrystallized from ethanol:water mixture (2:1) to give pale yellow plates (56.0 g, 47%). ^{1}H NMR ($CDCl_3$): δ 8.72 (s, 1H, NH), 4.27 (q, 2H, $J = 7.0$ Hz, OCH_2-CH_3), 3.65 (s, 3H, OCH_3), 2.69 (dd, 2H, $J = 6.5$ Hz, $J = 8.0$ Hz, $CH_2CH_2COOCH_3$), 2.42 (dd, 2H, $J = 7.5$ Hz, $J = 8.0$ Hz, $CH_2CH_2COOCH_3$), 2.26 (s, 3H, 5-CH_3), 2.20 (s, 3H, 3-CH_3), 1.35 (t, 3H, $J = 7.0$ Hz, OCH_2CH_3). Mp 103−104 °C.

4-(2′-Carboxyethyl)-2-carboxy-3,5-dimethylpyrrole XI. 4-(2′-Methoxycarbonylethyl)-2-ethoxycarbonyl-3,5-dimethylpyrrole **X** (1.79 g, 7.1 mmol) was added to a solution of NaOH (1.4 g; 35 mmol) in H_2O (7 mL) and ethanol (20 mL), and the mixture was refluxed for 2 h. Ethanol was removed in vacuum, and the mixture was neutralized with 10% HNO_3 under stirring at 0−4 °C. The precipitate was filtered, washed with ice−water, and vacuum-dried to give a pink powder (0.97 g, 65%). ^{1}H NMR ($CDCl_3$): δ 11.80 (s, 2H, 2 COOH), 10.91 (s, 1H, NH), 2.53 (t, 2H, $J = 7.5$ Hz, CH_2CH_2COOH), 2.26 (t, 2H, $J = 7.5$ Hz, CH_2CH_2COOH), 2.16 (s, 3H, 5-CH_3), 2.11 (s, 3H, 3-CH_3).

2-Formyl-3,5-dimethylpyrrole XIII. Phosphorus oxychloride (2.0 g; 13 mmol) was added dropwise during 15 min to DMF (0.96 g; 13 mmol) under stirring at 10 °C. After stirring for 15 min at ambient temperature, the solution was deluted with 1,2-dichloroethane (3 mL) and cooled to 5 °C and a solution of 2,4-dimethylpyrrole **XII** (1.12 g; 11.8 mmol) in 1,2-dichloroethane (3 mL) was added dropwise at 5 °C during 1 h. The mixture was refluxed for 15 min and cooled to room temperature, and sodium acetate (8.83 g; 65 mmol) in water

(12 mL) was added. The reaction mixture was refluxed for 15 min and cooled to room temperature, and the organic layer was separated. The water layer was extracted with diethyl ether (3 × 50 mL), and organic liquids were combined, washed with saturated aqueous solution of Na_2CO_3, and dried over anhydrous Na_2CO_3. The solvents were evaporated, and the solid residue was crystallized from water to give white crystals (1.2 g, 83%). ^{1}H NMR ($CDCl_3$): δ 9.97 (s, 1H, NH), 9.45 (s, 1H, CHO), 5.84 (s, 1H, H-4), 2.31 (s, 3H, 5-CH_3), 2.29 (s, 3H, 3-CH_3). Mp 89−90 °C.

4-(2″-Carboxyethyl)-3,3′,5,5′-tetramethylpyrromethene Hydrobromide XIV. A solution of 33% HBr in acetic acid (0.27 mL) was added to a solution of 2-carboxy-4-(2′-carboxyethyl)-3,5-dimethylpyrrole **XI** (105.6 mg; 0.5 mmol) and 3,5-dimethyl-2-formylpyrrole **XIII** (61.5 mg, 0.5 mmol) in acetic acid (2.5 mL) under stirring at 4−7 °C. The mixture was heated on a water bath for 10 min, cooled to room temperature and poured into diethyl ether (25 mL). After 12 h at 0 °C, the precipitate was filtered, washed with diethyl ether, and vacuum-dried to give a yellow-red powder (173 mg, 98%). UV−vis (MeOH): λ_{max} 474 nm (ϵ = 22000 M^{-1} cm^{-1}). ^{1}H NMR ($CDCl_3$): δ 13.08 (s, 2H, NH), 7.06 (s, 1H, H-6), 6.14 (s, 1H, H-4′), 2.75 (t, 2H, J = 7.5 Hz, CH_2CH_2COOH), 2.66 and 2.67 (2 × s, 6H, 5-CH_3 and 5′-CH_3), 2.51 (t, 2H, J = 7.0 Hz, CH_2CH_2COOH), 2.34 (s, 3H, 3-CH_3), 2.29 (s, 3H, 3′-CH_3).

3-(4,4-Difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-*s*-indacene-2-yl)pro pionic Acid XV. Boron trifluoride diethyl etherate (1.52 g, 1.35 mL, 10.7 mmol) was added to a solution of **XIV** (90 mg; 0.255 mmol) and *N*-ethyldiisopropylamine (130 mg; 1.0 mmol) in THF (9.0 mL). The mixture was stirred at 60 °C for 2 h, cooled to room temperature, and extracted with toluene (2 × 20 mL). The solvents were evaporated in vacuum at 35−40 °C. The residue was dissolved in cold toluene (100 mL), and the solution was washed with cold water (3 × 10 mL) and brine (10 mL), dried over Na_2SO_4, and filtered. The products were separated by flash chromatography on a silica gel column (20 × 90 mm). The column was washed subsequently with toluene (50 mL), toluene−acetic acid (30:2:60 mL), and toluene−acetic acid−THF (30:2, 60 mL). The solvents were evaporated at 30−35 °C and reevaporated with toluene to remove acetic acid. The title compound **XV** was obtained as a purple precipitate and was crystallized from toluene (64.5 mg; 79%). UV−vis (MeOH): λ_{max} 517 nm (ϵ = 72000 M^{-1} cm^{-1}). Fluorescence: λ_{max} 520 nm; ^{1}H NMR ($CDCl_3$): δ 7.01 (s, 1H, H-8), 6.02 (s, 1H, H-6), 2.72 (t, 2H, J = 8.0 Hz, CH_2CH_2-COOH), 2.69 (s, 6H, 3-CH_3, 5-CH_3), 2.49 (t, 2H, J = 8.0 Hz, CH_2CH_2COOH), 2.23 and 2.19 (s, 6H, 1-CH_3, 7-CH_3). Mp 167−168 °C; MALDI-TOF-MS: calcd for $C_{16}H_{19}BF_2N_2O_2$ (M^+) 320.14, found (M^+) 319.5, (M^+-19) 300.7.

***N*-Hydroxysuccinimide Ester of 3-(4,4-Difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-*s*-indacene-2-yl)propionic Acid XVI**. *N*,*N*′-Disuccinimidyl carbonate (124 mg; 0.484 mmol) was added to a solution of **XV** (62 mg; 0.194 mmol) in acetonitrile (5.8 mL) and pyridine (65 μL). The mixture was stirred at room temperature for 12 h, and the solvents were evaporated at 35−40 °C. The residue was coevaporated with toluene (2 × 3 mL) to remove the traces of pyridine. Title compound **XVI** was obtained as a semisolid substance. UV−vis (CH_3CN) λ_{max} 518 nm (ϵ = 73000 M^{-1} cm^{-1}). Fluorescence (CH_3CN): λ_{max} 521 nm; Mp > 250 °C. MALDI TOF MS: calcd $C_{20}H_{22}BF_2N_3O_4$ (M^+) 417.21, found (M^+) 416.0.

Elongation Reactions with Alkyl Triphosphates Ia−g Catalyzed by TdT. The reaction mixture (10 μL) contained 200 mM cacodylate buffer (pH 7.2), 20 nM [5′-^{32}P]-18-mer primer, 0.1 mM DTT, 2 mM $CoCl_2$, 0.2 U of TdT, and compounds **Ia−g** at the concentrations indicated in the legend to Figure 1. After incubation for 10 min at 37 °C, the reactions were quenched by the addition of 5 μL of sequencing loading buffer containing 98% (v/v) deionized formamide/10 mM EDTA/1 mg/mL of bromophenol blue and xylene cyanol each. The reaction mixtures were loaded onto 20% denaturing PAAG and subjected to electrophoresis for approximately 3 h at 2000 V. The gels were exposed to X-ray film (Kodak RX).

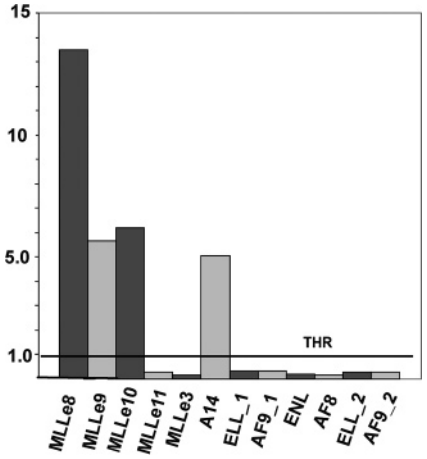

Figure 1. Histogram of a sample bearing t(4;11) translocation. The solid line indicates the cutoff value (THR = $<J> + 4\sigma$). Signals over the cutoff were recognized as true signals (MLLe8, MLLe9, MLLe10, AF4).

Microarray Analysis. The gel-based microarray developed for the analysis of MLL-translocations in leukemias was used as described earlier (*16*, *17*). Oligonucleotides for immobilization were synthesized on a 394 DNA/RNA automated synthesizer (Applied Biosystems) by the standard phosphoroamidite method. A spacer contained a free amino group at the 3′-end, which was introduced during synthesis with a C7 CPG 500 3′-amino modifier (Glen Research). Microarrays were obtained by photoinducible copolymerization of oligonucleotides and PAAG components as described previously (*16*). To prepare fluorescent labeled DNA, the target RNA was isolated from bone marrow of a leukemic patient and reverse transcribed, and cDNA was used as a matrix in multiplex PCR with specific primers. The two-round nested multiplex PCR was performed as described earlier (*18*). The 1/50 of reverse transcriptase reaction mixture (an equivalent of 20 000 cells) was added to 25-μL multiplex mixture containing 11 mM Tris-HCl (pH 8.3), 55 mM KCl, 1.5 mM $MgCl_2$, 0.2 mM each of deoxynucleotide triphosphates, a mixture of primers (0.2 μM each), and 1.5 units of Taq-polymerase (Sileks, Russia). Twenty-five cycles per each round were performed: 94 °C for 30 s, 58 °C for 30 s, and 72 °C for 1 min; the second round was followed by an extension at 72 °C for 4 min. In the case of translocation the estimated range of PCR products were from 150 to 300 bp in dependence on the breakpoint region in MLL-gene and gene-partner involved in translocation. To determine the sensitivity of the tests, cDNA from leukemic cells was serially diluted (10^{-4} up to 10^{-1} times) with cDNA from HL-60 cells carrying no translocations, and then the mixture was used in multiplex RT-PCR, followed by hybridization.

The PCR product was labeled with the synthesized monoesters of triphosphoric acid **Id−f** in the reactions catalyzed by TdT. The reaction mixture (50 μL) contained 200 mM cacodylate buffer, pH 7.2, 25 mM Tris, 0.01% Triton X-100, 2 mM $CoCl_2$, 30 units of TdT, and 500 pmol of synthesized compounds. DNA fragments labeled with Bio-dUTP or Cy5-dUTP were used as controls. The reactions were carried out at 37 °C for 1 h. The labeled DNA fragments were hybridized with an oligonucleotide microchip at 37 °C for 12 h. The microchip was washed briefly with distilled water and dried. For biotin-labeled probes, the microchip was washed and

$$[5'\text{-}^{32}P](pdN)_n + ppp\text{-}O\text{-}X\text{-}R \rightarrow [5'\text{-}^{32}P](pdN)_np\text{-}O\text{-}X\text{-}R + pp_i$$

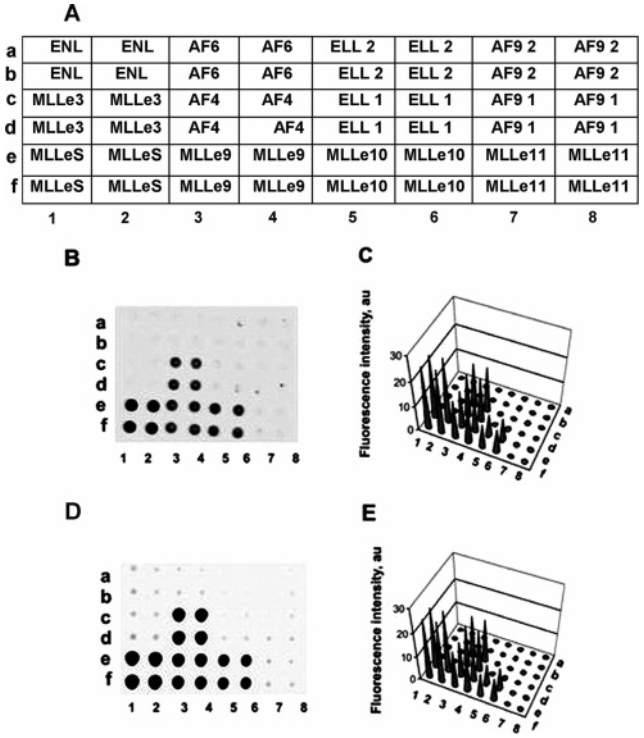
incubated with streptavidin conjugated with Cy5 in 0.9% NaCl for 1 h at 37 °C, washed again, and dried. The fluorescent signal was registered using a portable biochip analyzer equipped with CCD camera. The input data for the analysis were obtained from measurements of fluorescent intensity $J_m = (C_m - B_m)/B_m$, where C_m is the intensity per unit area in the internal region of a pad, B_m is the background intensity, and m is the enumerated pads on the chip ($m = 1, ...48$). Signal intensities of the translocation-specific probes that were spotted in quadruplicate were averaged, and the obtained values (group signals) were used in the posterior calculations. The five most outlying group signals equal to the maximal number of perfect duplexes formed in the presence of translocation in the sample were excluded. The remaining values J_m for oligonucleotide groups were defined as background signals. The mean $<J>$ and standard deviation σ of background signals were calculated, and THR = $<J> + 4 \times \sigma$ was established as the cutoff level (Figure 1). We regarded any signal over the cutoff level to be a significant signal.

RESULTS AND DISCUSSION



Synthesis of Triphosphoric Acid Monoesters. Two approaches were used for the synthesis of triphosphoric acid monoesters bearing fluorescent groups or biotin (Scheme 1). According to method A, the activated substance containing the marker group was coupled with the linker followed by phosphorylation. Compounds **IIa**,**b** were obtained by the reaction of DNS-Cl or DNP-F with ϵ-aminocaproic acid. Activation of **IIa**,**b** with CDI followed by the treatment with 2-aminoethylphosphate resulted in **IIIa**,**b**. For **IIIc** synthesis, 4-amino-1-butanol was treated with DNS-Cl followed by phosphorylation of alcohol **IV** with $POCl_3$. Compounds **IIIa**−**c** were diphosphorylated to give **Ia**−**c** by the imidazole method (*19*).

Compounds **Id**−**g** were synthesized by method B. The procedure included the synthesis of triphosphates bearing linkers followed by the addition of fluorescent labels or biotin. The key Fmoc-aminoalkyl esters of triphosphoric acid **Va**,**b** were prepared by the earlier developed procedure (*10*). The Fmoc-groups of **Va**,**b** were removed with aqueous ammonia, and the resulting **VIa**,**b** were coupled with either RdB *N*-methylimidazole or Flu isothiocyanates to give **Id** and **Ig**, respectively, or with *N*-hydroxysuccinimide esters of BDI or Bio to give **Ie** and **If**, respectively (*19*). Compounds of type **I** were purified by successive ion-exchange chromatography on DEAE-cellulose and reversed-phase silica gel chromatography. The structures of the compounds were confirmed by UV and ^1H and ^{31}P NMR spectra.

The diaza-bora-indacene dye (DBI) was synthesized (Scheme 2) using modified methods (*20*−*23*). The key 3-(4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-*s*-indacene-2-yl)propionic acid **XV** was obtained by condensation of boron trifluoride diethyl etherate and 4-(2″-carboxyethyl)-3,3′,5,5′-tetramethylpyrromethene hydrobromide **XIV** (*20*, *21*). The latter was prepared by the condensation of pyrroledicarbonic acid **XI** and formylpyrrole **XIII** according to the method described by Fischer and Orth (*22*). *N*-Hydroxysuccinimide ester **XVI** was obtained by the reaction of **XV** with *N*,*N*′-disuccinimidyl carbonate (*23*) and used without purification.

Substrate Properties. Substrate properties of alkyl triphosphates **I** toward TdT were evaluated by the ability of TdT to elongate the [5′-^{32}P]-primer in the presence of the synthesized **Ia**−**g** under the conditions described earlier (*8*, *9*). As reference compounds, ddGTP, dGTP, and Bio-dUTP were used.

Reaction products were analyzed by electrophoresis in 20% denaturing PAAG. Figure 2 presents the dose-dependent incorporation of **Ia**−**g** into the 18-mer primer 3′-ends. Bio-dUTP, ddGTP, and dGTP were used as control samples. As one can see, the compounds **Ia**−**g** could elongate the oligonucleotide, albeit with different potencies. The comparison of the intensities of the bands above the primer position shows that the substrate efficacies of **Ia**−**g** were 5−50-fold lower than that of ddGTP (lanes 1−4). In contrast to chain terminators **1a**−

Figure 3. Scheme of microarray (A). Examples of hybridization of the PCR-product obtained from the clinical sample carrying the translocation t(4;11) and labeled with **Id** (B, C) and Cy5-dUTP (D, E). The fluorescent signals on diagrams C and E above the threshold line indicate the presence of translocation.

g, Bio-dUTP (lanes 26−28) can be incorporated by TdT several times similarly to dGTP (lanes 29−31). Triphosphates bearing RdB residue **Id** (lanes 5−7) and DBI residue **Ie** (lanes 8−10) were the most effective substrates. Their efficacies differed from that of ddGTP by approximately fivefold. Compound **Ia** bearing a DNS residue and a long linker (lanes 14−16) was incorporated less effectively if compared with **Ic** (lanes 17−19) containing a DNS residue but a short linker. These results correlate with the previously reported data showing the dependence of substrate properties on length and structure of linker (*8*−*11*).

Microarray Analysis Using Fluorescent Labeled DNA Targets. The synthesized alkyl triphosphates **Id**−**f** were used for fluorescent labeling of DNA fragments during post-PCR target preparation for microarray analysis. Cy5-dUTP and Bio-dUTP were used as reference samples. The microarray was developed for the analysis of six translocations in leukemias, involving the *MLL*-gene: t(4;11) *MLL/AF4*, t(6;11) *MLL/AF6*, t(9,11) *MLL/AF9*, t(11;19) *MLL/ ELL*, t(11;19) *MLL/ENL*, and dup(11) *MLL/MLL* (*17*). The oligonucleotide sequences are given in Table 2. As a result of translocation, a fusion gene is formed, where the 5′-part is presented by the *MLL*-gene and the 3′-part is originated from one of the gene-partners. Chimeric RNA expressed in leukemic cells was the molecular target for the analysis. After RNA isolation and reverse transcription, the multiplex PCR with specific primers is used for the amplification of DNA fragment for further hybridization with microarray. The forward primer is located in the *MLL*-gene and the reverse one in gene-partner, so that PCR-product is formed only in the case of translocation. Figure 3 shows the microarray plot (A) and hybridization patterns of the clinical sample bearing translocation t(4;11) after labeling of PCR products with **Id** (B and C) and Cy5 dUTP (D and E). The rows (**a**−**d**) of the microarray (A) show the immobilized probes specific to different gene partners, and the rows (**e**, **f**) present oligonucleotide probes specific to different exons of MLL-gene. According to the hybridization pattern, the molecular structure of chimeric transcript was

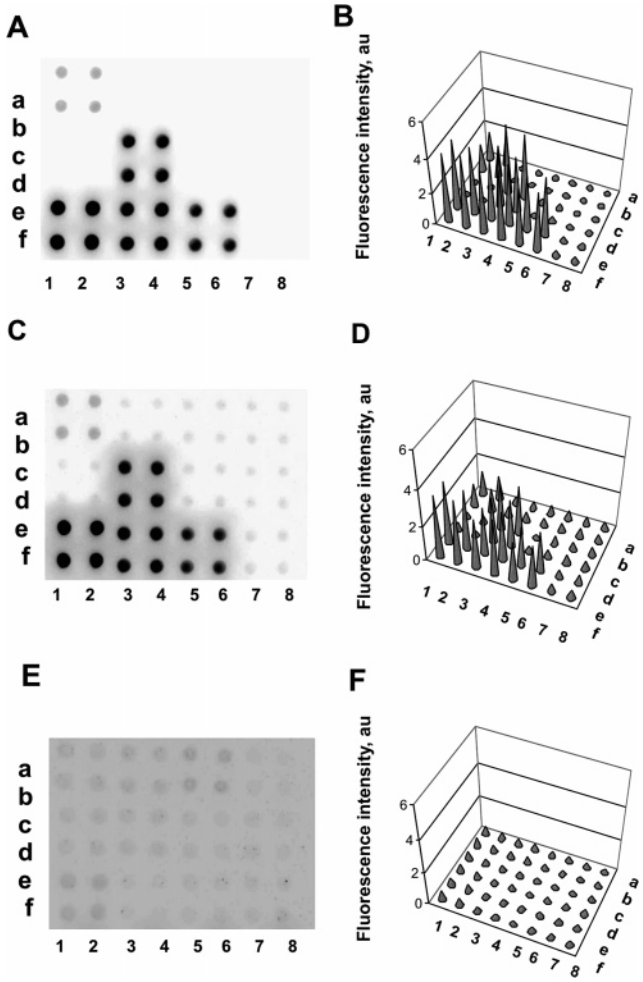

Figure 4. Examples of hybridization of the PCR-product obtained from the clinical sample carrying the translocation t(4;11) and labeled with **If** (A, B) and Bio-dUTP (C, D). Absence of fluorescent signals from the control sample carrying no translocation (E and F).

determined as *MLLex9/AF4*. The results of hybridization with microarray after labeling with **1f** (A and B) and Bio-dUTP (C and D) are presented in Figure 4. The fluorescent signals on diagrams (B and D) above the threshold line indicate the presence of t(4;11) translocation. In the case of negative sample carrying no translocation, no fluorescent signals were observed (E and F). Comparing the results of hybridization of PCR DNA fragments labeled with **1d** or commercially available Cy5-dUTP, we could notice that both compounds gave more sharp signals with lower background than that labeling with biotin-containing compounds. The efficacy of hybridization using compound **Id** is the same as that with Cy5-dUTP. The efficacy of hybridization of DNA labeled with **If** is even higher than that in the case of Bio-dUTP. The limit of detection was defined as dilution of cDNA carrying translocation with cDNA sample noncarrying translocation, which still allowed revealing the chimeric transcript using multiplex PCR and hybridization with biochips. For all translocations, the detection limit was found to be the dilution up to 10^{-3}, which corresponded to the detection of one blast cell per 10^3 normal cells. The sensitivity assay performed for **Id** or Cy5-dUTP compounds revealed the similar results for both labels.

To conclude, we developed a simple method of DNA labeling using monoesters of triphosphoric acid bearing fluorescent or ligand groups attached to the triphosphate moiety through different linkers. Two methods were used for the preparation of fluorescent triphosphates. According to the first method, the activated compounds bearing fluorescent labels were coupled

with a linker followed by phosphorylation. The second one included the initial synthesis of triphosphates coupled with linker followed by incorporation of fluorescent labels. This procedure allowed using different types of activating groups, namely sulfonyl chlorides, isothiocyanates, or *N*-hydroxysuccinimide esters for triphosphate labeling depending on ligand structure. All the synthesized compounds bearing fluorescent groups or biotin were successfully applied for effective labeling of DNA targets in microarray analysis during post-PCR target preparation.

Received August 8, 2006; Revised Manuscript Received February 8, 2007

Doxorubicin is one of the most potent anti-tumor drugs with a broad spectrum of use. To reduce its toxic effect and improve its pharmacokinetics, we conjugated it to an HPMA copolymer carrier that enhances its passive accumulation within solid tumors via the EPR effect and decreases its cytotoxicity to normal, noncancer cells. In this study, we compared the antiproliferative, pro-survival, and death signals triggered in EL-4 cancer cells exposed to free doxorubicin and doxorubicin conjugated to a HPMA copolymer carrier via either enzymatically (PK1) or hydrolytically (HYD) degradable bonds. We have previously shown that the intracellular distribution of free doxorubicin, HYD, and PK1 is markedly different. Here, we demonstrated that these three agents greatly differ also in the antiproliferative effect and cell death signals they trigger. JNK phosphorylation sharply increased in cells treated with HYD, while treatment with free doxorubicin moderately decreased and treatment with PK1 even strongly decreased it. On the other hand, treatment with free doxorubicin greatly increased p38 phosphorylation, while PK1 and HYD increased it slightly. PK1 also significantly increased ERK phosphorylation, while both the free doxorubicin and HYD conjugate slightly decreased it. Long-term inhibition of JNK significantly increased both proliferation and viability of EL-4 cells treated with free doxorubicin, showing that the JNK signaling pathway could be critical for mediating cell death in EL-4 cells exposed to free doxorubicin. Both activation of caspase 3 and decreased binding activity of the p50 subunit of NFκB were observed in cells treated with free doxorubicin and HYD, while no such effects were seen in cells incubated with PK1. Analysis of the expression of genes involved in apoptosis and regulation of the cell cycle demonstrated that free doxorubicin and HYD have very similar mechanisms of action, while PK1 has very different characteristics.

INTRODUCTION

Doxorubicin is one of the most effective anthracycline antibiotics with a broad anti-tumor spectrum. Unfortunately, numerous side effects such as severe cardiotoxicity, bone marrow suppression, and alopecia limit its use. Development of tumor-targeted formulations is one of the main lines of research for improving the safety and efficacy of anthracyclines. For this purpose, we have used a water-soluble, nontoxic copolymer based on *N*-(2-hydroxypropyl)methacrylamide (HPMA) as a carrier for anti-cancer drugs. Covalent conjugation of doxorubicin to HPMA copolymer eliminates its adverse cytotoxicity, as this conjugate is biologically inactive when circulating in the bloodstream (*1*). Enhanced and tumor-selective accumulation of HPMA conjugate within the solid tumor is achieved either passively due to the enhanced permeability and retention (EPR) effect (*2*) or actively by addition of a targeting moiety (e.g., antibodies, lectins, carbohydrates) (*3*).

Anthracyclines cause apoptosis of cancer cells by a complex network of events which include intercalation into the DNA, generation of reactive oxygen species, topoisomerase II inhibition, and DNA damage (*4*). HPMA conjugate that contains doxorubicin bound via a pH-sensitive bond (HYD) possesses similar biological properties as free doxorubicin (*5*), because doxorubicin is released inside the cell and then acts analogously to free doxorubicin. Controlled release of doxorubicin within cancer cells is achieved by hydrolysis of hydrazone conjugates having doxorubicin bound via pH-sensitive bonds (*6*). Those bonds are stable at physiological pH 7.4, but are effectively degraded at pH 5. Inside the cell, doxorubicin is released quickly in endosomes or lysosomes. Conjugates with doxorubicin bound to the HPMA carrier through a hydrazone bond are highly cytotoxic and cytostatic in vitro and in vivo (*7*).

On the other hand, intracellular events triggered by HPMA copolymer-conjugated doxorubicin via an enzymatically degradable bond (PK1) remain unclear. These conjugates were originally designed to release the drug from the oligopeptide side chain by the activity of lysosomal proteases (*8*). Some authors initially demonstrated that HPMA copolymer conjugates with enzymatically degradable bonds can be stronger pro-apoptotic inducers than free doxorubicin (*9*). However, later it was shown that both apoptosis and necrosis are induced in cells exposed to proteolytically cleavable HPMA copolymer conjugates (*10*−*12*). Our recent data do not support the idea that the enzymatic degradation and doxorubicin release from PK1 are the most important mechanisms responsible for target cell death. They rather suggest that immediately after penetrating the plasma membrane the whole conjugate intercalates into the membrane system of the cell, causing its collapse and death (*10*, *11*).

PK1 with enzymatically degradable bond between the oligopeptide spacer GFLG and doxorubicin was tested in phase I

and was recommended for phase II of clinical study (*13*). A conjugate similar to PK1 but containing human nonspecific antibody was used for the treatment of patients with advanced cancer (*14*).

In this study, we used the EL-4 T-cell lymphoma to determine the differences in intracellular action of free doxorubicin, PK1, and HYD. We determined their impact on intracellular signaling pathways (mitogen-activated protein kinases, NFκB, and apoptosis) and expression of genes involved in the regulation of cell cycle, and showed differences in their intracellular distribution.

EXPERIMENTAL PROCEDURES

Materials. Hydrazine monohydrate, methacryloyl chloride, 1-aminopropan-2-ol, 4-nitrophenol, 6-aminohexanoic acid, glycyl-L-phenylalanine, L-leucylglycine, 2,2′-azobis(isobutyronitrile) (AIBN), 2-(dimethylamino)ethyl methacrylate, dimethylformamide (DMF), *N*,*N*′-dicyclohexylcarbodiimide (DCC), 1-hydroxybenzotriazole (HOBT), dimethyl sulfoxide (DMSO), *tert*-butylcarbazate, and doxorubicin hydrochloride (Dox.HCl) were purchased from Fluka Chemie AG. 2,4,6-Trinitrobenzene-1-sulfonic acid was purchased from SERVA Feinbiochemica Heidelberg. All other reagents and solvents were of analytical grade.

Synthesis and Characterization of Monomers. *N*-(2-Hydroxypropyl)methacrylamide (HPMA) was synthesized as described in (*15*) using Na_2CO_3 as a base in the methacryloylation reaction (mp 70 °C; elemental analysis (calcd/found): 58.80/58.98% C; 9.16/9.18% H; 9.79/9.82% N). *N*-(*tert*-Butoxycarbonyl)-*N*′-(6-methacrylamidohexanoyl)hydrazine (Ma-AH-NHNH-Boc) was prepared by a two-step synthesis consisting of methacryloylation of 6-aminohexanoic acid followed by reaction of the resulting *N*-methacryloyl-6-aminohexanoic acid with *tert*-butylcarbazate as described in (*7*). Yield: 6.06 g (46%). Mp 110−114 °C. Elemental analysis: calcd C 57.70%, H 8.33%, N 13.46%; found C 58.66%, H 8.84%, N 13.16%.

N-Methacryloylglycyl-DL-phenylalanyl-L-leucylglycine and *N*-methacryloylglycyl-DL-phenylalanyl-L-leucylglycine 4-nitrophenyl ester (Ma-GFLG-ONp) were synthesized as described earlier (*1*). Mp 134−136 °C. Amino acid analysis: Gly/L-Phe/D-Phe/L-Leu = 2.05/0.54/0.47/1.00. Elemental analysis (calcd/found): C 59.89/59.21%; H 6.07/6.25%; N 12.04/12.32%. HPLC showed two peaks of equal areas at 14.41 min (L-Phe peptide) and 14.71 min (D-Phe peptide).

Purity of all monomers was examined by HPLC (LDC Analytical, U.S.A.) using a reversed-phase column Tessek SGX C_{18} (15 × 33 mm) with UV detection at 230 nm, eluent water−methanol with gradient 50−100 vol % methanol, flow rate 0.5 mL/min.

Synthesis of Polymer Precursors. *Copolymer poly(HPMA-co-MA-AH-NHNH$_2$)*. Copolymer poly(HPMA-*co*-MA-AH-NHNH-Boc) was prepared by radical solution polymerization (AIBN, 1 wt %; monomer concentration, 14 wt % in methanol solution; molar ratio HPMA/MA-AH-NHNH-Boc 93/7; 60 °C; 23 h) in a sealed ampule under nitrogen. The copolymer was isolated by precipitation into a mixture of acetone/diethyl ether (2:1). The protecting Boc group was removed by dissolution of the polymer in concd trifluoroacetic acid (TFE), and a final polymer was isolated after dilution with methanol by precipitation into ethyl acetate and purified by gel filtration using a column filled with Sephadex LH-20 and methanol as a solvent. The poly(HPMA-*co*-MA-AH-NHNH$_2$) was isolated by precipitation into ethyl acetate, separated by filtration, and dried in vacuum to constant weight.

Poly(HPMA-*co*- Ma-GFLG-ONp) was prepared by radical precipitation polymerization as described in (*15*).

HPMA homopolymer poly(HPMA) was prepared by radical solution polymerization using AIBN as initiator (0.8 wt %) and monomer concentration 16 wt % in methanol. Polymerization was carried out at 60 °C for 22 h in a sealed ampule under nitrogen; the polymer was isolated by precipitation into acetone and reprecipitated from methanol into acetone.

Synthesis and Characterization of Polymer−Dox Conjugates. The conjugate bearing Dox attached via a pH-sensitive hydrazone bond poly(HPMA-*co*-MA-AH-NHN = Dox) (HYD) and the conjugate bearing Dox attached via the enzymatically degradable oligopeptide sequence poly(HPMA-*co*- Ma-GFLG-Dox) (PK1) were prepared as described earlier, HYD in (*6*) and PK1 in (*15*).

The polymer−drug conjugates were freed of low-molecular-weight impurities (such as Dox, 4-nitrophenol) by gel filtration using a Sephadex LH-20 column with methanol elution and tested for the content of the free drug using a Pharmacia FPLC equipped with a Superose 6 column and by HPLC after extraction of free Dox from an aqueous polymer solution into chloroform. HPLC analysis of monomers was conducted on an HPLC analyzer (LDC Analytical, U.S.A.) using a reversed-phase column Tessek SGXC18 (125 × 4 mm) with UV detection at 230 nm, solvent methanol−water, gradient 50−100% methanol, and flow rate 0.5 mL/min. Content of Dox in the conjugates was measured spectrophotometrically in water using ϵ = 11 500 L mol^{-1} cm^{-1} at λ = 488 nm).

Amino acid analysis was performed using an amino acid analyzer (LDC Analytical, U.S.A.) (precolumn OPA derivatization, reversed-phase column Tessek SGX C_{18}, 250 × 4 mm, gradient sodium acetate buffer−methanol, fluorescence detector Fluoromonitor 4100).

Determination of the molecular weight of all polymers was carried out with a FPLC Pharmacia system equipped with RI, UV, and multiangle light scattering DAWN DSP-F (Wyatt Co., U.S.A.) detectors using 0.3 M acetate buffer pH 6.5 and a Superose 6 column.

The content of hydrazide groups in a precursor and HYD conjugate was determined by a modified TNBSA assay as described (*16*).

The following polymers were prepared: HPMA copolymer bearing Dox attached via enzymatically degradable spacer (PK1), M_w = 24.8 kDa, M_w/M_n = 1.5, total Dox content 5.2 wt %, free Dox content <0.1%. HPMA copolymer bearing Dox attached via pH-sensitive hydrazone bond (HYD), M_w = 25 kDa, M_w/M_n = 1.8, total Dox content 5.2 wt %, free Dox content <0.3%.

Detection of MAPK Phosporylation by Immunoblotting. 1−5 × 10^7 EL-4 cells were incubated with tested samples at a concentration corresponding to 3, 10, or 50 × IC_{50} of doxorubicin equivalent. After incubation periods of 5, 15, 30, 60, or 120 min, the media from the cell culture were aspirated, and cells were washed twice with an ice-cold Tris-buffered saline (TBS) with 1 μM Na_3VO_4 (phosphatase inhibitor) and centrifuged (4000 *g*, 4 °C). Then, EL-4 cells were resuspended in Extract buffer composed of 1% Nonidet P-40 (Pierce), 1 mM Na_3VO_4, 1 mM EDTA, 2 mM EGTA, 10 mM NaF, 1 mM DTT, 5% Protease mix (Sigma), 1 mM PMSF phenylmethylsulfonyl fluoride (PMSF), and TBS of pH 7.4, and passed ten times through a syringe needle (25-30G). After 60 min of incubation at 4 °C, cell lysates were centrifuged at 14 000 *g* (4 °C), and protein concentration in aspirated supernatants was determined by the Bradford method. 20 μg protein (final protein load per lane) aliquots were mixed 2:1 with 3× sample buffer composed of 62.5 mM Tris, 30% glycerol, 20.8 μM SDS, 50 mM DTT, and 0.03% w/v bromophenol blue and stored at −20 °C until needed. Then, standard electrophoresis using 10% polyacrylamide gel followed by standard blotting semidry procedure with

nitrocellulose membrane was performed. 5 μL of a biotinylated protein ladder (Cell Signaling, MA) was used to estimate the molecular weight of protein bands. The membrane was washed in 25 mL of TBS and blocked for 60 min in 5% low-fat milk or 2% BSA in TBS at room temperature before overnight incubation with 1:1000 primary rabbit-anti-mouse phospho-p38, phospho-SAPK/JNK, or anti-mouse phospho-ERK antibodies (Cell Signaling, MA) at 4 °C in TBS with 0.1% Tween 20 and 5% BSA. Proper washing with TBS containing 0.1% Tween 20 (TBS/T) preceded 60−120 min of incubation with anti-rabbit or anti-biotin, HRP-linked IgG (1:1000) (Cell Signaling, MA) in 5% low-fat milk or 2% BSA in TBS at room temperature. Finally, the membranes were washed in TBS/T, developed by chemiluminescence reaction and exposed to LAS-1000 CCD camera (Fujifilm). Then, the *Aida Image Analyzer* v 3.2.8. (Raytest, Germany) was used for data quantification.

The molecular weights of the respective kinases were used as internal standards of assay specificity. The molecular weights of detected phospho-proteins were determined by using protein markers, compared with the data provided by the manufacturer and found to be identical with respective MAPKs. Untreated cells were used as another internal control. The level of respective phosphorylated MAPK in the untreated cell was regarded as a reference value to which all other values were referred.

In Vitro Proliferation Assay. An EL-4 murine T-cell lymphoma cell line was grown in cultivation flasks at 37 °C with 5% CO_2 in RPMI 1640 medium supplemented with heat-inactivated 10% fetal calf serum (FCS), 2 mM L-glutamine, 50 mM 2-mercaptoethanol, 4.5 g/L glucose, 1 mM sodium pyruvate, 100 U/mL penicillin, and 100 μg/mL streptomycin. 2×10^5 cells/mL were cultured in Nunc 96-well flat-bottom plates with or without Dox.HCl, HYD, or PK1, and/or MAPK inhibitors. In order to exclude any effect of tested agents on noninhibited kinase pathways, EL-4 cells were pretreated with SP600125 (JNK inhibitor), SB203580 (p38 inhibitor), or with U0126 (ERK inhibitor) (Sigma) MAPK inhibitors for 30 min prior to addition of Dox, PK1, or HYD in 48 h proliferation assays. In short-term assays, which were performed in order to avoid indirect effects such as changes in gene expression that could happen during the 48 h inhibition, inhibitors were added 30 min prior to [^{3}H]thymidine addition in 5 h MAPK inhibition assays. All samples were tested in pentaplets. The plates were then cultured in 5% CO_2 for 48 h at 37 °C. 18.5 kBq of [^{3}H]-thymidine in 50 μL was added per well for the last 5 h of incubation. The cells were then harvested (Tomtec, Orange, CT) onto glass filter mats. After drying, the fiber filter was placed into a sample bag, a solid scintillator MeltiLex A (Wallac, Turcu, Finland) was applied, and the bags were sealed (Microsealer, Wallac). Counting was performed in a 1450 MicroBeta TriLux scintillation counter (Wallac).

Flow Cytometry. Control, Dox, HYD, or PK1 treated cells were incubated for 24 or 48 h with or without MAPK inhibitors, as described in the In Vitro Proliferation Assay section. To exclude any unspecific effect of tested agents on noninhibited kinase pathways, kinase inhibitors were added 30 min prior to Dox, HYD, or PK1 treatment. All agents were used at a concentration of $1 \times IC_{50}$. After incubation, cells were washed and collected at 4 °C in PBS. Then, 0.01 μg/mL of Hoechst 33258 (Molecular Probes, Oregon) in 10 μL was added. After 20 min of incubation at 4 °C in the dark, 50 μL of ice-cold PBS was added, and at least 50 000 cells were analyzed by FACS (LSRII, BD, San Jose, CA) with the use of *FowJo* software (Tree Star, San Carlos, CA).

Detection of Caspase 3 Activity. 5×10^6 EL-4 cells were incubated with tested samples at a concentration corresponding to $3 \times IC_{50}$ for different time intervals. After the incubation periods, the cells were washed twice with PBS, and the pellets were resuspended in 50 μL of Lysis buffer (Caspase 3 Assay Kit, Sigma). Cells were lysed on ice for 20 min, and 50 μL of supernatant was collected after centrifugation (12 000 rpm, 5 min, 4 °C). The Bradford method was used to determine protein concentration in cell lysates. The activity in cell lysates was measured spectrophotometrically at 405 nm using the Caspase 3 Assay Kit (Sigma). Caspase 3 activity was finally expressed as the amount of *p*-nitroaniline (nmol) released from synthetic Caspase 3 substrate/μg of total protein in cell lysate.

Binding Activity of NFκB. 5×10^6 EL-4 cells were incubated with tested samples at a concentration corresponding to $10 \times IC_{50}$ for different time intervals. After the incubation period, the cells were washed twice with PBS, and the pellets were resuspended in Lysis buffer (Nuclear Extraction Kit, Chemicon). Cells were lysed on ice and passed five times through syringe with small (25−30) gauge needle. After centrifugation at 8 000 *g* for 20 min at 4 °C, the pellets were resuspended in nuclear extraction buffer, and nuclei were disrupted by lysis with the use of a 27G needle. After centrifugation (16 000 *g*, 5 min, 4 °C), protein concentration was determined with the use of the Bradford method, and aliquots were frozen at −80 °C until needed. Then, the binding assay was performed with the use of the NFκB p50/p65 Assay Kit (Chemicon). Briefly, in the streptavidin-coated 96-well plate, the biotinylated DNA binding sequence for NFκB was mixed with nuclear extract. After addition of specific antibodies, the amount of p50 or p65 subunits was detected spectrophotometrically at 450/650 nm. The NFκB binding activity was finally expressed as percent of controls.

Intracellular Localization of Doxorubicin. 1×10^6 cells were incubated for 24 h with 5 μg/mL of free doxorubicin or an adequate equivalent contained in HYD conjugate. For PK1 conjugate, a concentration corresponding to 20 μg of doxorubicin per mL was used. The excitation of doxorubicin at 488 nm and emission at 560 nm was used to visualize the intracellular localization of doxorubicin under Leica TCS-SP2 Multiphoton Confocal Laser Scanning Microscope (TCS−MP). Intensity profiles were performed by using *AnalySIS* Software (SIS software, Germany).

RNase Protection Assay. Total RNA was extracted from EL-4 cells exposed to $3 \times IC_{50}$ for different time intervals using the RNA blue reagent (Top-Bio, Czech Republic). Total RNA was quantified specrophotometrically and dried by vacuum centrifugation for 1 h. To determine the levels of cytokine mRNA transcripts, a RiboQuant Multi-probe RNase Protection Assay System (Pharmingen) was used following the manufacturer's instruction. α[^{32}P] UTP (Izotop, Budapest, Hungary) was used for the synthesis of antisense RNA probe sets. ^{32}P-labeled protected fragments were resolved by electrophoresis on 5% long ranger gel (BMA, Rockland, Maine). Gels were dried and radioactivity visualized by phosphorimaging. The level of mRNA was evaluated for the genes involved in cell cycle regulation (cyclin A1, A2, B1, B2, C, D1, D2, D3, sin3, c-, n-, l-, b-myc, max, mad, mxi, mad3, mad4, mnt) and genes involved in apoptosis signaling (caspase 8, fasL, fas, fadd, fap, faf, trail, TNFRp55, tradd, rip, bcl-W, bfl-1, bcl-x, bak, bax, bcl-2, bad). For each individual sample including the control, mRNA levels for the genes listed above were expressed in % of mRNA level for the L32 housekeeping gene. Final results are presented as a ratio of mRNA levels for the particular gene in treated cells and nontreated controls.

Statistical Analysis. The significance of any differences obtained between experimental groups was evaluated by the Student's *t*-test. In all statistical analyses, significance was assessed at the $P \leq 0.05$ level.

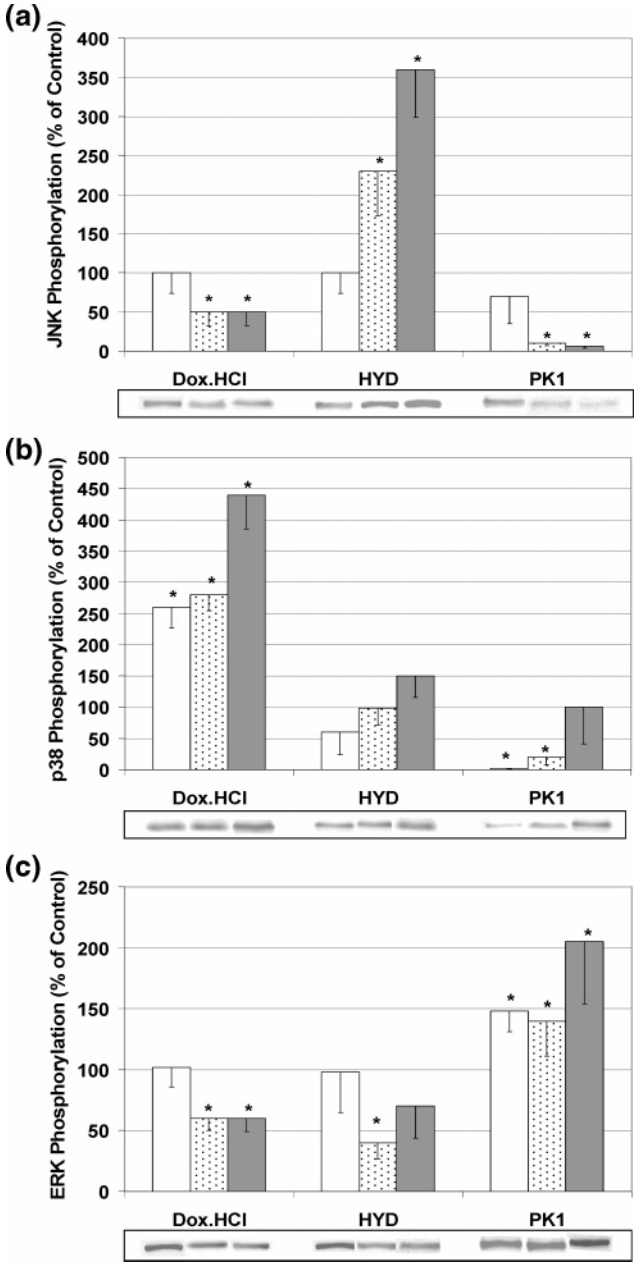

Figure 1. Phosphorylation of MAPKs in EL-4 cells treated with different forms of doxorubicin. Phosphorylation of JNK (a), p38 (b), and ERK (c) MAP kinases in lysates of EL-4 cells after 5 min (empty bars), 30 min (dotted bars), or 120 min (full bars) treatment with different forms of doxorubicin (50 × IC_{50}) relative to control cells (100%). Representative western blot bands are shown for each sample below the corresponding column. Dox.HCl, free doxorubicin; HYD, doxorubicin bound to HPMA copolymer via hydrolytically degradable bond; PK1, doxorubicin bound to HPMA copolymer via enzymatically cleavable bond. *The difference against control was significant at $P < 0.05$ (Student's *t*-test).

RESULTS

MAPKs Phosphorylation. In preliminary studies, we used the concentrations of 3×, 10×, and 50× IC_{50} of Dox, HYD, and PK1 on MAPK phosphorylation (not shown). The highest phosphorylation rates were achieved with the highest concentration of 50 × IC_{50}, and it was used in assays with phosphorylated JNK (Figure 1a), p38 (Figure 1b), and ERK (Figure 1c). Incubation of EL-4 cells with free doxorubicin stimulated phosphorylation of p38 kinase up to 450% of control, whereas it inhibited phosphorylation of JNK and ERK almost by 50% in comparison with control cells. The maximum stimulation of p38 phosphorylation was achieved during the longest incubation lasting 120 min, and inhibition of JNK and ERK was acheived during both the 30 and 120 min incubation periods. Hydrazone conjugate (HYD) stimulated the phosphorylation of the stress-activated protein kinase JNK up to 360% of controls in the 2 h incubation period. ERK phosphorylation was inhibited after both the 30 and 120 min incubation periods with HYD, whereas a slight inhibition of p38 phosphorylation turned into minute enhancement during the long-term incubation. Phosphorylation of ERK was enhanced up to 205% of controls after incubation with PK1 conjugate. PK1 achieved an almost total (95%) inhibition of JNK phosphorylation. During incubation of EL-4 cells with PK1 conjugate, previous almost absolute inhibition of p38 phosphorylation turned into the same level of phoshorylation as that of the control after longer incubation.

Table 1. Cytostatic Effects of Free Doxorubicin, HPMA-Bound Doxorubicin, and MAPK Inhibitors[a]

sample	IC_{50} concentration (μM) ± S.D.
Dox.HCl	0.014 ± 0.001
HYD	0.066 ± 0.013
PK1	45.970 ± 3.844
SP600125	6.36 ± 0.921
SB203580	8.12 ± 0.725
U0126	38.00 ± 3.453

[a] IC_{50} values determined in EL-4 cell line for free doxorubicin, HYD, PK1 conjugate, and JNK inhibitor SP600125, p38 inhibitor SB203580, and inhibitor of MEK/ERK U0126.

EL-4 Cell Proliferation Assay and IC_{50} Values. IC_{50} values summarized in Table 1 represent the concentration of doxorubicin or MAPK inhibitors required for 50% inhibition of EL-4 cell proliferation after 48 h. Free doxorubicin exhibited the highest cytostatic effect at 0.014 μM, IC_{50} value of hydrazone conjugate was 0.066 μM (doxorubicin equivalent), while PK1 conjugate showed the lowest cytostatic effect of 45.97 μM. IC_{50} of SP600125, SB203580, and U0126 were 6.36 μM, 8.12 μM, and 38 μM, respectively.

After 48 h of incubation with 1 × IC_{50} value of SP600125 (JNK pathway inhibitor), EL-4 cells proliferated about 50% less when coincubated with or without hydrazone or PK1. On the other hand, when coincubated with free doxorubicin, EL-4 cells proliferated twice more in comparison with control cells incubated only with free doxorubicin without SP600125. EL-4 cells incubated for 48 h with free doxorubicin or HYD conjugate followed by 5 h of JNK inhibition with SP600125 proliferated about 50% less than cells without SP600125 inhibitor with free doxorubicin or HYD conjugate. This short-term, 5 h JNK pathway inhibition did not have any effect on proliferation of control or PK1-treated cells (Figure 2a).

Neither 5 (not shown) nor 48 h inhibition of both the p38 pathway by SB203580 (Figure 2b) and ERK pathway by U0126 (Figure 2c) caused any significant differences in the proliferation of controls or cells treated with doxorubicin, HYD, or PK1. In those incubation assays, proliferation of all cells was inhibited approximately by 50% relative to corresponding untreated control cells.

FACS Analysis of Cell Viability. Inhibition of the JNK pathway by SP600125 (Figure 3a) for 48 h had no significant effect on cellular viability in controls, HYD-, or PK1-treated cells. Coincubation of EL-4 cells with doxorubicin and SP600125 reduced cellular viability up to 86% relative to the cells with uninhibited JNK pathway, whereas cells exposed only to Dox.HCl reduced their viability by approximately up to 60%. On the other hand, inhibition of the JNK pathway had no significant effect on viability of cells exposed to HYD or PK1 conjugates. A 24 h inhibition of the JNK pathway did not significantly affect the number of dead cells in controls or any tested samples.

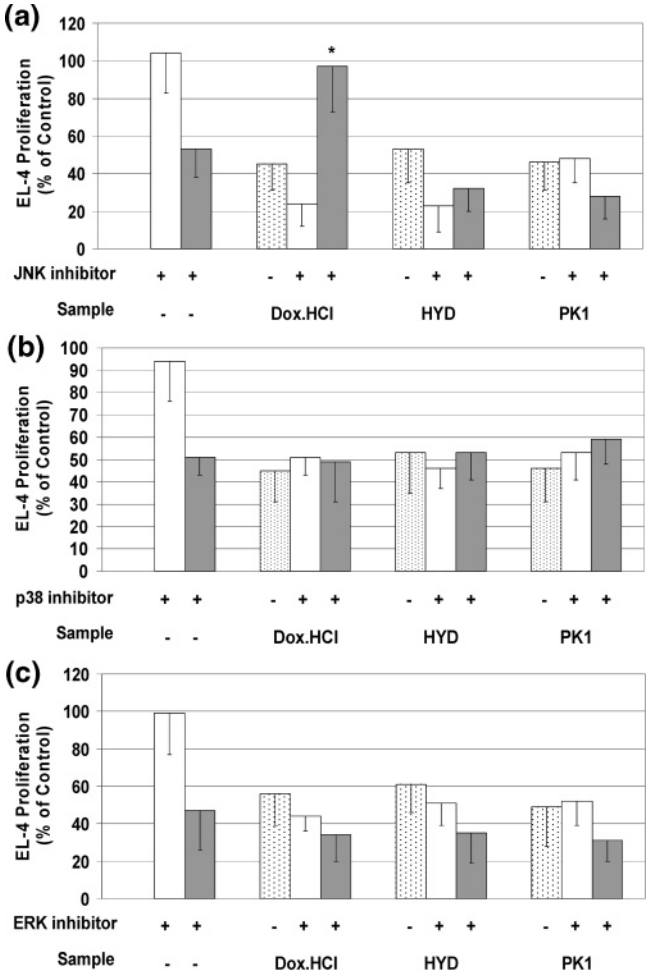

Figure 2. Proliferative activity of EL-4 cells incubated with different forms of doxorubicin and with/without MAPK inhibitors. Proliferation of EL-4 cells after a 48 h treatment with different forms of doxorubicin ($1 \times IC_{50}$) relative to control cells (100%). Dox.HCl, free doxorubicin; HYD, doxorubicin bound to HPMA copolymer via hydrolytically degradable bond; PK1, doxorubicin bound to HPMA copolymer via proteolytically cleavable bond. Cells were coincubated either for 5 h (empty bars) or for 48 h (full bars) with MAPKs inhibitors ($1 \times IC_{50}$) or without MAPK inhibitors (dotted bars). Inhibition of JNK (a), p38 (b), or inhibition of ERK (c). *The difference against the group without inhibitor but exposed to the same form of doxorubicin was significant at $P < 0.05$ (Student's *t*-test).

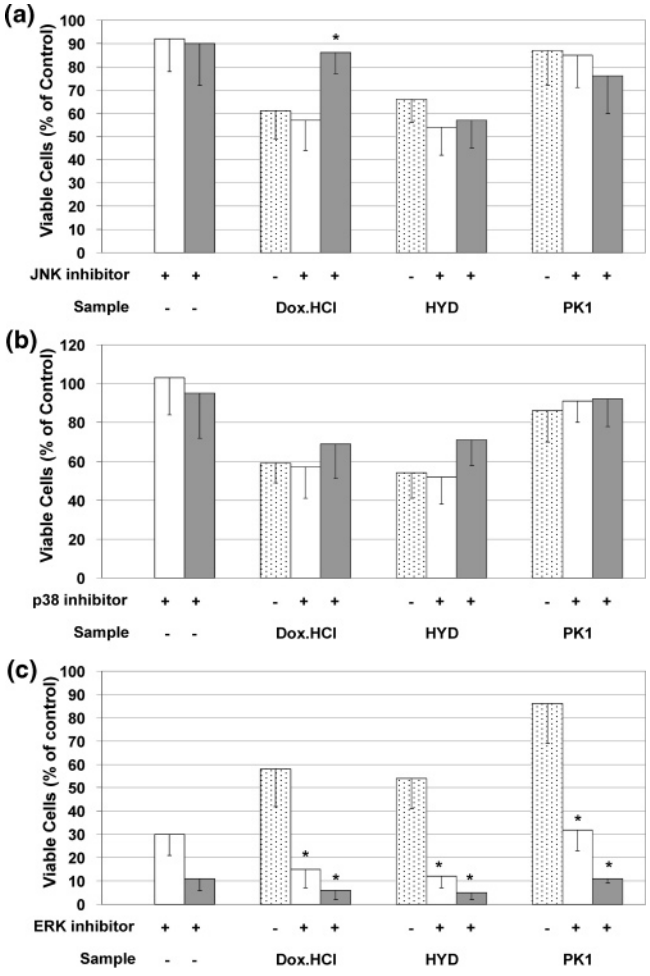

Figure 3. Viability of EL-4 cells incubated with different forms of doxorubicin and with/without MAPK inhibitors. Viability of EL-4 cells after a 48 h treatment with different forms of doxorubicin ($1 \times IC_{50}$) relative to control cells (100%). Dox.HCl, free doxorubicin; HYD, doxorubicin bound to HPMA copolymer via hydrolytically degradable bond; PK1, doxorubicin bound to HPMA copolymer via enzymatically cleavable bond. Cells were coincubated either for 24 h (empty bars) or for 48 h (full bars) with MAPKs inhibitors ($1 \times IC_{50}$) (a) inhibiting JNK, (b) p38, or (c) inhibiting ERK. Dotted bars show cells without inhibited MAPK pathway incubated with different forms of doxorubicin. *The difference against the group without inhibitor, but exposed to the same form of doxorubicin was significant at $P < 0.05$ (Student's *t*-test).

Inhibition of the p38 kinase pathway (Figure 3b) for 24 or 48 h did not significantly affect the viability of control cells nor of those treated with Dox.HCl, HYD, and PK1 conjugate when compared to cells exposed to free doxorubicin or HPMA conjugates without inhibitor.

U0126 inibitor had been shown to have toxic effects even on control EL-4 cells incubated in cultivation media only. Coincubation with free doxorubicin or HPMA conjugate enhanced U0126 toxicity. Cells exposed to Dox.HCl, HYD, or PK1 conjugate showed reduced viability by 94%, 95%, and 89%, respectively, in 48 h incubation. 24 h incubation showed 85%, 88%, and 68% viability reduction in Dox.HCl, HYD, and PK1 treated cells, respectively (Figure 3c).

Caspase 3 Activity. Caspase 3 was rapidly activated in EL-4 cells after treatment with free doxorubicin or hydrazone conjugate, and its activity increased more than 7- and 5-fold relative to controls, respectively. PK1 conjugate did not enhance the activity of this effector caspase even over an incubation period as long as 30 h (Figure 4a).

NFκB Binding Activity. The NFκB p50 binding activity was significantly reduced in cell lysates after treatment with free doxorubicin and hydrazone conjugate at all tested time intervals. The lowest binding was detected in the longest 16 h treatment and was as low as 43% with Dox.HCl and 42% with hydrazone conjugate, as compared with controls. On the other hand, in PK1-treated cells, the p50 binding was significantly reduced only after 4 and 8 h incubation (Figure 4b). The binding activity of the p65 subunit was not significantly changed either with Dox.HCl and with hydrazone, or in PK1-treated cells (data not shown).

Intracellular Localization. The confocal laser scanning microscopy visualizing the intracellular localization of free or HPMA-conjugated doxorubicin in native cells showed differences in the intracellular fate of these agents. The fluorescence of free doxorubicin was localized mainly inside the nucleus and endosomes, whereas the fluorescence of doxorubicin in the PK1 conjugate was clearly localized in cell membranes (cytoplasmic, nuclear, endosomal, Golgi apparatus, etc.). The doxorubicin contained in the hydrazone conjugate was shown to be localized in endosomes and lysosomes, and released doxorubicin was detected inside the nucleus (Figure 4c).

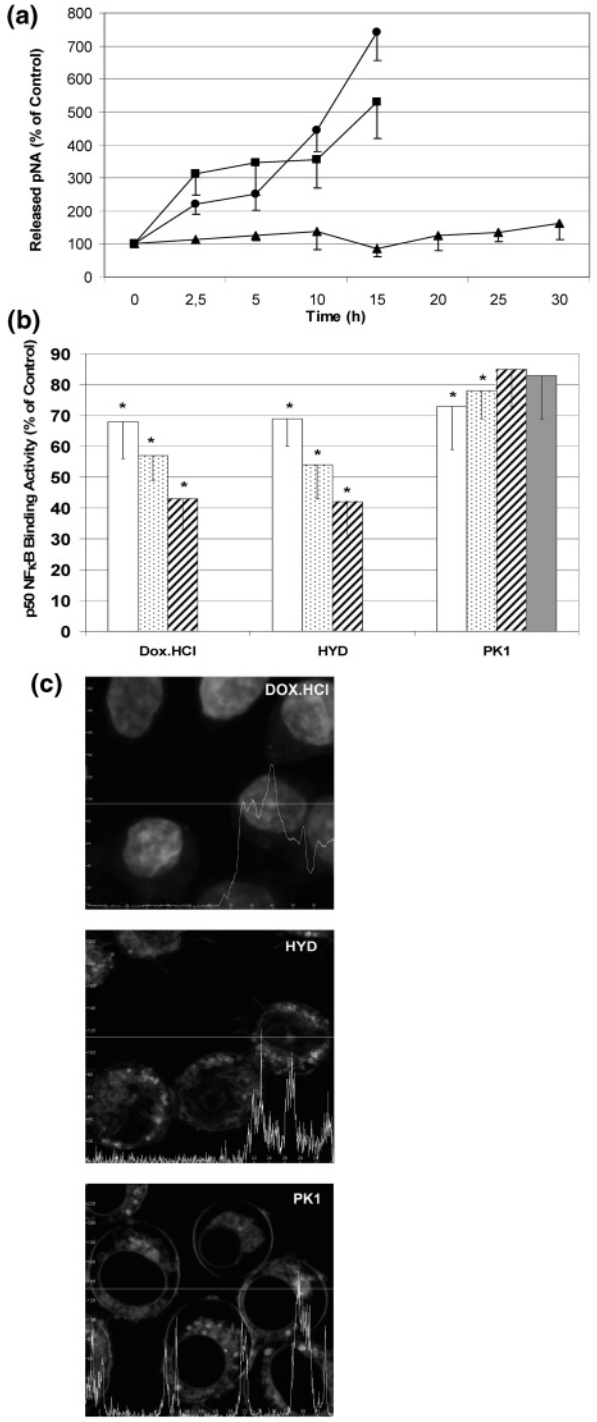

Figure 4. Caspase 3 activity, binding activity of p50 subunit of NFκB and intracellular distribution in EL-4 cells after treatment with different forms of doxorubicin. (a) The activity of caspase 3 in cells incubated with different forms of doxorubicin ($3 \times IC_{50}$). Caspase 3 activity is expressed as the amount of *p*-nitroaniline (nmol) released from synthetic caspase 3 substrate/μg of total protein in cell lysate and are related to control (control cells = 100%). (b) Binding activity of p50 subunit of NFκB in cells treated with $10 \times IC_{50}$ of different forms of doxorubicin for 4 (empty bars), 8 (dotted bars), 16 (hatched bars), or 24 (full bars) hours relative to control cells (100%). *The difference against control was significant at $P < 0.05$ (Student's *t*-test). (c) Intracellular localization of free doxorubicin, hydrazone conjugate, both with 5 μg of doxorubicin per mL and with PK1 conjugate with 20 μg of doxorubicin per mL in EL-4 cells after 24 h of treatment. Cross-section lines represent the intensity profiles demonstrating the fluorescence of doxorubicin. Free doxorubicin (-●-, Dox.HCl), doxorubicin bound to HPMA copolymer via hydrolytically degradable bond (-■-, HYD), doxorubicin bound to HPMA copolymer via proteolytically cleavable bond (-▲-, PK1).

Expression of Genes Involved in the Regulation of Cell Cycle and Apoptosis. Expression of selected mRNA for genes involved in the regulation of cell cycle and apoptosis was determined in EL-4 cells treated with $3 \times IC_{50}$ values of tested conjugates. The results for the most important genes with significantly altered expression are shown in Figure 5. Expression of an important proapoptotic gene bad was elevated up to 112% and 127% after incubation with free doxorubicin and the hydrazone conjugate, respectively, whereas the PK1 conjugate significantly reduced the level of mRNA for this gene to 48%, as compared with controls. Expression of another gene involved in apoptosis signaling − fas, were elevated after incubation with all tested forms of doxorubicin. The enhancement caused with the PK1 conjugate is significantly lower and more time-dependent in comparison with free doxorubicin or hydrazone conjugate. We did not observe any changes in the expression of bcl-2 family members tested, nor in the expression of bax and bak.

PK1-treated cells exhibited significantly increased levels of c-myc and max that are important for cell cycle progression. This nearly 150% and 120% increase of c-myc and max, respectively, turned into inhibition later on. Free doxorubicin and HYD conjugate quickly and strongly reduced the amount of those two genes.

The expression of all tested cyclines was quickly reduced after incubation with Dox.HCl and HYD conjugated, but this inhibition was slighter and slower after incubation of EL-4 cells with PK1 conjugates. Cyclines A2 and D2 are shown as typical indicators of action of tested forms of doxorubicin on expression of cycline genes.

DISCUSSION

The MAPK transfers signals from the cell membrane to the nucleus by phosphorylation of transcription factors like Elk-1. JNK, p38, and ERK are serine/threonine kinases that are activated by dual phosphorylation of the threonine/tyrosine motif by upstream kinases (*17*). Using specific antibodies, we found that Dox.HCl, HYD, and PK1 conjugates activate different MAPKs. Free doxorubicin and HYD activated the p38 and JNK, respectively. These kinases are typically activated in response to cell stress, DNA damage, and precede apoptotic cell death (*18*). Moreover, both the free drug and HYD conjugate enhanced the expression of proapoptotic gene bad and increased the activity of caspase 3, an effector apoptotic caspase whose activation is an irreversible step in apoptotic cell death. Both the Dox.HCl and HYD conjugate also increased the expression of Fas and thus made the cells more sensitive to FasL-mediated apoptotic cell death. These two agents also inhibited the activation of the p50 subunit of NFκB transcription factor that provides antiapoptotic signals.

On the other hand, the PK1 conjugate activated the ERK that is usually associated with cell growth and differentiation (*17*). In contrast to free doxorubicin and HYD conjugate, the PK1 conjugate reduced the expression of bad, did not enhance the activity of caspase 3 (up to 30 h of incubation), and was not inhibitory for p50 activation in longer time intervals. Surprisingly, neither free drug nor HPMA conjugates changed the expression of antiapoptotic genes as well as the expression of cyclin-dependent kinases (data not shown).

The mode of action of the HYD conjugate resembles that of free doxorubicin, as doxorubicin is released from the HYD conjugate by hydrolysis, a relatively fast process, and it acts as free doxorubicin by triggering apoptosis. This explains the similar mode of action of these agents in our study that has been demonstrated previously with another cell line (*5*). In contrast, the mechanism of action of the PK1 conjugate is less clear. Recently, we have shown new data which do not support the enzymatic degradation of PK1 conjugate in vivo and thus

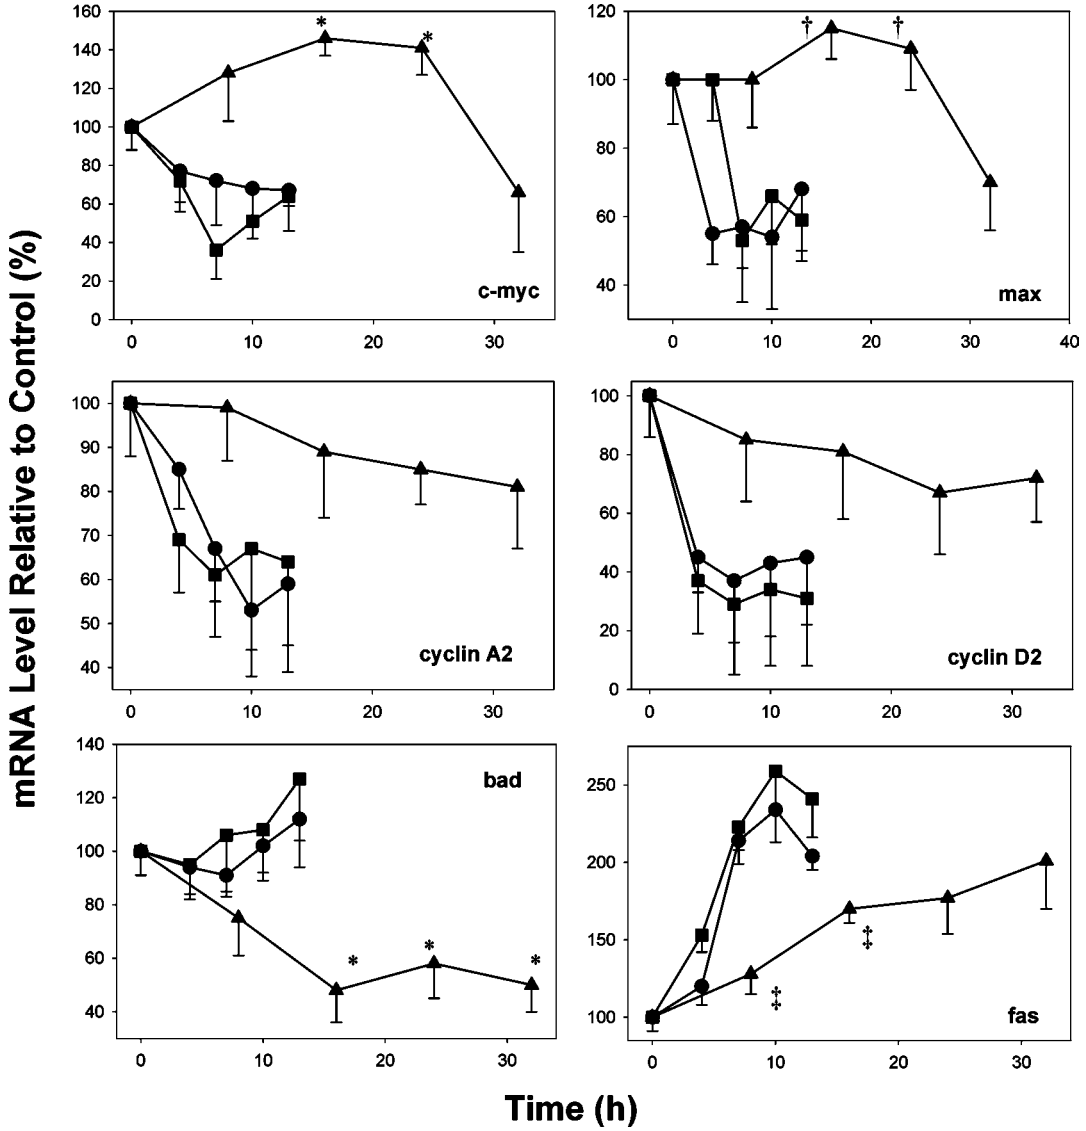

Figure 5. Expression of selected genes on mRNA level in EL-4 cells treated with different forms of doxorubicin. The level of mRNA for selected genes determined by RNAse protection assay in the EL-4 cells after treatment with different forms of doxorubicin ($3 \times IC_{50}$). For each individual sample including control, mRNA levels were expressed in % of mRNA level for L32 housekeeping gene. Final results are presented as a ratio of mRNA levels for the particular gene in treated cells and non-treated controls. Free doxorubicin (-●-), doxorubicin bound to HPMA copolymer via hydrolytically degradable bond (-■-), doxorubicin bound to HPMA copolymer via proteolytically cleavable bond (-▲-). *The difference against the free doxorubicin and hydrazone-treated groups was significant at $P < 0.05$. †The difference against the free doxorubicin and hydrazone (except for the 4 h incubation period with hydrazone) treated groups was significant at $P < 0.05$. ‡The difference against the free doxorubicin and hydrazone (except for the 4 h incubation period with both free doxorubicin and hydrazone) treated groups was significant at $P < 0.05$ (Student's *t*-test).

show that the release of free doxorubicin is not a dominant mechanism (*15*). Instead, we suggest that the whole PK1 conjugate interacts with cell membranes, causing their damage (changed permeability, blockade of intracellular trafficking, etc.) and subsequently resulting in cell death (*10, 11*). These data are supported by our recent finding that both the Dox.HCl and HYD conjugate trigger stress-activated signaling pathways JNK and p38 and strongly induce apoptosis. On the other hand, the PK1 conjugate activates ERK and suppresses the activation of JNK. Thus, PK1 shows an opposite pattern in activation of different MAPKs in comparison to Dox.HCl and HYD.

The data showing the effect of free or HPMA-conjugated doxorubicin on expression of genes involved in cell cycle (c-myc, max, and cyclines) demonstrate that Dox.HCl and HYD conjugate inhibit cell proliferation quickly, whereas the PK1 conjugate does not inhibit the cell cycle efficiently within the first 24 h.

Further, we used inhibitors specific for JNK, p38, and ERK to evaluate their impact on proliferation and cell death. These inhibitors alone showed some inhibition of proliferation which is shown in Table 1. Doxorubicin-treated cells with inhibited JNK proliferated more than twice as much as the cells without JNK inhibitor. Moreover, the viability of the cells with inhibited JNK was higher than that of cells treated only with free doxorubicin, which clearly shows that JNK plays a key role in mediating the cytostatic and cytotoxic effect of Dox.HCl. On the other hand, the death of control cells and HPMA conjugate treated cells was not significantly changed after treatment with the JNK inhibitor. It seems that, in doxorubicin treated cells, the JNK pathway triggers a lethal, probably proapoptotic signal, and blocking of this signal protects cells against doxorubicin-induced cell death (*19*). In contrast, this important role of the JNK pathway was not seen in cells treated with PK1 and even with HYD conjugate. This is surprising, because the HYD conjugate has been reported to possess properties very similar to the free drug (*5*). As shown previously with different cell lines (*10, 11*), the intracellular distribution of the PK1 conjugate greatly differs from that of free doxorubicin and the hydrazone

conjugate. These data discussed previously support our present results and show one of the possible mechanisms of action.

Furthermore, we used a confocal laser scanning microscopy to visualize the intracellular localization of doxorubicin in living cells exposed to different forms of doxorubicin. We demonstrated significant differences in the intracellular fate of these agents. The cells treated with free doxorubicin showed localization of the drug mainly inside the nucleus and acidic organelles (*10*). The fluorescence pattern within cells incubated with hydrazone conjugate was similar to that of the free drug, and the strong signal within the nucleus verified the effective release of doxorubicin from its carrier. By contrast, the fluorescence signal in cells treated with the PK1 conjugate was clearly localized almost solely within cell membranes (cytoplasmic, nuclear, endosomal, Golgi apparatus, etc.), and we were not able to detect any nuclear fluorescence. The latter finding indicates that PK1 conjugate was not intracellularly degraded and doxorubicin was not released in sufficient amount to be detected within cell nucleus. This seems to be in contradiction to the data published by Duncan's team (*20*), as well as two other groups who demonstrated nuclear localization of doxorubicin presumably released from the PK1 conjugate (*21, 22*). To put these conflicting data into accord, we propose that the differences might be due to the use of different cancer cell lines for the studies, as different cells have different trafficking pathways and the level of enzymes capable of cleaving doxorubicin from its carrier. Another explanation might be that doxorubicin detected within the nucleus was due to a contamination of the PK1 conjugate by free doxorubicin rather than to its intracellular release from the conjugate. This assumption is based on the fact that Duncan's group (*20*) reported that the PK1 conjugate used in their study contained 0.39% of free doxorubicin, while the content of free doxorubicin in our PK1 conjugate is up to the limit of 0.1% of total doxorubicin. In fact, the content of free doxorubicin in the PK1 conjugate synthesized by us is probably much lower, but the 0.1% content of free doxorubicin corresponds to doxorubicin concentration which is near the detection limit of the analytical assay. Unfortunately, the two remaining papers (*21, 22*) demonstrating the doxorubicin release from the PK1 conjugate do not even indicate free doxorubicin content in their PK1 conjugates and therefore neither disprove nor corroborate our hypothesis.

To sum up, we demonstrated that the conjugation of doxorubicin to HPMA copolymer carrier modulates the mechanism of its intracellular action. As mentioned before (*5*), the intracellular action of hydrazone conjugate resembles that of free doxorubicin, but in this study we have found different roles for MAP kinases. The PK1 conjugate has different and in some parameters opposite mechanisms of action from both free doxorubicin and the hydrazone conjugate. Since PK1 triggers different intracellular pathways involved in regulation of cell death and/or proliferation than free doxorubicin, one can hypothesize that there can also be a different spectrum of tumors sensitive to PK1. As an example, Dox.HCl is not used for the treatment of colorectal cancer at all, but PK1 showed some therapeutic effect in patients with this type of cancer (*13*). If such a hypothesis is shown to be true, the finding that the cancerostatic activity of a particular cytostatic drug toward different types of tumor can be modified by binding to a polymeric carrier is both scientifically interesting and important for the development of new polymer-bound drugs for treatment of tumors resistant to this drug in the free form.

Peptidyl Molecular Imaging Contrast Agents Using a New Solid-Phase Peptide Synthesis Approach

Byunghee Yoo and Mark D. Pagel*

Case Center of Imaging Research and Department of Biomedical Engineering, Case Western Reserve University, 10900 Euclid Avenue, Cleveland, Ohio 44106. Received August 11, 2006; Revised Manuscript Received November 1, 2006

A versatile method is disclosed for solid-phase peptide synthesis (SPPS) of molecular imaging contrast agents. A DO3A moiety was derivatized to introduce a CBZ-protected amino group and then coupled to a polymeric support. CBZ cleavage with Et_2AlCl/thioanisole was optimized for SPPS. Amino acids were then coupled to the aminoDOTA-loaded resin using conventional stepwise Fmoc SPPS to create a product with DOTA coupled to the C-terminus of the peptide. In a second study, the DO3A moiety was coupled to a glycine-loaded polymeric support, and amino acids were then coupled to the amino-DOTA-peptide-loaded resin using SPPS to incorporate DOTA within the peptide sequence. The peptide-(Tm^{3+}-DOTA) amide showed a paramagnetic chemical exchange saturation transfer (PARACEST) effect, which demonstrated the utility of this contrast agent for molecular imaging. These results demonstrate the advantages of exploiting SPPS methodologies through development of unique DOTA derivatives to create peptide-based molecular imaging contrast agents.

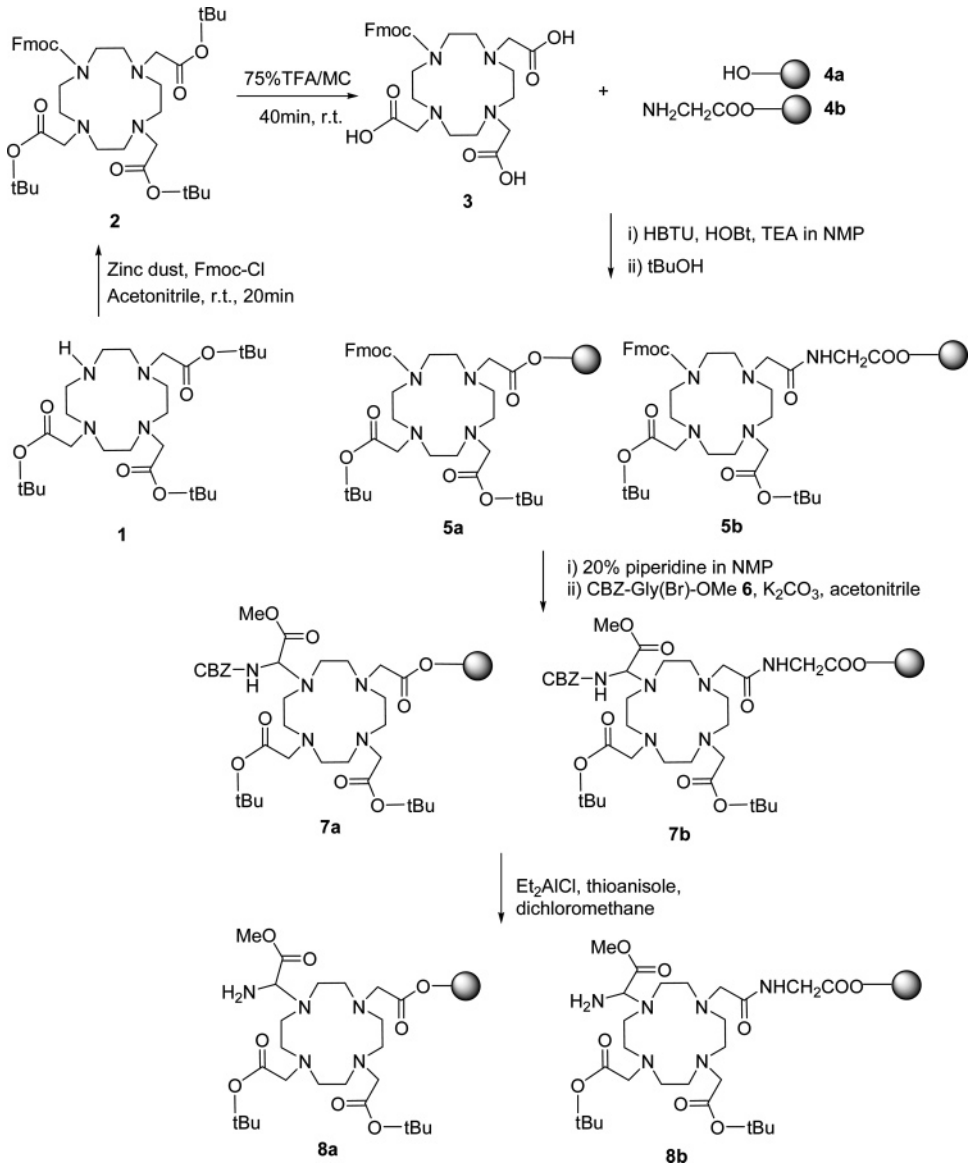
INTRODUCTION

Macrocyclic metal chelates using DOTA[1] (1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid) are often administered to patients and animal models to create or enhance contrast in biomedical molecular imaging studies (*1*, *2*). More recently, metal−DOTA chelates have been conjugated to peptides to affect the in vivo pharmacokinetics of the metal−DOTA imaging agent over a wide range of spatial scales. For example, subcellular scales can be assessed by coupling DOTA to membrane-penetrating peptides (*3*, *4*), cellular scales are assessed with cell receptor-targeting peptides attached to DOTA (*5*), and tissue scales are investigated with DOTA-bound peptides that interact with extracellular matrices (*6*) and have dramatically altered renal clearance rates (*7*). Numerous other applications have been reported, including peptide-DOTA probes for multimodality imaging studies (*8*−*10*).

To synthesize these peptidyl molecular imaging contrast agents, the carboxylates of DOTA have been conjugated to the amines of peptides, including the N-terminus of the backbone and the side chain of lysine (*5*, *11*−*19*). Other DOTA derivatives have been devised for conjugation to peptide amino groups, such as succinimide DOTA derivatives (*20*) and isothiocyanato DOTA derivatives (*21*). Unnatural amino acid derivatives have also been developed to couple DOTA to peptidyl amines, such as *p*-NH_2-phenylalanine (*13*) and diaminopropionic acid residues (*15*).

Standard solid-phase peptide synthesis (SPPS) methods have been used to couple DOTA to the backbone N-terminus of peptides bound to a PEGA Rink amide resin (*5*, *14*−*19*). Similar SPPS methodologies can be used to couple DOTA to other side chain amines of resin-bound peptides (*13*, *15*). However, coupling DOTA only to N-terminus or side chain amines of peptides can limit synthesis methodologies and may compromise the utility of the peptidyl contrast agent for molecular imaging applications (*22*). To alleviate this limitation, we developed an amine-derivatized DOTA (aminoDOTA) that can couple to the carboxylates of peptides (Scheme 1). We linked the aminoDOTA to a resin **8a** for use in standard SPPS methodologies in order to synthesize peptide-DOTA imaging agents with DOTA coupled to the C-terminus of the peptide (Scheme 2). We also linked aminoDOTA to an amino acid residue on the resin **8b** to demonstrate that this methodology can incorporate DOTA at any location within the peptide backbone (Schemes 1 and 2). Lanthanide chelates of the peptide-DOTA amide products were shown to affect magnetic resonance signals, thereby demonstrating that the peptide-bound DOTA moiety has practical utility for molecular imaging. This new approach greatly expands the opportunities to create peptide-based molecular imaging probes and is completely compatible with standard SPPS methods for facile production of products with good yield and high purity.

EXPERIMENTAL PROCEDURES



General Methods. All reactions were carried out under argon atmosphere. Dichloromethane (DCM) and carbon tetrachloride (CCl_4) were freshly distilled over phosphorus pentoxide (P_2O_5). Acetonitrile (ACN) was distilled over barium oxide (BaO). The peptide synthesis reagents fluorenylmethyloxycarbonyl (Fmoc) protected amino acids, *N*-hydroxybenzotriazole (HOBt), 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), acetic anhydride (Ac_2O), piperidine, triethylamine (TEA), *N*,*N*-diisopropylethylamine (DIEA), *N*,*N*-dimethylformamide (DMF), and *N*-methylpyrrolidone (NMP) were purchased from Applied Biosystems Co. (Foster City, CA). The 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″-tri(*tert*-butylacetate) (DO3A-tBu) was purchased from Macrocyclics Co. (Dallas, TX), and other reagents were purchased from Sigma-Aldrich Corp. (St. Louis, MO) and Fisher Scientific International, Inc. (Hampton, NH). Peptides were synthesized using a Wang resin

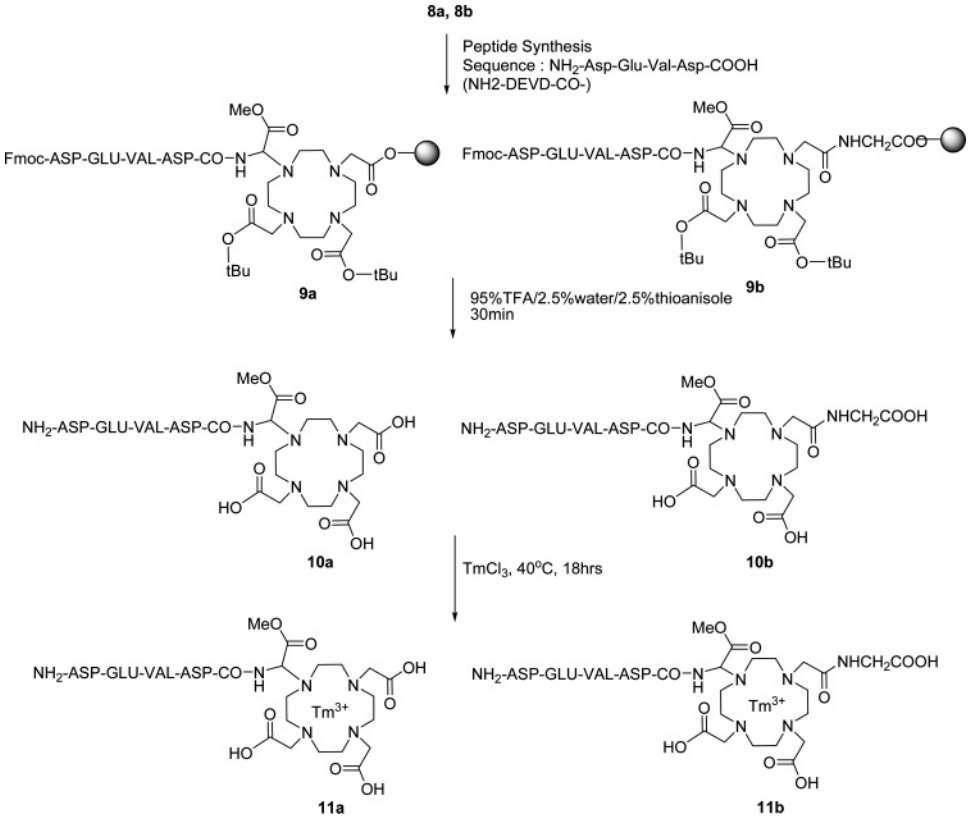
Scheme 1. Preparation of Amino-DOTA Preloaded Polymeric Support[a]



[a] For clarity, **5a**−**8a** and **5b**−**8b** only show ligands coupled to the cyclen ring in a 1,4 configuration. However, a 1,7 configuration is also possible.

(Fluka, Buchs Switzerland) and followed Fmoc chemistry methods with HOBt and HBTU as coupling agents (*23, 24*). The efficiencies of coupling DO3A-Fmoc **3** to resin **4b** and coupling **6** to resin Fmoc-deprotected **5a** and **5b** were checked with the Kaiser ninhydrin test (*25*−*27*). The starting resin had 1.0 mmol/g of hydroxyl groups or amino groups, and the scale of the peptide synthesis was calculated based on the substitution ratio of the resin. The loading efficiencies of the Fmoc compounds and the amine content of the resin were quantitatively analyzed with UV−vis/fluorescence spectroscopy using a Molecular Devices SpectraMax M2 spectrophotometer. IR spectroscopy was used to analyze the functional groups on the resin using an ABB BOMEM MB-104 spectrophotometer operating from 600 to 4000 cm^{-1}. To analyze the peptides and the peptide-DOTA amide final product, HPLC was used with a Grace Vydac OD-300 C-18 reverse-phase analytical column and a Perkin-Elmer Series 200 HPLC pump and UV detector operating at 222 nm. The lanthanide complexation reaction between peptide-DOTA amide and $TmCl_3$ was evaluated with an Arsenazo III solution color test (*28, 29*). ^1H and ^{13}C spectra were measured with a Varian Gemini 300 MHz NMR spectrometer and Varian Inova 600 MHz NMR spectrometer using $CDCl_3$ and DMSO-d_6 as solvents depending on solubility. Paramagnetic chemical exchange saturation transfer (PARACEST) spectra were measured in a solution of 5% D_2O in water (*30, 31*) using a Varian Inova 600 MHz NMR spectrometer. A series of 1D NMR spectra of the water signal were acquired with a selective saturation in 1 ppm increments between 100 and −100 ppm, and selective saturation was performed with a continuous wave pulse applied for 4 s at 31 μT. Analytical thin layer chromatography was performed on Merck silica gel 60 F254 plates. Compounds were visualized using a UV lamp operating at 254 nm, an iodine chamber, and ninhydrin solution. High-resolution mass spectral analyses were performed with a Bruker Daltonics Esquire HCT mass spectrometer and a Bruker BIFLEX III MALDI-TOF mass spectrometer using 3,5-dimethoxy-4-hydroxycinnamic acid as a matrix compound. Molecular modeling was accomplished using InsightII with the Discover-3 (Molecular Simulations Inc.).

Synthesis and Analysis. *Synthesis of 4,7,10-Tri(tert-butylacetate)-1-fluorenylmethoxycarbonyl-1,4,7,10-tetraazacyclododecane (Fmoc-DO3A-tBu)* ***2*** (*32*). To a solution of **1** (2.57 g, 5 mmol) in 10 mL of acetonitrile, activated zinc dust was added in small portions until the reaction mixture attained neutral pH.

Scheme 2. Synthesis of Peptidyl Contrast Agents[a]

[a] For clarity, **8a**−**9a** and **8b**−**11b** only show ligands coupled to the cyclen ring in a 1,4 configuration. However, a 1,7 configuration is also possible.

A solution of Fmoc-Cl (1.35 g, 5 mmol, 1 equiv) in 5 mL of ACN and zinc dust (325 mg, 5 mmol, 1 equiv) was added to the reaction mixture in one portion, and the reaction mixture was stirred at room temperature for 20 min. The progress of the reaction was monitored by TLC ($CHCl_3$/MeOH = 1/1, R_f = 0.75). The reaction mixture was filtered and dried in vacuo, yielding 3.32 g of white solid (yield 90%): ^{1}H NMR (600 MHz, DMSO-d_6) δ 1.47 (s, 27H), 2.50 (s, 8H), 2.71 (t, 4H), 2.79 (t, 4H), 3.39 (s, 6H), 5.15 (t, 1H), 6.29 (d, 2H), 7.42 (t, 2H), 7.47 (t, 2H), 7.63 (d,2H), 7.84 (d, 2H); ^{13}C (125 MHz, DMSO-d_6) δ 170.61, 153.83, 135.59, 135.36, 129.47, 127.23, 123.88, 121.36, 119.99, 81.22, 65.88, 55.14, 53.53, 50.48, 48.44, 47.10, 27.75; MALDI-mass *m*/*z* (calcd 736.94), 737.96 $[M + H]^+$.

Synthesis of 4,7,10-Tri(carboxymethyl)-1-fluorenylmethoxycarbonyl-1,4,7,10-tetraazacyclododecane (Fmoc-DO3A) ***3***. A 2.94 g (4 mmol) amount of **2** was dissolved in 5 mL of 75% TFA in DCM and treated for 40 min. The reaction was traced by TLC (chloroform/methanol = 1.1, R_f = 0.22). The solution was dried under reduced pressure. The remaining solid was redissolved in DCM and precipitated with diethyl ether. The precipitated solid was filtered and dried in vacuo, yielding 1.70 g (3.0 mmol, yield 75%): ^{1}H NMR (600 MHz, DMSO-d_6) δ 3.05 (s, 4H), 3.20 (s, 4H), 3.45 (t, 4H), 3.62 (t, 4H), 3.60 (s, 6H), 4.25 (t, 1H), 4.55 (d, 2H), 7.35 (t, 2H), 7.42 (t, 2H), 7.65 (d,2H), 7.94 (d, 2H); ^{13}C (125 MHz, DMSO-d_6) δ 174.21, 155.44, 143.85, 140.63, 127.08, 125.07, 120.01, 67.24, 54.30, 51.88, 50.65, 48.68, 45.79; MALDI-mass *m*/*z* (calcd 568.62), 569.64 $[M + H]^+$.

Coupling of Fmoc-DO3A on the Resin ***5a, 5b.*** To prepare **5a**, 1.0 g of Wang resin **4a** (substitution level = 1 mmol/g) was used after complete drying. Compound **3** (1.14 g, 2 mmol), HBTU (2.5 g, 6.6 mmol, 3.3 equiv), and HOBt (1.0 g, 6.6 mmol, 3.3 equiv) were dissolved in 30 mL of NMP for 40 min to activate carboxylates, and the solution was added to the peptide reaction vessel containing the resin. TEA (1.82 mL, 13 equiv) was added, and the reaction was continued for 12 h. After filtration, the resin was dispersed in a solution of *tert*-butyl alcohol (*t*-BuOH, 1.48 g, 20 mmol, 20 equiv) in 20 mL of NMP and the reaction was continued for 1 h. The resin was washed and dried in vacuo. To prepare **5b**, 1.3 g of **4b** (substitution level = 0.78 mmol/g) was treated with **3** following the same synthetic method as **4a**. During the reaction, a small amount of resin was sampled for uncoupled amines using the Kaiser test.

Loading Efficiency (Fmoc Titration). The Fmoc concentration on the resin was measured according to a previously reported method (*33*). Fmoc amino acyl resins (4−8 mg) were shaken or stirred in piperidine−DMF (3:7) (0.5 mL) for 30 min, after which MeOH (6.5 mL) was added and the resin was allowed to settle. The resultant fulvene−piperidine adduct had UV absorption maxima at 267 (ϵ = 17 500 M^{-1} cm^{-1}), 290 (ϵ = 5800 M^{-1} cm^{-1}), and 301 nm (ϵ = 7800 M^{-1} cm^{-1}). For reference, a piperidine−DMF−MeOH solution (0.3:0.7:39) was prepared. Spectrophotometric analysis was carried out at 301 nm with comparison to a free Fmoc amino acid (Fmoc-Ala) of known concentration treated under identical conditions. The measured Fmoc concentrations were determined to be 0.45 (±0.05) mmol per gram of resin (calcd 0.64 mmol/g) for **5a** and 0.47 (±0.05) mmol per gram of resin (calcd 0.54 mmol/g) for **5b**, based on 3 repetitions to synthesize each product.

Methyl N-(Benzyloxycarbonyl)-α-bromoglycinate ***6***. Phosphorus tribromide (8.2 g, 30 mmol, 3 equiv) was added to a suspension of methyl *N*-(benzyloycarbonyl)-α-methoxyglycinate (2.51 g, 10 mmol) in carbon tetrachloride (100 mL) under an argon atmosphere. The reaction mixture was stirred at room temperature for 7 days. The reaction solution was then concentrated in vacuo and triturated with dry *n*-hexane (100 mL) for 24 h. The reaction mixture was then filtered, yielding a white solid (75% to quantitative yield measured by weight): ^{1}H NMR (300 MHz, $CDCl_3$) δ 3.80 (s, 3H), 5.22 (s, 2H), 6.20 and 6.45 (split, 1H), 7.55 (s,5H); ^{13}C (125 MHz, DMSO-d_6) δ

170.71, 156.07, 137.37, 129.03, 128.57, 128.53, 73.78, 66.25; MS-ESI *m/z* (calcd 302.99), 304.07 $[M + H]^+$

*Coupling of **6** on the Resin **7a, 7b***. Both **5a** (2.22 g, substitution level = 0.45 mmol/g) and **5b** (2.13 g, substitution level =0.47 mmol/g) were treated with 20% piperidine for 30 min and sequentially washed with NMP, DCM, acetone, and acetonitrile. The Kaiser test was used to measure the content of free secondary amines after Fmoc deprotection. The resin was transferred to a flask with **6** (0.6 g, 2 mmol, 4.3 equiv) and K_2CO_3 (1.66 g, 12 mmol, 25.5 equiv) in dry acetonitrile (100 mL). The solution was stirred and heated to 70 °C for 6 h in anhydrous conditions. After the solution was filtered, the resin was sequentially washed with 50% MeOH in water, MeOH, and DCM and then dried in vacuo. The Kaiser test was used to monitor the coupling of **6** to **7b** by measuring the concentration of remaining free amines.

*Cleavage of the CBZ Group from the Resin **8a, 8b***. In each of three flasks, 0.20 g (0.1mmol) of **7a** was dispersed and swelled in DCM (5 mL) for 1 h and cooled to −78 °C. Et_2AlCl (*34*) was transferred into each flask with an airtight syringe in 1, 2, and 5 equiv amounts, and the mixture was stirred for 15 min. Aliquots of 2, 4, and 10 equiv of thioanisole (the molar ratio of Et_2AlCl:thioanisole was fixed at 1:2) were added to each flask, and portions of the resin were extracted after 5, 15, 30, and 60 min of cleavage reaction time. The sampled resin was immediately washed with DCM and titrated with picric acid according to a previously reported method (*35*). To account for tertiary amines on the cyclen ring, a CBZ-protected resin was treated and compared as a reference. CBZ cleavage was performed with conditions of 1 equiv of 33% Et_2AlCl in thioanisole for 20 min at −78 °C. The average amine content was 0.31 (±0.05) mmol/g for **8a** and 0.33 (±0.05) mmol/g for **8b**, based on 3 repetitions to synthesize each product.

*Peptide Synthesis **9a, 9b***. A 1.63 g (0.5 mmol) amount of **8a** was used to synthesize **9a** using standard SPPS methods. Fmoc-Asp(O^tBu)-OH (0.2 g, 0.5 mmol), Fmoc-Val-OH (0.17 g, 0.5 mmol), and Fmoc-Glu(O^tBu)-OH (0.23 g, 0.5 mmol) were used as building amino acids, and HBTU (0.19 g, 0.5 mmol) and HOBt (73 mg, 0.5 mmol) were used as coupling agents. Freshly distilled TEA (140 μL, 1 mmol) was used as a base in 70 mL of NMP. A solution of 20% piperidine in NMP was used to cleave the Fmoc groups on the resin, after which 1 equiv of an amino acid was reacted with the resin-bound peptide-DOTA amine. This coupling was repeated with a second reaction that was not preceded with Fmoc deprotection in order to follow a double-coupling SPPS strategy, which yielded 1.94 g of **9a** (calcd 1.97 g, yield 93%). Using the same procedure, 0.42 g (0.14 mmol) of **8b** was treated to synthesize 0.50 g of **9b** (calcd 0.52 g, yield 90%).

*Peptide Cleavage from the Resin and Characterization of **10a** and **10b***. After peptide synthesis, the Fmoc group of **9a** (0.55 g, 0.2 mmol) was removed from the resin and **10a** was cleaved from the resin with a 95% TFA/2.5% water/2.5% thioanisole cocktail for 40 min (*36*−*38*). After removing solvents, the product was washed with diethyl ether and dried in vacuo. The final product was purified with an Amberlite column, yielding 150 mg (0.17 mmol, yield 85%). Following the same procedure, 0.29 g of **9b** (0.1 mmol) was used to obtain 87 mg of **10b** (92 μmol, yield 92%). In both cases, the Amberlite column was used to remove impurities and residue from the cleavage cocktail and not intended to purify isomeric forms of **10a** or **10b**. The obtained products **10a** and **10b** were characterized by MALDI-mass (**10a** *m/z* (calcd 891.88): 892.89 $[M + H]^+$, 914.89 $[M + Na]^+$; **10b** *m/z* (calcd 948.93): 949.94 $[M + H]^+$, 971.95 $[M + Na]^+$) and HPLC (column: Symmetry C-18 3.5 μm, 4.6 × 75 mm, detector: 222 nm, flow rate: 0.5 mL/min, eluent: 0.1% TFA in water/acetonitrile, gradient from 100%/0% to 90%/10% for 5 min, 90%/10% for 25 min; retention time = 6.1 min for **10a** and **10b**).

*Complexation of Tm^{3+} with **11a** and **11b***. The obtained **10a** (100 mg, 0.11 mmol) was dissolved in water (3 mL) at pH 6.5 and 40 °C, and $TmCl_3$ (27 mg, 0.1 mmol) in water (0.5 mL) was added dropwise for 1 h and adjusted to pH 7.5 with 0.5 N NaOH. The solution was stirred for 18 h at 40 °C and adjusted to pH 7.5 when the pH dropped below 5. Complete complexation was evaluated with an Arsenazo III color test (*29*). When the test showed negative results for free lanthanide ions, the reaction mixture was cooled to room temperature. The pH was adjusted to 9, and the residual lanthanide−hydroxide white precipitate was removed by filtration. The solution was freeze-dried, yielding product **11a (**MALDI-mass *m/z* (calcd 1060.81): 1061.83 $[M + H]^+$, 1083.85 $[M + Na]^+$). **10b** was treated with a similar procedure to obtain the final product **11b (**MALDI-mass *m/z* (calcd 1117.86): 1118.87 $[M + H]^+$, 1140.92 $[M + Na]^+$).

RESULTS AND DISCUSSION

Scheme 1 demonstrates the synthesis strategies that were employed to create a DOTA-loaded resin for SPPS. Compound **2** was prepared by coupling **1** and Fmoc-Cl with activated Zn dust (*32*). Consequently, **2** was treated with 75% TFA in DCM for 40 min to remove ^{t}Bu esters. The deprotected product was a complex of **3** and TFA salt, as indicated by the NMR chemical shifts of the cyclen ring that were shifted to 3.05−3.62 ppm, relative to the NMR chemical shifts of 2.50−2.79 ppm of the cyclen ring of TFA-free **2**.

Compound **3** was coupled to a Wang resin **4a** (sub. lev. = 1.0 mmol/g) and a glycine-preloaded Wang resin **4b** (sub. lev. = 0.78 mmol/g) to create **5a** and **5b**, respectively. Compound **4b** was prepared to demonstrate the feasibility of incorporating DOTA within a peptide sequence. Compounds **5a** and **5b** showed 70% and 83% loading, respectively, as measured by quantitatively titrating the Fmoc group with a UV spectrometer operating at 301 nm. The lower loading of **5a** relative to **5b** is presumably caused by the closer proximity required by the hydrophilic **3** and relatively hydrophobic surface of **5a** in order to couple **3** to the short linker of **5a**. Adding an amino acid to the Wang resin lengthened the linker in **5b** and led to an improved loading efficiency, and comparable or improved results are anticipated if the Wang resin is preloaded with a longer peptide that would have even less potential for potentially adverse DOTA−resin interactions.

At the end of the coupling reaction to create **5a** and **5b**, an excess amount of *t*-BuOH was added to convert the remaining active carboxylates to *t*-Bu esters, and finally acetic anhydride was used to cap remaining functional active sites on the Wang resin (*39*, *40*). No active sites remained after this esterification and capping because analysis of **10a** and **10b** showed no evidence of synthesized peptide without DOTA or DOTA coupled to more than one peptide, which would be expected from any active sites that remain at this stage.

For clarity, Scheme 1 only shows coupling to the Wang resin at position 1 and Fmoc protection at position 4 (or 10) of the cyclen ring, and yet the Fmoc protection may also occur at position 7. This difference is inconsequential for **5a** because the resin is eventually cleaved from the DOTA to create **10a**. This difference may be significant for **5b** as the two peptidyl ligands of **10b** may have a 1,4 or 1,7 configuration. For comparison, studies of 1,4-DO2A vs 1,7-DO2A have demonstrated that the 1,4 isomer makes a more stable complex with manganese (*41*). Studies of RRSS and RSRS tetra(carboxyethyl) DOTA derivatives indicated different ratios of the 'major' square antiprismatic geometric isomer (M) vs the 'minor' twisted square-antiprismatic geometric isomer (m), although no sig-

nificant differences in hydration states were observed from these particular isomers (*42*). Yet the stabilities, hydration states, and water exchange rates of DOTA derivatives are known to be affected by different m/M geometric ratios (*43*, *44*). Therefore, more detailed investigations of the effects of 1,4 and 1,7 isomers on stabilities and water exchange rates of DOTA derivatives are warranted, and the SPPS methodology described herein may provide the versatility for synthesizing isomers for these investigations.

The α-bromo glycine template **6** was produced as racemates at approximately a 1 to 1 ratio, which was indicated by the NMR doublet on 5.20 and 5.46 ppm. The diastereomers of consequent steps were also determined to be the same ratio as **6**. The presence of diastereomers within a peptide may raise concerns because peptide conformations critically depend on the stereochemistry of each amino acid. However, this strategy to conjugate DOTA to peptide carboxylates is intended to label a peptide with an imaging contrast agent and not designed so that the DOTA directly participates in the conformation or biological function of the peptide. Therefore, racemization of **6** is acceptable for molecular imaging applications that simply require DOTA labeling of peptides. Use of brominated amino acid templates provides additional flexibility for creating peptide-DOTA imaging contrast agents, although other brominated amino acids besides bromoglycine were not investigated in this particular study.

After removal of the Fmoc group of **5a** and **5b** with 20% piperidine in NMP, **5a** and **5b** were coupled with α-brominated CBZ-Gly-OMe (*45*) **6** to obtain **7a** and **7b**, respectively. A comparison of results from the Fmoc titration and a Kaiser test of Fmoc-deprotected **5a** and **5b** indicated complete removal of the Fmoc groups. Similarly, a Kaiser test of **7a** and **7b** indicated that loading **6** onto the resin was performed with quantitative yield.

The CBZ group is commonly used to orthogonally protect amine groups in organic syntheses. Cleavage of CBZ groups is typically performed with H_2/Pd−C or 1,4-cyclohexadiene/Pd−C in EtOH (*46*). However, these cleavage conditions are not compatible with SPPS using polymeric supports, which lead to difficult problems with separation and purification. In this study, selective CBZ cleavage conditions were tested for SPPS. BF_3·Et_2O/dimethylthioether (*47*−*49*), trimethylsilyl iodide (*50*, *51*), and Et_2AlCl/thioanisole (*34*) conditions were investigated during initial trials. From the results of tracing the reactions for **7a** and **7b** with the Kaiser test, the strong Lewis acids BF_3·Et_2O/dimethylthioether and trimethylsilyl iodide were found to rapidly cleave the Wang linker on the resin and therefore failed to selectively cleave the CBZ group. Fortunately, the CBZ group was found to be selectively cleaved with Et_2AlCl/thioanisole by reducing the temperature to −78 °C and carefully controlling the reaction time and molar ratio of Et_2AlCl/thioanisole to optimize reaction conditions (Figure 1). The reaction rates were assessed by measuring the amine contents of ∼25 mg of resin after the start of the reaction using a picric acid titration and UV−vis spectrometer operating at 358 nm (*35*). These results were compared to the measured Fmoc concentrations of **5a** and **5b**. To eliminate the effect of tertiary amines in the cyclen ring, the results of picric acid titration of **7a** and **7b** that were not subjected to Et_2AlCl/thioanisole were subtracted from the measurements of the cleavage reaction. Optimized conditions were determined to consist of a reaction time of 15 min at −78 °C, 1 equiv of Et_2AlCl, and 2 equiv of thioanisole relative to the CBZ concentration on the resin. Under these conditions, cleavage of the benzyl ether group of the Wang linker or incomplete CBZ cleavage limited the overall yield of **8a** and **8b** to 70%. For the purposes of this particular study, a 70% yield was acceptable for subsequent steps. Although cross-

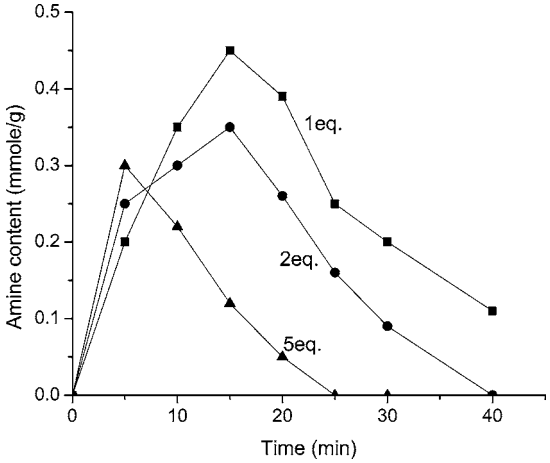


Figure 1. Amine content following CBZ cleavage versus reaction time. For 5 equiv of Et_2AlCl/thioanisole, the reaction was too fast to control cleavage of the CBZ group and benzyl ether linker group. A 1 equiv amount of Et_2AlCl/thioanisole showed the best CBZ cleavage conditions, and a similar reaction rate was obtained with 2 equiv of Et_2AlCl. The optimized CBZ cleavage reaction was carried out for 15 min with 1 equiv of Et_2AlCl at −78 °C.

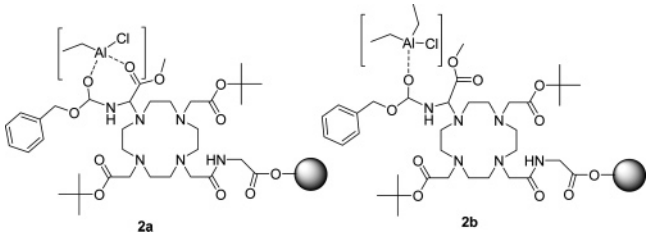

Figure 2. Two possible transition states of Et_2AlCl and CBZ-aminoDOTA Wang resin. The transition state in Figure 2a shows the bridging of Et_2AlCl between two carbonyl groups. This arrangement requires formation of an unstable 7-membered ring that also suffers from planar constraints of the amide and ester groups. Figure 2b represents a more stable interaction that forms a single bond between Et_2AlCl and one carbonyl group. This single-bond transition state is supported by mass spectral results of **10a** and **10b**.

linking between DOTA carboxylates and amines may also account for reduced yield after CBZ cleavage, MALDI-MS analyses of **10a** and **10b** showed no evidence for cross-linking, which is presumably due to the sparse population of DOTA within the Wang resin.

Additional temperature- and time-dependent studies to improve this deprotection step were under investigation in our laboratory as CBZ deprotection during SPPS has great potential for orthogonal synthetic strategies. The expected transition state is shown in Figure 2. Previous reports have shown that Et_2AlCl can bridge two carbonyl groups in a 1,3 position to form a stable 6-membered ring, which leads to bond cleavage adjacent to either carbonyl group (*52*−*53*). However, Et_2AlCl would form an unstable 7-membered ring by bridging the two carbonyl groups of CBZ-Gly-OMe, and this bridge would be further destabilized by the additional planar constraints of the amide and ester groups, so that Et_2AlCl is more likely to form a strong interaction with just one carbonyl group. This hypothesis is confirmed by the absence of cleavage of the methyl ester group as shown in the mass spectrum of **10a** and **10b**, which also shows that interaction of Et_2AlCl only occurs with the ester of the CBZ group.

As shown in Scheme 2, conventional Fmoc SPPS methods were then employed to perform stepwise coupling of amino acids to the aminoDOTA Wang resin (*33*). An Asp-Glu-Val-Asp (DEVD) peptide sequence was chosen for this demonstration because this peptide sequence is preferentially cleaved by the caspase-3 enzyme that is a focus of our molecular imaging

research (*55*). To enhance the coupling efficiency, two sequential applications (i.e., double coupling) of 4 equiv of each amino acid were applied to the SPPS after initial Fmoc deprotection. The total yield of stepwise SPPS of the four amino acids to aminoDOTA was 90% and 93% for the synthesis of **10a** and **10b**, respectively, as determined by weighing. Therefore, the coupling efficiency for coupling the first amino acid to aminoDOTA is no lower than 93%. This high coupling efficiency indicates that the CBZ-protected amine is sufficiently exposed after deprotection, even in the presence of the bulky DOTA moiety.

The SPPS products **10a** and **10b** were cleaved from the resin **9a** and **9b**. HPLC analyses of **10a** and **10b** showed a single peak, indicating that the peptide was successfully synthesized without additions or deletions of amino acids. HPLC analyses showed no evidence for separating stereoisomers of **10a** or **10b** or different relative ligand positions around the cyclen ring of **10b**.

These SPPS products **10a** and **10b** were used to chelate thulium using standard conjugation methods and an Arsenazo III color test (*29*) to create **11a** and **11b**. The weight of the reactants (including salt) and product indicated that chelation was quantitative. Although the final product was not desalted to approximate isotonic conditions during subsequent analyses, the presence of salts did not affect determination of the yield. In addition, mass spectrometry did not detect the presence of **10a** or **10b**, further indicating that complexation was quantitative. However, low amounts of unchelated **10a** and **10b** may still exist within the final product. Chelation of the lanthanide ion required lower temperatures and shorter reaction times relative to lanthanide chelations of DOTA-amide derivatives prepared in our laboratory. This facile chelation is attributed to the presence of three carboxylates and one carbonyl in **10a** and two carboxylates and two carbonyls in **10b** that participate in metal chelation relative to metal chelation with amide carbonyl groups in DOTA-amide derivatives. These results are similar to detailed chelation studies of other DOTA derivatives that indicate the advantage of employing carboxylates for metal binding, (*56*, *57*) and may indicate an improved stability and reduced toxicity of **11a** and **11b** relative to DOTA-amide formulations. Deprotection of the methyl ester of **11a** or **11b** would improve chelation. This deprotection was not performed in this study because the methyl ester group provides unique functionality for further derivatization of the peptide's C-terminus.

To demonstrate the application of the final product for molecular imaging, **11a** and **11b** were detected through the effect of paramagnetic chemical exchange saturation transfer (PARACEST) (*30*, *31*). The PARACEST effect is created by saturating a unique NMR chemical shift corresponding to an amide hydrogen (or more generally, a hydrogen of a functional group that that exchanges with water at a rate of approximately 100−5000 s^{-1}), and the effect is detected by observing a decrease in the water signal caused by transferring the saturation through chemical exchange. This novel mechanism for detecting imaging contrast agents has many advantages for biomedical applications that use magnetic resonance imaging. PARACEST exploits the close proximity between the amide group and the lanthanide ion to create a very unique NMR chemical shift for the amide group of the imaging agent, which facilitates selective saturation of this chemical shift. The synthesis strategy presented in this report is specifically designed to place amide groups in close proximity to the lanthanide ion.

Selective radio frequency irradiation at −51 ppm created a 7.8% PARACEST effect from 25 mM of **11a** (Figure 3). This PARACEST effect of **11a** occurs at the same chemical shift frequency and at a similar signal strength reported for a similar

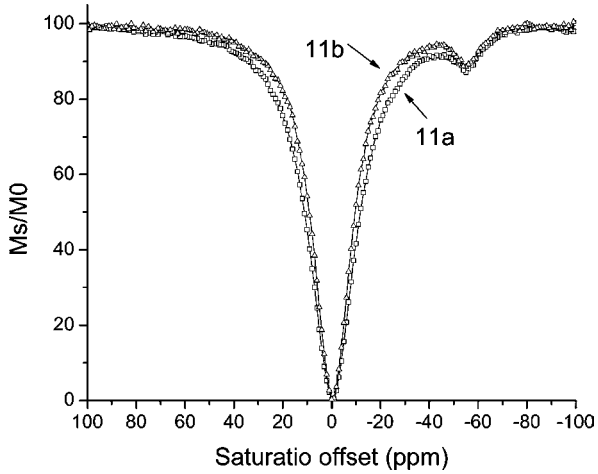

Figure 3. PARACEST spectrum of **11a** (25 mM in 5% D_2O in H_2O) and **11b** (12 mM in 5% D_2O in H_2O). PARACEST spectra were acquired using a Varian Inova 600 MHz NMR spectrometer with a modified presaturation pulse sequence that included a continuous wave saturation pulse, saturation pulse power of 31 μT, and saturation delay of 4 s. The 1D NMR spectra of water used to construct the PARACEST spectra were acquired with saturation in 1 ppm increments from 100 ppm to −100 ppm.

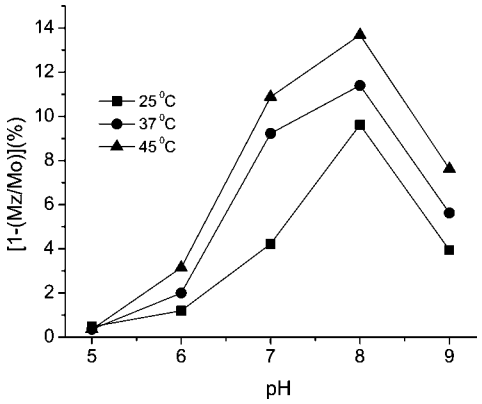

Figure 4. Effect of pH and temperature on the PARACEST effect of 25 mM of **11a**. PARACEST spectra were acquired using a Varian Inova 600 MHz NMR spectrometer with a modified presaturation pulse sequence that included a continuous wave saturation pulse, saturation pulse power of 31 μT, and saturation delay of 4 s at −51 and +51 ppm.

compound, DOTAMGly-Tm^{3+} (*58*). In addition, the PARACEST effect of **11a** shows good sensitivity at physiological pH and temperature, indicating that this contrast agent can be used for in vivo molecular imaging (Figure 4).

A similar PARACEST effect of 7.3% was observed from 12 mM **11b**. The PARACEST effects from the two amide hydrogens (Hb and Hc in Figure 5) both occurred at −51 ppm and were not distinguishable. To investigate the basis for this similarity, molecular modeling of the DOTA core of **11b** was performed with carboxylates constrained to conjugate the Tm^{3+} ion. These results revealed that Hb is positioned 4.1−4.3 Å from Tm^{3+} and Hc is positioned 4.9−5.1 Å from Tm^{3+}. Although a more detailed analysis of Tm^{3+} molecular orbitals is required for an accurate analysis of NMR chemical shifts, the very similar proximities of Hb and Hc to the lanthanide ion are sufficient to justify indistinguishable PARACEST effects that are measured in relatively coarse 1 ppm increments. The PARACEST effect is proportional to the number of water-exchangeable hydrogens that have the same NMR chemical shift. **11b** showed a PARACEST effect that was twice as strong as **11a** (on a per molar basis), demonstrating that multiple peptidyl ligands can

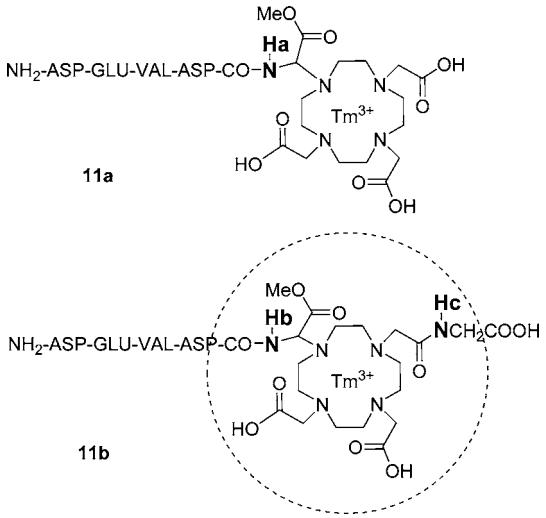

Figure 5. Proximity of amide hydrogens to Tm^{3+} in **11a** and **11b**. Molecular modeling results indicated that Hb is positioned 4.1−4.3 Å from Tm^{3+} and Hc is positioned 4.9−5.1 Å from Tm^{3+}. The dotted line of the 2D schematic is 5.4 Å from the lanthanide ion is provided as a visual aid. The PARACEST effects from two different amide hydrogens Hb and Hc were not distinguishable as only one PARACEST effect was detected at −51 ppm, which is consistent with the similar proximities of these hydrogens to the Tm^{3+}.

improve the detection sensitivity of PARACEST imaging contrast agents.

This synthesis methodology may also be applied to couple peptides to other metal chelators that are used for molecular imaging. For example, diethylenetriaminetetraacetic acid (DTTA) may be used in place of **1** to couple a peptide to diethylenetriaminepentaacetic acid (DTPA) (*1*, *59*). To couple more than two peptides to a molecular imaging contrast agent, 1,4,7,10-tetraazacyclododecaneacetic acid (DO1A) may be used in place of **1** to couple three peptides to DOTA following the scheme to synthesize **10a** or to couple four peptides to DOTA following the scheme to synthesize **10b**. Similarly, diethylenetriamineacetic acid (DT1A) may be used in place of **1** to couple four or five peptides to DTPA.

Larger derivatives of DOTA and DTPA, such as hexaazacyclohexadecane-*N*,*N*′,*N*″,*N*‴,*N*⁗,*N*⁗′-hexaacetic acid (HEHA) (*60*) and triethylenetetraaminehexaacetic acid (TTHA) (*61*), provide opportunities to couple additional peptides to a single molecular imaging agent. If the chemical shifts of all amides within multiple peptide−chelator linkages have the same MR chemical shift, then exploiting this SPPS method to link multiple peptides to a single chelator may increase the strength of the PARACEST effect and improve detection of these molecular imaging contrast agents.

This synthesis methodology may address other important applications in molecular imaging. Employment of standard SPPS techniques provides a convenient and robust method for synthesizing libraries of molecular imaging contrast agents, which may be useful for high-throughput screening to identify molecular imaging contrast agents with optimal properties. Because DOTA macrocyclic rings can strongly chelate a variety of ions, the peptide-DOTA product can be used to develop molecular imaging contrast agents for relaxivity-based MRI using Gd^{3+} or Dy^{3+} (*1*, *62*) or nuclear imaging using ^{64}Cu (*63*) or ^{111}In (*64*) in addition to PARACEST MRI as demonstrated in this report. Therefore, this synthesis strategy represents a platform technology for molecular imaging.

CONCLUSION

To summarize, a new SPPS approach has been developed to couple DOTA to the C-terminus of a peptide and incorporate DOTA within the peptide sequence in order to synthesize peptidyl contrast agents for molecular imaging. Selective cleavage of CBZ protecting groups in SPPS was investigated and optimized for the DOTA-loaded resin. The CBZ deprotection step and the step to load DOTA onto the resin were accomplished with acceptable yields for SPPS. Although *R*,*S* stereoisomers and 1,4 and 1,7 ligand isomers did not affect subsequent analyses in this report, the effect of isomeric forms on chelation stability, hydration, and water exchange rates is warranted, and development of isomeric forms for studies of isomers may be facilitated by this new SPPS strategy. Peptide-DOTA products were used to chelate thulium to create PARACEST imaging contrast agents that demonstrated good detection sensitivities at physiological conditions. This synthesis strategy provides great flexibility for coupling one or more peptides to DOTA to create peptide-DOTA imaging contrast agents for many molecular imaging applications.

Synthesis and Radiolabeling of Selective High-Affinity Ligands Designed to Target Non-Hodgkin's Lymphoma and Leukemia

Saphon Hok,[†] Arutselvan Natarajan,[‡] Rod Balhorn,[†] Sally J. DeNardo,[‡] Gerald L. DeNardo,[‡] and Julie Perkins*,[†]

Chemistry, Materials and Life Sciences Directorate, Lawrence Livermore National Laboratory, Livermore, California 94551, and Radiodiagnosis and Therapy Laboratory, University of California, Davis, Sacramento, California 95816. Received October 2, 2006; Revised Manuscript Received January 25, 2007

Selective high-affinity ligands (SHALs) were synthesized as molecular targeting agents for HLA-DR10, a cell surface receptor upregulated on malignant B-cell lymphocytes in non-Hodgkin's lymphoma and leukemia. SHALs are designed to mimic the affinity and selectivity of Lym-1, an antibody that binds to the β-subunit of HLA-DR10. To bind selectively to HLA-DR10, SHALs were constructed to bind to two adjacent pockets on the surface of the β-subunit of HLA-DR10 located within an epitope recognized by the Lym-1 antibody. A series of multivalent SHALs with molecular masses of 1500−3000 Da were synthesized using solid/polymer-supported synthesis on chlorotrityl chloride resin in 50−80% yield. To enable their use as radionuclide carriers in mouse studies, SHALs were conjugated to DOTA in a solution-phase reaction with 70−100% yield. $^{57}Co/CoCl_2$ titrations revealed that 50−60% of the DOTA in the DOTA-conjugated SHALs was available for radiometal chelation. These DOTA−SHALs were labeled with ^{111}In and used to carry out pharmacokinetic studies in mice. Radiolabeling reactions of DOTA−SHALs, with exactly one DOTA entity per targeting SHAL molecule, yielded products with greater than 90% radiochemical purity and specific activities ranging from 97 to 150 μCi/μg.

INTRODUCTION

Antibodies have evolved to be one of nature's most selective molecular targeting agents. These large proteins bind their target (small and large biological molecules) through two Fab arms, effectively a bivalent system. They typically have affinity constants ranging from 10^{-5} to 10^{-12} M for their target and are often used as therapeutic agents (*1*, *2*) among many other uses. The IgG_{2a} antibody, Lym-1, binds to the β-subunit of HLA−DR10, a surface-bound/trans-membrane protein found on lymphocytes (*3*−*5*). HLA−DR10 is more abundant on malignant lymphocytes than their normal precursor cells, and therefore, Lym-1 has been employed as a radionuclide carrier for the treatment of non-Hodgkin's lymphoma (*6*−*10*). While minimizing exposure to healthy cells (*11*, *12*), however, there are some disadvantages to using antibodies for treatment and imaging. As macromolecules, they have long residence time in the circulation, which limits the target contrast that can be achieved in tumor imaging (thus decreasing tumor detection). The long residence time also decreases the therapeutic index (ratio of damage to cancer cells relative to damage to normal cells) that can be obtained. Therefore, the design and realization of an alternative ligand that mimics the binding affinity and specificity of an antibody but with improved pharmacokinetic properties is an important contribution to future imaging and radiotherapeutic applications (*13*).

Although small molecules typically have low to moderate affinity for protein targets, linking two or more small molecules generates ligands that can exhibit a polyvalent effect (*14*−*19*). Affinity is a qualitative term commonly used to describe a binding constant. However, avidity refers to the association constant of a polyvalent interaction (*19*). Establishing the magnitude and individual contribution of the thermodynamic parameters of polyvalent interactions is complicated, however; it is generally accepted that multiple interactions or contacts on the surface of protein targets generally increases the avidity of the polyvalent ligand for the target (*19*). In many cases, the avidity of the polyvalent ligand is greater than the sum of the individual affinities of the component small molecules.

Small (molecular weight <300 Da) molecules, previously established to bind to the HLA−DR10 protein (*20*, *21*), have been linked together using a lysine/poly(ethylene glycol)-based linker to generate selective high-affinity ligands (SHALs), polyvalent ligands that exhibit multiple sites of contact with the target protein surface. These SHALs were shown to bind to lymphoma cells expressing HLA−DR10 with high specificity and nanomolar to picomolar binding avidity (*21*). The multiple sites of attachment generated SHALs with avidity and selectivity similar to Lym-1.

Here, the synthesis of six SHALs, the conversion of these SHALs to the DOTA−SHALs and the experimental determination of the radiochemical purity and specific activities of ^{111}In-DOTA−SHALs are described. Whole cell binding experiments to demonstrate specificity of the SHALs exhibiting the most promising binding properties for subsequent pharmacokinetic studies in mice are also briefly described.

EXPERIMENTAL PROCEDURES

Materials and Abbreviations. Unless otherwise stated, all reagents and solvents were obtained from commercial suppliers, were ACS grade or higher, and used as received. 2-Chlorotrityl chloride resin (100−200 mesh, 1% DVB, 1.2 mmol/g loading) and all Fmoc-protected amino acids were obtained from Novabiochem, Inc. Fmoc-8-amino-3,6-dioxaoctanoic acid was purchased from Peptides Int. The hexafluorophosphate (PF_6) salt of 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid mono-*N*-hydroxysuccinimide (DOTA−NHS) ester was purchased from Macrocyclics. *N*-Benzoyl-L-arginyl-4-amino-benzoic acid (Ba) was obtained from Bachem, Inc. *N*-(Biotinyloxy)-

Scheme 1. Solid-Phase Synthesis of Bidentate SHALs 3a−c

succinimide (biotinyl-OSu) was purchased from BACHEM. Dabsyl-L-valine (Dv) was purchased from TCI, Inc., and Boc-L-thyronine (T) was obtained from AnaSpec, Inc. Deoxycholic acid (D), 3,3′,5-triido-L-thyronine, diisopropylethylamine (DIEA), di-*tert*-butyldicarbonate (Boc-anhydride), hydrazine, trifluoroacetic acid (TFA), 1,3-diisoproylcarbodiimide (DIC), 1-hydroxybenzotriazole (HOBt), 20% piperidine/dimethylformamide (DMF), and triethylsilane (TES) were purchased from Sigma-Aldrich. Boc-L-triiodothyronine (It) was synthesized from 3,3′,5-triiodo-L-thyronine using standard coupling protocols with Boc-anhydride (*22*). Carrier-free $^{111}InCl_3$ was purchased from MDS Nordion (Vancouver, Canada) as the chloride in 0.05 M hydrochloric acid solution. $^{57}CoCl_2$ was obtained from ICN Radiochemicals (Irvine, CA). Streptavidin−horseradish peroxidase (HRP) was obtained from Invitrogen, goat anti-mouse IgG-HRP from Kirkegaard and Perry Laboratories (Gaithersburg, MD), and 2,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS) substrate and bovine serum albumin (BSA) were obtained from Sigma-Aldrich.

Instrumentation. Solid-supported syntheses were carried out in Pierce Biotechnology polyethylene columns (5 mL). All SHALs were purified by semipreparative HPLC at 10 mL/min on a Waters preparative machine with photodiode array detection (Waters Symmetryprep C18, 7 μm, 19 × 300 mm column) and lyophilized using a Kinetics Flexi-Dry freeze-dryer. The purity was confirmed by analytical HPLC carried out at 1 mL/min on an Agilent 1100 machine (Waters Symmetry C18, 5 μm, 4.2 × 150 mm column, diode array detector) with a linear gradient from 95% H_2O (1% TFA) to 80% MeCN (1% TFA) over 12 min. Nuclear magnetic resonance (NMR) spectra were obtained on a Bruker 500 MHz or a Varian 600 MHz machine in d_6-DMSO. Mass spectra were acquired on a Micromass Quattro Micro API mass spectrometer operating in positive ion mode. The samples were dissolved in MeCN/H_2O (1:1), 0.1% formic acid, for mass spectrometry analysis. Radiolabeled SHALs were purified and analyzed using a Beckman Coulter System Gold 128 HPLC system with a radioactive detector (Raytest USA, Wilmington, NC). Radioactivity of cellulose acetate electrophoresis (CAE) (Gelman Sciences, Inc., Ann Arbor, MI) was performed using 0.05 M sodium barbital buffer, pH 8.6, and a current of 5 mA per strip was applied. Radioactivity was counted by scanning on Fuji film BAS-1800 imager. Quality assurance (QA) of the radiochemical and purification was carried out using HPLC (Beckman Coulter System Gold, 128 with Ray test radioactive detector) and a linear gradient from 95% H_2O (1% TFA) to 90% CH_3CN (1% TFA) over 12 min. DOTA−SHALs were dissolved in 5−10% DMSO in PBS for radiolabeling experiments.

Preparation of Resin 1. (Scheme 1) 2-Chlorotrityl chloride resin (*23*, *24*) (150 mg, 0.18 mmol or 50 mg, 0.06 mmol) was suspended in dichloromethane (DCM) for 30 min and washed 3× with anhydrous DMF. The resin was treated with Fmoc-Lys(Boc)-OH (468.5 g/mol; 40 mg (85 μmol) for a larger or 20 mg (43 μmol) for a smaller-scale reaction) and DIEA (50 μL, 287 μmol) in 1.0 mL anhydrous DMF (Scheme 1). The reaction mixture was agitated on a nutator for 3 h. Ethanol (1.0 mL) and DIEA (100 μL) was added and agitated for 15 min to quench the excess chlorotrityl chloride groups. The reaction solution was removed by filtration, and the resin was washed 3× with DMF and treated with 20% piperidine in DMF (1 mL) for 20 min for fluorenylmethoxycarbonyl (Fmoc) deprotection (*25*, *26*). The Fmoc-deprotected resin-bound Boc-lysine was washed with DMF and subsequently coupled to the next Fmoc-protected residue using amide coupling chemistry employing 3 mol equiv of DIC and 3 mol equiv of HOBt (*25*, *27*). The washing and filtration cycle with DMF (2 mL, 3×, 1 min) was performed between every deprotection and coupling step.

Preparation of Resin 2. (Scheme 1) Resin **1** was treated with a solution of Fmoc-8-amino-3,6-dioxaoctanoic acid, DIC, and HOBt (3 equiv) in 1.0 mL anhydrous DMF for 3−5 h (coupling cycle 2). The resin was then treated with Dde-Lys-(Fmoc)-OH, HOBt, and DIC (3 equiv) in 1.0 mL anhydrous

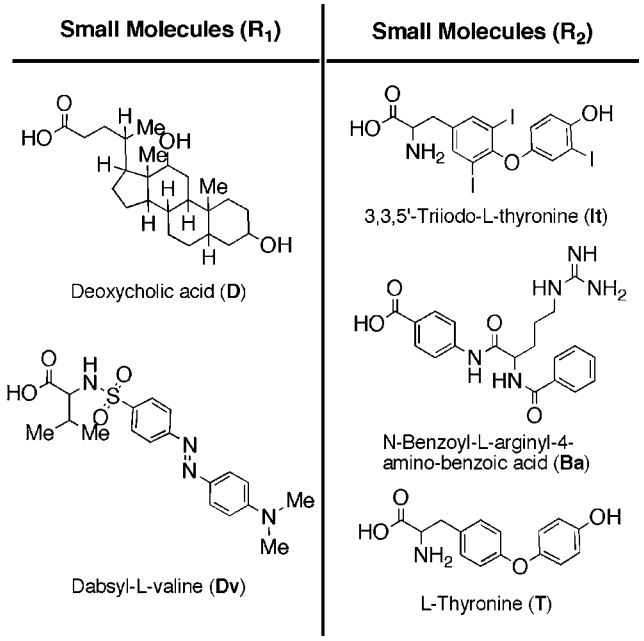

Figure 1. Chemical structure of molecules predicted to bind to two unique sites on the surface of target protein HLA−DR10.

DMF for 5 h (coupling cycle 3). Following Fmoc deprotection, the resultant free amine was subsequently coupled to one of the molecules R_1 in Figure 1 (2−3 equiv), HOBt, and DIC (3 equiv) in 1.0 mL anhydrous DMF for 5−12 h depending on molecule R_1. The reaction solution was filtered, and the resin was washed and treated twice with 4% hydrazine in DMF (40 μL hydrazine in 900 μL DMF for 10 min) to remove the 1-(4,4-dimethyl-2,6-dioxacyclohex-ylidene)ethyl (Dde) protecting group (*25*, *28*). After washing, resin **2** with a free α-amino on the second lysine residue was obtained.

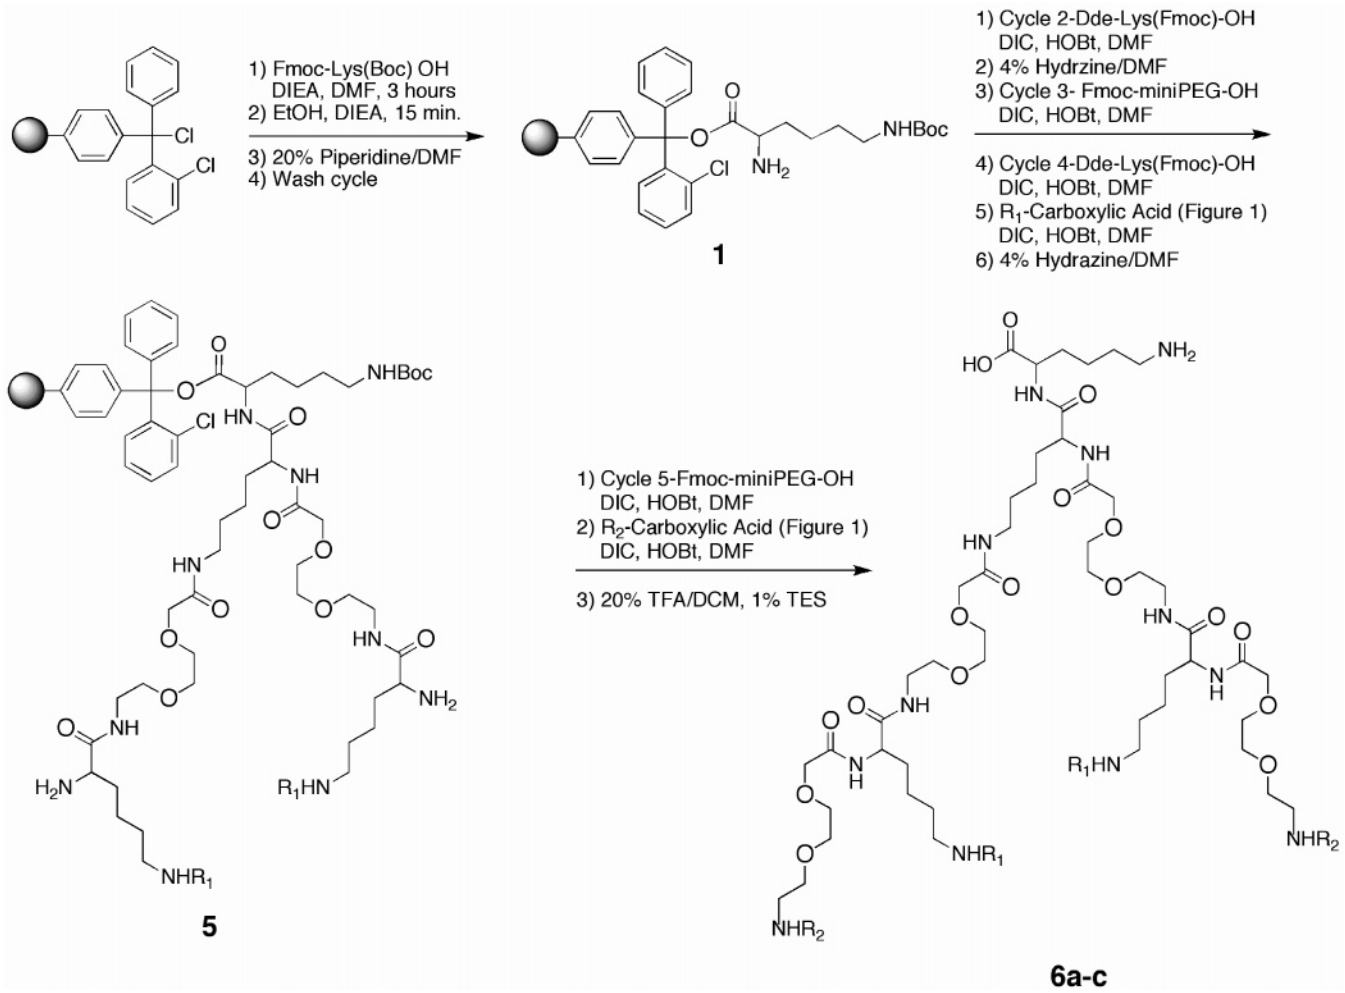
Synthesis of SHALs (3a−c). (Scheme 1) Resin **2** was treated with a solution of Fmoc-8-amino-3,6-dioxaoctanoic acid, HOBt, and DIC (3 equiv) in 1.0 mL anhydrous DMF for 3−5 h (coupling cycle 4). Following Fmoc deprotection, the resultant free amine was subsequently coupled to one of the molecules R_2 in Figure 1 (2−3 equiv), HOBt, and DIC (3 equiv) in 1.0 mL anhydrous DMF for 5 h. The solvent was exchanged to DCM (2 mL). The washed resin was then treated with 2 mL of 20% TFA/1% TES in DCM for 30 min to cleave the product from the resin and the Boc-protecting group on the ϵ-amine of the first lysine. The cleaved solution was filtered and collected, the resin washed with DCM, and the combined filtrate was reduced to dryness. The crude sample was analyzed by analytical HPLC to determine the ratio of product to impurities in the cleaved material using UV absorbance peak areas at 254 nm. Purification was performed using semipreparative HPLC, and the product fractions were lyophilized to dryness. Analytical HPLC chromatograms, electron spray ionization mass spectroscopy (ESI-MS), ^{1}H NMR spectra for **3a**−**c**, and ^{13}C NMR spectrum for **3a** are provided in the Supporting Information.

*SHAL **3a** (DLPItPLA).* Crude **3a** was treated with 100 mM NH_4HCO_3 to cleave TFA esters formed on deoxycholate alcohols during deprotection. HPLC of the crude material gave approximately 50% product (Rt = 8.44 min). This NH_4HCO_3/crude was lyophilized and purified by HPLC (85% H_2O (0.1% TFA) to 70% MeCN (0.1% TFA), 25 min gradient). The combined product fractions were lyophilized to yield 40 mg of isolated **3a**. ESI-MS: *m*/*z* calcd for $C_{79}H_{122}I_3N_{11}O_{22}$ $(M + H)^+$ 1573.21, found 1572.41; calcd for $(M + 2H)^{2+}$ 787.11, found 786.78.

*SHAL **3b** (DvLPBaPLA).* HPLC of the crude material gave approximately 73% product (Rt = 7.29 min), and 20 mg of red solid **3b** was isolated. ESI-MS: *m*/*z* calcd for $C_{63}H_{91}N_{15}O_{15}S$ $(M + H)^+$ 1331.58, found 1331.47; calcd for $(M + 2H)^{2+}$ 666.29, found 665.96; calcd for $(M + 3H)^{3+}$ 444.53, found 444.06.

*SHAL **3c** (DvLPTPLA).* HPLC of the crude material gave approximately 80% product (Rt = 7.31 min), and 20 mg of red solid **3c** was isolated. ESI-MS: *m*/*z* calcd for $C_{58}H_{83}N_{11}O_{15}S$ $(M + H)^+$ 1207.44, found 1206.49; calcd for $(M + 2H)^{2+}$ 604.22, found 603.89; calcd for $(M + 3H)^{3+}$ 403.15, found 402.95

Preparation of Resin 5. (Scheme 2) Resin **1** was treated with Dde-Lys(Fmoc)-OH, HOBt and DIC (3 equiv) in 1.0 mL anhydrous DMF for 5 h (coupling cycle 2). The reaction solution was filtered, and the washed resin was treated twice with 4% hydrazine/DMF (40 μL hydrazine in 900 μL DMF for 10 min) to remove the Dde protecting group (Scheme 2). In coupling cycle 3, Fmoc-8-amino-3,6-dioxaoctanoic acid (6 equiv) was coupled to the resin with DIC and HOBT (6 equiv) in 1.0 mL anhydrous DMF for 3 h. The washed resin was then treated with Dde-Lys(Fmoc)-OH, HOBt, and DIC (6 equiv) in 1.0 mL anhydrous DMF for 5 h (coupling cycle 4). Following Fmoc deprotection, the resultant free amine was subsequently coupled to one of the molecules R_1 in Figure 1 (2−3 equiv), HOBt, and DIC (6 equiv) in 1.0 mL anhydrous DMF for 5−12 h, depending on the R_1 molecule. The mixture was filtered, and the washed resin was treated twice with 4% hydrazine/DMF to remove the two Dde protecting groups. After washing, resin **5** with two primary amines (one on each lysine) was obtained.



Synthesis of SHALs (6a−c). (Scheme 2) Resin **5** was treated with a solution of Fmoc-8-amino-3,6-dioxaoctanoic acid, HOBt, and DIC (6 equiv) in 1.0 mL anhydrous DMF for 5 h (coupling cycle 5). Following Fmoc deprotection, the resultant free amine was subsequently coupled to one of the molecules R_2 in Figure 1 (2−3 equiv), HOBt, and DIC (6 equiv) in 1.0 mL anhydrous DMF for 5 h. The solvent was exchanged to dichloromethane (DCM, 2 mL). The washed resin was treated with 2 mL of 20% TFA/1% TES in DCM for 30 min to cleave the product from the resin and the Boc-protecting group on the ϵ-amine of the first lysine. The cleaved solution was filtered and collected, the resin washed with DCM, and the combined filtrate was concentrated. A sample was analyzed by analytical HPLC to determine the ratio of product to impurities in the cleaved material using UV absorbance peak areas at 254 nm. Purification was performed using semipreparative HPLC, and the product fractions were lyophilized to dryness. Analytical HPLC, ESI-MS, ^{1}H NMR for all compounds, and ^{13}C NMR spectra for **3a** and **6a** are provided in Supporting Information.

*SHAL **6a** ((DLPItP)$_2$LLA).* HPLC of the crude material gave approximately 65% product (Rt = 9.73 min), and 96 mg of white solid **6a** was isolated. ESI-MS: *m*/*z* calcd for $C_{126}H_{190}I_6N_{14}O_{29}$ $(M + 2H)^{2+}$ 1564.21, found 1564.10; calcd for $(M + 3H)^{3+}$ 1043.14, found 1043.15.

*SHAL **6b** ((DvLPBaP)$_2$LLA):* HPLC of the crude material gave approximately 62% product (Rt = 7.86 min), and 60 mg of red solid **6b** was isolated. ESI-MS: *m*/*z* calcd for $C_{126}H_{180}N_{30}O_{29}S_2$ $(M + 2H)^{2+}$ 1322.57, found 1322.43; calcd for $(M + 3H)^{3+}$ 882.05, found 881.92; calcd for $(M + 4H)^{4+}$ 661.05, found 661.51; calcd for $(M + 5H)^{5+}$ 529.63, found 529.42.

*SHAL **6c** ((DvLPTP)$_2$LLA):* HPLC of the crude material gave approximately 63% product (Rt = 8.09 min), and 40 mg of red solid **6c** was isolated. ESI-MS: *m*/*z* calcd for $C_{116}H_{164}N_{22}O_{29}S_2$ $(M + 2H)^{2+}$ 1198.43, found 1198.18; calcd for $(M + 3H)^{3+}$ 799.29, found 799.16; calcd for $(M + 4H)^{4+}$ 599.72, found 599.54; calcd for $(M + 5H)^{5+}$ 479.98, found 479.73.

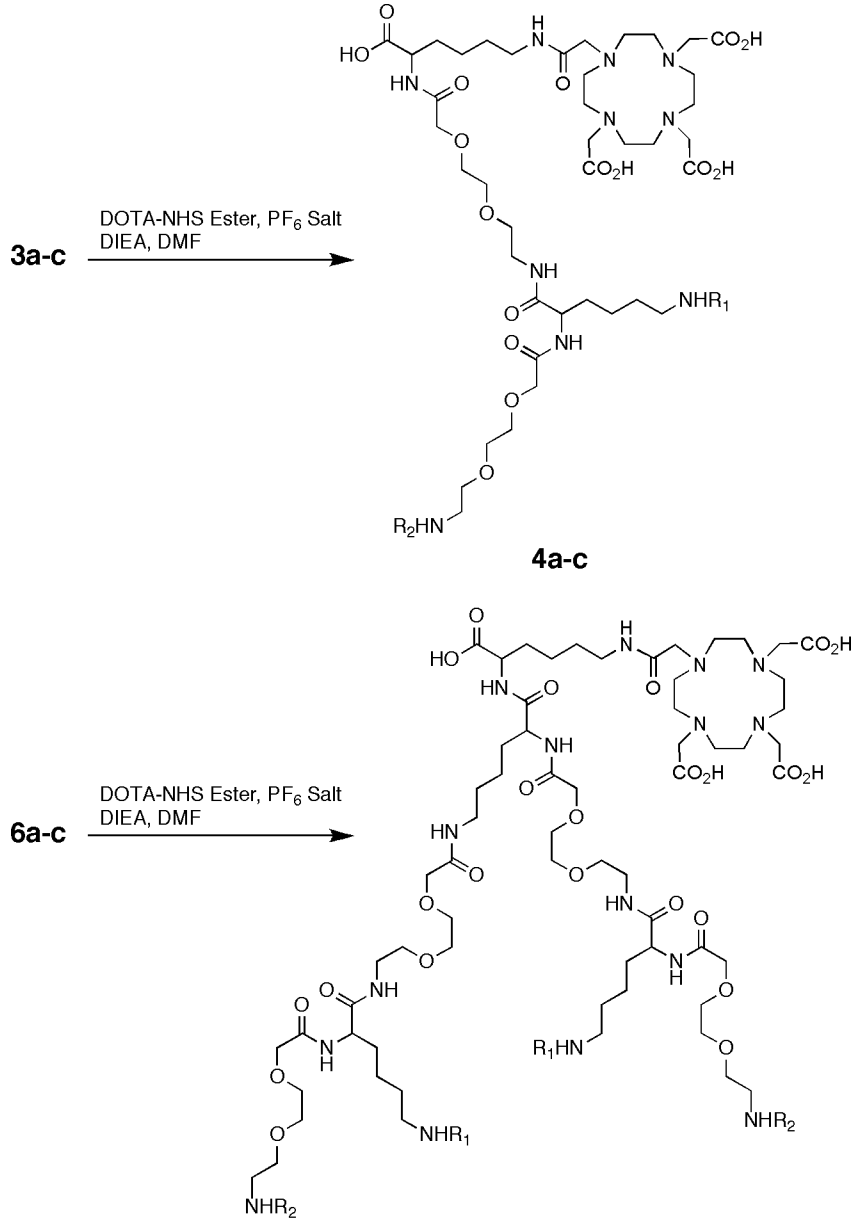
Scheme 2. Solid-Phase Synthesis of Bisbidentate SHALs 6a−c

Synthesis of DOTA SHALs. 3a−c and **6a−c** were converted to DOTA derivatives **4a−c** and **7a−c**, respectively (Scheme 3). Generally, a SHAL was dissolved in 500 μL anhydrous DMF and 100 μL DIEA. The PF_6 salt of DOTA NHS ester (933.36 g/mol, 0.95−1.1 equiv) was added to the mixture as a solid. The reaction was nutated for 15 min, and the reaction was monitored by analytical HPLC. Upon completion, the reaction solution was diluted with 300 μL H_2O and 300 μL MeCN, both containing 1% TFA, and directly HPLC purified into two 600 μL aliquots. The resulting purified lyophilized DOTA SHALs were analyzed by HPLC and ESI-MS (spectra provided in Supporting Information).

*DOTA SHAL **4a** (DLPItPLDo).* Reaction of **3a** (5.3 mg, 3.37 μmol) with DOTA NHS ester (3.5 mg, 3.75 μmol) gave 100% (Rt = 8.29 min) conversion by analytical HPLC and yielded **4a** (8.0 mg, white solid) after purification. ESI-MS: *m/z* calcd for $C_{79}H_{122}I_3N_{11}O_{22}$ $(M + H)^+$ 1959.62, found 1959.26; $(M + 2H)^{2+}$ 980.31, found 980.07.

*DOTA SHAL **4b** (DvLPBaPLDo).* Reaction of **3b** (6.2 mg, 4.66 μmol) with DOTA NHS ester (4.8 mg, 5.14 μmol) gave 93% (Rt = 7.07 min) conversion by crude analytical HPLC and yielded **4b** (6.5 mg, red solid) after purification. ESI-MS: *m/z* calcd for $C_{79}H_{117}N_{19}O_{22}S$ $(M + H)^+$ 1717.99, found 1718.20; calcd for $(M + 2H)^{2+}$ 859.49, found 859.46; calcd for $(M + 3H)^{3+}$ 573.33, found 573.29.

*DOTA SHAL **4c** (DvLPTPLDo).* Reaction of **3c** (5.8 mg, 4.81 μmol) with DOTA NHS ester (4.3 mg, 4.61 μmol) gave 75% (Rt = 7.17 min) conversion by crude analytical HPLC and yielded **4c** (7.0 mg, red solid) after purification. ESI-MS: *m/z* calcd for $C_{74}H_{109}N_{15}O_{22}S$ $(M + H)^+$ 1593.84, found 1594.01; calcd for $(M + 2H)^{2+}$ 797.42, found 797.36; calcd for $(M + 3H)^{3+}$ 531.42, found 531.88.



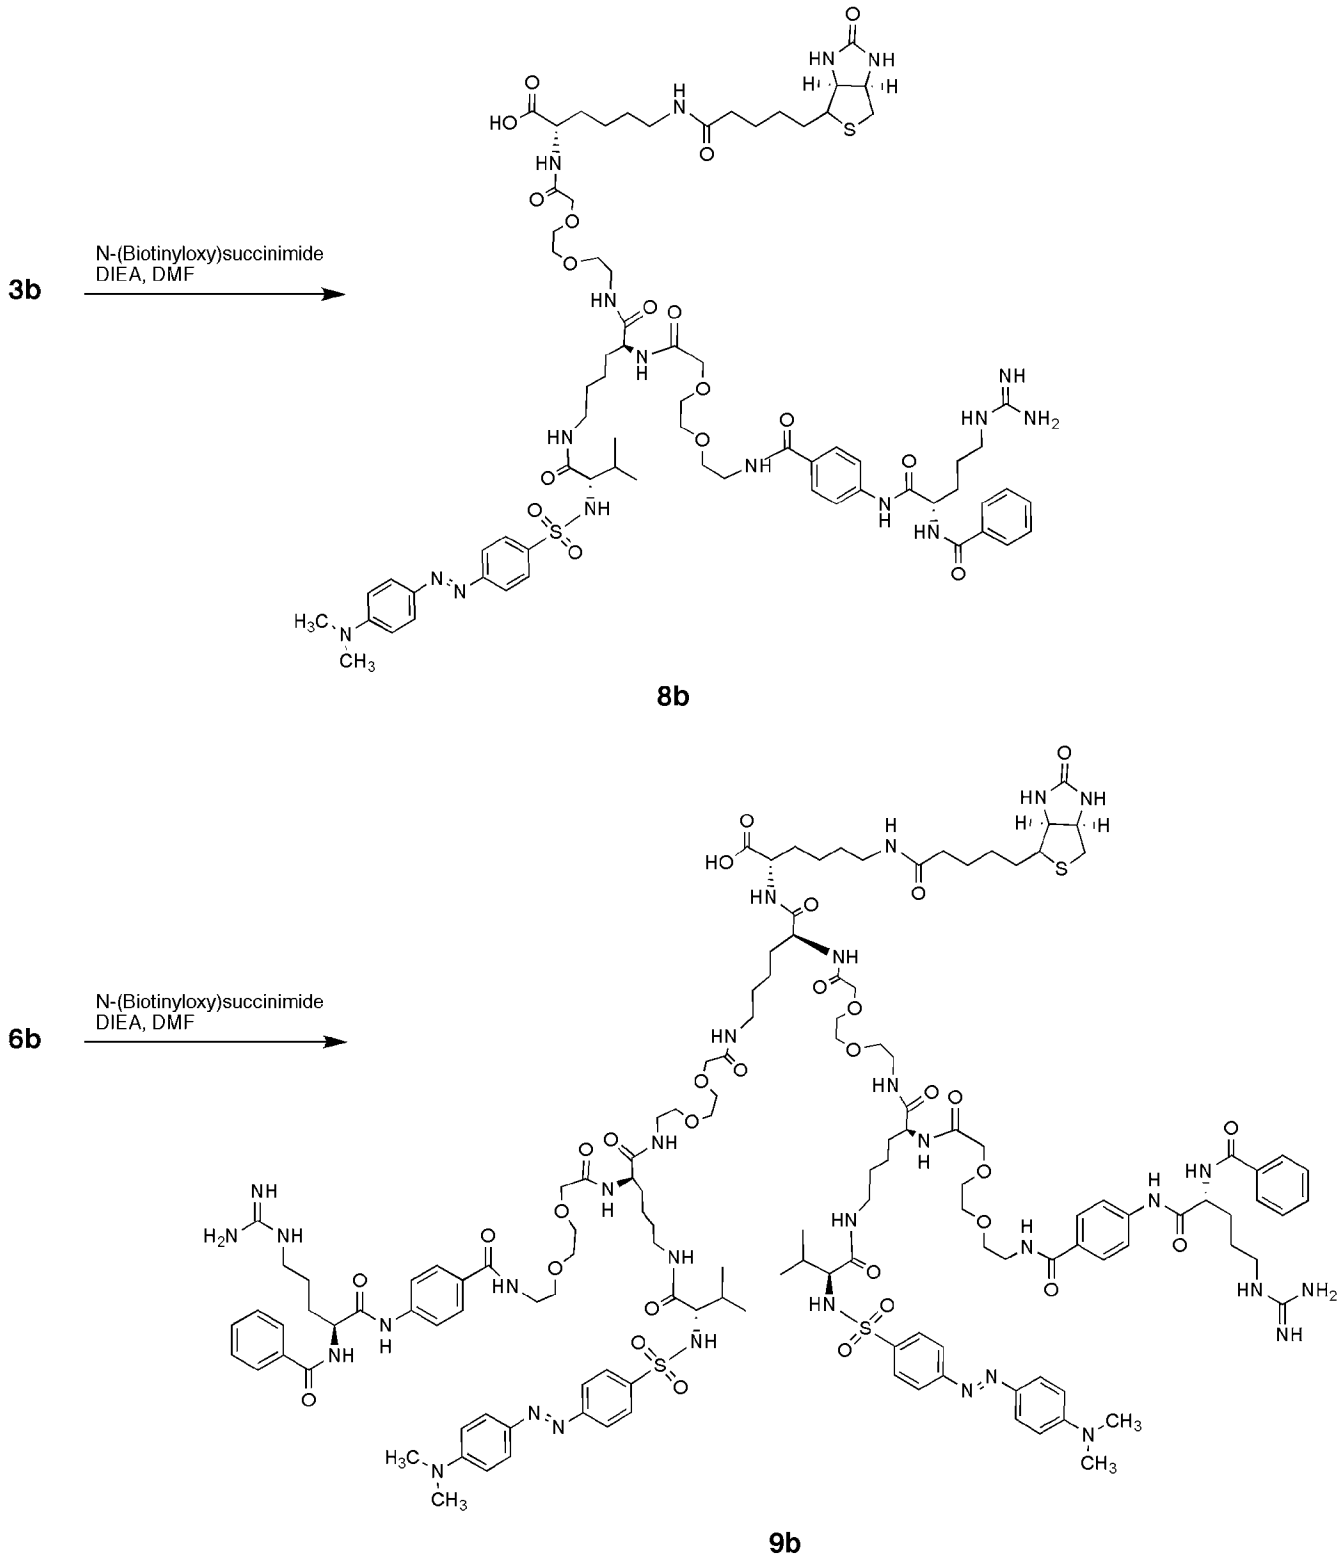
*DOTA SHAL **7a** ((DLPItP)$_2$LLDo).* Reaction of **6a** (11.0 mg, 3.52 μmol) with DOTA NHS ester (3.6 mg, 3.86 μmol) gave 70% (Rt = 9.53 min) conversion by crude analytical HPLC and yielded **7a** (12.0 mg, white solid) after purification. ESI-MS: *m/z* calcd for $C_{142}H_{216}I_6N_{18}O_{36}$ $(M + 2H)^{2+}$ 1757.41, found 1757.37; calcd for $(M + 3H)^{3+}$ 1171.94, found 1171.85; calcd for $(M + 4H)^{4+}$ 879.21, found 879.16.

*DOTA SHAL **7b** ((DvLPBaP)$_2$LLDo).* Reaction of **6b** (18.0 mg, 6.81 μmol) with DOTA NHS ester (8.0 mg, 8.57 μmol) gave 80% (Rt = 7.76 min) conversion by crude analytical HPLC and yielded **7b** (7.0 mg, red solid) after purification. ESI-MS: *m/z* calcd for $C_{142}H_{206}N_{34}O_{36}S_2$ $(M + 3H)^{3+}$ 1010.85, found 1010.82; calcd for $(M + 4H)^{4+}$ 758.39, found 758.30; calcd for $(M + 5H)^{5+}$ 606.91, found 606.78.

*DOTA SHAL **7c** ((DvLPIP)$_2$LLDo).* Reaction of **6c** (5.0 mg, 2.09 μmol) with DOTA NHS ester (2.5 mg, 2.68 μmol) gave 80% (Rt = 7.72 min) conversion by crude analytical HPLC and yielded **7c** (4.0 mg, red solid) after purification. ESI-MS: *m/z* calcd for $C_{132}H_{190}N_{26}O_{36}S_2$ $(M + 2H)^{2+}$ 1391.63, found 1391.41; calcd for $(M + 3H)^{3+}$ 928.09, found 928.11; calcd for $(M + 4H)^{4+}$ 696.31, found 696.33; calcd for $(M + 5H)^{5+}$ 557.26, found 557.21.

Synthesis of Biotinylated SHALs. 3b and **6b** were converted to the biotin derivatives **8b** and **9b**, respectively (Scheme 4). Generally, a SHAL was dissolved in 500 μL anhydrous DMF and 100 μL DIEA and biotinyl-OSu (341.39 g/mol, 1.1 equiv) was added to the mixture as a solid. The reaction was nutated for 15 min, and the reaction was monitored by analytical HPLC.

Scheme 3. Synthesis of DOTA-SHALs 4a−c and 7a−c. Free Amine of SHALs 3a−c and 6a−c were Reacted with the PF_6 Salt of DOTA−NHS Ester to Generate 4a−c and 7a−c, Respectively



Upon completion, the reaction solution was diluted with 300 μL H_2O and 300 μL MeCN, both containing 1% TFA, and directly HPLC purified into two 600 μL aliquots. The resulting purified/lyophilized biotinylated SHALs were analyzed by HPLC and ESI-MS (spectra provided in Supporting Information).

Biotin SHAL ***8b*** *(DvLPBaPLB).* Reaction of **3b** (10.0 mg, 7.52 μmol) with biotinyl-OSu (3.5 mg, 8.20 μmol) gave 100% (Rt = 7.70 min) conversion by analytical HPLC and yielded **8b (**7.0 mg, red solid) after purification. ESI-MS: *m*/*z* calcd for $C_{73}H_{105}N_{17}O_{17}S_2$ $(M + H)^+$ 1557.88, found 1557.99; $(M + 2H)^{2+}$ 779.44, found 779.41; $(M + 3H)^{3+}$ 519.96, found 519.80.

Biotin SHAL ***9b*** *((DvLPBaP)$_2$LLB).* Reaction of **6b** (10.0 mg, 3.78 μmol) with biotinyl-OSu (1.5 mg, 4.39 μmol) gave 100% (Rt = 8.23 min) conversion by crude analytical HPLC and yielded **9b** (8.7 mg, red solid) after purification. ESI-MS: *m*/*z* calcd for $C_{136}H_{194}N_{32}O_{31}S_3$ $(M + 2H)^{2+}$ 1435.72, found 1435.78; calcd for $(M + 3H)^{3+}$ 957.49, found 957.52; calcd for $(M + 4H)^{4+}$ 718.37, found 718.35; calcd for $(M + 5H)^{5+}$ 574.86, found 574.85.

Determination of metal-free DOTA. DOTA−SHALs **4a−c** and **7a−c** were assayed in triplicate using a cobalt metal binding assay to determine the ratio of DOTAs available, following synthetic and purification procedures, for metal chelation. The binding assay was modified from previously described procedures (*29*−*31*). Generally, an aliquot of DOTA−SHAL in 10% DMSO in PBS was diluted into 0.1 M $(NH_4)_3PO_4$, pH 5.3, and excess standardized aqueous solution of $^{57}CoCl_2$ was added (manufacturer provided batch-specific specific activity information). The final solution was adjusted to pH 7.0 using NH_4-OAc, and this mixture was held for 30 min at room temperature. The initial concentration of the metal-free DOTA−SHAL was estimated from HPLC peak area with UV absorbance at 254 nm. Subsequently, aqueous EDTA (Fisher Scientific) was added to a final concentration of 10 mM and incubated for 15 min to sequester nonspecifically bound and excess cobalt ions. Radiolabeled ^{57}Co-DOTA−SHAL was estimated by TLC (precoated silica gel plates (EM Science, Gibbstown, NJ) with 10% NH_4-OAc−MeOH 1:1 v/v as the eluent). The concentration of the cobalt chelated by the DOTA−SHALs was determined by

Scheme 4. Synthesis of Biotinylated SHALs 8b and 9b

radiation counting using 1282 Compu Gamma Counter (Pharmacia, Piscataway, NJ, or a Fuji film BAS-1800 imager) against a known quantity of standardized $^{57}CoCl_2$ solution. The metal-chelatable DOTA was calculated as the ratio of the molar concentration of the ^{57}Co-DOTA−SHAL chelate and metal-free DOTA−SHAL ligand (Table 3).

Radiolabeling with ^{111}In. DOTA−SHALs **4a-c** and **7a−c** were labeled with $^{111}InCl_3$ (*31*). Generally, an aliquot of $^{111}InCl_3$ (4−5 mCi, 150−185 MBq, 15−20 μL) was added to a solution of DOTA−SHAL (25−50 μg) in 0.1 M $NH_4CO_2CH_3$ (50 μL). The final pH of the reaction mixture was adjusted to 6.5 by adding 4 M NH_4OAc and incubated for 1 h at 37 °C. After 1 h, 0.1 M EDTA (10−20 μL) was added to sequester excess, free $^{111}In^{3+}$. The radiolabeled product was purified by HPLC with a 1000 Da cutoff dialysis membrane using PBS as dialyzer. The ^{111}In-conjugated DOTA−SHAL was eluted between 8 and 10 min. The radiopharmaceutical purity of the radiolabeled SHALs was determined by TLC (10% NH_4OAc−MeOH 1:1), HPLC, and Cellulose-acetate electrophoresis (CAE) (Table 3). HPLC-purified pharmaceuticals were concentrated using Speed-

Table 1. Crude Percent Yield and Milligrams of Isolated Yield of SHALs[a]

SHAL	R_1	R_2	crude yield (%)	isolated yield (mg)
3a	D	It	50	40

vac SC110 (Savant Instruments, Holbrook, NJ) and the product redissolved in 10% DMSO in PBS for further use.

Live Cell ELISA. Washed cells (1×10^6/100 μL) were added to wells of a 96-well plate containing either 10 μM biotinylated SHALs **8b** or **9b** that has been preincubated with 10 μg/mL of streptavidin−HRP or 10 nM Lym-1 that has been preincubated with 0.5 μg/mL of goat anti-mouse IgG-HRP (1 h preincubation at rt) and incubated at room temperature for 1 h with nutation. For control wells, cells were incubated with 10 μg/mL of streptavidin−HRP in assay buffer (PBS, 1% BSA pH 7.2).

After 1 h, the plate was centrifuged for 5 min at 300 *g*, the supernatant was carefully removed, and the wells washed three times. For each wash, the cells were resuspended in 200 μL assay buffer, centrifuged, and the supernatant removed. After the third wash, the cells were resuspended in 200 μL assay buffer, transferred to a new plate, and washed twice more with PBS. The supernatant was removed, and cells were resuspended in 200 μL ABTS substrate and incubated at rt for 20 min. The plate was centrifuged, 100 μL of the supernatant was transferred to a flat-bottom ELISA plate, and the OD 405 was determined using a Dynatech MRX ELISA plate reader.

RESULTS AND DISCUSSION

Small molecules that bind to two unique, but structurally distinct, cavities located on the surface of the β-subunit of HLA−DR10, an abundant cell surface HLA−DR protein found on non-Hodgkin's lymphoma and leukemia cells, have been identified using computational docking techniques (*32*, *33*). Pairs of these small molecules have been covalently linked and radiolabeled to generate multivalent ligands, termed SHALs, that exhibit high avidity for HLA-DR10 and potentially create a new generation of radiopharmaceuticals. Computational docking methods predicted two molecules shown in Figure 1, deoxycholic acid (D) and dabsyl-L-valine (Dv), to bind to one cavity on the surface of the β-subunit of HLA−DR10 (*34*). Three additional molecules, also shown in Figure 1, 3,3′,5-triido-L-thyronine (It), L-thyronine (T), and *N*-benzoyl-L-arginyl-4-aminobenzoic acid (Ba), were predicted to bind to an adjacent cavity. Subsequently, all five of these molecules have experimentally been shown to bind to native HLA−DR10 isolated from Raji cells and a recombinant form of the β-subunit (*20*, *21*). One attractive feature of all five molecules is that they each contain a carboxylic acid, which provides a convenient site for covalent attachment of a pair of these molecules onto a multivalent scaffold using amide coupling chemistry. Furthermore, the structure of the molecules predicted to bind to each site are sufficiently different to suggest that SHALs produced using each combination of molecules will exhibit differing properties in vivo.

SHALs **3a−c** were conveniently synthesized using a combination of orthogonally protected lysines and the incremental use of a commercially available Fmoc-protected poly(ethylene glycol) spacer unit to generate an amine-functionalized scaffold. Subsequently, the carboxylic acid-functionalized molecules shown in Figure 1 were coupled to the amine groups before the completed SHAL was cleaved from the resin. Scheme 1 shows the initial coupling of Fmoc-Lys(Boc)-OH to chlorotrityl chloride resin using standard procedures (*25*, *27*). The Boc-protected lysine was included to generate a free amine after cleavage of the SHAL from the resin to allow labeling of the SHAL with DOTA or biotin for example for subsequent binding assays. The Fmoc-protected poly(ethylene glycol) spacer was introduced to separate the target binding portion of the SHALs and the radiolabel. Finally, Dde-Lys(Fmoc)-OH was used to sequentially generate free amines to sequentially couple the small molecules (R_1 and R_2, Figure 1) predicted to bind to the two different sites on the target protein. The SHALs were cleaved from the resin and the Boc group removed by TFA treatment and the SHALs were purified using semipreparative HPLC. The SHALs cleaved from the resin were generally of high purity (Table 1), indicating that each coupling step went to near completion. SHALs were synthesized on various scales, yielding 20−100 mg of purified product (Table 1). However, the SHALs could be synthesized on a much larger scale using these solid-phase synthetic methods. During initial synthetic development, it was important to determine that the small molecules R_1 (Figure 1) could withstand the Dde-deprotection conditions (4% hydrazine in DMF). This was determined by small-scale reactions and mass spectrometry confirmation of product integrity. In addition, both R_1 and R_2 were determined to withstand TFA treatment for resin cleavage and Boc deprotection. SHALs containing deoxycholate (D) as R_1 required a treatment with 100 mM NH_4HCO_3 before purification to displace the TFA esters formed on the deoxycholate alcohols during resin cleavage.

SHALs **6a−c**, bis-versions of SHALs **3a−c**, were generated in an effort to increase avidity of the SHALs for the target protein even further. The increased multivalency of SHALs **6a−c** potentially increases avidity of the SHALs for tumor cells in two ways. First, it is possible that increasing the multivalency of the SHAL increases the local concentration of the binding molecules R_1 and R_2 at the protein surface, thereby increasing the likelihood that the two molecules are bound to the protein at the same time. Second, it is also possible that SHALs **6a−c** can bind to neighboring HLA−DR10 molecules, increasing avidity for the tumor cell. The distance between the covalently linked molecules R_1 and R_2 is sufficient to allow the SHALs **6a−c** to bind neighboring HLA−DR10 molecules. SHALs **6a−c** were synthesized using an incremental approach as outlined in Scheme 2. The use of these solid-phase scaffolds to

generate multivalent ligands allows the rapid generation of SHALs with a variety of small molecule pairs for subsequent radiolabeling and binding assays.

SHALs **3a**−**c** and **6a**−**c** were constructed for convenient conjugation to metal-chelating molecules DOTA (Scheme 3) or affinity tags, such as biotin (Scheme 4). The reaction between the commercially available NHS ester of the DOTA hexafluorophosphate (PF_6) salt with SHALs **3a**−**c** and **6a**−**c** in DMF and DIEA gave 70−100% conversion to DOTA−SHALs after 5−15 min as monitored by analytical HPLC (Table 2). Biotin-derivatized SHALs **8b** and **9b** were synthesized starting from **3a** and **6b**, respectively, using similar conditions (Scheme 4) to generate SHALs suitable for subsequent use in cell binding assays. Subsequently, the DOTA−SHALs were labeled with ^{57}Co to determine the ratio of DOTAs available for radiolabel chelation following synthetic and purification procedures. Generally, 50−60% of the DOTAs were available for radiolabel chelation (Table 3). While the percentage DOTAs available for chelation are in an acceptable range for the synthesis of a radiotherapy agent, this can be further improved through the implementation of stringent metal-free conditions during synthesis, and especially purification, to produce better radiolabeling yields and consequently higher specific activities.

Reaction parameters were optimized to achieve maximum efficiency in radiolabeling the DOTA−SHALs with ^{111}In. The concentration of DOTA−SHAL was varied from 0.5 to 12.5 nmol; it was observed that, while 40% complexation was achieved at 0.5 nmol, 90% complexation was achieved at 5 nmol DOTA−SHAL, determined by titration with an excess amount of ^{111}In. Therefore, 5 nmol DOTA−SHAL was the minimum concentration used in labeling reactions. The chelation yield was determined over pH range 5−7, with a maximum observed at pH 5.5, consistent with previous reports of the radiolabeling of immunoconjugates (*31*). The chelation reaction was incubated at 37 °C, and the yield was estimated over 90 min. Incubation for 60 min was sufficient to achieve the maximum chelation.

The ^{111}In-DOTA−SHAL conjugates were characterized by TLC and HPLC. The radiochemical yield and purity were further confirmed by CAE to estimate the degree of aggregation of the DOTA−SHAL, if any, during the radiolabeling process. In general, the CAE assay showed very distinct resolution between the ^{111}In-DOTA−SHALs and ^{111}In-EDTA complexes, and the radioactive peaks were observed at 2.3−2.7 cm and >6.5 cm, respectively (Table 3). No radioactivity peak was observed at the origin of the CAE, indicating that no aggregation had occurred. The same trend was observed in the TLC assay; the ^{111}In-DOTA−SHALs showed very little migration from the point of spotting (R_F = 0.25−0.3), whereas the ^{111}In-EDTA complex moved further toward the solvent front (R_F = 0.6). Conversely, HPLC analysis showed the ^{111}In-EDTA at 2.5−3.0 min and the ^{111}In-DOTA−SHALs at 9.5−10 min. This distinct resolution facilitated the HPLC purification of the radiolabeled products. CAE, TLC, and HPLC were also used to determine the stability of the radiolabeled conjugate, and the ^{111}In-DOTA−SHALs were stable up to 72 h at room temperature with radiochemical purity of >85%. Radiolabeled product yields are shown in Table 3 and are similar to those obtained when generating antibody agents, and those needed for practicality, but can be further optimized for large-scale use where 80−90% yield is desirable. If radiochemical yield is greater than 90%, then the elimination of a final purification step can be considered with additional improvements in product yield.

In comparison to antibody agents, SHALs have a 1:1 ratio of protein binding sites to DOTA. Generally, radiolabeled monoclonal antibodies are modified to optimally contain an average of two DOTAs in order to preserve immunoreactivity, but can have up to a maximum of four DOTAs per macromolecule. One DOTA per SHAL with a molecular weight of ∼3000 Da compared to 2 DOTAs per monoclonal antibody with a molecular weight of ∼150 000 Da translates to a potentially higher specific activity (μCi/μg) for SHALs, although μCi/μmol may be less. Considering their relative mass differences of a factor of 50−100, and DOTA per molecule of about 2 in the opposite direction, then SHALs with specific activities 25−50 times greater than those for antibodies is theoretically feasible.

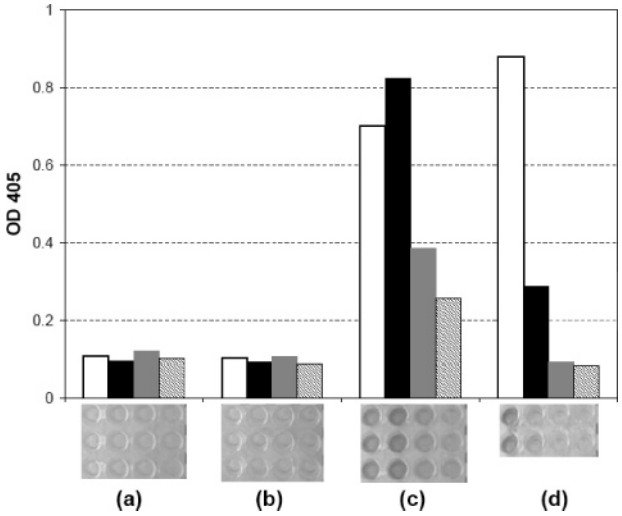

Figure 2. Live cell ELISA. (a) Buffer blank. (b) 10 μM biotinylated SHAL **8b**. (c) 10 μM biotinylated SHAL **9b**. (d) 0.5 μg/mL Lym 1. Cells: white, Raji; black, Nu-DHL-1; gray, MCF7; hashed, HBT-3477. Raji and Nu-DHL-1 are malignant lymphoma HLA−DR10 expressing cell lines, MCF7 and HBT-3477 are HLA−DR10-negative human breast epithelial cancer cell lines.

Whole-cell binding experiments conducted in vitro with ^{111}In-labeled SHALs **4b** and **7b** showed that both SHALs bind Raji HLA−DR10 positive non-Hodgkin's lymphoma cells. Linking the two molecules dabsyl-L-valine and *N*-benzoyl-L-arginyl-4-aminobenzoic acid together using a single lysine and poly(ethylene glycol) spacer resulted in the generation of a SHAL (**4b**) that binds to HLA−DR10-containing Raji cells with a K_d of ∼80 nM. Moreover, the bis-version of **4b**, SHAL **7b**, exhibited an avidity of 93 pM for Raji lymphoma cells (*21*). Biotinylated derivatives **8b** and **9b** of the two DOTA−SHALs **4b** and **7b** (in which biotin was conjugated to each SHAL in place of DOTA) were assessed using a live-cell ELISA, and the results are shown in Figure 2. The biotinylated SHALs were assayed against four cell types, two malignant lymphoma cell lines expressing HLA−DR10 (Raji and Nu-DHL-1) and two human breast epithelial cancer cell lines, known to not express HLA−DR10 (MCF7 and HBT-3477). Clearly, SHAL **9b** exhibits a much higher avidity than **8b**, again indicating that increased multivalency increases binding interactions. Morover, the SHAL **9b** exhibits a similar pattern of specificity to Lym-1, more specifically binding HLA−DR10-expressing cell lines.

The results presented here demonstrate that it is possible to create small-molecule-based targeting agents with an overall relatively small molecular weight (<5000 Da) that exhibit high avidity and specificity for their target protein, can be labeled with the appropriate radiolabel in high yield, and may prove useful as alternatives to traditional antibody-based targeting systems.

In conclusion, a convenient and rapid procedure for the generation of SHALs, relatively small molecular weight ligands, designed to bind HLA−DR10 has been established. In addition, the conditions for the reproducible radiolabeling of these SHALs have been determined. Significantly, it appears that increasing multivalent interactions significantly increases the avidity of a SHAL for the target protein. SHALs are a potential alternative

to antibodies as molecular targeting agents for the targeted radiotherapy of non-Hodgkin's lymphoma. By judicious selection of the small-molecule pairs used to generate SHALs, it should be possible to produce SHALs using the methods and procedures presented here that will not be significantly taken up by organs (liver, kidney) and are rapidly excreted, significantly decreasing the targeting agent's clearance time from the bloodstream. Synthetic molecules offer the additional advantage that they can be reproducibly synthesized in large amounts (g to kg), under QA procedures, while antibody production can be variable from batch to batch. Moreover, synthetic molecules can be produced in forms that are usually stable and do not degrade over prolonged periods of time. Small synthetic molecules are also less likely to elicit an immune response, and the small size of the reagent would allow it to penetrate tumors more effectively than an antibody counterpart, thereby increasing ionizing radiation to tumor cells, resulting in more homogeneous irradiation and hypothetically a better response.

Lomonosov Moscow State University, Department of Chemistry, 119992 Moscow, Russia. Received October 10, 2006; Revised Manuscript Received February 6, 2007

To optimize polycation-based gene delivery agents, the influence of molecular characteristics of the polycations on physicochemical properties of polycation/DNA complexes and their relationships to cellular gene transfer need to be understood. With this aim, we have synthesized a series of model polymers based on quaternized poly(4-vinylpyridine)s (C_nPVP-β) with the same DP of 1600 but differing by the number n of methylene groups in N-alkyl ester substituents from 1 to 6 and/or by degree of alkylation β from 25% to 95%. For polycations C_nPVP-95, the efficiency of transfection of a plasmid vector expressing a secreted form of alkaline phosphatase started to be detectable at $n = 4$, noticeable at $n = 5$, and again undetectable at $n = 6$. A decrease in β of active C_5PVP-95 from 95% to 65% resulted in a further noticeable increase of activity with a 9-fold increase for C_5PVP-65. This finding was attributed to the proton sponge mechanism due to protonation of non-alkylated pyridine moieties of C_nPVP-β/DNA complexes in slightly acidic media that was supported by the fluorescence quenching assay. The data demonstrate the advantages of partial alkylation of tertiary polyamines with medium-length alkyl agents for preparation of efficient nonviral gene delivery vectors.

INTRODUCTION

Gene therapy refers to the transfer of DNA encoding a therapeutic gene of interest into the target cells or organs with consequent expression of the transgene. In the past decade, gene therapy has received significant attention due to its potential application for treatment of acquired diseases (*1*, *2*). The most effective vectors for gene transfection are those based on viruses and viral peptide sequences (*3*, *4*). However, concerns with immunogenic and long-term oncogenic effects have prompted the concurrent development of synthetic gene delivery systems, such as liposomes, lipids, or polycations (*5*, *6*). Although naked DNA has been found to transfect some cells like the skeletal muscle cells of the cardiac and diaphragm regions, the pronounced negative charge of the double helix tends to inhibit DNA from entering cell membranes. Moreover, the unprotected DNA is rapidly degraded by nucleases. Linear cationic polymers, such as poly(lysine) and its conjugates (*7*−*9*), poly(*N*-ethyl-4-vinylpyridinium) bromide and its derivatives (*10*, *11*), branched polymers such as poly(ethylene imine) (*12*), and poly(amidoimine) dendrimers (*13*, *14*) effectively bind to the negatively charged DNA to form a polyelectrolyte complex that can be taken up by cells. The electrostatic binding of the polycation to the phosphate groups leads to DNA compaction. By being packed in the polyelectrolyte complex, DNA is shielded from contact with nucleases. It has been observed that in vitro transfection becomes efficient when complexes have a net positive charge to interact with negatively charged cell membranes.

Numerous works on liposomes or polymers for gene therapy indicated that the modification of positively charged chains with hydrophobic residues enhances their binding to cell membranes and penetration into cells. For gene transfer with cationic oligomers, long alkyl sequences were commonly used. For instance, the transformation of various mammalian cells was performed by DNA complexes with lipospermines that were synthesized by chemical modification of natural oligocation spermine with two long C_{18} alkyl tails (*15*, *16*). N-Terminal stearylation of oligoarginines consisting of 4−16 repeat units increased the transfection efficiency by 100 times with the maximal efficiency displayed by stearyl-Arg_8 (*17*), but the decrease in the number of methylene groups from 16 in the stearyl-Arg_8 to 10 in N-terminal lauryl-Arg_8 significantly reduced the efficiency. Few detailed reports are available for higher molecular weight structures. Thus, the introduction of 3−4% of C_{16} N-alkyl moieties in poly(*N*-ethyl-4-vinylpyridinium) bromide noticeably enhanced its affinity with DNA to negatively charged phosphatidylcholine/cardiolipin liposomes used as models of biological membranes (*18*). However, the hydrophobized polycation exhibited less transfection efficacy than unmodified poly(*N*-ethyl-4-vinylpyridinium) bromide (*19*, *20*). In another study, an increase of a number of methylene moieties in the side chain charge groups of cationic polyphosphoesters from 2 to 6 was accompanied by a 3-fold increase of the transfection efficacy (*21*). Similarly, an increase of the length of hydrophobic groups incorporated into the backbone of cationic polyvinyl ethers from 1 to 4 carbons was shown to significantly improve the transfection efficacy (*22*).

In the present study, combinations of length of the hydrophobic side chains and their content were evaluated using a series of model cationic copolymers of 4-vinylpyridine and *N*-alkyl-4-vinylpyridinium obtained by quaternization with ω-bromoesters. The hydrophobicity of the copolymers was controlled by a number of methylene groups in the ω-bromoesters and the degree of the quaternization. The main advantages of such model copolymers are their controllable hydrophilic−lipophilic balance and the presence of pH-induced ionizing 4-vinylpyridine units in their chains.

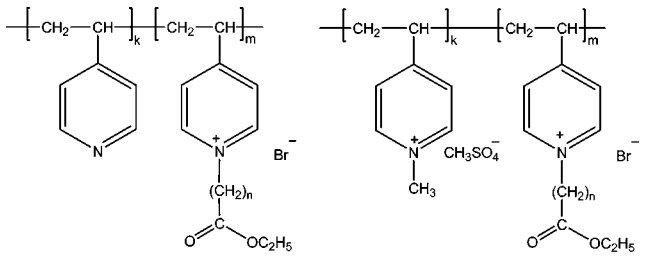
1 C_nPVP **2** C_nPB



EXPERIMENTAL SECTION

Materials. NaOH, HCl, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), Tris, MES, and HEPES buffers were purchased from Sigma (St. Louis, MO). In all experiments, twice-distilled water was used and purified by Milli-Q (Millipore, U.S.A.). Dulbecco's modified Eagle's media (DMEM) and fetal calf serum were obtained from BioMedia, France. Ethidium bromide was purchased from Sigma (St. Louis, MO). Concentration of ethidium bromide in solution was determined spectrophotometrically assuming molar extinction coefficient 5600 $L \cdot mol^{-1}\ cm^{-1}$ at 480 nm (*23*). Poly(ethylene imine) (PEI) was purchased from Aldrich (MW = 25 000 g/mol) or from Euromedex (ExGen 500, MW = 22 000 g/mol). Na salt of highly polymerized calf thymus DNA (~10 000 base pairs) was purchased from Sigma (St. Louis, MO) and used without further treatment. Concentration of DNA phosphate groups in the solutions was determined by UV absorbance measurements at 260 nm assuming molar extinction coefficient 6500 $L \cdot mol^{-1}\ cm^{-1}$ (*24*). pcDNA3-SEAP2 expression plasmid (pSEAP; 7443 base pairs) driven by the cytomegalovirus promoter was obtained by inserting the EcoRI-SalI fragment of the pSEAP2-control plasmid (Clontech), which contains the cDNA encoding for a secreted form of alkaline phosphatase (SEAP) preceded by the Kozak consensus translation initiation site and followed by the late polyadenylation signal of simian virus SV40, at the EcoR-SalI cloning sites of the pcDNA3 expression plasmid (Invitrogen).

Characterization Techniques. ^1H NMR spectra were recorded with a VARIAN Unity Inova 500 MHz spectrometer at 500.6 MHz using D_2O as solvent. IR spectroscopy was performed using a ThermoNicolet AVATAR 370 FTIR spectrometer (Thermo Electron Corparation, Waltham, MA).

Synthesis of Quaternized Poly(4-vinylpyridine)s (C_nPVP) (1). Quaternized poly(4-vinylpyridine)s that possessed the same average degree of polymerization, DP 1600, but differed by the number n of methylene groups in N-alkyl ester substituents (n = 1 to 6) were synthesized by alkylation of poly(4-vinylpyridine) sample (MW = 168 000 g/mol; Aldrich, U.S.A.) with esters of corresponding ω-bromocarboxylic acid (Scheme 1) as described elsewhere (*25*). The values of degree of alkylation of C_nPVP samples that were determined by FTIR measurements as described elsewhere (*26*) were 95 ± 3%.

Scheme 2. Structural Formulas of Copolymers (3) of 4-Vinylpyridine and *N*-Alkyl-4-vinylpyridinium (C_nPVP-β) with Different Content of N-Alkylpyridinium Moieties (β from 25% to 95%) and Copolymers (4) of *N*-Methyl-4-vinylpyridinium and *N*-Alkyl-4-vinylpyridinium (DMS−C_nPVP-β) Obtained by Exhaustive Alkylation of 4-Vinylpyridine Units of C_nPVP-β Samples with Dimethylsulfate

3 C_nPVP-β **4** DMS-C_nPVP-β

Synthesis of Polycarboxybetaines (C_nPB) (2). Polycarboxybetaines were obtained from the corresponding C_nPVP (n = 4 and 5) (Scheme 1) by alkaline hydrolysis that was performed by dropwise addition of concentrated NaOH solution to the solution of C_nPVP at 60 °C for several hours (*25*) according to the procedure described in ref 27. The hydrolysis was estimated from the potentiometric titration curves of aqueous solutions of the products that were conducted in the presence of sodium poly(styrene sulfonate) as described (*25*). The assay of aqueous solution of parent C_nPVP, as well as C_nPVP-β by the same approach, evidenced the absence of spontaneous hydrolysis in neutral media at room temperature even after storage of solutions for 2 weeks.

Synthesis of Copolymers of 4-Vinylpyridine and *N*-Alkyl-4-vinylpyridinium (C_nPVP-β) (3). Copolymers of 4-vinylpyridine and *N*-alkyl-4-vinylpyridinium (C_nPVP-β) with different content of N-alkylpyridinium moieties (β from 25% to 95%) were obtained by partial quaternization of poly(4-vinylpyridine) with the esters (Scheme 2). Samples were successively withdrawn from the reaction mixture during the course of the alkylation, and the values of β were estimated by FTIR spectroscopy (*26*). The presence of N-alkylpyridinium moieties in the copolymers was evidenced by ^1H NMR (e.g., the spectrum of C_5PVP-65 in D_2O with δ = 8.60, 7.43, 4.16, 2.41, 1.96, 1.67, and 1.26 ppm is depicted in Figure 1).

Synthesis of Copolymers of *N*-Methyl-4-vinylpyridinium and *N*-Alkyl-4-vinylpyridinium (DMS−C_nPVP-β) (4). Copolymers of *N*-methyl-4-vinylpyridinium and *N*-alkyl-4-vinylpyridinium (DMS−C_nPVP-β) were obtained by exhaustive

alkylation of 4-vinylpyridine units of C_nPVP-β samples with dimethylsulfate in methanol at room temperature.

Spectrophotometric Measurements were performed using Hitachi 150−20 Spectrometer (Japan) in water-thermostatic cell at 25 °C.

Fluorescence Measurements. Fluorescence intensity of the solutions was measured using a Jobin Yvon-3CS spectrofluorimeter (France) with water-thermostatic stirred cell holder. The measurements were made in a capped quartz fluorescence cell upon permanent stirring at 25 °C. The excitation and emission wavelengths in experiments with ethidium bromide were set at 535 and 595 nm, respectively.

Stability of C_nPVP/DNA Complexes in Water−Salt Solutions. The DNA solution was directly mixed in the fluorescence cell with ethidium bromide at a molar ratio [ethidium bromide]/[P] = 0.25 where [P] is molar concentration of DNA phosphate groups. At this ratio corresponding to 1 molecule of ethidium bromide per 2 base pairs (4 nucleotides), the maximum of ethidium bromide fluorescence intensity was observed (*28*). The concentration of DNA phosphate groups was 4×10^{-5} mol·L^{-1}. The solution of DNA/ethidium bromide complex was titrated with C_nPVP solution that was accompanied by quenching of ethidium bromide fluorescence due to displacement of the intercalated dye from DNA to the solution. The fluorimetric titration was conducted until the quenching was completed at a charge ratio [+]/[−] of 1.5. The mixtures were titrated with 4 M NaCl solution with a time interval between the titrant additions of 5 min. Destruction of the ion pairs in the C_nPVP/DNA polyelectrolyte complex by the added salt was monitored by the increase in fluorescence intensity I of the solution caused by re-intercalating of the dye into free sites of DNA. In parallel, a solution of DNA/ethidium bromide complex at the same concentration was titrated with 4 M NaCl solution, and the fluorescence intensity I_0 was measured. The stability of C_nPVP/DNA complexes was estimated by values of the salt concentration, [NaCl]*, corresponding to $I/I_0 = 1$, i.e., when a complete dissociation of the complex C_nPVP/DNA occurred (*29*). Note that the presence of the intercalated dye in the double helix weakens DNA binding to the polycations (*28*), but the contribution of this factor to the complex stability is relatively low and identical for all samples (*29*).

pH Profiles of Polycations with DNA. The fluorimetric titrations of DNA/ethidium bromide complex with solutions of C_5PVP-25, C_5PVP-65, or PEI were conducted at different pH values in 0.01 M MES or HEPES buffer solutions. This approach particularly applies for polycations with a large content of the ionizable amino groups that provides high accuracy in the calculations of a degree of conversion Θ in the polyelectrolyte coupling reaction (where Θ is the ratio of a current number of the protonated amino groups to the ultimate one). In neutral and slightly acidic media, the fluorescence intensity decreased linearly with the increase in charge ratio from 0 to 1 (*30*). The degree of conversion was determined in an equimolar mixture ([+]/[−] = 1) of polycations and DNA. The pH-independent contribution of (100 − β)% of N-alkylated units of C_5PVP-β polymers to the interaction with DNA that was accompanied by a displacement of ethidium bromide was determined but not taken into account upon calculation of the pH profile.

In Vitro Cell Transfection. Transfection experiments were carried out on rabbit vascular smooth muscle cells (SMCs; Rb-1 cell line (*31*)) cultured in DMEM supplemented with 1% penicillin, streptomycin, and amphotericin, 2% HEPES buffer, 1% glutamine, and 10% fetal calf serum. C_nPVP-β polycation and pSEAP solutions were filtered onto 0.22 μm Millipore filters before use. Twenty-four well plates were seeded with 5×10^4 cells per well 24 h before transfection. Ten microliters of pSEAP solution at 1 μg/μL was mixed with 10 μL of C_nPVP-β polycation solution at a concentration ranging from 0.06 μg/μL to 0.98 μg/μL, depending on the polycation, and corresponding to a charge ratio [+]/[−] of 1 or 5, assuming all amines were cationic. The resulting complex solution was diluted to a final volume of 50 μL with either serum-free or serum-containing culture medium, vortexed for 10 s, and allowed to stand at room temperature for 30 min. Cells were washed, and 450 μL of serum-free or serum-containing culture medium per well was added. The complex solution (C_nPVP-β/pSEAP) was then added to the wells, and cells were incubated at 37 °C in 95% air/5% CO_2 for 24 h. Cells were cultured for 72 h in serum-containing medium, and then the conditioned culture medium was removed and analyzed for SEAP activity. Phospha-Light kit (Tropix, Bedford, MA) was used for the measurement of SEAP activity, according to the manufacturer's protocol. Light output was measured using a luminometer (LUMAT LB9501, Berthold, Wildbach, Germany), as described elsewhere (*32*). SEAP activity was expressed as relative light units (RLU) per 10^5 cells. Cells incubated with culture medium alone or with pSEAP alone were used as controls. Cytotoxicity was assessed by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay (see below). For each condition, at least 3 experiments were performed.

Cell Viability. Evaluation of cell viability was performed with the MTT assay. At the end of the transfection experiments, the culture medium was replaced with 500 μL of fresh Hanks' Balanced Salt Solution and 50 μL of 5 mg/mL MTT. After 1 h incubation at 37 °C, MTT-containing medium was removed and 300 μL of DMSO was added to dissolve the formazan crystal formed by viable cells. Absorbance was measured at 540 nm. Cell viability was calculated according to the following equation: Cell viability (%) = $(OD_{540(sample)}/OD_{540(control)}) \times 100$, where the $OD_{540(control)}$ is measured with cells incubated in control medium.

Size and ζ-Potential Measurements. For each measurement, 750 μL of pSEAP at 0.03 μg/μL was mixed with 750 μL of polycation at concentrations ranging from 0.15 μg/μL to 0.29 μg/μL corresponding to a charge ratio [+]/[−] of 5. All the solutions were prepared in Tris buffer (pH = 7.4). The resulting mixtures were vortexed for 10 s and incubated for 30 min at room temperature before analysis. The size of polycation/DNA complexes was determined by quasi-elastic light scattering with a ZetaSizer 3000 instrument (λ = 633 nm, Malvern Instruments, U.K.) at 25 °C, using a sample refractive index of 1.59 and a viscosity of 0.89 cP. Data were collected at a scattering angle of 90° and sizes calculated from the correlation function using an automated method. Three series of five measurements were performed. ζ potentials were measured on the same instrument. Complexes used for the size determination were recovered and injected into the cell. The system was calibrated with a -50 ± 5 mV ζ-potential polystyrene standard from Malvern. The analysis parameters were as follows: viscosity = 0.89 cP, dielectric constant = 79, temperature = 25 °C, Smoluchowsky constant F (ka) = 1.50, dispersant refractive index = 1.33.

Statistical Analysis. All results are expressed as mean ± SD. Statistical comparisons were performed with the use of ANOVA and post-hoc PLSD test. A value of $p < 0.05$ was considered significant.

RESULTS AND DISCUSSION

A series of cationic copolymers based on quaternized poly(4-vinylpyridine) was synthesized. Schemes 1 and 2 indicate the synthesis conditions and the general formula of compounds from **1** to **4**. The advantages of utilizing quaternized poly(4-vinylpyridines) as model polycations were as follows: (i) All polycations possessed the same average degree of polymeriza-

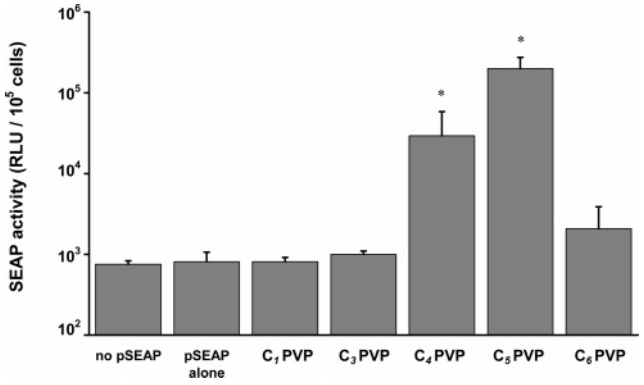

Figure 2. Effect of the number *n* of methylene groups in N-alkyl side chains of C_nPVP polycations on cell transfection efficacy. Plasmid pSEAP (1 μg) was used alone or with C_nPVP polycation solutions at charge ratio [+]/[−] of 5 in serum-free culture medium. The degree of alkylation was 95% for all polymers. Gene expression was measured 3 days after transfection. Transfection efficacy is expressed as relative light units (RLU) per 10^5 cells. Results represent the mean and standard deviation of 3 experiments. *, $p < 0.0001$ vs pSEAP alone.

tion, DP = 1600, that provided high stability of DNA/polycations and allowed circumvention of the possible influence of DP on the transfection efficiency (*33*). (ii) The opportunity to terminate the N-alkyl side chains with carboxylic groups by hydrolysis of the ester moieties (Scheme 1) allowed comparison of the transfection efficiency of polycarboxybetaines (**2**) to their parent polycations (**1**). (iii) The polycations remained soluble in aqueous media upon variation of the number of methylene groups in N-alkyl side chains (**3**) from 1 to 6 and/or the degree of alkylation $\beta \geq 25\%$. And, finally, (iv) non-alkylated pyridine units of all studied copolymers were accessible according to Scheme 2 to the alkylating agent dimethylsulfate, that allowed their quantitative quaternization (**4**) to establish the role of the pyridine groups in the transfection.

Alkylated C_nPVP Polycations (1). To elucidate the effect of hydrophobicity of the side chain on cell transfection, quaternized poly(4-vinylpyridine) polymers with the degree of quaternization of 95 ± 3% and an increasing number *n* of methylene groups from 1 to 6 in the N-alkyl substituents (Scheme 1) have been synthesized. The transfection efficiency was first estimated in the conditioned culture medium 3 days after incubation of cells for 24 h with mixtures of C_nPVP and a plasmid DNA encoding for the secreted form of alkaline phosphatase (pSEAP) in DMEM. No toxicity was noticed after incubation of cells with pSEAP and C_nPVP polycations (cell viability was 88.2 ± 9.9%). At a charge ratio [+]/[−] of 1, C_1PVP and C_5PVP were both inactive ($1.2 \pm 0.1 \times 10^3$ RLU/10^5 cells), whereas significant SEAP activity ($1.2 \pm 0.2 \times 10^5$ RLU/10^5 cells) was found with C_5PVP at a charge ratio [+]/[−] of 5. When all exhaustively alkylated poly(4-vinylpyridine) polymers were evaluated at a charge ratio [+]/[−] of 5, SEAP activity remained rather low for C_nPVP polycations with short N-alkyl substituents containing 1 to 3 methylene groups (Figure 2). At $n = 4$, there was noticeable SEAP activity that became pronounced at $n = 5$. However, at $n = 6$, the activity was rather low (Figure 2).

The *n*-dependent increase of transfection capacity correlated with previously reported data on transfection performed by cationic polyvinyl ethers with C_1−C_4 side chains in the backbone (*22*) whose efficacy was low with methyl- and ethyl-containing side chains, noticeably higher in the case of propyl residues, and significant with butyl moieties. Interestingly, C_6PVP was inactive as a gene transfer agent with cells (Figure 2). The reason is most likely the hydrophobic interactions between side chains that are strengthened upon lengthening of the side chains. In the case of C_6 N-alkyl substituents, the contribution of these intramolecular hydrophobic interactions could be large enough to hinder significantly the interaction of the C_6PVP polycation with DNA in a physiological buffer (DMEM; pH = 7, NaCl 0.15 M). This assumption is based on the *n*-dependent stability of C_nPVP/DNA complexes against the added salt that we studied by ethidium bromide displacement assay as described in the Experimental Section. The values of critical salt concentration determined by this approach for all C_nPVP polycations are listed in Table 1. It can be seen that the increase in *n* from 1 to 4 was accompanied by a progressive decrease in critical salt concentration [NaCl]* corresponding to complete dissociation of the C_nPVP/DNA complex. In the case of C_5PVP and most notably C_6PVP, the critical salt concentration was reduced markedly, suggesting that the side chains induced a pronounced steric hindrance that encumbered the electrostatic interactions between the charged pyridinium moieties and DNA phosphate groups.

Table 1. Critical Salt Concentration, [NaCl]*, Corresponding to Complete Dissociation of Different C_nPVP/DNA Complexes Measured by Ethidium Bromide Displacement Assay

C_nPVP	$n = 1$	$n = 2$	$n = 3$	$n = 4$	$n = 5$	$n = 6$
[NaCl]*, M	0.40	0.35	0.34	0.31	0.24	0.15

Thus, the maximum transfection capacity displayed by C_nPVP at $n = 5$ could be the result of optimal structure and composition of the C_5PVP chain that provided the balance between hydrophobic and electrostatic interactions needed for the transfection.

Polycarboxybetaines C_nPB (2). C_4PVP and C_5PVP polycations that exhibited significant transfection activity were transformed to the corresponding polycarboxybetaines, C_4PB and C_5PB (Scheme 1). The synthesis was performed by an exhaustive hydrolysis of ester moieties that terminated the N-alkyl substituents of polycations. Figure 3 shows the transfection efficacy determined upon incubation of cells with the polycarboxybetaine/DNA complexes. From the cell viability tests, it can be concluded that C_4PB and C_5PB polycarboxybetaines were nontoxic. Substitution in side chains of the ester moiety with a carboxylic group resulted in the complete loss of transfection activity for both polycarboxybetaines (Figure 3). For comparison, transfection activity for the parent polycations is also plotted in Figure 3. From a physicochemical point of view, the substitution is accompanied by a noticeable change of the hydrophilic−lipophilic balance of the side chain. Polycarboxybetaines that possess carboxylic groups are much more hydrophilic as compared to their precursors and, hence, less

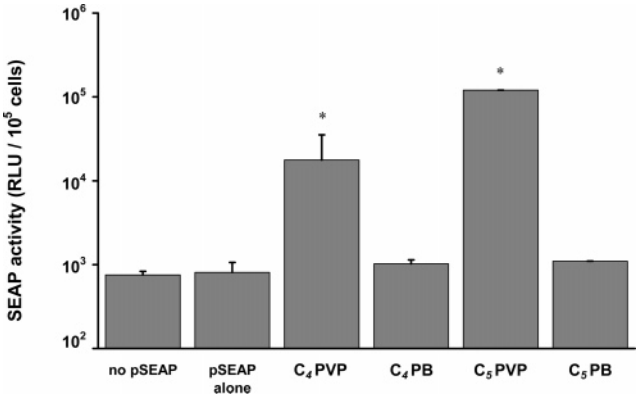

Figure 3. Cell transfection with polycarboxybetaines C_4PB and C_5PB. Plasmid pSEAP (1 μg) was used alone or with C_nPB polycation solutions at charge ratio [+]/[−] of 5 in serum-free culture medium. C_4PVP and C_5PVP (with similar methylene groups) are plotted for comparison. The degree of alkylation was 95% for all polymers. Gene expression was measured 3 days after transfection. Transfection efficacy is expressed as relative light units (RLU) per 10^5 cells. Results represent the mean and standard deviation of 3 experiments. *, $p < 0.0001$ vs pSEAP alone.

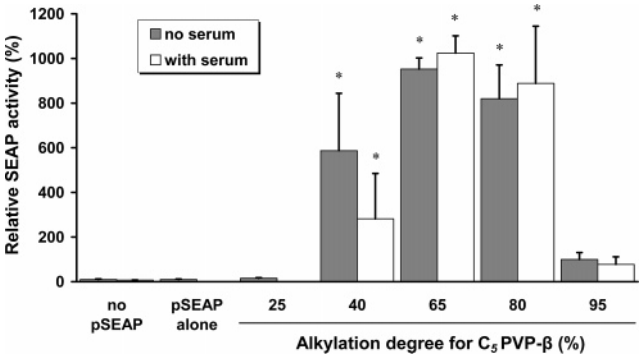

Figure 4. Effect of the alkylation degree (β) for C_5PVP-β polycations on cell transfection. Complex formation and incubation of cells were performed with either serum-free or serum-containing culture medium. Plasmid pSEAP (1 μg) was used alone or with C_5PVP-β solutions at charge ratio [+]/[−] of 5. Gene expression was measured 3 days after transfection. The data are presented as the relative SEAP activity taking as 100% the activity displayed by the corresponding exhaustively alkylated C_5PVP-95 in serum-free medium. Results represent the mean and standard deviation of 3 experiments. *, $p < 0.0001$ vs control (β = 95% in serum-free medium).

active in transfection. Besides, the carboxylic group being ionized in neutral media forms an ion pair with the pyridinium group in the betaine moiety. This weakens the electrostatic binding with DNA. Thus, the C_5PB/DNA complex was destroyed at physiological ionic strength (*25*).

Partially Alkylated C_nPVP-β Polycations (3) and Exhaustively Alkylated DMS−C_nPVP-β Polycations (4). To ascertain combinations of the length of the hydrophobic side chains and their content in the macromolecule, we have synthesized several series of cationic copolymers C_nPVP-β that possessed the same n but differed by degree of alkylation β. Note that the non-alkylated 4-vinylpyridine units are uncharged at physiological pH and their protonation occurred in acidic media according to the relatively low value of the apparent pK_a = 3.25 of poly(4-vinylpyridine). So, the composition of mixtures of partially alkylated polycations with pSEAP defined as a charge ratio [+]/[−] of 5 corresponds to the ratio of molar concentration of the quaternized N-alkylpyridinium moieties to molar concentration of phosphate groups. Figure 4 shows the transfection results obtained with the use of different C_5PVP-β copolymers. The data are presented as the relative SEAP activity taking the activity obtained with C_5PVP-95 in DMEM to be 100%. It can be seen that a decrease in β enhances the transfection of C_5PVP-95, with a maximal 9-fold increase for C_5PVP-65. For comparison, the relative SEAP activity obtained under the same conditions with ExGen 500, a commercial poly(ethylenimine) that is considered an excellent transfecting agent, was 6000%. It is remarkable that a further decrease in β for C_5PVP-β copolymers reduced the transfection efficiency that became negligible at β = 25%. Interestingly, cell transfection from inactive and highly hydrophobic C_6PVP-95 increased by reducing the alkylation degree with an optimum of significant transfection activity (85-fold increase from background level) at β = 40%.

To characterize the complex particles formed by C_5PVP-β with pSEAP, size and ζ-potential measurements were carried out at charge ratio [+]/[−] of 5 (Figure 5). It can be seen that all studied complexes including the complexes with exhaustively alkylated polycations did not differ both in size and in ζ potential being 150 ± 15 nm and 12 ± 2 mV, respectively. This suggests that the trends in transfection ability of C_5PVP-β copolymers cannot be attributed to the change of these parameters.

Contribution of N-alkyl substituents to intramolecular hydrophobic interactions may reduce flexibility of polycations and, hence, hinder their matching with DNA. To modulate polymer

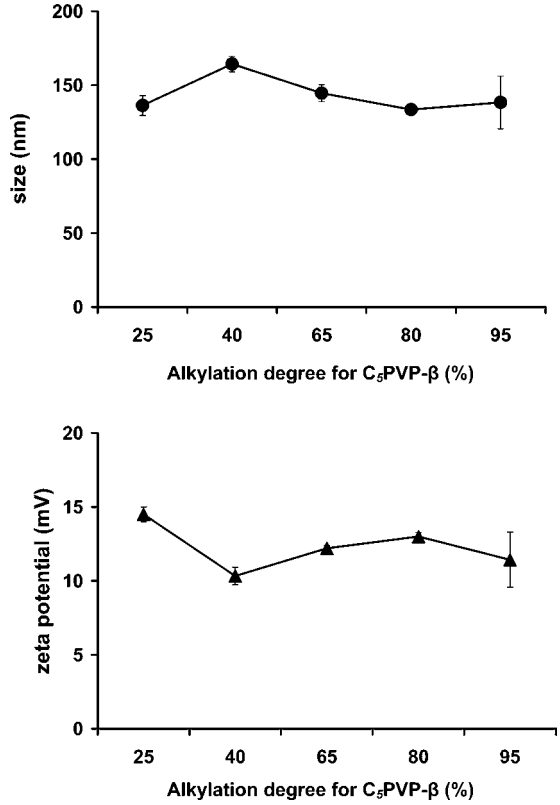

Figure 5. Size and ζ potential of complexes obtained with C_5PVP-β polycations and plasmid pSEAP. Sizes (circles) and ζ potentials (triangles) were measured in Tris buffer (pH 7.4) at a charge ratio [+]/[−] of 5 for all polycations.

flexibility, we performed quantitative alkylation of non-alkylated pyridine units of C_nPVP-β with dimethylsulfate treatment (**4**). The alkylation did not change the content and distribution of hydrophobic side chains along the macromolecule but transformed hydrophobic 4-vinylpyridine units that are not charged at physiological pH (non-alkylated poly(4-vinylpyridine) is insoluble in water at pH > 3.5) to hydrophilic quaternized 4-vinylpyridinium moieties containing relatively small N-methyl substituents (Scheme 2). Despite the higher net mean positive charge of the hydrophilized DMS−C_nPVP-β, the gene transfer activity of all these polycations was negligible (Figure 6).

pH Profiles of DNA Interaction with Polycations. The plausible explanation of the transfection activity of partially alkylated C_nPVP-β polycations is based on the ability of non-alkylated pyridine groups to be protonated in acidic media, according to a mechanism generally referred to as the "proton sponge hypothesis". When applied to a cell, the polycation/DNA complexes are thought to mediate transfection via a multistage process that includes hydrophobic and/or cationic binding to the cell membrane, internalization by endocytosis, and subsequent entry into the cytoplasm (*12*). The hypothesis asserts that polymers with high cationic charge potential, such as poly(ethylene imine) (PEI), act as a proton sponge upon acidification within endosomes or lysosomes. Under the acidic environment within lysosomes, every third nitrogen atom is protonated. The highly branched network of PEI absorbs a large amount of proton ions, like a sponge, upon lowering of the pH. The increased osmolarity resulted in endosomal or lysosomal swelling and subsequent escape of DNA into the cytosol. The proton sponge hypothesis has been built essentially around the transfecting activities of some cationic polymers such as PEI, PAMAM dendrimers, or polyhistidine (*34*) with apparent pK_a values close to pH 5.5, in relation to the acidic environment of endosomes and lysosomes. Yet, partially alkylated C_nPVP-β should be protonated in more acidic media, since aromatic

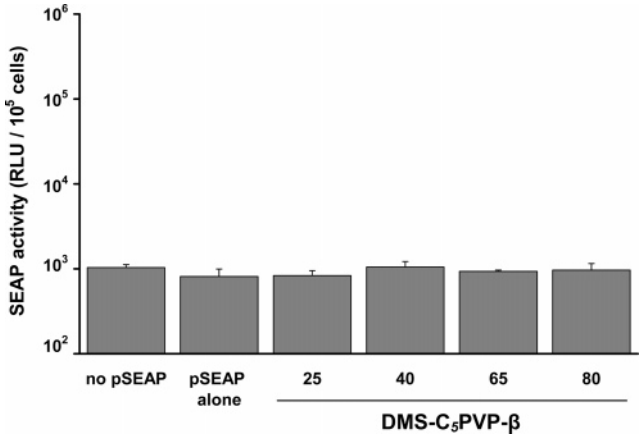

Figure 6. Effect of the exhaustive quaternization of C_5PVP-β polycations with DMS on cell transfection efficacy. Plasmid pSEAP (1 μg) was used alone or with the exhaustively quaternized DMS−C_5PVP-β polycation solutions at charge ratio [+]/[−] of 5 for the indicated alkylation degree (β). Gene expression was measured 3 days after transfection. Transfection efficacy is expressed as relative light units (RLU) per 10^5 cells. Results represent the mean and standard deviation of 3 experiments.

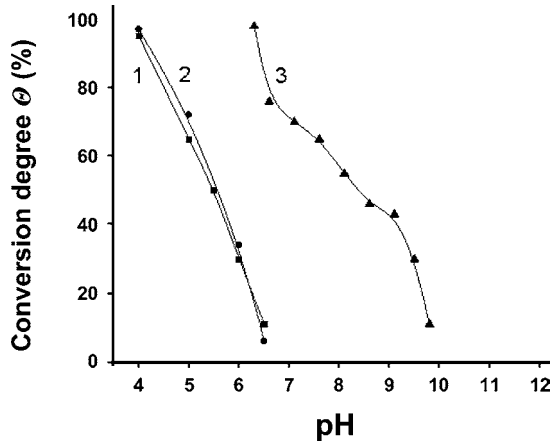

Figure 7. Protonation profiles of C_5PVP-25 (1), C_5PVP-65 (2), and PEI (3) determined by the ethidium bromide displacement assay. The degree of conversion (Θ) is plotted at the indicated pH for equimolar mixtures of polyamines and DNA (charge ratio [+]/[−] of 1).

tertiary amino groups of pyridine rings define relatively low apparent pK_a of 3.25 determined for poly(4-vinylpyridine) (*35*). As documented in Figure 7 by fluorimetric titration of polycations in the mixtures with DNA, the DNA promotes the protonation of polyamines that could occur with a ΔpH shift up to 2−3 units in the alkaline media as compared to ionization of free polyamine (*36*). The experimental procedure of estimating the protonation degree Θ of amino groups of polyamine bound in the complex with DNA is based on the ethidium bromide displacement assay performed at different pH (*29*). Figure 7 (curve 3) shows the protonation profile of PEI determined in an equimolar ([+]/[−] = 1) mixture of PEI and DNA. The inflection on curve 3 is in accordance with the basicity of the tertiary amino groups that noticeably differs from basicity of the primary and secondary amino groups of PEI. It is seen that the whole profile of PEI/DNA protonation is arranged in neutral, but not in slightly acidic, media, and hence, the transfection efficacy of PEI could not be attributed to protonation of the complex. Note that transfection with PEI or other polycations is commonly performed with a large excess of the polyamine. Consequently, apart from the ionizable amino group of PEI bound with DNA, a large number of amino groups that are not influenced by DNA are presented in endosomes and lysosomes and protonated in the acidic environment according to their intrinsic basicity. The protonation of these unbound amino groups appears to be the main reason for the well-documented high transfection efficacy of branched PEI. We used the same titration procedure for C_5PVP-65 (the most effective C_nPVP-β transfection agent) and for C_5PVP-25 that possessed the greatest amount of ionizable non-alkylated pyridine moieties in the series of C_5PVP-β copolymers but still remained soluble in aqueous media. The protonation profiles determined in equimolar mixtures of DNA with C_5PVP-25 (curve 1) or C_5PVP-65 (curve 2) are depicted in Figure 7. The left position of the protonation profile of C_5PVP-25 is in agreement with low pK_a of the pyridine rings. Nevertheless, the profile is markedly shifted to the right as compared to the ionization of free poly(4-vinylpyridine) (*35*). The protonation profile of the C_5PVP-65 copolymer (curve 2) practically coincided with the profile of C_5PVP-25 (curve 1) and also arranged in slightly acidic media. These findings support the hypothesis that the transfection activity of partially alkylated C_5PVP-β polycations could be related to the proton sponge mechanism that is accomplished due to protonation of non-alkylated pyridine moieties of C_nPVP-β/DNA complexes in slightly acidic media.

Complexation in Physiological Conditions. According to the literature, the transfection activity of polycations in the presence of serum could be noticeably reduced due to the interaction of the unbound polycation chains with serum proteins. In the present study, all studied C_nPVP polycations were shown to form stable complexes with DNA in salt concentration above the physiological conditions (Table 1). Moreover, complexation and incubation of cells with C_5PVP-β copolymers in serum-containing media resulted in transfection activity (Figure 4). No significant loss in SEAP activities was observed as compared to serum-free medium. The transfection capacity of C_5PVP-65 and C_5PVP-80 copolymers was even slightly higher in serum-containing medium. This finding also supports the explanation of their high activity by protonation of C_nPVP-β/DNA complexes and evidenced a suitable chemical structure of these polycations to bind to DNA in physiological conditions (Table 1, Figure 4) and then transfer pSEAP inside the cell, providing successful gene expression.

CONCLUSION

The data demonstrate the advantages of partial alkylation of tertiary polyamines with medium-length alkyl agents for the preparation of future efficient nonviral gene delivery vectors. With the DNA binding effect on protonation of polyamines in endosomes and lysosomes, this extends the range of polycations capable of improving the transfection, even in physiological conditions, by involvement of polyamines with tertiary amino groups that possess relatively low pK_a.

ACKNOWLEDGMENT

The authors are grateful to Laurent Véron and Thierry Delair (CNRS-bioMérieux, UMR 2714, ENS Lyon, France) for size and ζ-potential measurements and to Erwann Guénin (CNRS, UMR 7033 University Paris 13, France) for NMR measurements. Impact of Bidentate Chelators on Lipophilicity, Stability, and Biodistribution Characteristics of Cationic ^{99m}Tc-Nitrido Complexes

Young-Seung Kim, Zhengjie He, Wen-Yuan Hsieh, and Shuang Liu*

Civil Engineering Building, School of Health Sciences, Purdue University, 550 Stadium Mall Drive, West Lafayette, Indiana 47907. Received October 11, 2006; Revised Manuscript Received January 2, 2007

This report describes synthesis and evaluation of novel cationic ^{99m}Tc-nitrido complexes, $[^{99m}TcN(L)(PNP)]^+$ (L = ma, ema, tma, etma and mpo; PNP = PNP5, PNP6, and L6), as potential radiotracers for heart imaging. Cationic complexes $[^{99m}TcN(L)(PNP)]^+$ were prepared in two steps. For example, reaction of succinic dihydrazide with $^{99m}TcO_4^-$ in the presence of excess stannous chloride and PDTA resulted in the $[^{99m}TcN(PDTA)_n]$ intermediate, which then reacted Hmpo and PNP6 at 100 °C for 10−15 min to give $[^{99m}TcN(mpo)(PNP6)]^+$ in >90% yield. It was found that bidentate chelators have a significant impact on lipophilicity, solution stability, biodistribution, and metabolic stability of cationic ^{99m}Tc-nitrido complexes. The fact that $[^{99m}TcN(ema)(PNP6)]^+$ decomposes rapidly in the presence of cysteine (1 mg/mL) while $[^{99m}TcN(etma)(PNP6)]^+$ and $[^{99m}TcN(mpo)(PNP6)]^+$ remain stable for >6 h under the same conditions strongly suggests that thione-S donors in bidentate chelators increase the solution stability of their cationic ^{99m}Tc-nitrido complexes. Biodistribution studies were performed on four cationic ^{99m}Tc-nitrido complexes in Sprague−Dawley rats. $[^{99m}TcN(etma)(PNP5)]^+$ is of particular interest due to its high initial heart uptake (1.81 ± 0.35 %ID/g at 5 min postinjection), and long myocardial retention (1.99 ± 0.47 %ID/g at 120 min postinjection). The heart/liver ratio of $[^{99m}TcN(etma)(PNP5)]^+$ (6.06 ± 1.48) at 30 min postinjection is almost identical that of ^{99m}TcN-DBODC5 (6.01 ± 1.45), and is >2 times better than that of ^{99m}Tc-sestamibi (2.90 ± 0.22). Results from metabolism studies show that $[^{99m}TcN(etma)(PNP5)]^+$ has no significant metabolism in the urine, but it does show significant metabolism in feces samples at 120 min postinjection. Planar imaging studies suggest that $[^{99m}TcN(etma)(PNP5)]^+$ might be able to give clinically useful images of the heart as early as 30 min postinjection. $[^{99m}TcN(etma)(PNP5)]^+$ is a very promising candidate for more preclinical evaluations in various animal models.

INTRODUCTION

Recently, we reported a series of crown ether-containing cationic complexes $[^{99m}TcN(DTC)(PNP)]^+$ (Figure 1: DTC = L1−L5; PNP = PNP5 and L6)[1] as potential radiotracers for heart imaging (*1*). Results from biodistribution studies have clearly demonstrated that crown ether groups are very useful for improvement of the liver clearance of cationic ^{99m}Tc-nitrido complexes, some of which have the heart uptake comparable to that of ^{99m}Tc-sestamibi, the most successful radiotracer for myocardial perfusion imaging, with the heart/liver ratios being 4−5 times better than that of ^{99m}Tc-sestamibi at 120 min postinjection (p.i.). Results from imaging studies suggested that they might be able to give clinically useful images of heart as early as 30 min p.i. These promising results led us to explore other bidentate chelators for preparation of cationic ^{99m}Tc-nitrido complexes that have the heart/liver ratio substantially better than that of ^{99m}Tc-sestamibi while maintaining their high heart uptake.

As an extension of our previous studies, we now report the use of maltol (Hma), thiomaltol (Htma), ethylmaltol (Hema), ethylthiomaltol (Hetma), and 2-mercaptopyridine oxide (Hmpo) as the bidentate chelators for preparation of cationic complexes $[^{99m}TcN(L)(PNP)]^+$ (Figure 1: L = ma, ema, tma, etma, and mpo; PNP = PNP5, PNP6, and L6). These cationic ^{99m}Tc-nitrido complexes are designed in such a way that the lipophilicity and biodistribution characteristics can be modified by the choice of bidentate chelators and bisphosphines. Compared to the crown ether-containing DTCs (Figure 1: L1−L5), these bidentate chelators offer a greater structural diversity, which is very important for modification of biodistribution properties of cationic ^{99m}Tc radiotracers. To demonstrate their potential as radiotracers for heart imaging, we carried out biodistribution studies on four cationic ^{99m}Tc-nitrido complexes in Sprague−Dawley rats. Results from these studies will be compared to those of ^{99m}Tc-sestamibi and ^{99m}TcN-DBODC5 (DBODC = *N*,*N*-bis(ethyoxythyl)dithiocarbamate) reportedly having the best heart/liver ratio among the known cationic ^{99m}Tc radiotracers (*2*−*4*).

It is well-documented that maltol and ethylmaltol form neutral complexes with many biologically important metal ions (*5*−*10*). Their vanadyl(IV) complexes have been reported to possess insulin enhancing activity (*11*−*15*). The Co(II), Cu(II), and Cr(III) complexes of maltol have also been studied for their antihypoglycemic activity (*16*). Recently, thiolmaltol and ethylthiomaltol and their N-substituted derivatives have been used for preparation of their Cu(II), Ni(II), Zn(II), V(IV), group 13 and lanthanide metal complexes (*17*−*21*). The study described herein represents the first one to use these bidentate chelators to prepared cationic complexes $[^{99m}TcN(L)(PNP)]^+$ (Figure 1: L = ma, ema, tma, etma, and mpo; PNP = PNP5, PNP6, and L6).

Scheme 1 . Synthesis of Cationic Complexes $[^{99m}TcN(L)(PNP)]^+$ (L = Ma, Ema, Tma, Etma, and Mpo; PNP = PNP5, PNP6 and L6).

EXPERIMENTAL SECTION

Materials. Chemicals, such as 1,2-diaminopropane-*N*,*N*,*N*′,*N*′-tetraacetic acid (PDTA), maltol (Hma), ethylmaltol (Hema), and mercaptopyridine oxide (Hmpo), were purchased from *Sigma*/*Aldrich* (St. Louis) and were used as received. Thiomaltol (Htma) and ethylthiomaltol (Hetma) were prepared according to the literature methods (*17*−*21*). Synthesis of *N*-ethoxyethyl-*N*,*N*-bis[2-(bis(3-methoxypropyl)phosphino)ethyl]amine (PNP5), *N*-ethoxyethyl-*N*,*N*-bis[2-(bis(3-ethoxypropyl)phosphino)ethyl]-amine (PNP6), and *N*-methoxyethyl-*N*,*N*-bis[2-(bis(3-ethoxypropyl)phosphino)ethyl]amine (L6) has been described in our previous report (*1*). ^{99m}TcN-DBODC5 was prepared according to the literature method (*2*−*4*). *Cardiolite* vials were obtained as a gift from Bristol Myers Squibb Medical Imaging (North Billerica, MA) and were reconstituted according to the manufacturer's insert.

Methods. The radio-HPLC method used a LabAlliance semi-prep HPLC system with a β-Ram IN-US detector, and a Zorbax Rx C_8 column (4.6 mm x 150 mm, 100 Å pore size). The flow rate was 1 mL/min. The mobile phase was isocratic with 30% solvent A (25 mM NH_4OAc buffer, pH = 6.8) and 70% solvent B (methanol) at 0−5 min, followed by a gradient from 70% solvent B at 5 min to and 90% solvent B at 15 min.

General Procedure for Preparation of Cationic ^{99m}Tc-Nitrido Complexes. The solution containing SDH and PDTA was prepared according to the procedure described in our previous communication (*1*). To a 5 cc vial were added 1.0 mL of the solution containing SDH (5 mg/mL) and PDTA (5 mg/mL), 1.0 mL of $^{99m}TcO_4^-$ solution (2−10 mCi), and 20 μL of $SnCl_2$ solution (1 mg/mL in 1.0 N HCl). The reaction mixture was kept at room temperature for 15−30 min to form the ^{99m}Tc-nitrido intermediate. After addition of 0.5 mL of the solution containing the bidentate chelator (5−10 mg/mL) and the bisphosphine (5−10 mg/mL), the reaction mixture was heated at 95 °C for 10−15 min. After completion of radiolabeling, the vial was placed back into lead pig and allowed to stand at room temperature for 5−10 min. A sample of the resulting solution was analyzed by the radio-HPLC. The radiochemical purity (RCP) was >95% with minimal amount (<0.5%) of [^{99m}Tc]colloid formation.

Composition Studies. The mixed-ligand experiments were performed to determine the number of bidentate chelators or bisphosphines in cationic ^{99m}Tc-nitrido complexes according to the method described in our previous communication (*1*). The radiolabeling procedure was identical to that above except that two bidentate chelators or PNP-type bisphosphines were used as competing ligands in a the same vial. For example, a mixture of Hma (2 mg) and Hema (2 mg) was used to determine the number of bidentate chelators in cationic complexes [^{99m}TcN-

(L)(PNP6)]$^+$. The number of bisphosphines was determined in a similar fashion using a mixture L6 (2 mg) and PNP6 (2 mg).

Doses for Animal Studies. For biodistribution studies on [^{99m}TcN(L)(L6)]$^+$ (L = ema, tma and etma) and [^{99m}TcN(etma)-(PNP5)]$^+$, the radiotracer was purified by HPLC to remove all radioimpurities. Volatiles in the mobile phase were evaporated under reduced pressure. Doses were made by dissolving the residue to ~10 μCi/mL in saline with 15% (w/w) propylene glycol. The resulting solution was filtered with a 0.20 μm filter unit to eliminate particles before being injected into animals. The injection volume was 0.1 mL for each animal in biodistribution studies. For imaging studies with [^{99m}TcN(etma)-(PNP5)]$^+$ was first purified by HPLC. Volatiles in the mobile phase were completely removed under the reduced pressure. Doses were made by dissolving the residue to ~2.5 mCi/mL in saline containing ~15% (w/w) propylene glycol. The injection volume was ~0.25 mL for each animal in the imaging studies.

Determination of Log *P* Values. Log *P* values of cationic ^{99m}Tc-nitrido complexes were determined using the following procedure: the ^{99m}Tc radiotracer was prepared and purified by HPLC. The collected mobile phases were evaporated, and the residue was dissolved in a mixture of equal volume (3 mL:3 mL) of n-octanol and 25 mM phosphate buffer (pH = 7.4). After being vortexed for >20 min, the mixture was centrifuged at 8000 rpm for 5 min. Samples (in triplets) from aqueous and n-octanol were obtained and counted separately in a gamma counter (Beckman Gama 8000). The partition coefficients were calculated using the equation: P = (activity concentration in n-octanol)/(activity concentration in aqueous layer). The log *P* value was measured three different times and reported as an average of three different measurements.

Solution Stability. For solution stability in kit matrix, the radiotracer was prepared and analyzed by radio-HPLC at 0, 1, 2, 3, and 6 h postlabeling. For cysteine challenging experiment, the resulting reaction solution was mixed with an equal volume of a cysteine (1 mg/mL) solution. Samples of the mixture were analyzed by radio-HPLC at 0, 1, 2, 3, and 6 h.

Biodistribution Studies. Biodistribution studies were performed using Sprague−Dawley rats in compliance with NIH animal experiment guidelines (*Principles of Laboratory Animal Care*, NIH Publication No. 86−23, revised 1985). This animal model has been used as the screening tool for cationic ^{99m}Tc radiotracers (*51*−*56*). The protocols for these studies have been approved by the Purdue University Animal Care and Use Committee (PACUC). In short, 16 Sprague−Dawley rats (200−250 g) were anesthetized with intramuscular injection of a mixture of ketamine (80 mg/kg) and xylazine (19 mg/kg). A jugular vein was surgically exposed, and each animal was administered 1−3 μCi of the purified radiotracer in 100 μL of 10−20% propylene glycol. Four animals were sacrificed by sodium pentobarbital overdose at each time point (5, 30, 60, and 120 min p.i.). Blood was withdrawn from the heart through a syringe. Organs of interest (heart, brain, lung, liver, spleen, kidneys, muscle, and intestine) were excised, rinsed with saline, dried with tissues, weighed, and counted on a gamma counter (Beckman RD8000). Four extra standard doses were also weighed and counted before and after tissue samples. The organ uptake was calculated as a percentage of the injected dose per gram of wet tissue mass (%ID/g) and a percentage of the injected dose per wet organ (%ID/organ). The biodistribution data and T/B ratios are reported as an average plus the standard variation.

Imaging Studies. Two Sprague−Dawley rats (200−250 g) were anesthetized with intramuscular injection of a mixture of ketamine (80 mg/kg) and xylazine (19 mg/kg). The radiotracer (300−500 μCi) was administered via surgically exposed jugular vein. Animals will be monitored on the gamma camera (PhoGama large field-of-view Anger camera and NucLearMac computer system). Sequential anterior images were collected for 5 min at the specified time (5, 15, 30, 60, and 120 min) using 256 × 256 image matrix while animal are still under anesthesia. Images of rats administered with ^{99m}Tc-sestamibi and ^{99m}TcN-DBODC5 were obtained using the same protocol. After imaging, the animals were sacrificed by sodium pentobarbital overdose. The urine and feces samples were collected for metabolism studies.

Table 1. RCP Data and Radio-HPLC Retention Times of Cationic ^{99m}Tc-nitrido Complexes

compound	radiochemical purity (%)	HPLC retention time (min)	log *P* value
^{99m}Tc-sestamibi	>98	16.5	1.29 ± 0.15
^{99m}TcN-DBODC5	>90	16.2	1.10 ± 0.07
[^{99m}TcN(ma)(PNP5)]$^+$	90.5	9.3	-0.01 ± 0.01
[^{99m}TcN(ema)(PNP5)]$^+$	90.3	10.7	0.53 ± 0.08
[^{99m}TcN(tma)(PNP5)]$^+$	91.0	9.9	0.38 ± 0.10
[^{99m}TcN(etma)(PNP5)]$^+$	90.0	15.5	0.67 ± 0.15
[^{99m}TcN(mpo)(PNP5)]$^+$	91.2	15.8	0.51 ± 0.05
[^{99m}TcN(ma)(PNP6)]$^+$	91.2	15.8	1.19 ± 0.13
[^{99m}TcN(ema)(PNP6)]$^+$	90.8	16.7	1.48 ± 0.02
[^{99m}TcN(tma)(PNP6)]$^+$	85.7	15.3	1.29 ± 0.02
[^{99m}TcN(etma)(PNP6)]$^+$	92.5	16.4	1.51 ± 0.01
[^{99m}TcN(mpo)(PNP6)]$^+$	90.3	16.7	1.49 ± 0.05
[^{99m}TcN(ma)(L6)]$^+$	90.1	14.2	0.92 ± 0.16
[^{99m}TcN(ema)(L6)]$^+$	90.2	15.2	1.22 ± 0.13
[^{99m}TcN(tma)(L6)]$^+$	85.8	15.7	1.09 ± 0.17
[^{99m}TcN(etma)(L6)]$^+$	85.6	16.6	1.43 ± 0.05
[^{99m}TcN(mpo)(L6)]$^+$	90.3	13.4	1.32 ± 0.13

Metabolism. The urine samples were collected from rats at 30 and 120 min p.i. by manual void and were mixed with an equal volume of acetonitrile. The mixture was centrifuged at a speed of 8000 rpm. The supernatant was collected and filtered through a 0.20 μm Millex-LG syringe driven filter unit. The filtrate was analyzed by radio-HPLC. The feces samples were collected once they were sacrificed after the imaging study (at ~120 min p.i.). The sample was suspended in a mixture of 50% acetonitrile aqueous solution, and the resulting mixture was vortexed for 5−10 min. After centrifugation, the supernatant was collected and passed through a 0.20 μ filter. The filtrate was analyzed by radio-HPLC.

Data and Statistical Analysis. The biodistribution data and T/B ratios are reported as an average plus the standard variation based on the results from four animals for each time point. Comparison between two different radiotracers was made using the one-way ANOVA test. The level of significance was set at $p = 0.05$.

RESULTS

Radiochemistry. Cationic complexes [^{99m}TcN(L)(PNP)]$^+$ (L = ma, ema, tma, etma and mpo; PNP = PNP5, PNP6, and L6) were prepared according to Scheme 1. First, ^{99m}TcO$_4^-$ was allowed to react with SDH in the presence of excess PDTA and stannous chloride. The reaction mixture was allowed to stand at room temperature for 15−30 min to form the [^{99m}TcN-(PDTA)$_n$] intermediate, which was then reacted with the bidentate chelator and bisphosphine at 100 °C for 10−15 min to give the cationic complex [^{99m}TcN(L)(PNP)]$^+$ (L = ma, ema, tma, etma, and mpo; PNP = PNP5, PNP6, and L6). Using this procedure, all new radiotracers had >85% RCP with minimal amount (<0.5%) of [^{99m}Tc]colloid formation.

A reversed phase radio-HPLC method was used to analyze cationic complexes [^{99m}TcN(L)(PNP)]$^+$ (L = ma, ema, tma, etma, and mpo; PNP = PNP5, PNP6, and L6). Their HPLC retention times are listed in Table 1. Figure 2 illustrates representitive radio-HPLC chromatograms of [^{99m}TcN(ma)-(PNP6)]$^+$ and [^{99m}TcN(ema)(PNP6)]$^+$. There is always an impurity peak (5−10%) in their radio-HPLC chromatograms.

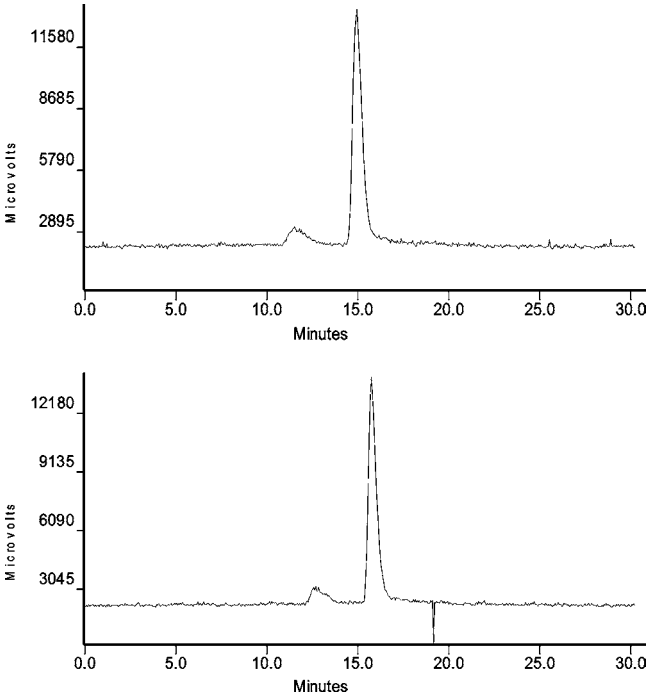

Figure 2. Typical radio-HPLC chromatograms of $[^{99m}TcN(ma)(PNP6)]^+$ (top) and $[^{99m}TcN(ema)(PNP6)]^+$ (bottom).

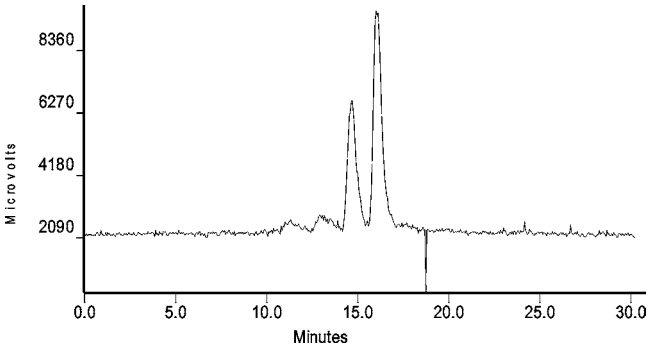

Figure 3. Radio-HPLC chromatogram of the reaction mixture containing $[^{99m}TcN(ma)(PNP6)]^+$ (left) and $[^{99m}TcN(ema)(PNP6)]^+$ (right).

These radioimpurities are most likely due to partial oxidation of the bisphosphine ligand during preparation or radiolabeling. This explanation is supported by the fact that the radioimpurities could be totally eliminated when the extra pure bisphosphine was used for radiolabeling.

The mixed-ligand experiment was performed to determine the composition (the number of bidentate chelators and bisphosphine ligands) of cationic ^{99m}Tc-nitrido complexes. In the first experiment, we used PNP6 as the bisphosphine ligand, and Hma and Hema as the competing chelators. After radiolabeling, the reaction mixture was analyzed by radio-HPLC. Figure 3 shows the typical radio-HPLC chromatogram of the reaction mixture containing $[^{99m}TcN(ma)(PNP6)]^+$ and $[^{99m}TcN(ema)(PNP6)]^+$. If only one bidentate chelator is bonded to the Tc, the HPLC chromatogram should show two peaks: one from $[^{99m}TcN(ma)(PNP6)]^+$ and the other from $[^{99m}TcN(ema)(PNP6)]^+$. If two bidentate chelators were bonded to the Tc, there would have been a third peak from the mixed-ligand complex, $[^{99m}TcN(ma)(ema)(PNP6)]$. The presence of two distinctive peaks at ~14.5 min and ~16.5 min for $[^{99m}TcN(ma)(PNP6)]^+$ and $[^{99m}TcN(ema)(PNP6)]^+$, respectively, clearly demonstrates that there is only one bidentate chelator in cationic complex $[^{99m}TcN(L)(PNP)]^+$. The number of bisphosphines in cationic complex $[^{99m}TcN(L)(PNP)]^+$ was determined in a similar fashion using Hema as the bidentate chelator, and L6 and PNP6 as the competing ligands. Figure 4 shows the radio-HPLC chromatogram of the resulting reaction mixture containing $[^{99m}TcN(ema)(L6)]^+$ and $[^{99m}TcN(ema)(PNP6)]^+$. The peak at 14.0 min is due to $[^{99m}TcN(ema)(L6)]^+$ and the peak at 15.5 min is from $[^{99m}TcN(ema)(PNP6)]^+$. This clearly demonstrates that there is only one bisphosphine in $[^{99m}TcN(L)(PNP)]^+$. Once again, the radioimpurities (~20%) at 10−12 min are caused by the partial oxidation of PNP6 during preparation.

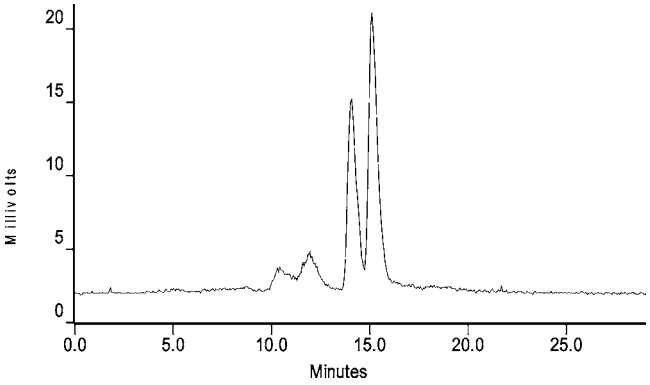

Figure 4. Radio-HPLC chromatogram of the reaction mixture containing $[^{99m}TcN(ma)(L6)]^+$ (left) and $[^{99m}TcN(ma)(PNP6)]^+$ (right). The radioimpurities (~20%) at 10−12 min are caused by the partial oxidation of PNP6.

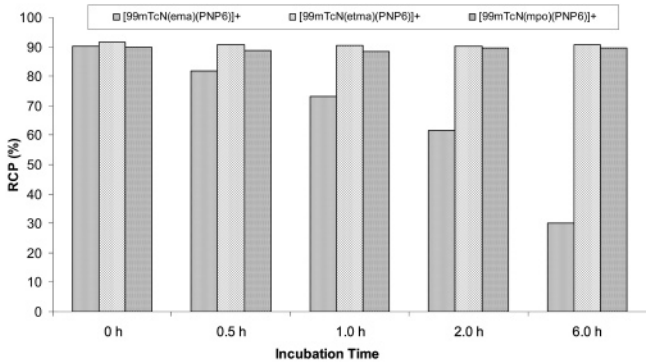

Figure 5. Solution Stability data for $[^{99m}TcN(ema)(PNP6)]^+$, $[^{99m}TcN(etma)(PNP6)]^+$ and $[^{99m}TcN(mpo)(PNP6)]^+$.

We studied the solution stability of $[^{99m}TcN(L)(PNP)]^+$ (L = ma, ema, tma, etma, and mpo; PNP = PNP5, PNP6 and L6) in the kit matrix and after purification. It was found that they all remain stable for more than 6 h. The cysteine challenge experiment was also performed for $[^{99m}TcN(L)(PNP6)]^+$ (L = ema, etma, and mpo). It was found that $[^{99m}TcN(ema)(PNP6)]^+$ decomposes rapidly in the presence of cysteine (~1.0 mg/mL). The RCP was >90% in the kit matrix and decreased to 61.6% at 2 h and 30.1% at 6 h (Figure 5). In contrast, $[^{99m}TcN(etma)(PNP6)]^+$ and $[^{99m}TcN(mpo)(PNP6)]^+$ remain stable (>6 h) in presence of excess cysteine (1.0 mg/mL) at ambient temperature (Figure 5). The use of thione-S donors in bidentate chelators increases solution stability of their cationic ^{99m}Tc-nitrido complexes.

Lipophilicity plays a significant role in the heart uptake and excretion kinetics of cationic ^{99m}Tc radiotracers (*1, 22−25*). Thus, it is important to explore the impact of bidentate chelators and bisphosphines on lipophilicity of their cationic ^{99m}Tc-nitrido complexes. Partition coefficient constants of $[^{99m}TcN(L)(PNP)]^+$ (L = ma, ema, tma, etma, and mpo; PNP = PNP5, PNP6, and L6) were determined by measuring their distribution in a mixture of equal volume n-octanol and 25 mM phosphate buffer (pH = 7.4). HPLC purification was needed to minimize the interference from other radioimpurities. The log *P* values are summarized in Table 1. In general, cationic complexes $[^{99m}TcN(L)(PNP)]^+$ (L = ma and tma) have lower lipophilicity than $[^{99m}TcN(L)$-

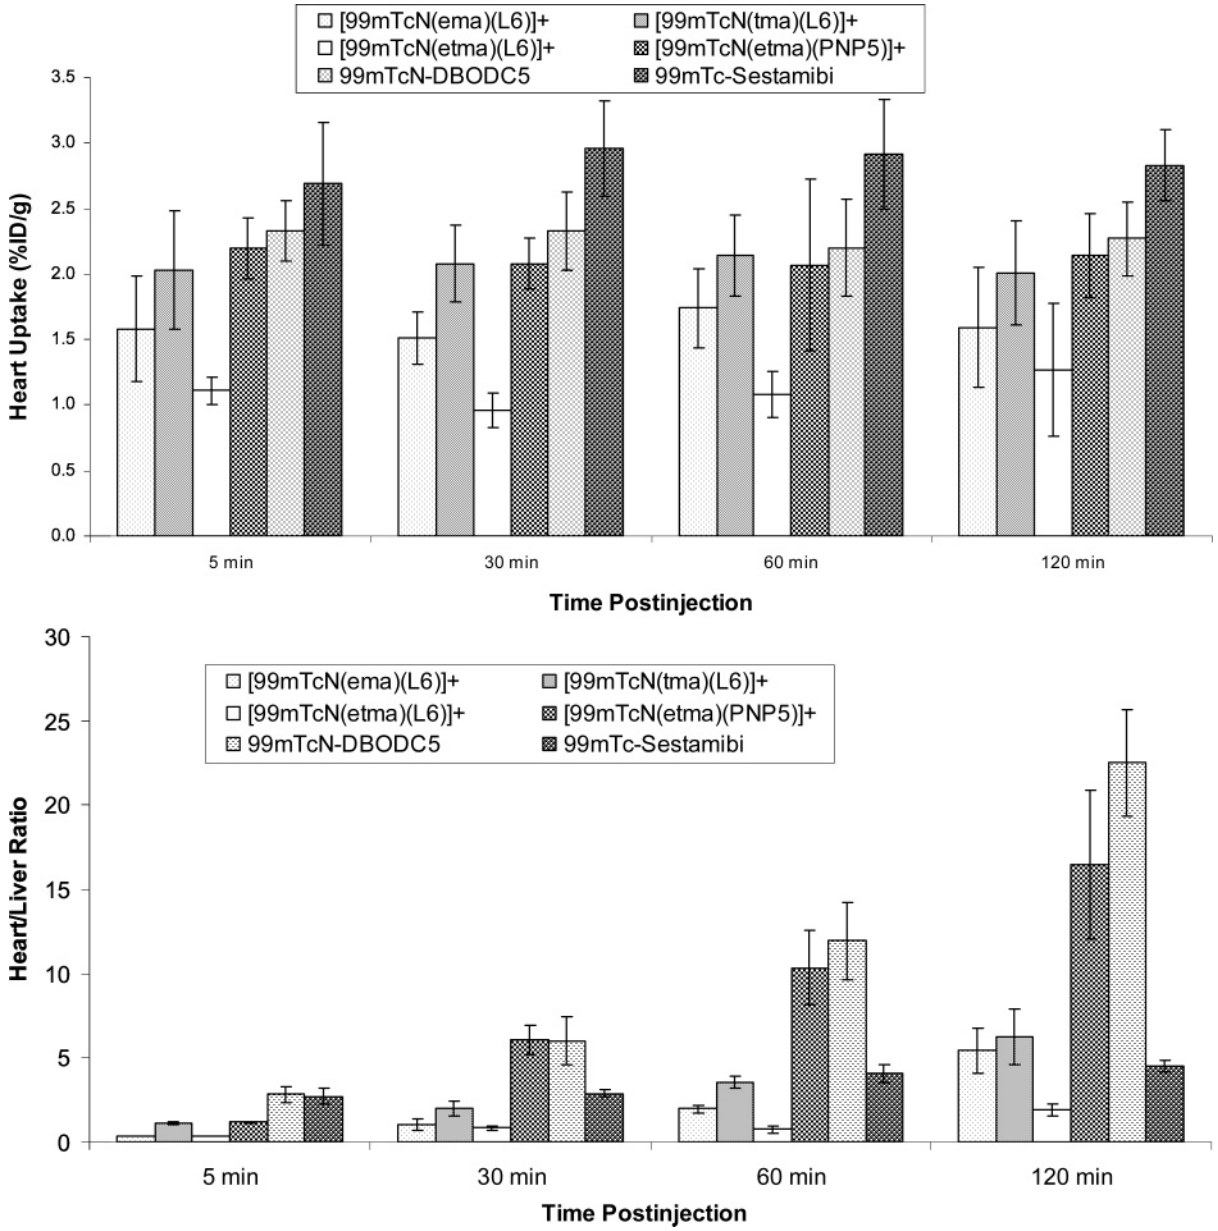

Figure 6. Comparison of heart uptake (top) and heart/liver (bottom) ratios between $[^{99m}TcN(ema)(L6)]^+$, $[^{99m}TcN(tma)(L6)]^+$, $[^{99m}TcN(etma)(L6)]^+$, $[^{99m}TcN(etma)(PNP5)]^+$, ^{99m}TcN-DBODC5, and ^{99m}Tc-Sestamibi.

$(PNP)]^+$ (L = ema and etma) due to the extra methylene group. $[^{99m}TcN(L)(PNP)]^+$ (L = tma and etma) are more lipophilic than $[^{99m}TcN(L)(PNP)]^+$ (L = ma and ema) due to the presence of thione-S donor. $[^{99m}TcN(L)(PNP6)]^+$ is more lipophilic than $[^{99m}TcN(L)(PNP5)]^+$ due to the presence of four ethoxypropyl groups in PNP6 instead of four methoxypropyl groups in PNP5. The lipophilicity of $[^{99m}TcN(mpo)(PNP)]^+$ is between that of $[^{99m}TcN(tma)(PNP)]^+$ and $[^{99m}TcN(etma)(PNP)]^+$.

Biodistribution Characteristics. Biodistribution studies in rats were performed on $[^{99m}TcN(etma)(PNP5)]^+$, $[^{99m}TcN(ema)(L6)]^+$, $[^{99m}TcN(tma)(L6)]^+$, and $[^{99m}TcN(etma)(L6)]^+$. We choose these four radiotracers to demonstrate the impact of solution stability and lipophilicity on their biodistribution characteristics. The biodistribution data and T/B ratios are listed in Tables SI−SIV. Figure 6 shows a direct comparison of their heart uptake and heart/liver ratios with those of ^{99m}Tc-sestamibi and ^{99m}TcN-DBODC5. Biodistribution data for ^{99m}Tc-sestamibi and ^{99m}TcN-DBODC5 in the same animal model were obtained from our previous report (*1*).

$[^{99m}TcN(ema)(L6)]^+$ has a lop *P* value of 1.22 ± 0.13, which is almost identical to that of ^{99m}Tc-sestamibi (1.29 ± 0.13). It had a moderate heart uptake (1.58 ± 0.41 %ID/g at 5 min p.i. and 1.60 ± 0.48 %ID/g at 120 min p.i.) with the heart/liver ratios being 0.35 ± 0.04, 1.06 ± 0.34, 2.56 ± 0.23, and 5.43 ± 1.37 at 5, 30, 60, and 120 min p.i., respectively. $[^{99m}TcN(etma)(L6)]^+$ has the log *P* of 1.43 ± 0.05. It has a low heart uptake (1.10 ± 0.10 %ID/g at 5 min p.i. and 1.27 ± 0.51 %ID/g at 120 min p.i.) and poor heart/liver ratios (0.37 ± 0.01, 1.21 ± 0.16, 1.17 ± 0.19, and 1.91 ± 0.31 at 5, 30, 60, and 120 min p.i., respectively). $[^{99m}TcN(tma)(L6)]^+$ has the log *P* value (1.09 ± 0.17) that is almost identical to that of ^{99m}TcN-DBODC5 (1.10 ± 0.07). It shows a high initial heart uptake (2.03 ± 0.75 %ID/g at 5 min p.i.) with a long myocardial retention (2.01 ± 0.40 %ID/g at 120 min p.i.). Its heart/liver ratios are 1.10 ± 0.09, 2.01 ± 0.41, 3.55 ± 0.34, and 6.25 ± 0.68 at 5, 30, 60, and 120 min p.i., respectively. The log *P* value of $[^{99m}TcN(etma)(PNP5)]^+$ is 0.67 ± 0.15. It has a relatively high heart uptake (1.81 ± 0.35 %ID/g at 5 min p.i.), a long myocardial retention (1.99 ± 0.47 %ID/g at 120 min p.i.), and high heart/liver ratios (6.06 ± 0.90, 10.36 ± 2.25, and 16.46 ± 4.24 at 30, 60, and 120 min p.i., respectively).

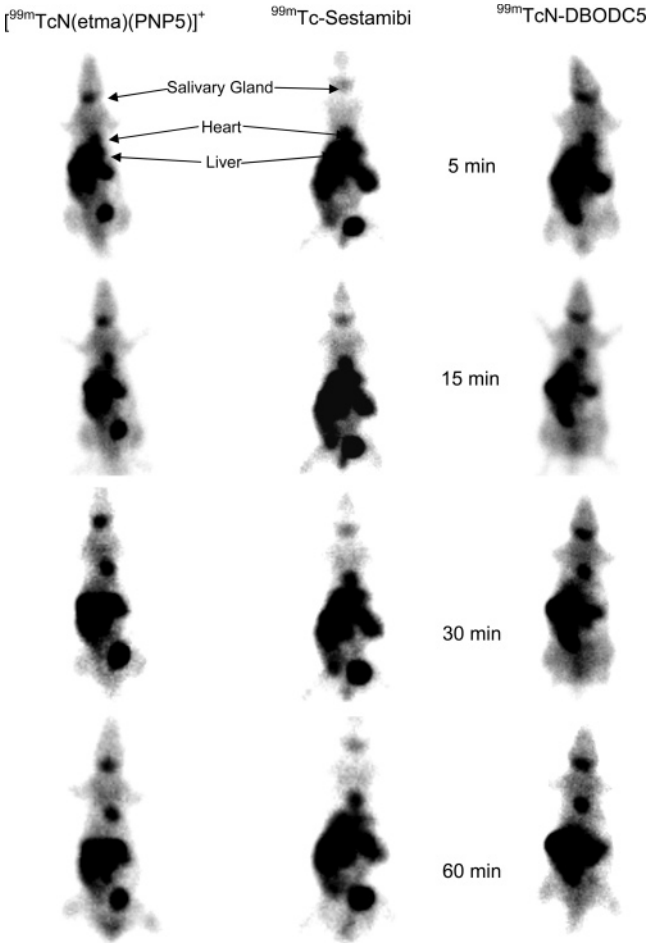

Figure 7. Planar images of rats administered with ~500 μCi of $[^{99m}TcN(etma)(PNP5)]^+$, ^{99m}Tc-sestamibi, and ^{99m}TcN-DBODC5. Arrows indicate the location of the heart, liver, and salivary gland (as determined by ex vivo gamma counting).

Imaging Studies. $[^{99m}TcN(etma)(PNP5)]^+$ was chosen for the imaging study in rats due to its much better heart/liver ratios than those of ^{99m}Tc-sestamibi. For comparison purposes, we also obtained images of rats administered with ^{99m}Tc-sestamibi and ^{99m}TcN-DBODC5. Figure 7 illustrates planar images of rats administered with $[^{99m}TcN(etma)(PNP5)]^+$, ^{99m}Tc-sestamibi, and ^{99m}TcN-DBODC5. In general, all the images acquired at 5 min p.i. show a very high liver uptake adjacent to the heart, but the lung activity was low for all three radiotracers. At 30 min p.i., the liver activity for $[^{99m}TcN(etma)(PNP5)]^+$ and ^{99m}TcN-DBODC5 is reduced significantly. By 60 min p.i., the liver activity almost disappeared for $[^{99m}TcN(etma)(PNP5)]^+$ and ^{99m}TcN-DBODC5 while the liver activity level for ^{99m}Tc-sestamibi remained high.

Metabolism. We examined metabolism of $[^{99m}TcN(etma)(PNP5)]^+$ by analyzing the urine and feces samples from the rats used in imaging studies. Figure 8 shows its radio-HPLC chromatograms in the kit matrix (A), in urine at 30 min p.i. (B), in urine at 120 min p.i. (C), and in feces at 120 min p.i. (D). Obviously, a very small amount of metabolite was detected in the urine samples (Figure 8: B and C), but a significant metabolism was observed in feces samples of rats administered with $[^{99m}TcN(etma)(PNP5)]^+$ (Figure 8D).

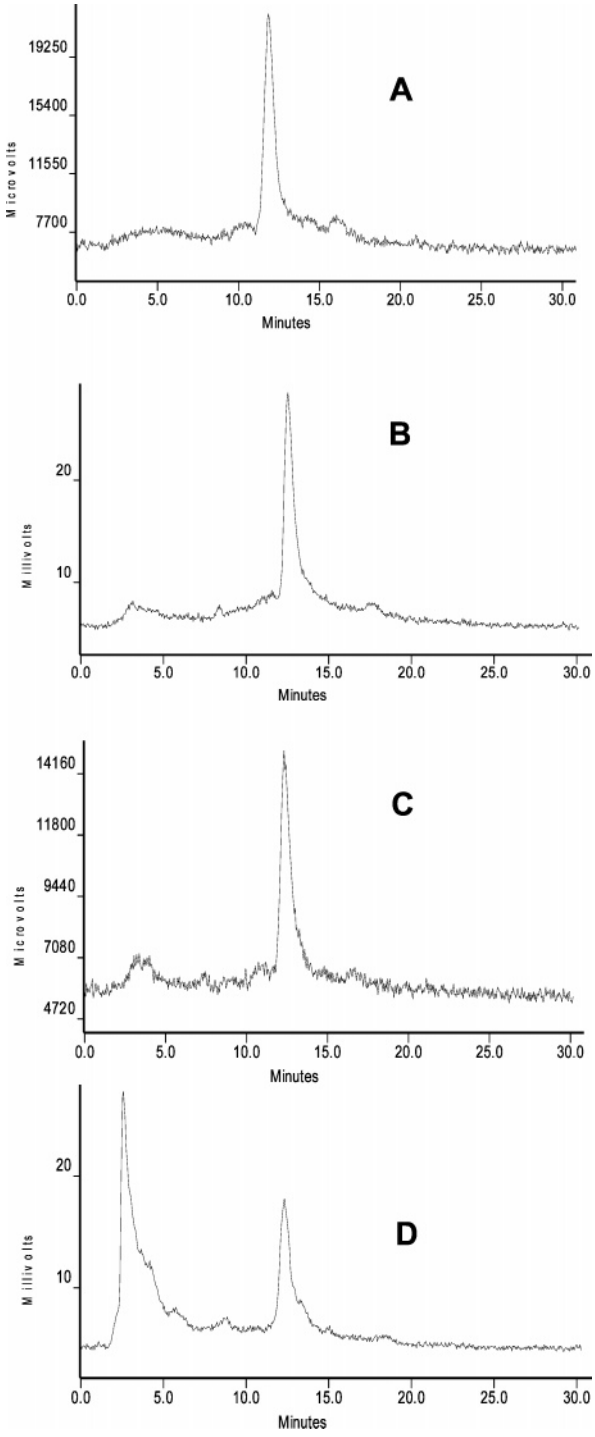

Figure 8. Radio-HPLC chromatograms of $[^{99m}TcN(etma)(PNP5)]^+$ in the kit matrix before injection (A), in the urine at 30 min p.i. (B), in the urine at 120 min p.i. (C), and in feces at 120 min p.i. (D). Each rat was administered with ~500 μCi of $[^{99m}TcN(etma)(PNP5)]^+$.

DISCUSSION

Myocardial perfusion imaging with radiotracers is an integral component of the clinical evaluation of patients with known or suspected coronary artery disease (*26*−*29*). Since the early 1980s, intensive research efforts have been directed toward development of cationic ^{99m}Tc complex radiotracers for heart imaging (*26, 27*). As a result these efforts, ^{99m}Tc-sestamibi and ^{99m}Tc-tetrofosmin have been approved as commercial products for myocardial perfusion imaging. Despite their widespread applications, both ^{99m}Tc-sestamibi and ^{99m}Tc-tetrofosmin do not meet the requirements of an ideal perfusion imaging agent, at least in part, due to their high liver uptake (*30*). Therefore, it would be a great advantage to develop a new radiotracer with substantially better heart/liver ratio than that of ^{99m}Tc-sestamibi.

The factors affecting biodistribution patterns of radiotracers include the charge, solution stability, lipophilicity, and protein-binding capability. For example, $[^{99m}TcN(ema)(L6)]^+$ and

^{99m}Tc-sestamibi share the same cationic charge and have very high lipophilicity (1.22 ± 0.13 and 1.29 ± 0.13, respectively). However, the heart uptake and heart/liver ratios of [^{99m}TcN-(tma)(L6)]$^+$ are significantly lower ($P < 0.01$) than that of ^{99m}Tc-sestamibi at 5−60 min postinjection. This difference is probably related to its solution instability of [^{99m}TcN(ema)(L6)]$^+$ in the presence of cysteine (Figure 5). The solution instability of [^{99m}TcN(ema)(L6)]$^+$ may also contribute to its high protein binding as indicated by its relatively high blood activity and low heart/blood ratios (Table SIII).

Compared to [^{99m}TcN(ema)(L6)]$^+$, [^{99m}TcN(etma)(L6)]$^+$ has better solution stability due to the thione-S donor atom in etma. However, it has a low heart uptake with low heart/lung and heart/liver ratios, suggesting that it is probably too lipophilic (log $P = 1.43 \pm 0.05$) to achieve the high heart uptake and fast liver clearance. [^{99m}TcN(tma)(L6)]$^+$ has a high solution stability. Its log P value is almost identical to that of ^{99m}TcN-DBODC5 (Table 1). The heart uptake of [^{99m}TcN(tma)(L6)]$^+$ is comparable to that of ^{99m}TcN-DBODC5 (Figure 6), but its heart/liver and heart/liver ratios are significantly lower ($p < 0.01$) than that of ^{99m}TcN-DBODC5 over the 2 h study period. In contrast, [^{99m}TcN(etma)(PNP5)]$^+$ is less lipophilic (log $P = 0.67 \pm 0.15$). Its heart uptake is comparable to that of ^{99m}TcN-DBODC5 within the experimental error (Figure 6). The heart/liver ratio of [^{99m}TcM(etma)(PNP5)]$^+$ is very similar to that of ^{99m}TcN-DBODC5 at 5−60 min p.i.

Another important factor influencing the *in vivo* biological properties of cationic ^{99m}Tc radiotracers is their metabolic properties. Cationic ^{99m}Tc radiotracers are generally excreted via hepatobiliary and renal routes. Metabolic products can be readily detected by analyzing the urine (renal excretion) and feces (hepatobiliary excretion) samples. In this study, we used a reversed phase radio-HPLC method to analyze the urine and feces samples from the rats administered with ~500 μCi of [^{99m}TcN(etma)(PNP5)]$^+$. The results indicated that [^{99m}TcN-(etma)(PNP5)]$^+$ remained intact in the urine over 2 h study period (Figure 8C), but it shows a significant metabolism (>70%) in feces samples at 120 min p.i. (Figure 8D). In contrast, ^{99m}TcN-DBODC5, which shares the same PNP5 bisphosphine ligand with [^{99m}TcN(etma)(PNP5)]$^+$, has very little metabolism in both urine and feces of rats under anesthesia (*1*). Changing the bidentate chelator from DBODC to ethylthiomaltolate (etma) has a significant impact on the metabolic fate of the cationic ^{99m}Tc-nitrido complex. The metabolic instability of [^{99m}TcN-(etma)(PNP5)]$^+$ may contribute to its lower heart/liver ratio than that of ^{99m}TcN-DBODC5 at 120 min p.i. (Figure 6).

It is well-documented that cationic ^{99m}Tc radiotracers, such as ^{99m}Tc-sestamibi and ^{99m}Tc-tetrofosmin, are able to penetrate plasma and mitochondrial membranes and accumulated in mitochondria because of the negative mitochondrial potential (*31*−*35*). Due to their similarity in molecular charge with ^{99m}Tc-sestamibi and ^{99m}Tc-tetrofosmin, it is reasonable to believe that cationic ^{99m}Tc-nitrido complexes might share the same localization mechanism. The difference in the heart uptake of cationic ^{99m}Tc radiotracers is most likely caused by their lipophilicity and capability to across the plasma and mitochondrial membranes. Cationic ^{99m}Tc radiotracers with the log $P >$ 1.5 often have a low heart uptake and a slow liver clearance while more hydrophilic cationic radiotracers with log $P < 0$ tend to show fast washout from the myocardium (*1*−*3*, *22*−*25*). In both cases, the heart/liver ratio is low because of either high liver uptake or fast myocardial washout. While there is no clear-cut "optimal" log P values, we believe that cationic ^{99m}Tc radiotracers should have a log P value of 0.6−1.2 in order to achieve a high heart uptake with the fast liver clearance at the same time.

CONCLUSIONS

This report describes synthesis and evaluation of cationic complexes [^{99m}TcN(L)(PNP)]$^+$ (Figure 1: L = ma, ema, tma, etma, and mpo; PNP = PNP5, PNP6, and L6) as potential radiotracers for heart imaging. The key finding of this study is that bidentate chelators have a significant impact on lipophilicity, solution stability, biodistribution patterns, and metabolism of their cationic ^{99m}Tc-nitrido complexes. The results from solution stability studies indicate that the thione-S donors in bidentate chelators increase solution stability of cationic ^{99m}Tc-nitrido complexes. Among four radiotracers evaluated in Sprague−Dawley rats for their biodistribution characteristics, [^{99m}TcN-(etma)(PNP5)]$^+$ has a high heart uptake, long myocardial retention, and fast liver clearance with the heart/liver ratio being >2 times better than that of ^{99m}Tc-sestamibi at 30 min p.i. Results from planar imaging studies are completely consistent with those from biodistribution studies. The fast liver clearance suggests that [^{99m}TcN(etma)(PNP5)]$^+$ might give clinically useful images of heart as early as 30 min p.i. [^{99m}TcN(etma)-(PNP5)]$^+$ is a promising candidate for evaluation of its blood flow characteristics in larger animal models, such as dogs and pigs. It is interesting to note that the heart/liver ratio of [^{99m}TcN(etma)(PNP5)]$^+$ is not as good as that of ^{99m}TcN-DBODC5 at 120 min p.i. probably due to its metabolic instability in the hepatobiliary system. Therefore, our future research will focus more on cationic ^{99m}Tc-nitrido complexes with better metabolic stability.

ACKNOWLEDGMENT

Authors would like to thank Lee Ann Grote, Carol Dowell, and Cheryl Anderson from the Department of Veterinary Clinical Sciences, Purdue University, for their assistance with biodistribution and imaging studies. Received October 19, 2006; Revised Manuscript Received January 13, 2007

The aim of this study is to evaluate the potential use of first-generation (G1) polyamidoamine (PAMAM) dendrimers as drug carriers to enhance the permeability, hence oral absorption, of drugs that are substrates for P-glycoprotein (P-gp) efflux transporters. G1 PAMAM dendrimer-based prodrugs of the water-insoluble P-gp substrate terfenadine (Ter) were synthesized using succinic acid (suc) or succinyl−diethylene glycol (suc−deg) as a linker/spacer (to yield G1−suc−Ter and G1−suc−deg−Ter, respectively). In addition, the permeability of G1−suc−deg−Ter was enhanced by attaching two lauroyl chains (L) to the dendrimer surface (L2−G1−suc−deg−Ter). All of the G1 dendrimer−terfenadine prodrugs were more hydrophilic than the parent drug, as evaluated by drug partitioning between 1-octanol and phosphate buffer at pH 7.4 (log K_{app}). The influence of the dendrimer prodrugs on the integrity and viability of human Caucasian colon adenocarcinoma cells (Caco-2) was determined by measuring the transepithelial electrical resistance (TEER) and leakage of lactate dehydrogenase (LDH) enzyme, respectively. The LDH assay indicated that the dendrimer prodrugs had no impact on the viability of Caco-2 cells up to a concentration of 1 mM. However, the IC_{50} of the prodrugs was lower than that of G1 PAMAM dendrimer because of the high toxicity of terfenadine. Measurements of the transport of dendrimer prodrugs across monolayers of Caco-2 cells showed an increase of the apparent permeability coefficient (P_{app}) of terfenadine in both apical-to-basolateral (A → B) and basolateral-to-apical (B → A) directions after its conjugation to G1 PAMAM dendrimer. The A → B P_{app} of the dendrimer prodrugs was significantly greater than B → A P_{app}. The surface-modified dendrimer prodrug L2−G1−suc−deg−Ter showed the highest A → B permeability among the conjugates.

INTRODUCTION

There has been growing interest in polyamidoamine (PAMAM) dendrimers as hyperbranched polymers possessing a well-defined structure that allow precise control of size, shape, and terminal group functionality (*1*). Dendrimers show potential as carriers for the development of drug delivery systems (*2*) that can be used in several pharmaceutical fields (*2*, *3*).

Dendrimers have the ability to cross cell barriers (*4*−*6*) by both paracellular and transcellular pathways (*7*, *8*). The cytotoxicity and permeability of PAMAM dendrimers were found to be concentration, generation, and charge dependent (*7*). Low-generation PAMAM dendrimers (G0 and G1) exhibit significantly less cytotoxicity and higher permeability than higher generations (G2, G3, and G4) (*9*). However, a significant reduction in cytotoxicity and enhancement in permeability can be achieved by surface-engineered cationic PAMAM dendrimers (*7*, *10*).

Recent observations on intestinal absorption of drugs suggest that an intestinal secretion process mediated by P-glycoprotein (P-gp) limits the bioavailability of drugs that are P-gp substrates, such as terfenadine, after peroral administration (*11*, *12*). Several attempts have been reported to enhance the oral absorption of P-gp substrates by (1) inhibiting the P-gp secretion activity using P-gp inhibitors such verapamil and nifedipine (*13*), (2) co-administrating with excipients such as Tween 80 and acacia which are known to inhibit the P-gp efflux activity (*14*), (3) improving the paracellular transport by co-administrating modulators of tight junctions such as sodium caprate (C10) (*15*), and (4) changing the physicochemical properties of the drug by synthesis of a prodrug that is able to bypass the P-gp efflux pump, for example, attaching paclitaxel to PEG 5000 resulted in a prodrug with a higher bioavailability than the parent drug (*16*).

Previous work by our group reported potential drug carrier systems based on third-generation (G3) PAMAM dendrimer that may be used to enhance the transport of propranolol across Caco-2 cells. Propranolol has poor water solubility and is a substrate for the P-glycoprotein (P-gp) efflux transporter. When conjugated to surface-modified G3 PAMAM dendrimer, propranolol was shown to bypass the efflux system. Thus, dendrimer prodrugs may be used to enhance the bioavailability of drugs that are substrates of efflux transporters and therefore overcome cellular barriers such as the gastrointestinal epithelium and the blood brain barrier (*6*, *17*). A natural extension of this work is the inclusion of a linker between the drug and the dendrimer to control drug release, use of a lower generation (less toxic) carrier than G3 PAMAM dendrimer, and use of a stronger and more unambiguous P-gp substrate than propranolol to confirm that PAMAM dendrimers have the ability to bypass P-gp efflux transporters. More recently, we explored the nature of the linker between the drug and the dendrimer. It is important to design a linker that is robust enough for the drug−dendrimer prodrug to be absorbed intact yet labile once absorbed. It has been found that a diethylene glycol linker between the drug and dendrimer gave esters with a high chemical stability in buffers, which readily released the drug in plasma. PAMAM dendrimer conjugates incorporating this linker have potential as carriers for low-bioavailability drugs (*18*).

In the present study, the design, characterization, and in vitro evaluation of a novel drug carrier system based on first-

generation PAMAM dendrimers (G1) (Figure 1) and utilizing a diethylene glycol linker are described. Terfenadine was selected as an unambiguous P-gp substrate and water-insoluble drug. It was attached to the dendrimer surface using succinyl linker (single ester linker) to give G1−suc−Ter or succinic−diethylene glycol linker (double ester linker) to give G1−suc−deg−Ter. The biological evaluation of both conjugates and the surface-modified conjugate (L2−G1−suc−deg−Ter) involved cytotoxicity studies (LDH assay) and measurement of transport across Caco-2 monolayers.

EXPERIMENTAL PROCEDURES

Materials. First-generation PAMAM dendrimers (G1) with ethylenediamine cores were purchased from Dendritech Inc. (Michigan). Trifluoroacetic acid (TFA), triethylamine (TEA), terfenadine, 4-nitrophenyl chloroformate, succinic anhydride, 1-dodecanol (lauroyl alcohol), trypan blue, 4-dimethylaminopyridine (DMAP), ethylenediamine tetraacetic acid (EDTA), lactate dehydrogenase assay kits, Sephadex 15, and Sephadex LH-20 were purchased from Sigma-Aldrich Co. Ltd. *N*-Hydroxysuccinimide (NHS), *N*,*N*′-dicyclohexylcarbodiimide (DCC), and diethylene glycol were purchased from Fluka (Poole, Dorset, U.K.). Cell culture materials were from Gibco BRL Life Technologies (Paisley, Scotland). Polycarbonate cell culture inserts (Transwell 12 mm diameter) and cluster plates (96 well) were purchased from Corning Costar UK (High Wycombe, Bucks, U.K.).

Dendrimer−terfenadine conjugates were characterized by ^{13}C and ^{1}H NMR spectroscopy (Bruker Avance 300, Bruker, Coventry, U.K.). ^{13}C NMR spectra were assigned with the aid of DEPT-135. HPLC analyses were carried out using a Hewlett-Packard Series II 1090 (Germany) instrument equipped with a Luna 5 μm, C18 column (250 × 4.6 mm, Phenomenex, Cheshire, U.K.). For the transport and partition studies the solvent systems were methanol:acetonitrile (ACN):H_3PO_4 (0.05% w/v) (48:32:20) with phenanthrene as internal standard for G1 conjugates, and ACN:Walpole's acetate buffer (pH = 4.5): methanol (40:48:12) with naproxen as internal standard for terfenadine, Ter−suc, and Ter−suc−deg. The flow rate was 1.2 mL/min, and UV detection was at λ = 230 nm. For characterization of dendrimer−terfenadine conjugates, the solvent system was 10:32:58 methanol:acetonitrile (ACN):H_3PO_4 (0.05% w/v) for 2 min then 48:32:20 methanol:acetonitrile-(ACN):H_3PO_4 for the remaining elution time. The flow rate was 1.2 mL/min, and UV detection was at λ = 230 nm.

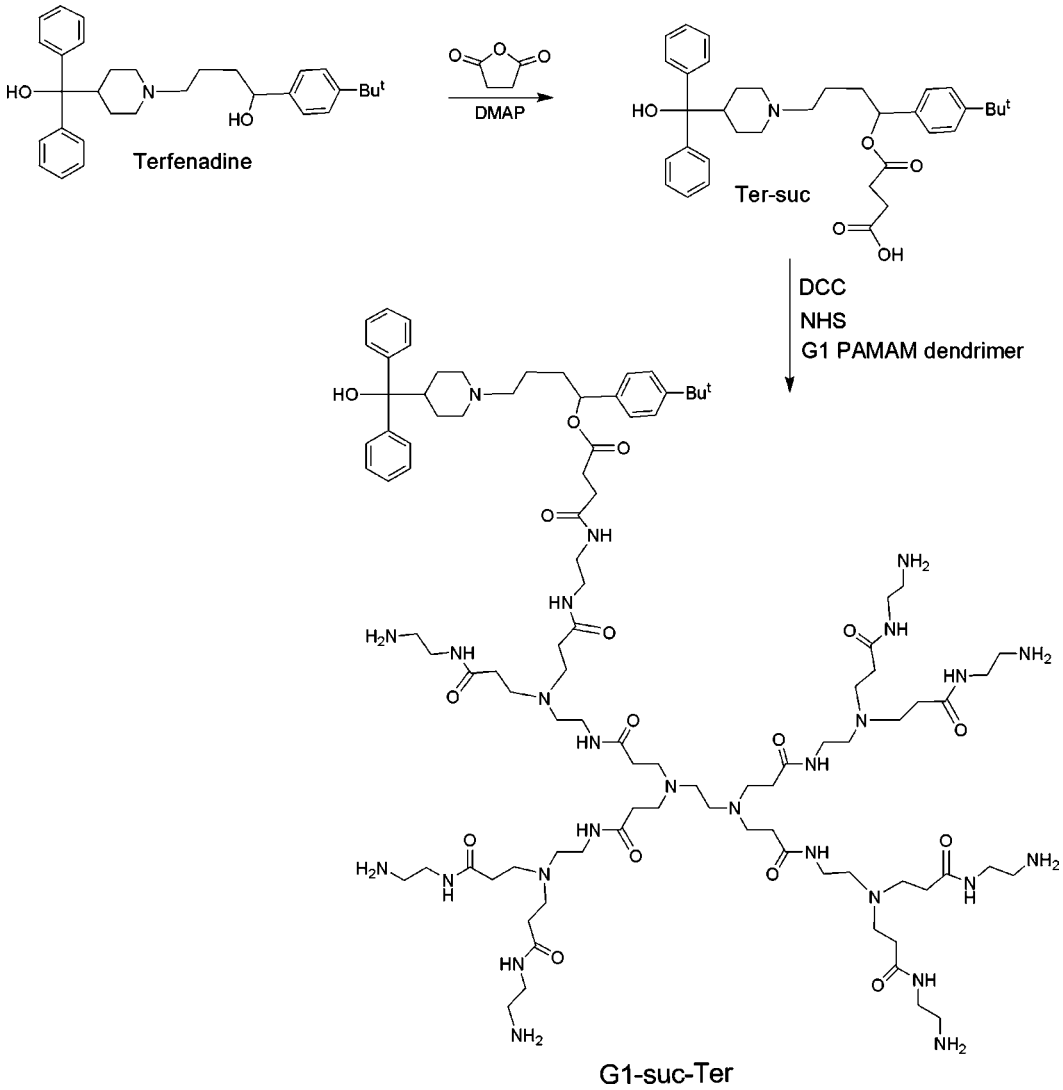
Synthesis of Terfenadine−Succinyl (Ter−suc). Terfenadine (471.7 mg, 1 mmol) was added to a solution of succinic anhydride (200 mg, 2 mmol) and 4-dimethylaminopyridine (DMAP) (12.2 mg, 0.1 mmol) (previously dried under vacuum for 2 h) in DMF (4 mL). Dry pyridine (0.8 mL) was added, and the solution was stirred overnight at room temperature. DMF was evaporated under vacuum, and the residue was washed with petroleum ether and purified by silica gel column chromatography, eluting with chloroform:methanol (90:10) to give Ter−suc with a yield of 91% (R_f = 0.3) (mp = 198−199 °C). ^{1}H NMR ($CDCl_3$): 1.29 (9H, s, $-Bu^t$) 1.51 (2H, br d, $NCH_2CH_2CH_2CH$, J = 13.4), 1.95−1.69 (4H, m, 2 × $CHCH_2CH_2N$), 2.21−2.01 (2H, m, $NCH_2CH_2CH_2CH$), 2.90−2.38 (9H, m, 2 × $CHCH_2CH_2N$, $CHCH_2CH_2N$, $CO-CH_2-CH_2-CO$), 3.39 (H, br d, J_1 = 13.8, $NCH_2CH_2CH_2$), 3.44 (H, br d, J_2 = 13.8, $NCH_2CH_2CH_2$), 5.81 (1H, br d, J = 7.9, CH−O), 7.55−7.10 (14H, m, Ar). ^{13}C NMR ($CDCl_3$): 20.0 ($NCH_2CH_2CH_2$), 23.4 (2 × $CHCH_2CH_2N$), 31.0 (CH_2COO), 31.1 (3 × CH_3), 31.3 (CH_2COOH), 33.7 ($NCH_2CH_2CH_2CH$), 42.6 ($-C(CH_3)_3$), 52.7 ($CHCH_2CH_2N$), 53.0 ($CHCH_2CH_2N$), 56.1 ($CHCH_2CH_2N$), 60.4 ($NCH_2CH_2CH_2$), 73.8 (CH−O), 78.7 (C−OH), 125.4 (2 × CH, Ar), 125.6 (4 × CH, Ar), 125.9 (2 × CH, Ar), 126.5 (2 × CH, Ar), 128.2 (4 × CH, Ar), 137.2 (C, Ar), 145.9 (2 × C, Ar), 150.8 (C, Ar), 173.1 (COO), 177.2 (COOH). (+)-ESI-MS: 572 [M^+ + H]. Accurate MS ($C_{36}H_{46}O_5N_1$): 572.3372 (theoretical: 572.3370).

Synthesis of Terfenadine−Succinyl−Diethylene Glycol (Ter−suc−deg). CDI (65 mg, 0.4 mmol) was added portion wise to a solution of Ter−suc (200 mg, 0.35 mmol) in DCM (10 mL). The mixture was stirred for 4 h at room temperature. An excess of diethylene glycol (deg) (149 mg, 1.43 mmol) was added and stirred overnight. The reaction mixture was washed with water (2 × 10 mL), aqueous 0.1 M HCl (2 × 10 mL), aqueous 0.1 M NaOH (2 × 10 mL), and water (2 × 10 mL), dried (anhydrous Na_2SO_4), filtered, and evaporated to dryness in vacuo. The product was purified by size exclusion chromatography using Sephadex LH 20 and eluting with methanol: water (5:1) to give Ter−suc−deg as an oil with a yield of 69%. TLC: R_f = 0.16 (chloroform:methanol, 90:10). ^{1}H NMR ($CDCl_3$): 1.29 (9H, s, $-Bu^t$), 1.60−1.38 (6H, m, $NCH_2CH_2CH_2$ and 2 × $CHCH_2CH_2N$), 1.99−1.83 (2H, m, $NCH_2CH_2CH_2CH$), 2.75−2.35 (9H, m, 2 × $CHCH_2CH_2N$, $CHCH_2CH_2N$, $CO-CH_2-CH_2-CO$), 2.98−2.87 (2H, m, $NCH_2CH_2CH_2$), 3.69−3.52 (6H, m, $COOCH_2CH_2OCH_2CH_2OH$), 4.28−4.15 (2H, m, $COOCH_2CH_2OCH_2CH_2OH$), 5.76−5.69 (1H, dd, J = 6.5 and 13.7, CH−O), 7.55−7.12 (14H, m, Ar). ^{13}C NMR ($CDCl_3$): 22.9 ($NCH_2CH_2CH_2$), 26.1 (2 × $CHCH_2CH_2N$), 29.0 (CH_2COO), 29.1 (CH_2COO), 31.3 (3 × CH_3), 34.2 ($NCH_2CH_2CH_2CH$), 44.1 ($-C(CH_3)_3$), 53.9 ($CHCH_2CH_2N$), 54.0 ($CHCH_2CH_2N$), 58.2 ($CHCH_2CH_2N$), 61.6 ($NCH_2CH_2CH_2$), 61.7 (OCH_2CH_2OH), 63.7 ($COOCH_2CH_2O$), 67.0 ($COOCH_2CH_2O$), 68.8 (OCH_2CH_2OH), 72.5 (CH−O), 79.4 (C−OH), 125.0 (2 × CH, Ar), 125.6 (4 × CH, Ar), 125.9 (2 × CH, Ar), 126.4 (2 × CH, Ar), 128.1 (4 × CH, Ar), 137.2 (C, Ar), 146.0 (C, Ar), 150.8 (C, Ar), 155.0 (C, Ar), 171.6 (COO), 172.2 (COOH). (+)-ESI-MS: 660 [M^+ + H]. Accurate MS ($C_{40}H_{54}O_7N_1$): 660.3893 (theoretical: 660.3895).

Synthesis of G1 Dendrimer−Succinyl−Terfenadine (G1−suc−Ter). DCC (93 mg, 0.45 mmol) was added to a solution of Ter−suc (200 mg, 0.35 mmol) in 3 mL of DMF. The mixture was stirred for 1 h, after which time NHS (52 mg, 0.45 mmol) was added and the mixture was stirred for 24 h. The reaction mixture was filtered, and the filtrate was concentrated. The residue was dissolved in DCM, washed with water (2 × 10 mL), aqueous 0.1 M HCl (2 × 10 mL), aqueous 0.1 M NaOH (2 × 10 mL), and water (2 × 10 mL), dried (anhydrous Na_2SO_4), filtered, evaporated to dryness in vacuo, and dissolved in DMF (3 mL). The solution was added dropwise (during 6 h) to 2 mL of DMF containing G1 dendrimer (429 mg, 0.3 mmol),

stirred for 5 days, and evaporated under vacuum. The residue was dissolved in 3 mL of water and filtered. The filtrate was purified by size exclusion chromatography, using Sephadex 15 and eluting with methanol:water (1:5). The product was further purified using Sephadex LH 20 and eluting with methanol:water (5:1). The yield of G1−suc−Ter was 39%. ^{1}H NMR (d_4-MeOD): 1.28 (9H, s, −Bu^t), 1.95−1.42 (8H, m, $NCH_2CH_2CH_2$, 2 × $CHCH_2CH_2N$, and $NCH_2CH_2CH_2CH$, Ter), 2.45−2.18 (61H, m, c-G1), 3.05−2.50 (61H, 3 m, a-G1, (2 × $CHCH_2CH_2N$, Ter), ($CHCH_2CH_2N$, Ter), (CO−CH_2−CH_2−CO, Suc), b-G1, f-G1), 3.73−3.10 (26H, e-G1 and ($NCH_2CH_2CH_2$, Ter)), 5.80−5.60 (1H, m, CH−O), 7.65−7.05 (14H, m, Ar). ^{13}C NMR (d_4-MeOD): 22.0 ($NCH_2CH_2CH_2$), 25.9 and 26.0 (2 × $CHCH_2CH_2N$), 30.8 (CH_2COO), 31.8 (3 × CH_3), 34.7 (12 × c-G1), 35.4 (CH_2CONH, Suc), 37.0 ($NCH_2CH_2CH_2CH$), 38.6 (8 × f-G1), 41.4 (12 × e-G1) 43.6 (−$C(CH_3)_3$), 51.1 (12 × b-G1), 52.2 ($CHCH_2CH_2N$), 53.0 ($CHCH_2CH_2N$), 53.4 (6 × a-G1), 54.3 ($CHCH_2CH_2N$), 57.8 ($NCH_2CH_2CH_2$), 75.8 (C−OH), 80.0 (CH−O), 126.4 (2 × CH, Ar), 127.0 (4 × CH, Ar), 127.1 (2 × CH, Ar), 127.5 (2 × CH, Ar), 129.1 (4 × CH, Ar), 138.9 (C, Ar), 147.5 (2 × C, Ar), 152.0 (C, Ar), 174.6 (COO), 175.2 (CONH, 12 × d-G1), 175.7 (CONH, Suc).

Synthesis of G1 Dendrimer−Succinyl−Diethylene Glycol−Terfenadine (G1−suc−deg−Ter). Ter−suc−deg (139 mg, 0.21 mmol) was dissolved in THF (5 mL), and TEA (43 mg, 0.42 mmol) was added. The mixture was stirred for 10 min, after which 4-nitrophenyl chloroformate (85 mg, 0.42 mmol) was added portion wise and stirred for 24 h at room temperature. THF was evaporated under vacuum, and the residue was dissolved in DCM, filtered, and concentrated. The residue was dissolved in DMF (1 mL) and added dropwise (during 6 h) to a stirred solution of G1 dendrimer (200 mg, 0.14 mmol) in DMF (2 mL). The reaction mixture was stirred for 5 days. DMF was evaporated under vacuum, and the residue was purified by size exclusion chromatography using Sephadex LH 20 and eluting with methanol:water (5:1). The yield of G1−suc−deg−Ter was 72%. ^{1}H NMR (d_4-MeOD): 1.29 (9H, s, −Bu^t), 2.10−1.38 (8H, m, $NCH_2CH_2CH_2$, 2 × $CHCH_2CH_2N$, and $NCH_2CH_2CH_2CH$, Ter), 2.44−2.24 (24H, m, c-G1), 3.11−2.47 (61H, 3 m, a-G1, (2 × $CHCH_2CH_2N$, Ter), ($CHCH_2CH_2N$, Ter), (CO−CH_2−CH_2−CO, Suc), b-G1, f-G1), 3.79−3.11 (30H, m, e-G1, ($NCH_2CH_2CH_2$, Ter), $COOCH_2CH_2OCH_2CH_2O$−, deg), 4.32−4.10 (4H, m, $COOCH_2CH_2OCH_2CH_2O$−), 5.84−5.73 (1H, t, J = 6.7, CH−O), 7.55−7.05 (14H, m, Ar). ^{13}C NMR (d_4-MeOD): 23.5 ($NCH_2CH_2CH_2$), 27.1 (2 × $CHCH_2CH_2N$), 29.9 (CH_2COO), 30.3 (CH_2COO), 31.8 (3 × CH_3), 34.4 (12 × c-G1), 35.4 ($NCH_2CH_2CH_2CH$), 38.6 (8 × f-G1), 41.4 (12 × e-G1) 45.2 (−$C(CH_3)_3$), 51.2 (12 × b-G1), 52.3 (2 × $CHCH_2CH_2N$), 53.5 (6 × a-G1), 55.1 ($CHCH_2CH_2N$), 59.3 ($NCH_2CH_2CH_2$), 62.2 ($COOCH_2CH_2OCH_2CH_2O$−), 65.1 ($COOCH_2CH_2OCH_2CH_2O$−), 68.1 ($COOCH_2CH_2OCH_2CH_2O$−), 70.5 ($COOCH_2CH_2OCH_2CH_2O$−), 77.3 (CH−O), 80.3 (C−OH), 127.0 (2 × CH, Ar), 127.2 (4 × CH, Ar), 127.3 (2 × CH, Ar), 128.3 (2 × CH, Ar), 128.9 (4 × CH, Ar), 137.0 (C, Ar), 138.9 (C, Ar), 148.0 (C, Ar), 152.0 (C, Ar), 156.6 (OCONH−), 173.4 (COO), 174.0 (COO), 175.2 (CONH, 12 × d-G1).



Synthesis of Lauroyl 4-Nitrophenyl Carbonate. Lauroyl alcohol (0.93 g, 5 mmol) was dissolved in THF (10 mL), and TEA (1.02 g, 10 mmol) was added. The mixture was stirred for 10 min, after which 4-nitrophenyl chloroformate (2.01 g, 10 mmol) was added portion wise and stirred for 24 h at room temperature. THF was evaporated under vacuum, and the residue was dissolved in hexane:EtOAc (85:15), filtered, and purified by silica gel column chromatography, eluting with the same solvent system to give lauroyl 4-nitrophenyl carbonate (R_f = 0.4) with a yield of 84%.^{1}H NMR ($CDCl_3$): 0.80 (3H, t, J = 6.9, CH_3), 1.35−1.15 (18H, m, 9 × $-CH_2-$), 1.68 (2H, pentet, J = 6.8, $-CH_2-$), 4.20 (2H, t, J = 6.8, $-CH_2-O-CO-$), 7.35−7.25 (2H, m, Ar), 8.2−8.15 (2H, m, Ar). ^{13}C NMR ($CDCl_3$): 14.5 ($-CH_3$), 23.1 ($-CH_2-$), 26.0 ($-CH_2-$), 30.0−28.9 (7 × $-CH_2-$), 32.3 ($-CH_2-$), 70.0 ($-CH_2-O-CO-$), 122.1 (2 × CH, Ar), 125.6 (2 × CH, Ar), 145.7 (CH, Ar), 152.9 (CH, Ar), 156.0 ($-CO-$).

Synthesis of (Lauroyl)$_2$−G1−suc−deg−Ter (L2−G1−suc−deg−Ter). Lauroyl 4-nitrophenyl carbonate (25 mg, 0.07 mmol) in DMF (1 mL) was added dropwise to a stirred solution of G1−suc−deg−Ter (51 mg, 0.023 mmol) in DMF (2 mL). The reaction mixture was stirred for 5 days. DMF was evaporated under vacuum, and the residue was purified by size exclusion chromatography using Sephadex LH 20 and eluting with methanol:water (5:1). The resulting product was dissolved in water and filtered; the filtrate was concentrated under vacuum and purified again by size exclusion chromatography (same conditions). The yield of L2−G1−suc−deg−Ter was 57%. ^{1}H NMR (d_4-MeOD): 0.89 (6H, t, J = 6.8, 2 × CH_3, L), 2.11−1.20 (60H, m, (−Bu^t, Ter), 2 × (10 × $-CH_2-$, L)), ($NCH_2CH_2CH_2$, 2 × $CHCH_2CH_2N$, and $NCH_2CH_2CH_2CH$, Ter)), 2.46−2.22 (24H, 24, c-G1), 3.78−2.48 (91H, 4 m, a-G1, (2 × $CHCH_2CH_2N$, Ter), ($CHCH_2CH_2N$, Ter), (CO−CH_2−CH_2−CO, suc), b-G1, f-G1, e-G1, ($NCH_2CH_2CH_2$, Ter), ($COOCH_2CH_2OCH_2CH_2O$−, deg)), 4.32−3.92 (8H, (2 × CH_2−O, L), ($COOCH_2CH_2OCH_2CH_2O$−, deg)), 5.76−5.66 (1H, t, J = 6.7, CH−O), 7.55−7.05 (14H, m, Ar). ^{13}C NMR (d_4-MeOD): 14.1 (2 × $-CH_3$, L), 22.8 ($NCH_2CH_2CH_2$), 23.4 (2 × $-CH_2-$, L), 26.6 (2 × $CHCH_2CH_2N$), 29.9 (CH_2COO), 30.1 (CH_2COO), 30.4 (14 × $-CH_2-$, L), 31.4 (3 × CH_3), 32.7 (2 × $-CH_2-$, L), 34.3 (12 × c-G1), 35.4 ($NCH_2CH_2CH_2CH$), 38.2 (8 × f-G1), 41.4 (12 × e-G1), 44.8 (−$C(CH_3)_3$), 50.7 (12 × b-G1), 51.8 (2 × $CHCH_2CH_2N$), 53.0 (6 × a-G1), 54.7 ($CHCH_2CH_2N$), 58.0 ($NCH_2CH_2CH_2$), 61.8 (2 × $-CH_2-$, L), 64.7 ($COOCH_2CH_2OCH_2CH_2O$−), 65.6 ($COOCH_2CH_2OCH_2CH_2O$−), 69.6 ($COOCH_2CH_2OCH_2CH_2O$−), 70.1 $COOCH_2-CH_2OCH_2CH_2O$−), 76.8 (CH−O), 79.9 (C−OH), 126.0 (2 × CH, Ar), 126.8 (4 × CH, Ar), 126.9 (2 × CH, Ar), 128.5 (2 × CH, Ar), 128.8 (4 × CH, Ar), 135.0 (C, Ar), 138.1 (C, Ar), 147.5 (2 × C, Ar), 156.6 (3 × OCONH−), 174.4 (2 × COO), 174.8 (CONH, 12 × d-G1).

Determination of Partition Coefficients. The apparent partition coefficients (P_{app}) of terfenadine and conjugates between 1-octanol and phosphate buffer (pH 7.4) were determined at 37 °C. Before use, the 1-octanol was saturated with phosphate buffer for 24 h by vigorous stirring. A known concentration of compound in phosphate buffer (pH 7.4, 5 mL) was shaken for 72 h with 1-octanol (5 mL) to achieve equilibrium, and the phases were separated by centrifugation at 9000*g* for 5 min. All experiments were performed in triplicate. The concentrations of the compounds in the buffer phase before and after partitioning were determined by HPLC.

Lactate Dehydrogenase (LDH) Leakage Assay (Cytotoxicity Studies). Human Caucasian colon adenocarcinoma cells (Caco-2) (passage 101−105) were seeded at 10 000 cells/well in 96-well plates and maintained at 37 °C in an atmosphere of 5% CO_2 and 95% relative humidity in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 1% foetal bovine serum, 1% nonessential amino acids, 50 IU/mL penicillin, and 50 mg/mL streptomycin. After 24 h the medium was removed and the cells were washed in phosphate-buffered saline. Hanks Balanced Salt Solution (HBSS, 200 μL) containing G1 PAMAM dendrimer, conjugates, or third-generation (G3) PAMAM dendrimer at concentrations of up to 1 mM was added to Caco-2 cells. Caco-2 cells were also treated with blank HBSS and 1% Triton X-100 as negative and positive controls, respectively. After 3 h of incubation at 37 °C, 100 μL/well supernatant was removed carefully and transferred into corresponding wells of an optically clear 96-well flat bottom microplate.

Scheme 1. Synthesis of G1−suc−Ter

LDH leakage in the compartment was quantified using an LDH assay kit following the manufacturer's specifications.

Transport Studies of Ter, Ter−suc, Ter−suc−deg, and G1 PAMAM Dendrimer Conjugates. Caco-2 cells (passage 104−112) were seeded onto polycarbonate filters (pore size 3.0 μm) at a density of 1.2×10^5 cells/cm^2. Cells were grown at 37 °C in an atmosphere of 5% CO_2 and 95% relative humidity in DMEM supplemented with 10% foetal bovine serum, 1% nonessential amino acids, 50 IU/mL penicillin, and 50 mg/mL streptomycin. The medium was changed every other day for 21−22 days. The integrity of each batch of cells was tested by measuring the TEER using a voltohmmeter (EVOM, World Precision Instruments, Sarasota, FL) before and after the experiments. Before the experiments, cells were equilibrated with HBSS for 20 min at 37 °C and the TEER was determined. The TEER value, corrected for the blank filter resistance, was in the range 800−1000 Ω cm^2. Only confluent monolayers were used for the transepithelial transport studies. Transport was determined in both A → B and B → A directions. The transport medium (TM) was HBSS with *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES, 25 mM) and placed in the donor and receiver compartments. Terfenadine, terfenadine prodrugs (each equivalent to 50 μM of terfenadine), or a mixture of G1 and terfenadine (50 μM each) was placed in the donor compartment, and cells were incubated in a humidified atmosphere at 37 °C. TEER was measured every 30 min during the experiment; samples (50 μL) were removed from the receiver compartment at time zero and after 60, 120, and 180 min and from the donor compartment after 180 min. The samples were analyzed by HPLC. The apparent permeability coefficient (P_{app}) was calculated from

$$P_{app} = dQ/dt \times (V/AC_o)\ (\text{cm s}^{-1})$$

where dQ/dt is the change in the donor concentration over time (mol L^{-1} s^{-1}), V is the volume in the reservoir in the receiver side (cm^3), C_o is the initial concentration in the donor compartment (mol L^{-1}), and A is the surface area of the membrane (cm^2).

RESULTS AND DISCUSSION

Synthesis and Characterization of Dendrimer−Ter Conjugates. A prodrug consisting of four components, the dendrimer, the drug, the spacer, and the permeability enhancer group, was synthesized. G1 dendrimer-based prodrugs of terfenadine with a succinyl linker (single ester linker, G1−suc−Ter) and succinic−diethylene glycol linker (double ester linker, G1−suc−deg−Ter) were evaluated in vitro as drug carriers.

G1−suc−Ter. Terfenadine was linked by its secondary hydroxyl (butan-1-ol) group with succinic anhydride (Scheme 1). The resulting product Ter−suc was characterized by ^{1}H NMR, ^{13}C NMR, and mass spectroscopy. Successful formation

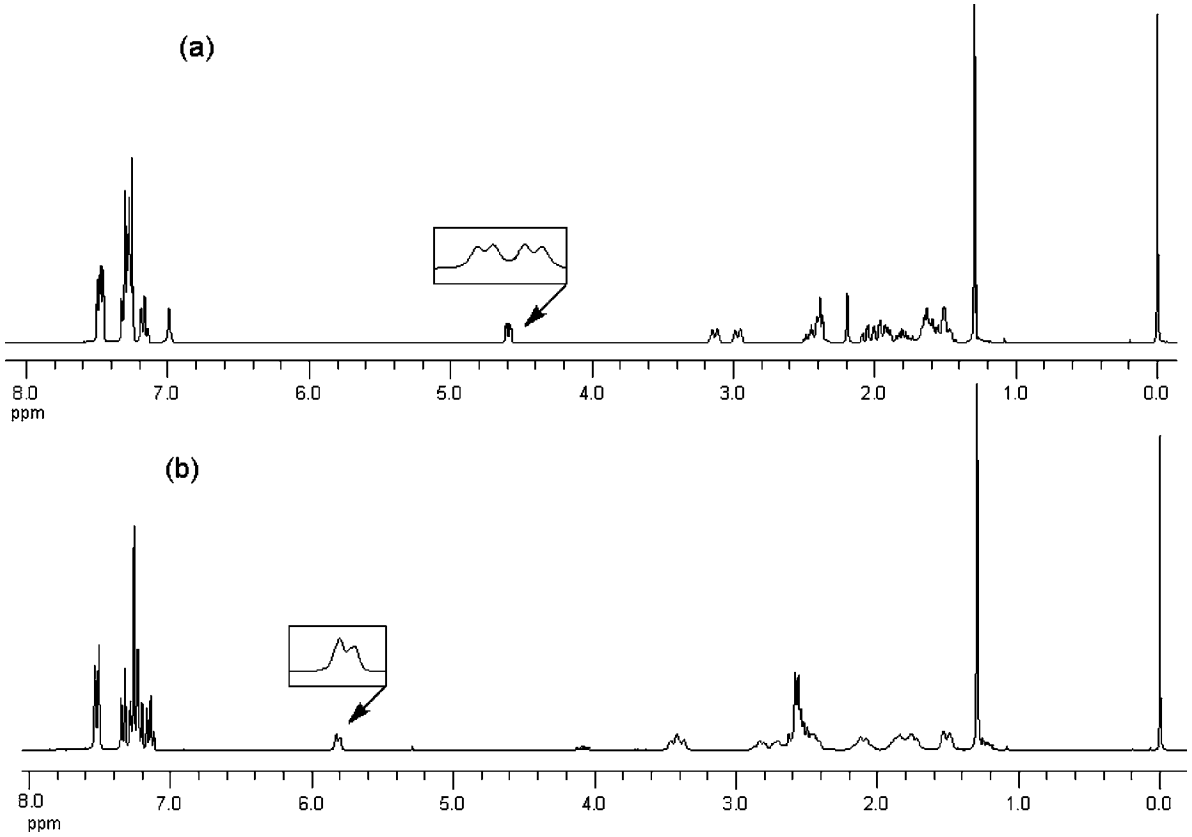


Figure 2. ^{1}H NMR spectra (300 MHz) of (a) terfenadine ($CDCl_3$) and (b) Ter−suc ($CDCl_3$).

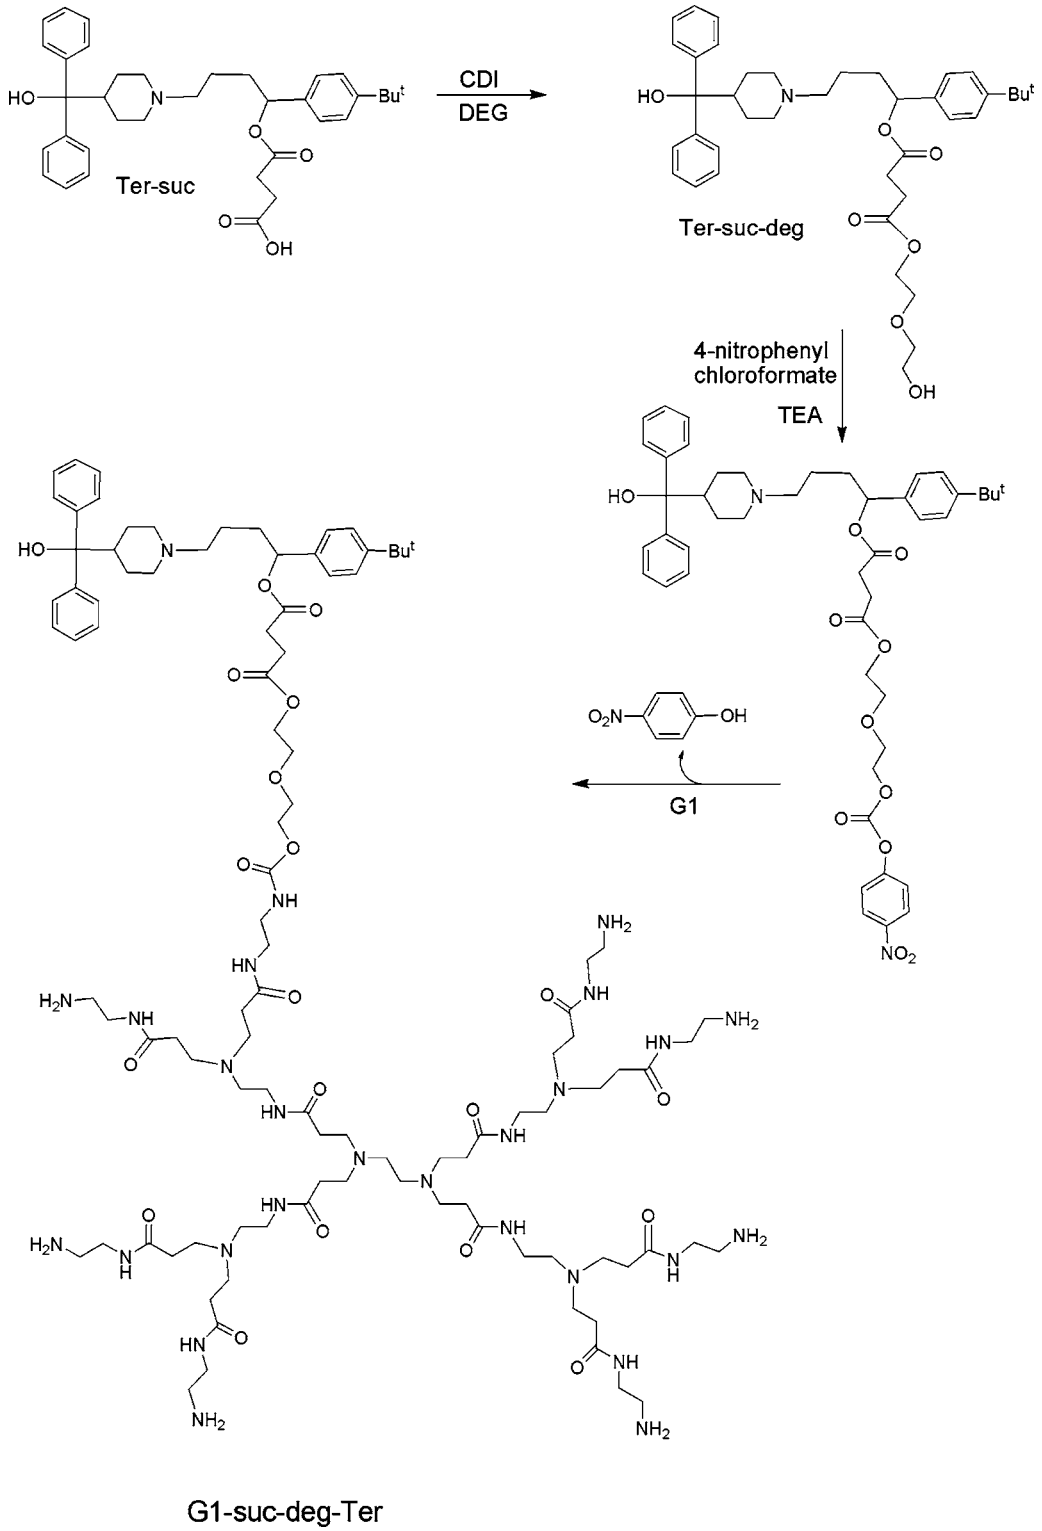
of the ester bond between the secondary hydroxyl group of terfenadine and the carboxyl group of succinyl linker was demonstrated by a downfield shift in the ^{1}H NMR chemical shift of the methine group (CH−O) from 4.60 ppm in terfenadine to 5.81 ppm in Ter−suc (Figure 2). Accurate mass spectrometry confirmed that only one succinyl group was attached to terfenadine via the secondary hydroxyl group and that the tertiary hydroxyl diphenyl group ($Ph_2C(OH)$−) remained free. The carboxyl group of the succinyl linker was utilized to conjugate Ter−suc to a surface amine group of the G1 dendrimer using the active ester method involving NHS (Scheme 1) as this method of dendrimer conjugation was found to be more efficient than direct condensation using coupling agents such as CDI (*18*). In order to obtain an approximately 1:1 ratio of dendrimer and terfenadine, Ter−suc or Ter−suc−deg was added to the reaction in quantities slightly higher than the equimolar ratio to dendrimer.

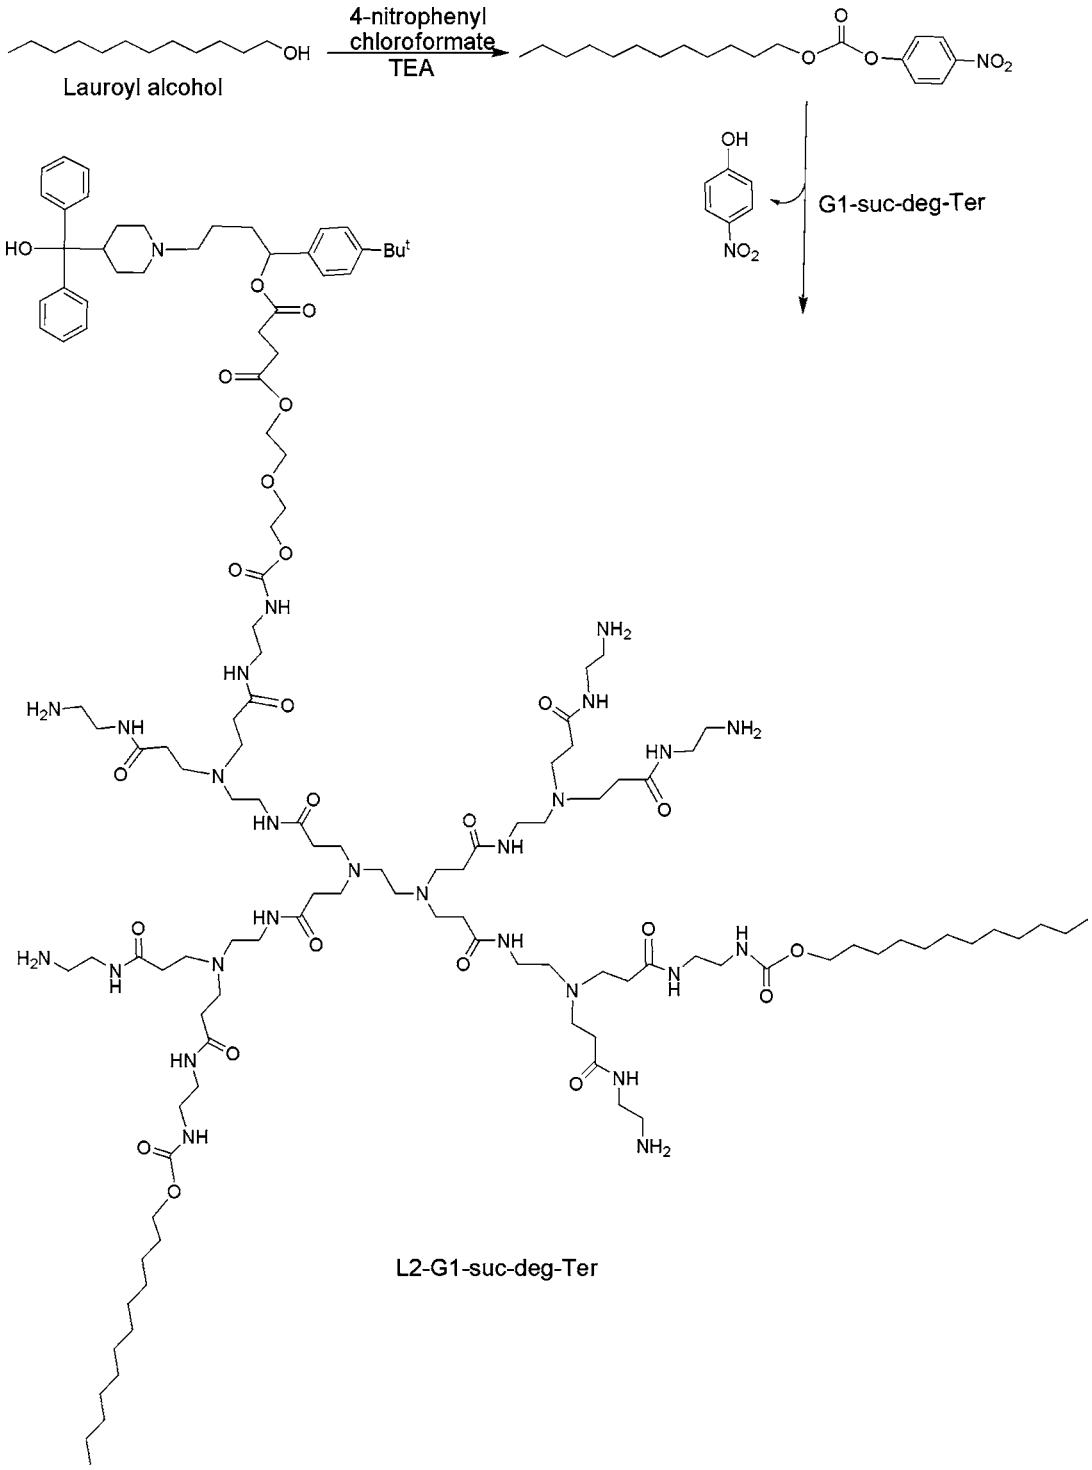


G1−suc−deg−Ter. Synthesis of Ter−suc−deg was performed by condensing diethylene glycol to the carboxyl of the succinic linker using CDI as coupling agent (Scheme 2). Adding diethylene glycol to Ter−suc changed its physical state from a solid to an oil without any noticeable enhancement in the water solubility. Ter−suc−deg (Scheme 2) and lauroyl alcohol (Scheme 3) were attached to the primary amines of G1 dendrimer using the 4-nitrophenyl chloroformate activation method.

Dendrimer conjugates were purified by size exclusion chromatography, solubilization in water (as terfenadine and lauroyl alcohol are insoluble in water), and dialysis (M_W cutoff = 1000 Da) for 48 h. The resulting conjugates were characterized by ^{1}H and ^{13}C NMR spectroscopy and RP-HPLC. As shown in Figure 3, the RP-HPLC chromatograms of the conjugates confirm that the drug is covalently bound to G1 PAMAM dendrimers; no traces of the free drug or drug linker were detected. The drug payloads in the conjugates were estimated using the relative intensities of the peaks in the ^{1}H NMR spectrum originating from attached compound compared to those of dendrimer (Table 1). In the ^{13}C NMR spectrum, the covalent bond between the succinyl linker and dendrimer was confirmed by the appearance of a new amide carbonyl peak at 175.7 ppm (CONH, Suc) for G1−suc−Ter. Similarly, the carbamate bond between diethylene glycol linker and/or lauroyl chain and G1 were represented by carbamate carbonyl peaks at 156.6 ppm for G1−suc−deg−Ter and L2−G1−suc−deg−Ter.

Partition Coefficients of Dendrimer Conjugates. Terfenadine, as an insoluble drug (*19*, *20*), is attached to the surface of a highly water-soluble dendrimer. Determination of solubility would require the synthesis of large amounts of the conjugates; therefore, the apparent partition coefficients (K_{app}) of terfenadine and conjugates between 1-octanol and phosphate buffer (pH 7.4) were determined as a parameter reflecting the change in the lipophilicity of terfenadine after attaching to G1 PAMAM dendrimer. Table 2 shows a significant decrease in the lipophilicity of terfenadine following its conjugation to the highly water-soluble G1 PAMAM dendrimer. L2−G1−suc−deg−Ter shows the highest lipophilicity among the G1−terfenadine conjugates (but lipophilicity is still significantly lower than that of terfenadine) as a result of the presence of two lipophilic lauroyl chains on the surface of the G1 PAMAM dendrimer.

Effect of PAMAM Dendrimer Prodrugs on Caco-2 Cell Viability (LDH Assay). The influence of PAMAM dendrimer prodrugs on the viability of Caco-2 cells was determined using the LDH assay. LDH, a cytosolic enzyme, has been found to leak into the culture medium upon damage to cell membranes (*21*). As shown in Figure 4, G1 PAMAM dendrimer was relatively nontoxic to Caco-2 cells, with less than 10% cytotoxicity at concentrations of 1 mM after 180 min incubation. A comparison between the IC_{50} of G1 and that of G3 PAMAM dendrimer shows that G1 is significantly less toxic than G3 (Table 3). This result is in agreement with previous observations which showed that the cytotoxicity of PAMAM dendrimers was concentration, generation, and charge dependent (*7*, *9*). Attach-



Scheme 2. Synthesis of G1−suc−deg−Ter

ing terfenadine via a linker to the G1 PAMAM dendrimer decreased the viability of Caco-2 cells as indicated by IC_{50} results (Table 3). G1 dendrimer−terfenadine conjugates showed concentration-dependent toxicity with a leakage of approximately 100% LDH for concentrations of 1 mM (Figure 4). These results are explained by the high toxicity of terfenadine, which has been reported to be both time and dose dependent as indicated by leakage of LDH from rat myocardial cells *(in vitro)* (*22*). However, G1 dendrimer−terfenadine conjugates were nontoxic toward Caco-2 cells at the concentration used in the transport study (50 μM).

Transport Studies of Ter, Ter−suc, Ter−suc−deg, and G1 PAMAM Dendrimer Conjugates Across Caco-2 Monolayers. The transport of terfenadine and prodrugs across Caco-2 monolayers was investigated in the A → B and B → A directions at nontoxic concentrations (as determined by the LDH assay). The stability of Ter−dendrimer conjugates was evaluated at pH 1.2, 7.4, and 8.5. After 24 h of incubation, the conjugates remained intact and no traces of drug were detected using HPLC (data not shown). Following transport studies, no free drug was detected in the receiver compartment.

Scheme 3. Synthesis of L2−G1−suc−deg−Ter

The apparent permeability coefficient (P_{app}) of terfenadine and prodrugs in both directions at 3 h is shown in Figure 5. Terfenadine, known as a strong substrate for the intestinal P-gp efflux transporter, showed B → A P_{app} significantly greater than A → B P_{app}, confirming previous reports showing the transport profile of terfenadine across Caco-2 monolayers (*23*). No significant difference can be observed on the permeability of terfenadine after attaching succinyl or succinic−diethylene glycol chains as shown in Figure 5 for Ter−suc or Ter−suc−deg. This suggests that attaching a linker to terfenadine had no impact on the permeability of the resulting prodrug.

In the presence of G1 there was no change in the transport profile of terfenadine in both directions (Figure 5). However, the permeability of G1−suc−Ter and G1−suc−deg−Ter across Caco-2 monolayers, especially in the A → B direction, was significantly higher than that of terfenadine, suggesting the ability of G1 dendrimer conjugates to bypass the P-gp efflux transporter. These results are in agreement with a previous report showing that propranolol (P-gp substrate) conjugated to G3 PAMAM dendrimer was also able to bypass the P-gp efflux system in Caco-2 monolayers (*17*). In the present study, terfenadine, an unambiguous, stronger P-gp substrate (*12*), was attached to G1 PAMAM dendrimer, a less toxic dendrimer than G3 PAMAM (*9*), via a linker/spacer. In addition, the A → B permeability of G1 PAMAM dendrimers was found to be several-fold higher than the A → B permeability of higher generations (G3 and G4) (*9*).

G3	0.25 ± 0.09

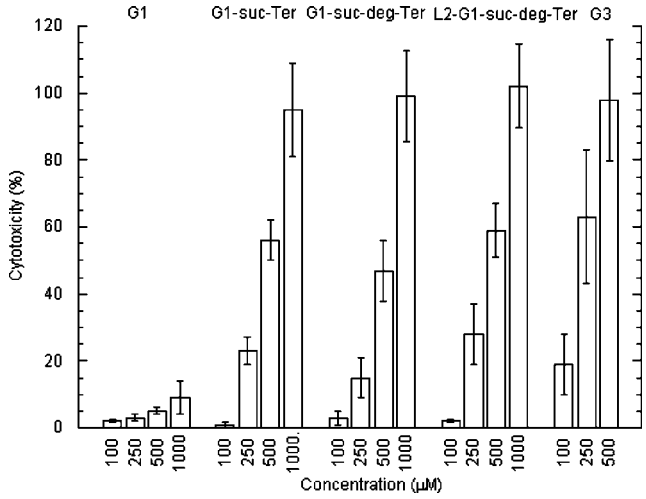

Figure 4. Effect of G1 PAMAM dendrimer, G1−terfenadine conjugates, and G3 PAMAM dendrimer on the viability of Caco-2 cells (LDH assay) (mean ± SD, $n = 4$).

The high permeability of G1 PAMAM−terfenadine conjugates may be attributed to the positively charged amine groups of the G1 PAMAM dendrimers. It has been reported that positively charged molecules permeate at a higher rate across Caco-2 monolayers compared to neutral or anionic molecules because of the favorable electrostatic interaction with the negatively charged epithelial surfaces (*24*). In addition, Jevprasesphant and co-workers found that the permeability of positively charged PAMAM dendrimers was higher than that of anionic PAMAM dendrimers (*7*). The apparent lack of impact of the G1 dendrimer on the transport profile of terfenadine may be a consequence of the transcellular rather than paracellular transport of terfenadine; G3 dendrimer was reported to enhance paracellular transport by opening up the tight junctions (*7*). Moreover, the significant increase in the permeability of terfenadine was only shown when terfenadine was covalently bound to G1 PAMAM dendrimers. It is proposed that G1 PAMAM dendrimer enhances the permeability of the conjugated drug by acting as an efficient carrier across the cellular membrane rather than influencing the transport mechanism of the drug. This suggestion is confirmed by reports showing that PAMAM dendrimers are neither P-gp inhibitors nor P-gp substrates (*8, 17*).

Lauroyl alcohol, known to function as a permeability enhancer (*25*), was used as a surface modifier of G1 PAMAM dendrimers to enhance the permeability of the resulting conjugates. Surface-modified dendrimers with medium chain fatty acids were also found to be significantly less cytotoxic and exhibited enhanced permeation through Caco-2 monolayers (*7*). Two lauroyl chains were attached to the surface amine group of G1−suc−deg−Ter to give the conjugate L2−G1−suc−deg−Ter. This conjugate showed the highest permeability in both directions across Caco-2 cell monolayers of all the G1 conjugates of this study with an A → B permeability over 25-fold higher than that of terfenadine alone.

Transepithelial electrical resistance (TEER) measurements were used to assess the influence of G1−terfenadine conjugates on the integrity of Caco-2 monolayers. TEER values were measured following apical incubation with Ter, Ter−suc, Ter−

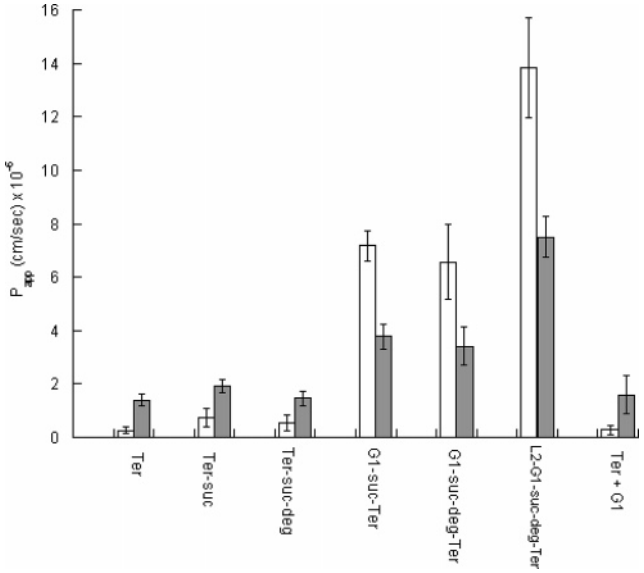

Figure 5. A → B (□) and B → A (■) permeability after 3 h across Caco-2 cell monolayers at 37 °C of free terfenadine, conjugates, and terfenadine in the presence of G1 PAMAM dendrimer (mean ± SD, $n = 4$).

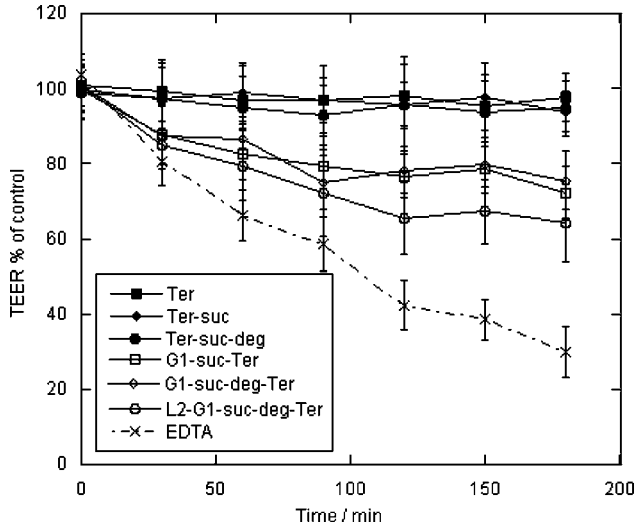

Figure 6. Effect of terfenadine and terfenadine prodrugs (each equivalent to 50 μM terfenadine) and EDTA (1 mM) on the TEER of Caco-2 cell monolayers after apical incubation (mean ± SD, $n = 4$).

suc−deg, and G1 PAMAM dendrimer conjugates (each equivalent to 50 μM of Ter) and EDTA (1 mM). EDTA (anionic permeation enhancer) was used as a positive control, modulating the tight junction by chelating the extracellular Ca^{2+} and Mg^{2+} ions required to maintain the integrity of tight junctions (*26*). Figure 6 shows that EDTA decreased the TEER values by approximately 65% compared to the control (HBSS with 25 mM HEPES) after 3 h of incubation. Ter, Ter−suc, and Ter−suc−deg had no significant impact on TEER values, which may suggest transcellular transport for these compounds. However, TEER values decreased by approximately 25% when exposed to G1−suc−Ter and G1−suc−deg−Ter and by approximately 35% for L2−G1−suc−deg−Ter. This suggests that the enhancement of permeability may be partly due to modulation of the tight junction. A previous report showed that transport of propranolol was increased when conjugated to lauroyl-modified G3 PAMAM and that this increase might involve endocytosis-mediated transport (*17*). However, as no significant differences were observed between the TEER values for L2−G1−suc−deg−Ter and other G1 conjugates, it is unlikely that the observed increase in the permeability of L2−G1−suc−deg−Ter (Figure 6) results from dilation of tight junctions, which suggests that transport of L2−G1−suc−deg−Ter may also involve a transcellular pathway. Previous work has demonstrated that transepithelial transport of dendrimer conjugates involves both paracellular and transcellular pathways (*6*).

CONCLUSIONS

The design, synthesis, characterization, and transport studies of terfenadine conjugates of G1 PAMAM dendrimer using biodegradable spacer/linkers are reported. Partition coefficient results indicate that the G1−terfenadine conjugates were significantly more hydrophilic than the parent drug. Cytotoxicity studies showed that G1 PAMAM dendrimer was only slightly toxic to Caco-2 monolayers with a significantly lower toxicity than that of G3 PAMAM dendrimer. The presence of G1 PAMAM dendrimer in the transport medium had no impact on the transport profile of terfenadine, but attaching terfenadine to the surface of G1 PAMAM dendrimers via a covalent bond significantly increased its A → B permeability across Caco-2 cell monolayers. A more pronounced increase of A → B terfenadine permeability was reported when lauroyl-modified dendrimer prodrug was used as a carrier. The transport mechanism of G1−terfenadine conjugates is thought to involve both transcellular and paracellular pathways. Our results suggest that G1 PAMAM dendrimers demonstrate potential as nanocarriers for enhancement of oral bioavailability of terfenadine as a model for low-solubility drugs that are P-glycoprotein substrates.

ACKNOWLEDGMENT

We thank Dr. Jeff Penny for use of Caco-2 cell facilities and Al-Baath University for financial support.

Improvement of a Recombinant Anti-Monkey Anti-CD3 Diphtheria Toxin Based Immunotoxin by Yeast Display Affinity Maturation of the scFv

Zhirui Wang, Geun-Bae Kim,† Jung-Hee Woo,‡ Yuan Yi Liu, Askale Mathias, Scott Stavrou, and David M. Neville, Jr.*

Section on Biophysical Chemistry, Laboratory of Molecular Biology, National Institute of Mental Health, Building 10 Rm 3D46, 10 Center Drive, Bethesda, Maryland 20892-1216. Received November 2, 2006; Revised Manuscript Received December 28, 2006

Recently, a bivalent recombinant anti-human CD3 diphtheria toxin (DT) based immunotoxin derived from the scFv of UCHT1 antibody has been made that shows enhanced bioactivity and is free from the side effects of Fc receptor interaction. In this case, the diminution of CD3 binding due to the placement of the scFv domain at the C-terminus of the truncated DT in single scFv immunotoxins was compensated by adding an additional scFv domain. However, this strategy was less successful for constructing an anti-rhesus recombinant immunotoxin derived from the scFv of FN18 antibody due to poor binding of the anti-rhesus bivalent immunotoxin. We report here that, by increasing the FN18 scFv affinity through random mutagenesis and selection with a dye-labeled monkey CD3$\epsilon\gamma$ recombinant heterodimer, we greatly improved the bioactivity of FN18 derived immunotoxin. The best mutant, C207, contained nine mutations, two of which were located in CDRs that changed the charge from negative to positive. Binding affinity of the C207 scFv to the monkey T cell line HSC-F increased 9.8-fold. The potency of the C207 bivalent immunotoxin assayed by inhibition of protein synthesis increased by 238-fold.

INTRODUCTION

Anti-CD3 immunotoxins induce profound but transient T cell depletion in vivo by inhibiting eukaryotic protein synthesis, and they have utility in nonhuman primate models of transplantation tolerance and autoimmune disease therapy. The chemically conjugated anti-human immunotoxin, UCHT1−CRM9, depleted 3 logs of xenografted human T leukemic cells in nude mice resulting in long-term regressions of 86% of the tumors in an animal model of T cell leukemia/lymphoma (*1*). The chemically conjugated anti-monkey immunotoxin, FN18−CRM9, depleted 1.5−2.0 logs of T cells from the lymph node compartment and markedly prolonged the survival of kidney allografts (*2*, *3*). In combination with a short-term course of deoxyspergualin, FN18−CRM9 produced long-term tolerance to pancreatic islet allografts in 3 out of 7 recipients (functioning graft survival over 5 years) (*4*). An anti-porcine anti-T cell conjugate was effective in maintaining long-term hematopoietic stem cell transplants in the absence of graft versus host disease (*5*). These conjugated immunotoxins were formed by chemically cross-linking the antibody or antibody fragment to a diphtheria toxin binding site mutant, CRM9. In this way, the binding site of the immunotoxin was dictated by the antibody moiety (*6*). Analysis of these 1:1 conjugates by SDS[1] reducing gels revealed that all of the possible linkages between the toxin A and B chains and the antibody heavy and light chains were formed, even though the average link per molecule was maintained at one. Although immunoglobulin receptor interactions could be eliminated by conjugation with $F(ab')_2$[2] antibody fragments, purified yields were low (2% of toxin input) and linkage heterogeneity remained.

In order to overcome the disadvantages of chemically conjugated immunotoxins, recombinant anti-human anti-T cell immunotoxins were developed. These immunotoxins, utilizing diphtheria toxin truncated at amino acid residue 390, were restricted to having the antibody moiety placed C-terminal to the truncated toxin, because antibody domains fused to the N-terminal of the toxin interfered with translocation of biologically active A chain (*7*, *8*). However, it was found that when the scFv of UCHT1 was fused to the C-terminus of DT390 its binding activity toward T cells was reduced by a factor of 0.033 compared to the free scFv. Since the monovalent scFv was reduced in binding by a factor of 0.3 compared to the parental divalent antibody, the overall binding reduction of this fusion immunotoxin was 0.01 compared to the parental antibody. By adding a second scFv moiety separated through a $(G_4S)_3$ linker, a 10-fold increase in binding activity was achieved compared

to monovalent fusion immunotoxin. This fusion immunotoxin, A-dmDT390biscFv(UCHT1), displayed an increase in potency of 10- to 30-fold compared to the chemically conjugated immunotoxin and depleted 2.4 logs of T cells in the lymph node compartment of transgenic mice expressing human CD3ϵ (*9*). The increase in potency of the fusion immunotoxins over the chemical conjugate normalized for equal cell binding was ascribed to an increase in the efficiency of postbinding processes within the intoxication pathway (*10*). The in vivo potency of the divalent fusion immunotoxin, A-dmDT390biscFv(UCHT1), was considered acceptable for clinical development. The expression and purification of this immunotoxin from *P. pastoris* under GMP compliant conditions has been described (*11*, *12*). Currently, gram quantities have been produced and are undergoing testing for an IND (investigational new drug) submission for the treatment of refractory human T cell leukemia (*36*).

This paper describes the steps used to develop a monkey analogue of the recombinant anti-T cell immunotoxin being readied for clinical trials. A monkey analogue is needed to explore preclinical immune tolerance protocols using a fusion immunotoxin that has similar potency, similar serum half-lives, and biodistribution as the clinical reagent. Preliminary evidence indicated that the scFv of the anti-monkey T cell antibody FN18 was even more sensitive than UCHT1 to positional affects of a neighboring DT390 domain, resulting in a much greater loss in affinity (*13*). We reasoned that increasing the affinity of FN18-scFv would compensate for the loss in affinity of recombinant immunotoxins and consequently increase their bioactivity. Therefore, we endeavored to affinity mature the scFv of FN18 through random mutagenesis and selection by sorting flow cytometry using dye-labeled CD3$\epsilon\gamma$ ectodomain heterodimers, and techniques developed by Boder and Wittrup (*14*). Here, we report the selection of scFv(FN18) mutants with increased binding affinity and the bioactivities of recombinant immunotoxins made with the highest affinity mutants. In additionally, we compare binding data of scFv(UCHT1) and biscFv(UCHT1) to those of the mutant scFv(FN18) and mutant biscFv(FN18) to illustrate differences in the divalent character of biscFvs made from FN18 versus UCHT1.

EXPERIMENTAL PROCEDURES

Plasmids, Bacterial and Yeast Strains, Antibodies, Cell Lines. *Pichia pastoris* strain GS115, plasmids pPICZα and pPIC9K, *Saccharomyces cerevisiae* strain EBY100, and anti-V5 monoclonal antibody were purchased from Invitrogen. Plasmids pET17b and pET27b and *E. coli* BL21 (DE3) pLysS were purchased from Novagen. Goat anti-mouse IgG2a antibody conjugated with PE /FITC was purchased from Caltag. Streptavidin Alexa Fluor-488 conjugate and streptavidin-FITC was from Molecular Probes. Goat anti-mouse IgG-HRP was purchased from Santa Cruz Biotechnology and used to detect the expression of FN18 scFv in *E. coli* BL21 (DE3) pLysS. The hybridoma secreting FN18 was kindly provided by Dr. Margreet Jonker, Biomedical Primate Research Center Rijswijk, and was produced and purified by the National Cell Culture Center, Minneapolis, MN. Chemically conjugated anti-monkey anti-CD3 immunotoxin, FN18−CRM9, was prepared as previously described (*15*). Biocytin-labeled monkey cyno/rhesus CD3$\epsilon\gamma$ ectodomain heterodimer ligand with alanine or valine at amino acid residue 35 of CD3ϵ was prepared as described by Wang and Neville (*16*). The Herpes Saimiri virus transformed cynomolgous cell T cell line HSC−F (*17*) was supplied by the Centralized Facility for AIDS Reagents supported by EU Programme EVA and the U.K. Medical Research Council. This cell line exhibits the moderate binding FN18 phenotype (*37*). The Herpes Saimiri transformed rhesus cell T cell line Mm357−2 was supplied by the NIH Nonhuman Primate Reagent Resource, Beth Israel Deaconess Medical Center, Boston MA. This cell line exhibits the high binding FN18 phenotype (*37*).

Codon Optimization of scFv(FN18) and Construction of biscFv(FN18). Footnote 2 details the protein domain structure of the recombinant monovalent and bivalent single chain antibody fragments scFv, and biscFv and the diphtheria toxin based immunotoxins derived from these single chain antibodies.

Our lab reported that codon optimization is necessary to express DT390-based immunotoxins in *Pichia pastoris* (*18*). We used the optimized DT390 nucleotide sequence described by Woo et al. (*18*) for the DT390 domain of the new anti-monkey immunotoxins. The initial anti-monkey immunotoxin A-dmDT390biscFv(FN18) was constructed from the scFv of FN18 following the strategy used to construct A-dmDT390biscFv-(UCHT1) in *P. pastoris* (*18*). A-dmDT390biscFv(FN18) was cloned into pnPICZα (*Xho*I-*Eco*RI), subcloned into pPIC9K (*Sac*I-*Eco*RI), which was used to transform *P. pastoris* strain GS115. Low yields (see results) prompted us to rebuild the new scFv(FN18) DNA using the *P. pastoris* preferred codons (*19*). Eight primers for VL and 10 primers for VH of scFv(FN18) were designed to cover the full length of scFv(FN18). The primer length was kept under 70 bases. There was about a 21 base overlap between any of the neighboring primers. Ten picomoles of the first and the last primers and 2 pmol of the rest of the primers were used. The PCR program was, after heating at 95 °C for 4 min, 25 cycles of 95 °C for 30 s, 55 °C for 30 s, 72 °C for 1 min, and then extension for another 10 min. The PCR products were checked with 1% agarose gel electrophoresis. The band with the correct size was cut out and extracted with the QIAquick Gel Extraction Kit. The VL PCR product was digested with *Bam*HI and the VH PCR product with *Bgl*II. Then, the VL part and VH part were ligated together with T4 ligase for 6 h. PCR amplification was done with the first primer (VL1a) of the VL carrying *Nco*I site at the 5′ end and the last primer of the VH (VH10b) carrying the *Eco*RI site at the 3′ end to get the full length of scFv(FN18). The PCR product was checked again with 1% agarose gel electrophoresis. The band with the correct size (VL + VH) was cut out and extracted with the QIAquick Gel Extraction Kit. The PCR product was digested with both *Nco*I and *Eco*RI and cloned into pET17b-DT390 at *Nco*I-*Eco*RI for sequencing analysis and *E. coli* BL21 expression analysis. To construct the rebuilt biscFv(FN18), we amplified the first scFv(FN18) with primers VL1a carrying *Nco*I site and VH10a carrying *Bam*HI site. We amplified the second scFv(FN18) with VL1b carrying *Bgl*II site and VH10b carrying stop codon and *Eco*RI site. Then, we cloned the first scFv(FN18) into pET27b and the second scFv(FN18) into pET17b for sequencing analysis. Then, the first and second scFv(FN18) were subcloned together into pET17b-DT390 (*Nco*I-*Bam*HI/*Bgl*II-stop codon-*Eco*RI) and confirmed by *E. coli* BL21 expression analysis. The DT390-biscFv(FN18) was then subcloned into pnPICZα (*Xho*I-*Eco*RI) (*18*) and then subcloned into pPIC9K (*Sac*I-*Eco*RI). The rebuilt DT390-biscFv(FN18) in pPIC9K was transformed into *Pichia pastoris* GS115.

Random Mutagenesis. The optimized scFv(FN18) sequence insert described in the previous section was randomly mutated with error-prone PCR using nucleotide analogues (*20*) as described by Colby et al. (*21*). Briefly, 6 of 50 μL-PCR reactions were set up with different concentration (200, 20, and 2 μM; two reactions for each of the concentrations) of the two nucleotide analogues: 8-oxo-dGTP and dPTP (8-oxo-2′-deoxyguanosine-5′-triphosphate and 2′-deoxy-p-nucleoside-5′-triphosphate, respectively, both from TriLink Biotech). Other components of the PCR mix were as follows: 10× PCR buffer without $MgCl_2$, 2 mM of $MgCl_2$, 0.5 μM of forward primer PYD5 For (5′ CAG TTA CTT CGC TGT TTT TCA ATA TTT TCT GTT ATT GCT AGC 3′, *Nhe*I site underlined), 0.5 μM

of reverse primer PYD5 Rev (5′ ATC GAG ACC GAG GAG AGG GTT AGG GAT AGG CTT ACC GAA TTC 3′, *Eco*RI site underlined), 200 μM of dNTP, 0.1−1 ng of pYD5 DNA containing the codon optimized FN18-scFv DNA, 2.5 units of Taq polymerase, adding dH_2O to the final volume of 50 μL. The PCR program used was 94 °C for 3 min; then cycles of 94 °C for 45 s, 55 °C for 30 s, 72 °C for 1 min, and finally an extension for another 10 min. PCR cycles were different for varying concentration of the nucleotide analogues (200 μM for 5 cycles, 200 μM for 10 cycles, 20 μM for 10 cycles, 20 μM for 20 cycles, 2 μM for 10 cycles, 2 μM for 20 cycles). The mutagenic PCR products were purified from SYBR Gold (Molecular Probes) stained agarose gel (1%) with QIAquick Gel Extraction Kit. In order to clear the DNA of incorporated nucleotide analogues and to generate sufficient mutated DNA for the transformations, a second round of PCR reactions was performed in the absence of the nucleotide analogues. Six 50 μL reactions were set up for each PCR product from the previous mutagenic reactions. This time, the PCR mix contained 2 μL of the gel-purified mutagenized DNA, 10× PCR−$MgCl_2$ buffer, 1.5 mM of $MgCl_2$, 0.2 μM of forward primer (same as above), 0.2 μM of reverse primer (same as above), 200 μM of dNTP, and 5 units of platinum Taq polymerase, with dH_2O added to the final volume. The PCR program was 95 °C for 5 min, 30 cycles of 95 °C for 30 s, 55 °C for 30 s, 72 °C for 1 min, and extension for another 10 min at 72 °C. The PCR products were again gel-purified. This protocol produces 40−100 μg of PCR products.

Preparation of the FN18-scFv Yeast Display Library. pYD5 (*13*) was digested with both *Nhe*I and *Eco*RI and purified with the QIAquick Gel Extraction Kit as the linear vector. The inserts produced by PCR and the linear vector were cotransformed into yeast *Saccharomyces cerevisiae* EBY100 using the standard transformation procedure in the Gietz Lab Transformation kit (Genomics One International, Inc., Buffalo, NY) as described by the instructions. The inserts were flanked by ∼42 nucleotides homologous to the 5′ and 3′ ends of the open vector, thus permitting homologous combination between the open vector and the insert within the yeast (upstream from *Nhe*I in the aga2 signal peptide region and downstream from *Eco*RI in the V5 epitope region). Transformations utilizing homologous recombination are highly efficient in *S. cerevisiae* (*22*).

Library size (number of transformants) was determined by plating 0.1 μL, 1 μL, and 10 μL of the 1 mL of the resuspended transformed *Saccharomyces cerevisiae* EBY100 cells onto a 100 mm screening plate. Using 1 μg of the linear pYD5 vector DNA (*Nhe*I-*Eco*RI) and 10 μg of the mutagenized library insert DNA (PCR product) cotransformed into 1×10^8 yeast *Saccharomyces cerevisiae* EBY100 cells, we obtained about 1×10^6 transformants. Normally, ten reactions were done and pooled, yielding about 1×10^7 transformants.

Growth and Induction. The growth and induction phases were modified as described by Wang et al. (*13*). The yeast display medium contained 0.67% YNB (Q.Biogene, with ammonium sulfate, without amino acids), 2% glucose (or galactose), 0.5% casamino acids (DIFCO), adjusting pH to 6.0 with pH 6.0 sodium phosphate buffer, 20 μg/mL of ampicillin, 20 μg/mL of kanamycin, 100 units/mL penicillin, and 100 μg/mL streptomycin. For plates, 1.5% agar and 1 M sorbitol were added to the medium. In the growth phase, glucose was used as the carbon source at 30 °C for 24 h, and in the induction phase, galactose was used as the carbon source at 20 °C for 24 h.

FACS Analysis, Sorting, and Sequencing. FACS analysis of yeast displayed scFv and K_D determination were conducted using biocytin-labeled monkey cyno/rhesus CD3$\epsilon\gamma$ ectodomain heterodimer ligand as described by Wang et al. (*13*). The sorting for higher-affinity FN18 sFv displaying yeast cells was performed on an Epics Elite ESP cell sorter (Beckman Coulter). The number of yeast cells screened was set as a factor of 10 greater than the library size to ensure that no unique clones were overlooked. Yeast cells were stained with anti-V5 antibody (Invitrogen) and CD3$\epsilon\gamma$ biocytin labeled ligand at 4 °C for 1.5 to 2 h. The amount of V5 antibody used was 1 μL/10^6 cells, while the molar amount of CD3$\epsilon\gamma$ biocytin to be used was predetermined by analytical FACS analysis and average K_D measurement on the mixed clone population (usually 0.1−0.05 × K_D). Yeast samples were then washed twice at 5000 *g* for 5 min at 4 °C. Staining with secondary reagents was done for 1 h at 4 °C with goat anti-mouse IgG2a-PE (Caltag) 5 μL and streptavidin Alexa Fluor 488 (Molecular Probes) 2 μL/10^6 cells, respectively. Samples were then washed twice at 5000 *g* for 5 min at 4 °C. Screening was done with an equilibrium screen (*21*) utilizing bivariate plots of the stained V5 and CD3$\epsilon\gamma$ ligand. Cells were initially gated on the characteristic of their forward and side light scatter to avoid cellular clumps and debris. If in the sort sample a double-positive diagonal was observed, the sample was sorted with a diagonal edge to normalize for expression of the scFv. In cases where no double-positive diagonal was present, almost the entire dual positive quadrant was collected. The first rounds of sorting were given a generous sort gate anywhere from 1% to 4% utilizing the gated logic mode. The purity mode was used for the third and fourth rounds as gate stringency was increased, reaching 0.1%. Sorted events were collected in yeast growth medium (see Growth and Induction section). After each round of mutagenesis, we did four rounds of sorting. Then, random clones picked up from selection plates were propagated, induced, and analyzed by FACS for their binding affinities as previously described (*13*). The yeast mutant plasmid DNA was extracted with a Zymoprep Yeast Plasmid Minipreparation kit (Zymo Research, Orange, CA) from those clones with the highest affinity and then transformed into *E. coli*. After the amplification in *E. coli*, the plasmid DNA was sequenced to determine the mutation(s) in the scFv sequence or used as template DNA for the next round of mutagenesis. We repeated the process until we failed to generate any new higher-affinity mutants. In this study, we did three rounds of the mutagenesis. Site-directed mutagenesis was applied to combine some the higher-affinity mutations into a single plasmid clone using a QuickChange Site-Directed Mutagenesis Kit (Stratagene, La Jolla, CA).

Expression and Purification of Mutant Immunotoxins in *P. pastoris*. To make DT390-biscFv(FN18−M20) bivalent immunotoxin, the first scFv(FN18−M20) and second scFv-(FN18−M20) genes were amplified by PCR (template DNA, M20 yeast plasmid; primers for the first scFv, WP-051 and WP-053; primers for the second scFv, WP-054 and WP-052. All of the WP and GP primers are listed in Table 1). The first scFv PCR product was digested with *Nco*I and *Bam*HI, and the second scFv PCR product was digested with *Bam*HI and *Eco*RI. Then, the two fragments were inserted into *Nco*I and *Eco*RI sites of pET17b-DT390 (pJW1019). The DT390-biscFv(FN18−M20) gene was subcloned into *Xho*I and *Eco*RI sites of pnPICZα. The resulting plasmid (pJW1020) was transformed into *Pichia pastoris* JW107, and the transformants were selected on YPD plates containing zeocin (100 μg/mL). Six colonies were randomly selected and cultivated in test tubes containing 5 mL YPD at 28 °C at 250 rpm for 2 days. The cultures were induced with methanol for 1 day, and then the culture supernatants were analyzed on SDS-PAGE under nonreducing condition. One clone (JW132) was selected and cultivated in shake-flasks to purify DT390-biscFv(FN18−M20) by phenyl hydrophobic interaction chromatography and then Super Q anion exchange chromatography. Solid sodium sulfate was added to 595 mL of culture supernatant to a final concentration of 500 mM. The

[a] Restriction sites are underlined. Boldface indicates the DNA sequences used to anneal two primers.

sample was loaded onto 50 mL phenyl 650M (Tosoh) in a 5 cm × 30 cm × K50 column (Amersham Biosciences). The bound DT390-biscFv(FN18−M20) was eluted with TEG buffer containing 5% glycerol, 20 mM Tris−HCl, and 1 mM EDTA (pH 8.0). Pooled fractions containing DT390-biscFv(FN18−M20) were dialyzed 3 times against TE buffer. The dialyzed sample was loaded to 3.5 mL of Super Q 650M (Tosoh) in a 1.5 cm × 10 cm Flex column (Kontes Glass Company). The bound DT390-biscFv(FN18−M20) was eluted with 50 mM NaCl in TEG buffer.

To make DT390-biscFv(FN18−C207) bivalent immunotoxin, the first scFv(FN18−C207) and second scFv(FN18−C207) genes were amplified by PCR (template DNA, C207 yeast display plasmid; primers for the first scFv, GP-089 and WP-053; primers for the second scFv, GP-090 and WP-052). The first scFv PCR product was digested with *Nco*I and *Bam*HI, and the second scFv PCR product was digested with *Bam*HI and *Eco*RI. Then, the two scFv parts in the vector pJW1020 (DT390-biscFv(FN18−M20) in pnPICZα) were sequentially replaced with C207 counterparts using *Nco*I and *Bam*HI for the first scFv and *Bam*HI and *Eco*RI for the second scFv. Purification of DT390-biscFv(FN18−C207) was performed as described for DT390-biscFv(FN18−M20) except that the loading of the anion exchange column was performed at pH 9.0 instead of pH 8.0 and the protein was eluted with 50 mM sodium borate at pH 8.5. In addition, the DT390-biscFv(FN18−C207) immunotoxin was fractionated on Superdex-200 10/300 GL to remove lower molecular weight breakdown products. Purity of both immunotoxins was judged by SDS gel electrophoresis and HPLC size exclusion chromatography on Superdex-200 10/300 GL (Amersham Biosciences).

Expression and Purification of Wild-Type, Mutant scFvs and biscFvs. For the production of the following scFvs and biscFvs, the original α-factor signal sequence in the vector system was replaced with killer toxin (kt) signal peptide due to the incomplete cleavage in the Kex2 cleavage site between the α-factor signal sequence and the inserted protein sequences of interest. This cleavage can be variable, since it is influenced by the first two amino acid residues of the post-Kex2 insert (*13*). To obtain scFv(FN18-WT), the scFv(FN18-WT) gene was PCR-amplified from the scFv(FN18-WT) yeast display plasmid using the primers (GP-080 and WP-052). After the PCR product was purified by gel elution, it was used for the second PCR using the primers WP-075 and WP-052. Primer WP-075 contained the 5′-sequence of the signal sequence of killer toxin from *Kluyveromyces lactis*. After the second PCR, the product was digested with *Sfu*I and *Eco*RI and purified by gel elution, and the treated PCR fragment was cloned into pwPICZα, which now contained the killer toxin signal peptide. The scFv(FN18−M20) and scFv(FN18−C207) genes were obtained by the same procedure using different primer sets for the first PCR (WP-073 and WP-052 for M20; GP-102 and WP-052 for C207). To make biscFv(FN18−C207), the first scFv(FN18−C207) and second scFv(FN18−C207) genes were PCR-amplified from the C207 yeast display plasmid. The first scFv was obtained by the two-step PCR as described in the previous section (primers GP-102 and WP-053 for the first PCR; primers WP-075 and WP-053 for the second PCR) and the second scFv was PCR-amplified using the primers (GP-090 and WP-052). The first scFv PCR product was digested with *Sfu*I and *Eco*RI, purified by gel elution, and cloned into pwPICZα. This constructed vector was digested with *Bam*HI and *Eco*RI and ligated with the scFv PCR product treated with the same enzymes. Transformation, growth, and induction conditions were similar to those used for the immunotoxins with the exception of biscFv(FN18−C207) where a modified version of strain mutEF2JC307 was used (*23*, *36*). Protein L affinity chromatography was used to purify the scFv and biscFv constructs; 1.8 mL of 5 M NaCl was added to 58 mL of culture supernatant and then loaded to 4 mL of Protein L agarose (Pierce) in a 1.5 cm × 10 cm Flex column (Kontes Glass Company) that was equilibrated with 100 mM potassium phosphate buffer, 150 mM NaCl (pH 7.0). The bound scFv(FN18−M20) was eluted with 100 mM glycine buffer (pH 2.5). 100 μL of 1 M Tris−HCl buffer (pH 8.0) was added to the eluted fractions. The eluted fractions were pooled and concentrated using an Amicon Ultra-4 (10 000 MWCO, Millipore). Purity was judged by SDS gel electrophoresis and HPLC Superdex 200 10/300 GL gel filtration (Amersham Biosciences). Purity was above 95% in all cases. Concentration was determined from the calculated absorption coefficients based on the amino acid sequences located at http://researchlink.labvelocity.com/tools/conversionTools/proteinExtinction.jhtml.

Protein Synthesis Inhibition Assay. This was performed by measuring the incorporation of ^{3}H-labeled leucine into HSC−F cells after a 20 h exposure to immunotoxins at different concentrations. Means and standard deviations of six replicates were calculated and divided by the means of non-immunotoxin treated controls × 100 to give % control protein synthesis as previously described (*9*).

T Cell Binding Assay of Recombinant scFv Antibodies And Immunotoxins. FN18−FITC conjugate was purchased from Biosource and added to 250 000 HSC−F cells at 5×10^{-9} M in the presence of varying concentrations of scFv and immunotoxin binding competitors at 4 °C for 30 min. The displacement of FN18−FITC was measured by FACS on a Beckman-Coulter Cytomics FC 500 instrument after washing the cells two times at 400 *g* at 4 °C and resuspending in 0.5 mL of 1 × PBS containing 2.5 μg of propidium iodide to exclude dead cells from further analysis. Mean channel fluorescent values, MCI, were corrected (MCF′) by subtracting an appropriate FITC-labeled isotope control from both the FN18−FITC tracer and the FN18−FITC tracer plus competitor MCF values. The % inhibition was determined as $[(MCF'_{FN18-FITC} - MCF'_{FN18-FITC+competitor})/MCF'_{FN18-FITC}] \times 100$. The relative binding affinity between any two competitors was determined

by dividing their respective concentrations at equal % inhibition obtained from plots of % inhibition versus concentration as previously described (*9*).

Immunotoxin-Induced Loss of $CD3^+CD4^+$ Resting Monkey T Cells. T cells from normal monkeys were isolated from blood by two centrifugations through Lymphocyte Separation Medium from BioWhittaker following the manufacturer's directions. The cells were washed and incubated in RPMI 1640 medium containing 25 mM HEPES with 10% fetal calf serum + 2 g/L $NaHCO_3$, adjusted to pH 7.4, plus 0.1 mM nonessential amino acids, 1.0 mM sodium pyruvate, and 50 μg/L of gentamicin sulfate with and without varying concentrations of immunotoxins for 72 h at 5% CO_2, 37 °C. Cells were washed and then stained for 30 min at 4 °C with anti-CD3 (SP34−2-PE BD Pharmingen), anti-CD4-FITC (BD Pharmingen), CD20-PE Cy7 (BD Biosciences), and the vital dye 7-ADD (BD Pharmingen) and analyzed on a Beckman-Coulter Cytomics FC 500 instrument counting 10^4 events. Cells were analyzed for uptake of the vital dye, the percent of cells within the lymphocyte forward scatter/side scatter gate, and the percent of cells within the lymphocyte gate within the quadrant displaying the $CD3^+$ and $CD4^+$ epitopes by two-color FACS. The % of cells within the lymphocyte gate at each immunotoxin concentration was divided by % of cells within the lymphocyte gate for the 72 h no-treatment control (G1). The % of cells within the $CD3^+CD4^+$ quadrant at each immunotoxin concentration was divided by % of cells within the $CD3^+CD4^+$ quadrant for the 72 h no-treatment control (Q1). The % loss of $CD3^+CD4^+$ cells was calculated as G1 × Q1 × 100.

RESULTS

Higher Immunotoxin Expression with Codon-Optimized scFv(FN18). Before codon optimization of the biscFv(FN18) domain of DT390biscFv(FN18), expression in *P. pastoris* strain GS115 yielded shake-flask culture supernatants with a barely visible band at 96.3 kDa corresponding to the DT390biscFv-(FN18) by Coomassie staining of SDS gels. Five clones screened from 91 clones by dot blots for higher expression gave supernatant concentrations of 1.3 to 2.7 ng/μL by comparison with a known concentration standard of DT390biscFv(UCHT1) in SDS gels. After rebuilding, 5 out of 12 transformants in GS115 had supernatant concentrations equal to 11 ng/μL after 24 h of induction judged by SDS gels (gel data not shown). A four-step purification procedure utilized absorption to Thiophilic Resin (Clonetech) followed by elution according to manufacturer's directions, dialysis versus 20 M Tris−HCl, pH 7.0, application to DEAE Sepharose (Amersham) followed by a step elution with 0.5 M NaCl and finally application to a Zorbax GF-250 column (DuPont). The major peak ran as a single band when analyzed on HPLC with a Zorbax GF-250 column. Purity was estimated as 95% by HPLC size exclusion and SDS gels.

Higher-Binding Mutants Selected with CD3$\epsilon\gamma$ Ectodomain Heterodimer. When this work was begun (*16*), we were using the monkey CD3ϵ sequence reported by Uda et al. (*24*) for the selecting ligand in the CD3$\epsilon\gamma$ ectodomain heterodimer used in flow cytometry. We encountered very low binding for the wild-type (WT) displayed scFvs and the initial mutant scFvs (*13*). Subsequently, through consulting the rhesus genome data base and by sequencing the CD3ϵ ectodomain of 24 rhesus and cynomolgous monkeys, we determined that high FN18-binding monkeys have a valine at amino acid residue 35 of CD3ϵ. The presence of alanine at this position is a frequently occurring polymorphism that reduces FN18 binding even when present in the heterozygote state (*37*). In our recent work, mutant selections utilized valine at position 35 of CD3ϵ of CD3$\epsilon\gamma$ ectodomain heterodimer. However, the change from A35 to V35 failed to select any new mutations.

Table 2. Representative scFv(FN18) Mutants Obtained from Yeast Display Selection[a]

scFv clones			Wt	L1	M20	C207
K_D[b] (nM)			13.9 ± 1.0	5.5 ± 0.3	4.4 ± 1.1	2.9 ± 0.3
mutations and locations	I 2 F	VL-FR1				+

	E 184 G	VH-CDR2				+
	A 207 V	VH-FR3				+
	S 225 A	VH-FR3			+	+

[a] Clone name indicates the mutation and residue within the scFv. Residue numbering proceeds from the NH_2 terminus of VL, the (G4S)3 linker and VH. [b] Mean equilibrium dissociation constants, K_D, determined as in Figure 1 from two titrations and curve fittings with CD3$\epsilon\gamma$ ectodomain heterodimer-35V batch L5−5. Errors are ±1 SD.

Random mutagenesis of yeast displayed FN18 scFv libraries selected by dye-labeled ectodomain CD3$\epsilon\gamma$ heterodimers for increased affinity yielded 43 mutations. Seven occurred in the first round in 3 clones, 31 in the second round in 20 clones, and 27 in the third round in 14 clones. Of these 43 mutations, only 9 showed significant increases in affinity when combined in single clones. These 10 mutations and their locations are summarized in Table 2. Three of these mutations occur in the complementary determining regions (CDR), two in the VL and one in the VH chains. The highest-affinity mutant, C207, contains a net increase of two positive charges over the wild-type. C207 was first made by combining several mutations by site-directed mutagenesis after the second round of mutagenesis and selection. However, C207 appeared spontaneously after three rounds of mutagenesis and selection. After the second round of mutagenesis and selection, no new affinity-enhancing mutants were found, although new favorable combinations were found in the third round of mutagenesis and selection.

The affinity of the yeast displayed scFv(FN18−C207) was increased 4.8-fold over the wild-type (WT) scFv. The titration curve and curve fitting for C207 and the WT scFv are shown in Figure 1. The binding curves appear saturable by inspection, and this is supported by the fact that the R values are >0.99 using a fitting equation that contains only a saturable term (see inserts in Figure 1 for the binding fitting equation and fit parameters). Nonspecific binding is by definition nonsaturable (*25*). If it were present here, it would appear as a linear increase in MFI as a function of ligand concentration superimposed on the saturable curve, and it would lower the R values (unless a nonsaturable term was added to the fitting equation). These considerations demonstrate that the measured increase in affinity caused by the C207 mutations is due to an increase in specific binding rather than nonspecific binding. The maximum mean fluorescent intensity at saturation increases by 2.4-fold in the C207 mutant compared to the WT, suggesting that the mutant has an increased protein folding stability within the yeast secretory pathway (*26*).

Purity of *P. pastoris* Mutant Immunotoxins. Following the three-step purification procedure, DT390-biscFv(FN18−M20) and DT390-biscFv(FN18−C207) displayed a major band on Coomassie-stained SDS nonreducing gels (Figure 2) migrating near the 97.3 kDa marker. DT390-biscFv(FN18−C207) showed several faint bands migrating near the 66.3 and 55.4 kDa markers. Western blots identified these as breakdown products. On Superdex-200 chromatography, these appeared as a small trailing shoulder accounting for 5.4% of the major band peak height. These bands were removed by subsequent fractionation on Superdex-200 as shown in the Figure 3 SDS nonreducing gel.

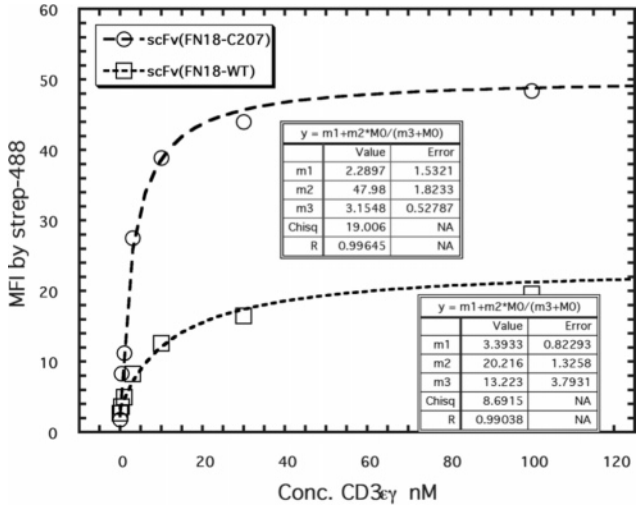

Figure 1. A comparison of titrations of CD3$\epsilon\gamma$ ectodomains labeled with streptavidin-488 on yeast displaying the wild-type scFv(FN18-WT), (□); and the highest-affinity selected mutant, scFv(FN18−C207), (○), is shown. The mean fluorescence intensity, MFI, is plotted vs the CD3$\epsilon\gamma$ concentration on the *x*-axis. The data points are fitted using nonlinear least-squares by *KaleidaGraph* software (Synergy Software, Reading, PA) using the hyperbolic equation $y = m_1 + m_2 \times M_0/(m_3 + M_0)$, where y = MFI at the given ligand concentration M_0, m_1 = MFI at 0 ligand concentration, m_2 = MFI at saturation minus m_2, and $m_3 = K_D$, the equilibrium dissociation constant in nM units. The top inserted box contains the C207 mutant fit data with a K_D of 3 nM. The CD3ϵ preparation contains V at residue 35.

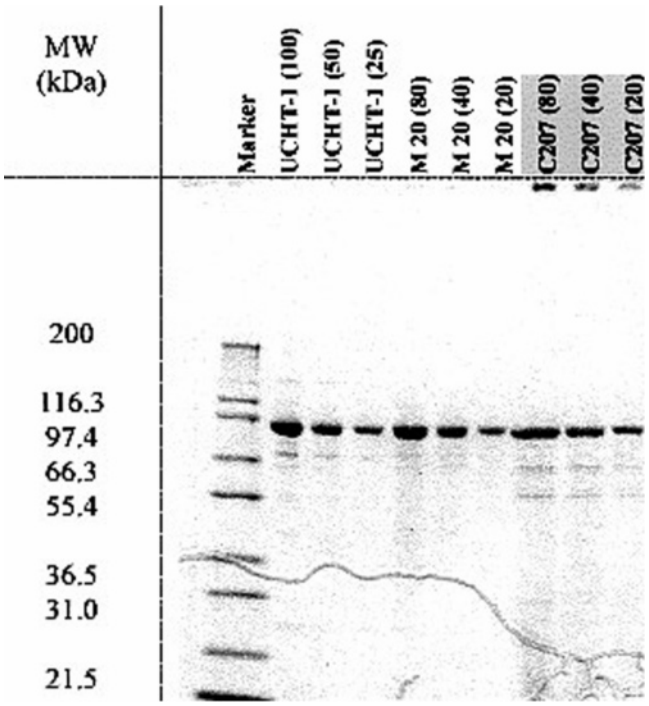

Figure 2. SDS 12% acrylamide bis-tris nonreducing gel of immunotoxins DT390biscFv(FN18−M20) and DT390biscFv(FN18−C207) are shown after the three-step purification procedure. From left to right, the lanes are (1) molecular weight markers, (2−4) immunotoxin standard DT390biscFv(UCHT1), (5−7) DT390biscFv(FN18−M20), and (8−10) DT390biscFv(FN18−C207). Numbers at the top indicate the load in μg applied. Marker MWs are given at the left.

Binding of Mutant scFvs and Their Derived Immunotoxins to T Cells. The binding activity of the *P. pastoris* expressed mutants and their derivative immunotoxins to the monkey TCR was explored in a binding competition assay using the continuous cultured monkey T cell line HSC−F. A tracer amount of FITC-labeled FN18 antibody was added to HSC−F cells along with varying concentrations of competitors, and the % inhibition of the FN18−FITC binding was determined by FACS (Figure 4). The binding activity of the scFv(FN18-WT) is reduced over the parental divalent FN18 by a factor of 0.29. Likewise, the binding activity of the immunotoxin derived from the scFv-(FN18-WT) is reduced by a factor of 0.01 compared to the parental antibody and by 0.04 compared to scFv(FN18-WT) as judged by the ratio of competitor concentrations at equal % inhibition values shown in Figure 4. The loss of binding activity of scFvs placed C-terminal to DT390 and other large proteins has been previously reported (*9*). However, the extent of the binding loss is 10-fold greater in the FN18 constructs compared to the anti-human CD3 UCHT1 constructs. This observation prompted us to undertake the affinity maturation of FN18 scFv in order to regain binding affinity within the immunotoxin

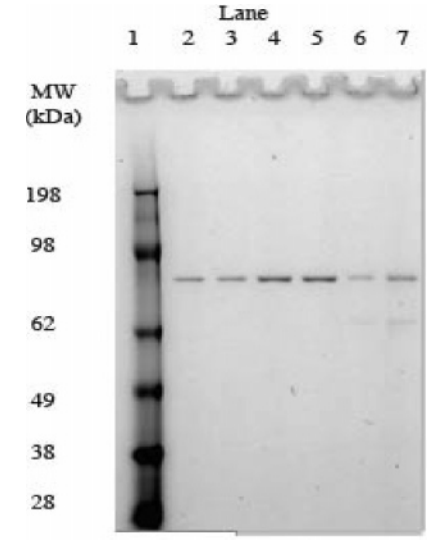

Figure 3. SDS 4−12% gradient tris-glycine nonreducing gel of DT390biscFv(FN18−C207) after an additional purification step of fractionation on Superdex-G200 to remove lower molecular weight contaminants. From left to right, the lanes are (1) molecular weight markers, (2,3) 22 μg of DT390biscFv(FN18−C207), (4,5) 44 μg of DT390biscFv(FN18−C207), and (6,7) standard DT390biscFv(UCHT1).

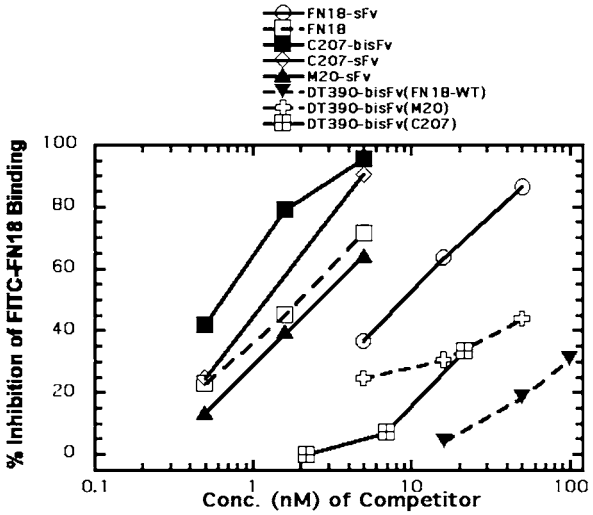

Figure 4. The % inhibition of tracer FITC-labeled FN18 binding to HSC−F monkey T cells is plotted vs the concentration of binding competitors consisting of mutant and wild-type scFvs, biscFvs, and immunotoxins derived from these scFvs. The relative binding affinity for any two competitors can be estimated from the ratio of their concentrations at equal % inhibition values. Estimates are considered to be reliable when comparing parallel curves or parallel curve regions. Means from replicate experiments comparing binding affinities relative to scFv(FN18-WT) are shown in Table 3.

Table 3. Relative Affinity Changes of Mutant scFvs(FN18)[a]

	mutant scFv affinity increase by yeast display relative to scFv-WT	*P. pastoris* expressed mutant scFv affinity increase by T cell binding relative to scFv-WT[b]
	scFv	
WT	1.0 ± 0.07	1.0 ± 0.014
M20	2.5 ± 0.14	3.0 ± 0.14
C207	4.8 ± 0.4	9.8 ± 0.2.4
	biscFv	
C207		16.7 ± 0.3

[a] Results are means + 1 SD for 2 or 3 determinations. [b] T cell binding affinity was measured displacement of FN18-FITC tracer from HSF cells by scFv competitors and ratioing equal displacement concentrations.

format. The scFv(FN18−M20) and scFv(FN18−C207) do exhibit increased binding in this assay, and the binding of biscFv(FN18−C207) is further enhanced. These results are summarized in Table 3, right-hand column, where the mean increases in binding affinity of the mutant scFvs relative to scFv-(FN18-WT) are listed from Figure 4 data and replicate experiments. The relative affinity changes determined from the yeast display K_D values are also listed for comparison. In Figure 4, the increase in the scFv(FN18−M20) is seen to be effective in increasing the affinity of the M20 derived immunotoxin, DT390-biscFv(FN18−M20). However, the increase is only about 4-fold over the WT immunotoxin, DT390-biscFv(FN18-WT). The DT390biscFv(FN18−C207) immunotoxin binding was not significantly different from the DT390-biscFv(FN18−M20) immunotoxin over the concentration range covered, although the steeper curve suggests that a difference might be observed at higher concentrations.

Increased Cytotoxicity of FN18−scFv Mutant-Derived Immunotoxin. In spite of the relatively small increase in binding affinity provided by the mutant M20 and C207 immunotoxins, the bioactivity of these immunotoxins exhibited large increases over the WT immunotoxins. Dose−response curves of a protein synthesis inhibition assay in HSC−F cells are shown in Figure 5 after a 20 h exposure to immunotoxins. In comparison to the DT390-biscFv(FN18-WT) immunotoxin, the M20 mutant immunotoxin is increased 68-fold, while the C207 mutant immunotoxin is increased 228-fold. Relative to the chemically conjugated immunotoxin, FN18−CRM9, these two mutant immunotoxins are increased 17- and 57-fold respectively. The receptor specificity of the assay is shown by the ability of a 10-fold excess of the FN18 antibody to compete with the cytotoxicity of each mutant immunotoxin at its highest concentration (filled symbols), and the lack of toxicity of the non-cross-reacting anti-human immunotoxin DT390biscFv(UCHT1). In another continuously cultured rhesus cell line, Mm357−2, M20 and C207 immunotoxins were increased 7-fold and 35-fold, respectively, over the chemically conjugated immunotoxin (data not shown).

In order to more closely replicate the in vivo status of T cells, we assayed the effects of these immunotoxins on freshly isolated T cells from peripheral monkey blood. Because the majority of these T cells are resting, the level of protein synthesis is too low to measure by the incorporation of labeled amino acids. However, resting T cells exposed to immunotoxins do incorporate the vital dye 7-AAD that is normally excluded from viable cells. We have found that these T cells also disappear from the normal lymphocyte gate. Those T cells that remain in the gate lose surface CD3 and CD4 epitopes in an immunotoxin dose- and time-dependent fashion. In Figure 6a, the DT390biscFv-(FN18−C207) mutant is seen to be 7.7-fold more potent than the chemical conjugate, 5.4-fold ± 3.3 for two replicate assays, while in Figure 6b, the DT390biscFv(FN18−M20) mutant is

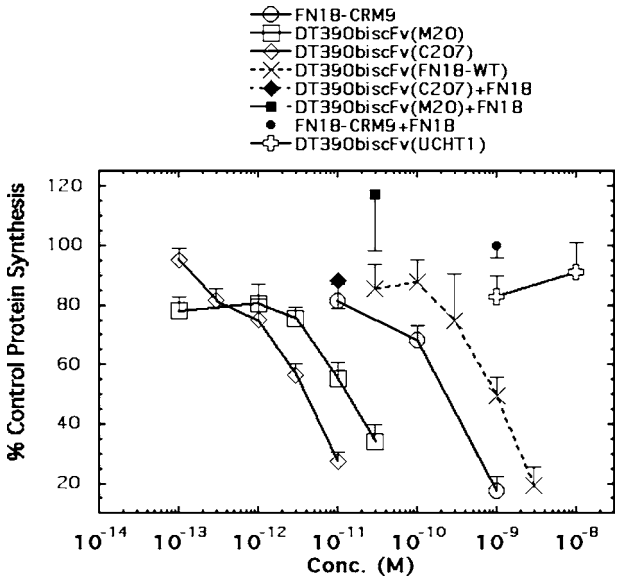

Figure 5. The % control inhibition of protein synthesis for four immunotoxins on HSC−F monkey T cells is plotted vs the immunotoxin concentrations on the *x*-axis after a 24 h exposure. Each point is the mean of six replicates and the positive sides of 1 SD single-sided error bars are shown. The mutant recombinant immunotoxin DT390-biscFv(FN18−C207) is the most potent immunotoxin, exceeding the wild-type recombinant immunotoxin by 238-fold. The receptor specificity of the assay is shown by the ability of a 10-fold excess of the FN18 antibody to compete the cytotoxicity of each immunotoxin at its highest concentration (filled symbols) and the lack of toxicity of the non-cross-reacting anti-human immunotoxin DT390biscFv(UCHT1).

seen to be 0.4-fold less potent than the chemical conjugate. Therefor, enhanced potency for the C207 mutant relative to the M20 mutant is 13.5-fold in resting T cells. Similar results were found when the assay measures the loss of the $CD3^+CD4^-$ cell population (data not shown). The possible causes for differences in relative potency between resting T cells and continuously cultured T cell lines are considered in the next section.

DISCUSSION

We increased the affinity of the anti-CD3 antibody FN18 by random mutagenesis combined with sorting flow cytometry selection using dye-labeled monkey CD3$\epsilon\gamma$ heterodimeric ectodomains. Although the affinity increase was modest in the best mutant, C207 (4.8-fold by yeast display), the increase was greater when judged by binding assays to T cells (9.8-fold) and further increased in the biscFv format used in diphtheria toxin based immunotoxins (16.7-fold). This resulted in an increase in bioactivity of 228-fold when measured on a continuously cultured monkey T cell line referenced to immunotoxin made with the wild-type scFv. Bioactivity toward monkey resting T cells isolated from peripheral blood increased 5.4-fold over the chemically conjugated immunotoxin, FN18−CRM9, that depletes resting T cells in monkey lymph nodes by 1.5−2 logs (*2*). Although the wild-type and the two mutant immunotoxins show the same rank order with regard to bioactivity between resting and transformed T cells, the large numerical differences imply differing rate-limiting steps within the intoxication pathway in resting versus transformed T cells. The rate-limiting step in diphtheria toxin intoxication of cells actively synthesizing protein has been ascribed to the translocation step of the toxin A chain into the cytosol compartment (*27*). However, resting T cells have very low rates of protein synthesis unless activated (*28*). In this situation, the toxin substrate, elongation factor-2, is continuously bound to the ribosome (as opposed to cycling on and off) and is protected against enzymatic inactivation by the toxin A chain (*29*). The rate of protein synthesis would then

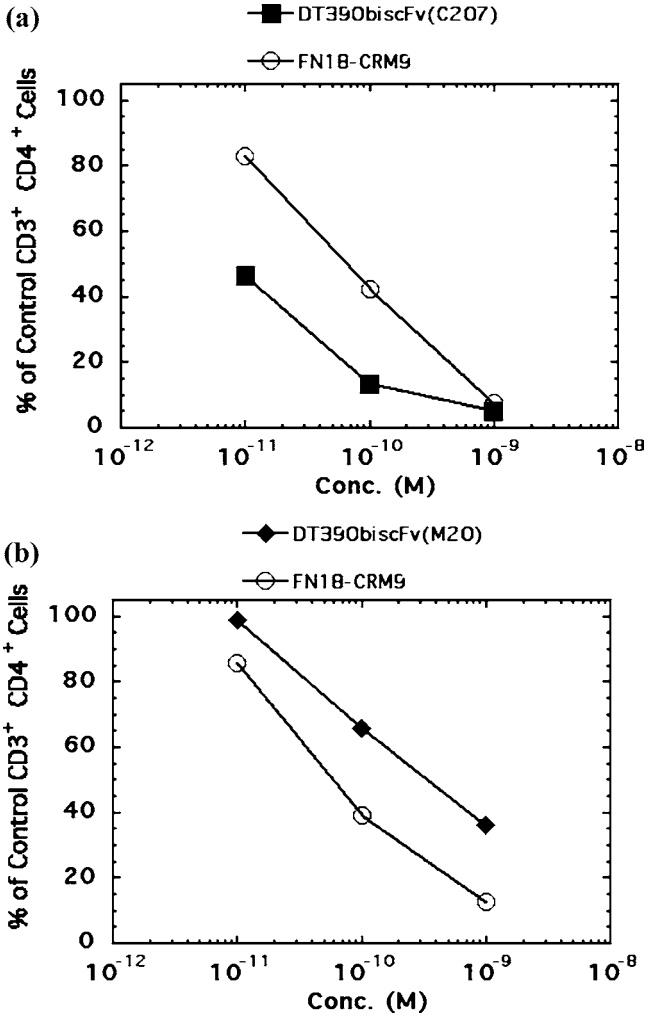

Figure 6. The loss of monkey peripheral blood $CD3^+CD4^+$ T cells from the FACS lymphocyte gate is shown after a 72 h exposure to immunotoxins as a function of immunotoxin concentration. In part a, the DT390biscFv(FN18−C207) mutant is seen to be 7.7-fold more potent than the chemical conjugate, 5.4-fold + 3.3 for two replicate assays; while in part b, the DT390biscFv(FN18−M20) mutant is seen to be 0.4-fold less potent than the chemical conjugate. The enhanced potency for the C207 mutant relative to the M20 mutant is 13.5-fold in resting T cells.

become rate-limiting for the intoxication process. It has been shown that the antibody moiety of an immunotoxin interacting with CD3ϵ provides an activating signal (*30*). The strength of this interaction may be determined by subtle features of the interaction and thus could enhance the intoxication rate. These considerations may explain why recombinant immunotoxins made with mutant C207 are active in depleting blood and lymph node T cells in monkeys in vivo, providing a homogeneous reagent for preclinical testing of tolerance induction in organ transplantation protocols (*38*).

The current study exploited the advantages of using *Pichia pastoris* for recombinant protein expression. All of the FN18 derivatives, mutant scFv, biscFv, and recombinant immunotoxins were expressed in *P. pastoris* using the secretory pathway ensuring optimal folding of each. This gave us confidence that the comparative numbers in binding and bioactivity assays reflected the advantages of the mutations rather than differences in protein folding that are often encountered when refolding proteins from insoluble granules in *E. coli*. Varying the signal peptide was found to be a valuable tool in optimizing the expression of these different constructs.

Analysis of the mutations in mutant C207 revealed that there was a net gain of two positive charges over the WT scFv within two CDR regions. Two recent crystallographic structures of anti-human CD3 antibodies OKT3 and UCHT1 bound to the human CD3$\epsilon\gamma$ (*31*) and human CD3$\epsilon\delta$ ectodomains (*32*) showed that the antibodies bind to an electronegative area on the exposed surface of CD3ϵ. It is possible that these new positive charges in the mutant are aiding the antibody CD3ϵ interaction.

The new mutations present in the C207 immunotoxin might cause some increase in immunogenicity and possibly compromise this methodology for human use. However, the major immunogen in this case is the toxin moiety. Preclinical animal studies have shown that T cell depletion sufficient for tolerating transplant protocols can be achieved with only 4 days of consecutive dosing, prior to the initiation of either a primary or secondary antibody response (*9*).

Our binding studies show that the scFv of FN18 loses affinity by a factor of 0.29 compared to the parental divalent antibody. This is nearly identical to the case of UCHT1 (0.3-fold) (*9*). Both scFvs lose affinity when placed C-terminal to DT390 (*33*). The strategy of using the biscFv format in DT-based immunotoxins was to compensate for this positional loss of affinity by introducing a bivalent interaction. However, the binding data presented here show that the biscFv format works less well for DT390-biscFv(FN18) than for DT390-biscFv(UCHT1), and the difference is 10-fold. The increase in affinity on going from scFv(UCHT1) to biscFv(UCHT1) is 5-fold (*9*). The increase in affinity on going from C207-scFv to C207-biscFv is only 16.7/9.8- or 1.7-fold (Table 3). This suggests that the biscFv of FN18 mutants has less divalent character than the UCHT1 biscFv. This could be the result of pairing preferences. In the biscFv structure, VL1-L-VH1-L-VL2-L-VH2, optimal divalent character will be achieved by binding of VL1 with VH1 and VL2 with VH2. However, other options for pairing are possible that will limit the divalent character of the biscFv. In the future, it will be necessary to explore other antibody formats for the biscFv domain of the anti-monkey immunotoxins derived from FN18. Diabody constructs with shortened linkers may be an option to force optimal pairing to achieve better divalent character (*34*, *35*).

ACKNOWLEDGMENT

This research was supported by the Intramural Research Program of NIMH, NIH. We thank Jim Nagle of the NINDS/NIH DNA Sequencing Facility for their generous support.

Supporting Information Available: The eight primers for VL and ten primers for VH to rebuild the scFv(FN18) for *P. pastoris* optimized codons. This material is available free of charge via the Internet as http://pubs.acs.org/BC.

Intermolecular enzyme complementation assay is a useful method for detecting protein−protein interactions. Specifically, bioluminescent signals produced from reconstructed split luciferase fragments are powerful tools for *in vivo* analysis because the bioluminescent signals have been visualized both in cultured cells and living animals. However, they are limited for detection and evaluation of biological events relevant to intermolecular protein−protein interactions. In this study, we constructed an intramolecular luciferase complementation probe for detecting target biomolecules other than protein−protein interactions. It consists of peptide-inserted firefly luciferase (PI-FLuc) containing a short peptide between internally divided firefly luciferase. The inserted short peptide triggers FLuc complementation or discomplementation and subsequent reactivation or inactivation of FLuc activity through its induced fit conformational changes. We chose RNA binding arginine rich motif (ARM) peptides, Rev and/or Tat, for model peptide insertion, and expressed constructed PI-FLuc probe variants using a wheat germ cell-free protein synthesis system. They showed FLuc activity changes, reactivation, or inactivation after binding to their specific RNA targets. Furthermore, to expand the versatility of the PI-FLuc RNA detection system, we designed split-RNA probes built to reform the ARM peptide binding site in the presence of arbitrarily selected target-RNA. As a result, the target RNA was homogeneously detected by FLuc luminescent signals mediated by a cooperative function of the PI-FLuc and split-RNA probe sets.

INTRODUCTION

Enzyme complementation and fluorescent resonance energy transfer (FRET) are typical assay systems for the detection of protein−protein interactions. The FRET assay is useful as a high-resolution assay since fluorescent signals provide both temporal and spatial resolution (*1*, *2*). In contrast, enzyme complementation is more precise than FRET, because enzymatic signals provide quantitative readout and signal amplification, resulting in more sensitive assays (*3*, *4*). Several proteins, such as dihydrofolate reductase (DHFR), β-galactosidase, and β-lactamase, have been used as reporter proteins, indicating intermolecular complementation and activity reconstruction (*4*−*8*). Recently, it was discovered that firefly luciferase (FLuc) and renilla luciferase (RLuc) could correspondingly function as reporter proteins for intermolecular complementation (*9*, *10*). Luciferase produces low background and highly sensitive bioluminescent signals simply by the administration of an appropriate substrate in the presence of cofactors. In addition, the bioluminescent signals produced from luciferase may be noninvasively visualized both in cultured cells and in living animals using cooled charge-coupled device (CCD) cameras (*11*, *12*). As a result, they are now becoming one of the most useful reporter proteins for analyzing protein−protein interactions especially for *in vivo* analysis. Using intermolecular luciferase complementation, previous studies have also reported direct protein−protein interactions or conditional protein−protein interactions mediated by chemical molecules in the living mouse (*9*, *13*, *14*).

In the meantime, there have also been efforts to construct recombinant protein probes, that can detect target biomolecules and antibodies intramolecularly, using an enzyme complementation assay (*15*−*18*). These recombinant proteins have been constructed by inserting domains or epitopes into internally divided reporter proteins. The inserted domains function as a response unit, undergoing conformational changes in response to the target biomolecules such as specific ligand bindings and signal transductions. In turn, conformational changes of the response units induce activity changes in reporter enzymes through a structural reorientation of the internally divided reporter enzyme. Such constructs would provide an advanced tool for analyzing target biomolecules other than protein−protein interactions and could be applied to *in vivo* analysis, especially in mammalian cells and living animals. However, until now it has seemed difficult to construct the intramolecular enzyme complementation probes via domain insertion as compared to similarly assembled intramolecular FRET probes (*19*−*22*). Only some enzymes are known to be available as reporter proteins, and only some domains have been successfully used for domain insertion (*18*). In the case of luciferase, just one group reported a successfully constructed intramolecular luciferase complementation probe (*23*, *24*). We posit that this failure is due to the detection principle of enzyme complementation. An intramolecular enzyme complementation probe requires the rational structural reconfiguration of divided reporter enzymes following the conformational changes of the response units, while FRET protein probes can detect such alterations directly by distant changes in fluorescent proteins (*25*). Therefore, the construction of an intramolecular luciferase complementation probe would be quite difficult if the inserted response unit is a relatively large domain.

In a previous report, we constructed an intramolecular FRET protein probe by using short peptides as response units for detecting specific RNAs (*26*). In that study, HIV-1 Rev-peptide (17 a.a.), which specifically binds to RRE-RNA and Rev-

aptamer, was inserted between EYFP and ECFP. The resulting FRET protein probe indicated FRET increase and decrease as mediated by the peptide's conformational change after binding to RRE-RNA and Rev-aptamer, respectively. Moreover, we were able to detect arbitrarily selected target-RNA by designing split-RNA probes containing variable sequence regions. On the basis of these results, we expected that the construction of an intramolecular luciferase complementation probe should be possible by inserting short peptides as response units. In this study, we constructed a novel peptide-inserted firefly luciferase (PI-FLuc) probe by using short RNA-binding peptides for insertion. We expected that the constructed PI-FLuc probe would retain FLuc activity since the inserted peptide was sufficiently small so as not to disturb the steric configurations of native FLuc. We also expected that the conformational change of the inserted peptide following specific RNA binding would induce FLuc activity changes through a structural reorientation of the internally divided FLuc domains, either by FLuc complementation or discomplementation.

EXPERIMENTAL SECTION

Plasmid Construction. All PI-FLuc probe variants were constructed on cloning vector pBluescript II SK (+) (Stratagene). Gene fragments coding NFLuc (N437, N445), CFLuc (C438, C446) and Full-FLuc were respectively amplified by PCR from PicaGene Basic Vector 2 (Toyo Ink) using primers combinations. Forward primers were split-FLuc-s (5′-GCGACTAGTATGGAATTCGAAGACGCCAAAAACATAAAG-3′), split-CFLuc-s438 (5′-GCGAGATCTCTGAAGTCTCTGATTAAGTAC-3′) and split-CFLuc-s446 (5′-CTTAGATCTGGCTATCAGGTGGCTCCCGCT-3′). Reverse primers were split-FLuc-as (5′-CTTGGGCCCGCGGCCGCTTAAGGCCTCGCGACCACGGCGATCTTTCC GCCCTT-3′), split-NFLuc-as437 (5′-GCGGGATCCGCGGTCAACGATGAAGAAGTG-3′) and split-NFLuc-as445(5′-GCGGGATCCTTTGTACTTAATCAGAGACTT-3′). Underlined bases are the restriction enzyme sites for gene recombination. Rev-peptide-inserted PI-FLuc probe variants were constructed replacing the EYFP and ECFP regions of FRET protein probe (YRG0C-11ad) (*26*) by NFLuc and CFLuc, respectively. Tat-peptide gene fragment was obtained from annealed oligonucleotide pair (5′-CAGACCTAGAGGCACCAGAGGCAAGGGCAGAAGAATCAGAAGAGGCGGCA-3′ and 5′-GATCTGCCGCCTCTTCTGATTCTTCTGCCCTTGCCTCTGGTGCCTCTAGGTCTGGTAC-3′), and Tat-peptide-inserted PI-FLuc probe variants were constructed replacing the Rev-peptide region by Tat-peptide coding annealed oligonucleotide. FLAG-tag gene fragment was obtained from annealed oligonecleotide pair (5′-CTAGTATGAGGCCTGATTACAAGGATGACGACGATAAGGAATTCTAAG CGGCCGCGGGCC-3′ and 5′-CGCGGCCGCTTAGAATTCCTTATCGTCGTCATCCTTGTAATCAGGCCTCATA-3′), and *Stu* I cut C-terminus FLAG-tag sequence was inserted between *Stu* I and *Apa* I site of PI-FLuc variants or Full-FLuc. Then, the constructed probe variants were transferred to expression plasmid for wheat germ cell free protein synthesis system (pEU-E01-MCS) using *Spe* I and *Not* I.

Protein Expression and RNA Synthesis. Constructed PI-FLuc probe variants and Full-FLuc were expressed using a cell-free protein synthesis system with wheat germ extract (*27*). Transcriptional templates were amplified by PCR from the constructed plasmids to make DNA fragments containing SP6 promoter sequence. Then, mRNAs were transcribed using SP6 RNA polymerase and translated according to a previously reported bilayer cell-free protein synthesis system (*28*). Translated protein variants were confirmed by SDS-PAGE and Western blotting using anti-FLAG M2 antibody (Eastman Kodak).

All short RNA oligonucleotides, RNA-targets, and split-RNA probes were synthesized and purified according to a previously reported method (*26*).

Native-PAGE Western Blotting. Five microliters of translated products in wheat germ extract and 30 pmol of synthesized RNA oligonucleotides were mixed in 15 μL of interaction buffer (10 mM HEPES−KOH, 100 mM KCl, 1 mM $MgCl_2$, 0.5 mM EDTA, 1 mM DTT, 10% glycerol, pH = 7.4). After 30 min of incubation on ice, samples were resolved on a 10% nondenaturing polyacrylamide gel with Tris/glycine running buffer at 4 °C. Then resolved proteins were transferred to PVDF membrane with Tris/glycine transfer buffer for 80 min at 350 mA. The PI-FLuc probe variants in transferred membrane were labeled using anti-FLAG M2 antibody and Alexa-546 conjugated anti-mouse IgG antibody and visualized using FluorImager595 (Molecular Dynamics).

FLuc Activity Assay. FLuc activities were evaluated using luminometer (Luminous CT-9000D: Dia-Iatron). One microliter of translated products were mixed with an aliquot amount of RNA-targets or constructed hybridized complexes in 50 μL of interaction buffer using 96-well black plates (Sumilon). After 30 min of incubation at room temperature, luminescent signals were measured by addition of 50 μL of substrate (Picagene Luciferase Assay Kit: Toyo Ink) and counting for 10 s. The luminescent signals were normalized by subtracting the signal obtained from nontranslated wheat germ extract.

Target-RNA Homogeneous Assay. Two microliters of translated products and a pair of split-RNA probes (final concentration at 500 nM) were previously mixed in interaction buffer. Varied concentrations of specific or nonspecific target-RNA were immediately added to the premixed probes in total 100 μL of interaction buffer using nonadsorption 96-well black plates (Sumilon). Luminescent signals were measured by addition of 100 μL of substrate and counting for 10 s after 90 min of incubation at 37 °C followed by 30 min of incubation at room temperature. The luminescent signals were normalized by subtracting the signal obtained from nontranslated wheat germ extract.

RESULTS

Design and Expression of PI-FLuc Probes. To construct an intramolecular luciferase complementation probe, two ARM peptides, HIV-1 Rev-peptide (17 a.a.) and BIV Tat-peptide (13 a.a.) peptide, were selected for insertion. These two peptides are both well-characterized RNA-binding peptides, showing induced fit conformational changes following specific RNA binding. NMR and circular dichroism experiments indicate that the BIV Tat-peptide undergoes a change to a β-sheet structure upon binding to TAR-RNA (*29*−*31*), while HIV-1 Rev-peptide takes on α-hilical and elongated conformation upon binding to RRE-RNA and Rev-aptamer, respectively (*32*−*35*). FLuc was selected as a reporter luciferase, and two dividing points after 437th arginine and 445th lysine were chosen for peptide insertion, referring the previously reported intermolecular FLuc complementation probes (*9*, *12*, *14*).

Then, eight variants of PI-FLuc probes were constructed by combining NFLuc domains (N437 and N445), CFLuc domains (C438 and C446), and ARM peptides (Rev and Tat) (Figure 1a). A FLAG-tag sequence was connected to the C terminus of each for subsequent Western blotting. These variants were expected to alter FLuc activity after binding specific RNA-targets via conformational changes of the ARM peptides. If RNA binding broke the steric configuration of the connected FLuc domains, we should expect FLuc activity and luminescent signal to decrease. On the other hand, if RNA binding corrected the steric configuration of connected FLuc domains, we would expect FLuc activity and luminescent signal to increase (Figure

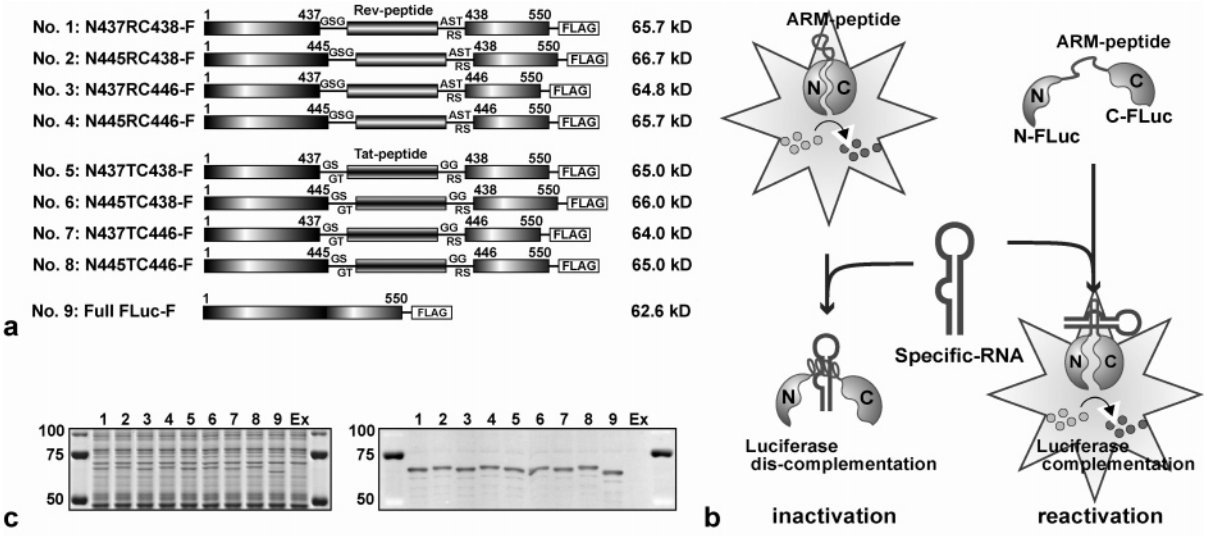

Figure 1. Principle of intramolecular luciferase complementation assay and PI-FLuc probe construction. (a) Rev-peptide (-TRQARRNRRRRWR-ERQR-) or Tat-peptide (-RPRGTRGKGRRIRR-) was inserted between NFLuc (N437, N445) and CFLuc (C438, C446). Control FLuc (No. 9) was constructed as wild type FLuc. A FLAG-tag sequence (-DYKDDDDK-) was connected to the C terminus of constructed variants. (b) PI-FLuc probes specifically bind to RNA-targets reflecting the inserted ARM peptide characteristics. If RNA binding induce discomplementation of the divided FLuc domains, luminescent signal would decrease (left). If RNA binding induce complementation of the divided FLuc domains, luminescent signal would increase (right). (c) Constructed split-FLuc probe variants were translated using a wheat germ cell-free protein synthesis system. An aliquot amount of translated products was resolved on an 8% SDS-PAGE and analyzed by CBB staining (3 μL: left) or Western blotting (1 μL: right). Lane numbers correspond to the numbers in part a). Nontranslated wheat germ extract was resolved as negative control (Ex).

1b). All constructed variants (Nos. 1−8) and the wild type FLuc (Full-FLuc No. 9) were expressed using a wheat germ cell-free protein synthesis system and confirmed by both SDS-PAGE and Western blotting (Figure 1c).

Characterization of Constructed PI-FLuc Probes. We next investigated whether the PI-FLuc probes have an ability to bind to specific RNA-targets (RRE-RNA, Rev-aptamer, TAR-RNA; see Figure 2a). The translated PI-FLuc probe variants and synthetic RNA were mixed in an interaction buffer and resolved on native-PAGE. After a transfer reaction to PVDF membrane, we analyzed gel-mobility shifted bands using anti-FLAG antibody (Figure 2b). In all constructed PI-FLuc probe variants, we found specific signal bands at the lanes mixed with their RNA targets, while there were no discriminative signal bands at control lanes (RNA −). In the case of Rev-peptide-inserted variants (Nos. 1−4), signal bands were observed at the lanes mixed with RRE-RNA and Rev-aptamer, which were the targets of the Rev-peptide. There were trends that the signal bands had clearly converged with RRE-RNA and widely spread with Rev-aptamer, except for variant No. 4. In constrast, in the case of Tat-peptide-inserted variants (Nos. 5−8), clearly converged signal bands were observed at the lanes mixed with TAR-RNA, the target of the Tat-peptide. Further, in all variants there were no distinctive signal bands at the lanes mixed with nonspecific RNAs corresponding to the control lanes. These results indicate that each inserted peptide has the ability to specifically bind to their corresponding RNA-targets.

Next, to evaluate whether PI-FLuc probe variants showed appropriate FLuc activity changes following specific RNA binding, we measured the luminescent signal produced after the addition of the respective RNA (Figure 2c). The results confirmed that the PI-FLuc probe variants, containing the N437 domain (Nos. 1, 3, 5, 7), have almost lost FLuc activity. These probes had luminescent signals as weak as the background signals obtained from nontranslated wheat germ extract (Ex) and did not show any luminescent signal change with addition of the relevant RNAs. In contrast, other variants, containing the N445 domain (Nos. 2, 4, 6, 8), retained FLuc activity. In addition, three of these four variants showed FLuc activity changes after addition of specific RNA-targets. Interestingly,

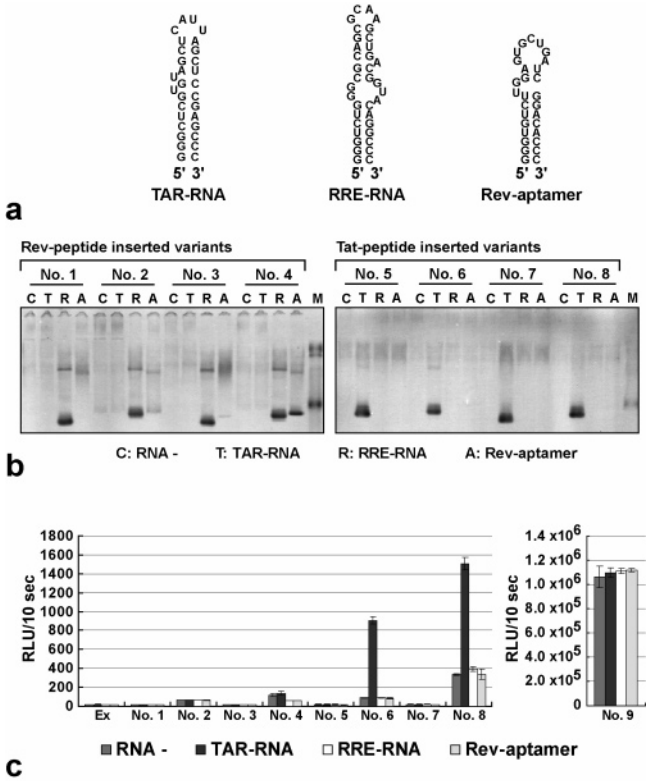

Figure 2. Detection of specific RNA-target with PI-FLuc probe. (a) Secondary structure of respective RNA-targets (TAR-RNA, RRE-RNA, Rev-aptamer). (b) Specific RNA binding was confirmed by native-PAGE gel mobility shift assay. Five microliters of translated products was mixed with 30 pmol of RNAs (C: RNA −, T: TAR-RNA, R: RRE-RNA, A: Rev-aptamer) and resolved on a 10% nondenaturing polyacrylamide gel. Transferred PI-FLuc probes were detected using Western blotting. (c) Luminescent signals were evaluated after the binding reaction of 1 μL of translated products and 25 pmol of respective RNAs. Values were average with standard deviation (n = 3).

in the case of the Rev-peptide-inserted variant No. 4, FLuc was inactivated after the addition of both RRE-RNA and Rev-

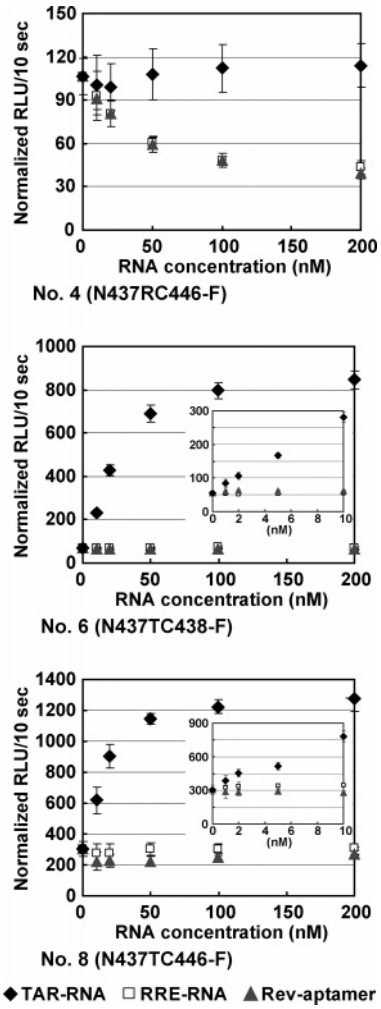

Figure 3. RNA concentration dependency in intramolecular luciferase complementation assay. Luminescent signals were evaluated after binding reaction of 1 μL of translated products and varied concentrations of respective RNAs. Values were average with standard deviation (n = 3).

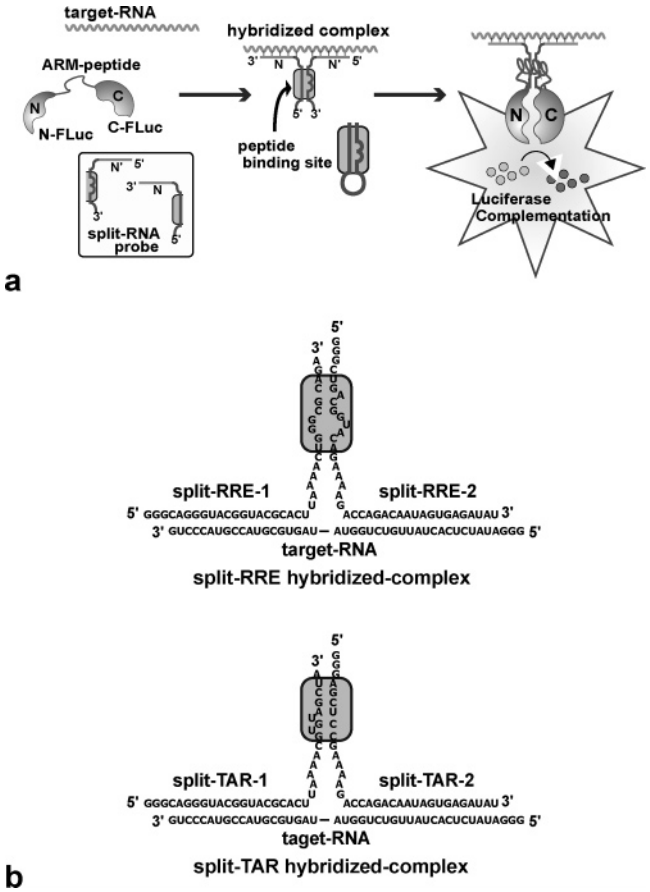

Figure 4. Principle of intramolecular luciferase complementation assay for arbitrarily selected target-RNA. (a) A pair of split-RNA probe hybridizes to an arbitrarily selected target-RNA and reforms the ARM peptide binding site. PI-FLuc probe binds to the ARM peptide binding site constructed on the hybridized complex. They indicate luminescent signal changes thorough the ARM peptide conformational change. (b) Secondary structure and sequence of designed hybridized complex. Surrounded region indicates minimal element necessary for the ARM peptide binding.

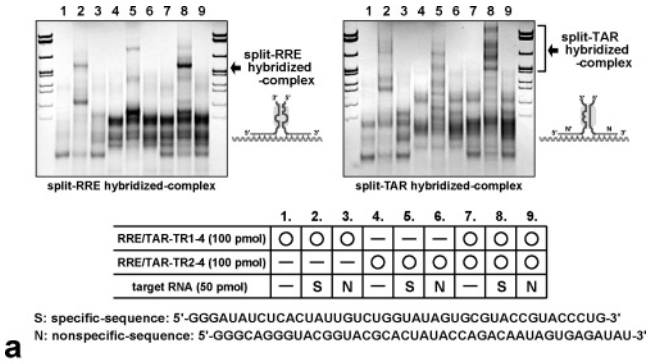

aptamer. On the other hand, in the case of the Tat-peptide-inserted variants No. 6 and No. 8, FLuc was reactivated after addition of the TAR-RNA. Moreover, no variants showed any change in their FLuc activity after the addition of nonspecific RNA.

RNA Detection by Intramolecular FLuc Complementation. We also investigated the RNA concentration dependency of FLuc activity changes in three variants (Nos. 4, 6, 8) (Figure 3). Varied concentrations of the RNA-targets were mixed with translated PI-FLuc variants, and FLuc activity was evaluated after the binding reaction. Variants No. 6 and No. 8 showed dose-dependent FLuc reactivation with TAR-RNA, while there were no signal changes with other RNAs. The signal change ratios corresponded to Figure 2c. In contrast, variant No. 4 showed dose-dependent FLuc inactivation with RRE-RNA and/or Rev-aptamer, while there were no signal changes with TAR-RNA. These results indicate that the RNA-targets were homogeneously detected by luminescent signal changes with sufficient specificity.

Intramolecular Complementation Assay for Arbitrarily-Selected Target-RNA. For detection of arbitrarily selected target-RNA other than specific RNA-targets, we designed split-RNA probes built to reform the ARM peptide binding site in the presence of the target-RNA. The split-RNA probes containing variable sequence regions respond to any target-RNAs. First, a split-RRE-RNA probe was constructed as previously described (*26*). Second, we designed a split-TAR-RNA probe according to our previous methodology. The TAR-RNA was split at its loop region, and RNA oligonucleotides containing complementary sequences of arbitrarily selected target-RNA were connected at the 5′ or 3′ end of the split-TAR-RNA. A minimal sequence for Tat-peptide recognition was retained for the split-TAR-RNA. Additionally, spacer-like sequences were inserted between the complementary sequence region and the split-TAR-RNA region.

By this design, the constructed split-RNA probes hybridize to adjacent regions of the arbitrarily selected target-RNA, and the ARM peptide binding site is subsequently reformed on the hybridized complex. Next, the PI-FLuc probe binds to the hybridized complex with the conformational change of the ARM peptide. Therefore, following this last step, the arbitrarily selected target-RNA should be detectable by FLuc luminescent signals through the cooperative functions of such self-assembled probe sets as the PI-FLuc probe and the split-RNA probe (Figure 4a). The secondary structure and sequence of the hybridized complexes (split-RRE hybridized complex and split-TAR hybridized complex) are displayed in Figure 4b.

Detection of Hybridized Complexes. To detect hybridized complexes, we first mixed split-RNA probes with arbitrarily selected target-RNA (specific-sequence) and confirmed hybridized formation by a polyacrylamide gel mobility shift assay (Figure 5a). Complementary sequence of the specific sequence was prepared as negative control (nonspecific-sequence). We found that there were new mobility shifted bands, indicative of

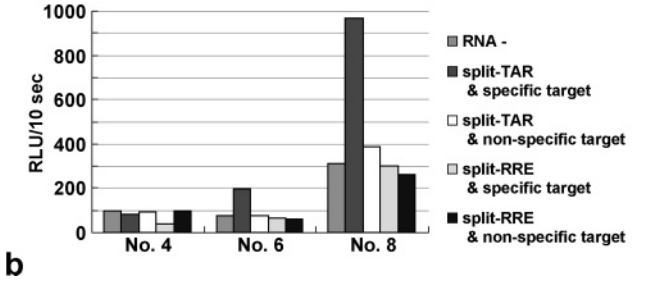

Figure 5. Detection of hybridized complex by luminescent signal change. (a) Construction of the hybridized complexes was confirmed by gel mobility shift assay. One-hundred picomoles of respective split-RNA probes was mixed with 50 pmol of specific-sequence or nonspecific-sequence. After 60 min of incubation at 37 °C, they were resolved on a 15% polyacrylamide gel and stained by EtBr. (b) An aliquot amount of hybridized complexes constructed in part a (50 pmol of split-RNA probes and 25 pmol of target-RNA) was mixed with 1 μL of translated products. Luminescent signals were evaluated after the binding reaction.

the hybridized complex, in the sample lanes including all components, split-RNA probe pair and specific-sequence (lane No. 8). To check for valid reporter activity, we next investigated whether the PI-FLuc probe reflected FLuc activity changes after the addition of the hybridized complexes. Aliquot amounts of the constructed hybridized complexes were mixed with translated products of the PI-FLuc probe variants, and luminescent signals were analyzed after a 30-min incubation at room temperature (Figure 5b). Three PI-FLuc probe variants (Nos. 4, 6, 8) showed FLuc activity changes corresponding to the addition of just the appropriate RNA-target. The Rev-peptide-inserted PI-FLuc probe variant showed FLuc inactivation with the addition of the hybridized complex constructed from the split-RRE-RNA probe (split-RRE hybridized complex). The Tat-peptide-inserted PI-FLuc probe variants showed FLuc reactivation with the addition of the hybridized complex constructed from the split-TAR-RNA probe (split-TAR hybridized complex). Further, neither showed FLuc activity changes with hybridized complexes constructed from nonspecific-sequence or nonspecific split-RNA probes. These results confirm that the observed FLuc activity changes were mediated by the binding of the correct hybridized complex, recognized by the inserted ARM peptide.

Homogeneous Detection of Arbitrarily-Selected Target-RNA. Arbitrarily selected target-RNA can also be homogeneously detected by FLuc activity changes. Figure 6 shows the target-RNA concentration dependency in a homogeneous assay. All PI-FLuc probe variants (Nos. 4, 6, 8) decreased or increased their luminescent signals through the intramolecular FLuc discomplementation or complementation. These probes also showed good concentration dependency with the specific-sequence, as well as no signal changes in the presence of nonspecific-sequence. Especially in the case of Tat-peptide-inserted PI-FLuc probe variants, relatively small error bars were

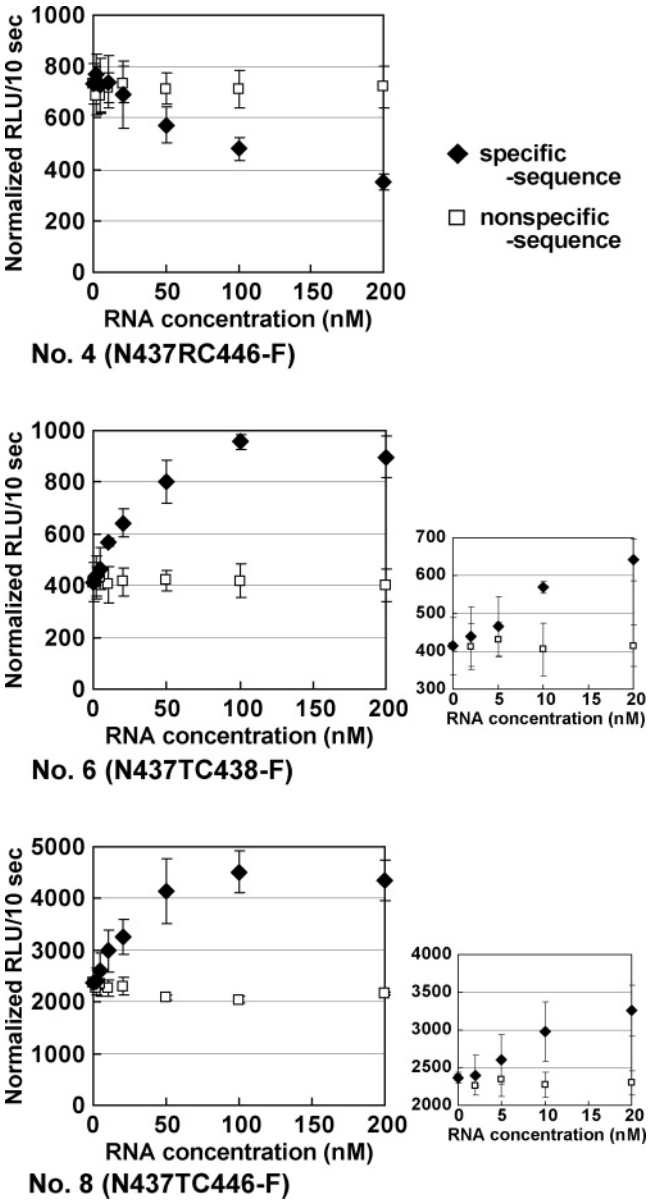

Figure 6. Homogeneous detection of arbitrarily selected target-RNA by intramolecular luciferase complementation assay. Varied concentrations of the target-RNA were mixed with a pair of split-RNA probes (final concentration at 500 nM) and 2 μL of translated products. Luminescent signals were evaluated after binding reaction. Values were average with standard deviation ($n = 3$).

observed at low target-RNA concentrations, and we obtained a significant increase of luminescent signal at 10 nM concentration. These results suggest that arbitrarily selected target-RNA was homogeneously and specifically detected by the cooperative function of PI-FLuc and split-RNA probes.

DISCUSSION

This study attempted to construct peptide-inserted FLuc (PI-FLuc) probes producing a high sensitivity luminescent signal mediated by intramolecular luciferase complementation in response to target biomolecules. Two essential factors were presumed to be required to achieve this objective. First, the PI-FLuc probe must be able to recognize target molecules reflecting inserted peptide characteristics. Second, the PI-FLuc probe must partly retain luciferase activity after peptide insertion. Consequently, we decided to construct several PI-FLuc probe variant patterns. Previously reported crystal structure analysis had demonstrated that FLuc could be separated to two distinct

domains (NFLuc and CFLuc) connected by a flexible linker-like amino acid sequence (*12*, *36*) Additionally, previously constructed intermolecular FLuc complementation probes had been divided into two parts around a linker-like amino acid sequence (*9*, *12*, *14*). This indicates that the linker-like region is not essential for enzymatic activity and can accept some degree of structural configuration variation. Making use of these results, we selected both ends of the linker-like amino acid sequence as the basis for FLuc dividing points, and eight variants of a PI-FLuc probe were constructed (Figure 1a).

The binding ability of PI-FLuc probes was confirmed by native-PAGE Western blotting (Figure 2b). We proposed that the converged signal bands, especially in the lanes with RRE-RNA (Nos. 1−4) and TAR-RNA (Nos. 5−8), indicated structural stabilization of PI-FLuc probes after the binding of respective RNA-targets, and that the spread signal bands in the lanes with Rev-aptamer (Nos. 1−3) indicated structural ambiguity after the binding of Rev-aptamer. We suspect that the complexes efficiently migrated in native-PAGE and transferred to PVDF membrane due to the negative charge of bound RNA, while the monomeric PI-FLuc probes in control and nonspecific RNA lanes did not migrate and transfer due to the positive charge of the inserted ARM peptide. In contrast, the monomeric wild type FLuc migrated in native-PAGE and an obvious signal band was observed by Western blotting, although band patterns were not changed by the addition of RNA (data not shown).

Retained FLuc activities and its alteration were evaluated via luminescent signal changes after RNA binding (Figure 2c and Figure 3). Since we could assess the expression levels of PI-FLuc probes equal via Western blotting (Figure 1c), we estimated that the variants Nos. 2, 4, 6, 8 retained FLuc activities approximately 0.01−0.03% of wild type FLuc. Although it was relatively low compared to our expectations, variants Nos. 4, 6, 8 showed dose-dependent FLuc inactivation or reactivation after RNA addition. We hypothesize that FLuc inactivation in the Rev-peptide-inserted variant is due to the intramolecular discomplementaion of divided FLuc domains mediated by intruding RNA (Figure 1a, left). We also suggest that FLuc reactivation in the Tat-peptide-inserted variants is due to the intramolecular complementation of divided FLuc domains mediated by domain contiguity outside TAR-RNA, because Tat-peptide takes on a β-sheet-like turned conformation in conjunction with TAR-RNA (Figure 1a, right). In addition, in the case of Tat-peptide-inserted variants, it seems that variant No. 6 shows a more effective structural reconfiguration after TAR-RNA binding, because No. 6 had higher relative FLuc activity without TAR-RNA versus with TAR-RNA addition (∼10.8) as compared to variant No. 8 (∼4.4). Moreover, both Tat-peptide-inserted variants displayed significant luminescent signal increases at 1.0 nM TAR-RNA concentration. Given these PI-FLuc probe characteristics, we conclude that the Tat-peptide-inserted PI-FLuc probes are potentially sensitive and useful RNA indicators, because their relative activity levels were higher and their RNA detection limits were lower than our previous FRET protein probe (*26*).

To expand the versatility of the intramolecular FLuc complementation assay system, we attempted to detect an arbitrarily selected target-RNA through the formation of hybridized complexes. From Figure 5a, it was suggested that some expanded bands, observed in the case of the split-TAR-RNA probe, represented structural variations of the split-TAR hybridized complex. Then, the arbitrarily selected target-RNA was dose-dependently detected under homogeneous and biocompatible conditions, namely, simultaneous incubation of all probe components at 37 °C (Figure 6). Particularly in the case of Tat-peptide-inserted variants No. 6 and No. 8, the resulting luminescent signal saturated when it reached 100 nM target-RNA levels. This corresponds to the detection of TAR-RNA alone, because the mixed PI-FLuc probes were at twice the volume of Figure 3, whose signal saturations were observed to be at 50 nM TAR-RNA levels. Furthermore, the relative FLuc activities after saturation of the signal increase (2.0−2.5) were at lower levels compared to the detection of TAR-RNA alone. We believe that the reason for lower relative FLuc activity in this case is due to the tertiary structure of the hybridized complex, specifically the more bulky and rigid structure of the target-RNA hybridized complex. Even so, the 10 nM detection limit of the arbitrarily selected target-RNA is relatively lower than other intramoleculer FRET detection or intramolecular enzyme complementation probes (*15*, *16*, *20*, *21*). In addition, we expect that this response could be improved by optimizing the design of hybridized complexes, as demonstrated in our previous report (*26*).

In this RNA detection system, the increase or decrease of luminescent signals is due to the intramolecular complementation or discomplementation of internally divided FLuc domains mediated by the inserted peptide's conformations changes. To extend this idea, recently peptides have drawn attention in the form of molecular recognition materials, such as peptide arrays and peptide aptamers (*37*, *38*). Some of these peptides may also have the necessary characteristics to show induced fit conformational changes after binding to their target molecules (*39*−*41*). If so, it is expected that the construction of PI-FLuc probes that target biomolecules other than RNA molecules would be possible by the same methodology. However, we suppose some more improvements are required in aspects of absolute activity and relative activity, because 10-s counting was needed to obtain sufficient luminescent signals and S/N values. It would require certain trial and error tests to optimize PI-FLuc variants. Even though these potential problems exist, we envisage that PI-FLuc probes could be an alternative strategy to the intramolecular FRET detection system for target biomolecules especially for in vivo detection, because PI-FLuc probes can be produced in living cells.

ACKNOWLEDGMENT

We thank Takashi Masaoka for assistance with translation of PI-FLuc probe variants using wheat germ extract. This study was in part supported by Grants-in-Aid from the Ministry of Education, Culture, Sports, Science and Technology (MEXT), Japan.

Received November 28, 2006; Revised Manuscript Received January 11, 2007

The design of glycoconjugates to allow the generation of multivalent ligands capable of interacting with the receptor DC-SIGN is a topic of high interest due to the role played by this lectin in pathogen infections. Mannose, a ligand of this lectin, could be conjugated at two different positions, 1 and 6, not implicated in the binding process. We have prepared mannose conjugates at these two positions with a long spacer to allow their attachment to a biosensor chip surface. Analysis of the interaction between these surfaces and the tetravalent extracellular domain (ECD) of DC-SIGN by SPR biosensor has demonstrated that both positions are available for this conjugation without affecting the protein binding process. These results emphasize the possibility to conjugate mannose at position 6, allowing the incorporation of hydrophobic groups at the anomeric position to interact with hydrophobic residues in the carbohydrate recognition domain of DC-SIGN, increasing binding affinities. This fact is relevant for the future design of new ligands and the corresponding multivalent systems for DC-SIGN.

INTRODUCTION

Carbohydrate−protein interactions are involved in several cell adhesion and cell communication processes that govern basically the social behavior of cells. Inflammation (*1*), tumor progression and metastasis (*2*), cell development and embryogenesis (*3*), and infection (*4*) are some of the important biological events where carbohydrates play a key role through the interaction with their corresponding protein receptors (*5*, *6*). These carbohydrate interactions are highly selective, calcium dependent, and very weak (*7*). Nature has overcome this problem with a multivalent presentation of carbohydrate epitopes such as glycosphingolipid clustering into lipid rafts and presentation of multiple copies of carbohydrates on glycoproteins. Therefore, the design and development of chemical tools to understand and intervene into these processes involving carbohydrates require the appropriate multivalent scaffolds that can be functionalized with selected carbohydrates (*8*−*10*).

Our research interest has been focused during the last years on a lectin named DC-SIGN[1] (dendritic cell-specific ICAM-3 grabbing nonintegrin) or CD209. This C-type lectin is expressed at the surface of immature dendritic cells and presents at its C-terminus a carbohydrate recognition domain (CRD) (*11*, *12*). Recognition of pathogens by dendritic cells takes place through an interaction involving glycosylated proteins at the surface of pathogens and the receptor DC-SIGN (*13*−*16*). This recognition process is one of the first steps in a complex pathway of events controlled by the immune system. Previous work of our laboratory has demonstrated that multivalent systems based on mannose as carbohydrate and hyperbranched dendritic polymer Boltorn as a multivalent scaffold are capable to interact with DC-SIGN and inhibit the infection process of a pseudotyped viral particle that expresses the GP1 glycoprotein of Ebola virus (*17*−*19*).

Functionalization of mannose to create these glycodendritic polymers was performed at the anomeric position. This election was based on two main reasons. First of all, the hydroxyl groups of mannose implicated on binding with C type lectins are those presented at positions 2, 3, and 4 (*20*). Second, the easiest position to functionalize carbohydrates to generate glycoconjugates is the anomeric position. Position 6 could be considered as another possibility to be functionalized, taking into account that this hydroxyl group is well differentiated from the others (it is the only primary hydroxy group on the sugars), and also it does not seem to participate in the recognition process by the C-type lectin (*21*). Moreover, introducing hydrophobic residues, such as aromatic rings, at the anomeric position can improve the binding affinities of mannoses due to noncovalent van der Waals contacts with amino acid residues of a hydrophobic pocket present at the carbohydrate recognition domain of the lectin (*22*, *23*). As proved previously in several examples, aryl mannopyranosides show higher binding affinities than the corresponding mannose with a free anomeric position (*24*−*27*). This fact could also be applied for DC-SIGN presenting this hydrophobic pocket, and it would mean a considerable increase of mannose binding affinity. Depending on the residues introduced at the anomeric position, in some cases it could be necessary to conjugate these mannose derivatives at a position different from the anomeric one, mainly at position 6 of the mannose.

To prove that functionalization of mannose position 6 with a linker will not interfere in the binding process with DC-SIGN, we have prepared two mannose conjugates with a linker at position 6 and position 1 (anomeric), respectively. We have studied the binding process of these mannoses with the tetrameric extracellular domain (ECD) of DC-SIGN using a biosensor with surface plasmon resonance (SPR) detection. The

glycoconjugates were prepared using a selected linker long enough to allow the attachment of these molecules to the biosensor chip surface without interfering in the binding process with the lectin. This biosensor is a very useful tool that provides quantitative analysis of binding processes in flow conditions using a tiny amount of ligands and receptors without any label (*28*). Biosensors have been succesfully used to measure binding affinities of carbohydrate ligands with lectins (*29*−*34*). In fact, a comparison of these binding affinities provides a rapid method to evaluate the best ligands for a specific receptor.

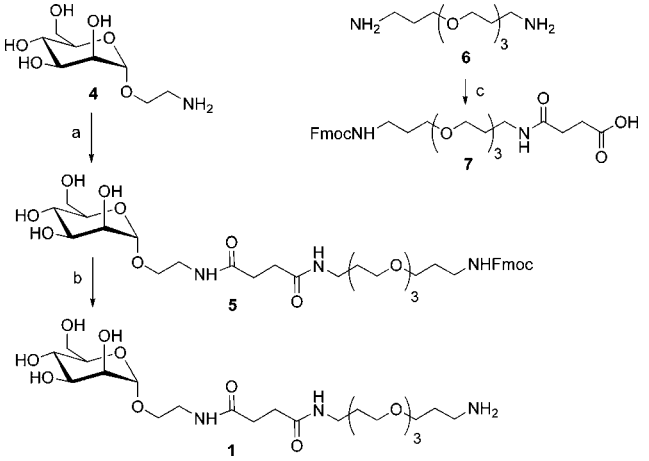
The mannose conjugates and the corresponding control surfaces have been used with a biosensor with SPR detection, and the analyses of the sensorgrams have demonstrated that both positions (1 and 6) of mannose were adequate to create glycoconjugates that can be used as monomers to prepare the corresponding multivalent systems.

MATERIALS AND METHODS

Materials. All purchased chemicals were used without further purification. Synthetic compounds were purified by flash chromatography using medium or fine silica gel. Reaction completion was observed by TLC using as development reagents phosphomolibdic acid, 10% sulfuric acid in methanol, or anisaldehyde. ^{1}H and ^{13}C NMR were recorded on Bruker Avance DPX 300 and DRX 500 MHz spectrometers. Chemical shift are in ppm with respect to TMS (tetramethylsylane) using the manufacturer indirect referencing method. IR spectra were recorded on a Bruker Vector 22. Optical rotations were measured with a Perkin-Elmer 341 polarimeter. Mass spectra were carried out with an Esquire 6000 ESI-Ion Trap from Bruker Daltonics. Methyl α-D-mannopyranoside (**7**) and 4,7,10-trioxa-1,13-tridecanediamine (**5**) were purchased from Aldrich.

Fmoc-Protected Mannose Derivative with a Linker at Position 1 (5). To a solution of **4** (18 mg, 0.088 mmol) and **7** (50 mg, 0.092 mmol) in DMF (3 mL) were added diisopropylcarbodiimine (DIC) (27 μL, 0.18 mmol) and hydroxybenzotriazole (HOBt) (24 mg, 0.18 mmol). The reaction mixture was stirring at 60 °C during 24 h and then evaporated. The final product was purified first by sephadex LH-20 (eluent: CH_2Cl_2−MeOH, 1:1) to eliminate the HOBt and later by silica gel column chromathography (eluent: CH_2Cl_2−MeOH, 9:1) to give **5** as a syrup (37 mg, 66%). $[\alpha]_D$ (MeOH, *c* 0.46) = +21.78; ^{1}H NMR (CD_3OD, 500 MHz) δ (ppm) 7.77 (d, 2H, J = 7.5 Hz, CH_{ArFmoc}), 7.62 (d, 2H, J = 7.5 Hz, CH_{ArFmoc}), 7.36 (t, 2H, J = 7.5 Hz, CH_{ArFmoc}), 7.28 (d, 2H, J = 7.5 Hz, CH_{ArFmoc}), 4.72 (d, 1H, J = 2.0 Hz, H_1), 4.34 (d, 2H, J = 6.5 Hz, CH_{2Fmoc}), 4.17 (t, 1H, J = 6.5 Hz, CH_{Fmoc}), 3.81 (dd, 1H, J = 2.0 and 11.7 Hz, H_6), 3.78 (dd, 1H, J = 1.5 and 3.0 Hz, H_2), 3.75−3.63 (m, 4H, $H_3 + H_4 + H_{6'} + H_7$), 3.63−3.45 (m, 14H, 6 × CH_2O, $H_{7'}$, H_5), 3.42−3.35 (m, 1H, H_8), 3.34−3.29 (m, 1H, H_8), 3.20 (t. 2H, J = 6.5 Hz, CH_2NH), 3.17 (t. 2H, J = 6.5 Hz, CH_2NH), 2.55−2.39 (m, 4H, $HNOCCH_2CH_2CONH$), 1.74−1.66 (m, 4H, 2 × $HNCH_2CH_2CH_2O$); ^{13}C NMR (CD_3OD, 125 MHz) δ (ppm) 173.4 (C═O), 173.1 (C═O), 144.0 (CAr_{Fmoc}), 141.2 (CAr_{Fmoc}), 127.4 (CAr_{Fmoc}), 126.7 (CAr_{Fmoc}), 124.7 (CAr_{Fmoc}), 119.5 (CAr_{Fmoc}), 100.3 (C_1), 73.4 (C_5), 71.1 (C_3), 70.7 (C_2), 70.1, 69.8, 68.5, 68.3, 67.3 (CH_2O− + C_4) 66.1 (CH_{2Fmoc}), 65.8 (C_7), 61.6 (C_6), 38.9 (C_8), 37.7 (CH_2NH), 36.5 (CH_2NH), 30.9 (N(O)CCH_2), 30.8 (N(O)CCH_2), 29.4 ($NHCH_2CH_2$-CH_2O), 29.0 ($NHCH_2CH_2CH_2O$); ESI-MS for $C_{37}H_{53}N_3O_{13}$: calcd, 747,4; found, 770.4 $(M + Na)^+$,786.3 $(M + K)^+$

Mannose Derivative with a Linker at Position 1 (1). 5 (7 mg, 9.36 × 10^{-3} mmol) was dissolved in DMF (1 mL), piperidine 20% in DMF (200 μL) was added, and the reaction was stirred during 2 h. Then the solvent was removed under low pressure. The residue was dissolved in water (10 mL) and washed with CH_2Cl_2 (10 mL). The water was eliminated under reduced pressure to give the desired product **1** as an oil (4 mg, 80%). $[\alpha]_D$ (MeOH, *c* 0.3) = + 23.20; ^{1}H NMR (CD_3OD, 500 MHz) δ (ppm) 4.73 (d, 1H, J = 1.7 Hz, H_1), 3.81 (dd, 1H, J = 2.0 Hz and 11.5 Hz, $H_{6'}$), 3.78 (dd, 1H, J = 1.7 Hz and 3.5 Hz, H_2), 3.74−3.71 (m, 1H, $H_{7'}$), 3.71−3.46 (m, 17 H, H_7, H_6, H_4, H_5, H_3 and 6x CH_2O), 3.46−3.37 (m, 1H, H_8), 3.35−3.29 (m, 1H, $H_{8'}$), 3.22 (t, 1H, J = 7.0 Hz, CH_2NH), 3.08 (t, 1H, J = 6.5 Hz, CHNH), 2.49−2.43 (m, 4H, $HNOCCH_2CH_2CONH$), 1.79−1.64 (m, 4H, 2 × $HNCH_2CH_2CH_2O$); ^{13}C NMR (CD_3OD, 125 MHz) δ (ppm) 173.4 (C═O), 173.1 (C═O), 100.3 (C_1), 73.4 (C_5), 71.9, 70.8, 70.1, 70.0, 69.7, 69.6, 69.0, 68.3, 67.3 (6 × CH_2O, C_2, C_3, C_4), 65.8 (C_7), 61.5 (C_6), 38.9 (C_8), 38.8 (CH_2NH), 38.3 (CH_2NH), 30.7 (N(O)CCH_2), 30.6 (N(O)-CCH_2), 29.3 ($NHCH_2CH_2CH_2O$), 29.3 ($NHCH_2CH_2CH_2O$); ESI-MS for $C_{22}H_{43}N_3O_{11}$: calcd, 525,3; found, 526.3 $(M + H)^+$



α-Methyl 6-tosylmannopyranoside (9) (*35*). α-Methyl mannopyranoside (**8**) (2.0 g, 10.30 mmol) was dissolved in dry pyridine (30 mL) and cooled to 0 °C. Then tosyl chloride (2.77, 14.53 mmol) was slowly added. The reaction was kept stirring at 0 °C overnight. The solvent was removed under reduced pressure, and the residue was purified by flash chromatography with silica gel (eluent: Hex−AcOEt, 7:1) to afford the desired product (5.1 g, 70% yield) as a white solid. $[\alpha]_D$ ($CHCl_3$, *c* 1.00) = +47.3; ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm) 7.80 (d, 2H, J = 8.3 Hz, 2H Ts), 7.33 (d, 2H, J = 2H, J = 8.0 Hz, 2H Ts), 4.67 (d, 1H, J = 1.2 Hz, H_1), 4.35(dd, 1H, J = 10.7 and 4.1 Hz, H_6), 4.26 (dd, 1H, J = 4 Hz and 10.7 Hz, H_6), 3.95−3.87 (m, 1H, H_2), 3.78−3.62 (m, 3H, $H_3 + H_4 + H_5$), 3.30 (s, 3H, OCH_3), 2.42 (s, 3H, CH_3−Ar); ^{13}C NMR ($CDCl_3$, 125 MHz) δ (ppm) 145.0 (C_{Ts}), 132.7 (C_{Ts}), 129.9 (CH_{Ts}), 128.0 (CH_{Ts}), 100.9 (C_1), 71.6 (C_3), 70.5 (C_2), 69.8 (C_4), 69.1 (C_6), 67.3 (C_5), 55.2(OCH_3), 21.7 (CH_{3Ts}); ESI-MS for $C_{14}H_{20}O_8S$: calcd, 348.1; found, 386.9 $(M + K)^+$

α-Methyl 6-Azido-6-deoxymannopyranoside (10). A mixture of α-methyl 6-tosylmannopyranoside (**9**) (2.8 g, 8.04 mmol) and sodium azide (4.18 g, 64.35 mmol) in dry DMF (40 mL) was stirred at 60 °C overnight. After the reaction was complete, the solvent was removed *in vacuo* and the residue was dissolved in ethyl acetate. The excess of sodium azide and sodium tosylate was removed by filtration, and the filtrate was evaporated and purified by flash chromatography (eluent: DCM−MeOH, 9.5:0.5) to afford **9** as an oil (1.52 g, 98% yield). $[\alpha]_D$ (MeOH, *c* 1.00) = +54.80; ^{1}H NMR (CD_3OD, 500 MHz) δ (ppm) 4.62 (d, 1H, J = 1.4 Hz, H_1), 3.77 (dd, 1H, J = 1.6 Hz and 3.2 Hz, H_2), 3.60 (dt, 1H, J = 3.3 Hz and 9.3 Hz, H_3), 3.61−3.56 (m, 1H, H_5) 3.54 (c, 1H, J = 9.3 Hz, H_4), 3.45 (dd, 1H, J = 2.2 Hz and 12.9 Hz, H_6), 3.43 (dd, 1H, J = 6.0 Hz and 12.9 Hz, H_6) 3.38 (s, 3H, OCH_3); ^{13}C NMR (CD_3OD, 125 MHz) δ (ppm) 101.5 (C_1), 72.3 (C_5), 71.0 (C_3), 70.6 (C_2), 68.1 (C_4), 53.9 (C_6), 51.5 (OCH_3); ESI-MS for $C_7H_{13}N_3O_5$: calcd, 219.1; found, 242.0 $(M + Na)^+$

α-Methyl 6-Amino-6-deoxy- mannopyranoside (11). α-Methyl 6-azido-6-deoxy mannopyranoside (**10**) (130 mg, 0.59 mmol) was dissolved in MeOH (30 mL). Pd−C 10% (cat) was added, and the reaction mixture was saturated with hydrogen (1 bar) until reduction was complete to give **11** (120 mg, quant.) as a white solid. $[\alpha]_D$ (MeOH, *c* 1.00) = +49.3; ^{1}H NMR (CD_3OD, 300 MHz) δ (ppm) 4.67 (d, 1H, J = 1.1 Hz, H_1), 3.84−3.74 (m, 1H, H_2), 3.71−3.63 (m, 1H, H_3) 3.60−3.45 (m, 2H, H_4 and H_5), 3.40 (s, 3H, OCH_3), 3.13 (d, 1H, J = 12 Hz, H_6), 2.95 (dd, 1H, J = 6 Hz and 13.2 Hz, H_6); ^{13}C NMR (CD_3OD, 75 MHz) δ (ppm) 102.9 (C_1), 72.7 (C_4), 72.3 (C_3), 72.0 (C_2), 69.7 (C_5), 55.5 (OCH_3), 43.0 (C_6); ESI-MS for $C_7H_{15}NO_5$: calcd, 193.1; found, 194.0 $(M + H)^+$ and 220.0 $(M + Na)^+$

Fmoc-Protected Mannose Derivative with a Linker at Position 6 (12). To a solution of **11** (33 mg, 0.175 mmol) and **7** (100 mg, 0.092 mmol) in DMF (7 mL) were added DIC (60

Scheme 1. Synthesis of Mannose Derivative 1 Functionalized at the Anomeric Position and Synthesis of Linker 7[a]

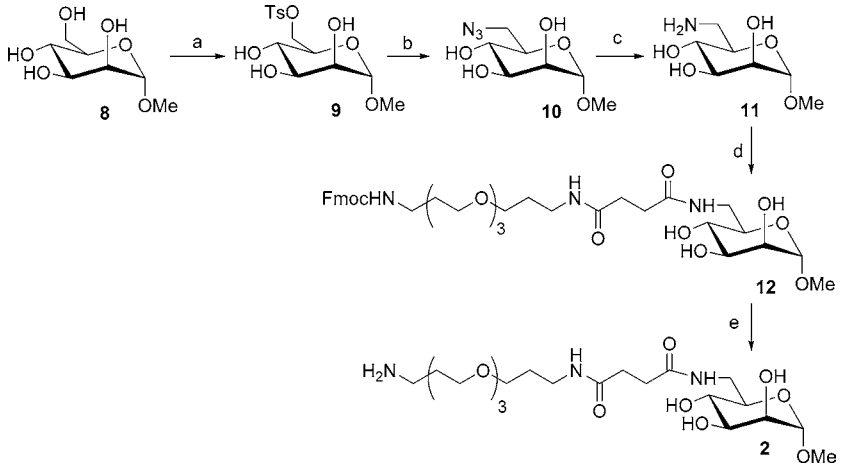
μL, 0.35 mmol) and HOBt (47 mg, 0.35 mmol). The reaction mixture was stirring at 60 °C during 24 h, and then the solvent was removed under low pressure. The final product was purified first by sephadex LH-20 (eluent: CH_2Cl_2−MeOH, 1:1) to eliminate the HOBt and later by silica gel column chromatography (eluent: CH_2Cl_2−MeOH, 95:5) to give **12** (75 mg, 60%) as a syrup. $[\alpha]_D$ (MeOH, *c* 1.00) = +19.02; ^{1}H NMR (CD_3-OD, 300 MHz) δ (ppm) 7.81 (d, 2H, J = 7.5 Hz, $CHAr_{Fmoc}$), 7.66 (d, 2H, J = 7.2 Hz, $CHAr_{Fmoc}$), 7.43 (t, 2H, J = 7.5 Hz, $CHAr_{Fmoc}$), 7.32 (t, 2H, J = 7.5 Hz, $CHAr_{Fmoc}$), 4.62 (d, 1H, J = 1.5 Hz, H_1), 4.38 (d, 2 H, J = 6.6 Hz, CH_{2Fmoc}), 4.21 (t, 1 H, J = 6.3 Hz, CH_{Fmoc}), 3.80 (dd, 1H, J = 1.8 and 3.3 Hz, H_2), 3.72−3.45 (m, 17H, 6 × CH_2O + H_3 + H_4 + H_5 + 2H_6), 3.35 (s, 3H, OCH_3), 3.29−3.17 (m, 4H, 2 × CH_2NH), 2.56−2.44 (m, 4H, 2 × N(O)CCH_2), 1.80−1.69 (m, 4H, 2 × $NHCH_2CH_2$-CH_2O); ^{13}C NMR (CD_3OD, 75 MHz) δ (ppm) 175.1 (C═O), 174.5 (C═O), 145.3 (CAr_{Fmoc}), 142.6 (CAr_{Fmoc}), 128.7 ($CHAr_{Fmoc}$), 128.1 ($CHAr_{Fmoc}$), 126.1 ($CHAr_{Fmoc}$), 121.9 ($CHAr_{Fmoc}$), 102.8 (C_1), 72.4, 72.2, 72.1, 71.5, 71.2, 69.8, 69.7, 69.4 ((CH_2O + C_2 + C_3 + C_4 + C_5), 67.5 (CH_{2Fmoc}), 55.3 (C_6), 48.5 (CH_{Fmoc}), 41.3 (CH_2NH), 39.1 (CH_2NH), 37.9 (CH_2NH), 32.3 (N(O)CCH_2), 32.2 (N(O)CCH_2), 30.8 ($NHCH_2CH_2CH_2O$), 30.3 ($NHCH_2CH_2CH_2O$); ESI-MS for $C_{36}H_{51}N_3O_{12}$: calcd, 717.3; found, 740.3 (M + Na)$^+$ and 756.3 (M + K)$^+$.



Mannose Derivative with a Linker at Position 6 (2). 12 (25 mg, 0.035 mmol) was dissolved in DMF (2 mL). Piperidine 20% in DMF (400 μL) was added, and the reaction was stirred during 2 h. Then the solvent was evaporated. The residue was dissolved in water (20 mL) and washed with CH_2Cl_2 (20 mL). The water was eliminated under reduce pressure to give the desired product **2** as an oil (17 mg, quant). $[\alpha]_D$ (MeOH, *c* 1.00) = +20.9; ^{1}H NMR (CD_3OD, 300 MHz) δ (ppm) 4.63 (d, 1H, J = 1.8 Hz, H_1), 3.80 (dd, 1H, J = 1.8 Hz and 3.6 Hz, H_2), 3.70−3.56 (m, 13H, H_3, H_5, H_4, 5 × CH_2O) 3.56−3.48 (m, 6H, 2H_6, CH_2O), 3.37 (s, 3H, OCH_3), 3.27 (t, 2 H, J = 6.9 Hz, CH_2NH), 2.85 (t, 2H, J = 6.9 Hz, CH_2NH), 2.57−2.44 (m, 4H, 2 × N(O)CCH_2), 1.86−1.71 (m, 4H, 2 × $NHCH_2CH_2$-CH_2O); ^{13}C NMR (CD_3OD, 75 MHz) δ (ppm) 175.1 (C═O), 174.6 (C═O), 102.8 (C_1), 72.4, 72.2, 72.1, 71.5, 71.4, 71.2, 71.1, 70.4, 69.8, 69.4 (C_2, C_3, C_4, C_5, 6 × CH_2O), 55.3 (OCH_3), 41.3 (C_6), 40.1 (CH_2NH), 37.8 (CH_2NH), 32.3 (N(O)CCH_2), 32.1 (N(O)CCH_2), 31.9 (C $CH_2CH_2CH_2O$), 30.4 (C CH_2CH_2-CH_2O); ESI-MS for $C_{21}H_{41}N_3O_{10}$: calcd, 495; found, 496.3 (M + H)$^+$.

Fmoc-Protected 4,7,10-Trioxa-1,13-tridecanediamine Succinimic Acid (7) (*36*). 4,7,10-Trioxa-1,13-tridecanediamine (**6**) (1.11 g, 5.045 mmol) was dissolved in acetonitrile (25 mL), and succinic anhydride (0.5 g, 5.045 mmol) in acetonitrile (12.5 mL) was added slowly over 1 h. The reaction was stirred at room temperature for an additional 3 h. Then the organic layer was decanted, the waxy oil was redissolved in 50% aqueous acetonitrile (50 mL) and cooled at 0 °C for 1 h, and then 1.3 equiv of Fmoc-OSu (2.2 g, 6.52 mmol) in acetonitrile (12.5 mL) was added slowly together with diisopropylethylamine to maintain pH 8−9. After stirring overnight at room temperature, solvents were removed under low pressure and the residue was dissolved in 5% $NaHCO_3$ (50 mL) and washed with AcOEt. The organic layer was discarded, and the aqueous phase was acidified to pH 2 with 5% HCl. Then the aqueous phase was extracted with AcOEt (3 × 25 mL). The combined organic layers were dried (Na_2SO_4), and the solvent was evaporated to give **7** (1.8 g, 66%). ^{1}H NMR (CD_3OD, 500 MHz) δ (ppm) 7.77 (d, 1H, J = 7.5 Hz, CH_{ArFmoc}), 7.62 (d, 1H, J = 7.5 Hz, CH_{ArFmoc}), 7.36 (d, 1H, J = 7.5 Hz, CH_{ArFmoc}), 7.28 (d, 1H, J = 7.5 Hz, CH_{ArFmoc}), 4.34 (d, 2H, J = 7.0 Hz, CH_{2Fmoc}), 4.17 (t, 1H, J = 6.5 Hz, CH_{Fmoc}), 3.62−3.42 (m, 12H, 6 × CH_2O), 3.21 (t, 2H, J = 6.5 Hz,), 3.16 (t, 2H, J = 6.5 Hz,) 2.53 (t, 2H, J = 6.7 Hz, N(O)CCH_2), 2.41 (t, 2H, J = 6.7 Hz, N(O)CCH_2), 1.75−1.66 (m, 2 × $NHCH_2$-CH_2CH_2O,); ^{13}C NMR (CD_3OD, 125 MHz) δ (ppm) 175.9 (C═O), 159.7 (C═O), 146.2 (C_{ArFmoc}), 143.5 (C_{ArFmoc}), 129.6 (C_{ArFmoc}), 129.0 (C_{ArFmoc}), 127.0 (C_{ArFmoc}), 121.8 (C_{ArFmoc}), 72.4 (CH_2O), 72.0 (CH_2O), 70.7 (CH_2O), 70.6 (CH_2O), 68.3 (CH_2O), 39.9 (CH_2NH), 38.6 (CH_2NH), 33.5 (N(O)CCH_2), 32.9 (N(O)CCH_2), 31.6 ($NHCH_2$-CH_2CH_2O), 31.2 ($NHCH_2$-CH_2CH_2O); ESI-MS for $C_{29}H_{38}N_2O_8$: calcd, 542.3; found, 543.3 (M + H)$^+$, 565.3 (M + Na)$^+$, and 581.2 (M + K)$^+$.

Fmoc-Protected Linker Ethanolamine (13). To a solution of 2-aminoethanol (5.5 μL, 0.092 mmol) and **7** (50 mg, 0.092 mmol) in DMF (4 mL) were added DIC (29 μL, 0.184 mmol) and HOBt (25 mg, 0.184 mmol). The reaction mixture was stirring at 60 °C during 24 h, and then the solvent was evaporated. The final product was first purified by sephadex LH-20 (eluent: CH_2Cl_2−MeOH, 1:1) to eliminate the HOBt and later by silica gel column chromatography (eluent: CH_2-Cl_2−MeOH, 95:5) to give **13** (34 mg, 64%) as a syrup. ^{1}H NMR (CD_3OD, 500 MHz) δ (ppm) 7.77 (d, 2H, J = 7.5 Hz, $CHAr_{Fmoc}$), 7.62 (d, 2H, J = 7.5 Hz, $CHAr_{Fmoc}$), 7.38 (t, 2H, J = 7.5 Hz, $CHAr_{Fmoc}$), 7.28 (t, 2H, J = 7.5 Hz, $CHAr_{Fmoc}$), 4.34 (d, 2 H, J = 6.5 Hz, CH_{2Fmoc}), 4.17 (t, 1 H, J = 6.5 Hz, CH_{Fmoc}), 3.65−3.50 (m, 12 H, CH_2O), 3.46 (m, 4 H, $NHCH_2CH_2CH_2O$), 3.26 (t, 2H, J = 5.5 Hz, CH_2NH), 3.20 (t, 2H, J = 6.5 Hz, CH_2NH), 3.16 (t, 2H, J = 5.5 Hz, CH_2NH), 2.47−2.41 (m, 4 H, N(O)CCH_2) 1.73−1.71 (m, 4 H, $NHCH_2CH_2CH_2O$). ^{13}C NMR (CD_3OD, 125 MHz) δ (ppm) 173.5 (C═O), 173.1 (C═O), 144.0 (CAr_{Fmoc}), 141.2 (CAr_{Fmoc}), 127.4 ($CHAr_{Fmoc}$), 126.7 ($CHAr_{Fmoc}$), 124.7 ($CHAr_{Fmoc}$), 119.5 ($CHAr_{Fmoc}$), 70.1 (CH_2O), 69.8 (CH_2O), 68.5 (CH_2O), 68.3 (CH_2O), 66.1 (CH_{2Fmoc}), 60.2 (CH_2OH), 47.2 (CH_{Fmoc}), 41.6 (CH_2NH), 37.7 (CH_2NH), 36.4 (CH_2NH), 30.9 (2 × N(O)CCH_2), 29.4 ($NHCH_2CH_2CH_2O$), 29.0 ($NHCH_2CH_2CH_2O$). ESI-MS for $C_{31}H_{43}N_3O_8$: calcd, 585.3; found, 608.3 (M + Na)$^+$ and 624.2 (M + K)$^+$.

Linker Ethanolamine (3). 13 (10 mg, 0.017 mmol) was dissolved in DMF (2 mL), and 20% of piperidine in DMF (400 μL) was added. The reaction was stirred during 2 h. Then the solvent was evaporated. The residue was dissolved in water (10 mL) and washed with CH_2Cl_2 (10 mL). The water was eliminated under reduce pressure to give the desired product **3** as an oil (6 mg, quant). ^{1}H NMR (CD_3OD, 500 MHz) δ (ppm) 3.65−3.50 (m, 12H, 5 × CH_2O− + CH_2OH), 3.49 (t, 2H, J = 6.0 Hz, CH_2O), 3.26 (t, 2H, J = 6.5 Hz, CH_2NH), 3.22 (t, 2H, J = 6.5 Hz, CH_2NH), 2.86 (t, 2H, J = 6.5 Hz, CH_2NH), 2.46−2.43 (m, 4H, 2 × N(O)CCH_2), 1.79 (q, 2H, J = 6.0 Hz, 2 ×

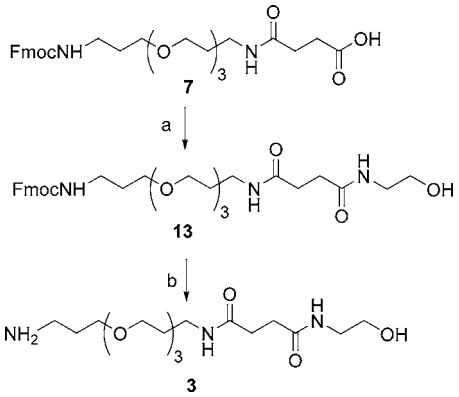
DC-SIGN ECD Expression and Purification. Plasmids pET30b (Novagen) containing a cDNA encoding the extracellular-domain of DC-SIGN (DC-SIGN ECD corresponding to amino acids 66−404) were used for protein overproduction as previously described (*29*). Proteins produced in inclusion bodies have been refolded as already described (*12*). Purification of functional DC-SIGN proteins were achieved by an affinity chromatography on Mannan-agarose column (Sigma) equilibrated with 25 mM Tris-HCl pH 7.8, 150 mM NaCl, 4 mM $CaCl_2$ (Buffer A) and eluted in same buffer lacking $CaCl_2$ but supplement with 10 mM EDTA. This step was followed by a Superose 6 size exclusion chromatography (Amersham) equilibrated in buffer A. Proteins were concentrated, frozen in liquid nitrogen, and stored at minus 80 °C.

Biosensor Experiments. Experiments have been conducted on a BIAcore 3000 instrument. Lyophilized compounds **1**, **2**, and **3** have been solubilized in HBS-N buffer reagent from BIAcore. These derivatives have then been used for functionalization of a CM5 chips (BIAcore). Flow cells were activated with a 50 μL injection of an EDC-NHS mixture as described by manufacturer and blocked, after functionalization, with 50 μL of 1 M ethanolamine. Flow cell one (control flow cell), two, and three were functionalized with 70 μL of control compound **3**, mannose conjugate compound **2**, and mannose conjugate compound **1** diluted at 50 μM in 10 mM acetate buffer pH 4, respectively. The corresponding immobilization levels were of 793, 961, and 848 RU for the flow cell one, two, and three, respectively.

For binding studies, 50 μL of DC-SIGN ECD, in running buffer A supplemented in 0.005% P20 surfactant, was injected, at a flow rate of 20μL.min^{-1}, onto the functionalized surfaces at increasing concentrations.



RESULTS AND DISCUSSION

Synthesis of Glycoconjugates. The 2-aminoethyl α-D-mannopyranoside (**4**) has been previously prepared in our laboratory and was used as starting material to prepare the mannose conjugate functionalized at position 1. We have considered that a longer linker should be more adequate to allow its attachment to the biosensor chip surface. For this reason, mannose derivative **4** was conjugated with linker **7** via an amide bond formation to obtain the glycoconjugate **1** with a longer spacer, after Fmoc removal. Linker **7** was prepared in two steps as described in the literature (*36*) from commercially available 4,7,10-trioxa-1,13-tridecanediamine (**6**) by reaction with succinic anhydride and subsequent amine protection as a carbamate with *N*-(9-fluorenylmethoxycarbonyloxy)succinimide (Fmoc-Osu) (Scheme 1). Reaction of 2-aminoethyl α-D-mannopyranoside (**4**) with linker **7** in the presence of DIC and HOBt at 60 °C gave selectively the mannose derivative **5** with an amide linkage in 66% yield. Using these conditions was not necessary to protect the mannose hydroxyl groups. After this coupling, the Fmoc protecting group was easily removed by treatment with 20% of piperidine in DMF at room temperature to give compound **1** in 80% yield, the mannosyl glycoconjugate functionalized at position 1 (Scheme 1).

To prepare a mannose derivative functionalized at position 6 we used as starting material the commercially available methyl α-D-mannopyranoside (**8**). To use the same type of linkage as that used with mannose derivative **4** we decided to introduce a primary amine at position 6 of the mannose. The 6-deoxy-6-aminomannose derivative **11** was prepared in three steps using the methodology described (*35*), introducing some modifications. We converted the 6-hydroxyl group into a good leaving group by reaction with tosyl chloride at 0 °C in pyridine using the procedure described in the literature (*35*) to give the mannose derivative **9** in 70% of yield. Then the tosyl group was substituted by an azide group by reaction with an excess of sodium azide in DMF. We tried the conditions previously described (*35*) to substitute the tosyl group by azide in a mixture acetone−water (*3*−*2*) under reflux, but the attempts using these conditions were fruitless, recovering the starting material in all the cases. Using DMF as solvent at 60 °C, the reaction was complete overnight to yield the methyl 6-deoxy-6-azidomannopyranoside (**10**) in 98% of yield. The last step to get the amine group at position 6 was the catalytic hydrogenation of the azide group using Pd/C at 1 atm of H_2 to obtain the methyl 6-deoxy-6-aminomannopyranoside (**11**) in quantitative yield (*35*) (Scheme 2).

Once the mannose derivative **11** was obtained, the coupling with the linker **7** was performed using the same conditions as those used with mannose derivative **4**, i.e., DIC and HOBt in DMF at room temperature, to give the glycoconjugate **12** in 60% of yield with the linker at the anomeric position. Again, the last step was the removal of Fmoc protecting group with 20% piperidine in DMF at room temperature to obtain mannose conjugate **2** in quantitative yield (Scheme 2).

Scheme 3. Synthesis of Control Compound 3[a]

[a] a) DIC, HOBt, ethanolamine, DMF, 64%; b) piperidine, DMF, 100%.

Finally, a control for the binding studies was prepared. We used the same spacer **7** coupled with ethanolamine using DIC and HOBt in DMF at 60 °C to give compound **13** in 64% of yield. Again, deprotection of amine group with 20% piperidine in DMF at room temperature gave compound **3** in quantitative yield which will be used as control (Scheme 3).

Surface Functionalization. In our mannose derivatives, the spacer added on position 6 or 1 has been designed with an amine terminal group. This function will allow further functionalization in order to produce future multivalent dendrimeric compounds. But this extremity can also be considered here as a mimics of a lysine side chain and may be used to functionalize the SPR surfaces using *N*-hydroxysuccinamide and EDC chemistry as usually done to covalently link proteins. Such protein functionalization methods lead to covalent attachment of the lysine residue to the carboxylic groups harbored by the dextran polymer present at the sensorchip surface. Similarly, compounds **1**−**3** were used to functionalize a CM5 sensorchip surface after activation with a mixed solution of EDC-NHS. After injections of the different compounds, an increase of the immobilization level (in resonance units) has been observed in the sensorgrams as a clear signal of covalent attachment of these compounds to the activated carboxylic acid surface via amide linkages (data not shown). An immobilization level of 793, 961.5, and 848 RU has been obtained for compounds **1**, **2**, and **3,** respectively. This validates this chemical strategy of "building block" production with this type of spacer, allowing a functional test of the carbohydrate unit in SPR analysis before getting to the expensive and time-consuming chemical step assembly of multivalent dendrimeric compounds. These functionalized surfaces were used to study the binding process with the ECD of DC-SIGN in a flow mode.

Surface Plasmon Resonance Binding Assays. Binding assays were performed using increasing concentrations of DC-SIGN ECD ranging from 0.1 μM to 100 μM. These solutions of lectin were injected over the functionalized surfaces. The interaction profile of DC-SIGN ECD (Figure 1) with the functionalized surfaces is indicative of a rapid association and dissociation process (high k_{on} and k_{off}) and of a weak affinity of DC-SIGN ECD for the monosaccharide derivatives used here, compounds **1** and **2**. This is in accord with the previously reported affinity for mannose of the DC-SIGN CRD in the millimolar range (*12*). By contrast, the surface functionalized with the control compound **3** only showed a small nonspecific response presenting the same RU level as observed on a surface without any functionalization (data not shown). This background interaction obtained with the control surface was subtracted from the signals obtained with surfaces functionalized with compounds **1** and **2** (Figure 1).

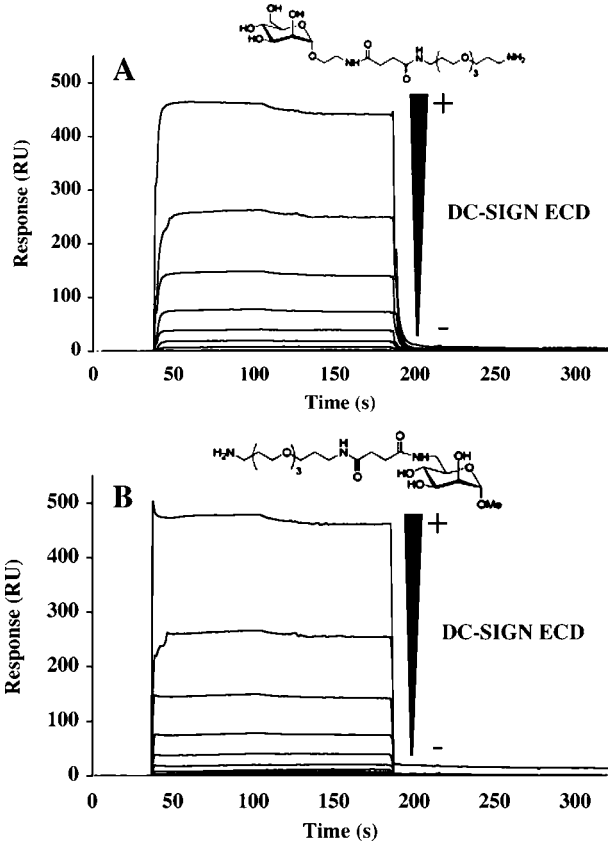


Figure 1. Sensorgrams corresponding to the injection of different concentrations of DC-SIGN ECD with surfaces functionalized with compound **1** (A) and compound **2** (B). The concentrations used were 0.1, 0.2, 0.4, 0.8, 1.55, 3.1, 6.2, 12.5, 25, 50, and 100 μM.

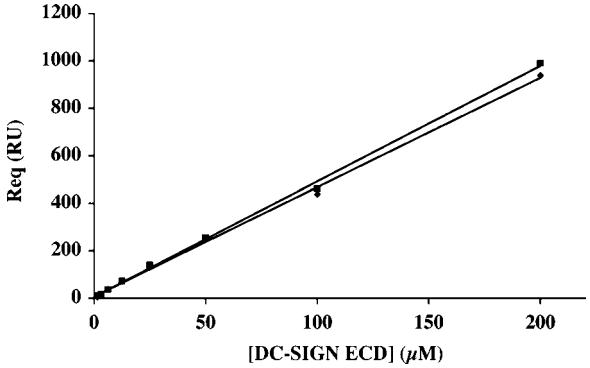

Figure 2. Representation of steady states response level (R_{eq}) for surfaces functionalized with glycoconjugates **1 (**filled diamond**)** and **2** (filled square) as a function of DC-SIGN ECD concentration.

An analysis of these curves by representation of DC-SIGN ECD concentration against the steady-state response level (R_{eq}) observed for each functionalized surface showed a similar behavior for both types of surfaces (functionalized, at an equivalent density, with the mannose conjugate linked at position 6 or at the anomeric position) (Figure 2). Because of the weak affinity observed for these carbohydrate−protein interactions, the saturation curve did not present a maximum because it was not possible to reach the saturation situation in the concentration range used for the DC-SIGN ECD. To get access to a K_d would require a high amount of DC-SIGN ECD and at a concentration in the millimolar range that may not be accessible for solubility reasons. Here we have access to the ascending part of the saturation curve. In the case of a marked difference in affinity of DC-SIGN ECD for both types of modified mannose, the change in K_d will be reflected not in the value of the maximum

plateau reached but rather in the position and evolution of the ascending part of the saturation curve. Here Figure 2 shows that there is no significant difference between the glycoconjugates **1** and **2**.

Our basic interest was centered on the qualitative comparison of both surfaces to determine if both positions in the mannose ring (anomeric position and position 6) were feasible as focal points for linkage of this carbohydrate in order to prepare glycoconjugates and finally multivalent systems. This SPR analysis demonstrated that both positions were appropriate to be used as points of functionalization to generate glycoconjugates, and it is also reasonable to say that position 6, as can be observed in Figure 2, is a good or even better than the anomeric position which is usually used to prepare carbohydrates conjugates.

CONCLUSIONS

In this work we have prepared two mannosyl conjugates at different positions, position 6, and position 1 or the anomeric position of the carbohydrate. With these conjugates, a CM5 chip surface of a biosensor was functionalized to create a carbohydrate surface to study the interaction with the tetrameric ECD of DC-SIGN. The analysis of the obtained sensorgrams showed that this binding process was fast and weak. In fact, for the concentration of protein used, it was not possible to reach saturation and therefore a quantitative calculation of K_d was not possible. However, an important feature of this binding process with the lectin DC-SIGN was demonstrated for the first time; functionalization of mannose at position 6 is a very good alternative, as good as glycoconjugates functionalized at the anomeric position, to prepare glycoconjugates.

This fact opens new possibilities in the design of ligands for this receptor. The introduction of selected hydrophobic groups at the anomeric position of the reducing end of the corresponding carbohydrate can be envisaged. These hydrophobic groups could establish contact with hydrophobic residues present in the carbohydrate recognition domain and increase the affinity of these ligands for the receptor. Introduction of linkers at position 6 will allow the preparation of glycoconjugates with these ligands without loss of activity and also will allow the preparation of the corresponding multivalent systems to interact with DC-SIGN.

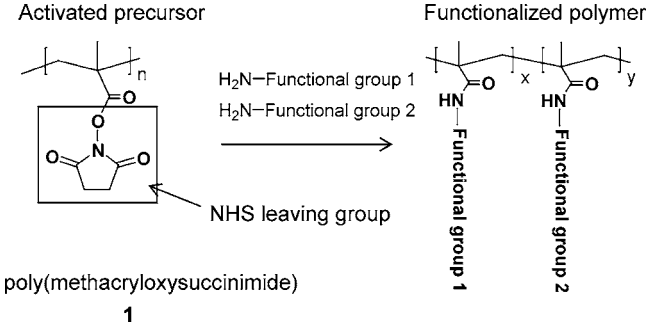
Overcoming Limiting Side Reactions Associated with an NHS-Activated Precursor of Polymethacrylamide-Based Polymers

Sharon Y. Wong[†] and David Putnam*[,†,‡]

Department of Biomedical Engineering and the School of Chemical and Biomolecular Engineering, Cornell University, Ithaca, New York 14853. Received December 7, 2006; Revised Manuscript Received February 12, 2007

Combinatorial polymer libraries have recently gained popularity for the development of novel materials for a variety of biomedical applications including non-viral gene delivery systems and biodegradable polymers for tissue engineering. To streamline the nontrivial task of library synthesis, activated ester homopolymers have been used to serve as a backbone to which primary amine-containing functional groups (NH_2-FGs) can be covalently bound at varying ratios. Polymethacryloxysuccinimide (poly(MAOS)) is one such homopolymer that was previously reported to be an attractive precursor for polymeric drug and gene delivery systems. The reported functionalization protocols entailed conjugating the precursor with 2 equiv of the NH_2-FG at a reaction concentration of 25 mg poly(MAOS)/150 μL DMSO for either 5 h at 50 °C or 16 h at 25 °C. More recently, both protocols were revealed to be associated with ring-opening and glutarimide-forming side reactions that compromise the utility of the homopolymer. Using 1-dimensional and 2-dimensional NMR spectroscopy techniques, we have characterized the side product distributions that result from conjugations performed at 50 °C/5 h and 25 °C/16 h. Moreover, by systematically altering the equivalents of the NH_2-FGs, polymer concentration, reaction time, and reaction temperature, we have established a protocol that overcomes these side reactions. Using a final reaction protocol of 5 equiv of the NH_2-FG at a reaction concentration of 25 mg poly(MAOS)/600 μL DMSO for 24 h at 75 °C, we have obtained functionalized polymers with minimal side products. This protocol is applicable for polymers ranging from 5000 to 50 000 g/mol, compatible with a variety of functional groups, and amenable to conjugating combinations of functional groups.



INTRODUCTION

With the ever-increasing demand for more sophisticated, multifaceted polymeric materials in various applications, many researchers have begun looking to combinatorial approaches to facilitate the materials discovery process. One of the first successful demonstrations of employing combinatorial strategies to develop degradable polymers for medical applications was reported almost a decade ago by Kohn and co-workers (*1*, *2*). Their work exemplified how combinatorial strategies can (1) offer a systematic approach to designing libraries of compounds that encompass a broad range of physicochemical properties and (2) assist in identifying structure−function relationships that correlate a polymeric structural feature to a biological response.

Building on this work, Brocchini and co-workers, Haddleton and co-workers, and others have applied the combinatorial approach toward developing water-soluble polymers for drug and gene delivery systems (*3*−*9*). To expedite the library synthesis process, the former two groups employed the use of the activated homopolymeric precursor, polymethacryloxysuccinimide (poly(MAOS) (**1**), to which primary amine-containing functional groups (NH_2-FGs) can be covalently bound via amidation chemistry (*10*) (Scheme 1).

Recently, greater resolution of the potential side reactions that can occur with the poly(MAOS) precursor was reported (*11*). In our hands, we also observed similar problems upon functionalizing poly(MAOS) that resulted in at least two unexpected side reactions: (1) ring opening of the succinimide moiety and (2) glutarimide formation between presumably neighboring active esters. These side products were confirmed by ^{1}H NMR, diffusion ordered spectroscopy (DOSY), heteronuclear multibond correlation spectroscopy (HMBC), and homonuclear correlated spectroscopy (COSY) analyses (Scheme 2).

Scheme 1. Theoretical Synthetic Scheme for Functionalizing the *N*-Hydroxysuccinimide (NHS)-Activated Precursor, Polymethacryloxysuccinimide (poly(MAOS) (1) to Form Polymethacrylamide-Based Polymers

However, these limitations do not ultimately preclude the use of this polymeric precursor as was previously suggested (*11*). In this report, we describe the protocol that we have established to overcome these side reactions allowing poly(MAOS) to serve as a viable precursor for polymethacrylamide-based materials. Additionally, we show that this protocol is applicable for polymers ranging from 5000 to 50 000 g/mol, compatible with a variety of functional groups, and amenable to conjugating combinations of functional groups.

Scheme 2. Side Reactions Can Occur during Conjugation of NH_2-FGs to 1 Resulting in a Functionalized Polymer with Three Pendant Groups: the Desired Amide-Bound Conjugate; a Hydrolytically Unstable Ring-Opened Conjugate; and a Glutarimide-Bound Conjugate

Scheme 3. Resultant Functionalized Polymer Produced from Previously Reported Protocols[a]

[a] Two unexpected side reaction products accompany the desired conjugation: (1) a labile ring-opened conjugate and (2) a glutarimide-bound conjugate. (protocol 1—ref 3; protocol 2—ref 4)

EXPERIMENTAL PROCEDURES

N-Methacryloxysuccinimide monomer was synthesized as previously reported (*12*). Cu(I)Br (99.999%), Cu(II)Br_2 (99.999%), 2,2′-dipyridyl (≥99%), ethyl 2-bromoisobutyrate (98%), benzylamine (≥99.5%), *n*-butylamine (≥99.5%), hexylamine (≥99.5%), 1-amino-2-propanol (≥98%), N-Boc-*N*-methylethylenediamine (≥98.0%), N-Boc-ethylenediamine (≥98%), *N*,*N*-dimethylethylenediamine (≥98%), 2-(aminoethyl)trimethylammonium chloride—HCl (99%), histamine (≥97%), anhydrous DMSO, DMSO-d_6, abd DMF-d_7 were all purchased from Aldrich.

General Procedure for Synthesis of Poly(methacryloxysuccinimide) (poly(MAOS)). The polymer precursor was synthesized with a slight modification to a previously reported method (*5*). A 5 mL pear-shaped flask with a flea magnetic stir bar was fitted with a rubber septum and flame-dried while purging with N_2(g) until cooled to ambient temperature. *N*-Methacryloxysuccinimide (0.5 g, 2.73 mmol), Cu(I)Br (0.0078 g, 0.055 mmol), Cu(II)Br_2 (0.0122 g, 0.055 mmol), and 2,2′-dipyridyl (0.0171 g, 0.11 mmol) were placed in the flask and placed under a nitrogen atmosphere for 10 min. Cu(II)Br_2 was added to the reaction as an inhibitor of chain terminations to control polydispersities (*13*). Deoxygenated anhydrous DMSO (0.2 mL) was injected into the flask, and the contents were stirred until dissolved. Ethyl-2-bromoisobutyrate (81 μL, 0.55 mmol) was weighed directly into a separate dram vial and dissolved in deoxygenated anhydrous DMSO (0.5 mL). Upon complete dissolution of the contents, a 1/10 aliquot (50 μL) of the ethyl 2-bromoisobutyrate solution was injected into the flask and immersed into a 100 °C thermostated oil bath. To stop the polymerization, the flask was quenched in an ice bath and the product was diluted with anhydrous DMSO (1.5 mL). The final polymer was isolated as a white powder by precipitating into stirring acetone. ^{1}H NMR (DMSO-d_6) δ: 1.44 (b, 3H, CH_3), 2.41 (b, 2H, CH_2), 2.78 (b, 4H, CH_2CH_2).

Molecular weight and polydispersity were determined by hydrolyzing poly(MAOS) to its Na salt. Upon dissolving poly(MAOS) (0.010 g, 0.055 mmol) in DMSO (0.080 mL), 22 μL of 5 M NaOH was added dropwise to the reaction and allowed to stir for 7 h at room temperature. The cloudy solution was redissolved with 0.8 mL of filtered deionized water and allowed to stir overnight at room temperature. The reaction was then dialyzed against deionized water using Spectra/Por regenerated cellulose tubing (MWCO 3500 Da) for 3 days. The dialysate was subsequently lyophilized to give a white feathery powder.

General Procedure for Functionalized Poly(MAOS). Prior to each reaction, a 5 mL pear-shaped flask with a flea magnetic stir bar was fitted with a rubber septum and flame-dried while purging with N_2(g) until cooled to ambient temperature. Poly(MAOS) (0.025 g, 0.14 mmol) was added to the flask and dissolved with deoxygenated anhydrous DMSO (0.6 mL). Upon dissolution of the contents, 5 equiv of the NH_2-FG was dropwise added via a Hamilton syringe and immersed in a 75 °C thermostated oil bath. For the binary conjugations, the first amine was dropwise added via a Hamilton syringe, followed immediately by dropwise addition of the second amine via a separate Hamilton syringe. The flask was removed from the oil bath after 24 h and the septum removed. To remove excess solvent, the flask mouth was covered with Parafilm, punctured approximately seven times with a 21 gauge needle, and placed in vacuo for 4 h. The final product was isolated via dropwise addition into stirring acetone and filtered through a fine-fritted

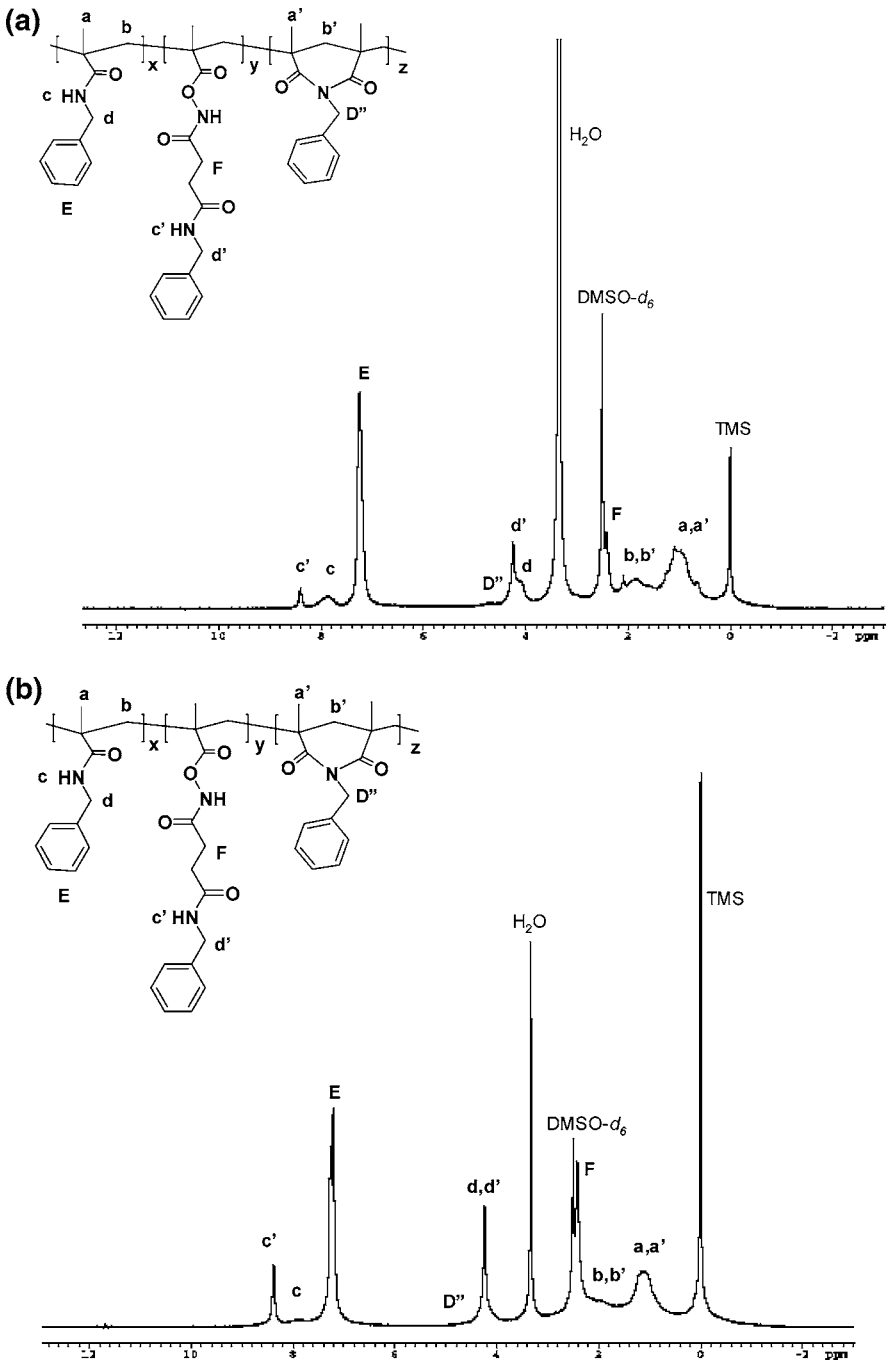

Figure 1. Representative ^{1}H NMR spectra of resultant functionalized polymer produced from (a) protocol 1 (2 equiv benzylamine, 50 °C, 5 h, 25 mg poly(MAOS)/150 μL DMSO) and (b) protocol 2 (2 equiv benzylamine, 25 °C, 16 h, 25 mg poly(MAOS)/150 μL DMSO). Both spectra provide evidence of a ring-opened side product (indicated by peaks F, d′, and c′) and glutarimide-bound side product (indicated by peak D′′). Peaks labeled in capital letters were used for quantification via signal integration of the respective pendant groups. Note: These spectra were obtained during our analysis but are consistent with the results of Devenish et al. and are shown here to clarify the method of quantification.

Buchner funnel and washed twice with acetone, twice with diethyl ether, and dried overnight in vacuo. N-Boc-protected functionalized polymers were isolated via dropwise addition into diethyl ether. The gummy precipitate was redissolved in methylene chloride and reprecipitated into diethyl ether as a white flaky powder. The powder was filtered through a fine-fritted Buchner funnel and immediately deprotected with 20 equiv of neat trifluoroacetic acid for 8 min. The final product was isolated via dropwise addition into stirring diethyl ether and filtered through a fine-fritted Buchner funnel. Polymers functionalized with water-solubilizing FGs, including all binary conjugations, were redissolved in, and dialyzed against, 0.1 N HCl in Spectra/Por regenerated cellulose tubing (MWCO 3500 Da) for 4 days. The dialysate was subsequently lyophilized to give a flaky solid.

Characterization. Benzylamine-functionalized poly (MAOS): ^{1}H NMR (DMSO-d_6) δ 0.89 (b, 3H, CH_3), 1.89 (b, 2H, CH_2), 7.86 (b, 1H, NH), 4.11 (b, 2H, CH_2), 7.26 (b, 5H, C_6H_5), 4.68 (b, 2H, glutarimide-CH_2). Butylamine-functionalized poly-(MAOS): ^{1}H NMR (DMSO-d_6) δ 0.89 (b, 3H, CH_3), 1.89 (b, 2H, CH_2), 7.29 (b, 1H, NH), 2.93 (b, 2H, CH_2), 1.25 (b, 4H, CH_2CH_2), 0.86 (b, 3H, CH_3). Determination of Relative Percent Conjugation. For monofunctionalized conjugations, a sample calculation of the relative percent conjugation of each pendant group is demonstrated with benzylamine-conjugated poly(MAOS) as determined from the [1]H NMR spectra using the following equations:

$$\% Z = \frac{I_{4.68}}{2} \times 100$$

$$\% Y = \frac{I_{2.4}}{4} \times 100$$

$$\% X = 100 - \% Y - \% Z$$

where Z = glutarimide-bound conjugate, Y = ring-opened conjugate, X = desired amide-bound conjugate, $I_{4.68}$ = signal intensity of the two glutarimide methylene protons, and $I_{2.4}$ =

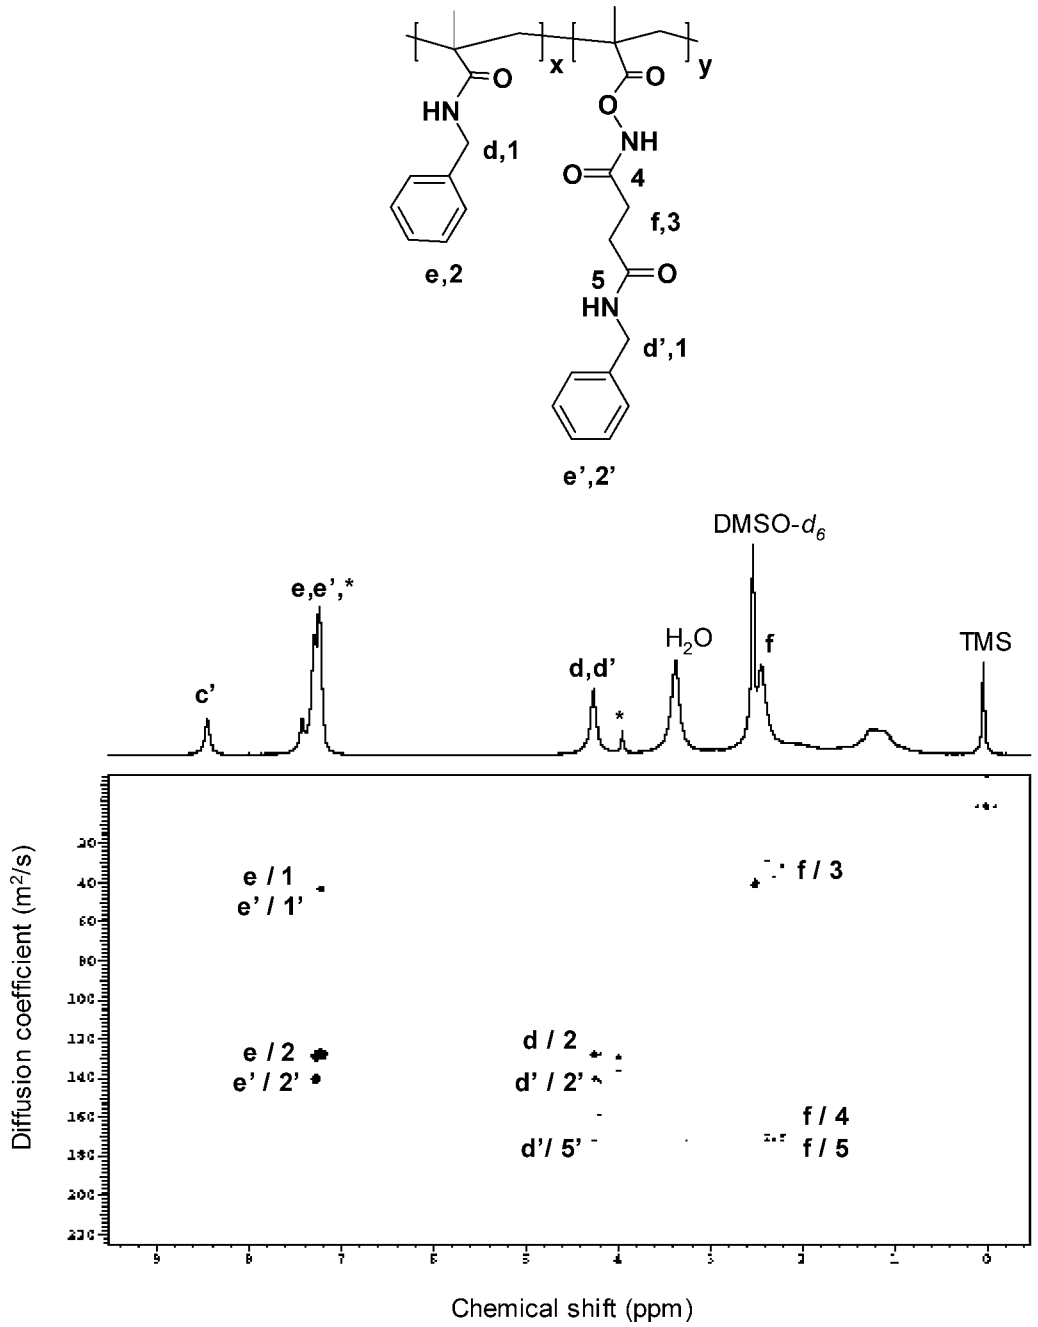

Figure 3. $^1H-^{13}C$ HMBC spectrum of poly(MAOS) functionalized with benzylamine following protocol 2 (2 equiv benzylamine, 25 °C, 16 h, 25 mg poly(MAOS)/150 μL DMSO). Peak f, corresponding to the ring-opened side product, is shown to correlate with carbonyl carbons, thus providing further evidence of the presence and identity of the ring-opened side product (correlations f/4 and f/5). Peaks labeled with letters correspond to protons, and numbers correspond to carbons. (* = excess benzylamine.)

signal intensity of the four ring-opened methylene protons. I_δ = signal intensity at δ ppm when $I_{7.26} = 5.0$.

For binary conjugations, the relative percent conjugation of each functional group is demonstrated with the *N*,*N*-dimethylethylenediamine(3N)/benzylamine conjugation as determined from the ^1H NMR spectra using the following equations:

$$\%\ \text{Benzylamine} = \frac{\frac{I_{7.26}}{5}}{1 + \frac{I_{7.26}}{5}} \times 100$$

$$\%\ 3N = 100 - \%\ \text{Benzylamine}$$

where $I_{7.26}$ = peak intensity of the five benzyl protons at 7.26 ppm when $I_{2.94} = 6.0$. $I_{2.94}$ = peak intensity of the six methyl protons of 3N.

Molecular Weight Characterization. Gel permeation chromatography was carried out using Waters Ultrahydrogel 250 and 500 columns in series coupled to UV (Waters 2487) and RI (Waters 2414) detectors. The mobile phase was phosphate buffered saline (pH = 7.4) at a flow rate of 0.8 mL/min at 30 °C. Calibration was performed using PMAA-Na standards (Polysciences, Inc., and Polymer Standards Service-USA, Inc.) in the range of 1.6 kg mol^{-1} to 110 kg mol^{-1}.

NMR Spectroscopy. All NMR analyses were performed with 7 mg of sample dissolved in 1 mL of deuterated solvent, and all spectra were processed using standard Varian software. One-

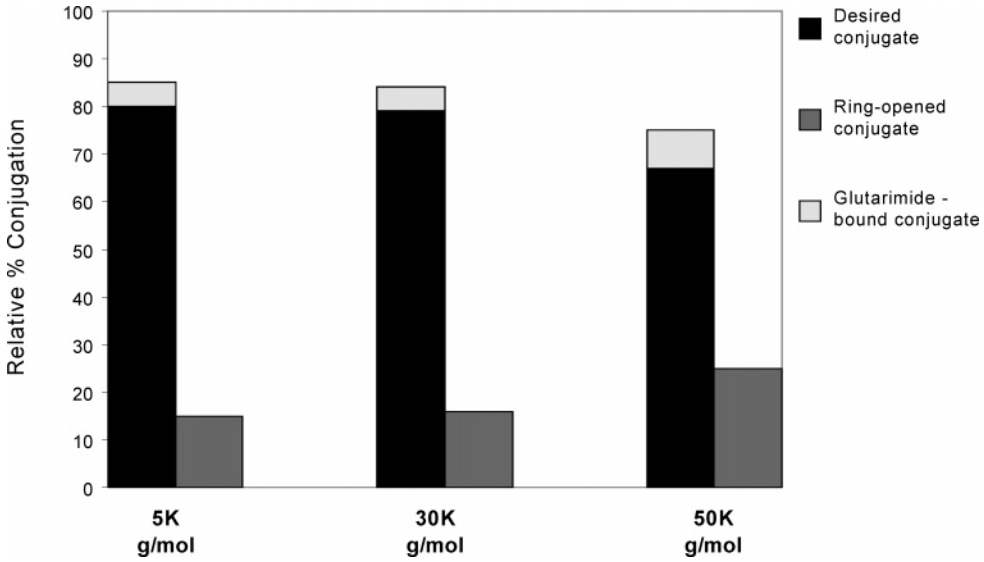

Figure 4. The effect of molecular weight on conjugation profile following protocol 1 (2 equiv benzylamine, 50 °C, 5 h, 25 mg poly(MAOS)/150 μL). Pendant distribution remained similar for all three molecular weights evaluated.

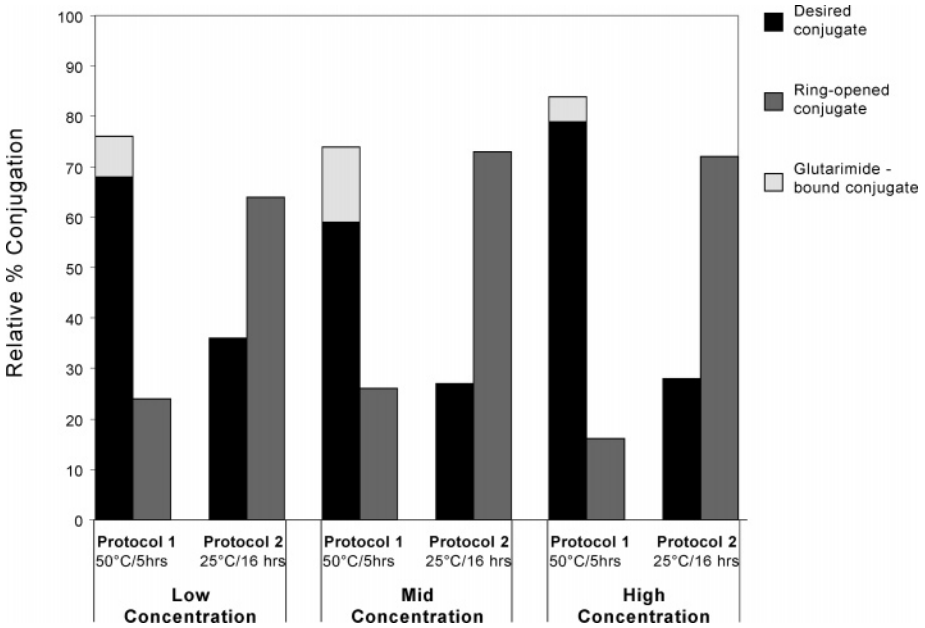

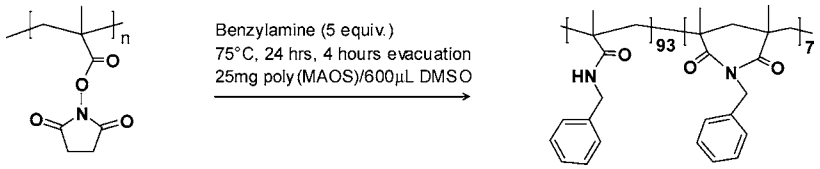

Figure 5. The effect of poly(MAOS) concentration on conjugation profile following two reported protocols. Each protocol results in similar pendant distributions regardless of precursor concentration. Low concn = 25 mg poly(MAOS)/1 mL DMSO; middle concn = 25 mg poly(MAOS)/600 μL DMSO; high concn = 25 mg poly(MAOS)/150 μL DMSO. 30 000 g/mol poly(MAOS) was used for all reactions. Reactions performed at low and mid concentrations included an additional 4 h in vacuo concentration of the reaction mixture prior to precipitation.

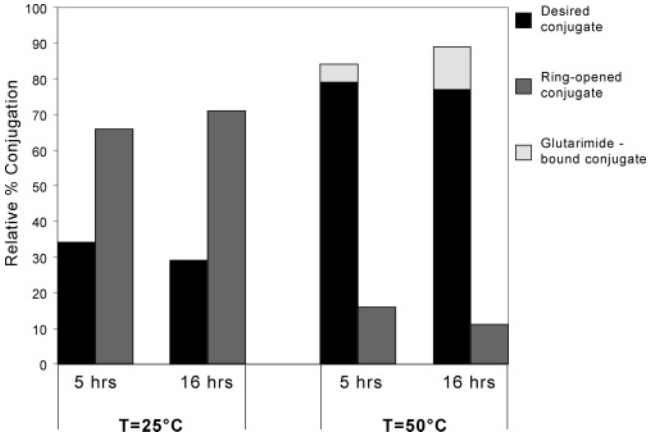
Scheme 4. Preparation of Functionalized Poly(MAOS) Free of Ring-Opened Side Product

dimensional ^{1}H NMR analyses were performed at room temperature on an Inova 600 MHz spectrometer with a proton observation frequency of 599.8 MHz. Chemical shifts were referenced relative to tetramethylsilane (0.0 ppm) when possible or the residual solvent signal: D_2O (4.8 ppm), DMSO-d_6 (2.5 ppm), or DMF-d_7 (2.75 ppm). Spectra were acquired with a 5.6 μs pulse width corresponding to a 45° flip angle, 3 s acquisition time, 4.8 kHz spectral width, 16 transients, and a 1 s recycle delay. An exponential multiplication of approximately 0.3 Hz was applied prior to Fourier transformation.

Proton homonuclear correlated spectroscopy (^{1}H−^{1}H COSY) was performed at 120 °C on an Inova 500 MHz spectrometer with a proton observation frequency of 499.9 MHz. Spectra were obtained using the gCOSY pulse program in the *VnmrJ* software with 1024 (t_2) × 512 (t_1) data points collected at two scans per t_1 increment. Spectral widths of 6.4 kHz in F2 and F1 were used along with a 0.1608 s acquisition time and a 1 s recycle delay time. Fourier transformation was done on a 2000 × 2000 data matrix with sine bell window function applied to F1 and F2.



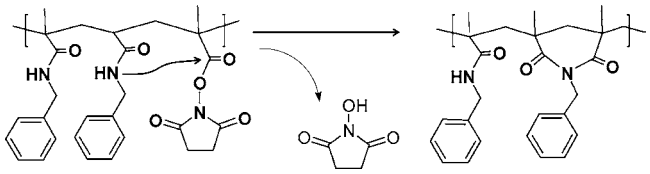


Figure 6. The effect of reaction time and temperature on conjugation profile. Increasing temperature leads to a greater proportion of the desired and glutarimide-bound conjugates and less of the ring-opened conjugate. 2 equiv benzylamine, 25 mg poly(MAOS)/150 μL DMSO, 30 000 g/mol poly(MAOS) was used for all reactions.

The long-range $^{1}H-^{13}C$ correlation spectroscopy (HMBC) was performed at room temperature on an Inova 600 MHz spectrometer with a proton frequency of 599.8 MHz. Spectra were obtained using the gHMBC pulse program in the *VnmrJ* software with 1024 (t_2) $\times$ 400 (t_1) data points collected at 28 scans per t_1 increment. Spectral widths of 7 kHz in F2 and 36.2 kHz in F1 were used along with a 0.1608 s acquisition time and a 1 s recycle delay. Fourier transformation was done on a 1000 (F2) $\times$ 4000 (F1) data matrix with Gaussian processing applied to F2 only.

Diffusion-Ordered NMR Spectroscopy (DOSY). ^{1}H detected DOSY experiments were performed at 22 °C on an Inova 600 MHz spectrometer equipped with a triple-resonance probe head capable of producing gradients in the *z* direction with strength of up to 70 G cm^{-1}. DOSY experiments were performed using a bipolar pulse pair double stimulated echo experiment. The gradient strength was logarithmically incremented in 16 steps from 2.3 up to 60 G cm^{-1}. Diffusion times and gradient pulse durations were optimized for each experiment in order to achieve a 90% decrease in the resonance intensity at the largest gradient amplitude. Diffusion times varied between 600 and 900 ms, and bipolar rectangular gradient pulses of 2 ms were employed. Data were analyzed using the *VnmrJ* software package.

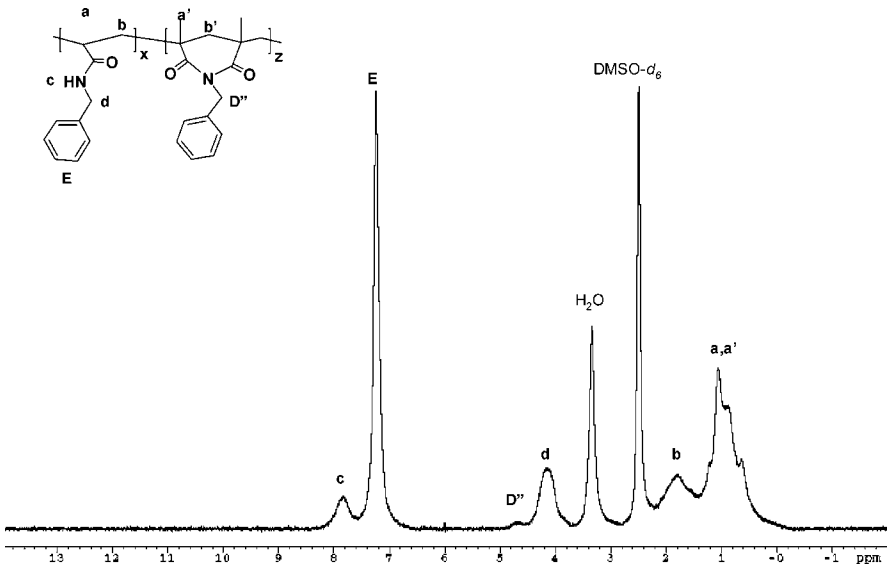
Scheme 5. Proposed Route for N-Substituted Glutarimide Formation Presumably between Amide-Bound Conjugates and Neighboring Active Esters

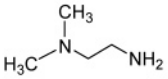
RESULTS AND DISCUSSION

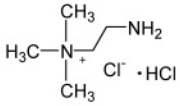
Our initial attempts to conjugate benzylamine to poly(MAOS) following two independent protocols resulted in two unexpected side reactions that accompanied the desired conjugation: (1) ring opening of the succinimide moiety and (2) glutarimide formation between presumably neighboring active esters. These side reactions were thoughtfully characterized and recently reported by Devenish et al. and shown again in Scheme 3 and Figure 1 for ease of reference (*11*).

To further verify that the ^{1}H NMR peak corresponding to the methylene protons of the ring-opened pendant group (peak F in Figure 1) was not just residual low molecular weight byproduct, we performed DOSY experiments to provide evidence of covalent linkage to the backbone (*14*). This pulsed field gradient NMR experiment yields a 2D spectrum with NMR chemical shifts on the horizontal axis and relative diffusion coefficients on the vertical axis. DOSY has been used for the analysis of polymer mixtures to determine the molecular weight (MW) of individual components (*15*). In this paper, DOSY was utilized to confirm that the ring-opened side reaction product was diffusing at a similar rate as the polymer and thus covalently bound to the polymer as evidenced in Figure 2. Additionally, HMBC experiments were performed to identify long-range (2−3 bonds) correlations between protons and neighboring carbons. Figure 3 reveals that the ring-opened methylene protons (peak f) are correlated to carbonyl carbons (carbons 4 and 5). Taken together, these data provide strong evidence that the ring-opened pendant group is indeed covalently bound to the polymer.

Using signal integration of the ^{1}H NMR spectra (Figure 1) to quantify the relative degree of conjugation of each pendant







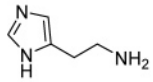


Figure 7. Representative ^{1}H NMR spectra of resultant functionalized polymer produced from the revised protocol (5 equiv benzylamine, 75 °C, 24 h, 4 h evacuation, 25 mg poly(MAOS)/600 μL DMSO) showing the absence of the ring-opened side product. Peaks labeled in capital letters were used for quantification via signal integration of respective pendant groups.

Table 1. Diverse Functional Groups Conjugated to Poly(MAOS)

Alkyl Functional Groups		
Name		Structure
butylamine		
hexylamine		
Water Solubilizing Functional Groups		
Name	Abbreviation	Structure
1-amino-2-propanol	1A2P	
ethylenediamine [a]	1N	
N-methylethylenediamine [a]	2N	
N,N-dimethylethylenediamine	3N	
2-(aminoethyl)-trimethylammonium chloride-HCl	4N	
histamine

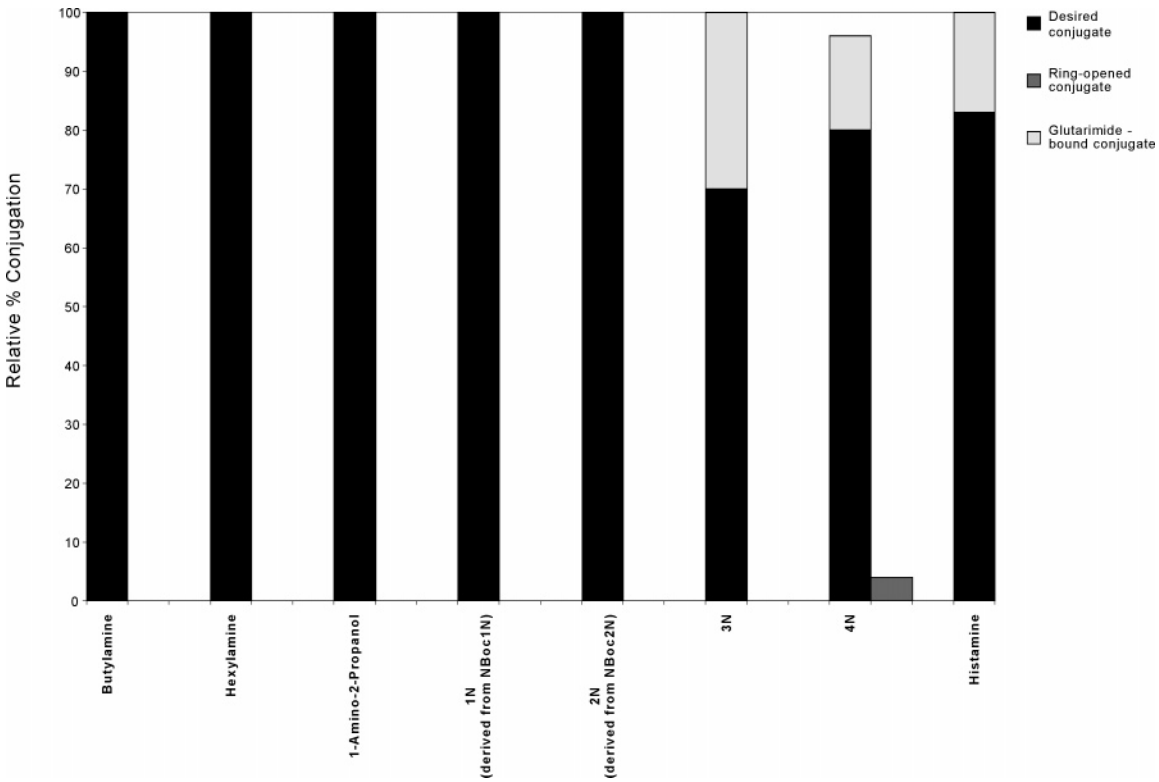

Figure 8. Conjugation profile of various NH_2-FGs to poly(MAOS). The revised protocol (5 equiv NH_2-FG, 75 °C, 24 h, 4 h evacuation, 25 mg poly(MAOS)/600 μL DMSO) results in the absence of any labile ring-opened conjugates for a diverse set of functional groups with only a minimal amount (~4%) remaining for the 4N conjugation. 50 000 g/mol poly(MAOS) was used for all reactions.

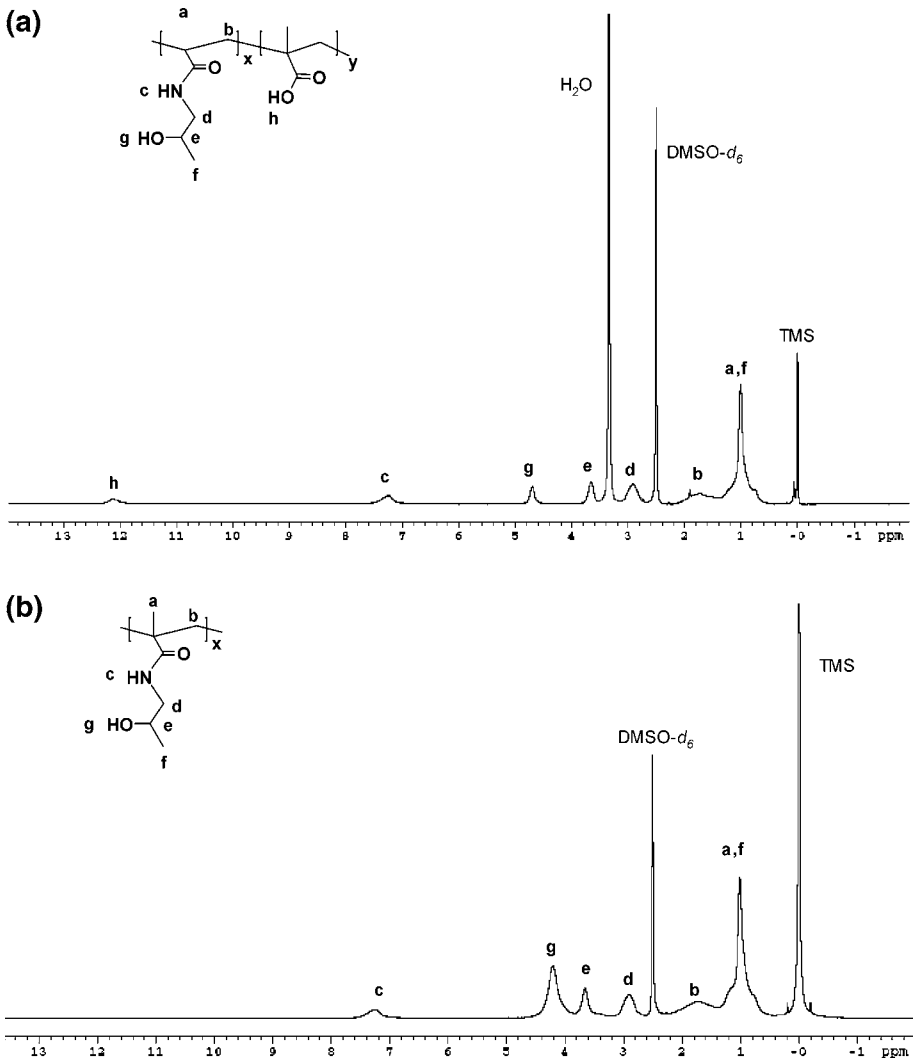
group, we observed a marked disparity in pendant distribution between the two protocols which essentially differ only by time and temperature. Protocol 1 produces approximately 75% of the desired conjugation (x), 20% ring-opened side product (y),



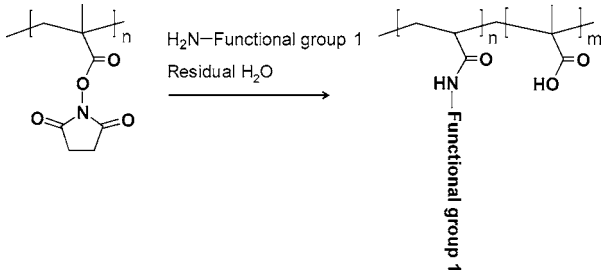


Figure 9. [1]H NMR spectra of poly(MAOS) functionalized with (a) 1A2P as received and (b) 1A2P dried over 3 Å molecular sieves. Note the absence of the hydroxyl peak in (b), thus indicating that premature hydrolysis of the activated ester to its carboxylic acid did not occur. Both conjugations followed the revised protocol (5 equiv 1-amino-2-propanol, 75 °C, 24 h, 4 h evacuation, 25 mg poly(MAOS)/600 μL DMSO). 50 000 g/mol poly(MAOS) was used for all reactions.

and 5% glutarimide-bound conjugate (z). Protocol 2 generates conjugations estimated to be about 30%, 70%, and 0%, respectively.

Monge and Haddleton's look at the feasibility of conjugating benzylamine to poly(MAOS) following protocol 1 resulted in a product whose published [1]H NMR spectrum appeared to be free of the ring-opened side product with only a small amount of the glutarimide-bound side product (*3*). By repeating their procedure following two alternative workup protocols—(1) direct purification of the reaction mixture through chromatography columns and (2) in vacuo concentration of the reaction mixture for 7 days at room temperature, followed by purification through chromatography columns—Devenish et al. reported a significant reduction of the ring-opened side product afforded by the latter workup protocol (*11*). This finding proposes the absence of any ring-opened side product in Monge and Haddleton's spectrum to be the result of longer than reported exposure to the benzylamine nucleophile upon in vacuo concentration of the reaction mixture prior to precipitation (*11*).

Incidentally, the benzylamine-conjugated polymer synthesized by Monge and Haddleton employed a low MW polymer precursor (~3000 g/mol). To examine whether MW might play a role in the resultant conjugation profile, we evaluated protocol 1 at three different MWs: 5000, 30 000, and 50 000 g/mol. We also explored the effects of several other reaction parameters,

Scheme 6. Potential Hydrolysis of NHS-Activated Ester to Methacrylic Acid from Residual Water May Occur during the Conjugation or Isolation Process[a]

[a] Due to proton exchange between the hydroxyl proton of the carboxylic acid and deuterium in D_2O, NMR analysis was performed in DMSO-d_6 to ensure the absence of a hydroxyl peak.

namely, poly(MAOS) concentration, reaction time, and reaction temperature, on the resultant conjugation profile. The data shown in Figures 4−6 suggest that the pendant distribution is independent of MW, precursor concentration, and reaction time, yet greatly dependent upon reaction temperature where an increase in temperature leads to a greater proportion of the desired and glutarimide-bound conjugates and less of the ring-opened conjugate. In contrast to the time dependency of the resultant conjugation profile reported by Devenish et al., our examination

did not reveal any appreciable reduction in the ring-opened side product at either temperature evaluated (25 °C and 50 °C). However, the reaction time range of 5 to 16 h evaluated in our study contrasts sharply with that of Devenish et al.'s 5 h to 7 days. As such, our time range may have been too narrow to produce any noticeable effects on conjugation profile and does not necessarily contradict the findings by Devenish et al.

Guided by the apparent time and temperature dependency of poly(MAOS) conjugation, we modified the previously reported protocols by increasing time, temperature, and equivalents of NH_2-FG while decreasing the precursor concentration. This revised protocol minimizes both labile ring-opened side products (as indicated by the disappearance of the 2.4, 4.3, and 8.4 ppm peaks) with a minimal amount of the glutarimide-bound conjugate (~7%) remaining. (Scheme 4, Figure 7) Because the glutarimide linkage is stable, its minimal presence is acceptable for polymer library synthesis. The revised protocol was further verified to be independent of MWs ranging from 5000 to 50 000 g/mol and reaction concentrations ranging from 25 mg poly(MAOS)/600 μL DMSO to 25 mg poly(MAOS)/mL DMSO (data not shown).

To address our initial goal of utilizing poly(MAOS) to synthesize molecularly diverse libraries, we extended the conjugation protocol to both single and binary conjugations of other alkyl (e.g., butylamine, hexylamine) and water-solubilizing functional groups (e.g., histamine, 1-amino-2-propanol) (Table 1).

No apparent side reaction conjugations resulted from butylamine and hexylamine functionalization presumably due to less steric hindrance relative to benzylamine functionalization. In the case of the water-solubilizing moieties, solvent solubility appears to be the predominant factor affecting conjugation dynamics. 3N and histamine, both soluble in DMSO in their free base state, render poly(MAOS) notably less soluble in DMSO upon functionalization, which we believe results in an increased presence of glutarimide-bound conjugation relative to the alkyl functional group conjugations. We hypothesize that, as conjugation proceeds, the decreasing solubility causes the semifunctionalized polymer precursor to assume a more tightly coiled and closed conformation. Consequently, accessibility of the primary amine to the activated esters becomes limited, leaving any remaining esters to form N-substituted glutarimides with neighboring amides (Scheme 5) (*11*).

To further support this hypothesis, we look to the 1A2P, 1N, and 2N conjugations. 1A2P, also miscible in DMSO in its primary amine reactant state, renders poly(MAOS) readily soluble in both water and DMSO upon conjugation. The proposed effect of the polymer coiling up upon conjugation would not be expected to occur to any appreciable degree which is supported by the absence of the glutarimide-indicating ^{1}H NMR peak. In the case of the 1N and 2N pendant groups, it is important to clarify that their pendant distributions shown in Figure 8 were quantified from polymers that were synthesized by functionalizing poly(MAOS) with their respective Boc-protected precursor and subsequently deprotected. Because 1N and 2N would render poly(MAOS) relatively insoluble in DMSO, one might expect their conjugation profiles to be like that of 3N conjugation. However, their conjugation dynamics were dictated by their Boc-protected precursor which results in a readily DMSO-soluble functionalized polymer. Thus, it is not surprising that their conjugation profiles are similar to those of other DMSO-soluble polymers, namely, the alkyl-functionalized polymers. Furthermore, direct conjugation of 2N (i.e., no Boc-protected precursor was used) resulted in a polymer whose NMR spectra yielded the expected desired and glutarimide-bound conjugates, presumably influenced by the hypothesized coiling-up effect, in addition to other side reaction products, presumably between the 2° amine and activated esters.

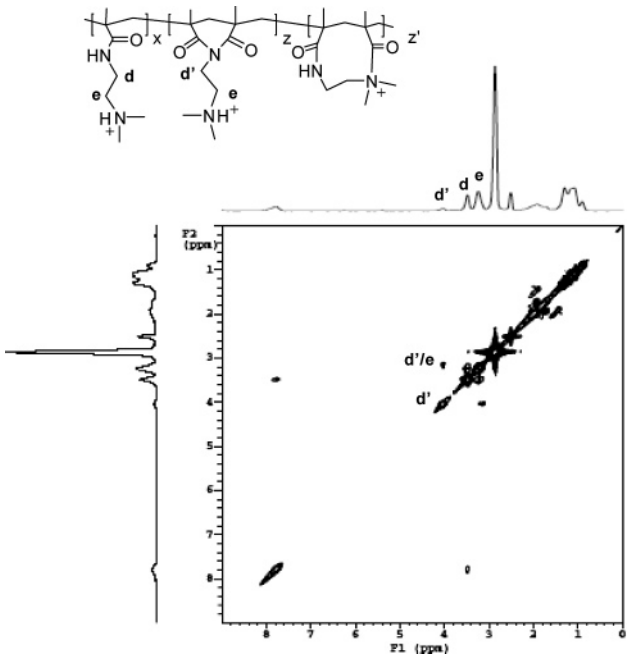

Figure 10. ^{1}H−^{1}H COSY of poly(MAOS) functionalized with *N*,*N*-dimethylethylenediamine (3N) following the revised protocol (5 equiv amine, 75 °C, 24 h, 4 h evacuation, 25 mg poly(MAOS)/600 μL DMSO. The correlation between the d′ and e protons provide evidence that side product z is formed as opposed to z′.

In addition to the solubility effects of the functionalized polymer, the solubility of the nucleophilic reactant also appears to influence conjugation behavior. 4N, insoluble in DMSO both in its salt reactant state and upon conjugating to poly(MAOS) resulted in a small, but persistent amount of the ring-opened pendant group remaining on the functionalized polymer. Efforts to eliminate all ring-opened conjugates by varying temperature and time conditions were ineffective and resulted in a similar pendant distribution at all conditions (See Supporting Information). Nevertheless, the conjugation behavior of 4N provides evidence that the solubility of both the nucleophilic reactant and the functionalized polymer plays a role in conjugation behavior.

Due to proton exchange between hydroxyl protons and deuterium in D_2O, ^{1}H NMR analysis was also performed for all water-soluble samples in DMSO-d_6 (*16*). This additional analysis was performed to ensure that premature hydrolysis of the activated ester to its carboxylic acid did not occur during either the conjugation reaction or isolation process (Scheme 6). The ^{1}H NMR spectra of the functionalized polymers in DMSO-d_6 were evaluated for the presence of a hydroxyl peak.

Polymers functionalized with 4N and 1N (i.e., NBoc-1N deprotected to the 1N form) were insoluble in DMSO and prevented this additional evaluation. To illustrate the analysis, Figure 9a shows the ^{1}H NMR spectrum of a polymer functionalized with 1A2P that was used as-received from the manufacturer. Residual water in the 1A2P may have contributed to premature hydrolysis of the activated esters during conjugation, resulting in the presence of a hydroxyl peak in the ^{1}H NMR spectrum (peak h in Figure 9a). Drying the 1A2P over 3 Å molecular sieves resulted in a functionalized polymer with no apparent hydrolysis as shown in Figure 9b. This analysis demonstrates the importance of using dried reagents with poly(MAOS) to ensure the desired products.

For functional groups with other nucleophilic atoms (e.g., 3° NH_2 on *N*,*N*-dimethylethylenediamine, imidazole on histamine), ^{1}H−^{1}H COSY was used to determine the presence of any

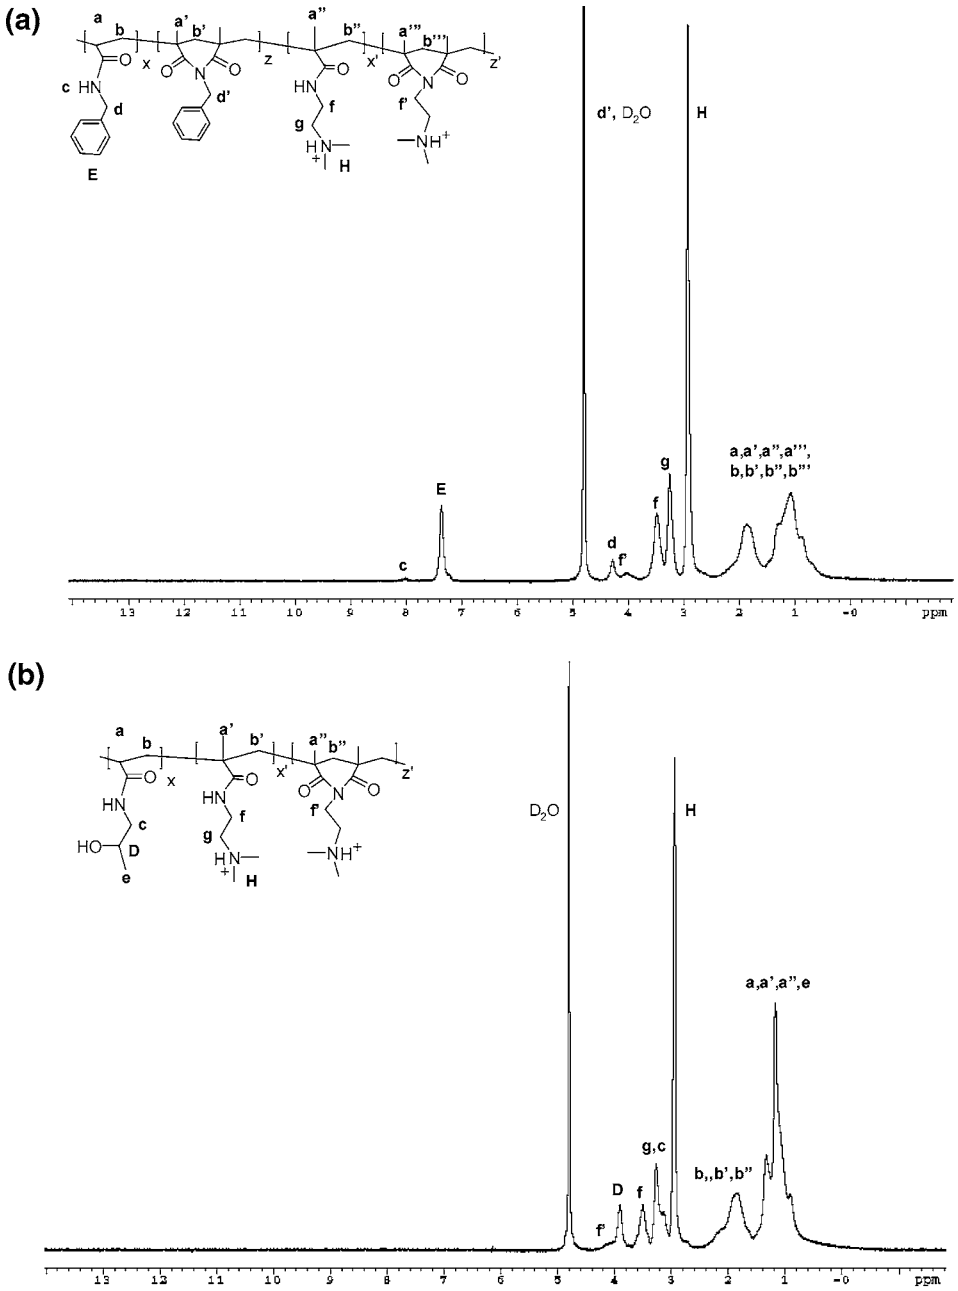

Figure 11. Representative ^{1}H NMR spectrum of poly(MAOS) functionalized with a binary mixture of (a) 2.5 equiv of *N*,*N*-dimethylethylenediamine (3N) and 2.5 equiv of benzylamine and (b) 2.5 equiv of *N*,*N*-dimethylethylenediamine (3N) and 2.5 equiv of 1-amino-2-propanol (1A2P). Both conjugations followed the revised protocol (5 total equiv of amine, 75 °C, 24 h, 4 h evacuation, 25 mg poly(MAOS)/600 μL DMSO). 50 000 g/mol poly(MAOS) was used for all reactions. Peaks labeled in capital letters were used for quantification via signal integration of respective pendant groups.

additional side reactions. Figure 10 exemplifies how we used this technique to determine the side reaction products for the 3N-conjugated polymer. The peak at 4.0 ppm (peak d′ in Figure 10) is shown to correlate with the 3.8 ppm peak (peak e in Figure 10), thus indicating the formation of side reaction z as opposed to side reaction z′.

Finally, we extended our protocol to binary conjugations using (1) benzylamine and 3N and (2) 1A2P and 3N as two independent model functional groups. Figure 11 shows the representative ^{1}H NMR spectra for both binary conjugations that were used to quantify the relative percent conjugations.

Figure 12 summarizes the conjugation profiles at various 3N equivalents for both binary conjugation experiments. The conjugation profile for the 3N/benzylamine system appears to follow a logarithmic trend compared to the linearly trending 3N/1A2P system. The difference in profiles is likely due to a dissimilarity in the degree of nucleophilicity between the conjugating pairs (i.e., 3N compared to benzylamine; 3N compared to 1A2P) (*17*). Further parametric studies, such as the effects of introducing each functional group at various times during the conjugation reaction, may be conducted to optimize the ligand distribution.

In conclusion, we have established a protocol that overcomes the side reactions that are associated with the NHS-activated polymer precursor, poly(MAOS). The revised protocol entails conjugating poly(MAOS) in the presence of a 5 mol excess of the primary amine-containing nucleophile for 24 h at 75 °C at a reaction concentration of 25 mg poly(MAOS)/600 μL DMSO. Using ^{1}H NMR and ^{1}H−^{1}H COSY analyses, we have quantified and characterized the resultant monofunctionalized polymer for a diverse range of functional groups. Moreover, we have also characterized the conjugation of two model binary systems: (1)

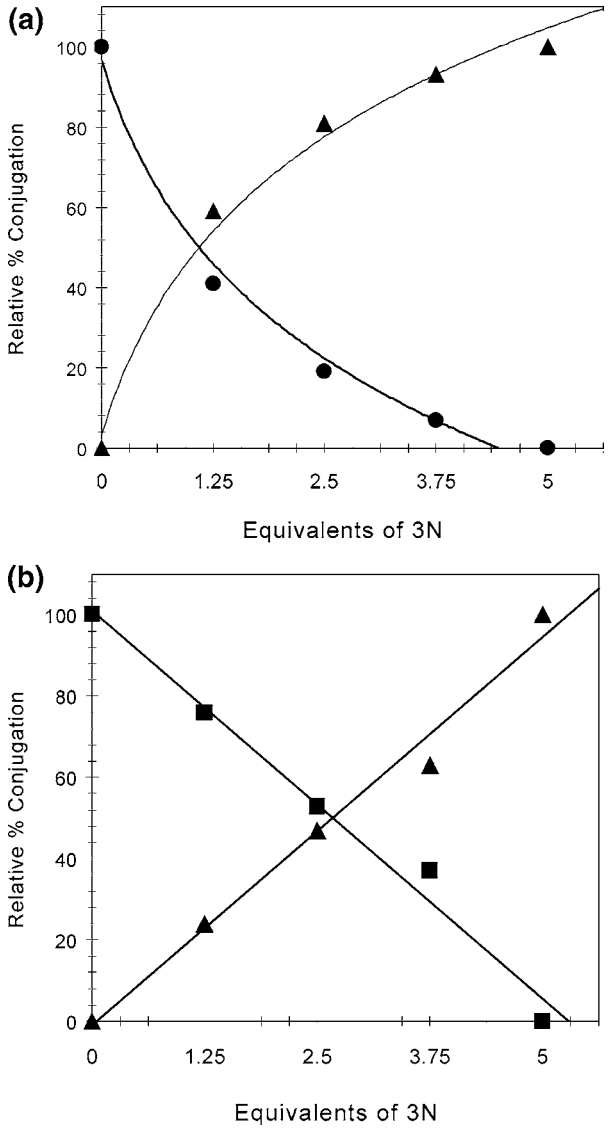

Figure 12. Conjugation profiles of (a) *N*,*N*-dimethylethylenediamine (3N) (▲)/benzylamine (●) binary mixtures (logarithmic fit; R^2 = 0.9893) and (b) 3N (▲) /1-amino-2-propanol (1A2P) (■) binary mixtures (linear fit; R^2 = 0.9844) at various feed equivalents of 3N. The conjugation profile of the 3N/1A2P mixtures resembles the theoretical conjugation and is likely due to a similar degree of nucleophilicity in contrast to the 3N/benzylamine conjugation profile.

N,*N*-dimethylethylenediamine (3N) and benzylamine and (2) *N*,*N*-dimethylethylenediamine (3N) and 1-amino-2-propanol (1A2P). Both systems were evaluated at various binary mixture compositions to demonstrate the compatibility of our protocol to conjugations comprising combinations of various functional groups.

An important and active area of research for which this work is applicable is the use of chemically and structurally diverse combinatorial libraries to develop polymeric biomaterials for drug and gene delivery systems. This area of research faces multiple challenges, including (1) a limited understanding of the biochemical and physical environment the materials must withstand, thereby making rational design an extremely difficult task, and (2) resource constraints associated with synthesizing and evaluating a large number of diverse compounds efficiently.

Combinatorial strategies offer a systematic approach to designing libraries of polymer candidates that encompass a broad range of properties. Subsequent screening of each polymer enables the identification of both "hits"—specific polymers that possess desirable properties—and trends that demonstrate how an incrementally varied feature affects the measured output (*1*). Hits are desired because they identify specific polymers that possess the desired biophysical and chemical properties (e.g., high drug/gene transfer efficiency, low cytotoxicity) as determined by screening assays. Equally important are the trends that are observed between polymers that share an incrementally varied feature. These trends may provide information about the functional effects of a particular structural feature and potentially shed light on the underlying biochemical and physical environment and mechanisms that govern the system. Ultimately, the information gained from these libraries can point to ways to improve the design of drug and gene delivery systems.

The protocol that we have established offers a facile method to use poly(MAOS) precursor as the molecular backbone for each compound in a combinatorial library where chemical and structural properties can be easily imparted and modified by conjugating different functional groups at various ratios to the precursor. Coupled with high throughput methods, these libraries can be feasibly synthesized and evaluated efficiently and reliably, posing the potential for these promising research tools to significantly change the way new materials are discovered.

ACKNOWLEDGMENT

The authors thank Dr. Ivan Keresztes for his expertise and assistance with the NMR work. This research was supported by a Biomedical Research Grant from the Whitaker Foundation.

TECHNICAL NOTES

An Improved Method for Covalently Conjugating Morpholino Oligomers to Antitumor Antibodies

Jiang He,[†] Guozheng Liu, Shuping Dou, Suresh Gupta, Mary Rusckowski, and Donald Hnatowich*

Division of Nuclear Medicine, Department of Radiology, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, Massachusetts 01655. Received July 10, 2006; Revised Manuscript Received December 13, 2006

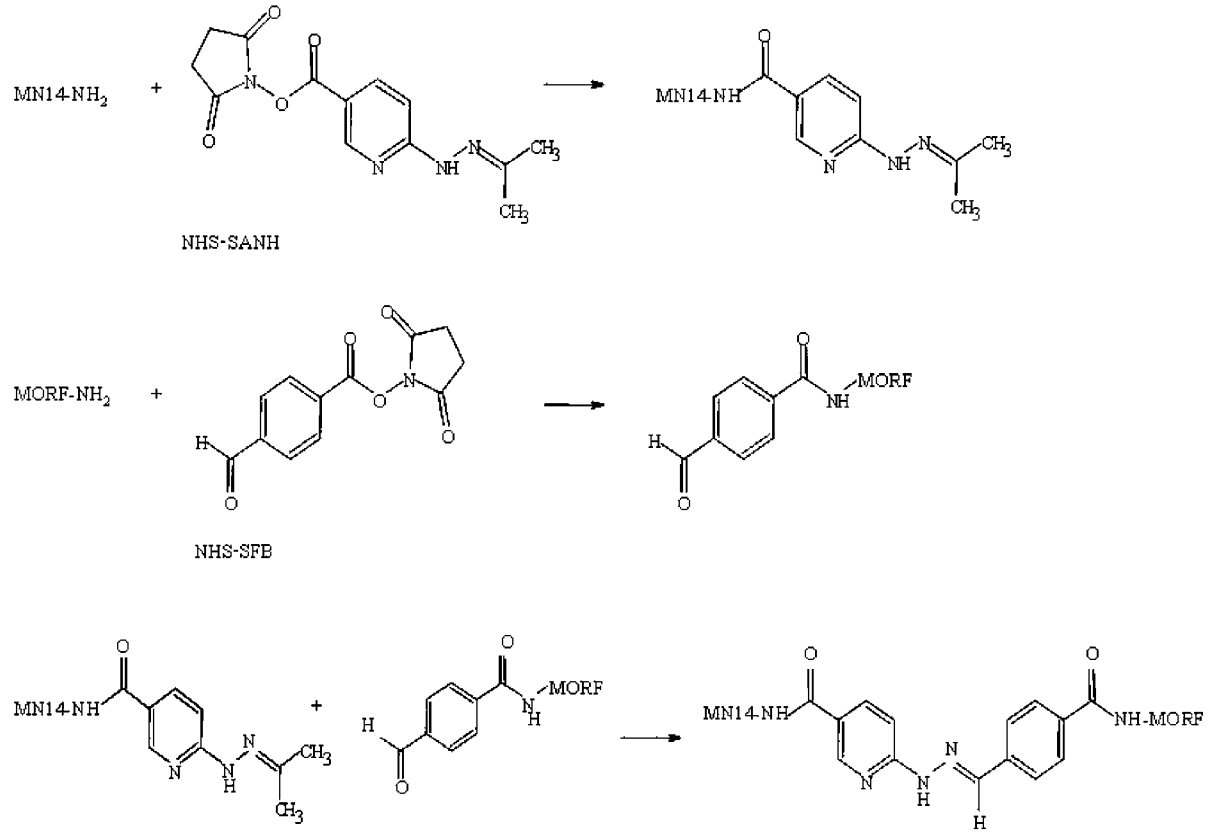
Whether for conventional pretargeting, amplification pretargeting, or affinity enhancement pretargeting, it will be necessary to conjugate an antitumor antibody as the first injectate. This laboratory is investigating phosphorodiamidate morpholinos (MORFs) for pretargeting, and accordingly we are examining methods of attaching MORFs to antitumor antibodies that provide at least one group per molecule (gpm) without adversely influencing antibody properties. The aim of this investigation was to evaluate the commercial Hydralink for the conjugation of the anti-CEA MN14 antibody with an 18 mer amine-derivatized MORF. The conjugation was approached in both directions by first reacting MN14 with the NHS derivatives of 4-hydrozinonicotinate acetone hydrazone (SANH) or 4-formylbenzoate (SFB) and then combining with MORF that was previously reacted with SFB or SANH to yield MN14(SANH)−MORF and MN14(SFB)−MORF respectively. The storage stability, immunoreactive fraction, and the biodistribution in normal mice were compared for both conjugates. Thereafter, MN14(SANH)−MORF was used in a pretargeting study in tumored nude mice, and the results were compared to that obtained historically with MN14−MORF prepared by carbodiimide (EDC) coupling. Both new methods of conjugation provided between 1 and 2 gpm compared to 0.2 achieved previously by EDC. Furthermore, by repeat SE HPLC with and without CEA, both showed an unimpaired immunoreactive fraction. MN14(SANH)−MORF tolerated long-term storage best. More importantly, when labeled by hybridization with ^{99m}Tc-labeled complementary MORF (^{99m}Tc-cMORF), the biodistribution of MN14(SANH)−MORF was more favorable than that of MN14(SFB)−MORF in normal mice with lower liver (5.7 vs 9.4 %ID/g at 18 h) and spleen (3.5 vs 8.4 %ID/g) accumulations and higher blood levels (4.8 vs 3.4 %ID/g). Accordingly, only MN14(SANH)−MORF was used in a pretargeting study in tumored mice. When targeted with ^{99m}Tc-cMORF and at 2 days postinjection of antibody−MORF, the results obtained with 6 μg of antibody prepared in this way were essentially identical to that obtained previously with 30 μg of antibody prepared via EDC. Hydralink was used successfully to conjugate MORF to MN14 at higher gpm than that achieved earlier and without an obvious compromise of properties. Using MN14(SANH)−MORF, the influence of the higher gpm on pretargeting permitted lowering the dosages of MN14 administered and may permit administering higher levels of radioactivity in connection with therapy.

INTRODUCTION

Pretargeting has become an important approach to improve tumor targeting. In pretargeting, the long-circulating antitumor antibody conjugate is first administered and allowed time for specific localization in tumor and clearance from blood and other normal tissues before the injection of a short-circulating small radiolabeled effector. This technique has been shown to provide tumor targeting comparable to that of conventional direct targeting with directly labeled antibody but much earlier at 1−3 h post-administration of radiolabeled effector and, moreover, to dramatically improve the target/nontarget ratio. The three approaches to pretargeting that have been reported thus far use biotin−(strep)avidin, bispecific antibodies, or oligonucleotides. Regardless of the approach, the high affinity and binding specificity of a tumor-associated antibody is employed as the first injectate (*1*−*5*). The effector molecule is usually monovalent, but bivalent effectors can show greatly enhanced residence time in tumor (*6*) by what has been called affinity enhancement (*3*, *7*, *8*).

This laboratory has recently begun exploring DNA and other oligomers, in particular phosphorodiamidate morpholios (MORFs), for amplification pretargeting (*9*, *10*), conventional pretargeting (*4*, *5*) and, most recently, affinity enhancement pretargeting (*11*). Our preliminary in vitro studies of affinity enhancement using surface plasmon resonance has shown that the target density is an important determinant of affinity enhancement pretargeting (*12*). One method of achieving the required higher density in MORF pretargeting is to increase the number of MORFs attached to each antibody. It therefore has become important to develop methods of conjugating antitumor antibodies with several MORFs per molecule and without compromising antibody immunoreactivity or adversely influencing antibody pharmacokinetics. We report herein on the use of commercially available reagents (Hydralink) for the conjugation of the antitumor antibody MN14 with MORF (Scheme 1).

MATERIALS AND METHODS



Reagents. All MORFs were purchased from Gene Tools (Philomath, OR) with an amine group on the 3′ equivalent

terminus for conjugation with either SANH/SFB or *S*-acetyl mercaptoacetyltriglycine (MAG3). Each MORF was analyzed by the manufacturer using size-exclusion high-performance liquid chromatography (HPLC) and MALDI-TOF MS to ensure quality. The base sequences and molecular weights of the 18 mer MORF and its complement (cMORF) are shown below: MORF: 5′-TCTTCTACTTCACAACTA-linker-amine, 6164 Da cMORF: 5′-TAGTTGTGAAGTAGAAGA-linker-amine, 6422 Da

The linker is $C(O)CH_2CH_2NH_2$ for primary amine modification. A high-affinity murine anti-CEA antibody (MN14, IgG 1 subtype, MW 160 kDa) was a gift from Immunomedics (Morris Plains, NJ). The CEA antigen from human liver metastasis of a primary colon carcinoma (180 kDa) was purchased from Scripps Laboratories (San Diego, CA). NHS-MAG3 was synthesized in house (*13*) and the structure confirmed by elemental analysis, proton NMR, and mass spectroscopy. The PD-10 column was purchased from Amersham Pharmacia Biotech (Piscataway, NJ). The ^{99m}Tc-pertechnetate was eluted from a ^{99}Mo-^{99m}Tc generator (Bristol-Myers Squibb Medical Imaging Inc., North Billerica, MA). A commercially available conjugation kit (Hydralink) consisting of acetone 5-(succinimidyloxycarbonyl)-pyridine-2-ylhydrazone (NHS-SANH), succinimidyl 4-formylbenzoate (NHS-SFB), and other reagents were purchased from Solulink (San Diego, CA). All other chemicals were reagent grade and were used without purification.

High Performance Liquid Chromatography. Size-exclusion HPLC analysis was performed on a Superose-12 HR10/30 column with an optimal separation range between 1×10^3 and 3×10^5 Da (Amersham Pharmacia Biotech, Piscataway, NJ) using 0.10 M pH 7.2 phosphate buffer as eluant at a flow rate of 0.6 mL/min. The HPLC was equipped with both an in-line radioactivity detector and a Waters 2487 dual wavelength absorbance detector (Milford, MA).

MN14−MORF Conjugation, Evaluation, and Radiolabeling. For the preparation of MN14(SANH)−MORF, typically the MN14 antibody was incubated with a 5- to 10-fold molar excess of NHS-SANH in 100 mM PBS (pH = 8.0) for 1 h at room temperature. The reaction mixture was purified on a PD-10 column using conjugation buffer (pH 5, 100 mM MES, 150 mM NaCl) as eluant. At the same time, the MORF was incubated with a 50-fold molar excess of NHS-SFB in 100 mM PBS (pH = 8.0), and after 1 h at room temperature, this reaction mixture was also purified on a PD-10 column with the same conjugation buffer. The degree of modification of both the SANH (hydrazine)-modified MN14 (i.e., MN14(SANH)) and SFB (aldehyde)-modified MORF (i.e., MORF(SFB)) were determined as described below. Thereafter, conjugation was achieved simply by mixing solutions of modified antibody with a 5-fold molar excess of modified MORF in conjugation buffer (pH = 5.0) overnight. The product was purified by dialysis against 100 mM PBS buffer (pH = 7.2) at 4 °C for 72 h and the purity of MN14−MORF established by HPLC. A similar procedure was applied to the conjugation and evaluation of MN14(SFB)−MORF.

MN14−MORF Immunoreactivity. A measurement of immunoreactivity (i.e., immunoreactive fraction) of the antibody conjugated by both methods was obtained by an HPLC shift assay of the antibody, radiolabeled by addition of trace ^{99m}Tc-cMORF, before and after the addition of a 3-fold molar excess of CEA. In this assay, immunoreactive antibody will bind to the excess CEA and shift to shorter elution times

Quantitation of Hydrazine and Aldehyde Modification and MN14 Conjugation. Originally, the intermediate incorporation of hydrazine or aldehyde on MN14 and the incorporation of MORF on MN14 was quantitated according to the manufacture's recommendations. In the course of these measurements, a modified and simpler approach to quantitation was developed as described below.

Alternative Quantitation of Hydrazine and Aldehyde Modification of MN14. To the 10 μL MN14 and NHS-SANH

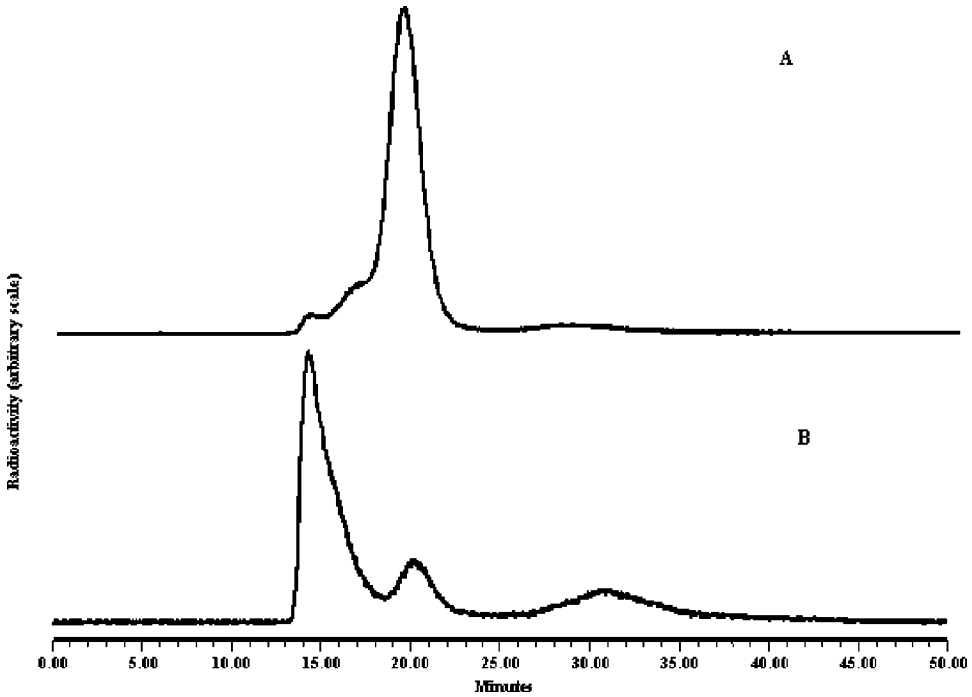

Figure 1. Size exclusion HPLC radiochromatograms of MN14(SANH)−MORF before (panel A) and after (panel B) the addition of CEA.

reaction mixture was added *p*-nitrobenzaldehyde in 200 μL of conjugation buffer at a 10-fold molar excess and the solution incubated at room temperature for 2 h. The free and antibody-bound hydrazone was then analyzed by size exclusion HPLC. The average number of SANH groups on MN14 (gpm) was then calculated from the initial molar ratio of SANH to MN14 corrected by the molar ratio of the MN14-bound SANH peak to that of free SANH quantitated by UV absorbance at 380 nm. The concentration of purified MN14(SANH) was taken as the initial MN14 concentration times the dilution factor of hydrazone concentration before and after purification and assuming the same loss of MN14 and MN14(SANH) during purification. The quantitation of the aldehyde modification of MN14 was achieved in a similar fashion but with corresponding solution of 0.50 mM 2-hydrazinopyridine (2-HP) in 100 mM MES, pH 4.7.

Quantitation of MORF Modification of MN14. Complete charcterization of the antibody−MORF conjugate requires measuring both the MORF gpm attached and the antibody concentration. In addition, for pretargeting, the "accessible" MORF gpm must also be measured since the number of MORF attached may not be equal to the number accessible. In this investigation, a method using UV absorbance at 265 and 280 nm was employed to measure the average number of attached groups (*16*).

Using a scanning UV spectrophotometer (U-2000, Hitachi Instruments, Inc, Danbury, CT), the maximum absorbance of MN14 was found to be at 280 nm and that of MORF at 265 nm (*16*). However since the SANH or SFB groups on MORF-conjugated MN14 contributes to UV absorbance, the UV absorbance of SANH and SFB was also measured by subtracting the absorbance of NHS from NHS-SANH or NHS-SFB at both wavelengths. Thus concentration curves were constructed by measuring the absorbance at different concentrations of native MN14, MORF, SANH, and SFB at both 280 and 265 nm. Under the assumption that the absorbance coefficients of MN14 and MORF do not change after conjugation, it was possible to plot the ratio of MN14−MORFs absorbance at 265 and 280 nm vs apparent gpm (i.e., molar ratio) of MORFs to MN14. This plot was also in agreement with the calculation based on derived equations from the relevant molar extinctions coefficients at 280 and 265 nm and then used to determine the MORF gpm "attached" in the conjugation solution by the absorbance ratio of 265 nm/280 nm of the MN14−MORF peak by size exclusion HPLC. The number of "accessible" groups was then determined by a size exclusion HPLC shift assay in which trace radiolabeled cMORF is added to the conjugation reaction mixture before purification.

Radiolabeling of cMORF. As previously described, cMORFs were conjugated with NHS-MAG_3 via the 3′ derivatized amine (*5*). Briefly, 1 mg of cMORF in 200 μL of 0.2 M pH 8.0 HEPES buffer was added to a vial containing 1.7−2.0 mg of *S*-acetyl NHS-MAG_3. The vial was vortexed immediately and incubated for 1 h at room temperature. The cMORF was then purified on a 0.7 × 20 cm P4 column with 0.25 M pH 5.2 NH_4OAc buffer as eluant. The peak fractions were pooled and were then adjusted from pH 5.2 to pH 7.6 with a pH 9.2 buffer (0.5 M Na_2HCO_3, 0.25 M NH_4OAc, 0.175 M NH_3). After heating for 20 min, the solution was again purified over P4 using the pH 5.2 NH_4OAc buffer as eluant. The peak fractions were again pooled as before and the concentration quantitated by UV absorbance at 265 nm (*5*). The ^{99m}Tc-cMORF-MAG_3 was prepared and analyzed as described previously (*5*). Radiolabeling was achieved by first adding ^{99m}Tc-pertechnetate generator eluant to a solution of 25 mL of cMORF-MAG_3 (concentrations 0.2−0.4 μg/μL), 25 μL of 0.25 mol/L ammonium acetate buffer, pH 5.2, 10 μL of pH 9.2 tartrate solution (50 μg sodium tartrate dehydrate per μL), and 4 μL of stannous chloride solution (1 μg stannous chloride dihydrate and 1 μg sodium ascorbate per μL in 10 mmol/L HCl), followed by heating in boiling water for 20 min. The product was purified on a P-4 column with 0.1mol/L phosphate buffer, pH 7.2, as eluant.

Animal Studies. All animal studies were performed with the approval of the UMMS Institutional Animal Care and Use Committee. The biodistribution of both MN14−MORFs radiolabled with trace ^{99m}Tc complementary MORF were evaluated in normal CD-1 mice (Charles River, Wilmington, MA). Each mouse was injected with 10 μg of MN14−MORF in 200 μL with 3.70 MBq (100 μCi). After sacrifice either at 1 h or 18 h postinjection, blood and selected organs were removed, weighed,

and counted in a NaI(Tl) well counter (Cobra II, Packard Instrument Company, CT) along with a standard of the injectate. Blood and muscle were assumed to constitute 7% and 40% of the body weight, respectively. In the case of tumored mice, the tumored thigh was also excised for counting but after the skin, and as much as possible of the muscle and bone had been removed. Radioactivity remaining in the carcass was measured in a dose calibrator. Summation of radioactivity in all organs sampled and in the remaining carcass was taken as the whole-body radioactivity.

Pretargeting Comparison. Pretargeting studies were conducted in Swiss NIH nude mice (Taconic Farms, Germantown, NY) bearing LS174T tumors of 0.6−0.8 g. Each animal received either 6 or 30 μg of MN14(SANH)−MORF 2 days before the administration of 0.2 μg or 1.0 μg, respectively, of ^{99m}Tc-cMORF with 3.70 MBq (100 μCi). Thus, the ratio of pretargeting antibody to effector was kept constant. The animals were sacrificed at 3 h postinjection of the radioactivity. The results are compared with those obtained in this laboratory earlier in identical studies using MN14−MORF conjugate via the EDC approach (*5*).

RESULTS

Preparation and Characterization of MN14−MORF Conjugates. The average number of SANH and SFB groups per antibody was between 2−4 for both while the average number

of MORFs incorporated was 1−2 per antibody. The yield in the modification of both the MORF and the antibody with SANH or SFB was 80−90%, and the antibody yield in the final conjugation step was 50−80%. The immunoreactivity measurements showed that greater than 86% of both MN14−MORFs were shifted by the addition of the antigen. In the only apparent difference, MN14(SFB)−MORF solution was cloudy and MN14(SANH)−MORF clear after storage at refrigerator temperatures for 6 months. Analysis by HPLC of the former conjugate also showed lower recoveries. Typical HPLC profiles of radiolabeled MN14(SANH)−MORF before (panel A) and after (panel B) the addition of CEA antigen are presented in Figure 1 and show an 86% shift of the radioactivity to higher molecular weight as the antibody binds to its antigen. The profiles for MN14(SFB)−MORF) were essentially identical.

Both MN14(SANH)−MORF and MN14(SFB)−MORF) were found to be virtually identical in properties. Averaged over two to six preparations, the attached MORFs per MN14 was identical within experimental error at 1.1−2.0 gpm while the average accessible MORF per MN14 was also identical at 1.0−2.0 gpm.

Figure 2 provides the standard curve (semilog scale) of gpm vs the 265 and 280 nm absorbance ratio for mixtures of MN14 to which MORF was added at designated molar ratios. The results obtained in this manner show a 90% agreement with the results obtained by the hydrazone bond method described by the Hydralink manufacturer (data not presented).

Animal Studies. Table 1 compares the biodistribution in normal mice at 1 and 18 h postinjection of both MN14(SFB)−MORF and MN14(SANH)−MORF radiolabeled by hybridization with ^{99m}Tc-cMORF. The results show no significant differences between the two conjugates except in the statistically higher liver and spleen values at 18 h postinjection in the case of MN14(SFB)−MORF ($p < 0.05$). Because of the lower liver and spleen accumulations and because of the higher storage stability mentioned above, the MN14(SANH)−MORF conjugate was used in all subsequent studies.

Table 2 presents the pretargeting results obtained in nude mice bearing LS174T tumors in one thigh and receiving either 0.2 or 1.0 μg of ^{99m}Tc-cMORF 3 h earlier to tumored mice having received 2 d earlier the MN14(SANH)−MORF conjugate at dosages of 6 μg or 30 μg, respectively. No significant differences in radiolabeled cMORF accumulation between the two dosages of antibody occurred in tissues ($p > 0.05$). Further, when compared with an earlier study using antibody conjugate with EDC (*5*), these results showed comparable tumor uptake (3.96 $\pm$ 0.70 vs 3.62 $\pm$ 0.45) %ID/g.

DISCUSSION

Some of the existing methods to couple DNA oligonucleotides and other oligomers to antibodies use biotin−streptavidin, use glutaraldehyde to cross-link amino groups (*17*−*22*), react sulfhydryl group-containing oligonucleotides with maleimide-modified antibodies (*23*−*25*), or cross-link a carboxyl group on an antibody with an amine-derivatized oligomer using EDC (*4*, *5*). The goal of this study was to evaluate Hydralink, a commercially available conjugation kit to conjugate the MN14 anti-CEA antibody with MORF for use in tumor pretargeting studies.

A novel and convenient method to determine the average gpm of attached MORF per MN14 conjugate was employed based on differential absorbance at 265 and 280 nm. By plotting the ratio of MN14−MORF absorbance at 265 and 280 nm vs gpm, the degree of conjugation during the conjugation reaction could be monitored by size-exclusion HPLC. The measurement of the degree of modification of an antibody or MORF in this manner by HPLC is possible because the UV absorbance of hydrazone is not affected by the presence of either the antibody or MORF.

The antibody conjugation was approached in both directions by first reacting MN14 with the NHS-SANH or NHS-SFB and then combined with MORF previously reacted with NHS-SFB or NHS-SANH respectively to yield MN14(SANH)−MORF and MN14(SFB)−MORF. We demonstrate that both approaches are effective and provide an average gpm of between 1 and 2 and therefore higher than the 0.2 value achieved earlier in this laboratory using a conventional EDC carbodiimide method (*5*). Because the pharmacokinetics in normal mice was slightly more favorable for the MN14(SANH)−MORF compared to the MN14(SFB)−MORF and because the former was more stable to storage, presumably due to side reaction from excess SFB on antibody which would require a blocking agent to eliminate, subsequent studies concentrated on MN14(SANH)−MORF. The MN14(SANH)−MORF was found to retain more than 86% immunorectivity (i.e., immunoreactive fraction), and when used in a pretargeting strategy, the biodistribution of MN14−MORF conjugates in tumored mice following a pretargeting strategy showed only minor differences in terms of tumor uptake between the two methods despite the order of magnitude difference in gpm.

In conclusion, the commercial Hydralink was shown to be an efficient and convenient method to conjugate MORF, and probably other oligomers, to antibodies or other biomolecules under mild conditions without compromising their properties.

"Click Labeling" with 2-[^{18}F]Fluoroethylazide for Positron Emission Tomography

Matthias Glaser and Erik Årstad*

Hammersmith Imanet Ltd, Cyclotron Building, Du Cane Road, London W12 ONN, U.K. Received September 29, 2006; Revised Manuscript Received March 1, 2007

As an effort in the development of more flexible ^{18}F-labeling chemistry, we report herein on the use of the Cu(I)-catalyzed Huisgen cycloaddition, also known as the "click reaction", to form ^{18}F-labeled 1,2,3-triazoles. Nucleophilic fluorination of 2-azidoethyl-4-toluenesulfonate followed by distillation provided 2-[^{18}F]fluoroethylazide in 55% radiochemical yield (decay-corrected). 2-[^{18}F]fluoroethylazide was reacted with a small library of terminal alkynes in the presence of excess Cu^{2+}/ascorbate or copper powder. The most reactive alkyne, *N*-benzylpropynamide provided nearly quantitative incorporation of 2-[^{18}F]fluoroethylazide after 15 min at ambient temperature, whereas the majority of the alkyne substrates provided excellent yields of the corresponding ^{18}F-labeled 1,2,3-triazoles following heating to 80 °C. Using the method described, a model peptide was obtained in 92.3 ± 0.3% (n = 3) radiochemical yield (decay-corrected) after purification by semipreparative HPLC.

INTRODUCTION

Positron emission tomography (PET) allows high-resolution quantitative imaging of biochemical processes in vivo by detecting the distribution pattern of labeled biomarkers over time. PET is increasingly used for diagnostic imaging, medical research, and drug development (*1*−*3*). ^{18}F is particularly attractive for PET, as it can be produced in high yields and has favorable decay characteristics ($t_{1/2}$ = 110 min) (*4*−*6*). As formation of electrophilic ^{18}F-labeling agents invariably leads to isotopic dilution (*2*), the use of nucleophilic [^{18}F]fluoride, which can be produced with excellent specific activity, is usually preferred for labeling. However, due to the low reactivity and high proton affinity of [^{18}F]fluoride, ^{18}F-labeled prosthetic groups are necessary for labeling complex biomolecules such as peptides and small molecules with H-acidic functions (*7*).

Currently, peptide labeling is mostly confined to conjugation of free amino groups, either by direct acylation using ^{18}F-fluorinated activated esters (*7*) or indirectly by functionalization, e.g., to an aminooxy group, which subsequently can undergo condensation with ^{18}F-fluorinated aldehydes (*8*). The lack of alternative labeling positions and the high lipophilicity of the coupling groups that are formed make optimization of peptide-based biomarkers difficult. An additional limitation is that ^{18}F-labeling agents often are complicated to produce, which restricts their use to specialized centers.

The recent discovery that Cu(I) catalyzes the Huisgen 1,3-dipolar cycloaddition of terminal alkynes and organic azides to form 1,2,3-triazoles (*9*, *10*) often referred to as "click chemistry" (*11*) has proven particularly valuable in combinatorial chemistry (*12*−*16*). The reaction provides a versatile tool for coupling druglike fragments in high yields and under mild conditions, and the 1,2,3-triazole formed is biologically stable, with a polarity and size similar to amide bonds (*17*). The reaction can be carried out in aqueous media, and as both alkynes and organic azides are relatively inert, there is no need for protection groups. In addition, there is a wide selection of commercially available alkynes, providing building blocks for library synthesis.

As an effort in the development of more flexible ^{18}F-labeling chemistry, we report herein on the use of Cu(I)-catalyzed Huisgen cycloaddition to form ^{18}F-labeled 1,2,3-triazoles (*18*).

EXPERIMENTAL PROCEDURES

General. Reagents and solvents were purchased from Sigma-Aldrich Co. Ltd. (Gillingham, United Kingdom) and used without further purification. Ethyl-2-acetylamino-4-pentynoate was purchased from Bachem (Merseyside, U.K.). The model peptide **11** was provided by the Proteomics and Peptide Synthesis Facility, MRC Clinical Science Center/Imperial College, Hammersmith Hospital London. Mass spectra were recorded on a Finnigan LCQ system using electrospray ionization (ESI). MALDI-TOF mass spectra were measured on a Finnigan Lasermat 2000 instrument. Accurate mass spectra (HRMS) were measured on a Micromass Q-Tof Ultima machine coupled with a nanoLC system using *Mass Lynx 3.5* software. NMR spectra were obtained from a JEOL Eclipse instrument (500 MHz), and the chemical shifts are reported in parts per million (ppm) relative to residual solvent peaks. The melting points were measured using an SMP-1 apparatus (Fisher Scientific UK). GC-MS data were acquired under electron ionization using an Agilent 6890N system. FT-IR spectra were recorded with a SpectrumBX2 (Perkin-Elmer). Analytical HPLC was carried out using a Beckman Gold instrument with *Karat32* software. The radio HPLC system was a Beckman System Gold instrument equipped with a γ detector (Bioscan Flow-count). A Phenomenex Luna C18(2) column (50 × 4.6 mm, 3 μm; flow rate 1 mL/min) was used for analytical HPLC. A semipreparative column (Phenomenex Onyx Monolithic C18, 100 × 10 mm, with a flow rate of 4 mL/min) was used for the final purification of the peptide [^{18}F]**12**. The following mobile phase systems were used both for analytical and preparative HPLC: solvent A, water/TFA (0.1%); solvent B, acetonitrile/TFA (0.1%); linear gradient of 5−80% solvent B over 15 min (gradient I), 5−60% solvent B over 15 min (gradient II), or 30−80% solvent B over 15 min (gradient III). Non-radioactive compounds were purified using an automated flash machine (Companion Presearch Ltd., 4 g RediSep silica cartridges, flow rate 18 mL/min), with the exception of peptide **12**, which was purified using a preparative HPLC (Agilent1200, column Phenomenex Luna C18(2), 75 ×

30 mm, 5 μm, gradient I, flow rate 15 mL/min). [^{18}F]Fluoride was produced by a cyclotron (Scanditronix MC40) using the ^{18}O(p,n)^{18}F nuclear reaction with 19 MeV proton irradiation of an enriched [^{18}O]H_2O target.

2-Fluoroethylazide (2). To a solution of 2-fluoroethyl-4-toluenesulfonate (**1**) (*19*) (128 mg, 0.586 mmol) in DMF (anhydr., 10 mL) was added sodium azide (114 mg, 1.76 mmol), and the resulting mixture was stirred at ambient temperature for 48 h. The reaction mixture was filtered, and the filtrate containing the title compound was used without isolation for subsequent reactions.

WARNING: Attempts to isolate neat 2-fluoroethylazide may result in an explosion.

1-(2-Fluoroethyl)-4-phenyl-1*H*-[1,2,3]triazole (3). To a stirred solution of copper(II) sulfate pentahydrate (12 mg, 0.0489 mmol) and L-ascorbic acid (16 mg, 0.0977 mmol) in water (0.3 mL) under nitrogen was added a solution of phenylacetylene (105 μL, 0.977 mmol) in DMF (1 mL). After addition of 2-fluoroethylazide (1.172 mmol) in DMF (5 mL), stirring was continued at room temperature for 21 h. The reaction mixture was diluted with water (5 mL), and the crude product was extracted with dichloromethane (3 × 5 mL) and washed with sodium bicarbonate solution (10%, 3 × 10 mL) and brine (1 × 5 mL). After drying over sodium sulfate, the solvent was removed under reduced pressure, and the crude material purified by means of flash chromatography (25% to 100% ethyl acetate in hexane for 10 min, t_R = 3.0 min) to provide the title compound (32 mg, 17% yield) as a white crystalline material. mp 83−85 °C. ^{1}H NMR ($CDCl_3$): δ 4.70 (m, 1H, CH_2), 4.76 (m, 1H, CH_2), 4.80 (m, 1H, CH_2), 4.89 (m, 1H, CH_2), 7.35 (tt, $J_{4,2}$ = 1.0 Hz, $J_{4,3}$ = 7.5 Hz, 1H, HAr), 7.44 (m, 2 H, HAr), 7.84 (m, 2H, HAr), 7.89 (d, J = 1.0 Hz, 1H, CH-triazole). GC-MS: m/z = 191 [M]$^+$. TOF-ES-MS: found m/z = 192.0935 [MH]$^+$, calcd for $C_{10}H_{10}N_3F$ m/z = 192.0932 [MH]$^+$.

1-(2-Fluoroethyl)-1*H*-[1,2,3]triazol-4-yl]carboxylic Acid (4). To a stirred solution of copper(II) sulfate pentahydrate (12 mg, 0.0489 mmol) and L-ascorbic acid (34 mg, 0.135 mmol) in water (0.4 mL) under nitrogen was added a solution of propargylic acid (60 μL, 0.977 mmol) in DMF (0.5 mL). After addition of 2-fluoroethylazide (1.172 mmol) in DMF (2.5 mL), stirring was continued at ambient temperature for 4 h. The reaction mixture was quenched with HCl (20 mL, 1 M), and the crude product was extracted with ethyl acetate (3 × 20 mL). After washing with brine (5 mL) and drying over sodium sulfate, the solvent was removed under reduced pressure. The residue was purified by recrystallization from ethyl acetate/hexane to give the title compound (16 mg, 10% yield) as a white crystalline material. mp 160−165 °C. ^{1}H NMR (DMSO-d_6): δ 4.74 (m, 1H, CH_2), 4.80 (m, 2H, CH_2), 4.90 (m, 1H, CH_2), 8.71 (s, 1H, CH-triazole). TOF-ES-MS: found m/z = 160.0518 [MH]$^+$, calcd for $C_5H_6N_3O_2F$ m/z = 160.0517 [MH]$^+$.

4-[1-(2-Fluoroethyl)-1*H*-[1,2,3]triazol-4-yl]benzoic Acid (5). To a stirred solution of copper(II) sulfate pentahydrate (3.7 mg, 0.0149 mmol) and L-ascorbic acid (10.5 mg, 0.0595 mmol) in water (0.2 mL) under nitrogen was added a solution of sodium 4-ethynylbenzoate (50 mg, 0.297 mmol) in DMF (1.5 mL). After addition of 2-fluoroethylazide (0.356 mmol) in DMF (0.76 mL), stirring was continued at ambient temperature for 12 h. The reaction mixture was diluted with HCl (20 mL, 1 M), the crude product was extracted with ethyl acetate (3 × 10 mL), and the organic phase washed with brine (10 mL). After drying over sodium sulfate, the solvent was removed under reduced pressure, and the crude material recrystallized from ethyl acetate/hexane to give the title compound (37 mg, 52% yield) as a white crystalline material. mp 236−240 °C (decomp.). ^{1}H NMR (DMSO-d_6): δ 4.74 (m, 1H, CH_2), 4.80 (m, 2H, CH_2), 4.90 (m, 1H, CH_2), 7.99 (m, 4H, HAr), 8.70 (s, 1H, CH-triazole). TOF-ES-MS: found m/z = 236.0838 [MH]$^+$, calcd for $C_{11}H_{10}N_3O_2F$ m/z = 236.0830 [MH]$^+$.

4-[1-(2-Fluoroethyl)-1*H*-[1,2,3]triazol-4-yl]aniline (6). To a stirred solution of copper(II) sulfate pentahydrate (129 mg, 0.516 mmol) and L-ascorbic acid (182 mg, 1.032 mmol) in water (1.2 mL) under nitrogen was added a solution of 4-ethynylaniline (40 mg, 0.344 mmol) in DMF (0.7 mL). After addition of 2-fluoroethylazide (0.287 mmol) in DMF (2.45 mL), stirring was continued at ambient temperature for 4 h. The reaction mixture was quenched with sodium hydroxide solution (1 M, 5 mL). The product was extracted with ethyl acetate (3 × 5 mL), and the organic phase was washed with water (5 mL) and brine (2 mL). After drying over sodium sulfate, the solvent was removed under reduced pressure and the crude material purified by means of flash chromatography (40% to 90% ethyl acetate in hexane for 10 min, t_R = 8.0 min) to give the title compound (15 mg, 25% yield) as a tan crystalline material. mp 79−82 °C. ^{1}H NMR ($CDCl_3$): δ 4.70 (m, 1H, CH_2), 4.72 (m, 1H, CH_2), 4.77 (m, 1H, CH_2), 4.88 (m, 1H, CH_2), 6.74 (d, J = 8.7 Hz, 2H, HAr), 7.64 (d, J = 8.7 Hz, 2H, HAr), 7.74 (d, J = 0.1 Hz, 1H, CH-triazole). TOF-ES-MS: found m/z = 207.1030 [MH]$^+$, calcd for $C_{10}H_{11}N_4F$ m/z = 207.1040 [MH]$^+$.

***N*-Benzyl-[1-(2-Fluoroethyl)-1*H*-[1,2,3]triazol-4-yl]formamide (7).** A solution of *N*-benzylpropynamide (*20*) (50 mg, 0.314 mmol) in DMF (1 mL) was added to a stirred solution of copper(II) sulfate pentahydrate (3.9 mg, 0.0157 mmol) and L-ascorbic acid (11 mg, 0.0628 mmol) in water (0.4 mL) under nitrogen. After addition of 2-fluoroethylazide (0.377 mmol) in DMF (3.2 mL), stirring was continued at room temperature for 48 h. The reaction mixture was diluted with sodium bicarbonate (10%, 5 mL), the crude product extracted with dichloromethane (3 × 5 mL), and the organic phase washed with brine (5 mL). After drying over sodium sulfate, the solvent was removed under reduced pressure and the crude material purified by recrystallization from ethyl acetate/diethyl ether to give the title compound (8 mg, 10% yield) as a white crystalline material. mp 165−167 °C. ^{1}H NMR ($CDCl_3$): δ 4.70 (m, 6H, CH_2), 7.34 (m, 5H, HAr), 7.46 (m, 1H, NH), 8.20 (s, 1H, CH-triazole). TOF-ES-MS: found m/z = 249.1143 [MH]$^+$, calcd for $C_{12}H_{13}N_4OF$ m/z = 249.1146 [MH]$^+$.

***N*-Benzyl-3-[1-(2-fluoroethyl)-1*H*-[1,2,3]triazol-4-yl]propionamide (8).** *N*-Benzyl-4-pentynamide was prepared from 4-pentynoic acid according to the method of Coppola and Damon (*20*). The spectroscopic data were consistent with reported values (*21*). To a stirred suspension of copper(I) iodide (255 mg, 1.335 mmol) in methanol (0.8 mL) under nitrogen was added a solution of *N*-benzyl-4-pentynamide (50 mg, 0.267 mmol) in methanol (0.5 mL), 2-fluoroethylazide (0.320 mmol) in DMF (2.62 mL), and diisopropylamine (0.233 mL, 1.335 mmol). Stirring was continued at ambient temperature for 2 h. The reaction mixture was diluted with a solution of sodium hydrogen phosphate (1 g) in water (10 mL) and filtered through Celite. The crude product was extracted with ethyl acetate (3 × 20 mL), and the organic phase was washed with brine (20 mL). After drying over sodium sulfate, the solvent was removed under reduced pressure and the crude material purified by column chromatography (silica, conditioned with ethyl acetate/hexane 1:1, elution with ethyl acetate/hexane 4:1) to afford the title compound (19 mg, 26% yield) as a white crystalline material. mp 127−133 °C. ^{1}H NMR ($CDCl_3$): δ 2.66 (t, J = 7.0 Hz, 2H, CH_2), 3.09 (t, J = 7.0 Hz, 2H, CH_2), 4.40 (d, J = 5.7 Hz, 2H, CH_2-benzyl), 4.56 (m, 1H, CH_2), 4.61 (m, 1H, CH_2), 4.70 (m, 1H, CH_2), 4.80 (m, 1H, CH_2), 6.0 (s, 1H, NH), 7.25 (m, 5H, HAr), 7.44 (s, 1H, CH-triazole). TOF-ES-MS: found m/z = 277.1474 [MH]$^+$, calcd for $C_{14}H_{17}N_4OF$ m/z = 277.1459 [MH]$^+$.

Ethyl-(2-acetylamino-3-[1-(2-fluoroethyl)-1*H*-[1,2,3]triazol-4-yl])propionate (9). A solution of ethyl-2-acetylamino-4-pentynoate (146 mg, 0.799 mmol) in DMF (1 mL) was added to copper powder (200 mg, 40 mesh) under nitrogen, followed by a solution of 2-fluoroethylazide (0.799 mmol) in DMF (2.16 mL). The mixture was stirred and heated at 80 °C for 3 h. Purification by means of reversed-phase flash chromatography (4.3 g RediSep C18-RP cartridge, 5% to 95% acetonitrile in water for 10 min, $t_R = 3.5$ min) provided the title compound as a white solid (196 mg, 90% yield). mp 55−60 °C. ^{1}H NMR (DMSO-d_6): δ 1.13 (t, $J = 7.1$ Hz, 3H, CH_2CH_3), 1.82 (s, 3H, CH_3), 3.02 (m, 2H, CH_2-propionate), 4.05 (m, 2H, OCH_2CH_3), 4.47 (m, 1H, CH), 4.46 (m, 1H, CH_2), 4.64 (m, 1H, CH_2), 4.70 (m, 1H, CH_2), 4.81 (m, 1H, CH_2), 7.89 (s, 1H, CH-triazole), 8.31 (d, 1H, NH). TOF-ES-MS: found $m/z = 273.1372$ $[MH]^+$, calcd for $C_{11}H_{17}N_4O_3F$ $m/z = 273.1357$ $[MH]^+$.

***N*-[1-(2-Fluoroethyl)-1*H*-[1,2,3]triazol-4-ylmethylene]benzamide (10).** A solution of *N*-propargylbenzamide (*22*) (100 mg, 0.628 mmol) in DMF (1 mL) was added to copper powder (200 mg, 200 mesh) under nitrogen followed by a solution of 2-fluoroethylazide (0.628 mmol) in DMF (1.75 mL). The mixture was stirred for 30 min at ambient temperature and subsequently heated to 80 °C for 1 h. After evaporation of the solvent under high vacuum, water (5 mL) and saturated sodium bicarbonate (1 mL) were added. The crude product was extracted with ethyl acetate (3 × 10 mL), and the organic phase was washed with brine (5 mL), filtered, and dried over sodium sulfate. The triazole **10** was obtained by recrystallization from ethyl acetate/hexane as a white solid (68 mg, 44% yield). mp 100−105 °C. ^{1}H NMR ($CDCl_3$): δ 4.63 (t, $J = 17.0$ Hz, 1H, CH_2), 4.68 (t, $J = 17.0$ Hz, 1H, CH_2), 4.75 (t, $J = 17.0$ Hz, 1H, CH_2), 4.84 (t, $J = 17.0$ Hz, 1H, CH_2), (d, $J = 23$ Hz, 2H, CH_2-amide), 6.87 (s, 1H, NH), 7.43 (m, 3H, HAr), 7.73 (s, 1H, CH-triazole), 7.85 (m, 2H, HAr). TOF-ES-MS: found $m/z = 249.1133$ $[MH]^+$, calcd for $C_{12}H_{13}N_4OF$ $m/z = 249.1146$ $[MH]^+$.

(*S*)-6-Amino-2-(2-{(*S*)-2-[2-((*S*)-6-amino-2-{[4-(2-fluoroethyl)-1*H*[1,2,3]triazol-4-yl-1-carbonyl]amino}hexanoylamino)-acetyl-amino]-3-phenylpropionylamino}acetylamino)-hexanoic Acid (12). To a stirred mixture of **11** (20.7 mg, 35.2 μmol), copper powder (200 mg, 40 mesh), and sodium phosphate buffer (0.2 mL, pH 6.0, 0.25 M) under nitrogen was added a solution of **2** (36.8 μmol) in DMF (97 μL). The mixture was heated to 80 °C for 2 h, the heating bath was removed, and stirring was continued for 48 h. The filtered solution was concentrated under vacuum and purified by means of preparative HPLC to provide the title compound **12** as a colorless oil (12 mg, 50% yield). MALDI-MS: found $m/z = 676.18$ $[M]^+$, calcd for $C_{30}H_{45}N_{10}O_7F$ $m/z = 676.75$ $[M]^+$.

Radiochemistry. 2-[^{18}F]Fluoroethylazide ([^{18}F]2). A mixture of Kryptofix 222 (5 mg, 13.3 μmol), potassium carbonate (1 mg, 7.2 μmol, dissolved in 50 μL water), and acetonitrile (1 mL) was added to [^{18}F]fluoride (74−370 MBq) in water (1 mL). The solvent was removed by heating at 80 °C under a stream of nitrogen (100 mL/min). Afterward, acetonitrile (0.5 mL) was added, and the distillation was continued. This procedure was repeated twice. After cooling to room temperature, a solution of 2-azidoethyl-4-toluenesulfonate (**1**) (1.5 μL, 7.5 μmol) in anhydrous acetonitrile (0.2 mL) was added. The reaction mixture was stirred for 15 min at 80 °C. After addition of acetonitrile (0.3 mL), [^{18}F]**2** was distilled at 130 °C under a flow of nitrogen (15 mL/min) into a trapping vial containing acetonitrile (0.1 mL). Compound [^{18}F]**2** was collected with a radiochemical yield of 54% (decay-corrected) and 63% distillation efficiency.

Preparation of [^{18}F]3-10 (See Table 1 for reaction times, temperatures, and yields). *Method A.* To a solution of copper-(II) sulfate (50 μL, 0.45 M), sodium L-ascorbate (50 μL, 1.5 M), and sodium phosphate buffer (100 μL, pH 6.0, 50 mM) under nitrogen was added a solution of the alkyne (0.015 mmol) in DMF (0.1 mL) followed by [^{18}F]**2** in acetonitrile (0.2 mL, 18.5−37 MBq).

Method B: To a mixture of sodium phosphate buffer (200 μL, pH 6.0, 50 mM) and copper powder (200 mg, 70 μm) was added a solution of the alkyne (0.015 mmol) in DMF (0.1 mL) followed by [^{18}F]**2** in acetonitrile (0.2 mL, 18.5−37 MBq).

[^{18}F](*S*)-6-Amino-2-(2-{(*S*)-2-[2-((*S*)-6-amino-2-{[4-(2-fluoroethyl)-1*H*[1,2,3]triazol-4-yl-1-carbonyl]amino}-hexanoylamino)acetylamino]-3-phenylpropionylamino}-acetylamino)hexanoic Acid ([^{18}F]12). To a solution of copper(II) sulfate pentahydrate (4.3 mg, 17 μmol) in water (50 μL) was added sodium ascorbate (3.4 mg, 17 μmol) in water (50 μL) under nitrogen. After 1 min at room temperature, a solution of alkyne peptide precursor **11** was added (2 mg, 3.4 μmol, in sodium phosphate buffer, pH 6.0, 0.5 M, 50 μL), followed by a solution of [^{18}F]**2** (24−32 MBq) in acetonitrile (50 μL). The mixture was left at room temperature for 15 min and diluted with HPLC mobile phase **A** (0.3 mL). The labeled peptide [^{18}F]**12** was isolated using semipreparative HPLC (gradient II, UV at 216 nm, $t_R = 6.4$ min).

RESULTS AND DISCUSSION

2-[^{18}F]-Fluoroethylazide ([^{18}F]**2**) was designed as the labeling agent, since alkynes in general are more readily available and less hazardous than organic azides. Nucleophilic fluorination of 2-azidoethyl-4-toluenesulfonate (**1**) (*23*) with anhydrous no-carrier-added Kryptofix 222 $K^+[^{18}F]F^-$ (acetonitrile, 80 °C, 15 min) provided the azide [^{18}F]**2** in 95% analytical yield, of which 55% yield (decay-corrected) was isolated by distillation (Scheme 1). While the "click reaction" has been extensively studied, the conditions reported so far either involve too long reaction times for ^{18}F-labeling or the use of microwave heating, which is difficult to implement in automated radiotracer production. Our main concern was therefore to investigate the scope and efficiency of the reaction with conventional heating within a time frame suitable for PET. Reportedly, the two most robust catalytic systems, Cu^{2+}/ascorbate (*10*) (method A) and copper metal (*24*) (method B), were used to evaluate the reaction of 2-[^{18}F]fluoroethylazide ([^{18}F]**2**) with a small library of terminal alkynes (Scheme 1, Table 1). The reactions were carried out in a buffered solution (pH 6.0, water/acetonitrile/DMF) under an inert atmosphere, using excess copper relative to the alkynes.

In order to evaluate the effect of the catalytic systems and the functional groups on the kinetics, radiochemical yields were measured after 15 min reaction time at ambient temperature and following subsequent heating to 80 °C for an additional 15 min. At ambient temperature, the degree of incorporation of [^{18}F]**2** varied considerably depending on the alkyne substrate and the catalytic system. *N*-Benzylpropynamide (entry 5, method A) performed particularly well, providing 98% yield as measured by radio-HPLC. Following heating to 80 °C for 15 min, excellent conversions of 2-[^{18}F]fluoroethylazide ([^{18}F]**2**) to the corresponding 1,2,3-triazoles were observed for the majority of the substrates, with the exception of propargylic acid, which provided 61% radiochemical yield (entry 2, method A). Thus, the click reaction is indeed compatible with the half-life of ^{18}F and has a high tolerance for functionalities α to terminal alkynes, including N- and C-terminal amides, which are attractive for labeling of peptides. With a suitable match of catalytic system and alkyne substrate, excellent yields can be obtained within a short time under very mild conditions, i.e., ambient temperature and neutral pH, which opens up the possibility of labeling fragile biomolecules that otherwise cannot be labeled with ^{18}F.

To further investigate the scope of the method, propargylic acid was coupled to a model peptide to provide the *N*-

8		>98 (34)	92 (51)

[a] Yields measured by analytical radio-HPLC after 15 min reaction time at ambient temperature (in brackets) and after subsequent heating to 80 °C for 15 min. Method A: To a solution of copper(II) sulfate (50 μL, 0.45 M), sodium L-ascorbate (50 μL, 1.5 M), and sodium phosphate buffer (100 μL, pH 6.0, 50 mM) under nitrogen was added a solution of the alkyne (0.015 mmol) in DMF (0.1 mL) followed by [^{18}F]**2** in acetonitrile (0.2 mL). Method B: To a mixture of sodium phosphate buffer (200 μL, pH 6.0, 50 mM) and copper powder (200 mg, 70 μm) was added a solution of the alkyne (0.015 mmol) in DMF (0.1 mL) followed by [^{18}F]**2** in acetonitrile (0.2 mL).

propargylamide precursor **11**. In accordance with previous reports (*17*), "click labeling" (method A, 15 min room temperature, Scheme 2) was unaffected by the functional groups present and provided nearly quantitative incorporation of 2-[^{18}F]-fluoroethylazide ([^{18}F]**2**) to form the corresponding triazole [^{18}F]-**12**. Purification by means of semipreparative HPLC provided [^{18}F]**12** in 92.3 $\pm$ 0.6% (n = 3) radiochemical yield (decay-corrected) with a radiochemical purity of 99% (Figure 1).

While the click reaction proceeds well in a wide range of pH values (*10*), it should be noted that 2-[^{18}F]fluoroethylazide ([^{18}F]**2**) rapidly decomposes in the presence of copper and trifluoroacetic acid (*25*). Interestingly, the labeling agent [^{18}F]**2** appears otherwise to be stable in acidic media and also in the presence of copper at neutral or basic pH values. As peptides often contain residual trifluoroacetic acid, the addition of a buffer to the reaction mixture is therefore recommended to achieve optimal results for click labeling with [^{18}F]2-fluoroethylazide ([^{18}F]**2**).

Scheme 2. Labeling of Model Peptide 11 with 2-[^{18}F]fluoroethylazide ([^{18}F]2) Using Cu^{2+}/Ascorbate Catalysis (method A)

CONCLUSION

The Cu-catalyzed Huisgen 1,3-dipolar cycloaddition provides a simple, flexible and highly efficient method for ^{18}F-labeling of small molecules and peptides. The labeling agent 2-[^{18}F]-fluoroethylazide ([^{18}F]**2**) can be produced in high yield in a one-step procedure, and subsequent Cu-catalyzed coupling with terminal alkynes to form the corresponding 2-[^{18}F]-fluoroethyl-1,2,3-triazoles proceeds in excellent yields within a short time under mild conditions.

ACKNOWLEDGMENT

We thank Geeta Patel (Proteomics and Peptide Synthesis Facility, MRC Clinical Science Center/Imperial College, Ham-

mersmith Hospital London) for the preparation of the model peptide and Emmanuel Samuel, School of Pharmacy London, for carrying out the mass spectrometry analysis. Finally, we thank Colin Steel and the cyclotron operators of Hammersmith Imanet Ltd. for providing us with ^{18}F.

Supporting Information Available: HPLC chromatograms of reference compounds and ^{18}F-labeled derivatives. This material is available free of charge via the Internet at http://pubs.acs.org.

1,2:3,4-Di-*O*-isopropylidene-α-D-galactopyranose (**2**), 1,2:5,6-di-*O*-isopropylidene-D-glucose (**5**), and 2,3:5,6-di-*O*-isopropylidene-α-D-mannofuranose (**7**) are efficiently O-acylated in 78−96% yields with readily available *N*-(Z-α-aminoacyl)benzotriazoles **1a**−**e**, **1d**+**1d′** under microwave irradiation to give chiral **3a**−**d**, **4**, **6a**−**d**, **8a**,**b** and diastereomeric mixtures **(3d**+**3d′)**, **(6a**+**6a′)**, and **(6d**+**6d′)**. The original chirality was retained as evidenced by HPLC. The diisopropylidene protecting groups were removed from compounds **3a**,**d**, **6d** to give the free *O*-(Z-α-aminoacyl) sugars **9a**,**b**, **10**.

INTRODUCTION

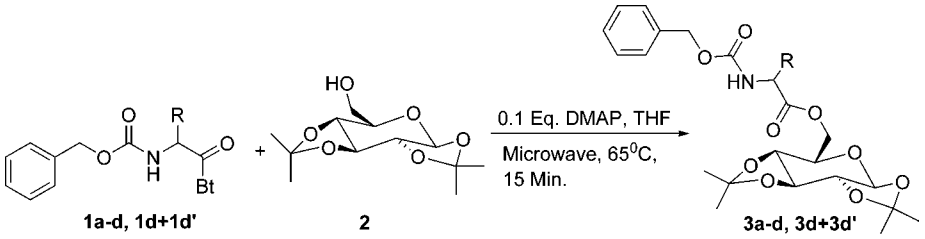
Various potential biologically active molecules cannot be used in the clinic due to undesirable physical properties such as low water solubility, low permeability in biological membranes, and rapid loss by metabolic degradation (*1*−*3*). For example, the intrinsic flexibility of short peptides can lead to multiple conformations which can consequently reduce the binding efficiency to a critical receptor and/or induce undesirable effects due to binding with other receptors present (*4*). Many of these drawbacks can be significantly mitigated by derivatization of the biomolecules. Thus, the incorporation of saccharide units into the peptide moiety can improve the physiochemical properties of various bioactive peptides and inter alia increase their immunizing performance (*5*), intestinal permeability (*6*), resistance to enzymatic degradation (*7*), molecular recognition, (*8*, *9*), and rigidity of the peptide backbone (*10*−*12*). Advantageously, sugar−amino acid conjugates can offer both improved properties and access to significant diversification. Such efficacy arises from the fact that these hybrids are made up of two biocompatible components with almost unlimited potential structural variations (*13*, *14*). Such findings have established a pivotal role for a carbohydrate moiety in numerous biological processes ranging from cell−cell communication, cell adhesion, protein folding, and their implication in various diseases such as chronic inflammation, microbial infections, and cancers (*10*, *15*−*35*).

In the past several years, considerable efforts have been devoted to the synthesis of sugar-amino acid conjugates utilizing solution and solid-phase methodologies and enzymatic synthesis. In solution-phase methodology, the desired conjugates are obtained using coupling reagents like DCC/DMAP, (*36*−*40*) succinic anhydride/DMAP (*40*), or $COCl_2$−pyridine in dichloromethane (*41*). Examples prepared using these reagents utilize hexose moieties with all hydroxyl groups protected except for 6-OH, which enters into the coupling reaction.

Coupling of an unprotected sugar with an N-protected amino acid can also be achieved via an active ester such as a pentachlorophenyl ester, in the presence of imidazole as catalyst (*3*, *12*, *42*−*46*) which requires reaction times of 20−24 h and provides a yield of 30−50% (*3*, *45*, *46*). Recently, solid-phase methodology has also been utilized for the preparation of such conjugates, (*47*) utilizing coupling reagents like DCC and DIC in the presence of a catalytic amount of DMAP in DMF as solvent on a solid support bound to the protected sugar template with a free 6-OH. Finally, sugar-amino acid conjugates are also prepared by enzymatic synthesis in pyridine using commercial protease, Optimase M-440 (*48*).

We have already used *N*-acylbenzotriazoles extensively for [N-acylation] (*49*−*53*), [C-acylation] (*54*−*58*), and [O-acylation] (*58*). Previously, 1-(α-Boc-, -Z-, and -Fmoc-aminoacyl)benzotriazoles enabled the preparation of chiral di-, tri-, and tetrapeptides in average yields of 88% from natural unprotected amino acids, both without (L-Ala, L-Phe, L-Val, L-Leu) and with unprotected side chain functionality (L-Trp, L-Tyr, L-Gln, L-Ser, L-Cys, L-Asn), in aqueous acetonitrile (*59*−*63*), as well as amino-amides from chiral amines (*50*). The original chirality was preserved in all cases (>95% as evidenced by NMR and >99% by HPLC) (*59*−*63*). Herein, we present a convenient and efficient formation of α-amino acid−sugar conjugates derived from *N*-(Z-α-aminoacyl)benzotriazoles (*59*−*61*) and sugar −OH groups under microwave irradiation.

EXPERIMENTAL PROCEDURES



General Methods. Melting points were determined on a capillary point apparatus equipped with a digital thermometer. NMR spectra were recorded in $CDCl_3$ or DMSO-d_6 with TMS for ^{1}H (300 MHz) and ^{13}C (75 MHz) as an internal reference. *N*-Z-Amino acids and amino acids were purchased from Fluka and Acros and were used without further purification. All the reactions were carried out under microwave irradiation with a single mode cavity Discover Microwave Synthesizer (CEM Corporation, NC) producing a continuous irradiation at 2450 MHz. Elemental analyses was performed on a Carlo Erba-1106 instrument. Optical rotation values were measured with the use of sodium D line. Column chromatography was performed on silica gel (200−425 mesh). HPLC analyses were performed on Beckman system gold programmable solvent module 126 using Chirobiotic T column (4.6 × 250 mm), detection at 254 nm, flow rate 1.0 mL/min, and methanol as solvent.

General Procedure for the Preparation of *O*-(Z-α-Aminoacyl)diisopropylidene Sugars 3, 4, 6, 8 under Microwave Irradiation. A dried heavy walled Pyrex tube containing a small stir bar was charged with *N*-(Z-α-aminoacyl)benzotriazole **1** (1.0 mmol), sugars **2**, **5**, **7** (1.5 mmol), DMAP (0.2 mmol), and THF (0.5 mL). For the preparation of **4**, 1.0 equiv of

General Procedure for the Cleavage of Diisopropylidene Group Present in *O*-(Z-α-Aminoacyl)diisopropylidene Sugars 3a,b, 6d. TFA−H_2O mixture was added to **3a,b, 6d** (0.200 g) at room temperature and were then stirred until **3a**,**b**, **6d** were completely consumed as monitored by TLC. The resulting mixture was concentrated under vaccum followed by washings with diethyl ether (5−6 times) and drying under reduced pressure to afford the desired compound **9a**,**b**, **10** with free OH groups.

(3,4,5,6-Tetrahydroxytetrahydro-2*H*-pyran-2-yl)methyl (2*S*)-2-[(benzyloxy)carbonyl]amino-3-phenylpropanoate, Z-L-Phe-*O*-D-glucose, 9a: White solid (92%), mp 110 °C, decomposed and turned black brown: $[\alpha]^{23}_D = +3.4$ (*c* 2.50, DMF); ^{1}H NMR (DMSO-d_6) δ α/β: 2.81−2.92 (m, 1H), 3.00−3.14 (m, 1H), 3.44−3.62 (m, 2H), 3.68−3.95 (m, 2H), 4.05−4.18 (m, 2H), 4.23−4.38 (m, 2H), 4.40−4.80 (m, 3H), 4.92−4.94 (m, 1H), 4.98 (s, 2H), 7.19−7.37 (m, 10H), 7.78−7.85 (m, 1H). ^{13}C NMR (DMSO-d_6) δ α/β: 36.5, 55.5, 64.1, 65.4, 67.4, 67.5, 71.7, 71.8, 73.0, 75.9, 81.2, 82.6, 92.7, 97.4, 101.8, 126.5, 127.6, 127.6, 127.8, 128.3, 128.3, 129.1, 136.9, 137.4, 137.6, 155.9, 171.8. RESULTS AND DISCUSSION

Preparation of *O*-(Z-α-aminoacyl)diisopropylidene sugars 3a-d, the diastereomeric mixture (3d+3d′) and Bis-*O*-(Z-α-aminoacyl)diisopropylidene Sugar 4 from 1,2:3,4-Di-*O*-isopropylidene-α-D-galactopyranose 2. *O*-(Z-α-Aminoacyl)-diisopropylidene sugars **3a−d**, **(3d+3d′)**, and **4** were prepared by coupling *N*-(Z-α- aminoacyl)benzotriazoles **1a−d, 1d+1d′**, and **1e**, respectively, with 6-OH present in **2**. In the presence of a catalytic amount of DMAP (0.2 equiv), under 100 W microwave irradiation at 65 °C for 15 min; the acylating reagent **1a−d** was completely consumed (Scheme 1). However, for the preparation of **(3d+3d′)** under similar conditions, the reaction takes 1 h to complete. This could be attributed to the slow reactivity of the D-component present in the DL-amino acid moiety. For the preparation of **4**, 0.4 equiv of DMAP were utilized (Scheme 2). The crude products **3a−d**, **(3d+3d′)**, **4** were subjected to silica-gel column chromatography using ethyl acetate/hexane (2:1) as an eluent. The desired products **3a−d**, **4**, and the diastereomeric mixture **(3d+3d′)** were obtained in yields of 88−96%.

NMR and HPLC analysis of **3a−d** and **4** revealed no detectable racemization. ^{1}H NMR of **3a−d**, **4** showed a prominent doublet for the α-NH proton of the amino acid fragment in the range of 5.30−5.45 ppm in $CDCl_3$. All the methyl protons from the diisopropylidene group in sugar appeared as singlets in the NMR analysis, supporting the absence of any undesired isomers of **3a−d**, **4**. In the ^{1}H NMR of **3d**, the doublet arising from the methyl protons present in the Ala fragment overlapped with one of the methyl protons of the sugar moiety. In addition, a clear doublet arising from the α-NH proton was observed. No splitting of the peaks was observed in the ^{13}C NMR of **3d**, in contrast to its corresponding diastereomeric mixture **(3d+3d′)**, supporting the enantiopurity of **3d**. HPLC analysis of **3a−d**, **4** gave single retention times whereas **(3d+3d′)** gave two retention times, confirming the enantiopurity of **3a−d**, **4** (Table 1 and Scheme 2).

Table 3. Preparation of *O*-(Z-α-Aminoacyl)diisopropylidene Sugars 8a,b from 7

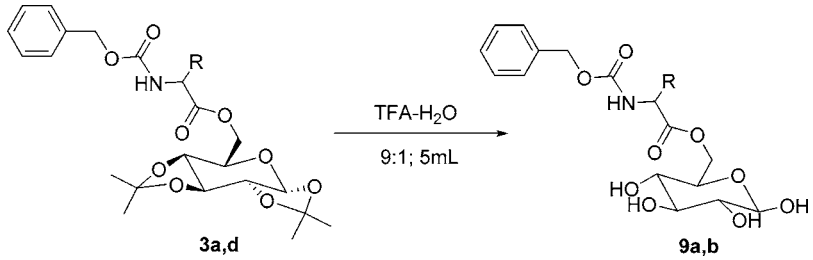
CH_2CH_2SMe **1c**	Z-L-Met-*O*-mannofuranose **8b**	93	3.00

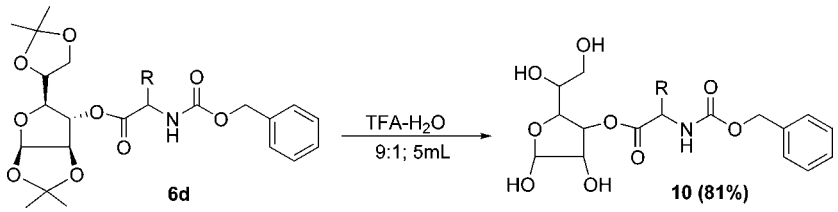
[a] Isolated yield. [b] For conditions, refer to Experimental Section.

Table 4. Cleavage of Diisopropylidene Groups Present in 3a,d Using TFA−H_2O (9:1; 5 mL)



entry	*O*-(Z-α-aminoacyl) diisopropylidene sugars	*O*-(Z-α-aminoacyl) sugars	yield[a]
1	**3a**	**9a**	92
2	**3d**	**9b**	94

[a] Isolated yield.



Preparation of *O*-(Z-α-Aminoacyl)diisopropylidene Sugars 6a−d, 8a,b and Diastereomeric Mixtures (6a+6a′), (6d+6d′) Using 1,2:5,6-Di-*O*-isopropylidene-D-glucose 5 and 2,3:5,6-Di-*O*-isopropylidene-α-D-mannofuraanose 7. *O*-(Z-α-Aminoacyl)diisopropylidene sugars **6a−d** were prepared by coupling *N*-(Z-α-aminoacyl)benzotriazoles **1a−d** with 3-OH of **5**, and the products **8a**,**b** were prepared by coupling **1a** and **1c** with 1-OH present in **7**, using similar reactions conditions as used for **3** (Scheme 3 and 4). However, for the preparation of **(6a+6a′)** and **(6d+6d′)** under similar microwave conditions, the reaction takes 1 h to complete (Scheme 3). The products **6a−d**, **8a**,**b** and the diastereomeric mixtures **(6a+6a′)** and **(6d+6d′)** were obtained in yields 78−94%.

NMR analysis of **6a−d**, **8a**,**b** revealed no detectable racemization. ^{1}H NMR demonstrated a prominent doublet for the α-NH proton of the amino acid fragment in the range of 5.44−5.66 ppm in $CDCl_3$. All the methyl protons from the diisopropylidene groups in the sugar appeared as singlets in the NMR spectra indicating the absence of any undesired isomers of **6a−d**, **8a**,**b**. For example, in **6d**, the methyl groups gave the desired singlet at 1.39 ppm and a doublet at 1.43 ppm as compared to the corresponding mixture **(6d+6d′)** which gave a multiplet at

Scheme 5

Scheme 6

1.37−1.42 ppm and two doublets at 1.43 and 1.45 ppm. HPLC analysis of **6a**−**d**, **8a**,**b** each gave single retention times whereas **(6a**+**6a′)** and **(6d**+**6d′)** gave two retention times, confirming the enantiopurity of **6a**−**d**, **8a**,**b** (Tables 2 and 3).

Cleavage of the Diisopropylidene Groups Present in *O*-(Z-α-aminoacyl)diisopropylidene Sugars 3a,d, 6d. The diisopropylidene protecting groups were cleaved using TFA−H_2O (9:1; 5 mL) (Scheme 5 and 6). The TFA−H_2O mixture was added to *O*-(Z-α-aminoacyl)diisopropylidene sugars **3a**,**d**, **6d** (0.200 g) at room temperature and was stirred until **3a**,**d**, **6d** were completely consumed as monitored by TLC. Each resulting mixture was concentrated under reduced pressure followed by subsequent washings with diethyl ether (5−6 times). The free amino acid−sugar conjugates **9a**,**b**, **10** were obtained in yields of 92−94% (Table 4 and Scheme 6) and characterized by ^{1}H and ^{13}C NMR spectroscopy, elemental analysis, melting point, and ORP. The other diastereomer was also observed in the NMR analysis, to the extent of 40−50%.

CONCLUSIONS

In conclusion, we have demonstrated a convenient and efficient preparation of chiral *O*-(Z-α-aminoacyl)diisopropylidene sugars **3a**−**d**, **4**, **6a**−**d**, **8a**,**b** and diastereomeric mixtures **(3d**+**3d′)**, **(6a**+**6a′)**, **(6d**+**6d′)** in yields of 78−96%. The original chirality of the resulting products was preserved in >97% ee as evidenced by NMR and HPLC. These advantages also suggest N-protected-(α-aminoacyl)benzotriazoles as a preferred choice for esterification among conventional coupling agents.

Binding of Streptavidin with Biotinylated Thermosensitive Nanospheres Based on Poly(*N*,*N*-diethylacrylamide-*co*-2-hydroxyethyl methacrylate)

M. Colonne, Y. Chen, K. Wu, S. Freiberg, S. Giasson, and X. X. Zhu*

Département de Chimie, Université de Montréal, C.P. 6128, Succursale Centre-ville, Montréal, QC, H3C 3J7, Canada.
Received September 29, 2006; Revised Manuscript Received February 19, 2007

Thermosensitive polymer nanospheres based on *N*,*N*-diethylacrylamide and 2-hydroxyethyl methacrylate (HEMA) have been prepared, characterized, and conjugated with biotin. The thermosensitivity of poly(*N*,*N*-diethylacrylamide) was enhanced by the incorporation of HEMA up to about 40 mol %. Atomic force microscopic images show that these particles can be closely packed even without the surface charges as in the latex particles. Biotinylation reduces the thermosensitivity of the copolymer nanospheres. The biotinylated hydrogel nanospheres showed a reduction in size upon binding with streptavidin, indicating the formation of a less hydrophilic conjugate. No aggregation of the biotinylated particles due to the cross-linking effect of streptavidin was observed. This size change could be reversed by the addition of free biotin to the system. The interaction is specific, and no such changes were observed when streptavidin was replaced by bovine serum albumin.

INTRODUCTION

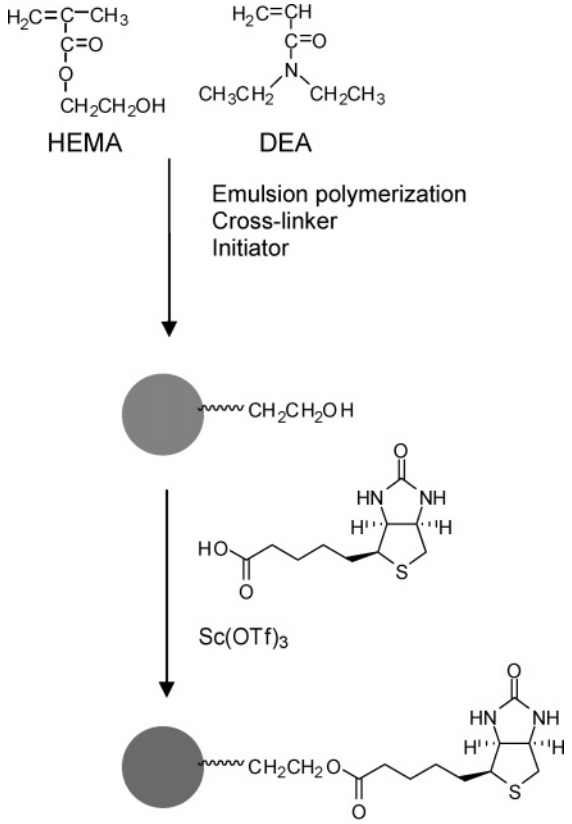
Biologically reactive polymer hydrogels represent an extension of the temperature- or pH-activated systems (*1*). Miyata et al. reported on the preparation of hydrogels conjugated with an antibody that exhibited a reduction in volume in response to a specific antigen by forming cross-links in the gel network that can be reversed upon the addition of free antigen (*2*). Thermosensitive hydrogels are known to swell in water below the lower critical swelling temperature (LCST) due to hydrogen bonding with water (*3*, *4*). Above the LCST, hydrogen bonds with water are disrupted, resulting in a shrinkage of the gels. Such hydrogels can be made into nanospheres by emulsion polymerization, and the size of spheres can be modulated by temperature (*5*, *6*). Bead size modulation by biochemical interactions may lead to biosensor applications. Using charged polystyrene particles which can form colloidal crystal arrays (CCA) induced by electrostatic repulsion, Asher and co-workers built biological sensing systems by embedding them in thermosensitive gels and monitoring the changes of interparticle distances (*7*−*10*). Polymerized CCA of charged particles based on thermosensitive poly(*N*-isopropylacrylamide) (PNIPAM) were also embedded in polyacrylamide matrix to induce a fast response to changes in temperature (within nanoseconds) (*9*).

The high and specific affinity between streptavidin and biotin (association constant, $K_a \approx 10^{15}$) is well-known, and their coupling has been used for the rapid isolation of biomolecules such as proteins (*11*, *12*) or for the preparation of biosensors (*13*−*17*). Streptavidin (60 kDa) is a tetrameric protein that can bind four biotin molecules. Hoffman, Stayton, and co-workers used linear thermosensitive polymers such as PNIPAM or poly(*N*,*N*-diethyl acrylamide) (PDEA) to conjugate genetically engineered streptavidin and then immobilized them on magnetic microbeads (*18*−*22*). Depending on the pH and temperature, the polymers could block biotin binding (*22*). Steric restriction could change the nature of streptavidin binding and cause streptavidin to bind only two biotin molecules instead of four (*18*). The preparation of fiberoptic biosensors (*14*) was also realized by attaching a biotinylated polymeric thin film to the end-face of an optic fiber. It was shown that the system linked to avidin can support biotinylated antigens or antibodies that can be used to detect an anti-cholera toxin antibody with satisfactory performance (*14*).

The change in hydrophilicity of the thermosensitive polymers can be caused not only by a temperature change but also by the interactions between conjugated biological molecules such as streptavidin and biotin. We have prepared a model system with noncharged thermosensitive polymeric nanospheres that can be biotinylated so that they can respond to the presence of streptavidin. PDEA was selected as the polymer matrix with varying amounts of 2-hydroxyethyl methacrylate (HEMA) as functional comonomers. The copolymer nanoparticles were conjugated with biotin, and the binding with streptavidin and the specificity of the binding have been investigated.

EXPERIMENTAL PROCEDURES

Materials and Chemicals. All chemicals were purchased from Aldrich-Sigma. Tetrahydrofuran (THF) was purified and dried prior to use. Biotin, streptavidin, bovine serum albumin (BSA), scandium triflate, potasium persulfate (KPS), sodium dodecyl sulfate (SDS), and 2-(4′-hydroxyazobenzene)benzoic acid (HABA) were used without further purification. *N*,*N*′-Methylene bis(acrylamide) (BA) was recrystallized from methanol. *N*,*N*-Diethylacrylamide (DEA) was prepared from diethylamine and acryloyl chloride (*4*, *23*) and vacuum-distilled before use. HEMA was also vacuum-distilled before use.



Cellulose sacks for dialysis (MW > 12 000) and Millipore Isopore membrane filters (2.0 μm) were purchased from Sigma. Water was purified by a water purification system from Millipore.

Preparation of Nanospheres and Biotinylation. The preparation of the biotinylated polymer nanospheres is shown in Scheme 1. Emulsion polymerization was done in a 500 mL three-necked flask with mechanical agitation at a constant rate of about 240 rpm. The monomers (DEA and HEMA), BA, and SDS were added to 200 mL of stirred Milli-Q water followed by nitrogen purging for 30 min at 70 °C. KPS, dissolved in 15 mL of Milli-Q water, was added to the solution. The mixture contained 1.5 mol % BA, 0.040 g SDS, and 0.120 g of KPS. A total amount of 26.5 mmol of monomers was used with HEMA

content varying from 0 to 100 mol %. The reaction was continued for 4 h and allowed to cool to room temperature before filtering the milky suspensions through 2.0 μm Millipore Isopore membrane filters. The filtrate was centrifuged for 40 min at about 15 000 rpm (relative centrifuge force (RCF) = 32 583 × *g*). The polymer spheres were collected and purified by dialysis for 1 week in Milli-Q water.

To conjugate biotin to the nanospheres containing HEMA, biotin (50 mg, 0.205 mmol) and scandium triflate (20 mg, 0.04 mmol) were stirred in an 8% solution of the spheres containing 0.205 mmol HEMA at 70 °C for 4 days. The resulting solution was centrifuged (15 000 rpm, RCF = 32 583 × *g*) at 20 °C for 20 min, rinsed with Milli-Q water, and dialyzed for 1 week.

For the binding studies, typically, 1 mg of streptavidin (17 nmol) was added directly to the biotinylated spheres in water (10 mL) in a cuvette and mixed for 30 min without filtration.

Sample Characterization and Binding Studies. To determine the amount of biotin attached on the nanospheres, the avidin−HABA assay (*24*−*26*) was used by monitoring the absorbance values at 500 nm for the avidin−HABA reagent and for the solution after addition of biotinylated nanospheres. UV−visible spectra were collected on a Cary 300 Bio UV−visible spectrophotometer. A calibration curve was generated by measuring the change in UV absorbance upon the gradual addition of free biotin of known concentration sequentially into the avidin−HABA reagent. The equivalent amount of free biotin available on the biotinylated nanospheres was calculated by comparing the absorbance change to that of the calibration curve.

Dynamic light scattering (DLS) was performed using a Brookhaven BI-200SM light scattering instrument setup with a Science/Electronics temperature controller and a 532 nm green JDS laser. Samples were prepared by suspending 1−2 drops of polymer spheres in about 20 mL of Milli-Q water followed by filtration through a 2 μm filter. To ensure data reproducibility, measurements were taken 25 min after the temperature was stabilized. At each temperature, 8 measurements were taken to determine the average diameter of the particles, and each temperature cycle was repeated at least 3 times per sample. The size variation due to measurement error is considered to be within 5% as confirmed by multiple measurements carried out by using the same sample on various heating and cooling cycles. The LCST of the aqueous system of the particles is defined as the midpoint of the inflection of the size change during heating.

Diffraction measurements were taken on a home-assembled spectrophotometer (Gamble Technologies USB2000) of wavelengths ranging from 350 to 1000 nm with a tungsten halogen source and an R200−7 VIS/NIR reflection probe. Measurements were taken after sample centrifugation at 15 000 rpm (RCF = 32 583 × *g*) for 30 min at 20 °C and ensuring that the reflectance probe was held 90° to the bead-containing cuvette.

Atomic force microscopy **(**AFM) was performed on a Digital Instruments Nanoscope III (Dimension 3100) in tapping mode with image set point at 75% of the pop-off value.

Table 1. Composition and Thermosensitive Properties of Poly(DEA-*co*-HEMA) Nanospheres

	HEMA/DEA molar ratio			
sample	feed	final[a]	LCST (°C)	size change[b] (%)
100% DEA	0/100	0/00	28	66.7
2% HEMA	2.5/97.5	2/98	28	68.9
9% HEMA	5/95	9/91	28	70.2

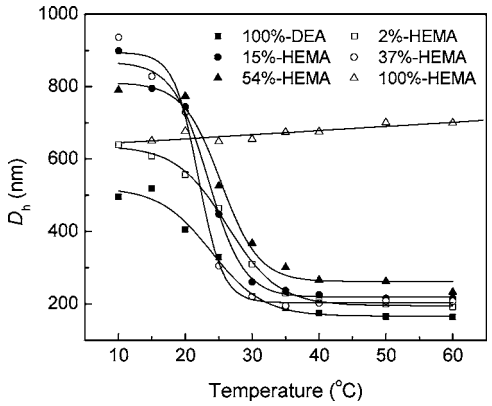

Figure 1. Thermosensitivity of the poly(DEA-*co*-HEMA) nanospheres as studied by DLS. HEMA enhances the thermosensitivity of the beads containing DEA, even if the homopolymer of HEMA itself does not exhibit thermosensitivity.

RESULTS AND DISCUSSION

Preparation and Thermosensitivity of the Nanospheres. Table 1 shows the list of the nanospheres prepared and the resulting compositions as obtained by elemental analysis. Colloidal stability is evident below a HEMA content of 48 mol %, but precipitation occurred over a period of several days with a higher HEMA content. At high HEMA contents (88 and 100 mol %), the samples precipitated readily, although dilute suspensions can be maintained.

DLS results at different temperatures are shown in Figure 1. It is interesting to note that the nanospheres made of PDEA alone, known to be thermosensitive, exhibited lower thermosensitivity than some of the copolymers with HEMA, although the HEMA homopolymer beads do not show any size change with

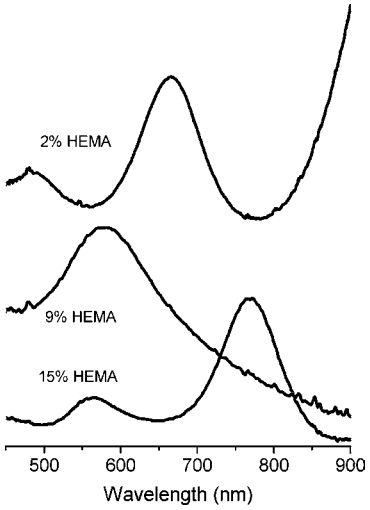

Figure 2. Poly(DEA-*co*-HEMA) nanospheres with different HEMA contents can diffract visible light at specific wavelengths as a result of the well-packed nanospheres of uniform size. Size of particles (measured by DLS at 20 °C): 15% HEMA, 744 nm; 9% HEMA, 571 nm; 2% HEMA, 556 nm.

temperature (Figure 1). The size differences (between 50 and 10 °C) of the thermosensitive nanospheres also increased with the HEMA content up to 37 mol % HEMA (Table 1). It is clear that HEMA enhances significantly the thermosensitivity of the PDEA beads at lower HEMA contents (even at just 2 mol % HEMA). At higher HEMA contents (above 50%), however, the opposite effect on thermosensitivity of the copolymers was observed. The results indicate an enhanced hydrogen bonding in the presence of small quantities of HEMA in the copolymer, with corresponding enhancement in the thermosensitivity of the gel. An increase in the HEMA content may result in a more rigid structure that is harder to contract upon the disruption of hydrogen bonds, which means that the enhancement of the thermosensivity was not accompanied by an enhanced hydrophilicity of the copolymers. The LCST of the spheres (Table 1) shows a general decreasing trend with increasing HEMA content to 48 mol %.

Self-Assembly of the Nanospheres. The centrifugation of the nanospheres (white color for a stable suspension) yielded samples that were iridescent when the HEMA content was less than 40 mol %. The color of the sample is dependent on the viewing angle. This indicates that the beads are packed in a regular fashion meeting conditions of the Bragg's law in the visible light wavelength range. Diffraction spectra obtained for various polymers are shown in Figure 2, and constructive interference is observed at specific wavelengths.

Self-assembly of the nanoparticles is also clearly seen by AFM (Figure 3). Upon spin-casting of the mixture, the beads assembled into hexagonally ordered arrays. AFM images of 37% HEMA beads showed that these soft beads are compressed from their expected spherical diameters. In solution, the particles are spherical with a diameter of approximately 450 nm at room temperature (obtained by DLS, Figure 1), but the dried samples form disclike particles with an average diameter of approximately 425 nm and a height of about 85 nm (data not shown). In an attempt to increase the spherical character of the particles after spin-casting and drying, beads with a higher degree of cross-linking (10% cross-linking agent) and 2.5% HEMA in the feed were synthesized. It was hoped that increased cross-linking density might reduce the amount of particle deformation upon drying. Figure 3 shows both the height and phase images of the particles. However, the AFM images still show they were in the form of discs (ca. 420 nm in diameter and ca. 110 nm in height). The phase image in Figure 3B shows

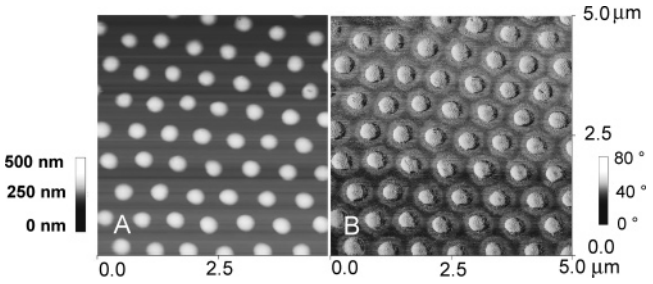

Figure 3. AFM images of hexagonally ordered poly(DEA-*co*-HEMA) nanospheres with 2% HEMA (size 394 nm measured by DLS at 20 °C) beads after spin-casting. (A) Height image. (B) Phase image showing a thin layer of polymer mass forming a ring around the core of the particles.

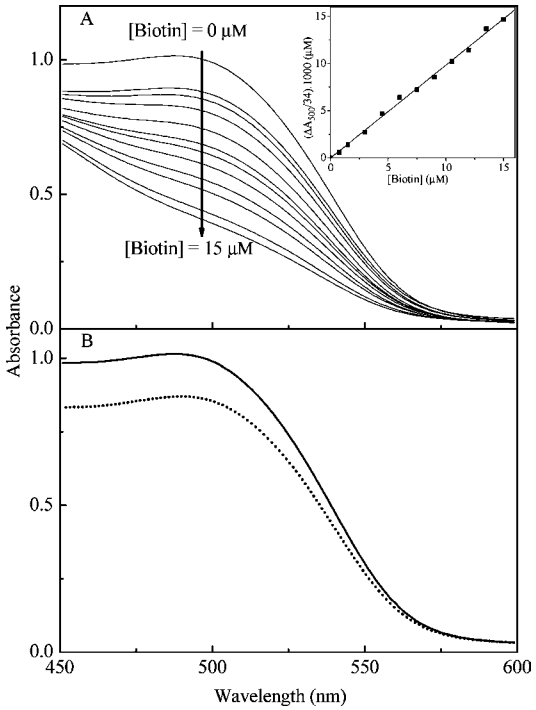

Figure 4. (A) The UV−visible spectra of the avidin−HABA complex, showing a decrease in the absorbance of the complex as free biotin concentration changed from 0 to 15 μM. The inset shows the calibration curve of the changes in absorbance as a function of biotin concentration (*26*). (B) UV−visible spectra of the avidin−HABA complex without (solid line) and with (dotted line) added biotinylated poly(DEA-*co*-HEMA) nanospheres containing 37% HEMA.

that each particle has a core size of ca. 420 nm surrounded by additional ring of ca. 120−130 nm in thickness increasing the diameter to ca. 670 nm. Therefore, this moderate increase in the degree of cross-linking did not help the particles to retain their spherical form upon centrifugation and dehydration.

The Biotinylated Spheres and Their Interaction with Streptavidin. The chemical conjugation of biotin to the polymer nanospheres (formation of an ester bond) can be evidenced by the reduced thermosensitivity of particles as shown in the example of the spheres containing 37% HEMA (Figure 5). Before biotinylation, the particles exhibited a sharp reduction in size from ca. 900 to 200 nm in water when the temperature was raised from 10 to 50 °C. After biotinylation, the change in size becomes much smaller (from ca. 800 to 450 nm). The results suggest a reduction in hydrophilicity upon biotinylation. Biotin coupling to the bead surface may render the outer layer of particle more hydrophobic, causing reduced thermosensitivity.

The amount of biotin attached on the polymer particles was quantified by the avidin−HABA assay (*24*−*26*). Figure 4 shows the UV−visible spectra of the avidin−HABA complex and the

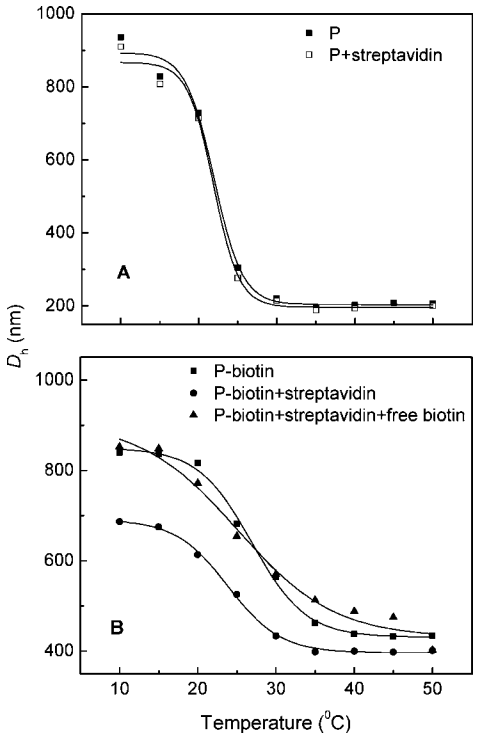

Figure 5. Thermosensitivity of the poly(DEA-*co*-HEMA) nanospheres (A) before and (B) after biotinylation, and in the presence or absence of streptavidin. "P" indicates the polymer particles containing 37 mol % HEMA.

spectroscopic changes of the complex upon the addition of biotinylated particles. The absorbance of the avidin−HABA complex at 500 nm decreased when biotinylated particles were added, since HABA (dissociation constant $K_d \approx 10^{-6}$ M) was replaced by biotin, which has a much higher binding affinity to avidin ($K_d \approx 10^{-15}$ M for avidin complex with free biotin) (*26*). On the basis of the calibration curve in Figure 4A, the amount of available biotin on the biotinylated particles was calculated (ca. 9.8 nmol/mL of the particle solution). The value can be further converted to ca. 2.0 μmol/g of particles. The amount of biotin detected may only correspond to those accessible for the avidin−HABA test, which may underestimate the total amount of biotin attached. The amount of biotin estimated in this test is still meaningful, since only the accessible biotin molecules can participate in the subsequent interaction studies. This amount corresponds only to 0.1% of the HEMA groups on the polymer spheres.

Figure 5A shows a blank experiment with unbiotinylated particles containing 37% HEMA. The addition of free streptavidin to these particles did not cause any appreciable change of their thermosensitivity, indicating the absence of any interactions. When streptavidin was added to a solution of biotinylated beads (Figure 5B), however, the change in the thermosensitivity curves is clearly shown. The size of these particles was reduced upon the interaction between steptavidin and biotin throughout the entire temperature range, with the largest reduction in size at temperatures below the LCST. The overall complex became less thermosensitive with a smaller size change than the original particles before the binding. Figure 6 shows that the change in particle size became more pronounced with subsequent additions of streptavidin due to increased biotin−streptavidin interactions. At the relatively low concentrations of the spheres used in this study, we did not observe any aggregation of the particles that may be caused by the cross-linking effect of streptavidin for the nanospheres. The reduction in size is due to reduced hydrophilicity of the particles upon binding with streptavidin,

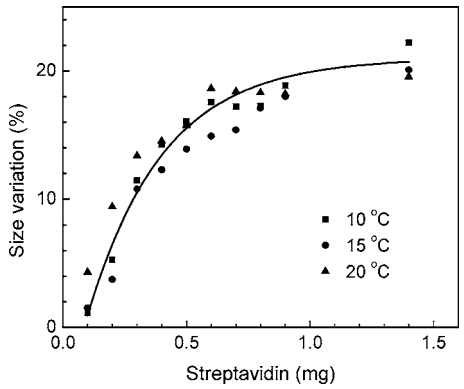

Figure 6. Size variation of biotinylated poly(DEA-*co*-HEMA) nanospheres containing 37% HEMA with different amounts of added streptavidin to 10 mL of a sample containing the nanospheres at three different temperatures.

similar to the process experienced by the thermosensitive particles upon heating.

Even at such low biotinylation levels, the presence of streptavidin was still clearly sensed by the biotinylated spheres. A high level of immobilized biotin may be desirable for a more efficient binding; care should be taken here since increased biotinylation may also reduce the thermosensitivity of the spheres (*19*) and hence its sensitivity toward the protein.

It is interesting to note that the binding between the protein (streptavidin) and the biotinylated particles was reversible. Figure 5B shows that the addition of free biotin to the streptavidin-containing system actually restored the particle size and their thermosensitivity to a state similar to that before their binding with streptavidin. Clearly, streptavidin has a higher affinity to free biotin than to the biotinylated particles. This reversibility indicates that such a system can even be reused if necessary. Results in Figure 5 also suggest that the streptavidin binding to the biotinylated particles may be disrupted above the LCST (as shown by the size change of the particles), which was suggested previously (*22*).

An experiment was performed to study the size variation of the beads at three different temperatures when increasing amounts of streptavidin were added to a sample containing 37% HEMA (Figure 6). The profiles are rather similar below the LCST of the gels. It is shown that the size change becomes more pronounced when the amount of streptavidin reaches about 0.6 mg (9 nmol) in 10 mL of the aqueous mixture which contains 2 mg of solid polymer particles (the amount of available biotin is 4 nmol). It is known that 1 molecule of streptavidin can bind up to 4 molecules of biotin. Therefore, this much lower stoichiometric ratio indicates that steric hindrance may have inhibited the binding of the immobilized biotin on the particles to streptavidin and that not all the binding sites were occupied.

To verify the specificity of the interaction between the biotinylated nanospheres and streptavidin, BSA, with a similar molecular weight (66 000 Da) to that of streptavidin, was also added to a solution of the beads. No size change of the nanospheres occurred, which indicates that the complexation is specific to the coupling between biotin and streptavidin.

CONCLUSION

It is clear that the hydrophilicity of the biotinylated hydrogel nanospheres changes upon binding with streptavidin. The biotin loading on the polymer spheres was relatively low, but already effective in triggering a response of the polymer spheres upon interaction with the protein. This is rather similar to the dehydration of the thermosensitive polymers in water when the temperature is raised, caused by the disruption of hydrogen bonds. The size change of the particles is more pronounced at

lower temperatures when the particles are most hydrated. The binding is reversible upon the addition of free biotin to the mixture, indicating its higher binding affinity in the solution in comparison to the biotinylated beads.

It may be interesting to selectively introduce extra HEMA surface groups to the particles by a delayed addition of HEMA during the polymerization. This may help in the optimization of this model sensor system. This work sets an example to attach other bioactive molecules in a similar fashion to noncharged soft hydrogel spheres for the development of useful biosensing systems with specificity.

Testing Oligothiophene Fluorophores under Physiological Conditions. Preparation and Optical Characterization of the Conjugates of Bovine Serum Albumin with Oligothiophene *N*-Hydroxysuccinimidyl Esters

Massimo Zambianchi,[†,*] Andrea Barbieri,[†] Alfredo Ventola,[‡] Laura Favaretto,[†] Cristian Bettini,[‡] Matteo Galeotti,[‡] and Giovanna Barbarella[†,*]

Istituto per la Sintesi Organica e la Fotoreattività (ISOF), Consiglio Nazionale delle Ricerche (CNR) and Mediteknology srl, Via Piero Gobetti 101, 40129 Bologna, Italy. Received October 24, 2006; Revised Manuscript Received January 22, 2007

Bovine serum albumin (BSA) was reacted with linear and newly synthesized branched oligothiophene *N*-hydroxysuccinimidyl ester fluorophores (TSEs) in moderately basic carbonate buffer solution. Optically stable BSA−TSE conjugates were obtained with a degree of labeling depending on experimental conditions. Conjugates with high fluorophore to BSA ratios (F/BSA = 8) displayed fluorescence quantum yields in the range of 10−30% in water at pH = 7.2, comparable to the quantum yield (25%) of the BSA−FITC conjugate prepared under the same conditions and with the same degree of labeling.

INTRODUCTION

Currently, there is a wide interest in polythiophenes as optical reporters of events of biological interest (*1*−*4*). Indeed, besides being important semiconductor materials, thiophene oligomers and polymers may also be strongly fluorescent compounds (*5*), and their optical properties are very sensitive to conformational changes induced by the environment (*6*). Charged polythiophenes have been used for polynucleotide detection, DNA hybridization, and sequence characterization, showing high selectivity and sensitivity useful for applications in medical diagnostics (*1*−*4*). The fluorescence properties of charged polythiophenes have been used for the specific detection of nucleic acids in sub-micromolar concentrations (*7*). Furthermore, it has been demonstrated that the optical phenomena observed in solution upon interaction of polynucleotides with charged polythiophenes can also be induced on surfaces, indicating that there is room for the development of inexpensive polythiophene-based gene chips for DNA detection (*3*).

Our interest in the field of biodiagnostics has brought us to develop new classes of thiophene-based fluorophores emitting light in the visible range and characterized by remarkable optical stability and fluorescence intensity (*8*, *9*). In particular, we have developed a rapid and high yield synthetic pattern for the preparation of oligothiophene *N*-hydroxysuccinimidyl esters and demonstrated that these fluorophores can be covalently linked to biological molecules and can be used to image specific antibody−antigen interactions in tumor cells by fluorescence microscopy or monitor polynucleotides hybridization by fluorescence spectroscopy methods (*9*).

Development of innovative fluorescent probes is highly required by the increasing number of applications of fluorescence techniques in biotechnologies (*10*, *11*). Fluorescence is a widely used readout modality employed in medical diagnostics, cellular imaging, microarrays, etc. and there is a recognized shortage of efficient fluorophores for biological applications. Developing new markers as probes for protein binding, DNA hybridization, immunoistochemistry, or other applications requires detailed knowledge on the spectroscopic and chemical properties of fluorophore-biopolymer conjugates to provide a basis for such applications. Newly developed markers should be easy to handle and to couple to biopolymers, be highly fluorescent under aqueous conditions, be resistant to photobleaching, and have large Stokes shifts between emission and absorption to facilitate fluorescence detection. The fluorophores should also be available in a great number of shades for multilabeling experiments and should be easy to couple to biopolymers with the same standard chemical methodology in all colors. Moreover, it is greatly desirable that all colors be excitable by means of the same light source. However, developing new fluorophores with all these characteristics at the same time is challenging, mainly because the optical response to excitation of a given molecular structure is not easy to predict. In this respect, thiophene oligomers are intriguing compounds, since the balance between radiative and nonradiative deexcitation pathways is greatly affected by the nature and the position of substituents, oligomers size, environment, etc. (*6*, *12*, *13*).

We report here a study on the optical properties of a set of newly synthesized oligothiophene *N*-hydroxysuccinimidyl esters (TSEs), together with the preparation and the optical characterization of the conjugates of linear and branched TSEs with bovine serum albumin (BSA). BSA, a major component in plasma protein, is one of the cheapest commercially available proteins and has been used as a model in a variety of studies (*14*−*16*). In the context of the present investigation, BSA is used to test the amino-reactive TSEs in the formation of bioconjugates in aqueous solvents and assess their fluorescence properties in physiological conditions.

MATERIALS AND METHODS

General Details. Bovine serum albumin (BSA), 2-bromothiophene (**3a**), succinic anhydride, aluminum chloride ($AlCl_3$), *N*-hydroxysuccinimide (HOSu), *N*,*N*′-dicyclohexylcarbodiimide (DCC), *N*-bromosuccinimide (NBS), tris(dibenzylideneacetone)dipalladium(0)−chloroform adduct, Tween-20, and triphenylarsine are commercially available compounds.

Synthesis of Fluorophores. The synthesis of compounds **1** and **5** has already been reported (*9*). The synthesis of compound **3** was performed as shown in Scheme 1. The synthesis of compounds **2**, **4**, **6**, **7** was performed as shown in Scheme 2.

4-(3′-Methylsulfanyl-[2,2′]bithiophenyl-5-yl)-4-oxo-butyric Acid 2,5-Dioxo-pyrrolidin-1-yl Ester (**3**). Yield: 55%. Pale yellow solid, mp 153−155 °C. EI-MS *m*/*z* 409 (M^+). ^{1}H NMR ($CDCl_3$, TMS/ppm) δ 7.69 (d, ^3J = 4.0 Hz, 1H), 7.35 (d, ^3J = 4.0 Hz, 1H), 7.31 (d, ^3J = 4.8 Hz, 1H), 7.07 (d, ^3J = 4.8 Hz, 1H), 3.36 (t, ^3J = 6.8 Hz, 2H), 3.10 (t, ^3J = 6.8 Hz, 2H), 2.84 (s, 4H), 2.51 (s, 3H); ^{13}C NMR ($CDCl_3$, TMS/ppm) δ 189.1, 168.9, 168.2, 144.2, 141.4, 132.8, 132.3, 131.8, 130.4, 126.2, 125.5, 33.3, 25.6, 25.4, 18.6. Anal. Calcd for $C_{17}H_{15}NO_5S_3$ (409.50): C, 49.86; H, 3.69. Found: C, 49.95; H, 3.81.

3′-Methylsulfanyl-[2,2′]bithiophenyl-5-carboxylic Acid 2,5-dioxo-pyrrolidin-1-yl Ester (**2**). Yield: 71%. Microcrystalline bright yellow solid, mp 131 °C; EI-MS *m*/*z* 353 (M^+); ^{1}H NMR ($CDCl_3$, TMS/ppm) δ 7.94 (d, ^3J = 4.4 Hz, 1H), 7.38 (d, ^3J = 4.4 Hz, 1H), 7.34 (d, ^3J = 5.2 Hz, 1H), 7.09 (d, ^3J = 5.2 Hz, 1H), 2.90 (s, 4H), 2.51 (s, 3H); ^{13}C NMR ($CDCl_3$, TMS/ppm) δ 169.1, 157.4, 145.9, 136.5, 133.2, 131.7, 130.7, 126.1, 125.8, 125.1, 25.6, 18.7. Anal. Calcd for $C_{14}H_{11}NO_4S_3$ (352.99): C, 47.58; H, 3.14. Found: C, 47.66; H, 3.23.

3′′-Methylsulfanyl-[2,2′;5′,2′′]terthiophene-5-carboxylic Acid 2,5-Dioxo-pyrrolidin-1-yl Ester (**4**). Yield: 80%. Microcrystalline bright orange solid, mp 156 °C; EI-MS *m*/*z* 435 (M^+); ^{1}H NMR ($CDCl_3$, TMS/ppm) δ 7.92 (d, ^3J = 4.0 Hz, 1H), 7.29 (d, ^3J = 4.0 Hz, 1H), 7.28 (d, ^3J = 4.0 Hz, 1H), 7.25 (d, ^3J = 5.2 Hz, 1H), 7.24 (d, ^3J = 4.0 Hz, 1H), 7.06 (d, ^3J = 5.2 Hz, 1H), 2.90 (s, 4H), 2.50 (s, 3H); ^{13}C NMR ($CDCl_3$, TMS/ppm) δ 169.1, 157.1, 147.6, 137.6, 137.4, 135.2, 132.9, 130.7, 130.6, 126.8, 126.1, 124.3, 124.1, 124.0, 25.6, 18.8. Anal. Calcd for $C_{18}H_{13}NO_4S_4$ (434.97): C, 49.64; H, 3.01. Found: C, 49.73; H, 3.07.

5′-Bromo-3′-methylsulfanyl-[2,2′]bithiophenyl-5-carboxylic Acid 2,5-Dioxo-pyrrolidin-1-yl Ester (**2b**). Under exclusion of light *N*-bromosuccinimide (0.33 g, 1.87 mmol) was added stepwise to a solution of **2** (0.60 g, 1.70 mmol) in acetic acid/methylene chloride 1:1 (30 mL). The mixture was left to stir overnight and then quenched with ice. After separation of layers, the aqueous phase was extracted with dichloromethane. The resulting organic layers were washed with potassium hydroxide (2 × 50 mL, 10% aqueous) and then dried over anhydrous sodium sulfate. Evaporation of the solvent under reduced pressure gave the crude product, which was isolated by flash chromatography on silica with increasing amounts of ethyl acetate in petroleum ether as eluent. Yield: 0.47 g (64%). Polycrystalline yellow solid; EI-MS *m*/*z* 432 (M^+); ^{1}H NMR ($CDCl_3$, TMS/ppm) δ 7.13 (d, ^3J = 4.0 Hz, 1H), 7.27 (d, ^3J = 4.0 Hz, 1H), 7.04 (s, 1H), 2.90 (s, 4H), 2.50 (s, 3H).

5′′-Methylsulfanyl-3′-methylsulfanyl-[2,2′;5′,2′′]terthiophene-5-carboxylic Acid 2,5-Dioxo-pyrrolidin-1-yl Ester (*6*). To a 5 mL dry toluene solution containing 0.0025 mmol of tetrakis-(triphenylarsine)palladium(0) prepared in situ was added compound **2b** (22 mg, 0.05 mmol) in toluene (2 mL). The mixture was heated to 80 °C, and 2-tributylstannyl-5-(methylthio)-thiophene (21 mg, 0.05 mmol) dissolved in 2 mL of toluene was added dropwise. The reaction mixture was stirred for 4 h at this temperature, and then the solvent was removed under reduced pressure. The crude mixture was purified by flash chromatography (silica gel, petroleum ether/ ethyl acetate 1:1) to provide 16 mg (66% yield) of the title product as microcrystalline yellow ocher solid, mp 106−108 °C; EI-MS *m*/*z* 481 (M^+); ^{1}H NMR ($CDCl_3$, TMS/ppm) δ 7.93 (d, ^3J = 4.0 Hz, 1H), 7.34 (d, ^3J = 4.0 Hz, 1H), 7.06 (d, ^3J = 4.0 Hz, 1H), 7.05 (s, 1H), 6.98 (d, ^3J = 4.0 Hz, 1H), 2.90 (s, 4H), 2.54 (s, 3H), 2.53 (s, 3H); ^{13}C NMR ($CDCl_3$, TMS/ppm) δ 169.2, 157.4, 145.5, 138.5, 137.2, 136.9, 136.5, 134.2, 131.3, 130.1, 126.3, 125.8, 125.0, 124.9, 25.8, 21.8, 18.7. Anal. Calcd for $C_{19}H_{15}NO_4S_5$ (481.65): C, 47.38; H, 3.14. Found: C, 47.61; H, 3.22.

3′′′-Methylsulfanyl-[2,2′;5′,2′′;5′′,2′′′]quaterthiophene-5-carboxylic Acid 2,5-Dioxo-pyrrolidin-1-yl Ester (**7**). Yield: 72%. Microcrystalline red-orange solid, mp 195 °C; EI-MS *m*/*z* 517 (M^+); ^{1}H NMR ($CDCl_3$, TMS/ppm) δ 7.92 (d, ^3J = 4.0 Hz, 1H), 7.27 (d, ^3J = 4.0 Hz, 1H), 7.26 (d, ^3J = 4.0 Hz, 1H), 7.21 (d, ^3J = 5.2 Hz, 1H), 7.20 (d, ^3J = 4.0 Hz, 1H), 7.16 (d, ^3J = 4.0 Hz, 1H), 7.15 (d, ^3J = 4.0 Hz, 1H), 7.04 (d, ^3J = 5.2 Hz, 1H), 2.89 (s, 4H), 2.50 (s, 3H); ^{13}C NMR ($CDCl_3/CS_2$, TMS/ppm) δ 168.6, 156.8, 147.2, 139.1, 137.3, 136.2, 135.6, 134.0, 133.4, 130.6, 130.0, 127.0, 126.6, 124.5, 124.3, 124.1, 124.0, 123.8, 25.6, 18.8. Anal. Calcd for $C_{22}H_{15}NO_4S_5$ (516.96): C, 51.04; H, 2.92. Found: C, 51.27; H, 3.05.

General Procedure for the Preparation of BSA−TSE Conjugates. In a 2 mL microtube with screw cap was dissolved the appropriate amount of BSA (calculated on the basis of a 1:15 BSA/fluorophore molar ratio) in a 0.05 M buffer carbonate/bicarbonate solution (1 mL, pH 9.3) at room temperature. Tween-20 (0.5%, w/v) was added to the buffered solution to

promote the solubility of the fluorophore in the aqueous medium. Then 100 μL of a dry DMF solution containing the fluorophore dissolved in concentration 2.5 mg/mL was added slowly to the BSA solution with gentle swirling, care being taken to avoid foaming. The microtube was then put on a rotating plate mixer (25 rpm), and conjugation was allowed to proceed at room temperature (21−24 °C) with continuous mixing for 30 min. The unreacted fluorophore was removed by passing the conjugate mixture through a Sephadex column (G-25, medium grade), previously equilibrated using phosphate-buffered saline (PBS, 80 mL, pH 7.4). Using this buffer as eluent, 500 μL fractions were collected at room temperature. All fractions were analyzed using a Perkin-Elmer spectrophotometer Lamda 20 for reading the absorbances. The conjugate was found in fractions 6−8 that were pooled in a 2 mL micro tube. Since the absorbance of these fractions was sometimes above 2, a 500 μL aliquot of the pooled solution was diluited 1:10 with PBS to give measurable readings. Before storing the solutions of the conjugates at 4 °C, sodium azide (0.1%, w/v) was added to inhibit bacterial growth. The protein content and the degree of labeling were determined by spectroscopic measurements as described (*17*).

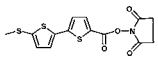
Absorption and Photoluminescence Measurements. The absorption spectra of dilute solutions of TSEs alone and of their conjugates with BSA were obtained with a Perkin-Elmer Lambda 45 UV/vis spectrophotometer. The luminescence spectra were measured at room temperature using a Spex Fluorolog II spectrofluorimeter, equipped with a Hamamatsu R928 phototube. Air-equilibrated sample solutions were excited at the indicated wavelength, and the concentration was adjusted to obtain absorption values ≤0.15 at the excitation wavelengths. While uncorrected luminescence band maxima were used throughout the text, corrected spectra were employed for the determination of the luminescence quantum yields (ϕ). The correction procedure was based on the use of a software taking care of the wavelength dependent response of the phototube. Luminescence quantum efficiencies (ϕ_{em}) were evaluated by comparing wavelength integrated intensities (I) with reference to quinine sulfate as the standard ($\phi_r = 0.546$ in air-equilibrated 1 N H_2SO_4) and by using the following equation:

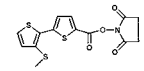
$$\phi_{em} = \frac{In^2}{OD} \cdot \frac{OD_r}{I_r n_r^2} \cdot \phi_r$$

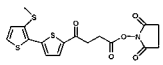
where OD and n are absorbance values at the employed excitation wavelength, and refractive index of the solvent, respectively. Band maxima and relative luminescence quantum yields were obtained with uncertainty of 2 nm and 20%, respectively. The luminescence lifetimes (τ) were obtained with an IBH single photon counting equipment by using pulsed diode NanoLED sources with excitation at 278 and 331 nm. Analysis of the luminescence decay profiles against time was accomplished by using software provided by the manufacturers, with an estimated error on the lifetime results of 10%.

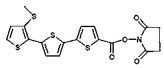
RESULTS

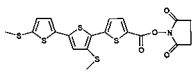
The molecular structures of all oligothiophene *N*-hydroxysuccinimidyl esters employed in this study are reported in Table 2 (see below). The tuning of the emission color from blue to orange was obtained by changing the oligomer size from dimer to tetramer and the number and the position of methylsulfanyl (SCH_3) substituents.

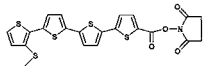












All fluorophores were soluble in DMF, while solubility in water was achieved by addition of a small amount (<1% v/v) of the Tween-20 surfactant. Owing to molecular distortion which prevents aggregation, fluorophores with substituents in β positions are the most soluble in all solvents.

Table 1. Effect of BSA to Fluorophore Molar Ratio, Reaction Time, pH, and Fluorophore Concentration on the Yields of Formation of the BSA−1 Conjugate in Phosphate-Buffered Solution

BSA−fluorophore molar ratio (60 min, pH 9.3, fluorophore 10 mg/mL)	F/BSA ratio[a]	reaction time (1:15 molar ratio, pH 9.3, fluorophore 10 mg/ mL)	F/BSA ratio[a]
1:20	4.9	120 min	5.4
1:15	4.4	60 min	4.4

1. Optimization of the Preparation Conditions of BSA−TSE Conjugates. The conjugation conditions were investigated by varying the BSA to fluorophore molar ratio, reaction time, pH, and fluorophore concentration on conjugation yields. Representative results are summarized in Table 1 for the BSA−**1** conjugate.

At pH = 9.3, reaction time 60 min, fluorophore **1** concentration 10 mg/mL, and a BSA−fluorophore **1** molar ratio of 1:5, a value F/BSA = 2.6 was obtained. For molar ratios of 1:10, 1:15, and 1:20 the F/BSA values were 4.8, 4.4, and 4.9, respectively. These values indicate that at the molar ratio 1:10 the fluorophore has already bound all the available (for conjugation) amino sites of the BSA.

In the subsequent step the BSA−fluorophore **1** molar ratio was kept at a value of 1:15, the pH at 9.3 and the fluorophore concentration at 10 mg/mL, while the reaction time was progressively incremented up to 120 min (Table 1). The F/BSA

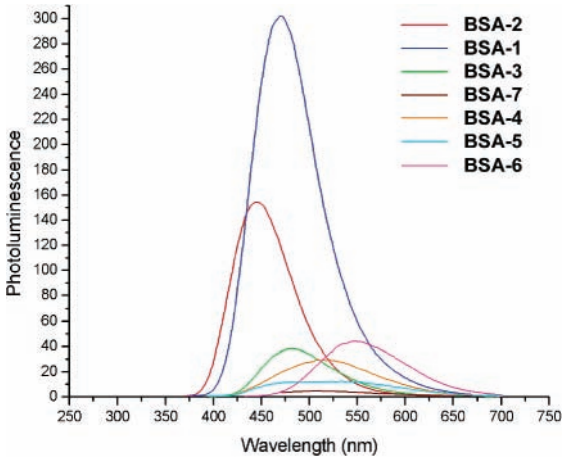

Figure 1. Photoluminescence spectra of the conjugates of BSA with fluorophores **1**−**7** (dilution 1:10) in PBS/Tween.

ratio increased upon an increase in the incubation time, from 3.5 (15 min) to 5.4 (120 min).

The effect of the pH value on the final BSA−**1** ratio was investigated using an incubation time of 30 min, a molar ratio BSA−fluorophore **1** of 1:15, and a fluorophore concentration at 10 mg/mL. The pH was varied from 8.1 to 8.5, 9.0 and 9.3. The F/BSA ratios were 1.1, 1.8, 2.9, and 4.0, respectively, indicating that only at pH value ≥9 conjugates with a good BSA to fluorophore ratios are obtained.

Finally, with an incubation time of 30 min, the pH at 9.3, and the BSA−fluorophore **1** molar ratio at 1:15, the fluorophore concentration was changed from 1.25 mg/mL to 2.5, 5.0, 10, and 20 mg/mL. The measured F/BSA ratios were 7.2, 8.1, 5.9, 3.3, and 3.2, respectively, indicating that the molar ratio needed to obtain the highest F/BSA ratio is 2.5 mg/mL.

On the basis of these results, the following conditions were employed for the conjugation of all fluorophores with BSA: pH 9.3, 1:15 BSA−fluorophore molar ratio, 2.5 mg/mL fluorophore concentration, and 30 min reaction time. Using these parameters about half of the employed fluorophore moles were bound to the protein, affording F/BSA ratios of 7−8 (Table 2).

For comparison, the BSA conjugate with FITC (fluorescein isothiocyanate), one of the most commonly employed fluorophores (*10*, *18*), was prepared using the same experimental conditions. A FITC/BSA ratio of 8.0 was measured under these conditions, the same value obtained for the conjugate of fluorophore **1** with BSA, as shown in Table 1.

2. Optical Properties. The absorption and emission data of free TSEs and of the corresponding conjugates with BSA obtained as described above are summarized in Table 2.

Figure 1 shows the photoluminescence spectra of the conjugates of the fluorophores with BSA. It is seen that the relative photoluminescence intensities at the maximum emission wavelength are: 1.00(BSA−**1**), 0.51 (BSA−**2**), 0.13 (BSA−**3**), 0.10 (BSA−**4**), 0.04 (BSA−**5**), 0.15 (BSA−**6**), 0.02 (BSA−**7**).

The width at half-maximum emission wavelength is 80−85 nm for the conjugates of **1**−**3**, 120 nm for that of **4**, 150 nm for **5** and 100 nm for the conjugates of **6**−**7**.

Fluorophores **1** and **5** have already been used for the labeling of monoclonal antibodies and toxins and demonstrated to be useful in cell imaging (*9*). We have now measured the fluorescence quantum yields and fluorescence lifetimes of these compounds and of their conjugates with BSA and compared to those of FITC and its conjugate with BSA under the same conditions. The fluorescence radiative constants, k_r, have been calculated from the relation $k_r = \phi/\tau$. The results are given in Table 3.

Table 3. Optical Properties of Fluorophores 1, 5 and FITC[a] in Different Solvents and in Conjugates with BSA

fluorophore	solvent	λ_{max} (nm)	ϕ	τ (ns)	k_r (s^{-1})
1	DCM	476	1.00 ± 0.05	2.87	3.76×10^8
	PBS	465	0.54 ± 0.01	3.44	1.57×10^8
	BSA-1	461	0.31 ± 0.01	3.13	0.99×10^8

	BSA−FITC	519	0.25 ± 0.01	3.71	0.67×10^8

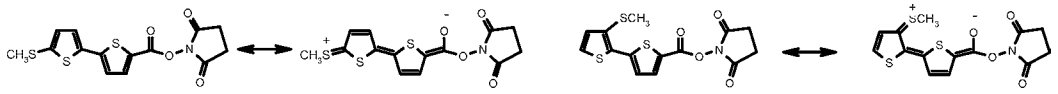
[a] Fluorescein isothiocyanate.

Table 3 shows that fluorophore **1**, a bithiophene derivative, in dichloromethane reaches a remarkable 100% fluorescence quantum yield (ϕ), almost 2 orders of magnitude higher than that of unsubstituted bithiophene (1.4−2.6%) in the same solvent (*6*).

Fluorophore **5**, a derivative of terthiophene, in dichloromethane achieves a fluorescence quantum yield of 76%, more than 1 order of magnitude greater than that (5.7−7.0%) of unsubstituted terthiophene (*6*). The ϕ values are drastically reduced in PBS (54 and 17% for **1** and **5**, respectively) and even more lowered in the corresponding conjugates with BSA (31 and 10%, respectively). Table 3 also shows that the conjugate of BSA with fluorescein displays a fluorescence quantum yield of 25%. The fluorescence lifetimes of free **1** and **5** in DCM are of the same order as those of unsubstituted oligothiophenes (*6*). Change of solvent from DCM to PBS increases slightly the fluorescence lifetimes, which are near those in the conjugates and similar to that of fluorescein. The bioconjugates can undergo several cycles of irradiation without significantly altering their structure and their optical properties and mantain their characteristics after storage for months.

DISCUSSION

It is well-known that *N*-hydroxysuccinimidyl esters react selectively with the aliphatic amino groups of proteins, generally the ϵ-amino group of lysine residues, to form a relatively stable amide bond (*10*):



$$\text{Protein-NH}_2 + \text{R-C(O)-O-Nsucc} \rightarrow \text{Protein-NH-C(O)-R}$$

Our data confirm that amino-reactive oligothiophene *N*-hydroxysuccinimidyl esters can easily be conjugated to proteins in aqueous conditions, achieving high fluorophore to protein ratios. The degree of labeling varies with the pH, the reaction time, the BSA to fluorophore molar ratio, and the fluorophore concentration. As shown in Table 1, conditions may be selected to obtain the desired degree of labeling in short conjugation times.

The fluorescence quantum yields measured for fluorophores **1** and **5** in methylene chloride (100% and 70%, respectively) are 2 orders of magnitude greater than those measured for unsubstituted bi- and terthiophene (*6*). Moreover, the molar absorption coefficients of these and the other fluorophores of Table 2 are much higher than those of unsubstituted oligothiophenes of the same size (compare, for example, the ϵ value of bithiophene, 12440 mol^{-1} cm^{-1} (*6*), with that of compound **1**, 27300 mol^{-1} cm^{-1}, or even **2**, 15200 mol^{-1} cm^{-1}). Also the absorption and emission wavelengths of the fluorophores are much larger (compare, for example, the λ_{max} and λ_{PL} values of **1**, 370 and 479 nm, with those of α-bithiophene, 303 an 362 nm (*6*)).

All these characteristics are likely to be related to the peculiar electronic structure of the fluorophores. Indeed, all compounds bear one or two methylsulfanyl (SCH_3) substituents. The electron donor nature of the SCH_3 substituent and the electron

Scheme 3. Mesomeric Effect in Fluorophores 1 and 2

1 **2**

acceptor properties of the carbonyl group at the opposite end of the molecule confer to the fluorophores of Table 2 the nature of 'push−pull' compounds (*19*), with extended delocalization of the $\pi-\pi$ system. Scheme 3 illustrates the mesomeric effect of α and β SCH_3 substituents (*20*) in fluorophores **1** and **2**.

Table 3 shows that in PBS the fluorescence efficiencies of **1** and **5** drop to 54% and 17%, respectively. The fact that the decrease in fluorescence quantum yields is much more accentuated in **5** than in **1** suggests that this might be related to the higher number of conformations of the terthiophene derivative, allowing for more vibrational deactivation pathways. On the basis of literature data (*21*), also an effect due to the presence of the surfactant could be operative.

Table 3 also shows that binding to the protein leads to a further fluorescence quantum yield decrease of **1** and **5**, as generally observed for most commercially available fluorophores (*21*). In the conjugates with BSA, **1** and **5** show fluorescence quantum yields of 31% and 10%, respectively. This decrease is probably due to the proximity of the dyes because of the high degree (8:1) of labeling and fluorophore−fluorophore interactions which lead to partial quenching (*22*). It is known that FITC can be quenched up to the 70% for a dye to protein ratio of 5 (*17*). In agreement with this, we observed for FITC in the conjugate with BSA and a dye−protein ratio of 8:1 a quantum yield of 25%, much lower than the >90/% efficiency of FITC in alkaline aqueous solutions (*22*). However, the flexibility of conjugation conditions of TSEs illustrated in Table 1 should allow the optimization, case by case, of the labeling degree of proteins with oligothiophene fluorophores to minimize self-quenching phenomena. Work is currently under way in this direction to establish the dependence of the fluorescence quantum yield of TSEs on the degree of labeling.

It is worth noting that what is important in the present context is that the molar absorption coefficients of TSEs fluorophores and their fluorescence quantum yields are sufficiently high to allow the easy detections of protein−fluorophore conjugates in micromolar and even lower concentrations. It is also to note that the fluorophores are characterized by linewidths on the order of 100 nm and by very large Stokes shifts between absorption and emission signals. These large Stokes shifts are even increased in the conjugates with proteins with respect to the free fluorophores. Moreover, as already observed in the case of oligothiophene isothiocyanates (*8*), the fluorophores show high resistence to photobleaching.

CONCLUSION

We have shown that oligothiophene *N*-succinimidyl esters, built using a few repeating and simple structural elements, i.e., thienyl and α or β SCH_3 substituents and characterized by efficient emission in the blue-orange interval, can easily be bound to BSA achieving high fuorophore to protein ratios. The fluorophore to protein ratio can be controlled by an accurate choice of the experimental conditions. BSA−TSE conjugates in water in physiological conditions display fluorescence quantum yields that are comparable to that of BSA−FITC conjugates in similar conditions. Considering the synthetic versatility of thiophene (*5*), it is easy to predict that thiophene-based fluorophores even more efficient than those described here will rapidly be developed.

ACKNOWLEDGMENT

This work was partially supported by the project "Synthesis of novel organic materials and supramolecular architectures for high efficiency optoelectronic and photonic systems" (SYNERGY, FIRB RBNE03S7XZ_005) and by CNR Projects PM.P04.010 and "Functional organic materials for Hi-Tech applications" (MAFO-HT). Thanks are also due to Mediteknology srl for providing some of the compounds used in this study.

The efficiency of nucleic acid-based drugs is usually hampered by the fact that, following their uptake by the cell, these drugs end up in acidic organelles (i.e., endosomes/lysosomes) from which they barely escape. This work relates to the preparation and characterization of polyion complex micelles (PICM) formed by the self-assembly of three polyelectrolytes: a diblock cationic copolymer; a membranolytic, methacrylic acid copolymer; and an oligonucleotide. It is demonstrated that a synthetic membrane-active polyanion can be successfully integrated within the structure of PICM to yield well-defined, narrowly distributed micelles (30 nm) with a core/shell architecture. Besides their ability to protect the oligonucleotide against nuclease degradation, PICM partly dissociate under mildly acidic conditions, releasing chain clusters that destabilize bilayer membranes. This association/dissociation behavior illustrates the potential of these pH-sensitive PICM for the transport and efficient delivery of polyionic drugs.

INTRODUCTION

Recent advances in the field of nanotechnology have led to the design of highly sophisticated nanoscale constructs and supramolecular assemblies prepared from well-defined synthetic macromolecules (*1*). Of such assemblies, micelles formed by the self-association of block copolymers in aqueous medium have received much attention due to their potential applications in the biomedical and pharmaceutical fields (*2*, *3*). In particular, colloidal carrier systems prepared from the complexation of a polynucleotide and a diblock copolymer composed of polycation and poly(ethylene oxide) (PEO) segments are being developed for the delivery of nucleic acids (*4*−*7*). Neutralization of the charged segments through electrostatic interactions yields hydrophobic complexes that self-assemble into polyion complex micelles (PICM) presenting a core/shell architecture. These micelles present numerous advantages including their straightforward preparation, high colloidal stability, solubility in aqueous media, small size, and narrow size distribution. Furthermore, they represent a promising approach to improve the in vivo efficiency of nucleic acid-based drugs, since protection against nuclease degradation and prolonged circulation times in the blood compartment would allow for enhanced drug deposition at the target site (*8*).

However, despite these attractive properties, the intracellular bioavailability of polynucleotides remains limited due to their sequestration in the endosomal/lysosomal compartment following the uptake of PICM by the cell. The escape of biomolecules from endosomes generally requires a membrane-destabilizing agent, which will provoke the release of the internalized compounds into the cytoplasm before they reach the lysosomes. Synthetic titratable polyanions can achieve such a goal by destabilizing membrane bilayers at pH values typically found in endosomes. Indeed, polymers such as poly(ethylacrylic acid) (PEAA) and poly(propylacrylic acid) (PPAA) undergo a pH-triggered conformational change at slightly acidic pH values (*9*, *10*). Upon protonation and charge neutralization in the acidic environment of endosomes, PPAA was shown to disrupt selectively the endosomal membrane (*11*), thereby enhancing the cytoplasmic delivery of macromolecules such as plasmid DNA and polymer−antibody complex (*12*, *13*).

Recently, our group demonstrated that pH-sensitive methacrylic acid (MAA) copolymers can also be used to improve the cellular delivery of nucleic acid-based drugs (*14*). In that study, nanoparticles in suspension were obtained following the electrostatic complexation of an MAA copolymer, a model oligodeoxynucleotide (ODN), and a cationic lipid. The particles bore a positive surface charge which facilitated their internalization into cultured cells. However, given their cationic nature, the complexes were unstable in physiological conditions (Yessine et al., unpublished observations), thus compromising their applicability for systemic administration. The present work describes the incorporation of an MAA copolymer into a system that could be more suitable for in vivo applications. We demonstrate that the copolymer can be intimately integrated within the structure of neutral, water-soluble, and well-defined PICM. More importantly, we show that, upon a decrease in pH, the resulting PICM partially dissociate to release membrane-active fragments that efficiently destabilize lipid bilayers.

EXPERIMENTAL PROCEDURES

Materials. Poly(ethylene oxide)-*b*-poly(aminoethyl methacrylate) (PEO-*b*-PAEMA, 75/25 mol %, M_n 4700) was synthesized by atom transfer radical polymerization as described previously (*15*). Poly(methacrylic acid-*co*-ethyl acrylate-*co*-butyl methacrylate) (P(MAA-*co*-EA-*co*-BMA), 50/40/10 mol %, M_n 19 800) was provided by Röhm GmbH (Darmstadt, Germany). It was prepared by free radical polymerization involving dodecyl mercaptane as chain transfer agent. The polymer was dissolved in ethanol and dialyzed against water for at least 5 days prior to use. P(MAA-*co*-EA-*co*-BMA) was labeled with Lissamine rhodamine B ethylenediamine (Molecular Probes, Eugene, OR) as described previously (*14*). Twenty-mer phosphorothioate ODN (5′-GTTCTCGCTGGTGAGTTTCA-3′) and its fluores-

cein- labeled derivative were provided by Medicorp, Inc. (Montreal, QC, Canada).

Preparation of the Ternary Polyion Complex Micelles (PICM). PEO-*b*-PAEMA (500 μg) was incubated with P(MAA-*co*-EA-*co*-BMA) (216 μg) in tris(hydroxymethyl)aminoethane (Tris) buffer (10 mM, pH 7.4) for 5 min at room temperature under mild agitation. The ODN (20 μg) was then added, and the formulation was incubated further for 5 min. The charge ratio was calculated from the degree of ionization of the polymers, as determined from titration experiments (Supporting Information). Micelles containing PMAA were prepared using a similar procedure using the same amounts of each component. Salt-containing samples were prepared by adding 0.5 mL of micelles to 0.5 mL of Tris 0.1 M, pH 7.4, containing 300 mM sodium chloride (NaCl) to yield a final salt concentration of 150 mM (isotonic conditions).

Determination of the Critical Association Concentration. The critical association concentration (CAC) was measured by the steady-state pyrene fluorescence method (*16*) based on the I_{336}/I_{333} intensity ratio of the excitation spectra of pyrene following its translocation from water to the PICM hydrophobic core. Serial dilutions of a stock solution of ternary PICM in Tris buffer, pH 7.4, were prepared to contain 2×10^{-7} M of pyrene (Sigma, St-Louis, MO) and were stirred overnight in the dark. Fluorescence intensity was measured ($\lambda_{ex1} = 333$ nm, $\lambda_{ex2} = 336$, $\lambda_{em} = 390$ nm) at room temperature or at 37 °C using a Series 2 Aminco Bowman fluorimeter (Spectronic Instruments, Inc., Rochester, NY). Experiments were performed in triplicate.

Dynamic Light Scattering, Multiangle Static Light Scattering, and ζ-Potential Measurements. Size, M_w, and ζ potential of the ternary PICM were all determined in triplicate in Tris buffer of the appropriate pH following filtration of the micelles through a 0.45 μm GHP filter. The mean hydrodynamic diameter, PI, and scattering intensity of PICM were determined using a Malvern Autosizer 4800 or a Malvern ZetaSizer Nanoseries ZS (Malvern Instruments, Worcestershire, U.K.). Measurements were performed at a scattering angle of 90° and temperatures of 25 and 37 °C. The *CONTIN* program was used to extract size distributions from the autocorrelation functions. Alternatively, MASLS measurements were conducted using a Malvern Autosizer 4800 at 25 °C at seven angles ranging from 70° to 130° for four micelle concentrations. The M_w values of the complexes were derived from eq 1, which describes the intensity of light scattered from a dilute solution of macromolecules. In this equation, *c* stands for the solution concentration

$$\frac{\mathrm{K}c}{R_0} = \frac{1}{M_w P(\theta)} + 2A_2 c + 3A_3 c^2 \qquad (1)$$

in PICM, R_0 is the Rayleigh ratio, and A_2 and A_3 are the second and third virial coefficients. K is in turn defined by

$$\mathrm{K} = \frac{4\pi^2 n_0{}^2 \left(\frac{\mathrm{d}n}{\mathrm{d}c}\right)^2}{\lambda^4 N} \qquad (2)$$

where n_0 is the refractive index of the solvent, λ the laser wavelength in vacuo, and *N* Avogadro's number. The specific refractive index increment ($\mathrm{d}n/\mathrm{d}c = 0.174$) was determined using a differential Rudolph J157 automatic refractometer (Rudolph Research Analytical, Flanders, NJ), at a wavelength of 589.3 nm. ζ potential was evaluated with a Malvern ZetaSizer Nanoseries ZS.

Transmission Electron Microscopy Imaging. Copper grids (200 mesh) were coated with pioloforme resin. Prior to sample deposition, a drop of an aqueous solution of poly(lysine) (17% w/v, Sigma) was placed onto the grid for 5 min. The excess solution was wicked off, the grid was allowed to dry, and a drop of ternary PICM (5 μL) in Tris buffer (pH 7.4 or 5.0) was placed onto the grid for 2 min. After removal of the excess solution, the sample was stained using uranyl acetate (3.5% w/v in water) for 5 min. The grid was then gently washed with water and allowed to dry. Prepared samples were imaged using a Philips CM100 transmission electron microscope (FEI Company, Japan) operating at 60 kV. Micrographs were taken at a 46 000 magnification.

Nuclear Magnetic Resonance Analysis. Polymer and micelle samples were prepared in deuterated Tris buffer (10 mM) adjusted to pH 7.4 using DCl and NaOD solutions (CDN Isotopes, Pointe-Claire, QC, Canada). Prior to analysis, the PICM were eluted on a Sephacryl 200 HR column (Sigma) to completely remove any free polymer in solution and concentrated at room temperature using a vacuum concentrator (Savant SpeedVac SC210A, Thermo Electron Corp., Waltham, MA). The NMR spectrum of the micelles was first acquired at pH 7.4 using a Bruker spectrometer operating at 400 MHz (Bruker, Milton, ON, Canada). The pH of the sample was then adjusted to 5.0 using DCl and the NMR acquisition repeated.

Enzymatic Degradation of ODN Incorporated into the Ternary PICM. Naked fluorescent ODN or fluorescent ternary PICM were incubated with DNAse I (50 U/μg ODN) (Sigma) in the presence of $MgCl_2$ (5 mM) at 37 °C. At predetermined time points, aliquots were withdrawn and degradation was stopped by adding EDTA (10 mM). Before being loaded onto a 20% polyacrylamide gel, heparin (280 μM) was added to the samples to induce ODN release from the PICM. Following migration, ODN was visualized directly on the gel after exposition to UV light using a ChemiImager 5500 imaging system (Alpha Innotech Corp., San Leandro, CA). The amount of intact ODN was quantified relatively to the fluorescent signal obtained with a sample containing 100% intact ODN (nonexposed to DNAse).

Assessment of Membrane-Destabilizing Properties of Micelles Using Liposomes as an Endosomal Membrane Model. Unilamellar liposomes (40 mM total lipid) mimicking the composition of the endosomal membrane (egg phosphatidylcholine/cholesterol/dioleoylphosphatidylethanolamine/dimiristoylphosphatidylglycerol, 61:17:16:6 molar ratio) (*17*) were prepared by hydration of a dried lipid film, followed by repeated extrusion through a 0.2 μm pore size membrane at room temperature. The highly water-soluble fluorophore trisodium 8-hydroxypyrene trisulfonate (HPTS) and the collisional quencher *p*-xylene-bis-pyrimidium (DPX) were included in the lipid hydration buffer (Tris 10 mM, NaCl 48 mM, HPTS 35 mM, DPX 50 mM, pH 7.4). Untrapped dye was removed by gel filtration on Sepharose 2B (Sigma). The membrane-destabilizing properties of the micelles were evaluated at 37 °C at different pH values by adding liposomes (10 μL) to the ternary PICM (previously purified on Sephacryl 200HR to remove free P(MAA-*co*-EA-*co*-BMA) or PMAA) in isotonic buffer of the appropriate pH. In all cases, the final MAA copolymer concentration was adjusted to 85 μg/mL. The release of liposome content was monitored for 20 min at 37 °C by a fluorescence dequenching assay (*18*). The extent of release was calculated from HPTS fluorescence ($\lambda_{ex} = 412$ nm, $\lambda_{em} = 513$ nm) relative to the fluorescence intensity measured following liposome lysis in 0.5% (v/v) Triton X-100, which accounted for the complete release of encapsulated HPTS and DPX.

Intracellular Distribution of the ODN. U937 cells were plated in 6-well tissue culture plates (1 mL medium containing 1×10^6 viable cells) containing coverslips and differentiated into macrophages using 80 nM phorbol myristate (Sigma). After 72 h, the phorbol was rinsed, and ternary micelles (2 mg PEO-

b-PAEMA, 0.862 mg P(MAA-*co*-EA-*co*-BMA) or PMAA, 80 μg ODN) containing fluorescein-labeled ODN (50% of total ODN) were prepared as described above and incubated with cells for 4 h at 37 °C in a humid atmosphere containing 5% CO_2. Two hours before the end of the incubation period, LysoTracker red (Invitrogen, Burlington, ON, Canada) was added to each well at a final concentration of 80 nM. After 4 h, the cells were washed three times with cold PBS and mounted on slides which were kept on ice. Live cells were then examined by laser scanning confocal microscopy (LSCM) under a Leica DMIRBE inverted microscope coupled with a Leica TCS SP confocal system (Leica Microsystems, Heidelberg, Germany). The cells were excited at 488 or 568 nm, and fluorescence was collected by emission windows set at 505−555 and 585−635 nm, respectively. Images collected by *LCS Lite* software (Leica Microsystems) were exported as TIFF files and prepared for publication by *Adobe Photoshop* v 7.0 software (Adobe Systems, San Jose, CA).

RESULTS AND DISCUSSION

At pH 7.4 and room temperature, small-sized (30 nm), narrowly distributed (PI ≈ 0.1) and neutral PICM were obtained at the nearly stoichiometric ± ratio of 0.7/1 (PEO-*b*-PAEMA/P(MAA-*co*-EA-*co*-BMA)/ODN 68%/29%/3% w/w) (Table 1 and Figure 1A). The size and PI of the micelles barely changed at 37 °C (data not shown). Micelles were formed when the PEO-*b*-PAEMA concentration reached the critical values of 11.7 and

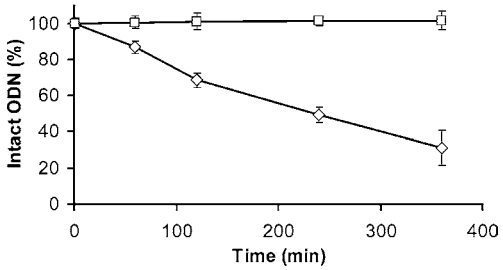

Figure 3. Stability toward nuclease degradation of naked ODN (◇) and ODN incorporated into ternary PICM (□) over a 6 h period.

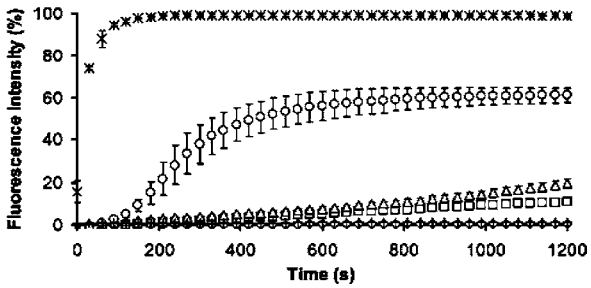

Figure 4. HPTS release induced by the ternary micelles at 37 °C and pH 7.4 (◇), 6.2 (□), 5.5 (△), and 5.0 (○). Star symbols represent the release induced by free P(MAA-*co*-EA-*co*-BMA) at pH 5.0 at equivalent concentration. Release induced by ternary micelles prepared with PMAA, pH 5.0, is represented by (+). Mean ± S.D. (n = 3).

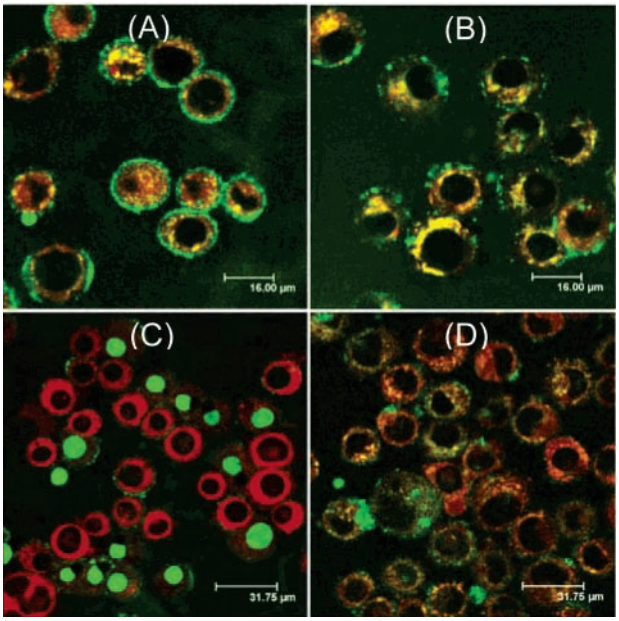

Figure 5. U937 macrophages on coverslips were incubated with ternary micelles prepared with P(MAA-*co*-EA-*co*-BMA) (A,C) or the non-endosomolytic polymer PMAA (B,D) for 4 h at 37 °C. Micelles were prepared using a fluorescein-labeled ODN, and acidic organelles were stained with LysoTracker red. After a 4 h incubation period at 37 °C, the cells were rinsed with cold PBS, mounted on slides, and kept on ice. Live cells were examined by LSCM 45 min (A,B) and 2 h (C,D) following the incubation period.

19.1 μg/mL at 25 and 37 °C, respectively, and remained stable in the presence of 150 mM NaCl (isotonic conditions). Incorporation levels of ODN and P(MAA-*co*-EA-*co*-BMA) reached 100% and 90%, respectively, as determined by gel electrophoresis and ultrafiltration of micelles containing a fluorescein-labeled ODN or a rhodamine-labeled copolymer (see Supporting Information). Table 1 reports the characteristics of the PICM at different pH values in Tris buffer. It is noteworthy that the individual copolymers did not self-associate in solution.

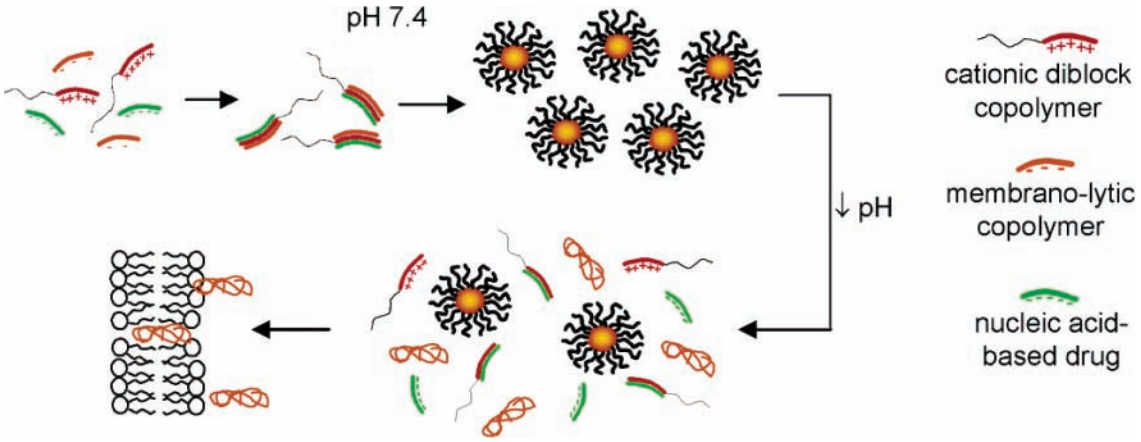

Figure 6. Schematic representation of the association/dissociation behavior of the ternary PICM as a function of pH.

At acidic pH, the micelle PI increased substantially. Moreover, upon lowering the pH from 7.4 to 5.0, a 2.3-fold decrease in the PICM M_w was observed, along with a decreased scattering intensity. This indicates partial dissociation and release of chain clusters and/or free polymeric chains in the external medium at acidic pH. The fact that 30 nm aggregates were still detected at pH 5.0 implies that micelle disruption was not complete. This was confirmed by TEM analysis (Figure 1B), which revealed the presence of small particles of appearance and size similar to those observed at neutral pH (see arrows), along with an excess of noncondensed material.

The association of the copolymers into a core/shell architecture was corroborated by ^{1}H NMR spectroscopy. Prior to analysis, the PICM were eluted on a Sephacryl column to completely remove any free polymer in solution. Figure 2 shows that PICM formation at neutral pH resulted in an important decrease in the intensity of the peaks corresponding to P(MAA-*co*-EA-*co*-BMA), while the signal of the PAEMA block completely disappeared. Interestingly, the peak attributed to the PEO block remained visible, confirming the micellization of the copolymers into core/shell assemblies (*19*). Indeed, the PEO chains forming the outer corona remain hydrated, while the (meth)acrylate monomers are segregated into a more viscous, less solvated internal core, causing a partial suppression of their signals. When the pH was reduced to 5.0, peaks corresponding to the cationic copolymer reappeared to some extent, which points toward enhanced solvation of the micellar core and/or polymer release due to partial micellar dissociation. No signal increase corresponding to P(MAA-*co*-EA-*co*-BMA) was observed at acidic pH because the relatively high concentrations required for the NMR analysis exceeded the copolymer solubility.

ODN stability toward nucleases was assessed by incubating free fluorescent ODN or ternary micelles containing the fluorescent ODN with DNAse I (50 U/μg ODN, 37 °C). Gel electrophoresis of aliquots withdrawn at predetermined time points showed that only 30% of the naked ODN remained intact after a 6 h incubation period. In contrast, no degraded ODN could be detected in the micellar samples at the end of the study (Figure 3). Thus, it is possible to protect the ODN upon incorporation in the ternary PICM structure.

The membrane-destabilizing properties of the micelles were evaluated at different pH values following removal of uncomplexed polymer. To do so, artificial phospholipid vesicles were used to mimic the endosomal membrane. The vesicles were loaded with the water-soluble fluorophore HPTS. They were then added to an isotonic micellar solution prepared at the appropriate pH value. Figure 4 illustrates the release profiles of the encapsulated probe. At pH 7.4, the ternary PICM did not destabilize the phospholipid bilayer as shown by the absence of released dye. As the pH was reduced, the extent of leakage progressively increased, reaching up to 60% at pH 5.0. When comparing the release kinetics obtained in the presence of free P(MAA-*co*-EA-*co*-BMA) to that associated with PICM at pH 5.0, one can note that the latter caused a lowered and delayed HPTS release. This suggests that the protonation of P(MAA-*co*-EA-*co*-BMA) led to its progressive removal from the micelles and to the subsequent destabilization of the vesicle membranes. Chung et al. (*20*) have reported that PEAA induces the formation of cation-selective channels through artificial membranes in a pH-dependent manner. Since P(MAA-*co*-EA-*co*-BMA) is structurally related to PEAA, a similar mechanism of vesicle destabilization may be hypothesized, although the exact nature of the membrane defects remains to be determined. Interestingly, control ternary PICM (35 nm) prepared using a well-known non-membranolytic polymer (PMAA) (*21*) instead of P(MAA-*co*-EA-*co*-BMA) were unable to trigger HPTS release at pH 5.0 (Figure 4), confirming that PEO-*b*-PAEMA does not destabilize the vesicles.

To verify whether the ternary micelles could facilitate the transfer of the ODN from the endosome to the cytoplasm, the intracellular distribution of the ODN in macrophages was examined by LSCM. In these in vitro experiments, macrophages were used, since the uptake of the PICM in non-phagocytic cells is inefficient due to the steric barrier created by the PEG corona (unpublished observations). Live cells were analyzed since it was previously demonstrated that cell fixation could affect membrane permeability and cause artifacts (*22*). Forty-five minutes after the incubation period, macrophages treated with ternary endosomolytic micelles showed multiple fluorescent intracellular vesicles, probably corresponding to phagocytic/endocytic compartments (Figure 5A). Colocalization of ODN and LysoTracker red was detected in most cells (yellow color), indicating that some micelles were localized in acidic organelles. Similar subcellular distribution was observed with the control micelles prepared with PMAA (Figure 5B). Two hours after the incubation period, bright green nuclear fluorescence could be seen in several cells incubated with endosomolytic micelles, indicating that the ODN was released from the endodomal/lysosomal compartments (Figure 5C) (*23*, *24*). These cells also exhibited a decreased red fluorescence indicating disruption of most of the acidic organelles. At that stage, the control, non-endosomolytic micelles were still mainly localized in intracellular globular compartments (Figure 5D), and staining of the nucleus of the cells was weak and, most of the time, undetectable. Collectively, these preliminary findings clearly demonstrate that cytoplasmic delivery of the ODN was facilitated by the incorporation of an endosomolytic polymer into PICM.

In conclusion, ternary PICM with a core/shell architecture, small size, and narrow size distribution were successfully

obtained at physiological pH following the sequential addition of a cationic diblock copolymer, an MAA copolymer, and an ODN. Besides their ability to protect the ODN against nuclease degradation, the ternary micelles were shown to release chain clusters capable of inducing membrane destabilization at slightly acidic pH and improving substantially the ODN subcellular distribution. This association/dissociation behavior is represented in Figure 6 and highlights the potential of these pH-sensitive PICM for the efficient transport and delivery of polyionic drugs. Future work will aim at evaluating the ability of the system to increase the efficacy of ODNs into human tumoral cells. To promote cellular internalization, the micelles will have to be decorated with a targeting ligand.

BRIGHT OLIGOTHIOPHENE *N*-SUCCINIMIDYL ESTERS FOR EFFICIENT FLUORESCENT LABELING OF PROTEINS AND OLIGONUCLEOTIDES

In our work (*1*), we have discovered an inconsistency in the definition of the molecular geometry of compound **5** used in the theoretical calculations. We used a molecular structure with a C═C double bond on the *succinimidyl* group, while the succinimidyl group instead has single C—C bonds. The structure employed in calculations is known as *maleimide* instead.

We repeated the theoretical calculations using the correct molecular structure. We found small changes in the electronic structure and optical properties. Molecular orbitals localized on the succinimidyl group are shifted in energy, so that now the LUMO is no longer localized on the succinimidyl group but rather on the bithiophene. New HOMO and LUMO orbitals are reported in Figure 1. The optically active state (computed at the CC2 level) is found at 4.01 eV, almost the same energy as in previous calculations, since the side group has a negligible effect on it, but now it is the lowest excited state and it is characterized by a HOMO → LUMO transition.

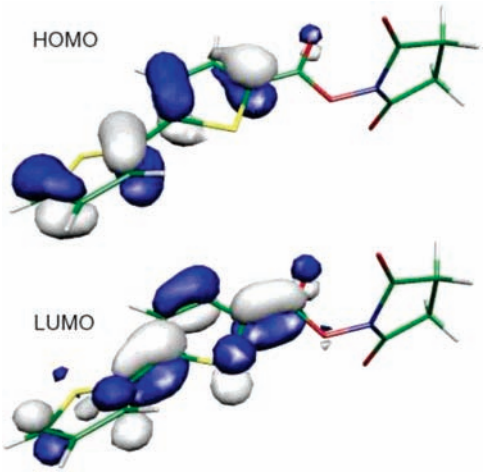

Figure 1. HOMO and LUMO wave functions for *N*-succinimidyl ester **5**.

Finally, we emphasize that the main conclusions drawn from theoretical calculations, based on considerations of optically active states and analysis of model compound **AT2**, still hold unaffected.

Studies on Aminoisonucleoside Modified siRNAs: Stability and Silencing Activity

Zong-Sheng Li,[†,#] Ren-Ping Qiao,[†,#] Quan Du,[‡] Zhen-Jun Yang,*[,†] Liang-Ren Zhang,[†] Pei-Zhuo Zhang,[§] Zi-Cai Liang,[‡] and Li-He Zhang*[,†]

Ltd., Z-J High Tech Park, Shanghai, 201203, China. Received December 26, 2006; Revised Manuscript Received May 11, 2007

A novel class of aminoisonucleoside was synthesized and incorporated into a luciferase gene-targeting siRNA. Structural and functional analyses of such a kind of siRNAs indicated that sense strand modifications with aminoisonucleoside at the 3′ or 5′ terminal, such as **ssIso-1** and **ssIso-2**, have less effect on RNA duplex thermal and serum stabilities, and their functional activities are also comparable to their native siRNAs. In contrast, antisense strand modifications with aminoisonucleoside at the corresponding positions, such as **asIso-2** or **asIso-1**, bring a striking negative effect on RNA duplex stability but still maintain around 40−50% of gene knockdown.

INTRODUCTION

RNAi[1] was first reported by A. Fire and co-workers in *Caenorhabditis elegans* (*1*) and represents a ubiquitous pathway of post-transcriptional gene silencing in nearly every eukaryote studied thus far. The real trigger of RNAi is a small double-stranded RNA (siRNA) that is ∼19 bases in length which assembles with RISC in the cytoplasm and initiates a complicated cascade for the ultimate degradation of sequence-homologous RNAs, The sequence-selective gene knockdown by siRNA and its rapid adoption as a powerful tool for gene regulation in mammalian cells has generated the expectation for its use to improve target therapeutics for cancer, metabolic, inflammatory, infectious, neurological, and other types of diseases (*2*).

Although a variety of methods have been developed to generate siRNA, such as plasmid vectors for transient transfection and viral vectors for stable transduction (*2*), chemical synthesis of siRNAs represents a more attractive resource for clinical purpose and has great advantages in accommodating chemical modifications and dosing changes (*3*−*6*). However, like the hindrances in development of antisense technology, which is the previous generation of RNA-targeting small RNA molecules, siRNA-based therapeutics is also obstructed by its intrinsic qualities, such as poor intracellular uptake, limited blood stability, and nonspecific immune stimulation, and so forth.

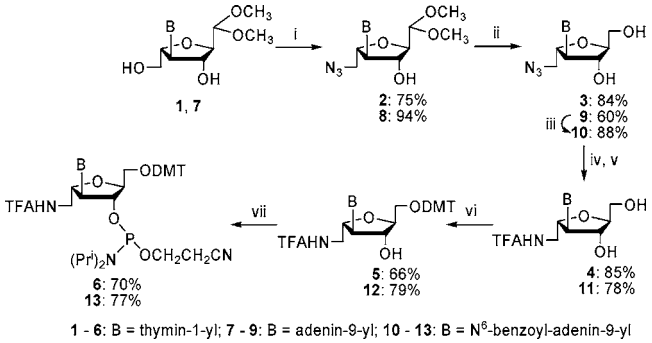
[a] Top strand depicts the sense strand in the 5′−3′ direction (same as the target sequence). Bottom strand depicts the antisense strand in the 3′−5′ direction (complementary to the target sequence). ***A*** and ***T*** letters indicate the aminoisonucleotide.

Chemical modification has been extensively explored to improve antisense serum stability and pharmacokinetics so as to extend circulation in blood for a sufficiently long time (*7*−*12*). Many modified antisense oligos are being tested in clinical trials with fomivirsen (Vitravene; Isis) as the first oligo drug approved by the U.S. FDA for the treatment of eye cytomegalovirus infection. Currently, such chemical modifications are also being applied to synthetic siRNAs, and some modified siRNAs have been reported to be more potent and stable than their native siRNAs (*6*, *13*−*15*). For example, phosphorothioate modification throughout the siRNA duplexes significantly enhanced gene-silencing activities (*16*, *17*). Alternative modification, 2′-position methylation within the pentose sugar, was generally well tolerated with siRNA silencing activity being comparable with the native form. Modification on base moieties is relatively less attempted with N^3-methyluridine, 5-bromouracil, 5-iodouracil, 2,6-diaminopurine, and inosine being reported so far (*3*, *16*). However, all three modifications resulted in a slight decrease of siRNA activity. Recently reported backbone modification, boranophosphate linkage, seems to be more attractive, since it makes siRNA 300-fold more active than the native form and 2-fold more stable than the classic phosphorothioate (*18*). Several of the siRNA reagents have already made their way into clinical trials, one with initially positive indications reported (*19*).

Isonucleosides represent a novel class of carbohydrate-modified nucleoside in which the nucleobase is linked to various positions of ribose other than C-1′, and some of these nucleosides have shown interesting biological activities. In our previous reports for synthesis and incorporation of isonucleosides into antisense oligos, we found that modified antisense oligos not only possess strong nuclease resistance but more interestingly become good substrates of RNase H (*20*). CD spectra and molecular modeling demonstrated that isonucleoside-modified DNA duplexes still adopt a B-like conformation, but the formation of Watson−Crick hydrogen bonding was perturbed by the torsion of the backbone (*21*, *22*), while isonucleoside-modified oligonucleotide/RNA duplex formed an A-like conformation in solution (*23*). An introduction of an amino group into the isonucleoside may increase the thermal stability of the isonucleoside-modified oligonucleotide with its complementary sequence. Here, we report the chemical synthesis and incorporation of aminoisonucleosides into the siRNA duplex and analyze the effect of such a modification at different positions on siRNA structural stability and functional activity.



Members of the wee1 kinase family control the timing of cell cycle events by acting as a negative regulator of entry into mitosis (G2 to M transition) by protecting the nucleus from cytoplasmically activated cyclin B1-complexed CDC2 before the onset of mitosis. These kinases have been evaluated as promising anticancer target genes. siRNA is used in the current experiment as designed against the 3′ end of the coding sequence of the wee1 mRNA (Table 1) (*24*).

MATERIALS AND METHODS

General. All solvents were dried and distilled prior to use. Chemical reagents were purchased from Acros and Sigma Co. Thin layer chromatography was performed on silica gel GF-254 (Qing-Dao Chemical Co., China) plates with detection by UV or by heating. Silica gel (200−300 mesh; Qing-Dao Chemical Co.) was used for short column chromatography. NMR spectra were recorded on a Varian VXR-300, Varian Inova-500 instrument. ^{1}H NMR spectra were referenced using internal standard TMS and ^{31}P NMR spectra using external standard 85% H_3PO_4. Mass spectra (ESI-TOF$^+$ MS) and high-resolution mass spectra (ESI-TOF$^+$ HRMS) were obtained at MDS SCIEX QSTAR and Bruker DALTONICS APEX IV 70e instruments. MALDI-TOF mass spectra for oligonucleotides were obtained at SIMADZU AXIMA CFR plus, and the data are reported in *m*/*e* (intensity to 100%). Optical rotations were recorded on Perkin-Elmer 243B Polarimeter. 4-Deoxy-4-(thymin-1-yl)-2,5-anhydro-L-mannofuranose dimethylacetal (**1**) and 4-deoxy-4-(adenine-9-yl)-2,5-anhydro-L-mannofuranose dimethylacetal (**7**) were synthesized according to Yang et al. (*22*) (Scheme 1).

Synthesis. 4,6-Dideoxy-4-(thymin-1-yl)-6-azido-2,5-anhydro-L-mannofuranose dimethyl acetal (**2**). To a mixture of compound **1** (4.41 g, 13.95 mmol), triphenylphosphine (4.02 g, 15.35 mmol), and sodium azide (5.00 g, 76.92 mmol) in dry DMF (100 mL) was added carbon tetrabromide (4.90 g, 14.80 mmol) at room temperature. The mixture was stirred at room temperature for 48 h, and then methanol was added until the mixture turned into clear solution. Stirring was continued for another hour. The solvent was removed under vacuum, and the residue was purified by a short-column chromatography using a gradient of MeOH in CH_2Cl_2 (2−2.5%) to yield **2** (3.57 g, 75%) as white foam. UV (CH_3OH): λ_{max} = 270.5 (ϵ = 8804). $[\alpha]_D^{20}$ = −34.50 (C 0.004 g/mL, CH_3OH). ^{1}H NMR (DMSO-d_6, 500 MHz): δ 1.79 (s, 3H, 5-CH_3), 3.29−3.54 (m, 2H, H-6′), 3.34 (s, 3H, 1′-OCH_3), 3.35 (s, 3H, 1′-OCH_3), 3.81 (t, $J_{2',1'} = J_{2',3'}$

HRMS (ESI-TOF$^+$) calcd for $C_{13}H_{20}N_5O_6$ (M^+ + H): 342.1408. Found: 342.1424.

4,6-Dideoxy-4-(thymin-1-yl)-6-azido-2,5-anhydro-L-mannitol (**3**). Compound **2** (0.15 g, 0.44 mmol) was dissolved in 1% hydrochloric acid in 50% water/50% THF (10 mL) and refluxed overnight. After cooling to 0 °C and neutralization with 2 M NaOH, sodium borohydride (0.032 g, 0.86 mmol) was added. The solution was stirred at room temperature for 4 h, then neutralized with 1% HCl at 0 °C. The solvent was removed under vacuum, and the residue was dissolved in C_2H_5OH. After filtration, the mixture was purified by a short-column chromatography using a gradient of MeOH in CH_2Cl_2 (5%) to yield **3** (0.11 g, 84%) as white foam. UV (CH_3OH): λ_{max} = 271 (ϵ = 8802). $[\alpha]_D^{20}$ = −48.25 (C 0.004 g/mL, CH_3OH). ^{1}H NMR (DMSO-d_6, 500 MHz) δ 1.77 (s, 3H, 5-CH_3), 3.32−3.63 (m, 2H, H-6′), 3.74−3.77 (m, 1H, H-2′), 4.09−4.12 (m, 1H, H-5′), 4.09−4.27 (m, 1H, H-3′), 4.71 (t, J = 8.5 Hz, 1H, H-4′), 4.81 (t, J = 5 Hz, 1′-OH), 5.57 (d, J = 5.5 Hz, 1H, 3′-OH), 7.56 (s, 1H, H-6), 11.27 (s, 1H, N-3). ^{13}C NMR (DMSO-d_6, 125.7 MHz): δ 12.0 (5-CH_3), 51.8 (C-6′), 61.4 (C-1′), 63.1 (C-4′), 72.4 (C-3′), 77.0 (C-5′), 83.0 (C-2′), 109.5 (C-5), 137.8 (C-6), 151.2 (C-2), 163.7 (C-4). HRMS (ESI-TOF$^+$) calcd for $C_{11}H_{16}N_5O_5$ (M^+ + H): 298.1145; Found: 298.1150.

4,6-Dideoxy-4-(thymin-1-yl)-6-trifluoroacetylamino-2,5-anhydro-L-mannitol (**4**). To a solution of compound **3** (0.37 g, 1.25 mmol) in 10 mL anhydrous methanol was added 10% Pd/C (0.18 g), then the mixture was reduced by hydrogen (4 kg/cm^2) for 16 h. After filtration, the solvent was removed under vacuum and the residue was dissolved in 25 mL methanol; triethylamine (0.96 mL, 6.90 mmol) and ethyl trifluoroacetate (0.5 mL, 4.14 mmol) were added, and the mixture was reacted overnight at room temperature. The solvent was removed under vacuum and the residue was purified by a short-column chromatography using a gradient of MeOH in CH_2Cl_2 (7%) to yield **4** (0.39 g, 85%) as white foam. UV (CH_3OH): λ_{max} = 271 (ϵ = 7965). $[\alpha]_D^{20}$ = −3.00 (C 0.004 g/mL, CH_3OH). ^{1}H NMR(DMSO-d_6, 500 MHz) δ 1.78 (s, 3H, 5-CH_3), 3.32−3.64 (m, 4H, H-1′ and H-6′), 3.75−3.78 (m, 1H, H-2′), 4.13−4.17 (m, 1H, H-5′), 4.26−4.30 (m, 1H, H-3′), 4.53 (t, J = 7.5 Hz, 1H, H-4′), 4.81 (t, J = 5.0 Hz, 1′-OH), 5.59 (d, J = 5.5 Hz, 1H, 3′-OH), 7.54 (d, J = 1.0 Hz, 1H, H-6), 9.51 (t, J = 5.0 Hz, 1H, 6′-NH-), 11.32 (s, 1H, N-3). ^{13}C NMR (DMSO-d_6, 125.7 MHz): δ 12.0 (5-CH_3), 41.9 (C-6′), 61.1 (C-1′), 65.3 (C-4′), 72.9 (C-3′), 76.1 (C-5′), 83.1 (C-2′), 109.5 (C-5), 138.2 (C-6), 151.0 (C-2), 156.3 and 156.5 (CF_3CO), 163.6 (C-4). 1-*O*-Dimethoxytrityl-4,6-dideoxy-4-(thymin-1-yl)-6-trifluoroacetylamino-2,5-anhydro-L-mannitol (**5**). Compound **4** (0.41 g, 1.1 mmol) was dissolved in dry pyridine (10 mL), and dimethoxytrityl (DMT) chloride (0.38 g, 1.1 mmol) was added at 0 °C. The solution was stirred at room temperature for 23 h. After evaporation, the mixture was purified by a short-column chromatography using a gradient of MeOH in CH_2Cl_2 (1.5%, 1% Et_3N added) to yield **5** (0.49 g, 66%) as white foam. ^{1}H NMR (DMSO-d_6, 500 MHz) δ 1.70 (s, 3H, 5-CH_3), 3.08−3.47 (m, 4H, H-1′ and H-6′), 3.73 (s, 6-H, Ph−OCH_3), 3.97−4.00 (m, 1H, H-2′), 4.24−4.29 (m, 2H, H-3′ and H-5′), 4.53 (t, J = 8.0 Hz, 1H, H-4′), 5.60 (d, J = 5.5 Hz, 3′-OH), 6.87−7.43 (m, 13H, Ph), 7.51 (s, 1H, H-6), 9.66 (t, J = 5.5 Hz, 1H, 6′-NH-), 11.34 (s, 1H, N-3). ^{13}C NMR (DMSO-d_6, 125.7 MHz): δ 11.9 (5-CH_3), 41.9 (C-6′), 54.9 (Ph−OCH_3), 64.3 (C-1′), 65.3 (C-4′), 72.8 (C-3′), 75.4 (C-5′), 81.1 (C-2′), 109.4 (C-5), 113.3, 126.6, 127.7, 129.7, 135.6 (Ph), 138.3 (C-6), 151.0 (C-2), 158.0 (CF_3CO), 163.6 (C-4). Anal. Calcd. for $C_{34}H_{34}F_3N_3O_8$ (669.2) C 60.98, H 5.12, N 6.27. Found: C 60.96, H 5.17, N 6.24.

1-*O*-Dimethoxytrityl-3-*O*-(2-cyanoethyl-*N*,*N*-diisopropyl)-phosphoramidite-4,6-dideoxy-4-(thymin-1-yl)-6-trifluoroacetylamino-2,5-anhydro-L-mannitol (**6**). Compound **5** (0.47 g, 0.7 mmol) was dissolved in anhydrous THF (5 mL) under argon. To this solution was added diisopropylethylamine (DIPEA, 0.5 mL, 2.8 mmol) and 2-cyanoethyl-*N*,*N*-diisopropylchlorophosphoramidite (0.3 mL, 1.4 mmol). The mixture was stirred at 0 °C for 10 min, then at room temperature for 2 h. The reaction mixture was quenched by addition of MeOH (0.6 mL). After stirring for 15 min, EtOAc (40 mL) was added, and the organic layer was washed with 5% aqueous $NaHCO_3$ (10 mL × 2), followed by H_2O (10 mL × 2) and saturated NaCl solution (10 mL × 2). The solution was dried (Na_2SO_4), then evaporated under vacuum to oil, and the oil was purified by a short-column chromatography eluting with petroleum ether/EtOAc (6:1−3:2, 0.5% Et_3N) to afford compound **6** as a white foam solid (0.43 g, 70%). ^{1}H NMR ($CDCl_3$, 500 MHz): δ 0.58 (d, J = 7.0 Hz, 3H, CH_3), 0.74 (d, J = 6.5 Hz, 3H, CH_3), 0.92 (d, J = 7.0 Hz, 6H, CH_3), 1.18 (t, J = 7.0 Hz, 2H, CH_2CN), 1.70 (s, 3H, 5-CH_3), 2.41 (m, 2H, CH), 3.08−3.47 (m, 6H, H-1′, H-6′ and -$POCH_2$), 3.72 (s, 6-H, Ph−OCH_3), 3.98−4.01 (m, 1H, H-2′), 4.22−4.28 (m, 2H, H-3′ and H-5′), 4.53 (t, J = 8.0 Hz, 1H, H-4′), 6.86−7.42 (m, 13H, Ph), 7.50 (s, 1H, H-6), 9.67 (t, J = 5.5 Hz, 1H, 6′-NH-), 11.30 (s, 1H, N-3). ^{31}P NMR ($CDCl_3$, 121.5 MHz): δ 154.18 and 154.84.

4,6-Dideoxy-4-(adenin-9-yl)-6-azido-2,5-anhydro-L-mannofuranose dimethyl acetal (**8**). Compound **8** (white foam, 2.15 g, 94%) was prepared from compound **7** (2.12 g, 6.52 mmol) in the same way as compound **2** from compound **1**. UV (CH_3OH): λ_{max} = 262 (ϵ = 13452). $[\alpha]_D^{20}$ = −27.50 (C 0.004 g/mL, CH_3OH). ^{1}H NMR (DMSO-d_6, 500 MHz): δ 3.36 (s, 3H, 1-OCH_3), 3.37 (s, 3H, 1-OCH_3), 3.29−3.56−3.47 (m, H-6′), 3.91 (t, J = 5.5 Hz, 1H, H-2′), 4.56−4.59 (m, 2H, H-1′ and H-5′), 4.72−4.80 (m, 2H, H-3′ and H-4′), 5.73 (d, J = 6.0 Hz, 1H, 3′-OH), 7.26 (br. s, 2H, 6-NH_2), 8.15 (s, 1H, H-2), 8.23 (s, 1H, H-8). ^{13}C NMR (DMSO-d_6, 125.7 MHz): δ 51.1 (C-6′), 53.8 (1′-OCH_3), 54.4 (1′-OCH_3), 63.4 (C-4′), 74.7 (C-3′), 77.6 (C-5′), 82.0 (C-2′), 103.7 (C-1′), 119.1 (C-5), 139.9 (C-8), 149.6 (C-4), 152.4 (C-2), 156.0 (C-6). 4,6-Dideoxy-4-(adenin-9-yl)-6-azido-2,5-anhydro-L-mannitol (**9**). Compound **9** (white foam, 0.40 g, 60%) was prepared from compound **8** (0.74 g, 2.1 mmol) in the same way as

compound **3** from compound **2**. UV (CH_3OH): $\lambda_{max} = 260.5$ ($\epsilon = 12802$). $[\alpha]_D^{20} = -13.8$ (C 0.004 g/mL, CH_3OH). ^1H NMR (DMSO-d_6, 500 MHz): δ 3.31−3.69 (m, 4H, H-1′ and H-6′), 3.84−3.87 (m, 1H, H-2′), 4.54−4.57 (m, 1H, H-5′), 4.64−4.68 (m, 1H, H-3′), 4.77 (t, $J = 8.5$ Hz, 1H, H-4′), 4.88 (t, $J = 5.5$ Hz, 1H, 1′-OH), 5.68 (d, $J = 5.5$ Hz, 1H, 3′-OH), 7.24 (br. s, 2H, 6-NH_2), 8.13 (s, 1H, H-2), 8.24 (s, 1H, H-8). ^{13}C NMR (DMSO-d_6, 125.7 MHz): δ 51.7 (C-6′), 61.3 (C-1′), 62.8 (C-4′), 73.3 (C-3′), 77.4 (C-5′), 83.4 (C-2′), 119.1 (C-5), 139.9 (C-8), 149.6 (C-4), 152.4 (C-2), 156.0 (C-6). HRMS (ESI-TOF$^+$) calcd for $C_{11}H_{15}N_8O_3$ ($M^+ + H$): 307.1261. Found: 307.1263.

4,6-Dideoxy-4-(N^6-benzoyladenin-9-yl)-6-azido-2,5-anhydro-L-mannitol (**10**). Compound **9** (0.33 g, 1.1 mmol) was dissolved in dry pyridine (10 mL) and TMSCl (1.4 mL, 11 mmol) was added at 0 °C. The solution was stirred at room temperature for 2 h. Then, benzyl chloride (0.7 mL, 6 mmol) was added at 0 °C and the solution was stirred at room temperature for 4 h. Then, the pH of the solution was adjusted to 8−9 by NH_4OH at 0 °C. After evaporation, the mixture was dissolved in CH_2Cl_2. After filtration, the solvent was evaporated under vacuum, and the residue was purified by short-column chromatography using a gradient of MeOH in CH_2Cl_2 (3.5%) to yield **10** (0.39 g, 88%) as white foam. UV (CH_3OH): $\lambda_{max} = 280.5$ ($\epsilon = 13051$). $[\alpha]_D^{20} = -14.5$ (C 0.004 g/mL, CH_3OH). ^1H NMR (DMSO-d_6, 500 MHz): δ 3.32−3.71 (m, 4H, H-1′ and H-6′), 3.88−3.91 (m, 1H, H-2′), 4.59−4.63 (m, 1H, H-5′), 4.69−4.73 (m, 1H, H-3′), 4.90−4.95 (m, 2H, H-4′ and 1′-OH), 5.77 (d, $J = 6.0$ Hz, 1H, 3′-OH), 7.52−8.04 (5H, Ph), 8.62 (s, 1H, H-2), 8.74 (s, 1H, H-8), 11.16 (s, 1H, 6-NH-). ^{13}C NMR (DMSO-d_6, 125.7 MHz): δ 51.7 (C-6′), 61.2 (C-1′), 62.9 (C-4′), 73.4 (C-3′), 77.4 (C-5′), 83.3 (C-2′), 125.8 (C-5), 128.4, 132.4 and 133.3 (Ph), 143.5 (C-8), 150.2 (C-4), 151.4 (C-2), 152.6 (C-6), 165.5 (Ph−CO-). HRMS (ESI-TOF$^+$) calcd for $C_{18}H_{19}N_8O_4$ ($M^+ + H$): 411.1523. Found: 411.1514.

4,6-Dideoxy-4-(N^6-benzoyl-adenin-9-yl)-6-trifluoroacetylamino-2,5-anhydro-L-mannitol (**11**). Compound **11** (white foam, 0.40 g, 89%) was prepared from compound **10** (0.39 g, 0.94 mmol) in the same method as compound **4** from compound **3**. UV (CH_3OH): $\lambda_{max} = 279$ ($\epsilon = 13764$). $[\alpha]_D^{20} = -17.00$ (C 0.004 g/mL, CH_3OH). ^1H NMR (DMSO-d_6, 500 MHz): δ 3.39−3.71 (m, 4H, H-1′ and H-6′), 3.87−3.90 (m, 1H, H-2′), 4.61−4.64 (m, 1H, H-5′), 4.69−4.73 (m, 1H, H-3′), 4.79 (t, $J = 8.0$ Hz, 1H, H-4′), 4.91 (t, $J = 5.5$ Hz, 1H, 1′-OH), 5.77 (d, $J = 6.0$ Hz, 1H, 3′-OH), 7.54−8.05 (5H, Ph), 8.53 (s, 1H, H-2), 8.73 (s, 1H, H-8), 9.56 (t, $J = 5.5$ Hz, 1H, 6′-NH-), 11.16 (s, 1H, 6-NH-). ^{13}C NMR (DMSO-d_6, 125.7 MHz): δ 41.7 (C-6′), 61.0 (C-1′), 64.5 (C-4′), 73.5 (C-3′), 76.3 (C-5′), 83.3 (C-2′), 125.8 (C-5), 128.4, 132.4 and 133.3 (Ph), 143.7 (C-8), 150.3 (C-4), 151.3 (C-2), 152.3 (C-6), 156.4 and 156.6 (CF_3CO), 165.5 (Ph−CO-). 1-*O*-Dimethoxytrityl-3-*O*-(2-cyanoethyl-*N*,*N*-diisopropyl) phosphoramidite-4-dideoxy-4-(N^6- benzoyladenin-9-yl)-6-trifluoroacetylamino-2,5-anhydro-L-mannitol (**13**). Compound **13** (white foam, 0.31 g, 77%) was prepared from compound **12** (0.32 g, 0.41 mmol) in the same method as compound **6** from compound **5**. ^1H NMR ($CDCl_3$, 500 MHz): δ 0.58 (d, $J = 7.0$ Hz, 3H, CH_3), 0.74 (d, $J = 6.5$ Hz, 3H, CH_3), 0.92 (d, $J = 7.0$ Hz, 6H, CH_3), 1.18 (t, $J = 7.0$ Hz, 2H, CH_2CN), 2.41 (m, 2H, CH), 3.21−3.56 (m, 6H, H-1′, H-6′ and -$POCH_2$), 3.74 (s, 6H, Ph−OCH_3), 4.08 (m, 1H, H-2′), 4.78−4.90 (m, 3H, H-3′, H-4′ and H-5′), 5.78 (d, $J = 6.0$ Hz, 1H, 3′-OH), 6.89−8.06 (18H, Ph), 8.51 (s, 1H, H-2), 8.73 (s, 1H, H-8), 9.65 (t, 1H, 6′-NH-), 11.14 (s, 1H, 6-NH). ^{31}P NMR ($CDCl_3$, 121.5 MHz): δ 153.98 and 154.56.

Oligonucleotides. siRNAs (21 nt, Table 1) were chemically synthesized by automatic DNA synthesizer (model NW3900) using commercial phosphoramidities as building blocks (Shanghai Gene Biotech Co.). Aminoisonucleoside-modified siRNAs were synthesized by the same method but replacing the regular **T** and **A** unit with building blocks **6** and **13** at the defined positions (Table 1) (synthesis scale, 0.2 μmol; coupling time, 10 min). Cleavage and deprotection of RNA oligos were carried out according to the standard protocol (treated with 29% $NH_3 \cdot H_2O$ in sealed vessel at 55 °C for 16 h; the trifluoroacetyl group was removed at this stage (*25*); then, treated with Bu_4NF; TBDMS group was removed). The synthetic oligoribonucleotides were then purified by reverse-phase HPLC (Shimadzu LC-6AD, C-18 column, 10 × 250 mm) eluting with 0.1 M TEAA/MeCN, and the pure oligonucleotides were lyophilized and stored at −20 °C. siRNA duplexes were prepared by mixing complementary sense- and antisense-strand RNAs at equal 50 μm in MQ water, and then incubated in boiling water for 1 min, followed by gradual temperature decrease to room temperature and then 4 °C, allowing the efficient formation of siRNA duplex. The quality of the RNA duplexes was assessed on a 15% PAGE gel.

T_m Measurement. UV melting experiments were recorded with a Pharmacia LKB Biochrom 4060 spectrophotomer. Samples were dissolved in a buffer solution containing 0.14 M NaCl, 0.01 M Na_2PO_4, and 0.1 mM EDTA, pH 7.2. The solution containing the sense-strand siRNA and complementary antisense-strand siRNA were heated to 95 °C for 3 min, then cooled gradually to 4 °C and used for the thermal denaturation studies. Thermally induced transitions of each mixture were monitored at 260 nm. Sample temperature was increased at 0.5 °C/min between 15 and 85 °C. In all experiments, the concentration of each oligonucleotide strand was 2 μM.

Serum Stability. Duplexes of single-stranded RNA or siRNA (330 ng/μl) were incubated at 37 °C in 500 μL of 50% fetal bovine serum containing 7.5 μL TBST. Aliquots of 5 μL were withdrawn at different time points and immediately frozen in 15 μL × TBE-loading buffer. Samples were subjected to electrophoresis in 15% polyacrylamide−TBE under nondenaturing conditions and visualized by staining with SYBR Gold nucleic acid staining reagents and quantified by Storm 840 hardware and *Imagequant* software (Amersham Biosciences, Uppsala, Sweden).

Transfection and Dual-Luciferase Assay. Human embryonic kidney cells (HEK293) were grown in DMEM (Life Technologies, Gibco) and seeded in 24-well plates. After the cells reached about 50% confluence, the culture medium was changed to OPTIMEM (Gibco) and then transfected with plasmids and siRNA duplex in the presence of 0.17% Lipofectamine 2000 (Invitrogen). For each well, 0.17 g of recombination plasmid and 0.017 g pRL-TK were used. The final

concentration of siRNA is 13 nM. The transfection medium was changed to culture medium (1 mL) after 4 h. All experiments were performed in triplicate and repeated at least twice. Cells were harvested 24 h after transfection and lyzed by passive cell lysis. Dual-luciferase assay was conducted. Luciferase activities were determined with 10 μL cell lysate using the Dual-Luciferase Assay System (Promega) by NOVOStar (BMG Labtechnologies Gmbh, Germany). The ratio between *firefly* and *Renilla* luciferase readings was generated for each well, and the inhibition efficiency of each siRNA was calculated by normalizing to respective buffer control.

RESULTS

Chemical Synthesis. Building blocks **6** and **13** for solid-phase oligonucleotide synthesis were synthesized from starting materials **1** and **7** (*22*), respectively (Scheme 1). The general method for synthesis of azido isonucleoside intermediates is to introduce a leaving group first and then substituted by azido group. Here, we developed a one-step method (step I) in which, at room temperature, compound **1** or **7** was directly reacted with sodium azide in the presence of triphenyl phosphine and carbon tetrabromide, giving the key intermediate **2** or **8** in good yield (*26*). Treatment of compound **2** or **8** with 1% HCl followed by sodium hydroxide and sodium borohydride in a second one-pot reaction at 0 °C (step II) gave unprotected azido isonucleoside **3** or **9** in 84% or 76% yield, respectively. Conversion of azidoisonucleosides into aminoisonucleosides was carried out by catalytic hydrogenation (step III). Prior to this reaction, compound **9** was first preprotected by a benzoyl group at the 6-amino group of the adenine moiety. After hydrogenation, the amino groups within the aminoisonucleosides were protected by trifluoroacetyl (step IV), yielding compounds **4** and **11**, which were then protected by a DMT group and a 2-cyanoethyl-*N*,*N*-diisopropylphosphoramidite group (steps V and VI) at the 1-hydroxyl and 3-hydroxyl positions for solid-phase chemistry.

Oligonucleotides. The obtained building blocks **6** and **13** were finally incorporated into the sequences of sense or antisense strand of designed siRNAs according to the solid-phase protocols. The coupling efficiency was determined by the release of DMT, and the efficiency was over 90% for coupling **6** and **13**. After the usual workup and purification by C-18 reverse HPLC, ten kinds of aminoisonucleoside-incorporated oligonucleotides were synthesized (Table 1). On the basis of the MALDI-TOF MS, the molecular weights of the aminoisonucleoside-modified sense strand and antisense strand of siRNA are concordant with the calculated value of the designed sequence (Table 2). The assessment results on a 20% PAGE gel showed the high quality of the RNA duplexes (Figure 1).

Thermal and Serum Stability of siRNA Duplexes. It has been reported that isonucleoside modification confers high nuclease resistance to oligonucleotides, but decreases the oligonucleotide binding ability to the complementary strand (*22*). In order to overcome the poor binding issue, we incorporated aminoisonucleosides instead of isonucleosides into siRNA duplexes. We found that incorporation of one aminoisonucleoside at the 3′ or 5′ terminal of sense strand of siRNA exhibited no effect on the duplex thermal stability with T_m = 66 °C for both **ssIso-1**/**asNC** and **ssIso-2**/**asNC**, which were equal to native siRNA form, **ssNC**/**asNC**. However, internal incorporation of one aminoisonucleoside into siRNA duplexes decreased the thermal stability with T_m = 62 °C for **ssIso-3**/**asNC**. Furthermore, when two or more aminoisonucleosides were incorporated into siRNAs, T_m values decreased strikingly with T_m = 56 °C for **ssIso-4**/**asNC** and 36 °C for **ssIso-5**/**asNC** (Table 3). Incorporation of aminoisnucleoside at a different position of the antisense strand of siRNA showed the same effect as the case of **ssIso1**−**5**/**asNC** (data were not shown).

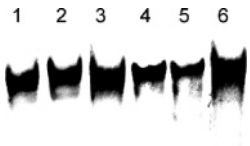

Figure 1. PAGE analysis of siRNAs: **ssNC/asNC** and **ssIsoX/asNC**. 20% polyacrylamide denaturing (7 M urea) gel electrophoresis and visualized by staining with SYBR gold and quantified by Model & Storm 860 hardware and *Imagequant* software (Amersham Biosciences, PKU, China). Lanes 1 to 6 represent: (1) **ssNC/asNC**; (2) **ssIso-1/asNC**; (3) **ssIso-2/asNC**; (4) **ssIso-3/asNC**; (5) **ssIso-4/asNC**; (6) **ssIso-5/asNC**.

Table 3. T_m and Serum Stability ($T_{1/2}$) of siRNAs: NC (ssNC/asNC) and ssIso-X/asNC (X = 1−5)

name	NCss NC/asNC	a ssIso-1/ asNC	b ssIso-2/ asNC	c ssIso-3/ asNC	d ssIso-4/ asNC	e ssIso-5/ asNC
T_m (°C)	66	66	66	62	56	36
$T_{1/2}$ (h)	16.53	14.96	13.79	13.51	4.06	5.86

After incubation of siRNAs with 50% FBS at 37 °C, the results indicated that siRNAs with a single aminoisonucleoside modification at the sense strand, such as **ssIso-1**/**asNC**, **ssIsio-2**/**asNC**, and **ssIso-3**/**asNC**, exhibited a slight decrease of serum stability compared with their native siRNA with all degraded in 24 h (Figure 2, **I**, **II**, and **III**) (Table 3). Modified siRNAs with two or more aminoisonucleosides at the sense strand, such as **ssIso-4**/**asNC** and **ssIso-5**/**asNC**, showed further weaker serum stability compared with the native siRNA and rapidly degraded within 1.5 h (Figure 2, **IV** and **V**) (Table 3).

Gene-Silencing Activities of Aminoisonucleoside-Modified siRNA. The firefly luciferse-targeting modified siRNAs with aminoisonucleosides in either the sense strand or antisense strand were evaluated on the basis of a dual-luciferase assay in which renillar luciferase acts as an internal control. We found that sense strand-modified siRNAs with a single aminoisonucleoside at the 3′- or 5′-end, such as **ssIso-1**/**asNC** and **ssIso-2**/**asNC**, exhibited comparative and even better activity than the native siRNA (**NC**) (Figure 3, Table 4). However, such an advantage was not observed when 3′- and 5′-terminal modifications combined together, such as **ssIso-4**/**asNC**; instead, the silencing activity somehow decreases. Alternative modifications with aminoisonucleoside at the siRNA internal region, such as **ssIso-3**/**asNC**, bring some negative effect on siRNA activity compared with the terminal modification, and such a negative effect further becomes apparent when internal and terminal modification in the sense strand were combined together, such as **ssIso-5**/**asNC**, which only maintains about 40% of gene-silencing activity (13 nM) (Figure 3, Table 4).

In contrast to the tolerance toward sense strand modifications, antisense strand modification brings a strikingly negative effect on the siRNA activity. We found that replacement of a single nucleotide with an aminoisonucleoside at the 5′-end of the antisense strand, such as **ssNC**/**asIso-2**, reduced siRNA activity by almost 60%. A similar modification at the 3′-end of the antisense strand, such as **ssNC**/**asIso-1**, reduced siRNA activity by around 50%, somehow better than the 5′-end modification.

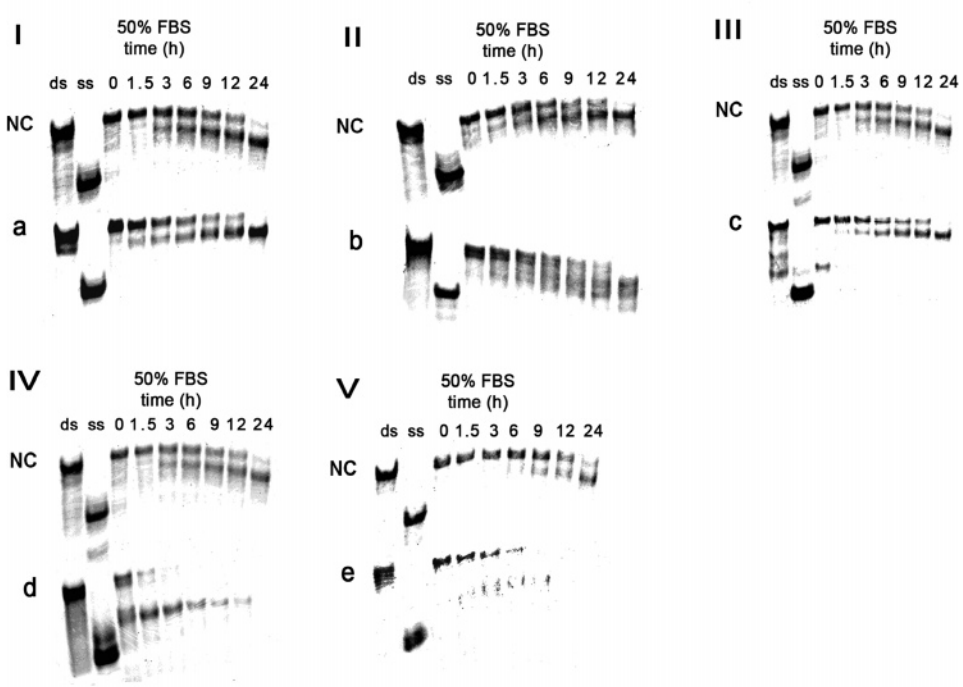

Figure 2. Serum stability of siRNAs: **NC** (**ssNC/asNC**) and **ssIso-X/asNC** (X = 1−5). The different **ssIso-X/asNC** were incubated in 50% FBS at 37 °C and withdrawn at indicated time points. The oligos were separated by PAGE and visualized with SYBR gold. ds depicts double-stranded siRNA marker and ss single-stranded. (a) **ssIso-1/asNC (I)**; (b) **ssIso-2/asNC(II)**; (c) **ssIso-3/asNC (III)**; (d) **ssIso-4/asNC(IV)**; (e) **ssIso-v/asNC(V)**.

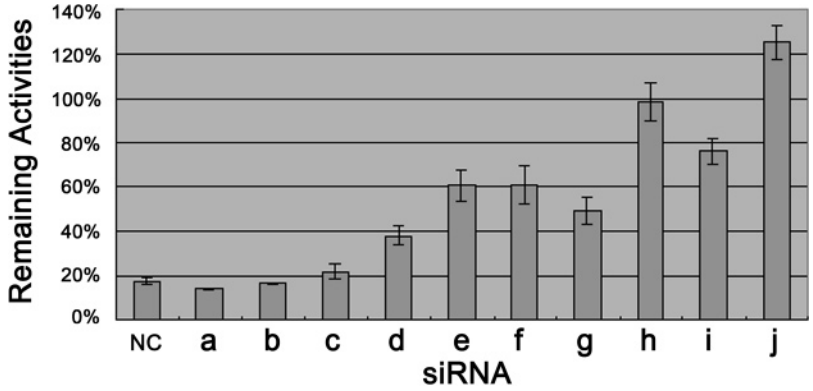

Figure 3. *Firefly renilla* luciferase activities of siRNAs: **NC (ssNC/asNC)**, **ssIso-X/asNC**, and **ssNC/asIso-X** (X = 1−5). All experiments were performed in triplicate and repeated at least twice.

Table 4. *Firefly renilla* Luciferase Activities of siRNAs: NC (ssNC/asNC), ssIso-X/asNC, and ssNC/asIso-X (X = 1−5)

NC ssNC/ asNC	a ssIso-1/ asNC	b ssIso-2/ asNC	c ssIso-3/ asNC	d ssIso-4/ asNC	e ssIso-5/ asNC
	15%	17%	22%	38%	61%
	f	**g**	**h**	**i**	**j**
18%	ssNC/ asIso-1	ssNC/ asIso-2	ssNC/ asIso-3	ssNC/ asIso-4	ssNC/ asIso-5
	61%	50%	98%	77%	126%

Simultaneous modifications of the 3′- and 5′-ends of the antisense strands by aminoisonucleosides lead to a further negative effect with just 20% activity remaining for **ssNC/asIso-4**. We also found that internal modification on siRNA antisense strand by replacing a single nucleoside with an aminoisonucleoside, such as **ssNC/asIso-3**, or combination of the terminal modification with internal modification on the antisense strand almost abolished the silencing activity, such as **ssNC/asIso-5** (Figure 3, Table 4).

DISCUSSION

RNA interference (RNAi) is the process of using a double-stranded RNA (dsRNA) with specific sequence to regulate the expression of a sequence-homologous gene. According to the RNAi pathway, the siRNA duplex is first incorporated into a large multiprotein known as RNAi-induced silencing complex (RISC), by which the sense strand is excluded via an undefined mechanism, and then the antisense strand together with RISC recognizes and cleaves the target mRNA (*27*−*30*). Therefore, the sense strand is more like a courier that delivers the antisense strand, the main effective component of RNAi, into the RISC complex. As a result, many different chemical modifications can be accommodated in the sense strand but not in the antisense strand. Schwarz et al. reported that siRNA duplexes function asymmetrically with two strands not equally eligible for assembly into RISC (*31*). By statistical analyses of the internal stability of siRNA, Khvorova et al. found that the functional siRNAs display lower stability at 5′ end of the antisense strand than nonfunctional dsRNAs, suggesting that altering the nature of the dsRNA, chemically or structurally, might be a means for optimization of siRNA activity (*32*).

Among the chemical modifications, aminoisonucleoside may represent a novel direction in which the nucleobase is linked to the 4-position rather than C1 of the sugar ring. It has been shown that incorporation of isonucleotides into a oligonucleotide causes a change in the conformation of 2,5-anhydro-L-mannitol, bringing torsion angles in the sugar−phosphate backbones. This alternation might make the modified oligonucleotide less recognized by nucleases and thus increase its stability toward various enzymes (*20*−*22*). However, the conformational change within isonucleotise-modified oligonucleotides decreases RNA duplex thermal stability with a lower T_m value. For aminoisonucleotide-modified oligonucleotides, the introduction of amino groups may increase their thermal stability via the strong binding of cationic amino groups with negatively charged phosphate backbones of the complementary sequences, as shown from the identical T_m values by comparisons of **ssIso-1**/**asNC** and **ssIso-2**/**asNC** with their native siRNA, **ssNC**/**asNC** (Table 1).

On the other hand, the alternations in torsion angles of the backbone of the oligonucleotide might promote the strand separation of the siRNA duplex that could potentially increase silencing activity. It might provide an explanation for the data above in which the siRNA duplex **ssIso-1**/**asNC** and **ssIso-2**/**asNC** with aminoisonucleoside substitution at the 3′-end or 5′-end of the sense strand exhibited better activity than the native siRNA (**NC**).

The comparable gene-silencing activities of **ssIso-1**/**asNC**, **ssIso-2**/**asNC**, and **ssIso-3**/**asNC** with their wild-type siRNA (Figure 3) indicate that introduction of a single aminoisonucleoside in the sense strand, at either the 3′-end or 5′-end or internally, is quite tolerant for maintaining siRNA activity. However, introduction of multiple aminoisonucleosides into the siRNA sense strand, such as **ssIso-4**/**asNC** and **ssIso-5**/**asNC**, seriously reduced its activity (Figure 3), potentially due to the lower serum and thermal stability (Table 1 and Figure 3). Even so, the combination of internal and terminal modifications at the sense strand, such as **ssIso-5**/**asNC** (T_m = 36 °C), still retains 40% (at 13 nM) gene-silencing activity. On the contrary, introduction of a single aminoisonucleoside at the antisense strand, either 3′- or 5′-end, such as **ssNC**/**asIso-2** or **ssNC**/**asIso-1**, strikingly affects siRNA function with 40% to 50% of gene-silencing activity left. Modification of the antisense strand at both ends, such as **ssNC**/**asIso-4**, further reduces siRNA silencing activity with just ∼20% left.

Hohjoh et al. have investigated the relationship of siRNA activity versus sense−antisense strand terminal mismatches, and found that the strand whose 3′-end is relatively easily unwound would be employed as the guider strand to incorporate into RISC for gene knockdown (*33*). Here, we conclude that siRNA sense-strand modification has less effect on siRNA activity, while antisense-strand modification significantly reduces siRNA activity. Our data also suggests the following: (i) the bases in modified siRNAs, despite their lower activity, retain their hybridization properties with complementary sequences; (ii) the torsion angles in the sugar−phosphate backbones would not perturb the entry of the modified siRNA into RISC; and (iii) the two strands of the siRNA duplex are not equally eligible for assembly into RISC.

The siRNA stability depends on the thermal stability of the siRNA duplex and the serum stability of each individual strand. We have found that single-stranded RNA oligos containing aminoisonucleoside were degraded rapidly when incubated with serum (data was not shown), but the siRNA duplex with aminoisonucleoside at either the 3′- or 5′-end of the sense strand exhibited a slight serum stability decrease compared with the unmodified siRNA. However, incorporation of two or four aminoisonucleosides into the sense strand reduces the duplex thermal and serum stability, which were potentially due to the combined torsion on siRNA backbone and the loose structure on the siRNA duplex.

Many efforts have been made to increase siRNA stability at the cost of a slight reduction of siRNA efficacy. Here, the aminoisonucleoside modification is superior to other chemical modifications, since such modified RNAs are good substrates of RNase H (*20*), and isonucleoside triphosphates can be recognized by many different DNA polymerases (*34*). Furthermore, siRNA sense-strand modification with aminoisonucleoside at the 3′- or 5′-end showed comparable gene-silencing activity and serum stability as their native siRNA. Taken together, aminoisonucleoside-modified oligonucleotide represents a novel direction and is a good mimic of natural oligonucleotide with the required biological and chemical properties.

SUMMARY

Ten modified siRNAs with aminoisonucleoside at various positions were synthesized and their thermal and serum stabilities and gene-silencing activities were studied. The sense-strand modification with aminonucleoside at the 3′- and 5′-end siRNAs showed similar duplex thermal and serum stability as the natural one. The identical gene activities indicated that such a modified siRNA is compatible with the intracellular siRNA machinery. It was also found that antisense strand modification with aminoisonucleoside, despite the reduction of gene-silencing activity, is still somehow tolerated. These findings are worthy of the further study.

Nanoparticles That Display Short Collagen-Related Peptides. Potent Stimulation of Human Platelet Aggregation by Triple Helical Motifs

Mabel A. Cejas, Cailin Chen, William A. Kinney,* and Bruce E. Maryanoff

Vascular Research Team, Johnson & Johnson Pharmaceutical Research and Development, Spring House, Pennsylvania 19477-0776. Received March 23, 2007; Revised Manuscript Received May 23, 2007

Collagen plays a key role in the activation and adhesion of blood platelets via their cell-surface receptors. Normally, collagen-related peptides (CRPs), even one as long as a 30-mer (10 Gly-Pro-Hyp (GPO) repeats), are unable to effectively express collagen's platelet-activating behavior. We attached two short CRPs, AcHN-(Gly-Pro-Hyp)$_n$Gly-OH with $n = 5$ (**1**) and $n = 10$ (**2**), via the C-terminus to amino-functionalized latex nanoparticles to create a multimeric display of triple helical motifs. These nanomaterials were characterized by dynamic light scattering and environmental scanning electron microscopy. The nanoparticles bearing the 31-mer CRP sequence, **2**, but not the 16-mer sequence, **1**, effectively induced the aggregation of human platelets, with a potency level approaching that of native type I collagen. Our results highlight the importance of presenting triple helical CRP motifs of sufficient length on a suitable scaffold in order to stimulate platelets.

Blood platelets are crucial for maintaining normal hemostasis. Through their activation and aggregation, platelets arrest bleeding caused by vascular injury and then encourage wound healing. However, excessive platelet-rich thrombus formation, especially in high-sheer arterial environments, can promote chronic cardiovascular diseases, such as unstable angina, acute myocardial infarction, and stroke (*1*). Collagen plays a pivotal role in initiating platelet activation and adhesion via two main collagen receptors: glycoprotein VI (GPVI) and the integrin $\alpha_2\beta_1$ (*2*−*5*). There are several types of collagen present in the blood vessel wall, with fibrillar type I and type III predominating in the subendothelial matrix. When a vessel's endothelial layer is damaged, such as in atherosclerosis, the underlying collagen fibers are exposed, thereby inducing platelet aggregation and triggering adverse cardiovascular events.

Synthetic triple helical peptides containing the main collagen repeat Gly-Pro-Hyp (GPO) have been used as models to study the structural basis of platelet activation by collagen (*6*−*13*). Rao et al. (*6*) were the first to report the promotion of platelet adhesion and aggregation by synthetic collagen-related peptides (CRPs). By using a branched assembly of three peptide chains containing a $(GPO)_8$ CRP and an α_1(IV)1263−1278 cell adhesion sequence, they demonstrated that a triple helix is required for platelet activation and suggested a role for the extra sequence. However, the potency observed in their study was much less than that of native collagen (by ∼1000-fold). A different approach involving the polymerization of short CRPs by cross-linking to obtain quaternary structures resulted in materials that were highly platelet-aggregatory (*7*), through direct action on GPVI (*8*). Interestingly, monomeric CRPs absorbed onto a glass surface can be as potent as cross-linked CRPs in aggregating platelets (*9*). Relative to structure−function requirements, Asselin et al. (*10*) found that short GPO containing monomeric CRPs are just partial agonists of GPVI, and in a review Nieswandt and Watson (*11*) present evidence that lengthy CRPs in a multimeric format are important for the clustering of GPVI and for robust signaling. The structural hypothesis for the collagen−GPVI interaction is supported by an X-ray investigation on the GPVI dimer (*12*).

Further understanding of the structural requirements for platelet signal transduction through GPVI could emerge from a system in which the CRPs are covalently attached to an inert support in a well-defined (nonrandom) manner. Such a construct would supply information about the importance of multivalency, spatial orientation, and chain length on collagen function. Thus, we sought to immobilize short CRPs of varying lengths onto a stable surface to present multiple peptide helices to platelets in a defined orientation. We now report a study in which we have covalently attached two different short CRPs by the C-terminus to the surface of latex nanoparticles. Some of these nanoparticle constructs, with a multimeric display of triple helical motifs, were able to induce the aggregation of human platelets with a potency level approaching that of native type I collagen.

Latex nanoparticles were chosen as a support because they are available in diameters similar to the diameters of the exposed collagen fibers in a damaged blood vessel (∼50 nm, Figure 1A) (*14*). In addition, they contain various chemical functionalities for attachment of the probe peptide ligands of interest. Nanoparticle scaffolds have been used effectively in drug delivery and diagnostics (*15*), as chemical sensors (*16*), and in presenting biomacromolecules for molecular recognition (*17, 18*). Recently, the preparation of gold CRP-coated nanoparticles and their interaction with collagen fibers has been described (*19*).

Peptides AcHN-(Gly-Pro-Hyp)$_n$Gly-OH, with $n = 5$ (**1**) and $n = 10$ (**2**), were synthesized on solid phase using standard FastMoc chemistry with an ABI 433A synthesizer (*20*). The N-terminus of the peptides was acetylated to avoid polymerization during the reaction with the nanoparticles. These CRPs were purified by HPLC and characterized by MALDI-TOF MS and CD spectroscopy. Their CD spectra showed a positive band at 225 nm, which is characteristic of a collagen triple helix (*21, 22*). The 225 nm band was more intense for 31-mer **2** vs 16-mer **1**, indicating that **2** has a more robust triple helical structure.

Each peptide was conjugated through its carboxyl terminus (via carbodiimide coupling) to 200 nm latex nanoparticles bearing primary amine-terminated, six-carbon spacer units. The degree of functionalization was determined by measuring the

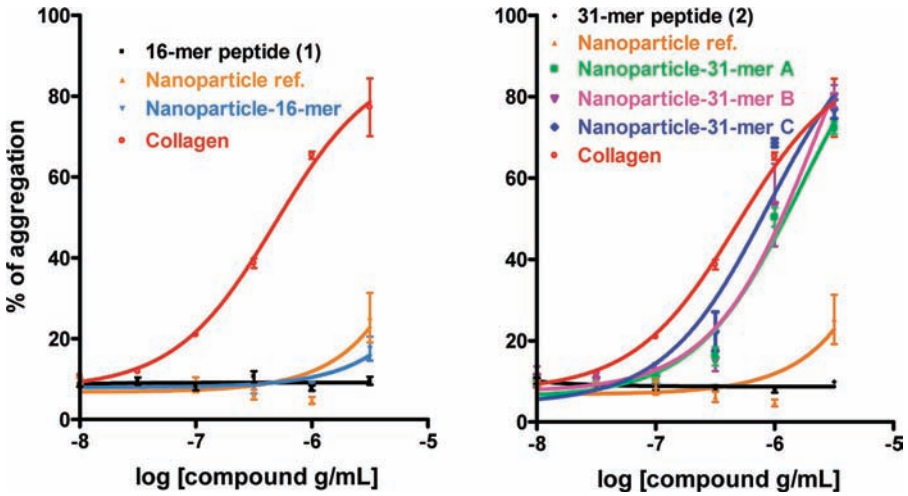

Figure 2. Percentage of platelet response to collagen, peptides, and nanoparticles before and after functionalization with CRPs.

amount of peptide that was cleaved off the nanoparticles following acid hydrolysis.[1] The amino acid analysis indicated that ~10% of the amino groups (molar basis) on the surface of the particles were conjugated to the peptides. The particle size of the resulting material was estimated by dynamic light scattering (DLS).[2] The average diameter of the reference particles suspended in water was determined to be approximately 200 nm, as expected. The values for the functionalized nanoparticles in solution were about 1000 nm, due to conglomeration.

The morphology of the various nanoparticles was visualized by environmental scanning electron microscopy (ESEM, Figure 1). The images illustrate that both functionalized nanoparticles tended to adhere to one another (Figure 1C,D) probably because of peptide−peptide interaction, while the reference nanoparticles remained loose (Figure 1B). The sizes of conglomerates here are larger than those determined by DLS, perhaps because of different experimental conditions. For DLS the nanoparticle clusters were moving freely in solution, whereas for ESEM the material was deposited on a solid support by drying a suspension. The display presented by multiple triple helices attached to the clustered nanoparticles is strikingly similar to the surface created by a severed murine blood vessel (compare part A of Figure 1 with parts C and D of Figure 1).

The effect of collagen nanoparticles on platelet function was evaluated in an in vitro platelet aggregation assay. Washed platelets were prepared from human platelet-rich plasma (from healthy volunteers), and platelet aggregation measurements were performed (*21*).[2] As depicted in Figure 2, free peptides **1** and **2**, unmodified nanoparticles, and nanoparticles functionalized with 16-mer **1** failed to aggregate platelets at concentrations below 1 μg/mL.[3] In sharp contrast, nanoparticles functionalized with 31-mer **2** markedly induced platelet aggregation in a dose-dependent manner (EC_{50} = 0.60 μg/mL). The potency of this material was comparable to that of equine type I collagen (EC_{50} = 0.40 μg/mL).

Experiments with three 31-mer nanoparticle preparations proved to be highly reproducible (experiments A−C). In the

[1] In preliminary experiments, smaller nanoparticles (20 nm) were found to be impractical because they did not centrifuge well and tended to associate.

[2] See Supporting Information.

[3] This concentration is based on peptide content in peptide-containing materials. Unmodified nanoparticles were processed in the same way, and used in the same volume, as the modified nanoparticles.

case of experiment B, the peptide was dissolved in MES buffer and kept at 4 °C for 1 h. The triple helix conformation was verified by CD before conjugation to the particles. For experiments A and C, the peptide was coupled without previous equilibration. The fact that all preparations yielded similar results in the platelet assays indicates the formation of a triple helix structure on the particle surface. Interestingly, while both conjugates form conglomerates of similar size, only the conjugate bearing the 31-mer peptide (**2**) is effective in the platelet aggregation assay, suggesting that functional activity depends on the nature of the peptide triple helix and not just on the multiple display.

Our study demonstrates that a CRP with a 31-mer sequence can mimic the function of collagen when this peptide is displayed in a multivalent fashion by linking its C-terminus to a nanoparticle scaffold. These results support the importance of multiple triple helical motifs for robust stimulation of platelets by CRPs via the GPVI receptor (*7*−*9*). Looking ahead, the covalent attachment of short CRPs to nanoparticles should provide a useful means to acquire new information about the structural requirements of such peptides for collagen-like function in cell biology.

ACKNOWLEDGMENT

We thank Pratik P. Joshi (Center for Advance Microscopy, University of Miami) for ESEM measurements. We also acknowledge the valuable guidance provided by Marian Kruszynski, Tami Raguse, and Albert Schmidt.

ARTICLES

Role of Sulfhydryl Groups in Transfection? A Case Study with Chitosan−NAC Nanoparticles

Brigitta Loretz, Marlene Thaler,† and Andreas Bernkop-Schnürch*

Department of Pharmaceutical Technology, Institute of Pharmacy, and Institute of Zoology, Leopold-Franzens-University Innsbruck, 6020 Innsbruck, Austria. Received October 4, 2006; Revised Manuscript Received February 20, 2007

This study investigated the use of chitosan−*N*-acetylcysteine (NAC) as a non-viral gene carrier. In particular, we aimed to elucidate whether the advantage of thiolation was more pronounced in the stabilization of particles or in the effect of nonspecific sulfhydryl reduction of the target cells. Low-viscosity chitosan was modified by covalent binding of NAC. The resulting conjugate displayed 1.35 mM SH/g polymer. Particles produced via self-assembly of chitosan conjugate and pDNA had a mean particle size of 113.7 nm and a positive ζ-potential. Sulfhydryl group content on the particle surface was investigated by Ellman's test and papain reactivation assay, with the result of about 100 nM SH groups/mL nanoparticle suspension. An oxidation step was performed to stabilize polyplexes via disulfide bonds. The enhanced stability of oxidized particles against both polyanion heparin and alkaline pH was proven by a gel retardation assay. The stabilization was demonstrated to be reversible by treatment with glutathione. Further, the effect of immobilized SH groups and of supplementation with free NAC on transfection efficacy on Caco-2 cells was investigated. The expression of the transgene was raised 2.5-fold and 10-fold with nonoxidized thiomer polyplexes in comparison to polyplexes of unmodified chitosan and oxidized chitosan−NAC, respectively. The impact of sulfhydryl reduction on transfection was assessed via thiol group inactivation with 5,5′-dithiobis-(2-nitrobenzoic acid) (DNTB). This inactivation resulted in a decrease of transfection efficacy. In conclusion, chitosan−NAC conjugate was demonstrated to be beneficial for transfection, either for stabilization via disulfide bonds or for raising the expression of transgene via shifting the redox potential of the target cells.

INTRODUCTION

Results in recent clinical trials have renewed interest in nucleic acid-based therapeutics. The transition of these promising molecules into drugs needs to address the still most urgent problem of efficient delivery (*1*). Development of novel delivery platforms that prevent their degradation and facilitate specific uptake into target tissues is therefore a key issue. Here, in particular, the field of nanotechnology is raising expectations and is a main focus of many recent approaches (*2*−*5*). Currently, there is an enormous interest in non-viral vectors in general and in cationic polymer-based gene delivery systems, so-called polyplexes, in particular (*2*, *6*−*9*). These systems have several advantages, such as ease of production and modification, lack of mutagenesis, and reduced potential of immunogenicity, in comparison to viral vectors.

Recently, thiolated polymers have been reported as a promising tool in gene delivery. Reversible cross-linking via disulfide bonds was proposed as a strategy to keep the polyplex structure stable in the extracytoplasmic environment, while inducing the efficient release of entrapped pDNA from the polyplexes after their arrival in the cytoplasmic compartment (*10*−*14*). This tuneable release should be triggered by the large concentration differential of intracellular glutathione compared to extracellular levels. In the intracellular reductive environment, the disulfide bonds should be cleaved. Few references so far have proposed that the reduced sulfhydryl group itself may enhance the transfection (*15*−*17*).

The present study aims to examine the role and potential of sulfhydryl groups for enhancement of transfection efficiency. The new thiomer chitosan−NAC was chosen because of the comparatively high degree of modification and the low toxicity of the ligand *N*-acetylcysteine. Particular attention was paid to the quantification of thiol groups displayed by the gene carrier system. Effects of cross-linked and non-cross-linked thiolated particles on stability and transfection efficacy were assessed *in vitro*. As a control and to get the first clues about the functional mechanism of thiolation-related improvement of transfection, experiments with thiol-inactivating agent 5,5′-dithiobis-(2-nitrobenzoic acid) (DNTB) were performed.

EXPERIMENTAL PROCEDURES

Polymer Synthesis and Characterization. For the synthesis of chitosan−*N*-acetylcysteine, 0.5 g of low-viscosity chitosan (Fluka, Vienna, Austria, lot number 455080/1) was dissolved in 50 mL 0.1% (v/v) acetic acid. *N*-Acetylcysteine (Fluka, Vienna, Austria) was dissolved in distilled water to obtain a 1 M solution. The pH of both solutions was adjusted to 5.0. The coupling reaction between the amino group of chitosan and the carboxyl group of *N*-acetylcysteine was mediated by 1′-ethyl-3(3-dimethylaminopropyl)carbodiimide-HCl (EDAC). Initially,

Published on Web 06/07/2007

250 mg of EDAC was added to 50 mL of the chitosan solution and stirred shortly before 25 mL of the NAC solution was added. This reaction mix was stirred at room temperature for 2 h. Subsequently, the polymer solution was extensively dialyzed in five steps for 12 h each. The first dialysis was performed against 5 L distilled water containing 0.2 mM HCl, the second against 5 L distilled water, 0.2 mM HCl, and 2 μM EDTA; and finally, three more times against 5 L distilled water containing 0.2 mM HCl. The purified polymer solution was frozen and lyophilized. Freeze-dried polymers were stored at 4 °C.

Determination of the Thiol Group Content. The amount of reduced sulfhydryl groups on modified chitosan was determined using the photometrical Ellman's test as described previously (*18*).

To determinate the total amount of sulfhydryl groups on the polymer, all disulfide bonds were reduced with an excess of sodium borohydride, following Leitner et al. (*19*). The amount of disulfide bonds was calculated by substracting the quantity of free thiol groups from the totality of thiol moieties present on the polymer and dividing the result by two.

Preperation of Nanoparticles. Unmodified chitosan and chitosan−NAC were dissolved in distilled water in final concentrations of 0.02% and 0.1% (w/v), respectively. The pH of both polymer solutions was adjusted to 4.5 with acetic acid, and the solutions were filtered through sterile filters with 0.2 μm pore size. As model plasmid pEGFP-C2 (Clontech, Mountain View, CA) coding for enhanced green fluorescence protein was used. DNA solution was prepared in distilled water with a pDNA content of 100 μg/mL. Polymer solutions and DNA solution were separately heated to 50 °C for 10 min. For formation of chitosan control particles (Cs NP), 400 μL of the 0.02% chitosan solution was added to 250 μL of pDNA solution, followed by immediate vortexing for 30 s. Chitosan−NAC nanoparticles (NAC NP) were produced in the same way with the modification that 250 μL of pDNA solution was diluted with 306 μL of distilled water before 94 μL of 0.1% chitosan−NAC solution was added.

In the case of oxidized nanoparticles (oxid. NP), immediately after preparation 3 and 6 μL of a 3% hydrogen peroxide solution, respectively, were added to the nanoparticle suspensions and mixed briefly.

A higher amount of chitosan−NAC polymer than unmodified chitosan was used in order to obtain particles of comparable size distribution and ζ potential. The calculated ratio of amino groups to phosphate groups was 5:1 for chitosan control particles and 4.7:1 for chitosan−NAC particles.

Characterization of Nanoparticles. *Photon Correlation Spectroscopy.* To determinate the hydrodynamic diameters of the polyplexes, dynamic light scattering measurements were carried out using PSS Nicomp 380 ZLS instrument (Nicomp Particle Sizing Systems, Santa Barbara, CA). At least 6 samples of each nanoparticle suspension were measured for 3 cycles of 5 min. The data obtained at a detection angle of 90° at 23 °C were analyzed by the Gauss volume-weighted method to calculate the mean diameter.

ζ-Potential Measurement. Determination of ζ potential was performed with a 1:5 dilution of nanoparticle suspensions in distilled water to reduce the shielding effect of ions in the suspension. A scattering angle of 14.7° and an electronical field of 5 V/cm were used for analysis.

Transmission Electron Microscopy. Nanoparticle suspensions were analyzed after 2 h of incubation at room temperature. Drops of 10 μL particle solution were placed on pioloform-coated grids and air-dried for 10 min. The redundant fluid was removed while the dried nanoparticles remained on the grids. These grids were dried and examined by a transmission electron microscope (ZEISS LIBRA120) with an in-column energy filter (EFTEM). Digital micrographs were obtained from a ProScan Slow Scan CCD camera system using *iTEM 5.0* Software from Soft Imaging System GmbH.

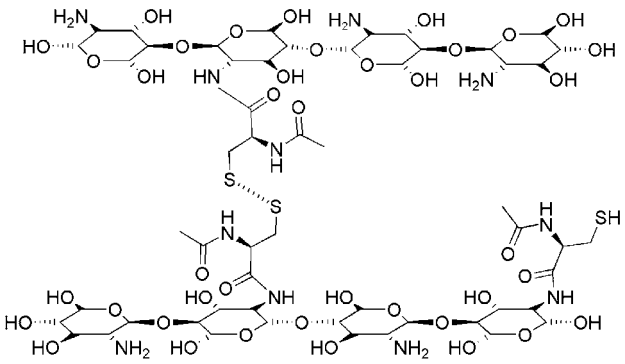

Figure 1. Chemical structure of chitosan−NAC as synthesized within this study. In addition, the possibility of cross-linking via disulfide bonds between two acetyl residues is displayed.

Table 1. Particle Characterization[a]

sample	mean size [nm]	ζ-potential [mV]
Cs NP	107.1 ± 29.2	+9.48 ± 1.2
NAC NP	113.7 ± 32.3	+6.54 ± 0.6
ox. NAC NP	73.0 ± 6.0	+17.01 ± 3.2

[a] Particle size and ζ potential of particles in suspension determined by photon correlation spectroscopy. Unmodified chitosan nanoparticles (Cs NP), chitosan−NAC nanoparticles (NAC NP), and disulfide-cross-linked chitosan−NAC particles (ox. NAC NP) all generated at 4.7:1 N/P ratio. Indicated values are means ± SD of at least six experiments.

Papain Reactivation Assay. Papain (Sigma-Aldrich, Vienna, Austria) was inactivated to papain−S−SCH_3 following the method of Singh (*20*). The papain reactivation assay was performed basically in the same way as described by Singh et al. (*20*) and Wright and Viola (*21*). Degassing of the solutions was not performed. For standards, a dilution series ranging from 0.9375 to 120 nM NAC was used. To aliquotes of 120 μL nanoparticle suspension, 14 μL of 100 mM sodium acetate buffer pH 4.5 were added. All samples were brought to the same volume of 280 μL by the addition of distilled water. An excess of papain (700 μL, 0.6 mg/mL) was added to each sample. The reaction mixtures were kept at room temperature for 1 h. Subsequently, 1 mL of 3.4 mM *N*-benzoyl-L-arginine-*p*-nitroanilide solution was added to all sample tubes. After 1 h further incubation at room temperature, the samples were briefly centrifuged. Finally, the absorbance was measured at 410 nm. The concentration of thiol groups in the test solutions was calculated with the linear function obtained from the calibration curve.

Ellman's Test. Aliquots of 120 μL of nanoparticle suspensions were diluted with 160 μL of 0.5 M PO_4 buffer, pH 8, before adding 280 μL of Ellman's reagent (0.3 mg/mL 5,5′-dithiobis-(2-nitrobenzoic acid) (DNTB)) dissolved in phosphate buffer. Following 2 h incubation at room temperature in the dark, the samples were briefly centrifuged, and the absorbance was measured at 450 nm.

Stability Test. Stability of various nanoparticle suspensions was investigated under challenging conditions such as 80-fold concentration of polyanion heparin (Sigma-Aldrich, Vienna, Austria) or minimum essential medium (MEM), pH 10, including 20% serum. For these assays, 50 μL aliquots of nanoparticle suspensions were mixed with 50 μL of aqueous heparin solution (16 mg/mL) and MEM medium, respectively. After an incubation period of 2 h at 37 °C and 400 rpm in an Eppendorf shaker, electrophoretic mobility assay on 0.7% agarose gel was performed.

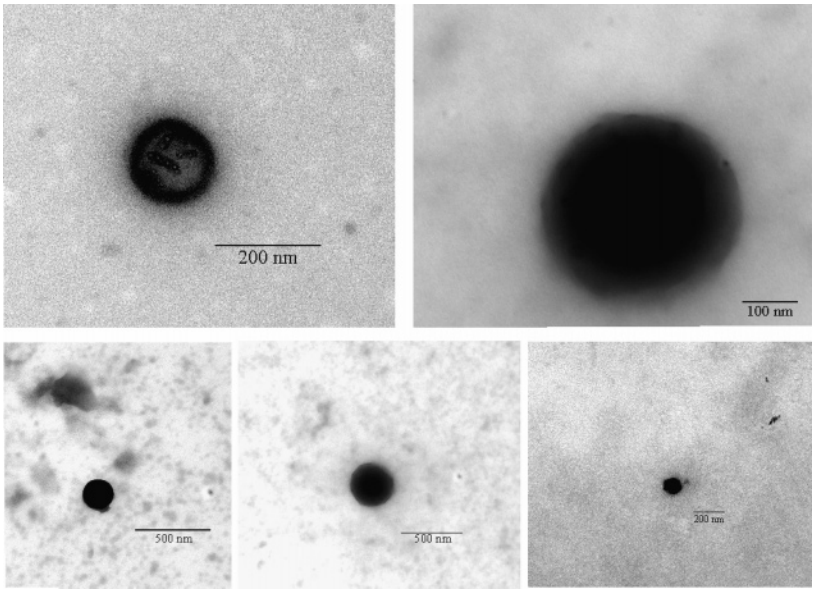

Figure 2. TEM micrograph of nonoxidized chitosan−NAC/pDNA nanoparticles at N/P ratio 4.7:1.

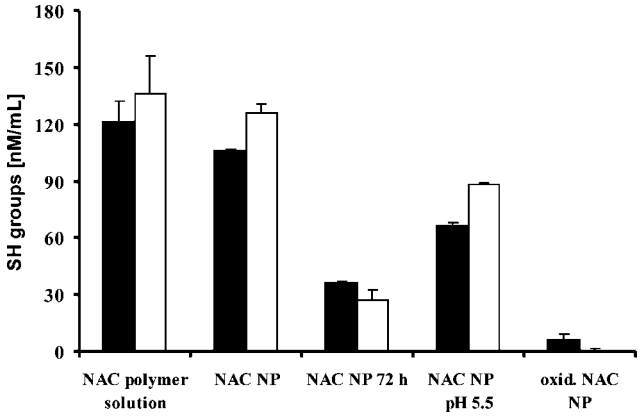

Figure 3. Quantization of thiol groups by two independent spectrophotometric assays. Black bars indicating the results of Ellman's test and open bars of papain reactivation assay. Investigated samples were 0.1% chitosan−NAC polymer solution, suspension of chitosan−NAC/pDNA nanoparticles, nanoparticle suspension after 72 h incubation at room temperature, suspension of chitosan−NAC/pDNA particles produced at pH 5.5, and nanoparticle suspension after oxidation step with 3 μL H_2O_2.

The degree of enzymatic degradation was analyzed by digestion of 50 μL nanoparticle suspension in 1×DNaseI buffer pH 8 (Promega, Madison, WI) with 0.2 units DNaseI (Promega, Madison, WI) at 37 °C for 30 min and subsequent gel electophoresis.

Release of pDNA charge from oxidized particles in a reducing environment like in cytoplasm was assessed in MEM medium containing 0 to 10 mM glutathione.

Cytotoxicity Tests. *LDH.* The Caco-2 human colon carcinoma cells (ATCC Nr. HTB-37) were grown in 12-well plates at an initial seeding density of 1×10^5 cells in 1 mL Eagle minimum essential medium (MEM) supplemented with 2.2 g/L sodium bicarbonate, 2 mM L-glutamine, penicillin/streptomycin, and 20% FCS (Gibco, Nr. 26140−079, Invitrogen, Lofer, Austria). After 24 h incubation, cells were washed once with phosphate buffered saline (PBS) before transfection with 260 μL of nanoparticle suspension per milliliter MEM was performed. MEM medium without serum and without phenol red was used during the cytotoxicity test. As a low control, cells were incubated with medium only. The high control was prepared with medium plus 2% Trition-X100. Samples of 100 μL supernatants were taken after 14 h of incubation and analyzed according to the manufactures protocol from Cytotoxicity Detection Kit (LDH) from Roche (Vienna, Austria). Cytotoxicity was calculated with the equation

$$\text{cytotoxicity [\%]} = (\text{experimental value} - \text{low control})/(\text{high control} - \text{low control}) \times 100$$

MTT. Caco-2 cells were plated into 12-well plates at a density of 5×10^4 cells/mL. After 24 h preincubation, culture medium was replaced by culture medium plus 260 μL nanoparticle suspension/well. Cells were incubated for 14 h before the medium with test solution was aspirated. Cells were washed once with PBS to remove traces of the particle solution. Subsequently, 1 mL MEM without phenol red, containing 0.5 mg/mL (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide) (MTT), was added to each well. After 3 h of further incubation, the medium with unreacted dye was aspirated. The converted dye was solubilized with 1 mL acidic isopropanol (0.04 M HCl in absolute isopropanol) by pipetting several times. The dye solution was transferred into tubes and centrifuged 2 min at 15.000 *g* prior to measurement of OD 570 nm with background subtraction of OD 650 nm. The relative cell viability [%] related to control wells was calculated according to the equation

$$\text{viability [\%]} = (\text{test Abs 570 nm} - \text{Abs 650 nm})/(\text{control Abs 570 nm} - \text{Abs 650 nm}) \times 100$$

Transfection. 1×10^5 Caco-2 cells in 1 mL MEM medium were seeded into 12-well plates and incubated for 24 h. Medium was aspirated, and cells were washed once with PBS. First, 260 μL nanoparticle suspension, containing 10 μg of pDNA, was added to the cells and overlaid with 740 μL medium including 20% serum. Cells were incubated with the nanoparticles for 14 h. After this transfection step, cells were washed once with PBS, fed with 1 mL fresh medium, and incubated for another 48 h. Fluorescent cells were monitored with a fluorescent microscope using UV light and the appropriate filter for green fluorescence. Cells were washed once with PBS. Thereafter, 100 μL lysis buffer (0.25 M Tris, pH 7.4, 0.25% (v/v) Trition X-100 and 2.5 mM EDTA) were added and the plate shaken at room temperature for 5 min. To enhance cell lysis, a freeze−thaw

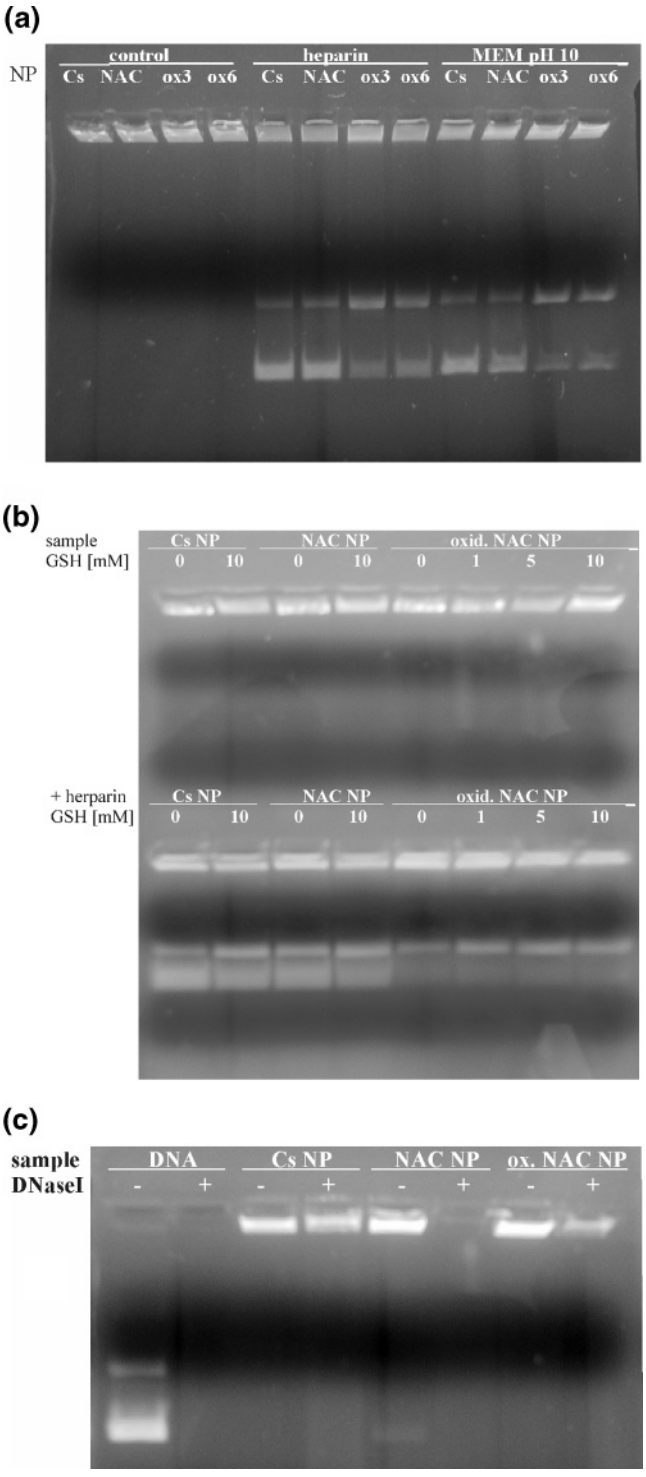

Figure 4. (a) Gel retardation assay for particles of unmodified chitosan (Cs), chitosan−NAC nanoparticles, (NAC) and oxidized Cs-NAC nanoparticles treated with 3 and 6 μL H_2O_2, respectively (ox3 and ox6) (lanes 1−4), and release of pDNA after challenge with 80-fold excess of heparin (lanes 5−8) and at pH 10 (lanes 9−12). (b) Release of pDNA from non-thiolated chitosan particles (Cs NP), thiolated nonoxidized particles (NAC NP), and oxidized chitosan−NAC particles (oxid. NP) achieved by treatment with 10 mM glutathione. (c) Agarose-gel electrophoresis after 30 min DNaseI (0.2 unit) digestion of chitosan control particles (Cs NP), nonoxidized (NAC NP) and oxidized Cs-NAC particles (oxid.NP).

cycle was performed. Cell lysate was transferred into tubes and cell debris was separated by centrifugation. For fluorescence measurement, 50 μL of cellular extract were transferred into a microtiter plate, and the fluorescence was measured at 485/520 nm excitation/emission. Fluorescence of untransfected cells was substracted as background.

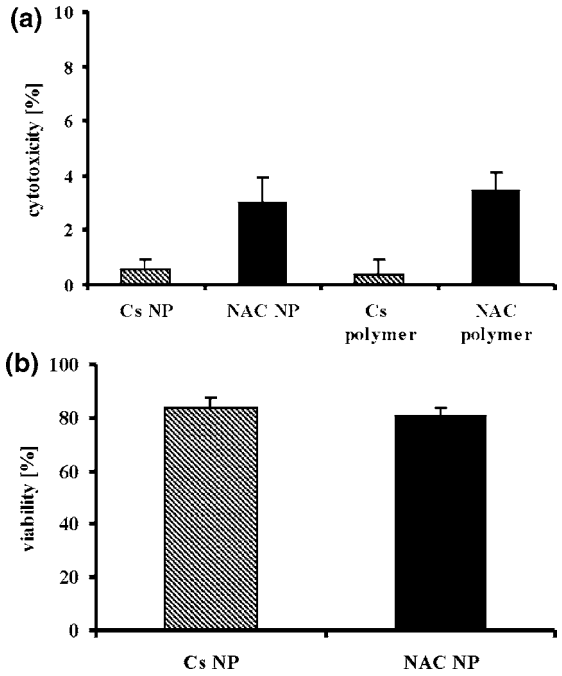

Figure 5. Toxicity of nanoparticle suspensions and viability of Caco-2 cells after challenge, respectively, were determined by (a) lactate dehydrogenase assay and (b) MTT assay. For both cytotoxicity tests, 14 h incubation was performed. Samples: 260 μL chitosan/pDNA nanoparticle suspension (Cs NP), 260 μL chitosan−NAC/pDNA nanoparticle suspension (NAC NP) 38 μL chitosan solution 0.1% 38 μL chitosan−NAC solution 0.1%.

Effect of Thiol Group Modification by DNTB. The dithiol-oxidizing agent 5,5′-dithiobis-(2-nitrobenzoic acid) (DNTB) was used to inactivate sulfhydryl groups on both cell surface and nanoparticles, to study the impact of active sulfhydryl group on the expression of transgene. A solution of 10 mM DNTB in 0.5 M phosphate buffer pH 8 was freshly prepared before every experiment. Caco-2 cells were treated with 200 μM DNTB in cell culture medium for 5 min followed by washing with PBS immediately before transfection. In a second experiment, DNTB solution was added to the nanoparticle suspension to reach a final concentration of 100 μM DNTB and preincubated for 30 min. The transfection was performed as described in the previous section.

Statistical Data Analysis. Results were depicted as mean value ± SD from at least three experiments. Significance among the mean values was calculated using Student's *t* test (software package *SPSS 11.0*). Probability value $p < 0.05$ was considered significant.

RESULTS

***N*-Acetylcysteine-Modified Chitosan.** Chitosan−NAC conjugates, as shown in Figure 1, were synthesized by covalent attachment of *N*-acetylcysteine to the amino group of the chitosan backbone. The colorimetric quantification of free sulfhydryl groups on the conjugate by Ellman's test displayed a thiol content of 1.356 mM/g polymer. Investigation of the amount of disulfide bonds present in the conjugate without any oxidation process performed revealed 0.484 mM disulfide bonds per gram polymer.

The lyophilized chitosan−NAC conjugate had the appearance of a white, odorless, fibrously structured substance. The conjugate was easily dissolved in 0.1% acetic acid. In aqueous solution of pH 4.5 and stored at 4 °C, it was stable for up to 1 month without detectable loss in transfection efficiency.

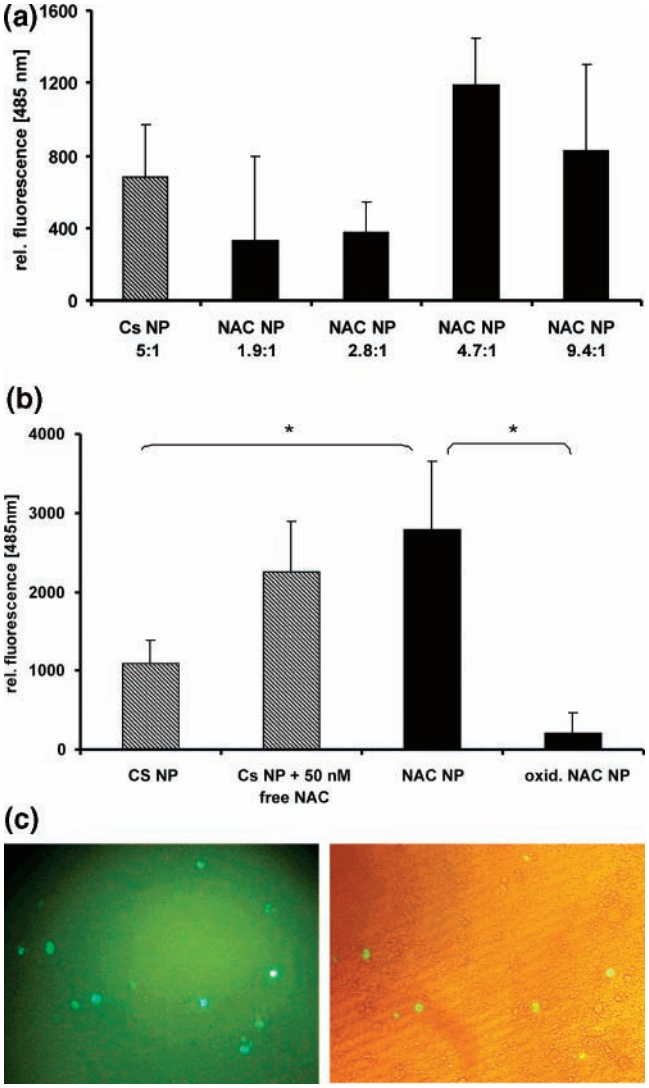

Figure 6. (a) Impact of N/P ratio on the transfection efficancy. Transfection of sub-confluent Caco-2 cells was performed for 14 h with nanoparticle suspension containing 10 μg pDNA each. (b) Gene expression of pEGFP after transfection of Caco-2 cells with suspension of chitosan nanoparticles (Cs NP), chitosan nanoparticle suspension supplemented with 50 mM NAC solution, nonoxidized (NAC NP) and oxidized chitosan−NAC nanoparticle (oxid. NAC NP) suspension. Dose of pDNA was 10 μg/well in all cases. *Significance level of $p < 0.05$. (c) Qualitative analysis of green fluorescence protein expression. Fluorescence microscopy image of chitosan−NAC transfected Caco-2 cells without and with overlaid light microscopy image.

Chitosan−*N*-Acetylcysteine Nanoparticles. Particles produced at N/P ratio 5:1 for chitosan and 4.7:1 for chitosan−NAC, respectively, were characterized. The measured mean size of 113.7 nm (±32.3 nm) for chitosan−NAC nanoparticles was in a comparable range to that of the control particles of unmodified chitosan at 107.1 nm (±29.2 nm). Disulfide bond stabilization caused a decrease in size down to 73.0 nm (±6.0 nm). Chitosan−NAC particles as well as chitosan control particles displayed positive ζ potentials of +6.54 mV and +9.48 mV, respectively (Table 1). The moderate decline in ζ potential was based in the slightly lower N/P ratio.

Transmission electron microscopy images, shown in Figure 2, supported the nanoscale size of the particles. Sedimentation and subsequent removal of the solution favored the small fraction of bigger particles in the suspension. This effect might also explain the bigger size of particles in TEM micrographs compared to the measured mean size with photon correlation spectroscopy. Particles displayed spherical shape and high density, indicating tight packing of polymer and nucleic acid chains.

Evaluation of the thiol group content was done with two methods, papain reactivation assay and Ellman's test, respectively. The results, as presented in Figure 3, obtained with both tests are in good accordance. The advantage of papain activation assay and possibly the reason for higher values determined with this assay was the incubation at pH 7.5 instead of pH 8 in Ellman's buffer. Moreover, the papain assay should measure just the thiol groups displayed on the particle surface, as the size of the enzyme does not allow its penetration into inner parts of the particles. Freshly prepared non-oxidized chitosan−NAC nanoparticle suspension displayed about 100−120 nM/mL SH groups. During 3 days storage at room temperature, the suspension lost about two-thirds of its functional SH groups. Preparation with polymer solution above pH 5 resulted in a loss of SH groups in the nanoparticle suspension. The comparatively milder oxidation processes was sufficient to oxidize almost all sulfhydryl groups present on the polymer.

Reversible Stabilization via Disulfide Bonds. To investigate the enhanced stability of oxidized chitosan−NAC/DNA particles, an excess of the polyanion heparin and pH 10 was used. In these extreme environments, the stabilizing effect of disulfide bonds was clearly demonstrated (Figure 4a). Further, the triggered release of payload in the reducing milieu of 10 mM glutathione was shown in the gel retardation assay illustrated in Figure 4b. The agarose gel shown in Figure 4c demonstrated the stabilization against nuclease challenge. Oxidized chitosan−NAC particles were more stable in comparison to nonoxidized chitosan−NAC particles, but not more stable than control particles of unmodified chitosan.

Moderate Toxicity of Chitosan−NAC Nanoparticles. Since chitosan−NAC is a new polymer, we were also interested in the possible toxic effects of this polymer and the resulting chitosan−NAC/pDNA nanoparticles.

The level of plasma membrane damage was investigated with lactate dehydrogenase assay (Figure 5a). In addition, the viability of Caco-2 cells after overnight exposure at the same concentrations and conditions as in transfection was assessed with MTT assay (Figure 5b).

Both toxicity tests revealed moderate toxicity. The membrane damage was higher with chitosan−NAC compared to unmodified chitosan, although overall in the moderate range of less than 4% cytotoxicity. The increase in acetylation by attaching *N*-acetylcysteine should not have caused the higher damage, since other research groups reported a higher toxicity of chitosan with a high degree of deacetylation (*22*, *23*). The difference in cell viability between exposure to chitosan nanoparticles and to chitosan−NAC nanoparticles assessed with MTT assay was less pronounced.

Transfection Enhancement with Chitosan−NAC Nanoparticles. To maximize transfection efficiency, the optimum ratio of polymer/pDNA was determined. At N/P ratio of 4.7:1, chitosan−NAC particles resulted in the highest expression of transgene as demonstrated in Figure 6a. Particles suitable for transfection were prepared at ratios from 1.9:1 to 9.4:1, indicating the broad range of loading capacity.

Figure 6b illustrates the effect of chitosan−NAC for transfection. These thiomer particles enhanced transfection 2.5-fold in comparison to unmodified chitosan. The dilution of nanoparticle suspension in cell culture medium reached a final concentration of 31 nmol SH /mL. The addition of 50 nmol/mL free *N*-acetylcysteine to control chitosan nanoparticles also led to an increase in transgene expression, but not to the same extent as immobilized NAC. Oxidized chitosan−NAC nano-

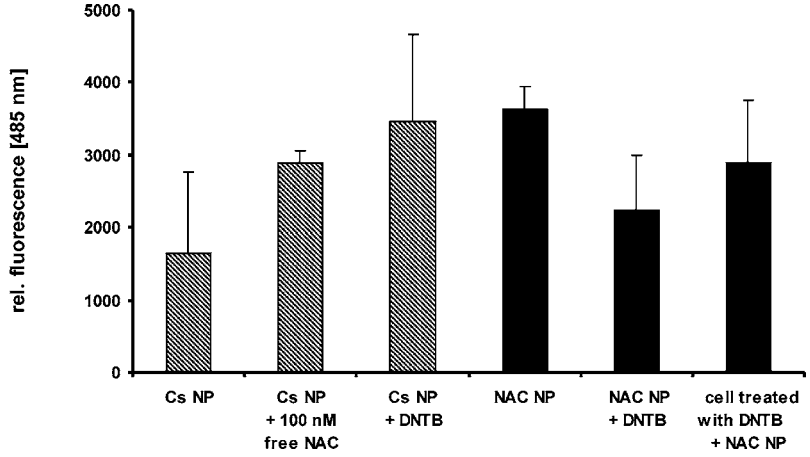

Figure 7. Partial reversibility of transfection enhancement by inhibition of thiol groups with DNTB. Nanoparticle suspension was supplemented with DNTB solution to achieve a final concentration of 100 μM and preincubated 30 min prior to transfection. Cells were pretreated with 200 μM DNTB for 5 min prior to transfection. Hatched bars indicate suspension of unmodified chitosan nanoparticles and black bars chitosan−NAC nanoparticles.

particles were apparently overstabilized for *in vitro* transfection. Their efficiency was decreased below the efficiency of control particles.

As a qualitative control of transfection, UV microscopy images overlaid with light microscopy images are displayed in Figure 6c.

Reversal of the Transfection Enhancement by DNTB Treatment. If SH groups acted as functional groups to enhance transgene expression, the inactivation of these SH via the quantitative formation of S−S bonds performed with DNTB should inhibit the enhancement. Results of sulfhydryl group inactivation are shown in Figure 7. Because DNTB is a cell-impermeable agent, treatment of Caco-2 cells inactivated just the accessible SH groups of proteins on the outside of the plasma membranes. This inhibition caused a decrease in transfection efficiency. The decrease was more pronounced when the SH groups on the nanoparticles were inactivated. Addition of DNTB to control chitosan nanoparticles caused an increase in transfection. Since unmodified chitosan did not carry any sulfhydryl groups to which DNTB could bind, the reagent remained in an active form in solution and resulted in a comparable effect to free NAC.

DISCUSSION

Chitosan−*N*-acetylcysteine represents an interesting new thiomer, as it exhibits a comparatively high amount of immobilized thiol groups and low toxicity. The relative reactivities of thiols with oxidants were demonstrated to be inversely related to the pK of the thiol group (*24*). The thiol group of *N*-acetylcysteine has a pK_a of 9.5 and is therefore a compromise between highly reactive thiols like glutathione (pK_a = 8.8) and cysteine (9.2) and more stable thiols like thioglycolic acid (pK_a = 10.4). This should facilitate the production by preventing excessive loss of SH at alkaline conditions and further grant a moderate but effective action in physiologic pH range.

The formulation process of nanoparticles demonstrated in this study is simple and feasible for a broad range of polymer/DNA ratios. The obtained nanoparticles were of a size which facilitates endocytosis (*25*). Polyplexes have been demonstrated to be taken up by two mechanisms, clathrin-coated pits and caveolae-mediated endocytosis, depending on particle size (*26*). Particles <200 nm in diameter were rapidly internalized via clathrin-coated pits, while particles between 200 and 500 nm in diameter were more slowly internalized via caveolae-mediated uptake (*26*). According to these results, the vast majority of chitosan−NAC/DNA nanoparticles should have been taken up by the clathrin-mediated process. The size of all used nanoparticles was in the same range and seems therefore not to be responsible for differences in the obtained transfection efficacy.

The particles employed in this study had no specific targeting ligand. A positive ζ potential of particles was therefore desired. Particle immobilization on the cell surface resulted in nonspecific ionic interaction between the positive charge of the particles and the negative charge of the cell surface, such as, for example, heparin sulfate proteoglycans that may act as nonspecific receptors for cationic charged molecules.

Results of papain and Ellman's test indicated that almost all thiol groups present on the polymer were displayed on the particle surface. A likely explanation for this result was the excess of polymer in solution. Unfortunately, particles and polymer could not be separated by centrifugation to avoid this distorting effect. However, it made sense to determine the amount of sulfhydryl groups in particle suspension, like it was applied in transfection.

In recent years, it has been well-established that chitosan/DNA particles provide good stability (*27*−*29*). Nevertheless, *in vivo* results are still rare and rather moderate (*30*, *31*), In particular, for challenging routes of application like the oral route, the stability still may be not adequate. Beyond this, to be useful, *in vivo* extracellular stability needs to be changed to lability once the nanoparticles have entered the cytoplasm. The intracellular reducing environment was reported to be in the range 1−10 mM glutathione, depending on the cell type (*11*). An amount of 10 mM glutathione was shown to be sufficient to reduce disulfide cross-linking to thiol groups within this study. However, troubles encountered with these oxidized nanoparticles in Caco-2 cell transfection demonstrated that Caco-2 cells did not exhibit enough intracellular reducing properties for a rapid onset of transcription. The combination of two stabilizing mechanisms, strong electrostatic interaction between negatively charged DNA and positively charged polymer, and, additionally, disulfide bond cross-linking caused overstabilization. The effect of overstabilization was also reported by Miyata et al. for block catiomer polyplexes stabilized via disulfide bonds (*11*). This research group suggested the use of a modification where a disulfide bond replaces amino groups. Although coupling of NAC to chitosan effected such a replacement, the degree of modification was probably not sufficient to prevent overstabilization in a cell culture experiment. Nevertheless, in some cell types of high intracellular glutathione levels, stabilized particles

may be favorable. Moreover, *in vivo* results of stabilized particles may be different from the controlled environment of cell culture model.

Transfection efficacy was also raised by addition of unbound *N*-acetylcysteine. The difference was not highly significant in the cell culture. *In vivo*, the immobilization via covalent attachment of the thiol groups on the particles will prevent dilution. Thus, the advantage of covalently attached thiol groups against supplementation of free SH groups should be more pronounced *in vivo*.

What are the mechanisms by which thiol groups act on transfection efficacy? A first attempt to answer this question was made by the inhibition with DNTB. Sulfhydryl groups may act as an anchor to tightly bind particles to the cell surface via S−S bonds to SH groups of plasma membrane proteins. However, the effect of blocking SH on the cell membrane was not the same effect as the blocking on the particles. Moreover, the addition of free, not attached to the particle, *N*-acetylcysteine also had a positive effect. Therefore, disulfide bonds to cell surface proteins may be one, but presumably not the only, mode of action of thiol groups.

There is evidence that reduced thiol groups may also have an important role in transport processes and/or translational processes. For example, the human cytomegalovirus infectivity could be blocked by DNTB (*32*). Treatment of normal primary keratinocytes with NAC was shown to result in a 10-fold greater rapid differentiation (*33*). The nonspecific sulfhydryl reduction by supplementation of 0.1−10 mM NAC led to terminal differentiation of normal and cancer cells (*34*). Transgene protein expression could possibly take advantage of the differentiation process. Further, the antioxidant *N*-acetylcysteine, a membrane-permeable aminothiol, is able to reduce oxidized glutathione and to act as a precursor for cellular cysteine and glutathione. A great deal of further experiments will be needed to resolve the mechanism and to check whether the results obtained here are conferrable to other cell lines and tissues.

CONCLUSION

Our data indicate a different potential role of thiol groups in the efforts to raise transfection efficacy of non-viral vectors. For cell culture applications, the reduced sulfhydryl groups enhanced transfection efficacy and were of more benefit than stabilization. In contrary, for challenging *in vivo* applications, like oral gene delivery, the stabilization may be of higher impact.

Moreover, we conclude that the chitosan−NAC conjugate may be an interesting vector for gene delivery, offering opportunities to perform both sulfhydryl reduction and stabilization via disulfide bonds.

Design and Synthesis of Efficient Fluorescent Dyes for Incorporation into DNA Backbone and Biomolecule Detection

Wei Wang[†] and Alexander D. Q. Li*

Department of Chemistry and Center for Materials Research, Washington State University, Pullman, Washington 99164. Received June 1, 2006; Revised Manuscript Received January 11, 2007

We report here the design and synthesis of a series of π-conjugated fluorescent dyes with D-A-D (D, donor; A, acceptor), D-π-D, A-π-A, and D-π-A for applications as the signaling motif in biological−synthetic hybrid foldamers for DNA detection. The Horner−Wadsworth−Emmons (HWE) reaction and Knoevenagel condensation were demonstrated as the optimum ways for construction of long π-conjugated systems. Such rodlike chromophores have distinct advantages, as their fluorescence properties are not quenched by the presence of DNA. To be incorporated into the backbone of DNA, the chromophores need to be reasonably soluble in organic solvent for solid-phase synthesis, and therefore a strategy of using flexible tetraethylene glycol (TEG) linkers at either end of these rodlike dyes was developed. The presence of TEG facilitates the protection of the chain-growing hydroxyl group with DMTrCl (dimethoxytrityl chloride) as well as the activation of the coupling step with phosphoramidite chemistry on an automated DNA synthesizer. To form fluorescence resonance energy transfer (FRET) pairs, six synthetic chromophores with blue to red fluorescence have been developed, and those with orthogonal fluorescent emission were chosen for incorporation into DNA−chromophore hybrid foldamers.

INTRODUCTION

Syntheses of deoxyribonucleic acid (DNA) and dye conjugates (*1*−*3*) have enabled many optical probes; these conjugate probes provide a means to study biomolecules within living cells in detail via fluorescence imaging (*4*, *5*) and single-molecule fluorescence spectroscopy (*6*−*8*). However, introducing multiple fluorescent dyes ($N > 2$) into the backbone of a single DNA chain remains largely an unsolved challenge for organic chemistry. To study complex biochemical assemblies and reactions, it is necessary in some systems to have multiple fluorescence probes on a single DNA chain. One such interesting architectural motif in supramolecular chemistry is to use the self-assembling amphiphilic properties of the dyes to induce folded nanostructures with alternating single-strand DNA looping around the folded cores (*9*). Using this principle, hybrid biological and synthetic foldamers have been readily developed for DNA detection (*10*). The strategy is that organic fluorescence chromophores function as an optical reporter while the biological domain, in this case, a specific DNA sequence, functions as a high-fidelity molecular recognition element. The rationale here is that, when the built-in DNA sequences in the hybrid foldamer complement the target DNA in a completely or partially matched situation, the folded nanostructure of the foldamer will be converted to an extended one, a process in which the fluorescence color of the foldamer will change dramatically because of FRET between two adjacent chromophores (*11*). Different mismatched DNA sequences lead to various degrees of emission color changes due to different levels of FRET between the organic chromophores at a given time. From the structural skeleton point of view, molecular beacons usually have organic dyes at both ends of a single DNA sequence, and therefore their termini are a dead-end for incorporation into long DNA sequences (*12*−*16*); the hybrid foldamers have the organic dyes inserted between multiple DNA sequences, which allow further biological manipulation such that the DNA ends can be cut by endonucleases and incorporated into genes with a DNA polymerase or ligase. These special structural features make the hybrid foldamers unique and suitable candidates for studying biological mechanisms.

Since the foldamer probe with alternating hydrophobic and hydrophilic structures is constructed via solid-phase synthesis using an automated DNA synthesizer (Applied Biosystem 8909) (*9*), it is imperative to develop fluorescent building blocks with an activated linker which can be attached to the growing end of the DNA chain and a temporary blocking group to prevent undesired coupling reactions and permit further chain extension after deprotection. The resulting hybrid foldamers have multiple fluorescent chromophores, and the emission color is controlled by the distance between the chromophores separated by the DNA sequences (Figure 1). For completely mismatched sequences, no hybridization occurs between the foldamer and the mismatched target; therefore, the flexible single-stranded DNA chains allow individual chromophores to come in close proximity due to the hydrophobic and π-stacking effect, and the net result is that fluorescence emission is in the long-wavelength region because of the high degree of FRET between individual organic dyes. For perfect matched sequences, however, hybridization turns flexible single-stranded DNA into rigid double helixes, which in turn separates chromophores and reduces the level of FRET between the organic dyes. In this case, the emission color from the foldamer will depend on the short-wavelength chromophore. Therefore, we have designed and synthesized a series of fluorescent chromophores with emission wavelength ranging from blue to red; all fluorescent compounds bear tetraethylene glycol side chains with −OH termini, which are amenable to DMTr protection and phosphoramidite chemistry.

As a class of bis(styryl)benzene derivatives, the donor-π-donor (D-π-D), acceptor-π-acceptor (A-π-A), donor-acceptor-donor (D-A-D), and acceptor-donor-acceptor (A-D-A) structural motifs have received a great deal of attention, because they exhibit exceptionally large two-photon absorption cross sections,

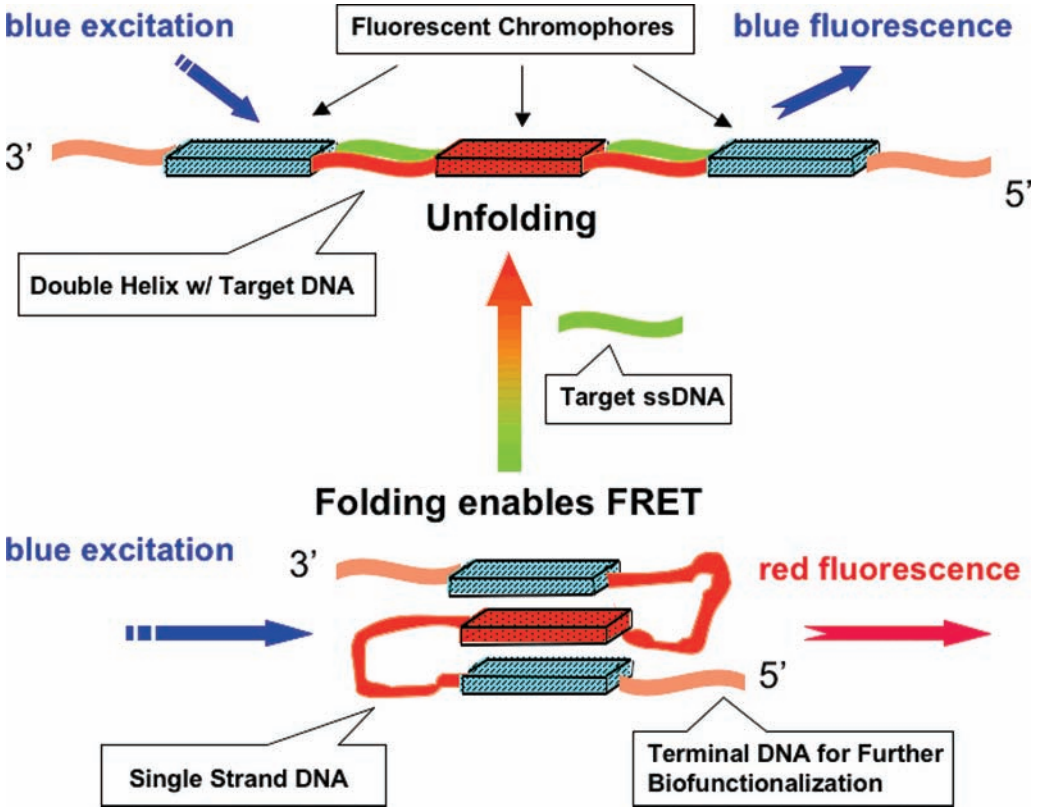

Figure 1. Incorporation of highly fluorescent chromophores into DNA main chains enables many biotechnologies, including DNA monitoring and detection.

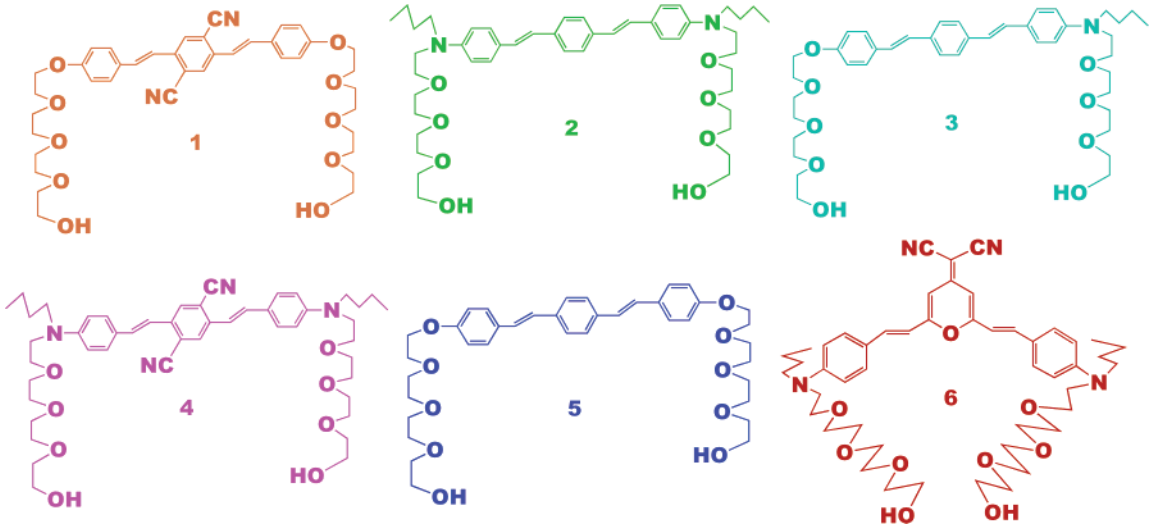

Figure 2. Chemical structures of highly fluorescent dye molecules that are amenable to the general strategy developed here: one hydroxyl group is protected with a dimethoxy trityl (DMTr) group and the other hydroxy group is activated with phosphoramidite.

up to ~400 times that of trans-stilbene (*17*). Compared to our prior perylene tetracarboxylic diimide unit, these new chromophores have desired features such as higher fluorescence quantum yield when incorporated into DNA, and adjustable excitation and emission wavelength via structural variations on similar molecular architectures. Meanwhile, a red fluorescence dye based on the symmetric structure of (2,6-dimethyl-4*H*-pyran-4-ylidene)malononitrile (DCM laser dye) has been developed according to a recent report (*18*); the large dipole moment and high decomposition temperature of this Y-shaped structure make it an attractive candidate for red fluorescence signaling reporter. Consequently, we have developed a series of organic chromophores with different fluorescent colors as molecular building blocks (Figure 2), which are suitable for construction of new hybrid foldamers as molecular probes (*10*).

EXPERIMENTAL SECTION

General Methods. Solvents and reagents were purified where necessary using literature methods (*31*). In particular, *N*,*N*-dimethylformamide (DMF) was distilled from 4 Å MS (molecular sieve) under reduced pressure and stored under argon. Acetonitrile (MeCN) was heated under reflux over calcium hydride and distilled under argon. MALDI mass spectra was obtained with an ABVS-2025 spectrometer. ^{1}H NMR spectra were recorded with a Mercury 300 (300 MHz) spectrometer for solutions in $CDCl_3$ (CD_3OD) at ambient temperature. ^{13}C NMR spectra were recorded at 75.48 MHz with a Mercury 300

spectrometer for solutions in $CDCl_3$ (CD_3OD) adopting 77.23 ppm for the central line of $CDCl_3$. ^{31}P NMR chemical shifts were reported in ppm using 85% H_3PO_4 as an external reference. Reactions were monitored by thin-layer chromatography (TLC) on a precoated plate of silica gel 60 F_{254} (EM Science). Column chromatography was performed on silica gel 60 (230−400 mesh, EM Science).

Compounds in Tetraethylene Chain Optimization and Modification. *4-(2-(2-(2-Hydroxyethoxy)ethoxy)ethoxy)benzaldehyde (**7**).* A mixture of 2-(2-(2-Chloroethoxy)ethoxy)-ethanol (commercial) (1.0 g, 5.9 mmol), 4-hydroxybenzaldehyde (0.8 g, 6.5 mmol, 1.1 equiv), and K_2CO_3 (1.8 g, 2.2 equiv) in dry *N,N*-dimethylformamide (DMF) (10 mL) was heated to 120 °C (oil bath 110 °C) under argon. After the stirring was continued at this temperature for 16 h, the reaction mixture was cooled to room temperature. The solvent (DMF) was evaporated in vacuum, and the residue was diluted with $CHCl_3$. The obtained suspension was suction-filtered and the filtrate was collected. After drying over Na_2SO_4, the organic phase was concentrated, and the residue was purified by chromatography on a silica gel column eluted with EtOAc/MeOH (20:1) to give the title product (950 mg, yield, 63%) as a yellow oil. R_f = 0.33 (EtOAc/MeOH 20/1). ^1H NMR ($CDCl_3$) δ (ppm): 9.89 (s, 1H, -C*H*O), 7.82 (dt, 2H, J_1 = 9.0 Hz, J_2 = 2.7 Hz, benzaldehyde), 7.02 (dt, 2H, J_1 = 9.0 Hz, J_2 = 2.7 Hz, benzaldehyde), 4.21 (t, 2H, J = 4.8 Hz, triethylene glycol chain), 3.89 (t, 2H, J = 4.8 Hz, triethylene glycol chain), 3.75−3.67 (m, 6H, triethylene glycol chain), 3.61 (bt, 2H, J = 4.8 Hz, triethylene glycol chain), 2.40 (bt, 1H, J = 6.0 Hz, -O*H*).

*4-(2-(2-(2-Trityloxyethoxy)ethoxy)ethoxy)benzaldehyde (**8**).* A mixture of **7** (0.5 g, 2.0 mmol), trityl chloride (1.2 g, 4.3 mmol, 2.2 equiv), and a catalytic amount of 4-(dimethylamino)pyridine (DMAP) in dry pyridine (5 mL) was heated to 40−50 °C under argon. After the stirring was continued at this temperature for 24 h, the reaction mixture was cooled to room temperature. The solvent was removed in vacuum, and the residue was diluted with EtOAc. The obtained suspension was suction-filtered and the filtrate was collected. After drying over Na_2SO_4, the organic phase was concentrated, and the residue was purified by chromatography on a silica gel column eluted with cyclohexane/EtOAc/pyridine (300/100/4, v/v) to give the title product (770 mg, yield 99%). R_f = 0.31 (300/100/4, v/v). ^1H NMR ($CDCl_3$) δ (ppm): 9.87 (s, 1H, -C*H*O), 7.80 (dt, 2H, J_1 = 8.7 Hz, J_2 = 2.1 Hz, benzaldehyde), 7.48−7.43 (m, 6H, benzene ring of trityl group), 7.46−7.18 (m, 9H, benzene ring of trityl group), 6.98 (dt, 2H, J_1 = 8.7 Hz, J_2 = 2.1 Hz, benzaldehyde), 4.20 (bt, 2H, J = 4.8 Hz, triethylene glycol chain), 3.92 (bt, 2H, J = 4.8 Hz, triethylene glycol chain), 3.78−3.67 (m, 6H, triethylene glycol chain), 3.24 (t, 2H, J = 4.8 Hz, triethylene glycol chain).

*4-[2-[2-[2-(2-hydroxyethoxy)ethoxy]ethoxy]ethoxy]-benzaldehyde (**10**).* A mixture of 2-(2-(2-(2-chloroethoxy)-ethoxy)ethoxy)ethanol (**9**) (*19*) (2.0 g, 9.4 mmol), 4-hydroxy-benzaldehyde (1.4 g, 1.2 equiv), and K_2CO_3 (2.5 g, 2 equiv) in dry *N,N*-dimethylformamide (DMF) (10 mL) was heated to 100 °C (oil bath 110 °C) under argon. The stirring was continued at this temperature for 72 h. After the reaction mixture was cooled to room temperature, the solvent (DMF) was evaporated in vacuum and the residue was diluted with $CHCl_3$. The obtained suspension was suction-filtered and the filtrate was collected. After drying over Na_2SO_4, the organic phase was concentrated, and the residue was purified by chromatography on a silica gel column eluted with EtOAc/MeOH (20:1) to give the title product (2.25 g, yield 80%) as a yellow oil. R_f = 0.3 (EtOAc/MeOH 20/1). ^1H NMR ($CDCl_3$) δ (ppm): 9.87 (s, 1H, -CHO), 7.82 (dt, 2H, J_1 = 9.0 Hz, J_2 = 2.7 Hz, benzaldehyde), 7.01 (dt, 2H, J_1 = 9.0 Hz, J_2 = 2.7 Hz, benzaldehyde), 4.22 (bt, 2H, J = 4.8 Hz, tetraethylene glycol chain), 3.89 (bt, 2H, J = 4.8 Hz, tetraethylene glycol chain), 3.77−3.59 (m, 12H, tetraethylene glycol chain), 2.53 (t, 1H, J = 6.0 Hz, -O*H*). ^{13}C NMR ($CDC1_3$) δ (ppm): 190.9, 163.9, 132.1, 130.1, 115.0, 72.65, 71.07, 70.86, 70.78, 70.53, 69.68, 67.92, 61.95. MS (MALDI-TOF): 299.01 $[M + H]^+$, 320.99 $[M + Na]^+$.

*4-(2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)ethoxy)-ethoxy)ethoxy)ethoxy)benzaldehyde (**11**).* A mixture of **10** (0.5 g, 1.7 mmol), DMTrCl (1.2 g, 3.5 mmol, 2 equiv), and a catalytic amount of 4-(dimethylamino)pyridine (DMAP) in dry pyridine (10 mL) was stirred at room temperature under argon. After 6 h, the reaction solvent was removed in vacuum, and the residue was directly subjected to a silica gel column eluted with cyclohexane/EtOAc (gradient elution with 1% pyridine: 500/150 → 300/150 → 150/150, v/v) to give the title product (1.056 g, yield 96%). R_f = 0.42 (cyclohexane/EtOAc 1/1, v/v). ^1H NMR ($CDCl_3$) δ (ppm): 9.87 (s, 1H, -C*H*O), 7.79 (dt, 2H, J_1 = 8.7 Hz, J_2 = 2.1 Hz, benzaldehyde), 7.45 (m, 2H, benzene ring of DMTr group), 7.36−7.15 (m, 3H, benzene ring of DMTr group), 7.34 (dt, 4H, J_1 = 9.0 Hz, J_2 = 2.7 Hz, methoxybenzene ring of DMTr group), 6.97 (dt, 2H, J_1 = 8.7 Hz, J_2 = 2.1 Hz, benzaldehyde), 6.81 (dt, 4H, J_1 = 9.0 Hz, J_2 = 2.7 Hz, methoxybenzene ring of DMTr group), 4.15 (bt, 2H, J = 4.8 Hz, tetraethylene glycol chain), 3.87 (bt, 2H, J = 4.8 Hz, tetraethylene glycol chain), 3.77 (s, 6H, -OC*H*$_3$), 3.77−3.64 (m, 10H, tetraethylene glycol chain), 3.22 (t, 2H, J = 4.8 Hz, tetraethylene glycol chain). ^{13}C NMR ($CDC1_3$) δ (ppm): 191.0, 164.0, 158.5, 145.3, 136.5, 132.1, 130.3, 130.2, 128.4, 127.9, 126.8, 123.9, 115.1, 113.2, 86.2, 71.2, 71.1, 71.0, 69.7, 68.0, 63.4, 55.5, 27.3.

*2-(2-(2-(2-N-n-Butylaminoethoxy)ethoxy)ethoxy)ethanol (**12**).* To a solution of 2-(2-(2-(2-chloroethoxy)ethoxy)ethoxy)ethanol (2 g, 9.4 mmol) in *n*-butylamine 10 mL at room temperature was added K_2CO_3 (1 g, 0.77 equiv). The reaction mixture was heated to reflux for 24 h. Then, another 10 mL of *n*-butylamine was added into the mixture, and the reaction was continued to reflux another 12 h. The reaction mixture was cooled to room temperature, and the *n*-butylamine was removed in vacuum. The residue was diluted with $CHCl_3$ and the suspension was suction-filtered. The filtrate was collected and concentrated to give the title product as a yellow syrup in quantitative yield, which could be used directly in the next step without further purification. ^1H NMR ($CDCl_3$) δ (ppm): 3.55−3.51 (m, 14H, tetraethylene glycol chain), 2.66 (bt, 2H, J = 5.1 Hz, tetraethylene glycol chain), 2.47 (t, 2H, J = 7.2 Hz, *n*-butyl chain), 1.43−1.31 (m, 2H, *n*-butyl chain), 1.30−1.16 (m, 2H, *n*-butyl chain), 0.80 (t, 3H, J = 7.2 Hz, *n*-butyl chain). ^{13}C NMR ($CDC1_3$) δ (ppm): 72.9, 70.6, 70.4, 70.3, 70.2, 61.3, 49.5, 49.2, 32.1, 20.6, 14.1. MS (MALDI-TOF): 249.92 $[M + H]^+$, 271.92 $[M + Na]^+$, 287.86 $[M + K]^+$.

*4-N-n-Butyl-N-[2-[2-[2-(2-hydroxyethoxy)ethoxy]ethoxy]ethyl]-amino benzaldehyde (**13**).* A mixture of 2-[2-[2-(2-*N*-*n*-butylaminoethoxy)ethoxy]ethoxy]ethanol (**12**) (2.3 g, 9.4 mmol), 4-fluorobenzaldehyde (1.0 mL, 9.4 mmol), and K_2CO_3 (1.5 g, 1.1 equiv) in dry *N,N*-dimethylformamide (DMF) (10 mL) was heated with stirring to 120 °C (oil bath 128 °C) under argon. The stirring was continued at this temperature for 72 h, and the reaction mixture was cooled to room temperature. After the solvent (DMF) was evaporated in vacuum, the residue was diluted with $CHCl_3$. The obtained suspension was washed with brine (2 × 200 mL) and dried over Na_2SO_4. The organic layer was concentrated, and the residue was purified by chromatography on a silica gel column eluted with EtOAc/MeOH (20:1) to give the title product (1.2 g, 36% in two steps based on **9** as a yellow oil. R_f = 0.4 (EtOAc/MeOH 20/1). ^1H NMR ($CDCl_3$) δ (ppm): 9.56 (s, 1H, -CHO), 7.57 (bd, 2H, J = 9.3 Hz, aromatic ring), 6.58 (bd, 2H, J = 8.7 Hz, aromatic ring), 3.65−3.40 (m, 16H, tetraethylene glycol chain), 3.29 (t, 2H, J = 7.8

Hz, *n*-butyl chain), 1.59−1.40 (m, 2H, *n*-butyl chain), 1.30−1.18 (m, 2H, *n*-butyl chain), 0.85 (t, 3H, $J = 7.5$ Hz, *n*-butyl chain). ^{13}C NMR ($CDC1_3$) δ (ppm): 189.7, 152.4, 131.9, 124.5, 110.6, 72.4, 70.5, 70.4, 70.3, 70.1, 68.1, 61.4, 51.1, 50.3, 28.9, 20.0, 13.9. MS (MALDI-TOF): 353.23 $[M]^+$.

*4-((2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)ethoxy)-ethoxy)ethoxy)ethyl)butylamino)benzaldehyde (**14**).* A mixture of **13** (475 mg, 1.35 mmol), DMTrCl (912 mg, 2.7 mmol, 2 equiv), and a catalytic amount of 4-(dimethylamino)pyridine (DMAP) in dry pyridine (10 mL) was stirred at room temperature under argon. After the stirring was continued overnight, the reaction solvent was removed in vacuum and the residue was directly subject to a silica gel column eluted with cyclohexane/EtOAc (gradient elution with 1% pyridine: 500/150 → 300/150 → 150/150, v/v) to give the title product (800 mg, yield 90%). $R_f = 0.19$ (cyclohexane/EtOAc 1/1, v/v). ^{1}H NMR ($CDCl_3$) δ (ppm): 9.69 (s, 1H, -C*H*O), 7.68 (bd, 2H, $J = 9.0$ Hz, benzaldehyde), 7.46 (m, 2H, benzene ring of DMTr group), 7.32−7.15 (m, 3H, benzene ring of DMTr group), 7.34 (dt, 4H, $J_1 = 9.0$ Hz, $J_2 = 3.0$ Hz, methoxybenzene ring of DMTr group), 6.81 (dt, 4H, $J_1 = 9.0$ Hz, $J_2 = 3.0$ Hz, methoxybenzene ring of DMTr group), 6.66 (bd, 2H, $J = 9.0$ Hz, benzaldehyde), 3.77 (s, 6H, -OCH_3), 3.68−3.53 (m, 14H, tetraethylene glycol chain), 3.37 (bt, 2H, $J = 7.9$ Hz, -NCH_2CH$_2$CH$_2$CH$_3$), 3.22 (t, 2H, $J = 5.2$ Hz, tetraethylene glycol chain), 1.62−1.52 (m, 2H, -NCH$_2$CH_2CH$_2$CH$_3$), 1.40−1.28 (m, 2H, -NCH$_2$CH$_2$CH_2CH$_3$), 0.95 (t, 3H, $J = 7.2$ Hz, -NCH$_2$CH$_2$CH$_2$CH_3).

Compounds in Preparation of Asymmetric Pyridinium Bistyryl Benzene. *4-(2-(2-(2-(2-(tert-Butyldimethylsilanyloxy)-ethoxy)ethoxy)ethoxy)ethoxy)benzaldehyde (**20**).* A mixture of **10** (1.4 g, 4.7 mmol), *tert*-butyldimethylsilyl chloride (TBDMSCl) (0.85 g, 5.6 mmol, 1.2 equiv), and *N*,*N*-diisopropylethylamine (DIPEA) (1.2 mL, 1.5 equiv) in dry CH_2Cl_2 (15 mL) was stirred at room temperature under argon. After 5 h, half of the starting material had gone. Another batch of DIPEA and TBDMSCl as well as a catalytic amount of DMAP was added. The reaction mixture was stirred overnight. The solvent (CH_2Cl_2) was evaporated in vacuum, and the residue was purified by chromatography on a silica gel column eluted with cyclohexane/EtOAc (1/1) to give the title product (1.5 g, yield 77%). $R_f = 0.44$ (cyclohexane/EtOAc, 1/1). ^{1}H NMR ($CDCl_3$) δ (ppm): 9.88 (s, 1H, -C*H*O), 7.83 (dt, 2H, $J_1 = 9.0$ Hz, $J_2 = 2.1$ Hz, benzaldehyde), 7.02 (dt, 2H, $J_1 = 9.0$ Hz, $J_2 = 2.1$ Hz, benzaldehyde), 4.22 (t, 2H, $J = 5.1$ Hz, tetraethylene glycol chain), 3.89 (t, 2H, $J = 5.1$ Hz, tetraethylene glycol chain), 3.75 (bt, 2H, $J = 5.1$ Hz, tetraethylene glycol chain), 3.71−3.59 (m, 8H, tetraethylene glycol chain), 3.49 (bt, 2H, $J = 5.1$ Hz, tetraethylene glycol chain), 0.83 (s, 9H, -Si(CH$_3$)$_2$C(CH_3)$_3$), 0.06 (s, 6H, -Si(CH_3)$_2$C(CH$_3$)$_3$). ^{13}C NMR ($CDC1_3$) δ (ppm): 190.9, 164.0, 132.1, 130.2, 115.1, 72.9, 71.2, 71.0, 70.99, 70.94, 69.7, 68.0, 63.0, 26.3, 18.7, −4.9.

*4-(2-(4-(2-(2-(2-(2-(tert-Butyldimethylsilanyloxy)ethoxy)ethoxy)-ethoxy)ethoxy)phenyl)vinyl)benzonitrile (**22**).* A solution of diisopropylamine (3.2 mL, 22.8 mmol, 4.3 equiv) in THF (40 mL) at room temperature under argon was cooled to −78 °C, and *n*-BuLi (12.5 mL, 1.6 M in hexanes, 3.8 equiv) was added via syringe. The mixture was warmed to 0 °C for 30 min and recooled to −78 °C. A solution of 4-cyanobenzylphosphonic acid diethyl ester **21** (2.3 g, 9 mmol) in THF (15 mL) was precooled and transferred via cannula into the LDA solution at −78 °C, and then the reaction mixture was warmed up to 0 °C. Another solution of **20** (2.2 g, 5.3 mmol) in THF (15 mL) was added into the reaction via cannula at 0 °C, and the reaction was warmed up to room temperature. After 24 h of stirring at room temperature, the reaction mixture was diluted with CH_2Cl_2 and the organic phase was washed with aqueous $NaHCO_3$ twice, then brine. The solvent (CH_2Cl_2) was evaporated in vacuum, and the residue was purified by chromatography on a silica gel column eluted with CH_2Cl_2/EtOAc (5/1, v/v) to give the title product (2.1 g, yield 84%). $R_f = 0.66$ (DCM/EtOAc, 5/1). ^{1}H NMR ($CDCl_3$) δ (ppm): 7.61 (dt, 2H, $J_1 = 8.7$ Hz, $J_2 = 1.8$ Hz, styryl benzene), 7.55 (dt, 2H, $J_1 = 8.7$ Hz, $J_2 = 1.8$ Hz, styryl benzene), 7.45 (dt, 2H, $J_1 = 8.7$ Hz, $J_2 = 2.1$ Hz, ethoxybenzene), 7.14 (d, 2H, $J = 16.2$ Hz, double bond trans linkage), 6.94 (d, 2H, $J = 16.2$ Hz, double bond trans linkage), 6.93 (dt, 2H, $J_1 = 8.7$ Hz, $J_2 = 2.1$ Hz, ethoxybenzene), 4.16 (t, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.88 (t, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.76 (bt, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.76−3.64 (m, 8H, tetraethylene glycol chain), 3.56 (bt, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 0.89 (s, 9H, -Si(CH$_3$)$_2$C(CH_3)$_3$), 0.06 (s, 6H, -Si(CH_3)$_2$C-(CH$_3$)$_3$). ^{13}C NMR ($CDC1_3$) δ (ppm): 159.5, 142.4, 132.7, 132.1, 129.4, 128.4, 126.8, 124.8, 119.4, 115.2, 110.3, 72.9, 71.2, 71.0, 70.99, 70.95, 70.0, 67.8, 63.0, 26.3, 18.7, −4.7.

*4-(2-(4-(2-(2-(2-(2-(tert-Butyldimethylsilanyloxy)ethoxy)ethoxy)-ethoxy)ethoxy)phenyl)vinyl)benzaldehyde (**23**).* A solution of **22** (710 mg, 1.47 mmol) in Et_2O (40 mL) was cooled to −78 °C. DIBALH (2.9 mL, in hexane 1 M, 2 equiv) was added to the reaction solution dropwise via syringe in two equal portions. The reaction was stirred for 7 h at −78 °C, then for 30 min at 0 °C. The reaction mixture was transferred via cannula into 10% AcOH aqueous solution (150 mL) with stirring. The obtained solution was stirred vigorously until the organic layer was separated from the aqueous layer. The organic layer was washed twice with aqueous $NaHCO_3$ (sat). Then, the solvents were evaporated in vacuum, and the residue was purified by chromatography on a silica gel column eluted with CH_2Cl_2/EtOAc (5/1, v/v) to give the title product (428 mg, yield 57%). $R_f = 0.50$ (CH_2Cl_2/EtOAc, 5/1). ^{1}H NMR ($CDCl_3$) δ (ppm): 9.98 (s, 1H, -C*H*O), 7.85 (bd, 2H, $J = 8.4$ Hz, benzaldehyde), 7.62 (bd, 2H, $J = 8.4$ Hz, benzaldehyde), 7.47 (dt, 2H, $J_1 = 8.7$ Hz, $J_2 = 1.8$ Hz, ethoxybenzene), 7.19 (d, 2H, $J = 16.2$ Hz, double bond trans linkage), 7.02 (d, 2H, $J = 16.2$ Hz, double bond trans linkage), 6.93 (dt, 2H, $J_1 = 8.7$ Hz, $J_2 = 1.8$ Hz, ethoxybenzene), 4.16 (t, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.88 (t, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.76 (bt, 2H, $J = 5.1$ Hz, tetraethylene glycol chain), 3.76−3.66 (m, 8H, tetraethylene glycol chain), 3.56 (bt, 2H, $J = 5.1$ Hz, tetraethylene glycol chain), 0.89 (s, 9H, -Si(CH$_3$)$_2$C(CH_3)$_3$), 0.06 (s, 6H, -Si(CH_3)$_2$C(CH$_3$)$_3$). ^{13}C NMR ($CDC1_3$) δ (ppm): 191.7, 159.3, 144.0, 135.1, 131.9, 130.4, 129.6, 128.3, 126.7, 125.3, 115.1, 72.9, 71.1, 71.0, 70.93, 70.88, 69.9, 67.7, 62.9, 26.2, 18.7, −4.9.

*4-(2-(4-(2-(2-(2-(2-Hydroxyethoxy)ethoxy)ethoxy)ethoxy)-phenyl)vinyl)benzaldehyde (**24**).* To a solution of **23** (100 mg, 0.19 mmol) in THF (10 mL) was added tetrabutylammonium fluoride (TBAF) (0.2 mL, 1.1 equiv, 1.0 M in THF) slowly at room temperature. After 5 min, another 0.1 mL TBAF was added. Then, several drops of 10% AcOH/THF was added to quench the reaction. The solvent was evaporated in vacuum, and the crude product was purified by flash chromatography on a silica gel column eluted with CH_2Cl_2/MeOH (20/1) to give the title product (78 mg, yield 100%). From ^{1}H NMR, the isomers (trans/cis double bond linkages) were observed. The isomerization was conducted: the isomers were dissolved in DMF (12 mL), and a catalytic amount of I_2 was added. The system was heated to 140 °C for 36 h to give the trans product (ee ≥ 95%). $R_f = 0.26$ (CH_2Cl_2/MeOH, 20/1). ^{1}H NMR ($CDCl_3$) δ (ppm): 9.93 (s, 1H, -C*H*O), 7.80 (bd, 2H, $J = 8.4$ Hz, benzaldehyde), 7.57 (bd, 2H, $J = 8.4$ Hz, benzaldehyde), 7.43 (bd, 2H, $J = 9.0$ Hz, ethoxybenzene), 7.15 (d, 2H, $J = 16.5$ Hz, double bond trans linkage), 6.96 (d, 2H, $J = 16.5$ Hz, double bond trans linkage), 6.90 (bd, 2H, $J = 9.0$ Hz, ethoxybenzene), 4.12 (t, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.84

(t, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.74−3.62 (m, 10H, tetraethylene glycol chain), 3.60−3.55 (m, 2H, tetraethylene glycol chain).

*4-(2-(4-(2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)ethoxy)ethoxy)ethoxy)ethoxy)phenyl)vinyl)benzaldehyde (**25**).* A mixture of **24** (180 mg, 0.45 mmol), DMTrCl (0.5 g, 1.5 mmol, 3 equiv), and a catalytic amount of 4-(dimethylamino)pyridine (DMAP) in dry pyridine (5 mL) was stirred at room temperature under argon. After the stirring was continued overnight, the reaction solvent was removed in vacuum and the residue was directly subject to a silica gel column eluted with CH_2Cl_2/EtOAc/pyridine (100/10/1, v/v) to give the title product (210 mg, yield 66%). $R_f = 0.36$ (CH_2Cl_2/EtOAc 10/1, v/v). ^{1}H NMR ($CDCl_3$) δ (ppm): 9.98 (s, 1H, -C*H*O), 7.85 (bd, 2H, $J = 8.4$ Hz, benzaldehyde), 7.62 (bd, 2H, $J = 8.4$ Hz, benzaldehyde), 7.46 (m, 2H, benzene ring of DMTr group), 7.45 (bd, 2H, $J = 8.7$ Hz, ethoxybenzene), 7.34 (dt, 4H, $J_1 = 9.0$ Hz, $J_2 = 2.4$ Hz, methoxybenzene ring of DMTr group), 7.32−7.15 (m, 4H, benzene ring of DMTr group and double bond trans linkage), 7.00 (d, 1H, $J = 16.2$ Hz, double bond trans linkage), 6.91 (dt, 2H, $J_1 = 8.7$ Hz, $J_2 = 2.1$ Hz, ethoxybenzene), 6.81 (dt, 4H, $J_1 = 9.0$ Hz, $J_2 = 2.4$ Hz, methoxybenzene ring of DMTr group), 4.12 (bt, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.86 (bt, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.77 (s, 6H, -OC*H*$_3$), 3.74−3.65 (m, 10H, tetraethylene glycol chain), 3.22 (t, 2H, $J = 5.1$ Hz, tetraethylene glycol chain).

*4-(2-(4-(2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)ethoxy)ethoxy)ethoxy)phenyl)vinyl)phenyl)vinyl)-1-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)ethyl)pyridinium Chloride (**26**).* A mixture of **25** (200 mg, 0.28 mmol), 1-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)ethyl)-4-methylpyridinium chloride (90 mg, 0.29 mmol, 1 equiv), and a catalytic amount of piperidine in absolute EtOH (30 mL) was heated to 80 °C for 12 h. After the system was cooled to room temperature, the reaction solvent was removed in vacuum and the residue was directly subject to a silica gel column eluted with CH_2Cl_2/MeOH/pyridine/H_2O (400/60/5/5, v/v) to give the title product (85 mg, yield 30%). $R_f = 0.32$ (CH_2Cl_2/MeOH/pyridine/H_2O, 400/60/5/5, v/v). ^{1}H NMR ($CDCl_3$) δ (ppm): 9.27 (d, 2H, $J = 6.6$ Hz, pyridinium), 7.91 (d, 2H, $J = 6.6$ Hz, pyridinium), 7.64 (d, 1H, $J = 16.8$ Hz, double bond trans linkage), 7.60 (d, 2H, $J = 8.4$ Hz, styryl benzene), 7.53 (d, 2H, $J = 8.4$ Hz, styryl benzene), 7.47−7.42 (m, 2H, benzene ring of DMTr group), 7.45 (bd, 2H, $J = 8.7$ Hz, ethoxybenzene), 7.34 (dt, 4H, $J_1 = 9.0$ Hz, $J_2 = 2.1$ Hz, methoxybenzene ring of DMTr group), 7.28−7.15 (m, 3H, benzene ring of DMTr group), 7.16 (d, 1H, $J = 16.5$ Hz, double bond trans linkage), 7.12 (d, 1H, $J = 16.8$ Hz, double bond trans linkage), 6.97 (d, 1H, $J = 16.5$ Hz, double bond trans linkage), 6.89 (bd, 2H, $J = 8.7$ Hz, ethoxybenzene), 6.81 (dt, 4H, $J_1 = 9.0$ Hz, $J_2 = 2.1$ Hz, methoxybenzene ring of DMTr group), 5.07 (bt, 2H, tetraethylene glycol chain), 4.12 (bt, 4H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.85 (bt, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.77 (s, 6H, -OC*H*$_3$), 3.74−3.55 (m, 22H, tetraethylene glycol chain), 3.22 (t, 2H, $J = 5.1$ Hz, tetraethylene glycol chain).

*Detritylation of **26** (**34**).* To a solution of **26** (20 mg, 0.02 mmol) in $CHCL_3$ (5 mL) was added Cl_2HCOOH (1 drop with a 9 in Pasteur pipet). After the completion of the reaction, the solvent was removed in vacuum and the residue was directly subjected to a silica gel column eluted with CH_2Cl_2/MeOH/pyridine/H_2O (400/60/5/5, v/v) to give the detritylated product **34** in quantitative yield. $R_f = 0.23$ (CH_2Cl_2/MeOH/pyridine/H_2O, 400/60/5/5, v/v). ^{1}H NMR ($CDCl_3$) δ (ppm): 9.11 (bs, 2H, pyridinium), 7.92 (bs, 2H, pyridinium), 7.60 (d, 1H, $J = 16.5$ Hz, double bond trans linkage), 7.55 (d, 2H, $J = 8.4$ Hz, styryl benzene), 7.47 (d, 2H, $J = 8.4$ Hz, styryl benzene), 7.42 (d, 2H, $J = 8.7$ Hz, ethoxybenzene), 7.10 (d, 1H, $J = 16.2$ Hz, double bond trans linkage), 7.06 (d, 1H, $J = 16.5$ Hz, double bond trans linkage), 6.91 (d, 1H, $J = 16.2$ Hz, double bond trans linkage), 6.89 (d, 2H, $J = 8.7$ Hz, ethoxybenzene), 4.91 (bs, 2H, tetraethylene glycol chain), 4.15 (bt, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 4.02 (bs, 2H, tetraethylene glycol chain), 3.86 (bt, 2H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.78−3.55 (m, 24H, tetraethylene glycol chain).

*1-(2-(2-(2-(2-Hydroxyethoxy)ethoxy)ethoxy)ethyl)-4-methylpyridinium Tetraphenylborate (**27**).* A mixture of picoline (1 g, 11 mmol) and 2-(2-(2-(2-chloroethoxy)ethoxy)ethoxy)ethanol (1.5 g, 7.1 mmol) was heated to 140 °C for 4−6 h under argon. After the system was cooled to room temperature, the excess picoline was removed in vacuum. The obtained brown oil was dissolved in acetonitrile, and tetraphenylboron sodium (2.5 g, 7.3 mmol) was added into the solution. The mixture was refluxed for 20 min and concentrated to a residue, which was directly subjected to a silica gel column eluted with CH_2Cl_2/MeOH (10/1, v/v) to give the title product (4.2 g) in a quantitative yield. $R_f = 0.42$ (CH_2Cl_2/MeOH, 10/1, v/v). ^{1}H NMR ($CDCl_3$) δ (ppm): 7.52−7.44 (m, 8H, benzene ring of BPh_4), 6.96 (t, 8H, $J = 7.2$ Hz, benzene ring of BPh_4), 6.80 (bt, 4H, $J = 7.2$ Hz, benzene ring of BPh_4), 6.63 (d, 2H, $J = 7.5$ Hz, pyridinium), 6.60 (d, 2H, $J = 7.5$ Hz, pyridinium), 3.67−3.34 (m, 12H, tetraethylene glycol chain), 3.22−3.16 (m, 4H, tetraethylene glycol chain), 2.49 (t, 1H, $J = 6.0$ Hz, -O*H*), 2.21 (s, 3H, -C*H*$_3$). ^{13}C NMR ($CDC1_3$) δ (ppm): 165.2, 164.5, 163.9, 163.2, 158.2, 143.2, 136.2, 128.0, 126.2, 126.1, 122.3, 72.6, 70.7, 70.5, 70.3, 70.27, 68.8, 61.8, 59.9, 22.2.

*1-(2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)ethoxy)ethoxy)ethoxy)ethyl)-4-methylpyridinium Tetraphenylborate (**28**).* A mixture of **27** (510 mg, 0.87 mmol), DMTrCl (600 mg, 1.77 mmol, 2 equiv), and a catalytic amount of 4-(dimethylamino)-pyridine (DMAP) in dry pyridine (10 mL) was stirred at room temperature under argon. After 12 h, the reaction solvent was removed in vacuum, and the residue was directly subjected to a silica gel column eluted with CH_2Cl_2/MeOH/pyridine (750/25/7, v/v) to give the title product (450 mg, yield 58%). $R_f = 0.33$ (CH_2Cl_2/MeOH/pyridine 750/25/7, v/v). ^{1}H NMR ($CDCl_3$) δ (ppm): 7.52−7.44 (m, 10H, benzene ring of BPh_4 and DMTr groups), 7.32 (bd, 4H, $J = 9$ Hz, methoxybenzene ring), 7.34−7.15 (m, 3H, benzene ring of DMTr group), 6.96 (t, 8H, $J = 7.2$ Hz, benzene ring of BPh_4), 6.80 (bt, 4H, $J = 7.2$ Hz, benzene ring of BPh_4), 6.79 (bd, 4H, $J = 9$ Hz, methoxybenzene ring), 6.67 (bd, 2H, $J = 6.9$ Hz, pyridinium), 6.63 (bd, 2H, $J = 6.9$ Hz, pyridinium), 3.75 (s, 3H, -OC*H*$_3$), 3.67−3.60 (m, 4H, tetraethylene glycol chain), 3.58−3.52 (m, 2H, tetraethylene glycol chain), 3.52−3.44 (m, 2H, tetraethylene glycol chain), 3.44−3.36 (m, 2H, tetraethylene glycol chain), 3.24−3.14 (m, 6H, tetraethylene glycol chain), 2.17 (s, 3H, -C*H*$_3$). ^{13}C NMR ($CDC1_3$) δ (ppm): 165.2, 164.6, 163.9, 163.3, 158.6, 158.1, 145.2, 143.2, 136.3, 136.2, 130.3, 128.4, 128.00, 127.97, 127.3, 127.0, 126.2, 126.1, 122.3, 113.3, 86.2, 71.0, 70.9, 70.88, 70.7, 70.5, 68.8, 63.4, 59.9, 55.6, 22.1.

*1-(2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)ethoxy)ethoxy)ethoxy)ethyl)-4-(2-(4-(2-4-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)phenyl)vinyl)phenyl)vinyl)pyridinium Tetraphenylborate (**29**).* A mixture of **28** (230 mg, 0.26 mmol), **24** (105 mg, 0.26 mmol, 1 equiv), and a catalytic amount (6 drops, 9 in Pasteur pipet) of piperidine in absolute EtOH (30 mL) was heated to 100 °C for 12 h. After the reaction was cooled to room temperature, the reaction solvent was removed in vacuum and the residue was directly subject to a silica gel column eluted with CH_2Cl_2/MeOH/pyridine/H_2O (800/60/4/3, v/v) to give the title product (73 mg, yield 22%). $R_f = 0.37$ (CH_2Cl_2/MeOH/pyridine/H_2O, 400/60/5/5, v/v). ^{1}H NMR ($CDCl_3$) δ (ppm): 7.56−7.43 (m, 16H, benzene ring of BPh_4 (8H), benzene ring of DMTr group (2H), styryl benzene (6H)), 7.36−

7.18 (m, 4H, benzene ring of DMTr group (3H) and double bond trans linkage (1H)), 7.32 (bd, 4H, J = 9 Hz, methoxybenzene ring), 7.17 (d, 1H, J = 15.9 Hz, double bond trans linkage), 7.06 (d, 2H, J = 8.7 Hz, pyridinium), 7.02 (t, 8H, J = 7.5 Hz, benzene ring of BPh_4), 6.98 (d, 1H, J = 15.9 Hz, double bond trans linkage), 6.94 (d, 2H, J = 8.7 Hz, pyridinium), 6.85 (bt, 4H, J = 7.5 Hz, benzene ring of BPh_4), 6.78 (bd, 4H, J = 9 Hz, methoxybenzene ring), 6.74 (d, 1H, J = 16.2 Hz, double bond trans linkage), 4.18 (bt, 2H, J = 4.8 Hz, tetraethylene glycol chain), 3.88 (t, 2H, J = 4.8 Hz, tetraethylene glycol chain), 3.73 (s, 6H, -OCH_3), 3.78−3.58 (m, 18H, tetraethylene glycol chain), 3.58−3.52 (m, 2H, tetraethylene glycol chain), 3.52−3.47 (m, 2H, tetraethylene glycol chain), 3.46−3.36 (m, 4H, tetraethylene glycol chain), 3.23 (bt, 2H, J = 4.8 Hz, tetraethylene glycol chain). ^{13}C NMR ($CDC1_3$) δ (ppm): 158.2, 152.5, 149.5, 144.8, 143.7, 141.1, 135.9, 134.5, 132.8, 130.3, 129.9, 129.5, 128.6, 128.0, 127.9, 127.6, 126.9, 126.7, 125.8, 125.7, 125.2, 123.6, 122.8, 121.9, 114.8, 112.9, 85.8, 72.4, 70.7, 70.6, 70.5, 70.3, 70.2, 69.6, 68.8, 67.4, 63.0, 61.7, 55.1.

*2-(2-(2-(2-(4-(E-2-(4-(E-2-Pyridin-4-yl-vinyl)phenyl)vinyl)-phenoxy)ethoxy)ethoxy)ethoxy)ethanol (**30**).* A mixture of **24** (180 mg, 0.45 mmol), 4-picoline (1 mL, 10.3 mmol, 23 equiv), acetic anhydride (1.3 mL), and acetic acid (0.6 mL) was heated to 100 °C for 12 h. A complex was then obtained after chromatography. The improved procedure is as follows: A mixture of **24** (60 mg, 0.15 mmol), 4-picoline (1.8 mL, 18 mmol), and 37% HCl (0.72 mL, 8.8 mmol) gave a yellow solution. The reaction mixture was heated to 100 °C for 48 h and cooled to room temperature. The reaction was diluted with $CHCl_3$, washed with aqueous $NaHCO_3$, and extracted with $CHCl_3$. The organic layer was collected, dried over Na_2SO_4, and concentrated, and the residue was subjected to a silica gel column eluted with CH_2Cl_2/MeOH (20/1, v/v) to give the title product (18 mg, yield 25%). R_f = 0.28 (CH_2Cl_2/MeOH, 20/1, v/v). ^{1}H NMR ($CDCl_3$) δ (ppm): 8.57 (d, 2H, J = 6.0 Hz, pyridinium), 7.51 (bs, 4H, styryl benzene), 7.44 (dt, 2H, J_1 = 8.7 Hz, J_2 = 1.8 Hz, ethoxybenzene), 7.37 (bd, 2H, J = 6.0 Hz, pyridinium), 7.28 (d, 1H, J = 16.2 Hz, double bond trans linkage), 7.10 (d, 1H, J = 16.5 Hz, double bond trans linkage), 7.02 (d, 1H, J = 16.5 Hz, double bond trans linkage), 6.98 (d, 1H, J = 16.2 Hz, double bond trans linkage), 6.92 (dt, 2H, J_1 = 8.7 Hz, J_2 = 1.8 Hz, ethoxybenzene), 4.16 (bt, 2H, J = 4.8 Hz, tetraethylene glycol chain), 3.87 (t, 2H, J = 4.8 Hz, tetraethylene glycol chain), 3.77−3.64 (m, 10H, tetraethylene glycol chain), 3.61 (bt, 2H, J = 5.1 Hz, tetraethylene glycol chain). ^{13}C NMR ($CDC1_3$) δ (ppm): 158.8, 150.2, 145.0, 138.4, 135.1, 133.1, 130.3, 129.1, 128.0, 127.6, 126.9, 126.1, 125.6, 121.0, 115.1, 72.8, 71.1, 71.0, 70.9, 70.6, 70.0, 67.7, 62.1.

*2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)ethoxy)ethoxy)-ethoxy)ethylene Chloride (**32**).* A mixture of 2-(2-(2-(2-chloroethoxy)ethoxy)ethoxy)ethanol (1.5 g, 4.7 mmol), DMTrCl (3.18 g, 9.4 mmol, 2 equiv), and a catalytic amount of 4-(dimethylamino)pyridine (DMAP) in dry Pyridine (40 mL) was stirred at room temperature under argon. After 12 h, the reaction solvent was removed in vacuum. The reaction mixture was diluted with CH_2Cl_2 and washed with aqueous $NaHCO_3$ and brine. The organic layer was collected, dried over Na_2SO_4, and concentrated, and the residue was subject to a silica gel column eluted with cyclohexane/EtOAC (3/1 w/ 1% pyridine, v/v) to give the title product in a quantitative yield. R_f = 0.35 (cyclohexane/EtOAc 3/1, v/v). ^{1}H NMR ($CDCl_3$) δ (ppm): 7.44 (bd, 2H, J = 7.2 Hz, benzene ring of DMTr group), 7.36 (dt, 4H, J_1 = 9.0 Hz, J_2 = 2.1 Hz, methoxybenzene ring of DMTr group), 7.28 (bt, 2H, J = 7.2 Hz, benzene ring of DMTr group), 7.20 (tt, 1H, J_1 = 7.2 Hz, J_2 = 2.1 Hz, benzene ring of DMTr group), 6.83 (dt, 4H, J_1 = 9.0 Hz, J_2 = 2.4 Hz, methoxybenzene ring of DMTr group), 3.78 (s, 6H, -OCH_3), 3.74 (bt, 2H, J = 5.1 Hz, tetraethylene glycol chain), 3.71−3.66 (m, 10H, tetraethylene glycol chain), 3.60 (bt, 2H, J = 5.7 Hz, tetraethylene glycol chain), 3.24 (t, 2H, J = 5.1 Hz, tetraethylene glycol chain). ^{13}C NMR ($CDC1_3$) δ (ppm): 158.5, 145.3, 136.5, 130.3, 128.4, 128.0, 126.9, 113.3, 86.2, 71.6, 71.1, 71.0, 70.99, 63.4, 55.5, 43.1, 27.3.

*2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)ethoxy)ethoxy)-ethoxy)ethylene Iodide (**33**).* A mixture of **32** (506 mg, 0.98 mmol), KI (1.4 g, 8.4 mmol, 8.6 equiv), and NaI (1.2 g, 8 mmol, 8 equiv) in dry acetone (25 mL) was stirred at room temperature. During the reaction, another two batches of NaI (3 g) were added. After 72 h, the reaction solvent was removed in vacuum. The reaction mixture was diluted with CH_2Cl_2 and washed with aqueous $NaHCO_3$ and brine. The organic layer was collected, dried over Na_2SO_4, and concentrated, and the residue was subjected to a silica gel column eluted with cyclohexane/EtOAc (3/1 w/ 1% Pyridine, v/v) to give the title product in a 90% yield. R_f 0.38 (Cyclohexane/EtOAc, 3/1, v/v). ^{1}H NMR ($CDCl_3$) δ (ppm): 7.46 (bd, 2H, J = 7.2 Hz, benzene ring of DMTr group), 7.35 (dt, 4H, J_1 = 9.0 Hz, J_2 = 2.4 Hz, methoxybenzene ring of DMTr group), 7.28 (bt, 2H, J = 7.2 Hz, benzene ring of DMTr group), 7.20 (tt, 1H, J_1 = 7.2 Hz, J_2 = 2.4 Hz, benzene ring of DMTr group), 6.82 (dt, 4H, J_1 = 9.0 Hz, J_2 = 2.4 Hz, methoxybenzene ring of DMTr group), 3.78 (s, 6H, -OCH_3), 3.74 (bt, 2H, J = 6.9 Hz, tetraethylene glycol chain), 3.71−3.66 (m, 10H, tetraethylene glycol chain), 3.23 (bt, 2H, J = 6.9 Hz, tetraethylene glycol chain). ^{13}C NMR ($CDC1_3$) δ (ppm): 158.5, 145.3, 136.5, 130.3, 128.4, 128.0, 126.9, 113.3, 86.2, 71.6, 71.1, 71.0, 70.99, 63.4, 55.5, 43.1, 27.3.

*1-(2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)ethoxy)-ethoxy)ethoxy)ethyl)-4-(2-(4-(2-(4-(2-(2-(2-hydroxyethoxy)-ethoxy)ethoxy)ethoxy)phenyl)vinyl)phenyl)vinyl)pyridinium Iodide (**31**).* A mixture of **30** (18 mg, 0.038 mmol) and **33** (60 mg, 0.1 mmol, 2.6 equiv) in anhydrous CH_2Cl_2 (10 mL) was heated to 60 °C for 24 h. After the system was cooled to room temperature, the reaction solvent was removed in vacuum and the residue was directly subject to a silica gel column eluted with CH_2Cl_2/MeOH/pyridine/H_2O (400/60/5/5, v/v) to give the title product (20 mg, yield 49%). R_f = 0.5 (CH_2Cl_2/MeOH/pyridine/H_2O, 400/60/5/5, v/v). ^{1}H NMR ($CDCl_3$) δ (ppm): 9.07 (bs, 2H, pyridinium), 7.89 (bs, 2H, pyridinium), 7.52 (s, 4H, styryl benzene), 7.51 (d, 1H, J = 16.2 Hz, double bond trans linkage), 7.46 (d, 2H, J = 9.0 Hz, ethoxybenzene), 7.48−7.42 (m, 2H, benzene ring of DMTr group), 7.33 (dt, 4H, J_1 = 9.0 Hz, J_2 = 2.1 Hz, methoxybenzene ring of DMTr group), 7.28−7.15 (m, 3H, benzene ring of DMTr group), 7.16 (d, 1H, J = 15.3 Hz, double bond trans linkage), 6.98 (d, 1H, J = 16.2 Hz, double bond trans linkage), 6.97 (d, 1H, J = 15.3 Hz, double bond trans linkage), 6.93 (bd, 2H, J = 9.0 Hz, ethoxybenzene), 6.78 (dt, 4H, J_1 = 9.0 Hz, J_2 = 2.1 Hz, methoxybenzene ring of DMTr group), 4.17 (bt, 2H, J = 4.8H, tetraethylene glycol chain), 4.05 (bs, 2H, tetraethylene glycol chain), 3.88 (bt, 4H, J = 4.8 Hz, tetraethylene glycol chain), 3.75 (s, 6H, -OCH_3), 3.76−3.55 (m, 22H, tetraethylene glycol chain), 3.24 (bt, 2H, J = 4.8 Hz, tetraethylene glycol chain).

Compounds in Preparation of *E,E*-1,4-Bis-4,4′-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)ethoxy)styryl Benzene Derivatives. *E,E-1,4-Bis-4,4′-(2-(2-(2-tritylethoxy)ethoxy)ethoxy)-styryl Benzene (**15** trans).* To a solution of 1,4-phenylenebis-(methylene)bis(chlorotriphenyl) phosphorane (500 mg, 0.715 mmol) in THF (5 mL) was added *n*-BuLi (0.89 mL, 1.4 mmol, 1.6 M in hexanes) at 0 °C under argon. The mixture was stirred at room temperature for 0.5 h and cooled to −78 °C. A solution of **8** (770 mg, 1.55 mmol) in THF (4 mL) was precooled and added dropwise to the cooled mixture via syringe. After 0.5 h, the reaction mixture was warmed up to room temperature and

stirred for another 1 h. The reaction solvents were removed in vacuum, and the reaction mixture was diluted with $CHCl_3$. The organic phase was washed with brine, dried over Na_2SO_4, and concentrated. Then, the title product was precipitated with ethanol or methanol as a yellow solid. Isomerization: the solid was dissolved in DMF with a catalytic amount of I_2 and the mixture was refluxed overnight. After evaporation of the solvent, the residue was purified by chromatography on a silica gel column eluted with cyclohexane/EtOAc (2/1, v/v) to give the double bond trans linked product in a yield of 17%. $R_f = 0.38$ (cyclohexane/EtOAc, 2/1). ^{1}H NMR ($CDCl_3$) δ (ppm): 7.51−7.46 (m, 16H, benzene ring of styryl benzene and trityl group), 7.44 (d, 4H, $J = 8.7$ Hz, ethoxybenzene), 7.30 (bt, 12H, $J = 6.9$ Hz, benzene ring of trityl group), 7.23 (bt, 6H, $J = 7.2$ Hz, benzene ring of trityl group), 7.07 (d, 2H, $J = 16.2$ Hz, double bond trans linkage), 6.97 (d, 2H, $J = 16.2$ Hz, double bond trans linkage), 6.91 (d, 4H, $J = 8.7$ Hz, ethoxybenzene), 4.16 (bt, 4H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.91 (t, 4H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.80−3.68 (m, 20H, tetraethylene glycol chain), 3.26 (bt, 2H, $J = 5.1$ Hz, tetraethylene glycol chain).

*For the Double Bond Cis Linked Product: Z, Z-1,4-Bis-4,4′-(2-(2-(2-tritylethoxy)ethoxy)ethoxy)styryl Benzene (**15** cis).* ^{1}H NMR ($CDCl_3$) δ (ppm): 7.48−7.44 (m, 12H, benzene ring of trityl group), 7.26 (bt, 12H, $J = 6.9$ Hz, benzene ring of trityl group), 7.19 (bt, 3H, $J = 6.9$ Hz, benzene ring of trityl group), 7.15 (bd, 4H, $J = 9.0$ Hz, ethoxybenzene), 7.12 (bs, 4H, styryl benzene), 6.74 (bd, 4H, $J = 9.0$ Hz, ethoxybenzene), 6.48 (d, 2H, $J = 12.3$ Hz, double bond cis linkage), 6.42 (d, 2H, $J = 12.3$ Hz, double bond cis linkage), 4.07 (bt, 4H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.85 (bt, 4H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.76−3.64 (m, 20H, tetraethylene glycol chain), 3.23 (bt, 2H, $J = 5.1$ Hz, tetraethylene glycol chain).

*E,E-1,4-Bis-4,4′-(2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylethoxy)ethoxy)ethoxy) ethoxy)ethoxy)styryl Benzene (**17**).* To a solution of bis-ylide precursor, 1,4-phenylenebis(methylene)bis(chlorotriphenyl) phosphorane (550 mg, 0.79 mmol) in THF (5 mL) was added *n*-BuLi (1 mL, 1.6 mmol, 1.6 M in hexanes) dropwise at 0 °C under argon. The mixture was stirred at room temperature for 0.5 h and cooled to −78 °C. A solution of **11** (1 g, 1.6 mmol) in THF (5 mL) was precooled and added dropwise to the cooled mixture via syringe. After 0.5 h, the reaction mixture was warmed up to room temperature and stirred for another 4 h. The reaction solvents were removed in vacuum and the reaction mixture was diluted with $CHCl_3$. The organic phase was washed with brine, dried over Na_2SO_4, and concentrated. Then, the residue was dissolved with $CHCl_3$ and precipitated with ethanol. A yellow solid was collected as the title product with pure double bond trans linkages (150 mg, yield 15%). $R_f = 0.5$ (cyclohexane/EtOAc 1/2). Isomerization: the impure part (trans−cis double bond linkages) was deprotected (DMTr-group off) via Cl_2HCOOH in CH_2Cl_2. The obtained solid was dissolved in DMF with a catalytic amount of I_2, and the mixture was refluxed for 4 days. After evaporation of the solvent, the residue was purified by chromatography on a silica gel column eluted with CH_2Cl_2/MeOH (400/30, v/v) to give the double bond trans linked product (190 mg) in a yield of 35%. $R_f = 0.31$ (CH_2Cl_2/MeOH, 20/1.5). For **17**: ^{1}H NMR ($CDCl_3$) δ (ppm): 7.49−7.43 (m, 8H, benzene ring of DMTr group and styryl benzene), 7.42 (d, 4H, $J = 8.7$ Hz, ethoxybenzene), 7.34 (bd, 8H, $J = 9.0$ Hz, methoxybenzene ring of DMTr group), 7.31−7.23 (m, 4H, benzene ring of DMTr group), 7.19 (bt, 2H, $J = 7.2$ Hz, benzene ring of DMTr group), 7.05 (d, 2H, $J = 16.2$ Hz, double bond trans linkage), 6.96 (d, 2H, $J = 16.2$ Hz, double bond trans linkage), 6.89 (d, 4H, $J = 8.7$ Hz, ethoxybenzene), 6.81 (bd, 4H, $J = 9.0$ Hz, methoxybenzene ring of DMTr group), 4.12 (bt, 4H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.85 (bt, 4H, $J = 4.8$ Hz, tetraethylene glycol chain), 3.77 (s, 12H, -OCH_3), 3.75−3.64 (m, 20H, tetraethylene glycol chain), 3.22 (t, 4H, $J = 5.1$ Hz, tetraethylene glycol chain). ^{13}C NMR ($CDC1_3$) δ (ppm): 158.7, 158.6, 145.3, 136.8, 136.5, 130.5, 130.3, 128.4, 128.1, 128.0, 127.9, 126.9, 126.8, 126.5, 115.1, 113.3, 86.2, 71.2, 71.1, 71.06, 70.0, 67.7, 63.5, 55.5.

*E,E-1,4-Bis-4,4′-((2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)ethoxy)ethoxy)ethoxy)ethyl)butylamino)styryl Benzene (**18**).* To a solution of bis-ylide precursor, 1,4-phenylenebis(methylene)bis(chlorotriphenyl) phosphorane (430 mg, 0.62 mmol), in THF (5 mL) was added *n*-BuLi (0.76 mL, 1.2 mmol, 1.6 M in hexanes) dropwise at 0 °C under argon. The mixture was stirred at room temperature for 0.5 h and cooled to −78 °C. A solution of **14** (800 mg, 1.2 mmol) in THF (7 mL) was precooled and added dropwise to the cooled mixture via syringe. After 0.5 h, the reaction mixture was warmed up to room temperature and stirred for another 12 h. The reaction solvents were removed in vacuum and the reaction mixture was diluted with $CHCl_3$. The organic phase was washed with brine, dried over Na_2SO_4, and concentrated, and the residue was purified by chromatography on a silica gel column eluted with cyclohexane/EtOAc/pyridine (300/200/5, v/v) to give the double bond trans linked product (220 mg, yield 26%). $R_f = 0.32$ (cyclohexane/EtOAc, 3/2). Isomerization: the impure part (trans−cis double bond linkages) was detritylated (DMTr-group off) via Cl_2HCOOH in CH_2Cl_2 within 3 h. The deprotection reaction then was diluted with $CHCl_3$, washed with $NaHCO_3$ aqueous solution/brine, and concentrated. The obtained solid was dissolved in DMF with a catalytic amount of I_2 and the mixture was refluxed for 12 h. After evaporation of the solvent, the residue was purified by chromatography on a silica gel column eluted with CH_2Cl_2/MeOH (400/20, v/v) to give the double bond trans linked product **2** (27 mg) in a yield of 5.6%. $R_f = 0.31$ (CH_2Cl_2/MeOH, 20/1). For **18**: ^{1}H NMR ($CDCl_3$) δ (ppm): 7.56−7.50 (m, 4H, benzene ring of DMTr group), 7.48−7.38 (m, 8H, styryl benzene and ethoxybenzene), 7.42 (bd, 8H, $J = 9.0$ Hz, methoxybenzene ring of DMTr group), 7.36−7.20 (m, 6H, benzene ring of DMTr group), 7.06 (d, 2H, $J = 16.2$ Hz, double bond trans linkage), 6.92 (d, 2H, $J = 16.2$ Hz, double bond trans linkage), 6.86 (bd, 4H, $J = 9.0$ Hz, methoxybenzene ring of DMTr group), 6.70 (d, 4H, $J = 8.7$ Hz, methoxybenzene), 3.78 (s, 12H, -OCH_3), 3.76−3.64 (m, 24H, tetraethylene glycol chain), 3.61−3.54 (bt, 4H, $J = 5.4$ Hz, tetraethylene glycol chain), 3.40−3.31 (m, 4H, -NCH_2CH_2CH_2CH_3), 3.29 (bt, 4H, $J = 5.1$ Hz, tetraethylene glycol chain), 1.68−1.56 (m, 4H, -NCH$_2$CH_2CH$_2$CH$_3$), 1.46−1.31 (m, 4H, -NCH$_2$CH$_2$CH_2CH$_3$), 0.997 (t, 6H, $J = 7.2$ Hz, -NCH$_2$CH$_2$CH$_2$CH_3). ^{13}C NMR ($CDC1_3$) δ (ppm): 158.6, 147.7, 145.4, 136.9, 136.6, 130.3, 128.5, 128.4, 128.0, 126.9, 126.5, 125.3, 124.0, 113.3, 112.0, 86.2, 71.1, 71.09, 68.9, 63.5, 55.5, 51.6, 50.9, 29.7, 21.0, 14.5.

HWE reagent tetraethyl 1,4-xylylenediphosphonate was obtained according to literature (*32, 33*).

*E,E-1,4-Bis-4,4′-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)-ethoxy)styryl Benzene (**5**).* A mixture of tetraethyl 1,4-xylylenediphosphonate (1.05 g, 2.78 mmol) and 3 equiv of 4-[2-[2-[2-(2-hydroxyethoxy)ethoxy]ethoxy]ethoxy]benzaldehyde (**10**) (2.45 g, 8.22 mmol) was dried in vacuum overnight and dissolved in anhydrous DMF (25 mL) under argon. To the stirred solution of bisphosphonate and aldehyde at 0 °C was added dropwise a solution of potassium *tert*-butoxide (KOtBu) (922 mg, 3 equal) in anhydrous DMF (15 mL) over 15 min by syringe. After stirring for 0.5 h at 0 °C, the reaction mixture was slowly warmed up to room temperature and stirred for another 12 h, then the reaction was quenched with water. The crude product was collected by suction filtration and the filtrate was evaporated to dryness. The residue was resolved with $CHCl_3$ and washed

with water (2 × 100 mL). The organic layer was dried over Na_2SO_4 and concentrated to dryness. The crude product was then purified by being washed with tetrahydrofuran (THF) twice to give 1.69 g (91%) of the title compound (**5**). ^{1}H NMR ($CDCl_3$) δ (ppm): 7.47 (s, 4H, aromatic ring), 7.45 (d, 4H, J = 8.7 Hz, aromatic ring), 7.06 (d, 2H, J = 16.2 Hz, double bond trans linkage), 6.97 (d, 2H, J = 16.2 Hz, double bond trans linkage), 6.92 (d, 4H, J = 8.7 Hz, aromatic ring), 4.16 (bt, 4H, J = 4.8 Hz, tetraethylene glycol chain), 3.87 (bt, 4H, J = 4.8 Hz, tetraethylene glycol chain), 3.78−3.58 (m, 24H, tetraethylene glycol chain). ^{13}C NMR ($CDC1_3$/CD_3OD, 0.3 mL/0.2 mL) δ (ppm): 158.2, 136.5, 130.3, 127.6, 127.5, 126.4, 126.2, 114.6, 72.5, 70.55, 70.50, 70.38, 70.02, 69.63, 67.3, 61.2. MS (MALDI-TOF): m/z 666.8 $[M]^+$, 667.8 $[M + 1]^+$, 689.7 $[M + Na]^+$.

*Monotritylation of E,E-1,4-Bis-4,4′-(2-(2-(2-(2-hydroxyethoxy)-ethoxy)ethoxy)ethoxy)styryl Benzene (**40**).* *E,E*-1,4-Bis-4,4′-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)styryl benzene (**5**) (375 mg, 0.56 mmol) was dissolved in dry pyridine (50 mL), followed by addition of DMTrCl (415 mg, 1.23 mmol) and DMAP (∼10 mg). The mixture was stirred at room temperature under argon overnight, and TLC monitoring (10/0.75, CH_2Cl_2/MeOH) showed the formation of monosubstituted (R_f 0.32) and disubstituted (R_f 0.74) products, as well as the starting material (R_f 0.14). The reaction mixture was concentrated in vacuum, and the residue was subject to a silica gel column with CH_2Cl_2/MeOH/pyridine (100/5/0.5) as eluents affording the title product (160 mg, yield 30%) as a yellow powder. Meanwhile, the disubstituted fraction was also collected, and further monodetritylation was carried out as follows: A detritylation solution was made by mixing $ZnCl_2$ (1.5 g) into 110 mL of CH_2Cl_2/MeOH (10/1, v/v). Then, the disubstituted compound (150 mg, 0.12 mmol) was dissolved by 50 mL of the detritylation solution, and the reaction mixture was monitored by TLC (20/1, CH_2Cl_2/MeOH). As soon as the spot corresponding to starting material (*E,E*-1,4-bis-4,4′-(2-(2-(2-(2-hydroxyethoxy)-ethoxy)ethoxy)ethoxy)styryl benzene) appeared on the TLC plate, the reaction was quenched by pouring into a saturated aq $NaHCO_3$ solution. The mixture was extracted by $CHCl_3$, and the organic layer was washed with brine, collected, dried over Na_2SO_4, concentrated, and subjected to a silica gel column (100/5/0.5, CH_2Cl_2/MeOH/pyridine) to give the title product **40** (48 mg, yield 42%). On the basis of the starting material, the total yield of the monosubstituted product is 38%. The product is stored with a stabilizer (diisopropylethylamine) under argon at −80 °C. ^{1}H NMR ($CDCl_3$) δ (ppm): 7.46 (s, 4H, aromatic ring of styryl benzene), 7.49−7.38 (m, 6H, aromatic rings of styryl benzene and DMTr), 7.34 (dt, 4H, J_1 = 8.7 Hz, J_2 = 2.3 Hz, methoxylbenzene ring), 7.31−7.15 (m, 3H, benzene ring of DMTr), 7.06 (d, 1H, J = 16.2 Hz, double bond trans linkage), 7.05 (d, 1H, J = 16.2 Hz, double bond trans linkage), 6.96 (d, 1H, J = 16.2 Hz, double bond trans linkage), 6.95 (d, 1H, J = 16.2 Hz, double bond trans linkage), 6.94−6.84 (m, 4 H, aromatic ring of styryl benzene), 6.81 (dt, 4H, J_1 = 8.7 Hz, J_2 = 2.3 Hz, methoxylbenzene ring), 4.19−4.08 (m, 4H, tetraethylene glycol chain), 3.89−3.82 (m, 4H, tetraethylene glycol chain), 3.80−3.58 (m, 28H, C*H*$_3$O and tetraethylene glycol chain), 3.22 (t, 2H, J = 5.1 Hz, DMTrOC*H2*). ^{13}C NMR ($CDC1_3$) δ (ppm): 158.57, 158.55, 158.43, 145.2, 136.74, 136.70, 136.4, 130.47, 130.40, 130.2, 128.3, 128.00, 127.96, 127.87, 127.79, 126.77, 126.67, 126.44, 126.38, 115.0, 113.2, 86.1, 72.7, 71.09, 71.04, 70.98, 70.95, 70.88, 70.81, 70.56, 69.95, 67.64, 63.4, 62.0, 55.4.

*The Phosphoramidite of Monotritylated E,E-1,4-Bis-4,4′-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)ethoxy)styryl Benzene (**43**).* To a solution of monotritylated *E,E*-1,4-bis-4,4′-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)ethoxy)styryl benzene (**40**) (86 mg, 0.089 mmol) in 15 mL CH_2Cl_2 (dry) was added 5 equiv of diisopropylethylamine (0.08 mL). Then, chloro-*N,N*-diisopropylaminocyanoethoxyphosphane (0.04 mL, 0.18 mmol, ∼2 equal) was added dropwise at room temperature under argon. After 20 min of stirring under argon at room temperature, the reaction mixture was diluted with 100 mL of CH_2Cl_2/Et_3N (300/15, v/v), and the organic phase was washed with a saturated aq $NaHCO_3$ solution and brine. The organic layer was dried over Na_2SO_4, filtered, and evaporated to dryness. The residue was subject to a silica gel column (CH_2Cl_2/EtOAc/Et_3N, 3/6/1) to give the title product (88 mg, yield 85%) as a yellow powder, which should be used freshly for the next phosphotriester step in order to achieve a higher coupling yield.

*E,E-1,4-Bis-4,4′-((2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)-ethyl)butylamino)styryl Benzene (**2**).* To a solution of tetraethyl 1,4-xylylenediphosphonate (1.5 g, 3.9 mmol) and 4-*N*-*n*-butyl-*N*-[2-[2-[2-(2-hydroxyethoxy)ethoxy]ethoxy]ethyl]amino benzaldehyde (**13**) (4 g, 11 mmol, 3 equiv) in anhydrous DMF (20 mL) was added KOBut (1.2 g, 11 mmol, 3 equiv) predissolved in DMF (10 mL) dropwise via syringe at 0 °C under argon. After stirring for 0.5 h at 0 °C, the reaction mixture was slowly warmed up to room temperature and stirred for another 12 h, and then the reaction was quenched with water. The crude product was collected by suction filtration and the filtrate was evaporated to dryness. The residue was redissolved with $CHCl_3$ and washed with brine (2 × 100 mL). The organic layer was dried over Na_2SO_4 and concentrated to dryness. The crude product was then purified by chromatography on a silica gel column eluted with EtOAc/MeOH (20/1, v/v) to give the double bond trans linked product (1.54 g, yield 51%). R_f = 0.33 (EtOAc/MeOH, 20/1). ^{1}H NMR ($CDCl_3$) δ (ppm): 7.42 (s, 4H, styryl benzene), 7.36 (bd, 4H, J = 8.7 Hz, ethoxybenzene), 7.02 (d, 2H, J = 16.2 Hz, double bond trans linkage), 6.88 (d, 2H, J = 16.2 Hz, double bond trans linkage), 6.66 (d, 4H, J = 8.7 Hz, ethoxybenzene), 3.76−3.51 (m, 28H, tetraethylene glycol chain), 3.34 (bt, 4H, J = 7.5 Hz, -NC*H*$_2$CH$_2$CH$_2$CH$_3$), 1.65−1.52 (m, 4H, -NCH$_2$C*H*$_2$CH$_2$CH$_3$), 1.44−1.28 (m, 4H, -NCH$_2$-CH$_2$C*H*$_2$CH$_3$), 0.96 (t, 6H, J = 7.5 Hz, -NCH$_2$CH$_2$CH$_2$C*H*$_3$). ^{13}C NMR ($CDC1_3$) δ (ppm): 147.7, 136.8, 128.3, 127.9, 126.4, 125.3, 124.0, 111.9, 72.8, 71.0, 70.9, 70.88, 70.6, 68.8, 62.1, 51.5, 50.7, 29.6, 20.6, 14.4. MS (MALDI-TOF): 776.6 $[M]^+$.

*E,1-(4-((2-(2-(2-(2-(Bis-(4-methoxyphenyl)phenylmethoxy)-ethoxy)ethoxy)ethoxy)ethyl)butylamino)styryl)-E,4-(4-((2-(2-(2-(2-(bis-(4-methoxyphenyl)phenylmethoxy)ethoxy)ethoxy)ethoxy)-ethyl)butylamino)styryl) Benzene (**39**).* *E,E*-1,4-Bis-4,4′-((2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)ethyl)butylamino)styryl benzene (**2**) (1.116 g, 1.44 mmol) was dissolved in dry pyridine (50 mL), followed by addition of DMTrCl (1.55 g, 4.3 mmol, 3 equiv) and DMAP (∼10 mg). The mixture was stirred at room temperature under argon overnight, and TLC monitoring (CH_2Cl_2/MeOH, 400/15, v/v) showed the formation of monosubstituted (R_f = 0.64) and disubstituted (R_f = 0.88) products, as well as the starting material (R_f = 0.31). The reaction mixture was concentrated in vacuum, and the residue was subject to a silica gel column with CH_2Cl_2/MeOH/pyridine (400/15/2) as eluents to give the title product (390 mg, yield 25%) as a yellow powder. Meanwhile, the disubstituted fraction was also collected, and further monodetritylation was carried out as follows: A detritylation solution was made by mixing $ZnCl_2$ (1.5 g) with 110 mL of CH_2Cl_2/MeOH (10/1, v/v). Then, the disubstituted compound (1150 mg, 0.83 mmol) was dissolved by 50 mL of the detritylation solution and the reaction mixture was monitored by TLC (CH_2Cl_2/MeOH, 400/15). As soon as the spot corresponding to starting matrerial **2** appeared on the TLC plate, the reaction was quenched by pouring into a saturated aq $NaHCO_3$ solution. The mixture was extracted by chloroform, and the organic layer was washed with brine, collected, dried over Na_2-

SO_4, concentrated, and subjected to a silica gel column (CH_2Cl_2/MeOH/pyridine, 400/15/2) to give the title product (470 mg, yield 53%).

On the basis of the starting material, the total yield of the monosubstituted product is 55%. The product is stored with a stabilizer (diisopropylethylamine) under argon at −80 °C. ^{1}H NMR ($CDCl_3$) δ (ppm): 7.48−7.44 (m, 2H, benzene ring of DMTr group), 7.42 (bs, 4H, styryl benzene), 7.40−7.32 (m, 4H, butylaminobenzene), 7.34 (bd, 4H, J = 9.0 Hz, methoxybenzene ring of DMTr group), 7.31−7.24 (m, 2H, benzene ring of DMTr group), 7.19 (bt, 1H, J = 7.2 Hz, benzene ring of DMTr group), 7.02 (d, 1H, J = 16.2 Hz, double bond trans linkage), 7.01 (d, 1H, J = 15.9 Hz, double bond trans linkage), 6.88 (d, 2H, J = 16.2 Hz, double bond trans linkage), 6.87 (d, 1H, J = 15.9 Hz, double bond trans linkage), 6.81 (bd, 4H, J = 9.0 Hz, methoxybenzene ring of DMTr group), 6.67 (d, 2H, J = 8.7 Hz, butylaminobenzene), 6.64 (d, 2H, J = 8.7 Hz, butylaminobenzene), 3.77 (s, 6H, -OCH_3), 3.76−3.50 (m, 30H, tetraethylene glycol chain), 3.38−3.26 (m, 4H, -NCH_2CH$_2$CH$_2$-CH$_3$), 3.22 (bt, 2H, J = 5.1 Hz, tetraethylene glycol chain), 1.64−1.52 (m, 4H, -NCH$_2$CH_2CH$_2$CH$_3$), 1.42−1.28 (m, 4H, -NCH$_2$CH$_2$CH_2CH$_3$), 0.96 (t, 3H, J = 7.2 Hz, -NCH$_2$CH$_2$-CH$_2$CH_3), 0.94 (t, 3H, J = 7.2 Hz, -NCH$_2$CH$_2$CH$_2$CH_3). ^{13}C NMR ($CDC1_3$) δ (ppm): 158.5, 147.7, 145.3, 136.9, 136.9, 136.5, 130.3, 128.4, 128.2, 128.2, 127.94, 127.91, 126.9, 126.4, 125.3, 125.3, 123.9, 123.9, 113.2, 111.92, 111.89, 86.2, 72.8, 71.1, 71.0, 70.98, 70.95, 70.88, 70.6, 68.8, 63.4, 62.1, 55.5, 51.5, 50.8, 29.6, 20.6, 14.4.

*The Phosphoramidite of E,1-(4-((2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)ethoxy)ethoxy)ethoxy)ethyl)butylamino)-styryl)-E,4-(4-((2-(2-(2-(2-(Bis(4-methoxyphenyl)phenylmethoxy)-ethoxy)ethoxy)ethoxy)ethyl)butylamino)styryl) Benzene (**41**).* To a solution of *E*,1-(4-((2-(2-(2-(2-(bis(4-methoxyphenyl)phenyl-methoxy)ethoxy)ethoxy)ethoxy)ethyl)butylamino)styryl)-*E*,4-(4-((2-(2-(2-(2-(bis(4-methoxyphenyl)phenylmethoxy)ethoxy)ethoxy)-ethoxy)ethyl)butylamino)styryl) benzene (**39**) (770 mg, 0.71 mmol) in 80 mL CH_2Cl_2 (dry) was added 7 equiv of diisopropylethylamine (0.8 mL). Then, chloro-*N*,*N*-diisopropylaminocyanoethoxyphosphane (0.47 mL, 2.1 mmol, ∼3 equiv) was added dropwise at room temperature under argon. After 20 min of stirring under argon at room temperature, the reaction mixture was diluted with 100 mL of CH_2Cl_2/Et_3N (300/15, v/v), and the organic phase was washed with a saturated aq $NaHCO_3$ solution and brine. The organic layer was dried over Na_2SO_4, filtered, and evaporated to dryness. The residue was subject to a silica gel column (CH_2Cl_2/EtOAc/Et_3N, 3/6/1) to give the title product (870 mg, yield 96%) as a yellow powder, which should be used freshly for the next phosphotriester step in order to achieve a higher coupling yield. ^{1}H NMR ($CDCl_3$) δ (ppm): 7.48−7.44 (m, 2H, benzene ring of DMTr group), 7.42 (bs, 4H, styryl benzene), 7.40−7.32 (m, 4H, butylaminobenzene), 7.34 (bd, 4H, J = 9.0 Hz, methoxybenzene ring of DMTr group), 7.31−7.15 (m, 3H, benzene ring of DMTr group), 7.01 (d, 1H, J = 16.2 Hz, double bond trans linkage), 7.00 (d, 1H, J = 16.2 Hz, double bond trans linkage), 6.88 (d, 2H, J = 16.2 Hz, double bond trans linkage), 6.87 (d, 1H, J = 16.2 Hz, double bond trans linkage), 6.81 (bd, 4H, J = 9.0 Hz, methoxybenzene ring of DMTr group), 6.67 (d, 2H, J = 8.7 Hz, butylaminobenzene), 6.64 (d, 2H, J = 8.7 Hz, butylaminobenzene), 3.77 (s, 6H, -OCH_3), 3.90−3.75 (m, 2H, -OCH_2CH$_2$CN), 3.70−3.48 (m, 32H, -N(CH(CH$_3$)$_2$)$_2$ and tetraethylene glycol chain), 3.38−3.26 (m, 4H, -NCH_2CH$_2$CH$_2$CH$_3$), 3.22 (bt, 2H, J = 5.1 Hz, tetraethylene glycol chain), 2.63 (bt, 2H, J = 6.5 Hz, -OCH$_2$CH_2-CN), 1.64−1.52 (m, 4H, -NCH$_2$CH_2CH$_2$CH$_3$), 1.42−1.28 (m, 4H, -NCH$_2$CH$_2$CH_2CH$_3$), 1.19 (d, 6H, J = 6.8 Hz, -CH(CH_3)$_2$), 1.17 (d, 2H, J = 6.8 Hz, -CH(CH_3)$_2$), 0.96 (t, 3H, J = 7.2 Hz, -NCH$_2$CH$_2$CH$_2$CH_3), 0.94 (t, 3H, J = 7.2 Hz, -NCH$_2$CH$_2$-CH$_2$CH_3). ^{13}C NMR ($CDC1_3$) δ (ppm): 158.6, 147.7, 145.3, 136.9, 136.6, 130.3, 128.4, 128.3, 128.3, 127.98, 127.95, 126.9, 126.4, 125.37, 125.32, 124.0, 123.95, 113.3, 111.9, 86.1, 71.5, 71.4, 71.0, 70.98, 70.94, 70.90, 70.8, 68.8, 63.4, 62.9, 62.7, 58.9, 58.6, 55.4, 51.4, 50.7, 43.4, 43.2, 29.6, 24.93, 24.86, 24.83, 24.77, 20.6, 20.5, 14.4, 14.3. ^{31}P NMR ($CDC1_3$) δ (ppm): 149.6.

*(4-(2-(4-(Butyl-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)ethyl)-amino)phenyl)vinyl)benzyl)phosphonic Acid Diethyl Ester (**19**).* To a solution of tetraethyl 1,4-xylylenediphosphonate (466 mg, 1.2 mmol, 1.2 equiv) and 4-*N*-*n*-butyl-*N*-[2-[2-[2-(2-hydroxy-ethoxy)ethoxy]ethoxy]ethyl]amino benzaldehyde (**13**) (360 mg, 1.1 mmol) in anhydrous DMF (15 mL) was added KOBut (123 mg, 1.1 mmol, 1 equiv) predissolved in DMF (4 mL) dropwise via syringe at 0 °C under argon. After stirring for 0.5 h at 0 °C, the reaction mixture was slowly warmed up to room temperature and stirred for another 12 h. The crude product was then purified by chromatography on a silica gel column eluted with EtOAc/MeOH (20/1, v/v) to give the double bond trans linked product **2** (130 mg, yield 31%) and the title product (trans/cis 3/1) in a yield of 45% (281 mg). R_f = 0.25 (EtOAc/MeOH, 20/1). ^{1}H NMR ($CDCl_3$) δ (ppm): double bond trans/cis linkage (3/1): 7.40 (d, 2H (3/4), J = 8.1 Hz, aromatic ring), 7.35 (d, 2H (3/4), J = 8.7 Hz, aromatic ring), 7.28 (d, 2H (1/4), J = 8.4 Hz, aromatic ring), 7.24 (dd, 2H (3/4), J_1 = 8.1 Hz, J_2 = 2.4 Hz, aromatic ring), 7.16 (dd, 2H (1/4), J = 8.4 Hz, aromatic ring), 7.10 (d, 2H (1/4), J = 8.7 Hz, aromatic ring), 7.00 (d, 1H (3/4), J = 16.5 Hz, double bond trans linkage), 6.84 (d, 1H (3/4), J = 16.5 Hz, double bond trans linkage), 6.65 (d, 2H (3/4), J = 8.7 Hz, aromatic ring), 6.48 (d, 2H (1/4), J = 8.7 Hz, aromatic ring), 6.42 (d, 1H (1/4), J = 12.3 Hz, double bond cis linkage), 6.33 (bd, 1H (1/4), J = 12.3 Hz, double bond cis linkage), 4.06−3.95 (m, 4H, -OCH_2CH$_3$), 3.74−3.46 (m, 16H, tetraethylene glycol chain), 3.35 (bt, 2H (3/4), J = 7.5 Hz, -NCH_2-CH$_2$CH$_2$CH$_3$), 3.27 (bt, 2H (1/4), J = 7.5 Hz, -NCH_2CH$_2$CH$_2$-CH$_3$), 3.17 (bs, 1H (3/4), benzyl), 3.16 (bs, 1H (1/4), benzyl), 3.10 (bs, 1H (3/4), benzyl), 3.08 (bs, 1H (1/4), benzyl), 1.63−1.50 (m, 2H, -NCH$_2$CH_2CH$_2$CH$_3$), 1.40−1.28 (m, 2H, -NCH$_2$-CH$_2$CH_2CH$_3$), 1.24 (t, 6H, J = 7.1 Hz, -OCH$_2$CH_3), 0.95 (t, 3H (3/4), J = 7.2 Hz, -NCH$_2$CH$_2$CH$_2$CH_3), 0.92 (t, 3H (1/4), J = 7.2 Hz, -NCH$_2$CH$_2$CH$_2$CH_3). *Monotritylation of E,E-4-Dicyanomethylene-2,6-bis-p-N,N′-n-butyl-N,N′-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)ethyl)-aminostyryl Pyran (**38**).* *E,E*-4-Dicyanomethylene-2,6-bis-*p*-*N,N′*-*n*-butyl-*N,N′*-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)-ethyl)aminostyryl pyran (**6**) (538 mg, 0.64 mmol) was dissolved in dry pyridine (50 mL), followed by addition of 3 equiv of DMTrCl (684 mg) and DMAP (∼10 mg). The mixture was stirred at room temperature under argon for 5 days, and TLC monitoring (20/1, CH_2Cl_2/MeOH) showed the formation of monosubstituted (R_f = 0.25) and disubstituted (R_f = 0.98) products, as well as the starting material (R_f = 0.09). The reaction mixture was concentrated in vacuum, and the residue was directly subjected to a silica gel column using the gradient elution technique with CH_2Cl_2/MeOH/pyridine (500/10/3 to 500/20/3) as eluents affording the monosubstituted product (250 mg,

yield 35%), disubstituted product, and recovered starting material (123 mg). Meanwhile, the disubstituted fraction was collected, and further monodetritylation was carried out according to the following procedure: A detritylation solution was made by mixing $ZnCl_2$ (1.5 g) with 110 mL of CH_2Cl_2/MeOH (10/1, v/v). Then, the crude disubstituted compound (~900 mg) was dissolved by 50 mL of the detritylation solution, and the reaction mixture was monitored by TLC (20/1, CH_2Cl_2/MeOH). As soon as the spot corresponding to the starting material (*E,E*-4-dicyanomethylene-2,6-bis-*p*-*N,N′*-*n*-butyl-*N,N′*-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)ethyl)aminostyryl pyran) appeared on the TLC plate, the reaction was quenched by addition of a saturated aq $NaHCO_3$ solution (100 mL). The mixture was extracted by chloroform, and the organic layer was washed with brine, collected, dried over Na_2SO_4, concentrated, and subjected to a silica gel column (500/10/3, CH_2Cl_2/MeOH/pyridine) to give the title product **38** (128 mg, yield 17.5%). If the recovered starting material was counted, the total yield of the monotritylation would be 67% based on the consumed starting material. ^{1}H NMR ($CDCl_3$) δ (ppm): 7.49−7.38 (m, 8H, aromatic rings and double bond trans linkage), 7.34 (dt, 4H, $J_1 = 2.7$ Hz, $J_2 =$ 9 Hz, methoxylbenzene ring), 7.31−7.15 (m, 3H, benzene ring), 6.81 (dt, 4H, $J_1 = 2.7$ Hz, $J_2 = 9$ Hz, methoxylbenzene ring), 6.69 (d, 2H, $J = 8.7$ Hz, benzene ring), 6.66 (d, 2H, $J = 9.0$ Hz, benzene ring), 6.54 (d, 1H, $J = 2.1$ Hz, pyran ring), 6.52 (d, 1H, $J = 2.1$ Hz, pyran ring), 6.48 (d, 1H, $J = 15.9$ Hz, double bond trans linkage), 6.46 (d, 1H, $J = 15.9$ Hz, double bond trans linkage), 3.77 (s, 6H, C*H*$_3$O), 3.56−3.50 (m, 30H, tetraethylene glycol chain), 3.44−3.31 (m, 4H, *n*-butyl chain), 3.22 (t, 2H, $J = 5.1$ Hz, tetraethylene glycol chain), 1.69−1.49 (m, 4H, *n*-butyl chain), 1.48−1.42 (m, 4H, *n*-butyl chain), 0.97 (t, 3H, $J = 7.5$ Hz, *n*-butyl chain), 0.96 (t, 3H, $J = 7.5$ Hz, *n*-butyl chain). ^{13}C NMR ($CDC1_3$) δ (ppm): 159.5, 158.4, 156.2, 149.8, 145.1, 138.2, 136.4, 130.2, 129.9, 128.3, 127.8, 126.7, 122.2, 122.1, 116.5, 113.1, 112.94, 112.88, 111.8, 111.7, 105.4, 86.1, 72.7, 71.0, 70.92, 70.84, 70.76, 70.5, 68.6, 63.3, 61.9, 56.1, 55.4, 51.4, 50.6, 29.4, 20.5, 14.3. *The Phosphoramidite of Monotritylated E,E-4-Dicyanomethylene-2,6-bis-p-N,N′-n-butyl-N,N′-(2-(2-(2-(2-hydroxyethoxy)-ethoxy)ethoxy)ethyl)aminostyryl Pyran (**42**).* To a solution of monotritylated *E,E*-4-dicyanomethylene-2,6-bis-*p*-N,N′-*n*-butyl-N,N′-(2-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)ethyl)-aminostyryl pyran (**38**) (200 mg, 0.17 mmol) in dry CH_2Cl_2 (20 mL) was added 2.7 equiv of diisopropylethylamine (0.08 mL). Then, chloro-*N,N*-diisopropylaminocyanoethoxyphosphane (0.05 mL, ~1.2 equiv) was added dropwise at room temperature under argon. After 20 min of stirring under argon at room temperature, the reaction mixture was diluted with CH_2Cl_2/Et_3N (300/15, v/v) 100 mL, and the organic phase was washed with a saturated aq $NaHCO_3$ solution and brine. The organic layer was dried over Na_2SO_4, filtered, and evaporated to dryness. The residue was immediately subjected to a silica gel column (CH_2Cl_2/EtOAc/Et_3N, 3/6/1) to give the title product (200 mg, yield 88%) as a red powder, which should be used freshly for the next phosphotriester step in order to achieve a higher coupling yield. ^{1}H NMR ($CDCl_3$) δ (ppm): 7.48−7.38 (m, 8H, aromatic rings and double bond trans linkage), 7.34 (dt, 4H, $J_1 = 2.4$ Hz, $J_2 = 9$ Hz, methoxylbenzene ring), 7.31−7.15 (m, 3H, benzene ring of DMTr group), 6.81 (dt, 4H, $J_1 = 2.4$ Hz, $J_2 =$ 9 Hz, methoxylbenzene ring), 6.69 (d, 2H, $J = 8.7$ Hz, benzene ring), 6.67 (d, 2H, $J = 9.0$ Hz, benzene ring), 6.56 (d, 1H, $J =$ 2.1 Hz, pyran ring), 6.54 (d, 1H, $J = 2.1$ Hz, pyran ring), 6.50 (d, 1H, $J = 15.9$ Hz, double bond trans linkage), 6.48 (d, 1H, $J = 15.6$ Hz, double bond trans linkage), 3.91−3.70 (m, 4H, -C*H*$_2$CH$_2$CN, -C*H*(CH$_3$)$_2$), 3.77 (s, 6H, C*H*$_3$O), 3.70−3.50 (m, 30H, tetraethylene glycol chain), 3.44−3.31 (m, 4H, -NC*H*$_2$-CH$_2$CH$_2$CH$_3$), 3.22 (t, 2H, $J = 5.4$ Hz, tetraethylene glycol chain), 2.64 (t, 2H, $J = 6.5$ Hz, -CH$_2$C*H*$_2$CN), 1.70−1.52 (m, 4H, -NCH$_2$C*H*$_2$CH$_2$CH$_3$), 1.48−1.30 (m, 4H, -NCH$_2$CH$_2$C*H*$_2$-CH$_3$), 1.18 (d, 6H, $J = 6.9$ Hz, -CH(C*H*$_3$)$_2$), 1.17 (d, 6H, $J =$ 6.6 Hz, -CH(C*H*$_3$)$_2$), 0.97 (t, 3H, $J = 7.5$ Hz, -NCH$_2$CH$_2$-CH$_2$C*H*$_3$), 0.96 (t, 3H, $J = 7.5$ Hz, -NCH$_2$CH$_2$CH$_2$C*H*$_3$). ^{13}C NMR ($CDC1_3$) δ (ppm): 159.2, 158.1, 155.9, 149.5, 144.9, 137.9, 136.1, 129.9, 129.6, 128.0, 127.5, 126.5, 121.9, 121.8, 117.6, 116.2, 112.8, 112.7, 111.5, 105.1, 85.8, 71.2, 71.1, 70.7, 70.6, 70.53, 70.49, 68.3, 63.0, 62.6, 62.4, 58.5, 58.3, 55.9, 55.1, 51.1, 50.3, 46.1, 43.1, 42.9, 29.1, 24.65, 24.58, 24.55, 24.49, 20.3, 20.24, 20.18, 14.0. ^{31}P NMR ($CDC1_3$) δ (ppm): 149.5.

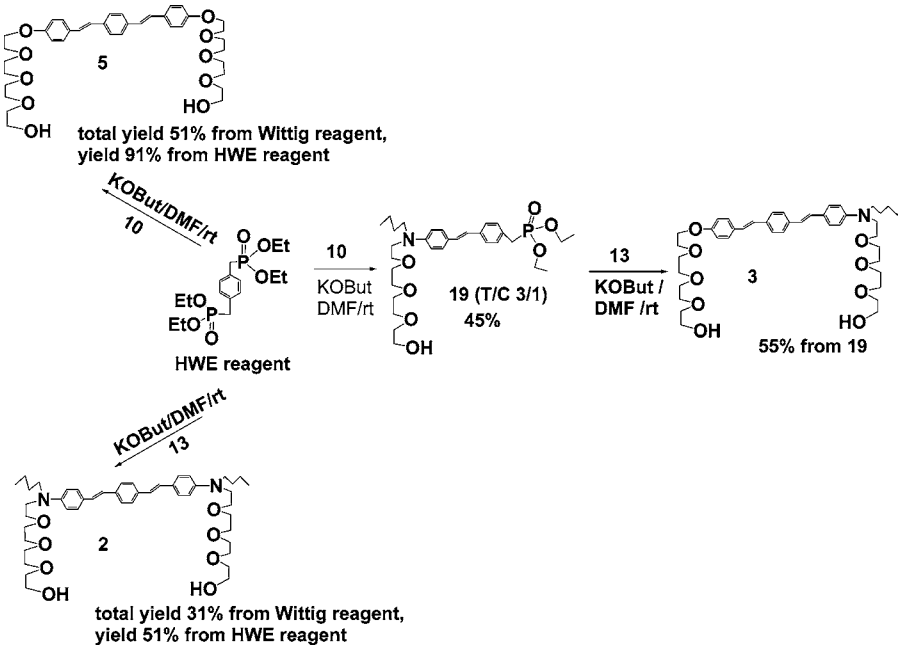
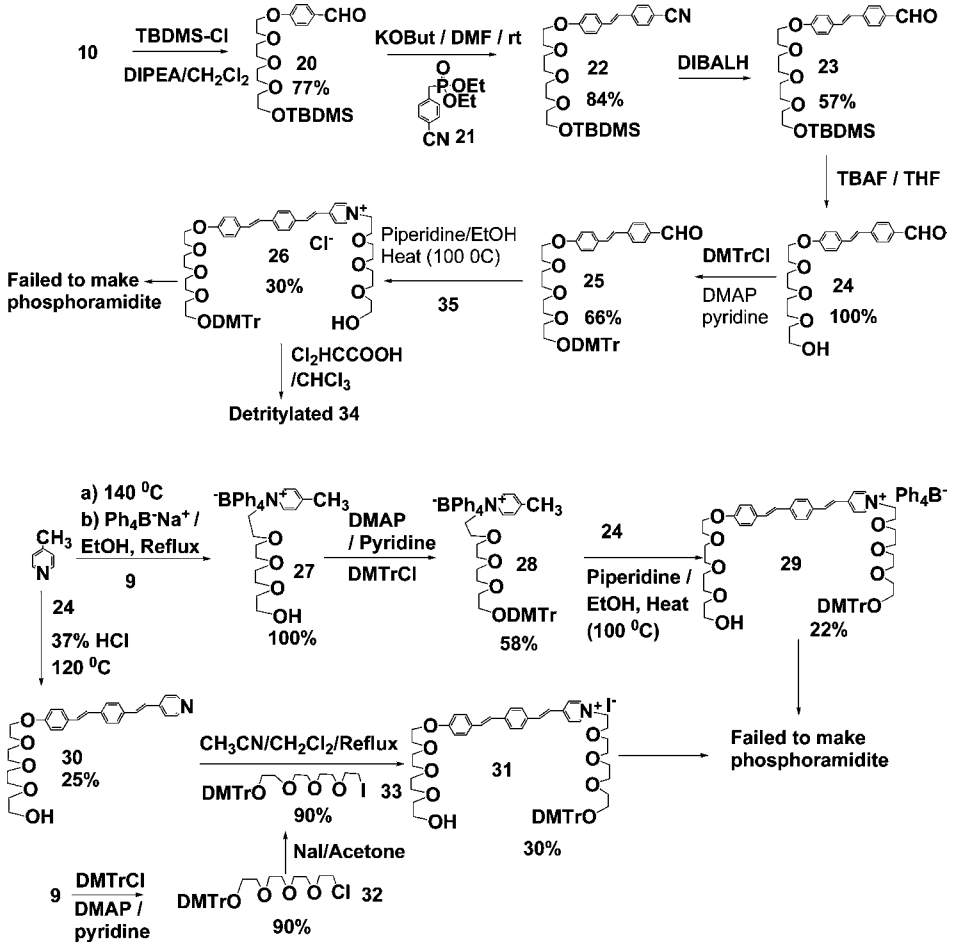
Solid-Phase Synthesis of DNA−Chromophore Conjugates. The solid-phase syntheses were carried out on an Expedite Nucleic Acid Syntheses System. The DNA bases were synthesized on either glass beads or polystyrene spheres using software protocol supplied by PerSeptive Biosystems (Framingham, MA), and the phosphoramidite reagents of DNA bases were obtained from Applied Biosystems. The phosphoramidite reagents of organic chromophores were synthesized according to procedures described in this report, and their solid-phase syntheses were carried out using custom protocol in order to improve the reaction yields. Typically, the phosphoramidite concentrations of the organic dyes used for the solid-phase syntheses were greater than 40 mg/mL. Standard DNA base coupling delivers the phosphoramidite reagent with activator to the

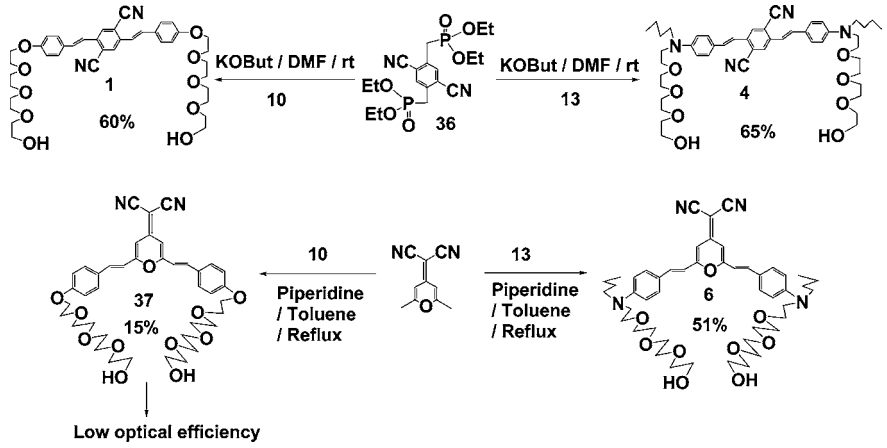


Scheme 1

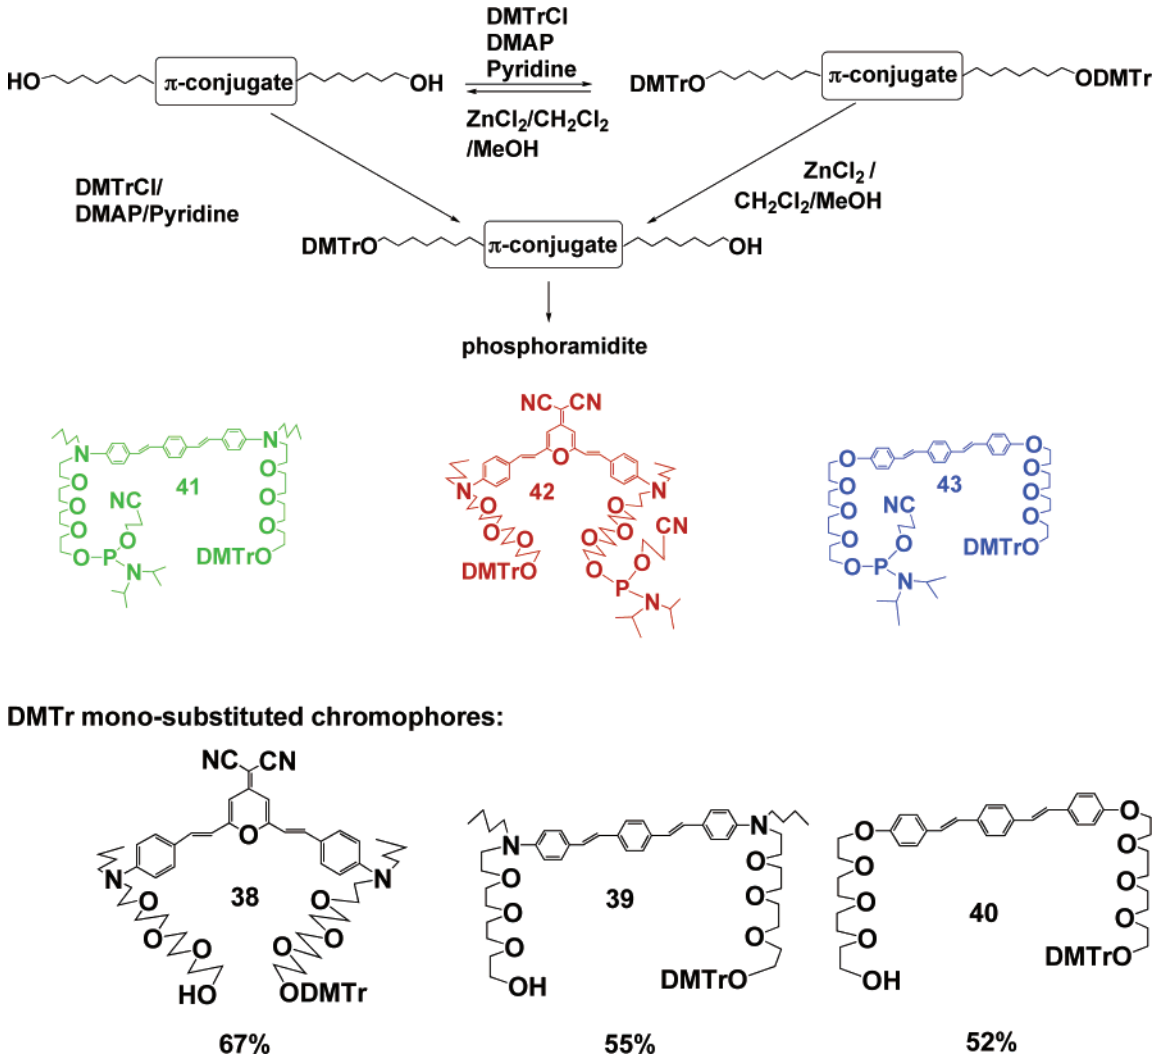


Scheme 2

Scheme 3



Scheme 4



solid-phase column immediately and allows 47 s for coupling reaction. This reaction time is not adequate for coupling chromophoric phosphoramidite to DNA bases, and hence, the chromophoric coupling protocol was modified by delivering the phosphoramidite reagents to the column over a 4 s period (instead of immediately) and the reaction time was extended to 140 s (instead of 47 s). For a high yield of coupling, phosphoramidite reagents must be prepared and purified with silica gel columns immediately before carrying out the solid-phase syntheses. Using the modified protocol described here, the yield of the coupling reaction is typically greater than 80% as indicated by the trityl data.

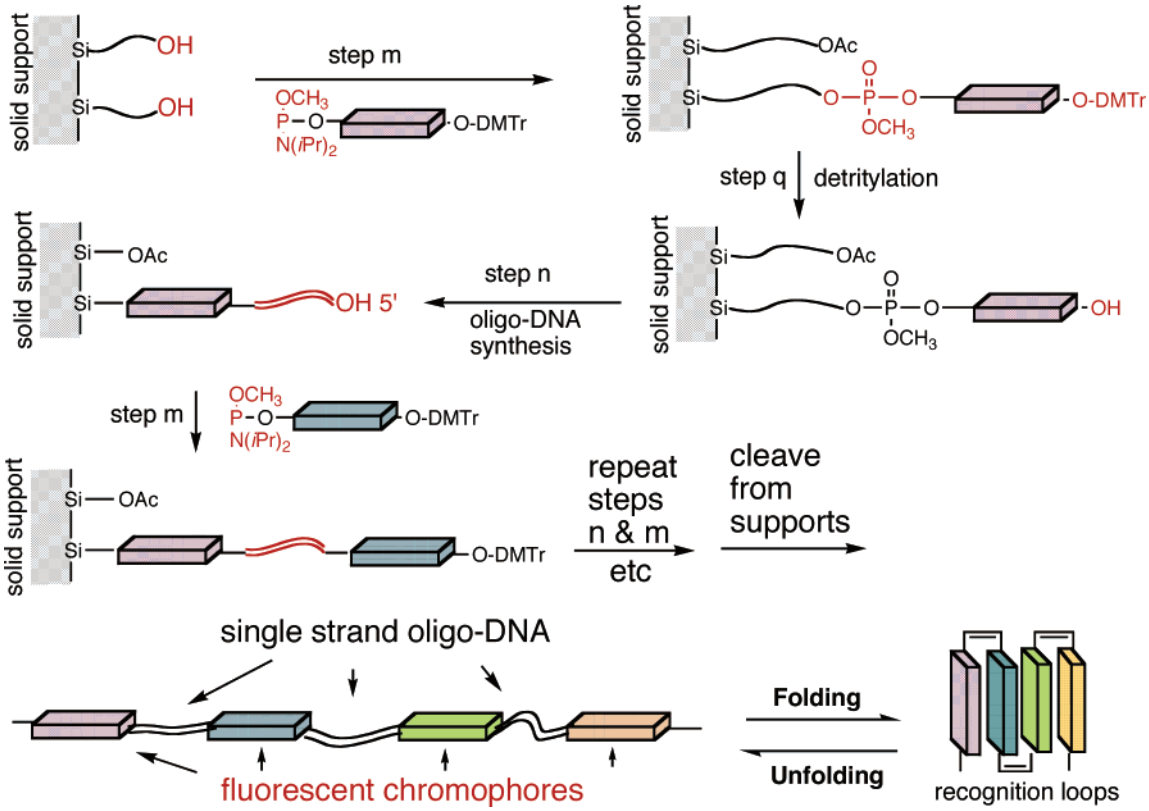
Scheme 6



RESULTS AND DISCUSSION

The strategy for incorporating rigid dyes, which typically have poor solubility, into biomolecules is to functionalize them with very soluble ethylene glycol chains. In Scheme 1, all precursor compounds with flexible ethylene glycol chains were synthesized (*19*, *20*) as the appropriate benzaldehyde **7**−**14**, which can be further condensed with ylids to make large π-conjugated systems. The experimental procedures for the synthesis are described in the Experimental Section.

Our initial attempt was to use commercially available monochlorotriethylene glycol as the precursor for introducing soluble groups. Accordingly, in Scheme 2, compound **15** was synthesized using the conventional Wittig reaction with poor yield, and its detritylated derivative **16** is insoluble in organic solvents. The poor solubility of the final product **16** hinders further chemical manipulation and promotes us to make a longer tetraethylene glycol chain for more soluble amphiphilic chromophores. Again, the Wittig reaction was used in the initial

Scheme 7

coupling reaction between the desired aldehyde **11** and the bis-ylid precursor. The reaction yielded only 15% of all-trans **17**, mainly due to the formation of cis−trans isomers of **17** at low temperature (−78 °C). Detritylation of **17** yielded the final product **5**, which could be dissolved in chloroform or dichloromethane. Following the above procedure, soluble compound **2** was also synthesized. Comparing the solubility difference between **16** and **2** or **5**, we have concluded that tetraethylene glycol was an excellent flexible spacer for enhancing solubility of rigid chromophores. Furthermore, tetraethylene glycol proved to be an excellent hinge when inserted into the DNA sequence, and the influence of the spacers on the folding or unfolding behaviors of resulting hybrid foldamers was minimal.

However, the above method for synthesizing all-trans double bond π-conjugates still needs improvement. Thus, the Horner−Wadsworth−Emmons (HWE) reaction was used instead of the conventional Wittig reaction, and all three bis(styryl)benzene derivatives were synthesized again by condensing the phosphonate ylid with corresponding benzaldehyde derivatives as shown in Scheme 3. The HWE reagent (phosphonate ylid) was readily prepared from α,α′-dibromo-*p*-xylene according to the reported procedure (*21*). In dried DMF, 3 equiv of desired aldehyde **10** or **13** was reacted with phosphonate ylid using KOBut as the promoter at room temperature to give the final product **2** or **5** in a high yield. Even with the bulky tetraethylene glycol chain, the HWE condition still favored the formation of all-trans double bond configuration. To prepare polar chromophore **3**, intermediate **19** was prepared following the same procedure for **2** and **5** except that 1 equiv of benzaldehyde **10** was used. Then, final stepwise coupling reaction of **19** and **13** afforded the asymmetric π-conjugate **3**.

It was reported (*22*) that different donor or acceptor substituents on the ends of bis(styryl)benezene π-conjugate could significantly change their emission colors because of the electron donating or withdrawing effects. The oxygen substituents on both ends of the π-conjugate in **5** can be regarded as weak electron donors, involving in the symmetric electron transfer from both ends to the middle of the conjugated system; compound **5** has bright blue fluorescence. In **2**, *n*-butyl amino groups were used to terminate the π-conjugate instead of an oxygen atom as the electron donor to make a stronger donor-π-donor system, which gives green fluorescence. The trend appears that stronger electron donating groups will red-shift fluorescence emission. Following this trend, the featured asymmetric compound **3** has a fluorescence emission wavelength between those of **2** and **5**. The fact that asymmetric compound **3** does not have a fluorescence emission longer than that of symmetric compound **2** may suggest that an acceptor is required in the asymmetric compound in order to have yellow to red fluorescence. With efficient blue fluorophores in hand, our efforts have shifted to prepare similar bis(styryl)benzene structures with red fluorescent emission; the strategy is to vary the structure of the middle π-conjugated bridge and tune the electronic properties of the end substituents. In Scheme 4, three asymmetric bis(styryl)benzene structures were synthesized with the pyridinium ion as an extremely strong electron acceptor in the π-conjugated structure (**20**−**33**); the resulting D-π-A structures have yellow-orange emissions (*23*−*26*). However, the phosphoramidite products of all three precursors, **26**, **29**, and **31**, were not isolated because of low mobility on the silica column despite the fact that three different counterions with various polarity and DMTr protection were attempted (Experimental Section).

Scheme 5 shows the syntheses of the chromophore blocks with red-orange fluorescence based on a donor-acceptor-donor (D-A-D) structure with electron rich-poor-rich distribution. Phosphonate ylid **36** was synthesized as reported previously (*27*, *28*). The same HWE procedures as described for preparation of **2** and **5** were carried out except that tetraethyl 1,4-xylylenediphosphonate was replaced by **36**; consequently, **1** and **4** were synthesized in good yields. Because of the electron withdrawing properties of the dicyano groups, the hydrogen atoms on the methyl group of (2,6-dimethyl-4*H*-pyran-4-ylidene)malononitrile are acidic, and in the presence of base,

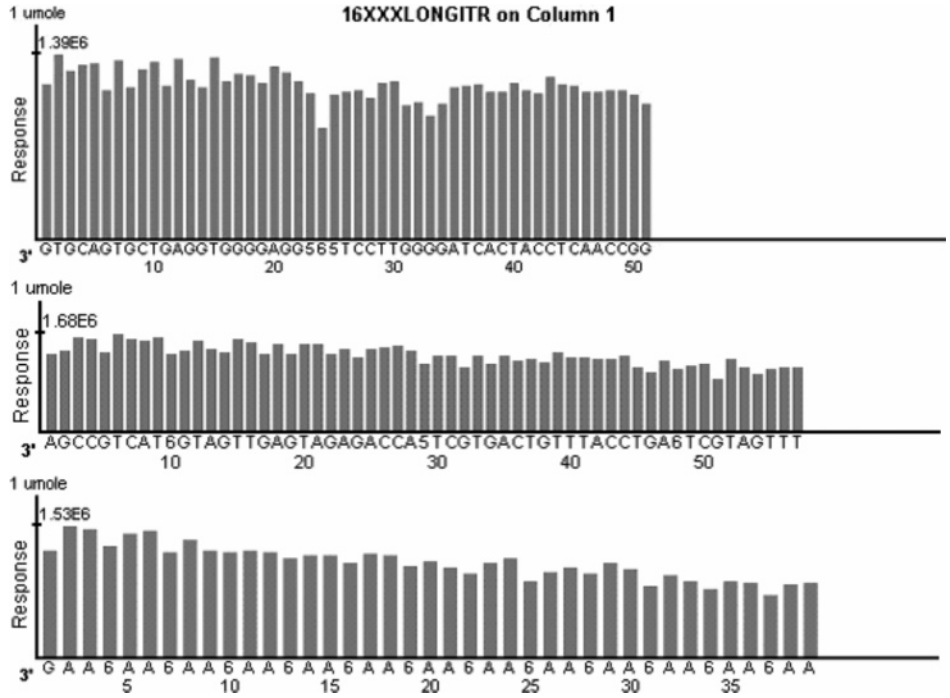


Figure 3. A, T, C, and G stand for single DNA bases linked by phosphotriester and number "5" or "6" stands for synthetic chromophores. Specifically, number "6" here is the red-emitting chromophore with TEG chains linked by phosphotriester (compound **42**) with either DNA bases or chromophores, and number "5" represents the blue-emitting chromophore with TEG chains linked by phosphotriester (compound **41**) with other DNA bases or chromophores. Note that the coupling yields for the two chromophores to DNA bases are almost as high as those of the coupling efficiency of DNA bases. Conversely, coupling of DNA bases to the chromophores is equally high.

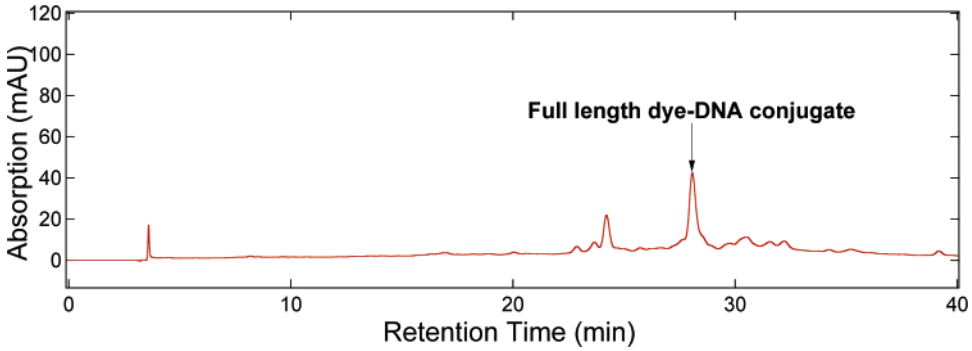

Figure 4. HPLC purification of a DNA 40mer containing one orange-fluorescence dye (compound **42**) and two blue-fluorescence dyes (compound **43**) in the sequence. Full-length DNA sequence containing three organic dyes has an elution time of approximate 28 min while using a linear gradient of H_2O and acetonitrile containing 0.1 M TEAA (triethylamine acetate).

the methyl groups can directly react with a desired aldehyde in a Knoevenagel condensation. The simplicity of the Knoevenagel condition leads to compounds **6** and **37** in one step (*18*). While compound **37** has low optical density and weak fluorescence properties, compound **6** emits impressive red fluorescence with peak maximum at 612 nm in organic solvents.

One important requirement for these fluorescent chromophores is to have asymmetric substitutions at either end of the rodlike or Y-shaped structure. This way, they can be protected with a DMTr group on one end and activated with a phosphoramidite group on the other. Such DMTr-protected and phosphoramidite-activated chromophores are suitable for incorporation into automated DNA synthesis.

Therefore, one of the key steps is the phosphoramidite activation and its efficiency will depend on the yield and purity of its precursor—monotritylated derivative of the chromophoric building blocks. To improve the yield of the monotritylated product, we have developed an efficient route as shown in Scheme 6. In a typical monotritylation process, two products were formed: monotritylated product and bistritylated product. The monotritylated product was purified as the desired product, while the bistritylated product can be further converted to the monotritylated product using a weak Lewis acid zinc chloride as the detritylation reagent (*29*).

A typical detritylation solution consists of $ZnCl_2$ (1.5 g) with 110 mL of CH_2Cl_2/MeOH (10/1, v/v). The detritylation procedure involves treating the bistritylated product in the detritylation solution. The reaction can be monitored with TLC, and typically detritylation finishes within an hour. Once the spot corresponding to the original, nonsubstituted chromophore appeared on the TLC plate, the reaction was quenched by pouring its contents into an aqueous solution saturated with $NaHCO_3$. After chromatography, the yield of the monotritylated product exceeded 40% based on the bistritylated compound. While combining with the direct monotritylation product, the total yield of the monotritylated product had been significantly improved (from ~30% to 56−77%). This method can

Table 1. UV and Fluorescence Data[a]

chromophore	absorbance (λ_{max}) wavelength (nm)	excitation wavelength (nm)	emission (λ_{max}^{EM}) wavelength (nm)
1	379	379	469
2	398	399	473

[a] The solvent used is chloroform; the concentrations of various chromophores are ~10 μM.

be applied to large-scale preparation of monotritylated derivatives of chromophoric building blocks, and the resulting monosubstituted products can be kept in an −80 °C freezer under basic atmosphere for several months without noticeable decomposition.

Finally, a few fluorescent chromophores, which have orthogonal fluorescence emission, were chosen for phosphoramidite activation. They are compound **38**, the precursor **6** of which emits red fluorescence with an intensity maximum at 612 nm, compound **40**, the precursor **5** of which emits blue fluorescence with an emission maximum at 430 nm, and compound **39**, the precursor **2** of which emits (at 473 nm) in the blue-green region (Table 1). The fluorescence spectra of the red-blue or red-blue/green FRET pairs have little overlap, hence are orthogonal in fluorescent emissions. For efficient FRET pairs, the absorption maximum of the red-fluorescence chromophore (488 nm) should overlap perfectly with the fluorescent emission of the blue-fluorescence donor.

The phosphoramidite derivatives were made according to our prior report (*30*). It is worth mentioning that methylene chloride or methylene chloride/acetonitrile (1/1) was employed as the reaction solvent to ensure the maximum solubility of the chromophore precursor, as is the key point to reach the highest yield of the phosphoramidite derivatives. Also, 5−10% triethylamine in the system was necessary to stabilize the phosphoramidite compounds. The procedure describing the synthesis of phosphoramidites is presented in the Experimental Section. The yields of crude phosphoramidites from the monotritylated derivatives usually exceeded 90%, suitable for solid-state synthesis of phosphoramidite chemistry. The stability of these phosphoramidite chromophores was not optimum in solutions such that the phosphoramidite reagents must be prepared immediately before solid-phase synthesis. Because of the presence of tetraethylene glycol units, the phosphoramidite reagents usually cannot be purified with crystallization, but flash chromatography was effective for their final purification before usage. Additionally, the dumbbell-shaped spots on TLC plates, which correspond to the two steric isomers due to the chiral phosphorus atom in the phosphoramidite of normal DNA bases, were hardly observed in these phosphoramidite chromophores.

Solid-phase synthesis was employed to incorporate the final chromophoric candidates into single-strand DNA backbones as shown in Scheme 7. Our ability to synthesize asymmetrically substituted chromophoric building blocks has established a firm foundation for preparation of foldamers with a controlled molecular orientation, well-defined biological and synthetic sequences. All fluorescent chromophores have been functionalized with hydroxyl groups at their termini. Furthermore, one hydroxyl group will be protected with DMTr and the other will be activated with the β-cyanoethyl phosphoramidite group.

Foldamer synthesis employs the same strategy as DNA synthesis, i.e., one end of the chromophore is activated with phosphoramidite group for attacking the hydroxyl group at the growing chain terminal, and the other end can be regenerated for chain growth by removing the DMTr protected hydroxyl group. The essential steps are coupling between a chain-terminal hydroxyl group and a phosphoramidite group, followed by detritylation to regenerate the chain-terminal hydroxyl group for chain growth.

Unlike DNA synthesis that uses phosphoramidite on the *secondary* hydroxyl group of deoxyribose, the chromophoric blocks use phosphoramidite groups on *primary* hydroxyl groups, which have *completely different* inherent activities. Therefore, their stability and activity toward hydroxyl groups at chain termini are critical to the success of solid-phase synthesis. Nonetheless, we have achieved coupling yields as high as 95% by increasing the phosphoramidite concentration and reaction time and by repeating the coupling step. The *solid-phase synthesis* of foldamer is compatible with DNA synthesis; fluorescent chromophores can be incorporated *anywhere* in the sequence, for example, a juxtaposition of blue and red chromophores (**41-42-41**) embedded in the DNA main chains as shown in Figure 3 (51-mer). Using the trityl monitor reading of the five bases before the three chromophore sequence and five bases after the chromophore sequence, we obtained a *total yield* for coupling three chromophores consecutively of 92%, which corresponds to 97% yield per chromophore coupling. When the chromophore is coupled to a DNA base, followed by another DNA base (57-mer), the yield is also very high. For example, at the 48th position, chromophore **42** is introduced, and the yield of 95% is obtained using the three bases immediately before and after this position. Although trityl absorption does not provide extremely accurate yields for coupling reactions, it should be a good indicator to gauge these high yield coupling reactions

Another example of our state-of-the-art coupling synthesis is shown in Figure 3 with alternating sequences of **42** and double A bases (39-mer); again, the yields of each individual step are high. For example, using the ratio of the two bases before and after position 13 (**42**), we obtained a yield of 92%. Because of such high coupling efficiency, the overall yield is 40% at 39-mer. In the finished sequence, altogether 12 fluorescent dyes are introduced into the DNA backbone; this demonstrates the power of synthetic organic chemistry in biological applications.

As long as the dye number density in the DNA sequence is not too high, the resulting hybrid sequence behaves frequently like oligo-DNA. For example, the dye−DNA conjugates can be cleaved from the solid support using concentrated ammonium hydroxide, and the crude product can be further purified with HPLC as shown in Figure 4. Monitoring at the absorption ($\lambda^{max} \approx 485$ nm) of the red-fluorescence dye (**42**), the major isolated product is, typically, the desired full-length dye−DNA conjugates. The HPLC-purified dye−DNA conjugates have good purity and are suitable for most biological assays.

CONCLUSION

In conclusion, we have developed a new method for converting normal organic fluorescent dyes into asymmetrically functionalized phosphoramidite reagents, which has enabled bioconjugation of many fluorescent chromophores at multiple desired positions of DNA backbones. By using the Horner−Wadsworth−Emmons (HWE) reaction and Knoevenagel condensation, a series of highly fluorescent amphiphilic compounds was constructed; these compounds are suitable for labeling DNA since they can be conveniently protected with DMTr and activated with phosphoramidite and their fluorescence is not quenched by the presence of DNA bases.

The improvement of commonly used Gd^{3+}-based MRI agents requires the design of new systems with optimized *in vivo* efficacy, pharmacokinetic properties, and specificity. To design these contrast agents, two parameters are usually considered: increasing the number of coordinated water molecules or increasing the rotational correlation time by increasing molecular weight and size. This has been achieved by noncovalent or covalent binding of low-molecular weight Gd^{3+} chelates to macromolecules or polymers. The grafting of these high-spin paramagnetic gadolinium chelates on metal oxide nanoparticles (SiO_2, Al_2O_3) is proposed. This new synthetic strategy presents at least two main advantages: (1) a high T_1-relaxivity for MRI with a 275% increase of the MRI signal and (2) the ability of nanoparticles to be internalized in cells. Results indicate that these new contrast agents lead to a huge reconcentration of Gd^{3+} paramagnetic species inside microglial cells. This reconcentration phenomenon gives rise to high signal-to-noise ratios on MR images of cells after particle internalization, from 1.4 to 3.75, using Al_2O_3 or SiO_2 particles, respectively. The properties of these new particles will be further used to get new insight into gene therapy against glioma, using microglial cells as vehicles to simultaneously transport a suicide gene and contrast agents. Since microglia are chemoattracted to brain tumors, the presence of these new contrast agents inside the cells will lead to a better MRI determination of the *in vivo* location, shape, and borders of the tumors. These Gd^{3+}-loaded microglia can therefore provide effective localization of tumors by MRI before applying any therapeutic treatment. The rate of carcinoma remission following a suicide gene strategy is also possible.

INTRODUCTION

Numerous strategies have been developed for cellular imaging (*1*, *2*). Noninvasive imaging techniques such as magnetic resonance imaging (MRI) appear suitable since they can operate on soft tissues and cells in real time. When highly paramagnetic contrast agents are used, this technique allows for high contrast as well as spatial resolution (*3*, *4*). Such an approach strongly improves the analysis of images and facilitates their interpretation (*5*−*11*). Further developments for specific cellular imaging require the synthesis of new contrast agents, which should be able on one hand to increase contrast and on the other hand, to target cells.

Previous studies have demonstrated the utility of using circulating cells of the immunological system like lymphocytes, monocytes, and microglial cells after the uptake of contrast agents with a superparamagnetic core (*12*, *13*). These contrast agents with various and controlled sizes are easily taken up. With their high susceptibility effect, iron oxide nanoparticles can be detected at very low concentration at high magnetic fields. With T_2* weighted images, they allow the detection of single cells *in vitro* (*4*). Nevertheless, in this situation, the signal due to the iron oxide nanoparticles can only be a hyposignal, and this appears as a limit in image analysis (*12*). Moreover, the precise anatomic localization of this iron contrast agent is limited by the breakdown of spatial resolution due to a high local susceptibility effect. Consequently, the detection of a defined cellular population in a localized area *in vivo* becomes a major difficulty.

Therefore, there is a real need to design MRI contrast agents, which can produce detectable changes in the MR signal intensity of the target tissue or organ by changing their MR relaxation properties (*14*, *15*). Among them, the Gd^{3+} DTPA chelate was the first FDA approved contrast agent in clinical use (*16*). These contrast agents require (i) a large number of paramagnetic centers (seven unpaired electrons for Gd^{3+}) selectively bound to the target tissue and (ii) an adapted molecular weight of the MRI agents in order to extend their vascular retention (*17*, *18*) and to slow their tissue clearance (*19*).

Over the past decade, various approaches have been used to address both of these issues such as the conjugation of paramagnetic chelates to macromolecules (*20*) and linear polymers (*21*). Recent reports are on polymeric paramagnetic liposomes (*22*, *23*), micelles (*24*), and dendrimer-based metal chelates (*25*). These studies have shown that Gd-DTPA (DTPA: diethylenetriaminepentaacetic acid)-based contrast agents of high molecular weight have extended circulation times and can accumulate at specific sites. The liposomes are made by incorporating DTPA-conjugated lipids into liposomes. The conjugated lipids form chelating sites for gadolinium ions. Because of its excellent metal-chelating properties, DTPA is one of the most widely used organic ligands in MRI and positron emission tomography (PET) (*26*−*28*). This approach can be

extended to the MR imaging of any receptors once the targeting ligands are conjugated to the lipids.

A new class of polymeric metal-loaded nanoparticles with core−shell morphology has been developed and shows a great potential as a contrast agent for medical imaging (*29*). The Gd^{3+}-loaded nanoparticles could reduce relaxation times *in vitro*, and provide excellent contrast when used to image the heart and the gastrointestinal tract in rat animal models.

However, the utility of these contrast agents might be limited. First, the relaxivity of the entrapped paramagnetic species is lowered because of the limited exchange of bulk water with the contrast agents (*30*, *31*). Indeed, this exchange is dependent on the permeability of the liposome or polymeric membrane to water (*29*, *32*).

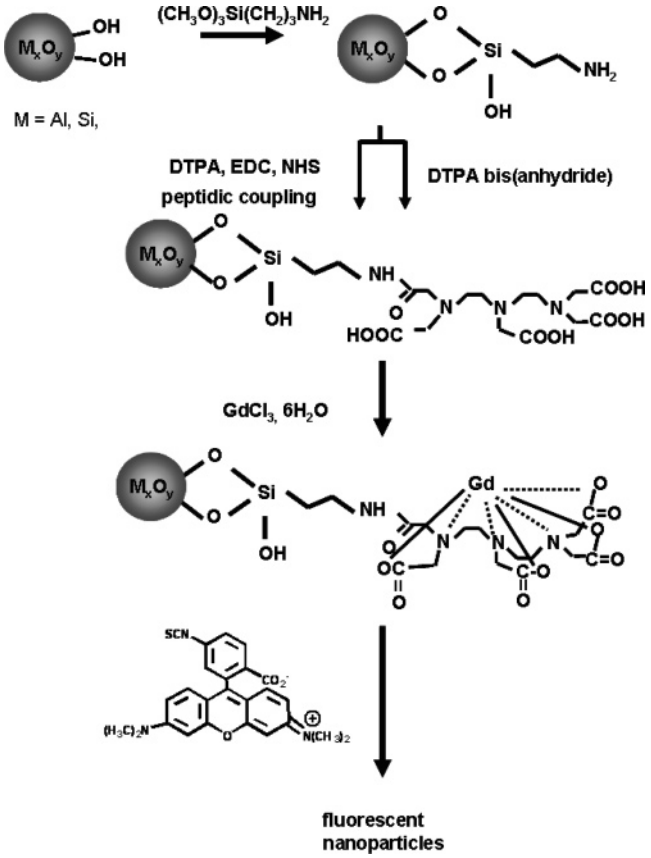
For this reason, the development of biocompatible nanoparticles with an external shell of high-spin paramagnetic lanthanide contrast agents like gadolinium chelate appears to be advantageous for targeted imaging (*33*). The gadolinium nucleus generates a hypersignal with a T_1-weighted sequence, even at high magnetic field and, consequently, a much easier interpretation of the MR images. However, these low molecular weight gadolinium chelates accumulate in the extra cellular space only where the "blood−brain barrier" breakdown took place. They undergo rapid diffusion through the interstitial as well as renal elimination and therefore have the limitation of providing a time-dependent image of tumor margins (*34*).

The chemical grafting of such contrast agents on metal oxide nanoparticles will be an alternative route to change their biodistribution and increase their half-lives, since they are internalized by macrophages. Moreover, they will also exhibit a more pronounced hypersignal with a T_1-weighted sequence. Indeed, silica, for example, would be an excellent carrier for the lanthanide chelates, as it is porous enough for water to freely move in and out of the frame. The size of the particles will slow the rotational movement of the chelates and improve the relaxation of water. Additionally, the biocompatible silica particles (*35*, *36*) can be easily derivatized, and targeted contrast agents can be synthesized (*37*). These nanoparticles could be radio-opaque and thus show X-ray contrast due to the presence of these electron-dense metal ions. Nanosized particles of about 20 nm, are small enough to pass through the body, and above all are able to enter cells since they can be easily internalized (pynocytosis, phagocytosis, or both). In the following experiments, we have modified SiO_2 nanoparticles and alumina nanoparticles with an aminosilane to bind Gd^{3+}-DTPA on their surface. Then, *in vitro* microglial cells were used to validate the increased MRI contrast, owing to internalized gadolinium particles and not free particles located in the intercellular space. These experiments were performed with the particles linked to tetramethyl rhodamine isothiocyanate (TRITC) as a fluorochrome and analyzed by microscopy and flow cytometry before the MRI characterizations and observations.

EXPERIMENTAL PROCEDURES

Characterizations. TEM was performed at room temperature on a JEOL JEM-2000 FX transmission electron microscope using an accelerating voltage of 200 kV. DRIFT characterizations were performed using a Bruker IFS Equinox 55FTIR spectrometer (signal averaging 64 scans at a resolution of 4 cm^{-1} in KBr pellets containing ca. 2 mass % of material). The zeta potential of the nanoparticles was assessed by using a Zetasizer 3000HSA setup (Malvern Instruments) equipped with a He−Ne laser (50 mW, 532 nm). The zeta potential measurement based on laser Doppler interferometry was used to assess the electrophoretic mobility of nanoparticles. Measurements were performed for 20 s using a standard capillary electrophoresis cell. The dielectric constant was set to 80.4 and the Smoluchowsky constant f(ka) was 1.5. Thermogravimetric analyses (TGA) were performed using a SETARAM apparatus (5 °C min^{-1} from 30 to 600 °C, air with a 2-h plateau at 170 °C). X-ray photoelectron spectra were recorded with a VG 220i-XL ESCALAB spectrometer. Irradiation was a non-monochromatized Al source operating at 110W ($h\nu = 1486.6$ eV). Acquisition was done at constant pass energy (i.e., 40 eV for high resolution) with a flood gun, and analyzed area was about 150 μm diameter. Spectra were fitted with the AVANTAGE software by THERMO Election. Fluorescence analysis by flow cytometry was performed on a FACScan cytometer (BD BioSciences, Le pont de Claix, France) using Cell Quest Pro software.

X-ray photoelectron spectra were obtained using a VG 220i-XL Escalab spectrometer, employing non-monochromatized Mg Kα source ($h\nu = 1253.6$ eV). The X-ray gun was operated at 10 kV and 20 mA (pressure: 10^{-8} bar). Powdered samples were pressed onto small indium foils and survey spectra obtained in the constant pass energy mode of 150 eV. The C1s contamination line (BE = 284.6 eV) was used to calibrate all binding energy values.



MR images were acquired on a 4.7 T Biospec system (Bruker, Ettlingen, Germany). The system was equipped with a 6-cm BG6 gradient system capable of 950 mT/m maximum strength. Measurements were performed with a birdcage resonator (35-mm diameter and 80-mm length) tuned at 200.3 MHz. Longitudinal relaxation time constants were measured with the inversion recovery technique (48 points, inversion delay from 20 to 5000 ms) and transverse relaxation time using the CPMG pulse sequence (32 echoes) on different nanoparticle concentrations (20.4, 17, 14.57, 12.75, 11.33, 10.2, 6.8, 5.1 μM). 2D images were acquired with a T_1-weighted sequence (FLASH sequence, TE/TR = 2/75 ms, flip angle: 75°, 8 slices, FOV = 27 × 27 mm, matrix = 128 × 128, average of 16, total acquisition time = 2 min 35 s) on microglial cell phantoms before and after internalization of the MRI contrast agent particles. For Al_2O_3 particles, TE/TR was 1.7/100 ms and the flip angle was 90°. T_1-relaxation time was also evaluated on these two samples.

The lanthanide content has been measured by inductively coupled plasma mass spectrometer ICP-MS (HP 4500, Agilent Technologies) equipped with a crossflow nebulizer. The instrumental conditions have been optimized with a 10 μg/L solution of lithium, yttrium, and bismuth. Plasma gas flow rate: 15 L/min; auxiliary gas flow rate: 0.8 L/min; nebulizer gas flow rate: 1.1 L/min; power: 1350 W; oxide (CeO/Ce): <0.5%; doubly charged (Ba^{2+}/Ba): <3%. The analyses have been performed using an external calibration. A 1 g/L gadolinium solution has been used to prepare the standard solutions (Techlab, Metz, France). Rhodium (Techlab, Metz, France) has been used as internal standard to evaluate the instrumental drift.

Materials. $LnCl_3{:}6H_2O$, tetramethyl rhodamine isothiocyanate (TRITC), 3-aminopropyltrimethoxy-silane (APS), diethylenetriamine pentaacetic acid (DTPA), diethylenetriamine pentaacetic anhydride (DTPAA) (Aldrich), SiO_2 (negatively charged silica sol Ludox HS-40 (DuPont) (composition: 40% SiO_2, 60% H_2O, <1% Na_2O, average diameter of 20 nm, surface area ~220 m^2/g), ammonia, ethanol, and DMF from Aldrich were used without further purification. Alumina C (with an average diameter of 13 nm according to the manufacturer, surface area ~ 100 m^2/g) was generously provided by Degussa.

(1) Synthesis of APS-Grafted Nanoparticles. A 2 g amount of the metal oxide nanoparticles was dispersed by sonication in 100 mL of distilled water purged with argon or anhydrous toluene. A 2 mL amount of freshly distilled APS was added under argon and maintained under rapid stirring for 36 h. The suspension was then put under reflux for 2 h to achieve the

Scheme 1. Chemical Modification of the Metal Oxide Nanoparticles

reaction. The nanoparticles were then washed and purified by centrifugation four times with ethanol and then water to remove unreacted APS. The samples were redispersed and stored in water in which they are stable for months or dried at 70 °C under low pressure for 24 h for analysis.

(2) Synthesis of DTPA-Grafted Nanoparticles. Two ways of synthesis have been used and gave similar results. In the first method, the amine nanoparticles prepared above were diluted with 50 mL of water or 50 mL of DMF. Diethylene triaminepentaacetic anhydride (DTPAA) was slowly added to the solution (10/1 DTPAA/-NH_2 for the synthesis in water and 2/1 DTPAA/-NH_2 for the synthesis in DMF). After 24 h in both cases, the particles were filtered and purified five times by centrifugation−redispersion in water. The final products were stored in water as colloidal suspensions (at a concentration of 100 g/L) or dried at 70 °C under low pressure for 24 h for analysis.

In the second method, DTPA is linked to amino group using peptide synthesis with a carbodiimide coupling agent in the presence of NHS (*N*-hydroxysuccinimide) (*38*). A suspension of 2 g of the amino nanoparticles in 50 mL of water was prepared. A pH 5 solution of 1.67 g of DTPA in water was activated with 1.1 g of EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide) and 1.1 g of NHS (*39*, *40*). The resulting solution was added into the colloidal suspension while maintaining pH 5 (HEPES buffer) and reacted for 24 h. The nanoparticles were washed and cleaned five times by centrifugation−redispersion in water. The final product was stored in water as a colloidal suspension or dried at 70 °C under low pressure for 24 h for analysis. This second procedure was finally chosen because H_2O is the only solvent used for the entire synthesis.

(3) Synthesis of Lanthanide Chelate-Grafted Nanoparticles. A colloidal suspension of 1 g of DTPA-grafted nanoparticles in 20 mL of water was added to 0.5 g of hydrated

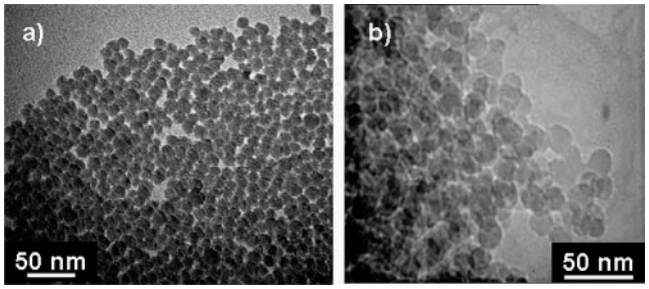


Figure 1. TEM images of (a) bare and (b) APS-grafted silica nanoparticles.

Table 1. Grafted-APS Surface Density for Al_2O_3 and SiO_2 Nanoparticles

	H_2O	toluene
Al_2O_3−APS	5.1 ± 0.3 μmol/m^2	12.8 ± 0.3 μmol/m^2
SiO_2−APS	5.3 ± 0.3 μmol/m^2	9.0 ± 0.3 μmol/m^2

$GdCl_3$:$6H_2O$ at room temperature. After 24 h, the excess of unreacted Gd(III) was removed by centrifugation−redispersion five times in water, and the absence of free Ln(III) was checked with arsenazo III indicator. The final product was stored in water as a colloidal suspension or dried at 70 °C under low pressure for 24 h for analysis.

(4) Synthesis of Rhodamine-Loaded Nanoparticles. A colloidal suspension of 0.25 g of amino-grafted nanoparticles in 50 mL of water was added to 0.5 g of tetramethyl rhodamine isothiocyanate (TRITC) and reacted for 5 h in a 0.1 M carbonate/bicarbonate buffer at pH 9. The excess of unreacted TRITC was removed by five cycles of centrifugation−redispersion until no more signals was detected in the supernatant by UV−visible spectroscopy. The final product was stored in water as a colloidal suspension.

(5) Cell Culture. Human microglial cell line was grown as a monolayer. C6 glioma rat membrane extracts and serum starvation were used in this study to activate microglial cells 24 h before the experiments (this allows the cells to acquire phagocytosis ability). After a 4-h incubation with the lanthanide-grafted nanoparticles (170 nmol/L), the cellular monolayers were washed three times with phosphate-buffered saline (PBS), collected, fixed, and trapped in agarose gels (1% in H_2O) for the MRI analysis. The biological internalization characterization of the contrast agent by the microglia was controlled using nanoparticles modified with TRITC fluorochrome (0.5 mM) and both qualitative microscopy and quantitative flow cytometric measurements.

RESULTS AND DISCUSSION

The choice of approach of silica and alumina nanoparticles grafted with lanthanide contrast agents was motivated because they present a large range of particle sizes (10 to 1000 nm) which can be tailored to the requirements of biological applications (intravenous (IV) injections for example). They also exhibit a good selectivity, low cytotoxicity (SiO_2 (*41*), Al_2O_3 (*42*), and high tissue clearance properties. These particles are modified with Gd^{3+} to provide contrast in MR, and a fluorescent probe for cytometry analysis. The grafting of the metal oxide nanoparticles (Al_2O_3, SiO_2) was performed according to Scheme 1.

The surface of the nanoparticles were chemically modified by reacting the surface hydroxyl groups with the 3-aminopropyltrimethoxysilane (APS) leading to an aminated surface. This reaction was stirred overnight at room temperature and for 2 h under a gentle reflux to promote covalent bonding of the organosilane to the surface of the nanoparticle (*43*). The

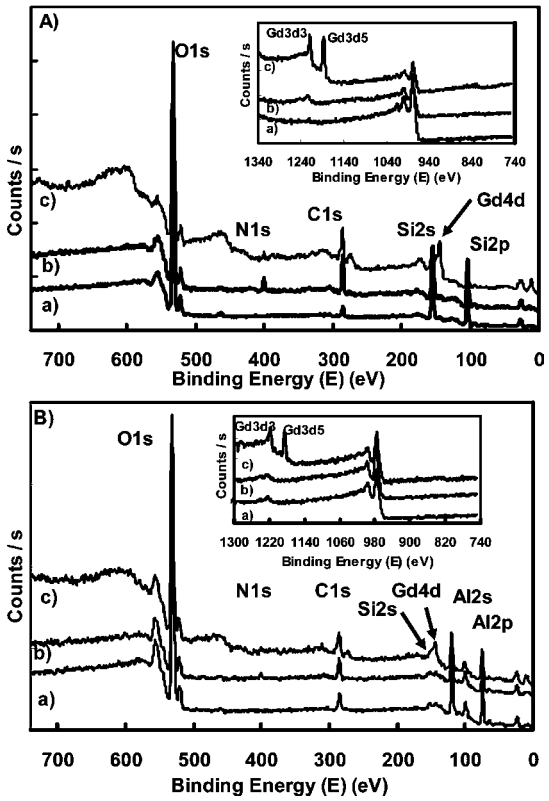

Figure 3. (A) XPS data of the (a) SiO_2, (b) SiO_2-APS, and (c) $SiO_2-APS-DTPA$ Gd nanoparticles (0−740 eV survey); insert: 740−1340 eV survey. (B) XPS data of the (a) Al_2O_3, (b) Al_2O_3-APS, and (c) $Al_2O_3-APS-DTPA$ Gd nanoparticles (0−740 eV survey); insert: 740−1340 eV survey.

chemical attachment of DTPA to these aminated nanoparticles was carried out by the formation of an amide linkage between the primary amine group and one of the five carbonyl groups of DTPA, using either a reaction directly with the dianhydride or a peptidic coupling by esterification with EDC catalyzed by NHS (*38*) to facilitate the amide linkage (*39*). The coordination of DTPA with Gd^{3+} was subsequently followed by reaction with an aqueous solution of $GdCl_3{:}6H_2O$.

The particles were characterized at each step to ensure the efficiency of the chemical modification. Quantification of the grafting agent was calculated from the thermogravimetric mass loss. The APS surface density is expressed in mol/m^2 as $d_{APS} = \Delta m/M_{cx}Spm$, on the assumption that the thermal degradation proceeds (*44*) at the Si−C bond breaking level between 200 and 650 °C (Table 1). $\Delta m/m$ is the measured mass loss between the two concerned temperatures (200 and 650 °C), M_{cx} is the molecular weight of the concerned fragment, and Sp the specific surface area of metal oxide (220 m^2/g for Ludox and 100 m^2/g for alumina C).

The APS surface density is higher when the reaction is performed in refluxing toluene for both nanoparticles. This is characteristic of the formation of more than one monolayer of silane at the surface of the particles (*45*). Ishida estimated that the surface area occupied by an APS molecule is $S_{APS} = 40$ Å^2 (*46*). The number of APS layers (NL_{APS}) can be estimated according to the following equation: $NL_{APS} = N_A \times d_{APS} \times S_{APS}$ where N_A is the Avogadro's constant $= 6.02 \times 10^{23}$ molecules mol^{-1} and d_{APS} is the silane surface density, given in Table 1. The number of layers (between 2 and 3) depends on the reaction solvent (*47, 48*) and does not modify the particle size, as shown by TEM images (Figure 1).

Diffuse reflectance infrared Fourier transform (DRIFT) spectroscopy is another very useful technique for probing the effectiveness of the chemical grafting (*48*). The bare silica nanoparticles present simple infrared spectra, with two kinds of hydroxyl groups: (i) the bound Si−OH, characterized by a very broad IR absorption band in the 2800−3700 cm^{-1} region; (ii) the so-called free Si−OH groups, which provide a narrow IR absorption band at 3750 cm^{-1}. The stretching at 1622 cm^{-1} still shows the presence of residual physisorbed water molecules. The large bands centered on 1866, 1093, 794 are assigned to the Si−O and Si−O−Si stretching modes. Alumina nanoparticles exhibit a large band (3200−3800 cm^{-1}) centered at 3450 cm^{-1} coupled with a thinner one at 1634 cm^{-1} attributed to the deformation mode of the hydroxyl groups. The subsequent effective APS-silanization of the mineral oxides is evidenced by the modification of the DRIFT spectrum of the resulting powders. Grafting of the organic APS on the silica particles is illustrated by (i) the disappearance of the single Si−OH (with respect to the Al−OH) vibration; (ii) the shape modification of the band around 3500 cm^{-1}, due to the NH vibrations, and the 2937 and 2873 cm^{-1} bands of the grafted alkyl chain which are assigned to the asymmetric and symmetric stretching vibrations of CH_2 groups, confirming that the amino propyl groups get anchored; and (iii) the presence of the 1624 and 1544 (respectively, the free and hydrogen-bonded NH_2), 787 (NH bending mode), and 1406 ($SiCH_2$) cm^{-1}. The chemical grafting of the DTPA units is pointed out by the new stretching bands due to the amide and carboxylic functions (1660, 1635, 1542 cm^{-1}) while the complexation with Gd^{3+} induces a slight

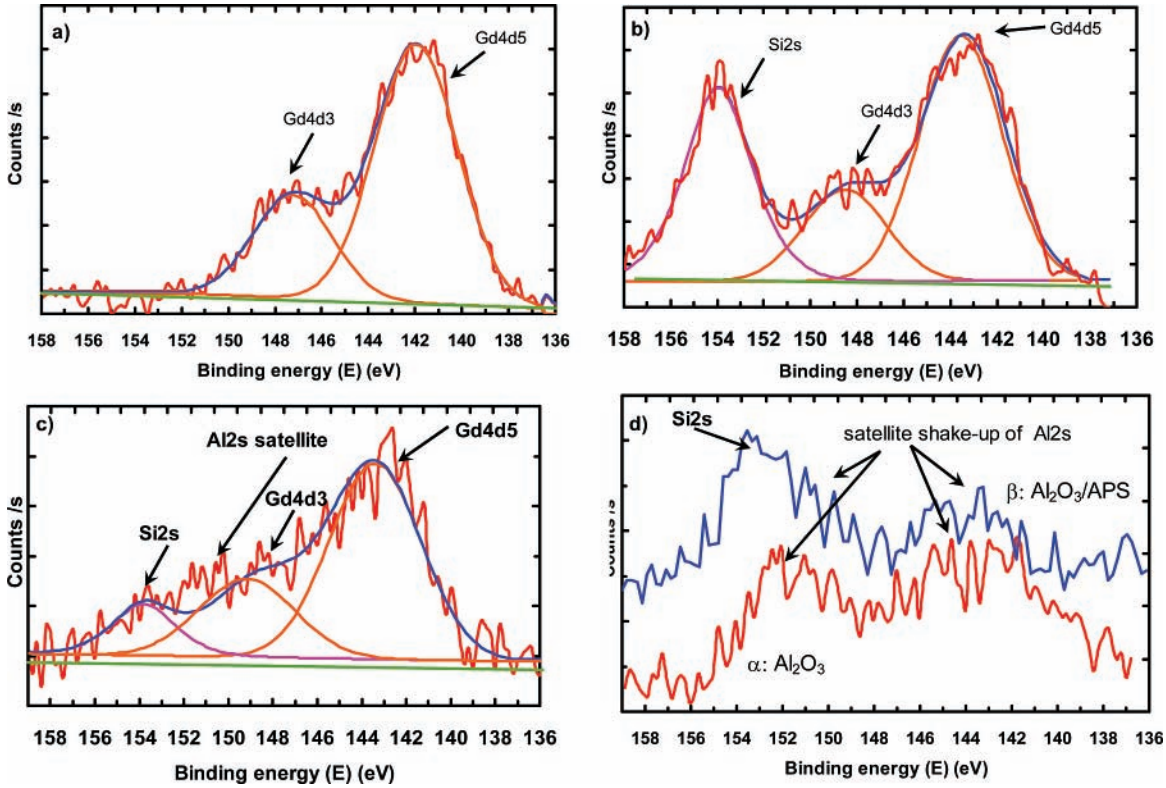

Figure 4. High resolution spectra of the 136−158 eV zone for (a) commercial Gd DTPA complex, (b) SiO_2−APS−DTPA Gd nanoparticles, (c) Al_2O_3−APS−DTPA Gd nanoparticles, (d) (α) satellite "shake-up" of Al2s in the 136−158 eV zone for pristine Al_2O_3 and (*β*) satellite "shake-up" of Al2s in the 136−158 eV zone for Al_2O_3/APS particles showing both the satellite "shake-up" of Al2s and the Si2s peak.

Table 2. Surface Elemental Composition of Al_2O_3, SiO_2 Particles before and after Chemical Modification

	Al_2O_3						SiO_2				
atomic %	C	O	Al	Si	N	Gd	C	O	Si	N	Gd
unmodified	10.2	58.4	31.4	-	-	-	8.1	64.7	27.2	-	-
APS	13.1	52.8	29.9	2.6	1.6	-	20.7	50.8	23.9	4.6	-
DTPA	10.5	54.1	31.9	1.6	1.9	-	22.5	49.4	22.8	5.0	-
Gd	15.0	54.9	24.0	2.9	1.0	2.2	27.7	46.6	18.2	3.5	3.9

bathochromic shift of these bands to 1632, 1592, 1561 cm^{-1} respectively. As far as the grafted alumina particles are concerned, identical trends were observed, with an additional vibration attributed to the Al−O−Si vibration located at 1152 cm^{-1} (*44*).

Zeta potential titrations as a function of pH (obtained by adding 0.01 M HNO_3 or KOH solutions) were realized to verify the isoelectric points (IEP) of Al_2O_3 and SiO_2 as well as their pH range of stability (Figure 2). The IEP values were 7.8 and 2.3, respectively. The evolution of the IEPs with the different modification steps also provided an additional confirmation of the silane immobilization as well as the lanthanide complexation. Indeed, after the APS coating, the two suspensions exhibited isoelectric points of 8.4 (Figure 2a) and 10.2 (Figure 2b), respectively. This IEP displacement toward higher values is characteristic of the presence of free amines on the surface of the particles. Once the peptidic coupling was achieved, there was another shift of the IEP toward lower pH values due to the introduction of the pentaacid ligand. The final IEPs were, respectively, 4.5 and 4.2 pH units for Al_2O_3 and SiO_2 nanoparticles, which confers upon them a high stability in a medium with a pH down to 4.5.

XPS studies were carried out for the different samples. Figure 3 shows the XPS general survey scans of the SiO_2 and Al_2O_3 nanoparticles at each step of the chemical modification (traces a, b, and c) until the final coating with DTPA-Gd complex (*49*).

No nitrogen was detected on the unmodified particles, but an unavoidable contaminant carbon peak due to impurities from processing (*50*) was observed. However, the increase of the C1s peak as well as the presence of the N1s peak in trace b) for the SiO_2−APS and Al_2O_3−APS nanoparticles confirms that the reaction with the aminopropylsilane occurred (Table 2).

In the case of the alumina particles, a detectable Si2s contribution is due to the silicon atom of the aminosilane. SiO_2−APS−DTPA and Al_2O_3−APS−DTPA samples presented the same trends (data not shown). The introduction of the gadolinium ion is illustrated by the appearance of the Gd photoelectron peaks at a binding energy of 143 eV for Gd4d and at 1186 and 1219 eV for $Gd3d_{5/2}$ and $Gd3d_{3/2}$, respectively (Figure 3A and 3B inserts). Study of the high-resolution $Gd4d_{5/2}$ and $Gd4d_{3/2}$ spectra lead to a quantitative estimation of Gd grafted onto silica or alumina materials. As the literature gives poor information on the sensitivity factor of Gd (*51*), we carried out a calibration using a commercial reference of Gd-DTPA complex, adjusting the $Gd4d_{5/2}$ and $Gd4d_{3/2}$ sensitivity factors from a Scofield table to obtain the ratios expected between chemical elements (i.e., 6.5 for $Gd4d_{5/2}$ after Gd4d fitting, Figure 4a).

In the case of silica nanoparticles, fitting in the 136−158 eV binding energy range gave the well-defined Si2s and $Gd4d_{3/2}$−$Gd4d_{5/2}$ components (Figure 4b) leading to a surface quantification of 4 atomic % of Gd (Table 2). Concerning alumina, fitting

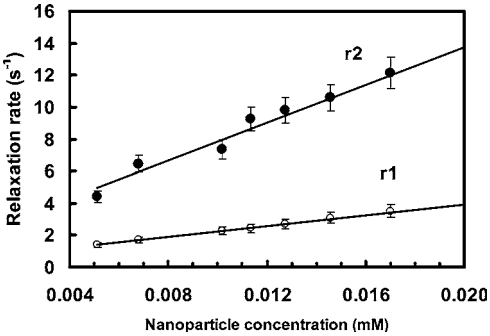

Figure 5. Plots of the relaxation rates R1 and R2 with respect to the concentrations of SiO_2−APS−DTPA Gd nanoparticles (20.4; 17; 14.57; 12.75; 11.33; 10.20; 6.8; 5.1 μM of beads). Proton relaxivities (r_1 and r_2) were determined based on these linear relationships.

of the same energy range (Figure 4c) was more complex due to the presence of satellite "shakeup" of Al2s (Figure 4dα) and Si2s photoelectron peaks from APS (Figure 4dβ) observed, in addition to the chemical modification of alumina with the aminosilane. The percentage of Gd on Al_2O_3 was found to be around 2 atomic % (Figure 4c, Table 2)).

These nanoparticles were also studied by NMR. They generated contrast on both longitudinal and transverse proton relaxation time-weighted sequences. The proton relaxivities were calculated by measuring the change in R1 and R2 for increasing concentrations of nanoparticles in distilled water (Figure 5). The r_1 and r_2 relaxivities of these Gd-doped silica nanoparticles were, respectively, 168 ± 4 mM^{-1} s^{-1} and 589 ± 38 mM^{-1} s^{-1} at 4.7 T, respectively.

The relaxivity of the SiO_2−APS−DTPA Gd nanoparticles is much higher than the one determined for commercial Gd-DOTA (DOTAREM, Guerbet, Aulnay-sous-Bois, France, r_1 = 4.5 mM^{-1} s^{-1} at 4.7 T). An amount of four Gd complexes per silica bead has been estimated by ICP MS titration of Gd^{3+}. This means that the relaxivity of this kind of Gd-DTPA is very high (42 mM^{-1} s^{-1}). This value is of the same order as those obtained for similar sized Gd-loaded dendrimers: 36 mM^{-1} s^{-1} (*52*) or 40 mM^{-1} s^{-1} despite a very low number of Gd per particle. This enhancement could be explained by a slow down of the rotational motion of the particle (*17*, *53*). This increase in relaxivity is thus consistent with the increase in rotational correlation time, which results both from the increase in molecular weight and maximum compactness of the SiO_2 structure as compared to organic molecules. Indeed, the rigid nature of the inorganic nanoparticle tends to avoid the Gd^{3+} chelate from freely rotating or even folding back (*54*).

The other advantage of Gd inorganic nanoparticles is that they exhibit a high ability for internalization in cells, inducing a relatively close vicinity of the contrast agents which could also be responsible for this strong increase in the r_1 value. Furthermore, these particles, once internalized in specific cells, favor the visualization and the characterization of tissue territories where these cells can accumulate during long periods. In fact, their biological half-life inside the cell is increased as compared to that in the extracellular circulating stream (*12*).

The cellular uptake of the Gd-TRITC fluorochrome-modified nanoparticles were tested for internalization in microglial cells. Microglial cells were grown as monolayer cultures. After activation, they were first incubated with the TRITC fluorescent particles (0.5 mM) and studied by fluorescence microscopy. An illustration of modified silica nanoparticle internalization is given in Figure 6. The results concerning Al_2O_3 nanoparticle uptake are given in Supporting Information.

Microglia monolayer cultures displayed a typical morphology with either elongated (Figure 6b, top thin arrow) or ovoid cell bodies (Figure 6b, bottom thin arrow). When activated, these
