Bioconjugate Chemistry

EDITORIAL: What's New

Associate Editors

Associate Editors Paul Miller, Teruo Okano, and Peter Senter have been essential to the success of the journal. Professor Okano is moving on to new responsibilities and will no longer be able to serve, but in this time of growth we have appointed three new Associate Editors to maintain and broaden our coverage of new science. The new Associate Editors are:

Ferenc Hudecz, *Department of Organic Chemistry, Eötvös Lorand University, Budapest, Hungary*

Yasuhiko Tabata, *Department of Biomaterials, Institute for Frontier Medical Sciences, Kyoto University, Japan*

Masayuki Yokoyama, *Laboratory of Polymer and Nanomedicine, Kanagawa Academy of Science and Technology, Kawasaki, Japan*

Editorial Advisory Board

Editorial Advisory Board members not only review manuscripts but also advise on journal policy. New members appointed this year are:

Darryl Bornhop, *Vanderbilt University*
Patrick Couvreur, *Université de Paris-Sud*
M. G. Finn, *The Scripps Research Institute*
Shiroh Futaki, *Kyoto University*
Wim E. Hennink, *Utrecht University*
Kazunori Kataoka, *The University of Tokyo*
Kenji Kono, *Osaka Prefecture University*
Robert Langer, *Massachusetts Institute of Technology*
Michael R. Lewis, *University of Missouri-Columbia*
Harri Lönnberg, *University of Turku*
Jong-sang Park, *Seoul National University*
Tae Gwan Park, *Korea Advanced Institute of Science and Technology*
Tariq Rana, *University of Massachusetts Medical School*
Steve Roffler, *Academia Sinica*
David A. Tirrell, *California Institute of Technology*
M. Graca H. Vicente, *Louisiana State University*
Ernst Wagner, *Ludwig Maximilian University*
Michael J. Welch, *Washington University School of Medicine*
Karen L. Wooley, *Washington University in St. Louis*

Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 2006 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the 17th volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The reviewers are listed on the following page.

In Memoriam
Robert E. Feeney
August 30, 1913 − September 21, 2006

One of the inspirations for *Bioconjugate Chemistry*, prominent specialist in the chemical modification of proteins, and unmistakable personality, Bob Feeney passed away recently. We remember him as a sprightly colleague who was never, never at a loss for words. He was likely to pop up at the most unlikely times and places, deliver a few amusing remarks, and leave us all laughing. During his years as Professor of Food Science at the University of California, Davis, Feeney had a memorable style of educating younger scientists in the treatment of biological molecules with organic reagents. What was formerly an arcane and rather mysterious set of practices has evolved into rational approaches to drug design and development. Bob Feeney was a leader of that parade and enjoyed every minute of it. We all benefited from his presence. We will miss him.

Polyketal Microparticles: A New Delivery Vehicle for Superoxide Dismutase

Sungmun Lee,[†,§] Stephen C. Yang,[†,§] Michael J. Heffernan,[†] W. Robert Taylor,[‡] and Niren Murthy*[,†]

The Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, Georgia 30332, and Division of Cardiology, Department of Medicine, Emory University School of Medicine, Atlanta, Georgia 30322. Received August 21, 2006; Revised Manuscript Received November 6, 2006

There is currently great interest in developing microparticles that can enhance the delivery of proteins to macrophages. In this communication, we present a new acid-sensitive polymer for drug delivery, poly(cyclohexane-1,4-diyl acetone dimethylene ketal) (PCADK). PCADK is designed to hydrolyze, after phagocytosis by macrophages, in the acidic environment of the phagosome and enhance the intracellular delivery of phagocytosed therapeutics. Other key attributes of PCADK for drug delivery are its well-characterized degradation products and straightforward synthesis. PCADK hydrolyzes into 1,4-cyclohexanedimethanol, a compound used in food packaging, and acetone, a compound on the FDA GRAS list. PCADK was synthesized using the acetal exchange reaction between 1,4-cyclohexanedimethanol and 2,2-dimethoxypropane, and could be obtained on a multigram scale in one step. The hydrolysis kinetics of the ketal linkages in PCADK were measured by ^{1}H NMR and were determined to be pH-sensitive, having a half-life of 24.1 days at pH 4.5 and over 4 years at pH 7.4. The therapeutic enzyme superoxide dismutase (SOD), which scavenges reactive oxygen species, was encapsulated into PCADK-based microparticles using a double emulsion procedure. Cell culture experiments demonstrated that PCADK-based microparticles dramatically improved the ability of SOD to scavenge reactive oxygen species produced by macrophages. We anticipate numerous applications of PCADK in drug delivery, based on its acid sensitivity, well-characterized degradation products, and straightforward synthesis.

Reactive oxygen species (ROS) produced by macrophages play a central role in causing inflammatory diseases, such as acute liver failure, arthritis, and sepsis (*1*−*4*). Superoxide dismutase (SOD) is an enzyme that scavenges reactive oxygen species and has the potential to treat inflammatory diseases by suppressing ROS production by macrophages (*5*−*7*). Unfortunately, clinical trials with free SOD have been ineffective, due to its membrane impermeability, and SOD delivery vehicles are therefore being investigated. Liposome-based SOD delivery vehicles have shown promise for enhancing the delivery of SOD in animal models; however, their poor shelf life has prevented their progression into clinical trials (*8*, *9*). Polymeric microparticles, based on PLGA and polycaprolactone, are also being investigated for the delivery of SOD (*10*−*12*). Although polyester-based microparticles have an excellent shelf life and well-characterized degradation products, their application for the treatment of inflammatory diseases is potentially problematic because their acidic degradation products can cause inflammation (*13*).

Polymeric microparticles based on acid-degradable polymers also have the potential to enhance the delivery of SOD to macrophages. Acid-degradable polymers, such as polyorthoesters and polyacetals, hydrolyze in the acidic environment of lysosomes and phagosomes and have previously been used for intracellular drug delivery (*14*−*17*). The polyketals are a new family of acid-degradable polymers that have ketal linkages in their backbones (*18*, *19*). The polyketals have several properties that make them an attractive delivery vehicle for SOD. Polyketals degrade into neutral compounds and may avoid the inflammatory problems associated with the acidic degradation products of polyesters and polyorthoesters. Polyketals also have the potential to disrupt phagosomes, by degrading in the phagosome and osmotically destabilizing it. The ketal linkage has excellent hydrolysis kinetics for intracellular drug delivery, hydrolyzing approximately 1000 times faster at the phagosomal pH of 4.5 versus the pH 7.4 environment of the blood. Although the polyketals have potential for protein delivery to macrophages, poly(1,4-phenyleneacetone dimethylene ketal) (PPADK) is the only polyketal developed for drug delivery; however, it degrades into benzene dimethanol, an aromatic compound with potential toxicity, and new polyketals with better characterized toxicity profiles would be preferable.

In this communication, we present a new polyketal for drug delivery, poly(cyclohexane-1,4-diyl acetone dimethylene ketal) (PCADK), which degrades into acetone, a compound on the FDA GRAS list, and 1,4-cyclohexanedimethanol, a compound with an excellent toxicity profile. For example, the LD_{50} of 1,4-cyclohexanedimethanol in rats is 3200 mg/kg for an oral dosage. 1,4-cyclohexanedimethanol also does not undergo significant enzymatic transformations in vivo; for example, a 400 mg/kg peritoneal gavage of 1,4-cyclohexanedimethanol in rats led to 97.5% of it being excreted intact (*20*). In addition, 1,4-cyclohexanedimethanol is a commonly used food packaging material and has approval for human consumption as an indirect food additive (Food Contact Notification (FCN) no. 000087).

Scheme 1. PCADK, a New Polymer for Drug Delivery[a]

[a] (A) Synthesis of PCADK from 1,4-cyclohexanedimethanol (CDM) and 2,2-dimethoxypropane (DMP), and acid hydrolysis of PCADK into CDM and acetone. (B) Formulation of SOD-loaded microparticles by w/o/w double emulsion. Microparticles degrade after phagocytosis, in the acidic environment of the phagosome.

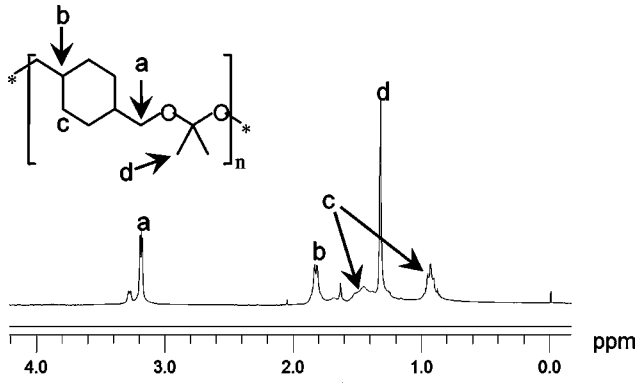

Figure 1. ^{1}H NMR of PCADK. ^{1}H NMR spectrum of PCADK in $CDCl_3$: per repeating unit, peaks at $\delta = 3.26-3.18$ (a, 4H), 1.83 (b, 2H), 1.60−0.93 (c, 8H), and 1.32 ppm (d, 6H).

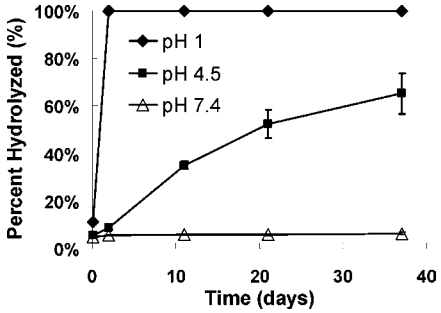

Figure 2. The hydrolysis of PCADK is pH-sensitive. Hydrolysis kinetics of PCADK (ground powder) was determined at pH 1.0, 4.5, and 7.4 at 37 °C by ^{1}H NMR. Half-lives of PCADK are 24.1 days (pH 4.5) and over 4 years (pH 7.4). PCADK was completely hydrolyzed in 2 days at pH 1.0.

In this report, SOD was encapsulated into PCADK-based microparticles via a double emulsion procedure. Cell culture experiments with macrophages demonstrated that these microparticles dramatically improved the ability of SOD to scavenge superoxide produced by macrophages. On the basis of these observations, we anticipate numerous uses for PCADK-based microparticles in drug delivery.

PCADK was synthesized, on a multigram scale, using the acetal exchange reaction between 1,4-cyclohexanedimethanol and 2,2-dimethoxypropane, as shown in Scheme 1, generating polymers with an M_w of approximately 6000 (Supporting Information Figure S1). A ^{1}H NMR spectrum of PCADK is shown in Figure 1, confirming its chemical structure. Although the acetal exchange reaction has been extensively used for the protection of alcohols, it has been rarely used for the synthesis of polyketals. In 2005, Heffernan and Murthy reported the synthesis of PPADK through the reaction of 2,2-dimethoxypropane and 1,4-benzenedimethanol (*18*). While PPADK has many of the characteristics needed for drug delivery, its degradation products have potential toxicity. PCADK, in contrast, degrades into 1,4-cyclohexanedimethanol and acetone, both of which have excellent toxicity profiles.

PCADK has ketal linkages in its backbone and should therefore degrade after phagocytosis, in the acidic environment of the phagosome. The hydrolysis kinetics of PCADK, in the form of ground powder, was measured at the pH values of 4.5 and 7.4, to estimate the behavior of PCADK-based delivery vehicles after phagocytosis. Figure 2 demonstrates that the hydrolysis of the ketal linkages in PCADK is indeed pH-sensitive, having a half-life of 24.1 days at pH 4.5 and an estimated half-life of over 4 years at pH 7.4. The hydrolysis of the ketal linkage in PCADK is considerably slower than that of a water-soluble ketal, which has a half-life of approximately 1.6 min at pH 5.0 (*21*). This observation leads us to speculate that the rate-limiting step in the hydrolysis of PCADK is the diffusion of hydronium ions into the polymer matrix, rather than the cleavage of ketal bonds. This hypothesis is further supported by the faster hydrolysis rate of the more hydrophilic polyketal, PPADK, which has a half-life of 35 h at pH 5.0.[1] This trend suggests that the hydrolysis of polyketal microparticles can be tailored by manipulating their hydrophobicity.

SOD was encapsulated into PCADK microparticles using a w/o/w double emulsion procedure. An experimental protocol was developed on the basis of procedures used to formulate SOD into PLGA-based microparticles (*10*). Briefly, a 100 μL aqueous solution of SOD (40 mg/mL) was dispersed by homogenization (21 500 rpm, 30 s) into 1.0 mL of methylene chloride, containing 125 mg of PCADK, generating a water in oil (w/o) emulsion. This w/o emulsion was then dripped into 5 mL of an 8% (w/v) aqueous polyvinyl alcohol (PVA) solution and was stirred with a homogenizer at 6000 rpm for 5 min. The resulting w/o/w emulsion was then poured into 25 mL of pH 7.4 buffer and was stirred for several hours, evaporating the methylene chloride. The resulting particles were isolated by centrifugation and freeze-dried, generating a white solid powder. The protein encapsulation efficiency of the SOD−PCADK microparticles was 36.7%, as determined by UV absorbance at 280 nm. An SEM image of the SOD−PCADK microparticles, shown in Figure 3, demonstrates that they are 3 to 15 μm in diameter, which is suitable for both intracellular and extracellular delivery. This may be beneficial in the case of SOD delivery, because superoxide causes both intracellular toxicity and extracellular tissue damage during inflammation.

[1] PCADK was determined to be more hydrophobic than PPADK on the basis of the log *P* values of their respective monomers, 0.359 for 1,4-cyclohexanedimethanol versus −0.149 for 1,4-benzenedimethanol.

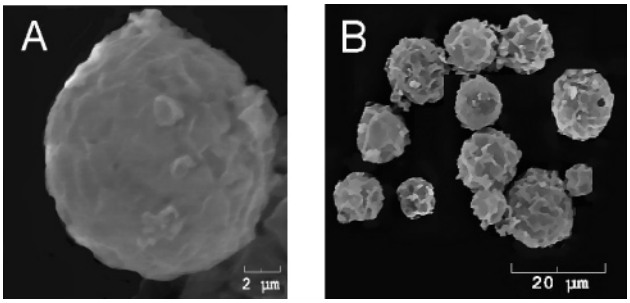

Figure 3. SEM images of SOD−PCADK microparticles: (A) 6000× magnification, (B) 1000× magnification. SEM images were taken on a Hitachi S-800.

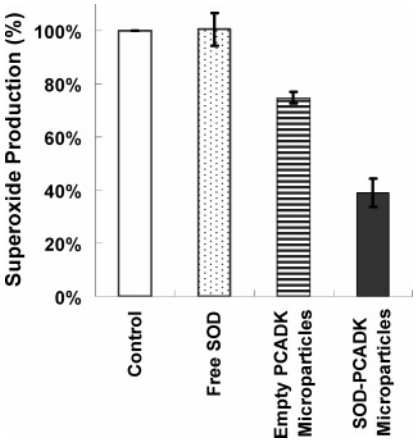

Figure 4. PCADK microparticles enhance the delivery of SOD to macrophages. Macrophages were incubated with either SOD−PCADK microparticles (black bar), empty PCADK microparticles (horizontal stripe), free SOD (dotted bar), and media only (white bar). For statistical analysis, three independent wells were measured for each sample. Significance of results was determined via the *t*-test with $p < 0.05$.

The ability of SOD−PCADK microparticles to scavenge superoxide from macrophages was investigated in cell culture. TIB-186 macrophages (1×10^5 cells/well, 96-well plate) were incubated with 0.1 mg/mL SOD−PCADK microparticles (1.14 μg SOD in 0.1 mg microparticles), free SOD (1.14 μg/mL SOD), or empty PCADK microparticles for 2 h. The cells were washed 3 times and then stimulated with 0.2 μg/mL phorbol myristate acetate (PMA) for 30 min. The superoxide production from these macrophages was then measured using a cytochrome c based assay, following the procedure of Voter et al. (*22*). Figure 4 demonstrates that free SOD by itself caused very little inhibition of superoxide production, whereas SOD−PCADK microparticles caused a 60% reduction in superoxide production. Empty microparticles also reduced superoxide production by macrophages by approximately 20%. This is most likely due to the toxicity of the particles, which caused approximately 20% toxicity under these experimental conditions (0.1 mg/mL for 2 h) as determined by an MTT assay (Supporting Information Figure S3).

In conclusion, we have developed a new acid-sensitive polyketal for drug delivery, PCADK, which is designed to hydrolyze in the acidic environment of the phagosome and enhance the intracellular delivery of phagocytosed therapeutics. Key attributes of PCADK are its well-characterized degradation products and straightforward synthesis. PCADK was synthesized on a multigram scale in one step and hydrolyzes into acetone and 1,4-cyclohexanedimethanol. The hydrolysis of PCADK is pH-sensitive, having a half-life of 24.1 days at pH 4.5 and over 4 years at pH 7.4. The therapeutic protein SOD was encapsulated into PCADK-based microparticles, 3−15 μm in size, using a double emulsion procedure. In cell culture experiments, PCADK microparticles significantly improved the ability of SOD to scavenge superoxide generated by macrophages. We anticipate widespread interest in PCADK for drug delivery, based on its acid sensitivity, well-characterized degradation products, and ease of synthesis.

ACKNOWLEDGMENT

This project was funded in part by the Georgia Tech/Emory Center for the Engineering of Living Tissues (funded by NSF-EEC-9731643), NSF-BES-0546962 CAREER AWARD, NIH UO1 HL80711-01, NIH R21 EB006418, and J&J/GT Health Care Innovation Seed Grant Proposal. N-(Iodoacetyl)-*N*′-(anthraquinon-2-oyl)-ethylenediamine (IAED): A New Heterobifunctional Reagent for the Preparation of Biochips

Satyakam Patnaik, Archana Swami, Dalip Sethi, Atul Pathak, B. S. Garg,† K. C. Gupta,* and P. Kumar*

Nucleic Acids Research Laboratory, Institute of Genomics and Integrative Biology, Mall Road, Delhi University Campus, Delhi − 110 007, India. Received August 24, 2006; Revised Manuscript Received October 23, 2006

Design and synthesis of a new heterobifunctional reagent, *N*-(iodoacetyl)-*N*′-(anthraquinon-2-oyl)-ethylenediamine (IAED), have been described for the preparation of oligonucleotide-based biochips. The performance of the featured reagent is probed by the immobilization of thiolated and thiophosphorylated oligonucleotides on modified glass microslides via two routes (routes A and B). The immobilization procedure was accelerated by performing a chemical reaction between thiolated oligomers and the iodoacetyl moiety of the reagent under microwaves (MW), where it is completed in just 10 min. The quality of the constructed oligonucleotide microarrays was tested by performing a hybridization assay with a complementary target and subsequently used for the detection of base mismatches. The immobilized probes were found to be thermally stable.

INTRODUCTION

DNA microarray (biochip) technology is one of the hottest areas of biological research today, having enormous applications in the area of monitoring of gene expression, disease diagnosis, gene mapping, detection of single nucleotide polymorphisms, and other genome analysis (*1*−*3*). For this purpose, several surface materials, viz., glass, silicon wafers, PMMA,[1] nylon, polyurethane, polypropylene, gold, and so forth, have been tried. Among them, glass has been the most preferred one owing to its features such as easy availability, handling, functionalization by well-known silane chemistry, and low intrinsic background, as well as adaptability to latest laser scanners.

Basically, two approaches, viz., in situ synthesis of oligonucleotides on the surface of choice (*4*, *5*) and post-synthesis immobilization of oligonucleotides (spotting method) (*6*−*9*), have been explored for the preparation of oligonucleotide microarrays. The first method produces high-density biochips, albeit, it lacks flexibility and involves sophisticated and expensive instruments. The second approach, employing spotting techniques that use presynthesized oligonucleotides, is widely used for most of the applications in biological research and, thus, has become the method of choice. Following the later approach, a number of reports on covalent and non-covalent attachment of oligonucleotides have appeared in the literature (*10*−*13*). Usually, this approach involves immobilization of suitably modified oligonucleotides on the surface of choice in the presence of condensing reagents. Here, the oligonucleotide is modified with a functional group that allows covalent attachment to a reactive group generated on the surface. Many of the attachment strategies are also based on heterobifunctional crosslinking reagents (*7*, *8*). A few of them, viz., NTMTA and NTPAC, have already been reported from the authors' laboratory (*10*−*12*).

[1] TET, tetrachlorofluoresceinyl; NTPAC, *N*-(3-trifluoroethanesulfonyloxypropyl)-anthraquinone-2-carboxamide; NTMTA, *N*-(2-trifuoroethanesulfonatoethyl)-*N*-(methyl)-triethoxysilylpropyl-3-amine; PMMA, polymethylmethacrylate; DMF, *N*,*N*-dimethylformamide; DMSO, dimethylsulfoxide; NHS, *N*-hydroxysucciniimde.

The use of oligonucleotide arrays is expanding beyond their high-profile role in sequencing the genome to other fundamental applications such as diseases diagnostics. To fulfill the changing requirements, alternative approaches are required for the fabrication of oligonucleotide arrays that would guarantee a high level of reproducibility and fast immobilization reaction. In search of a novel chemistry, which would respond to these specifications, we have explored the fast kinetics of reactions attained under microwaves for microarray fabrication.

Here, we describe the design, synthesis, and use of a new heterobifunctional reagent, *N*-(iodoacetyl)-*N*′-(anthraquinon-2-oyl)-ethylenediamine (IAED), for construction of oligonucleotide microarrays on a modified glass surface under microwaves, an alternative energy source (*14*−*18*) to reduce the reaction times from hours to minutes with improved selectivity and yields. The method is suitable for the preparation of oligonucleotide-based biochips without employing any additional activating/condensing reagent, making the strategy efficient and rapid. The potential of the proposed reagent has been evaluated for immobilization of oligomers via two different routes. For comparison purposes as well as to highlight the significance of the projected strategy, the immobilization of thiolated oligonucleotides was carried out under thermal conditions. The rate of reaction involving thiolated oligonucleotides and IAED was found to be much faster under MW (10 min) vs 2 h and 45 min at 45 °C for −SH and $-OPSO_2^{2-}$ oligomers, respectively. The prepared biochips (oligonucleotide microarrays) were subjected to hybridization assay using labeled complementary oligonucleotides, followed by visualization of fluorescent spots under a laser scanner. Subsequently, the biochips were also successfully used for detection of base mismatches.

EXPERIMENTAL PROCEDURES

Preparation of Modified Glass Microslides. Poly-prep glass microslides were soaked in a capping solution, acetic anhydride/triethylamine/*N*-methylimidazole/dichloroethane (1:1:0.4:6, v/v), for 1 h at 35 °C. Subsequently, the slides were rinsed thoroughly with dichloroethane (3 × 100 mL) and diethylether (2 × 100 mL), respectively, and dried under vacuum for further use.

Oligonucleotide Synthesis and Purification. Oligonucleotides were synthesized at 0.2 μmol scale on a Pharmacia Gene

Assembler Plus (see Supporting Information) using the standard phosphoramidite approach following the manufacturer's protocol (Pharmacia.LKB Gene Assembler Plus Manual, Uppsala, Sweden, 1988).

Buffers. (i) Reaction buffer: 0.1 M sodium phosphate, pH 8.5. (ii) Washing buffer: 0.1 M sodium phosphate, pH 7.1. (iii) Hybridization buffer: 0.1 M sodium phosphate containing 1 M sodium chloride, pH 7.1.

Preparation of *N*-(anthraquinon-2-oyl)-ethylenediamine (AED) 2. To a solution of anthraquinone-2-carboxylic acid (5.0 mmol) **1** and *N*-hydroxysuccinimide (6.0 mmol) in anhydrous *N*,*N*-dimethylformamide (DMF) (25 mL) was added DCC (6.0 mmol). The reaction was allowed to stir for 3 h at room temperature. After completion of reaction (monitored on TLC), the reaction mixture was filtered and the residue washed once with THF (5 mL). The filtrate was added dropwise to a solution of ethylenediamine (7.5 mmol) in dry tetrahydrofuran (25 mL) containing triethylamine (5 mmol). The reaction was allowed to stir for 4 h at room temperature. Then, the reaction mixture was concentrated under vacuum to a syrupy mass, which was dissolved in dichloromethane (150 mL) and washed with aqueous solutions of 5% citric acid (2 × 25 mL), 5% sodium bicarbonate (2 × 25 mL), and a saturated solution of sodium chloride (1 × 25 mL), respectively. The organic phase was collected, dried over anhydrous sodium sulfate, and, after filtration, concentrated under vacuum to obtain *N*-(anthraquinon-2-oyl)-ethylenediamine **2** as a solid material in ∼70% yield. The compound was characterized Ir, by ^{1}H NMR and mass spectroscopy. ^{1}H NMR (DMSO), δ: 2.92 (t, 2H), 3.4 (t, 2H), 7.98−8.75 (m, 7H), 9.11 (br, 1H). MS (*m*/*z*): 295.2 $(M + H)^+$. IR, ν (cm^{-1}): 1202, 1651, 2935, 3393.

Preparation of *N*-(iodoacetyl)-*N*′-(anthraquinon-2-oyl)-ethylenediamine (IAED) 3. To a solution of iodoacetic acid (2.0 mmol) and *N*-hydroxysuccinimide (2.5 mmol) in anhydrous *N*,*N*-dimethylformamide (DMF) (10 mL) was added DCC (2.5 mmol). The reaction was allowed to stir for 3 h at room temperature. After completion of reaction, dicyclohexylurea was removed by filtration, and to the filtrate, *N*-(anthraquinon-2-oyl)-ethylenediamine (1.8 mmol), dissolved in DMF (5 mL) containing triethylamine (1.8 mmol), was introduced dropwise over a period of 10 min with continuous stirring at room temperature. The reaction was allowed to stir for 4 h at room temperature. Then, it was concentrated under vacuum to a syrupy mass, which was dissolved in dichloromethane (75 mL) and washed with an aqueous solution of 5% sodium bicarbonate (2 × 25 mL) and a saturated solution of sodium chloride (1 × 25 mL), respectively. The organic phase was collected, dried over anhydrous sodium sulfate, and, after filtration, concentrated under vacuum to obtain crude *N*-(iodoacetyl)-*N*′-(anthraquinon-2-oyl)-ethylenediamine **3**. Subsequently, the crude material was purified by silica gel column chromatography to obtain the title compound in ∼80% yield. The compound was characterized Ir, by ^{1}H NMR and mass spectroscopy. ^{1}H NMR (DMSO), δ: 3.35−3.55 (m, 4H), 3.95 (s, 2H), 7.08 (br, 1H), 7.95−8.74 (m, 7H), 8.97 (br, 1H). MS (*m*/*z*): 463.3 $(M + H)^+$. IR, ν (cm^{-1}): 1286, 1670, 1709, 2931, 3317.

Determination of Threshold Concentration of Oligonucleotides on Glass Surface for Fluorescent Detection. To arrive at the threshold concentration of immobilized oligonucleotides required for visualization on a glass surface, an oligomer sequence, TET-OPO_3-d(TTC GTC ATC AAG TAG TTC CT)-OPO_3-$(CH_2)_6NHCO(CH_2)_2SH$, was serially diluted with reaction buffer, containing DMSO (10%), in five different concentrations (10, 5, 2.5, 1.0, and 0.5 μM) and applied onto an IAED-activated glass microslide (route B) in duplicate with the help of a pipettman. The spotted microslide was kept inside a microwave oven and irradiated for 10 min (30 × 20 s) (see Supporting Information). Each exposure was 20 s, followed by cooling in an ice bath for 5 s. Subsequently, the glass slide was subjected to washings with washing buffer (3 × 10 mL), dried under vacuum, and visualized under a laser scanner set at 570 nm. Similarly, thiophosphate oligomer, TET-OPO_3-d(TTC GTC ATC AAG TAG TTC CTT TTT T)-$OPSO_2^{2-}$, was immobilized on the activated glass slide and, after usual washings, visualized under a laser scanner.

Specificity of Immobilization Chemistry and Detection of Base Mismatches. Oligonucleotide sequences, viz., $HS(CH_2)_6$-OPO_3-d(CCT CTG TTC AGA TGC TCT GC), $HS(CH_2)_6OPO_3$-d(CCT CTG TTC AGA T<u>T</u>C TCT GC), $HS(CH_2)_6OPO_3$-d(CC<u>A</u> CTG TTC AGA T<u>T</u>C TC<u>T</u> GC), $HS(CH_2)_6OPO_3$-d(ACT GG<u>C</u> GTC CGT CAG <u>G</u>CA TT), were dissolved in reaction buffer containing DMSO (10%) and spotted onto an IAED-activated glass microslide (route B). The spotted slide was processed, as described above, and after drying, the slide was subjected to hybridization assay. In a glass Petri dish, the spotted glass slide was kept on a wet blotting paper, and the complementary oligomer, TET-OPO_3-d(GCA GAG CAT CTG AAC AGA GG) (25 μM dissolved in 50 μL of hybridization buffer), was spread on the spotted area. The area was covered with a coverslip, and the slide kept at 60 °C for 5 min, and later at ambient temperature for 2 h and at 10 °C for another 2 h. After removal of the coverslip, the slide was washed with washing buffer (3 × 10 mL), dried under vacuum, and subsequently, visualized under a laser scanner.

Similarly, thiophosphorylated oligomers, viz., d(CCT CTG TTC AGA TGC TCT GCT TTT T)-$OPSO_2^{2-}$, d(CCT CTG TTC AGA T<u>T</u>C TCT GCT TTT T)-$OPSO_2^{2-}$, d(CC<u>A</u> CTG TTC AGA T<u>T</u>C TCT GC)-$OPSO_2^{2-}$, d(ACT GGC GT<u>C</u> CGT CAG GCA <u>T</u>TT TTT T)-$OPSO_2^{2-}$, were immobilized and fluorescent spots visualized under a laser scanner after hybridization assay.

Under each of the above experimental conditions, the experiment was repeated 2−3 times. The immobilization and hybridization data presented are the average of these repeat experiments, and the error bars represent the percentage error (±2−4%) observed. In order to determine the immobilization and hybridization efficiencies, a calibration curve was constructed using a labeled oligomer (see Supporting Information).

RESULTS AND DISCUSSION

The present study has been undertaken with the objective to design a versatile general purpose heterobifunctional reagent to immobilize modified oligonucleotides on a variety of polymer matrices. The reactive groups in the heterobifunctional reagent were carefully selected, keeping in mind that one of the reactive groups must have reactivity toward oligonucleotides bearing a thiol or thiophosphate or phosphorothioate group, as they can easily be introduced during solid-phase synthesis of oligonucleotides using commercially available reagents and chemicals. A perusal of literature revealed that the iodoacetyl group would be an ideal choice, as it has specificity and sufficient reactivity toward these functionalities. We reckoned that the second group which would effectively functionalize a variety of polymer matrices such as polypropylene (PP), polyethylene (PE), nylon, modified glass, and so forth may be the photoactivable anthraquinone molecule which does not suffer from the intrinsic drawbacks of functionalities such as nitrenes and carbenes (*19*, *20*). Moreover, the use of anthraquinone in the synthesis of a heterobifunctional reagent has many attributes, viz., the reactions associated are fast, clean, and result in high yields. Recently, a heterobifunctional reagent, *N*-(3-trifluoroethanesulfonyloxypropyl)-anthraquinone-2-carboxamide (NTPAC), has been reported from our laboratory for the immobilization of biomolecules on various polymeric surfaces (*12*). However, its preparation requires the

Scheme 1. Strategy for the Synthesis of IAED and Immobilization of Modified Oligonucleotides (−SH and -$OPSO_2^{2-}$) on Activated Glass Surface via Two Routes

use of an expensive and a highly moisture sensitive reagent, trifluoroethanesulfonyl chloride. In the present methodology, the iodoacetyl group reacts selectively with thiol functions present in modified oligonucleotides to produce a thioether/thioester linkage, and the anthraquinone moiety reacts with C−H-containing polymer surfaces under UV light, generating stable covalent bonds. Both the reactions proceed under mild conditions. However, to speed up the reaction of thiols (i.e., −SH, $-OPSO_2^{2-}$, $-OPSO_2^{-}-$) with the iodoacetyl group of IAED, reactions were performed under MW, where it completes in just 10 min with all three functionalities. The sufficient stability and high solubility of the new reagent in water-miscible solvents, such as DMF and DMSO, are among its desired features.

Synthesis of *N*-(iodoacetyl)-*N′*-(anthraquinon-2-oyl)-ethylenediamine (IAED) 3. The two-step preparation of the reagent, IAED, is illustrated in Scheme 1. In the first step, anthraquinone-2-carboxylic acid **1** was converted into its NHS ester, followed by reaction with ethylenediamine to obtain *N*-(anthraquinon-2-oyl)-ethylenediamine (AED) **2** as a solid material in ∼70% yield. The compound **2** was further reacted with iodoacetic acid-*N*-hydroxysuccinimide ester to obtain a syrupy mass, which was then purified by silica gel column chromatography to obtain the desired reagent, IAED **3**, in ∼80% yield. The reagent and its precursor were characterized by IR, ^{1}H NMR, and mass spectroscopy (vide experimental).

Threshold Concentration to Visualize Fluorescent Spots. In order to arrive at the optimal concentration required for visualization of an oligonucleotide on the modified glass microslide, an iodoacetylated glass microslide was prepared using IAED (route B). Subsequently, an oligomer, TET-OPO_3-d(TTC GTC ATC AAG TAG TTC CT)-OPO_3-$(CH_2)_6$NHCO-$(CH_2)_2$SH, was immobilized in different concentrations under MW. After usual washings with the buffer solution and drying under vacuum, the slide was subjected to scanning under a laser scanner set at 570 nm. The pictorial view of the slide is depicted in Figure 1A. The immobilization efficiency (lane 2) against each concentration (lane 1) was also determined with the help of a standard curve, which was plotted between fluorescence intensity (A.U.) of the spot vs concentration. The spots corresponding to 0.5−2.5 μM concentration were visible; however, to construct a good quality biochip, a concentration of 5 μM was selected and used for immobilization purposes. Similar data was observed in case of 3′-thiophosphorylated oligomer (Figure 1B).

Hybridization. The applicability of the projected strategy was evaluated by performing hybridization assay of slides fabricated via both the routes (A and B). (see Supporting Information).

Specificity of the Proposed Methodology. In order to demonstrate the efficacy of the proposed heterobifunctional reagent to construct biochips and to detect base mismatches, a series of oligonucleotides, viz., $HS(CH_2)_6OPO_3$-d(CCT CTG TTC AGA TGC TCT GC), $HS(CH_2)_6OPO_3$-d(CCT CTG TTC AGA T$\underline{T}$C TCT GC), $HS(CH_2)_6OPO_3$-d(CC$\underline{A}$ CTG TTC AGA T$\underline{T}$C T$\underline{C}$T GC), $HS(CH_2)_6OPO_3$-d(ACT GG$\underline{C}$ GTC CGT CAG G$\underline{C}$A TT), were covalently fixed on a modified glass slide via route B. After the usual capping and washings, the slide was subjected to hybridization with a complementary labeled oligomer, TET-OPO_3-d(GCA GAG CAT CTG AAC AGA GG). After thorough washings, the glass slide was visualized under a laser scanner. On the basis of fluorescence intensity, base mismatches were identified and the results are revealed in Figure 2A,B. The perfectly matched duplex flashed the maximum intensity (lane 1), while the spots having one (lane 2) and two (lane 3) mismatches showed fluorescence intensity values in decreasing order, and the non-complementary material (lane 4) did not glow at all. It is apparent from the results that the immobilized oligonucleotides are specific toward complementary oligonucleotides. The signal-to-noise ratio was on an average >97, as calculated from the signal obtained from hybridized (lane 1) and unhybridized oligomers (lane 4) at 5 μM concentration. Figure 3A,B depicts the results obtained with thiophosphorylated probes. The low background in this system may be attributed to the fact that the surface is not positively charged and, therefore, not prone to non-specific interactions with negatively charged oligonucleotides.

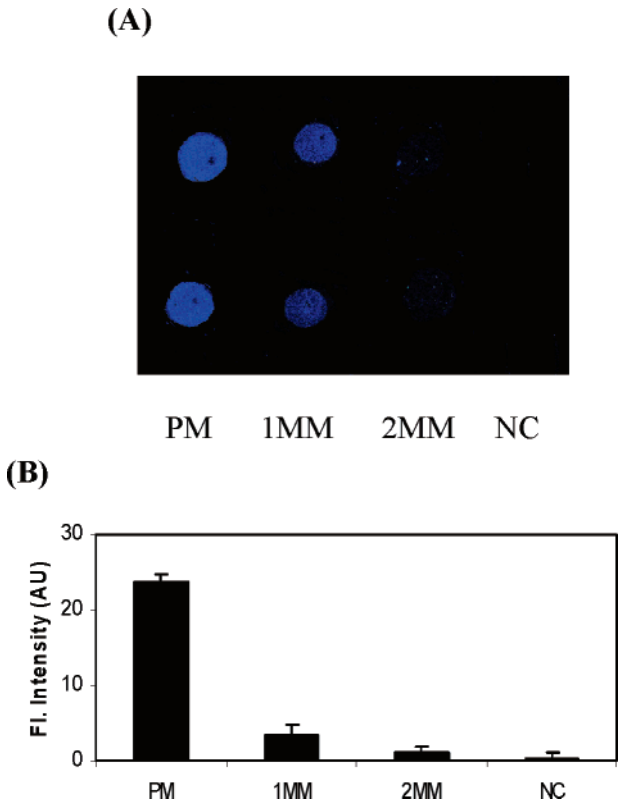

Figure 3. (A) Fluorescence map showing the detection of nucleotide mismatches and specificity of immobilization via hybridization with TET-OPO_3-d(GCA GAG CAT CTG AAC AGA GGT TTT T) (25 μM). Lane 1, d(CCT CTG TTC AGA TGC TCT GCT TTT T)-$OPSO_2^{2-}$; Lane 2, d(CCT CTG TTC AGA T$\underline{T}$C TCT GCT TTT T)-$OPSO_2^{2-}$; Lane 3, d(CC$\underline{A}$ CTG TTC AGA T$\underline{T}$C TCT GCT TTT T)-$OPSO_2^{2-}$; Lane 4, d(AC$\underline{T}$ GGC GTC CGT C$\underline{A}$G GCA TTT TTT T)-$OPSO_2^{2-}$, each spotted at 5 μM. Slide was scanned at 85% of laser power and 80% of photomultiplier gain. (B) Comparison of fluorescence intensity observed with zero, single, and double mismatch in probe after hybridization with target (complementary to zero mismatch).

Thermal Stability. The thermal stability of the constructed arrays (biochips) using the projected reagent was also evaluated by subjecting the spotted slide to PCR-like conditions. The results demonstrate that linkages employed for immobilization are stable for exploitation in biological research (see Supporting Information).

CONCLUSIONS

In summary, a new heterobifunctional reagent has been synthesized and used for fabrication of oligonucleotide microarrays on the glass surface. The preparation of the projected reagent is straightforward, and it displays sufficient stability on storage. Using the new reagent, we have demonstrated the rapid immobilization of oligonucleotides bearing mercaptoalkyl and thiophosphate functions on the uncharged glass surface. The immobilized probes are stable during PCR-like conditions. The strategy can be used for biological assays involving higher

temperatures. The data demonstrate that the featured strategy may be useful for the preparation of new devices for DNA arrays.

ARTICLES

Visualization of the Degradation of a Disulfide Polymer, Linear Poly(ethylenimine sulfide), for Gene Delivery

Yan Lee, Heejung Mo, Heebeom Koo, Jong-Yeun Park, Min Yi Cho, Geun-woo Jin, and Jong-Sang Park*

School of Chemistry and Molecular Engineering, Seoul National University, San 56-1, Gwanak-gu, Seoul, 151-742, Korea.
Received May 2, 2006; Revised Manuscript Received August 24, 2006

Polyethylenimine (PEI) shows high transfection efficiency and cytoxicity due to its high amine density. The new disulfide cationic polymer, linear poly(ethylenimine sulfide) (*l*-PEIS), was synthesized for efficient and safe gene delivery. As the amine density of *l*-PEIS increased, the transfection efficiency also increased. *l*-PEIS-6 and *l*-PEIS-8 show transfection efficiencies that are similar to that of PEI. However, cytotoxicity of *l*-PEIS was not observed due to the biodegradable disulfide bond. The disulfide bonds are stable in the oxidative extracellular condition and can be degraded rapidly in the reductive intracellular condition. The degradation of *l*-PEIS in HeLa cells was visualized by fluorescence microscopy using the probe−probe dequenching effect of BODIPY-FL fluorescence dye. *l*-PEIS was degraded completely within 3 h.

INTRODUCTION

Various polymers are used in the field of drug and gene delivery (*1*−*4*). Much research has concentrated on the development of a polymer with high transfection efficiency. However, high transfection efficiency often induces cytotoxicity. For example, polyethylenimine (PEI) is one of the most effective nonviral gene-delivery carriers, but its cytotoxicity is too high for in vivo gene delivery (*5*, *6*).

Polyethyleneglycol (PEG)-conjugated PEI (*7*) and low-molecular-weight PEI (*8*) have lower toxicity, but also lower transfection efficiency, than high-molecular-weight PEI (22 kDa or 25 kDa). On the basis of these results, low-molecular-weight amine derivatives have been conjugated to each other with biodegradable bonds, and the resulting polymers tested for gene delivery to determine whether a higher molecular weight would increase transfection efficiency and whether subsequent biodegradation to lower molecular weights would reduce cytotoxicity. Although the biodegradable amine derivatives reduced cytotoxicity, most of them were less efficient than PEI for transfection (*9*−*12*).

It has been reported that the exceptionally high transfection efficiency of PEI is due to the endosome buffering effect of its high amine density (*13*). Among many commercially available cationic polymers, the amine densities (Da/1N) of three representative polymers, PEI, poly(L-lysine) (PLL), and poly(amidoamine) (PAMAM) G4, are shown in Table 1. Since high amine density appears to be an important factor for high efficiency of PEI, a polymer having both a high amine density and biodegradability may be required.

Esters, acetals, orthoesters, and disulfides are the most widely used among many possible biodegradable bonds. Ester bonds in biopolymers usually are unstable in aqueous solution (*14*, *15*). Therefore, ester polymers must be manipulated carefully, and it is hard to control the release of the drugs or genes. In contrast, acetals and orthoesters can be used for controlled release because they are stable at neutral pH but degraded at acidic pH (*16*, *17*). It also has been reported that disulfide bonds are stable in the oxidative extracellular environment but are degraded rapidly in the reductive intracellular environment due to the 5 mM concentration of reduced glutathione (*18*). Thus, polymers linked with disulfide bonds can be useful for selective release in the cytosol (*19*). However, it is not known whether the polymer can be degraded in the cytosol as well as in a buffer with 5 mM glutathione. No clear proof of degradation within the cell has been presented clearly in experiments with other biodegradable polymers.

Table 1. Amine Density, M_n, and M_w of Commercially Available Cationic Polymers and *l*-PEIS Derivatives

	amine density (Da/1N)	M_n/ M_w	PD
PEI	42		
PLL	128		
PAMAM G4	113		
l-PEIS-2	89	10970/18830	1.716
l-PEIS-4	66	17150/20430	1.191
l-PEIS-6	58	7786/11340	1.457
l-PEIS-8	55	7143/11680	1.635

Therefore, we have synthesized the linear poly(ethylenimine) derivatives with disulfide bonds having various amine densities as shown in Scheme 1. In this paper, we would measure the transfection activity and cytotoxicity of these derivatives, linear poly(ethylenimine sulfide) (*l*-PEIS), and want to prove the degradation of *l*-PEIS in the cytosol as well as in the buffer with 5 mM glutathione.

Scheme 1. Synthesis of *l*-PEIS-2, -4, -6, and -8[a]

[a] Conditions: (a) TsCl, DMAP, TEA/dichloromethane at 0 °C; (b) ethanolamine, dimethylformamide at 50 °C; (c) potassium thioacetate/dimethylformamide at RT; (d) phenol, 33% HBr/acetic acid at 90 °C; (e) aqueous solution under oxygen pressure at RT.

($CDCl_3$), deuterium oxide (D_2O), poly(ethylenimine) (PEI, average molecular weight 25 kDa), Hepes, and 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma-Aldrich (St. Louis, MO). The Luciferase 1000 Assay System and Reporter Lysis Buffer were purchased from Promega (Madison, WI). Minimal Essential Medium (MEM), Dulbecco's Modified Eagle's Medium (DMEM), trypsin-EDTA, and antibiotic−antimycotic were purchased from GIBCO (Gaithersburg, MD). Phosphate-buffered saline (PBS) was purchased from Cambrex Bio Science (Walkersville, MD). Fetal bovine serum (FBS) was purchased from JBI (Korea). The Micro BCA Protein Assay Kit was purchased from Pierce (Rockford, IL). The BODIPY-FL STP ester was purchased from Invitrogen (Carlsbad, CA). ExGen 500 was purchased from Euromedex (France).

Synthesis of 5, 6, 7, and 8 (step a). **1**, **2**, **3**, and **4** (10 mmol) were dissolved in 40 mL dichloromethane. 4-(Dimethylamino)-pyridine (DMAP) (1 equiv, 10 mmol), triethylamine (9.2 equiv, 92 mmol), and *p*-toluenesulfonyl chloride (4.4 equiv, 44 mmol) were added. The mixture was stirred at 0 °C for 1 day. The solvent was removed by evaporation and dissolved in 100 mL chloroform. The solution was washed three times with 0.1 N HCl. The organic layer was dried with $MgSO_4$ and evaporated. The final products were obtained as white or pale yellow powder from silica column chromatography. Yield was about 60−80%. ^{1}H NMR spectra of the products were obtained using a Bruker DPX-300 NMR spectrometer (300 MHz). In the deuterium solvent, TMS (3-(trimethylsilyl)propionic acid sodium salt) was used as an internal reference (0 ppm). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm) of **5**: 2.45 (s, 12H, tosyl $-CH_3$), 3.30 (s, 4H, $-CH_2N(Ts)CH_2CH_2OTs$), 3.37 (t, 4H, $-N(Ts)CH_2CH_2OTs$), 4.14 (t, 4H, $-N(Ts)CH_2CH_2OTs$), 7.35 (d, 8H, aromatic protons of tosyl groups), 7.72 (d,d, 8H, aromatic protons of tosyl groups). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm) of **6**: 2.42 (s, 12H, *N*-tosyl $-CH_3$), 2.45 (s, 16H, *O*-tosyl $-CH_3$), 3.27 (m, 8H, $-CH_2N(Ts)CH_2CH_2OTs$), 3.43 (m, 8H, $-CH_2N(Ts)CH_2-CH_2N(Ts)CH_2CH_2OTs$), 4.16 (t, 4H, $-N(Ts)CH_2CH_2OTs$), 7.34 (m, 12H, aromatic protons of tosyl groups), 7.78 (m, 12H, aromatic protons of tosyl groups). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm) of **7**: 2.41 (s, 18H, *N*-tosyl $-CH_3$), 2.43 (s, 6H, *O*-tosyl $-CH_3$), 3.26 (m, 8H, $-CH_2N(Ts)CH_2CH_2OTs$), 3.37 (m, 16H, $-CH_2N(Ts)CH_2CH_2N(Ts)CH_2CH_2N(Ts)CH_2CH_2OTs$), 4.13 (t, 4H, $-N(Ts)CH_2CH_2OTs$), 7.31 (m, 16H, aromatic protons of tosyl groups), 7.77 (m, 16H, aromatic protons of tosyl groups). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm) of **8**: 2.43 (m, 30H, tosyl $-CH_3$), 3.28 (m, 8H, $-CH_2N(Ts)CH_2CH_2OTs$), 3.42 (m, 24H, $-CH_2N(Ts)CH_2CH_2N(Ts)CH_2CH_2N(Ts)CH_2CH_2N(Ts)CH_2CH_2-OTs$), 4.16 (t, 4H, $-N(Ts)CH_2CH_2OTs$), 7.32 (m, 20H, aromatic protons of tosyl groups), 7.83 (m, 20H, aromatic protons of tosyl groups).

Synthesis of 2, 3, and 4 (step b). **5**, **6**, and **7** (1 mmol) were dissolved in 20−30 mL DMF. After the solute was dissolved completely, ethanolamine (10 equiv, 10 mmol) was added slowly. The solution was stirred at 50 °C for 1−2 days. After evaporation, the mixture was dissolved in DMSO and evaporated again for the removal of the remaining ethanolamine.

Synthesis of 9, 10, 11, and 12 (step c). **5**, **6**, **7**, and **8** (10 mmol) were dissolved in 50 mL DMF. Potassium thioacetate (2.5 equiv) was added and stirred at RT overnight. The DMF solution was evaporated and poured into 100 mL of water. The mixture was extracted three or four times with chloroform, and the organic layer was collected, dried with $MgSO_4$, and evaporated to give the final products. Yield was about 75%. ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm) of **9**: 2.34 (s, 6H, $-COCH_3$), 2.44 (s, 6H, *N*-tosyl $-CH_3$), 3.04 (t, 4H, $-N(Ts)CH_2-CH_2S-$), 3.25 (t, 4H, $-N(Ts)CH_2CH_2S-$), 3.39 (s, 4H, $-CH_2N(Ts)CH_2CH_2S-$), 7.33 (d, 4H, aromatic protons of tosyl groups), 7.75 (d, 4H, aromatic protons of tosyl groups). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm) of **10**: 2.32 (s, 6H, $-COCH_3$), 2.41 (s, 6H, inner *N*-tosyl $-CH_3$), 2.44 (s, 6H, outer *N*-tosyl $-CH_3$), 3.03 (t, 4H, $-N(Ts)CH_2CH_2S-$), 3.23 (t, $-CH_2CH_2N(Ts)CH_2-CH_2S-$), 3.37 (m, 12H, $-CH_2N(Ts)CH_2CH_2N(Ts)CH_2CH_2S-$), 7.32 (m, 8H, aromatic protons of tosyl groups), 7.77 (d, 8H, aromatic protons of tosyl groups). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm) of **11**: 2.31 (s, 6H, $-COCH_3$), 2.41 (m, 18H, *N*-tosyl $-CH_3$), 3.02 (t, 4H, $-N(Ts)CH_2CH_2S-$), 3.23 (t, 4H, $-CH_2-CH_2N(Ts)CH_2CH_2S-$), 3.36 (m, 20H, $-CH_2N(Ts)CH_2CH_2N-(Ts)CH_2CH_2N(Ts)CH_2CH_2S-$), 7.31 (m, 12H, aromatic protons of tosyl groups), 7.78 (m, 12H, aromatic protons of tosyl groups). ^{1}H NMR (300 MHz, $CDCl_3$, δ ppm) of **12**: 2.32 (s, 6H, $-COCH_3$), 2.41 (m, 24H, *N*-tosyl $-CH_3$), 3.01 (t, 4H, $-N(Ts)CH_2CH_2S-$), 3.23 (t, 4H, $-CH_2CH_2N(Ts)CH_2CH_2S-$), 3.36 (m, 28H, $-CH_2N(Ts)CH_2CH_2N(Ts)CH_2CH_2N(Ts)CH_2-CH_2N(Ts)CH_2CH_2S-$), 7.29 (m, 16H, aromatic protons of tosyl groups), 7.77 (m, 16H, aromatic protons of tosyl groups).

Tosyl and Acetyl Deprotection (step d). A solution of **9** (1 mmol) and phenol (0.41 mmol) in 33% HBr/AcOH (15.4 mL) was refluxed for 24 h. The reaction mixture was filtered, and the resulting pale brown solid was washed with ethanol. After refluxing for 1 h with ethanol, the solution was filtered and the resulting solid was washed twice with diethyl ether to obtain the pale brown powder (**13**). The syntheses of **14**, **15**, and **16** were performed in the same way. ^{1}H NMR (300 MHz, D_2O, δ ppm) of **13**: 3.03 (t, 4H, $-NHCH_2CH_2SH$), 3.41 (m, 8H, $-CH_2-NHCH_2-$). ^{1}H NMR (300 MHz, D_2O, δ ppm) of **14**: 3.07 (t, 4H, $-NHCH_2CH_2SH$), 3.23 (s, 4H, $-CH_2NH\ CH_2CH_2\ NH\ CH_2CH_2SH$), 3.32 (t, 4H, $-CH_2CH_2NHCH_2CH_2SH$), 3.45 (t, 4H, $-CH_2NHCH_2CH_2SH$), 3.55 (t, 4H, $-CH_2CH_2SH$). ^{1}H NMR (300 MHz, D_2O, δ ppm) of **15**: 3.07 (t, 4H, $-NHCH_2-$

CH_2SH), 3.22−3.32 (m, 16H, $-CH_2NHCH_2CH_2NHCH_2CH_2NHCH_2CH_2SH$), 3.39 (t, 4H, $-CH_2NHCH_2CH_2SH$), 3.52 (t, 4H, $-CH_2CH_2SH$). ^{1}H NMR (300 MHz, D_2O, δ ppm) of **16**: 3.10 (t, 4H, $-NHCH_2CH_2SH$), 3.22−3.32 (m, 24H, $-CH_2NHCH_2CH_2NHCH_2CH_2NHCH_2CH_2NHCH_2CH_2SH$), 3.39 (t, 4H, $-CH_2NHCH_2CH_2SH$), 3.52 (t, 4H, $-CH_2CH_2SH$).

Polymerization (step e). After the deprotection reactions, **13**, **14**, **15**, and **16** were dissolved in water, and the final concentrations of monomers were adjusted to 100 mM. These solutions were stirred at RT for 2 days under oxygen pressure (1 atm). The polymer solutions were evaporated, washed with diethyl ether, and dried to give the final polymer products. ^{1}H NMR (300 MHz, D_2O, δ ppm) of **17**: 3.07 (t, 4H, $-CH_2SS-$), 3.31 (t, 4H, $-CH_2CH_2SS-$), 3.54 (s, 4H, $-CH_2NHCH_2CH_2SS-$). ^{1}H NMR (300 MHz, D_2O, δ ppm) of **18**: 3.05−3.30 (m, 16H, $-CH_2NHCH_2CH_2NHCH_2CH_2SS-$), 3.45 (t, 4H, $-CH_2CH_2SS-$). ^{1}H NMR (300 MHz, D_2O, δ ppm) of **19**: 3.07−3.51 (m, 28H). ^{1}H NMR (300 MHz, D_2O, δ ppm) of **20**: 3.07−3.65 (m, 36H).

Molecular Weight Measurements of *l*-PEIS. The molecular weights of *l*-PEIS were determined by multiangle laser-light-scattering (MALLS) in combination with size-exclusion chromatography (SEC). The SEC system included a P680 HPLC pump from Dionex Corporation (Sunnyvale, CA). Polymer samples were detected by a three-angle laser-light-scattering detector (miniDAWN Tristar, 30 mW GaAs laser, 690 nm, K5 cell) and an interferometric refractometer (Optilab DSP, P10 cell) from Wyatt Technologies (Santa Barbara, CA). The MALLS system was operated by *Astra* software version 4.90. A 1% formic acid aqueous solution was used as an eluent after filtration through a 22-nm filter and degassed before use. Ultahydrogel columns (7.8 × 300 mm no. WAT011525 and no. WAT 011545) from Waters (Milford, MA) were used. The solution was delivered to a flow cell inlet at a constant flow rate of 0.4 mL/min. The d*n*/d*c* values for *l*-PEIS-2, *l*-PEIS-4, *l*-PEIS-6, and *l*-PEIS-8 are 0.1881, 0.2092, 0.1771, and 0.1649 (mL/g), which were measured by an interferometric refractometer (Optilab DSP, P10 cell) from Wyatt Technologies (Santa Barbara, CA).

Plasmid Preparation. The firefly luciferase gene was used as a reporter gene to monitor the results of gene transfection. The luciferase expression plasmid (pCN-Luci) was constructed by subcloning the cDNA of *Photinus pyralis* luciferase, with its 21-amino-acid nuclear localization signal, from the SV40 large T antigen to pCN. The pCN vector is known to result in higher expression than the vector with the CMV promoter alone. Plasmid DNA was transformed into *E. coli* TOP10 competent cells, and highly purified covalently closed circular plasmid DNA was isolated by using plasmid purification Giga kits from Qiagen (Valencia, CA) according to the manufacturer's instructions. Plasmids were precipitated with isopropyl alcohol, washed twice with a 70% ethanol solution, and resuspended in distilled water. DNA was stored at −70 °C until use.

Cell Culture. Human liver carcinoma HepG2 cells were grown in MEM, and human cervical cancer HeLa cells were maintained in DMEM. Both media contained 10% fetal bovine serum (FBS) and 1% antibiotic−antimycotic agent. The cell lines were obtained from the Korean Cell Line Bank and incubated at 37 °C in 5% CO_2.

In Vitro Transfection Assay. Cells were seeded at a density of 5 × 10^4 cells/well in 24-well plates in 600 μL of media containing 10% FBS and grown to 70−80% confluence. Prior to transfection, the medium was changed to serum-free medium. Polyplexes were formed by mixing 2 μg of plasmid DNA and polymer at different N/P ratios in 120 μL of a serum-free medium, followed by incubation for 30 min at RT. Cells were treated with the polyplex solution. After 4 h incubation at 37 °C, the medium was replaced with fresh medium containing 10% FBS. After incubation for 2 days at 37 °C, the luciferase activity of transfected cells was analyzed using a LB 9507 luminometer (Berthold, Germany), and the protein content was measured with Micro BCA assay reagents (Pierce, Rockford, IL). The transfection activities shown in Figure 1A are those at the optimum N/P ratios. The optimum N/P ratios are 8 for ExGen 500, *l*-PEIS-2, and *l*-PEIS-4, and 16 for *l*-PEIS-6 and *l*-PEIS-8.

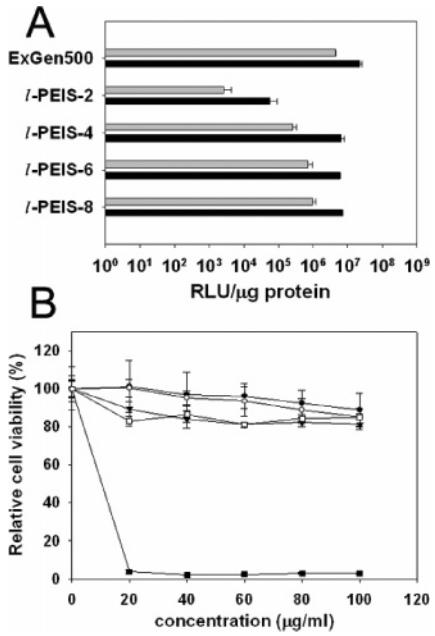

Figure 1. Transfection efficiency (A) (gray bar, HeLa; black bar, HepG2) and cytotoxicity (B) on the HeLa cell line of *l*-PEIS-2 (●), *l*-PEIS-4 (○), *l*-PEIS-6 (▼), *l*-PEIS-8 (□), and ExGen 500(■).

In Vitro Cytotoxicity Assay. MTT assay was used to measure cytotoxicity. HeLa cells were seeded in 96-well tissue culture plates at 10^4 cells/well in 90 μL DMEM medium containing 10% FBS. Cells achieving 70−80% confluence after 24 h were exposed to 10 μL of various concentrations of the polymer solutions for 4 h, after which 26 μL of stock solution of MTT (2 mg/mL in PBS) was added to each well. After 2 h of incubation at 37 °C, the media was exchanged with 150 μL of DMSO extraction buffer. The absorbance was measured at 570 nm using a microplate reader (Molecular Devices Company, Menlo Park, CA). The results were calculated as a percent absorbance to untreated control cells.

Synthesis of *l*-PEIS-BODIPY-FL. *l*-PEIS-6 (10 mg, 1.3 μmol) was dissolved in 2 mL of 5% DMSO aqueous solution. BODIPY-FL STP ester (FW = 542.19) (6 equiv, 7.7 μmols, 4.2 mg) in 200 μL of DMSO was added slowly to the solution. After stirring for 3 h at 37 °C, the solution was dialyzed against deionized water. The dialysis membrane (MWCO = 1000) was purchased from Hankook Spectrum Company. Following 24-hr dialysis, the product solution was lyophilized. The molar ratio between *l*-PEIS-6 and BODIPY was calculated from the M_n of *l*-PEIS-6 and the integration ratio in the ^{1}H NMR spectrum of *l*-PEIS-6-BOD. The molar ratio of BODIPY to *l*-PEIS-6 was 2.0 in the experiment below. The BODIPY-conjugated ExGen 500 was prepared by the same method.

The Degradation of *l*-PEIS-6 in a GSH Solution. *l*-PEIS-6 was dissolved in PBS (pH = 7.4) and combined with a glutathione solution in PBS. The final concentrations of *l*-PEIS-6 and glutathione were 1.0 mg/mL and 5 mM, respectively. The mixture was stirred at 37 °C. After some time, 500 μL was collected, and excess iodoacetic acid (10 mM) was added to prevent further degradation during the measurement of the

molecular weight. The molecular weight analysis was performed as described above for *l*-PEIS.

The Degradation of *l*-PEIS-BODIPY-FL in a GSH Solution. *l*-PEIS-BODIPY-FL was dissolved in PBS (pH = 7.4) containing 1% (v/v) DMSO. The solution was combined with a glutathione solution in PBS containing 1% DMSO. The final concentrations of *l*-PEIS-BODIPY-FL and glutathione were 10 μg/mL and 5 mM, respectively. The mixture was incubated at 37 °C. The fluorescence was measured with an FP-750 spectrofluorometer (Jasco) at RT. The excitation and emission wavelengths were 504 and 513 nm, respectively. The fluorescence of the solution was measured every 30 min.

The Degradation of *l*-PEIS-BODIPY-FL in the Cell. Cells were seeded at a density of 5×10^3 cells/well in 24-well plates in 600 μL of medium containing 10% FBS. After a 1-day incubation at 37 °C, the medium was aspirated, and 600 μL of PBS (pH = 7.4) containing 1% DMSO and *l*-PEIS-BODIPY-FL were added. The final concentration of *l*-PEIS-BODIPY-FL was 10 μg/mL. As a positive control, 5 mM glutathione was added to one well with *l*-PEIS-BODIPY-FL. As a negative control, 10 μg/mL of *l*-PEIS-6 was added to a well without *l*-PEIS-BODIPY-FL. After some time, the cells were observed with an Axiovert 25 fluorescence microscope (Carl Zeiss) with the filter set 09 (488009-0000).

RESULTS AND DISCUSSION

Synthesis of *l*-PEIS Derivatives. To obtain both high amine density and biodegradability, oligoethylenimine (*20*) or low-molecular-weight PEI (*21*) have been linked with disulfide or ester bonds in the previous reports. The resulting irregular polymers have transfection efficiencies that are somewhat satisfactory. Therefore, the linear poly(ethylenimine) derivatives with disulfide bonds having various amine densities were synthesized, as shown in Scheme 1. The number following *l*-PEIS indicates the number of internal amines in the monomer.

Secondary amine and hydroxyl groups of bis(2-hydroxyethyl) derivatives (**1**, **2**, **3**, and **4**) were tosylated by *p*-toluenesulfonyl chloride. The terminal tosyl esters were the activating groups for the next substitution reaction, and the internal tosyl amides were the protecting groups. The tosylated derivatives (**5**, **6**, **7**, and **8**) could be elongated by the substitution with two ethanolamines (**2**, **3**, and **4**) or thioacetylated (**9**, **10**, **11**, and **12**). Deprotection of tosyl amide and thioacetyl groups was performed by hydrobromic acid/acetic acid solution.

Each deprotected monomer (**17**, **18**, **19**, and **20**) was polymerized by the stirring under oxygen pressure. Molecular weights measured by gel permeation chromatography are not reliable, because polymer having high amine density can nonspecifically adsorb to the column. Therefore, the molecular weights of *l*-PEIS were measured by the multiangle laser-light-scattering method (MALLS) (*22*). The molecular weights ranged from about 10 000 to 20 000 as shown in Table 1.

Transfection Efficiency and Cytotoxicity of *l*-PEIS. *l*-PEIS-2 with two amines between the disulfide bonds has one-half the amine density (1 N per 89 Da) of PEI (1 N per 42 Da). As the number of amines between the disulfide bonds increases, the amine density of *l*-PEIS increases. *l*-PEIS-8, with a monomer of eight amines, has an amine density (1 N per 55 Da) similar to that of PEI.

Figure 1A shows the transfection efficiency of *l*-PEIS in HepG2 and HeLa cell lines as compared to that of the linear PEI derivative, ExGen 500 (22 kDa). As the amine density of *l*-PEIS increases, the transfection efficiency in both cell lines increases. *l*-PEIS-6 and *l*-PEIS-8 have amine densities and transfection efficiencies that are similar to those of ExGen 500.

The cytotoxicity of *l*-PEIS derivatives was measured in the HeLa cell line, as shown in Figure 1B. ExGen 500, with a non-biodegradable backbone, shows very high cytotoxicity at a concentration of 20 μg/mL. In contrast, all of the *l*-PEIS derivatives with degradable disulfide linkages show very low or negligible cytotoxicity at that concentration and even at concentrations of 100 μg/mL. Thus, it appears that *l*-PEIS can transfect cells with high efficiency due to its high amine density, but has low toxicity because they can be degraded into low-molecular-weight monomers with small charges.

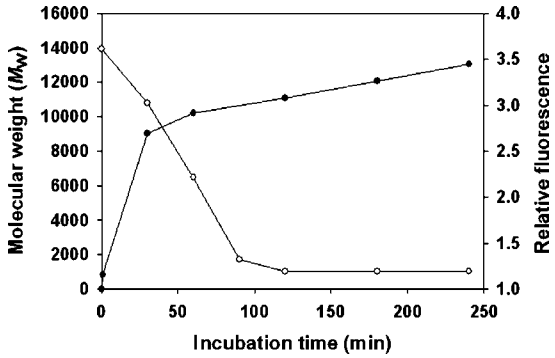

Figure 2. The decrease in molecular weight (○) and fluorescence enhancement (●) of *l*-PEIS-6.

Degradation of *l*-PEIS in a GSH Solution. Recently, we reported the degradation of poly(ethylene oxide sulfide) (PEOS), which is composed of disulfide-linked oligoethylene oxide (*23*). PEOS is degraded completely within 2 h in 5 mM glutathione buffer. By the same way, after a 37 °C incubation of *l*-PEIS-6 in 5 mM glutathione in phosphate-buffered saline, the molecular weight of a sample from the degradation buffer was measured by MALLS. As shown in Figure 2, like PEOS, *l*-PEIS-6 is degraded completely within 2 h. However, there is no clear proof of degradation within the cytosol in experiments with these and other types of biodegradable polymers.

Therefore, a fluorescence method was chosen to measure the degradation in the cytosol. BODIPY fluorescent dye is well-known for its probe−probe quenching effect. When more than two BODIPY dyes are conjugated to one molecule, the fluorescent intensity decreases sharply (*24*). However, if the molecule is degraded into small molecules and the dyes are separated, the fluorescence can be enhanced. This process is illustrated in Figure 3. BODIPY fluorescent dye has been used to measure the degradation of a BODIPY-conjugated polymer (*25*) and for the visualization of viral capsid degradation (*26*).

Two BODIPY-FL molecules were conjugated to an *l*-PEIS-6 molecule, and the recovery of fluorescence was observed during incubation under reductive conditions (Figure 2). As the molecular weight of *l*-PEIS-6-BOD decreases, its fluorescence increases more than 3-fold. Therefore, this material can be used to measure degradation within the cell.

Visualization of the Degradation of *l*-PEIS in the Cytosol. Fluorescence microscopy was used to observe the development of fluorescence in HeLa cells after addition of *l*-PEIS-6-BOD. Fluorescence in the cell interior begins to develop after 0.5 h (Figure 4A). The green fluorescence intensity of BODIPY in the cytosol increases after 2 h (Figure 4C) and is clearly shown in Figure 4E. No further increase of the fluorescence was observed after 3 h. The fluorescence outside of the cell is low in all images. However, when 5 mM of reduced glutathione is added to the cell medium as a positive control, the strong fluorescence of the *l*-PEIS-6-BOD is outside, as well as inside, the cell (Figure 4G).

Meanwhile, the fluorescence of nondegradable BODIPY-conjugated ExGen 500, a negative control, did not show any dependence upon time (Figure 4B,D,F) or the concentration of GSH (Figure 4H). Low fluorescence in the cell interior probably

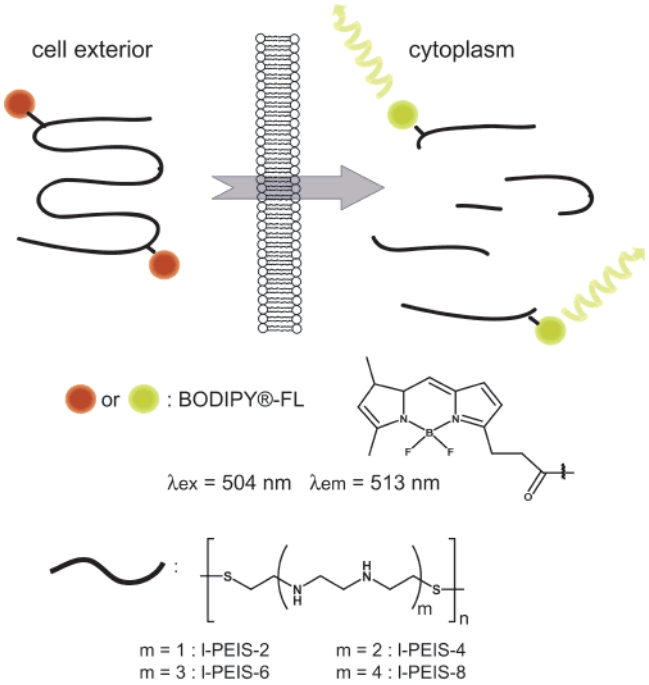

Figure 3. Structure and diagram of the intracellular degradation of *l*-PEIS.

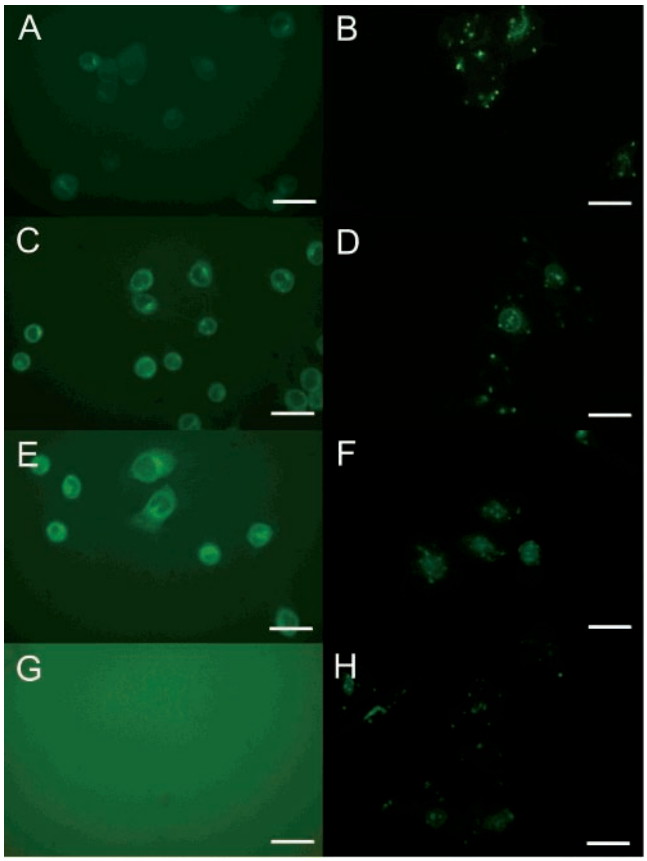

Figure 4. Fluorescence microscopic images treated with *l*-PEIS-6-BOD (A,C,E,G) and ExGen 500-BOD (B,D,F,H). After 0.5 hr (A,B), 2 hr (C,D), 3 hr (E,F), and 0.5 hr treatment with 5 mM glutathione (G,H). The white bars represent 40 μm.

originated from a portion of ExGen 500 with low density of conjugated BODIPY-FL. These results demonstrate that BODIPY-conjugated *l*-PEIS can be degraded, emitting enhanced fluorescence, in the reductive environment of the cell.

CONCLUSION

Using the characteristics of disulfide bonds—stability in the oxidative extracellular environment and degradability in the reductive intracellular environment, we have developed a disulfide derivative of poly(ethylenimine), linear poly(ethylenimine sulfide). The transfection efficiency of *l*-PEIS increases as the amine density increases. *l*-PEIS-6 and *l*-PEIS-8 have transfection efficiencies that are similar to that of PEI, without the high cytotoxicity. Above all, we have proposed methods for measuring and observing the degradation of a biodegradable polymer in the cell interior.

l-PEIS has the characteristics of an ideal nonviral gene delivery carrier: high efficiency and low toxicity. *l*-PEIS has potential applications in many gene-delivery experiments, through improvements in the efficiency, specificity, and stability in serum by cross-linking, ligand coupling, PEGylation, and so forth. In addition, the visualization and measurement of a biodegrading polymer will be of great benefit in investigations of the relationship between polymer degradation and delivery and controlled release.

Poly(glycoamidoamine)s for Gene Delivery. Structural Effects on Cellular Internalization, Buffering Capacity, and Gene Expression

Yemin Liu and Theresa M. Reineke*

Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221-0172. Received February 3, 2006; Revised Manuscript Received August 17, 2006

The study of polymeric nucleic acid delivery vehicles has recently grown because of their promise for many biomedical applications. In an effort to understand how the chemical traits of polymers affect the biological mechanisms of nucleic acid delivery, we have calculated the buffering capacity in the physiological pH range of a series of 10 poly(glycoamidoamine)s with systematic structural variations in the amine stoichiometry (from 1 to 4), carbohydrate moiety (D-glucarate or L-tartarate), and amine spacer (ethylene or butylene) within their repeat units. In addition, we have compared the buffering capacity of these polymeric vectors to their polyplex (polymer−DNA complex) stability, cellular internalization, and gene expression profiles to understand the parameters that are important for increasing gene delivery efficiency. The results indicate that the buffering capacity is not always the primary characteristic that determines the gene delivery efficiency for all the poly(glycoamidoamine)s. We have found that the buffering capacity may affect the gene delivery efficiency only when analogous structures containing the same number of amines but different carbohydrates are compared. We reveal that the cellular internalization is the key step in the gene delivery process with systems containing different amine stoichiometry. Also, increasing the number of methylene groups between the secondary amines increases toxicity to a large degree. This systematic and heuristic approach of studying the correlations between structural variables and gene delivery efficiency will facilitate the development of effective synthetic vectors for specific nucleic acid delivery applications.

INTRODUCTION

Synthetic polymers that exhibit positively charged functionalities at physiological pH (e.g., amine groups) readily bind to the negatively charged phosphate groups in nucleic acids and can serve as carriers to deliver genetic materials into cells. It has been shown that the complex (also named polyplex) formed between polymers and DNA can associate with the negatively charged cell surface membrane and trigger uptake via endocytosis (*1*). The study of synthetic nucleic acid carriers has become extremely important to the areas of gene therapy, genetic vaccines, siRNA, and oligonucleotide drugs (*2*−*4*). For this reason, developing polycations as practical delivery vectors has recently grown because of their simplicity of use, ease of large-scale production, and lack of eliciting an immune response in vivo (*5*). However, the chemical traits of polymers can significantly affect the mechanisms and kinetics involved with cellular uptake via endocytosis and intracellular trafficking. To date, general chemical structure−biological property relationships are poorly understood, which has hampered efforts to produce highly efficient nonviral gene delivery vectors by a systematic and rational approach.

The "proton sponge" theory has been a main hypothesis in the field of polymeric gene delivery that has been used to explain how polyplexes are released into the cytoplasm from endocytic vesicles. This theory states that after polyplexes are endocytosed, the polycations can buffer the acidification event by absorbing protons, which causes a further influx of HCl to compensate for this extra buffering capacity. This leads to an osmotic influx of water, endosome membrane disruption due to vesicle swelling, and release of polyplexes into the cytoplasm (*6*). According to the proton sponge theory, the buffering capacity of polymeric vectors is a key characteristic to interpret and estimate the transfection efficiency. Theoretically, the higher the polymer buffering capacity, the greater the osmotic effect, which increases endosomal disruption. This theory is valid for polyethylenimine (PEI) and some other polymers containing amine groups, such as poly(amidoamine) dendrimers (*7*) and histidylated polylysine (*8*). However, several recent studies have shown that the proton sponge mechanism does not always hold true for polymeric vectors. For example, Pack et al. revealed that decreasing the buffering capacity of PEI by acetylating the amines actually increased gene expression (*9*). Hennink et al. found that the enhanced buffering capacity in polydiamine methacrylate did not increase the gene delivery (*10*). Davis et al. did not observe a correlation between the buffering capacity and gene expression within a series of β-cyclodextrin-containing polymers and modified PEI (*11*). To address this contradiction, Duncan et al. have demonstrated that optimization of the counterion within a series of poly(amidoamine)s (PAAs) was significant for pH-dependent endosomal membrane permeability (*12*). It has also been suggested that the biological properties of tailored PAAs are mediated predominantly by cell membrane interaction and not by the proton sponge effect (*13*, *14*).

Our group has recently created a library of carbohydrate-containing polymers that we have termed poly(glycoamidoamine)s and studied the correlation between the polymer structure and the bioactivity toward gene delivery (e.g., cytotoxicity and gene delivery efficiency) (*15*−*18*). Although we have found that these structures all retain high biocompatibility, the delivery efficacy was significantly affected by the number of amines within the polymer repeat units. When the amine number in the repeat unit was increased from 1 to 4, a significant enhancement in gene expression was found. In those studies, we assumed that the improvement in delivery efficacy upon increasing the amine density was due to a higher buffering capacity of the polymer within the physiological pH range. In the present study, we further investigate how the structural traits

of these polymeric vectors are related to their abilities to buffer the endosomal environment and enhance the delivery efficacy. Here, the buffering capacity of a subset of these poly(glycoamidoamine)s with systematic variations in the amine stoichiometry (from 1 to 4), carbohydrate moiety (D-glucarate or L-tartarate), and amine spacer (ethylene or butylene) has been calculated in the physiological pH range through nonlinear fitting of titration data. In this study, the D-glucarate and L-tartarate polymers were chosen because their monomer precursors (D-glucaric acid and L-tartaric acid) are both natural sugar acids. In addition to the buffering capacity, we have also characterized the polyplex stability, the cellular internalization, and luciferase gene expression with BHK-21 cells for each type of polyplex. Herein, we demonstrate that both the cellular uptake and endosomal release are essential steps in the delivery of genetic material mediated by poly(glycoamidoamine)s. For example, when analogous structures containing the same carbohydrate unit but different amine stoichiometry are compared, the gene delivery efficiency is highly dependent on the cellular uptake efficiency, but not the buffering capacity. Yet, when analogous structures containing the same amine number but a different carbohydrate unit are compared, the structures with higher buffering capacity tend to yield higher gene expression values. This examination has provided insights into the physiochemical properties of poly(glycoamidoamine)s and their relationship to the "proton sponge" hypothesis, which is essential to the future rational design of effective delivery vehicles.

EXPERIMENTAL PROCEDURES

General. All reagents used in the synthesis, if not specified, were obtained from Acros (Morris Plain, NJ). Esterified D-glucaric acid (**D**) was synthesized according to reported procedures (*19*). Melting points of polymers were measured with a Netzsch simultaneous TG-DTA/DSC apparatus (Selb/Bayern, Germany). IR spectra were taken with a Perkin-Elmer Spectrum One Fourier transform infrared spectrometer (Boston, MA) as KBr pellets. NMR spectra were collected on a Bruker AV-400 MHz spectrometer (Billerica, MA). Plasmid DNA (pDNA) gWiz-Luc and pCMVβ were purchased from Aldevron (Fargo, ND) and PlasmidFactory (Bielefeld, Germany), respectively. Heparin was purchased from Sigma (St. Louis, MO) as heparin ammonium salt from porcine intestinal mucosa. Dulbecco's Modified Eagle medium (DMEM), reduced serum medium (Opti-MEM), supplements, nuclease-free water, and phosphate-buffered saline (PBS) were purchased from Invitrogen (Carlsbad, CA). BHK-21 cells were purchased from ATCC (Rockville, MD) and cultured according to ATCC specifications in DMEM (supplemented with 10% FBS, 100 units/mg penicillin, 100 μg/mL streptomycin, and 0.25 μg/mL amphotericin) in 5% CO_2 at 37 °C. All polyplexes were prepared in nuclease-free water unless otherwise specified. N/P ratios (the ratio of the number of amines/phosphates from pDNA) were calculated by using the number of amine groups in the polymer repeat unit (and not the amide nitrogens).

Polymerization. The poly(glycoamidoamine)s **D1**−**D4** and **T1**−**T4** were synthesized as previously described (*17*, *18*). The spermine-based polymers were synthesized through condensation polymerization of esterified D-glucaric acid (**D**), or dimethyl L-tartarate (**T**) with spermine (**S**) in methanol at room temperature as detailed below (*19*, *20*). After polymerization, each product was dissolved in ultrapure water, exhaustively dialyzed to purity in a Spectra Por 1000 molecular weight cutoff membrane (Rancho Dominguez, CA), and then lyophilized to dryness with a Flexi-dry MP lyophilizer (Stone Ridge, NY).

Poly(D-glucaramido-*N*,*N*′-bispropyl-diaminobutane) (DS). Spermine (0.09 g, 0.42 mmol) was mixed with esterified D-glucaric acid (0.10 g, 0.42 mmol) in 2.8 mL of methanol and stirred at room temperature for 48 h. Yield: 0.05 g, 0.13 mmol, 31%. mp: 194.2 °C (dec). IR (KBr): 3356 cm^{-1} (O−H and N−H stretching), 2939 cm^{-1} and 2870 cm^{-1} (C−H stretching), 1651 cm^{-1} (amide C═O stretching), 1539 cm^{-1} (amide N−H bending), 1476−1398 cm^{-1} (CH_2 scissoring), 1350 cm^{-1} and 1285 cm^{-1} (CH_2 twisting and wagging), 1110 cm^{-1} and 1048 cm^{-1} (amine C−N stretching). ^{1}H NMR (D_2O): δ 4.24 (d, 1H), 4.14 (d, 1H), 4.02 (t, 1H), 3.86 (t, 1H), 3.21 (br, 4H), 2.70 (br, 8H), 1.72 (br, 4H), 1.52 (br, 4H).

Poly(L-tartaramido-*N*,*N*′-bispropyl-diaminobutane) (TS). Spermine (0.11 g, 0.56 mmol) was mixed with dimethyl L-tartarate (0.10 g, 0.56 mmol) in 1.2 mL of methanol and stirred at room temperature for 48 h. Yield: 0.03 g, 0.10 mmol, 16%. mp: 221.5 °C (dec). IR (KBr): 3366 cm^{-1} (O−H and N−H stretching), 2939 cm^{-1} and 2870 cm^{-1} (C−H stretching), 1650 cm^{-1} (amide C═O stretching), 1540 cm^{-1} (amide N−H bending), 1476 − 1400 cm^{-1} (CH_2 scissoring), 1355 cm^{-1} and 1285 cm^{-1} (CH_2 twisting and wagging), 1114 cm^{-1} and 1047 cm^{-1} (amine C−N stretching). ^{1}H NMR (D_2O): δ 4.42 (s, 2H), 3.21 (br, 4H), 2.62 (br, 8H), 1.67 (br, 4H), 1.47 (br, 4H).

Gel Permeation Chromatography (GPC). The molecular weight, polydispersity index, and Mark−Houwink−Sakurada (MHS) parameter α for each polymer were measured with a Viscotek GPCmax Instrument (Houston, TX) equipped with a ViscoGEL $GMPW_{XL}$ column coupled to a triple detection system (static light scattering, viscometry and refractive index). Mobile phase (0.5 M sodium acetate, pH 5.5) was prepared in ultrapure water containing 20% acetonitrile. Each sample (100 μL, 10−15 mg/mL) was dissolved in the mobile phase, immediately injected onto the column, and eluted at 1.0 mL/min.

Titration of the Poly(glycoamidoamine)s. Each poly(glycoamidoamine) was dissolved in 5 mL PBS (pH = 7.4). The concentration of each polymer was expressed in terms of total concentration of amine groups and was kept between 0.064 and 0.068 M for each polymer solution. This polymer concentration was calculated by assuming that each endosome is 200 nm, one polyplex is endocytosed, and each polyplex formulated at an N/P ratio of 15 consists of one pDNA molecule (gWizLuc, 6.7 kbp). The titration of each polymer solution was performed with an aqueous solution of HCl (0.1 M standard) in thermo-stat flasks. The temperature was maintained at 37 °C throughout each titration with a Fisher Scientific isotherm circulator model 3016 (Pittsburgh, PA). The pH values were recorded with an Accumet pH meter model AB15 (Pittsburgh, PA). Nonlinear regression of the experimental data was performed with the software Graphpad Prism 4.0 (San Diego, CA).

Zeta Potential Measurements. The poly(glycoamidoamine)s were dissolved in PBS buffer as described for titration experiments and adjusted to various pH conditions between 3.5−8.5 using an aqueous solution of HCl (0.1 M standard). The zeta potential values were measured at 37 °C with laser doppler velocimetry (633 nm) on a Zetasizer (Nano ZS) instrument (Malvern Instruments, Worcs, UK).

Heparin Competitive Displacement Assay. This experiment was performed as previous described for **D4** (*16*), and **T4** (*15*). In brief, each polymer (10 μL) was combined with pCMVβ (1 μg in 10 μL of H_2O) to form polyplexes at N/P = 20. The polyplexes were allowed to incubate for 30 min. A series of heparin solutions were prepared by diluting aliquots of a heparin stock solution (2700 μg/mL). The polyplex solutions were then incubated with 10 μL of each heparin solution above for 15 min. After the addition of loading buffer (1 μL), an aliquot (10 μL) of each sample was subjected to electrophoresis in a 0.6% agarose gel containing 60 μg of ethidium bromide/100 mL TAE buffer (40 mM Tris-acetate, 1 mM EDTA).

Salt-Induced Polyplex Dissociation. Polyplexes were prepared as described above in the heparin competitive displace-

ment assay and diluted with water to a concentration of 0.3 μg of DNA/100 μL solution. PicoGreen (Molecular Probes, Eugene, OR) solutions were prepared by 200-fold dilution with 10 mM HEPES (Sigma, St. Louis, MO) buffer containing various concentrations of NaCl. After the polyplex solution was arrayed into a Costar black flat-bottom 96-well plate, 100 μL of the PicoGreen solutions were added to each well to achieve the desired concentration of NaCl. The fluorescence of PicoGreen (excitation 485 nm, emission 535 nm) for each sample was measured with a TECAN US plate reader (Research Triangle Park, NC). Fractional dye exclusion was determined by the following relationship:

$$\text{Dye Exclusion} = 1 - (F_{\text{sample}} - F_{\text{blank}})/(F_{\text{DNAonly}} - F_{\text{blank}})$$

Luciferase Reporter Gene Transfection and Cell Viability Assays. Prior to transfection, BHK-21 cells were seeded at 5 $\times$ 10^4 cells/well in 24-well plates and were incubated for 24 h. Polymer solutions (150 μL) were incubated with gWiz-Luc (150 μL, 0.02 μg/μL) at N/P ratios of 5, 10, 15, 20, 25, and 30 at room temperature for 1 h to form the polyplexes. The mixtures were then diluted to 900 μL with serum-free media (Opti-MEM, pH = 7.2). Each well of cells was transfected with 300 μL of the polyplex solution containing 1 μg of gWiz-Luc pDNA complexed with each poly(glycoamidoamine) at N/P ratios between 0 (pDNA only) and 30 in triplicate. Untransfected cells and cells transfected with naked gWiz-Luc (1 μg of pDNA, N/P = 0) were used as negative controls. Four hours after the transfection, 800 μL of the supplemented DMEM was added to each well. Twenty-four hours after transfection, the media was replaced with fresh supplemented DMEM (1 mL). Forty-seven hours after initial transfection, the media was removed and the cells were washed with 500 μL of PBS and treated with cell culture lysis buffer (Promega, Madison, WI). The amount of protein in the cell lysates (as milligram of protein) was determined against a standard curve of bovine serum albumin (98%, Sigma, St. Louis, MO), using a Bio-Rad DC protein assay kit (Hercules, CA).

Cell lysates were analyzed for luciferase activity with Promega's luciferase assay reagent (Madison, WI). For each sample, luminescence was measured over 10 s in duplicate with a luminometer (GENios Pro, TECAN US, Research Triangle Park, NC), and the average was utilized. The cell viability profiles were characterized by the amount of protein in the cell lysates. The protein levels of the transfected cells were normalized to the protein amount obtained for untransfected cells.

Flow Cytometry. pCMVβ was labeled with a Cy5 nucleic acid labeling kit (Mirus, Madison, WI), and purified by QIAquick PCR purification kit (QIAGEN, Valencia, CA). BHK-21 cells were seeded on 12-well plates at 1.0 $\times$ 10^5 cells/well and allowed to incubate in supplemented DMEM at 37 °C and 5% CO_2 for 24 h. The polyplexes were prepared by combining 100 μL of Cy5 labeled pCMVβ (0.02 μg/μL) and 100 μL of **D1**−**D4** or **T1**−**T4** at the N/P values of maximum luciferase gene expression (N/P = 20 for **D1**, and N/P = 30 for **D2**−**D4** and **T1**−**T4)**. The cells were then transfected with 0.2 mL of polyplex solution (2 μg of pDNA/well) in 0.4 mL of serum-free media (Opti-MEM). The cells were incubated with each solution for 4 h to allow endocytosis and internalization of the polyplexes. After transfection, the cells were rinsed with PBS multiple times to remove the cell surface bound polyplexes. Supplemented DMEM was then added and the cells were incubated for another 30 min to allow further polyplex internalization. Four and half hours after initial transfection, the cells were trypsinized, pelleted, and resuspended in PBS containing 2% FBS for fluorescent activated cell sorting (FACS) analysis. A FACSCalibur (Becton Dickenson, San Jose, CA) equipped with a helium-neon laser to excite Cy5 (633 nm) was used. Five thousand events were collected twice for each sample. The positive fluorescence level was established by visual inspection of the histogram of untransfected cells such that less than 1% appeared in the positive region.

RESULTS AND DISCUSSION

The intracellular delivery of genetic materials involves a complex pathway requiring several biological steps: (i) cell membrane binding; (ii) cellular uptake via endocytosis; (iii) endosomal release and vector unpacking; and (iv) nuclear entry and gene expression (*21*). The biological properties of polycationic vectors, such as binding affinity to DNA, cell membrane binding and entry, and the buffering capacity of polymers in the endosome may influence the gene delivery efficiency (and gene expression) by affecting different stages in the cellular trafficking pathway. Previous studies have shown that subtle structural differences, such as the addition of one ethyl amine group in the repeat unit, can significantly affect the delivery efficacy (*15*−*18*). Here, we have further investigated the polymer structural effects on the polyplex stability, the polymer buffering capacity under physiological pH, cellular internalization of polyplexes, and the luciferase gene expression with BHK-21 cells. We show that an increase in the polymer buffering capacity within the physiological pH range does not necessarily correlate to an increase in gene expression, indicating that the buffering capacity is not always the main characteristic that determines the efficiency for all the poly(glycoamidoamine) delivery vectors. This study provides more insight into the rational design of poly(glycoamidoamine) gene delivery vectors for various applications.

Synthesis and Characterization of Poly(glycoamidoamine)s. D1−**D4** and **T1**−**T4** were synthesized as previously described (*17*, *18*) and named according to the carbohydrate moieties (**D** for D-glucarate; **T** for L-tartarate) and the number of amine groups (**1**−**4**) in the repeat units. As shown in Figure 1, the amine groups are separated by an ethylene group in **D1**−**D4** and **T1**−**T4**. In the polymers synthesized with spermine, **DS** and **TS**, the adjacent amines are separated by a butylene group, which makes the distance between the amine groups twice as long as that in **D2** and **T2**. Also, in the **DS** and **TS** structures, a propane group separates the amine groups from the amides in the repeat unit. As shown in Table 1, the polymerization conditions were optimized so all of the structures had similar degrees of polymerization between 11 and 14 (*17*, *18*). This ensured that the results obtained in this study were not affected by differences in the degrees of polymerization.

Titration of the Poly(glycoamidoamine)s and Nonlinear Regression. In an effort to understand how the polymer buffering capacity affects their DNA delivery efficiency as a function of polymer structure, titration experiments were performed to calculate the fraction of protonated amines in each structure. The poly(glycoamidoamine)s were titrated in PBS at 37 °C to simulate the intracellular environment. Because the protonation of an amine is concentration dependent (*22*), the titrations were performed within the approximate concentration range that would be encountered in an endosome. This concentration range was chosen by assuming that the average endosome diameter of BHK-21 cells is about 200 nm (*23*) and that each endosome could only entrap one polyplex during endocytosis [the polyplex sizes formed with these structures are between 100−500 nm (*16*)]. According to these assumptions, the theoretical polymer concentration in an endosome, where the polyplexes would have been formulated at an N/P = 15 (and consist of one plasmid), was approximately 0.064−0.068 M. As shown in Figure 2, the experimental data were plotted as pH vs volume of added HCl. The nonlinear regression fitting of the titration data was carried

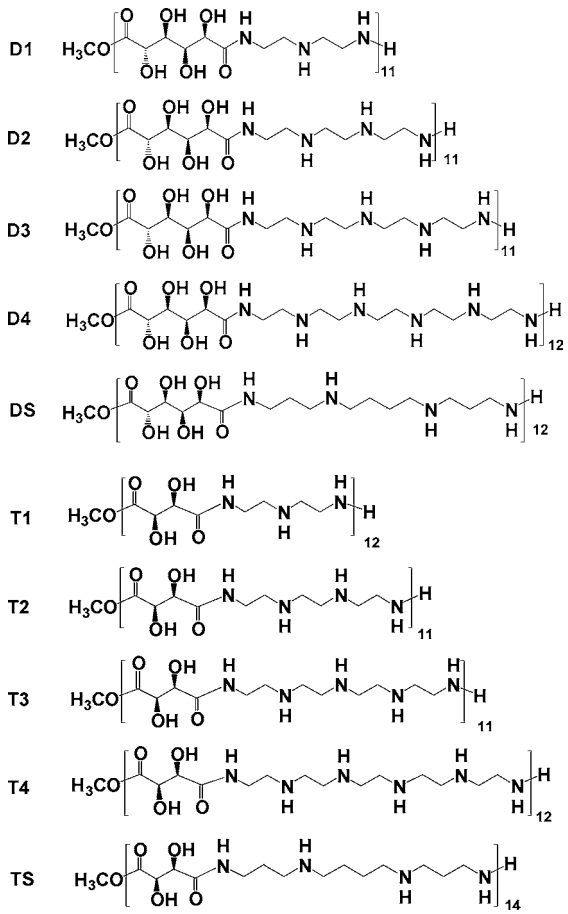

Figure 1. Structures of poly(glycoamidoamine)s.

Table 1. MHS Parameter (α), Molecular Weight (M_w), Polydispersity (M_w/M_n), and Degree of Polymerization (n) Data for the Poly(glycoamidoamine)s

polymer	a	M_w (kDa)	M_w/M_n	n
D1	0.68	3.0	2.0	11
D2	0.67	3.4	1.4	11
D3	0.64	3.9	1.4	11
D4	0.61	4.9	1.6	12
DS	0.66	4.4	1.4	12
T1	0.73	2.7	1.3	12
T2	0.76	2.9	1.3	11
T3	0.77	3.2	1.2	11
T4	0.83	4.3	1.2	12
TS	0.76	4.5	1.2	14

out according to a modified method (*22*), using equilibrium constants [K_{a1}, K_{a2}, and K_{a3} for phosphoric acid (eqs 1−3), K_w of water (eq 4), and K_a of the amine groups (eq 5)] as well as charge (eq 6) and mass balances (eqs 7−11). In these equations, N stands for an amine group in the polymers, whereas v_0 and v represent the initial volume of the polymer solutions (5 mL in PBS) and the volume of the added HCl solution (where $[HCl]_0 = 0.1$ M), respectively. In addition, we assumed that the amide groups [−HN−C(═O)] are not protonated in the pH range of titration (pH > 2), where pK_a value of a protonated amide [$-H_2N^+-C(=O)$] is much lower than 2 (e.g., p$K_a = -0.51$ for acetamide) (*24*). The components of PBS and available equilibrium constants are listed in Table 2.

Equilibrium constants:

$$K_{a1} = \frac{[H_2PO_4^-][H^+]}{[H_3PO_4]} \quad (1)$$

$$K_{a2} = \frac{[HPO_4^{2-}][H^+]}{[H_2PO_4^-]} \quad (2)$$

$$K_{a3} = \frac{[PO_4^{3-}][H^+]}{[HPO_4^{2-}]} \quad (3)$$

$$K_w = [H^+][OH^-] \quad (4)$$

$$K_a = \frac{[N][H^+]}{[NH^+]} \quad (5)$$

Charge balance:

$$[K^+] + [H^+] + [Na^+] + [NH^+] = [Cl^-] + [H_2PO_4^-] + 2[HPO_4^{2-}] + 3[PO_4^{3-}] + [OH^-] \quad (6)$$

Mass balance:

$$[NH^+] + [N] = \frac{v_0}{v_0 + v}[N]_0 \quad (7)$$

$$[Cl^-] = \frac{v}{v_0 + v}[HCl]_0 + \frac{v_0}{v_0 + v}[Cl^-]_0 \quad (8)$$

$$[H_3PO_4] + [H_2PO_4^-] + [HPO_4^{2-}] + [PO_4^{3-}] = \frac{v_0}{v_0 + v}([H_2PO_4^-]_0 + [HPO_4^{2-}]_0) \quad (9)$$

$$[K^+] = \frac{v_0}{v_0 + v}[K^+]_0 \quad (10)$$

$$[Na^+] = \frac{v_0}{v_0 + v}[Na^+]_0 \quad (11)$$

On the basis of these equations, eq 12 was derived:

$$v = v_0 \frac{[H^+] + \dfrac{[N]_0}{1 + K_a/[H^+]} + [K^+]_0 + [Na^+]_0 - [Cl^-]_0 - \dfrac{K_w}{[H^+]} - A}{[HCl]_0 + \dfrac{K_w}{[H^+]} - [H^+]} \quad (12)$$

where

$$A = [H_2PO_4^-] + 2[HPO_4^{2-}] + 3[PO_4^{3-}] = \frac{\dfrac{[H^+]}{K_{a2}} + 3\dfrac{K_{a3}}{[H^+]} + 2}{1 + \dfrac{K_{a3}}{[H^+]} + \dfrac{[H^+]}{K_{a2}}\left(1 + \dfrac{[H^+]}{K_{a1}}\right)}([H_2PO_4^-]_0 + [HPO_4^{2-}]_0)$$

Obviously, the ionization constant K_a of all individual amine groups present in the polymer structures will not be equivalent. One reason is that there are different types of amines in the polymer structures, such as primary amines (oligo-amine monomer-based termination groups of the polymer chain), and

The pink lines indicate the experimental data; the blue lines indicate the calculated data after nonlinear regression using eq 14 and the hypothesized relationship between log Q and pH (eqs 16 or 17).

Table 2. Components of PBS and Equilibrium Constants

components of PBS[a] (mol/L)					equilibrium constants[b]			
$[K^+]_0$	$[Na^+]_0$	$[Cl^-]_0$	$[H_2PO_4^-]_0$	$[HPO_4^{2-}]_0$	K_{a1}	K_{a2}	K_{a3}	K_w
1.06×10^{-3}	1.60×10^{-1}	1.54×10^{-1}	1.06×10^{-3}	2.97×10^{-3}	7.58×10^{-3}	6.17×10^{-8}	4.79×10^{-13}	1.00×10^{-14}

[a] Subscript "0" indicates the initial ion concentrations. [b] Taken from ref *24*.

secondary amines (backbone of the polymer chain). The other reason is that the protonation of an amine group electrostatically suppresses the protonation of neighboring amines. In this study, to determine the total protonated fraction of all amine groups regardless of K_a values, the parameter quotient Q was introduced (eq 13) and was defined as the ratio of the fraction of unprotonated amine groups to the fraction of protonated amines (*22*). Therefore, eq 12 was modified to eq 14 to substitute K_a with quotient Q.

$$Q = \frac{[N]}{[NH^+]} = \frac{f_N}{f_{NH^+}} \tag{13}$$

$$v = v_0 \frac{[H^+] + \frac{[N]_0}{1+Q} + [K^+]_0 + [Na^+]_0 - [Cl^-]_0 - \frac{K_w}{[H^+]} - A}{[HCl]_0 + \frac{K_w}{[H^+]} - [H^+]} \tag{14}$$

From the parameter quotient Q, the total protonated fraction of the amine groups (f_{NH^+}) in the polymer structures at various pH values can be calculated (eq 15):

$$f_{NH^+} = \frac{1}{1+Q} \tag{15}$$

$$\log Q = \alpha pH + \beta \tag{16}$$

$$\log Q = \alpha pH^{\beta} + \gamma pH^{(\beta-1)} + \delta pH^{(\beta-2)} + \epsilon \tag{17}$$

On the basis of the shapes of experimental titration plots (Figure 2), we assumed a linear correlation between log Q and pH (eq 16) for polymers **D2**−**D4** and **T1**−**T4**, and a nonlinear correlation between log Q and pH (eq 17) for **D1**, **DS**, and **TS**. Equation 14 and the hypothesized correlations between log Q and pH for each polymer (eq 16 or eq 17) were combined, and the nonlinear regression of experimental titration data was calculated using software GraphPad Prism 4.0. The goodness of fit (R^2) and the estimated parameters ($\alpha - \epsilon$) from nonlinear regression are summarized in Table 3. The R^2 values for all of

Table 3. Goodness of Fit (R^2) and Calculated Parameters for the Titration of Poly(glycoamidoamine)s

polymers	R^2	α	β	γ	δ	ϵ

the fits are higher than 0.98, indicating satisfactory nonlinear regression of the experimental data. Figure 2 shows the overlay of the experimental titration plots and the calculated plots. The data for polymers **D3**−**D4** and **T3**−**T4** were not shown because the plot shapes were very similar to those obtained for **D2** and **T2**. The calculated data correlated well with the experimental data.

Effects of Carbohydrate Moiety and Amine Unit on the Protonation of Polymers. As previously mentioned, because the protonation of an amine is concentration dependent (*22*), a series of assumptions were made to approximate the initial concentration of amine groups in an endosome for each poly(glycoamidoamine). The polymer was dissolved in PBS such that the amine concentration was between 0.064−0.068 M to compare how the protonation of the amines is affected by the chemical structure. The protonated fraction of amines for each polymer within the physiological pH range between pH = 7.5 (pH of extracelluar space) and pH = 4.5 (pH of intracellular lysosomes) was calculated from eq 15, and the resulting data were plotted vs pH (Figure 3). From these data, it was obvious that the protonation of the polymers increased as the pH decreased from pH 7.5 to pH 4.5. In addition, three trends were noticed: (i) the protonated fraction of total amine groups in the molecules increased as the amine stoichiometry in the structural repeat units decreased (**D1** > **D2** > **D3** > **D4** and **T1** > **T2** > **T3** > **T4**, Figure 3a,b); (ii) the L-tartarate polymers (**T1**−**T4**, Figure 3b; **TS**, Figure 3c) revealed a higher protonated fraction than the corresponding D-glucarate polymers (**D1**−**D4**, Figure 3a; **DS**, Figure 3c); (iii) as the pH decreased, the protonation of **D2** and **T2** increased faster than their spermine-based analogues (**DS** and **TS**). As shown in Figure 3c, the protonated fraction of amines for the spermine-based polymers was compared to their analogues synthesized from triethylenetetramine. At pH = 7.5, the spermine analogues had a higher protonated fraction (**DS** > **D2**, **TS** > **T2**); however, as the pH decreased to 4.5, a different trend was observed. Polymer **D2** revealed a higher protonated fraction than **DS**, but the fraction of protonated amines for polymer **T2** was equivalent to **TS**.

As previously discussed, within a polymer repeat unit, the presence of a cationic ammonium group will electrostatically suppress the protonation of neighboring amines. An "intra-repeat unit interaction" between cationic ammonium groups and unprotonated amines may explain the first trend that is observed when the polymers within each carbohydrate family (**D1**−**D4** and **T1**−**T4**) are compared. The further protonation of amines within a repeat unit is strongly disfavored when one cationic ammonium group is present. Thus, as the number of amines within a repeat unit is increased, a decrease in the protonated fraction is observed. Similarly, an "inter-repeat unit interaction" of protonated amine groups may explain the second trend observed when L-tartarate polymers (have higher protonation) are compared to their corresponding D-glucarate polymers (have lower protonation). There is a significant overall structural difference between the **T** and **D** series of polymers. The L-tartarate polymers polymerize in a stereoregular manner (due to the symmetry of the L-tartarate monomer); however, the D-glucarate polymers polymerize in an atactic fashion. The stereoregularity of the L-tartarate moiety renders the backbones of these polymers to be more rigid than the D-glucarate polymers

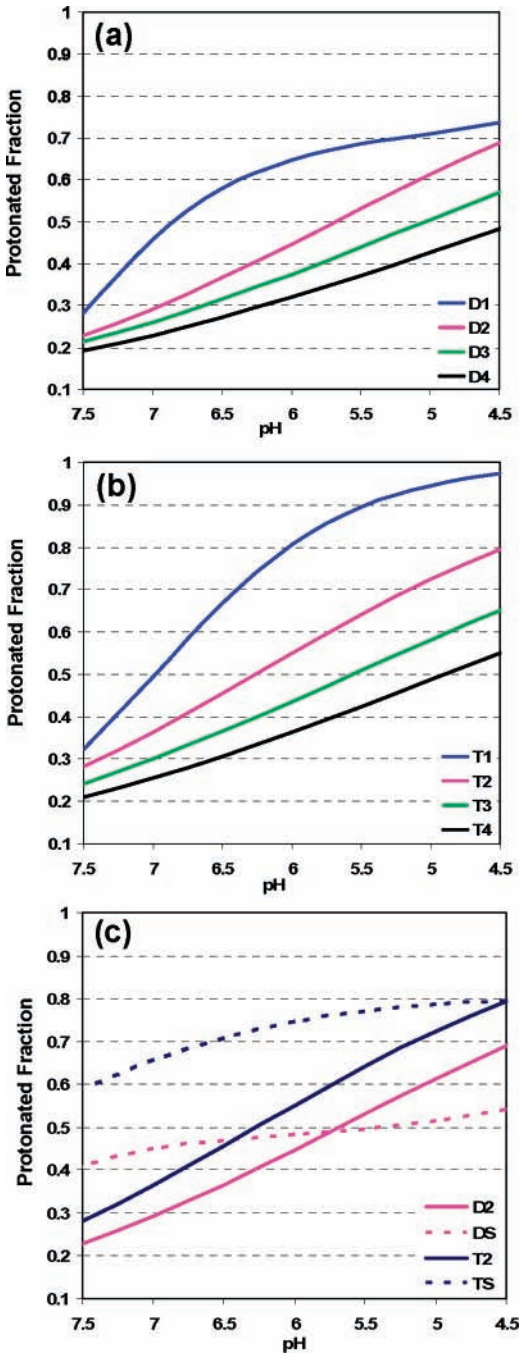

Figure 3. The protonated fraction of amines vs pH for the poly(glycoamidoamine)s calculated from eqs 14−17. (a) Plots for **D1**−**D4**; (b) plots for **T1**−**T4**; (c) comparison of calculated protonated fraction for **DS** and **TS** with **D2** and **T2**.

(*16*, *25*), which is supported by the higher MHS values (α = 0.73−0.83) observed for **T1**−**T4** and **TS** listed in Table 1 (*16*). Consequently, within the secondary structures of the L-tartarate polymers, the distance between oligoamine repeat units is likely greater than that in the D-glucarate polymers because of this stiffness. According to viscosity measurements, the D-glucarate polymers appear to form more random coil-like structures in solution (MHS values between 0.61−0.68), where the smaller distance between repeat units may electrostatically suppress amine protonation via this "inter-repeat unit interaction". With less influence from inter-repeat unit amine groups, the L-tartarate polymers should have a higher degree of protonation in the physiological pH range than the D-glucarate polymers. Lastly, the third trend observed with the spermine based polymers (**DS** and **TS**) may be attributed to a cyclic conformation that the repeat unit may adopt, which is stabilized by H-bonding. Spermine moieties can cyclize, which is induced by delocalization of the cationic charge on the ammonium group with the other unprotonated amine within the same repeat unit and is made possible by the flexible butylene spacer between the amine groups. This cyclization event has been previously observed by Karpas et al. (*26*) where spermine molecules can form a seven-membered ring stabilized by a hydrogen bond between the two central amine groups. Such cyclization within the **DS** and **TS** polymer structures may cause the protonation of the second amine group to be disfavored, thus resulting in a lower fraction of protonated amines with decreasing pH (e.g., 4.5). In addition, the increased hydrophobicity of the spermine moiety may also contribute to the reduced accessibility of the second amine group when titrated in aqueous solution (*27*).

Changes in the protonation of a polycation result in charge variations within the macromolecule that can be characterized by zeta potential measurements. We hypothesized that plotting the zeta potential values as a function of pH for polymers **D2**, **DS**, **T2**, and **TS** would reveal similar trends as the plots of the protonated fraction values (Figure 3c), thus confirming the titration results obtained for these polymers. We tested this hypothesis and found that the L-tartarate polymers had higher zeta potential values than the D-glucarate polymers within the whole endosomal pH range (Figure 4). These data were consistent with the calculated protonation values shown in Figure 3c. For **DS** and **TS**, the zeta potential values increased slower (as the pH decreased) than the zeta potential values for **D2** and **T2**. At higher pH, **DS** and **TS** showed higher zeta potential values (indicating a higher cationic charge), while at lower pH, they had similar zeta potential values to **D2** and **T2**, respectively. These results support the data obtained from the titrations of these polymers and the previously discussed theories regarding electrostatic suppression of amine protonation via "inter-repeat unit interaction" for the D-glucarate polymers and proton-induced cyclization for the spermine polymers.

Buffering Capacity. The buffering capacity of each polymer (Table 4) was calculated via eq 18 by determining the differences in the protonated amine fractions between pH 7.5 (extracellular pH) and pH 4.5 (intracellular lysosome pH). The buffering capacity is the percentage of amines that can be protonated during the acidification event in the endosomes.

$$\text{buffering capacity} = [f_{NH^+}(\text{pH } 4.5) - f_{NH^+}(\text{pH } 7.5)] \times 100\% \quad (18)$$

As shown in Table 4, the L-tartarate-based polymers (**T** series) have a higher buffering capacity than D-glucarate polymer analogues (**D** series), which, again, is likely due to their stiff chain character and the fact that the protonation of the D-glucarate polymers is suppressed by more inter-repeat unit interaction. In addition, the buffering capacity of the polymers in this pH range generally decreased as the number of amines increased in the repeat unit (e.g., **T1** (56.4%) > **T2** (51.2%) > **T3** (40.8%) > **T4** (34.0%)]. The trends for both the **D** and **T** series were similar to those found when the protonated fraction was correlated to the polymer structures (Figure 3). It should be noted that the buffering capacity is a function of the protonated fraction of a polymer. Even though polymer structural variations are reflected in their buffer capacities, the correlations between the buffering capacity and the polymer structures are not as direct as the correlation between their protonated fractions and structural variations. Thus, if the polymer already has a high protonated fraction of amines at pH 7.5, the buffering capacity will be lower because there are fewer amines available to be further protonated. For this reason, it was observed that the buffering capacities for the D-glucarate polymers had a slightly different trend compared to that of the L-tartarate polymers [**D2** (46.2%) > **D1** (45.4%) > **D3** (35.7%) > **D4** (29.2%), Table 4]. The spermine-based polymers had the lowest buffering capacity in each series (13.2% for **DS** and 20.5% for **TS**). Again, this may be explained by the proton-induced cyclization theory, where the protonation of one amine group in the spermine moiety limits the ability of the other amine to be protonated. This leads to a slower increase in the protonated fraction with a decrease in pH.

Heparin- and Salt-Induced Polyplex Dissociation. The stability of the polyplexes formed between polymer and pDNA under physiological environments is one of the properties that can affect the efficacy of intracellular pDNA delivery. The ideal polyplex should be resistant to premature pDNA release during transport yet still retain the ability to unpack the genetic materials after delivery. As previously hypothesized, if the polyplexes are not stable from the dissociation during cell surface-binding to negatively charged cell membrane glycosaminoglycans (such as heparin or heparan sulfate), they may release pDNA before cellular uptake (*16*, *28*). One way to examine polyplex stability is through the heparin displacement assays, where heparin is used to simulate the cell membrane glycosaminoglycans. After the polyplexes were formulated in water, they were exposed to heparin solutions of different concentrations and then run on agarose gels to examine the heparin concentration that promoted dissociation of pDNA from

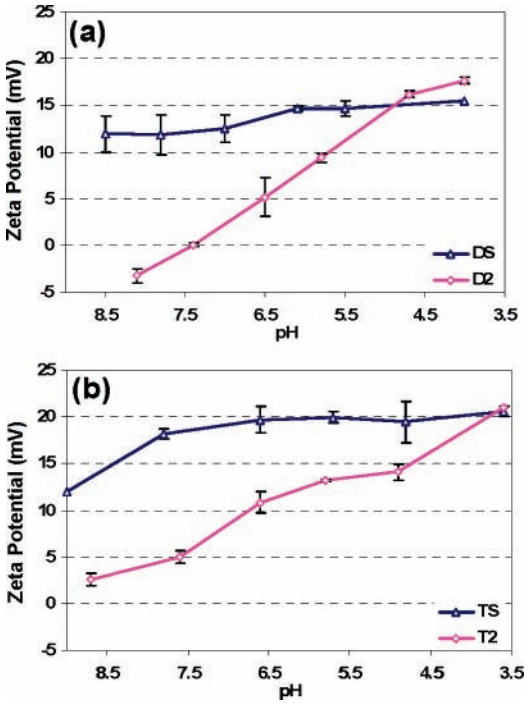

Figure 4. Plots of the zeta potential values vs pH for (a) **D2** and **DS**; (b) **T2** and **TS**.

Table 4. Percentage of Amines Protonated at pH 7.5 and 4.5 and the Buffering Capacity of the Poly(glycoamidoamine)s Calculated with eq 18

	D1	D2	D3	D4	DS	T1	T2	T3	T4	TS
$f_{NH^+} \times 100\%$ (pH 7.5)	28.2%	22.7%	21.2%	19.1%	41.0%	32.2%	28.1%	24.2%	21.0%	59.2%
$f_{NH^+} \times 100\%$ (pH 4.5)	73.6%	68.9%	56.9%	48.3%	54.2%	97.3%	79.3%	65.0%	55.0%	79.7%
buffering capacity	45.4%	46.2%	35.7%	29.2%	13.2%	65.1%	51.2%	40.8%	34.0%	20.5%

the poly(glycoamidoamine)s. In this experiment, if higher heparin concentrations are needed to dissociate the polyplexes, then the polyplexes are likely more stable and have less premature pDNA release than polyplexes that dissociate at lower heparin concentrations. It was observed that the heparin concentration needed to dissociate polyplexes formed with polymers **D1**−**D4** increased as the amine number increased in the repeat unit (Figure 5a). Such a trend was not observed with **T1**−**T4** polyplexes. Polymer **T3** revealed the highest binding affinity (heparin concentration needed to release pDNA was 700 μg/mL), while **T4** yielded the lowest affinity (heparin concentration needed to release pDNA was 560 μg/mL). The polyplexes formed with spermine-based polymers, **DS** and **TS**, required an even higher heparin concentration (700 and 960 μg/mL, respectively) to dissociate than those of **D1**−**D4** and **T1**−**T4**. This may be explained by the fact that the longer spacer between the amine groups in the repeat unit of **DS** and **TS** leads to a higher protonated amine fraction at pH = 7.5 (Table 4), which facilitates stronger electrostatic interactions with pDNA. In addition, polyplexes formed with the **T** polymers revealed a higher stability than their **D** analogues, which may be a result of the higher cationic charge exhibited by the **T** series polymer (increases electrostatic interactions) and the closer spacing of the amine groups (enhances cooperative binding).

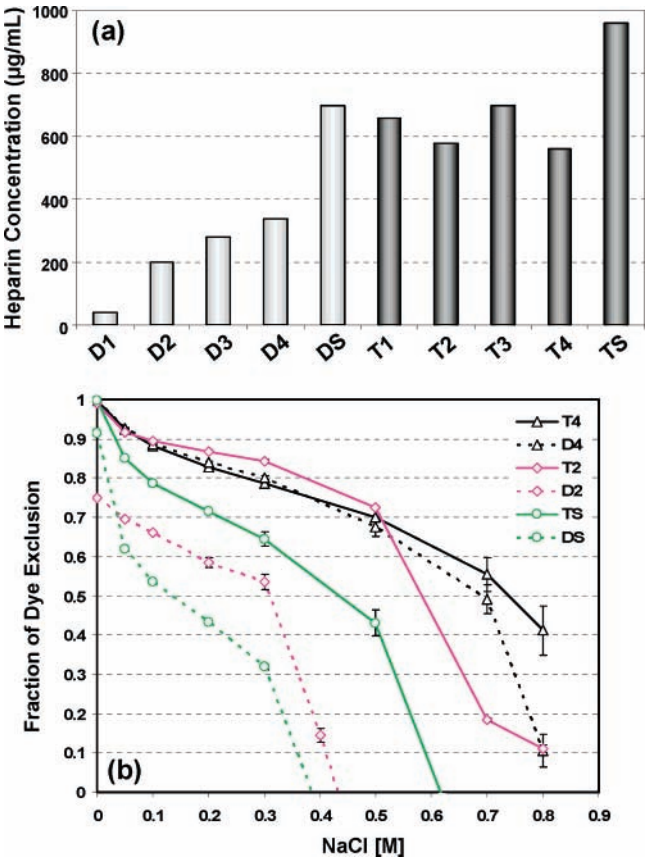

Figure 5. (a) Heparin concentration needed (μg/mL) to release pDNA from polyplexes formed with each of the poly(glycoamidoamine)s. (b) The fraction of dye exclusion [(1 − fraction of PicoGreen intercalation normalized to PicoGreen intercalation of naked pDNA)] when polyplexes formed with **T4**, **D4**, **T2**, **D2**, **TS**, and **DS** are exposed to different concentrations of NaCl.

Unpacking of the loaded genetic materials after the delivery has been hypothesized as another barrier in the transfection process (*29*, *30*), because various proteins need to access pDNA to promote gene expression. To evaluate the vector unpacking properties of poly(glycoamidoamine)s, the binding interaction between the polymer and pDNA were studied by the intercalation of PicoGreen, a dsDNA dye, as a function of NaCl concentration (*29*). Increased salt concentrations can destabilize the binding between polymer and DNA due to the decreased electrostatic interaction. This leads to decomplexation and/or pDNA release, thus increasing PicoGreen intercalation and enhancing fluorescence. As shown in Figure 5b, without NaCl addition (0 point, HEPES buffer only), the PicoGreen did not intercalate into pDNA molecules carried by vectors **T4**, **D4**, **T2**, and **TS**, resulting in almost 100% PicoGreen exclusion. However, for polyplexes formed with polymers **D2** and **DS**, we observed some PicoGreen inclusion in HEPES buffer only, signifying weaker binding. The concentrations of NaCl that allowed 50% dye inclusion (50% PicoGreen excluded) for polymers **T4**, **D4**, **T2**, **TS**, **D2**, and **DS** were roughly 0.75, 0.70, 0.60, 0.45, 0.30, and 0.15 M, respectively. Polyplexes formed with L-tartarate polymers generally had a higher fraction of PicoGreen excluded than their D-glucarate analogues under various NaCl concentrations. This indicates that the **T** polymers can facilitate more stable pDNA binding than the **D** polymers, which is consistent with the results of the heparin displacement assay. Although the greater stability of the **T** polyplexes can help to stabilize the polyplexes from the glycosaminoglycan dissociation, it also may hinder the DNA unpacking process. When the amine stoichiometry effects were compared, polyplexes formed with **D4** were observed to be more stable (higher PicoGreen exclusion) under various salt concentrations than **D2**. However, polyplexes formed with **T4** had similar exclusion as **T2** polyplexes below 0.5 M NaCl, and higher exclusion than **T2** polyplexes when the salt concentration was above 0.5 M. These observations are also consistent with the heparin displacement assay, where **D4** required a higher heparin concentration to cause polyplex dissociation than **D2**, and the heparin concentrations needed to dissociate **T4** and **T2** were very similar. When the amine spacer effects were compared, spermine based polymers **DS** and **TS** had significant lower PicoGreen exclusion (higher inclusion) than their analogues **D2** and **T2**, indicating easier vector unpacking. This was a surprise because **DS** and **TS** showed the strongest pDNA binding in the heparin displacement assay. Thus polyplexes of **DS** and **TS** may not only have higher resistance from dissociation by cell membrane glycosaminoglycans but also unpack the pDNA more easily than their analogues, **D2** and **T2**, after cell membrane entry.

Correlations Between Buffering Capacity and Gene Delivery Efficiency. The gene delivery efficiency represented by the maximum luciferase gene expression in BHK-21 cells for polymers **D1**−**D4** and **T1**−**T4** [previously published in reference (*17*, *18*)], and their buffering capacities (Table 4) are overlaid in Figure 6. First, when the amine stoichiometry was considered, it was noticed that as the number of amines in the repeat unit increased, the overall buffering capacity decreased while the gene delivery efficiency significantly increased [statistical significances of gene expression are shown with * (e.g., **T4** vs **T3**) in Figure 6]. In general, there was not a positive correlation relating a high buffering capacity to an increase in

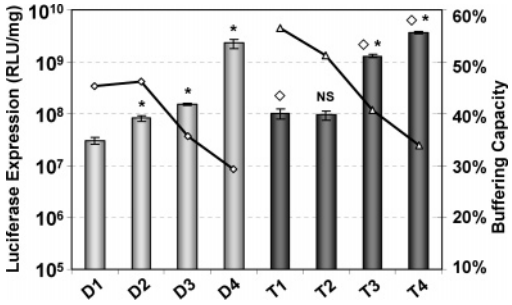

Figure 6. Maximum luciferase gene expression (bars) and buffering capacity (lines) for the polymeric vectors **D1**−**D4** and **T1**−**T4** (polyplexes formulated at N/P = 30 for all vectors except **D1**, which yielded max expression at N/P = 20). Statistical significances in luciferase expression are shown with * or ◇ as $p < 0.05$. The symbol * indicates that a significant difference in gene expression was observed between polymers with the same carbohydrate moiety but having a variation of one amine group in the repeat unit (e.g., **D4** vs **D3**). The symbol ◇ indicates that a significant difference in gene expression was observed between polymers with the same amine stoichiometry but different carbohydrate moieties (e.g., **D4** vs **T4**). The symbol NS in the chart indicates that the gene expression of **T2** is not statistically higher than **T1** or **D2**.

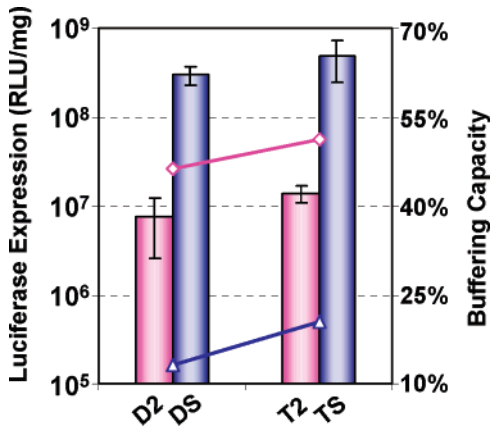

Figure 7. Luciferase gene expression (bars) and buffering capacity (lines) for the polymeric vectors **D2** and **T2** (pink), as well as **DS** and **TS** (blue) at N/P = 10.

gene delivery efficiency in this case. These results go against the relationship predicted by the proton sponge theory (*6*).

Second, when the relationship between the buffering capacity and delivery efficiency was compared between analogous structures in the **T** and **D** series, the **T** polymers had slightly higher buffering capacities and higher gene expression values than their **D** analogues [statistical significances of gene expression are shown with ◇ (e.g., **T4** vs **D4**) in Figure 6], which is consistent with the proton sponge theory in this study. An exception to this trend was found when the delivery efficiency and buffering capacity data for polymers **T2** and **D2** were compared.

Third, when the structural variation of spacer length between the amine groups was considered (e.g., **DS** vs **D2** or **TS** vs **T2**), **DS** and **TS** showed lower buffering capacities than **D2** and **T2**. However, **DS** and **TS** facilitated higher gene expression than **D2** and **T2** (Figure 7). These results go against the proton sponge theory again (*6*). This observation may be attributed to the higher stability in the presence of heparin and easier salt-induced unpacking properties of vectors **DS** and **TS** when compared to **D2** and **T2**, which may lead to an increase in the polyplex amount entering the cells and increased pDNA unpacking after cellular entry. In addition, **TS** had a higher buffering capacity and higher gene expression values than **DS**, which was consistent with the previous observed phenomena when the relationship between the buffering capacity and delivery efficiency was compared between analogous structures in the **T** and **D** series. It should be noted that these data were compared at N/P = 10 due to the high cytotoxicity (low cell survival) exhibited by the spermine-based polymers **DS** and **TS** at N/P ratios higher than 10 (see cell viability data in Figure 8).

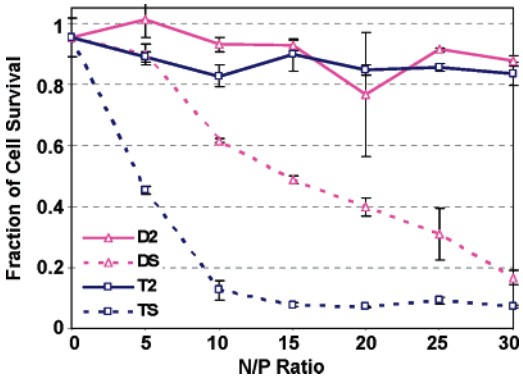

Figure 8. Fraction of cell survival of **D2**, **DS**, **T2**, and **TS** at N/P ratios between 0 (pDNA only) and 30.

Cell Viability. As previously described (*17*, *18*), a high fraction of cell survival was retained (typically greater than 80%) after cellular exposure to polyplexes formed with **D1**−**D4** and **T1**−**T4** at the N/P ratios required for maximum gene expression (N/P = 30 for **D2**−**D4** and **T1** − **T4**; N/P = 20 for **D1**). Here, the cytotoxicity profiles of **D2**, **DS**, **T2**, and **TS** were compared (Figure 8). As reported previously, the fraction of cell survival with **D2** and **T2** was greater than 80% even at high N/P ratio such as 30. However, polyplexes formed with **DS** and **TS** revealed significant toxicity, where **TS** revealed higher toxicity than **DS**. At the N/P ratios of maximum gene expression for **DS** and **TS** (N/P = 30 and 10, respectively), only 17 and 13% cell survival was retained, respectively. Spermine-based polymers have been reported to yield high cytotoxicity by inhibiting the uptake of oligoamines such as putrescine, spermidine, and spermine, which play essential regulatory roles in cell growth and differentiation (*31*). Here, the extremely high cytotoxicity observed with **DS** and **TS** may be caused by the same mechanism. Although **DS** and **TS** do not exhibit the proper biocompatibility for effective gene delivery, they may be promising to be utilized as anticancer drugs to suppress tumor cell proliferation by blocking the transmembrane transport of oligoamines (*31*).

Cellular Uptake of Polyplexes. To explain why the overall buffering capacity decreased while the gene delivery efficiency increased (when the amine stoichiometry was considered) for the poly(glycoamidoamine)s, we performed flow cytometry to quantify the cellular internalization of Cy5-labeled pDNA complexed with polymers **D1**−**D4** and **T1**−**T4** at the N/P ratios required for maximum gene expression. This experiment yields the number of cells that uptake pDNA, as well as the average intensity of fluorescence (relative amount of pDNA) in the cells. The cells were incubated with each polyplex solution for 4 h to allow endocytosis. After removing the cell surface-bound polyplexes and further incubating for 30 min, the cells were trypsinized and isolated for FACS analysis. The flow histograms of BHK-21 cells are shown in Figure 9a (**D1**−**D4**) and 9b (**T1**−**T4**). The mean fluorescence intensity and the percentage of positive cells are shown in Figure 9c. When comparing the polymers in the **D** or **T** series, both the number of transfected cells and the mean fluorescence intensity increased with the increasing of the number of amine units in the polymer repeat unit, with the exception of polymer **T1**, which is not understood at this time. This indicates that in general the cellular internalization of the polyplexes is enhanced when the number of amines is increased in the polymer repeat unit. This observation

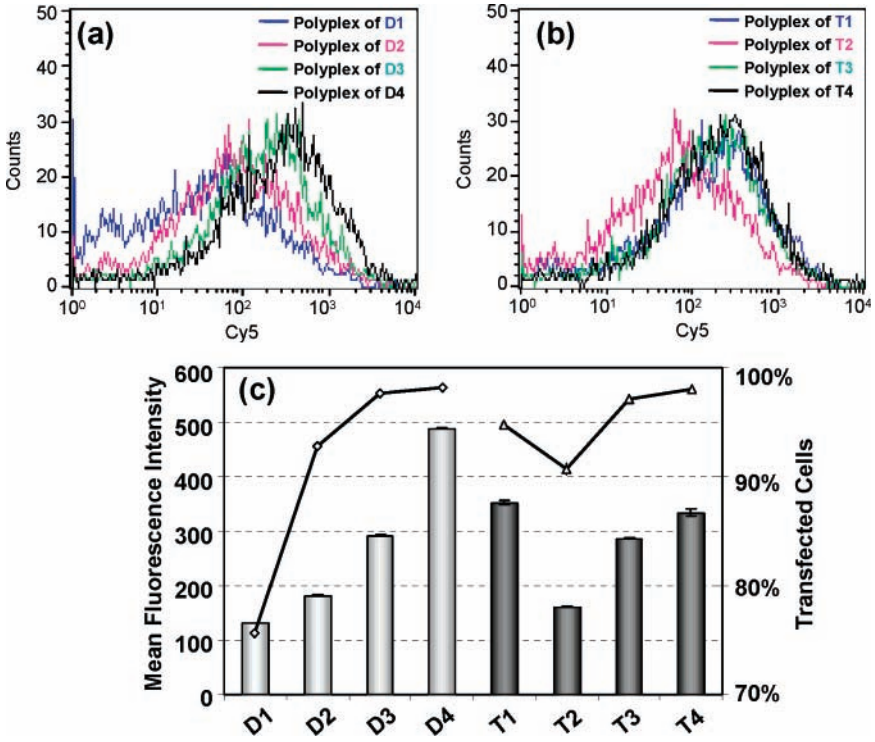

Figure 9. Cellular uptake of Cy5-labeled pDNA complexed with **D1**−**D4**, and **T1**−**T4**. (a) Flow histogram of BHK-21 cells after transfection with polyplexes of **D1**−**D4**. (b) Flow histogram of BHK-21 cells after transfection with polyplexes of **T1**−**T4**. (c) Mean fluorescence intensity (bars) and the percentage of cells positive for Cy5 (lines).

may be attributed to the spacing of the amine blocks along the polymer backbones. Negatively charged proteoglycans found on the cell surface are believed to play an integral role in mediating cellular uptake of cationic polyplexes (*28*). If more polyplexes are internalized, more pDNA enters the cells to be expressed. Different cell types have diverse distributions of proteoglycans on their surfaces. Polymers with higher amine stoichiometry may facilitate better BHK-21 cell surface binding and endosomal membrane disruption through multivalent interactions with these membrane proteins. The increased interaction of these polymers with the cell surface could result in higher polyplex uptake. After the cellular uptake, endosomal escape could then occur through polymer−proteoglycan chelation (could form leaky holes in the endosomal membrane leading to endosomal escape) and increased gene expression (shown in Figure 6). Banaszak Holl et al. have shown that PAMAM dendrimers with terminal amine groups can strongly interact via electrostatic interactions with negatively charged phospholipids, which can induce defects in the cellular membrane and cause membrane leakage (*32*). A similar interaction may also allow leakage of endosomal contents into the cytoplasm. Further experiments to study this effect are ongoing in our lab.

When the results were compared between analogous structures in the **T** and **D** series, we did not observe systematically higher cellular uptake of polyplexes formed with **T1**−**T4** when compared to the **D1**−**D4** systems (Figure 9c). For example, **T1** yielded higher cellular uptake and transfected a greater percentage of cells than **D1**. However, **D2**−**D4** yielded higher cellular uptake and transfected more BHK-21 cells than **T2**−**T4** (for **D3**, **D4**, **T3**, and **T4**, the percentages of positive cells were higher than 95%). Here, it is interesting to note that the **T** series (**T1**−**T4**) generally yield higher gene expression values than their **D1**−**D4** analogues (Figure 6). This result further indicates that the greater buffering capacity and higher protonation capacity of these materials in the endosomal pH range could allow osmotic release and/or electrostatic defect formation in the endosomal membrane, facilitating vesicle release, which does agree with the proton sponge hypothesis.

CONCLUSION

In this study, we have calculated the buffering capacity of polymers with systematic variations in the carbohydrate moiety (D-glucarate or L-tartarate), amine stoichiometry (from 1 to 4), and amine spacer (ethylene or butylene) within the physiological pH range through nonlinear fitting of titration data. By analyzing these data, along with polyplex stability, flow cytometry, and reporter gene expression studies, we sought to further understand how and why structural variables within poly(glycoamidoamine)s affect cellular internalization, buffering capacity, and gene delivery efficiency in BHK-21 cells. We have found that the tested structural variables differentially influence the biological properties of the polymers in a case-specific manner. When comparing poly(glycoamidoamine)s that have the same carbohydrate moiety but different amine stoichiometry (e.g., **D3** vs **D4**), there is no correlation between the buffering capacity and the delivery efficacy. The cellular uptake of polyplexes seems to be the key step in the gene delivery process that determines their efficacy in this case. Polyplexes formed with polymers containing a higher number of amines in the repeat unit clearly facilitate greater cellular uptake. This observation is likely due to the increased multivalent interaction of the amine groups with the cell surface. This stronger interaction of the polymers with cell surface proteoglycans may also aid endosomal release of the polyplexes. These structures may chelate the cell surface proteins and/or insert into membranes and form leaky regions in the endosomes. This, in turn, would promote higher gene expression. Similar observations between the cellular uptake and the gene delivery efficiency were also obtained by Lim et al. in a series of chitosan vectors (*33*).

When polymers that have the same amine stoichiometry but different carbohydrate moieties (e.g., **D4** vs **T4**) are compared, it appears that the buffering capacity and the higher cationic character are the key properties that determine the gene expression level. Structures with an enhanced buffering capacity can increase endosomal release according to the proton sponge hypothesis. Also, the higher amine density materials (**T** series

polymers have shorter molecular distance between the oligoamine moieties, which leads to a higher amine density than **D** series) could possibly cause release via membrane defect formation.

For the polymers containing the same carbohydrate and amine stoichiometry but a different amine spacer, no correlations are observed between the gene delivery efficacy and buffering capacity. The buffering capacity of spermine-based polymers (butylene spacer) is dramatically decreased (possibly by proton-induced cyclization), while the gene expression is increased. This may be due to the higher stability in the presence of heparin and easier vector unpacking properties of spermine based polyplexes. Although these properties are promising, the high toxicity exhibited by the spermine-based polymers (possibly by inhibiting the uptake of oligoamines that are essential to cell growth and differentiation) inhibits their use for many applications.

Our findings indicate the buffering capacity cannot effectively predict the gene delivery efficiency since the polymer structure can have a profound effect on many biological properties such as the polyplex stability, cellular uptake, and gene expression. A systematic and heuristic approach to study the correlations between the polymer structural variables and gene delivery efficiency seems to be a more direct and effective way toward determining the most effective synthetic gene delivery vectors for particular applications (*18*, *34*). Even though correlations that try to connect the physical properties of polymers to the gene delivery process (e.g., "proton sponge" theory) may not be generally valid for the large number of emerging synthetic delivery vectors, they have played a valuable role in inspiring the synthesis of many novel molecular structures.

ACKNOWLEDGMENT

We sincerely thank Professor Ann E. Hagerman for providing the thermostat flasks in the titration experiments, and Professor Ruth Duncan for helpful discussions about endosomal trafficking of nonviral delivery systems. We gratefully acknowledge funding of this work from the National Institutes of Health (1-R21-EB003938-01), National Science Foundation Career Award (CHE-0449774), the Beckman Young Investigators Program, and the UC Institute for Nanoscale Science and Technology. Yemin Liu thanks the University of Cincinnati for the Chemical Sensors and Laws-Stecker graduate fellowships.

Dendritic cells (DCs) play a pivotal role in both immune tolerance and the initiation of immunological responses. The ability to track DCs in vivo is imperative for the development of DC-based cellular therapies and to advance our understanding of DC function and pathophysiology. Here, we conjugate a cell permeable peptide, Tat, to near-infrared (NIR) emissive polymersomes in order to enable efficient intracellular delivery for future DC tracking with these optical probes. NIR imaging allows quantitative, repetitive, in vivo detection of fluorophore-laden cells, at centimeter tissue depths without disturbing cellular function. Flow cytometry and confocal microscopy results indicate that Tat-mediated polymersome delivery to DCs is concentration and time dependent, resulting in punctate intracellular localization. Further, loading cells with Tat NIR emissive polymersomes does not interfere with cytokine-induced DC maturation and has modest effects on DC viability, but has a significant effect on mature DC-induced activation of naive T cells. We observe significant uptake of NIR emissive polymersomes when conjugated to the peptide, with a lower detection limit of 5000 labeled DCs. The extent of polymersome delivery is estimated as 70 000 ± 10 000 vesicles/cell, equivalent to 0.7 ± 0.1 fmol of NIR fluorophore. Our studies will enable future in vivo tracking of ex vivo labeled DCs by NIR fluorescence based imaging.

INTRODUCTION

Dendritic cells (DCs)[1] play a pivotal role in both initiation and regulation of immune responses (*1*−*4*). Immature DCs (iDCs) specialize in sampling the tissue microenvironment for pathogens. Upon encountering pathogens, DCs mature by upregulating adhesion and antigen presenting molecules, thereby enabling migration to local lymphoid tissue and subsequent activation of antigen specific B and T cells (*5*). This central role in the immune response has highlighted the ability of DCs to generate potent anticancer activity and has motivated the development of cell-based vaccines using ex vivo generated DCs. DC-based vaccines have shown promising results in preclinical models (*6*−*9*). However, several obstacles and questions remain before they can be viable therapies. At present, only 1−5% of intradermally administered mature DCs reach peripheral lymph nodes (*6*). Current studies are limited by a lack of intricate knowledge of both DC trafficking and how to best manipulate such cells for optimal therapeutic outcomes (*10*). In addition, clinical trials lack standard methods for evaluating DC treatment efficacy.

The development of in vivo cellular tracking techniques is imperative to ultimately advancing DC-based therapy. By utilizing imaging methods for cellular tracking, numerous aspects of DC therapy could be evaluated including DC sources, maturation states, antigen delivery methods, activation stimuli, routes of administration, and the doses and frequencies of DC vaccinations (*11*). In addition, basic dendritic cell biology could be addressed to expand our understanding of DC function and dysfunction.

Relatively few studies have attempted to track DCs mainly due to the low concentration of this specialized cell type (0.5−1.5% of peripheral blood mononuclear cells (PBMC)) (*12*). Current noninvasive, in vivo imaging modalities employed to follow DCs include magnetic resonance imaging (MRI), scintigraphic imaging (*13*), and ^{19}F-MRI (*14*). Conventional ^{1}H-MRI-based cell tracking typically utilizes iron oxide, a T_2-weighted ("negative") contrast agent, while scintigraphic imaging utilizes γ-emitting radionuclides such as ^{111}In-oxine. Both MRI and scintigraphy were used by de Vries et al. to track DCs loaded with tumor-derived peptides in stage III melanoma patients (*13*). MRI provides exquisite anatomical detail while scintigraphic imaging offers superior sensitivity but with low spatial resolution. By combining these techniques, the investigators were successful in detecting 1.5×10^5 cells (*13*). Neverthe-

less these techniques are inherently limited. ^{1}H-MRI imaging is not quantitative, requires millimolar concentrations of contrast agent, and is subject to artifacts due to the negative contrast. Scintigraphy requires potentially harmful radioisotopes and lacks spatial resolution. The difficulty of detecting negatively contrasted cells by MRI has motivated the use of perfluoropolyether (PFPE) particles that create positive contrast with ^{19}F-MRI (given the lack of endogenous ^{19}F). During the same imaging session, an ^{1}H-MRI image can also be acquired to assess the anatomical location of the cells. With this approach, Ahrens et al. successfully detected 2×10^5 cells/voxel (*14*).

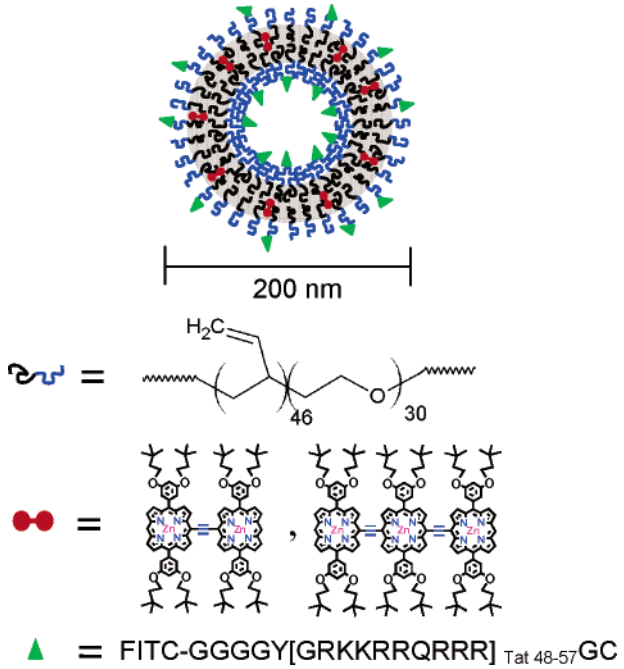
Fluorescence-based imaging of cells labeled with near-infrared fluorophores (NIRFs) is an alternative noninvasive imaging modality capable of cell tracking. This approach is comparable to labeling cells with fluorescent tags and performing immunohistochemistry on fixed tissue slices at selected endpoints. With NIR imaging, however, the fluorophore-laden cells can be detected in vivo at centimeter tissue depths, repeatedly, without disturbing cellular function. Additional benefits of optical imaging include extremely high sensitivity (sub-nanomolar concentrations of exogenous contrast agents), fast acquisition times, low patient risk, and the potential mobility and low cost of optical imaging hardware in comparison to MRI or scintigraphy (*15*, *16*).

Recently, our lab developed near-infrared emissive polymersomes (NIR-OBs), self-assembled polymeric vesicles with porphyrin-based NIRFs loaded within their hydrophobic membranes (*17*, *18*). Both the polymer, poly(ethylene oxide(1300)-*b*-butadiene(2500)) (OB), and porphyrin-based NIRF, meso-to-meso ethyne-bridged oligomeric (porphinato)zinc(II) chromophore (**PZn$_n$** species) macrocycles, are fully biocompatible (*19*−*24*). NIR-OB vesicles are multifaceted with mechanically robust membranes, have an ability to sequester both hydrophobic and hydrophilic reagents, possess 100% PEGylated surfaces for coupling to bioactive moieties, and are tunable from 50 nm to 10 μm in diameter (*25*, *26*). Further, a single 200 nm diameter NIR-OB vesicle having less than 3 mol % loading of **PZn$_n$** NIR fluorophores possesses ≥2500 membrane-bilayer dispersed copies of these emitters, creating an unparalleled fluorescent contrast agent suitable for in vivo applications.

These NIR-OB polymersome characteristics led us to investigate the application of these optical agents for cell tracking. In order to optimize the intracellular delivery of polymersomes, we coupled the vesicles to HIV-derived Tat, a highly cationic peptide shown to enhance cellular delivery of nanoparticles (*27*−*35*). A schematic of the Tat-NIR-OB vesicle is presented in Figure 1. The goals of this study include maximizing cellular delivery of Tat-NIR-OB polymersomes to DCs, investigating the effect of polymersome loading on cellular function, and evaluating the detection sensitivity of the labeled cells using a preclinical imager.

EXPERIMENTAL PROCEDURES

Synthesis of Succinamidyl Carbonate Modified Polymer. The PEO terminal hydroxyl of the copolymer was derivatized with succinimidyl carbonate (SC) as presented in Scheme 1 and according to the procedure established by Miron and Wilchek (*36*). Briefly, disuccinimidyl carbonate was mixed with copolymer, PEO(1300)-*b*-PBD(2500) (Polymer Source Inc., Montreal, Quebec), in dioxane. The reaction was catalyzed upon the addition of 4-(dimethylamino)pyridine and stirred overnight at room temperature. The activated polymer (SC-PEO-*b*-PBD) was then precipitated using diethyl ether and purified using high performance liquid chromatography. The final product was vacuum-dried and stored under argon gas at 4 °C until use. The extent of derivatization of the polymer was determined by ^{1}H-NMR (data not shown).



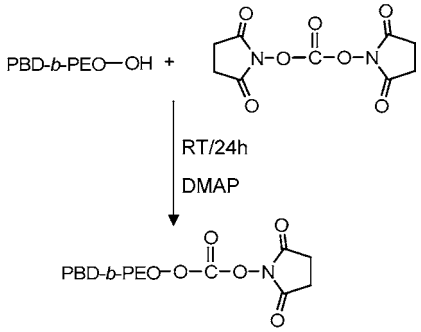


Figure 1. Tat-conjugated NIR emissive polymersomes. The FITC-Tat peptide (▲) is covalently conjugated to the terminal PEG moiety while the NIR emissive fluorophore (●—●) segregates to the hydrophobic bilayer core during self-assembly.

Scheme 1. Reaction Scheme for Terminal Hydroxyl Derivatization to Succinimidyl Carbonate

Tat Conjugation. SC-PEO-*b*-PBD polymer (MW = 3925) was dissolved in methylene chloride and added to nonderivatized PEO-PBD (MW = 3800) to achieve a 10 mol % mixture of the SC-PEO-*b*-PBD. This polymer blend was dried under vacuum and subsequently resuspended in 1 mL of anhydrous methanol. Tat (1760 Da) or FITC-Tat (2260 Da) (Alta Bioscience, Birmingham, U.K.) was then added, in a 1:1 molar ratio with the reactive polymer, and kept overnight at 4 °C. Nonconjugated Tat was removed following polymersome formation by extensive dialysis in isotonic phosphate buffered saline, pH 7.4. Finally, conjugation was verified by ^{1}H-NMR (data not shown) and confocal microscopy.

Polymersome Formulation. All NIRF-laden polymersomes were prepared as described by Ghoroghchian et al. (*17*, *18*). In brief, the selected polymer and fluorophore were dissolved in methylene chloride at a 40:1 molar ratio of polymer to NIRF. The solution was then plated onto a roughened Teflon film and dried under vacuum overnight. Polymersomes were formed upon the addition of 285 mOsm sucrose solution and either heated (60 °C for 48 h) or sonicated (1 h), in a bath sonicator. Heating yielded micron-sized polymersomes for confocal microscopic evaluation while sonication yielded nanoscale polymersomes utilized in the cellular uptake studies. A narrow size distribution of nanosized polymersomes was achieved with serial extrusion using a Liposofast Basic hand-held extruder equipped with 400,

200, and 100 nm polycarbonate membranes (Avestin Inc., Ottawa, Ontario).

In this work, the polymer component was either 10 mol % Tat-PEO-PBD with 90 mol % PEO-PBD or pure PEO-PBD. Polymersomes loaded with the porphyrin-based NIR fluorophores, **PZn_2**, were utilized for in vitro flow cytometry and confocal studies, while those that dispersed **PZn_3** ($\lambda_{excitation}$ = 785 nm, $\lambda_{emission}$ = 800 nm) were used for NIR optical imaging of cell populations. NIR emissive polymersomes were prepared using a 40:1 polymer:**PZn_n** molar ratio. The concentration of the **PZn_n** emitter in the polymersomal membrane was quantified via the established extinction coefficients of the far red absorbance of these species, λ_{PZn2} = 708 nm and λ_{PZn3} = 795 nm (*18*, *21*−*24*). Upon measurement of fluorophore absorbance in solution, the concentration of **PZn** was obtained using Beer's Law and previously established extinction coefficients ($\epsilon_{PZn2(708nm)}$ = 59 000 M^{-1} cm^{-1}, $\epsilon_{PZn3(795nm)}$ = 125 000 M^{-1} cm^{-1}) (*17*). Finally, the polymer concentration was directly related to the porphyrin concentration by the initial molar ratio deposited as a thin film (40:1 polymer:porphyrin) (*37*).

Dendritic Cell Preparation. Immature dendritic cells (iDCs) were prepared from human peripheral blood mononuclear cells (PBMC). PBMC were isolated by Ficoll−Paque density-gradient centrifugation on day 0. Plastic adherence at 37 °C for 90 min was used to separate adherent monocytes from nonadherent lymphocytes. The adherent cells were cultured for 6 days in serum free AIM-V media containing recombinant GM-CSF at 800 U/mL (Leukine, Berlex Laboratories) and recombinant IL-4 at 500 U/mL (Cytokine Inc). Cytokines were replenished on day 3 of culture. Immature DCs were recovered on day 6 by washing with cold PBS and gentle pipetting. A Multisizer3 Coulter Counter (Beckman Coulter, Fullerton, CA) and trypan blue exclusion were used to determine viable cell concentrations. Cells were resuspended in media (phenol free RPMI supplemented with 10% FCS, 1% HEPES, and 1% penicillin/streptomycin) and plated at a final cell concentration of 1 × 10^6 DC/mL.

Cell Treatments with Polymersomes. DCs were incubated in media (37 °C, 5% CO_2) with either PBS (control), NIR emissive polymersomes, or Tat NIR emissive polymersomes at controlled concentrations (50 μM to 800 μM polymer) over various time intervals (1−24 h). Following incubation, cells were collected using two cold PBS (4 °C) washes. An additional volume of PBS was added (>30× cell incubation volume) before centrifugation (5 min, 1700 rpm). The polymersome containing supernatant was then removed and the wash cycle subsequently repeated twice. Labeled cells were either used immediately as described, returned to culture in fresh media, or fixed with 2% PFA in PBS and stored at 4 °C.

Dendritic Cell Maturation Treatment. Dendritic cell maturation was induced with a cytokine mixture containing GM-CSF (800 U/mL), IL-4 (500 U/mL), TNF-α (10 ng/mL), IL-6 (0.15 μg/mL), IL-1β (10 ng/mL), and PGE_2 (1 μg/mL). In parallel, immature DCs were maintained with the addition of only GM-CSF and IL-4. Both treatments were added to culture 5 h after polymersome addition and incubated overnight.

Confocal Laser Scanning Microscopy (LSM). Fluorescence scanning confocal microscope images were obtained with a Carl Zeiss LSM-510 Meta confocal microscope (Oberkochen, Germany) equipped with a C-Apochromat 40×/1.2 W objective. Both FITC and **PZn_2** excitation were achieved with a 488 nm argon laser. Fluorescence emission was captured using either 505−530 nm band-pass (FITC) or 650 nm long-pass (**PZn_2**) filters. Cells were kept on ice and imaged by directly plating live cells (10 μL) on a glass slide and covering with coverslip. Images were modified for contrast and brightness using Photoshop software (Adobe Systems, San Jose, CA).

Cryogenic Transmission Electron Microscopy (Cryo-TEM). Nanometric Tat functionalized polymersomes were formulated as described above. Vitreous samples were prepared within a controlled environment vitrification system (CEVS) (*38*). A droplet of solution (~10 μL) was deposited on a copper TEM grid coated with a porous polymer film. A thin film (<300 nm) was obtained by blotting with filter paper. After allowing the sample sufficient time to relax from any residual stresses imparted during blotting (~30 s), the grid was plunge cooled in liquid ethane at its freezing point (−180 °C), resulting in vitrification of the aqueous film. Sample grids were examined in a JEOL 1210 transmission electron microscope operating at 120 kV, and images were recorded with a Gatan 724 multiscan digital camera.

Dynamic Light Scattering (DLS). A photon correlator spectrometer (DynaPro-LSR, ProteinSolutions, Lakewood, NJ) was used to measure the hydrodynamic radius of prepared vesicles. Quartz cuvettes were filled with 50 μL of polymersome suspensions and were thermostatically controlled at 25 °C throughout the experiment. All DLS measurements were made at a scattering angle of 90°. Data analysis was performed using DYNAMICS software provided by ProteinSolutions. The results are given as hydrodynamic radius versus percent intensity.

Flow Cytometry. A BD FACSCalibur flow cytometer (BD Biosciences, Franklin Lakes, NJ) was employed to determine both the extent of fluorescent labeling achieved by NIR emissive polymersome uptake and the DC maturation state as assessed by surface molecule phenotyping. DCs were gated using the forward versus side scatter parameters. All experiments analyzed a minimum of 10 000 DC events. The NIR fluorophores were excited using an argon ion laser (15 mW, 488 nm) and probed with fluorescence detection in the FL3 channel (650 nm long-pass filter).

For phenotypic analysis, cells were first incubated with human serum (15 min, 4 °C) to block nonspecific Fc-receptor binding. Subsequently, cells were incubated for 30 min at 4 °C with the following antibodies: FITC-CD3, CD14, CD16, CD19, PE-CD86, PE-CD83, or isotype controls. Following incubation, cells were washed and fixed with 2% PFA prior to data acquisition.

Mixed Lymphocyte Reaction (MLR). Dendritic cell function was assayed by a mixed lymphocyte reaction in a 96-well plate. Three 2-fold serial dilutions of treated DCs (stimulator cells) were plated in triplicate for each treatment. Stimulator cells were irradiated with 30 GY prior to coculture with 50 000 responder PBMC per well in serum free AIM-V media. T-cell proliferation was assessed by ^{3}H-thymidine incorporation over the last day of coculture (day 3). Anti-CD3/CD28 coated paramagnetic beads (M450 Dynal, Invitrogen) were used as a positive control for T-cell proliferation with a 3:1 bead to responder PBMC ratio (*39*).

Near-Infrared Molecular Imaging with ExPlore Optix Imaging System (EOIS). Dendritic cell populations were imaged with an ExPlore Optix Imaging System (GE Healthcare-Advanced Research Technologies Inc.; Schenectady, NY) for preclinical optical molecular imaging. Cell detection studies were performed in an opaque 96-well plate (BD Falcon, Franklin Lakes, NJ). Labeled cells were plated at dilutions of 50 000, 5000, or 500 cells per well. NIR emissive polymersomes were plated in parallel with 5-fold dilutions ranging from 10 to 0.08 pmol of fluorophore per well for calibration purposes.

Images were acquired with the following parameters: 785 nm excitation laser, 803 μW laser power, 850 ± 50 nm band-pass filter, 2 s integration time, 1.5 mm step size, and 37 °C stage temperature. Images were analyzed with Analysis WorkStation 1.1.3.0 (Advanced Research Technologies, Quebec, Canada).

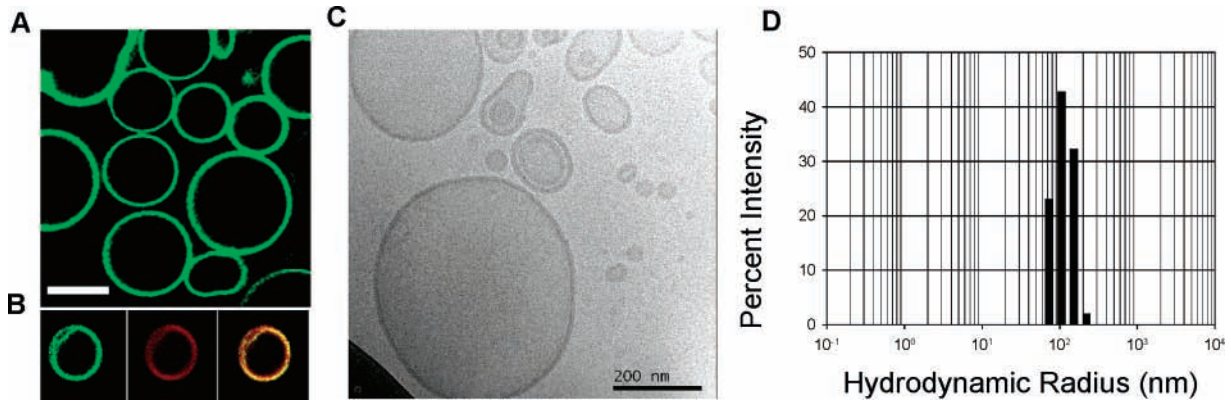

Figure 2. Tat-conjugated NIR emissive polymersome characterization. (A, B) Confocal LSM images of micron-size polymersomes. (A) FITC-Tat functionalized vesicle and (B) FITC-Tat functionalized vesicle surface with NIRF (**PZn$_2$**) loaded within the membrane. Green = FITC, red = NIRF, yellow = fluorophore colocalization; scale bar = 10 μm. (C) Cryo-TEM image of nanometer-sized Tat-conjugated polymersomes. (D) Representative DLS size distribution for serially extruded Tat-conjugated polymersomes.

The average photon count per well was correlated to fluorophore concentration using the calibration samples (n = 4). This calibration allowed estimation of the fluorophore number per cell. The number of polymersomes per cell was then computed using the molar conversion of NIRF to polymer chains (1:40) and the geometric approximation of 220 000 polymer chains per 200 nm vesicle (1 chain/nm^2).

RESULTS AND DISCUSSION

Tat NIR Polymersome Visualization. Conjugation of Tat peptide to the polymersome surface was confirmed by confocal microscopy. In Figure 2A, FITC-Tat is observed at the vesicle membrane. All visualized vesicles were fluorescently labeled, suggesting that the reacted polymer is evenly dispersed during polymersome self-assembly. The addition of the NIR fluorophore, **PZn$_2$**, to the polymer film yields similar FITC-Tat membrane functionalization (Figure 2B, green). **PZn$_2$** also localizes within the polymersome membrane (Figure 2B, red). The hydrophobic nature of this fluorophore drives its segregation into the hydrophobic core of the bilayer during polymersome formation. The presence of both FITC-Tat and NIR fluorophore within the same vesicle suggests that the fluorophore does not interfere with peptide presentation nor does the peptide interfere with fluorophore loading and fluorescence. Cellular delivery of polymersomes was studied using approximately 200 nm vesicles prepared by serial extrusion. We employed cryo-TEM to confirm vesicle morphology of these nanometric Tat−polymersomes. As observed in Figure 2C, vesicle morphology is maintained with Tat peptide conjugation.

Polymersome Size Distribution by DLS. The final distribution of vesicle sizes was measured using DLS with a representative histogram presented in Figure 2D. The mean hydrodynamic radius of the presented Tat−polymersome distribution is 115 ± 34 nm. This characterization was performed for all preparations as a quality control measure to guarantee that each batch contained equivalent size vesicles.

Cellular Localization of Tat−Polymersomes by Confocal LSM. We imaged live DCs incubated with FITC-Tat conjugated NIR polymersomes to visualize both the conjugated peptide and polymer cargo independently. In Figure 3, serial confocal z-slices of a single DC incubated for 3 h are presented to demonstrate the cellular distribution of FITC-Tat (green) and NIR emissive polymersomes (red). Predominantly, the intracellular peptide and polymersomes colocalize in a punctate distribution and appear blocked from nuclear entry. This colocalization suggests that the peptide remains in association with the polymersome once internalized. The serial slices show that the polymersomes distribute both to the cell surface and throughout the intracellular volume. These results agree with the current understanding of Tat-mediated cellular delivery.

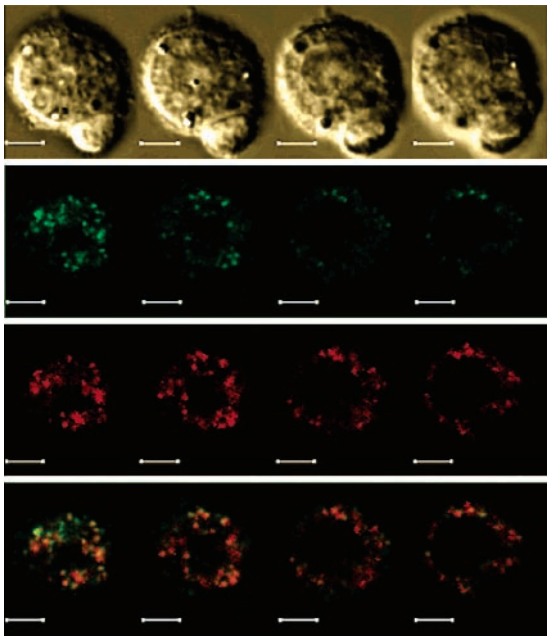

Figure 3. Confocal LSM images of an immature dendritic cell labeled with FITC-Tat NIR emissive polymersomes. (FITC = green, NIRF (**PZn$_2$**) = red.) Cells were incubated for 3 h with 100 μM polymer. Consecutive z-slices (Δ 2 μm) are presented from left to right. Scale bar is 5 μm. The DC is in contact with a lymphocyte; note that the lymphocyte does not load with polymersomes.

While initial studies suggested that Tat directed translocation of the attached cargo across the membrane into the cytoplasm, recent investigations point toward intracellular entry through typical membrane internalization pathways including endocytosis and macropinocytosis (*33*, *40*−*42*). These pathways result in punctate localization in intracellular vesicles as was observed by both Ferrari and Sandgren in CHO cells (*43*, *44*). More specifically, Ferrari utilized real time imaging to follow the distribution of Tat-GFP in CHO cells. This study found that Tat-GFP localized in intracellular vesicles accumulated in the perinuclear space as observed for polymersomes.

Concentration and Time Dependence of Tat NIR Emissive Polymersome Uptake. In order to maximize the intracellular uptake of polymersomes necessary for optimal cellular labeling, the effects of varying both the polymersome concentration and incubation time on DC uptake were examined. Flow cytometry was used to measure the intensity of cellular-associated **PZn$_2$**-

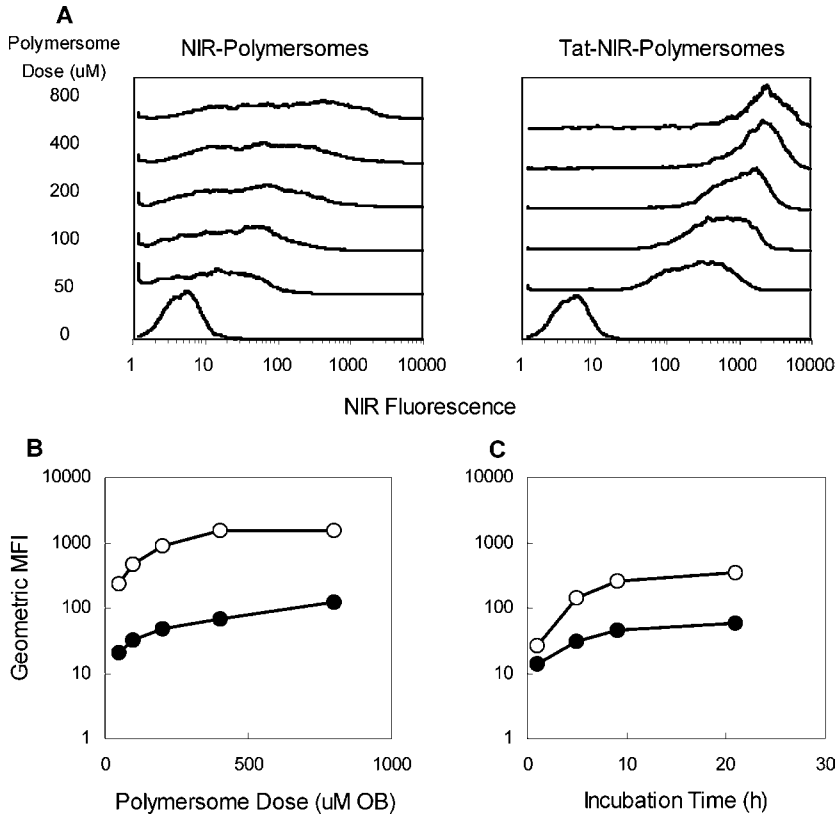

Figure 4. (A) Representative histograms for DCs treated overnight with either control or Tat-conjugated NIR emissive polymersomes at the indicated polymer dose. (B) Geometric mean fluorescent intensity of the presented histograms versus polymersome dose for immature DCs treated with control NIR emissive polymersomes (●) or Tat-conjugated NIR emissive polymersomes (○). based fluorescence following cell incubation and washing. These experiments evaluated the uptake of both Tat-conjugated polymersomes and nonfunctionalized controls (polymersomes with a 100% PEO brush) in order to distinguish the impact of Tat conjugation on intracellular delivery. The histograms presented in Figure 4A demonstrate clear Tat- and dose-dependent DC uptake.

In the absence of conjugated Tat, the extent of uptake varies greatly among the cell populations as indicated by the broad distribution of cellular fluorescence. In contrast, cells labeled with Tat NIR emissive polymersomes display a narrow distribution with a much lower coefficient of variation (CV). Tat-mediated intracellular delivery therefore generates a more uniformly labeled DC population. The concentration dependence of DC uptake is also evident for both Tat-conjugated and nonconjugated (control) polymersomes. The uptake of Tat NIR emissive polymersomes becomes saturated after an overnight incubation with a concentration of 400 μM polymer. This saturation is clearly observed in Figure 4B where the geometric mean fluorescence intensities of the presented histograms are plotted against the treatment concentration. In addition, Figure 4C shows the time dependence of polymersome uptake. The extent of dendritic cell labeling reaches half-maximal fluorescent intensity at 7 h for control NIR emissive polymersomes (MFI_{max} = 58), and at 5 h for Tat-conjugated NIR emissive polymersomes (MFI_{max} = 350).

Effect of Polymersome Labeling on Dendritic Cell Function. In order to determine the effects of polymersomes on DC function and viability, we studied the ability of immature dendritic cells to undergo cytokine-induced maturation and activate naive lymphocytes. In the presence of cytokines, immature dendritic cells (iDCs) are induced to differentiate into mature dendritic cells (mDCs), or professional antigen presenting cells (*45*). In vivo, this maturation is induced by an encounter with foreign antigen and results in DC migration to nearby lymph nodes with subsequent activation of T cells. In vitro, the addition of GM-CSF, IL-4, TNF-α, IL-6, IL-1β, and PGE_2 directs this maturation pathway, which can be evaluated by identifying a change in expression of the surface molecules: CD86 and CD83 (*46*). CD86 is a costimulatory molecule required for antigen presentation while CD83 is an accepted marker for mature dendritic cells with a function that remains to be fully elucidated (*47*). The expression levels of these molecules and the absence of other lymphoid lineage markers (CD3, T cell; CD14, monocyte; CD19, B cell; CD56, natural killer cell; and CD66b, granulocyte) were assayed via flow cytometry. Dendritic cells were selected according to their forward and side scatter properties and lack of lineage markers as shown in Figure 5A. In the left column of Figure 5B, untreated iDCs (thick line) were CD83−/CD86+ while mDCs (thin line) were CD83+/CD86++. It is clear that the maturation treatment upregulates both CD83 and CD86 as expected. Remarkably, dendritic cells treated with either control or Tat-conjugated NIR emissive polymersomes, presented in the middle and right columns, respectively, show nearly identical shifts in surface expression when compared to cells treated with media alone. In addition, the immature phenotype is maintained for cells incubated with both polymersome treatments. These results demonstrate that internalized NIR emissive polymersomes do not interfere with iDC differentiation into DCs with a mature phenotype.

The viability of treated cells is essential for cell tracking studies. Here, we assessed dendritic cell viability by trypan blue exclusion as a function of treatment, incubation time, and maturation state. Figure 6 shows that only an overnight incubation with Tat-conjugated NIR emissive polymersomes caused a measurable but not overwhelming amount of cytotoxicity, ~25%. This cytotoxicity is independent of maturation

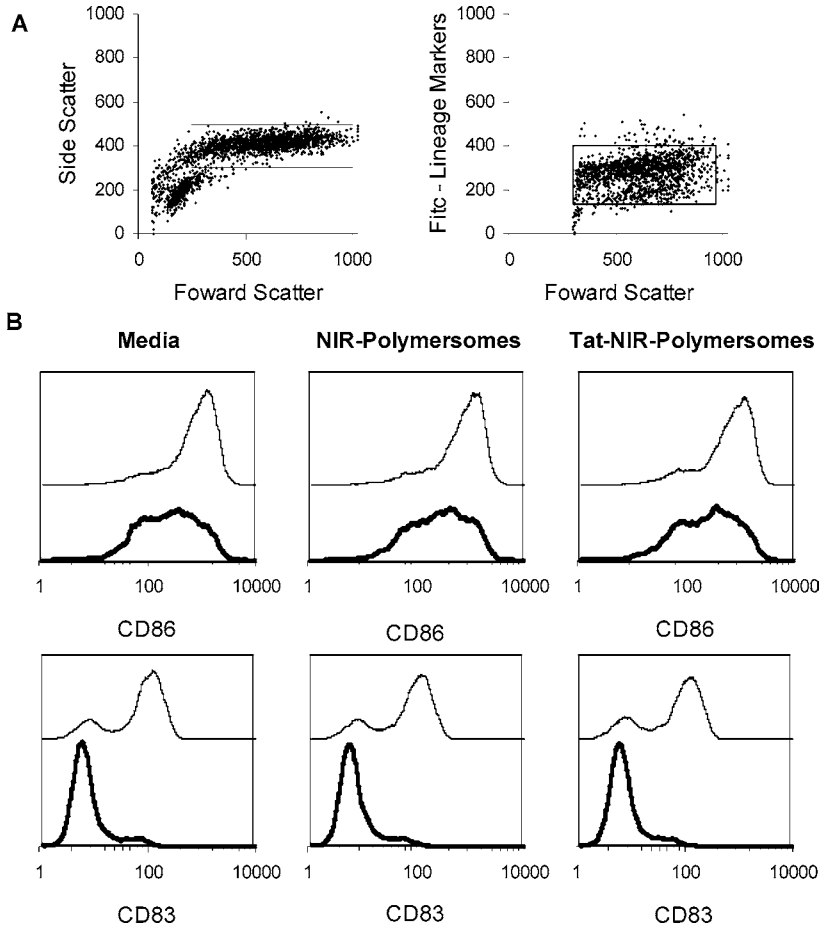

Figure 5. Dendritic cell phenotype characterization by flow cytometry. (A) DC gating approach. Cells were first selected by forward versus side scattering parameters and second for lineage negative status. (B) For each of the treatments (Media, control polymersomes, Tat-conjugated NIR-emisisve polymersomes), cells were maintained with a maturation cocktail (thin line) or in culture with only GM-CSF/IL-4 (wide line).

state. The high level of uptake that occurs with an overnight incubation of Tat-conjugated vesicles is likely responsible for this moderate cytotoxic effect. Similar levels of toxicity have been observed in other Tat-mediated particle delivery systems (*35*, *48*).

While surface marker phenotyping suggests that the iDC to mDC differentiation is unaltered by either control or Tat-conjugated NIR emissive polymersomes, we sought to confirm these results with an allogeneic mixed leukocyte reaction (MLR) (*49*, *50*). Both iDCs and mDCs labeled with polymersomes were assayed to detect any effect of internalized polymersomes on cellular activity. The MLR assay measures the ability of DCs to stimulate naive alloreactive T-cell proliferation. In our work, T-cell proliferation was measured radioactively via ^{3}H-thymidine incorporation into dividing T cells. The stimulatory activity results for iDCs and mDCs are presented in Figure 7A and 7B, respectively. For all cases, T-cell proliferation increases monotonically with DC number. This result confirms that DC activity is maintained with polymersome labeling. The ability of immature DCs to stimulate T-cell proliferation was relatively unaffected by treatment with Tat-polymersomes (Figure 7A). Mature DCs treated with Tat-conjugated NIR emissive polymersomes, however, stimulated a significantly lower level of T-cell proliferation relative to non-Tat-labeled polymersomes. Mature DCs treated with NIR polymersome lacking Tat showed a significant increase in T-cell proliferation. The factors contributing to the result with Tat−polymersomes remain unclear. For example, cell membrane associated polymersomes may sterically interfere with mature DC−T lymphocyte interactions, or a decrease in viable Tat−polymersome laden mature DCs over the course of the MLR assay could reduce the apparent stimulation capacity. Further investigation is merited to determine the cause for this weakened stimulation. Nonetheless, DCs labeled with Tat-conjugated NIR emissive polymersomes maintain the ability to stimulate T-cell proliferation. However, if the ultimate goal is to ensure T-cell proliferation, NIR-labeled polymersomes lacking Tat would be sufficient.

Cell Associated NIR Emissive Polymersome Stability. Effective cellular tracking requires that the probes remain associated with the cell of interest during longitudinal in vivo imaging. As such, we studied the stability of labeled cell fluorescence, for both iDCs and mDCs incubated with Tat-conjugated NIR emissive polymersomes, over the course of 3 days using flow cytometry. In Figure 8, the cellular geometric mean fluorescent intensity is plotted against time post removal of polymersome treatment (day 0). As expected, immature DCs take up a greater number of Tat-conjugated NIR emissive polymersomes per cell. This cellular fluorescence appears to initially decrease during the first 24-hour period following the wash but stabilizes by day 2. A similar profile is observed for mDCs labeled with Tat-conjugated NIR emissive polymersomes. In contrast, the fluorescence for DCs labeled with control NIR emissive polymersomes is stable. In examining the initial loss in DC-associated fluorescence during the first 24 h, we trypsinized a subpopulation of cells that had undergone each treatment condition in order to remove any surface associated polymersomes. These trypsinized cells displayed a fluorescent signal intensity equivalent to the stabilized levels observed for nontrypsinized cells. These results suggest that DC surface-associated polymersomes shed over time, while fully internalized polymersomes are stably incorporated over the course of 3 days. The percent of internalized polymersomes varied between

(B) DC treated for 24 h with NIR emissive polymersomes (200 μM polymer) either with or without maturation cytokines. Error bars indicate standard deviation.

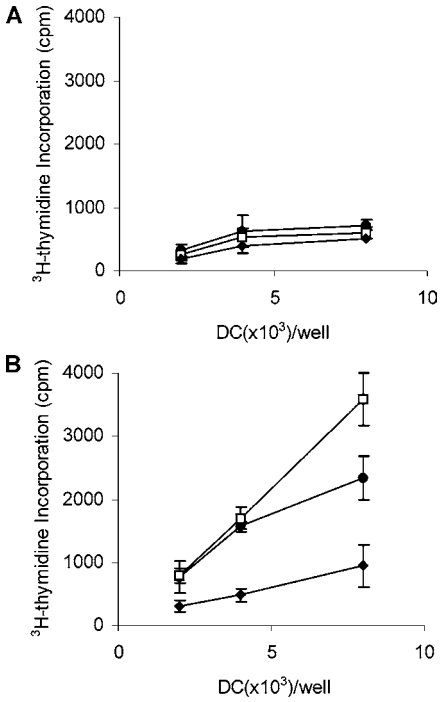

Figure 7. Representative result for mixed lymphocyte reaction (MLR). Relative T-cell proliferation (measured via ^{3}H-thymidine incorporation) is presented as a function of dendritic cell number for iDCs (A) or mDCs (B) and the following incubation treatments: (□) PBS, (●) control NIR emissive polymersomes, (◆) Tat-conjugated NIR emissive polymersomes. Error bars indicate the standard deviation of triplicate wells.

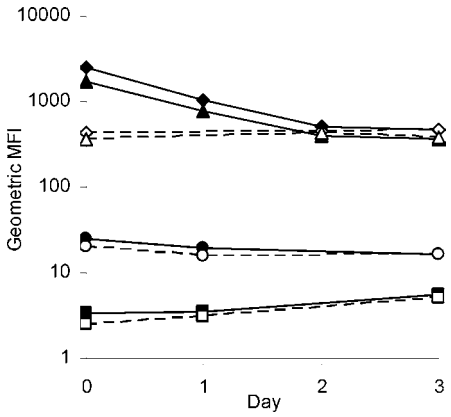

Figure 8. Geometric mean fluorescence intensity (MFI) of labeled DCs following an overnight incubation and removal of extracellular polymersomes on day 0. Cells were washed each day with subpopulations collected for analysis. Surface associated polymersomes were either undisturbed (solid line) or removed by trypsinization (dotted line). Treatment conditions include (◆) Tat-conjugated NIR emissive polymersomes, (▲) Tat-conjugated NIR emissive polymersomes + maturation cytokines, (●) control NIR emissive polymersomes, and (■) PBS control. The corresponding open circles indicate trypsinized cells from the same treatment group.

experiments with a range of 15−50% of the cell associated polymersomes. The inconsistency is likely due to Tat NIR polymersome and cell donor batch to batch variability.

In Vitro Optical Imaging of Labeled Dendritic Cells. Ultimately, in vivo fluorescence-based imaging of labeled DCs is expected to depend on the extent of NIR emissive polymersome uptake, the cellular density at a particular location, and the tissue depth of the labeled cells. In preparation for such studies, we sought to investigate, in vitro, the cell number and maturation state dependence of DCs labeled with **PZn$_3$**-based NIR emissive polymersomes. The NIR excitation and emission wavelength maxima for **PZn$_3$** make it an optimal molecular probe for in vivo optical imaging (*17*, *18*, *20*). A representative image of plated cells is presented in Figure 9A. A population of 5000 labeled DC is visible in a single well. Assuming that these cells are evenly distributed within the well, we estimate the lower limit for detection as ∼150 cells/mm^2. A calibration of the number of NIR fluorophores versus total photon counts per well (Figure 9B) enables estimation of the amount of fluorophore associated with each cell population, and ultimately a number of polymersomes per cell (see Experimental Procedures). A single immature DC can be effectively labeled with 0.7 ± 0.1 fmol of NIRF, equivalent to 70 000 ± 10 000 polymersomes/DC. The number of polymersomes per cell as a function of maturation state and treatment is presented in Figure 9C. Again, the extent of NIR emissive polymersome uptake is strongly dependent upon Tat conjugation, with iDCs taking up the greatest numbers of polymersomes.

Since both EOIS imaging and flow cytometry measure the fluorescence per cell, we compared results from each of these assays by normalizing individual values with the maximum fluorescence signal intensity observed in each method. These results are presented in Table 1 and show that the independent assays are in close agreement. In both assays, the extent of labeling is greatest for iDCs labeled with Tat-conjugated NIR emissive polymersomes followed closely by mDCs labeled with the same treatment. Cellular labeling levels in the absence of Tat are an order of magnitude lower. The corroboration of both the NIR imaging and flow cytometry-based assays shows the reliability of our imaging methods.

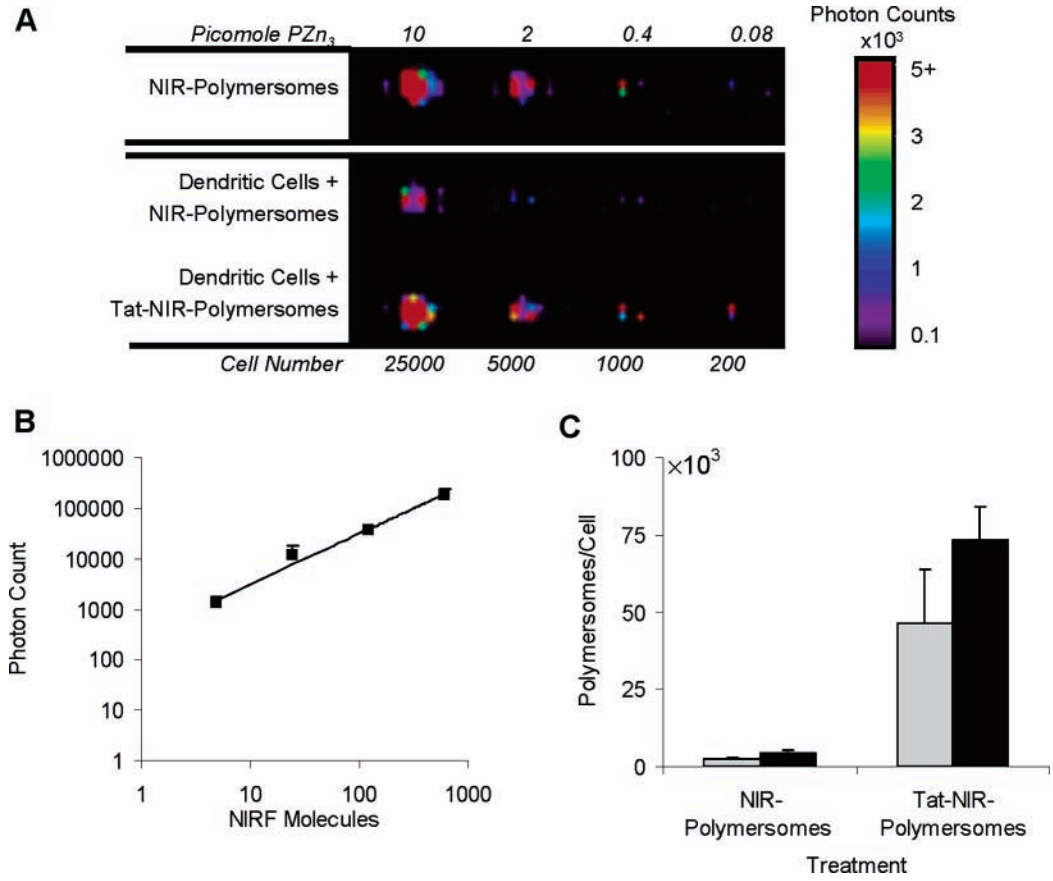

Figure 9. (A) Representative EOIS image of 96-well plate with 5-fold serial dilutions of immature DCs and control polymersomes. (B) Fluorescence calibration with total photon counts versus the number of fluorophore molecules (**PZn_3**) per well ($n = 4$). Error bars indicate standard deviation, linear fit $R^2 = 0.99$. (C) The calculated number of polymersomes per cell as a function of cellular treatment condition. Error bars represent standard deviation.

Table 1. Comparison of Fluorescence per Cell Value Generated from EOIS Image or Flow Cytometry Analysis

	normalized fluorescence/cell	
	NIR polymersomes	Tat NIR polymersomes
	EOIS[a]	
immature DC	0.06 ± 0.01	1.00 ± 0.14
mature DC	0.03 ± 0.01	0.63 ± 0.23
	Flow Cytometry[b]	
immature DC	0.06	1.00
mature DC	0.06	0.66

[a] Normalized average photon counts per cell (mean ± SD). [b] Normalized geometric mean fluorescence of 10 000 events.

CONCLUSIONS

This study demonstrates that NIR emissive polymersomes are promising reagents for cellular tracking. Intracellular delivery of these agents was significantly enhanced by conjugation to the Tat peptide. Upon incubation of the Tat-coupled NIR emissive polymersome with dendritic cells, it was found that DC uptake of the probes was predictably saturated after reasonable incubation times or high concentrations. Maximum polymersome uptake was achieved in immature DCs incubated with Tat-coupled NIR emissive polymersome at a 400 μM concentration of polymer for >10 h. In addition, we established that neither control nor Tat-conjugated NIR emissive polymersomes interfere with DC maturation and that Tat NIR polymersome uptake only modestly affects DC viability but significantly affects T-cell stimulation. Fully internalized vesicles were found to localize in endocytic compartments and remain associated with the cell for at least 3 days. Upon in vitro imaging of the labeled DCs a lower detection limit of approximately 5000 cells per well, or ~150 DC/mm^2, was established.

In addition to incorporating porphyrin-based NIRFs in their thick hydrophobic membranes, polymersomes can encapsulate a range of molecules including doxorubicin (*51*, *54*), high molecular weight dextrans (*25*), and hemoglobin (*52*) within their internal aqueous cavities. While the unmodified PEO surfaces of the polymersomes are immunologically invisible (*19*), it might be possible to build in antigenic features. For dendritic cell applications, polymersomes could potentially encapsulate antigens or cytokine cocktails thereby serving simultaneously as an antigen and contrast agent delivery vehicle. It is interesting to note that liposome-based antigen delivery is more immunogenic than antigen alone. This effect is attributed to the particulate nature of liposomes which more closely mimic the uptake of viruses or bacteria (*53*). It is possible that polymersomes would possess this adjuvant quality as well.

While PEO-PBD is a biocompatible polymer, it is unlikely that it will be implemented clinically. Fully biodegradable polymersomes, however, have also been developed using polyethyleneglycol-*block*-polycaprolactone (PEO-PCL) as the constituted vesicle forming material (*54*). These acid-labile vesicles would potentially enable endocytic escape and cytoplasmic delivery of the encapsulated reagents that would be advantageous for cross-presentation of peptide via both MHC I and MHC II antigen presenting molecules. In addition, exchanging the functional moiety on the polymersome surface for a dendritic cell targeting peptide could allow in situ delivery of antigen and NIRF. McGuire et al. isolated a targeting peptide (TPXS52.1) from a peptide library designed to target Langerhans cells (LCs), the DC variant found in skin (*55*). When presented on the surface of liposomes, this peptide was able to target LCs

in vivo. In situ DC delivery is attractive because it reduces the high cost of ex vivo cell culture for each patient.

In conclusion, the results of the current study clearly establish NIR emissive polymersomes as useful cell tracking reagents for future small animal studies. Further, the use of degradable polymersomes or DC targeting peptides may generate multifunctional polymersomes suitable for clinical applications.

Tumor Cell Targeting of Transferrin−PEG−TNF-α Conjugate via a Receptor-Mediated Delivery System: Design, Synthesis, and Biological Evaluation

Yan-Yan Jiang, Chen Liu, Ming-Huang Hong, Sai-Jie Zhu, and Yuan-Ying Pei*

Department of Pharmaceutics, School of Pharmacy, Fudan University, Shanghai, China, 200032. Received May 25, 2006; Revised Manuscript Received October 9, 2006

PEGylation is a procedure of growing interest for enhancing the therapeutic and biotechnological potential of peptides and proteins. Transferrin (Tf) has been proposed to be useful for targeting cancer cells. The aim of this study was to modify PEGylated recombinant human tumor necrosis factor alpha (PEG−TNF-α) with Tf to form Tf−PEG−TNF-α conjugates, which would maintain the advantages of PEGylation and also achieve the function of active targeting to tumor cells. In PEGylation reactions with 5-, 20-, 40-, and 60-fold molar excess of 3.4 kDa *N*-hydroxysuccinimide-PEG-maleimide (PT1, PT2, PT3, and PT4, respectively), PEG−TNF-α conjugates with different PEG chains were synthesized. A perfusion chromatography technique using a cation-exchange column was introduced to purify PEG−TNF-α conjugates. PT4 with about five PEG chains was selected as a lead candidate due to highest extent of PEGylation and maximum reaction yield. Thiolated Tf was conjugated to the maleimide group at the distal end of the PEG chains on the PEG−TNF-α conjugates, with the resulting Tf−PEG−TNF-α conjugates after purification containing approximately one Tf ligand on one TNF-α molecule. The conjugate of Tf and PT4 (TPT4) was selected to assess the specificity and affinity to transferrin receptor (TfR) on two kinds of tumor cells, K562 and KB. Both the receptor binding assays and the competition experiments were performed using radioligand binding analysis. The results demonstrated that TPT4 as well as Tf bound specifically to the TfR on the tumor cell surface and the affinity of the conjugate to TfR was similar to that of native Tf. In contrast, PEG−TNF-α demonstrated no specificity. The biodistribution and antitumor effects were investigated in S-180 tumor-bearing mice. It was found that TPT4 could markedly alter in vivo behavioral characteristics of TNF-α. Compared with TNF-α and PT4, extravasated TPT4 in tumor tissues exhibited a significantly delayed blood clearance and the highest intratumoral TNF-α levels. Furthermore, the inhibitory rate of tumor of TPT4 enhanced 5.3- and 1.8-fold over that of TNF-α and PT4, indicating that TPT4 exhibited the highest antitumor activity. These results suggested that Tf−PEG−TNF-α was a useful long circulating conjugate with the capabilities of specific receptor binding resulting in enhanced antitumor activity of TNF-α.

INTRODUCTION

Tumor necrosis factor alpha (TNF-α), an antitumor cytokine, has numerous bioactivities such as direct cytotoxicity against various tumor cells, activation of immune antitumor response, and selective impairment of tumor vascular endothelial cells (*1*). However, very high doses of TNF-α as a systemic antitumor agent were required to obtain the sufficient clinical potency, since TNF-α can be rapidly cleared from the blood and is widely distributed to various tissues. As a result, TNF-α exhibits severe toxic side effects to patients (*2*, *3*). These drawbacks are also found in the clinical applications of other bioactive proteins (*4*).

An approach that may solve these problems is the use of polyethylene glycol (PEG)-conjugated proteins (*5*). Our previous studies have shown that PEGylated TNF-α was more effective than its corresponding unmodified parent molecule while the accumulated level of PEG−TNF-α in the tumor was not significantly higher than that in normal organs including liver, spleen, lung, and kidney (*6*, *7*). This phenomenon may be due to the passive and nonspecific process of PEG−TNF-α extravasation, which is improved by the prolonged residence time of the protein in circulation and repeated passages through the tumor microvascular bed.

To improve this nonspecific targeting of PEGylation, ligand−receptor-mediated delivery systems to cell surface receptors (*8*, *9*) is a potentially desirable approach to treat diseased but spare healthy cells. Transferrin (Tf) holds promise as a targeting agent because of the larger number of transferrin receptors (TfRs) on the surface of tumor cells (*10*). Tf is potentially important as a targeting ligand to deliver a wide range of drugs, including anticancer drugs, peptides, proteins, and even genes, into malignant cells that overexpress TfRs (*11*−*16*). In the current report, a targeting TNF-α delivery system was devised. Thiolated Tf was bound to the maleimide group at the distal end of PEG−TNF-α to form a Tf−PEG−TNF-α conjugate. The binding of the Tf conjugate to TfR on K562 and KB cells was performed by using radioligand binding analysis. The specificity and affinity of the conjugate for TfR were assessed and compared with native Tf. Aiming at expanding the application of TNF-α, ^{125}I-labeled Tf−PEG−TNF-α was prepared, and tumor localization in S-180 tumor-bearing mice after intravenous injection was compared with those of ^{125}I-labeled TNF-α and PEG−TNF-α, respectively. On the basis of the findings in biodistribution studies, the antitumor effect of Tf−PEG−TNF-α was investigated and compared with free TNF-α and PEG−TNF-α on S-180 tumor-bearing mice. The results of this study will provide fundamental information enabling us to design useful Tf−PEG−TNF-α conjugate with the double effect from passive and active mechanisms.

EXPERIMENTAL PROCEDURES

Reagents and Assays. Recombinant human tumor necrosis factor-α (TNF-α, MW 17 kDa, IP = 8.0) was obtained from

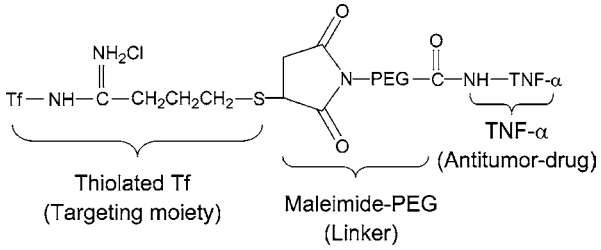

Figure 1. Design of Tf−PEG−TNF-α conjugate.

Department of Neurobiology, Second Military Medical University (Shanghai, China). *N*-hydroxysuccinimide-PEG-maleimide (NHS-PEG-MAL; MW 3.4 kDa) was from Nektar Therapeutics (San Carlos, CA). The concentration of TNF-α was estimated using bovine serum albumin as a standard using the Bradford dye assay (*17*), and the average number of PEG molecules on the conjugate was determined by spectrophotometric analysis (*18*). Human transferrin (iron-free, Tf) with MW 76−81 kDa was purchased from Sigma (St. Louis, MO) and modified with 2-iminothiolane (Traut's Reagent from Sigma). The amount of free mercapto groups was determined using the Ellman assay at 412 nm (*19*) using 5,5′-dithiobis(2-nitrobenzoic acid) (Sigma). HiTrap Desalting and HiPrep 16/60 Sephacryl S-200HR prepacked gel filtration columns for protein purification and separation were obtained from Amersham Biosciences (Stockholm, Sweden). $Na^{125}I$ was purchased from Sigma. Other reagents and solvents were of analytical grade. The specific radioactivity of the radiocompound was assessed in an autogamma instrument (Packard Instruments, CT). The radiochemical purity was determined using thin-layer chromatography.

Radiolabeling of Proteins. The Tf and purified PEG−TNF-α were labeled with ^{125}I using a protocol based on the use of Iodogen for the following experiments. Briefly, human Tf (300 μg) in 30 μL of PB (0.1 M potassium phosphate buffer, pH 7.2) was layered over a freshly prepared film of Iodogen (100 μg) and incubated for 8 min at 4 °C in presence of 0.5 mCi of $Na^{125}I$. PEG−TNF-α (100 μg based on TNF-α) in 90 μL of PB was iodinated with 3 mCi of $Na^{125}I$ accordingly. The reaction mixtures were brought up to 0.1 mL volume with PBS, and the unbound ^{125}I was removed by gel filtration chromatography on a Sephadex G-25 PD 10 column equilibrated with HB (30 mM HEPES, pH 8.5) for ^{125}I-Tf and HBS (20 mM HEPES with 150 mM NaCl, pH 7.1) for PEG−^{125}I−TNF-α (^{125}I-PT), respectively. The specific activity of ^{125}I-Tf was approximately 92 kCi/mol, and that of PEG−^{125}I−TNF-α was 87 kCi/mol. Both radiocompounds were obtained in 95% yield with a radiochemical purity higher than 99%.

Design and Synthesis of Tf−PEG−TNF-α Conjugate. The design of the conjugate is shown in Figure 1. TNF-α, the antitumor protein, was modified with 3.4 kDa PEG via an amide bond. The other end of PEG is linked to Tf, the targeting moiety.

The conjugate was synthesized in three steps. Step 1: PEGylation of TNF-α (PEG−TNF-α) using the NHS group of the NHS−PEG-maleimide. Step 2: Thiolation of Tf (Tf−SH). Step 3: Conjugation of Tf−SH to PEG−TNF-α utilizing the maleimide group of the PEG−TNF-α conjugate. The PEGylation reaction mixtures contained TNF-α (23.5 nmol, 0.40 mg/mL) and NHS−PEG−MAL reagent at a 1:5, 1:20, 1:40, and 1:60 molar ratios in 1 mL of 15 mM HEPES pH 8.0, for samples PT1, PT2, PT3, and PT4, respectively. The reactions were carried out at 4 °C for 0.25, 0.5, 1.0, 1.5, and 2.0 h, respectively. SDS-PAGE of the PEG−TNF-α mixture using 14% polyacrylamide on a Mini-PROTEIN III cell system (Bio-Rad, Hercules, CA) was carried out as described (*20*). TNF-α, as a control protein, and the PEG−TNF-α mixture equivalent to 26.7 μg of protein were run on the gels. Gel-separated proteins were stained with Coomassie brilliant blue R250. The molecular weights of the conjugated and unconjugated proteins were estimated relative to molecular weight markers.

The ImageMaster VDS-CL system (Amersham Pharmacia Biotech, Sweden) was used for acquisition of the digital image from the SDS-PAGE gels using the white light tray. Image data was imported into a PC using the Image Capture Kit and ImageMaster VDS Software. The integrated optical densities (IOD) were determined for the full width of each protein band. The amount of unconjugated protein in each gel was estimated by contrasting the IOD value with that of the control protein band. The percentage of PEGylated protein (*P*%) was calculated by the formula

$$P\% = \frac{\mathrm{IOD_c} - \mathrm{IOD_u}}{\mathrm{IOD_c}} \times 100\%$$

where IOD_c and IOD_u represent the IOD values of control protein and the remaining unconjugated protein, respectively.

Purification of PEG−TNF-α conjugates for the reaction products at 1 h was carried out by cation-exchange perfusion chromatography. The entire mixture was subjected to semi-preparative HPLC (BioCAD 700E, Applied Biosystems) using a POROS 20 HS column (20 μm, 100 × 4.6 mm i.d., 1.66 mL). The flow rate was 1.5 mL/min, with the mobile phase starting from 50% deionized water and 50% solvent A (5 mM NaH_2PO_4−Na_2HPO_4, pH 6.8) (0−2 min) to 50% solvent A and 50% solvent B (3 M NaCl in solvent A) at 33 min. The absorbance of protein and MAL−PEG−NHS was detected at 280 nm. The reaction mixture was separated into three fractions (see Figure 4). To identify the components in the three fractions, PT1 was subject to electrophoresis using SDS-PAGE. Each fraction of PT1 at 1 h was collected and loaded on 14% SDS−polyacrylamide gels. The gels were stained with Coomassie brilliant blue (for protein) and with barium iodide solution (for PEG) (*21*).

The fraction of the PEG−TNF-α peak between 0.3 and 0.8 M NaCl was collected, the solution was concentrated, and the buffer replaced simultaneously with HBS using an Amicon Ultra-4 centrifugal filter device (cutoff 5 kDa, Millipore, Bedford, MA). The purified PEG−TNF-α conjugates in HBS (PT1−PT4) were collected, where the molar ratios of TNF-α/PEG were 1:1.9, 1:2.6, 1:3.7, and 1:4.8, respectively. The yields based on TNF-α were 18.9% (PT1), 50.4% (PT2), 60.8% (PT3), and 85.7% (PT4), respectively.

To determine the amount of Tf attached to PEG−TNF-α in the third step, Tf was radioiodinated as described above. The ^{125}I-Tf solution in HB was supplemented with unlabeled Tf to a concentration of 250 μM. A calibration curve of ^{125}I-Tf was constructed by a linear regression analysis between the measured cpm values and the known concentrations of ^{125}I-Tf.

A solution of 0.25 μmol of ^{125}I-Tf in 1.0 mL of HB was mixed under argon with a solution of 1.95 μmol of 2-iminothiolane in 150 μL of 15 mM HEPES (pH 8.5). After 3 h at room temperature, purification was performed by gel filtration (Hitrap desalting column) under argon with HBS, at a flow rate of 1.5 mL/min. 4.5 mL, containing the desalted protein, was collected and concentrated using an Amicon Ultra-4 centrifugal filter device (cutoff 10 kDa, Millipore). The resulting 2.5 mL of product (^{125}I-Tf-SH) contained 0.19 μmol of ^{125}I-Tf modified with 0.59 μmol of thiolane linker (molar ratio of 1:3.1). The ^{125}I-Tf-SH solution was mixed under argon with PEG−TNF-α in 1.5 mL of HBS, at a molar ratio of 1:1.2 (maleimide linker/SH group) and kept under argon for 24 h at 4 °C. The reaction mixture and ^{125}I-Tf-SH were loaded separately onto a column of Sephacryl S-200 HR (HiPrep 16/60). The elution of product was monitored by the absorbance at 280 nm and the radioactivity of the fractions. The ^{125}I-Tf−PEG−TNF-α fraction was collected and concentrated using a centrifugal filter device (cutoff

5 kDa, Millipore). The purified ^{125}I-Tf−PEG−TNF-α conjugates for the reactions between Tf-SH and PT1−PT4 had molar ratios of Tf/PEG/TNF-α of 0.8:1.9:1 (TPT1), 0.9:2.6:1 (TPT2), 0.9:3.7:1 (TPT3), and 1.1:4.8:1 (TPT4), respectively. The radiochemical purity of each conjugate was higher than 98%. The yields of TPT1, TPT2, TPT3, and TPT4 conjugates based on TNF-α were 38.6%, 40.1%, 42.3%, and 52.7%, respectively.

Cell Culture. The cell lines, including human erythroleukemia K562 cells, human epidermoid carcinoma KB cells, and normal human hepatocyte L02 cells, were purchased from the Institute of Biochemistry and Cell Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences (Shanghai, China). Cells were grown in fresh RPMI-1640 (Gibco) medium supplemented with 10% (v/v) heat-inactivated fetal calf serum (FCS), 2 mM glutamine, and 0.1 mg/mL of both penicillin and streptomycin, at 37 °C in humidified air containing 5% CO_2. All experiments were performed on cells in the logarithmic phase of growth. For subculture, monolayer cells (KB cells and L02 cells) were dispersed with 0.25% trypsin plus 1 mM EDTA at 37 °C for 30 min. The cells were collected by centrifugation and resuspended in fresh medium. Cell growth did not show any appreciable change under all the experimental conditions. Cell viability was checked at the end of the treatments using the Trypan blue exclusion method and was found to be consistently >95%.

In order to wash out the endogenous Tf, the cells were washed twice with ice-cold RPMI-1640 medium supplemented with 1% bovine serum albumin (BSA/RPMI) before the experiments.

Receptor Binding. To assess the targeting potential of TNF-α conjugates, ^{125}I-PT4 was modified by Tf−SH using the same procedure as described above. After Tf−PEG−^{125}I−TNF-α (^{125}I-TPT4) was purified, iron incorporation into ^{125}I-TPT4, as well as into ^{125}I-Tf, was carried out by addition of 1.25 μL of 10 mM iron (III) citrate buffer (containing 200 mM citrate and adjusted to pH 7.8 with sodium bicarbonate) per milligram of transferrin. To remove the excess iron (III), the ^{125}I-Tf-Fe_2 or ^{125}I-TPT4-Fe_2 was treated with HBS in the centrifugal filter device (cutoff 10 kDa, Millipore) and centrifuged twice at 7000 × *g* at 4 °C for 10 min.

For binding assays, K562 cells (1.5×10^6), KB cells (2×10^6), and L02 cells (2×10^6) in 0.5 mL fresh BSA/RPMI were incubated at 4 °C for 2 h with 0.5 mL of ^{125}I-labeled ligands (0.31−59 nM based on Tf concentration) while shaking. After incubation, 1 mL of ice-cold BSA/RPMI medium was added to terminate the binding. The cells were then centrifuged at 4 °C for 10 min at 3000 × *g*. The radioactivity incorporated was counted in cellular pellet with a γ-counter after twice being washed in the same medium. To correct for nonspecific binding, control assays were performed in parallel by addition of a 100-fold molar excess of unlabeled Tf for 5 min before the addition of the radiolabeled ligand. Specific binding was calculated by subtracting nonspecific binding from total binding. The maximum number of binding sites per cell (B_{max}) and the apparent dissociation constant (K_d) were calculated using an iterative, nonlinear, least-squares curve fitting program (*GraphPad Prism 4.0*, GraphPad Software, San Diego, CA).

To assess the specific binding of TPT4 to TfR, competitive binding assays were performed: K562 cells (1.5×10^6 /mL in BSA/RPMI) were incubated at 4 °C for 2 h while shaking, with the addition of 3.1×10^{-9} M ^{125}I-Tf-Fe_2 and different concentrations (from 10^{-11} to 10^{-6} M) of unlabeled ligands (Tf-Fe_2, TPT4-Fe_2, or PT4). After centrifuging and washing, ^{125}I radioactivity was measured to obtain the specifically bound tracer activity (*B*) at each competitor concentration and the maximum binding, carried out without unlabeled competitor (B_0). The corresponding competition curves were obtained by plotting B/B_0 versus the log concentration of each competitor. The analysis of competition assays and the calculation of ED_{50} (effective dose) was performed using the *GraphPad Prism* program.

Tumor Models. Female Kunming strain mice (18−22 g) were supplied by Shanghai Experimental Animal Center, Chinese Academy of Sciences (Shanghai, China). The animals were acclimatized at a temperature of 25 ± 2 °C and a relative humidity of 70 ± 5% under natural light/dark conditions for one week before dosing. Sarcoma 180 (S-80) cells were collected from the Kunming mice which were transplanted with S180 cells in the intraperitoneal cavity. Mice at 6 weeks of age were injected subcutaneously in the right armpit with 10^6 S180 cells suspended in PBS. Tumors were permitted to reach 8−10 mm in diameter (7 d after implant) before initiation of the studies.

Biodistribution and Antitumor Effects in Mice. For biodistribution experiments, the S-180 tumor-bearing mice received ^{125}I-TNF-α, ^{125}I-PT4, and ^{125}I-TPT4. Each animal was given intravenously the dose of 0.4 μg TNF-α with a trace of ^{125}I (~5 μCi). Mice ($n = 5$ per time point) were sacrificed after defined time periods, and then tissues were collected, wet-weighed, and counted in a γ-counter.

In vivo anticancer activity was evaluated against S-180 solid tumors in mice. Five groups of mice ($n = 10$ per group) were used, and S-180 cells were implanted subcutaneously into the armpits of the mice. After 2 d, the mice were injected intravenously with saline, TNF-α, PT4, and TPT4 once every 2 days (8 times) for 16 days, respectively. Groups 1−2 (control groups) were treated with saline, and groups 3−5 (treatment groups) with TNF-α, PT4, and TPT4 at the dose of 0.67 μg per mouse. Tumor volumes (V_t = [major axis] × [minor axis]^2 × 1/2) were measured in two perpendicular directions every 2 days. The inhibitory rate of tumor (IR) was calculated using the following equation:

$$\mathrm{IR} = \frac{[(V_t \text{ of control group}) - (V_t \text{ of treatment group})]}{(V_t \text{ of control group})} \times 100\%$$

The experimental design of this study was approved by the appropriate ethical committee on animal study in Fudan University.

RESULTS

Characterization of PEGylated TNF-α. To assess the effect of the molar ratio of PEG on the degree of PEGylation of TNF-α, and to select an appropriate reaction time, the PEG−TNF-α conjugates produced under the different reaction conditions were analyzed by SDS-PAGE. SDS-PAGE profiles (Figure 2) show that the reaction mixtures contained different PEG−TNF-α conjugates along with some unconjugated TNF-α. The molecular weight (MW) of each band was estimated relative to molecular weight markers. The MW of unconjugated TNF-α was 16.9 kDa. The PEG−TNF-α was separated into three major bands, band A (24.1 kDa), B (30.9 kDa), and C (39.9 kDa). On the basis of the apparent MW of the PEGylated TNF-α conjugates on SDS-PAGE, we estimate that they contain over two, four, and six PEG molecules, respectively. The amount of conjugated protein increased significantly with an increase in the molar ratio of PEG to protein, since the band intensity of the unconjugated protein (band TNF in lanes 3−7) reduced as the PEG concentration was increased.

The level of the unconjugated protein in the SDS-PAGE gels was quantified using the ImageMaster VDS-CL system (Figure 3). The peak labeled TNF represents unconjugated TNF-α, while peaks A, B, and C refer to the major conjugated species. The IOD value of the unconjugated TNF-α (peak labeled TNF) was

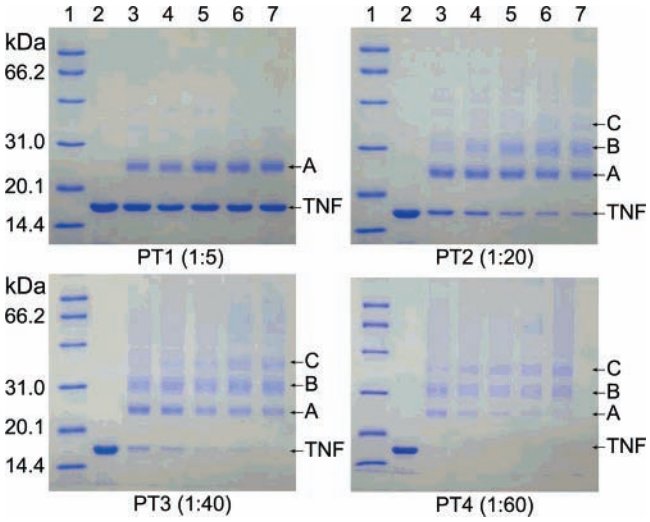

Figure 2. SDS-PAGE profiles of native (lane 2) and PEGylated TNF-α for different reaction times (0.25, 0.5, 1.0, 1.5, and 2.0 h on lanes 3−7, respectively). PEGylation of TNF-α was carried out using different molar ratios of TNF-α to PEG (PT1, 1:5; PT2, 1:20; PT3, 1:40; and PT4, 1:60 PEG/TNF-α, respectively). Molecular weight markers are shown in lane 1 on each gel. The various bands of PEGylated TNF-α are shown as A, B, and C.

determined, and the percentage of unconjugated protein (*P*%) calculated and used to indirectly represent the degree of PEGylated TNF-α. The *P*% values increased from about 20% for PT1 (1:5 TNF-α/PEG) to over 95% for PT4 (1:60 TNF-α/PEG), indicating that the degree of PEGylation increased with an increase in the molar ratio of NHS−PEG−MAL to TNF-α. Moreover, the *P*% values increased only slightly after 1.0 h of incubation, and we therefore chose this reaction time for the preparation of the PEG−TNF-α conjugates.

For purification of PEG−TNF-α, a perfusion chromatography technique was developed to separate the reaction products of TNF-α and NHS−PEG−MAL. Figure 4 shows that the crude reaction product was separated into three fractions (peaks Fr1, Fr2, and Fr3). Comparison to the chromatograms of NHS−PEG−MAL and TNF-α (Figure 4a,b) showed that the retention times of peak Fr1 and peak Fr3 were identical to those of NHS−PEG−MAL and TNF-α, respectively, while that of peak Fr2 was between those of peak Fr1 and peak Fr3. Presumably, the fractions of peaks Fr1, Fr2, and Fr3 were free NHS−PEG−MAL, PEG−TNF-α conjugates, and free TNF-α, respectively.

Identification of the components in the fractions was further confirmed by staining the gel after electrophoresis. Figure 5 shows that the staining was very selective and specific for PEG and protein. Only free or protein-bound PEG was stained by barium iodide solution. As shown in Figure 5A, the bands of the NHS−PEG−MAL standard (PEG), Fr1, and Fr2 were visible after barium iodide staining, and the mobility of Fr1 band was consistent with that of PEG band, whereas the Fr2 band had a lower mobility. The TNF-α standard (TNF) and the unconjugated protein (Fr3) were not stained with barium iodide (Figure 5A), but were with Coomassie blue (Figure 5B). Moreover, the band of Fr1 was not detected using Coomassie blue, while the components of Fr2 were stained and had a lower mobility than the TNF-α standard (Figure 5B). These results indicated that peaks Fr1, Fr2, and Fr3 correspond to the fractions of the excess free NHS−PEG−MAL, PEG−TNF-α, conjugates and free TNF-α, respectively.

Synthesis of Tf−PEG−TNF-α Conjugates. After the conjugation reactions of ^{125}I-Tf-SH to PT1−PT4, excess free ^{125}I-Tf-SH was removed by gel filtration using a Sephacryl S-200 HR column. The elution profiles of the reaction mixture of ^{125}I-Tf-SH and PT4 were monitored for absorbance at 280 nm and radioactivity. The ^{125}I-Tf−PEG−TNF-α conjugate was eluted first, followed by a separate peak corresponding to unreacted ^{125}I-Tf-SH. Additionally, no unreacted PEG−TNF-α was observed. All purified Tf−PEG−TNF-α conjugates contained approximately one Tf ligand per TNF-α molecule.

Specificity and Affinity of Tf−PEG−TNF-α for TfR. To compare the binding characteristics of Tf to the TfRs on the surface of normal and tumor cells, ligand binding assays were carried out at 4 °C. Assuming one type of binding site, the equilibrium binding of ^{125}I-Tf-Fe$_2$ to three kinds of cells resulted in a saturation isotherm, and Scatchard plots of the data gave a nonlinear regression line from which the values of K_d and B_{max} were calculated (Table 1).

The B_{max} of Tf on L02 cells was about 10-fold smaller than that on K562 cells and KB cells, while the apparent K_d values of Tf−receptor binding for L02 cells was approximately 4-fold higher than that for both tumor cell lines. These results indicate that both Tf receptor levels and Tf binding affinity on tumor cells were far higher than on the normal cells. Therefore, Tf was capable of binding to tumor cells more effectively than to normal cells, providing a useful targeting agent for antitumor drugs to tumor cell lines.

As shown in Table 1, the B_{max} values of ^{125}I-TPT4-Fe$_2$ on K562 cells and KB cells were slightly smaller than that of Tf-Fe$_2$ on the corresponding cells. The apparent K_d values of ^{125}I-TPT4-Fe$_2$ on both K562 cells and KB cells were similar to that of ^{125}I-Tf-Fe$_2$ on the corresponding cells. Additionally, it was found that the binding amount of PEG−TNF-α to both tumor cells was only 20% of that of Tf (data not shown). The above results suggest that Tf−PEG−TNF-α as well as native Tf was bound specifically, probably by TfR, while the binding of PEG−TNF-α to tumor cells may be nonspecific.

To determine the role of TfR in conjugate binding, competition experiments were conducted on K562 cells with varying amounts of unlabeled ligands (Tf-Fe$_2$, TPT4-Fe$_2$, or PT4) and a constant amount of ^{125}I-Tf-Fe$_2$. The monophasic nature of the inhibition curves (Figure 6) confirms a single population of binding sites. Competition curves showed similar decreases of ^{125}I-Tf-Fe$_2$ binding with increasing concentrations of either Tf-Fe$_2$ or TPT4-Fe$_2$. Using the *GraphPad Prism* program, ED_{50} values were calculated: 3.1 nM for Tf-Fe$_2$ and 5.4 nM for TPT4-Fe$_2$. The data showed that the inhibition of binding of ^{125}I-Tf-Fe$_2$ to the surface of K562 cells was dependent upon the concentration of Tf-Fe$_2$ and TPT4-Fe$_2$, indicating that the Tf conjugate and native Tf compete for the same receptor. This result was supported by the observation that the ligand−receptor interactions, Tf-Fe$_2$-TfR and TPT4-Fe$_2$-TfR, exhibited dissociation constants of the same order of magnitude. In contrast, when PT (10^{-11} to 10^{-6} M) was used as competitor, ^{125}I-Tf-Fe$_2$ binding did not change. As a result, the binding of TPT4-Fe$_2$ to TfRs is indeed receptor-specific, but PEGylated TNF-α (PT4) cannot specifically bind to TfR due to the absence of the corresponding Tf ligand.

In Vivo Evaluation. Since S-180 cells were one of the classical tumor models for a long time and their surface overexpress transferrin receptors (*22*), S-180 tumor-bearing mice were selected as animal models in this study. The distribution profiles of free drug and its conjugates in S-180 solid tumor-bearing mice after intravenous administration were shown in Figure 7. It was found that free TNF-α showed the lowest plasma levels as compared with TPT4 and PT4 at the same time points after dosing. Moreover, the plasma levels of free TNF-α were decreased by 36-fold from 0.25 h (539 cpm/mg) to 12 h (15 cpm/mg), indicating that free drug was quickly removed from the circulating system. In contrast, TPT4 and PT4 exhibited a significantly delayed blood clearance, and the plasma levels were decreased by 4.5-fold for TPT4 (from 1134

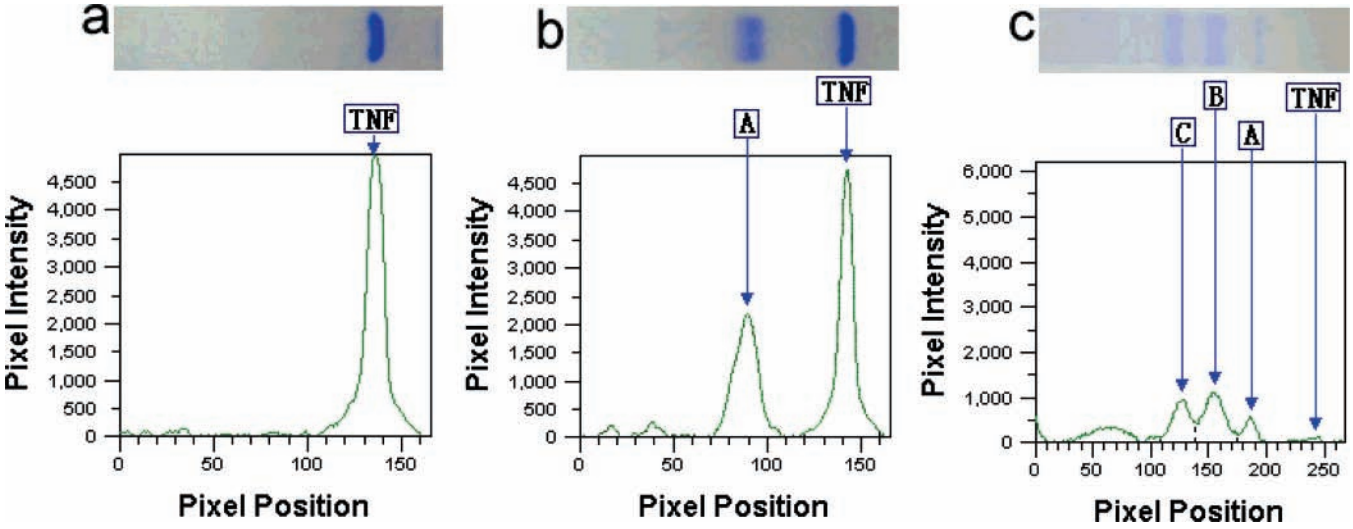

Figure 3. Profiles of band detection based on the gel image intensity using ImageMaster bioimaging system. (a) control protein (based on 26.7 μg TNF-α); (b) reaction mixture PT1 (1:5 TNF-α/PEG), and (c) PT4 (1:60 TNF-α/PEG).

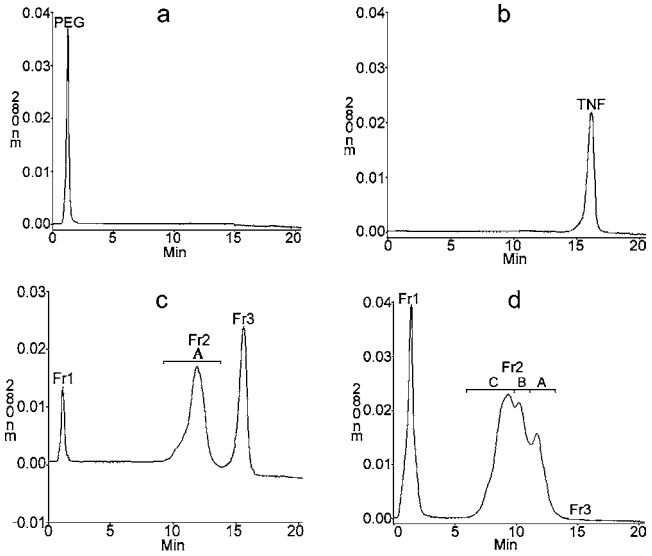

Figure 4. Purification of PEG−TNF-α conjugates by cation-exchange perfusion chromatography. NHS−PEG−MAL (a), TNF-α (b), and the crude reaction mixture of TNF-α/PEG molar ratios of 1:5 (c) and 1:60 (d) were purified on a POROS 20 HS column. The reaction mixture was separated into three fractions identified as NHS−PEG−MAL (Fr1), PEG−TNF-α (Fr2), and TNF-α (Fr3).

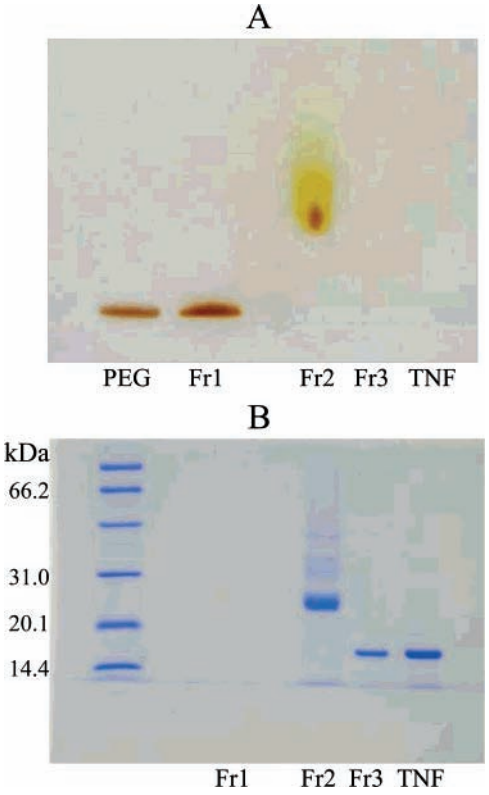

Figure 5. Identification of the three fractions of PT1 corresponding to Figure 4c by SDS-PAGE. Gel A was stained for protein with Coomassie blue, whereas gel B was stained for PEG with barium iodide solution. Two SDS-gels were loaded as follows: left lane, NHS−PEG−MAL (A) and protein markers (B); right lane (TNF), TNF-α; lanes Fr1, Fr2, and Fr3, fractions corresponding to peaks Fr1, Fr2, and Fr3.

cpm/mg to 253 cpm/mg) and 6.6-fold for PT4 (from 1043 cpm/mg to 157 cpm/mg), respectively. At 0.25 h after intravenous injection, free TNF-α was mainly distributed to normal tissues, successively: kidney > liver > lung > spleen. The tumor accumulation of TNF-α was very low, but that of TPT4 was remarkably higher than free TNF-α and PT4 ($P < 0.05$). At 2 h after administration, free TNF-α was gradually eliminated from all tissues including the S-180 tumors. There were no large differences in distribution of the TNF-α conjugates compared with free TNF-α in normal tissues. However, the TNF-α levels in tumor for TPT4 and PT4 were time-dependently increased. Tumor accumulation of TPT4 and PT4 were dramatically increased at 2 h after injection, which were about 5- and 3-fold over that of free TNF-α ($P < 0.01$), respectively. In particular, the TNF-α levels for TPT4 in tumor were much higher than those in all normal tissues examined ($P < 0.01$), while the differences between the TNF-α levels in tumor and normal tissues were found to be little for PT4. At 12 h after dosing, the tumor took up only small amounts of free TNF-α, whereas the tumor accumulation of TPT4 was still significantly higher than free TNF-α and PT4.

The inhibitory action of the TNF-α conjugates against S-180 solid tumors in mice was shown in Figure 8. A control group of 20 mice injected with saline solution induced the average tumor volume of 9.79 ± 2.38 cm^3 on day 17 after tumor cells inoculation. The TNF-α group at dose of 0.67 μg per mouse exhibited the average tumor of 8.52 ± 1.95 cm^3 on day 17, indicating that tumor volume was insignificantly suppressed as compared with the control group ($P > 0.05$). In the case of the PT4 treatment group, average tumor volume on day 17 (6.03

Table 1. Binding Parameters of ^{125}I-Tf-Fe$_2$ and ^{125}I-TPT4-Fe$_2$ on K562 Cells, KB Cells, and L02 Cells at 4 °C (n = 3)

ligand	cell lines	B_{max} ($\times 10^4$ sites/cell)	K_d (nmol/L)	goodness of fit (R^2)
Tf	K562	17.2 ± 0.7	8.9 ± 0.5	0.9717
	KB	13.5 ± 0.6	9.6 ± 1.3	0.9838
	L02	1.5 ± 0.1	35.4 ± 2.8	0.9866
TPT4	K562	14.7 ± 1.1	9.2 ± 0.4	0.9826
	KB	11.1 ± 1.0	10.5 ± 2.2	0.9855

± 0.75 cm^3) was smaller than that of the control group (P = 0.02) and the TNF-α group (P = 0.03). For the TPT4 group, the obvious antitumor response was observed from day 11 after inoculation as compared with the TNF-α group (P < 0.05). Moreover, the average tumor volume of the TPT4 group on day 17 was 3.02 ± 1.71 cm^3, which was significantly smaller than that of the control group (P = 0.0007), TNF-α group (P = 0.0008), or PT4 group (P = 0.002).

The IR was calculated on the basis of average tumor volume on day 17 after tumor cells inoculation. The IR values of the TNF-α, PT4, and TPT4 treatment groups were 12.95%, 38.42%, and 69.11%, respectively. The IR of TPT4 enhanced 5.3- and 1.8-fold over that of TNF-α and PT4 (P < 0.01), indicating that TPT4 exhibited the highest antitumor activity. No side effect was observed, such as decrease in body weight, in any mice administered TPT4.

DISCUSSION

Ligand−receptor-mediated delivery systems have received major attention in the past few years (*23*, *24*), because naturally occurring ligands are not only able to achieve site-specific targeting to ligand-specific biosites, but are also biodegradable, and potentially nontoxic and nonimmunogenic. Some of the expected advantages of transferrin−drug conjugates are a preferable tissue distribution, prolonged half-life of the drug in the plasma, and controlled drug release from the conjugates (*10*). PEG has been used widely to increase the circulation half-life of rapidly eliminated drug, to impart enhanced permeability and retention (EPR) (*25*), to increase passive targeting of anticancer drugs, and to act as a spacer in numerous delivery systems like PEG-grafted liposomes and nanoparticles (*26*).

This paper proposes a new targeted conjugate for delivering TNF-α specifically to tumor cells by coupling Tf to TNF-α via a PEG linker. The combination of active targeting, based on the use of ligands, and passive targeting, based on the PEGylation due to EPR, may provide a tumor-selective targeting strategy. To our knowledge, this is the first report of Tf-mediated TNF-α targeting to tumor cells.

The conjugate, Tf−PEG−TNF-α, was successfully synthesized using a simplified three-step procedure as shown in Scheme 1. In the first step, TNF-α was modified with the heterobifunctional (α-maleimide-ω-*N*-hydroxysuccinimide ester) 3.4 kDa PEG derivative via the formation of an amide bond

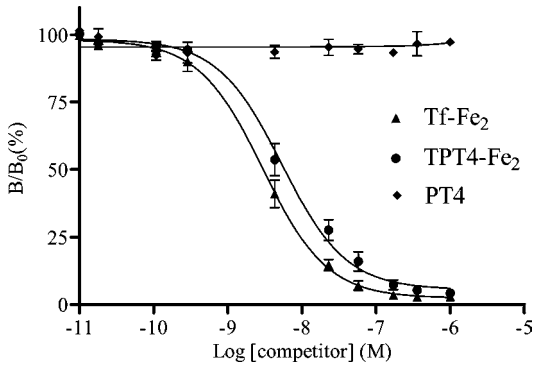

Figure 6. Competition curves among ^{125}I-Tf-Fe$_2$ and Tf-Fe$_2$, TPT4-Fe$_2$, and PT4 for the binding to K562 surface Tf receptors. The *y*-axis corresponded to B/B_0 (B = dpm corresponding to tracer bound at each competitor concentration; B_0 = dpm measured in absence of competitor), and the *x*-axis to the competitor logarithmic concentration.

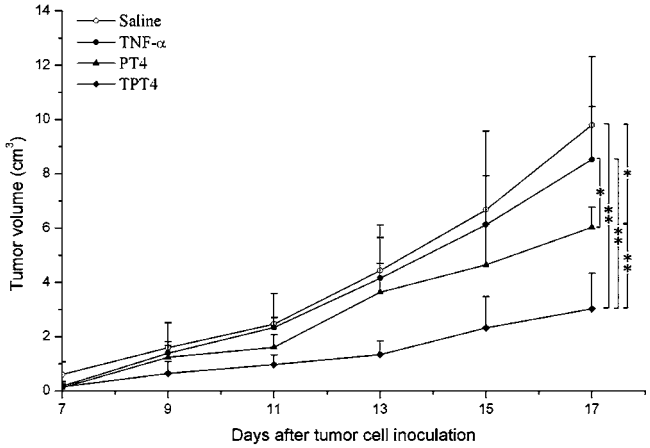

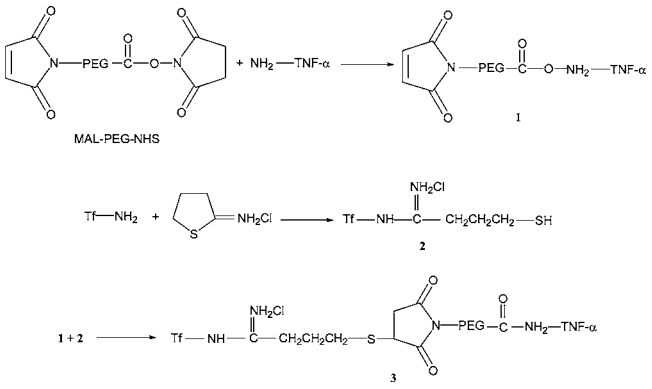

Figure 8. Antitumor effect (in terms of tumor growth) of TPT4 (◆), PT4 (▲), and free TNF-α (●) on S-180 solid tumors. Control mice were injected with 0.9% (w/v) NaCl (○). Tumor volume was monitored, mean ± SD are presented; n = 20 animals in control group, n = 10 animals per group in all treatment groups. *P < 0.05; **P < 0.01.

Scheme 1. Synthesis of PEG−TNF-α (1), Tf−SH (2), and Tf−PEG−TNF-α (3)

between amino groups of TNF-α and the terminal *N*-hydroxylsuccinimide (NHS) group of NHS−PEG−MAL. In the second step, the reaction of Tf with 2-iminothiolane was carried out to form Tf-SH. In the third step, the Tf−PEG−TNF-α conjugate was prepared by reacting the maleimide group at the distal end of the PEG chain in the TNF-α conjugate with thiolated transferrin. The HS group adds to the double bond of the maleimide group in a fast and selective reaction forming a stable thioether bond.

For the first step, it was necessary to estimate the degree of PEGylated TNF-α. In this study, an ImageMaster VDS-CL system, equipped with a multifunction bioimaging station designed for quick and accurate photodocumentation of electrophoretic results, was used to quantify proteins in SDS-PAGE gel bands. It was reported that the PEG chains attached to the protein surface would interfere with the effect of Coomassie blue staining (*27*). This phenomenon was also observed in our experiments. As seen in Figure 2, the PEG−protein band color (bands A, B, and C) with a high degree of PEGylation is rather pale (particularly in sample PT4) compared to that with a low degree of PEGylation. For this reason, the quantitative analysis of PEGylated protein based on the PEG−protein band intensity in SDS-PAGE gels was not appropriate. On the contrary, it is reliable to quantify unconjugated TNF-α compared with the control protein based on the IOD value of the free protein band. Therefore, the percentage of PEGylated TNF-α (*P*%) used to represent the degree of PEGylation can be accurately calculated. This method might be applicable to the other PEGylated protein for its simplicity.

Purification of PEGylated biomacromolecules (peptides, proteins, etc.) is a challenge due to the complexity of conjugates, heterogeneous population of molecules (*28*), and unstable structure of the resulting conjugate. Furthermore, the purification protocol must not alter or decrease the biological activity of the bioconjugates. Several purification protocols have been described including reverse-phase high-performance liquid chromatography (*29*), ion-exchange chromatography (*30*, *31*), size-exclusion chromatography (*32*, *33*), and affinity chromatography (*34*), most of which are time-consuming and result in poor yields. Perfusion chromatography is a technique based on fluid dynamics for reducing stagnant mobile-phase mass transfer in liquid chromatography and thereby reducing peak broadening. This technique involves the flow of liquid through a noncompressible porous chromatographic particle (POROS Media, PerSeptive Biosystems) with 6000−8000 Å pores which transect the particle (*35*). It therefore has high dynamic capacity, high resolution, and separation speed typically 10−100-fold faster than that obtained with conventional media. Perfusion chromatography has been shown in the past to be ideally suited for purification of large biomolecules (*36*−*38*). In this study, perfusion ion-exchange chromatography was used for rapid purification of the PEGylated TNF-α. The PEGylated protein was separated from excess free protein and PEG. The excess free PEG was eluted first before the gradient due to its electrical neutrality, while the free protein was retained on the cation-exchange column due to its positive charges until it was eluted with a salt gradient. By contrast, the PEG−TNF-α peaks A, B, and C, were eluted between free TNF-α and PEG due to the reduced charge. Since the PEG−TNF-α peak was well-resolved from free TNF-α and PEG, this method can be easily scaled up. Also, since the analysis time for the entire procedure was short (less than 20 min), larger amounts of sample can be obtained by simply repeating the procedure several times.

Many studies have demonstrated that the residence time in the bloodstream of PEG−protein conjugates increases according to the molecular size (*7*, *26*). Among those, Chapman et al. indicated that the increase is governed by the total polymer mass, regardless of the number of chains or the polymer molecular weight (*39*). In addition, size enlargement promotes the accumulation into tumor tissues by the passive EPR mechanism. With a few exceptions, the molecular weights of PEGs used for synthesis of biologically active conjugates are in the range 2−20 kDa (*40*). According to these reports and our previous studies, it is reasonable to speculate that conjugates with few low-molecular-weight 3.4 kDa PEG chains, such as PT1, may be unable to achieve a longer circulating half-life and a better tumor targeting as compared to conjugates with about five 3.4 kDa PEG chains (PT4). Therefore, PT4 with a maximum reaction yield was selected as a lead candidate, intending to produce conjugates with multiple PEGs attached to achieve the benefits similar to the ones afforded by a single larger PEG.

The thiolation of Tf and conjugation of Tf-SH to PEG−TNF-α were carried out according to the published procedures (*41*, *16*). After preparation of ^{125}I-PT4 and ^{125}I-TPT4-Fe_2, the binding parameters of the conjugates to tumor cell receptors were determined. It was found that the numbers of binding sites and the competitive ability of the TPT4-Fe_2 conjugate were slightly smaller than that of Tf-Fe_2. It may be postulated that the chemical modification of Tf with PT results in molecule size enlargement, which in turn sterically hinders Tf−receptor binding. However, the TPT4-Fe_2-TfR and Tf-Fe_2-TfR complexes exhibit the K_d, B_{max}, and ED_{50} values on the same order of magnitude, which would be unable to induce remarkable differences in specificity and affinity.

Successful treatment of cancer by TNF-α requires the selective delivery of relatively high concentration of TNF-α to tumor tissue. The Tf−PEG−TNF-α conjugate prepared in this study appears to satisfy these requirements and should be very useful for cancer therapy. It was found that in vivo behavior of TNF-α was altered by PEG and Tf modifications. Owing to rapid clearance of free TNF-α from the circulation, uptake of free TNF-α in tumor tissue exhibited the smallest levels as compared with those of TPT4 and PT4. In contrast, the tumor accumulation of TPT4 and PT4 were time-dependently increased, and the order of the accumulation amount in tumor was TPT4 > PT4 > TNF-α.

The highest tumor accumulation of Tf−PEG−TNF-α resulted in its maximal antitumor effect. As observed in Figure 8, the tumor volume of the TNF-α group was insignificantly different from that of the saline group during the experiment, indicating that a dose of 0.67 μg per mouse for the TNF-α group was not effective for tumor growth inhibition. However, this problem did not arise with PT4 or TPT4, which had significant antitumor response at a dose of 0.67 μg, especially TPT4, which showed the maximal antitumor effect. It is important to discuss why TPT4 had the greatest antitumor potency as compared with PT4 and TNF-α. It is well-known that TNF-α must bind to the extracellular domain of TNF-α receptor type I (TNF−RI, p55)

for intracellular signal transduction to occur leading to apoptosis or programmed cell death (*42*). We speculated that extravasated Tf−PEG−TNF-α in the tumor was likely to bind to two receptor types (Tf receptor and TNF-α receptor) on the tumor cell surface. Owing to specific recognition by overexpressed Tf receptors on tumor cell surface and PEGylation by the passive EPR mechanism, the accumulation amount of Tf−PEG−TNF-α at the tumor site was higher than that of TNF-α and PEG−TNF-α. Moreover, the PEG molecule as a spacer between TNF-α and Tf is a flexible long chain and could offer chances to make the TNF-α molecule move randomly. When Tf at the distal terminal of the PEG chain on Tf−PEG−TNF-α binds to the Tf receptor on the tumor cell surface, TNF-α at another terminal would also have chances to bind to the extracellular TNF receptor simultaneously. In general, the time course of cytokines binding to the membrane receptor and initiating signal transduction is transient, whereas that of internalization via ligand−receptor-mediated endocytosis is much longer. Thus, it could be reasonably speculated that antitumor activity of Tf−PEG−TNF-α mediated via TNF receptor had occurred before it was internalized into tumor cells via Tf receptor-mediated endocytosis. Therefore, it was confident that Tf−PEG−TNF-α, as a more potent systemic antitumor therapeutic agent than PEGylated TNF-α, not only improved the therapeutic index of TNF-α, but also obviated the need for repeated high doses. Of course, the identification of the mechanism of antitumor effects of the Tf−PEG−TNF-α is the subject for further studies.

In summary, a novel strategy for the formation of transferrin−PEG−TNF-α conjugate by coupling Tf to PEG−TNF-α using PEG as a spacer was established. The overall procedures were performed in neutral medium at 4 °C. These mild conditions of synthesis and purification would be suitable for the preparation of other protein conjugates. The conjugate could bind specifically to the transferrin receptor and exhibit similar affinity to tumor cells as native transferrin. As compared with TNF-α and PEG−TNF-α, Tf−PEG−TNF-α exhibited a significantly delayed blood clearance, the highest tumor accumulation, and the maximal antitumor activity. The increase of accumulation in tumors could be mainly governed by two mechanisms: active targeting using the Tf ligand and passive targeting by the EPR effect. Thus, the design of Tf−PEG−TNF-α conjugate could potentially provide a tumor-selective targeting strategy. Such targeting Tf−PEG−drug conjugates should be useful for systemic antitumor therapy.

Stability of Cell-Penetrating Peptide−Morpholino Oligomer Conjugates in Human Serum and in Cells

Derek S. Youngblood, Susie A. Hatlevig, Jed N. Hassinger, Patrick L. Iversen, and Hong M. Moulton*

AVI BioPharma, Incorporated, 4575 SW Research Way, Corvallis, Oregon 97333. Received May 25, 2006; Revised Manuscript Received October 25, 2006

Cell penetrating peptides (CPPs) have been shown to enhance the cellular uptake of antisense oligonucleotides (AOs). However, the effectiveness of the CPPs for cytoplasmic or nuclear delivery of therapeutic AOs must take into account the possible entrapment of the CPP−AO conjugates in endosomes/lysosomes and the overall stability of the CPP−AO conjugates to enzymes. This includes the stabilities of the CPPs and AOs themselves as well as the linkage between them. In this study, we investigated the effects of several structural features of arginine-rich CPPs on the metabolic stability of CPP conjugated to phosphorodiamidate morpholino oligomers (PMOs) in human serum and in cells. Those structural features include amino acid configurations (D or L), incorporation of non-α-amino acids, peptide sequences, and types of linkages between CPPs and PMOs. Using matrix-assisted laser desorption ionization time-of-flight mass spectrometry, we found that the stability of the CPP portion was varied although the PMO portion of the conjugate was completely stable both in cells and in human serum. D-Configuration CPPs were completely stable, while L-CPPs were degraded in both serum and HeLa cells. Insertions of 6-aminohexanoic acid residues (X) into an R_8 peptide increased the corresponding CPP's serum stability with the degree of stability being dependent upon the positions of X. However, X-containing CPPs were degraded rapidly intracellularly. Insertions of β-alanines (B) into the R_8 peptide increased its serum stability and intracellular stability. An amide or a maleimide linkage was stable in both serum and cells; however, an unhindered disulfide linkage was not stable in either. By using fluorescent microscopy, flow cytometry, and an antisense splice correction assay, the cellular uptakes of an X-containing conjugate and its fragments were compared to their antisense activities. We found that a large fraction of the conjugate was trapped within vesicles and the degraded fragments cannot escape from the vesicles. This study indicates that the incorporation of non-α-amino acids into L-CPPs can increase the metabolic stability of CPP−PMOs without using costly D-CPPs. However, the position and type of non-α-amino acids affect the degree of stability extracellularly and intracellularly. In addition, this study reveals that the degradation of an X-containing CPP−PMO conjugate is a more rapid process than degradation of a B-containing conjugate. Last, the endosomal/lysosomal trapping limits the effectiveness of a CPP−PMO conjugate, and the stability of the CPP is one of the factors affecting the ability of the conjugate to escape the endosomes/lysosomes.

INTRODUCTION

Antisense oligonucleotide analogs (AOs[1]) must be present at a sufficient concentration in the cytoplasm or in the nucleus to inhibit mRNA translation or to alter pre-mRNA splicing. The therapeutic potential of these molecules has been limited by a lack of suitable in vivo delivery methods. The discovery of the cell-penetrating property of HIV Tat (*1*−*3*) and antennapedia proteins (*4*) has stimulated efforts to develop cell-penetrating peptides (CPPs) as a delivery technology (*5*−*8*). The CPP-based approach is a simple and elegant delivery method, because these are short peptides of 10−30 amino acid residues which are easily manufactured and are capable of being conjugated to an AO cargo in a quality-controlled manner.

A class of CPPs under study is the Tat-like peptides, rich in the basic amino acids lysine and arginine (*9*, *10*). The arginine-rich CPPs enhance cellular delivery of uncharged AOs such as phosphorodiamidate morpholino oligomers (PMOs) (*11*) and peptide nucleic acids (PNAs) (*12*). Conjugation of PMOs to the $(RXR)_4$ (X = 6-aminohexanoic acid) or R_9F_2 CPPs enhanced the PMOs' abilities to cause exon skipping in dog muscle cells and in human tissue carrying Duchenne muscular dystrophy (*13*, *14*), as well as to inhibit replications of various viruses (*15*−*20*). A Tat−PNA conjugate inhibited HIV-1 Tat-dependent transactivation in cells (*21*). However, high (micromolar) concentrations of CPP−PMO or CPP−PNA conjugates are required for these biological effects. Recent studies of internalization mechanisms of these conjugates revealed that they are taken up by endocytotic mechanisms and the majority of conjugates are trapped within the endosome/lysosome compartments (*21*−*23*), consistent with the observations for the free Tat and oligoarginine peptides (*24*−*26*). An effective CPP−AO conjugate should be (i) stable in blood, (ii) efficiently taken up by cells, (iii) able to effectively escape from endosomes/lysosomes, (iv) non- or minimally toxic, and (v) target-specific. Factors that likely affect these properties include the metabolic stability of a conjugate in circulation and in cells, the structural features of a CPP, the linkage between a CPP and an AO. Studies of CPP structure−activity relationships (SARs) will give insights into factors affecting these properties.

Here, we investigated several SAR features of CPPs on the metabolic stabilities of CPP−PMO conjugates in both human serum and cells. These include amino acid configurations, incorporation of non-α-amino acids, amino acid sequences, and

types of linkages between CPPs and PMOs. In addition, the cellular uptake and antisense activities of a conjugate and its fragments were determined in an attempt to correlate the stability and the activity.

EXPERIMENTAL PROCEDURES

Synthesis of CPP−PMO Conjugates. The sequences and nomenclature of CPPs and PMOs are listed in Table 1. Both CPPs and PMOs were synthesized at AVI BioPharma to >90% purity. PMO syntheses have been described previously (*11*, *27*), while the CPPs were synthesized using standard Fmoc chemistry (*28*). The method for the conjugation of CPPs and PMOs through a thioether (maleimide), a disulfide, or an amide linker has been described previously (*8*, *29*, *22*).

Short peptides simulating enzymolysis fragments of CPPs were conjugated to the PMO in the same manner as described previously (*22*), with the exception that the N-terminus was blocked with Fmoc during conjugation. After conjugation, the N-terminus was unblocked by adding the crude reaction mixture to a tenfold volumetric excess of concentrated ammonium hydroxide and allowing the mixture to react at 45 °C for 24 h. The truncated peptide conjugates were purified by strong cation-exchange HPLC using a 4.6 × 100 mm Source 15s tricorn column (GE Healthcare, Piscataway, NJ) and the following run conditions: buffer A (20 mM NaOAc/25% CH_3CN), buffer B (1.0 M NaCl, 20 mM NaOAc/25% CH_3CN), gradient (0−15% B in 11.25 min), and flow rate of 1.3 mL/min. The XB dipeptide conjugate was further purified by reverse-phase HPLC using a 4.6 × 150 mm PLRP-S column (Polymer Labs, Amherst, MA) and the following run conditions: buffer A (20 mM NH_4OAc), buffer B (20 mM NH_4OAc, 60% CH_3CN), gradient (10−80% B in 34.5 min), and flow rate of 1.0 mL/min. After purification, both conjugates were desalted using the reverse-phase columns as described above.

The final products were analyzed by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS). The purity of conjugates was determined by HPLC using a Propac SCX-10 column (Dionex, Sunnyside, CA) with the following run conditions: buffer A (15 mM KH_2PO_4/25%CH_3CN), buffer B (15 mM KH_2PO_4/1.5 M KCl/ 25%CH_3CN), gradient (10−100% B in 15 min), and flow rate at 1 mL/min.

Cell Lines. HeLa (ATCC, Manassas, VA) and HeLa pLuc705 (pLuc705) cells (Gene Tools, Philomath, OR) were cultured in RPMI 1640 supplemented with 2 mM glutamine, 100 μg/mL streptomycin, 100 U/mL penicillin, and 10% fetal bovine serum (Hyclone, Logan, UT).

Extraction of CPP−PMO Conjugates from Human Serum. CPP−PMO (10 nmol) conjugates were incubated in 100 μL pooled human serum (Innovative Research, Inc., Southfield, MI) at 37 °C for 2 and 24 h. Samples were diluted to 300 μL with guanidinium−HCl solution (10 mL of 1 M guanidinium−HCl with 1 tablet of complete *mini* protease inhibitor cocktail (Roche Diagnostics, Alameda, CA)). Samples were further diluted with 600 μL ice-cold CH_3CN and centrifuged at 14 000*g* for 3 min. The supernatant was collected and lyophilized.

Extraction of Cell-Internalized CPP−PMO Conjugate. pLuc cells were seeded at 3×10^6 cells in a T-75 cm^2 flask and incubated at 37 °C for 24 h. The medium was replaced with fresh medium for control samples or with fresh medium containing a conjugate (10 μM) for test samples, and the cells were incubated at 37 °C for a designated time. The flask was washed with 1× sterile PBS twice. Cells were treated with 5 mL trypsin solution (0.25%, Hyclone) for 10 min at 37 °C, and trypsin activity was stopped by addition of the culture medium. The sample was centrifuged for 3 min at 2000*g*. The supernatant was removed, and the cells were washed with PBS and centrifuged three more times. The final cell pellet was reconstituted in 300 μL of the guanidinium−HCl solution.

[a] The peptide consists of amino acids with the D configuration. [b] X = 6-aminohexanoic acid; B = β-alanine. [c] The peptide contains D-arginines. [d] This sequence targets a mutant splice site at nucleotide 705 of the human globin β-thalassemic intron 2.

Two separate controls were undertaken. A "background" control consisted of a cell pellet, without a conjugate, reconstituted in 300 μL of the guanidinium−HCl solution spiked with 30 μL H_2O. A "post-treatment degradation control" consisted of a cell pellet, without a conjugate, reconstituted in 300 μL of the guanidinium−HCl solution spiked with 30 μL of a conjugate at 10 μM. Cells were lysed by a freeze-and-thaw method: 5 min incubation in a dry ice−acetone bath and 5 min in a room-temperature water bath, repeated three times. Cellular debris was precipitated out by adding 600 μL of ice-cold CH_3CN. The samples were centrifuged at 14 000*g* for 3 min, and the supernatant was collected and lyophilized.

Characterization of Extracted Products by MALDI-TOF MS. All reagents were purchased from Sigma-Aldrich unless specified. Lyophilized samples were reconstituted in 20 μL H_2O and kept on dry ice. The well plate was precrystallized with matrix solution: approximately 1 μL of matrix solution was placed on each well of a stainless steel well plate (Applied Biosystems, Foster City, CA), some crystallization was allowed by air-drying the solvent, and then the plate was lightly wiped with a Kimwipe. Samples were kept on dry ice for up to 1 h, thawed, immediately diluted 1:10 in water, placed into matrix solution, and spotted on the precrystallized well plate. The matrices employed were 3,5-dimethoxy-4-hydroxycinnamic acid (sinapic acid, SA), 2,4,6-trihydroxyphenone monohydrate (THAP) (98%), and α-cyano-4-hydroxycinnamic acid (CHCA) (Waters, Milford, MA). SA/Amp was prepared as a supersaturated solution by placing 10 ± 1 mg into a 1.7 mL microcentrifuge tube and adding 1 mL 1:2 acetonitrile/water, then 120 μL 0.5 M ammonium phosphate (≥99%). THAP/DiAmCit was prepared by dissolving 10 ± 1 mg into a 1.7 mL microcentrifuge tube and adding 1 mL 1:1:1 acetonitrile/water/citric acid (0.2 M, diammonium salt) (98%). The CHCA/AmP solution was prepared by placing 2.0 ± 0.2 mg into a 1.7 mL microcentrifuge tube and adding 1 mL 2:3 acetonitrile/0.1% trifluoroacetic acid (99%), then 60 μL 0.5 M ammonium phosphate. All matrices were mixed, then spun down using a microcentrifuge. One microliter of sample solution was taken up into 4 μL SA/AmP, 3 μL THAP/DiAmCit, or 4 μL CHCA/AmP. If sample-in-matrix crystallization was poor, an additional microliter of matrix solution was added to the top of the sample on the well plate, and the mixture was swirled with a pipet tip. After air-drying, the wells were washed with water by placing approximately 1 μL H_2O onto each well and then pulling it up with a fresh pipet tip.

All mass spectrometric analyses were performed on a Voyager DE-PRO Biospectrometry Workstation MALDI-TOF MS (Applied Biosystems), and the instrument was calibrated before each run of samples (Applied Biosystems Sequazyme Peptide Mass Standards Kit). System calibration checks were also performed before and after each run of samples. Mass accuracy is within 0.05%. Instrument parameters were as follows: 337 nm nitrogen laser in positive ion mode with linear detection; acceleration voltage, 25 kV; grid voltage, 95%; guide wire, 0.05%; extraction delay, 400 ns; shots, 100−200.

Determination of Extraction Efficiency. Extraction efficiencies of conjugates from human serum or cells were determined by fluorescent spectroscopy. The fluorescence of each sample was determined by mixing 5 μL of serum or cell lysate and 95 μL of 0.1 M Na_2CO_3 (pH 11) and measuring with a Flx 800 microplate fluorescence/luminescence reader (Bio-tek, Winooski, Vermont) with excitation at 485 nm and emission at 524 nm. A standard curve was determined for each conjugate using the same buffer and measurement conditions as those for the serum and lysate samples.

Cellular Uptakes and Antisense Activities of $(RX)_8B$−PMOF and Its Degraded Fragments. PLuc705 cells were seeded at 0.5×10^6 cells in a six-well plate (VWR, Bisbane, CA) and incubated at 37 °C for 24 h. The medium was replaced with 1.5 mL fresh medium containing a test compound (10 μM), in triplicate. Samples were allowed to incubate in the presence of the compound at 37 °C for 24 h (nonscraped), or cells were lifted from the bottom of the well with a rubber spatula (scraped). Scraped cells were triturated several times to mix, combined with replicates, and centrifuged for 7 min at 272*g*. The supernatant was removed, and the cells were washed with PBS and reconstituted in medium, equally replated (in triplicate) in a new six-well plate and incubated at 37 °C for 24 h.

All samples were harvested by rinsing each well with 1 mL PBS, incubating in 500 μL trypsin at 37 °C for 10 min, and neutralized with 700 μL media. Each sample was aliquoted to three portions: (i) a 200 μL aliquot was taken for determining cell viability and for fluorescent microscopy, (ii) a 500 μL aliquot was taken for determining luciferase activity, and (iii) a 500 μL aliquot was taken for flow cytometry. Cell viability was determined by trypan blue exclusion assay using a cell viability analyzer (Vi-Cell, Beckman Coulter, Fullerton, CA). Cells were imaged directly in the culture medium without fixation with a Nikon Diaphot 300 inverted microscope. Images were captured with an Olympus digital camera and processed using *MagnaFire* software (Optronics, Goleta, CA). To determine luciferase activity, the 500 μL aliquot was centrifuged 5 min at 1000*g*, supernatant was removed, and the cells were reconstituted in 300 μL lysis reagent (Promega, Madison, WI) and then incubated at 4 °C for 20 min. The cell debris was removed from the lysate by centrifugation for 5 min at 2000*g*. The protein concentration and luciferase activity were determined on lysate as described elsewhere (*8*). The 500 μL aliquot for flow cytometry was centrifuged for 3 min at 2000*g*, supernatant was removed, and the cells were washed with 1 mL PBS twice, reconstituted in PBS buffer containing 1% FBS, and then analyzed by a FC 500 Beckman Coulter cytometry. Data were analyzed using *FCS Express 2* (De Novo Software, Thornhill, Ontario, Canada).

RESULTS

CPP−PMO Conjugates. The nomenclature and characterization of the CPP−PMO conjugates are listed in Table 2 (see Table 1 for peptide and PMO sequences). HPLC and MS analyses reveal that the final product contained >84% CPP conjugated to the full-length PMO with the balance composed of conjugates with incomplete sequences of PMO and a small amount of the unconjugated full-length and incomplete PMOs. MS analysis shows that the *m*/*z* values of the major peaks match the calculated molecular weights of the desired conjugates. To assess the effect of the linker on the stability of CPP−PMO conjugates, three types of linker were used for the conjugation: thioether (maleimide), amide, and disulfide (see Figure 1 for structures).

Extraction Efficiency of CPP−PMO Conjugates. We first determined the validity of the guanidinium−HCl/CH_3CN extraction procedure in both human serum and cells. We reasoned that guanidinium moieties should inhibit binding of CPPs to proteins and other cellular components based on the observation that guanidinium−HCl (1 M) effectively eluted >95% CPP−PMO conjugates from a CM−sepharose strong cation exchange column. The extraction efficiency was only 5% if the procedure was performed without guanidinium−HCl (data not shown). PMO and CPP−PMO conjugates have excellent solubility in H_2O containing 50% CH_3CN (unpublished data), and the addition of CH_3CN precipitates most proteins and other cellular components leaving the conjugate or PMO in solution. Therefore, a high-concentration guanidinium−HCl washing step followed by a CH_3CN precipitation step was included in the procedure. Protease inhibitors were added to the guanidinium−HCl solution to preclude post-treatment protease activities.

To determine the amount of a conjugate in the extracted sample, the fluorescence of the extract was compared to the standard curve of the conjugate stock solution. The percent recovery of each conjugate was calculated from the nanomoles of recovered sample compared to the nanomoles of added sample. The carboxyfluorescein-tagged conjugates were incubated in human serum for either 2 or 24 h at 37 °C. The recoveries from serum were 50−70% for all conjugated and unconjugated (PMOF) samples except for $(RXR)_4$C−S−S−PMOF (16%) and $(RB)_8$B−PMOF (40%) (Figure 2A). The low extraction efficiency of $(RXR)_4$C−S−S−PMOF is likely due to the loss of one of the degradation products, HS−PMOF (see Table 3), since its free thiol group is very reactive toward cysteine-containing serum proteins and the reaction products (protein-PMOF conjugates) are insoluble in the extraction solution. After a similar analysis in cell lysate samples was performed, the extraction efficiencies were between 50% and 80% for all samples except for Tat−PMOF (32%), R_9F_2C−PMOF (45%), and $(RXR)_4$C−S−S−PMOF (40%) (Figure 2B).

This percent recovery is a conservative estimate, and the actual recovery should be higher because the loss in fluorescence caused by the photobleaching of the fluorescein tag and any loss in the plastic vials used for incubation and extraction were not accounted for. These losses averaged about 15% (data not

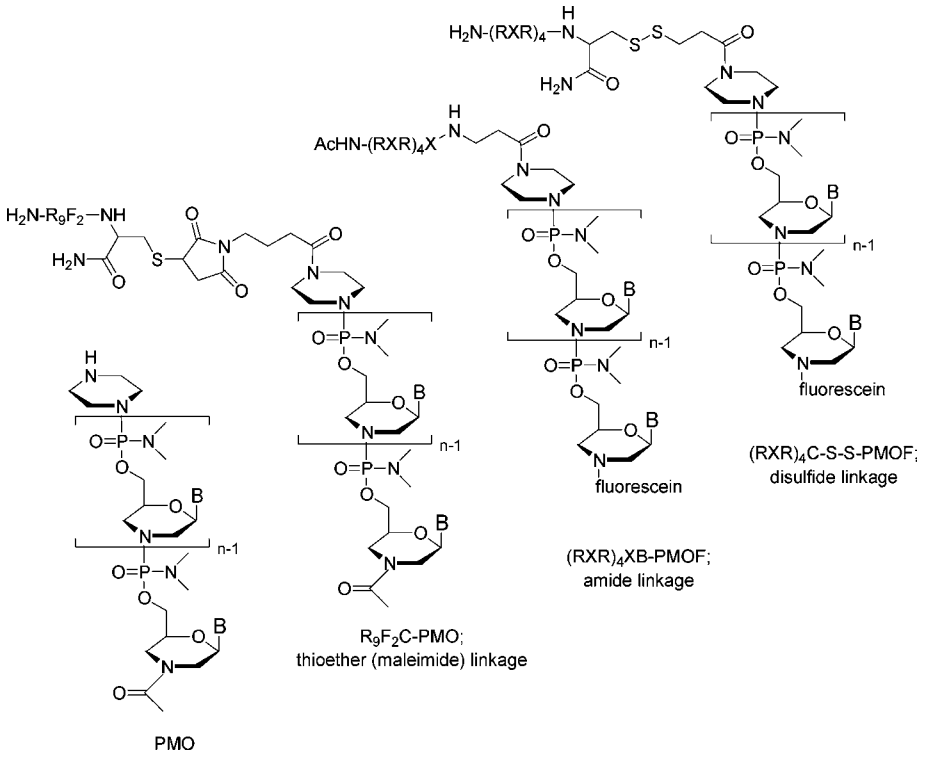

Figure 1. Structures of 3′-acetyl PMO (PMO) and CPP−PMO conjugates with maleimide (R_9F_2C−PMO), amide ($(RXR)_4$-PMOF), and disulfide ($(RXR)_4C$−S−S−PMOF) linkages.

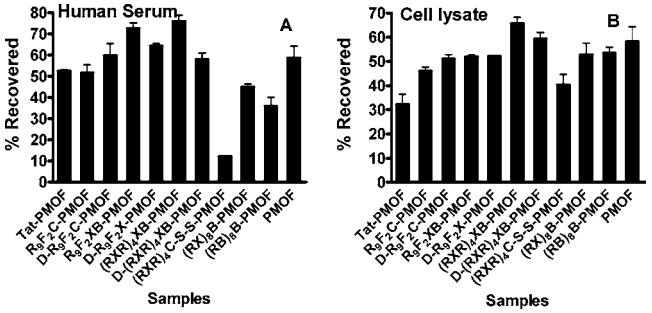

Figure 2. Extraction efficiency of the conjugates from human serum (A) and pLuc705 cells (B). (A) Human serum was spiked with 10 nmol of a CPP−PMOF conjugate and incubated at 37 °C for 24 h. (B) Cells in a T75 flask were harvested and spiked with 0.3 nmol of CPP−PMOF. The cells were lysed and the conjugate extracted. The quantity of nanomoles recovered was calculated from the fluorescence of the extract of a sample (background-subtracted) and the standard curve of the sample. The quantity of nanomoles recovered was normalized to the nanomoles added, and the data are presented as the percent recovery: mean ± SD from triplicate samples of two independent experiments ($n = 6$).

shown) and were determined by spiking the conjugates into equivalent volumes of water and then processing using the same recovery procedure as that for the treatment samples.

Effects of MALDI-TOF MS Matrices on Analysis. The MALDI-TOF MS matrix solution plays a key role in the efficiency of crystallization and ionization of particular classes of compounds (*30*). High molecular weight compounds such as PMOs and conjugates are usually analyzed using sinapic acid (SA) matrix, while lower molecular weight compounds are often analyzed in 2,4,6-trihydroxyphenone monohydrate (THAP) and α-cyano-4-hydroxycinnamic acid (CHCA) matrices, the latter especially being used for peptides and proteins. It is also known that mass discrimination effects can occur due to different rates of crystallization and/or ionization with mixtures of components (*31*). Since the possibility exists for free peptide, free PMO, and conjugate to be present in a sample, all three matrices were employed in this study to optimize identification.

Cell lysate extract was co-spiked with PMOF and either R_9F_2C−PMOF, $(RXR)_4$XB−PMOF, or $(RX)_8$B−PMOF at PMOF/CPP−PMOF molar ratios of 1:1, 1:0.75, 1:0.5, and 1:0.25. Examples of the MS spectra of a mixture of PMOF and $(RXR)_4$XB−PMOF are shown in Figure 3. The PMO peak (*m*/*z* of 6345) is clearly observed using SA and THAP matrices but is less intense using a CHCA matrix due to its poor ionization in this matrix. All conjugate peaks (*m*/*z* of 8275) were clearly observed in all three matrices with the peptide portion of the conjugate allowing good ionization in CHCA. The intensity of the conjugate peak decreases with a corresponding decrease in conjugate concentration, but at a concentration at $^1/_4$ of the PMOF concentration, the conjugate is still identifiable in all three matrices (Figure 3B).

Stability of CPP−PMO Conjugates in Human Serum. Effects of CPP sequences, amino acid configurations, and linker types on the stability of CPP−PMO conjugates in human serum were determined by MALDI-TOF MS. We studied several different CPP sequences composed of α-amino acids (L- or D-configurations), β-amino acids (β-alanine, B), and/or ϵ-amino acids (6-aminohexanoic acid, X) that were linked to the PMO by a thioether (maleimide), an amide, or a disulfide linkage (Figure 1).

The PMO portion of the conjugates was completely stable in human serum, consistent with a published report (*32*). The stability of the CPP portion of the conjugates depends on the sequences and amino acid configurations of the CPPs (Table 3). As expected, the CPPs composed of all D-amino acids, D-R_9F_2C and D-R_9F_2X, were stable even with 24 h serum treatment. This was also true of the CPPs composed of L-arginines (Arg) with the RX or RB repeats, $(RX)_8$B and $(RB)_8$B, and the one composed of D-Arg and X residues, D-$(RXR)_4$XB. However, replacement of D-Arg with L-Arg decreased the latter peptide's stability; $(RXR)_4$XB was stable to 2 h treatment but was partially degraded after 24 h treatment. The degradation products have *m*/*z* values corresponding to $(RXR)_3$-, $(RXR)_2$-, and RXR−PMOF conjugates, indicating the protease cleavage sites occur between each adjacent arginine

[a]After 2 and 24 h incubations, the samples were analyzed by MALDI-TOF MS, and the identities of the observed *m/z* peaks were determined. D = detected; ND = not detected. Two independent experiments were performed on duplicate samples for each conjugate ($n = 4$), and observed products were found in all replicates of each experiment.

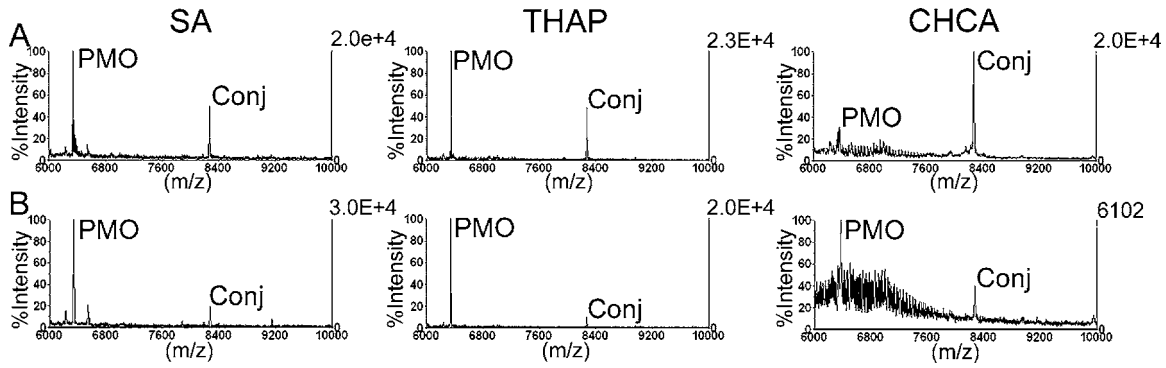

Figure 3. Matrix effect on identification of a mixture of PMO and the $(RXR)_4$XB−PMOF conjugate (Conj). pLuc705 cells were grown in the same manner outlined for the internalization study. (A) 20 μL of cell lysate extract was co-spiked with 0.3 nmol PMOF (*m/z* = 6345) and 0.25 nmol $(RXR)_4$XB−PMOF (*m/z* = 8275). (B) 20 μL of cell lysate extract was co-spiked with 0.3 nmol PMOF and 0.075 nmol $(RXR)_4$XB−PMOF. The samples were analyzed by MALDI-TOF MS in SA, THAP, and CHCA matrices. The spectra above display *m/z* corresponding to the calculated molecular weights of these compounds.

(Figure 4). The CPP−PMOF with Tat, R_9F_2C, and R_9F_2XB sequences were the least stable. Tat−PMOF was mostly degraded to C−PMOF within 2 h with no partially degraded products observed. Degradation products of R_9F_2C−PMOF were seen within the 2 h treatment and identified as R_2F_2C-, RF_2C-, and F_2C−PMOF, and the intact CPP conjugate peak had completely disappeared after the 24 h treatment. These results indicate that incorporation of non-α-amino acids into a CPP sequence can increase its serum stability. However, the degree of stability is affected by the positions of the non-α-amino acids.

Three types of linkages, thioether, disulfide, and amide, were assayed for their stability in the serum. Both thioether (used in R_9F_2C−PMOF) and amide linkages (used in R_9F_2XB−PMOF and $(RXR)_4$XB−PMOF) reveal no evidence of breakage. However, the unhindered disulfide linkage (used in $(RXR)_4$C−S−S−PMOF) was not stable as shown by appearance of the *m/z* peak corresponding to HS−PMOF, the degradation product produced by removal of the $(RXR)_4$C−SH portion from the $(RXR)_4$C−S−S−PMOF conjugate.

Intracellular Stability of CPP−PMO Conjugates. The above conjugates were studied for their intracellular stability. In order to ensure that only internalized conjugates were analyzed, a proteolysis treatment followed by a wash step prior to the cell lysis procedure was used to eliminate cell-bound material (*33*). In addition to using protease inhibitors in the lysis solution to eliminate the possibility of post-treatment degradation, a parallel "post-treatment degradation control" sample was constructed for each conjugate.

The post-treatment degradation control samples were from cells undergoing exactly the same procedure as the treatment samples, except the conjugate was not added to the treatment flask. Instead, the conjugate was spiked into the cells collected in a tube following the trypsin treatment step and prior to the lysis, extraction, and precipitation procedure. The amount of a conjugate spiked into control cells was based on the amount that was internalized in the treatment sample (about 0.3 nmol) as determined by measuring the background-subtracted fluorescence of cells treated with the CPP−PMOF. The MS spectra of the control samples for all conjugates show only peaks corresponding to intact conjugates, demonstrating that the conjugates were not degraded by the post-treatment procedure. An example set of MS spectra is shown in Figure 5A for

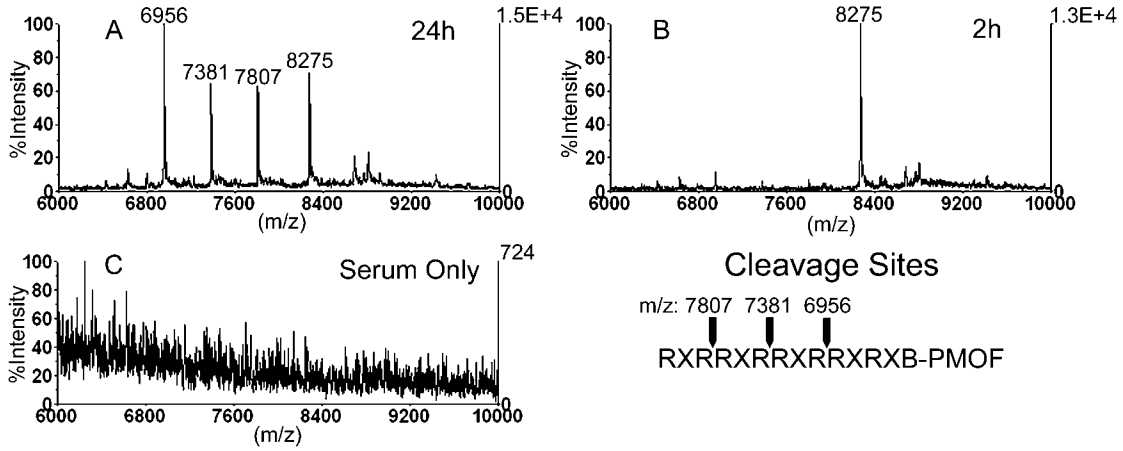

Figure 4. The stability of $(RXR)_4XB-PMOF$ in human serum. The human serum samples were treated with the conjugate for 24 h (A), 2 h (B), and without the conjugate (C) at 37 °C. The extracted materials were analyzed by MALDI-TOF MS. The spectra of the samples using the THAP matrix are shown here. The cleavage sites of the conjugate corresponding to 2 h treatment are indicated by the arrows.

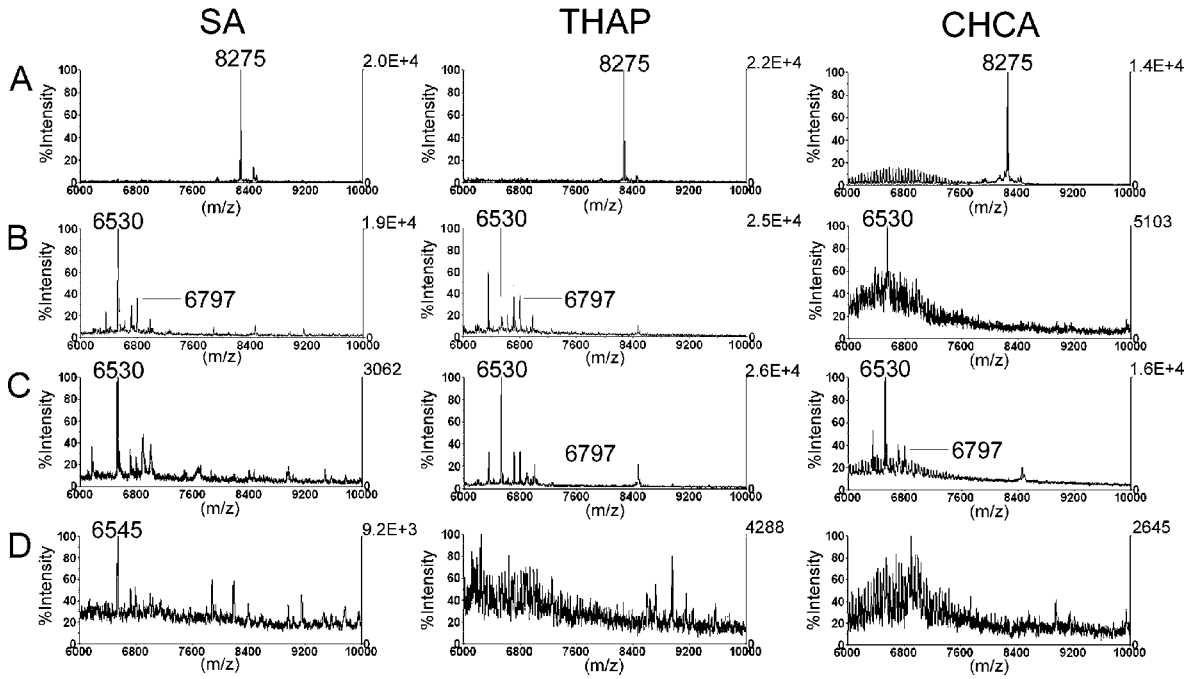

Figure 5. Mass spectra of cells treated with $(RXR)_4XB-PMOF$. (A) pLuc705 cells were harvested then spiked with 0.3 nmol of the conjugate, immediately followed by the lysis/extraction procedure (post-treatment degradation control). (B) pLuc705 cells were treated with 10 μM of the conjugate for 24 h, harvested, lysed, and extracted. (C) An extract of the wild-type HeLa cells treated with 10 μM of the conjugate for 24 h. (D) An extract of pLuc705 cells treated with vehicle control H_2O without a conjugate (background control). All extracted materials were subjected to MALDI-TOF MS analysis in SA, THAP, and CHCA matrices.

$(RXR)_4XB-PMOF$. The result indicates that the post-treatment procedure is a valid method for extraction and analysis of internalized conjugates.

All samples were analyzed using all three MS matrices. The results for internalized conjugates after 24 h of treatment are summarized in Table 4, and the corresponding MS spectra are shown in Figures 5 and 6. The mass spectra of internalized $(RXR)_4XB-PMOF$ analyzed in three matrices are shown in Figure 5B,C for pLuc705 and wild-type HeLa cells, respectively. Figure 5D shows spectra of the "background control" lysate extract. Figure 6 shows spectra of internalized R_9F_2C, $(RX)_8B$, $(RB)_8B$, D-$(RXR)_4XB$, and Tat conjugates.

The MALDI-TOF MS analysis of the PMO portion of all CPP–PMO conjugates reveals no observable peaks corresponding to the degraded PMO. To our knowledge, this is the first study that shows PMOs are totally stable intracellularly. The CPP portion of the conjugates with D-amino acids, D-R_9F_2C, D-R_9F_2X, and D-$(RXR)_4XB$ (Table 4, Figure 6D for D-$(RXR)_4$-PMO), are also stable. Cells treated with Tat, R_9F_2C, R_9F_2X, $(RXR)_4XB$, and $(RX)_8$ conjugates produced spectra containing no identifiable intact conjugate peaks in any of the three matrices (Figure 5B,C and Figure 6). Tat–PMOF, $R_9F_2C-PMOF$, and $R_9F_2XB-PMOF$ were degraded to C–PMOF, C–PMOF, and XB–PMOF, respectively (Figure 6 and Table 4). $(RX)_8B-PMOF$ was degraded to XB–PMOF (Figure 6B). The major degradation product of $(RXR)_4XB-PMOF$ was XB–PMOF with a minor product corresponding to XRXB–PMOF (Figure 5B). The $(RB)_8B-PMOF$ spectrum contains *m*/*z* peaks corresponding to BB–PMOF and intact conjugate (Figure 6C). $(RB)_8B-PMOF$ is the only conjugate not composed of D-amino acids to contain a significant amount of identifiable intact conjugate.

Because the above studies were carried out in HeLa pLuc705 cells that are stably transfected with the pLuc705 plasmid, the pre-mRNA target for the PMO (*34*), we investigated whether the degradation event is related to the RNA targeting process.

[a]HeLa pLuc705 cells incubated in 10 μM conjugate for 24 and 1 h at 37 °C were trpsinized, washed, and lysed, and the PMO and any remaining portion of CPP were recovered. Samples were analyzed by MALDI-TOF MS, and the observed *m/z* peaks were identified. The table shows the peptide sequences and their calculated mass of the intact conjugates and the observed single-ionization *m/z* peaks of the cell-internalized recovered sample. At least two complete independent experiments were performed on duplicate samples for each conjugate ($n = 4$), and observed products were found in all replicates of each experiment. D = detected; ND = not detected; NA = not available.

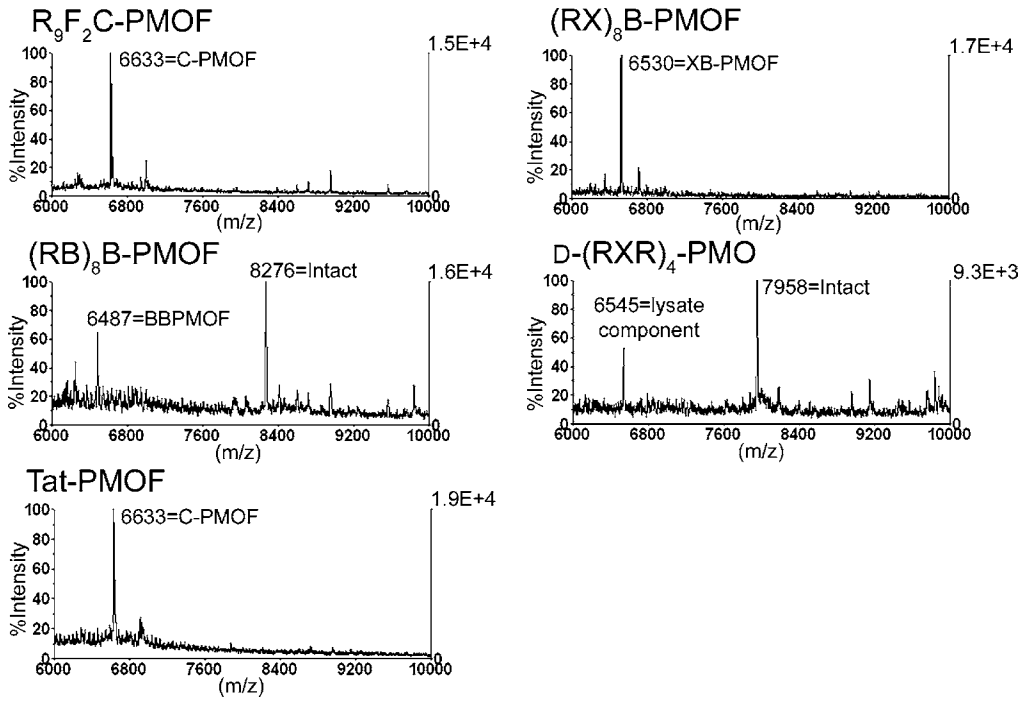

Figure 6. Intracellular stability of CPP−PMO conjugates. MALDI-TOF mass spectra of extracts of the pLuc705 cells treated with 10 μM of R_9F_2C−PMOF, $(RX)_8$B−PMOF, $(RB)_8$B−PMOF, D-$(RXR)_4$−PMO, or Tat−PMOF conjugate. The peak identifications are indicated in the graphs.

$(RXR)_4$−PMOF was incubated in wild-type HeLa cells which do not have the pLuc705 plasmid. The spectra from the wild-type HeLa cells treated with $(RXR)_4$−PMOF displayed the same *m/z* peaks as those from the HeLa pLuc705 cells (Figure 5C), indicating that conjugate degradation is not related to the RNA targeting process.

The intracellular stabilities of $(RXR)_4$XB−PMOF and $(RX)_8$B−PMOF conjugates were also studied for shorter treatment times, treating pLuc705 cells with the conjugates for 1 and 5 h. For both conjugates at both time points, the major observed *m/z* peak corresponds to degradation product XB−PMOF with a minor peak for XRXB−PMOF (Table 4). These peaks were clearly identifiable in the SA matrix for both time points, while they are less intense in the THAP matrix for the 1 h time point and not identifiable in the CHCA matrix (data not shown), although the 24 h time point gives spectra with identifiable peaks in all three matrices (Figure 5 and Figure 6). This is likely due to higher concentrations of the materials recovered, since the uptake of the conjugate is a time-dependent process (*22*). In any case, the degraded peaks are identifiable in all three time points for both conjugates, and the peaks corresponding to the intact conjugates were not observed. This indicates that degradation is a fairly quick process.

Cellular Uptakes and Antisense Activities of $(RX)_8$−PMOF and the Degraded Fragments. To understand whether the CPP degradation affects the activity of a CPP−PMO, we determined the cellular uptakes and antisense activities of the $(RX)_8$−PMOF conjugate and its fragments, XRXB−PMOF and XB−PMOF. The compounds were delivered with or without mechanically scraping cells (*35*). After the cells were treated

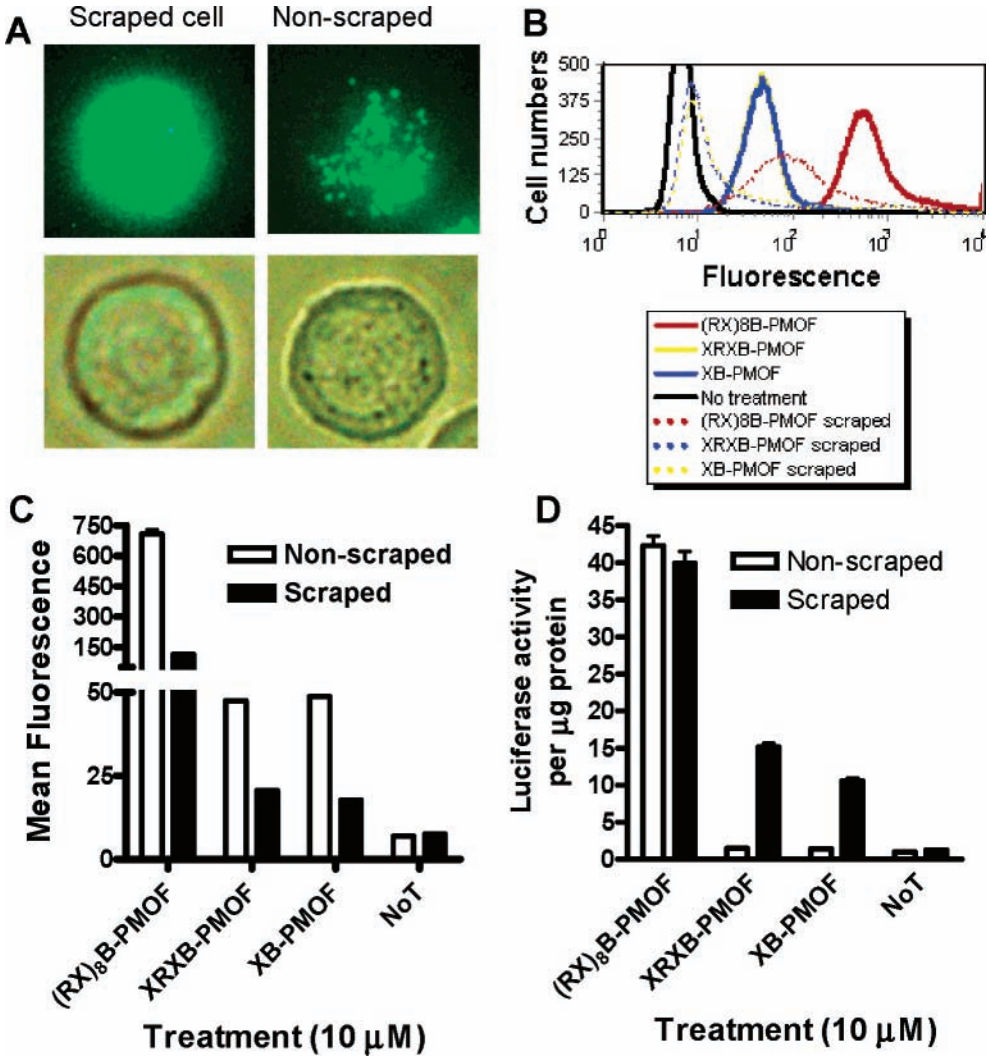

Figure 7. Cellular uptakes and antisense activities of $(RX)_8$−PMOF and the degraded fragments. Nonscraped treatment: 10 μM of the full-length conjugate or fragments in the cultural medium were added to the HeLa pLuc705 cells. Scraped treatment: 10 μM of the full-length conjugate or fragments in the cultural medium were added to cells and immediately followed by scraping, washing, and plating cells. Cells that had undergone both treatments were incubated for 24 h, washed, trypsinized, washed, and divided for the following assays. (A) Fluorescent and light images (400×) of scraped (left panel) and nonscraped (right panel) live cells treated with $(RX)_8$B−PMOF. (B) Flow cytometry histograms of scraped (dot lines) and nonscraped (solid lines) cells treated with $(RX)_8$−PMOF (red) and the fragments XRXB−PMOF (yellow) and XB−PMOF (blue). 20 000 events were collected for each histogram, and the data were presented without gating. (C) The bar graph of the mean fluorescence of scraped (black) and nonscraped (empty) cells. Each bar represents an average of fluorescence ± SEM from triplicate samples. (D) Luciferase activities of scraped (black bars) and nonscraped (empty bars) treated with the conjugate and fragments. Each bar represents an average of fluorescence ± SEM from triplicate samples.

with a compound for 24 h, the cells from each well were harvested for the determination of cell viability, cellular uptake by fluorescent microscopy, and flow cytometry as well as the antisense activity.

The harvested cells had 97−99% viable cells for all treatments as determined by a trypan blue exclusion assay. Fluorescent microscopy revealed that the scraped cells treated with $(RX)_8$−PMOF exhibited diffused fluorescence throughout the cells, while the nonscraped cells had generally brighter but punctate fluorescence as seen in the image in Figure 7A. This indicates that the majority of the compound was sequestered within vesicles and/or cellular compartments other than the cytosol and nucleus. Flow cytometry showed that nonscraped cells had higher amounts of the internalized conjugate and fragments than the scraped cells. Figure 7B and 7C show fluorescence histograms and the corresponding bar graphs of the treated cells. The nonscraped cells treated with the full-length conjugate had the highest fluorescence with mean fluorescence (MF) of 709, while the scraped cells treated with the conjugates had a much lower fluorescence (MF of 104), more than 6-fold lower. Similar trends were observed for the two fragment treatments with nonscraped cells having higher MF than scraped cells. The antisense activity was determined by the splice correction assay developed by R. Kole's group (*34*). The conjugate-treated scraped and nonscraped cells had a similar luciferase activity at approximately 40-fold over the background. The fragment-treated scraped cells produced the activity at 11−15-fold above the background, while the fragment-treated nonscraped cells had no activity (Figure 7D).

DISCUSSION

Although CPP-based delivery of therapeutic AOs is a promising technology, its effectiveness is hampered by entrapment of CPP−AO conjugates in endosomal and lysosomal compartments, as shown for the Tat− and oligoarginine−AO conjugates (*21*−*23*). Various approaches have been undertaken to induce endosomal release of CPP−AO conjugates, including the use of chloroquine (*23*), calcium ions (*36*), and a photochemical method (*37*). These approaches are not easy to use in vivo. An alternative approach is to design more effective CPPs.

We have shown that a $(RXR)_4$−PMO conjugate could escape from these compartments more effectively than the corresponding Tat− and R_9F_2−PMO conjugates (*22*). The stabilities of these conjugates in circulation and in cells are largely unknown.

SAR studies addressing enzymatic stability may assist in designing CPPs that are stable in blood, are inexpensive to manufacture, and can effectively escape from endosomes/lysosomes. As a first step in the use of SAR studies to search for more effective CPPs, we investigated several structural features of CPPs that may affect the metabolic stabilities of CPP conjugated to a therapeutically relevant AO analog (PMO): (i) amino acid configurations (L vs D), (ii) non-α-amino acids, (iii) sequences, and (iv) linker types. MALDI-TOF MS was used to analyze the samples due to its sensitivity, its tolerance to salts and impurities, and its quick analysis time.

We undertook several steps to ensure that the data from these studies are valid. First, we determined that the sample extraction/preparation procedure is adequate for MALDI-TOF MS analysis. The extraction/preparation procedure generally recovered 65−85% of PMO after taking into account the losses in vials and fluorescence photobleaching. We also controlled for any procedure-related degradation and showed that the procedure causes no detectable post-treatment degradation. We then determined the matrix effects and the relative sensitivity of MALDI-TOF MS analysis of the PMO and the conjugates in these matrices with cotitration experiments. Finally, all samples were analyzed in three matrices to take into account any mass discrimination or crystallization effects. The interpretations of MS data were based on the peak identifications from the spectra of all three matrices.

In human serum, the PMO portion of the CPP−PMO conjugates was completely stable while the CPP portions and the linkage varied. The stability of the CPP portion was ranked in the order of D-CPPs = $(RX)_8B$ = $(RB)_8B$ > $(RXR)_4$ > R_9F_2 = Tat. D-CPP conjugates were completely stable, while the L-CPP conjugates may not be, in agreement with the report of D-pVEC analogs (*38*). The utility of a D-CPP as a drug carrier may be limited by the cost of D-amino acids. CPPs consisting of non-α-amino acids interspersed with L-amino acids are an alternative for increasing blood stability with lower cost. Although insertions of *β*-alanine or 6-aminohexanoic acid into R_8 sequences increased the serum stability of R_8 (Table 3), the degree of stability was affected by the positions of these amino acids. The sequences containing no adjacent arginines, $(RX)_8B$ and $(RB)_8B$, were completely stable, while ones containing RR motifs, $(RXR)_4$, R_9F_2, and Tat were less stable, with the cleavages occurring at the amide bonds between adjacent arginines (Figure 4).

The stability of the linkage between a CPP and a PMO was ranked in the order of amide = maleimide > disulfide. No cleavage occurred at the amide or maleimide linkage, but cleavage occurred at the disulfide linkage (Tables 3 and 4). These results are consistent with other reports that an unhindered disulfide bond is not stable in blood circulation (*39*, *40*), and so it is not useful for conjugating therapeutic AOs.

In HeLa cells, the stability of the PMO portion of the CPP−PMO conjugates was excellent with no degraded products observed; the stability of the CPP portion of the conjugates was ranked in the order of D-CPPs > $(RB)_8B$ > $(RX)_8B$ = $(RXR)_4$ = R_9F_2 = Tat. No degradation products were seen for D-CPP conjugates, and no intact conjugates were observed for any L-CPP conjugates made of α-amino acids. The intact conjugate was observed for the $(RB)_8B$−PMO along with a degraded fragment after 24 h treatment, indicating that *β*-alanine increased the intracellular stability of L-CPPs. The degradation of $(RX)_8B$−PMO or $(RXR)_4$−PMO in cells was relatively rapid in contrast to degradation of these conjugates in human serum. After only 1 h treatment within cells, neither full-length conjugate was observed. Cleavage between R and X residues was observed for both CPP conjugates, and this was not seen in human serum.

We hypothesize that the rapid intracellular degradation of the conjugates may be a factor that limits the effectiveness of CPPs as AO carriers. In an attempt to address this issue, the activities of $(RX)_8B$−PMOF and its degraded fragments obtained by two delivery methods, with or without mechanically scraping cells, were compared. Mechanically scraping cells produces transient holes in the cell membranes, which permits a CPP−PMO to directly enter the cytosol/nucleus (*35*), bypassing an endosomal entry route. In nonscraped cells, the conjugate and the fragments were likely taken in by an endocytosis route, as has been shown for a similar conjugate $(RXR)_4$−PMOF (*22*).

Nonscraped cells took up $(RX)_8$−PMO much more efficiently than the scraped cells, as indicated by their >6-fold higher fluorescence (Figure 7C). However, the luciferase activities, an indicator for the antisense activity of PMO in nucleus, of the two treatments were similar (Figure 7D). In addition, the fluorescence signal of nonscraped cells was punctate compared to the diffuse signal of scraped cells (Figure 7A). These results indicate that a large fraction of internalized conjugate in the nonscraped cells was trapped within the vesicles and was not available for the pre-mRNA target in the nuclei. The cell extracts analyzed by mass spectrometry contained no full-length conjugate (Table 4), indicating that the observed fluorescent signal corresponded, at least largely, to the degraded fragments.

To address whether the observed fragments, with a major portion of the CPP degraded, can escape from endosomal/lysosomal compartments, we synthesized the fragments of $(RX)_8$−PMOF and compared their activities in nonscraped and scraped cells. The nonscraped cells treated with either of the two fragments had no luciferase activity despite their 7-fold higher fluorescence over the background. In contrast, the scraped cells treated with the fragments had luciferase activity at 11−15-fold over the background with only 2-fold over-background fluorescence. This indicates that, if the degradation occurs prior to escaping from vesicles, the internalized fragments in the nonscraped cells could not escape to reach the nucleus despite their higher cellular uptake. If they could escape the vesicles and reach the nucleus, the fragments would produce antisense activity as seen with the scraped cells.

Despite these results, a fraction of full-length or nearly full-length conjugate must be able to escape from the endosomes/lysosomes over time in order to explain the sequence-specific activities of CPP−PMO conjugates reported by our and other laboratories (*13*−*22*). Our extraction or analysis techniques may not be sensitive enough to detect a small amount of intact conjugate that has escaped. Alternatively, it is possible that escaped conjugates could be degraded in the cytosol or nucleus after they escaped from the vesicles.

At this point, the mechanisms of endosomal escaping of CPP-AO conjugates are not understood. Our results here suggest that the CPP stability is one of the several possible factors that affect its escaping ability. Other factors may include the structure, hydrophobicity/hydrophilicity, and charge density of CPP−AO conjugates. SAR studies are underway to further understand the relative importance of these aspects.

In summary, this study provides a method for determining the stability of CPP−AO conjugates in human serum and inside of cells. It shows that the stability of a CPP−cargo conjugate is affected by amino acid configurations of CPPs as well as the type of linkage to the cargo. Insertions of non-α-amino acids into L-CPP sequences increase their serum stability, which may increase the potential of CPPs as carriers for therapeutic drugs without using costly D-amino acids. In addition, we have found that degradation of the CPPs containing 6-aminohexanoic acid

was a faster process than for the CPP containing β-alanine. The degraded fragments did not escape effectively from the endosomes/lysosomes, and the majority of conjugates internalized were not available for the target. The instability of a CPP likely contributes to the endosomal trapping. Last, the study shows that PMO is completely stable both in cells and in human serum.

ACKNOWLEDGMENT

We would like to thank Dr. Jon D. Moulton for the critical reading of the manuscript. We are grateful to the chemistry team at AVI BioPharma for the synthesis, purification, and analysis of peptides and PMO.

The covalent conjugation of a functionalized poly(ethylene glycol) (PEG) to multiple nucleophilic amine residues results in a heterogeneous mixture of PEG positional isomers. Their physicochemical, biological, and pharmaceutical properties vary with the site of conjugation of PEG. Yields are low because of inefficient conjugation chemistry and production costs high because of complex purification procedures. Our solution to these fundamental problems in PEGylating proteins has been to exploit the latent conjugation selectivity of the two sulfur atoms that are derived from the ubiquitous disulfide bonds of proteins. This approach to PEGylation involves two steps: (1) disulfide reduction to release the two cysteine thiols and (2) re-forming the disulfide by bis-alkylation via a three-carbon bridge to which PEG was covalently attached. During this process, irreversible denaturation of the protein did not occur. Mechanistically, the conjugation is conducted by a sequential, interactive bis-alkylation using α,β-unsaturated β′-monosulfone functionalized PEG reagents. The combination of (a) maintaining the protein's tertiary structure after disulfide reduction, (b) the mechanism for bis-thiol selectivity of the PEG reagent, and (c) the steric shielding of PEG ensure that only one PEG molecule is conjugated at each disulfide bond. PEG was site-specifically conjugated via a three-carbon bridge to 2 equiv of the tripeptide glutathione, the cyclic peptide hormone somatostatin, the tetrameric protein L-asparaginase, and to the disulfides in interferon α-2b (IFN). SDS-PAGE, mass spectral, and NMR analyses were used to confirm conjugation, thiol selectivity, and connectivity. The biological activity of the L-asparaginase did not change after the attachment of four PEG molecules. In the case of IFN, a small reduction in biological activity was seen with the single-bridged IFN (without PEG attached). A significantly larger reduction in biological activity was seen with the three-carbon disulfide single-bridged PEG-IFNs and with the double-bridged IFN (without PEG attached). The reduction of the PEG-IFN's in vitro biological activity was a consequence of the steric shielding caused by PEG, and it was comparable to that seen with all other forms of PEG-IFNs reported. However, when a three-carbon bridge was used to attach PEG, our PEG-IFN's biological activity was found to be independent of the length of the PEG. This property has not previously been described for PEG-IFNs. Our studies therefore suggest that peptides, proteins, enzymes, and antibody fragments can be site-specifically PEGylated across a native disulfide bond using three-carbon bridges without destroying their tertiary structure or abolishing their biological activity. The stoichiometric efficiency of this approach also enables recycling of any unreacted protein. It therefore offers the potential to make PEGylated biopharmaceuticals as cost-effective medicines for global use.

INTRODUCTION

Covalent conjugates of poly(ethylene glycol) (PEG) with amino residues of native proteins are typically mixtures of positional isomers (*1*−*5*). The relative amount of each PEG−protein isomer depends upon the PEG's terminal chemical functionality, its molecular weight, its morphology, and the specific reaction conditions used for conjugation (*6*). Some amine-specific PEG reagents (e.g., active esters, carbonates, isocyanates) also have a short half-life in aqueous solution, while others are inefficient for conjugating proteins (e.g., aldehydes). Typically, a large stoichiometric excess of the PEG reagent is required. These characteristics often lead to complex purification procedures for removing the excess PEG and the unwanted protein side products.

Conjugation strategies and PEG reagents have been developed to address the important issue of site specificity (*7*−*18*). Of these, thiol-specific reagents are notable because some of them can lead to efficient conjugation reactions. However, in order to utilize thiol-specific PEG reagents, it has become necessary to recombinantly engineer a new and free cysteine into the protein (*19*). This is technically demanding and expensive, and the presence of an accessible free thiol often leads to disulfide scrambling, protein misfolding, and an increased propensity for irreversible protein aggregatation during its purification.

Our approach is particularly relevant to those therapeutic proteins whose mode of action is via cell surface receptors because they often have paired disulfides but seldom have a free cysteine residue (*20*). Typically, these proteins have an even number of cysteines that pair up as disulfides (*21*−*23*). Our strategy exploits the chemical reactivity of *both* of the sulfur atoms in an accessible disulfide bond. While disulfides influence a protein's properties in subtle and complex ways (*24*), the accessible disulfides typically contribute to the stability of the protein rather than to its structure or its function (*21*). In contrast, the disulfides that are present in a protein's hydrophobic interior

Published on Web 11/29/2006

(*21*, *25*) typically contribute to the maintenance of its tight packing and its function. Although there are examples where chemical modification of a disulfide results in a major loss of tertiary structure (*26*) and biological activity (*27*−*29*), there are also examples where chemical modification, especially of accessible disulfides, does not lead to a loss of protein structure or activity (*30*, *31*).

We have found that mild reduction of an accessible native disulfide bond to liberate the cysteine thiols can be followed by PEGylation with a bis(thiol)-specific reagent. This leads to the bridging of the two cysteine thiols with PEG attached. We have recently shown that (i) a single intrachain three-carbon bridge (with and without PEG attached) can be inserted across a native disulfide bond in interferon α-2b (IFN), and (ii) a single interchain three-carbon disulfide bridge with PEG attached can be inserted into an anti-CD4 antibody fragment using PEG monosulfone. There is no disruption of the tertiary structure or the biological activity of either protein (*32*, *33*). We now report further details of the synthesis of the disulfide bridging PEGylation reagents and their use with (i) reduced glutathione, (ii) somatostatin, (iii) the multimeric protein L-asparaginase, and (iv) interferon α-2b (IFN).

EXPERIMENTAL SECTION

Materials. Reduced (GSH) and oxidized (GSSG) glutathione, somatostatin, dithiothreitol (DTT), tris(2-carboxyethyl) phosphine (TCEP-HCl), *O*-(2-aminoalkyl)-*O*′-methyl poly(ethylene glycol) 5 kDa, *E. coli*-derived L-asparaginase (L-asparagine amidohydrolase, E.C. 3.5.1.1) and the commercial PEG−L-asparaginase were from Sigma-Aldrich. The IFN is in clinical use as Shanferon (Shantha Biotechnics, India). It is manufactured using a yeast-based protein expression system, and it shows chemical and biological equivalence to the NIBSC (U.K.) international biological standard (*34*). *O*-(2-aminoethyl)-*O*′-methyl poly(ethylene glycol) (10 and 20 kDa) were purchased from NOF Corporation, Japan. Superdex 200 prep grade, Sephadex G-25 desalting (PD-10), HiTrap SP FF cation exchange, and HiTrap Q FF anion exchange columns were from GE Healthcare. All other reagents and solvents were purchased from Sigma-Aldrich and used as received.

Preparation of 4-[2,2-bis[(*p*-tolylsulfonyl)methyl]acetyl) Benzoic Acid−NHS Ester 2. Under an argon atmosphere, a stirred mixture of 4-(2,2-bis[(*p*-tolylsulfonyl)methyl]acetyl) benzoic acid **1** (2.00 g, 4.0 mmol) prepared as described (*35*, *36*), *N*-Hydroxysuccinimide (0.483 g, 4.2 mmol, NHS) and anhydrous dichloromethane (5 mL) were cooled using an ice bath. Neat 1,3-diisopropylcarbodiimide (657 μL, 4.2 mmol, DIPC) was then added dropwise. A further 60 μL of DIPC was added after 1.5 h. After 3 h, the reaction mixture was passed through a nonabsorbent cotton wool filter. The homogeneous filtrate was diluted with dichloromethane (∼30 mL), washed with water (2 × 15 mL), and dried with magnesium sulfate. Gravity filtration followed by removal of volatiles under vacuum gave the desired active NHS ester **2** as a solid product (1.89 g, 79% yield).

^{1}H NMR: ($CDCl_3$, 400 MHz) δ 2.48 (s, 6H, CH_3), 2.94 (s, 4H, CH_2CH_2), 3.56 (A2B2X, 4H, CH_2C), 4.38 (quintet, 1H, C*H*, J = 6.3 MHz), 7.37, 7.70 (AB q, SO_2Ar, 8H, J = 8.0 and 8.3 MHz, respectively), 7.76, 8.14 (AB q, CO*Ar*, 4H, J = 8.6 MHz).

^{13}C NMR: ($CDCl_3$, 400 MHz) δ 195.29, 168.92, 160.95, 145.63, 139.11, 135.29, 130.92, 130.24, 129.59, 128.73, 128.28, 55.67, 35.89, 25.70, 21.70.

MALDI-TOF-MS: m/z = 620.3070 ± 0.43 RSD $[M + H]^+$.

Preparation of PEG Bis(sulfone) 3. To anhydrous dichloromethane (4 mL) in an argon atmosphere was added 4-(2,2-bis[(*p*-tolylsulfonyl)methyl]acetyl) benzoic acid−NHS ester **2** (300 mg, 503 μmol). This solution was cooled with an ice bath, and to this was added an anhydrous dichloromethane (5 mL) solution of *O*-(2-aminoethyl)-*O*′-methyl poly(ethylene glycol) (5000 g/mol) (0.5 g, 100 μmol). The reaction solution was stirred for 48 h. Volatiles were removed under vacuum, and the crude solid PEG bis(sulfone) **3** was redissolved in acetone (15 mL) with gentle warming. The stirred solution was then cooled in an ice bath to precipitate the desired product **3**, which was isolated using a no 3 sintered glass funnel and washed with chilled acetone (∼30 mL). Drying in vacuo gave the PEG bis-(sulfone) **3** as a white solid product (0.46 g, 84% yield).

^{1}H NMR: ($CDCl_3$, 400 MHz) δ 2.49 (s, 6H, CH_3Ar), 3.38 (s, 3H, CH_3OPEG), 3.44−3.84 (m, PEG + 4H, CH_2SO_2), 4.34 C*H*CO (qn, 1H, C*H*CO), 7.36, 7.69 (AB q, SO_2Ar, 4H, J = 8.3 MHz), 7.64, 7.81 (AB q, CO*Ar*, 4H, J = 8.3 MHz).

^{13}C NMR: ($CDCl_3$, 500 MHz) δ 195.11, 166.14, 145.51, 139.43, 136.19, 135.37, 130.19, 128.63, 128.31, 127.68, 71.94, 70.57, 69.59, 59.01, 55.56, 40.01, 35.61, 21.72.

Preparation of PEG Bis(sulfone) 3 Directly from Bis-(sulfone) Carboxylic Acid 1. To a Schlenk flask containing *O*-(2-aminoethyl)-*O*′-methyl poly(ethylene glycol) (5000 g/mol, 0.5 g, 0.33 equiv, 100 μmol) was added 4-(2,2-bis[(*p*-tolylsulfonyl)methyl]acetyl) benzoic acid **1** (150 mg, 1 equiv, 300 μmol) and *N*,*N*′-dicyclohexylcarbodiimide (62 mg, 1 equiv, 300 μmol). The flask was sealed with a rubber septum and then subjected to high vacuum for 30 min through the side arm. Argon was introduced into the flask, which was then placed in an ice bath to cool the solution. Anhydrous dichloromethane (10 mL) was injected and the contents stirred to form a homogeneous solution that was allowed to warm slowly to room temperature. The reaction mixture was then stirred for 3 h and filtered through a sintered glass filter no 3 to remove insoluble dicyclohexylurea. Dichloromethane was removed from the filtrate by rotoevaporation, and the viscous crude product residue was redissolved in acetone (20 mL) with gentle warming. The flask was then placed in a dry ice bath for 5 min to precipitate the product, which was isolated by filtration (no 3 sintered glass) and dried in vacuo to afford the desired PEG bis(sulfone) **3** as a white solid product (0.4 g, 73%).

^{1}H NMR: ($CDCl_3$, 400 MHz) δ 2.49 (s, 6H, CH_3Ar), 3.38 (s, 3H, CH_3OPEG), 3.44−3.84 (m, PEG + 4H, CH_2SO_2), 4.34 C*H*CO (qn, 1H, C*H*CO), 7.36, 7.69 (AB q, SO_2Ar, 4H, J = 8.3 MHz), 7.64, 7.81 (AB q, CO*Ar*, 4H, J = 8.3 MHz).

^{13}C NMR: ($CDCl_3$, 500 MHz) δ 195.11, 166.14, 145.51, 139.43, 136.19, 135.37, 130.19, 128.63, 128.31, 127.68, 71.94, 70.57, 69.59, 59.01, 55.56, 40.01, 35.61, 21.72.

Preparation of PEG Monosulfone 4. The PEG bis(sulfone) **3** (∼5500 g/mol, 0.20 g, 36 μmol) was dissolved in 10 mL of sodium phosphate buffer, pH 7.8 (20 mg/mL), and incubated overnight at ambient temperature. The reaction solution was added to a reverse-phase (C-18) packed sintered glass funnel that had been pre-equilibrated with deionized water. Water was removed from the filter by vacuum. The column was then washed with 25% aqueous acetonitrile to remove the buffer salts and the eliminated sulfinic acid. The reaction mixture was eluted with 75% aqueous acetonitrile and the filtrate freeze-dried to obtain the PEG monosulfone **4** (which was 80% pure by ^{1}H NMR with the remainder being the starting PEG bis(sulfone) **3**) as a white solid (0.16 g, 82% yield).

^{1}H NMR: ($CDCl_3$, 400 MHz) δ 2.35 (s, 3H, CH_3Ar), 3.31 (s, 3H, CH_3OPEG), 3.39−3.76 (m, PEG), 4.28 (s, 2H, CH_2-SO_2), 5.93, 6.22 (s, 2H, CH_2═C), 7.26, 7.64 (AB q, SO_2Ar, 4H, J = 8.3 and 8.6 MHz, respectively), 7.72, 7.81 (AB q, CO*Ar*, 4H, J = 8.1 and 8.3 MHz, respectively).

Conjugation of PEG to Reduced Glutathione (GSH). A microfuge tube was charged with PEG bis(sulfone) **3** (16 mg, 2.91 μmol, 1 equiv, 5500 g/mol) and GSH (2 mg, 2.24 equiv,

6.51 μmol) followed by 900 μL of 50 mM sodium phosphate buffer, pH 7.8, containing 10 mM EDTA. The tube was gently shaken to dissolve the solids and left for 18 h at ambient temperature. To ensure complete reaction, 100 μL of 1 N NaOH was added. The solution (1 mL) was loaded onto a PD-10 desalting column pre-equilibrated with 90:10 (v/v) H_2O/D_2O and the elution (1 mL) discarded. Additions of 1 mL each of fresh 90:10 (v/v) H_2O/D_2O to the PD-10 column were made while collecting the eluting 1 mL fractions separately. Each eluted 1 mL fraction was analyzed by UV absorbance at 215 nm. Typically, the initial two fractions which did not contain the conjugate (wash volume 2 mL) were discarded. The third fraction with the maximum amount of reaction product was analyzed by ^{1}H NMR with water suppression, 2D [^{1}H,^{1}H]-TOCSY, and 2D [^{1}H,^{1}H] NOESY.

PEGylation of Somatostatin. The PEG bis(sulfone) **3** (25 mg, 4.55 μmol, 5500 g/mol**)** was incubated in 50 mM sodium phosphate buffer (1 mL), pH 7.8, for 20 h and purified by reverse-phase (C-18) HPLC using a gradient of 30−60% acetonitrile in 30 min at a flow rate of 1 mL/min with UV detection at 215 nm. The collected fraction was subjected to freeze-drying to obtain the PEG monosulfone **4** (0.7 mg). Somatostatin (0.25 mg/mL in 50 mM sodium phosphate buffer, 0.15 μmol, pH 6.2) was disulfide-reduced with 1 equiv of TCEP-HCl (*37*) for 1 h at ambient temperature. PEG monosulfone **4** (0.7 mg, 0.13 μmol, 0.86 equiv) was added to the reduced peptide. The reaction solution was gently mixed and left overnight at 4 °C. The solution was then loaded onto a PD-10 desalting column pre-equilibrated with deionized water and the elution (1 mL) discarded. Additions of 1 mL each of fresh deionized water were made to the PD-10 column while collecting the eluting 1 mL fractions separately. Each eluted 1 mL fraction was analyzed by UV absorbance at 215 nm. Typically, the initial two elution fractions, which did not contain the conjugate (wash volume 2 mL), were discarded. The third fraction, which had the maximum amount of conjugate, was analyzed by MALDI-TOF-MS. A control reaction was conducted with somatostatin that was not previously incubated with TCEP-HCl and was followed by PD-10 desalting. MALDI-TOF-MS analysis showed only the presence of the PEG reagent, indicating that the conjugation reaction had not occurred. Unreacted somatostatin was removed during the desalting step.

Preparation of a Three-Carbon Disulfide-Bridged Somatostatin. Carboxylic acid bis(sulfone) **1** (5.7 mg) was incubated in 2:3 (v/v) acetonitrile/50 mM sodium phosphate buffer, pH 8.0 (1 mL), for 24 h. The rate of formation of the corresponding monosulfone was monitored by ^{1}H NMR (data not shown), and the pH was then adjusted to 6.2 using 1 N HCl. Somatostatin (0.25 mg/mL, 1 mL) in 2:3 (v/v) acetonitrile/50 mM sodium phosphate buffer, pH 6.2, was disulfide-reduced using 2 equiv of TCEP−HCl for 1 h at ambient temperature. The solution containing ∼1.4 equiv of the monosulfone moiety was added to the reduced peptide. The reaction solution was gently shaken and left overnight at 4 °C. It was then subjected to freeze-drying to remove volatiles. The solids were resolubilized in water and filtered (0.2 μm). The filtrate was subjected to reverse-phase (C-18) HPLC using acetonitrile/water solvent system (gradient: 20−40% acetonitrile in 10 min) containing 0.05% trifluoroacetic acid (TFA) with UV detection at 215 nm. The peptide peak (retention time 8.03 min; chromatogram not shown) was collected and mass-analyzed.

PEGylation of L-Asparaginase. To a solution of L-asparaginase (0.5 mg/mL, 1 mL) in 50 mM sodium phosphate buffer, pH 7.8, containing 10 mM EDTA was added DTT (100 mM, 15.4 mg). The solution was incubated for 30 min at ambient temperature and then loaded onto a PD-10 desalting column pre-equilibrated with 50 mM sodium phosphate buffer, pH 7.8, containing 10 mM EDTA and the elution (1 mL) discarded. Fresh 2 mL buffer (wash volume) was then added to the PD-10 and the elution discarded again. More fresh 2.5 mL buffer was added while collecting the elution for PEGylation. To the reduced protein solution (∼0.19 mg/mL, 2.5 mL; yield was 96% of the starting protein concentration) was added PEG monosulfone **4** (1.3 equiv for each disulfide) as a freshly prepared 20 mg/mL solution in 50 mM sodium phosphate buffer, and the solution was allowed to react for 16 h at 4 °C (approximately 5, 10, and 20 μL PEG monosulfone solution for 5, 10, and 20 kDa PEGylation reactions, respectively). The reaction solution (2.5 mL) was buffer-exchanged to 50 mM Tris buffer, pH 8.6, using a PD-10 desalting column (giving 0.13 mg/mL, 3.5 mL; yield 91% of the starting concentration). The solution was then loaded onto a HiTrap Q FF 1 mL column aided by a peristaltic pump. The column was washed manually using a syringe with 5 mL (2 column volumes) of fresh 50 mM Tris buffer, pH 8.6. The pure conjugate eluted on washing the column with 1 M sodium chloride in 50 mM Tris buffer (2.0 mL). The conjugates were further characterized by size exclusion chromatography (SEC) using a Superdex 200 prep grade column.

PEGylation of IFN. To a solution of IFN (0.5 mg/mL, 1 mL) in 50 mM sodium phosphate buffer, pH 7.8, containing 10 mM EDTA was added DTT (100 mM, 15.4 mg). The solution after incubation for 30 min at ambient temperature was loaded onto a PD-10 desalting column pre-equilibrated with 50 mM sodium phosphate buffer, pH 7.8, containing 10 mM EDTA and the elution (1 mL) discarded. Fresh 2 mL buffer (wash volume) was then added to the PD-10 and the elution discarded again. Further fresh buffer (2.5 mL) was added while collecting the elution for PEGylation. To the reduced protein solution (∼0.19 mg/mL, 2.5 mL; yield 96% of protein remaining) was added 1 equiv of 10 kDa PEG monosulfone **4** or 10 kDa PEG bis(sulfone) **3** (13 μL of a freshly prepared 20 mg/mL solution in 50 mM sodium phosphate buffer, pH 7.8), and the solution was allowed to react for 16 h at 4 °C. Glutathione refolding solution (50 μL of 50 mM GSH/50 mM GSSG solution to yield a reaction concentration of 1 mM GSH/1 mM GSSG) (*38*) was added to the reaction mixture and allowed to incubate for 24 h at 4 °C. The reaction solution (2.5 mL) was buffer-exchanged to 20 mM sodium acetate, pH 4.0, using a PD-10 desalting column. The resulting 3.5 mL solution had a protein concentration of 0.13 mg/mL (91% of protein remaining). The solution was then loaded onto a HiTrap SP FF 1 mL column aided by a peristaltic pump. The column was washed manually using a syringe with 5 mL (2 column volumes) of fresh 20 mM sodium acetate buffer, pH 4.0. The pure conjugate eluted on washing the column with 1 M sodium chloride in 20 mM sodium acetate buffer (0.185 mg/mL, 2 mL, yield 74%). The conjugates were further isolated by size exclusion chromatography (SEC) using a Superdex 200 prep grade column, and the yields with PEG monosulfone **4** (10 kDa, 1 equiv) were as follows: three-carbon disulfide single-bridged 10 kDa PEG−IFN, 64.3%; three-carbon disulfide double-bridged 10 kDa PEG−IFN, 17.4%; IFN, 13.4%; and aggregated IFN, 4.8%. The yields with PEG bis(sulfone) **3** (10 kDa, 1 equiv) were as follows: three-carbon disulfide single-bridged 10 kDa PEG−IFN, 56.69%; three-carbon disulfide double-bridged 10 kDa PEG−IFN, 8.69%; IFN, 32.36%; and aggregated IFN, 2.25%.

Preparation of Three-Carbon Disulfide Double-Bridged IFNs. To a solution of IFN (0.2 mg/mL, 1 mL) in 50 mM sodium phosphate buffer at pH 7.8 containing 10 mM EDTA was added dithiothreitol (DTT, 100 mM, 15.4 mg). The solution after incubation for 30 min at ambient temperature was loaded onto a PD-10 desalting column pre-equilibrated with 50 mM sodium phosphate buffer, pH 7.8, containing 10 mM EDTA and the elution (1 mL) discarded. Fresh 2 mL buffer (wash

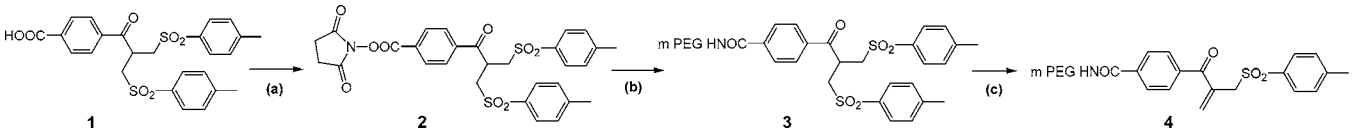
volume) was then added to the PD-10 and the elution discarded again. More fresh 2 mL buffer was added while collecting the elution for reaction. To the solution containing the reduced IFN (~75 μg/mL, 2 mL) was then added 8 equiv of the carboxylic acid bis(sulfone) **1** as a solution in acetonitrile (50 μL of 0.625 mg/mL). The mixture was gently shaken and incubated for 2 h at 4 °C. The reaction solution was made up to 2.5 mL and then buffer-exchanged to 20 mM sodium acetate, pH 4.0, using a PD-10 desalting column to obtain the three-carbon double-bridged IFN (3.5 mL, ~40 μg/mL).

MALDI-TOF-MS. Mass spectra were acquired using an Applied Biosystems Voyager System DE PRO MALDI-TOF mass spectrometer using a nitrogen laser. The matrix was a saturated solution of α-cyano-4-hydroxycinnamic acid in a 50:50 mixture of acetonitrile and water containing 0.1% trifluoroacetic acid. Sample and matrix were mixed 1:1, and 1 μL was spotted onto a 100-well sample plate. All spectra were acquired in positive mode over the range 600−2500 Da under reflectron conditions (20 kV accelerating voltage, 350 ns extraction delay time) and 2−100 kDa under linear conditions (25 kV accelerating voltage, 750 ns extraction delay time).

Tryptic Digestion and MALDI-TOF Analysis. IFN and the bridged IFN solutions (1 mL each of 0.2 mg/mL in 10 mM sodium phosphate buffer, pH 8.0) were concentrated to 200 μL using Vivaspin 6 mL concentrators (Sartorius). Sequencing grade modified trypsin (50 μL of 0.2 mg/mL, Promega) was added to each of the samples followed by incubation at 37 °C for 14 h. To each solution was added acetonitrile (30 μL), and the incubation continued at 37 °C for another 4 h. Finally, each digest was diluted with 220 μL of acetonitrile and the resulting samples analyzed using a Voyager MALDI-TOF-MS. High-resolution reflectron mode was used to observe low molecular masses. Low-resolution linear mode was used to observe high molecular masses.

NMR Spectroscopy. NMR spectra of all reactants were obtained on a Bruker Avance 400 MHz spectrometer, while the spectra of glutathione and conjugates were acquired using a Bruker Avance 500 MHz. Both instruments were equipped with a 5 mm BBO probe including *Z*-axis pulse field gradients. Assignments for the ^{1}H spectra of peptides were achieved using standard sequential assignment procedures of protein spectra (*39*). 2D [^{1}H,^{1}H]TOCSY (*40*) were acquired employing 60 ms mixing time and 2D [^{1}H,^{1}H] NOESY (*41*) employing mixing times from 100 to 300 ms. NMR spectra were processed using Bruker *NMR Suite 3.5* and Amix *Viewer 3.1.5* (Bruker Biospin GmbH). Chemical shifts were referenced to the residual solvent signals when the sample was dissolved in an organic solvent and to sodium trimethylsilyl-(2*H*4)-propionate (TSP) when it was dissolved in D_2O/H_2O.

Enzymatic Assay for L-Asparaginase. The concentration of the PEG−L-asparaginase was determined by microBCA protein assay using an L-asparaginase standard curve. The enzymatic activities of L-asparaginase, our PEGylated L-asparaginase, and the commercially available PEGylated L-asparaginase (15 μg/mL) were determined by measuring ammonia formation (i.e., hydrolysis of L-asparagine to L-aspartic acid and ammonia) after incubation with 10 mM L-asparagine in 50 mM Tris-HCl buffer (pH 8.6) for 30 min at 37 °C (*42*, *43*). The reaction was stopped by the addition of 1.5 M trichloroacetic acid and Nessler's reagent. The ammonia that was produced was determined using ammonium sulfate as a standard.



Antigenicity Assay for L-Asparaginase. The concentration of PEGylated (20 kDa) L-asparaginase was determined with a microBCA protein assay using an L-asparaginase standard curve. Enzyme immunoassay plates (96-well) were coated overnight at 4 °C with 10 μg/mL each of L-asparaginase (Sigma-Aldrich), PEG−L-asparaginase, and commercial PEG−L-asparaginase conjugate (Sigma-Aldrich) in 0.2 M carbonate coating buffer solution, pH 9.6. The plate wells were then washed four times with 0.5% v/v solution of Tween20 in PBS (PBS-T). A 0.5% BSA in PBS (200 μL) solution was added to the wells and incubated at 37 °C for 1 h. The wells were then washed with PBS-T. Rabbit anti-asparaginase polyclonal antibody (Chemicon Int., U.S.A.) (100 μL of a 1:1000 dilution) was added and incubated for 1 h at 37 °C. After washing with PBS-T, an anti-rabbit IgG−horseradish peroxidase conjugate (Sigma-Aldrich), which had been diluted 1500-fold in PBS-T, was added and incubated for 1 h at 37 °C. After washing, 100 μL of tetramethylbenzidine, 0.03% v/v hydrogen peroxide solution in 0.1 M sodium acetate buffer, pH 6.0, was added and incubated for 5 min at ambient temperature. The reaction was stopped using 100 μL of 2.5 M sulfuric acid and absorbance measured at 405 nm.

In Vitro IFN Antiviral Assay. The human lung fibroblast cell line A549 was maintained in DMEM media supplemented with 10% fetal calf serum (FCS), 50 units/mL penicillin, and 50 μg/mL streptomycin. For the antiviral assay, A549 cells were resuspended at 0.3×10^6 cells in assay media and then aliquotted at 50 μL/well into 96-well microtiter plates. Twelve hours later, 50 μL of each protein sample was prepared in assay media and added to the test wells in serial doubling dilutions. Each protein sample was tested in quadruplicate. Control wells contained either cells (negative control) or cells and virus (positive control). The plates were then incubated overnight at 37 °C. The media was then removed and the cells infected with encephalomyocarditis virus (EMCV) for 1 h after resuspending the virus in 50 μL/well of DMEM supplemented with 2% FCS, penicillin, and streptomycin. Assay media containing EMCV was then removed and 100 μL of fresh assay media added to each well. On the next day, the positive control wells were monitored until there was cell death in 80% of the wells. Each well was then washed twice with PBS and 50 μL 4% formaldehyde/0.1% methyl violet 2B solution added for 30 min. The plates were then washed twice with PBS and air-dried. The dye used was solubilized by agitation with 10% SDS (50 μL/well) and the OD measured at 570 nm.

2′,5′-Oligoadenylate Synthetase mRNA Assay. Molt-4 cells were grown in RPMI 1640 media supplemented with 10% FCS, penicillin, and streptomycin, and resuspended at 10^6 cells/mL. They were then aliquoted into a 48-well tissue culture plate at 1 mL/well. Protein samples were added in serial doubling dilutions and the plates incubated for 24 h. The cells were then washed and the mRNA (200 ng) extracted using a total mRNA extraction kit (Nucleospin RNA II, Machery-Nagel, Germany) in accordance with the manufacturer's instructions. Fifty microliters of the total RNA extract was then reverse-transcribed for 2 h to generate the cDNA. Quantitative PCR was performed on 60 ng of this cDNA for 2′,5′-oligoadenylate synthetase (2′,5′-OAS) using a RotorGene 3000 real-time PCR machine (Corbett Research, U.K.). The forward and reverse primers used were GGC TAT AAA CCT AAC CCC CAA ATC and AGC TTC CCA AGC TTC TTC TTA CAA, respectively. The PCR amplification conditions used were denaturation at 95 °C for 3 s, annealing at 59 °C for 5 s, extension of 72 °C for 8 s, and fluorescence acquisition at 83 °C for 5 s. Melting curve analysis was performed over the range 72−95 °C. mRNA quantitation was achieved by coamplifying with an in-house plasmid containing the 2′5′-OAS gene sequence.

Molecular Modeling Studies. All computational studies were carried out using integrated molecular modeling package *Maestro v6.5* (Maestro) and *Macromodel v9.1* (*44*). The OPLS-2005 force field (*45*) was used with extended cutoff values for nonbonded interactions (Van der Waals, 8 Å; electrostatic, 20

Scheme 1. Preparation of PEG Monosulfone 4[a]

[a] (a) DIPC, NHS; (b) methoxy-PEG-NH_2; (c) 50 mM sodium phosphate buffer, pH 7.8.

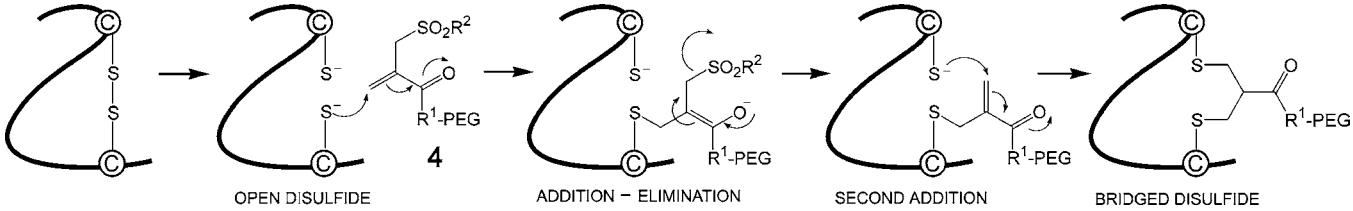


Figure 1. Site-specific PEGylation of a protein disulfide bond. The disulfide was reduced, and this was followed by reaction with a monofunctionalized PEG that was capable of sequential, interactive bis-alkylation. Mechanistically, PEGylation involves a first thiol addition to a PEG monosulfone followed by sulfinic acid elimination to generate a second double bond, which then undergoes a second thiol addition to complete the conjugation.

Å; and hydrogen bond, 4 Å). Solvent effects were considered as an aqueous generalized Born/surface area (GB/SA) solvent model (*46*). All protein and peptide models were subjected to the modified stochastic simulation protocol at 300 K used for proteins with chemically modified disulfides (*32*): 1500 steps of conjugated gradient minimization, time step of 1 ps, equilibration time of 10 ps, and 2000 ps of simulation time using the SHAKE algorithm for all bonds to hydrogen atoms. Snapshots of molecular structures were recorded at every 20 ps during simulations and energy minimized.

PEG with linker subunit was constructed as a linear chain comprising 230 monomers (10 kDa) and the simulation performed using the parameters defined above—except that molecular dynamics was used instead of stochastic dynamics. The 3D structure of the IFN was obtained as described (*33*) and imported using the *Maestro* program. Hydrogen atoms were added and the structure subjected to 1500 steps of gradient minimization using the AMBER force field and *Macromodel v8.5* (*44*). Water was defined as an aqueous generalized Born/surface area (GB/SA) solvent model to consider the solvent effect. The IFN with a three-carbon bridge across Cys1-Cys98 and across Cys29-Cys138 was built and subjected to the modified stochastic simulation protocol used for proteins with chemically modified disulfides (*32*). The initial 100 steps of conjugate gradient minimization using OPLS-2005 force field and GB/SA solvent model were used to remove clashes between added atoms and the rest of the protein. This was followed by equilibrating models at 300 K for 1 ps and stochastic simulation of 2000 ps in 1.0 fs steps at 300 K. The SHAKE algorithm was applied to bonds containing hydrogen atoms. Snapshots of the molecular structures were recorded every 2 ps during simulations and energy minimized. The modeled structure was compared to IFN α-2a by calculating the root-mean-square displacement (rmsd) values. They were determined using the McLachlan algorithm (*47*) as implemented in the program *ProFit v1.8* (*48*). The molecular model of IFN with both disulfide bonds reduced was subjected to the molecular simulation protocol, and the final snapshot structure was used to build the IFN model with a PEG attached at Cys1-Cys98 and at Cys29-Cys138. This model was subjected to the stochastic dynamics protocol after removing initial clashes between atoms.

RESULTS AND DISCUSSION

Thiol-Specific Bis-Alkylation. Our approach to protein PEGylation involves the mild reduction of a protein disulfide to free the two cysteine sulfur atoms followed by reaction with the bis-thiol-specific PEG reagent **4** (*33*). The conjugating moiety of the PEG reagent **4** (Scheme 1) is a substituted propenyl system. It contains a thiol-specific bis-alkylating group which comprises a carbonyl electron withdrawing group, an α,β-unsaturated double bond, and a β′ leaving sulfonyl group. The latter is susceptible to elimination. This juxtaposition of chemical functionality allows for a sequence of interactive and sequential addition−elimination reactions (Figure 1) that can occur at neutral or slightly acidic pH with the two free thiols that are derived from a reduced disulfide bond (*33*). Lawton et al. (*35, 36, 49, 50*) first demonstrated that this type of chemical functionality could undergo bis-thiol alkylation to cross-link proteins (e.g., ribonuclease (*49*) and antibodies (*35, 36*)). Wilbur et al. subsequently examined this functionality with antibody fragments (*51*). Other substituted propenyl systems capable of bis-alkylation with nucleophiles have also been used in organic synthesis (e.g., refs 50, 52−56 and references therein).

Our results show that appending the bis-alkylating functionality to the terminus of PEG (*33*), as shown in structure **4**, results in a water-soluble reagent that is more susceptible to an intramolecular protein thiol-specific reaction. Competitive intermolecular alkylation reactions are unlikely to occur, because the conjugation reaction occurs in aqueous conditions. This ensures that the protein's tertiary structure is maintained after the gentle reduction of a disulfide. It is also important to keep the free thiols close to each other because (a) this ensures that irreversible denaturation or aggregation of the protein does not occur during the conjugation reaction with the PEG monosulfone **4** (*33*) and (b) disulfide scrambling reactions do not occur when more than one disulfide is reduced.

The PEG monosulfone **4** is fundamentally different from the other PEGylation regents that can undergo conjugation reactions with two thiols. The dithiol reactive PEGylation reagents that have been described have two separate thiol-accepting moieties (e.g., two maleimides (*10, 57*)), which are chemically independent and which are not capable of the controlled sequential reactions of PEG monosulfone **4**. In addition, the distance between the sites for addition of the two sulfur atoms with these other reagents is much greater than the distance for our three-carbon bridge. Therefore, these reagents are unable to rebridge reduced disulfides in the way that our PEG monosulfone **4** can bridge the reduced disulfide bond.

Synthesis of PEG Conjugation Reagents. The PEG monosulfone **4** was prepared from the known carboxylic acid bis(sulfone) acid **1** (*35, 36, 50*) (Scheme 1). Coupling of methoxyamino-terminated PEG was routinely accomplished using the active ester bis(sulfone) **2** or by direct carbodiimide-mediated coupling with acid bis(sulfone) **1**. The synthesis of PEG monosulfone **4** was accomplished by incubation of the PEG bis(sulfone) **3** (25 mg/mL) in 50 mM sodium phosphate buffer

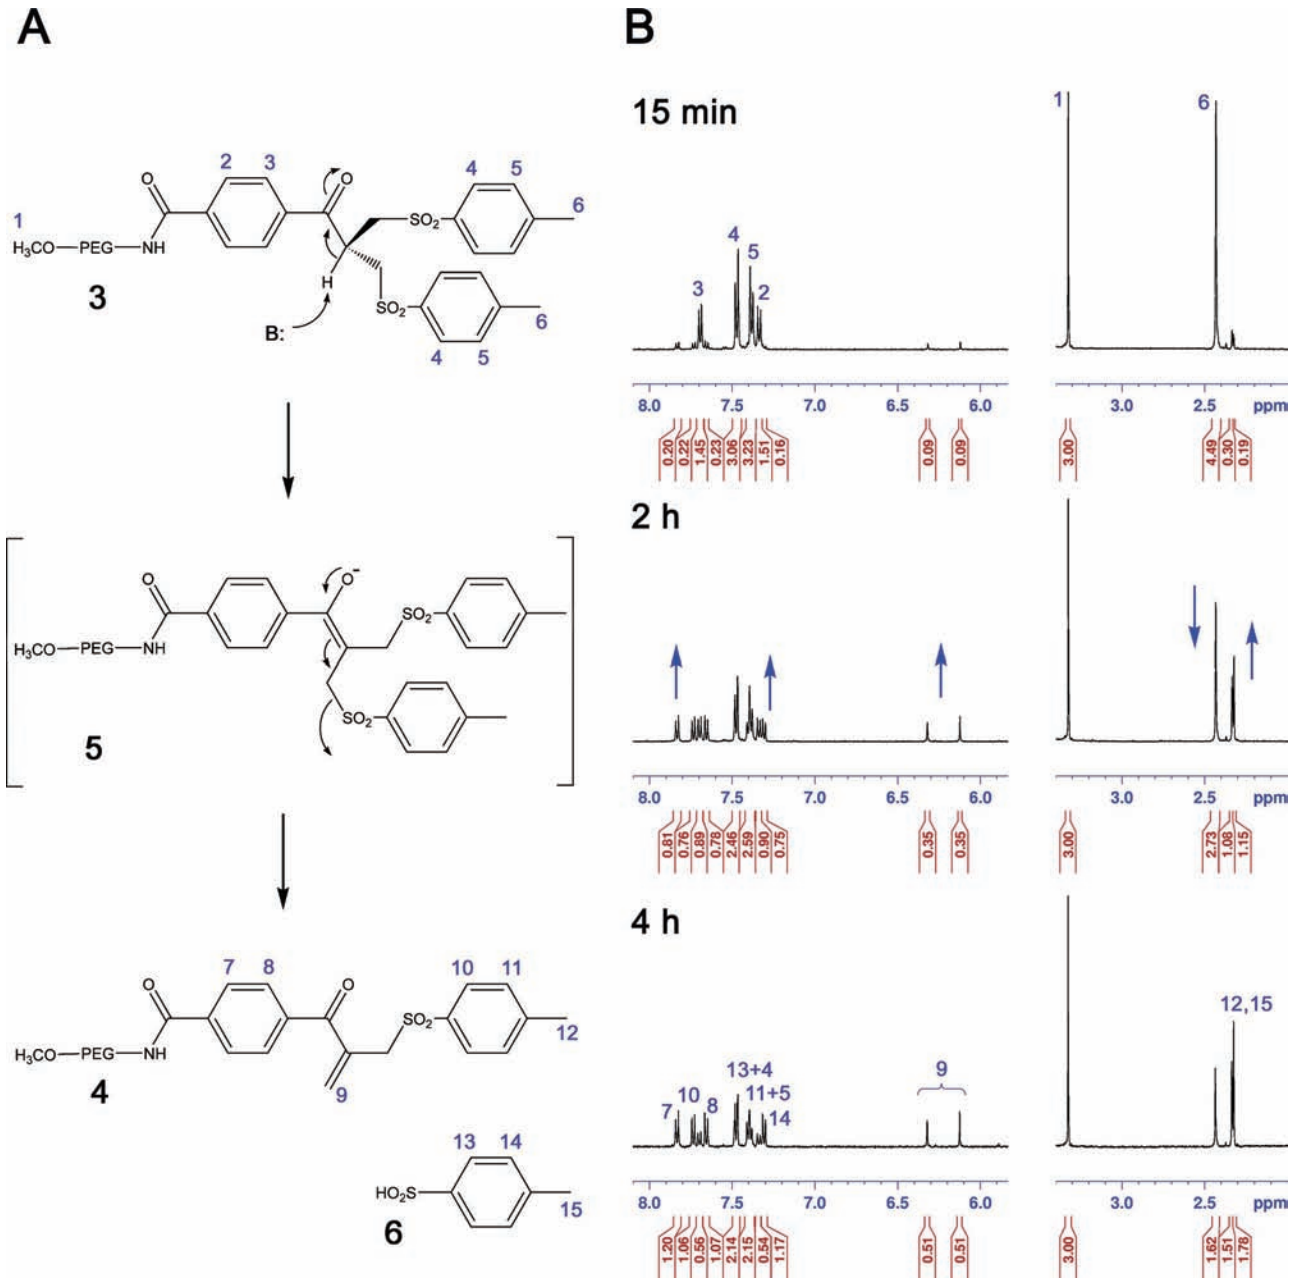

Figure 2. A. Elimination of toluene sulfinic acid **6** from PEG bis(sulfone) **3** via the enolate **5** to generate PEG monosulfone **4** is required for the first thiol addition reaction to occur. B. The elimination reaction was monitored by ^{1}H NMR in 50 mM phosphate buffer in D_2O (pH 7.2) with 51% conversion to PEG monosulfone **4** observed after 4 h as calculated by integration of the geminal vinylic protons. Typically, overnight incubation at ambient temperature was required for maximum conversion of the reagent.

(pH 7.8) and purified by RP-HPLC. PEG bis(sulfone) **3** undergoes elimination of toluene sulfinic acid **6** to give the PEG monosulfone **4** at pH values of 7.0 or higher. The elimination reaction was monitored by ^{1}H NMR (Figure 2) and reverse-phase RP-HPLC (Figure 3). The rate at which this elimination reaction occurred from the PEG bis(sulfone) **3** was dependent on pH and temperature (Figure 4). Although a decreased rate of elimination was observed at pH 6.0, this suggested that PEGylation could also be conducted at a slightly acidic pH value as was seen for somatostatin at pH 6.3 (see below).

These observations indicate that the rate to generate the double bond in the PEG monosulfone **4** can be tailored to the protein thiol's reactivity after disulfide reduction. Therefore, PEGylation was usually conducted using the PEG bis(sulfone) **3** which gave the monosulfone **4** in situ. This means that the optimized conjugation conditions can be tailored to balance the rate of the first elimination with the rate of the first thiolate addition reaction and thereby avoid the competitive conjugation of PEG to each of the thiols that are derived from a disulfide. When it is necessary to conduct PEGylation at an acidic pH value (because of issues related to protein solubility or stability, such as those described for somatostatin below), it is best to isolate and use the PEG monosulfone **4** directly in the conjugation reaction.

Bis-Thiol Selectivity of the Reagents. The tripeptide GSH was used to study the thiol reactivity and selectivity of the PEG bis(sulfone) **3** in the aqueous conditions that would typically be used for proteins. The conjugate, $PEG(SG)_2$ (Figure 5A) was derived from 2 equiv of GSH (each possessing one cysteine thiol), and it was purified by desalting column. The two glutathione molecules were conjugated to PEG via a three-carbon bridge. The conjugate structure (Figure 5A) was characterized and compared to oxidized glutathione (GSSG) by 1D and 2D ^{1}H NMR analysis. The set of 1D and 2D ^{1}H NMR spectra of GSSG was acquired and assigned using the standard procedure for proteins. The amide region of the 1D spectrum

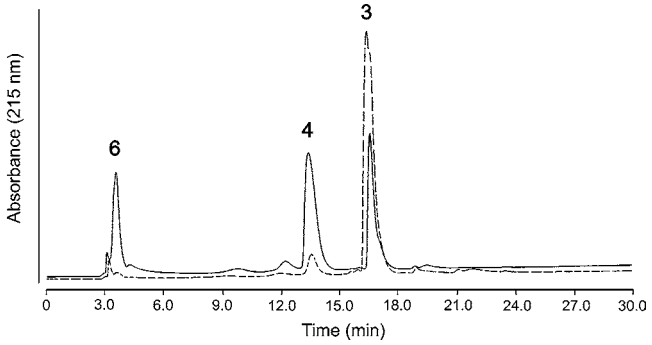

Figure 3. Reverse-phase HPLC chromatograms at $t = 15$ min (broken line) and $t = 5$ h (solid line) for the elimination of toluene sulfinic acid **6** from PEG bis(sulfone) **3** to give PEG monosulfone **4**. The elimination reaction was conducted in 50 mM phosphate buffer, pH 7.8, at ambient temperature.

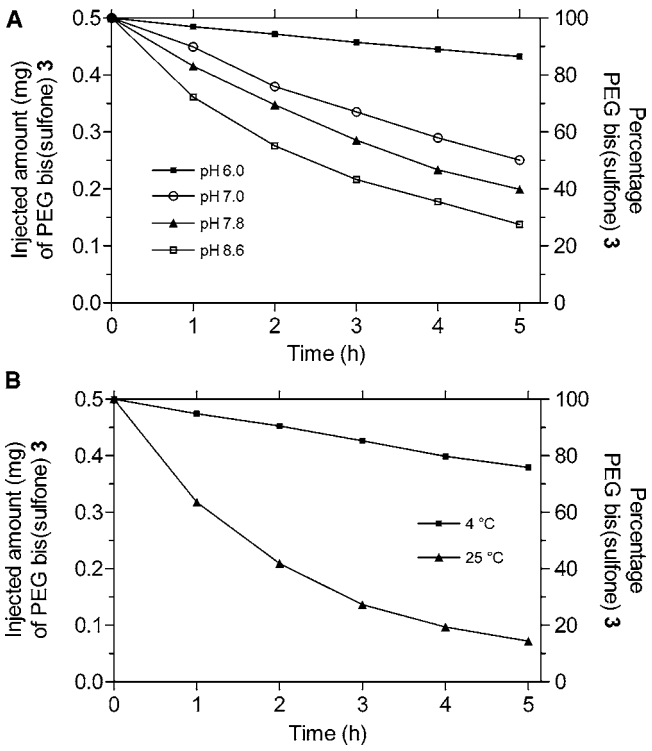

Figure 4. Effect of (**A**) pH on elimination of PEG bis-sulfone **3** (25 mg/mL) at 25 °C and (**B**) temperature on elimination of PEG bis-sulfone **3** (10 mg/mL) as monitored by reversed phase-HPLC using a C_{18} Phenomenex column (5 μm, 250 × 4.6 mm). Solvent A: acetonitrile containing 0.05% CF_3COOH (TFA), Solvent B: water containing 0.05% TFA. The gradient used was 30−60% B in 30 min with a flow rate of 1 mL/min at room temperature. UV detection was at 215 nm. The sample injection volumes for the temperature experiments were adjusted to give PEG bis(sulfone) **3** in the amount of 0.5 mg per injection.

had only two peaks: the doublet for NH of Cys and the triplet for the NH of Gly. The presence of only one set of peaks in both regions of the NMR spectra (amide and side chain) indicated that the two peptide chains of the tripeptide were connected by thiol ether bonds with a similar conformation. The two β-methylene protons of Cys are nonequivalent (2.8−3.25 ppm) in GSSG due to the restricted rotation of the disulfide bone. These methylene protons are the same in GSH where there is free rotation of the Cys side chain.

The assignment of NMR spectra for PEGylated glutathione ($PEG(SG)_2$) was achieved by observing spin system patterns in TOCSY (Figure 5B) for Cys and Gly. These corresponded to the NH doublet of Cys at 8.3 ppm and the NH triplet of Gly 8.05 ppm. The NOESY cross-peak at 8.39 and 4.45 ppm (Figure 5C) confirmed the sequential connectivity between the α-hydrogen of Cys (*) and NH of Gly. The triplet for the NH of the amide in the PEG reagent was at 8.7 ppm. This signal had a cross-peak in the TOCSY spectrum to the methylene hydrogen atoms of PEG at 3.7 ppm. This confirmed that the two GSH tripeptides and the PEG were in solution, while the 1:2 ratio for the integration of amide hydrogen atoms of the PEG reagent and the amide hydrogen atoms of the peptides was consistent with that expected for conjugation. Furthermore, the Cys β-methylene hydrogen atoms were nonequivalent, indicating the loss of free rotation seen in GSH and that the sulfur atoms were no longer in the form of free thiols. These β-hydrogen atoms from the two Cys residues are diasterotropic and without free rotation. They are therefore not magnetically equivalent, and they display slightly different chemical shifts. The possibility of conjugation on the NH_2 of the N-terminal can be ruled out, as no new peak for the hydrogen atom as a consequence of amine alkylation was observed and the keto α-proton was at ∼4.1 ppm.

The reaction of PEG bis(sulfone) **3** with reduced glutathione after overnight incubation and purification showed only the presence of the PEG−$(GS)_2$ conjugate. No unreacted PEG bis or monosulfone (**3** or **4**) was seen. If the reaction had been stopped earlier (e.g., 5 h), there was a mixture of $PEG(SG)_2$ conjugate and PEG bis(sulfone) **3**. There was no evidence of a monoglutathione adduct or of the PEG monosulfone **4**. This indicated that the second elimination−addition reaction to give a PEG alkenyl monoglutathione intermediate was thermodynamically driven and that this compound was consumed to give the final $PEG(SG)_2$ conjugate.

Mono-PEGylation of the Cyclic Peptide Somatostatin. Somatostatin is a naturally occurring cyclic peptide hormone with 14 amino acid residues (molecular mass 1637.9 Da) and a disulfide bond between Cys3 and Cys14. The disulfide reduction of somatostatin was accomplished with equimolar TCEP−HCl, pH 6.2, at ambient temperature. Reduction at higher pH values caused the peptide to precipitate out of solution. TCEP−HCl (*37*) was ideal for disulfide reduction at acidic pH values, and it could be used at stoichiometric equivalence. Once oxidized, TCEP was not nucleophilic, and it did not react with PEG monosulfone **4**; therefore, its removal (*58*) before conjugation was unnecessary.

The disulfide-bridging PEGylation of the reduced somatostatin was performed using an equimolar amount of the PEG monosulfone **4**. Further purification by simple desalting and MALDI-TOF-MS analysis indicated the presence of PEG−somatostatin (Figure 6C). To determine whether the three-carbon linker without PEG attached could be inserted, the conjugation was also performed with the carboxylic acid monosulfone, which was obtained from the carboxylic acid bis(sulfone) **1**. As removal of PEG from the reagent led to a loss of water solubility, this conjugation reaction was performed in a 2:3 (v/v) acetonitrile and 50 mM sodium phosphate buffer mixed-solvent system at pH 6.2. The three-carbon bridged somatostatin was analyzed by MALDI-TOF. The increase in mass of 190 Da confirmed the presence of 4-[2,2-bis(methylene acetyl)]-benzoic acid (Figure 6B). This suggested that the bis-alkylation reaction of the monosulfone moiety with somatostatin could occur at a slightly acidic pH. These experiments also showed that the PEG monosulfone **4** could be used for site-specific PEGylation in acidic pH conditions.

PEGylation of the Multimeric Protein L-Asparaginase. *E. coli* derived L-asparaginase is a protein (MW 133−138 kDa) that consists of four identical subunits, each of which contains 326 amino acids and a single disulfide bond between Cys77-Cys105 (*59*, *60*). L-Asparaginase must exist in its tetrameric

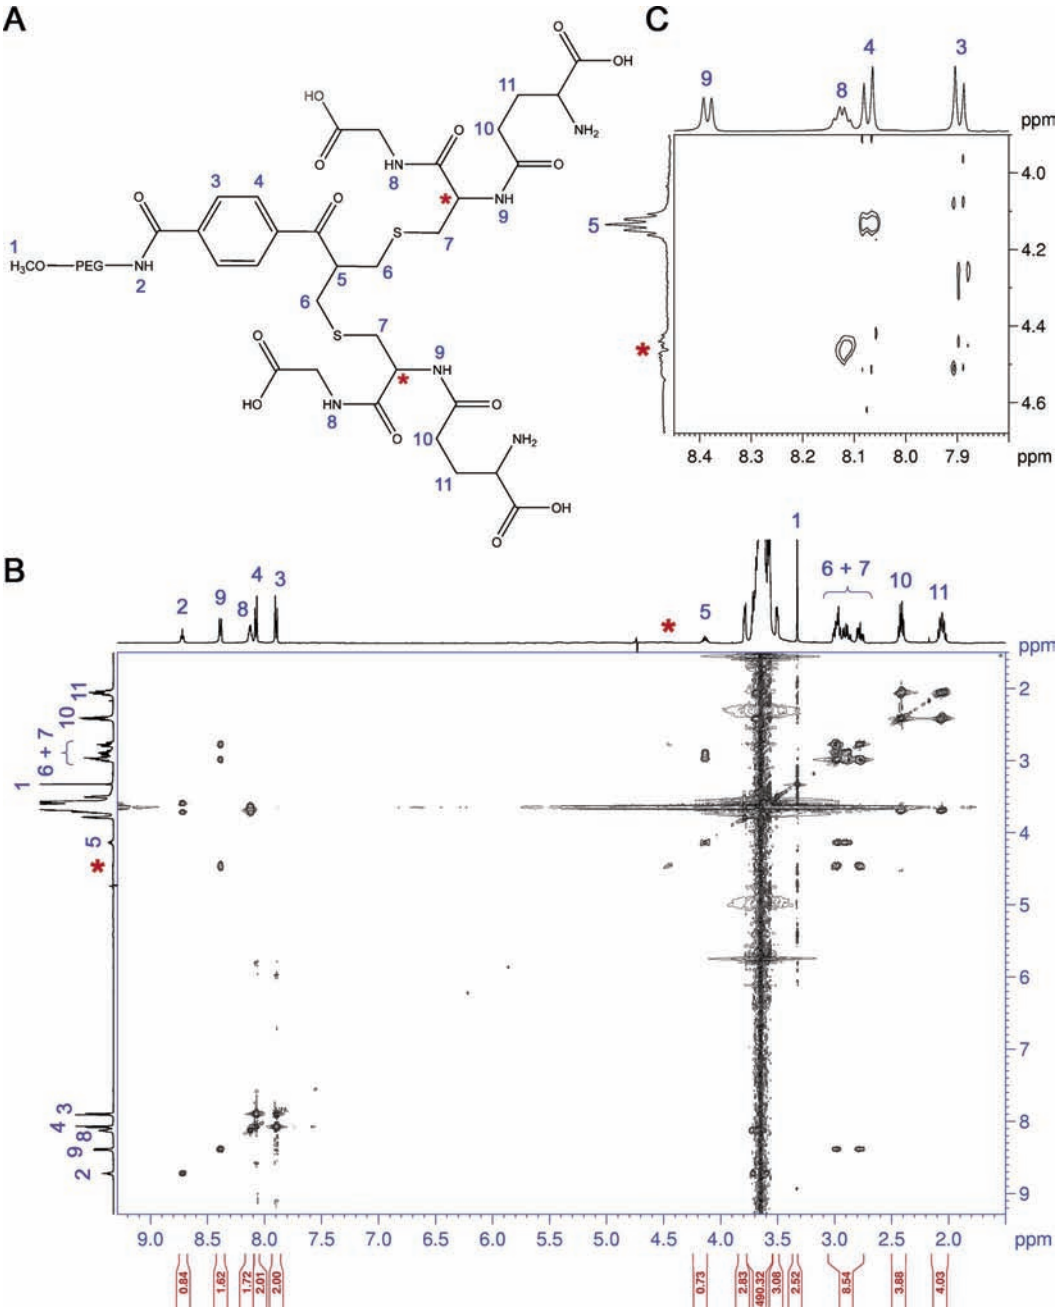

Figure 5. Thiol selectivity of PEGylation was demonstrated with reduced glutathione (GSH) to give PEG−$(SG)_2$. A. Chemical structure of PEG−$(SG)_2$; bond connectivity of the cysteine thiols was confirmed by ^{1}H-TOCSY as shown in B and ^{1}H-NOESY as shown in C.

form to display its biological activity. Structurally, the disulfide is accessible, because it lies on the outer edge of the protein and it is distant from the protein's enzymatic site (*61*). This explains why the L-asparaginase tetramer remains biologically active after reduction and carboxymethylation of its disulfides (*31*). We have PEGylated asparaginase to determine the biological effect of inserting a three-carbon bridge with PEG attached into each of the four subunits of this multimeric protein.

PEGylation of reduced L-asparaginase was examined with PEG monosulfones **4** of varying molecular weight (i.e., 5, 10, and 20 kDa as shown in Figure 7A, lanes 4, 5, and 6). The native L-asparaginase was seen at ~35 kDa on SDS-PAGE gels because of dissociation of the tetramer into the four monomers (Figure 7A, lane 2). The reduced protein displayed an apparently larger size than the unreduced protein (Figure 7A, lane 3). PEGylation only occurred if the L-asparaginase was first incubated with DTT (Figure 7A, lanes 7−9). Conjugation with 1.3 equiv of the PEG monosulfone **4** to each disulfide gave nearly quantitative conversion to the mono-PEGylated L-asparaginase monomer (Figure 7A, lanes 4−6).

Anion exchange chromatography followed by SEC−HPLC was used to purify PEG−L-asparaginase. Single peaks eluted with different retention times depending upon the size of the PEG (Figure 7B). MALDI-TOF-MS (Figure 7C,D) was used to confirm the mass of the PEG−L-asparaginase. The enzymatic activity of L-asparaginase and our PEG−L-asparaginase were similar irrespective of the size of PEG attached (Figure 8A). In an enzyme immunoassay (Figure 8B) that was based upon the use of a rabbit anti-asparaginase polyclonal antibody, the in vitro antigenicity of the PEG−L-asparaginase was similar to that of L-asparaginase. A representative, computationally calculated structure of PEG−L-asparaginase is shown in Figure 8C. These results are consistent with the site-selective conjugation of PEG to a site that is distant to the enzyme's antigenic site.

E. coli derived L-asparaginase cannot be used as a safe therapeutic drug in man, because it causes severe hypersensitiv-

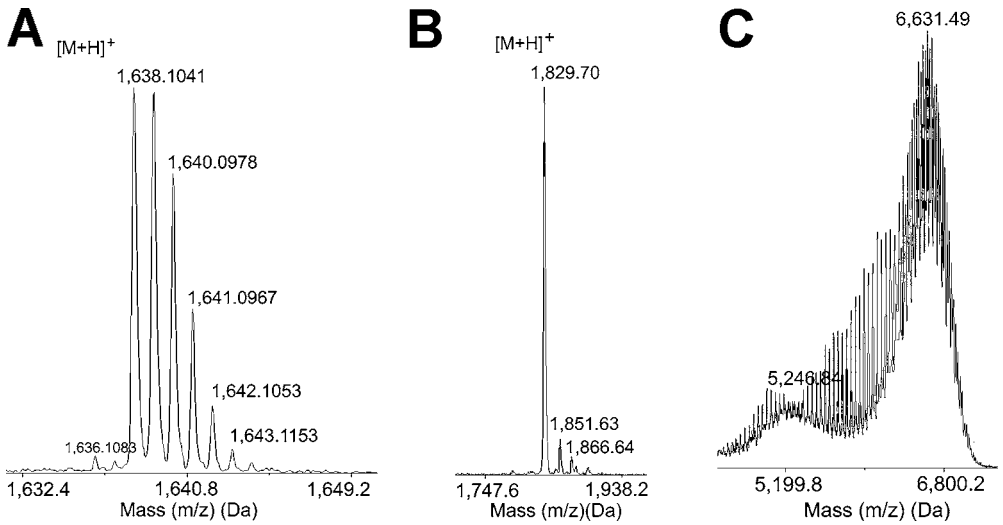

Figure 6. MALDI-TOF-MS: A. Native somatostatin showing its isotope signals. B. Three-carbon disulfide bridged somatostatin with its salt adducts. C. Reaction mixture of PEGylated somatostatin. Also seen is the unreacted PEG in the region of 5246 Da.

ity reactions. This is due to its multiple antigenic sites (*62*). PEGylation has been used to reduce this antigenicity and thereby enable its use for the treatment of acute lymphoblastic leukemia and of lymphomas (*63*, *64*). We have found that, after disulfide site-specific PEGylation, our PEGylated L-asparaginase retained its enzymatic activity and its antigenicity, irrespective of the size of PEG attached. In contrast, commercially available amine PEGylated L-asparaginase had lower enzymatic activity and was less antigenic (Figure 8B). This could be due either to the amine-based site of PEGylation of the commercially available PEG−L-asparaginase and/or to it having ∼40 molecules of 5 kDa PEGs per protein molecule. Our results show that it is possible to attach four PEG molecules to sites on a protein that are distant to its biologically active site using disulfide site-specific PEGylation without disrupting its biological activity. In this context, we have also illustrated the biological benefits of PEGylating at sites that are distant to a protein's receptor binding site by PEGylating the interchain disulfide of an antibody fragment to CD4. Both the anti-HIV-1 activity and the antigenicity of the PEGylated antibody fragment were preserved (*33*).

Three-Carbon Disulfide Single- and Double-Bridged PEGylation of IFN. We have already shown that a single native disulfide in IFN can be modified by site-specific bis-alkylation of two cysteine sulfur atoms to form a three-carbon bridged PEGylated IFN (*33*). The yield of three-carbon disulfide single-bridged PEG−IFN was high (65%). It was a mixture of the two isomers Cys1-CC[PEG]C-Cys98 and Cys29-CC[PEG]C-Cys138. The tertiary structure of IFN was retained. The stability of the three-carbon bridge was maintained under reducing conditions, at temperatures up to 90 °C, and in human serum for 24 h at 4 °C. It also had a prolonged circulation half-life in vivo of 12 h compared to 1 h for IFN.

In contrast to the multimeric L-asparaginase described above, IFN also provided an opportunity to determine the effect of introducing two PEGylated bridges into a monomeric protein. In molecular modeling studies, both disulfide bonds were replaced with three-carbon bridges linked by thioether bonds from the respective cysteines and the modified structure subjected to simulations of 2000 ps. A C-2 substituted *p*-benzoic acid acetophenone was also placed in the carbon bridge to mimic the entire linking moiety that was used for PEGylation. The conformations were recorded every 20 ps, and they resulted in a trajectory that was analyzed by calculating the rmsd values for the backbones of the starting model of IFN and for each conformation of the modified protein at the different time frames. A plot of the calculated rmsd values versus time indicated that the overall structures deviated by <4 Å from the native conformation (Figure 9A). All of the conformations were then superimposed and a ribbon plot created with the positions of the linkers at different time points shown in CPK representation (Figure 9B). These results showed that the double-bridged IFN retained its primary, secondary (i.e., helices), and tertiary structure.

The carbon bridge between Cys29-Cys138 had a lower conformational flexibility than the bridge between Cys1-Cys98 because of the restricted movements of the interhelical connecting loops. The aromatic moiety at C-2 of the carbon bridge between Cys1-Cys98 had greater freedom to move, because the N-terminal was not constrained by interactions. This resulted in greater conformational space sampling by the C-2 benzoic acid causing different interactions with the surface of the protein. These results show that the insertion of a carbon bridge that was linked by thioether bonds displayed greater conformational mobility than the native disulfide bond, and they could explain how the three-carbon bridge modified IFN was able to retain its tertiary structure.

As an example of reagent efficiency, IFN was then conjugated with 2 equiv of PEG monosulfone **4** to give the three-carbon disulfide double-bridged PEG−IFN. In order to define the structural and biological effects of the three-carbon bridges (i.e., without PEG attached) and to aid the mass-spectral analysis, a double-bridged IFN adduct was also prepared from the carboxylic acid bis(sulfone) **1**. This reaction had to be conducted in a mixed organic−aqueous solvent system to solubilize the carboxylic acid sulfone **1**. In the case of the bis(sulfone) **1**, the SDS-PAGE gel showed that the disulfide-reduced IFN had a larger apparent size, which was a consequence of the open disulfides (Figure 10A, lane 3) when compared to (a) IFN (Figure 10A, lane 2) and (b) the double-bridged IFN in which conjugation and formation of the two bridges had occurred (Figure 10A, lane 4). MALDI-TOF-MS analysis showed that the mass of the IFN had increased by 380 Da, thereby confirming the insertion of two bridges of 190 Da each (Figure 10B). Tryptic digestion of the IFN and the double-bridged IFN followed by MALDI-TOF-MS of the fragments confirmed the site-specific insertion of a carbon bridge at Cys1-Cys98 and at Cys29-Cys138 (Figure 10C,D).

Stoichiometrically efficient PEGylation reactions could be conducted with either PEG monosulfone **4** or PEG bis(sulfone) **3**. When 1 equiv of the PEG monosulfone 20 kDa **4** was used for the conjugation, a mixture of the three-carbon disulfide

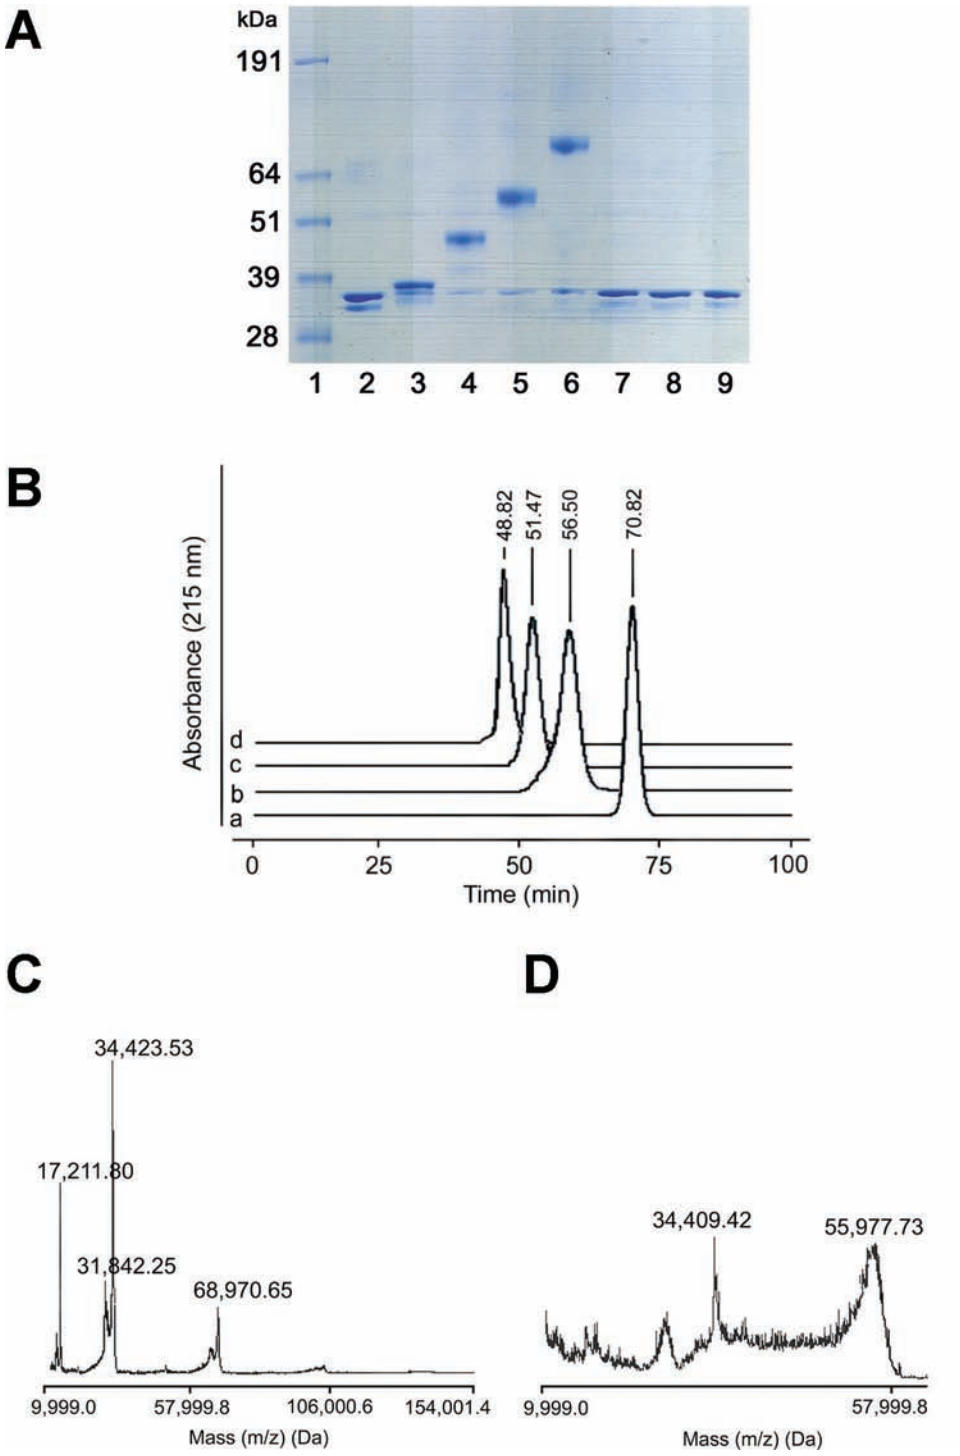

Figure 7. A. SDS-PAGE gel stained with colloidal blue to show the L-asparaginase three-carbon disulfide-bridged PEGylation reactions. Lane 1: prestained markers. Lane 2: L-asparaginase. Lane 3L disulfide-reduced L-asparaginase. Lane 4: 5 kDa PEGylation reaction. Lane 5: 10 kDa PEGylation reaction. Lane 6: 20 kDa PEGylation reaction. Lanes 7−9: control reactions with 5 kDa, 10 kDa, and 20 kDa PEG reagents **4**, respectively, in which the L-asparaginase was not reduced. Dissociation of the tetramer on SDS-PAGE resulted in monomeric L-asparaginase, and it was observed as two bands. UnPEGylated monomers of L-asparaginase (16% by densitometry) were seen in lanes 4−6. B. Size exclusion chromatography of L-asparaginase and the three-carbon disulfide-bridged PEG−L-asparaginase on a Superdex 200 prep grade column. The protein elutes in a tetrameric form: (a) L-asparaginase at 70.57 min; (b) 5 kDa PEG−L-asparaginase at 56.50 min; (c) 10 kDa PEG−L-asparaginase at 51.47 min; (d) 20 kDa PEG−L-asparaginase at 48.82 min. C. MALDI-TOF-MS of L-asparaginase ionized as a monomer with a MW range of 31 842−34 423 Da. D. MALDI-TOF-MS of the three-carbon disulfide-bridged 20 kDa PEG−L-asparaginase.

single-bridged PEG−IFN (65%), three-carbon disulfide double-bridged PEG−IFN (23.5%), IFN (4.9%), and aggregated IFN (6.6%) was obtained (*33*). When 1 equiv of the 10 kDa PEG monosulfone **4** was used for the conjugation, a mixture of the three-carbon disulfide single-bridged PEG−IFN (64.3%), three-carbon disulfide double-bridged PEG−IFN (17.4%), IFN (13.4%), and aggregated IFN (4.8%) was obtained (Figure 11B). When 1.5 equiv of PEG monosulfone **4** was used, a mixture of the three-carbon disulfide double-bridged PEG−IFN (61%) and the three-carbon disulfide single-bridged PEG−IFN (38%) was obtained (Figure 11C). There was no residual IFN, and only 1% of the IFN was aggregated.

When 1 equiv of PEG bis(sulfone) **3** was used, the conjugation reaction was similar and the three-carbon disulfide single-

bridged PEG-IFN was the main product (Figure 11A, lane 4). When 2 equiv of the PEG bis(sulfone) **3** was used (Figure 11A, lane 5), the three-carbon disulfide double-bridged PEG−IFN was the main product. In order to produce the three-carbon disulfide double-bridged PEG−IFN, the disulfide-reduced IFN was allowed to react with the PEG bis(sulfone) **3** immediately after the protein had been separated from the reducing agent and stored overnight at 4 °C. The PEG−IFN conjugates were purified by cation exchange chromatography followed by size exclusion chromatography and then analyzed by MALDI-TOF-MS (Figure 12A,B with the reference MALDI of IFN shown in Figure 12C). The presence of IFN in the PEG−IFN was confirmed by silver stain and by Western immunoblotting with an anti-IFN antibody (Figure 13). This study also confirmed the absence of un-PEGylated IFN in these particular fractions. As both disulfides were reduced for the mono-PEGylation of IFN, it was also necessary to reoxidize any cysteines that had not been PEGylated with glutathione. This led to increased amounts of the three-carbon disulfide single-bridged PEG−IFN and of IFN. Aggregation of the reduced IFN was not observed in 50 mM sodium phosphate buffer, pH 7.8, containing 10 mM EDTA. However, aggregation was found after buffer exchange of the non-glutathione-treated reaction mixture to 20 mM sodium acetate buffer, pH 4.0. Reannealing of the open disulfides with glutathione (1 mM GSH/1 mM GSSG) decreased the formation of aggregates while buffer exchanged to 20 mM sodium acetate buffer, pH 4.0 (Figure 14).

The biological effects of modified IFNs were studied using the A549-EMC antiviral assay and the 2′,5′-OAS mRNA induction assay (Figure 15A−D). The unreacted IFN after purification had an ED_{50} of 17 (antiviral) to 38 (2′,5′-OAS mRNA) pg/mL. The addition of a single three-carbon bridge (i.e., single-bridged IFN) reduced this slightly (given the doubling dilution format of the assays) to 41 (antiviral ED_{50}) to 97 (2′,5′-OAS mRNA ED_{50}) pg/mL. This is a remarkably small change in antiviral activity, given our expectation at the outset of our studies that manipulation of a disulfide bond would severely disrupt the biological activity of IFN. The addition of a single PEG molecule (i.e., three-carbon disulfide single-bridged PEG−IFN) reduced it significantly to 175−265 pg/mL (antiviral assay ED_{50} for the 20 and 10 kDa PEGs) and

338−441 pg/mL (2′,5′-OAS mRNA ED_{50} for the 10 and 20 kDa PEGs, respectively). The length of the PEG had no effect on the biological activity of the PEG−IFN. Taken together, these results show that the insertion of a single three-carbon disulfide bridge into IFN contributed ∼11%, and the addition of PEG to that bridge contributed ∼89% to the reduction in the in vitro biological activities of the single-bridged PEG−IFNs. Therefore, the antiviral activity of our three-carbon disulfide single-bridged PEG−IFN was ∼8% of IFN and, as such, is the same as the reported activity of the mono-PEGylated IFN (∼7% of IFN) in clinical use (*65*−*69*).

The insertion of two three-carbon bridges in IFN (i.e., double-bridged IFN) caused a significant reduction in the biological activity of IFN (104 pg/mL (antiviral assay ED_{50}) and 414 pg/mL (2′,5′-OAS mRNA ED_{50}); Figure 15A−D). This was a surprising biological result, given that our molecular modeling studies had shown that the double-bridged IFN retained its primary, secondary (i.e., helices), and tertiary structure. It is possible that, as the experiment to add the two three-carbon linkers to IFN (without PEG attached) was conducted in the presence of acetonitrile (in order to solubilize the conjugation reagent shown as structure **1**), the IFNs receptor binding domains might have been significantly disrupted. This study was necessary in order to complete our mass spectral analysis (Figure 10 and (*33*)). The reduction in the biological activity of the double-bridged IFN was similar to that of adding a PEG molecule to a single-bridged IFN (175−265 pg/mL (antiviral assay ED_{50}) and 338−441 pg/mL (2′,5′-OAS mRNA ED_{50})). While the three-carbon disulfide double-bridged PEG−IFNs had only ∼2% of the activity of IFN, once again, we found that the length of the PEG had no effect on the biological activity of the PEG−IFN; the three-carbon disulfide double-bridged 10 kDa PEG−IFN had an antiviral ED_{50} of 639 pg/mL and the three-carbon disulfide single-bridged 20 kDa PEG−IFN had an antiviral ED_{50} of 697 pg/mL. Therefore, in the case of IFN, it was better to increase the MW of a single PEG molecule to optimize the molecule's pharmacokinetic profile rather than attach a second PEG molecule to the protein. This property has not previously been described for PEG−IFNs, presumably because each PEG reagent used for amine conjugation of IFN gives a different mixture of positional PEG−IFN isomers.

The reduction of the in vitro biological activity of the PEG−IFNs is a consequence of the steric shielding caused by PEG, and it is seen with all the PEG−IFNs described in the literature that have been biologically evaluated (*6*, *65*−*69*). The complex nature of the binding of IFN to its receptor (i.e., at least two receptor−ligand interactions occur) is disrupted by the presence of PEG, which is at least as large in solution as the IFN (*70*). When amine PEGylation is used, reduction of the antiviral activity of the IFN can be minimized by attaching a very short PEG to certain residues, but this is at the expense of a considerably reduced in vivo half-life. In the clinical context, the increase in the in vivo half-life of IFN to at least 12 h (*68*) is more important than the reduction in its in vitro antiviral activity, because the markedly enhanced in vivo therapeutic efficacy of IFN more than compensates for the reduced biological activity seen in vitro. This is the case for all of the IFNs that have been described in the literature (*65*−*69*). Therefore, the decrease in the in vitro activity and the decrease

in the in vivo clearance of a PEG−IFN are a direct consequence of the presence of PEG.

Using BIAcore measurements and cell binding assays, Kubetzko et al. (*71*) have recently shown that attachment of a 20 kDa PEG to an antibody fragment distal to the binding region results in a 5-fold reduction in the apparent affinity of the PEGylated antibody fragment for its receptor. This was due to a reduction in the association rate of the PEGylated molecule

properties of the conjugated protein with its hydrodynamic radius becoming much larger than would be expected for the PEG-associated increase in molecular mass. While only a modest effect was seen with a 5 kDa PEG, conjugates modified with a 20 kDa PEG displayed a 100-fold reduction in the association rate. Their modeling studies also suggested that PEGylation results in <7% of a PEGylated molecule being available for binding to its receptor at any moment in time. The remainder has intramolecularly blocked binding interfaces and is in rapid equilibrium with the functional molecule. Although this reduces the observed association rate, all of the PEGylated molecules can eventually bind to the receptor. Similar and related observations have been made for PEG−IFN (*6*, *69*). In addition, the PEGylated molecules intermolecularly block the attachment of neighboring molecules, causing an apparent reduction in the number of binding sites, minimizing protein aggregation, and increasing protein stability (*72*). This masking of proteins by PEG also explains their lower immunogenicity, lower toxicity, and longer circulation half-life.

CONCLUSION

PEGylation reagents that undergo sequential bis-alkylation with two thiols are described and shown to undergo site-specific conjugation with the cysteine sulfur atoms that are liberated by

the mild reduction of a protein's disulfide bond. Most therapeutic proteins, antibody fragments, and enzymes have at least one disulfide bond which can be modified using disulfide site-specific PEGylation without disrupting either their tertiary structure or their biological activity (*33*). This approach does not require the incorporation of a new cysteine into the protein to exploit selective thiol conjugation chemistry. As our approach is stoichiometrically very efficient and enables the recycling of any unreacted protein, it offers the potential to make cost-effective PEGylated biopharmaceuticals as global medicines. In this context, clinical trials are now in progress with our three-carbon disulfide single-bridged PEG−IFN as a cost-effective treatment for the epidemic of hepatitis C in developing countries.

ACKNOWLEDGMENT

We are grateful to the Wellcome Trust (068309), BBSRC-UK (BB/D003636/1) and PolyTherics for funding, and to The School of Pharmacy and Avecia for contributing towards the costs of S. Balan's Ph.D. studies.

The development of multicomponent biotherapeutic carriers is an important challenge in the field of drug delivery, particularly in the area of protein-based vaccines. While the delivery of protein antigens to antigen presenting cells (APCs) is crucial for this type of vaccination, the incorporation of additional adjuvants may be just as important in order to generate more potent immune responses. This article presents the synthesis and biological evaluation of carrier particles that both deliver a protein payload to APCs and display receptor ligands for the enhancement of APC immunostimulation. Particles displaying CpG oligonucleotide ligands for Toll-like receptor 9 were synthesized. The addition of CpG DNA to the particles led to a 45-fold increase in the secretion of interleukin-12, a cytokine that aids in T-cell activation, and a significant increase in the expression of costimulatory molecules by APCs. Moreover, vaccination with particles containing both ovalbumin (OVA) and CpG DNA induced a superior OVA-specific CD8 T-cell response in vivo, as measured by increased OVA-specific CD8 T-cell proliferation, secretion of the proinflammatory cytokine IFN-γ, and the induction of OVA-specific cytotoxicity.

INTRODUCTION

The development of multicomponent drug carriers is an important objective of drug delivery research, especially in the area of protein-based vaccines. To generate protective immunity, these vaccines need to deliver protein antigens to antigen presenting cells (APCs). In previous work, we have described acid-degradable particles that accomplish this goal on the basis of a cross-linked polymer network encapsulating a model protein, ovalbumin (OVA) (*1*, *2*). The particles were designed to degrade in the mildly acidic environment of lysosomes after phagocytosis by APCs, followed by release of the protein payload into the cytoplasm for MHC class I processing, presumably due to destabilization of the lysosomal membrane caused by the swelling and breakdown of the particles into many molecules.

While it is clear that antigen delivery is a key step in developing protein-based vaccines, a number of additional steps can contribute greatly to the generation of a more potent immune response. One such step is the stimulation of APCs for increased expression of costimulatory molecules and cytokines that aid in T-cell activation. This process can be initiated by binding receptors, such as the Toll-like receptor 9 (TLR9).

One pattern that is recognized by the immune system as nonself is unmethylated CpG dinucleotides, as these motifs, in which a cytidine is linked via a phosphodiester bond to guanosine, are common in bacterial DNA but are suppressed in vertebrates. CpG sequences in vertebrate DNA are typically methylated, whereas significantly less methylation is observed in bacterial DNA (*3*). Short, single-stranded DNA containing these unmethylated dinucleotide motifs, called CpG oligonucleotides, has been shown to possess immunostimulatory properties (*4*). They bind to the TLR9, which is found in lysosomal compartments of APCs, triggering both maturation of APCs and cytokine release (*5*−*7*). Moreover, TLR signals induced by TLR agonists, such as CpG, play a crucial role in reversing tumor-induced T-cell tolerance (*8*, *9*). Previous studies have analyzed the length and sequence of CpG oligonucleotides necessary to generate an optimal immunostimulatory response (*5*, *10*).

Our aim was to investigate the potential of multicomponent delivery systems that can both release an OVA payload and display receptor ligands for protein-based vaccine applications. Therefore, a CpG oligonucleotide ligand was conjugated to the acid-degradable particles to aid in APC immunostimulation. Incorporation of this adjuvant was achieved by modifying the particle preparation protocol to include a ligand monomer in the copolymerization with acid-degradable cross-linker **1** and acrylamide (Scheme 1) (*1*, *2*). One advantage of this tailorable vaccine carrier is that it ensures that the oligonucleotide and protein will be delivered to the same APC. Once the new particles were obtained, their effects on dendritic cells (DCs), the most potent APCs capable of inducing immunity, and on the induction of an OVA-specific T-cell response were investigated. DC maturation and cytokine production experiments were performed to determine the effect of CpG incorporation.

EXPERIMENTAL PROCEDURES

General Methods. Monomers, surfactants, and reagents were purchased from Aldrich (Milwaukee, WI) or Sigma (St. Louis, MO) and used without further purification unless otherwise noted. Cascade Blue was obtained from Molecular Probes (Eugene, OR). Water for buffers was purified to a resistance of 18 MΩ using a Barnstead NANOpure DIamond purification system. MALDI-TOF data was collected on a PerSeptive

[a] (i) Inverse emulsion polymerization. (ii) Acetal hydrolysis.

Biosystems Voyager-DE instrument (Applied Biosystems, Foster City, CA) in negative ion mode: accelerating voltage, 25 000 V; grid, 95%; guide wire, 0.1%; delay time, 550 ns. MALDI samples were prepared using a matrix of 0.1 M ammonium citrate and 0.35 M 3-hydroxypicolinic acid in a 1:1 mixture of acetonitrile and water (*11*). Absorbance and fluorescence readings were taken on a SPECTRAmax 190 and SPECTRAmax Gemini XS microplate readers (Molecular Devices, Sunnyvale, CA). Particles were imaged using a scanning electron microscope (WDX ISI-ds130C, Microspec Corporation, Inc.) at 15 kV after drying and sputter-coating with a 20 nm gold film.

Acid-Degradable Cross-Linker (1) was prepared as described elsewhere (*2*).

Synthesis of CpG Oligonucleotide Macromonomer (2). The phosphorothioate oligonucleotide was synthesized on solid phase on a 1 μmol scale with 500 Å controlled pore glass support using an Expedite 8909 DNA Synthesizer (Applied Biosystems, Foster City, CA) and UltraMILD phosphoramidites (Glen Research Corporation, Sterling, VA). A sulfurizing step was substituted in the oxidation cycle, using Beaucage's Reagent, 3*H*-1,2-benzodithiole-3-one-1,1-dioxide, to generate a phosphorothioate as the internucleotide linkage (*12*). To add the polymerizable moiety, the 5′ end was modified on the solid phase with an Acrydite Amidite ((6-*N*-methylacryl)-aminohexyl-(*O*-2-cyanoethyl)-(*N*,*N*-diisopropyl) phosphoramidite, Matrix Technologies, Hudson, NH) to generate a methacrylamide-derivatized oligonucleotide. The sequence was cleaved from the solid support under basic conditions of concentrated NH_4OH at room temperature (rt) for 4 h. Solvent was removed using a vacuum concentrator, and crude oligonucleotide was taken up in 500 μL of H_2O. After filtering off the support resin, the sample was purified by reverse-phase HPLC (1100 series, Agilent Technologies, Palo Alto, CA) using 0.1 M triethylammonium acetate buffer pH 7.0 containing 5% acetonitrile and a gradient of 0% to 30% acetonitrile over 10 min at 1 mL/min with a Zorbax 300 SB-C18 column (9.14 mm × 25 cm, Agilent). The desired fractions were collected and lyophilized. The sample was then taken up in 100 μL of H_2O and further purified by ethanol precipitation with 10 μL of 3 M ammonium acetate and 1 mL of ethanol. The resulting DNA pellet was recovered by centrifugation at 4 °C for 30 min and then dried in air. $[M - H]^-$ m/z = 6626.6. Found MALDI-TOF: $[M - H]^-$ m/z = 6640.5.

Protein-Loaded Particle Preparation. To synthesize the degradable particles, an inverse emulsion free radical polymerization technique was utilized (*1*, *2*). Acrylamide, cross-linker **1,** and polymerizable ligand **2** were dissolved in 0.3 M phosphate buffer (pH 8, 250 μL). Then, OVA (7 mg, ovalbumin labeled with Cascade Blue or unlabeled) and ammonium peroxodisulfate (6.5 mg) were dissolved in this aqueous solution. The organic phase consisted of a 3 wt % surfactant solution in hexanes, using a 3:1 weight ratio of Span 80 (sorbitan monooleate) and Tween 80 (poly(ethylene glycol) sorbitan monooleate). The aqueous monomer solution (250 μL) was added to 2.5 mL of the organic phase, and the two phases were emulsified by sonicating for 30 s using a Branson Sonifier 450 with an output setting of 2 and a duty cycle of 40%. Polymerization was initiated by the addition of *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (25 μL), and the mixture stirred at rt for 10 min. The particles were isolated by centrifugation, rinsed with hexanes, washed four times with acetone, and then centrifuged. The solvent was decanted and the particles dried overnight in vacuo. Particles that did not contain protein were made in the same manner, omitting OVA.

Unmodified OVA-Particles. The monomer composition contained 62.3 mg of acrylamide and 62.8 mg of cross-linker **1** dissolved in the aqueous phase.

CpG−OVA-Particles. Here, the aqueous phase consisted of 62.2 mg of acrylamide, 62.8 mg of cross-linker **1**, and 4 mg of monomer **2** in 250 μL of the phosphate buffer.

Protein Encapsulation Measurements. The protein loading was determined by preparing particles with Cascade Blue labeled OVA. Particle hydrolysis and quantification of OVA were conducted as described previously (*2*).

Oligonucleotide Quantification. Oligonucleotide quantification assays were performed using OliGreen (Molecular Probes, Eugene, OR). To quantify the amount of oligonucleotide incorporated into the particles, the beads were dispersed in 300 mM sodium phosphate buffer pH 7.4 at a concentration of 1 mg/mL. The particles were then collected as a pellet by centrifuging for 10 min. The wash supernatant was removed by pipet, and an equivalent volume of acidic buffer (pH 5.0, 300 mM acetic acid) was added to maintain the concentration. The sample was then left at rt overnight, and the hydrolyzed solution analyzed for the concentration of DNA by incubating with OliGreen, and the fluorescence of the resulting solution was quantified.

Interleukin-12 Enzyme Linked Immunosorbent Assay. Bone marrow derived dendritic cells (BMDCs) were isolated as previously described (*13*, *14*). BMDCs were plated at a density of 2×10^4 cells/well and incubated overnight in 100

μL of a 1 mg/mL solution of particles in media. Control wells consisted of untreated cells and cells exposed to particles without OVA. The media was then analyzed using an ELISA assay for interleukin-12 (Pierce, Rockford, IL). Absorbance values were measured at $\lambda = 450$ nm and corrected using $\lambda = 550$ nm as a background reference. Interleukin concentrations were calculated using a standard curve. The Student's *t*-test was used to determine statistical significance.

Analysis of DC Surface Marker Expression. BMDCs were incubated in 6-well plates at the density of 2×10^6 cells/well. After overnight cultivation, cells were further incubated with 1 mL of a 1 mg/mL solution of various particles encapsulating OVA to examine immunostimulatory effects. After incubating overnight, cells were washed, trypsinized, and treated with anti-mouse CD16/CD32 (Fcγ III/II) for 1 h to prevent nonspecific adsorption. The cells were then stained with R-Phycoethrin-labeled monoclonal antibodies specific to mouse CD40, 80, 86, and H-2K^b (MHC I) and I-A^b (MHC II) (all from Pharmingen, San Diego, CA) at 4 °C for 2 h. Relative expressions of surface molecules were analyzed and compared with fluorescence intensity determined by flow cytometry.

Animals. Male C57Bl/6 mice and CD45.1 congenic C57Bl/6 mice, 6 to 8 weeks of age, were purchased from the Jackson Laboratory (Bar Harbor, ME). The 1100Mjb mice (OT-I mice) express an H-2K^b restricted T-cell receptor (TCR) specific for the octamer peptide SIINFEKL (ovalbumin 257−264) (*15*). All mice were housed in the Stanford Animal facility in accordance with the NIH guidelines.

In Vitro T-Cell Priming Studies. For in vitro T-cell proliferation, 6×10^4 DC derived from d5 bone marrow cultures were incubated with 500 μg/mL particles (corresponding to a concentration of 20 μg/mL OVA) with or without addition of the DC activator CpG (30 μg/mL). After overnight culture, DCs were washed twice and co-cultured with 3×10^5 naive SIINFEKL(ovalbumin $_{257-264}$) /H-2K^b-specific OT−I T-cells isolated from the spleens of TCR transgenic OT-I mice for 5 d. After restimulation of the T-cells using SIINFEKL-pulsed irradiated spleen cells (30 Gy) for 3 d, T-cell proliferation was measured by ^{3}H thymidine incorporation. 1 μCi of ^{3}H thymidine was added to each well of the culture. Cells were harvested 18 h later, and ^{3}H thymidine uptake was measured in a Microbeta counter (Wallac, Gaithersburg, MD). Results are presented as the mean of triplicate cultures ± standard deviation.

In Vivo T-Cell Proliferation Assay. CD45.1$^+$ C57Bl/6 mice received subcutaneous injections of 125 μg particle in 200 μL PBS into the right flank followed by adoptive transfer of 5×10^6 CD45.2$^+$ OT-I T-cells 24 h later. The OT-I T-cells were labeled with 10 μM 5-(and-6)-carboxyfluorescein diacetate, succinimidyl ester (CFSE) (Molecular Probes) prior to adoptive transfer in order to follow their proliferation by CFSE dilution. Mice vaccinated with corresponding amounts of free OVA or free OVA plus free CpG served as controls. Three days after adoptive transfer, draining inguinal lymph nodes were harvested from vaccinated mice, and single cell suspensions were stained with fluorochrome-labeled monoclonal antibodies against CD45.2, TCR, and CD8α (all Pharmingen San Diego, CA). The CFSE proliferation profile of gated CD45.2$^+$ CD8 T-cells was determined by flow cytometry.

IFN-γ ELISPOT Assay. C57Bl/6 mice were vaccinated with 1.25 mg of particle samples in 200 μL PBS or corresponding amounts of OVA and CpG. Splenocytes were isolated 10 d after vaccination. After lysis of red blood cells, splenocytes were resuspended at a final concentration of 1×10^7 cells/mL in RPMI/10% FBS, and 100 μL of this cell suspension were then cultivated at 37 °C for 24 h in ELISPOT plates coated with anti-mouse IFN-γ with or without 10 μg/mL SIINFEKL. IFN-γ secreting cells were then detected using the anti-mouse IFN-γ ELISPOT Kit (R&D Systems, Inc., Minneapolis, MN) according to manufacterer's protocol. Results are presented as the mean of triplicate cultures + standard deviation.

Cytotoxicity Assay. C57Bl/6 mice (6 mice total per group) were vaccinated with 1.25 mg of particle samples in 200 μL PBS or corresponding amounts of OVA and CpG. At day 7 after vaccination, mice were injected intravenously with 5×10^6 CFSE-labeled target cells consisting of 50% SIINFEKL-pulsed splenocytes labeled with 5 μM CFSE and 50% unpulsed splenocytes labeled with 0.5 μM CFSE. Mice were bled 18 h after adoptive transfer, and the CFSE profile of transferred cells was determined by flow cytometry for analysis of OVA-specific cytotoxicity.

RESULTS AND DISCUSSION

Synthesis of CpG Macromonomer. The preparation of immunostimulatory CpG particles began with the synthesis of the methacrylamide-modified oligonucleotide **2**. The sequence chosen for incorporation, TCCATGACGTTCCTGACGTT, was previously shown (*16*) to induce DC maturation and cytokine secretion and has also been used as a coadjuvant for protein-based therapy, demonstrating an enhanced efficiency of vaccination. This sequence was also chosen because it is well-tolerated when administered in vivo (*16*). CpG macromonomer **2** was synthesized in a solid-phase synthesizer. A sulfurizing step was substituted in the oxidation cycle to generate phosphorothioates as the internucleotide linkages, because this linkage is known to be less susceptible than native phosphate bonds to enzymatic cleavage by nucleases prevalent in serum and within the cell cytoplasm (*17*). The polymerizable end group was added by coupling Acrydite Amidite, a methacrylamide-based phosphoramidite, to the 5′ end. The polymerizable handle of **2** enabled its covalent attachment to the polymer network, which was necessary because, unlike the protein antigens, the CpG sequence is too small to be physically entrapped into the particle and would therefore diffuse out of the particle if unbound (see Supporting Information). The macromonomer was purified by reverse-phase HPLC and was further characterized by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS). The observed molecular weight of 6640.5 agrees within 0.2% with the calculated value of 6626.6.

Preparation of CpG-Containing Particles. Multicomponent particles encapsulating OVA and including CpG ligands conjugated throughout the polymer network (CpG−OVA-particles) were successfully synthesized and characterized to investigate the possibility of enhancing APC activation using a TLR9 agonist. The synthetic flexibility of the inverse emulsion particle preparation process enabled the addition of functional monomers, such as **2**, to the polymerization mixture. Therefore, compound **2** was copolymerized with acrylamide and acid-sensitive cross-linker **1** under conditions similar to those described previously (*2*), forming protein-loaded polymer particles with the CpG ligand covalently attached throughout the polymer scaffold (Scheme 1). In this process, monomers and protein were dissolved in a slightly basic aqueous buffer to prevent cross-linker hydrolysis, and the aqueous phase was then dispersed as droplets in hexanes. Free radical polymerization was initiated within the aqueous droplets, resulting in cross-linked hydrophilic polymer particles encapsulating OVA (*1, 2*).

SEM images showed that the particles were 250−500 nm in diameter in the dry state (Figure 1), as observed previously for ligand free particles. Protein encapsulation measurements indicated a loading of 40 μg OVA/mg particles. Oligonucleotide incorporation was measured by hydrolyzing a sample of particles and analyzing the concentration of DNA using OliGreen, a

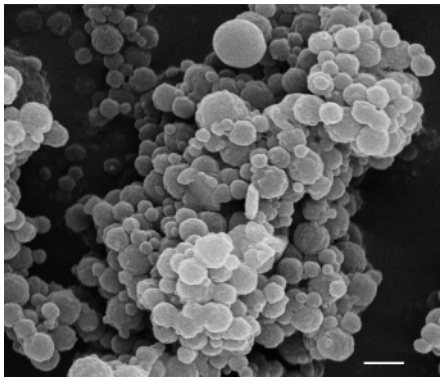

Figure 1. SEM image of CpG-particles. Scale bar = 500 nm.

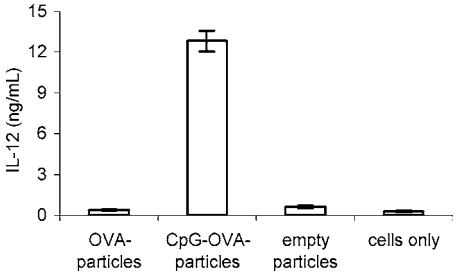

Figure 2. Interleukin-12 production by BMDCs incubated with particles.

fluorescent dye that binds to single-stranded DNA. The oligonucleotide content in the particles was 25 μg CpG DNA/mg particle. Alteration of the DNA during free radical polymerization was not expected to occur, because both oligonucleotides and plasmid DNA have previously been shown to be stable under these polymerization conditions (see Supporting Information) (*18*).

Unmodified OVA-particles free of CpG DNA were also prepared using the inverse emulsion method by omitting monomer **2**. These particles contain the same mole percent cross-linking and protein loading as the functionalized particles described above.

DC Activation by CpG−OVA-Particles. The APC receptor associated with generating potent immune responses we investigated is the TLR9, which binds CpG oligonucleotides and triggers DC activation. Soon after encountering the CpG danger signal, a DC maturation process is initiated in which the cells become less proficient at antigen uptake but increase their antigen presentation capabilities. This immunostimulation serves to enhance the effect of protein-based vaccines by inducing the production of cytokines, such as interleukin 12 (IL-12), which aid in T-cell activation (*19*−*21*). The expression of surface costimulatory molecules also rises, turning mature DCs into potent T-lymphocyte activators (*22*). Previous studies have shown that combining immunostimulatory DNA sequences with protein-based vaccines leads to a more effective therapy (*16*, *23*, *24*).

The effect of CpG−OVA-particles on the activation of DCs was investigated by analyzing cytokine secretion levels. Particle samples were incubated with murine BMDCs, and the levels of IL-12 secreted were recorded as a measure of immunostimulation (Figure 2). Unmodified OVA-particles and CpG−OVA-particles and empty particles that contained neither protein nor ligands were tested. This study revealed that the addition of immunostimulatory CpG moieties to the particles had a highly significant influence on the secretion of IL-12, with 45 times more cytokine produced than was the case for the other particle samples or for cells incubated without particles ($p < 0.001$). The other particle samples produced IL-12 cytokine levels

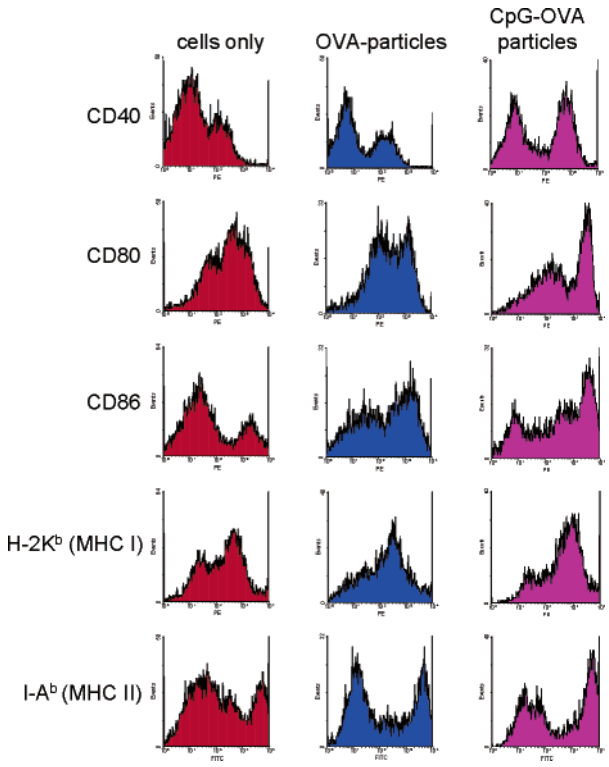

Figure 3. Surface marker expression by BMDCs incubated with particle samples. For each individual graph, the *y*-axis is number of events, *x*-axis is fluorescence.

comparable to the endogenous secretion of cells alone. Therefore, this CpG modification should enhance the vaccine efficiency of the particle system, because the secretion of this activating cytokine is expected to promote highly effective T-cell responses.

Flow cytometry was used to monitor DC maturation after exposure to the various particle formulations. Murine BMDCs were incubated with two different particle samples: OVA-particles and CpG−OVA-particles. Multiple cell surface markers associated with dendritic cell activation such as CD40, CD80, CD86, MHC I (H-2K^b), and MHC II (I-A^b) molecules, were stained with the corresponding fluorescently labeled antibodies, and the cells were analyzed by flow cytometry to determine the immunostimulatory effects of the particles. A shift to the right and increase in intensity of the peaks in Figure 3 indicate an increase in the expression of the surface molecule. Unmodified OVA-particles enhanced CD40, CD80, CD86, and MHC II expression compared to cells incubated without particles, indicating moderate DC maturation. CpG−OVA-particles significantly increased expression of surface markers CD40, CD80, and CD86 compared to the unmodified particles but had a similar response for MHC II. MHC I expression for the CpG−OVA-particle sample was also slightly upregulated. The CpG−OVA-particles generated the strongest response, demonstrating that the oligonucleotide provides an additional danger signal that initiates the transformation of immature DCs, which are efficient at antigen capture, to mature DCs, which are proficient at antigen presentation and T-cell activation. These studies indicate that the presence of CpG on the protein-loaded particles leads to strong immunostimulation, which should in turn lead to more effective therapy.

T-Cell Priming by Antigen-Loaded DC Requires CpG. As the particles were designed to specifically deliver antigen into the MHC class I presentation for induction of primary antigen-specific CD8 T-cell responses, we decided to study the capacity of BMDCs pulsed with different particle samples to induce the proliferation of naïve SIINFEKL(ovalbumin$_{257-264}$)/

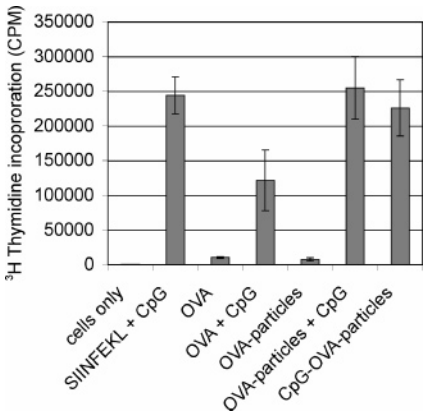

Figure 4. BMDCs loaded with OVA-particles and activated by CpG prime OVA-specific CD8 T-cells in vitro.

H-2K^b-specific CD8 T-cells isolated from TCR transgenic OT-I mice. As shown in Figure 4, only BMDCs pulsed with CpG−OVA-particles efficiently stimulated the proliferation of naïve CD8 OT-I T-cells in vitro. T-cell stimulatory capacity by BMDCs pulsed with OVA-particles could be rescued by the addition of CpG to the BMDC culture, thus demonstrating that the lack of T-cell proliferation is due to insufficient DC activation and not because of a failure of antigen delivery (Figure 4). These results indicate that codelivery of a TLR agonist, such as CpG, together with the antigen is essential to induce a primary antigen-specific T-cell response.

Induction of OVA-Specific T-Cell Immunity by CpG-Particles In Vivo. As DC activation seems to be critical for T-cell priming, and in vitro studies have limited capacity to predict the efficacy of vaccines due to the complexity of the immune system, we decided to further explore the capacity of CpG−OVA-particles to induce T-cell responses in vivo. Consistent with the in vitro results, CFSE-labeled CD45.2$^+$ naïve OT-I T-cells transferred into CD45.1$^+$ C57Bl/6 recipient mice proliferated best after vaccination with CpG−OVA-particles compared to unmodified OVA-particles or even free OVA + free CpG (Figure 5), as measured by the dilution of the CFSE with each cell division. Vaccination with empty particles induced no significant T-cell proliferation.

In order to determine if OVA-specific CD8$^+$ T-cells induced after vaccination with particles are functional, we decided to quantify IFN-γ secreting cells present in the spleen by an IFN-γ-ELISPOT assay upon stimulation with the CD8 T-cell epitope SIINFEKL. IFN-γ represents a proinflammatory cytokine that promotes antitumor immunity by inhibition of tumor cell proliferation and angiogenesis (*25*). Vaccination with CpG−OVA-particles resulted in the highest number of IFN-γ-secreting cells upon stimulation with SIINFEKL compared to plain OVA-particles or a mixture of free OVA + free CpG demonstrating that SIINFEKL/H-2k^b-specific CD8 T-cells are not only expanded after vaccination but are capable to respond with IFN-γ secretion upon TCR stimulation (Figure 6). Low numbers of IFN-γ-secreting cells were observed in the absence of SIINFEKL peptide, which proves that the immune response induced by the CpG−OVA-particles is specific for ovalbumin (Figure 6). Moreover, vaccination with CpG−OVA-particles induced at least twice as many IFN-γ-secreting cells in response to SIINFEKL stimulation compared to a mixture of OVA-particles and free CpG, consistent with reports that codelivery of antigen and TLR agonist to the same antigen-presenting cell is important for generating optimal immune responses (*23*, *26*). It is likely that the current experiments underestimate the true potential of the CpG-particles, as an arbitrary CpG concentration was used to generate these particles and the optimal CpG load has yet to be determined. We expect that future studies will show that the amount of CpG needed for optimal vaccination effect can be significantly lowered if CpG is linked to the particles compared

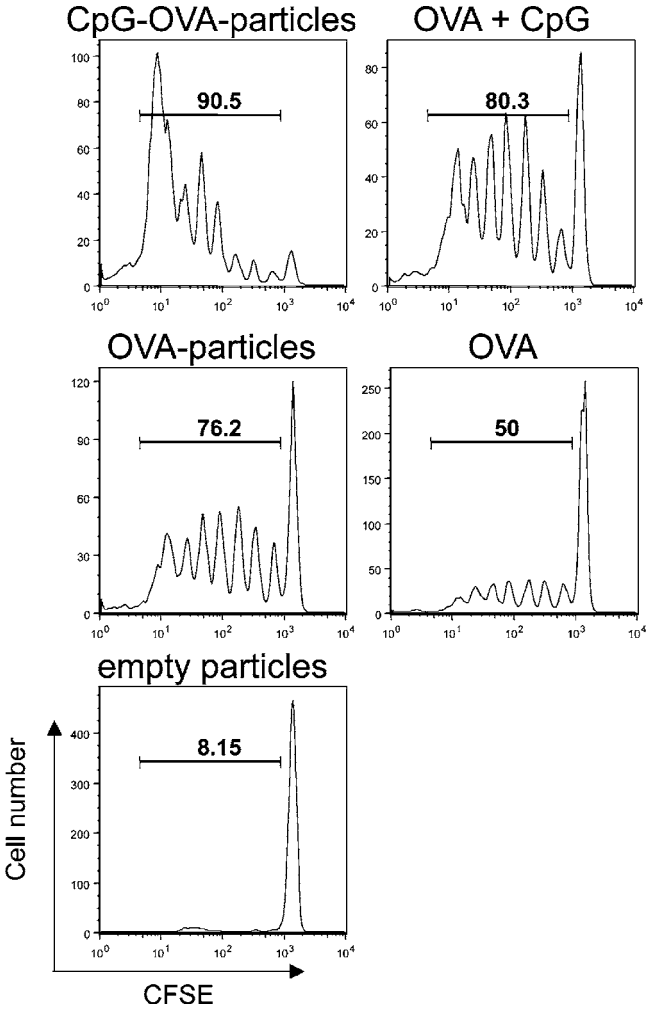

Figure 5. In vivo proliferation of SIINFEKL(ovalbumin$_{257-264}$)/H-2K^b-specific naïve CD8 T-cells induced by CpG−OVA-particles. Histograms show CFSE profiles of gated CD45.2$^+$ CD8$^+$ T-cells isolated from the lymph nodes of vaccinated mice 3 d after adoptive transfer. Numbers represent the percentages of the proliferating cells of total OT-I T-cells. Experiments were performed three times with similar results.

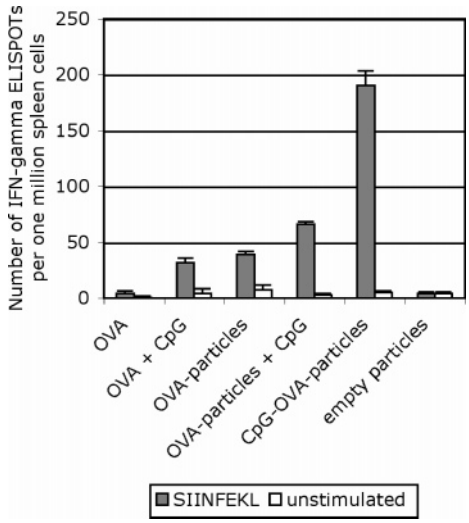

Figure 6. Vaccination with CpG−OVA-particles leads to potent IFN-γ secretion upon stimulation with the OVA-derived peptide (SIINFEKL). Data are representative of two experiments with similar results.

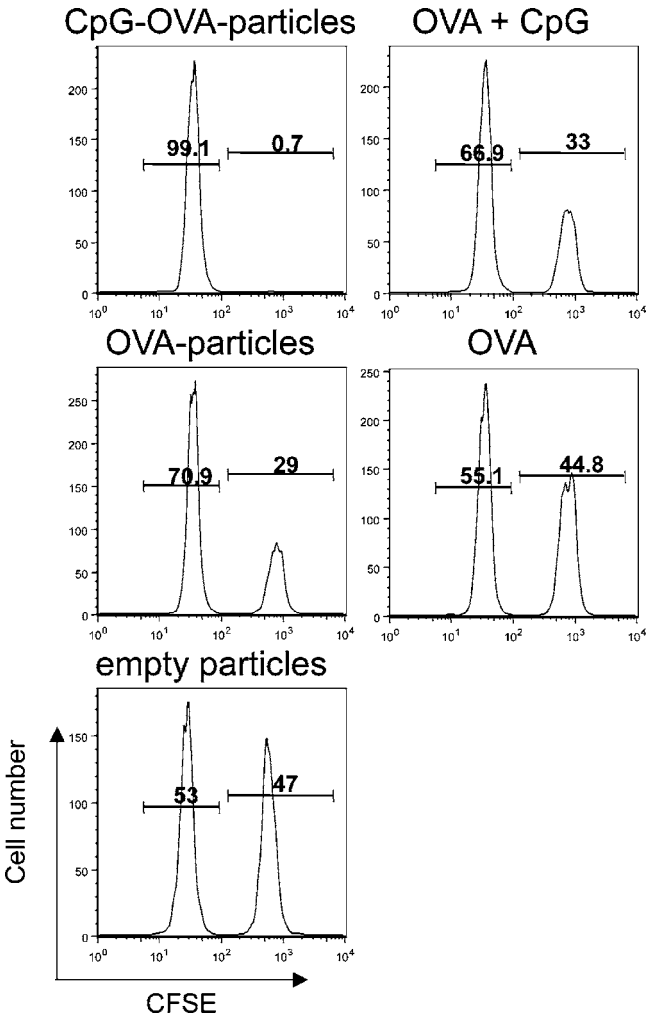

Figure 7. CpG−OVA-particles induce specific lysis of SIINFEKL-pulsed cells in vivo. Histograms show percentages of remaining SIINFEKL-pulsed spleen cells (right peak) versus unpulsed spleen cells (left peak) of total transferred cells. Data are representative of three experiments with similar results.

to the use of free CpG as an adjuvant, thus reducing the risk of toxicity caused by CpG-induced systemic inflammation (*27*).

In addition to cytokine secretion, the induction of antigen-specific cytotoxic effector cells represents probably the most important criterion for evaluating vaccine efficacy, as antigen-specific lysis of cells (e.g., tumor cells, virus-infected cells) is desirable in many vaccine applications and is especially critical for antitumor immunity. In order to measure OVA-specific cytotoxicity, C57Bl/6 mice were vaccinated by subcutaneous injection with 1.25 mg samples of particle or corresponding amounts of OVA and CpG followed by intravenous injection of an equal mixture of SIINFEKL-pulsed and unpulsed CFSE-labeled C57Bl/6 spleen cells. As SIINFEKL-pulsed cells were labeled with a higher CFSE concentration than the unpulsed spleen cells prior to injection, OVA-specific cytotoxicity can be measured by flow cytometric analysis of blood cells obtained from vaccinated mice. At 18 h after transfer, mice vaccinated with CpG−OVA-particles lacked nearly completely the CFSE high population of SIINFEKL-pulsed spleen cells in the blood, indicating that high numbers of SIINFEKL/H-2k^b-specific cytototoxic effector cells were present in these mice (Figure 7). In contrast, no OVA-specific cytotoxicity was induced after vaccination with empty particles or OVA alone (*28*), as SIINFEKL-pulsed (high CFSE concentration) and unpulsed spleen cells (low CFSE concentration) were still present at similar levels.

CONCLUSION

Protein-loaded particles incorporating CpG oligonucleotide ligands designed to trigger DC maturation and activation were successfully prepared using an inverse emulsion polymerization procedure. Incorporation of the CpG sequence into the particles significantly increased DC IL-12 secretion and costimulatory molecule expression when compared to analogous but CpG free particles. CpG-modified particles also induced a strong antigen-specific T-cell immunity in vivo, which was superior to both plain OVA-particles and a mixture of free OVA plus free CpG. This enhanced DC immunostimulation should lead to more effective vaccine therapies. In future studies, it will be critical to determine the optimal CpG ligand density in a particle formulation for maximum vaccine efficacy.

ACKNOWLEDGMENT

We thank the National Institutes of Health (grant RO1 EB005824) for funding of this research. We also thank Dr. Kelly Flook (Lawrence Berkeley National Laboratory, Berkeley, CA) for assisting with SEM images and Steve Guillaudeu for assistance with oligonucleotide purification.

Influence of Different Spacers on the Biological Profile of a DOTA−Somatostatin Analogue

Patricia Antunes,[†] Mihaela Ginj,[†] Martin A. Walter,[†] Jianhua Chen,[†] Jean-Claude Reubi,[‡] and Helmut R. Maecke*,[†]

Division of Radiological Chemistry, Department of Radiology, University Hospital Basel, and Divison of Cell Biology and Experimental Cancer Research, Institute of Pathology, University of Berne, Switzerland. Received June 13, 2006; Revised Manuscript Received October 19, 2006

Radiolabeled somatostatin analogues have been successfully used for targeted radiotherapy and for imaging of somatostatin receptor (sst_{1-5})-positive tumors. Nevertheless, these analogues are subject to improving their tumor-to-nontarget ratio to enhance their diagnostic or therapeutic properties, preventing nephrotoxicity. In order to understand the influence of lipophilicity and charge on the pharmacokinetic profile of [1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA)]−somatostatin-based radioligands such as [DOTA,1-Nal^3]−octreotide (DOTA−NOC), different spacers (X) based on 8-amino-3,6-dioxaoctanoic acid (PEG_2), 15-amino-4,7,10,13-tetraoxapentadecanoic acid (PEG_4), *N*-acetyl glucosamine (GlcNAc), triglycine, β-alanine, aspartic acid, and lysine were introduced between the chelator DOTA and the peptide NOC. All DOTA−X−NOC conjugates were synthesized by Fmoc solid-phase synthesis. The partition coefficient (log *D*) at pH = 7.4 indicated that higher hydrophilicity than [^{111}In-DOTA]−NOC was achieved with the introduction of the mentioned spacers, except with triglycine and β-alanine. The high affinity of [In^{III}-DOTA]−NOC for human sst_2 ($hsst_2$) was preserved with the structural modifications, while an overall drop for $hsst_3$ affinity was observed, except in the case of [In^{III}-DOTA]−β-Ala−NOC. The new conjugates preserved the good affinity for $hsst_5$, except for [In^{III}-DOTA]−Asn(GlcNAc)−NOC, which showed decreased affinity. A significant 1.2-fold improvement in the specific internalization rate in AR4-2J rat pancreatic tumor cells (sst_2 receptor expression) at 4 h was achieved with the introduction of Asp as a spacer in the parent compound. In sst_3-expressing HEK cells, the specific internalization rate at 4 h for [^{111}In-DOTA]−NOC (13.1% ± 0.3%) was maintained with [^{111}In-DOTA]−β-Ala−NOC (14.0% ± 1.8%), but the remaining derivatives showed <2% specific internalization. Biodistribution studies were performed with Lewis rats bearing the AR4-2J rat pancreatic tumor. In comparison to [^{111}In-DOTA]−NOC (2.96% ± 0.48% IA/g), the specific uptake in the tumor at 4 h p.i. was significantly improved for the ^{111}In-labeled sugar analogue (4.17% ± 0.46% IA/g), which among all the new derivatives presented the best tumor-to-kidney ratio (1.9).

INTRODUCTION

A new challenge in nuclear oncology came with the advent of radiolabeled regulatory peptides having favorable pharmacokinetics and specific targeting characteristics (*1*). The importance of these ligands is endorsed by the overexpression of their receptors in cancerous tissue (*2*). Among an array of relevant peptides, somatostatin derivatives established themselves as successful radiopharmaceuticals. The five somatostatin receptor subtypes (sst)[1] are overexpressed and widely distributed in cancerous tissues, in a homogeneous or heterogeneous manner (*3*, *4*). In addition, there is a considerable variation in sst subtype expression between different tumor types and among tumors of the same type (*3*, *4*). The most frequently overexpressed sst receptor in human tumors is sst_2 (*5*). Nevertheless, there are exceptions, namely, in inactive pituitary adenomas and in thymomas where sst_3 is predominantly expressed (*3*, *6*). Human lung tumors were shown not only to overexpress sst_5, but also sst_2 and sst_3 (*7*).

Somatostatin-based peptides labeled with radiohalogens, like fluorine-18 (^{18}F-octreotide) (*8*), or conjugated with a bifunctional chelator suitable for labeling with radiometals such as ^{111}In, $^{67/68}$Ga, ^{90}Y, or lanthanides, like ^{177}Lu, have been investigated for applications in PET and SPECT or in peptide receptor-mediated radionuclide therapy (PRRT) (*9*, *10*). For the visualization of neuroendocrine tumors, [^{123}I-Tyr^3]-octreotide ([^{123}I]-TOC) was tested clinically (*11*), giving somewhat disappointing results due to its in vivo deiodination and unfavorable pharmacokinetics. It showed extensive hepatic uptake, which led to a high background in the abdomen (*12*, *13*). Later, an extensive clinical study comparing [^{123}I]-TOC with [^{111}In-DTPA]-octreotide (OctreoScan) demonstrated that the ^{111}In-labeled

ligand is mainly excreted via the kidneys; it has a better pharmacokinetic profile and higher sensitivity regarding the localization of neuroendocrine tumors (*14*). Nowadays, OctreoScan, an FDA approved agent, is successfully used to visualize and stage sst-positive tumors (*15*). Nevertheless, this radiotracer presents a limited binding affinity profile: from the five somatostatin receptor subtypes, [^{111}In-DTPA]-octreotide binds with low affinity to $hsst_3$ and $hsst_5$ ($IC_{50} = 182 \pm 13$ nM and 237 ± 52 nM, respectively) and with intermediate affinity to $hsst_2$ ($IC_{50} = 22 \pm 3.6$ nM) (*3*, *5*). Moreover, for therapeutic applications a β-emitter such as yttrium-90 is desirable. But, as the complex [^{90}Y-DTPA] is unstable in vivo, DTPA was replaced by DOTA, a chelator, which shows much higher kinetic inertness when complexed with yttrium (*16*−*18*). Several DOTA-octreotide derivatives with improved features compared to OctreoScan were reported (*19*, *20*). One superior example is [DOTA,Tyr^3]-octreotide (DOTA−TOC). Clinical trials with [^{111}In]-, [^{177}Lu], or [^{90}Y]-labeled DOTA−TOC have shown good tumor uptake and therapeutic effectiveness (*21*−*24*). However, the potential nephrotoxicity continues to be a drawback of these radiopharmaceuticals (*25*), and [Y^{III}-DOTA]−TOC binds with an affinity worth considering only to $hsst_2$ ($IC_{50} = 11.4 \pm 1.7$ nM) (*5*). Although PRRT with these analogues is one of the most valuable methods regarding therapy of neuroendocrine tumors, the low tumor sensitivity to radiation requires a high dose, which is limited by the high kidney uptake.

However, to cope with nephrotoxicity, amino acid infusion is currently used in the clinic (*26*). Those amino acids, usually lysine/arginine, show a blocking effect, as they most likely bind to the negative charges on the extracellular domain of the megalin/cubilin system, which might be one of the major causes for the accumulation of renal radioactivity (*27*, *28*). At the same time, it is of major importance to increase the tumor uptake. Strategies like the introduction of a spacer based on a cathepsin-B-labile peptide sequence between DOTA and [Tyr^3]-octreotate (TATE) could improve the in vitro retention time in AR4-2J tumor cells without affecting the binding affinity (*29*). The tumor uptake can also be improved by extending the sst profile of the radiotracer. A new ligand [DOTA,1-Nal^3]-octreotide (DOTA−NOC) was developed, which showed high affinity for $hsst_2$, $hsst_3$, and $hsst_5$, when complexed with In^{III}/Y^{III}; its increase of tumor uptake in relation to [^{111}In-DOTA]−TOC was verified by preclinical and clinical studies performed with [^{68}Ga]-, [^{111}In]-, and [^{177}Lu]-labeled DOTA−NOC (*30*−*34*). In spite of that, therapeutic clinical studies showed that it is still necessary to use amino acid infusions to effectively decrease the kidney uptake. Also, in some cases, [^{111}In/^{177}Lu-DOTA]−NOC exhibits higher background activity than [^{111}In-DOTA]−TOC (*30*), probably due to the higher lipophilicity of radiolabeled DOTA−NOC (*30*, *31*).

As shown in the examples specified, several somatostatin-based radioligands were developed with improved pharmacokinetics compared to [^{111}In-DTPA]-octreotide. However, the structural factors influencing the pharmacokinetic profile of these radioligands are not fully understood yet.

In this systematic study, we examine how the introduction of different spacers (X) between the chelator and the peptide in DOTA−NOC (Chart 1) modulates its properties, such as lipophilicity and charge, and how these changes influence its pharmacokinetic profile. In this evaluation, special attention was paid to the tumor-to-kidney ratio.

EXPERIMENTAL PROCEDURES

Reagents. H-Thr(tBu)-ol-(2-chloro-trityl)-resin was purchased from Advanced ChemTech (Giessen, Germany). All Fmoc-amino acids were obtained from NovaBiochem AG (Läufelfingen, Switzerland), Bachem (Bubendorf, Switzerland), and Neosystems (France), with the exception of Fmoc-PEG_4-OH that was commercially available from Quanta Biodesign (Powell, U.S.A.). DOTA(tBu)$_3$ was acquired from Macrocyclics (Richardson, Texas). [^{111}In]Cl_3 was purchased from Mallinckrodt Med. (Petten, The Netherlands). Other chemicals and solvents were obtained from commercial sources and used without further purification.

Instrumentation. Solid-phase peptide synthesis was performed on a semiautomatic peptide synthesizer commercially available from Rink Combichem (Bubendorf, Switzerland). Analytical reversed-phase high-performance liquid chromatography (RP-HPLC) was carried out on a Hewlett-Packard 1050 HPLC system (Waldbronn, Germany) coupled to a multiwavelength detector and a flow-through Berthold LB506C1 γ-detector. Preparative HPLC was performed on a Bischof HPLC system (Metrohm AG, Switzerland) with HPLC pumps 2250 and a Lambda 1010 UV detector (Metrohm AG, Switzerland). Analytical RP-HPLC and preparative HPLC were performed using CC250/4 Nucleosil 120-3C18 columns from Macherey-Nagel and a VP250/21 Nucleosil 200-5C15 column, respectively. Both columns were eluted with a gradient system of mixtures of H_2O with 0.1% trifluoroacetic acid (TFA) (solvent A) and acetonitrile (solvent B). Electrospray ionization mass spectrometry (ESI-MS) was carried out with a Finnigan SSQ 7000 spectrometer (Bremen, Germany). Lyophilization was performed on a Christ α1−2 lyophilisator (Osterode, Germany). Quantitative γ-counting was performed on a COBRA 5003 γ-system well counter from Packard Instruments (Switzerland).

Syntheses. DOTA−NOC was synthesized by standard Fmoc SPPS techniques on H-Thr(tBu)-ol-(2-chloro-trityl)-resin as reported previously (*30*). The same resin-based synthetic methods were used to develop new DOTA−X−NOC derivatives. All Fmoc-amino acid couplings were completed after 2 h, with the exception of Fmoc-PEG_2-OH, Fmoc-PEG_4-OH, and Fmoc-Asn(Ac_3AcNH-β-Glc)-OH whose reaction times were extended to 16−24 h. DOTA(tBu)$_3$ (2.5 equiv relative to the

peptide−resin) was conjugated to the *N*-terminus of the peptide using HATU activation (2.5 equiv) in NMP. The pH was adjusted to 7−8 using DIPEA. Double couplings of DOTA(tBu)$_3$ were performed for the PEG$_4$ derivative. The reaction time for the chelator conjugation usually was 5 h and increased to 18−24 h for derivatives with spacers like PEG$_2$, PEG$_4$, and the sugar moiety. The protected conjugates were cleaved from the resin with 0.5% TFA, 0.5% H_2O, and 20% TFE in DCM. Then, the Cys-Cys disulfide bond formation was achieved with excess of I_2 (10 equiv) in MeOH/H_2O = 9:1. The peptides were deprotected with 5% H_2O, 3% thioanisole, and 3% TIS in TFA for 4−5 h. In the sugar derivative, the O-acetyl groups were cleaved with a solution of N_2H_4/MeOH/H_2O (3:3:4) for 15 min. All compounds were purified by HPLC, lyophilized, and characterized by ESI-MS and RP-HPLC.

[In^{III}-DOTA]−X−NOC. DOTA−X−NOC analogues were complexed with [In^{III}]Cl$_3$, using the following procedure: Approximately 1 mg of the DOTA−X−NOC in 150 μL of 0.2 M sodium acetate buffer (pH 5) and 3 equiv of [In^{III}]Cl$_3$ were incubated at 95 °C for 25 min. After cooling, the complex was purified over a SepPak C18 cartridge (Millipore, Switzerland) preconditioned with 10 mL of MeOH and 10 mL of H_2O. The cartridge was washed with H_2O to remove the excess of [In^{III}]Cl$_3$, followed by the elution with MeOH to recover the desired [In^{III}-DOTA]−X−NOC. After evaporation of MeOH and lyophilization, the In^{III} complexes were characterized by ESI-MS and RP-HPLC with a flow of 0.75 mL/min and a linear gradient: 0−30 min, 10% B to 60% B.

Radiotracers. The radiopeptides were prepared (*9*) by dissolving 10 μg of the DOTA−X−NOC in 150 μL of 0.2 M sodium acetate buffer (pH 5); after addition of [^{111}In]Cl$_3$ (37−148 MBq), the solution was incubated at 95 °C for 25 min to afford the radioligand with a specific activity up to 28 GBq/μmol. [In^{III}]Cl$_3$ was then added and incubated at 95 °C for 25 min. In all cases, a quality control was performed by RP-HPLC with a flow of 0.75 mL/min and a linear gradient: 0−30 min, 10% B to 60% B. For all the preclinical studies, the labeling was performed as described in this section, with an exception for biodistribution studies, where the labeling was carried out accordingly without the addition of [In^{III}]Cl$_3$.

Serum Stability. To 1 mL of freshly prepared human serum, previously equilibrated in a 5% CO_2 (95% air) environment at 37 °C, 0.6 nmol of [^{111}In-DOTA]−X−NOC was added. The mixture was incubated in a 5% CO_2, 37 °C environment. At different time points, 100 μL aliquots (in triplicate) were removed and treated with 200 μL of EtOH. Samples were then cooled (4 °C) and centrifuged for 15 min at 500 *g* and 4 °C to precipitate serum proteins. The supernatants were removed, and the sediment was washed twice with 1 mL of EtOH. The activity in the ethanolic phase and in the proteic precipitate was measured in a γ-counter. Both counts were compared to give the percentage of peptides not bound to proteins or radiometal transferred to serum proteins. The supernatant was checked by HPLC using the equipment mentioned above.

Receptor Binding Assays. CHO-K1 and CCL39 cells stably expressing human sst$_{1-5}$ were grown as described previously (*5*). All culture reagents were supplied by GIBCO/BRL and Life Technologies (Grand Island, NY). Cell membrane pellets were prepared, and receptor autoradiography was performed on pellet sections (mounted on microscope slides) as described in detail previously (*5*). For each of the tested compounds, complete displacement experiments were performed with the universal somatostatin radioligand [^{125}I][Leu^8,D-Trp^{22},Tyr^{25}]somatostatin-28 using increasing concentrations of the unlabeled peptide ranging from 0.1 to 1000 nM. Somatostatin-28 was run in parallel as a control using the same increasing concentrations. IC$_{50}$ values were calculated after quantification of the data using a computer-assisted image processing system. Tissue standards (autoradiographic [^{125}I]microscales Amersham, U.K.) containing known amounts of isotopes, cross-calibrated to tissue-equivalent ligand concentrations, were used for quantification (*5*). The concentrations of the peptide solutions were measured by UV spectroscopy (ϵ_{NOC} 280 nm = 9855 dm^3 mol^{-1} cm^{-1}).

Lipophilicity. Determination of log $D_{(pH=7.4)}$ was performed by the "shake-flask" method: to a solution containing 500 μL of octanol and 500 μL of PBS (pH 7.4) (obtained from saturated octanol-PBS solution), 10 μL of 100 nM [^{111}In-DOTA]−X−NOC derivatives were added. The resulting solutions were vortexed at room temperature and centrifuged at 3000 rpm for 10 min. Aliquots of 100 μL were removed from the octanol and from the saline phase, and the activity measured in a γ-counter. The lipophilicity was calculated as the average log ratio value of the radioactivity in the organic fraction and the PBS fraction from the three samples.

Cell Culture. AR4-2J rat pancreatic tumor cells expressing sst$_2$ were cultured in high-glucose DMEM, enriched with 4 mM glutamine, 10% FBS, amino acids, vitamins, and penicillin−streptomycin from BioConcept (Allschwil, Switzerland). Human embryonic kidney 293 cells stably expressing rat sst$_3$ (HEK-sst$_3$) and sst$_5$ (HEK-sst$_5$) receptors (a gift from Dr. S. Schulz, Magdeburg, Germany) (*32*) were grown in DMEM supplemented with 10% fetal bovine serum, penicillin−streptomycin, and G418 (500 μg/mL). Cells were maintained in a humidified 5% CO_2/air atmosphere at 37 °C. The viability of the cells was assessed using trypan blue stain and counted under a microscope with a "Neubauer's counting chamber".

Internalization Studies. Cells (10^6/well) were distributed in six-well plates at 37 °C in a 5% CO_2/air atmosphere for one night in culture medium (DMEM with 10% FBS). The medium was removed; the cells were washed and incubated for 1 h, with internalization medium (DMEM with 1% FBS) under the same conditions as described above. Approximately 0.02 MBq/well of the radioligand (2.5 pmol/well) was added to the medium, and the cells were incubated at 37 °C, 5% CO_2, with and without excess of NOC (1 μM) to determine nonspecific internalization. At appropriate time periods, the internalization was stopped by removing the medium and washing the cells with ice-cold PBS. To remove the receptor-bound radioligand, an acid wash was carried out twice with a 0.1 M glycine buffer pH 2.8 for 10 min on ice. This procedure permits one to distinguish between membrane-bound (acid-releasable) and internalized radioligand (acid-resistant). Finally, cells were solubilized with 1 N NaOH and incubated for 10 min at 37 °C. The radioactivity of the culture medium, the receptor-bound, and the internalized fractions were measured in a γ-counter.

Externalization Studies. For externalization experiments, the AR4-2J cells (10^6/well) were incubated with 2.5 pmol/well of radioligand. After 2 h internalization at 37 °C and 5% CO_2, the medium was removed and the cells were washed twice with cold PBS. An acid wash was performed, as described in the previous section. Internalization medium (3 mL) was added to each well, and the cells were incubated at 37 °C. At different time points, the external medium was collected and exchanged with 37 °C fresh medium. Thereafter, the cells were treated with 1 N NaOH to extract the internalized radioligand. The radioactivity of the external medium and of the internalized radioligand fractions was quantified in a γ-counter. The recycled fraction was expressed as a percentage of the total internalized amount per 1 million cells.

Biodistribution. All animal experiments were performed in compliance with the Swiss laws on animal protection (approval no. 789). Six-week-old Lewis male rats were implanted subcutaneously with 10 to 12 million of AR4-2J rat pancreatic tumor cells freshly suspended in PBS. Fourteen days after the

[c] Significant differences ($p < 0.05$) between ^{111}In-**1** and other ^{111}In derivatives.

inoculation, the animals were injected in the femoral vein, under anesthesia, with 2−3 MBq of 0.34 nmol [^{111}In-DOTA]−X−NOC diluted in saline solution. For the determination of nonspecific uptake in tumor or receptor-positive organs, rats were coinjected in the femoral vein with 100 μg DOTA−NOC and with the radiotracer in 100 μL saline. At 4 h and 24 h p.i., rats were sacrificed under anesthesia. Tissue samples of blood and organs of interest were collected, weighed, and their radioactivity measured by use of a γ-counter. The percentage of injected activity per gram (% IA/g) was calculated for each tissue. The total counts injected per animal were determined by extrapolation from counts of an aliquot taken from the injected solution. Urine samples were analyzed for possible metabolites by RP-HPLC.

Scintigraphy. For imaging, 0.34 nmol/100 μL of [^{111}In-DOTA]−PEG_4−NOC (3 MBq) was injected into the femoral vein of an AR4-2J tumor-bearing Lewis male rat. The same procedure was applied to another rat coinjected with the same amount of radiotracer and 100 μg/100 μL (64.7 nmol) DOTA−NOC. Four hours after injection, rats were anesthesized and images were acquired in the prone position using a γ-camera equipped with a medium-energy parallel hole collimator (Basicam, Siemens, Erlangen, Germany).

Statistical Method. The correlation between binding affinities and rates of specific internalization was tested using linear regression analysis on *Microsoft Excel*. All data are expressed as the mean ± standard deviation (mean ± SD), otherwise stated. Data comparisons are performed using the Student's t-test where differences at the 95% confidence level ($p < 0.05$) were considered statistically significant.

RESULTS

Syntheses. The synthesis of DOTA−NOC and the new compounds was achieved by Fmoc-based SPPS protocols. With the introduction of spacers, the overall yield of around 30% achieved for DOTA−NOC (*29*) decreased to 17−18% based on the first Fmoc cleavage. All compounds were characterized by ESI-MS and RP-HPLC (Table 1).

Lipophilicity. Log *D* values were determined by the "shake-flask" method using 1-octanol-to-PBS (pH 7.4). The partition coefficient of [^{111}In-DOTA]−NOC (−2.06 ± 0.2) at pH = 7.4 is similar to ^{111}In-**4** and ^{111}In-**5** (−2.13 ± 0.00 and −1.97 ± 0.06) and significantly higher than for the other radiopeptides (Table 1).

Somatostatin Receptor Affinity Profiles. In vitro binding studies were performed using cells stably expressing human sst_1−sst_5 ($hsst_{1-5}$). Affinity profiles of the [In^{III}-DOTA]−X−NOC analogues are summarized in Table 2, with native somatostatin 28 (SS28) as the control peptide, which binds with high affinity to all five hsst subtypes. All newly synthesized compounds bind specifically to $hsst_2$ with IC_{50} values ranging from 1.7 to 5.2 nM. Moderate affinity to $hsst_3$ was found for In^{III}-**4** (33.5 ± 4.9 nM), whereas the IC_{50} values of $hsst_3$ for the remaining analogues were >80 nM. IC_{50} values for $hsst_5$ were found to vary between 3.8 and 44.9 nM.

Serum Stability. Incubation of [^{111}In-DOTA]−NOC and its derivatives in fresh serum at 37 °C showed high metabolic stability with more than 98% of intact analogues after 24 h of incubation.

Internalization/Externalization Studies. The uptake of the new ^{111}In-labeled DOTA−X−NOC conjugates was evaluated using AR4-2J (exclusive sst_2-expression) and HEK-sst_3 cells. All radiolabeled compounds showed time-dependent uptake into AR4-2J cells with high specific internalization rates, as shown in Table 3. After 4 h, ^{111}In-**1** showed 23.9% ± 0.10% specific uptake, and ^{111}In-**4** and ^{111}In-**7** presented 17.50% ± 0.36% and 29.41% ± 3.30%, respectively. Equivalence in the specific internalization rate was observed between ^{111}In-**2** (14.03% ± 0.21%) and ^{111}In-**8** (13.00% ± 1.65%), or between ^{111}In-**3** (19.89% ± 0.92%), ^{111}In-**5** (20.37% ± 0.98%), and ^{111}In-**6** (20.33% ± 0.15%). No internalization in HEK-sst_5 was observed at physiological conditions, receptor subsaturation conditions.

The externalization kinetics was assessed after 2 h of internalization of the radioligand, showing time-dependent behavior (Table 4). Within 4 h, 46.50% ± 1.40% of ^{111}In-**1** were externalized, similar to ^{111}In-**6** (43.74% ± 0.67%) and ^{111}In-**7** (41.70% ± 3.60%). The other radioligands presented 57.32% to 77.52% release from the AR4-2J cells within 4 h. The assessment of the specific internalization rate of the new compounds into sst_3-expressing cells was performed using HEK-sst_3. During 4 h, [^{111}In-DOTA]−NOC and [^{111}In-DOTA]−β-Ala−NOC internalized 14.0% ± 1.8% and 13.1% ± 0.3%, respectively, while all the other radiopeptides showed <2% specific internalization (Table 3).

Biodistribution Studies. Biodistribution was performed in AR4-2J tumor-bearing rats at 4 h and 24 h p.i. to assess the specific uptake of all new radiotracers in sst-receptor-positive and -negative organs (Table 5). The main excretion organ was the kidney for all conjugates. ^{111}In-**6** showed a high uptake in the tumor and in sst-positive organs. Also, in the case of ^{111}In-**2** and ^{111}In-**5**, the adrenals, pancreas, stomach, and pituitary exhibit rather high uptake. The tumor-to-kidney ratio at 4 h p.i. (Figure 1) for ^{111}In-**1** is 2.16, followed by ^{111}In-**6** (1.90), ^{111}In-**5** (1.48), ^{111}In-**2** (1.45), ^{111}In-**7** (0.96), ^{111}In-**4** (0.94), ^{111}In-**3** (0.58), and finally ^{111}In-**8** (0.17).

The coinjection of 68.7 nmol/100 μL of DOTA−NOC with 0.34 nmol/100 μL of the radiolabeled peptide provided a significant blocking for sst-positive organs, as shown for the pancreas and the AR4-2J rat pancreatic tumor (Figure 2).

For all [^{111}In-DOTA]−X−NOC derivatives, urine sample analysis by analytical RP-HPLC at 4 h p.i. showed intact radioligands, which at 24 h p.i were completely degraded (data not shown).

Imaging of Tumor-Bearing Rats. Figure 3 shows the γ-scintigraphy of two Lewis rats bearing AR4-2J tumors 4 h after injection of ^{111}In-**2** without and with (blocked) coinjection of In^{III}-**1** as a blocking agent. This in vivo experiment showed selective binding of ^{111}In-**2** to pancreas and tumor as evidenced by the effective blocking of sst. Although the kidneys and bladder are visible, the fast clearance of this radiotracer from other sst-negative organs is remarkable.

DISCUSSION

Despite all the efforts to improve the pharmacological properties of somatostatin-based radiotracers, at present their effectiveness for targeted radionuclide therapy still is somewhat limited by the pharmacokinetics. Therefore, it is of interest to

understand the pharmacologic properties as a function of different structural parameters. This knowledge may allow predictable ligand functionalization to modulate the pharmacokinetic profile of the sst radiotracers in order to obtain high tumor-to-nontumor ratios.

We performed a systematic study by introducing different spacers between DOTA and NOC to understand their influence on the pharmacokinetics. ^{111}In/^{90}Y-DOTA−NOC was shown to have a broader somatostatin receptor affinity profile than first- and second-generation somatostatin-based radioligands (*30*). In addition, DOTA−NOC labeled to different radionuclides showed superior tumor localization in patients (*30*−*32*) but also a higher general background uptake leading to a higher myelotoxicity in some early therapy attempts (*36*). The latter is possibly due to the higher lipophilicity of radiolabeled DOTA−NOC. Therefore, we decided to use this peptide and introduce different spacer molecules to study their influence on the pharmacokinetics with emphasis on tumor-to-kidney as well as tumor-to-background ratio.

To study the increase in hydrophilicity of radiolabeled DOTA−NOC while preserving its overall net charge, strategies involving its derivatization through polyethylene glycol units or carbohydration were chosen. For that purpose, we employed an asparagine side chain modified with *N*-acetyl glucosamine and two PEGs with different lengths (PEG_2 and PEG_4), ready to use in SPPS protocols. To modulate the overall charge of the radiopeptide with simultaneous increase of hydrophilicity, aspartic acid and lysine were selected. A triglycine spacer was also chosen, as the insertion of this type of cleavable linkers was already successfully employed in the modification of antibodies. The introduction of a spacer based on a triglycine unit between DOTA and $F(ab')_2$ enhanced the tumor uptake, upholding the kidney uptake with the increment of the tumor-to-kidney ratio from 0.7 ± 0.3 to 1.3 ± 0.2 (*37*).

As expected, log $D_{(pH=7.4)}$ values show significantly reduced lipophilicity of the modified ^{111}In-**1** conjugates, with exception for ^{111}In-**4** and ^{111}In-**5**.

The introduction of the spacer influenced the binding affinities to the hsst subtypes in different ways. In general, the $hsst_2$ affinities of the new [In-DOTA]−X−NOC peptides are only marginally influenced by the spacers, except for the neutral compound, ^{111}In-**7**, showing a significant improvement of the $hsst_2$ affinity by a factor of 1.7. The affinity to $hsst_5$ also is not substantially influenced by the spacers, and as for the parent radiopeptide, no affinity to $hsst_1$ and $hsst_4$ was found. Surprisingly, one outcome of the present study is the almost complete loss of $hsst_3$ affinity of the [In^{III}-DOTA]−X−NOC peptides. It is difficult to understand the influence of the spacers on the $hsst_3$ affinity. The spacers increase both the flexibility and the hydrophilicity of the peptides. Higher hydrophilicities explaining the loss of hsst affinity would parallel earlier studies from our laboratories where we showed that lowering the hydrophilicity of DOTA-peptides leads to increased affinity to the $hsst_3$ subtype (*5*, *30*). Only a few structural/conformational studies in solution or in the solid state have been performed with this group of metallopeptides, and only octreotide was studied by X-ray diffraction (*38*). We have recently performed ^{1}H and ^{13}C solution NMR studies along with modeling studies to potentially understand the difference in sst_2 affinity and tumor uptake between [^{67}Ga-DOTA^0,Tyr^3]-octreotide and [^{90}Y-DOTA^0,Tyr^3]-octreotide (*39*). This study showed that the different coordination

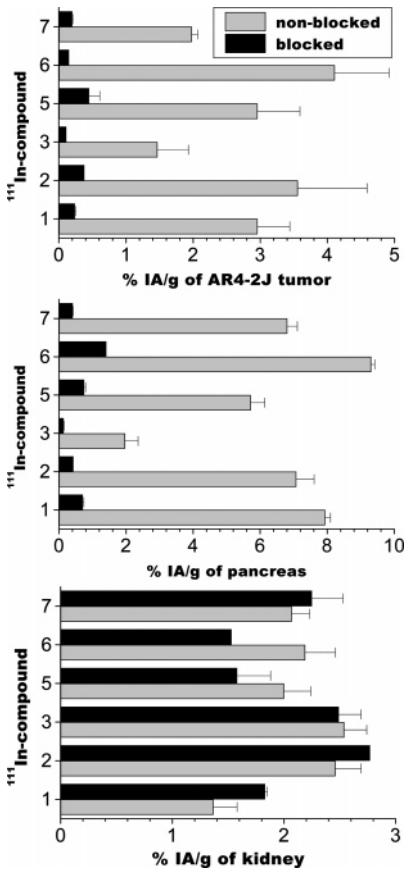

Figure 2. Comparison of biodistribution at 4 h p.i. of some ^{111}In compounds in AR4-2J rat pancreatic tumor, kidney, and pancreas without (nonblocked) and with (blocked) coinjection of excess In^{III}-**1**.

chemistry of Ga^{3+} vs Y^{3+} (6-coordinate and 8-coordinate, respectively) causes differences for the "spacing" D-Phe[1] residue leading to two conformers: they were identified as cis−trans isomers at the amide bond between DOTA and D-Phe[1]. The peptidic part could be characterized by a fast equilibrium of two predominant conformations displaying a helical and sheet-like structure not greatly influenced by the two metals incorporated. Additional conformational analysis is necessary to possibly understand the conformational contribution to subtle differences in biological potency of the metallopeptides.

The internalization of the radioligands in AR4-2J cells clearly correlates with their $hsst_2$ affinity as demonstrated in Figure 4. The best $hsst_2$ affinity of ^{111}In-**7** visibly induces an increased internalization by a factor of 1.2 at 4 h compared to ^{111}In-**1**. The radioligand array used herein presented no internalization into sst_5-transfected cells (HEK-sst_5). This confirms earlier data from our group (*40*) and from Cescato et al. (*41*) who studied sst_5 internalization with high-affinity agonists using immunocytochemical methods. In regard to $hsst_3$ affinity, ^{111}In-**4** was the only tracer that could conserve a moderate affinity for this receptor with a good internalization rate into HEK-sst_3 cells comparable to ^{111}In-**1**. ^{111}In-**5** and the most hydrophilic compounds show low affinities to $hsst_3$ corresponding with their

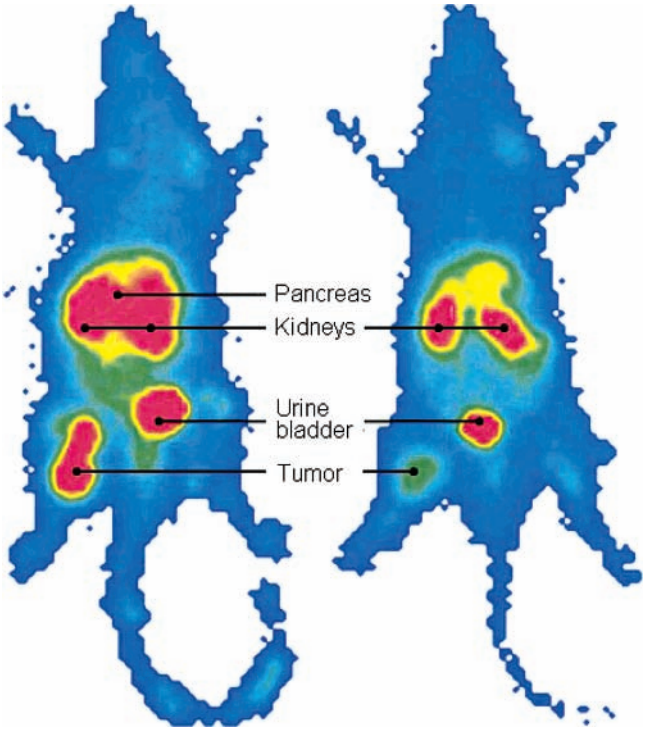

Figure 3. Scintigraphy of two male Lewis rats bearing AR4-2J rat pancreatic tumors after 4 h p.i. of ^{111}In-**2** with (right animal) and without (left animal) coinjection with excess of In^{III}-**1**.

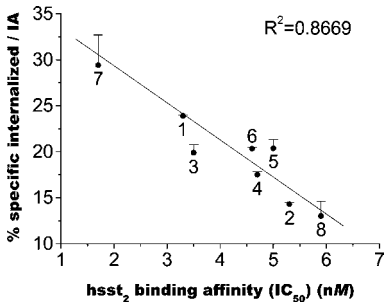

Figure 4. Correlation of rate of internalization at 4 h (% specific internalized/10^6 cells) and $hsst_2$ binding affinity for all metallopeptides involved in this study.

low internalization in HEK-sst_3 cells. In biodistribution studies, the AR4-2J tumor uptake values at 4 h p.i. of ^{111}In-**2**,**4**,**5**,**8** were equivalent to those of ^{111}In-**1**, despite their lower rates of internalization into AR4-2J cells in comparison to ^{111}In-**1**. Unpredictably, the specific uptake in sst-positive organs like the adrenals and the pancreas was in general higher for ^{111}In-**2**,**4**,**5**,**6** compared to ^{111}In-**1**. The contrary was observed for ^{111}In-**3** where the specific uptake in sst-positive organs was lower than for ^{111}In-**1**, as has already been described for [^{125}I]-(PEG_2-octreotate) (*42*). The uptake in the tumor and sst-positive organs is specific as demonstrated by blocking studies using a large excess of DOTA−NOC (Figure 2 and Figure 3). ^{111}In-**6** showed a 1.4-fold increase in the tumor uptake compared to ^{111}In-**1**. Higher tumor uptake was also achieved when glucose was introduced N-terminally into [^{125}I]-TOC via an Amidori reaction (*43*, *44*). This increase was accompanied by a significant 1.6-fold increase in kidney uptake from ^{111}In-**1** to ^{111}In-**6** and an unchanged hepatobiliary radioactivity accumulation.

The optimal features found in our in vitro affinity and internalization studies with ^{111}In-**7** were not conferred into a higher specific tumor uptake in vivo; in fact, tumor uptake decreased 1.5-fold and the kidney uptake increased also 1.5-fold compared to ^{111}In-**1**. Therefore, we could not confirm what previous studies have shown concerning the lowering of the renal accumulation by the introduction of a negative charge between DTPA and a somatostatin-based peptide (*45*, *46*). Moreover, our findings validate previous studies done in our laboratory, showing higher kidney uptake for the negatively charged conjugates (*47*). As expected, the introduction of a positive charge (Lys) into DOTA−NOC significantly increased the kidney uptake, potentially due to megalin (*48*).

Despite the enhancement of the hydrophilicity of most of the new radiopeptides, ^{111}In-**1** presents the lowest renal accumulation among all ligands. This indicates that other elimination mechanisms not controlled by hydrophilicity are active.

CONCLUSIONS

The structural tuning performed in DOTA−NOC did not result in a straightforward correlation between in vivo and in vitro studies, but it indicated a high impact of hydrophilicity and charge on its pharmacokinetic profile. An increased hydrophilicity seems to lead to a lower $hsst_3$ affinity, also resulting in a decreased internalization into sst_3-expressing cells. The excretion profile was found not to depend on the lipophilic character, while it is strongly influenced by the addition of a positive charge leading to a significantly higher renal uptake. Nevertheless, all the new compounds still bind with high affinity to $hsst_2$ and present a high specific internalization into sst_2-expressing cells. This study also indicates that carbohydration of metallopeptides, similar to iodinated radiopeptides, may lead to a higher tumor uptake as for the sugar derivative presented here. They deserve more attention if new conjugates with improved pharmacokinetics will be designed. We hypothesize that, concerning sst_2-overexpressing tumors, ^{111}In/^{90}Y/^{177}Lu-**6** may be superior to ^{111}In/^{90}Y/^{177}Lu-**1** regarding the therapeutic window, as it has a very similar tumor-to-kidney ratio (1.9 vs 2.1) but a higher tumor uptake. Its higher hydrophilicity may lower the background detected in the clinical trials with radiolabeled DOTA−NOC.

ACKNOWLEDGMENT

P. Antunes acknowledges the Ph.D. Fellowship of the Fundação para a Ciência e Tecnologia (ref SFRH/BD/3136/2000). In addition, P. Antunes, M. Ginj, M. Walter, and H. Maecke acknowledge the support from the Swiss National Science Foundation project 3100A0-100390, BBW No. C00.0091, and BBT project 4668.1 EUS. The support provided by Novartis Pharma in respect of ESI-MS analysis is gratefully acknowledged. We thank Dr. S. Schulz for the sst_3-transfected human embryonic kidney 293 cells. The authors thank K. Hinni and S. Tschumi for biological technical assistance. This work was performed within the COST B12 action. The technical personnel of nuclear medicine are acknowledged for imaging the rats.

Received June 16, 2006; Revised Manuscript Received September 21, 2006

Five novel proflavine−dithiazolidinone derivatives **4a**−**4e** have been designed and synthesized by the reaction of dialkyl acridin-3,6-diyl dithioureas **3a**−**3e** with methyl bromoacetate. The binding affinity of dithiazolidinone hydrochlorides **5a**−**5e** with calf thymus DNA and plasmid (pUC19) DNA was investigated by a variety of spectroscopic techniques including UV−vis, fluorescence, and CD spectroscopy. The effects of **5a**−**5e** on the thermal denaturation profiles of calf thymus DNA were also studied. From spectrophotometric and spectrofluorimetric titrations, the binding constants for the pUC19 DNA−drug complexes were determined ($K = 6.2-2.2 \times 10^4$ M^{-1}). In vitro cytotoxic activities of compounds **5a**−**5e** toward murine leukemia cell line L1210 and human uterus carcinoma HeLa cells were also examined. 2′,2″-[(Acridin-3,6-diyl)diimino]-3′,3″-dipropyl-1,3-dithiazolidin-4-one hydrochloride (**5b**) showed the highest activity against these cells with IC_{50} values of 6.3 μM and 12.9 μM over the course of 72 h.

INTRODUCTION

The interactions of small organic molecules with nucleic acids have been the focus of enhanced interest for DNA complexes over the past three decades (*1*). The understanding and recognition of the mode of action has allowed considerable progress to be made in the area of anticancer drug design, including acridinyl derivatives (*2*−*8*). One of the earliest and most well-known agents possessing a mutagenic effect toward DNA and inhibition of protein synthesis (*9*) is 3,6-diaminoacridine (proflavine, **1**). As a consequence, simple acridine compounds such as **1** have been used as antibacterial agents (*10*) and as probes to examine mutagenesis (*11*). Recently, the interaction of **1** with herring sperm DNA was investigated by cyclic voltametry and UV−vis spectroscopy to determine the binding constant (*12*). In our previous work, we observed the binding affinities and estimated the binding constants for *N*-(acridin-9-ylthiocarbamoyl)amino acids with plasmid DNA (pUC 19) (*13*). These findings inspired us to exploit the considerable intercalation capability of the highly fluorescent proflavine chromophore and prepare novel DNA-binding compounds in combination with the biologically active thiazolidinone skeleton. We wanted to ascertain the influence of structural changes on the intercalation properties, in particular, with reference to alkyl chain elongation. UV−vis spectrophotometry, fluorescence titration, circular dichroism (CD), and quantum chemical calculations (AM1) were all used to study the interaction of the compounds with DNA. The anticancer inhibitory effects were also tested against two tumor cell lines, viz., murine leukemia L1210 and human uterus carcinoma HeLa cells.

EXPERIMENTAL PROCEDURES

Materials and Instrumental Techniques. Plasmid isolation and purification processes have been described in detail previously (*14*). Solutions of calf thymus DNA (Sigma Chemical Co.) in TE (Tris-EDTA) buffer were sonicated for 5 min and the DNA concentration determined by absorbance at 260 nm. The purity of the DNA was determined by monitoring the value of A_{260}/A_{280}. UV−vis spectra were measured on a Varian Cary 100 UV−vis spectrophotometer in 0.1 M Tris buffer. Fluorescence measurements were made using a Varian Cary Eclipse spectrofluorometer with a slit width of 10 nm for the excitation and emission beams. Fluorescence intensity is expressed in arbitrary units. Thermal denaturation studies were conducted using a Varian Cary 100 UV−vis spectrophotometer supplied with a thermostatic cell holder. The temperature was controlled by a thermostatic bath (±0.1 °C). CD spectra were recorded on a Jasco J-810 spectropolarimeter in 1 cm quartz cuvettes and are the mean result of three scans from which the buffer background had been electronically subtracted.

AM1 quantum chemical calculations were performed using the Gamess (version 6) program package (*15*).

The binding affinities were calculated using absorbance spectra according to the method of McGhee and von Hippel using data points from a Scatchard plot (*16*, *17*). The binding data were fitted using *Grafit 4* software.

^{1}H (400 MHz) and ^{13}C (100 MHz) NMR spectra were measured on a Varian Mercury Plus NMR spectrometer at room temperature in $CDCl_3$ using TMS as an internal standard (0 ppm for both nuclei). IR spectra were recorded on a Specord 75 IR spectrophotometer (Zeiss, Jena) as KBr discs (0.8 mg/300 mg KBr). Melting points were determined with a Koffler hot-stage apparatus and are uncorrected. Elemental analyses were performed on a Perkin-Elmer CHN 2400 analyzer. Reactions were monitored by thin-layer chromatography (TLC) using Silufol plates with detection at 254 nm. Preparative column chromatography was conducted using Kiesegel Merck 60 column, type

9385 (grain size 250 nm), or aluminum oxide Merck 90 neutral (grain size 200 nm).

Murine leukemia cell line (L1210) and human uterus carcinoma cells (HeLa) were obtained from the American Type Culture Collection (Rockville, MD). The L1210 cell line was kept in a RPMI 1640 medium supplemented with 10% fetal calf serum (FCS) (Grand Island Biological Co., Grand Island, NY), penicillin (100 units/mL), and streptomycin (100 μg/mL). HeLa cells were grown as monolayers in DMEM (Dulbecco's Modified Eagle's Medium, Sigma) supplemented with 10% FCS and antibiotics penicillin (100 units/mL) and streptomycin (100 μg/mL). Trypsin (0.25%, Boehringer, Mannheim) was routinely used for subculture. The cells were incubated at 37 °C in a humidified atmosphere of 5% CO_2/95% air. Cell viability in the presence or absence of the experimental agent was determined using the MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-dimethyl tetrazolium bromide; Sigma) microculture tetrazolium assay as described previously (*18, 19*). Cells harvested in the log phase of growth were counted and seeded (2.5×10^4 cells/100 μL well) in 96-well microtiter plates. After 24 h of incubation at 37 °C and 5% CO_2, cultures were treated with varying concentrations of a drug. After 45 h or 69 h exposure to the compound, MTT (50 μL, 1 mg/mL) was added to each well. After 3 h, the cell cultures were centrifuged, the supernatant discarded, and then the resulting pellets thoroughly extracted into 200 μL of DMSO. Absorption at 540 nm was recorded using the MicroPlate Reader (Labsystem Multiscan, Multisoft, Finland). The MTT assay was performed three times for each compound.

DNA fragmentation in HeLa and L1210 cells was measured after extraction of the DNA from a constant number of cells. After treatment of both cells lines for 24 h, 2×10^6 cells were collected and washed twice with cold PBS, resuspended in 200 μL TE lytic solution (10 mM Tris (pH 8.0), 1 mM EDTA, 0.5% Triton X-100) and incubated for 10 min with RNase (2.5 mg/mL) at 50 °C and then with proteinase K (2.5 mg/mL) for 30 min at 50 °C. The DNA was extracted with NaCl (1 mM), EDTA (1 mM), and 2-propanol (200 μL) for 6 h at −20 °C. After centrifugation, the DNA precipitates were washed with ethanol, resuspended in TE (Tris-EDTA) buffer and then separated by electrophoresis over a 1.5% agarose gel containing ethidium bromide (0.5 μg/mL) and the running buffer TAE (40 mM Tris-acetate, 1 mM EDTA, pH 8.0). The gel was run at 6 V/cm for 45 min after which it was photographed under UV transillumination.

Synthesis of 3,6-Diisothiocyanatoacridine (2). An aqueous solution (40 mL) of Na_2CO_3 (400 mg) was added dropwise during 1 h to a well-mixed suspension of 3,6-diaminoacridine hemisulfate hydrate (500 mg, 1.93 mmol) and thiophosgene (0.296 mL, 3.87 mmol) in chloroform (50 mL). Following this, a saturated aqueous solution of $NaHCO_3$ was slowly added until pH 8 was attained (approximately 2 h). The organic layer was then separated and the water layer extracted with chloroform (3×15 mL). The combined organic fractions were collected and dried over $CaCl_2$. After filtration, the solution was evaporated in vacuo leaving behind the dark red crude product (approximately 500 mg). The crude product was then taken up in chloroform (100 mL) and purified by flash chromatography over neutral alumina using chloroform (50 mL) as the eluent to provide 300 mg of dark yellow solid product. Yield: 60%, mp 195−197 °C. IR (KBr, cm^{-1}): 2012 (NCS), 1607 (C═C). ^{1}H NMR ($CDCl_3$, TMS/ppm): δ 8.73 (s, 1H, C*H*-9), 7.99 (m, 2H, C*H*-4,5), 7.97 (m, 2H, C*H*-1,8), 7.38 (dd, 2H, C*H*-2,7, J = 1.70 Hz, J = 8.90 Hz). ^{13}C NMR ($CDCl_3$, TMS/ppm): δ 149.12 (C-4a,10a), 138.57 (NCS), 136.41 (C-9), 133.98 (C-3,6), 130.12 (C-1,8), 124.97 (C-8a,9a), 124.74 (C-2,7), 124.16 (C-4,5). Anal. calculated for $C_{15}H_7N_3S_2$ (293.37): C, 61.41; H, 2.41; N, 14.32. Found: C, 61.37; H, 2.37; N, 14.13.

General Procedure for the Preparation of 1′,1″-(Acridin-3,6-diyl)-3′,3″-dialkyldithioureas 3a−3e. To a methanol (3 mL) suspension of 3,6-diisothiocyanatoacridine (50 mg, 0.17 mmol), a ten-molar excess of the appropriate amine was added. The reaction mixture was stirred for approximately 1 h while the progress of the reaction was monitored by TLC (toluene/acetone 3:1) until completion. The solid product was filtered off and dried in vacuo.

1′,1″-(Acridin-3,6-diyl)-3′,3″-diethyldithiourea (**3a**). Yield: 65%, mp 228−230 °C. ^{1}H NMR (DMSO, TMS/ppm): δ 9.93 (bs, 2H, 2 × N*H*), 8.86 (s, 1H, C*H*-9), 8.27 (s, 2H, C*H*-4,5), 8.21 (bs, 2H, 2 × N*H*), 8.02 (d, 2H, C*H*-1,8, J = 9.20 Hz), 7.59 (d, 2H, C*H*-2,7, J = 9.20 Hz), 3.53−3.60 (m, 4H, 2 × NC*H*$_2$), 1.18 (t, 6H, 2 × C*H*$_3$, J = 7.04 Hz). ^{13}C NMR (DMSO, TMS/ppm): δ 179.78 (CS), 149.27, 141.25, 134.95, 128.56, 122.59, 122.45, 115.91, 48.49 (NCH_2), 13.92 (CH_3). Anal. calculated for $C_{19}H_{21}N_5S_2$ (383.54): C, 59.50; H, 5.52; N, 18.26. Found: C, 59.30; H, 5.25; N, 18.20.

1′,1″-(Acridin-3,6-diyl)-3′,3″-dipropyldithiourea (**3b**). Yield: 62%, mp 222−223 °C. ^{1}H NMR (DMSO, TMS/ppm): δ 9.93 (bs, 2H, 2 × N*H*), 8.86 (s, 1H, C*H*-9), 8.32 (s, 2H, C*H*-4,5), 8.21 (bs, 2H, 2 × N*H*), 8.02 (d, 2H, C*H*-1,8, J = 8.60 Hz), 7.59 (d, 2H, C*H*-2,7, J = 8.60 Hz), 3.46−3.53 (m, 4H, 2 × NC*H*$_2$), 1.56−1.66 (m, 4H, 2 × C*H*$_2$), 0.94 (t, 6H, 2 × C*H*$_3$, J = 7.81 Hz). ^{13}C NMR (DMSO, TMS/ppm): δ 180.08 (CS), 149.21, 141.40, 135.02, 128.54, 122.57, 122.43, 115.78, 45.62 (NCH_2), 21.55 (CH_2), 11.37 (CH_3). General Procedure for the Preparation of 2′,2″-[(Acridin-3,6-diyl)diimino]-3′,3″-dialkyl-1,3-dithiazolidin-4-ones 4a−4e and the Corresponding Hydrochlorides 5a−5e. To a

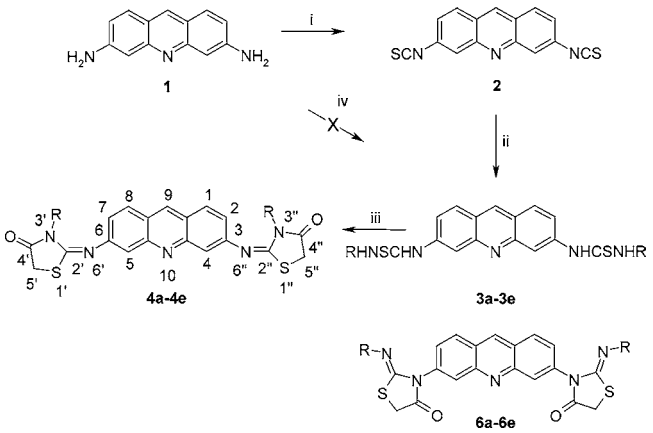
dichloromethane (3 mL) suspension of the appropriate thiourea (0.13 mmol), triethylamine (0.04 mL, 0.286 mmol) was added. The mixture was stirred well for 10 min, followed by the addition of methyl bromoacetate (0.03 mL, 0.316 mmol), and monitored by TLC (toluene−acetone 3:1) until completion, at which time the reaction mixture was homogeneous. The solvent was evaporated in vacuo and the crude product purified over silica gel (toluene−acetone 3:1 as eluent). To produce **5**, the product **4** was dissolved in acetone (0.5 mL), and an equimolar solution of HCl in methanol (1 mL of 35% hydrochloric acid in 9 mL of methanol) was added. The mixture was stirred for 1 h followed by the addition of diethyl ether. The resulting precipitant was filtered off and dried in vacuo.

2′,2″-[(Acridin-3,6-diyl)diimino]-3′,3″-diethyl-1,3-dithiazolidin-4-one (**4a**). Yield: 71%; yellow oil. ^{1}H NMR ($CDCl_3$, TMS/ppm): δ 8.68 (s, 1H, C*H*-9), 7.98 (d, 2H, C*H*-1,8, J = 8.80 Hz), 7.70 (s, 2H, C*H*-4,5), 7.20 (d, 2H, C*H*-2,7, J = 8.80 Hz), 3.99 (q, 4H, 2 × NCH_2, J = 7.20 Hz), 3.84 (s, 4H, 2 × SCH_2), 1.36 (t, 6H, 2 × CH_3, J = 7.20 Hz). ^{13}C NMR ($CDCl_3$, TMS/ppm): δ 171.53 (CO), 155.03 (CN), 150.14, 150.05, 135.72, 129.58, 124.04, 122.88, 116.96, 38.44 (NCH_2), 32.88 (SCH_2), 12.55 (CH_3). Anal. calculated for **5a**, $C_{23}H_{21}N_5O_2S_2$·HCl, yellow solid (500.05), mp 215−216 °C: C, 55.25; H, 4.43; N, 14.01. Found: C, 55.43; H, 4.39; N, 13.89.



2′,2″-[(Acridin-3,6-diyl)diimino]-3′,3″-dipropyl-1,3-dithiazolidin-4-one (**4b**). Yield: 65%; yellow oil. ^{1}H NMR ($CDCl_3$, TMS/ppm): δ 8.69 (s, 1H, C*H*-9), 7.97 (d, 2H, C*H*-1,8, J = 8.80 Hz), 7.74 (s, 2H, C*H*-4,5), 7.20 (d, 2H, C*H*-2,7, J = 8.80 Hz), 3.89 (t, 4H, 2 × NCH_2, J = 7.20 Hz), 3.84 (s, 4H, 2 × SCH_2), 1.77−1.86 (m, 4H, 2 × CH_2), 1.02 (t, 6H, 2 × CH_3, J = 7.20 Hz). ^{13}C NMR ($CDCl_3$, TMS/ppm): δ 171.72 (CO), 155.12 (CN), 150.25, 149.87, 135.14, 129.84, 123.05, 122.55, 116.35, 43.66 (NCH_2), 32.38 (SCH_2), 19.79 (CH_2), 10.91 (CH_3). Anal. calculated for **5b**, $C_{25}H_{25}N_5O_2S_2$·HCl, yellow solid (528.10), mp 178−180 °C: C, 56.86; H, 4.96; N, 13.26. Found: C, 56.70; H, 4.89; N, 13.29.

Scheme 1. Synthesis of the Novel Proflavine Derivatives 4a−4e[a]

[a] Reagents and conditions: R = ethyl - **a**; *n*-propyl - **b**; *n*-butyl - **c**; *n*-pentyl - **d**; *n*-hexyl - **e**; (i) $CSCl_2$, $CHCl_3/H_2O$, Na_2CO_3, RT; (ii) RNH_2, CH_3OH, RT; (iii) $BrCH_2CO_2CH_3$, CH_2Cl_2, RT; (iv) RNCS, CH_2Cl_2, RT.

RESULTS

Synthesis of the Novel Proflavine Derivatives 4a−4e. The reaction course for the synthesis of 2′,2″-[(acridin-3,6-diyl)-diimino]-3′,3″-dialkyl-1,3-dithiazolidin-4-ones **4a**−**4e** is depicted in Scheme 1. Physicochemical values as well as the methods used for the structure determination are given in the Experimental Procedures section.

Spectroscopic Properties. The absorption spectra of proflavine derivatives **5a**−**5e** with pUC19 DNA all exhibited broad absorption bands in the region 250−500 nm and the spectra of the acridine derivatives significant absorption peaks in the range 350−460 nm. Figure 1 provides an example illustrating the characteristic changes in the absorption spectra during titration

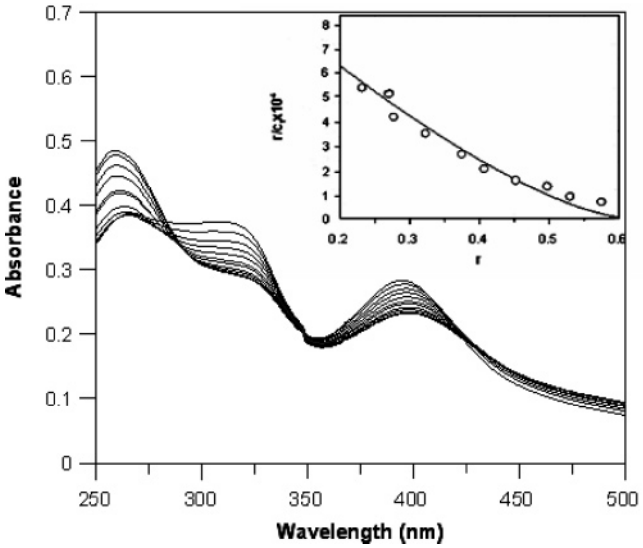

Figure 1. Absorption titration of compound **5b** (2.6 μM) in 0.1 M Tris buffer (pH 7.4) with increasing concentration of pUC19 DNA (from top to bottom: 0, 2, 4, 6, 8, 10, 12, 14, 16, 18, and 20 μM bp). Inset: Scatchard plot of **5b** complexation.

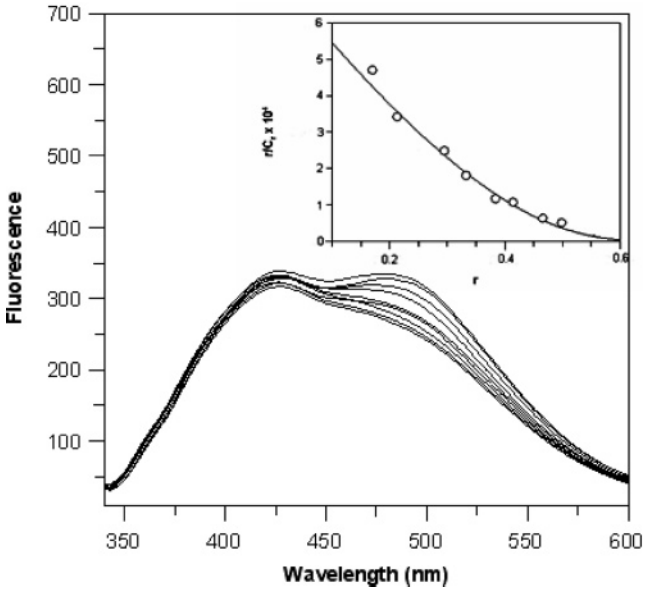

Figure 2. Changes in emission fluorescence spectra of **5b** (5.2 μM) in 0.1 M Tris buffer (pH 7.4) with increasing concentration of pUC19 DNA from top to bottom: 0, 25, 41, 62, 83, 101, 124, 145, and 163 μM bp; λ_{ex} = 320 nm. Inset: Scatchard plot of **5b** complexation.

of compound **5b** with increasing amounts of pUC19 DNA. The binding of the drugs to DNA was characterized by bathochromic shifts and marked hypochromism. The red shift of the drug absorption band was pronounced with **5c** and **5d**, whereas only mild shifts occurred for **5a**, **5b**, and **5e** (Table 1).

The representative fluorescence spectra of **5b** with pUC19 DNA were obtained by the addition of the DNA to the drug solution which resulted in a decrease of fluorescence (Figure 2). Similar fluorescence quenching was observed for all investigated derivatives.

Binding parameters for the interactions of **5a**−**5e** with DNA obtained from spectrophotometric and spectrofluorimetric analysis are summarized in Table 2. Correlation of the chain length (Å) of the alkyl substituents in **5a**−**5e** with the DNA binding constants *K* obtained from spectrophotometry ($k = -2.135$; $r = 0.965$; $S = 0.572$) and spectrofluorimetry ($k = -1.512$; $r = 0.983$; $S = 0.159$) are depicted in Figure 3.

As seen in Figure 4, the addition of **5b** to calf thymus DNA induced a slight increase of the CD signal centered at 275 nm

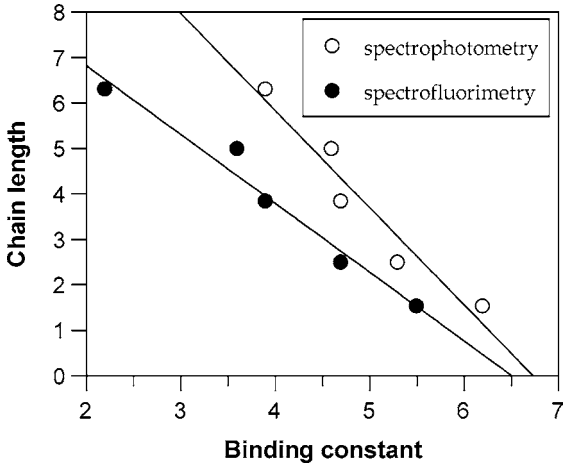

Figure 3. Correlation of the chain length (Å) of the alkyl substituents in **5a**−**5e** with the DNA binding constants *K* obtained from spectrophotometry ($k = -2.135$; $r = 0.965$; $S = 0.572$) and spectrofluorimetry ($k = -1.512$; $r = 0.983$; $S = 0.159$).

and the negative peak at 243 nm. Similar CD changes were also observed for the complexes with the other drugs.

Figure 5 provides thermal denaturation curves of DNA melting experiments for the calf thymus DNA in the presence of **5a**−**5e**, whose T_m values are presented in Table 1.

AM1 Calculations. To establish the steric structure of the intercalators under study, AM1 calculations were performed (Figure 6, Table 3).

Cytotoxic Activity in Vitro. The inhibitory effects of compounds **5a**−**5e** against two tumor cell lines (L1210, HeLa) were tested and the resulting concentration−response curve plotted. The concentrations that produced 25% (IC_{25}) or 50% (IC_{50}) inhibition of cell viability were calculated and the results collected in Table 4. Effects of **5b** on the viability of HeLa (A) and L1210 cells (B) incubated for 0−72 h without (control) or with 0−100 μM **5b** are shown in Figure 7. Changes of cells morphology have been examined using fluorescent and light microscopy (Figure 8). The induction of apoptosis by **5b** in L1210 and HeLa cells has been evaluated by electrophoresis of fragmented DNA (Figure 9).

DISCUSSION

We report an efficient strategy for the synthesis of novel proflavine−dithiazolidinone derivatives. As the starting com-

[a] The fluorescence quantum yields were calculated using 2′,2″-[(acridin-3,6-diyl)diimino]-3′,3″-dihexyl-1,3-dithiazolidin-4-one hydrochloride (**5e**) as a standard ($\Phi_f = 1$). [b] The standard Gibb's free energy change ($\Delta G° = -RT \ln K$) for derivatives **5a**−**5e** is approximately −26.52 kJ mol^{-1} at 25 °C, thereby indicating the spontaneity of the binding with DNA.

pound for the preparation of newly designed intercalators, the commercially available proflavine hemisulfate was used. We attempted to prepare the intermediate thioureas **3a**−**3e** by the treatment of the free base proflavine (**1**) with aliphatic isothiocyanates to incorporate aliphatic chains into the resulting structures. The free base was obtained by the addition of triethylamine to the solution of proflavine hemisulphate in a mixture DMSO/methanol, then poured into brine, and the resulting precipitate filtered off and dried overnight in vacuo. Unfortunately, the reaction of **1** did not proceed even with a ten-molar excess of ethylisothiocyanate and 30 h heating. In addition, proflavine (**1**) as the free base underwent decomposition during the course of the reaction, and an attempt to carry out the reaction with free base **1** released in situ also failed. The reason for these failures is probably the poor nucleophilicity of the amino group in **1** and the low electrophilicity of the NCS carbon of the alkylisothiocyanates. The problem was circumvented by preparing thioureas **3a**−**3e** using a reverse approach via reaction of the corresponding alkyl amines with the novel synthon, 3,6-diisothiocyanatoacridine (**2**) (*20*). To obtain a higher yield of **2**, the synthesis was reduced to a one-pot procedure by in situ reaction of free base **1** with thiophosgene.

Table 3. Structural and Electronic Features of Proflavine−Thiazolidinone Derivatives 4a−4e

structural/electronic parameters	compound				
	4a	**4b**	**4c**	**4d**	**4e**
φ (C4−C3−N6′−C2′)	104.57°	104.60°	105.56°	105.08°	105.28°
φ (C5−C6−N6″−C2″)	104.33°	104.63°	105.51°	104.94°	105.07°
alkyl chain length (Å)	1.52	2.48	3.83	4.98	6.29
dipole moment (D)	2.02	1.98	1.92	1.89	1.88

Diisothiocyanate **2** reacted readily with the amines in methanol, whereas in chloroform, toluene, and methylene chloride, decomposition of the products was observed. The obtained thioureas **3a**−**3e** were filtered off and dried in vacuo. Because of their low stability, they were immediately employed after drying in the subsequent reaction. Aliphatic nonbranched amines were used to study the structural dependence of the chain length vs DNA intercalation capability of the final products **5a**−**5e**. For the preparation of the corresponding thiazolidin-4-ones **5a**−**5e**, our previous experience with the regioselectivity of thiazolidin-4-one formation was exploited (*21*). The synthesis was performed by the reaction of methyl bromoacetate with thioureas **3a**−**3e** in the presence of triethylamine under anhydrous conditions; the resulting products **4a**−**4e** were obtained pure by column chromatography over silica gel. The regioselective formation of the product **4a** was proven by a gHMBC NMR experiment revealing a cross peak between the methylene signal of the ethyl group and the carbonyl carbon. In the case of compounds **4b**−**4e**, the structure was verified by the presence of a SCH_2 signal at ca. 3.8 ppm, typical for regioisomers analogous to **4** (*21*−*23*). To enhance their water solubility, the products **4a**−**4e** were converted to their corresponding hydrochlorides **5a**−**5e**. The alternative regioisomers **6a**−**6e** were not observed.

Electronic absorption spectra of the synthesized derivatives exhibited significant absorptions in the range 350−460 nm, which are typical for transitions between the π-electronic energy levels of the acridine ring.

To obtain additional information on the new proflavine derivatives **5a**−**5e**, fluorescence measurements were also performed. The fluorescence spectra of the proflavine derivatives **5a**−**5e** each exhibited a broad absorption band in the range 350−600 nm. Differences were found in the fluorescence intensities of the compounds with the highest intensity displayed by the derivative **5e**.

Binding constants (K) and neighbor exclusion parameters (n) clearly indicate a direct dependence between the structural changes and the resulting intercalation capability. Because n ranges from 2.1 to 3.9, multiple-site binding is occurring which affects interaction at the neighboring sites. Aslanoglu (*12*) determined the binding constant ($K = 2.32 \times 10^4$ M^{-1}) and the binding site size ($n = 2.07$ bp) for the interaction between proflavine and DNA. Our binding constants determined by UV−vis measurements ranged above this from 3.9 to 6.2×10^4 M^{-1}

[a] Cell viability was evaluated by MTT assay. Cells were incubated for 0−72 h without (control) or with 0−100 μM of compound. IC_{25} and IC_{50} are concentrations that produced 25% and 50%, respectively, inhibition of cell viability. ND: inhibition was not obtained (IC_{50} > 100 μM). Results are expressed as a mean ± S.D. (n = 3).

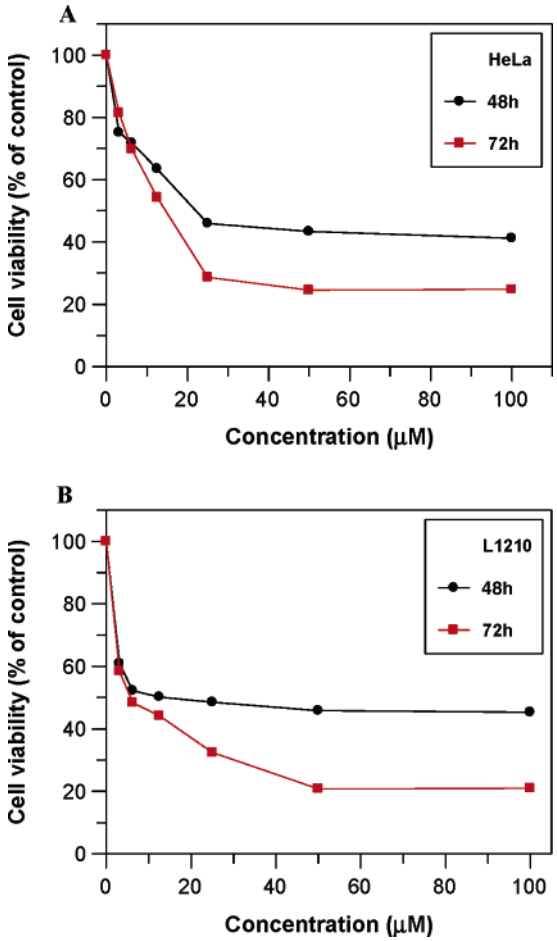

Figure 7. Effects of **5b** on the viability of HeLa (A) and L1210 cells (B). Cells were incubated for 0−72 h without (control) or with 0−100 μM **5b**. Cell viability was evaluated by MTT assay. Results are expressed as a percentage of the control.

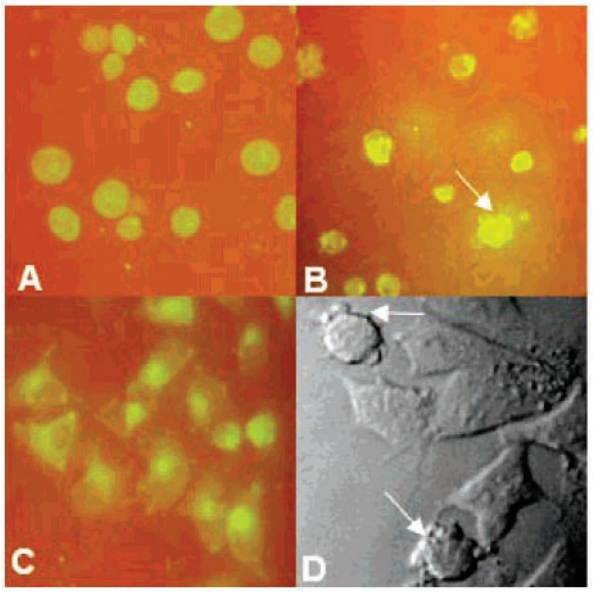

Figure 8. Morphology of leukemia cells L1210 (A,B) and cervical carcinoma HeLa cells (C,D) treated with **5b** (24 h incubation, 10 μM). Magnification 400×. Image A: control L1210 cells stained with Hoechst 44433 and propidium iodide. Images A, B, and C were obtained using a fluorescence microscope and image D using a light microscope. Arrows indicate membrane blebbing.

and by spectrofluorimetry from 2.2 to 5.5 × 10^4 M^{-1} while the binding site sizes were similar to the value determined by Aslanoglu. The slight changes are induced by the thiazolidinone moiety on the proflavine skeleton which is supposed to stabilize the double helix DNA structure. This interpretation was also supported by thermal denaturation studies.

The melting of DNA is a phenomenon observed when the double-stranded DNA molecules are heated and separate into two single strands; it occurs due to the disruption of the intermolecular forces such as $\pi-\pi$ stacking and hydrogen-bonding interactions between the DNA base pairs. DNA melting experiments revealed that the T_m of calf thymus DNA (76 °C) increases in the presence of **5a**−**5e** to within the range 77−80 °C. An increase in the helix stabilization is due to intercalation of proflavine−dithiazolidinone derivatives into DNA.

To elucidate the drug binding mechanism, CD was also used. It is one of the spectroscopic methods most amenable for determining a drug-binding mode. Changes in the CD spectrum of DNA as a result of complexation can often be ascribed to alteration of the DNA structure. Agents intercalating into the DNA generally give no induced CD or weakly negative signals in the drug absorption band (*24*). Our observations suggest that intercalation exists between **5a**−**5e** and calf thymus DNA.

To determine the steric effects of the drugs, AM1 calculations were performed. From these studies, it was deduced that the structure depicted in Figure 6 is the most suitable for DNA intercalation. The results indicate that steric influence on the size of the binding constants is negligible, as the values of the analogous dihedral angles of the thiazolidin-4-one and proflavine rings were nearly identical. However, Joseph et al. demonstrated that, by introducing a subtle steric factor, one could alter the DNA binding properties of aryl-substituted acridinium derivatives (*25*).

The values of the dipole moments, which are related to some extent to the polarity, can be considered a measure of lipophilicity of **5a**−**5e** (Table 3). Despite only small differences in the values of the binding constants, we have found that there exists a linear correlation between the chain length (Å) and binding ability.

The cells showed different responses to the tested compounds, though the L1210 cells appeared to be more sensitive than the HeLa cells. The results clearly indicate that substances **5a**−**5c** possess strong cytotoxic effects toward cancer cell lines. In the present study, **5b** is one of the most effective compounds in

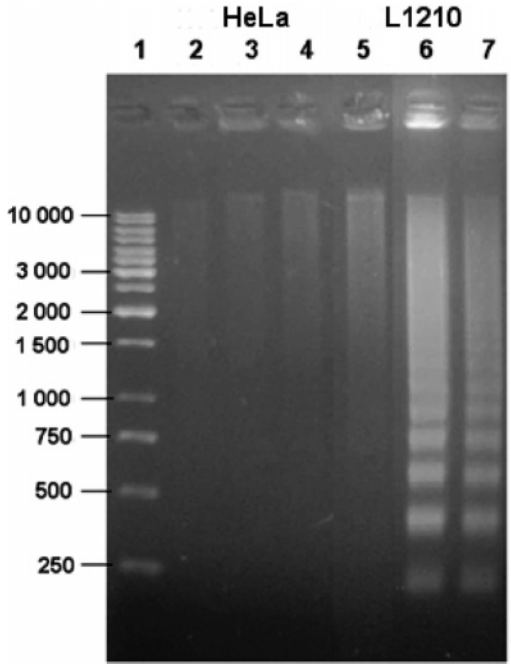

Figure 9. Agarose gel electrophoresis of DNA fragments from cells treated with **5b**. HeLa and L1210 cells were incubated with **5b** (5 or 10 μM) for 24 h. DNA fragmentation was visualized by ethidium bromide after DNA agarose gel electrophoresis. Lane 1: size marker (10000−250 bp). HeLa cells: lane 2, control; lane 3, treated with 5 μM **5b**; lane 4, treated with 10 μM **5b**. L1210: lane 5, control; lane 6, treated with 5 μM **5b**; lane 7, treated with 10 μM **5b**.

terms of its ability to inhibit proliferation in a time- and dose-dependent manner (IC_{50} 6.3 and 12.9 μM; 72 h treatment). Incubation of cells in the presence of **5b** at concentrations higher than 3 μM resulted in significant growth inhibition. The ability of **5b** to inhibit cancer cell proliferation and the aforementioned properties of drug binding into DNA suggests that this compound could cause apoptosis, also known as programmed cell death. Apoptosis is characterized by distinct morphological features such as cell shrinkage, chromatin condensation, plasma membrane blebbing, oligonucleosomal DNA fragmentation, and finally, the breakdown of the cell into smaller units.

Changes in cell morphology were examined using fluorescent microscopy to predict mode of death induced by **5b**. The fluorescence of **5b** is sufficient for intracellular localization of this drug and propidium iodide was utilized for identification of necrotic cells. The altered morphology of L1210 cells was evident after 24 h treatment with 10 μM **5b** (20% of necrotic cells), and this compound was accumulated by L1210 cells which clearly exhibited cytoplasmic blebbing (a hallmark of apoptosis) and shape irregularity (Figure 8B). When human cervical carcinoma HeLa cells were treated with 10 μM **5b**, the nuclei and the cytoplasms exhibited green fluorescence (Figure 8C), and although necrotic features were not observed, membrane blebbing was evident (Figure 8D).

In addition to characteristic changes in morphology, the induction of apoptosis by **5b** in L1210 and HeLa cells has been evaluated by electrophoresis of fragmented DNA. L1210 cells cultured with **5b** (5 μM or 10 μM) for 24 h exhibited a characteristic DNA ladder pattern of apoptosis. Negligible cleavage of DNA into nucleosomal fragments was seen with **5b**-treated HeLa cells. Since drug action usually requires internalization of the drug, a high rate of uptake of the most potent antiproliferative drug **5b** by L1210 was confirmed (about 50% of **5b** was accumulated after rapid incubation of the cells with the compound).

A linear correlation between the binding constants of **5a**−**5e** to DNA and the length of the alkyl chain has been established whereby the binding affinity decreases with increasing length of the side chain. All of the compounds displayed cytotoxic activity in vitro and inhibited the growth of cancer cells. We can therefore summarize that the newly synthesized molecules afford interesting possibilities to develop novel DNA-targeted anticancer agents.

ACKNOWLEDGMENT

This work was supported by the Slovak Grant Agency VEGA, grants no.1/1274/04, 1/1173/04, 1/ 1272/04, and 1/2471/05 and by the State NMR Programme no. 2003SP200280203. Dr. Karel D. Klika is thanked for correction of the language and assistance in manuscript preparation.

Received June 18, 2006; Revised Manuscript Received October 5, 2006

The objective of the present study was to construct epidermal growth factor receptor (EGFR) targeting cetuximab-immunoliposomes (ILs) for targeted delivery of boron compounds to EGFR(+) glioma cells for neutron capture therapy. The ILs were synthesized by using a novel cholesterol-based membrane anchor, maleimido-PEG-cholesterol (Mal-PEG-Chol), to incorporate cetuximab into liposomes by either surface conjugation or a post-insertion method. For post-insertion, the transfer efficiency of MAb conjugates from micelles to liposome was examined at varying temperatures, $mPEG_{2000}$-DSPE ratios, and micelle-to-liposome lipid ratios. Following this, the cetuximab-ILs were evaluated for targeted delivery of the encapsulated boron anion, dodecahydro-*closo*-dodecaborate (2−) ($B_{12}H_{12}^{2-}$), to human EGFR gene transfected $F98_{EGFR}$ glioma cells as potential delivery agents for boron neutron capture therapy (BNCT). In addition, cellular uptake of cetuximab-ILs, encapsulating a fluorescence dye, was analyzed by confocal fluorescence microscopy and flow cytometry, and boron content was quantified by ICP−MS. Much greater (∼8-fold) cellular uptake of boron was obtained using cetuximab-ILs in EGFR(+) $F98_{EGFR}$ compared with nontargeted human IgG-ILs. On the basis of these observations, we have concluded that cholesterol can serve as an effective anchor for MAb in liposomes, and cetuximab-ILs are potentially useful delivery vehicles for BNCT of gliomas.

INTRODUCTION

Boron neutron capture therapy (BNCT) is a binary therapeutic modality based on tumor-selective delivery of boron-10 followed by external radiation with low energy (e.g., ∼0.025 keV) thermal neutrons. The resulting neutron capture and fission reactions produces high linear energy transfer (LET) α-particles and recoiling ^{7}Li nuclei ($^{10}B + {}^{1}n \rightarrow [{}^{11}*B] \rightarrow {}^{4}He\ (\alpha) + {}^{7}Li +$ 2.39 MeV), which are highly lethal to both proliferating and nonproliferating cells. Currently, BNCT primarily has been used to treat high-grade brain tumors, such as glioblastoma multiforme (GBM) and anaplastic astrocytomas (AA) (*1*−*3*). The efficacy of BNCT is highly dependent upon the selective delivery of a sufficient amount of ^{10}B (∼20 μg/g tumor) to tumor cells to sustain a lethal ^{10}B (n, α)^{7}Li capture reaction (*4*, *5*).

Liposomes, which are spherical vehicles formed by a phospholipid bilayer, are attractive drug carriers due to their biocompatibility and capacity to carry both hydrophobic and hydrophilic drugs (*6*, *7*). Encapsulation of drugs into liposomes significantly alters their pharmacokinetics and biodistribution, which may result in reduced toxicity and an expanded therapeutic window. Nontargeted liposomes rely on "passive targeting" to accumulate in solid tumors due to their porous vascular endothelium, reduced lymphatic drainage, and the resulting enhanced permeability and retention (EPR) effect (*8*, *9*). In order to increase tumor-specific delivery, liposomes can be linked to tumor targeting ligands (*10*) such as antibodies to produce immunoliposomes (ILs) (*11*, *12*), receptor ligands such as folate, transferrin, and epidermal growth factor (EGF)-liposomes (*13*, *14*), as well as peptides such as RGD-liposomes (*15*, *16*).

The EGF receptor (EGFR) frequently is overexpressed in GBM and AA but is undetectable or weakly expressed in the normal brain (*17*, *18*). Therefore, EGFR is an attractive molecular target for the specific delivery of therapeutic agents to high-grade gliomas. Delivery of ^{10}B-containing agents via liposomes conjugated to the anti-EGFR monoclonal antibody (MAb) cetuximab (C225) and L8A4, which is directed against $EGFR_{vIII}$, is an attractive approach for BNCT because of their high payload capacity (*4*, *19*). The use of EGFR-targeting boron-containing bioconjugates as delivery agents for BNCT of brain tumors has been a major focus of our laboratories (*4*, *19*−*22*). Highly boronated polyamidoamine (PAMAM) dendrimers have been linked to either EGF (*19*), cetuximab (*22*), or L8A4 (*23*) for targeted delivery of ^{10}B to gliomas. In order to bypass the blood−brain barrier, the bioconjugates have been administered by either direct intratumoral (i.t.) injection (*19*) or by convection-enhanced delivery (CED) (*21*, *23*). These studies, carried out in rats bearing either EGFR or $EGFR_{vIII}$ human gene transfected rat gliomas, designated $F98_{EGFR}$ or $F98_{EGFRvIII}$, respectively, have resulted in a doubling or tripling of the mean survival times (MST) compared to untreated control animals, thereby establishing *proof-of-principle* for the use of these agents.

To construct ILs, antibodies can be linked to the liposome surface via noncovalent or covalent coupling (*10*). Noncovalent coupling usually is accomplished by using biotinylated antibodies, which are bound to avidin-derivatized liposomes (*25*,

Scheme 1. Synthetic Scheme for Mal-PEG-Chol

26). Covalent coupling utilizes a variety of bioconjugation techniques, such as the forming of thioether, disulfide, or amide bonds between lipids and the antibody molecules (*27*). In general, antibodies can be directly linked to liposomes through covalent conjugation to functional groups on the liposome surface (*28*), or they can be post-inserted into preformed liposomes via micelles of an antibody−lipid conjugate (*29*, *30*).

Liposomes typically consist of phospholipids and cholesterol, both of which are potentially suitable for anchoring receptor-targeting ligands to its lipid bilayer. For example, both phospholipid- and cholesterol-anchored folate (folate-PEG-DSPE, folate-PEG-Chol) have been used in the preparation of folate receptor targeted liposomes (*31*, *32*). In this report, we have evaluated a new cholesterol derivative, maleimido-PEG-cholesterol (Mal-PEG-Chol), for the anchoring of cetuximab (C225) in ILs. Furthermore, the EGFR-targeting efficiency and subsequent internalization of the C225-ILs by the EGFR overexpressing $F98_{EGFR}$ cells have been determined both by fluorescence microscopy and by flow cytometry. Our results, described in detail in the following report, have demonstrated that ILs potentially could be useful delivery vehicles for BNCT of gliomas.

EXPERIMENTAL PROCEDURES

Materials. Hydrogenated soy phosphatidylcholine (HSPC), methoxy-poly(ethylene glycol)$_{2000}$-phosphatidylethanolamine ($mPEG_{2000}$-DSPE), were purchased from Avanti Polar Lipids (Alabaster, AL). Cholesterol (Chol), cholesteryl chloroformate, sheep IgG, 2-iminothiolane (Traut's reagent), mercaptoethylamine·HCl (MEA), ninhydrin, PEG_{3350}-bis-amine, 4-(2-hydroxyethyl)-1-piperazine ethanesulfonic acid (HEPES), 8-hydroxypyrenetrisulfonic acid trisodium salt (HPTS), Sepharose CL-4B resin, and triethylamine (TEA) were purchased from Sigma-Aldrich Co. (St. Louis, MO). Octadecylrhodamine B (R18) was purchased from Molecular Probes (Eugene, OR). Dilithium-dodecahydro-*closo*-dodecaborate ($Li_2B_{12}H_{12}$) was obtained as a gift from Callery Chemical Company (Pittsburgh, PA). DMEM, fetal bovine serum (FBS), and antibiotics were purchased from Life Technologies (Grand Island, NY). Sephadex LH20 resin and PD-10 desalting columns were purchased from GE Healthcare (Piscataway, NY). Bradford protein assay kit and *N*-[β-maleimidopropyloxy]succinimide ester (BMPS) were purchased from Peirce Chemical Co. (Rockford, IL). Polycarbonate membranes were obtained from Avestin, Inc. (Ottawa, ON, Canada). Cetuximab (C225) was generously provided by Dr. Daniel Hicklin at ImClone Systems, Inc. (New York, NY). All other chemicals were of reagent grade.

Cell Culture. Parental (wild-type) $F98_{WT}$ glioma cell line (*33*) and human EGFR gene transfected $F98_{EGFR}$ glioma cell lines, expressing 10^5 receptor sites per cell (*19*), were cultured as a mononlayer in DMEM media supplemented with 100 units/mL penicillin, 100 μM/mL streptomycin, 200 mg/mL of Geneticin, and 10% FBS in a humidified atmosphere containing 5% CO_2 at 37 °C.

Synthesis of Maleimido-PEG-Cholesterol (Mal-PEG-Chol) (5). The synthetic scheme for of Mal-PEG-Chol (**5**) is shown in Scheme 1. PEG_{3350}-bis-amine (**1**) (335 mg, 0.1 mmol) was dissolved in anhydrous CH_2Cl_2 (30 mL) and TEA (14 μL, 0.1 mmol). Then, cholesteryl chloroformate (**2**) (49 mg, 0.11 mmol, 1.1 equiv), also dissolved in anhydrous CH_2Cl_2 (2 mL), was slowly added. After 4 h reaction at room temperature, thin layer chromatography (TLC) analysis (mobile phase $CHCl_3$/MeOH/H_2O at 3:1:0.2, visualized with ninhydrin and $KMnO_4$ staining) indicated the formation of dicholesteryl (Chol-PEG-Chol) (R_f = 0.65), monocholesteryl (Chol-PEG-NH_2) (**3**) (R_f = 0.47), and unreacted PEG-bis-amine (R_f = 0.12). The reaction mixtures were separated by silica gel column chromatography using a step gradient of methanol (0−20%) in chloroform. The fractions containing monocholesteryl PEG (Chol-PEG-NH_2) (**3**) were pooled and evaporated to dryness under vacuum to yield 56% product. The MALDI mass spectrum of (**3**) showed a series of 44-Da spaced lines, corresponding to the mass of a single ethylene oxide unit, that were centered around 3819. ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 5.31 (d, 1H), 4.68 (m, 1H), 3.70−3.50 (br, m, PEG protons, ∼320H), 2.46 (d, 2H), 2.04−1.05 (m, Chol protons, ∼26H), 1.00 (s, 3H), 0.91 (d, 3H), 0.86 (d, 6H), 0.683 (s, 3H).

Monocholesteryl PEG (**3**) (30 mg, 7.9 μmol) and BMPS (**4**) (3.2 mg, 11.8 μmol, 1.5 equiv) were dissolved in anhydrous CH_2Cl_2 (20 mL) under N_2 and under darkness. After 1 h,

ninhydrin assay showed the disappearance of the free primary amine group. The reaction was quenched by ethylenediamine, and the reaction mixture was concentrated on a rotary evaporator and then passed through a Sephadex LH20 column, using CH_2Cl_2/MeOH (1:1 v/v) as the mobile phase. Fractions containing product Mal-PEG-Chol (**5**) (identified by $KMnO_4$ staining) were pooled and dried by rotary evaporation. The yield was 93%. Analytical data for (**5**): MALDI showed cluster of peaks centered around 3992. ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 6.70 (s, 2H), 5.31 (d, 1H), 4.68 (m, 1H), 3.80−3.50 (br, m, PEG protons, ∼312H), 2.46 (d, 2H), 2.04−1.00 (m, Chol protons, ∼26H), 0.99 (s, 3H), 0.90 (d, 3H), 0.85 (d, 6H), 0.663 (s, 3H).

Preparation of Immunoliposomes. *Liposome Preparation.* Unilamellar liposomes were prepared by the polycarbonate membrane extrusion method (*34*). A chloroform solution of lipids consisting of HSPC/Chol/$mPEG_{2000}$-DSPE (60:40:1−4 mol %), with or without Mal-PEG-Chol (0.5 mol %), was dried into a thin film in a round-bottom flask on a rotary evaporator and then further dried for 2 h under vacuum. The resulting thin lipid film was hydrated in 1 mL of a solution of fluorescent dye HPTS (25 mM, in PBS, pH 7.4). The resulting suspension was subjected to five cycles of freezing and thawing and extruded five times through a track-etched polycarbonate membrane with a pore size of 100 nm using a Lipex Extruder (Northern Lipids, Vancouver, Canada). Unentrapped HPTS was separated from liposomes by gel filtration on a 10 mL PD-10 desalting column equilibrated in PBS (pH 7.4). Liposome size was determined by dynamic light scattering on a Nicomp Particle Sizer model 370. The mean liposome diameter obtained by this method was 106.1 ± 35.6 nm by volume-weighted averaging. The phospholipid content was measured using a colorimetric assay (*35*). The liposomes were stored at 4 °C until use.

For boron uptake studies, dodecahydro-*closo*-dodecaborate (2−) ($B_{12}H_{12}^{2-}$) (50 mM) was encapsulated in liposomes by the extrusion method described above. The boronated liposomes were sterilized by passing through a 0.22 μm filter and stored at 4 °C.

Construction of C225-ILs. ILs were constructed by conjugation with either an intact MAb or an Fab′ fragment. MAb (IgG, as nontargeting control MAb, and C225, as the targeting MAb) were thiolated for 1 h at room temperature by reacting with 5-fold excess of Traut's reagent in degassed HEPES buffer (20 mM HEPES, 140 mM NaCl, 2 mM EDTA, pH 8.0). Unreacted Traut's reagent was removed by PD-10 column and eluted with degassed HEPES buffer (pH 6.5). The thiolated MAb was stored at 4 °C and used within 1 h of preparation.

For direct coupling of MAb to liposomes, thiolated MAb (or Fab′ fragment) was added to preformed liposomes (HSPC/Chol/$mPEG_{2000}$-DSPE/Mal-PEG-Chol at 60:40:2:0.5 mole ratio) at 40 μg MAb per micromole of lipids, and then gently shaken at room temperature for 4 h under N_2. Excess maleimide groups were quenched by incubation with MEA (1 mM) for 30 min at room temperature. Unbound MAb and MEA were then removed by Sepharose CL-4B gel filtration. A Bradford protein assay was performed to determine the coupling efficiency (*36*).

Fab′ fragments of C225 were produced, as described by Mamot et al. (*37*). Briefly, intact C225 was digested with pepsin (at a C225 to pepsin weight ratio of 1:20) in 0.1 M sodium citrate buffer (pH 4.5) at 37 °C for 4 h, followed by dialysis against HEPES buffer (pH 6.5). The resulting C225-F(ab)$_2$ fragment was reduced by MEA (15 mM) under N_2 for 15 min and then purified by PD-10 gel filtration.

ILs also were constructed by the post-insertion method. First, liposomes composed of HSPC/Chol (60:40, mole ratio) and varying amounts of $mPEG_{2000}$-DSPE were prepared by extrusion, as described above. To synthesize MAb−lipid micelle conjugate, Mal-PEG-Chol was dissolved in chloroform and dried into a thin film in a round-bottom flask on a rotary evaporator and then further dried overnight under vacuum. The lipid film was then rehydrated with degassed HEPES buffer (pH 6.5) at a concentration above the critical micelle concentration (cmc) of Mal-PEG-Chol with gentle vortexing, followed by incubation at 60 °C. Mal-PEG-Chol micelles were mixed with thiolated MAb (or Fab′ fragment) at 40 μg MAb (or 80 μg Fab′) per microgram of lipid and gently shaken for 4 h at room temperature. This was followed by quenching of free thiols by MEA (1 mM) and PD-10 gel filtration. The resulting MAb-PEG-Chol micelles were evaluated for efficiency of MAb transfer into preformed liposomes under varying conditions, including temperatures (37 °C and 60 °C), percentages of $mPEG_{2000}$-DSPE (1, 2, 3, and 4 mol %), and micelle-to-liposome lipid ratios (up to 1:10). Unincorporated MAb-PEG-Chol micelles were separated from ILs by Sepharose CL-4B gel filtration. Bradford protein assays were performed to determine the antibody content of ILs which enabled calculation of incorporation efficiency.

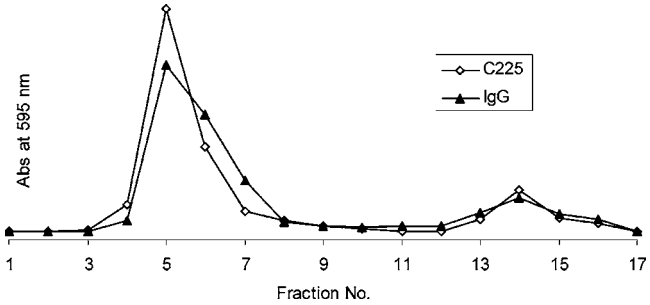

Figure 1. Elution profiles of ILs constructed with Mal-PEG-Chol and unbound MAbs. The reaction mixture was loaded onto a Sepharose CL-4B gel filtration column and eluted with PBS (pH 7.4). The peak in fractions 4−8 represents the C225 or IgG ILs. Fractions 12−17 are free, unbound C225 and IgG. Each fraction contained 0.5 mL. The protein content was measured by Bradford protein assay, which measures absorbance at 595 nm.

Binding and Internalization of Liposomes. $F98_{EGFR}$ and $F98_{WT}$ cells, cultured as monolayers in T75 flasks, were harvested by treatment with PBS containing 5 mM EDTA. The detached cells were pelleted by centrifugation at 1000 rpm for 5 min, resuspended in serum-supplemented media at a density of 2.5×10^5 cell/mL, and then aliquoted into 1.5-mL microcentrifuge tubes. Cells were incubated for 2 h at 37 °C under gentle shaking with either targeted or nontargeted ILs (at 5 μM phospholipid concentration) encapsulating HPTS. After washing three times with PBS (pH 7.4), the cells were kept on ice and subjected to flow cytometric analysis on a BD FACS Calibur analyzer and visualization by laser scanning confocal microscopy on a Zeiss 510 META microscope.

Kinetic analysis of cell surface bound and endocytosed ILs was performed as described previously (*12*, *38*). $F98_{EGFR}$ glioma cells were incubated with HPTS-loaded C225-ILs for 2 h at 37 °C, washed with ice-cold PBS, and then harvested with PBS-EDTA. Due to the pH sensitivity of HPTS and the relatively low internal pH of endosomes (pH 4−5), surface binding and internalization of ILs were quantified on the basis of measurement of the ratio between fluorescence intensity at excitation wavelengths (λ_{ex}) of 413 nm (isosbestic point) and 454 nm.

For quantitation of boron uptake, $F98_{EGFR}$ glioma cells (10^6 cells/mL) were incubated with IgG or C225 ILs, prepared by post-insertion method, encapsulating $Li_2B_{12}H_{12}$ for 2 h at 37 °C. These liposomes had 144 and 117 μg boron/mL and mean diameters of 135.6 ± 41.5 and 126.8 ± 39.5 nm, respectively. After washing with PBS (pH 7.4) three times, the cells were subjected to boron content analysis by inductively coupled

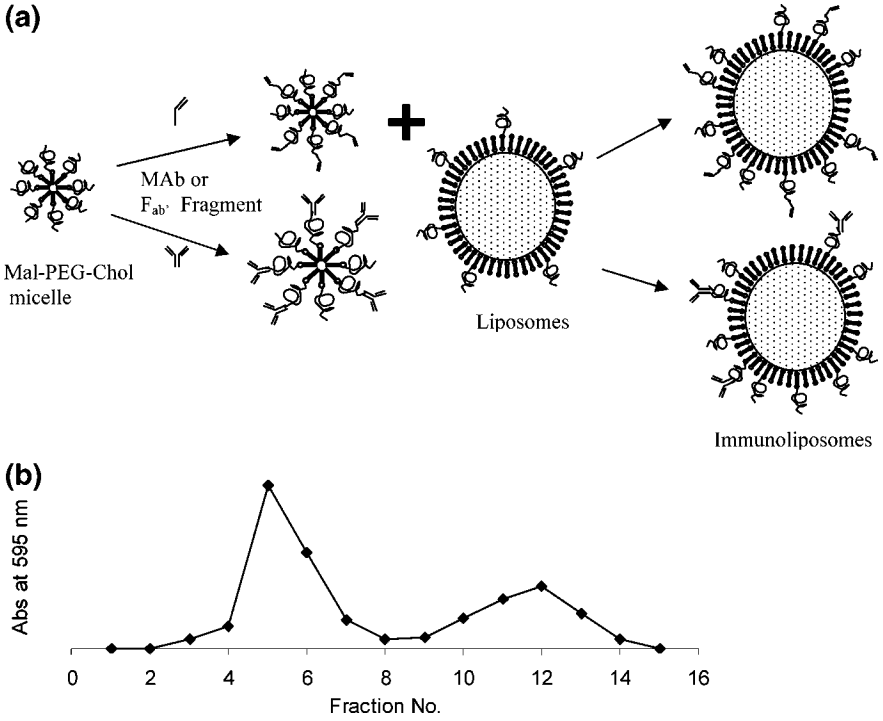

Figure 2. Post-insertion method for IL construction. (a) Schematic representation of post-insertion method for IL construction. Antibodies or antibody fragments are coupled to micelles formed by Chol-PEG-Mal and then incubated with preformed boron-loaded liposomes to form ILs. (b) A typical elution profiles of IgG-ILs constructed by post-insertion method at 60 °C for 1 h. IgG micelles were formed by coupling thiolated IgG with Mal-PEG-Chol micelles. After post-insertion, the mixture was loaded onto a Sepharose CL-4B gel filtration column and eluted with PBS (pH 7.4). The peak of fractions 4−7 represents the IgG-ILs. Fractions 9−14 are IgG−lipid micelles. Each fraction contained 0.5 mL. The protein content was measured by Bradford protein assay, which measures absorbance at 595 nm.

plasma mass spectroscopy (ICP−MS) on a Perkin-Elmer Sciex ELAN 6000.

RESULTS

Synthesis of Immunoliposomes (ILs). *Direct Coupling.* Liposomes, composed of HSPC/Chol/PEG-DSPE/Mal-PEG-Chol (60:35:5:0.5, mol %), were prepared by the lipid hydration and extrusion method and had a mean diameter of ∼100 nm. Thiolated antibodies (IgG and C225) were reacted with the maleimide group on the distal termini of PEG chains on these liposomes to form thioether linkages, yielding ∼25−35 μg MAb per micromole of lipid (Figure 1).

Post-insertion. The cmc of Mal-PEG-Chol was evaluated by monitoring changes in turbidity via OD at 254 nm, as previously described (*39*). Regression analysis indicated that micelles were formed at 2 μM (data not shown). To investigate whether micelles, formed by MAb conjugates with cholesterol anchors, could be incorporated into preformed liposomes, their transfer efficiency was examined at varying incubation temperatures, $mPEG_{2000}$-DSPE contents in the liposome, and micelle-to-liposome lipid ratios (Figure 2a). Sepharose CL-4B gel filtration chromatography was used to determine the amount of MAb incorporated into liposomes. Unincorporated micelles were eluted in a broad peak, which was well-separated from ILs that were eluted in the void volume (Figure 2b).

The incorporation of MAb into preformed liposomes was determined at 37 °C and at 60 °C. The incorporation rate at 60 °C was higher than that at 37 °C (Table 1). This was expected, since 60 °C is above the transition temperature of the bilayer, which would facilitate lipid transfer. Concomitantly, the mean diameters of the particles also were increased at 60 °C, possibly due to lipid exchange (Table 1).

The presence of $mPEG_{2000}$-DSPE, which sterically stabilized the liposomes, adversely affected the incorporation efficiency of the MAb (Table 1). The higher the $mPEG_{2000}$-DSPE content of the liposomes, the lower the efficiency of MAb insertion into the liposomes. In liposomes containing 4 mol % of $mPEG_{2000}$-DSPE, the insertion of MAb was significantly inhibited, even at 60 °C. In contrast, MAb insertion efficiency was minimal at 37 °C, when $mPEG_{2000}$-DSPE content exceeded 2 mol %.

Saturation of MAb insertion was observed at high micelle-to-liposome lipid ratios. The percent of MAb incorporation at the ratio of 1:30 was close to that at the ratio of 1:10 (Table 2), which indicated that incorporation had essentially reached a

[a] Unilamellar preformed liposomes composed of HSPC/Chol (60:40, mole ratio) and various $mPEG_{2000}$-DSPE (1, 2, 3, and 4 mol %) were prepared by thin film hydration-extrusion, as described in the Experimental Procedures section. Micelles were incubated with liposome (1:30, lipid molar ratio) for 1 h at 37 °C or 60 °C.

Table 2. Effect of Micelle-to-Liposome Lipid Ratio on IgG-PEG-Chol Incorporation into Preformed Liposomes[a]

micelle-to-liposome lipid molar ratio	% Mab incorporated
1:100	72
1:30	55
1:15	36
1:10	21

[a] The liposomes, composed of HSPC/Chol/$mPEG_{2000}$-DSPE (60:40:2 mole ratio) were incubated with the micelles at 60 °C for 1 h.

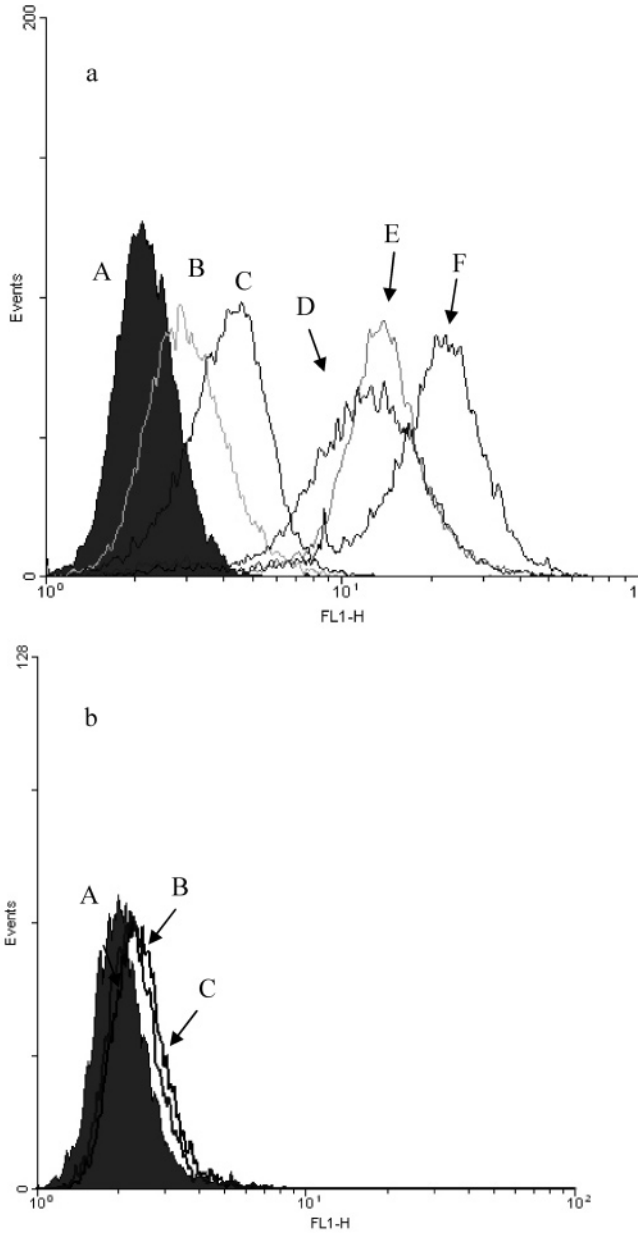

Figure 3. Binding of ILs to $F98_{EGFR}$ cells evaluated by flow cytometric assay. (a) ILs encapsulating HPTS were incubated with cells for 2 h at 37 °C, washed three times, and stored on ice until analysis: (A) untreated $F98_{EGFR}$ cells, (B) IgG-ILs, (C) C225-ILs with free C225 as a blocking agent, (D) C225-ILs prepared by post-insertion method with preformed liposomes containing 2 mol % $mPEG_{2000}$-DSPE, (E) C225-Fab′ ILs constructed by post-insertion with preformed liposomes containing 2 mol % $mPEG_{2000}$-DSPE, and (F) C225-ILs prepared by direct coupling. (b) C225-Fab′ ILs with non-EGFR-expressing $F98_{WT}$ cells: (A) untreated $F98_{WT}$ cells, (B) C225-Fab′ ILs plus free C225, and (C) C225-Fab′ ILs.

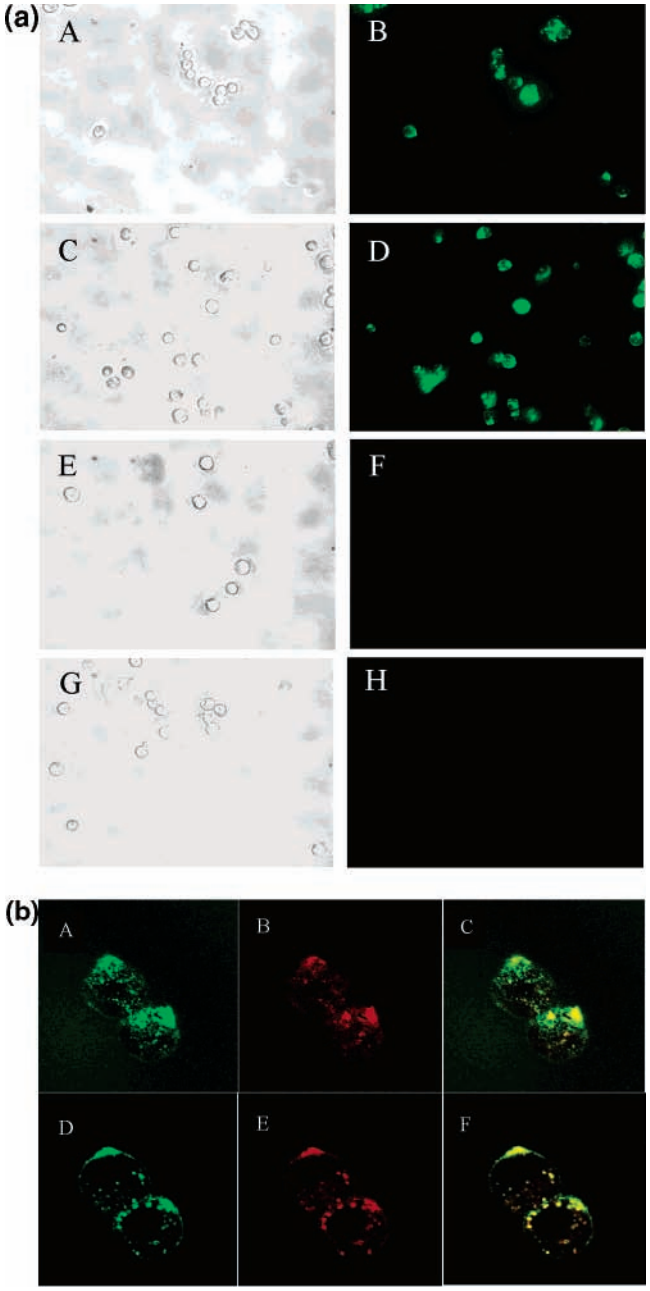

Figure 4. Fluorescence micrographs of F98 cells treated with Ils. (a) Internalization of C225-Fab′ ILs and nontargeted IgG-Fab′ ILs in EGFR-expressing $F98_{EGFR}$ cells. $F98_{EGFR}$ cells were incubated with C225-Fab′ or IgG-Fab′ ILs, containing HPTS fluorescent dye for 2 h at 37 °C. Left panels show cells visualized in the phase contract mode; right panels show cells visualized in the fluorescence mode: (A,B) $F98_{EGFR}$ cells treated with C225-Fab′ ILs constructed by directed coupling; (C,D) $F98_{EGFR}$ cells treated with C225-Fab′ ILs prepared by post-insertion method; (E,F) $F98_{EGFR}$ cells treated with nontargeted IgG-Fab′ ILs; (G,H) $F98_{WT}$ cells with C225-Fab′ ILs. (b) Confocal micrographs of $F98_{EGFR}$ cells incubated with C225-Fab′ ILs constructed by post-insertion method with preformed liposomes containing 2 mol % $mPEG_{2000}$-DSPE. The ILs were loaded with HPTS and labeled with R18. Left column, green HPTS fluoresence; central column, red rhodamine fluorescence; right column, superimposed images. (A−C) Top-view image showing cell surface-bound liposomes; (D−F) central stack image showing liposomes accumulated in the endosomal compartments.

plateau. The micelles of Fab′ also were prepared by the same method, and the incorporation rate was close to that of the whole MAb. Approximately 60% C225-Fab′ was transferred to liposomes containing 2 mol % of $mPEG_{2000}$-DSPE with micelle-to-liposome lipid ratio of 1:30, following incubation at 60 °C for 1 h.

Cellular Binding and Internalization. Cellular binding and internalization of ILs were evaluated by flow cytometry in $F98_{WT}$ and $F98_{EGFR}$ rat glioma cells. In this study, IgG-ILs and C225-ILs, constructed by direct coupling or by the post-insertion method, were loaded with fluorescent dye HPTS and incubated with the cells for 2 h at 37 °C. The uptake of C225-ILs was 10-fold higher than that of the nontargeted IgG-ILs. In a competitive binding assay, free C225 was added, which significantly reduced binding of C225-ILs by $F98_{EGFR}$ cells (Figure 3a). Both directly coupled and post-inserted C225 in the liposomes appeared to greatly increase liposome binding to EGFR-expressing $F98_{EGFR}$ cells but not to $F98_{WT}$ cells. Mean-

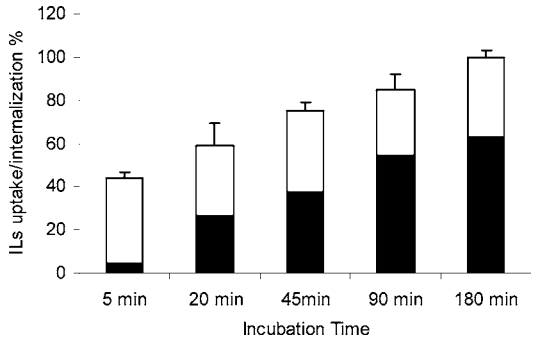

Figure 5. Kinetics of C225-Fab′ IL internalization in the EGFR overexpressing $F98_{EGFR}$ cells. C225-Fab′ ILs were constructed by post-insertion method with preformed liposomes containing 2 mol % $mPEG_{2000}$-DSPE and loaded with pH-sensitive dye HPTS and incubated with $F98_{EGFR}$ cells at 37 °C. At various time points, the sample was analyzed by measuring the fluorescence intensity at excitation wavelengths of 454 and 413 nm. Surface-bound fraction □; internalized fraction ■. The 180 min time point was set at 100%; $n = 3$.

while, C225-Fab′ liposomes, constructed by the post-insertion method, were evaluated using $F98_{WT}$ and $F98_{EGFR}$ cells. The C225-Fab′ containing liposomes showed extensive binding to $F98_{EGFR}$ cells but minimal binding to $F98_{WT}$ cells (Figure 3b). These results clearly demonstrated selective uptake of anti-EGFR ILs between two congenic cell lines based on differing EGFR expression levels.

Confocal fluorescence microscopy was used to visualize the binding and subsequent intracellular localization of C225-Fab′ ILs by F98 cells. $F98_{EGFR}$ cells, incubated with ILs prepared by either direct coupling or the post-insertion method, both showed high levels of fluorescence. In contrast, cells exposed to nontargeted IgG-Fab′ ILs showed little fluorescence (Figure 4a, A−F). Finally, the C225-Fab′ ILs did not show significant binding to non-EGFR expressing $F98_{WT}$ cells (Figure 4a, G and H). Overall, the results of the confocal fluorescence microscopy studies were consistent with those of the flow cytometric assays.

C225-Fab′ liposomes, containing 2 mol % PEG_{2000}-DSPE prepared by the post-insertion method, were loaded with pH-sensitive fluorophore HPTS in the aqueous core and labeled with octadecyl rhodamine B (R18) (0.5 mol %) in the lipid bilayer. These liposomes were incubated with $F98_{EGFR}$ cells for 2 h at 37 °C. Fluorescence was distributed throughout the cell, including cell plasma membrane, intracellular vesicles, and the cytosol (Figure 4b). Superimposition of fluorescence images based on HPTS and R18 indicated that the fluorescence was not due to HPTS leakage or R18 lipid exchange.

The pH sensitivity of the HPTS absorption spectrum allowed for the simultaneous analyses of both surface-bound (neutral pH) and endosome-localized (low pH) liposomes based on the I445/413 nm excitation ratios. C225-Fab′ liposomes bound to $F98_{EGFR}$ cells were detected within 5 min of incubation. Meanwhile, intracellular accumulation was observed within 20 min (Figure 5). The results clearly showed increasing lysosomal uptake of the liposomes over a 3-h incubation period.

For quantitative analysis of boron uptake, boron-loaded C225-ILs delivered ∼8 times more boron (509.75 ± 148.85 μg B/10^9 F98 cells) to $F98_{EGFR}$ cells than nontargeted IgG-ILs (61.00 ± 1.76 μg B/10^9 F98 Cells), greatly exceeding the required level of boron (∼20 μg/g tissue) for NCT (*1*).

DISCUSSION

A novel cholesterol-based anchor (Mal-PEG-Chol (**5**)) has been synthesized for the attachment of receptor-targeting ligands to the lipid bilayer of liposomes. Factors affecting post-insertion efficiency, in vitro targeting, internalization of IgG-ILs, anti-EGFR C225-ILs, C225-Fab′-ILs, and their drug carrying capacity were evaluated in EGFR(−) $F98_{wt}$ and EGFR overexpressing $F98_{EGFR}$ cells. Functionalization of liposomes with receptor-targeting ligands previously had been carried out by using phosphatidylethanolamine (PE) derivatives as anchors to the lipid bilayer. These have included Mal-PEG-DSPE, Hz-PEG-DSPE, and PDP-PEG-DSPE (*40*). Cholesterol, which is less expensive than PE-based lipids, is a major component of the biological membranes. PEG-Chol derivatives have been used for the preparation of sterically stabilized liposomes with long circulating time (*41*). We previously prepared a cholesterol-based folate conjugate, folate-PEG-Chol, which was successfully used for the construction of folate receptor targeted liposomes (*32*). Carrion et al. have used cholesterol derivatized with SPDP for the preparation of ILs (*42*). The present data have clearly demonstrated that cholesterol is an attractive alternative to PE as an effective lipid anchor for the construction of ILs. The strategy for the synthesis of Mal-PEG-Chol (**5**) from readily available starting materials is simple and efficient. The maleimide group in the cholesterol derivative proved to be especially useful for conjugation to Fab′ fragments, which contain a free thiol group. Moreover, MAbs-PEG-Chol in micelles was found to be efficiently incorporated into preformed liposomes during post-insertion, which is a convenient method for the construction of targeted liposomes.

The use of C225-ILs as ^{10}B delivery vehicles for BNCT of GBM is particularly attractive due to the potential synergy between the high LET radiation produced in the ^{10}B (n, α)^{7}Li neutron capture and the potential signal transduction cascade that ILs upon multivalent binding of the ILs to the cellular EGFRs. Therefore, C225-ILs also were evaluated in vitro as boron delivery vehicles with EGFR expressing $F98_{EGFR}$ glioma cells. The excellent cell-targeting capabilities of anti-EGFR ILs was demonstrated by fluorescence microscopy and flow cytometry. Nontargeted IgG-ILs showed only minimal fluorescence, while C225-ILs showed preferential binding and internalization by $F98_{EGFR}$ cells, which was indicative of EGFR-specific binding and subsequent endocytosis. Another important feature of ILs as boron delivery vehicles was their ability to selectively target only those cells overexpressing EGFR, which was demonstrated by the low binding and uptake by $F98_{WT}$ cells. In the present study, the boron-rich compound, dodecaborate anion ($B_{12}H_{12}^{2-}$) was used. This previously has been encapsulated in RGD-liposomes for the delivery of ^{10}B to human umbilical vein endothelial cells (HUVEC) (*16*). In the present study, boronated C225-ILs delivered 509.75 ± 148 μg ^{10}B per 10^9 (∼1 g) $F98_{EGFR}$ cells, which was ∼8 times greater than the amount delivered by nontargeted IgG-liposomes. This exceeded the therapeutically required amount of ^{10}B (∼20 μg/g tissue).

In conclusion, our studies have demonstrated that both MAbs and Fab′ fragments could be efficiently linked to Mal-PEG-Chol. The resulting MAb and Fab′-PEG-Chol bioconjugates could be efficiently incorporated into preformed liposome to yield ILs by the post-insertion method. C225-ILs were internalized by EGFR overexpressing $F98_{EGFR}$ cells in vitro, presumably by receptor-mediated endocytosis, resulting in the selective and efficient intracellular delivery of boron. This approach could also be applied to the delivery of other therapeutic agents to EGFR-positive tumor cells. In vivo studies are planned to further explore the tumor-targeting potential of anti-EGFR ILs for potential use for BNCT and stereotactic synchrotron radiotherapy (*43*, *44*).

Enzymatic and Nonenzymatic Synthesis of Glutathione Conjugates: Application to the Understanding of a Parasite's Defense System and Alternative to the Discovery of Potent Glutathione *S*-Transferase Inhibitors

Wei-Jen Lo,[†,#] Yu-Ching Chiou,[§,#] Yu-Ting Hsu,[‡] Wing See Lam,[‡] Ming-Yun Chang,[§] Shu-Chuan Jao,[⊥] and Wen-Shan Li*[,‡]

Department of Chemistry & Biochemistry, National Chung Cheng University, Chia-Yi 621, Taiwan, Department of Chemistry, National Taiwan Normal University, Taipei 116, Taiwan, Institute of Biological Chemistry, Academia Sinica, Taipei 115, Taiwan, and Institute of Chemistry, Academia Sinica, Taipei 115, Taiwan. Received June 18, 2006; Revised Manuscript Received November 27, 2006

A primary pathway for metabolism of electrophilic compounds in *Schistosoma japonicum* involves glutathione *S*-transferase (*Sj*GST)-catalyzed formation of glutathione (GSH) conjugates. As part of a program aimed at gaining a better understanding of the defense system of parasites, a series of aromatic halides (**1**−**8**), aliphatic halides (**9**, **10**), epoxides (**11**−**20**), α,*β*-unsaturated esters (**21**, **22**), and α,*β*-unsaturated amides (**23**, **24**) were prepared, and their participation in glutathione conjugate formation was evaluated. Products from enzymatic and nonenzymatic reactions of these substances with glutathione were characterized and quantified by using reverse-phase high-performance liquid chromatography (HPLC), NMR, and fast atom bombardment mass spectrometry (FAB-MS) analysis. Mechanisms for formation of specific mono(glutathionyl) or bis(glutathionyl) conjugates are proposed. Although the results of this effort indicate that *Sj*GST does not catalyze addition or substitution reactions of **1**, **3**, **4**, **7**−**9**, **11**−**13**, **15**−**17**, **19**−**21**, and **24**, they demonstrate that **2**, **5**, **6**, **14**, **18**, and **23** undergo efficient enzyme-catalyzed conjugation reactions. The k_{cat} values for *Sj*GST with **23** and **18** are about 886-fold and 14-fold, respectively, larger than that for **5**. This observation suggests that **23** is a good substrate in comparison to other electrophiles. Furthermore, the initially formed conjugation product, **23a**, is also a substrate for *Sj*GST in a process that forms the bis(glutathionyl) conjugate **23b**. Products arising by enzymatic and nonenzymatic pathways are generated under the conditions of *Sj*GST-activated GSH conjugation. Interestingly, production of nonenzymatic GSH conjugates with electrophilic substrates often overwhelms the activity of the enzyme. The nonenzymatic GSH conjugates, **9a**−**11a**, **16a**, **21a**, and **22a**, are inhibitors of *Sj*GST with respective IC_{50} values of 1.95, 75.5, 0.96, 19.0, 152, and 0.36 μM, and they display moderate inhibitory activities against human GSTA2. Direct evidence has been gained for substrate inhibition by **10** toward *Sj*GST and GSTA2 that is more potent than that of its GSH conjugate **10a**. The significance of this work is found in the development of a convenient NMR-based technique that can be used to characterize glutathione conjugates derived from small molecule libraries as part of efforts aimed at uncovering specific potent *Sj*GST and GSTA2 inhibitors. This method has potential in applications to the identification of novel inhibitors of other GST targets that are of chemotherapeutic interest.

INTRODUCTION

Because it serves as the preferred substrate for different glutathione (GSH)-related enzymes (*1*−*4*) involved in demonstrated detoxification pathways, GSH (*γ*-Glu-Cys-Gly) has garnered considerable medicinal interest. Also this substance is the precursor of a prooxidant species (thiyl radical) in the main pathway for intracellular antioxidant defense (*5*−*7*). GSH, the most abundant natural tripeptide (1−10 mM), forms covalent bonds with electrophilic molecules (endogenous and exogenous xenobiotics) through its sulfhydryl group leading to the generation of more hydrophilic GSH conjugates (*8*). The resulting GSH conjugates are generally considered to be metabolites in the defense system of the cell (*9*−*10*). Furthermore, these conjugates play a medicinal role as bioactive agents (*e.g.*, inhibitors of therapeutic enzymes (*11*−*13*), antiprotozoal agents against parasites (*14*, *15*), and enzyme-activated prodrugs (*16*−*19*)).

Glutathione *S*-transferases (GSTs), a family of GSH-dependent enzymes, participate in detoxification processes by catalyzing the conjugation of GSH to a wide variety of xenobiotics. Cytosolic GSTs in mammals were originally divided into the α, *κ*, *μ*, *ω*, *π*, *σ*, *θ*, and *ζ* classes on the basis of their biofunctional properties and sequence identities. *Schistosoma japonicum* GST (*Sj*GST), having a similar structure to members of the *μ* class of cytosolic GSTs, plays a key role in the primary defense system of parasites. This enzyme has several biochemical functions, which are common to the α, *μ*, and *π* classes (*20*, *21*). Gaining greater knowledge about *Sj*GST catalysis and the way a broad variety of substrates bind in its hydrophobic binding site (H site) are important components of understanding glutathione-dependent metabolism in the worm *S. japonicum*, a parasite that causes the tropical disease schistosomiasis, which infects 200 million people and causes 280 000 deaths in the world annually (*21*−*28*).

Herein, we report the results of an investigation aimed at determining possible metabolites and mechanistic pathways for *Sj*GST-catalyzed conjugation reactions of various electrophiles. In the effort, enzymatic and nonenzymatic conjugation reactions of glutathione with the electrophiles were explored. The results of this study show that GSH conjugates arising from nonenzy-

matic rather than enzymatic coupling reactions are micromolar to nanomolar inhibitors of *Sj*GST and its human counterpart hGSTA2.

EXPERIMENTAL PROCEDURES

Analytical Instrumentation and Characterization Techniques. NMR spectra were recorded on Bruker AMX400, AV400, or AV500 MHz instruments. Chemical shifts were reported in ppm and are referenced to the chemical shift of residual solvent. Mass spectra were obtained on a fast atom bombardment (FAB) JMS-700 double focusing mass spectrometer (JEOL, Tokyo, Japan), MALDI Voyager DE-PRO (Applied Biosystems, Houston, TX), and ESI Finnigan LCQ mass spectrometer (Thermo Finnigan, San Jose, CA) in negative mode. Chromatography was performed at room temperature using a high-performance liquid chromatography (HPLC) Breeze system consisting of a Waters model 1525 binary pump system with a Vydac 214SP510 C18 (10 mm × 250 mm, 5 μm) or a Waters Symmetry C18 (3.9 mm × 150 mm, 5 μm) column equilibrated in H_2O/CH_3CN as eluents, at a flow rate of 1 mL/min. GSH conjugate elution was recorded with the use of an online Waters 2487 UV dual absorbance detector that measured simultaneously the absorbance at 220 and 254 nm, unless indicated otherwise. The HPLC fraction containing the conjugate product was dried in a vacuum concentrator (Speedvac SC110, Savant Instruments, Holbrook, NY). The absorbances of all samples for *Sj*GST assays were measured at 340 nm using a SpectraMax Plus384 plate reader (Molecular Devices, Sunnyvale, CA).

Materials. Unless stated otherwise, all chemicals and reagents were purchased from Acros and used as provided. Restriction enzymes were obtained from New England Biolabs. Minipreps and gel extraction DNA purification kits were obtained from Qiagen. *Escherichia coli* strains BL21(DE3) and Rosetta(DE3) and plasmids pET-15b and pET-28a were from Novagen. Oligonucleotide synthesis and DNA sequencing reactions were conducted by using MDBio. HisTrap affinity and PD-10 columns were purchased from Amersham Biosciences. 2-Chloromethyl-4-nitrophenol, *R*-(+)-3-chlorostyrene oxide, methyl-*trans*-3-(4-methoxyphenyl)glycidate, 7-oxabicyclo[4,1,0]heptan-2-one, and sodium phosphate (NaH_2PO_4) were purchased from Sigma-Aldrich. 1,3,5-Triacryloyl-hexahydro-*s*-triazine was purchased from TCI-EP, and ethacrynic acid (EA) was purchased from MP. Crotonic anhydride and 2-bromo-4-nitroacetophenone were purchased from TCI.

Screening Assay of GSH Conjugate Formation (Table 1). *(a) With SjGST*. A typical reaction included GSH (7.7 mg, 25 μmol) in H_2O (46.5 mL), 1 M sodium phosphate (pH 7.0, 1 mL), and *Sj*GST (0.42 mg). Reactions were started by adding the corresponding electrophile (25 μmol) in methanol (2.5 mL) to a mixed solution of enzyme, GSH, and buffer (25 °C preincubated). Reactions were stopped after 10 min or 5 h by the addition of acetone (40 mL). After evaporation of the organic solvent, each solution was washed with dichloromethane (4 × 20 mL) to remove unreacted electrophiles, and the aqueous layer was concentrated *in vacuo*. The crude GSH conjugates were characterized by ^{1}H NMR spectroscopy (Figure 1) and reverse-phase HPLC analysis. In order to observe the enzymatic formation of the GSH conjugates from electrophiles **6** and **14**, the same procedure was carried out at pH 6.5 and 4 °C to reduce the rate of nonenzymatic reaction.

(*b) Without SjGST*. Nonenzymatic reactions were preformed by using the same protocol as that described in the enzymatic reaction except that *Sj*GST was not included.

Synthesis of GSH Conjugates. *(a) Enzymatic synthesis*. To 285 mL of reaction solution, containing 0.3 μM *Sj*GST, 20 mM sodium phosphate, and 0.5 mM GSH (pH 7.0), was added 15 mL of a methanol solution containing 10 mM of the corresponding electrophile. The mixture was shaken at 25 °C until the completion of the reaction (monitored by TLC) and washed with dichloromethane (4 × 50 mL) to remove the unreacted electrophile. The aqueous layer was concentrated *in vacuo*, and the residue was triturated with 20 mL of H_2O. The triturate was poured into a centrifuge tube with cold acetone (30 mL) at −15 °C, allowed to stand for 15 min, and centrifuged at 4000 rpm for 10 min. The supernatant was concentrated under reduced pressure to remove acetone. The resulting aqueous solution was dialyzed (SpectraPor, MWCO 100) against H_2O for 18 h. The dialysate was concentrated, and the residue obtained was subjected to reverse-phase HPLC. The eluant was lyophilized to afford the pure product as a white powder.

(b) Nonenzymatic synthesis. All GSH conjugates were prepared by using the same protocol as that described in the enzymatic synthesis except *Sj*GST was not included.

[a] Values shown are averages of integral ratios from two independent NMR experiments. [b] Reactions were carried out in 0.5 mM GSH and 20 mM sodium phosphate buffer (pH 7.0) at 25 °C in the presence or absence of enzyme for 10 min or 5 h. [c] Reaction type: N (no reaction in both chemical and enzymatic reaction), E (enzymatic reaction only), M (mixed reactions including chemical and enzymatic reaction), C (chemical reaction only), X (chemical reaction but cannot confirm the existence of enzymatic reaction). [d] Reactions were performed in sodium phosphate buffer (pH 6.5) at 4 °C. [e] No products were detected under the same conditions. [f] Trace.

Characterization of Electrophilic Substrates and GSH Conjugates. *N-(5-Chloro-2-nitrophenyl)-N-(cyclopropylmethyl)-amine (**1**).* ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.07 (d, J = 9.1 Hz, 1H), 7.27 (d, J = 2.1 Hz, 1H), 6.63 (dd, J = 2.1 Hz, J = 9.1 Hz, 1H), 2.55−2.52 (m, 1H), 1.54 (br, 1H), 0.95−0.90 (m, 2H), 0.67−0.63 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 142.5, 127.9, 116.5, 114.7, 24.5, 7.9. HRMS-FAB: calcd for $C_9H_{10}O_2N_2Cl$ $(M + H)^+$ 213.0431; found 213.0431.

*8-Chloro-10-propylbenzo[g]pteridine-2,4(3H,10H)-dione (**8**).* ^{1}H NMR (400 MHz, D_2O): δ 8.46 (s, 1H), 8.23 (d, J = 9.3 Hz, 1H), 7.58−7.57 (m, 1H), 4.59 (t, J = 7.6 Hz, 2H), 1.95−1.85 (m, 2H), 1.13 (t, J = 7.4 Hz, 3H). ^{13}C NMR (100 MHz, DMSO-d_6): δ 159.6, 155.6, 150.5, 139.6, 138.8, 133.5, 133.4, 133.3, 126.3, 115.9, 45.7, 19.7, 10.9. HRMS-FAB: calcd for $C_{13}H_{12}O_2N_4Cl$ $(M + H)^+$ 291.0649; found 291.0653.

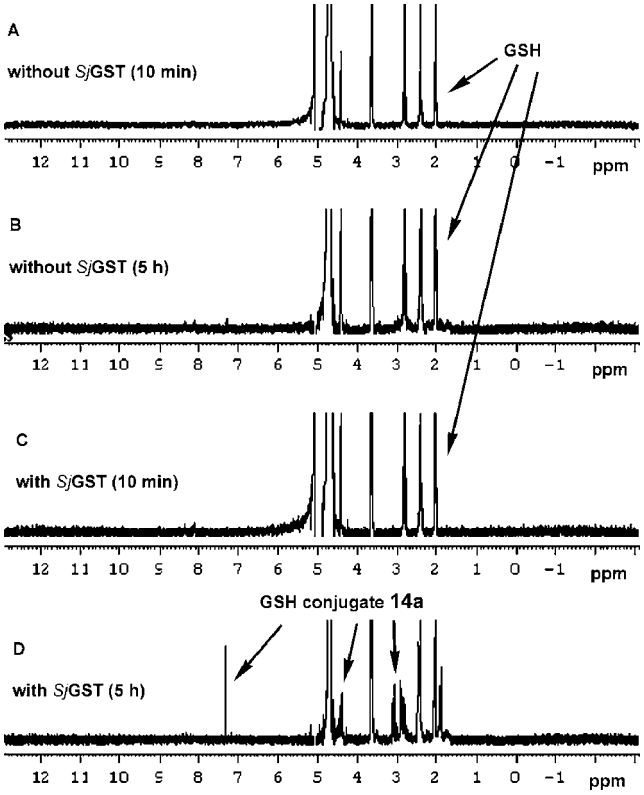

Figure 1. ^{1}H NMR spectra of the chemical conjugation product mixture from **14** and GSH for 10 min (A) and 5 h (B) and of the conjugation product mixture of **14** and GSH catalyzed by *Sj*GST for 10 min (C) and 5 h (D).

*17-Hydroxy-10,13,17-trimethyl-tetradecahydro-20-oxa-cyclopropa[4,5]cyclopenta[a]-phenanthren-3-one (**16**).* ^{1}H NMR (400 MHz, $CDCl_3$): δ 4.07 (br, 1H, OH), 2.90 (s, 1H), 2.30−0.8 (m, 28H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 206.8, 81.3, 70.2, 62.8, 50.0, 46.5, 45.5, 38.7, 37.2, 35.8, 32.4, 31.1, 29.9, 29.7, 26.1, 25.7, 23.1, 21.1, 20.9, 13.8. HRMS-FAB: calcd for $C_{20}H_{31}O_3$ $(M + H)^+$ 319.2273; found 319.2265.

*N-(5-Chloro-2-nitrophenyl)-N-propylamine (**26**).* ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.08 (d, J = 9.1 Hz, 1H), 6.81 (s, 1H), 6.56 (dd, J = 2.1 Hz, J = 9.1 Hz, 1H), 3.25−3.21 (m, 2H), 1.78−1.73 (m, 2H), 1.05 (t, J = 7.4 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 145.9, 142.7, 130.3, 128.2, 115.5, 113.1, 44.8, 22.0, 11.4. HRMS-FAB: calcd for $C_9H_{12}O_2N_2Cl$ $(M + H)^+$ 215.0587; found 215.0582.

*N-(2-Amino-5-chlorophenyl)-N-propylamine (**27**).* ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.09 (d, J = 9.1 Hz, 1H), 6.81 (d, J = 2.1 Hz, 1H), 6.56 (dd, J = 2.1 Hz, J = 9.1 Hz, 1H), 3.25−3.20 (m, 2H) 1.79−1.71 (m, 2H) 1.04 (t, J = 7.4 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 139.1, 132.2, 125.9, 117.6, 117.3, 111.6, 45.9, 22.6, 11.7. HRMS-FAB: calcd for $C_9H_{13}N_2Cl$ $(M + H)^+$ 184.0767; found 184.0764.

*2-Glutathionyl-5-nitropyridine (**5a**).* ^{1}H NMR (400 MHz, D_2O): δ 9.26 (d, J = 2.6 Hz, 1H), 8.42 (dd, J = 2.6 Hz, J = 8.9 Hz, 1H), 7.56 (d, J = 8.9 Hz, 1H), 4.82 (br, 1H), 4.06−4.04 (m, 1H), 3.98 (s, 2H), 3.85 (dd, J = 5.2 Hz, J = 14.5 Hz, 1H), 3.58 (dd, J = 8.2 Hz, J = 14.5 Hz, 1H), 2.54−2.50 (m, 2H), 2.19−2.15 (m, 2H). ^{13}C NMR (100 MHz, DMSO-d_6): δ 171.2, 170.4, 170.0, 169.7, 165.9, 144.3, 140.8, 130.8, 121.2, 52.2, 51.1, 40.6, 31.6, 30.7, 26.0. HRMS-FAB: calcd for $C_{15}H_{20}O_8N_5S$ $(M + H)^+$ 430.1033; found 430.1028.

*2-Glutathionyl-3,5-dinitropyridine (**6a**).* ^{1}H NMR (500 MHz, D_2O): δ 9.55 (s, 1H), 9.08 (s, 1H), 8.62 (br, 2H, NH), 4.66 (br, 1H), 3.88 (br, 1H), 3.74 (s, 2H), 3.45 (s, 1H), 2.29 (br, 2H), 1.90−1.84 (m, 2H). ^{13}C NMR (125 MHz, DMSO-d_6): δ 172.3, 171.4, 170.9, 170.7, 163.2, 148.3, 141.3, 140.7, 129.9, 53.4, 51.6, 41.6, 33.5, 31.8, 27.1. HRMS-FAB: calcd for $C_{15}H_{19}O_{10}N_6S$ $(M + H)^+$ 475.0883; found 475.0879.

*8-Glutathionyl-10-propylisoalloxazine (**8a**).* ^{1}H NMR (500 MHz, DMSO-d_6): δ 11.3 (s, 1H, NH), 8.65 (br, 1H, NH), 8.55 (d, J= 8.2 Hz, 1H, NH), 7.99 (d, J = 8.6 Hz, 1H), 7.72 (s, 1H), 7.55 (d, J = 8.6 Hz, 1H), 4.63−4.57 (m, 3H), 3.81−3.73 (m, 3H), 2.35 (br, 3H), 1.97−1.96 (m, 2H), 1.77−1.72 (m, 2H), 1.02 (t, J = 7.3 Hz, 3H). ^{13}C NMR (125 MHz, DMSO-d_6): δ 171.6, 170.8, 170.7, 169.9, 159.9, 155.8, 150.6, 147.2, 136.7, 133.2, 131.9, 124.5, 111.3, 51.9, 51.7, 45.5, 40.9, 33.3, 30.8, 26.0, 19.8, 11.0. HRMS-FAB: calcd for $C_{23}H_{28}O_8N_7S$ $(M + H)^+$ 562.1720; found 562.1720.

*2-(Glutathionylmethyl)-4-nitrophenol (**9a**).* ^{1}H NMR (500 MHz, DMSO-d_6): δ 8.46 (t, J = 5.7 Hz, 1H), 8.32 (d, J = 8.4 Hz, 1H), 8.13 (s, 1H), 7.98 (dd, J = 2.9 Hz, J = 8.9 Hz, 1H, NH), 7.02 (d, J = 8.9 Hz, 1H, NH), 4.53−4.49 (m, 1H), 3.74−3.71 (m, 3H), 3.48 (t, J = 6.5 Hz, 1H), 2.86 (dd, J = 4.6 Hz, J = 13.6 Hz, 1H), 2.64 (dd, J = 8.9 Hz, J = 13.6 Hz, 1H), 2.35−2.32 (m, 2H), 1.97−1.94 (m, 2H). ^{13}C NMR (125 MHz, DMSO-d_6): δ 171.3, 170.6, 170.3, 162.6, 162.4, 138.4, 125.9, 125.5, 124.2, 115.1, 52.6, 51.9, 40.6, 30.9, 29.1, 26.3. HRMS-FAB: calcd for $C_{17}H_{23}O_9N_4S$ $(M + H)^+$ 459.1186; found 459.1191.

*2-Glutathionyl-1-(4-nitrophenyl)ethanone (**10a**).* ^{1}H NMR (400 MHz, D_2O): δ 8.38−8.35 (m, 2H), 8.20−8.18 (m, 2H), 4.60−4.56 (m, 1H), 4.19 (s, 2H), 4.08−4.06 (m, 1H), 3.97 (s, 2H), 3.13 (dd, J = 5.2 Hz, J = 14.2 Hz, 1H), 2.96 (dd, J = 8.8 Hz, J = 14.2 Hz, 1H), 2.58−2.54 (m, 2H), 2.23−2.17 (m, 2H). ^{13}C NMR (100 MHz, D_2O): δ 196.9, 174.5, 173.1, 172.6, 150.6, 139.8, 130.1, 124.2, 53.1, 52.9, 41.3, 33.3, 31.2, 25.8. HRMS-FAB: calcd for $C_{18}H_{23}O_9N_4S$ $(M + H)^+$ 471.1186; found 471.1193.

*2-(3-Chlorophenyl)-2-glutathionylethanol (**11a**).* ^{1}H NMR (400 MHz, D_2O): δ 7.47 (s, 1H), 7.37−7.31 (m, 3H), 4.28−4.25 (m, 1H), 4.08−3.99 (m, 2H), 3.97 (s, 2H), 3.89−3.86 (m, 2H), 3.08 (dd, J = 4.2 Hz, J = 11.1 Hz, 1H), 2.83 (dd, J = 6.8 Hz, J = 11.1 Hz, 1H), 2.51−2.48 (m, 2H), 2.17−2.14 (m, 2H). ^{13}C NMR (100 MHz, D_2O): δ 174.1, 173.0, 172.7, 171.9, 142.1, 134.0, 130.4, 128.0, 126.7, 64.7, 53.0, 52.6, 51.4, 41.2, 32.7, 31.0, 25.7. HRMS-FAB: calcd for $C_{18}H_{25}O_7N_3ClS$ $(M + H)^+$ 462.1102; found 462.1091.

*2-Glutathionylcyclohex-2-en-1-one (**14a**).* ^{1}H NMR (500 MHz, D_2O): δ 7.46 (t, J = 4.3 Hz, 1H), 4.55−4.54 (m, 1H), 4.08 (t, J = 6.5 Hz, 1H), 4.02 (s, 2H), 3.2 (dd, J = 5.1 Hz, J = 14.1 Hz, 1H), 3.00 (dd, J = 8.5 Hz, J = 14.1 Hz, 1H), 2.63−2.54 (m, 6H), 2.27−2.24 (m, 2H), 2.05−2.03 (m, 2H). ^{13}C NMR (100 MHz, D_2O): δ 200.7, 174.2, 172.8, 172.4, 171.8, 156.6, 131.2, 52.4, 41.0, 37.9, 32.6, 30.9, 27.2, 25.5, 21.8. HRMS-FAB: calcd for $C_{16}H_{24}O_7N_3S$ $(M + H)^+$ 402.1335; found 402.1341.

HRMS-FAB: calcd for $C_{30}H_{46}O_8N_3S$ $(M + H)^+$ 608.3006; found 608.3014.

*Methyl 3-Glutathionyl-2-hydroxy-3-(4-methoxyphenyl)propanoate (**18a**). Isomer 1:* ^{1}H NMR (400 MHz, D_2O): δ 7.33

(d, $J = 8.6$ Hz, 2H), 6.93 (d, $J = 8.6$ Hz, 2H), 4.70−4.69 (m, 1H), 4.34 (d, $J = 4.9$ Hz, 1H), 4.29 (dd, $J = 5.4$ Hz, $J = 8.9$ Hz, 1H), 3.95−3.92 (m, 3H), 3.80 (s, 3H), 3.65 (s, 3H), 3.06 (dd, $J = 4.9$ Hz, $J = 14.4$ Hz, 1H), 2.81 (dd, $J = 8.9$ Hz, $J = 14.4$ Hz, 1H), 2.45 (t, $J = 7.4$ Hz, 2H), 2.12−2.08 (m, 2H). ^{13}C NMR (100 MHz, D_2O) : δ 174.1, 173.5, 172.6, 172.2, 171.4, 158.7, 130.1, 129.0, 114.7, 73.1, 55.2, 52.8, 52.5, 52.1, 51.5, 40.9, 32.1, 30.8, 25.4. HRMS-FAB: calcd for $C_{21}H_{30}O_{10}N_3S$ $(M + H)^+$ 516.1652; found 516.1645.

Isomer 2: ^{1}H NMR (400 MHz, D_2O): δ 7.35 (d, $J = 8.7$ Hz, 2H), 6.96 (d, $J = 8.7$ Hz, 2H), 4.67−4.66 (m, 1H), 4.47 (dd, $J = 5.4$ Hz, $J = 9.0$ Hz, 1H), 4.31 (d, $J = 5.4$ Hz, 1H), 3.92 (s, 3H), 3.82−3.80 (m, 4H), 3.65 (s, 2H) 2.83 (dd, $J = 5.4$ Hz, $J = 14.3$ Hz, 1H), 2.77 (dd, $J = 9.0$ Hz, $J = 14.3$ Hz, 1H), 2.52−2.48 (m, 2H), 2.18−2.16 (m, 2H). ^{13}C NMR (125 MHz, D_2O): δ 173.9, 173.6, 172.8, 172.6, 171.8, 158.6, 130.1, 129.7, 113.9, 73.4, 55.4, 52.6, 52.5, 52.4, 51.8, 41.0, 32.7, 30.8, 25.5. HRMS-FAB: calcd for $C_{21}H_{30}O_{10}N_3S$ $(M + H)^+$ 516.1652; found 516.1645.

*2-Glutathionylmethyl-2-cyclohexenone (**21a**).* Compound **21a** was characterized as previously described by Creighton and coworkers (see refs *42*−*45*). ^{1}H NMR (400 MHz, D_2O): δ 7.16 (t, $J = 3.6$ Hz, 1H), 4.54 (dd, $J = 5.3$ Hz, $J = 8.6$ Hz, 1H), 4.09 (t, $J = 6.6$ Hz, 1H), 3.99 (s, 2H), 3.30 (s, 2H), 2.96 (dd, $J = 5.1$ Hz, $J = 14.0$ Hz, 1H), 2.78 (dd, $J = 8.8$ Hz, $J = 14.0$ Hz, 1H), 2.64−2.51 (m, 2H), 2.48−2.43 (m, 4H), 2.30−2.15 (m, 2H), 2.06−1.94 (m, 2H). ^{13}C NMR (100 MHz, D_2O): δ 203.3, 174.2, 172.7, 172.6, 171.3, 152.9, 134.2, 52.8, 51.9, 40.9, 37.7, 32.4, 30.8, 29.9, 25.6, 25.3, 22.1. HRMS-FAB: calcd for $C_{17}H_{26}O_7N_3S$ $(M + H)^+$ 416.1502; found 416.1501.

*{2,3-Dichloro-4-[2-(glutathionylmethyl)butanoyl]phenoxy}-acetic Acid (**22a**).* ^{1}H NMR (500 MHz, D_2O): δ 7.46 (d, $J = 8.3$ Hz, 1H), 6.94 (d, $J = 8.3$ Hz, 1H), 4.54 (dd, $J = 6.6$ Hz, $J = 10.5$ Hz, 1H), 4.09 (t, $J = 8.1$ Hz, 1H), 4.01−3.92 (m, 2H), 3.43−3.41 (m, 1H), 2.96 (dd, $J = 5.1$ Hz, $J = 13.7$ Hz 1H), 2.87−2.81 (m, 2H), 2.70−2.55 (m, 3H), 2.23−2.20 (m, 2H), 2.05 (s, 1H), 1.62−1.45 (m, 2H), 0.73 (t, $J = 5.8$ Hz, 3H). ^{13}C NMR (100 MHz, D_2O): δ 205.7, 174.0, 172.8, 172.4, 171.5, 156.3, 132.8, 131.2, 128.6, 123.2, 111.3, 65.9, 53.2, 52.4, 51.7, 41.2, 34.1, 32.5, 31.2, 25.6, 24.4, 10.5, 0.9. HRMS-FAB: calcd for $C_{23}H_{30}O_{10}N_3Cl_2S$ $(M + H)^+$ 610.1029; found 610.1022.

*1,3-Diacryloyl-5-(3-glutathionylpropanoyl)-1,3,5-triazinane (**23a**).* ^{1}H NMR (400 MHz, D_2O): δ 6.77 (m, 2H), 6.23 (m, 2H), 5.90 (m, 2H), 5.46−5.42 (m, 6H), 4.55−4.52 (m, 1H), 4.05 (t, $J = 5.9$ Hz, 4H), 3.98 (s, 2H), 3.00 (dd, $J = 5.4$ Hz, $J = 14.2$ Hz, 1H), 2.85−2.79 (m, 5H), 2.60−2.51 (m, 2H), 2.28−2.15 (m, 2H). ^{13}C NMR (100 MHz, D_2O): δ 174.1, 172.1, 172.6, 171.3, 167.6, 130.8, 126.3, 56.5, 52.9, 52.0, 40.9, 32.9, 32.5, 30.7, 26.7, 25.3. HRMS-FAB: calcd for $C_{22}H_{33}O_9N_6S$ $(M + H)^+$ 557.2024; found 557.2030.

*1-Acryloyl-3,5-bis(3-glutathionylpropanoyl)-1,3,5-triazinane (**23b**).* ^{1}H NMR (400 MHz, D_2O): δ 6.79−6.75 (dd, $J = 10.4$ Hz, $J = 16.7$ Hz, 1H), 6.25−6.21 (d, $J = 16.7$ Hz, 1H), 5.92−5.90 (d, $J = 10.4$ Hz, 1H), 5.43−5.37 (m, 6H), 4.56 (m, 2H), 4.00−3.97 (m, 6H), 3.00−2.99 (m, 2H), 2.87−2.81 (m, 10H), 2.58−2.53 (m, 4H), 2.21−2.18 (m, 4H). ^{13}C NMR (100 MHz, D_2O): δ 174.2, 172.8, 172.6, 172.4, 171.4, 167.6, 130.8, 126.4, 56.6, 56.4, 53.0, 52.1, 41.1, 33.1, 32.6, 30.9, 26.8, 25.4. HRMS-FAB: calcd for $C_{32}H_{50}O_{15}N_9S_2$ $(M + H)^+$ 864.2868; found 864.2867.

Expression and Purification of *Sj*GST. *E. coli* pET-15b−GST was cloned, expressed, and purified by using the previously described procedures (*28*) and stored in 20% glycerol at −80 °C.

Cloning, Expression, and Purification of Human GSTA2. Total RNA isolated from HeLa cells was subjected to oligo-(dT)-directed cDNA synthesis. The resulting cDNA population was used as a template, and primers *Sna*BI−*Nde*I−hGSTA2-S and hGSTA2-*Sac*I-A were used in PCR to obtain the hGSTA2 transcripts. The resulting full-length hGSTA2 cDNA was cloned into pET-28a using the *Nde*I/*Sac*I restriction sites. The plasmid containing the hGSTA2 was confirmed by sequence analysis. The overnight culture of *E. coli* Rosetta(DE3) clones carrying recombinant hGSTA2 plasmid was diluted 1:100 with fresh LB medium and grown until $A_{600} = 0.9$ was attained. The synthesis of recombinant hGSTA2 was induced by addition of 1 mM isopropyl-β-D-thiogalactopyranoside (IPTG) (Amresco) and then incubation was continued for 5 h at 30 °C. The bacteria were collected by centrifugation for 10 min at 6000 rpm. The protein was then purified using HisTrap affinity column and exchanged to 20 mM Tris-HCl (pH 7.6) by passing PD-10 column twice. The purity of hGSTA2 was confirmed by SDS−PAGE. The resulting hGSTA2 was added to 16% glycerol before storage at −80 °C.

Table 2. Catalytic Rate Constants (k_{cat}) for the Reactions of *Sj*GST with Substrates 2, 5, 14, 18, and 23

substrate	conjugate product	k_{cat} (s^{-1})	relative k_{cat}
5	**5a**	0.044 ± 0.007^a	1
18	**18a**	0.63 ± 0.14^a	14
23	**23a**	39 ± 9.9^a	886
2	**2a**	187 ± 35^b	
14	**14a**	0.037 ± 0.002^b	

[a] Conditions: 0.5 mM GSH, 20 mM sodium phosphate (pH 7.0), 25 °C. [b] Conditions: 0.5 mM GSH, 20 mM sodium phosphate (pH 6.5), 4 °C.

Determination of Catalytic Turnover Constant for Various Electrophiles (2, 5, 14, 18, and 23; Table 2). Enzymatic reaction mixtures, containing 0.5 mM GSH, various amounts of *Sj*GST (depending on the rate of reaction in different electrophile), and 95 mL of 20 mM sodium phosphate buffer (pH 7.0), were mixed with 5 mL of methanol solutions of the corresponding electrophiles (10 mM). Aliquots were removed from each mixture at five appropriate time points (*e.g.*, 2, 4, 6, 8, and 10 min for electrophile **23**) and mixed with 80 mL of acetone. After concentration, the resulting aqueous solutions were washed with dichloromethane (4 × 30 mL) to remove unreacted electrophile, and the aqueous layer was concentrated *in vacuo*. The reaction mixtures were then analyzed by using ^{1}H NMR spectroscopy to determine the distributions of GSH conjugates and GSH. The presaturation technique was used to suppress the water signal, and a total of 32 000 data points were collected per scan over a spectral width of 12 ppm. The concentration of GSH conjugate was determined from the integral ratio of GSH conjugate/GSH based on original concentration of glutathione. Initial reaction velocities were calculated over time spans that are within the linear range, and data were transferred into Excel for calculations of k_{cat}.

Determination of *Sj*GST Specific Activities and Inhibition of *Sj*GST. The specific activity of *Sj*GST with 1 mM 1-chloro-2,4-dinitrobenzene (CDNB) as a substrate was determined at pH 6.5 and 30 °C. Product formation was monitored by absorption spectroscopy (340 nm) (*28*). *Sj*GST inhibition assays were performed as previously described (*28*). Various concentrations of inhibitors, ranging from 10 nM to 500 μM, in DMSO were incubated with *Sj*GST for 3 min prior to initiation by the addition of 1 mM GSH.

hGSTA2 Activity and IC_{50} Determinations. hGSTA2 activity and IC_{50} values were determined spectrophotometrically at 340 nm and according to the procedure of Habig *et al.* (*29*). Recombinant hGSTA2 was incubated with or without inhibitor in the presence of 1 mM CDNB in ethanol (1% ethanol in assay mix) at 30 °C for 3 min in 0.1 M potassium phosphate buffer (pH 6.5). For the determination of IC_{50} values, six different

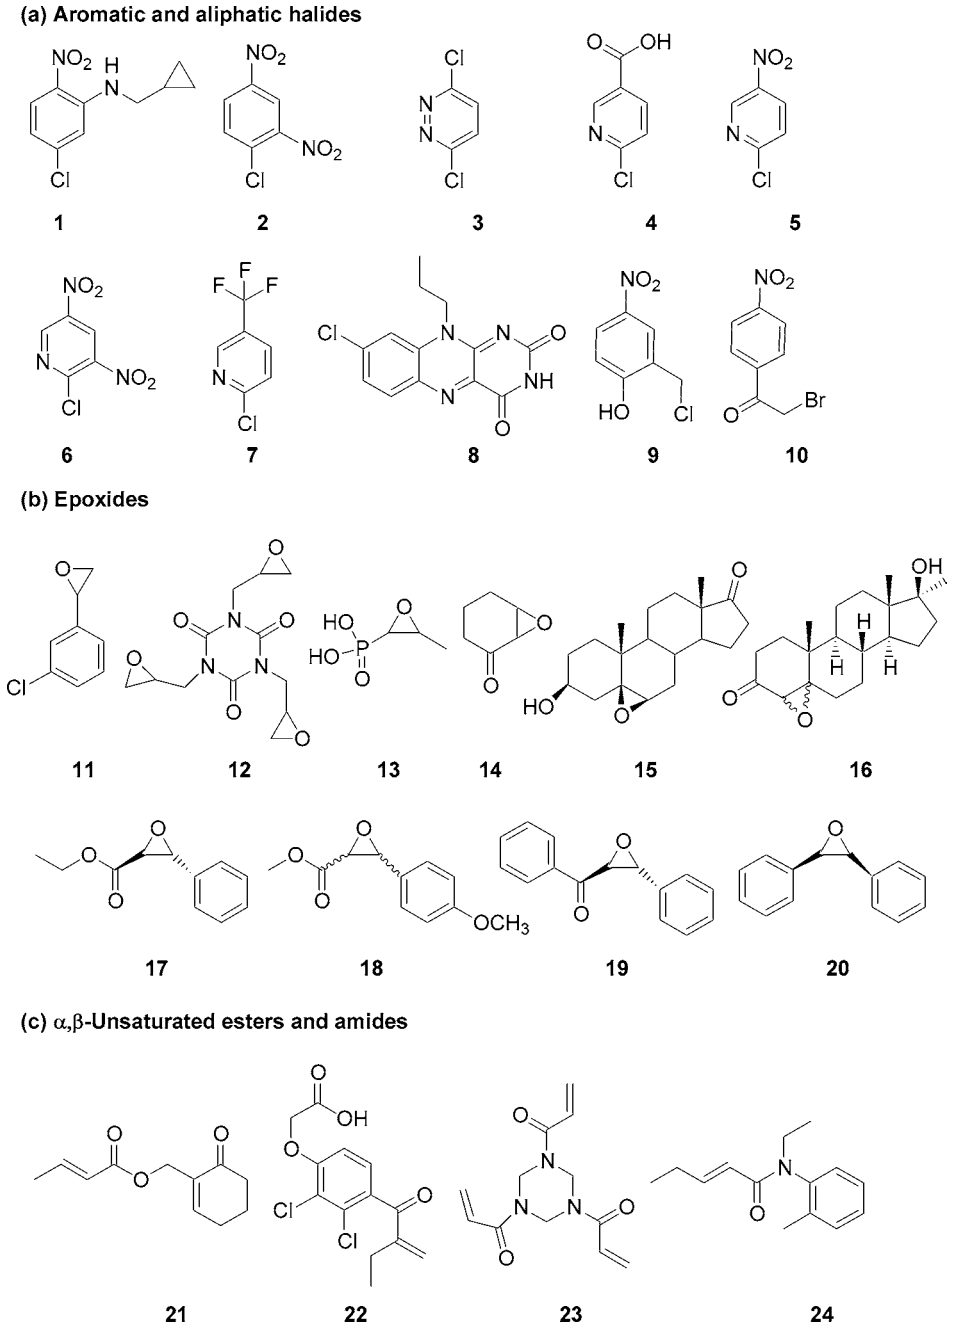

Figure 2. Chemical structures of the electrophiles.

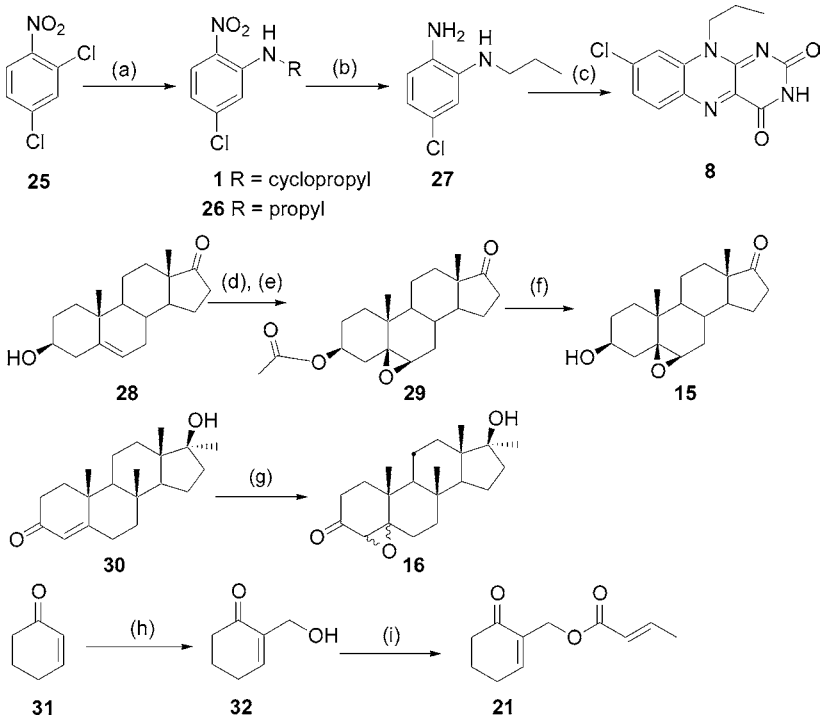
inhibitor concentrations were tested (depending on inhibitor efficacy). The reactions were initiated by the addition of 0.25 mM GSH.



RESULTS AND DISCUSSION

Preparation and Catalytic Reaction Promoted by *Sj*GST. *Sj*GST was expressed and purified to homogeneity (SDS−PAGE) by using the protocol we previously described (*28*). The products of *Sj*GST-catalyzed reactions of the electrophilic substrates **1**−**24** with GSH were characterized by using ^{1}H NMR spectroscopy. In addition, the inhibitory properties of **9**−**11** and **22** toward *Sj*GST were determined. Finally, nonenzymatic products, **9a**−**11a**, **16a**, **21a**, and **22a**, inhibiting the activity of *Sj*GST were studied.

Selection of Substrate Library and Synthesis of Electrophilic Substrates. The common electrophilic substrates of the GSTs include epoxides, aliphatic and aromatic halides, α,*β*-unsaturated carbonyl compounds, and alkenes (*8*, *30*). The electrophilic substrates **1**−**24** (Figure 2), used in this study, include aromatic halides (**1**−**8**), aliphatic halides (**9**, **10**), epoxides (**11**−**20**), and α,*β*-unsaturated esters (**21**, **22**) and amides (**23**, **24**). The routes used for syntheses of **1**, **8**, **15**, **16**, and **21** are outlined in Scheme 1, while the other substances used are commercially available.

The cyclopropane **1** and flavin analog **8** used in this effort were synthesized starting with 2,4-dichloronitrobenzene (**25**). Regioselective aromatic substitution reactions (*31*) of **25** with cyclopropylamine or *n*-propylamine in the presence of K_2CO_3 afford **1** and **26**, respectively. Catalytic hydrogenation of **26** (methanol at 0 °C, 10% Pd/C and ammonium formate) results in dehalogenation of the arene ring. Consequently, diamine **27** was prepared by reacting **26** with Raney nickel in the presence of hydrazine at 70 °C (*32*). Condensation of **27** with alloxan monohydrate in acetic acid and boric acid under an anaerobic conditions (*33*) provides the desired flavin analogue **8**. The preparation of **15** began with acetylation of the Δ^5-unsaturated

Scheme 1. Synthetic Routes Used To Prepare the Electrophilic Substrates 1, 8, 15, 16, and 21[a]

[a] Reagents and conditions: (a) cyclopropylamine/*n*-propylamine, K_2CO_3, DMF, 90 °C, 57%; (b) RaNi, hydrazine, MeOH, 70 °C, 70%; (c) alloxan monohydrate, H_3BO_3, HOAc, 56%; (d) acetic anhydride, pyridine, 97% (e) $KMnO_4$, $CuSO_4 \cdot 5H_2O$, CH_2Cl_2, *t*-butyl alcohol, H_2O, 50%; (f) NaOMe, MeOH, 90%; (g) 30% H_2O_2, 10% NaOH, MeOH, 0 °C, 64%; (h) DMAP, CH_2O, THF, rt, 62%; (i) DMAP, crotonic anhydride, pyridine, rt, 89%.

sterol **28** followed by selective epoxidation with $KMnO_4$−$CuSO_4$ in dichloromethane containing a catalytic amount of water and *tert*-butyl alcohol. This produced the steroidal *β*-epoxide **29** (*34*). Removal of the acetyl group gave compound **15**. Alkaline hydrogen peroxide-promoted epoxidation of **30** at 0 °C afforded a mixture of the corresponding α- and *β*-epoxides **16** (*35*). Baylis−Hillman reaction (formaldehyde and 4-(dimethylamine)pyridine) of cyclohex-2-enone (**31**) was used to produce the hydroxymethyl-cyclohexenone **32**. Esterification of **32** by crotonic anhydride afforded **21** (*36*).

Identification of Glutathione Conjugates Formed in Nonenzymatic Reactions. Nonenzymatic conjugation of glutathione is one of the mechanisms associated with the development of drug resistance. Therefore, an understanding of the nonenzymatic reactivity of selected substrates with GSH could provide clues about the chemical basis for conjugation. To investigate whether nonenzymatic substrate−GSH conjugation processes, observed in aqueous solution reactions, would also be important under physiological conditions, reactions of the electrophiles in 20 mM phosphate buffer (pH 7.0) at 25 °C in the presence of 0.5 mM glutathione were explored. Formation of glutathione conjugates were monitored by using ^{1}H NMR spectroscopy. Among the substances tested, **6**, **8**−**11**, **16**, **21**, and **22** (Figure 2) were found to undergo adduct formation producing the respective conjugates **6a**, **8a**−**11a**, **16a**, **21a**, and **22a** (Table 1 and Figure 3). This suggests that these electrophilic substrates have a high potential for generating nonenzymatic metabolites under physiological conditions. Interestingly, the other compounds were found to be stable in the presence of glutathione up to 5 h under the conditions employed.

***Sj*GST-Catalyzed Formation of Glutathione Conjugates.** In view of the protective function of *Sj*GST against potentially toxic foreign chemicals, we carried out studies to elucidate the nature of the conjugation reactions that this enzyme catalyzes with selected substrates. ^{1}H NMR spectroscopic analysis was used for this purpose, and the contributions of nonenzymatic conjugation reactions were taken into account. The results, summarized in Table 1, show that electrophiles **5**, **18**, and **23** (Figure 2) participate in *Sj*GST-catalyzed reactions with glutathione to form the respective adducts **5a**, **18a**, and **23a** (Figure 3). In each of these cases, no reaction occurs in the absence of the enzyme. In addition, *Sj*GST catalyzed the reaction of glutathione with **2** to give **2a**. The nonenzymatic contribution to this process is negligible (Table 1). For substrates **6**, **10**, **14**, and **22** (Figure 2), where incubation with glutathione at room temperature leads to fast reactions, the *Sj*GST-catalyzed processes were conducted in phosphate buffer (pH 6.5) at 4 °C to retard the competition from nonenzymatic reactions. The results show that under these conditions enzyme-catalyzed GSH conjugation is the primary route followed for **14** leading to **14a** and only a minor pathway for the conversion of **6** to **6a** (Table 1). On the other hand, it is not possible to distinguish between enzymatic and nonenzymatic reactions of **10** and **22** owing to the high rates of the latter processes. The accumulated observations demonstrate that **2**, **5**, **6**, **14**, **18**, and **23** are good substrates for *Sj*GST and that **1**, **3**, **4**, **7**−**9**, **11**−**13**, **15**−**17**, **19**−**21**, and **24** are not. This is the case even though some members of the latter group of electrophiles, including **8**−**11**, **16**, **21**, and **22**, undergo nonenzymatic reactions with glutathione to form GSH conjugates (Table 1).

Structural Identification of Glutathione Conjugates and Mechanistic Studies. Studies were conducted to elucidate the chemical structures and mechanisms of formation of the GSH conjugates. Reverse-phase HPLC was used to separate products **2a**, **5a**, **6a**, **14a**, **18a**, and **23a** from mixtures generated by *Sj*GST-catalyzed reactions of the electrophilic substrates **2**, **5**, **6**, **14**, **18**, and **23** with GSH. Assignments of the structures of **2a**, **5a**, and **6a** (Figure 3) were made by using ^{1}H, ^{13}C NMR, and HRMS methods. For the more complex GSH conjugates, **14a**, **18a**, and **23a**, structural determinations were made by using a combination of MS and two-dimensional NMR spectroscopic techniques. In Figure 4 is displayed the HPLC chromatogram

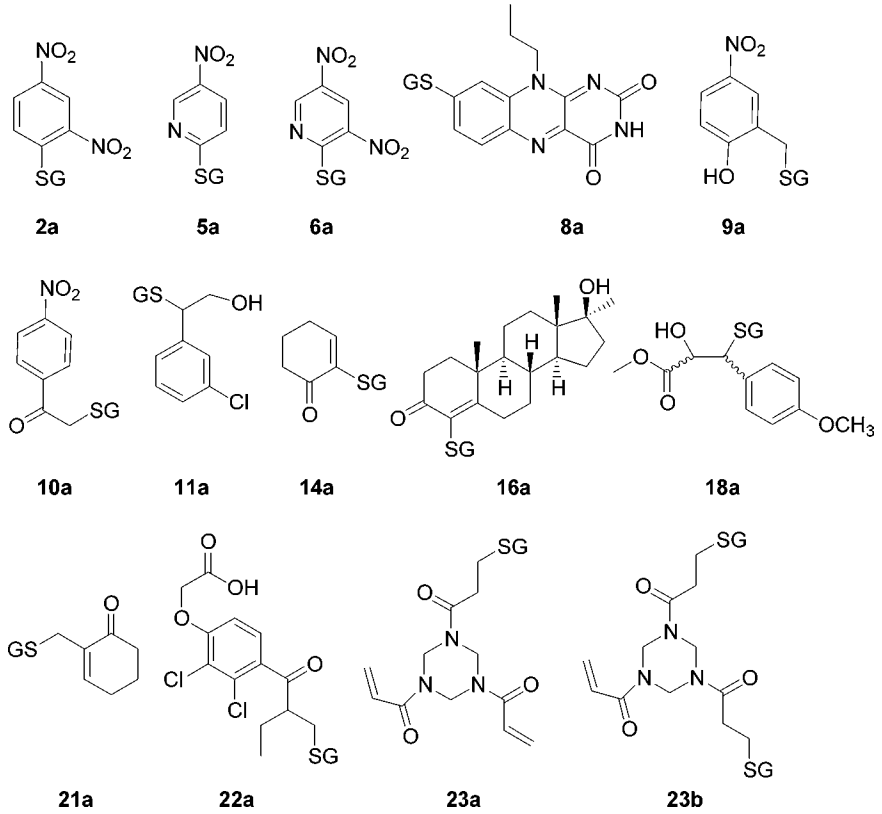


Figure 3. Structures of glutathione conjugates derived from nonenzymatic and enzymatic reactions.

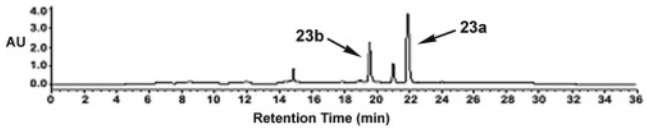

Figure 4. Reverse-phase HPLC chromatogram ($\lambda = 220$ nm) of the product mixture from *Sj*GST-catalyzed conjugation of **23**. Fractions were collected and identified with FAB-MS. The peaks containing the mono(glutathionyl) conjugate **23a** and bis(glutathionyl) conjugate **23b** are indicated with arrows.

of the mixture formed by reaction of **23** with *Sj*GST. The fractions corresponding to the peaks with retention times of 14.9, 19.2, 21.1, and 22.0 min were individually collected, lyophilized, and analyzed by fast atom bombardment (FAB) mass spectrometry and NMR spectroscopic methods (^{1}H and ^{13}C NMR, heteronuclear multiple-quantum coherence (HMQC), and heteronuclear multiple-bond correlation (HMBC)). FAB-MS analysis showed that two substances corresponding to GSH−**23** conjugates are formed in this process, a bis(glutathionyl) conjugate **23b** (retention time of 19.2 min) with $[M + H]^+$ ion at *m*/*z* 864 and a mono(glutathionyl) conjugate **23a** (retention time of 22.0 min) with $[M + H]^+$ ion at *m*/*z* 557 (Figure 5). The ratio of **23b**/**23a** is *ca.* 1:3 after 5 h as determined by integration of the well-resolved HPLC peaks. Only **23a** (without formation of **23b**) is observed to form during short reaction times, indicating that **23** most likely undergoes enzymatic activation *in vitro* to form the mono(glutathionyl) intermediate, **23a**. This substance then reacts with GSH to form the bis-(glutathionyl) conjugate, **23b**. This finding shows that the enzyme catalyzes Michael addition reactions of GSH with both **23** and **23a**. MS analysis indicates that no other types of GSH conjugates are formed in this process.

*Sj*GST was found to promote GSH conjugation reactions of the *cis* and *trans* isomers of epoxide **18**. The two products formed in these reactions were purified by reverse-phase HPLC (retention times 21.8 and 23.7 min) and found to have identical molecular ions ($[M + H]^+ = 516$). This is consistent with the assignment of *erythro* and *threo* structures of **18a** to these substances (Scheme 2). ^{1}H NMR and ^{13}C NMR spectra of these adducts are in agreement with the proposed structures, reported to form in Lewis acid-catalyzed reactions of the epoxides (*37*). *Sj*GST-catalyzed ring opening of the *cis* and *trans* isomers of epoxide **18** is expected to yield the *erythro* and *threo* isomers, respectively (Scheme 2).

Incubation of **14**, GSH, and *Sj*GST in phosphate buffer (pH 6.5) at 4 °C gives rise to **14a**, a substance that has a *m*/*z* of 402 ($[M + H]^+$). This corresponds to a substance formed by loss of one molecule of water from an initially formed GSH conjugate **33** (Scheme 3). The ^{1}H NMR spectrum of **14a** contains a chemical shift at 7.46 ppm (1 H) indicating the presence of an olefinic methine hydrogen, which is assigned to the β-proton of the α,β-unsaturated ketone moiety in **14a**. The observation of a methine proton (H-3) as a triplet (1H) with a coupling constant of 4.3 Hz, arising by coupling with C-4 methylene protons, further confirms this assignment. Additional evidence for the assignment of the structure of **14a** comes from analysis of 2D NMR (HMQC and ^{1}H−^{1}H correlation spectroscopy (COSY)) data. The HMQC spectrum of this substance shows a correlation between H-3 (7.46 ppm) and H-4a/H-4b (2.54 ppm) and carbon signals at δ 156.6 ppm (C-3) and 27.2 ppm (C-4), respectively. In the ^{1}H−^{1}H COSY spectrum (Figure 6), the H-3 methine triplet at δ 7.46 ppm shows a cross-peak at δ 2.54 ppm, attributed to the H-4a/H-4b methylene protons. These results confirm that the α,β-epoxylketone **14** undergoes *Sj*GST-catalyzed addition of glutathione to the C-α position and that the initially formed β-hydroxy sulfide **33** spontaneously loses water to produce the alkenyl sulfide **14a** (Scheme 3). It is also noteworthy that a similar mechanistic pathway is followed in the nonenzymatic reaction of **14** and in other reactions between α,β-epoxylketones and alkyl/aryl thiols (*38*).

Nonenzymatically generated GSH conjugates **8a**−**11a**, **16a**, **21a**, and **22a** were purified by reverse-phase HPLC and analyzed by using FAB-MS. The observation of *m*/*z* values of 562 ([M

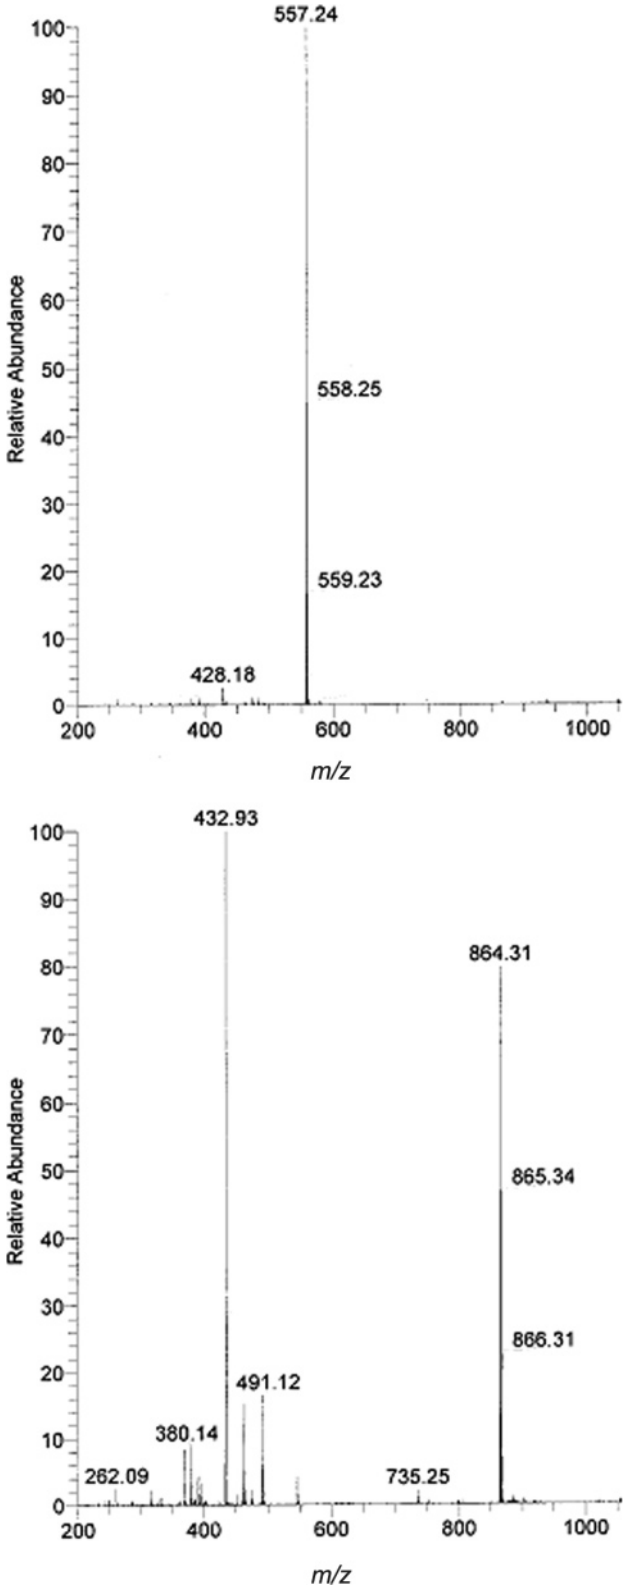

Figure 5. FAB-MS of the parent ions $[M + H]^+$ of mono(glutathionyl) conjugate **23a** and bis(glutathionyl) conjugate **23b** at *m*/*z* 557 and 864, respectively.

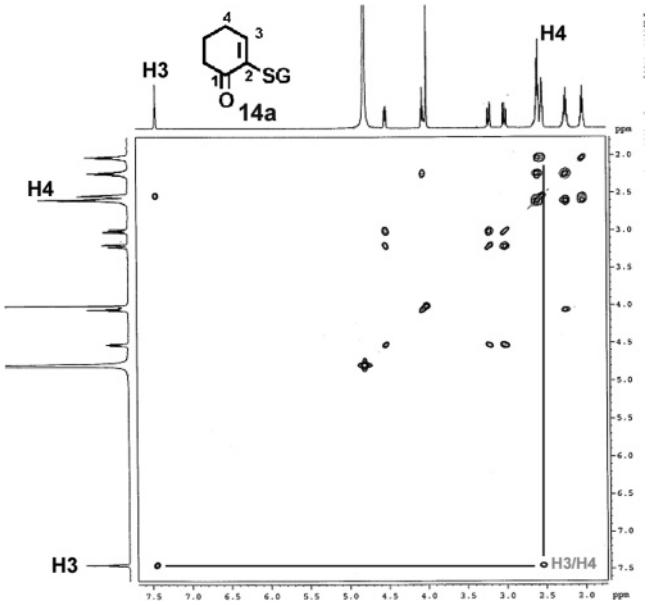
$+ H]^+$) for **8a**, *m*/*z* of 459 ($[M + H]^+$) for **9a**, *m*/*z* of 471 ($[M + H]^+$) for **10a**, *m*/*z* of 462 ($[M + H]^+$) for **11a**, and *m*/*z* of 610 ($[M + H]^+$) for **22a** (*39*) shows that they all are glutathione adducts. Also, **16a** and **21a**, obtained from HPLC peaks eluting at 25.82 and 6.63 min, respectively, have molecular weights of 608.3006/608.3014 and 416.1502/416.1501 (calculated molecular weight/measured molecular weight). These results indicate



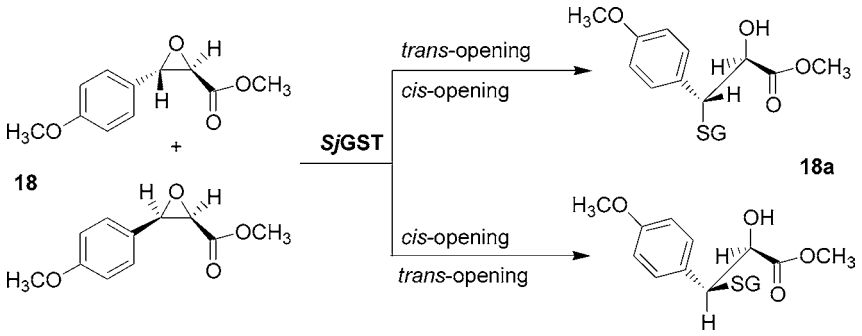


Figure 6. $[^1H,^1H]$-COSY NMR spectrum of GSH conjugate **14a** with assigned cross-peak of the H-3 methine and H-4 methylene protons (underlined).

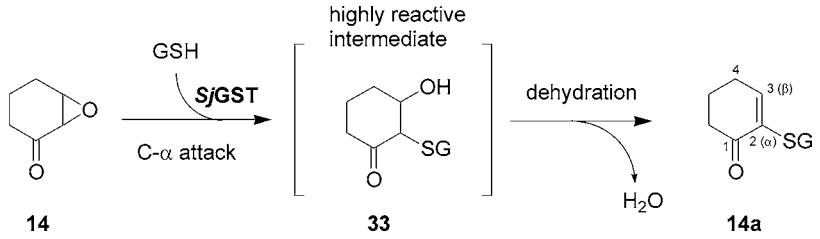
that **16a** might be produced by loss of water from the intermediate GSH conjugate **34** (Scheme 4). The ^{13}C NMR spectrum of **16a** closely resembles that of *N*-(13-(*t*-butoxycarbonylamino)-4,7,10-trioxatridecanyl)-3-(pregn-4-ene-3,20-dione-4-yl)thiopropanamide (Chart 1) (*40*), in which the α,β-unsaturated carbon resonances at 125.6 (4-C) and 171.7 (5-C) ppm are characteristic of an alkenyl thiol. The chemical shifts associated with an alkenyl thiol moiety are observed in the ^{13}C NMR spectrum of **14a** and aromatase inhibitors (*41*). The ^1H NMR spectrum of **21a** contains a resonance at δ 7.16 ppm (triplet) indicating the presence of H3 of an β,γ-unsaturated 2-cyclohexenone. Moreover, the ^1H and ^{13}C NMR spectra of **21a** match those reported for **21a** (see the Supporting Information) from human glutathione transferase-catalyzed conversion of **21**, which arises by addition of glutathione to form the exocyclic enone intermediate, **35** (Scheme 5) (*42*−*45*).



Kinetics of Glutathione Conjugate Formation. *Sj*GST was observed to accelerate the reaction of GSH with the electrophilic substrates **5**, **14**, **18**, and **23**. To determine which substrate reactions are sufficiently kinetically competent for *in vivo* metabolism, we measured k_{cat} values for *Sj*GST-catalyzed conjugation of **5**, **18**, and **23** in phosphate buffer (20 mM, pH 7.0) at 25 °C. In these processes, the amounts of products formed increased in a linear manner with increasing incubation times up to 10 or 50 min (data not shown). For these substrates, k_{cat} values were determined by measuring the initial rates of the GSH conjugation reactions as functions of substrate concentrations. The results of triplicate experiments are summarized in Table 2. The k_{cat} values for **23** and **18** are about 886-fold and about 14-fold larger than that for **5**, respectively. Due to the considerable amount of nonenzymatic reaction seen with **14**, the k_{cat} (0.037 ± 0.002 s^{-1}) was obtained in sodium phosphate buffer (20 mM, pH 6.5) at 4 °C. Similarly, the k_{cat} (187 ± 35 s^{-1}) value for **2** was measured under the same conditions due to the fast enzymatic reaction and the detectable nonenzymatic reaction. Among the electrophilic substrates tested except **2**, the reactivity order as determined by k_{cat} is **23** > **18** > **5** > **14**. Based on these results, it can be concluded that *Sj*GST might contribute to the detoxification of 1,3,5-triacryloylhexahydro-1,3,5-triazine (**23**) *in vivo*.

Inhibition of *Sj*GST by Nonenzymatically Derived GSH Conjugates 9a−11a, 16a, 21a, and 22a and Electrophilic

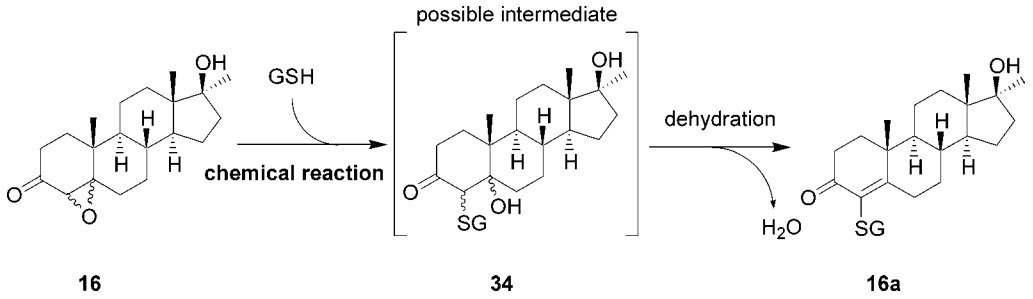
Scheme 3. Proposed Pathway for the Formation of GSH Conjugate 14a

Scheme 4. Proposed Pathway for the Conversion of 16 to 16a via Intermediate 34



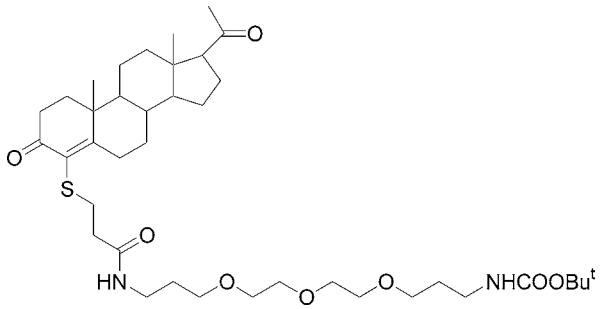


Chart 1. Chemical Structure of *N*-(13-(*t*-Butoxycarbonylamino)-4,7,10-trioxatridecanyl)-3-(pregn-4-ene-3,20-dione-4-yl)thiopropanamide

Substrates (9−11 and 22). The results of a number of earlier efforts have demonstrated that glutathione protects against the cytotoxicity of anticancer agents by causing either an increased level of GSH-mediated nucleophilic attack or an elevation in the level of cellular GST-catalyzed GSH conjugation. GSH conjugates are usually good inhibitors of GSTs *in vitro* or *in vivo*. Based on these reports, it was important to determine whether the nonenzymatically generated glutathione adducts have an effect on the *Sj*GST-catalyzed reactions. Additionally, the electrophilic substrates themselves might also play an inhibitory role in *Sj*GST-promoted reactions. To determine whether nonenzymatic products or electrophilic substrates could inhibit *Sj*GST, we incubated the enzyme with the nonenzymatic GSH conjugates **9a**−**11a**, **16a**, **21a**, and **22a** and the electrophiles **9**−**11** and **22** along with 0.25 mM GSH and 1 mM CDNB. The results, summarized in Table 3, show that nonenzymatic GSH conjugates **9a**−**11a**, **16a**, **21a**, and **22a** are inhibitors of *Sj*GST; **9a**−**11a**, **16a**, and **22a** displayed IC_{50} values of 1.95, 75.5, 0.96, 19.0, and 0.36 μM, which represent respective 78-, 2-, 158-, 8-, and 422-fold inhibitory enhancements over **21a** (IC_{50} = 152 μM). Together, the data serve to explain why conjugation reactions of some of electrophilic substrates are not catalyzed by *Sj*GST when the formation of nonenzymatic GSH conjugates occurs rapidly.

The ethacrynic acid **22** (EA) at concentrations in the 5 μM range is a significant inhibitor of *Sj*GST (*ca.* 80%). In contrast, when this substance is used in the 0.5 μM range, it is displays less efficient inhibition (*ca.* 45%). However, the adduct **22a** is a significant inhibitor of *Sj*GST (*ca.* 70%) even when it is used at the lower end of this concentration range (Figure 7). The results support the proposal that **22a**, owing to its rapid rate of formation, is able to efficiently inhibit the *Sj*GST process when low concentrations of **22** are used.

Results from studies of the inhibitory effects of substrates **9**−**11** and **22** are shown in Table 3, where the inhibitory data displayed are not corrected for contributions from the formation of glutathione conjugates. Both the substrate **10** and its GSH conjugate **10a** are micromolar inhibitors of *Sj*GST, with **10** being slightly more potent (IC_{50} = 65.0 μM) than **10a** (IC_{50} = 75.5 μM). It is interesting to note that this is the only example uncovered in this study that unambiguously provides direct evidence of substrate inhibition toward *Sj*GST. As expected, **22** has an IC_{50} value more than 2-fold lower than that of its GSH conjugate **22a** (IC_{50} = 0.36 μM) at 0.87 μM. This result is in line with the previous conclusion (see above) that the effect of **22a** on *Sj*GST occurs when low concentrations of **22** are used. Substrates **9** and **11** are weak *Sj*GST inhibitors (IC_{50} >

11a	0.96 ± 0.71	141 ± 37
16a	19.0 ± 7.2	10.5 ± 0.3
21a	152 ± 26	20 ± 7
22a	0.36 ± 0.01	2.08 ± 0.25

[a] Inhibitor concentration at which half-maximal enzyme activity is obtained (IC_{50}, mean ± SEM, $n = 3$). [b] The percent (%) inhibition, in parentheses, at 10 μM is expressed as the percent (%) inhibition of enzyme activity without correction for the contribution of the formation of glutathione conjugate. [c] The percent (%) inhibition, in parentheses, at 500 μM is expressed as the percent (%) inhibition of enzyme activity without correction for the contribution of the formation of glutathione conjugate. [d] The percent (%) inhibition, in parentheses, at 250 μM is expressed as the percent (%) inhibition of enzyme activity without correction for the contribution of the formation of glutathione conjugate.

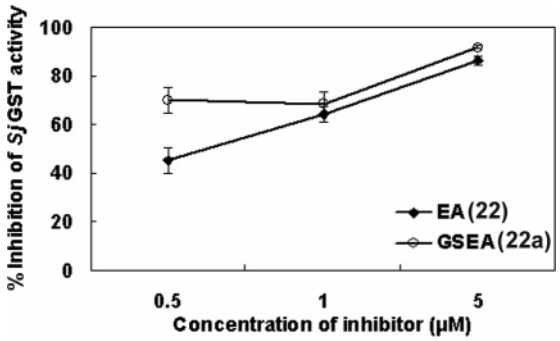

Figure 7. The inhibitory effects of EA **22** (0.5−5.0 μM) and GSEA **22a** (0.5−5.0 μM) on *Sj*GST activity. The data are expressed as % inhibition of *Sj*GST activity by **22** and **22a**.

10 μM for **9** with 14% inhibition at 10 μM, IC_{50} > 500 μM for **11** with 27% inhibition at 500 μM).

Cloning, Expression, Purification, and Characterization of Human GSTA2. Total RNA isolated from HeLa cells was subjected to oligo(dT)-directed cDNA synthesis. The resulting cDNA population was used as template in PCR to obtain the hGSTA2 transcripts (Figure 8A). The *E. coli* Rosetta(DE3) clone carrying recombinant hGSTA2 plasmid was expressed, and the hGSTA2 proteins were purified using HisTrap affinity column (Figure 8B). The specific activity of hGSTA2 (33.4 ± 0.6 μmol/(min·mg)) was measured by using the spectrophotometric assay procedure. The results show that the recombinant His-tagged protein has a higher specific activity than that reported earlier (*46*, *47*).

Inhibition of Human GSTA2 by Nonenzymatic GSH Conjugates and Selected Electrophilic Substrates. Given that nonenzymatic GSH conjugates **9a**−**11a**, **16a**, **21a**, and **22a** and electrophilic substrates **9**−**11** and **22** show inhibitory activity toward *Sj*GST, we examined the inhibition of hGSTA2 by these compounds. The results demonstrate that hGSTA2 is inhibited by these nonenzymatic GSH conjugates and electrophilic substrates in the same manner as is *Sj*GST. It is important to note that the conjugate **22a** is at least 2- to 120-fold more potent than the other conjugates (Table 3). Interestingly, the results reveal that **22a** is a potent inhibitor of human GSTA2 with an IC_{50} value of 2.08 μM, which is similar to the value (2.3 μM) obtained from the human GSTA1-1 inhibition assay (*48*). As expected, substrate **10** displays at least 4-fold greater inhibitory potency than that of the corresponding GSH conjugate **10a**. This observation indicates that the glutathionyl moiety in **10a** is not required for binding to hGSTA2. This contrasts with other substrate/GSH conjugate pairs (*e.g.*, **9**/**9a**, **11**/**11a**, and **22**/**22a**) where attachment of the glutathionyl group to substrate does enhance binding in the active site of GSTA2. As is evident from inspection of the data in Table 3, **11a** and **21a** and **22a** are potent and selective inhibitors of *Sj*GST and GSTA2, respectively.

In conclusion, the results of the study described herein demonstrate that electrophilic compounds, including aliphatic and aromatic halides (**2**, **5**, and **6**), epoxides (**14** and **18**), and an α,*β*-unsaturated carbonyl compound (**23**), undergo *Sj*GST-catalyzed *in vitro* reactions with glutathione to form the corresponding mono(glutathionyl) or bis(glutathionyl) conjugates. By using reverse-phase HPLC, NMR, and FAB-MS analysis, GSH conjugates formed in the enzymatic reactions

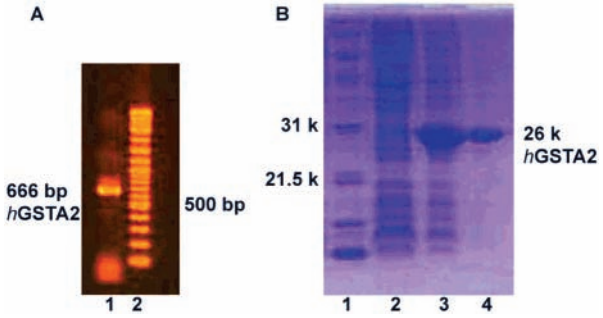

Figure 8. (A) hGSTA2 PCR products using HeLa cells total cDNA as template. Using RT-PCR, a 666-bp product corresponding to human GSTA2 was observed (lane 1). A 1-Kb DNA ladder is shown in lane 2. (B) Preparations of hGSTA2 are shown at various stages of purification on a Coomassie-stained 10% SDS−PAGE gel. and in nonenzymatic processes were characterized and quantified. In comparison to other electrophiles except **2**, **23** was found to be a good substrate for *Sj*GST and the initially formed conjugation product **23a** also undergoes *Sj*GST-catalyzed glutathione conjugation to form **23b**. Additionally, we have demonstrated that both enzymatic and nonenzymatic products are produced under the conditions used for *Sj*GST-activated GSH conjugation. Moreover, the nonenzymatic GSH conjugates and electrophilic substrates probed in this effort have been found to inhibit catalysis by *Sj*GST. Also, these substances exhibit significant inhibitory activity against the human GST isozyme, hGSTA2. These inhibitors have considerable promise in explorations of the physiological relevance of hGST-mediated drug resistance in tumor cells.

ACKNOWLEDGMENT

We thanks Dr. Y.-J. Chen for generously providing us with total RNA of Hela cells. We thank the National Science Council (Grant NSC 94-2113-M-001-017) and Academia Sinica (Program Project AS-92-TP-A04) for financial support.

Copper-Activated DNA Photocleavage by a Pyridine-Linked Bis-Acridine Intercalator

María-José Fernández,[†] Beth Wilson,[‡] Marta Palacios,[†] María-Melia Rodrigo,[§] Kathryn B. Grant,*[,‡] and Antonio Lorente*[,†]

Departamento de Química Orgánica and Departamento de Química-Física, Universidad de Alcalá, 28871-Alcalá de Henares, Madrid, Spain, and Department of Chemistry, Center for Biotechnology and Drug Design, Georgia State University, P.O. Box 4098, Atlanta, Georgia 30303-4098. Received June 26, 2006; Revised Manuscript Received October 16, 2006

We report the synthesis of new photonuclease **4** consisting of two acridine rings joined by a pyridine-based copper binding linker. We have shown that photocleavage of plasmid DNA is markedly enhanced when this ligand is irradiated in the presence of copper(II) (419 nm, 22 °C, pH 7.0). Viscometric data indicate that **4** binds to DNA by monofunctional intercalation, and equilibrium dialysis provides an estimated binding constant of 1.13 $\times$ 10^5 M^{-1} for its association with calf thymus DNA. In competition dialysis experiments, **4** exhibits preferential binding to GC-rich DNA sequences. When Cu(II) is added at a ligand to metal ratio of 1:1, electrospray ionization mass spectrometry demonstrates that compound **4** undergoes complex formation, while thermal melting studies show a 10 °C increase in the T_m of calf thymus DNA. Groove binding and intercalation are suggested by viscometric data. Finally, colorimetric and scavenger experiments indicate that the generation of Cu(I), H_2O_2, and superoxide contributes to the production of DNA frank strand breaks by the Cu(II) complex of **4**. Whereas the strand breaks are distributed in a relatively uniform fashion over the four DNA bases, subsequent piperidine treatment of the photolysis reactions shows that alkaline labile lesions occur predominantly at guanine.

INTRODUCTION

The design and synthesis of small molecules that bind to and cleave nucleic acids are still major challenges. These artificial nucleases have important applications as tools in molecular biology and as potential therapeutic agents for the treatment of cancer and viral diseases. DNA cleavage is often associated with redox-active or photoactivated transition metal complexes (*1*−*3*). To date, a number of metal complexes capable of inducing double-stranded DNA lesions have been developed (*4*−*7*).

Photosensitization of intercalating units can promote DNA damage by three main mechanisms: (a) electron transfer from DNA nucleobases, especially guanine, to a photochemically excited state of the intercalator, (b) photogeneration of hydroxyl radicals, an intermediate reactive species which can abstract hydrogen atoms from the DNA sugar backbone, and (c) preferential oxidation of guanines by singlet molecular oxygen generated through energy transfer from an electronically excited photosensitizer (*8*−*11*). In some cases, photoreduction of metal complexes is an important step in DNA cleavage reactions (*12*−*16*).

Photochemical DNA-cleaving molecules can be used as photonucleases, as photofootprinting agents, and as drugs in photodynamic therapy. Copper exists at micromolar levels in serum and other biological fluids (*17*) and is closely associated with nucleic acids and chromosomes (*18*−*20*), where it is thought to play a role in regulating gene expression (*21*, *22*). Taking this into account, photonucleases which bind to copper may be of greater utility at the cellular level in comparison to photonucleases containing other transition metals or to chemical nucleases which require an external reducing agent. Accordingly, a number of references on copper binding complexes with photolytic activity have appeared in the literature (*14*−*15*, *23*−*35*). While in vivo levels of free copper are tightly controlled by proteins (*36*−*38*), the kinetically labile nature of this metal allows ion exchange between small ligands and proteins to take place (*38*, *39*).

Herein, we present the synthesis, characterization, and DNA photocleaving properties of a pyridine-linked bis-acridine intercalator (**4**). We have found that **4** is a good DNA photocleaver, but that cleavage efficiency is markedly enhanced in the presence of Cu(II), converting pUC19 plasmid DNA into its nicked and linear forms upon exposure to visible light (419 nm, pH 7.0, 22 °C). Use of the colorimetric reagent bathocuproinedisulfonic acid disodium salt hydrate (BCS) indicates that the DNA photocleavage reaction involves acridine-sensitized photoreduction of Cu(II) to Cu(I).

MATERIALS AND METHODS

General Procedures. Merck silica gel 60 (230−400 ASTM mesh) was employed for flash column chromatography. TLC was performed on precoated aluminum silica gel plates (Merck or Macherey-Nagel 60F254 0.25 mm). Melting points were determined in an Electrothermal digital IA9100 apparatus. Infrared spectra were taken on an FT−IR Perkin-Elmer 1725X spectrophotometer. All ^1H and ^{13}C NMR spectra were recorded at 300 and 75 MHz, respectively, on a Varian Mercury-VX-300 spectrometer. Chemical shifts are reported in parts per million (ppm) using the residual peaks of either chloroform (δ 7.26 and 77.0 ppm) or methanol (δ 3.30 and 49.0 ppm) as an internal reference. Carbon and proton assignments were based on HSQC and HMBC experiments. CI mass spectra were generated on a Hewlett-Packard HP-5988a spectrometer at 70 eV. An Automass Multi GC/API/MS Finnigan spectrometer was used for ESI mass spectra. Elemental analyses were performed with a Heraeus CHN analyzer. A Cary Bio100 UV−visible

spectrophotometer (Varian) was used to plot thermal melting curves, while all other UV−visible spectra were recorded with a Shimadzu UV-1601 or a Lambda 18 Perkin-Elmer spectrophotometer. DNA photolysis reactions were run in an aerobically ventilated Rayonet Photochemical Reactor fitted with eight RPR−4190 Å lamps (The Southern New England Ultraviolet Company).

Reagents were of the highest available purity and were used without further purification. L-Ascorbic acid, catalase, copper(II) chloride dihydrate, sodium phosphate monobasic and dibasic salts, and superoxide dismutase were purchased from Sigma. Glycogen and G-50 Sephadex columns were from Roche Applied Science. Sequenase Version 2.0, Sequenase Stop Solution, and [^{35}S]dATPαS were supplied by Amersham Biosciences. *Eco*RI and *Fsp*I restriction endonucleases were from New England Biolabs. All other chemicals including bathocuproinedisulfonic acid disodium salt hydrate, dimethyl sulfoxide, ethanol, ethidium bromide, D-mannitol, piperidine, and sodium azide were obtained from the Aldrich Chemical Company. Both 2,6-bis[(2-hydroxyethyl)methylaminomethyl]-pyridine (**1**) (*40*) and (6-amino-3-acridinyl)carbamic acid methyl ester (**3**) (*41*) were prepared according to reported procedures.

Transformation of *E. coli* competent cells (Stratagene, XL-1 blue) with pUC19 plasmid DNA (Sigma) and growth of bacterial cultures were performed according to established methods (*42*). Purification of the plasmid DNA was accomplished using a Qiagen Plasmid Mega Kit. All enzymes were used according to manufacturer's instructions in the buffers supplied.

2,6-Bis[(2-chloroethyl)methylaminomethyl]pyridine (2). Thionyl chloride (10 mL) was added to 348 mg (1.32 mmol) of 2,6-bis[(2-hydroxyethyl)methylaminomethyl]pyridine (**1**). The reaction mixture was stirred at room temperature for 24 h and then was concentrated at reduced pressure, affording a syrup characterized as **2**·HCl. IR (film): ν 3393, 2968, 2666, 1598, 1463, 1407, 1217, 1160, 756 cm^{-1}. ^{1}H-NMR (CD_3OD): δ 8.04 (t, J = 7.7 Hz, H4), 7.56 (d, J = 7.7 Hz, 2H, H3, H5), 4.62 and 4.80 (AB, 4H, J = 14 Hz, CH_2-pyr), 4.12 (t, J = 6.4 Hz, 4H, CH_2Cl), 3.69 (m, 4H, CH_2N), 3.01 (s, 6H, CH_3). ^{13}C-NMR (CD_3OD): δ 151.44 (C2, C6), 140.92 (C4), 125.41 (C3, C5), 60.54 (CH_2-pyr), 58.33 (CH_2N), 42.21 (CH_3), 38.04 (CH_2Cl). To a solution of 1.23 g (3.08 mmol) of **2**·HCl in methanol (20 mL), 1.14 g (10.78 mmol) of Na_2CO_3 was added. The mixture was stirred for 3 h and then concentrated to dryness. The residue was treated with dichloromethane (25 mL), and the mixture was washed three times with water (10 mL). The organic layer was dried over $MgSO_4$, filtered, and concentrated at reduced pressure to yield **2** as a brown oil (580 mg, 65%). IR (film): ν 2950, 2795, 1591, 1577, 1455, 1353, 1305, 1262, 1118, 1062, 739 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ 7.65 (t, J = 7.7 Hz, 1H, H4), 7.35 (d, J = 7.7 Hz, 2H, H3, H5), 3.73 (s, 4H, CH_2-pyr), 3.59 (t, J = 6.9 Hz, 4H, CH_2Cl), 2.81 (t, J = 6.9 Hz, 4H, CH_2N), 2.35 (s, 6H, CH_3). ^{13}C-NMR ($CDCl_3$): δ 158.23 (C2, C6), 136.93 (C4), 121.31 (C3, C5), 63.59 (CH_2-pyr), 58.69 (CH_2N), 42.59 (CH_3), 41.56 (CH_2Cl). MS (CI) m/z 290 ([M + H]$^+$, 39%), 254 (100) (calcd $C_{13}H_{21}Cl_2N_3$ 289.1). Anal. Calcd for $C_{13}H_{21}Cl_2N_3$: C, 53.80; H, 7.29; N, 14.48; Cl 24.43. Found: C, 53.94; H, 7.09; N, 14.77.

2,6-Bis{[((6-amino-acridin-3-yl)methoxycarbonylamino)-ethyl]methylaminomethyl}pyridine (**4**). To a solution of (6-amino-3-acridinyl)carbamic acid methyl ester (**3**) (184 mg, 0.69 mmol) in dry DMF (5 mL), 80% NaH (41 mg, 1.38 mmol) was added. The reaction mixture was stirred under an argon atmosphere for 20 min, and then a solution of 2,6-bis[(2-chloroethyl)methylaminomethyl]pyridine (**2**) (100 mg, 0.345 mmol) in dry DMF (6 mL) was added. The reaction mixture was heated at 50 °C for 20 h, and then concentrated at reduced pressure. The crude product thus obtained was purified by flash column chromatography on silica gel using ethyl acetate/acetone/triethylamine (5:3:1), affording unreacted carbamate **3**. Continued elution with ethyl acetate/methanol/triethylamine (10:2:1) afforded the desired product as an oil. The product was then dissolved in chloroform and precipitated with diethyl ether, affording 81 mg (31%) of an orange solid. Mp: 128−130 °C. IR (KBr): ν 3414, 1702, 1638, 1612, 1459, 1383, 1158 cm^{-1}. ^{1}H-NMR ($CDCl_3$): δ 8.49 (s, 2H, H9), 7.85 (d, J = 2.2 Hz, 2H, H4), 7.80 (d, J = 9.0 Hz, 2H, H1), 7.77 (d, J = 9.0 Hz, 2H, H8), 7.35 (t, J = 7.7 Hz, 1H, H4 pyr), 7.30 (dd, J = 9.0, 2.2 Hz, 2H, H2), 7.19 (d, J = 2.2 Hz, 2H, H5), 7.09 (d, J = 7.7 Hz, 2H, H3, H5 pyr), 7.00 (dd, J = 9.0, 2.2 Hz, 2H, H7), 3.95 (t, J = 6.9 Hz, 4H, CH_2N-acridine), 3.68 (s, 6H, OCH_3), 3.55 (s, 4H, CH_2-pyr), 2.63 (t, J = 6.9 Hz, 4H, CH_2NMe), 2.17 (s, 6H, NCH_3). ^{13}C-NMR ($CDCl_3$): δ 158.40 (C2, C6 pyr), 155.86 (CO), 151.16 (C10a), 149.51 (C4a), 148.65 (C6), 143.57 (C3), 136.57 (C4 pyr), 135.42 (C9), 129.72 (C8), 128.57 (C1), 124.63 (C2), 124.06 (C4), 123.20 (C9a), 121.94 (C8a), 120.82 (C3, C5 pyr), 120.15 (C7), 106.00 (C5), 63.77 (CH_2-pyr), 55.46 (CH_2NMe), 52.96 (OCH_3), 48.31 (CH_2N-acridine), 42.52 (NCH_3). MS (ESI) m/z 752 [M + H]$^+$ (calcd for $C_{43}H_{45}N_9O_4$ 751.36). Anal. Calcd for $C_{43}H_{45}N_9O_4$: C, 68.69; H, 6.03; N, 16.77. Found: C, 68.81; H, 6.13; N, 16.49. A stock solution of **4** was prepared in dimethyl sulfoxide (purity ≥99.9%) and was stored at −20 °C until use.

Viscometric Titrations. UltraPure Calf Thymus DNA (Invitrogen Catalog Number 15633−019, average size ≤2000 bp, 10 mg/mL in ddH_2O) was used without further purification. Viscosity experiments were conducted in a Cannon-Ubbelohde size 75 capillary viscometer immersed in a thermostated, circulating water bath maintained at 25 ± 0.2 °C. Compound **4** was titrated in buffer A: 6 mM Na_2HPO_4, 2 mM NaH_2PO_4, 1 mM Na_2EDTA, and 15 mM NaCl (pH 7.0). Alternatively, Cu(II) and Cu(II)−**4** (ligand to metal ratio of 1:1) were titrated in buffer B: 20 mM sodium phosphate (pH 7.0). In three separate titrations, a total of five 10-μL aliquots of each of the following three stock solutions were sequentially added to 1000 μL of the appropriate buffer in the viscometer containing 200 μM bp calf thymus (CT) DNA: (i) **4** (400 μM in buffer A); (ii) Cu(II)−**4** (400 μM each, in buffer B), and Cu(II) (400 μM in buffer B). After each sequential addition, the resulting solution was allowed to equilibrate for 15 min before the flow time was recorded with a stopwatch. (The final concentrations of **4**, Cu(II)−**4**, and Cu(II) ranged from 4 to 20 μM in each of the three titrations.) The flow times of the buffer and then of the DNA in the buffer were also recorded. All measurements were averaged over four trials to an accuracy of ±0.2 s. After subtracting the averaged flow time of the buffer, DNA (η_0) and dye-DNA (η) averaged flow times were plotted as $(\eta/\eta_o)^{1/3}$ versus the molar ratio r of dye to DNA bp (*43*). Slopes were generated by conducting linear least-square fits to these data (*KaleidaGraph* version 3.6.4 software).

Competition Dialysis Assay. Calf thymus (CT), *Clostridium perfringens* (CP), and *Micrococcus lysodeikticus* (ML) DNAs and the synthetic polynucleotides poly(dA)-poly(dT), [poly-(dGdC)]$_2$, and [poly(dAdT)]$_2$ were purchased from Sigma and were used without further purification. A buffer containing 6 mM Na_2HPO_4, 2 mM NaH_2PO_4, 1 mM Na_2EDTA, and 185 mM NaCl (pH 7.0) was utilized in the preparation of all nucleic acid stock solutions. The concentrations of the nucleic acid solutions were determined by UV−visible spectrophotometry using the λ_{max} values and extinction coefficients listed in Table S1 (Supporting Information). In a buffer consisting of 6 mM Na_2HPO_4, 2 mM NaH_2PO_4, 1 mM Na_2EDTA, and 15 mM NaCl (pH 7.0), competition dialysis experiments were performed as described by Chaires (*44*, *45*). For each dialysis assay, a 0.5 mL volume of DNA (75 μM bp DNA in buffer; Table S1) was

pipetted into one of six individual Spectra/Por DispoDialyzer units (S135062, Spectrum Laboratories, Inc.). The six dialysis units were then placed in a beaker containing 225 mL of a 1.5 μM solution of **4** in buffer. The beaker was covered with Parafilm and wrapped in foil, and its contents were allowed to equilibrate with continuous stirring for 24 h at room temperature (20−22 °C). At the end of the equilibration period, the DNA solutions inside the dialysis units were carefully transferred to microcentrifuge tubes, and a 10.0% (w/v) stock solution of sodium dodecyl sulfate (SDS) was added to give a final concentration of 1.0% (w/v). The DNA−SDS solutions were allowed to equilibrate for 2 h, after which the total concentration of ligand **4** (C_t) was determined by UV−visible absorbance measurements using the extinction coefficient for free ligand **4** in the presence of 1.0% SDS ($\epsilon_{451} = 22\,716\ M^{-1}\ cm^{-1}$). An appropriate correction for the slight dilution of the sample resulting from the addition of SDS stock solution was made. The concentration of free ligand **4** (C_f; $\epsilon_{451} = 12\,500\ M^{-1}\ cm^{-1}$) was also determined spectrophotometrically using an aliquot of the dialysate solution. The amount of DNA-bound **4** (C_b) was calculated by the difference ($C_b = C_t - C_f$).

Thermal Melting Studies. Individual 3 mL solutions containing 15 μM bp of calf thymus DNA (Invitrogen cat. #15633−019) in 20 mM sodium phosphate buffer pH 7.0 or in 20 mM sodium phosphate buffer pH 7.0, 10 μM **4**, and/or 10 μM $CuCl_2$ were placed in 3 mL (1 cm) quartz cuvettes (Starna). The DNA was then denatured by increasing the temperature from 25 °C to 100 °C at a rate of 0.5 °C min^{-1}, while absorbance was monitored at 260 nm. *KaleidaGraph* version 3.5 software was used to approximate the first derivative of $\Delta A_{260}/\Delta T$ vs temperature, where the T_m value for each melting transition was marked by the maximum of the first derivative plot.

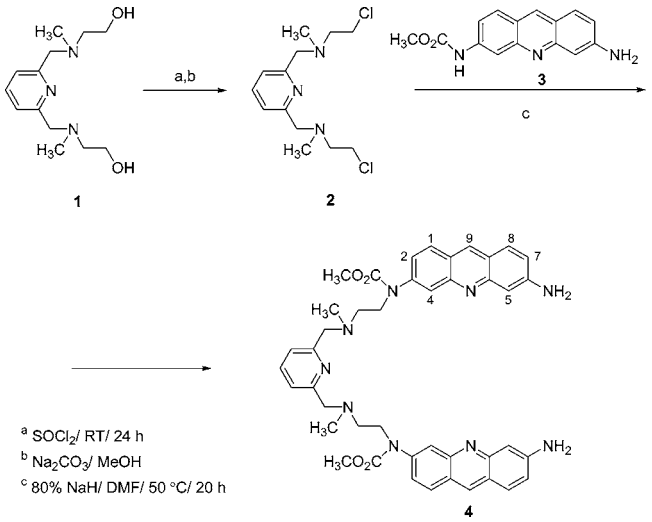
Photocleavage of Supercoiled Plasmid DNA. Concentration profile reactions were conducted in a volume of 20 μL as follows. A total of 38 μM bp of pUC19 plasmid DNA in 20 mM sodium phosphate buffer pH 7.0 or in 20 mM sodium phosphate buffer pH 7.0, 50 μM, 30 μM, 20 μM, 10 μM, 5 μM, or 2 μM of $CuCl_2$ and/or 1 mol equiv (50 μM, 30 μM, 20 μM, 10 μM, 5 μM, or 2 μM) of **4** was irradiated for 50 min at 419 nm and 22 °C. A parallel control reaction consisting of 20 mM sodium phosphate buffer pH 7.0, 38 μM bp of pUC19, 50 μM of $CuCl_2$, and 50 μM of **4** was kept in the dark for 50 min.

Individual time course reactions were conducted in a volume of 20 μL. A total of 38 μM bp of pUC19 plasmid DNA in 20 mM sodium phosphate buffer pH 7.0 or in 20 mM sodium phosphate buffer pH 7.0, 50 μM $CuCl_2$, and/or 50 μM **4** was irradiated at 419 nm and 22 °C. The 20 μL reactions were removed from the Rayonet Photochemical Reactor at 10, 20, 30, 40, or 50 min time intervals. Parallel controls consisting of 20 mM sodium phosphate buffer pH 7.0, 38 μM bp of pUC19 plasmid, 50 μM of $CuCl_2$, and/or 50 μM of **4** were kept in the dark for 50 min.

After the addition of 3 μL of electrophoresis loading buffer to the photocleavage reactions (15.0% (w/v) Ficoll, 0.025% (w/v) bromophenol blue), cleavage products were separated on a 1.0% nondenaturing agarose gel stained with ethidium bromide (0.5 μg/mL). To determine the percent conversion of supercoiled plasmid DNA to nicked and linear forms, the gel was visualized on a transilluminator set at 302 nm, photographed, and then quantitated using *ImageQuant* v. 5.2 software (Amersham Biosciences).

Colorimetric Detection of Copper(I). A series of 500 μL reactions was prepared in which each contained 20 mM sodium phosphate buffer pH 7.0 and one or more of the following reagents: 50 μM of **4**, 50 μM of $CuCl_2$, and 38 μM bp of pUC19 plasmid DNA. The samples were irradiated at 419 nm in the absence and presence of 100 μM of bathocuproinedisulfonic acid disodium salt hydrate, while a parallel set of reactions was kept in the dark. After 50 min, the solutions were visually examined for color change, placed in 500 μL quartz cuvettes, and monitored between 200 and 600 nm for evidence of Cu(I)−bathocuproine complex formation. As a positive control, 500 μL samples containing 20 mM sodium phosphate buffer pH 7.0 and 100 μM bathocuproinedisulfonic acid disodium salt hydrate in the presence of 50 μM $CuCl_2$ or 50 μM $CuCl_2$ and 50 μM L-ascorbic acid were reacted at 22 °C for 1 min, after which, UV−visible spectra were recorded.

Inhibition of DNA Photocleavage. Twenty microliter reactions containing 20 mM sodium phosphate buffer pH 7.0, 38 μM bp pUC19 plasmid DNA, 50 μM of **4**, and 50 μM of $CuCl_2$ were irradiated at 419 nm for 50 min in the presence of either 100 mM sodium azide, 100 mM D-mannitol, 100 U superoxide dismutase, 100 U catalase, or 100 μM bathocuproinedisulfonic acid disodium salt hydrate. Reaction products were then resolved on a 1.0% nondenaturing agarose gel and quantitated as described above. The percent inhibition of DNA photocleavage was calculated on the basis of a comparison to parallel reactions run in the absence of scavenger or chelator.



DNA Photocleavage at Nucleotide Resolution. *Eco*RI linearized pUC19 plasmid was 3′-end-labeled using *Sequenase* version 2.0 and [^{35}S]dATPαS according to an established laboratory protocol (*46*). Unincorporated nucleotides were removed with a G-50 Sephadex spun column. The DNA was then digested with *Fsp*I to produce a restriction fragment 138 bp in length and resolved on a 2.0% agarose gel. The fragment was excised, and DNA was isolated using a QIAquick Gel Extraction Kit purchased from Qiagen. The purified DNA was stored in a total volume of 400 μL of deionized, distilled water at −78 °C.

Typical photocleavage reactions contained 15 μM bp of the 138 bp DNA fragment in 20 mM sodium phosphate buffer pH 7.0 or in 20 mM sodium phosphate buffer pH 7.0, 5 μM **4** and 5 μM $CuCl_2$ (50 μL total volume). The samples were irradiated for 2 h at 419 nm, after which, DNA was precipitated with 40 μg glycogen/2.5 volumes EtOH, and washed with 70.0% EtOH. A duplicate set of reactions was precipitated, dissolved in 100 μL of 1.0% piperidine, heated at 90 °C for 30 min, and then lyophilized to dryness. Cleavage products without and with piperidine treatment were dissolved in 4 μL of Sequenase Stop Solution (95.0% (v/v) deionized formamide, 10 mM EDTA, 0.1% (w/v) xylene cyanol and 0.1% (w/v) bromophenol blue), denatured for 3 min at 95 °C, and resolved on a 10.0% denaturing polyacrylamide gel adjacent to G, G + A, and T chemical sequencing reactions. To determine yields, the gel was scanned with a *FujiFilm Image Reader* v. 2.01 Gel Imaging System. The resulting storage-phosphor autoradiogram was quantitated using *FujiFilm ImageGauge* v. 3.41 software. The DNA sequencing reactions were performed as previously described (*46*).

RESULTS AND DISCUSSION

Our approach to the design of ligand **4** combines a 2,6-bis-(aminomethyl)pyridine-based copper binding moiety and two photochemically active 3,6-acridinediamine groups as DNA recognition elements. The ligand 2,6-bis(aminomethyl)pyridine and its amino-*N*-substituted analogs form stable 1:1 complexes with Cu(II) ($\log Q_{Cu(II)} = 15.2-15.7$, equilibrium quotient $Q = [ML]/[M][L]$; refs 47 and 48). Alternatively, acridine orange, proflavin, and other 3,6-acridinediamines intercalate into DNA and, upon irradiation with visible light, efficiently effect DNA photocleavage (*16*, *49*−*51*). Therefore, the acridine rings of **4** were intended to increase DNA binding and to initiate DNA photocleavage. We also took into account that cleavage levels might be enhanced by acridine-sensitized photoreduction of pyridine-bound copper(II).

Scheme 1. Synthesis of Ligand 4

Synthesis of Ligand 4. Compound **4** was obtained from 2,6-bis[(2-hydroxyethyl)methylaminomethyl]pyridine (**1**) (*40*), which upon treatment with thionyl chloride at room temperature for 24 h, followed by basification with sodium carbonate, afforded 2,6-bis[(2-chloroethyl)methylaminomethyl]pyridine (**2**) as a brown oil in 65% yield. Compound **2** was reacted with (6-amino-3-acridinyl)carbamic acid methyl ester (**3**) (*41*) in anhydrous DMF with 80% NaH as base at 50 °C for 20 h (Scheme 1). Purification of the crude product afforded **4** in 31% yield.

Viscometric Analysis. In order to test for the intercalating ability of **4** and to further examine its behavior as a groove binder or as a mono- or bis-intercalator, DNA viscosity measurements were conducted. In the process of intercalation, helical DNA unwinds to accommodate planar aromatic ring systems that become inserted in between DNA base pairs. This process is accompanied by an effective increase in contour length that adds to the intrinsic viscosity of the DNA polymer. Because groove binding compounds do not markedly lengthen helical DNA, there is no significant change in viscosity (*52*). Consequently, viscometric titrations represent a highly reliable method for establishing the binding modes of DNA interacting ligands (*52*).

The viscometry data for compound **4** and copper(II) are presented as plots of $(\eta/\eta_o)^{1/3}$ versus r (the molar ratio of added compound to DNA base pairs) according to the theory of Cohen and Eisenberg (*43*). Figure 1 shows that compound **4** increases the relative viscosity of calf thymus DNA as a function of increasing r and that the slope (0.82) obtained from the $(\eta/\eta_o)^{1/3}$ versus r plot falls within the range expected for monofunctional intercalators (*53*). It is conceivable that the lowest-energy conformation of **4** is incompatible with the neighbor exclusion principle and therefore permits the intercalation of only one acridine ring. In contrast, the viscometric data of copper(II) with CT DNA yield slopes of −0.12 and 0.41 in the absence and presence of 1 mol equiv of **4**, respectively. The observed reduction in slope from 0.82 to 0.41 may indicate that interaction of the compound's 2,6-bis(aminomethyl)pyridine linker with copper(II) induces a conformational change that introduces a competing, non-intercalative DNA binding mode, most likely groove binding. Notwithstanding, the increase in the apparent DNA contour length by the copper(II) complex of **4** is still substantial, suggesting some degree of intercalative binding (*54*).

Electrospray Ionization Mass Spectrometry. Our next goal was to obtain direct evidence of copper(II) complex formation. Ligand **4** was reacted with $CuCl_2$ in HPLC-grade methanol at a ligand to metal ratio of 1:1 (90 min, 22 °C), after which a positive-ion electrospray (ESI) mass spectrum was recorded (Figure S1 in Supporting Information). Isotopic distributions of molecular ions corresponding to the following 1:1 metallic complexes were observed: (i) $[\mathbf{4}HCuCl]^{2+}$ between 425 and 428 *m*/*z* (calcd for $[C_{43}H_{46}N_9O_4CuCl]^{2+}$ 425.13); (ii) $[\mathbf{4}CuCl]^{1+}$ between 849 and 855 *m*/*z* (calcd for $[C_{43}H_{45}N_9O_4CuCl]^{1+}$ 849.26); and (iii) $[\mathbf{4}HCuCl_2]^{1+}$ between 885 and 892 *m*/*z* (calcd for $[C_{43}H_{46}N_9O_4CuCl_2]^{1+}$ 885.24).

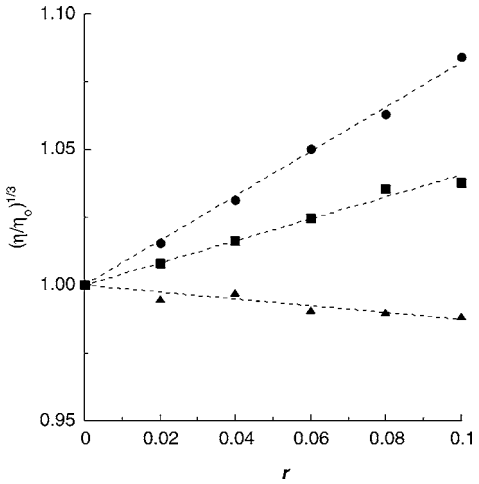


Figure 1. Change in relative viscosity $(\eta/\eta_o)^{1/3}$ of CT DNA as a function of r, the molar ratio of compound to DNA base pairs. Viscometric titrations were conducted in the presence of (i) compound **4** (•; slope = 0.82; 6 mM Na_2HPO_4, 2 mM NaH_2PO_4, 1 mM Na_2EDTA, and 15 mM NaCl buffer pH 7.0); (ii) compound **4** and copper(II) at a ligand to metal ratio of 1:1 (■; slope = 0.41; 20 mM sodium phosphate buffer pH 7.0); (iii) copper(II) (▲; slope = −0.12; 20 mM sodium phosphate buffer pH 7.0).

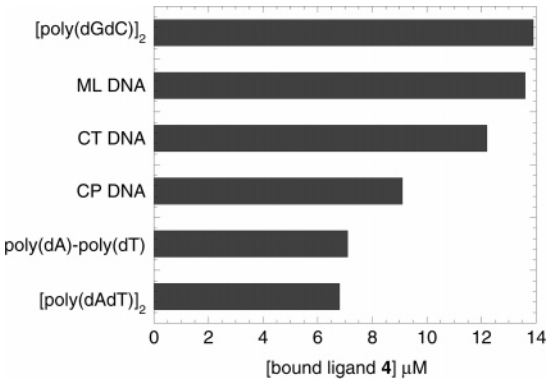

Figure 2. The bar graph indicates the concentrations of DNA-bound ligand **4** detected after a 24 h equilibration in competition binding dialysis studies of six DNA sequences.

Competition Dialysis. The results of dialysis experiments are depicted in a bar graph which shows the concentrations of ligand **4** bound to calf thymus, *Clostridium perfringens*, and *Micrococcus lysodeikticus* DNAs and to the synthetic, double-helical polynucleotides poly(dA)-poly(dT), $[poly(dGdC)]_2$, and $[poly(dAdT)]_2$ (Table S1, Figure 2). The data were obtained after equilibrating 1.5 μM of **4** (in the dialysate solution) and 75 μM bp of nucleic acid (in each sample dialysis unit) for 24 h. At the end of the equilibration period, UV−visible spectra were recorded in order to determine the concentrations of free ligand **4** and DNA-bound **4**. The amount of the DNA-bound ligand was averaged over three trials, and the estimated error was between 5% and 10% for each nucleic acid structure tested. The competition dialysis data were then used to calculate the apparent association constants of ligand **4**, given by $K_{app} = C_b/C_f$ [DNA], where C_b and C_f are the DNA-bound and free ligand

Table 1. Apparent Association Constants Obtained by Competition Dialysis[a]

deoxyribonucleic acid	$K_{app} \times 10^5\ M^{-1}$
$[poly(dGdC)]_2$ (100% GC)	1.30
ML DNA (72% GC)	1.26
CT DNA (42% GC)	1.13
CP DNA (31% GC)	0.85
poly(dA)-poly(dT) (0% GC)	0.66
$[poly(dAdT)]_2$ (0% GC)	0.63

[a] The abbreviations ML DNA, CT DNA, and CP DNA correspond to *Micrococcus lysodeikticus*, calf thymus, and *Clostridium perfringens* DNAs, respectively.

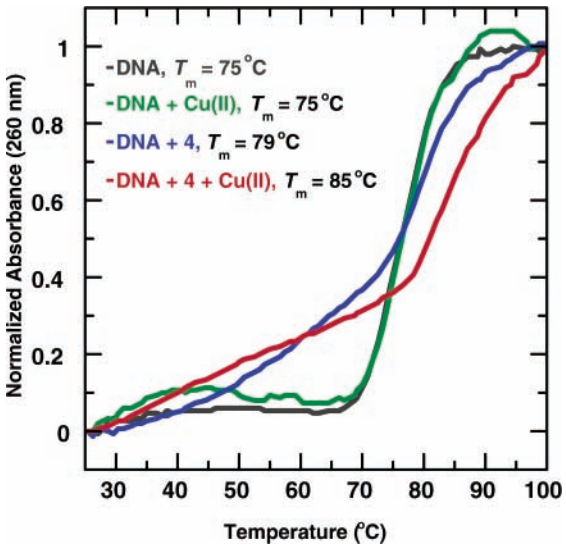

Figure 3. Thermal melting curves and T_m values of 15 μM bp calf thymus DNA in the absence and presence of 10 μM **4** and/or 10 μM $CuCl_2$ (20 mM sodium phosphate buffer pH 7.0).

concentrations, respectively, and [DNA] is the concentration of DNA in molar base pairs (Table 1).[1] Clearly, the data in Figure 2 and Table 1 indicate that ligand **4** shows a preference for GC base pairs as exemplified by an increase in levels of binding to ML DNA (71% GC, $K_{app} = 1.26 \times 10^5\ M^{-1}$) relative to CP DNA (31% GC; $K_{app} = 0.85 \times 10^5\ M^{-1}$).

Thermal Melting Studies. The majority of DNA intercalators bind to double-helical DNA through a combination of $\pi-\pi$ stacking and electrostatic interactions. As a consequence, double-helical DNA is stabilized, and the melting temperature (T_m) of the duplex is increased as a function of the increasing binding affinity of the intercalator (*55*). Melting temperature (T_m) values of 15 μM bp calf thymus DNA in 20 mM sodium phosphate buffer pH 7.0 were derived from thermal melting curves recorded at 260 nm (Figure 3). While 10 μM of Cu(II) had no effect in the absence of the ligand, 10 μM of **4** increased the T_m of calf thymus DNA by 4 °C and 10 °C in the absence and presence of 10 μM concentrations of Cu(II), respectively. Taken together, these data indicate that **4** binds to double-helical DNA, thereby increasing its stability. Duplex stability is then further enhanced by the interaction of **4** with copper(II). In light of the above viscometric data, this result would appear to suggest that groove binding and intercalation of **4** in the presence of Cu(II) might stabilize duplex DNA to a greater degree than

[1] Competition dialysis experiments were conducted at room temperature in sodium phosphate buffer pH 7.0. Under these conditions, the UV−vis spectra of the Cu(II) complex of **4** and of ligand **4** were found to be nearly superimposable. Therefore, the K_{app} of the Cu(II) complex of **4** could not be accurately determined by competition dialysis because the concentration of the Cu(II) complex of **4** versus that of **4** could not be ascertained.

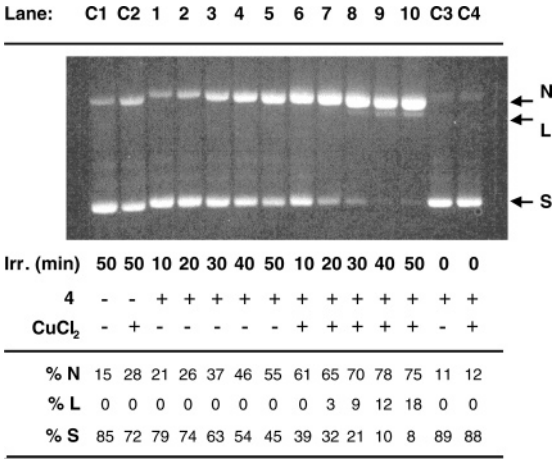

Figure 4. A photograph of a 1.0% nondenaturing agarose gel showing photocleavage of pUC19 plasmid DNA in the presence of 50 μM of **4** without and with 50 μM of $CuCl_2$ (22 °C, pH 7.0). C1 and C2 correspond to DNA irradiated at 419 nm, without and with $CuCl_2$, respectively (no **4**). C3 and C4 correspond to DNA treated for 50 min with **4,** without and with $CuCl_2$, respectively (no *hν*). Lanes 1−10 correspond to DNA irradiated at 419 nm for 10, 20, 30, 40, and 50 min in the presence of **4**, without and with $CuCl_2$. The above yields corresponding to C1, C2, Lane 5, and Lane 10 were averaged over three trials with standard deviations of ±3%, ±5%, ±3%, and ±2%, respectively. S, L, and N designate supercoiled, linear, and nicked forms of pUC19 plasmid DNA.

simple monointercalation. It is also conceivable that complex formation with positively charged copper might enhance electrostatic interactions between **4** and the negatively charged phosphate backbone of the DNA duplex. Notwithstanding, the increase in T_m observed when Cu(II) is added to **4** indicates that the apparent DNA association constant K_{app} of the Cu(II) complex of **4** is higher than the K_{app} of the free ligand **4**.[1] The small increases in low-temperature absorbance produced by compound **4** and its Cu(II) complex probably arise from thermally induced changes in the ratio of DNA-bound ligand to free ligand (Figure 3; ref 56).

Photocleavage of Supercoiled Plasmid DNA. To detect the formation of DNA frank strand breaks,[2] a preliminary concentration profile was conducted in which individual samples containing 38 μM bp of pUC19 plasmid DNA in 20 mM sodium phosphate buffer pH 7.0 were equilibrated with 50 μM to 2 μM of **4** in the absence and presence of 1 mol equiv of $CuCl_2$. The samples were irradiated for 50 min at 419 nm and 22 °C in an aerobically ventilated Rayonet Photochemical Reactor, after which, DNA photocleavage products were resolved on a 1.0% nondenaturing agarose gel. The results of the profile showed that 1 mol equiv of Cu(II) enhanced DNA photocleavage produced by 50 to 20 μM concentrations of compound **4** in a concentration-dependent fashion, with maximum levels of photocleavage occurring in the 50 μM reaction (Figure S2 in Supporting Information).

DNA photocleavage as a function of time was studied next. Reactions consisting of 20 mM sodium phosphate buffer pH 7.0 with 38 μM bp pUC19 plasmid DNA, 50 μM of compound **4**, and 50 μM of $CuCl_2$ were irradiated as described above, except that the reactions were removed at 10 to 50 min time points prior to agarose gel electrophoresis. While 50 μM of intercalator **4** clearly demonstrated time-dependent DNA photocleavage (Figure 4, lanes 1 to 5), reaction yields were markedly enhanced at all time points upon the addition of

[2] DNA frank strand breaks are defined as single- or double-stranded DNA breaks directly induced by the effects of a cleaving reagent, in the absence of subsequent treatment with alkaline or with a secondary amine such as piperidine.

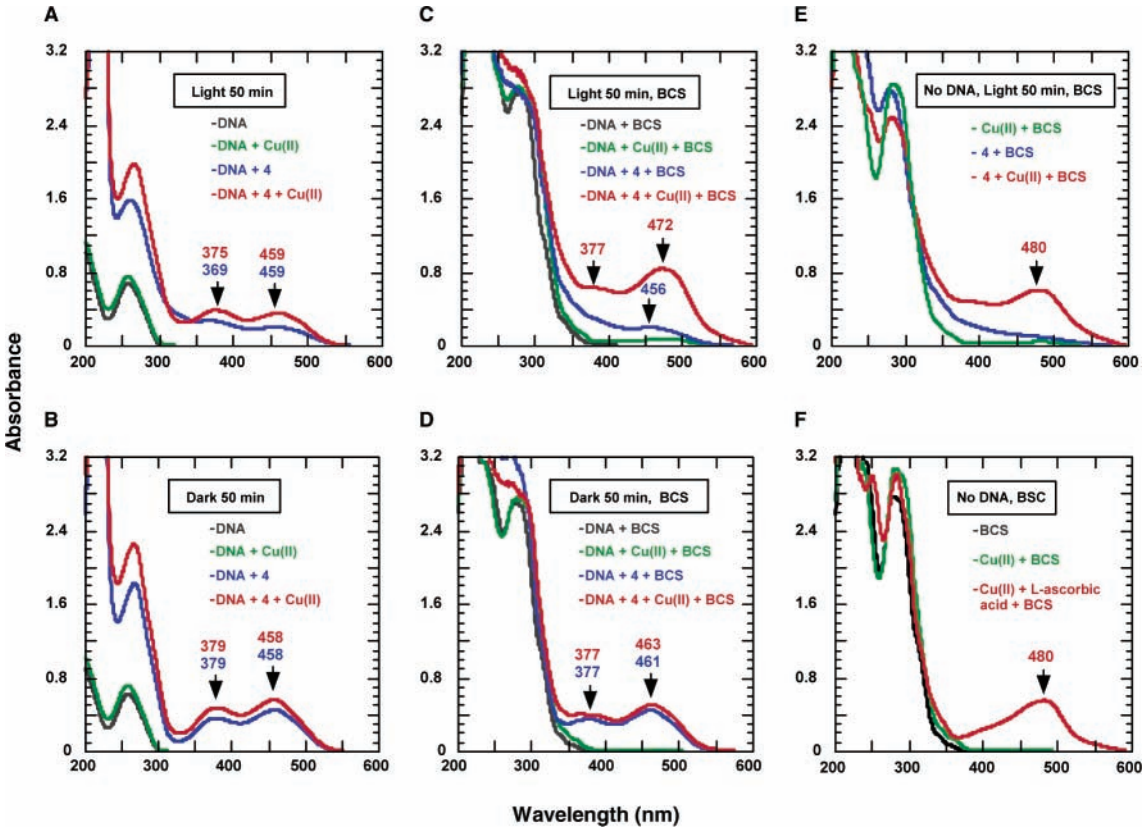

Figure 5. UV−visible spectra to assay for Cu(I)-BCS complex formation in 20 mM sodium phosphate buffer pH 7.0, 22 °C.

equivalent concentrations of $CuCl_2$ (Figure 4, lanes 6 to 10). (Virtually no cleavage was observed in parallel control reactions run in the dark; Figure 4, lanes C3 and C4.) Notably, after 50 min of irradiation, supercoiled plasmid was converted into 28% nicked DNA in the presence of Cu(II)/buffer, 55% nicked in **4**/buffer, and 75% nicked plus 18% linear when **4**/Cu(II)/buffer were present in combination (Figure 4, lanes C2, 5, and 10, respectively). Taking into consideration that 15% of photonicked DNA was produced in buffer alone, it is evident that ligand **4** and Cu(II) interact in a synergistic rather than additive fashion. Because photoreduction of Fe(III) is readily effected with visible light by means of electron transfer from the photochemically excited triplet states of acridine orange and other 3,6-diaminoacridines (*57*, *58*), we hypothesized that a potential source of synergism might involve acridine-sensitized photoreduction of pyridine-bound Cu(II). Subsequent reaction of Cu(I) with O_2 would be expected to generate DNA cleaving, reactive oxygen species (*59*−*61*).

Colorimetric Detection of Copper(I). Our next goal was to obtain experimental evidence that would substantiate photoreduction of Cu(II) by ligand **4**. We utilized a colorimetric assay based on bathocuproinedisulfonic acid disodium salt hydrate (BCS), which forms a 2:1 stable, brightly colored orange complex with Cu(I) (λ_{max} = 480 nm; ϵ = 13 500 M^{-1} cm^{-1}; ref 62). Photolysis reactions in 20 mM sodium phosphate buffer pH 7.0 were irradiated at 419 nm and 22 °C for 50 min in the presence of one or more of the following reagents: 50 μM **4**, 50 μM $CuCl_2$, 38 μM bp pUC19 plasmid DNA, and 100 μM BCS; after which UV−visible spectra were immediately recorded (Figure 5). Parallel reactions run in the dark were used as negative controls (Figure 5B,D). As a control for BCS−Cu(I) complex formation, 100 μM BCS was reacted with 50 μM $CuCl_2$ in the absence and presence of 50 μM of the reducing agent L-ascorbic acid (Figure 5F).

As expected, the addition of BCS to Cu(II) produced a bright orange color and signature 480 nm absorption in the L-ascorbic acid control reaction (Figure 5F), but not in any of the dark DNA reactions (even those containing **4** and/or Cu(II); Figure 5B,D), and not in any reactions in which BCS was omitted (Figure 5A,B). However, the DNA reaction irradiated in the presence of ligand **4**, Cu(II), and BCS produced a significant orange color change. In addition, a strong hyperchromic absorption band indicative of the formation of a BCS−Cu(I) complex was observed at 472 nm (Figure 5C: DNA + **4** + Cu(II) + BCS). (Spectral overlap with **4** and/or one of its photoproducts most likely accounts for the 8-nm blue shift relative to 480 nm: Figure 5C compared to Figure 5E,F.) Importantly, there was no evidence of BCS−Cu(I) complex formation when **4** was omitted from the photocleavage reaction (Figure 5C: DNA + Cu(II) + BCS). When DNA was left out, significant absorption and color were still produced (Figure 5E: **4** + Cu(II) + BCS). Therefore, the BCS data collectively indicate that bis-acridine ligand **4** sensitizes photoreduction of Cu(II) to Cu(I) and that DNA is not required for photoreduction.

Inhibition of DNA Photocleavage. To further investigate mechanism(s) underlying the Cu(II)-assisted formation of DNA frank strand breaks, we conducted the following inhibition experiments. Individual photocleavage reactions consisted of 38 μM bp of pUC19 plasmid DNA, 50 μM of **4**, and 50 μM of $CuCl_2$ pre-equilibrated with one of the following reagents: the singlet oxygen ($^1O_2$) scavenger sodium azide, the hydroxyl radical (•OH) scavenger D-mannitol, the hydrogen peroxide (H_2O_2) scavenger catalase, the superoxide (O_2•$^-$) scavenger superoxide dismutase (SOD), and the Cu(I)-specific chelating agent BCS. From examination of the data in Table 2, it is evident that sodium azide, catalase, and BCS blocked frank stand break formation to a significant degree, while D-mannitol was almost completely ineffective. Intermediate levels of inhibition were produced by SOD, indicating that superoxide contributes to photocleavage. (SOD produces H_2O_2, which can itself play a part in cleavage and thereby lower inhibition by this enzyme.) Although the piperidine-labile lesion 8-hydroxyguanosine is the

Table 2. Average % Inhibition of DNA Photocleavage by Scavengers and BCS[a]

scavenger/chelator	species targeted	percent inhibition
D-mannitol (100 mM)	•OH	5 ± 1
superoxide dismutase (100 U)	O_2•$^-$	29 ± 1
(BCS 100 μM)	Cu(I)	51 ± 2[b]
catalase (100 U)	H_2O_2	56 ± 2
sodium azide (100 mM)	$^1O_2$	61 ± 3

[a] Individual reactions consisting of 38 μM bp of pUC19 plasmid DNA equilibrated with 50 μM of **4** and 50 μM of $CuCl_2$, and one of the above reagents were irradiated under aerobic conditions at 419 nm for 50 min at 22 °C. Percent inhibition was averaged over three trials with error reported as standard deviation. Final reagent concentrations are in parenthesis. [b] In control experiments, we observed direct photocleavage of DNA by BCS in the absence of **4** (data not shown). Therefore, the 51% inhibition produced by BCS may be lower than the actual % inhibition value.

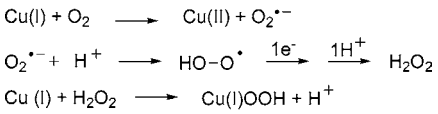

Figure 6. A proposed model in which superoxide (O_2•$^-$), hydrogen peroxide (H_2O_2), and Cu(I) contribute to the formation of a Cu(I)-peroxide complex.

primary form of DNA damage produced by singlet oxygen, the relative efficiency of sodium azide implies that singlet oxygen may play a major role: singlet oxygen is capable of cleaving DNA directly by producing frank strand breaks at guanine bases (*63*). However, because frank strand breaks account for no more than 5% of total DNA damage produced by $^1O_2$ (*64*), it is conceivable that cleavage inhibition by sodium azide involves a copper−peroxide-type complex (*60*) of ligand **4**. The relatively strongly inhibitory effects of catalase and of the Cu(I)-specific chelating agent BCS clearly indicate that hydrogen peroxide and Cu(I) participate in DNA photocleavage. Alternatively, the ineffectiveness of the hydroxyl radical scavenger D-mannitol suggests that freely diffusible hydroxyl radicals do not make a significant contribution. This latter result is consistent with the majority of literature reports in which copper−peroxide-type complexes rather than hydroxyl radicals were found to be the principal reactive species involved in DNA cleavage by Cu(II)/Cu(I) redox cycling systems (*59*−*61*, *65*). A mechanism consistent with the above photocleavage inhibition data is shown in Figure 6 (*61*). It is conceivable that Cu(II) bound to the pyridine linker of ligand **4** is photoreduced to Cu(I), which in turn reacts with hydrogen peroxide to produce a DNA-damaging Cu(I)-peroxide complex. Because the colorimetric BCS assay detected Cu(I) only when **4** was present, it can also be inferred that DNA photocleavage involves acridine-sensitized photoreduction of Cu(II) to Cu(I).

DNA Photocleavage at Nucleotide Resolution. In order to map the sequence specificity of Cu(II)-assisted DNA photocleavage, pUC19 plasmid was linearized with *Eco*RI, 3′-end-labeled with [^{35}S]dATPαS, and then cut with *Fsp*I to produce a 138 bp restriction fragment (*58*). Reactions containing 15 μM bp of the radiolabeled DNA fragment in the absence and presence of 5 μM **4** and 5 μM $CuCl_2$ were irradiated at 419 nm for 2 h (20 mM sodium phosphate buffer pH 7.0). Half of the reactions were subsequently treated with 1.0% piperidine (90 °C, 30 min) in order to produce strand breaks at alkaline-labile lesions in the DNA. Products were electrophoresed adjacent to G, G + A, and T chemical sequencing reactions on a 10.0% denaturing polyacrylamide gel, after which, cleavage patterns were analyzed. Shown in Figure 7 are cleavage plots of a representative 40 bp sequence within the radiolabeled restriction fragment. The top 20 bases producing the highest levels of

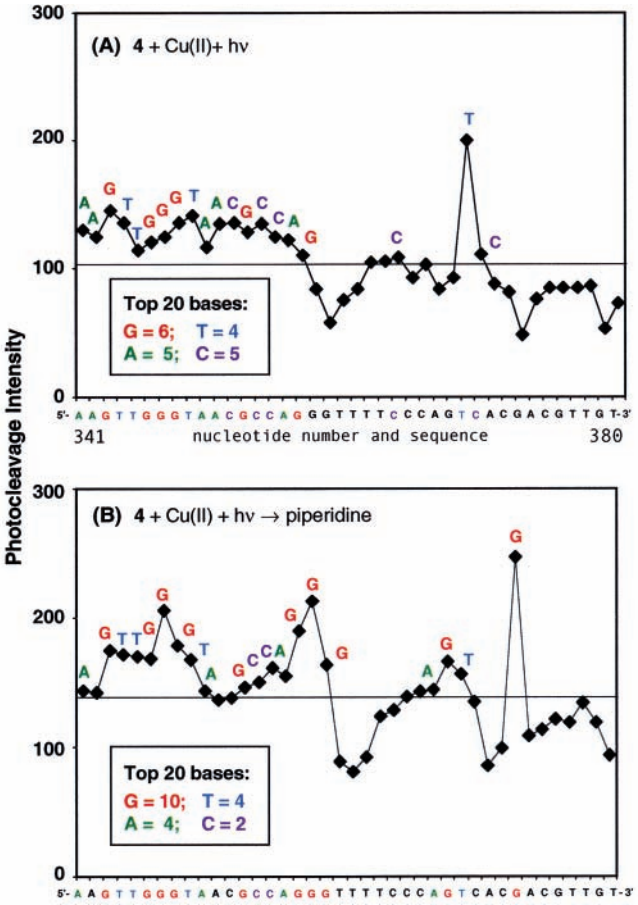

Figure 7. Cleavage plots of a representative 40 bp DNA sequence. Photocleavage intensities as a function of DNA base were calculated by quantitating a storage-phosphor autoradiogram of DNA photocleavage products resolved on a 10.0% denaturing polyacrylamide gel (Figure S3 in Supporting Information). A total of 15 μM bp of ^{35}S 3′-end labeled 138 bp restriction fragment was irradiated at 419 nm in the presence of 5 μM **4** and 5 μM $CuCl_2$ without (A) and with (B) subsequent piperidine treatment. The ordinate is in units of $f_a - f_c$, where f_a is the fractional cleavage intensity produced in the photocleavage reaction and f_c is fractional cleavage intensity in a parallel control reaction in which DNA was irradiated in the absence of the Cu(II) complex of compound **4,** without (A) and with (B) the piperidine treatment. A horizontal line has been drawn through each plot in order to identify the top 20 DNA bases (inset) producing the highest levels of cleavage.

photocleavage appear in the inset of each plot. In the absence of piperidine, it is evident that the Cu(II) complex of **4** almost always produces frank strand breaks without a marked base preference (Figure 7A). This result suggests that photocleavage may involve hydrogen atom abstraction from deoxyribose. Because sugar residues are present in every nucleotide, reagents which function by hydrogen atom abstraction are expected to cleave at all nearby DNA sequences irrespective of base composition (*11*). Singlet oxygen and direct electron transfer from DNA nucleobases produce DNA damage predominately at guanine bases (*11*, *63*) and are therefore unlikely to have made overriding contributions to the formation of frank strand breaks. Alternatively, the cleavage pattern was changed after the DNA photolysis reactions were treated with piperidine, showing preferential damage at guanine. This result indicates that alkaline-labile lesions were formed at guanine bases, either through the production of singlet oxygen and/or by direct electron transfer from DNA (Figure 7B).

CONCLUSION

In summary, our data indicate that Cu(II) markedly enhances DNA photocleavage by ligand **4** under near-physiological

conditions of temperature and pH. Although the precise cleavage mechanism is unknown, at this time we believe that the formation of frank strand breaks may involve acridine-sensitized photoreduction of Cu(II) to Cu(I) followed by reaction of **4**/Cu(I) with hydrogen peroxide to form a copper−peroxide complex. Considering the bioavailability of copper at the cellular level, copper-based photonucleases are advantageous in comparison to complexes based on other metals or to chemical nucleases which require an external reducing agent for their activity. To the best of our knowledge, bis-acridine **4** is only the third example of a photonuclease that has been shown to cleave DNA by a process that involves direct photochemical reduction of copper (*14*, *15*). Our future work will focus on mechanistic studies and on synthetic endeavors to develop new copper-based photonucleases for use in chemical and medical applications.

Calpains, the intracellular proteolytic enzymes, play important roles in various processes in cells. The lack of calpain or its overexpression is thought to be an underlying factor in some diseases. In this study, we report the synthesis of a new group of cell-penetrating calpastatin−peptide conjugates with the activating capacity of m-calpain intracellularly. In these constructs, peptides related to the calpastatin A or C subunit with the capabiliy of activation of isolated m-calpain was covalently conjugated to the C-terminal of penetratin via amide, thioether, or disulfide bond. These conjugates were prepared by solid-phase synthesis and/or by chemical ligation and properly characterized (MS, HPLC). Our results using isolated m-calpain suggest that conjugation does not interfere with the enzyme-activating effect of the calpastatin peptides; in fact, the efficiency of the conjugates was markedly higher. The conjugates with different bonds showed essentially the same level of activation. Internalization experiments with fluorophore (4-[7-hydroxycoumaryl] acetic acid (Hca) at the N-terminal of penetratin and/or 5(6)-carboxyfluorescein (cf)) labeled conjugates show that these constructs are taken up by COS-7 cells. Using cell lysates produced after incubation with the 1:1 (mol/mol) mixture of calpastatin A and C peptide conjugates, we found a significant calpain activating effect. We also noticed that the conjugate even with a disulfide bond between the components seems to be stable and activate m-calpain after intracellular translocation under the conditions studied. To the best of our knowledge, this is the first report to describe conjugates with an m-calpain activating effect on isolated enzymes and more importantly within living cells after transmembrane delivery. Thus, these conjugates seem to be appropriate as molecular tools to activate intracellular m-calpain and to study calpain functions in living cells.

INTRODUCTION

Calpains are intracellular cysteine proteases whose catalytic site is analogous to those of papain-like proteases (*1*, *2*). In mammals, the family has 14 members showing various patterns of expression. The ubiquitous forms are the μ- and m-calpains (calpains 1 and 2, respectively). Calpains play crucial roles in cell adhesion and motility, exocytosis, signal transduction, cell cycle progression, and regulation of gene expression (*3*−*7*). Their activation leads to the limited proteolytic modification of a variety of substrate proteins. However, the overactivation of calpains is associated with the pathogenesis of a wide range of disorders (*8*).

The activation of calpain by Ca^{2+} binding is mechanistically clear, but the key aspects of activation in vivo are still enigmatic. Namely, calpains require nonphysiologically high Ca^{2+} concentrations in vitro (*9*). Various mechanisms have been proposed for calpain sensitization to Ca^{2+} in the cell. One may be the fragmentation of calpastatin, the endogenous inhibitor of calpains. Calpastatin contains four inhibitory domains (*10*). Each domain contains three short, conserved sequences of about 20 amino acids, termed subdomains A, B, and C. Functional studies showed that only subdomain B is responsible for inhibition of calpains (*11*, *12*). Subdomains A and C exert no inhibitory effect on calpain (*12*−*14*). However, peptides corresponding to subdomain A (S^{12}GKSGMDAALDDLIDTLGG^{31}) or subdomain C (S^{86}KPIGPDDAIDALSSDFTS^{105}) significantly activate both human erythrocyte μ-calpain and rat m-calpain and increased the Ca^{2+} sensitivity in vitro (*15*). Peptides, when applied separately, activate the enzyme, but their 1:1 (mol/mol) mixture exhibited the maximal effect. On the basis of these findings, it was postulated that calpastatin might be fragmented, and the fragments could play a role in calpain activation in vivo.

In the extensive studies on calpains physiological function, almost invariably calpain inhibitors were used. These, however, lack strict specificity. They may react with the proteosome, lysosomal proteinases, or even with nonproteolytic enzymes (*16*, *17*). In general, the results obtained with calpain inhibitors cannot always be unequivocally attributed to the action of calpain. In contrast, peptides derived from calpastatins A and C are likely to be specific to calpain.

In recent years, several oligopeptides of natural and/or synthetic origin have been described with cell membrane penetrating capability. The first peptide sequences came from the HIV-1 Tat (*18*, *19*) and the antennapedia protein of *Drosophila* (*20*). These peptides can cross the cell membrane with different cargos (peptides, peptide−nucleic acid, oligonucleotide) (*21*).

There have been efforts to prepare specific calpain inhibitors based on calpastatin and cell-penetrating peptides capable of transmembrane trafficking of covalently attached cargo (*22*−*24*). The alternative strategy was to produce, by genetic manipulation, fusion constructs containing the cell-penetrating motif and the sequence derived from calpastatin (*25*). In these studies, calpastatin or its inhibitory region was joined with cell-penetrating peptides. Croce et al. developed an inhibitor of calpain by conjugating with amide bond the minimal inhibitory

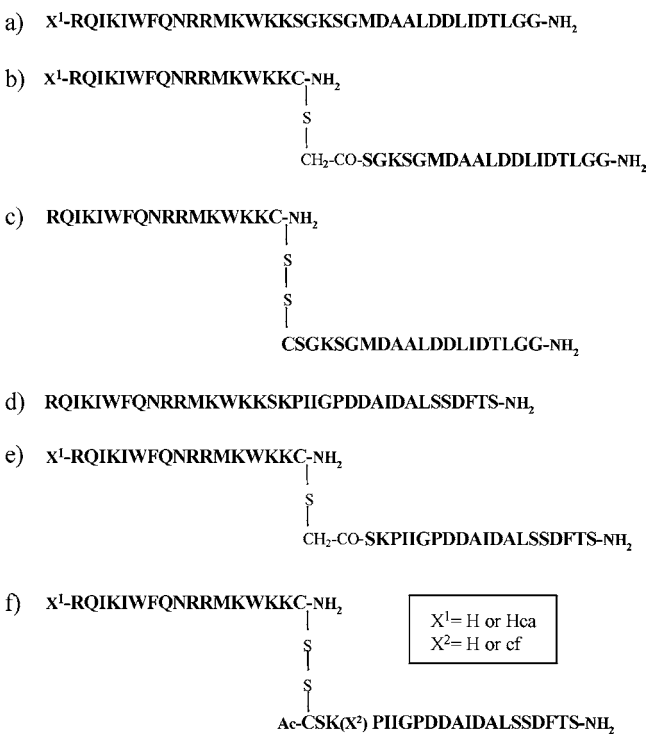

Figure 1. Outline of the structure of the penetratin−calpastatin A (a−c) and penetratin−calpastatin C (d−f) conjugates with amide (a,d), thioether (b,e), or disulfide (c,f) linkage.

sequence (EKLGERDDTIPPEYRELLEKKTGV) of calpastatin to the C-terminal of the signal-sequence-based penetrating peptide, AAVALLPAVLLALLAP. Using this chimera and a set of peptidyl calpain inhibitors, with appropriate specificity controls, it was demonstrated that calpain regulates platelet degranulation, aggregation, and spreading (*22*).

The peptide related to subdomain B of calpastatin (DPMSSTYIEELGKREVTIPPKYRELLA) was prepared with N-terminal 11-mer arginine also via amide bond by solid-phase peptide synthesis (*23*). The conjugated calpastatin peptide was able to inhibit calpain activity in a primary culture of rat cortical neurons. In the other study, the same calpastatin peptide with Cys at the N-terminal was coupled to penetratin containing Cys at the N-terminal position by disulfide bond (*24*). This conjugate was also able to penetrate LCLC 103H cells and inhibit calpain activation in vivo. Sengoku et al. fused the full-length calpastatin or calpastatin subdomain I (115−248 residues) with the Tat peptide (Tat_{47-57}, YGRKKRRQRRR) and observed that the fusion proteins were able to enter primary rat cortical neurons and also exhibited a potent m-calpain inhibitory effect in a cell-free activity assay but did not influence the activity of intracellular calpain (*25*). The authors found that the fusion protein with Tat peptide was taken up by the endosomal route, which might be in relation to the loss of inhibitory property of the cargo.

In the present work, our aim was to prepare a new class of calpastatin peptide conjugates in which the related peptide (calpastatin A or calpastatin C) with calpain-activating properties is conjugated with the well-known cell-penetrating peptide, penetratin. In contrast to the impermeable calpastatin A and C peptides, we expected that these contructs will possess membrane translocating properties and provide activation of calpain intracellularly. The conjugation of calpastatin A and C peptides was carried out via amide, thioether, and disulfide bond formation to study the effect of linkage between the components on both calpain activation and cellular uptake. In these constructs, penetratin (RQIKIWFQNRRMKWKK) was at the N-terminus as outlined in Figure 1. Conjugates with amide bond were built up by solid-phase peptide synthesis. For conjugates with thioether or disulfide bonds, nonprotected peptide fragments with added N- or C-terminal Cys residues were prepared, and appropriate ligation techniques were utilized in solution. Here, we report on our findings that the calpain-activating properties of calpastatin peptides were not only preserved after conjugation with penetratin but significantly increased in both cell-free (isolated enzyme) and cellular assays. Internalization experiments with fluorophore (4-[7-hydroxycoumaryl] acetic acid (Hca) at the N-terminal of penetratin and/or 5(6)-carboxyfluorescein (cf)) labeled conjugates show that these constructs are taken up by COS-7 cells We found that a conjugate even with disulfide bonds between the components seems to be stable and can activate calpain after intracellular translocation.

EXPERIMENTAL PROCEDURES

All amino acid derivatives were purchased from Novobiochem (Laufelfingen, Switzerland) and Reanal (Budapest, Hungary), while *p*-cresol, thioanisole, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), piperidine, *N*,*N*′-diisopropylethylamine (DIEA), tris(hydroxymethyl)aminomethane (Tris), trifluoroacetic acid (TFA), triisopropylsilane (TIS), 1-hidroxybenztriazole (HOBt), *N*,*N*′-diisopropylcarbodiimide (DIC), *N*,*N*′-dicyclohexylcarbodiimide (DCC), 5(6)-carboxyfluorescein (cf), 4-[7-hydroxycoumaryl] acetic acid (Hca), and hydrogen fluoride (HF) were Fluka (Buchs, Switzerland) products. The 4-methylbenzhydrylamine (MBHA, 1.4 mmol/g) and Rink amide resin (0.64 mmol/g) were purchased from Novobiochem (Laufelfingen, Switzerland). Solvents (DMF, DCM, diethyl ether, acetonitrile) for syntheses and purification were obtained from Reanal (Budapest, Hungary). The chloroacetic acid pentachlorophenyl ester and the 5(6)-carboxyfluorescein pentachlorophenyl ester were prepared in our laboratory.

Synthesis of Calpastatin Peptides. Calpastatin A peptide with N-terminal Cys residue ($C(Npys)S^{12}$GKSGMDAALDDLIDTLGG^{31}) was synthesized manually by solid-phase methodology on MBHA resin (0.5 g, 1.4 mmol/g). The amino acid side-chain protecting groups were benzyl ether for Ser and Thr and cyclohexyl ester for Asp. The side chain of Lys was protected with *tert*-butyloxycarbonyl group, and of Cys was protected by 3-nitro-2-pyridinesulfenyl (Npys) group.

The synthesis was carried out by the Boc/Bzl strategy up to the incorporation of Asp at position 18. Then, the Fmoc/^{t}Bu strategy was applied. The N^{α}-Boc group was removed with 33% TFA in DCM (2 + 20 min) followed by washing with DCM (5 × 0.5 min), neutralization with 10% DIEA in DCM (3 × 1 min), and DCM washing again (4 × 0.5 min). For coupling, amino acid derivatives and DCC and HOBt dissolved in a minimal amount of DCM−DMF 4:1 (v/v) mixture were used in 3 molar excess for the resin capacity. The reaction proceeded at room temperature (RT) for 60 min. Then, the resin was washed (DMF 2 × 0.5 min, DCM 3 × 0.5 min). The efficiency of coupling was checked by ninhydrin (*26*) or isatin (*27*) tests. The N^{α}-Fmoc group was removed with 2% piperidine plus 2% DBU in DMF (2 + 2 + 5 + 10 min) followed by washing with DMF (8 × 0.5 min). For coupling, amino acid derivatives and DIC and HOBt dissolved in DMF were used in 3-fold molar excess for the resin capacity. The reaction proceeded at RT for 60 min. Then, the resin was washed (DMF 2 × 0.5 min, DCM 3 × 0.5 min). Finally Boc-Cys(Npys) was added as the N-terminal residue. The Boc group was removed by 33% TFA in DCM in the presence of 0.5 g Met as a scavenger. The peptide was cleaved from the resin by 10 mL HF using 0.5 g *p*-cresol scavenger at 0 °C for 1.5 h. Crude products were precipitated with dry diethyl ether, filtered, washed, dissolved in 10% acetic acid, and freeze-dried.

The N^{α}-choloroacetylated calpastatin A peptide (ClAc−S^{12}-GKSGMDAALDDLIDTLGG^{31}) was synthesized manually by

solid-phase methodology on Rink amide resin (0.1 g, 0.64 mmol/g) using the Fmoc/^{t}Bu strategy. The amino acid side-chain protecting groups were *tert*-butyl ether for Thr and Ser and *tert*-butyl ester for Asp. The side chain of Lys was protected with the *tert*-butyloxycarbonyl group. After the removal of the last N^α-Fmoc group, a chloroacetic group was introduced to the N-terminal of the peptidyl resin using 5 molar excess chloroacetic acid pentachlorophenyl ester dissolved in DMF at RT for 10 h (*28*). Chloroacetylated peptide was removed from the resin by cleavage with 10 mL TFA containing 0.5 g phenol, 0.5 mL distilled water, 0.5 mL thioanisole, and 0.6 mL TIS as scavengers. The crude product was precipitated by dry diethyl ether, dissolved in 10% acetic acid, and freeze-dried.

The calpastatin C peptide (Ac−C(Npys)S^{86}KPIGPDDAIDALSSDPFTS^{105}) was synthesized manually by solid-phase methodology on MBHA resin (0.2 g, 1.4 mmol/g) using Boc/Bzl strategy. The amino acid side-chain protecting groups were benzyl ether for Ser and Thr and cyclohexyl ester for Asp. The side chain of Lys was protected with a 2-chlorobenzyloxycarbonyl group. After the cleavage of the last Boc group, the N-terminus was acetylated by acetic anhydride in DMF in the presence of DIEA (1:1 = mol/mol). The acetylated peptide was cleaved from the resin by 10 mL HF using 0.5 g *p*-cresol scavenger at 0 °C for 1.5 h. The crude product was precipitated with dry diethyl ether, filtered, washed, dissolved in 10% acetic acid, and freeze-dried.

Choloroacetylated calpastatin C peptide (ClAc−S^{86}KPIGPDDAIDALSSDPFTS^{105}) was prepared manually by solid-phase methodology on MBHA resin (0.15 g, 1.4 mmol/g) as described above. After the removal of the last N^α-Boc group, the peptidyl resin was chloroacetylated by 5 molar excess of chloroacetic acid pentachlorophenyl ester dissolved in DMF for 10 h. The peptide was cleaved from the resin by 10 mL HF using 0.5 g *p*-cresol scavenger at 0 °C for 1.5 h. The crude product was precipitated with dry diethyl ether, filtered, washed, dissolved in 10% acetic acid, and freeze-dried.

The fluorophore-labeled calpastatin C peptide (Ac−C(Npys)-S^{86}K(cf)PIGPDDAIDALSSDPFTS^{105}) was prepared in solution using 5(6)-carboxyfluorescein pentachlorophenyl ester. 5 mg (2.2 μmol) calpastatin C peptide was dissolved in 0.5 mL DMF. 2.8 mg (4.4 μmol) 5(6)-carboxyfluorescein pentachlorophenyl ester and 0.7 μL (4 μmol) DIEA were added to the solution. The reaction was carried out at RT overnight.

The crude peptides were purified by RP-HPLC (see below).

Synthesis of Penetratin Peptides with C-Terminal Cys. Penetratin with C-terminal Cys (RQIKIWFQNRRMKWKKC) was synthesized manually by solid-phase methodology on Rink amide resin (0.5 g, 0.64 mmol/g) using the Fmoc/^{t}Bu strategy as described above. The amino acid side-chain protecting groups were trityl for Asn, Gln, and Cys and the 2,2,4,6,7-pentamethyldihydrobenzofuran-5-sulfonyl group for Arg. The side chain of Lys was protected with the *tert*-butyloxycarbonyl group. After assembly, the peptide was cleaved from the resin with 10 mL TFA using 0.75 g phenol, 0.5 mL distilled water, 0.5 mL thioanisole, and 0.25 mL ethandithiol as scavengers. The crude product was precipitated by dry diethyl ether, dissolved in 10% acetic acid, and freeze-dried.

4-[7-Hydroxycoumaryl]acetic acid (Hca)-labeled penetratin C peptide (Hca−penetratinC) was synthesized the same way, but after the cleavage of the last N^α-Fmoc group, Hca was introduced into the sequence using the same coupling reagents and conditions as amino acid derivatives. Labeled penetratin C peptide was cleaved from the resin as the penetratin. The peptides were purified by RP-HPLC.

Synthesis of Calpastatin Conjugates. Conjugates with an amide bond were prepared manually by solid-phase methodology using the Fmoc/^{t}Bu strategy on Rink amide resin (0.05 and 0.1 g, 0.64 mmol/g). The amino acid side-chain protecting groups were trityl for Asn, Gln, and Cys and the 2,2,4,6,7-pentamethyldihydrobenzofuran-5-sulfonyl group for Arg. The side chain of Lys was protected with the *tert*-butyloxycarbonyl group. The amino acid side chains of Thr and Ser were protected by *tert*-butyl ether and that of Asp by *tert*-butyl ester. The peptides were cleaved from the resin by 10 mL TFA using 0.75 g phenol, 0.5 mL distilled water, 0.5 mL thioanisole, and 0.25 ethandithiol as scavengers. The crude products were precipitated by dry diethyl ether, dissolved in 10% acetic acid, and freeze-dried. Hca-labeled penetratin−calpastatin A conjugate with an amide bond was prepared the same way, but after the cleavage of the last N^α-Fmoc group, Hca was introduced into the sequence using the same coupling reagents and conditions as amino acid derivatives. The labeled conjugate was cleaved from the resin as the unlabeled one.

Conjugates with a thioether bond were prepared in solution. 15 mg penetratin C (6.4 μmol) or Hca−penetratinC (5.9 μmol) peptides were added in small portions into the buffered (0.1 M TRIS, pH 8.1) solution of 10 mg (5 μmol) chloroacetylated calpastatin A or C peptide (c = 1 mg/mL) every 15 min. The reaction mixture was stirred at RT and followed by RP-HPLC. After 5 h, the solution was freeze-dried.

The synthesis of conjugates with a disulfide bond was carried out in 0.16 M phosphate buffer (pH = 6). 15 mg (6.4 μmol) penetratin C was added in small portions into the buffered solution of 10 mg (4.8 and 4.5 mmol) calpastatin A or C peptides (c = 2 mg/mL) every 15 min. The reaction mixture was stirred at RT and followed by RP-HPLC. Dual-labeled Hca−penetratinCys−Cyscalpastatin(cf)C conjugate with a disulfide bond was prepared in the same way.

All crude conjugates were purified by RP-HPLC as described below.

Reverse-Phase High-Performance Liquid Chromatography (RP-HPLC). Analytical HPLC was performed on a Knauer (Herbert Knauer GmbH, Berlin, Germany) system using a Phenomenex SYNERGI MAX-RP column (250 × 4.6 mm i.d., 4 μm silica, 80 Å pore size) (Torrance, CA) as a stationary phase. Linear-gradient elution (0 min 0% B; 5 min 0% B; 50 min 90% B) was generated using 0.1% TFA in water as eluent A and 0.1% TFA in acetonitrile−water (80:20, V/V) as eluent B. A flow rate of 1 mL/min was applied at ambient temperature. Peaks were detected at λ = 220 nm. The samples were dissolved in eluent B. The crude products were purified on a semipreparative Phenomenex Jupiter C18 column (250 × 10 mm i.d., 10 μm silica, 300 Å pore size) (Torrance, CA). The flow rate was 4 mL/min. The following gradients were applied: 0 min 30% B, 5 min 30% B, and 50 min 75% B for calpastatin A and its conjugates; 0 min 20% B, 5 min 20% B, and 50 min 60% B for calpastatin C, its conjugates, and penetratin.

Amino Acid Analysis. The amino acid composition of peptides was determined by amino acid analysis using a Beckman (Fullerton, CA) model 6300 amino acid analyzer. Prior to analysis, the samples were hydrolyzed in 6 M HCl in sealed and evacuated tubes at 110 °C for 24 h.

Mass Spectrometry. Positive-ion electrospray ionization mass spectrometric analysis was performed on a Bruker Esquire 3000 plus (Germany). The samples were dissolved in acetonitrile−water (50:50, v/v) containing 0.1% acetic acid.

Activation of Calpain in Vitro. Activity of purified recombinant m-calpain was measured in a Jasco FP-6300 spectrofluorometer (Essex, U.K.) in a 3 × 3 mm quartz cuvette, continuously recording the increase of fluorescence corresponding to the cleavage of the substrate FRET (DABCYL-TPLK-SPPPSPR-EDANS) (*29*). The excitation wavelength was 320 nm, and emission was monitored at 480 nm. Reactions were

set up in a final volume of 50 μL at room temperature. Data were recorded for 60 s.

Comparison of the Calpain-Activating Capacity of Conjugates. Maximum activity was measured at 5 mM free Ca^{2+} concentration. Reaction mixtures contained 50 mM Tris-HCl (pH 7.5), 150 mM NaCl, 1 mM EDTA, 2 mM benzamidine, 0.2 mM phenylmethylsulphonyl fluoride and 15 mM β-mercaptoethanol, 200 μM substrate, and 0.2 μM m-calpain. The reaction was started by the rapid mixing of $CaCl_2$ into the sample immediately before starting the measurement. Activation by the conjugates was measured under the same conditions, with the sole difference in the free Ca^{2+} concentration, which was 0.1 mM in these cases. Conjugates were used at 75 μM concentration.

Calpain Activation with the Conjugates with Amide Bond. m-Calpain activity was measured as described above. Different concentrations (0, 5 10, 20, 30, 50, and 100 μM) of the conjugates were used at a constant (0.1 mM) free Ca^{+} level.

Uptake of Fluorescent-Labeled Penetratin−Calpastatin Conjugates. COS-7 cells were grown in Dulbecco's modified Eagle's medium (Sigma) at 37 °C and 5% CO_2 content. Peptides or peptide conjugates were dissolved in a minimal amount of 10% (v/v) acetic acid and diluted with 0.01 M PBS (pH = 7.4) and used at a final concentration of 330 μM. Cells were incubated for 4 h with peptides, then washed with PBS. The fluorescence of cells after fixation (3% paraformaldehyde for 10 min) or without fixation were mounted with MOWIOL 4−88 (Calbiochem) and analyzed by a Leica DMLS fluorescent microscope equipped with a Spot RT color digital camera (Diagnostic Instruments, Livingston, U.K.). According to the type of fluorophores, the Chroma UV and narrow-band GFP filters (Chroma Technology Corp, Rockingham, VT) were used.

Flow Cytometry Analysis of Cellular Uptake. The stock solution of conjugate labeled with 5(6)-carboxyfluorescein dissolved in HPMI (c = 0.4 mM) was used for the treatment of COS-7 cells. Cells were seeded in 24-well plate, and before treatment, the cells were washed with PBS, and they were incubated with the 5(6)-carboxyfluorescein-labeled compound (c = 10 μM) for 1, 1.5, and 3 h at 37 °C. After incubation, cells were washed three times with PBS, trypsinized for 10 min, and resuspended in HPMI. The increase in COS-7 cell fluorescence following incubation was monitored by flow cytometry (BD LSR II, BD Bioscience, San Jose, CA). Data were analyzed with *FACSDiva* software.

Measurement of Endogenous Calpain Activity in COS-7 Cell Lysate. The COS-7 cells were treated with 330 μM conjugates at 37 °C for 4 h. Confluent cells were than washed three times with 0.01 M PBS (pH = 7.4) and were scraped in 1 mL of ice-cold 0.01 mM PBS (pH = 7.4). Cells were collected by centrifugation at 1500 × g at 4 °C for 2 min, resuspended in a 0.1 M Tris-HCl buffer containing 5 mM EDTA, 1 mM dithioerythritol, 5 mM benzamidine, 0.5 mM phenylmethylsulfonyl fluoride, and 10 mM β-mercaptoethanol and sonicated (16 μm, MSE sonicator, West Sussex, U.K.) four times for 10 s with 1 min breaks. The cell lysate was than centrifuged at 15 000 × g at 4 °C for 20 min to remove the cell debris, and the supernatant was used for fluorometric calpain activity measurements as described above. In these experiments, either 1 mM EDTA containing 1 mM $CaCl_2$ or 10 mM $CaCl_2$ was added to 30 μL of lysates. The change in fluorescence intensity was monitored with the FRET peptide substrate (*29*).

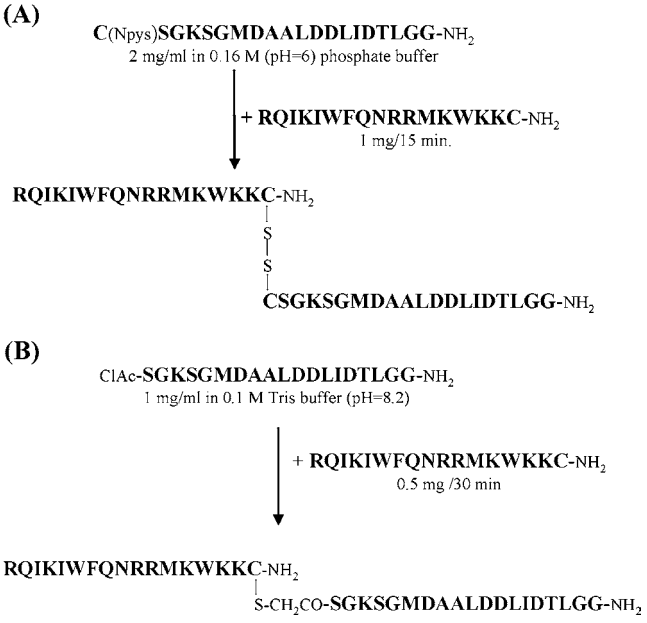
RESULTS AND DISCUSSION

Calpains are important proteases involved in several intracellular processes. In studying their function, mainly inhibitors have been used so far. These, however, are not specific for calpains; therefore, the results obtained cannot always be unequivocally associated with the action of calpain (*16*, *17*). We have demonstrated earlier that peptides corresponding to two regions of calpastatin, the protein inhibitor of calpains, exert activation on isolated calpains (*15*). This effect may also be utilized to study calpain function in living cells. To achieve this, we have produced conjugates containing calpastatin peptides derived from subdomains A and C (*12*) as well as cell-penetrating peptide, penetratin (*20*), in the N-terminal part for transmembrane delivery. Here, we report on the synthesis of a new set of penetratin conjugates with an amide, thioether, or disulfide bond between the components (Figure 1). The amide and thioether linkages are considered stable in the cell, while the disulfide bond could be cleaved in the reducing environment of the cytoplasm (*30*). These conjugates were assayed for their calpain activation properties using isolated m-calpain and also COS-7 cell lysate after incubation with the test compounds. We have demonstrated that fluorescent-labeled penetratin conjugates enter cells, and the nature of the covalent linkage between the components has no marked effect on the calpain activation and membrane translocation of the conjugates.

Synthesis of Calpastatin Conjugates. Conjugates, including the 4-[7-hydroxycoumaryl]acetic acid (Hca) labeled variant of penetratin−calpastatin A, with an amide bond were prepared by solid-phase synthesis on Rink amide resin to produce peptide−amides by the Fmoc/^{t}Bu strategy. The completed conjugates were cleaved from the resin by the TFA cleavage mixture. The compounds were obtained without any difficulties, and their characteristics are summarized in Table 1.

Conjugates with a disulfide or thioether bond were prepared in solution. Considering that none of the partner molecules contain the Cys residue, the original sequences were modified by the incorporation of Cys at an adequate position. First, penetratin and Hca−penetratin elongated at the C-terminal by a Cys residue was synthesized on Rink amide resin by the Fmoc/^{t}Bu strategy and used for conjugates with either disulfide or thioether linkages. The peptides were removed from the resin by the TFA/phenol/thioanizol/EDT/water cleavage mixture. Simultaneously, calpastatin A and C peptide amides extended with a Cys at their N-terminal were also produced on the solid phase.

To build up the heterodimer via disulfide bond, the 3-nitro-2-pyridinesulfenyl (Npys) group was used in the calpastatin peptides as a thiol-blocking group. The Npys group was originally proposed for the protection of amino and/or hydroxyl functions during solid-phase peptide synthesis (*31*, *32*). The greatest potential of Npys, however, has gradually been realized to lie in the side-chain protection of Cys (*31*). Indeed, the most attractive feature of Npys is its dual character as an S-protecting and S-activating group. The calpastatin C derivative with Npys-protected and N-acetylated Cys was synthesized on MBHA resin by the Boc/Bzl strategy. However, in the case of the calpastatin A peptide, from position Asp^{18}, the Fmoc/^{t}Bu strategy was used. This combination of Boc/Bzl and Fmoc/^{t}Bu strategies is to avoid oxidation-related side reactions of Met. After completion of the assembly of the sequences, the HF/*p*-cresol cleavage mixture was used for detachment of the peptides from the resin. The calpastatin C peptide labeled with 5(6)-carboxyfluorescein (cf) at the ϵ-amino group of the Lys residue at position 87 was produced after the detachment of the peptide from the resin in DMF solution by using the active ester derivative of cf. The peptides were characterized and used in the conjugation reaction (Table 1.).



For conjugate preparation, the coupling procedure between the Cys(Npys) peptide and the free SH groups of the protein or polypeptide are usually carried out in solution under acidic conditions (pH 4.5−7.0) to prevent the oxidation of the thiol−peptide (*33*). In our case, the Cys(Npys) containing calpastatin

[a] ESI-MS analysis was carried out on a Bruker Esquire 3000 plus (Germany). The samples were dissolved in acetonitrile−water (50:50, v/v), 0.1% acetic acid. [b] HPLC retention time, column: Phenomenex SYNERGI MAX-RP (250 × 4.6 mm, 4 μm, 80 Å). Linear gradient elution: 0 min 0% B; 5 min 0% B; 50 min 90% B with eluent A (0.1% TFA in water) and eluent B (0.1% TFA in acetonitrile−water (80:20, v/v)) was used at a flow rate of 1 mL/min at ambient temperature. Peaks were detected at λ = 220 nm. [c] cf, 5(6)-carboxyfluorescein.

Scheme 1. Outline of the Synthesis of Conjugates with Disulfide (a) or Thioether (b) Bond

A or C peptide was dissolved in 0.16 M phosphate buffer (pH = 6.0) at 2 mg/mL concentration, and penetratin with unprotected C-terminal Cys was added in small portions into this solution as outlined in Scheme 1. The advancement of the reaction was monitored by RP-HPLC, and after completion, the conjugates were purified and characterized (Table 1). Under the conditions used, we found a negligible amount of penetratin dimer.

Conjugation resulting in a thioether bond is a simple method, which can be carried out even with unprotected fragments. For this reaction, penetratin with C-terminal Cys and calpastatin peptides chloroacetylated at their N-terminal were produced. The chloroacetylated calpastatin A was synthesized on Rink amide resin by the Fmoc/^{t}Bu strategy and cleaved from the resin by TFA in the presence of scavengers. It should be noted that EDT was replaced by TIS as a scavenger. Considering the differences in the sequence, the chloroacetylated calpastatin C was synthesized on MBHA resin by the Boc/Bzl strategy and cleaved from the resin by HF. It is important to notice that the chloroacetyl group is stable under the normal HF deprotection conditions, even in the presence of appropriate thiols as scavengers (*34*). The peptides were properly characterized and used in the conjugation reaction (Table 1). Since the reaction of the thiol and Cl−Ac group is fast and selective enough, the protection of the side-chain functional groups in the peptide is not necessary. The thioether bond forms rapidly under mild alkaline conditions (*35*); therefore, the reaction was carried out in 0.1 M Tris buffer (pH 8.1) as outlined in Scheme 1. In most cases, this reaction is faster than the competing oxidation, which could lead to disulfide bridge formation. To avoid this side reaction, the choloroacetylated peptides were dissolved in the buffer, and the Cys-containing penetratin with or without the N-Hca-label was added in small portions into the mixture. We essentially did not observe formation of the oxidized product. It should be noted that this side reaction could be dependent on the position of Cys in the peptide chain (*36*).

In Vitro Activation of Calpain. We have demonstrated earlier that the calpastatin A and C peptides can activate the isolated m-calpain in vitro (*15*). This activating effect was the most pronounced when a 1:1 (mol/mol) mixture of both peptides was used for incubation with calpain. Therefore, using the same assay (*15*), we have performed a comparative study to investigate the effect of conjugation on the enzyme activation effect of calpastatin A plus C peptides. Conjugates with different bonds were also compared for activation of isolated rat m-calpain. The activity of isolated enzyme measured at 5 mM Ca^{2+} concentration was taken as the positive control (100%) (Figure 2, column A), while activation observed in the presence of 0.1 mM Ca^{2+} concentration was considered the "negative" one (2.4%) (Figure 2, column B). At this low Ca^{2+} concentration, the calpain activity was tested in the presence of peptide or conjugate mixtures at equimolar concentration. The mixture of free calpastatin A and C peptides moderately increased the enzyme activity to 9.4% (Figure 2C). A more pronounced effect was observed in the case of the conjugate mixtures (Figure 2D−F). All three samples induced a much higher level of activation of isolated m-calpain (41.7−54.1%). The results show that the conjugation of the calpastatin A and C peptides with penetratin at the N-terminal increased, rather then decreased, the activating potential of the peptides. Penetratin alone had no influence on the calpain activity (data are not shown). Seemingly, the type of linkage between the calpastatin A or C peptides and penetratin had no significant influence on the calpain-activating effect. Perhaps conjugates with an amide bond possessed a slightly higher effect (54.1%). The concentration dependence of calpain

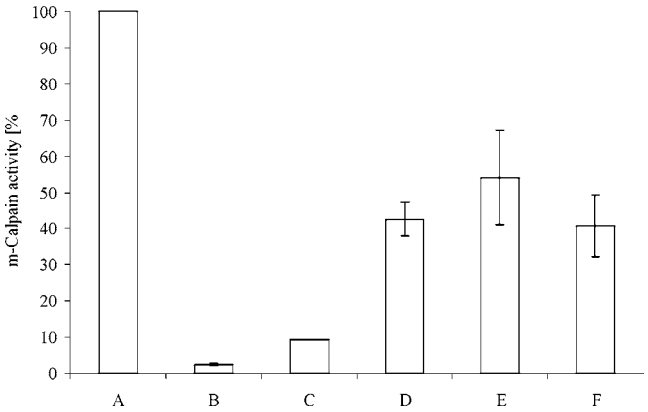

Figure 2. Activation of purified m-calpain with the mixture of calpastatin A and C peptides and with penetratin−calpastatin A and C conjugates. The m-calpain activity was measured at 5 mM $CaCl_2$ (A), at 0.1 mM $CaCl_2$ (B) concentration in the presence of the mixture of 75 μM calpastatin A + 75 μM calpastatin C peptides (C), at 75 μM penetartin−calpastatin A + 75 μM penetratin−calpastatin C conjugates with disulfide bond (D), at 75 μM penetratin−calpastatin A + 75 μM penetratin−calpastatin C conjugates with amide bond (E), and at 75 μM penetratin−calpastatin A + 75 μM penetratin−calpastatin C conjugates with thioether bond (F).

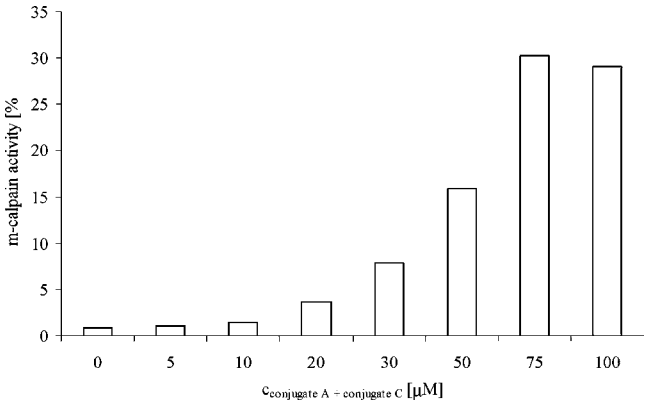

Figure 3. Activity of m-calpain at 0.1 mM $CaCl_2$ using different concentrations of the mixture of penetratin−calpastatin A and C conjugates with amide bond. For details, see Experimental Procedures.

activation was further studied by the mixture of penetratin−calpastatin A and C conjugates with amide bonds (Figure 3.). The m-calpain was measured in the presence of 0.1 mM Ca^{2+} concentration after the addition of 5−100 μM conjugate mixture. The concentration versus activity curve obtained has a sigmoidal pattern, like in the case of the mixture of free calpastatin A and C peptides (*15*). The effect reaches its maximum value at ∼75 μM. These data indicate that the presence of the penetratin sequence is beneficial for the activation of m-calpain perhaps by promoting the binding of calpastatin peptides to calpain. However, further studies are needed to understand the mechanism of action.

Uptake of Penetratin Conjugates. We studied the membrane translocation of conjugates by COS-7 cell by fluorescent microscopy and also by FACS analysis as a function of time. In these experiments, the internalization ability of the conjugates with different bonds was tested. COS-7 cells were incubated with 330 μM Hca−penetratin−CalpA or Hca−penetratinCys-(CalpC) conjugates containing the amide or thioether linkage, respectively. After 4 h at RT, the cells were examined with and without fixation by fluorescent microscopy. The Hca-related fluorescence detected showed that both kinds of conjugates could penetrate into the COS-7 cells and distribute nearly homogeneously in the cells (Figure 4). It should be noted that no effect of fixation on the translocation of Hca−penetratinCys-

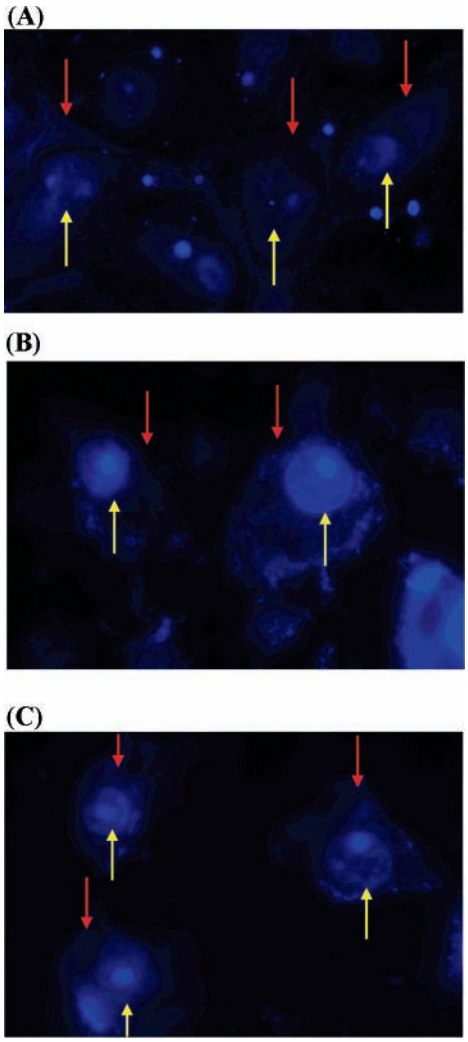

Figure 4. Uptake of Hca−penetratin−calpastatin peptide conjugates by COS-7 cells with (A,B) or without (C) fixation. Hca−penetratin−CalpA conjugate with amide bond (A); Hca−penetratinC−CalpC conjugate with thioether bond (B); and Hca−penetratinC−CalpC conjugate with thioether bond (C). COS-7 cells were treated with 330 μM solution of the conjugate at 37 °C for 4 h. Cells were fixed, and fluorescence was visualized on a Leica DMLS fluorescent microscope. Cell bodies and the nucleus can be distinguished, the conjugates distribute nearly homogeneously in the cells, and the nucleolus is most dense. Red arrows indicate cells, while yellow ones indicate the nucleus. The strong blue patches are aggregates of the conjugates outside the cells. Fixed and living cells provided essentially the same microscopic result, as can be seen in parts B and C.

(CalpC) conjugate was observed under the conditions studied. Similar findings could be detected with other conjugates (data not shown). To study the stability of the disulfide bond, COS-7 cells were also treated with the dual-labeled Hca−penetratin-Cys−CysCalp(cf)C conjugate as described above. The conjugate showed essentially the same cellular uptake and intracellular distribution as compared to conjugates with amide or thioether linkages (Figure 5). The signals derived from both fluorophores inside the cells provided practically the same pattern, suggesting similar intracellular distribution. Apparently, the disulfide bond was stable under the experimental conditions. Furthermore, these data suggest that by this construct calpastatin peptide can be efficiently transported into COS-7 cells. In order to study the viability of cells under conditions used for uptake studies, MTT-based cytotoxicity experiments were carried out. We found that, after the treatment with the conjugate for 3 h, almost 80% of the COS-7 cells were alive, indicating that the 330 μM concentration of the conjugate is not harmful.

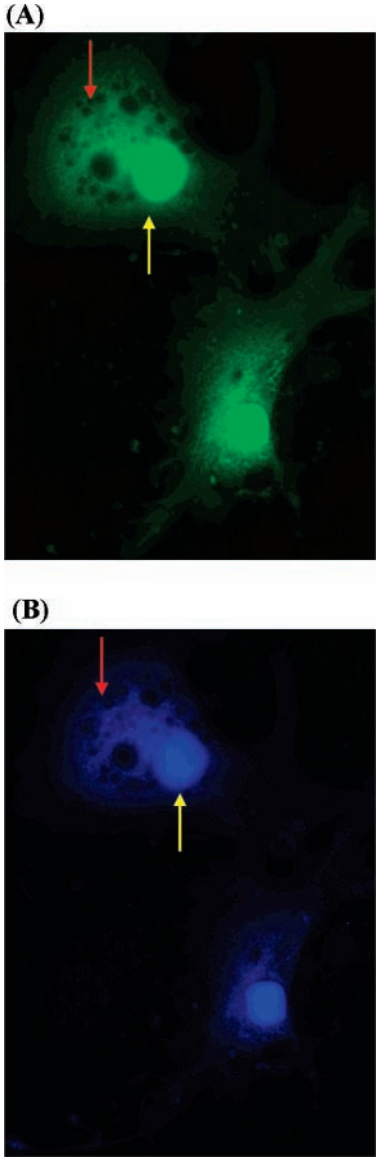

Figure 5. Uptake of double-labeled Hca−penetratinCys−CysCalp-(cf)C conjugate with disulfide bond by COS-7 cells. Signal of the 5(6)-carboxyfluorescein (A). Signal of the Hca (B). COS-7 cells were treated with 330 μM solution of the conjugate at 37 °C for 4 h. Then, fixed cells were visualized on a Leica DMLS fluorescent microscope. Red arrows indicate cells, while yellow ones indicate the nucleus. The conjugate distributes nearly homogeneously in the cell body; the nucleus is denser. Fixed and living cells gave essentially the same microscopic images.

Time dependence of the dual-labeled conjugate was examined by flow cytometry after 1, 1.5, and 3 h treatment of COS-7 cells with the compound under the conditions described above. Data obtained are shown in Figure 6, for a typical experiment. The internalization of the conjugate by cells was in direct proportion to the duration of the incubation time. Even after 1 h, uptake could be demonstrated (*F*(mean): 6), which increases after 1.5 h (*F*(mean): 90) and seems to be saturable since only modest elevation of fluorescence intensity was detected after 3 h (*F*(mean): 200) treatment. For detailed analysis and characterization of the mechanism of internalization, further studies (e.g., temperature dependence, inhibition) are in progress.

Calpain Activity in COS-7 Cell Lysate. In order to study the intracellular calpain-activating potency of conjugate, COS-7 cells were treated with the 1:1 (mol/mol) mixture of penetratin−calpastatin A and C conjugates containing an amide bond at 37 °C for 4 h. Cells without treatment were used as controls. After

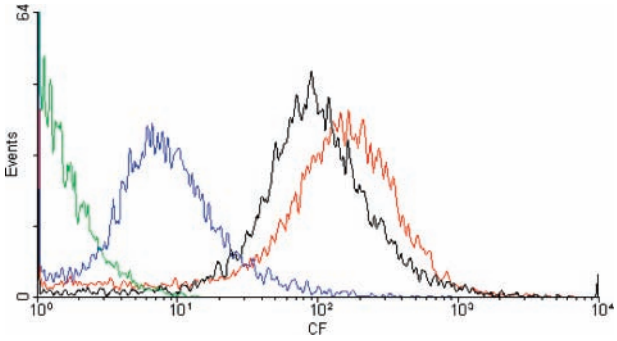

Figure 6. Uptake of the 5(6)-carboxyfluorescein (cf) labeled penetratin−calpastatin C conjugate by COS-7 cells. Cells were treated with a solution of the Hca−penetratinCys−CysCalp(cf)C conjugate with disulfide bond at $c = 10$ μM for 60 min (blue), 90 min (black), and 180 min (red). The fluorescence intensity was measured by FACS analysis. The green line represents the untreated control. For details, see Experimental Procedures.

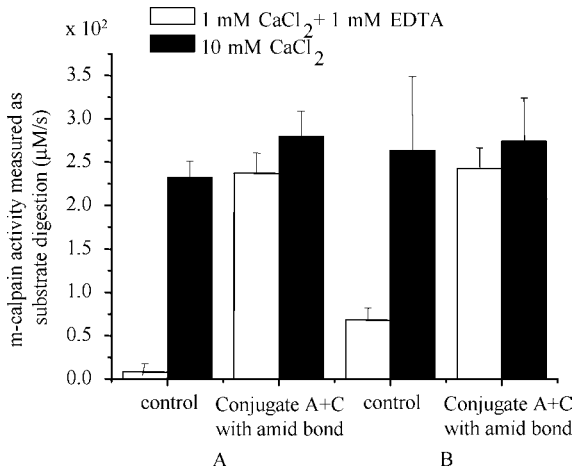

Figure 7. Calpain activity in COS-7 cell lysate in the presence or absence (control) of the mixture of penetratin−calpastatin A plus C conjugates with amide bond. COS-7 cells were treated with the mixture of penetratin−calpastatin A and C conjugates with amide bond using $c = 330$ μM (final), at 37 °C for 4 h. Cells were lysed, and calpain activity was measured in the presence of 1 mM EDTA and 1 mM $CaCl_2$, or of 10 mM $CaCl_2$. The activity of lysates were measured immediately (A) or after 30 min at RT (B). Each column represents the mean value of three independent measurements.

this period of time, the cells were washed and lysated, and the supernatant was used for fluorometric calpain activity measurements in the presence of 1 mM EDTA and 1 mM $CaCl_2$, or of 10 mM $CaCl_2$. Results are shown in Figure 7. Each column represents the mean value of three independent measurements. The activity of lysates was measured immediately (Figure 7A) or after 30 min at RT (Figure 7B). In the case of measurements immediately after cytolysis, calpain activity was only noticeable at 10 mM $CaCl_2$ concentration. However, the calpain activity in the cell lysate treated with the conjugate mixture was clearly higher at both low and high $CaCl_2$ concentrations as compared to the untreated control. We recorded essentially the same tendency in the case of experiments performed after 30 min. These results suggest that the calpastatin conjugates not only before cellular uptake but also after internalization possess a calpain-activating effect.

CONCLUSIONS

In this study, we report the synthesis of a novel group of cell-penetrating calpastatin−peptide conjugates. In these constructs, peptides related to the calpastatin A or C subunit with in vitro calpain-activating capacity were covalently conjugated

to N-terminal penetratin via amide, thioether, or disulfide bond. Our results show that conjugation does not interfere with the m-calpain-activating effect of the calpastatin peptides; in fact, the efficiency of the conjugates was markedly higher. The conjugates with different bonds showed essentially the same level of activation of isolated m-calpain. We have demonstrated that the penetratin conjugates are internalized by COS-7 cells, and the 1:1 (mol/mol) mixture of calpastatin A and C peptides retained their calpain-activating effect even inside the cells. By the help of the dual-labeled penetratin−calpastatin C conjugate, we proved that the disulfide bond is stable enough to transport the attached cargo into the cells under the conditions studied. To the best of our knowledge, this is the first report to describe conjugates with m-calpain-activating effect on isolated enzyme and more importantly within living cells after transmembrane delivery. Thus, these conjugates seem to be appropriate as molecular tools to activate intracellular calpain and to study calpain functions in living cells.

Box 80082, 3508 TB, Utrecht, The Netherlands. Received July 6, 2006; Revised Manuscript Received November 8, 2006

A series of novel bioreducible poly(amido amine)s containing multiple disulfide linkages (SS-PAAs) were synthesized and evaluated as nonviral gene vectors. These linear SS-PAAs could be easily obtained by Michael-type polyaddition of various primary amines to the disulfide-containing cystamine bisacrylamide. The SS-PAA polymers are relatively stable in medium mimicking physiological conditions (pH 7.4, 150 mM PBS, 37 °C), but are rapidly degraded in the presence of 2.5 mM DTT, mimicking the intracellular reductive environment (pH 7.4, [R−SH] = 5 mM, 37 °C). The polymers efficiently condense DNA into nanoscaled (<200 nm) and positively charged (>+20 mV) polyplexes that are stable under neutral conditions but are rapidly destabilized in a reductive environment, as was revealed by both dynamic light scatting measurement and agarose gel assays. Moreover, most of the poly(amido amine)s possess buffer capacities in the pH range pH 7.4−5.1 that are even higher than polyethylenimine (pEI), a property that may favorably contribute to the endosomal escape of the polyplexes. Polyplexes of four of the seven SS-PAAs studied were able to transfect COS-7 cells in vitro with transfection efficiencies significantly higher than those of branched pEI, being one of the most effective polymeric gene carriers reported to date. Importantly, also in the presence of serum, a high level of gene expression could be observed when the incubation time was elongated from 1 h to 4 h. XTT assays showed that SS-PAAs and their polyplexes possess essentially no or only very low cytotoxicity at concentrations where the highest transfection activity is observed. The results indicate that bioreducible poly(amido amine)s have excellent properties for the development of highly potent and nontoxic polymeric gene carriers.

1. INTRODUCTION

A prerequisite for the success of human gene therapy is the availability of safe and efficient gene delivery systems (*1*−*3*). Although viral vectors can efficiently deliver therapeutic nucleotides into cells, clinical application of these vectors is associated with considerable safety and immunogenicity risks. In the past decade, cationic polymers have emerged as important synthetic alternatives, as they have many potential advantages such as absence of specific immune response, large DNA loading capacity, and the ease of large-scale production (*4*−*6*). The currently investigated polymeric gene delivery systems, however, have not yet advanced to clinical evaluation, mainly because of their inferior transfection ability and high degrees of toxicity (*7*−*9*). Improvements have been aimed at developing polymeric vectors that are hydrolytically degradable (*10*−*15*), and a particular example of that approach is the large library of linear poly(β-amino ester)s synthesized and screened by Langer and co-workers (*16*−*18*). Indeed, these hydrolyzable carrier systems generally display decreased cytotoxicity by avoiding the accumulation of positively charged high molecular weight polymers in cells. Degradation of the polymeric vector was also proposed to increase the transfection efficiency by facilitating the unpacking of the polymer/DNA complexes (polyplexes) after endocytosis. The latter process has been identified as one of the major barriers for efficient transfection for many nonviral gene delivery systems (*6*, *19*). However, in the design of hydrolytically degradable carriers, a compromise has to be found between hydrolytic stability in the extracellular environment and fast degradation inside the cell, and this conflicting requirement might explain that in practice the transfection performance of many degradable systems has not improved as compared to their nondegradable counterparts. Furthermore, polymers which are very sensitive for hydrolysis may give difficulties in vector handling and further modification (*20*).

Poly(amido amine)s (PAAs) are hydrolytically much more stable than poly(amino ester)s, and important improvement of the extracellular stability is obtained with these polymers. Generally, linear PAAs have good water solubility and biodegradability, which makes these polymers interesting for biomedical applications, including drug and gene delivery, as was recently pointed out by Ferruti and Duncan et al. (*21*, *22*). These authors reported that an amphiprotic PAA with carboxylic acid side groups give a transfection efficiency comparable to that of 25 kDa branched polyethylenimine (pEI) (*23*), and a conformational change of this polymer upon protonation in the endosomes was proposed to contribute to the endosomal escape of the polyplexes (*24*). The degradation of PAAs under physiological conditions is, however, very slow, and it can be expected that amide hydrolysis does not contribute to the intracellular release of DNA from polyplexes of this polymer.

In this paper, we report a novel family of linear poly(amido amine)s containing repetitive disulfide linkages in their main chain (SS-PAAs) as highly efficient intracellularly degradable gene delivery vectors. These SS-PAAs are relatively stable in the extracellular setting but are prone to fast degradation in a reductive environment analogous to that in the cytoplasm (Scheme 1). Remarkably, the polyplexes based on these SS-PAAs were essentially nontoxic, and a number of them showed

transfection efficiencies in COS-7 cells much higher than those of 25 kDa branched pEI, one of the most effective gene delivery polymers reported to date.

It has been well-established that disulfide linkages can be rapidly cleaved in the intracellular compartment due to the presence of relatively high concentrations of glutathione and thioredoxin reductases. This phenomenon has been successfully exploited for the intracellular release of carrier-conjugated therapeutics (*25*−*28*), and cross-linking of various polymer (*29*−*31*), lipid (*32*, *33*), and peptide (*34*, *35*) based carrier systems. However, only a few reports have appeared on disulfide-containing polymers applied for reduction-triggered gene delivery. Read and Seymour et al. (*36*, *37*) showed that reducible cationic polypeptides $(Cys\text{-}Lys_{10}\text{-}Cys)_n$ give a 187-fold higher level of gene expression than nonreducible polylysine. Significant improvement of the transfection efficiency could also be obtained by Middoux et al. (*38*) by substitution of the amino groups of polylysine with 3-(2-aminoethyldithio)propionyl residues. Lee et al. (*39*, *40*) reported that disulfide cross-linking of low molecular weight pEI results in largely improved transfection properties, attaining levels comparable to 25 kDa branched pEI, while maintaining low degrees of cytotoxicity. During the study described in this paper, Ferruti et al. reported the synthesis and chemical characterization of two disulfide-containing poly(amido amine)s derived from 2-methyl piperazine with *N*,*N*-bisacryloyl cystamine and *N*,*N*-bisacryloyl (L)-cystine, respectively (*22*).

Here, we describe the synthesis of a novel series of functionalized poly(amido amine)s with disulfide linkages in their main chain and the evaluation of their chemical and biophysical properties in relation to their capacity as gene delivery vectors. The influence of variation in the side groups of the polymers and the favorable effect of the presence of the disulfide linkages on the transfection efficiency and cytotoxicity is illustrated.

2. EXPERIMENTAL PROCEDURES

2.1. Materials. All monomers, 4-amino-1-butanol (ABOL, Aldrich), 5-amino-1-pentanol (APOL, Aldrich), *N*,*N*-dimethyl-1,3-ethylenediamine (DMEA, Aldrich), 2-(2-aminoethoxy) ethanol (AEEOL, Aldrich), 3-methoxypropylamine (MOPA, Aldrich), 3-morpholinopropylamine (MPA, Aldrich), histamine (Fluka), dithiothreitol (DTT, Sigma), *N*,*N*′-methylenebisacrylamide (MBA, Aldrich), 1,4-bis(acryloyl)piperazine (BAP, Aldrich), *N*,*N*′-hexamethylenebisacrylamide (HMBA, Polysciences, U.S.A), *N*,*N*′-cystaminebisacrylamide (CBA, Polysciences, U.S.A.), branched polyethylenimine (B-pEI, M_w 25 kDa, Aldrich) were purchased in the highest purity and used without further purification. The plasmid pCMVLacZ, containing a bacterial LacZ gene preceded by a nuclear localization signal under control of a CMV promoter, was purchased from Plasmid Factory (Bielefeld, Germany). pDMAEMA (M_w 1.94×10^5 Da) was synthesized as described previously (*41*).

2.2. Synthesis of Bioreducible Poly(amido amine)s (SS-PAAs). SS-PAAs were synthesized by polyaddition of a primary amine to *N*,*N*′-cystaminebisacrylamide (CBA). In a typical experiment, CBA (0.250 g, 1.1 mM) and histamine (HIS) (0.145 g, 1.1 mM) were added into a brown reaction flask and dissolved in methanol/water mixture (1.1 mL, 4/1 v/v). Polymerization was carried out in the dark at 45 °C under nitrogen atmosphere. The reaction mixture became homogeneous in less than 2 h. The reaction was allowed to proceed for 10 days yielding a viscous solution. Subsequently, 10 mol % excess HIS (0.0145 g, 0.11 mM) was added to consume any unreacted acrylamide groups, and stirring was continued for 2 days at 45 °C. The resulting solution was diluted with 30 mL water, acidified with 6 M HCl aqueous solution to pH ∼3, and then purified by ultrafiltration operation (1000 g/mol cutoff) with acidic deionized water (pH ∼4). The polymers in their HCl−salt form were collected as solid powder after freeze-drying (0.14 g, 35%). The same experiment procedure was applied to the synthesis of p(MBA-HIS), p(BAP-HIS), and p(HMBA-HIS) polymers, but water instead of methanol/water as a solvent was used for p(MBA-HIS) and p(BAP-HIS) polymers. The yields of these polymers ranged from 25% to 35% after ultrafiltration.

2.3. Polymer Characterizations. The ^1H spectra of the synthesized SS-PAAs (in D_2O), recorded on a Varian Inova spectrometer operating at 300 MHz, are given in the Supporting Information.

The molecular weight and polydispersity of the SS-PAAs were determined by GPC relative to PEO standards (Polymer Labs) as described by Jiang et al. (*42*). In short, GPC measurements were performed using a Waters 2695 LC system (Milford, MA) and two thermostated (30 °C) PL aquagel-OH 30 columns (8 μm, 300 × 7.5 mm, Polymer Labs, with a low-molar-mass separation range (200−40 000)). Data were collected using a differential refractometer (model 2414). 0.3 M NaAc aqueous solution (pH 4.4) plus methanol (70/30 v/v) was used as eluent at a flow rate of 0.5 mL/min. (The GPC data of the polymers are given in the Supporting Information.)

The buffering capacity of the SS-PAAs was determined by acid−base titration. Therefore, a known amount of poly(amido amine), which was isolated as its HCl salt with 0.25 mmol of

protonable amine groups, was dissolved in 5 mL of 150 mM NaCl aqueous solution. The pH of the polymer solution was set at 2.0, and the solution was titrated with 0.1 M NaOH solution using an automatic titrator (Metrohm 702 SM Titrino). For comparison, branched PEI ($M_w = 25$ kDa) dissolved in 150 mM aqueous solution adjusted to pH 2.0, was also titrated using the same method. The buffering capacity is defined as the percentage of (protonable) amine groups becoming protonated from pH 7.4 to 5.1 and can be calculated from the following equation (*43*):

$$\text{Buffer capacity (\%)} = \frac{\Delta V_{\text{NaOH}} \times 0.1\ \text{M}}{N\ \text{mol}} \times 100\%$$

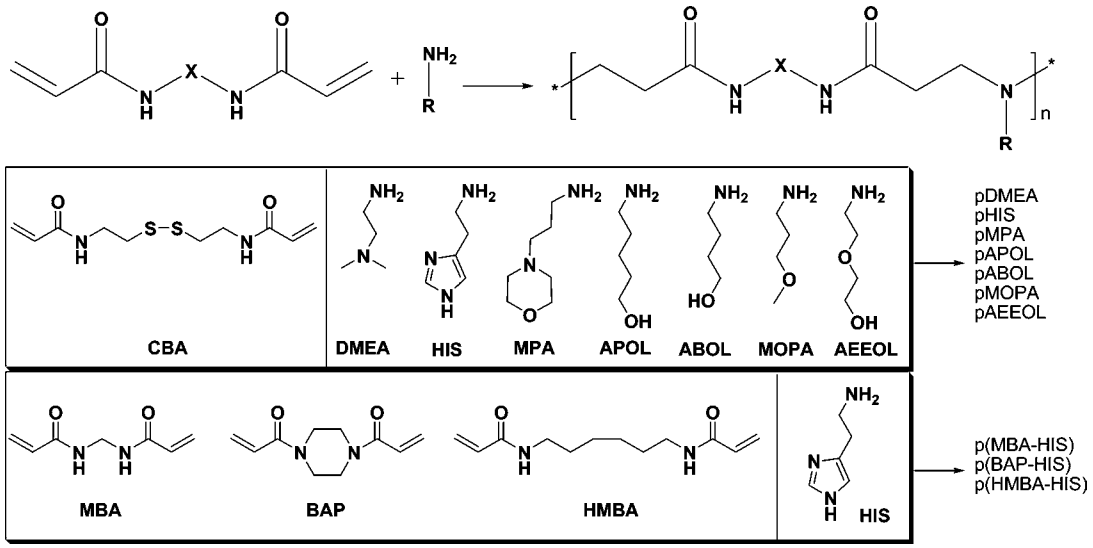
wherein ΔV_{NaOH} is the volume of NaOH solution (0.1 M) required to bring the pH value of the polymer solution from 5.1 to 7.4, and N mol (0.25 mmol), is the total moles of protonable amine groups in the known amount of poly(amido amine) polymer.

2.4. Polymer Degradation Studies. In the polymer degradation studies, pABOL was selected as a representative polymer. For the estimation of the rate of hydrolytic degradation, 20 mg of pABOL (0.05 mmol in monomeric units) was dissolved in 2 mL of PBS buffer pH 7.4, and the obtained homogeneous solution was incubated at 37 °C. Aliquots of the solution (100 μL) were taken at regular time intervals (24 h) and analyzed by GPC measurements. For the reductive degradation study, 2 mg of pABOL (0.005 mmol in monomeric units) was dissolved in 0.5 mL PBS buffer pH 7.4, and then DTT (0.0025 mmol) in 0.5 mL of PBS buffer (final [R−SH] = 5 mM) was added. The obtained homogeneous solution (1 mL) was incubated at 37 °C, and aliquots of the solution (50 μL) were taken at regular time intervals (5 min) and analyzed by GPC measurements (see Supporting Information).

2.5. Particle Size and ζ-Potential Measurements. SS-PAA/plasmid DNA polyplexes at a polymer/DNA mass ratio of 48/1 were prepared by adding a HEPES buffer solution (20 mM, pH 7.4, 5 wt % glucose) of poly(amido amine)s (800 μL, 900 μg/mL) to a HEPES buffer solution (20 mM, pH 7.4, 5 wt % glucose) of plasmid DNA (200 μL, 75 μg/mL), followed by vortexing for 5 s and incubating at room temperature for 30 min. The surface charge and the size of polyplexes were measured at 25 °C with a Zetasizer 2000 instrument and a Zetasizer 4000, respectively (Malvern Instruments Ltd., Malvern, U.K.).

2.6. Agarose Gel Retardation. Polyplexes were made by adding 10 μL of polymer solution (various concentrations in 20 mM HEPES buffered saline (HBS)) to 10 μL plasmid solution (80 μg/mL in HBS buffer, pH 7.4), followed by vortexing for 5 s, and the dispersions were incubated for 30 min at room temperature. Next, 10 μL of HBS buffer solution (as control) or HBS buffer containing DTT was added to give final 2.5 mM DDT in the resultant solution, and the dispersions were incubated for 30 min. After addition of 5 μL of 6× loading buffer containing bromophenol (Ferments), 10 μL of this mixture was applied onto a 0.7% agarose gel containing 0.5 μg/mL ethidium bromide. After development of the gel, DNA was visualized with a UV lamp using a GelDoc system (Imago).

2.7. In Vitro Transfection and Cell Viability Assays. Transfection experiments were performed with COS-7 cells (SV-40 transformed African green monkey kidney cells) by using the plasmid pCMV-LacZ as reporter gene as reported previously (*41, 44*). Two parallel transfection series, one for the determination of reporter gene expression (β-galactosidase) and the other for the evaluation of cell viability by XTT assay, were carried out in separate 96-well plates (ca.1.0×10^4 cells per well). Different polymer/plasmid DNA weight ratios ranging from 0.75 /1 to 96 /1 (w/w) were used to prepare polyplexes. In brief, the polyplexes were prepared by adding a HEPES buffer solution (20 mM, 130 mM NaCl, pH 7.4, 200 μL) of poly(amido amine)s with varying concentrations (from 9.4 to 1200 μg/mL) to a HEPES buffer solution (20 mM, 130 mM NaCl, pH 7.4, 50 μL) of plasmid DNA (50 μg/mL), followed by gentle shaking and incubating at room temperature for 30 min. The incubations of the polyplexes with the cells were performed in either the presence or absence of 5.0% serum. All transfection and toxicity assays were carried out in triplicate. In a standard transfection experiment, the cells were incubated with desired amounts of polyplexes (100 μL dispersion with 1 μg plasmid DNA per well) for 1 h at 37 °C in a humidified 5% CO_2-containing atmosphere. Next, the polyplexes were removed. 100-μL fresh culture medium was added, and the cells were cultured for 2 days. The transfection efficiency was determined by measuring the enzyme activity of β-galactosidase using the ONPG assay (*41*). A pDMAEMA/DNA formulation prepared at a polymer/DNA ratio of 3/1 (w/w) was used as a reference. The number of viable cells was measured using an XTT assay (*45*). The XTT value for untreated cells (i.e., cells not exposed to transfection systems) was taken as 100% cell viability.



The influence of transfection time on the transfection efficiency of pABOL/pDNA polyplexes at a mass ratio of 54/1 was examined by using the same transfection experiment operation mentioned above; in this case, the polyplexes were incubated with COS-7 cells in varying transfection times (1, 2, or 4 h).

The XTT assay on the cytotoxicity of poly(amido amine) polymers (i.e., pABOL and pAPOL) was carried out with same operation steps mentioned above; in this case, only plain polymer in varying concentration from 9.4 to 600 μg/mL was incubated with COS-7 cells.

3. RESULTS AND DISCUSSION

3.1 Synthesis and Characterization of SS-PAAs. Seven different bioreducible poly(amido amine) polymers with repetitive disulfide linkages in their main chain (SS-PAAs) were synthesized via Michael addition of the corresponding primary amine monomers to *N*,*N*′-cystamine bisacrylamide (Scheme 2). Furthermore, for use as control polymers, three poly(amido amine)s lacking the disulfide linkages were prepared from polyaddition of histamine (HIS) to *N*,*N*′-methylenebisacrylamide (MBA), 1,4-bis(acryloyl)piperazine (BAP), and *N*,*N*′-hexamethylenebisacrylamide (HMBA), respectively (Scheme 2). The Michael-type addition of the difunctional amine to the conjugated acrylamide bond is compatible with a diversity of functional groups, and therefore this reaction allows the introduction of a large variety of side groups in the polymer. In our study, we have selected a number of side groups that appeared to be favorable in a gene delivery screening of a large library of poly(amino ester)s by Langer et al. (*17*). Since the addition polymerization is a stepwise process, equal monomer ratios were used in the synthesis in order to obtain PAAs of highest theoretical molecular weight. In the final stage of the reaction, an excess of the amine monomer was added in order to ensure that all potentially toxic acrylamide end groups are consumed and the polymers have only amino end groups. All 10 PAAs were finally isolated in their HCl−salt form and are readily soluble in water, alcohols, and dimethyl sulfoxide, but not in chloroform or ether. The ^{1}H NMR spectra of the polymers were in full accordance with the expected structures. Moreover, the absence of any proton signals between 5 and 7 ppm shows that the polymer did not contain any residual acrylamide end groups. Gel permeation chromatography (GPC) measurements showed that the weight-average molecular weights (M_w) of these

Scheme 2. Synthesis of Bioreducible Poly(amido amine)s (SS-PAAs) and Nonreducible Control Polymers (p(MBA-HIS), p(BAP-HIS), and p(HMBA-HIS))[a]

[a] SS-PAAs were coded in terms of the used primary amine monomer.

Table 1. Characteristics of Poly(amido amine)s: Weight-Average Molecular Weight (M_w), Polydispersity Index (PDI), and Buffer Capacity[a] in the Range pH 5.1−7.4

polymers	M_w (kDa)	PDI	buffer capacity in the range pH 5.1−7.4 (%)
pDMEA	8.70	1.41	13
pHIS	7.84	1.89	58
pMPA	7.60	1.53	59
pAPOL	3.57	1.26	74
pABOL	5.24	1.29	72
pMOPA	3.15	1.35	74
pAEEOL	3.54	1.63	75
p(MBA-HIS)	26.2	2.51	62
p(BAP-HIS)	17.4	2.31	72
p(HMBA-HIS)	7.7	1.57	66
branched pEI[b]	9.54	1.47	24

[a] Conditions: 5 mL of a solution of the polymer (50 mM in amino nitrogen atoms) was titrated with 0.1 M NaOH solution. [b] The absolute weight-average molecular weight of branched pEI is 25KDa.

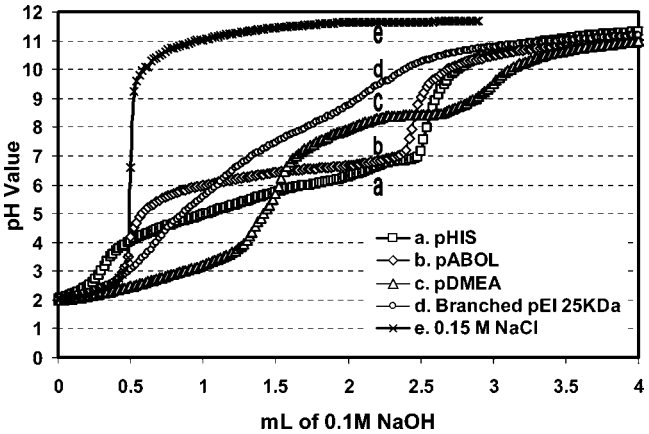


Figure 1. Titration curves obtained by titrating aqueous solutions (pH 2, adjusted with 1 M HCl) of poly(amido amine)•HCl salt (50 mM amino nitrogen atoms) in 150 mM aqueous NaCl with 0.1 M NaOH. For comparison, the titration curve of branched pEI 25 kDa is also presented.

SS-PAAs were in the range from 3000 to 8000 g/mol, with polydispersity indexes (PDI) ranging from 1.26 to 2.51 (Table 1).

It is assumed that the buffering effect of cationic polymers like pEI facilitates the endosomal escape of polyplexes (proton sponge hypothesis) (*46*, *47*). The buffer capacity of the SS-PAA polymers, defined as the percentage of amine groups that becomes protonated on decrease of the pH from 7.4 to 5.1 (i.e., the pH change from the extracellular environment to the lower pH of the endosomes), was measured by acid−base titration (Table 1 and Figure 1). All SS-PAAs, except pDMEA, showed excellent buffer capacity ranging from 42% to 75% protonation, which is significantly higher than that of pEI (24%). Interestingly, pDMEA possessing the dimethylamino group in the side chain has only poor buffer capacity (13%), whereas polymers like pABOL, lacking a proton-acceptor side group show good buffer capacities. The presence of the protonated dimethylamino group in pDMEA (pK_a ~8.5) may largely suppress the protonation of the tertiary nitrogen in the polymer backbone, resulting in a low buffer capacity. The high buffer capacities of the SS-PAAs, as well as their large change in the degree of protonation, may play an important role in the endosomal escape of SS-PAAs/DNA polyplexes and consequently may favorably contribute to the high transfection efficiency of these polymers (vide infra).

The hydrolytic and reductive degradation profiles of the SS-PAAs, using pABOL as a representative example, were investigated in buffer solution (pH 7.4, 150 mM) at 37 °C in the absence and presence of the reduction agent dithiothreitol (DTT, 2.5 mM), mimicking the physiological and intracellular environment, respectively. Monitoring of the decrease in M_w of the polymer by GPC measurements revealed that the pABOL polymer only slowly degrades under physiological conditions, with 5% decrease of M_w after 3 days and 60% decrease after 20 days, which is, as expected, much slower than that of branched and linear poly(amino ester)s (*16*, *20*). However, in the presence of 2.5 mM DTT, a very rapid degradation of the pABOL polymer was observed, and degradation was completed within 5 min. These results suggest that SS-PAA-based polyplexes will not be prone to hydrolytic destabilization under physiological conditions, but can rapidly disintegrate by reductive cleavage of the disulfide linkages in an intracellular reductive environment.

3.2. DNA Condensation and Release. A requirement for cationic polymers to function as gene delivery vectors is that they are able to condense DNA into nanosized polyplexes. Dynamic light scattering (DLS) and ζ-potential measurements show that five SS-PAAs condense DNA at a polymer/DNA mass ratio of 48/1 into polyplexes with small particle size (<200 nm)

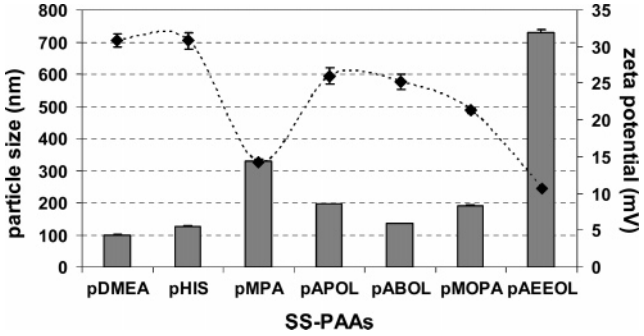

Figure 2. Average particle size (solid bars) and ζ potential (◆) of polyplexes formed with various SS-PAAs and DNA at a polymer/DNA mass ratio of 48/1.

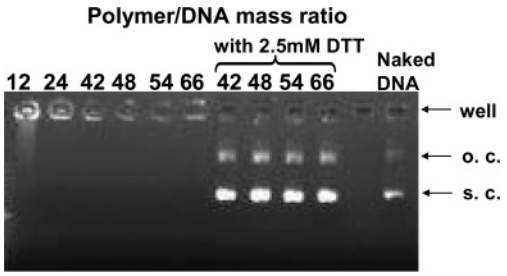

Figure 3. Agarose gel electrophoresis of pAPOL/pDNA polyplexes prepared at different polymer/DNA mass ratios before and after addition of DTT (final concentration of 2.5 mM). o.c. = open circular, s.c. = supercoiled form of plasmid DNA.

and positive surface charge (>+20 mV) (Figure 2). The smallest size and a relatively high surface charge was observed for the polyplexes of pDMEA containing protonated dimethylamino moieties, whereas polyplexes of pMPA and pAEEOL, containing an ether moiety, display a relatively large particle size and a low surface charge. The condensation ability of the SS-PAAs gives the following tendency: pDMEA, pHIS > pAPOL, pABOL, pMOPA > pMPA, pAEEOL. Obviously, the charge density of the polymers plays an important role in their complexation capacity. Polymers pDMEA and pHIS with (partially) protonated side groups, possessing the highest charge density, give polyplexes of small particle size and high surface charge. However, comparison of pABOL and pAPOL with pAEEOL also shows that subtle changes in side chain structure, like the introduction of an ether oxygen in the side chain, have large effects on the condensation ability and surface charge.

For efficient gene transfer, DNA should eventually be released from the polymeric vector. It has been reported that insufficient unpacking of polyplexes can form a major barrier in the transfection process (*6*, *19*). Consequently, the rapid cleavage of the disulfide linkages in the intracellular reductive environment (containing 0.1−10 mM glutathione) is biologically relevant to induce fast dissociation of SS-PAA-based polyplexes and efficient DNA release, leading to increased levels of gene expression. In order to prove the concept of efficient release of DNA from the polyplexes upon disulfide reduction, the complexation−decomplexation behavior of polyplexes based on the 7 PAAs was investigated by agarose gel retardation. A typical example is given in Figure 3, which shows that the migration of negatively charged DNA is retarded by positively charged pAPOL polymer at polymer/DNA mass ratios at and above 24/1. As expected, incubation of the polyplexes for 30 min to dithiothreitol (DTT, 2.5 mM), mimicking the reducing intracellular environment, resulted in total DNA release even at higher ratios of 42/1 and 66/1. The same behavior was observed for the other SS-PAA-based polyplexes, except pAEEOL. However, DNA release did not occur with polyplexes based on the nonreducible control polymers and branched pEI under otherwise identical conditions (data not shown). The concept of fast polyplex destabilization in a reductive environment is further supported by DLS measurements that show that the size of pAPOL-based polyplexes rapidly increases from 200 nm to more than 1 μm within 10 min after the addition of DTT, whereas the size of polyplexes based on the reference polymers remain stable in the presence of DTT.

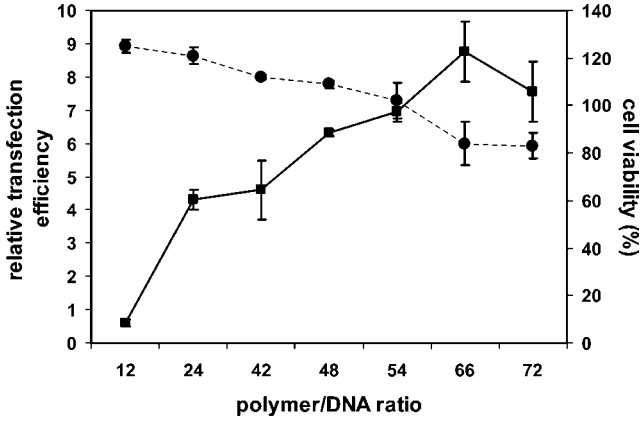

Figure 4. Relative transfection efficiencies (■) and corresponding cell viabilities (●) for pAPOL-based polyplexes formed at various polymer/DNA mass ratios. Transfection efficiencies were normalized to that of pDMAEMA/DNA complexes at a ratio of 3/1 (w/w) (i.e., the transfection efficiency of pDMAEMA polyplexes at their optimal polymer/DNA ratio of 3/1 (w/w) was taken as 1.0). Cell viability was determined by the XTT assay. The data were expressed as mean values (standard deviations) of three experiments.

3.3. In Vitro Transfection Efficiency and Cytotoxicity. The transfection of polyplexes based on the seven SS-PAAs was studied in vitro by using COS-7 cells and the plasmid pCMV-LacZ as reporter gene. Transfection efficiencies were optimized as a function of polymer/DNA mass ratios, ranging from 0.75/1 to 96/1 (Figure 4). As a typical example, a bell-shaped transfection curve was observed for pAPOL-based polyplexes with increasing mass ratios. The optimal transfection of the polyplexes was revealed at a mass ratio of 66/1 (N/P ≈ 50) with an efficiency of about ninefold higher than that of the polyplexes of poly(2-(dimethylamino)ethyl methacrylate) (pDMAEMA) at their optimal (3/1) ratio (*41*). Moreover, remarkably high gene expressions are accompanied with essentially absent or only very low cytotoxicities (≥85% cell viability) (Figure 4).

Figure 5A shows that four of the seven SS-PAAs polyplexes transfect COS-7 cells, with transfection efficiencies higher than that of 25 kDa branched pEI, being the "golden standard". All of these four polymers exhibit considerable buffer capacity (Table 1). In the series of polymers, it appears that the polymers with more hydrophobic side groups give higher transfection, as the transfection efficiency increases in the sequence: pAPOL, pABOL > pMOPA ≫ pAEEOL. Notably, the low transfection efficiency of the polyplexes based on pDMEA, pMPA, and pAEEOL coincides with their less favorable biophysical characteristics, i.e., low buffer capacity, low surface charge, and large particle size, respectively. In the series of the histamine-based polymers, it is clear that polyplexes of the disulfide-containing pHIS show a much higher transfection efficiency and a lower cytotoxicity than those of the control PAAs, indicating that reductive disulfide cleavage indeed plays an important role in the gene delivery process.

It is well-known that the presence of serum often causes aggregation of polyplexes, resulting in decreased transfection efficiencies (*48*). As is shown in Figure 5A, the presence of 5% serum decreases the transfection efficiency of polyplexes of 25 kDa branched pEI ca. 2 times, and even larger effects are observed for polymers like pAPOL. However, it should be noted

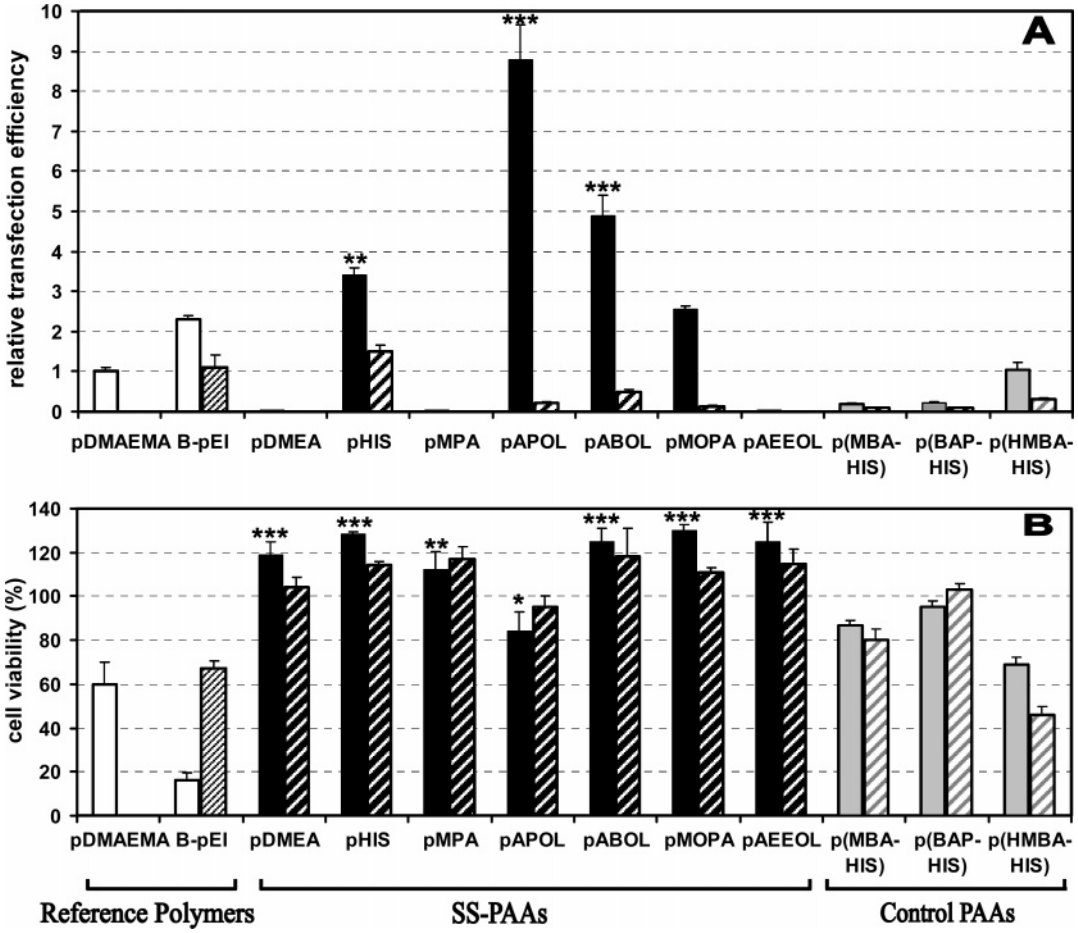

Figure 5. Relative transfection efficiencies (A) and corresponding cell viabilities (B) of polyplexes formed with various poly(amido amine)s and DNA in COS-7 cells at optimized polymer/DNA mass ratios in the absence (solid bars) and presence (slashed bars) of 5% serum. Polymer/DNA ratios for the disulfide containing SS-PAAs p(HIS), p(APOL), p(ABOL), and p(MOPA) were 12/1, 66/1, 54/1, and 48/1 respectively. The transfection efficiency of pDMAEMA polyplexes in the absence of serum at the optimal polymer/DNA ratio of 3/1 (w/w) was taken as reference (set at 1.0). Polyplexes of 25 kDa branched pEI (B-pEI) at an optimized mass ratios of 6/1 was also measured for comparison. Polyplexes of the PAAs without disulfide linkages, p(MBA-HIS), p(BAP-HIS), and p(HMBA-HIS) at optimized mass ratios of 6/1, 96/1, and 48/1, respectively, were used as a control. Cell viability was determined by the XTT assay. The data were expressed as mean values (standard deviations) of three experiments. (Student's *t*-test, $*p < 0.05$, $**p < 0.01$, $***p < 0.001$, poly(amido amine) vs B-pEI).

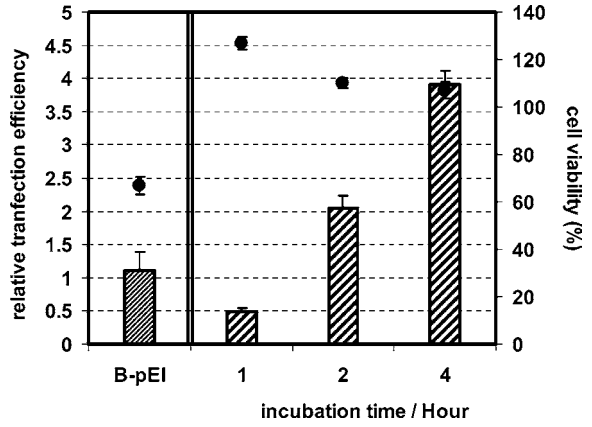

Figure 6. Effect of cell incubation time on transfection efficiency (slashed bars) and corresponding cell viability (●) of pABOL-based polyplexes in COS-7 at an optimized polymer/DNA mass ratio of 54/1 in the presence of 5 wt % serum. The transfection efficiency of pDMAEMA polyplexes in the absence of serum at their optimal polymer/DNA mass ratio of 3/1 was taken as 1.0. Polyplexes of 25 kDa branched pEI (B-pEI) at an optimized mass ratios of 6/1 in the presence of 5 wt % serum were used as a control. Cell viability was determined by the XTT assay. The data were expressed as mean values (standard deviations) of three experiments.

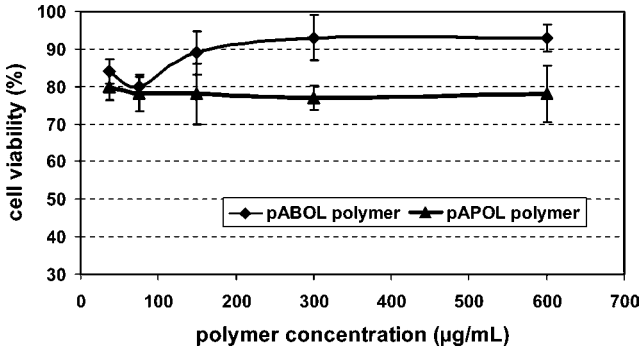

Figure 7. Cell viability of pABOL (◆) and pAPOL (▲) in COS-7 cells at varying polymer concentrations. Cell viability was determined by the XTT assay. The data were expressed as mean values (standard deviations) of three experiments.

that the transfection efficiencies given in this figure were not optimized for serum conditions and that the low toxicity profiles of the PAAs allow considerable optimization by increasing the incubation time of the cells with the polyplexes. For example, a remarkable increase of about 8 times in transfection efficiency of pABOL-based polyplexes is observed in the presence of 5% serum when the incubation time is increased from 1 h to 4 h (Figure 6).

The cell viability experiments, as evaluated by XTT assay, showed that the SS-PAA-based polyplexes are essentially nontoxic (~100% cell viability), illustrating superior properties compared to 25 kDa branched pEI (20% cell viability) and the

control polymers (70−95% cell viability) at polymer/DNA mass ratios of highest transfection efficiency (Figure 5B). As was tested for pABOL and pAPOL also, the plain polymers have a much lower cytotoxicity than 25 kDa branched pEI (IC_{50} of ~30 μg/mL); even at the high concentration of 600 μg/mL, about 80% of the cells retain their metabolic activity (Figure 7).

4. CONCLUSIONS

We have demonstrated that the novel family of functionalized poly(amido amine)s containing repetitive disulfide linkages in their main chain (SS-PAAs) have very promising characteristics for the development of highly potent and nontoxic gene carriers. Their easy and versatile synthesis is compatible with the use of a large variety of functionalized amine monomers, allowing large variation in the structure of the polymers. This enables the tuning of various chemical and biophysical properties important for efficient gene delivery as well as the attachment of stealth polymers and homing devices for gene delivery in vivo. These latter modifications are the subject of current studies.

Sugar−Quantum Dot Conjugates for a Selective and Sensitive Detection of Lectins

Ponnusamy Babu, Sharmistha Sinha, and Avadhesha Surolia*

National Institute of Immunology, Aruna Asaf Ali Marg, New Delhi 110067, India. Received July 9, 2006; Revised Manuscript Received November 13, 2006

One-pot synthesized neoglycoconjugates with a reactive thiol group are introduced here for functionalization with carbohydrates for solubilization and stabilization of CdSe−ZnS quantum dots in aqueous solution. Three different sizes of quantum dots (QDs) with lactose, melibiose, and maltotriose on their surface have been utilized, for the first time, for lectin detection through agglutination assay. The sugar−QDs thus synthesized were characterized by transmission election microscopy (TEM), fluorescence, and absorption spectroscopy. Agglutination of sugar−QDs by three different lectins occurred through specific multivalent carbohydrate−lectin interactions and was studied extensively by monitoring the scattered light at 600 nm. This assay was very selective, which has been demonstrated by a more selective binding of soybean agglutinin (SBA) with melibiose−QD, as compared to lactose−QD, and specific deagglutination caused by α-D-galactose, while α-D-mannose did not show any effect. The detection sensitivity of the maltotriose−QD was tested with Concanavalin A (ConA), and as little as 100 nM of the lectin was detected using light scattering. The detection sensitivity of this protocol has been enhanced considerably by the fluorescence properties of QDs. This agglutination process seems to occur through formation of smaller soluble aggregates, which further associate to form larger aggregates.

INTRODUCTION

Lectins are proteins or glycoproteins of nonimmune origin that bind to mono/oligosaccharides with a high degree of stereospecificity. Since this carbohydrate recognition is very selective and often multivalent, lectins have been implicated in many important functions like cell−cell interactions, homing of leukocytes, host pathogen interactions, biosynthesis and quality control of glycoproteins, immune response, malignancy, and metastasis (*1*, *2*). Lectins also find applications in bioanalytical chemistry and molecular biology (*3*).

Agglutination refers to the process of clumping of cells, such as bacteria or red blood cells, in the presence of an antibody or a lectin (*4*). As this clumping reaction occurs rapidly, agglutination has become an important tool in microbiology and bioanalytical chemistry to identify blood groups, antigens, antibodies, prion proteins (*5*), bacteria such as *S. aureus* (*6*), and metal ions (*7*). Agglutination of erythrocytes has been the preliminary and rapid detection method for lectins since its discovery in the 19th century (*8*−*9*). Hemagglutination assay is qualitative, subjective, requires animal bleeding, and is not very sensitive. Various strategies have been adopted to develop an alternative method for agglutination assay. Although suitably derivatized carbohydrate lysozymes were able to detect nanograms of lectins, this strategy is not a direct method and could not be applied for the determination of the affinities of oligosaccharides (*10*). Carbohydrate-functionalized poly(*p*-phenylene ethynylene) (*11*−*13*) and commercially available Latex particles (*14*) have also been used for agglutination. A few reports of mono- or oligosaccharide functionalized gold (*15*−*16*) and semiconductor (*17*−*18*) nanomaterials have been explored for the study of carbohydrate-binding proteins. Penadés et al., very recently, have reported an excellent account of synthesis and application of various glyconanoparticles published so far in the literature (*19*).

Quantum dots (QDs) are semiconductor nanocrystals, which display very interesting optical properties such as single-wavelength excitation, size-dependent narrow emission, high luminescence, and low photobleaching. These properties make quantum dots very attractive candidates for biolabeling. However, insolubility in water has limited the utility of QDs in bioimaging, thus necessitating work on functionalization and solubilization to exploit QDs in imaging applications. Micellar (*20*), polymer encapsulation (*21*) and covalent coupling to thiol containing hydrophilic functional derivatives (*22*) are the two extreme strategies used frequently for the solubilization and functionalization of CdSe−ZnS QDs. Bioconjugated QDs have been utilized in various fields of in vivo bioimaging including early cancer detection (*23*), multiplexed optical coding (*24*), signal transduction (*25*), sensing (*26*), imaging (*27*), and in Western blot analysis (*28*). Some of the advantages of these nanomaterials in biodetection and biodiagnostics are (i) small size (1−100 nm) and large surface-to-volume-ratio, (ii) physical properties tailored readily according to the end application, (iii) unusual target binding properties, and (iv) structural robustness (*29*).

Here, we report a simple and easy-to-perform detection assay for lectins using a two-step-synthesized, water-soluble, carbohydrate conjugated core−shell CdSe−ZnS quantum dots. This non-erythrocyte agglutination strategy is versatile, reversible, selective, and highly sensitive to lectin detection.

EXPERIMENTAL PROCEDURES

^{1}H NMR spectra were recorded on a Bruker AMX-400 MHz spectrometer, and the mass spectra were recorded on Bruker Daltonics ESI mass spectrometer. The lectins, SBA and Jacalin, were isolated to homogeneity from soybean and jack beans, respectively. Concanavalin A and other chemicals were obtained from Sigma-Aldrich. All the agglutination assays involving

* National Institute of Immunology, Aruna Asaf Ali Marg, New Delhi 110067, India. Tel: +91-11-26717102/03; Fax: +91-11-26162125. E-mail: surolia@nii.res.in.

ConA was prepared in pH 7.2 HEPES (0.1 M) buffer containing NaCl (0.15 M), Ca^{2+}, and Mg^{2+} (10 mM each); SBA and jacalin were prepared in pH 7.4 phosphate salined buffer (20 mM).

Synthesis of Core−Shell CdSe−ZnS Quantum Dots and Surface Modification with Pyridine. Core−shell CdSe−ZnS nanocrystals emitting green (QD-555), orange (QD-589), and red (QD-613) light were synthesized in one pot following a literature procedure (*30*) with slight modification (see Supporting Information).

The surface exchange of TOPO-capped QDs with pyridine was performed by heating a solution of CdSe−ZnS in chloroform with pyridine (three times the volume of chloroform) at 60 °C in an open vial for 3 h. The pyridine solution was precipitated with hexane and centrifuged. The obtained precipitate was redissolved in pyridine, and this stock solution was used for further reactions.

Preparation of Neoglycoconjugates of 2-Aminoethanethiol. For the synthesis of thiol-appended sugar molecules, reducing sugars were reductively aminated with 2-aminoethanethiol. Briefly, 2-aminoethanethiol hydrochloride (125 mg) was dissolved in water (100 μL) in a screw-capped vial (airtight), and pH was adjusted to ∼7.5 (by adding aqueous NaOH solution). To this, $NaCNBH_3$ (40 mg, 0.64 mmol) and a solution of sugar (0.04 mmol) in water (100 μL) were added, and the reaction mixture was heated at 90 °C with stirring. After 1 h, the reaction mixture was cooled to room temperature. The solution was concentrated in speedvac, and the obtained solid was extracted with absolute ethanol (three times) to remove excess starting material. The product was further purified in a Sephadex G-10 column (2 × 17.5 cm) by eluting with water. The products contained ∼5% of compound with a disulfide bond between the product and 2-aminoethane thiol. However, the presence of the disulfide compound is not expected to affect the conjugation with QDs, and hence, no further treatment of these compounds prior to the coupling with QDs was carried out. The compounds were characterized by ^{1}H NMR and ESI-MS.

***β*-D-Galactopyranosyl-(1→4)-(1-deoxy-D-glucityl)-(1→N)-cysteamine 1.** Yield 85%. ^{1}H NMR (400 MHz, D_2O): δ 4.39 (d, J = 7.8 Hz, 1H), 3.9 (m, 1H), 3.85−3.8 (m, 2H), 3.79−3.74 (m, 3H), 3.72−3.65 (m, 3H), 3.64−3.54 (m, 3H), 3.52 (m, 1H), 3.2−2.8 (br. m, 5H). The mass (*m/z*) values calculated for $C_{14}H_{29}NO_{10}S$: 404.16 $(M + 1)^+$, observed 404.1.

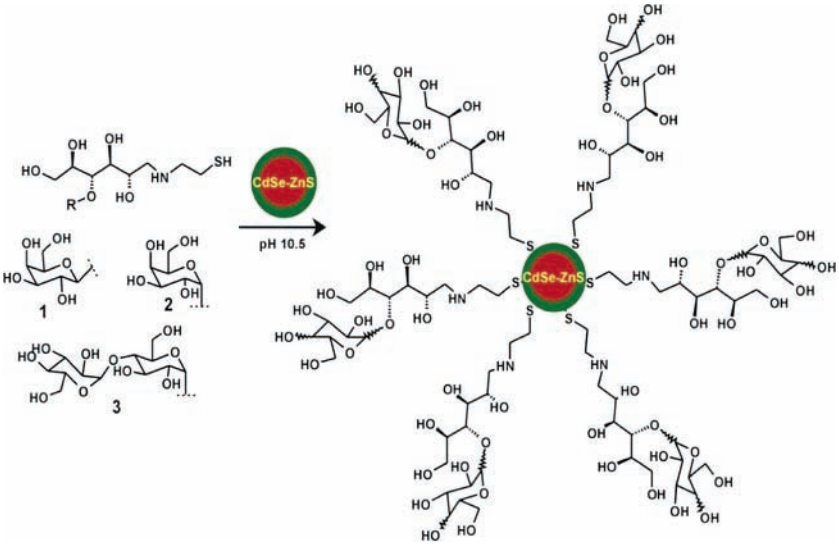
α-D-Glucopyranosyl-(1→4)-α-D-Glucopyranosyl-(1→4)(1-deoxy-D-glucityl)-(1→N)-cysteamine 2. Yield 91%. ^{1}H NMR (400 MHz, D_2O): δ 5.27 (d, J = 3.4 Hz, 1H), 4.99 (d, J = 3.3 Hz, 1H), 4.13 (m, 1H), 3.87−3.84 (m, 3H), 3.75 (m. 2H), 3.72−3.66 (m, 4H), 3.64 (br. d, J = 4.1, 2H), 3.60 (br. s, 1H), 3.59−3.41 (m, 5H), 3.37−3.32 (m, 1H), 3.28 (br. t, J = 9.24 Hz, 1H), 3.15 (br. s, 2H), 2.94 (t, J = 6.34 Hz, 1H). The mass (*m/z*) values calculated for $C_{20}H_{39}NO_{15}S$: 566.21 $(M + 1)^+$, observed 566.2.

Surface Capping of CdSe−ZnS QDs with Neoglycoconjugates. Water solubilization and surface functionalization of CdSe−ZnS was achieved in a single step by covalently coupling QDs with thiol-derivatized sugar molecules. The excess of thiol-appended sugar derivative (**2**, 8 mg) was dissolved in doubled distilled water (50 μL) and DMSO (200 μL) in a microcentrifuge tube. To this solution was added a known concentration of pyridine-capped CdSe−ZnS (QD-589, 2.5 mg) in pyridine (200 μL). The thiol coupling with the ZnS shell of CdSe−ZnS was initiated by adding tetramethylammonium hydroxide (∼5 μL, pH ≈ 10.5) in methanol. The whole mixture was quickly vortexed and centrifuged. The obtained precipitate was resuspended in 50 μL of distilled water and centrifuged (15 000 rpm for 5 min) again. Resuspension and centrifugation were repeated three times to remove excess sugar derivatives. Finally, the precipitate was dissolved in water at pH ≈ 7 (by adding ∼3 μL of 10% AcOH/water) to get a clear solution. The concentration of carbohydrate-capped QD particles was estimated using the extinction coefficients of 0.736×10^5, 3.159×10^5, and 1.531×10^6 M^{-1} cm^{-1} at 350 nm for QD-555, QD-589, and QD-613, respectively (*31*).

For the preparation of a variable number of melibiose per QD particle, a solution of melibiose thiol derivative (20 mg) in 100 μL of water was prepared. From that stock solution, 2, 8, 30, and 40 μL were transferred to four different microcentrifuge tubes and dried. These samples were used for conjugation with QD-589 as described earlier.

Estimation of Concentration of Carbohydrates per Sugar−QD. The concentration of carbohydrate molecules coated on CdSe−ZnS was determined by the phenol-sulfuric acid method using a microtiter plate (*32*). The concentration of sugar molecules in each well was determined by the following procedure. Sugar−QD solution (50 μL) was added to the microtiter plate, followed by quick addition of concentrated sulfuric acid (150 μL) and freshly prepared aqueous phenol solution (5% w/v, 30 μL). The microtiter plate was carefully heated in a water bath at 90 °C. After 5 min, the plate was cooled at room temperature for another 5 min before measuring the absorbance at 490 nm. S−QD solution and sulfuric acid were used as a control. The concentration of sugar (nmol/well) was estimated by comparing the sample absorption with a standard curve. The number of sugar molecules per QD particle was calculated from the ratio of the concentration of sugar and the concentration of CdSe−ZnS QD particles.



Kinetic Study of Agglutination of S−QDs by Lectins. When the sugar/sweet−QDs (S−QDs) were mixed with lectins, the clear solution slowly turned turbid, and after ∼2 h, the colloidal mass settled down at the bottom of the cuvette or microcentrifuge tube. Since this agglutination reaction occurred through the formation of aggregates of lectins binding to multivalent sugar-dots, we monitored the kinetics of agglutination by measuring the scattered light at 600 nm (in 1 cm cell). For example, a known concentration of lectin in the appropriate buffer was mixed with a solution of S−QD in the same buffer (total volume 120 μL), and the change in absorbance was monitored. An exponential growth curve was obtained as a function of time. The kinetic data were best fitted with $f = y_0 + a(1 - e^{-bx})$ equation, and the apparent rate constants were obtained. At high concentrations of QD and/or lectin, the apparent absorbance increases to a maximum and starts to decrease, which is due to the precipitation of agglutinated product.

Electron Microscope. TEM images were recorded in a TECHNAI F30 instrument with an acceleration voltage of 200 KV. The aqueous sample solutions were loaded in 200-mesh carbon-coated copper grids and stained with 2% uranyl acetate solution. The grids were dried completely before imaging.

RESULTS AND DISCUSSION

Synthesis of Neoglycoconjugates and Functionalization of QDs. The strategy adopted here for the preparation of carbohydrate-functionalized QDs was to first prepare sugar derivatives with reactive sulfhydryl groups and then couple them to CdSe−ZnS quantum dots. Hence, reducing sugars D-melibiose (Gal-1-α-4-Glc), D-lactose (Gal-1-β-4-Glc), and D-maltotriose (Glc-1-α-4-Glc-1-α-4-Glc) were reacted with an excess of 2-amino-

Scheme 1. Schematic Representation of Synthesis of Neoglycoconjugate CdSe−ZnS QD Constructs

ethanethiol hydrochloride salt at 90 °C, and subsequent in situ imine reduction by sodium cyanoborohydride furnished the corresponding carbohydrates with a thiol arm. This synthetic protocol consisted of two steps and therefore has an advantage over some of the other reported methods, where multiple-step, protection, and deprotection strategies were employed (*33*−*36*). Moreover, this neoglycoconjugation method can be applied to higher oligosaccharides as well. In these neoglycoconjugates, the reducing end of the sugar unit became acyclic and the nonreducible part remained cyclic (with retention of stereochemistry). We anticipated that these carbohydrate−thiol derivatives are appropriate molecules not only for the solubilization of quantum dots but also for the functionalization of the periphery in a single step. Furthermore, attachments of two or more sugar−thiol molecules to QDs resulted in the formation of a dendritic architecture with multiple functional carbohydrates on the surface (Scheme 1). The acyclic hydroxylated spacer chain would also reduce the diffusion of oxygen molecules, thereby protecting the CdSe−ZnS dots from surface oxidation. Thus, these multi-carbohydrate nanoparticles have tremendous potential in a number of applications in analytical chemistry.

The covalent coupling reaction of carbohydrate−thiol molecules with three different sizes (555-QD (OD = 3.5 nm), 589-QD (3.8 nm), and 613-QD (4.3 nm)) of CdSe−ZnS QDs was achieved at higher pH (see Experimental Procedures). The sugar−quantum dots were soluble in water at around neutral pH but not above pH 8. The water-soluble sugar−QDs were characterized by TEM, fluorescence microscopy, and absorption spectroscopy. Furthermore, these S−QDs emitted bright green (555-QD), orange (589-QD), and red (613-QD) colors upon excitation (at 400 nm). The number of sugar molecules present on the QD surface was estimated by the simple and very sensitive phenol-sulfuric acid method (see Experimental Procedures). To our expectation, these S−QDs were agglutinated by lectins rapidly and very selectively. The agglutinated product was reversibly deagglutinated/disaggregated by addition of selective carbohydrate molecules. This reversal of agglutination demonstrated that the interaction between the S−QDs and lectin is specific and reversible. The agglutinated products were characterized by TEM (Figure 1).

Effect of the Number of Sugar Molecules per Particle and Size of QDs on Agglutination. Our initial aim was to estimate the stability and agglutinability of various carbohydrate-capped CdSe−ZnS quantum dots. Hence, a series of S−QDs with varying number of melibiose−neoglycoconjugate (MB, **2**), approximately 2, 4, 6, 12, and 18 molecules per QD-589 particle, were prepared by appropriately changing the concentration of **2** (see Experimental Procedures). The ability of 589-MB-QDs to remain stable in solution (without aggregation) was monitored at room temperature and found to be <20, 47, 52, 72, and 180 h for QDs with 2, 4, 6, 12, and 18 molecules of **2** per particle, respectively. Thus, the stability of S−QDs increased upon increasing the number of sugar units. However, all the S−QD solutions were stable for months when kept in the dark at 4 °C. The agglutination efficiency of a variable number of melibiose-coated 589-QD was studied with an excess of Jacalin (533 μM)—an α-galactose specific lectin. A plot of variable numbers of melibiose-containing 589-MB−QDs as a function of the agglutination rate constant showed a linear behavior (Figure 2). Reversal of agglutination occurred when α-D-galactose (14 mM) was added to the agglutinated product of 589-MB−QDs and Jacalin (data not shown). These results suggested that, as the number of melibiose−neoglycoconjugate per QD increased, because of the multivalent nature, a greater number of lectins bound to S−QDs through specific carbohydrate-mediated interaction.

In order to study the effect of agglutination on the size of CdSe−ZnS QDs, 589-QD and 613-QD were surface-modified with **2**. The concentrations of melibiose conjugate and QD were adjusted to get an approximately equal number of average melibiose per unit area of particles of two different sizes of QDs. The mean numbers of melibiose moieties per unit area (percentage) of QD are 34.7 and 35 for 589-MB−QD and 613-MB−QD, respectively. The agglutination assay was performed, keeping concentrations of QD (6.4 μM) and Jacalin (107 μM) constant. The obtained data were fitted, and apparent rate constant values for orange and red emitting MB−QDs are 4.585

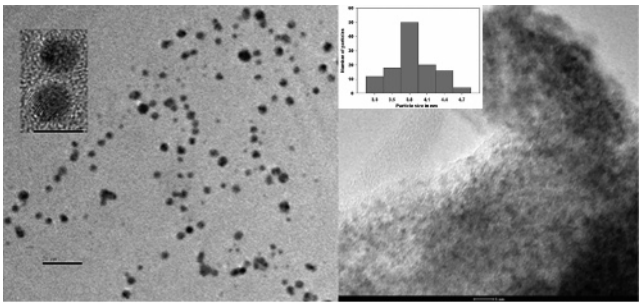


Figure 1. TEM images of melibiose−QD-589 conjugate (left, scale bar 20 nm), inset scale bar 5 nm, and its agglutinated product with jacalin (right, scale bar 5 nm; negatively strained with uranyl acetate). Inset graph shows the histogram of the TEM.

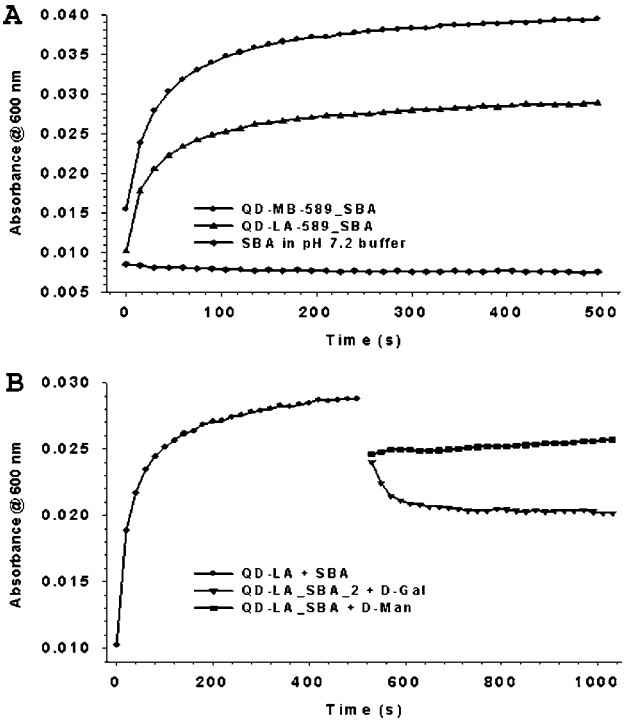

Figure 3. (A) Kinetics of agglutination of 589-MB−QD (5.9 μM particles) and 589-LA−QD (7.1 μM particles) by SBA (5.0 μM). (B) Deagglutination of the 589-LA−QD−SBA agglutinated product by α-D-Gal (100 mM) and α-D-Man (100 mM).

$\times 10^{-3}$ and 12.6×10^{-3} s^{-1}, respectively. Hence, an increase in the QD size appears to increase the apparent rate of agglutination, presumably because of the increase in the surface area and subsequently more accessible carbohydrate units.

Stereospecific Binding of S−QDs with Lectins. In order to assess the stereospecificity of the S−QD based agglutination assay, we studied the agglutinability of 589-MB−QD and 589-LA−QD (α-D-lactose−thiol−QD) with soybean agglutinin (25 μM). The binding constant of SBA with Me-α-Gal is slightly higher (1.2 times) compared to Me-β-Gal (*37*). The agglutination kinetics data of 589-LA−QD (6.8 μM, 6 LA/QD) and 589-MB−QD (6.8 μM, 6 MB/QD) with SBA indeed showed that MB−QD was able to agglutinate slightly more effectively than LA−QD (Figure 3A). The better agglutination observed for 589-LA−QD with SBA was ascertained when only α-D-galactose (7.7 mM) was able to deagglutinate, while α-D-mannose (7.7 mM) did not show any effect (Figure 3B). In order to further

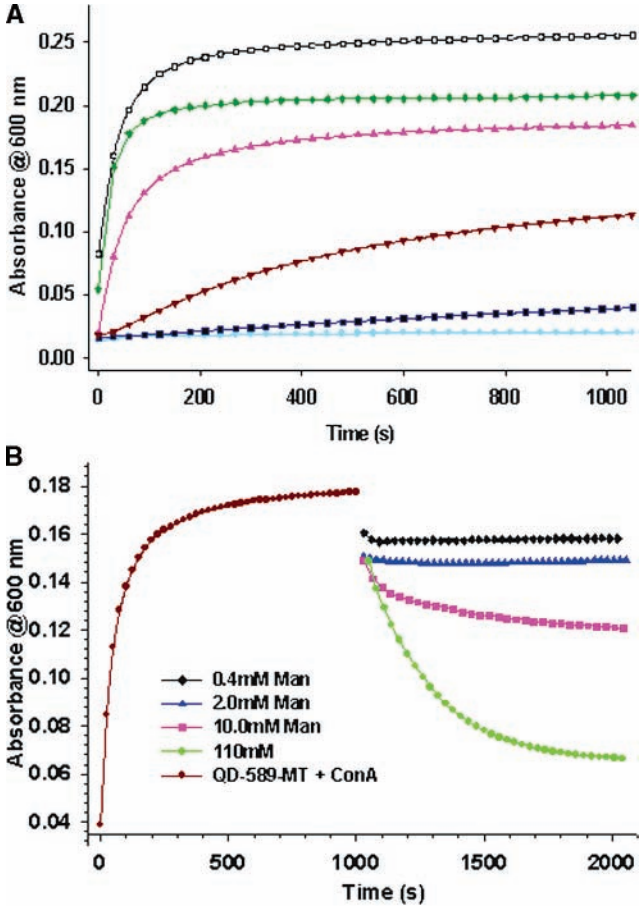

Figure 4. (A) Kinetic study of agglutination of 589-MT−QD (13.0 μM particles) by varying concentrations of ConA (top to bottom: 7.3, 3.6, 1.0, 0.5, 0.2, 0.1 μM). (B) Disaggregation study of agglutinated product of 589-MT−QD (13.0 μM particles) and ConA with variable concentrations of α-D-mannose.

confirm the specificity of the sugar−QDs, an agglutination experiment was performed between lacto−QD/melibio−DQ and ConA, and maltotrio−QD with Jacalin/SBA. In both cross combinations, we did not observe any agglutination. These studies suggest that even after conjugation to QDs the stereospecific binding and selectivity of the neoglycoconjugates toward lectins are retained.

Sensitivity of S−QD Based Agglutination Assay. In order to establish the detection sensitivity of the S−QD assay for agglutination, 589-MT−QD (D-maltotriose−thiol−QD) and a glucose-binding lectin Concanavalin A were studied. Here, the concentration of 589-MT−QD (13 μM, ~10.8 MT per particle) was kept constant, and the ConA concentration was varied from 7.3 μM to 100 nM. As the concentration of ConA decreased, the extent of agglutination also reduced, which is reflected in the intensity of the scattered light. Notably, we were able to follow the agglutination reaction between a very low concentration (100 nM) of ConA and 589-MT−QD by monitoring the change in absorbance at 600 nm (Figure 4A). We have also studied the inhibition or deagglutination by adding a variable concentration of α-D-mannose from 0.4 mM to 110 mM to the preformed agglutinated product of ConA 1.0 μM and MT-QD (13 μM). As the concentration of D-mannose was increased, the degree of deagglutination also increased (Figure 4B). These results again proved that agglutination is due to a very specific interaction between the lectin and the carbohydrates on the surface of QDs.

Sensitive Fluorescence Detection for Agglutination. Although studies discussed so far were primarily based on light

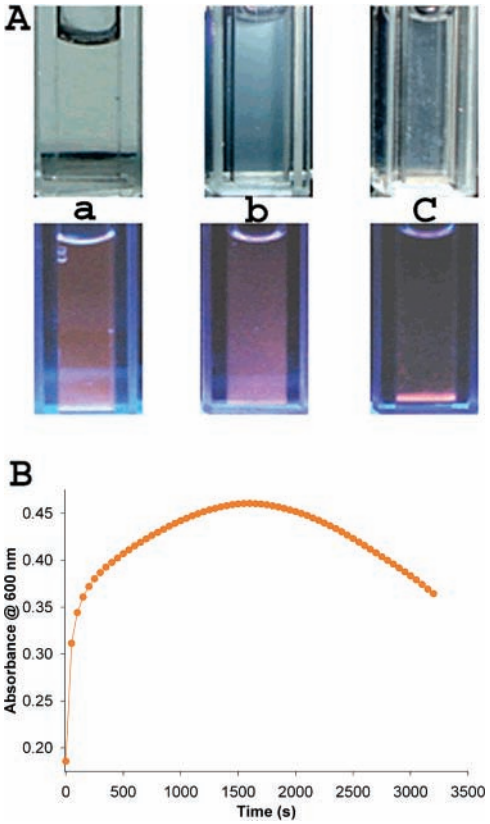

Figure 5. (A) Photographs of (a) 589-MT−QD alone, (b) 5 min after ConA addition (10 μM, pH 7.2 HEPES buffer), (c) 2 h after ConA addition, taken under white (top) and UV light (bottom). (B) Change in the absorbance of 589-MT−QD (0.103 μM particles) immediately after mixing with ConA (5 μM) as a function of time.

scattering data, the use of CdSe−ZnS quantum dots for sugar conjugation and agglutination assay can be rationalized as follows. First of all, the S−QDs are smaller in size. The larger surface-to-volume ratio allows the attachment of a greater number of functional groups. Second, the CdSe−ZnS QDs can easily be functionalized through a variety of chemical and noncovalent methods. In addition, the fluorescence property of QDs allow for a more sensitive detection of the agglutination. Thus, we tried to use fluorescence spectroscopy to study agglutination kinetics and to improve the detection limit of lectins. However, the data obtained from the fluorescence experiments could not be interpreted satisfactorily because of the simultaneous occurrence of various processes, like scattering and precipitation, and so forth, during the course of the experiment. Nevertheless, we went ahead and used a UV transilluminator for visual detection of lectins upon agglutination. In fact, agglutination of MT−QD by <100 nM of ConA was detected under UV irradiation, which was barely seen under normal light. This study thus confirms that sugar−QDs can be used for the detection of very small amounts of carbohydrate-binding proteins with high sensitivity. Furthermore, snapshots of the agglutination at various intervals may reveal insights into the process of agglutination which can be correlated with kinetic studies. The top row of Figure 5A shows the pictures of (a) QD-589−MT solution, (b) QD-589−MT and ConA (10 μM) 5 min after mixing, (c) and 2 h after mixing in a 200 μL fluorescence cuvette under white light, while the pictures at the bottom row are those of respective samples under UV illumination (see Supporting Information for emission spectra). It is quite evident from the above results that the detection of agglutinated products by quantum dot fluorescence has more advantages in terms of detection sensitivity and the ease with which the experiments are conducted.

On the basis of the kinetic studies (Figure 5B), the agglutination process of sugar−QDs by lectins can be hypothesized to occur in a stepwise manner as shown graphically (Figure 6). At first, soluble smaller S−QD−lectin aggregates are formed through specific interaction of carbohydrates and multivalent lectins, which lead to an increase in turbidity and consequently an increase in the scattering. Further association of the smaller aggregates into much larger aggregates induces the precipitation and subsequent decrease in the absorbance at longer time scales as observed experimentally.

CONCLUSIONS

The results reported here demonstrate that di- and oligosaccharides can be covalently attached via thiol functionality to CdSe−ZnS quantum dots without using protection and deprotection in two steps. The water-soluble, sugar-functionalized QDs were selectively agglutinated by lectins, which indicates that the synthesized neoglycoconjugates retain their lectin specificity. The selective deagglutination by specific sugars showed that this process is reversible and selective. The sensitivity of this nanomaterial-based assay was extended to nanomolar concentrations of the analyte—a lectin. Moreso, the value of this method has been enhanced further by using fluorescence properties of QDs. The present work not only has implications in the area of nanomaterials in analytical context but has a broad potential to study various carbohydrate−protein interactions, which are of considerable interest in both medicine and biology.

Ricin Antitoxins Based on Lyotropic Mesophases Containing Galactose Amphiphiles

P. G. Hartley,*,† M. R. Alderton,‡ R. M. Dawson,‡ and D. Wells†

CSIRO Molecular & Health Technologies, Private Bag 10, Clayton South, Victoria 3169, Australia, and Defence Science and Technology Organisation, PO Box 4331, Melbourne, Victoria 3001, Australia. Received July 14, 2006; Revised Manuscript Received November 14, 2006

Lyotropic mesophases of the inverse hexagonal or cubic type are nanostructured materials that result from the self-assembly of amphiphilic surfactant molecules in water. The extremely large area of the surfactant−water interface inherent within these structures makes them attractive media for sorbent or encapsulant systems. Here, we report on the development of a new class of polyvalent materials that are based on the incorporation of bioactive ligands within lyotropic mesophases. In particular, we have studied the potential for these materials to behave as polyvalent antitoxins by incorporating synthetic galactose amphiphiles, which mimic the natural cell surface ligand for the protein toxin ricin. The study demonstrates that cubic morphology lyotropic mesophases containing galactose amphiphiles exhibit high specificity ricin uptake, with favorably high dissociation constants and high capacities. We suggest that lyotropic mesophase polyvalent ligands are thus promising materials for the incorporation of a broad range of cell surface recognition moieties and hence may have wide applicability as materials capable of partaking in biological recognition processes.

INTRODUCTION

Polyvalent ligand−receptor interactions are employed in many biological recognition processes (*1*). There has been recent interest in designing synthetic polyvalent inhibitors for the therapeutic inactivation of biological entities, including viruses, bacteria, and toxins. In such systems, molecular architectures are employed to act as scaffolds for the presentation of high densities of bioactive ligands. These polyvalent ligands act to saturate receptor sites on the target, thereby blocking its ability to bind to cellular recognition sites, reducing uptake and cytotoxicity. Of particular interest have been polyvalent ligand systems based on synthetic branched polymer architectures such as dendrimers. Such systems are currently under commercial development for antiviral and microbiocidal applications (*2*).

Pathogenic protein toxins are produced by a number of microbial species such as *Clostridium botulinim*, *Vibrio cholera*, and *Shigella* species (*3*). Numerous plant protein toxins with pathogenic activity have also been identified (*4*). Within the latter family, the toxin ricin, derived from the castor bean plant *Ricinus communis*, has unprecedented toxicity and has been utilized as the active agent within immunotoxins (*5*) and as a potent poison or biowarfare agent (*6*, *7*).

Both plant and bacterial toxins act by binding with high specificity to cell surface moieties. This recognition process then triggers cellular uptake *via* several possible routes, resulting in the transport of the cytotoxic component of the toxin to its site of action.

In the case of ricin, the cell binding component (ricin B chain) specifically attaches to multiple cell surface galactose moieties and facilitates internalization of the cytotoxic A chain within the cell, which acts to disrupt ribosomal function (*5*).

The spontaneous self-assembly of certain lipid and synthetic surfactant molecular architectures results in the formation of extended three-dimensional hydrated structures in solution (*8*−*12*). Under certain circumstances, these structures exist in equilibrium with an excess of solution and are thus stable against dilution. In particular, the structures of the lyotropic mesophases of glyceryl monooleate (monoolein) and 3,7,11,15,-tetramethyl-1,2,3-hexadecanetriol (phytantriol) have been extensively studied, and proposed for use in drug delivery formulations (*13*−*17*).

These materials also possess attractive properties with respect to the development of polyvalent ligand systems. Most notably, they exhibit an extraordinarily large surfactant−water interface, which is potentially available for incorporation of biological or chemical functionality. Additionally, the formulation of lyotropic mesophase colloidal dispersions has been demonstrated in several systems (*10*, *11*, *15*, *18*, *19*). These low viscosity dispersions are readily amenable to *in vivo* administration.

In an earlier paper, we studied the ricin binding activity of a number of dendrimer systems derivatized with pendent galactose functional groups (*20*). We also introduced a new class of polyvalent ligand, in the form of the biofunctionalized lyotropic mesophase, which compared favorably with the dendrimer systems with regard to ricin binding.

In the current study, we have developed a variety of novel synthetic surfactant systems, which form dilutable lyotropic mesophases and which incorporate high concentrations of biologically active ligands for ricin based on galactose surfactants. We discuss the role of surfactant chemical and anomeric structure in determining the efficacy of these materials for ricin binding and uptake. The broad aim of this work is to demonstrate unequivocally the potential for employing lyotropic mesophase systems as a new class of polyvalent ligands.

EXPERIMENTAL PROCEDURES

Surfactant Synthesis and Formulation. Synthesis and chemical characterization information for the novel galactose surfactants discussed in this paper are available in the Supporting Information. In particular, synthesis was directed toward surfactants that possessed alkylation of galactose at the C1 position.

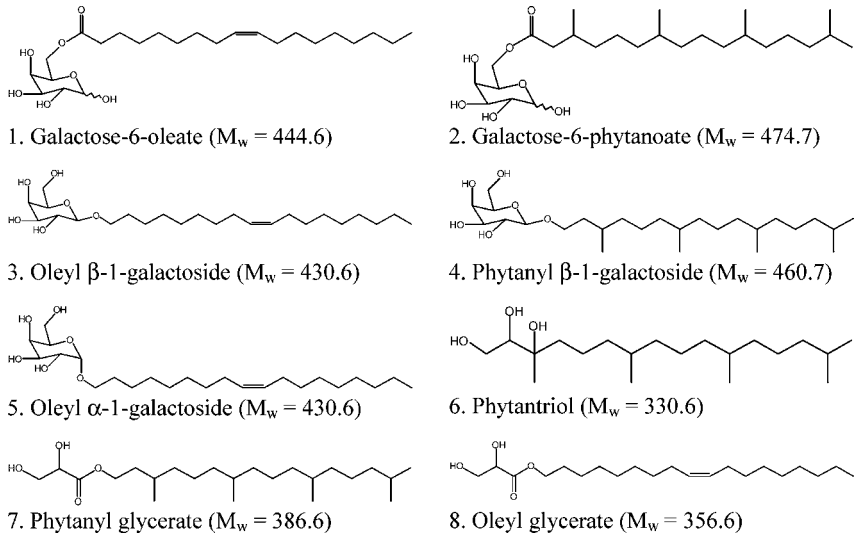

Figure 1. Structures of surfactant amphiphiles used in this study. Galactose-6-oleate existed as a solid (melting point 90−98 °C). Galactose-6-phytanoate and all galactosides (oleyl α and *β* and phytanyl *β*) existed as viscous mesomeric liquids at room temperature.

In this way, free galactose functionality in the C3−C6 positions is retained, and it is these positions that are known to be important in galactose binding to ricin (*21*). C6 alkylations were also performed for comparative purposes. The various surfactants employed in this study are shown in Figure 1. Mixed surfactant formulations were prepared by dissolving the appropriate proportions of each compound in dichloromethane to a total surfactant concentration of ∼40−100 mg/mL. Phytantriol was obtained from Sigma-Aldrich Pty. Ltd. Castle Hill, NSW. All water used in these experiments was Milli-Q grade.

Surfactant Lyotropic Phase Behavior. *Water Penetration Behavior.* Small samples of each surfactant were sandwiched beneath a coverslip on a microscope slide and stabilized at room temperature prior to addition of water at the edge of the coverslip. Capillary action drew the water between the two glass surfaces to surround the surfactant island. The optical behavior of the surfactant−water interface was observed during water penetration using an Olympus IMT-2 microscope equipped with crossed polarizing lenses. The sample was then heated at 2 °C/min or less in a Mettler FP82HT hot stage controlled by a FP90 central processor and changes in the optical textures at the surfactant−water interface were monitored and correlated with phase structures according to established correlations (*22*). Water penetration scans were usually performed in the temperature range 22−99 °C. Images were captured *via* a video camera, and observations were noted concerning viscosity of any observed mesophase forms.

Further detailed confirmation of the structure of selected surfactant mesophases was obtained using small-angle X-ray scattering (SAXS). Samples of surfactant in excess water solution were loaded into a small sample cell consisting of two very thin mica windows separated by a 1 mm stainless steel spacer ring. A Bruker "nanostar" SAXS camera equipped with a position sensitive 2-D "Hi-Star" detector using point collimated copper Kα radiation was employed. Experiments were performed under vacuum or under a helium atmosphere to minimize background scattering. Sample transmissions were estimated using a glassy carbon standard, which avoided the need to remove the instrument beam stop and thus protect the detector.

Data acquisition was performed at a sample-to-detector distance of 23 cm, which allowed analysis of intensity behavior over the wavevector range $0.0498\ \text{Å}^{-1} \le q \le 0.950\ \text{Å}^{-1}$. The scattering profiles of the empty sample geometries were subtracted from the final scattering profile of the sample (per-pixel subtraction) after first correcting for the intensity of the X-ray beam.

Ricin Binding Efficiency. Ricin binding to lyotropic mesophases was facilitated by the addition of 10 *μ*L aliquots of ∼49 mg/mL surfactant solutions in dichloromethane or dichloromethane−methanol to glass test tubes and allowing the solvent to evaporate. The final mass of surfactant deposited in the tubes was in the range 0.43−1.28 mg. Ricin solutions, of known concentrations between 6.25 and 200 ng/mL in blocking buffer (130 *μ*L, 0.25% bovine serum albumin in 0.05%Tween/PBS, pH 7.4), were added to the tubes, and they were placed on a rocker platform and gently oscillated for 24 h at room temperature. Aliquots (100 *μ*L) of the supernatants from these tubes were then assayed for ricin, as described below. Aliquots (100 *μ*L) of ricin control solutions (known ricin concentrations) were also analyzed in each experiment.

Ricin concentrations in control and test solutions were quantified using an enzyme-linked immunosorbent based microtiter plate binding assay described elsewhere (*23*).

Briefly, Nunc microtiter test plates were prepared by treating overnight with 0.1 mL per well of 2 *μ*g/mL of the ricin binding protein asialofetuin in 0.1 M carbonate/bicarbonate buffer, pH 9.6. After washing with PBS−Tween and incubating 1 h with blocking buffer, the plates were incubated sequentially for 1 h each with ricin-containing control and test solutions, followed by rabbit anti-ricin antibody (1:15 000 dilution), and goat anti-rabbit IgG alkaline phosphatase conjugate (1:4000 dilution), each in blocking buffer, with washing of the plate with PBS−Tween 3 times after each incubation. An additional wash with distilled water followed the incubation with antibody−enzyme conjugate. The substrate for alkaline phosphatase (*p*-nitrophenyl phosphate in Tris buffer) was then added, and the rate of increase of absorbance at 405 nm was recorded for either 17.5 min (at 2.5 min intervals) or 55 min (at 5 min intervals) with a Titertek-Plus MS212 plate reader. All incubations were at room temperature (approximately 20 °C).

The known ricin concentration control solutions were used to construct a calibration curve for solution ricin concentration versus absorbance change per minute (Abs/min) for each ELISA assay. Calibration curves were recorded to accompany each ricin binding experiment, in order to reduce errors resulting from solution preparation and handling. The calibration curve data was conveniently fit in the ricin concentration limit 0−100 ng/mL using a logarithmic relationship, $\text{Abs/min} = A + B\ \ln[\text{ricin}]$. The *A* and *B* factors in this relationship were obtained from the linear plot of Abs/min vs ln[ricin] for control solutions. These factors were then used to derive a residual ricin concentration (final [ricin]) in test solutions (i.e., ricin solutions that were

exposed to lyotropic mesophase samples). In this way, the relationship between initial [ricin] and final [ricin] following exposure to lyotropic mesophase samples was quantified.

The ricin affinity constants (K_a) and dissociation constants ($K_d = 1/K_a$) for the different mesophase formulations were ascertained from the ELISA assay data by assuming 1:1 binding and using the initial and final equilibrium solution ricin concentrations ($[ricin]_{in}$ and $[ricin]_{eq}$) with the initial concentration of galactose surfactant monomers within the mesophase ($[active]_{in}$), in the relationship: $K_a = [\text{bound ricin}]_{eq}/([\text{unbound active}]_{eq}[ricin]_{eq})$, where $[\text{bound ricin}]_{eq} = [ricin]_{in} - [ricin]_{eq}$ and $[\text{unbound active}]_{eq} = [active]_{in} - [\text{bound ricin}]$.

RESULTS

A number of surfactant amphiphiles possessing a galactose headgroup that might be capable of self-assembling into lyotropic mesophases of the cubic or inverse hexagonal type were synthesized (Figure 1). The approach was based on employing hydrophobic moieties (phytanyl and oleyl groups) found in surfactants that exhibit these mesophase behaviors (*9*, *14*). Once produced, we found that addition of water to these materials at room temperature resulted in the formation of myelinic lamellar phases, as determined by polarizing light microscopy.

Since we were seeking to produce materials that existed in the dilutable cubic or inverse hexagonal mesophase phase forms, a second approach was adopted that relied on incorporation of the galactose surfactants within binary surfactant mixtures. Secondary "matrix surfactants" were selected for these mixtures on the basis of their known propensity to support mesophase formation.

The phase behavior properties of these matrix surfactants are described in detail elsewhere (*10*, *14*). To summarize, oleyl glycerate (OG) shows a viscous anisotropic phase (inverse hexagonal, H_{II}) in equilibrium with water above 22 °C, which melts into a mobile isotropic phase at 66−73 °C (inverse micellar, L_{II}). Phytanyl glycerate (PG) also forms an H_{II} phase spontaneously in equilibrium with water, which melts at a slightly lower temperature, 39.5 °C.

Phytantriol exhibits a cubic phase in equilibrium with water over a broad temperature range with an inverse hexagonal phase appearing at higher temperatures (*14*). In our measurements, the cubic−inverse hexagonal phase transition occurred at 54.5 °C, which contrasts with a literature value of 44 °C (*14*). From discussions with other researchers, we understand that these elevated phase transition temperatures for different phytantriol samples are not an uncommon observation.

Addition of water at room temperature to mixtures of monoalkyl galactose surfactants with matrix surfactants yielded a number of systems, which exhibited lyotropic mesophase behavior of the desired type (cubic and inverse hexagonal, see Figure 2 and Table 1).

We found that the mesophase behavior of these mixtures could be manipulated by adjusting the ratios of the component surfactants. The aim of this approach was to obtain mixtures in which a high concentration of galactose surfactant could be incorporated within a dilutable mesophase material while retaining the mesophase structure. As such, the compositions (Figure 2 and Table 1) represent the upper limit of galactose surfactant concentrations that could be added while retaining the desired mesophase structure, as determined by the polarizing microscopy−water penetration technique.

We found that high concentrations of the galactose surfactants (20−50%) could be incorporated within these mixtures. This is an important observation, since it suggests that a high surfactant−water interfacial concentration of ligand (galactose) should be available for binding to the protein toxin ricin within the mesophase structure, which was the aim of this work.

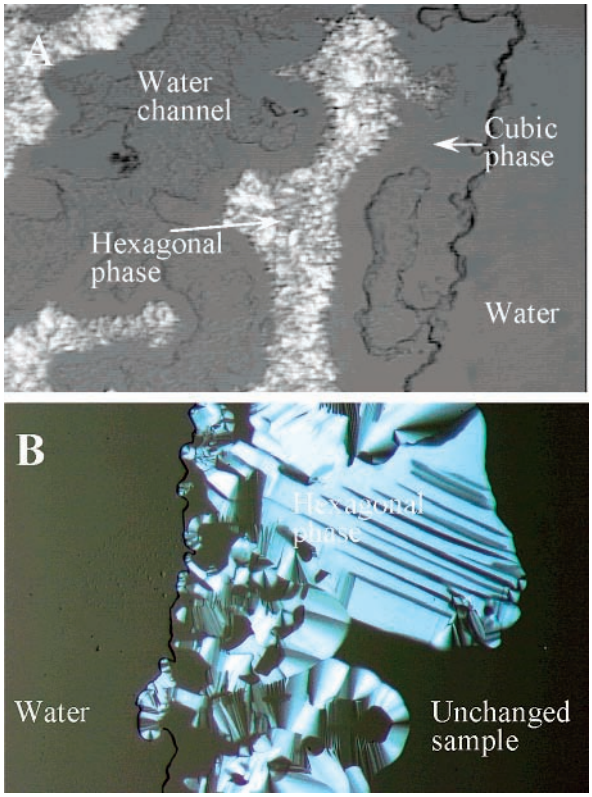

Figure 2. Lyotropic phase behavior as viewed through cross polarizers. The optical textures are used to assign mesophase forms. The viscosity of both the isotropic and anisotropic phases is clear from the "rough" nature of the interface of the phases with water and is a hallmark of dilutable mesophases of the inverse type. Panel A shows water penetration behavior of 40% oleyl α-1-galactoside/60% oleyl glycerate initial penetration at room temperature (25 °C). Panel B shows the water penetration behavior of 20% oleyl α-1-galactoside/80% oleyl glycerate at room temperature for 30 min (23 °C).

Broadly speaking, the phase behavior of the mixed surfactant systems appears to lie between the behavior of the two isolated components. This can be rationalized by considering the curvature of the surfactant−water interface, according to the model suggested by Israelachvili (*24*). Isolated galactosyl surfactants preferentially form lamellar phases (of minimal curvature), while the matrix surfactants discussed above preferentially form structures of greater (inverse) curvature, the cubic and inverse hexagonal phases.

For mixtures comprising >20% galactose surfactants in oleyl glycerate, addition of the lamellar-preferring galactoside reduces the preference for the negatively curved inverse hexagonal phase, yielding a cubic phase in equilibrium with water. We postulate that the low concentration of galactoside in the 20% oleyl α-1-galactoside/oleyl glycerate mixture is insufficient to significantly alter the phase behavior from the pure oleyl glycerate system; hence the inverse hexagonal phase is retained. We note the absence of phase behavior data for one of the surfactant mixtures prepared, namely, 40% oleyl β-1-galactoside/60% oleyl glycerate. This surfactant was prepared in quantities sufficient only for ricin binding analysis (see later). The phase behavior for this mixture is expected to be qualitatively similar to 40% oleyl β-1-galactoside/60% oleyl glycerate, which showed a cubic phase in equilibrium with water at all temperatures studied.

When phytanyl glycerate was employed as the matrix surfactant, the effect of adding the galactoside surfactants was less marked, and the inverse hexagonal phase was retained in

Table 1. Summary of Compositions and Lyotropic Phase Behavior Observed through Cross Polarizers Using Water Penetration Analysis

sample	optical textures observed	temperature range	likely phases present
40% galactose-6-oleate/60% oleyl glycerate	100% water		
	viscous isotropic	RT to 65 °C	cubic (C_{II})
	viscous isotropic	RT to >100 °C	cubic (C_{II})
	isotropic	24−92 °C	cubic (C_{II})

	100% surfactant		

most cases. This suggests that the phytanyl-chained surfactants exhibit more robust inverse phases, probably due to the large volume occupied by the hydrophobe, and the disorder that it confers within self-assembly structures.

The addition of galactosides to the less negatively curved matrix surfactant phytantriol (cubic phase), results in a slight reduction in the curvature relative to the pure phytantriol system. This manifests itself in the elimination of the high temperature inverse hexagonal phase of phytantriol, as was observed in phytantriol mixtures comprising 30% oleyl α-1-galactoside or 40% phytanyl-*β*-1-galactoside. These mixtures also showed the presence of a lamellar phase at lower water contents, which is also a feature of the pure phytantriol−water phase diagram.

In order to study the structural properties of the mesophase systems in more detail, small-angle X-ray scattering (SAXS) was employed on a selection of the samples, which were prepared in equilibrium with excess water, and analyzed at room temperature (Figure 3). As expected from the polarizing microscopy optical texture observations, the 50% phytanyl glycerate/50% phytanyl *β*-1-galactoside in equilibrium with excess water at room temperature (∼22 °C), exhibited Bragg reflections with scattering vector (q) spacings consistent with the (inverse) hexagonal phase ($1{:}\sqrt{3}{:}\sqrt{4}$). SAXS analysis of the 40% phytanyl *β*-1-galactoside/60% phytantriol, 30% oleyl α-1-galactoside/70% phytantriol and 40% oleyl α-1-galactoside/60% oleyl glycerate mixtures in equilibrium with excess water revealed *Pn*3*m* cubic symmetry (Bragg peak spacings $\sqrt{2}{:}\sqrt{3}{:}\sqrt{4}{:}\sqrt{6}{:}\sqrt{8}{:}\sqrt{9}$), (*25*) again consistent with the polarizing microscopic observation of viscous isotropic phases in these systems.

SAXS analysis also allows the quantification of structural parameters associated with lyotropic mesophases (*25*). The lattice parameter, a, is readily derived from the q spacings of the Bragg reflections (Figure 3). The straight line relationship again reinforces the assignment of the *Pn*3*m* space group for the cubic phases (Figure 3B−D). The lattice parameter for the inverse hexagonal phase (Figure 3A) was obtained from the scattering vector position of the initial [10] reflection *via* the relationship $a = q(\sqrt{3}/4\pi)$.

Lattice parameters supply information regarding the center-to-center distances of repeating structural units within the mesophases. Larger lattice parameters indicate larger center to center distances, implying a more expanded mesophase structure (*26*). For the inverse hexagonal phase, this can readily be envisaged as the distance between the centers of adjacent aqueous channels. For inverse cubic phases, it corresponds to the cubic unit cell dimension. Considering the similarity between the various surfactant molecular dimensions involved in this study, changes in the lattice parameter within the cubic phases can reasonably be assumed to correlate with the diameter of aqueous channels within the structure. The addition of galactoside surfactants dramatically increases the lattice parameter from the previously described value of 64−66 Å for pure phytantriol (*14*) to values for the mixtures of 90.9−93.5 Å (Figure 3). Expansion of the mesophase structure is to be expected for the addition of the relatively bulky sugar headgroups possessed by the galactoside surfactants, causing reduced negative interfacial curvature, as discussed earlier. The phytantriol-derived mesophases do possess somewhat narrower aqueous channel diameters than the corresponding oleyl glycerate mixture, with the largest lattice spacing encountered for 40% oleyl α-1-galactoside/60% oleyl glycerate (a = 121.2 Å).

The inverse hexagonal phase structure based on phytanyl glycerate possesses the most compressed (narrowest) unit cell (a = 60 Å). These are important observations with regard to understanding the optimal mesophase structures for protein uptake within mesophase polyvalent ligands, as will be discussed later.

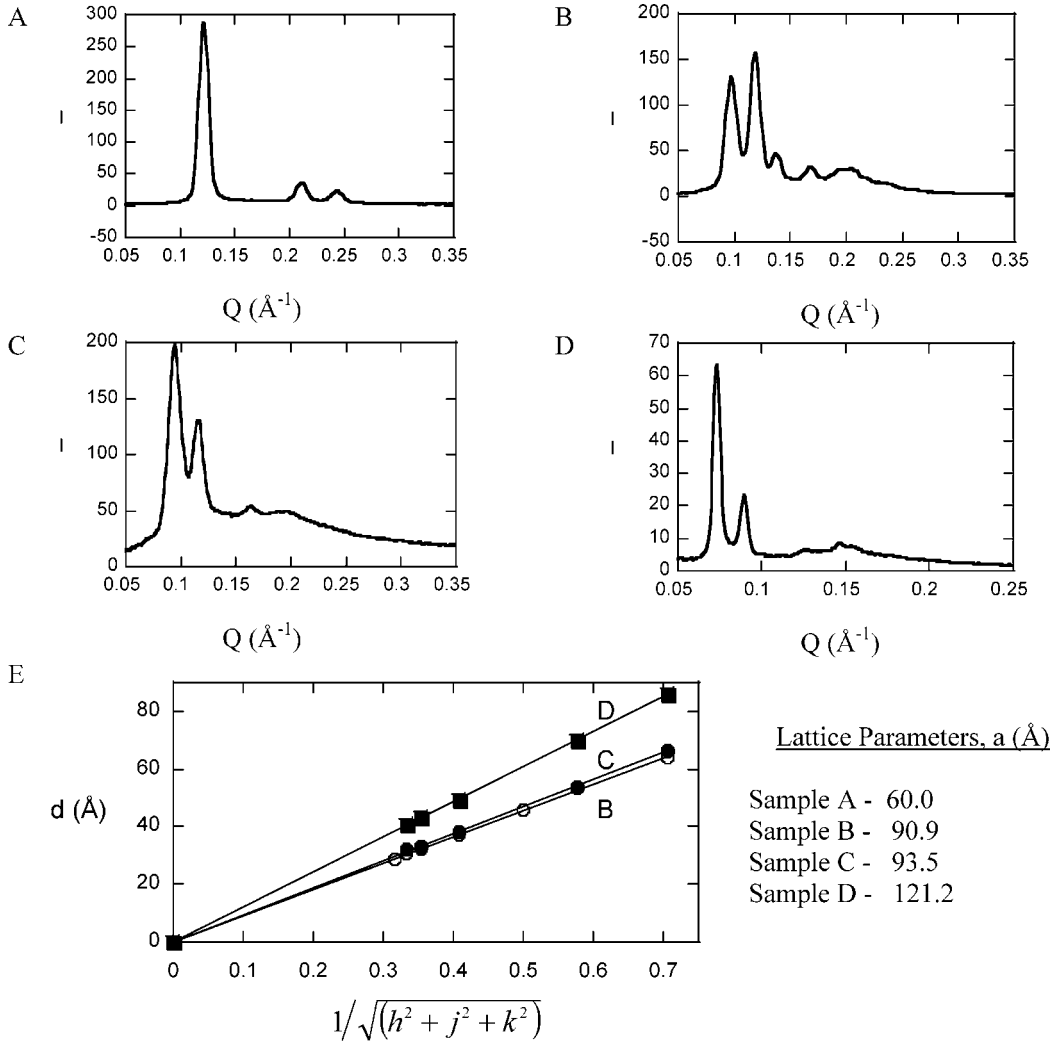

Figure 3. SAXS data for different surfactant formulations recorded at room temperature (22 °C): (A) 50% phytanyl β-1-galactoside/50% phytanyl glycerate; (B) 40% phytanyl β-1-galactoside/60% phytantriol; (C) 30% oleyl α-1-galactoside/70% phytantriol; (D) 40% oleyl α-1-galactoside/60% oleyl glycerate; (E) plots used to derive lattice parameters from SAXS data for cubic phase mixtures; *h*, *j*, and *k* refer to the Miller indices for *Pn*3*m* symmetry assigned to each peak in the scattering data.

The ricin binding exhibited by surfactant mixtures possessing inverse hexagonal mesophase morphology was examined using the enzyme-linked immunosorbent binding assay (ELISA) described in the methods (Figure 4). This assay measures the residual ricin in solution following exposure of known ricin concentration solutions to small samples of mesophase formulations.

A control measurement for a pure phytantriol mesophase sample shows that the galactoside-free mesophase has little or no affinity for the ricin in solution, since final [ricin] approximates initial [ricin] over the initial ricin concentration range studied. A similar poor affinity for ricin is demonstrated for mesophase samples containing galactose-6-phytanoate. Measurable reduction in [ricin] is however observed for mesophases containing galactosides possessing alkyl groups attached at the C1 carbon of the sugar (phytanyl β-1-galactoside and oleyl α-1-galactoside). Referring to Table 2, we find that the maximum proportion of ricin removed from solution for these inverse hexagonal materials is 39.6%, (for the 20% oleyl α-1-galactoside/oleyl glycerate formulation). The linear nature of the initial versus final ricin concentration relationship indicates that an equilibrium between bound and unbound ricin exists in these systems. The lack of an observable plateau in the binding relationship also suggests that these systems are not saturated at the ricin concentrations that we have investigated. The equilibrium nature of the ricin binding to the mesophase systems permits calculation of the affinity constant for ricin binding, as described in the methods section (Table 2).

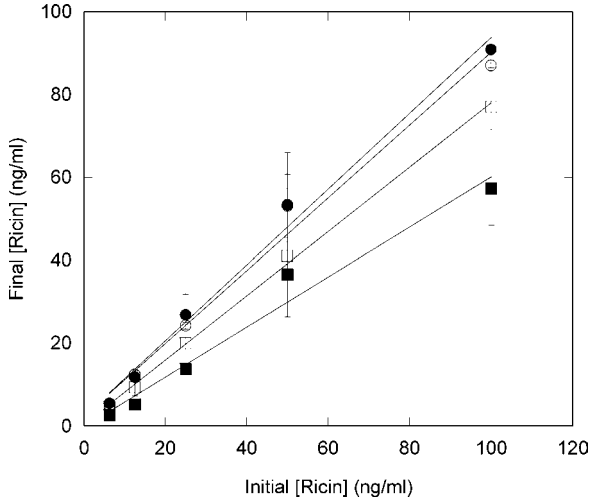

Figure 4. Ricin binding assay data for inverse hexagonal phase structures (with phytantriol control): (●) phytantriol (control); (○) 40% galactose-6-phytanoate/phytanyl glycerate; (□) 50% phytanyl β-1-galactoside/phytanyl glycerate; (■) 20% oleyl α-1-galactoside/oleyl glycerate.

Table 2. Efficiency of Removal of Ricin from Solution by Mesophase Formulations with Calculated Affinity and Dissociation Constants

composition	% ricin removed	K_a (M^{-1})	K_d (mM)
phytantriol (control)	8.6	8.3	120
Inverse Hexagonal Mesophase Mixtures			
40% galactose-6-phytanoate/ phytanyl glycerate	12.2	43.7	23
50% phytanyl β-1-galactoside/ phytanyl glycerate	22.4	70.6	14
20% oleyl α-1-galactoside/ oleyl glycerate	39.6	374.5	2.7
Inverse Cubic Mesophase Mixtures			
40% galactose-6-oleate/ oleyl glycerate	40.5	200.7	5.0
40% oleyl α-1-galactoside/ 60% oleyl glycerate	80.3	1164.2	0.86
40% oleyl β-1-galactoside/ oleyl glycerate	85.1	1631.2	0.610
40% phytanyl β-1-galactoside/ 60% phytantriol	90.3	2844.6	0.35
30% oleyl α-1-galactoside/ phytantriol	91.3	3996.2	0.25

The inverse cubic mesophase formulations showed considerably different ricin binding behavior (Figure 5). When incorporated within a cubic mesophase, galactose-6-oleate is able to bind a significant quantity of ricin from solution (40.5%), which is in contrast to the analogous galactose-6-phytanoate, when contained within an inverse hexagonal mesophase (12.2%, Figure 4).

However, it is again the C1-substituted galactose surfactants that show the most dramatically increased potency for binding ricin when contained within inverse cubic mesophase structures (Figure 5 and Table 2). These materials are capable of binding 80−91.3% of ricin in solution over the concentration range studied. The optimal ricin binding activity (91.3%) was observed for a 30% oleyl α-1-galactoside/phytantriol mixture.

The most unequivocal observation from this data is the superior ability of cubic phase materials to absorb ricin. A direct comparison between different mesophase forms possessing identical ligands may be made by comparing the 40−50% phytanyl β-1-galactoside containing inverse hexagonal and inverse cubic mesophases. Here, despite decreasing the galactoside concentration by 10% in moving from inverse hexagonal to inverse cubic morphologies, a 40-fold decrease in ricin dissociation constant (K_d) is observed (14 mM for 50:50 phytanyl β-1-galactoside/phytanyl glycerate versus 0.35 mM for 40:60 phytanyl β-1-galactoside/phytantriol). A similar comparison can be made between oleyl α-1-galactoside/phytantriol formulations. Twenty percent oleyl α-1-galactoside (inverse hexagonal phase) yields $K_d = 2.7$ mM, while 30% oleyl α-1-galactoside (cubic phase) gives $K_d = 0.25$ mM.

DISCUSSION

The high affinity for ricin of the cubic morphology galactoside mixtures may be explained through analysis of the SAXS data. The typical lattice parameters for the cubic mesophases are on the order of 9.1−12.1 nm (Figure 3) versus 6 nm for the inverse hexagonal mesophase of 50% phytanyl glycerate/50% phytanyl β-1-galactoside. A significantly increased pore diameter within the cubic phase for the phytantriol-based systems is therefore observed. We propose that this allows greater diffusion of the ricin protein (whose longest dimension is on the order of 12 nm according to crystallographic data (*21*)) within the mesophase aqueous channels and hence greater opportunity to bind to the ligands immobilized therein. This further suggests that the mesophases incorporate a molecular size exclusion capability, which may have implications for other delivery and uptake applications (*17*). Further work is currently underway in our laboratory to probe this phenomenon.

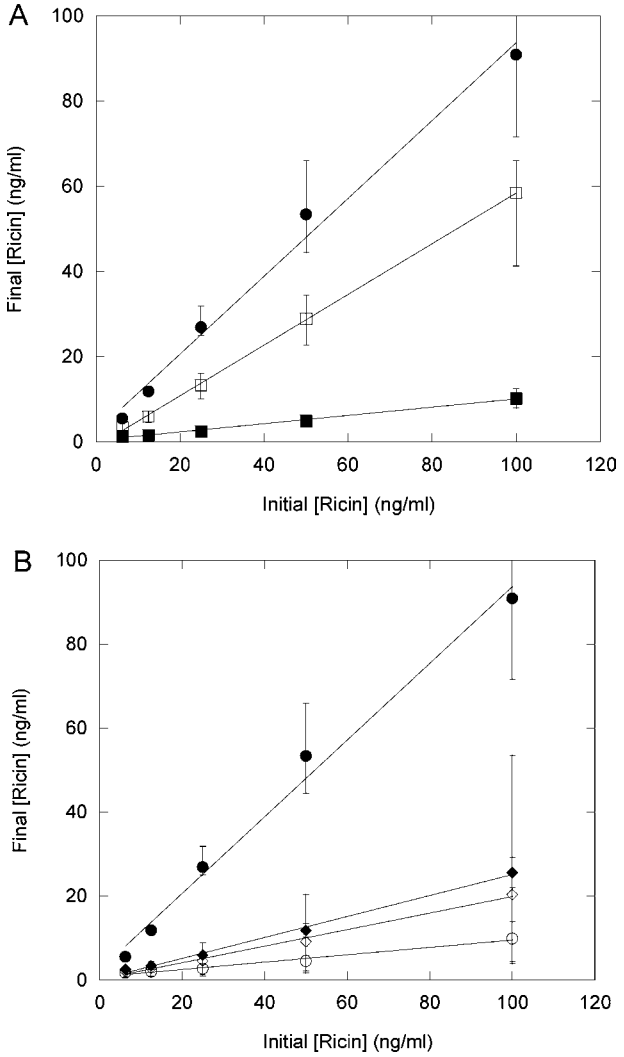

Figure 5. Ricin binding asay data: inverse cubic structures (with phytantriol control): (A) ●, phytantriol (control); □, 40% galactose-6-oleate/oleyl glycerate (cubic phase 24−100 °C); ■, 40% phytanyl β-1-galactoside/60% phytantriol (cubic phase 24−100 °C); (B) ●, phytantriol (control); ◇, 40% oleyl α-1-galactoside/60% oleyl glycerate; ◆, 40% oleyl β-1-galactoside/oleyl glycerate; ○, 30% oleyl α-1-galactoside/phytantriol.

In the current work, the role of the anomeric form of the galactose ligand on ricin binding was also probed. The data indicates that the anomeric conformation of the galactoside has little influence on mesophase ricin binding, since little difference in ricin binding was observed between oleyl α-1 and oleyl β-1 surfactant containing mesophases. This observation contrasts with earlier evaluation of methyl-substituted galactose inhibitors of ricin, which indicated that the β anomer of the methyl-substituted sugar exhibited significantly greater binding to ricin (*27*).

Comparing binding data between the C6 and C1 alkylated galactose surfactants reveals that alkylation at the C1 position is optimal for ricin binding. This is not surprising, given that the major protein−sugar interactions for ricin appear to occur through the C3, C4, and C6 OH groups (*21*).

An indicative lower limit to the ricin binding capacity of the mesophases investigated here is obtained by assuming 100% binding of a 130 μL aliquot of 100 ng/mL ricin by approximately 1 mg of mesophase. This yields a capacity of ∼13 μg of ricin per gram of mesophase. It is important to reiterate

that this represents a lowest limit to binding capacity. Work is currently underway to define the upper limits of mesophase binding capacity for ricin; however, it is interesting to note that the lethal dose (LD_{50}) of ricin for humans is on the order of 0.1−1 μg/kg (*28*).

We note that the kinetics of ricin binding have not been explored in the current study, since the measurements were performed after a 24 h incubation period. This is clearly a key consideration for the development of either an effective antitoxin or sequestration material. Preliminary measurements suggest that equilibrium ricin binding is attained within 5−10 h of incubation with ricin solutions. The kinetics of binding will be critically dependent on the diffusion of ricin within the mesophase, which in turn will depend on the surface area of the mesophase in contact with ricin binding solution. Given that these materials can be readily prepared in microparticulate dispersion form (*10*), we would anticipate that dramatic improvements in binding kinetics should be achievable. Further work is underway to prepare these materials in dispersion form and elucidate the ricin binding kinetics in such systems.

In summary, we have prepared a number of dilutable (i.e., insoluble) mesophase materials, incorporating the biological ligand galactose, which is known to specifically bind the B-chain of the protein toxin ricin. The aim of this work was to demonstrate that lyotropic mesophases can be effective in the selective separation of biological solutes, by virtue of their internally mobile structure and high interfacial area with respect to water. The self-assembly behavior exhibited by these systems has been characterized by polarizing microscopy and small-angle X-ray scattering. Specific ricin uptake characteristics have been measured by means of a modified ELISA assay. Mesophase materials composed of C1 alkylated galactose surfactants that formed cubic phase structures were found to be highly effective at the specific extraction of ricin from solution. This efficacy was not found for inverse hexagonal mesophase structures. This is explained on the basis of the structural parameters of the different mesophase forms. We postulate that the more open cubic mesophase structure permits in-diffusion and uptake of the toxin more readily. Ricin assay data shows that in all cases, binding occurs *via* an equilibrium that can be manipulated through changes in mesophase structural form or ligand chemistry. In these studies, 0.49 mg samples of mesophase materials were capable of removing in excess of 90% of ricin from a 100 ng/mL ricin solution, with a corresponding dissociation constant of 0.25 mM, which compares favorably with literature values for dissociation constants measured for the active component of the natural cell surface receptor, galactose (0.15−0.6 mM) (*23*).

While this binding efficiency is at the lower level of that required to compete with cell surface receptors for ricin binding *in vivo*, these data show that synthetic mesophase materials represent promising systems for ricin sequestration. Optimization of these systems by, for example, improving accessibility for ricin binding by incorporating spacer groups between surfactant alkyl chains and galactose moieties can readily be envisaged.

In forthcoming publications, we demonstrate the incorporation of biological lipid ligands into mesophase materials and their increased effectiveness in the extraction of ricin from solution. Work is now underway to determine the efficacy of these materials in cytotoxicity inhibition assays and to form dispersions from them. The ease with which mesophase materials can be prepared further offers an economic route to their development. The fact that self-assembled mesophase forms mimic to some extent the surface properties of the plasma membrane of the cell offers the possibility of exploring many cell surface recognition processes using this approach.

ACKNOWLEDGMENT

We thank Dr. Jamie Booth and Prof. Suresh Bhargava of RMIT, Melbourne, for assistance with SAXS measurements. We also thank Dr. Peter Gray of DSTO for valuable discussions.

Sequence-Specific Targeting of RNA with an Oligonucleotide−Neomycin Conjugate

Irudayasamy Charles,† Hongjuan Xi, and Dev P. Arya*

Laboratories of Medicinal Chemistry, Clemson University, Clemson, South Carolina 29634. Received August 9, 2006; Revised Manuscript Received September 22, 2006

The synthesis of neomycin covalently attached at the C5-position of 2′-deoxyuridine is reported. The synthesis outlined allows for incorporation of an aminoglycoside (neomycin) at any given site in an oligonucleotide (ODN) where a thymidine (or uridine) is present. Incorporation of this modified base into an oligonucleotide, which is complementary to a seven-bases-long α-sarcin loop RNA sequence, leads to enhanced duplex hybridization. The increase in T_m for this duplex ($\Delta T_m = 6$ °C) suggests a favorable interaction of neomycin within the duplex groove. CD spectroscopy shows that the modified duplex adopts an A-type confirmation. ITC measurements indicate the additive effects of ODN and neomycin binding to the RNA target ($K_a = 4.5 \times 10^7$ M^{-1}). The enhanced stability of the hybrid duplex from this neomycin−ODN conjugate originates primarily from the enthalpic contribution of neomycin {$\Delta\Delta H_{obs} = -7.21$ kcal/mol ($\Delta H_{neomycin\ conjugated} - \Delta H_{nonconjugated}$)} binding to the hybrid duplex. The short linker length allows for selective stabilization of the hybrid duplex over the hybrid triplex. The results described here open up new avenues in the design and synthesis of nucleo−aminoglycoside−conjugates (N−Ag−C) where the inclusion of any number of aminoglycoside (neomycin) molecules per oligonucleotide can be accomplished.

INTRODUCTION

Aminoglycoside antibiotics interact with a variety of RNA molecules and exhibit bactericidal activity by inducing the misreading of codons (*1*, *2*) as well as inhibition of translocation (*3*). A number of RNA molecules have been known to interact with aminoglycosides; group I introns (*4*, *5*), ribonuclease P RNA (*6*), hairpin ribozyme (*7*, *8*), hammerhead ribozyme (*9*−*11*), hepatitis delta virus ribozyme (*12*, *13*), untranslated region of thymidylate synthase mRNA (*14*), hTR RNA component (*15*), human mRNAs and both reverse response element and transactivating response element RNA motifs of HIV-1 (*16*−*19*). We have identified neomycin (Figure 1) as the most potent DNA/RNA/hybrid triplex stabilizing groove binder (*20*, *21*). Neomycin, an aminoglycoside, had largely been known to bind different RNA structures (*10*, *14*, *22*−*24*). Recent studies from our laboratory have, however, revealed that aminoglycosides (in particular, neomycin) can bind to other A-form structures (*25*). The stabilization of the poly(dA)•2poly(dT) (*20*), small triplexes (*26*), DNA•RNA hybrid duplexes, RNA triplex, and hybrid triple helices (*27*) by neomycin has recently been reported by us. Aminoglycosides most likely bind in the major groove of these structures (much like RNA, as the A-form nucleic acids have a narrower major groove) (*25*, *28*).

Carbohydate (Neomycin)−DNA Conjugates. In contrast to abundant glycosylated protein and lipids in nature, few examples of glycosylayted nucleic acids have been reported. A few reports discuss glycosylated nucleosides (*29*−*31*) and their role in gene expression (*32*, *33*). The presence of these glycosylated nucleosides modulates the functions of *Escherichia coli* bacteriophages of the T-even series (*34*), genome of *Trypanosoma brucei (*a protozoan found in phages and known to cause African sleeping sickness) (*35*), and *Diplonema* (a small phagotrophic marine flagellate) (*36*). These reports in carbohydrate−nucleic acid interactions have also ignited interest in the development of such conjugates. The importance of aminoglycosides in the recognition of nucleic acids prompted us to design, synthesize, and evaluate aminoglycoside−oligonucleotide conjugates. If carbohydrates (aminoglycosides) can be conjugated to DNA without affecting the structure and stability of DNA, and bind to their nucleic acid target (RNA) with specificity, then these conjugates will be of interest as a new class of artificial glycoconjugate materials applicable to cell-targeted gene therapy techniques. A few examples are also known in which carbohydrate ligands have been used to increase the uptake of antisense oligonucleotides (*38*). These examples include the use of mannosylated polylysine (*39*) and galactosylated polylysine (*40*) in receptor-mediated endocytosis of antisense oligonucleotides. We have recently shown that neomycin assists in the lipid-mediated delivery of plasmid DNA and oligonucleotides (*41*). Delivery of oligonucleotides has been a major impediment in the

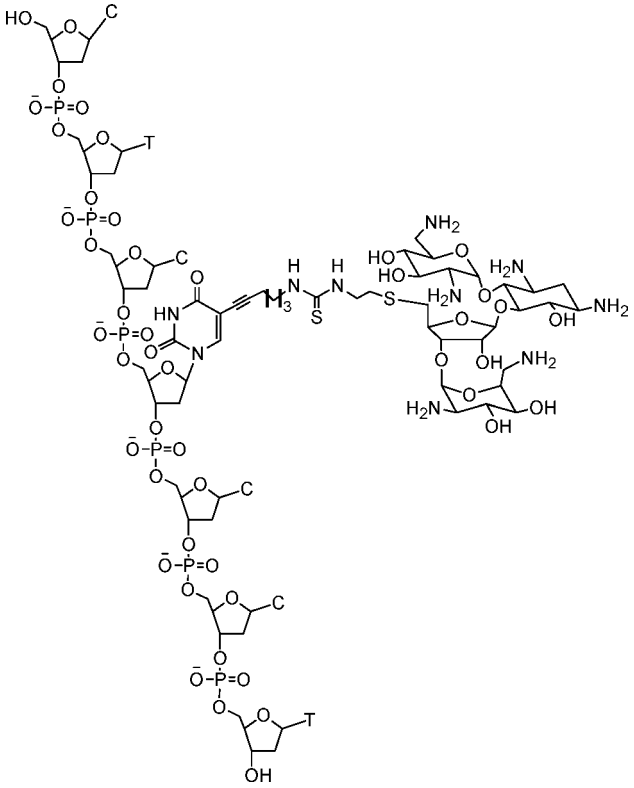

Figure 2. Structure of the 7mer−neo conjugate.

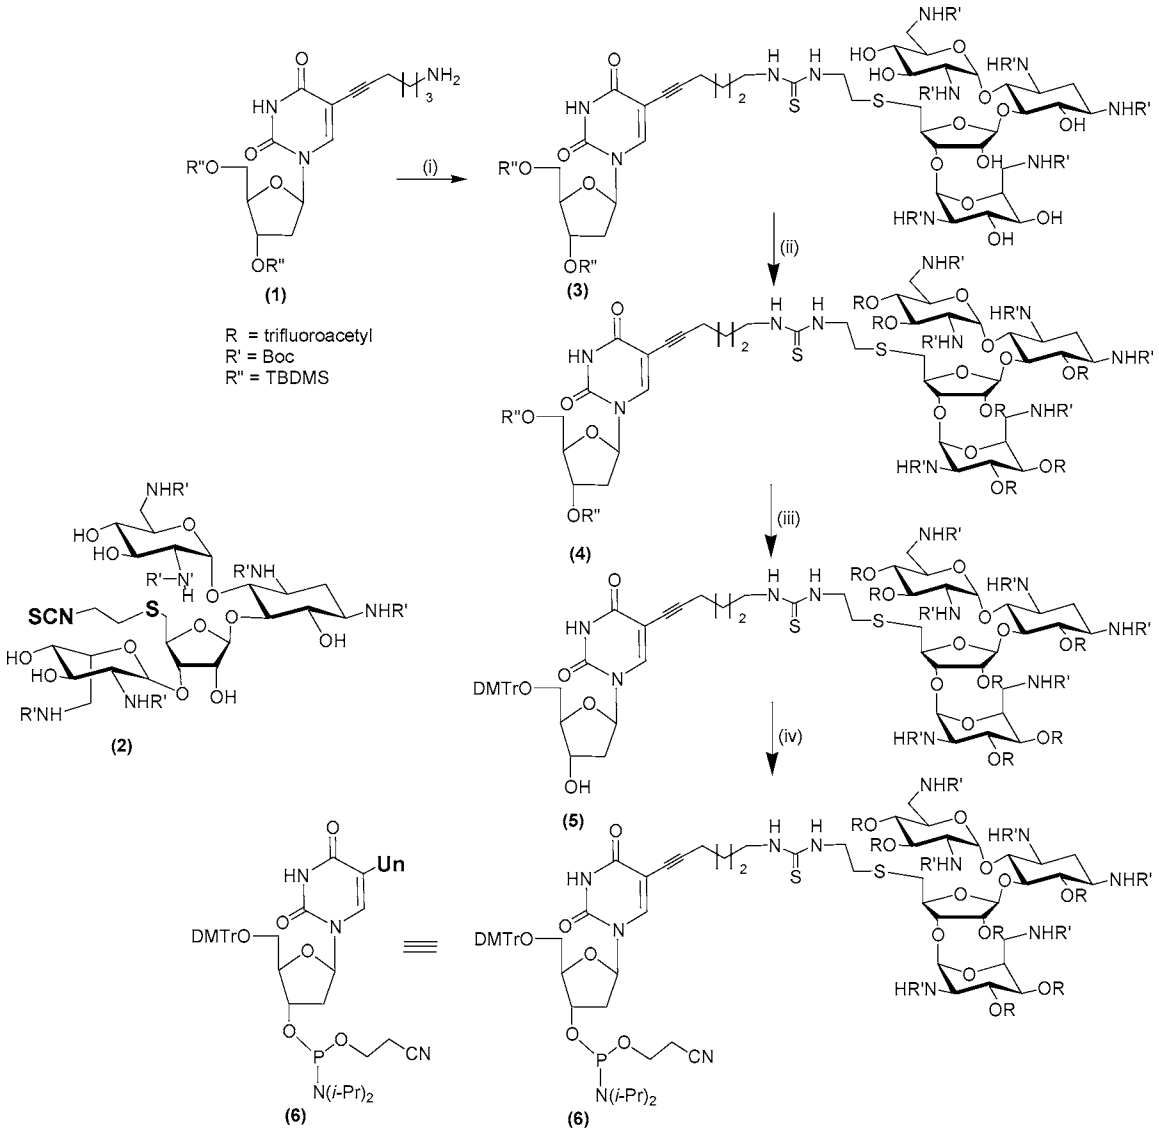
development of all nucleic acid based drugs. We recently showed that neomycin, an aminoglycoside antibiotic, when combined with a cationic lipid preparation, like DOTAP, enhances transfection efficiency of both reporter plasmids and oligonucleotides and results in a significant increase in transgene expression (*41*).

To take advantage of these unique findings of aminoglycoside−nucleic acid interaction, we have initiated the development of aminoglycoside−nucleic acid conjugates. Recently, we reported synthesis of neomycin conjugates in which neomycin was conjugated at the 5′-end of the nucleic acid analogs (DNA/PNA) via thiourea linkage (*42*, *43*). The application of such conjugates, however, is limited, as the drug can be added only at the 5′-end of the oligomer. The applicability of conjugating a drug molecule to any given site in an oligonucleotide can be accomplished if the drug is attached to the base or sugar using an appropriate linker, leaving 5′- and 3′-ends free for suitable oligomer elongation. With this methodology, the addition of drug−phosphoramidite conjugates to the growing strand during oligonucleotide synthesis can be monitored using trityl monitor. Herein, we describe an efficient phosphoramidite-based method for the synthesis of neomycin attached to the C5-position of 2′-deoxyuridine through a hexynyl linker, its extension to oligonucleotide−neomycin synthesis (Figure 2), and its hybridization with a complementary RNA structure. These conjugates will be referred to as nucleo−aminoglycoside conjugates (N−Ag−C), of which the first example, nucleo−neomycin conjugate (N-Neo-C), is reported here.

Selection of Target RNA. Among functionally active 16S rRNA target sites, A-site (*1*, *44*−*47*) and α-sarcin loop (*47*−*50*) are important, as they have a profound effect on protein synthesis. The α-sarcin loop is the region where α-sarcin catalyzes the hydrolysis of the phosphodiester bond that links its eighth and ninth residues (*50*). This causes improper binding of ribosomes to elongation factors, which eventually terminates protein synthesis (*47*). The importance of this single phosphodiester linkage emphasizes the significance of the α-sarcin loop as an attractive target for antisense oligonucleotides. We therefore chose this target for our initial studies.

EXPERIMENTAL PROCEDURES

Materials. All commercial reagents were used without further purification. Pyridine, methylene chloride, and *N*,*N*-dimethylformamide (DMF) were refluxed over calcium hydride and distilled. All reactions were carried out in oven-dried glassware under N_2/argon atmosphere. All reactions were monitored by thin-layer chromatography (TLC) with precoated silica gel on glass plate. Visualization of the TLC plate was achieved with either UV light or spraying ethanolic ninhydrin solution followed by heating the plate with a heat gun. ICN silica gel 32−63 (60 Å) was used for column chromatography. ^{1}H NMR spectra were recorded by using either 300 MHz or 500 MHz NMR. IR was recorded on a Nicolet Magna-IR Spectrometer 550 as a solution of either 1,2-dichloroethane or CCl_4, and the peaks corresponding to the solvent was subtracted manually. MALDI-TOF mass was recorded on a Bruker Daltonics OmniFLEX Bench-Top MALDI-TOF mass spectrometer. Preparative anion exchange HPLC was carried out on a Phenomenex SAX 80 Å column (10 × 250 mm, 5μ), and for analytical anion exchange HPLC, a Waters Gen-Pak FAX (4.6 × 100 mm) column was used. Preparative and analytical RP-HPLC were carried out with Alltima C8 100 Å (250 × 4.6 mm, 10μ) column.



Please see Supporting Information for experimental procedures for synthesis of monomers. 7mer DNAs (dY, N-dY, and dY′) were synthesized on Expedite Nucleic Acid System (8909) and purified by HPLC. RNA (rR) was purchased from Dharmacon, Inc., (Lafayette, CO) and was used without further purification (lot numbers COFRA-0001 and CHAIB-0001). The concentrations of all the nucleic acid solutions were determined spectrophotometrically using the following extinction coefficients (on a per strand basis, M^{-1} cm^{-1}): e_{260} = 81 900 for rR, and e_{260} = 54 000 for dY. Neomycin (lot 129H0918) was purchased from Sigma (St. Louis, MO) and was used without further purification.

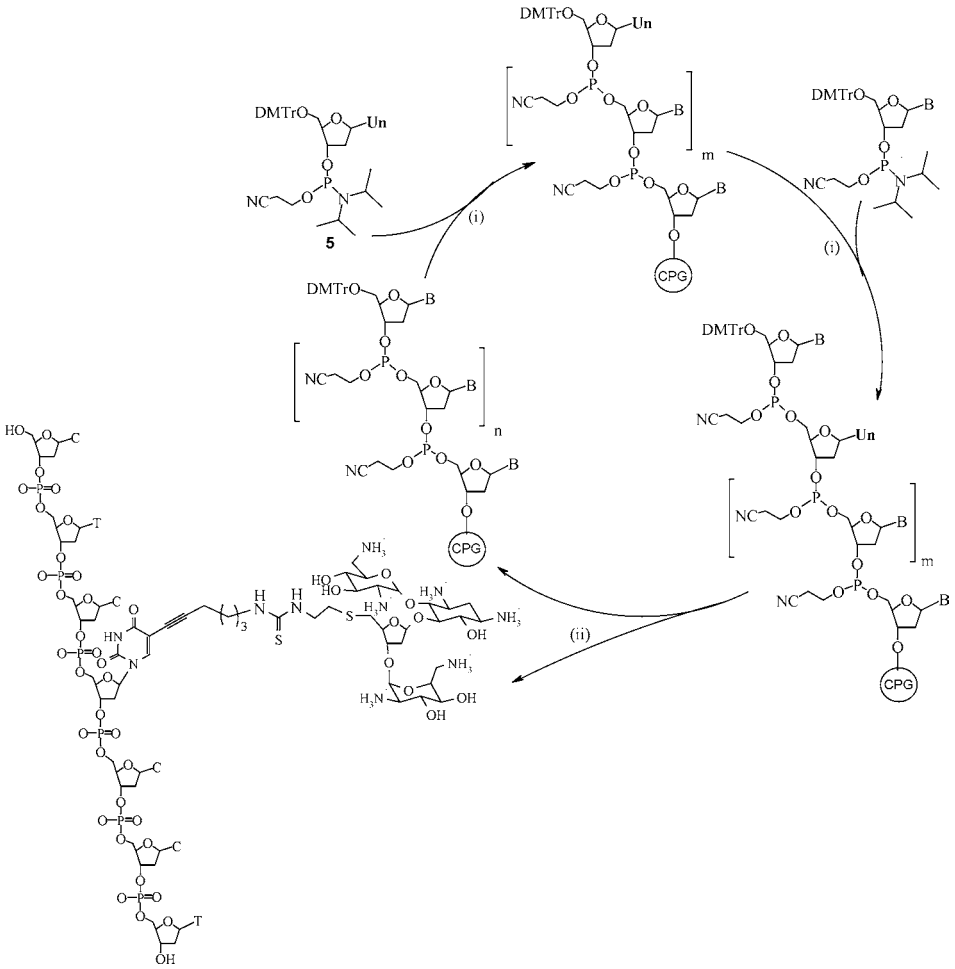
UV Spectroscopy. UV spectra were recorded at λ = 200−300 nm on a Cary 1E UV/vis spectrophotometer equipped with temperature programming. Spectrophotometer stability and λ alignment were checked prior to initiation of each melting point experiment. For accurate T_m determinations, first-derivative functions were used. Data were recorded every 1.0 °C. In all UV experiments, the samples were heated from 20 to 95 °C at a rate of 5 °C/min, annealed (95 to 5 °C, at a rate of 0.2 °C/min), and again melted (5 to 90 °C, at a rate of 0.2 °C/min), and the samples were brought back to 25 °C at a rate of 5 °C/min. During melting and annealing, the absorbance of each solution was monitored at the following wavelengths: 260, 280, and 284 nm. The second melting stage was used for calculating melting temperature.

CD Spectroscopy. All CD experiments were conducted at 15 °C on a JASCO J-810 spectropolarimeter equipped with a thermoelectrically controlled cell holder. A quartz cell with a 1 cm path length was used in the CD studies. CD spectra were recorded as an average of 3 scans from 220 to 320 nm with data recorded in 1 nm increments with an averaging time of 2 s. The hybrid duplex solution was incubated at 4 °C for 16 h before CD titration. After each addition of 5 μL of neomycin (1 mM) to a 2 mL solution of hybrid duplex (10 μM per duplex), the solution was inverted 3 times to ensure thorough mixing and incubated for 3 min prior to scanning. Buffer conditions for CD titration are as follows: 10 mM sodium cacodylate, 0.5 mM EDTA, 60 mM total Na^+, and pH 6.0.

ITC Measurements. Isothermal titration calorimetric measurements were performed at 10 °C on a MicroCal VP-ITC (MicroCal, Inc.; Northampton, MA). In a typical experiment, 5

Scheme 1[a]

[a] Reagents and conditions: (i) (a) Neo−S-CH_2CH_2SCN, DMAP, pyridine (76%); (ii) $(CF_3CO_2)O$, *i*-Pr_2EtN, CH_2Cl_2 (75%); (iii) TBAF, DMF; and then DMTrCl, pyridine, DMAP (78%); (iv) $NCCH_2CH_2OP[N(i\text{-}Pr)_2]_2$, bis(diisopropylammonium) tetrazolide and CH_2Cl_2 (89%).



μL aliquots of 200 μM single strand were injected from a rotating syringe (300 rpm) into an isothermal sample chamber containing 1.42 mL of a RNA solution that was 20 μM per strand. Each experiment was accompanied by control experiments in which 5 μL aliquots of the single strands were titrated into buffer. The duration of each injection was 5.0 s, and the delay between each injection was 300 s. The initial delay prior to the first injection of 2 μL was 60 s. Each injection generated a heat burst curve (microcalories per second vs seconds). The area under each curve was determined by integration using the *Origin 5.0* software (MicroCal, Inc.; Northampton, MA) to obtain a measure of the heat associated with that injection. The buffer used in the experiment was 10 mM sodium cacodylate, 0.5 mM EDTA, 60 mM total Na^+, and pH 7.0.

Covalent Attachment of Neomycin to an Oligonucleotide. The oligonucleotide synthesis (1 μM) was carried out on Expedite Nucleic Acid Synthesis System (8909) using standard phosphoramidite chemistry (*51*). The coupling of deoxyuridine−neomycin conjugate 6 (0.2 M) to the oligomer was carried out for 30 min. After the oligomer synthesis, the CPG column was dried using argon gas. Then, the conjugate was detached from the solid support using NH_4OH, and the resulting solution was evaporated. The lyophilized sample was treated with 1 mL of 1,4-dioxane solution containing 3% CF_3CO_2H and 1% *m*-cresol (v/v/v %). After 30 min, the conjugate (Scheme 2) was precipitated with 10 mL of diethyl ether and the precipitate was washed with 3 × 10 mL of diethyl ether. The solution was evaporated, and the residue was resuspended in triethylammonium acetate buffer 10 mM and extracted twice with ether. Ether was removed, and the aqueous layer was dried under vacuum for 1 h. The solid was redissolved in 1 mL of water, purified by anion-exchange chromatography, and lyophilized.

RESULTS AND DISCUSSION

Design. Our design is based on a computer model of neomycin bound to the hybrid duplex major groove, shown in Figure 3. There are two ways of approaching the major groove: either through a 5′-OH conjugation or through conjugation with a base. Only one neomycin can be conjugated through 5′-OH conjugation, which left the 5-uridine position as the desirable site for conjugation of multiple neomycins. The linker length (12 atoms between 5-uridine and neomycin 5′-CH_2-) chosen by us allows enough flexibility for neomycin to fit into the major groove and maintain the favorable contacts. Our previous results show that the amino groups on rings I, II, and

IV (Figure 1) of neomycin are necessary in stabilizing and recognizing various nucleic acid forms (aminoglycosides without any of these amines do not stabilize A-form structures as efficiently) (*20*).

Synthesis. On the basis of prior results mentioned above, the 5″-OH on ring III of neomycin was modified to neomycin isothiocyanate **2** as described in our earlier report (*42*). The precursor **1** was prepared from 2′-deoxyuridine by following a literature procedure (*52*). Then, neomycin isothiocyanate **2** was coupled with hexynylamino group of the modified 2′-deoxyuridine **1** to give conjugate **3** with an isothiourea linkage (Scheme 1). The hydroxyl groups on the neomycin molecule need to be protected in order to use phosphoramidite chemistry. The literature survey shows that the hydroxyl groups on aminoglycosides can be protected with an acetyl group (*53*). Deacylation can be carried out at the end of the oligonucleotide-conjugate synthesis with aqueous ammonia treatment, which can also perform the following in a single step: cleavage of the oligonucleotide from the solid support and β-elimination. Thus, the hydroxyl groups on neomycin were protected with a trifluoroacetyl group to get acetylated neomycin **4** in 75% yields. Deprotection of *t*-butyl dimethylsilyl (TBDMS) groups on the sugar with tetrabutylammonium fluoride (TBAF) followed by protection of 5′-hydroxyl group with DMTr-Cl in the presence of DMAP in pyridine gave the required TBDMS-free compound **5** in 78% yield. Further reaction of compound **5** with 2-cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropyl phosphoramidite in the presence of bis-(diisopropylammonium) tetrazolide gave phosphoramidite **6** in good yields (*54*). For synthesis and characterization of compounds **1**−**6**, please see Supporting Information.

After synthesizing phosphoramidite **6**, the 7mer oligonucleotide (Figure 1) was prepared on a CPG column using standard phosphoramidite synthesis protocols (Scheme 2) (*51*). After introducing three bases, the modified base was coupled with the oligonucleotide on the solid support for 30 min, which was followed by the addition of the remaining three bases. Then, the conjugate was detached from the solid support using NH_4OH and purified by preparative reverse phase HPLC using a triethylammonium acetate buffer. The dried sample was treated with 1,4-dioxane solution containing 3% CF_3CO_2H and 1% *m*-cresol (v/v/v %). After 30 min, the deprotected conjugate was precipitated and washed with excess diethyl ether. The deprotected conjugate was finally purified by preparative anion exchange HPLC using a Tris-HCl buffer. As shown in Figure 4, neomycin-conjugated DNA elutes faster than the unmodified DNA. The identity of the conjugate (N-dY) was confirmed by MALDI−TOF mass spectrometry (MS (MALDI−TOF) *m*/*z* calcd $[M + H]^+$ 2795, found −2796.21, Figure 5).

Evidence of Incorporation of a Modified Base. The base composition of the conjugate was determined by complete enzymatic hydrolysis using snake-venom phosphodiesterase followed by alkaline phosphatase and subsequent reverse phase HPLC chromatography. The modified and unmodified oligonucleotides (0.2 A_{260} unit) were subjected to digestion with snake venom phosphodiesterase (10 units/mL) and alkaline phosphatase (100 units/mL) in 50 μL of 50 mM Tris-HCl buffer

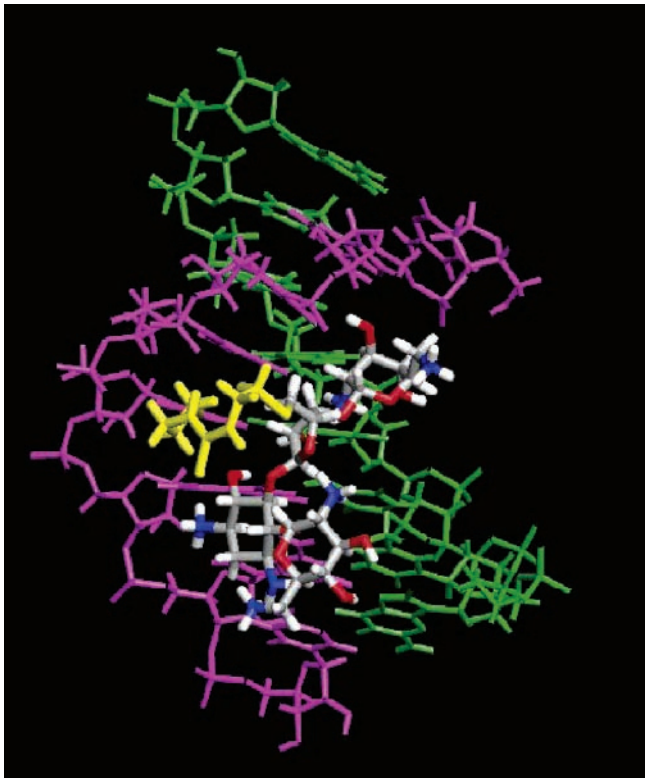

Figure 3. A model of neomycin−7mer DNA conjugate. The linker is shown in yellow and neomycin is shown in atom colors. The molecule was generated from a NMR solution structure file (PDB: 124D). The structure was optimized with *Maestro* program using the AMBER* force field to a gradient of 0.05 kJ/mol Å. The continuum GB/SA model of water, as implemented in *MacroModel*, has been used in all calculations. The force field atomic charges were used for the hybrid duplex. Neomycin was built and optimized in *MacroModel* as described previously (*21*).

(pH 7.2) containing 10 mM $MgCl_2$ at 37 °C for 24 h. The reaction mixtures were analyzed by reverse phase HPLC. As shown in Figure 6, an extra peak appears at approximately 10 min, which integrates to a base ratio of 1 (X = dU−neomycin conjugate) compared to base ratio of 4 (dC) to 2 (dT). In the unmodified DNA, only two peaks elute, with ratios of 4(dC)/3(dT).

Spectroscopic Studies of Interaction of Single Strand RNA with N−Neo Conjugate. We then investigated using UV thermal denaturation studies to determine if the stabilization shown by neomycin can also be observed with the neomycin−DNA conjugate. Covalent conjugation of a large molecule like neomycin can easily lead to unfavorable base/backbone contacts, if the molecule is not placed in the major groove with needed flexibility. The thermal denaturation of the rR•dY1 duplex (Scheme 3) in the absence and presence of 4 μM of neomycin was carried out in the presence of various concentrations of sodium ions (Table 1). In the absence of NaCl, the hybrid duplex (rR•dY1) melts at 26.3 °C. As the NaCl concentration was increased (0−100 mM), the T_m of the hybrid duplex increased from 26.3 °C to 30.0 °C. With 60 mM NaCl, the hybrid duplex showed a T_m of 28.1 °C. The presence of 4 μM of neomycin at 60 mM NaCl increases the T_m of the hybrid duplex (rR•dY) by 3.2 °C (Figure 7). When the DNA strand (dY1) was replaced with the modified oligonucleotide−neomycin conjugate (N-dY), the ΔT_m of the hybrid duplex (rR•N-dY) was 6.9 °C (with 60 mM NaCl) compared to the hybrid duplex (rR•dY1) without neomycin. Control experiments with just the amino linker led to a 1.8 °C change in T_m (see Supporting Information).

Sequence Specificity of the Conjugate. The effect of neomycin on the presence of a mismatch in this duplex (mismatch present on strand-rR^1) was also carried out. The mismatch was chosen on the RNA base which is complementary to the modified base. The presence of a single mismatch on the RNA strand decreases the melting temperature of the hybrid duplex (rR^1•dY1) from 35.3 °C to 8 °C when there is 4 μM of neomycin and 60 mM NaCl present in the solution. The mismatch penalty was similarly observed with the hybrid duplex (rR^1•N-dY) (with neomycin−oligonucleotide conjugate (N-dY) as one of the DNA strands) showing a T_m of 8 °C. This clearly suggests that neomycin's presence does not disrupt the Watson−Crick hybridization and the stabilization seen by neomycin is dependent on the retention of this fidelity leading to the A-form hybrid duplex.

Conformation of the Resulting Hybrid Duplex: Circular Dichroism (CD) Studies. The interaction of the aminoglycoside with hybrid nucleic acids can be monitored by CD spectroscopy. Depending upon the nature of the spectrum obtained from the CD scan, one can predict whether the complex exists in A-, B-, or canonical forms. The literature shows the preference of aminoglycosides for nucleic acids with A-like conformation (*55*−*58*). In some cases, transition of B- to A-conformation has also been observed with aminoglycosides, a phenomenon observed with cationic ligands such as spermine and $Co(NH_3)_6^{3+}$ (*59*, *60*). In a recent report, a complex formed between an 8-base-pair hybrid duplex and paramomycin was shown to exist in an A-like canonical conformation (*61*). Our earlier competition dialysis results have shown the preference of neomycin conjugates for A-form nucleic acids. The CD spectra of both the hybrid duplexes ((rR•dY1 and (rR•N-dY) were therefore analyzed. The spectra show that the conjugate shifts the maximum in the CD spectrum from 275 nm to 271 nm when compared to nonconjugated hybrid duplex (Figure 8). This observation suggests that the conjugate hybrid duplex prefers to be in canonical A-form (*61*−*64*) and retains the form exhibited by the unmodified RNA•DNA hybrid duplex.

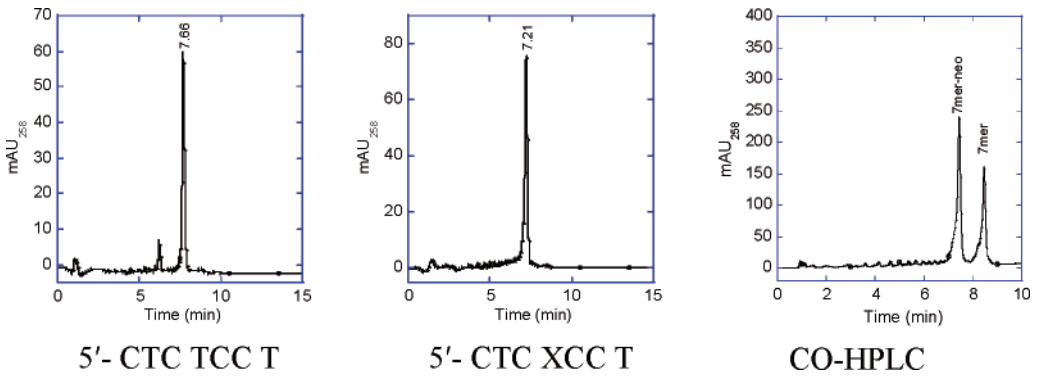

Figure 4. Conditions. Buffer A: 25 mM tris-HCl and 1 mM EDTA, pH = 8.0. Buffer B: buffer A + 1 M $NaClO_4$, pH = 8.0. 2% buffer B in buffer A for 2 min; 2−40% during 15 min; flow rate was 0.75 mL/min. X corresponds to deoxyuridine−neomycin conjugate base.

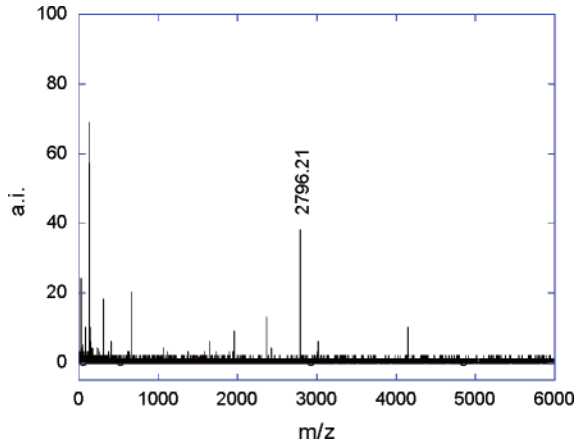

Figure 5. MALDI-TOF profile of 7mer−neomycin conjugate recorded with picolinic acid as the matrix and ammonium tartarate as the co-matrix.

Thermodynamic Basis of Interaction of Neomycin with the Target: Isothermal Titration Calorimetry. The effect of neomycin binding to the host rR•dY duplex was also studied using ITC experiments. The experiment was conducted at 15 °C in sodium cacodylate buffer at pH 6.0. Each injection gave the corresponding heat burst curve, and integration of the areas under these curves corresponds to the associated injection heats. These injection heats were subtracted from the dilution heats, which were obtained by two separate blank titrations of the corresponding drug vs buffer and the duplex vs buffer.

The thermodynamic properties for the binding of the conjugate N-dY with RNA (rR) were determined with the help of isothermal calorimetry. Monophasic transition was observed when N-dY conjugate was titrated against rR, and the injection heat data was fit with a model for a single binding site (Figure 9). For comparison, a titration of rR against nonconjugated DNA (dY1) was also carried also out, and the results are presented in Table 2.

The results show that rR single strand prefers to form the duplex approximately two times more with the N-dY conjugate than the nonconjugated dY single strand. A 2-fold change

Scheme 3. Base Sequences Used in the Present Study[a]

rY : 5'-r(C U C U C C U)
rR : 3'-r(G A G A G G A)
rR[1] : 3'-r(G A G U G G A)
dR : 3'-d(G A G A G G A)
dY1 : 5'-d(C T C T C C T)
dY2 : 5'-d(T C C T C T C)
N-dY : 5'-d(C T C X C C T)

[a] X indicates the presence of neomycin conjugated to 2′-deoxyuridine at the 5-position.

Table 1. UV Melting Profiles of the 7-mer Hybrid Duplex in the Presence of Various Concentrations of NaCl[a]

		T_m (°C)		
	concn of NaCl (mM)	without neomycin	with 4 μM neomycin	with N−Neo−C
1	0	26.3	30.0	32.1
2	10	27.1	31.1	32.1
3	25	27.1	31.1	32.3
4	60	28.1	31.3	35.0
5	100	30.0	31.0	36.1

[a] Solution conditions: [DNA] = 4 μM per strand; 10 mM sodium cacodylate buffer, 0.5 mM EDTA, pH 7.0. Samples were heated from 5 to 90 °C at 0.2 °C/min, and were brought back to 20 °C at a rate of 5 °C/min.

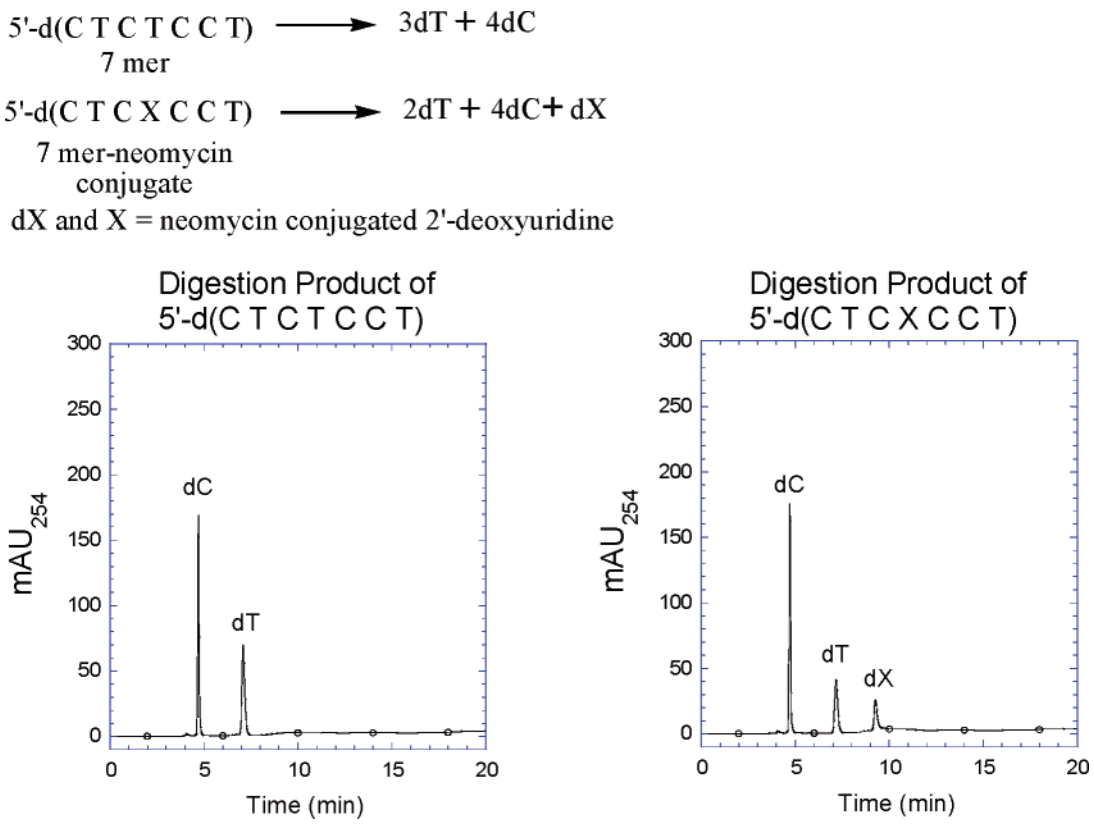

Figure 6. Conditions. Buffer A: 100 mM triethylammonium acetate and 5% of acetonitrile. Buffer B: 95% of acetonitrile and 5% of 100 mM triethylammonium acetate, pH = 7.0; 1−10% of buffer B over buffer A during 15 min, flow rate was 0.5 mL/min; 10−23% during 8 min, flow rate was 1.0 mL/min.

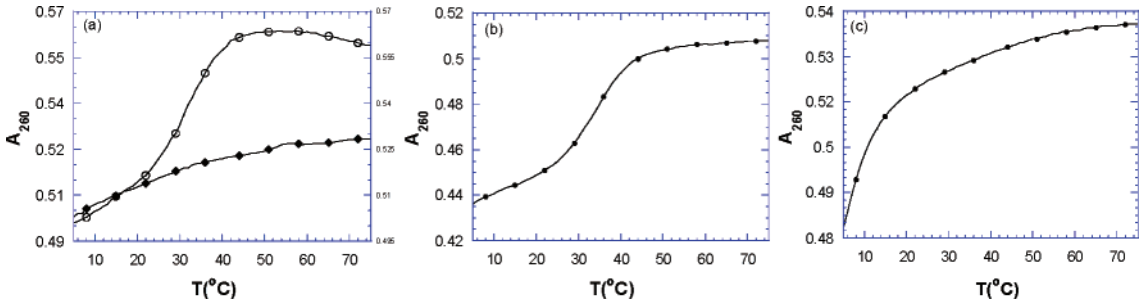

Figure 7. UV melting profiles of (a) rR•dY1 hybrid duplex in the absence (filled squares) and presence of 4 μM of neomycin (open circles); (b) rR•N-dY hybrid duplex; (c) rR^1•N-dY hybrid duplex. The spectra were recorded at 260 nm in the presence of 60 mM Na^+ ion concentration. [DNA] = 4 μM/strand. Buffer conditions: 10 mM sodium cacodylate, 0.1 mM EDTA, pH 7.0. The melting rate was 0.2 °C/min.

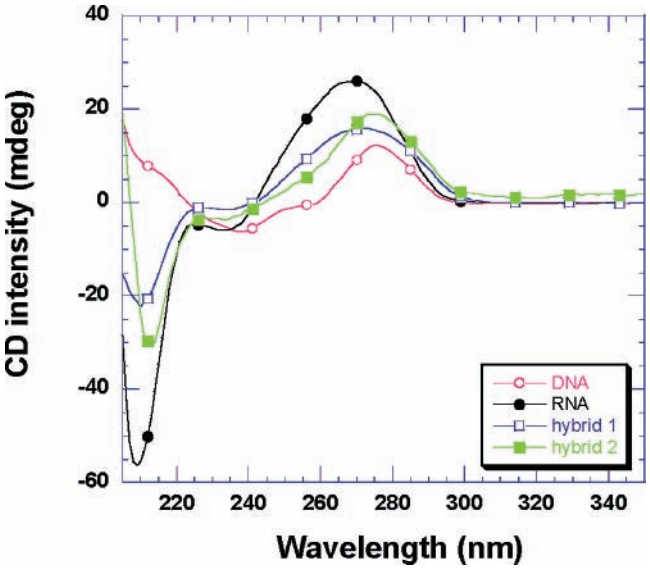

Figure 8. CD scans of 10 μM DNA duplex (dR·dY1, open circle), RNA duplex (rR·rY, filled circle), hybrid 1 (rR·N-dY, open square), and hybrid 2 (rR·dY1, filled square) at 10 °C. Buffer conditions: 10 mM sodium cacodylate, 0.5 mM EDTA, 60 mM total Na^+, and pH 7.0.

reflects the synergistic effect of DNA and covalently bound neomycin on the duplex structure. The increased stability of the duplex is driven mainly by a larger and more negative enthalpy {$\Delta\Delta H_{obs} = -7.21$ kcal/mol ($\Delta H_{neomycin\ conjugated} - \Delta H_{nonconjugated}$)}. This increase in enthalpy matches the enthalpy of interaction of aminoglycoside binding to the hybrid duplex (*61*). Interestingly, lowering the pH (to pH 6.0) leads to a decrease in K_a, such that the effect of neomycin conjugation is almost negligent (please see Supporting Information). Normally, when neomycin binds to a nucleic acid target, loss of pH leads to a lowering of binding-induced protonation (less favorable enthalpy of binding), but that is compensated by a favorable entropy such that the overall affinity of the drug to nucleic acid decreases slightly as the pH is lowered (please see Supporting Information) (*65*). Conjugation of neomycin to DNA in N−Neo−Cs leads to a similar decrease in $\Delta\Delta H$ (−7.2 kcal/mol at pH 7.0 to −5.5 kcal/mol at pH 6.0), but covalent attachment of neomycin does not allow for a favorable change in entropy as the pH is lowered. The unfavorable entropy changes in binding are dominated by the binding of larger DNA oligomer to its RNA target and are affected almost equally for dY1 and N-dY binding when the pH is lowered. The binding results of N-dY to RNA is also of interest in light of the general problem of the attribution and additivity of the binding free energies of ligand substituents. In general, if a ligand molecule A and ligand molecule B bind to a receptor, ligand A−B is then expected to bind so that the binding constant of A−B equals the product of two individual binding constants. DNA (dY) binds to RNA with 100 nM affinity, whereas neomycin shows very little binding to small single strand RNA. Therefore, the conjugation of the two, as observed here, is not expected to result in a major change in DNA to RNA binding constant at room temperature. The increase in T_m of the duplex, as seen with the effect of neomycin on the hybrid duplex, is retained with this conjugation. Neomycin binding to the target is therefore dependent on the ability of the single strand DNA to bind single strand RNA and form the hybrid duplex. A corollary to the discussion is also that neomycin conjugation to DNA is not likely to result in a lack of sequence specificity in RNA binding. We have previously shown the ability of neomycin to stabilize DNA and RNA triplexes as well (*27*). We therefore investigated if conjugation of neomycin to DNA using this linker will allow for triplex stabilization (dY1•rR•dY2). Addition of a third strand DNA or RNA, in the absence of neomycin, does not result in the formation of the triplex, since such triplexes only form with much longer sequences in high salt conditions. We have previously shown the ability of neomycin to induce intermolecular DNA triplexes with at least 16 base pairs (*26*). Addition of high concentrations of neomycin did not induce the formation of the 7-base-pair triplex (dY1•rR•dY2 or dY1•dY•dY2). When the studies were conducted with neomycin-linked DNA, no change in the T_m (UV or CD melting; please see Supporting Information) was observed. These results substantiate our model where a shorter linker, such as used here, allows a better fit of neomycin to the hybrid duplex, whereas longer linkers are better suited for reaching into the triplex Watson−Hoogsteen groove (*26*). The short size of the triplex also contributes to its instability, and more direct comparisons of duplex vs triplex stabilization can only be carried out with longer sequences. Nevertheless, using the appropriate linker and sequence design, one can, in principle, make the N−Neo−Cs specific for targeting a single strand RNA or a duplex DNA/RNA target. Additionally, variation of linker lengths in future studies are also likely to lead to much larger affinity increases per neomycin conjugation.

CONCLUSION

To investigate the advantage of nucleic acid based specificity coupled with aminoglycoside charge/shape complementarity, we have initiated the development of aminoglycoside−nucleic acid conjugates (N−Ag−Cs) (*42*, *43*, *66*, *67*). This report focuses on the development of such conjugates and their binding to a biologically relevant target—ribosomal RNA.

In conclusion, we have synthesized a modified oligonucleotide, where an aminoglycoside is covalently linked to one of the bases of a 7-base-long oligonucleotide. When we began this work, there was considerable doubt that a large molecule such as neomycin can be placed in the major groove of an RNA duplex using a covalent linkage. This report is the first of its kind that shows the ability of such a large covalently linked

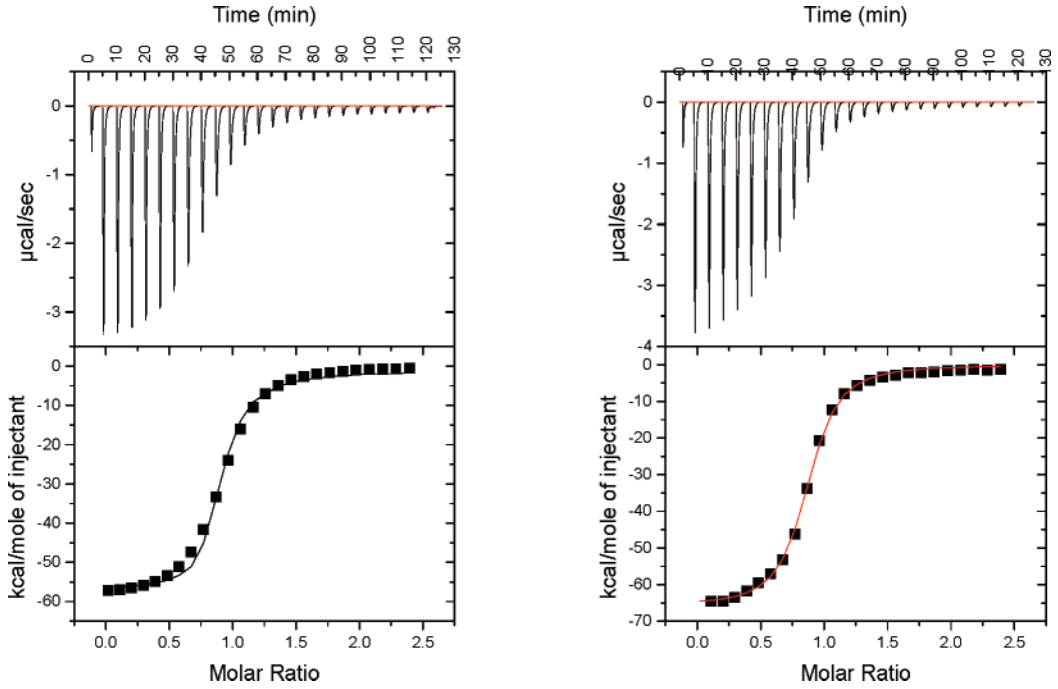

Figure 9. ITC profile of rR single strand titrated against (a) dY single strand (b) neomycin conjugate (N-dY) at 10 °C and pH 7.0 in sodium cacodylate buffer. Buffer conditions: 10 mM sodium cacodylate, 0.1 mM EDTA, pH 7.0 and 60 mM total Na^+ ions. Each heat burst curve is a result of a 10 μL injection of 200 μM of rR into 15 μM of N-dY solution. A plot of corrected ITC injection heats as a function of the [rR]/[N-dY] ratio (r_{dup}). The heats were derived by subtraction of the heats obtained by the titration of rR SS against the N-dY SS with the heats obtained by blank titration of the corresponding buffer vs buffer. The data points reflect the experimental injection heats, while the line denotes calculated fit using a model for one set of binding.

Table 2. Binding Parameters for the Complexation of the rR SS (single strand) with N−dY SS in Cacodylate Buffer at pH 7.0 and a Temperature of 10 °C Obtained from ITC

duplex	N	K_a (M^{-1})	ΔH_{obs} (kcal/mol)	$T\Delta S$ (kcal/mol)
rR•dY	0.97 ± 0.01	$2.8 \times 10^6 \pm 3.8 \times 10^5$	-58.7 ± 0.9	−50.4
rR•N-dY	0.93 ± 0.01	$5.0 \times 10^6 \pm 2.3 \times 10^5$	-65.9 ± 0.5	−54.5

carbohydrate (neomycin) to aid in RNA•DNA hybrid complexation. In addition, we have demonstrated that the N−Neo− conjugate and a 7-base-long RNA sequence present in the α-sarcin loop can form a stable hybrid duplex. The stability of the rR•dY1 hybrid duplex with 1 equiv of neomycin is comparable to the stability of the rR•N-dY hybrid duplex. The presence of a single mismatch decreases the melting temperature of both neomycin conjugated and nonconjugated hybrid duplexes. This is an important finding, as it supports the fact that association of the conjugate is driven by DNA−RNA base-pair association and not through non-sequence-specific electrostatic interactions between neomycin and the phosphodiester linkages. The linker length used here does not induce the formation of the short triplexes and will thus be specific for RNA targeting as opposed to duplex DNA targeting. Since the formation of such hybrid duplexes can be used to control gene expression by inhibition of the steps of translation, slicing, or by activation of RNase H leading to degradation of the mRNA, these conjugates have potential applications that include drug and oligonucleotide delivery to a specific RNA site.

The design, construction, and preliminary analysis of a new class of carbohydrate−DNA conjugates, which we term nucleoaminoglycoconjugates (N−Ag−C), has been described. The example shown here—a nucleoneomycinconjugate (N−Neo−C)—illustrates that these aminoglycoside−DNA hybrids are efficiently synthesized, chemically stable, and behave similarly to an unmodified DNA strand in solution. The synthetic methodology described here allows for inclusion of any number of aminoglycoside (neomycin) molecules per oligonucleotide. These conjugates can provide a platform for the development of a new form of hybrid biomaterials. They combine the unique specificity of nucleic acids and the recognition/binding ability of the aminoglycosides. N−Neo−Cs could have enormous potential in oligonucleotide therapeutic strategies (duplex as well as triplex approaches) and in the engineering of novel DNA-based materials. These applications will be further investigated and reported in due course.

Protein Delivery by the Cell-Penetrating Peptide YTA2

Helena Myrberg,*,† Maria Lindgren,‡ and Ülo Langel†

Department of Neurochemistry, Stockholm University, Svante Arrhenius v. 21A, SE-106 91 Stockholm, Sweden, and Cepep II AB, Box 45029, SE-104 30 Stockholm, Sweden. Received August 30, 2006; Revised Manuscript Received November 13, 2006

In most cases, the transport of cell-penetrating peptide (CPP) with a cargo molecule over the plasma membrane requires a cross-linking of the cargo molecule to the peptide. Lately, a method of cargo delivery, coincubation with CPP, has been applied. We have studied uptake and toxicity of the CPP, YTA2, in the Bowes human melanoma cell line and human MDA-MB-231 breast cancer cell line and compared the results with known cell-penetrating peptides. The results show that fluoresceinyl YTA2 is taken up by the Bowes cells with 3.23 nmol/mg protein and shows low membrane toxicity to the cells with an EC50 of 60 μM. Furthermore, we show that YTA2 is capable of delivering cargo proteins, such as β-galactosidase and tetramethyl rhodamine iso-thiocyanate (TRITC) labeled streptavidin into cells by coincubation. The delivery of TRITC-labeled streptavidin was quantified to 42.4 pmol streptavidin/mg protein. The delivery of proteins into the cells by mere coincubation is an advantage, since the chemical coupling between the CPP and the cargo molecule, which adds time-consuming synthesis and purification steps, can be omitted. In addition, the flexibility in CPP cargo delivery is increased.

INTRODUCTION

In the past decade, cell-penetrating peptides (CPPs[1]), also called protein transduction domains (PTDs), have drawn major attention for their capability to translocate the cellular membranes (for review, see ref 1). CPPs also have the aptitude of transporting conjugated cargoes over different cellular membranes both in vivo and in vitro (*2*, *3*). So far, most CPPs require a cross-linking to their cargo to be able to transport it inside the cell (*4*, *5*). In the case of a chemical coupling, it demands additional attention when synthesizing and purifying the peptide−cargo complexes and is therefore time-consuming. The presence of a conjugated peptide might also affect the cargo inside the cell. Morris et al. developed a new technique for protein delivery based on a peptide, Pep-1 (*6*). Pep-1 has the capability to deliver different peptides, proteins, and antibodies inside different cells, in vivo and in vitro, without any chemical coupling between the cargo and Pep-1 (*7*). The same group, Morris et al., has also developed other peptides, MPG and Pep-2, that have been shown to deliver nucleic acids, oligonucleotides and HypNA-*p*PNAs, respectively, by mere coincubation (*8*−*10*).

We have studied the uptake and toxicity of the CPP YTA2 (*11*) and compared the results with known CPPs. Interestingly, YTA2, like Pep-1, also has the capability to deliver proteins into cells by simply coincubation of the peptide−protein with the cells. The proteins that are used in this study are a 119 kDa subunit of β-galactosidase and TRITC-labeled streptavidin with a molecular weight of 66 kDa. β-Galactosidase is a protein consisting of four subunits. In this work, one 119 kDa subunit has been used. β-Galactosidase is the gene product of lacZ and catalyzes the hydrolysis of X-gal while blue color is produced (*12*). The cells that have been successfully transfected with β-galactosidase will, due to appearance of a blue color, be easily visualized by light microscope. The other protein used, streptavidin, is a tetramer that is a mainly neutral and a nonglycosylated protein. In this study, we have used TRITC-labeled streptavidin to quantify the uptake of YTA2 coincubated with the TRITC-labeled streptavidin.

The disclosure that YTA2 can deliver, e.g., proteins, inside cells by mere coincubation is an advantage, since the need of a chemical coupling between the CPP and the cargo molecule might no longer be necessary for transport over the cell membrane in vitro.

MATERIALS AND METHODS

Cell Culture. The human breast cancer cell line MDA-MB-231 was cultured in RPMI-1640 and Bowes human melanoma cells (ATCC CRL-9607) in MEM media with Glutamax I (InVitrogen, Sweden) supplemented with 10% fetal bovine serum, sodium pyruvate (1 mM), penicillin (100 U/mL), streptomycin (100 μg/mL), and 1% nonessential amino acids. All cells were incubated at 37 °C in 5% CO_2.

Quantitative Uptake of Peptide. Bowes and MDA-MB-231 cells (100 000 cells/well) was seeded on a 12-well plate 2 days before the experiment. On the day of the experiment, the cells were washed with HEPES-buffered Krebs Ringer solution (HKR) (2 × 1 mL) and exposed to drug solution (500 μL, 5μM) for 30 min at 37 °C. Cells were washed (2 × HKR) whereafter trypsin (200 μL) was added and incubated for 5 min at 37 °C. HKR was added (1000 μL), and cells were transferred to Eppendorf tubes and centrifuged (10 min, 1000 *g*). Cells were lysed in sodium hydroxide solution (0.1 M, 300 μL) for 45 min and centrifuged (10 min, 10 000 *g*). The fluorescence (492/518 nm) was measured with SPEKTRAmax GEMINI XS spectrofluorometric plate reader (Molecular Devices). The amount of internalized peptide was normalized against the amount of protein (Lowry BioRad, U.S.A.).

Membrane Integrity. The assay was performed using the CytoTox-ONE Homogeneous Membrane Integrity Assay (Prome-

ga, Madison, WI), which is based on the measurement of lactate dehydrogenase leaking from cells with damaged membrane. The cells were seeded on 12-well plates 2 days before the experiment, with 100 000 cells/well in 1 mL of the respective medium. On the day of the experiment, the cells were washed twice with 0.5 mL HKR and exposed to drug solution (500 μL, 5 μM), or 0.1% Triton X-100 in HKR (500 μL) for 30 min at 37 °C. Then, 100 μL of the exposure solution was transferred to a black polypropylene FluoroNunc plate, and CytoTox-ONE reagent (100 μL) was added. The mixture was incubated for 10 min at room temperature (RT), and fluorescence was measured (560/590 nm) in the spectrofluorometric plate reader.

Cell Viability. Bowes cells (20 000 cells/well) were seeded on a 48-well plate 2 days before the experiment. The cells were exposed to peptides in different concentrations in full media containing 1% FBS for 48 h at 37 °C. The plate was cooled to RT, and CellTiter-Glo Reagent (Promega) was added. The plate was incubated for 10 min at RT whereafter the luminescence was measured with SPEKTRAmax GEMINI XS spectrofluorometric plate reader (Molecular Devices).

Protein Transfection with β-Galactosidase. Cells (100 000 cells/well) were seeded the day before the experiment on a 24-well plate. β-Galactosidase (1 μL, 0.25 μg/μl) was mixed with phosphate buffered saline (PBS) (50 μL). Peptides (3.5 μL or 6 μL, 1 mM) were mixed with H_2O (50 μL). The β-galactosidase solution was mixed with the peptide solution and incubated for 30 min at RT. The cells were washed with PBS. The peptide−protein solution was added to the cells whereafter serum-free media (100 μL) was added and cells were incubated for 60 min at 37 °C. At this time, complete media (150 μL) was added to the cells, and incubation was continued for 90 min at 37 °C.

β-Galactosidase Staining. Cells were fixed and stained according to the β-galactosidase staining kit (Active Motif). Cells were fixed in PBS containing 0.7% formaldehyde and 0.05% glutaraldehyde for 10 min at RT. Cells were washed three times with PBS and stained with a solution of PBS containing potassium ferricyanide (40 mM), potassium ferrocyanide (40 mM), magnesium chloride (20 mM), and 2 mg/mL of X-gal for 90 min at 37 °C. Cells were studied under a phase-contrast microscope (Olympus) at 300× magnification and imaged using a CCD camera (Olympus DP50).

Quantitative Protein Transfection with TRITC-Labeled Streptavidin. Cells (100 000 cells/well) were seeded 2 days before experiment on a 12-well plate. TRITC-labeled streptavidin (purchased from Zymed Laboratories) (1 μL, 1 μg/μl) was mixed with PBS (100 μL). Peptides (3.5 μL, 1 mM) were mixed with H_2O (100 μL). The TRITC-labeled streptavidin solution was mixed with the peptide solution and incubated for 30 min at RT. The cells were washed with PBS (1 × 0.5 mL). The peptide−protein solution was added to the cells whereafter serum-free media (150 μL) was added, and the cells were incubated for 60 min at 37 °C. Complete media (200 μL) was added to cells, and incubation was continued for 90 min at 37 °C. Cells were washed (2 × PBS) whereafter trypsin (200 μL) was added and incubated for 5 min at 37 °C. PBS was added (1000 μL), and cells were transferred to Eppendorf tubes and centrifuged (10 min, 1000 *g*). Cells were lysed in sodium hydroxide solution (0.1 M, 300 μL) for 45 min and centrifuged (10 min, 10 000 *g*). The fluorescence (550/570 nm) was measured with SPEKTRAmax GEMINI XS spectrofluorometric plate reader (Molecular Devices). The amount of internalized peptide was normalized against the amount of protein (Lowry BioRad, U.S.A.).

RESULTS

Quantitative Uptake of Fluoresceinyl Peptides. The uptake of fluoresceinyl YTA2 was studied and compared with penetratin, *p*VEC, TP10, and Tat, well-characterized fluoresceinyl CPPs. Fluoresceinyl peptides at a concentration of 5 μM were added to cells and incubated at 37 °C for 30 min whereafter the amount of internalized peptide was normalized against the amount of total protein content (Figure 1). The uptake was studied in two different cell lines, Bowes human melanoma cell line and human MDA-MB-231 breast cancer cell line. For all studied peptides, the amount of internalized peptide is slightly higher in the MDA-MB-231 cells than in the Bowes cells, but the peptides show a similar pattern in both cell lines. For clarity, only the internalization into the Bowes cells will be discussed. The amount of internalized peptide is lowest, 0.064 nmol peptide/mg protein, for the Tat peptide, slightly higher for TP10 and penetratin with 1.57 and 2.32 nmol peptide/mg protein, respectively. The peptides internalizing with the highest amounts appear to be *p*VEC and YTA2 with 7.79 and 3.23 nmol peptide/mg protein, respectively. Since the amount of a peptide inside the cell may be connected to the toxicity of the peptide, we continued with two different membrane toxicity studies.

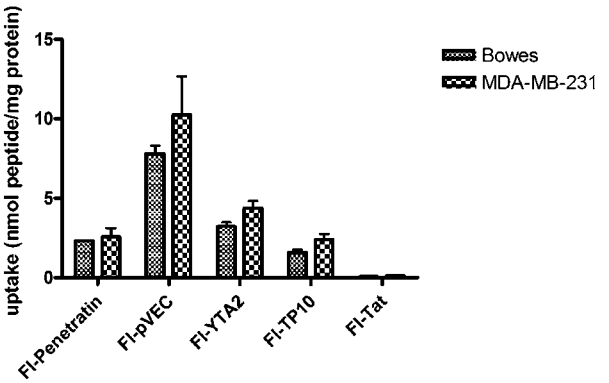

Figure 1. Uptake in nanomoles of fluoresceinyl (Fl) peptides in Bowes cells and MDA-MB-231 cells. Cells were exposed to a 5 μM peptide solution for 30 min whereafter the peptide attached to the cell membrane was removed by trypsination. Cells were lysed in sodium hydroxide solution, the fluorescence (492/518 nm) was measured, and the amount of internalized peptide was normalized against the amount of protein.

Lactate Dehydrogenase Leakage. To investigate if the cell-penetrating capacity was not due to toxicity of the peptides, two different toxicity assays were used. First, we studied the amount of disrupted membranes by means of the amount of leaked lactate dehydrogenase (LDH) in the HKR−peptide solution that was added to the cells. LDH is an enzyme that exists in the cytosole in eukaryotic cells. If LDH can be detected outside the cells, it is a mark of damaged cell membranes. The peptides were studied at 5 μM, and the LDH leakage of lysed cells was set to 100%. Figure 2 shows the Triton X-100-induced LDH leakage. The LDH leakage is studied in Bowes cells and MDA-MB-231 cells, and all studied peptides show the same pattern in both cell lines, but with a slightly higher effect in the MDA-MB-231 cells. Here, only the LDH leakage from the Bowes cells will be discussed. The peptides YTA2 and *p*VEC that had the highest amount of internalized peptides also show the highest LDH leakage with 5.56% and 1.66%, respectively. TP10, Penetratin, and Tat show less membrane toxicity with 1.63%, 0.59%, and 0.37%, respectively. This indicates that to some extent the membrane toxicity and the amount of internalized peptide are related to each other. The LDH leakage of Pep-1 was also studied and measured to only 0.47%. From a general point of view, an LDH leakage below 10% is no major membrane leakage (*13*).

Measurement of ATP Content. To investigate concentration-dependent toxicity, CellTiter-Glo has been used to study the amount of viable cells. This assay uses luciferase to measure the ATP content of the cells after incubation with the peptide in different concentrations (Figure 3). The ATP content is

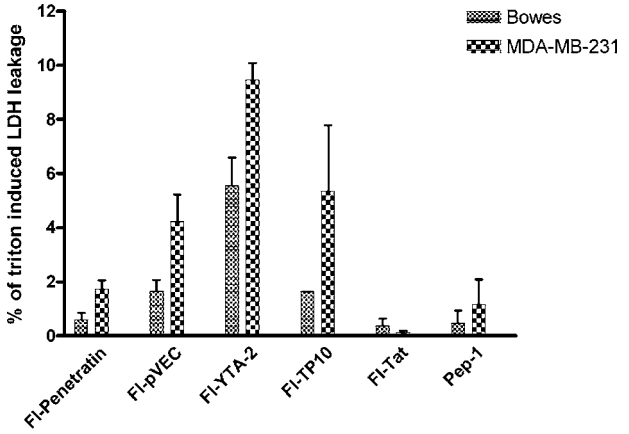

Figure 2. LDH leakage from Bowes cells and MDA-MB-231 cells. Cells were exposed to a 5 μM peptide solution for 30 min whereafter the amount of lactate dehydrogenase in the supernatant was measured (560/590 nm).

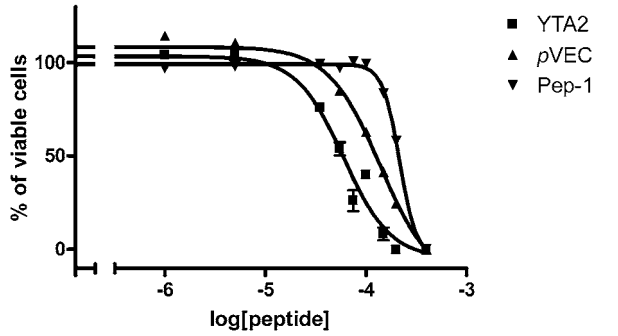

Figure 3. Cytotoxicity based on the ATP level in the Bowes cells. Cells were exposed to different concentration of drug in media containing 1% fetal bovine serum, for 48 h.

relative to the amount of viable, metabolically active cells. We studied the toxicity of the peptides after incubation for 48 h. Figure 3 gives the EC50 values of *p*VEC, Pep-1, and YTA2, that is 138 μM, 216 μM, and 60 μM, respectively. This suggests that the peptides are not toxic at the concentrations where we study uptake of fluoresceinyl peptides and peptide−protein complexes. To sum up, the uptake of peptide and peptide−protein complexes can not only be due to damaged cell membranes and thereby damaged cells.

Protein Transfection with *β*-Galactosidase. We studied whether YTA2 is capable of delivering proteins inside cells without chemical coupling between the peptide and the cargo protein. The peptides were first coincubated with the 119 kDa subunit of β-galactosidase and then added to the cells. Cells were fixed and stained according to the β-galactosidase staining kit (Active Motif). Figure 4 shows the delivery of β-galactosidase inside Bowes cells. The delivery of β-galactosidase with YTA2 (Figure 4C,D) was compared to the delivery of β-galactosidase with *p*VEC (Figure 4E,F) and Pep-1 (Figure 4A,B). *p*VEC (*14*) is another well-characterized CPP, and Pep-1 is also a CPP with the additional well-known capability to deliver proteins inside cells by coincubation. YTA2 is at the least as effective as Pep-1 to deliver β-galactosidase inside Bowes cells, while *p*VEC appears not to be as efficient. Merely β-galactosidase was used as a negative control (Figure 4G,H), and as expected, no uptake of β-galactosidase was detected.

Quantitative Protein Transfection with TRITC-Labeled Streptavidin. The amount of delivered protein by coincubation between the peptides YTA2 and Pep-1 with the protein TRITC-labeled streptavidin was investigated. The peptides were coincubated with 66 kDa streptavidin and then added to the cells. The result is presented in Figure 5 where internalized streptavidin is normalized against the amount of total protein in the cell culture well. The pattern of the result is similar in both Bowes cells and MDA-MB-231 cells, and for clarity, only the results in the Bowes cells will be discussed. YTA2 and Pep-1 have the ability to deliver TRITC-labeled streptavidin with 42.4 and 70.9 pmol of internalized streptavidin/mg protein, respectively. However, in contrast to the uptake with β-galactosidase

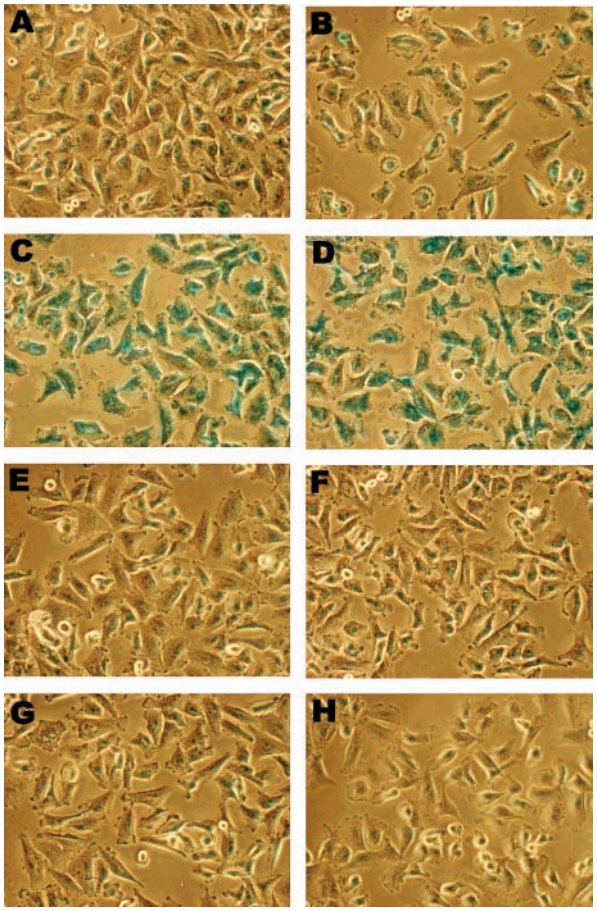

Figure 4. Uptake of β-galactosidase in Bowes cells. Cells were exposed to a peptide protein complex solution for 3 h whereafter cells were fixed and stained according to the β-galactosidase staining kit (Active Motif). In parts A−H, the amount of β-galactosidase is 8.4 pmol. In the left column, the peptide amount is 3.5 nmol, and in the right column, the peptide amount is 6 nmol. Parts A and B show coincubated β-galactosidase and Pep-1. Parts C and D show coincubated β-galactosidase and YTA2. Parts E and F show coincubated β-galactosidase and *p*VEC. Parts G and H show merely β-galactosidase.

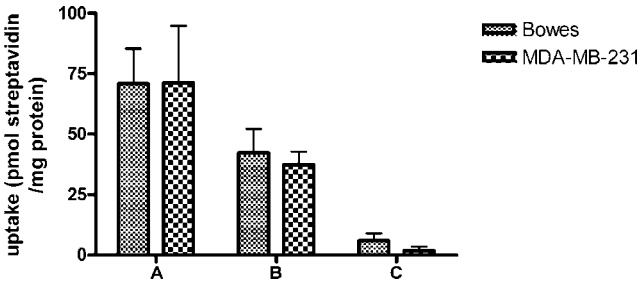

Figure 5. Uptake in picomoles of TRITC-labeled streptavidin in Bowes cells and MDA-MB-231 cells. Bar A shows coincubated TRITC-labeled streptavidin and Pep-1. Bar B shows TRITC-labeled streptavidin and YTA2. Bar C shows merely TRITC-labeled streptavidin. Cells were exposed to a peptide (3.5 nmol) and protein (15 pmol) solution for 3 h whereafter the protein attached to the cell membrane was removed by trypsination. Cells were lysed in sodium hydroxide, the fluorescence (550/570 nm) was measured, and the amount of internalized TRITC-labeled streptavidin was normalized against the amount of protein in the well.

where YTA2 seemed to be superior to Pep-1 to deliver proteins inside cells, here Pep-1 is better than YTA2 to deliver streptavidin over the cell membrane. This difference is probably due to the difference between the two proteins β-galactosidase and TRITC-labeled streptavidin. Merely TRITC-labeled streptavidin was used as a negative control, and as expected, no uptake of TRITC-labeled streptavidin was detected.

DISCUSSION

The discovery and development of CPPs has tremendously facilitated the transport and delivery of conjugated cargoes over the cell membrane (for review, see ref 1). CPPs can be divided into different classes depending on their origin. There are CPPs derived from naturally occurring peptides/proteins (TAT, antennapedia, and *p*VEC) (*14*−*17*), chimeric peptides (transportan) (*18*), and synthetic peptides (Pep-1, YTA2) (*6*, *11*). Common for all classes is that the CPPs are short peptide sequences, less than 30 amino acids, and that the peptides are often highly rich in basic amino acid residues (*1*). The translocation mechanism of CPPs has been debated for a long time and was at the start believed to be receptor- and endocytosis-independent (*19*). Nowadays, different types of endocytosis seem to be important for the uptake of CPPs (*20*−*22*).

Morris et al. developed a new technique based on coincubation of the CPP Pep-1, with the cargo that should be transported over the cell membrane (*6*). In this way, the CPP and the cargo form a complex which can be transported over the cell membrane, and once inside the cell, the cargo will be released from the CPP (*6*, *7*). This finding is of great importance, since the chemical coupling between the peptide and the cargo is no longer needed. This chemical coupling requires additional attention when synthesizing the peptide−cargo complex, and the CPP might also affect the cargo inside the cell.

Pep-1 is an amphipathic peptide consisting of 21 amino acids from 3 different domains. One domain is hydrophobic with 5 tryptophan residues, which seem to be important for forming hydrophobic interactions with proteins. The other domain is hydrophilic with 5 lysine residues that improve the cellular delivery of the peptide. This hydrophilic domain originates from the nuclear localization sequence of simian virus 40 (SV-40) large T-antigens. The hydrophobic and hydrophilic domains are separated by a short sequence of 3 amino acids (serine, glutamine, and proline) (*6*).

YTA2 (*11*) is a CPP with similar uptake abilities to those of penetratin (*17*, *19*), *p*VEC (*14*), TP10 (*23*), and Tat (*15*), other well-characterized fluoresceinyl CPPs (Table 1). The CPP YTA2 was designed according to a method outlined in Hällbrink et al. (*24*). In short, new transport peptides were designed by extending an amino acid sequence corresponding to a matrix metalloprotease-2 substrate (*25*). The seeding peptide sequence was selected from an already published phage library screening, with the aim to find a higher selectivity for matrix metalloprotease-2 over several other matrix metalloproteases. The original sequence was SGESLAY-YTA (*25*), with the hyphen representing the protease cleavage site. The newly designed CPP was named YTA2 after the substrate sequence. The CPP YTA2 was designed for a new approach to overcome the setback of drug resistance by conjugating of a cell-penetrating peptide and the cytostatic agent methotrexate.

The uptake of fluoresceinyl peptide was studied in two different cell lines, Bowes human melanoma cell line and human MDA-MB-231 breast cancer cell line. The uptake shows a similar pattern in both cell lines. After incubating the peptides with the cells, peptides bound to the outside of the cell membrane were removed by trypsination. Before measuring the fluorescence of internalized peptide, the lysed cells were centrifuged to eliminate the possibility of peptide in the cell membrane. To confirm that the cell-penetrating ability was not due to toxicity of YTA2, two different toxicity studies were performed. First, we studied membrane leakage, or acute toxicity, of lactate dehydrogenase from the cytosole. Since almost no LDH could be detected outside the cells, it could be concluded that the cell membranes were not damaged, i.e., leaky. A longer exposure- and concentration-dependent toxicity study was made to describe the amount of living, metabolically active cells dependent on the amount of ATP produced. Moreover, this study shows that YTA2 is not toxic at the concentrations used in the peptide and protein uptake studies. Hence, the fluoresceinyl−YTA2 uptake and the protein−YTA2 uptake are likely due to cell-penetrating abilities of the YTA2.

To investigate whether YTA2, just as Pep-1, has the ability to deliver proteins over the cell membrane, YTA2 was coincubated with two different proteins, β-galactosidase and TRITC-labeled streptavidin, whereafter the complexes were added to the cells. The uptake of β-galactosidase was studied under a phase-contrast microscope, and it showed that YTA2 is at least as effective as Pep-1 at delivering β-galactosidase inside the Bowes cells. TRITC-labeled streptavidin was used to quantify the uptake of the coincubated peptide−protein complex. Here, YTA2 appears to be approximately half as effective as Pep-1 at delivering TRITC-labeled streptavidin inside cells. This indicates that the uptake of protein seems to be dependent on which protein is delivered.

In summary, we have characterized the cell-penetrating ability of YTA2 and confirmed that the cell-penetrating ability is not just due to the toxicity. It was also established that a chemical coupling between YTA2 and the cargo is not needed for transport of the cargo, in this case, β-galactosidase and TRITC-

labeled streptavidin, over the cellular membrane in vitro. This finding facilitates, in respect to both time and synthesis, the transport of proteins over the cellular membrane.

New strategies are needed to protect normal organs from radiation in cancer radioimmunotherapy (RIT). This can be achieved by rapid clearance of radiometal in the circulation after accumulation of radioimmunoconjugates (RIC) in the tumor. Our strategy is to place highly efficient and specific cleavable linkers between radiometal chelates and the tumor targeting agents. Such linkers must be resistant to cleavage by enzymes present in the plasma and the tumor. After radiotargeting agents have accumulated in the tumor, a cleaving agent can be administered "on demand" to cleave a specific linker, resulting in the release of radiometal from the circulating RIC in a form that will have rapid renal clearance. We have selected TNKase, a thrombolytic agent approved for patient use, as our model on-demand cleaving agent. To identify TNKase-specific linkers, we screened fluorescent-quenched random "one-bead-one-compound" (OBOC) combinatorial peptide libraries. D-Amino acid containing peptides that were specific for TNKase but were resistant to cleavage by plasma and tumor-associated proteases were identified. One of these peptide substrates (rqYKYkf) was used to link the DOTA chelate to ChL6, a monoclonal antibody known to target breast cancer. This antibody conjugate was stable in plasma for 7 days while preserving the immunoreactivity to intact tumor cells. The addition of TNKase at clinical achievable plasma level (10 μg/mL) resulted in the release of 28% of the radiometal from the radioimmunoconjugate within 72 h. This lead linker, after further optimization to increase its response to TNKase, may be useful in the development of more effective radioimmunotherapeutic and radioimaging agents.

INTRODUCTION

Radioimmunotherapy (RIT)[1], in which a targeting agent is conjugated to a radiometal, is a promising approach to treat cancer (*1*−*3*). However, its potential is limited by radiation exposure to normal organs, particularly bone marrow (*4*−*6*). One approach to clear nontargeted radioactivity is to increase renal excretion of circulating radiometal from the body after tumor targeting (*7*−*9*). Immunoadsorption has been utilized to remove circulating radioimmunoconjugates (RIC) and reduce radiation dose to normal tissues (*10*). Removal of free circulating RIC after adequate tumor uptake has been tried preclinically and clinically with modest success (*11*, *12*). DeNardo *et al.* used a similar approach by treating B-cell lymphoma patients using ^{131}I Lym-1, an anti-lymphoma monoclonal antibody, with and without immunoadsorption (*13*, *14*). Results for two patients receiving RIT with immunoadsorption on four occasions demonstrated that RIC was reduced by 75% in blood and by 50% in the bone marrow when their plasma was pumped through an anti-gammaglobulin column for removing the circulating ^{131}I Lym-1 antibodies. It is clear that a large portion of the RIC can be removed with this approach. However, the procedure is cumbersome and expensive, and there is need for a simpler strategy.

Various forms of pretargeting RIT delivery have been developed to overcome this problem and used in clinical trials, for example, by administering tumor targeting molecules that bind subsequently injected radiochelates. The small radiochelates that do not bind to the tumor are cleared quickly from body. This results in a high therapeutic index (tumor dose vs normal tissue dose) (*15*−*18*). However, continued circulating pretargeting molecules have presented interference in tumor targeting of the radiochelates; clearing agents, such as biotin-*N*-acetyl-galactosamine for the antibody−strepavidin conjugates, have resulted in effective radiochelate tumor targeting (*15*−*17*). Although pretargeting approaches have great promise, these systems require multiple injections and administration of reagents at specific time points. Some of the reagents used in such systems, e.g., streptavidin, can be immunogenic. Another approach is to introduce a cleavable linker between the targeting agent and the radiochelate. For example, RIC with linkers cleavable by endogenous proteases such as liver-specific cathepsin-D or by an exogenous hydrolytic enzyme β-lactamase have been reported (*19*−*21*).

Repeated usage of exogenous enzymes of nonhuman source, such as β-lactamase, however, may elicit an immune response. An ideal on-demand cleavable (ODC) enzyme should be of human origin and be primarily restricted to the intravascular space so that only the circulating radioconjugates will be cleaved. Recombinant tissue plasminogen activator (t-PA),

currently used as a thrombolytic agent in patients (TNKase) provides these characteristics (*22*). Thus, the aim of this study is to develop TNKase substrates with high specificity and efficiency that can be used as an ODC linker between radiometal chelate and tumor targeting agents such as mAbs.

In this study, we have shown that currently known TNKase peptide substrates are not stable in plasma and cancer cell supernatants. We have utilized the one-bead-one-compound (OBOC) combinatorial library method (*23*, *24*) to develop an ODC linker that is highly susceptible to TNKase but highly resistant to other proteases in plasma or in a tumor. In this study, we have selected one such TNKase peptide substrate as a lead ODC linker and have evaluated its potential to reduce radiation to normal tissues.

EXPERIMENTAL PROCEDURES

Materials and Instruments. PEGA resin (0.40 mmol/g) was purchased from Polymer Laboratories (Amherst, MA). Boc-2-Abz-OH and Boc-Tyr(3-NO2)-OH were purchased from ChemImpex (Wood Dale, IL). All other amino acid derivatives and HOBt (1-hydroxybenzotriazole) were purchased from SynPep (Dublin, CA). DOTA-NHS-ester (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid mono(*N*-hydroxysuccinimide ester) and DOTA-mono-NHS-tris(*t*-Bu)-ester-(1,4,7,10-tetraazacyclododecane-1,4,7-tris(*t*-butyl acetate)-10-acetic acid mono(*N*-hydroxysuccinimide ester)) were purchased from Macrocyclics (Dallas, TX). DIC (*N*,*N*′ diisopropylcarbodiimide) was purchased from Advanced ChemTech (Louisville, KY). DMF (*N*,*N*′-dimethylformamide), DCM (dichloromethane), MeOH (methanol), diethyl ether, and acetonitrile were purchased from Fisher (Houston, TX). All other chemical reagents were purchased from Aldrich (Milwaukee, WI). Analytical HPLC analyses (Vydac column, 4.6 mm × 250 mm, 5 μm, 300 Å, C_{18}, 1.0 mL/min) and preparative HPLC purification (Vydac column, 20 mm × 250 mm, 5 μm, 300 Å, C_{18}, 7.0 mL/min, 45 min gradient) were performed on a Beckman System Gold HPLC system (Fullerton, CA). MALDI-TOF MS analysis was performed on a Bruker BIFLEX III mass spectrometer (Billerica, MA). All of the experiments are carried out at room temperature unless otherwise noted. ChL6 (Bristol-Myers Squibb Pharmaceutical Research Institute, Seattle, WA) was a chimera consisting of human IgG1-constant regions and the murine L6 MAb antigen-variable region. Carrier-free ^{111}In(MDS Nordion, Vancouver, Canada) was purchased as chloride in 0.05 M HCl solution. Sephadex G50-80 (Pharmacia, Uppsala, Sweden), molecular sieving high-performance liquid chromatography (HPLC) (Beckman Coulter System Gold 127; Beckman, San Ramon, CA; SEC-3000 molecular sieving column), cellulose acetate electrophoresis (CAE) (Gelman Sciences, Inc., Ann Arbor, MI) were used for purification and characterization of RIC. TNKase was purchased from Genentech (San Francisco, CA) and reconstituted with distilled water to get 10 mg/mL concentration. The reconstituted samples were stored in −80 °C in aliquots.

Synthesis of "Fluorescent-Quenched" Peptide Library. An OBOC combinatorial library, containing random Y(NO_2)-peptide-K(Abz), was synthesized on PEGA resin with a standard "split-mix" approach (*25*). The following fluorescent-quenched libraries were prepared on PEGA beads: Y(NO_2)-xxxxxxx-K(Abz), Y(NO_2)-xxXxx-K(Abz), Y(NO_2)-xxxXXxxx-K(Abz), and Y(NO_2)-xxXXXxx-K(Abz). For these random peptides, Y(NO_2) represents 3-nitrotyrosine, K(Abz) represents lysine bearing a 2-aminobenzoyl group on its ϵ-amino group, X represents one of 19 natural L-amino acids excluding cysteine, and x represents one of the D-isomers of 18 natural L-amino acids plus glycine. Theoretically, there are $19^7 = 8.9 \times 10^8$ possible permutations of peptide sequences in this library.

Screening and Sequencing. Four different combinatorial libraries were screened against TNKase enzyme. Approximately 1 mL of the beads (about 325 000 beads) was used in each screening experiment, and a total of 1 million beads from each library were screened. Fluorescent-quenched combinatorial libraries were first incubated with pooled plasma, isolated from citrate-treated human blood obtained from normal volunteers. The beads were incubated with 50% plasma containing PBS overnight at 37 °C with occasional shaking. Beads with peptides that were labile in plasma and therefore fluoresced and those beads that autofluoresced were removed by a fluorescence bead sorter (COPAS, Union Biometrica). The remaining nonfluorescent beads were washed several times with PBS to remove plasma proteins. 10 μg/mL TNKase in PBS was added and incubated for 1 h at 37 °C with occasional shaking. After 1 h, beads were incubated with 8 M guanidine HCl to terminate the enzyme activity and washed with water several times to remove all the proteins attached on the beads. Positive fluorescent beads were picked under a fluorescent microscope at 360/410 excitation/emission spectrum and sequenced with Edman chemistry using an automatic microsequencer (ABI, Procise 494). On the basis of the plasma stability and TNKase susceptibility, 12 peptides were selected as candidate substrates for TNKase. For in vitro stability assay, the selected candidates were synthesized as soluble fluorescent-quenched substrates without tethering to beads as described below.

Synthesis of Individual "Fluorescent-Quenched" ODC Linkers. Rink amide MBHA resin (70 mg, 0.09 mmol) was swollen in DMF overnight. The supernatant was removed, and 20% piperidine solution in DMF (2 mL) was added to the resin. The mixture was agitated for 15 min, and the supernatant was drained. This process was repeated. The resin was thoroughly washed with DMF, MeOH, and DMF. Fmoc-Lys(Alloc)-OH (122.2 mg, 0.27 mmol), HOBt (36.5 mg, 0.27 mmol), and DIC (42.3 μL, 0.27 mmol) in DMF (2 mL) were added to the resin. The resulting mixture was agitated until the ninhydrin test was negative. The resin was washed with DMF, MeOH, and DCM. In the presence of argon, a solution of $PhSiH_3$ (266.5 μL, 2.16 mmol) in DCM (1 mL) was added to the resin, followed by a solution of $Pd(PPh_3)_4$ (26.0 mg, 0.0225 mmol) in DCM (2.2 mL). The mixture was shaken in an argon atmosphere for 30 min. This process was repeated. The supernatant was removed, and the resin was washed thoroughly with DCM, DMF, MeOH, and DMF. To the resin was added a solution of Boc-2-Abz-OH (64.1 mg, 0.27 mmol), HOBt (36.5 mg, 0.27 mmol), and DIC (42.3 μL, 0.27 mmol) in DMF (2 mL). The resulting mixture was agitated until the ninhydrin test was negative. The supernatant was removed. The resin was washed with DMF, and the α-Fmoc protecting group of the lysine was removed by piperidine treatment as described above. The peptide was then synthesized on the α-amino group of the lysine using standard Fmoc chemistry. Boc-Tyr(3-NO2)-OH was used as the last amino acid. After the peptide sequence was finished, the resin was washed with DMF, MeOH, and DCM, and then dried under vacuum. 4 mL of cleavage mixture (TFA (trifluoroacetic acid)/phenol/thioanisole/water/TIS (triisopropylsilane), 82.5:7.5:5:5:2.5, v/w/v/v/v) was added to the dried resin at 0 °C. The mixture was slowly warmed to room temperature and allowed to mix for 6 h. The supernatant was then collected, and the resin was washed with TFA (3 × 1 mL). The combined supernatants were concentrated to 1 mL under a stream of nitrogen. The peptide was precipitated by dilution with ethyl ether (10 mL), separated by centrifugation, washed with ethyl ether, and dried under vacuum. The crude peptide was analyzed and purified by HPLC and characterized by MALDI-TOF MS.

Synthesis of DOTA-ODC Linker with an Aminooxyacetyl (Aoa) Group. The DOTA-ODC linker (DOTA-spacer-rqYKYkf-

spacer-K(Aoa)-NH_2) was synthesized using a procedure similar to the synthesis of fluorescent-quenched peptides. After the Alloc deprotection, instead of Boc-2-Abz-OH, Boc-Aoa-OH was coupled to the ϵ-amino group of the lysine. The α-Fmoc protecting group was then removed by piperidine treatment as described above. To increase ODC accessibility for TNKase digestion, a short hydrophilic spacer was introduced on both sides of the ODC linker. This linear hydrophilic spacer has a diamine component at the N-terminal end derived from 2,2′(ethylenedioxy)-bis(ethylamine) and an anhydride component at the C-terminal end derived from succinic anhydride, respectively (*26*). A Fmoc-protected spacer was coupled to the α-amino group of the lysine using our previously published procedure (*26*). After the coupling of the last amino acid, the N-terminus Fmoc protection group was removed by piperidine treatment. An additional spacer was introduced between the DOTA and the peptide. After Fmoc deprotection, the resin was incubated with a solution of DOTA-NHS-ester (112.0 mg, 0.135 mmol) and DIEA (156.8 μL, 0.9 mmol) until the ninhydrin test was negative. The peptide was released from the resin and purified using the procedure described above. A total of 26 mg of DOTA-spacer-rqYKYkf-spacer-K(Aoa)-NH_2 was obtained from 200 mg of resin (yield 14%), and mass (2088.1) was calculated by MALDI-TOF MS $(M + H)^+$. All the substrates were purified by preparative HPLC, and purity was verified by both analytical and MALDI-TOF mass spectrometry. The products that showed $\geq$95% purity were taken for the TNKase susceptibility and stability assay.

Linker Stability Analysis. 100 nmol/mL of fluorescent-quenched ODC linkers were incubated in PBS containing 10% human plasma at 37 °C. The susceptibility was monitored every hour in a fluorescence plate reader (Tecan) at 360/410 nm excitation/emission spectrum. The ODC linker that was stable in plasma overnight was taken for further stability analysis. For this, the cell culture supernatant was isolated from several cancer cell lines (approximately 1−5 million cells/mL) that were split 1 day before the collection. 100 nmol/mL of the ODC linkers was incubated with the cancer cell culture supernatant, and its susceptibility was monitored in a fluorescence plate reader at 360/410 nm excitation/emission spectrum. ODC linkers that were stable in both plasma and various cancer cell culture supernatants were taken for the TNKase susceptibility assay.

TNKase Susceptibility Assay. Potential ODC linkers (100 nmol/mL) were incubated with TNKase (10 μg/mL) in PBS at 37 °C with occasional shaking. To simulate the in vivo condition, plasma was added (10%) in the assay medium. The susceptibility was monitored at various time intervals at 360/410 nm excitation/emission spectrum using a Tecan fluorescence plate reader. The entire assay was done in triplicate, and two independent experiments were performed.

Antibody-Linker Conjugation and MALDI-MS Analysis. For on-demand cleavable studies, ChL6, an antibody targeted against tumor antigen expressed in colon, lung, and breast cancer cells, was used (*27*, *28*). DOTA-ODC-aminoxyamine was conjugated with ChL6 by the ketone−oxime method developed in our lab (*29*). In brief, primary amines (mainly lysine) present ChL6 mAb was coupled with levulinic succinimidyl esters by incubating a 1:30 molar ratio in 40 mM TEA, pH 8.0, for 5 h in a cold room. The uncoupled levulinic succinimidyl esters were removed by dialysis with 40 mM TEA, pH 5.5 buffer. ChL6 was equilibrated with 40 mM TEA, pH 5.5, and incubated with 20 molar excess of DOTA-ODC-ONH_2 linkers for 5−12 h. To verify that ChL6 Ab was conjugated, a small aliquot was removed at various time intervals, and the degree of conjugation was determined by the expected mass shift in MALDI-TOF MS.

Estimation of Metal-Chelatable DOTA (c) per MAb (a) in RIC. The DOTA−ODC−ChL6 conjugate was purified by Sephadex G50 column chromatography (*30*) and was tested for its pyrogen-free status by standard procedures. DOTA−ODC−ChL6 was assayed in triplicate by cobalt metal binding assay to determine the ratio of the metal chelatable DOTA-ODC (chelate) per ChL6 (c/a) (*30*−*32*). Generally, an aliquot of DOTA−ODC−ChL6 (480 μg, 3 nmol) dissolved in 0.1 M tetramethylammonium phosphate buffer at pH 7.0 was treated with excess standardized aqueous solution of $^{57}CoCl_2$ (ICN Radiochemicals, Irvine, CA) and incubated for 30 min at room temperature. To this reaction mixture, aqueous EDTA solution (Fisher Scientific, Fair Lawn, NJ) was added to a final concentration of 10 mM and incubated for 15 min to complex with excess unbound cobalt ions. This EDTA chased mixture was purified by a Penefsky column. The concentration of the $^{57}Co/CoCl_2$-chelated DOTA−ODC−ChL6 was determined by radiation counting using a γ counter against a known quantity of the standardized $^{57}CoCl_2$ solution. The metal-chelatable DOTA was calculated as the ratio of the molar concentration of the ^{57}Co-DOTA−ODC−ChL6 (chelate) and ChL6 (MAb).

Radiolabeling of DOTA−ODC−ChL6 and Quality Control (QA). To prepare RIC, DOTA−ODC−ChL6 and ^{111}In were combined in 0.1 M ammonium acetate (pH 5.3) and incubated for 30 min at 37 °C. To scavenge unbound ^{111}In, EDTA was added to a final concentration of 10 mM for 30 min at room temperature. The final RIC was purified by molecular sieving chromatography. QA of the RIC was established by SEC-3000 HPLC, cellulose acetate electrophoresis (CAE), and immunoreactivity (*32*, *33*).

Immunoreactivity, Plasma Stability, and TNKase Cleavage Assay. ^{111}In-DOTA−ODC−ChL6 was incubated with ChL6 antibody-binding breast cancer cells (HBT 3477) and ChL6 nonbinding lymphoma cancer cells (Raji). Immune reactivity was assayed by performing a competitive assay against lightly iodinated ^{125}I-ChL6. Approximately 1 million cells were incubated for 1 h and washed with PBS to remove any unbound antibody. This experiment was carried out in triplicate and repeated twice. The cells were counted using a β counter. The in vitro plasma stability of RIC was evaluated by mixing 10 μg of ^{111}In-DOTA−ODC−ChL6 incubated in freshly prepared human plasma (1:1 v/v dilution; total volume, 1 mL) at 37 °C in a humidified incubator maintained at 5% CO_2 and 95% air. At various intervals (1, 3, 5, 7, 9, 13, and 14 days), aliquots were taken and analyzed by CAE and high-performance liquid chromatography (*32*, *33*). For TNKase susceptibility assay, RIC (0.39 μCi/μg)) was incubated in human plasma with and without TNKase at the clinical dosage level (10 μg/mL). Plasma samples were fractioned by HPLC. Radioactivity and UV absorption (280 nm) from each fraction were monitored. The degree of susceptibility was calculated by either decreased radioactivity to the peak corresponding to the ChL6 mAb or increased radioactivity to the fractions corresponding to the peptide peak.

RESULTS

Identification of TNKase (t-PA) Specific Substrates. To be effective, ODC linkers need to be (i) stable to proteases present in the plasma, (ii) stable to proteases present in normal tissues and tumor, and (iii) highly susceptible to TNKase. Prior to screening with TNKase, the four OBOC fluorescent-quenched combinatorial libraries were prescreened with human plasma so that those beads with peptides susceptible to plasma could be identified and removed. A library with more L-amino acids in their structure yielded more positive beads. In fact, about 10−15% of the bead library (xxXXXxx) became fluorescent after mixing with plasma for 1 h at room temperature. Fluorescent beads from the plasma-treated peptide libraries were physically removed either manually or by passing through a fluorescence bead sorter (COPAS); the residual beads were

screened with TNKase. Similar to the plasma experiment, the xxXXXxx peptide library yielded more positive beads than the xxxXXxxx library. xxXxx and xxxxxxx libraries, on the other hand, were totally resistant to digestion by TNKase. Since only a portion of the peptides on each positive bead were cleaved by the enzyme, there were enough intact peptides left on each bead for sequence determination. On the basis of the microsequencing result (Edman degradation), we determined the precise TNKase cleavage site. The amino acid sequences of the 12 TNKase-susceptible peptides isolated from the xxXXXxx bead library are shown in Table 1.

All twelve peptides except one were found to be cleaved at the peptide bond between the fourth and fifth residues. One peptide (pGRRHkp) was cleaved between the third and fourth residues. In both cases, the peptides were all cleaved between two L-amino acids. This is not unexpected, as peptide bonds between two D-amino acids or one D- and one L-amino acid are generally resistant to proteolysis. Table 1 also includes the peptide sequence (PGRVVGG) of the cleavage site of plasminogen, the native substrate for TNKase, and a peptide substrate, PFRGSA, identified by the phage-display peptide library method. The P_1 position of all fourteen peptides was found to contain either an Arg or a Lys. Tyr and Phe are the preferred amino acids in the P_2 position. Eight of the twelve substrates have one basic residue (D-Arg or D-Lys) at either the P_3 or P_4 position. Similarly, there is at least one basic residue in position P_1', P_2', or P_3'. Peptides rqYKYkf and kqYKYkl share the same structural homology.

Stability in Biological Fluids. For in vitro stability and susceptibility studies, the identified candidates were synthesized in a free form that is not tethered to beads to rule out steric effects of beads on TNKase digestion. As shown in Figure 1, all the peptides listed in Table 1 were stable in plasma over a 12 h period except for PFRGSA (phage display peptide) and GrFKMat. Peptides yvRKQwk, kqYKYkl, flHKSri, frQKWGk, and rqYKYkf were susceptible to TNKase digestion. Of these, rqYKYkf, frQKWGk, and yvRKQwk were the most susceptible and were completely cleaved within 1 h of TNKase addition (10 μg/mL). Since an effective ODC linker needs to be stable to proteolytic enzymes at the tumor site, we evaluated the susceptibility of these peptide substrates against tissue culture supernatants from various cancer cell lines: pancreatic cancer (Panc1), prostate cancer (PC3), B-cell lymphomas (Raji, Ramos), T-cell lymphomas (Jurkat), and normal immortalized hepatocytes (PHH) (Figure 2). Even though most of the peptides showed stability up to 5 h in the supernatant, peptides flHKSri and rqYKYkf were stable in cancer cell supernatants and plasma for at least 10 h. Out of these two peptides, rqYKYkf was more susceptible to TNKase (Figure 1), and this peptide (Table 1) was also identified twice from library screening. Therefore, we elect rqYKYkf as the first prototype ODC linker for further characterization.

Conjugation and Radiolabeling. Peptide rqYKYkf was derivatized with DOTA and conjugated to a chimeric ChL6 antibody for radiolabeling and in vitro susceptibility studies with TNKase. Prior to conjugation, ChL6 was analyzed by HPLC, CAE, and PAGE, and its purity was found to be over 95% (data not shown). After conjugation, as revealed by MALDI-TOF mass spectrometry, the number of DOTA peptides conjugated to ChL6 was determined to be 1−3 (Figure 3). $^{57}Co/CoCl_2$ was utilized, which demonstrated that 0.5 c/a was available to chelate radiometal. The ^{111}In-DOTA−ODC−ChL6 was purified by Sephadex-G50 column chromatography, and the purity was confirmed by the HPLC and CAE radioactive profiles.

Linker Stability and Immunoreactivity Studies. The plasma stability and TNKase susceptibility of ^{111}In-DOTA−ODC−ChL6 was assayed in vitro prior to in vivo study. ^{111}In-

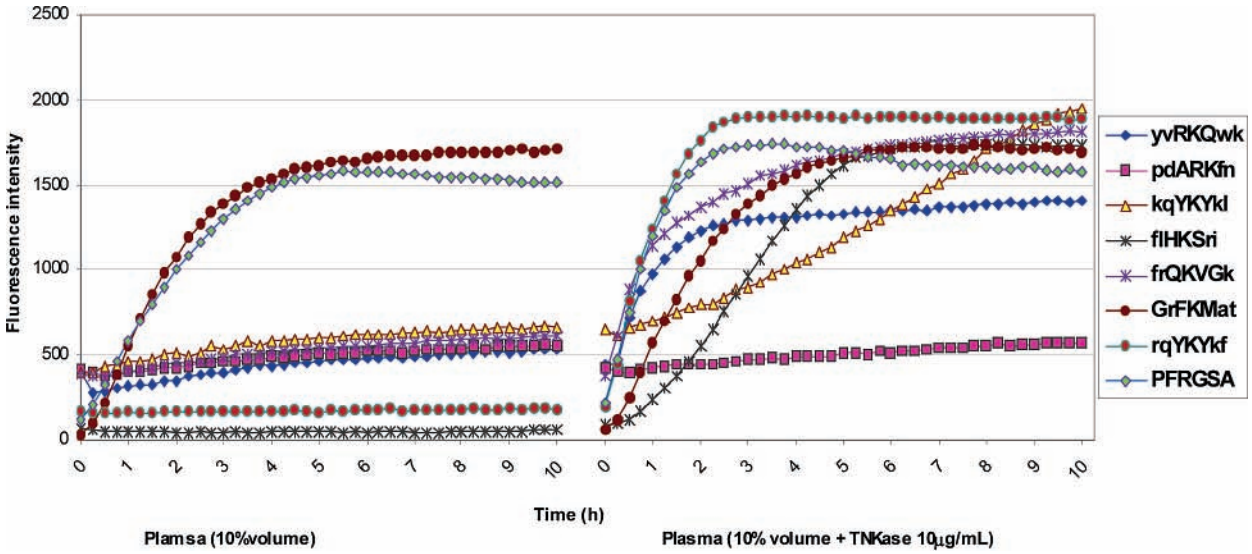

Figure 1. The fluorescence intensity of the ODC-peptides (100 nmol/mL) with plasma (10%) alone is shown on the left. On the right, the fluorescence intensity of the peptides (100 nmol/mL) with 10% of plasma containing 10 μg/mL of TNKase. Peptide "rqYKYkf" is stable in plasma and highly susceptible to TNKase digestion.

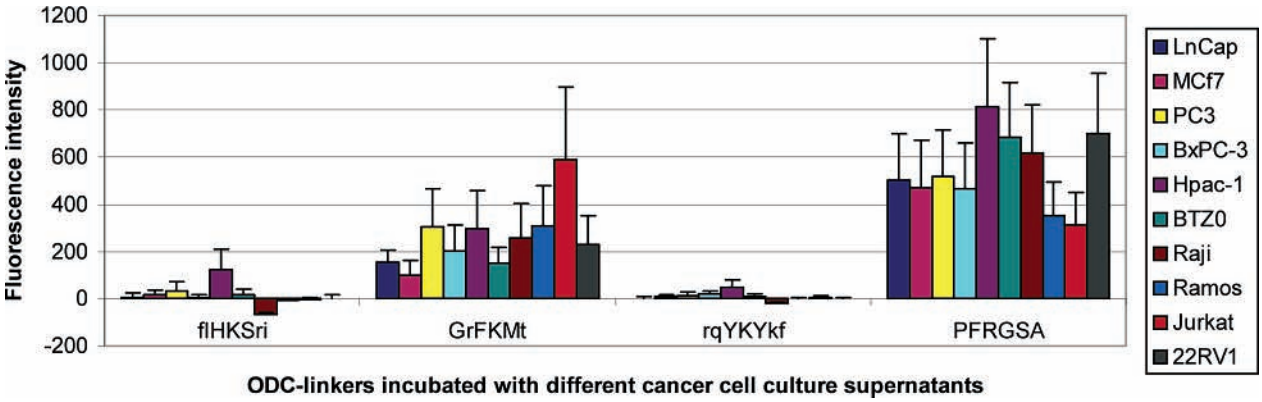

Figure 2. The ODC-linker (rqYKYkf) demonstrated notable stability, while others demonstrated varying degrees of susceptibility to enzymes present in these cell supernatants.

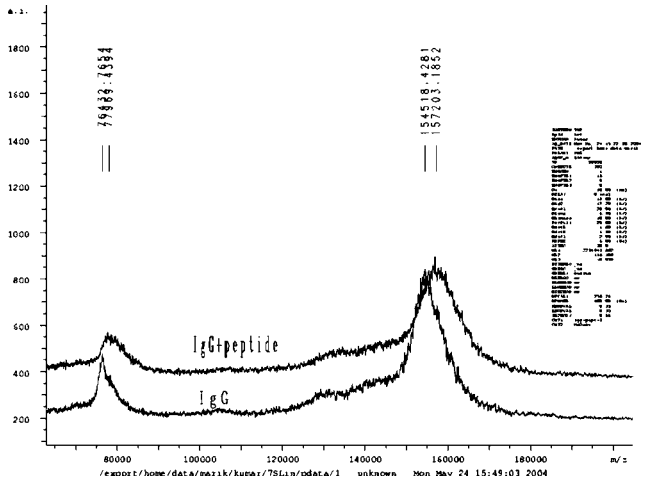

Figure 3. ChL6 antibody mass spectrum is designated as IgG and ChL6−ODC−DOTA mass spectrum designated as IgG + peptide. On the basis of the mass spectrum, we estimate that ~1 to 3 peptides were conjugated per antibody (calculated by shift in mass).

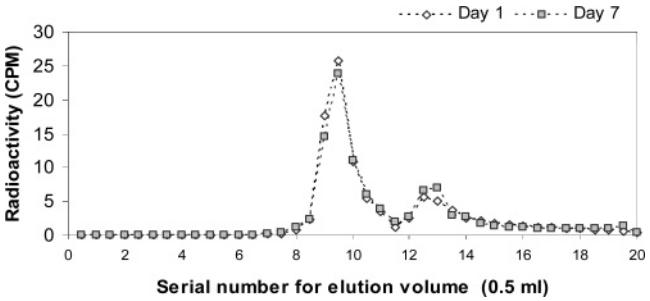

Figure 4. HPLC analysis was performed at UV 280 nm, and each 0.5 mL fraction was collected and radioactivity was counted. The radioactive profiles of ^{111}In-DOTA−ODC−ChL6 with human plasma at days 1 and 7 are identical. Thus, the RIC was essentially stable for a minimum of 6 days.

DOTA−ODC−ChL6 was monitored for 14 days in plasma. Stability of the conjugated ODC-linker in RIC was assessed by HPLC for radioactive and protein peak. Figure 4 showed that the RIC was intact for 7 days (Figure 4). The appearance of small MW species at days 1 and 7 was due to a small amount (≤5%) of ^{111}In-EDTA present in the original preparation. CAE and HPLC analysis indicated that ≥95% of the radiometal was associated with RIC, and ≥98% of RIC was in monomeric form (Figure 5). The appearance of a small percentage of radioactivity on small molecular peaks was noticed after 7 days of incubation with plasma. ^{111}In-DOTA−ODC−ChL6 selectively bound to specific breast cancer cells (HBT) and did not bind to negative control cells (Raji). Immunoreactivity of the ^{111}In-DOTA−

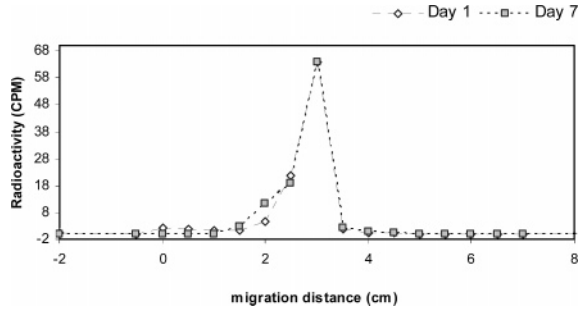

Figure 5. Cellulose acetate electophoresis (CAE): 45 min analysis was carried out at pH 8.6, with CAE strip. After 45 min, the strips were cut at 0.5 cm of each and counted on a γ counter. The radioactivity traces represented are migration patterns of ^{111}In-DOTA−ODC−ChL6 on CAE strips of days 1 and 7 with human plasma. The traces are identical. No radioactivity was observed in the lower molecular weight region for any breakdown product.

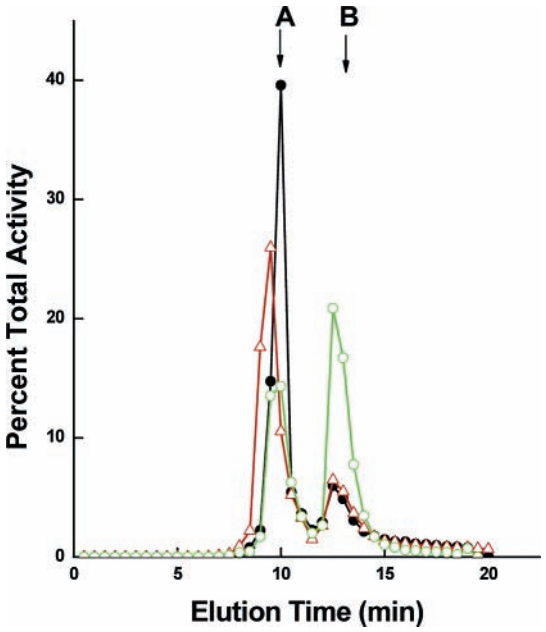
ODC−ChL6 on HBT cells was greater than 50%, whereas it was only 6% to Raji cells. In the competitive assay, the RIC competed with ^{125}I-labeled ChL6. This further suggests that conjugating the ODC linker to the antibody did not alter its antigen binding site (data not shown). ^{111}In-DOTA−ODC−ChL6 was incubated in plasma with and without TNKase at 37 °C, and we found that 10−15% and 28% of the radiometal were released from ChL6−ODC−DOTA conjugates at the clinical dosage level in 2 and 72 h, respectively (Figure 6).

DISCUSSION

To protect vital organs in myeloablative RIT, an equal amount of unlabeled mAb is preinfused before the radiolabeled mAb infusion. The unlabeled mAb will saturate nonspecific antibody-binding sites and Fc receptors in the host body, that will aid labeled mAb in targeting the tumor and reduce nonspecific binding during targeting. In spite of that, radioactive uptake in normal organs is still very high, resulting in bone marrow abalation (*34*, *35*), and nonhematological toxicity such as lung, gastrointestinal, liver, and kidney toxicity (*36*−*39*). It has been proven that complete removal of radioimmunoconjugates from circulation after tumor targeting is the best way to protect the vital organs. Various methods have been developed, but none has reached the clinic because of practical difficulties and cost associated with the techniques. Thus, to date, no optimal strategy has been developed to limit the radiation toxicity to normal organs. Introduction of cathepsin-D degradable linkers between Ab and radiometal-DOTA-chelate has shown partial protection for the liver that is dose-limiting for myeloablative RIT using radiometals (*20*). Pretargeting approaches are promising but have limitations. The administration of exogenous protease from a nonhuman source, such as β-lactamase, has been shown to



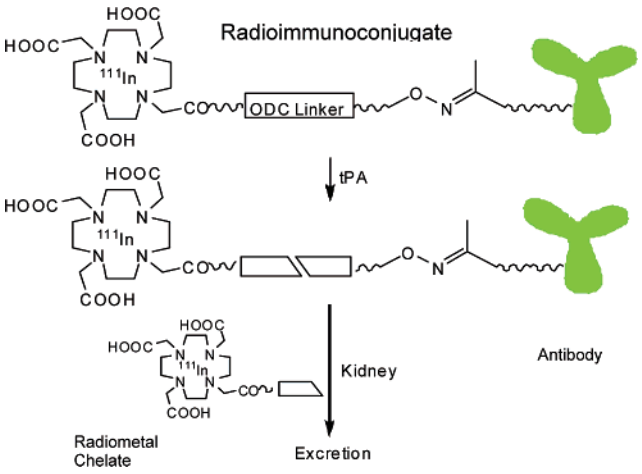


Figure 6. ^{111}In-DOTA−ODC−ChL6 was incubated with human plasma containing 10 μg/mL of TNKase. HPLC radiochromatograms are shown from samples, before (●) and after [2 h (red △) and 72 h (green ○)] the addition of TNKase. Peak A: ^{111}In-DOTA−ODC−ChL6, 150 kD. Peak B: ^{111}In-DOTA−ODC, 5 kD. At 10 μg/mL, TNKase digested 28% of RIC by 72 h.

Scheme 1. Schematic Representation of ODC Linker Hypothesis

cleave the radioconjugates in circulation; however, radioconjugates at tumor sites are also cleaved, suggesting that such agents should be active only in circulation in order to be effective (*21*).

In this study, we provide an alternative novel approach to lower radiation exposure to all normal organs by producing radioimmunoconjugates with TNKase-susceptible "on-demand cleavable" (ODC) linkers. After adequate uptake of radiometal in the tumor, TNKase can be administered intravenously to cleave the ODC linker, resulting in the release of radiometal-DOTA-chelate from the circulating RIC for renal excretion (Scheme 1). Consequently, the unbound radiometal-DOTA-chelate can be rapidly eliminated from the circulation, resulting in diminished toxicity to normal organs. TNKase was chosen over other proteases as an on-demand cleavage agent because (i) it has already been used safely for several years as a thrombolytic agent (*22*, *40*), (ii) it has one known physiological substrate, plasminogen (*41*), (iii) it is already commercially available in both the short-acting (Ativase) and longer-acting forms (TNKase) (*42*), and (iv) its volume of distribution is very similar to the blood volume, indicating that the enzyme resides predominantly within the intravascular space. Bleeding is the main side effect of the t-PA therapy at clinical dosage (10 μg/mL), so we intend to use only one-tenth of the clinical dosage (1 μg/mL) or less, by developing highly susceptible ODC linkers.

A linear peptide substrate derived from the primary sequence of plasminogen (t-PA's physiological substrate) is not cleaved efficiently as intact plasminogen, suggesting that it is not a good candidate for an ODC linker (*43*, *44*). Ding *et al.* described the use of phage-display combinatorial peptide libraries to identify PFGRSA peptide as an efficient substrate for t-PA (*44*). However, this peptide is also highly susceptible to cleavage by proteases present in plasma (Figure 1) and cancer cell supernatants (Figure 2). Thus, it is unsuitable for use as an ODC linker. One main reason that PFGRSA is rapidly degraded in human plasma and cancer cell supernatant is that it is an all L-amino acid peptide. Every peptide bond within this hexapeptide is a potential cleavage site for the numerous proteases present in plasma or tissue proteases. In order to eliminate many of the unwanted cleavage sites by other proteases but still retain appropriate amino acid side chains at the P_2, P_3, P_4, P_2', P_3', and P_4' sites for specific interaction with TNKase, we needed to develop peptide libraries with a combination of D-amino acids and L-amino acids. This is impossible with phage-display libraries but can be easily accomplished with synthetic peptide libraries such as the OBOC combinatorial peptide library method.

Screening an OBOC library is one of the best strategies to identify potential enzyme substrates and novel cancer-specific targeting ligands. We have recently reported the use of the focused OBOC library strategy to develop a lymphoma-targeting ligand with binding affinity of approximately 2 pM (*45*, *46*). By screening the OBOC libraries with a fluorescence-quench assay, we identified unique peptide linkers that were susceptible to TNKase cleavage but stable in human plasma and cancer cell supernatants. One of these peptides rqYKYkf, containing both D- and L-amino acids, is particularly promising, as it can be completely degraded by TNKase within 2 h, resulting in an enzyme level that is clinically achievable (10 μg/mL), and yet it is stable in plasma and cancer cell supernatants. When rqYKYkf was used as an ODC linker to ligate DOTA to ChL6 antibody and DOTA was labeled with ^{111}In, only 28% of the radiometal was released from the RIC after incubation with TNKase (10 μg/mL) for 72 h. The less-efficient cleavage of rqYKYkf when linked to an antibody when compared to a solution peptide may in part be explained by steric hindrance caused by the antibody molecule or by the DOTA.

CONCLUSION AND FUTURE PLAN

We have demonstrated that highly specific and efficient ODC-peptide linkers can be discovered through screening OBOC combinatorial peptide libraries containing both D- and L-amino acids. To improve the efficiency of on-demand cleavage by eliminating possible steric hindrance caused by DOTA and/or the antibody molecule, we plan to insert short PEG linkers between DOTA and rqYKYkf and between rqYKYkf and the antibody. We also plan to link two rqYKYkf peptides serially so that cleavage of any of the two peptides will lead to radiometal-DOTA-chelate release. Furthermore, we plan to design focused OBOC libraries based on the rqYKYkf sequence and use a more stringent screening method, e.g., a much lower dose of TNKase (1μg/mL), to further optimize a highly specific and efficient substrate for TNKase.

Encapsulated Magnetic Nanoparticles as Supports for Proteins and Recyclable Biocatalysts

Aimee R. Herdt, Byeong-Su Kim, and T. Andrew Taton*

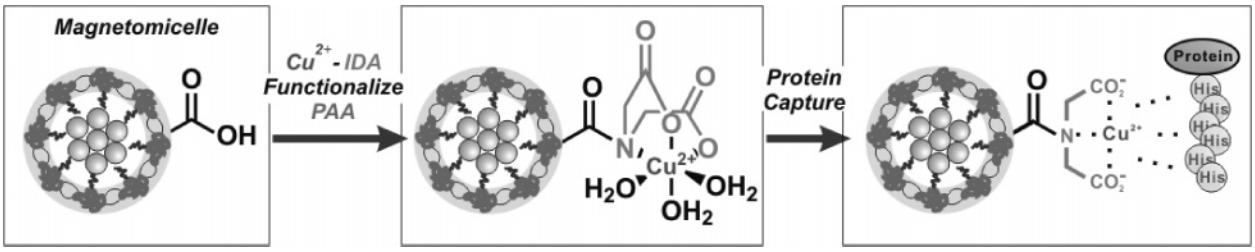
University of Minnesota, Department of Chemistry, 207 Pleasant Street SE, Minneapolis, Minnesota 55455.
Received July 14, 2006; Revised Manuscript Received November 13, 2006

This paper describes the bioconjugation of histidine-tagged enzymes and other proteins to the surface of composite "magnetomicelles" consisting of magnetic γ-Fe_2O_3 nanoparticles encapsulated within cross-linked polystyrene-*block*-polyacrylate copolymer micelle shells. Free carboxylic acid groups on the magnetomicelle surface were converted to Cu^{2+}-iminodiacetic acid (IDA) for protein capture. The conjugation of T4 DNA ligase and enhanced green fluorescent protein to magnetomicelles revealed that proteins were captured with a high surface density and could be magnetically separated from reaction mixtures and subsequently released from the nanoparticle surface. Additionally, bioconjugation of T7 RNA polymerase yielded a functional enzyme that maintained its biological activity and could be recycled for up to three subsequent transcription reactions. We propose that protein−magnetomicelle bioconjugates are effective for protein bioseparation and enzymatic recycling and further strengthen the idea that nanoparticle surfaces have utility in protein immobilization.

INTRODUCTION

Protein-modified particles (*1*), both microparticles and nanoparticles, have many biotechnological uses, including protein separation and purification, protein detection and analysis, in vivo imaging, bioelectrodes and biosensors, and biocatalytic transformations (*2*−*7*). Particle-bound enzymes are of special interest as recyclable catalysts. In principle, magnetic nanoparticles should be excellent solid supports for enzymes (*8*); nanoparticle supports inherently maximize the surface area available for enzyme attachment, and magnetic nanoparticles with sufficient magnetization are easily recovered from aqueous suspension by applying a static magnetic field. One significant challenge to practical use of magnetic nanoparticles as enzyme supports is the availability of general bioconjugate chemistries for connecting proteins to particles. Current methods for attaching proteins to particles include physical adsorption/deposition (*9*, *10*), entrapment (*11*, *12*), cross-linking (*5*), and covalent attachment (*13*). One attractive strategy for specifically conjugating proteins to particles uses fusion tags to attach a specific locus, usually the N- or C-terminus, to reactive or coordinating groups on the particle surface (*14*−*17*). For example, Xu and co-workers recently demonstrated that hexahistidine (His_6)-tagged GFP could be selectively captured onto nitriloacetic acid (NTA)-modified FePt (*18*) or M/Fe_2O_3 (M = Co or $SmCo_{5.2}$) (*19*) nanoparticles when appropriate ligands were covalently installed on the particle surfaces.

In order to control the stability and surface functionality of magnetic nanoparticles, our group has developed a method for the encapsulation of hydrophobic γ-Fe_2O_3 particles (d = 10.9 nm) in amphiphilic polystyrene$_{250}$-*block*-poly(acrylic acid$_{13}$) (PS_{250}-*b*-PAA_{13}) block copolymer (*20*). The outer PAA block of the micelles renders these nanostructures water-soluble and displays carboxylic acid groups used to (*1*) permanently fix the micelle shell with EDC-activated 2,2′-(ethylenedioxy)bis(ethylamine) cross-linker and (*2*) facilitate the attachment of biomolecules. Herein, we demonstrate the covalent immobilization of proteins onto these hybrid nanoscale materials, termed "magnetomicelles", by attaching iminodiacetic acid (IDA) to the micelle surface, and use the functionalized Cu^{2+}-IDA magnetomicelles to selectively capture His_6-tagged proteins (Scheme 1) (*18*, *21*). We establish that the encapsulated magnetic nanoparticles are suitable for biological environments and permit the external manipulation of conjugated biomolecules. Specifically, we report the bioseparation of His_6-tagged T4 DNA ligase (T4 DNAL) and enhanced green fluorescent protein (EGFP). In addition, we show that T7 RNA polymerase (T7 RNAP) maintains enzyme activity while conjugated to magnetomicelles and that the enzyme bioconjugate is recoverable for recycled enzyme use.



EXPERIMENTAL PROCEDURES

Magnetomicelle Preparation and Functionalization. Magnetomicelles were prepared as previously reported (*20*). Briefly, magnetomicelles were prepared from 10.9 nm γ-Fe_2O_3 magnetic nanoparticles ($[\gamma\text{-}Fe_2O_3]_{initial}$ = 0.30 mg/mL in 50:50 DMF/THF) and PS_{250}-*b*-PAA_{13} ($[PS_{250}\text{-}b\text{-}PAA_{13}]_{final} = 2.0 \times 10^{-2}$ mg/mL). Assembled, copolymer-coated particles were exposed to 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC) to activate 50% of the PAA block carboxylates, followed by 2,2′-(ethylenedioxy)bis(ethylamine) to cross-link these carboxylates. For IDA functionalization, 5.0 mL of magnetomicelle solution (effective carboxylic acid groups in PAA block = 2.41×10^{-8} mol) was mixed with 21.5 μL of freshly prepared EDC solution (1.0 mg/mL in H_2O, 3.0 equiv to carboxylic acid groups in the PAA block) with vigorous stirring. After 30 min of activation, 31.4 μL of *N*-hydroxysulfosuccinimide sodium salt (sulfo-NHS) (1.0 mg/mL in H_2O, 6.0 equiv to carboxylic acid groups in the PAA block) was added to the suspension. Solutions were stirred for 1.5 h, and the suspension was added dropwise to 32 μL of iminodiacetic acid (IDA) (1.0 mg/mL in H_2O, 10 equiv to carboxylic acid groups in the PAA block) in 1.0 mL of 10 mM $Na_2CO_3/NaHCO_3$ buffer (pH 9.5) (*22*). The solution was vigorously mixed for 24 h at room temperature and dialyzed against diH_2O (Spectra/Por 4 Regenerated Cellulose Membrane, MWCO = 12−14K) over 48 h. To this solution was added 7.2 μL of aqueous $CuSO_4 \cdot 5H_2O$ (10 mg/mL in H_2O, 10 equiv of carboxylic acid groups in the PAA block), and the mixture was

allowed to stand for 3 h to load IDA groups with Cu^{2+}; excess reagents were removed with extensive dialysis.

Characterization of Functionalized Magnetomicelles. Transmission electron microscopy (TEM) images were obtained on a JEOL 1210 electron microscope equipped with a Gatan video camera and a Gatan Multiscan CCD camera (1024 × 1024 pixels). Magnetomicelle solutions were dropped onto 300-mesh Formvar-graphite-coated copper TEM grids (Electron Microscopy Science, Hartfield, PA) and air-dried for TEM imaging. All images were obtained at an operating voltage of 120 kV.

Protein Preparation, Purification. Recombinant T4 DNA ligase (BL21(DE3)p-lysS, p3H11) (*23*), EGFP (pBAD-18-Cm) (*24*), and T7 RNA polymerase (M15:pDMI.1, p6HRNAP) (*25*), all containing His_6 fusion tags, were overexpressed in *E. coli* according to previously published protocols. Proteins were purified by affinity chromatography using Ni^{2+}-NTA-agarose resin (Qiagen) and eluted with imidazole-containing buffer. Product protein solutions were buffer-exchanged and concentrated by centrifugal dialysis using Centriprep YM-10 tubes (Amicon, Bedford, MA) and stored at −20 °C. Proteins were analyzed by 8% SDS-PAGE and their concentrations estimated by standard BCA protein assay.

Bioconjugate Preparation and Magnetic Separation. Suspensions of Cu^{2+}-IDA magnetomicelles were mixed with His_6-tagged proteins in Eppendorf tubes for 2 h at 4 °C. Magnets (NdFeB magnet, 0.14 T) were applied to the bottom and one side edge of the tubes for 1 h, and the supernatant (top 70% of solution) was pipetted away, in order to isolate the magnetomicelle−protein conjugates from unconjugated, free protein. The magnetomicelle−protein bioconjugates were then washed two to four times with diH_2O prior to protein analysis, elution, or enzymatic reaction. To wash, the magnet was removed from the bottom of the Eppendorf tube, residue was resuspended in an equal volume diH_2O, the magnets were reapplied for 1 h, and the supernatant (top 50%) was pipetted away.

T4 DNA Ligase−Magnetomicelle Assay. 450 μL of Cu^{2+}-IDA magnetomicelle solution was mixed with T4 DNAL and 10% SDS for a total reaction volume of 500 μL. Reactions were treated as described above in Bioconjugate Preparation and Magnetic Separation. T4 DNAL could be eluted from the magnetomicelles by resuspending magnetically separated residue in 75 μL 1 M imidazole, followed by a round of magnetic separation. The flow-through, washes, and final elution fraction were dialyzed overnight against diH_2O using Slide-A-Lyzer Mini Dialysis units (Pierce, Rockford, IL) at 4 °C. Dialyzed samples were lyophilized to dryness and resuspended in 10 μL for gel analysis by 8% SDS-PAGE. In control experiments, magnetomicelles were treated as described above, except that IDA and Cu^{2+} were omitted.

GFP−Magnetomicelle Assay. 200 μL of Cu^{2+}-IDA magnetomicelle solution was mixed with EGFP. Reactions were treated as described in Bioconjugate Preparation and Magnetic Separation. All washes and the final 60 μL fraction of EGFP−magnetomicelle bioconjugates were resuspended to 140 μL for fluorescence analysis. EGFP−magnetomicelle data reported is the average of six individual experiments. The steady-state fluorescence measurements were obtained with a Quantamaster Fluorimeter (PTI London, Ontario) at room temperature, using an excitation wavelength of 395 nm and emission and excitation slit widths of 2 nm. In all experiments, the raw average of two emission scans was reported. An EGFP fluorescence calibration curve was generated by magnetically separating 200 μL of nonfunctionalized magnetomicelle suspension, then removing 60 μL of the supernantant. The resulting 140 μL of micelle solution was mixed with known amounts of EGFP and the fluorescence intensity measured.

T7 RNA Polymerase Activity. 200 μL of Cu^{2+}-IDA magnetomicelle solution was mixed with T7 RNAP. Reactions were treated as described in Bioconjugate Preparation and Magnetic Separation. The final 60 μL fraction of T7 RNAP−magnetomicelle bioconjugates were added to transcription reactions, performed at 37 °C for 4 h, in the presence of 10× transcription buffer (0.4 M Tris·Cl, pH 8.0, 60 mM $MgCl_2$, 0.01 M spermidine, 0.1% 1090 Triton, BSA and DTT), 4 mM each NTPs, 1 μM template DNA, 20 mM $MgCl_2$, and 10 mM DTT for a final reaction volume of 100 μL. Template DNA was (i) a 155-mer, PCR-generated synthetic template containing the DNA sequence for the T7 RNAP promoter or (ii) plasmid DNA (3.4 kb), which contains the T7 RNA promoter and the DNA template for *E. coli* $tRNA^{Pro}$ RNA (76-mer) (*26*). Plasmid DNA was digested with *Bst*N1 and gel-purified prior to transcription. For T7 RNAP−magnetomicelle recycling experiments, after the first transcription reaction, the reaction solution was magnetically separated and 70% of the free reaction solution was removed (70 μL) for gel analysis. The remaining 30 μL of T7 RNAP−magnetomicelle bioconjugates were resuspended to 120 μL with diH_2O and treated according to Bioconjugation Preparation and Magnetic Separation, described above. The final 60 μL was reused in a second transcription reaction. Transcription products (RNA) were analyzed by denaturing 12% PAGE. Control experiments were preformed as described above, except that all the fractions were collected without the application of the magnets. In addition, reactions were run with unconjugated T7 RNAP and T7 RNAP mixed with magnetomicelles that were not washed from T7 RNAP free in solution.

RESULTS

On the basis of our previous studies on the synthesis and functionalization of copolymer micelle-encapsulated nanoparticles (*20, 27, 28*), we anticipated that γ-Fe_2O_3 magnetomicelles would be excellent supports for proteins. Encapsulation of γ-Fe_2O_3 magnetic nanoparticles within cross-linked surfactant shells makes it possible to take advantage of the nanoparticles' intrinsic properties without the need to develop specific chemistries for directly attaching proteins to the nanoparticle surface. The surfactant shell also stabilizes the particles to physical and chemical manipulation in biological buffers and protects proteins from direct contact with the core nanoparticle surfaces. In this study, we used magnetomicelles in which 50% of the PAA carboxylates were cross-linked, leaving the other 50% available for bioconjugation.

The bioconjugate chemistry used in this study is based on immobilized metal affinity chromatography (IMAC), a common

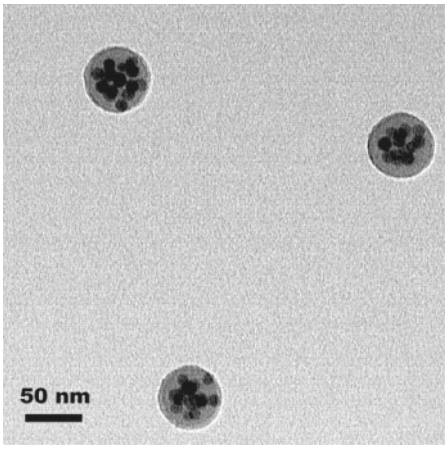

Figure 1. Representative TEM micrograph of Cu^{2+}-IDA functionalized magnetomicelles. Multiple γ-Fe_2O_3 nanoparticles are confined within each polymer micelle core, and the average Cu^{2+}-IDA magnetomicelle diameter is 50 nm.

technique for the purification of recombinant proteins (*29*, *30*). In IMAC, His_6−protein fusions are initially bound to Ni^{2+}- or Co^{2+}-loaded nitriloacetic acid (NTA) groups on functionalized resin and can be subsequently eluted from the support by exposure to imidazole solution. Interactions between His_6 tags and metal-NTA groups have recently been used to capture proteins on the surfaces of various types of nanostructures, including gold (*21*) and magnetic nanoparticles (*18*, *19*) and magnetic nanorods (*31*). We chose to functionalize magnetomicelles with Cu^{2+}-IDA rather than Ni^{2+}- or Co^{2+}-NTA due to its higher binding affinity for the polyhistidine fusion tag (*32*, *33*). Magnetomicelle carboxylates were converted to IDA groups via EDC coupling. Particles were then exposed to Cu^{2+} and washed to prepare them for protein loading. TEM micrographs of Cu^{2+}-IDA functionalized magnetomicelles appeared identical to those taken prior to functionalization (Figure 1). Further characterization by X-ray photoelectron spectroscopy (XPS) confirmed the presence of copper in dialyzed Cu^{2+}-IDA magnetomicelle preparations. By contrast, control samples in which EDC was omitted from the magnetomicelle functionalization exhibited no XPS peak corresponding to copper (data not shown). This experiment indicates that IDA functionalization was required to bind Cu^{2+}. Suspensions of Cu^{2+}-IDA magnetomicelles were stable for at least several months but were typically bound to proteins soon after synthesis. Assuming that functionalization with IDA was similar to that of primary amines studied previously in our group, we estimate that several hundred Cu^{2+}-IDA molecules can be attached to the surface of a single, 50-nm magnetomicelle (*20*).

We initially evaluated Cu^{2+}-IDA magnetomicelles as protein supports by using them to capture His_6-tagged T4 DNA ligase (T4 DNAL). These experiments were designed to mimic standard, column-based IMAC protein purification protocols. Proteins were first captured by suspended nanoparticles, which were washed to remove unbound protein. Then, an IMAC-competing ligand, imidazole, was added to elute the protein from its nanoparticle supports (*34*). In all experiments, excess T4 DNAL was added to the functionalized magnetomicelles to saturate the particles with protein. Numerous cycles of magnetic separation and washing were used to remove unbound protein. The supernatant recovered from each step of protein bioconjugation and purification was analyzed by gel electrophoresis (Figure 2a). Excess unbound protein was recovered only in initial washing steps; subsequent magnetic separations and redispersion showed no loss of bound T4 DNAL to the supernatant. Elution with imidazole, however, yielded a single band on the SDS-PAGE gel corresponding to pure T4 DNAL.

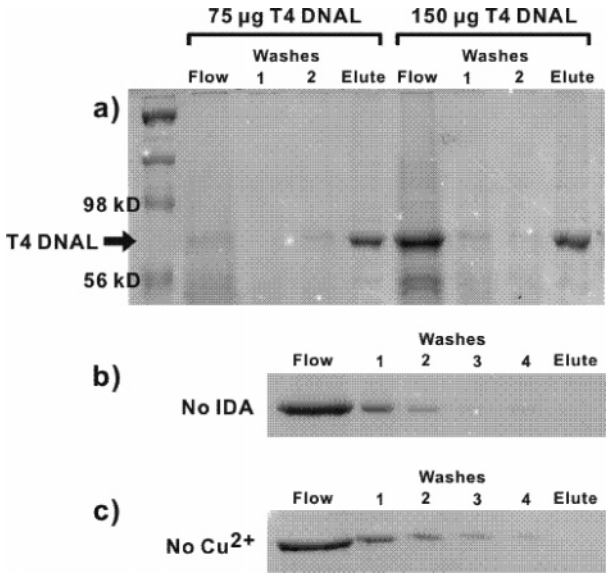

Figure 2. SDS-PAGE gel of T4 DNA ligase (68 kD) captured and isolated from ~2 × 1011 magnetomicelles (400 μL magnetomicelle solution), where (a) micelles were conjugated with varying amounts of T4 DNA ligase, or where (b) IDA or (c) Cu^{2+} was omitted from the preparation. Flow: Unbound material collected from supernatant after initial conjugation. Washes: Material collected from diH_2O wash steps. Elute: Material collected after exposure to 500 μM imidazole.

The binding capacity for T4 DNAL was dependent on the magnetomicelle concentration, such that the amount of T4 DNAL captured by equal suspensions of magnetomicelles was qualitatively reproducible, regardless of the amount of protein initially mixed with the nanoparticles. For example, magnetomicelle preparations mixed with 75 or 150 μg of T4 DNAL eluted similar quantities of protein after T4 DNAL−magnetomicelle purification (Figure 2a, elute lanes; additional data not shown).

Control experiments verified the specificity of the interaction between the Cu^{2+}-loaded IDA groups and the His_6 tags. In general, proteins lacking His_6 fusion tags did not bind to the surfaces of magnetomicelles. As a result, when particles were mixed with impure preparations of T4 DNAL, the imidazole-eluted protein was always observed to be more pure than the starting material by SDS-PAGE analysis (Figure 2a; additional data not shown). In addition, control experiments in which magnetomicelles were either not functionalized with IDA or not loaded with Cu^{2+}, exposed to T4 DNAL, and then subjected to elution conditions showed negligible protein capture. Instead, the T4 DNAL mixed with these preparations was recovered from the reaction solution during magnetic separation and washing (Figure 2b,c). This data confirms that the interaction between the particle-bound Cu^{2+}-IDA groups and the His_6 tag is highly specific. Similar work on monolithic, PAA-coated surfaces that had been modified with metal-NTA groups has shown low nonspecific binding in the absence of metal or ligand (*35*).

In order to quantify the protein bound to magnetomicelles, we analyzed particles conjugated to His_6-tagged enhanced green fluorescent protein (EGFP). The intrinsic fluorescence of GFP has been previously used in protein attachment to surfaces (*36*, *37*), supported membranes (*38*), and particles (*18*, *39*). Here, to further quantify the effectiveness of magnetomicelle protein loading, as well as to verify protein integrity after conjugation, His_6-tagged EGFP was captured by the magnetomicelles. As with His_6-T4 DNAL, gel electrophoresis experiments demonstrated that His_6-EGFP could be bound to the magnetomicelle surface and eluted with imidazole (*34*).

The conjugation and surface density of His_6-EGFP was also monitored by fluorescence spectroscopy. Overall, the fluores-

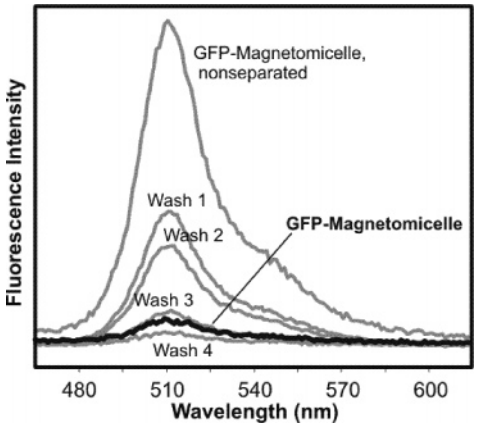

Figure 3. Fluorescence spectra of GFP−magnetomicelles, prior to magnetic separation, after all subsequent washes and after recovery of the bioconjugate solution. Bioconjugates were washed until the fluorescence intensity was negligible (wash 4), followed by GFP−magnetomicelle analysis.

cence spectrum of EGFP was not affected by conjugation to the particles. After mixing His_6-EGFP with the magnetomicelle suspension, the mixture was magnetically separated and washed until the supernatant exhibited no significant fluorescence (Figure 3). Then, the fluorescence signal from the EGFP−magnetomicelle bioconjugates was measured. When limiting amounts of His_6-EGFP were added to the preparation, the fluorescence intensity of these suspensions increased with increasing EGFP concentration. At the saturating concentration of His_6-EGFP, we estimate that 300 molecules of EGFP are attached to each 50-nm-diameter magnetomicelle in solution, based on the final fluorescence intensity of the suspension, or one molecule of EGFP per 26 nm^2 of particle surface. Given that GFP has a footprint of 12 nm^2 (*40*), this corresponds to a fairly high surface density of attached protein. The high density of conjugated EGFP molecules is consistent with our previous study, which indicated that around 600 molecules of NH_2-(ethylene glycol)$_5$-fluorescein functionalized the surface of a single magnetomicelle (*20*). The fluorescence intensity of the conjugates also suggests that EGFP remains intact while conjugated to the surface of the magnetomicelles, due to the retention of the protein's intrinsic fluorescence. Attaching GFP to magnetomicelles gives us a quantitative way to measure the magnetomicelle−protein loading capacity.

In order for magnetic nanoparticles to be useful as supports for enzymes, the bound enzyme must maintain its native activity even after repeated physical manipulation. A variety of enzymes have been used as models for evaluating the activity of particle-bound enzymes, including *Candida rugosa* lipase (*41*), horseradish peroxidase (*21*, *42*), proteases (*43*, *44*), and glucose oxidase (*3*). To test the use of magnetomicelles as recyclable supports for enzymes used in molecular biology, we used magnetomicelles in conjunction with an enzyme routinely used for the in vitro transcription of RNA, T7 RNA polymerase (T7 RNAP). Like most enzymes in molecular biology protocols, T7 RNAP is by far the most expensive reagent used in a transcription reaction, and we expected that attaching the enzyme to magnetomicelles would allow it to be recycled after use. However, T7 RNAP is susceptible to inhibition by a variety or reaction contaminants (*45*), and so we first tested whether transcription was inhibited by the magnetomicelle supports. Cu^{2+}-IDA magnetomicelles (with no protein attached) were added to otherwise ordinary transcription reactions of two separate dsDNA templates: a 155-nt, linear template that generates a 135-mer mRNA, and 3.4 kb plasmid that yields the 76-mer $tRNA^{Pro}$ (*26*). Gel electropherograms of the RNA

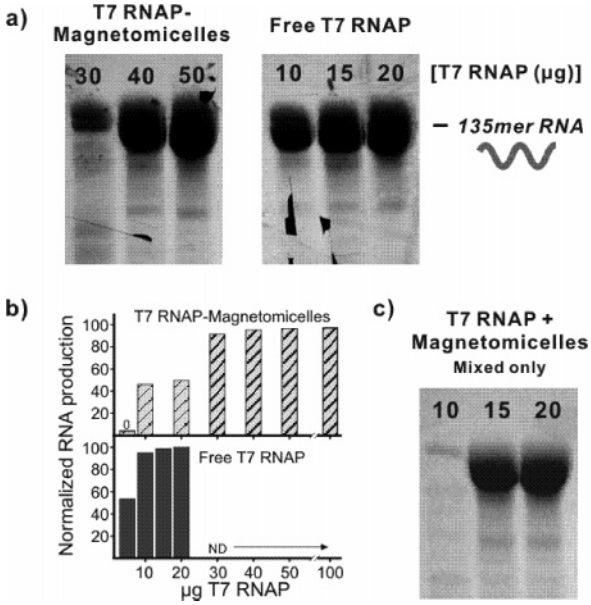

Figure 4. (a) Representative urea-PAGE gel images of RNA produced by T7 RNAP−magnetomicelles or free T7 RNAP, at concentrations where the enzyme was the limiting reagent. (b) Graphical analysis of densitometry studies of numerous gel images. Transcription data for free T7 RNAP at concentrations above 20 μg were not determined (ND), because the maximum level of RNA production was reached by 20 μg of enzyme. The data was normalized, such that the RNA generated with 20 μg of free T7 RNAP was set to 100%. No RNA was detected with 5 μg of T7 RNAP bound to the magnetomicelles. (c) Urea-PAGE gel of RNA produced when magnetomicelle suspension was added to a transcription reaction already in progress.

products produced in the absence or presence of Cu^{2+}-IDA magnetomicelles were indistinguishable (data not shown).

Additional experiments with magnetomicelle-bound RNA polymerase demonstrate that these materials are active, recoverable catalysts for transcription. Magnetomicelles were loaded with His_6-T7 RNAP, washed exhaustively, and used in place of free T7 RNAP to transcribe the two DNA templates described above. Conjugated T7 RNAP successfully transcribed both linear and plasmid DNA to RNA under standard reaction conditions (*34*). Cu^{2+}-IDA magnetomicelles that had been incubated with T7 RNAP that lacked a His_6 tag, by contrast, failed to catalyze DNA transcription (*34*). We conclude that, as was true for His_6-T4 DNAL and His_6-GFP, the hexahistidine tag is required to conjugate T7 RNAP to Cu^{2+}-IDA magnetomicelles and nonspecific adsorption of active catalyst was not significant.

In order to relate the activity of T7 RNAP−magnetomicelles to that of free T7 RNAP, we compared the amount of RNA product generated in side-by-side reactions using both catalysts. Experiments were conducted in which the enzyme was a limiting reagent for RNA production, and in all cases, the amount of DNA template was held constant at 1 μM. As is true for T7 RNAP alone, increasing concentrations of RNAP-loaded magnetomicelles increased transcription efficiency (Figure 4a). Collectively, using densitometry to quantify the amount of RNA produced, these transcription assays reveal that efficient transcription requires 3−4 times the amount of T7 RNAP to be conjugated to the magnetomicelle surfaces versus free enzyme in solution (Figure 4b). However, we found that any manipulation of the standard transcription reaction, including adding magnetomicelles to a transcription reaction already in progress, causes a slight decrease in RNA production (Figure 4c). As a result, it is possible that the magnetomicelle solution is slightly inhibitory to T7 RNAP, regardless of its bound or unbound state, or causes RNA degradation, perhaps due to the presence of RNases.

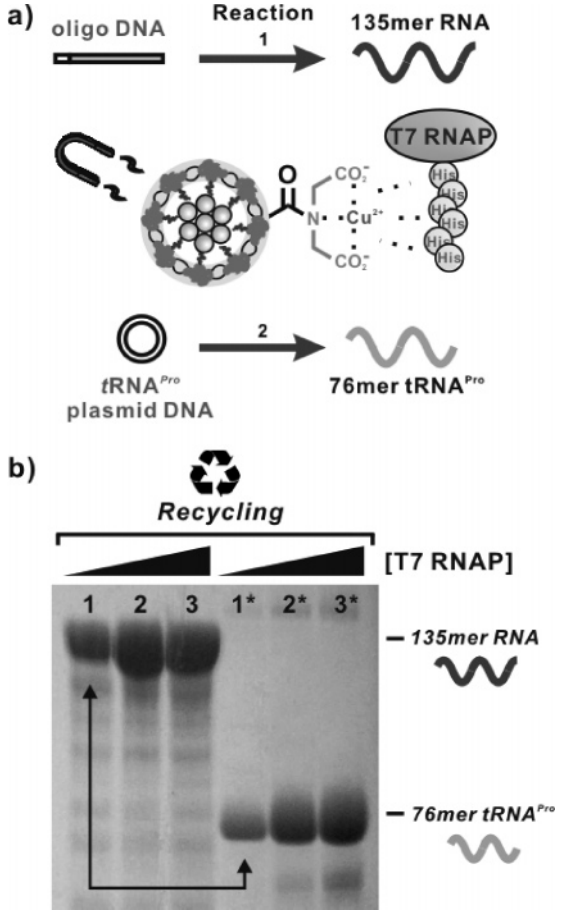

Figure 5. (a) T7 RNAP−magnetomicelle recycling scheme. (b) Urea-PAGE gel of RNA produced by T7 RNAP−magnetomicelles. Starred lanes represent the second reaction performed with the recycled T7 RNAP−magnetomicelle bioconjugates from the similarly numbered but unstarred lanes. The concentration of T7 RNAP conjugated to the magnetomicelles increased from lanes 1−3.

Consequently, to further justify the utility of our protein−magnetomicelle bioconjugates, we tested the recyclability of the conjugates. Recycling biologically relevant enzymes, for as little as one or two subsequent assays, could greatly reduce experimental times and costs. To test whether magnetomicelle-bound enzymes could be recycled and reused without contamination from prior reactions, we designed a transcription assay using T7 RNAP−magnetomicelles and the two different DNA templates (for 135-nt mRNA and 76-nt $tRNA^{Pro}$) described above. The first reaction was performed in the presence of one DNA template, followed by magnetic separation of the T7 RNAP−magnetomicelles, removal of the RNA product generated, washing, and a second transcription with the separated bioconjugates and the opposite DNA template (Figure 5a). Incomplete washing of the recycled T7 RNAP−magnetomiclles would be assayed by the production of the first RNA product in the second reaction. As a result, up to four T7 RNAP−magnetomicelle washes were required to remove DNA contamination in a second reaction (*34*). To our surprise, T7 RNAP−magnetomicelles successfully transcribed RNA up to three times, although only the first two reactions produced levels of RNA with no qualitative loss in T7 RNAP activity (Figure 5b). Additionally, the amount of RNA produced from recycled T7 RNAP was dependent on the concentration of T7 RNAP conjugated to the magnetomicelle surface. The recovery and reuse of T7 RNAP is significant, considering the complexity of the transcription reaction and the fragility of T7 RNAP.

DISCUSSION

Nanoparticle-supported proteins have considerable potential in a variety of biotechnological areas, mostly limited by the bioconjugation chemistries available for joining proteins and particles and the biocompatibility of the protein for the solid support. In the present study, we have proposed a new composite nanostructure suitable for protein bioseparation and enzymatic recycling. Our method takes advantage of IMAC chemistry and requires His-tagged recombinant proteins for attachment to encapsulated, magnetic γ-Fe_2O_3 particles. Specifically, using His_6-tagged T4 DNAL, we demonstrated reproducible binding capacity on the surface of the magnetomicelles and specific protein capture through the His_6-Cu^{2+}-IDA interaction. This highly specific protein attachment is likely a factor for the retention of enzyme function in subsequent experiments. We argue that these nanoparticle supports should be versatile, as the carboxylic acid groups available on the surface of the magnetomicelles could be further functionalized to recognize other distinctive protein features for bioconjugation and could in turn provide additional scenarios for specific protein capture.

Additionally, by quantifying the amount of His_6-EGFP conjugated to a magnetomicelle surface, we revealed large loading capacities of bound, intact protein. The high surface-to-volume ratio afforded by conjugating proteins to nanoparticle supports is a clear advantage over other solid-supported enzyme techniques. Furthermore, the Cu^{+2}-IDA magnetomicelles utilized in these examples were prepared by cross-linking 50% of available carboxylic acid groups prior to Cu^{+2}-IDA functionalization and subsequent protein attachment. We envision that this system could be modified to accommodate more or fewer IDA groups to tailor the number of conjugated proteins.

Most importantly, Cu^{+2}-IDA magnetomicelles were biocompatible in transcription reactions performed with bound T7 RNAP, with only subtle losses in enzyme activity. This lower activity could be due to enzyme denaturation or a structural change at the particle surface, as has been previously demonstrated for adsorbed protein−nanoparticle conjugates (*10*), or a portion of the bound protein may be less accessible for catalysis than in free solution. Although the loss in RNA production after T7 RNAP bioconjugation to magnetomicelles was not favorable, we are optimistic that magnetomicelle supports could be applicable for the conjugation of other proteins. Reports of catalyst activity on magnetic supports is diverse for particle-bound enzymes, ranging from a significant or complete loss in activity to an increase in catalytic function (*41*, *46*−*48*). Therefore, despite the variability in surface-bound enzyme activity, there remains great interest in the potential for magnetic enzyme carriers that permit easy enzyme separation and reuse.

Recyclable biocatalysts are becoming more widely used for organic transformations in industrially relevant reactions (*6*). Our work, by contrast, is one of the first examples of magnetic recycling of an enzyme used in a molecular biology transformation under strict biological conditions. In principle, our enzyme−magnetomicelle system could be broadly applied for the separation and reuse of a variety of enzymes under diverse reaction conditions. In addition to the advantages that protein−magnetomicelles offer to protein separation, analysis, and enzyme reuse, we envision that proteins attached to the surface of magnetomicelles could also facilitate targeted, magnetic drug delivery (*49*) or be used in in vivo imaging systems (*50*, *51*).

ACKNOWLEDGMENT

We would like to acknowledge the NIH (EB003809) for support of this research; A.R.H. also acknowledges Abbey E. Rosen and the Karin Musier-Forsyth group for their generous gift of the $tRNA^{pro}$ plasmid DNA, as well as clones for T4

DNAL and T7 RNAP. Additionally, A.R.H. would also like to thank Jennifer Maynard for the EGFP clone. K.B.S. thanks Dr. Taewoon Cha for XPS analysis.

Received July 27, 2006; Revised Manuscript Received November 17, 2006

Renal localization of radiolabeled antibody fragments constitutes a problem in targeted imaging and radiotherapy. We have reported that Fab fragments labeled with 3′-[^{131}I]iodohippuryl N^{ϵ}-maleoyl-lysine (HML) showed markedly low renal radioactivity levels even shortly after injection, due to a rapid and selective release of *m*-[^{131}I]iodohippuric acid by the action of brush border enzymes. To estimate the applicability of the molecular design to metallic radionuclides, [^{188}Re]tricarbonyl(cyclopentadienylcarbonate)rhenium ([^{188}Re]CpTR-COOH) was conjugated with N^{ϵ}-tert-butoxycarbonyl-glycyl-lysine or N^{ϵ}-maleoyl-glycyl-lysine to prepare [^{188}Re]CpTR-GK-Boc or [^{188}Re]CpTR-GK. The cleavage of the glycyl-lysine linkage of the two compounds generates a glycine conjugate of [^{188}Re]-CpTR-COOH ([^{188}Re]CpTR-Gly), which possesses in vivo behaviors similar to those of *m*-iodohippuric acid. The hydrolysis rate of the peptide bond in [^{188}Re]CpTR-GK-Boc was compared with that in 3′-[^{125}I]iodohippuryl N^{ϵ}-Boc-lysine ([^{125}I]HL-Boc) using brush border membrane vesicles (BBMVs) prepared from rat kidneys. [^{188}Re]-CpTR-GK was conjugated to thiolated Fab fragments to prepare [^{188}Re]CpTR-GK-Fab. The biodistribution of radioactivity after injection of [^{188}Re]CpTR-GK-Fab was compared with that of [^{125}I]HML-Fab and [^{188}Re]CpTR-Fab prepared by conjugating *N*-hydroxysuccinimidyl ester of [^{188}Re]CpTR-COOH with antibody fragments. While [^{188}Re]CpTR-GK-Boc liberated [^{188}Re]CpTR-Gly in BBMVs, [^{125}I]HL-Boc liberated *m*-[^{125}I]iodohippuric acid at a much faster rate. In addition, although [^{125}I]HL-Boc was hydrolyzed by both metalloenzymes and nonmetalloenzymes, metalloenzymes were responsible for the cleavage of the peptide linkage in [^{188}Re]CpTR-GK-Boc. In biodistribution studies, [^{188}Re]CpTR-GK-Fab exhibited significantly lower renal radioactivity levels than did [^{188}Re]CpTR-Fab. However, the renal radioactivity levels of [^{188}Re]CpTR-GK-Fab were slightly higher than those of [^{125}I]HML-Fab. The analysis of urine samples collected for 6 h postinjection of [^{188}Re]CpTR-GK-Fab showed that [^{188}Re]CpTR-Gly was the major radiometabolite. In tumor-bearing mice, [^{188}Re]CpTR-GK-Fab significantly reduced renal radioactivity levels without impairing the radioactivity levels in tumor. These findings indicate that the molecular design of HML can be applied to metallic radionuclides by using a radiometal chelate of high inertness and by designing a radiometabolite of high urinary excretion when released from antibody fragments following cleavage of a glycyl-lysine linkage. This study also indicates that a change in chemical structure of a radiolabel attached to a glycyl-lysine linkage significantly affected enzymes involved in the hydrolysis reaction. Since there are many kinds of enzymes that cleave a variety of peptide linkages on the renal brush border membrane, selection of a peptide linkage optimal to a radiometal chelate of interest may provide radiolabeled antibody fragments that exhibit renal radioactivity levels similar to those of [^{131}I]HML-labeled ones. The in vitro system using BBMVs might be useful for selecting an appropriate peptide linkage.

INTRODUCTION

When injected into body, radiolabeled antibody fragments and peptides show high and persistent localization of radioactivity in the kidneys from early postinjection times, which impairs diagnostic accuracy and limits therapeutic potential (*1*−*5*). To circumvent the problem, we have developed a radioiodination reagent for antibody fragments, 3′-iodohippuryl N^{ϵ}-maleoyl-L-lysine (HML, Figure 1A), based on the hypothesis that the glycyl-lysine linkage in HML would be cleaved by the action of enzymes present on the lumen of renal tubules while the antibody fragments are taken up by renal cells (*6*). Indeed, [^{131}I]-HML-conjugated Fab fragments (Figure 1) significantly reduced renal radioactivity levels shortly after injection without impairing radioactivity levels in the tumor (*6, 7*). Subsequent in vivo and in vitro studies supported that the cleavage of the glycyl-lysine linkage occurred at the membrane fraction of renal cells (*8*) and that enzymes on the renal brush border membrane were responsible for cleaving the glycyl-lysine linkage in HML (*9*).

Since high and persistent radioactivity levels in the kidney are observed with antibody fragments and peptides particularly labeled with metallic radionuclides (*4, 10*−*13*), application of the molecular design of HML to metallic radionuclides constitutes an attractive approach to reduce renal radioactivity levels. Recently, Li et al. developed bifunctional chelating agents with glycyl-lysine linkages to reduce renal radioactivity levels of ^{111}In-labeled diabodies (*14*). Although one of the ^{111}In-labeled diabodies significantly reduced renal radioactivity levels, further reduction in the renal radioactivity levels was required for clinical application.

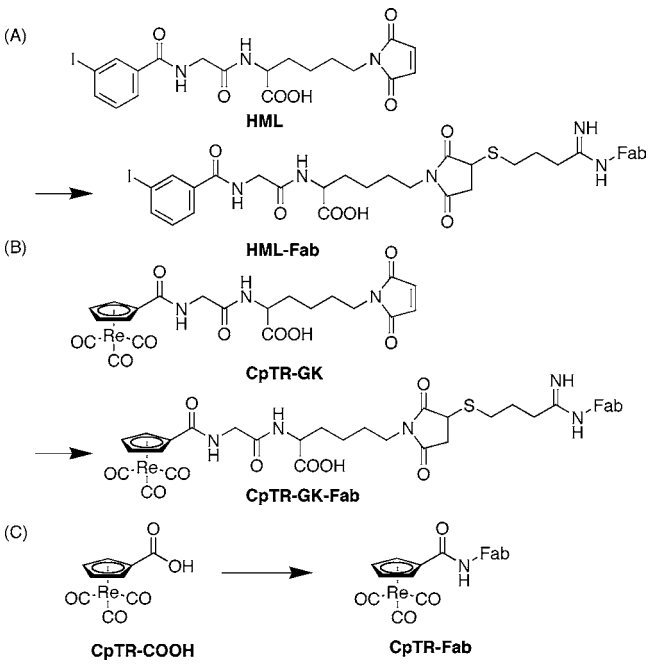

Figure 1. Chemical structures of (A) HML, (B) CpTR-GK, and (C) CpTR-COOH and their Fab conjugates. Both HML and CpTR-GK were conjugated to thiol groups of 2-iminothiolane-modifided Fab fragments, while CpTR-COOH was coupled directly to amine residues of Fab fragments.

Since HML was designed to liberate a radiometabolite of urinary excretion from covalently conjugated antibody fragments by the action of renal brush border enzymes, a radiometal chelate released from antibody molecules following cleavage of a glycyl-lysine linkage should possess biological behaviors similar to those of *m*-iodohippuric acid. In addition, our prior study indicates the involvement of some metalloenzymes in cleaving the glycyl-lysine linkage in HML (*9*). Since the majority of chelating agents in radiolabeled antibody fragments are free of radiometal ions, care should be taken so as not to inactivate metalloenzymes on the renal brush border membrane. On these bases, we estimated applicability of the molecular design of HML to metallic radionuclides using organorhenium compounds, due to their extremely high chemical inertness (*15*). Our previous study also indicated that [188Re]tricarbonyl-(cyclopentadienylcarbonate)rhenium ([188Re]CpTR-COOH) was metabolized to glycine conjugate ([188Re]CpTR-Gly) in vivo and that [188Re]CpTR-Gly possessed in vivo behaviors similar to those of *m*-iodohippuric acid (*16*). In addition, chemical structures of CpTR-Gly and its derivatives are well-characterized using non-radioactivity rhenium compounds.

In this study, [188Re]CpTR-COOH was coupled with N^{ϵ}-maleoyl-glycyl-lysine or N^{ϵ}-*tert*-butoxycarbonyl-glycyl-lysine to prepare [188Re]CpTR-GK or [188Re]CpTR-GK-Boc (Figure 1B). In vitro hydrolysis rates of the glycyl-lysine linkages in [188Re]CpTR-GK-Boc and 3′-[125I]iodohippuryl N^{ϵ}-Boc-lysine ([125I]HL-Boc) were compared using renal brush border membrane vesicles (BBMVs) (*9*). The biodistribution of radioactivity was compared after injection of Fab fragments conjugated with [188Re]CpTR-GK, [125I]HML, or [188Re]CpTR-COOH (Figure 1) to estimate in vivo cleavage of the glycyl-lysine linkage in [188Re]CpTR-GK. The applicability of the molecular design of HML to metallic radionuclides was assessed, and future application of the strategy will be discussed.

EXPERIMENTAL PROCEDURES

Materials. 188W was supplied as [188W]Na_2WO_4 in sodium hydroxide solution (17−29 MBq/mL) by the Japan Atomic Energy Agency (Tokai-Mura, Japan). 188Re was eluted from a 188W/188Re generator system prepared by the method of Callahan et al. (*17, 18*). Reversed-phase HPLC (RP-HPLC) was performed with a Cosmosil 5C_{18}-AR-300 column (4.6 × 150 mm, Nacalai Tesque, Kyoto, Japan) at a flow rate of 1 mL/min with a gradient mobile phase starting from 80% A (0.1% aqueous trifluoroacetic acid (TFA)) and 20% B (acetonitrile with 0.1% TFA) to 20% A and 80% B at 30 min (solvent system 1) or from 100% A (water) and 0% B (acetonitrile) to 0% A and 100% B at 30 min (solvent system 2). Size-exclusion HPLC (SE-HPLC) was performed using a Cosmosil Diol-300 column (7.5 × 600 mm, Nacalai Tesque) eluted with 0.1 M phosphate buffer (pH 6.8) at a flow rate of 1 mL/min. Each eluent was collected with a fraction collector (RadiFlac, GE healthcare bioscience, Tokyo, Japan) at 30-s intervals, and the radioactivity levels in each fraction (500 μL) were determined with an auto well gamma counter (ARC-380M, Aloka, Tokyo). TLC analyses were performed with silica plates (Silica gel 60 F_{254}, Merck, Tokyo) developed with chloroform (solvent system 3) or 80% methanol (solvent system 4). 188Re complexes were purified by SepPak plus cartridge (C_{18} short body, 360 mg/cartridge, Waters, Tokyo) activated with 6 mL each of ethanol and water prior to use. Proton nuclear magnetic resonance (^{1}H-NMR) spectra were recorded on a JEOL JNM-ALPHA 400 spectrometer (JEOL Ltd., Tokyo) with tetramethylsilane as an internal standard. FAB-MS was taken on a JEOL JMS-HX-110A mass spectrometer (JEOL Ltd., Tokyo). Elemental analyses were performed by PE-2400 (Perkin-Elmer Japan, Tokyo). Two masses were reported for rhenium-containing fragments to indicate the significant isotopic abundances of both 185Re and 187Re. Each peak was observed to have the proper relative abundances. The following compounds were prepared as described previously: [188Re]tricarbonyl(cyclopentadienylcarbonate)rhenium ([188Re]-CpTR-COOH), non-radioactive CpTR-COOH and [188Re]tricarbonyl[(cyclopentadienylcarbonyl amino)-acetic acid]rhenium ([188Re]CpTR-Gly) (*16*), *N*-methoxycarbonylmaleimide (**5**) (*19*), 3-(tri-*n*-butylstannyl)hippuric acid, 3-iodohippuric acid, and [125I]HML-Fab (*20*) and 3′-[125I]iodohippuryl N^{ϵ}-*tert*-butoxycarbonyl-L-lysine ([125I]HL-Boc) (*9*). Human carcinoembryonic antigen (CEA)-positive human gastric cancer strain (MKN-45) and a monoclonal antibody against CEA (1B2) were supplied by Immuno-Biological Laboratories Co. Ltd. (Takasaki, Japan). Other reagents were of reagent grade and used as received.

Tumor and Monoclonal Antibody. CEA-positive human gastric cancer strain MKN-45 was transplanted into subcutaneously and pieces of tumor tissue (∼0.5 g) were used for the in vivo study. The Fab fragment of monoclonal antibody against CEA (1B2) was prepared using a Fab preparation kit (ImmunoPure IgG_1 Fab and $F(ab')_2$ Preparation kit, Pierce, Rockford, USA).

Synthesis of N^{α}-(*tert*-Butoxycarbonyl)-glycyl-N^{ϵ}-carbobenzoxy-L-lysine-*tert*-butyl Ester (3). *N*-(*tert*-Butoxycarbonyl)-glycine (**1**) (2.8 g, 16.1 mmol), N^{ϵ}-carbobenzoxy-L- lysine-*tert*-butyl ester hydrochloride (**2**) (5.0 g, 13.4 mmol), and 1-hydroxybenzotriazole (HOBt, 2.4 g, 16.1 mmol) were dissolved in dimethylformamide (DMF, 80 mL). After the sample was cooled to 0 °C, 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC, 4.26 g, 22.5 mmol) and diisopropylethylamine (DIEA, 6.1 mL, 35.9 mmol) in DMF (20 mL) was added dropwise to the solution, and the reaction mixture was stirred for 4 h at 0 °C. After the sample was stirred overnight at room temperature, the solvent was removed in vacuo, and the residue was dissolved in ethyl acetate (20 mL). The organic phase was washed with 1% H_2SO_4 (20 mL × 3), saturated NaCl solution (20 mL × 3) and saturated $NaHCO_3$ solution (20 mL× 3), successively, and dried over anhydrous $CaSO_4$. After the solvent was removed, the residue was purified with silica gel chroma-

tography using a mixture of chloroform and methanol (9:1) as an eluent to produce compound **3** (4.7 g, 71.2%) as a colorless oil. ^{1}H-NMR ($CDCl_3$): δ 1.25−1.81 (6H, m, $(CH_2)_3$), 1.40−1.43 (9H, s, Boc), 1.40−1.43 (9H, s, *tert*-butyl), 3.14 (2H, t, CH_2), 3.75 (2H, d, CH_2), 4.37 (1H, q, CH), 4.93 (1H, s, NH), 5.07 (2H, s, CH_2), 5.14 (1H, s, NH), 6.58 (1H, s, NH), 7.22−7.33 (5H, m, phenyl); FAB-MS $(M + H)^+$: *m/z* 494, Found: 494.

Synthesis of N^{α}-(*tert*-Butoxycarbonyl)-glycyl-L-lysine-*tert*-butyl Ester (4). Compound **3** (4.7 g, 9.6 mmol) and 10% Pd on activated carbon (0.9 g) in 13% aqueous methanol was stirred under a hydrogen atmosphere for 2 h. The catalyst was removed by filtration, and the filtrate was evaporated in vacuo to provide compound **4** (3.1 g, 90%) as a colorless oil. ^{1}H-NMR (CD_3OD): δ 1.33−1.95 (6H, m, $(CH_2)_3$), 1.48−1.49 (9H, s, Boc), 1.48−1.49 (9H, s, *tert*-butyl), 2.94 (2H, t, CH_2), 3.77 (2H, d, CH_2), 4.35 (1H, s, CH); FAB-MS $(M + H)^+$: *m/z* 360, Found: 360.

Synthesis of N^{α}-(*tert*-Butoxycarbonyl)-glycyl-N^{ϵ}-maleoyl-L-lysine-*tert*-butyl Ester (6). Compound **6** was synthesized according to the procedure described previously with slight modifications (*19*). To a solution of compound **4** (1.37 g, 3.8 mmol) in saturated $NaHCO_3$ (18.8 mL) was added a solution of compound **5** (0.71 g, 4.6 mmol) dissolved in tetrahydrofuran (37.6 mL) at 0 °C, and the reaction mixture was stirred for 2 h while the pH was maintained at 8.7 by the addition of 2 N NaOH. After the solution was acidified to pH 3−4 with conc. H_2SO_4, crude compound **6** was extracted with ethyl acetate (20 mL × 3) and dried over anhydrous $CaSO_4$. After the solvent was removed in vacuo, the residue was purified with silica gel chromatography using a mixture of chloroform and methanol (99:1) as an eluent to produce compound **6** (1.05 g, 61.7%) as a colorless oil. ^{1}H-NMR ($CDCl_3$): δ 1.18−1.76 (6H, m, $(CH_2)_3$), 1.36−1.40 (9H, s, Boc), 1.36−1.40 (9H, s, *tert*-butyl), 3.40 (2H, t, CH_2), 3.73 (2H, d, CH_2), 4.37 (1H, q, CH), 5.34 (1H, s, NH), 6.62 (2H, s, maleimide), 6.69 (1H, s, NH); FAB-MS $(M + H)^+$: *m/z* 440, Found: 440.

Synthesis of Glycyl-N^{ϵ}-maleoyl-L-lysine-*tert*-butyl Ester Hydrochloride (7). Compound **7** was synthesized according to the procedure of Kinoshita et al. (*21*) with slight modifications. Compound **6** (180 mg, 0.68 mmol) and anisole (0.5 mL) was dissolved in HCOOH (8.5 mL) and ether (1.0 mL) at 0 °C. After the sample was stirred at 15−17 °C for 3 h, the solvent was evaporated in vacuo. The residue was purified with reversed phase chromatography using a mixture of acetonitrile containing 0.01% HCl and water containing 0.01% HCl (20:80) as an eluent. The combined fractions were lyophilized to produce compound **7** (30 mg, 16.7%) as a white solid. ^{1}H-NMR (CD_3OD): δ 1.37−1.76 (6H, m, $(CH_2)_3$), 1.36−1.50 (9H, s, *tert*-butyl), 3.54 (2H, t, CH_2), 3.77 (2H, d, CH_2), 4.34 (1H, q, CH), 6.85 (2H, s, maleimide); FAB-MS $(M + H)^+$: *m/z* 340, Found: 340.

Synthesis of Tricarbonyl(cyclopentadienylcarbonyl glycyl-N^{ϵ}-maleoyl-L-lysine-*tert*-butyl ester)rhenium (8). CpTR-COOH (189.4 mg, 0.5 mmol), compound **7** (250 mg, 0.65 mmol) and HOBt (101.1 mg, 0.75 mmol) were dissolved in DMF (5 mL) at 0 °C, and a solution of EDC (118.8 mg, 0.62 mmol) in DMF (1 mL) and DIEA (217 μL, 1.27 mmol) were successively added to the solution. The reaction mixture was stirred for 4 h at 0 °C and overnight at room temperature. After the solvent was removed in vacuo, the residue was dissolved in ethyl acetate (20 mL), and the organic layer was successively washed with 1% H_2SO_4 (20 mL × 3), saturated NaCl (20 mL × 3), and saturated $NaHCO_3$ (20 mL × 3). After the sample was dried over anhydrous $CaSO_4$, the solvent was evaporated in vacuo, and the residue was purified by silica gel chromatography using a mixture of ethyl acetate:hexane (3:1) as an eluent to produce compound **8** (40 mg, 11.4%) as a colorless oil. ^{1}H-NMR ($CDCl_3$): δ 1.21−1.82 (6H, m, $(CH_2)_3$), 1.43 (9H, s, *tert*-butyl), 3.46−3.50 (2H, t, CH_2), 4.00 (2H, d, CH_2), 4.37−4.40 (1H, q, CH), 5.33−6.00 (4H, t, Cp), 6.67 (2H, s, maleimide), 6.77 (1H, d, NH), 7.30 (1H, t, NH); FAB-MS $(M + H)^+$: *m/z* 700/702, Found: 700/702.

Synthesis of Tricarbonyl(cyclopentadienylcarbonyl glycyl-N^{ϵ}-maleoyl-L-lysine)rhenium (CpTR-GK). Compound **8** (10 mg, 14.3 μmol) and anisole (25 μL) were dissolved in TFA (475 μL), and the mixture was stirred for 1 h. After the solvent was removed with a stream of N_2 gas, the residue was purified by RP-HPLC using solvent system 2 to produce CpTR-GK (4.6 mg, 50%). ^{1}H-NMR (CD_3OD): δ 1.21−1.82 (6H, m, $(CH_2)_3$), 3.46−3.50 (2H, t, CH_2), 4.15 (2H, d, CH_2), 4.46 (1H, q, CH), 5.37−6.08 (4H, t, Cp), 6.67 (2H, s, maleimide), 7.56 (1H, t, NH); FAB-MS $(M + H)^+$: *m/z* 644/646, Found: 644/646. Anal. ($C_{21}H_{21}N_3O_9Re$): C, H, N.

Synthesis of Carbobenzoxy-glycyl-N^{ϵ}-*tert*-butoxycarbonyl-L-lysine Methyl Ester (11). Carbobenzoxy-glycine (**9**) (84 mg, 0.40 mmol), N^{ϵ}-*tert*-butoxycarbonyl-L-lysine methyl ester hydrochloride (**10**) (100 mg, 0.34 mmol) and HOBt (54 mg, 0.40 mmol) were dissolved in DMF (5 mL) and cooled to −5 °C. A solution of EDC (77 mg, 0.40 mmol) in DMF (0.5 mL) and triethylamine (TEA; 56 μL, 0.40 mmol) were added to the solution, and the mixture was stirred for 3 h on ice. After the sample was stirred for an additional 6 h at room temperature, the solvent was removed in vacuo. The residue was resolved in chloroform (5 mL), and the organic phase was successively washed with 1% citric acid (5 mL × 3) and saturated $NaHCO_3$ (5 mL × 3) and was dried over anhydrous $CaSO_4$. After the solvent was removed in vacuo, compound **11** was obtained as a white solid (141 mg, 89.1%). ^{1}H-NMR ($CDCl_3$): δ 1.12−1.83 (15H, overlapped, Boc, $(CH_2)_3$), 3.06 (2H, d, CH_2), 3.71 (3H, s, OCH_3), 3.91 (2H, d, CH_2), 4.59 (1H, d, CH), 4.77 (1H, s, NH), 5.12 (2H, s, CH_2), 5.76 (1H, s, NH), 6.88 (1H, s, NH), 7.31 (5H, multi, aromatic); FAB-MS $(M + H)^+$: *m/z* 452, Found: 452.

Synthesis of Tricarbonyl(cyclopentadienylcarbonyl glycyl-N^{ϵ}-*tert*-butoxycarbonyl-L-lysine-methyl ester)rhenium (13). Compound **11** (67.7 g, 150 mmol) and 10% Pd on activated carbon (0.9 g) was dissolved in 5% aqueous methanol (2 mL), and the mixture was stirred under a hydrogen atmosphere for 12 h. The catalyst was removed by filtration, and the filtrate was evaporated in vacuo to produce crude compound **12**.

A mixture of crude compound **12** (47.6 mg, 150 mmol), CpTR-COOH (68.3 mg, 180 mmol), and HOBt (24.3 mg, 180 mmol) was dissolved in DMF (5 mL), and the mixture was cooled to −5 °C. A solution of EDC (48.3 mg, 0.25 mmol) in DMF (0.5 mL) and TEA (35 μL, 0.1.68 mmol) were added to the solution before reaction mixture was stirred for 3 h on ice. After the sample was stirred for an additional 6 h at room temperature, the solvent was removed in vacuo. The residue dissolved in chloroform (5 mL) was successively washed with 1% H_2SO_4 (5 mL × 3) and saturated $NaHCO_3$ (5 mL × 3) and dried over anhydrous $CaSO_4$. After the solvent was removed in vacuo, compound **13** was obtained as a white solid (53 mg, 53.5%). ^{1}H-NMR ($CDCl_3$) δ: 1.29−1.82 (15H, Boc, $(CH_2)_3$), 3.01 (2H, d, CH_2), 3.66 (3H, s, OCH_3), 3.96 (2H, d, CH_2), 4.46 (1H, d, CH), 4.77 (1H, s, NH), 5.32−5.99 (4H, t, Cp), 7.10 (1H, s, NH), 7.61 (1H, s, NH); FAB-MS $(M + H)^+$: *m/z* 678/680, Found 678/680.

Synthesis of Tricarbonyl(cyclopentadienylcarbonyl glycyl-N^{ϵ}-*tert*-butoxycarbonyl-L-lysine)rhenium (CpTR-GK-Boc). A solution of 2 N NaOH (600 μL) was added dropwise to a solution of compound **13** (53 mg, 14.7 μmol) in dioxane (300 μL). After the sample stood for 30 min at room temperature, the pH of the solution was adjusted to 3 by 5.6 N H_2SO_4 (about 240 μL). The reaction mixture was loaded onto SepPak plus

cartridge, and the cartridge was washed with water (5 mL) and eluted with acetonitrile (3 mL). The first elution acetonitrile fraction (100 μL) was discarded, and the combined eluents were evaporated in vacuo to provide CpTR-GK-Boc as a white solid (51.5 mg, 57.1%). ^{1}H-NMR (CD_3OD) δ: 1.44−1.90 (15H, Boc, $(CH_2)_3$), 3.04 (2H, t, CH_2), 3.85 (2H, d, CH_2), 4.42 (1H, d, CH), 5.60−6.12 (4H, t, Cp); FAB-MS $(M + Na)^+$: *m*/*z* 686/688, Found 686/688, Anal: ($C_{22}H_{28}N_3O_9Re$): C, H, N.

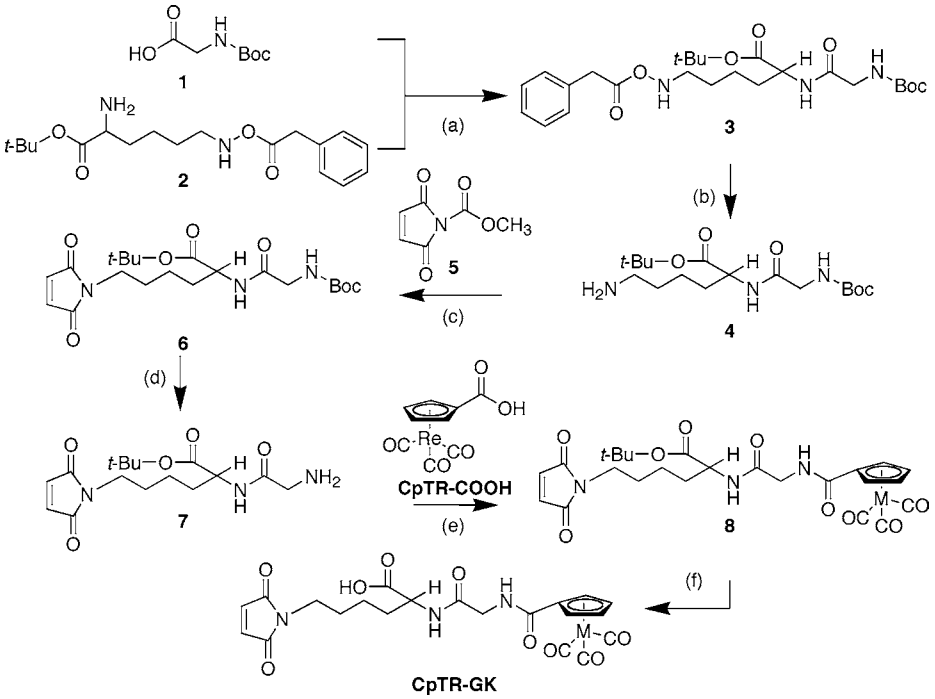
Radiosynthesis of [188Re]tricarbonyl(cyclopentadienylcarbonyl glycyl-N^ϵ-maleoyl-L-lysine-*tert*-butyl ester)rhenium ([188Re]Compound 8). A mixture of [188Re]CpTR-COOH, HOBt (2.0 mg, 14.8 μmol), and EDC (2.0 mg, 10.2 μmol) in dichloromethane (200 μL) was stirred for 5 min. The solvent was then removed in vacuo, and the residue dissolved in DMF (150 μL) was added to a mixture of compound **7** (1.5 mg, 4.0 μmol) and DIEA (0.17 μL, 1.0 μmol) in DMF (50 μL). After the sample stood for 20 min, acetic acid (100 μL) was added dropwise to the solution, and the pH was adjusted to 6.5−7.5 with saturated $NaHCO_3$. After the sample stood for 10 min, the reaction mixture was loaded onto a SepPak plus cartridge. The cartridge was successively washed with 0.01 M phosphate buffer (pH 8.0, 5 mL), 0.01 M phosphate buffer (pH 6.0, 5 mL), and water (5 mL) before the product was eluted with acetonitrile (3 mL). The first elution acetonitrile fraction (100 μL) was discarded, and the combined eluents were evaporated in vacuo to produce [188Re]compound **8** in radiochemical yield and purity of 54% and over 95%.

Radiosynthesis of [188Re]Tricarbonyl(cyclopentadienylcarbonyl glycyl-N^ϵ-maleoyl-L-lysine)rhenium ([188Re]CpTR-GK). [188Re]compound **8** and anisole (10 μL) were dissolved in TFA (190 μL). After the sample stood for 10 min, the solvent was removed by a stream of N_2 gas. The residue was dissolved in 0.1 M phosphate buffer (pH 6.5, 100 μL) and subjected to RP-HPLC purification (solvent system 2) to produce [188Re]-CpTR-GK in radiochemical yield and purity of 73% and over 95%.

Radiosynthesis of [188Re]tricarbonyl(cyclopentadienylcarbonyl glycyl-N^ϵ-*tert*-butoxycarbonyl-L-lysine)rhenium ([188Re]CpTR-GK-Boc). To a solution of [188Re]CpTR-COOH in dichloromethane (200 μL) was added HOBt (1.0 mg, 14.8 μmol) and DCC (1.0 mg, 4.8 μmol). After the sample stood for 5 min, the solvent was removed in vacuo, and the residue was added to a solution of compound **12** (1 mg, 3.2 μmol) in DMF (200 μL). After the sample stood for 20 min, a solution of 2 N NaOH (600 μL) was added dropwise to the solution, and the reaction mixture was kept for 10 min. A solution of 5.6 N H_2SO_4 (240 μL) was added to the solution before the solution was loaded onto a SepPak plus cartridge. The cartridge was washed with water (5 mL) and eluted with acetonitrile (3 mL). The first elution acetonitrile fraction (100 μL) was discarded, and the combined eluents were evaporated in vacuo to produce [188Re]CpTR-GK-Boc in radiochemical yield and purity of 92% and over 95%.

Preparation of 188Re-Labeled Fab Fragments. A solution of Fab (200 μL, 2 mg/mL) in well-degassed 0.16 M borate buffer (pH 8.0) containing 2 mM EDTA was allowed to react with 7.2 μL of 2-iminothiolane (2-IT) solution (1 mg/mL) prepared in the same buffer. After gentle agitation of the reaction mixture for 30 min at room temperature, excess 2-IT was removed by a centrifuged column procedure using Sephadex G-50 equilibrated and eluted with 0.1 M phosphate buffer (pH 6.5) containing 2 mM EDTA. Aliquots of this mixture were sampled to estimate the number of thiol groups with 2,2′-dipyridiyl disulfide (*22*). The filtrate (100 μL) was then added to a reaction vial containing freshly prepared [188Re]CpTR-GK. After gentle agitation of the reaction mixture for 1.5 h at room temperature, 14.8 μL of iodoacetamide (10 mg/mL) in 0.1 M phosphate buffer (pH 6.5) were added. The reaction mixture was further incubated for 30 min to alkylate the unreacted thiol groups. [188Re]CpTR-GK-Fab was subsequently purified by the centrifuged column procedure, equilibrated, and eluted with 0.5 M acetate buffer (pH 6.0). [188Re]CpTR-GK-Fab was diluted with saline prior to the animal study.

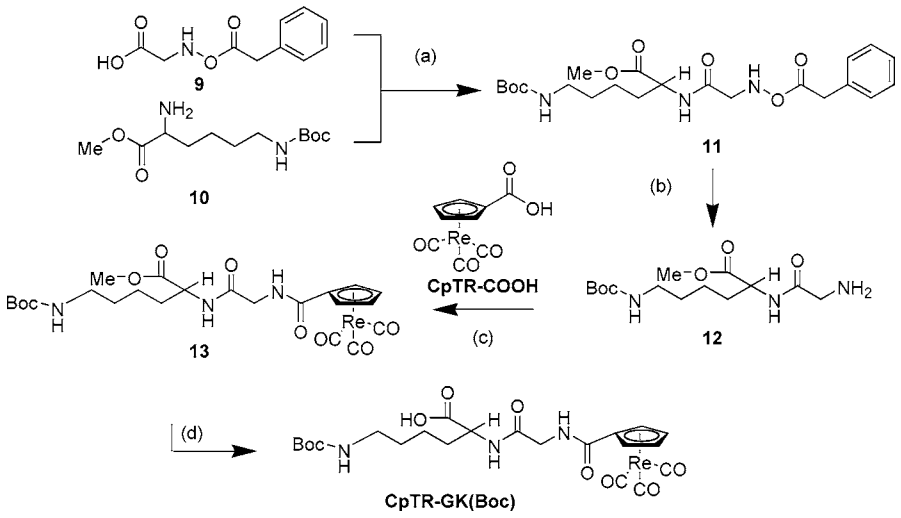
[188Re]CpTR-COOH was also conjugated to Fab fragment according to the procedure of Spraudau et al. (*23*) with slight modification as follows. *N*-Hydroxysuccinimide (1.0 mg) and DCC (1.0 mg) were added successively to a solution of [188Re]-CpTR-COOH in dichloromethane (200 μL), and the reaction mixture was stirred for 5 min. After purification by RP-HPLC (solvent system 2), the solvent was removed in vacuo, and the residues were dissolved in DMF (10 μL). This solution was then added to a solution of Fab fragment (2 mg/mL, 100 μL) in 0.16 M borate buffer pH 8.0. After gentle agitation of the reaction mixture for 2 h at 4 °C, [188Re]CpTR-Fab was obtained by the centrifuged column procedure, as described above. Radiochemical purities of radiolabeled Fab fragments were also determined by SE-HPLC.



Preparation of Brush Border Membrane Vesicles (BBMVs). BBMVs were isolated from the renal cortex of male Wistar rats according to the Mg/EGTA precipitation method reported previously (*9*). For incubation studies, the vesicles were diluted with 0.1 M phosphate buffer (pH 7.0) to give the final protein concentration of 10 mg/mL. The γ-glutamyltransferase and aminopeptidase activities on BBMVs were 5.69 μmol (mg of protein)$^{-1}$ min^{-1} and 639 nmol (mg of protein)$^{-1}$ min^{-1}, respectively, when determined using L-γ-glutamyl-*p*-nitroanilide (*22*) and L-leucine-*p*-nitroanilide as substrates (*24*). The β-galactosidase activity on BBMVs was not detected when determined using *p*-nitrophenyl-β-D-galactopyranoside as a substrate (*25*), indicating that BBMVs were free from cross-contamination by lysosomal enzymes.

In Vitro Studies. A solution of BBMVs (20 μL) was preincubated for 2 h at 4 °C, followed by the addition of [125I]HL-Boc or [188Re]CpTR-GK-Boc (20 μL) in 0.1 M phosphate buffer (pH 7.0). After incubation for 3 h at 37 °C, samples were taken from the solution and analyzed by RP-HPLC (solvent system 1 or 2) after ultrafiltration through a 10 kDa cutoff membrane (Microcon-10, Millipore, Tokyo). Similar studies were performed in the presence of an activator (Co^{2+}) or an inhibitor (DL-2-mercaptomethyl-3-guanidinoethylthiopropanoic acid: MGTA) for brush border enzymes (*26*, *27*) at a final concentration of 1 mM, as reported previously (*9*).

Biodistribution of Radiolabeled Fab Fragments. The biodistribution of radioactivity after intravenous administration of [188Re]CpTR-GK-Fab, [188Re]CpTR-Fab, or [125I]HML-Fab (0.3 μCi, 100 μL) to 6-week-old mice was determined at 10 and 30 min, 1, 3, and 6 h postinjection. Groups of 3−4 mice, each receiving 20 μg of Fab fragments, were used for the experiments. Organs of interest were removed and weighed, and the radioactivity counts were determined with an auto well gamma counter. Urine and feces were colleted for 6 h postinjection, and the radioactivity counts were also determined. The radiolabeled species excreted in the urine for 6 h postinjection of [188Re]CpTR-GK-Fab were analyzed by SE-HPLC after filtration through a polycarbonate membrane with a pore diameter of 0.45 μm (Cosmonice Filter, Nacalai Tesque) and RP-HPLC (solvent system 1) after filtration through a 10 kDa cutoff ultrafiltration membrane (Microcon-10, Millipore).



Athymic mice bearing an MKN-45 tumor were also treated intravenously with 100 μL of [188Re]CpTR-GK-Fab, [188Re]-CpTR-Fab, or [125I]HML-Fab, prepared as described above. The animals were sacrificed at 3 h postinjection (6−7 mice). Organs of interest were removed and weighed, and the radioactivity counts in each tissue were determined.

Scheme 1. Synthetic Procedure for CpTR-GK[a]

[a] Reagents: (a) HOBt, EDC, DIEA; (b) 10% Pd/C; (c) saturated $NaHCO_3$ solution, pH 8.7; (d) HCOOH, anisole; (e) HOBt, EDC, DIEA; (f) TFA, anisole.

[a] Reagents: (a) HOBt, EDC, TEA; (b) 10%Pd/C; (c) HOBt, EDC, TEA; (d) 2 N NaOH.

Statistical Analysis. Data are expressed as the means ± SD where appropriate. Results were statistically analyzed using the unpaired Student's *t*-test. Differences were considered statistically significant when p was <0.05.

RESULTS

Preparation of [^{188}Re]CpTR Derivatives and Its Fab Conjugates. [^{188}Re]CpTR-GK was synthesized according to the procedure outlined in Scheme 1. A key intermediate compound (compound **7**) was prepared by selective deprotection of N^{α}-Boc group in compound **6** by HCOOH (*21*). [^{188}Re]CpTR-GK was obtained by the reaction of [^{188}Re]CpTR-COOH with compound **7**. The low molecular weight model substrate, [^{188}Re]-CpTR-GK-Boc, was synthesized by the reaction of compound **12** with [^{188}Re]CpTR-COOH, followed by the hydrolysis of methyl ester, as outlined in Scheme 2. Similar synthetic procedures were employed for the preparation of non-radioactive rhenium compounds.

The treatment of Fab fragments with 2-IT introduced two thiol groups per molecule of Fab, as determined by 2,2′-dipyridyl disulfide. The conjugation of [^{188}Re]CpTR-GK with Fab fragments was performed by reacting the thiolated Fab fragments with maleimide groups of [^{188}Re]CpTR-GK. After purification by centrifuged column procedure, [^{188}Re]CpTR-GK-Fab was obtained with a radiochemical yield and purity of 21% and over 95%, as determined by TLC (solvent system 4). [^{188}Re]CpTR-Fab was prepared by the active ester method with a radiochemical yield and purity of 31% and over 95%, as determined by TLC (solvent system 4). Both [^{188}Re]CpTR-GK-Fab and [^{188}Re]CpTR-Fab showed SE-HPLC retention times similar to that of unmodified Fab fragment (19.5 min), as shown in Figure 2.

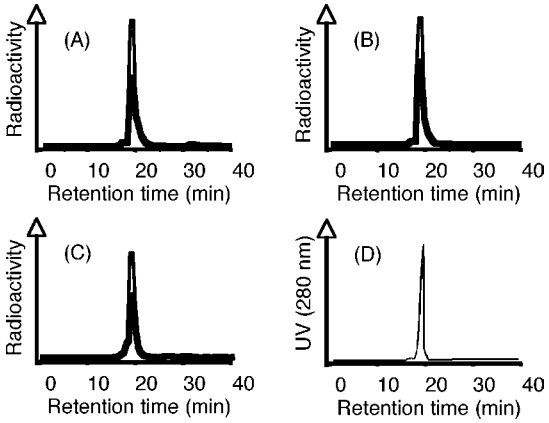

Figure 2. Radiochromatograms of (A) [188Re]CpTR-GK-Fab, (B) [188Re]CpTR-Fab, and (C) [125I]HML-Fab by SE-HPLC. The three radiolabeled Fab fragments showed SE-HPLC retention times similar to that of unmodified Fab fragment (19.5 min) as determined by the UV (280 nm) trace (D).

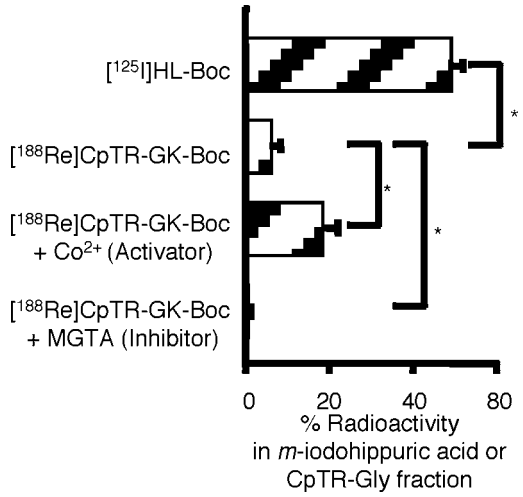

Figure 3. The amount of [188Re]CpTR-Gly or *m*-[125I]iodohippuric acid liberated from [188Re]CpTR-GK-Boc or [125I]HL-Boc after incubation with BBMVs for 3 h at 37 °C. [188Re]CpTR-GK-Boc was also incubated with BBMVs for 3 h at 37 °C in the presence of Co^{2+} or MGTA. Significance was determined by unpaired Student's *t*-test (*: $p < 0.05$ compared to [188Re]CpTR-GK-Boc).

Reactivities of [188Re]CpTR-GK-Boc with Enzymes on BBMVs. Figure 3 shows the percentage of radioactivity in the fraction of CpTR-Gly or *m*-iodohippuric acid after incubation of [188Re]CpTR-GK-Boc or [125I]HL-Boc with BBMVs at 37 °C for 3 h, respectively. The rate of [188Re]CpTR-Gly release from [188Re]CpTR-GK-Boc was significantly ($p < 0.05$) slower than that of *m*-[125I]iodohippuric acid from [125I]HL-Boc. The rate of [188Re]CpTR-Gly release significantly ($p < 0.05$) increased when [188Re]CpTR-GK-Boc was incubated with BBMVs in the presence of Co^{2+}, whereas the [188Re]CpTR-Gly release was almost completely inhibited in the presence of MGTA.

Biodistribution Studies. The biodistribution of radioactivity after simultaneous injection of [188Re]CpTR-GK-Fab and [125I]HML-Fab, or [188Re]CpTR-Fab and [125I]HML-Fab to normal mice is summarized in Table 1. The biodistribution of [125I]-HML-Fab was expressed as a mean of the two studies. No significant differences were observed in the radioactivity levels in the blood between the three radiolabeled Fab fragments up to 3 h postinjection. However, significant differences were observed in renal radioactivity levels between the two 188Re-labeled Fab fragments. Although [188Re]CpTR-Fab showed high radioactivity levels in the kidney and reached its peak at 30 min (41.69% ID/g), [188Re]CpTR-GK-Fab showed significantly lower renal radioactivity levels at all postinjection time points examined. However, [188Re]CpTR-GK-Fab showed higher renal radioactivity levels when compared with [125I]HML-Fab at all postinjection intervals. The kidney-to-blood ratios of radioactivity of the three radiolabeled Fab fragments are summarized in Figure 4. [188Re]CpTR-Fab showed the highest kidney-to-blood ratios of radioactivity, reaching a peaked ratio of 7.1 at 3 h postinjection. In contrast, [188Re]CpTR-GK-Fab and [125I]HML-Fab exhibited almost constant radioactivity ratios of about 1.6 and 1 from 10 min to 6 h postinjection.

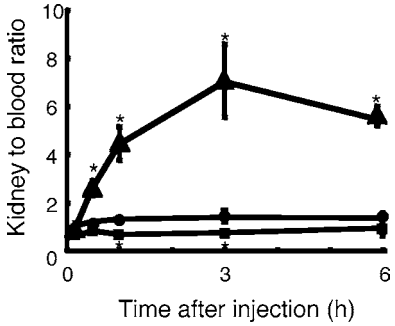

Figure 4. Comparison of the kidney-to-blood ratios of radioactivity after injection of [188Re]CpTR-GK-Fab (circle), [188Re]CpTR-Fab (triangle), and [125I]HML-Fab (square) to normal mice. Significances were determined by unpaired Student's *t*-test (*: $p < 0.05$ compared to [188Re]CpTR-GK-Fab).

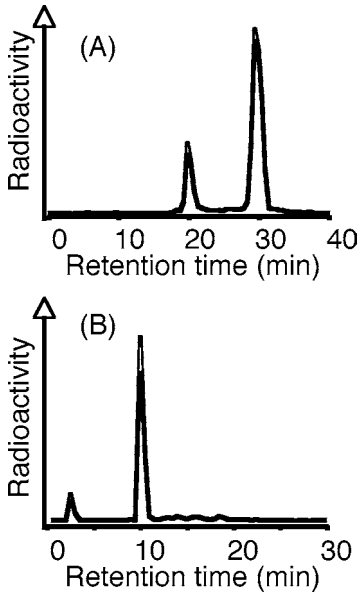

Figure 5. Radiochromatograms of urine sample collected for 6 h postinjection of [188Re]CpTR-GK-Fab (A) by SE-HPLC after filtration through a 0.45 μm polycarbonate membrane and (B) by RP-HPLC after filtration though a 10 kDa cutoff membrane.

Figure 5 shows the radiochromatograms of urine samples collected for 6 h postinjection of [188Re]CpTR-GK-Fab when analyzed by SE-HPLC (Figure 5A) and RP-HPLC (Figure 5B). On SE-HPLC, 73% of the radioactivity was observed in the low molecular weight fractions with over 20% being eluted in fractions similar to those of intact [188Re]CpTR-GK-Fab. On RP-HPLC, 72% of radioactivity in the low molecular weight fractions of the urine samples was observed with a retention time of 10.5 min, identical to that of CpTR-Gly.

The biodistribution of radioactivity after the administration of [188Re]CpTR-GK-Fab, [188Re]CpTR-Fab, or [125I]HML-Fab in nude mice bearing an MKN-45 tumor is summarized in Figure 6. No significant differences were observed in the radioactivity levels in the tumor and blood among the three radiolabeled antibodies. However, [188Re]CpTR-GK-Fab reg-

[a] Tissue radioactivity is expressed as % ID/g [for each group, $n = 3-4$; results are expressed as the mean (SD). [b] Expressed as %ID. [c] Significance determined by unpaired Student's *t*-test; $p < 0.05$ compared to [^{188}Re]CpTR-GK-Fab.

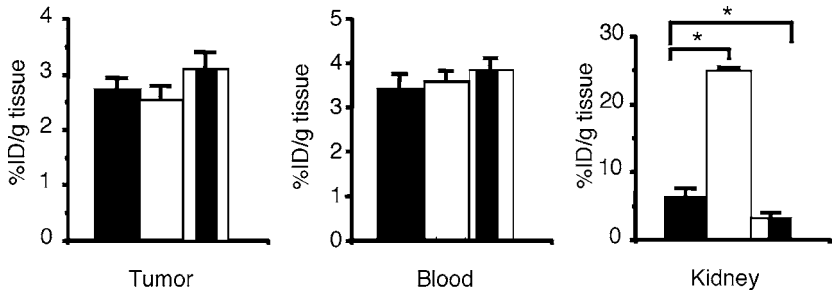

Figure 6. Radioactivity levels in the tumor, blood and kidney at 3 h postinjection of [^{188}Re]CpTR-GK-Fab (solid bar), [^{188}Re]CpTR-Fab (open bar), and [^{125}I]HML-Fab (stripe bar) into nude mice bearing MKN-45 tumor. Significances were determined by unpaired Student's *t*-test (*: $p < 0.05$ compared to [^{188}Re]CpTR-GK-Fab).

istered significantly lower radioactivity level in the kidney than did [^{188}Re]CpTR-Fab. [^{188}Re]CpTR-GK-Fab also showed renal radioactivity slightly higher than did [^{125}I]HML-Fab.

DISCUSSION

Our prior studies of the stability of metabolizable ester bonds in radiolabeled antibodies showed the involvement of many parameters that affect esterase-mediated hydrolysis of the chemical bonds. These include chemical structures of linkages and radiolabels attached to ester bonds, distance between an ester bond and an antibody molecule, and molecular size of antibody molecules (*28*, *29*). These parameters may also be involved in cleaving a glycyl-lysine linkage by enzymes on renal brush border membrane. Indeed, Li et al. documented an importance of the nature of chemical linkage from the antibody fragment to the lysine group in cleaving the glycyl-lysine linkage (*14*). Since the application of the molecular design of HML to metallic radionuclides should accompany a significant change in chemical structure of radiolabels, *m*-iodobenzene in HML or HL-Boc was replaced with CpTR to prepare CpTR-GK or CpTR-GK-Boc, respectively (Figure 1). The effect of a change in a radiolabel on brush border enzyme-mediated hydrolysis rate and renal radioactivity levels was estimated.

The significantly slower rate of [^{188}Re]CpTR-Gly release from [^{188}Re]CpTR-GK-Boc than that of *m*-[^{125}I]iodohippuric acid from [^{125}I]HL-Boc indicated that the change in a radiolabel from *m*-iodobenzene to CpTR significantly impaired recognition and cleavage of the glycyl-lysine linkage by enzymes on BBMVs (Figure 3). In addition, while the glycyl-lysine linkage in HL-Boc was cleaved by both metalloenzymes and nonmetalloenzymes (*9*), the peptide linkage in CpTR-GK-Boc was predominantly cleaved by metalloenzymes, as indicated by the facilitated [^{188}Re]CpTR-Gly release by the addition of an activator for metalloenzymes (Co^{2+}) and almost complete inhibition of [^{188}Re]CpTR-Gly release by the addition of an inhibitor for metalloenzymes, MGTA (Figure 3). These results indicate that a change in the size and the shape of a radiolabel attached to a glycyl-lysine linkage significantly affected enzymes involved in the hydrolysis reaction.

In biodistribution studies, the three radiolabeled Fab fragments exhibited similar radioactivity levels in the blood from 10 min to 3 h, indicating that similar radioactive portions of the three radiolabeled Fab fragments would be filtered through the glomerulus and transported to the proximal tubules of the kidney during these intervals (Table 1). However, significant differences were observed in renal radioactivity levels between [^{188}Re]-CpTR-GK-Fab and [^{188}Re]CpTR-Fab. This was more clearly demonstrated when the kidney-to-blood ratios of radioactivity were compared (Figure 4). In addition, [^{188}Re]CpTR-Gly was excreted as the major radiometabolite in the urine following

injection of [188Re]CpTR-GK-Fab (Figure 5). These studies along with the in vitro studies indicate that the low renal radioactivity levels by [188Re]CpTR-GK-Fab would be attributable to a release of [188Re]CpTR-Gly by the action of enzymes on renal brush border membrane.

Since in vivo behaviors of [188Re]CpTR-Gly are similar to those of *m*-[125I]iodohippuric acid (*16*), the different renal radioactivity levels between the simultaneously administered [188Re]CpTR-GK-Fab and [125I]HML-Fab would reflect in vivo cleavage of the glycyl-lysine linkage of the two radiolabeled Fab fragments by enzymes on renal brush border membrane. As expected from the in vitro studies using BBMVs, [188Re]-CpTR-GK-Fab showed higher renal radioactivity levels than did [125I]HML-Fab. However, the differences in the renal radioactivity levels of the two radiolabeled Fab fragments were smaller than those expected from the in vitro studies. The differences in densities of the enzymes between the two experiments might account for the discrepancy. In addition, the glycyl-lysine linkage in [188Re]CpTR-GK-Fab might gain access to enzymes on brush border enzymes during the internalization process of the antibodies into renal cells, which may have facilitated the cleavage of the linkage in vivo.

The ability of [188Re]CpTR-GK to reduce the renal radioactivity levels without impairing the radioactivity levels in the tumor was demonstrated in biodistribution study in nude mice model (Figure 6). [188Re]CpTR-GK-Fab exhibited radioactivity levels in the blood and tumor similar to those of [188Re]CpTR-Fab and [125I]HML-Fab, indicating that the three radiolabeled Fab fragments possessed similar binding affinities to tumor cells in vivo. However, the renal radioactivity levels of [188Re]CpTR-GK-Fab was significantly lower than those of [188Re]CpTR-Fab. These findings suggest that [188Re]CpTR-GK may constitute a useful radiolabeling agent for antibody fragments if a new chemistry to prepare [188Re]CpTR-GK in high yields with easier procedure can be developed.

In conclusion, the findings in this study indicate that the molecular design of HML can be applicable to metallic radionuclides by using a radiometal chelate of high inertness and by designing a radiometabolite of high urinary excretion following cleavage of a glycyl-lysine linkage. This study also indicates that a change in chemical structure of a radiolabel attached to a glycyl-lysine linkage significantly affected enzymes responsible for the hydrolysis reaction. There are many kinds of enzymes on renal brush border membranes, and they recognize and cleave a variety of peptide linkages. The key concept of HML is to liberate a designed radiometabolite of urinary excretion from covalently conjugated antibody fragments or peptides by the action of enzymes present on lumen of renal tubules. Thus, the peptide linkage should be optimized to a radiometal chelate of interest so that a designed radiometabolite of urinary excretion can rapidly and selectively be released from antibody molecules by the action of enzymes on the renal brush border membrane. The in vitro system using renal brush border membrane vesicles might be useful to select an appropriate peptide linkage from a variety of candidates.

ACKNOWLEDGMENT

The authors appreciate Immuno-Biological Laboratories Co. Ltd. for providing a monoclonal antibody, 1B2, and CEA-positive tumor cells, MKN-45. This study was supported in part by a grant-in-aid for scientific research (B), scientific research on priority area, and exploratory research from the Ministry of Education, Culture, Sports, Science and Technology, Japan, and a grant-in-aid from the Fugaku Trust for Medicinal Research. The authors are also grateful to Mr. Takio Kobayashi for financial support.

The development of electrochemical probes useful for investigating the occupancy by other molecules of sites on complex proteins such as human serum albumin (HSA) is described. Ferrocenyl-(oxoethylene)-fatty acid compounds of different fatty acid chain length probed different binding sites on HSA. The interaction could be changed from one primarily with a drug binding site, when the probe was ferrocene methanol, to one predominantly with medium-chain fatty acid binding sites, by adding an (oxoethylene)-fatty acid substituents. Finally, the interaction could be changed to one interacting primarily with high-affinity long-chain fatty acid binding sites, as the fatty acid chain length in ferrocene-(oxoethylene)-fatty acid molecules increased. These results strongly implied that the binding could be further tailored by relatively simple modifications to the probe, for example, by changing the balance of hydrophobicity and hydrophilicity. The possibility of a procedure using mass-produced electrochemical cells to determine the fractional occupancy of different sites on HSA is demonstrated.

INTRODUCTION

Serum albumin is of significance as a carrier for small molecules in blood (*1*, *2*). Arguably, the fractional occupancy of different binding sites on albumin could be an important medical diagnostic indicator (*1*, *3*). In particular, the binding of fatty acid to serum albumin is an important interaction in mammalian metabolism. It has previously been demonstrated that the binding of fatty acids to human serum albumin (HSA) influences the binding of a number of other drug and biomolecules in the body (*4*). The ability of serum albumin to bind a number of medium- and long-chain fatty acids simultaneously enables it to be an effective carrier for these molecules, which play a key role in cell functioning. The buffer capacity of albumin for fatty acid concentration in the blood has been proposed as a significant diagnostic indicator, for cardiac ischemia (*5*). Fatty acids are also known to bind to a number of other proteins, particularly the class of fatty acid binding proteins (FABP) (*6*). The work reported here has aimed to provide probes for fatty acid interactions with proteins, which are complementary to other methods such as the electronic spin resonance (ESR) spectroscopy method using binding of the spin-probe 16-doxyl stearate, described in ref *3*. Our focus has been to develop electrochemical methods, in view of their instrumental convenience. Here we demonstrate the principle of electrochemical probes of site occupancy and that implementation in mass-produced electrochemical cells is feasible, while highlighting some of the challenges raised by such procedures.

Fatty acid−protein interactions and, in particular, fatty acid−HSA interactions have been studied by various methods including X-ray crystallography (*7*), in which distinct binding sites for a range of fatty acids were identified. HSA has been specifically labeled with a fluorescent molecule and used to study oleate binding (*8*). The binding of a fluorescently labeled fatty acid such as 11-(dansylamino)undecanoic acid (DAUDA) to HSA (*9*) and to FABP (*10*) was studied by measuring the fluorescent signal response to the changing microenvironment around the fluorescent moiety on binding. DAUDA was also used to investigate the binding of other fatty acids as well as other molecules such as bilirubin in competitive studies with HSA (*9*). Equilibrium dialysis has been used with radiolabeled fatty acids to study the binding of a range of fatty acids to albumin (*11*); analysis was done in terms of a multiple non-interacting binding sites. Binding of a range of fatty acids to an acrylodan modified FABP (ADIFAB) has been characterized by fluorescence, and subsequently the binding characteristics of these fatty acids to HSA was determined by using the modified FABP to determine the free fatty acid concentration in the presence of HSA (*12*).

We have previously demonstrated the design and synthesis of a range of molecules consisting of a functional group that confers some specific biochemical activity, linked to an electrochemical label, to enable the reporting of activity (*13*). The two groups were linked by a spacer group, which was chosen to influence the solubility and enhance the electrochemical properties of the molecule, and may also improve the biochemical functionality through structural or specific chemical interactions. We report here the use of a range of molecules based on the earlier design, consisting of a fatty acid group, linked to a solubilizing spacer group, which in turn is linked to a ferrocene based electrochemically active signaling moiety, of the general structure **1** shown in Figure 1. The ideal structural characteristics were identified in compound **2**, as an amide at linker **A**, carbamate at linker **B**, and a short poly(ethylene glycol) (PEG) unit, for investigating fatty acid binding to a number of fatty acid binding molecules.

In this paper, we illustrate how *m*, the length of the fatty acid, may be varied (compounds synthesized for $m = 2, 5, 7,$

10, 13, and 15) to allow us to study specifically the interactions of different fatty acids with proteins, particularly albumin. The approach is a general one, so that other small molecules might be electrochemically labeled using similar methods. One of the key aspects is the use of carefully chosen signaling, linker, and spacer groups to deliver a compound that has fast electrochemistry at a potential accessible in biologically relevant media such as blood and plasma and which has the desired solubility, stability, and probe characteristics. This work is related in concept to the studies using fluorescently labeled fatty acids (*9*). However, the earlier studies on DAUDA (*9*) showed it interacting with the bilirubin site rather than the fatty acid binding sites of albumin. Hence, we have varied the length of the labeled fatty acid and to some extent altered the balance of aromatic, aliphatic, hydrophobic, and hydrophilic elements to provide a range of probes that might access different sites on HSA.

Comparison with theory for noninteracting multiple binding sites (*11*, *12*, *14*, *15*), using binding constants already determined for fatty acids to HSA, allowed investigation of the competitive binding of labeled fatty acids with natural fatty acids and demonstrated the feasibility of using instrumentally simple methods and mass-produced electrochemical cells to probe fractional occupancy of different sites on HSA.

EXPERIMENTAL PROCEDURES

Syntheses of Compounds Based on the General Structure, 2, but with Different Numbers of Carbons in the Fatty Chain. The ferrocene PEG-amide **3** was activated (*13*) as the *N*-hydroxysuccinimidyl (NHS) ester, which was isolated, and then coupled with the commercially available amino acids β-alanine, 6-aminohexanoic acid, 8-aminooctanoic acid, to give **4**, **5**, and **6** in 40−80% yield (Scheme 1). Two longer chain analogues were prepared using 14-aminotetradecanoic acid and 16-aminohexadecanoic acid, which were synthesized via the phthalimides using established synthetic manipulations (*16*, *17*). 14-Aminotetradecanoic acid (**7**) was prepared from 1-bromo-14-(tetrahydropyran-2-yloxy)tetradecane via the addition of phthalimide, OTHP deprotection, oxidation using Jones' reagent to the acid, and finally removal of the phthalimide group using hydrazine. 16-Aminohexadecanoic acid (**8**) was prepared in 84% overall yield from methyl 16-phthalimide hexadecanoate through removal of the phthalimide group and hydrolysis of the ester. 14-Tetradecanoic acid (**7**) and 16-aminohexadecanoic acid (**8**) were coupled with the NHS ester of **3** as before to give the PEG conjugates **9** and **10**, respectively (Scheme 1).

Materials. Unless otherwise noted, solvents and reagents were reagent grade from commercial suppliers and used without further purification. Tetrahydrofuran (THF) was dried by distillation from a sodium/benzophenone suspension under a dry N_2 atmosphere. CH_2Cl_2 was dried by distillation from CaH_2 under a dry N_2 atmosphere. All moisture-sensitive reactions were performed under a nitrogen atmosphere using oven-dried glassware. Reactions were monitored by TLC on Kieselgel 60 F_{254} plates with detection by UV, or permanganate, ninhydrin, and phosphomolybdic acid stains. Flash column chromatography was carried out using silica gel (particle size 40−63 μm). Melting points are uncorrected. ^{1}H NMR and ^{13}C NMR spectra were recorded in $CDCl_3$ at the field indicated unless otherwise indicated. 1-Bromo-14-(tetrahydropyran-2-yloxy)tetradecane was prepared as previously described (*18*). Methyl 16-phthalimide hexadecanoate was prepared as previously reported (*19*).

3-(Ferrocenoylamide-3-oxapentanyloxycarbonylamino)-propanoic Acid (4). The reaction was carried out under anhydrous conditions. Compound **3** was activated as the *N*-hydroxysuccinimide ester (NHS) as previously described (*13*). The NHS intermediate (150 mg, 0.33 mmol) was dissolved in DMF (2 mL), and triethylamine (54 μL, 0.39 mmol) was added. To this solution was added β-alanine (30 mg, 0.33 mmol), dissolved in a mixture of water/DMF (3.3 mL/1.3 mL). The reaction was stirred at room temperature (rt) for 18 h, and the solvents were then evaporated in vacuo. The resulting oil was purified by flash silica chromatography (5% methanol in CH_2Cl_2) to afford **4** (102 mg, 73%) as an orange oil. ^{1}H NMR (300 MHz; methanol-d_4) 2.25 (t, 2H, J 6.1 Hz, CH_2CO_2H), 3.18 (m, 2H, CH_2NH), 3.32 (dt, J 10.3 and 5.2 Hz, 2H, CH_2NH), 3.44 (t, J 5.2 Hz, 2H, CH_2O), 3.49 (t, J 5.2 Hz, 2H, m, CH_2O), 3.99 (m, 2H, C_5H_2), 4.03 (m, 2H, CH_2OCO), 4.17 (s, 5H, C_5H_5), 4.57 (m, 2H, C_5H_2); ^{13}C NMR (75 MHz; methanol-d_4) 34.2, 36.4, 39.3, 63.6, 68.0, 69.3, 69.6, 69.7, 70.5, 75.0, 156.7 (C═O carbamate), 171.7 (C═O amide), 174.6 (C═O acid); m/z HRMS calculated for $C_{19}H_{24}N_2O_6FeNa$ $(MNa)^+$ 455.08760, found (ES+) 455.08592.

6-(Ferrocenoylamide-3-oxapentanyloxycarbonylamino)-hexanoic Acid (5). The reaction was carried out under anhydrous conditions. Compound **3** was activated as the *N*-hydroxysuccinimide ester as previously described (*13*). The NHS intermediate (50 mg, 0.11 mmol) was dissolved in DMF (0.7 mL) and triethylamine (18 μL, 0.13 mmol) was added. To this solution was added 6-aminohexanoic acid (15 mg, 0.11 mmol), dissolved in a mixture of water/DMF (1.1 mL/0.4 mL). The reaction was stirred at rt for 18 h, and the solvents were then evaporated in vacuo. The resulting oil was purified by flash silica chromatography (5% methanol in CH_2Cl_2) to afford **5** (42 mg, 80%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.33 (quin, J 7.2 Hz, 2H), 1.47 (quin, J 7.2 Hz, 2H), 1.61 (quin, J 7.2 Hz, 2H), 2.33 (t, 2H, J 7.2 Hz, CH_2CO_2H), 3.12 (m, 2H, CH_2NH), 3.54 (m, 2H, CH_2NH), 3.65 (m, 4H, CH_2O), 4.19 (s, 5H, C_5H_5), 4.22 (m, 2H, CH_2OCO), 4.33 (m, 2H, C_5H_2), 4.73 (m, 2H, C_5H_2), 5.04 (m, 1H, NH), 6.59 (m, 1H, NH); ^{13}C NMR (75 MHz; $CDCl_3$) 25.8, 29.4, 29.7, 34.1, 39.3, 39.6, 63.9, 68.4, 69.7, 69.8, 70.5, 72.3, 75.7, 156.5 (C═O carbamate), 171.0 (C═O amide), 177.9 (C═O acid); m/z HRMS calculated for $C_{22}H_{31}N_2O_6Fe$ M^+ 474.14532, found (ES+) 474.14527.

8-(Ferrocenoylamide-3-oxapentanyloxycarbonylamino)-octanoic Acid (6). The reaction was carried out under anhydrous conditions. Compound **3** was activated as the *N*-hydroxysuc-

cinimide ester as previously described (*13*). The NHS intermediate (150 mg, 0.33 mmol) was dissolved in DMF (2 mL) and triethylamine (55 μL, 0.39 mmol) was added. To this solution was added 6-aminooctanoic acid (15 mg, 0.11 mmol), dissolved in a mixture of water/DMF (3.3 mL/1.3 mL). The reaction was stirred at rt for 18 h and the solvents were then evaporated in vacuo. The resulting oil was purified by flash silica chromatography (5% methanol in CH_2Cl_2) to afford **6** (63 mg, 40%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.28 (m, 6H), 1.39 (quin, *J* 6.6 Hz, 2H), 1.60 (quin, *J* 5.8 Hz, 2H), 2.31 (t, 2H, *J* 6.6 Hz, CH_2CO_2H), 3.09 (dt, *J* 6.8 and 5.8 Hz, 2H, CH_2-NH), 3.55 (dt, *J* 5.3 and 4.9 Hz, 2H, CH_2NH), 3.65 (m, 4H, CH_2O), 4.19 (s, 5H, C_5H_5), 4.20 (t, *J* 4.5 Hz, 2H, CH_2OCO), 4.31 (m, 2H, C_5H_2), 4.71 (m, 2H, C_5H_2), 4.90 (br m, NH), 6.59 (br m, 1H, NH); ^{13}C NMR (75 MHz; $CDCl_3$) 24.7, 26.5, 28.78, 28.79, 29.7, 34.0, 39.4, 41.0, 63.7, 68.3, 69.7, 69.8, 70.1, 70.5, 75.8, 156.5 (C═O carbamate), 171.0 (C═O amide), 177.9 (C═O acid); *m/z* HRMS calculated for $C_{24}H_{34}N_2O_6Fe$ M^+ 502.17661, found (FAB$^+$) 502.17918.

14-Aminotetradecanoic Acid (7). The reaction was carried out under anhydrous conditions. 1-Bromo-14-(tetrahydropyran-2-yloxy)tetradecane (63 mg, 0.17 mmol) and potassium phthalimide (48 mg, 0.26 mmol) in DMF (1 mL) were heated at 40 °C for 4 h. Water (10 mL) was added, and the product was extracted into CH_2Cl_2 (3 × 10 mL). The organic phase was dried ($MgSO_4$) and evaporated to give 2-(14-tetrahydropyran-2-yloxy-tetradecyl)-isoindole-1,3-dione (64 mg, 58%) which was used without further purification. ^{1}H NMR (300 MHz; $CDCl_3$) 1.25 (m, 20H), 1.51 (m, 6H), 1.62 (m, 4H), 3.33 (m, 2H), 3.45 (m, 2H), 3.68 (m, 2H, CH_2O), 4.52 (m, 1H, CHO), 7.68 (m, 2H, ArH), 7.78 (m, 2H, ArH); ^{13}C NMR (75 MHz; $CDCl_3$) 19.8, 25.5−31.7 (signals superimposed), 38.0, 62.3, 67.7, 99.4, 123.0, 132.1, 134.3, 168.4 (C═O); *m/z* (ES+) 466 (MNa^+, 25%), 377 (100).

To 2-(14-tetrahydropyran-2-yloxy-tetradecyl)-isoindole-1,3-dione (64 mg, 0.15 mmol) in methanol (2 mL) was added dilute hydrochloric acid (6 N; 0.5 mL). The reaction was heated at reflux for 2 h, ether was added (20 mL) and the solution washed with sodium carbonate solution (2 × 20 mL), saturated sodium chloride solution (1 × 20 mL) and dried ($MgSO_4$). After evaporation in vacuo, the product was purified by flash silica chromatography (hexane/EtOAc, 1:1) to give 2-(14-hydroxy-tetradecyl)-isoindole-1,3-dione (37 mg, 67%) (*17*). ^{1}H NMR (300 MHz; $CDCl_3$) 1.29 (m, 18H), 1.60 (m, 6H), 3.60 (m, 4H), 7.68 (m, 2H, ArH), 7.78 (m, 2H, ArH); ^{13}C NMR (75 MHz; $CDCl_3$) 25.7−29.6 (signals superimposed), 32.8, 38.1, 63.1, 123.2, 132.2, 133.8, 168.5 (C═O); *m/z* (ES+) 360 (MH^+, 10%).

To 2-(14-hydroxytetradecyl)-isoindole-1,3-dione (37 mg, 0.10 mmol) in acetone (1 mL) was added Jones reagent (0.085 mL; for 1 mL of Jones reagent- 0.23 mL H_2SO_4, 270 mg CrO_3, 0.77 mL H_2O). The reaction was stirred at rt for 1 h, 2-propanol (5 mL) was added and the mixture diluted with water (5 mL), then the acetone removed in vacuo. The solution was extracted with CH_2Cl_2 (2 × 20 mL), dried ($MgSO_4$) and evaporated, then purified by flash silica chromatography (hexane/EtOAc, 3:2) to give 14-(1,3-dioxo-1,3-dihydroisoindol-2-yl)tetradecanoic acid (20 mg, 50%). ^{1}H NMR (300 MHz; $CDCl_3$) 1.22 (m, 18H), 1.57 (m, 4H), 2.26 (m, 2H), 3.63 (m, 2H, CH_2N), 7.68 (m, 2H, ArH), 7.78 (m, 2H, ArH); ^{13}C NMR (75 MHz; $CDCl_3$) 25.7−29.6 (signals superimposed), 32.4, 34.1, 38.1, 123.2, 132.2, 133.8, 168.5 (C═O), 171.3 (C═O acid).

Hydrazine hydrate (0.25 mL, 0.50 mmol) was added to 14-(1,3-dioxo-1,3-dihydroisoindol-2-yl)-tetradecanoic acid (20 mg, 0.05 mmol) in ethanol (1 mL). The reaction was heated at reflux for 4 h, and the solvents were evaporated in vacuo. The residue was dissolved in CH_2Cl_2, and the precipitated phthalimide was removed by filtration. The CH_2Cl_2 was removed in vacuo to give 14-aminotetradecanoic acid (**7**) (10 mg, 80%) (*16*) as a colorless solid. mp 176−178 °C (CH_2Cl_2); ^{1}H NMR (300 MHz; $CDCl_3$) 1.10 (m, 18H), 1.36 (m, 4H), 2.05 (t, *J* 7.5 Hz, 2H, CH_2CO_2H), 2.57 (m, 2H, CH_2N); ^{13}C NMR (75 MHz; $CDCl_3$) 25.7−29.6 (signals superimposed), 32.9, 34.1, 40.1, 171.2 (C═O acid); *m/z* (ES+) 261 ($M^+ + H_2O$, 100%), 258 ($M^+ + NH_3$, 21), 244 (MH^+, 5).

16-Aminohexadecanoic Acid Hydrochloride (8). A solution of methyl 16-phthalimide hexadecanoate (*19*) (200 mg, 0.48 mmol) and hydrazine hydrate (97 mg, 1.94 mmol) in ethanol (5 mL) was heated at reflux for 3 h. The solvents were evaporated in vacuo, the residue was dissolved in ethanol (5 mL) and dilute hydrochloric acid (2 N; 0.5 mL), and the mixture was heated at reflux for a further 3 h. Ethanol (2 mL) was removed in vacuo and the precipitated phthalimide removed by filtration. Dilute sodium hydroxide solution (6 N; 0.5 mL) was added to the filtrate and the mixture was stirred for 4 h, then neutralized with 2 N hydrochloric acid solution. The remaining ethanol was removed in vacuo, and the suspension was filtered, then washed with water (20 mL) and CH_2Cl_2 (3 × 10 mL) to give **8** (*16*) as a colorless powder (125 mg, 84%), which was used directly in the next step (see synthesis of **10** below).

14-(Ferrocenoylamide-3-oxapentanyloxycarbonylamino)-tetradecanoic Acid (9). The reaction was carried out under anhydrous conditions. Compound **3** was activated as the *N*-hydroxysuccinimide ester as previously described (*13*). The NHS intermediate (38 mg, 0.08 mmol) was dissolved in THF (1 mL) and triethylamine (14 μL, 0.09 mmol) was added. To this solution was added **7** (10 mg, 0.04 mmol), in a mixture of water/DMF (1 mL/1.3 mL). The reaction was stirred at rt for 18 h, and the solvents were evaporated in vacuo. The resulting oil was purified by flash silica chromatography (5% methanol in CH_2Cl_2) to afford **9** (2 mg, 62%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.13 (m, 18H), 1.46 (m, 4H), 2.15 (t, 2H, *J* 7.5 Hz, CH_2CO_2H), 3.08 (m, 2H, CH_2NH), 3.54 (m, 2H, CH_2-NH), 3.65 (m, 4H, CH_2O), 4.21 (s, 5H, C_5H_5), 4.23 (m, 2H, CH_2OCO), 4.32 (m, 2H, C_5H_2), 4.72 (m, 2H, C_5H_2), 4.90 (br m, 1H, NH), 6.59 (br m, 1H, NH); *m/z* (ES+) 609 (MNa^+, 10%), 340 (100).

16-(Ferrocenoylamide-3-oxapentanyloxycarbonylamino)-hexadecanoic Acid (10). The reaction was carried out under anhydrous conditions. Compound **3** was activated as the *N*-hydroxysuccinimide ester as previously described (*13*). The NHS intermediate (50 mg, 0.11 mmol) was dissolved in THF (5 mL), and triethylamine (34 μL, 0.24 mmol) and **8** (37 mg, 0.12 mmol) in a mixture of water/THF (3 mL/2 mL) were added. The reaction was stirred at rt for 18 h, and the solvents were evaporated in vacuo. The resulting oil was solubilized in EtOAc (20 mL), washed with water (2 × 20 mL), dried (Na_2SO_4), evaporated, and purified by flash silica chromatography (100% EtOAc, then EtOAc/methanol 90:10) to afford **10** (20 mg, 30%) as an orange oil. ^{1}H NMR (300 MHz; $CDCl_3$) 1.26 (m, 20H), 1.45 (m, 2H), 1.65 (m, 2H), 2.38 (t, 2H, *J* 7.5 Hz, CH_2CO_2H), 3.15 (m, 2H, CH_2NH), 3.59 (m, 2H, CH_2NH), 3.64 (m, 2H, CH_2O), 3.70 (m, CH_2O), 4.21 (s, 5H, C_5H_5), 4.26 (m, 2H, CH_2-OCO), 4.34 (m, 2H, C_5H_2), 4.72 (m, 3H, C_5H_2 + NH), 6.25 (br m, 1H, NH); *m/z* HRMS calculated for $C_{32}H_{50}N_2O_6FeNa$ $(MNa)^+$ 637.29105, found (ES+) 637.28895.

Electrochemistry. *Materials and Cells.* The basic reagents were phosphate buffered saline (PBS: 0.01 M phosphate buffer, 0.137 M NaCl, 0.0027 M KCl, pH 7.4), sodium oleate, human serum albumin (all Sigma) and Nafion perfluorinated ion-exchange resin 10 wt % dispersion in water (Aldrich). All solutions were filtered using a 0.2 μm cutoff filter. All measurements were performed with electrodes screen-printed onto alumina tiles using polymer-bonded, heat-cured inks (Gwent Electronic Materials Ltd), with the cell area defined by

over-printing an insulator with a circular hole to expose the electrodes: carbon working (area = 3.0×10^{-2} cm^2) and counter electrodes and a silver/silver chloride reference electrode. In repeat measurements of cyclic voltammetry of the ferrocene probe molecules in PBS, cells mass-produced in this way reproduced peak currents to better than ± 15% and $E_{1/2}$ to better than ± 5 mV (2 standard deviations). Nafion coating of the electrodes was achieved by pipetting 3 μL of a 1% v/v dilution in water of the as-supplied Nafion solution onto the cell so as to cover the entire exposed disc with the working, counter and reference electrodes. The resulting assembly was left to dry at room temperature in the dark. The volume and dilution required were determined empirically. Given the cell area (0.12 cm^2) this implied a fully dense membrane thickness of approximately 0.1 μm. When the sample was fully swollen in water, the thickness would be significantly greater. The electrode coating method was not optimized and introduced a degree of variability into the results (variation in peak current ± 20%). All electrochemical measurements were performed with a general purpose electrochemical system (Autolab: Eco Chemie B.V Netherlands).

For measurement, 20 μL of sample was applied to the sample/working area of the electrode ensuring complete coverage of the working, counter, and reference electrodes. All samples were premixed before being applied to the electrode, and a new electrode tile was used for each measurement. All ferrocene-labeled fatty acid probe molecule stock solutions were dissolved in methanol due to poor solubility at high concentrations in PBS. Subsequent dilutions were made with PBS, and the final concentration of methanol was no more than 5% v/v. Methanol binds weakly to albumin through the methylene group (*20*) and will probably compete on the drug binding sites. This competition will introduce an error into the determination of binding constants, which is assessed in the Discussion. Cyclic voltammetry measurements were made immediately on uncoated electrodes and after a 2 min period on Nafion-coated electrodes. All potentials are quoted with respect to the Ag/AgCl reference electrode in the measurement solution. The potential ramp was a digitally generated staircase. Cyclic voltammetry scan parameters were as follows, hold at 0 V for 5 s, start potential 0 V, vertex potential 0.7 V, staircase step potential 0.002 V, and scan rate 0.05 V s^{-1}.

Electrochemical System Design. The binding of the probe to a protein, the competition with other molecules in the solution, and measurement through electrochemistry is overall a complicated system. The electrochemical process has a second-order reaction preceding the electrochemical step and probably another following. Also, as we showed in our previous paper (*13*), the ferricenium product can decompose to electrochemically inactive species.

$$\mathrm{E} + \mathrm{A} \underset{k_a}{\overset{k_d}{\rightleftharpoons}} \mathrm{EA}$$

$$\mathrm{E} \leftrightharpoons \mathrm{E}^+ + \mathrm{e}^-$$

$$\mathrm{E}^+ + \mathrm{A} \underset{k_{a,1}}{\overset{k_{d,1}}{\rightleftharpoons}} \mathrm{E}^+\mathrm{A}$$

$$\mathrm{E}^+ \xrightarrow[k_2]{} \text{products} \qquad (1)$$

The behavior is determined by the value of the characteristic time constants for the chemical processes relative to the characteristic time constant for the electrochemical experiment, which for cyclic voltammetry is $\upsilon F/RT$ where υ denotes the potential scan rate, F is Faraday's constant, R is the gas constant and T is the Kelvin temperature. If the electrochemistry is fast, so that E and E$^+$ (eq 1) can be considered at equilibrium at the electrode surface, with concentrations determined by the Nernst equation, then the ratio of electrochemical to chemical rate constants is $V = \upsilon F/(RT\{(k_{a,1} + k_{a,2})c_{E,T} + k_{d,1} + k_{d,2} + k_2\})$ where $c_{E,T} = c_E + c_{E^+} + c_{EA} + c_{E^+A}$ is the total concentration of the species E. With decrease of V below unity, reactions in the boundary layer on the time scale of the scan have a profound effect on the wave shape and peak height in cyclic voltammetry. Literature data for fatty acid binding (*21*) show one should expect $k_{a,1}c_{E,T} + k_{d,1} \sim 1$ s^{-1}, and hence for potential scan rates around 50 mV s^{-1}, indeed $V \sim 1$.

Although the full system is complex, the behavior can be calculated easily using finite difference solution of the diffusion−reaction equations. We used a spreadsheet to do this. Figure 2 illustrates the wave shift that could be caused, calculated using representative parameters deduced in Results and from the literature. Figure 2 also shows that, in these circumstances, the concentration of "unbound" probe in the presence of protein cannot be obtained by using a simple calibration in the absence of the protein. Therefore, for quantitation of the equilibrium solution concentrations of the probe, E, the complicating effects of the preceding and following chemical reactions need to be avoided. While in principle a sufficiently high scan rate would suffice, quantitation is most conveniently achieved by use of a membrane that defines the boundary layer and excludes the protein from it. Figure 2 also illustrates the theoretical effect of a membrane on the voltammetry of a second-order CEC process. If the membrane is sufficiently thick, then the concentration changes of E and E$^+$ near the surface, that determine the electrochemical response, are confined within the membrane and are largely uninfluenced by the protein. The peak current, though obviously dependent on the membrane thickness, the diffusion coefficient of E and E$^+$ within the membrane and the decomposition rate of E$^+$ within the membrane, becomes the same for the same bulk solution concentration of free label whether or not protein is present. The theory shows that even a very thin membrane could allow deduction of the bulk solution concentration of free label from a calibration made in the absence of protein, without too much error. A compromise is clearly achievable wherein the voltammetry can be simplified and a reasonable calibration obtained without too much diminution of the peak current.

A suitably chosen membrane also has the advantage of mitigating the effects of protein and probe adsorption on the electrode surface. Proteins adsorb strongly on carbon and can unfold across the hydrophobic surface. There is also the possibility that the long-chain fatty acid analogues used as electrochemical probes could adsorb on a hydrophobic carbon surface. These considerations all indicate the use of a hydrophilic, protein-excluding membrane over the electrode. The major interferences in electrochemistry in blood are due to the anionic species ascorbate and uric acid. A cationic membrane should exclude these species. We indeed found that a Nafion membrane essentially eliminated the interference, and in view of the other considerations outlined above, used such coated electrodes for the measurements reported here.

RESULTS

Electrochemical Characterization. In the previous paper (*13*) the optimal linkers **A** and **B** and the ferrocene solubilizing group were identified in order to obtain molecules with the desired electrochemistry, solubility and stability. The selected structure **2** consisted of a monosubstituted ferrocene with an amide bond linking the cyclopentadienyl ring to a short (two unit) PEG spacer group, linked to the fatty acid through a carbamate bond (Figure 1).

Compounds **4**−**6** (m = 2, 5, 7) showed half-wave potentials at approximately 350 mV Ag/AgCl (Table 1). A further increase

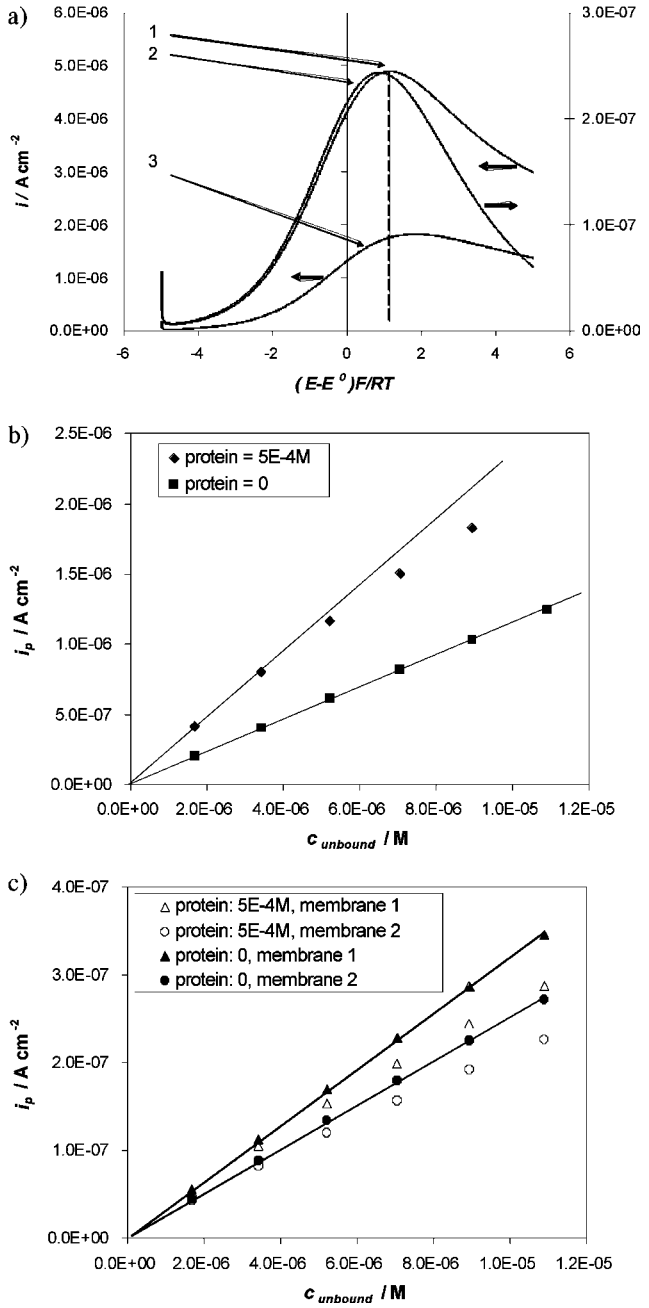

Figure 2. Effects of the CEC process described by eqs 1 on linear sweep voltammetry, illustrating the effect of a membrane. (a) Simulation of linear sweep voltammetry. 1: E only, no membrane; 2: E, protein, and membrane 1 (current density on right-hand axis); 3: E and protein, no membrane. (b) Simulated voltammetric peak current density, i_p, dependence on the concentration of electrochemically active species, E, that is not bound to protein, $c_{unbound}$, in the absence of a membrane, showing that a calibration deduced in the absence of protein would result in a significant error in $c_{unbound}$; (c) as for (b), but with a membrane covering the electrode, illustrating that, with a sufficiently thick membrane a calibration deduced in the absence of protein would give a reasonably reliable measure of $c_{unbound}$. Parameters assumed: $c_{E,T} = 5 \times 10^{-5}$ mol dm^{-3}, $c_{A,T} = c_A + c_{EA} + c_{E^+A} = 5 \times 10^{-4}$ mol dm^{-3}, $k_d = k_{d,1} = 1$ s^{-1}, binding constant, $K = k_d/k_a = k_{d,1}/k_{a,1} = 1 \times 10^{-4}$ mol dm^{-3}, solution diffusion coefficients of E and E^+ 1×10^{-6} cm^2 s^{-1}, scan rate 50 mV s^{-1}, start potential $F(E - E^0)/RT = -5$. Assumed membrane characteristics are that protein, A, is totally excluded and membrane 1, thickness 5×10^{-4} cm, diffusion coefficient of E and E^+ 1×10^{-7} cm^2 s^{-1}; membrane 2: thickness 1×10^{-3}cm, diffusion coefficient of E and E^+ 5×10^{-8} cm^2 s^{-1}. The diffusion coefficients of the protein species A, EA, and E^+A are assumed much less than those of the electrochemically active species E and E^+. The decomposition of E^+ is neglected.

Table 1. Electrochemical Data for the Probe Molecules[a]

compd	*m*	$E_{1/2}$/V Ag,AgCl	$E_{a,p} - E_{a,p/2}$/V	$E_{a,p} - E_{c,}/V_p$	$I_{c,p}/I_{a,p}$
4	2	0.349	0.063	0.074	0.88
5	5	0.356	0.065	0.072	0.91
6	7	0.351	0.061	0.071	0.91
2	10	0.363	0.059	0.072	0.65
9	13	0.379	0.071	0.095	0.43
10	15	0.507	0.105	0.125	0.06

[a] 50 mM in PBS with MeOH content for **10** = 5%, others approximately 1−2%, on uncoated screen-printed carbon electrodes, recorded at 50 mV s^{-1} scan rate. $E_{1/2}$ was taken as the mean of the peak potentials for anodic and cathodic peaks. The peak current ratio was determined by the extrapolation method illustrated in ref *22*.

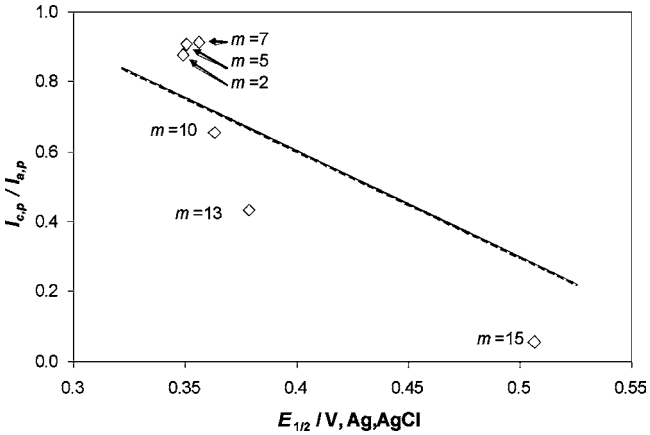

Figure 3. Correlation of peak current ratio $I_{c,p}/I_{a,p}$ with half-wave potential $E_{1/2}$ for the ferrocene probe molecules. The dotted line illustrates the correlation for the series of different compounds given in ref *13*.

in *m* caused $E_{1/2}$ to move anodic. For a given concentration, the peak current generally increased with increasing *m*. When the length of the carbon chain in the fatty acid was longer than C11 (e.g., compound **10**) the oxidation potential shifted significantly anodic and the ferricenium reduction wave virtually disappeared. As noted in a previous paper (*13*), there was a systematic trend of half-wave potential, $E_{1/2}$ and anodic/cathodic peak current ratio with the length of the substituent chain (Figure 3). These effects are consistent with the trend in electrochemical behavior that was identified in previous work (*13*). The difference between the potential at the anodic peak and that at half the peak current, $E_{a,p} - E_{a,p/2}$, was ~60 mV for $m = 10$ or less, and somewhat higher for greater *m*, (Table 1).

Figure 4 shows the effect of the Nafion membrane on the voltammetry of the ferrocene compounds. The half-wave potential was shifted significantly cathodic, to around 0.28 V Ag/AgCl and the variation in $E_{1/2}$ with substituent chain length was eliminated. The cathodic peak height, for reduction of ferricenium, was significantly increased.

Binding to Human Serum Albumin. The ferrocene labeled fatty acid probe molecules investigated were ferrocene methanol ($FcCH_2OH$), **4** ($m = 2$), **5** ($m = 5$), **6** ($m = 7$), **2** ($m = 10$), and **10** ($m = 15$). Experiments with no membrane coating the electrodes showed the expected effects of the CEC process on the wave shape in cyclic voltammetry, different for different chain lengths, *m* (Figure 5). The effects on the peak position and wave shape were eliminated by the use of the Nafion membrane (Figure 5). Therefore, in view of the theory given in the System Design section, the membrane coating used was assumed sufficiently thick to allow reasonably reliable determination of the concentration of the probe free in solution, based on a calibration made in the absence of protein.

The binding of the ferrocene labeled poly(oxoethylene)-fatty acid probe molecules as a function of the number of carbons in

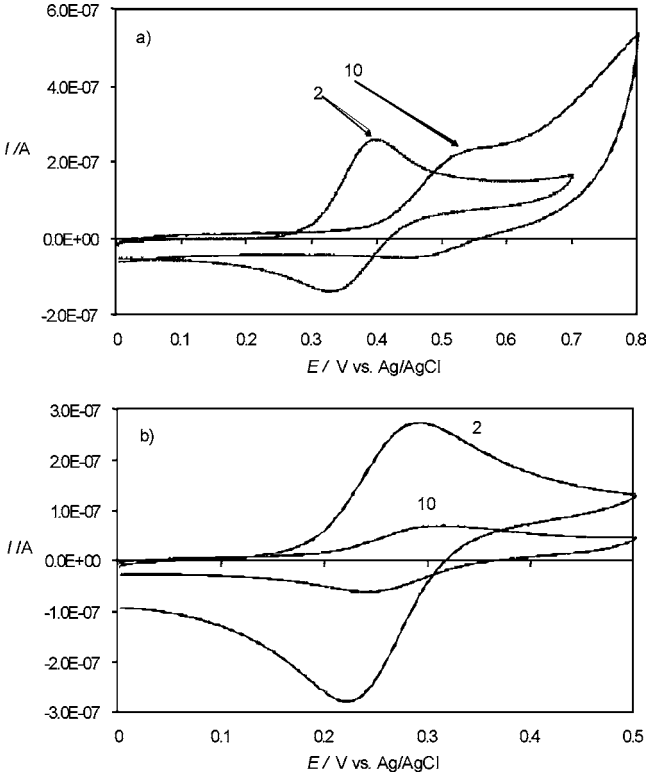

Figure 4. Cyclic voltammetry of ferrocenyl compounds illustrating the effect of a Nafion membrane. The curves are labeled with the compound number. (a) On uncoated electrodes; (b) on Nafion-coated electrodes. Compounds 2 and 10 at 50 μM in PBS with MeOH content 10 = 5%, 2 = 2%, recorded at 50 mV s^{-1} scan rate.

the fatty acid chain is further illustrated in Figure 6. The degree of binding of the probes to HSA can be changed by varying the fatty acid carbon chain length, as expected. The data show a gradual decrease in the degree of binding from 15 to 5 carbons. There was little detectable binding for two and five carbons. However, $FcCH_2OH$ (no poly(oxoethylene) chain) did bind to HSA.

Electrochemical Probe of Site Occupancy on HSA. We explored the possibility of an electrochemical measurement of site occupancy on albumin, using **2** ($m = 10$) and **10** ($m = 15$), as examples of a medium chain length and a long-chain length probe, respectively, competing with decanoate and oleate. Figures 7 and 8 show the amount of free **2** and **10**, respectively, taken from I_p in cyclic voltammetry on membrane-coated electrodes, in a solution containing different concentrations of HSA. Comparison has been made with the calculated amounts that would be bound, based on the binding constants of other fatty acids given by Spector et al. (*11*) (multiple binding sites and different binding constants to each site). Compound **2** did not bind as strongly to HSA as a fatty acid of similar chain length such as decanoate, but more like one with eight methylene groups. The binding of **2** was also well-represented by a three-site model, each site having dissociation constant, $K_d = 1 \times 10^{-4}$ mol dm^{-3}. However, the measurements at higher albumin concentration showed unbound probe concentration, determined electrochemically in the manner described, higher than expected. Figure 7 also illustrates that the fluorescent probe 11-(dansyl-amino)undecanoic acid (DAUDA) bound much more strongly to HSA than either the electrochemical probe, or fatty acids of similar chain length. Compound **10**, with 15 methylene groups in the hydrocarbon chain, bound with similar strength to a fatty acid with 12−14 methylene groups. Curry et al. (*7*) described seven binding sites for fatty acids on albumin. A simple model in which **10** binds equally to seven sites gave reasonable

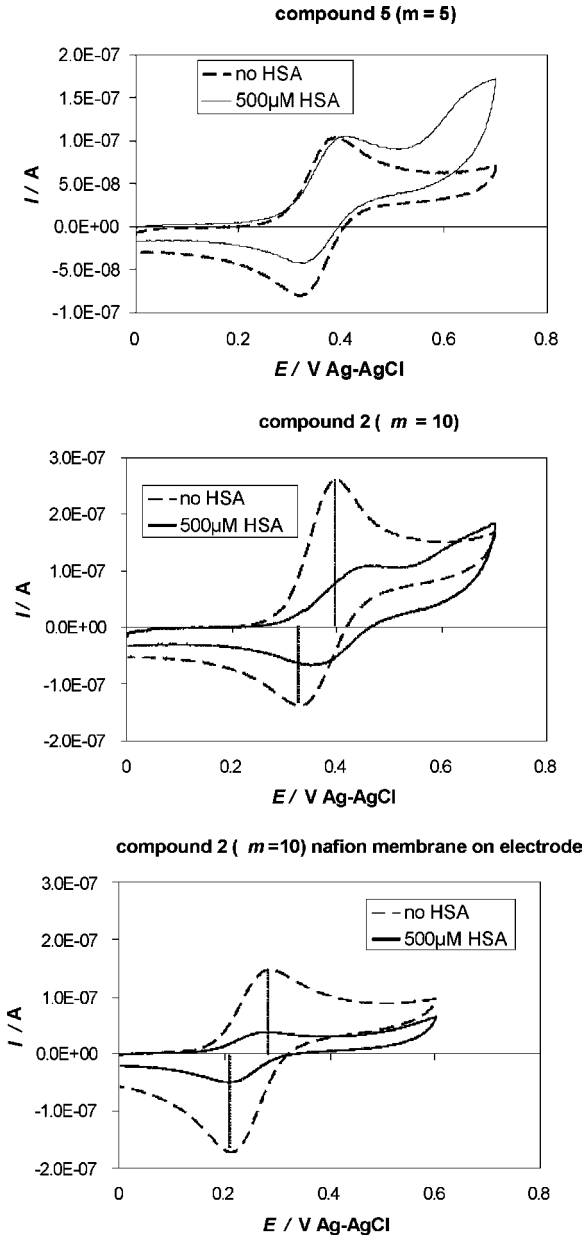

Figure 5. Effect of HSA on cyclic voltammetry of **2** and **5** at uncoated carbon electrodes and of **2** at a Nafion-coated electrode. The dotted lines are added to show the change in peak positions. PBS; compound concentration 50 μM, 50 mV s^{-1}.

agreement to the data with $K_d = 5 \times 10^{-6}$ mol dm^{-3}. Again, the measurement at highest albumin concentration showed a higher than expected unbound probe concentration, determined electrochemically in the manner described.

The competition of compounds **2** and **10** with fatty acids for binding sites on HSA is shown in Figures 9−11. Comparison is made with theoretical predictions assuming binding to different classes of site on HSA. The binding constants determined using the stepwise equilibrium model for oleate (*12*) and decanoate (*11*) have been used.

In competition with decanoate, there was a steady increase in the concentration of **2** in the solution with an increasing molar ratio of decanoate to albumin. However, even when decanoate was at 10 times excess of HSA, there was still significant **2** bound to HSA. Competition of **2** with oleate showed a different pattern of behavior. For molar ratios oleate/HSA up to approximately 5, **2** was not significantly displaced by oleate. At higher ratios, **2** was completely displaced by oleate. The behavior of compound **10** was different, as expected. At low molar ratio

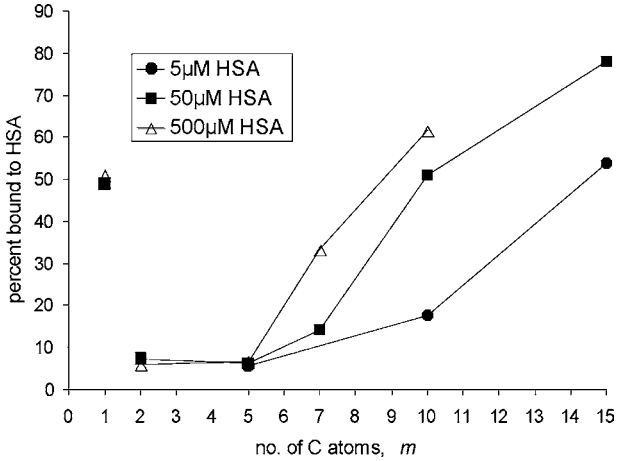

Figure 6. Binding of ferrocene labeled fatty acid probes (50 μM) to HSA, determined by the % decrease in anodic peak height in cyclic voltammetry on membrane-covered electrodes, as a function of the number of carbon atoms in the fatty acid chain. The points for $m = 1$ are for $FcCH_2OH$ (ferrocene methanol).

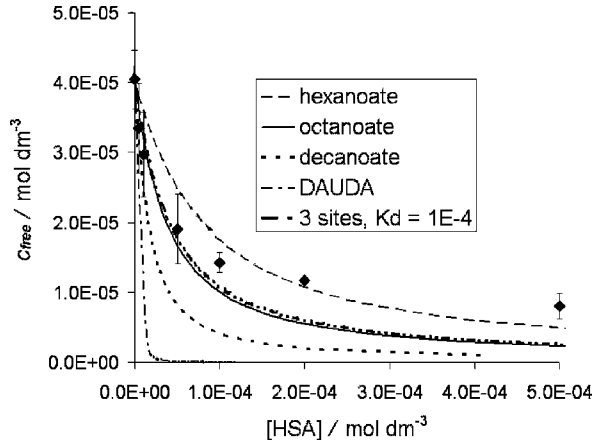

Figure 7. Measurement of bulk solution unbound concentration of compound **2**, c_{free}, (symbols) by cyclic voltammetry at a Nafion-coated carbon electrode, as a function of concentration of HSA, [HSA]. Total concentration of **2** in the solution 40 μM. Solid lines show c_{free} calculated at the same total concentration for different fatty acids, for 11-(dansylamino)undecanoic acid (DAUDA), using literature values for the binding constants (*9*, *11*), and for a simple three-site binding model with each site having $K_d = 1 \times 10^{-4}$ mol dm^{-3}.

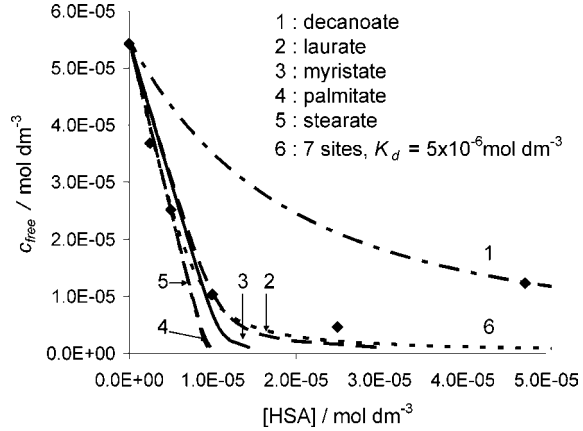

Figure 8. Measurement of bulk solution unbound concentration of compound **10**, c_{free}, (symbols) by cyclic voltammetry at a Nafion-coated carbon electrode, as a function of concentration of HSA, [HSA]. Total concentration of **10** in the solution 55 μM. Solid lines show c_{free} calculated at the same total concentration for different fatty acids, using literature values for the binding constants (*11*, *12*).

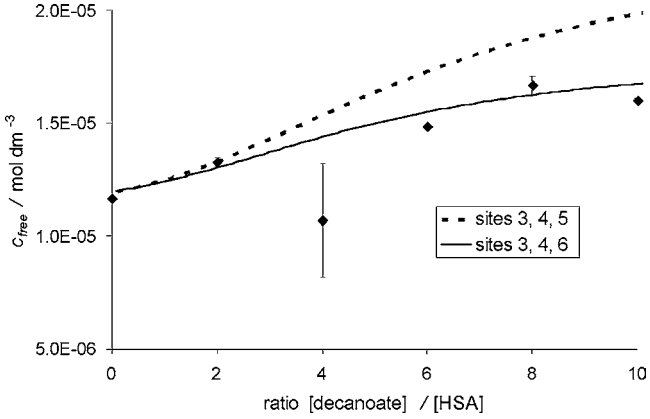

Figure 9. Competition of **2** with decanoate for sites on HSA. $[\mathbf{2}]_{total} = 25$ μM, and $[HSA]_{total} = 50$ μM. Solid lines correspond to calculated values of the concentration of **2** free in the solution, c_{free}, assuming that decanoate binds to HSA at five sites according to Spector et al. (*11*), numbered in order of decreasing affinity, and that **2** binds to three of them, specified in the legend, with $K_d = 1 \times 10^{-4}$ mol dm^{-3}. Site 6 in the calculation is an additional site for which it is assumed that **2** binds but decanoate does not; c_{free} determined from I_p in cyclic voltammetry at Nafion-coated carbon electrodes.

oleate/HSA, the solution concentration of **10** increased, indicating its displacement from the higher affinity sites. Compound **10** was essentially completely displaced into solution at molar ratio oleate/HSA > 8.

DISCUSSION

Electrochemistry of the Ferrocenes. In our previous paper (*13*), we deduced that the electrochemical behavior of variously substituted ferrocenes was strongly determined by the effect of the substituent on the stability of the ferricenium cation. The ability of the substituent to disperse the positive charge on ferricenium, and steric effects that caused the two cyclopentadiene rings to move out of coplanarity were also identified as important. The peak shape, as measured by the difference between peak and half-peak potential, indicated that the electrochemical reaction was fast on the time scale of the scan in cyclic voltammetry. The ratio of cathodic to anodic peak current implied decomposition of the ferricenium product in the boundary layer near the electrode. The behavior reported here (Figure 3, Table 1) is consistent with this interpretation. The peak potential difference implied that the electrochemical process was fast in comparison with the time scale of the scan, perhaps decreasing in rate with increasing chain length, *m*. The variation of half-wave potential and peak current ratio indicated decreasing stability of the ferricenium cation with increasing substituent chain length. The observed increase of anodic peak current with increasing substituent chain length is similarly consistent with the interpretation: increasing the size of the molecule should decrease the diffusion coefficient and so decrease the peak current; however, if the electrochemistry is fast and the product decomposes then the peak current would be increased.

Effect of the Nafion Membrane on the Electrochemistry of the Ferrocenes. The increase of the cathodic peak current, the cathodic shift of the wave, and the removal of the effect of the chain length on the half-wave potential and peak current ratio (Figure 4) can be interpreted simply as a consequence of stabilization of the ferricenium cation in the membrane. The cathodic peak current is significantly increased. We showed, by holding the potential at the anodic limit of the scan for a time, that ferricenium could be accumulated in the cation exchange membrane. The decrease in current with increasing *m* is attributable to interaction of the hydrocarbon chain with

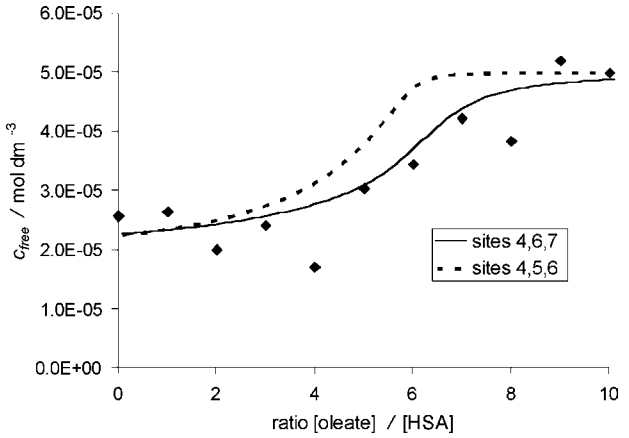

Figure 10. Competition of **2** with oleate for sites on HSA. $[\mathbf{2}]_{total} = 50\ \mu M$, and $[HSA]_{total} = 50\ \mu M$. Solid lines correspond to calculated values of concentration of **2** free in the solution, c_{free}, assuming that oleate binds to HSA at seven sites numbered in order of decreasing affinity, and that **2** binds to three of them, specified in the legend, with $K_d = 1 \times 10^{-4}$ mol dm^{-3}. Sites 1−6 in the calculation are those identified by Richieri et al. (*12*). Site 7 is an assumed additional weak binding site with $K_d = 1 \times 10^{-5}$ mol dm^{-3}; c_{free} determined from I_p in cyclic voltammetry at Nafion-coated carbon electrodes.

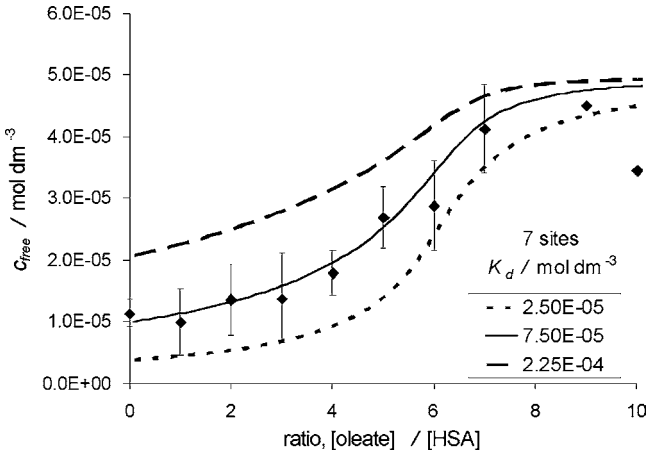

Figure 11. Competition of **10** with oleate for sites on HSA $[\mathbf{10}]_{total} = 50\ \mu M$, and $[HSA]_{total} = 50\ \mu M$. Symbols give the concentration of **10** free in the solution, c_{free}, determined from I_p in cyclic voltammetry at Nafion-coated carbon electrodes. Solid lines correspond to calculated values c_{free} assuming that oleate binds to HSA at seven sites numbered in order of decreasing affinity. Sites 1−6 in the calculation are those identified by Richieri et al. (*11*). Site 7 is an additional weak binding site with assumed $K_d = 1 \times 10^{-5}$ mol dm^{-3}. Compound **10** is assumed to bind to all seven sites with equal binding constant, K_d, specified in the legend.

the polymer membrane decreasing the diffusion coefficient through the membrane.

Electrochemistry in the Presence of Albumin. The effects on cyclic voltammetry at an uncoated electrode (Figure 5) were consistent with a dissociation rate of any complex increasing significantly, and a binding affinity decreasing significantly with decreasing chain length. The decrease in the presence of albumin of cathodic peak current relative to anodic peak current indicated that the ferricenium cation was also complexed by albumin. For compound **2**, taken with the estimates of binding constant deduced below, the effect on the voltammetry was consistent with a dissociation rate constant $\sim 1\ s^{-1}$, which is consistent with values reported in the literature (*21*). With a Nafion membrane, the protein had no effect on either the peak position or the relative peak height. On the basis of the theory given under Electrochemical System Design, it was therefore reasonable to assume that calibration in the absence of protein would give a reliable measure of the unbound concentration of the probe. However, the theory (Figure 2) also showed that this assumption could fail as the unbound concentration increased. The assumption could also fail at higher protein concentration. The effect would be to indicate a free probe concentration higher than that actually present, because the effect of the complexation with protein would be to increase the concentration gradients in the boundary layer immediately outside the membrane and hence increase the observed current.

Binding of the Ferrocene Probes to Albumin. There appeared to be three effects operative (Figure 6): binding of the ferrocene group, binding of the hydrocarbon chain, and the effect of the poly(oxoethylene) part of the chain in decreasing the binding to albumin. With $m = 7$, 10, 15 (compounds **6**, **2**, and **10**), the carboxylic acid chain was long enough to interact with the fatty acid binding sites of HSA, and the observed good binding of these molecules to HSA is likely to be due to the fatty acid part. The result with ferrocene methanol showed that ferrocene itself could bind reasonably strongly to HSA. Albumin has sites that bind drug molecules (*2*), for example, paracetamol and aspirin, which have a conjugated ring as does ferrocene, and one of these sites may be involved in the ferrocene binding. The results show that the addition to ferrocene of a PEG chain, if this was terminated by a sufficiently short carboxylic acid chain ($m = 2$, 5: compounds **4** and **5**), prevented the ferrocene from binding to HSA. A likely explanation is improved solvation by water conferred by the PEG. However, effects caused by the chain and the carbamate linking group such as steric hindrance of binding, or restriction in the orientation of the ferrocene with respect to the protein, cannot be discounted.

Figures 7 and 8 show that the system can reasonably measure the binding of the probes to albumin, although with a deviation from the expected behavior at high protein concentration. The deviation is expected in view of the theory above, and the solution to the problem would be to increase the membrane thickness. The binding of the ferrocene probes was similar to that of fatty acids with a slightly shorter chain length. We can attribute the reduction in binding affinity to the steric effects of the carbamate linker and the affinity for water conferred by the short PEG chain. The result indicates the possibility of fine-tuning the probe by altering the balance of hydrophilicity and hydrophobicity in the molecule. The behavior contrasts to that of DAUDA. Wilton (*9*) has interpreted data on binding to HSA of DAUDA, a fluorescently labeled fatty acid with 10 CH_2 units in the carbon chain, to deduce three binding sites with $K_d < 10^{-7}$ M at the high-affinity site, and $K_d = 8 \times 10^{-7}$ M at the other two sites (*8*). The calculated binding of DAUDA to HSA, using the K_d given by Wilton, plotted in Figure 7, demonstrates the much stronger binding of that compound than either fatty acids or the ferrocene probe of similar chain length. As noted below, the bilirubin binding site was deduced as one major binding site for DAUDA implying that, for this compound, binding was dominated by the effect of the large aromatic fluorescent label.

The competition studies (Figures 9−11) showed that the ferrocene probes did indeed bind to the fatty acid binding sites of albumin, with behavior modified by the presence of PEG and carbamate linker. Thus, Figure 9 shows that **2** bound to the sites accessed by decanoate, since it could be displaced from albumin by decanoate. However, compound **2** was not completely displaced, implying the presence of another site. The ferrocene probe appeared to bind weakly to a site not accessed by fatty acids. Given the binding observed for ferrocene methanol, it is reasonable to presume that this was a site that bound the cyclopentadienyl ring, perhaps one of the drug binding sites. Figure 9 shows that it is possible to make quantitative comparison with a site binding model and deduce the binding constants. Reliable deduction of the binding constants would

require further development of the electrochemical method and better design of the membrane coating of the electrode.

Figure 10 shows that the high-affinity sites accessed by oleate were not accessed by **2**. Compound **2** could only access sites with low affinity for oleate, from which it was displaced at a sufficiently high oleate/HSA ratio. The results are consistent with previous measurements carried out with DAUDA (10 CH_2 fatty acid chain). Wilton (*9*) deduced that DAUDA does not bind to the high-affinity sites for long-chain fatty acids, since it was displaced only at higher fatty acid/HSA ratios. Similarly, DAUDA was not completely displaced by medium-chain fatty acids. However, bilirubin displaced DAUDA significantly indicating that DAUDA shared with this molecule its major binding site, termed drug site I (*2*). As noted above, it is probable that compound **2** also bound weakly at this site, perhaps through the ferrocene group.

Extending the fatty acid chain of the ferrocene allowed these probes to access the high-affinity binding sites for long-chain fatty acids. Figure 11 shows that compound **10** was displaced from HSA at low molar ratios of oleate to HSA. Hence, this compound accessed the highest affinity sites for oleate. As indicated in Figure 11, the data could be interpreted with a simple competitive binding model assuming seven binding sites accessible to both species—the six sites identified by Richieri et al. (*12*) together with an additional weak binding site to account for the data when oleate/HSA > 6.

Interaction with Methanol. The possible interaction with methanol used to introduce the probes and consequently present at concentrations up to 5% v/v is a complication that does not, however, affect the major conclusions of the work. Alcohols have a large effect on albumin in acid solution, promoting α-helix formation. However, the effects at neutral pH are small (*23*). Lubas et al. (*20*) showed a weak interaction of methanol with albumin, through the methylene group. By using the ethanol binding constant reported by Avdulov et al. (*24*) and comparing the results for methanol and ethanol in ref *20*, an approximate binding constant for methanol can be deduced: 0.17 mol dm^{-3}. Ha et al. (*25*) showed that ethanol could displace drugs such as warfarin from HSA. However, Rosenberg et al. (*23*) showed no effect of ethanol on the binding of methyl orange to HSA. The effect of methanol will be less than that of ethanol (*20*). If the added methanol competed equally with the probes for all the binding sites, with a binding constant of 0.17 mol dm^{-3}, then the binding constants for the probes, deduced above, could be a factor of 10 times too high. If, however, the methanol competed only for the drug binding site where we have deduced that the ferrocene group also bound, then only the estimate of binding constant for this site would be in error, although it could be substantially so.

CONCLUSION

We have shown how to design both an instrumentally simple electrochemical system and a set of probe molecules that can be used to determine the occupancy of different classes of fatty acid binding sites on human serum albumin. We have shown how variation in the fatty acid chain length on the probe results in interaction with different classes of sites on HSA and deduced that the interaction can be changed from primarily with a drug binding site, when the probe is ferrocene methanol, to one interacting primarily with medium-chain fatty acid binding sites, by adding a poly(oxoethylene)-fatty acid substituent, to one interacting primarily with high-affinity long-chain fatty acid binding sites as the fatty acid chain length in ferrocene-poly-(oxoethylene)-fatty acid molecules is increased. The results strongly imply that the binding could be further tailored by relatively simple modifications to the probe, for example, to change the balance of hydrophobicity and hydrophilicity. The approach is a general one, in that other small molecules might be electrochemically labeled using similar methods and these probe molecules used to access different classes of binding sites.

Neighboring Group-Controlled Hydrolysis: Towards "Designer" Drug Release Biomaterials

Colin P. McCoy,* Ryan J. Morrow, Christopher R. Edwards, David S. Jones, and Sean P. Gorman

School of Pharmacy, Queen's University Belfast, Belfast BT9 7BL, U.K. Received August 1, 2006; Revised Manuscript Received October 17, 2006

To give the first demonstration of neighboring group-controlled drug delivery rates, a series of novel, polymerizable ester drug conjugates was synthesized and fully characterized. The monomers are suitable for copolymerization in biomaterials where control of drug release rate is critical to prophylaxis or obviation of infection. The incorporation of neighboring group moieties differing in nucleophilicity, geometry, and steric bulk in the conjugates allowed the rate of ester hydrolysis, and hence drug liberation, to be rationally and widely controlled. Solutions (2.5×10^{-5} mol dm^{-3}) of ester conjugates of nalidixic acid incorporating pyridyl, amino, and phenyl neighboring groups hydrolyzed according to first-order kinetics, with rate constants between $3.00 \pm 0.12 \times 10^{-5}$ s^{-1} (fastest) and $4.50 \pm 0.31 \times 10^{-6}$ s^{-1} (slowest). The hydrolysis was characterized using UV−visible spectroscopy. When copolymerized with poly(methyl methacrylate), free drug was shown to elute from the resulting materials, with the rate of release being controlled by the nature of the conjugate, as in solution. The controlled molecular architecture demonstrated by this system offers an attractive class of drug conjugate for the delivery of drugs from polymeric biomaterials such as bone cements in terms of both sustained, prolonged drug release and minimization of mechanical compromise as a result of release. We consider these results to be the rationale for the development of "designer" drug release biomaterials, where the rate of required release can be controlled by predetermined molecular architecture.

INTRODUCTION

The design of enhanced performance, particularly drug eluting, bone cement biomaterials is an area of active current interest. Clinically used poly(methyl methacrylate) (PMMA)-based acrylic bone cements use a strategy of direct incorporation of a particulate anti-infective agent (typically gentamicin) as prophylaxis against postoperative infection. Particulate drug incorporation represents a suboptimal strategy for two main reasons. First, release is initially a burst from near-surface (*1*) and is not prolonged (*2*, *3*). Second, the voids left by this initial release act as stress foci for the bulk PMMA material, which act as nucleation sites for cracks (*4*−*6*). These cracks can subsequently propagate and compromise the mechanical function of the cement (*7*). Additionally, the development of these cracks exposes small amounts of additional particulate drug for release, which then elute at subtherapeutic levels, potentially leading to the emergence of resistant infective organisms.

A rational strategy to improve this situation is therefore to develop labile drug−polymer conjugates, whereby the copolymerization of the appropriate conjugate allows drug to be liberated from a pendant side chain of the main polymer chain. Such release would move toward elimination of the development of stress foci for crack formation, as a particulate drug is no longer dissolved from the release matrix. Additionally, if the rate of liberation of drug from the drug−polymer conjugate can be controlled, materials can be developed which offer sustained release over longer periods than that offered by current technology. Suitable, labile functional groups which undergo hydrolysis at a variety of rates under differing conditions are esters or amides. However, such bonds are frequently very stable, resulting in an extremely slow bond cleavage and subsequent slow release of drug. Attempts to overcome this problem have included the use of enzymatically sensitive spacers between the drug and polymer which are designed to break in vivo and thus improve the release profile (*8*). However, such enzyme-dependent systems require specific, predictable biological conditions, which are frequently not found in biological systems. This can lead to unpredictable drug liberation profiles. Consequently, conjugates which do not rely upon biological enzymes to control the drug release rate make attractive target systems. In particular, hydrolysis of an appropriate drug from a polymer backbone to which it is covalently attached via an ester group is appropriate for adaptation to the fields of bone cement and non-blood contact biomaterials, where esterases are absent, to give both improved release profiles and mechanical properties to drug-eluting drug particle-incorporated strategies in current clinical use. By controlling the rate of drug liberation, the development of "designer" biomaterials, where drug release rate can be controlled precisely and as required clinically, will be possible.

A technology which can be adapted to provide control of the hydrolysis rate for drug−polymer conjugates is that of neighboring group-assisted hydrolysis. In this established technology, an intramolecular nucleophile can accelerate the rate of hydrolysis of a hydrolytically labile functional group, such as an ester (*9*) or amide (*10*). The process involves incorporating a neighboring group (NG) moiety in an appropriate geometry so as to facilitate intramolecular reaction at the carbonyl carbon of the labile group. This process is termed neighboring group participation (NGP). To accelerate NGP-assisted hydrolysis, the NG must contain a nucleophile, such as that found on the lone pair of a nitrogen atom in an amine (*11*), a sulfur atom in a thiol or thioacetal (*12*), or a nitrogen-containing heterocycle such as imidazolyl or pyridyl (*13*, *14*). Phenolate NGs can similarly provide an intramolecular nucleophile through the oxygen bearing a negative charge (*15*). The molecule must also be able to adopt a conformation whereby minimum strain is required to facilitate the attack of the NG at the carbonyl carbon. NGs

which form pseudo five- or six-membered rings during the first mechanistic stage of the hydrolysis reaction have been reported to be particularly successful at accelerating overall hydrolysis rates. As an example, Bruice et al. found that the hydrolysis of 4-(2′-acetoxyphenyl)-imidazole was approximately 10^3 times faster with the intramolecular assistance of an imidazolyl group in a pseudo six-membered ring position than without assistance (*16*).

To apply this technology to enhanced release profile bone cements and related medical device biomaterials, it is first necessary to fully elucidate the effect of different neighboring groups and the conformations adopted during NGP on hydrolysis rates for discrete molecular species (i.e., in solution). Once these effects are fully understood, they inform their performance as pendant drug−polymer conjugates, where additional factors such as porosity and surface density must be considered together with the NGP effect. The current study therefore presents the first account of neighboring group-assisted drug release and examines the effect in solution of various NG-containing drug conjugates of nalidixic acid, an appropriate model quinoline antibiotic. We also demonstrate the drug elution behavior of conjugate-incorporated PMMA biomaterials.

METHODS AND MATERIALS

Materials. Pyridine-2-carboxaldehyde, pyridine-3-carboxaldehyde, benzaldehyde, allylmagnesium bromide, *N*-phenylethanolamine, triethylamine, allyl bromide, ethyl chloroformate, methyl methacrylate, and benzoyl peroxide were obtained from Aldrich Chemical Co., Poole, Dorset, U.K. Anhydrous magnesium sulfate, nalidixic acid, hydrochloric acid, and sodium hydroxide were obtained from BDH Chemicals Ltd., Poole, Dorset, U.K. Ethyl acetate, hexane, benzene, acetone, anhydrous dichloromethane, and anhydrous tetrahydrofuran (THF) were of analytical grade and were obtained from Lab-Scan Limited, Dublin, Ireland. Nuclear magnetic resonance spectra were recorded on a General Electric GN-Ω500 instrument operating at 500 MHz. Chemical shifts are given in parts per million (ppm, δ), downfield of tetramethylsilane (TMS), used as an internal standard. A Nicolet Protégé 460 Fourier Transform infrared (FTIR) spectrometer interfaced with *Omnic E.S.P.* software was used to record infrared spectra as potassium bromide discs (Sigma, Poole, Dorset, U.K.) from 4000 cm^{-1} to 400 cm^{-1}. Mass spectra were recorded on a Finnegan MAT 900 XLT high-resolution double focusing mass spectrometer operating at 70 eV. Melting points were recorded on an Electrothermal 9100 melting point apparatus and are uncorrected. Elemental analysis was carried out using a Perkin-Elmer PE-240 automatic CHN analyzer.

Synthesis of 1-Pyridin-2-yl-but-3-en-1-ol, 1. Pyridine-2-carboxaldehyde (2.00 g, 1.78 mL, 18.7 mmol) was dissolved in dry ether (180 mL) in a three-necked round-bottomed flask. Allylmagnesium bromide (24 mmol, 24.0 mL) was injected through a septum, and the reaction mixture was stirred under a stream of dry nitrogen for 2 h. After this time, the reaction was quenched with water (10 mL). A further 100 mL of water was added to the mixture and the product extracted with ethyl acetate (3 × 50 mL). The combined organic phases were dried over anhydrous magnesium sulfate, filtered, and evaporated to dryness under reduced pressure. The crude product was purified by flash chromatography over silica gel using ethyl acetate/hexane (2:3 v/v) as the mobile phase to afford 2.17 g (78%) of a yellow oil. IR (KBr, cm^{-1}): 3369 (OH), 3075 (=C−H), 2907 (C−H), 1641 (C=C), 1595, 1571 (Ar C=C), 1064 (CO), 1001, 916. NMR δ ^{1}H ($CDCl_3$): 2.51 (1H, m, C*H*^{1}CH^{2}CH=CH_2); 2.62 (1H, m, CH^{1}C*H*^{2}CH=CH_2); 4.47 (1H, s, OH); 4.82 (1H, t, J = 4.8 Hz, CH_2−C*H*−OH); 5.08 (2H, m, CH=*CH_2*); 5.82 (1H, m, C*H*=CH_2); 7.18 (1H, m, Ar−H); 7.31 (1H, d, J = 7.5 Hz, Ar−H); 7.67 (1H, d,d, J_1 = 7.7 Hz, J_2 = 7.8 Hz, Ar−H); 8.52 (1H, d, J = 4.9 Hz, Ar−H).

Synthesis of 1-Pyridin-3-yl-but-3-ene-1-ol, 2. This was prepared by a method analogous to that used for **1**, using pyridine-3-carboxaldehyde (2.00 g, 1.78 mL, 18.7 mmol) in place of pyridine-2-carboxaldehyde. The product was purified by flash chromatography over silica gel using ethyl acetate as the mobile phase to afford 2.11 g (76%) of a pale orange oil. IR (KBr, cm^{-1}): 3213 (OH), 3077 (=C−H), 1580 (Ar C=C), 1427, 1061 (CO), 1028 (CN), 918. NMR δ ^{1}H ($CDCl_3$): 2.52 (2H, m, C*H*$_2$CH=CH_2); 4.03 (1H, s, OH); 4.75 (1H, t, J = 6.5 Hz, CH_2−C*H*−OH); 5.12 (2H, m, CH=C*H*$_2$); 5.75 (1H, m, C*H*=CH_2); 7.25 (1H, m, Ar−H); 7.70 (1H, d, J = 7.9 Hz, Ar−H); 8.37 (1H, d, J = 4.8 Hz, Ar−H); 8.44 (1H, s, Ar−H).

Synthesis of *N*-Allyl, *N*-Phenyl-2-aminoethanol, 3. *N*-Phenylethanolamine (1.00 g, 0.92 mL, 7.3 mmol) was dissolved in benzene (20 mL). To this solution, triethylamine (7.3 mmol, 1.01 mL) and allyl bromide (7.3 mmol, 0.62 mL) were added. This solution was stirred for 24 h. Benzene was evaporated under reduced pressure, and the reaction mixture dissolved in acetone (20 mL) and cooled in ice for 1 h. This caused precipitation of triethylammonium bromide which was removed by filtration and the filtrate evaporated to dryness under reduced pressure. The product was purified by flash chromatography over silica gel with a mobile phase of ethyl acetate/hexane (2:3 v/v) to afford 0.57 g (44%) of yellow oil. IR (KBr, cm^{-1}): 3384 (OH), 2879 (C−H), 1598 (Ar C=C), 1505, 1037 (CO), 748 (Ar−H). NMR δ ^{1}H ($CDCl_3$): 2.01 (1H, s, OH); 3.49 (2H, t, J = 5.8 Hz, NCH_2CH_2OH); 3.77 (2H, t, J = 5.8 Hz, N*C*H$_2$CH$_2$-OH); 3.09 (2H, d, J = 5 Hz, NC*H*$_2$CH=CH_2); 5.16 (2H, m, CH=C*H*$_2$); 5.75 (1H, m, C*H*=CH_2); 6.70 (1H, m, Ar−H); 6.75 (2H, d, J = 8 Hz, Ar−H); 7.20 (2H, m, Ar−H).

Synthesis of 1-Phenyl But-3-en-1-ol, 4. This was prepared by a method analogous to that used for **1**, using benzaldehyde (1.98 g, 1.89 mL, 18.7 mmol) in place of pyridine-2-carboxaldehyde. The product was purified by flash chromatography over silica gel using ethyl acetate/hexane (4:1 v/v) as the mobile phase to afford 2.44 g (88%) of pale yellow oil. IR (KBr, cm^{-1}): 3381 (OH), 3075 (=C−H), 3029 (Ar−H), 2906 (C−H), 1640 (C=C), 1047 (CO), 1000 (CN), 757 (Ar−H). NMR δ ^{1}H ($CDCl_3$): 2.00 (1H, s, OH); 2.46 (2H, m, C*H*$_2$CH=CH_2); 4.68 (1H, t, J = 7.1 Hz, CH_2−C*H*−OH); 5.15 (2H, m, CH=C*H*$_2$); 5.79 (1H, m, C*H*=CH_2); 7.36 (5H, m, Ar−H).

Synthesis of [(1-Ethyl-7-methyl-4-oxo-1,4-dihydro-[1,8]-naphthyridine-3-carbonyl)-amino]-acetic Acid Ethyl Ester, 6. 1-Ethyl-7-methyl-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylic acid (nalidixic acid, 3.65 g, 15.7mmol) was dissolved in anhydrous dichloromethane (100 mL). Triethylamine (3.11 mL, 2.26 g, 22.3 mmol) and ethyl chloroformate (2.03 mL, 2.30 g, 21.2 mmol) were added, and the solution was allowed to stir at ambient temperature for 30 min. The reaction mixture was washed with 0.20 M HCl (2 × 20 mL) and water (1 × 40 mL). The organic phase was dried over anhydrous magnesium sulfate, filtered, and evaporated to dryness under reduced pressure. Recrystallization from acetonitrile gave a white solid (3.36 g, 70.4%). Melting point 122−124 °C. IR (KBr, cm^{-1}): 1014 (C−O stretch), 1174 (O=C−O−C stretch), 1243 (C=O stretch), 1609 (phenyl). NMR δ ^{1}H ($CDCl_3$): 1.31 (3H, t, C$^{15}H_3$); 1.41 (3H, t, C$^{11}H_3$); 2.61 (3H, s, C$^9H_3$); 4.37 (2H, q, C$^{14}H_2$); 4.48 (2H, q, C$^{10}H_2$); 7.3 (1H, d, C^6*H*); 8.67 (1H, d, C^5*H*); 8.69 (1H, s, C^2*H*).

Synthesis of Drug Conjugates. The appropriate alcohol from **1**−**4** (8.0 mmol) was dissolved in dry THF (100 mL), and sodium hydride (8.8 mmol, 0.211 g) was added. The solution was refluxed for 1 h and cooled to ambient temperature. **6** (8.0 mmol, 2.43 g) was added over 15 min, and the reaction mixture stirred for a further 10 min. Ethanol (5 mL) was added to the

solution to deactivate any residual sodium hydride. The reaction mixture was evaporated to dryness under reduced pressure, ethyl acetate (70 mL) was added to the oily residue, and any solid material was removed by filtration to precipitate and remove any nalidixic acid that was present in the reaction mixture. The product was purified by flash chromatography over silica gel using ethyl acetate as the mobile phase in each case to give conjugates **7**−**10** from alcohols **1**−**4**, respectively.

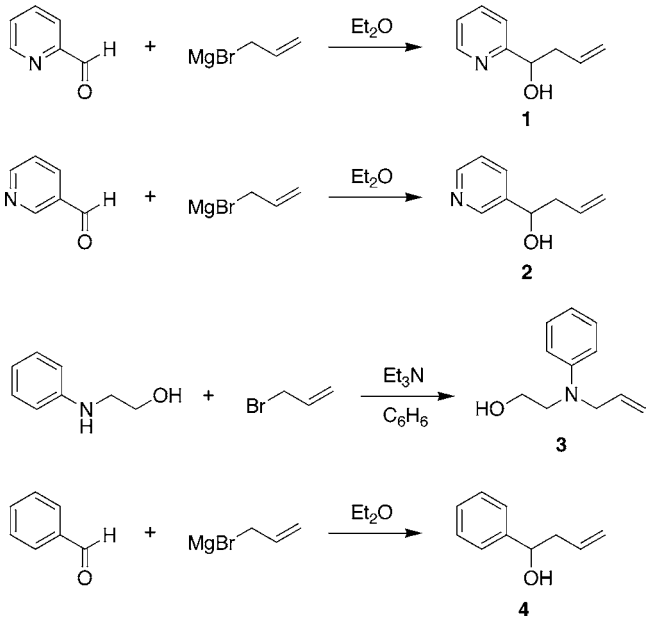
Synthesis of PMMA−Drug Conjugate Copolymers. Methyl methacrylate (MMA) (20 mL) was washed with 0.10 M sodium hydroxide (3 × 20 mL) followed by deionized water (3 × 20 mL) to remove monomethyl ether hydroquinone inhibitor. The MMA layer was isolated, dried over anhydrous magnesium sulfate, and filtered. To a stirred solution of this MMA (12.0 g), the appropriate conjugate from **7**−**10** (4% w/w), a loading equivalent to that used in commercial bone cement biomaterials, and benzoyl peroxide (1% w/w) were added. The mixture was injected into a mold comprising two glass plates separated with 1 mm medical grade silicone tubing lined with release liner. The molds were incubated at 60 °C for 2 h. The resulting polymer sheets were washed with deionized water for 12 h to remove residual MMA.

Characterization of Hydrolysis of Conjugates 7−**10.** A solution of each of the conjugates **7**−**10** (10 mL, 2.5 × 10^{-5} mol dm^{-3}) was prepared in acetonitrile, and aqueous sodium hydroxide solution (0.10 mol dm^{-3}, 1.0 mL) was added. Hydrolysis was characterized by recording UV−visible absorption spectra between 200−400 nm using a Perkin-Elmer LAMBDA 650 UV−visible spectrophotometer at various time intervals for each solution in a 1 cm path length quartz cuvette.

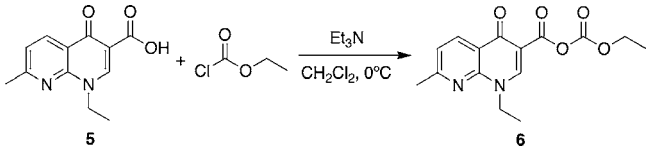
Subsequently, to characterize the products of hydrolysis, the solvent was removed under reduced pressure, yielding a colorless oil. Separation of the products by preparative-scale thin layer chromatography using ethyl acetate as the eluant allowed the identification of the products by means of ^{1}H NMR, infrared spectroscopy, and mass spectrometry.

In Vitro Characterization of Drug Release from Copolymers. Copolymers were cut into 1 cm × 1 cm square samples and suspended using a needle in phosphate buffered saline (pH 7.4, 10.0 mL, 0.254 M ionic strength). Samples were incubated in an orbital incubator at 37.4 ± 0.1 °C for defined periods and the release of nalidixic acid quantified using UV−visible spectroscopy. At each sampling, the copolymers were transferred to fresh, prewarmed buffer to maintain sink conditions. For each copolymer, only nalidixic acid could be detected in the release medium. The identity of nalidixic acid was confirmed by ^{1}H NMR and mass spectrometry following preparative-scale thin layer chromatography following release.



Statistical Analysis. Differences in the hydrolysis rates, amount released from copolymers, and percentage hydrolysis at 60 min were statistically evaluated using the Kruskal-Wallis test. Individual differences between conjugates were identified using Dunn's test. In all cases, at least three replicates were analyzed and $p \leq 0.05$ denoted significance.

RESULTS AND DISCUSSION



Synthesis and Characterization of Drug Conjugates. A series of novel, polymerizable conjugates of nalidixic acid (1-ethyl-7-methyl-4-oxo-1,4-dihydro-1,8-naphthyridine-3-carboxylic acid), **5**, was synthesized by a three-step process. First, a series of four alcohols, **1**−**4**, were prepared from commercial materials via Grignard reaction with allylmagnesium bromide as summarized in Scheme 1. Alcohols **1**, **2**, and **4** were prepared from pyridine-2-carboxaldehyde, pyridine-3-carboxaldehyde, and benzaldehyde, respectively, in high yield (76−88%). Alcohol **3** was prepared from *N*-phenyl ethanolamine and allyl bromide using triethylamine as a base in dry benzene. Following workup and purification by column chromatography, all alcohols were characterized by FTIR and ^{1}H NMR spectroscopies and were determined to be analytically pure and suitable for use in subsequent syntheses.

The second synthetic step involved synthesis of a suitably reactive derivative of nalidixic acid, **5**, for coupling with alcohols **1**−**4**. Direct esterification, even under catalytic conditions, of nalidixic acid is unsuccessful due to the relatively strong intramolecular hydrogen bond between the hydrogen of the carboxylic acid group with the carbonyl oxygen of the carbonyl group of the naphthyridine ring. The stability of this intramolecular hydrogen bond can be ascribed to the cyclic pseudo six-membered ring geometry which the hydrogen-bonded system adopts (*17*). Additionally, synthesis of a reactive acyl chloride derivative has been hampered by the reactivity of the methyl

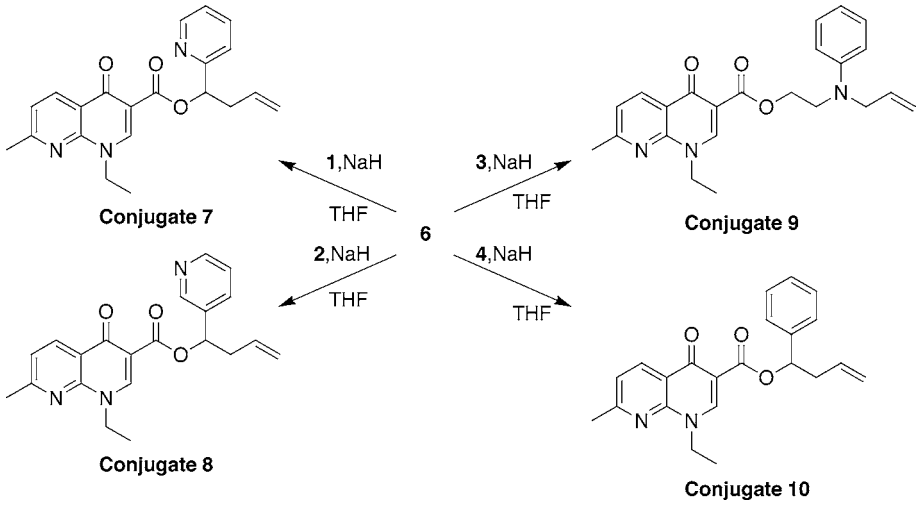
Scheme 1. Synthesis of Alcohol Intermediates 1−4

Scheme 2. Synthesis of 6, a Mixed Anhydride of Nalidixic Acid, 5

group directly attached to the naphthyridine ring toward thionyl chloride and phosphorus oxychloride, resulting in chlorination of the methyl group preferentially to production of acyl chloride (*17*). Attempts at esterification using coupling reagents dicyclohexylcarbodiimide (DCC) and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDCI) also failed, which we ascribe to the inhibition of formation of the required imide intermediate by the intramolecular hydrogen bond. A successful strategy for the synthesis of amides of nalidixic acid has employed a mixed anhydride as a reactive intermediate (*18*, *19*). We have adapted this strategy to the synthesis of esters of nalidixic acid by isolating the mixed anhydride formed by the reaction of nalidixic acid with ethyl chloroformate, as shown in Scheme 2, and subsequently reacting this anhydride with an appropriate deprotonated alcohol. Reaction of nalidixic acid with ethyl chloroformate in dichloromethane at 0 °C in the presence of triethylamine gave mixed anhydride, **6**, after workup in 70% yield.

The third, convergent step of the synthesis involved coupling of the mixed anhydride of nalidixic acid, **6**, with each of the alcohols **1**−**4** separately, to give conjugates **7**−**10** as summarized in Scheme 3. To achieve efficient reaction, each alcohol was deprotonated with sodium hydride, and nucleophilic attack of the resulting alkoxide with the reactive carbonyl carbon of **6** yielded the corresponding drug conjugate in good yield following workup and purification by column chromatography. Each conjugate was fully characterized using FTIR and ^{1}H NMR spectroscopies, mass spectrometry, and elemental analysis, and each was determined to be analytically pure. All alcohols and conjugates were synthesized as racemates.

Nalidixic acid, a broad-spectrum quinoline antibiotic, was chosen as the model antibiotic to demonstrate the system, as it is active against typical pathogens found in infected, cemented hip arthroplasties (*20*). The design of synthesized conjugates **7**−**10** is such that each conjugate incorporates nalidixic acid covalently linked via an ester functionality to a moiety (a vinyl group) capable of taking part in free radical polymerization with, for example, acrylates, methacrylates (as used in bone cements), and related free-radical polymerization biomaterials (*21*). Additionally, a further moiety is included in each conjugate which is designed to either accelerate or retard the rate of liberation of nalidixic acid by hydrolysis. This moiety, separated from the ester via an inert spacer and termed the neighboring group (NG), is varied in the conjugates studied to explore how variations in two key factors—intramolecular nucleophilicity (for facilitated hydrolysis) and steric bulk (for hindered hydrolysis)—affect the rate of drug release. A schematic representation of the molecular design is shown in Figure 1.



Conjugates **7** and **8** incorporate a pyridyl moiety which is either 2- or 3-substituted with respect to the potential nitrogen nucleophile. Conjugate **10** shares the steric geometry of these conjugates but lacks the intramolecular nucleophile. Conjugate **9** offers a different (amino) intramolecular nucleophile and was thus expected to offer a further, different rate of hydrolysis. The conjugates were thus designed to exemplify how the ability to act as an intramolecular nucleophile and steric bulk can be simultaneously controlled to give a wide control of hydrolysis, and hence drug release, rates. The choice of and geometry of intramolecular nucleophile were informed by related neighboring group participation ester hydrolysis systems incorporating amines, pyridyl (*14*), and other nucleophilic moieties such as imidazole (*16*) and related moieties (*13*).

Characterization of Drug Liberation in Solution. To characterize the drug liberation behavior of the conjugates, hydrolysis studies were carried out in acetonitrile solution containing 1% (v/v) water. Overlaid UV−visible spectra for each of the conjugates **7**−**10** at various times during the course of hydrolysis show very similar behavior for each conjugate. As a representative example, overlaid spectra for conjugate **8** are shown in Figure 2.

Prior to hydrolysis, all conjugates show maxima at 231, 257, and 335 nm (334 nm for conjugate **7** and 336 nm for conjugate **10**) with a shoulder at 326 nm (325 nm for conjugate **7**). As hydrolysis progresses, these bands show a hypsochromic shift, and the longest-wavelength band with a shoulder resolves, with a hypsochromic shift of 3 nm, to a single band. During the hydrolysis, the spectra for each conjugate show an isosbestic point at 344, 345, 345, and 342 nm for conjugates **7**−**10**, respectively. The closely similar spectral trends for conjugates **7**−**10** indicate that similar processes occur for each conjugate. Such spectral changes, with a clear isosbestic point, indicate that a single reaction is taking place with no side reactions. The longest-wavelength absorption is, for all conjugates, due to the nalidixate chromophore, which has an extended π-system. Large wavelength changes upon hydrolysis are not expected, as nalidixic acid, with the same π-system, is liberated. The observed 3-nm hypsochromic shift, together with a broadening of the band, indicates the loss of a small, stabilizing interaction arising from the relevant NG. This stabilization may arise from the nonbonded nitrogen lone pair in conjugates **7**−**9** or, more likely, a small degree of overlap with the aromatic π-system for all conjugates, which is lost upon hydrolysis. Monitoring of absorbance changes with time at an appropriate wavelength therefore provides a sensitive probe to the progress of the hydrolysis reaction. Quantification of the first-order rate constant using spectral data at either 257 nm or 334 nm ($r^2 > 0.99$ in all cases) and the percentage hydrolysis completed after 1 h is shown in Table 1. The only significant difference between the conjugates is the time required for the hydrolysis reaction to proceed to completion, which is ascribed to the nature of the neighboring group.

At the conclusion of the hydrolysis experiments, chromatographic separation and identification of the reaction products

Scheme 3. Synthesis of Drug Conjugate Monomers 7−10

showed that free nalidixic acid was liberated in all cases. This is in agreement with related NGP hydrolyses reported in the literature and indicates that drug is liberated in the manner expected.

Data from Table 1 demonstrate that the nature of the neighboring group has a very significant effect on the drug liberation characteristics of each conjugate. The order of hydrolysis rate from fastest to slowest is conjugate **9** > **8** > **7** > **10**, which is reflected in the percentage of hydrolysis shown in each system after 1 h. After this time, 48.8% of conjugate **9** is hydrolyzed in comparison to 11.1% for conjugate **10**. The strong influence of the neighboring group on the hydrolysis rate can be rationalized in terms of the nucleophile strength and relative stability of the required intramolecular intermediate. Conjugate **9**, which hydrolyzes most rapidly, has the strongest potential nucleophile of the series. As an aliphatic amine, its NG is significantly more basic than the pyridyl NGs of conjugates **7** and **8**. Additionally, the nature of the intermediate can be predicted from the examination of precision space-filling Corey−Pauling−Koltun (CPK) molecular models (Harvard Apparatus, Massachusetts) (*22*). These models use accurate bond angles according to both the nature and the hybridization of both atoms participating in that bond and also accurately reflect typical van der Waals atomic radii. As such, space-filling CPK models are considered accurate to within 0.3 Å (*23*). Models show that intramolecular attack of the amine for conjugate **9** is conformationally accessible through an unstrained five-membered intermediate. This conformation is therefore expected to be readily thermally accessible in solution; hence, hydrolysis can proceed relatively rapidly.

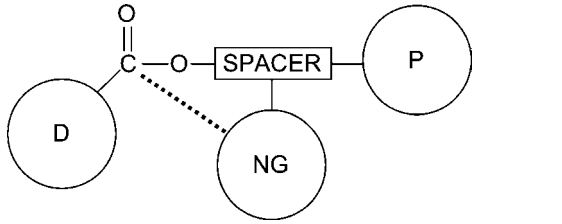


Figure 1. Schematic representation of design of neighboring group-controlled drug ester conjugates where D = drug, NG = neighboring group, and P = polymerizable group. Interaction of NG with the ester group is indicated by a dashed line.

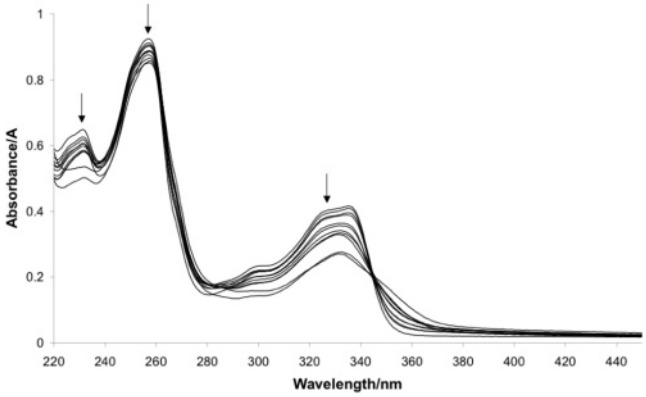

Figure 2. Overlaid UV−visible spectra of conjugate **8** after various times during hydrolysis in acetonitrile containing 1% (v/v) 0.10 M aqueous sodium hydroxide. The spectral changes are representative of conjugates **7**−**10**. Arrows indicate trends in spectral change with time. Spectra shown were recorded at times of 0, 0.25, 0.5, 1, 2, 3, 4, 5, 6, 9, and 25 h.

Table 1. Hydrolysis Rate Constants and Percentage Hydrolysis after 60 Min for Conjugates 7−10

conjugate	hydrolysis rate constant k (s^{-1})	hydrolysis after 60 min (%)
7	$7.51 \pm 0.52 \times 10^{-6}$	12.5%
8	$1.79 \pm 0.39 \times 10^{-5}$	30.1%
9	$3.00 \pm 0.12 \times 10^{-5}$	48.8%
10	$4.50 \pm 0.31 \times 10^{-6}$	11.1%

The trend in hydrolysis rate also implies that the 3-pyridyl NG conjugate, **8**, participates more readily as an intramolecular nucleophile than the 2-pyridyl NG conjugate, **7**. This is not necessarily expected from a simple examination of the structures; however, a more detailed examination using space-filling molecular models allows a rationale for this behavior to be achieved. For intramolecular nucleophilic reaction of the pyridyl nitrogen with the ester carbonyl carbon, a pseudo five-membered ring must form as an intermediate for conjugate **7**, while a pseudo six-membered ring must form for conjugate **8**. Six-membered species are usually considered marginally more stable than five-membered species. Additionally, in the case of conjugate **7**, the geometry of the nitrogen lone pair is such that it cannot be in line with the rear side of the carbonyl carbon−oxygen σ bond, which is optimal for nucleophilic attack. Conversely, conjugate **8** can achieve this geometry, and the more rapid observed drug release can thus be accounted for in terms of this improved geometry for reaction compared to conjugate **7**, given that the nature of the nucleophiles for conjugates **7** and **8** are the same. Conjugate **10**, which lacks an intramolecular nucleophile, but has almost identical steric considerations as conjugates **7** and **8**, is observed to have the slowest hydrolysis rate. This conjugate demonstrates that each of the conjugates

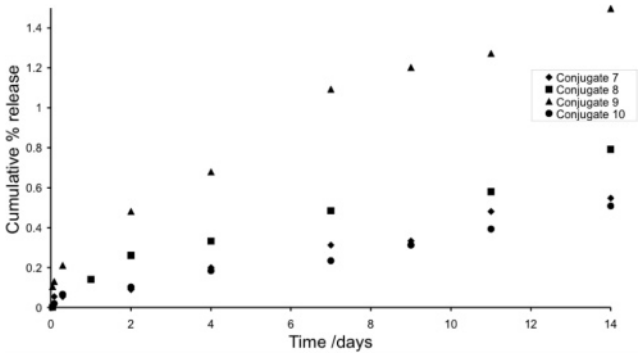

Figure 3. Plot of cumulative release with time for copolymers of MMA with conjugates **7**−**10**. Error bars (±1 standard deviation), in all cases, were less than the indicated point size and have been omitted for clarity.

with an intramolecular nucleophile shows an accelerated hydrolysis rate.

Characterization of Drug Liberation from Copolymers. To characterize the in vitro drug liberation behavior of the conjugates in model bone cement biomaterials, conjugates **7**−**10** were each copolymerized separately with methyl methacrylate with a conjugate loading of 4% (w/w), which is a similar drug loading to commercial drug-eluting PMMA bone cements (*1*−*4*). Release into phosphate buffered saline over 14 days demonstrated that only nalidixic acid was released. The conjugate design is such that the neighboring group remains covalently attached to the copolymer backbone following hydrolysis and is not observed in the release medium, which is important, as only the active drug is released and thus bioavailable. Quantitation of the cumulative relative amount of nalidixic acid released from each copolymer at various times is shown in Figure 3.

Importantly, Figure 3 demonstrates that the polymeric matrices give the same order of kinetic release as seen in solution, with the relative release rate decreasing in the order conjugate **9** > **8** > **7** > **10**. This reinforces the mechanism of drug liberation and demonstrates that NGP-controlled hydrolysis can applied to polymeric biomaterials. The observed release is primarily from the copolymer surface, as PMMA-based materials are hydrophobic and show only a small degree of subsurface ingress of water. The resulting reduced steric availability of water, and use of physiological pH, leads to a slower release rate than that in solution while retaining the neighboring group-controlled trend in release rate.

As release is from the material surface only, 0.5−1.5% of the total incorporated drug is released over 14 days. This is in line with the surface release of drug from drug-incorporated PMMA biomaterials (*1*). Prolonged release from these copolymers introduces several additional considerations, such as the formation of cracks and voids, common in drug-eluting PMMA-based biomaterials (*4*−*6*), which provides additional, fresh polymer surface for hydrolytic release, and the consideration of relatively slow drug diffusion from nonsurface, hydrated subsurface areas of the copolymers, which adds an additional phase of release to the hydrolysis-induced surface release demonstrated here (*1*). Such considerations, particularly of crack and void formation, relate to the important biomaterial considerations of tensile properties (*7*). The mechanical, porosity, and diffusion aspects are beyond the scope of this paper and will be published elsewhere with data on prolonged release.

The system demonstrated here is well-suited to relatively nonporous biomaterials such as PMMA-based bone cement, where surface burst release currently observed would be minimized by the judicious combination of conjugates in a composite biomaterial giving different release rates of the same drug, depending on the nature of the neighboring group, to give a sustained release profile. In conventional, drug-incorporated systems, the rapid (<1 day) burst of release from the surface, followed by elution of low, subinhibitory amounts of drug, makes their clinical performance nonideal. Also, as particulate drug is not dissolved during release in the present system, fewer stress foci and nucleation sites for crack formation and propagation will be formed using this technology, thereby improving mechanical performance.

In conclusion, this study demonstrates the rational synthesis and characterizes the solution hydrolysis of a range of drug conjugates suitable for subsequent copolymerization in biomaterials for acrylate-based bone cements or other medical device biomaterials, where release from current materials is not optimal. The kinetic control of drug liberation rate translates to PMMA-based conjugate copolymers. The ability to control the rate of drug release by neighboring group participation-assisted hydrolysis through the judicious choice of intramolecular nucleophile is shown to give a greater than an order of magnitude control of the release rate. This paradigm is also of general applicability to the design of sustained release formulations.

ACKNOWLEDGMENT

This study was funded by the Engineering and Physical Sciences Research Council (U.K.) under grant GR/N63604/01 and the European Social Fund. The receipt of a Royal Society University Research Fellowship (to McCoy) and use of the EPSRC National Mass Spectrometry Service Centre, Swansea, are acknowledged.

Received May 10, 2006; Revised Manuscript Received September 25, 2006

Technetium-labeled fatty acids intended for myocardial metabolism imaging and the respective rhenium model complexes were synthesized according to the "4 + 1" mixed-ligand approach and investigated *in vitro* and *in vivo*. The non-radioactive rhenium model complexes were characterized by NMR, IR, and EA, and the geometrical impact of the chelate unit on the integrity of the fatty acid head structure was determined by single-crystal X-ray analyses. To estimate the diagnostic value of the ^{99m}Tc-labeled fatty acids, the compounds were investigated in experiments *in vitro* and in biodistribution studies using male Wistar rats. The new fatty acid tracers contain the metal core in the oxidation states +3, well-wrapped in a trigonal-bipyramidal coordination moiety, which is attached at the ω-position of a fatty acid chain. This structural feature is considered to be a good imitation of the well-established iodinated phenyl fatty acids. High heart extraction in perfused heart studies (up to 26% injected dose (ID)) and noticeable heart uptake of the ^{99m}Tc tracers *in vivo* being in the order of 2% ID/g at 5 min (postinjection, pi.), accompanied by a good heart to blood ratio of 8, confirms that the new Tc compounds are suitable as fatty acid tracers.

INTRODUCTION

The present work aims at the development of new technetium-based radiopharmaceuticals that are suited for the noninvasive diagnosis of myocardial diseases. In particular, efforts have been directed toward the design, synthesis, and biological evaluation of ^{99m}Tc-labeled fatty acids (Tc−FAs) searching for representatives that show biodistribution patterns similar to the well-known iodophenyl FA (*1*, *2*). Such technetium compounds are of potential use as tracers for myocardial FA metabolism single-photon emission tomography (SPET) imaging. Despite many attempts, an appropriate technetium FA is still not available (*3*).

The crucial point in developing Tc-"labeled" FAs is the impact of the metal technetium on the structure and biological properties of the FA. Therefore, the successful design of Tc−FAs requires a chelating moiety that enables strong binding of the FA to the metal center but at the same time preserves the physiological integrity of the FA.

The recent progress in coordination chemistry of technetium provided a variety of new neutral and small-sized mixed-ligand Tc chelate types that can be used for this purpose. They form almost exclusively square-pyramidal Tc(V)-oxo complexes of tetradentate ligands (*4*) and in some rare cases strong lipophilic Tc(I)-carbonyl species (*5*, *6*). Our preliminary approach to label FAs with technetium was based on oxotechnetium(V) complexes as well (*7*, *8*). All these systems suffer from the fact that molecular properties and the *in vivo* patterns of biomolecule−chelate conjugates are strongly influenced by the presence of the polar metal-oxo unit, making them unsuitable for mimicking FAs.

Previously, we have developed mixed-ligand Tc(III) and Re(III) complexes with a "4 + 1" donor atom arrangement, where the metal is coordinated by both a tripodal tetradentate ligand and a monodentate ligand (*9*) (Figure 1).

The "4 + 1" approach was applied for Tc−FAs as shown exemplarily for the dodecanoic acid technetium derivative with $n = 4$, [12-[isocyano-κC]dodecanoic acid][2,2′,2″-(nitrilo-κN)-triethanethiolato(3−)-κS]technetium(III) (IUPAC name). Such Tc complexes seem to be a promising alternative to the oxotechnetium-derived chelates, since they are rather lipophilic and highly stable, particularly toward challenging SH agents (*10*). Therefore, we have focused on this system to design Tc−FA compounds. The coordination chemistry of technetium with the FA-coupled ligands as well as *in vitro* and *in vivo* evaluations of their applicability as radiotracers is described.

EXPERIMENTAL PROCEDURES

Chemicals. Commercially available substances and all solvents were of reagent grade and used without further purification. Bis(triphenylphosphine)palladium(II) chloride, ω-amino undecanoic acid and ω-amino dodecanoic acid were purchased from Aldrich (Taufkirchen, Germany). Syntheses of the tetradentate tripodal ligand tris(2-mercaptoethyl)amine (NS_3) and the rhenium precursor complex designated **RePMe$_2$Ph** have been reported elsewhere (*11*). (Since all the complexes differ

only in the nature of the monodentate ligand, the abbreviation "**ReMonodentate**" is used throughout the text.) Tris(2-mercaptoethyl)amine was isolated and applied as the oxalate. Sodium pertechnetate ($Na^{99m}TcO_4$) was eluted from a $^{99}Mo/^{99m}Tc$ generator (Mallingkrodt, Le Petten, The Netherlands).

Instrumentation. Nuclear magnetic resonance spectra were recorded on a 400 MHz Varian Inova 400 spectrometer. The ^1H and ^{13}C chemical shifts are reported relative to residual solvent signals or TMS as reference. Mass-spectrometric measurements were performed with a Micromass tandem quadropole mass spectrometer (Quadro LC) operating in the MS mode. Mass-spectral data were recorded in the positive ESI mode. About 10^{-4} mol of the sample dissolved in 1.0 mL of methanol or acetonitrile were injected at a flow rate of 5 mL/min. Element analyses were performed on a LECO Element Analyzer CHNS-932. UV/vis spectra were recorded on a SPECORD S10 spectrometer (Carl Zeiss Jena). HPLC analysis and purification of ^{99m}technetium complexes were performed using a Perkin-Elmer instrument consisting of a Turbo LC system with a quaternary pump (series 200 LC pump) and a programmable absorbance detector model 785A. Nonradioactive rhenium complexes were monitored by their UV absorption at 254 nm, and ^{99m}technetium complexes by γ-ray detection (Bohrloch, NaI(Tl) crystal).

General Procedure for Alkyl ω-(Formylamino)alkanoates (3a−d, 11a−e, and 16). ω-Methoxy ω-oxoalkan-1-aminium chloride (5 mmol) was dissolved in 20 mL of methanol, 20 mL of ethyl formate, and 750 μL (5.4 mmol) of triethylamine and heated under reflux for 36 h. After removal of the solvent, the remaining white residue was dissolved with chloroform, and this solution was washed with water before separation.

Ethyl 8-(Formylamino)octanoate (3a). Yield: 50% colorless oil. Anal. ($C_{11}H_{21}NO_3$ (215.29)): calcd C 61.37%, H 9.83%, N, 6.51%; found C 61.31%, H 10.04%, N 6.48%. ^1H NMR (400 MHz, $CDCl_3$): 8.14 (s, 1H), 5.6 (s, H), 4.09 (q, 2H, OC*H*$_2$-CH$_3$, J = 7.2 Hz), 3.26 (t, 2H, C*H*$_2$CN, J = 6.8 Hz) 2.26 (t, 2H, C*H*$_2$, J = 7.5 Hz), 1.48−1.60 (m, 8H, 4xC*H*$_2$), 1.22 (t, 3H, OCH$_2$C*H*$_3$, J = 7.1 Hz). ^{13}C NMR (100.6 MHz, $CDCl_3$): 174.1 (*C*OO), 161.4 (*O* = *C*), 60.4 (O*C*H$_2$CH$_3$), 38.3 (*C*H$_2$N), 34.5, 29.6, 29.1, 29.0, 26.8, 25.0, 14.5 (OCH$_2$*C*H$_3$). Phenylene-Inserted FA Body by Sonogashira Coupling. To the ice-cooled (0 °C) solution of 6-phthalimido-1-hexine **13** (2.5 mmol) and p-iodophenylethylacetate **14** (1.8 mmol) in acetonitrile (10 mL) was added triethylamine (5 mmol) followed by the addition of bis(triphenyl-phosphine)palladium(II) chloride (0.15 mmol) and CuI (0.025 g) under an argon atmosphere. The reaction mixture was stirred for 30 min at 0 °C and then at room temperature for 2 h. The orange-colored solution was concentrated under reduced pressure, and the residue was partitioned between 5% citric acid (50 mL) and ethyl acetate (50 mL). The organic layer was washed with 5% citric acid (3 × 15 mL) and water, dried with Na_2SO_4, and concentrated. The crude product was purified by column chromatography on silica gel (hexane/ethylacetate, 3:2).

Ethyl {4-[6-(1,3-Dioxo-1,3-dihydro-2*H*-isoindol-2-yl)hexynyl]-phenyl}acetate (15). Yield: 68% of orange waxy solid. Anal. ($C_{24}H_{23}NO_4$ (389.44)): calcd C, 74.02; H, 5.95; N, 3.60; found C, 73.98; H, 5.86; N, 3.37. Ethyl {4-[6-(Formylamino)hexyl]phenyl}acetate (16). The catalytic reduction of **15** (711 mg = 1.828 mmol) was accomplished in 10 mL of methanol under addition of 150 mg of 10% palladium on charcoal under pressure of 1.5 bar H_2 in a 150 mL autoclave and stirring at room temperature for 12 h. After filtration of the mixture, the solvent was removed *in vacuo*, and the waxy residue was redissolved in 15 mL of ethanol. The addition of 1.1 equiv of hydrazine hydrate and 2 h refluxation leads to the desired substituted ω-amino fatty acid ester. This crude product was used for the general formylation procedure. Yield: 78% colorless oil. Anal. ($C_{17}H_{25}NO_3$ (291.39)): calcd C 70.07%, H 8.65%, N, 4.81%; found C 70.22%, H 8.34%, N 4.77%. ^{1}H NMR ($CDCl_3$): 8.14 (s, 1H, NC*H*O), 7.32 (d, 2H, phenyl, J = 7.82 Hz), 7.18 (d, 2H, phenyl, J = 8.10 Hz), 5.63 (s, 1H, N*H*), 4.16−4.08 (q, 2H, OCH_2CH$_3$), 3.56 (s, 2H, CH_2-Ph), 3.21 (t, 2H, CH_2N, J = 6.98 Hz), 2.58 (t, 2H, CH_2, J = 7.78 Hz), 1.71−1.59 (m, 8H, 4xCH_2), 1.22 (t, 3H, OCH$_2$CH_3, J = 7.08 Hz). ^{13}C NMR ($CDCl_3$): 171.5 (*C*OOEt), 161.4 (N*C*HO), 133.9, 131.9, 129.1, 128.9, 61.1 (O*C*H$_2$CH$_3$), 39.8 (*C*H$_2$N), 35.5, 31.1, 29.2, 28.3, 27.6, 26.2, 14.2 (OCH$_2$*C*H$_3$). ESI-MS (MeOH): *m*/*z* (%) = 292 (100) $[C_{17}H_{26}NO_3]^+$.

General Procedure for Alkyl ω-Alkyl-isocyanoalkanoates (4a−d, 12a−e, and 17) Methyl ω-(formylamino)alkanoate (1.5 mmol) was dissolved in 15 mL of anhydrous pyridine, and 330 mg (1.73 mmol) of *p*-toluenesulfonyl chloride was added under ice cooling. After having been stirred for 1.5 h at 0 °C, the mixture was transferred in a flask filled with 75 g of ice. After the temperature was slowly raised above the freezing point, the oily product was extracted three times with diethyl ether, and the organic layer was washed with a saturated solution of sodium chloride. The product was purified by column chromatography on silica gel 60 using a mixture of diethyl ether and *n*-hexane (2:5) as eluent.

General Procedure for the Synthesis of "4 + 1"-Re−FA Complexes. A 65 mg (125 μmol) sample of **RePMe$_2$Ph** was dissolved in 6 mL of CH_2Cl_2 and 155 mmol (1.24 equiv) of alkyl isocyanoalkanoate **4**, **12**, or **17** dissolved in further 4 mL of CH_2Cl_2 was added. The mixture was stirred 12 h at room temperature. The solvent was stripped *in vacuo*, and the complex was purified by column chromatography ($CHCl_3$/acetone = 20/1). Dissolved in 10 mL of dioxane and stirred with 2 mL 0.5 N sodium hydroxide 48 h at rt, the ester functions were saponified. After neutralization with 1 N citric acid, the solvent was removed *in vacuo*. Further purification was carried out by column chromatography ($CHCl_3$/acetone/AcOH = 90/10/0.1)

General Procedure for Cu(I) Complex Preparation. A well-stirred mixture of the corresponding isocyanide (4 mmol) and copper(I) chloride (1 mmol) in 10 mL of MeOH was refluxed for 10 min. After stirring over a period of 1 h at ambient temperature, the resulting solution was concentrated *in vacuo*. The residue was extracted with $CHCl_3$, filtered off, and dried *in vacuo* (purification of this crude product can be done by recrystallization from Et_2O, EtOAc/hexane).

[Cu(methyl 11-isocyanoundecanoate)$_4$]Cl (4bCu). Crystallized from diethyl ether. Yield: 85%. (Cu{methyl 5-[(7-isocyanheptyl)thio]pentanoate}$_4$)Cl (12c-CuCl). Yield: 90% oily product. ^{1}H NMR (400 MHz, $CDCl_3$): 1.21−1.40 (m, 6H, CH_2), 1.52−1.59 (m, 4H, CH_2), 1.67−1.72 (m, 4H, CH_2), 2.29 (t, 2H, CH_2 CH_2COOMe, J = 7.5 Hz), 2.46 (m, 4H, CH_2SCH_2), 3.50 (broad, 2H, CH_2NC), 3.62 (s, 3H, CH_3). ^{13}C NMR (100.6 MHz, $CDCl_3$): 24.3, 26.5, 28.5, 28.7, 28.8, 29.3, 29.6, 32.0, 32.3, 33.8, 43.1, 51.6, 143.6 (broad), 173.9. IR (KBr): 2196.6 ν(N≡C), 1739.2 ν(C═O). ESI-MS (MeOH): *m*/*z* (%) = 1148 (10) $[C_{56}H_{100}CuN_4O_8S_4]^+$.

General Radiolabeling Procedure. The procedure is exemplified for the ^{99m}TcC11−FA (C11): 0.5 mL of pertechnetate solution (100−500 MBq generator eluate) was added to a before prepared EDTA kit, which contains 1 mg of EDTA, 0.04 mg of stannous(II) chloride and 5 mg of mannitol. After 20 min tempering by 37 °C, a purity control by TLC (silica gel/acetone) followed. In most cases, the ^{99m}Tc(III)−EDTA complex was recovered with over 99% radiochemical purity. The EDTA complex solution was added to a mixture of 0.3 mg of 2,2,2-nitrilotris(ethanethiol) (oxalate), dissolved in 0.1 mL of water and 0.05 mg of tetra(methyl 11-isocyanoundecanoate)copper-(I) chloride in 0.2 mL of *n*-propanol, and kept for 30 min at 90 °C. Subsequently the ester function was saponified by addition of 0.1 mL of 1 N sodium hydroxide to the reaction mixture kept at 75 °C for 10 min. After neutralization with 1 N hydrochloric acid, the ^{99m}Tc−FA complex was purified by semipreparative HPLC (Hypersil RP-18, eluent methanol/0.01 M phosphate buffer, pH 7.4; gradient in 10 min from 60 → 100% methanol; flow rates 2 mL/min (semipreparative), 1 mL/min (analytical); retention time between 7 and 8 min). After the removal of methanol by vacuum evaporation 200 μL of propylene glycol was added. The radiochemical yield was 85%.

X-ray Data Collection and Processing. The X-ray data were collected at room temperature (293 K or 273 K) on a SMART-CCD diffractometer (SIEMENS), using graphite monochroma-

tized Mo Kα radiation (λ = 0.710 73 Å). A summary of the crystallographic data of **ReC15−FA**, **Re12b**, and **4cCu** is given in Table 1. The structures were solved by direct methods. After anisotropic refinement of the non-hydrogen atoms, the hydrogen positions were calculated according to ideal geometries. Empirical absorption corrections were made. Most of the calculations were carried out in the SHELXTL system with some local modifications. Selected bond lengths and angles are reported in figure legends of the crystal structures. CCDC 287047 (**ReC15−FA**), CCDC 287049 (**Re12b**), and CCDC 287048 (**4cCu**) contain the supplementary crystallographic data for this paper. These files can be obtained free of charge via http://www.ccdc.cam.ac.uk/data_request/cif, by emailing data_request@ccdc.cam.ac.uk, or by contacting The Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K.; fax: +44 1223 336033.

Determination of the Surface Activity in Aqueous Solution. *Sample Preparation.* For surface tension, **ReC12−FA** was vacuum-dried from 1 mM $CHCl_3$ solution overnight and redissolved in ethanol at 5 mM. A portion (20 μL) was added to 580 μL of distilled water, and surface tension was determined using a KIBRON μ-trough. Subsequent dilutions by a factor of 2 were made and measured in the same way. The effect of residual ethanol was found to be less than 4 mN/m.

For FTIR, phosphatidylcholine and **ReC12−FA** compound were dissolved in chloroform in a ratio of 50:1 lipid/rhenium−FA and vacuum-dried overnight. Distilled water (1 mL) was added; the mixture was homogenized and sonicated in a bath sonicater (5 min). The resulting suspension was extruded through a polycarbonate filter (0.2 μm) using an Avestin extruder. Large unilamellar vesicles obtained in this way were dried on a diamond attenuated total reflectance (ATR) cell (Resultec). Infrared spectra were obtained from this liposome film at room temperature with a VECTOR 22 FTIR spectrophotometer (BRUKER, Karlsruhe) using 2 cm^{-1} resolution (256 scans). Samples were exposed to an atmosphere of either saturated H_2O or D_2O to observe isotope-sensitive absorptions. The effect of pH was studied by adding defined amounts of unbuffered solutions of NaOH or HCl at pH 9 and pH 2, respectively, and evaporating the water.

Activation of Tc−FA Tracers by Acyl-CoA Synthetase. The activation of ^{99m}Tc-labeled fatty acids by acyl-CoA synthetase was determined in cell extracts obtained from cultured human hepatoma cell line HepG2 and in isolated rat mitochondria. The cultivation of HepG2 cells and isolation of mitochondria from rat liver homogenates were performed according to established standard protocols. ^{99m}Tc-labeled FAs, for example, $^{99m}TcNS_3$C12−FA, were added to 1 mL of reaction mixtures containing 200 mM Tris-HCL, pH 7.5, 8 mM $MgCl_2$, 2 mM EDTA, 20 mM sodium fluoride, 0.1% Triton X-100, and 0.2 mM dithiothreitol with and without 0.5 mM ATP and 0.5 mM CoA (*12*, *13*). The reactions were initiated by adding either the cell extracts or the isolated mitochondria and terminated by a mixture of 2-propanol, *n*-heptane, and 1 M H_2SO_4 (40:10:1). Separation of hydrophilic and lipophilic reaction products was performed by triplicate extraction with 2.0 mL of *n*-heptane. The radioactivity of the separated phases was measured using an activimeter for ^{99m}Tc. Furthermore, all phases were analyzed by HPLC, TLC, and ESI-MS analyses.

Isolated Heart Preparation. An isolated retrogradely perfused Langendorff rat heart preparation (*14*) was used in our study. The investigation conformed to the guidelines of the German Regulations for Animal Welfare. The protocol was approved by the local Ethical Committee for Animal Experiments. Male and female Wistar rats (n = 22, 200−250 g) purchased from Charles River (Sulzfeld, Germany) were used. Anesthesia was performed in two steps: After resting in a diethyl chamber for a short time, deep anesthesia was achieved by an intraperitoneal (ip) injection of 2−3 mL of urethane (15%). In addition, 1000 U/kg ip heparin was injected. Hearts were rapidly removed during continuous cooling (Krebs−Henseleit buffer (KHB), 4 °C) and mounted within 1 min via the aorta vertically on a perfusion cannula. Perfusion was immediately started according to the Langendorff technique (*14*) with a modified KHB containing the following (mmol/L): NaCl 116, KCl 4.6, $MgSO_4$ 1.2, KH_2PO_4 1.2, $NaHCO_3$ 25, $CaCl_2$ 2.5, glucose 11, and pyruvate 2. The buffer was equilibrated with a 95% O_2/5% CO_2 gas mixture (resulting pH 7.38) and FA-free bovine albumin (0.1%, 14.9 μmol/L) and maintained at 37 °C. The pulmonary artery was catheterized to permit

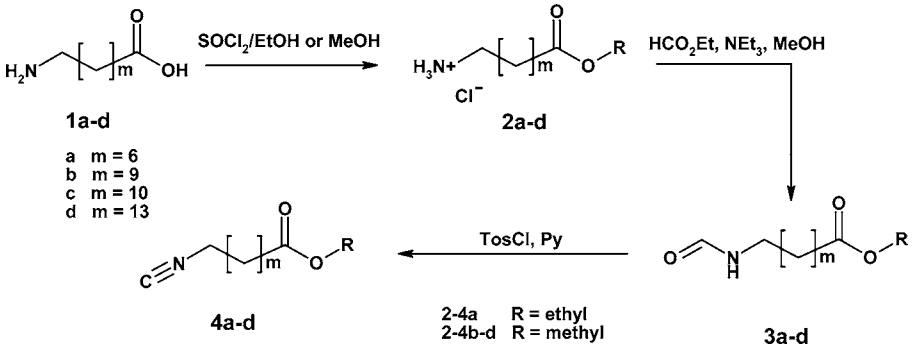

Figure 2. Synthesis of alkyl isocyano alkanoates **4a**−**d**.

anaerobic collection of the coronary venous effluent perfusate. Total coronary flow was measured using an ultrasonic transit-time flowmeter (T206, Transonic Systems Inc., Ithaca, NY) inserted in the arterial perfusion line and kept constant at 10 mL/min. Coronary perfusion pressure (CPP) was measured through a pressure transducer (Gould Statham, USA) connected to the perfusion cannula. Heart rate was calculated manually from a CPP print-out. "Arterial" and "venous" perfusate samples collected anaerobically were analyzed for pO_2, pCO_2, pH, and HCO_3^- (AVL 990S, AVL Scientific Corporation, Roswell, GA) before each intervention. At the start of interventions, the perfusion pressure and heart rate were stable at 91 ± 4 mmHg and 270 ± 6 beats/min, respectively. The influent O_2 tension was 510 mmHg. After 30 min of steady-state perfusion with 10 mL/min of normotherm KHB enriched with 0.1% albumin, isolated hearts were perfused with FA tracers for 180 s in a 1:1000 ratio. The venous effluent perfusate was collected in intervals of 15 s for 225 s following the start of tracer infusion. Perfusion was stopped, the heart was dissected into atria and ventricle compartments, and γ-activity was measured. A total of seven compounds were tested in this way.

***In Vivo* Stability of FA Tracers.** *In vivo* experiments in rats were performed to investigate the stability of FA tracers. Briefly, ^{99m}Tc-labeled FA (50 MBq) were administered intravenously into male Wistar rats (Kyoto−Wistar strain; aged 5−6 weeks; 150 ± 15 g). At 60 min postinjection (pi.), the animals were sacrificed and plasma samples and organ homogenates (liver, intestine) were obtained. Analysis was performed by radio-HPLC (Hewlett-Packard series 1050, LiChroCART RP18 reversed phase, 7 μm particle size, 250 mm × 4 mm).

Biodistribution Studies in Rats. All animal experiments were carried out with male Wistar rats (Kyoto−Wistar strain; aged 5−6 weeks; 150 ± 15 g) according to the guidelines of the German Regulations for Animal Welfare. The protocol was approved by the local Ethical Committee for Animal Experiments. Animals were kept under a 12 h light−dark cycle and fed with commercial animal diet and water *ad libitum*.

For biodistribution studies, the complexes were injected into the tail vein of the animals under light ether anesthesia. The injection volume of ^{99m}Tc−FA solution (0.5 MBq; radiochemical purity >96%) was 0.5 mL. Biodistribution was determined in groups of eight rats sacrificed 5 and 60 min pi. by heart puncture under ether anesthesia. Organs and tissues of interest were rapidly excised and weighed, and the radioactivity was determined (Cobra II gamma counter, Canberra-Packard, Meriden, CT). The accumulated radioactivity in organs and tissues was calculated as the percentage of the injected dose per organ (%ID/organ) or per gram of tissue (%ID/g tissue). Data are given as mean ± standard deviation (SD) of four animals.

Statistical Analysis. All data are presented as means ± standard deviations (SD). Statistical analyses were carried out using SPSS software for MS Windows (Release 11.0, SPSS Inc., Chicago, IL) using ANOVA and LSD *post hoc* adjustment. The error probability $p < 0.05$ was taken to indicate a statistical significance.

RESULTS AND DISCUSSION

1. Synthesis of Isocyano-Functionalized Fatty Acids and Derived "4 + 1" ^{99m}Tc/Re Complexes. The development of Tc/Re(III)-labeled FA analogues making use of the "4 + 1" mixed-ligand concept can be accomplished by the metal coordination with the tetradentate (tripodal) tris(2-mercaptoethyl)amine and one exchangeable monodentate neutral ligand; the latter should combine σ-donor and π-acceptor properties. Both the isocyanide and phosphane functionality fulfill this requirement (*9*, *15*, *16*). In this study, we have preferred sterically less demanding long-chain alkanoate substituted isocyanides to mimic FA. The instability of the free isocyano-substituted acids requires the conversion of the appropriate carboxyl group into the alkyl ester during the ligand synthesis and the complex preparation. The alkyl isocyano alkanoates **4a**−**d** were synthesized according to Figure 2.

In the first step, the ω-amino-FAs **1** were transformed into their alkyl ester hydrochloride form **2** by reaction with thionylchloride in ethanol or methanol. The appropriate ω-methoxy-ω-oxoalkane-1-aminium chlorides **2** were converted into the corresponding formamides **3** via the reaction with ethylformate in presence of triethylamine. The formation of the isocyano function follows the method described by Corey *et al.* (*17*). using tosylchloride and pyridine as dehydrating agents. The long-range couplings of the CH_2 protons to the ^{14}N (tt, $^2J_{NH}$ = 1.9 Hz, $^3J_{HH}$ = 6.8 Hz, 2H, CH_2N) in the neighborhood of the isocyano group (*18*) are characteristic ^{1}H NMR signals for alkyl isocyano compounds (for examples of ^{1}H and ^{13}C NMR spectra, see Supporting Information) and can be used as an analytical probe.

The thia-inserted FA derivatives (Figure 3) were generated in a six step procedure starting from the commercially available 5-bromovaleric acid **5** related to the preparation of the mercapto-substituted FA ligands (*7*). After nucleophilic substitution of the terminal halogenide by a mercapto unit **6**, the FA body **8** was built up by coupling to a ω-bromo-1-alkanol **7** under basic conditions. Conversion of the hydroxyl group into the bromide **9** was accomplished via an adapted version of the Appel reaction (*19*). With a further nucleophilic substitution of the bromide atom in **9** by azide, subsequent reduction to an amino function, and the analogous conversion of the amino group (formylation to **11a**−**e**, dehydration), the isocyano fatty acid ligands **12a**−**e** were accessible in good yields.

Spectroscopic data (IR, ^{1}H NMR, ^{13}C NMR), as well as element analyses, confirm the expected structures.

Isocyano-Substituted FA Containing a Phenylene Blocking Group. The insertion of a phenylene group into the FA chain appears as an experimentally easily accessible and alternative route for the induction of metabolic interferences in analogy to the already described iodine-labeled derivative ^{123}I-PHIPA (*20*).

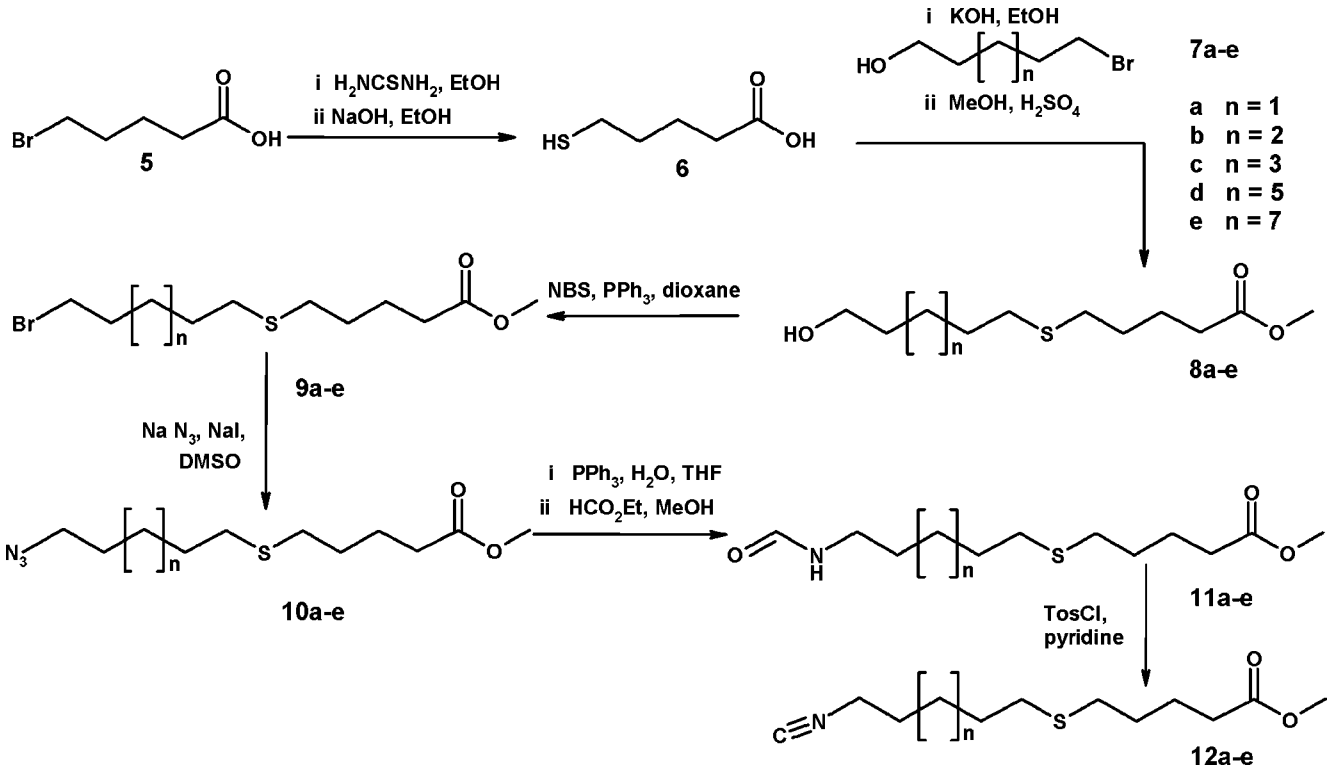

Figure 3. Synthesis of the sulfur-containing isocyano FA ligands **12a**−**e**.

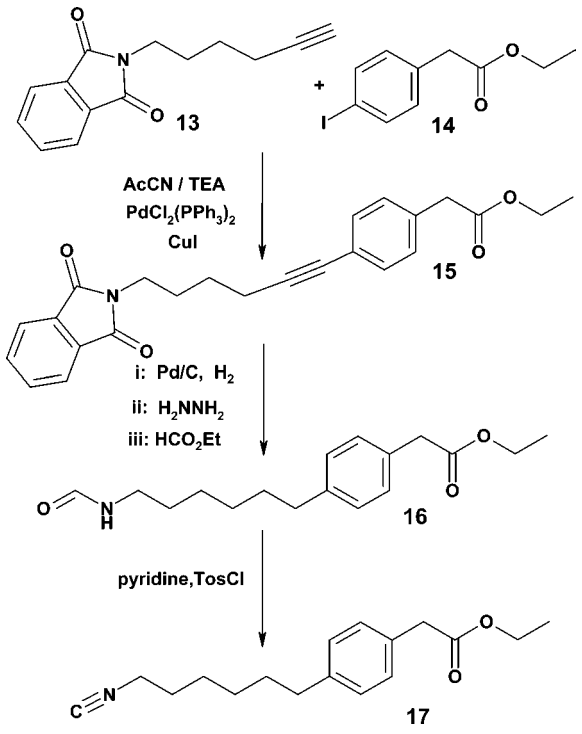

Figure 4. Example of a phenylene-bridged ω-isocyano FA **17**.

Thus, we developed a synthesis of ω-isocyano phenylene-inserted FA. The new phenylene-inserted FA **17** (Figure 4) was prepared starting from the commercially available end-standing alkine 6-phthalimido-1-hexine **13** and *p*-iodophenylethylacetate **14** by Sonogashira coupling (*21*) to the phenyl-substituted alkyne **15**. The catalytic reduction of the triple bond and the liberation of the amine unit with hydrazine hydrate resulted in the saturated amino FA ester. According to the analogous conversion of the amino group (formylation to **16**, dehydration as in former experiments), the isocyanide **17** was accessible in suitable yield. Spectroscopic data (^{1}H NMR, ^{13}C NMR, MS) were collected and confirm the expected structure.

Isocyano FA Ester Copper(I) Complexes. Additional advantages for handling and storage of isocyano FA ligands have been achieved by their conversion into the corresponding copper(I) complexes (*22*). Isocyanido copper(I) complexes are described as alternative sources of isocyanides, especially as precursors for the commonly used ^{99m}Tc routine radiopharmaceuticals ^{99m}Tc(I) SESTAMIBI (*23*).

The desired complexes are easily accessible by mixing the isocyanide solution with a copper(I) chloride solution in methanol in the appropriate 4:1 ratio (Figure 5).

The crystal structure in Figure 6 reveals the expected tetrahedral geometry of the copper(I) complex despite the long chain FA ester substituents on the isocyano ligands. The C−N distances of around 116 pm in the coordinating isocyano groups (exemplary N(2)−C(15) 115.9(5) pm) are characteristic for the bond order of three and appear unchanged compared with free isocyanides (*22*).

The ^{13}C NMR signals of the four chemically equivalent isocyano carbon atoms of the copper(I) complexes are positioned around 142 ppm but are difficult to locate because of their broad line width, $h_{1/2}$, of up to 50 Hz (see Supporting Information Figure 2). The reason for this strong broadening of the resonance signals should be the presence of the $^{63/65}$Cu-quadrupole nuclei as has been described for Cu(I)-phosphane complexes (*24*).

"4 + 1" Re and ^{99m}Tc Complexes. The "4 + 1" rhenium(III) phosphane complex **RePMe$_2$Ph** serving as precursor in the manner described (*11*) reacts in dichloromethane with the appropriate alkyl isocyanoalkanoate **4**, **12**, or **17** to the ester compound, which leads to the desired model complex of the free FA after saponification (Figure 7, additional analytical data of isolated ester compounds **Re4b**−**d** and **Re12a**−**e** were given in Supporting Information). These nonradioactive rhenium

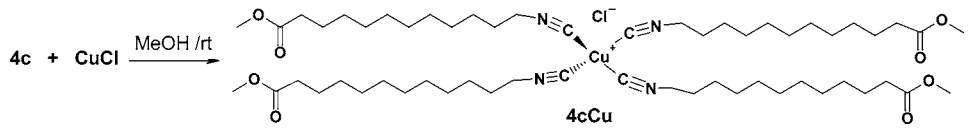

Figure 5. Preparation of the isocyano FA ester copper(I) complex **4cCu**.

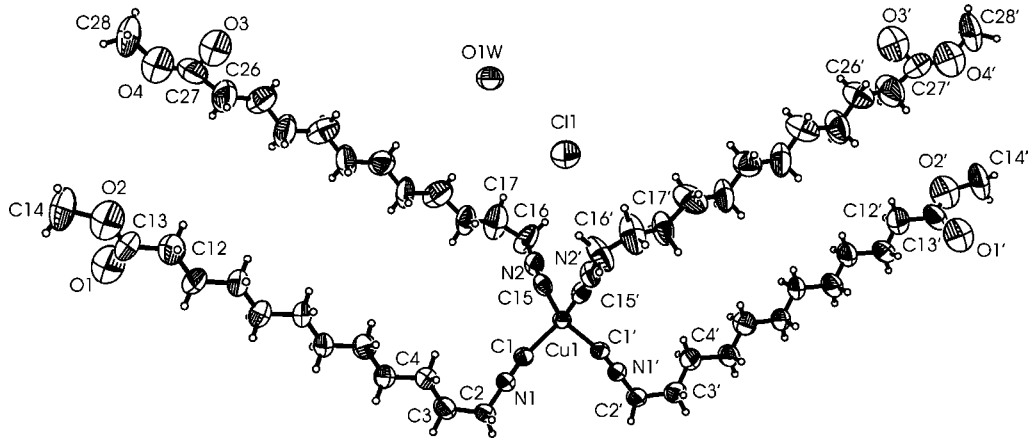

Figure 6. Molecular structure of the FA copper(I) complex **4cCu.** Selected bond lengths [pm] and angels [deg]: Cu−C(15) 198.0(5), N(2)−C(15) 115.9(5), C(15)−N(2)−C(16) 175.1(5).

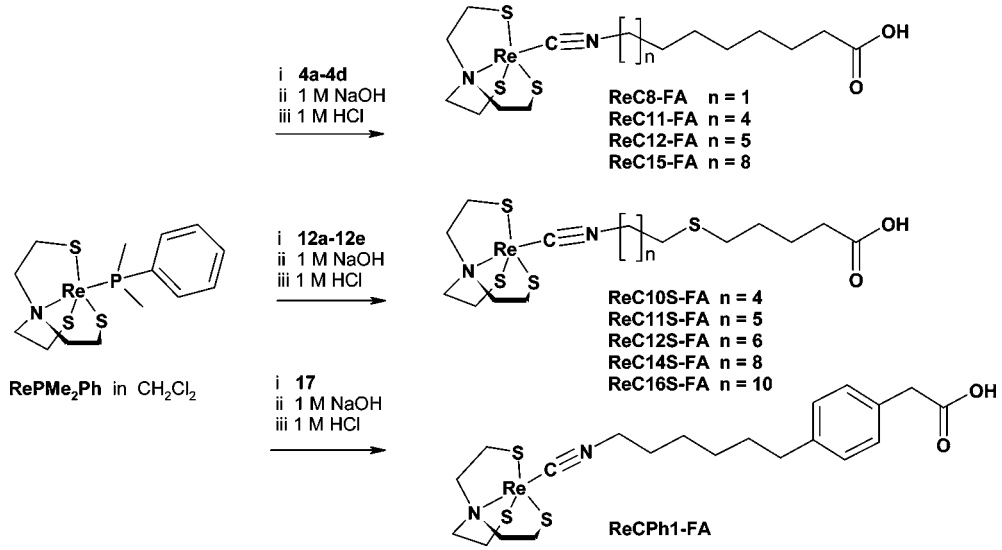

Figure 7. Synthesis of the rhenium FA model complexes.

complexes were used as reference compounds for the chemical characterization and identification of the corresponding ^{99m}Tc complexes especially by comparison of the retention times on HPLC.

The different chemical properties of the (acid-) labile free isocyanides, of the rhenium complexes with high stability in a large pH range, and of the quite stable copper(I) complexes correlate with different spectroscopic behaviors. Both types of isocyano complexes show opposite changes of the chemical shifts of the isocyano carbon atom, depending on the metal type. In comparison to the free isocyanide **4d** (155.7 ppm), the rhenium complex **ReC15−FA** shows a noticeable low field shift to 162.5 ppm compared with the high field shift to 142.2 ppm in the copper(I) complex **4dCu** (for selected extracts of ^{13}C NMR spectra see Supporting Information). The same general tendency is seen in the absorption bands of the different isocyano groups in the appropriate IR spectra of **4d** (2148 cm^{-1}), **ReC15−FA** (2038 cm^{-1}), and **4dCu** (2179 cm^{-1}). These results indicate a slightly reduced CN bond order in the Re complexes: the isocyano carbon tends to sp^2-character caused by back-donation. This contrasts the sp character of the carbon atom in the CN triple bond of the isocyano copper(I) complexes, where back-donation in Cu(I)- or Ag(I)-isocyano complexes plays a minor role (*25*). This explanation was supplemented and confirmed further by the crystal structure data of **4cCu** and **ReC15−FA**.

Structural Characterization of the Re Model Complexes. Figures 8 and 9 show examples for the ester complex **Re12b**, as well as the FA complex **ReC15−FA**. A summary of the crystallographic data is given in Table 1, and selected bond lengths and angles are reported in the figure legends. Both complexes crystallize in the triclinic space group $P\bar{1}$, and crystals contain no solvents or other interactions. The two complexes adopt a trigonal-bipyramidal geometry where the three NS_3 thiolate sulfurs form the trigonal plane and the amine nitrogen of the tetradentate ligand and the isocyano carbon occupy the apical positions. The N2−C7 bond lengths of 119.3(16) pm and 118.9(13) for the isocyano ligands in **Re12b** and **ReC15−FA**, respectively, show the expected prolongation compared with the isocyano FA copper(I) complex.

The molecular structure of **ReC15−FA** obtained by X-ray structure analysis is presented in Figure 9. The carbon chain of

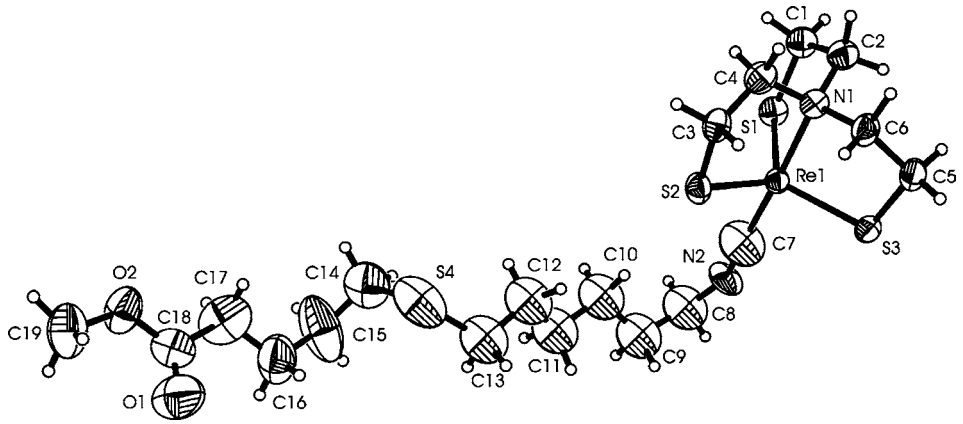

Figure 8. ReC11S−FA-methyl ester (**Re12b**). Selected bond lengths [pm] and angels [deg]: Re−C(7) 195.1(12), N(2)−C(7) 119.3(16), Re−N(1) 220.1(8), C(7)−Re−N(1) 178.5(4), N(2)−C(7)−Re 177.9(12).

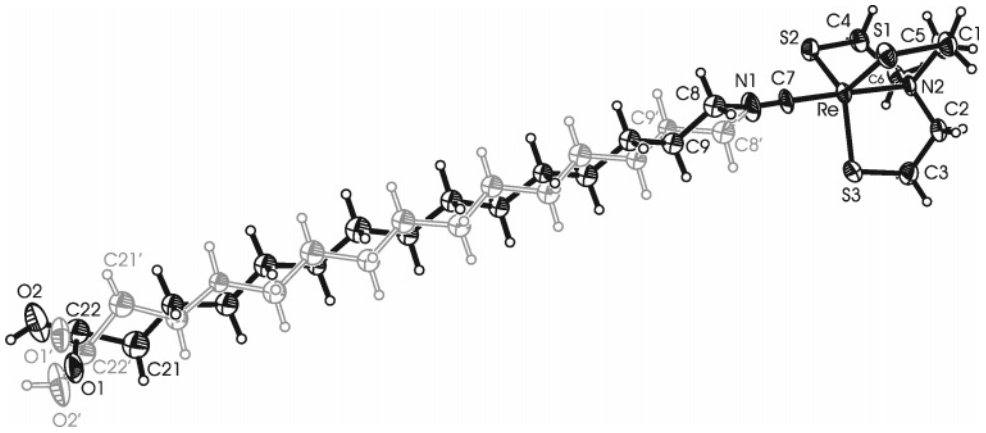

Figure 9. The molecular structure of the **ReC15−FA** model complex. Selected bond lengths [pm] and angels [deg]: Re−N(2) 217.8(8), Re−C(7) 190.7(10), N(1)−C(7) 118.9(13), C(7)−Re−N(2) 177.3(4), N(1)−C(7)−Re 176.8(10).

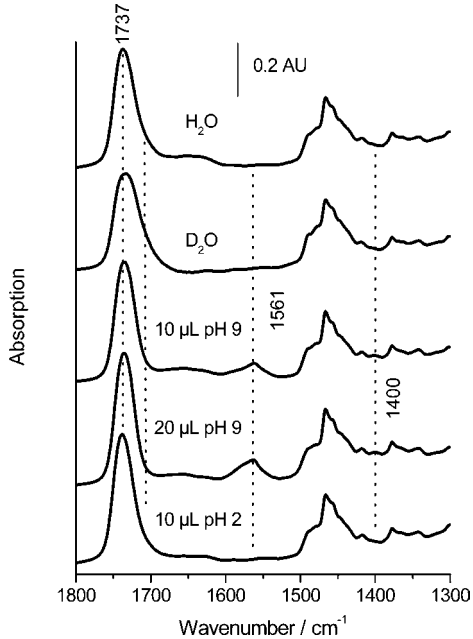

Figure 10. FTIR spectra of **ReC12−FA**-reconstituted liposomes: (a) dried from H_2O; (b) dried from D_2O; (c) dried after addition of 10 μL of NaOH (10 μM); (d) dried after addition of 20 μL of NaOH (10 μM); (e) same sample as in panel d after addition of 10 μL of HCl (10 mM).

the complex **ReC15−FA** is positionally disordered over two positions. Dimers are formed in the crystal structure and are stabilized by H-bonds (O2−O1 = 265.8 pm; O2′−O1′ = 261.5 pm).

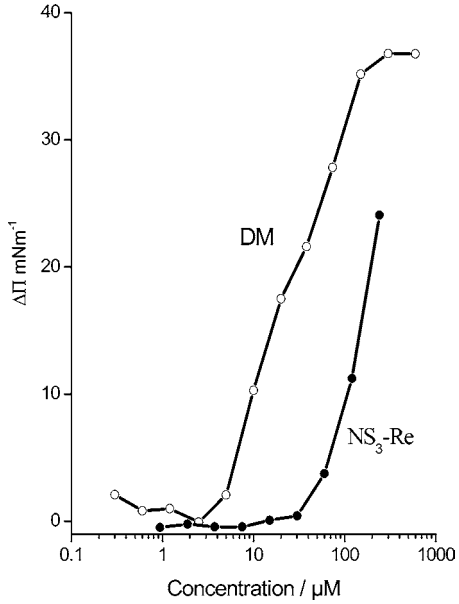

Figure 11. Concentration dependence of surface tension at the air−water interface. DM = dodecyl-β-D-maltoside; NS_3−Re = **ReC12−FA**.

Physicochemical Characterization: Determination of the Surface Activity in Aqueous Solution. Transport and membrane passage of lipophilic Tc/Re−FAs are influenced to a high extent by hydrophobicity/hydrophilicity relations at the lipid−water interface. Therefore, their amphipathic nature was assessed by surface tension measurements, which revealed the surface activity of this kind of compound as exemplified for the rhenium

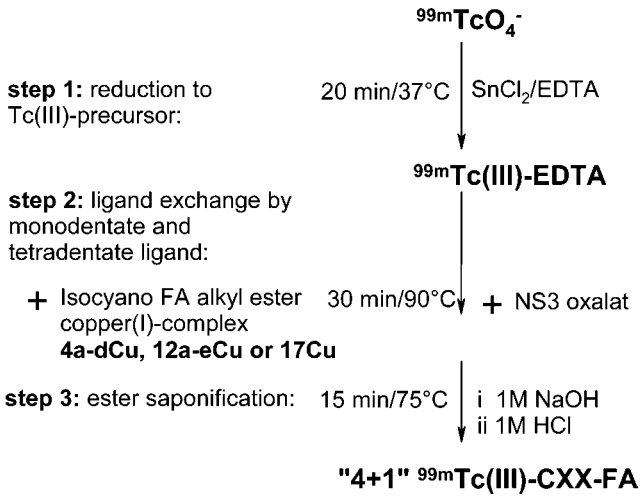

Figure 12. "4 + 1" ^{99m}Tc−FA preparations on nca level.

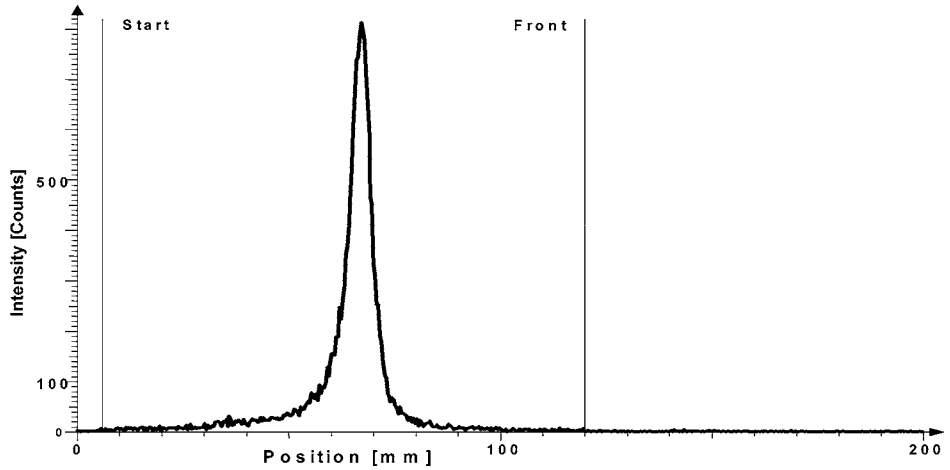
model complex **ReC12−FA.** The surface tension of water is decreased by 20−25 mN/m at 200 μM concentration of **ReC12−FA**. For comparison, a comparable change of the surface tension is observed with the detergent *n*-dodecyl β-D-maltoside at 20 μM. The amphipathic nature of **ReC12−FA** suggests that, when incorporated into liposomes, the transmembrane positioning will match hydrophobicity/hydrophilicity at the lipid−water interface. Accordingly, the free carboxylic acid is likely to be exposed to the aqueous phase near the lipid head groups, whereas the rhenium chelate is more likely to be buried within the lipid acyl chains. To address this question, the aqueous accessibility and titratability of the carboxyl group was determined by FTIR spectroscopy (Figures 10 and 11). FTIR spectra of **ReC12−FA**-reconstituted liposomes exhibit a strong ester carbonyl vibration at 1737 cm^{-1}. Upon H/D exchange, the center of the peak shifts to 1733 cm^{-1} and the low-frequency part of the band broadens. These spectral alterations indicate the additional presence of non-ester carbonyls from protonated/deuterated carboxylic acids in which the C═O stretching mode is coupled to OH bending. The coupling is abolished in D_2O, leading to the down shift of the C═O stretching frequency in the liposomes when dried from a D_2O atmosphere. To further prove the presence of a carboxylic acid group and to determine its solvent accessibility, we have recorded IR spectra at different pH. Addition of small amounts of 10 μM NaOH (pH 9) followed by evaporation of water to ambient humidity induces spectral changes consistent with deprotonation of a carboxylic acid group. The strong 1737 cm^{-1} band becomes narrower at the low-frequency side with increasing addition of base. Simultaneously, a band at 1560 cm^{-1}, not present in the original liposome spectra, appears and increases with addition of base. These spectral changes evidence the deprotonation of a carboxylic acid, causing the disappearance of its C═O stretching mode around 1730 cm^{-1} (i.e., at a position also deduced from H/D exchange) and a concomitant appearance of the antisymmetric COO^- mode at 1561 cm^{-1} during the transition from a COOH to a COO^- group. Consistent with this interpretation, also the weaker absorption increase of the symmetric COO^- mode upon addition of base can be identified at 1400 cm^{-1}, although on a broad background. As expected for a titration-dependent signal, the spectral changes are completely reversed by acidification (addition of small amounts of 10 mM HCl, pH 2), which also re-establishes the band broadening in the 1700−1730 cm^{-1} range, where the C═O stretch of protonated carboxyl groups overlaps with the ester carbonyl absorption. The only carboxylic group present in the sample is that of **ReC12−FA**. Since the FTIR data evidence its titration, it must be exposed to the liposome surface. This indicates that the rhenium-carrying moiety is buried in the hydrophobic core of the lipid bilayer, whereas the polar carboxylic acid group is positioned close to the polar lipid head groups, where it can exchange protons (deuterons) with the environment.

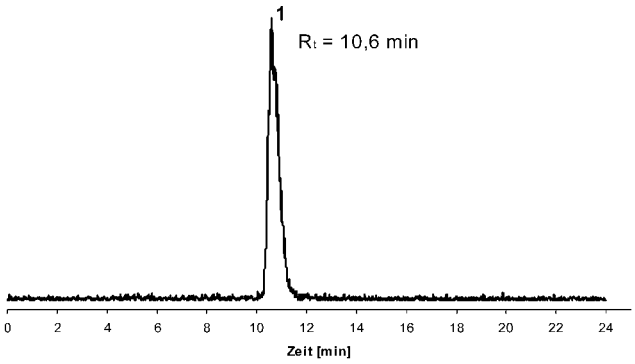
Preparation of No-Carrier-Added (nca) ^{99m}Tc−FA. The nca preparation of the "4 + 1" ^{99m}Tc−FA was carried out in a three-step procedure and based on the use of ^{99m}Tc(III)−EDTA complexes as precursors, which react with the NS3-ligand (as oxalate) and the copper(I) complex of the isocyano fatty acid ester at 90 °C (Figure 12). After saponification of the ester function the radiochemical yields range from 50% to 80% depending on the FA chain length. Purification is carried out by HPLC and can be controlled by radio-TLC. Under the above-mentioned conditions, the radiochemical yields in case of the **C11** derivative were about 80%. Figure 13 illustrates the TLC characterization of selected ^{99m}Tc−FA.

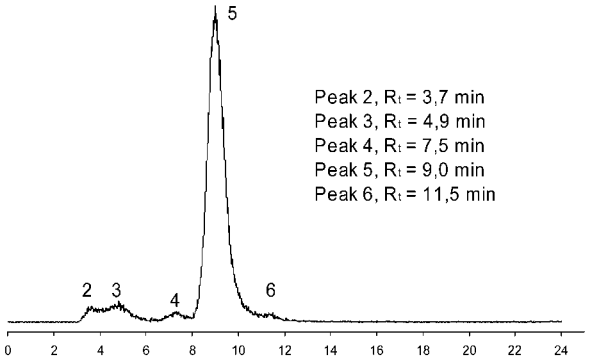
2. In vitro studies. *Metabolism of Tc−FA: Activation by Acyl-CoA Synthetase.* The activation of Tc−FA by acyl-CoA synthetase was investigated for selected Tc−FA to ascertain their potential acceptability as metabolism tracers. Figure 14 shows radio-HPLC chromatograms of **C12** tracer in enzyme reaction mixture containing ATP and CoA in both the aqueous phase (B) and the heptane phase (C).

The data indicate that the Tc−FA (chromatogram A) was activated by acyl-CoA synthetase in cell extracts. The aqueous phase (chromatogram B) contained one major hydrophilic metabolite, suspected to be the corresponding FA−acyl-CoA.

These data show the formation of a FA−acyl-CoA conjugate and confirm in part our results from experiments using the







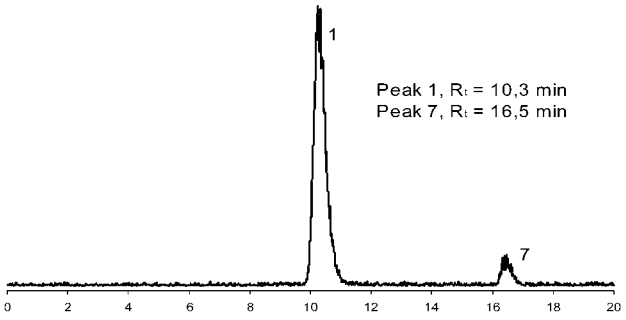


Figure 13. Radio-TLC characterization of ^{99m}TcC11−FA (**C11**), CH_3CN/H_2O + 0.1% TFA, 8/2, RP 18 R_f value = 0.65.

B) RC of the aqueous phase of enzyme reaction mixture containing both ATP and CoA

C) RC of the heptane phase of enzyme reaction mixture containing both ATP and CoA

Figure 14. Representative radio-HPLC analysis of the activation of TcNS$_3$C12−FA (**C12**) by acyl CoA-synthetase in HepG2 cell extracts.

^{99m}TcNS$_3$C12−FA (**C12**). Similar results have been obtained with rat liver mitochondria.

To confirm the identity of the suspected product, ESI-MS analyses were carried out with the corresponding nonradioactive **ReC12−FA**. For ESI-MS analysis, the **ReC12−FA** was applied to the enzyme reaction mixture (see Supporting Information Figure 3). Figure 3a of Supporting Information shows the spectrum of the original **ReC12−FA** before and Figure 3b that after application to HepG2 cell extracts. This spectrum reveals unequivocally the presence of the **ReC12−FA**−acyl-CoA conjugate.

Metabolism of Tc−FA: Degradation of Fatty Acid Moiety from C12 to C2. The ^{99m}TcC12−FA (**C12**) was injected into Wistar rats, and samples were taken from plasma and intestine (homogenated) 60 min pi. Figure 15 shows the radio-HPLC chromatograms of the respective samples. As seen in Figure 15, the Tc−FA was completely metabolized *in vivo* to form one major metabolite. We hypothesize that this metabolite is the **C2−FA** (^{99m}TcNS$_3$−tripod−CN−CH$_2$−COOH), which has been designated **Tc4** in previous studies on its synthesis, stability, and biodistribution studies (*10*). The reported stability of the isocyano ester complex **Tc4** in rat plasma and the biodistribution study are obviously equivalent to investigations of the free **C2** fatty acid generated by the well-known very fast ester cleavage in rat plasma (*27*). This assumption is supported by HPLC analysis showing coelution of the corresponding rhenium **ReC2−FA** (*9*) at the same retention time as the radioactive metabolite.

The metabolic *in vivo* studies reveal the complete β-oxidation within 1 h. This is consistent with observations made with Tc-tripod-derived tracers, showing that the chelate remains unattacked in metabolic studies. However, liver activity is mainly responsible for metabolism, and the contribution of the heart has to be proven.

Extraction Studies on Perfused Rat Heart. Experiments on isolated perfused rat hearts provide a simple and well reproducible approach to detect promising ^{99m}Tc compounds in biodistribution experiments. Although many compounds have been

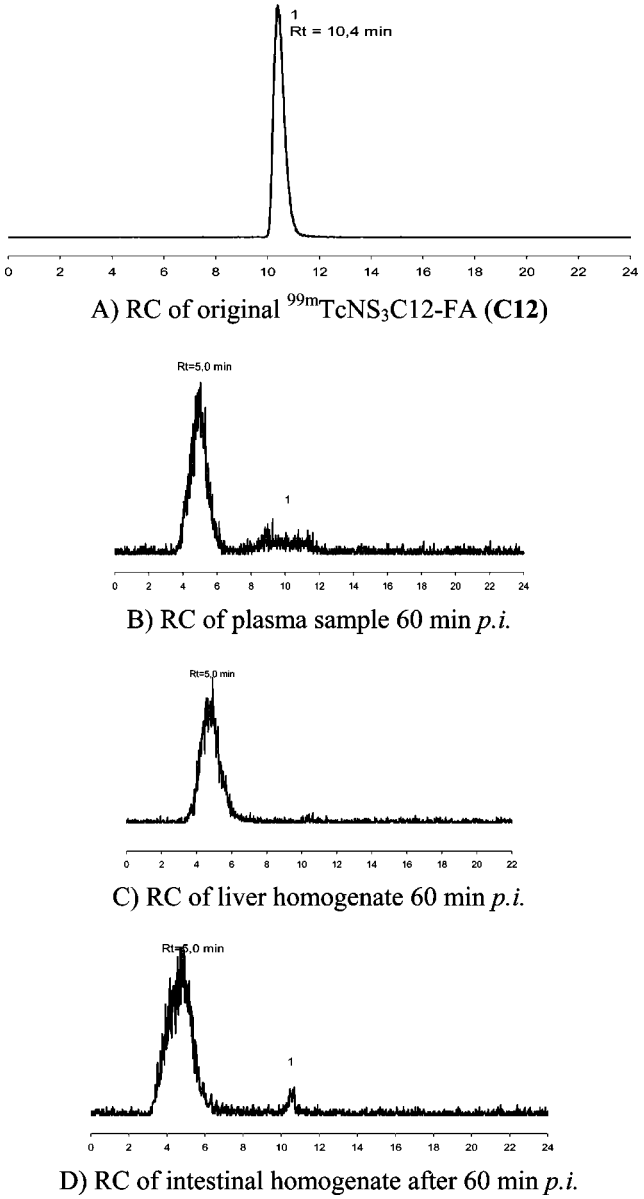

Figure 15. Representative radio-HPLC analysis of plasma samples and organ homogenates 60 min after *iv* administration of ^{99m}TcC12−FA (**C12**) in male Wistar rats.

synthesized, the ideal structure of a Tc−FA compound with high ventricular extraction (and a designated lower liver uptake) is not entirely clear. It is known, however, that the ventricular extraction primarily depends on the type of FA, the chain length, and the lipophilicity.

In the isolated beating heart model, the investigated compounds showed slightly different results compared with the biodistribution studies. Here, the highest ventricular extraction was obtained with the **C11** compound (26.65% ± 3.71%, n = 12), followed by the **C12** (24.42% ± 4.92%, n = 5) and **C11S** (23.38% ± 4.86%, n = 5) FA complexes. These extraction rates were much higher than those achieved with the established iodinated FA **^{123}IPPA** (15.51% ± 1.10%, n = 5). Shortening of the fatty acid chain length down to **C8** or lengthening it up to **C15** resulted in significantly lower extraction rates (5.96% ± 0.72% and 3.21% ± 1.10%, respectively, n = 4 for each compound; Figure 16). The synthesized phenylene inserted **CPh1** FA showed a poor myocardial extraction of only 3.83% ± 0.33% (n = 2).

Biodistribution Studies. Figure 17a,b summarizes the distribution of ^{99m}Tc radioactivity (decay-corrected) in male Wistar rats

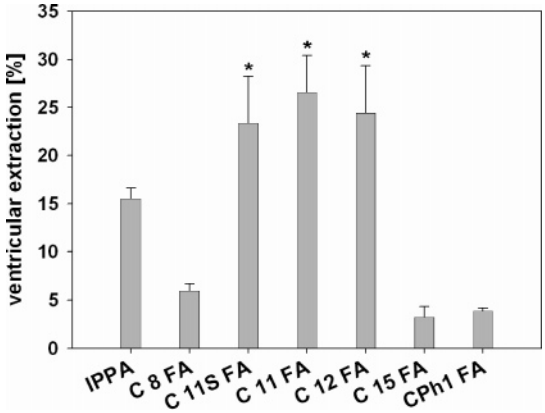

Figure 16. Ventricular extraction (in % of infused activity) of selected ^{99m}Tc-labeled FA compared with **^{123}IPPA** (mean ± SD, ∗ denotes p < 0.05 ANOVA *post hoc* LSD vs all other substances).

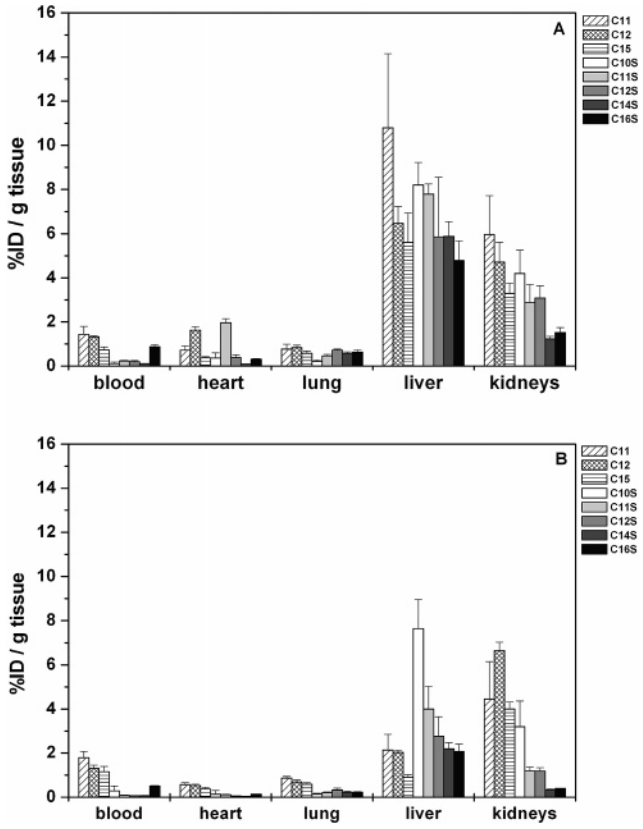

Figure 17. Biodistribution of ^{99m}Tc radioactivity concentration (%ID/g tissue) in male Wistar rats (n = 4) at 5 min (A) and 60 min (B) after intravenous injection of ^{99m}Tc-labeled FA.

after a single intravenous injection of various ^{99m}Tc-labeled FA. Data were obtained at 5 and 60 min pi.

A very rapid disappearance of ^{99m}Tc radioactivity concentration from the blood circulation was observed for all compounds. **C11S** showed the highest uptake with 2% ID/g tissue in the rat heart followed by **C12** and **C11** with 1.6% and 0.7% ID/g tissue.

Only **C11S** and **C12** showed a heart/blood ratio greater than one up to 5 min pi. (Figure 18). Remarkably, the heart/blood ratio of **C11S** was 8.6 ± 0.1 at 5 min and still 1.3 ± 0.1 at 60 min.

In principle, these *in vivo* findings show some parallels to the data obtained by *in vitro* investigation using the perfused rat heart model. "4 + 1"-Tc−FA with chain lengths close to C12 exhibits the highest heart uptake. However, in contrast to the 2-fold ventricular *in vitro* uptake, the heart extraction rate at 5 min pi. reached maximally 30−40% of the described *in*

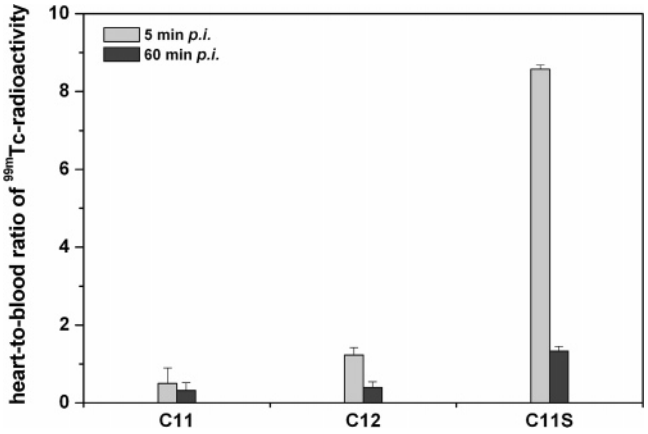

Figure 18. Heart : blood ratio of ^{99m}Tc-radioactivity in male Wistar rats ($n = 4$) at 5 and 60 min after intravenous injection of ^{99m}Tc-labeled FA **C11**, **C12**, and **C11S**.

vivo values from different iodophenyl−FA (*26*). This effect is caused by the concurrent high liver affinity accompanied by slow liver clearance. The direct comparison with recent results of other Tc−FA investigations (*4*, *5*) is not possible because of the use of different species (mice versus rats) in the biodistribution studies.

Liver and kidneys are mainly responsible for fast removal of ^{99m}Tc radioactivity from the circulation. At 5 min after injection, approximately 50% of the injected dose is liver-associated. A substantial fraction is cleared by the kidneys and approximately 6% of the injected dose is kidney-associated at 5 min pi. Overall, fast systemic clearance of ^{99m}Tc radioactivity after injection of ^{99m}Tc-labeled FA in the rat is explained by the rapid hepatobiliary and renal elimination of ^{99m}Tc radioactivity.

On the other hand, the low mean accumulation of ^{99m}Tc radioactivity in the thyroid gland (<0.07% ID at 5 min; <0.07% ID at 60 min) and the stomach (<1.7% ID at 5 min; <3.9% ID at 60 min), which both express the sodium iodide transporter is indicative of a very low abundance of pertechnetate *in vivo*.

CONCLUSION

Ten ^{99m}Tc-labeled FAs and their corresponding nonradioactive rhenium model complexes have been prepared according to the "4 + 1" mixed-ligand approach, where the metal is coordinated by both a tetradentate NS_3 chelator and a monodentate isocyano FA coligand. The FA bodies varied in their chain length and by sulfur or phenylene insertion in order to introduce two different sites of potential metabolic interference. The Re complexes have been fully characterized by spectroscopic methods, and in the case of both the Re−C11S−FA methyl ester (**Re12b**) and the **ReC15−FA**, the structure was confirmed additionally by X-ray crystallography. Furthermore, the surface activity in aqueous solution was determined for the **ReC12−FA** exemplarily and compared with the known detergent *n*-dodecyl β-D-maltoside. An important fact in the labeling procedure with technetium-99m is the conversion of the isocyano ligands **4**, **12**, and **17** into their copper(I) complexes **4Cu**, **12Cu**, and **17Cu.** This allows improvements of both handling of the ligands and, as a consequence, of the nca ^{99m}Tc−FA preparation. Experiments on isolated perfused rat hearts showed very high ventricular extraction rates of the FA complexes, in the order **C11** compound (26.65% ± 3.71%, $n = 12$), **C12** (24.42% ± 4.92%, $n = 5$), and **C11S** (23.38% ± 4.86%, $n = 5$). These extraction rates exceed considerably those achieved with the established iodinated FA **^{123}IPPA** (15.51% ± 1.10%). Biodistribution studies in Wistar rats reveal a heart uptake of 2% ID/g 5 min pi. and heart/blood ratio of 8.6 ± 0.1 at 5 min pi. for **C11S**. In this respect, the tracer **C11S** is superior to other described Tc−FA mimics in biodistribution studies. The heart/liver ratio of 0.25 ± 0.1 at 5 min pi. has to be improved, which may be achieved by alterations of the FA binding mode to the "4 + 1" chelate unit and variations of the chelate position in the FA chain. Corresponding studies and investigations aiming at the activation of other FA tracers, as well as the identification of metabolites *in vitro* and *in vivo*, are currently underway.

ACKNOWLEDGMENT

This study was supported by an intramural grant (MedDrive program 2003) funded by the Medical Faculty Carl Gustav Carus, by the DFG (Deutsche Forschungsgemeinschaft) Grant SP 401, and by Nihon Medi-Physics Co., Inc. 9-8 Rokutanjicho, Nishinomiya-shi, Hyogo, 662-0918, Japan. Fluorescent Ligands for the Hemagglutinin of Influenza A: Synthesis and Ligand Binding Assays

V. Ranjit N. Munasinghe,[†] John E. T. Corrie,*[,†] Geoff Kelly,[‡] and Stephen R. Martin[†]

MRC National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA, U.K., and MRC Biomedical NMR Centre, The Ridgeway, Mill Hill, London NW7 1AA, U.K. Received June 22, 2006; Revised Manuscript Received September 21, 2006

Two fluorescent conjugates of sialic acid have been prepared, with a convenient synthetic route that involves preparation of an unsaturated benzyl ester by cross-metathesis, followed by combined hydrogenation/ hydrogenolysis to provide a sialoside bearing a δ-carboxybutyl group, suitable for coupling with the chosen fluorophores. The fluorescent conjugates bound to bromelain-cleaved hemagglutinin (BHA) with affinities in the low μM range. Binding was accompanied by ~4.5-fold fluorescence enhancement for the dansyl conjugate **1** and ~3-fold fluorescence quenching for the pyrene conjugate **3**.

INTRODUCTION

The influenza A virus is a cause of significant human disease and can on occasion result in devastating pandemics, as in the 1918 outbreak that caused at least 20 million deaths worldwide (*1*). The infection process is initiated by hemagglutinin on the viral surface binding to terminal α-sialosides of glycoproteins and glycolipids on the surface of the target cell (see ref *2* for a recent review). It is believed that the aquatic bird population is a reservoir for the virus (*3*). Avian viruses bind preferentially to sialosides with an α2,3-linkage (*4*), whereas those subtypes of the virus that have caused human pandemics recognize α2,6-linked sialosides (*5*), and changes in binding specificity as a result of mutations are likely required for human infection.

As part of studies of viral infectivity, we wished to develop a fluorescence-based assay system that might have potential to evaluate affinities of hemagglutinins from different viral strains for relevant sialosides. Three types of fluorescent sialoside ligands have been previously described, one with a dansyl group attached via a linker to position 4 of the sialoside and an additional naphthyl group linked to the anomeric position to enhance the affinity for hemagglutinin (*6*), a second with a range of aromatic species (not all fluorescent) attached in the α-orientation to the glycosidic position via linkers of different lengths (*7*), and a third with a dansyl group linked via a spacer at the 9-position (*8*). Among these derivatives, only that with the 4-O-linked dansyl group has a report of its fluorescence properties (*6*) upon binding to hemagglutinin. It showed only a small (<20%) change in fluorescence intensity upon binding, although larger fluorescence anisotropy changes enabled competitive titrations to be performed with several related compounds. For our purpose, the compounds linked at the glycosidic position seemed the most likely to have differential competitive binding with sialosides of different regiochemistry, and we therefore aimed to prepare compounds **1**−**3** shown in Figure 1. These target compounds were chosen for the following reasons: the dansyl derivative **1** had been prepared in previous work (*7*) so could be considered as a reference material, although the previous study gave little experimental detail. The coumarin derivative **2** was selected because of our use of this fluorophore as an environmentally sensitive probe in other applications (e.g., *9*, *10*), and the pyrene compound **3** was chosen because previous work (*7*) suggested that an increased number of aromatic rings in the attached fluorophore resulted in increased affinity for hemagglutinin. For reasons discussed below, we were only able to prepare compounds **1** and **3**, and the binding properties of these two compounds were tested with BHA, the trimeric, soluble portion of hemagglutinin released from the virus by bromelain digestion (*11*).

EXPERIMENTAL PROCEDURES

General Details. Reagents were purchased from Sigma-Aldrich, except for benzyl acrylate from Lancaster Synthesis and *N*-acetylneuraminic acid from Quisuo Biotech Co. Ltd, Shenzhen, China (http://www.sialicacid.com). Silver salicylate (*12*) and the chlorosugar **11** (*13*) were prepared by previously described methods. Flash chromatography was on Merck type 9385 silica gel. Preparative reverse-phase HPLC was carried out on a 2 × 30 cm column (Waters C_{18} packing, Cat. No. 20594) using mobile phases described below, at flow rates of 2 mL min^{-1}. Analytical reverse-phase HPLC was on a Merck Lichrospher 250 × 4 mm RP8 column at flow rates of 1.5 mL min^{-1}. Detection for both preparative and analytical work was at 254 nm. 1D ^{1}H NMR spectra were determined on JEOL FX90Q or Varian Unityplus 500 spectrometers for solutions in

$CDCl_3$ with TMS as internal reference, unless otherwise specified. 2D spectra used to assign resonances in compounds **1** and **3** were run on Varian Inova and UnityPlus spectrometers operating at 500−800 MHz. Methods used were $^1H-^1H$ COSY, $^1H\{^{13}C\}$-HSQC, HMBC, HSQC−TOCSY, plus 1D ^{13}C and 1D $^1H\{^1H\}$ steady-state NOE spectra.

Fluorescence measurements were made using a Spex Fluoromax fluorimeter and titrations were performed with BHA derived from X-31 (H3N2) influenza A virus. The BHA concentration was determined from absorption at 280 nm using an extinction coefficient of 1.5 cm^{-1} $(mg/mL)^{-1}$ and a monomer molecular weight of 69.5 kDa.

(4-Carboxy-1-butyl) 2,3,4,6-Tetra-*O*-acetyl-*β*-D-glucopyranoside (8). A mixture of benzyl acrylate (0.89 mL, 5.82 mmol), but-3-enyl 2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranoside **6** (*14*) (1.22 g, 3.03 mmol), and Grubbs second generation catalyst (110 mg, 0.13 mmol) in CH_2Cl_2 (14.6 mL) was refluxed for 8 h. The solution was evaporated and flash chromatography (Et_2O−hexanes 4:1) gave 5-benzyloxy-5-oxopent-3-en-1-yl 2,3,4,6-tetra-*O*-acetyl-*β*-D-glucopyranoside **7** as an oil (1.34 g, 82%); ^1H NMR δ 7.32−7.37 (m, 5H, ArH), 6.95 (dt, J = 15.7, 6.8 Hz, 1H, C*H*═CHCO), 5.92 (dt, J = 15.7, 1.7 Hz, 1H, CH═C*H*CO), 5.19 (t, J = 9.5 Hz, 1H, H-3), 5.16 (s, 2H, PhCH_2), 5.08 (t, J = 9.7 Hz, 1H, H-4), 4.98 (dd, J = 9.6, 7.9 Hz, 1H, H-2), 4.51 (d, J = 7.9 Hz, 1H, H-1), 4.25 (dd, J = 12.3, 4.7 Hz, 1H, H-6), 4.14 (dd, J = 12.3, 2.4 Hz, 1H, H-6′), 4.00 (dt, J = 9.7, 5.7 Hz, 1H, pentenoyl-H5), 3.69 (ddd, J = 9.7, 4.7, 2.4 Hz, 1H, H-5), 3.59 (ddd, J = 9.7, 7.7, 5.6 Hz, 1H, pentenoyl-H5′), 2.42−2.55 (m, 2H, OCH_2CH_2), 2.08 (s, 3H, Ac), 2.02 (s, 3H, Ac), 2.00 (s, 3H, Ac), 1.96 (s, 3H, Ac). The spectrum reported above is that of the *E*-isomer. A small proportion (7%) of the *Z*-isomer was present, as shown by integration of the signal at 6.29 p.p.m (J = 11.5, 7.3 Hz) from the *β*-position of the unsaturated ester. The proton on the α-position was at 5.91 ppm (J = 11.5, 1.5 Hz) and was partly overlapped by the much larger signal for the same proton of the *E*-isomer.

Without further characterization, a solution of this material (1.0 g, 1.87 mmol) in EtOH (80 mL) was hydrogenated over 10% Pd−C at room temperature for 1 h, then filtered and evaporated to give **8** as a foam (0.81 g, 97%); ^1H NMR δ 5.21 (t, J = 9.6 Hz, 1H, H-3), 5.08 (t, J = 9.8 Hz, 1H, H-4), 4.98 (dd, J = 9.6, 7.8 Hz, 1H, H-2), 4.50 (d, J = 7.8 Hz, 1H, H-1), 4.27 (dd, J = 12.2, 4.4 Hz, 1H, H-6), 4.15 (dd, J = 12.2, 2.4 Hz, 1H, H-6′), 3.87−3.89 (m, 1H, pentanoyl-H5), 3.69−3.72 (m, 1H, H-5), 3.48−3.51 (m, 1H, pentanoyl-H5′), 2.26−2.31 (m, 2H, CH_2CO), 2.09 (s, 3H, Ac), 2.05 (s, 3H, Ac), 2.03 (s, 3H, Ac), 2.01 (s, 3H, Ac), 1.59−1.68 (br m, 4H, CH_2CH_2); HRMS: *m*/*z* calcd for $(C_{19}H_{28}O_{12} + H)^+$, 449.1653; found, 449.1665. This compound has been reported in a patent application (*15*) but without details of its NMR spectrum.

7-Diethylamino-2-oxo-2*H*-chromene-3-carbohydrazide (9). An ice-cold solution of 7-diethylamino-2-oxo-2*H*-chromene-3-carboxylic acid (*16*) (0.26 g, 1.0 mmol) and Bu_3N (360 μL, 1.51 mmol) in dry DMF (10 mL) was treated with isobutyl chloroformate (135 μL, 1.04 mmol), and the solution was stirred for 0.5 h at 0 °C. *tert*-Butyl carbazate (0.145 g, 1.1 mmol) was added, and the reaction was brought to room temperature and stirred overnight. The solution was diluted with Et_2O washed with water, 1 M HCl, saturated $NaHCO_3$, and brine, dried, and evaporated. Flash chromatography (EtOAc−hexanes 1:1) and crystallization (EtOH) gave *tert*-butyl 2-(7-diethylamino-2-oxo-2*H*-chromene-3-carbonyl)hydrazinecarboxylate as yellow crystals (0.28 g, 75%), mp 195.5−197 °C; ^1H NMR δ (90 MHz, $CDCl_3$) 8.68 (s, 1H, H-4), 7.42 (d, J = 8.8 Hz, 1H, H-5), 6.65 (dd, J = 8.8, 2.6 Hz, 1H, H-6), 6.65 (br s, 1H, NH), 3.46 (q, J = 7.0 Hz, 4H, CH_2), 1.51 (s, 9H, CH_3), 1.25 (t, J = 7.0 Hz, CH_3). Anal. Found: C, 60.52; H, 6.97; N, 10.96. $C_{19}H_{25}N_3O_5$ requires C, 60.79; H, 6.71; N, 11.19%.

The above compound (1.84 g, 4.91 mmol) was dissolved in TFA (25 mL) and kept for 1 h at room temperature. The TFA was evaporated, and the residue was partitioned between $CHCl_3$ and saturated $NaHCO_3$. The organic layer was dried and evaporated to give **9** as yellow crystals (1.25 g, 4.54 mmol, 92%), mp 162−165 °C ($CHCl_3$−hexanes), (lit. mp (*17*) 160−165 °C).

5-[2-(7-Diethylamino-2-oxo-2*H*-chromene-3-carbonyl)hydrazino]-5-oxo-1-pentyl 2,3,4,6-Tetra-*O*-acetyl-*β*-D-glucopyranoside (10) and Its Hydrolysis. A solution of **8** (0.28 g, 0.62 mmol), 1-hydroxybenzotriazole (92 mg, 0.68 mmol), and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (130 mg, 0.68 mmol) in CH_2Cl_2 (5 mL) was stirred for 3 h at room temperature. A solution of **9** (196 mg, 0.71 mmol) in CH_2Cl_2 (2.5 mL) was added, and the mixture was stirred overnight at room temperature. The solution was diluted with CH_2Cl_2, washed with water and brine, dried, evaporated, and flash chromatographed (MeOH−$CHCl_3$ 4:96) to give **10** (0.36 g, 0.51 mmol, 83%); ^1H NMR δ 10.93 (d, J = 5.5 Hz, 1H, NH), 8.65 (s, 1H, H-4′), 8.38 (d, J = 5.5 Hz, 1H, NH), 7.43 (d, J = 9.2 Hz, 1H, H-5′), 6.65 (dd, J = 9.2, 2.4 Hz, 1H, H-6′), 6.51 (d, J = 2.4 Hz, 1H, H-8′), 5.22 (t, J = 9.6 Hz, 1H, H-3), 5.09 (t, J = 9.6 Hz, 1H, H-4), 5.01 (dd, J = 9.7, 8.2 Hz, 1H, H-2), 4.51 (d, J = 8.2 Hz, 1H, H-1), 4.26 (dd, J = 12.3, 4.4 Hz, 1H, H-6), 4.18 (dd, J = 12.3, 2.4 Hz, 1H, H-6′), 3.92 (dt, J = 9.5, 6.0 Hz, 1H, pentanoyl-H5), 3.70 (ddd, J = 9.9, 4.4, 2.4 Hz, 1H, H-5), 3.54 (dt, J = 9.5, 6.1 Hz, 1H, pentanoyl-H5′), 3.46 (q, J = 7.2 Hz, 4H, CH_2Me), 2.28−2.40 (m, 2H, CH_2CO), 2.10 (s, 3H, Ac), 2.07 (s, 3H, Ac), 2.02 (s, 3H, Ac), 2.00 (s, 3H, Ac), 1.79 (m, 2H, CH_2CH_2CO), 1.69 (m, 2H, C$H_2CH_2CH_2CO$), 1.25 (t, J = 7.2 Hz, 6H, Me); assignments were confirmed by a COSY spectrum. HRMS: *m*/*z* calcd for $(C_{33}H_{43}N_3O_{14} + H)^+$, 706.2818; found, 706.2786.

NaOH (0.69 mL) (2 M aq) was added to a solution of **10** (0.21 g, 0.3 mmol) in MeOH (1.9 mL) at room temperature. TLC analysis (MeOH−$CHCl_3$ 1:9) after 5 min showed a strong yellow spot that had the same R_f as 7-diethylamino-2-oxo-2*H*-chromene-3-carboxylic acid, and a more polar but much less intense yellow spot. After 30 min, the latter spot was absent from the reaction mixture, and only the spot corresponding to the above acid was observed under visible or UV illumination.

Methyl [But-3-enyl 4,7,8,9-Tetra-*O*-acetyl-5-(acetylamino)-3,5-dideoxy-D-glycero-α-D-galacto-2-nonulopyranosid]-onate (5b). Silver salicylate (0.69 g, 2.81 mmol) was added to a stirred solution of the chloro sugar **11** (2.16 mmol) in a mixture of dry benzene and 3-buten-1-ol (1:1, 14.4 mL). The flask was flushed with nitrogen, sealed, and stirred in the dark at room temperature for 4.5 days. The solution was diluted with $CHCl_3$ (30 mL) and filtered through a small pad of Celite, and the filter cake was washed with MeOH−$CHCl_3$ (1:9; 10 mL). The total filtrate was evaporated and the residue was dissolved in ether and washed with 5% aq sodium thiosulfate, water, 0.1 M NaOH (×2), and water, dried, evaporated, and flash chromatographed (MeOH−$CHCl_3$ 3:97) to give **5b** (0.47 g, 0.86 mmol, 40%); ^1H NMR δ 5.80 (ddt, J = 17.1, 10.4, 6.6 Hz, 1H, C*H*═CH_2), 5.40 (ddd, J = 8.5, 5.9, 3.0 Hz, 1H, H-8), 5.33 (dd, J = 8.3, 2.0 Hz, 1H, H-7), 5.14 (d, J = 9.6 Hz, 1H, NH), 5.09 (dq, J = 17.1, 1.5 Hz, 1H, ═CH), 5.04, (dq, J = 10.4, 1.5 Hz, 1H, ═CH), 4.85 (ddd, J = 12.3, 9.6, 4.4 Hz, 1H, H-4), 4.31 (dd, J = 12.3, 2.8 Hz, 1H, H-9), 4.04−4.13 (m, 3H, H-5, H-6, H-9′), 3.83 (dt, J = 9.3, 6.5 Hz, 1H, butenyl-H5), 3.80 (s, 3H, OMe), 3.29 (dt, J = 9.3, 6.6 Hz, 1H, butenyl-H4′), 2.59 (dd, J = 12.7, 4.6 Hz, 1H, H-3_{eq}), 2.29−2.33 (m, 2H, OCH_2CH_2), 2.03 (s, 3H, Ac), 2.04 (s, 3H, Ac), 2.14 (s, 3H, Ac), 2.15 (s, 3H, Ac), 1.96 (t, J = 12.7 Hz, 1H, H-3_{ax}), 1.88 (s, 3H, NAc).

This compound has been reported previously (*18*) but without NMR details.

Methyl [4-Carboxy-1-butyl 4,7,8,9-Tetra-*O*-acetyl-5-(acetylamino)-3,5-dideoxy-D-glycero-α-D-galacto-2-nonulopyranosid]onate (4). Benzyl acrylate (0.27 mL, 1.76 mmol) was added to a mixture of **5b** (0.5 g, 0.92 mmol) and Grubbs second generation catalyst (53 mg, 0.062 mmol) in CH_2Cl_2 (4.4 mL), and the solution was refluxed for 8 h, evaporated to ~1 mL, and flash chromatographed (MeOH−$CHCl_3$ 2.5:97.5) to give methyl [5-benzyloxy-5-oxopent-3-en-1-yl 4,7,8,9-tetra-*O*-acetyl-5-(acetylamino)-3,5-dideoxy-D-glycero-α-D-galacto-2-nonulopyranosid]onate (0.46 g, 0.68 mmol, 74%); ^{1}H NMR δ 7.31−7.39 (m, 5H, Ar-H), 6.98 (dt, J = 15.7, 6.5 Hz, 1H, C*H*═CHCO), 5.95 (d, 1H, J = 15.7 Hz, CH═C*H*CO), 5.39 (ddd, J = 8.5, 5.9, 3.0 Hz, 1H, H-8), 5.31 (dd, J = 8.3, 2.0 Hz, 1H, H-7), 5.18 (s, 2H, CH_2Ph), 5.11 (d, J = 10.1 Hz, 1H, NH), 4.85 (ddd, J = 12.3, 9.6, 4.4 Hz, 1H, H-4), 4.29 (dd, J = 12.4, 2.6 Hz, 1H, H-9), 4.02−4.13 (m, 3H, H-5, H-6, H-9′), 3.91 (dt, J = 9.7, 5.7 Hz, 1H, pentenoyl-H5), 3.76 (s, 3H, OMe), 3.34 (dt, J = 9.7, 5.6 Hz, 1H, pentenoyl-H5′), 2.57 (dd, J = 12.8, 4.6 Hz, 1H, H-3$_{eq}$), 2.42−2.50 (m, 2H, CH_2CH_2O), 2.14 (s, 3H, Ac), 2.13 (s, 3H, Ac), 2.03 (s, 3H, Ac), 2.02 (s, 3H, Ac), 1.92−1.96 (m, 1H, H-3$_{ax}$), 1.88 (s, 3H, NAc). A solution of this material (0.43 g, 0.635 mmol) in EtOH (27 mL) was hydrogenated at room temperature over 10% Pd−C (~45 min), then filtered through Celite and evaporated to give **4** as a white foam (0.37 g, 0.63 mmol, 100%); ^{1}H NMR δ 5.41 (ddd, J = 8.5, 5.9, 3.0 Hz, 1H, H-8), 5.30 (dd, J = 8.7, 1.8 Hz, 1H, H-7), 5.16 (d, J = 9.5 Hz, 1H, NH), 4.85 (ddd, J = 12.3, 9.6, 4.4 Hz, 1H, H-4), 4.32 (dd, J = 12.5, 2.4 Hz, 1H, H-9), 4.05−4.12 (m, 3H, H-5, H-6, H-9′), 3.80 (s, 3H, OMe), 3.78 (dt, J = 9.3, 6.5 Hz, 1H, pentanoyl-H5), 3.26 (dt, J = 9.5, 6.1 Hz, 1H, pentanoyl-H5′), 2.57 (dd, J = 12.9, 4.6 Hz, 1H, H-3$_{eq}$), 2.36−2.43 (m, 2H, CH_2CO), 2.15 (s, 3H, Ac), 2.15 (s, 3H, Ac), 2.04 (s, 3H, Ac), 2.03 (s, 3H, Ac), 1.95 (t, J = 12.7 Hz, 1H, H-3$_{ax}$), 1.89 (s, 3H, NAc), 1.59−1.76 (m, 4H, CH_2CH_2). This material has been reported previously (*7*) but without NMR details.

[5-{2-[(5-Dimethylamino-1-naphthalenyl)sulfonyl]hydrazino}-5-oxo-1-pentyl 5-(Acetylamino)-3,5-dideoxy-D-glycero-α-D-galacto-2-nonulopyranosid]onic Acid (1). A mixture of **4** (0.68 g, 1.15 mmol), 1-hydroxybenzotriazole (173 mg, 1.28 mmol), and EDC (245 mg, 1.28 mmol) was stirred in dry CH_2Cl_2 (28 mL) for 3 h at room temperature. Dansyl hydrazine (340 mg, 1.28 mmol) and DMAP (156 mg, 1.28 mmol) were added, and the solution was stirred at room temperature for 4 days. The solution was diluted with CH_2Cl_2 (150 mL) and washed successively with saturated aq $NaHCO_3$, H_2O, and brine, dried, and evaporated to give a yellow-green foam that contained two fluorescent spots on TLC (MeOH−$CHCl_3$ 2.5:97.5), of which the less polar corresponded to dansyl hydrazine. Flash chromatography (MeOH−$CHCl_3$ as above) gave the more polar component (0.42 g), which was dissolved in methanol (45 mL), mixed with 1 M aq NaOH (5 mL), and kept at room temperature for 3 h. Glacial acetic acid (1 mL) was added, and the solution was concentrated to ~10 mL and then diluted to 50 mL with 25 mM Na phosphate, pH 6, and adjusted to pH 6. Analytical reverse-phase HPLC (mobile phase: 25 mM Na phosphate, pH 6−MeCN 3:1 v/v) showed a major peak, t_R 3.0 min, assigned as the required compound **1** and a very small peak (t_R 11.9 min), assigned as the methyl ester of **1** since it had been present in gradually diminishing amount during the alkaline hydrolysis.

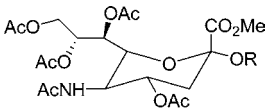
The solution was pumped onto the preparative reverse-phase HPLC column (previously equilibrated in 25 mM Na phosphate, pH 6), and the column was eluted with 25 mM Na phosphate, pH 6, for 2 h and then with 25 mM Na phosphate, pH 6−MeCN (5:1 v/v) for 2 h to elute **1**. Analysis by reverse-phase HPLC as above showed essentially a single peak with no later eluting material. Combined fractions containing the required conjugate were quantified by UV−visible spectroscopy [based on ϵ_{330} 4600 M^{-1} cm^{-1} for the dansyl chromophore in aqueous solvent (*16*)], and the solution was evaporated to remove acetonitrile. The residue was dissolved in water, adjusted to pH 6, and reapplied to the preparative HPLC column, again equilibrated in 25 mM Na phosphate, pH 6. The column was eluted with this buffer for 3 h and then with water. After some very minor contaminants that eluted with water up to 2.5 h, the dansyl conjugate began to elute after ~3.5 h, and the mobile phase was changed to water−MeCN (4:1 v/v) to elute the majority of the material. The combined fractions were concentrated under vacuum to remove acetonitrile and finally lyophilized. The residue was dissolved in water (19.5 mL), and the solution (19.8 mM, i.e., 386 μmol, 34%) was stored at −20 °C. ^{1}H NMR δ (D_2O, acetone reference) 8.54 (d, J = 8.5 Hz, 1H, Ar-H4), 8.45 (d, J = 8.9 Hz, 1H, Ar-H8), 8.31 (d, J = 7.3 Hz, 1H, Ar-H2), 7.72 (t, J = 8.2 Hz, 1H, Ar-H7), 7.71 (t, J = 7.9 Hz, 1H, Ar-H3), 7.44 (d, J = 7.6 Hz, 1H, Ar-H6), 3.85−3.89 (m, 2H; centers of signals within this envelope were assigned as follows: 3.87, H-9; 3.86, H-8), 3.79 (t, J = 10.1 Hz, 1H, H-5), 3.63−3.70 (m, 3H; centers of signals within this envelope were assigned as follows: 3.66, H-4,6; 3.65, H-9′), 3.55−3.61 (m, 2H; centers of signals within this envelope were assigned as follows: 3.59, H-8; 3.57, pentanoyl-H5), 3.28 (dt, J = 9.5, 6.4 Hz, 1H, pentanoyl-H5′), 2.89 (s, 6H, NMe_2), 2.71 (dd, J = 12.2, 4.6 Hz, 1H, H-3$_{eq}$), 2.04 (s, 3H, NHAc), 1.99 (t, J = 7.2 Hz, 2H, pentanoyl-H2), 1.60 (t, J = 12.2 Hz, 1H, H-3$_{ax}$), 1.23 (quintet, J = 7.5 Hz, 2H, pentanoyl-H3), 1.14−1.19 (m, 2H, pentanoyl-H4); ^{13}C NMR δ (D_2O, acetone ref) 178.1 (CH_3*C*O), 177.5 (pentanoyl-C1), 176.3 (C-1), 153.3 (Ar-C5), 134.5 (Ar-Cq), 134.3 (Ar-C2), 133.8 (Ar-C4), 132.8 (Ar-Cq), 131.4 (Ar-C7), 131.3 (Ar-Cq), 126.7 (Ar-C3), 122.4 (Ar-C9), 118.7 (Ar-C6), 103.4 (C-2), 75.4 (C-6), 74.6 (C-7), 71.1 (C-4), 71.0 (C-8), 66.6 (pentanoyl-C5), 65.4 (C-9), 54.6 (C-5), 47.7 (NMe_2), 43.2 (C-3), 35.1 (pentanoyl-C2), 30.7 (pentanoyl-C4), 24.7 (Me), 24.0 (pentanoyl-C3); LRMS *m*/*z*: calcd for $(C_{27}H_{39}N_4O_{12}S)^-$, 655.2; found *m*/*z* 655.4.

[5-(Pyren-1-ylmethylamino)-5-oxo-1-pentyl 5-(Acetylamino)-3,5-dideoxy-D-glycero-α-D-galacto-2-nonulopyranosid]onic Acid (3). 1-Pyrenemethylamine (165 mg, 0.71 mmol) was coupled with **4** (367 mg, 0.62 mmol) as described above for the dansyl conjugate **1**. After incubation overnight at room temperature, the reaction mixture was diluted with CH_2Cl_2, washed with 1 M HCl, saturated $NaHCO_3$, H_2O, and brine, dried, and evaporated. Flash chromatography (MeOH−$CHCl_3$ 3:97) gave a pale brown oil (0.44 g), that on TLC [MeOH−$CHCl_3$ (1:9)] had one principal product, R_f 0.4. Without further purification, this material was dissolved in MeOH (45 mL) and mixed with 1 M aq NaOH (5 mL). After 3 h at room temperature, the solution was treated with glacial AcOH (5 mL), concentrated to ~10 mL, and then diluted to 50 mL with 25 mM sodium phosphate, pH 6, and adjusted to pH 6. Analytical reverse-phase HPLC (mobile phase: 25 mM Na phosphate, pH 6−MeCN 2:1 v/v) showed a major peak, t_R 3.6 min, assigned as the required compound **3** and a very small peak at t_R 13.6 min, assigned as the methyl ester of **3** (see similar comment for **1** above). The solution was pumped onto the preparative reverse-phase HPLC column (previously equilibrated in 25 mM sodium phosphate, pH 6), and the column was eluted with the same buffer for 1.5 h. The mobile phase was changed to 25 mM sodium phosphate, pH 6−MeCN (4:1) for 2.5 h and then to 25 mM sodium phosphate, pH 6−MeCN (3.5:1). The product eluted in the latter solvent. Fractions were analyzed by reverse-phase HPLC as above, and those containing only **3** were combined and quantified by UV spectroscopy (based on the reported (*19*) absorbance coefficient of ϵ_{342} 35700 M^{-1} cm^{-1} for a water-

soluble 1-alkylpyrene compound). The solution containing **3** (201 μmol) was evaporated, dissolved in water (20 mL), adjusted to pH 6, and reapplied to the preparative HPLC column (equilibrated with 25 mM sodium phosphate, pH 6). The column was eluted with the same buffer for 1 h, and the mobile phase was changed to water for 1.5 h and then to $H_2O-MeCN$ (4:1) for 2.5 h. Fractions containing **3** were analyzed and quantified as above (186 μmol), the solution was evaporated and then re-evaporated from water (2×10 mL) to remove all acetonitrile, and the residue was dissolved in water (19 mL, 9.8 mM) and stored at -20 °C. ^{1}H NMR δ (D_2O, acetone reference) 8.13 (d, $J = 7.6$ Hz, 1H, Ar-H6 or 8), 8.11 (d, $J = 7.6$ Hz, 1H, Ar-H8 or 6), 7.98 (t, $J = 7.6$ Hz, 1H, Ar-H7), 7.96 (d, $J = 7.8$ Hz, 1H, Ar-H), 7.94 (d, $J = 9.5$ Hz, 1H, Ar-H), 7.92 (d, $J = 9.5$ Hz, 1H, Ar-H), 7.88 (d, 1H, $J = 9.5$ Hz, 1H, Ar-H), 7.85 (d, 1H, $J = 9.5$ Hz, 1H, Ar-H), 7.74 (d, 1H, $J = 7.8$ Hz, 1H, Ar-H), 4.69 (s, 2H, ArCH_2), 3.54−3.81 (m, 8H; centers of signals within this envelope were assigned as follows from 2D experiments: 3.79, H-7; 3.76, H-9; 3.69, H-5; 3.65, pentanoyl-H5; 3.63, H-4; 3.62, H-6; 3.57, H-9′; 3.55, H-8), 3.37 (dt, $J =$ 9.5, 6.5 Hz, pentanoyl-H5′), 2.65 (dd, $J = 12.3$, 4.5 Hz, 1H, H-3_{eq}), 2.20 (t, $J = 7.6$ Hz, 2H, pentanoyl-H2), 2.02 (s, 3H, Me), 1.60 (quintet, $J = 7.5$ Hz, 2H, pentanoyl-H3), 1.51 (t, $J = 12.1$ Hz, 1H, H-3_{ax}), 1.46 (quintet, $J = 7.5$ Hz, 2H, pentanoyl-H4); ^{13}C NMR δ (D_2O, acetone reference) 178.6 (pentanoyl-C1), 177.6 (CH_3CO), 176.4 (C-1), 133.5 (Ar-C), 133.1 ($2 \times$ Ar-C), 132.9 (Ar-C), 130.5 (Ar-C), 130.2 (Ar-CH), 130.0 (Ar-CH), 129.8 (Ar-CH), 129.2 (Ar-CH), 129.0 (Ar-C7), 128.0 (Ar-C6 & C8), 127.4 (Ar-CH), 126.5 (Ar-C), 126.4 (Ar-C), 125.0 (Ar-CH), 103.3 (C-2), 75.4 (C-6), 74.5 (C-7), 71.0 (C-4,8), 66.7 (pentanoyl-C5), 65.2 (C-9), 54.5 (C-5), 43.8 (CH_2NH), 42.9 (C-3), 37.7 (pentanoyl-C2), 30.7 (pentanoyl-C4), 24.7 (pentanoyl-C3), 24.5 (Me); LRMS *m/z*: calcd for $(C_{33}H_{37}N_2O_{10})^-$, 621.2; found, *m/z* 621.3.

Hemagglutinin Binding Assays. Dissociation constants for binding of the sialic acid conjugates **1** and **3** to X31-BHA were determined at 20 °C in phosphate-buffered saline, pH 7.4 (140 mM NaCl, 10 mM KCl, 20 mM phosphate), using direct fluorometric titrations. Measurements were made at constant probe concentration (1.9 μM for **1** and 1.25 μM for **3**). Excitation/emission wavelengths were 321/521 nm for **1** and 340/394 nm for **3**. The titrations were fit to the equation:

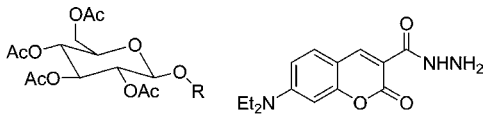
$$\text{fluorescence} = F_{(SA)}[SA] + F_{(BHA\cdot SA)}[BHA\cdot SA]$$



where the F values are the appropriate molar fluorescence intensities and SA is the relevant sialic acid derivative. A value for the dissociation constant (K_d) was obtained from a nonlinear least-squares fit to this equation with concentrations calculated by solving:

$$[BHA\cdot SA]^2 - (K_d + [BHA_T] + [SA_T])[BHA\cdot SA] + [BHA_T][SA_T] = 0$$

where BHA_T and SA_T are the total concentrations of BHA and sialic acid conjugate, respectively.



RESULTS AND DISCUSSION

Synthesis of the proposed compounds required the functionalized α-sialoside **4** as the key intermediate. Many related sialosides have been described, with functional groups such as amino, hydroxyl, formyl, thioalkyl, and carboxyl, as well as olefins, at the end of an oligomethylene chain (see ref *20* for typical examples). In the previous synthesis of **1**, the acid **4** was obtained by synthesis of olefin **5a**, which was then oxidized to **4** with potassium permanganate (*7*). Although this approach has been used elsewhere in synthesis of sialosides, we aimed

to apply current methods in our work to simplify access to the required compounds and therefore began our studies with a convenient model glucoside.

Following precedents described above, we planned to install the linker chain onto the sugar by a Koenigs−Knorr procedure, using an unsaturated alcohol to provide a site for further functionalization. Subsequently, it seemed likely that olefin cross-metathesis (*21*) using benzyl acrylate, followed by hydrogenation to reduce the double bond and concurrently cleave the benzyl ester, would allow ready access to the required carboxylic acid side chain. There are numerous previous examples of this combined hydrogenation/hydrogenolysis procedure (e.g., *22*) although the substituted benzyl acrylates used have generally been assembled by routes other than cross-metathesis. As a convenient model, we used the readily accessible 3-butenyl glucoside **6** (*14*) that underwent clean cross-metathesis with benzyl acrylate in the presence of Grubbs second generation catalyst (*23*) to give the unsaturated ester **7** as a mix (93:7) of *E* and *Z* isomers. Hydrogenation then gave the saturated acid **8** in near-quantitative yield. To check the remainder of the intended synthesis of **1**−**3**, this crude acid was coupled with the hydrazide **9** and the product **10** was subjected to mild base treatment in the expectation of hydrolyzing the acetyl groups from the sugar. In practice, we found that the C−N bond between the coumarin and the hydrazine moiety was rapidly cleaved, releasing the coumarin-3-carboxylic acid. We had previously encountered unexpected lability of this C−N bond in an amide of a related coumarin-3-carboxylic acid (*24*), but the present results imply that any coumarin-3-carboxamide system is vulnerable to hydrolysis under relatively mild alkaline conditions. Results from other reactions of 3-acylated coumarins support this view (*25*). It thus seemed certain that construction of the related sialoside conjugate **2** would encounter the same problem, and we therefore restricted subsequent work to compounds **1** and **3**.

With the basic methodology established, we turned to the sialosides themselves. Although there is a large literature on O-sialylation [reviewed in ref *26*], it required several trials to

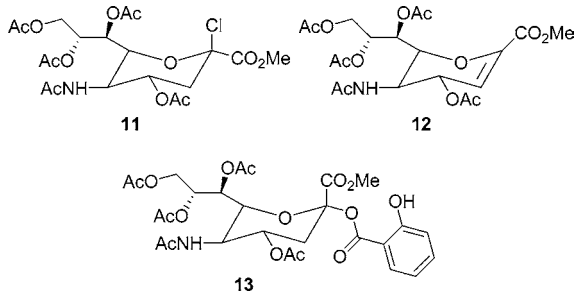

Figure 4. Structures of compounds **11**−**13** used as starting material or formed as byproducts during synthesis of compounds **1** and **3**.

establish convenient and reliable methods for our purpose. We summarize these conclusions here as an aid to other workers. *N*-Acetylneuraminic acid was peracetylated and converted to its methyl ester as described (*27*) in 73% overall yield. Subsequent transformation to the β-chloro sugar **11** was readily and best achieved with anhydrous HCl in cold dichloromethane, as previously described (*13*). This convenient method routinely gave material of excellent quality for use in glycosylation reactions and in our hands was more satisfactory than alternative procedures using acetyl chloride (e.g., *27*).

To optimize the glycosylation of but-3-en-1-ol with **11**, we surveyed three promoter reagents, namely mercury(II) cyanide as previously used by Toogood et al. (*7*) in their preparation of fluorescent sialic acid conjugates, silver carbonate, and silver salicylate [both reviewed in ref *26*]. As expected, mercury(II) cyanide gave a mixture of α- and β-glycosides (~1:1 ratio) and was not investigated further. Silver carbonate in CH_2Cl_2 gave a product mix of the dehydro sugar **12** and the α- and β-glycosides, in which **12** constituted ~13% of the mixture while the α:β ratio was ~85:15. While this was reasonably satisfactory, we found that the extent of reaction was very dependent on the batch of commercial silver carbonate, and significant quantities of unreacted **11** were frequently present, despite prolonged reaction times or increased amounts of promoter. In contrast, silver salicylate routinely resulted in complete reaction of **11**, giving a product mix that contained only ~3% of the dehydro sugar **12** and an anomeric ratio of the glycosides that was >99:1 in favor of the required α-product **5b**. Under our conditions, 20−30% of the total product was the salicylate ester **13**, but this compound was easily removed during workup by washing the organic extract with dilute sodium hydroxide. The byproduct was identified as the ester **13** rather than the isomeric aryl glycoside principally because of a sharp singlet at δ 10.1 that exchanged with D_2O and was consistent with a phenolic hydroxyl rather than a carboxylic acid. Both types of byproduct (i.e., ester or aryl glycoside) have been observed in other glycosylations mediated by silver salicylate (*28*).

The olefin **5b** was smoothly transformed to the acid **4** by the sequence of olefin cross-metathesis and hydrogenation/hydrogenolysis described above, and the crude acid was coupled with either dansyl hydrazine or 1-pyrenemethylamine in carbodiimide-mediated reactions. Subsequent alkaline hydrolysis gave the required conjugates **1** and **3** that were each purified by reverse-phase HPLC, and each compound was used in fluorescence titrations with BHA.

The emission spectrum of the dansyl conjugate **1** (Figure 5A) has a single broad band with an emission maximum at approximately 524 nm. Its binding to BHA results in ~4.5-fold intensification of the fluorescence at saturation (see below) and a small blue shift to ~521 nm. The emission spectrum of **3** (Figure 6A) shows two sharp bands at 376 and 395 nm, with a broad long wavelength shoulder at ~416 nm. Its binding to BHA quenches the fluorescence ~3-fold at saturation (see below),

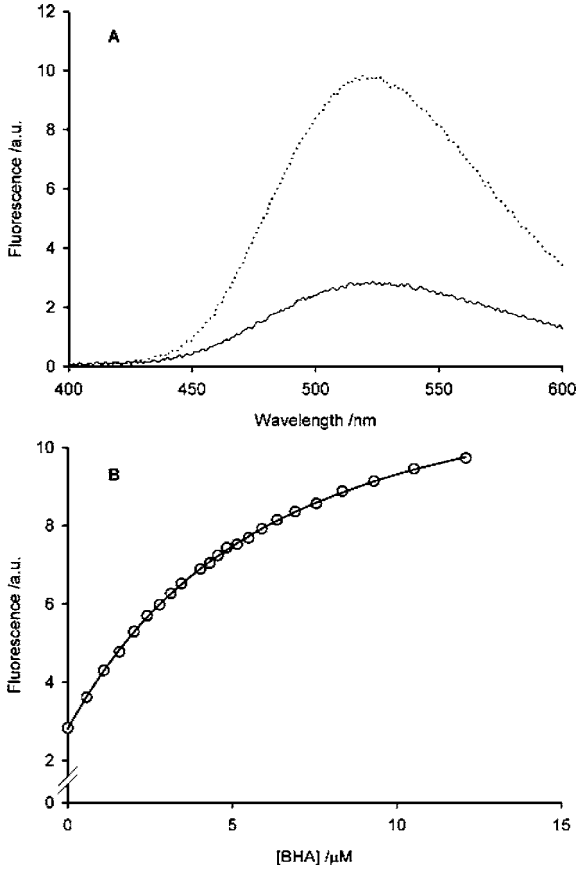

Figure 5. (A) The emission spectrum of the dansyl conjugate **1** (1.9 μM) in the absence (solid line) and presence (dotted line) of 12.5 μM BHA trimer. (B) Fluorescence intensity at 521 nm as a function of the concentration of BHA trimer. Excitation was at 321 nm.

with no significant change in band shape. These changes in fluorescence were used to estimate affinities and stoichiometries for the binding of the compounds to BHA. However, to be able to determine binding stoichiometry it would be necessary to perform titrations at concentrations that are typically at least 3-fold higher than K_d for the ligand, in order that essentially all the BHA added in the early part of the titration is saturated with ligand. This was impractical in the present experiments, where for reasons of availability we were unable to use high enough concentrations of BHA to make unambiguous determinations of stoichiometry. We therefore analyzed the titration data for two plausible models: a one-site model in which there is a single binding site for sialic acid in the BHA trimer and a three-site model in which each monomer within the trimer contains a site for binding. In the latter case we assumed that these sites were identical and noninteracting.

For **1**, the fit using the one-site model (Figure 5B) gave $K_d = 4.7 \pm 0.7$ μM and $F_{(BHA\cdot\mathbf{1})}/F_{(\mathbf{1})} = 4.58 \pm 0.45$; the corresponding values for the three-site model were $K_d = 17.9 \pm 2.4$ μM and $F_{(BHA\cdot\mathbf{1})}/F_{\mathbf{1})} = 4.83 \pm 0.59$. The computed best fit for the one-site model (shown as the solid line in Figure 5B) is marginally better than that for the three-site model (not shown) as judged by χ^2 values of 1.09 and 1.43, respectively. For **3**, analysis using the one-site model gave $K_d = 2.3 \pm 0.4$ μM and a fluorescence intensity ratio $F_{(BHA\cdot\mathbf{3})}/F_{(\mathbf{3})}$ of 0.31 ± 0.02. The corresponding values for the analysis using the three-site model were $K_d = 8.7 \pm 1.7$ μM and $F_{(BHA\cdot\mathbf{3})}/F_{(\mathbf{3})} = 0.28 \pm 0.03$. As above, the best fit for the one-site model (shown as the solid line in Figure 6B) is marginally better than that for the three-site model (not shown) as judged by χ^2 values of 1.23 and 1.69, respectively, but the differences are too small to distinguish between the models.

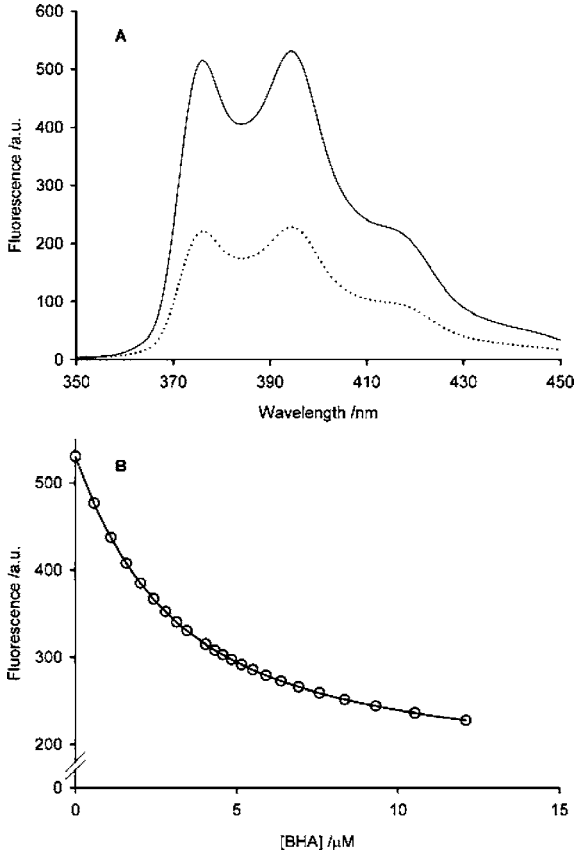

Figure 6. (A) The emission spectrum of the pyrenyl conjugate **3** (1.25 μM) in the absence (solid line) and presence (dotted line) of 12.5 μM BHA trimer. (B) Fluorescence intensity at 394 nm as a function of the concentration of BHA trimer. Excitation was at 340 nm.

The binding of BHA to the pyrene conjugate is only 2-fold tighter than for the dansyl one, which is somewhat different from expectations based on previous data (*7*), in which a trend to higher affinity was associated with an increased number of aromatic rings in the fluorophore (or related pendent group). However, two factors may explain this divergence from the earlier results. First, those data were derived from hemagglutination inhibition experiments, and it has been noted that such assays may not give identical results to fluorescence assays (*20d*). Second, although the dansyl conjugate **1** described here was identical to that in the earlier study, the series of aromatic hydrocarbon conjugates described previously had six-carbon linkers to the sialic acid rather than the four-carbon one in the present pyrene conjugate **3**. The previous data suggest that the linker length can influence the binding constant for these compounds, but there are insufficient data to draw definitive conclusions.

Both compounds show much tighter binding (low μM range) than simple α-methyl sialoside [K_d 2.8 mM (*7*)], implying that the fluorophores and/or linker have interactions with hemagglutinin. Although it seems most probable that the sialic acid moiety does bind to the specific binding site of hemagglutinin, positive demonstration of this will be required and studies to obtain structural evidence for specific binding are planned. These and further application of the binding assays will be described elsewhere.

ACKNOWLEDGMENT

We thank the Division of Virology (NIMR) for provision of BHA. We are grateful to the EPSRC Mass Spectrometry Centre, Swansea, for low-resolution negative ion spectra, and to the MRC Biomedical NMR Centre for access to facilities.

Fluoro-pegylated (FPEG) Imaging Agents Targeting Aβ Aggregates

Karin A. Stephenson, Rajesh Chandra, Zhi-Ping Zhuang, Catherine Hou, Shunichi Oya, Mei-Ping Kung, and Hank F. Kung*

Departments of Radiology, University of Pennsylvania, 3700 Market Street, Room 305, Philadelphia, Pennsylvania 19104. Received August 1, 2006; Revised Manuscript Received November 2, 2006

A novel approach of producing positron emission tomography (PET) imaging agents through the formation of bioconjugates based on a pegylation−fluorination strategy resulting in fluoro-pegylated (FPEG) molecules is reported. This approach offers a simple and easy method by which to incorporate ^{18}F in the target molecule without an appreciable increase in the lipophilicity. After ^{18}F labeling, this convenient approach leads to PET imaging probes binding to Aβ aggregates in the brain (an important factor associated with Alzheimer's disease) using the known core structures, such as [2-(4-dimethylaminophenyl)-vinyl]-benzoxazol **(3′)** or 2-phenylbenzothiazole (**4**). This approach appears to be effective in some core structures, but it cannot be uniformly applied to all structures.

INTRODUCTION

Alzheimer's disease (AD) is an important neurodegenerative disorder of the brain affecting millions of older Americans, and yet the diagnosis of this disease based on neurological observations is often difficult and unreliable. The only definitive diagnosis of the disease is by pathological examination of postmortem staining of affected brain tissues. The presence of β-amyloid (Aβ) aggregates in the brain is generally accepted as the hallmark of AD (*1*−*4*). Recent success in developing radionuclide-labeled agents targeting the Aβ aggregates provides a window of opportunity to improve the diagnosis of AD (*5*−*8*). Preliminary reports of positron emission tomography (PET) imaging suggested that 4-*N*-methylamino-4′-hydroxystilbene ([^{11}C]**1**, SB-13) (*9*) and [^{11}C] 2-(4′-(methylaminophenyl)-6-hydroxybenzothiazole ([^{11}C]**4**, also known as PIB) (*10*) (Figure 1) showed differential uptake and retention in the brain of AD patients as compared to controls. Since ^{11}C is a positron emitting isotope with $T_{1/2}$ = 20 min, which limits its usefulness for widespread clinical application, efforts are being made to develop comparable agents labeled with a longer half-life isotope—^{18}F ($T_{1/2}$ = 110 min). Preliminary studies with [^{18}F]-2-(1-(2-(*N*-(2-fluoroethyl)-*N*-methylamino)naphthalen-6-yl)ethylidene)malononitrile ([^{18}F]FDDNP) (*7*) showed differential uptake and retention in the brain of AD patients, but this a highly lipophilic tracer, binding to both tangles and plaques, making it difficult to measure the specific signal contribution from plaques. In 2002, Mathis et al. reported a series of [^{18}F]-fluoroalkoxy-BTA-1 derivatives, which showed excellent binding affinities and brain penetration (*11*). Two other potential series of Aβ-specific imaging agents, 6-iodo-2-(4′-dimethylamino)phenylimidazo[1,2-*a*]pyridine (**2**, IMPY) (*12*−*14*) and 2-(4-methylaminostyryl)-6-(2-fluoroethoxy)benzoxazole (**3**, BF-168) (*15*, *16*), have also shown high specific binding affinities to Aβ aggregates of AD brain homogenates (K_i < 10 nM; see Table 1).

We are interested in replacing the labeling isotope with ^{18}F, but the challenge is to maintain the Aβ aggregate-binding affinity and maintain suitable in vivo kinetics of the agents with sufficient selective uptake in the brain (*6*, *17*). Incorporating a radioactive fluoride atom (^{18}F) is typically accomplished using either electrophilic or nucleophilic conditions (*18*−*20*). Fluoride nucleophilic displacement reactions are advantageous, as they often result in higher yields and higher specific activities and the fluoride can be produced more readily (*19*, *20*). [^{18}F] fluoride can be added via an SN2-type reaction with good leaving groups such as either the mesylate or tosylate precursor. One of the commonly used methods to append a fluorine atom involves adding a fluoroethyl or fluoropropyl group to the target compound. However, when these short fluoro alkyl chains were added to the core structures, the results were sometimes not promising. This is often due to an increase in lipophilicity; the resulting ^{18}F-labeled agents tend to have a higher nonspecific binding to the Aβ aggregates. To circumvent these undesirable effects, we have exploited a novel approach by using fluoro-

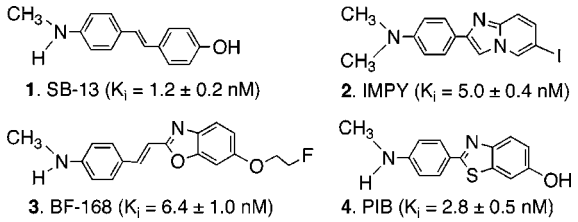

Figure 1. Structures of four imaging agents (**1**−**4**) targeting Aβ aggregates in the brain. The K_i values indicate the in vitro binding affinity to Aβ aggregates (*15*, *27*, *31*).

pegylation (FPEG) of the core structures for ^{18}F labeling of stilbene derivatives (*21*). It is generally assumed that the *p-N*-methylaminophenyl or the *p-N,N*-dimethylaminophenyl group is critical for binding affinity; modification on the opposite end of these core structures may not alter the binding affinity (*17*).

Pegylation (PEG) is a common approach for changing in vivo pharmacokinetics of various biologically interesting proteins or peptides, through which the in vivo stability and pharmacokinetics can be improved, leading to better therapeutics (*22*, *23*). Recently, the "pegylation" technique has been applied to modify the pharmacokinetic properties of radiopharmaceuticals (*24*, *25*). Conjugating PEG macromolecules (high molecular weight PEGs, $M_w = 10\,000-20\,000$) to labeled peptides may be efficacious in changing biodistribution in vivo and leading to improvements in specific localization of agents targeting peripheral tissues. However, it will be ineffective to use macromolecular PEG-conjugated radiopharmaceuticals as imaging agents for the brain due to the limitation of such macromolecules to cross the blood−brain barrier. In an attempt to modulate the lipophilicity of ^{18}F-labeled stilbene derivatives (*21*, *26*), we have adopted a novel approach by adding a short length of FPEG ($n = 2-5$) and capping the end of the ethylene glycol chain with a fluorine atom (*21*). The resulting FPEG derivatives of SB-13 displayed excellent Aβ aggregate-binding affinities and high brain penetrations. The success of this FPEG approach has prompted us to expand this simple strategy to different Aβ-targeting small core structures (**1**−**4**).

In this report, we explored fluoro-pegylated compounds with IMPY (**2**), BF168 (**3**), and PIB (**4**) core structures with various chain lengths ($n = 1-8$) for biological evaluations. F-18 radiolabelings were attempted on several compounds with each core ([^{18}F]**5a**−**c** for PIB, [^{18}F]**12c** for IMPY, and [^{18}F]**8b** for BF168), and the initial biodistributions and autoradiograms of [^{18}F]**5a**−**c** were obtained. Reported herein is a structure−binding activity study of attaching a short chain length FPEG ($n \leq 8$) to these molecules for labeling with ^{18}F and concomitantly maintaining in vitro binding affinities and in vivo biological properties.

EXPERIMENTAL PROCEDURES

General. All reagents in the syntheses were commercial products used without further purification unless otherwise indicated. ^{1}H NMR spectra were obtained on a Bruker DPX spectrometer (200 MHz) in $CDCl_3$ unless otherwise indicated. Chemical shifts are reported as δ values (parts per million) relative to internal TMS. Coupling constants are reported in hertz. The multiplicity is defined by s (singlet), d (doublet), t (triplet), br (broad), and m (multiplet). High-resolution electron ionization (HREI) mass spectra were performed at the McMaster Regional Centre for Mass Spectrometry using a Micromass/Waters GCT instrument (GC-EI/CI time-of-flight mass spectrometer). Semipreparative HPLC was performed using a Phenomenex Gemini C18 column [(5.0 × 250 mm, 5 μm); acetonitrile/water 70/30; flow rate 3 mL/min] and analytical HPLC conditions using a Phenomenex Gemini C18 analytical column [(5.0 × 250 mm, 5 μm); acetonitrile/water 80/20; flow rate 1 mL/min)].

Synthesis of 2-(4′-(methylaminophenyl)-6-hydroxybenzothiazole (PIB, 4) Derivatives. Compound **4** (2-(4′-(methylaminophenyl)-6-hydroxybenzothiazole (PIB) was prepared using the approach of Mathis and co-workers (*27*). Monomethylation was accomplished via standard reported procedures (*28*) to yield **4** that was used in the subsequent steps.

*General Procedure for the Pegylation of **4**.* To a solution of **4** (1 equiv) in anhydrous *N,N*-dimethylformamide (2 mL/0.1 mmol of **4**) in a microwavable vial (from Biotage) was added anhydrous cesium carbonate (2.5 equiv) and the mixture stirred at room temperature under argon for 30 min. Pegylation agent (1.2 equiv) followed by sodium iodide (1.5 equiv) were then added to the vial. The vial was then sealed and subjected to microwave irradiation (Biotage Initiator system). The microwave conditions were 200 °C for 10 min with 10 s pre-stirring. After cooling the reaction mixture to room temperature, the vial was opened, the contents were transferred to a round-bottom flask, and the volatiles were removed under reduced pressure. The residue was extracted with ethyl acetate (3 × 10 mL), and the ethyl acetate layer was washed with water (1 × 10 mL) and brine (1 × 10 mL). The organic layer, after drying over anhydrous magnesium sulfate, was evaporated, and the residue was purified on silica PTLC (PTLC) to afford the corresponding PEGylated derivatives.

*Preparation of Compounds **5a**−**d**.* Treatment of *4* with the fluoromesylates according to the general procedure afforded compounds **5a**−**d**.

2-[4′-(Methylamino)phenyl]-6-[2-(2-fluoroethoxy)ethoxy]benzothiazole (**5a**). Yield: 84%. (PTLC, 50% ethyl acetate in hexane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.83−7.89 (3H, m), 7.33 (1H, d, $J = 2.5$ Hz), 7.06 (1H, dd, $J = 8.9$, 2.5 Hz), 6.63 (2H, d, $J = 8.9$ Hz), 4.60 (2H, dt, $J = 47.6$, 4.2 Hz), 4.21 (2H, t, $J = 4.5$ Hz), 3.89−3.94 (3H, m), 3.76 (1H, d, $J = 4.2$ Hz), 2.90 (3H, s). HRMS (EI) *m/z* calcd. for $[C_{18}H_{19}FN_2O_2S]^+$ 346.1151, found 346.1141.

2-[4′-(Methylamino)phenyl]-6-(2-(2-(2-fluoroethoxy)ethoxy)-ethoxy)benzothiazole (**5b**). Yield: 78%. (PTLC, 60% ethyl acetate in hexane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.82−7.88 (3H, m), 7.32 (1H, d, $J = 2.5$ Hz), 7.05 (1H, dd, $J = 8.8$, 2.5 Hz), 6.63 (2H, d, $J = 8.8$ Hz), 4.56 (2H, dt, $J = 47.6$, 4.2 Hz), 4.19 (2H, t, $J = 4.5$ Hz), 3.65−3.88 (8H, m), 2.89 (3H, s). HRMS (EI) *m/z* calcd. for $[C_{20}H_{23}FN_2O_3S]^+$ 390.1413, found 390.1386.

2-[4′-(Methylamino)phenyl]-6-(2-(2-(2-(2-(2-(2-fluoroethoxy)ethoxy)ethoxy)ethoxy)ethoxy)ethoxy)benzothiazole (**5c**). Yield: 72%. (PTLC, 80% ethyl acetate in hexane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.82−7.87 (3H, m), 7.33 (1H, d, $J =$ 2.4 Hz), 7.05 (1H, dd, $J = 8.8$, 2.4 Hz), 6.63 (2H, d, $J = 8.8$ Hz), 4.54 (2H, dt, $J = 47.6$, 4.1 Hz), 4.18 (2H, t, $J = 4.5$ Hz), 3.65−3.90 (20H, m), 2.89 (3H, s). HRMS (EI) *m/z* calcd. for $[C_{26}H_{35}FN_2O_6S]^+$ 522.2200, found 522.2175.

2-[4′-(Methylamino)phenyl]-6-(2-(2-(2-(2-(2-(2-(2-fluoro-ethoxy)ethoxy)ethoxy)ethoxy)ethoxy)ethoxy)ethoxy)-benzothiazole (**5d**). Yield: 71%. (PTLC, ethyl acetate). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.81−7.87 (3H, m), 7.33 (1H, d, $J =$ 2.4 Hz), 7.05 (1H, dd, $J = 8.8$, 2.4 Hz), 6.63 (2H, d, $J = 8.8$ Hz), 4.55 (2H, dt, $J = 47.7$, 4.2 Hz), 4.19 (2H, t, $J = 4.4$ Hz), 3.63−3.90 (28H, m), 2.89 (3H, s). HRMS (EI) *m/z* calcd. for $[C_{30}H_{43}FN_2O_8S]^+$ 610.2724, found 610.2705.

*Preparation of Compounds **6a**−**c**.* Treatment of **4** with hydroxymesylates according to the general procedure afforded compounds **6a**−**c**.

2-(2-(2-(4-Methylaminophenyl)benzothiazol-6-yloxy)ethoxy)-ethanol (**6a**). Yield: 82%. (PTLC, 1% methanol in dichloromethane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.85−7.89 (3H, m), 7.33 (1H, d, $J = 2.4$ Hz), 7.06 (1H, dd, $J = 8.8$, 2.4 Hz), 6.64 (2H, d, $J = 8.8$ Hz), 4.20 (2H, d, $J = 4.3$ Hz), 3.90 (2H, d, $J = 4.6$ Hz), 3.69−3.78 (m, 4H), 2.90 (s, 3H). HRMS (EI) *m/z* calcd. for $[C_{18}H_{20}N_2O_3S]^+$ 344.1195, found 344.1188.

2-(2-(2-(2-(4-Methylaminophenyl)benzothiazol-6-yloxy]ethoxy)-ethoxy)ethanol (**6b**). Yield: 74%. (PTLC, 1% methanol in dichloromethane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.83−7.88 (3H, m), 7.31 (1H, d, $J = 2.5$ Hz), 7.05 (1H, dd, $J = 8.8$, 2.5 Hz), 6.63 (2H, d, $J = 8.8$ Hz), 4.19 (2H, t, $J = 4.5$ Hz), 3.88 (2H, t, $J = 4.6$ Hz) 3.58−3.78 (8H, m), 2.90 (3H, s). HRMS (EI) *m/z* calcd. for $[C_{20}H_{24}N_2O_4S]^+$ 388.1457, found 388.1444.

2-(2-(2-(2-(2-(2-(4-Methylaminophenyl)benzothiazol-6-yloxy)ethoxy)ethoxy)ethoxy)ethoxy)ethoxy)ethanol (**6c**). Yield: 66%. (PTLC, 2% methanol in dichloromethane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.83−7.88 (s, 3H), 7.33 (1H, d, J = 2.41 Hz), 7.06 (1H, dd, J = 8.8, 2.5 Hz), 6.63 (2H, d, J = 8.8 Hz), 4.19 (2H, t, J = 4.5 Hz), 3.88 (2H, t, J = 4.8 Hz), 3.56−3.53 (20H, m), 2.90 (3H, s). HRMS (EI) *m*/*z* calcd. for $[C_{26}H_{36}N_2O_7S]^+$ 520.2243, found 520.2282.

*Preparation of Compounds **7a**−**c**.* Alkylation of **4** with *tert*-butyldimethylsilyl protected mesylates as per the general procedure afforded compounds **7a**−**c**.

2-[4′-(Methylamino)phenyl]-6-(2-(2-*tert*-butyldimethylsilyloxyethoxy)ethoxy)benzothiazole (**7a**). Yield: 70%. (PTLC, 50% ethyl acetate in hexane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.84−7.88 (3H, m), 7.32 (1H, d, J = 2.4 Hz), 7.06 (1H, dd, J = 8.8, 2.4 Hz), 6.64 (2H, d, J = 8.8 Hz), 4.20 (2H, d, J = 4.3 Hz), 3.90 (2H, d, J = 4.6 Hz), 3.64−3.78 (m, 4H), 2.90 (s, 3H), 0.88 (9H, s), 0.05 (6H, s).

2-[4′-(Methylamino)phenyl]-6-(2-(2-(2-*tert*-butyldimethylsilyloxyethoxy)ethoxy)ethoxy)benzothiazole (**7b**). Yield: 62%. (PTLC, 60% ethyl acetate in hexane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.82−7.87 (3H, m), 7.30 (1H, d, J = 2.5 Hz), 7.05 (1H, dd, J = 8.8, 2.5 Hz), 6.62 (2H, d, J = 8.8 Hz), 4.21 (2H, t, J = 4.5 Hz), 3.88 (2H, t, J = 4.6 Hz), 3.58−3.74 (8H, m), 2.90 (3H, s), 0.88 (9H, s), 0.05 (6H, s).

2-[4′-(Methylamino)phenyl]-6-(2-(2-(2-(2-(2-(2-*tert*-butyldimethylsilyloxyethoxy)ethoxy)ethoxy)ethoxy)ethoxy)ethoxy)benzothiazole (**7c**). Yield: 55%. (PTLC, 80% ethyl acetate in hexane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.85−7.89 (3H, m), 7.32 (1H, d, J = 2.4 Hz), 7.05 (1H, dd, J = 8.4, 2.4 Hz), 6.64 (2H, d, J = 8.4 Hz), 4.19 (2H, t, J = 4.7 Hz), 3.88 (2H, t, J = 4.9 Hz), 3.44−3.77 (20H, m), 2.90 (3H, s), 0.88 (9H, s), 0.05 (6H, s).

General Procedure for the Preparation of Compounds 10a−c. *General Procedure for Boc Protection to Form 7′(a−c).* Compounds **7a**−**c** (1 equiv) were dissolved in anhydrous tetrahydrofuran (10 mL/mmol of **7**), and to the resulting solution, di-*tert*-butyldicarbonate (2 equiv) and 4-dimethylaminopyridine (catalytic) were added and the mixture heated to reflux. After 16 h, another batch of di-*tert*-butyldicarbonate (1 equiv) was added and the mixture was further refluxed for another 20 h. The reaction mixture was then cooled to room temperature, and the solvent was removed under reduced pressure. The residue was taken in ethyl acetate (25 mL/mmol of **6**), washed successively with water (1 × 10 mL) and brine (1 × 10 mL), and dried over anhydrous magnesium sulfate. The residue after removing the solvent was purified by silica PTLC.

2-[4′-(*N*-*tert*-Butyloxycarbonyl-*N*-methylamino)phenyl]-6-(2-(2-*tert*-butyldimethylsilyloxyethoxy)ethoxy)benzothiazole (**7′a**). Yield: 55%. (PTLC, 20% ethyl acetate in hexane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.91−8.01 (3H, m), 7.34−7.38 (3H, m), 7.08 (1H, dd, J = 8.8, 2.4 Hz), 4.22 (2H, d, J = 4.3 Hz), 3.89 (2H, d, J = 4.6 Hz), 3.60−3.76 (m, 4H), 3.02 (s, 3H), 1.47 (9H, s), 0.88 (9H, s), 0.05 (6H, s).

2-[4′-(*N*-*tert*-Butyloxycarbonyl-*N*-methylamino)-phenyl]-6-(2-(2-(2-*tert*-butyldimethylsilyloxyethoxy)ethoxy)-ethoxy)benzothiazole (**7′b**). Yield: 48%. (PTLC, 30% ethyl acetate in hexane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.90−7.99 (3H, m), 7.34−7.37 (3H, m), 7.06 (1H, dd, J = 8.6, 2.5 Hz), 4.20 (2H, t, J = 4.5 Hz), 3.88 (2H, t, J = 4.6 Hz), 3.54−3.69 (8H, m), 3.01 (3H, s), 1.46 (9H, s), 0.88 (9H, s), 0.05 (6H, s).

2-[4′-(*N*-*tert*-Butyloxycarbonyl-*N*-methylamino)phenyl]-6-(2-(2-(2-(2-(2-*tert*-butyldimethylsilyloxyethoxy)ethoxy)ethoxy)-ethoxy)ethoxy)ethoxy)benzothiazole (**7′c**). Yield: 40%. (PTLC, 50% ethyl acetate in hexane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.92−8.01 (3H, m), 7.36−7.40 (3H, m), 7.05 (1H, dd, J = 8.4, 2.4 Hz), 4.20 (2H, t, J = 4.7 Hz), 3.88 (2H, t, J = 4.9 Hz), 3.44−3.77 (20H, m), 3.02 (3H, s), 1.47 (9H, s), 0.88 (9H, s), 0.05 (6H, s).

*General Procedure for Deprotection Followed by Preparation of the Mesylate Derivatives **10a**−**c**.* *tert*-Butyl carbonate (BOC) protected compounds **7′a**−**c** were dissolved in anhydrous tetrahydrofuran (3 mL/0.1 mmol of **7′**), and the resulting solution was cooled to 0 °C. Tetrabutylammonium fluoride (2 equiv, 1 M in tetrahydrofuran) was added to the ice cold solution and stirred at the same temperature for 15 min followed by room temperature for 2 h. The solvent was then removed, and the residue dissolved in ethyl acetate (30 mL) and washed with water (1 × 10 mL), brine (1 × 10 mL), and dried over anhydrous magnesium sulfate. The resultant solution was then concentrated and redissolved in anhydrous dichloromethane (1 mL/0.1 mmol of **7′**). Anhydrous triethylamine (4 equiv) was then added and the mixture cooled in an ice−acetone bath (∼ −5 °C). Methanesulfonyl choride (3 equiv) was added and the mixture stirred at the same temperature for 15 min. The reaction mixture was brought to room temperature gradually and stirred for an additional 2 h. It was then quenched with ice and extracted with dichloromethane (3 × 5 mL). The organic layer after drying over anhydrous magnesium sulfate was purified by silica PTLC.

2-(4′-(*N*-*tert*-Butyloxycabonyl-*N*-methylamino)phenyl)-6-(2-(2-methylsulfonyloxyethoxy)ethoxy)benzothiazole (**10a**). Yield: 92%. (PTLC, 1% methanol in dichlormethane, 92%). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.91−8.01 (3H, m), 7.34−7.38 (3H, m), 7.08 (1H, dd, J = 8.8, 2.4 Hz), 4.39−4.44 (2H, m), 4.19−4.23 (2H, m), 3.84−3.89 (4H, m), 3.30 (3H, s), 3.05 (3H, s), 1.47 (9H, s).

2-(4′-(*N*-tert-Butyloxycarbonyl-*N*-methylamino)phenyl]-6-(2-(2-(2- methylsulfonyloxyethoxy)ethoxy)ethoxy)benzothiazole (**10b**). Yield: 95%. (PTLC, 1% methanol in dichloromethane, 95%). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.90−8.01 (3H, m), 7.33−7.38 (3H, m), 7.09 (1H, dd, J = 8.8, 2.5 Hz), 4.35−4.39 (2H, m), 4.17−4.22 (2H, m), 3.86−3.91 (2H, m), 3.69−3.80 (6H, m), 3.31 (3H, s), 3.05 (3H, s), 1.47 (9H, s).

2-[4′-(*N*-tert-Butyloxycarbonyl-*N*-methylamino)phenyl]-6-(2-(2-(2-(2-(2- methylsulfonyloxyethoxy)ethoxy)ethoxy)ethoxy)-ethoxy)ethoxy)benzothiazole (**10c**). Yield: 90%. (PTLC, 2% methanol in dichloromethane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.91−8.01 (3H, m), 7.34−7.38 (3H, m), 7.11 (1H, dd, J = 8.8, 2.4 Hz), 4.33−4.38 (2H, m), 4.18−4.23 (2H, m), 3.87−3.92 (2H, m), 3.62−3.78 (18 H, m), 3.31 (3H, s), 3.06 (3H, s), 1.47 (9H, s).

Preparation of [2-(4-dimethylaminophenyl)vinyl]benzoxazol Derivatives. *2-(2-(4-dimethylaminophenyl)vinyl)benzoxazol-6-ol (3′).* 2-Methylbenzoxazol-6-ol (prepared following Schreiner and co-workers method (*29*)) (1.7 mmol) was dissolved in anhydrous tetrahydrofuran (8 mL) and cooled to 0 °C. Trimethylsilyl chloride (1.8 mmol) and diisopropylethylamine (1.84 mmol) were then added and the resultant solution stirred for 2 h at room temperature. After cooling to −78 °C, sodium hexamethyldisilazane (11.7 mmol, 1.0 M solution in tetrahydrofuran) was added slowly over 1.5 h and then stirred at −78 °C for an additional hour. 4-(Dimethylamino)benzaldehyde was then added and the reaction allowed to warm to room temperature overnight. The reaction was then poured into a 1 M solution of sodium hydrogen sulfate and extracted with ethyl acetate. The organic layer was then washed with brine, dried over magnesium sulfate, and concentrated to yield a yellow solid that was purified using column chromatography (3% methanol in dichloromethane). Yield: 45%. ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.57 (2H, d, J = 8.9 Hz), 7.55 (1H, d, J = 16.0 Hz), 7.43 (1H, d, J = 8.5 Hz), 6.99 (1H, d, J = 2.1 Hz), 6.89 (1H, d, J = 16.0 Hz), 6.78 (1H, dd, J = 8.5, 2.1 Hz), 6.73 (2H, d, J = 8.9 Hz), 2.98 (6H, s). HRMS (EI) *m*/*z* calcd. for $[C_{17}H_{16}N_2O_2]^+$ 280.1212, found 280.1205.

*General Procedure for Pegylation of **3′***. To a solution of **3′** (1 equiv) in anhydrous *N*,*N*-dimethylformamide (2 mL) in a microwavable vial (from Biotage) was added potassium carbonate (3.0 equiv) and pegylating agent (1.2−1.5 equiv). The vial was sealed and subjected to microwave irradiation (Biotage Initiator system) at 200 °C for 10 min with 10 s pre-stirring and with fixed hold time "on". After cooling the reaction mixture to room temperature, the vial was opened and the contents poured into water and extracted with ethyl acetate (3 × 10 mL). The ethyl acetate layer was washed with water (2 × 10 mL) and brine (2 × 10 mL). The organic phase was then dried over anhydrous sodium sulfate and evaporated. The residue was purified by silica PTLC to afford the corresponding PEGylated derivatives (**8a**−**d**).

6-(2-Fluoroethoxy)-[2-(4-dimethylaminophenyl)vinyl]benzoxazol (**8a**). Yield: 68%. ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.64 (1H, d, J = 16.2 Hz), 7.54 (1H, d, J = 8.7 Hz), 7.47 (2H, d, J = 8.8 Hz), 7.06 (1H, d, J = 2.3 Hz), 6.93 (1H, dd, J = 8.7, 2.3 Hz), 6.80 (1H, d, J = 16.2 Hz), 6.72 (2H, d, J = 8.8 Hz), 4.78 (2H, dt, J = 47.4, 4.0 Hz), 4.26 (2H, dt, J = 27.7, 4.0 Hz), 3.02 (6H, s). HRMS (EI) *m*/*z* calcd. for $[C_{19}H_{19}FN_2O_2]^+$ 326.1434, found 326.1431.

6-(2-(2-(2-Fluoroethoxy)ethoxy)ethoxy)-[2-(4-dimethylaminophenyl)vinyl]benzoxazol (**8b**). Yield: 71%. ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.63 (1H, d, J = 16.2 Hz), 7.52 (1H, d, J = 8.8 Hz), 7.47 (2H, d, J = 9.0 Hz), 7.06 (1H, d, J = 2.1 Hz), 6.92 (1H, dd, J = 8.8, 2.1 Hz), 6.80 (1H, d, J = 16.2 Hz), 6.72 (2H, d, J = 9.0 Hz), 4.57 (2H, dt, J = 47.6, 4.1 Hz), 4.19 (2H, t, J = 4.5 Hz), 3.92−3.67 (10H, m), 3.02 (6H, s). HRMS (EI) *m*/*z* calcd. for $[C_{23}H_{27}FN_2O_4]^+$ 414.1955, found 414.1946.

6-(2-(2-(2-(2-(2-Fluoroethoxy)ethoxy)ethoxy)ethoxy)ethoxy)-[2-(4-dimethylaminophenyl)vinyl]benzoxazol (**8c**). Yield: 66%. ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.63 (1H, d, J = 16.2 Hz), 7.51 (1H, d, J = 8.1 Hz), 7.46 (2H, d, J = 8.7 Hz), 7.05 (1H, d, J = 2.1 Hz), 6.91 (1H, dd, J = 8.1, 2.1 Hz), 6.80 (1H, d, J = 16.2 Hz), 6.71 (2H, d, J = 8.7 Hz), 4.54 (2H, dt, J = 47.5, 3.8 Hz), 4.17 (2H, t, J = 5.1 Hz), 3.90−3.65 (20H, m), 3.02 (6H, s). HRMS (EI) *m*/*z* calcd. for $[C_{29}H_{39}FN_2O_7]^+$ 546.2741, found 546.2740.

6-(2-(2-(2-(2-(2-(2-(2-Fluoroethoxy)ethoxy)ethoxy)ethoxy)ethoxy)ethoxy)ethoxy)[2(4-dimethylaminophenyl)vinyl]-benzoxazol (**8d**). Yield: 95%. ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.62 (1H, d, J = 16.2 Hz), 7.50 (1H, d, J = 8.6 Hz), 7.48 (2H, d, J = 8.9 Hz), 7.08 (1H, d, J = 2.2 Hz), 6.92 (1H, dd, J = 8.6, 2.2 Hz), 6.80 (1H, d, J = 16.2 Hz), 6.73 (2H, d, J = 8.9 Hz), 4.53 (2H, dt, J = 47.7, 4.0 Hz), 4.17 (2H, t, J = 4.39 Hz), 3.87−3.59 (30H, m), 3.02 (6H, s). HRMS (EI) *m*/*z* calcd. for $[C_{33}H_{47}FN_2O_9]^+$ 634.3266, found 634.3242.

*Preparation of 2-(2-(2-(2-(4-(dimethylamino)styryl)benzoxazol-6-yloxy)ethoxy)ethoxy)ethanol (**9**).* To a solution of **3′** (1 equiv) in anhydrous *N*,*N*-dimethylformamide (2 mL) in a microwavable vial (from Biotage) was added potassium carbonate (3.0 equiv) and 2-(2-(2-chloroethoxy)ethoxy)ethanol (1.5 equiv). The vial was sealed and subjected to microwave irradiation (Biotage Initiator system) at 200 °C for 10 min with 10 s pre-stirring and with fixed hold time "on". After cooling the reaction mixture to room temperature, the vial was opened and the contents poured into water and extracted with ethyl acetate (3 × 10 mL). The ethyl acetate layer was washed with water (2 × 10 mL) and brine (2 × 10 mL). The organic phase was then dried over anhydrous sodium sulfate and evaporated. The residue was purified by silica PTLC (25% hexanes in ethyl acetate) to afford the corresponding hydroxy PEGylated derivative (**9**) in 80% yield. ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.61 (1H, d, J = 16.2 Hz), 7.52 (1H, d, J = 8.8 Hz), 7.48 (2H, d, J = 9.0 Hz), 7.05 (1H, d, J = 2.2 Hz), 6.92 (1H, dd, J = 8.8, 2.2 Hz), 6.80 (1H, d, J = 16.2 Hz), 6.72 (2H, d, J = 9.0 Hz), 4.17 (2H, t, J = 4.4 Hz), 3.88 (2H, t, J = 4.4 Hz), 3.76−3.59 (8H, m), 3.00 (6H, s).

*Preparation of 2-(2-(2-(2-(4-(dimethylamino)styryl)benzoxazol-6-yloxy)ethoxy)ethoxy)ethyl methanesulfonate (**11**).* Compound **9** was dissolved in dichloromethane, followed by the addition of triethylamine (4.0 equiv). Methanesulfonyl chloride was then added via a syringe and the resultant solution stirred for 3 h at room temperature. The solution was then poured into water and extracted with dichloromethane, washed with brine, and dried over sodium sulfate. The residue was purified via silica PTLC (25% hexanes in ethyl acetate) to afford the mesylated precursor (**11**) in 75% yield. ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.63 (1H, d, J = 16.2 Hz), 7.52 (1H, d, J = 8.8 Hz), 7.48 (2H, d, J = 9.0 Hz), 7.05 (1H, d, J = 2.1 Hz), 6.92 (1H, dd, J = 8.8, 2.1 Hz), 6.80 (1H, d, J = 16.2 Hz), 6.72 (2H, d, J = 9.0 Hz), 4.37 (2H, t, J = 4.4 Hz), 4.19 (2H, t, J = 4.4 Hz), 3.87 (2H, t, J = 4.3 Hz), 3.79−3.61 (6H, m), 3.05 (3H, s), 3.02 (6H, s).

Synthesis of 6-Iodo-2-(4′-dimethylamino)phenylimidazo-[1,2-*a*]pyridine (IMPY) (2) Derivatives. Preparation of **2** (IMPY core) has been described elsewhere (*30*). The general procedure for the synthesis of 6-FPEG substituted-IMPY conjugates was accomplished using the following procedures.

Method A. Conventional synthesis: The mixture of **2** (prepared as reported previously (*30*)), fluoro-polyglycols (2−5 equiv), CuI (10% mol), Cs_2CO_3 (2 equiv), 1,10-phenanthroline (20% mol) in toluene (1 mL/0.1 mmol **2**) was stirred in a sealed tube for 48 h. The solvent was then removed and the residue purified by silica PTLC (ethyl acetate or 95% dichloromethane/5% methanol as the developing solvent) to give the desired product.

Method B. Microwave synthesis: The mixture of reactants and reagents described above in a sealed tube was put in the microwave oven at the following conditions: 170 °C, 60 min, normal absorption level (yields were similar to those used for the conventional synthesis).

6-(2-Fluoroethoxy)-2-(4-dimethylamino)phenylimidazo[1,2-a]pyridine (**12a**). Yield: 17%. (Method A) ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.78 (2H, d, J = 8.8 Hz), 7.68 (1H, d, J = 2.2 Hz), 7.67 (1H, s), 7.50 (1H, d, J = 9.7 Hz), 6.96 (1H, dd, J = 9.7, 2.2 Hz), 6.74 (2H, d, J = 8.8 Hz), 4.75 (2H, dt, J = 47.7, 4.1 Hz), 4.16 (2H, dt, J = 25.9, 4.1 Hz), d 2.99 (6H, s). HRMS (EI) *m*/*z* calcd. for $[C_{17}H_{19}FN_3O]^+$ $(M + H)^+$ 300.1512, found 300.1500.

6-(2-(2-Fluoroethoxy)ethoxy)-2-(4-dimethylamino)phenylimidazo[1,2-*a*]pyridine (**12b**). Yield: 59%. (Method A) ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.78 (2H, d, J = 8.8 Hz). 7.66 (1H, d, J = 2.2 Hz), 7.64 (1H, s), 7.46 (1H, d, J = 9.7 Hz), 6.94 (1H, dd, J = 9.7, 2.2 Hz), 6.76 (2H, d, J = 8.8 Hz), 4.59 (2H, dt, J = 47.6, 4.1 Hz), 4.08 (2H, t, J = 4.2 Hz), 3.88 (2H, t, J = 4.2 Hz), 3.80 (2H, dt, J = 25.9, 4.1 Hz), 2.98 (6H, s). HRMS (EI) *m*/*z* calcd. for $[C_{19}H_{23}FN_3O_2]^+$ $(M + H)^+$ 344.1774, found 344.1768.

6-(2-(2-(2-Fluoroethoxy)ethoxy)ethoxy)-2-(4-dimethylamino)-phenylimidazo[1,2-*a*] pyridine (**12c**). Yield: 60%. (Method A) ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.77 (2H, d, J = 8.8 Hz), 7.65 (1H, d, J = 2.2 Hz), 7.63 (1H, s), 7.45 (1H, d, J = 9.7 Hz), 6.93 (1H, dd, J = 9.7, 2.2 Hz), 6.75 (2H, d, J = 8.8 Hz), 4.54 (2H, dt, J = 47.7, 4.1 Hz), 4.06 (2H, t, J = 4.6 Hz), 3.82 (2H, t, J = 4.6 Hz), 3.70−3.59 (6H, m), 2.97 (6H, s). HRMS (EI) *m*/*z* calcd. for $[C_{21}H_{27}FN_3O_3]^+$ $(M + H)^+$ 388.2036, found 388.2032.

6-(2-(2-(2-(2-(2-Fluoroethoxy)ethoxy)ethoxy)ethoxy)ethoxy)-2-(4-dimethylamino)phenylimidazo[1,2-*a*]pyridine (**12d**). Yield: 18%. (Method A) ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.78 (2H, d, J = 8.8 Hz), 7.71 (1H, d, J = 1.9 Hz), 7.67 (1H, s), 7.48 (1H, d, J = 9.7 Hz), 6.93 (1H, dd, J = 9.7, 2.2 Hz), 6.76

(2H, d, $J = 8.8$ Hz), 4.53 (2H, dt, $J = 47.7$, 4.1 Hz), 4.09 (2H, t, $J = 4.6$ Hz), 3.85 (2H, t, $J = 4.6$ Hz), 3.89−3.64 (18H, m), 2.98 (6H, s). HRMS (EI) *m/z* calcd. for $[C_{27}H_{39}FN_3O_6]$ $(M + H)^+$ 520.2823, found 520.2808.

6-(2-(2-(2-(2-(2-(2-(2-(2-Fluoroethoxy)ethoxy)ethoxy)ethoxy)-ethoxy)ethoxy)ethoxy)ethoxy)-2-(4-dimethylamino)phenylimidazo[1,2-*a*]pyridine (**12e**). Yield: 58%. (Method A) ^{1}H NMR (200 MHz, $CDCl_3$): δ 7.75 (2H, d, $J = 8.8$ Hz), 7.68 (1H, d, $J = 1.9$ Hz), 7.62 (1H, s), 7.52 (1H, d, $J = 9.7$ Hz), 6.95 (1H, dd, $J = 9.7$, 2.2 Hz), 6.71 (2H, d, $J = 8.8$ Hz), 4.50 (2H, dt, $J = 47.7$, 4.0 Hz), 4.07 (2H, t, $J = 4.6$ Hz), 3.64−3.85 (28H, m), 2.95 (6H, s). HRMS (EI) *m/z* calcd. for $[C_{31}H_{47}FN_3O_8]^+$ $(M + H)^+$ 608.3347, found 608.3329.

*Synthesis of 2-(2-(2-(2-(4-(Dimethylamino)phenyl)imidazo-[1,2-a]pyridin-6-yloxy)ethoxy)ethoxy)ethanol (**13**).* Method 1. The mixture of **2** (prepared as reported previously (*30*)) (36 mg, 0.1 mmol), triethylene glycol (135 mg, 1mmol), CuI (19 mg, 0.1 mmol), Cs_2CO_3 (65 mg, 0.2 mmol), and 1,10-phenanthroline (927 mg, 0.15 mmol) in toluene (1 mL) was reacted in MW (170 °C, absorption: normal) for 1 h. The solvent was removed, and the residue was purified by silica PTLC (CH_2Cl_2/MeOH = 95:5) to give 28 mg of product (73.6%).

Method 2. The above mixture was stirred at 120 °C in a sealed tube for 48 h. The same workup as described in Method 1 gave the desired product in 36% yield.

^{1}H NMR (200 MHz, $CDCl_3$): d 7.75 (2H, d, $J = 7.8$ Hz), 7.67 (2H, s), 7.58 (2H, d, $J = 9.2$ Hz), 6.96 (2H, d, $J = 8.9$ Hz), 6.69 (2H, d, $J = 7.8$ Hz), 4.07 (2H, t, $J = 4.5$ Hz), 3.84 (2H, t, $J = 4.5$ Hz), 3.71−3.76 (6H, m), 3.61 (2H, t, $J = 4.5$ Hz), 2.95 (6H, s).

*Synthesis of 2-(2-(2-(2-(4-(Dimethylamino)phenyl)imidazo-[1,2-a]pyridin-6-yloxy)ethoxy)ethoxy)ethyl 4-Methylbenzene-sulfonate (**14**).* To a solution of **13** (45 mg, 0.12 mmol) dissolved in pyridine (1 mL) was added tosyl chloride (45 mg, 0.24 mmol) in solid form at 0 °C followed by DMAP (10 mg), and the resultant solution stirred at room temperature for 3 h. The reaction mixture was then poured into ice water and the mixture extracted with a mixed solvent (CH_2Cl_2/MeOH = 95:5). The combined organic solvent was dried over Na_2SO_4, filtered, and the filtrate concentrated to yield the crude product which was purified by silica PTLC (CH_2Cl_2/MeOH = 95:5) to give 29 mg of product (46%). ^{1}H NMR (200 MHz, $CDCl_3$): d 7.77 (2H, d, $J = 8.7$ Hz), 7.70 (1H, d, $J = 2.2$ Hz), 7.67 (1H, s), 7.48 (2H, d, $J = 9.6$ Hz), 7.29 (2H, d, $J = 8.2$ Hz), 6.94 (2H, dd, $J = 9.7$, 2.1 Hz), 6.76 (2H, d, $J = 8.8$ Hz), 4.16 (2H, t, $J = 4.7$ Hz), 4.07 (2H, t, $J = 4.6$ Hz), 3.83 (2H, t, $J = 4.6$ Hz), 3.53−3.69 (6H, m), 2.98 (6H, s), 2.40 (3H, s).

Radiochemistry. *General Procedure for ^{18}F Labeling of **10a**.* [^{18}F]Fluoride was produced by the JSW-type BC3015 cyclotron at the Cyclotron Facility, University of Pennsylvania, using ^{18}O-(p,n)^{18}F reaction. An [^{18}O]-enriched aqueous solution of [^{18}F]-fluoride was passed through a Sep-Pak Light quaternary methyl ammonium (QMA) cartridge (Waters) and the cartridge dried by airflow. The ^{18}F activity was then eluted using 1.2 mL of a Kryptofix 222/potassium carbonate solution, which is made up of 22 mg of Kryptofix 222 and 4.6 mg of potassium carbonate in acetonitrile/water (1.77/0.23). The solvent was removed under a stream of nitrogen at 120 °C and the residue azeotropically dried twice with 1 mL of anhydrous acetonitrile, also at 120 °C. The mesylate precursor (**10a**) (0.5, 1, 3, and 6 mg) was then dissolved in 0.2 mL of dimethyl sulfoxide and added to the reaction vessel containing the dry ^{18}F. The reaction was subsequently carried out under different temperatures for different time periods as shown in Table 2. 10% aqueous HCl (0.5 mL) was then added and the resultant mixture heated for an additional 10 min. Following completion of the reaction, water (2 mL) was added and the resultant solution loaded onto a Waters Oasis HLB cartridge (3 cm^3) previously washed with 2 × 3 mL ethanol and 2 × 3 mL of water. The cartridge was washed with 4 mL of water and the crude product eluted with 2 mL of acetonitrile. The Waters C18 Sep Pak could be used alternatively. However, the recovery yield of radioactivity by acetonitrile was lower.

Table 2. Optimization Studies for Compound [^{18}F]5a, Examining the Effect of Precursor Mass, Temperature, and Time for Traditional Heating vs Microwave Heating Strategies

entry	heating method	precursor mass (mg)	time (min)	temperature (°C)	radiochemical yield (%)
1	oil	0.5	4	120	32
2	oil	1	4	120	50
3	oil	3	4	120	50
4	oil	6	4	120	30
5	oil	1	8	120	59
6	oil	1	12	120	64
7	oil	1	16	120	62

9	oil	1	4	90	26
10	oil	1	4	105	45
11	MW (80W)	0.25	1	100	24
12	MW (80W)	0.5	1	100	30
13	MW (80W)	1	1	100	41
14	MW (80W)	3	1	100	24
15	MW (80W)	1	2	100	42
16	MW (80W)	1	3	100	40
17	MW (80W)	1	4	100	60
18	MW (80W)	1	1	90	54
19	MW (80W)	1	1	110	52
20	MW (80W)	1	1	130	48
21	MW (80W)	1	1	150	43

Acetonitrile solution was then injected onto a semipreparative HPLC for purification. The retention time of the major hydrolysis byproduct ($R_t = 3.6$ min) was well-resolved from the desired ^{18}F-labeled product ($R_t = 5.2$ min), which was isolated in >99% radiochemical purity, and the specific activity was estimated to be 500−1000 Ci/mmol after purification (specific activity was estimated by comparing UV peak intensity of purified [^{18}F]**5a** with reference to a nonradioactive compound of known concentration). Radiochemical yields are summarized in Table 2.

*General Procedure for ^{18}F Labeling of **10b**, **10c**, **11**, and **14**.* Compounds **10b**, **10c**, **11**, and **14** were labeled with ^{18}F using the similarly described procedure for **10a**. Subsequent Boc deprotection was carried out for **10b** and **10c**. For all these compounds, the reaction was carried out at 120 °C for 4 min, which is the optimum condition with regard to time and temperature.

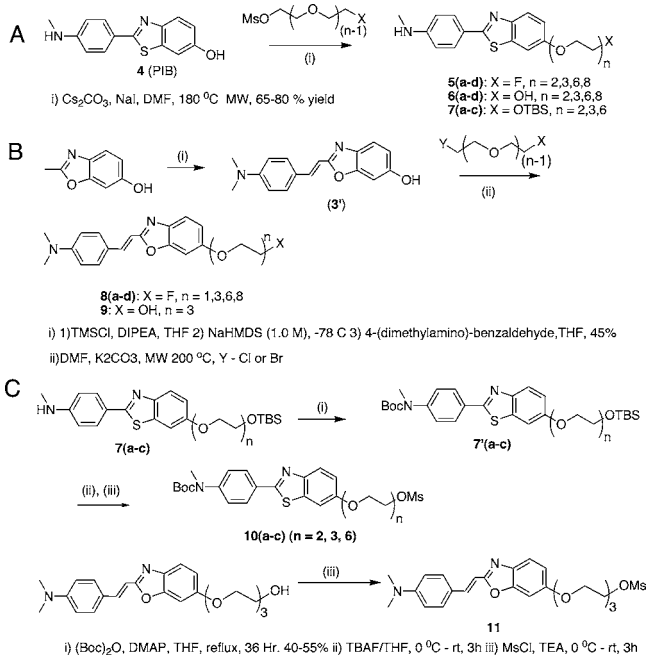
The crude reaction was purified via HPLC using the same conditions (except **11**, which used the same columns with solvent composition acetonitrile/water 60/40 at the same flow rate). Radiochemical yields ranged between 11% and 35%, and all were isolated in good radiochemical purity (>90%) with the exception of [^{18}F]**8b** wherein a second peak was evident within minutes of isolation. Specific activities for [^{18}F]**5b**, **c**, and [^{18}F]**12c** ranged between 800 and 1500 Ci/mmol.

Preparation of Brain Tissue Homogenates. Postmortem brain tissues were obtained from AD patients at autopsy, and neuropathological diagnosis was confirmed by current criteria (NIA-Reagan Institute Consensus Group, 1997). Homogenates were then prepared from dissected gray matter from AD patients in phosphate buffered saline (PBS, pH 7.4) at the concentration of approximately 100 mg wet tissue/mL (motor-driven glass homogenizer with setting of 6 for 30 s). The homogenates were aliquoted into 1-mL portions and stored at −70 °C for 6−12 months without loss of binding signal.

Binding Studies. As reported previously, [^{125}I]IMPY (*12*), with 2200 Ci/mmol specific activity and greater than 95%

radiochemical purity, was prepared using the standard iodo-destannylation reaction and purified by a simplified C-4 minicolumn (*12*). Binding assays were carried out in 12 × 75 mm borosilicate glass tubes. The reaction mixture contained 50 μL of brain homogenates (20−50 μg), 50 μL of [^{125}I]IMPY (0.04−0.06 nM diluted in PBS), and 50 μL of inhibitors (10^{-5}−10^{-10} M diluted serially in PBS containing 0.1% bovine serum albumin, BSA) in a final volume of 1 mL. Nonspecific binding was defined in the presence of IMPY (600 nM) in the same assay tubes. The mixture was incubated at 37 °C for 2 h, and the bound and free radioactivity were separated by vacuum filtration through Whatman GF/B filters using a Brandel M-24R cell harvester followed by 2 × 3 mL washes of PBS at room temperature. Filters containing the bound ^{125}I ligand were assayed for radioactivity content in a γ counter (Packard 5000) with 70% counting efficiency. Under the assay conditions, the specifically bound fraction was less than 15% of the total radioactivity. The results of inhibition experiments were subjected to nonlinear regression analysis using EBDA by which K_i values were calculated.

Film Autoradiography. Brain sections from AD subjects were mounted onto glass slides and incubated with F-18 tracers (300 000−600 000 cpm /200 μL) for 1 h at room temperature. The sections were then washed in saturated Li_2CO_3 in 40% EtOH (two 2-min washes) and in 40% EtOH (2 min) followed by rinsing with water for 30 s. After drying, the F-18 labeled sections were exposed to Kodak MR film overnight.



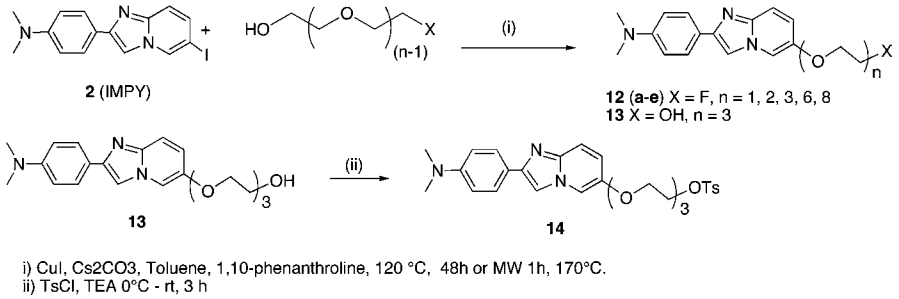
Partition Coefficient. Partition coefficients were measured by mixing the [^{18}F]-labeled sample with 3 g each of 1-octanol and buffer (0.1 M phosphate, pH 7.4) in a test tube. The two layers in the test tube were vortexed for 3 min followed by centrifugation for 5 min at room temperature. The radioactivity content values of two weighed samples (0.5 g each) from the 1-octanol and buffer layers were counted in a well counter. The partition coefficient was determined by calculating the ratio of cpm/g of 1-octanol to that of buffer. A sample from the 1-octanol layer was repartitioned with buffer solution, and each layer was counted again. This procedure was repeated until a consistent value of partition coefficient values was obtained (usually the third or fourth partition). The measurements were repeated three times.

Biodistribution Studies in Normal Mice. While under isoflurane anesthesia, 0.15 mL of a saline solution containing the [^{18}F] tracers (10−20 uCi) was injected directly into the lateral tail vein of male ICR mice. The mice (n = 3 for each time point) were sacrificed by cervical dislocation. At 2, 30, 60, and 120 min postinjection, organs of interest were removed, weighed, and assayed for radioactivity content with an automatic γ counter. The percentage dose per organ was calculated by a comparison of the tissue counts to counts of 1% of initial dose (100 times diluted aliquots of the injected material). Total activities of blood and bone were calculated under the assumption that they were 7% and 14% of the body weight, respectively. The % dose/g of samples was calculated by comparing the sample counts with the count of the diluted initial dose.

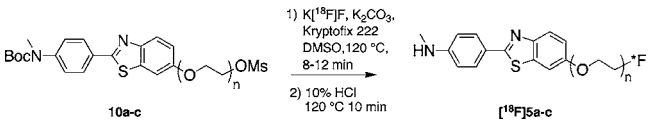
RESULTS AND DISCUSSION

One of the major advantages of our FPEG approach is incorporation of the fluoro tag at the end of a polyethylene glycol chain. The preparation of these compounds is readily achieved in a relatively simple and straightforward manner. In this report, we describe the FPEG derivatives of three cores: PIB (**4**), [2-(4-dimethylaminophenyl)vinyl]benzoxazol (**3′**), and IMPY (**2**), previously reported as imaging agents for Aβ aggregates (*10*, *12*−*16*). Syntheses of core compounds **2** and **4** and polyethylene glycol precursors were accomplished following literature procedures with minor modifications (*21*, *26*). Compound **3′** was

Scheme 1. Syntheses of FPEG Conjugates and Radiolabeling Precursors



prepared from 6-hydroxy-2-methylbenzoxazole followed by in situ trimethylsilyl protection of the phenolic OH, deprotonation, and condensation with *N*,*N*′-dimethylaminobenzaldehyde as described during the synthesis of similar compounds by Schreiner and co-workers (Scheme 1) (*29*). Conjugation of the free phenolic hydroxy groups to compounds **3′** and **4** with various oligoethylene glycol precursors was accomplished under microwave irradiation in good yields (68−95%) (Scheme 1A and B). By utilizing the same methodology, the radiofluorination precursors can be generated quickly and efficiently, conveniently allowing the radioactive fluoride to be added in the last step of the synthesis. Preparation of the mesylate precursor was generated following synthesis of the hydroxy derivative using a similar microwave procedure (Scheme 2C). It was important to also prepare and identify the hydroxy derivatives of FPEG, as they compete for binding to β-amyloid plaques and they are the major byproducts during radiolabeling.



The synthetic versatility of this strategy was further demonstrated with conjugates of compound **2** wherein FPEG was conjugated to **2** via a copper-catalyzed coupling reaction with the aryl iodide and corresponding fluoro/hydroxy PEG derivative (Scheme 3). The desired FPEG derivatives were prepared in moderate to good yields (17−60%).

In vitro binding studies to evaluate the binding affinities of the FPEG conjugates (**5a**−**d**, **8a**−**d**, and **12a**−**e**) to Aβ aggregates were carried out in AD brain homogenate with [^{125}I]-IMPY (**2**) as the ligand (*31*) (Table 1). Previous experience in preparing FPEG−stilbene (**1**) derivatives suggested that FPEG n = 3 was an ideal compromise between the addition of PEG groups to reduce lipophilicity and the need for a small neutral molecule to maintain good brain penetration (*21*). However, when similar n = 3 derivatives (**5b**, **8b**, and **12c**) were prepared and evaluated in vitro, it was evident this was not always the case. Only **5b** and **8b** retained high binding affinities for the n = 3 FPEG conjugates with K_i values of 3.8 and 14.5 nM, respectively. Compound **12c** was not nearly as potent, with a K_i value of 30 nM. In fact, further derivatization of **12** only increased the K_i (96 and 387 nM for **12d** and **12e**, respectively) (i.e., reducing the binding affinity), while the other core compounds remained highly potent in their binding affinities. On the basis of these initial in vitro results, FPEG conjugation

Scheme 2. Synthesis of FPEG-IMPY Conjugates 12a−e, 13, and the Corresponding Precursor 14 for Radiolabeling

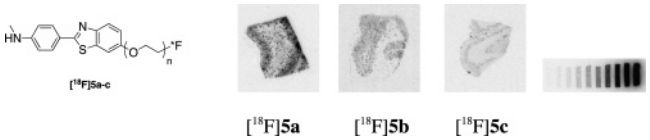
Scheme 3. ^{18}F Radiolabeling of 10a−c

clearly failed for conjugates **12a**−**e** (IMPY (**2**) derivatives) but was quite successful with the other two core compounds (PIB conjugates **5a**−**d** and BF conjugates **8a**−**d**).

^{18}F labeling was performed on either the mesyl or tosyl precursors undergoing a nucleophilic displacement reaction with the fluoride anion. Radiolabeling with ^{18}F was successfully performed on all core structures from precursors **10a**−**c** (Scheme 3), **11**, and **14** to generate [^{18}F]**5a**−**c**, [^{18}F]**8b**, and [^{18}F]**12c**, respectively. We labeled FPEG conjugates $n = 3$ initially on the basis of our past experience and success using this approach (*21*, *26*). Both core conjugates [^{18}F]**12c** (IMPY, **2**) and [^{18}F]**5b** (PIB, **4**) were labeled in moderate yields (30−35%) and with good radiochemical purities (>90%) from the tosyl and mesyl precursors, respectively. Retention times of the ^{18}F-labeled products (R_t([^{18}F]**12c**) = 6.5 min and R_t([^{18}F]**5b**) = 8.0 min) were well-separated from the major hydrolysis products (R_t = 4.0 and 4.5 min). An example of HPLC profile is shown in Figure 3. The preparation was about 80−90 min, and the specific activity for all prepared ^{18}F compounds was estimated to be 500−1500 Ci/mmol at the end of synthesis. Radiolabeled [^{18}F]-**8b**, which was prepared from the mesylate precursor in moderate radiochemical yield (23%), unfortunately could not be prepared in good radiochemical purity due to the instability of this compound. The formation of a second peak was evident within minutes of labeling upon standing at room temperature in ethanol or the acetonitrile/water HPLC solvent mixture. These results are consistent with those found by Shimadzu et al. during their labeling of a similar substrate (*32*). They attributed the formation of a second peak to the facile formation of *E* and *Z* isomers (*32*). On the basis of the promising in vitro binding affinities of **5a**−**d** and initial labeling results of [^{18}F]**5b**, we then prepared both [^{18}F]**5a** and [^{18}F]**5c** using the standard approach in good yields (35% and 11%, respectively) and purity (>98%).

For many years, use of mesylate precursors for radiofluorination chemistry has been demonstrated (*19*); however, the utility of these precursors for radiolabeling FPEG conjugates is relatively new. In order to study the radiofluorination reaction with FPEG, we prepared a large batch of precursor **10a** and evaluated the effects of precursor mass, temperature, reaction time, and sep-pak purification strategies.

Initially, using 1 mg of precursor **10a** dissolved in 250 μL of DMSO, the reaction temperature was varied from 75 °C to 120 °C using standard oil-bath heating for 4 min. Deprotection of the Boc protecting group was then achieved by adding 10% HCl and heating for 10 min. Water was then added (2 mL) and the solution loaded onto an Oasis HLB sep-pak cartridge. Following washing with water, the crude labeled product was eluted with 2 mL of acetonitrile and injected onto the HPLC. Labeling yields were highest at 120 °C (Table 2). Next, the amount of precursor (**10a**) was varied from 0.5 mg to 6 mg with oil-bath heating at 120 °C for 4 min. Boc deprotection was then accomplished as described above, leading to radiochemical yields ranging from 30% to 50%, with the highest between 1 and 3 mg. The final study performed with traditional oil-bath heating evaluated the effect of increasing the reaction times from 4 min to 16 min using 1 mg of precursor and heating at 120 °C. We found that reaction times from 8 min to 16 min all led to high radiochemical yields of greater than 59%. The radiochemical purity for all reactions was greater than 98%.



Microwave heating methods were also studied in the same manner, evaluating the effect of precursor mass, increased temperatures, and reaction times. In general, the precursor mass did not have an affect when ranging between 0.25 and 3 mg. Increasing the reaction times from 1 to 4 min showed significant improvement in the radiochemical yield (up to 60% with 4 min at 80 W, 100 °C using 1 mg of precursor dissolved in 250 μL of DMSO), while increasing the temperature at a constant power level seemed to decrease the yields (Table 2).

From these studies, it is evident that both traditional oil-bath and microwave heating strategies can prepare radiolabeled [^{18}F]-**5a** (FPEG PIB, $n = 2$) conjugates in good radiochemical yields (60−64%). The optimized oil bath conditions are 1−3 mg of precursor heated at 120 °C for 12 min, followed by the standard deprotection. Traditional oil-bath heating is still preferred in our hands, as it has led to more reproducible results.

The lipophilicity (log *P*) of the labeled tracers ([^{18}F]**5a**−**c**, **8b**, and **12c**) was evaluated, as log *P* values between 0 and 3 can often indicate good blood−brain barrier penetration. The log *P* value of [^{18}F]**12c** was 2.69, and that of the parent compound, IMPY (**2**), was 2.19 (*33*), suggesting that addition of the FPEG unit does not significantly change the lipophilicity of the compound. Furthermore, all ^{18}F-labeled tracers were within an appropriate range (log *P* values between 2.69 and 3.04, Table 1) and similar to those of the stilbene−FPEG conjugates (log $P = 2.05-2.53$) (*21*).

The binding of these radiofluorinated probes to Aβ plaques in AD brain sections was evaluated by in vitro autoradiography and labeling of Aβ plaques in confirmed AD brain sections was observed for [^{18}F]**5a**−**c**. [^{18}F]**5a** especially displayed a superior Aβ plaque labeling showing a strong signal and a low background (Figure 2). The results strongly confirm the binding of these ^{18}F tracers to the Aβ aggregates in the brain of AD patients. Similarly, [^{18}F]**8b** was able to label the plaques using the mixture of isomers (data not shown). However, unlike the other conjugates, [^{18}F]**12c** did not display a significant labeling under similar labeling conditions (data not shown).

Biodistribution studies in normal mice with [^{18}F]**5a**−**c** (displayed in Table 3) and [^{18}F]**12c** were performed. [^{18}F]**8b** was not evaluated for the distribution study on the basis of the higher molecular weight, lower brain penetration of the parent core (**3**, BF-168) (*15*, *16*), and the facile racemization seen during labeling. We use normal mice as a convenient animal model to evaluate the brain penetration of these ^{18}F tracers.

[a] % dose/g, avg of 3 mice ± SD.

Normal mice are not expected to have Aβ plaques in the brain, and therefore an ideal compound will have a high initial brain uptake that washes out quickly, because there are no plaques to cause retention of Aβ aggregate specific probes. [^{18}F]**5a**−**c** were all able to penetrate the blood−brain barrier with [^{18}F]**5a** showing the highest initial brain uptake (10.27% dose/g at 2 min post iv injection) and a fast washout (3.94% dose/g at 60 min post iv injection). [^{18}F]**5b** also displayed a good initial brain uptake and washout (5.53% and 2.18% dose/g at 2 and 60 min post iv injection, respectively). The brain uptakes of these compounds ([^{18}F]**5a**,**b)** are similar to those of the stilbene series (6.6−8.1% dose/g at 2 min post iv injection and 1.2−2.62% dose/g at 60 min post iv injection, (*21*)). However, the washout rate of this series of compounds is slower compared to that of the stilbene derivatives. Rapid initial brain uptake in normal mouse brain coupled with a fast washout are highly desirable properties for Aβ plaque-targeting imaging agent, as these would lead to high signal to background ratios. Unlike [^{18}F]**5a** and **b**, [^{18}F]**5c** showed a much lower initial brain uptake (1.68% dose/g), indicating low penetration of the compound through the intact blood−brain barrier. The poor penetration of [^{18}F]**5c** (FPEG $n = 6$) led us to not pursue the studies using the further extended chain length of $n = 8$ (**5d**). It was also observed that in vivo defluorination was likely occurring with [^{18}F]**5a**, because the bone uptake increased with time (6.35% dose/g at 2 h) but was minimal with [^{18}F]**5b** and [^{18}F]**5c**. In addition, the biodistribution of [^{18}F]**12e** was performed and showed low brain uptake and slow washout (results not shown), further confirming that FPEG conjugation with the IMPY core is not successful.

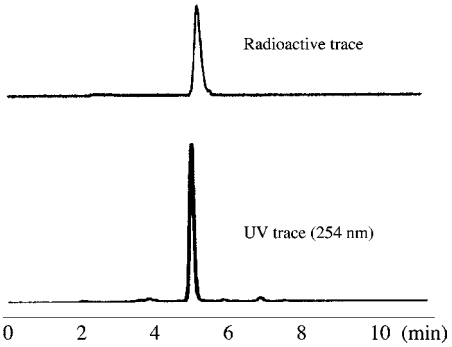

Figure 3. HPLC profiles of [^{18}F]**5a** (top) and **5a** (bottom). HPLC condition: Agilent 1100 series; Phenomenex Gemini C-18 analytical column CH_3CN/water 8/2 1 mL/min. $t_R = 4.80$ min (UV), 5.03 min (γ). The slight difference in retention time between UV and γ is due to the sequential configuration of the detector system.

Our approach toward preparing ^{18}F-labeled FPEG tracers is based on four critically important attributes: 1. The end-capped fluoropegylation with a short PEG chain ($n = 2-5$) connecting to the core structure will lead to a small and neutral molecule that can penetrate the intact blood−brain barrier. 2. The FPEG derivatives retain high binding affinities with K_i values comparable to those of the parent compounds in most cases but are not universally applicable. 3. The fluorine atom at one end of the pegylation chain can be readily labeled through the use of a simple nucleophilic substitution reaction of either the *O*-mesylate or *O*-tosylate group by ^{18}F fluoride in moderate to good radiochemical yields. It is also revealed that precise optimization of reaction conditions (amount of precursor, reaction time, and temperature) are needed to maximize the radiochemical yield. The resulting ^{18}F-labeled FPEG compounds are relatively stable in vivo after an iv injection. These unique features may provide a suitable approach for the preparation of other novel ^{18}F-labeled tracers.

In summary, we present here examples of a novel approach toward preparing PET imaging agents via a fluorinated pegylation approach. These examples illustrate a simple, efficient, and highly flexible methodology. This approach has proven effective for two core structures, but unfortunately, it was not universally applicable. However, the full power of this approach toward the development of other novel ^{18}F-labeled imaging agents is yet to be explored, and it will be interesting and exciting to see its application to other new imaging agents.

Received September 18, 2006; Revised Manuscript Received November 28, 2006

Aldehyde functions are widely used for immobilization of biomolecules on glass surfaces but have found little attention for biofunctionalization of self-assembled monolayers (SAMs) on gold, due to interference between thiol and aldehyde functions. This problem was recently solved by synthesis of an alkanethiol that carried a vicinal diol group [Jang et al. (2003) *Nano Lett. 3*, 691−694]. The latter served as a latent aldehyde function that was unmasked by short exposure of the vicinal diol-terminated SAM to aqueous periodate. However, the synthesis of the new vicinal diol-terminated alkane thiol was time-consuming and had an overall yield of ∼3.5%. In the present study, a general modular strategy was introduced by which SAM components with vicinal diol functions were rapidly synthesized with high yield: this was accomplished by amide bond formation between a SAM-forming carboxylic acid (exemplified by lipoic acid and 16-mercaptohexadecanoic acid) with 3-aminopropane-1,2-diol, using suitable protecting groups. The disulfide or free thiol group afforded SAM formation on gold and, after periodate oxidation of the vicinal diol functions, proteins were covalently bound via their lysine residues. At 1 mg/mL protein concentration, complete surface coverage was reached within minutes. No further protein was bound by nonspecific adsorption, but cognate proteins were specifically bound with high capacity. Pyrogallol-*O*-hexadecanoic acid and 10-undecenoic acid were also coupled with 3-aminopropane-1,2-diol by amide bond formation, thereby producing latent aldehyde-containing SAM components for metal oxides and hydrogen-terminated silicon, respectively, to show the general usefulness of the new synthetic design.

INTRODUCTION

Functionalized self-assembled monolayers (SAMs)[1] on gold surfaces are key elements in many affinity biosensors and biocatalytic sensors (*1*−*5*). Moreover, functionalized gold surfaces are increasingly used for cell arrays (*6*−*8*) and for chip assays, whether readout is label-dependent (*9*−*12*) or via label-free detection (*4*, *13*−*14*) or MALDI-MS (*15*−*16*). Functionalization of gold is facilitated by selective binding of thiol or disulfide groups toward gold; thus, densely packed SAMs can be formed with a wide range of physical properties and chemical functionalities, or a mixture of functional groups, at the exposed surface (*4*).

SAMs with selective coupling functions, such as biotin (*17*−*21*), maleimide (*9*, *12*), NTA (*22*−*24*), hydroquinone (*10*, *25*), acetylene (*26*), and suicide inhibitors, (*27*) have been developed for selective, oriented, and/or triggered binding of probe molecules that then serve as capture probes in sensors and chip assays. Complementary coupling functions, such as biotin, free thiols, His_6 tags, cyclopentadiene, azide, or enzyme domains, respectively, are required on the probe molecules, which may be present in particular cases but not in general.

In contrast to these selective coupling functions, amino-reactive coupling functions are almost generally applicable, for the following reasons: (i) Most proteins can be immobilized via one/few of their many lysine residues without impeding protein function. (ii) DNA probes with reactive aliphatic NH_2 groups are easily obtained by standard methods and commercially supplied in this form. (iii) Many other natural or synthetic ligands are also available with primary amino groups for coupling to amino-reactive SAMs (*28*−*29*). (iv) Amino-reactive groups on a SAM can easily be adapted with other coupling functions such as reactive disulfides (*30*) or hydrazide (*31*).

SAMs with reactive carboxyls are the most widely used kind of amino-reactive SAMs. In some cases, the SAMs have been

formed with the carboxyl groups present in their activated form, for example, as NHS ester (*32*−*33*). More often, SAMs have been activated shortly before ligand coupling, for example, with EDC and NHS (*21*, *22*, *28*, *29*). This activation step is simple and efficient, and the same applies to subsequent amide bond formation with a primary amine. Nevertheless, this method has problematic aspects: First, the activation reagent (EDC) and the transiently formed NHS ester are very sensitive to hydrolysis (*34*); thus, the timing of EDC dissolution, carboxyl activation, and amine coupling is critical (*35*), which complicates application of this method in automated systems, especially in microspotting. Second, nonactivated carboxyls or hydrolyzed NHS esters are present as negatively charged carboxylate functions which are strongly adsorptive toward proteins in simple SAMs (*36*−*37*), weakly adsorptive in OEG-terminated SAMs (*28*), or strongly repulsive in case of dextran-coated SAMs (*35*). Third, the kinetics of NHS ester hydrolysis, the coupling of amines to NHS esters, and the above named adsorption/repulsion effects are dependent on pH, and in addition the coupling protocols have to be optimized for individual proteins (*35*).

These complications are eliminated if aldehyde functions are used in place of activated carboxyls because aldehydes have no electric charge, they are spontaneously reactive toward amino groups over a wide pH range, and their reactivity is retained for a long time under ambient conditions (*9*, *36*−*40*). However, a new problem was encountered when forming aldehyde-terminated SAMs on gold: the free thiol needed for chemisorption toward gold is known to reversibly form a hemithioacetal with a free aldehyde function (*38*). Fortunately, this effect has been shown not to impede SAM formation, at least with 5-mercaptopentanal, which actually gave an aldehyde-terminated SAM on gold although a large fraction of the SAM component was present as the cyclic 2-hydroxypentamethylene sulfide (*38*).

The problem of hemithioacetal formation from thiol and aldehyde was altogether avoided in two other approaches: In the first method, the thiol was oxidized into a disulfide before the aldehyde function was generated in the synthesis of the SAM component (*9*). Disulfides are known to form the same kind of SAMs on gold as do free thiols, only the kinetics of chemisorption is somewhat reduced (*41*). Another group of authors has obviously used the same strategy (*36*, *37*, *39*) even though these authors stated to have worked with 3-mercapto-1-propanal and 11-mercapto-1-undecanal. More likely, the actual compounds were 3,3′-dithio-*bis*-propanal and 11,11′-dithio-*bis*-undecanal because the aldehyde function had been prepared by oxidation of 3-mercapto-1-propanol and 11-mercapto-1-undecanol with pyridinium dichromate (*36*) and because the closely similar reagents pyridinium or picolinium chlorochromate will first oxidize all free thiols into disulfides before they will even start to oxidize alcohol groups into aldehydes (*42*, *43*). For the particular application, the disulfide form was the better choice anyway, and only for the critical interpretation of the data (*36*, *37*, *39*) are these considerations important.

In the second method, the SAM has been formed with a latent, rather than an actual, aldehyde function, thereby avoiding mutual interference between free thiol and aldehyde (*40*). A vicinal diol group was used as a latent aldehyde, permitting the aldehyde function to easily be generated after SAM formation by use of sodium metaperiodate (*40*). While the latter strategy offers an elegant route to aldehyde-terminated SAMs, the major drawback of the above study (*40*) was the long synthetic scheme and the low overall yield (∼3.5%) of the SAM component. We therefore looked for an easier synthesis of alkanethiol derivatives with a vicinal diol on the second end of the molecule. As shown below, this was accomplished by introducing the vicinal diol in the form of 3-aminopropane-1,2-diol (APD), preferably with the vicinal diol group protected as acetonide (APD-ac, **2**, see Figures 1 and 3).

EXPERIMENTAL PROCEDURES

Compounds **3**, **4**, **7**, **8**, **11**, **12**, **13**, **14**, **15**, and **17** were synthesized by standard procedures (see Figures 1, 3, 5, and 6), as described in detail in Supporting Information. Preparation of biotin-IgG by reaction of goat IgG (Sigma I-5256) with biotin-cap-NHS is also described in Supporting Information. Affinity-purified streptavidin (Fluka 85878), fatty acid-free BSA (Roche 775 827) and 99% pure D-biotin (Sigma B-4501) were used. D-Biotin (10 mM) was dissolved in 50 mM Na_2HPO_4, (final pH ∼7.2) and aliquots for single use were stored at −20 °C.

SAMs were formed on commercial gold slides (BIAcore SIA kit) that had been pretreated either by sonication in ethanol (see legend to Figure 4) or by two cycles of boiling in SC1 (water/25% ammonia/30% H_2O_2 = 5/1/1) at 70−80 °C for 20 min and rinsing (5×) in ultrapure water (Milli-Q50) after each SC1 treatment (as in Figure 2 and in Supporting Information) (*24*, *44*). The chips were dried with a stream of nitrogen and incubated in a thiol solution (0.1−1 mM) either overnight or for 36 h, as specified in the figure legends. Unless stated otherwise, the chips were rinsed in ethanol (3×) and water (3×), with 3 min of sonication each in the third rinsing cycle. The chips were stored in water at 4 °C for up to 3 days. Before use, chips with intact Lip-APD-ac (**3**) were deprotected by incubation in a 1:1 mixture of THF and 1 M HCl (90 min), followed by rinsing in THF (3×), ethanol (3×), and water (3×) and applying 3 min of sonication in the third rinsing cycle with ethanol and water each.

SAMs with vicinal diol termini were incubated for 30 min in the dark in a freshly prepared solution of 50 mM $NaIO_4$ in buffer 5.5 (100 mM sodium acetate, pH 5.5 adjusted with HCl). After being rinsed in water (5×), the chip was blown dry with nitrogen gas and mounted in the BIAcore X setup. Degassed PBS (140 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 1.8 mM KH_2PO_4, pH 7.3) was run over the chip at 5 μL/min until the SPR readout from the two flow cells (solid and dotted trace for FC1 and FC2, respectively, in Figures 2 and 4) remained constant. This took <30 min for SAMs of oxidized MHD-APD (**9**) and <2 h for SAMs of oxidized Lip-APD (**5**). Meanwhile, a 1 M solution of $NaCNBH_3$ was prepared by dissolving 32 mg of $NaCNBH_3$ in 0.5 mL of 10 mM NaOH.

For covalent coupling of proteins to the aldehyde chip, 150 μL of protein (1 mg/mL in PBS) was mixed with 3 μL of 1 M $NaCNBH_3$, 140 μL thereof were pulled into the yellow tip of a digital pipet, another 10 μL of air was pulled into the lower end of the yellow tip, and all was loaded into the sample loop, the air bubble serving to replace all old liquid from the sample loop, as recommended by BIAcore. The content of the 100 μL sample loop was then injected onto the chip by the system at a flow rate of 5 μL/min. Unlabeled IgG was applied to flow cell 2 only (FC2, dotted trace in the figures), with no flow in FC1. Vice versa, biotin-IgG was applied to FC1 only. Then, BSA was applied to both flow cells, the flow serially passing through FC1 and FC2 with a time delay of a few seconds.

Noncovalent binding of proteins (streptavidin and biotin-IgG, always at 2 μM protein concentration) to immobilized biotin-IgG (in FC1, solid traces in Figures 2 and 4) and unlabeled IgG (in FC2, dotted traces in Figures 2 and 4) was measured in PBS at a flow of 10 μL/min, the flow passing the two measuring cells with a time delay of a few seconds. "Blocked streptavidin" was used as a negative control for streptavidin; it was prepared by mixing 150 μL of 2 μM streptavidin with 3 μL of 10 mM

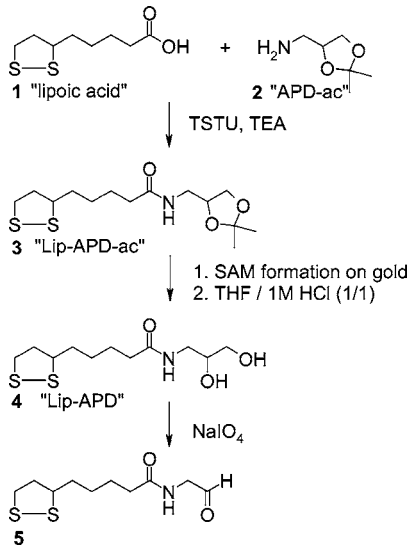

Figure 1. Conjugation of lipoic acid (**1**) with APD-ac (**2**), followed by SAM formation on gold, acetonide cleavage, and periodate treatment to generate an aldehyde SAM.

D-biotin, resulting in a final biotin concentration of 0.2 mM. Unlabeled goat IgG was used as a negative control for biotin-IgG.

RESULTS AND DISCUSSION

Lipoic Acid Derivative with Latent Aldehyde Function. The goal of this study was to devise an easy method to equip SAM forming molecules with a vicinal diol group that can be converted into an aldehyde by periodate treatment after SAM formation. In the literature, we found examples in which APD had been coupled to nitrophenyl esters (*45*, *46*), yielding a stable urethane with a vicinal diol group (comparable to the amide **4** in Figure 1). This provoked the idea to couple APD with a carboxyl-terminated SAM component and thereby to obtain a new SAM component with a terminal vicinal diol (Gruber et al., Austrian patent application 1469/2006). Fortunately, many fatty acids with terminal thiols or disulfides, as well as lipoic acid (see **1** in Figure 1), are known to form stable SAMs on gold. We therefore attempted direct coupling of APD to the NHS ester of lipoic acid (**1**), but this reaction gave a mixture of products, none of which had the desired structure (according to the NMR spectrum, data not shown). In contrast, the protected form of APD (APD-ac, **2**) was easily coupled to NHS-activated lipoic acid (**1**), resulting in pure amide conjugate (Lip-APD-ac, **3**) after extraction (see Figure 1 and Supporting Information). In our first batch, this product could also be deprotected to give pure Lip-APD (**4** in Figure 1), which was mixed with 19 parts (w/w) of lipoamide (Lip-NH_2) and successfully used to form a mixed SAM with periodate-reactive vicinal diol groups on its surface (see Figure 8S in Supporting Information). In several subsequent batches, however, a considerable fraction of the deprotected product (**4**) contained polymeric fractions, as judged from the smaller elution volume in comparison to product (**4**) when the mixture was gel filtered in methanol on Sephadex LH-20 (1.5 × 95 cm column, 0.4 mL/min). The inclination of lipoic acid and its derivatives toward polymerization has been described before (*47*, *48*). Removal of the polymerized components was possible by gel filtration in methanol on Sephadex LH-20 (data not shown), but the yield of pure **4** was low, and after storage at −20 °C the polymerized components (R_f < $R_{f,\text{product}} = 0.58$ in chloroform/methanol/25% ammonia, 70/30/4, v/v/v) were seen again.

In contrast to Lip-APD (**4**), the protected form Lip-APD-ac (**3**) showed no sign of polymerization during synthesis and storage; therefore, it was decided to form the SAM with protected Lip-APD-ac (as in Figure 2). The acetonide function of (**3**) was cleaved on the chip by incubation of the SAM in the usual deprotection reagent for 90 min (see Figure 1). After being washed with ethanol and water, the chip was also incubated in metaperiodate for 30 min, washed with water, dried, and mounted in the BIAcore X setup. This system has two flow cells (FC1 and FC2, see solid and dotted traces in Figures 2 and 4) that can be operated in series, in which case the buffer (or sample) passes FC1 and FC2 with a few seconds delay in between. Alternatively, FC1 or FC2 can individually be addressed, in which case the entrance to the other flow cell is always blocked.

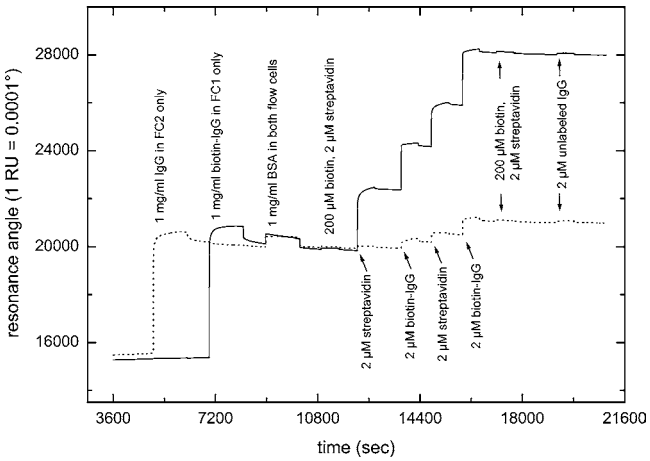

Figure 2. Functionalization and characterization of a sensor chip with a SAM of Lip-APD-ac (**3**) on gold. The SAM was formed by overnight incubation in ethanol containing 1 mM Lip-APD-ac (**4**), rinsed, and sequentially treated with THF/1 M HCl (1/1) and 50 mM periodate (see Experimental Section). For covalent coupling, 100 µL of protein solution (always at 1 mg/mL, with 20 mM $NaCNBH_3$) was applied at a flow of 5 µL/min. For noncovalent binding (after $t = 10800$ s), 100 µL of protein solution (2 µM of streptavidin or biotin-IgG or unlabeled IgG) was applied at a flow of 10 µL/min. Blocked streptavidin contained 200 µM of D-biotin besides 2 µM of streptavidin.

Figure 2 depicts the sensorgrams (SPR angles of FC1 and FC2 versus time) for a chip with a SAM of compound **5** (see Figure 1) prepared as described in the previous paragraph. In the first step, unlabeled goat IgG (1 mg/mL, with 20 mM $NaCNBH_3$) was injected into the control cell only (FC2, dotted trace in Figure 2). After 20 min, the injection (100 µL) was over, and uncoupled IgG was removed by PBS flow. The sensorgram shows that over 4000 RU of unlabeled IgG were immobilized in FC2, which is more than the 2500 RU observed for a monolayer of IgG molecules immobilized in the side-on orientation (*28*). The same efficiency of immobilization was also observed when biotin-IgG was injected into FC1 only (solid trace). From then on, both flow cells were operated in series, i.e., exposed to the same buffer or sample almost simultaneously. Injection of BSA (1 mg/mL, with 20 mM $NaCNBH_3$) gave no additional immobilization of protein in any flow cell; thus, the initial exposure to IgG or biotin-IgG had sufficed to completely cover the chip surface with protein.

The functionalized chip was then tested for specific capture and/or nonspecific adsorption of different proteins. First, "blocked streptavidin" (200 µM D-biotin and 2 µM streptavidin) was injected. This caused no SPR angle shift in any of the two flow cells, proving complete absence of nonspecific binding. Unblocked streptavidin, however, was vigorously bound in FC1 (solid trace in Figure 2, +2500 RU step increase after washout), while very little streptavidin was bound to unlabeled IgG in the control cell (dotted line, +18 RU). The streptavidin-covered surface, in turn, showed high affinity for biotin-IgG (solid line), and binding was similarly strong in another cycle of streptavidin

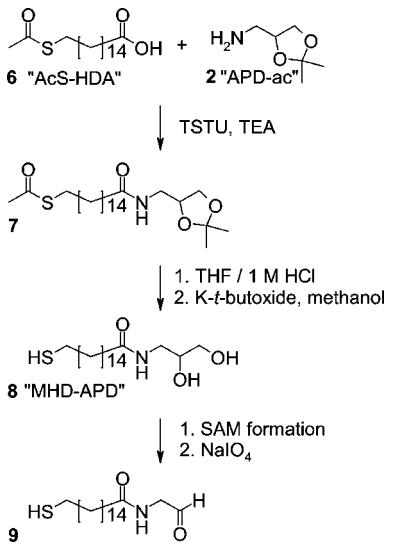

Figure 3. Conjugation of AcS-HDA (**6**) with APD-ac (**2**), followed by acetonid cleavage, SAM formation on gold, and periodate treatment to generate an aldehyde SAM.

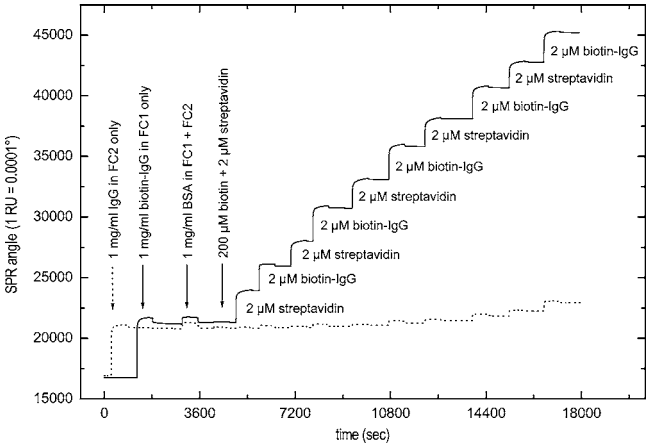

Figure 4. Functionalization and characterization of a sensor chip with a SAM of MHD-APD (**8**) on gold. The commercial gold slide had been sonicated in ethanol, washed with chloroform/methanol (3/1), incubated overnight in a chloroform/methanol (3/1) solution of 1 mM MHD-APD (**8**), and washed with chloroform/methanol (3/1, 2/2, 1/3, 0/4) and methanol/water (3/1, 2/2, 1/3, 0/4), followed by periodate treatment outside the BIAcore setup, as usual (see Experimental Section). After the chip was mounted in the BIAcore X setup, PBS was run over the chip at 5 μL/min. The protocol for covalent binding of IgG (in FC2, dotted line) or biotin-IgG (in FC1, solid line) and of BSA (in both flow cells) was the same as in Figure 2. The protocol for alternating binding of streptavidin and biotin-IgG was equal to the protocol in Figure 2, except that five double layers were prepared instead of two. Absence of nonspecific binding was tested with blocked streptavidin (containing 200 μM D-biotin) before protein multilayer formation.

and subsequent biotin-IgG injection. For easy visualization of the protein multilayer formed in FC1, a sketch is offered in Supporting Information (Figure 7S).

At first sight, there appears to be significant nonspecific binding of protein in the control cell. A closer look, however, reveals that this was exclusively caused by specific binding to the biotin binding sites of streptavidin. This is concluded from the fact that neither blocked streptavidin (i.e., with 200 μM D-biotin) nor unlabeled IgG showed any significant binding in FC1 and FC2, whether measured immediately after the BSA injection or at the end of the total injection sequence (see Figure 2). A possible explanation for the paradoxical behavior of "specific binding in the control cell" is the hypothesis that the unlabeled goat IgG in FC2 (dotted line) contained traces of biotinylated protein which caused a progressive buildup of undesired *specific* binding in the control cell in the alternating injections of streptavidin and biotin-IgG. This interaction, however, was fully dependent on the availability of empty biotin-binding sites in streptavidin, as demonstrated by the complete blocking of streptavidin binding by 200 μM D-biotin, as well as by the complete absence of unlabeled IgG binding at the end of the injection sequence.

Mercaptohexadecanoic Acid Derivative with Latent Aldehyde Function. Admittedly, the use of Lip-APD-ac (**3**) for preparation of SAMs with latent aldehydes has two practical disadvantages: (i) Each chip must be incubated for 90 min in the THF/HCl mixture, and the organic solvent must be removed by careful rinsing and sonication. (ii) After periodate treatment and insertion in the SPR setup, another 90 min of rinsing with PBS is required to obtain a stable baseline. Since these problems were caused by the imminent polymerization tendency of the lipoyl residue in **3** upon acid treatment (see above), we synthesized an analogous molecule (**7**, Figure 3) in which lipoic acid was replaced by AcS-HDA (**6**, Figure 3), a well-known precursor for gold-selective SAM components (*44*, *49*). The conjugate (**7**) was sequentially treated with acid to deprotect the vicinal diol and with base to hydrolyze the thioester protecting group, resulting in an alkanethiol derivative (**8**) which was stable during storage.

Compound **8** was used to form SAMs with latent aldehyde functions, and the vicinal diol group was oxidized with metaperiodate to generate reactive aldehyde groups (**9**), either before insertion of the chip into the SPR setup (Figure 4) or inside the SPR setup (Figure 9S in Supporting Information).

The protocol and the data in Figure 4 were closely similar to those in Figure 2; that is, unlabeled IgG was first immobilized in the control cell (FC2, dotted trace), followed by coupling of biotin-IgG in FC1 (solid trace in Figure 4), and the step increases (+4000 RU for IgG and +3900 RU for biotin-IgG) were quite similar as in Figure 2. The chip surfaces in FC1 and FC2 were completely covered with biotin-IgG and IgG, respectively, as is concluded from the fact that neither BSA nor blocked streptavidin were measurably bound in the next two injections. Moreover, the IgG-covered surface in FC2 (dotted trace) proved to be inert in several alternating injections of streptavidin and biotin-IgG, except that after several such cycles some initially adsorbed traces of streptavidin and/or biotin-IgG caused a gradual buildup of clusters with alternating layers of streptavidin and biotin-IgG in the control cell also (dotted trace). Unblocked streptavidin, however, is avidly bound to the biotin-IgG surface in FC1 (solid line), followed by strong binding of biotin-IgG in the next injection. In the five cycles of alternating streptavidin and biotin-IgG injection, the step increases per protein layer were rather constant, indicating the formation of a dense protein monolayer in each injection.

Finally the stability of the protein multilayer was tested by 100 μL injections of D-biotin (200 μM, in PBS), of acetic acid (100 mM, in water), and of SDS (0.5%, in water), none of which could remove a significant amount of bound protein (data not shown). Similarly, SDS (0.5%) could not remove IgG that had been bound and fixed (with 20 mM $NaCNBH_3$) to a chip surface with periodate-treated MHD-APD, whereas before periodate treatment, the same chip had shown weak adsorption of IgG all of which had been removed by 0.5% SDS (see Figure 10S in Supporting Information).

Monolayer Components with Latent Aldehydes for Metal Oxides and Hydrogen-Terminated Silicon. Alkane derivatives with terminal phosphate or phosphonate groups are known to form stable SAMs on metal oxides, such as titanium oxide, tantalum oxide, or ITO, which are increasingly used in bio-

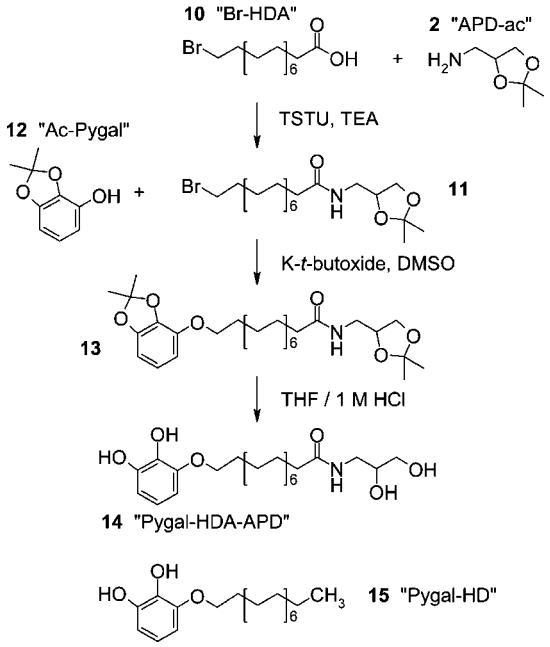

Figure 5. Synthesis of a heterobifunctional SAM component with a catechol function on one end and a latent aldehyde on the other end. The amide conjugate (**11**) of Br-HDA (**10**) and APD-ac (**2**) was used to alkylate Ac-Pygal (**12**). Removal of the acetonide functions from **13** gave the final product Pygal-HDA-APD (**14**). By analogy, the hydrophobic SAM component Pygal-HD (**15**) was synthesized by alkylation of Ac-Pygal (**12**) with 1-bromohexadecane and cleavage of the acetonide function.

sensors and biochips (*4*). Recently, catechol functions were also shown to confer tight binding to metal oxides, at least of PEG chains with 1−3 terminal DOPA residues (*50*). As shown in Figure 5, we have introduced the catechol function on the hydrophobic end of hexadecanoic acid by forming an ether bond between acetonide-protected pyrogallol (**12**) and the amide conjugate (**11**) of 16-bromohexadecanoic acid (**10**) and APD-ac (**2**). Removal of the acetonide functions on both ends of **13** gave the final product (**14**), which contains a catechol function for binding to metal oxides and an aliphatic vicinal diol that serves as a latent aldehyde. For preliminary studies, the monofunctional pyrogallol-*O*-hexadecyl ether (**15**) was also synthesized and chemisorbed from a 3 mM solution in ethanol (36 h at room temperature) to ITO-covered glass slides that had been cautiously precleaned in SC1 (2 × 10 min at 40 °C). These slides indeed showed contact angles of 84 ± 5°, in contrast to the 47 ± 2° measured on control slides that had been incubated in pure ethanol. This result has encouraged further studies with the bifunctional SAM component **14** which are underway.

In recent years, monolayers of 1-alkenes and their derivatives on hydrogen-terminated silicon have become increasingly popular (*4*). When the monolayer was formed at high temperature, only aprotic molecules such as 1-alkenes or esters of 10-undecenoic acid were uniformly bound to Si−H with their terminal vinyl group (*51*). In contrast, monolayers with unprotected carboxyl- or hydroxyl-terminated 1-alkenes could directly be prepared when using UV light (*52*) or a nitroxide catalyst (*53*) for grafting at room temperature; nevertheless, esters are preferred over free carboxylates and Boc-protected amines over free amino groups (*54*). On the basis of these findings, we devised a 10-undecenoic acid derivative with a latent aldehyde function by coupling 10-undecenoic acid (**11**) with APD-ac (**2**). Functional studies have not yet been conducted because hydrogen-terminated silicon is presently outside of our topical interest, yet compound **17** and analogous monolayer components (e.g., with −NH−PEG−CO− between the undecenoyl residue

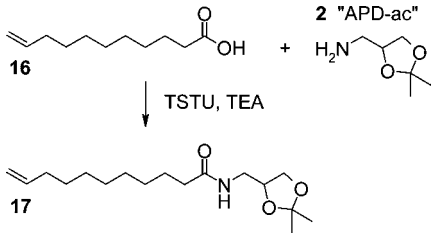

Figure 6. Synthesis of a heterobifunctional SAM component (**17**) with a double bond on one end and a latent aldehyde on the other end.

and APD, see below) should be of high interest to others working in this field. As in case of Lip-APD-ac (**3**, see Figures 1 and 2), SAM formation with the acetonide form and subsequent deprotection with mild acid appear most appropriate to arrive at a SAM with vicinal diol groups, i.e., with latent aldehyde functions.

CONCLUSIONS

This study offers a versatile design for SAM components with latent aldehyde functions: amide bond formation between a SAM-forming carboxylic acid with 3-amino-1,2-propanediol (APD). Usually it will be preferable to couple APD with the vicinal diol in its protected form (APD-ac, **2**). Some SAM-forming carboxylic acids, however, can be used in their final form, as exemplified by lipoic acid (see Figure 1) and 10-undecenoic acid (see Figure 6), and the disulfidic forms of ω-mercapto-fatty acids would be further candidates for this simple route. Alternatively, the SAM-forming function needs to be protected while forming the amide bond with APD-ac, as can be seen in Figure 3 where the thiol function was protected as thioester that was easily unmasked in the last step. A third variant of the same basic strategy is shown in Figure 5. In this case, a precursor of the SAM-forming carboxylic acid (Br-HDA, **10**) was first coupled to APD-ac (**2**), and only then the SAM-forming function (the catechol) was attached by O-alkylation, taking advantage of the high stability of the amide bond and the acetonide protecting group in **11** under basic conditions. Given the wide variety of SAM-forming carboxylic acids and their precursors, the attachment of APD or APD-ac appears to be a fairly general method to prepare SAM components with latent aldehyde functions for most types of inorganic surfaces. Moreover, we have shown that insertion of NH_2-PEG-COOH between the SAM-forming carboxylic acid and APD produces protein-resistant SAMs with latent aldehyde functions (Hölzl et al., submitted manuscript, Austrian patent application 1469/2006), indicating further extensions of the simple modular design principle.

ACKNOWLEDGMENT

3,4,6-Tri-*O*-acetyl-2-deoxy-2-[^{18}F]fluoroglucopyranosyl Phenylthiosulfonate: A Thiol-Reactive Agent for the Chemoselective ^{18}F-Glycosylation of Peptides

Olaf Prante,*[‡] Jürgen Einsiedel,[†] Roland Haubner,[§] Peter Gmeiner,[†] Hans-Jürgen Wester,[#] Torsten Kuwert,[‡] and Simone Maschauer[‡]

Laboratory of Molecular Imaging, Clinic of Nuclear Medicine, Friedrich-Alexander University, 91054 Erlangen, Germany, Department of Medicinal Chemistry, Emil Fischer Center, Friedrich-Alexander University, 91052 Erlangen, Germany, Universitätsklinik für Nuklearmedizin, Medizinische Universität Innsbruck, 6020 Innsbruck, Austria, and Department of Nuclear Medicine, Klinikum rechts der Isar, Technische Universität München, 81675 Munich, Germany. Received October 29, 2006

3,4,5-Tri-*O*-acetyl-2-[^{18}F]fluoro-2-deoxy-D-glucopyranosyl 1-phenylthiosulfonate (Ac_3-[^{18}F]FGlc-PTS) was developed as a thiol-reactive labeling reagent for the site-specific ^{18}F-glycosylation of peptides. Taking advantage of highly accessible 1,3,4,6-tetra-*O*-acetyl-2-deoxy-2-[^{18}F]fluoroglucopyranose, a three-step radiochemical pathway was investigated and optimized, providing Ac_3-[^{18}F]FGlc-PTS in a radiochemical yield of about 33% in 90 min (decay-corrected and based on starting [^{18}F]fluoride). Ac_3-[^{18}F]FGlc-PTS was reacted with the model pentapeptide CAKAY, confirming chemoselectivity and excellent conjugation yields of >90% under mild reaction conditions. The optimized method was adopted to the ^{18}F-glycosylation of the $\alpha_v\beta_3$-affine peptide c(RGDfC), achieving high conjugation yields (95%, decay-corrected). The $\alpha_v\beta_3$ binding affinity of the glycosylated c(RGDfC) remained uninfluenced as determined by competition binding studies versus ^{125}I-echistatin using both isolated $\alpha_v\beta_3$ and human umbilical vein endothelial cells ($K_i = 68 \pm 10$ nM ($\alpha_v\beta_3$) versus $K_i = 77 \pm 4$ nM (HUVEC)). The whole radiosynthetic procedure, including the preparation of the ^{18}F-glycosylating reagent Ac_3-[^{18}F]FGlc-PTS, peptide ligation, and final HPLC purification, provided a decay-uncorrected radiochemical yield of 13% after a total synthesis time of 130 min. Ac_3-[^{18}F]FGlc-PTS represents a novel ^{18}F-labeling reagent for the mild chemoselective ^{18}F-glycosylation of peptides indicating its potential for the design and development of ^{18}F-labeled bioactive S-glycopeptides suitable to study their pharmacokinetics in vivo by positron emission tomography (PET).

INTRODUCTION

Positron emission tomography (PET) using peptide-based radiopharmaceuticals has gained considerable importance in the field of nuclear medicine and radiopharmaceutical sciences (*1*, *2*). In particular, the increasing knowledge about improved automated solid-phase peptide synthesis and advanced methods for structure−activity relationship studies of receptor-specific peptides accelerated the development of suitable candidates as agents for diagnostic and also therapeutic applications. Furthermore, the positron emitter fluorine-18 has been characterized as a suitable nuclide for radiochemical approaches toward peptide labeling. The short-lived positron emitter fluorine-18 has excellent physical characteristics, such as a relatively low positron energy of 635 keV, limiting the patient's absorbed dose, and a prolonged half-life of 109.7 min allowing extended and multistep radiochemical syntheses and prolonged PET imaging protocols. These features support an exceptional position of ^{18}F as a beneficial PET radionuclide in comparison with alternative positron emitters such as ^{11}C or ^{13}N.

Moreover, the development of new ^{18}F-labeled prosthetic groups for the radiofluorination of peptides strongly increased the availability of peptide-based radiopharmaceuticals for PET over the past years. A commonly used strategy to label peptides relies on the use of *N*-succinimidyl-4-[^{18}F]fluorobenzoate ([^{18}F]SFB) targeting the N-terminus or lysine side chains of the target peptide. According to Wester et al., [^{18}F]SFB can be efficiently prepared by a simplified method affording an overall radiochemical yield ranging between 50% and 60% based on [^{18}F]fluoride within a preparation time of 35 min (*3*). Besides [^{18}F]SFB, 4-nitrophenyl 2-[^{18}F]fluoropropionate proved to be an effective and suitable ^{18}F-acylation agent. The prevalent application of these two ^{18}F-labeled prosthetic groups has resulted in a large number of ^{18}F-labeled peptide-based imaging agents, such as [^{18}F](D-Phe^1)octreotide (*4*), [^{18}F]galacto-RGD (*5*), [^{18}F]FB−PEG−RGD (*6*), [^{18}F]NT(8−13) (*7*), [^{18}F](Nle^4, D-Phe^7)-α-MSH) (*8*), and ^{18}FB−AHx−insulin (*9*). Among these, [^{18}F]galacto-RGD already provided promising results for the noninvasive assessment of $\alpha_v\beta_3$ expression on tumor and endothelial cells in patients with malignant tumors by PET (*10*).

The development of chemoselective ^{18}F-labeling strategies that are favorable for routine large scale syntheses of short-lived ^{18}F-labeled radiopharmaceuticals have been intensively studied in recent years. For instance, [^{18}F]fluorothiols have been prepared for the chemoselective labeling of N-terminal chloroacetylated peptides (*11*). Recently, Poethko et al. developed a convenient ^{18}F-labeling method for peptides by oxime conjugation of [^{18}F]fluorobenzaldehyde with unprotected aminooxy peptides yielding chemoselectively labeled RGD peptides and somatostatin analogs (*12*). Moreover, chemoselective ^{18}F-labeling strategies being based on the radiosynthesis of ^{18}F-labeled maleimide derivatives as thiol-reactive reagents were investigated (*13*, *14*). Toyokuni et al. reported the ^{18}F-radiosynthesis of a new heterobifunctional maleimide derivative, namely, *N*-[4-(aminooxy)butyl]maleimide ([^{18}F]FBABM, Figure

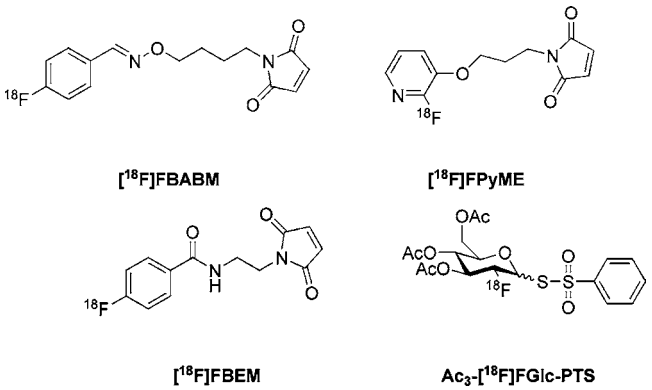

Figure 1. Chemical structures of ^{18}F-labeled thiol-reactive prosthetic groups for site-selective ^{18}F-labeling of peptides: *N*-[4-(aminooxy)-butyl]maleimide ([^{18}F]FBABM (*13*)), 1-[3-(2-fluoropyridin-3-yloxy)-propyl]pyrrole-2,5-dione ([^{18}F]FPyME (*14*)), *N*-[2-(4-[^{18}F]fluorobenz-amido)ethyl]maleimide ([^{18}F]FBEM (*15*)), and 3,4,6-tetra-*O*-acetyl-2-deoxy-2-[^{18}F]fluoro-glucopyranosyl phenylthiosulfonate (Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**), this work).

1), within a two-step synthesis that was followed by a conjugation step with the cysteine-containing peptide in phosphate-buffered saline (*13*). Using this strategy, radiochemical yields (RCYs) of 70% for the model compound glutathione were possible, whereas for a 5′-thiol-functionalized oligodeoxynucleotide only 5% (decay-corrected) RCY was achieved.

Meanwhile, de Bruin et al. developed the alternative pyridinyl-substituted maleimide reagent [^{18}F]FPyME (Figure 1) for the prosthetic ^{18}F-labeling of peptides via conjugation with a thiol function (*14*). A three-step process is needed for the preparation of [^{18}F]FPyME, advantegeously making use of a nucleophilic heteroaromatic substitution in ortho position of the pyridinyl moiety, followed by cleavage of an *N*-BOC protective group and ultimately maleimide formation. This strategy provides a RCY of about 30% for the preparation of [^{18}F]FPyME and a non-decay-corrected yield of 65% for the final conjugation of target peptides (*14*). More recently, a similar approach for the radiosynthesis of a thiol-reactive ^{18}F-labeled maleimide starting from [^{18}F]SFB has been described (*15*). [^{18}F]SFB was isolated and subsequently converted to the benzamide derivative [^{18}F]FBEM (Figure 1, non-decay-corrected RCY of about 5% within 150 min), which was suitable for ^{18}F-labeling of thiolated RGD peptides. Following this 200 min procedure, the overall decay-corrected RCY was 20% including two HPLC purification steps.

2-Deoxy-2-[^{18}F]fluoroglucose ([^{18}F]FDG) represents by far the most frequently used radiopharmaceutical for PET imaging in nuclear medicine, not least because of its highly efficient radiosynthesis (*16*). Despite its very high availability, only few approaches toward a chemoselective glycoconjugation of an ^{18}F-labeled glycosyl donor with peptides have been described in previous short communications (*17*, *18*). Such a strategy could be beneficial for the development of ^{18}F-labeled glycopeptides as PET tracers with improved biokinetics, since glycosylation of peptides has often been shown to enhance bioavailability and improve blood−brain barrier (BBB) permeability and in vivo clearance properties (*19*−*21*). As an extension to the available ^{18}F-labeling agents, we recently investigated the applicability of tetra-O-acetylated 2-[^{18}F]fluoro-2-deoxy-glucopyranose as a ^{18}F-glycosylation reagent (*22*, *23*). However, this approach did not include a chemoselective ligation of the glycosyl residue and suffered from the necessity of Lewis acids as promotors.

The aim of this study was to develop a thiol-reactive ^{18}F-labeled glycosyl donor for a chemoselective ^{18}F-glycosylation approach. Besides maleimide-activated carbohydrates (*24*), glycosyl 1-phenylthiosulfonates (*25*) have recently been reported to be well-suited for site-specific glycosylation of cysteine-containing peptides and proteins. In this study, we present the radiosynthesis of 3,4,6-tri-*O*-acetyl-2-deoxy-2-[^{18}F]fluoroglucopyranosyl phenylthiosulfonate (Ac_3-[^{18}F]FGlc-PTS, Figure 1) as a new ^{18}F-labeled thiol-reactive glycosyl donor for ^{18}F-glycosylation of peptides and its application for bioconjugation using the cyclic peptide c(RGDfC). Furthermore, we studied the in-vitro binding affinities of the glycosylated RGD peptide using immobilized $\alpha_v\beta_3$ integrin and human endothelial cells.

EXPERIMENTAL PROCEDURES

General. All chemicals and reagents were of analytical grade and obtained from commercial sources if not stated otherwise. *N*,*N*′-Dimethylformamide (DMF), dichloromethane (CH_2Cl_2), acetonitrile, and dimethyl sulfoxide (DMSO) were obtained from Fluka as SureSeal bottles. Benzotriazol-1-yl-oxy-tris-pyrrolidino-phosphonium hexafluorophosphate (PyBOP) and *N*-hydroxy-benzotriazole (HOBt) were purchased from Bachem. [^{18}F]-Fluoride was obtained from PET Net GmbH (Erlangen, Germany). ^{125}I-Echistatin was purchased from Amersham Biosciences (GE Healthcare, Germany). Purified $\alpha_v\beta_3$ integrin was obtained as a Triton X-100 formulation from Chemicon Europe (Southampton, U.K.). Radio-thin layer chromatography (radio-TLC) was carried out on plastic sheets using ethyl actetate/*n*-hexane (1:1, v/v) as eluent (Polygram, Sil G/UV_{254}, Macherey Nagel). Analytical HPLC was performed on an Agilent 1100 system with a quarternary pump and variable wavelength detector and radio-HPLC detector D505TR (Canberra Packard). Computer analysis of the HPLC data was performed using FLO-One software (Canberra Packard). Electronic autoradiography (Instant Imager, Canberra Packard) was used to analyze radio-TLC data. Electron-spray-ionization (ESI) mass spectrometry analysis was performed using a Bruker esquire 2000 instrument. LC-MS analyses were performed on an Agilent 1100 series analytic HPLC system coupled to a Bruker esquire 2000 mass spectrometer. Matrix-assisted laser desorption/ionization time-of-flight (MALDI) mass spectrometry was performed using a MALDI-3 apparatus (Kratos Instruments) at the Department of Nuclear Medicine of the University of Heidelberg. NMR spectra were recorded on a Varian Gemini-300 system for ^{19}F NMR (Deutero GmbH, Germany) and on a Bruker Avance 600 system for ^{1}H NMR. The syntheses of the ^{18}F-labeling precursor 1,3,4,6-tetra-*O*-acetyl-2-*O*-trifluoromethanesulfonyl-β-D-mannopyranose (*26*) and of 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-α-D-glucopyranose 1-bromide (**1**) were described elsewhere (*22*).

Peptide syntheses. *CAKAY*. The peptide synthesis was achieved by manual solid-phase techniques, when microwave irradiation (Discover reactor, CEM corporation) supported short reaction times and enhanced coupling effectivities. Fmoc-Tyr(*t*-Bu)-Wang resin (Fluka) with a loading of 0.8 mmol/g was used as the solid support incorporating amino acids as their N^{α}-(9-fluorenylmethyloxycarbonyl) (Fmoc)-protected derivatives. For the protection of the amino acid side chains, *tert*-butoxycarbonyl (Boc) and trityl (Trt) were used for lysine and cysteine, respectively. Elongation of the peptide chain was done by repetitive cycles of Fmoc deprotection applying 20% piperidine in DMF (microwave irradiation 5 × 5 s, 100 W), followed by five washings with DMF and subsequent peptide coupling employing 5 equiv of the corresponding Fmoc-amino acid/PyBOP/diisopropylamine and 7.5 equiv of HOBt, dissolved in a minimum amount of DMF (irradiation 15 × 10 s, 50 W). Between every irradiation step, cooling of the reaction mixture to a temperature of −10 °C was achieved by sufficient agitation in an ethanol−ice bath. Cysteine was introduced as the pentafluorophenyl ester (Fmoc-Cys(Trt)-OPfp, Fluka) and solely used as a solution in DMF without any additive. After each acylation step, the solid support was washed five times with

DMF. Subsequently, the N-terminal Fmoc residue was deprotected as described above, the resin was rinsed 10 times with CH_2Cl_2 and dried under vacuum. Cleavage from the resin was performed by using a mixture of trifluoroacetic acid (TFA)/phenol/water/thioanisole/ethanedithiole/triisopropylsilane 81.5:5:5:5:2.5:2 for 2 h. After evaporation of the solvent, the peptide was precipitated and washed four times in *t*-butyl methyl ether, while N_2 was bubbled through the suspension before each washing. Purification of the crude material was done using preparative RP-HPLC (Agilent 1100 preparative series, column Zorbax 300 SB-C18, 21.2 mm × 250 mm, 7 μm particles). The eluting system was 0.1% TFA in acetonitrile (A) and 0.1% TFA in water (B) applying a linear gradient from 5.0% to 6.3% A over 15 min at a flow rate of 21.2 mL/min. Chemical purity of CAKAY was 96% as determined by HPLC (Lichrosorb RP-18, 250 mm × 4.6 mm, 1.5 mL/min, 10−100% acetonitrile in water (0.1% TFA) over 40 min; t_R = 4.23 min). ESI-MS: *m/z* 555.3 $[M + H]^+$.

Cyclic RGD Peptides. c(RGDfC) and c(RGDfS) were synthesized by Fmoc-assisted peptide solid-phase synthesis using a trityl chloride polystyrene (TCP) resin (PepChem, Tübingen, Germany). Loading of the TCP resin, synthesis of the peptide, subsequent cyclization, and deprotection were carried out following the protocol described elsewhere (*5*, *19*, *27*). Side-chain protection was 2,2,4,6,7-pentamethyldihydrobenzofuran-5-sulfonyl (Pbf) for arginine, *tert*-butyl (tBu) for aspartic acid and serine, and trityl (Trt) for cysteine. Chemical purities of cyclic RGD peptides were ≥96% as determined by HPLC and LC-MS. c(RGDfS): HPLC Lichrosorb RP-18, 250 mm × 4.6 mm, 1 mL/min, 0−50% acetonitrile in water (0.1% TFA) over 30 min, t_R(c(RGDfS)) = 15.5 min; ESI-MS *m/z* 563.2 $[M + H]^+$. c(RGDfC): HPLC Lichrosorb RP-18, 250 mm × 4.6 mm, 1.5 mL/min, 10−100% acetonitrile in water (0.1% TFA) over 40 min, t_R = 8.8 min; ESI-MS *m/z* 579.3 $[M + H]^+$, 601.2 $[M + Na]^+$; LC-MS 579.0 $[M + H]^+$.

Sodium Phenylthiosulfonate (NaPTS). The synthesis of NaPTS was performed as described by Gamblin et al. (*25*). Sodium benzenesulfinate (2 g, 12 mmol) and 390 mg (12 mmol) of sulfur were dissolved in 12 mL of anhydrous pyridine to give a yellow suspension. The reaction was stirred in a nitrogen atmosphere at room temperature for 1 h until a white suspension occurred. The mixture was filtered and washed with anhydrous diethyl ether. The crude product was crystallized from ethanol to yield 2.1 g (11 mmol, 92%) of NaPTS as a white solid. ^{1}H NMR (360 MHz, DMSO-d_6): δ 7.76−7.71 (m, 2H), 7.38−7.31 (m, 3H). ESI-MS: *m/z* 173.2 $[M- Na]^-$, 219.1 $[M + Na]^+$.

*3,4,6-Tri-O-acetyl-2-deoxy-2-fluoro-β-*D*-glucopyranosyl Phenylthiosulfonate, **2** (Ac$_3$-FGlc-PTS).* 3,4,6-Tri-*O*-acetyl-2-deoxy-2-fluoro-α-D-glucopyranosyl bromide (207 mg, 558 μmol, **1**) was dissolved in 5 mL of acetonitrile and 216 mg (1.1 mmol) of NaPTS and 18 mg (558 μmol) of tetrabutylammonium bromide (TBABr) were added. The mixture was stirred at 70 °C under a nitrogen atmosphere for 1.5 h. Afterward the solvent was removed in vacuo, the residue was partitioned between CH_2Cl_2 and water, and the aqueous phase was re-extracted with CH_2Cl_2. The combined organic phases were dried over Na_2SO_4, and the solvent was removed in vacuo. The resulting residue was purified by flash column chromatography (ethyl acetate/hexane 1:1) to afford 189 mg (407 μmol, 72%) of Ac$_3$-FGlc-PTS (**2**) as a yellow oil. TLC: ethyl acetate/hexane 1:1, R_f = 0.6. HPLC (Lichrosorb RP-18, 250 mm × 4.6 mm, 1.5 mL/min, 10−100% acetonitrile in water (0.1% TFA) over 40 min): t_R = 21.52 min. ^{1}H NMR (360 MHz, DMSO-d_6): δ 8.04−7.94 (m, 2H, Ar−H), 7.81−7.64 (m, 3H, Ar−H), 6.33 (d, 0.2H (α), H-1, $J_{1,2}$ = 5.8 Hz), 5.73 (dd, 1H (β), H-1, $J_{1,2}$ = 9.4 Hz, $J_{1,F}$ = 2.0 Hz), 5.62 (dt, 1H, H-3, $J_{3,F}$ = 14.8 Hz, $J_{2,3} = J_{3,4}$ = 9.7 Hz), 4.85 (t(dd), 1H, H-4, $J_{4,5} = J_{4,3}$ = 9.7 Hz), 4.79 (ddd, 1H, H-2, $J_{2,F}$ = 50.0 Hz, $J_{2,3}$ = 9.7 Hz, $J_{2,1}$ = 9.4 Hz), 4.14 (ddd, 1H, H-5, $J_{5,4}$ = 9.7 Hz, $J_{5,6a}$ = 4.6 Hz, $J_{5,6b}$ = 2.3 Hz), 4.02 (dd, 1H, H-6a, $J_{6a,6b}$ = 12.6 Hz, $J_{6a,5}$ = 4.6 Hz), 3.68 (dd, 1H, H-6b, $J_{6a,6b}$ = 12.6 Hz, $J_{6b,5}$ = 2.3 Hz), 2.03 (s, 3H, OAc), 1.98 (s, 3H, OAc), 1.95 (s, 3H, OAc). ^{19}F NMR (DMSO-d_6): δ −192.51 (dd, $J_{F,2}$ = 49.8 Hz, $J_{F,3}$ = 14.9 Hz, α-anomer), −191.93 (ddd, $J_{F,2}$ = 50.0 Hz, $J_{F,3}$ = 14.8 Hz, $J_{F,1}$ = 2.0 Hz, β-anomer); α/β = 20:80. ESI-MS: *m/z* 465.0 $[M + H]^+$, 487.0 $[M + Na]^+$.

L-*(S-3,4,6-Tri-O-acetyl-2-deoxy-2-fluoro-β-*D*-glucopyranosyl disulfide)-cysteinyl-*L*-alanyl-*L*-lysyl-*L*-alanyl-*L*-tyrosine, **3** (C(S,S′-Ac$_3$-FGlc)AKAY).* To a solution of 1.3 mg (2.3 μmol) of CAKAY in 1 mL of buffer (50 mM Tris, pH 7.7) was added 19 mg (40 μmol) of Ac$_3$-FGlc-PTS (**2**) in 100 μL of acetonitrile/water, 8:2. After the reaction time of 30 min, the absence of free thiol was shown by Ellman's analysis, and the product was isolated by semipreparative HPLC (Lichrosorb RP-18, 125 mm × 8 mm, 4 mL/min, 10−100% acetonitrile in water (0.1% TFA) over 40 min) and subsequently lyophilized to afford C(S,S′-Ac$_3$-FGlc)AKAY (**3**) (1.8 mg, 2 μmol, 90%) as a white powder. HPLC (Lichrosorb RP-18, 250 mm × 4.6 mm, 1.5 mL/min, 10−100% acetonitrile in water (0.1% TFA) over 40 min, 220 nm): t_R = 9.7 min. ^{1}H NMR (600 MHz, DMSO-d_6): δ 9.23 (b, 1H, COOH), 8.69 (d, 1H, $J_{HN/H\alpha}$ = 7.5 Hz, NH), 8.12 (d, 1H, $J_{HN/H\alpha}$ = 8.0 Hz, NH), 8.10 (d, 1H, $J_{HN/H\alpha}$ = 7.8 Hz, NH), 7.83 (d, 1H, $J_{HN/H\alpha}$ = 7.4 Hz, NH), 7.67 (b, 1H, NH_2), 7.01 (m, 2H, Ar-Tyr), 6.65 (m, 2H, Ar-Tyr), 5.53 (dt, 1H, $J_{3,F}$ = 14.1 Hz, $J_{3,2} = J_{3,4}$ = 9.5 Hz, H-3), 5.17 (dd, 1H, $J_{1,2}$ = 9.5 Hz, $J_{1,F}$ = 1.8 Hz, H-1, β-anomer), 4.94 (t(dd), 1H, $J_{4,3} = J_{4,5}$ = 9.5 Hz, H-4), 4.73 (dt(ddd), 1H, $J_{2,F}$ = 49.7 Hz, $J_{2,1} = J_{2,3}$ = 9.5 Hz, H-2, β-anomer), 4.54 (q, 1H, $J_{H\alpha/H\beta}$ = 6.1 Hz, α-CH), 4.39 (p, 1H, *J* = 7.5 Hz, α-CH), 4.32−4.07 (m, 5H, 3 × α-CH, H-5, H-6a, H-6b), 3.23 (dd, 1H, $J_{H\beta/H\beta}$ = 14.0 Hz, $J_{H\beta/H\alpha}$ = 6.1 Hz, β-CH), 3.09 (dd, 1H, $J_{H\beta/H\beta}$ = 14.0 Hz, $J_{H\beta/H\alpha}$ = 7.5 Hz, β-CH), 2.90 (dd, 1H, $J_{H\beta/H\beta}$ = 14.0 Hz, $J_{H\beta/H\alpha}$ = 5.4 Hz, β-CH), 2.79 (dd, 1H, $J_{H\beta/H\beta}$ = 14.0 Hz, $J_{H\beta/H\alpha}$ = 8.3 Hz, β-CH), 2.73 (b, 2H, H^{ϵ}-Lys), 2.05 (s, 3H, OAc), 2.00 (s, 3H, OAc), 1.99 (s, 3H, OAc), 1.51 (d, 4H, β-CH-Lys, γ-CH-Lys), 1.29 (m, 2H, H^{δ}-Lys), 1.25 (d, 3H, β-CH_3-Ala, $J_{H\beta/H\alpha}$ = 7.0 Hz), 1.19 (d, 3H, β-CH_3-Ala, $J_{H\beta/H\alpha}$ = 7.0 Hz). ESI-MS: *m/z* 877.4 $[M + H]^+$, 439.3 $[M + 2H]^{2+}$.

*Cyclo[*L*-arginyl-*L*-glycyl-*L*-asparagyl-*D*-phenylalanyl-*L*-(S-3,4,6-tri-O-acetyl-2-deoxy-2-fluoro-β-*D*-glucopyranosyl disulfide) cysteine], **4** (c(RGDfC(S,S′-Ac$_3$-FGlc))).* To a solution of 1.3 mg (2.2 μmol) of c(RGDfC) in 1 mL of buffer (50 mM Tris, pH 7.7) was added 18.5 mg (40 μmol) of Ac$_3$-FGlc-PTS (**2**) in 100 μL of acetonitrile/water, 8:2. After a reaction time of 30 min, the absence of free thiol was shown by Ellman's analysis, and the product was isolated as described for C(S,S′-Ac$_3$-FGlc)AKAY (**3**) to afford 1.8 mg (2 μmol, 90%) of c(RGDfC(S,S′-Ac$_3$-FGlc)) (**4**) as a white powder. MALDI: *m/z* 900.6. ESI-MS: *m/z* 901.3 $[M + H]^+$, 922.7 $[M + Na]^+$.

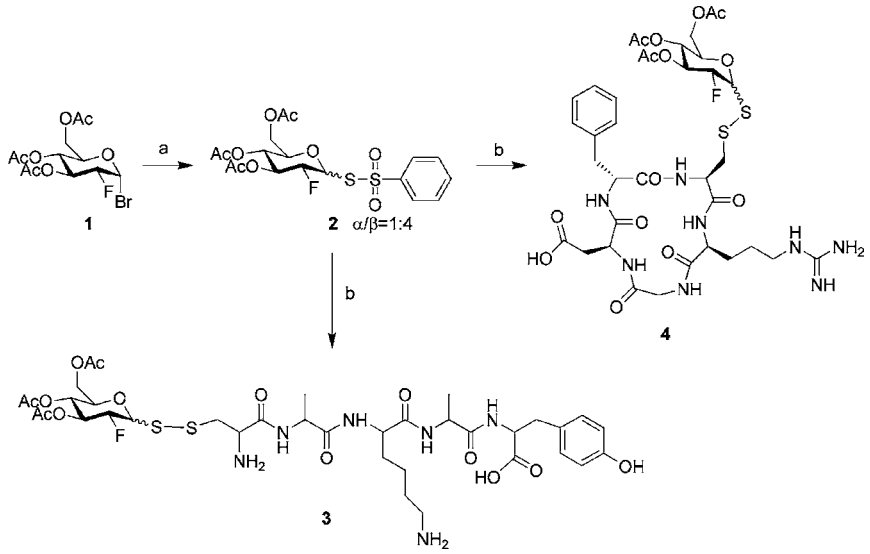
Ellman's Analysis. The absence of the free thiol was shown using Ellman's test (*28*). An aliquot (10 μL) of the reaction mixture was diluted in 990 μL of phosphate buffer (0.1 M NaH_2PO_4, pH 8). Subsequently, 90 μL of this solution was added to 60 μL of Ellman's reagent (10 mM 5,5′-dithio-bis(2-nitrobenzoic acid) in phosphate buffer) in a 96-well plate. After incubation for 30 min at room temperature, the optical density was measured at 450 nm using an ELISA reader. A calibration curve was measured using cysteine as the reference in concentrations of 0, 5, 10, 20, 30, 40, 50, and 60 μM in phosphate buffer.

Solid-Phase Receptor Binding Assay. The receptor binding assay was performed following the procedure described by Orlando and Cheresh (*29*) with slight modifications. Commercially available purified $\alpha_v\beta_3$ (Chemicon International) was diluted at 250 ng/mL in coating buffer (25 mM Tris-HCl, 150 mM NaCl, 1 mM $CaCl_2$, 0.5 mM $MgCl_2$, 1 mM $MnCl_2$, pH 7.4), and an aliquot of 100 μL/well was added to a 96-well microtiter plate (Maxisorb, Nunc, Wiesbaden, Germany) and incubated overnight at 4 °C. The wells were washed once with 200 μL of blocking buffer (coating buffer + 1% (w/v) bovine serum albumin) and incubated an additional 2 h with 200 μL of blocking buffer at room temperature. The plate was rinsed twice with binding buffer (coating buffer with 0.1% (w/v) bovine serum albumin) and incubated in the presence of varied amounts of competing ligand (0.5 pM to 500 nM echistatin; 0.05 nM to 50 μM RGD peptide) for 3 h with 370 Bq/well (0.05 nM) ^{125}I-echistatin (Amersham, Germany) in a total volume of 100 μL of binding buffer. After the incubation time, the wells were washed three times with binding buffer, and bound ^{125}I-echistatin was solubilized with hot 2 N NaOH. Radioactivity in the resulting suspension was measured by a γ-counter (Wallac Wizard). Nonspecific binding was measured in the presence of 200-fold molar excess of echistatin and was substracted from total binding to yield specific binding. When ^{125}I-echistatin incubations were performed without receptor, negligible nonspecific adsorption (0.04%) to the microtiter well was detected. Each data point is an average of values from triplicate wells. All measurements were repeated at least three times. K_i values were calculated by use of the software program GraphPad Prism in consideration of the equation for "heterologous competitive binding with ligand depletion".



Cell Binding Assay. Human umbilical vein endothelial cells (HUVEC) (Cambrex, Walkersville, MD) were cultured in endothelial growth medium (EGM) (endothelial basal medium (EBM) supplemented with SingleQuotKits (1 mL/L hEGF, 0.4 mL/L hydrocortisone, 1 mL/L VEGF, 4 mL/L hFGF-B (with heparin), 1 mL/L R^3-IGF-1, 1 mL/L ascorbic acid, 1 mL/L GA-1000, 50 mL/L fetal calf serum, Cambrex) as described previously (*30*) and used in passage 5−8. For cell binding assay, HUVEC were harvested and suspended in EGM at a concentration of 500 000 cells per Eppendorf tube. Each Eppendorf tube was centrifuged at 210*g* for 4 min. After the cells were blocked with blocking buffer for 15 min at room temperature, they were washed twice with binding buffer. Subsequently, the HUVEC were incubated on a shaker in the presence of varied amounts of competing ligand (0.5 pM to 500 nM echistatin; 0.05 nM to 50 μM RGD peptide) with 370 Bq/Eppendorf tube (0.025 nM) ^{125}I-echistatin (Amersham, Germany) in a total volume of 200 μL of binding buffer. After the incubation time of 1 h, cells were rinsed three times with binding buffer, the supernatant was sucked off, and the cell pellets with bound ^{125}I-echistatin were transferred to counting tubes for measuring the radioactivity with a γ-counter (Wallac Wizard). Nonspecific binding was measured in the presence of 200-fold molar excess of echistatin and was substracted from total binding to yield specific binding. Each data point is an average of values from triplicate or quadruplicate wells. All measurements were repeated at least three times. K_i values were calculated by use of the software program GraphPad Prism in consideration of the equation for "heterologous competitive binding with ligand depletion".

Radiosynthesis of 3,4,6-Tetra-*O*-acetyl-2-deoxy-2-[^{18}F]-fluoro-glucopyranosyl Phenylthiosulfonate, [^{18}F]2 (Ac_3-[^{18}F]-FGlc-PTS). Starting from [^{18}F]fluoride (500 MBq), 3,4,6-tri-*O*-acetyl-2-deoxy-2-[^{18}F]fluoro-glucopyranosyl bromide (**[^{18}F]1**) was synthesized in 45 min as described elsewhere (*22*, *23*). The bromide **[^{18}F]1** (275 MBq) was fixed on a RP-18 cartridge (Merck Lichrolut, 100 mg), eluted with 1.0 mL of acetonitrile in a new reaction vessel, and dried in a stream of nitrogen. Subsequently, 10 mg (50 μmol) of NaPTS and 5 mg (15 μmol) of dry TBABr in 200 μL of anhydrous acetonitrile and 50 μL of DMF was added. The reaction mixture was stirred at 70 °C for 20 min, diluted with 250 μL of water, and transferred to a semipreparative HPLC system (Kromasil C8, 125 mm × 8 mm, 4 mL/min, 40−100% acetonitrile in water (0.1% TFA) over 40 min). Subsequent solid-phase extraction (SPE, Merck Lichrolut, 100 mg) yielded 95 MBq of Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**) after 45 min (related to [^{18}F]fluoride). The chemical identity was confirmed by analytical gradient HPLC by reference to Ac_3-FGlc-PTS (**2**) (Lichrosorb RP-18, 250 mm × 4.6 mm, 1.5 mL/min, 10−100% acetonitrile in water (0.1% TFA) over 40 min, t_R = 21.7 min).

Radiosynthesis of L-(*S*-3,4,6-tri-*O*-acetyl-2-deoxy-2-[^{18}F]-fluoro-glucopyranosyl disulfide)-cysteinyl-L-alanyl-L-lysyl-L-alanyl-L-tyrosine, [^{18}F]3 (C(S,S′-Ac_3-[^{18}F]FGlc)AKAY). To a solution of 95 MBq of Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**) in 100 μL of acetonitrile/buffer (1:1, 50 mM Tris, pH 7.7) was added 200 nmol of CAKAY dissolved in 100 μL of 50 mM Tris buffer (pH 7.7) at room temperature. The reaction was complete within 15 min (RCY 90−95%) as determined by analytical HPLC (Lichrosorb RP-18, 250 mm × 4.6 mm, 1.5 mL/min, 10−100% acetonitrile in water (0.1% TFA) over 40 min; t_R(C(S,S′-Ac_3-[^{18}F]FGlc)AKAY, **[^{18}F]3**) = 9.7 min. The chemical identity of C(S,S′-Ac_3-[^{18}F]FGlc)AKAY (**[^{18}F]3**) was confirmed by analytical gradient HPLC by co-injection with the reference compound C(S,S′-Ac_3-FGlc)AKAY (**3**).

Radiosynthesis of Cyclo[L-arginyl-L-glycyl-L-asparagyl-D-phenylalanyl-L-(*S*-3,4,6-tri-*O*-acetyl-2-deoxy-2-[^{18}F]fluoro-glucopyranosyl disulfide) cysteine], [^{18}F]4 (c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc))). To a solution of 95 MBq of Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**) in 100 μL of acetonitrile/buffer (1:1, 50 mM Tris, pH 7.7) was added 200 nmol of c(RGDfC) dissolved in 100 μL of 50 mM Tris buffer (pH 7.7) at room temperature. The reaction was complete within 15 min (RCY 90−95%) as determined by analytical HPLC (Lichrosorb RP-18, 250 mm × 4.6 mm, 1.5 mL/min, 10−100% acetonitrile in water (0.1% TFA) over 40 min; t_R(c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)), **[^{18}F]4**) = 14.9 min). The reaction mixture was diluted with 300 μL of acetonitrile/water (1:9) and subjected to semipreparative HPLC (Lichrosorb RP-18, 125 mm × 8 mm, 4 mL/min, 10−100% acetonitrile in water (0.1% TFA) over 40 min). The product fraction was diluted with water (1:10), and the product was isolated by solid-phase extraction (C18-cartridge, Merck, 100

Scheme 1. Synthesis of the Glycosyl Donor Ac_3-FGlc-PTS (2) and Subsequent Glycosylation Reaction Using Cysteine-Containing Peptides[a]

[a] Reaction conditions: (a) NaPTS, acetonitrile, 70 °C; (b) 50 mM Tris buffer (pH 7.7, containing 7% CH_3CN), 1 mM CAKAY or 1 mM c(RGDfC).

mg). After elution of the product with acetonitrile, the solvent was evaporated in vacuo, and PBS was added to obtain a solution for further experimental use. Starting from 500 MBq of [^{18}F]fluoride, this procedure yielded about 65 MBq of c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**) after a total synthesis time of 130 min. The chemical identity of c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**) was confirmed by analytical gradient HPLC by co-injection with the reference compound c(RGDfC(S,S′-Ac_3-FGlc)) (**4**).

Metabolic Stability. c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**) dissolved in 200 μL of PBS was added to 2 mL of human serum and incubated at 37 °C. Aliquots (100 μL) were taken at various time intervals (5−90 min) and quenched in 500 μL of methanol/CH_2Cl_2 (1:1). The samples were centrifuged, and the supernatants were analyzed by radio-TLC (ethyl acetate/hexane 1:1).

RESULTS AND DISCUSSION

Chemistry. Glycosyl phenylthiosulfonates have been introduced as suitable glycosyl donors for the glycoconjugation of thiols, peptides, and proteins (*25*). These reagents provided enhanced stability under basic conditions compared with the earlier described methanethiosulfonates (*31*). In this paper, we adopted the synthesis of glycosyl phenylthiosulfonates to provide the 2-deoxy-2-fluoro-glycosyl derivative **2** that served as a reference compound for the corresponding ^{18}F-labeled analog (Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**), Figure 1). The synthesis of the glycosylating reagent 3,4,6-tri-*O*-acetyl-2-fluoro-2-deoxy-β-D-glucopyranosyl 1-phenylthiosulfonate (**2**) is outlined in Scheme 1. Starting from tetraacetylated 2-deoxy-2-fluoro-β-D-glucopyranose, which was available by acetylation of an anomeric mixture of mannose and subsequent fluorination with diethylamino sulfur trifluoride (DAST), the initial α-bromide (**1**) was easily obtained in 90% yield by reaction with HBr at room temperature as previously described (*23*). Following the procedure of Gamblin et al. (*25*), displacement of the halide from **1** using NaPTS in acetonitrile at 70 °C readily afforded Ac_3-FGlc-PTS (**2**) in 70% yield. Ac_3-FGlc-PTS (**2**) consisted of a β/α anomeric ratio of >80:20 as analyzed by ^{19}F NMR spectroscopy.

Glycosylation properties of the resulting 2-deoxy-2-fluoro-glycosyl donor (**2**) were evaluated using the model peptide CAKAY and the $\alpha_v\beta_3$ targeting c(RGDfC). The glycosylation of cysteine-containing peptides using glycosyl phenylthiosulfonates proceeds via a highly specific and quantitative coupling reaction of the thiol function, that is, cysteine β-SH, and the thiosulfonate moiety resulting in the formation of a disulfide bond (*32*). On the one hand, the peptide CAKAY was chosen to demonstrate the chemoselectivity of Ac_3-FGlc-PTS (**2**) and also to optimize ^{18}F-labeling conditions (see paragraph below). On the other hand, the cyclic RGD peptide was selected because of its biological relevance (*33*) allowing study of the influence of S-glycosylation on $\alpha_v\beta_3$ binding affinity in vitro. Glycosylation of CAKAY and c(RGDfC) with Ac_3-FGlc-PTS (**2**) were carried out under similar reaction conditions using an aqueous buffer system (pH 7.7; for details, see Scheme 1). Ligations proceeded rapidly within 30 min and quantitatively, as confirmed by monitoring the reaction progress by titration of residual free thiol groups with Ellman's reagent (*28*). Both S-glycosylated peptides, C(S,S′-Ac_3-FGlc)AKAY (**3**) and c(RGDfC(S,S′-Ac_3-FGlc)) (**4**), were isolated by RP-HPLC, and their structures were confirmed by NMR spectroscopy, ESI-MS, and, in the case of c(RGDfC(S,S′-Ac_3-FGlc)) (**4**), MALDI mass spectroscopy. Importantly, the prevailing β-anomeric configuration as given by Ac_3-FGlc-PTS (**2**) was retained in the S-glycosidic linked products C(S,S′-Ac_3-FGlc)AKAY (**3**) and c(RGDfC(S,S′-Ac_3-FGlc)) (**4**). Hence, the anomeric stereochemistry was maintained during the glycosylation process, which is consistent with the observation that α- and β-glycosyl thiols also do not mutarotate even under basic reaction conditions (*34*). Noteworthy, the determination of the anomeric configuration of such 2-deoxy-2-fluoro-glycoconjugates was simplified because of the fluorine substituent at C-2, since the $^3J_{F,1}$ coupling constant provides an excellent tool to distinguish between α ($^3J_{F,1}$ < 0.5 Hz) and β ($^3J_{F,1} \approx$ 2.5 Hz) configuration by ^{19}F NMR spectroscopy.

In Vitro Binding Assays. In order to compare the affinities of c(RGDfS), c(RGDfC), and the S-glycosylated derivative c(RGDfC(S,S′-Ac_3-FGlc)) (**4**) to $\alpha_v\beta_3$ integrin, competitive displacement assays were performed (Figure 2). It is well-known that the disintegrin echistatin displays high affinity for $\alpha_v\beta_3$ and also for other integrins, such as $\alpha_8\beta_1$ and $\alpha_{3/5/v}\beta_1$ with K_i values ranging between 1 and 4 nM (*35*, *36*). Besides echistatin, we introduced c(RGDfS) as a competitor of ^{125}I-echistatin binding in our experiments, since this cyclic RGD peptide has already been characterized as an inhibitor of vitronectin binding to

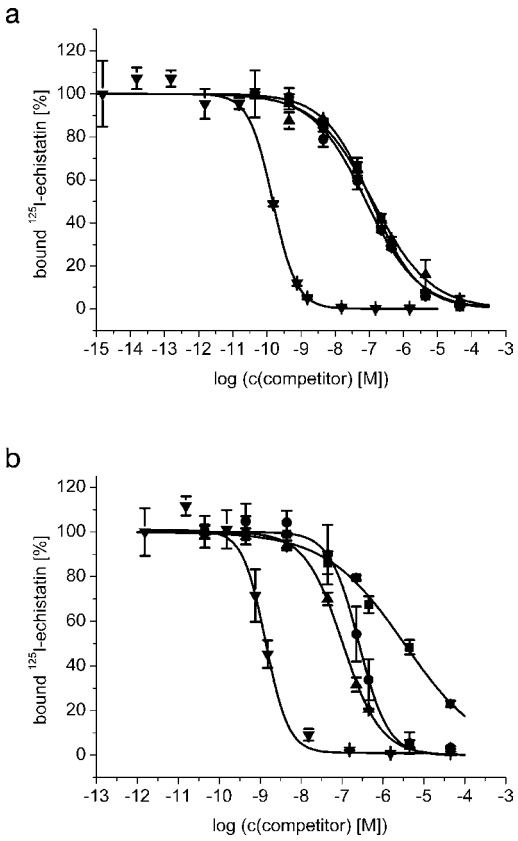


Figure 2. Effect of the concentration of unlabeled echistatin (▼), c(RGDfS) (■), c(RGDfC) (●), and c(RGDfC(S,S′-Ac$_3$-FGlc)) (**4,** ▲) on ^{125}I-echistatin binding in a competition binding experiment using (a) immobilized $\alpha_v\beta_3$ integrin or (b) human endothelial cells (HUVEC). Data are from four independent experiments each performed in triplicate or quadruplicate ($n = 12-16$).

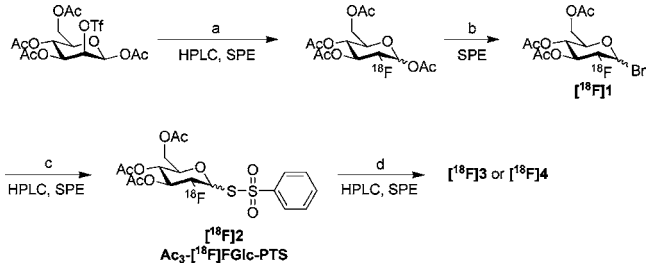
Table 1. Binding Affinities of RGD Peptides to Immobilized $\alpha_v\beta_3$ and to HUVEC[a]



compound	K_i (nM) $\alpha_v\beta_3$	K_i (nM) HUVEC
echistatin	0.052 ± 0.001	0.43 ± 0.11
c(RGDfS)	53 ± 12	541 ± 99
c(RGDfC)	41 ± 0.5	241 ± 40
c(RGDfC(S,S′-Ac$_3$-FGlc)) (**4**)	68 ± 10	77 ± 4

[a] Values are given as mean ± standard deviation from four independent experiments performed in triplicate or quadruplicate.

isolated $\alpha_v\beta_3$ ($IC_{50} = 12$ nM (*27*)). Therefore, c(RGDfS) represents a structurally related RGD peptide that was used as a reasonable reference compound to assess the influence of glycosylation on $\alpha_v\beta_3$ binding affinity by comparing c(RGDfC-(S,S′-Ac$_3$-FGlc)) (**4**) with its non-glycosylated analog c(RGDfC).

In the presence of echistatin, c(RGDfS), c(RGDfC), and c(RGDfC(S,S′-Ac$_3$-FGlc)) (**4**) binding of ^{125}I-echistatin to immobilized $\alpha_v\beta_3$ integrin was inhibited in a concentration-dependent manner. All of the peptides demonstrated the capability to completely inhibit ^{125}I-echistatin binding to isolated $\alpha_v\beta_3$ integrin (Figure 2a). Due to a significant change of the free radioligand concentration during the incubation period, we used an equation for curve analysis that considered this finding. The obtained K_i values are presented in Table 1. Chen et al. also tested RGD peptides using the same in-vitro assay and found K_i values of 30−70 nM (*37*). Using the $\alpha_v\beta_3$ solid-phase binding assay, we obtained K_i values within the same range for all tested cyclic peptides (column 2, Table 1), which are also comparable with Chen's data. Moreover, these data confirm that $\alpha_v\beta_3$ binding affinity is not substantially impaired by S-glycosylation of the cysteine moiety in c(RGDfC).

Scheme 2. Radiosynthetic Pathway for the Chemoselective ^{18}F-Glycosylation of CAKAY or c(RGDfC) Using the Thiol-Reactive Reagent Ac$_3$-[^{18}F]FGlc-PTS ([^{18}F]2)[a]

[a] Reaction conditions: (a) [K⊂222]$^+$[^{18}F]F$^-$, 9 mg (20 μmol) of 1,3,4,6-tetra-*O*-acetyl-2-*O*-trifluoromethanesulfonyl-β-D-mannopyranose, 500 μL of acetonitrile, $T = 85$ °C, $t = 5$ min (*16*); (b) 33% HBr/AcOH, rt; (c) 200 mM NaPTS, 60 mM TBABr, acetonitrile/DMF, 4:1 (v/v), $T = 70$ °C, $t = 20$ min; (d) 50 mM Tris buffer (pH 7.7)/acetonitrile, 3:1 (v/v), 1 mM CAKAY or 1 mM c(RGDfC).

In addition, we performed a competition study using human endothelial cells, in order to qualitatively assess the binding affinity of the peptides under investigation to interfering receptors in a comparative experiment (Figure 2b). We chose human umbilical vein endothelial cells (HUVEC), since the expression of various integrins, such as $\alpha_2\beta_1$, $\alpha_3\beta_1$, $\alpha_v\beta_1$, and $\alpha_v\beta_3$ is well-known for this cell type (*38*). As shown in Figure 2b and Table 1, the peptides c(RGDfS) and c(RGDfC) revealed significant differences in K_i values when comparing $\alpha_v\beta_3$ binding results to the values obtained from HUVEC binding experiments. In particular, the curve for inhibition of ^{125}I-echistatin binding to HUVEC by c(RGDfS) showed a decreased steepness with a Hill slope factor lower than 1. This finding clearly indicated the presence of additional low-affinity binding sites for c(RGDfS) and c(RGDfC) on HUVEC. In contrast, the K_i value of the glycosylated derivative c(RGDfC(S,S′-Ac$_3$-FGlc)) (**4**) was determined to be almost unchanged, when comparing the K_i value obtained from competition studies using pure $\alpha_v\beta_3$ with that of HUVEC binding experiments (Table 1). However, the assay using HUVEC cells cannot discriminate between different integrins present on the cell surface, but it provided additional information, that the affinity of the S-glycosylated peptide c(RGDfC(S,S′-Ac$_3$-FGlc)) (**4**) toward ^{125}I-echistatin binding sites was not significantly affected.

Radiosynthesis of the ^{18}F-Labeled Glycosyl Donor Ac$_3$-[^{18}F]FGlc-PTS ([^{18}F]2). Our radiochemical synthesis of Ac$_3$-[^{18}F]FGlc-PTS (**[^{18}F]2**) was based on the first step of the [^{18}F]FDG synthesis (*16*), as shown in Scheme 2. Starting from 1,3,4,6-tetra-*O*-acetyl-2-*O*-trifluoromethanesulfonyl-β-D-mannopyranose (*26*), cryptate-assisted nucleophilic substitution was performed at 85 °C for 5 min following the procedure of Hamacher et al. (*16*). After solid phase (SiO_2) purification and semipreparative RP-HPLC (*22*), no-carrier-added tetraacetylated 2-deoxy-2-[^{18}F]fluoroglucose was converted into the α-bromide **[^{18}F]1** using HBr in acetic acid as previously reported (*23*). **[^{18}F]1** was generally obtained in a 55% non-decay-corrected yield within 45 min starting from [^{18}F]fluoride, providing adequate quantities for the following reaction steps. The reaction conditions for the conversion of **[^{18}F]1** to the phenylthiosulfonate Ac$_3$-[^{18}F]FGlc-PTS (**[^{18}F]3**) were studied in detail by varying the reaction solvent, the reaction time, the concentration of the promoter TBABr, and the amount of NaPTS used. As shown in Figure 3, the use of acetonitrile/DMF (4:1) resulted in highest radiochemical yields for the synthesis of Ac$_3$-[^{18}F]FGlc-PTS (**[^{18}F]2**) (approximately 47% related to **[^{18}F]1**) within a reaction time of 20 min, whereas acetonitrile alone, acetonitrile/DMSO (4:1), and DMF turned out to be less suitable. Presumably, this is due to an improved solubility of NaPTS in acetonitrile/DMF. Moreover, it turned out that important factors for an optimized

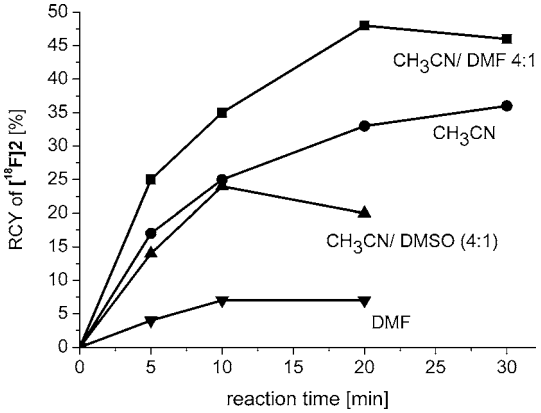


Figure 3. Dependence of the radiochemical yield (RCY, decay-corrected and related to **[^{18}F]1**) of the ^{18}F-labeled glycosyl donor Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**) on the reaction solvent.

RCY are (a) the use of recrystallized and intensively dried NaPTS for the reaction with **[^{18}F]1** (in general, moisture has to be excluded, since limited RCY (<10%) of Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**) were obtained when insufficiently dried NaPTS was used), (b) that reaction temperatures >100 °C should be avoided, due to an accelerated degradation of Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]-2**) with higher temperatures, and (c) the presence of TBABr as promoter (data not shown). Under optimized reaction conditions (200 mM NaPTS, 60 mM TBABr, acetonitrile/DMF (4:1), 70 °C, 20 min), the ^{18}F-labeled glycosylating reagent Ac_3-[^{18}F]-FGlc-PTS (**[^{18}F]2**) was isolated in 33% decay-corrected RCY (related to [^{18}F]fluoride) after semipreparative HPLC.

^{18}F-Glycosylation of CAKAY and c(RGDfC). In a set of preceding experiments in order to assess the ^{18}F-labeling ability of Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**), varied concentrations of CAKAY were used in the conjugation step (Scheme 2, step d). As shown in Figure 4, a peptide precursor concentration of 1 mM in aqueous buffer (pH 7.7) was adequate to achieve a RCY of C(S,S′-Ac_3-[^{18}F]FGlc)AKAY) (**[^{18}F]3**) of about 95% (related to Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**)) as determined by radio-HPLC within a reaction time of 15 min. With adoption of these optimized coupling conditions for the chemoselective S-glycosylation of c(RGDfC) using Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**), quantitative ligation yielding c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**) was successfully demonstrated. It should be mentioned that a possible complication in the synthesis of mixed disulfides, such as c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**), is the formation of a peptide−peptide disulfide (*32*). This could occur via a disulfide exchange reaction between c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**) and the peptide thiol, which is present in excess under no-carrier-added reaction conditions. However, such a reaction pathway would result in the degradation of the ^{18}F-glycosylated product, which we did not observe by radio-HPLC analysis in our experiments, even after a prolonged reaction time of 30 min (Figure 4a). Thus, the conjugation proceeded efficiently in 95% coupling yield (decay corrected), illustrating the excellent ability of Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**) as a thiol-reactive ^{18}F-labeling agent for cysteine-containing peptides under mild reaction conditions. Both ^{18}F-labeled peptides, C(S,S′-Ac_3-[^{18}F]FGlc)-AKAY (**[^{18}F]3**) and c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**), were characterized by reference to the respective ^{19}F-substituted standards C(S,S′-Ac_3-FGlc)AKAY (**3**) and c(RGDfC(S,S′-Ac_3-FGlc)) (**4**) and co-injection using HPLC (Figure 5). The overall-radiochemical yield of C(S,S′-Ac_3-[^{18}F]FGlc)AKAY (**[^{18}F]3**) and c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**) was about 13% (decay-uncorrected and related to [^{18}F]fluoride) after a total synthesis time of 130 min, following a three-step procedure (Scheme 2). Finally, to verify the stability of the formed glycosidic bond toward degradation, we performed incubation

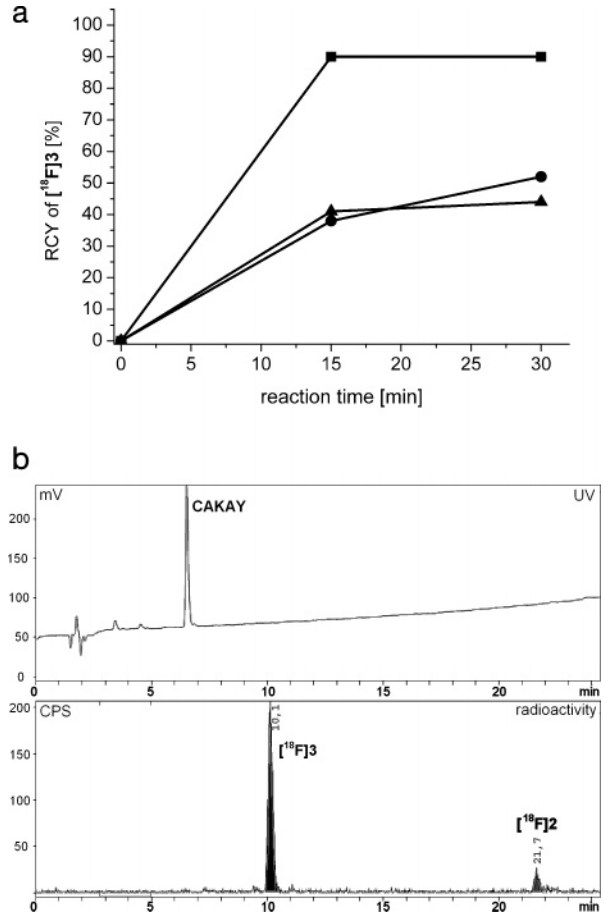

Figure 4. (a) Dependence of the radiochemical yield (RCY) of C(S,S′-Ac_3-[^{18}F]FGlc)AKAY (**[^{18}F]3**) for ^{18}F-glycosylation of CAKAY using Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**) on the concentration of CAKAY (10 μM (▲), 0.1 mM (●), and 1 mM (■)) and (b) representative HPLC analysis of a sample withdrawn from the reaction mixture containing 1 mM CAKAY after 15 min.

experiments with c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**) using human serum at 37 °C. Radio-TLC of the incubation mixture revealed no cleavage of the carbohydrate moiety of the glycopeptide c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**), thereby indicating high in-vitro metabolic stability of c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**) for at least 90 min (>98%). This finding is consistent with the known resistance of thioglycosides to chemical and enzymatic hydrolysis (*39*).

In comparison with chemoselective ^{18}F-radiolabeling methods using maleimide derivatives (*13*−*15*), our approach provided radiochemical yields within the same range, additionally gaining the opportunity to perform glycosylation and ^{18}F-labeling of peptide target compounds simultaneously within the same reaction step. In our study, we successfully developed a suitable radiosynthesis for the novel ^{18}F-labeled glycosyl donor Ac_3-[^{18}F]FGlc-PTS (**[^{18}F]2**) and focused on the optimization of the ligation of **[^{18}F]2** with cysteine-containing peptides. In view of the rapid and chemoselective conjugation under mild reaction conditions, together with the improved stability of S-linked glycopeptides toward acid/base or enzyme-mediated hydrolysis compared with their O-linked counterparts (*39*), the ^{18}F-glycosylation reaction described herein could find valuable use in the radiosynthesis of ^{18}F-labeled S-glycopeptides to study their pharmacokinetics by PET. The development of a facilitated radiochemical procedure for an efficient automated synthesis of fully unprotected ^{18}F-labeled glycopeptides taking advantage of this mild ligation procedure is a topic of further studies.

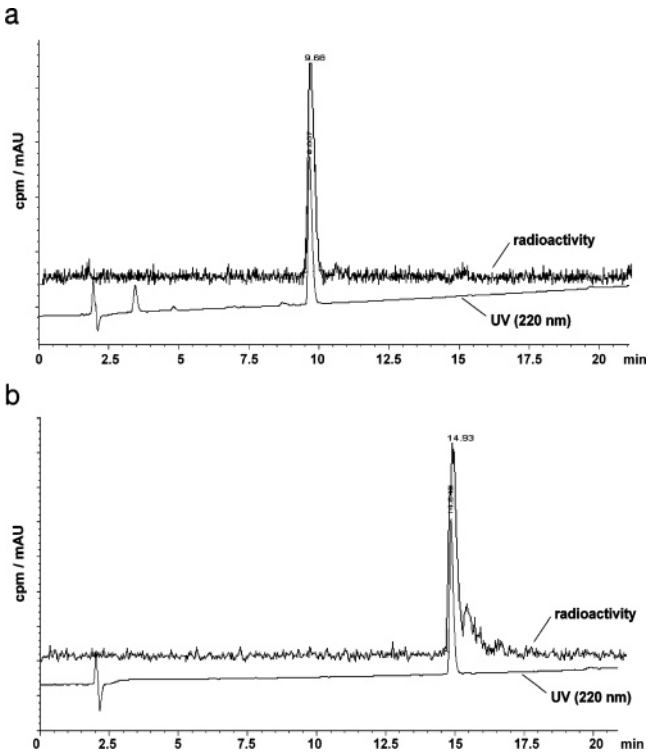

Figure 5. Analytical HPLC profiles of (a) the ^{18}F-labeled CAKAY **[^{18}F]3** coinjected with the standard C(S,S′-Ac_3-FGlc)AKAY (**3**) and (b) the ^{18}F-labeled peptide c(RGDfC(S,S′-Ac_3-[^{18}F]FGlc)) (**[^{18}F]4**) coinjected with the standard c(RGDfC(S,S′-Ac_3-FGlc)) (**4**). HPLC column and elution protocol: Lichrosorb RP-18, 250 mm × 4.6 mm, 1.5 mL/min, 10−100% CH_3CN in water (0.1% TFA) over 40 min.

CONCLUSION

Ac_3-[^{18}F]FGlc-PTS, a novel phenylthiosulfonate derivative of [^{18}F]FDG, has been introduced as a new thiol-reactive ^{18}F-glycosylation reagent for labeling of peptides. This strategy combines both site-specific ^{18}F-labeling and glycosylation of a cysteine-containing target peptide. As illustrated by glycosylation of c(RGDfC), the in-vitro $\alpha_v\beta_3$ binding affinity of this representative peptide remained unaffected, providing evidence for the suitability of this ^{18}F-glycosylation method. Due to the excellent yield for the conjugation step between cysteine-containing peptides and the ^{18}F-labeled glycosyl phenylthiosulfonate, this method is promising for the design and development of ^{18}F-labeled bioactive glycopeptides.

ACKNOWLEDGMENT

The authors thank Dr. Walter Mier (Department of Nuclear Medicine, University of Heidelberg) for performing MALDI mass spectrometry and Stephan Schwarz (Medizinische Universität Innsbruck) for excellent technical assistance. This work was supported by the ELAN-Fonds of the Friedrich-Alexander-Universität Erlangen-Nürnberg (Grant 06.01.04.1).

TECHNICAL NOTES

Soluble Camptothecin Derivatives Prepared by Click Cycloaddition Chemistry on Functional Aliphatic Polyesters

Bryan Parrish and Todd Emrick*

Polymer Science & Engineering Department, University of Massachusetts, Conte Center for Polymer Research, Amherst, Massachusetts 01003. Received July 6, 2006; Revised Manuscript Received October 19, 2006

Aliphatic polyesters are of interest as biomaterials and drug-delivery vehicles, as their ability to degrade under physiological conditions provides a mechanism for both drug release and clearance of the polymer from the body. Presented here is the synthesis of a polyester−drug graft copolymer conjugate, enabled by click cycloaddition of azide-functionalized camptothecin derivatives with alkyne-functionalized aliphatic polyesters. Further grafting of residual alkyne groups with azide-terminated poly(ethylene oxide) gave a water-soluble polyester−camptothecin conjugate. Control over PEGylation and drug loading, inherent to the graft copolymer design, opens versatile routes to new materials with potential utility in polymer therapeutics.

INTRODUCTION

Central issues associated with chemotherapy include the methods and mechanisms by which drugs are introduced to the body and delivered to cancer tissue (*1*−*3*). As potent anticancer drugs such as doxorubicin, camptothecin, and paclitaxel have poor aqueous solubility, and in some cases short-term aqueous stability, introduction of these drugs into the bloodstream is enhanced by modification of their chemical structures or by their encapsulation in liposomal or polymeric formulations (*4*). In order to improve delivery efficiency and avoid high levels of dosing to achieve therapeutic drug levels, new conjugation methods to attach drugs to polymer materials are needed (*5*−*6*).

A number of polymer−drug conjugates have been reported to enhance drug solubility and stability in aqueous media, in turn providing longer circulation time of the drug in the bloodstream relative to the nonconjugated drugs (*7*−*10*). In addition, the high molecular weight of the polymer−drug conjugates enables tumor targeting by the enhanced permeability and retention effect (*11*). Polymer−drug conjugates that utilize poly(ethylene glycol) (PEG), *N*-(2-hydroxypropyl)methacrylamide (HPMA), and poly(glutamic acid) (PGA) as the polymeric component have been investigated, as have a variety of polymer architectures including linear, graft, and dendritic systems (*12*−*17*). The conjugates are too large to permeate the vasculature of healthy tissue, and thus preferably enter the leaky vasculature of cancerous tissue, where they accumulate due to poor lymphatic drainage in this environment. Following localization in cancer tissue, the polymer−drug conjugates can be taken up by cancer cells through endocytosis, then may be delivered to the lysosomal compartment. The relatively acidic environment of the lysosome makes attractive the use of acid-cleavable linking groups between the polymer and the drug (*18*).

Here, we present the synthesis of a water-soluble form of camptothecin by its conjugation to a PEGylated aliphatic polyester graft copolymer. Aliphatic polyesters are particularly attractive as biomaterials and drug delivery vehicles, as their in vivo degradation products are relatively benign (*19*). However, conventional aliphatic polyesters are insoluble in water, and thus not inherently well-suited for aqueous-based injectable formulations. Moreover, water-soluble PEG−aliphatic polyester diblock copolymers have drug carrying capabilities limited to physical encapsulation and/or substitution at the PEG chain end(s) with one (or two) drug molecules.

EXPERIMENTAL PROCEDURES

Materials. 6-Bromohexanoic acid (98%), bromotris(triphenylphosphine) copper(I) (98%), 20(*S*)-camptothecin (95%), copper(II) sulfate pentahydrate (>98.0%), *N*,*N*′-dicyclohexylcarbodiimide (DCC) (99%), *N*,*N*-diisopropylethylamine (≥99%), (4-(dimethylamino)pyridine (DMAP) (99%), and sodium azide (99.5%) were obtained from Aldrich. Sodium ascorbate (crystalline) was purchased from Source Naturals. Dialysis tubing (Spectra/Por Membrane MWCO 6−8000) was obtained from VWR. CH_2Cl_2 was washed according to standard procedures and distilled over CaH_2. All other materials were used without further purification.

Instrumentation. NMR spectra were recorded on $CDCl_3$ solutions using a Bruker DPX300 or Bruker Avance400 spectrometer ($\omega^{13}_C = 0.25^*\omega^1_H$) with residual solvent signal as calibration. Molecular weights and polydispersity indices were measured by gel permeation chromatography in THF relative to polystyrene standards (Scientific Polymer Products M_n = 503, 700, 1306, 2300, 4760, 12 400, 196 700, and 556 000 g/mol) on a system equipped with a three-column set (Polymer Laboratories 300 × 7.5 mm; 5 μm; 10^{-5}, 10^{-4}, and 10^{-3} Å pore sizes) and a refractive-index detector (HP 1047A) at room temperature with a flow rate of 1 mL/min. High-resolution mass spectral (HRMS) data were obtained on a JEOL JMS700 MStation. IR absorbance data was obtained on a Perkin-Elmer Spectrum One FT−IR spectrometer equipped with a universal ATR sampling accessory.

Synthesis of 6-Azidohexanoic Acid (2). 6-Bromohexanoic acid (5.0 g, 25.6 mmol) and sodium azide (8.37 g, 128 mmol)

were dissolved in DMSO and stirred at room temperature for 8 h. The reaction mixture was then dissolved in CH_2Cl_2, washed with water, brine, and $NaHCO_{4(aq)}$, dried over $MgSO_4$, and concentrated by rotary evaporation. Residual DMSO was removed by Kugelrohr distillation at 120 °C. Distillation at 160 °C gave 6-azidohexanoic acid **2** as a colorless liquid (2.98 g, 74%). MS-ESI (*m*/*z*): $[M + Na]^+$ calculated for $C_6H_{11}N_3O_2$ 180.1, found 180.1. ^{1}H NMR ($CDCl_3$, 300 MHz): δ ($CHCl_3$ = 7.26 ppm) 11.43 (br, 1H, COO*H*), 3.28 (t, 2H, CH_2N$_3$), 2.38 (t, 2H, CH_2COOH), 1.65 (m, 4H, CH$_2$CH_2CH$_2$CH_2CH$_2$), 1.43 (m, 2H, CH$_2$CH$_2$CH_2CH$_2$CH$_2$) ppm. ^{13}C NMR ($CDCl_3$, 75 MHz): δ ($CHCl_3$ = 77.0 ppm) 180.1 (*C*═O), 51.2 (*C*H$_2$N$_3$), 33.9 (*C*H$_2$COOH), 28.5 (*C*H$_2$CH$_2$N$_3$), 26.2 (*C*H$_2$CH$_2$CH$_2$N$_3$), 24.2 (*C*H$_2$CH$_2$COOH) ppm. IR(ATR): N═N═N 2090 cm^{-1}.

Synthesis of Camptothecin Azide (3) Camptothecin (100 mg, 0.27 mmol), 6-azidohexanoic acid **2** (85 mg, 0.54 mmol), and DMAP (4 mg) were dissolved in CH_2Cl_2 (5 mL). DCC (110 mg, 5.4×10^{-1} mmol) was added, and the solution was stirred at room temperature for 8 h. The reaction mixture was then precipitated into diethyl ether (50 mL) and isolated by filtration. Recrystallization from MeOH/CH_2Cl_2 (95:5) gave camptothecin azide **3** as a slightly yellow, crystalline solid (114 mg, 87%). HRMS-EI (*m*/*z*): $[M]^+$ calculated for $C_{26}H_{25}N_5O_5$ 487.186, found 487.186. ^{1}H NMR ($CDCl_3$, 300 MHz): δ ($CHCl_3$ = 7.26 ppm) 8.40 (s, 1H, C-16*H*), 8.23 (d, J = 8.4 Hz, 1H, C-18*H*), 7.95 (d, J = 8.4 Hz, 1H, C-21*H*), 7.84 (t, J = 6.8 Hz, 1H, C-19*H*), 7.67 (t, J = 7.6 Hz, 1H, C-20*H*), 7.21 (s, 1H, C-25*H*), 5.70 (d, J = 17.2 Hz, 1H, C-11H_2), 5.43 (d, J = 17.2 Hz, 1H, C-11H_2), 5.29 (s, 2H, C-14*H*), 3.22 (t, J = 6.8 Hz, 2H, C-1H_2), 2.51 (m, 2H, C-5H_2), 2.28 (m, 1H, C-8H_2) 2.16 (m, 1H, C-8H_2), 1.67 (m, 2H, C-2H_2), 1.62 (m, 2H, C-4H_2), 1.43 (m, 2H, C-3H_2), 0.98 (t, J = 7.2 Hz, 2H, C-9H_3) ppm. ^{13}C NMR ($CDCl_3$, 75 MHz): δ ($CHCl_3$ = 77.0 ppm) 172.5 (*C*═O$_{\text{lactone C−10}}$), 167.7 (*C*═O$_{\text{ester C−6}}$), 157.5, 152.5, 149.0, 146.4, 146.0, 131.4, 130.9, 129.7, 128.6, 128.4, 128.3, 128.2, 120.4, 96.0, 75.9, 67.2, 51.3 (*C*H$_2$N$_{3\ C-1}$), 50.1, 33.7, 32.0, 28.6, 26.2, 24.3, 7.7 (*C*H$_{3\ C-9}$) ppm. IR (ATR): N═N═N 2096 cm^{-1}.

Synthesis of Polyester−Camptothecin Conjugate (4). Aliphatic polyester **1** (52 mol % acetylene, $M_n = 9.2 \times 10^3$ g/mol, PDI = 1.17, 500 mg, 2.1 mmol acetylene) was dissolved in CH_2Cl_2 (2 mL) in a small reaction vessel. Camptothecin azide **3** (205 mg, 0.42 mmol, *N*,*N*-diisopropylethylamine (31 μL, 0.16 mmol), and bromotris(triphenylphosphine) copper(I) (77 mg, 8.4×10^{-2} mmol), to target 20 mol % camptothecin grafting, were then added sequentially, and the reaction mixture was stirred at room temperature for 48 h. The crude reaction mixture was precipitated into ether (50 mL) and isolated by filtration. The resulting solid was then dissolved in CH_2Cl_2 (2 mL) and dialyzed against pure CH_2Cl_2 (400 mL) for 48 h. Removal of the solvent and washing with cold hexanes (5 mL) afforded polyester−camptothecin conjugate **4** as a slightly yellow, viscous liquid (580 mg, 82%). GPC (THF): $M_n = 14.3 \times 10^3$ g/mol, PDI = 1.19, 18 mol % camptothecin grafting. ^{1}H NMR ($CDCl_3$, 300 MHz): δ ($CHCl_3$ = 7.26 ppm) 8.41 (s, 1H, camptothecin **3** C-16*H*), 8.20 (d, J = 8.3 Hz, 1H, camptothecin **3** C-18*H*), 7.94 (d, J = 8.3 Hz, 1H, camptothecin **3** C-21*H*), 7.86 (t, J = 6.9 Hz, 1H, camptothecin **3** C-19*H*), 7.67 (m, 1H, camptothecin **3** C-20*H*), 7.37 (m, 1H, R$_2$C═C*H*), 7.19 (s, 1H, camptothecin **3** C-25*H*), 5.68 (d, J = 15.2 Hz, 1H, camptothecin **3** C-11H_2), 5.40 (d, J = 15.3 Hz, 1H, camptothecin **3** C-11H_2), 5.29 (s, 2H, camptothecin **3** C-14*H*), 4.25 (br, 2H, CH_2NR$_2$ camptothecin **3**), 4.04 (br, 4H, CH_2OC═O polyester), 3.22 (t, J = 6.6 Hz, 2H, camptothecin **3** C-1H_2), 3.01 (br, 2H, R$_2$CHCH_2 polyester), 2.51 (m, 2H, camptothecin **3** C-5H_2), 2.35 (br, 4H, C═OC*H* polyester + C═OCH_2 polyester + camptothecin **3** C-8H_2), 2.15 (m, 1H, camptothecin **3** C-8H_2), 2.03 (m, 1H, C≡C*H* polyester), 1.65 (br m, 12H, CH_2CH_2CH$_2$O polyester + CH_2CH$_2$CH_2CH$_2$O polyester + camptothecin **3** C-2H_2 + camptothecin **3** C-4H_2), 1.36 (br m, 4H, CH_2CH$_2$CH$_2$O polyester + camptothecin **3** C-3H_2), 0.95 (t, J = 7.1 Hz, 2H, camptothecin **3** C-9H_3) ppm. ^{13}C NMR ($CDCl_3$, 75 MHz): δ ($CHCl_3$ = 77.0 ppm) 174.2 (*C*═O polyester), 173.4 (*C*═O polyester), 172.5 (*C*═O camptothecin **3** C-10), 167.6 (*C*═O camptothecin **3** C-6), 157.5, 152.5, 149.0, 146.4, 146.0, 144.5, 131.4, 130.9, 129.7, 128.6, 128.3, 128.3, 128.2, 122.5, 120.4, 96.0, 75.9, 67.2, 64.6, 64.1, 53.3, 50.1, 49.9, 44.7, 34.1, 33.7, 32.1, 28.6, 28.4, 27.6, 26.2, 25.9, 25.4, 24.5, 24.3, 7.7 (*C*H$_3$ camptothecin **3** C-9) ppm.

Synthesis of PEG-Grafted Polyester−Camptothecin Conjugate (5). Polyester−camptothecin conjugate **4** (580 mg, 1.4 mmol acetylene) was dissolved in a minimal amount of acetone and added by syringe to a rapidly stirred solution of azide-functionalized PEG-1100 (1.8 g, 1.5 mmol) in water (2 mL). Sodium ascorbate (120 mg, 6.0×10^{-1} mmol) and copper(II) sulfate (150 mg, 6.0×10^{-1} mmol) were added, and the resulting dispersion was heated to 80 °C overnight. The crude reaction mixture was then diluted with water (50 mL) and extracted five times with CH_2Cl_2 (50 mL). The combined organics were dried over $MgSO_4$ and concentrated by rotary evaporation. The resulting solid was then dissolved in PBS (2 mL) and dialyzed against pure PBS for 48 h to remove residual PEG-azide. After removal of the solvent, the product was dissolved in acetone (2 mL) and precipitated into cold hexanes (50 mL). The product was isolated by filtration and dried in a vacuum oven overnight to give PEG-grafted polyester−camptothecin conjugate **5** as an off-white powder (1.80 g, 76%). GPC (THF): $M_n = 23.5 \times 10^3$ g/mol, PDI = 1.20. ^{1}H NMR ($CDCl_3$, 300 MHz): δ ($CHCl_3$ = 7.26 ppm) 8.42 (s, 1H, camptothecin **3** C-16*H*), 8.17 (d, J = 8.3 Hz, 1H, camptothecin **3** C-18*H*), 7.94 (d, J = 8.3 Hz, 1H, camptothecin **3** C-21*H*), 7.84 (t, J = 6.7 Hz, 1H, camptothecin **3** C-19*H*), 7.66 (m, 1H, camptothecin **3** C-20*H*), 7.51 (br, 1H, R$_2$C═C*H* PEG), 7.46 (br, 1H, R$_2$C═C*H* camptothecin), 7.18 (s, 1H, camptothecin **3** C-25*H*), 5.66 (d, J = 14.9 Hz, 1H, camptothecin **3** C-11H_2), 5.40 (d, J = 14.9 Hz, 1H, camptothecin **3** C-11H_2), 5.28 (s, 2H, camptothecin **3** C-14*H*), 4.48 (m, 2H, R$_2$NCH_2), 4.26 (br, 2H, CH_2NR$_2$ camptothecin **3**), 4.02 (br, 2H, CH_2OC═O polyester), 3.84 (t, J = 5.15 Hz, 2H, R$_2$NCH$_2$CH_2), 3.61 (br m, 96H, CH_2CH_2O PEG), 3.43 (t. RESULTS AND DISCUSSION

We recently reported the preparation of novel, water-soluble PEGylated aliphatic polyester graft copolymers by the controlled ring-opening polymerization of alkyne-functionalized lactones, followed by PEGylation of the polyester by click chemistry with azide-terminated PEG (*20*). Tailored graft densities of PEG were achieved by copolymerization of unfunctionalized lactones (i.e., ϵ-caprolactone) with the acetylene-functionalized derivatives. These aliphatic polyesters proved soluble in water when ~25

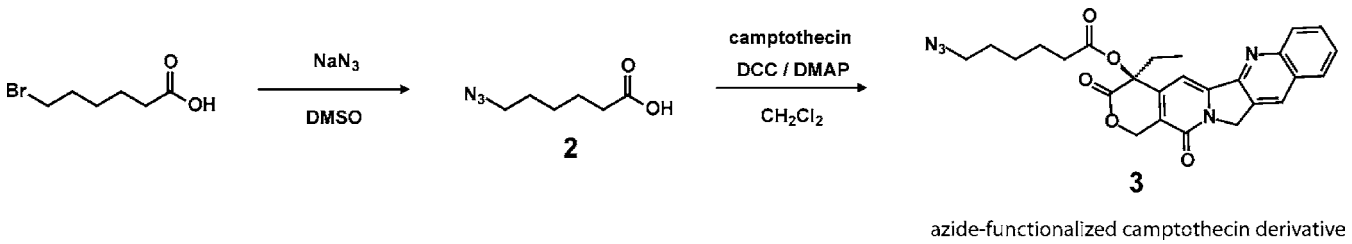

Figure 1. Synthesis of azide-functionalized camptothecin derivative **3** by carbodiimide coupling of camptothecin with 6-azidohexanoic acid **2**.

mol % of the monomer units in the backbone were grafted with PEG 1100 g/mol (~70 wt % PEG), using click chemistry. This provides the opportunity to intentionally leave unreacted acetylene in the backbone for additional click cycloaddition reactions. Click chemistry is useful for functionalization of aliphatic polyesters, as unlike the wide variety of acid- or base-induced chemistries, the mild nature of click chemistry allows it to occur in the absence of polyester degradation. The particular click chemistry employed here is the Cu(I)-catalyzed cycloaddition of azides and alkynes to give triazoles, which has been demonstrated, for example, by Sharpless and Fokin (*21*) to be efficient, selective, and tolerant of many functional groups, and thus advantageous not only for maintaining the integrity of the polyester backbone following conjugation but also potentially for conjugation of a variety of therapeutic drugs to the polymer backbone, as such drugs often contain numerous types of functionality that could interfere with conventional organic coupling reactions. In this study, we demonstrate the synthesis of water-soluble PEG- and camptothecin-functionalized aliphatic polyesters, where both PEGylation and camptothecin grafting is accomplished using click chemistry. For the camptothecin coupling, it was necessary to prepare the requisite azide derivative of the drug.

Sn(II)-mediated ring-opening copolymerization of α-propargyl-δ-valerolactone and ϵ-caprolactone was conducted to give aliphatic polyester **1** with a nearly 1:1 ratio of the two monomers, as confirmed by integration of the ^{1}H NMR spectrum of the polymer. Gel permeation chromatography of polyester **1**, performed in THF against polystyrene molecular weight standards, gave an estimated number-average molecular weight (M_n) of 9200 g/mol and a polydispersity index (PDI, M_w/M_n) of 1.17. Click cycloaddition of camptothecin to the alkyne-functionalized polyester required the synthesis of an azide-functionalized camptothecin derivative. For this, esterification of camptothecin at the 20-OH position was carried out, as upon cleavage of the ester bond in aqueous-based delivery applications, the drug would be released in its active, unmodified form. Moreover, Greenwald and co-workers recently reported that PEG-esterification of camptothecin at the 20-OH position led to stabilization of the drug in its lactone form under physiological conditions, as characterized by NMR and UV−vis spectroscopy (*22*). Buffer hydrolysis experiments at different pH values further demonstrated that camptothecin remained in its lactone form until exocylic ester cleavage, at which point the active drug was released. Thus, on the basis of Greenwald's important study, we chose to integrate azides onto camptothecin using an ester linkage at the 20-OH position, for both enhanced aqueous stability of the conjugate and the ultimate release of free, unmodified camptothecin, leaving behind the degradable aliphatic polyester.

Azide-functionalized camptothecin **3** was prepared as shown in Figure 1. 6-Azidohexanoic acid **2** was obtained by nucleophilic substitution of 6-bromohexanoic acid with sodium azide in 74% yield after purification by Kugelrohr distillation. Compound **2** was characterized by ^{1}H NMR spectroscopy (methylene triplet $-CH_2N_3$ at 3.28 ppm, shifted slightly relative to the $-CH_2Br$ methylene group of the starting material at 3.42 ppm), ^{13}C NMR spectroscopy ($-CH_2N_3$ at 51.2 ppm), infrared spectrometry (azide signal at 2108 cm^{-1}), and mass spectrometry (MS ESI (*m*/*z*) $[M + Na]^+$ calcd 180.1, found 180.1). While azide **2** was reported previously as a synthetic intermediate (*23*), its detailed synthesis and characterization were not. α,ω-Azide-carboxylic acid **2** was then used to esterify camptothecin at the 20-OH position, using dicyclohexylcarbodiimide coupling conditions. This esterification occurred readily at room temperature in dichloromethane to give azide-functionalized camptothecin **3** in 87% yield after purification by crystallization from 95:5 MeOH/CH_2Cl_2. The structure of **3** was confirmed by ^{1}H and ^{13}C NMR spectroscopy, FTIR spectrometry (azide signal at 2096 cm^{-1}), and high-resolution mass spectrometry (HRMS-EI (*m*/*z*): $[M]^+$ calculated for $C_{26}H_{25}N_5O_5$ 487.186, found 487.186.

Coupling of acetylene-functionalized polyester **1** with camptothecin azide **3** was then performed by targeting 20 mol % camptothecin incorporation (or one camptothecin per five monomer repeat units). Initial attempts to use aqueous click chemistry for this coupling were unsuccessful, due to the poor aqueous solubility of both components. Thus, organic soluble copper(I) catalysts for click chemistry were used as alternatives (*24*−*25*); bromotris(triphenylphosphine) copper(I) with *N*,*N*-diisopropylethylamine in dichloromethane solution was found to be effective for the cycloaddition of camptothecin azide **3** and acetylene-functionalized polyester **1**, as shown in Figure 2a. The reaction was complete in 48 h, at which point the crude polymer−drug conjugate was precipitated into ether. The resulting solid was dissolved in CH_2Cl_2 and dialyzed against pure CH_2Cl_2 using a Spectra/Por Membrane MWCO 6−8000. Removal of the solvent and washing with cold hexanes gave polyester−camptothecin conjugate **4** as a slightly yellow, viscous liquid in 82% yield. ^{1}H NMR spectroscopy of **4** revealed signals characteristic of both camptothecin and the aliphatic polyester backbone, with new signals at 7.37 and 4.25 ppm, corresponding to the triazole proton $R_2C{=}CHR$ and the methylene group adjacent to the triazole CH_2NR, respectively. The relative integrations of the signals at 4.04 ppm (CH_2O polyester backbone) and 4.25 ppm (CH_2-triazole) indicated a nearly quantitative incorporation of camptothecin azide **3** into the polyester backbone. GPC analysis in THF indicated a substantial increase in molecular weight, from $M_n \approx 9200$ g/mol before conjugation to ~14 300 after conjugation of the drug. The narrow polydispersity (PDI = 1.19) of the polyester−camptothecin product demonstrated that these click cycloaddition conjugation conditions caused no substantial degradation of the polyester, a key feature of click chemistry that makes it especially attractive for polyester modification.

While these hydrophobic polymer−drug conjugates can in principle be used to prepare hydrophobic aliphatic polyester microparticles with covalently bound camptothecin, further grafting, for example, with PEG, is necessary to impart water solubility to the conjugate. In the ^{1}H NMR spectrum of **4**, the signal at 2.03 ppm ($-C{\equiv}C-H$) indicated the presence of substantial residual alkyne (~30−35 mol %) available for further coupling, as expected from the use of camptothecin azide **3** as the limiting reagent. Click cycloaddition of these residual acetylene groups with azide-terminated PEG (*19*) (i.e., CH_3O-

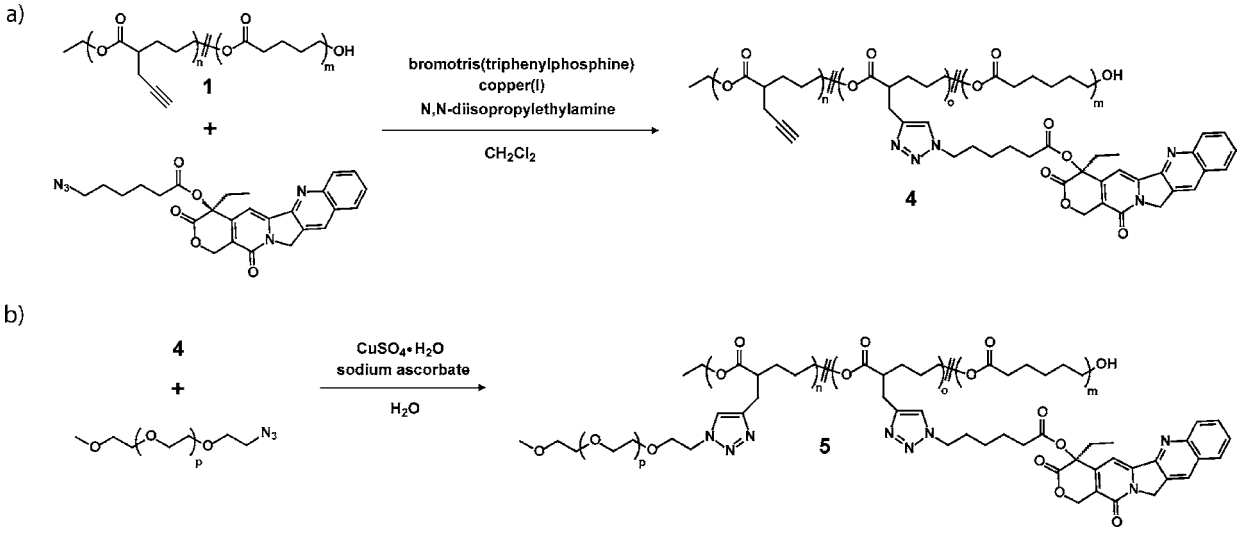

Figure 2. (a) Preparation of hydrophobic polyester−camptothecin conjugate **4** by click cycloaddition of azide-functionalized **3** to acetylene-functionalized copolymer **1** and (b) preparation of hydrophilic PEG-grafted polyester−camptothecin conjugate **5** by further grafting of conjugate **3** with PEG−azide.

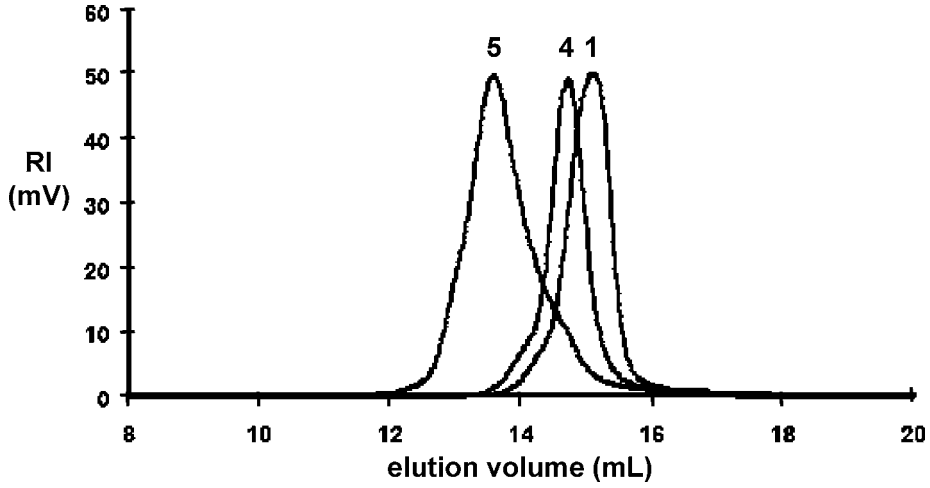

Figure 3. Gel permeation chromatography traces (THF relative to polystyrene standards) of acetylene-functionalized polyester **1**, polyester−camptothecin conjugate **4**, and PEG-grafted polyester−camptothecin conjugate **5**.

PEG−N_3; M_n = 1100), as shown in Figure 2b, was performed successfully in water. The acetylene-containing polyester was dissolved in a minimal amount of acetone, then added to a rapidly stirred, aqueous solution of azide-terminated PEG to ensure good dispersion. Copper sulfate and sodium ascorbate were then added, and the resulting reaction mixture heated to 80 °C and stirred overnight. Purification of the PEGylated camptothecin−polyester conjugate **5** was performed by extraction into CH_2Cl_2, dialysis in phosphate buffered saline, and finally precipitation into cold hexanes to give a slightly yellow, semicrystalline solid in 74% yield. Successful grafting of both the PEG and camptothecin components onto the aliphatic polyester backbone was confirmed by ^{1}H NMR spectroscopy of **5**, by the triazole proton resonance from the camptothecin (7.36 ppm, $R_2C{=}CHR$) and PEG (7.51 ppm, $R_2C{=}CHR$) grafts, as well as methylene signals at 4.26 and 4.48 ppm, corresponding to the R_2NCH_2 groups from the camptothecin and PEG grafts, respectively. The relative integrations of the NMR signals at 4.46 (2H−PEG), 4.23 (2H−camptothecin), and 4.04 (2H−polyester backbone) ppm indicated a grafting density, in terms of percent monomers containing the grafts, of ∼18% camptothecin and ∼33% PEG. GPC analysis of **5**, shown in Figure 3, gave an estimated M_n of ∼23 500 g/mol, a significant increase over the polyester−camptothecin conjugate **4**. Moreover, the narrow polydispersity of **4** was maintained in **5** (PDI ≈ 1.20), again confirming the absence of degradation reactions during the coupling procedure.

Importantly, PEG grafting had a tremendous influence on the solubility properties of the polyester−camptothecin conjugate **5**, which proved highly soluble in water, as well as many organic solvents (e.g., acetone, DMSO, and CH_2Cl_2), due to the amphiphilicity of PEG. The water solubility of this conjugate, coupled with the biodegradable features of the polyester backbone, holds potential for enhancing the ability of camptothecin to be used in polymer therapeutics. Future studies will center on active targeting of the conjugate by the incorporation of oligopeptide sequences (*26*), as well as pH-dependent release of camptothecin from the backbone and in vitro cytotoxicity toward cancer cell lines. In addition, the convenient synthesis of camptothecin azide **3** reported here may prove useful for click cycloaddition to other polymer scaffolds, oligopeptide sequences, and/or modified proteins.

Direct Ring Conjugation of Catecholamines and Their Immunological Interactions

John S. Mitchell,[†,‡] Yinqiu Wu,*[,†] Christian J. Cook,[†] and Lyndsay Main[‡]

Bioengineering Sector, HortResearch, East Street, Private Bag 3123, Hamilton, New Zealand, and Department of Chemistry, University of Waikato, Private Bag 3105, Hamilton, New Zealand. Received July 17, 2006; Revised Manuscript Received October 26, 2006

Catecholamine derivatives were synthesized with potential applications as coating antigens in biosensors or in the raising of specific antibodies. Thioether-bridged derivatives of the catecholamines dopamine, norepinephrine, and epinephrine that attach carboxylic acid functionalities directly to the aromatic ring via an easily incremented linker chain were synthesized by an electrochemical method. These derivatives were purified by convenient ion-exchange chromatography, exact positions of conjugation determined by NMR, and a dopamine derivative immobilized in situ in a BIAcore surface plasmon resonance (SPR) biosensor and its antibody binding studied in comparison with immobilization via the catecholamine primary amine. Binding of an antibody raised to an amine-conjugated protein conjugate showed clear distinction between conjugations at different positions on the catecholamine, illustrating the importance of rational conjugate design in immunosensing of the catecholamines.

INTRODUCTION

For small molecules with few functional groups and relatively simple shape, such as the catecholamine neurotransmitters, the formation of conjugates to the molecule for recognition by specific antibodies or for the generation of specific antibodies requires a conjugation that does not disrupt existing functional groups and has the minimum effect on the overall shape of the hapten. To date, conjugations of the catecholamines have relied upon attachment via the primary amine of the neurotransmitter, principally through the formation of a glutaraldehyde-mediated linkage (*1*−*4*) or through Mannich conjugations *ortho* to the hydroxyl moieties (*5*). Glutaraldehyde and carbodiimide conjugations compromise the primary amine and have been shown to alter the charge state in the hapten and sterically alter the hapten structure (*6*). Furthermore, antibodies raised to such conjugates have been demonstrated to bind much more strongly to the original conjugate than to the free catecholamine (*3*). Similar binding has also been observed with Mannich conjugation (*5*, *7*), and Mannich reactions require protection of the primary amine before conjugation and result in a mixture of isomeric conjugation products (*8*, *9*).

There is a clear need to develop a new conjugation technique for attachment to catecholamines that is not via existing functional groups and for which purified products with a known conjugation position can be produced. Such conjugations when used to link the antigen to a carrier protein could in the future be used to raise specific antibodies able to recognize all the functional groups of the antigen that would have extensive applications in neurological and immunological research and immunoassay development.

This conjugation technique could also be used in the formation of biosensor surfaces for detection of important catecholamines in biological fluid. Catecholamine immunoassay in body fluids is important for evaluation of the activity of the sympathetic nervous system (*10*) and for supporting diagnosis of many diseases including the biochemical detection of catecholamine-secreting tumors such as pheochromocytoma (*11*). Catecholamine biosensors to date have usually relied upon immobilization of antibodies or enzymes on sensor surfaces mainly for electrochemical detection (*12*, *13*), but the ability to conjugate the antigen to a sensor surface and still retain specific antibody binding would allow a range of optical biosensor formats to be used. Flow-through surface plasmon resonance (SPR)[11] immunoassay and antibody and receptor binding studies require a high mass agent to bind to the surface to generate the signal (*14*, *15*), which means that the small-molecule antigen must be immobilized to the sensory surface or a high mass label (*16*, *17*). Until now, there has been no means of doing this for the catecholamines without substantially compromising the existing functional groups on the molecule that are essential to specific antibody or receptor recognition. The attachment of colorimetric, fluorescent, and enzymatic labels to the catecholamines to produce conjugates capable of strong and specific recognition by receptors in biological samples would also benefit from this type of conjugation.

Thioether conjugation direct to the aromatic rings of the catecholamines offers a potential route for production of conjugates that retain the original antigen functional groups intact. Such conjugations using cysteine and glutathione are known in nature for the metabolism of catecholamines (*18*−*20*) and estrogens (*21*) but have not been used as a synthetic method for conjugations used in antibody binding. We report the synthesis of a range of thioether conjugates direct to the aromatic ring of the catecholamines dopamine, norepinephrine, and epinephrine and the ion-exchange purification of these and clear identification of the conjugation position by NMR. We also report the antibody binding interactions of dopamine-conjugated surface plasmon resonance (SPR) biosensor surfaces and examine the effect of different ring conjugation positions and linker lengths on antibody binding.

EXPERIMENTAL PROCEDURES

General. All chemicals were purchased from Sigma Aldrich (Milwaukee, WI). The dopamine was used as the racemate, and

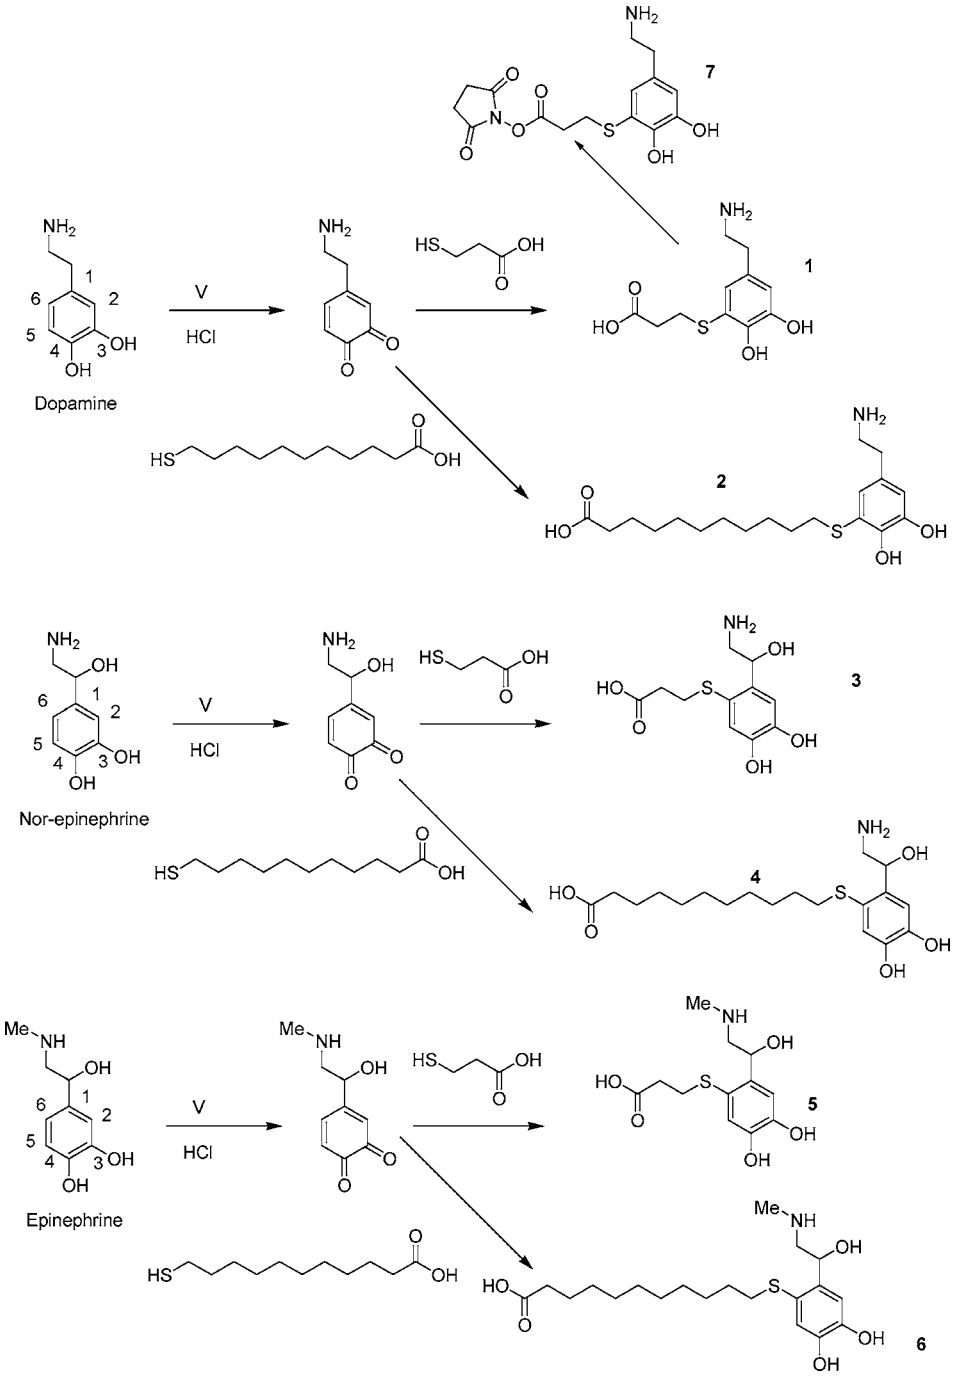
the norepinephrine bitartrate and epinephrine were used as the R-isomer. All solvents were analytical grade except for HPLC solvents (HPLC grade). The silica gel for column chromatography was Merck 60 Å, grade 9385, 230−400 mesh. Melting point determinations were done using a Reichert Thermopan instrument and were uncorrected. ^{1}H, ^{13}C, and DEPT 135 NMR spectra were obtained on Bruker AC300 300 MHz and Bruker Avance 400 MHz spectrometers. Chemical shifts (ppm) were referenced to tetramethylsilane. Low-resolution mass spectra were obtained on a VG Platform II electrospray mass spectrometer (ESI-MS). High-resolution mass spectra were obtained on a VG-70SE mass spectrometer with *MASPEC 2* data analysis software. BIAcore SPR analysis was done on a BIAcore 3000 instrument (BIAcore, Inc., Piscataway, NJ) using CM5 research-grade chips and 10 mM (*N*-[2-hydroxyethyl]piperazine-*N*′-[2-ethanesulfonic acid]), 150 mM NaCl with 0.11% w/v ethylenediaminetetraacetic acid, and 0.05% v/v P-20 surfactant, pH 7.4, as running buffer. All BIAcore experiments were performed at 25 °C. The monoclonal antibody used was mouse anti-human dopamine (US Biological, Swampscott, U.S.A., D-9000) raised to dopamine−bovine serum albumin conjugate, conjugated through the primary amine by the glutaraldehyde method, and with an affinity of $\sim 1 \times 10^7$ L/M.

HPLC was performed on a Shimadzu instrument and data analyzed using *Class-VP* software (5.032 1999). The reversed-phase HPLC column used was a Prodigy 3 μm ODS 100 × 4.6 mm, 00D-4243-E0, 111274−4 from Phenomenex (Milford, New Zealand). All mobile phases were filtered (Nylon 0.45 μm filter) and degassed before use. The mobile phases were as follows: A = 50%v/v MeCN pH 2.15 (adjusted with TFA), B = 5% MeCN pH 2.15. All experiments were done at 40 °C oven temperature and flow rate of 1 mL/min. All tubing was stainless steel. The ion-exchange column was a Dowex-50W strongly acidic cation-exchange resin column (10 g dry resin, slurry packed in deionized water with final bed dimensions of 150 mm × 15 mm). The resin was cleaned thoroughly before use with cycles of deionized water, acetone, methanol, deionized water, 2 M HCl, and deionized water and then vacuum-dried after diethyl ether wash.

Positions of attachment for the catecholamines were determined by analysis of cross-peaks in homonuclear correlated spectroscopy (COSY) and nuclear Overhauser enhancement spectroscopy (NOESY) 2D-NMR spectra. A positive cross-peak in the NOESY and no cross-peak in the COSY suggest attachment at the 5-position, no NOESY cross-peak and a cross-peak in the COSY suggest attachment at the 2-position, and no cross-peaks suggests attachment at the 6-position (numbering as indicated in Scheme 1). Analytical RP-HPLC was performed to determine compound purity using the same HPLC apparatus as above. Retention times (t_R) are provided with the compound experimentals. All reported binding response differences in SPR were analyzed by the Student's *t*-test and found to be significant ($P < 0.05$). Errors quoted are standard errors.

3-(5-(2-Aminoethyl)-2,3-dihydroxyphenylthio)propanoic Acid (1). Dopamine (30 mg, 0.158 mmol) was dissolved in 0.1 M HCl (80 mL). A 2 V potential difference was applied for 3 h between graphite bar electrodes and *o*-quinone formation monitored by HPLC. 10% v/v 3-mercaptopropionic acid (MPA) solution (413 μL, 0.473 mmol in 0.1 M HCl) was then added rapidly with vigorous stirring. After 18 h, the reaction mixture pH was adjusted to 5 with NaOH and the solution poured into the ion-exchange column. The column was flushed with deionized water until no more MPA could be seen by HPLC, and the column was then flushed with HCl (1 M) and ethanol (10% v/v). Yield: 34% (14 mg, 0.0545 mmol). mp: decomposes. IR (KBr disc): 1241, 1400, 1638, 3434. ^{1}H NMR (D_2O) δ: 2.49 (2H, t, J = 7.9 Hz, CH_2-COO^-), 2.72 (2H, t, J = 9.2 Hz, CH_2-Ar), 2.95 (2H, t, J = 7.0 Hz, CH_2-S), 3.07 (2H, t, J = 9.2 Hz, CH_2-N), 6.68 (1H, s, 2-H), 6.77 (1H, s, 6-H). ^{13}C NMR (D_2O) δ: 28.6, 32.0, 34.1, 40.6, 116.5, 120.5, 125.3, 129.3, 144, 144.5. ESI-MS *m*/*z* (MeCN/H_2O 1:1 5 V) 258.9 $[M + H]^+$. HPLC: purity 95%, t_R = 7.2 min (100% B, 0−6.5 min; 100−50% B, 6.5−11 min).



11-(5-(2-Aminoethyl)-2,3-dihydroxyphenylthio)undecanoic Acid (2). Dopamine (30 mg, 0.158 mmol) was dissolved in HCl solution (80 mL, 0.2 M in 1:1 MeCN/H_2O) and electrolyzed at 2 V with vigorous stirring for 2.5 h. 11-Mercaptoundecanoic acid (MUA) (104 mg, 0.475 mmol, in 6 mL of 50% v/v MeCN, 0.2 M HCl total) was added rapidly to the vigorously stirring solution. After 1 h, the pH was adjusted to 5 with NaOH. The solution was run into the ion-exchange column, and the column was then washed extensively with 50% v/v MeCN to remove all MUA. HPLC analysis revealed that MUA alone eluted through the column and all other compounds were retained.

The column was then eluted with the following elution scheme to separate the products and reactant chromatographically: 10% v/v EtOH 1 M HCl total, 20% v/v EtOH 1 M HCl total, 30% v/v EtOH 1 M HCl total, 40% v/v EtOH 1 M HCl total, 50% v/v EtOH 1 M HCl total, 20% v/v EtOH 2 M HCl total. Fractions were combined and solvent removed in vacuo. Yield: 16% (9.2 mg, 0.025 mmol). IR (film): 1413, 1638, 2855, 2929, 3437 cm^{-1}. ^{1}H NMR (D_2O) δ: 1.21 (10H, main chain CH_2 of MUA), 1.36 (2H, MUA), 1.56 (4H, MUA), 2.36 (2H, CH_2-COO^-), 2.87 (2H, CH_2-S), 2.88 (2H, CH_2-Ar), 3.22 (2H, CH_2-N), 6.78 (1H, m, 2-H), 6.88 (1H, m, 6-H). ^{13}C NMR (D_2O) δ: 24.3, 28.3, 32.1, 33.3, 33.9, 40.6, 115.5, 122.6, 123.8, 129.3, 143.0, 144.4, 179.1. ESI-MS *m*/*z* (CH_3CN/H_2O 1:1) 370.6 $[M + H]^+$. HRMS: Calcd. 370.2052, found 370.2047 MH^+. HPLC: purity 94%, t_R = 7.7 min (100−50% B, 0−4 min; 50−0% B, 4−8 min; 0% B 8−13.5 min).

3-(2-(2-Amino-1-hydroxyethyl)-4,5-dihydroxyphenylthio)-propanoic Acid (3). Norepinephrine bitartrate (40 mg, 0.125 mmol) was dissolved in HCl solution (80 mL; 0.1 M) and electrolyzed at 2 V until maximum conversion to *o*-quinone was observed (2 h). MPA (328 μL of 1/10 solution in 0.1 M HCl, 0.375 mmol) was added with rapid stirring. The reaction was stirred vigorously for 18 h. The reaction mixture was adjusted to pH 5 with NaOH before eluting into the ion-exchange column, the column then being flushed with deionized water until no more MPA was visible eluting from the column. The column was then eluted using the following eluant scheme: 100 mL 0.01 M HCl, 100 mL 0.1 M HCl, 100 mL 0.1 M HCl 10% v/v EtOH, 100 mL 0.2 M HCl, 460 mL 0.4 M HCl, 100 mL 0.3 M HCl 10% v/v EtOH, 100 mL 0.3 M HCl, 700 mL 0.4 M HCl. Yield 41% (14 mg, 0.0512 mmol). IR (film): 1193, 1470, 1633, 3450 cm^{-1}. ^{1}H NMR (D_2O) δ: 2.67 (2H, t, J = 7.2 Hz, CH_2-COO^-), 3.15 (2H, m, CH_2-S), 3.27 (2H, m, CH_2-N), 4.55 (1H, s, CH−OH), 6.91 (1H, s, 2-H), 7.07 (1H, s, 5-H). ^{13}C NMR (D_2O) δ: 40.5, 41.0, 123, 129, 139. ESI-MS *m*/*z* (MeCN/H_2O 1:1, 20 V) 274.3 $[M + H]^+$. HPLC: purity 94%, 3.31 min (100% B, 0−6.5 min; 100−50% B, 6.5−11 min).

11-(2-(2-Amino-1-hydroxyethyl)-4,5-dihydroxyphenylthio)undecanoic Acid (4). Norepinephrine bitartate (40 mg, 0.125 mmol) was dissolved in HCl solution (80 mL; 0.2 M in 1:1 MeCN/H_2O) and electrolyzed at 2 V until maximum conversion to *o*-quinone was observed (2 h). MUA (82 mg, 0.375 mmol in 5 mL of 0.2 M HCl in 1:1 MeCN/H_2O) was added quickly to the rapidly stirring solution. The solution was stirred for 18 h. The reaction mixture was pH-adjusted to 5 with 2 M NaOH and 0.1 M NaOH and then eluted into the column and the column flushed with 50% v/v acetonitrile in deionized water until all the MUA had eluted according to the HPLC analysis. The column was then eluted using the following elution

Scheme 1. Reaction Scheme for the Synthesis of Thioether Derivatives of the Catecholamines Dopamine, Norepinephrine, and Epinephrine Presenting Carboxylic Acid Functionalities for Linker Attachment and Conjugation

scheme: 0.4 M HCl, 0.6 M HCl, 0.6 M HCl total 10% v/v EtOH, 0.6 M HCl total 20% v/v EtOH, 0.8 M HCl total 10% v/v EtOH, 1 M HCl total 10% v/v EtOH, 1 M HCl total 20% v/v EtOH, 1 M HCl total 30% v/v EtOH, 1 M HCl total 20% v/v EtOH, 1 M HCl total 30% v/v EtOH. Yield 28% (14 mg, 0.0353 mmol). IR (film): 1456, 1616, 3394, 3429 cm^{-1}. ^1H NMR (D_2O) δ: 1.15 (12H, m, MUA chain CH_2), 1.44 (4H, m, MUA CH_2), 2.26 (2H, m, CH_2-COO^-), 2.62 (2H, m, CH_2-S), 3.10 (2H, m, $CH_2-NH_3^+$), 6.92 (1H, m, 2-H), 7.07 (1H, m, 5-H). ^{13}C NMR (D_2O) δ: 24.3, 28.7, 115.8. ESI-MS *m/z* (MeCN/H_2O, 20 V): 386.5 $[M + H]^+$. HRMS: Calcd. 386.2001, found 386.2010 (MH^+). HPLC: purity 95%, t_R = 5.77 min (100−50% B, 0−4 min; 50% B−0% B, 4−8 min; 0% B, 8−13.5 min).

3-(4,5-dihydroxy-2-(1-hydroxy-2-(methylamino)ethyl)phenylthio)propanoic Acid (5). Epinephrine (30 mg, 0.164 mmol) was dissolved in aqueous HCl (0.1 M; 80 mL) and electrolyzed at 2 V until maximum *o*-quinone formation was observed by HPLC. MPA (428 μL, 0.491 mmol diluted 1/10 in 0.1 M HCl) was then added quickly to the rapidly stirring solution and stirred for 30 min. The product was purified by silica gel column chromatography using successively MeCN, 5% v/v H_2O in MeCN, 10% v/v H_2O in MeCN, 20% v/v H_2O in MeCN, 10% 0.01 M HCl in MeCN, 10% 0.1 M HCl in MeCN, 20% 0.1 M HCl in MeCN, 10% 1 M HCl in MeCN, 20% 2 M HCl in MeCN, and 2 M HCl. Yield: 21% (10 mg, 0.035 mmol) mp: decomposes. IR (KBr disc): 1123, 1638, 3447 cm^{-1}. ^1H NMR (D_2O) δ: 2.75 (3H, s, $NH-CH_3$), 2.86 (2H, t, J = 6.7 Hz, CH_2-COO^-), 3.01 (2H, t, J = 7.1 Hz, CH_2-S), 6.91−7.09 (2H, m, aromatics). ^{13}C NMR (D_2O) δ: 16.7, 28.7, 42, 57.4, 115, 117, 126, 130, 138, 140, 167. ESI-MS *m/z* (CH_3CN/H_2O 1:1, 30 V) 288.5 $[M + H]^+$. (H_2O, 5 V): 214.5 [M-amine side chain +

H]$^+$, 306.3 [M + H_2O + H]$^+$. HPLC: purity 96%, t_R = 7.0 min (100% B, 0−6.5 min; 100−50% B, 6.5−11 min).

11-(4,5-dihydroxy-2-(1-hydroxy-2-(methylamino)ethyl)-phenylthio)undecanoic Acid (6). Epinephrine (30 mg, 0.164 mmol) was dissolved in HCl solution (80 mL; 0.2 M in 1:1 MeCN/H_2O) and electrolyzed at 2 V until maximum *o*-quinone formation was observed by HPLC. MUA (107 mg, 0.491 mmol, in 9 mL 0.2 M HCl in 1:1 MeCN/H_2O) was added to the rapidly stirring solution and stirring continued for 18 h. The reaction was separated by silica gel column chromatography using successively MeCN, 5% H_2O in MeCN, 10% H_2O in MeCN, 20% H_2O in MeCN, and 10% 0.1 M HCl in MeCN. Yield: 36% (24 mg 0.0596 mmol). mp: decomposes. IR (KBr disc): 1120, 1638, 3437 cm^{-1}. ^{1}H NMR (D_2O) δ: 1.24 (10H, s, MUA chain CH_2), 1.33 (2H, m, MUA chain CH_2), 1.51 (2H, m, MUA chain CH_2 β to COOH), 1.66 (2H, m, MUA chain CH_2 β to S), 2.23 (2H, t, J = 9.8 Hz, CH_2−COOH), 2.71 (3H, m, N−CH_3), 2.84 (2H, m, CH_2−S), 3.13 (1H, m, CH−NH), 3.21 (1H, m, CH−NH), 6.87 (2H, m, aromatic). ^{13}C NMR (D_2O + CD_3OD) δ: 24.0, 27.8, 28.3, 28.5, 28.5, 33.1, 54.6, 68.4, 113.9, 114.5, 116.4, 118.7, 132.2. ESI-MS *m/z* (MeCN/H_2O 1:1, 40 V): 454.6 [M + MeOH + Na]$^+$. HPLC: purity 96%, t_R = 7.7 min (100% B−50% B, 0−4 min; 50−0% B, 4−8 min; 0% B, 8−13.5 min).

HPLC Mobile Phase Sequences. *Compounds **1**, **3**, **5.*** Mobile phases: A, 50% v/v MeCN pH adjusted to 2.15 with trifluoroacetic acid (TFA); B, 5% v/v MeCN pH adjusted to 2.15 with TFA. Gradient: 100% B for 6.5 min, then linear gradient to 50% B until 11 min.

*Compounds **2**, **4**, **6.*** Mobile phases: A, 50% MeCN, pH 2.15 with TFA; B, 5% MeCN pH 2.15 with TFA. 1: 0−6.5 min 100% B, 6.5−14.5 min 100% B−0% B, 14.5−20 min 0% B. 2: 0−4 min 100% B−50% B, 4−8 min 50% B−0%, 13.5 min 0% B.

2,5-Dioxo-1-pyrrolidinyl-3-(5-(2-amino-1-hydroxyethyl)-2,3-dihydroxyphenylthio)propionate (7). 1 (5 mg, 0.019 mmol) was dissolved in dimethylformamide (1 mL, dimethylformamide pH adjusted to 4.2 with HCl), and dicyclohexylcarbodiimide (96 mg, 0.465 mmol in 125 μL of dimethylformamide pH 4.2) and *N*-hydroxysuccinimide (NHS) (54 mg, 0.465 mmol in 125 μL of dimethylformamide pH 4.2) were then added dropwise to the stirring solution of catecholamine. The reaction was stirred at room temperature in the dark for 3 h. The production of the ester was confirmed by ESI-MS and the raw reaction mixture used as is immediately to minimize risk of internal cyclization. ESI-MS: (MeOH, 40 V) 354.4 [M + H]$^+$.

Immobilization of SPR Flow Cells. A CM5 carboxymethylated dextran chip (BIAcore) was activated with *N*-ethyl-*N*-(3-dimethylaminopropyl)carbodiimide (EDC) and *N*-hydroxysuccinimide (NHS) (1:1, 100 μL, 5 μL/min) for each flow cell in turn. To one flow cell, 4,7,10-trioxa-1,13-tridecanediamine was injected (2 × 200 μL of 1% w/v pH 9.7 aqueous, and then 2 × 200 μL 1% w/v pH 11.3, 5 μL/min). The flow cell was then deactivated with ethanolamine (50 μL, 5 μL/min). Another flow cell was treated in the same fashion but with 1,6-hexanediamine. The flow cells were treated with NaOH and $NaHCO_3$ washes, and then into each of the two flow cells, a solution of **7** was injected (1/4 dilution in deionized water, centrifuged at 14 000 *g*, then 1 × 200 μL and 4 × 50 μL injected at 5 μL/min). Another flow cell was activated as above with ϵ-aminocaproic acid (1% w/v, pH 9.7 aqueous, 2 × 200 μL injections at 5 μL/min and then again at pH 11.3). The surface was deactivated with ethanolamine as above, equilibrated with deionized water, and then the exposed carboxylic acid groups were activated with EDC/NHS as above (200 μL). Dopamine (1% w/v, pH 5.5 aqueous, 1 × 200 μL, 4 × 50 μL, 5 μL/min, and 8 × 50 μL at pH 7.0) was then injected over the flow cell before final deactivation with ethanolamine as above.

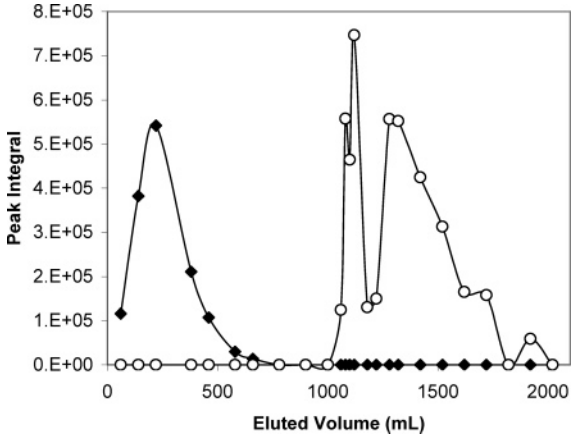


Figure 1. Ion-exchange chromatographic separation plot (peak integral vs elution volume) of dopamine (◆) and compound **2** (○).

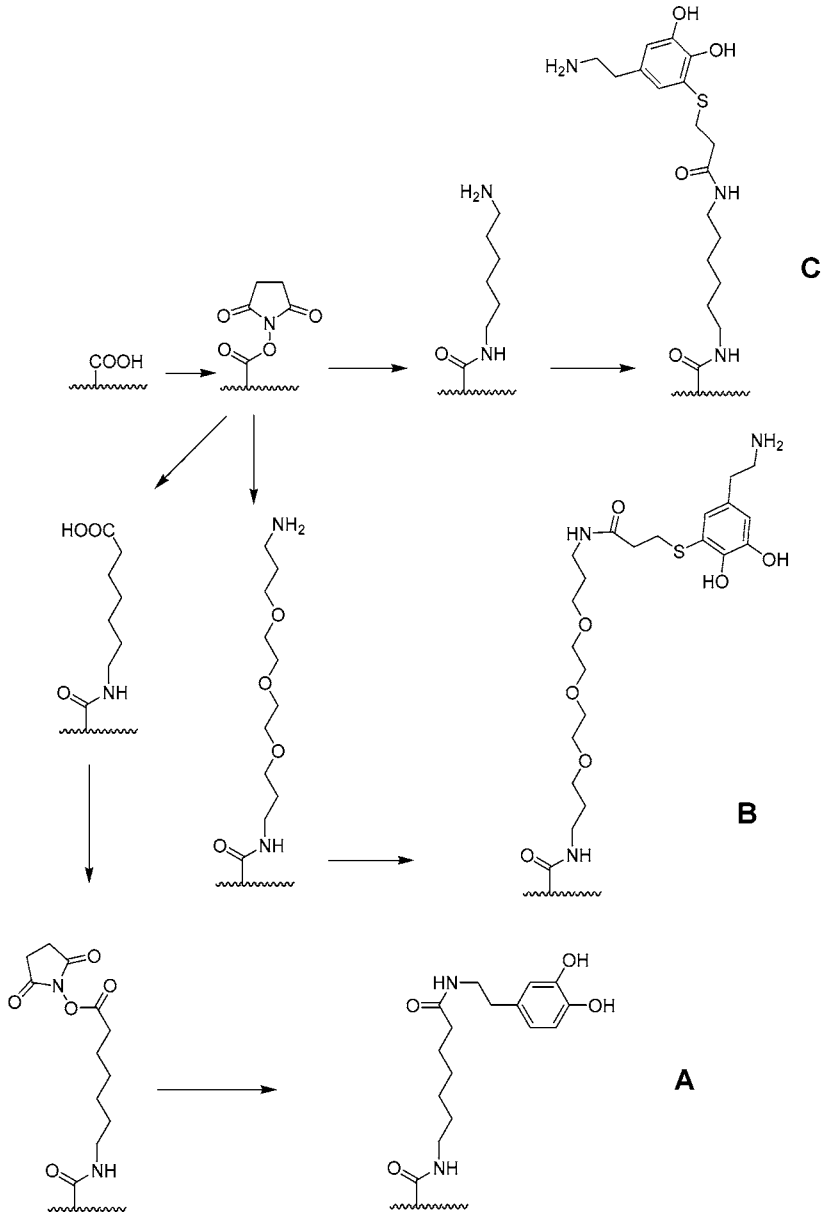

Antibody Binding Tests. 0.15 M NaCl, 0.01 M phosphate buffer pH 5.2 was used as the running buffer. Monoclonal anti-dopamine was injected (100 μg/mL and 50 μg/mL, 60 μL, 20 μL/min, three replicates each). Surfaces were regenerated with HCl solution (pH 3.5 in 20% v/v MeCN).

RESULTS AND DISCUSSION

Derivatization of Catecholamines by Thioether Linkage. Until now, there has been no reliable method for conjugating the catecholamine neurotransmitters for potential use in immunology and biosensor design such that conjugation does not compromise existing functional groups or result in an impure mixture or require protection of existing functional groups. In this study, we employed electrolysis to produce the *o*-quinones of the catecholamines dopamine, norepinephrine, and epinephrine, making use of their *o*-hydroxyl moieties and generating the intensely orange colored *o*-quinone solutions by simple application of electrical potential difference (Scheme 1). These *o*-quinones are susceptible to conjugation by thiols as has been demonstrated in biological systems with conjugation to cysteine and glutathione residues, and that has been successfully synthetically replicated for these amino acids (*22*). In this study, two different carboxylic acid bearing thiols of different chain lengths (3- and 11-carbons) were added to the catecholamines to generate a mixture of thiol-conjugated products with attachment directly to the aromatic ring of the catecholamines (Scheme 1). This reaction is envisaged to proceed by an addition mechanism with proton migration. The reaction results in a range of different products corresponding to the three substitution positions possible around the aromatic ring. This reaction method has the advantage that it is rapid: most of the reaction occurs within minutes, is one step only, and requires no complex apparatus. Conversion to the *o*-quinone can be monitored by HPLC and thiol added at the point of maximum conversion. Linker chain length can be easily adjusted as required for different applications.

The reaction mixtures next needed to be purified, and this posed significant challenges, as the product mixtures are quite complex. Ion-exchange chromatography offers an inexpensive and effective means of purifying such compounds by making use of the differing functional groups of the products and starting materials to separate them. Previously, such techniques have been applied only for very low concentrations of biological catecholamine mixtures (*23*, *24*). By use of a strongly acidic cation-exchange column, it was possible to adsorb the amine-bearing catecholamines on the column while eluting out the remaining unreacted thiol from the reaction mixture. Once all unreacted thiol had eluted as determined by HPLC, then application of mineral acid at carefully controlled concentrations

Scheme 2. Immobilization of Dopamine by Primary Amine Linkage to ϵ-Aminocaproic Acid (A), 4,7,10-Trioxa-1,13-tridecanediamine (B), and by Thioether Linkage to 1,6-Hexanediamine (C)

along with organic solvent (ethanol) to compress the elution volumes enabled chromatographic elution of the catecholamines and purification to a single product with attachment at one position only on the aromatic ring of the catecholamine.

The chromatographic purification can be traced by HPLC (Figure 1) and the product isolated to one peak by fraction collection. The resolution of the ion-exchange column was adequate to resolve one of the major products from the starting neurotransmitter and the other products with minimal overlap for dopamine and norepinephrine, but in the case of epinephrine, the polarities of products and starting materials were too close to enable complete resolution. The epinephrine products were sufficiently nonpolar to allow separation on normal-phase silica gel by flash chromatography, whereas the dopamine and norepinephrine products were too polar. The carboxylic acid bearing products could not be separated from the original catecholamine by use of an anion-exchange resin column after the cation-exchange resin, as binding to the anion-exchange column released OH^- ions, which cause oxidation of the catecholamines in situ. This separation approach allows rapid, convenient, and inexpensive purification of the catecholamine derivatives to one position of conjugation.

Position of attachment can be determined by the use of 2-dimensional NMR techniques. Homonuclear correlated spectroscopy (COSY) enabled assessment of the presence of coupling between close neighboring protons, and nuclear overhauser enhancement spectroscopy (NOESY) enabled the determination of proton pairs that were within ∼5 Å of each other. This data combined with chemical-shift increments enabled all products to be identified relative to their position of attachment around the aromatic ring. The isolated products had substitution at the position *meta* to the amine side chain (4-position in Scheme 1) for both dopamine derivatives, whereas for the norepinephrine and epinephrine derivatives, attachment was *ortho* to the amine side chain (6-position in Scheme 1). Conjugation to the position *ortho* to the amine side chain and hydroxyl moiety (position 2 in Scheme 1) is sterically disfavored by the bulk of the two neighboring groups.

Surface Plasmon Resonance Studies and Antibody Interactions. It is of interest to consider the effects of different conjugation positions and techniques on the ability of antibodies to bind to immobilized antigens. Because of the small size of the catecholamine molecules, it is envisaged that conjugation through an existing functional group will have a profound effect

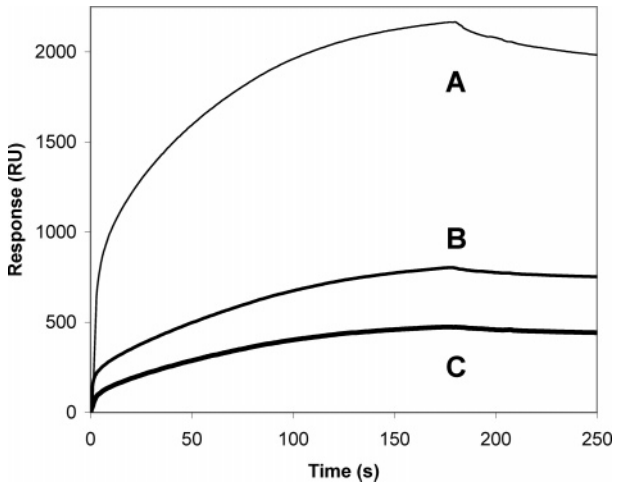

Figure 2. Antibody binding sensorgrams for surfaces immobilized by primary amine linkage to ϵ-aminocaproic acid (A), by thioether linkage to 4,7,10-trioxa-1,13-tridecanediamine (B), and by thioether linkage to 1,6-hexanediamine (C) at 100 μg/mL antibody concentration.

on the ability of the antigen to mimic the free catecholamine effectively. Commercially available antibodies have so far relied upon use of conjugates through existing functional groups to generate the antibody. In the design of possible immunobiosensors for catecholamines, it is of interest to consider how important biosensor surface conjugation techniques may be in determining antibody binding levels, signal strength, and thus assay performance. Surface plasmon resonance provides an excellent tool for assessing antibody binding properties (*14*, *25*).

In this study, dopamine was immobilized to a surface plasmon resonance biosensor surface using immobilization technology that employs in situ addition of linkers and then attachment of dopamine (Scheme 2). To attach the synthesized dopamine derivative, it is necessary to first pass a homobifunctional linker over the sensor surface to generate an amine terminus and provide further spacing from the biosensor surface. Two different linker types were selected in this instance: one was the nonpolar linker chain 1,6-hexanediamine, and the other was the more water-soluble oligoethylene glycol chain 4,7,10-trioxa-1,13-tridecanediamine. The dopamine−propanoic acid derivative (compound **1**) was attached by formation of the NHS active ester (compound **7**) and flowing the compound over the biosensor surface in large excess to ensure maximum immobilization. Conjugation via the primary amine of the dopamine was possible by first modifying the surface with attachment of the heterobifunctional linker ϵ-aminocaproic acid and then flowing dopamine over the surface (Scheme 2). This system offers a convenient in situ means of constructing a biosensor surface with the antigen spaced from the sensor surface, to ensure maximum projection in the fluid stream and thus minimizing steric hindrance to antibody binding.

The catecholamines are sensitive to base-catalyzed oxidation, and as such, the running buffer was kept acidic to help to preserve the biosensor surface. Monoclonal anti-dopamine was applied to the surfaces to assess its binding. The antibody was raised to a glutaraldehyde-linked protein conjugate through the primary amine. The sensorgrams obtained for the binding indicated clearly that the strongest binding was obtained for the surface with dopamine conjugated through the primary amine, as expected given that the antibody was raised to a conjugate through the primary amine, whereas antibody binding to the sensor surfaces with dopamine immobilization via its aromatic ring directly was only about 35% of that of the binding to the primary amine immobilized surface at 100 μg/mL antibody (Figure 2 and Table 1). Such great differences in binding response have demonstrated clearly that a catecholamine

Table 1. Surface Plasmon Resonance Binding Responses (RU) for Different mAb Concentrations for Each of the Sensor Surfaces

mAb concentration (μg/mL)	surface A (RU)	surface B (RU)	surface C (RU)
50	313 + 39	153 + 21	175 + 19
100	1670 + 210	580 + 100	650 + 140

monoclonal antibody's binding strength is strongly dependent upon the site of conjugation around the aromatic ring of the immobilized analyte relative to the site used to raise the antibody and that careful selection of immobilization conjugation position is required to maximize antibody binding signal in flow-through biosensors.

In general, immunizing haptens should be designed as a close mimic of the target molecule, retaining all functional groups, preserving as much as possible the original steric and electronic characteristics of the analyte (*26*). From our results (Figure 2 and Table 1), it is suggested that the commercial antibody, raised to a catecholamine conjugate through the existing primary amine (not a close mimic of the free catecholamine), is most likely to have much stronger recognition of coated antigens (catecholamine conjugates) through the same amine conjugation, compared with recognition of the free catecholamines having the similar chemical structure to our aromatic-linked catecholamine derivatives (B and C) where all original functional groups including primary amine were retained and which gave lower antibody-binding responses (Figure 2 and Table 1). These results support previous reports (*3*) that suggest anti-dopamine antisera raised with glutaraldehyde conjugation preferentially recognize the catechol moiety and any modification of the aromatic ring significantly disrupts binding of the antibody. Such poorer antibody binding will probably lead to poor inhibition by the free catecholamine, and thus, higher catecholamine concentrations would be required to inhibit antibody binding to any surface-bound catecholamine conjugates, which results in lower assay sensitivity. Speculatively, for development of a highly sensitive competitive assay, better antibody recognition of the full catecholamine structure or higher affinity to free catecholamine, and thus better inhibition by the catecholamine and sensitivity of detection, could potentially in the future be achieved by using the thioether attachment to the aromatic ring in protein conjugations to raise antibodies. Antibodies raised in this manner should clearly distinguish between neurotransmitters with differences in their amine side chain. Raising of such antibodies is an area of possible future research.

It is generally accepted that the type and length of the hapten spacer arm are important factors in preparation of surface coated hapten conjugates. A long spacer arm is thought to offer the ability to space the antibody binding site out from the solid surface. However, a spacer arm which is too long may cause entwining around the hapten molecules and blocking of antibody binding on the coated surface. Therefore, an optimal type and length of spacer arm should be applied. In the present study, biosensor surface bound catecholamine molecule (B) through a relatively long oligoethylene glycol (OEG) spacer arm provided a hydrophilic molecular layer as a favorable binding medium and more space for antibody binding than the surface-coated catecholamine (C) with a short hexanediamine linker. In this study, changing the type and length of the linker did not result in a statistically definitive change in binding response (Table 1), indicating that these parameters are less significant than changing conjugation position. The binding of antibody further confirms the viability of an OEG spacer arm for covalent immobilization of small molecules on a biosensor surface (*16*).

The catecholamine sensory surface is somewhat unstable, being prone to gradual oxidation, and this is shown in gradually declining binding responses on the surfaces. This instability has made the construction of an assay or full antibody saturation

curves based on these surfaces difficult, due to high variation, without the introduction of additional measures to minimize surface degradation such as the use of powerful antioxidants. Furthermore, the monoclonal antibody used has a comparatively low affinity, even to the homologous antigen (10^7 L/M), further hindering generation of saturation curves.

These studies have shown how conjugation directly to the aromatic ring of the catecholamine can be achieved with purification to a single product and without the need to protect existing functional groups, thus offering a very convenient conjugation method for biosensor design and potentially for future use in antibody generation, one that much more closely mimics the free catecholamines. These derivatives have great application for biosensor construction, and this study has shown that monoclonal antibodies raised to conjugates through the catechol primary amine can discriminate between different conjugation positions for dopamine in a flow-through type biosensor.

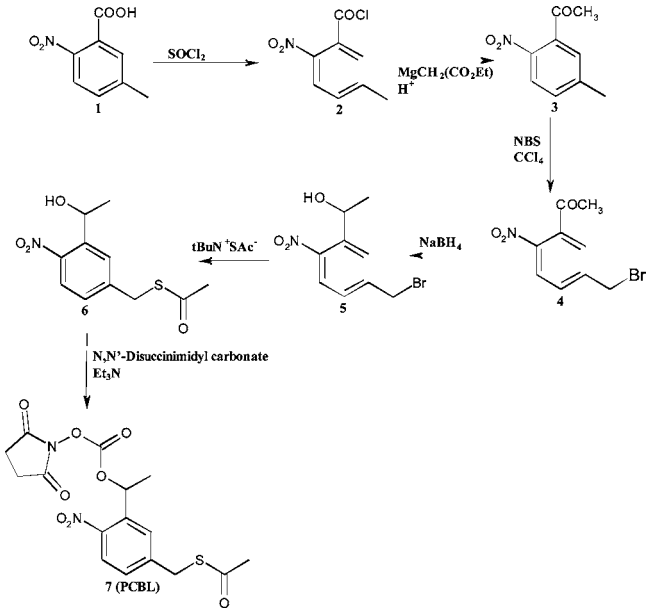
Received July 20, 2006; Revised Manuscript Received October 14, 2006

Covalent photocleavable attachment of small molecules or peptides to oligonucleotides is an integral strategic element in the selection of novel nucleic acid enzymes. Here, we report the synthesis of a multipurpose, photocleavable bifunctional linker (PCBL) suitable for nucleic acid selections and other biotechnology applications. PCBL contains a photocleavable *O*-nitrobenzyl group flanked on one side by an *N*-hydroxysuccinimidyl ester (reactive toward primary amines) and on the other side by a sulfhydryl. To demonstrate the utility of PCBL, the linker was used to couple an analog of the antibiotic chloramphenicol (Cam) to the 5′ end of an amino-modified 8-mer DNA oligo. Coupling was confirmed by MALDI-TOF spectrophotometry. Decoupling was performed by irradiating the coupled species with near-UV light (approximately 360 nm), regenerating the original amino-modified oligo. Ligation of the Cam−PCBL−DNA conjugate to random-sequence RNA generated a diversity library appropriate for the selection of new ribozymes that catalyze reactions involving the tethered substrate. Coupling and decoupling of the Cam analog from the library was monitored on a trilayered organomercurial polyacrylamide gel. The coupling/decoupling strategy described here is readily generalized to many combinations of macromolecules and small molecules. For example, analogs of this small molecule−DNA conjugate can be generated as synthons for ligation to nucleic acid diversity libraries during each round of novel ribozyme selections, or they can be immobilized onto chips for addresssably reversible microarray analysis.

INTRODUCTION

Covalent modifications of nucleic acids have found broad application in chemistry and biology. In particular, there has been growing interest in the coupling of functional groups to nucleic acids. For example, conjugation of peptides to oligos has been used to improve biological stability, cellular uptake efficiency, and cell-specific targeting of antisense RNAs, aptamers, and siRNA (*1*−*4*). Nucleic acids have also been conjugated to chromophores for target detection or tertiary structural analysis, or to immobilizing agents for the production of high-density DNA arrays (*5*−*7*). Similar conjugation is also very useful in the *in vitro* selections of catalytic nucleic acids such as ribozymes that catalyze Michael addition, Diels−Alder cycloaddition, or oxidoreduction reactions (*8*, *9*).

The *in vitro* selection of ribozymes involves multiple cycles of partitioning and amplification of reactive nucleic acids from among a vast number of starting molecules (10^{14} or more). The partition often takes advantage of the conversion of a nucleic-acid-tethered substrate into a nucleic-acid-tethered product, followed by preferential purification and amplification of nucleic acids that are tethered to product. Each selection cycle increases the number of copies of catalytically active nucleic acid strands relative to nonspecifically recovered molecules, until the population is dominated by nucleic acids with autocatalytic activity. This strategy is highly effective at recovering reactive RNA species but can be limited by poor control of regiospecificity and cumbersome synthesis of substrate-linked nucleic acid libraries. Several selections that were originally intended to target nucleic-acid-tethered substrates have instead yielded ribozyme libraries dominated by species that modify themselves at internal sites on the RNA, such as 2′ hydroxyls, rather than modifying the intended substrate (*10*−*13*). This is especially problematic for catalysis of condensation reactions that label active nucleic acids with an affinity tag, such as biotin or a free sulfhydryl. Depending on the method used for recovering product-linked ribozymes, this unwanted background can be difficult to separate from the desired ribozymes.



A productive strategy for overcoming this limitation has been to introduce a cleavable moiety between the RNA and the tethered substrate, such that the desired product−RNA conjugates can be easily decoupled from unreacted substrate−RNA conjugates (*14*, *15*). In this strategy, the partition step of the selection includes three stages: recovery of all nucleic acid species that have become modified during the course of the reaction (including product−RNA conjugates and internally reacted species), cleavage of the tether joining the substrate/product to the ribozyme, and elimination of all RNA species that still retain internal covalent modifications. A second limitation is that the attachment of small-molecule substrates to the nucleic acids can be challenging in the absence of considerable synthetic expertise. Although there is a limited repertoire of commercially available mono- and oligonucleotides with covalently attached pendants, such as nucleoside analogs and fluorescent dyes, the use of such reagents is not readily generalizable to the attachment of new pendants. Importantly, most attachment strategies do not allow facile reversal of the coupling using benign conditions.

The present work addresses both of these concerns by introducing a photocleavable *O*-nitrobenzyl group (ONB) into the linker. ONB derivatives are especially convenient photocleavable moieties and have been used for a variety of applications, because they are synthetically tractable and photocleave upon irradiation in the near-UV at 330−370 nm. Examples include the covalent attachment of immobilizing agent to the

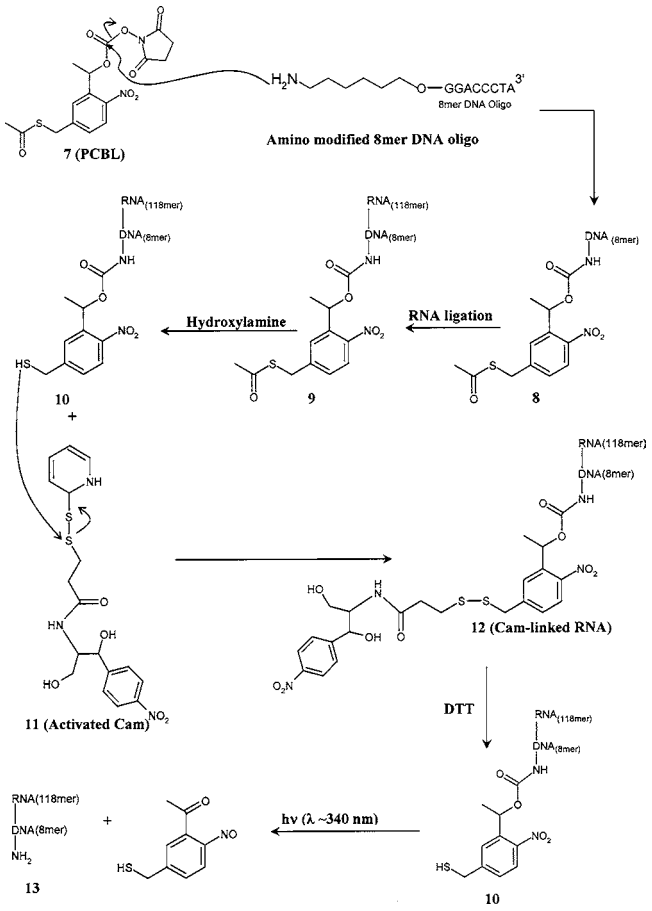
termini of nucleic acids and proteins for substrate surface modifications and purification and analyses (*16*−*18*), conjugation of protein toxin to an antibody for cellular delivery (*19*), protection of amines and carboxylic acid groups during chemical synthesis of amino acids and nucleotides (*20*−*22*), synthesis of many caged fluorophores, proteins, and other caged compounds (*23*), and synthesis of multifunctional mono- and dinucleotide analogs (*15*). Photoreversible fluorescent chain terminators and fluorescent oligonucleotides have been generated for DNA sequencing by synthesis (*5*, *24*, *25*), and aptamers to hepatitis C virus RNA polymerase have been immobilized to affinity chromatography columns via ONB linkers to allow photoelution of the bound polymerase (*26*).

This paper reports a time-effective, inexpensive, easy-to-use general scheme for the synthesis and evaluation of a multipurpose, photocleavable, bifunctional linker (PCBL). The PCBL can be used to couple any pair of amine-containing and thiol-reactive species, and the linkage is labile to near-UV irradiation at 360 nm under conditions that are benign for nucleic acids. The utility of the PCBL is demonstrated experimentally by coupling an analog of the antibiotic chloramphenicol (Cam) to the 5′ end of a DNA oligonucleotide and to a random-sequence RNA library and subsequently decoupling it in both contexts by near-UV irradiation.

EXPERIMENTAL PROCEDURES

Synthesis of Photocleavable Bifunctional Linker (PCBL) (Scheme 1). Photocleavable bifunctional linker was synthesized as shown in Scheme 1.

Compound 2. 5-Methyl-2-nitrobenzoic acid (**1**; 1.81 g, 0.01 mmol) and 2 drops of DMF were added to 25 mL of $SOCl_2$ and refluxed at 80 °C for 3 h under inert atmosphere. The mixture was evaporated to a yellow oil, washed after dissolving in ether, and further evaporated to dryness.

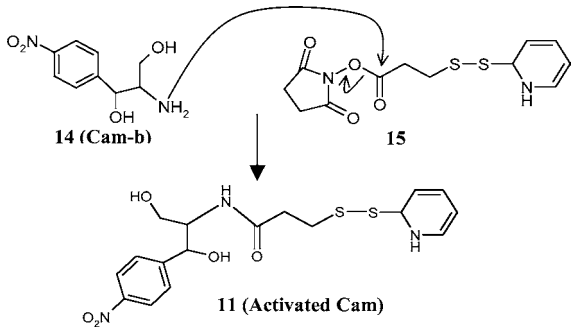


Compound 3. Compound **3** was prepared according to the procedure discussed by Reynolds et al. (*27*). Magnesium turnings (270 mg) were mixed with 0.25 mL of absolute ethanol and 0.025 mL of carbon tetrachloride in a three-neck, round-bottom flask and stirred at room temperature under inert (N_2) atmosphere. If the reaction did not start immediately (no effervescence), the flask was heated for a few minutes on a steam bath. The reaction was allowed to continue for 5 min, then 10 mL of ether was added slowly with constant stirring. A solution of 1.66 mL of diethyl malonate, 1 mL of absolute ethanol, and 1.25 mL of absolute ether was added at a rate that maintained constant boiling, and the mixture was refluxed over a steam bath until most of the magnesium was dissolved. Compound **2**, 5-methyl-2-nitrobenzoyl chloride, (0.01 mmol) was dissolved in 2.5 mL of ether and was very slowly added to the gray solution. Reflux was continued throughout the addition until the resulting green solution became too viscous to stir. The reaction mixture was cooled and dissolved in dilute sulfuric acid (0.69 mL of H_2SO_4 in 10 mL of H_2O). The ether layer was separated, and the aqueous layer was extracted with 2.06 mL of ether. Ether extracts were combined, and solvent was removed to yield crude diethyl-5-methyl-2-nitrobenzoylmalonate. A solution of 2 mL of glacial acetic acid and 0.38 mL of concentrated sulfuric acid was added, and the mixture was refluxed until no more carbon dioxide was evolved. The reaction mixture was cooled on an ice bath and made alkaline with NaOH solution, and the product 5-methyl-2-nitroacetophenone **3** was extracted with ether and purified by flash column chromatography on a column of silica (3 × 20 cm, grade 230−400 mesh, purchased from Scientific Adsorbance), using 20% ether in hexane as eluent. This product is characterized by ^{1}H NMR ($CDCl_3$) δ: 2.582 (s, 3H, CH_3), 2.637 (s, 3H, Ar−CH_3), 7.324 (s, H, ArH), 7.485 (d, H, ArH), 8.078 (d, H, ArH).

Compound 4. Synthetic protocols for compounds **4** through **6** were adapted from Senter et al. (*19*). 2 g (11 mmol) of compound **3**, 2.18 g (12.3 mmol) of *N*-bromosuccinimide, 27 mg (0.11 mmol) of benzoyl peroxide, and 20 mL of CCl_4 were mixed and refluxed for 6 h under Ar or until the succinimide produced in the reaction floated on the top of the solution. The reaction mixture was cooled and filtered, and the filtrate was evaporated to dryness. The product was further dissolved in CH_2Cl_2, washed with water, and dried. Formation of 5-Bromomethyl-2-nitroacetophenone (**4**) was confirmed by monitoring the new ^{1}H NMR (s, 2H, CH_2Br) peak at δ 4.573. Additional peaks in the NMR spectra indicated a small amount of unreacted starting material and dibrominated product, but further purification at this step was deemed unnecessary.

Compound 5. Compound **4** (2.0 g, 7.7 mmol) was dissolved in a mixture of 10 mL dioxane and 14 mL methanol and kept on ice. $NaBH_4$ (150 mg, 3.94 mmol) was added in the ice-cold solution of the reaction mixture and allowed to stir for 2 h at 0 °C. The reaction was quenched with acetone, and solvent was evaporated to dryness. The crude product was dissolved in 25 mL of $CHCl_3$, washed with brine water, and evaporated to a yellow oil. The formation of 1-(5-bromomethyl-2-nitrophenyl) ethanol (**5**) was confirmed by NMR without further purification. ^{1}H NMR ($CDCl_3$) δ: 1.582 (d, 3H, CH_3), 4.571 (s, 2H, Ar−CH_2Br), 5.458 (q, H, CHOH), 7.28 (s, H, ArH), 7.36 (d, H, ArH), 7.88 (d, H, ArH).

Compound 6. 3.28 mL (5.0 mmol) of 40% aq tetrabutylammonium hydroxide was slowly added to a solution of 0.35 mL (5.0 mmol) of thioacetic acid in 5 mL DMF at room temperature. A solution of compound **5** (1.0 g, 3.85 mmol) in 6.37 mL DMF was slowly added, and the mixture was stirred for 3 h. The solvent was evaporated, and the residue was redissolved in 25 mL ether and washed with saturated aqueous NaCl, then with saturated $NaHCO_3$, and dried under vacuum. 1-[5-(Methyl-3-*S*-acetylthioic acid ester)-2-Nitrophenyl] ethanol [**6**] was purified by silica flash column chromatography (grade 230−400 mesh, purchased from Scientific Adsorbance), using 35% ether in hexane as eluent. ^{1}H NMR ($CDCl_3$) δ: 1.582 (d, 3H, CH_3), 2.395 (s, 3H, $COCH_3$), 4.178 (s, 2H, Ar−CH_2Br), 5.458 (q, H, CHOH), 7.28 (s, H, ArH), 7.36 (d, H, ArH), 7.88 (d, H, ArH).



Scheme 2. Synthesis of Cam-Linked RNA Pool and Decoupling Reaction of Cam from RNA

PCBL, Final Compound (7). Compound **6** (50 mg, 0.20 mmol) was dissolved in 0.8 mL of DMF. 80 mg (0.33 mmol) of *N*,*N*′-disuccinimidyl carbonate was added, followed by 84.5 mL (0.6 mmol) of triethylamine, and the mixture was stirred for 6 h at room temperature. Solvent was evaporated to dryness, and the residue was washed thoroughly with 0.1 M $NaHCO_3$ and water. Finally, the crude product 1-[5-(methyl-3-*S*-acetyl-thioic acid ester)-2-nitrophenyl] ethyl-*N*-hydroxysuccinimidyl carbonate [**7**] was dissolved in minimum CH_2Cl_2 and purified over preparative TLC (250 μ glass-backed silica gel plate) using a solvent system of 70:30 ratio $CHCl_3/CH_3OH$. ^1H NMR ($CDCl_3$) δ: 1.79 (d, 3H, CH_3), 2.395 (s, 3H, $COCH_3$), 4.19 (s, 2H, Ar−CH_2Br), 6.41 (q, H, CHOH), 7.28 (s, H, ArH), 7.45 (d, H, ArH), 7.98 (d, H, ArH).

Synthesis of Conjugated RNA Pool (Scheme 2). 1 mM 5′ amino-modified DNA oligo was incubated with 5 mM PCBL in 80% DMSO for 12 h at room temperature. The product was purified on a 1 mL size-exclusion column (G25 Sephadex, purchased from Sigma), dried under vacuum, and resuspended in water. Ligation was performed by incubating 118 nt RNA (1 μM) carrying 70 random nucleotides (*13*) with purified PCBL-linked 8-mer DNA oligo (1.5 μM) and 24-mer DNA bridge (3 μM) in a buffer that contained 1 mM ATP and T4 DNA ligase at 37 °C for 5 h. RNA was internally radiolabeled by transcription in the presence of [α-^{32}P] UTP. The sequence of the DNA bridge (5′-GATTCGCTTTTCCCTAGGGTCC-3′) is complementary to both the 8-mer DNA oligo and to the 5′ terminal 14 nucleotides of the RNA. Deacylation was accomplished by incubating 10 μM hybrid RNA (**9**) with 25 mM hydroxylamine at pH 7.5 and purifying it on a trilayer APM gel. 10 μM of deacylated product (**10**) was incubated with 10 μM DTT (1 equiv) for 5 min. Activated Cam in 60% DMSO was added to a final concentration of 50 μM (5 equiv). The mixture was incubated for 4 h at room temperature, and the product Cam-linked RNA pool (**12**) was purified on an 8% denaturing (8 M urea) polyacrylamide gel. Activated Cam was synthesized by incubating 1 mM chloramphenicol base (Cam-b) (**14**) with 1 mM *N*-succinimidyl 3-(2-pyridyldithio)-propionate (SPDP) (**15**) in DMSO for 2 h at room temperature (Scheme 3).

Scheme 3. Activation of Cam Analog with Commercially Obtained Crosslinker

Photolysis of Conjugate from the RNA Pool. A 1 μM solution of DTT-treated, Cam-linked RNA pool in 25 mM phosphate buffer at pH 7.4 was irradiated with a hand-held, long-wavelength UV lamp (UVP, Inc., model no UVGL-25) at approximately 360 nm from a distance of 10 cm for 5 or 10 min, as indicated in the text.

RESULTS

PCBL Design and Synthesis. The photocleavable bifunctional linker (PCBL) carries two reactive groups separated by a photocleavable *O*-nitrobenzyl moiety. It was designed to permit reversible coupling of any amine-containing and sulfur-reactive species (Figure 1). The *N*-hydroxysuccinimide group is highly reactive toward primary amines, which react to form a stable carbamate. The sulfur at the other end of the PCBL is initially protected by an acetyl group to avoid premature reactivity or disulfide bond formation. Deacetylation of the thioester with hydroxylamine exposes the sulfhydryl, which is highly reactive toward numerous reagents. This PCBL reagent was synthesized as described in methods and summarized in Scheme 1.

Coupling to, and Photorelease from, a DNA Oligo. PBCL was dissolved in DMSO and allowed to react with 5′ amino-modified DNA oligo (Scheme 2). The PBCL−DNA conjugate (**8**) was purified from the reaction mixture containing DMSO and other contaminants by gel filtration on a size-exclusion column (pre-equilibrated with water), eluting with multiple 1 mL fractions of water. A second column was loaded in parallel with 5′ radiolabeled 8-mer DNA oligo to identify the elution fraction likely to contain the purified DNA. The fraction containing the DNA was concentrated, and product formation was confirmed by MALDI-TOF (Figure 2). A peak of molecular

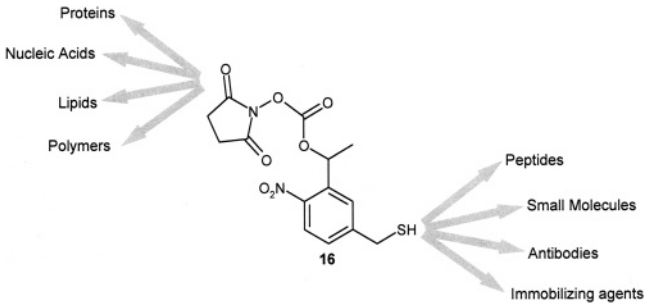


Figure 1. Some of the potential combinations of attachment of macromolecules with small molecules using PCBL [**7**].

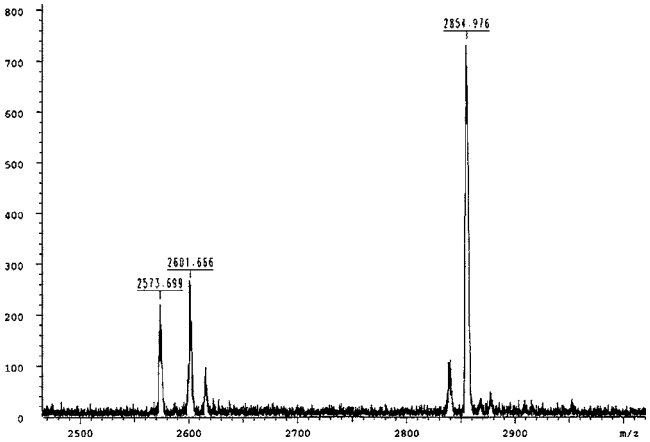

Figure 2. MALDI-TOF spectra of PBCL-linked 8-mer DNA oligo. The calculated molecular weight of the starting material (amino-linked 8-mer DNA oligo) is 2573. Reaction with PCBL is expected to increase the molecular weight by 282 (396 for PCBL minus 114 for released NHS), yielding a product with expected molecular weight of 2854. Peak at 2854.9 confirms the product formation.

weight 2573, which is the molecular weight of both the starting material and the photolytic product, was always present in the spectrum, generated by photolysis of the product by the 337 nm laser of the MALDI-TOF instrument. Essentially identical spectra were obtained irrespective of the amount of excess PCBL relative to DNA in the coupling reaction, suggesting that the peak at MW 2573 is due to photocleaved product and not to leftover starting material.

A Model Substrate-Linked RNA Library. For the PCBL to be useful in ribozyme and DNAzyme selections, it must be suitable for tethering potential substrates to a nucleic acid library, followed by releasing the substrate or product after the intended reaction. To this end, the PCBL−DNA conjugate (**8**) was enzymatically ligated to a random-sequence, radiolabeled RNA library (Scheme 2). The 118 nt input RNA and the 126 nt ligated product (**9**) were separately loaded onto a trilayer organomercurial polyacrylamide gel (*13*, *28*) in which the middle layer was doped with *N*-acryloylaminophenylmercuric chloride (APM) (*29*). The strong Hg−S interaction impedes the migration of nucleic acids carrying a free thiol. Because neither of these two input RNAs carries a free thiol, there was no appreciable material retained in the APM layer (lanes 1 and 2 of Figure 3a; columns 1 and 2 of Figure 3b). In contrast, exposing the sulfhydryl by deprotecting compound **9** with hydroxylamine to yield compound **10** resulted in retention of >60% of the input RNA in the APM layer (lane 3 of Figure 3a; column 3 of Figure 3b). PCBL attachment to the 5′ end of the DNA oligo did not affect ligation efficiency of T4 DNA ligase (data not shown). Compound **10** was purified from the APM layer and incubated with thiopropyl-activated Cam **11** (Scheme 3). To minimize the formation of disulfide via spontaneous oxidation, 1 equiv of dithiothreitol (DTT) was added to the RNA pool prior to incubating it with activated Cam. 5 equiv of activated Cam analog was used in the coupling reaction to minimize disulfide reduction of the product by unused DTT. Coupling of Cam to the library was confirmed by loading the product onto a trilayer APM gel. The Cam-coupled library (**12**) no longer carries a free thiol, and it again passed through the APM (lane 4 of Figure 3a; column 4 of Figure 3b). However, when this material was incubated with DTT to reduce the disulfide bond between the linker and the Cam, the free sulfhydryl is regenerated (**10**), and the reduced product was again retained at the APM layer (lane 5 of Figure 3a; column 5 of Figure 3b). Thus, Cam can be attached to an RNA library via ligation of a PCBL-modified oligo and released by reduction with DTT.

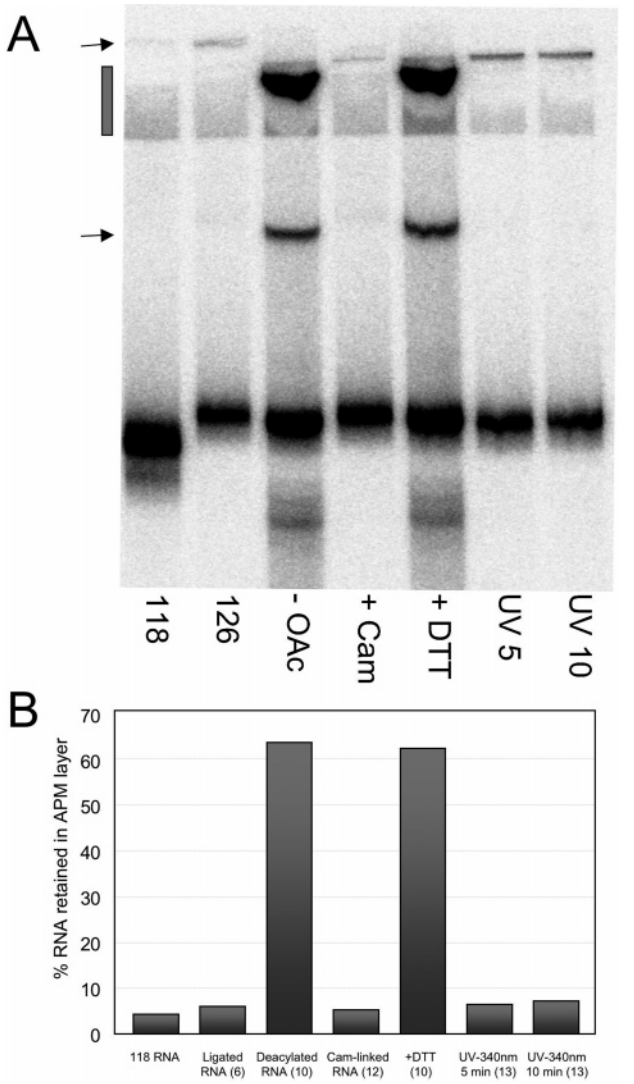

Figure 3. Attachment to, and decoupling from, random-sequence RNA library. (A) Trilayer APM gel of internally radiolabeled RNA treated as described in the text. Top arrow, wells; box, APM layer; bottom arrow, disulfide-oxidized side product. The sulfhydride can be retained in reduced form without interfering with APM electrophoresis by including tris-carboxyethyl phosphine (not shown) (*13*, *28*). (B) Percentage of internally radiolabeled RNA retained in the APM layer is plotted for individual constructs given under each column.

Photocleavage of Pendant from Library. While chemical reduction with DTT is convenient in some circumstances, it is not feasible in cases where the intended selection is based upon acquisition of a new sulfhydryl in the product or where the initial coupling is performed using thioether linkages (reaction with maleimides or iodoacetyl groups) or via interactions with inorganic compounds or surfaces (such as nanoparticles or chip arrays) rather than via a disulfide. Photocleavage is much more convenient in these cases.

To test the photodecoupling efficiency of the linker, compound **10** was purified from the APM layer and irradiated with near-UV light at 360 nm for 5 or 10 min. Decoupling of the *O*-nitrobenzyl moiety from the RNA removes the free sulfhydryl, allowing the RNA (**13**) to migrate through the APM layer. The reaction is complete within 5 min, with no additional product observed after 10 min of irradiation (lanes 6 and 7 of Figure 3a; columns 6 and 7 of Figure 3b). The results are in agreement with previous studies on the time requirements for *O*-nitrobenzyl derivative photocleavage (*16*, *17*).

DISCUSSION

We have successfully synthesized an *O*-nitrobenzyl-containing, photocleavable bifunctional linker (PCBL). This linker enabled coupling an analog of Cam to the 5′ end of an RNA library and its photorelease by near-UV irradiation. Analogs of this small molecule−DNA conjugate can be generated as synthons that are ligated to a nucleic acid diversity library during each round of a ribozyme selection. Alternatively, they could be annealed to immobilized oligonucleotides for chip array analysis. Diverse substrates can be readily coupled to nucleic acid libraries for use in novel nucleic acid enzyme selection using the PCBL. In this context, photochemical release of the tethered product (vs internal products) can be exploited to ensure regiospecific control of the reactions catalyzed by those selected ribozymes. Photocleavable, heterobifunctional crosslinkers such as PCBL and analogous compounds reported previously (*18*) are also highly versatile for applications in proteomics and nanotechnology, as they enable reversible coupling of a wide variety of other combinations of amine-containing species (oligonucleotides, peptides, proteins, fluorophores, and immobilizing agents) with thiol-reactive species (maleimides, iodoacetyl groups, activated disulfides, semiconductor surfaces, and organomercurial compounds and several metallic or semiconductor surfaces) (Figure 1).

ACKNOWLEDGMENT

The authors thank Dr. Rajesh Viswanathan and Dr. Jeffrey N. Johnston for providing the lab space and critical comments on the synthetic scheme of the synthon, and members of the Burke lab for insightful comments on the manuscript. This work was supported by Exobiology Award NAG5-12360 from NASA and by an Interdisciplinary Science Award from the David and Lucille Packard Foundation.

Poly(vinyl alcohol) Functionalized Poly(dimethylsiloxane) Solid Surface for Immunoassay

Ling Yu,[†] Chang Ming Li,*[,†] Qin Zhou,[†] and John H. T. Luong[‡]

School of Chemical and Biomedical Engineering, Nanyang Technological University, 639798, Singapore, and Nanobiotechnology and Biosensor Group, Biotechnology Research Institute, Canada National Research Council, 6100 Royalmount Avenue, Montreal, Quebec, Canada H4P 2R2. Received April 24, 2006; Revised Manuscript Received January 29, 2007

In this communication, we describe a simple and robust method for the covalent bonding of poly(vinyl alcohol) (PVA) on a silanized poly(dimethylsiloxane) (PDMS) surface. Nonspecific adsorption of proteins via hydrophobic−hydrophobic interactions of the PVA-coated surface is greatly reduced, and biomolecules can be rapidly anchored on the PVA-coated surface with high loading and uniformity. On the basis of a sandwich immunoassay with the anti-rabbit IgG and IgG pair as a model, the detection limit for IgG is down to 1 pg/mL with linearity up to 11 μg/mL, the levels often encountered in biological, forensic, and environmental samples.

Immunoassays performed in polystyrene-based microtiter plates are superior to other heterogeneous solid-phase immunoassays with respect to sensitivity and specificity (*1*). The current trend in analytical sciences is to miniaturize the assay format to reduce the diffusion paths and the cost associated with the reagent consumption. The revolution in microfabrication has been long rooted in the polymer sciences, since the use of polymers has proven to reduce the time, complexity, and cost of prototyping and manufacturing (*2*). Poly(dimethylsiloxane), PDMS, is of particular interest in the fabrication of microfluidics (*3*) since it can be cast in a suitable mold with high fidelity. However, nonspecific interaction between contaminants and hydrophobic PDMS greatly debilitates its potential applications (*4*), i.e., a low signal-to-noise ratio in analytical procedures. Since various factors affect protein adsorption, the surface chemistry of the substrate has been studied most intensively to alleviate nonspecific protein adsorption via a plethora of surface modification procedures. In general, proteins adsorb in higher amounts at hydrophobic than at hydrophilic surfaces owing to hydrophobic interactions between the solid surface and hydrophobic domains in the protein (*5*). In particular, proteins usually give higher adsorption at methylated than at the nonmethylated counterparts. For instance, when glass surfaces are progressively hydrophobized, the adsorbed amount of fibrinogen increases from 2 to ~5 mg/m^2 (*5*). Although proteins often rely on hydrophobic interactions and electrostatic attractions in the nonspecific binding, at most surfaces, the hydrophobic interaction is the governing factor (*5*).

Polymer coatings designed to reduce protein adsorption have been used to modify a variety of polymeric substrates. The hydrophobic part of the polymers is first adsorbed onto the substrate, with the hydrophilic end serving as the barrier for protein adsorption from aqueous solutions. Poly(vinyl alcohol), or PVA, is one of the most hydrophilic polymers with stable

chemical properties, good dissolution, and strong adhesion power. PVA can be irreversibly adsorbed on some hydrophobic surfaces, but less significant on PDMS (*6*). In addition, it is very difficult to produce homogeneous PVA films on a hydrophobic surface by adsorption. Nevertheless, PVA can be adsorbed on oxygen plasma treated PDMS, since the resulting surface possesses a highly hydrophilic layer with hydroxyls, silanols, and carboxylic acids. Hydrogen bonding, instead of hydrophobic interaction, is probably the dominant driving force for the PVA adsorption on such a treated PDMS surface (*7*). Notice that the functional groups generated by the oxygen plasma treatment are not stable, particularly in air. Coatings of the nonionic PVA has also proven effective in reducing adsorption of certain proteins (β-lactoglobulin and bovine serum albumin) onto polysulfone surfaces (*8*).

Here, we have prepared and silanized poly(dimethylsiloxane (PDMS) with 3-aminopropyltriethoxysilane (APTES), followed by glutaraldehyde activation to convert the amino groups on the PDMA surface to the aldehyde groups (*9*). PVA was then coupled to the aldehyde groups at pH 1 (Supporting Information). Indeed, this reaction was used by Belder et al. (*6a*) in an attempt to cross-link this polymer during the coating process and thus immobilize it into fused silica capillary in order to modify the electroosmosis flow.

In our preparation, PVA cross-linking did not occur, since only one aldehyde group was available from the bifunctional aldehyde. Therefore, we reasoned that PVA formed a firm hydrophilic layer on the glutaraldehyde-activated PDMS surface. The procedure was rapid with high coupling efficiency as discussed later by probing the morphological changes by AFM. Pristine PDMS probed by AFM exhibited a smooth, featureless, and continuous surface with a corresponding contact angle of 101.8°. After the treatment with PVA, the contact angle decreased to 71.5° and the morphology of PDMS changed from a flat feature to a surface dominated by circles (Figure 1a,b). The decrease of the contact angle was due to the hydroxyl groups of PVA immobilized on PDMS after the cross-linking process. As the crystalline PVA is characterized by doubly hydrogen bonded alcohols, the lower contact angle suggests that PVA is highly disordered and less capable of ordering or crystallizing. PVA is an atactic material but exhibits crystallinity, as the hydroxyl groups are small enough to fit into the lattice

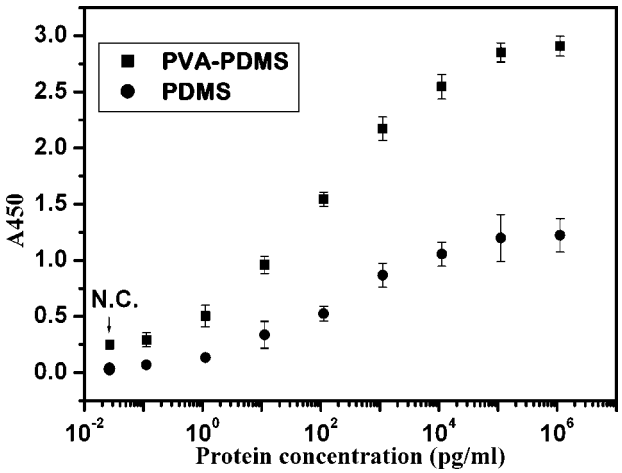

Figure 3. Sandwich ELISA results on PVA-modified PDMS and pristine PDMS.

without disrupting it. Regarding the protein nonspecific adsorption, only an insignificant amount of bovine serum albumin (BSA) or immunoglobulin was adsorbed by the PVA-modified PDMS surface (Figure 1c). In contrast, unmodified PDMS exhibited a drastic change in morphology after its exposure to such proteins, indicative of nonspecific adsorption via hydrophobic−hydrophobic interaction (Figure 1d). Such data confirmed that the modification of PDMS with PVA suppressed protein adsorption and reduced nonspecific bonding, although the immobilized surface was not totally hydrophilic, as confirmed by the value of the measured contact angle. This might be attributed to the blocking reagent application after the probe immobilization on the PVA−PDMS surface, which could not be applicable on a PDMS surface that solely relies on hydrophobic nonspecific bindings for probe immobilization. Rafati et al. (*10*) studied the interactions of a homologous series of cationic surfactants with BSA and reported that the hydrophobic interactions play an important role in the BSA-surfactant binding, whereas electrostatic interactions play only a minor one.

The PVA-modified PDMS surface was then reacted with one aldehyde group of glutaraldehyde, whereas the second aldehyde became available for coupling with bovine IgM or BSA (Supporting Information). It should be noted that glutaraldehyde might cross-link two adjacent PVA chains or even react with two hydroxyls of the same PVA molecule. Therefore, the reaction was performed with excess glutaraldehyde to ensure the availability of abundant aldehydes for the subsequent bimolecular attachment. As shown in Figure 1e, BSA (67 kDa), as represented by small dots with an average diameter of 100 nm, was distributed rather evenly on the surface. The obtained data were in agreement with the FESEM micrograph performed at low accelerating voltage (5 kV), which provided comparable resolution to conventional SEM performed at 15−25 kV (Figure S1, Supporting Information). Notice also that, with prolonged FESEM testing, PDMS is undergoing a noticeable distortion under the vacuum condition, and the twisted PDMS covers up the entire surface of the adsorbed protein. Bovine IgM (900 kDa) consists of five subunits of a Y-shaped immunoglobulin structure (900 kDa). The covalent bonding of this circular protein resulted in much larger circles; presumably, the protein was linked to the PVA backbone (Figure 1f).

AFM morphological changes were then used to monitor the kinetics of protein immobilization. The protein immobilization by covalent binding at the PVA-modified surface was completed within 30 min with an even distribution across the modified surface. In contrast, the amount of protein adsorbed nonspecifically by unmodified PDMS was much lower, and the protein distribution was nonuniform (Figure 2). A sandwich immunoassay was then conducted using the PVA-modified PDMS to anchor anti-rabbit IgG via the glutaraldehyde-activated surface for the detection of rabbit IgG. HRP-conjugated anti-rabbit IgG formed a tertiary complex with the anti IgG−IgG pair and was detected spectrophotometrically (Supporting Information). The detection range of the PVA-modified PDMS substrate was 1.12 pg/mL to 11.2 μg/mL (Figure 3), significantly wider than the unmodified PDMS surface (112 pg/mL to 11.2 μg/mL). The detection limit is also much lower than the reported value of 15 ng/mL immunoglobulins on non-PVA-treated PDMS (*11*). Together with AFM imaging, our results revealed that the PVA-modified substrate provided uniformly distributed aldehyde groups at the backbone of PVA. High densities of such functional groups coupled with the hydrophilic property of PVA led to the capture of a high amount of antibody, i.e., improved detection sensitivity as well as reduced false positive response. The tendency to capture the protein nonspecifically by unmodified PDMS resulted in a higher detection limit. Such results were not completely unexpected, since the binding sites of protein/antibody are mostly located in the hydrophobic domain and are no longer available for a target binding because of their preoccupied association with PDMS.

In brief, this communication describes a simple but effective technique to suppress nonspecific adsorption toward the development of a solid-phase material for immunoassay. Hydrophobicity of PDMS can be silanized with APTES followed by PVA coating and glutaraldehyde activation. Biomolecules can be covalently attached to the modified surface with even distribution. The application of the PVA-functionalized surface in sandwich ELISA results in excellent detection sensitivity (1 pg/mL) and linearity up to 11.2 μg/mL with negligible nonspecific protein adsorption.

Besides hydrophobic−hydrophobic interaction, nonspecific protein adsorption is affected by several factors such as protein properties (size, charge, shape, composition, and pH), surface properties (charge, chemistry, and topology), coadsorption of low-molecular-weight ions, intermolecular forces between adsorbed molecules, and strength of functional group bonds (*12*). Therefore, work is in progress to extend the applicability of the PVA-modified PDMS materials for immunoassays for pathogens with significant impact on clinical, environmental, and food monitoring. The prevention of nonspecific protein adsorption can also be exploited in many areas to enhance the performance and function of the materials including bioreactors, affinity chromatography, materials for cell colonization, and biosensors.

Received May 5, 2006; Revised Manuscript Received December 1, 2006

The synthesis and characterization of a Hepatitis B virus vaccine (HBsIC−ISS) candidate composed of Hepatitis B surface antigen (HBsAg) bionanoparticles conjugated to multiple copies of immunostimulatory sequence oligodeoxynucleotides is presented. An efficient tangential flow filtration (TFF) method has been developed to purify the conjugated bionanoparticles from the excess conjugation reagents. The TFF technique presented can serve as a rapid and convenient alternative to current methods like ultracentrifugation for the separation of excess small molecule/polymeric conjugation reagents from chemically modified viruses and other viruslike particles.

The branch of bionanotechnology in which naturally occurring biomacromolecular assemblies are modified and manipulated for biomedical and material science applications is a newly emerging field of research (*1*−*4*). A few biomacromolecular assemblies like viruses and protein cages such as ferritin have been recently used as reactors for biomineralization (*3*−*5*) and as nanoscaffolds for the polyvalent display of small molecules (*6*, *7*) and synthetic polymers (*8*−*10*) Future applications and breakthroughs in the field will depend on the conjugation of novel functional polymers and ligands to biomacromolecular assemblies and the development of efficient purification methods for producing these conjugates. In this paper, we have used recombinant Hepatitis B surface antigen (HBsAg) as a nanoscaffold for polyvalent display (clinical-grade HBsAg is composed of a mixture of bionanoparticles and small aggregates of particles formed by the spontaneous self-assembly of 100−150 copies of 25.4 KD recombinant protein subunits) (*11*). HBsAg is a therapeutically relevant protein and has one covalently accessible lysine residue that can be modified with lysine-specific reagents; each protein subunit has fourteen cysteines and one lysine. The current commercial hepatitis B virus (HBV) vaccine consists of HBsAg adsorbed to alum which acts as an adjuvant. The current vaccine is preventive and requires three immunizations over 6 months. Immunostimulatory sequence oligodeoxynucleotides (ISS) are synthetic CpG DNA sequences that mimic the immunostimulatory effects of bacterial DNA (*12*). We have shown that ISS (5-TGACTGTGAACGTTCGAGATGA-3) noncovalently mixed with HBsAg serves as a potent adjuvant, and the resulting improved preventive HBV vaccine provides protective HBsAg-specific antibody titers in humans after two immunizations over a 2 month period (*13*). The covalent linkage of multiple copies of ISS to HBsAg could produce a more potent HBV vaccine. In this communication, we present the conjugation, purification (using tangential flow filtration), and characterization of a potentially therapeutic polyvalent HBsIC−ISS vaccine. Tangential flow filtration (TFF) is a pressure-driven separation technique that utilizes size-selective ultrafiltration (UF) membranes or hollow fibers to separate molecules in solution on the basis of differences in size (23). Molecular species larger than the pore size of the membrane are retained by the membrane and recirculate in the retentate loop of the TFF system (retentate fraction); molecules smaller than the pores sieve through under applied pressure and are removed from the sample and the system via the filtrate (permeate fraction) (*14*−*16*). Tangential flow filtration has been previously used to purify excess poly(vinyl alcohol) from nanoparticle dispersions generated from poly(lactide-*co*-glycolide) and poly(vinyl alcohol) (*14*). TFF has also been used to purify viruses such as influenza virus and adenovirus from host cell proteins and DNA, to concentrate viruses, and to purify virus particles from large host cell fragments (*15*,*16*). To the best of our knowledge, this is the first time TFF has been used to purify chemically modified bionanoparticles from excess bioconjugation reagents.

The synthesis of HBsIC−ISS was a challenging problem, since clinical-grade HBsAg (Green Cross Vaccine Corporation) was supplied at a low concentration for bioconjugation (1 mg/mL). The conjugation process we first adopted was to block any free cysteine residues present on HBsAg with an excess of *N*-ethyl maleimide (NEM) (see Scheme 1, **1b**). This was followed by activation of lysine residues using sulfosuccinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (sulfo-SMCC). This reaction modified the amino acid side chains of L-lysine residues and produced a particle polyvalently displaying maleimide groups (Scheme 1, **1c**). The excess reagents were removed by chromatography on a G-25 desalting column (GE Biosciences, Piscatway, NJ). 5′-Disulfide-linked phosphorothioate ISS (TGACTGTGAACGTTCGAGATGA-3′) was reduced with 200 mM Tris-(2-carboxyethyl)phosphine (TCEP) at room temperature for 1 h, and the residual reagents were removed by chromatography on a G-25 desalting column to produce 5′-thio-ISS. Since the concentration of **1c** was too low for effective conjugation to 5′-thio-ISS, the sample was concentrated by

Scheme 1. Synthesis of HBsAg Conjugate withISS (HBsIC-ISS)

centrifugation using a centricon filter; this caused precipitation and loss of sample. The remaining concentrated sample of **1c** was conjugated to 5′-thio-ISS. After conjugation, the excess 5′-thio-ISS was removed using a Superdex HR 200 30/10 column (GE Biosciences, Piscatway, NJ) to produce the final product HBsIC−ISS (Scheme 1, **1d**). The process described above is inefficient; the overall yield for the process was very low (∼20%), and the final concentration of the product was less than 0.2 mg/mL.

To overcome these limitations, we developed a tangential flow filtration (TFF)-based process. HBsIC−ISS conjugate was synthesized and then purified via the TFF process in accordance with the steps described below and summarized in Scheme 1. The cysteine residues of HBsAg (**1a**) were capped with an excess of *N*-ethyl maleimide (NEM) to produce (**1b**). The lysine residues of **1b** were activated with excess sulfosuccinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (sulfo-SMCC) to produce the maleimide-labeled bionanoparticles (**1c**). Sample **1c** was conjugated with 5′-thio-ISS to produce the final conjugated product HBsIC−ISS (**1d**) (see Supporting Information). We employed a 300 kDa molecular weight cutoff cellulose membrane to retain the large nanoparticles (**1c** and **1d**) in the sample vessel (retentate fraction) (Figure 1A). Excess reagents DMSO, NEM, and sulfo-SMCC were separated from the maleimide-labeled HBsAg particle via the filtrate (permeate fractions) during constant volume diafiltration (Figure 1).

The same diafiltration process was performed after conjugation of the maleimide-labeled HBsAg with polymeric ISS (7500

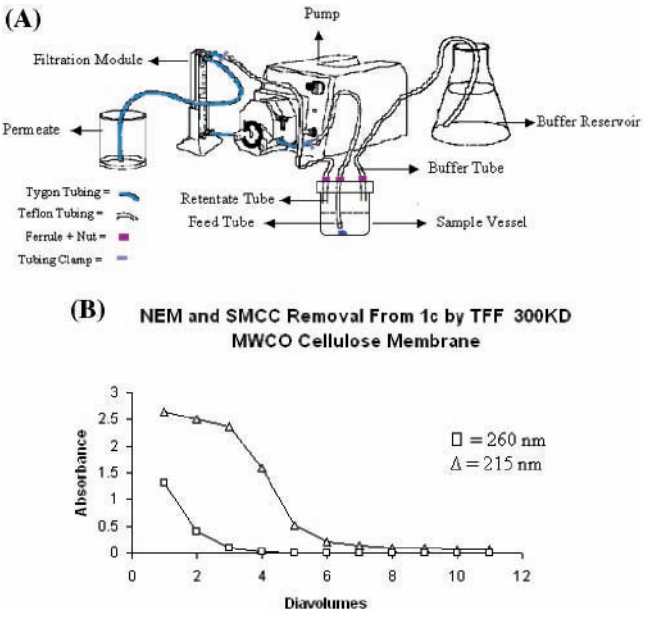

Figure 1. (A) Tangential flow filtration (TFF) setup for one-pot synthesis, purification, and formulation of conjugated HBsAg and ISS (HBsIC−ISS). (B) NEM and sulfo-SMCC removal from HBsAg−sulfoSMCC conjugate by TFF using a PXC300C50 300 kDa MWCO cellulose membrane monitored at △ = 215 nm and □ = 60 nm. MW) in order to remove excess 5′-thio-ISS. The extent of removal of small molecules was monitored by measuring the UV spectra of the permeate fractions at 215 nm and 260 nm after each diavolume (1 diavolume = volume of reaction mixture) (Figure 1B). The removal of unconjugated ISS was also similarly monitored (see Supporting Information). Over ∼99% removal of excess conjugation reagents was achieved in less than 1 h. The buffer used in the ISS removal step was in-house formulation buffer (PBS, pH 7.4). The final formulated vaccine was tested for endotoxin content and used for preclinical experiments. Vaccines are formulated in a buffer which is physiologically compatible; in this TFF step, both ISS purification and formulation were achieved simultaneously. The fact that 20 nm particles were retained by the 300 kDa MWCO TFF membrane was previously confirmed by performing a system qualification experiment using 20 nm green nanobeads (absorbance maximum 466 nm) as a model for HBsAg in the sample reservoir.

The overall yield of HBsIC−ISS (**1d**) was determined by a Lowry-based assay using a Biorad, Inc., DC assay kit for proteins to be 77% (see Supporting Information). The fact that the presence of DNA does not affect the DC assay was previously confirmed using a noncovalent mix of **1a** and ISS (Dynavax Technologies, unpublished results). Overall yields of HBsIC−ISS were ∼80%; in contrast, yields by conventional G25 desalting chromatography were considerably lower at ∼20% (Rodriguez, R., unpublished results). In our TFF experiment, the concentration of the final conjugated product (**1d**) was 0.9 mg/mL. This is quite remarkable because the starting concentration of the surface antigen (**1a**) was 1 mg/mL. In contrast, the conventional chromatographic approach produced HBsIC−ISS at less than 0.2 mg/mL concentration; the additional concentration step in the chromatographic approach was time-consuming and resulted in a reduced yield.

The conjugate HBsIC−ISS (**1d**) was characterized by capillary zone electrophoresis (CZE). CZE separates sample components on the basis of differences in mass/charge ratio (see Supporting Information). The highly charged conjugated product HBsIC−ISS (**1d**) eluted very early as a narrow peak at 3.7 min,

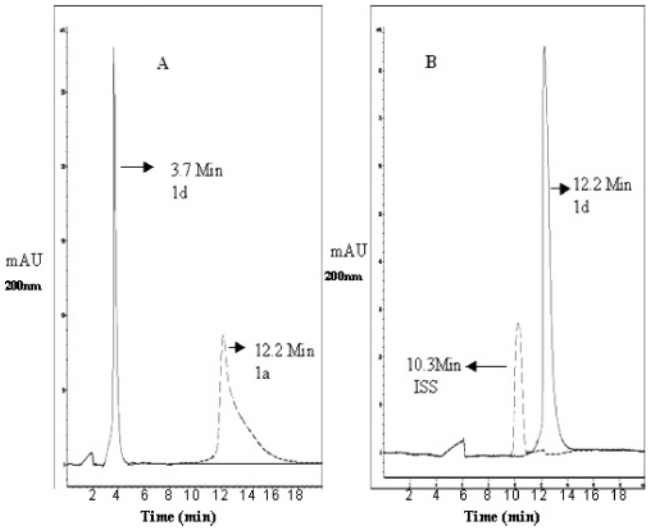

Figure 2. Capillary zone electrophoresis. (A) Separate injections of HBsIC−ISS conjugate and starting surface antigen HBsAg. (B) Separate injections of HBsIC−ISS conjugate 1d and starting 5-thio-ISS−oligodeoxy nucleotide.

and the relatively uncharged HBsAg (**1a**) eluted as a broad peak at 12.2 min (Figure 2A). A second CZE method was employed to clearly distinguish between the starting ISS and the conjugate HBsIC−ISS (**1d**) (Figure 2B).

The oligodeoxynucleotide concentration in HBsIC−ISS was determined by measuring the UV spectrum of the DNA component of the conjugate after subtracting the absorbance contribution from the protein; the validity of this approach was established by performing suitable control experiments (see Supporting Information). The oligodeoxynucleotide/protein subunit ratio in the conjugate HBsIC−ISS (**1d**) was determined to be 1/1. The modification of HBsAg by oligodeoxynucleotide (in the case of **1d**) was also confirmed by HPLC. In our HPLC experiments, we observed that the ratio of the absorbance at 215 nm to the absorbance 260 nm (A_{215}/A_{260} ratio) (using a Phenomenex BioSEp-SEC-3000 column) was more sensitive to the presence of ISS conjugated to the protein than if we used an A_{280}/A_{260} ratio. The HBsAg control sample (**1a**) and the HBsIC−ISS conjugated product (**1d**) eluted at the void volume due to their large size; the peak areas at 215 nm and 260 nm were integrated (see Supporting Information). The A_{215}/A_{260} ratios were 13.1 for the HBsAg control sample (**1a**) and 5.9 for the HBsIC−ISS sample (**1d**), indicating the presence of oligodeoxynucleotide in the conjugate. This reduced A_{215}/A_{260} ratio for the HBsIC−ISS conjugate suggests that several copies of oligodeoxynucleotide are attached to HBsAg particles; this ratio was very consistent among different batches of conjugate synthesized.

Preliminary light scattering characterization for HBsAg (**1a**) and HBsIC−ISS (**1d**) using a PSS NICOMP ZLS particle sizing system provided mean diameters of 30 nm for HBsAg (**1a**) and 40 nm for the conjugate HBsIC−ISS (**1d**), respectively (see Supporting Information). The size of recombinant HBsAg has previously been determined in the literature to be 27.5 nm using high-resolution transmission electron microscopy (*17*).

Transimssion electron microscroscopy of the HBsIC−ISS conjugate (**1d**) confirms the intact nature of the conjugated particles (see Supporting Information for TEM of **1d**).

The SEC chromatogram of HBsAg (**1a**) (Figure 3) indicates a bimodal distribution. The conjugate (**1d**) chromatogram was shifted to a slightly lower retention time (higher MW); although bimodal, the molecular weight distribution was narrower than that of unmodified HBsAg (Figure 3A). The bimodal nature of the SEC chromatogram of the clinical-grade HBsAg control sample and the HBsIC−ISS conjugate is ascribed to the presence of individual particles and small aggregates of particles. The intact nature of the particles after conjugation can be inferred from the following facts: (a) The retention times in the SEC chromatogram for both the surface antigen (commercially obtained intact particles) and the conjugate **1d** are similar, indicating that both of them are of approximately the same size. (b) The conjugate (**1d**) is retained by a 300 kDa molecular weight cutoff TFF membrane (if the particle had disassembled

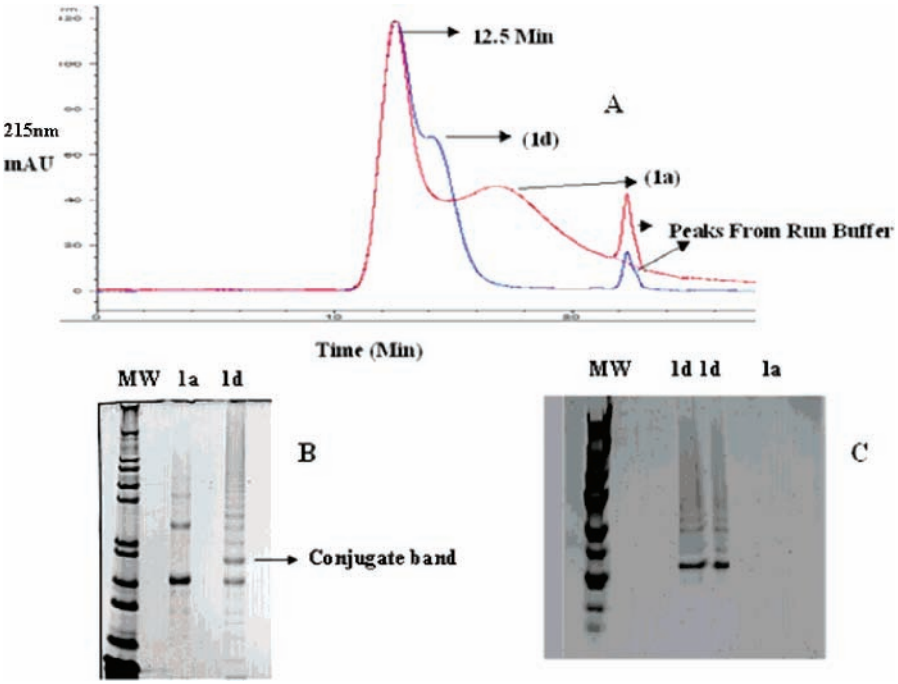

Figure 3. Characterization of HBsAg (1a) and HBsIC−ISS conjugate (1d). (A) Size-exclusion HPLC. (B) SDS PAGE analysis using Mark 12 as the molecular weight standards (MW), visualized with gel code blue protein stain; the arrow denotes the shifted band of the ISS-modified monomeric protein subunit (1d). (C) SDS PAGE analysis using Bio-Rad Blue molecular weight standards (MW), visualized with a DNA-specific silver stain kit; HBsAg (1a) which has no DNA is not visible. The DNA modified protein bands in the conjugate is visible (1d).

during conjugation, the 25.4 kDa subunits produced would be too small to be retained by the 300 kDa MWCO membrane), and (c) the preliminary light scattering data suggest sizes of ~30 nm for unmodified HBsAg (**1a**) and ~40 nm for the HBsIC−ISS conjugate (**1d**) (see Supporting Information). (d) TEM images of the HBsIC−ISS conjugate **1d** clearly indicate intact particles (see Supporting Information).

The samples were analyzed by denaturing gel electrophoresis. HBsIC−ISS conjugate (**1d**) displayed an additional band at 32 KD (Figure 3B) that corresponds to monomeric protein subunit modified by one ISS, and there are additional faint bands corresponding to ISS-modified protein multimers (a protein-specific stain was used to stain the gel shown in Figure 3b). The modification of HBsAg with ISS (DNA) in the conjugate product was further confirmed by using a DNA-specific silver stain (Figure 3C). The starting HBsAg (**1a**) was not visible, because it lacks DNA. In contrast, the ISS modified protein bands in the conjugate HBsIC−ISS (**1d**) were clearly visible (Figure 3C). The presence of faint high molecular weight protein bands observed in the SDS PAGE gels of clinical-grade HBsAg control and HBsIC−ISS conjugate is possibly due to disulfide cross-links between cysteine residues from protein subunits (each subunit has 14 cysteine residues).

The rapid TFF-based approach we present here is bound to be generally applicable in the separation of a wide range of conjugated nanoparticles from small molecules/polymer reagents and will be useful in the areas of nanomedicine and material science. The advantages of TFF over other methods of separation are that TFF is a very rapid process; a synthesis, purification, and formulation can be performed within a few hours in a single reaction vessel. The standard method of purification of bionanoparticles from excess conjugation reagents is ultracentrifugation over sucrose gradients, pelleting, and resuspension of the conjugate. This is a multistep 2 day process and requires expensive equipment (*4*−*7*) In the specific application of separating nanoparticles from small molecules/polymers, the vast difference in size between the entities makes TFF an efficient and high-yield technique. TFF is a scaleable method allowing aseptic processing; sample volumes of milliliters up to hundreds of liters could be easily processed with inexpensive equipment. Furthermore, unlike using dialysis or chromatography, TFF allows concentration of samples when run in the concentration mode. This method would be the equivalent of "flash chromatography" in contrast to "regular column chromatography" for the virus/protein cage-based chemistry community.

The biological activity of the HBsIC−ISS vaccine in mice indicates that it generates robust immune responses (antibody, Interferon-γ, and Cytotoxic T Lymphocyte); a detailed study of the biological activity is currently underway and will be reported in the future. A similar polyvalent display of ISS on other bionanoparticles like the human papilloma virus (HPV) antigen could lead to an improved vaccine against HPV infection.

ACKNOWLEDGMENT

We thank Dr. Gary Ott for many valuable discussions regarding the project.

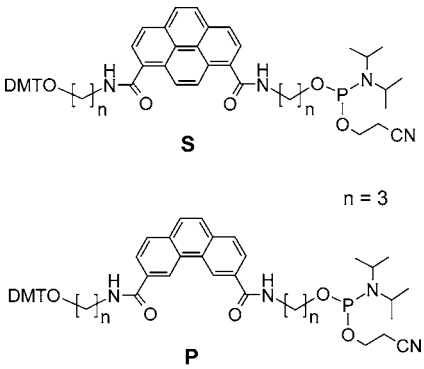
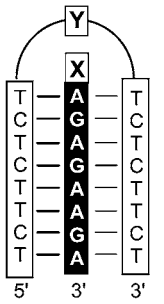
Triple-Helix Mediated Excimer and Exciplex Formation

Ivan Trkulja and Robert Häner*



Department of Chemistry and Biochemistry, University of Bern, Freiestrasse 3, CH-3012 Bern, Switzerland. Received October 20, 2006

The synthesis and properties of triple-helical hybrids containing non-nucleosidic polyaromatic building blocks are described. Clamp-type oligonucleotides containing a non-nucleosidic pyrene linker form stable triple helices with a polypurine target strand containing a terminal pyrene or phenanthrene moiety. Stacking interactions between the unnatural building blocks enhance triplex stability and lead to strong excimer or exciplex formation, which is monitored by fluorescence spectroscopy.



The formation of triple-helical structures is a well-documented feature of nucleic acids (*1*−*6*). Although generally limited to homopurine/homopyrimidine regions, triplex formation is of interest as a method of targeting DNA with high selectivity (*7*−*11*). In particular, synthetic oligonucleotides have been shown to adopt clamp-type motifs (*12*−*21*) in which a single-stranded homopurine strand is recognized by an oligonucleotide through simultaneous formation of Watson−Crick and Hoogsteen bonds. Aromatic linkers have also been used as loop replacements in clamps to tether the Watson−Crick and the Hoogsteen bond-forming strands of a DNA triplex (*22*, *23*). Recently, we reported the synthesis and properties of non-nucleosidic, polyaromatic building blocks and their incorporation into DNA (*24*, *25*). Interstrand stacking of such polyaromatic building blocks was subsequently shown by excimer formation (*26*) of pyrenes placed in opposite positions (*27*, *28*). The fluorescence properties of pyrene building blocks render them valuable for structural studies of the resulting oligomers and the hybrids they form (*29*−*34*). The strength of excimer formation as well as the ratio between excimer and monomer is determined by overall structure and, most importantly, the distance between the pyrene molecules. As part of our research, we designed chemically and structurally stable mimics of a triple helical structure that would bring the pyrenes and/or other aromatic moieties into a favorable position for excimer or exciplex formation. The approach makes use of a clamp-type oligomer that, upon binding to a homopurine strand, brings the two aromatic structures in close proximity. Here, we report the formation and spectroscopic properties of clamp-based triple helices with oligonucleotides containing pyrene- and phenanthrene-derived building blocks.

The synthesis of the pyrene and phenanthrene phosphoramidites **S** and **P** (Scheme 1) was performed as described (*24*, *27*). The building blocks were further used for the preparation of the oligomers **1**, **2**, and **3** by automated oligonucleotide synthesis. Incorporation of the pyrene and phenanthrene monomers proceeded with coupling yields comparable to those of the unmodified nucleotide phosphoramidites. The obtained oligomers were purified by reverse-phase HPLC and characterized by mass spectrometry (see Supporting Information). Oligonucleotides **4** and **5** were used for control purposes. Hybridization of the clamp oligonucleotides (**1** or **5**) with either of the homopurine strands (**2** to **4**) results in formation of a triple helix as illustrated in Scheme 1.

[a] Schematic representation of triplex formation between clamps **1** or **5** and targets **2**−**4** (for simplicity, **S** and **P** are used for both phosphoramidites as well as incorporated building blocks; DMT = 4,4′-dimethoxytrityl).

Thermal denaturation experiments revealed a strong influence of the modifications on the stability of the triple helical complex at pH 5.0 and 7.0 (Table 1). In comparison to the control triplex (**4*****5**), a slight increase in stability (ΔT_m approximately 4 °C) is observed upon introduction of a pyrene moiety (**S**) in the loop of clamp **1** observed in its complex with **4**. This increase is comparable with the one observed for phenanthrene-containing hairpin structures containing this type of building block as loop replacement (*35*). A considerably larger increase (ΔT_m = 8.6 and 10.2 °C at pH 5.0 and 7.0, respectively) in stability is found, however, when a pyrene residue is present (triplex **1*****2**). A further substantial rise in structural stability (ΔT_m = 12.8 and 17.3 °C) results from introduction of a phenanthrene modification at the 5′-end of the homopurine target strand (triplex **1*****3**). For all hybrids, a single transition was observed in the melting diagrams. Also, as expected, lower pH favors the stability of all triple helices.

The large increase in the T_m observed for all pyrene- or phenanthrene-modified hybrids is most likely the result of

Table 1. T_m Values of Pyrene and Phenanthrene-Modified Triple Helices[a]

	pH 5.0[b]		pH 7.0[c]	
	T_m[d] [°C]	ΔT_m[e] [°C]	T_m[d] [°C]	ΔT_m[e] [°C]
1*2	55.3	8.6	33.2	10.2
1*3	59.5	12.8	40.3	17.3
1*4	50.5	3.8	27.8	4.8
4*5	46.7		23.0	

[a] Conditions: oligomer concentration 1.0 μM, 100 mM NaCl, 20 mM $MgCl_2$, temperature gradient: 0.5 °C/min. [b] 10 mM sodium acetate buffer. [c] 10 mM sodium cacodylate buffer. [d] Melting temperatures were determined from the maximum of the first derivative of the melting curve (A_{260} against temperature); exptl error: ±0.5 °C. [e] Difference in T_m relative to that of control triplex **4*5**.

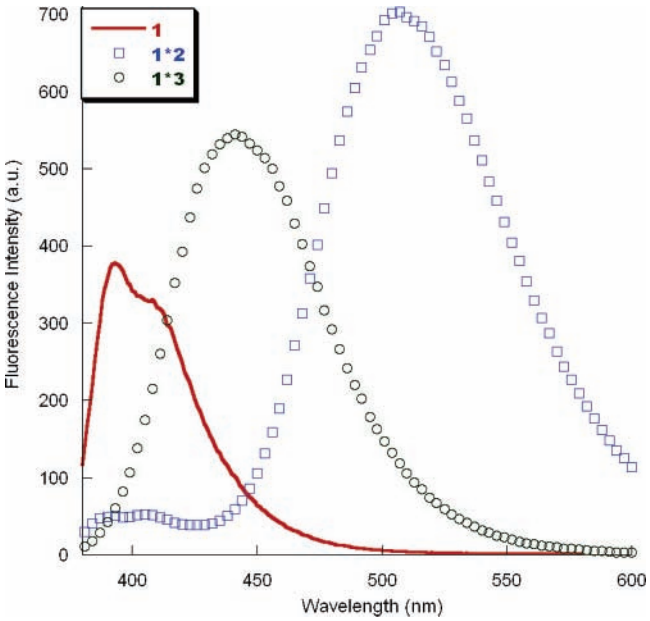

Figure 1. Fluorescence spectra of pyrene- and phenanthrene-containing triplexes **1*2** and **1*3**, as well as of the oligonucleotide **1**. Conditions: oligomer concentration 1.0 μM, 10 mM acetate buffer, 100 mM NaCl, 20 mM $MgCl_2$, pH 5.0, 25 °C. Excitation wavelength, 356 nm; excitation slit, 10 nm; emission slit, 5 nm.

favorable stacking interactions between two pyrenes (**S**/**S**) or pyrene and phenanthrene (**S**/**P**), respectively. This implies that the aromatic systems are in a favorable position for excimer and exciplex formation upon excitation, and the interactions of the aromatic residues should, thus, be observable by fluorescence spectroscopy (Figure 1). Upon excitation at 356 nm, oligonucleotide **1** shows pyrene monomer fluorescence (approximately 380−420 nm). For hybrid **1*2**, strong pyrene excimer fluorescence is observed at 500 nm. Only traces of emission at 394 nm are observed in this hybrid, indicating very efficient excimer formation. The change from monomer to excimer fluorescence is in close analogy to the findings obtained with duplex formation by pyrene-containing oligonucleotides (*27*). Surprisingly, a very strong signal with maximum intensity at 437 nm was observed for hybrid **1*3**, which can be attributed to formation of an exciplex between pyrene and phenanthrene. The high intensity of the pyrene/phenanthrene exciplex fluorescence is remarkable. Phenanthrene is known to form exciplexes with amino-substituted aromatic hydrocarbons (*36*, *37*), but to our knowledge, exciplex formation between phenanthrene and pyrene has not been described (*38*). The formation of the exciplex in hybrid **1*3** is also noteworthy in light of the interest in exciplex formation as a tool for genetic diagnostics (*39*).

Temperature-dependent fluorescence spectroscopy was carried out to monitor the change of emission at 394 nm and 500 nm

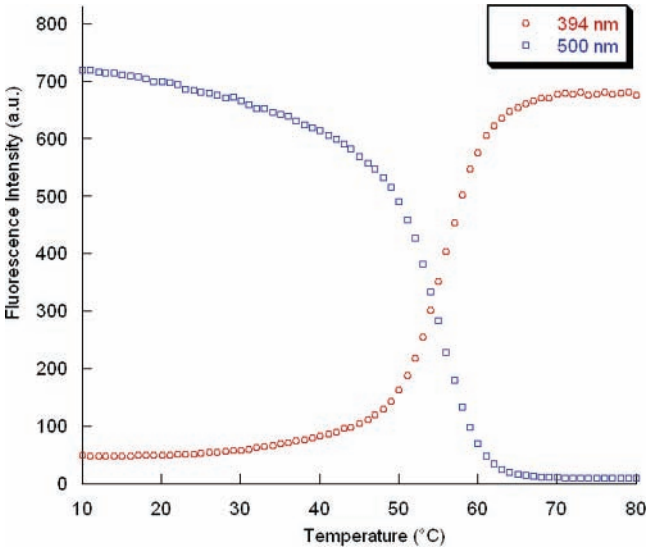

Figure 2. Temperature-dependent fluorescence measurements for triplex **1*2**; 80 °C to 10 °C at 0.5 °C /min; conditions: see Figure 1. T_m values: 55.9 °C (394 nm); 55.5 °C (500 nm).

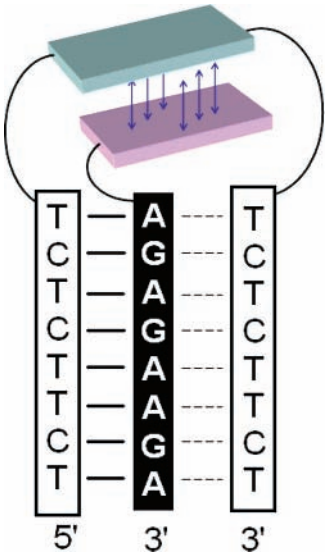

Figure 3. Illustration of triplex formation between a homopyrimidine oligonucleotide and a homopurine target strand, both modified with polyaromatic building blocks.

for hybrid **1*2** at pH 5.0 (Figure 2). Upon formation of the triple helix (80 °C to 10 °C), monomer emission decreases and excimer fluorescence increases simultaneously. The shape of the curves is coherent with the UV−Vis thermal denaturation curves, and the T_m values are in close agreement to the ones calculated from the thermal denaturation experiments monitored by UV absorbance (difference in the values is <1 °C).

Similar data were also obtained for the **1*3** hybrid by monitoring the exciplex fluorescence at 437 nm and at different pH values (see Supporting Information). This provides additional evidence that excimer or exciplex formation proceeds in close connection to the formation of the triplex helix between the oligonucleotide clamp **1** and homopurine sequences **2** and **3**, respectively. Upon association of the strands, the pyrene modification in the loop is brought in close contact to the pyrene or phenanthrene modification at the 5′-end of the homopurine strand (illustrated in Figure 3). This positioning enables the formation of an excited dimer or complex. At higher temperatures, as the strands dissociate, the excimer or exciplex fluorescence disappears and the monomer fluorescence increases.

The data show that stable triple-helix formation is possible with clamp-type oligonucleotides containing a non-nucleosidic pyrene linker. The pyrene strongly interacts with aromatic residues (pyrene or phenanthrene) attached to the target strand, resulting in a considerable increase in the T_m values (up to 17 °C at pH 7.0 against an 8-mer target strand). Pyrene−phenanthrene interactions have a more pronounced stabilizing effect than pyrene−pyrene interaction in the present system. The interactions can be monitored by fluorescence spectroscopy. Strong pyrene excimer or pyrene−phenanthrene exciplex emission is observed below the melting temperature of the hybrids. At room temperature, monomer fluorescence is completely absent, which underlines the close and tight association of the aromatic building blocks. In light of the biological relevance of the triple helix (*40*), mimics of the kind described here may serve as chemically and structurally stable analogues of naturally occurring structures. Introduction of unnatural building blocks not only increases chemical and structural stability but at the same time also leads to the generation of a fluorescent signal.

ACKNOWLEDGMENT

Financial support by the Swiss National Science Foundation (grant 200020-109482) is gratefully acknowledged.

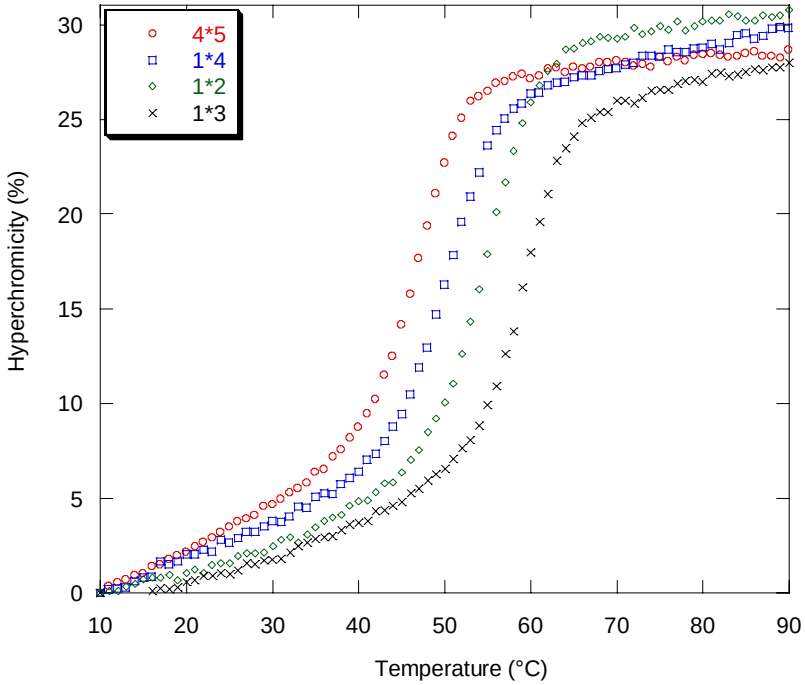
Experimental Section

Oligonucleotide Synthesis. Pyrene-derived phosphoramidite building block **S** and Phenanthrene-derived building block **P** were incorporated into oligonucleotides *via* standard automated oligonucleotide synthesis (ABI 394 DNA/RNA Synthesizer) using I_2/pyridine/water in the oxidation step. Coupling yields with **S** and **P** were comparable to the ones obtained with standard phosphoramidite building blocks. Average per-step-yield was between 95 and 97% for modified oligonucleotides. Oligonucleotides were purified by reverse phase HPLC and characterized by MS (Table 1). Unmodified oligonucleotides **4** and **5** were obtained from *Microsynth AG* (Balgach, Switzerland).



Thermal Denaturation Experiments. A *Varian Cary 3e* UV/Vis spectrophotometer equipped with a *Peltier* block temperature-controller and Varian *WinUV* software were used to determine the melting curves at 260nm, a heating-cooling-heating cycle in the temperature range 10-90ºC was applied with a temperature gradient of 0.5ºC min^{-1}. The data were collected and analyzed with *KaleidaGraph* software from Synergy Software. T_m values were determined as the maximum of the first derivative of the melting curve. Each T_m shown is the average the second (cooling) and third (heating) curve of three independent experiments; experimental error ± 0.5 ºC.

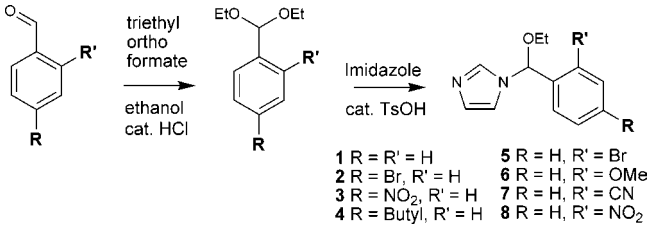
Received July 20, 2006; Revised Manuscript Received November 24, 2006

This paper describes the development of a new class of N-linked imidazoles as potential pH-sensitive, cleavable linkers for use in cancer drug delivery systems. Kinetic analysis of eight derivatives of *N*-ethoxybenzylimidazoles (NEBIs) showed that their rates of hydrolysis are accelerated in mild aqueous acidic solutions compared to in solutions at normal, physiological pH. Incorporation of electron donating or electron withdrawing substituents on the phenyl ring of the NEBI resulted in the ability to tune the rates of hydrolysis under mild acidic conditions with half-lives ranging from minutes to months. A derivative of NEBI carrying doxorubicin, a widely used anticancer agent, also showed an increased rate of hydrolysis under mild acid compared to that at normal physiological pH. The doxorubicin analogue resulting from hydrolysis from the NEBI exhibited good cytotoxic activity when exposed to human ovarian cancer cells. These results demonstrate a potentially useful, general strategy for conjugating a wide range of drugs to imidazole-containing delivery vessels via NEBI functionalities for controlled release of therapeutics for drug delivery applications.

Herein, we describe the development of a class of pH-sensitive molecules that hydrolyze with tunable rates under physiological conditions. Organic functional groups that decompose slowly in an aqueous environment have attracted wide interest as potential linkers for the covalent conjugation of drugs to polymers for a range of drug delivery applications (*1*). Functional groups that decompose in mildly acidic environments, for instance, may be useful for the development of cancer drug delivery systems where an acid-sensitive group could exploit the lower extracellular pH (pH $\approx$ 6.4−6.9) of some tumor cells compared to that of blood or normal tissues (*2*) to trigger the release of therapeutic agents from suitable delivery vessels (*3*). Functional groups that cleave under mild acid may also exploit the low pH of endosomes (pH $\approx$ 5.5−6) and lysosomes (pH $\approx$ 4.5−5) to trigger the release of covalently linked therapeutics from drug delivery carriers after endocytosis by targeted cells (*4*).



In the course of developing new drug delivery systems, we have explored the possibility of using N-linked imidazoles as functionalities that could undergo hydrolysis in aqueous acidic solutions at physiological temperature. We hypothesized that the expected difference in the protonated state of certain N-linked imidazoles in mild acid (e.g., pH = 5.5) compared to normal, physiological pH (pH = 7.4) (*5*) might be useful for initiating the rapid release of molecules (e.g., drugs) linked to imidazole-containing delivery vessels when exposed to tumor-like environments. Here, we present a study of the hydrolysis of a new class of N-linked imidazoles that cleave under physiologically relevant conditions upon protonation of the imidazole group. We designed these molecules on the basis of a previously reported (*6*) ethoxyethyl protecting group for imidazoles that was shown to be hydrolytically unstable in aqueous acidic conditions at elevated temperatures. Mechanistically, the cleavage of ethoxyethyl groups on imidazoles had been proposed to involve the protonation of the imidazole nitrogen (N3 in Scheme 1) followed by breaking of the C6−N1 bond as the rate-determining step (RDS, Scheme 1). To attain a related N-linked imidazole that could undergo acid hydrolysis at physiological temperatures, we explored whether substitution of the ethyl group (i.e., bearing the C6 carbon in Scheme 1) with benzyl groups could lower the activation energy required for this hydrolysis reaction and facilitate the cleavage of the C6−N1 bond under physiological conditions.

[a] Rates of hydrolysis were measured by ^1H NMR. See Supporting Information for details. [b] 0.5 M MES buffer solution. [c] 0.5 M HEPES buffer. [d] No hydrolysis detected after >8 weeks.

(Scheme 2). The Supporting Information summarizes the details of the synthesis. At 37 °C in 0.5 M HEPES buffer in D_2O (pD = 7.4), we measured by ^1H NMR that **1** hydrolyzes with a half-life of 25 h to give imidazole, ethanol, and benzaldehyde as the only products detected (Scheme 1) (*7*). At 37 °C in 0.5 M MES buffer in D_2O (pD = 5.5), **1** hydrolyzed to give the same products as at higher pD (Figure 1) but with a much shorter half-life of 1.7 h for hydrolysis. Kinetic analysis indicated that the hydrolysis of **1** is first-order dependent on the concentration of **1** and zero-order dependent on the concentration of buffering agent (see Figure S1 in the Supporting Information) (*8*). As expected from the proposed mechanism shown in Scheme 1, the benzyl group (R = phenyl) appears to stabilize the transition state of the rate-determining step better than the previously reported (*6*) ethyl group (R = methyl) and, thus, facilitates hydrolysis of **1** at physiological temperatures. Having measured the pK_a of the protonated form of **5** (as a representative NEBI) to be 5.4 (*9*), the observed acceleration of the rate of hydrolysis of **1** in mild acidic solution compared to physiological pH is also consistent with the proposed mechanism (Scheme 1).

To investigate whether electronic effects might influence the rate of hydrolysis of NEBIs, we incorporated electron donating and electron withdrawing groups at the ortho or para positions of the phenyl ring and compared the rates of hydrolysis for **1**−**8**. Incorporation of an electron donating methoxy group at the ortho position in **6**, for instance, resulted in a half-life of 0.6 h for the hydrolysis of **6** at 37 °C in 0.5 M MES buffered D_2O (pD = 5.5); we observed a slower rate of hydrolysis for **6** ($t_{1/2} \approx 5$ h) at 37 °C in 0.5 M HEPES buffered D_2O (pD = 7.4) compared to the rates of hydrolysis at pD = 5.5 (Table 1). Incorporation of electron withdrawing substituents at the ortho or para positions of the phenyl ring of **1**, on the other hand, resulted in slower rates of hydrolysis in acidic and neutral solutions. Incorporation of a relatively weak electron withdrawing bromo substituent at the ortho position in **5**, for example, resulted in a significant decrease in the rate of cleavage of the NEBI moiety, with measured half-lives of 280 and 2300 h for the hydrolysis of **5** at 37 °C in buffered D_2O at pD = 5.5 and pD = 7.4, respectively. Furthermore, incorporation of strong electron withdrawing nitro substituents at the ortho or para position of the phenyl ring resulted in remarkably slow rates of hydrolysis of the NEBI moiety at 37 °C, with measured half-lives of 6900 h for both **3** and **8** in buffered D_2O at pD = 5.5 and no hydrolysis detected after >8 weeks at pD = 7.4.

To further probe the mechanism of cleavage of NEBIs in acidic solutions, we plotted the linear free energy relationship

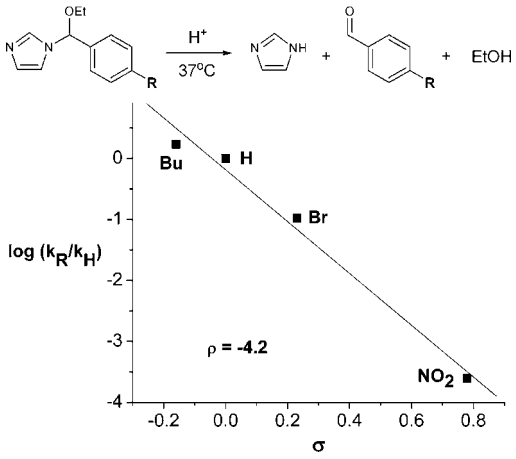

Figure 1. Linear Hammett correlation for the hydrolysis of **1**−**4** in 0.5 M MES buffered D_2O (pD = 5.5) at 37 °C, where R = *n*-butyl (Bu), H, Br, and NO_2.

(*10*) for the hydrolysis of **1**−**4** in D_2O at pD = 5.5 (Figure 1). We calculated a ρ-value of −4.2 for the hydrolysis of the NEBIs, which is consistent with an increase in positive charge (e.g., on the benzylic carbon of **1**−**8**) in the rate-determining step of the reaction. This observed linear Hammett correlation, combined with the finding that the rate of hydrolysis of **1** is independent of the concentration of buffering agent (see Figure S1 in the Supporting Information), supports a specific acid-catalyzed mechanism (*10*) for the hydrolysis of **1**−**8** as shown in Scheme 1.

With these results from kinetic and mechanistic studies in hand, we were interested in determining whether a NEBI carrying an antitumor agent—here, doxorubicin (*11*)—would also hydrolyze with accelerated rates under mild acidic solutions compared to at normal, physiological pH. We synthesized **9** by formation of an amide bond between a reactive amine group on doxorubicin and a carboxylate group on the para position of the phenyl ring of the NEBI (Figure 2). The Supporting Information describes the details of the synthesis and characterization of **9**. We measured a half-life by RP-HPLC of 55 h for the hydrolysis of **9** at 37 °C in MES buffered H_2O (pH = 5.5) (*12*). As expected, we observed a slower rate of hydrolysis of **9** ($t_{1/2}$ = 1150 h) at 37 °C in HEPES buffered H_2O (pH = 7.4) compared to the rates of hydrolysis at pH = 5.5 (Figure 2). Cytotoxicity studies indicated that **10** (i.e., the analogue of doxorubicin resulting from hydrolysis of **9** in mild acidic solutions) retains anticancer activity against human ovarian carcinoma 2008 cells with an IC_{50} of ∼12 μM (Figure 3). For comparison, compound **9** had a 2-fold higher IC_{50}, and doxorubicin had a >10-fold lower IC_{50} than **10** against this cell line. Although less potent than doxorubicin, compound **10** also has similar cytotoxic activity compared to other clinically used anticancer agents being developed for controlled release from drug delivery systems via pH-sensitive linkers (*4c*).

We have thus demonstrated that NEBIs hydrolyze in aqueous solutions at physiological temperatures with hydrolysis occurring approximately 10 times faster in mildly acidic solutions compared to solutions at normal, physiological pH. By incorporating electron donating or electron withdrawing substituents, we demonstrated the ability to tune the rates of hydrolysis of these N-linked imidazoles in mild acidic solutions with half-lives ranging from ∼30 min to >9 months. A NEBI carrying doxorubicin also exhibited accelerated rates of hydrolysis in acidic solution compared to at neutral pH, with the product of hydrolysis showing potentially useful cytotoxic activity against human cancer cells. Previous studies have shown that drugs conjugated to delivery vessels via pH-sensitive linkers with hydrolytic properties similar to those of **9** can exhibit useful

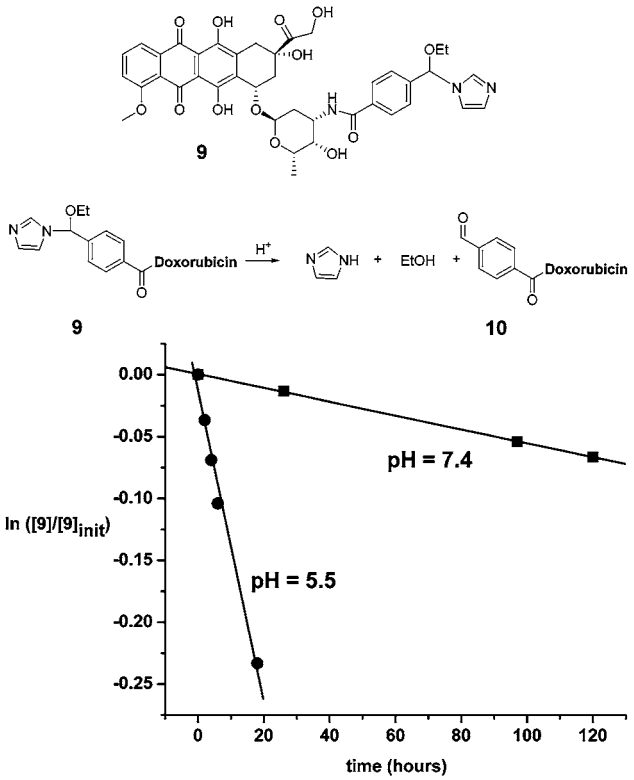

Figure 2. Hydrolysis of a NEBI conjugated with doxorubicin (**9**) in MES buffer (pH = 5.5) and HEPES buffer (pH = 7.4). The pH-dependent rate of hydrolysis of **9** to aldehyde **10** was determined by RP-HPLC. See Supporting Information for details.

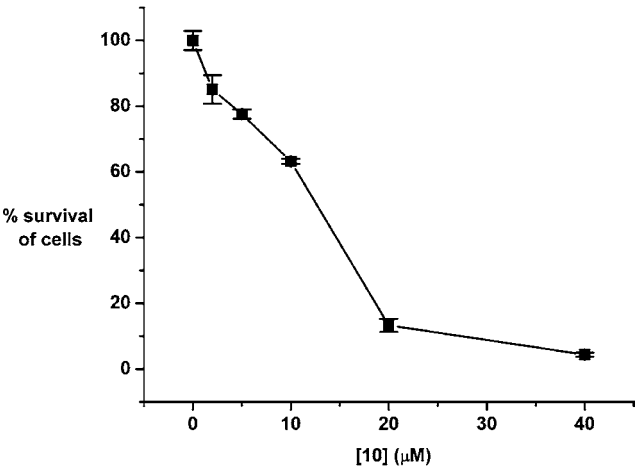

Figure 3. Concentration-dependent cytotoxicity of *N*-(4-formylbenzoyl)doxorubicin **10** on human ovarian carcinoma 2008 cells. Cells were exposed to various concentrations of **10** for 1 h, and survival was determined after a further 7 day period of growth in drug-free medium. See Supporting Information for details of the cell survival assay.

antitumor activity in vivo (*1d*). These drugs conjugated to delivery vessels using pH-sensitive linkers also showed reduced toxicity to normal, healthy tissues compared to administration of equivalent concentrations of free drug. The ability to tune the rates of hydrolysis of the NEBIs may make it possible to optimize the rate of release of drugs attached to delivery vessels via these acid-sensitive functionalities for maximal efficacy for cancer therapy.

The described N-linked imidazoles possess many desired features (*1*, *4*) for use as acid-sensitive linkers in cancer drug delivery. In addition to (1) their tunable rates of hydrolysis, (2) their nontoxic byproducts from hydrolysis (i.e., ethanol), and (3) their versatility for the range of alcohol- and amine-containing therapeutics that can be linked to drug carriers, the known ability to tune the pK_a's of protonated imidazoles (*5*) may make it possible to optimize the operational pH range of NEBIs for specific drug delivery applications. The mild conditions required to synthesize NEBIs carrying anticancer agents also provides a simple route to incorporate this functionality into tumor-targeting vessels. It may be possible, for instance, to use NEBI linkers to covalently attach therapeutics to imidazole-containing derivatives of known delivery systems (*1*, *4*) that can target tumors and exploit the endocytotic pathway for internalization in cells. The synthesis and detailed study of a range of potential therapeutic agents conjugated to drug delivery carriers via NEBI linkers is currently under way.

Fluorescent Nanoparticles for Multiplexed Bacteria Monitoring

Lin Wang, Wenjun Zhao, Meghan B. O'Donoghue, and Weihong Tan*

Center for Research at the Bio/Nano Interface, Department of Chemistry, Shands Cancer Center and UF Genetics Institute, University of Florida, Gainesville, Florida 32611-7200. Received August 16, 2006;
Revised Manuscript Received December 14, 2006

Rapid, sensitive, and selective detection of pathogenic bacteria is extremely important for proper containment, diagnosis, and treatment of diseases like foodborne illness, sepsis, and bioterrorism. Most current bacterial detection methods are time-consuming and laborious and can detect only one bacterial pathogen at a time. We have developed a method for sensitive, multiplexed monitoring of bacterial pathogens within 30 min using multicolored FRET (fluorescence resonance energy transfer) silica NPs (nanoparticles). By varying the ratio of three tandem dyes coencapsulated into the NPs, we have synthesized NPs that emit unique colors upon excitation with a single wavelength. When these NPs were conjugated to monoclonal antibodies specific for the pathogenic bacteria species *Escherichia coli*, *Salmonella typhimurium*, and *Staphylococcus aureus*, and then incubated with small concentrations of the bacteria, simultaneous and sensitive detection of the multiple bacterial targets was achieved.

INTRODUCTION

Under the appropriate conditions, bacterial pathogens can survive and spread easily in the environment. As a result, trace concentrations (~10−100 cells) of bacterial pathogens in food, donated blood, or the environment can pose a serious threat to human health. An estimated 76 million illnesses, over 300000 hospitalizations, and over 5000 deaths are attributable to foodborne illness in the United States every year (*1*). In all of these pathogenic situations, there are several likely bacterial suspects of infection. For example, *E. coli* O157:H7, *Salmonella* spp., and *Staphyllococcus* spp. are the most common causes of foodborne illness and are responsible for 20% of deaths related to sepsis from blood transfusions (*2, 3*). Consequently, there has been a critical demand for techniques that can recognize numerous bacterial pathogens simultaneously in a single assay (multiplexing), thereby giving an early warning of bacteria contamination. However, the currently accepted bacteria detection methods require PCR amplification and/or cell culturing (*4*−*6*) which are slow, time-consuming, laborious, and have a limited ability to multiplex (*7*−*13*). Many attempts have been made to improve the sensitivity of bacterial detection of numerous strains simultaneously without the need for bacterial culturing or PCR (*14*−*18*) but have met with limited success.

To address this issue, we have developed triple-dye-doped FRET silica nanoparticles (NPs) (*19, 20*) to serve as promising substrates for multiplexed bacteria monitoring. Previously, our group has used single-dye-doped NPs for in situ pathogen quantification down to a single bacterium (*21*). These dye-doped NPs, each encapsulating ~10 000 dye molecules in a ~60 nm silica sphere, provide an extremely strong fluorescent signal for bioanalysis and are easily conjugated to biorecognition molecules, such as antibodies, for fluorescence-based immunoassays. Now, by varying the ratio of three fluorescence energy transfer tandem dyes coencapsulated into the silica NPs, excitation with a single wavelength leads to emission of numerous different colors (*20*), thereby permitting simultaneous and sensitive detection of multiple targets. The work described here assesses the use of FRET NPs for multiplexed bacterial detection. *Escherichia coli* (*E. coli*), *Salmonella typhimurium* (*ST*), and *Staphylococcus aureus* (*SA*) were used as model pathogens in our system because they are major human pathogens responsible for foodborne illness and sepsis (*22*). Thus, if routine testing of food and blood products could rapidly detect these three pathogens, both the safety and the shelf life of these products could be increased (*2, 3, 23*). Our results show that FRET NPs can be used as highly sensitive and selective platforms for sensing multiple microorganisms simultaneously.

EXPERIMENTAL PROCEDURES

Reagents and Apparatus. Biotinylated rabbit anti-*E. coli* IgG, biotinylated rabbit anti-*ST* IgG, and goat anti-rabbit IgG were ordered from Biodesign International (Saco, ME). Biotinylated rabbit anti-*SA* IgG was bought from Cortex Biochem (San Leandro, CA). NanoOrange, DAPI (4′-6-diamidino-2-phenylindole), and amine reactive dyes FAM-SE (5-carboxyfluorescein succinimidyl ester), R6G-SE (5-carboxyrhodamine 6G, succinimidyl ester), ROX-SE (6-carboxy-X-rhodamine, succinimidyl ester), and TMR-SE (carboxytetramethylrhodamine, succinimidyl ester) were ordered from Invitrogen Corporation (Carlsbad, CA). NHS−PEG_{5000}−biotin was purchased from Nektar Therapeutics (San Carlos, CA). TEOS (tetraethyl orthosilicate) and APTS [(3-aminopropyl)triethoxysilane)] were purchased from Aldrich Chemical Co., Inc. (Milwaukee, WI). Sulfo-NHS (*N*-hydroxysulfosuccinimide sodium salt) and EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride) were ordered from Pierce Chemicals (Rockford, IL). Tween-20 and MES (2-(*N*-morpholino)ethanesulfonic acid) were obtained from Sigma Chemical Co. (St. Louis, MO). Carboxylated silica microspheres (5.06 μm in diameter) were ordered from Bangs Laboratories (St. Louis, MO). All other chemicals were of analytical reagent grade. Distilled deionized water (Easy Pure LF) was used for the preparation of all aqueous solutions.

A Hitachi S-4000 scanning electron microscope was used for imaging bacteria−NP conjugates. Optical and fluorescence images were obtained on a fluorescence microscope (Zeiss, U.S.A.) and a laser scanning confocal microscope (Olympus, Japan).

NP Preparation. TMR-doped and triple-dye-doped silica NPs (diameter $\Phi = 70$ nm) were prepared through a modified Stöber

synthesis method (*20*, *24*, *25*). First, amine-reactive dye molecules (TMR-SE, FAM-SE, R6G-SE, ROX-SE) were individually dissolved in 1.5 mL of anhydrous DMF (dimethylformamide), combined with an excess of APTS (molar ratio of dye to APTS = 1:2), and stirred under a dry nitrogen atmosphere for 24 h in the dark. Second, the TMR−APTS conjugate or the three tandem dye−APTS conjugates (FAM−APTS, R6G−APTS, ROX−APTS) mixed at desired ratios (1:0.5:1, 0.5:1:4, 0.5:0.5:3) were added to a clean glass reaction vessel containing 16.75 mL of ethanol and 1.275 mL of ammonium hydroxide, respectively. The mixture was stirred for 24 h. 0.71 mL of TEOS (0.00375 mol) was added afterward and stirred for another 24 h. After the reaction, the samples were centrifuged at 14 000 rpm for 30 min to collect the silica NPs. The NPs were further washed with ethanol and deionized water by centrifugation and decanted several times to remove unreacted chemicals.

NP Surface Modification. *Amine Group Modification.* After washing the NPs, approximately 10 mg of NPs were dispersed in 1 mL of deionized water with sonication and mixed with 20 μL of glacial acetic acid. 20 μL of (3-trimethoxysilylpropyl)-diethylenetriamine was added with sonication, and the suspension was stirred for 3−4 h. The particles were washed and dispersed in 10 mM MES buffer (pH = 5.5).

Carboxyl Group Modification. Carboxyl group modification was accomplished by mixing 10 mg of NPs in 1 mL of phosphate buffer (10 mM, pH 7.4) and 20 μL of carboxyethylsilanetriol sodium salt, 25% in water (Gelest, Inc., Kent, ME). The mixture was stirred for 3−4 h, washed with phosphate buffer, and dispersed in the same buffer.

NP−Antibody Bioconjugation. *Strategy A*: Carbodiimide chemistry was used to cross-link free carboxylic acid groups on NPs with amine-containing antibodies. Briefly, 100 μL of a 0.22% (w/v) suspension of COOH-modified NPs was washed by centrifuging once with deionized water. The pellet was then resuspended in 1 mL of 0.1 M MES (pH 5.5). Aqueous solutions of 10 mM sulfo-NHS and 4 mM EDC dissolved in MES buffer were freshly prepared, and 0.5 mL of each solution was immediately added to the NP solution. The NPs were incubated at room temperature with gentle agitation. After 15 min, the NPs were centrifuged and washed with 10 mM phosphate buffer (pH 7.4), then resuspended in 1.5 mL phosphate buffer, followed by addition of 50 μL of antibodies (rabbit anti-*ST*-IgG) at a concentration of 1 mg/mL. The mixture was incubated at room temperature for 2 h with gentle end-to-end shaking. NPs were washed in 10 mM phosphate buffer and then resuspended in the quenching solution (40 mM Tris−HCl with 0.05% (w/v) BSA) for 60 min to block free carboxylates. Protein-coated NPs were purified by alternately centrifuging and resuspending in phosphate buffer (10 mM, pH 7.4) with 1% BSA and stored at 4 °C until use. Covalent coupling of secondary antibodies (goat anti-rabbit-IgG) to carboxylated silica microspheres followed the same procedures.

Strategy B. Streptavidin conjugation to NPs used the above procedure except that the antibody was changed to streptavidin. After the centrifugation and washing steps, biotin-labeled antibody was added to the solution with a final concentration ratio of biotin-Ab:NP = 1000:1. The solution was allowed to gently mix for 1 h, washed, and centrifuged to remove free biotin−antibody.

Strategy C. Amine-modified NPs were reacted with the activated ester of biotin (NHS−PEG_{5000}−biotin) in the phosphate buffer for 2 h to couple biotin molecules to the NPs. The complexes were centrifuged and washed several times with phosphate buffer to remove the unbound biotin. Streptavidin and NP−biotin were then mixed at a 1000:1 ratio to ensure sufficient saturation of streptavidin on the NP surface, and the mixture was slowly shaken for 2 h. The complexes were centrifuged and washed several times with phosphate buffer to remove unbound streptavidin. Biotin-labeled antibody was further mixed into the above solution with a final concentration ratio of biotin−Ab to NP of 1000:1. The solution was allowed to gently mix for 1 h, washed, and centrifuged to remove free biotin−antibody.

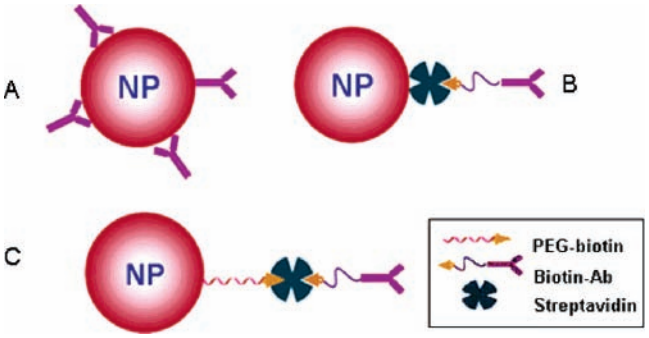

Figure 1. Schematic representation of three antibody-labeling strategies on NPs.

NP−Antibody Conjugation with Bacteria. Antibody-labeled NPs and bacteria were mixed at an experimentally optimized ratio (10 000:1), diluted in the incubation buffer (10 mM phosphate buffer, pH 7.4, 0.05% Tween-20), and gently shaken at room temperature for 30 min. The resultant product was washed three times by centrifugation (3000 rpm, 5 min) to remove all unbound antibody-conjugated NPs.

RESULTS AND DISCUSSION

Antibody Labeling Strategy Optimization. Before applying FRET NPs for multiplexed detection of pathogenic bacteria, single dye (TMR)-doped NPs were used in the initial assay to test bacteria binding efficiency and specificity. TMR-doped NPs were prepared using the Stöber method (*24*, *25*). The amine-reactive dye TMR-SE was first chemically bound to an amine-containing silane agent APTS, and then APTS and TEOS were allowed to hydrolyze and co-condense in a mixture of water, ammonia, and ethanol, resulting in TMR-doped silica NPs. The NPs were then modified with surface functional groups and covalently conjugated to antibodies specific to three bacteria individually.

Considering the effects of strong steric hindrance between the rigid NP and the bacterial surface, different antibody labeling strategies were designed (Figure 1). In strategy A, we directly immobilized monoclonal antibody onto COOH−NP surface using carbodiimide chemistry (*19*, *26*, *27*) to cross-link free carboxylic acid groups on NPs with amine-containing antibodies; in strategy B, we first linked COOH−NP surface with streptavidin as a bridge molecule (*28*), then immobilized biotin−antibody onto streptavidin; in strategy C, we immobilized NHS−PEG−biotin molecules onto NH_2-modified NPs (*20*); after incubation with streptavidin, biotin-labeled antibody was anchored onto NP surface. For strategy A, we assumed that, due to the random attachment of antibody onto the NPs, some of the antigen binding sites of the antibody may be blocked. In strategy B, the bridge molecule streptavidin was bound to the biotin attached to the antibody ensuring that the antibody recognition sites were oriented away from the NP surface, so that they do not lose their ability to bind to a target bacterium. The third strategy added hydrophilic PEG linkers between NP and antibody to further improve the NP solubility and dispersivity, and allow the conjugated biotin−antibody to extend out from the NP surface, reducing the binding steric hindrance and benefiting the binding efficiency. To verify the functionality of conjugating antibody onto NPs and mimic the bacteria−NP interaction, goat-anti-rabbit IgG-coated microspheres and rabbit

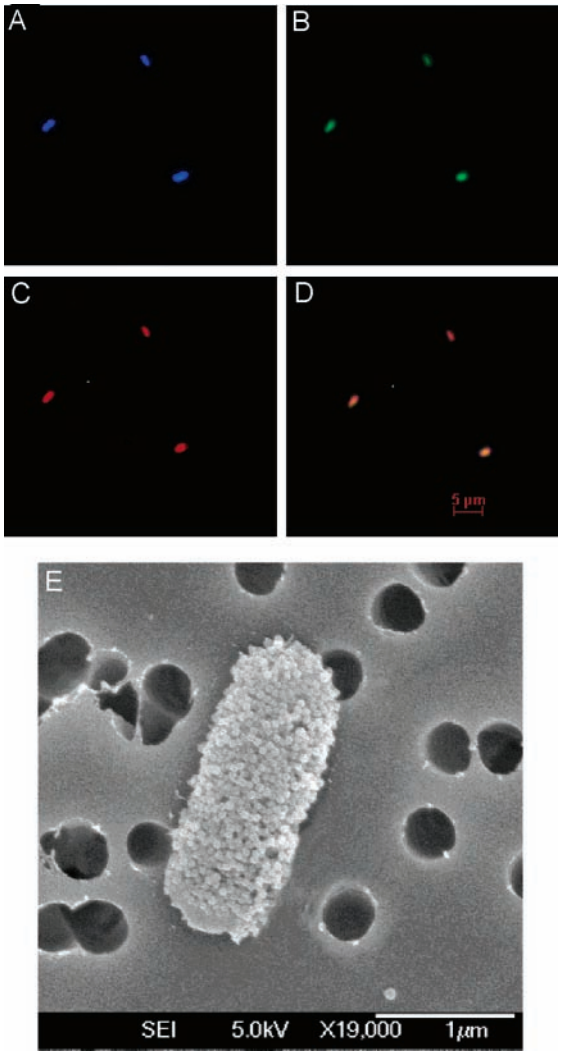

Figure 2. (A−D) *ST* bacteria conjugated with antibody-labeled TMR NPs and stained with DAPI and NanoOrange. (A) Blue channel, DAPI; (B) green channel, NanoOrange; (C) red channel, TMR; (D) combinatorial color of the three detection channels. (E) SEM image of an *ST* bacterium coated with PEG-*ST*-biotin-antibody labeled NPs.

anti-*ST*-IgG conjugated NPs prepared with the three strategies were mixed and allowed to react for 30 min. As expected, we found that NPs prepared with the third strategy exhibited the best colloidal stability and binding performance.

NP−Antibody Binding with Bacteria. *ST* was used for the initial bacteria monitoring. Anti-*ST*-IgG conjugated TMR−NPs were allowed to bind to *ST* bacteria. The resultant product was washed three times by centrifugation to remove all unbound antibody-conjugated NPs. To clarify the bacterial configuration and differentiate bacteria from NP aggregates, the *ST* bacteria were stained with DAPI (4′-6-diamidino-2-phenylindole, which stains double-stranded DNA) and NanoOrange (protein stain). Fluorescence images of the NP-coated *ST* were taken by exciting them with a 100 W mercury lamp, while three orthogonal detection channels monitored fluorescence for DAPI, NanoOrange, and TMR, respectively. Both the fluorescence and SEM images (Figure 2) display the successful binding between NPs and *ST* bacteria.

NP−Bacteria Binding Specificity. One critical issue when detecting large numbers of targets simultaneously is specificity of binding. Cross-reactivity in highly multiplexed assays will lead to potentially disastrous false positives. The next experiment was designed to specifically detect the target bacteria *ST* in the presence of other pathogenic bacteria. Before incubation with NP−antibody conjugates, only target bacteria *ST* were stained with NanoOrange. Free NanoOrange unbound to *ST* was removed by centrifugation, mixed with the other two bacteria species (*E. coli* and *SA*), and incubated with rabbit anti-*ST*-IgG-NPs. After 30 min, the sample was washed three times by centrifugation to remove free antibody-conjugated NPs that did not bind to the bacteria, and the sample was stained together with DAPI before imaging. The fluorescence image demonstrates that only those bacteria stained with NanoOrange fluoresced red due to the bound NPs, verifying that the antibody-conjugated NPs specifically associated with *ST* cell surfaces (Figure 3).

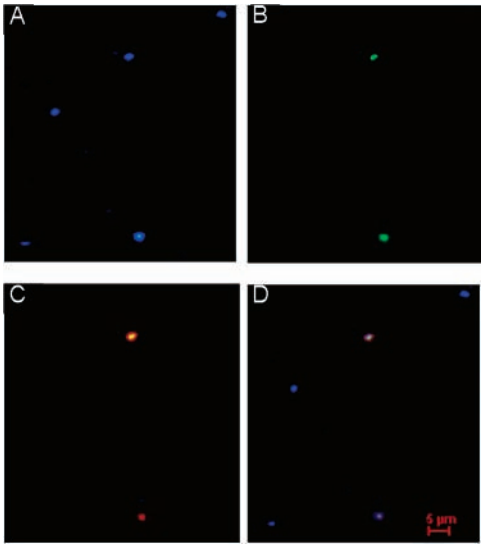

Figure 3. Fluorescence images of all three bacteria species incubated with NPs labeled with antibody to *ST*. (A) All three bacteria species were stained with DAPI. (B) Target bacteria *ST* were prestained with NanoOrange. (C) Only target bacteria *ST* fluoresced—the color of the NPs. (D) Combination of the three channels.

Simultaneous Monitoring of Multiple Bacteria. Simultaneous multiple bacteria monitoring was achieved using color-encoded FRET NPs. To prepare the FRET NPs, the three amine-reactive energy-transfer tandem dyes (FAM-SE, R6G-SE, ROX-SE) were first covalently linked to the silane coupling agent APTS. The three APTS−dye conjugates were then mixed at desired ratios (1:0.5:1, 0.5:1:4, 0.5:0.5:3), and each mixture was added to a clean glass reaction vessel containing pure ethanol and ammonium hydroxide. After stirring for 24 h, TEOS was added, and the mixture was stirred for 24 h. When the reaction was complete, the solution was centrifuged to collect the silica NPs. The NPs were further washed with ethanol and deionized water to remove the unreacted chemicals.

During the NP preparation process, the three APTS−dye conjugates were first allowed to prehydrolyze for 24 h before adding TEOS to start the colloid formation. During the prehydrolysis step, the three tandem dyes were covalently attached to one another and shortened the distance between them to the benefit of the FRET efficiency (*20*). In the FRET NPs, FAM was used as a common donor for R6G and ROX, while R6G acted as both an acceptor for FAM and a donor for ROX. By exciting at the maximum excitation wavelength for FAM (488 nm), efficient energy transfer between the three dyes in the same NP occurred, and NPs exhibited three emission peaks corresponding to the three encapsulated dyes, while the combinatorial color varies due to the different dye doping ratio. Figure 4A−C displays the fluorescence images of the three types of NPs taken under a confocal microscope. Circles a, b, and c display the fluorescence images of NPs close to the three emission peaks, while circle d exhibits the resultant combina-

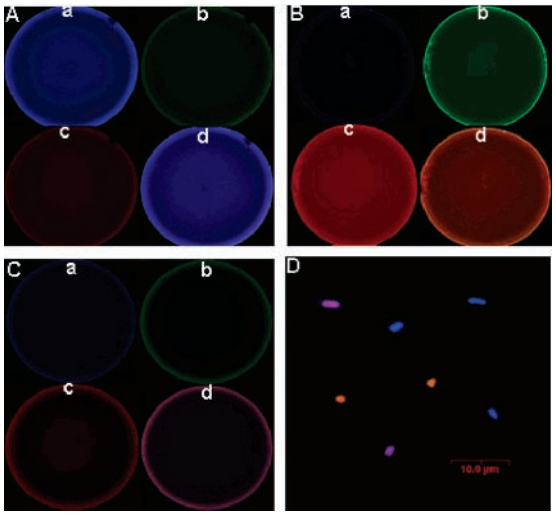

Figure 4. (A−C) Fluorescence images of three types of FRET NPs taken under a confocal microscope. (a) FAM emission channel; (b) R6G emission channel; (c) ROX emission channel; (d) combinatorial color of the three channels. The three types of NPs exhibit blue, orange, and purple colors. (D) Confocal image of three bacteria species specifically covered with the corresponding antibody labeled NPs.

torial color of the three detection channels. When excited at 488 nm, the three types of NPs fluoresce blue, orange, and purple.

These three types of FRET NPs were further conjugated with the PEG−streptavidin−biotin−IgG complex. Blue NPs were conjugated with antibody to *E. coli*; orange NPs were coated with antibody to *SA*; while the purple NPs were linked with antibody to *ST*. These three antibody-labeled NPs and three bacteria species were mixed together in the buffer (10 mM phosphate buffer, pH 7.4, 0.05% Tween-20) and incubated for 30 min. After the centrifugation and washing steps, the confocal image of the resultant bacteria−NP complexes shows that three bacteria species were specifically covered with their corresponding antibody-labeled NPs and exhibit the coding colors of the attached NPs (Figure 4D). Furthermore, using the recently established two NP assay (*29*), it is feasible to use both antibody-conjugated magnetic NPs and fluorescent NPs to achieve multiple bacteria extraction and detection.

In summary, we have been the first to apply multicolor FRET NPs for multiplexed monitoring of bacteria species. This method is fast and accurate with high sensitivity and specificity. By changing the dye doping ratios of the energy-transfer dye series, a large FRET NP bar-coding library can be built permitting multiplexed detection of numerous bacterial pathogens. By eliminating the sample enrichment and amplification steps required with current cell culture and PCR-based methods, our method can achieve the diagnosis of disease at the earliest stage of its development. Routine bacteria testing of food or blood using this method could allow for increased safety and shelf life (especially important for blood platelets whose current shelf life is 3−5 days). FRET silica NPs hold great promise to develop multiplexed bacterial detection kits.

Gene transfer represents an important advance in the treatment of both genetic and acquired diseases. In this article, the suitability of cationically modified solid-lipid nanoparticles (SLN) as a nonviral vector for gene delivery was investigated, in order to obtain stable materials able to condense RNA. Cationic SLN were produced by microemulsion using Compritol ATO 888 as matrix lipid, Pluronic F68 as tenside, and dimethyldioctadecylammonium bromide (DDAB) as cationic lipid. The resulting particles were approximately 100 nm in size and showed a highly positive surface charge (+41 mV) in water. Size and shape were further characterized by scanning electron microscopy (SEM) measurements. Moreover, we utilized the sea urchin as a model system to test their applicability on a living organism. To evaluate cationic SLN ability to complex the in vitro transcribed *Paracentrotus lividus bep3* RNA, we utilized both light scattering and gel mobility experiments, and protection by nuclease degradation was also investigated. By microinjection experiment, we demonstrated that the nanoparticles do not inference with the viability of the *P. lividus* embryo and the complex nanoparticles-*bep3* permits movement of the RNA during its localization in the egg, suggesting that it could be a suitable system for gene delivery. Taken together, all these results indicate that the cationic SNL are a good RNA carrier for gene transfer system and the sea urchin a simple and versatile candidate to test biological properties of nanotechnology devices.

INTRODUCTION

Gene delivery is an area of considerable current interest for molecular medicine. DNA and proteins have been extensively investigated for their application in nanotechnology as a possible approach to gene therapy (*1*, *2*). Minor attention has been given to other important biological molecules such as RNA until now. In nature, RNA exhibits a single-stranded conformation, but it is versatile enough to form, through specific complementary sequences, stems, loops, and hairpins, providing elements of adaptability to nanotechnology that is based on a double-helical structure. The use of antisense or sense RNA is a specific and powerful tool for selectively modulating the expression of a gene target to identify loss-of-function or gain-of-function phenotypes (*3*−*8*). The use of RNA interference (RNAi), based on gene-silencing of key molecules involved in many diseases, has been an improvement in this technology (*9*). All these kinds of synthetic RNAs are generally introduced into the cells by electroporation and/or microinjection, but their poor stability is often the cause of failure. Another technology to introduce RNA molecules employs viral vectors, but undesirable effects can occur (*10*, *11*). In the past decade, many studies have shown that nonviral vectors, as cationic liposomes and polycations, are valid tools for delivering nucleic acids to specific cell types both to inhibit some undesirable gene expression or to express therapeutic proteins (*12*, *13*). The use of nonviral vectors permits one to avoid some risk factors such as pathogenesis, immunogenicity, and so forth(*14*−*16*). Among them, cationic solid-lipid nanoparticles (SLN) as a carrier system for the delivery of genetic materials may offer several technological advantages (*17*). These include excellent storage stability, relatively easy production without the use of any organic solvent, the possibility of steam sterilization and lyophilization, and large-scale production utilizing substances that are approved for use in pharmaceutical human applications (*18*−*22*). These particles consist of a lipid core bearing cationic lipids on its surface.

The aim of this study was to prepare and utilize cationically modified SLN as specific RNA carriers and to evaluate their potential as a nonviral vector for gene delivery. Moreover, we have utilized, as a living organism, the sea urchin *Paracentrotus lividus* and its *bep3* maternal messenger RNA (*23*, *24*). Among the classical model systems, the sea urchin provides a powerful model for a great variety of studies in molecular and cell biology and biochemistry. Moreover, the sea urchin occupies a key phylogenetic position as the only nonchordate detereustomes, and the results obtained on this embryo can be extrapolated and compared to those of higher eukaryotes. Eggs and embryos are transparent, allowing direct observation of cell division and movement, and specific techniques permit us to visualize the presence of exogenous nucleic acids inside the cells. more, *bep3* RNA codifies for a cell surface protein, localized after fertilization at the animal pole of the *Paracentrotus lividus* egg by moving along cytoskeleton elements (*24, 25*). Thus, this RNA represents a good model to study the delivery of nucleic acids. Interestingly, it has been demonstrated that *bep3* 3′UTR, necessary for its localization, could fold in secondary structures; that is a required element for nanotechnology (*26*). The ability to form complexes between SLN and *bep3* and the effect on its mobility have been tested.

EXPERIMENTAL PROCEDURES

Materials. Compritol ATO 888 is a mixture of approximately 15% mono-, 50% di-, and 35% triglycerides of behenic acid (C_{22}). The melting point lies between 69 and 74 °C. It was a gift from Gattefossé (D-Weil am Rhein, Germany). Pluronic F68 and the cationic surfactant dimethyldioctadecylammonium bromide (DDAB) were purchased from Sigma-Aldrich.

Preparation of Solid-Lipid Nanoparticles. The SLN were prepared from a warm oil-in-water (o/w) microemulsion by using Compritol ATO 888 and DDAB as the lipid matrix. Briefly, 0.273 mmol of Compritol were heated to 10 °C above its melting point and mixed with 2.5 mL of a hot aqueous solution of Pluronic F68 (0.158 mmol) and DDAB (1.45 mmol) to form a clear microemulsion, under mechanical stirring. Then, cationic nanoparticles were obtained by dispersing under mechanical stirring at 1000 rpm the warm o/w microemulsion in cold water (2−3 °C) (organic/aqueous volume ratio equal to 1:10). The obtained cationic nanoparticles were purified by dialysis using a Visking Tubing Dialysis 18/32″ (with a molecular weight cutoff of 12 000−14 000 Da). Then, cationic nanoparticles were freeze-dried using a Modulo freeze-dryer (Labconco Corporation, Missouri). To label SLN, fluorescein free acid was added to the lipid phase during preparation of the microemulsion.

In Vitro Synthesis of the Transcript. To synthesize *bep3* RNA, the plasmid containing this clone was linearized by digestion at the Xho I site (*24*). Transcription by T7 polymerase was carried out utilizing the DIG-RNA labeling kit and DIG-UTP as the substrate according to the manufacturer's instructions in the kit (Roche). The DIG-labeled RNA probe was detected by immunoassay using an anti-digoxigenin alkaline phosphatase conjugate (anti DIG-AP) according to the manufacturer's instructions (Roche).

Preparation of Cationic SLN−RNA Complexes and RNA Retardation Assay. To four equal aliquots of a *bep3* DIG-RNA (50 ngr) solution in 5 mM Hepes, increasing amounts of nanoparticle suspensions were added to obtain the final w/w ratios of 50:1, 100:1, 200:1, and 400:1. In order to evaluate the effect of the preparation method on the nature of the obtained complexes, these were prepared also by adding the RNA solutions to the cationic SLN suspensions. All the cationic SLN−RNA complexes prepared by using both methods were characterized in terms of mean size, ζ potential, and electrophoretic mobility, and the same results were achieved.

After 30 min incubation at room temperature, RNA binding was studied by assaying for agarose gel retardation. Samples were electrophoresed through a 1% agarose gel at 80 V for 1 h. RNA was visualized by a UV transluminator using ethidium bromide staining.

Size and ζ Potential Measurements. Particle or complex size was analyzed by photon correlation spectroscopy (PCS) using a Zetasizer Nano ZS (Malvern Instrument, Herrenberg, Germany) which utilizes the noninvasive back-scattering (NIBS) technique. PCS gives information about the mean diameter of the bulk population (so-called *z*-average) and the width of distribution via the polydispersity index (PI). Samples were appropriately diluted with filtered (0.2 μm) twice-distilled water, and the readings were carried at a 173° angle with respect to the incident beam. The reported values were the averages of three measurements.

The surface charge was determined using the same equipment. The ζ potential value was measured using principles of the laser Doppler velocimetry and phase analysis light scattering (M3-PALS technique). Samples were dispersed in filtered (0.2 μm) twice-distilled water and analyzed in triplicate.

Light Scattering Measurements. A water dispersion of SLN at a final concentration of c1.2 mg/mL was filtered via a 0.45 μm filter directly into a cylindrical quartz cuvette. To study the interaction between SLN and *bep3* RNA, a small aliquot of RNA solution (about 25 ng) was added in situ into the cuvette containing the filtered SLN suspension. A Brookhaven Instrument BI200-SM goniometer, equipped with a 100 mW Ar laser tuned at $\lambda_0 = 488$ nm, was used in a temperature-controlled setup, as reported elsewhere (*27*). Simultaneous measurement of the intensity autocorrelation function and static light scattered at 90° proved the stability of the SLN suspension for 60 min. Immediately after mixing the RNA into the suspension of nanoparticles, the interaction between SLN and *bep3* RNA was monitored by time-resolved light scattering experiments. Both the intensity autocorrelation function measured at 90° and static light scattered at 90°, averaged for 3 min, were measured independently to follow the process at $T = 25$ °C. From the measured intensity autocorrelation functions, $g_2(t)$, we calculated the electric field autocorrelation functions, $g_1(t)$, considering the Siegert relation: $g_1(t) = \sqrt{g_2(t) - 1}$ (*28*). The autocorrelation functions $g_1(t)$ were analyzed using a smoothing constrained regularization method, in order to obtain the distribution $P(D)$ of the apparent diffusion coefficients D, according to the fact that $g_1(t) = \int P(D)e^{-Dq^2t}\,dD$, where q is the scattering vector defined as $q = 4\pi n/\lambda_0 \sin\theta/2$, with n the medium refractive index and θ the scattering angle (*29*). By using the Stokes Einstein relationship, $D = KT/3\pi\eta D_h$ (k is the Boltzmann's constant, T the absolute temperature, η the solvent viscosity, and D_h the *z*-averaged hydrodynamic diameter), we obtain the distribution $P(D_h)$ of the *z*-averaged hydrodynamic diameters of the species in suspension. The mean hydrodynamic diameter relative to a restricted interval of the distribution was estimated by calculating the harmonic average of the hydrodynamic diameter in the region of interest. Absolute scale for the scattered intensity was obtained by normalizing data to the toluene Rayleigh ratio at 488 nm, taken 39.6×10^{-6} cm^{-1}.

Scanning Electron Microscopy (SEM). A scanning electron microscope (SEM) (XL-30 Philips, The Netherlands) was used to evaluate both size and morphology of cationic SLN and SLN−RNA complexes obtained by using a w/w ratio of 200:1. Before the SEM analysis, the samples were coated under an argon atmosphere with a 10-nm gold thickness. The samples were stuck onto aluminum stubs, which were then fixed into a sample holder and placed in the vacuum chamber of the microscope and observed under low vacuum (10^{-3} Torr).

RNAse Degradation Assay. To evaluate the nuclease activity, the complex between cationic SLN−RNA obtained at a 200:1 w/w ratio was chosen, and the incubation was continued in the presence of 0.1, 1, and 10 u of RNAse T1 (Roche) or 0.1, 1, and 10 u of RNAse A (Roche) for an additional 30 min at room temperature. Electrophoresis of the RNA nanoparticle complex was carried out in 1% agarose gel at 80 V for 1 h. The gel was visualized by a UV transilluminator.

Microinjection in Sea Urchin Eggs. Dejellied *P. lividus* unfertilized eggs were microinjected as described by McMahon (*30*). When we microinjected the nanoparticles alone, 200 of the eggs were fertilized and left to develop for 48 h (pluteus stage). When we microinjected the complex SNL−*bep3* in the 200:1 w/w ratio, before and after fertilization the eggs were

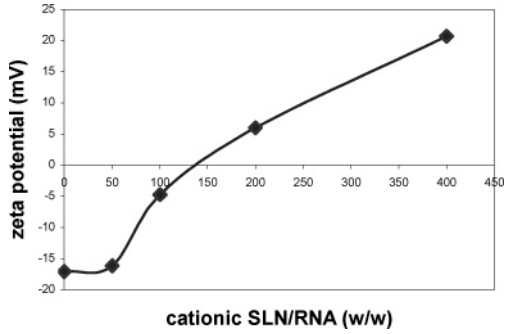

Figure 1. ζ potential values of cationic SLN−RNA complexes at different weight ratios, measured in twice-distilled water after 30 min of incubation.

fixed in 4% paraformaldeide. The presence and movement of exogenous RNA were detected by immunoassay using an anti-digoxigenin alkaline phosphatase conjugate (anti-Dig-AP) according to the manufacturer's instructions of the DIG Nucleic Acid Detection kit (Roche).

Viability Assay. Cell viability was determined using MTS assay according to manufacturer's instructions (PROMEGA). This assay uses the tetrazolium compound (3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium, inner salt (MTS), and the electron coupling reagent, phenazine methosulfate (PMS). MTS is chemically reduced by cells into formazan, which is soluble in culture medium. Briefly, MTS was added to embryos at 48 h of development (pluteus stage), to a final concentration of 0.8 mg/mL, and incubated for 5 h. The measurement of the absorbance of the formazan was carried out using a spectrophotometer at 495 nm.

RESULTS

Production of Cationic SLN. The aim of this study was to prepare cationic nanoparticles consisting of Compritol, dimethyldioactadecylammonium bromide (DDAB), and Pluronic F68, to characterize them in water suspension (particle size and surface charge), and to study their interaction process with RNA. The SLN formulation was produced, as previously described, from a warm oil-in-water (o/w) microemulsion. In order to obtain a positive surface charge, a cationic lipid/surfactant DDAB was employed. The characterization of particle size by photon correlation spectroscopy (PCS) revealed that the average particle size of these particles was 100 nm (PI = 0.215). The surface charge value was highly positive (+41 mV), demonstrating the successful incorporation of DDAB onto the nanoparticle surface. The formulation was stored in the dark and at room temperature. It showed excellent storage stability, with the average particle diameter changing only by a few nanometers during 180 days (data not shown). The binding of RNA with cationic SLN was evaluated by measurements of the ζ potentials of complexes at different cationic SLN−RNA weight ratios. The trend of the ζ-potential measurements of these complexes in water as a function of SLN−RNA weight ratios is illustrated in Figure 1. It is shown that, by increasing the used weight amount of nanoparticles in the complex formation, ζ potential values increased, starting from a value of −17 mV for naked RNA, up to 20 mV, passing through a neutral condition at a SLN−RNA weight ratio of 200:1. These results confirm the good capacity of these cationic nanoparticles to complex RNA and neutralize its anionic charge.

SLNs are Able to Complex RNA. To investigate if cationic SLN can be applied in RNA nanotechnology, we followed the aggregation kinetics of the two components by light scattering. For this aim, we utilized *Paracentrotus lividus bep3* RNA whose characteristics have been described before (*24*−*26*). The static light scattered and the intensity autocorrelation functions both

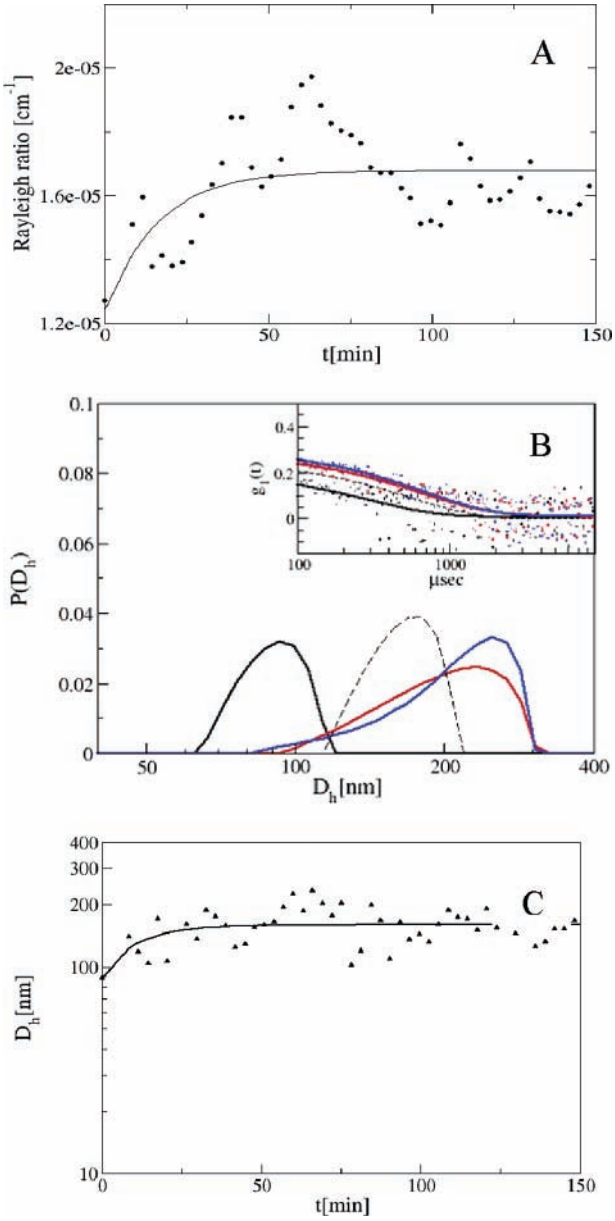

Figure 2. (A) Static light scattered at 90° after mixing of SNL and *bep3* RNA particles. The continuous line represents the best fit by using an exponential function. (B) Distribution functions of the hydrodynamic diameter, $P(D_h)$, at four different times during the kinetic process, at $t = 0$ without RNA (continuous black line), at $t = 25$ min after mixing (dashed black line), at $t = 35$ min after mixing (red line), and at $t = 155$ min after mixing (blue line). The distribution functions were obtained by using a smoothing constrained regularization method to analyze the field autocorrelation functions ($g_1(t)$ data and resulting fits are shown in the inset). (C) Time dependence of the *z*-average hydrodynamic diameter corresponding to the region 40 nm < D_h < 400 nm.

at 90° have been measured simultaneously and independently in order to follow the interaction process between SLN and *bep3* RNA. Figure 2A shows an appreciable, though noisy, Rayleigh ratio increase. The data fit, by using an exponential growth function, gives an estimate of the characteristic interaction time, τ, of 16 min and of the process saturation time on the order of 100 min.

Figure 2B reports on the distribution function of hydrodynamic diameters in the range 40−400 nm at different times during the interaction process obtained by the analysis of the field autocorrelation function data. From the field autocorrelation functions (data shown in the inset), one can notice a decay in

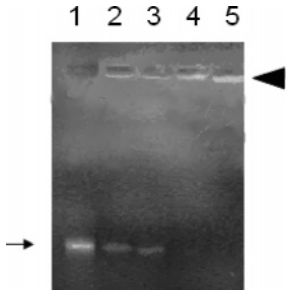

Figure 3. Binding of sense RNA to cationic nanoparticles. 50 ng of RNA was incubated with increasing amounts of cationic nanoparticles. Uncomplexed *bep3* RNA (1), cationic SLN−*bep3* complexes in a w/w ratio of 50:1 (2), 100:1 (3), 200:1 (4), and 400:1 (5). The arrow indicates the uncomplexed RNA; the arrowhead indicates the RNA trapped in the well.

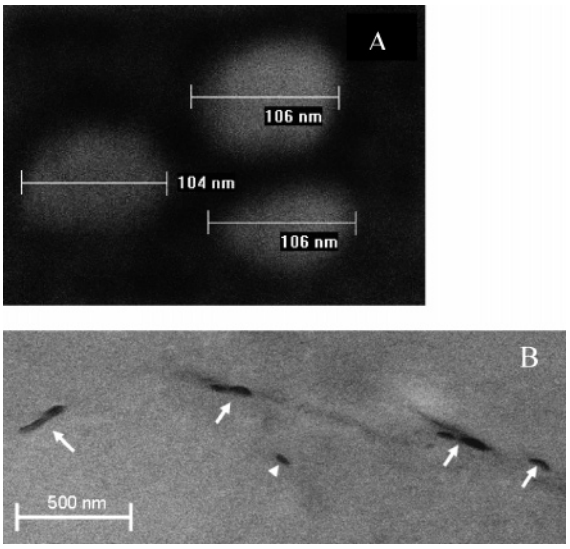

Figure 4. SEM images of (A) cationic SLN and (B) group of representative cationic SLN−RNA complexes obtained at a w/w ratio of 200:1. The arrows indicate the complexes; the arrowhead indicates the free nanoparticles.

the time interval 0.1−1 ms, corresponding to particles with hydrodynamic diameters between 40 and 400 nm, that is to SLN at the beginning ($t = 0$) and to SLN−RNA complexes later on during their formation. A faster decay due to smaller particles with hydrodynamic dimensions of about 5 nm was noticed in the autocorrelation functions (data not shown). Such a contribution, constant during the entire process, suggested the probable presence in solution of small lipid aggregates not interacting with RNA. Figure 2C shows the values of the mean hydrodynamic diameter calculated for the band of particles with hydrodynamic dimensions between 40 and 400 nm. The increase of the hydrodynamic diameter for the SLN−RNA particles has been fitted by using a function expressing an exponential growth giving a characteristic time, τ, of 13 min, a saturation time process of about 100 min, and an average diameter increase, ΔD_h, of about 80 nm.

***Bep3* RNA Mobility is Retarded by SNL.** In order to evaluate the ability of cationic SLN to bind *bep3* RNA, the RNA electrophoretic mobility shift within an agarose gel was investigated. Efficient complexation of *bep3* by cationic SNL led to immobilization and prevention of ethidium bromide intercalation with RNA. In vitro transcribed *bep3* RNA was incubated with increasing amounts of cationic SLN for 30 min. 50 to 100 weight equivalent were sufficient to bind most of RNA, while 200 to 400 completely immobilized RNA. As shown in Figure 3, *bep3* is able to form complexes with

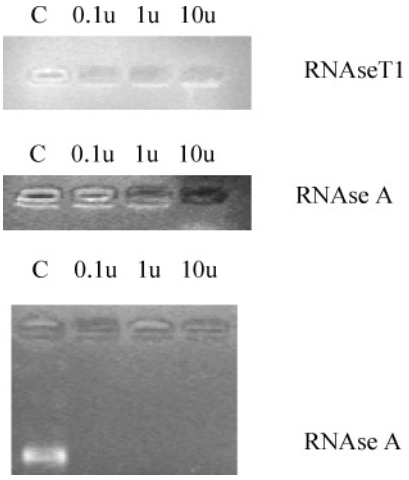

Figure 5. *bep3* RNA−SNL complex is protected by RNAse enzymatic degradation. The RNA−cationic nanoparticle complexes were incubated without (C) or with RNA T1 A or with RNAse A at different amounts (0.1; 1; 10 units). Uncomplexed RNA incubates or not (C) with RNAse A.

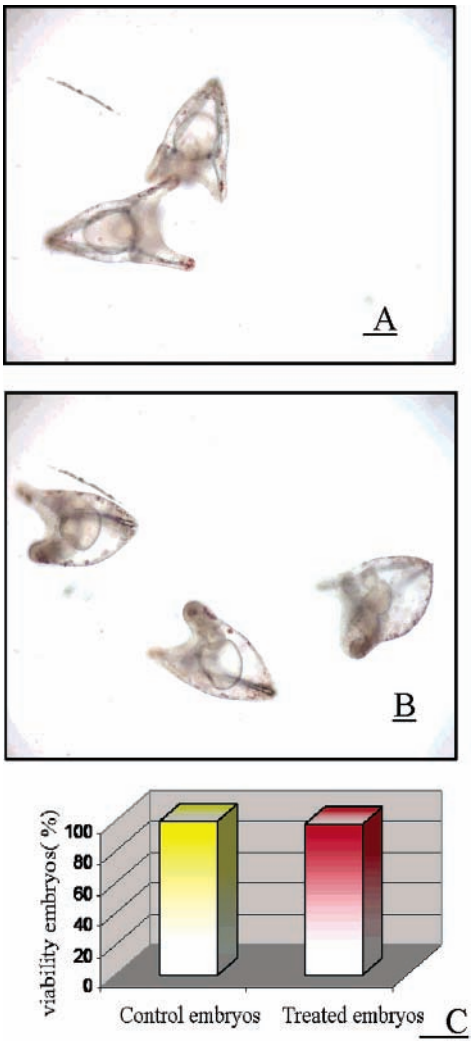

Figure 6. SNL microinjection into *Paracentrotus lividus* unfertilized eggs. Cationic nanoparticles were microinjected into unfertilized eggs and left to develop for 48 h until pluteus stage (B) as control embryos (A). nanoparticles in a dose-dependent manner. As nanoparticle concentration increased, the RNA exhibited decreased migration

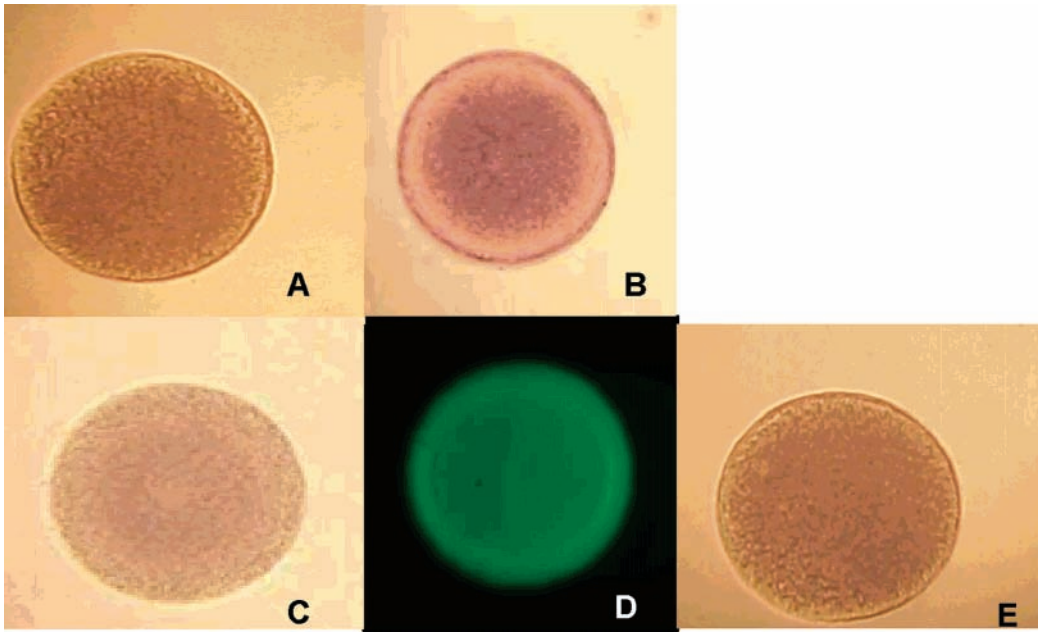

Figure 7. Localization of *bep3* RNA in *Paracentrotus lividus* unfertilized (A) or fertilized (B) eggs after microinjection with cationic nanoparticles. (C) Untreated *P. lividus* egg as control. strength, and when the complex was too large, it did not enter into the gel, staying trapped in the well. This behavior was probably due both to the increased mass and to the modification of the RNA's electric charges.

Cationic SLN, indeed, spontaneously reacted with the negatively charged RNA molecules by the formation of ion pairs between the hydrophobic cations and the negatively charged phosphate groups of the nucleic acid chain, forming complexes with 100% RNA molecules involved in the reaction, in a self-assembling manner. When all the RNA negative charges are neutralized by the positive charges of the SLN surface, the RNA is no longer able to migrate.

Analysis of Cationic SLN and SLN−RNA Complexes by SEM. To examine the size and the shape of the produced cationic SLN and SLN−RNA complexes obtained at a w/w ratio equal to 200:1, SEM analysis was performed on the sample. Figure 4A,B shows cationic SLNs and SLN−RNA complexes, respectively. By SEM images, we detected that the nanoparticles alone are spherical and have a diameter of approximately 100 nm (Figure 4A). Figure 4B shows an overview of SLN−RNA complexes; many coupled nanoparticles, with diameters between 200 and 300 nm, are present in the sample, indicating that the complex with RNA probably involves two or three nanoparticles. Moreover, free cationic SLN were found into the same sample (Figure 4B).

SLN Protect RNA by Enzymatic Degradation. A peculiar problem, when RNA molecules are in vitro or in vivo transferred in any type of cells, is their susceptibility toward nuclease activity. Thus, nuclease could destroy an RNA molecule before it is able to arrive to the target site. Exogenous RNA is, indeed, unstable in biological fluid or intracellular environments. To test the protection ability of the nanoparticles toward RNA by nuclease attack, we have incubated the *bep3*−SNL complex with increasing amounts until excessive concentrations of two types of ribonucleases RNAse A and RNAse T1 are reached. The difference between these two endonucleases consists of the ability of T1 to digest only unprotected RNA with respect to the ability of A to digest any RNA. After separate digestion with RNAse A and T1, the complexes underwent to electrophoresis. Results, shown in Figure 5, suggest that nanoparticles protect *bep3* RNA by RNAse T1 enzymatic degradation, while it remains exposed to digestion by RNAse A only when a huge excess, in any case not present in the cellular environment, was utilized.

Microinjection of SLN in Sea Urchin Eggs. To investigate the eventual SLN toxicity on a living organism and if they are harmful for RNA delivery, we utilized a classical model system such as the sea urchin *Paracentrotus lividus.* Different amounts of SLN were injected into *P. lividus* eggs. After fertilization, the embryos were left to develop for 48 h until the control arrived at the so-called pluteus stage (a primordial larva). Both microinjected embryos and the control showed the correct morphological aspect of this sea urchin embryonal stage, demonstrating that SLN are not toxic for this living organism (Figure 6A,B). Moreover, the viability of microinjected *P. lividus* embryos was monitored by MTS assay (Figure 6C). Successively, to investigate the RNA delivery ability of SLN, the complex SLN-*bep3* RNA in unfertilized *P. lividus* eggs was microinjected and its localization was observed before and after fertilization. The RNA movement was detected after incubation with anti-DiG, an antibody able to recognize the UTP−DIG conjugate of the in vitro transcribed *bep3*. As shown in Figure 7A, before fertilization, *bep3* RNA is distributed throughout the cytoplasm. After fertilization (see Figure 7B), instead, staining both under the cellular membrane and particularly in the subcortical region around the nucleus was detected, indicating that the SLN have not interfered with the normal movement of this RNA (*24*). Moreover, the possibility of SLN passing through the biological cellular membrane was tested. Fluorescein-loaded SLN, alone or complexed with RNA, were incubated with sea urchin eggs and after 16 h were observed with a fluorescence microscope. As shown in Figure 7D, the eggs are completely fluorescent, in particular forming a layer around the egg and indicating the perfect ability of SLN to diffuse through the cellular membrane. Finally, fluorescein-loaded SNL complexed to *bep3* were incubated with *P. lividus* eggs and the ability of the RNA to enter the SNL by diffusion was detected after incubation with anti-DIG (Figure 7E).

DISCUSSION

The emergent field of nanotechnology generally involves the characterization, modification, and assembly of organized

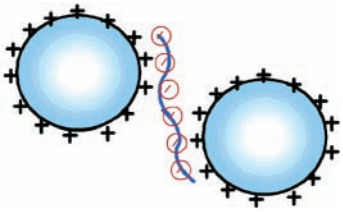

Figure 8. Schematic representation of the interaction between RNA and cationic nanoparticles in the complex.

materials on the nanoscale level. The application of nanotechnology in life sciences is already having an impact on diagnostics and gene therapy in the fight against cancer and genetic disorders. Since biological macromolecules have intrinsic features at the nanometer scale, they have the potential characteristics for formation of nanostructures or nanodevices. RNA is a particular candidate for such application and can exhibit the right versatility to form complexes with nonviral vectors such as cationic nanoparticles. The use of this kind of vector can help genetic material cross the plasmatic membrane and enter the cytoplasm of a living cell and could avoid immunogenic and cytotoxic problems. In this paper, we describe the production of a new type of cationic nanoparticle, and we test both their ability to form a complex and protect RNA and their toxicity and biocompatible properties on a living organism such as the sea urchin.

Cationic SLN have been used to incorporate RNA, and the self-assembled RNA nanostructures are formed with dimensions that fit well within the range of nanotechnology.

As measured by dynamic light scattering, the average hydrodynamic diameter of cationic SLN with RNA in a water solution can be estimated at about 100 nm. After 100 min of mixing, the increase of the average hydrodynamic diameter to about 180 nm confirms the formation of SLN−RNA complexes. From these data, which can only give averaged information, it is hard to assume any kind of model for the complex. However, an indication that very few SLN (two or three) are involved in the complex can be ruled out (Figure 8). SEM microscopy support this result, suggesting that mainly two or three SLN are involved in the complex formation with RNA (Figure 4B).

As shown in gel shift experiments, depending on the cationic SLN−RNA w/w ratio, complexes were produced in a self-assembling manner. Thus, at an SLN−RNA w/w ratio of 200:1 the negative charges on RNA, as also confirmed by ζ-potential measurements, are neutralized and the charge complex is positive. This is relevant for the bioelectrochemistry and the biodistribution of RNA−nanoparticles complexes, increasing their adsorption efficiency in the negatively charged cellular membranes. Moreover, nanoparticles are able to protect *bep3* by RNAase T1 enzymatic degradation even at high concentration and by RNAse A in concentration consistent with a cellular environment, strengthening the idea of a high affinity for RNA molecules. This might permit major RNA stability inside the cellular environments that results in a required condition for nanobiotechnology applications.

To utilize SLN for eventual medical applications, we need to understand if they have a potential toxic effect. To address this question, we decided to utilize the sea urchin as a model system. This organism is very sensitive to different chemical or environmental agents (*31*, *32*). Microinjection of cationic nanoparticles into the *Paracentrotus lividus* eggs permits normal embryonic development as observed by their high viability, regular cell cycle, and correct morphogenesis, indicating their high biocompatibility within the cellular environment. Thus, cationic SLN are composed by physiologically well tolerated ingredients, indicating that they may be suitable for pharmacological applications. Moreover, we took advantage of the characteristic movement of *bep3* RNA along the cytoskeleton to test the potential delivering ability of SLN. The observed correct biodistribution of the RNA suggests that the +/− charge ratio and the ζ potential of the complexes allows an efficient transfer of *bep3* into the cell that maintains its functionality. All these data, together with the ability of SLN to diffuse through the cellular membrane and its potential controlled release of a bioactive molecule, such as *bep3* RNA, suggest that they may have specific characteristics for being a good tool for gene delivery in human therapy.

Synthesis and Characterization of a Novel Arginine-Grafted Dendritic Block Copolymer for Gene Delivery and Study of Its Cellular Uptake Pathway Leading to Transfection

Tae-il Kim,[†] Jung-un Baek,[†] Jae Keun Yoon,[†] Joon Sig Choi,[‡] Kwan Kim,[†] and Jong-sang Park*[,†]

School of Chemistry and Molecular Engineering, Seoul National University, San 56-1, Shillim-dong, Gwanak-gu, Seoul 151-742, and Department of Biochemistry, Chungnam National University, 220 Gung-dong, Yuseong-gu, Daejeon 305-764, Korea. Received June 2, 2006; Revised Manuscript Received November 29, 2006

We synthesized a novel arginine-grafted dendritic block copolymer, R-PAMAM-PEG-PAMAM-R G5 (PPP5-R) for gene delivery systems. Its Mw was measured as 2.74×10^4 Da by MALDI-TOF, and approximately 36 arginine residues are found to be grafted to the polymer by ^{1}H NMR. PPP5-R was able to form polyplexes with plasmid DNA, the average size of which was about 200 nm. Positive ζ-potential values (+22 to +28 mV) of PPP5-R polyplex indicate the formation of positively charged stable polyplex particles and suggest that large dendritic blocks with high positive charge may not be fully shielded by PEG chains even after PEG-coated complex formation. PPP5-R polyplex shows enhanced water solubility due to the polymer's PEG core and also shows low cytotoxicity, representing the potential for in vivo application. We identified the greatly enhanced transfection efficiency of PPP5-R in comparison with that of native PPP5 on various cell lines. Moreover, in view of the result of various cellular uptake inhibitor treatments during a transfection step, the cellular uptake of PPP5-R polyplex leading to effective transfection is thought to be not dependent on one exclusive pathway and to have the possibility of multiple pathways (caveolae-, clathrin-, and macropinocytosis-mediated pathways), contrary to the caveolae-dependent uptake of the PPP5 polyplex lacking arginine residues.

INTRODUCTION

The necessity of developing efficient gene delivery carriers is increasing gradually both in basic sciences and in clinical research fields. Viral vectors (adenoviruses, adeno-associate viruses, retroviruses, etc.) have been successfully applied to various clinical tests for gene therapy because of their high gene delivery efficiency, but their side effects such as severe pathogenicity occasionally limited further application (*1*). On the other hand, nonviral vectors have been studied as alternatives to viral vectors because of their lower cytotoxicity, nonimmunogenicity, more convenient handling, and larger capacity of gene to deliver (*2*−*4*).

However, nonviral vectors including cationic polymers and lipids show much lower transfection efficiency than viral vectors. They also need to overcome the barriers of considerable polyplex aggregation due to the decreased water solubility induced by charge neutralization through the electrostatic interaction between polycationic vectors and polyanionic DNA (*5*).

Our recent report suggested PAMAM-PEG-PAMAM (PPP[1]) as a novel triblock dendritic polymeric vector (*6*). PPP could form polyplexes with plasmid DNA showing much enhanced water solubility. However, the polymer did not show satisfactory transfection efficiency in vitro experiments, urging us to improve the efficiency of the polymer. Recently, Tat-mediated molecular delivery into cells was highlighted and is the subject of intensive research (*7*−*9*). Arginine residues of Tat peptide are thought to perform an important role for the intracellular translocation of molecular delivery (*10*). Also, the synthetic lipidic vectors with a guanidinium headgroup of arginine showed great potential for a gene delivery system (*11*). Moreover, we recently reported that the arginine conjugation of PAMAM dendrimer surfaces led to highly enhanced transfection efficiency of the polyplex (*12*). So, we designed a novel dendritic polymeric vector by conjugating arginine residues to the periphery of PPP in order to increase the transfection efficiency of the polymer, keeping the good water solubility.

Here, we report the synthesis of R-PAMAM-PEG-PAMAM-R (PPP-R), characterization of its self-assembly with plasmid DNA, and its transfection results in vitro.

Meanwhile, the cellular uptake mechanism of cell-penetrating peptides containing arginine residues was reported by many groups (*13*−*15*). However, the cellular uptake mechanism of arginine-grafted dendritic polymer/DNA complex leading to effective transfection has not been reported yet. So, we also report the cellular uptake pathway of PPP-R polyplex by comparing with that of PPP polyplex lacking arginine residues for the first time.

EXPERIMENTAL SECTION

Materials. Poly(ethylenimine) (25 kDa), methyl acrylate, ethylenediamine, *N*,*N*-diisopropylethylamine (DIPEA), piperidine, 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT), 2,5-dihydroxybenzoic acid (DHB), and fucose were purchased from Sigma-Aldrich (St. Louis, MO). Poly(ethylene glycol)-*bis*-amine (MW 3400) was purchased from Shearwater Polymers (Huntsville, AL). *N*-Hydroxybenzotriazole (HOBt) and 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluro-

Scheme 1. Synthetic Scheme of PPP5-R

nium hexafluorophosphate (HBTU) were purchased from Anaspec, Inc. (San Jose, CA). Fmoc-L-Arg(pbf)-OH was purchased from Novabiochem (San Diego, CA). Luciferase 1000 Assay System and Reporter Lysis Buffer were purchased from Promega (Madison, WI). The luciferase expression plasmid, pCN-Luci, was constructed by subcloning cDNA of *Photinus pyralis* luciferase with the 21-aminoacid nuclear localization signal from SV40 large T antigen to pCN (*16*). The GFP expression plasmid, pEGFP-N3 (4.7 kb), was purchased from BD Biosciences Clontech (Mountain View, CA). PicoGreen reagent was purchased from Molecular Probes (Eugene, OR). Fetal bovine serum (FBS), minimal essential medium (MEM), and Dulbecco's modified Eagle's medium (DMEM) were purchased from GIBCO (Gaithersburg, MD). The Micro BCA protein assay kit was purchased from Pierce (Rockford, IL). All other chemicals were purchased and used without any further purification.

Synthesis of PPP5-R. The backbone polymer, PAMAM-PEG-PAMAM G5 (PPP5) was synthesized according to the methods of our previous work (*6*). Briefly, PPP5 was synthesized using poly(ethylene glycol)-*bis*-amine(PEG) (MW 3400) as a polymeric supporter through iterative multistep reactions of Michael addition of methyl acrylate (step 1) followed by amidation of ethylenediamine (step 2) as shown in Scheme 1.

Synthesis of PPP0.5 (step 1). First, PEG was dissolved in methanol and added dropwise to 100 equiv of methyl acrylate kept at 37 °C. After 48 h, methanol and unreacted methyl acrylate were removed under vacuum. The residue was precipitated with an excess of cold ethyl ether and dried under vacuum to remove ethyl ether, leaving a white solid, PAMAM-PEG-PAMAM G 0.5 (PPP0.5). ^{1}H NMR (MeOD): δ PEG(CH_2CH_2O) = 3.63; δ PAMAM($-COOCH_3$) = 3.66; δ PAMAM($-CH_2COOCH_3$) = 2.51; δ PAMAM(protons next to tertiary amines) = 2.85.

Synthesis of PPP1 (step 2). PPP0.5 was dissolved in methanol and added dropwise to 100 equiv of ethylenediamine kept at 37 °C. After 48 h, methanol and ethylenediamine were removed under vaccum. The residue was precipitated with an excess of ethyl ether to remove residual ethylenediamine and dried under vacuum to remove ethyl ether, leaving a pale yellow solid, PAMAM-PEG-PAMAM G 1.0 (PPP1). ^{1}H NMR (D_2O): δ PEG(CH_2CH_2O) = 3.72; δ PAMAM($-CH_2CONH-$) = 2.46; δ PAMAM($-CONHCH_2-$) = 3.32; δ PAMAM(protons next to amines) = 2.6−3.0.

Synthesis of PPP1.5−PPP5. Steps 1 and 2 were consecutively repeated to obtain the higher-generation copolymers. Synthesis of higher-generation copolymer is identical to the above methods, and so we omit them and show the ^{1}H NMR result of each generation copolymer.

Synthesis of PPP1.5. ^{1}H NMR (MeOD): δ PEG(CH_2CH_2O) = 3.63; δ PAMAM($-COOCH_3$) = 3.67; δ PAMAM($-CONHCH_2-$) = 3.27; δ PAMAM($-CH_2COOCH_3$) = 2.46; δ PAMAM($-CH_2CONH-$) = 2.39; δ PAMAM(protons next to tertiary amines) = 2.6−3.0.

Synthesis of PPP2. ^{1}H NMR (D_2O): δ PEG(CH_2CH_2O) = 3.72; δ PAMAM($-CH_2CONH-$) = 2.45; δ PAMAM($-CONHCH_2-$) = 3.31; δ PAMAM(protons next to amines) = 2.6−3.0.

Synthesis of PPP2.5. ^{1}H NMR (MeOD): δ PEG(CH_2CH_2O) = 3.63; δ PAMAM($-COOCH_3$) = 3.67; δ PAMAM($-CONHCH_2-$) = 3.26; δ PAMAM($-CH_2COOCH_3$) = 2.46; δ PAMAM($-CH_2CONH-$) = 2.39; δ PAMAM(protons next to tertiary amines) = 2.6−3.0.

Synthesis of PPP3. ^{1}H NMR (D_2O): δ PEG(CH_2CH_2O) = 3.72; δ PAMAM($-CH_2CONH-$) = 2.46; δ PAMAM($-CONHCH_2-$) = 3.36; δ PAMAM(protons next to amines) = 2.6−3.0.

Synthesis of PPP3.5. ^{1}H NMR (MeOD): δ PEG(CH_2CH_2O) = 3.68; δ PAMAM($-COOCH_3$) = 3.71; δ PAMAM($-CONHCH_2-$) = 3.30; δ PAMAM($-CH_2COOCH_3$) = 2.51; δ PAMAM($-CH_2CONH-$) = 2.43; δ PAMAM(protons next to tertiary amines) = 2.6−3.0.

Synthesis of PPP4. ^{1}H NMR (D_2O): δ PEG(CH_2CH_2O) = 3.72; δ PAMAM($-CH_2CONH-$) = 2.46; δ PAMAM($-CONHCH_2-$) = 3.31; δ PAMAM(protons next to amines) = 2.6−3.0.

Synthesis of PPP4.5. ^{1}H NMR (MeOD): δ PEG(CH_2CH_2O) = 3.66; δ PAMAM($-COOCH_3$) = 3.69; δ PAMAM($-CONHCH_2-$) = 3.28; δ PAMAM($-CH_2COOCH_3$) = 2.48; δ PAMAM($-CH_2CONH-$) = 2.41; δ PAMAM(protons next to tertiary amines) = 2.5−3.0.

Synthesis of PPP5. ^{1}H NMR (D_2O): δ PEG(CH_2CH_2O) = 3.72; δ PAMAM($-CH_2CONH-$) = 2.45; δ PAMAM($-CONHCH_2-$) = 3.31; δ PAMAM(protons next to amines) = 2.6−3.0.

Synthesis of PPP5-R. Arginine coupling to the PPP5 was performed in anhydrous DMF for 1 day at room temperature with 4 equiv of HOBT, HBTU, and Fmoc-Arg(pbf)-OH and 8 equiv of DIPEA. The product was precipitated with an excess of diethyl ether three times and mixed with an equal volume of piperidine (30% in DMF) at room temperature for 20 min to remove the Fmoc groups of coupled Fmoc-Arg(pbf)-OH. The reaction mixture was precipitated again with diethyl ether and

the reagent (95:2.5:2.5, trifluoroacetic acid/triisopropylsilane/water, v/v) was used to deprotect the pbf groups of coupled arginine residues at room temperature for 6 h. After the reaction, the final product, PPP5-R, was dialyzed against ultrapure water overnight and lyophilized before use for analysis and assay.

^{1}H NMR (D_2O): δ arginine($-HCCH_2C\mathbf{H_2}CH_2NH-$) = 1.66; δ arginine($-HCC\mathbf{H_2}CH_2CH_2NH-$) = 1.86; δ PAMAM($-C\mathbf{H_2}$-$CONH-$) = 2.50; δ PAMAM(protons next to amines) = 2.7−2.9; δ arginine($-HCCH_2CH_2C\mathbf{H_2}NH-$) = 3.24; δ PAMAM($-CONHC\mathbf{H_2}-$ and $-CONHCH_2C\mathbf{H_2}NHCO-$) = 3.37; δ PEG($-C\mathbf{H_2}C\mathbf{H_2}O-$) = 3.71; δ arginine($-\mathbf{H}CCH_2CH_2CH_2NH-$) = 3.86.

^{1}H NMR Spectroscopy. ^{1}H NMR spectra of the polymers were obtained using a Bruker DPX-300 NMR spectrometer (300 MHz). For analysis, the polymer samples were dissolved in MeOD or D_2O containing 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid sodium salt as an internal reference (0 ppm).

MALDI-TOF Mass Spectroscopy. MALDI-TOF mass spectra were obtained using a Voyager-DE STR Biospectrometry Workstation (Applied Biosystems, Inc.) in the linear delayed-extraction mode. A polymer solution was prepared by dissolving 1 mg of the polymer in 1 mL of water. The matrix solution was prepared by dissolving 10 mg of matrix (DHB/fucose = 1:1) in 1 mL of the 1:1 mixture of the water and acetonitrile. The samples were prepared by mixing them to a final volume of 2 μL at various ratios.

Gel Retardation Assays. PPP5-R/plasmid complexes at various weight ratios ranging from 0.5 to 8.0 were prepared in Hepes buffered saline (10 mM Hepes, 1 mM NaCl; pH 7.4). After 30 min incubation at room temperature for the complex formation, the samples were electrophoresed on a 0.7% (w/v) agarose gel and stained in an ethidium bromide solution (0.5 μg/mL), and analyzed on a UV illuminator to show the location of the DNA.

Polymer/DNA Self-Assembly Analysis by PicoGreen Assay. PicoGreen assay was carried out to analyze the self-assembly of PPP5-R/plasmid DNA quantitatively as reported recently (*12*, *16*). Briefly, PicoGreen reagent (200×) was diluted to 200-fold in TE buffer before the experiment. 200 μL of the diluted PicoGreen stock solution was mixed with the same volume of blank solution or polyplex solution (1 μg DNA, 1× HBS) prepared at various weight ratios ranging from 0 to 10. After 2 min incubation, each solution was added to 1.6 mL of TE buffer in a test tube. Fluorescence was measured with a FP-750 spectrofluorometer (Jasco) at room temperature. Excitation and emission wavelengths were set at 480 and 520 nm, respectively. Values were represented as relative fluorescence (%) to the value of plasmid DNA.

Polyplex Size Measurements. The hydrodynamic diameters of the PPP5-R/plasmid DNA complexes were determined by light scattering. 2 mL of polyplex solutions containing 5 μg of DNA were prepared at various weight ratios ranging from 1 to 20. After 30 min incubation, polyplex sizes were measured using a Zetasizer 3000HS (Malvern Instruments, U.K.). The laser used is a nominal 5 mW HeNe laser having a 633 nm wavelength. Scattered light was detected at a 90° angle. The refractive index (1.33) and the viscosity (0.89) of ultrapure water were used at 25 °C for measurements. *Zetasizer 3000 (Advanced) Size Mode* v1.61 software was used for data acquisition. Data analysis was performed in automatic mode. Measured sizes were presented as the average values of five runs.

ζ-Potential Measurements. 2 mL of polyplex solutions containing 5 μg of DNA were prepared in Hepes buffered saline (10 mM Hepes, 1 mM NaCl; pH 7.4) at various weight ratios ranging from 0.5 to 20. After 30 min incubation, each polyplex solution was diluted to a 10 mL final volume prior to measurements. ζ-Potential measurements were carried out using a Zetasizer 3000HS (Malvern Instruments, U.K.) at 25 °C. *Zetasizer 3000 (Advanced) Zeta Mode* v1.61 software was used for data acquisition. The sampling time was set to automatic. Potential values were presented as the average values of five runs.

Atomic Force Microscopy (AFM). The particle shapes and sizes of the polymer/plasmid DNA complexes were analyzed using atomic force microscopy (Nanoscope IIIa system, Digital Instruments, Inc., Santa Barbara, CA). The samples were prepared by mixing 0.1 μg of plasmid DNA with aqueous polymer solution at various weight ratios to obtain a final DNA concentration of 10 ng/μL. After 30 min incubation, 1 μL aliquots of the complex solutions were placed on a freshly cleaved mica surface and allowed to stick for 1−2 min. Excess solution was removed by careful absorption onto filter paper, and the mica surface was further dried at room temperature for 24 h. The image mode was set to tapping mode, and the scanning speed was 1−5 Hz.

Polyplex Solubility Measurements in Water. The solubility of polyplex was evaluated by the method developed by Wadhwa et al. with a slight modification (*17*). The PAMAM-R G 4 dendrimer was used as a control reagent (*12*). Polymers were mixed with 20 μg of plasmid DNA at various weight ratios in 0.5 mL of 25 mM Hepes buffer. After incubation for 30 min at room temperature, each mixture was centrifuged for 5 min at 13000 rpm and 10 °C. Then, the absorbance of each supernatant was measured at 260 nm. The solubility was calculated as a percentage ratio of the absorbance of pure DNA solution and each supernatant.

Cytotoxicity Assay. The cytotoxicity of the polymers was measured by MTT assay. HepG2 human hepatocellular carcinoma cells were seeded in a 96-well tissue culture plate at 10^4 cells per well in 90 μL MEM medium containing 10% FBS. Cells achieving 70−80% confluence after 24 h were exposed to 10 μL of the polymer solutions having various concentrations for 24 h. Then, 26 μL of stock solution of MTT (2 mg/mL in PBS) were added to each well. After 4 h of incubation at 37 °C, each medium was removed, and 150 μL of DMSO was added to each well to dissolve the formazan crystal formed by proliferating cells. Absorbance was measured at 570 nm using a microplate reader (Molecular Devices Co., Menlo Park, CA) and recorded as a percentage relative to the value of untreated control cells.

In Vitro Transfection. HepG2, HeLa human adenocarcinoma cells were seeded at a density of 5×10^4 cells/well in a 24-well plate in a medium containing 10% FBS and grown to reach 70−80% confluence prior to transfection. C2C12 mouse myoblast cells were seeded at a density of 3×10^4 cells/well. Before transfection, the cells were rinsed with PBS, and serum-free or serum-containing medium was added to each well. The cells were treated with polyplex solution containing 2 μg of plasmid DNA at different weight ratios for 4 h at 37 °C. In the presence of serum, the cells were incubated for 24 h after transfection. After exchange of medium, cells were further incubated for 2 days after transfection. Then, the growth medium was removed, and the cells were rinsed with PBS and shaken for 30 min at room temperature in 120 μL of Reporter Lysis Buffer. Luciferase activity was measured by a luminescence assay, and a protein assay was performed using a Micro BCA Protein Assay Reagent Kit. 10 μL of the lysate was dispensed into a luminometer tube, and luciferase activity was integrated over 10 s with a 2 s measurement delay in a Lumat LB 9507 luminometer (Berthold, Germany) with an automatic injection of 50 μL of luciferase assay reagent. The final results were reported in terms of RLU/mg cellular protein.

Fluorescence Miscroscopy. HeLa cells were seeded at a density of 2×10^4 cells/well in a 24-well plate in a medium containing 10% FBS. The cells were treated with polyplex solution containing 2 μg of plasmid DNA (pEGFP-N3) at different weight ratios for 4 h at 37 °C. After exchange of medium, cells were further incubated for 24 h, and the fluorescence of expressed GFP was viewed using Axiovert 25 microscopy (Carl Zeiss, Germany). The images were obtained using *AxioVision 3.1* software.

Treatment with Inhibitors. HeLa cells were seeded at a density of 1×10^5 cells/well in a 24-well plate. After 1 day of incubation in normal conditions, cells were pretreated with genistein (200 μM) (*18*), wortmannin (100 nM) (*19*), or chlorpromazine (10 μg/mL) (*20*) for 1 h, or chloroquine (100 μM) for 30 min, before addition of polyplexes. Genistein is reported to inhibit caveolae-mediated uptake processes, and chlorpromazine is known to block clathrin-mediated endocytosis. Wortmannin is an inhibitor of phosphatidyl inositol-3-phosphate (PI3) kinase completing macropinocytosis, and chloroquine is well-known to inhibit endosome acidification. Polyplexes of PPP5 and PPP5-R, containing 2 μg of plasmid DNA, were prepared at weight ratios of 15 and 10, respectively. After 2 h of polyplex incubation, all media were washed with PBS and replaced with fresh media containing 10% serum, then cells were further incubated for 2 days before assay.

Potassium Depletion. HeLa cells were seeded at a density of 1×10^5 cells/well in a 24-well plate and treated with a procedure described by Larkin et al., which results in rapid depletion of cellular potassium (*21*). Potassium depletion of the cells is known to perturb clathrin-mediated endocytosis. After 1 day of incubation in normal conditions, cells were rinsed with K^+-free buffer (140 mM NaCl, 20 mM Hepes, 1 mM $CaCl_2$, 1 mM $MgCl_2$, 1 mg/mL D-glucose; pH 7.4) and subsequently rinsed for 5 min with hypotonic buffer (K^+-free buffer diluted 1:1 with distilled water), followed by washing three times with K^+-free buffer. Control cells were treated with buffer (K^+-free buffer + 10 mM KCl). Polyplexes were incubated with the cells for 2 h and washed with PBS. Then, all media were replaced with fresh media containing 10% serum, and cells were further incubated for 2 days before assay.

RESULTS AND DISCUSSION

Synthesis and Characterization of PPP5-R. Backbone polymer, PAMAM-PEG-PAMAM G5 (PPP5), was synthesized according to the previous report (*6*). The synthesis of PPP5 was monitored by ^{1}H NMR spectroscopy. Arginine conjugation of PPP5 was performed with the HOBt/HBTU coupling method in DMF. Fmoc groups of conjugated arginines were removed by piperidine solution, and the reagent (95:2.5:2.5, trifluoroacetic acid/triisopropylsilane/water, v/v) was used to deprotect the pbf groups of coupled arginines. Scheme 1 shows the entire synthetic procedure of PPP5-R. The synthesis of PPP5-R was confirmed by ^{1}H NMR spectroscopy and MALDI-TOF. The ^{1}H NMR spectra is shown in Figure 1.

The number of grafted arginines was calculated by comparing the NMR peak intensities between the protons of PEG and arginine. Approximately 36 molecules of arginine were found to be conjugated to 1 molecule of PPP5. From this result, the molecular weight of PPP5-R was calculated to be 2.37×10^4 Da. Meanwhile, the Mn and Mw of PPP5-R were experimentally measured using MALDI-TOF. Figure 2 shows the MALDI-TOF MS of PPP5-R. 1:1 DHB/fucose mixture, a well-known "cold" matrix was used as a matrix (*22*). The Mn was estimated to be 2.34×10^4 Da and the Mw to be 2.37×10^4 Da. The polydispersity index of the polymer was determined to be 1.01. The MALDI-TOF result was found to correspond well with the ^{1}H NMR result.

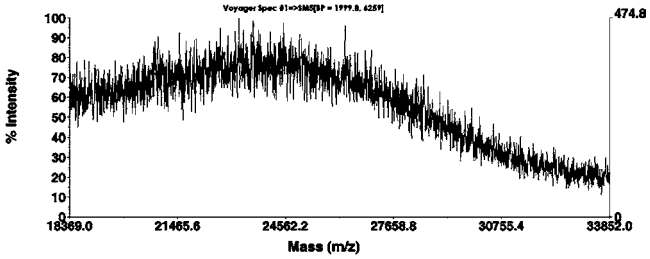

Figure 2. MALDI-TOF MS of PPP5-R.

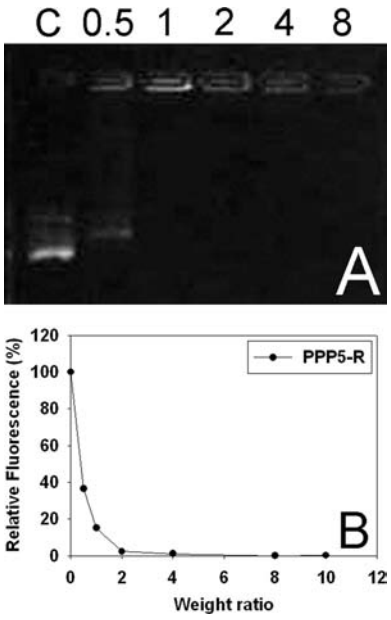

Figure 3. (a) Agarose gel retardation of PPP5-R polyplexes. The numbers represent the weight ratios of the polyplexes. C: plasmid DNA only. (b) PicoGreen reagent assay of PPP5-R polyplexes. Values were represented as relative fluorescence (%) to the value of plasmid DNA.

Self-Assembly of PPP5-R and Plasmid DNA. The self-assembly of PPP5-R and plasmid DNA was examined by agarose gel retardation assay and PicoGreen reagent assay, respectively. PicoGreen reagent is a highly sensitive probe for monitoring polymer/DNA self-assembly (*23*). Figure 3a shows the gel retardation assay result of PPP5-R. PPP5-R could retard the migration of plasmid DNA by forming polyplexes at a weight ratio of 1. Nonmigration of DNA in the gel indicates condensation of DNA by PPP5-R. In a PicoGreen reagent assay experiment (Figure 3b), the polymer is thought to possess a strong DNA condensing ability, as the relative fluorescence intensity of polyplex is abruptly decreased to 15% at a weight ratio of 1 and even to 2% at a ratio of 2.

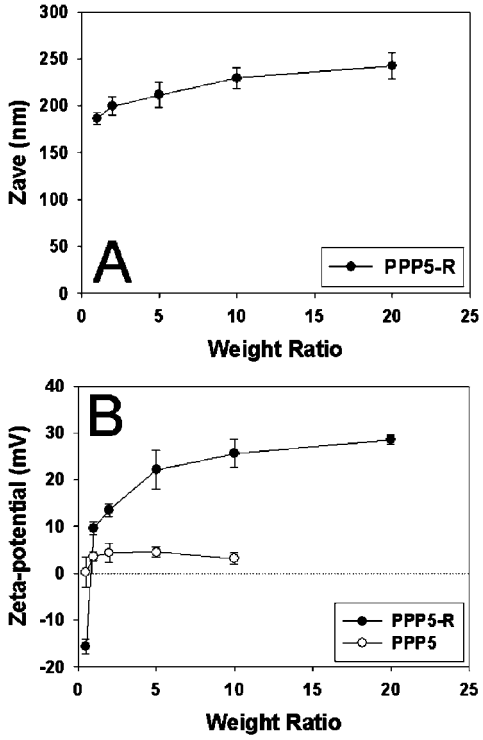

Figure 4. (a) Average size measurements of PPP5-R polyplexes. (b) ζ-Potentials of PPP5-R and PPP5 polyplexes.

Size and ζ-Potential Measurements of the PPP5-R Polyplexes. The proper size of polyplexes is thought to be essential for efficient gene delivery. We performed the average size measurements of PPP5-R polyplexes using a Zeta-sizer. Polyplexes were prepared at various weight ratios ranging from 1 to 20. As shown in Figure 4a, the average size of the polyplexes was 186 nm at a weight ratio of 1 and gradually increased to 242 nm at 20. A plateau of size values from a weight ratio of 5 indicated the formation of stable polyplexes with a size appropriate for gene delivery.

The ζ-potential values of the polyplexes were also estimated at various weight ratios ranging from 0.5 to 20 using a Zeta-sizer (Figure 4b). We also performed ζ-potential measurements for native PPP5 polyplexes to analyze the effect of the arginine modification of PPP5. The positive potential value of the polyplex is thought to be important to adhere to the negatively charged cellular membrane, leading to the intracellular uptake of the polyplex. The ζ-potential value of PPP5-R polyplex was negative (−15.6 mV) at a weight ratio of 0.5 and abruptly increased to 9.7 mV at a ratio of 1. In addition, the values were around 22−28 mV at the ranges over weight ratio 5, displaying stable complex formation with plasmid DNA. On the other hand, the ζ-potential values of PPP5 polyplex were around 3−5 mV even at a weight ratio of 10. In addition, we have reported an interesting result about the ζ-potential experiments of dendritic

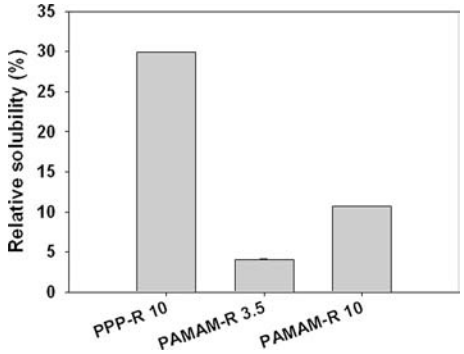

Figure 6. Water solubility of PPP5-R polyplex. The numbers represent the weight ratios of the polyplexes.

triblock copolymer, poly(L-lysine) dendrimer-PEG-poly(L-lysine) dendrimer (PLLD-PEG-PLLD) (*24*). The potential value of PLLD-PEG-PLLD polyplex did not rise to a positive value even at a charge ratio of 8, suggesting that two PLL dendrimer blocks located at each end of the copolymer self-assemble with DNA, and accordingly, the surface of the polyplex is coated with hydrophilic PEG chains. There are big differences in the pK_a value of surface functionalities and molecular size of the dendritic blocks of each block copolymer. The pK_a value of guanidine group of arginine residue is over 12, although that of the primary amine of PLLD and PAMAM is about 10. So, the dendritic blocks of PPP5-R would possess stronger positive charges than others at the same pH condition. Moreover, the molecular weights of the dendritic block of $PLLD_4$-PEG-$PLLD_4$, PPP5, and PPP5-R are about 1920, 6760, and 10 590, respectively. Therefore, it is thought that large dendritic blocks with high positive charges may not be fully shielded by PEG chains even after PEG-coated complexation.

Atomic Force Microscopy (AFM). The morphologies of PPP5-R polyplexes were observed by AFM. Polyplexes were prepared at various weight ratios ranging from 0.5 to 10. As shown in Figure 5a, PPP5-R could not condense plasmid DNA compactly, and so DNA stretched out from hundreds of nanometer-scale semicondensed polyplex cores like a corona at a weight ratio of 0.5. At a ratio of 1, the polymer could condense plasmid DNA to a complex, but we could still observe the small projections around the core, which were inferred to be a portion of noncondensed plasmid DNA (Figure 5b). At a ratio of 10, it was observed that PPP5-R could form compact spherical polyplexes with plasmid DNA with homogeneity and about a 200-nm size (Figure 5c). These results agreed well with the size measurement results obtained by Zeta-sizer.

Water Solubility. After complexation, some polyplexes show a tendency to aggregate in water because of increased hydrophobicity caused by charge neutralization, limiting their in vivo application (*5*). So, we examined the water solubility of the PPP5-R polyplex. PAMAM-R G4 was used as a control reagent because its molecular structure was identical to that of PPP5-R

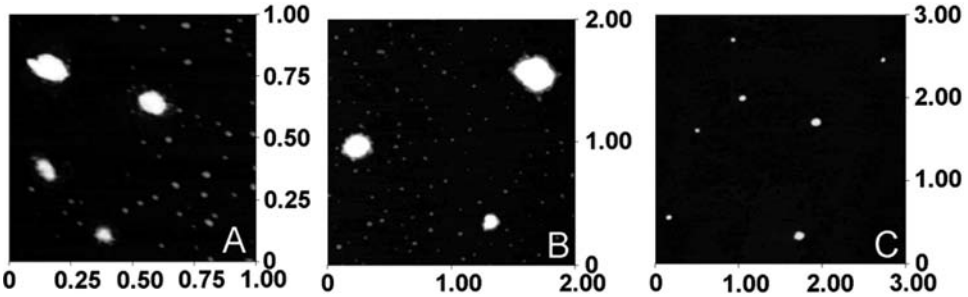

Figure 5. AFM images of PPP5-R polyplexes: at weight ratios of (a) 0.5, (b) 1, and (c) 10. The numbers around the figures represent μm-scaled sizes.

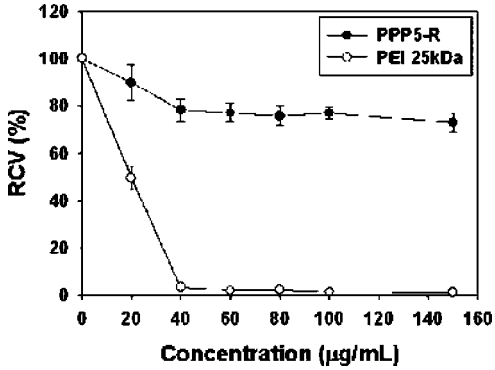

Figure 7. Cytotoxicity of PPP5-R in HepG2 cells by MTT assay. RCV: relative cell viability. Data were expressed as mean ± standard deviation ($n = 5$).

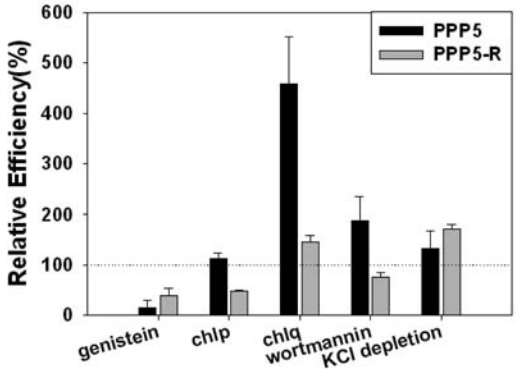

Figure 9. Relative transfection efficiency (RTE) of each polyplex in treating various cellular uptake inhibitors and in potassium depletion condition. chlp , chlorpromazine; chlq, chloroquine; RTE = experimental value/control value × 100 (%). Data were expressed as mean ± standard deviation ($n = 3$).

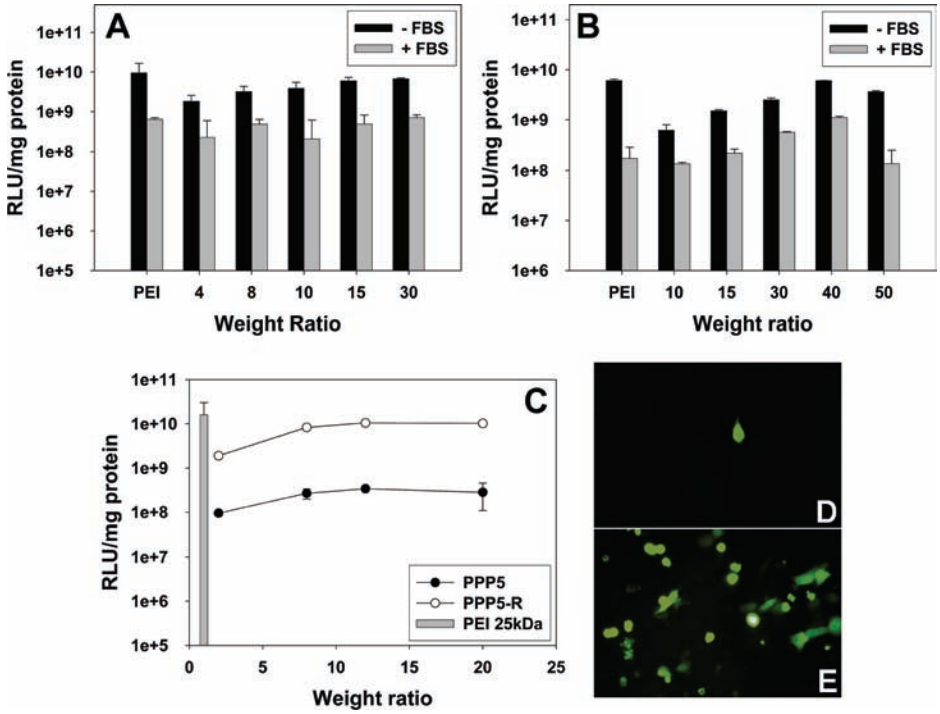
except the core part. As shown in Figure 6, we can find that PPP5-R polyplex has a sixfold enhanced water solubility compared to PAMAM-R G4 polyplex in an optimal ratio for transfection. From this result, it is obvious that the PEG core of PPP5-R plays an important role for increasing the water solubility of the polyplex.

Cytotoxicity. The cytotoxicity of PPP5-R was examined on HepG2 cell lines by MTT assay. PEI was used as a control. The cytotoxicity of PEI is well-known. As shown in Figure 7, cell viability of PEI was 50% at 20 μg/mL and decreased to 4% at 40 μg/mL of concentration, while PPP5-R displayed 77−90% cell viability in the same concentration range, suggesting that the cytotoxicity of PPP5-R is minimal.

Transfection Experiments. Transfection efficiency of PPP5-R was examined on HeLa, C2C12, and HepG2 cells. PEI was used as a control reagent in optimal condition. PPP5-R showed very high transfection efficiency comparable to that of PEI in the presence or absence of serum in HeLa and C2C12 cells in Figure 8a,b. The transfection efficiencies of both PEI and PPP5-R were observed to be reduced in the presence of serum. Interestingly, transfection efficiency ratios (+FBS/−FBS) of PEI were 0.03 and 0.07 in C2C12 and HeLa cells, respectively, while the ratios of PPP5-R were in a range between 0.10 and 0.23. Considering our previous data for native PPP5 (transfection efficiency ratio = 0.85−1.3) (*6*), the PEG core of the copolymers is thought to coat the surface of the polyplex and inhibit the nonspecific interaction of polyplexes with serum compartments, suppressing the reduction of the transfection efficiency. However, in the case of PPP5-R, PEG could not coat the polyplex completely, reducing its efficiency ratio, as described in the ζ-potential experiment. The transfection efficiency of PPP5-R was also compared with that of native PPP5 on HepG2 cells (Figure 8c). PPP5-R showed a transfection efficiency value 20−36 times higher than that of native PPP5.

Furthermore, we can also identify a much increased transfection activity of PPP5-R in fluorescence microscopy. A considerable number of cells expressed green fluorescence protein in treatment with PPP5-R/pEGFP polyplex (Figure 8e), unlike with PPP5/pEGFP polyplex (Figure 8d). This greatly increased transfection efficiency of PPP5-R must be due to the arginine residues grafted onto the periphery. From these results, we hypothesize that arginine residues of PPP5-R would function



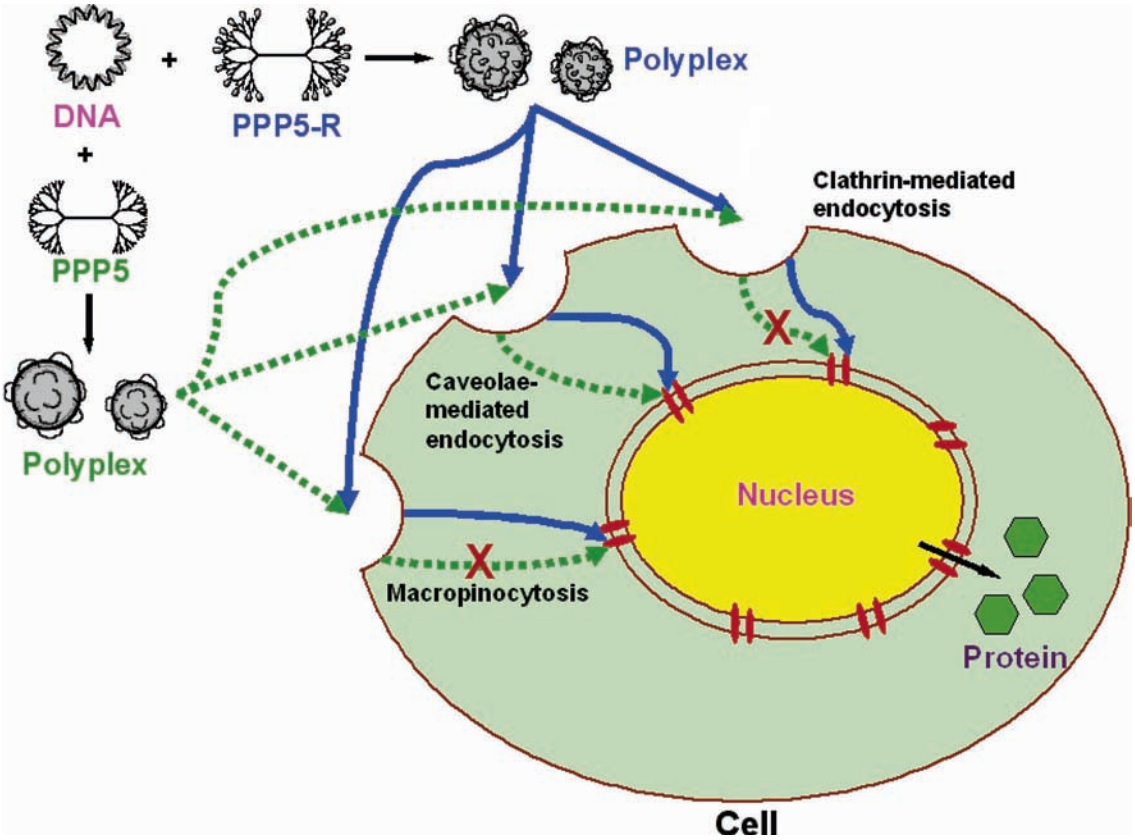


Figure 8. Transfection experiments in (a) HeLa cells, (b) C2C12 cells, and (c) HepG2 cells. PEI and PPP5 are used as control reagents. (d,e) represent GFP expression in HeLa cells by PPP5 and PPP5-R, respectively. Data were expressed as mean ± standard deviation ($n = 3$).

Scheme 2. Schematic Diagram of the Proposed Cellular Uptake Mechanism of PPP5 Polyplex and PPP5-R Polyplex

as a key to a cellular membrane gate, which guides the PPP5-R polyplex to the cellular uptake pathway for efficient transfection.

Cellular Uptake Pathway Leading to Enhanced Transfection. These transfection results raise a question about the differences of the cellular uptake pathway leading to enhanced transfection between native PPP5 and arginine-grafted PPP5-R. The cellular uptake pathway of cell-penetrating peptides containing Tat sequences and oligo-arginine peptides has been reported by many groups (*13*−*15*), but that of arginine-grafted dendritic polymer polyplex is not well-understood. We performed the transfection experiments on HeLa cells by treatment with various cellular uptake inhibitors and compared the effect in order to examine the cellular uptake pathway leading to effective transfection of PPP5 and PPP5-R polyplexes, for the first time. Genistein is reported to inhibit caveolae-mediated uptake processes (*18*), and chlorpromazine is known to block clathrin-mediated endocytosis (*20*). Wortmannin is an inhibitor of phosphatidyl inositol-3-phosphate (PI3) kinase completing macropinocytosis (*19*), and chloroquine is a well-known endosome acidification inhibitor.

Figure 9 represents the relative transfection efficiencies of PPP5 and PPP5-R polyplexes in the presence of each inhibitor. In the case of PPP5, only genistein reduced the efficiency considerably, and chlorpromazine did not affect the efficiency. The result suggests that PPP5 polyplexes entering through caveolae-mediated uptake lead the effective transfection and agrees well with the other report (*25*). In the presence of chloroquine, its enhanced efficiency leads us to believe that the cellular uptake of PPP5 polyplex also happens through clathrin-mediated endocytosis but the polyplex may not escape from the endosome efficiently, not leading to effective transfection. It is thought that chloroquine helps the PPP5 polyplex escape from the endosome by inhibiting acidification of the endosome and leading to mechanical swelling of the polymer. This view is well-supported by the previous result that the transfection efficiency of PPP5 is relatively lower in HepG2 cells lacking caveolin-1 than in 293 cells (*6*). Macropinocytosis inhibition by treatment with wortmannin led to a somewhat increased transfection efficiency of PPP5 polyplex. It is thought that this may be associated with the fact that the cellular uptake of polyplex through macropinocytosis is reported to impair the transfection efficiency (*19*).

Interestingly, unlike with PPP5, the transfection of the PPP5-R polyplex is reduced in the presence of both genistein and chlorpromazine by 39% and 47%, respectively, and is not particularly affected in the presence of chloroquine. This result represents evidence that the effective transfection of arginine-grafted dendritic polymer is carried out through the cellular uptake of both caveolae- and clathrin-mediated pathways to some degree. A relatively small effect of chloroquine on PPP5-R in comparison with PPP5 and the inhibition of transfection by chlorpromazine suggest that PPP5-R polyplex may have its own specific competency to escape from the compartments of a clathrin-dependent pathway, unlike PPP5 polyplex. Macropinocytosis inhibition by wortmannin reduced the transfection efficiency by 76%, unlike in the recent report by Nakase et al. that the cellular uptake of arginine-rich peptides was significantly suppressed by a macropinocytosis inhibitor (*26*). Our results show that arginine-rich peptide and arginine-grafted dendritic copolymer polyplex have distinct internalization mechanisms. Scheme 2 shows the proposed cellular uptake mechanisms leading to transfection of both PPP5 polyplex and PPP5-R polyplex.

Moreover, we performed the transfection experiments of both polyplexes in the depletion of potassium ion in order to confirm the chlorpromazine experimental result (Figure 9). Potassium depletion of the cells is also known to perturb clathrin-mediated endocytosis (*21*). In line with our expectations, the transfection of PPP5 polyplexes was not affected by potassium depletion, which corresponded with the chlorpromazine result. However, on the contrary, the transfection efficiency was increased about twofold in the case of PPP5-R. Discordance with the previous

chlorpromazine result leads us to preconclude that another factor could be affecting the cellular uptake of arginine-grafted dendritic polymer. Recently, Rothbard et al. reported that the membrane potential of cells strongly induces the translocation of guanidinium-rich peptides, and the membrane potential is related to the negative log value of the concentration ratio of extracellular (K_o) and intracellular (K_i) potassium ions (*27*). In KCl-containing buffer, generally K_o and K_i are known to be about 10 mM and 140 mM, respectively. In potassium depletion condition, K_o may become a micromolar concentration at most and K_i drops to 40% (about 50 mM) when polyplex solution is added after about 15 min of cell rinsing (*21*). According to Rothbard et al.'s formula, the membrane potential would become more negative in the potassium depletion condition, and it may induce more cellular uptake of polyplexes and the following enhanced transfection efficiency.

In summary, these results strongly suggest that the cellular uptake leading to the effective transfection of arginine-grafted dendritic polymer polyplex is not dependent on one exclusive pathway and has the possibility of combination of multiple pathways, unlike with the caveolae-dependent uptake of PPP5 polyplex lacking arginine residues. Therefore, this unique uptake mechanism of the PPP5-R polyplex is thought to be one of the important reasons for the enhanced transfection efficiency of the polyplex. Moreover, we are studying the nuclear localization ability of the arginine residues, which may provide another key explanation for the result. This finding would help us to understand arginine-based polymeric gene carriers and to develop more efficient gene delivery carriers in the future.

Finally, PPP5-R would be a less toxic and high transfection efficient gene delivery carrier unrelated to cell type because of its multiple uptake mechanisms. Also, it would show the potential for drug delivery systems by conjugation of drugs to the polymer due to its great cell-penetrating ability.

CONCLUSION

We synthesized a novel arginine-grafted dendritic block copolymer, R-PAMAM-PEG-PAMAM-R G5 (PPP5-R), for gene delivery systems. PPP5-R could form nanosized polyplexes with plasmid DNA, which was examined by agarose gel electrophoresis, PicoGreen reagent assay, Zeta-sizer, and AFM. The positive ζ-potential values of the PPP5-R polyplex show the formation of positively charged stable polyplex particles and suggest that large dendritic blocks with high positive charge may not be fully shielded by PEG chains even after PEG-coated complexation. The PPP5-R polyplex showed enhanced water solubility due to the PEG core and low cytotoxicity. The PPP5-R polyplex represented the greatly enhanced transfection efficiency in comparison with native PPP5 on various cell lines. By treating various cellular uptake inhibitors, we concluded that the cellular uptake leading to the effective transfection of arginine-grafted dendritic polymer PPP5-R polyplex is not dependent on one exclusive pathway and has the possibility of multiple pathways, unlike with the caveolae-dependent uptake of PPP5 polyplex lacking arginine residues. Moreover, this particular cellular uptake pathway of PPP5-R is proposed to be one of the important reasons for the enhanced transfection efficiency.

Oligothiophene Molecular Beacons

Antonella Cazzato,† Massimo L. Capobianco,* Massimo Zambianchi, Laura Favaretto, Cristian Bettini, and Giovanna Barbarella

Istituto per la Sintesi Organica e la Fotoreattività del Consiglio Nazionale delle Ricerche (ISOF-CNR), Via. P. Gobetti 101, 40129 Bologna, Italy. Received June 16, 2006; Revised Manuscript Received November 21, 2006

Oligomers of thiophene are widely studied compounds for their electronic and optoelectronic properties. Despite their strong fluorescence, their use as markers for biomolecules, especially for oligonucleotides (ONs), is still largely unexplored. Here, we describe the synthesis of a series of ON molecular beacons employing different oligothiophenes as fluorescent probes and discuss their fluorescence emissions in comparative experiments with and without dabcyl as a quencher, in their hairpin and linear conformations, and as duplexes after hybridization with a complementary target.

INTRODUCTION

Oligomers of thiophene are well-studied compounds for their (opto)electronic properties. For instance, they have been used for the preparation of thin-film-based organic devices (LED, FET, etc.) (*1*, *2*). An important characteristic of this class of compounds is that their absorption and emission wavelength can be rationally predicted and easily obtained by a careful design of their molecular structure and positioning of substituents (*3*). We have recently started a program aimed at exploring the biological potential of this class of compounds as fluorescent markers for biomolecules such as proteins (*4*) and, more recently, oligonucleotides (*5*, *6*). The use of fluorescence as a tag for oligonucleotides is a useful alternative to radioactive labeling in quantitative experiments (*7*); it also allows an easy localization of oligonucleotides in cells (*8*). The emission of a fluorescent molecule is extremely sensitive to its environment, since small conformational changes of the fluorophore due to solvent effects or to interactions with other molecules through complex formation or energy transfer (FRET) may lead to dramatic changes in emitted light (*9*). In 1996, Tyagi showed a stunning application of FRET in the field of molecular recognition using double-labeled oligonucleotides called "molecular beacons" (*10*). Probes based on this principle are oligonucleotides (ONs) that spontaneously form a hairpin structure (see Figure 1) that puts their 5′ and 3′ ends in close proximity. In such a conformation, the fluorescence of a fluorophore tagged to one of the extremities can be quenched by a suitable moiety linked to the other end through Forster's energy transfer mechanism (*11*) and other mechanisms (*9*). When the ON probe in its quenched form is hybridized with a complementary strand, its conformation changes from hairpin to a distended double helix in which the fluorophore is moved away from the quencher and the fluorescence is (at least in part) restored. In ideal conditions, the ON probe behaves like a molecular beacon (MB): a strong fluorescence emission indicates the formation of the distended duplex (hence the presence of the target), while a weak response to the exciting light reveals the hairpin structure (indicating the absence of the target).

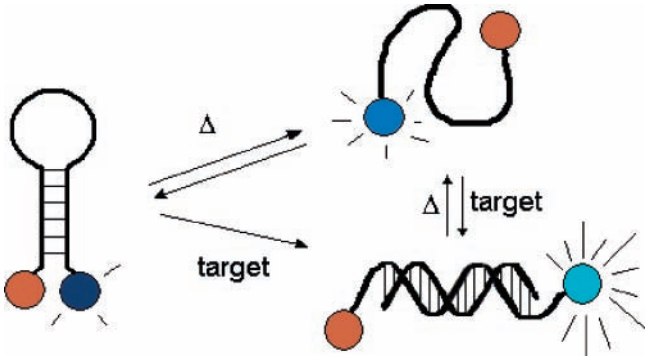

Figure 1. In the hairpin form, the fluorescence of the molecular beacon is quenched by the proximal quencher (orange circle). After denaturation by heat or after a hybridization event, the hairpin structure is broken and the quencher is moved away, restoring the fluorescence signal.

EXPERIMENTAL PROCEDURES

Synthesis and Purification of Oligonucleotides and Conjugates. The **MB** sequence was synthesized in our laboratory starting with commercial DMTr-C6-phtalimido-CPG. The compound was purified by ionic exchange chromatography on Sephacell using a gradient of triethylammonium hydrogen carbonate. Pure fractions were pooled, lyophilized several times, quantified, and split in vials of about 20 OD. The vials were eventually lyophilized and stored at −20 °C until use.

Similarly, the **dabcyl-MB** sequence was synthesized on a 10 μM scale on the same CPG, using DMTr-dabcyl-C6-amidite as the last monomer. This compound was purified on a C-18 reversed-phase column using a gradient of acetonitrile in 0.1 M of aq triethylammonium acetate. Pure fractions were collected, lyophylised several times, and split in amount of 20 OD in separate vials, stored at −20 °C.

The target sequence was purified by *n*-BuOH precipitation and found to be more than 80% pure at 260 nm by HPLC analysis on both reversed-phase and ionic exchange columns. It was kept solid at −20 °C until the moment of use.

Succinimidyl Esters. The succinimidyl esters of fluorophores **A**, **B**, and **D** (Figure 2) were synthesized according to the modalities described in ref 5. Succinimidyl esters of derivatives **C** and **E** are gifts from Mediteknology srl.

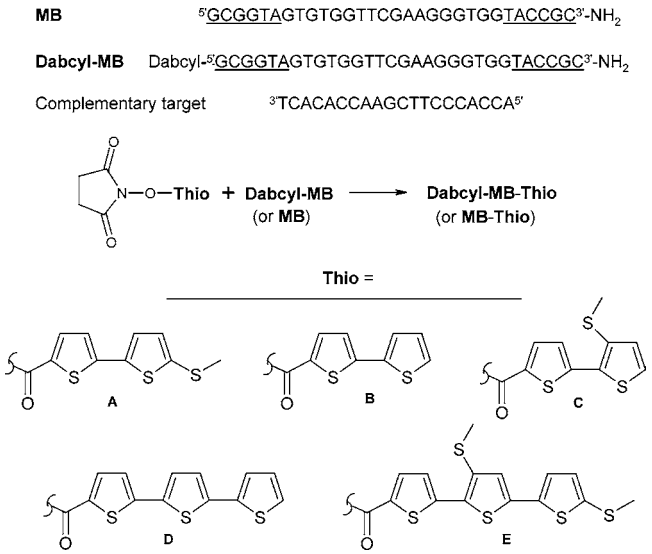

Figure 2. List of used compounds. The underlined bases form the hairpin stem.

Fluorescent ON Molecular Beacons. Fluorescent molecular beacons (with or without dabcyl) were obtained by mixing 20 OD of the corresponding 3′-amino-oligonucleotide with 1 mg of the succinimidyl ester of the oligothiophene in a buffer containing 160 μL of DMF and 18 μL of HEPES 0.2 M, pH 8.0, in water. The mixture was kept at 40 °C overnight. The reaction mixture was then diluted with 1 mL of water, and the excess of thiophene succinimidyl ester was extracted by repeated washing with dichloromethane. The aqueous phase was concentrated and purified by HPLC reversed-phase chromatography using a gradient of acetonitrile in 0.1 M aq TEAA. The collected fractions were judged more than 90% pure by absorbance at 260 nm and more than 95% pure by fluorescence detection using the appropriate λ_{ex} and λ_{em} for each compound. Usually, 5−7 OD of pure conjugate were obtained. The UV/vis profile of each conjugate was carefully checked to verify the correct incorporation of the oligothiophene and dabcyl. Finally, the identity of the ON MBs was confirmed by mass spectrometry (Bruker Esquire 3000 plus) in ESI mode with the following results: **MB-A** calcd *m*/*z* 9792.7, found 9791.4; **dabcyl-MB-A** calcd *m*/*z* 10255.1, found 10256.6; **MB-B** calcd *m*/*z* 9746.6, found 9746.3; **dabcyl-MB-B** calcd *m*/*z* 10209.0, found 10209.6; **MB-C** calcd *m*/*z* 9792.7, found 9792.7; **dabcyl-MB-C** calcd *m*/*z* 10255.1, found 10255.5; **MB-D** calcd *m*/*z* 9828.7, found 9831.2; **dabcyl-MB-D** calcd *m*/*z* 10291.1, found 10290.8; **MB-E** calcd *m*/*z* 9920.9, found 9920.0; **dabcyl-MB-E** calcd *m*/*z* 10383.3, found 10383.5.

Sample Preparation. To prevent manipulation errors, especially in the fluorescence readings, all experiments were done starting from a 1 μM concentration of the sample in a 3.0 mL fluorescence cuvette. The sample was then used for UV scan and fluorescence measurements, and then 5 μL of complementary target ON was added to the very sample to perform the hybridization experiments.

RESULTS AND DISCUSSION

In this work, we used fluorophores made of two and three thiophene rings (see Figure 2) tagged to the 3′-end of the ON strand, while the other end was kept free or conjugated to a dabcyl moiety.

The stem part of the sequence **MB** was chosen for the strong T_m found to be about 38 and 50 °C for **MB** and **dabcyl-MB** (data not shown), respectively, while its loop region was chosen to be complementary to an oligo already used by our group (*6*). The 3′-amino group was obtained by use of commercial DMTr-C6-phthalimido-CPG (Glen research). The use of dabcyl as a quencher was dictated by its large absorption region and by the commercial availability of its DMTr-dabcyl-C6-amidite (Chem Genes).

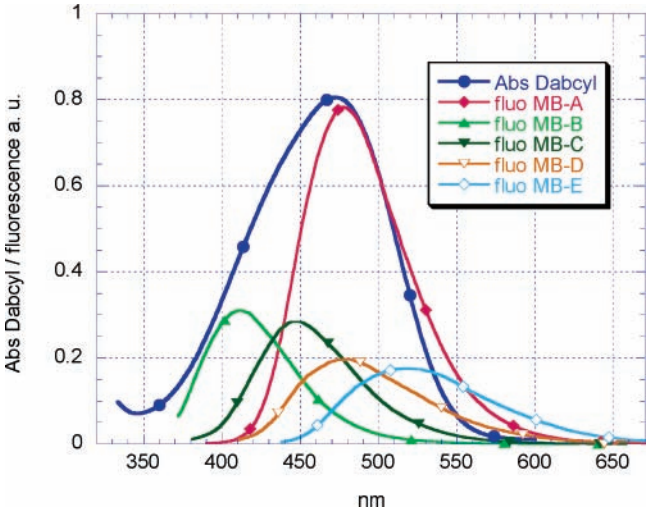

Figure 3. Superimposition of UV absorption spectrum of the dabcyl moiety of **dabcyl-MB** with fluorescence emissions of **MB-A**−**MB-E** conjugates. Each thiophene derivative was excited at its maximum excitation frequency. The intensities of the emission spectra, on an arbitrary scale, are proportional among all members. The absorption of the dabcyl derivative is also on an arbitrary scale. All fluorescence spectra were recorded at 1 μM concentration in 100 mM NaCl, 10 mM sodium cacodylate buffer pH 7.0.

Table 1. List of Maximum Frequency of Excitation and Emission of Succinimide and Oligonucleodide Derivatives

	succinimidyl ester		oligo conjugate	
entry	λ_{ex}	λ_{em}	λ_{ex}	λ_{em}
A	370	479	360	479
B	352	418	335	410
C	361	479	350	445
D	390	460	410	480
E	418	549	425	520

Oligothiophene fluorophores **A**−**D** were chosen for their intense fluorescence in water and for the overlap of their emission within the absorption range of the dabcyl as illustrated in Figure 3.

After conjugation, we noticed, in aqueous solution, some small variations at both wavelengths of absorption and emission of thiophene derivatives with respect to those of their succinimidyl ester parents in dichloromethane. A list of absorption and emission wavelength is reported in Table 1.

All the compounds were analyzed by the same methodology described below for **MB-A** and **dabcyl-MB-A**.

MB-A and **dabcyl-MB-A** were analyzed by UV at 10, 20, 30, 40, 50, 60, and 70 °C. The spectra had the expected UV/vis intensity ratio and did not shown any significant variation in the shape of the signal in the visible region, a strong indication that neither the tagged chromophore nor the quencher was involved in formation of complexes directly affected by temperature change (as would be expected in the case of intercalation of the dabcyl or thiophene moieties between base pairs of the stem of the hairpin of the molecular beacons) (see Figure 4). (A similar behavior was shown by all the other members, derivatives **B**−**E**, not shown.)

Compoud **MB-A** showed no clear melting point (from hairpin to random coil) in melting experiments, while the **dabcyl-MB-A**

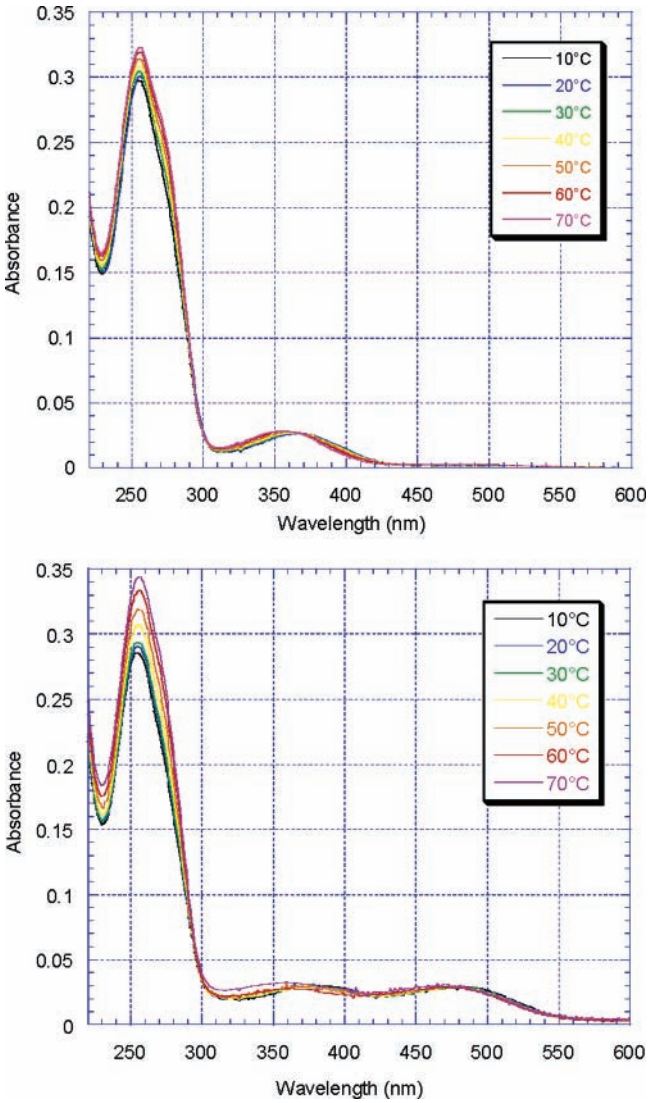

Figure 4. UV/vis scan at various *T* of **MB-A** (top panel) and **dabcyl-MB-A** (bottom panel) at 1 μM concentration in 100 mM NaCl and 10 mM sodium cacodilate pH 7.0.

showed a clear transition centered at 58 °C. (In all tested compounds, the melting point was not clearly detectable in the **MB** series, while in the **dabcyl** series, it was in the range 56−58 °C.)

Next, we analyzed the emitted fluorescence of **MB-A** and **dabcyl-MB-A** at different temperatures (Figure 5).

As expected, in the absence of dabcyl, the emission was slightly affected by heating; the intensity decreased by less than 10% from 10 to 70 °C (as in the corresponding succinimidyl parent compound; data not shown). This decrease can be attributed to a partial loss of coplanarity between the thiophene rings with heating. The **dabcyl-MB-A** showed a marked increase in fluorescence emission on going from 40 to 70 °C due to the thermal opening of the hairpin structure (molecular beacon effect). It is remarkable that even at high temperature the fluorescence emission of **dabcyl-MB-A** is lower than that of the corresponding compound without the quencher. This indicates that even in the random coil conformation the dabcyl moiety is able to quench part of the emission of the thiophene derivative **A** (dabcyl effect). This quenching was found to be independent of the concentration.

Next, we determined, by UV, the melting point of both **thiophene A** conjugates with their complementary strand (Figure 6).

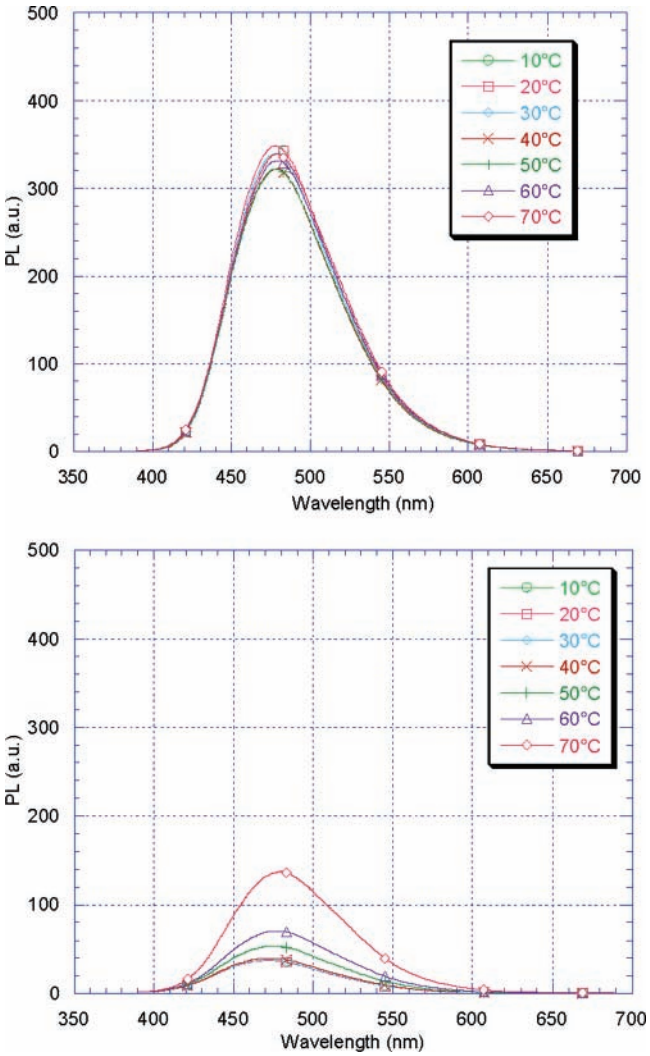

Figure 5. Variation of fluorescence with the temperature. Top panel **MB-A**; bottom panel **dabcyl-MB-A**.

Both molecular beacons showed a clear melting point (48 and 64 °C, respectively) higher than that of the hairpin, thus demonstrating that in the presence of the target the favored form is the duplex with the complementary strand.

Eventually, we studied the variation of fluorescence of the formed duplex with temperature (Figure 7).

By comparing all the above experiments, several conclusions can be drawn:

- The double labeling favors the stability of the hybrid with the target.
- The fluorescence of **MB-A** is enhanced (about 1.4 times) by hybridization (duplex effect).
- After hybridization with the target, the fluorescence of **dabcyl-MB-A** is more than 7 times higher than that of its hairpin form ("diagnostic effect": combination of molecular beacon and duplex effects).
- After hybridization, the fluorescence of **dabcyl-MB-A** is higher than that of the same compound in random coil form.

The experiments illustrated for **thiophene-A** derivatives were performed with all the compounds in Figure 2. A summary of the findings are shown in Figure 8.

Data in Figure 8 show that dabcyl is a quencher for all derivatives; however, while for derivatives **D** and **E** after hybridization with the complementary strand the fluorescence of the dabcyl derivative is equal to that of the relative compound without dabcyl, in cases **A** to **C**, the signal remains lower. This can indicate that for these derivatives the distance between the

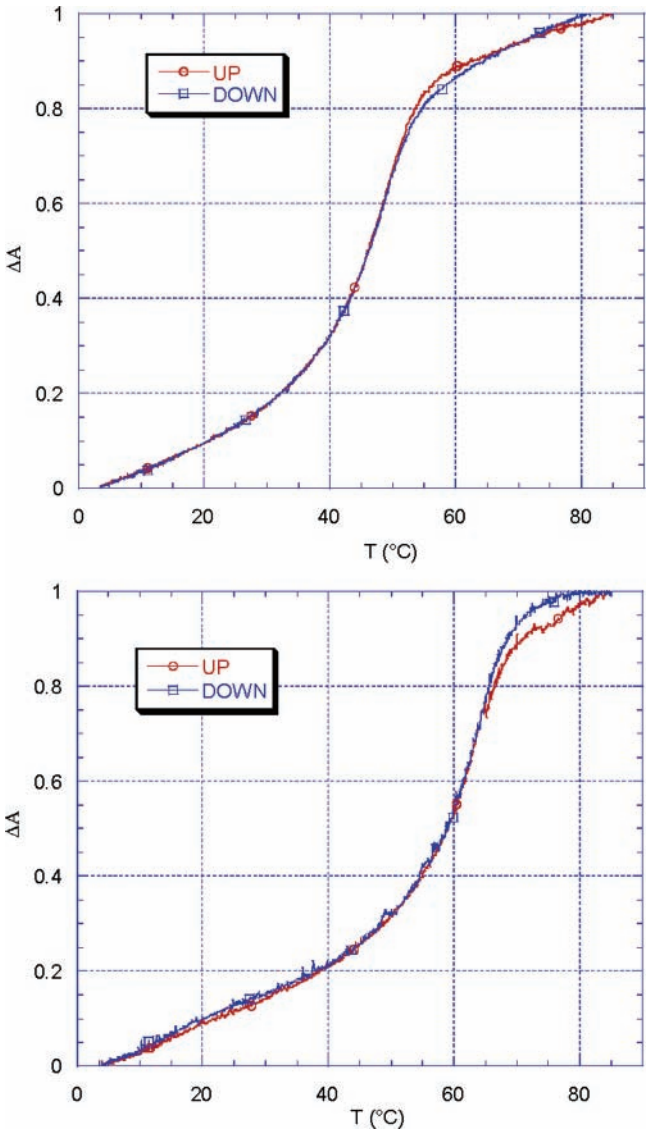

Figure 6. Melting of duplex **MB-A** (top panel) and **dabcyl-MB-A** (bottom panel) with their target (1.2 equiv). For each melting, heating and cooling curves are shown. The melting was performed on a buffer containing 100 mM NaCl and 10 mM sodium cacodilate at pH 7.0. Heating up and cooling down rates were of 0.2 °C/min. Normalized variations of absorbance were plotted.

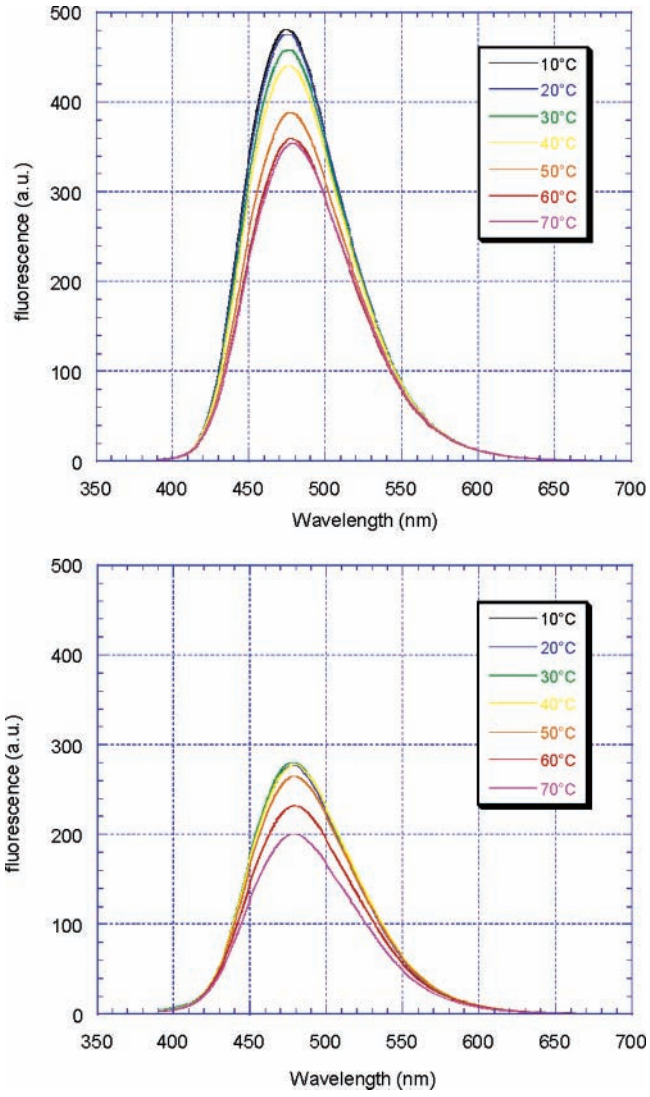

Figure 7. Variation of fluorescence emission with temperature for **MB-A** (top panel) and **dabcyl-MB-A** (bottom panel) after hybridization.

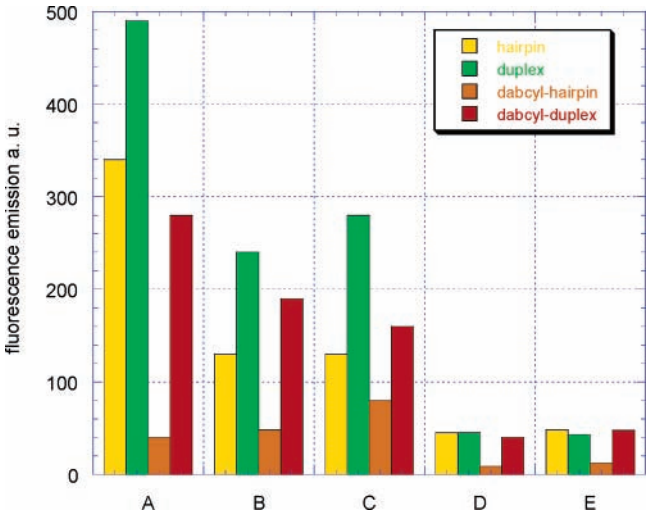

Figure 8. For each compound, the intensity of the emitted fluorescence at room temperature (on the same scale for all compounds) is reported. For each group, left to right: yellow bars, **MB hairpins**; green bars, **duplex MBs/target**; orange bars, **dabcyl-MB hairpins**; red bars, **duplex dabcyl-MBs/target**.

fluorophore and the quencher, even in the distended duplex, does not reach the Forster's radius. Oligonucleotide conjugates of **A**, **B**, and **C** are, at least within this system, quite sensitive to the hairpin−duplex transition even in absence of dabcyl as a quencher. We still do not know if this change of emission intensity depends on a possible quenching from bases on the 5′ region that came in proximity to the fluorophore in the hairpin structure (*12*, *13*) or if the formation of the duplex puts the fluorophore in a more favorable condition to increase the fluorescence quantum yield. Luckily for our systems, the molecular beacon effect and the duplex effect combine favorably to enhance the "diagnostic value" of probes **dabcyl-MB-A** and **dabcyl-MB-B**.

Derivatives **A**, **B**, and **C** (two thiophene rings) show a higher fluorescence than derivatives **D** and **E** (three thiophene rings), as well as their precursors; among the first three, derivative **A** has the strongest quantum yield.

In conclusion, we have described the fluorescence properties of a series of oligothiophene conjugated oligonucleotides. All compounds show a high fluorescence emission (they are easily detectable at 10−100 nM concentration). All derivatives are suitable for preparation of molecular beacons with dabcyl as a

quencher. Derivatives **A**−**C** are sensitive enough, at least in this system, to reveal a hybridization event even in absence of dabcyl.

We report a robust and practical method for the preparation of water-soluble luminescent quantum dots (QDs) selectively coupled through an amine or thiol linkage to peptide ligands targeted to G-protein coupling receptors (GPCRs) and demonstrate their utility in whole-cell and single-molecule imaging. We utilized a low molecular weight (~1200 Da) diblock copolymer with acrylic acids as hydrophilic segments and amido-octyl side chains as hydrophobic segments for facile encapsulation of QDs (QD 595 and QD 514) in aqueous solutions. As proof of principle, these QDs were targeted to the human melanocortin receptor (hMCR) by chemoselectively coupling the polymer-coated QDs to either a hexapeptide analog of α-melanocyte stimulating hormone or to the highly potent MT-II ligand containing a unique amine. To label QDs with ligands lacking orthogonal amines, the diblock copolymers were readily modified with water-soluble trioxa-tridecanediamine to incorporate freely available amine functionalities. The amine-functionalized QDs underwent facile reaction with the bifunctional linker NHS−maleimide, allowing for covalent coupling to GPCR-targeted ligands modified with unique cysteines. We demonstrate the utility of these maleimide-functionalized QDs by covalent conjugation to a highly potent Deltorphin-II analog that allowed for selective cell-surface and single-molecule imaging of the human δ-opioid receptor (hDOR).

INTRODUCTION

Semiconductor nanocrystals, also called quantum dots (QDs), have received considerable attention due to their novel electronic and optical properties that are desirable for applications in biological imaging (*1*−*3*). Their broad absorption spectra, as well as their narrow and size-tunable emissions, by altering particle size, make it possible to excite all colors of QDs simultaneously with a single light source for multiplexing without substantial spectral overlap. The long photo luminescent lifetime of QDs (30−100 ns) also allow for imaging of living cells with minimal interference from background autofluorescence, while their resistance to photobleaching makes them useful for continuous monitoring of biological processes (*4*). These emerging probes can potentially aid in refining existing methods for drug targeting and in facilitating studies in basic biology (*5*, *6*).

Organometallic chemistry has provided synthetic pathways to robust, monodisperse, highly emissive nanomaterials, such as CdSe nanocrystals capped with ZnS shells. However, for biological imaging it remains challenging to choose appropriate organic coating agents to generate water-soluble QDs that maintain high luminescent quantum yields and stability. Ligand exchange is the most common method for generating water-soluble QDs; for example, simple thiol-containing molecules, such as mercaptoacetic acid, have been used to replace hydrophobic TOPO (trioctylphosphine oxide) coatings on the surface of CdSe/ZnS nanoparticles (*7*−*10*). In this case, the mercapto group thiolates the nanocrystal surface, while the carboxylic acid provides solubility. This method is simple, but the stability of the QDs in water is decreased (*11*) and the thiolation leads to eventual dissolution of the nanocrystals, resulting in the release of heavy atoms into solution (*12*). Phospholipid (*13*), polypeptide (*14*), bovine serum albumin (*15*), and silica (*12*) have also been used as capping agents but potentially lack simple and reliable methods for further bioconjugation to the targeting ligand for cell-surface imaging applications. Alternatively, amphiphilic di- and triblock copolymers for encapsulating QDs via a spontaneous self-assembly process (*16*, *17*) allow one to circumvent these potential drawbacks while maintaining the photoluminescent properties of the QD label. Besides generating water-soluble QDs, the conjugation of ligands to QDs is also critically important. Most reported methods for QD−ligand conjugation are achieved by precoupling the QDs with antibodies or streptavidin, followed by addition of hapten- or biotin-modified ligands. However, nonspecific interactions between the antibody or streptavidin with cell-surface targets are possible. Furthermore, both antibodies and streptavidin significantly increase the size of the QD complex (~50 nm), which could potentially affect accessibility to crowded cell-surface locations (*18*, *19*) and also interfere with receptor dynamics.

Though QDs are now commercially available, few robust literature methods have been reported for covalently conjugating peptide and peptidomimetic ligands to QDs. In a recent study, Schmidt and co-workers synthesized a small peptide ligand (RGD) with an added cysteine, which was directly used to coat bare quantum dot surfaces together with mercaptoacetic acid (*20*). However, the thiol coating may possibly lead to QD dissolution, as previously discussed. In more recent work, Rosenthal and co-workers coupled angiotensin II to carboxylic acid modified QDs by EDC (*21*). This method, though very useful, cannot be easily utilized when a ligand of interest contains two or more free amines and especially in instances

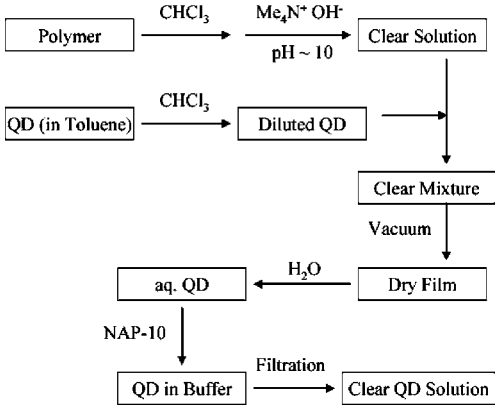
where the amines are important for bioactivity. Thus, it still remains challenging to optimize the chemistry as well as the process for generating water-soluble polymer-coated QDs that allow for facile covalent coupling to peptidic ligands that maintain their bioactivity.

Herein, we present a practical method for generating water-soluble QDs and the necessary chemistry for covalently coupling the QDs with G-protein couple receptor (GPCR) targeted ligands (Figure 1). GPCRs constitute a large and diverse family of proteins whose primary function is to transduce extracellular stimuli into intracellular signals. Since 50% of pharmaceuticals target GPCRs, new methods for imaging GPCRs at cell surfaces are of much interest. As proof of principle, we chose to target the QDs to the human melanocortin and δ-opioid receptors. We demonstrate the feasibility of QD514 conjugated to α-MSH analogs that effectively image melanocortin receptors overexpressed on HEK293 cells. We also demonstrate that QDs conjugated to Deltrophin-II analogs can be utilized for selectively imaging δ-opioid receptors on cell surfaces and for single-molecule imaging.

EXPERIMENTAL PROCEDURES

Instruments. QD absorbance was recorded by a Beckman DU520 instrument. Fluorescence spectra were recorded on a PTI fluorimeter (814 photomultiplier detection system and LPS-220B power supply). ^{1}H NMR spectra were recorded on a Bruker DRX-500 instrument.



General. All Fmoc-protected amino acids, BOP, HOBt, and Rink-amide resin used for peptide synthesis were purchased from Novabiochem. Boc-AEEEA (Boc-11-amino-3,6,9-trioxaundecanoic acid) was purchased from Peptides International. Bare QDs were synthesized using published methods (*22*) or purchased from Evident Technology. All other chemicals were purchased from Aldrich. Peptides were purified by reverse-phase HPLC (Varian) using a C18 column (Vydac.)

Synthesis of Octylamine-Modified Poyacrylic Acid (OPA). *A.* 10 mL of a poly(acrylic acid) sodium salt solution (MW ~1200, 45 wt % in water) was acidified by 5 mL of 12 N HCl, followed by addition of 200 mL of acetone under stirring to precipitate NaCl. After filtration, the acetone was removed from the filtrate by vacuum. The crude product was redissolved with 20 mL of water, frozen, and lyophilized. 4.5 g of white poly(acrylic acid) solid was collected.

B. 2.16 g of poly(acrylic acid) solid (0.03 mol of carboxylic acid) and 2.85 g of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDAC, 0.015 mol) were transferred into a 100 mL round-bottom flask. 20 mL of DMF was added to dissolve the mixture. About 1.6 mL of octylamine (0.0096 mol) was added dropwise into the reaction flask. The clear solution was stirred overnight under argon. TLC ($CH_2Cl_2/CH_3OH = 7:1$, $R_{f(\text{octylamine})} = 0.55$, $R_{f(\text{product})} = 0.24$) was used to monitor the reaction. When the reaction was complete, DMF was removed by vacuum, and the residue was mixed with 10 mL of acetone and transferred into a centrifuge tube. 25 mL of water was added, and the gummy precipitated product was separated by centrifugation (3000 rpm for 5 min) and washed with water (25 mL $\times$ 3). The solid product was dissolved in 40 mL of ethyl acetate (gentle heating 40−50 °C was applied), and a tetramethylammonium hydroxide (6.4 g in 25 mL water) solution was added to the polymer solution and stirred for 10 min, before being transferred into a separation funnel. The yellowish aqueous layer was isolated in a centrifugation tube and acidified by 1 N HCl to pH 2. The precipitate was separated by centrifugation and washed with H_2O (15 mL $\times$ 2). The sticky solid was redissolved in ethanol, at which point the ethanol was removed under vacuum and 1.63 g of the yellow solid OPA was collected (45 $\pm$ 5% of the carboxylic acids were converted to octyl amide). ^{1}H NMR (*d*-CH_3OH): δ 0.85−0.92 (m, 3H), 1.20−1.35 (m, 10H), 1.40−1.55 (m, 2H), 1.55−1.95 (m, 3.2H), 2.05−2.50 (m, 2.4H), 2.95−3.28 (m, 2H).

Synthesis of Amine-PEG-Modified Polymer (APOPA). *A. Synthesis of Mono-Boc-Protected 4,7,10-trioxatridecanediamine.* 80 g of 4,7,10-trioxatridicanediamine (0.364 mol) was dissolved in 250 mL dichloromethane in a 500 mL round-bottom flask. 3.2 g of *t*-Boc anhydride (0.0147 mol) was dissolved in 20 mL of dichloromethane and added dropwise to the diamine solution

Scheme 1. Processing QDs with Water-Soluble Amphiphilic Shells

over 4 h with stirring. After the addition, the solution was stirred overnight. The solution was reduced to 150 mL under vacuum and extracted with water (300 mL × 6) to remove excess diamine. The organic layer was dried over Na_2SO_4, and the dichloromethane was removed under vacuum. About 2.54 g of mono-Boc-protected 4,7,10-trioxatridicanediamine (oily precipitate) was collected (yield 54%). ^{1}H NMR ($CDCl_3$): δ 1.45 (s, 9H), 1.74 (m, 4H), 2.80 (t, 2H), 3.22 (m, 2H), 3.52−3.67 (m, 12H).

B. Synthesis of Amine-PEG-Modified Triblock Copolymer. 383 mg of the octylamine-modified poly(acrylic acid) (OPA, ~0.2 mmol) and 190 mg of EDAC (1 mmol) were dissolved in 6 mL DMF in a 25 mL round-bottom flask, and the solution was stirred for 10 min. 128 mg of mono-Boc-protected 4,7,-10-trioxatridecanediamine (0.4 mmol) dissolved in 1 mL DMF was added into the reaction flask. The solution was stirred overnight, and the Kaiser test (*23*) was used to monitor the reaction. When the Kaiser test indicated no free amine in solution, DMF was removed by vacuum and the residue was transferred into a centrifuge tube, which contained 20 mL of H_2O. The precipitated product was isolated by centrifugation (3500 rpm for 8 min) and washed with 5 mL of H_2O. The product was redissolved in 3 mL of ethanol, which was subsequently removed by vacuum. 8 mL of 50% TFA in dichloromethane was added to the container to dissolve the residue and remove the Boc group. After a short reaction time, the solvent was removed by vacuum. The crude oily product was redissolved with 2 mL of ethyl acetate, and the solution was added dropwise into a centrifuge tube, which contained 30 mL of cold ether. The solid product was separated by centrifugation (3500 rpm for 5 min) and washed with 20 mL of ether. After drying, 120 mg of yellowish solid APOPA was obtained (12−14% of carboxylic acids were converted to amide-PEG-amine). ^{1}H NMR ($CDCl_3$): δ 0.80−0.95 (m, 3H), 1.02−1.39 (m, 10H), 1.39−1.60 (m, 2H), 1.60−2.15 (m, 3.1H), 2.15−2.55 (m, 1.4H), 2.78−3.00 (m, 1.1H), 3.0−3.4 (m, 2.9H), 3.5−3.88 (m, 3.3H).

Process for Coating QD with Amphiphilic Polymer Shell (Scheme 1). 50 mg of the OPA was dissolved in 4 mL of dichloromethane. Tetramethylammonium hydroxide (25 wt % in methanol) was used to adjust pH to 10. 500 μL of 0.12 mM bare QD514 in toluene (λ_{em} = 514 nm, Evident) were added to the solution and stirred for several minutes, at which time the solvent was removed under vacuum. The solid was redissolved in 500 μL of water and loaded onto a NAP-10 column (Amersham Biosciences). Phosphate buffer A (10 mM, pH 7.35) was used to elute the QDs. Fluorescent fractions were combined (~2 mL) and further filtered through a 0.45 μm Acrodisc syringe filter. The filtrate was dialyzed overnight in a Slide-A-Lyzer dialysis cassette (MWCO 7000, Pierce) against 400 mL of buffer A. The final aqueous QD stock solution was stored at 4 °C. QD concentration was determined by the absorption at 496 nm (ϵ = 50 000 M^{-1} cm^{-1}) based on the first excitation state of QD514.

The same process was repeated for coating QD595 (λ_{em} = 595 nm) with OPA. Twice the amount of OPA (100 mg) was used because of the larger size of QD595 (5 nm) compared to QD514 (3.2 nm). After dialysis, 2 mL of OPA-coated QD595 was collected. (Concentrations were determined by absorbance at 586 nm, based on the first excitation state of QD595 (ϵ = 400 000 M^{-1} cm^{-1}). Primary amine modified QD514 and QD595 were prepared using a similar protocol (Scheme 1), but starting with the amine-PEG-modified polymer, APOPA.

Peptide Synthesis and Purification. All ligands (NDP, MT-II, Deltorphin-II (Ile−Ile), and CCK; see Figure 2) were synthesized by solid-phase peptide synthesis using a standard fluorenylmethoxycarbonyl (Fmoc) strategy starting with Rink amide resin (*24*). The cyclization reaction of MT-II was performed according to the method reported by Hruby et al. (*25*) in 2002. Boc-AEEEA (PEG linker) was coupled at the N-terminal of norleucine before deprotection of glutamic acid and lysine, followed by cyclization.

The final peptides were cleaved from the resin and all protecting groups were removed by cleavage cocktail (100 mg of peptide resin was treated with 1 mL of cocktail) composed of TFA and scavengers (81.5% TFA, 5% H_2O, 5% thioanisole, 5% phenol, 2.5% ethanedithiol, and 1% triisopropylsilane) for 4 h at room temperature. The solution was filtered and precipitated by transferring into a centrifuge tube containing precooled ether. After centrifugation and 3× washes with fresh ether, the white solid was collected and lyophilized to yield crude product. The crude peptides were purified by reverse-phase HPLC (Varian) using a C18 column (Vydac). Peptides were purified with a linear gradient of 20% to 80% acetonitrile containing 0.1% TFA at a flow rate of 8 mL/min, for 50 min. The purified peptides were reinjected on reverse-phase HPLC and found to be >95% pure. The k' value of each product was determined by a C18 column with a linear gradient of 20% to 80% actonitrile containing 0.1% TFA at a flow rate of 1 mL/min for 20 min.

AEEEA-Nle-Glu-His-(D)Phe-Arg-Trp-NH$_2$ (NDP α-MSH Analogue). Mass spectroscopy (ESI): observed 886.5 (calculated 886.5). k' = 0.64.

MT-II (α-MSH Analogue). Mass spectroscopy (ESI): observed 1171.5 (calculated 1171.6). k' = 0.84.

Tyr-(D)Ala-Phe-Glu-Ile-Ile-Gly−Gly-(PEG)$_2$-Cys-Gly-NH$_2$ (Deltorphin II Analogue). Mass spectroscopy (ESI): observed 1345.5 (calculated 1346.8). k' = 0.95.

AEEEA-Asp-Tyr-N-MeNle-Gly-Trp-N-MeNle-Asp-Phe-NH$_2$ (CCK−B Ligand). Mass spectroscopy (ESI): observed 1244.3 (calculated 1244.8). k' = 1.50.

Preparation of NDP−QD514. 1.1 mL of 5 μM OPA-coated QD514 (5.5 nmol) was mixed with 10 μL of EDAC solution (0.05 mg/μl) and stirred for 10 min. 170 μL of 6.4 mM NDP-α-MSH stock solution (concentration was determined by absorption at 280 nm in 8 M guanidine) was added to the coated QD514 solution with stirring. The pH was adjusted to 7−8 with 25% tetramethylammonium hydroxide in methanol, and the Kaiser test was used to monitor reaction progress. After 6 h, the Kaiser test showed no free amine in solution, and the solution was loaded on a NAP-10 column and eluted with buffer A. The fluorescent fractions (~1.5 mL) were collected and dialyzed in a MWCO 3500 dialysis cassette against 500 mL of buffer A. After 10 h, fresh buffer was used for another 10 h dialysis. The final NDP−QD514 conjugate solution was 3 μM as determined by the absorption at 496 nm, described above.

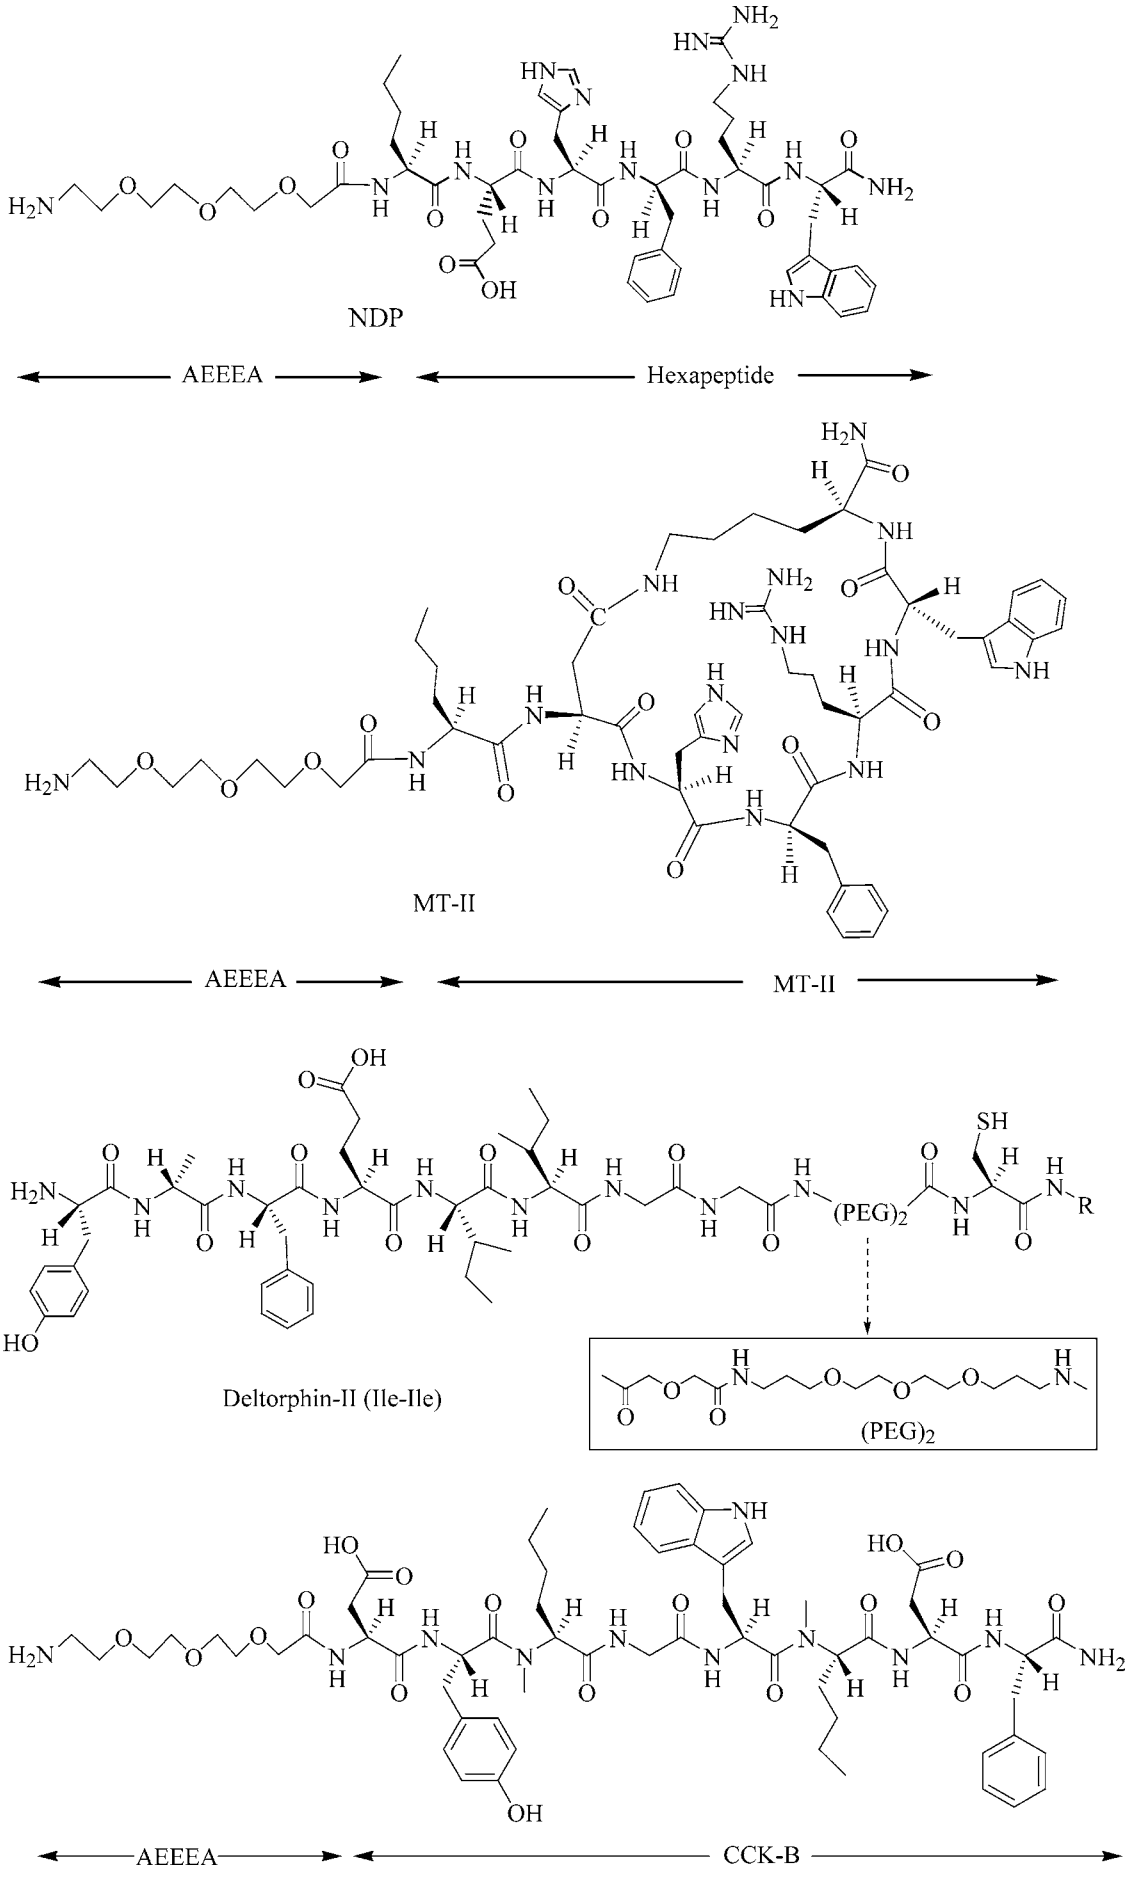


Figure 2. Structures of the GPCR-targeting ligands investigated.

Preparation of MT-II−QD595 and MT-II−QD514. 500 μL of 1.1 μM OPA-coated QD595 (0.55 nmol) was mixed with 20 μL of 2.8 mM MT-II (56 nmol) solution (concentration was determined by absorption at 280 nm in 8 M guanidine) in 80 μL of 0.1 M pH 9.2 sodium bicarbonate buffer. Under stirring, 20 μL of EDAC solution (40 mM) was added, and another 20 μL was added after 2 h. The Kaiser test was used to monitor the reaction. When the reaction was over (4−6 h), the solution was filtered with a 0.45 μm Acrodisc followed by dialysis in a MWCO 10 000 dialysis cassette against 400 mL × 2 of buffer A. Finally, ∼1.7 mL of 0.2 μM of the MT-II−QD595 conjugate solution was collected in which the ratio of MT-II to QD595 is about 100:1. The same procedure was used to conjugate MT-II to OPA-coated QD514.

Preparation of Deltorphin-II−QD595 and Deltorphin-II−QD514. 2.5 mg of *N*-(β-maleimidopropyloxyl)succinimide ester was dissolved in 1 mL DMSO to obtain a 10 mM cross-linker stock solution. 0.6 mg Deltorphin-II (Ile−Ile) was dissolved in 200 μL H_2O to obtain a 2 mM δ-opioid ligand stock solution (concentration was determined by the DTNB test based on the free thiol concentration (*26*)). 120 μL of APOPA-coated QD595 (2.8 μM, 0.33 nmol) was mixed with 10 μL of the cross-linker stock solution and incubated at room temperature for 1 h. The resultant clear solution was loaded on a NAP-10 column and eluted with buffer A. Fluorescent fractions (∼250 μL) were collected and mixed with 8 μL of the Deltorphin-II (Ile−Ile) stock solution (16 nmol) and 42 μL of buffer A. The mixture was equilibrated at room temperature for 1 h, at which time 3 μL of 100 mM β-mercaptoethanol was added to quench the unreacted maleimide. After 30 min, the reaction solution was filtered through a 0.45 μM Acrodisc and dialyzed in a MWCO 10 000 dialysis cassette against 400 mL × 2 of buffer A. The final 0.75 μM Deltorphin-II−QD595 solution was collected in which the maximal ratio of ligand/QD is about 50:1. A similar procedure was used to conjugate Deltorphin-II to APOPA-coated QD514. All QD or QD−ligand conjugate concentrations were determined as described above.

Immunocytochemistry. Cells grown on 25 mm round #1 coverslips were fixed with 3% paraformaldehyde, rinsed with 25 mM glycine, and permeabilized with 0.1% Triton X-100. The cells were incubated with the primary antibodies (rabbit polyclonal) against the δ-opioid receptor (Neuromics, Northfield, MN) or MC4R (RDI, Flanders, NJ) for 1 h at 25 °C. Cells were washed three times (5 min each) in phosphate buffered saline to remove unbound primary antibody. Since the MC4R antibody recognized an epitope on the cell exterior, live cells also were incubated with this antibody (10 μg/mL) for 5 min, washed in antibody-free buffer (2×, 5 min each), then fixed for subsequent processing. At this point, all fixed and permeabilized cells were incubated with secondary anti-rabbit IgG labeled with either Cy5 (Jackson ImmunoResearch) or FITC (Sigma) for 45 min at 25 °C. After washing, coverslips were mounted onto glass slides using a 50% glycerol/saline solution containing the antibleach agent paraphenylendiamine (0.1%). NDP−QD514 and Deltorphin-II(Ile−Ile)−QD595 were used for imaging MC4R or δ-opioid receptors as described in the results and discussion section.

For standard wide-field imaging, slides were mounted on the stage of an Olympus IX-70 microscope equipped with a 60 × 1.4 NA objective. Illumination was provided by a 100 W Hg lamp, and images were acquired using a liquid-cooled CCD camera (Roper Scientific) equipped with a Kodak CCD array (KAF1401E).

Single-Molecule Imaging: Incorporation of hDOR in Lipid Bilayer. The lipid bilayer was formed on a fused silica coverslip surface covered by a thin polyacrylamide film. It is possible to make a polymer brush of controlled thickness by the surface-initiated atom transfer radical polymerization (ATRP) (*27*, *28*). A 5-nm-thick polyacrylamide brush was prepared on the coverslip according to the same procedure previously reported (*29*). The lipid bilayer of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC) with cholesterol (0−10%) was formed on the polyacrylamide-modified coverslip surface using a standard vesicle fusion procedure (*29*, *30*). The isolation and purification procedure of hDOR was as described previously (*29*, *31*). The receptor has a His tag and myc epitope on its C terminus, and is solubilized in buffered 1% dodecyl-β-D-maltoside solution. The hDOR solution was added into the buffer on the lipid membrane described above. This dilution of hDOR suspension allowed hDOR to be incorporated into the lipid bilayer. The lipid membrane was rinsed multiple times, then 50 mM phosphate buffer (0.5 M NaCl, pH 7.5) was added.

Single-Molecule Fluorescence Imaging. Single-molecule fluorescence imaging of the ligand binding was achieved by using a highly sensitive CCD camera coupled to an argon ion laser as an excitation source. The microscope (TE2000-U, Nikon) was designed for total internal reflection fluorescence imaging. For the excitation of the QDs, the blue line of the argon ion laser (488 nm, 0.05 mW) was used. The green line (514.5 nm, 0.26 mW) was used for Cy3 excitation. The laser beam was used to irradiate the sample in a total internal reflection mode via an oil-immersion 100× TIRF objective (NA 1.4, Nikon). A high-sensitivity CCD camera, PhotonMAX (512 × 512 pixels, Princeton Instruments), was used to detect emitted fluorescence from the QDs or Cy3 dye after reduction of stray light by the emission filter (595AF60, Omega Optical). The fluorescence image was captured as a 500 frame movie, in which the exposure (integration) time was 3 s for each frame.

RESULTS AND DISCUSSION

Design and Syntheses of Polymer-Coated QDs. For facile encapsulation of QDs, we chose to synthesize amphiphilic diblock (OPA) and triblock (APOPA) copolymers that would potentially impart solubility to the QDs in aqueous systems for biological imaging. In order to synthesize the block copolymers, we chose three different commercially available poly(acrylic acid) polymers with average molecular weights of 1200, 8000, and 100 000. For each polymer, 40% of the free acids were transformed to the hydrophobic octylamide groups such that the octyl chains would encapsulate and stabilize the QD while the unmodified carboxylic acids would provide solubility in an aqueous environment. The red QD 595 and green QD 514 were both coated with the amphiphilic diblock polymers in dichloromethane and were subsequently purified by size exclusion chromatography (NAP-10 column) followed by dialysis (Scheme 1). Nie and co-workers have recently utilized a similar strategy utilizing octylamine-modified triblock copolymer (MW 100 000, 25% of the free carboxylic acid was derivatized) as the QD coating polymer. All three copolymers afforded soluble QDs. Notably, the low molecular weight diblock polymer (MW 1200) provided the most reproducible coating for both the green and red QDs, where the copolymer contains ∼16 acid units of which 40% are modified with octylamine as evidenced by NMR. Both green and red QDs coated with this low molecular weight polymer were water-soluble and maintained high luminescence in aqueous solution. The absorption and emission spectra are very similar compared with those of TOPO-coated commercial QDs in toluene (Figure 3). We investigated whether these coatings provide extended stability and observed no changes in solubility or fluorescence over a 6 month period (stored at 4 °C). We also tested whether these coatings are stable to various pHs that may be found in different cellular environments and are also required in bioconjugation chemistries. We found that the QDs are stable between pH 3.5 and pH 10.5. Thus, our

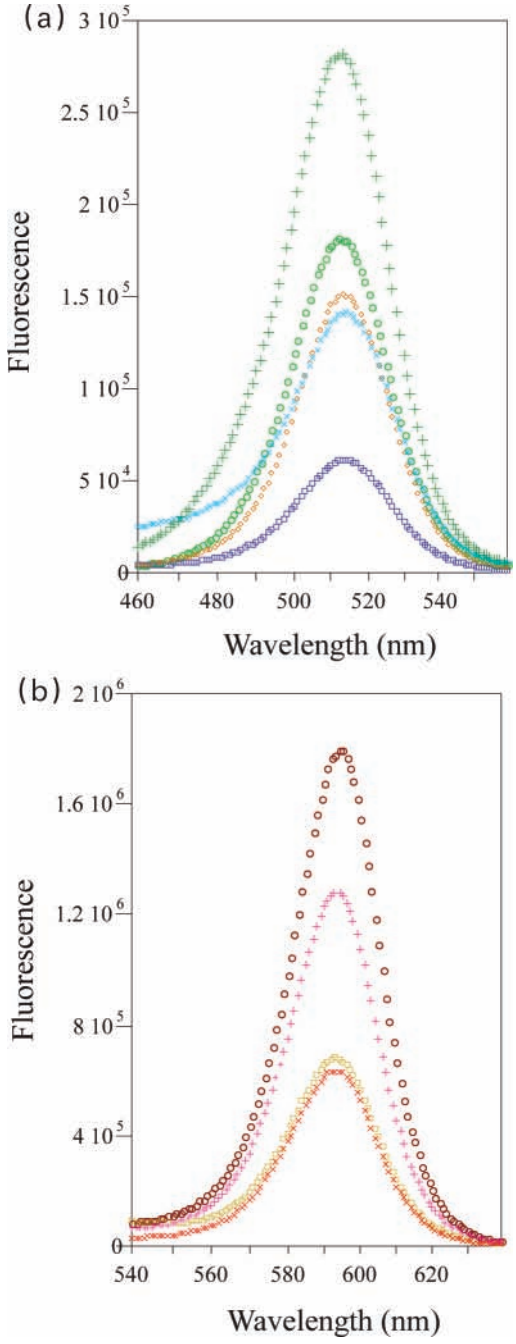

Figure 3. Photoluminescence of uncoated QDs and their GPCR−ligand conjugates. results provide a robust method for synthesizing stable water-soluble QDs suitable for covalent labeling with any macromolecule containing free amines via EDAC-mediated amide bond formation.

In many peptide ligands, the amino terminal and/or free amines play an important role in ligand/receptor interactions. For such ligands, the EDAC-mediated coupling to carboxylic acid functionalized QDs is not feasible. Thus, we also synthesized amino functionality containing amphiphilic copolymers as an alternate QD coating that can be further modified with standard NHS containing bifunctional cross-linkers. We chose to functionalize the 40% octylamine modified poly(acrylic acid) (OPA) with 4,7,10-trioxatridecanediamine. We protected one of the amines with *t*-Boc, while the free amine was coupled to the polymer using EDAC followed by deprotection of *t*-BOC with TFA to give the amino-modified OPA. ^{1}H NMR showed that each polymer chain contained an average of six octyl chains and two free amines. The new amino-amphiphilic polymer (APOPA) was utilized to successfully encapsulate the QDs utilizing the same protocol described for the diblock copolymer (OPA) (Scheme 1). The properties of these amine-functionalized APOPA-coated QDs were found to be very similar to the OPA-coated QDs, with excellent water solubility, stability, and luminescent properties. With both types of water-soluble QDs in hand, we turned to applying them for ligand conjugation for biological imaging.

Bioconjugation of Ligands to QDs for GPCR Imaging. In order to showcase our bioconjugation chemistries and provide useful biological reagents, we chose to target two different G-protein-coupled receptors (GPCRs), the human melanocortin receptor (hMCR) and the human δ-opioid receptor (hDOR). Cell-surface receptors, particularly GPCRs, play a central role in cellular signaling and are important targets for modern pharmaceuticals (*32*). Hence, there is a continuing demand for reliable methods to directly probe cellular localization, receptor density, and trafficking. As such, we chose ligands with high affinity for the chosen GPCRs to allow for imaging with the QD label. For hMCR targeting, we utilized two analogues of α-melanocyte-simulating hormone (α-MSH), NDP and MT-II, developed by Hruby and co-workers (*33*, *34*). NDP and MT-II (Figure 2) ligands were synthesized by standard solid-phase peptide synthesis and purified. The purified peptides were directly conjugated to the OPA copolymer coated QD514 and QD595 by utilizing the water-soluble EDAC-coupling reagent. The carboxylic acids on the QD surface were activated with EDAC followed by addition of the amine-containing ligands to generate the QD−α-MSH conjugate (Figure 1, route a). We also synthesized another potent ligand, Asp-Tyr-*N*-MeNle-Gly-Trp-*N*-MeNle-Asp-Phe-NH_2 (CCK−B), which has been shown to be a selective CCK−B-type analogue with an IC_{50} of 0.13 nM (*35*) and conjugated this ligand to our soluble QDs using the above-described methodology to yield CCK−B−QD514 and CCK−B−QD595.

In an effort to provide a general strategy for QD conjugation, we also considered the possibility that many peptide ligands could contain two or more free amines and thus not allow for selective conjugation to QDs. Alternatively, the N-terminal amine in the ligand could be important for biological activity, which would preclude the EDAC-mediated coupling reaction described above. Considering this situation, we prepared QDs coated with amine functionalities (APOPA) that could be modified by a suitable bifunctional linker, where one end provides an activated ester that can react with a free amine on the QD surface while the other end provides a maleimide that can specifically react with a unique thiol that is engineered into a ligand. To demonstrate the feasibility of this approach, we synthesized a highly potent Deltorphin-II analog, Tyr-(D)Ala-Phe-Glu-Ile-Ile-Gly (Deltorphin-II(Ile−Ile)), developed by Sasaki (*36*) to selectively target the δ-opioid receptor (K_d = 67 pM). We incorporated a short linker and a cysteine at the C-terminus of this ligand for facile conjugation at pH 6−8 to the maleimide-functionalized amine-bearing QDs (Figure 1, route b). The peptide was conjugated to the QDs to yield Deltorphin-II(Ile−Ile)−QD514 and Deltorphin-II−QD595.

Having all of the four different sets of GPCR ligand−QD conjugates in hand, we compared them to the commercial QDs in toluene. All the water-soluble ligand-modified QDs were shown to maintain high photoluminescence in aqueous conditions (Figure 3). NDP−QD514 and Deltorphin-II(Ile−Ile)−QD514 almost have the same fluorescence intensity as the bare

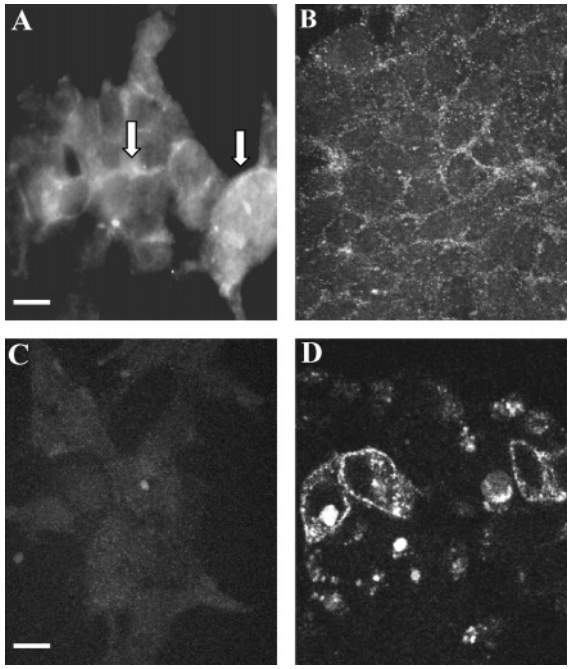

Figure 4. NDP−QD514 targeted hMC4R. (a) HEK293 cells incubated with an MC4R specific antibody after cell fixation and permeabilization showing the distribution of all expressed receptors. Arrows indicate labeling at cell membranes. (b) HEK293 cells incubated with MC4R-specific antibody prior to cell fixation showing the distribution of cell-surface expressed receptors. (c) Live HEK293 cells lacking hMC4R expression, incubated with 10^{-7} M NDP−QD514 15 min prior to imaging. (d) Live cells overexpressing the hMC4R, incubated with 10^{-7} M NDP−QD514. Scale bars = 20 μM.

QD514. The fluorescence values of MT-II−QD514, MT-II−QD595, and Deltorphin-II(Ile−Ile)−QD595 decreased to about one-third those of the bare QDs, but still high enough for bioimaging because of the strong QD photoluminescence.

GPCR Imaging Utilizing QDs. *Targeting hMC4R.* The utility of the EDAC coupling chemistry in generating ligand-modified water-soluble QDs was evaluated. NDP-QD514 was used to target overexpressed melanocortin 4 receptor (MC4R) in HEK293 cells (Figure 4). An MC4R-specific antibody was used to validate receptor expression and determine the cellular distribution of MC4R for comparison with NDP−QD514 mediated imaging. The distribution of total MC4R expression is shown in Figure 4A where cells were permeabilzied then probed with the receptor-specific antibody. This image shows the distribution of all expressed receptor. However, this antibody recognizes an extracellular epitope of the MC4R; therefore, MC4R-transfected HEK293 cells were also incubated with the receptor-specific antibody prior to fixation. Figure 4B shows the distribution of surface-expressed receptor. Control cells without receptor do not show significant fluorescence under either condition (data not shown). Having established that hMC4R was stably expressed, we turned to testing the selectivity of NDP−QD514. HEK293 cells that either did not express (Figure 4c) or expressed hMC4R (Figure 4d) were incubated with NDP−QD514 (10^{-7} M). We clearly observe cell-surface labeling by the NDP−QD514 of the HEK293 cells expressing hMC4R (Figure 4d) with almost no background labeling. These results clearly show that our small ligand labeled water-soluble QDs are easily comparable to commercial fluorescently labeled antibody-based detection methods. Importantly, most receptor antibodies are not raised against extracellular epitopes and therefore do not label only the surface receptors, but rather show the distribution of all receptors (functional or nonfunctional) including those in subcellular compartments such as seen in Figure 4A. Therefore, ligand-conjugated QDs provide an important tool for specifically evaluating the functional receptor complement on the cell surface.

Targeting hDOR. To determine the utility of the APOPA−QDs functionalized with maleimides for conjugation with thiol-bearing ligands, we tested the Deltorphin-II(Ile−Ile)−QD595 targeting to human δ-opioid receptors (hDOR) expressed in CHO cells (Figures 5 and 6). CHO cells with stably expressed receptors were incubated with 0.75 nM Deltorphin-II(Ile−Ile)−QD595 for 1 min, washed, and subsequently imaged (Figure 5). The surface distribution of hDOR can be clearly observed. Since Deltorphin-II(Ile−Ile) is a known agonist, it can activate hDOR and therefore should be internalized. Cells expressing hDOR were incubated for 1 min or 20 min with the Deltorphin-II(Ile−Ile)−QD595. Interestingly, after 1 min we only observed cell-surface labeling, while at 20 min, we can directly observe receptor internalization. As shown in Figure 5, this agonist-mediated activity is retained when the ligand is conjugated on the QD. Control experiments show no cellular labeling or receptor internalization. Thus, these results not only show that the amine-modified QDs are suitable for ligand conjugation and cellular labeling of GPCRs but that they can also be internalized in a receptor-dependent fashion.

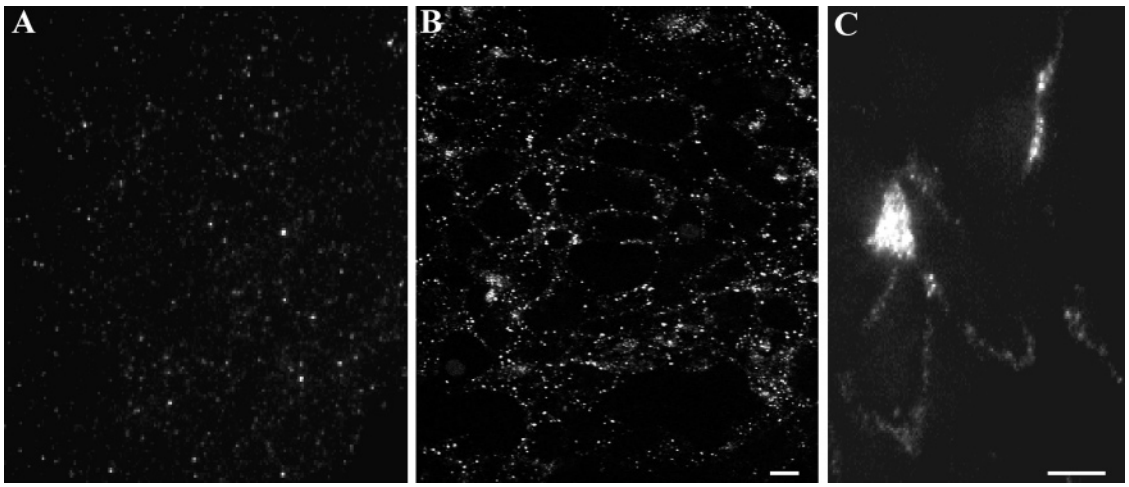

Figure 5. Images of Deltorphin-II(Ile−Ile)−QD595 mediated targeting of human δ-opioid (hDOR) expressed CHO cells. Live cells were incubated for 1 min with 0.75 nM QD−ligand. (a) Cells imaged after 1 min postincubation showing only surface labeling. (b) Cells imaged after incubating for 20 min showing significant organization of Deltorphin-II(Ile−Ile)−QD595 distribution at or near cell surfaces. Scale bars are 10 μm. (c) Image is a magnification showing distribution in four cells, 15 min following the 1 min labeling period.

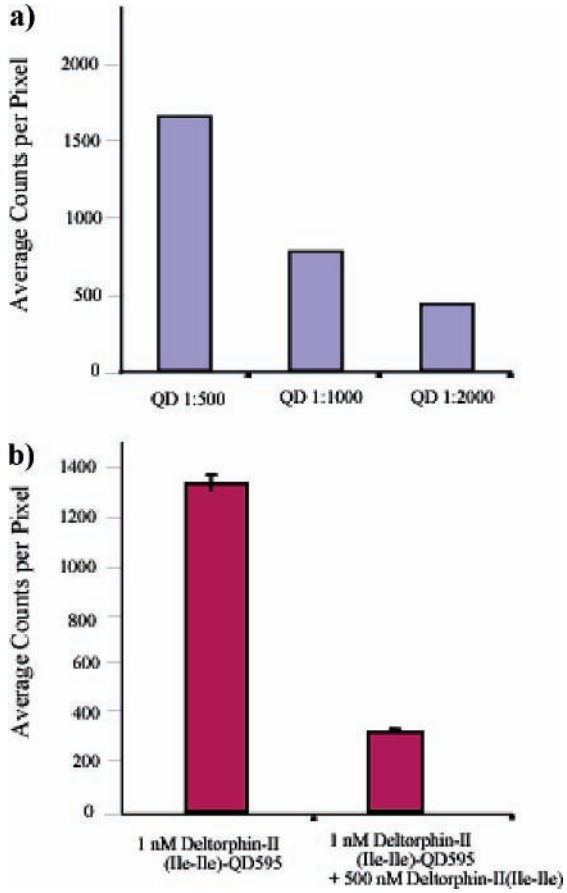

Figure 6. Specificity of Deltorphin-II(Ile−Ile)−QD595 for hDOR on CHO cells. (a) In all experiments, 500 nM of free Deltorphin-II(Ile−Ile) was mixed with varying amounts of Deltorphin-II(Ile−Ile)−QD595 and added to hDOR-expressing CHO cells. (b) Deltorphin-II(Ile−Ile)−QD595 conjugate (1.5 nM) targeting hDOR on CHO cells in the absence and presence of 500 nM of free ligand with prior incubation for 5 min. Measurements are averaged on ten cells per image and five independent images.

In the above experiments, the average number of Deltorphin-II(Ile−Ile)/QD is ∼200; thus, we expected that multivalent interaction (avidity effects) could possibly result in tighter apparent binding constants for Deltorphin-II(Ile−Ile)−QD595 when compared to free Deltorphin-II(Ile−Ile). In a first set of experiments, CHO cells overexpressing hDOR were incubated with 500 nM free Deltorphin-II(Ile−Ile) in the presence of varying concentrations of the Deltorphin-II(Ile−Ile)−QD595. Interestingly, QD−conjugate concentrations in the range 0.375−1.5 nM showed clear cellular labeling, even in the presence of 500 nM of free Deltorphin-II(Ile−Ile) ligands (Figure 6a). These data suggest that the multivalent or avidity effects increase the binding of the labeled QDs which cannot be competed off by the free ligand. In a second experiment, we envisioned that adding free ligand prior to adding QD-conjugated ligand would possibly prevent QD binding. To test this, we added 500 nM of free Deltorphin-II(Ile−Ile) ligand to the cells and incubated for 5 min prior to adding the QD−Deltorphin-(Ile−Ile). The QD−Deltorphin-II(Ile−Ile) was added for 1 min followed by washing the cells and imaging. As expected, incubation of cells with 500 nM of free Deltorphin-II(Ile−Ile) prior to adding the QD−Deltorphin-II(Ile−Ile) prevented significant QD binding as seen by the decrease in the average signal per pixel, from ∼1350 to ∼300 (Figure 6b). The competition experiments taken together establish that the QD conjugates target the hDOR specifically but with a much higher binding constant possibly due to a strong multivalent effect, which may aid in visualizing low copy number receptors. Future experiments will aim to develop approaches for controlling and measuring ligand density on QD surfaces as well as to systematically explore the utility of avidity effects.

Single-Molecule Detection of GPCRs. Single-molecule imaging has emerged as a particularly useful method for investigating receptor localization and trafficking in live cells and in model bilayers (*37*). QDs provide certain advantages over traditional fluorophores due to their broad absorption spectra, tunable emission, and resistance to photobleaching. In order to test the suitability of our ligand-conjugated QDs for single-molecule imaging studies, we chose the human δ-opioid receptor (hDOR) as a target. In these experiments, we directly compare the Deltorphin-II(Ile−Ile)−QD595 conjugate to a Deltorphin-II(Ile−Ile) ligand labeled with Cy3, a widely used fluorophore.

Purified hDOR was incorporated into an artificial lipid bilayer formed on a fused silica coverslip modified by a thin 5-nm-thick polyacrylamide brush. Single-molecule fluorescence was recorded with a total internal reflection fluorescence system, by excitation with an argon ion laser at 488 nm for QDs and 514.5 nm for Cy3. Fluorescence images for hDOR binding for both Deltorphin-II(Ile−Ile)−QD595 and Deltorphin-II(Ile−Ile)−Cy3 were captured as a 500 frame movie, in which the exposure (integration) time was 3 s for each frame. We observed that both Deltorphin-II(Ile−Ile)−QD595 and Deltorphin-II(Ile−Ile)−Cy3 had similar average residence times (bimodal: ∼30 s and hundreds of seconds) on single hDORs (Figure 7). This would at first appear to be in contradiction to the avidity effect observed at cell surfaces; however, in the single-molecule model

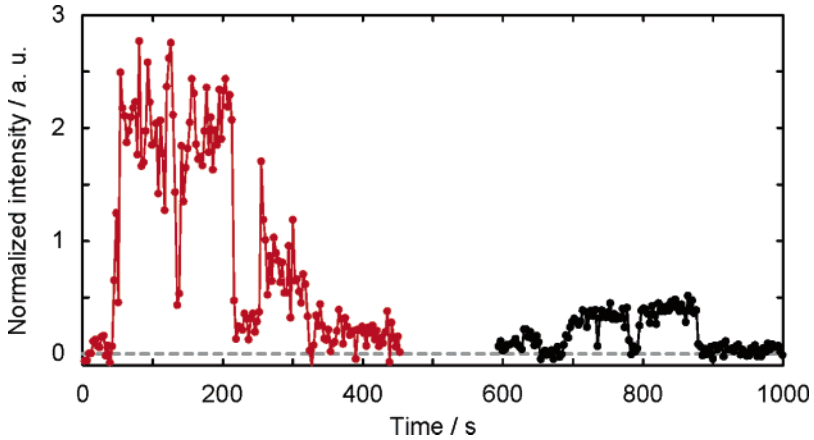

Figure 7. Comparison of fluorescence intensity of Deltorphin-II(Ile−Ile)−QD595 (red) and Deltorphin-II(Ile−Ile)−Cy3 (black) in the presence of hDOR in a lipid bilayer. (Fluorescence intensities after background subtraction.) Fluorescence is normalized at a laser power of 0.05 mW. The one-step increase and decrease indicate one single-molecule event.

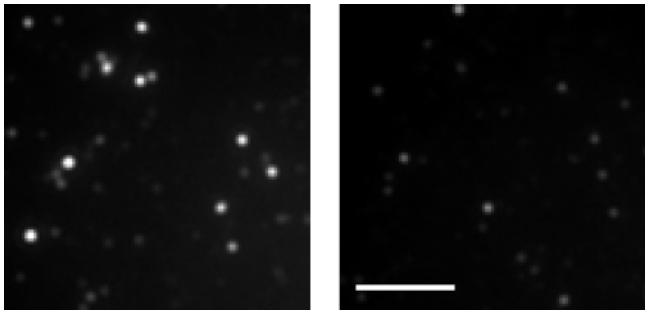

Figure 8. Specific targeting in single-molecule experiments. Cumulative fluorescence images of Deltorphin-II(Ile−Ile)−QD595 (2 nM) bound to hDOR in a lipid bilayer: (a) with and (b) without free Deltorphin-II(D-Ala2) (19 μM). (Same contrast. Image size 16 μm × 16 μm. Scale and illumination are identical in both images, and scale bar is 5 μm.) The 300-frame movies for both (a) and (b) are available online in the Supporting Information.

system, the receptors are at a very low concentration and thus several microns apart, which likely precludes multivalent binding. Most importantly, the fluorescence from QD conjugates was measured to be about sixfold stronger than that from Cy3. This increased fluorescence, combined with other advantages of the QDs such as resistance to photobleaching and multiplexing, provides a potential alternative imaging agent in single-molecule experiments for both model systems and in live cells.

We also considered the possibility that the QD conjugates could possibly bind nonspecifically to the model bilayer. Thus, in order to test the binding specificity, 2 nM of the Deltorphin-II(Ile−Ile)−QD595 conjugate was incubated with hDOR in the absence and presence of excess (19 μM) free Deltorphin-II(D-Ala2) ligand. The cumulative fluorescence images showed that free ligand significantly reduces Deltorphin-II(Ile−Ile)−QD595 from binding the hDOR (Figure 8). Thus, these experiments clearly demonstrate that observed binding is due to specific interaction of Deltorphin-II(Ile−Ile)−QD595 with the immobilized hDOR. Together with the whole-cell experiments, the single-molecule experiments also suggest that careful control experiments, with and without the targeted receptor, must be routinely performed to distinguish between specific versus nonspecific binding for ligand-targeted QDs.

In conclusion, we have developed a convenient method for synthesizing two types of water-soluble QDs with carboxylic acid and amine functionalities. We tested our approach with two different sizes of bare CdSe/ZnS QDs (QD595 and QD514). Both types of polymer-coated QDs displayed excellent solubility, stability, and fluorescence properties in a wide pH regime. We envisioned that the carboxylic acid functionalized QDs can be utilized for directly coupling amine-containing ligands, while the amine-functionalized QDs can be used for conjugating cysteine-containing ligands. Three small peptide ligands were successfully conjugated to our water-soluble QDs in order to target G-protein-coupled receptors (hMCR and hDOR). The ligand-conjugated QDs were shown to be specific for the targeted receptor and could be utilized for fluorescence imaging of receptors in cells as well as in single-molecule experiments in model bilayers. Thus, our methodology provides an expeditious route for constructing new fluorescent bioconjugates that are amenable for multiplexing and may have utility in studying the localization and trafficking of GPCRs in live cells and in single-molecule experiments.

ACKNOWLEDGMENT

We thank the Bio5, University of Arizona, and the NSF (CHE-0548264 and CHE-0433779) for supporting aspects of this research. We thank members of the Ghosh lab for helpful comments. All ligand labeled and unlabeled water-soluble QDs are freely available from the Ghosh lab for research purposes.

Supporting Information Available: Two movies showing single-molecule GPCR binding events in the presence and absence of inhibitors. This material is available free of charge via the Internet at http://pubs.acs.org.

Highly-Efficient Purification of Native Polyhistidine-Tagged Proteins by Multivalent NTA-Modified Magnetic Nanoparticles

Jason S. Kim,[†] C. Alexander Valencia,[‡] Rihe Liu,*[,‡] and Wenbin Lin*[,†]

Department of Chemistry and School of Pharmacy and Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, North Carolina 27599. Received July 3, 2006; Revised Manuscript Received January 2, 2007

A new bis-nitrilotriacetic acid (NTA) chelate with catechol anchor was synthesized and immobilized on superparamagnetic iron oxide nanoparticles. When loaded with Ni(II), these bis-NTA-immobilized nanoparticles were shown to bind polyhistidine (His × 6-tagged) fusion proteins in their native, folded conformations that commercial microbeads failed to bind under identical conditions. Control experiments with a mono-NTA chelate immobilized on iron oxide nanoparticles indicate a similarly high affinity for His × 6-tagged native proteins, suggesting that the high density of the mono-NTA chelate presented by the nanoparticles allows the binding of the His × 6-tag to more than one Ni-NTA moiety on the surface. This study shows that the multivalency strategy can be utilized to enhance the binding of His × 6-tagged proteins in their native, folded conformations. We further demonstrated the selective purification of His × 6-tagged proteins from crude cell lysates by using the Ni(II)-loaded iron oxide nanoparticles. The present platform is capable of efficient purification of His × 6-tagged proteins that are expressed at low levels in mammalian cells. This work thus presents a novel nanoparticle-based high-capacity protein purification system with shorter incubation times, proportionally large washes, and significantly smaller elution volumes compared to commercially available microbeads.

INTRODUCTION

As we enter the proteomic era, there is an ever-increasing need for efficient protein purification techniques that allow for direct isolation of proteins from cell lysates (*1*). Among many currently used protein purification strategies (*2*), immobilized metal affinity chromatography (IMAC) has emerged as one of the most powerful techniques for the purification of recombinant proteins (*3*). In the most common IMAC implementation, a His × 6 tag that comprises six consecutively placed histidine residues is incorporated into the C- or N-terminus of a recombinant protein. The His × 6 tag binds strongly to a divalent metal chelate such as the Ni(II) nitrilotriacetate complex (Ni-NTA) which is in turn immobilized on a resin. It is believed that four of the six coordination sites on the octahedral Ni(II) center are occupied by the NTA ligand and the remaining coordination sites are occupied by two of the six imidazole moieties in the His × 6 tag (*4*).

The IMAC strategy allows the purification of His × 6-tagged proteins in one or two steps to achieve a moderate degree of purity. Moreover, the His × 6 tag is relatively small and generally does not interfere with the native structure and function of the tagged protein. Since its discovery in the late 1980s, Ni-NTA-based IMAC has been widely used for purifying recombinant proteins, and many His × 6-tagged proteins are now commercially available. While this strategy has proven to be largely successful, a significant percentage of recombinant proteins remain difficult to purify by IMAC (*5*). Low protein expression is a key contributor to such difficulties, as the target protein concentration may be less than 0.1% of the cleared crude lysate when overexpressed in *E. coli*, and much lower when overexpressed in mammalian cells. Numerous functionally active proteins can only be expressed in mammalian cells, which poses new challenges to protein purification techniques. The target protein structure may also add to purification difficulties by blocking the His × 6-tag from the Ni-NTA moiety on the surface of microbeads. Consequently, commercial Ni-NTA resins cannot capture a large number of His × 6-tagged proteins under native conditions. To overcome this problem, purification under denaturing conditions has been used to gain full access to the His × 6-tag, but overall protein purification efficacy significantly decreases because of the unreliability and inefficiency of in vitro protein refolding to their native functional conformations.

Significant efforts have been devoted to gaining a better understanding of the Ni-NTA/His × 6-tag interactions and thus improving the IMAC protein purification efficiency over the past few years. The strength of the Ni-NTA/His × 6-tag interaction was, for example, recently assessed using scanning force microscopic techniques (*6*). Ebright et al. elegantly demonstrated enhanced binding of the His × 6-tag to a bivalent Ni-NTA system over a monovalent Ni-NTA control using fluorescence anisotropy and fluorescence resonance energy transfer measurements (*7*). Piehler et al. has further studied the enhanced affinity of multivalent Ni-NTA-derived molecules toward the histidine tag in great detail (*8*−*10*). In the present work, we wish to design a superparamagnetic iron oxide immobilized bivalent Ni-NTA chelate system with the aim of improving IMAC purification of His × 6-tagged proteins by strengthening the interactions between the His × 6-tag and the bivalent Ni-NTA chelate. The bis-Ni-NTA-immobilized nanoparticles were shown to be capable of binding His × 6-tagged proteins in their native, folded conformations that failed to bind commercial microbeads under identical conditions. We have demonstrated that the present system is superior to commercial magnetic beads in binding to His × 6-tagged proteins and is useful for isolating target proteins that are overexpressed at low levels in the mammalian cells. Control experiments with a mono-NTA chelate immobilized on iron oxide nanoparticles

indicated a similarly high affinity for His × 6-tagged proteins, suggesting that the very high density of the mono-NTA chelate presented by the nanoparticles allows the binding of the His × 6-tag to more than one NTA moiety on the surface. Thus, this work demonstrates that the multivalency strategy can be utilized to enhance the binding of His × 6-tagged proteins in their native, folded conformations.

MATERIALS AND METHODS

General. N_α,N_α-bis(carboxymethyl)-L-lysine was purchased from Fluka. 2-(3,4-Bis-benzyloxyphenyl)ethylamine trifluoroacetate salt (Bn-DA-TFA) and N_α,N_α-bis(carboxymethyl)-L-lysine tribenzyl ester trifluoroacetate salt (Bn-NTA-lys-TFA) were prepared from literature procedures (*1*, *11*). All other chemicals were purchased from Sigma-Aldrich and used as received unless otherwise noted. Carboxy-terminated magnetic microparticles were purchased from Bangs Laboratories, Inc. Purified recombinant His × 6-endostatin (His × 6-rmES) was purchased from Calbiochem. Recombinat human His × 6-ubiquitin (His × 6-Ub) and mouse His × 6-ubiquitin C-terminal hydrolase L-1 (His × 6-UCH-L1) were from Boston Biochem. ^{1}H and ^{13}C{^{1}H} NMR spectra were obtained on a Bruker 400 MHz AVANCE or Bruker 400 MHz DRX. Mass spectra were obtained from Voyager DE-Pro MALDI-MS or HP/Agilent LC/Ion-trap MS in the Department of Chemistry at Duke University. Liquid scintillation counting experiments are performed on a Tri-Carb 2900TR liquid scintillation analyzer. SDS-PAGE gels were quantified using the AlphaEaseFC program. The molecular markers used for the SDS gels have molecular weights of 175, 83, 62, 47, 32, 25, and 16 kDa, respectively. Transmission electron microscopy (TEM) images were taken with a JEM-100CXII transmission electron microscope at 100 KV.

Synthesis of Dimethyl 5-(3,4-Bis(benzyloxy)phenethylcarbamoyl)benzene-1,3-dioate (1). To a stirring solution of benzene-1,3,5-tricarbonyltrichloride (1.7 g, 6.40 mmol) in dry CH_2Cl_2 (170 mL) at 0 °C was added Bn-DA-TFA (0.536 g, 1.20 mmol) in dry CH_2Cl_2 (100 mL) dropwise over 5 h. The solution was allowed to warm to room temperature. The solvent was removed under reduced pressure to produce a white residue. Methanol was added and stirred for a few hours. The excess methanol was removed under reduced pressure to produce a white solid. The product was isolated using flash column chromatography (ethyl acetate/hexanes, 2:3 v/v; $R_f = 0.4$). The solvents were removed under reduced pressure to yield a white solid of **1** (0.225 g, 0.408 mmol, 34.0% yield). ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.75 (s, 1H), 8.52 (s, 2H), 7.40 (d, 4H), 7.29 (m, 6H), 6.90 (d, 1H), 6.81 (s, 1H), 6.72 (d, 1H), 5.11 (s, 2H), 5.01 (s, 2H), 3.92 (s, 6H), 3.64 (q, 2H), 2.83 (t, 2H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 165.4, 165.3, 149.0, 147.6, 137.2, 137.0, 135.4, 132.9, 132.0, 131.9, 130.9, 128.3, 127.7, 127.2, 121.5, 115.5, 115.3, 71.3, 71.2, 52.4, 41.4, 34.9, 31.5. MALDI-MS: $[M + H]^+$ *m*/*z* 554.0 (calcd 554.6); $[M + Na]^+$, *m*/*z* 577.2 (calcd 576.6); $[M + K]^+$ *m*/*z* 592.8 (calcd 592.7).

Synthesis of 5-(3,4-Bis(benzyloxy)phenethylcarbamoyl)-benzene-1,3-dioic acid (2). To a stirring solution of **1** (0.160, 0.289 mmol) in acetone (6 mL) was added 1 N NaOH (4 mL). After 3 h, complete deprotection was confirmed by TLC. The solution was acidified to pH 3 using 1 N HCl. The solvent was removed, and the product was stirred in H_2O. The precipitate of **2** was collected by suction filtration and recrystallized in acetone (0.145 g, 0.276 mmol, 95.5% yield). ^{1}H NMR (400 MHz, MeOD) δ 8.42 (s, 1H), 8.21 (s, 2H), 7.15−6.90 (m, 10H), 6.67 (s, 1H), 6.62 (d, 1H), 6.49 (d, 1H), 4.73 (s, 4H), 3.28 (t, 2H), 2.54 (t, 2H). ^{13}C NMR (DMSO, 100 MHz) δ 166.4, 164.6, 148.3, 146.8, 137.5, 137.4, 135.5, 132.7, 132.2, 132.0, 131.8, 128.4, 127.8, 127.7, 127.6, 127.5, 121.2, 115.2, 114.8, 70.3, 70.2, 41.1, 34.4. MALDI-MS: $[M + H]^+$ *m*/*z* 525.9 (calcd 526.6).

Synthesis of 5-(3,4-Bis(benzyloxy)phenethylcarbamoyl)-benzene-1,3-benzyl-NTA-lysine (3). The diacid **2** (0.140 g, 0.266 mmol) was stirred in dry CH_2Cl_2 (13 mL) to form a cloudy suspension. 0.40 mL of $SOCl_2$ was slowly added and stirring continued at 50 °C for 6 h to form a clear solution. The solvent was removed under reduced pressure to give the 5-(3,4-bis(benzyloxy)phenethylcarbamoyl)benzene-1,3-dioyl dichloride intermediate which was used without further purification.

To a stirring mixture of Bn-NTA-lys-TFA (0.408 g, 0.632 mmol), TEA (0.5 mL), and $CHCl_3$ (5 mL) was added a solution of 5-(3,4-bis(benzyloxy)phenethylcarbamoyl)benzene-1,3-dioyl dichloride in $CHCl_3$ (10 mL) dropwise at 0 °C. The reaction was allowed to warm to room temperature and stir overnight. After removal of solvents under reduced pressure, column chromatography (ethyl acetate/hexanes, 3:2 v/v; $R_f = 0.5$) was used to isolate a pure white solid of **3** (0.281 g, 0.181 mmol, 67.9% yield). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.33 (s, 3H), 7.41−7.25 (m, 35H), 6.95 (t), 6.86 (d, 2H), 6.80 (s, 2H), 6.69 (d, 2H), 5.10 (s, 8H), 5.06 (s, 2H), 4.98 (s, 4H), 3.68 (s, 4H), 3.59 (t, 4H), 3.46 (t, 1H), 3.32 (t, 2H) 2.75 (t, 4H), 1,69−1.24 (m, 6H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 172.8, 171.7, 166.3, 149.3, 148.0, 137.6, 137.5, 135.9, 135.8, 135.6, 135.4, 132.4, 128.8, 128.7, 128.6, 128.5, 128.0, 127.7, 121.7, 116.2, 115.9, 71.6, 66.8, 66.7, 64.5, 53.1, 40.2, 35.4, 29.9, 28.5, 23.1. MALDI-MS: $[M + H]^+$ *m*/*z* 1556.3 (calcd 1555.8); $[M + Na]^+$, *m*/*z* 1577.5 (calcd 1577.8); $[M + K]^+$, *m*/*z* 1593.1 (calcd 1593.9).

Synthesis of 5-(3,4-Bis(hydroxy)phenethylcarbamoyl)-benzene-1,3-NTA-lysine (4). 3 (0.043 g, 0.052 mmol) was dissolved in 1.5 mL of $CHCl_3$ and 6 mL of MeOH and placed in a Parr flask with 15 mg Pd/C (10%). The mixture was shaken in a Parr reactor for 24 h under H_2 (60 psi). Upon complete deprotection, the palladium catalyst was filtered off using Celite and solvent removed under reduced pressure. The product was purified by recrystallization in MeOH/CH_2Cl_2 to give **4** in a quantitative yield. ^{1}H NMR (MeOD, 400 MHz) δ 8.29 (s, 3H), 6.60 (s, 1H), 6.59 (s, 1H), 6.47 (d, 2H), 3.71−3.21 (m, 16H), 2.68 (t, 2H), 1.63−1.45 (m, 8H), 1.18 (m, 4H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 174.1, 173.0, 168.6, 146.7, 144.7, 136.6, 132.0, 130.0, 121.1, 117.0, 116.4, 66.9, 54.3, 43.1, 40.7, 35.9, 29.8, 29.8, 24.4. MALDI-MS: $[M]^+$, *m*/*z* 833 (calcd 833.8); $[M + Na]^+$, *m*/*z* 856 (calcd 856.8).

Synthesis of Methyl 3,5-Bis(3,4-bis(benzyloxy)phenethylcarbamoyl)benzoate (5). To a stirring solution of benzene-1,3,5-tricarbonyltrichloride (0.320 g, 1.20 mmol) in dry CH_2Cl_2 (170 mL) at 0 °C was added Bn-DA-TFA (0.536 g, 1.20 mmol) in dry CH_2Cl_2 (100 mL) dropwise over 5 h. The solution was allowed to warm to room temperature. The solvent was removed under reduced pressure to produce a white residue. Methanol was added and allowed to stir for a few hours. The excess methanol was removed under reduced pressure to produce a white solid. The product was isolated using silica flash column chromatography (ethyl acetate/hexanes, 1:1 v/v; $R_f = 0.4$). The solvents were removed under reduced pressure to yield a white solid of **5** (0.298 g, 0.349 mmol, 29.0% yield). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.44 (s, 2H), 8.28 (s, 1H), 7.45−7.25 (m, 20H), 6.88 (d, 2H), 6.81 (s, 2H), 6.71 (d, 2H), 6.56 (t, 2H), 5.10, (s, 8H), 3.88 (s, 3H), 3.60 (q, 4H), 2.80 (t, 4H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 165.6, 165.3, 148.7, 147.4, 136.9, 136.8, 135.1, 131.9, 130.5, 130.3, 129.6, 128.2, 127.6, 127.2, 127.1, 121.4, 115.4, 115.0, 71.1, 52.2, 41.3, 34.7. MALDI-MS: $[M + Na]^+$, *m*/*z* 877.0 (calcd 878.0); $[M + K]^+$, *m*/*z* 893.0 (calcd 894.1).

Synthesis of 3,5-Bis(3,4-bis(benzyloxy)phenethylcarbamoyl)benzoic acid (6). 5 (0.250 g, 0.292 mmol) was stirred in a solution of 3 mL of acetone and 1 mL of 1 M NaOH overnight. The solution was acidified to pH 3 using 1 N HCl, added dropwise. The solvent was removed, and the product was stirred in H_2O. The precipitate was collected by vacuum filtration to

give **6** in quantitative yield. ^{1}H NMR (MeOD, 400 MHz) δ 8.53 (s, 2H), 8.37 (s, 1H), 7.40−7.20 (m, 20H), 6.93 (s, 2H), 6.91 (s, 2H), 6.76 (d, 2H), 5.03 (s, 8H), 3.54 (t, 4H), 2.81 (t, 4H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 169.2, 164.9, 150.4, 148.9, 138.9, 138.8, 136.3, 134.3, 131.9, 129.8, 129.5, 128.9 128.8, 123.1, 117.2, 116.9, 72.7, 72.5, 42.8, 37.0. MALDI-MS: $[M + Na]^+$, *m/z* 863.4 (calcd 864.0).

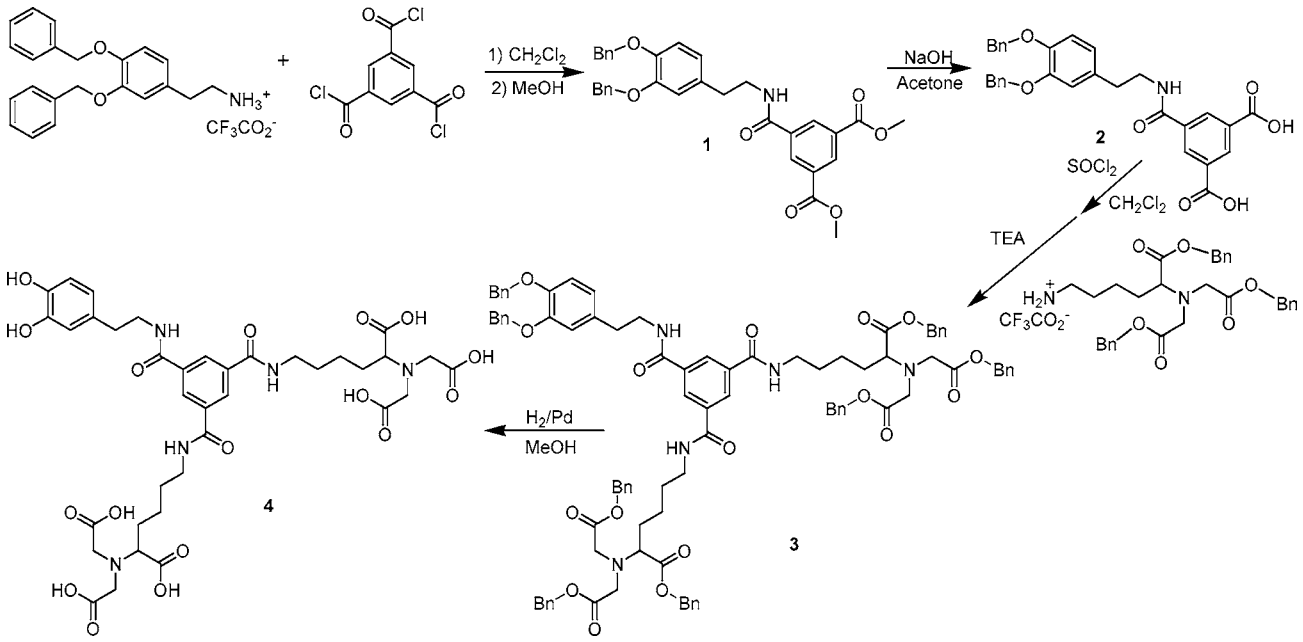
Synthesis of Benzyl 6-(N_3, N_5-Bis(3,4-bis(benzyloxy)phenethyl)benzene-1,3,5-tricarboxamido)-2-(bis(((benzyloxy)carbonyl)methyl)amino)hexanoate (7). A mixture of Bn-NTA-lys-TFA (0.060 g, 0.071 mmol), **6** (0.075 g, 0.142 mmol), and HOBt (0.010 g, 0.074 mmol) was stirred in 3 mL anhydrous DMF for 5 min. Dicyclohexylcarbodiimide (0.015 g, 0.073 mmol) was added, and the mixture was allowed to stir overnight. The solvents were removed under reduced pressure. The product **7** was isolated with silica gel flash column chromatography (ethyl acetate/hexanes, 3/2 v/v; R_f = 0.4). Yield: 0.094 g (97.7%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 8.43 (s, 1H), 8.41 (s, 2H), 7.50−7.26 (m, 40H), 7.04 (s, 3H), 6.87 (s, 1H), 6.85 (d, 1H), 6.72 (d, 1H), 5.12 (s, 8H), 5.07 (s, 8H), 3.74 (s, 8H), 3.59 (t, 2H), 3.51 (t, 2H), 3.35 (t, 4H), 2.79 (t, 2H), 1.75−1.28 (m, 12H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 172.5, 171.5, 165.9, 148.9, 147.6, 137.2, 137.1, 135.3, 132.0, 128.5, 128.4, 128.3, 128.2, 128.1, 127.7, 127.4, 127.3, 121.5, 115.7, 115.2, 71.3, 66.5, 66.4, 64.0, 52.8, 41.5, 39.9, 35.0, 27.9, 25.5, 24.8. MALDI-MS: $[M + H]^+$, *m/z* 1356.4 (calcd 1355.6); $[M + Na]^+$, *m/z* 1378.0 (calcd 1378.6); $[M + K]^+$, *m/z* 1393.9 (calcd 1394.7).

Synthesis of 6-(N_3, N_5-Bis(3,4-dihydroxyphenethyl)benzene-1,3,5-tricarboxamido)-2-(bis(carboxymethyl)amino)hexanoic acid (8). To a solution of **7** (0.094 g, 0.069 mmol) in of 5 mL of MeOH and 10 mL of $CHCl_3$ was added 20 mg Pd/C (10%). The mixture was placed in a Parr reactor bottle and rocked for 24 h at 60 psi H_2. Upon complete deprotection, the catalyst was filtered off using Celite, and the solvents were removed under reduced pressure. **8** was purified by recrystallization in MeOH/CH_2Cl_2 in a quantitative yield. ^{1}H NMR (MeOD, 400 MHz) δ 8.34 (s, 3H), 6.69 (s, 2H), 6.67 (s, 2H), 6.56 (d, 2H), 3.64 (t, 4H), 3.60 (t, 1H), 3.33 (s, 4H), 3.29 (t, 2H), 2.77 (t, 4H), 1.90−1.50 (m, 4H), 1.27 (p, 2H). ^{13}C NMR ($CDCl_3$, 100 MHz) δ 175.3, 174.1, 168.5, 146.1, 144.7, 136.6, 132.0, 129.4, 121.1, 117.0, 116.4, 68.2, 55.1, 43.1, 40.3, 35.9, 26.4, 25.9, 23.6. MALDI-MS: $[M + H]^+$, *m/z* 724.8 (calcd 725.7); $[M + Na]^+$, *m/z* 746.8 (calcd 747.7).

Surface Modification of Iron Oxide Nanoparticles with Bis-NTA-derived Ni(II) Chelate and Mono-NTA-derived Ni-(II) Chelate. The ligand **4** (0.5 mL of a 10 mg/mL MeOH solution) was placed in 1.25 mL distilled water. To this aqueous solution was added 1 mL of iron oxide nanoparticles in *n*-hexanes (16.3 mg/mL). The two layers were sonicated for 1 h and repeatedly washed with *n*-hexanes, then methanol, until the nanoparticles were readily dispersed in distilled water. Using a magnet, the nanoparticles were collected and placed in 2 mL of distilled water. The bis-NTA-pendant ligand-immobilized nanoparticles (0.5 mL) were placed in 2 M $NiCl_2$ solution and sonicated for 1 h. The Ni(II)-loaded nanoparticles were stored in the $NiCl_2$ solution before use. Iron oxide nanoparticle modified with mono-NTA Ni(II)-loaded nanoparticles were similarly prepared.

Preparation of Ni(II)-Loaded Magnetic Microparticles. An aliquot of 0.5 mL (2.4 μmol carboxyl) BioMag Carboxyl magnetic iron oxide microparticles (~1.5 μm mean diameter, ~20 mg/mL particle concentration, ~4.8 μmol/mL carboxy-surface titration) was washed with distilled water (3 × 500 μL), then with acetone (3 × 500 μL). Aliquots of *N*-hydroxysuccinimide (NHS) (25 μL, 30 mg/mL acetone) and dicyclohexylcarbodiimide (50 μL, 50 mg/mL acetone) were added and incubated overnight. The NHS-activated particles were washed with acetone and used without further purification.

A 240 μM solution of N_α,N_α-bis(carboxymethyl)-L-lysine was prepared by dissolving 0.629 mg N_α,N_α-bis(carboxymethyl)-L-lysine in 35 μL of triethylamine, 500 μL of acetone, and 500 μL of distilled water. The NHS-activated microparticles were washed with distilled water, then placed in 100 μL of the N_α,N_α-bis(carboxymethyl)-L-lysine solution. After overnight incubation, the particles were washed with distilled water. The particles were placed in a 1 M $NiCl_2$ solution for 1 h before use.



Isolation of Recombinant Mouse His × 6-Endostatin (His × 6-rmES) with Ni(II)-Loaded Nanoparticles. The Ni(II)-loaded nanoparticles (7−10 μL; 16.3 mg/mL) were washed in distilled water (3 × 50 μL) and a binding buffer (3 × 50 μL; 50 mM phosphate buffer system, 300 mM NaCl, 10 mM imidazole, pH 8.0). The washed nanoparticles were incubated with 10 μg of His × 6-rmES in 40 μL of binding buffer for 5−60 min at 4 °C. Using a centrifuge and magnet, the supernatant was collected and nanoparticles washed in 50 μL aliquots of binding buffer (FT, flow through; W1, wash 1; W2, wash 2; W3, wash 3). After the third wash, 50 μL of the elution buffer (50 mM phosphate buffer system, 300 mM NaCl, 250 mM imidazole, pH 8.0) was added and the mixture tumbled for 10 min at 4 °C. The eluents were similarly collected by centrifugation and magnetic immobilization (E1, elution 1; E2, elution 2). Nonspecifically bound protein was released from the nanoparticles by boiling at 95 °C for 4 min in a Laemmli SDS-PAGE gel loading buffer. The volumes of the aliquots were reduced in a Speedvac before loading to an SDS-PAGE (12.5%, 180 V, 50 min). After separation, the SDS-PAGE gel was stained in a Coomassie blue solution (0.1% Coomassie blue, 10% acetic acid, 40% methanol) overnight. Recombinant human His × 6-ubiquitin (His × 6-Ub) and recombinant mouse His × 6-ubiquitin C-terminal hydrolase L-1 (His × 6-UCH-L1) were isolated with Ni(II)-loaded nanoparticles in the same fashion. Protein isolation by commercial magnetic agarose beads was performed according to the manufacturer's instructions (Qiagen).

Isolation of His × 6-rmES by Ni(II)-Loaded Microparticles. The Ni(II)-loaded microparticles (10 μL, 20 mg/mL) were washed in distilled water (3 × 50 μL) and binding buffer (3 × 50 μL). The washed microparticles were incubated with 10 μg of His × 6-rmES in 40 μL of binding buffer for 60 min at 4 °C. The beads were washed and the bound protein eluted similarly. All the fractions were loaded to an SDS-PAGE for analysis as previously described.

Expression of [^{35}S]-Methionine-Labeled His × 6-GMAP-210. The gene coding a 70 kDa fragment of GMAP-210 (Golgi-associated microtubule-binding protein) was PCR-amplified from a human total RNA library (Stratagene). After introducing the T7 promoter and TMV 5′-UTR by second PCR, the cDNA was used as the template for a coupled in vitro transcription/translation (TNT) reaction in the presence of 10 μCi [^{35}S]-methionine (Perkin-Elmer) in a total volume of 25 μL for 90 min at 30 °C. Protein synthesis was confirmed by SDS-PAGE and autoradiography. The protein was stored at −80 °C until used.

Isolation of [^{35}S]-Methionine-Labeled His × 6-GMAP-210 with Ni(II)-Loaded Nanoparticles. The Ni(II)-loaded nanoparticles (10 μL; 16.3 mg/mL) were washed in distilled water (3 × 50 μL) and binding buffer (3 × 50 μL). The washed nanoparticles were incubated with 5 μL of TNT reaction mixture in 100 μL of binding buffer for 60 min at 4 °C. The nanoparticles were washed and the bound protein eluted according to the procedures detailed above. All the fractions including the remaining nanoparticles were transferred to scintillation vials for radioactivity measurements using a liquid scintillation counter. Protein isolation using commercial mag-

Scheme 1

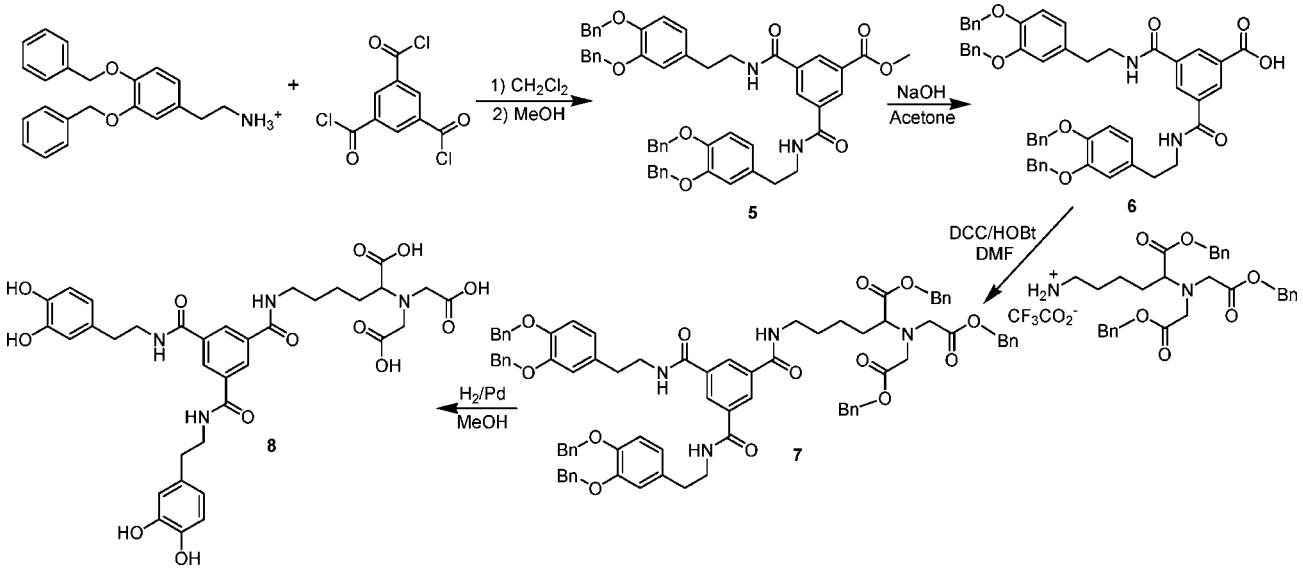
netic agarose beads (Qiagen) was performed according to the manufacturer's instructions, and scintillation counts were measured as mentioned above.

Expression and Purification of His × 6-UGT from 293T Cells Using Nanoparticles. The cDNA corresponding to the open reading frame of *C. elegans* UGT was amplified from a *C. elegans* cDNA library (Invitrogen) using high-fidelity platinum *Pfx* DNA polymerase (Invitrogen) and sequence-specific primers with CACC at the 5′-end of the forward primer. The full-length cDNA was gel-purified and subcloned into the pcDNA3.1D/V5-His TOPO vector (Invitrogen) according to the manufacturer's instructions. The resulting gene-containing plasmid was confirmed by PCR and sequence analysis.

293T cells were cultured in Dulbecco's Minimal Essential Media (DMEM, Gibco) supplemented with 10% fetal bovine serum (FBS, Sigma), 1% L-glutamate (Gibco), and 1% penicillin/streptomycin. Cell culture was maintained at 37 °C with 5% CO_2. On the day of transfection, the preformed UGT plasmid DNA−lipofectamine complex (500 μL) in DMEM serum-free media was added directly to each well. Cells were incubated at 37 °C in 5% CO_2 for 4 h. Afterward, the media was changed and 2 mL of fresh DMEM (with 10% FBS and 1% L-glutamate) was added. After incubation at 37 °C in a 5% CO_2 incubator for a total of 24 h to allow protein expression, cells were harvested and lysed using a commercial extraction buffer (Biovision). Intact cells were removed by centrifugation, and the supernatants were cleared at 21 000 *g* for 15 min at 4 °C. Levels of protein expression were assessed by separation on SDS-PAGE gels, followed by Western blotting onto nitrocellulose membranes (Amersham Pharmacia), and probing with anti-V5 antibody (Invitrogen). The lysates that were prepared were used for binding studies.

To purify the His × 6-UGT expressed in 293T cells, the prewashed, Ni(II)-loaded nanoparticles (10 μL; 16.3 mg/mL) were incubated with 50 μL of cleared crude cell lysate (∼4 μg/μL total protein) in 50 μL of binding buffer for 15 min at 4 °C. After washing nanoparticles three times using 50 μL of binding buffer, the bound proteins were eluted using 15 μL of elution buffer. Aliquots of each fraction were loaded to an SDS-PAGE for separation. The protein was detected by Coomassie blue staining.

RESULTS AND DISCUSSION



Surface Modification of Iron Oxide Nanoparticles with Bis-NTA and Mono-NTA Ni(II) Chelates. The iron oxide magnetic nanoparticles were synthesized using protocols previously described (*12*−*14*). The nanoparticles were washed in ethanol and transferred into *n*-hexanes and used without further purification. The concentration of the nanoparticles was estimated on the basis of the dry mass after the removal of the solvents. Iron oxide nanoparticles prepared by different routes gave similar results for protein binding and purification experiments.

Although a number of functional groups have been immobilized on iron oxide nanoparticles, their binding strength and their ease of surface immobilization vary significantly. Since Xu and co-workers recently demonstrated the efficient immobilization of dopamine derivatives on iron oxide nanoparticles (*15*), we have decided to use this strategy to immobilize bis-NTA Ni(II) chelate for protein purifications. The new bis-NTA ligand with a catechol group (**4**) was synthesized according to Scheme 1. Compound **4** was synthesized in 22% overall yield in four steps starting from known benzyl-protected dopamine trifluoroacetate salt and benzene-1,3,5-tricarbonyltrichloride. New compounds **1**−**4** were characterized by ^{1}H and ^{13}C{^{1}H} NMR spectroscopy and mass spectrometry.

In order to determine the effects of multivalency on protein binding, we have also prepared a new mono-NTA ligand with two catechol groups (**8**) by using a 1:1 ratio of dopamine hydrochloride and benzene-1,3,5-tricarbonyltrichloride as shown in Scheme 2. Compound **8** was synthesized in an overall yield of 28% in four steps. New compounds **5**−**8** were characterized by ^{1}H and ^{13}C{^{1}H} NMR spectroscopy and mass spectrometry.

Surface modification of iron oxide nanoparticles with new NTA-derived ligands was accomplished by simply stirring a biphasic mixture of the ligand in water and iron oxide nanoparticles in hexanes. The NTA−ligand-immobilized nanoparticles were charged with Ni(II) ions by ultrasonic mixing in 2 M $NiCl_2$. The iron oxide nanoparticles with different coatings were characterized by transmission electron microscopy (TEM). TEM images of ∼10 nm monodisperse iron oxide nanoparticles (prepared by thermal decomposition) before and after surface modifications illustrate the retention of nanoparticle size and shape and monodispersity throughout monovalent and bivalent

Scheme 2

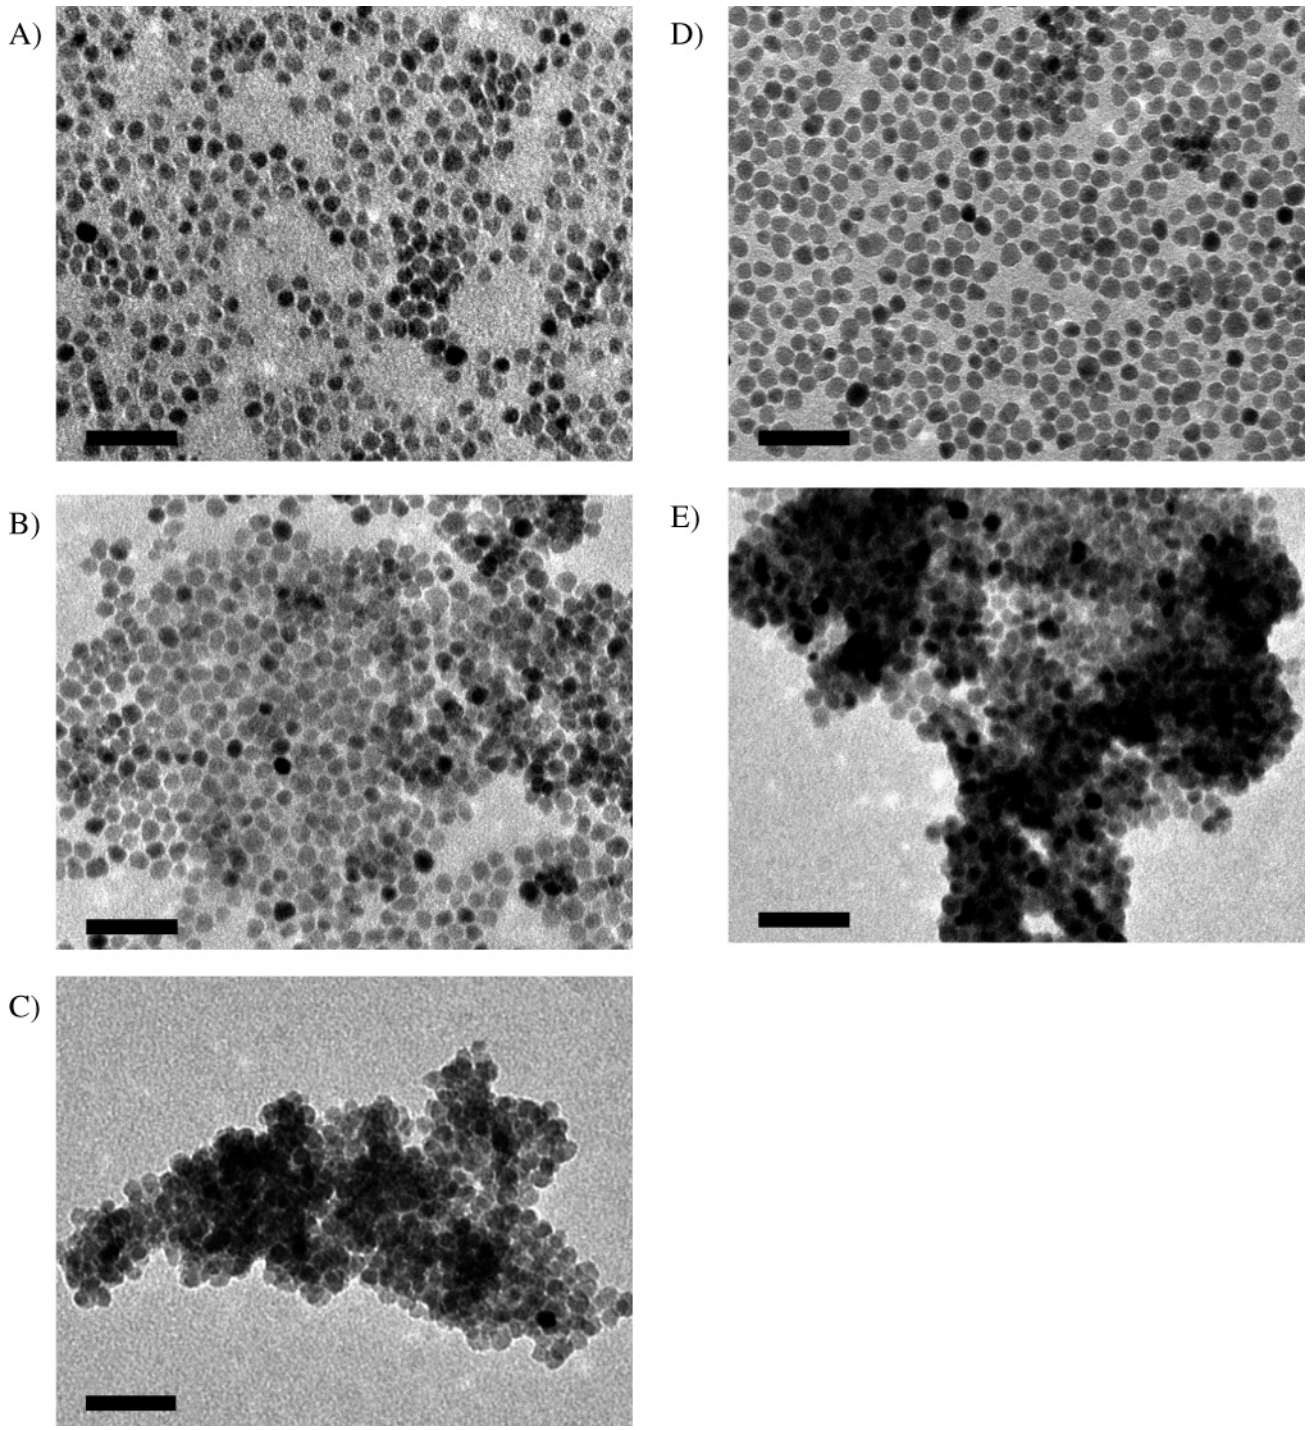
NTA−ligand surface modification and Ni(II)-loading. Slight aggregation of Ni(II)-loaded nanoparticles was, however, observed in the TEM images (Figure 1).

Binding of His × 6-Tagged Proteins Labeled with [^{35}S]-Methionine. Immobilization of proteins onto the nanoparticles and subsequent elution were initially demonstrated with His × 6-tagged, [^{35}S]-methionine-labeled GMAP-210 protein synthesized via coupled in vitro transcription and translation (Scheme 3). In a typical binding-elution experiment, the direct lysate (DL) signal is equal to the sum of the flow through (FT), washes (W1, W2, W3), elutions (E1, E2), and residual resin signals. The signal from each fraction was measured using liquid scintillation counting.

Since only a small percentage of [^{35}S]-methionine was incorporated into the recombinant protein in the TNT reaction, a majority of the radioactivity in both the commercial beads and nanoparticle systems came from unbound free [^{35}S]-methionine in the FT (Figure 2 and Supporting Information Table S1). Following the removal of FT, the resin was washed three times until the background was low, before elution by imidazole. This scintillation counting assay demonstrates that the NTA-modified nanoparticles can specifically capture His × 6-tagged proteins followed by efficient elution with imidazole. We also examined the relative protein binding capacity of nanoparticles as compared to the commercial beads. It was found that the 10 μL (0.32% v/v suspension, assuming Fe_3O_4 density of 5.15 g/cm^3) of nanoparticles (16.3 mg/mL) had a similar binding capacity to 10 μL (5% v/v suspension) of commercial magnetic agarose beads. It appears that the unoptimized nanoparticles used in this work have higher residual radioactivity after elutions when compared to the commercial beads, presumably due to relatively strong nonspecific binding. This result was within expectation, since the commercial beads were coated with agarose, which has low nonspecific binding to proteins. We think that the nonspecific binding of the nanoparticles could be minimized if the surface is modified with hydrophilic molecules such as PEG that are known to resist nonspecific protein binding (*16*).

Binding of Overexpressed His × 6-Tagged Proteins. We next carried out protein binding studies of several commercially available recombinant His × 6-tagged proteins. One of the major problems in using Ni-NTA in protein purification is that numerous His × 6-tagged proteins can only be purified under denaturing conditions. Consequently, a complicated refolding process is needed that often results in low yield of the active protein. In this work, we focus on examining whether the NTA-modified nanoparticles can be used under native conditions to purify His × 6-tagged proteins that require denaturing conditions when commercial NTA beads are used. We used recombinant murine His × 6-endostatin as an example. Endostatin is a potent angiogenesis inhibitor that has shown therapeutic suppression of tumor-induced angiogenesis in mice implanted with tumors (*17*). O'Reilly et al. reported that recombinant murine endostatin with His × 6 tag could be expressed in *E. coli* as insoluble inclusion bodies and purified using Ni-NTA resin under denaturing conditions. Endostatin thus purified underwent an inefficient refolding process before it could be used in xenograft mouse studies. We found that the already folded endostatin could not be captured when commercial Ni(II)-NTA beads were used. As shown in Figure 3, approximately 90% of His × 6-rmES was present in the FT, and almost no protein was detected in the elutions, indicating that commercial beads failed to capture His × 6-rmES under native conditions. Significantly, Ni(II)-loaded nanoparticles readily bound His × 6-rmES without the use of denaturing conditions. A 10 μL volume of Ni(II)-loaded nanoparticles (163 μg) is found to have a binding capacity of 5.6 μg under unoptimized conditions. The His × 6-rmES was readily eluted by imidazole and was shown to be biologically active in inducing apoptosis in cow pulmonary artery endothelial cells (Supporting Information Figure S1) (*18*). Confocal microscopic images showed characteristic apoptotic rings for the cow pulmonary artery endothelial cells after annexin-V PE staining. This result indicates that milligrams of a biologically active native protein can be purified using approximately 30 mg of Ni(II)-loaded nanoparticles. We have also successfully recycled and reused the modified nanoparticles in His × 6-rmES binding without Ni(II) reloading. The recycled nanoparticle appears to have a similar binding capacity to the pristine sample on the basis of SDS-PAGE analysis (Supporting Information Figure S2).

We also compared the binding of other His × 6-tagged proteins that do not require denaturing conditions for Ni-NTA-based purifications. Ubiquitin is a protein found throughout all eukaryotic cells and plays key roles in highly specific protein degradation. The small His × 6-tagged ubiquitin (9.3 kDa) is expected to have an affinity for both the commercial beads as well as the surface-modified nanoparticles. SDS-PAGE analysis confirms the affinity of the commercial beads and the Ni(II)-loaded nanoparticles (Table 1 and Supporting Information Figure S3). Densitometry analysis shows the binding capacity of 20



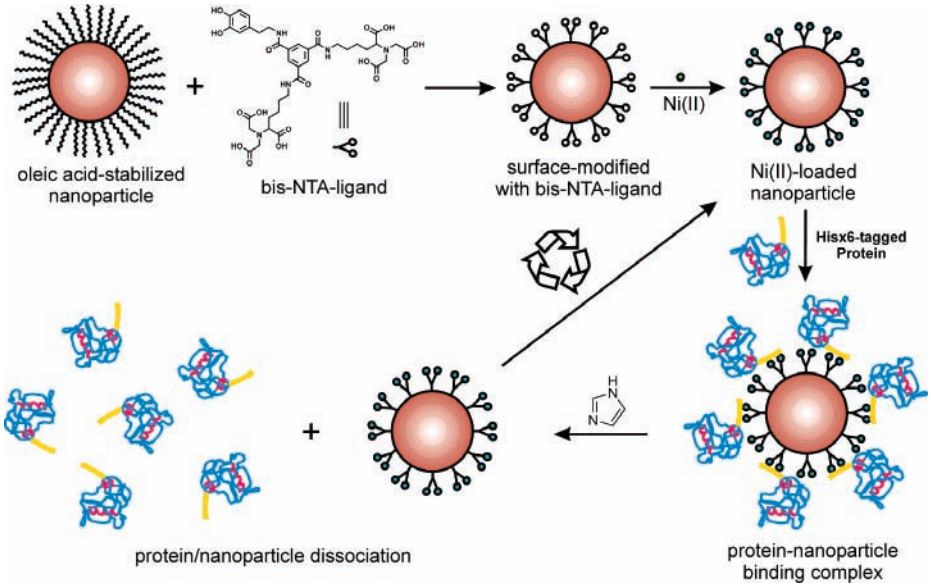


Figure 1. TEM images of monodisperse iron oxide nanoparticles (~10 nm in diameter): (A) Prepared by thermal decomposition and stabilized with oleic acid. (B) Modified with bis-NTA ligand. (C) Ni(II)-loaded bis-NTA nanoparticle. (D) Modified with mono-NTA ligand. (E) Ni(II)-loaded mono-NTA nanoparticle. The scale bar is 50 nm.

μL (5% v/v suspension) of commercial beads is 1.1 μg His × 6-Ub, while that of 10 μL (0.32% v/v suspension) of bis-NTA-Ni(II)-loaded nanoparticle is 2.3 μg. In comparing the binding of 10 μL (0.32% v/v suspension) of nanoparticle for His × 6-rmES (21.3 kDa, 5.6 μg) and 6 × His-Ub (9.3 kDa, 2.3 μg), it is estimated that the binding capacity of the Ni(II)-loaded nanoparticles is approximate 25 pmol of proteins/μL.

Binding studies on His × 6-UCH-L1 (~25 kDa) were also used to demonstrate the nanoparticle's ability to capture His × 6-enzymes (Table 1 and Supporting Information Figure S4). Binding capacities of 40 μL (5% v/v suspension) of commercial beads and 10 μL (0.32% v/v suspension) of nanoparticles are 0.06 μg and 3.48 μg His × 6-UCH-L1, respectively. One major concern in NTA microbeads based protein purification is the large elution volume that requires additional concentration steps before being used in the subsequent experiments. While lyophilization can be used to concentrate most proteins, the process reduces the biological activity of many other proteins. Ultrafiltration is another widely used method in volume reduction. However, the loss of purified proteins could be significant, presumably due to nonspecific interactions with the membrane. Our Ni(II)-loaded nanoparticles disperse well in aqueous solution, and therefore significantly smaller elution volume can be used. This advantage eliminates the need of volume reduction and makes it possible to directly use the proteins after purification. Our studies clearly demonstrated that the present magnetic,

Scheme 3

recyclable nanoparticles are able to bind important His × 6-proteins in native, active conformations with a high capacity and thus show significant advantages over the commercial microbeads. Since the chosen His × 6-proteins have a wide range of molecular weights (9387.6−74406.8 Da) and isoelectric points (5.43−9.33), we do not believe that their binding to the present Ni(II)-loaded nanoparticles are due to simple electrostatic interactions.

Purification of Recombinant His × 6-Tagged Proteins from Crude Mammalian Cell Lysate. Proteins expressed in mammalian cells are usually soluble and active, and therefore extremely useful in studying their physiological significances. The biggest drawback is that their expression levels are very low, making the purification challenging. The nanoparticle platform was previously used for protein purification from *E. coli* cell lysate (*15*), in which proteins are much more easily overexpressed. We investigated whether our NTA-loaded nanoparticles could be used to purify recombinant proteins expressed in mammalian cells. 293T cells were used to express a recombinant His × 6-UGT protein. The lysate was prepared for purification of 6 × His-UGT protein by the bis-Ni(II)-NTA modified nanoparticles. Figure 4 shows the staining of DL, FT, W3, E1, E2, and nanoparticle fractions and clearly indicates the purification of desired His × 6-tagged protein from the mammalian crude lysate. The elution E1 is significantly cleaner than the direct lysate, with few impurities. These nonspecifically bound impurities are probably due to proteins with many amino acid residues that can coordinate to the immobilized metal ion. Nonetheless, the present nanoparticle system has shown great promise in the purification of His × 6-tagged proteins from crude mammalian cell lysates.

Nonspecific Interactions. Nonspecific interactions between the protein and nanoparticles do not appear to be significant when the NTA nanoparticles are chelated with Ni(II). Table 1 shows that approximately 8.7% of His × 6-rmES remained on the Ni(II) loaded bis-NTA-modified nanoparticles after elution, slightly higher than that on commercial microbeads. Without the chelation of Ni(II), His × 6-rmES was found to have a high affinity for the bis-NTA-modified nanoparticle (Supporting Information Figure S5). Densitometry measurements show that more than 45% of the 6 × His-rmES was present in the sum of the washes and elutions, while 39% of the protein remained on the bis-NTA-modified nanoparticles.

On the other hand, freshly prepared iron oxide nanoparticles (without surface modifications) had little interaction with His × 6-rmES. Over 70% of the 10 μg of loaded protein was detected in the FT, and over 90% was detected in the sum of the FT and washes. The nanoparticles retained approximately 7% of the His × 6-rmES after elution, a significant reduction from the 39% retention of Ni(II)-free bis-NTA-modified nanoparticles. The nonspecific interaction of the rmES to the nanoparticle is thus a result of the surface modifications. To rule out the potential role of residual oleic acid on the nanoparticle surface, we carried out a binding experiment using

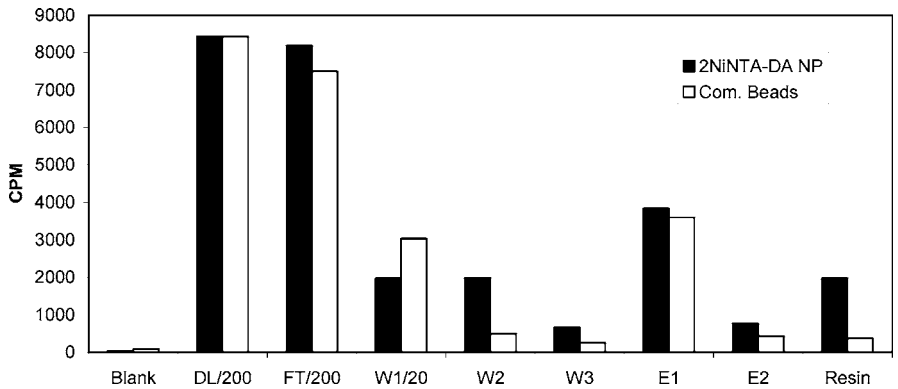

Figure 2. Graphical representation of [^{35}S]-labeled His × 6-GMAP-210 binding scintillation counting assay for bis-Ni-NTA nanoparticles (solid bars) and commercial Ni-NTA agarose beads (open bars). Fractions collected and radioactivity quantified in counts per minute (CPM). DL = direct lysate, FT = flow through, W1 = wash 1, W2 = wash 2, W3 = wash 3, E1 = elution 1, E2 = elution 2.

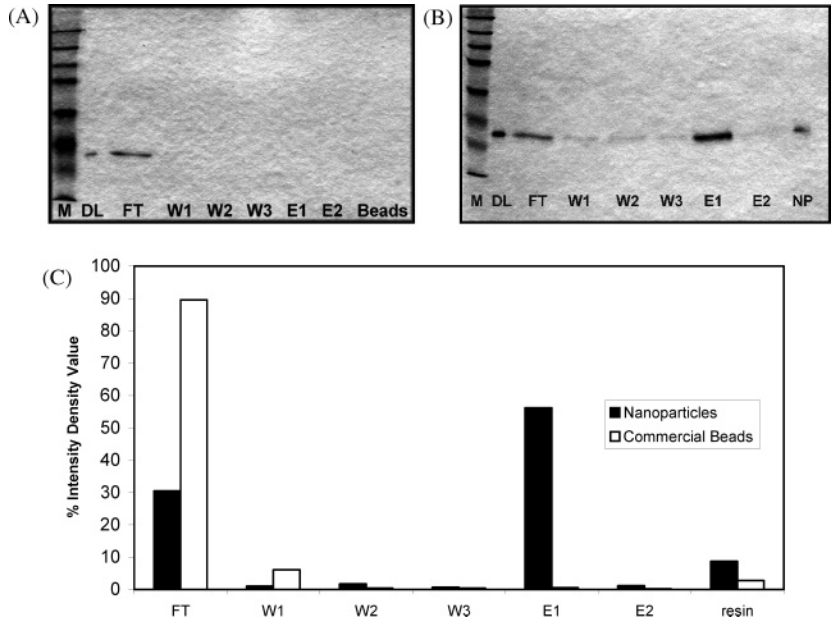

Figure 3. Binding assay of His × 6-rmES. (A) Commercial magnetic agarose beads (Qiagen): no protein was bound to the bead or eluted by imidazole. Most of the protein was washed away unbound in the FT. (B) Bis-Ni-NTA NPs: His × 6-tag protein was bound and a majority was eluted from the nanoparticles by imidazole. (C) Graphical representation of densitometry quantification of SDS-PAGE gels.

Table 1. Intensity Density Values (% IDV) Compiled from Densitometry Quantification of SDS-PAGE Results for Collected Fractions Comparing Bis-Ni-NTA-Modified Nanoparticles and Commercial Ni-NTA Agarose Beads in His × 6-Tagged Protein Binding Experiment (10 μg total protein)

	FT	W1	W2	W3	E1	E2	NP/resin

particles without oleic acid stabilization. Nonspecific interaction was observed for the oleic acid-free nanoparticles as well.

As the ratio of His × 6-rmES (μg) to bis-Ni(II)-loaded NTA nanoparticle (mg) is increased from 10.2 to 61.3, the amount of nonspecifically bound protein appears to remain constant (Figure 5). The specific his-tag binding to Ni(II)-NTA occurs after the full capacity of the nonspecific interaction is reached at a 6 × His-rmES (μg) to bis-Ni(II)-loaded NTA nanoparticle (mg) ratio between 10.2 and 15.3. Maximum binding capacity of the nanoparticle via the His × 6-tag appears to have been reached with a His × 6-rmES (μg) to bis-Ni(II)-loaded NTA nanoparticle (mg) ratio of 61.3, since some 6 × His-rmES is detectable in the FT.

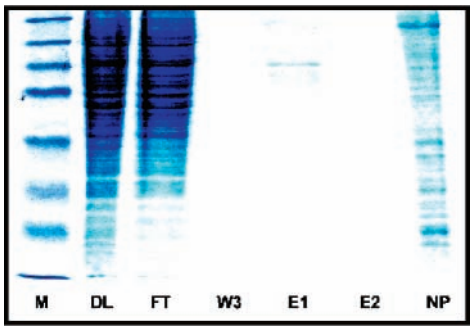

Figure 4. Mammalian cell lysate fractionation. SDS-PAGE (12.5% separation gel) results of flag-His × 6-UGT expressed in 293T cells showing marker (M), direct lysate (DL, 10% dilution), flow through (FT, 10%), wash 3 (W3), elution 1 (E1), elution 2 (E2), and protein residue on nanoparticle (NP).

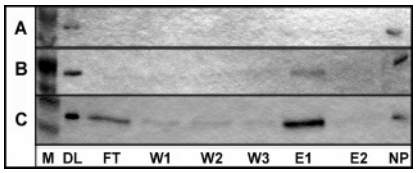

Figure 5. Preference toward nonspecific interaction before his-tag−Ni-NTA interaction demonstrated through increasing ratios of 6 × His-rmES protein (μg) to bis-Ni-NTA nanoparticle (mg) A, 10.2; B, 15.3; C, 61.3. (M = marker, FT = flow through, W1 = wash 1, W2 = wash 2, W3 = wash 3, E1 = elution 1, E2 = elution 2, NP = protein bound nonspecifically to nanoparticle.) The molecular markers have molecular weights of 25 and 16 kDa.

Various attempts were made to block the nonspecific interaction of the target protein (Supporting Information Figure S6). We first attempted to block the nonspecific binding with BSA. The surface-modified nanoparticles were preincubated with BSA before the His × 6-rmES binding experiment was performed. Unfortunately, BSA did not effectively block the His × 6-rmES nonspecific binding. An attempt to block the His × 6-rmES nonspecific interaction of the nanoparticle with a smaller protein (His × 6-Ub) did not seem to result in any noticeable improvement by SDS-PAGE analysis.

Surface Density of the Ni-NTA Chelates. The mono-NTA ligand with two dopamine anchors was synthesized to present monovalency of the Ni(II)-NTA moiety onto the nanoparticle surface. Interestingly, an SDS-PAGE binding assay of the mono-Ni(II)-NTA-modified nanoparticle showed a similarly effective binding with His × 6-rmES (Supporting Information Figure S7). Furthermore, we compared the mono- and bis-Ni(II)-NTA ligand-modified nanoparticles by elution with variable imidazole concentrations, and no significant difference was observed. Unlike commercial Ni-NTA beads, the His × 6-rmES could not be eluted from the mono- and bis-Ni(II)-NTA-modified nanoparticles at a pH as low as 4.0 (without the use of imidazole, Supporting Information Figure S8). These results are suggestive of similar binding affinity of mono- and bis-Ni(II)-NTA-modified nanoparticles, probably a result of high surface coverage of mono-Ni(II)-NTA moieties.

To demonstrate the importance of high surface coverage, we conjugated Ni(II)-NTA to micrometer-sized, carboxy-terminated commercial beads (~1.5 μm diameter). NTA-lysine was con-

jugated to the beads via the amide bond using the DCC/NHS coupling protocol. Upon loading with Ni(II), these beads were found to bind His × 6-rmES as effectively as mono- and bis-Ni(II)-NTA modified nanoparticles (Supporting Information Figure S9). This experiment unambiguously supports the notion that enhanced binding of His × 6-tagged protein can be achieved by taking advantage of the multivalency effect.

CONCLUSIONS

New bis-nitrilotriacetic acid (NTA) chelates with catechol anchors were synthesized and immobilized on superparamagnetic iron oxide nanoparticles. When loaded with Ni(II), these NTA-immobilized nanoparticles were shown to bind His × 6-tagged proteins in their native, folded conformations with retained activity that commercial microbeads fail to bind under identical conditions. A series of control experiments suggest that the multivalency strategy can be utilized to enhance the binding of His × 6-tagged proteins in their native, folded conformations. We further demonstrated the selective purification of His × 6-tagged proteins from direct cell lysates by using the Ni(II)-loaded magnetic nanoparticles. The present platform is capable of efficient purification of His × 6-tagged proteins that are expressed at low level in mammalian cells. This work thus presents a novel nanoparticle-based high-capacity protein purification system with shorter incubation times, proportionally large washes, and significantly smaller elution volumes compared to currently available microbeads.

Received July 10, 2006; Revised Manuscript Received November 19, 2006

For many therapeutic applications, it has become more and more important to find synthetic compounds that have the ability to transport a variety of drugs and cargo molecules into cells and tissues. Like arginine-rich cell-penetrating peptides (CPPs), it is already known that peptide mimetics such as β-peptides and peptoids can also express a transport function. In this study, ten fluorophore-labeled chiral and achiral peptoids with different backbone lengths and side chains as well as three peptoids coupled to a therapeutically active porphyrin moiety were prepared using a highly modular solid-phase synthesis (SPP) approach. To compare the structural determinants with the cellular uptake efficiency, all peptoids were analyzed by live cell imaging. All cells show an even vesicular distribution of the internalized peptoids, also revealing that a vesicular escape into the cytosol was stronger for peptoids with longer backbones. Moreover, the uptake efficiency correlated with both the incubation time and the given concentration. Toxicology tests and uptake experiments with porphyrin-coupled peptoids indicate their suitability for application as robust and readily available drug delivery systems or intracellular probes.

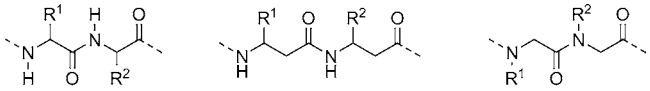
INTRODUCTION

During studies on viruses in the late 1980s, it was found that HIV-1 trans-activator of transcription (Tat), a protein of 101 amino acids essential for HIV-1 replication, is rapidly taken up from the culture medium by cultured cells (*1*, *2*). It turned out that only a small proportion of the protein was responsible for the internalization of the whole protein. The relevant peptide comprises residues 49−57, which mainly are basic amino acids (*3*−*7*).

Similar properties were found for short basic domains in the *Drosophila* Antennapedia homeobox protein (*8*) and in the *Herpes simplex* protein VP22 (*9*). Thus, a rapid development was triggered, in which more peptides with the capability to enter cells were discovered, and a broad variety of cargo molecules was delivered into cultured cells.

Initial assays suggested that these peptides could directly penetrate the plasma membrane by a novel mechanism that became known as protein transduction. Therefore, the new class of peptides was referred to as protein transduction domains (PTDs). After the development of synthetic delivery peptides, the term cell-penetrating peptides (CPP) was coined to refer to naturally occurring PTDs and their functional homologs from organic synthesis (*10*−*12*).

It has been shown that cell-penetrating peptides (CPPs) have a high potential to deliver drugs and reporter molecules into cultured cells, and even into cells in fully grown organisms (*13*, *14*). However, many CPPs derived from natural polypeptide sequences do not fulfill any known function *in vivo*. Presumably, they have not been optimized by evolutionary processes. This creates the possibility to improve the cell-penetrating function of these molecules by varying their amino acid sequence. Synthetic peptides with enhanced delivery properties have already been synthesized (*6*, *15*−*19*), and the synthesis of many peptide analogs that mimic CPP function are already described (*3*, *20*−*24*). Most of these contain a majority of basic amino acids.



However, arginine-rich peptides are sensitive to oxidation and degradation by proteases, which requires great care to be taken when working with CPP-coupled substances. This sensitivity also reduces their lifespan, bioavailability, and blood circulation time *in vivo* making them unsuitable for oral application and preventing them to reach the target tissue. Moreover, peptides may be recognized as epitopes and trigger immunogenic responses. Peptide mimetics that circumvent these disadvantages provide a wider range of possible application in living organisms. Once the synthesis of effective structures is established, the process can further be improved to achieve structures exhibiting low toxicity and optimized pharmacokinetic properties.

As shown for natural and synthetic CPP analogs, an α-helical and amphipathic structure can be advantageous for cellular uptake (*25*). Apparently, a high density of positively charged side chains appears to be the most important feature for enhanced cellular uptake efficiency. Therefore, backbone mimetics need to be equipped with basic functional groups such as amine or guanidinium groups in order to exhibit cell-penetrating behavior.

In particular, β-peptides (*2*) have been studied intensively in recent years (Figure 1) (*24*). With one methylene unit inserted between the carboxyl group and the former α-carbon, these backbone analogs constitute higher homologs of the α-peptides (*1*). They form stable helices that are structurally more confined

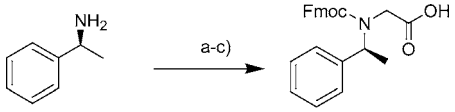
than those formed by α-peptides or α-peptide analogs. Furthermore, they are stable against protease degradation. It has also been shown that β-peptides equipped with amino and guanidino groups can be internalized by cultured mammalian cells (*3*). However, they are more or less resistant to clearance through the kidneys.

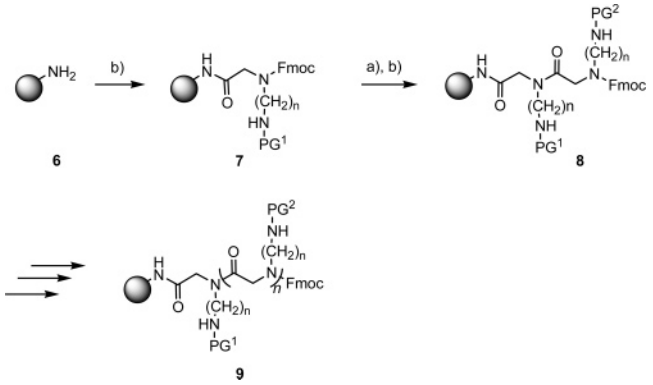


Likewise, oligo-N-alkylglycines (*3*), more commonly known as peptoids, have been subject to intensive studies to investigate cell behavior and synthetic pathways (*3*, *26*, *27*). As opposed to α-peptides, the side chains are attached to the nitrogen so that the monomers can be readily synthesized from a reaction of functionalized diamines with 2-bromoacetic acid (Figure 1). Peptoids with guanidinium headgroups attached to alkyl chains of varying lengths are taken up by mammalian cells (*3*). These peptoids have been successfully used to mimic peptide hormones, antibiotics, and receptor ligands (*28*).

Besides the studies that already exist on peptoids as molecular transporters, the aim of this study was to compare the cellular uptake efficiency and the toxicology of cargo-coupled peptoids with different chiral and achiral side chains and backbone length to design effective molecular transporters for use in drug delivery or as molecular probes for bioconjugation.

EXPERIMENTAL PROCEDURES

Synthesis of the Building Blocks. Monomeric building blocks were built up from diamines **4**{*x*} (*x* = 4, 6, 8) (90.0 mmol, 1.00 equiv) with varying lengths (C4, C6, and C8, respectively) (Scheme 1). After protecting the amino group with either *tert*-butyloxycarbonyl (Boc) (11.7 mmol, 0.13 equiv) or 2-nitrophenylsulfonyl (*o*-nosyl) (11.7 mmol, 0.13 equiv), in order to permit orthogonal deprotection of the side chains the monoprotected diamines were subsequently reacted with ethyl bromoacetate (1.00 equiv). Then, the resulting amino acetic acid esters were hydrolyzed with sodium hydroxide. The secondary amines were finally protected with 9-fluorenylmethoxycarbonyl (Fmoc) (1.00 equiv) to yield ready-to-use **5**{*x*} (*x* = 4, 6, 8) as building blocks for solid-phase synthesis (Scheme 1). An additional chiral building block **5**{**1***} was also synthesized (Scheme 2). Instead of a protected amino side chain, it contains an aromatic ring derived from (*S*)-1-phenylethylamine (**4**{**1***}) (*29*, *30*) that had been reacted with ethyl bromoacetate, hydrolyzed, and protected with Fmoc to yield a chiral monomer **5**{**1***}, which enforced steric restrictions upon the conformation of the assembled peptoid (Scheme 2).



Scheme 2. Chiral Building Block 5{1*} Derived from (*S*)-1-Phenylethylamine 4{1*} in a Three-Step Synthesis[a]

4{1*} **5{1*}**

[a] Reaction conditions: (a) *tert*-butyl bromoacetate, KI, K_2CO_3, DMF; (b) 9*H*-fluorene-9-ylmethoxycarbonyl-*N*-hydroxy succinimide, THF, 0 °C − RT, 12 h; (c) HCl/H_2O, reflux, 2 h.

Scheme 3. Solid-Phase Synthesis of Peptoids[a]

6 **7** **8** **9**

[a] (a) 20% Piperidine in DMF, 3 × 2 min; (b) 2.00 equiv monomer, 2.00 equiv PyBrOP, 4.00 equiv DIPEA, CH_2Cl_2, RT, 24 h.

Solid-Phase Synthesis. *General Procedure A (Construction of the Peptoids).* For activation, the amino-functionalized Rink amide resin **6** (0.510 mmol, 1.00 equiv) was suspended in dichloromethane (5 v/v) and allowed to swell at room temperature for 30 min. After removal of the solvent, the Fmoc protection group of the linker amine was removed by incubation of the resin with 6 mL piperidine solution (20% in DMF) for 2 min. This procedure was repeated twice. For the coupling step, the crystalline Fmoc-protected building block **5a**{*x*} (**5b**{*x*}) (1.530 mmol, 3.00 equiv) was added to the resin followed by PyBrOP (1.02 mmol, 2.00 equiv) and DIPEA (2.04 mmol, 4.00 equiv), and the mixture was suspended in dichloromethane (6 mL) and shaken at room temperature for 24 h. Then, the resin was filtered and sequentially washed with MeOH/DMF/MeOH (2 cycles each), THF/MeOH/THF/MeOH/THF/pentane/dichloromethane (3 cycles each) and pentane (4 cycles). Finally, the resin was dried *in vacuo* (10^{-2} mbar) for 48 h. Coupling of the respective monomers to the growing peptoid chain proceeded under the same conditions as the attachment of the first building block to the solid support. All reaction procedures were succeeded by repetitive cycles of coupling and deprotection until a peptoid of the desired length was obtained. The procedure is outlined in Scheme 3.

General Procedure B (Labeling and Bioconjugation). Prior to attaching a fluorophore or other cargos to the peptoids, *N*-Fmoc-aminohexanoic acid was coupled as a spacer to prevent steric hindrance between fluorophore/conjugate and transporter. The immobilized peptoid was first deprotected as described in general procedure A. This step was repeated twice. For the coupling step of the spacer, *N*-Fmoc-aminohexanoic acid (0.250 mmol, 3.00 equiv) was added to the resin. PyBrOP (0.160 mmol, 2.00 equiv) and DIPEA (0.330 mmol, 4.00 equiv) were added as activating reagents and the suspension was agitated at room temperature for 24 h in 6 mL of dichloromethane. Then, the resin was filtered and washed as described in General Procedure A. Finally, the resin was dried *in vacuo* for 48 h. After reswelling of the resin and deprotection with piperidine solution (as described in General Procedure A), the fluorophore **11a**

(**11b**) or carboxyporphyrin **12** (0.250 mmol, 3.00 equiv) was attached as described in General Procedure B1.

General Procedure B1. For activation of the fluorophore, 5(6)-carboxyfluorescein (**11a**) or carboxyporphyrin **12** (0.250 mmol, 3.00 equiv) and HOBt (0.250 mmol, 3.00 equiv) were transferred into a 50 mL flask and dissolved in 2 mL of dichloromethane/DMF (1:1 (v/v)). After addition of DIC (0.250 mmol, 3.00 equiv), the mixture was shaken at room temperature for 20 min and eventually added to the prepared resin derived from General Procedure B. The suspension was agitated at room temperature for 5 h (5(6)-carboxyfluorescein (**11a**)) and 24 h (carboxyporphyrin **12**), respectively.

For rhodamine labeling, rhodamine-B-isothiocyanate (**11b**) (3.00 equiv in dichloromethane) was added to the prepared resin derived from General Procedure B, without activation. The mixture was agitated in dichloromethane/DMF (5 vol according to the initial resin volume) for 4 days.

General Procedure C (Nosyl Deprotection). For the deprotection of the nosyl-functionalized amino groups, the resin (0.090 mmol, 1.00 equiv) was suspended in dichloromethane (3 v/v) and allow to swell at room temperature for 30 min. After filtration, the resin was deprotected by treatment with 3 mL of 2-mercaptoethanol/DBU (diaza-[5.4.0]-bicycloundecene) (0.3 M) in DMF. The suspension was shaken for 45 min. The solution was removed, and the deprotection step was repeated twice. The resin was filtered, washed, and dried as described in General Procedure A.

General Procedure D (Cleavage and Isolation). For the cleavage of the peptoid from solid support, the resin was transferred into a 25 mL flask and suspended in 1 mL of TFA/TIS (95:5 (v/v)). The suspension was gently agitated at room temperature for 3 h under argon atmosphere. Then, the resin was filtered and rinsed with TFA (2 × 3 mL): The filtrates were collected and combined. The peptoid was precipitated from the filtrate by gently pivoting with 50 mL of cold diethyl ether (−78 °C). It was filtered and finally dried in vacuo.

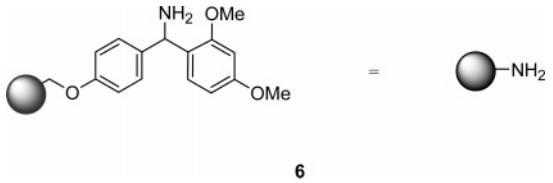
Fluorophore-Coupled Peptoids. *Fluo-{4,4,4,4}-NH₂.* Following General Procedures A, B, and D, the tetramer was obtained as yellow solid in a yield of 0.173 g (quant). TLC (silica gel: RP-18 F_{254s}): CH_3CN/H_2O (1:1 (v/v) (+1 drop TFA)); $R_f = 0.55$. MS (FAB, matrix: glycerol), *m/z* (%) [norm: 472]: 1001 (50) $[M + H]^+$, 873 (32) $[M -$ monomer$]^+$, 745 (18) $[M - 2\times$ monomers $+ H]^+$, 600 (97) [Fluo + spacer + monomer + H]$^+$, 472 (100) [Fluo + spacer]$^+$. HRMS (FAB): exact mass ($C_{51}H_{72}N_{10}O_{11}$), calcd 1000.5382 g/mol, found 1000.5380 g/mol. IR (drift): $\nu = 3046$ (s), 2949 (s), 2088 (vs), 1679 (s), 1204 (s), 1182 (s), 1137 (s), 837 (s), 800 (s). UV/vis (CH_3OH): λ_{max} (log ϵ) = 202 (4.8), 459 (2.8).

Fluo-{6,6,6,6}-NH₂. Following General Procedures A−D, the peptoid was obtained as a brown, viscous solid in a yield of 0.051 g (46%). TLC: chloroform/methanol (5:1 (v/v)); R_f = 0.2; strong, green fluorescence in UV light. MS (FAB, matrix: mNBA), *m/z* (%): 1113 (4) $[M + H]^+$, 755 (4) [M − Fluo + H]$^+$, 486 (16) [trimer + H]$^+$, 307 (100) $[2M_a + H]^+$. HRMS (FAB): exact mass ($C_{59}H_{89}N_{10}O_{11}$), calcd 1113.671 g/mol, found 1113.667 g/mol. IR (drift): $\nu = 2942$ (w, br), 1679 (w), 1547 (w), 1468 (w), 1317 (w), 1203 (w), 1137 (w).

Rhod-{8,8,8,8}-NH₂. The dry resin was reacted as in General Procedures A, B, and D. The tetramer was obtained as a purple solid in a yield of 0.165 g (74%). TLC (silica gel: RP-18 F_{254s}): CH_3CN/H_2O (1:1 (v/v) (+1 drop TFA)); $R_f = 0.49$. MS (FAB (LR), matrix: glycerol), *m/z* (%) [norm: 867]: 1367 (6) $[H]^+$, 1183 (5) $[M -$ monomer$]^+$, 867 (100) $[M -$ Rhod$]^+$, 683 (31) [M − Rhod − monomer]$^+$, 500 (66) [Rhod]$^+$. HRMS (FAB): exact mass ($C_{46}H_{95}N_{10}O_5$), calcd 867.7487 g/mol, found 867.7484 g/mol. IR (drift): $\nu = 2940$ (s), 2864 (s), 2088 (vs), 1682 (s), 1204 (s), 1181 (s), 1137 (s). UV/vis (CH_3OH): λ_{max} (log ϵ) = 196 (4.5), 256 (3.6), 283 (3.5), 351 (2.9), 399 (2.6), 553 (4.0).

Fluo-{6,1,6,1*,6}-NH₂.* As in General Procedures A−D, the pentamer was obtained as a brown solid in a yield of 0.200 g. Strong, green fluorescence in UV light (366 nm).

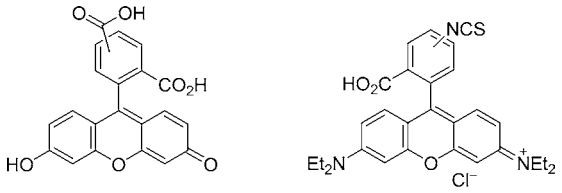
Rhod-{4,4,4,4,4,4}-NH₂. The resin were treated as in General Procedures A, B, and D. The product was obtained as a red-brown solid. Yield: 0.088 g (39%). TLC (silica gel: RP-18 F_{254s}): CH_3CN/H_2O (1:1 (v/v) (+1 drop TFA)); $R_f = 0.42$. MS (FAB (LR), matrix: glycerol), *m/z* (%) [norm: 899]: 1399 (76) $[M]^+$, 1271 (22) $[M -$ monomer$]^+$, 1144 (18) [M − 2 monomers + H]$^+$, 916 (32) [M − 3× monomers + H]$^+$, 899 (100) [M− Rhod]$^+$, 888 (56) [M − 4× monomers + H]$^+$, 760 (52) [M − 5× monomers + H]$^+$. HRMS (FAB): exact mass ($C_{42}H_{87}N_{14}O_7$), calcd 899.6882 g/mol, found 899.6879 g/mol. UV/vis (CH_3OH): λ_{max} (log ϵ) = 200 (4.7), 257 (3.8), 354 (3.0), 547 (4.0).



Fluo-{6,6,6,6,6,6}-NH₂. As described in General Procedures A−D, the product was obtained as a brown solid. Yield: 0.066 g (60%). TLC: chloroform/methanol (5/1); $R_f = 0.03$; strong, green fluorescence in UV light (366 nm). MS (MALDI, matrix: DHB), *m/z* (%): 1463.891 (52) [M + K]$^+$, 1447.914 (100) [M + Na]$^+$, 1425.923 (62) [M + H]$^+$, 799 (45) [pentamer + H]$^+$, 486 (6) [trimer + H]$^+$. IR (drift): $\nu = 2940$ (m, br), 2100 (vw), 1677 (m), 1466 (w), 1203 (w), 1135 (w).

Fluo-{8,4,8,4,8,4}-NH₂. The resin was reacted as in General Procedures A, B, and D. The peptoid was obtained as a red-brown solid in a yield of 0.042 g. TLC: chloroform/methanol (2/1); $R_f = 0.05$; strong, green fluorescence in UV light (366 nm). MS (MALDI, matrix: DHB), *m/z* (%): 1463.814 (31) [M + K]$^+$, 1447.914 (41) [M + Na]$^+$, 1425.863 (28) [M + H]$^+$, 771(94) [pentamer + H]$^+$, 458 (88) [trimer + H]$^+$. IR (drift): $\nu = 2937$ (w, br), 2082 (vw), 1758 (m), 1682 (w), 1457 (w), 1203 (w), 1136 (w).

Rhod-{6,6,6,6,6,6,6,6}-NH₂. Followed General Procedures A, B, and D, the product was received as a purple solid. Yield: 0.268 g (89%). TLC (silica gel: RP-18 F_{254s}): CH_3CN/H_2O (1:1 (v/v) (+1 drop TFA)); $R_f = 0.32$. MS (FAB (LR), matrix: glycerol), *m/z* (%) [norm: 1223]: 1880 (20) [M+ H]$^+$, 1722 (26) [M − monomer]$^+$, 1567 (36) [M − 2× monomers + H]$^+$, 1380 (66) [M − Rhod]$^+$, 500 (>100) [Rhod]$^+$. HR−MS (FAB (HR), matrix: glycerol), *m/z* (%): exact mass ($C_{40}H_{84}N_{11}O_5$), calcd 798.6657; found 798.6655. IR (drift): $\nu = 2945$ (s), 2868 (s), 2088 (vs), 1680 (s), 1204 (s), 1182 (s), 1136 (s). UV/vis (CH_3OH): λ_{max} (log ϵ) = 196 (4.8), 257 (3.8), 282 (3.6), 353 (3.2), 550 (4.1).



Fluo-{8,8,8,8,8,8,8,8}-NH₂. The resin was processed following General Procedures A, B, and D. Yield: 0.245 g (79%). The peptoid was a yellow-orange solid. TLC (silica gel: RP-18 F_{254s}): CH_3CN/H_2O (1:1 (v/v) (+1 drop TFA)); $R_f = 0.41$. MS (FAB (LR), matrix: glycerol), *m/z* (%) [norm: 1123]: 1960 (3) [M − H]$^+$, 1778 (20) [M − monomer + H/M* + H]$^+$, 1603 (10) [M − Fluo + H]$^+$, 1419 (98) [M − monomer − Fluo + H/M* − Fluo + H]$^+$, 938 (150) [5er + H]$^+$. HR−MS (FAB (HR), matrix: glycerol), *m/z* (%): exact mass ($C_{50}H_{104}N_{11}O_5$), calcd 938.8222; found 938.8220. IR (drift): ν = 2940 (m), 2864 (s), 2102 (vs), 1680 (m), 1204 (m), 1137 (s).

Fluo-{8,4,8,4,8,4,8,4}-NH₂. As in General Procedures A, B, and D, the product was obtained. Yield: 0.021 g. The peptoid was a brown, viscous solid. Strong, green fluorescence in UV light (366 nm). MS (MALDI, matrix: DHB), *m/z* (%): 1760.149 (33) [M + Na]$^+$, 1738.170 (15) [M + H]$^+$, 793 (100) [pentamer + Na]$^+$, 648 (89) [tetramer − NH_2 + Na]$^+$. IR (drift): ν = 2939 (m, br), 2101 (vw), 1758 (w), 1682 (m), 1472 (w), 1203 (m), 1134 (w).

For further information and detailed experimental procedures for the synthesis of the building blocks and the solid-phase synthesis, see Supporting Information.

Purification of Peptoids. Lyophilized samples of peptoids were dissolved in methanol to yield a 10 mM stock solution. To analyze the peptoid composition, 1 μL of the stock solution was diluted in 1 mL of methanol and was analyzed by MALDI-TOF mass spectrometry. A 2 μL aliquot of the stock solution was diluted in 120 μL of low-salt buffer (5% acetonitrile, 100 mM TEAB), and 100 μL of this solution was purified chromatographically on a Nucleosil-120 RP-18 column (Knauer)

Cellular Uptake of the Peptoids. For general cell culture procedures, preparation of mammalian cells and cell fixation procedures, see Supporting Information.

RESULTS

To mimic CPP function and to enhance cellular uptake, the peptide structure was altered to that of a peptoid. In spite of previous work, showing peptoid suitability as molecular transporters carrying a variety of cargo into cells, there are still many unanswered questions. For example, the correlation between backbone and side chain length is yet uncertain, and the composition, the uptake efficiency, and the mechanisms of cellular uptake are not yet elucidated. In our approach, ten different peptoids (Figure 5) with varying lengths, side chain lengths, and compositions were synthesized, as depicted in Schemes 1−4 and Figures 5 and 6. After initial experiments, the various peptoids were tested in cell culture in order to assess the effect of structural deviation patterns on uptake efficiency and cellular distribution.

The outlined syntheses are somewhat modified from those described by Bradley et al. (*31*, *32*), which are all performed on solid support. Solid-phase reactions greatly facilitate the synthesis, as the growing oligomer attached to a solid support can easily be purified from excess reactants by washing the resin with the appropriate solvents and subsequently filtering. Scheme 3 represents the outline of the peptoid synthesis on solid support using different monomeric building blocks and fluorophores or cargo. For this study, a Rink amide resin **6** (Figure 2) was chosen due to its stability at ambient conditions, the ease of the first coupling step, and the mild cleavage conditions. Moreover, the reaction conditions for almost all coupling steps are the same as for the attachment of the first building block to the resin. The outlined synthesis allowed the protection of the free amino groups of the side chains with either o-nosyl (Ns) or Boc, while the N-terminal amino group was protected with Fmoc. Fmoc has been well-established in peptide chemistry, as it can be quantitatively removed under mild conditions in a short reaction time. The peptoid-backbone synthesis was finished by either the coupling of a fluorophore or a cargo (Scheme 4, Figures 3 and 4). The fluorophore was required to monitor the cellular uptake of the different peptoids by live cell imaging. 5(6)-Carboxyfluorescein **11a** (λ_{abs} = 492 nm, λ_{em} = 517 nm) as well as rhodamine-B-isothiocyanate **11b** (λ_{abs} = 550 nm, λ_{em} = 580 nm) (Figure 3) were coupled to the peptoids (designated as **Fluo** and **Rhod**) (Figure 3) prior to cleavage from the solid phase to permit simultaneous tests of different labeled peptoids on the same cultured cells for future investigations. 6-Aminohexanoic acid was used as a linker to prevent interactions of the fluorophore or cargo with the peptoid moiety. As outlined in Scheme 4, the Fmoc-protected linker molecule was attached to the amino terminus of the peptoids under standard coupling conditions. 5(6)-Carboxyfluorescein **11a** formed a peptide bond via its carboxyl group under mild coupling conditions without detectable side reactions. In this reaction step, 1-hydroxybenzotriazole (HOBt) and diisopropylcarbodiimide (DIC) were used to activate the carboxyl function, while no activating substances were required to form the thiourea bond between rhodamine-B-isothiocyanate and the amine.

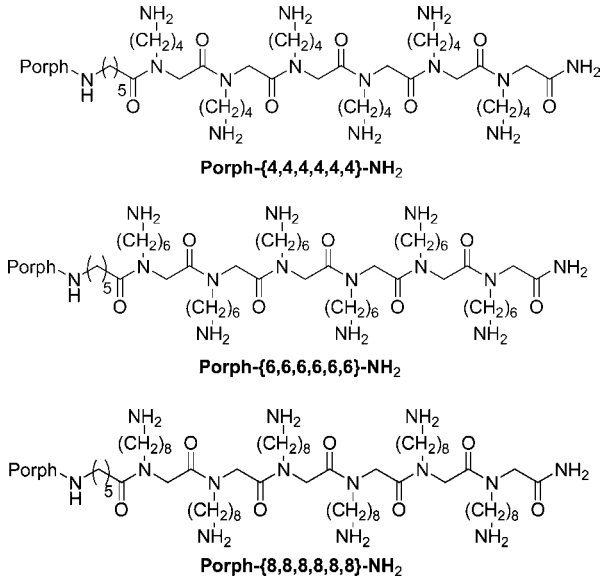

Figure 6. Peptoids conjugated with carboxyporphyrin **12** after deprotection and cleavage from the solid phase.

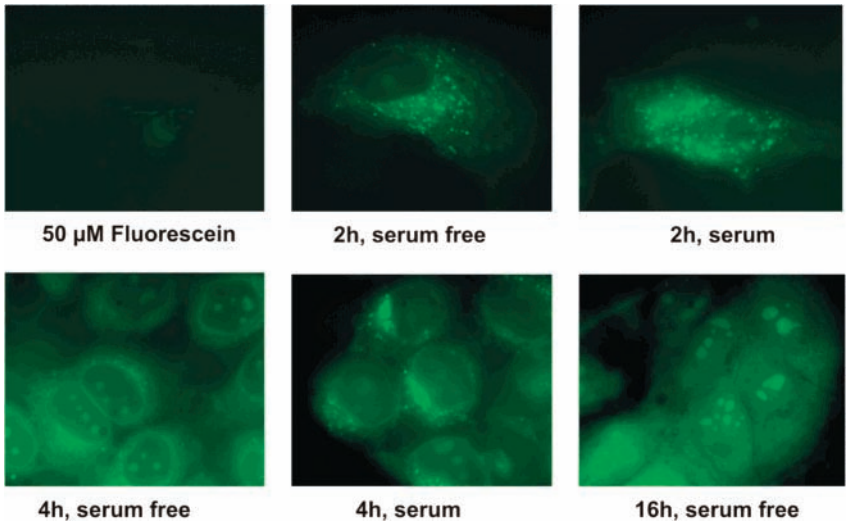

Figure 7. Decreases in serum levels led to changes in cell morphology already after 2 h of incubation. COS7 cells incubated for 2, 4, and 6 h in −FCS and +FCS culture media treated with 50 μM of hexapeptoid **Fluo**-{**6,6,6,6,6,6**}-$\mathbf{NH_2}$ are shown.

In the final step, the labeled peptoids **Rhod**-{$\boldsymbol{n^m}$}-$\mathbf{NH_2}$/**Fluo**-{$\boldsymbol{n^m}$}-$\mathbf{NH_2}$ were simultaneously deprotected and cleaved from the solid phase by treatment with trifluoroacetic acid (TFA)/triisopropyl silane (TIS). Peptoids containing the o-nosyl protection group had to be deprotected by treatment with 2-mercaptoethanol and diaza-[5.4.0]-bicycloundecene (DBU) prior to cleavage from the solid support. The free peptoids were precipitated with cold diethyl ether and dried *in vacuo*. The peptoids were characterized by nuclear magnetic resonance spectroscopy and mass spectrometry and were subjected to reversed-phase chromatography on RP-18 to reveal a purity of >95%.

Figure 5 represents the ten peptoids that were used for the study. The peptoids comprise different building blocks, which are indicated by the nomenclature used in Figure 5. Each number in the brackets indicates one monomeric building block that was synthesized from a diamine **4**{$\boldsymbol{x}$} ($x = 4, 6, 8$) of a certain chain length x (x = 4, 6, and 8 from C4, C6, and C8, respectively). As shown in Figure 5, the peptoid backbone comprises 4, 5, 6, and 8 of such building blocks. Peptoid **Fluo**-{**6,6,6,6**}-$\mathbf{NH_2}$ was composed of four monomers with C6 side chains (**5**{**6**}), in which the side chain amino groups were protected during SPPS with o-nosyl or Boc protecting groups. Likewise, peptoid **Fluo**-{**6,6,6,6,6,6**}-$\mathbf{NH_2}$ was assembled with two additional Boc-protected C6-building blocks. Peptoids **Fluo**-{**8,4,8,4,8,4**}-$\mathbf{NH_2}$ and **Fluo**-{**8,4,8,4,8,4,8,4**}-$\mathbf{NH_2}$ were synthesized with six and eight building blocks, respectively, with alternating C4 (**5b**{**4**}) and C8 (**5b**{**8**} (n = 3)) side chains (Scheme 1).

Peptoid **Fluo**-{**6,1*,6,1*,6**}-$\mathbf{NH_2}$ was synthesized as a pentamer starting with an o-nosyl protected C6-monomer **5b**{**6**} followed by an alternating sequence of two chiral building blocks **5**{**1***} and two Boc-protected C6 monomers **5**{**6**} (see Scheme 2 and 3).

The peptoids **Fluo**-{**4,4,4,4**}-$\mathbf{NH_2}$, **Rhod**-{**4,4,4,4,4,4**}-$\mathbf{NH_2}$, **Rhod**- {**6,6,6,6,6,6,6,6**}-$\mathbf{NH_2}$, **Rhod**-{**8,8,8,8**}-$\mathbf{NH_2}$, and **Fluo**-{**8,8,8,8,8,8,8,8**}-$\mathbf{NH_2}$ were synthesized with Boc-protected building blocks **5a**{**4**}, **5a**{**6**}, and **5a**{**8**} (Scheme 1).

All further experiments with the fluorescein (Fluo), rhodamine (Rhod), and porphyrin-labeled compounds were performed in the dark to avoid photobleaching of the light-sensitive chromophores. Further synthesis details can be found in the Supporting Information.

Cellular Uptake of Fluorescein-Labeled Peptoids. The fluorescein and rhodamine-labeled peptoids obtained by solid-phase synthesis were tested in cultured mammalian cells for their potential to act as molecular transporters. The minimal concentrations required for visible uptake and the maximum nontoxic concentrations were estimated. Live cell imaging by fluorescence and confocal microscopy enabled visualization of the uptake mode and intracellular localization of the internalized compounds.

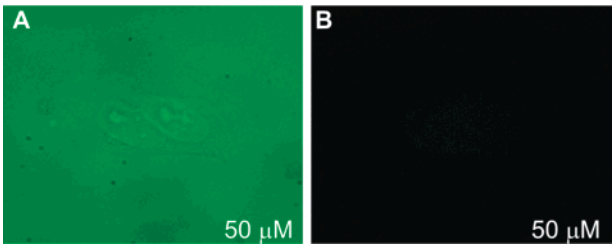

Figure 8. Uncoupled 5(6)-carboxyfluorescein **11a** was not taken up by mammalian cells. HeLa cells were incubated with 50 μM 5(6)-carboxyfluorescein **11a** for 16 h at 37 °C. The same picture was taken in transmission (A) and fluorescence mode (B).

The peptoids were tested on both human and simian cancer cell lines (HeLa and COS7, respectively), as well as on human primary fibroblasts. At the beginning of the cell culture experiments, the appropriate treatment conditions had to be determined. Serum-free media versus serum-containing media was tested, since many drug delivery and transfection reagents have been shown to be sensitive to serum due to interaction with serum proteins and other serum ingredients. On the other hand, the cells might suffer from lack of serum for prolonged times.

With reference to recent findings, which demonstrated that fixation procedures led to artifactual uptake and nuclear localization of cationic amphiphiles and other cationic molecules (*23*, *33*, *34*), cellular uptake of the amphiphilic peptoids was visualized by live cell imaging. Cells fixed with paraformaldehyde (PFA) did indeed show different intracellular distribution of the peptoids from living cells. They exhibited cytosolic staining with remarkably fewer vesicular structures and an accumulation of fluorescence in the nucleus.

To avoid fixation artifacts, all images were taken from living cells. Tetrapeptoid **Fluo**-{**6,6,6,6**}-$\mathbf{NH_2}$ was dissolved in serum-containing (+FCS) or serum-free (−FCS) culture media to yield final concentrations of 5, 10, 50, 100, and 500 nM and 1 μM, respectively. Uncoupled 5(6)-carboxyfluorescein was used as a control (Figure 8)

The cells were grown to 10−20% confluency in an eight-well LabTek chamber slide coated with fetal calf serum (FCS).

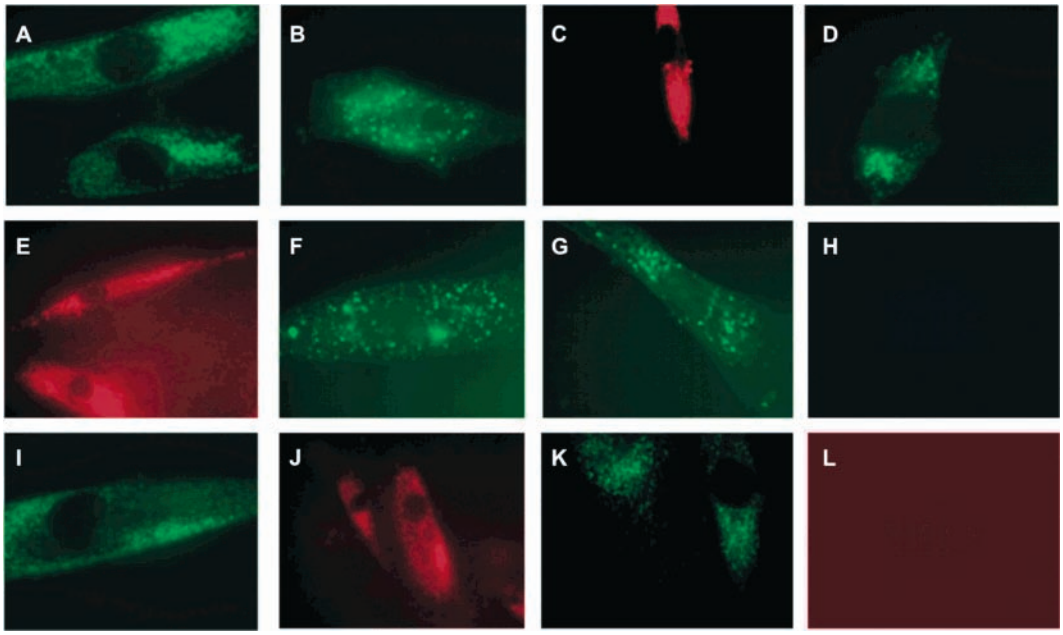

Figure 9. Comparison of the ten peptoids A, **Fluo**-{**4,4,4,4**}-NH_2; B, **Fluo**-{**6,6,6,6**}-NH_2; C, **Rhod**-{**8,8,8,8**}-NH_2; D, **Fluo**-{**6,1*,6,1*,6**}-NH_2; E, **Rhod**-{**4,4,4,4,4,4**}-NH_2; F, **Fluo**-{**6,6,6,6,6,6**}-NH_2; G, **Fluo**-{**8,4,8,4,8,4**}-NH_2; I, **Fluo**-{**8,4,8,4,8,4,8,4**}-NH_2; J, **Rhod**-{**6,6,6,6,6,6,6,6**}-NH_2; K, **Fluo**-{**8,8,8,8,8,8,8,8**}-NH_2; and as controls H, 5(6)-carboxyfluorescein, **11a**; (50 μM) and L, rhodamine-B-isothiocyanate, **11b** (50 μM). All peptoids were tested on human primary fibroblasts in a concentration of 10 μM. To visualize uptake, the cells were incubated with the peptoids solution for 24 h and analyzed by confocal microscopy.

The medium was replaced by half of the final volume of medium +FCS or −FCS, and a doubly concentrated peptoid solution in Dulbecco's Modified Eagle Medium (DMEM) was added dropwise, while constantly rocking the culture dish to ensure a homogeneous distribution of the compound. After an incubation of 5, 20, 60, or 120 min at 37 °C, the peptoid-containing medium was removed and the cells were washed with fresh medium without phenol red to facilitate the imaging.

No signal could be detected at concentrations below 1 μM, which could be attributed to the weak intensity of fluorescein fluorescence or to the small amounts taken up by the cells. Therefore, subsequent experiments were carried out at 10, 20, 50, and 100 μM as described for the related peptoid in a similar study (Figure 7) (*31*). Although these dosages were high, and despite the fact that cationic amphiphiles are mainly stored in the endosomal compartment and will eventually lead to the disruption of the latter (*35*), the experiments were still performed to determine the fate of the peptoids.

In all experiments, the fluorescent peptoids were detected in vesicular structures, in which the fluorescence accumulated. However, after short incubation, the nucleus remained devoid of fluorescence.

Similar to other cationic amphiphiles, it was assumed that the peptoids were protonated, when they reach the acidic compartments. Thus, they interacted with any kind of negatively charged lipids or aggregate, while slowly being released into the cytosol by endosomal escape, a mechanism, which is currently under investigation but not fully understood (*36*). Alternatively, the amide bond linking the fluorophore to the transporter could have been cleaved so that the nonpolar cargo molecule could diffuse into the cytosol. Apart from the staining of those vesicular structures, a perinuclear accumulation of these fluorescent structures was visible in almost all experiments.

In control experiments with hexameric **Fluo**-{**6,6,6,6,6,6**}-NH_2, prolonged incubation in FCS-depleted (−FCS) media led to significant changes in cell morphology and cell death, as depicted in Figure 7. Therefore, subsequent tests were carried out in serum-containing media.

The observed vesicular structures indicated an endocytosis-like mechanism for the uptake of the peptoids. Thus, the

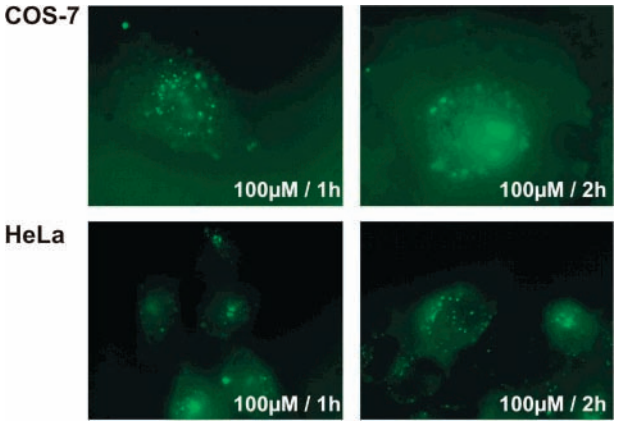

Figure 10. Treatment of COS7 (top row) and HeLa cells (bottom row) with 100 μM of the tetrameric peptoid **Fluo**-{**6,6,6,6**}-NH_2 coupled to fluorescein. Left panel: Vesicular structures accumulated in the perinuclear region can be seen after 1 h. Right panel: 2 h after treatment, the compound has entered the nucleoli of both cell types.

experiment was repeated with incubation times of 4 and 16 h, to monitor the fate of the vesicular structures and to investigate whether the fluorescent peptoids were able to escape into the cytosol. Cell treatment was facilitated by direct application of the peptoid-containing medium without rocking of the culture plate. To avoid strong background fluorescence normally observed at high peptoid concentrations, additional washing steps with 0.2% BSA solution in PBS and a short trypsin treatment were carried out.

Under the given conditions, uncoupled 5(6)-carboxyfluorescein (**11a**) was not taken up by mammalian cells, even when incubated overnight at high concentrations (16 h, Figure 8).

In further experiments, it was shown that the other fluorescein-labeled peptoids **Fluo**-{**8,4,8,4,8,4**}-NH_2, **Fluo**-{**8,4,8,4,8,4,8,4**}-NH_2, and **Fluo**-{**6,1*,6,1*,6**}-NH_2 were taken up by all cell types. Fluorescence and confocal microscopy also revealed that all peptoids had entered the interior of all cells.

At the applied concentrations of 10 μM to 100 μM, intracellular fluorescence was clearly visible (Figures 9−14).

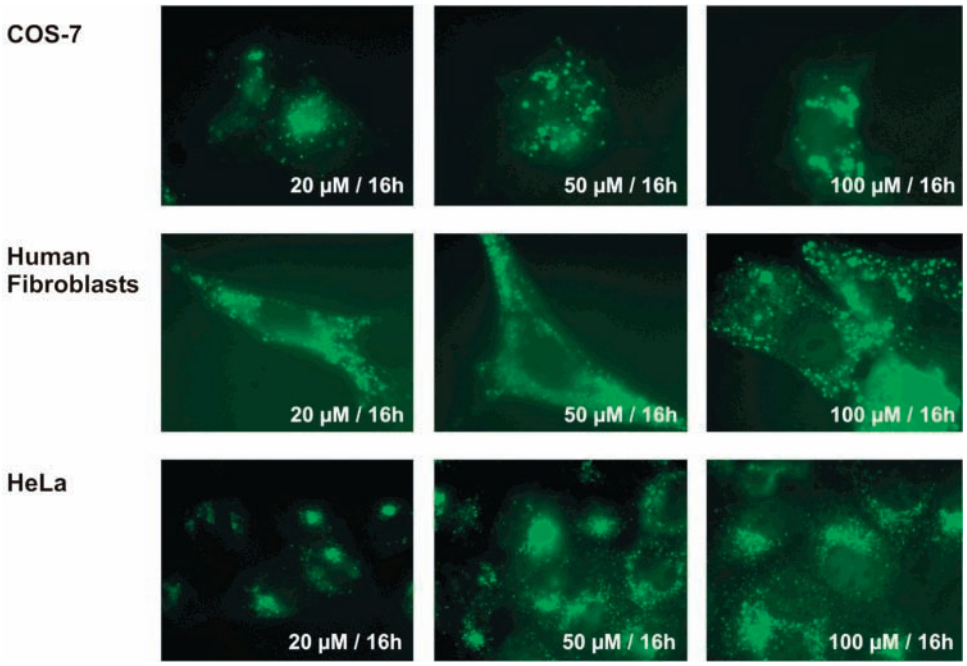

Figure 11. Overnight incubation of COS7 (top row), human fibroblasts (middle row), and HeLa-cells (bottom row) with the chiral pentameric peptoid **Fluo**-{**6,1*,6,1*,6**}-$\mathbf{NH_2}$. At concentrations of 20, 50, and 100 μM, the fluorescence was localized in vesicular structures after incubation overnight. Diffuse fluorescence was observed within the interior of all cells.

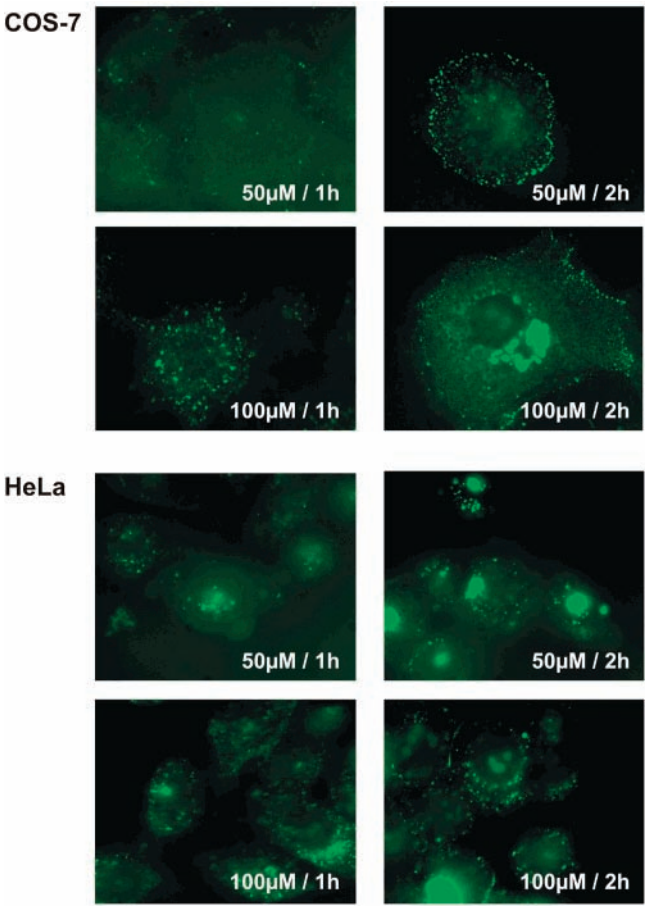

Figure 12. Overnight incubation of COS7 and HeLa cells with 100 μM of the hexameric fluorescein-labeled peptoid **Fluo**-{**6,6,6,6,6,6**}-$\mathbf{NH_2}$. Fluorescence was found concentrated in vesicular structures and more diffuse within the interior of the cells. Note the assembly of vesicular structures along the plasma membrane of the COS7 cells.

However, it is worth mentioning that the uptake rate of all tested peptoids was dependent on the applied concentration in correlation to the duration of the incubation. At lower concentrations, as low as 1−10 μM, all peptoids could only be detected after longer exposure times (24 h and longer) (Figure 9). All peptoids showed similar uptake efficiency and no significant differences in cellular distribution at 10 μM, suggesting no need for the synthesis of longer peptoids than tetramers (Figure 9). At 50−100 μM concentrations, internalization of the peptoids was already detected after 1−2 h. At these times, punctated fluorescence could be seen on the plasma membrane. Fluorescence accumulated in vesicular structures was observed throughout the cells and with higher density in the perinuclear region. After overnight incubation, cytosol staining increased. Thus, it was assumed that a minor part of the labeled molecules had escaped from the vesicles into the cytosol. Whether this was due to active transport or to rupture of the endosomal compartment requires a more detailed analysis.

The tetramer **Fluo**-{**6,6,6,6**}-$\mathbf{NH_2}$ showed a perinuclear localization of the vesicular structures and a distinct homogeneous fluorescence throughout the cells even after 1 and 2 h at 100 μM. Weak staining of the nuclei was also observed (Figure 10). The chiral pentameric peptoid **Fluo**-{**6,1*,6,1*,6**}-$\mathbf{NH_2}$ was trapped in vesicular structures. A tendency to accumulate in the perinuclear region was only observed in HeLa cells and was much less pronounced in COS7 cells. Staining of the nuclei was only visible after overnight incubation with 100 μM (Figure 11). The hexameric peptoid **Fluo**-{**6,6,6,6,6,6**}-$\mathbf{NH_2}$ was visible in vesicular structures even after 1 h of incubation at 50 and 100 μM. Remarkably, after 2 h, a clear distinction could be made among peptoids associated with the plasma membrane, peptoids accumulated in vesicular structures, and those localized in the perinuclear region (Figure 12). After treatment with the hexameric peptoid with alternating C4 and C8 side chains **Fluo**-{**8,4,8,4,8,4**}-$\mathbf{NH_2}$, an increased amount of diffuse fluorescence was observed throughout the interior of the cells, in addition to the vesicular structures of bright fluorescence. In COS7 cells and HeLa cells, these structures accumulated in the perinuclear region, which was less obvious for the fibroblasts even after overnight incubation. The nuclei of all cells were stained, with bright fluorescence in the nuclei of COS7 cells and the weakest staining in the nuclei of the fibroblasts (Figure 13). Finally, the
